Table of contents

Preface XXV

Organisation XXVII

Volume 1

Section 1: Underground city design, planning of underground constructions

Largest transportation system – Metro and road in the same tunnel 3
V.M. Abramson & S.Yu. Loubotski

Anchor recovery under extreme conditions in downtown Leipzig, Germany 7
L. Babendererde & P. Elsner

Construction of Metro IV.C2 Ládví – Letňany in Prague 13
V. Bartoň, M. Kochánek, V. Valeš & J. Kutil

Planning for Canada's first bored road tunnel in over 40 years Kicking Horse Canyon Project 19
D. Brox, S. Bean, P. Branco & T. Coulter

Preparation of Metro's A line extension in Prague 27
V. Cigánek & J. Růžička

Preparation of Metro's new D line in Prague 33
V. Cigánek & J. Růžička

The Turecký Vrch railway tunnel 39
M. Dávid, J. Mára & J. Korejčík

Collectors – System approach to the regeneration of technical infrastructure in the city of Prague 45
F. Dvořák & M. Hradecký

Years of planning and implementation: Two major urban tunneling projects in Los Angeles, California, USA 51
M.A. Elioff, B.W. Miya & J.H. Albino

Geological and geotechnical conditions in underground structures design of Rome subway: The B-Line extension 59
R. Enrione, A. Eusebio, L. Soldo, R. Funiciello & L. Solimene

Ontologies, thesauruses and information systems for tunnels 65
N. Faure

Building the underground infrastructure of Lausanne's new m2 metro line 69
F. Gaj & M. Badoux

Metro Santiago – Building an urban tunneling industry from the ground up 75
A.R.A. Gomes, M. Böfer & P. Muñoz

The slivenec tunnel on the Prague city ring road 81
O. Hasík & K. Závora

Portals – The architecture visible in cities and landscape 87
O. Hasík & P. Šourek

Study of the ship lift structure at the Slapy Dam 91
M. Jakoubek, J. Kuňák & P. Uher

Design of the District Heating Tunnel in Copenhagen 97
T. Kasper, C. Edvardsen & M. Faurschou

Excavation connecting the underground ventilation station and the underground expressway tunnels 103
Y. Konishi, I. Kamegaya, A. Ueda & Y. Imanaka

Prague – Beroun, new railway connection 111
D. Krása, J. Růžička & O. Hasík

Underground high-speed railway – The phenomenon of urbanistic development in Prague 117
E. Kyllar

Railway line Prague centre – Ruzyně airport 125
J. Martinec & P. Zobal

The Trans Hudson Express (THE) Tunnel 131
N. Munfah & A.D. Silber

CTA Block 37 Tunnel Connection in downtown Chicago 137
V. Nasri & P. Razgha

Construction of a large underground station under a station in operation 143
T. Niibori, Y. Seki, T. Sato, T. Yamada & T. Fujiwara

The next step: The Very Long Tunnel (VLT) 149
H. Ostlid, W.C. Grantz, J. Saveur & B. Jakobsen

Planning and construction of major infrastructure works in Croatia 155
J. Radic, P. Djukan & Z. Zderic

The Dulles Corridor Metrorail Project – Tunneling aspects of the Metrorail extension to Washington, DC Dulles International Airport Phase I and Phase II 161
J. Rudolf, V. Gall & K. Zeidler

Experience from architectural design and Build of the underground space 167
P. Šafránek

Study on underground space planning of Shanghai EXPO 2010 173
H.H. Zhu, P. Li, X. Wang, F.L. Peng & Y.S. Li

Section 2: Geotechnical survey and improvement of ground mass

Part 2.1 Geotechnical survey

The impact of puncturing support on the expansion of seismic effects during blasting activities in tunnels 179
H. Antičević, Z. Ester & M. Dobrilović

Two different concepts of geotechnical survey and monitoring in exploration galleries for tunnels in Prague – Lahovská exploration gallery and Blanka exploration gallery 191
R. Chmelař & B. Březina

Inverse analysis on measurements realized during a tunnel excavation 197
S. Eclaircy-Caudron, D. Dias & R. Kastner

Prediction of the ground conditions ahead the TBM face in the tunnels of Guadarrama (Spain), using geophysical methods and in situ testing 203
J.M. Galera, S. Pescador, A. Rodríguez & M. Torres

Risk analysis of soil transition in tunnel works 209
Q.F. Hu & H.W. Huang

Feasible Boulder treatment methods for soft ground shielded TBM 217
W.W. Jee & S.-G. Ha

Reasons of swelling of miocene clays near Třebovice in Bohemia 223
F. Kresta

Geophysics method used to recognize the boundary between different deposits 227
R. Kuszyk & M. Superczyńska

Geotechnical exploration for the Dobrovského Tunnel in Brno 231
J. Pavlík, D. Rupp & L. Klímek

Design and construction of a large underground cavern in Atlanta, Georgia, USA 237
T.W. Pennington, R.F. Cook, D.P. Richards & G. Barnes

Development of in-situ tunnel-ahead detection system using electromagnetic wave 243
H.H. Ryu, G.C. Cho, Y.J. Sim, G.H. Lee & J.K. Lee

A modified design of a large section tunnel as an auxiliary spillway along large faults 249
Y.W. Shin, I.K. Lee, T.S. Park, H.S. Choi, S.C. Park, J.K. Kim, M.S. Lee, K.H. Shin & B.H. Han

Geotechnical control during the excavation of the tunnel of Guadarrama 255
I. Tardáguila, B. Celada, J.M. Galera

Assessment of rock mass properties using machine performance data from roadheaders 261
K. Tsukamoto, H. Hamada & S. Ebisu

Deep tunnelling in hardrock with large diameter TBM: What's up? An experience from the Gotthard Base Tunnel 267
I. Vicenzi, S. Pedrazzini, A. Ferrari, G. Gubler & O. Böckli

Laboratory tests for EPB tunnelling soil conditioning 273
R. Vinai, D. Peila, C. Oggeri & S. Pelizza

3D geo-modeling for spillway tunnel construction in the complex fault region 279
W.S. Yoon, U. Jeong, B.H. Han, K.H. Shin, S.S. Lee & Y.K. Kim

Dilatometer tests in deep boreholes in investigation for Brenner base tunnel 283
M. Zalesky, Ch. Bühler, U. Burger & M. John

Part 2.2 Improvement of ground mass

The dimensioning of tunnel face reinforcement 289
G. Anagnostou & K. Serafeimidis

Cost-effective pre-injection with rapid hardening microcement and colloidal silica for water ingress reduction and stabilisation of adverse conditions in a headrace tunnel 297
A.K. Bahadur, K.G. Holter & A. Pengelly

Experimental investigation on backfill grouting deformation characteristics of shield tunnel in sand 303
Y.-w. Han, W. Zhu, X.-c. Zhong & R. Jia

Advances in synthetic injection technology, do they improve tunnel construction productivity? 307
W. Kay, T. Yang

Injection techniques used at the old workings and karst voids abandonment under the built-up residential areas in the Urals 311
A.B. Kondratov

Instabilities at the Messochora tunnel, Greece: Ground improvement and safety evaluation based on observational data 315
V. Kontogianni & Y. Thanopoulos

Rock bolt integrity evaluation in tunnelling using ultrasonic NDT techniques 321
J.S. Lee, H.J. Kim, I.M. Lee, S.I. Han & Y.J. Lee

Jet-grouting in underground construction 327
A.G. Malinin & P.A. Malinin

Modelling of ground freezing in tunnelling 331
E. Pimentel, A. Sres & G. Anagnostou

Performance evaluation of ground improvement by electrical resistivity tomography 337
T. Shimizu, K. Narumoto & S. Ebisu

Reinforcing Effects around tunnel face by crown & face reinfored 345
J.H. Shin, S.H. Choi & S.B. Woo & Y.K. Choi

Laboratory testing of chemical grouting effects in rocks 353
K. Souček, L. Staš, R. Šňupárek & I. Kroutilová

Section 3: Research, development and design of underground constructions in built-up areas

Deformation computation based on numerical modelling for urban NATM tunnelling 359
M.Z.A. Elrehim

Numerical analysis of TBM road tunnels under Suez Canal at Port Said 367
A. Abu-Krisha

Numerical modeling of face stability for TBM tunneling 373
A.A. Krisha

Impact of the face anchoring on the stability of underground working 377
J. Aldorf, E. Hrubešová & L. Duris

Bentonite and grout flow around a TBM 383
A. Bezuijen

Volume changes in grout used to fill up the tail void 389
A. Bezuijen & W.H. van der Zon

Laboratory tests on compensation grouting, the influence of grout bleeding 395
A. Bezuijen, M.P.M. Sanders, D. den Hamer & A.F. van Tol

Software solutions for sensitivity studies in design of tunnels 403
E. Bieth, L. Chantron & P. Roure

Safety problems of underground structures in the design 409
N. Bulychev, N. Fotieva & A. Levchenko

Stability and deformations in large-scale underground constructions 415
A. Butovič

Particular design for nuclear long term interim storage 421
N. Dias, J. Triclot, H. Lagrave & E. Breton

Design and construction of a tunnel using the technology for controlling muck flow in the cutting chamber of an earth pressure balance shield of large cross section 427
H. Dobashi, M. Matsuda, K. Matsubara & A. Kitayama

Estimation of front-end stability using field displacement 435
R.M. Faure, J.F. Thimus, F. Demoulin & S. Delvaux

Influence of soil grouting on the shallow tunnel linings stress state in urban areas 439
N. Fotieva, N. Bulychev, S. Antziferov, A. Sammal & P. Deev

Analyses of underground structures crossing an active fault in Coronado, California 445
T. Gregor, B. Garrod & D. Young

Numerical modeling of tunnel excavation and lining under high initial stresses and high underground water pressures at Jinping Mountain 451
W. Chen & H.-N. Ruan

Simulation of failure around a circular tunnel using a bonded particle model 457
D.S. Cheon, C. Park, S. Jeon & Y.-S. Jeong

Deformation prediction for tunnels at PiccEx junction in London Heathrow – An engineering approach 463
J. Jäger & A. Stärk

Improved design method for 2-arch tunnel 469
W.G. Jeon, K.-H. Jeong, J.H. Lee, H.-H. Ahn & S.-W. Lee

Evaluation of strength parameters for the single shell tunnel in Korea 475
K.H. Joon, L.S. Ho, S.H. Seong & B.G. Jin

Measurements and seismic effects of vibrations caused by urban tunneling 481
Z. Kaláb & J. Knejzlík

Design method considering construction loads during shield tunneling using a three-dimensional FEM analysis model 487
K. Kasuga, N. Kawada, A. Shiratori, N. Fukai & M. Saitou

Development of a new center-cut method: SAV-cut (Stage Advance V-cut) 493
D. Kim, S. Noh, S. Lee, B. Park & S. Jeon

A study of the invert tunnel's behavior in a weathered-rock using laboratory model test and numerical analysis 501
K.J. Kim, S.Y. Koh, S.Y. Choo, C.S. Hong & D.J. Hwang

Design and installation waterproofing system for access shafts of service tunnels on Palm Jumeirah Island 507
M.K. Kundu, M.E. Ryjevski & D.G. Solter

Seismic behavior of Tubular Roof & Trench Method (T.R.&T) by numerical analysis 513
C.-w. Kwak, I.-j. Park, S.-h. Kim & J.-y. Kim

A laboratory test for determination of the optimum installation number of face bolts 519
K.W. Seo, S.W. Lee, T. Domon & K. Nishimura

Development of tunnel drainage system using drain board 523
G.P. Lee, H.S. Shin, G.J. Bae & S.W. Lee

The effects of tunnelling on an adjacent single pile 527
C.J. Lee, S.H. Jun, N.J. Yoo & G.W. Kim

Loads on the center pillar of two-arch tunnel under the influence of discontinuity planes in the ground 533
S.D. Lee, G.W. Byun, B.J. Oh & I.W. Lee

A case study of tunnel excavation adjacent to a steep slope 539
S.-C. Lee, L.-B. Chiou & G.-F. Lin

Subsurface settlement profiles above shallow and deep model tunnels at large ground loss 545
Y.-J. Lee & C.S. Yoo

Application of digital image processing in tunnel excavation 553
L. Biao, Q.W-ge, L. Yang & Wei, Hong-chun

Recent development of tunneling techniques in Taiwan 559
H.S. Liu, P.C. Hou & C.T. Chang

Construction method of connecting tunnel in a shield-driven tunnel 567
J. Liu, F. Zhang & H. Kong

Closely constructing influence forecast of hydraulic tunnel under-cross existing railway tunnel 571
G. Lun, Q. Wen-ge & W. Fei

Monitoring of the state of pipes in sewage networks as an element of adapting such networks to the technical demands of modern, urban subterranean infrastructure 577
C. Madryas & B. Przybyła

Investigation behavior of vertical shaft under loadings of intake tower at first filling of Doosti Dam 583
D. Massoud

Membrane waterproofing – Activation of the grouting system and its re-sealing ability 589
R. Matzner & M. Grossmann

Geomechanical studies for a road tunnel in volcanic formations 595
A.T. Menezes, F.M. Varela, L. Ribeiro e Sousa & F. Moura

Large-scale model tests for the verification of Braced Rib Arch Method for shallow overburden tunnel 603
S.M. Na, S.H. Moon, S.P. Lee, S.H. Cho & S.D. Lee

An investigation into the effects of Shiraz metro tunnels on the stability of Ghadir bridge 609
I. Namazi, R. Rahmannejad, M.A.E. Farsangi & H. Jamshidi

Extension of the Underground Space Information Management System: Road tunnel maintenance 613
Y. Ohnishi, P.A. Bruines, T. Nakai, M. Ryu, T. Katou & K. Tsujimori

Performance of pile due to tunneling-induced soil movements 619
C.W. Ong, C.F. Leung, K.Y. Yong & Y.K. Chow

The continual load development measurement of the central concrete pillar in the Valík tunnels 625
J. Pacovský, J. Svoboda Jun. & R. Vašíček

The Josef underground educational facility project 631
J. Pacovský, J. Svoboda Jun. & R. Vašíček

Displacements estimate due twin tunnel excavation under low overburden 635
E.A. Palma Filho, A.C. Zingano, J.C. Koppe & J.F.C.L. Costa

Parametric study of displacements on sequential and full-face tunnel excavation 639
S. Papakonstantinou & W. Schubert

Characteristics of the ice-ring with phase change of water to ice for LNG underground storage 645
C. Park, D.S. Cheon, S.K. Chung, H.D. Lim, Y.J. Park & S.D. Lee

Underground exploitation of a granite mine by large voids: stability aspects 651
D. Peila, S. Pelizza & C. Guardini

Analysis of input parameters of the rock mass 661
J. Pruška

Study on neighboring construction of three parallel shield tunnels in soft ground by centrifugal model test 667
W. Qiu, Y. Zheng, S. Li, R. Wu & H. Guo

The effect of advance rate on shield loading in squeezing ground 673
M. Ramoni & G. Anagnostou

Benefits and life-cycle costs of underground projects 679
J. Reilly & H. Parker

New York Second Avenue Subway – Initial support design of shallow rock caverns 685
K. Rossler & C. Stone

Laboratory and numerical investigation of tunnel reinforced with face bolts 693
K.W. Seo, T. Domon & K. Nishimura

Non-linear FE analysis of a grouted pipe-roofing reinforcement applied to a tunnel portal area 697
H.S. Shin, G.J. Bae, D.G. Kim & S.W. Lee

An enhanced pre & post processing techniques for three dimensional tunnel analysis: Tunnel Modelling Wizard 705
J.H. Shin, J.H. Moon & D.S. Shin

Design parameter determination for modeling of pre-reinforced zones in a tunnel 713
K.I. Song, G.C. Cho, S.R. Lee & J.H. Lee

Computer aided hierarchical ground characterization for underground structures 721
A. Steiner & W. Schubert

Developments of structural performance assessment for sewer liners 727
C. Madryas & A. Szot

Experimental verification of final tunnel lining performance 733
P. Šourek & J.L. Vítek

Stability analysis and excavation schemes of large-span highway tunnel under complex geological conditions 739
J.S. Tang, S.Y. Liu, L.Y. Tong & C.H. Shen

Introductory tunnel design – Lining types and selection: A case history of large span soft ground tunnel design 745
B.F. Townsend & C.R. Speers

Effectiveness of zonal ground mass pre-stressing round an opening at grouting 751
K. Vojtasík & J. Aldorf

Geotechnical model for pipe roof supports in tunneling 755
G.M. Volkmann & W. Schubert

Model analysis of pre-lining methods used in tunnel construction 761
V. Vrba & J. Barták

L-Surf – Large scale underground research facility for safety and security 767
V. Wetzig

New high-speed railway lines Stuttgart 21 and Wendlingen-Ulm -approximately 100 km of tunnels 771
W. Wittke

Estimation of multi-well dewatering induced pile foundation settlement in phreatic zones 779
Y. Xiang, S. Chen & C. Yu

Estimation of rock load for the design of 2-arch tunnel lining 785
K. You, M. Sagong & J.S. Lee

An analytical solution of shield tunnel based on force method 791
X. You, Z. Zhang & Y. Li

Expert system for D&B tunnel construction 799
C.W. Yu & J.C. Chern

Progress of drill and blast tunnelling efficiency with relation to excavation time and costs 805
S. Zare & A. Bruland

Analysis of the ultimate states of the underground tunnel lining 811
J. Zlámal

Author Index 817

Volume 2

Section 4: Urban tunnelling and its monitoring: conventional and mechanized tunnelling

Part 4.1 Monitoring

Redesign and monitoring of a portal structure in built-up area 827
E. Akis, Z. Etkesen, T. Solak, R. Mucukgil, E. Durukan & M. Unver

The influence of vibrations and noice on the housing development on the cover of the Mrazovka tunnel in Prague during tunnel driving and its putting into service 833
L. Bartoš & L. Bartoš

Advanced online monitoring for urban tunneling projects 837
N. Benecke, P. Althaus & U. Kalz

Geotechnical monitoring of the Valik tunnel construction near Pilsen 841
R. Bernard

The use of guide lines in tunnelling 847
G. Cassani & L. Mancinelli

Rio de janeiro subway – Challenges of the access tunnel to the cantagalo station 851
A.A. Coutinho, M.A.L. Rocha, L.E. Sozio & W. Bilfinger

Prediction of subsidence during tunnel construction 857
K. Grossauer, R. Leitner, W. Schubert & P. Sellner

Monitoring of ground massif using TR-GEO georadars while drifting tunnels 863
S.V. Izyumov & I.I. Goltsman

Application of tunnel information system for construction supported by international cooperation 867
C.Y. Kim, K.Y. Kim, Y.Z. Lee, S.W. Hong, S.H. Baek, K.W. Seo, W. Schubert & Y.S. Seo

Influence of water back rise on tunnels and surface 871
M. Kolečkář, J. Němeček & I. Zemánek

Geotechnical support of construction and operation of the Underground and transport tunnels 877
N.I. Kulagin & K.P. Bezrodny

Influence of the primary support stiffness on the surface subsidence during tunnel construction 883
J. Likar & M. Venta

Deformation behavior of west Mao mountain highway tunnel in gravel deposits layers during excavation 889
L.Y. Tong, S.Y. Liu, C.H. Shen & L.M Liu

EPB-Tunnelling control and monitoring in a urban environment: The experience of the "Nodo di Bologna" construction (Italian High Speed Railway system) 895
V. Marchionni & V. Guglielmetti

Monitoring of structures and environment under construction and service of underground transportation projects in Russia 903
V. E. Merkin, S.N. Vlasov

Geotechnical monitoring of the excavation exploratory galleries for the Dobrovského tunnel in Brno 907
D. Rupp, J. Pavlík & L. Klímek

An optimised monitoring of critical buildings adjacent to tunnel construction in urban area 913
S.H. Shin, C.Y. Kim, K.Y. Kim, K.S. Jue & S.W. Hong

Monitoring during the construction of a shallow urban tunnel and counter measures 917
T. Solak, Z. Etkesen, A. Sirin & T. Düzgün

Longitudinal surface settlements induced by EPB tunneling in Bangkok Clay 921
S. Suwansawat

Tunnel excavation by controlling water pressure in the ground with unevenly distributed water bearing strata 927
H. Takahara, J. Yorita, Y. Tuzuki & H. Takahashi

Prognosis of underground structures deterioration based on in-situ measurements 933
M. Vaníček, I. Vaníček, J. Pruška, M. Bubeníček, D. Jirásko & K. Soga

Interaction between tunnelling and groundwater – its impact on tunnel behavior and ground settlement 939
C.S. Yoo, S.B. Kim, Y.J. Lee, S.H. Kim & H.T. Kim

Part 4.2 Conventional tunnelling

Integrated design and construction of Klashnice tunnels 947
P. Anagnosti & D. Lukich

Tunneling in an urban critical area – A case study 953
J.M. Carvalho, A.T. Cavalheiro & P. Teixeira

Construction of city service tunnel in Ostrava without preliminary protection of surface 961
K. Franczyk & K. Dolinek

Aspects of urban tunneling within the project of Sitina tunnel 965
M. Frankovský, T. Aoki, S. Choma, V. Chomová & V. Kotrík

New Austrian Tunneling Method: Directly under an expressway on weak silt 971
K. Fujimoto, J. Yorita, Y. Sasaki, N. Yamaki & M. Okamura

The Prague new connection tunnels 977
M. Gramblička, D. Cyroň & M. Chyba

Development of rock fracturing method, and application of EG-Slitter method to the tunnel 983
T. Hara, M. Okamura, T. Kimura & K. Ishiyama

The Sir Adam Beck II intake tunnels – homage to the builders 987
D. Heath & C. Murdock

Královopolský Tunnel in Brno, CZ 995
V. Horák, J. Pechman & J. Rožek

Planning and design of the A3 Hindhead tunnel, Surrey, UK 1001
T.J. Ireland, T.A. Rock & P. Hoyland

Geotechnical investigations and construction conditions for the tunnel “Strazevica” on E-75 motorway near Belgrade 1009
B. Jelisavac, S. Jotic, S. Savic, V. Vujanic, M. Roljic, M. Jotic & S. Milenkovic

The construction of tunnel “Lipak” within the framework of E-75 motorway on Belgrade city bypass stretch 1015
S. Jotic, S. Savic, M. Jotic & V. Vujanic

Settlement control during the construction of urban tunnels by NATM Construction of Kitayama tunnel on national highway 455 1021
T. Komatsu, H. Kitamura, K. Matsubara & T. Sakurai

Highways in the Czech Republic in terms of tunnel construction 1027
P. Laušman

Urban tunneling under existing structure 1031
H.S. Lee, K.S. Jue, D.Y. Kim, W.H. Jung & Y.N. Lee

Large double adjoined binocular tunnels in shallow and soft ground – Shoji tunnel project 1037
M. Mori, M. Nakano, K. Shirakawa, M. Koike & M. Iwano

Stability estimation method and analysis for pillar considering the reinforcement during twin-tunnel excavation 1045
S. Park, S.W. Yoon & J.S. Hwang

Design and construction of the longest road tunnel with eight-lane in China 1049
H.F. Qu, H.H. Zhu, Y.C. Cai & X.Y. Zhuang

Experiences from driving dual-rail tunnels on Prague metro's IV.C2 route 1055
J. Růžička, M. Kochánek & V. Valeš

Development of grade separation structures with small cross-sections 1063
M. Shimizu, A. Watanabe, T. Genjyun, M. Kurisu, Y. Hagihara, T. Maeda & H. Watanabe

Civil tunnelling with electronic blasting systems – Early experience from Korea 1071
Y.-S. Song & D. Kay

Blanka tunnel complex in Prague 1079
P. Šourek, L. Šajtar, F. Polák, J. Dvořák, A. Butovič & M. Hadrava

Study on the behavior of an ultra-large section tunnel project in unconsolidated ground-Design and construction of the Minoh toll road tunnel 1085
K. Taketomo, Y. Mitarashi, H. Shiokawa, S. Nishimura & K. Konishi

Large deformations in squeezing ground in the Saint-Martin La Porte gallery along the Lyon-Turin base tunnel 1093
J. Triclot, M. Rettighieri & G. Barla

Geotechnical conditions, methods, and issues of building the transportation tunnels in the wider area of Belgrade 1099
V. Vujanic, M. Jotic, S. Milenkovic, J. Josipovic & B. Jelisavac

Construction of major trunk road tunnels in Moscow 1105
B.I. Yatskov, A.M. Zemelman, S.N. Vlasov & I.S. Bubman

Selecting auxiliary construction methods for NATM tunnel excavation in urban areas 1111
J. Yorita, Y. Sasaki, N. Yamaki & M. Okamura

Part 4.3 Mechanizing tunnelling

Construction update and TBM Excavation Seymour Capilano Twin Tunnels Project, Vancouver, Canada 1119
D. Brox, D. Phelps, B. Garrod, T. Morrison & A. Saltis

Stress–strain soil behavior during tunneling in soft ground: Experimental study on 1g-earth pressure balanced shield model 1125
D. Branque, C. Boutin & H.V. Doan

Conquering the construction challenges of the arrowhead tunnels 1133
B. Fulcher, J. Bednarski, M. Bell & W. Burger

Ground loss control in EPB TBM tunnel excavation 1141
M.C. Gatti & G. Cassani

City-Tunnel Leipzig, a challenge for the shield drive 1147
W. Glitsch & T. Maidl

Integral studies on mechanical functions of mudding agents and the properties of muddified soils in the EPB shield tunneling technology 1153

Preface

The Czech Tunnelling Committee ITA/AITES – as organizer of the 33rd World Tunnel Congress 2007 in Prague – has been elected by the ITA member countries three years ago. We have been very honoured by their confidence and grateful to the ITA for its support.

The ITA annual congresses and meetings have become premier events in the international tunnelling and underground construction calendar.

The theme of the WTC 2007 "Underground Space – the 4th Dimension of Metropolises" has been chosen as we feel it to be still more and more topical regarding the permanent growth of concentration of the world population into metropolises and megacities. The underground offers the hope of help to solving of related problems.

Hundreds of potential participants and interested companies and institutions from all over the world had been invited to submit their papers and contribute to the development of underground construction. The response to free paper submission was very impressive and many of the accepted papers contained new information and demonstrated further growth in the significance of our industrial branch. We would like to reaffirm our appreciation to all our colleagues for their great willingness to share knowledge and for their continued support.

The Proceedings of the ITA-AITES WTC 2007 – the book and the CD-ROM – present the full papers accepted by the Scientific Council of the Congress. Authors submitted 382 abstracts which were reviewed and 316 full papers were selected for publication. The published papers have been grouped into 9 sections – main discussion topics of the Congress.

Organisation

The following groups have been closely involved in the organization of the Congress:

INTERNATIONAL ADVISORY COMMITTEE:

Chairman: Zdeněk D. EISENSTEIN (Canada)
Members: André ASSIS (Brazil)
Jean-Paul GODARD (France)
Gyula GRESHIK (Hungary)
Wojciech GRODECKI (Poland)
Alfred HAACK (Germany)
Jindřich HESS (Czech Republic)
Martin KNIGHTS (United Kingdom)
Koichi ONO (Japan)
Harvey PARKER (USA)
Sebastiano PELIZZA (Italy)
Sergey N. VLASOV (Russia)
Harald WAGNER (Austria)
Jian ZHAO (Switzerland)

ORGANIZING COMMITTEE:

Chairman: Georgij Romancov
Members: Josef Aldorf, Jiří Barták, Claude Berenguier (ITA-AITES Secretary General), Eva Bundová, Josef Dvořák, Matouš Hilar, Ivan Hrdina, Miroslav Kadlec, Štefan Kovalčik (Slovakia), Jana Lepičová, Libor Mařík, Karel Matzner, Petr Mičunek, Miloslav Novotný, Stanislav Sikora, Jiři Smolík, Petr Vozárik

SCIENTIFIC COUNCIL:

Chairman: Jiří Barták
Secretary: Karel Matzner
Members: Josef Aldorf, Radko Bucek, František Dvořák, Josef Dvořák, Otakar Hasík, Matouš Hillar, Miroslav Kolečkář, Václav Krch, Bernhard Maidl (Germany), Libor Mařík, Jaroslav Pacovský, Jiří Pavlík, Pavel Polák, Jan Pruška, Pavel Přibyl, Alexandr Rozsypal, Jiří Smolík, Martin Srb, Ermín Stehlík, Ludvík Šajtar, Richard Šňupárek, Jan Vítek, Petr Vozárik, Jaromír Zlámal

ITA-AITES 2007 OFFICIAL WTC ORGANIZERS:
CZECH TUNNELLING COMMITTEE ITA/AITES
GUARANT INTERNATIONAL, spol. s r. o.
AGENTURA BONUS

The editors would like to acknowledge the great effort expended by all these colleagues and friends in the organization of the ITA-AITES 2007 Congress in Prague.

Largest transportation system – Metro and road in the same tunnel

V.M. Abramson & S.Yu. Loubotski
Sistema GALS OJSC, Russia

ABSTRACT: Brief description of design and construction features of a unique project, Serebrianoborsky tunnels, is presented in the article. The project comprises three tunnels, each 1514 m long, including two 14.2 m diameter transport tunnels, one 6.3 m diameter service tunnel and five cross drifts connecting these tunnels. The tunnels are built using Herrenknecht TBMs with shields of respective diameters operating according to the bentonite face hydraulic support technology. The design was awarded prize of International Exhibition of Innovations in Brussels.

In accordance with the new Moscow Master Plan, extensive trunk street/road development program is underway in the city.

A trend seems to evolve for new trunk roads to be laid in tunnels crossing the whole city districts and leaving intact both the habitat and surface buildings, man-made structures and architectural monuments; it means that there appear long trunk road urban tunnels. This is particularly important for such a complex urban body as Moscow where the historically formed ring/radial trunk street system makes it insistent to create a transportation system capable of providing for both perfect traffic control and links between peripheral districts and the centre.

On the basis of the Master Plan, a new radial transportation corridor, Krasnopresnenski Avenue, is being formed in Moscow, the corridor making it possible both to create a new trunk road in the western sector of the capital and to provide conditions for road users to comfortably pass from the city center to the "Baltiya" Moscow – Riga Federal Highway.

The first "Baltiya" Moscow – Riga Federal Highway section joining the Moscow Ring Road (MKAD) was completed in 1996. However, the highway could not enter the city owing to the fact that the alignment crossed two protection zones: the Serebryany Bor forest park and the Krylatskoye dwelling and nature territory. Construction of a surface road could infringe ecological situation of the region since it would have been inevitable to cut trees in the Serebriany Bor forest, to demolish some important dwelling buildings and to disturb natural landscape.

At present, the Moscow – Riga trunk road is linked with the city centre through MKAD and its interchanges at Roubliovskoye and Volokolamskoye Chaussees resulting in essential superfluous run and additional traffic load at MKAD section between these interchanges.

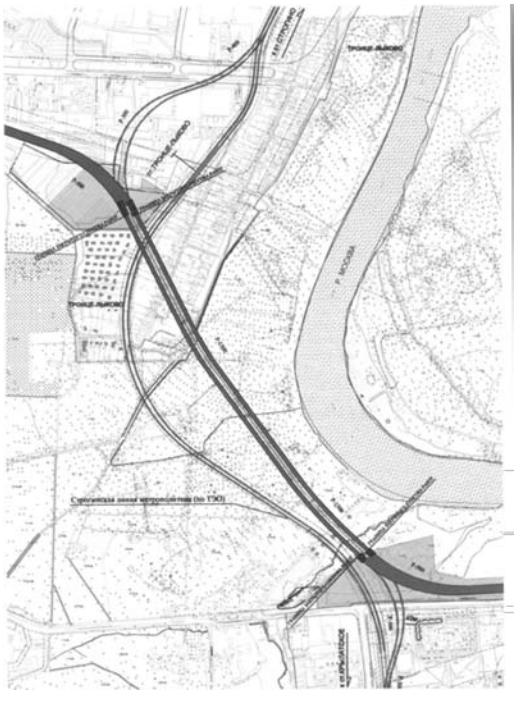

Figure 1. Tunnel site with approaches combined with Stroguinskaya metro line.

Besides, the Stroguinskaya metro line from Krylatskoye Station to Stroguino Station linking household areas of this region with the city centre is currently under construction along an alignment close to that of the proposed tunnels (Figure 1).

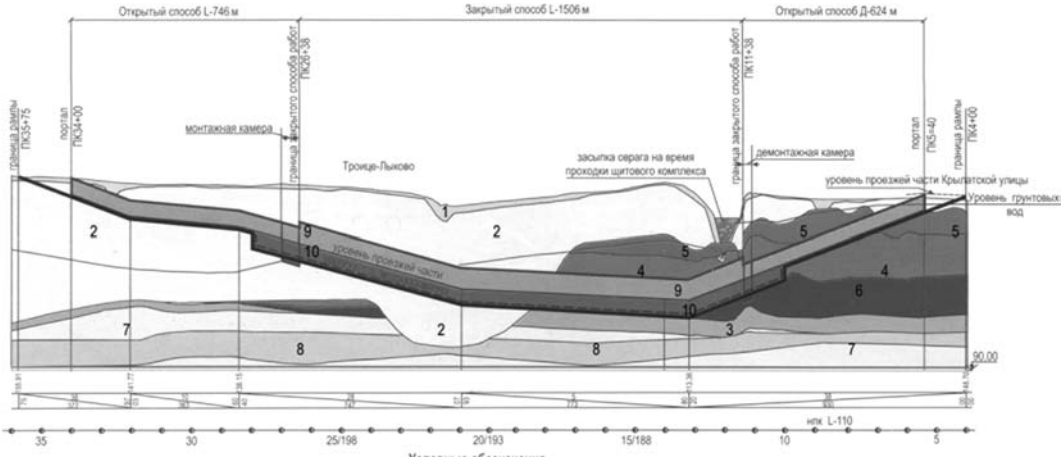

Figure 2. Longitudinal profile of tunnel section with approaches combined with Stroguinskaya metro line. 1 – filled-in soils: sand, sandy-loam, unconsolidated loam with brick and concrete breakage; 2 – wet and water-saturated alluvial and aqua-glacial sand of various grain size with layers of sandy-loam and loam, locally with gravel and boulders; 3 – tough-plastic and semi-hard (occasionally hard) Jurassic clay; 4 – semi-hard (occasionally hard) Jurassic clay; 5 – water-saturated chalk sand and sandy-loam, soft loam with sandy-loam layers; 6 – tough-plastic and semi-hard Jurassic loam, water-saturated sandy-loam; 7 – medium-hard and hard fractured and badly fractured water-saturated coal limestone; 8 – hard and semi-hard coal clay and clayey marl; 9 – road right-of-way; 10 – metro right-of-way.

Thus, serious problems that arose in the prestigious North-West region of Moscow were to be urgently solved to improve transportation conditions of the city.

Metroguiprotrans designers could find the solution having proposed basically new engineering and construction approach consisting in laying two 14.2 m diameter tunnel barrels under the whole protection and household zone, each tunnel accommodating two transportation modes: road for 3 traffic lanes in the upper level and metro tracks in the lower one. This approach was patented and awarded with a prize of International Exhibition of Innovations held in Brussels in 2003; at present, such world-first "dual-purpose" tunnel barrels are being built at the section where alignments of Krasnopresnenski Avenue and Stroguinskaya line of Moscow Metro coincide.

Construction site is located at the second and the third right flood land terraces of the Moskva River, absolute elevations of the graded surface varying from 145 to 155 m.

Geological composition of the region is represented with deposits of the Quaternary, Cretaceous, Jurassic and Coal periods.

The Quaternary deposits encountered at many sites are represented with technogenic as well as with alluvial and aqua-glacial soils, presumably those of sandy and sandy-loam types.

There are several ground water tables along the alignment including Jurassic, Ratmir and Souvorov water-bearing layers.

The free ground water table is measured at absolute elevations from 126 to 130 m. Thickness of the layers vary from 12 to 30 m. Permeability factor varies from 4 to 15 m/day (Figure 2).

Implementation of this project has become possible owing to the fact that principally new Herrenknecht tunnel boring machines were used, the machines operating with combined hydraulic and air face support 14.2 m diameter shields at depths providing for complete safety of the city habitat independently of geological and hydrological conditions. It made possible to successfully complete driving all Krasnopresnenski Avenue tunnels (Figure 3).

The Krasnopresnenski Avenue tunnel section thus consists of three tunnels – two 14 m diameter 1514 m long transport tunnels and one 6 m diameter 1514 m long service tunnel located between the transport ones (Figure 4). The service tunnel is used to accommodate utilities, to perform ventilation functions and, in case of emergency, to provide for evacuation of the passengers and for unhampered approach of fire and rescue teams to the site of emergency. Cross drifts connecting the three tunnels are made every 250 m to provide for the approach. Total length of the transport tunnels including the ramp sections makes 2550 m, two 1514 m long tunnels having been driven in closed techniques using one tunnel boring machine. The following construction sequence was used: first the left transport tunnel, then the service tunnel (while driving the service tunnel, the main TBM was dismantled, transported to the base ground and reassembled to drive the

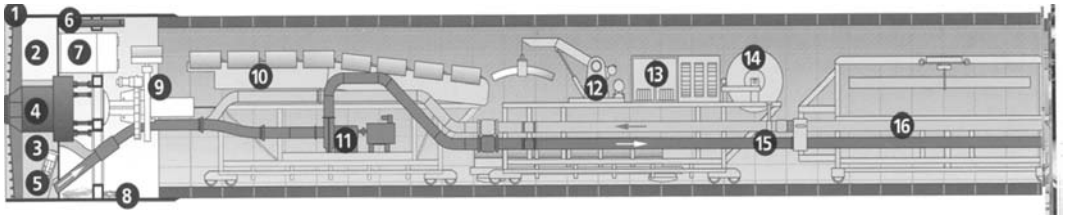

Figure 3. Mixshield design. 1 – cutterhead; 2 – air cushion; 3 – bentonite suspension; 4 – drive; 5 – stone crusher; 6 – cylinder; 7 – decompression chamber; 8 – navigation cylinder; 9 – segment erector; 10 – segment transporter; 11 – muck pump; 12 – segment lifting crane; 13 – power shield; 14 – cable drum; 15 – muck removal pipeline; 16 – feeding pipeline.

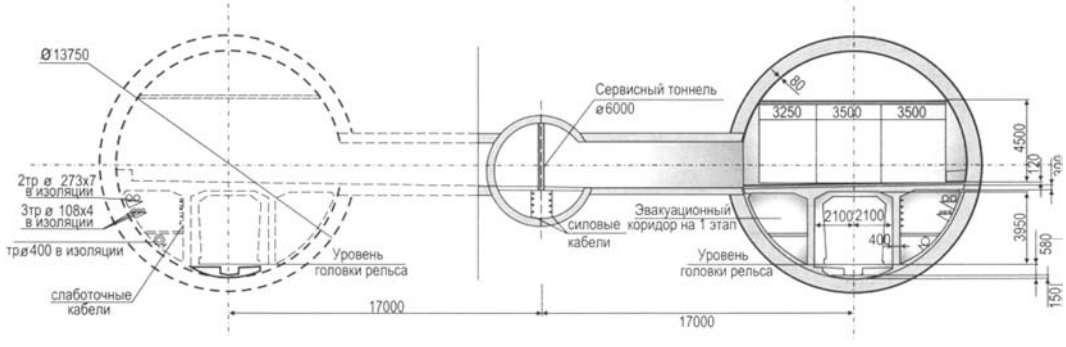

Figure 4. Cross-sections of Serebryanoborsky Tunnels.

right transport tunnel); the right tunnel was the last to be driven. In order to provide for the tunnels to be built, a 9.2 m^2 base ground was arranged with start shafts for all the tunnels, building for all separation equipment, storage ground for lining segments, compressor room and utilities.

In order to be able to drive all three tunnels from the same base ground, a 6.3 m diameter TBM of the same type as TBM for the main tunnels. Reinforced concrete segments for lining rings were manufactured at an updated plant in Moscow in accordance with design prepared by Metroguiprotrans OJSC specialists. Rings for the main tunnels are as wide as 2 m, each consisting of 8 main segments and a locking one.

The left tunnel driving commenced in May 2004. At present, all the three tunnels are driven, while construction of the cross drifts and the roadway as well as installation of technological equipment is underway. Average and maximum advance rates of the main TBM made 200 m and 250 m per month respectively. Owing to strict adherence to the design face support hydraulic pressure values, surface settlement in the course of driving were brought to minimum and did not exceed 10–12 mm.

At two thirds of the alignment, the tunnels pass through water-saturated sand soils and through clay soils at the remaining third. Given the difficult ground conditions, the cross drifts are built using special soil stabilization forestalling methods. The techniques used for each drift differ depending on particular soil properties. Horizontal jet-grouting, cement grouting, stabilization with various materials and soil freezing are used.

In order to provide for the required air quality and safety parameters in the tunnels in case of fire, forced feeding and extraction ventilation and powerful smoke-removal systems are installed. Each tunnel is ventilated with respective individual systems. The tunnels are built according to the highest fire-safety requirements; the whole inner surface of each tunnel is protected with special cover capable of withstanding open fire action within 3 hours.

Completion of this tremendous project scheduled for December 2007 will finalize creation of the direct transport communication between the “Baltiya” expressway and the centre of Moscow resulting in mitigation for the traffic-overloaded Volokolamskoye and Roubliovskoye Chaussees. Besides, 1.5 km long metro line will be built.

Tunneling practice will get enriched with one of the world most important underground structures, a complex of combined road and metro systems making it possible for major cities to more efficiently solve their transportation problems.

Anchor recovery under extreme conditions in downtown Leipzig, Germany

Dipl.-Ing. Lars Babendererde & Dipl.-Ing. Philipp Elsner
Babendererde Ingenieure GmbH, Bad Schwartau, Germany

ABSTRACT: In the inner city of Leipzig, Germany, the London, U.K. based AMEC group, an international infrastructure specialist, faced the problem that old cable anchors from the construction pit of a multiplex shopping centre built by AMEC in 1999/2000 had to be recovered from under existing buildings. The anchors were finally recovered by a pile borer and a slurry wall excavator in a first stage and by pipe jacking under compressed air along the anchor axes in a second stage.

1 INTRODUCTION

In the years 1999 and 2000 the British AMEC group, represented by its Leipzig office, built and afterwards managed the multiplex centre "Petersbogen", which is in the heart of the inner city of Leipzig. The centre is comprised of shops, restaurants, a cinema, a casino and the judicial branch of the Leipzig University. The complex is four (4) stories high and has four (4) basement levels of which the first is a shopping area, whereas the others are used for underground parking and building utilities.

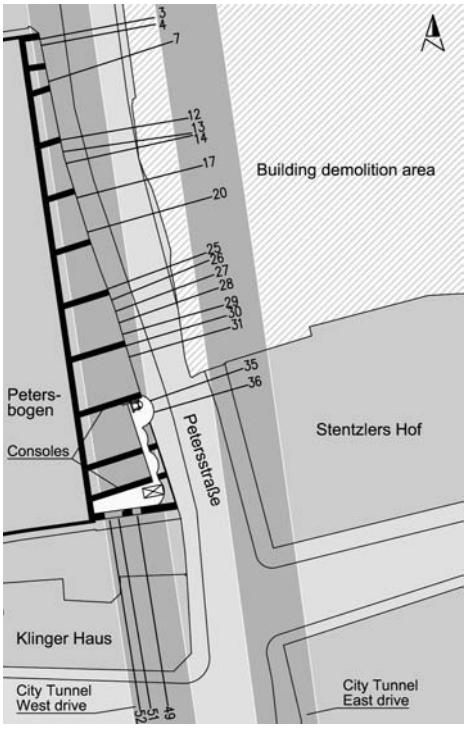

Figure 1. General layout.

During the design phase of the building AMEC had to consider that a future underground railway line, the so-called "City Tunnel Leipzig" consisting of two tubes, would pass in a shallow alignment under the property of the Petersbogen's southeast corner. As part of the building permit AMEC had to guarantee that no permanent installations would be positioned within the future tunnel cross sections.

Due to the high ground water level with permeable layers of soil on top of impermeable ones, a water tight construction pit was planned, enclosed by deep slurry walls reaching into the impermeable layers. In the slurry walls, steel beams were positioned to stabilise the free standing part of the wall. In order to reduce wall movement and the steel beam cross section two layers of cable anchors were planned by the designer. The anchor geometry accounted for limitations from the tunnel.

2 THE TROUBLE STARTED

In 1999, the contractor for the construction pit began the work as designed and tendered. Soon after the work began he ran into remnants of foundation from former buildings, which had been announced in the tender documents. Due to excavation problems the contractor changed the building pit design to three rows of anchors. But now the bottom layer was ending right in the future City Tunnel cross section.

The contractor promised to get the anchors back out of the ground by explosive recovery. This meant small ductwork would be interlaced within the cables of the anchors, so that the grout bulb could be loaded

with explosives in the form of a cortex. Through the explosion, the grout bulb would then be cracked, making the steel cables easy to pull out of the ground. Also, a back-up method was offered.

The work continued according to the alternative plan. Unfortunately, when time came to recover the anchors, the contractor found that he could not fill some of the ductworks with any cortex and others could only be filled with a smaller and less effective cortex than planned. The result was that the contractor failed to recover 43% of the anchors. As if that wasn't enough, the alternative recovery method with the hollow drill rods also failed.

The contractor tried several other recovery methods. First, he tried to loosen the bedding of the anchors in the soil with the help of jet grouting lances. After that, he tried to destroy the grout bulbs with large amount of explosives which were detonated in extra boreholes bored parallel to the anchors. Even the pulling technique was varied from pulling all cables of an anchor at once to pulling only single cables or smaller groups. But all methods failed.

Finally, the construction schedule became so pressing on AMEC that the regular construction works had to continue.

3 A NEW ATTEMPT

At this stage AMEC requested Babendererde Ingenieure to prepare new solutions for the anchor recovery. As specialists for TBM tunnelling, the first solution was to check whether the slurry TBMs of the City Tunnel could simply drive through the cable anchors. This idea was quickly abolished due to unpredictable high risks and costs.

It was then investigated what would be necessary to recover the anchors from inside of the TBMs. Although it was technically feasible, the costs were enormous and unacceptable for AMEC.

The third alternative was to construct small, hand driven ducts, secured with fibre reinforced shotcrete under compressed air. Starting from within the basement level of the Petersbogen, miners would have to dig a tunnel towards the critical zone of the anchors and then, from one anchor to the next, to cut away the sections within the City Tunnel alignment. The shotcrete ducts would have been no match for the TBMs, which were equipped for mixed face conditions comprising cohesive and non cohesive soils with stones and layers of hard, abrasive quartzite.

After the preparation of this solution the client suddenly learned that a building opposite to the Petersbogen, under which 15 of the 20 remaining anchors were lying, was about to be demolished to make space for a new department store.

New options were considered. The final solution was to pull the anchors out of the ground with the help

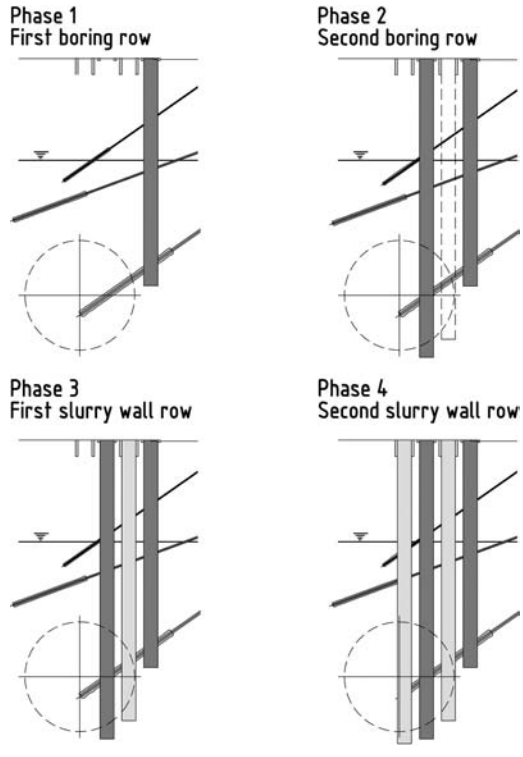

Figure 2. Working steps for recovery from above ground.

of pile borers and slurry wall excavators which were already available due to required site preparations for the new department store. So in the summer 2004 a 75t pile borer and a 120t slurry wall excavator were driven to Leipzig to dig for cable anchor pieces with a maximum weight of 30 kg.

4 GOING FISHING

The final plan was to cut the anchors with a pile borer ID 1,2 m. Two (2) rows of cuts were foreseen. The first row was supposed to cut each anchor into two (2) sections, one (1) within the tunnel and one outside of the tunnel. The second row was supposed to cut the sections within the tunnel into two (2) sections of equal size ranging between 3 and 4 m in average length. The bore holes were to be filled with a one-phase boring suspension which hardened after a while to form an artificial soil of similar strength compared to the natural soil in this area.

Then the slurry wall excavator would perform two (2) rows of excavation to pull out the remaining sections of the cable anchors. The trenches were to be stabilized by the same suspension which was already being used for the borings.

Figure 3. Construction site.

5 RECOVERY FROM ABOVE

The excavation works were no problem for the pile borer and the trench excavator. The pile borer cut even through anchors with nine (9) steel cables without any recognisable evidence for the driver. Thus, every single bucket of excavated material from the ground had to be closely observed while pulled above ground and dumped into the bucket of waiting wheel loader. Often cables of an anchor were obviously hanging in the teeth of the boring bucket. In general, the cable sections were between 60 and 120 cm long and heavily twisted because of the boring rotation. Yet some cable sections also were squeezed into the bucket and were spotted during the dumping onto the wheel loader bucket. The emptying of the wheel loader was also closely observed. Some cables were disintegrated to single wires and it was often only during the last dumping from the wheel loader that such wires were found.

Time and again a “hit” on an anchor was indicated by steel cable sections hanging from the boring bucket. Then, in the next one or two buckets coming up, more pieces from that hit were found. Nevertheless, it also happened that just a few distorted wires were the only indication of a successful hit.

The important task of the Supervising Engineer in this stage was to explicitly map, record and photograph every single finding, and then identify which anchor was cut. The mapping was used to get a closer idea where exactly each anchor was lying to verify the positions of the following slurry wall excavations. If one considers that there were two (2) more layers of cable anchors above the one searched for and that through the deviations of the anchors and the borings alike sometimes anchors were found where none had been expected, the identification became a big puzzle which finally was solved.

After all findings had been interpreted, the excavation with the slurry wall excavator began. Whilst watching and searching through the excavated material during the borings was often tedious work, now the big hits were being made. As planned, the trench excavator easily pulled out the remaining sections of the cable anchors.

Up to 4 m long sections were brought to the surface in one piece. As the locations of the anchors were quite well known through the borings, it could even be predicted at which position and depth anchors should be found. The job advanced well and was finished within the tight and unmodifiable time frame which was given to AMEC by their neighbour and his construction works.

Figure 4. Anchor section under slurry wall excavator.

Figure 5. Recovered and cleaned anchor section.

6 FIVE TO GO

After the successful recovery of the first 15 anchors there were still five (5) to get out. All five (5) anchors were located in the southeast corner of the shopping centre. Anchor no. 35 and 36 extended to the east. They were 19 m long, bored at an angle of 35° and had a 9.5 m long grout bulb each. The anchors were perpendicular to the City Tunnel axis and the last approximately 4.5 m of the grout bulbs were directly within City Tunnel east drive cross section. The intersection between the anchors and the tunnel was under one of the neighbour's buildings, the so-called "Stenzlers Hof".

The other three anchors no. 49, 51 and 52 extended to the south. They were 32 m long, bored at an angle of 35° as well and had a 11.5 m long grout bulb each. The anchors were parallel to the City Tunnel west drive crossing it from the top to the bottom at a length of about 15 m. Due to their length, the anchors' grout bulb started shortly under the tunnel's invert. Also in this case the intersection between the anchors and the tunnel was situated under a listed building, the so-called "Klinger Haus".

Again, as previously mentioned, a recovery from above was impossible as the important sections of the anchors were covered by buildings. So the designer, as well as the client, accepted that the only solution left was to recover the anchors from underground, although it was unclear at this moment how, and from where, this should be done. The deepest parts of the anchors to recover were about 25 m below the surface and 17 m below the ground water table.

Digging down from the Petersstraße was impossible. It is the main shopping street in Leipzig. The compensation alone to shop owners due to construction work in front of their shops would have been enormous. In addition, any work from within the basements of the buildings above the anchors was impossible. The rooms were too small for any sensible operation and they were occupied by the tenants. Therefore, the only possible solution was to start from somewhere within the property of the client, which was the Petersbogen building.

The anchor heads were lying roughly at a depth at the middle of the third basement level and 1 m below the ground water level. Fortunately, the construction of the building in the southeast corner was different from the rest of it. In general, the building had four basement levels. But in the area of the later City Tunnel the client had been allowed to build only two basement levels, thus the third and fourth basement levels had to be reduced in their expansion. In order to keep the future tunnel free from massive loads from the overhanging building part, it was constructed on huge reinforced concrete consoles which were attached to the side walls of the third and fourth basement levels.

As a result of the special construction, the five anchors ended actually under the Petersbogen building. Due to the fact we decided to cut an opening into the slab of the parking level in the southeast corner and dig tunnels under the cover of the slab to reach the anchor heads. Then micro tunnels could be launched, one for each anchor.

With the help of 1.2 m ID pipes driven under 35° downwards over each anchor, the anchors could be dug out and cut to pieces parallel to the jacking progress. The excavation had to be performed by hand, by a man sitting in the head of the pipe. Since pipes would end in the City Tunnel cross section, a pipe material had to be selected which later would mean no harm to the TBMs of the City Tunnel.

The decision was made to use CC-GRP (centrifugally cast glass fiber reinforced plastics) pipes made by HOBAS. A Slurry TBM with discs is able to cut through such pipes when it comes upon them in the ground. Nevertheless, any steel elements permanently installed in the pipes were forbidden.

For steering and as protection for the first pipe's face, a mini steel shield was necessary although it had to be dismantled and carried back out of the pipe of each tunnel drive.

The biggest challenge and impact during excavation was coming from the ground water. The ground water table was equal to the level of the slab. It was impossible to lower it by pumping with mainly sands to excavate through, buildings all around and the deepest anchor sections being at 17 m below the ground water table. Under the given boundary conditions, ground freezing was also impossible. Therefore the only option left was excavation under compressed air. A service room, in the very south-east corner of the second basement level, was chosen as the entry point to the tunnels.

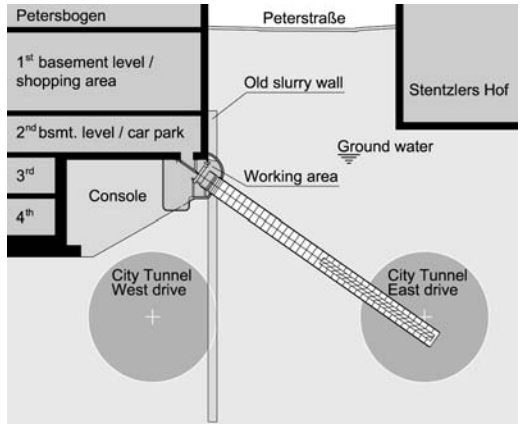

Figure 6. Recovery from underground.

The decision was made to cut a hole $3.0 \times 1.5\,m^2$ into the floor and excavate downwards from there. The service room walls consisted of reinforced concrete and it had just one door. The door had to be taken out and an air lock was connected to the opening. Static calculations confirmed that the walls would withstand 1.8 bar inner air pressure.

7 SITE INSTALLATION

After a short tender phase with a hand picked group of candidates site installation began in December 2005. The winning bidder Gildemeister GmbH & Co. KG from Berlin, Germany, started to alter the service room of the parking level. The hole was cut into the floor, a rented air lock was installed to the door opening and a serial of core drillings was set through the upper working chamber wall to enable installation of all the required utility lines needed in the working chamber. A rail system from the parking area through the air lock into the upper working chamber for hand pushed lorries and a rail crane under the ceiling completed the preparations in the building. Meanwhile outside of the building, the compressed air stations, a medical air lock, stores and accommodations were installed in an area next to the Petersbogen. This area was held free by AMEC for future expansions of the shopping centre.

8 RECOVERY FROM UNDERGROUND

In January 2006 the compressed air works began. The south working chamber along anchors 49, 51 and 52 was excavated between the first two consoles under complete cover of the slab of the second basement level. The east wall of the chamber, which was the only one open to the in-situ soil beneath the basement levels, was secured with an arch of reinforced shotcrete. Then openings were cut into the first console at the positions of anchors 49 to 52 in preparation of the pipe jacking. After that, an opening was cut into the second console to dig a tunnel towards anchors 35 and 36, where the north working chamber was excavated.

Figure 7. Air lock in underground car park.

Meanwhile, the contractor transported a custom made jacking frame to the position of anchor 52 and installed it between the two consoles. He then installed the mini-shield.

After a learning period, the overall excavation speed became faster than expected with exception of tunnelling through a quartzite layer, which was time consuming and which each of the five tunnels had to pass through. The pipe jacking got underway with 40 cm long pipes because longer pipes could not pass through the air lock. Soil transport was carried out with a small lorry going up and down the pipe. The sand and silt was taken from the face with a small blade. Hand-held core drills were used to drill holes into the quartzite rock and a hydraulic splitter was used to break it.

Parallel to the excavation, the anchor became visible more and more and it was regularly cut every 40 cm parallel to the laying of a new pipe.

After the intended depth of the tunnel was reached, the mini shield had to be dismantled and transported up to the working chamber again. The tunnel was cleared of all installations and finally filled with artificial soil. Afterwards, the jacking frame was moved to anchor 51

Figure 8. Jacking station for anchor 51.

Figure 9. Excavation in the head of the pipe.

Figure 10. Anchor in the face.

and modified to fit to the new position and then the working cycle started again. One after another, anchors 51, 49, 36 and 35 were recovered.

9 COMPRESSED AIR PROBLEMS

It was obvious that the air pressure had to be increased concurrent with the increasing depth of the excavation. It was discovered during the excavation of anchor 52 that losses of compressed air were much higher than expected and finally they exceeded the capacity of the compressor stations.

Extensive sealing efforts became necessary. The working chambers were sprayed completely on all surfaces with a water reacting polymer, forming a rubber-like inliner. The ring gap around the jacking pipes (the shield had a small over-cut) was filled with bentonite, and the pipe joints were sealed with a custom made rubber gasket. Together, these measures significantly stopped the air losses enough to continue excavation.

10 IMPACT ON THE NEIGHBOURHOOD

The excavation continued with hardly any affect on the neighbourhood given that the setup of the construction site was in an empty building pit, as well as in the basement of the Petersbogen. Only the compressed air was responsible for some excitement during the middle of the construction. It is normal when compressed air is pressed into the ground that it tries to rise to the surface. In open areas the air dissipates over a wide area, but in this case, in the heart of the city with only buildings and bitumen paved sidewalks and roads, the air concentrated around only the few escape points available. This time it was on a 50 m long strip along the curbstone of the Petersstraße. One night after some heavy rain, unexpectedly a lot of bubbles became visible. The police was called on the scene three (3) times in 24 hours (once, every shift) looking for gas leaks.

An additional point where the air exited was on the opposite side of the Petersstraße, in the basement of the Stentzlers Hof. The air was coming in through a joint in the foundation slab. Together with the air, a small amount of water was pressed in as the slab was only marginally above the ground water level. It took a few words of reassurance to convince the owner that there was no danger to his property.

11 END OF WORKS

Finally, by the end of May 2006, the last anchor was recovered and the working chambers were all filled with artificial soil. Not only had all anchors been recovered, but it was also revealed by in depth investigations of all anchor pieces that design and execution faults on the explosive recovery were the reason why that method failed for 43% of the anchors. The ductwork had been designed at the lower limit of the theoretical required cross section.

Nevertheless, it is the opinion of the authors that the explosive recovery is a capable method, which was demonstrated successfully at another construction site in Berlin, Germany, where 175 cable anchors were recovered. In Leipzig, if the design had simply chosen larger ductwork, accounting for the importance of the recovery, and the realisation that sometimes an increase of effort is necessary, explosive recovery could have worked as well.

12 CONCLUSIONS

In the inner City of Leipzig, Germany, 20 cable anchors had to be recovered. Dependent on the individual boundary conditions two different, innovative recovery methods were designed and successfully executed with hardly any influence on the public life around the construction sites: the recovery with pile borers and slurry wall excavators from above the ground and the excavation with the help of pipe jacking tunnels starting under an existing building. Both methods proved successful and it was even possible to find out why the intended recovery by explosions in the grout bulbs failed.

Construction of Metro IV.C2 Ládví – Letňany in Prague

V. Bartoň, M. Kochánek & V. Valeš
METROPROJEKT Praha, Prague, The Czech Republic

J. Kutil
IDS, Prague, The Czech Republic

ABSTRACT: The construction of another leg of Prague Metro's C line is currently in progress. The extension with the length totalling 3.9 km is designed as an underground Metro route with 3 stations in open foundation pits. The technology of building the sections between stations is subject to the geological composition of the area. Under the layer of made-up ground, argillaceous earths and arenaceous marls there are layers of sand rocks and clay stones, the characteristics of which allow building part of the sections between stations by tunnelling technologies. For the most favourable sections the project authors suggest driven dual-rail tunnels of a closed profile with the floor arch of the stope area of 58–66 sq. metres. For the other sections they suggest using single-rail tunnels or sections in open foundation pits. The conceptual design of the stations is based on the latest trends used in the construction of the section put into operation in 2004. The Stříškov station is designed as a single-nave hall. The bearing structure of the glass areas is designed from steel. The common hall area integrates the vestibule and platforms. The height of the station's interior consists of three functional levels, i.e. the platform level, the mezzanine level and the ambient ground level – the ground floor. All the three publicly accessible levels form a lockable area, which is only available to the public when the Metro operates. The Prosek station is designed as a classic monolithic reinforced-concrete building with three operational levels – the level below the platform, the platform and the vestibule (underground). The structure is designed with steel columns located between rails. The Letňany station is designed as a monolithic reinforced-concrete frame with a variable width of three plus one fields. The platform area features a simple frame with an opening for direct lighting. The station consists of three storeys, with two stories at the platform. A single-storey structure of a side-track building, with two rows of columns, is adjacent to the station.

1 INTRODUCTION

The underground is the main backbone system of the Prague transport skeleton. The new routes improve the transport serviceability of the localities, create new development areas and increase the value of areas around the new stations. The implemented extension of line C from the Ládví station onwards will bring about all these advantages. The transport situation will improve not only in Prosek and Letňany, but also in the whole north-eastern area of Prague. There will be a large bus terminus station at the Letňany station, and a park-and-ride yard (P + R), which is highly needed in this part of the city.

In relation to the completed 1st stage of the 4th operating section of underground line C (section Holešovice railway station – Ládví), the construction of its extension commenced in 2004 in the direction of Prosek and Letňany, with a long-term municipal transport terminal station in the area of the Prague exhibition ground in Letňany. The track is laid under the ground in a relatively shallow depth, the stations are performed by cut and covered method, the tunnels are partly driven and partly performed by cut and covered method and they are mostly double-tracked. The construction is located in Prague 8, 9 and 18, i.e. in the cadastral districts of Kobylisy, Libeň, Prosek, Střížkov, Vysočany and Letňany.

As every similar project of metro line, even this one includes a number of interesting structural solutions from the field of tunneling, concrete construction and architectural ideas that, according to our opinion, are worth attention.

The investor of the project is Dopravní podnik hl.m. Prahy a.s. (a public transport operator), represented by the contracting authority, Inženýring dopravních staveb a.s.

The building permit documentation, tender documentation and the detailed design documentation have been elaborated by METROPROJEKT Praha a.s.

2 CONSTRUCTION OF THE UNDERGROUND AS A PART OF THE PRAGUE TRANSPORT INFRASTRUCTURE DEVELOPMENT

2.1 *Principles of the transport-urban solution*

The track leads from the existing terminus Ládví to the Střížkov station, which will serve the locality of Prosek, and the remaining part of the locality will be served by the Prosek station. A temporary park-and-ride yard with 203 parking places is designed at the Střížkov station. At the new terminus in Letňany, which has two vestibules, a bus terminal station is designed with a large parking area and a park-and-ride yard with 683 parking places next to the northern vestibule. Both these vestibules meet requirements for future connecting to the planned Prague exhibition ground.

2.2 *Basic data on the construction*

Length of construction IV.C2 4599 m Maximum longitudinal gradient of the track 3,95% Minimum horizontal radius of the track rails 500 m Number of stations 3.

1. Střížkov – an excavated station with a side platform and a single vestibule incorporated into the station hall. The level of the platform is 5.6 m under the surface level,
2. Prosek – an excavated station with a side platform and a single underground vestibule connected to underpasses under Vysočanská and Prosecká Sts. The level of the platform is 10.6 m under the ground,
3. Letňany – a long-term terminus, excavated, with an island platform connected to 2 underground vestibules. The level of the platform is 10.3 m under the landscaped surrounding ground.

3 STRUCTURAL AND ARCHITECTONIC DESIGN OF THE STATIONS

3.1 *Střížkov station*

The Střížkov station is a wayside excavated station with side platforms, located at the crossroads of Vysočanská and Teplická Sts. Along with the track section in the direction of the Prosek station it represents a part of track IV.C2, where the underground track level is closest to the surface.

It is an open hall room and thank to a light steel structure of the roofing it enables maximum glazing of the peripheral jacket of the station and thus lightening of the station hall by daylight, which makes it look like an overground station, although both the platforms are deeper compared to the surroundings ground. By opening of one sidewall into the opened excavated atrium, the station is in a direct visual contact with the external space and enables future level connecting with a shopping centre connected directly to the atrium room. On the other side, the station is connected to an underpass under Vysočanská St., enabling comfortable disability access to both platform edges. The internal room of the public part of the station is vertically divided into three functional levels, i.e. the platform level, the counterlevel and the level corresponding to the surrounding ground. The operating-technical part of the station is located under the ground, the underpass under Vysočanská street and the structure of the intermediate ceiling over the platform including the flooring of the foot-bridges are made of cast-in-situ reinforced concrete.

The supporting structure of the glazed roof of the station consists of two slanted steel arches decussating each other with a box cross section of a changeable height. They are fixed in massive concrete foundation

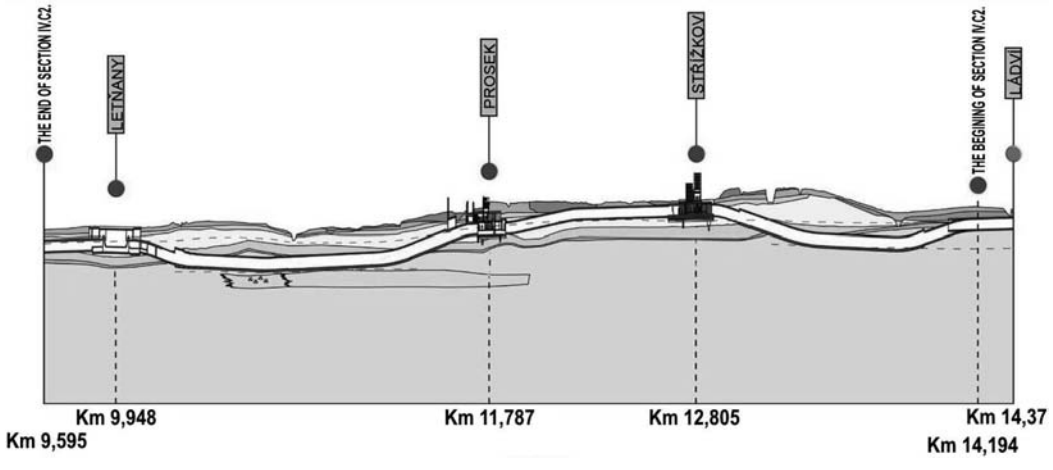

Figure 1. Longitudinal profile of metro IV.C2.

blocks hidden in the underground parts of the station. Four rows of tow bars suspended on the arches hold the roof structure. The main central box girder consists of two plain-web components, interconnected in the lower and upper parts with a framed girder. The girder is equipped with a number of transverse ribs – beams of changeable height. Ribs are interconnected by horizontal steel plate girder of circular shape on the side of the roof . The roof periphery is supported by steel socketed stanchions of "Y" shape with a changeable cross section. The glazed peripheral jacket is connected to these stanchions.

The total length of the Střížkov station structure is 228 m and the steel roofing structure with a ground plan shaped like a lens is 130 m long and its greatest width is 42 m.

3.2 *Prosek station*

The Prosek station is a wayside excavated station with side platforms, located at the crossroads of Prosecká and Vysočanská. Given a greater depth of the underground (the platform level is 10.6 m under the ground), the station is fully covered under the ground, with square glazes skylights designed in the steel structure in the area of the vestibule and the connecting shopping passages enabling partial lighting of the interior of the station by daylight. The street level is reached by the

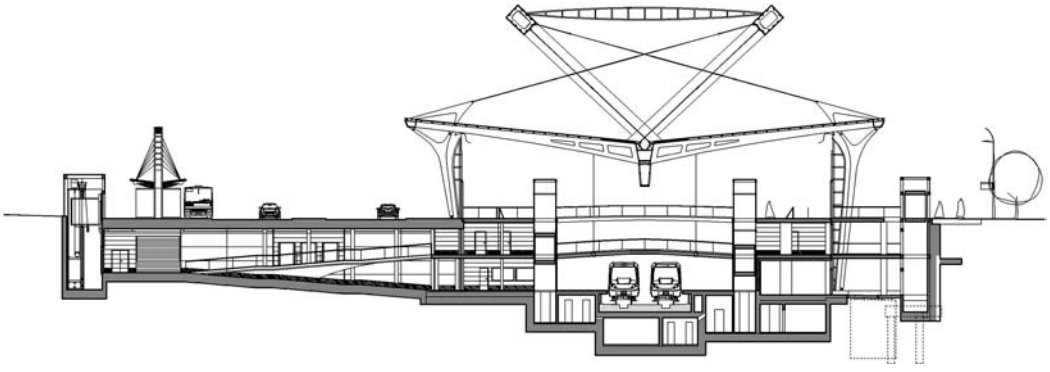

Figure 2. Cross section of the Střížkov station.

Figure 3. Design of the Střížkov station.

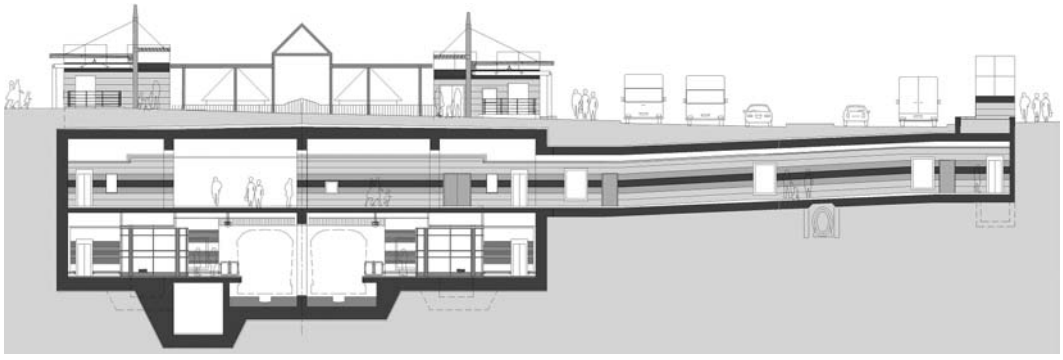

Figure 4. Cross section of the Prosek station.

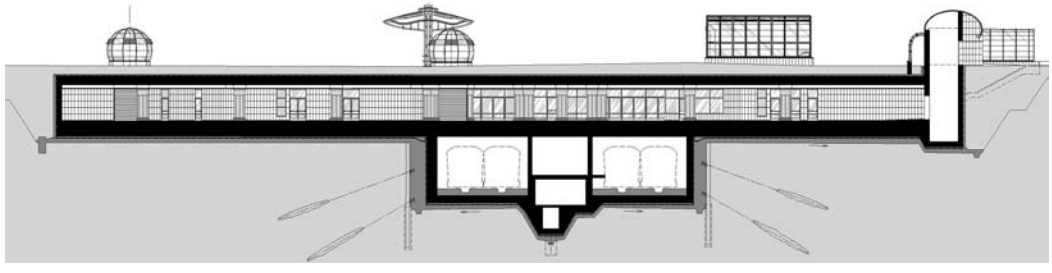

Figure 5. Cross section of the Letňany station.

skylights and exits with staircases and lifts for immobile people. The supporting structure of the station in the cross section consists of a closed cast-in-situ reinforced concrete frame with various internal divisions. The basic internal element of the internal division is a series of columns along the whole length of the station in the centre between the underground rails. The basic module interval of the columns in the longitudinal direction is 7.0 m. In terms of height, the structure of the station in the area of the platform and the technical-operating room is divided into three levels: the platform level, the level under the platform and the level of the vestibule with connected shopping passages and underpasses. In the remaining areas the division is into 2 height levels, i.e. the foundation slab under the underground rails and the intermediate ceiling at the level of the vestibule. A part of the underpasses with exits reaching beyond the ground plan of the station is naturally only at a height of one floor. The total length of the station structure is 210 m, the width ranges between 10–24 m. The height in the parts with three levels is 14.0 m and in parts with two internal levels it reaches 10 m.

3.3 *Letňany station*

The Letňany station is a long-term terminus located north of Kbelská St. and it should be a part of the entrance room of the future Prague exhibition ground replacing the existing temporary halls. The station is excavated with an island platform connected to 2 underground vestibules with exits ascending over the ground level. The platform level is 10.3 m under the landscaped surrounding ground.

The structure of the station in the cross section consists of a closed cast-in-situ reinforced concrete frame with an angular foundation slab in a constant width of 24.8 m in the whole station and a shunting track, i.e. a total length of 416.0 m. In the related part towards the Prosek station in a length of 176 m, the width of the structure continuously decreases to 16.4 m in the place of connection to the driven single-track tunnels. In the area of the platform the frame structure of the station is dipteral with a number of columns located in the axis of the platform in an interval of 6.4 m in the longitudinal direction. As regards the height, this part of the structure is divided by an intermediate ceiling at the level of the platform into the technological part under the platform with headroom of 2.3 m. The hall of the platform itself has a headroom of 8.35 m with a reinforced longitudinal girder over a number of columns and it will be covered by a lower ceiling lowered by 600 mm. Outside the platform space, the structure of the platform is prevailingly divided by longitudinal walls or wall pillars (in the shunting track) into a three-wing structure and in terms of height it is divided into three

levels – the level under the platform, the level of the platform and the level of the vestibules. The total height of the closed frame of the station is 12.65 m, in the section of the shunting track and excavated tunnels in front of the station the structure is single-floored, height of 6.8 m.

4 TRACK TUNNELS

The design of the track tunnels related to the construction of the underground IV. C2 was based on the effort to construct two-track tunnels in the maximum possible extent. A great advantage of this design in the case of station tunnelled two-track tunnels consists in larger profiles of the tunnel, which makes it possible, especially if the New Austrian Tunnelling Method is used (NATM), to introduce high-performance station tunnelling techniques enabling flexible changing of the machines in the working face. This is reflected in increased speed of tunnelling, resulting in costs reduction of the tunnel construction.

A great benefit of this conception is mainly experienced in the excavated track tunnel between the Střížkov and Prosek stations. The pit excavated for the construction of the tunnel has a width of approx. 12 m. For the construction of 2 two-track tunnels connected to the station with island platforms, it would be 20.5 m i.e. 70% greater volume of excavation work. The aforementioned reasons had an essential impact on the design of the Střížkov and Prosek stations, which are designed with side platforms. On the contrary, as regards the long-term terminus in Letňany, the island platform is advisable for operating reasons.

Base inter-axial distance of the tracks in the cut two-track tunnel is 3.7 m and in the excavated two-track tunnel 3.6 m. This distance determines the diameter of the cross section of the proposed tunnels. In the sections aligning to the stations, the inter-axial distance of the tracks usually continually increases, and thus the cross section of the tunnels also increases in relation to the layouts of the station.

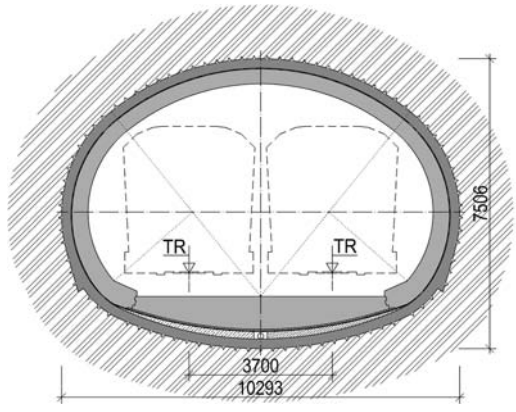

Figure 6. Cross section of the double-track driven tunnel.

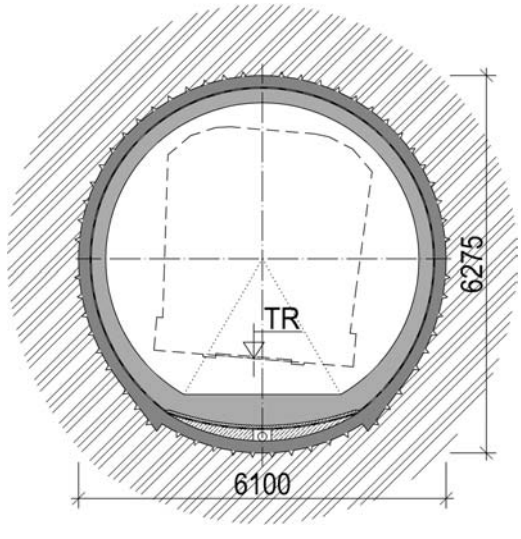

Figure 7. Cross section of the single-track driven tunnel.

4.1 *Driven track tunnels*

A double-track tunnel was constructed here in the section of Ládví – Střížkov (975) m and in the section of Prosek – Letňany (1,280 m). The double-track tunnel was connected to two single-track driven tunnels in the direction of the Letňany station (length of 2×63 m). All cross sections of the double-track tunnels have a closed oval shape with stope surface of approx. 64 m^2. The tunnelling employed the NATM technologies – the tunnel was tunnelled by a primary lining of air-placed concrete with a thickness of 200–350 mm (based on the quality of the rock massif) reinforced by steel mesh combined with bar rock anchors. The tunnels were prevailingly tunnelled by horizontal division of the stope into a calotte and the lower part of the tunnel. In exceptional cases in a short section below the residential areas with thin hanging layer, the stope was also divided vertically. Following the completion of the tunnelling, waterproofing using a PVC foil, thickness of 3.0 mm, was installed on the front of the lining and the secondary lining was concreted using cast-in-situ reinforced concrete. This lining was made in 10-m strips so that the tunnel bottom was concreted at the first stage and the vault was concreted in a moving formwork at the second stage. The minimum clear width of the double-track tunnel is 8.9 m, the minimum clear height is 5.5 m and the minimum thickness of the internal steel-concrete lining is 400 mm.

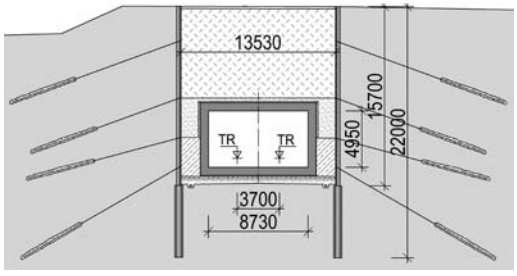

Figure 8. Cross section of the double-track excavated tunnel.

4.2 *Excavated track tunnels*

In construction of metro IV.C2 the two-track excavated tunnels are implemented of total length of 1251 m, of which in the Ládví – Střížkov section of 337 m, in the Střížkov – Prosek section of 772 m and in the Prosek – Letňany section of 142 m. Single-track excavated tunnels are not intended for the track. The double-track excavated tunnel has a minimum clear width of 8.4 m and a clear height of 4.95 m. From the structural point the simple closed frames of cast-in-situ reinforced concrete are designed. The thickness of the slabs and walls ranges from 700 to 800 mm, according to respective hydrogeological conditions. The tunnels were made in 12 m strips. On the inside, the tunnel is fitted with closed waterproofing PVC foil, min. thickness 2 mm with underlayers and protective layers. The tunnels were made in open excavation pit, secured with anchored strutted sheeting or pile timbering. The depth of the excavation pit ranges from 9.0 to 17.0 m. The backfill is performed to reach the original ground level above the tunnel roof.

ABSTRACT: The Kicking Horse Canyon Project (KHCP) involves upgrading approximately 26 kilometers of the Trans-Canada Highway in BC from the town of Golden to the western boundary of Yoho National Park to a modern four-lane standard. The KHCP is being undertaken in three Phases. Phase 1 comprised the replacement of the Yoho Bridge which was completed in 2004. Phase 2 comprises the replacement of the Park Bridge and grading work that is currently under construction, and Phase 3 comprises upgrading of the remaining stretches from the Yoho Bridge to Golden and the Brake Check to the Yoho Park Boundary. The preliminary design for the Phase 3 West section between Yoho Bridge and Golden is currently in progress and is evaluating new highway alignments through the steepest terrain section of the canyon that include two to three short (<1 km) tunnels as well as one alignment that includes a nearly 2.9 km tunnel that would be the longest bored road tunnel in North America. If constructed, the tunnel requirements for the highway improvement will represent the first major road tunnels in Canada in over 40 years. The preliminary design for the road tunnels comprises twin tube, 2-lane road tunnels. The road tunnels would be constructed within mixed sedimentary bedrock comprising limestones, dolostones, and shales with rock strengths varying from 30 MPa to 240 MPa. State-of-the-art road tunnel fire, life and safety requirements following NFPA requirements have been adopted given the increasing awareness for road tunnel safety measures. Comprehensive geotechnical site investigations have been completed as part of preliminary design studies. Portal location and tunnel design and constructability issues have been evaluated as part of the preliminary design work and are presented.

1 INTRODUCTION

The Kicking Horse Canyon Project (KHCP) involves upgrading approximately 26 kilometers of the Trans-Canada Highway in B.C. from the town of Golden to the western boundary of Yoho National Park to a modern four-lane standard. Due to the rugged nature of the canyon section and the requirements of the BC Ministry of Transportation this upgrading has required the consideration of tunnels as part of the preliminary stage of the project.

The KHCP is being undertaken in three phases. Phase 1 comprised the replacement of the Yoho Bridge which was completed in 2004. Phase 2 comprises the replacement of the Park Bridge and a major through cut in rock to a depth of 80 m that is currently under construction and planned for completion in late 2007, and Phase 3 comprises upgrading of the remaining stretch westwards from the Yoho Bridge to Golden and east of Phase 2.

The preliminary design for the Phase 3 section has evaluated several new highway alignments through the canyon that include two to three short (<1 km) tunnels as well as one alignment that includes a nearly 2.9 km tunnel. The construction for the Phase 3 section may commence in 2008/2009 and both traditional Design-Bid-Build and Design-Build-Finance-Operate (DBFO) contract approaches are being considered.

Both contract approaches have been implemented to date on past and current works. If constructed, the tunnel requirements for the highway upgrading represent the first major road tunnels in Canada in over 40 years since the construction of tunnels along the Trans-Canada Highway in the Fraser River Canyon. Most notably, the nearly 2.9 km tunnel option would be the longest road tunnel in North America.

Figure 1. Kicking Horse Canyon circa 1920's.

Figure 2. Kicking Horse Canyon.

Figure 1 shows a historical photograph of the highway through the canyon section.

2 PROJECT LOCATION

The Kicking Horse Canyon Project is located immediately east of the town of Golden, B.C. which is over 700 km northeast of Vancouver, B.C. and over 250 km west of Calgary, Alberta within the East Kootenay region of B.C. The section of the highway improvement project comprises 26 km of existing 2-lane highway from the town of Golden to the west gate of Yoho National Park. The Kicking Horse Canyon comprises a fairly narrow and winding canyon with maximum relief of nearly 500 m exhibiting very steep rock slopes as shown in Figure 2.

The elevation of canyon section of the alignment is approximately 1000 m and the main canyon section of the project is generally trending east-west with the Kicking Horse River flowing westwards through the canyon. The main CP Rail line is present along the lower slopes of the canyon and mostly along the northern side of the canyon below the existing

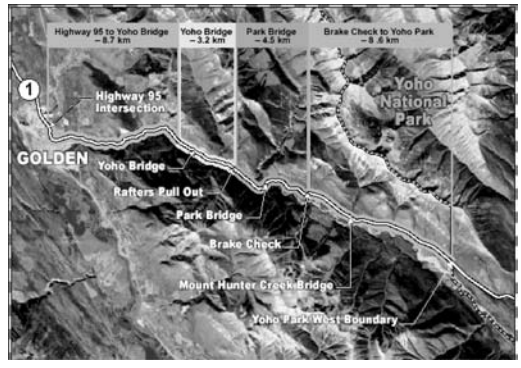

Figure 3. Project location and works phases.

highway. Figure 2 illustrates the project location and Phases of the project.

3 ROAD TUNNEL ALIGNMENT OPTIONS

Several studies have been completed since the early 1990's to identify highway improvement solutions for the Kicking Horse Canyon Project. The work from some of these studies identified several highway alignments along both the north and south sides through the canyon section. Recent preliminary work including terrain and natural hazard studies have indicated that a major ancient landslide is present along the south side of the canyon thereby precluding a highway alignment on the south side.

The remaining alignments along the north side of the canyon were evaluated further in terms of natural hazards and constructability in terms of maintaining the existing highway during construction. Following further work to date there exist two preferred alignment options referred to as the NB-2 and NC-2 alignments as shown in Figure 4.

The NB-2 alignment comprises a single, approximately 2.9 km tunnel that deviates northwards below a sharp ridge known as Frenchman's Ridge, passes under Dart Creek valley, a 400 m wide U-shaped hanging glacial valley, and continues eastward below the Black Wall Bluffs. The west portal is sited near the grade of the existing highway and the east portal is sited about 20 m below grade and at a sharp bend of the existing highway. Figure 3 shows the NB-2 alignment. The maximum cover along the NB-2 alignment is about 300 m below the Black Wall Bluffs. The minimum cover along the NB-2 alignment occurs within the Dart Creek valley and is under investigation at the time of writing.

The NC-2 alignment comprises three, short tunnels with lengths of about 555 m, 565 m and 565 m respectively for a total tunnel length of about 1685 m.

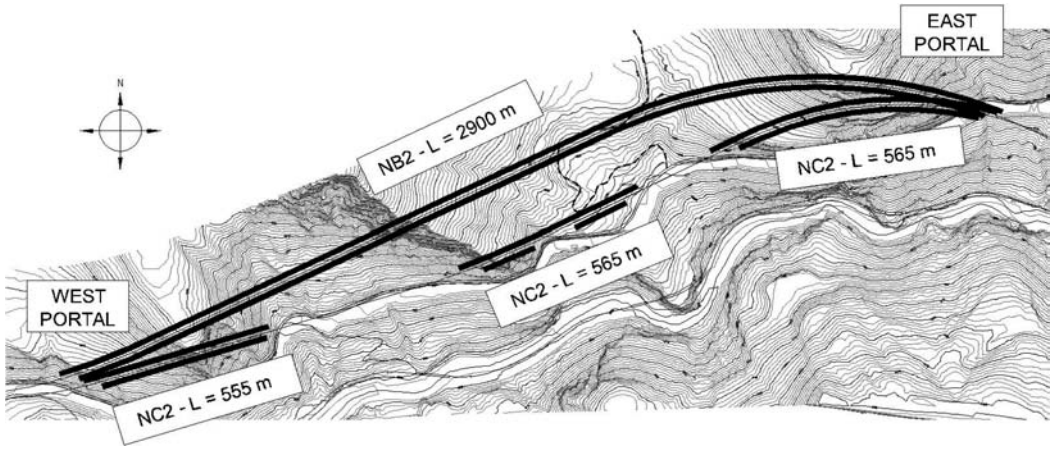

Figure 4. Road tunnel alignments.

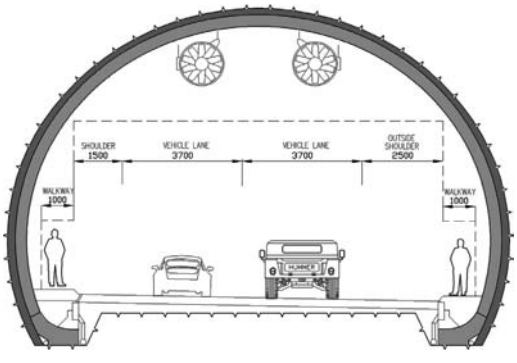

Figure 5. Large tunnel cross section.

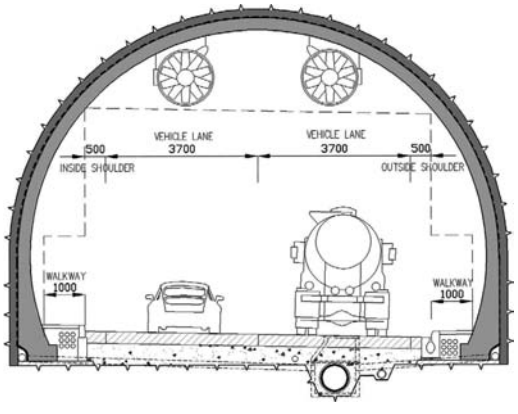

Figure 6. Small tunnel cross section.

The NC-2 alignment deviates not as much northwards as the NB-2 alignment but rather cuts through the series of bluffs/ridges along the canyon. The six portals required for the NC-2 alignment are sited both above and below grade of the existing highway.

With the development of possible new alignments through the canyon section it has been recognized that it is necessary to address the requirements of the external stakeholders. These requirements include maintaining access for CP Rail and river rafting businesses operating from upstream of the canyon, and to allow safe passage through the canyon for bi-cyclists. These requirements indicate that at least one lane of the existing highway will have to be maintained.

4 ROAD TUNNEL CROSS SECTION

Tunnel cross-section geometry was evaluated during the early stages of the preliminary design in recognition of the potential cost sensitivity and traffic safety requirements. As it was recognized that no tunnel roadway geometry criteria for road tunnels neither in Canada nor elsewhere in the world, a review of tunnel roadway geometry was undertaken and three options were developed for safety and costing consideration. The original tunnel cross sections varied from 115 m^2 to 127 m^2 and were based on lane widths of 3.7 m, walkways on both sides of 1.0 m, and varying shoulder widths of 1.5 m, 1.75 m, and 2.5 m, the largest allowing for emergency vehicle access (Figure 5). The initial tunnel cross section options were based on adopting large sized tunnels rather than minimized size tunnels similar to those in Europe. Cost comparison of these initial cross sections did not indicate significant cost increases for the largest size tunnel of 127 m^2. Smaller tunnel cross section options (90 m^2) have also been developed based on minimum shoulder dimensions for consideration based on acceptable international practice (Figure 6).

Figure 7. Geotechnical drilling by helicopter.

5 GEOTECHNICAL INVESTIGATIONS

Comprehensive geotechnical site investigations have been completed as part of the preliminary design work for both tunnel alignments. Historical geotechnical investigations have been completed throughout the canyon dating as far back as 1985. The recent fieldwork has comprised seismic refraction surveys at all portal locations as well as across the Dart Creek valley, over 1900 m of rotary core drilling, point load strength testing, in situ packer permeability testing, and laboratory rock strength and abrasivity testing. Piezometers have been installed in many of the boreholes completed along the tunnel alignments.

Access to some of the boreholes at portal locations and along the tunnel alignments was difficult and was only accomplished by helicopter. All boreholes were drilled vertically and the deepest borehole completed was about 250 m along the Black Wall Bluffs. Figure 7 illustrates drilling of one of the deepest boreholes from the upper reaches of the Black Wall Bluffs by helicopter assistance.

6 TUNNELLING CONDITIONS

6.1 *Site geology*

The geology along the proposed tunnel alignments comprises sedimentary bedrock of the McKay Group and the lower part of the Glenogle Formation that has been subjected to eastward thrust faulting and folding with overturning. The McKay Group of rocks comprises five main sub-units (COMk2 to COMk6) that can be characterized as shaley limestones (odd numbered sub-units) and dolomitized limestones (even numbered sub-units). These five sub-units are present along the western and central sections of the alignment. The shaley limestones are finely laminated whereas the dolomitized limestones appear to be more massive in nature. The lower part of the Glenogle Formation can be described as a mixed slate/shale/dolomitic siltstone with finely laminated dolomitic beds.

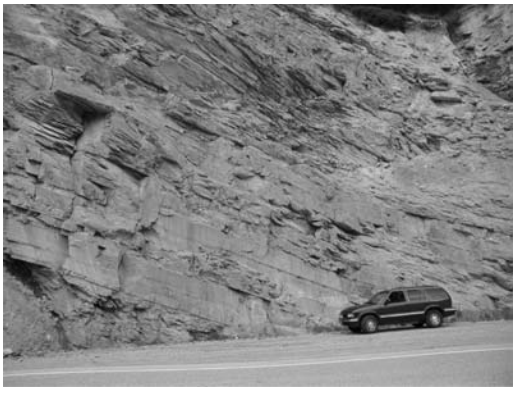

Figure 8. Existing rock cut.

Extensive bedrock outcrops are present in massive sub-vertical rock cuts formed by the original highway construction and appear along almost the entire tunnel alignments. Figure 8 shows a typical large rock cut of bedded limestone along the central section of the tunnel alignments.

6.2 *Rock strength and abrasivity*

Numerous point load strength index tests and uniaxial compressive strength (UCS) test were completed on the drill core. The rock strength of the shaley and dolomitized limestones generally varies from 15 MPa to 100 MPa with an average strength of about 60 MPa. The rock strength of the dolomitic shales and siltstones generally varies from 20 MPa to 240 MPa with an average strength of about 100 MPa. Figures 9 and 10 illustrate the variation of rock strength based on UCS lab testing results of the limestones and shales respectively. Rock abrasivity was evaluated based on CERCHAR Testing. CERCHAR Abrasivity Index (CAI) values for the limestones indicated values generally ranging from 0.8 to 2.4 characterizing the rock as slightly to non-abrasive. CAI values for the shales indicated values generally ranging from 2.0 to 4.0 characterizing the rock as very abrasive.

6.3 *Rock fracturing*

Rock fractures are pervasive within the limestone and siltstone/shale bedrock in the form of bedding and sub-vertical fractures that can be identified from both

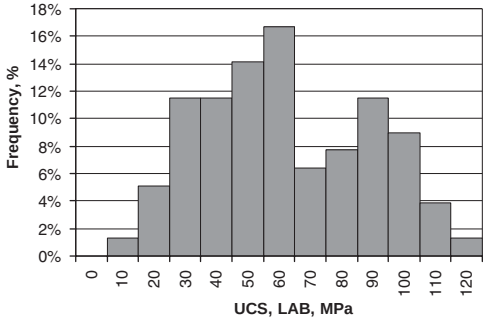

Figure 9. Rock strength – limestones.

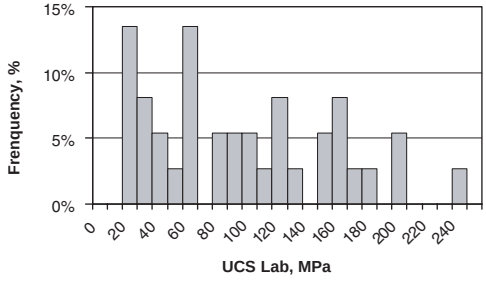

Figure 10. Rock strength – shales.

drillcore and surface outcrops. The dip of the bedding within both the limestones and shales typically ranges from 15 to 20 degrees. The dip direction of the bedding is northeasterly for the limestone and northerly for the shales. The main sub-vertical fractures sets are prominent as orthogonal fractures and are generally oriented both perpendicular and sub-parallel to the strike of the bedding. Bedding fractures are typically very smooth and planar. Figures 11 and 12 illustrate stereonets of the rock fractures within the limestones and shales respectively.

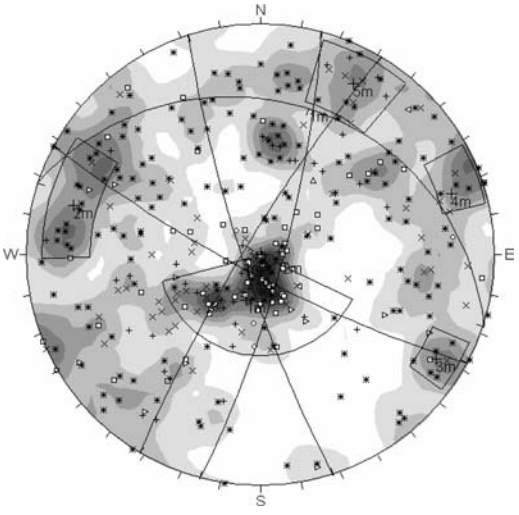

Figure 11. Rock fractures – limestones.

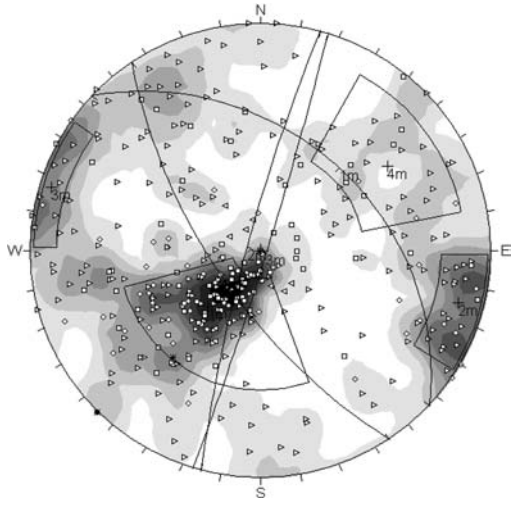

Figure 12. Rock fractures – shales.

6.4 *Major fault/shear zones*

The geology along the tunnel alignments has been intruded by both sub-vertical and sub-horizontal thrust type faults. Sub-vertical fault/shears have been mapped from outcrops below the tunnel alignment along the CP Rail right-of-way and are expected to be present across the tunnel alignments. The most distinct sub-vertical faults are referred to as the West, Middle and Dart Creek Faults. The thicknesses of the West and Middle Faults are inferred to be no more than 10 m while the Dart Creek Fault is inferred to be as much as 20 m in thickness.

The most prominent major fault/shear feature along the tunnel alignments is referred to as the Black Wall Bluffs Fault. This fault zone is a thrust fault that is clearly visible in a sub-vertical rock cut at the western edge of the Black Wall Bluffs. This zone is comprised of highly distorted siltstone and shale bedrock as shown in Figure 13 and is currently inferred to be undulating in nature and may also be present near the east portal. The overall orientation of this fault is inferred to be dipping less than 20 degrees towards the northeast. The fault is present in the exposed rock cut over a vertical height of about 15 m and may have an overall thickness as much as 25 m based on a limited number of borehole intersections from targeted drilling. It is noted that complete recovery of this fault was obtained in one of the boreholes that were targeted.

Figure 13. Black Wall Bluffs Fault exposure.

Interpretation of the possible length of intersection of this major fault with the proposed tunnels has been made based on a 3D geological model using surface outcrop and borehole data. Results from the model suggest that the length of the intersection of this fault with the tunnel could be as much as 250 m extending over much of the eastern portion of the tunnel alignment. The geotechnical relevance of this fault zone in terms of construction cost is not considered to be significant enough to justify modification of the tunnel alignment to reduce this intersection length versus the possible increased costs associated with higher capacity tunnel support that may or may not be necessary.

6.5 *Groundwater conditions*

The groundwater table is inferred to be at a shallow depth below surface along the tunnel alignments. A limited number of packer permeability tests were completed in the dolomitized limestones along the Dart Creek valley section of the tunnl alignments. These tests indicated rock mass permeability of this generally massive bedded bedrock is in the order of 5×10^{-7} m/s to 5×10^{-10} m/s. Given the relatively low cover along the alignments, the magnitude of groundwater inflows from most of the bedrock is not expected to be significant. Significant groundwater inflows can however be expected from the identified sub-vertical faults at Dart Creek valley and possibly from the Black Wall Bluffs Fault.

Artesian groundwater conditions are indicated from two boreholes completed into bedrock in Dart Creek. These conditions are inferred to represent groundwater flow under pressure either along the top of bedrock in the Dart Creek valley or within the extensive thickness of glacial overburden in which the Dart Creek stream course has disappeared and then re-appears at a location on the north side of the existing highway. These artesian groundwater conditions may pose problems for surface excavation in the overburden at Dart Creek but are not expected to have any influence on tunnel excavation in bedrock below Dart Creek valley.

7 FIRE, LIFE AND SAFETY DESIGN ISSUES

The fire, life and safety design requirements for road tunnels is currently undergoing significant changes and improvements as a result of the recent series of significant fires within major road tunnels in Europe. No such requirements are established for road tunnels in Canada as a code of practice and therefore the current approach for the proposed tunnel options is to adopt those standards set out by the National Fire Protection Agency (NFPA) of the United States that are considered to represent state-of-the-art industry practice. These standards set out requirements for the maximum spacing of pedestrian cross passages, fire suppression, communications, lighting, ventilation, and operations monitoring. In Europe, there currently exist a number of research groups dedicated to establishing a suggested code of practice for fire, life and safety requirements for road tunnels. The cost of the fire, life, and safety requirements for road tunnels is a significant portion of the overall construction costs. Significant costs are also associated with providing a tunnel operations center and operations monitoring and maintenance.

8 CONSTRUCTABILITY ISSUES

8.1 *Tunnel excavation and support*

The stability of the tunnels will be predominantly influenced by the formation of potentially unstable rock wedges formed along the crown and haunches due to the presence of the pervasive bedding in conjunction with orthogonally oriented sub-vertical fractures. Large bedding slabs can be expected to form and be unstable, requiring regular support for stability and safety.

Owing to the generally strong and bedded nature of most of the bedrock it is expected that the tunnels can be excavated by a standard 2-stage top heading and bench approach or even possibly full face method depending on the final size of the tunnels. Conventional tunnel support measures comprising pattern rock bolts with mesh and shotcrete are expected to provide adequate support for the majority of the tunnels. Enhanced tunnel support measures comprising lattice girders in conjunction with mesh and shotcrete and possibly supplemented with forepoling or self-boring anchors may be necessary at the intersection of major fault zones such as the Black Wall Bluffs Fault.

Kinematic and numerical analyses have been competed to assess excavation stability in terms of the

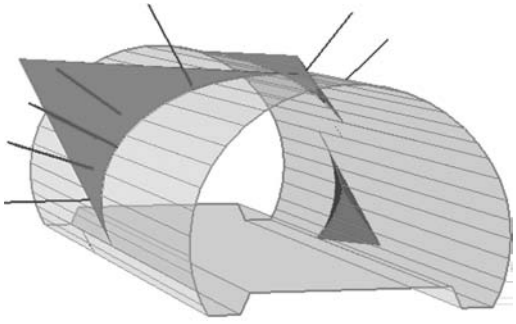

Figure 14. Typical large unstable wedge.

maximum size of potentially unstable wedges formed around the tunnels and any potential for overstressing to confirm the adequacy of conventional tunnel support requirements. Figure 14 shows an example of a large unstable wedge that may form along the sidewall of the proposed tunnels that would be required to be supported using pattern rock bolts during excavation.

8.2 *Portal excavation*

The proposed portal locations are sited in very close proximity to the existing highway. Bedrock is present at very shallow depth for most of the portals for the NC-2 alignment and the west portal for the NB-2 alignment. The main challenge for excavation of the portals in rock will be controlled blasting and management of traffic due to the close proximity of the existing highway.

In comparison, mixed overburden materials are present to a depth greater than 10 m at the east portal of both alignments. The nature of these materials is not well defined but is believed to comprise loose side-cast material from the construction of the original highway.

The east portal is sited below the existing highway and presents a challenge for excavation and support in order to prevent any impact to the existing highway. An initial portal layout was developed based on commencing tunnel excavation in bedrock for minimum tunnel costs that requires significant excavation into the existing highway as shown in Figure 15.

A preferred alternative to this layout has been developed based on commencing tunnel excavation as soon as possible with minimum cover through overburden material as shown in Figure 16.

This alternative layout provides an appropriate buffer from the existing highway however would require specialized tunnel support measures including some form of pre-support such as forepoling or self-boring anchors at a higher cost for the initial section of tunnel.

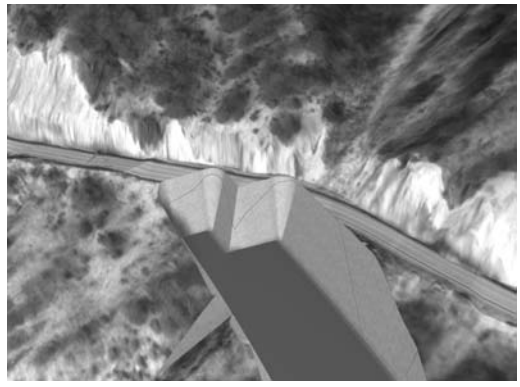

Figure 15. East portal excavation in rock.

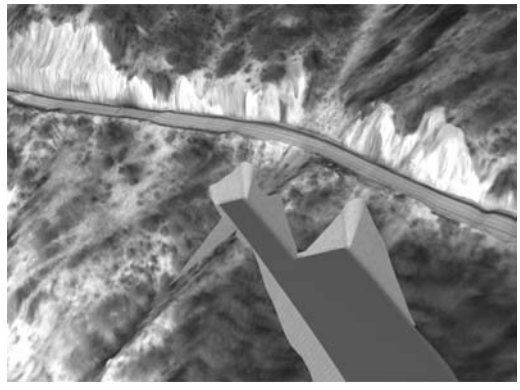

Figure 16. East portal excavation in overburden.

A portal excavation layout for the east portal that does not impact the existing highway also provides the benefit that the highway serves as an avalanche and rockfall catchment bench during operations. The east portal is located immediately adjacent to hazardous avalanche chutes that would otherwise require some form of protection-shed structure at the east portal.

8.3 *Dart creek intermediate access tunnel*

Owing to the expected relatively large portal excavations required to be formed prior to tunnel excavation, it has been recognized that the low cover section of the Dart Creek valley offers an opportunity for the construction of an intermediate access tunnel and laydown area that provides great benefits to the project. In addition to independent access for tunnel excavation, the intermediate access tunnel prevents any need for muck haulage along the existing highway to the designated spoil disposal site in the Dart Creek valley. Also, the intermediate access tunnel may be used for permanent emergency access during operations from

Figure 17. Dart Creek intermediate access tunnel/laydown/spoil site.

a tunnel control center that is currently proposed to be located near the access tunnel at Dart Creek.

The proposed intermediate access tunnel would be constructed entirely in bedrock after surface excavation and the establishment of an appropriate laydown area located immediately north of the highway in Dart Creek as shown in Figure 17.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the permission of the BC Ministry of Transportation to publish this paper. The Owner's Engineer Team for the preliminary design work comprises Focus Corporation, UMA-AECOM, Hatch Mott MacDonald, and Thurber Engineering Ltd., along with several specialist consultants. Geophysical surveys were completed by Frontier Geoscience of Vancouver. Geotechnical drilling was completed by Sea to Sky Drilling of Burnaby, BC. Laboratory testing was completed by Thurber Engineering Ltd. and packer permeability testing was completed by Golder Associates of Burnaby, BC. Abrasivity testing was completed by SubTerra in Seattle, USA.

Preparation of metro's a line extension in Prague

V. Cigánek & J. Růžička
METROPROJEKT Praha, Prague, The Czech Republic

ABSTRACT: Metro network is the backbone of the public transport system of any large city and, from this point of view, a further development of this system is a substantial question and one of the priorities. The current Metro network in Prague consists of three lines: A, B and C, with 53 stations and the total line length of approximately 54 km. There is a dedicated depot for each line (in Hostivař, Zličín and Kačerov). One of the primarily monitored construction projects in the Metro network is currently the extension of Metro's A line westwards. Given the overall extent of the project, it is envisaged that the project will be divided into stages: – The operation section of the A line, from Dejvická to Motol; the newly considered extension westwards to the area of the Petřiny housing estate and to the Motol Teaching Hospital; operation length of 6.0 km, 4 stations. If required, this operation section can be flexibly shortened so that it will terminate at Petřiny. (operation length of 4.5 km, 3 stations), – The continuing operation section Motol – Prague Ruzyně Airport (the north branch), operation length of approximately 7 km, 4 stations. A study work is currently in progress to check the construction and technical feasibility of the route designed in this way (the penetration through the Prague Ruzyně Airport in the lane of railway transport, new station layout, etc.). The implementation of this route, if any, directly depends on how it will be actually needed in relation to the transport from and to Prague Ruzyně by rail, – South branch – Motol – Zličín, operation length of 5.0 km, 3 stations. The Motol – Bílá hora section is identical with the route of the above-mentioned north branch of the line, further continuing to the Řepy housing estate and the Zličín station (approximately 3.8 km). In this regard, the line can be branched at Bílá hora. This south branch is only viewed as a prospective development of the Metro network in this quadrant of the city.

1 INTRODUCTION

An extension of the Metro Line A is planned to generally improve the quality of the City's northwest sector traffic service by capacitive rail traffic. The improvement should become evident by a total reduction of bus lines in this area of Prague. In combination with the so far considered railway connection, a possibility to achieve a tranfer terminal in the area of Dlouhá Míle and Ruzyně Airport via a new track has been considered, having no impact on the railway fixed under the Prague Capital's City Plan. At the same time, a plan to remove the existing Metro Line A terminus from the Dejvická station to a more suitable and less exposed location, in terms of town planning, towards the outskirts of the Town, has been considered.

2 GENERAL DESIGN PRINCIPLES

Within the context to the new facts, the planned solution represents a basic change of the concept of the Metro Line leading to the area of Dědina housing estate, then actually directly to the Dlouhá Míle terminal and, finally, to the Ruzyně Airport alone. At the same time, an effort has been maintained to keep the advantages of the initial solution, enabling the basic route to branche in the area of Bílá Hora to Řepy housing estate and Zličín terminus. It is possible to consider the priority of the selected direction of routes' leading according to specific needs in given time. In light of progress of the line construction, the possibility to terminate its phase in the Petřiny station has been moved to the Motol station.

An expected final option of the solution is to lead the line from the existing Dejvická station in the track Červený Vrch – Veleslavín – Petřiny – Motol – Bílá Hora – Dědina – Dlouhá Míle – Ruzyně Airport with a possibility of branching behind the Bílá Hora station to Řepy – Zličín direction with a linkage to Zličín Depot of the Line B. A subject matter to modify the line via Ruzyně Old Airport with a possibility to insert another station into such area was verified as a consequence of reaction on Metro routing in a new track led through Prague Airport area of interest.

In terms of train traffic operation, railcards for train set turning and deposition are dislocated en route within the context of the particular stations, taking

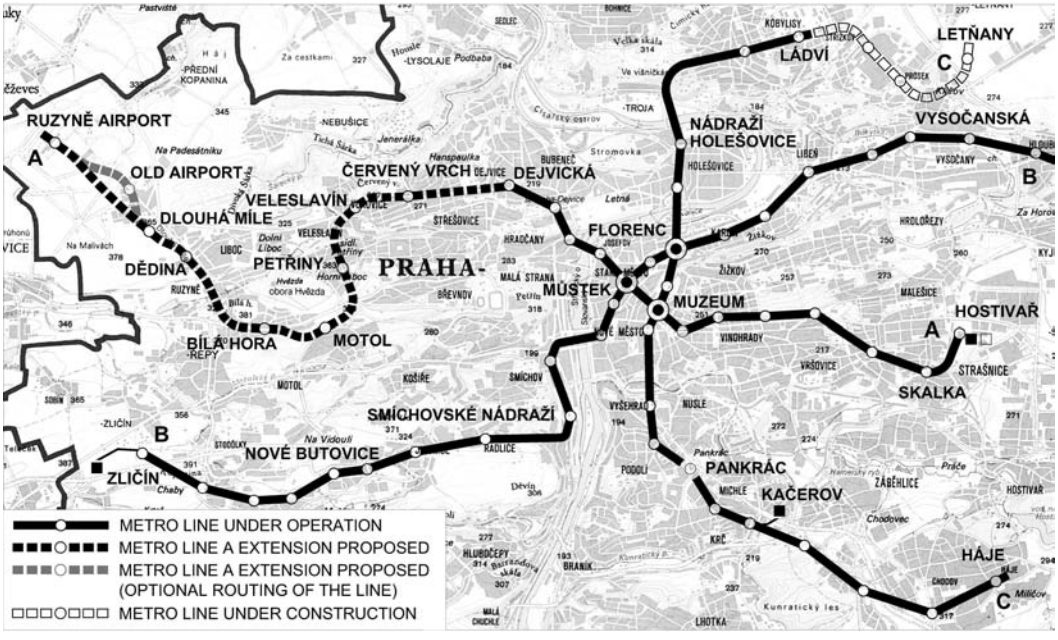

Figure 1. Section of the Prague Metro network.

into account a possibility to put the Line into service step by step as well as traffic organization during extraordinary operation situations and variability of service train rides to provide the maintenance during regular night exclusions. The railcard for set turning and deposition is projected in the Ruzyně Airport Terminal station as well as in the Motol and Bílá Hora Phases terminal stations. Such arrangement enables train turnings up to ca. 5 km down the Line.

According to standards, the following description of the Line's final solution was compiled down the stationing direction, i.e. from Ruzyně Airport to Dejvická stations. On the basic level of knowledge, it discusses the designed issue in terms of specific stations and sections between the stations.

2.1 *The Ruzyně Airport station*

The Ruzyně Airport station is a driven single-nave station with a central platform in depth of 20.9 m below ground surface. Its location, height position and links to the area comply with the Airport's development plans and expected railway terminus of the railway line Airport – Town Centre. At the same time metro terminus location accepts possibility of further extension of railway line under the new Sever II Airport Terminal's building and expand the stop by including another rail with a platform on the northern side.

The station is designed as terminus on a long-term basis, having a rail arrangement to enable turning and depositions of train sets. Therefore, siding and stabling rails in a four-rail arrangement are designed behind the station. The station tunnel including coherent the siding and stabling rails is regarded as a cavern with cross section of the excavation area of about 220 m^2 in length of 450 m. The cavern shall be driven by NRTM with a vertical and horizontal excavation segmentation of the stope. It will be partially driven in Jurassic rocks (calotte) and partially in Upper Palaeozoic and Proterozoic rocks. Two single-track tunnels 2310 m long will connect terminus with the station Dlouhá Míle. The tunnels will be largely driven in Upper Palaeozoic and Proterozoic rocks. They will rise to Jurassic formations solely in the neighbourhood of the Dlouhá Míle station. The tunnels will be performed by TBM with mounted reinforced lining. An open building pit for the Dědina station and adjacent tunnels will be used for deployment of TBM complex. Total length of the open building pit will be 450 m. The sequence of the works has to enable passing of TBM through the Dlouhá Míle station.

2.2 *The Dlouhá Míle station*

In terms of its location, the Dlouhá Míle station is fixed to have a direct linkage to the stop included in the Airport and Town Centre railway connection, similarly as the Ruzyně Airport station. The main importance of the station generally lies in an option to form a quality traffic terminal, especially for transfers from

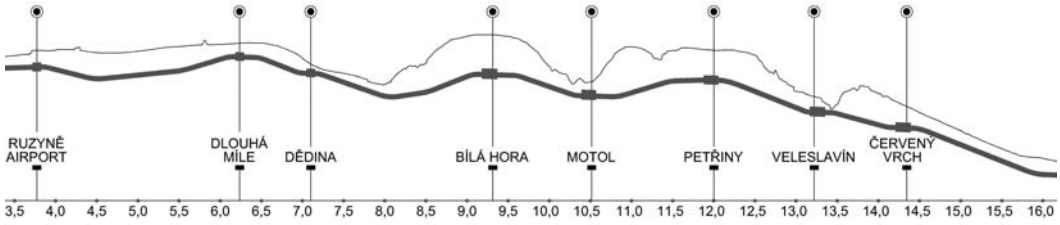

Figure 2. Exaggerated longitudinal profile metro line A extension.

long distance bus lines and regional bus transports. The junction also comprises a capacity parking (P + R System), located in a close linkage to the Metro and railway station on its eastern side.

The station is designed as driven station with a platform 17.3 m under the ground surface across under the projected railway stop. In this way a direct interconnection of the Metro station central platform to both railway stop departure edges is ensured, serving as departure edges of coherent bus transport as well. A direct exit from the Metro station to the surface via lift systems ended in the P + R parking premises is designed in the south part of the station.

The Dlouhá Míle station including the section of rail crossover behind the station is regarded as a cavern with a cross section of ca. 220 m^2. The excavation is regarded by use of NRTM with a vertical as well as horizontal segmentation, similarly as in the Ruzyně Airport. It will be driven in Jurassic formations. Two single-track tunnels 620 m long towards the Dědina station will follow the cavern. Again, TBM is considered concerning the tunnel excavation. As mentioned above, it is considered that the TBM will be deployed at the Dědina station. The track tunnels will be largely driven in Jurassic rocks, however, they will dip into Ordovic layer environment in front of station Dědina.

2.3 *The Old Airport station – an optional routing of the line*

The direction of the above described general routing of the Line is re-arranged in the section between Ruzyně Airport and Dlouhá Míle stations in order to be possible to insert another metro station near the Old Ruzyně Airport. Driven one nave station was proposed with a platform in depth of 12.2 m below ground surface. Distances between the station's centre and Ruzyně Airport/Dlouhá Míle stations make 1710 m, eventually 917. Total prolongation of the Line using this option then makes ca. 150 m.

The building pit premises of the driven Old Airport station would be utilized to deploy TBM to excavate single-track tunnels both in direction to the Ruzyně Airport and Dlouhá Míle stations and then to the Dědina station, where the pit may be utilize either to dismount the TBMs or turn and subsequent reverse excavation. In this option, the track tunnel will rise up to the environment of Jurassic formations ca. 500 m before the Old Airport station, in which they will be driven up to the Dlouhá Míle station.

2.4 *The Dědina station*

The Dědina station is designed as a driven one nave station with a central platform in approximated depth of 12.2 m below ground surface. It is located northwest from the Krnovská – Vlastina Streets crossing. The distance between the station's centre and a following The Bílá Hora station is 2211 m.

Beyond the Dědina station, the line sharply slopes down to Ruzyně area to safely undergo the existing residential area. Then it grades up to Bílá Hora, to the following station. The maximum longitudinal gradient is 39.5%. The line routes through Litovice Brook flood plain in this section. Saturated quaternary sediments in the area where the proposed Metro single-track tunnels undergo the bed of the brook have approximate thickness of 8 to 10 m. The metro vertical alignment is designed approximately 8 m under the base of the mantle formations. The bedrock here is formed by Ordovic slates of Letná strata. It is possible to excavate the designed single-track tunnels by TBMs in such rock environment and to warrant very small gradients of the existing Ruzyně low-floor residential area as well. The TBM will be deployed in the section of the open building pit beyond the Dědina station and will be dismounted either in the cavern of the driven one nave station Bílá Hora or as long as the station is passed in the area near to stabling rails before the Motol station.

2.5 *The Bílá Hora station*

The Bílá Hora station is situated transversally under Karlovarská Street between Karlovarská – K Motolu and Karlovarská – Turnova crossings. The station is driven with a platform in depth of 49.2 m below ground surface. One underground vestibule situated under the centre of the existing tramway line loop is considered. A thickness of the quaternary mantle formations

moves in the range of 2 to 6 m. The rock overburden of the station is largely formed by Jurassic formation sediments. The stratum is about 35 m high. However, the station itself is situated to Ordovic strata. It is possible to project any type of driven station including the most sophisticated one nave station under such given geological conditions.

The line continues through driven single-track tunnels to the area near to the Motol Hospital's northern entrance, where a metro station of the same name is located. The section has a maximum longitudinal gradient of 34.6%, and is approximately 1100 m long.

2.6 *The Motol station*

The Motol station is located north of Kukulova Street in the service area near of the Motol Hospital area's northern entrance. The station is orientated in east-west direction with a single vestibule accessible from the west front of the platform. A subway under Kukulova Street follows the vestibule. The station is designed as shallow driven station with a platform in depth of 18.1 m below ground surface. Concerning the projected vertical and horizontal alignment of the track, the station is situated in very unfavourable geological conditions. A slumping gradient at the edge of the Jurassic plate is in the overburden of the station. The bedrock where the station would be executed is formed by Ordovic strata. It would be suitable to consider that the station should be driven, preferably consisting of two separate tunnels with a sufficient rock intermediate pillar, interconnected by transversal corridors followed by the access to the station.

Due to the expected phasing of the works the station is equipped as a temporary terminus with a rail yard for set turning as well as deposition during the phase. Three-rail arrangement beyond the station (against the direction of stationing) is expected. Within a context of standard requirements, the direction and height design of turning rails is different from the track rails of the future status. A rectification of the section will be necessary if the line will continue in future.

The line turns to the north via a left-oriented curve beyond the Motol station and is led to the Petřiny station. The driven single-track tunnels are 1085 m long.

2.7 *The Petřiny station*

The Petřiny station is situated under Brunclíkova Street with a centre approximately in a prolongation of Fajmanové Street. The station is designed as a driven one nave station with a platform in depth of 36.5 m below ground surface. It has a single underground vestivule located before a crossing with Na Petřinách Street. A subway with exits on both sides of the Na Petřinách Street including exits to rearranged tramway platforms follows the vestibule. Eventually, a long direct section and track tunnel gradient conditions in direction to the Motol station allow to execute the station as a temporary terminal as well (in frame of phasing of the works). Siding and stabling rails a four-rail arrangement are designed concerning the station. Due to operation and technological reasons, such arrangement is completed by two single rail junctions (before and beyond the station), allowing to achieve a maximum operation's versatility.

A thickness of mantle formations moves around 2 m. There is a bulky Jurassic formation strata of app. thickness 18 m and a bedrock, in which a cavern of the station including shunt rails will be driven, is formed by Ordovic rocks. A thickness of rock missive's overburden without the mantle formations will move around 26 m. The line turns to the northeast via a curve beyond the station and is led to the Veleslavín station. The section has a maximum longitudinal gradient of 39.5%, and the driven single-track tunnels are 1110 m long.

2.8 *The Veleslavín station*

The Veleslavín station with a centre approximately under Evropská Street is situated in the area between the existing ČD line (the Veleslavín Railway Station) and eastern section of K Červenému vrchu Street. The station is designed as shallowly driven with a platform in depth of 19.4 m below ground surface. It has a single underground vestibule situated between the ČD line and Evropská – Kladenská Streets crossing. The location of the station, vestibule and individual exits is designed to allow direct linkages to a temporary bus terminal during the phase and at the same time to respond in advance to the planned modernization of the existing ČD line without any need for reconstruction.

The projected routing direction and height of the line and given geological conditions allow designers to propose a construction of a two naves driven station with a row of bearing pillars in the axle of the station, on which a reinforced girder supporting inside footing of station tunnel vaults is placed. Such station's design allows a sectioning progress of the station's construction even in less convenient geological conditions and a low height of the overburden. To ease a dispersal of passengers from escalators to the area of the driven part of the station, the driven part situated under Evropská Street may be combined with the excavated section to the Petřiny station, where the exit escalators will be placed and the structure will have no internal supports.

In direction to the Červený Vrch station, excavated track tunnels will follow the driven part of the station between which a technological part of the station may be placed. The line then continues as driven up to the Červený Vrch station. There is a maximum gradient 26.9% in the section.

			2175
Dejvická	existing		

2.9 *The Červený Vrch station*

The Červený Vrch station is situated under Evropská Street, in the area between Evropská – Arabská and Evropská – Horoměřická Streets crossings. The station is designed as driven one nave station with a single excavated vestibule. The platform's depth under ground surface is 26.7 m in the centre of the station. The rock environment around the station is formed by Skalec quartzites with a thickness in the overburden of the station between 13 and 22 m.

Table 3. Basic information on line's optional routing.

	Final status	Motol phase
Construction length of the projected section	12.946 4 km	5.663 8 km
Operational length of the projected section	12.9 km	6.0 km
Number of the stations	9	4
Prolongation of optional route	153 m	

Table 4. Basic information on the stations (Line's Optional Routing)

Station name	Station type	Platform depth under ground surface, m	Distance between stations, m
Ruzyně Airport	driven	20.9	
			1701
Old Airport	cut and cover	12.2	
			917
Dlouhá Míle	driven	17.3	

The vestibule accessible from the eastern front of the station is situated to the crossing with Horoměřická Street with a linkage to considered small terminal of town and suburban bus lines, destined especially from Nebušice, Jenerálka and Horoměřice areas. A subway under Evropská Street follows the hall, allowing a direct transfer to the existing tramway line on Evropská Street as well.

Beyond the Červený Vrch station this Metro Line continues via two one-rail track tunnels 1835 long and ends in shunt rails of the existing Dejvická terminus station on the Prague's Metro Line A. The track tunnels decline in a maximum gradient of 39.5% in direction to the Dejvická station. They will be largely mined in quaternary soils and below the underground water level. A tunnel construction by use of excavating machines is considered with regard to geological conditions and considerably big length of the Line's section.

Preparation of Metro's new D Line in Prague

V. Cigánek & J. Růžička
METROPROJEKT Praha, Prague, The Czech Republic

ABSTRACT: Metro network is the backbone of the public transport system of any large city and, from this point of view, a further development of this system is a substantial question and one of the priorities. The current Metro network in Prague consists of three lines: A, B and C, with 53 stations and the total line length of approximately 54 km. There is a dedicated depot for each line (in Hostivař, Zličín and Kačerov). One of the primarily monitored construction projects in the Metro network is currently the construction of the new fourth Metro line, line D. The operation length of its first planned operation section is 10.2 km with 10 stations. Given the overall extent of the project, it is envisaged that the project will be internally divided into two or three operation sections, which will directly follow one another. The implementation of Metro's new D line has been monitored for a long time and gradually stabilized into the current form. The D line, located in the southern sector of the city, is a completely new rail transport element, thus reacting to the current completely inconvenient situation when buses are used as the means of public transport there. What is more, the buses mostly transport the passengers to Metro's C line (the Kačerov station) and partly also to the B line (the Smíchovské nádraží station). The transport characteristics of the D line are different from those of the currently operated Metro lines because surveys show that the D line traffic will be much lower than that of the other Metro lines. The use of a new light system is being considered for the Prague Metro, its new D line, in view of the above-mentioned facts and the worldwide trends of the overall modernization of rail transport systems. The 'light Metro' is viewed as the base of a new transport system, which will serve the city and can also penetrate into the region.

1 INTRODUCTION

The Line D is the fourth diameter in the Prague metro network. Its objective is to provide radial transit to the centre from the areas of Krč, Lhotka, Libuš, Nové Dvory, Písnice and the development territories on the southern edge of Prague.

The first operational section of the Line D should partially improve the operational situation on the Line C. By opening the Line D to traffic, a portion of the traffic load will be transferred from the Line C to the Line D, thus the train occupancy on the operating Line C will be partially reduced.

The main benefit of the first operational section of Line D must, however, be sought for in the replacement of the extensive bus traffic leading along Vídeňská Street, and a decrease in the high passenger traffic intensity at the Kačerov metro station. At the same time we can expect that the passenger interchange volume at the Muzeum station will also be diminished.

Not negligible advantage is also elimination of operational vulnerability of the Line C on the Nusle Bridge, as well as the development of a new metro line from the southern region of the city to the city centre. The pre-stressed reinforced concrete structure of the Nusle Bridge is threatened in the long term by the effects of stray currents, and by the fact that the need for overall reconstruction of the bridge in the future cannot be excluded.

A section of the metro network with the three operating lines A, B and C and the Line I D under preparation, is shown in Fig. 1. The Line C is shown including its section IV C2 Ládví – Letňany, which is under construction with the completion scheduled for the middle of next year.

2 BASIC DATA

- Region: the City of Prague
- Employer: Municipality of Prague
- User: Dopravní podnik hlavního města Prahy (a passenger transport authority)
- Construction period: commencement after 2008

3 ROUTE DESCRIPTION

The basic range, or the sphere of service provided by this section of the Line D marked as I D is currently understood to cover an area from Písnice to the Hlavní

Nádraží station. Variants to the solution are focused specially on the vehicle category and corrections in the details of the horizontal and, above all, vertical alignment associated with the selected vehicle category. At the same time, the issue of compatibility with the other kinds of rail transit existing in the PID (Prague integrated transit system), is under consideration, from the aspect of possible utilization of the system in a regional scale.

The above-mentioned extent of the line differs from the expectations of the planning department of the City of Prague. It roughly represents unification of the originally discussed two operational sections of this line (the section I D from Náměstí Míru to Nové Dvory and section II D from Nové Dvory to Písnice), with an extension comprising one interstation section toward the south (a part of the originally discussed section III D) to the Hlavní Nádraží metro station. The internal division of the project and of both the process of opening the Line I D to traffic into phases has not been stabilized unambiguously; it will be a subject of further design preparation.

A total of 10 metro stations have been included into the design of the first operational section of the Line D, i.e. the Hlavní Nádraží, Náměstí Míru, (the crossing with the Line A), Náměstí Bratří Synků, Pankrác, (the crossing with the Line C), Olbrachtova, Nádraží Krč, Nemocnice Krč, Nové Dvory, Libuš and Písnice stations.

It will be possible to design 60–100 m long trains for the Line D, considering the transport demand. The line will be serviced by a new depot in Písnice with a planned capacity of 20 trains 100 m long.

The newest documentation prepared by METROPROJEKT Praha a.s. in 2004 in two variants agrees with the positions of stations and general horizontal alignment of this line determined by previous studies.

The dissected topography of Prague, the considerable differences in elevations of individual valleys and terraces above them (e.g. the Vltava River valley, Nusle valley, Pankrác terrace, Krč valley, Nové Dvory and Libuš terraces, etc.) puts heavy demands on the design of the alignment for lines using traditional rail systems. Within the scope of rail systems used for urban mass, traditional heavy metro rail lines with their standard design parameters (horizontal curve diameter $R \geq 500$ m, rising gradient up to 40‰, stations on straight line or up to a radius $R \geq 800$ m) are especially difficult to accommodate to Prague terrain configuration. This often results in stations placed at great depths, with demanding access roads, time losses for passengers, and significant operational costs, incurred namely due to escalators (see Fig. 2).

With respect to the above problems and because of the fact that the order had specified neither a particular system nor a vehicle, the following basic design parameters of a light rail mass transit system were formulated at the beginning of the work on the design:

Horizontal curves on a running track: in general $R \geq 305$ m (80 km/hour)

Horizontal curves at a station: min $R = 300$ m (at max. platform length of 100 m)

Maximum rising gradient on a running track: 60‰

Maximum rising gradient at a station: 15‰

Figure 1. Section of the Prague Metro network.

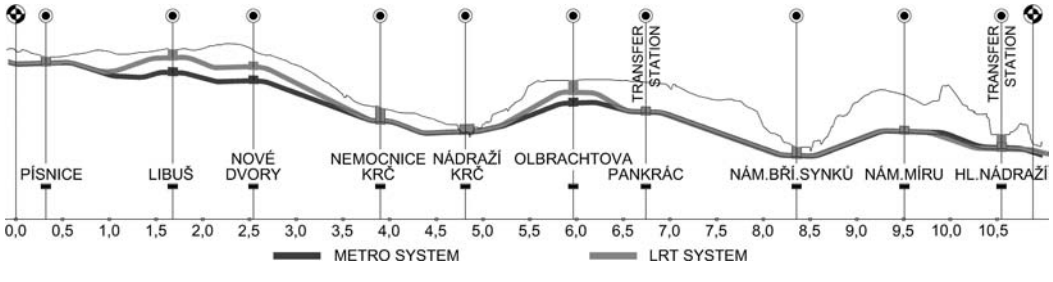

Figure 2. Exaggerated longitudinal profile metro line I.D of the Variant 1 and 2.

3.1 *The variant 1*

The variant 1 represents the conception of the Line D as a "traditional metro" in the meaning of the principles developed by the planning department of the City of Prague, excepting the overall extent of the Line I D and the route deviation from the originally intended Zálesí station to the Nemocnice Krč station. The operational length of this variant amounts to 10.2 km.

3.2 *The variant 2*

The variant 2 deals with a light rail mass transit concept. Regarding the horizontal alignment, it keeps the horizontal alignment designed for the traditional metro (Variant 1), but individual stations are closer to the surface, as allowed by local conditions. The Zálesí station is, similarly as in the variant 1, replaced by the Nemocnice Krč station. The Hlavní Nádraží station is situated in a position set off in the northwest direction to the close vicinity of railway areas. The operational length of this variant of the route is also of 10.2 km.

It must be added for the sake of completeness that also legislative issues will probably have to be solved should the light rail system or another similar system be introduced. The technical level of today produced trains eliminates differences between metro cars and tramway cars. The LRT or light metro conception has been used for rather a long time. Those trains are capable of safe operation in the conditions of tramlines while providing travelling comfort of traditional metro. No explicit regulations exist currently for this track conception. The main issues are the spatial arrangement of railway structures and geometrical configuration of rails; the current regulations valid for tramlines allow more economic alignment, differing clearance profiles for the tramline and metro, and other aspects. The Ministry of Transport, the Department of Railway Tracks and Railway Transport, are not preparing any regulation for the light metro or LRT. It would certainly by possible to start from regulations used in other EU member countries.

4 DESCRIPTION OF THE VARIANT 1 STATIONS AND ROUTE SECTIONS

4.1 *The Písnice station*

The Písnice station is very important both for the overall line D and the southern sector, but also, above all, for the onward transport services operating outside the agglomeration. This is because the station will become a large traffic terminal for buses and for car traffic. At the same time, the station is probably to be a three-rail terminal. Running rails continue further as a connecting track to the planned depot for the Line D in Písnice. This arrangement is suitable in the case of the Line D definitively terminating at this location. This cut and cover station, which is designed to have an intermediate platform and two surface concourses, is at a depth of 8.3 m under the ground surface. Connecting route section creates two single-track tunnels. The length of these tunnels is 1258 m.

4.2 *The Libuš station*

The position of the Libuš station is designed in compliance with the principles of the town planning scheme. It is in the neighbourhood of Novodvorská Street, across the Libuš residential area and its servicing facilities centre. The station is designed as a mined single-span structure, at a depth of about 25 m under the ground surface, with one at-grade concourse oriented toward the south, toward a pedestrian subway under Novodvorská Street.Route section in direction to the station Nové Dvory is formed by two single-track tunnels as well. The total length of these tunnels is 763 m.

4.3 *The Nové Dvory station*

This station is designed as a mined station, the top of rail (TR) about 34 m under the ground surface, with two concourses. It is of an underground, mined, single-span, two-concourse type, capable of functioning as a terminus. The northern, main concourse is connected to Durychova Street, which is a place where a transfer link to onward means of transport is provided. The southern concourse is oriented toward Chýnovská Street. It is designed as an at-grade structure, which will be easy to incorporate to the new urban structure in the future. Next part of metro line is formed by driven double-track tunnel except part of line adjacent to the stations with central platforms. The total length of this section is 1259 m.

4.4 *The Nemocnice Krč station*

The station is designed as a cut-and-cover structure, with an intermediate platform connected at the ends with concourses via vertical roads. Both concourses are designed as lightweight glazed pyramid-shaped pavilions. The station is 13–15.5 m deep under the surface. There are two short single-tract driven tunnels at the station. Next part is formed by double-track tunnel which is 550 metres long. Small thickness of overburden does not allow to perform driven double-track tunnel under the street Nad Havlem. For this reason 282 m of special single-track tunnels combination was designed in front of metro station Nádraží Krč.

4.5 *The Nádraží Krč station*

This is the only at-grade station on this line. It has side platforms and two at-grade concourses. It is built partially on a bridge structure spanning Kunratice Brook between the "Southern Connection" expressway and

the area of the railway station Prague – Krč. Despite the fact that the station is likely to be the least exploited station of the Line D in terms of the volume of passenger traffic, its undisputed significance lies in the unquestionable importance of the transfer to railway in the context of the development of the Prague integrated transit system and gradual implementation of an interval urban railway traffic system.

The other, not less important town design aspect of the Nádraží Krč station is the fact that owing to the pair of opposite at-grade concourses and connected pedestrian subways (the northern subway is under the "Southern Connection" expressway, and the southern under the station yard) the metro station allows the interconnection of the area found north of the Southern Connection, the grassed areas around an original manor-house and along a stream, and areas south of the railway station, which are today completely isolated from each other. In this way the metro station will make the green areas accessible for pedestrians, thus it will help to overcome the existing urban barriers formed by a couple of nearly parallel line traffic structures. A glazed steel structure of the platform and connected concourses will provide a pleasant contrast with the other underground metro stations. Daylight penetrating to the platform, the possibility to watch surrounding greenery and immediately adjoining water surfaces from the metro car interior, as well as the night illumination of the grounds, should represent architectural aspects for overall cultivation of this, today "forgotten" corner of Prague. Behind the station there is a double track tunnel perform by cut and cover method Length of this section is 283 m. Section from street V Podzámčí to the Station Olbrachtova is formed by double-track tunnel. Length of this section is 872 m.

4.6 *The Olbrachtova station*

This is a mined single-vault station with a pair of side platforms. It is situated under Na Strži Street, with the top of rail (TR) level about 26 m under the ground surface. The only at-grade vestinbule hall is placed to the free space of the south-western quarter of the intersection of Jeremenkova, Olbrachtova and Na Strži Streets. Route section between Olbrachtova and Pankrác stations is formed by double-track tunnel. Rail connection to metro line C is inserted into this section. Rail branching forced itself the enlargement of tunnel cross section.

4.7 *The Pankrác station*

This single-vault mined station with side platforms and the TR level about 33 m under the ground surface is situated in the close vicinity of the cut-and-cover station existing on the Line C, in an area delimited on one side by the intersection of Na Pankráci and Na Strži Streets. The construction will create a passenger interchange node comprising the station on the Line C and the station on the Line D. Nearly the whole route section between Pankrác and Náměstí Bratří Synků is formed by double-track tunnel. Merely a short part in front of the Náměstí Bratří Synků station is formed by single-track tunnels. Access gallery length of 450 m enabling transport of tunneling equipment was designed in this section. This gallery will be exploited as a ventilation shaft in the final stage.

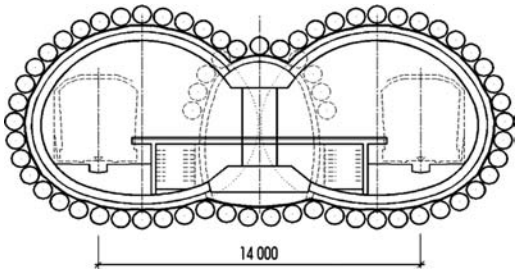

Figure 3. Cross section through the mined part of the Náměstí Bratří Synků station.

4.8 *The Náměstí Bratří Synků station*

This is a structure where combined techniques are to be utilised. The 30 m long part of the station that is situated at a shallow depth under existing buildings is an atypical double-vault mined structure with load bearing pillars in the centre of the platform. The station is situated to the flood plain of Botič Brook, and a major portion of the tunnel profile will extend into saturated fluvial sediments. A special microtunnelling technique is therefore being under consideration, i.e. a continuous canopy consisting of micro-tunnels installed along the profile of the future station tunnel to stabilize the subsequent partial excavation faces. The other part is situated outside the building. It is a large-span cut-and-cover structure with 2 rows of internal columns. The TR level is about 11 m under the ground surface. The station has side platforms and two concourses. The southern at-grade concourse is situated directly to the space of Bratří Synků Square.

Behind the northern part of this station short section of single-track tunnels was designed. Tunnelling of under Botič brook bed will be complicated for geological conditions which are very unfavourable. Water-bearing sediments of Botič valley wold and adjacent houses pose many problems for tunneling technology. Next part of route will be performed in open building pit. Remaining part of section between Náměstí Bratří Synků and Náměstí Míru stations form double-track tunnel and two single-track tunnels close to Náměstí Míru station.

Table 1. Basic information on the stations.

Station name	Station type	Platform depth under ground surface Variant 1 (2), m	Distance between stations, m
Písnice	cut-and-cover	8.3	
			1358
Libuš	driven*	25.0 (12.0)	
			863

			1613
Nám. bratří Synků	combined	11.0	
			1153
Náměstí Míru	driven	40.0	
			1040
Hlavní nádraží	under the protective structure	15.0	

*Variant 2 allows cut-and-cover design for the stations.

4.9 *The Náměstí Míru station*

The Náměstí Míru station with the TR level at a depth of roughly 40 m under the ground surface is designed as a mined single-vault station with an intermediate platform, with direct transfer to the Line A, and with two concourses situated towards the points where Sázavská Street meets Vinohradská Avenue and Francouzská Street respectively. This design allows direct transfer from the Line D and Line A to all tramlines in the given area. The barrier-free access from the ground level to the platform of the Line D is provided by vertical lifts with their entrances in Korunní Avenue. The platforms on the lines D and A are also interconnected by a lift. Two single-track tunnels length of 940 m continue to the Hlavní nádraží station.

4.10 *The Hlavní Nádraží station*

One of the deciding traffic structures important for the whole city, which significantly affects the possibilities of making use of the area of reconstruction existing in the south-western quarter of the intersection of Seifertova and Italská Streets, is also the planned metro Line D, or the metro station Hlavní Nádraží. This station will be built under an inverted U-shaped protective structure. This structure will allow both the commercial buildings that are to be built in advance of the metro to be founded, and the metro station to be constructed subsequently inside this space. The client for the above ground part of the project will take care of technical feasibility of execution of openings in the protective structure required for the passage of vertical routes leading from the station (the northern concourse) and for the access ramps built for metro construction purposes.

Three driven single-track tunnels of stabling siding are part of this station.

5 DESCRIPTION OF THE VARIANT 2

The basic principle of this variant is the effort to get the light metro alignment as close to the surface as possible. The aim of utilization of smaller vehicles is to achieve a smaller clearance profile, steeper longitudinal gradients along the route (accommodation of the alignment to the terrain configuration so that the project is cheaper) and possibly automatic operation.

The spatial design of the stations is identical with the design used in the variant 1, although the stations are placed closer to the ground surface, to a position that is allowed by the maximum longitudinal gradient possible in the framework of the given terrain configuration. Regarding the Náměstí Míru and Náměstí Bratří Synků stations, even the elevation remains the same as the elevation used in the variant 1. The reason is that the Náměstí Bratří Synků station cannot be closer to the surface because of the existing structures in the underground space, and the priority for the Náměstí Míru station is to have short transfer relationships to the existing station on the Line A.

In general, from the aspect of the horizontal alignment designed in the variant 2, it can be stated that the alignment copies the trace of the variant 1, which means that the design parameters are fully compatible with a traditional metro system. Regarding the gradients, for the reason of virtual invariability of the elevation of the stations within the section Pankrác – Hlavní Nádraží, the route gradient is left identical with that designed in the variant 1. It is therefore again fully compatible with the traditional metro. Gradients over 40‰ are designed for the section Nové Dvory – Pankrác. This solution gets the Nové Dvory station closer to the ground surface approximately by 14 m (TR – 19 m, the station remains to be mined, three-vault type) and the Olbrachtova station roughly by 12 m (TR – 14 m, cut-and-cover design). The risen station Nové Dvory allowed also the Libuš station to get closer to the surface (TR – 12 m, cut-and-cover design). Conception of technical solution of track tunnels is the same as in variant 1.

The Turecký Vrch railway tunnel

M. Dávid, J. Mára, J. Korejčík
Metroprojekt Praha, Prague, The Czech Republic

ABSTRACT: The project of the modernisation of main railway corridors is in progress in Slovakia. The project includes the railway route Nové Mesto nad Váhom – Púchov. This route leads through a rugged country, which, in the Turecký Vrch section, is listed as a protected landscape area. Authors of the design studied several variants. The straightened alignment, and environmental reasons in particular eventually contributed to their preference to the tunnel variant over an up to 40 m deep side-hill cut leading along the entire length of the hill side. The mined double-rail tunnel is 1,775 m long, with the length of the mined section amounting to 1,740 m. The cut-and-cover sections total 35 m. The maximum overburden depth is 100 m. Complicated geological conditions, verified by an exploration gallery, were the reason why the authors of the design selected the New Austrian Tunnelling Method, which allows a flexible response to changes expected in geological conditions. The lining of the mined tunnel consists of two shells with an intermediate waterproofing membrane covering the vault and side walls. The tunnel profile is designed with regard to train aerodynamics, for the speed of 160 km/h (prospectively 200 km/h).

INTRODUCTION

At present, the railway line curves round the side of Turecký Vrch (Turecký Hill) in close proximity to a national road and the Biskupice canal. The current conditions in the narrow basin do not allow changes in the alignment which are required for increasing the speed limit over the track. This is why a new alignment has to be designed, with the best variant containing a mined double-rail tunnel. This variant provides the best solution to the conflict between the interest in protecting the Turecký Hill protected landscape area and the interest in the space for the modernisation of the railway line. The alignment passing through Turecký Hill begins in an extremely confined space in front of the entrance (southern) portal, where the railway line, the I/61 national road and a protective embankment of the Biskupice canal run in parallel with each other. It leaves the exit portal on the northern side via a right-hand curve, designed to minimise the work in the unfavourable environment of secondary loess. The portal proper can be built in a minimised construction trench.

The double-track railway tunnel is designed for the UIC C clearance profile, with firm trackbed and the track-centre distance of 4200 mm, on two R 2000 m and 1995 m reverse curves and a tangent section, and on minimum longitudinal gradients of 3.5‰ and 4‰; this design satisfies the speed up to 200 km/h. The clearance profile is unified for the entire length of the tunnel, with the exception of two contact-line tensioning chambers with an enlarged profile, which are approximately in the middle of the tunnel. The primary excavation support with a variable thickness of the lining will provide protection for a time sufficient for application of the waterproofing system and subsequent erection of the permanent secondary cast-in-situ reinforced concrete lining. Revetment walls are designed for both portal sections to allow the construction of the cut-and-cover tunnel blocks with a minimised impact on the surrounding protected landscape area. Natural and unforced incorporation of the portals into the landscape will be achieved by utilisation of free stone from a local quarry.

1 GEOLOGICAL CONDITIONS

The Turecký Hill massif consist mainly of carbonate rock layers and, partly, from the north, Quaternary sediments. The tunnel overburden depth varies from a minimum of about 3 m at the southern mined portal to approximately 100 m.

The northern (exit) portal and the about 80 m long initial section of the tunnel will be built in a complex of Quaternary sediments of aeolian and diluvial origin, which are represented mostly by strata of yellow to yellow-grey secondary loess. In the initial 40 m long section, the thickness of the series of strata is expected to cover the entire height of the tunnel cross section combined with polygenetic sediments consisting of brown-coloured aeolian-diluvial sandy shales. These sediments are frequently mixed with diluvial debris, which have an underlier consisting of about

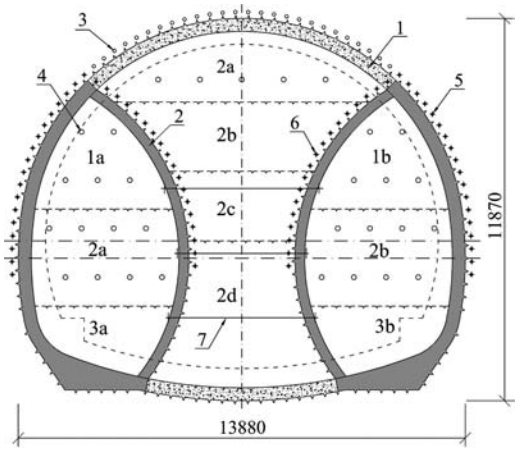

Figure 1. The cross section for the excavation through the Quaternary sediments. 1-Primary lining 400 mm thick, 2-Temporary lining 300 mm thick, 3-ø 108/16 tube micropiles or self-drilling micropiles injected with cement grout, 4-FACE SUPPORT: GRP anchors injected with cement grout, 5-Side drifts: GRP forepoles, 6-Side drifts: GRP self-drilling forepoles, 7-Tie rods.

2 m thick layer of Neogene claystone and sandy clay; the bedrock consists of dolomites weathered to the depth of about 2 m. The tunnel overburden is about 10 m to 15 m thick. An increased amount of diluvial debris mixed with loam, larger cobles and boulders is expected in the following 20 m long section, where the overburden thickness will increase to 25 m. In the remaining 20 m long section, the tunnel bottom will probably pass through the weathered bedrock, which will gradually rise to cover the entire tunnel cross section. The overburden will be 30 m to 35 m thick.

The other tunnel section, which is 60 m long, will be driven through a rock mass consisting of dolomite layers in the invert and bench, overlaid by a series of limestone layers in the excavation crown. Apart from several dip faults, there will also be effects of weathering encountered in this section; karst phenomena cannot be excluded in this section.

The rock massif through which the 1600 m long tunnelled sections will pass consists of Mesozoic series of layers of carbonate rocks (dolomites and limestone). Based on the results of surveys, we can state that the Mesozoic massif of Turecký Hill and mainly the dolomite series of strata are intensely tectonically disturbed. The blocks of carbonate rock are not affected by a more significant process of deep weathering. A larger depth of weathering may be bound to the faults; the weathering depth can be expected to vary between several meters and first tens of metres. Apart from sinkholes, the karst phenomena will even be present in subsurface parts of the massif. They will be mainly bound to the zones or more intense fracturing and loosening of the rock mass, or to the zones of tectonic failures and open faults. The carbonate massif is expected outside the zones of tectonic faults and rock loosening should be water saturated to a minimum degree. Despite the nearly continuous covering by impervious aeolian sediments, loess and secondary loess, ground water is supplied to the undisturbed blocks of the massif nearly exclusively through infiltration of precipitation. No significant impact on the existing regime of surface water or underground water due to the tunnel construction is expected.

2 THE DOUBLE-TRACK MINED TUNNEL

2.1 *Tunnel excavation*

The main proportion of the excavation is expected to be performed from the northern portal, only a smaller part will be driven from the southern portal. The reason is the large volume of earthmoving and large extent of the support of the construction trench required at the southern portal, problems with dump location in the vicinity of this portal, and the necessity for solving the crossing of the large-volume muck transport with the existing operating railway line. The drill-and-blast technique (controlled blasting) is expected to be utilised for breaking the competent rock. Soil and fractured rock mass will be disintegrated mechanically by excavators or even heavy impact breakers.

The New Austrian Tunnelling Method (the NATM) is designed to be utilised, with the primary support consisting of C 16/20 sprayed concrete, welded mesh, rock bolts, lattice girders and spiles. Based on the engineering geological survey, the following excavation support classes are anticipated: 2, 3, 4, 5a1 and 5a2 in the rock environment and 5b1 a 5b2 in the environment consisting of Quaternary sediments (a soil environment).

In terms of complexity and the geological conditions encountered, the tunnel being designed is categorised as geotechnical category 3, which belongs among the most difficult in the field of tunnel construction. The poor quality of the rock massif is a result of the existence of discontinuities, weathering, proximity of significant faults and possibility of occurrence of karst phenomena. The above-mentioned difficulties adversely affect not only the process of breaking the rock by the drill-and-blast technique, but also the process of the rock massif deformation lasting until a new state of equilibrium is reached. It will, therefore, be necessary, even with respect to the size of the excavated cross sections, to divide the excavation face in both directions, horizontal and vertical.

The excavated cross section for the soil environment (an 80 m long drive) is 13.9 m wide and 11.9 m high; the excavated cross-section area is 137.2 m^2. The

tunnel profile is closed by an invert and is divided into two side-wall partial excavation faces and a central partial excavation face. The partial excavation faces are sub-divided into top headings and cores with bottoms. When both side-wall excavation sequences are finished, the excavation of the central pillar will start. When the entire soil environment tunnel excavation section is completed, the invert will be cast in parallel with the construction of the central tunnel drain and toe drains. When the required strength of the invert concrete is reached, a temporary roadway will be constructed and the tunnel excavation through the rock massif (toward the southern portal) will start. The primary lining thickness of 400 mm is designed for this environment, while the temporary lining of the central pillar excavation will be 300 mm thick. The tunnel length is divided into three sections differing in terms of the method of the crown support. The stability in the first section will be provided by a two-tier canopy of ø108/16 × 25 m long grouted pre-support tubes, which will be installed from the portal excavation trench. The second section, where the crown is found in relatively cohesive soil, will utilise a canopy consisting of fans of grouted self-drilling or driven spiles 6 m long, with 5 m overlaps. The third section lies at the soil/rock massif interface, where layers of little cohesive soil and debris may occur. For this reason, the canopy designed for this section consists of fans of ø108/16 × 10 m long grouted pre-support tubes with 5 m overlaps. All of the partial faces will be protected by a layer of shotcrete. The stability of the faces will be provided by glass fibre reinforced plastic anchors (a 40/5 mm GRP band grouted with cement mortar). Effectiveness and the necessity for these anchors will be verified in the first section of the excavation.

The excavated cross section of the tunnel driven in the rock environment (a 1660 m long drive) is 13.1 m to 13.7 m wide and 10.3 m to 11.4 m high. The cross-section area ranges from 105.1 m^2 to 129.7 m^2. A horizontal excavation sequence consisting of the top heading (the maximum height of 6.8 m) and the bench with the bottom is designed for the whole length of this section. This sequence meets the requirements for keeping the excavation face stable, as well as for accessibility and sufficient room for usual tunnelling equipment. The thickness of the primary lining is designed at 150 mm to 300 mm.

There are two 11 m long contact-line tensioning chambers with the excavated cross-section area of 194.4 m^2 designed at chainage 103.325 and 103.425. The enlargement to the profile designed for the chambers will be carried out subsequently when the entire tunnel length excavation is completed with the basic cross section maintained. The enlargement work will start in the top heading, then the remaining part of the profile will be enlarged. The chambers are provided with an invert and 400 mm-thick primary lining. There will be safety recesses on both sides of the tunnel, at intervals of 20 m.

Based on mathematical modelling, we expect that deformations of the primary lining in the crown in the support classes 2 to 4 will be up to 50 mm, in the class 5A up to 80 mm and in the class 5B up to 150 mm. There are no buildings inside the settlement trough. Contingent increased settlement cases pose no threat to the surrounding area; they are only a problem in terms of the tunnelling work.

2.2 *The final lining and tunnel equipment*

The final lining of the mined double-track tunnel will be constructed using travelling tunnel formwork. The casting will be divided into two phases: the invert or strip foundation casting and casting of the vault and side-walls. The casting blocks will be 10 m long. A minimum 2 m wide and 2.2 m high (measured from the walkway surface) safety recess is located in every other block. The recess contains an inspection shaft built on the drainage, and a manhole on the cable duct. Cable chambers for installation of the contact-line tensioning equipment will be cast in two phases, identically with the entire tunnel.

The internal radius of the final C25/30 reinforced concrete lining is 6.1 m. There are several variants of the lining designed, depending on the excavation support class and foundation conditions. The thickness of the lining reaches 300 mm to 400 mm. The reinforcement consists of lattice arches combined with welded mesh or strap pieces if necessary. The major part of the tunnel is founded on strip foundation; the 600 mm thick invert is designed only for the portal blocks and the section driven through soil. In both above-mentioned cases, tie-up reinforcement is designed. Blinding concrete and infill concrete is of the C 16/20 and C 8/10 grade. The intermediate waterproofing system is of the umbrella type, i.e. covering only the vault and side walls and ending at the level of the toe drains.

The central tunnel drainage duct consisting of a 500 mm-diameter PE pipe is embedded in the tunnel bed between the two rails. Toe drains consisting of 200 mm-diameter flat-bottom PVC drainage pipes are on both sides, behind the outer surface of the final lining. The toe drains pass through inspection manholes built in the safety recesses; transverse drains lead from each manhole to manholes on the central drainage duct. Both drainage pipelines are embedded in porous concrete, at a gradient identical with that of the railway track. They terminate in a pair of interconnected shafts, from which water flows to fire protection reservoirs.

Walkways about 900 mm wide are designed on either side of the tunnel. There are steel handrails installed at a height of 1.1 m above the pavements; the lines of the handrails are broken at the safety recesses. There is a 12-way PE cable duct embedded in the

walkways. The cable duct is cut in the safety recesses by manholes containing outlets for electrical equipment (tunnel illumination, sockets, switches). The dry fire main (a 110 mm-diameter PE pipeline), which is fed with water from the fire protection reservoirs, is found under both walkways. A hydrant valve is installed in the inspection manhole in each safety recess. Both branches of the dry fire main are interconnected every 100 m; the connecting pipelines are terminated by outlet valves installed in shafts on the central drainage duct to make emptying of the fire main possible.

The numbers of all tunnel blocks, safety recesses and escape routes and their distance from the closest portal or the escape gallery entrance will be marked in the tunnel. There are oblique guide-strips interconnecting the neighbouring safety recesses designed with the aim of facilitation of safe movement and search for a shelter in the tunnel. The marking will be painted on the internal surface of the final lining. Sign tables will be imprinted into the concrete surface during the casting.

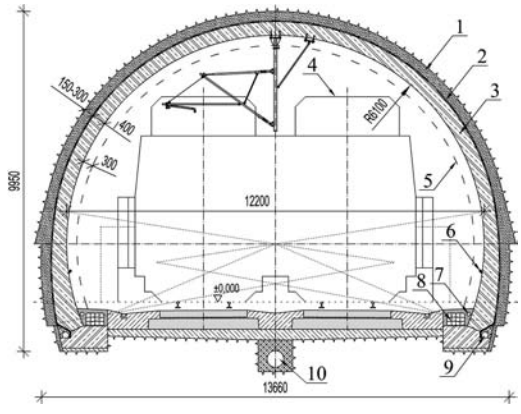

Figure 2. Typical tunnel cross section 1-primary lining C16/20 shotcrete, 2-waterproofing layers, 3-secondary lining C25/30 reinforced concrete, 4-safety margin, 5-clearance envelope, 6-steel handrail, 7-fire main, 8-cable duct, 9-drainage behind outer surface, 10-central drainage duct.

3 THE NORTHERN (EXIT) PORTAL

The exit portal is located in a deep erosion furrow in the northern slope of Turecký Hill. The terrain surface in front of the portal will be cut to comply with requirements of a mustering area for the fire rescue service equipment and emergency vehicles, including an access road with a bridge over Bošáčka stream. This area will be supported by retaining walls and provided with a handrail above the stream. There will be a small building housing a standby power unit and the tunnel equipment control elements there, and a fire protection reservoir, which is built in an excavation box lined with secant pile walls. The reservoir is fed with water from the stream, and also with the water from the tunnel drainage treated by means of a downflow baffle. The water from the reservoir flows again to the stream, via a safety overflow. The exit portal area is at a distance approximately of 100 m west of the existing railway track.

The construction of the cut-and-cover tunnel and a permanent revetment wall requires a 24 m × 32 m construction trench to be excavated and provided with temporary support. The rock massif in the area of the trench consists of a complex system of Quaternary sediments (see Geological conditions – the northern portal), which extends approximately 4 m under the tunnel structure. The water table is found roughly 7 m under the structure. The vertical walls of the construction trench will be supported by a system of vertical micropiles (ø152/18 tubes) provided with a layer of C20/25 sprayed concrete with welded mesh. The walls will be anchored at six anchoring tiers by 24 m to 30 m long stranded anchors (10 m-long roots). The tops of the micropiles are covered by anchored reinforced concrete capping pieces; in the lower tiers, the anchors pass through steel wallers. The anchoring of the reinforced concrete capping pieces skirting the terrain is permanent. There are parapet walls built on the top of the capping pieces, and gutters diverting rainwater flowing down the slope outside the portal area are laid behind the parapet walls. A pile wall which will be built from the level of 1.6 m above the top of rail will extend the northern micropile wall (parallel with the railway track), thus the maximum depth of the excavation will reach 18 m. The former pile wall consists of 1.20 m-diameter, 12.3 m long piles. The toe of each reinforced concrete pile is keyed into weathered dolomites; each pile is extended by means of three pieces of 8 m long micropiles (ø108/16 tubes). The top of each pile is anchored by a 34 m long temporary stranded anchor (a 10 m long root). The opposite southern pile wall, with the length equal to the length of the cut-and-cover tunnel, will consist of the same type of piles, 10.2 m long, with the tops at the level 0.5 m under the top of rail. The piles are again extended by micropiles; the tops are not anchored. The two opposite pile walls built along the cut-and-cover section will be braced against each other under the invert by an 800 mm thick vaulted reinforced concrete slab. The entire above-mentioned structural system is designed to transfer the load to the competent bedrock. In addition, a protective 500 mm thick reinforced concrete transition slab will be cast between the portal and railway bridge, which is designed to eliminate the differential settlement existing in this section.

The construction of the final lining in the cut-and-cover sections will start only when the casting of the adjacent blocks of the mined tunnels has been completed. The same travelling form is planned to be used

for both the mined and cut-and-cover tunnel sections; formwork for moulding of the outer surface will be added in the cut-and-cover section. The cut-and-cover portal block is 10 m long; it is provided with the invert. The front end of the portal block is vertical. The thickness of the upper vault lining of 550 mm is uniform; the invert is 800 mm thick; tie-up reinforcement will be used. The tunnel equipment is identical with that used in the mined section.

A final reinforced concrete revetment wall (C 25/30) lining the excavation box will be built in parallel to the railway track in front of the entrance portal and perpendicularly to the track behind the portal. The walls provide permanent support to the slope in the environment consisting of Quaternary sediments which are liable to sliding. The walls are supported with permanent 34 m long stranded anchors installed in three tiers. An unreinforced concrete block originates around the portal block of the mined tunnel. The block is found between the revetment walls. Its surface, inclining at 5:1, is clad in natural stone obtained from a local quarry to be properly incorporated into the landscape.

4 THE SOUTHERN (ENTRANCE) PORTAL

The new alignment declines from the existing route toward the entrance portal at a very acute angle, and it runs along a side-hill cut in rock, which gradually grows in the depth. The slope of the cutting reposing at 40° to 60° is stabilised. The new alignment is at a 1 m distance only from the original route at the beginning of the cut; the distance reaches 16 m at the end. A temporary relocation of the track shifting the rails approximately 3 m from the existing track in the direction from the hill side is designed for the period of the works to allow enlargement of the site facility in front of the portal and increase the safety of operations during the course of the construction. The portal is located in a distinct erosion furrow in the eastern slope of the massif, which consists chiefly of carbonate series of strata containing the Wetterstein Limestone and, in the top layers, Quaternary sediments. A hard surfaced area for mustering of the fire rescue service and an access road with a bridge over the Biskupice canal will be provided in front of the portal. There will be a small building on the edge of this area, which will house a standby power unit and the tunnel equipment control elements. A cut-and-cover fire protection reservoir (partially covered with the backfill of the portal block) will be built beside the portal. The reservoir is supplied with rainwater collected in the erosion furrow and flowing via a trough and a storm-water inlet, and water from the tunnel drainage treated by means of a downflow baffle. The safety overflow is provided via an old culvert leading to the Biskupice canal.

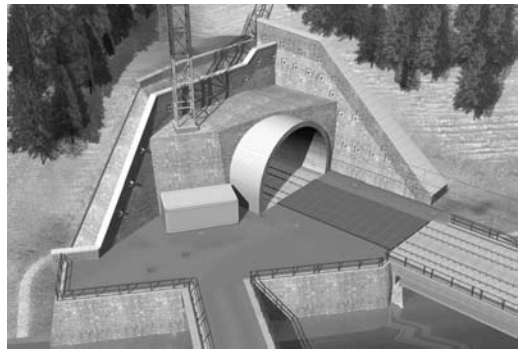

Figure 3. The northern (exit) portal.

The entrance portal is part of the cut-and-cover tunnel section; it is built in a 25 m long excavation box, which is located in a side-hill cut with the rock wall about 17 m high and is an extension of the side-hill cut excavated in front of the portal. The vertical walls of the excavation box will be supported by micropiles (ø152/18 tubes) and C 16/20 sprayed concrete with welded mesh. The tops of the micropiles will be fixed in a reinforced concrete capping piece, which will be anchored with 6 m to 8 m long pre-stressed stranded steel rock anchors. The lower tier of anchors will pass through steel wallers. A canopy consisting of horizontal ø108/16 × 25 m long grouted pre-support tubes will be constructed at the front end of the excavation box to stabilise the excavation at the beginning of the tunnel drive, where the overburden will be very shallow and its transverse gradient is very steep.

The final lining of the cut-and-cover tunnel is constructed in the same way as in the case of the exit portal. Two cut-and-cover tunnel blocks have the invert. The front end of the portal block is slanted and provided with a flange preventing rainwater from flowing over the edge. The final liners of the vault and invert are 550 mm and 600 mm thick respectively. The tie-up reinforcement system is designed. The tunnel equipment is identical with the equipment used in the mined section. The backfill of the cut-and-cover tunnel plus the portal will be carried out approximately at a slope angle identical with that of the original slope. The stability of the slope will be improved by spreading a layer of natural stone.

The side of the 120 m long side-hill cut excavated in front of the portal will be supported by a revetment wall parallel with the rails; the height of the wall will increase in the direction toward the portal. The lower part of the wall will consist of one or two levels of a 500 mm thick masonry wall built using free stone selected in a local quarry. The wall is inclined at 5:1, and the individual levels are separated by a berm. The upper part of the revetment wall, which is separated by a berm lined with a handrail, is clad in grass pavers

laid at a 70° incline. The total thickness of the structure amounts to 600 mm. In both above-mentioned cases, the surface of the side-hill cut is supported by shotcrete with welded mesh tied to the surface with anchors. Grass pavers will stabilised, if necessary, using 4 m to 6 m long corrosion-protected rockbolts. The part clad in natural stone will be stabilised by an anchoring system using the above-mentioned rockbolts. The berm is not designed for the lower part of the 10 m long section of the masonry revetment wall found just before the portal so that sufficient space is available in front of the portal.

5 THE ESCAPE GALLERY

The escape route, which is designed in compliance with the fire safety concept and results of the risk analysis, leads via a 244.7 m long transverse gallery driven on a 0.5% downward gradient from the tunnel and ends on the surface in the location of a former bridge over the railway track. The escape gallery has a horseshoe shaped profile. It will be driven by the NATM, with the support consisting of C 16/20 sprayed concrete primary lining, welded mesh, rock bolts, lattice arches and spiles. Based on the engineering geological survey, the design specifies 2 excavation support classes: class 2 and class 3.

The casting of the gallery lining is expected to be divided into two phases, the bottom and the vault plus side walls. The 120 mm thick bottom will be cast using C 25/30 concrete reinforced with welded mesh combined with tie-up reinforcement. The drainage sub-base will be made from porous concrete. The round vault with the inner radius of 1.65 m and the side walls will be made of C25/30 reinforced concrete with the minimum thickness of 200 mm. The main reinforcement elements are lattice girders and welded mesh. The intermediate waterproofing membrane covers the vault and side walls, and ends at the bottom in the longitudinal toe drainage.

A 17 m long air lock chamber is provided in the part of the gallery adjacent to the tunnel. It is separated from the tunnel by a 2.2 m wide fire resistant door, and from the escape gallery by a 2.2 m wide steel door. The air lock is positively pressurised by a forced ventilation system independent of the escape gallery ventilation system to prevent smoke entry from the tunnel to the escape gallery.

The rock wall created on the surface in the location of the escape gallery mouth is supported by a 300 mm thick retaining wall provided with side wings.

6 CONCLUSION

The process of underground construction significantly differs from the other construction branches due to the specific nature, limited knowledge of geological conditions, often unpredictable circumstances, dependence on the means and methods of construction, and significant construction risks. The application of the NATM makes the construction process as well as the completed structure safe through the observational method and thorough geomonitoring. Geology is the factor which affects the complexity, technique and duration of construction. It is best visible at the northern portal where the Quaternary sediments represented by secondary loess significantly complicate the work on the excavation box, tunnel excavation and erection of the final lining. The most serious complication will be the task to excavate the side-hill cut in rock in the constrained conditions existing at the southern portal, in close proximity to the existing railway track, which will be in service throughout the construction period. Despite all problems, the design tries to respect the character of the natural forest-steppe environment in the protected landscape area of Turecký Hill.

Regarding the construction organisation, the construction time could be shortened if necessary by implementation of additional one or two points of attack in the middle of the tunnel, at the end of the escape gallery, which would be driven and provided with primary lining in advance. This solution would, however, require widening of the access road to the escape gallery and possibly even enlargement of the gallery cross section according to the tunnelling equipment used.

The detailed design for the Turecký Hill tunnel was issued in 2005. In Slovakia, it is a kind of a “pilot design” developed within the framework of the “Upgrade of Railway Lines of the Slovak Republic to speeds up to 160 km/h”, prospectively 200 km/h. The completion of the Turecký Vrch tunnel will add an important section to the quality and fast link between Bratislava, the Slovak capital, and Žilina, a centre of northwestern Slovakia. The tunnel construction is expected to start in 2007.

Collectors – System approach to the regeneration of technical infrastructure in the city of Prague

F. Dvořák & M. Hradecký
INGUTIS Ltd., Prague, The Czech Republic

ABSTRACT: Collectors represent a new element in the quality of distribution and regeneration of technical infrastructure, which in a long-term perspective enables its inspection and maintenance as well as the increase in capacity without negatively affecting the environment. For their successful spatial integration into the city, it is necessary to asses closely a set of limiting factors. These factors not only include the geological conditions, but also the existing buildings, technical infrastructure, traffic and city operation. New collector ducts generate an open system, which enables their further expansion. Their concept must respect the principles of underground urbanism and requires consistent coordination with other underground structures in the area with respect to land-use planning.

1 INTRODUCTION

Historical centre of Prague, the capital city of the Czech Republic is a collection of substantial cultural, architectural and urban values that developed over the last centuries. Its high significance is proved by the registration of the Prague historical reserve among the city zones that are protected by the UNESCO organization. However, an increasing number of the city's and country's social and cultural activities is based in the centre, which creates a great demand for traffic and technical infrastructure with prevailing citywide character. Every activity is dependent upon the infrastructure's full functionality and sufficient capacity.

For attractiveness of the city centre and development of its operation and service and due to the lack of surface space, a new resource for further development of the city is the underground. Many linear and solitary structures of various functional uses are situated in the underground. These involve a complex solution for technical infrastructure regeneration in terms of aggregation of two or more underground service ducts into collectors.

2 COLLECTORS – PRINCIPLES AND REASONS

2.1 *Structures' characteristics and their reasons*

For more than 30 years, laying of pipes and cables is being designed into underground man-sized ducts, mainly in new residential areas in the suburbs of Prague. This way of underground services laying has a significant and substantial role in the regeneration and development of technical infrastructure within the Prague historical reserve. Existing cable and especially pipe service ducts are often old and considerably defective, very often with reduced or exceeded lifetime. Moreover, with increasing demands on the city development, their capacity becomes insufficient.

A gradually updated plan of collectorisation of the municipality is being created for the purpose of land-use planning. According to this plan, an open system of collector ducts is being created. This system enables further expansion into other parts of town and branching-off into adjacent streets. Therefore, this is not only a local solution of technical infrastructure laying or realignment but a system solution of problems with technical infrastructure in city centres.

2.2 *Advantages of building collectors*

Advantages that result from laying of underground services into collectors are stated in the following notes. The advantages are from a long-term perspective obvious especially for consumption collectors that immediately supply particular surface buildings:

- Main aspect represents an easy inspection and maintenance of inbuilt utility lines without an impact on the surface, as well as the safety of the operation of the utility lines secured by a system of control measurements and centralized control of operation from one control centre.
- Increase in lifetime of utility lines by diminishing the negative effects of ground environment (corrosion, stray currents, dynamic effects of traffic etc.).

This relates to economical operation and a reduction in losses during faster search for damaged utility lines.
- Elimination of surface excavations for all subsequent maintenance and repair works on the utility lines. This results in a cut-down in traffic limitations as well as environmental impact.
- Possibility of easy increase in capacity of particular medium by laying a utility line of a greater size or even a change of a medium.

3 INITIALIZATION OF BUILDING COLLECTORS

The impulse for building collectors is a need for an analysis of possible solutions for sets of problems linked to the development of the surface and the underground of the city centre. Assessments of present conditions and prognosis of the future development are monitored in areas involving city territory and surface buildings, technical and traffic infrastructure and environment.

3.1 *Development of city territory and surface buildings*

This area includes assessment of complex development of a city zone or reconstruction of a city block. This also involves territorial preparations of locally situationally defined large solitary structures. A dispositional utilization of underground levels including the solution for regeneration of underground services must form an integral part of the historical district's land-use plan.

3.2 *Condition and development of underground services*

A Large amount of cable and pipe utility lines is in dissatisfactory state. Pipe ducts that are 80–100 years old can be considered in emergency conditions and over their lifetime limit. Outflow of water into subsoil is a common occurrence. However, even for relatively newer utility lines, negative effects of ground environment (humidity, corrosion, stray currents, dynamic effects of traffic etc.) contribute to shortening of lifetime. With the problem of lifetime and technical condition also comes the problem of insufficient capacity of existing utility lines for their extensive use as well as absence of sufficient reserve for their perspective development.

As an alternative to laying utility lines into the ground and persistent excavation works, a system of collector network has been under development in Prague since 1985.

3.3 *Traffic infrastructure solution*

Due to constantly rising traffic demands in the city centre, new solutions that enable both road capacity increase and solutions for present problem sites are being searched for. Conception of rail and non-rail traffic must respect specifics of the historical city centre and conditions of the city historical reserve, which limits the increase of traffic in the centre. A motivation for solving the problems of utility lines is also the modernization of tram tracks (including solutions for traffic narrows, which are very common in the city centre).

One of the solutions is the use of city underground levels, which are mainly used by linear structures (metro, road tunnels). This incites the need for solutions for exposed traffic junctions by building overpasses and underground garages. This usually incites the need for realignment of great number of utility lines (preferably into matched structures – collectors).

3.4 *Environment*

Construction works that relate to utility lines constantly disturb the environment of the city centre. These construction works are either intended (during expansion or renovation of utility lines) or unintended (during emergency). They always cause a negative impact on the city. Therefore, collectors represent an alternative solution for utility lines regeneration.

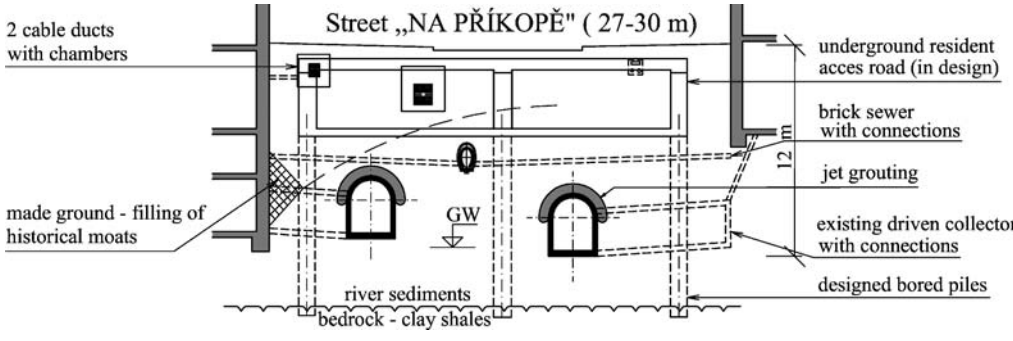

Figure 1. Prikopy Collector – prerequisite for utility lines realignment and possible future execution of an underground road.

Their execution represents a short-term environmental impact. Long-term positive effects will appear during their operation over the whole lifetime period.

4 CATEGORISATION OF COLLECTORS AND THEIR APPLICATION IN PRAGUE CENTER

4.1 *Philosophy of development of collectors in Prague*

A concept for systematic approach in collector network generation that represents a system solution for underground services in the centre of Prague was executed in a land-use planning documentation called "General plan of collectorisation in central Prague". The first concept was published in 1982 and covered a broader territory of the centre with an estimated development timescale of few decades. It was updated several times during the subsequent years to reflect new standards in the concept of the city and underground services development. The extent of collectorised territory was then partly modified to cover the area of "The Prague Historical Reserve". The last study, which specified the changes in the land-use plan, was completed in 2005. Its purpose is to include the main supply 2nd category collector ducts (see below) into the land-use plan – a basis for area development.

At present, the total length of operational collector ducts in Prague is more than 90 km. Out of this length, almost 18 km of operational collector ducts of both further described categories are in the historical centre. Other collectors are being constructed or are in an advanced phase of designing. The rest of about 80% of underground reinforced concrete collectors represent structures in new residential areas in the suburbs of Prague.

A Collector Control Centre at Senovazne Square is a part of the system and is the only control centre in the network. Constant operational monitoring and control of the branched collector system of the whole Prague (centre and suburbs) is performed there.

4.2 *Collector types*

Collectors are divided into two separate, but technologically connected systems according to their functional purpose. Besides the below stated character of inbuilt utility lines, both systems differ in situational and depth level positioning as well as cross section, which results in differentiation of applied construction technologies caused by geological conditions:

– 2nd category collectors – supply – essential distribution of utility lines of city-wide character in greater depths and wider territory with surface outlets in limited number of locations and blocks of houses. These ducts are intended to transport media into individual city zones. They lead straight and if possible in bedrock. Branch ducts, which end in shafts in duct crossings, connect deep technical chambers on 2nd category collectors with 3rd category collectors.
– 3rd category collectors – consumption – direct supply of adjacent buildings with particular media. Their situational and depth level positioning is close to place of consumption – adjacent buildings. They therefore usually lead on city owned land. Connection into the buildings is done by a side collector and then by borings for pipes and cables into basements of the buildings. Depth level of the collector, as close to the surface as possible, significantly affects the choice of suitable construction technologies. Influence of construction works on this type of collectors is highly notable on the surrounding area – especially on buildings and utility lines. This usually invokes big geotechnical challenges like acceptable deformation and the effect of driving on the surrounding area.

5 ASPECTS OF COLLECTORS' SITUATION INTO THE CITY

A complex assessment of all limiting aspects of collector construction as well as all specific conditions according to the characteristics of the place and structure is necessary for spatial situation of the underground structure into cramped situational and depth level conditions of the city centre.

5.1 *Surface structures*

Existing surface and underground structures represent a basic input for the solution. Definition of extent of surface structures in relation to public land is necessary for positioning collectors and all their structures, which are in contact with the surface.

For ducts in smaller depths, underground parts which stick out from facades into the area of the public

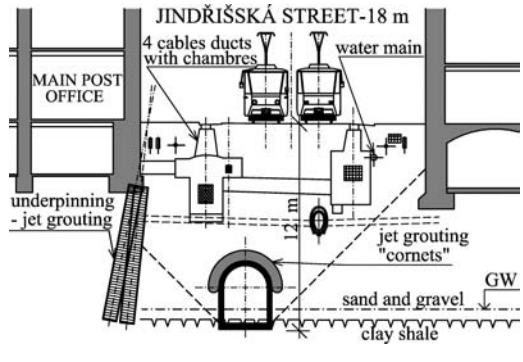

Figure 2. Design of most driven 3rd category collectors in the centre of Prague, under the level of sewer ducts.

land are crucial, as well as all underground premises of other structures. Unknown remains of filled and unfilled underground spaces and relicts of former area redevelopment are crucial, too. Logical demands for historical monuments preservation and archaeological research are respected when situating collectors in the town historical reserve.

From a geotechnical point of view, the character and quality of adjacent surface structures is crucial, as well as their static and constructive systems. Static securing of the structures before start of construction might be necessary.

5.2 *Existing underground services*

Utility lines are an issue for all underground structures in Prague. Search for pipe and cable utility lines of all owners in the area is crucial, as well as definition of inviolable ones (cannot be realigned), possibly realignable and realignable without problems. The inviolable utility lines of citywide character include trunk sewers, large pipelines and telecommunication cables matched into cable ducts with frequent chambers.

It is usually impossible to respect normative protective zones of all utility lines in the city centre. It is therefore necessary to adopt all protective and securing measures before and during the construction.

Another factor which comes into play is the demand by utility lines owners for full functionality of their existing lines during realignment. Therefore, the new realigned utility lines must be built in a different place.

Acceptable levelling of underground collectors is an issue as well. This is significantly limited by levelling of other media (especially sewers and cable ducts).

Levelling of sewer tubing (including sewer connection inlets) in depths of 6–7 m under the surface divides the subsoil into two levels.

This affects the possible levelling of the collector, either above or below the sewer.

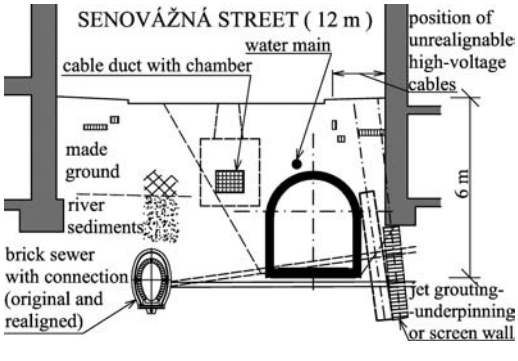

Figure 3. 3rd category collector whose execution brought up difficulties with utility lines and adjacent buildings supporting.

The collector must not be situated in the protective zone of the sewer and affect the structures of the sewer. The levelling is therefore possible either above the sewer (4–5.5 m under the surface) or below the structures of the sewer. Levels between 10–14 m below the surface are most common for collectors in the centre. Their least statically suitable levelling is due to execution in cohesionless soils, which are partly saturated. Position below the level of footing bottoms of most buildings demands complex static measures for securing the overburden and the adjacent structures.

5.3 *Traffic and city operation*

Traffic and city operation represents the third basic requirement for incorporation of collectors into the city. This is a very delicate problem not only during the concept phase but also during the execution phase of the collector, when it usually affects the public. Minimization of local negative effects on the operation of the city (its traffic and supply) and their duration is therefore demanded. Basic demand is functionality of traffic and rail mass transport. Construction works in protective zones of the metro are subject to special reviews and execution procedures. There is a strict requirement for structural and static inviolability of all metro structures.

Compromise solutions for possible temporary traffic replacements, which are acceptable by traffic and city authorities, are being searched for during the documentation reviews as well as solutions for construction site traffic (including acquisition of public land for construction site installations).

Enabling access to existing buildings and commercial objects in them (possibly by an alternative entrance) represents another measure during the construction works. Fulfilling of this demand is usually bound to applied construction technology, work processes and phasing.

In some cases, construction works on the collector might closely relate to works on a traffic structure. For example a parallel alignment of a collector and a traffic tunnel or underground collector and a tram track.

5.4 *Possibilities of execution*

Selection of possible application of specific technologies for collector execution depends on spatial resources of the site, geological conditions and assessment of impact of the works on the vicinity. Cut and cover technology and pre-cast constructions are mainly used for collectors in the new residential zones in the suburbs.

On the other hand, in town centres, feasibility of execution of cut and cover linear structures is restricted to entrance shafts in crossings and branching of collector ducts, as the effect of construction works on the city operation and environment is substantial in the centre.

Underground tunnels for particular collector ducts are driven from these shafts, which represent initial structures. Differentiation of used technologies, procedures and supporting measures is determined by the collector category and therefore its levelling (depth under the surface).

3rd category collectors are designed in small depths. They therefore require large amount of additional measures for stability securing and safety of boring, as well as static supporting of adjacent structures and underground services. 2nd category collectors are driven deeper, usually in bedrock, which is, if possible, unaffected by weathering.

5.5 *Collector preparation specifics*

This issue is also important for incorporation of collectors into the city. Public benefit of these structures is not that obvious, when all the utility lines situated in the ground are still functional. Moreover, expansion of the metro is more appreciable by the public and city authorities.

Specifics of preparation mainly result from great amount of parties to an action during the documentation reviewing at every level of administrative action. Property ownership matters of adjacent buildings are difficult. This incites the need for permits of all the owners (mainly for connections into their buildings). Present standard practice of the construction process creates harder relations between the involved partners. Demands for responsibility for damage done to others' property and the environment are applied consequentially. Complex evaluation of the present state of all structures before the start of works is necessary for further negotiations about damage caused during execution of the collector. This is performed by monitoring of present state of the buildings and sewer ducts as well as geotechnical monitoring during the execution performed on the surface as well as in the underground.

6 GEOTECHNICAL PROBLEMATICS OF DESIGN AND EXECUTION

6.1 *Solving geotechnical tasks*

For incorporation of a collector into the city, in addition to the above stated spatial aspects, it is necessary to work out a geotechnical analysis of static behaviour of the structure and its effect on the surrounding environment. It is necessary to review the process of execution of the collector during all construction phases as well as effect of the structure during the whole life time. Solving the geotechnical tasks, is therefore one of the limiting factors of the conceptual solution in which both limit states (ultimate, serviceability) must be respected.

The effect of construction works on the progression of strains in bedrock and the creation of subsidence zone is monitored with respect to safety system "collector structure – bedrock environment – buildings and underground services". Disposition, design, technology and process of execution, as well as a set of measures as a part of advanced works or driving of the collector arise from analysis of acceptable strains of surface structures and utility lines in overburden.

Consistent evaluation of static aspects of possible levelling of the collector is an integral part of these analyses. This was closely described in the categorization paragraph.

6.2 *Rock conditions*

Local geological conditions are a basic input data for geotechnical analysis. Their complexity in the centre of Prague is not only caused by historical development and broken morphology, but also by lithological evolution of rock environment and tectonic deformation of bedrock. Another factor is the erosion caused by the Vltava River. Two characteristic units can be defined in the geological profile – bedrock and quaternary sediments. Bedrock is situated in depth between 12 and 15 m under the surface level, in areas with terraced levels, the depths drop down to 6 m.

Bedrock usually consists of Ordovician shale of various compositions (clay, sand, silt) with insets of solid layers of sandstone and quartzite. Differentiation of separate layers of shale causes big differences in physical and mechanical characteristics, as well as in weathering processes resistance.

Overburden layers of quaternary terraced sediments are formed by clayey sands and sands with gravel, which turn into gravels at the base of the quaternary. Specifics of the made-up ground result from their variable thickness and composition affected by anthropogenic processes. Known and unknown underground spaces from former buildings are common. Usual thickness varies between 3 and 4 m, in places with filled moats up to 6–7 m. Made-up ground is relatively compact, with common archaeological findings.

6.3 *Hydrological conditions*

Hydrological conditions are another important input, which directly affects the phases of the concept and execution of the collector. Groundwater table, which creates a continuous level in a permeable environment of gravelous sand and especially gravel, runs approximately between 10 and 12.5 m below the surface in a depth range depending on the terrain morphology.

Thickness of saturated layer varies between 1 and 5 m depending on the shape of the bedrock. Groundwater level and its changes over time depend upon the water level in the Vltava River. It was necessary to revalue the levels of groundwater used for designing collectors after the floods in 2002 and to raise the

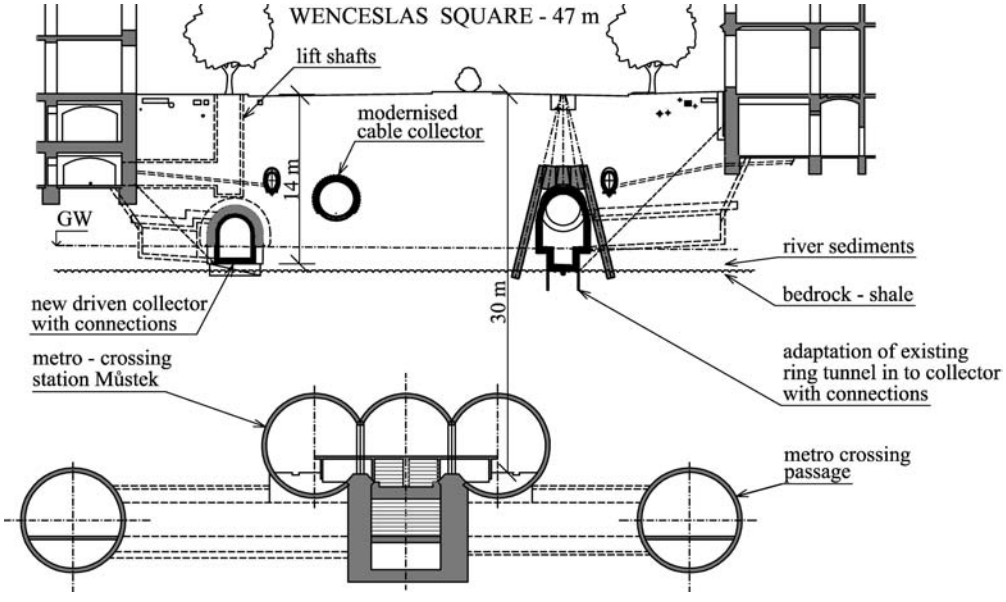

Figure 4. Further development of collectors in Prague – Collector at Wenceslas Square. Current execution of a new duct and proposed difficult adaptation of a present duct into a collector with connections into all adjacent buildings.

values of cent-year's flood level. Analyses of environment permeability, yield of water inflows and groundwater chemistry are necessary for determining the effect of the construction works on the area. A basic task is monitoring the behaviour of groundwater and its acceptable changes with respect to existing buildings.

7 COLLECTORS A UNDERGROUND URBANISM

Underground space has a great value in cramped conditions of the city centre for possibility of its utilization for purposes, which can't be placed on the surface or which would significantly affect the environment. There is therefore a necessary demand for systematic solution of proposed and planned underground structures including urban plans for underground utilization. Plans for utility lines development are an integral part of these solutions. Open system of collectors with the possibility of expansion is an appropriate solution in the centre of Prague.

Consistent coordination of all structures including qualified prognoses of future solutions and procedures is necessary, so that the planned structure isn't limited or restrained by previous inappropriate actions. The aim is to eliminate spontaneity and collisions in the underground utilization and to establish a system, similar to the existing system of urban plans of the surface. In case of collector network, this mainly means defining the levelling and solving collisions with metro and main utility lines of citywide character.

This also involves a sense of permanent value of all underground structures and their difficult dismantling. These financially demanding structures (usually with long pay-off period) are designed for long time operation (in terms of decades). Complex conception of the task of spatial incorporation of the structure demands a multidisciplinary approach of all participants.

8 PROGNOSIS OF FURTHER DEVELOPMENT

Development of collectorisation in Prague will continue. More than 3 km of consumption collectors are being built or prepared. Expansion of deep supply collectors (including an underground crossing of the Vltava river) in total length of more than 3.2 km is being prepared at the same time.

Operating collectors, as well as collectors in preparation, contribute to valuation of existing facilities in the area, improvement of operation of the city and its environment within the historical centre. Therefore, it is important to include the system of collectors among the components forming the city.

Years of planning and implementation: Two major urban tunneling projects in Los Angeles, California, USA

M.A. Elioff & B.W. Miya
Parsons Brinckerhoff, Los Angeles, California, USA

J.H. Albino
Stanford University, Palo Alto, California, USA

ABSTRACT: One of the world's major metropolitan areas, Los Angeles, California, has seen construction of over 80 km (50 miles) of large diameter tunnels for subway, wastewater, and water supply over the last 25 years. Two of these tunneling projects, the East Central Interceptor Sewer (ECIS), and the Los Angeles Metro Gold Line Eastside Extension (MGLEE) are examined to describe the 15 to 20 year durations of planning, design, and construction of the tunnels and to provide an overview for future planning and scheduling in urban settings. Aspects of the projects contributing to the complexity and schedule are discussed, including; identification of need and initial planning, the environmental processes, design and changes in technology, impacts of public perceptions on tunneling, protection of property, funding, and changes in all of the above over the duration of the project. The two projects are very different in terms of ultimate use. The complex process planning and design for tunneling in urban areas, however, are similar.

1 TUNNELS IN LOS ANGELES – OVERVIEW

Over 80 km of large diameter tunnels have been constructed in Los Angeles, California (USA) over the past 20 years for transportation and water projects. Project duration, including construction, planning, and design can be well over about 15 years for these tunnel projects in urban areas. In this paper the Metropolitan Transportation Authority's (Metro) Gold Line Eastside Extension (MGLEE), and the City of Los Angeles' East Central Interceptor Sewer (ECIS) are described.

The recently complete ECIS project involved over 18 km of Earth Pressure Balanced (EPB) driven tunnel using four TBMs through a densely populated area of central Los Angeles. The MGLEE tunnels are under construction as of September 2006 and represent 4.3 km of underground construction within a 10 km light rail project, also in a densely populated urban area of East Los Angeles. Two EPB TBMs are being used to drive the MGLEE tunnels.

Both tunnel projects are successful in terms of tunneling performance. Although the two projects are very different in terms of ultimate use; the complex process of tunneling in urban areas in the United States is similar. The following provides short summaries of project history for use in future planning of urban tunneling projects. As these two projects were constructed along the same approximate timeline (over 15 years), we also present some of the relationships between the projects; for example, changes in technology and local perceptions of tunneling. Other projects in Los Angeles are presented supporting case history.

2 METRO GOLD LINE EASTSIDE EXTENSION

The MGLEE tunnels have been in planning, design, and construction for over 20 years. Figure 1, Project Timelines, illustrates the overall schedules. The MGLEE project will extend the existing Metro Gold Line Light Rail (LRT) presently in operation from Pasadena to Union Station in downtown Los Angeles. MGLEE includes the construction of a dual track system, in three cross-sections: Aerial (3 bridges), tunnel (2.7 km) and at-Grade (7.1 km). The underground segment was placed under narrower sections of 1st Street in the older Boyle Heights neighborhood of East Los Angeles. Underground structures include two portals, cut-and-cover sections adjacent to portals, twin-bored tunnels (6.7 m diameter), and two stations.

Upon completion, the LRT will extend the Metro Rail system, currently comprised about 118 km of

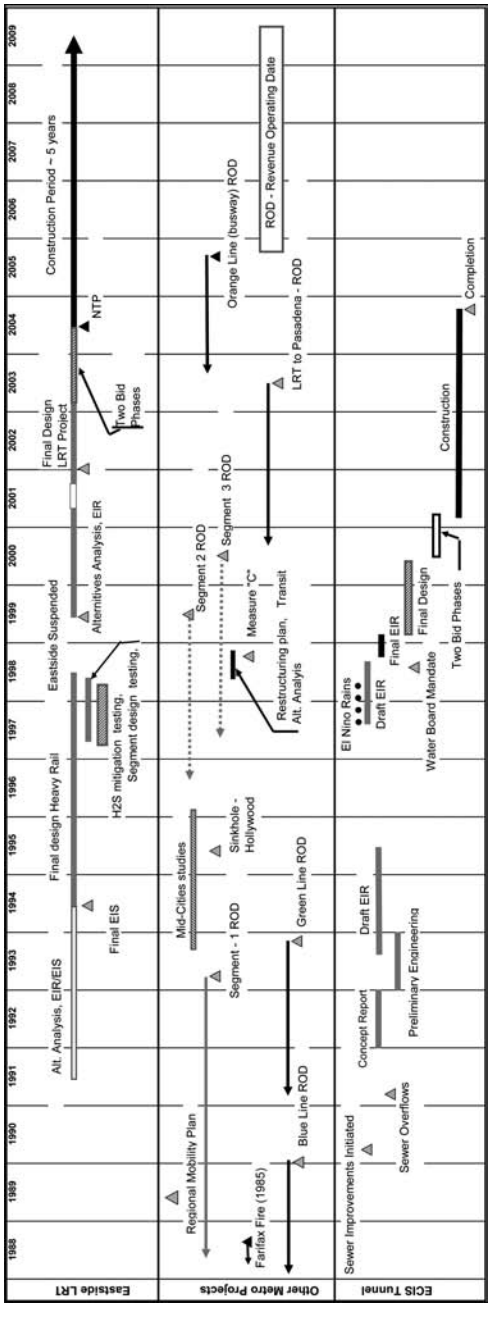

Figure 1. Project timelines.

urban rail and 22 km of busway. Figure 2, Metro Rail Systems, Existing and Planned, illustrates the MGLEE alignment relative to the subway system, and previously planned Metro segments. The existing

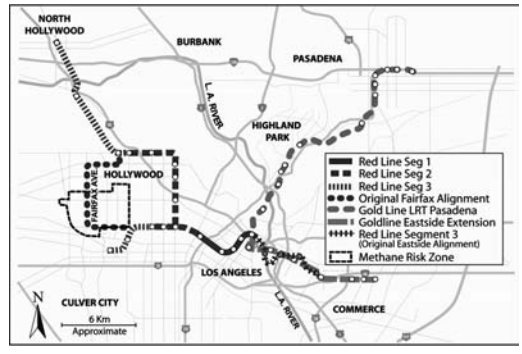

Figure 2. Metro Rail Systems, existing and planned (Blue and Green Line LRTs not shown).

Metro system includes three LRT lines (Blue, Green and Gold), the first becoming operational in 1990).

2.1 *Planning and environmental issues*

To understand some of the planning issues for the MGLEE project, a brief history of Metro Rail is presented. After two failed ballot measures in 1968 and 1974, Los Angeles County voters approved Proposition A in 1980, which authorized a half-cent sales tax to build the regional rail transit system. The Draft Environmental Impact Statement (EIS) concluded that a Rapid Transit System (ultimately heavy rail) would provide a high-capacity system for the regional core. The final EIS (1983) presented a 30 km subway from downtown Los Angeles west along Wilshire Blvd., and north on Fairfax Ave. (USDOT 2002). A methane explosion occurred in 1985 under a building in the Fairfax area, and subsequent studies recommended that "methane zones" be created in Los Angeles, requiring building code changes for construction in these areas. Tunneling was deemed unsafe, and Metro began studying alternative alignments to avoid the methane zone along Wilshire Blvd.

Metro re-aligned the subway or "Red Line" system to avoid the methane zone, and began design and construction of the system in three Major Operating Segments (1, 2 and 3) for funding purposes and to deliver completed operating segments in series. Segment 3 originally included plans for an Eastside Extension of the Redline Subway, a Mid-City Extension, and a Northern route. Of these Segments-3 routes, only the northern extension has been completed to date. The Mid-City Extension began planning to circumvent the methane zone.

Planning for the Eastside began in 1989 – with a Regional Mobility plan that formally identified the need for major rail transit improvements in the region and Metro's and the adoption of the 30-year Integrated Transportation Plan (Metro 1994).

Environmental Phases for projects in the USA were established after the National Environmental Policy Act (NEPA) became federal law in 1970. NEPA requires that alternatives be evaluated and subjected to public review. The preferred alternative(s) are carried forward for further environmental review during preparation of Draft and Final Environmental Impact Statements (EIS), with public comments addressed during the Draft phase. The state of California has similar requirements under the California Environmental Quality Act (CEQA), resulting in preparation of an Environmental Impact Report (EIR).

In April 1993, Metro and the Federal Transportation Authority (FTA) completed the Alternatives Analyses evaluate the Eastside Options. The preferred alignment would use heavy rail technology and continue Red Line Segment-1 from Union Station approximately 11 km east in two phases, the first being a 6.4 km tunneled segment. The Final EIS/EIR was completed in 1994 and final engineering began in early 1995, nearly in parallel with the Mid-City Extension.

2.2 *Design and technology Red Line Eastside extension*

Los Angeles geology presents some additional tunneling "constraints," namely seismic conditions and the presence of naturally occurring subsurface gas. Both conditions require additional provisions for design, construction, and final operations.

For all Red Line segments, a "two-pass" tunnel lining system was developed to include a "high-density polyethylene" (HDPE) water and gas barrier. Underground stations were also constructed using the HDPE barriers to "wrap" all underground structures. Open face shields were used for all soft-ground tunnels, as this was the traditional tunneling method used in Los Angeles, and most of the tunnel reaches were above groundwater.

Initial design for the Eastside Red Line tunnels included new challenges for Metro – given construction issues on prior tunnels – as well as discovery of new seismic feature and subsurface contamination, in addition to the overall seismic and naturally occurring gas conditions.

2.2.1 *Tunnels*

Final tunnel design began just as the Metro Red Line System construction had suffered from some highly publicized events: ground surface settlement of up to 30 mm was experienced along Hollywood Blvd's "Walk of Fame," (1994) and a sinkhole (1995) also in Hollywood, occurred during the enlarging of a Segment 2 tunnel to correct tunnel alignment.

Much of the planned Eastside subway length was non-linear, and meant that tunnel reaches were often under commercial and residential properties – as well as city streets. Tunneling risks were "elevated" due to recent experiences and the added potential property impacts.

In part due to publicized events, Metro commissioned an expert Tunnel Advisory Panel to assess tunneling conditions in Los Angeles with respect to world-wide experience. The Panel concluded in November 1995 that compared to world-wide experience, geologic conditions in Los Angeles were generally more favorable, the cost of tunneling relatively low, and tunneling performance, based on surface settlements, was "slightly better." The panel recommended consideration of EPB TBMs for future projects (Eisenstein et. al., 1995).

Designers were already recommending pressure-face TBMs, and slurry TBMs exclusively, for the Mid-City alignment. In Mid-City, additional geotechnical investigations were evaluating subsurface gas conditions – which were found to be as high as those in the methane zone, and with the addition of high hydrogen sulfide (H2S) levels. Studies for Mid-City concluded that not only should the gas-bearing formations be avoided, but also recommended consideration of ground pre-treatment, such as use of an oxidizing agent, and that tunnel construction should proceed using slurry TBMs to further contain gases in pipelines until they could be treated at the surface.

The studies on the Mid-City segment became applicable to the Eastside Extension, as ground contamination was found in an industrial area west of the Los Angeles River. H_2S and methane were present which lead to specification of slurry machines for this reach only. For other reaches, the Contractor would be given an option for pressure-face technology (EPB or slurry). Soil-gas studies for the Eastside included pre-treatment of the ground.

Use of pressure-face TBMs would also reduce the potential for surface settlement – as compared to open shield methods. Given that the alignment was not consistently within the public right-of-way, many buildings would be directly over the tunnels. Designers evaluated over 200 structures near or over the tunnel and developed a comprehensive compaction grouting program for additional building protection.

2.2.2 *Linings*

In addition to precautions taken for tunnel construction in gassy ground, tunnel final liners had to be "gas-proof." The traditional two-pass system with expanded initial liners would not be acceptable with the use of pressure-face machines, since effective use of pressure-face tunneling also requires gasketed segments and grouting immediately after the rings are assembled. No precedent for one-pass liners in gassy ground was found, and Metro undertook further studies in 1997–98 to develop a one-pass liner with additional gas sealing properties.

This one pass liner consisted of a double-gasketed segment with convex radial joints – principally to "flex" during earthquakes so that the tunnel remained sealed from gas. A six-month, full scale, laboratory testing was conducted, at the University of Illinois, to evaluate tunnel structural capacity under seismic and ground loadings. Tests of gas leakage through gaskets were also performed. For another level of redundancy against potential gas intrusion, the final liner design also included a slightly oversized tunnel – about 15 cm on the radius, to allow for future placement of HDPE and additional concrete to secure it. As for the existing operating portions of the subway, Eastside Extension design called for continuous gas detection in the operating tunnels and additional emergency ventilation.

2.2.3 *Fault crossing*

During geotechnical explorations for the tunnel in 1996, geologists postulated that an escarpment (approximately 13 m rise in the ground surface over 200 m) actually represented a potentially active buried thrust fault. (A buried thrust fault ruptures at depth, and causes surface deformation (bending) but not an abrupt offset). Extensive geotechnical investigations were carried-out to estimate recurrence intervals and deformations – should a seismic event along this feature occur – and develop design criteria. Neither the tunnel nor the thrust fault are linear features, and the tunnel crossed the fault in three locations. At two locations, Metro designed a more flexible steel liner to accommodate movement.

2.3 *Politics and public perceptions*

Legislation, both federal and local, has impacted Metro System overall, and stopped the Red Line Eastside Extension as it was going to construction.

Overall system delays occurred after the methane explosion investigation in 1985, when the Los Angeles congressional representative amended the subway's funding bill to contain the provisions that tunnels would not be constructed in the methane zone. (A reversal of this legislation – given new technology (for example pressure-face TBMs), was approved 30 years later in September 2006).

Mainly due to some publicized events, including those briefly described in section 2.2.1, along with an economic recession, and the perception of construction cost over-runs, local legislation was passed by Los Angeles County voters in 1998, prohibiting use of local funds (the half-cent sales tax) on subway construction.

After discussions on funding and tunneling safety, Metro conducted a "re-structuring plan" and a "Regional Transit Alternatives Analysis" to evaluate available funding and fixed guideway alternatives to heavy rail for the three transit corridors – including the Eastside. The Alternatives Analysis and environmental process was repeated 1999–2002, with the preferred alternative for final design being light rail technology (LRT), for the most part at-grade, with a 2.7 km of tunnel and two underground stations. The LRT project, The Metro Gold Line Eastside Extensions (MGLEE) would extend an existing LRT, the Metro Gold line, from Union Station to East Los Angeles.

2.3.1 *Final design MGLEE*

The new alignment had some tunneling advantages in that it became aerial or at-grade west of the Los Angeles River and thus avoided highly contaminated areas. Much of the previous tunnel design could be used (pressure-face TBM specifications, double gaskets, etc.) with adjustments for LRT tunnel diameter. On the other hand, the relationship between the tunnel alignment and the escarpment changed, and additional geotechnical investigations were undertaken to evaluate station design, where one station was nearly parallel to the feature.

Final design included assessment of construction contract form and packaging, with consideration of bidder qualifications, possible incentives for performance, and use of the Design-Build (DB) contracting methods. Ultimately, the project was let in three contracts: an underground segment (station excavations and tunnels, by Design Bid Build (DBB)), the at-grade portion (including final station structures), and a bridge. The at-grade/station finish contract was DB. The underground contract was advertised first and separately, but was re-bid months later concurrently with the DB contract. Initial bid to award duration was over 18 months.

2.4 *Right-of-Way, permits and third party items*

The LRT tunnels were aligned more closely with the public streets, however, the street alignments, had some abrupt changes that could not be accommodated with TBM tunneling radii.

This along with some shallower reaches led to design of a grouting program for about 30 structures. Thus, in addition to property acquisition for the station sites, subsurface easement for the tunnels, and construction easements for grouting had to be obtained. Over 30 properties needed to be researched for title and negotiations with property owners etc.

2.5 *Funding*

Transit funds in the United States typically consist of Federal, state, and local money – and much competition between public agencies for available funds. To receive the funds, agencies must comply with various conditions; e.g. completion of Alternatives Analyses and the EIR, which involves a significant

public comment element. The MGLEE went through this process twice for the environmental documents, and was finally granted $490.7 million from the US Department of Transportation, or slightly over half of the estimated $899 million required for the project. Of this, approximately $200 million was estimated for the underground (DBB) portion of the project. The construction of both contracts was awarded to a Joint Venture (JV) of Washington Group, Obayashi and Shimmick, with the tunnels subcontracted to Traylor Brothers and Frontier Kemper JV.

2.6 *Construction*

Construction of the MGLEE project began in July 2004 with tunneling beginning in February 2006. At this writing, underground stations have been excavated and tunnel construction is about 70 percent complete. The EPB technology has performed better than expectations, as measured ground settlement has not exceeded 1.0 cm.

3 EAST CENTRAL INTERCEPTOR SEWER

ECIS is an 18.4 km, 4.7 m excavated diameter sewer that increases Los Angeles' wastewater infrastructure capacity. Construction was recently completed, and the new sewer was placed into full operation in August 2004. From any perspective, the project is considered highly successful. There were few construction impacts to the community, costs were within budget, and schedule slippage was managed. Nevertheless, the total duration from concept to completion was over 15 years.

The tunnel alignment runs west from the Los Angeles River east of Downtown, and generally stays under east-west oriented streets until it turns south onto La Cienega Boulevard. Finally, it turns west under the Baldwin Hills and connects to an existing Sewer in Culver City. Figure 3 shows the ECIS with respect to the Metro Rail System.

3.1 *Planning and environmental processes*

The City completed various planning studies for ECIS, including an Alternative Alignment analysis and an initial draft environmental impact report in the early 1990's. Opposition to the project from various neighborhood associations – objecting to construction disruption and potential sewer odors – caused the project to be placed on hold in 1995. The initial Environmental Impact Report was never completed.

"El Nino" rainstorms in the 1997–98 winter season caused the city's sewer system to overflow and major sewage spills. The State of California Regional

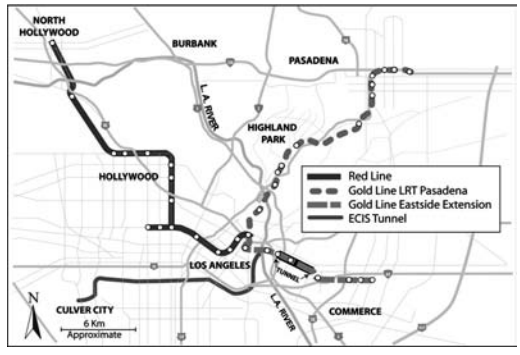

Figure 3. ECIS and existing Metro Rail Systems.

Water Quality Control Board took action and mandated the completion of the ECIS and six other sewer projects within a tight time schedule. Fines were established for exceeding the scheduled completion milestones.

A second EIR addressed concerns raised during the first Draft EIR. For this process, the City emphasized having community leaders endorse the project. There was still considerable community opposition to the project, but the City Council approved the Final EIR in November 1998. (City of Los Angeles, 1998).

The decision to tunnel the entire 18 km as opposed to using cut and cover methods was made during this planning and environmental documentation phase. An outcome was that drop structures had to be designed to divert flows from the existing collector sewers into the new ECIS pipe. The existing collector sewers averaged in depth around 7.6 m, and the invert for the ECIS tunnel averaged about 20 m.

3.2 *Design and technology*

The final design began in 1999 and took approximately 18 months to complete. There were several significant technical challenges for tunneling including minimizing ground settlement. This specific issue drove the City to specify pressure-face (EPB or slurry) TBMs. Discussions among designers and the City's Board of Consultants transpired as open shield technology could still be considered appropriate for much of the tunnel's reach, and cost savings might be realized. Ground was mostly very dense sand with clays and silts, above the water table, and generally considered ideal for the open shield. In addition, given the relatively small diameter, at over 15 m depth in many reaches, meant that predicted settlements would be within the 20 mm allowable presented in EIR. Ultimately, given the Metro experience and the raised public awareness of tunneling risks, pressure-face machines were specified.

3.3 *Bid and award of the tunnel contract*

Given this first use of pressure-face TBMs in Los Angeles, The City implemented a contractor prequalification process to ensure that only experienced tunnel contractors would be allowed to bid.

The project went to bid twice due to issues related to these prequalifications. In the first bid period, advertising began in March 2000. The second bid package advertised in September 2000 and was awarded to Kenny/Shea/Traylor/Frontier-Kemper, JV for $240.4 million in January 2001.

3.4 *Politics and public perception*

As described above for the MGLEE project, during the mid 1990's, there was a high level of public apprehension concerning tunneling in Los Angeles.

During this time, the City had investigated alternative construction methods including open trench construction, which initially appeared more cost-effective and would impose less tunneling risk. The advantages and disadvantages were raised with the community during the Environmental phase. The process resulted in demonstrating that the advantages of tunnel construction greatly outweighed the impacts caused by open trench methods. Public comments during the process also resulted in a change of alignment for the final design.

3.5 *Right-of-Way and protection of property*

Acquisition of shaft sites, laydown areas, temporary easements, and subsurface easements was a critical activity. The intent was to locate the ECIS under public right-of-way, but there were areas along the alignment where the sewer had to cross under private properties. For the 18 km tunnel, over 1,000 real estate transactions were performed including title searches, appraisals, negotiations, purchases, construction easements, and subsurface easements, and starting eminent domain proceedings.

This effort took over 18 months to complete, running in parallel with final design, as the Environmental Process requires that no real estate transactions be made until the Final EIR has been adopted.

3.6 *Construction of ECIS project*

The original construction schedule estimate was 3.5 years. During construction, there were several unforeseen events. These resulted in seeking a contract extension to avoid fines for late completion. The milestone date to place ECIS into service was changed from November 30, 2003 to August 30, 2004. Major unforeseen events impacting schedule included:

- Discovery of a Native American grinding stone
- Re-sequencing work at a work site to allow access to four homes
- Additional precautionary permeation grouting at selected locations
- Complex real estate transactions for acquisition of one shaft site
- Slower tunneling excavation rates

3.7 *Funding*

The project costs were paid through the City's Sewer Construction and Maintenance Fund, and a State of California Revolving Fund that loans to water agencies.

Documentation required by the State for loan eligibility included:

- A Value Engineering study
- Minority/Women/Other Business Enterprise quarterly reports
- The City's water conservation plan
- Draft revenue program
- Project performance certification after one year of operation

3.8 *Changes in the duration of the project*

To offset the delays caused by the unforeseen events, various activities were accelerated. Some of these included:

- Awarding the contract before all right-of-way was acquired: The City assumed a risk of property not being available
- Specifying a fourth TBM
- Acquisition of additional land for a second pipe laying operation
- A 6-day workweek with two 10-hour shifts
- Change to a prefabricated pipe at one drop structure – in lieu of a concrete cast-in-place option

4 CONCLUSIONS

For tunnel projects in urban areas to be built in a reasonable time frame, planners and designers must expect and plan mitigations for interruptions in the project schedule due to environmental issues, funding, and the bid process as well as develop technical solutions for design. From these examples alone, we see that major changes are not uncommon as a result of the Environmental Studies and public comment.

Planning, design and construction of major infrastructure projects in urban environments requires many years and is costly. In planning, the agency must also use demand projections that look 50 to 100 years into the future to maximize the value to the public. The examples presented here are a clear indication of

the long-term effort associated with providing a very much needed improvements to the communities they serve.

Geological and geotechnical conditions in underground structures design of Rome subway: the B-Line extension

R. Enrione, A. Eusebio & L. Soldo
Geodata S.p.A., Turin, Italy

L. Solimene
Comune di Roma – Dipartimento VII, Rome, Italy

ABSTRACT: Underground works, in complex urban areas, can present prominent levels of risk connected with various ambits: low overburden, buildings facing the line, interference with acquifers, soil of poor geotechnical characteristics, presence of man-made cavities. The knowledge of the geological – technical context is the first and inevitable stage of study, for the development of an underground construction project, by which it is possible to achieve a high level of sensibility about the underground space and to propose mitigation measures for the risks associated, both during the construction phase and during exploitation. The case of Rome subway B-line extension is presented, where a rigorous procedure, involving geotechnical investigations and consecutive phases of study, has been applied both for the preliminary design and for the construction phase (PAT – Protocol for Advancement of Tunnel excavation). The illustrated approach has been consolidated from the experience of many similar completed projects, and has become a standard practice.

1 THE WORK AND THE TRANSPORTATION SYSTEM OF ROME

1.1 *The "Mobility System" of Rome*

The transportation planning of a city like Rome presents a high level of complexity and requires the choice of strict planning tools.

The "Mobility System", drawn up and approved by the local administration, is the reference programmatic document, in which the different existing transportation networks, the actions for their development and updating find a rational placement and harmonization.

According to the "Mobility System", the subway network proves to be a necessary means of transport, which is able to connect, in a rather short time, the highly populated areas of the suburbs to the city center. This aim is being further developed, as shown in the ambitious enlargement plan (Fig. 1).

1.2 *The subway B-line extension*

The B-line extension project coherently fits in the above described mobility scenario, enabling the old line to settle close to the existing ring-road highway (Grande Raccordo Anulare, GRA) and thus representing an important nodal exchange (Fig. 2).

The B-line extension includes 3 km of new line, 3 intermediate stations and a new depot. In this way, the San Basilio, Torraccia and the new Casal Monastero districts will be served for the first time, with the view of a contextual requalification of their urban and social context and also installing new services.

From a technical point of view, the new metropolitan section will be realized entirely underground, with excavation between retaining structures and below the cover slab (top-down method). This will allow the surface conditions to be restored quickly, limiting the disturbance to the public to a relatively short time and ensuring the separation of underground works from ordinary daily activities.

1.3 *The assignment*

The engineering services, necessary to the preliminary and definitive design of B-line extension, has been assigned by the local administration (Comune di Roma) to the group of companies composed of C. Lotti & Associati, Geodata, Siteco and A2G.

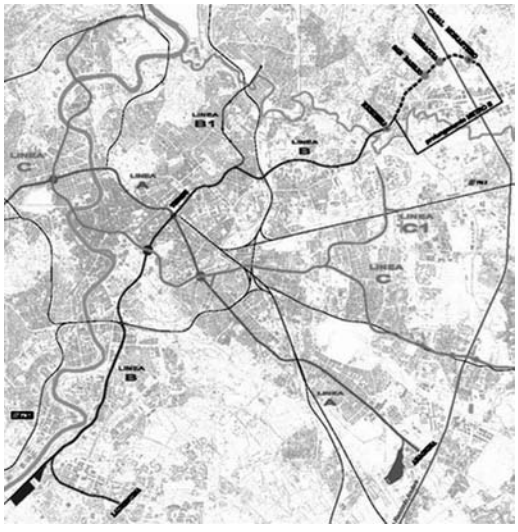

Figure 1. The subway network enlargement plan and the location of the B-line extension.

Figure 2. The B-line extension design in the Casal Monastero area.

2 TERRITORIAL CONTEXT, POSSIBLE DIFFICULTIES AND BASIC PHILOSOPHY

The project of the new subway section had to face many difficulties, connected to the insertion of the works in the already complex territorial context of reference, due to specific technical uncertainties, which were pointed out since the very first planning stages, as being associated with an initial level of high risk.

More specifically, the major difficulties were proved to be directly or indirectly connected to the geological-technical context that consequently assume high priority on the design agenda, even before specific studies and geotechnical investigation took place.

Figure 3. Collapse of a cavity in Rome (Via Bricci).

The most important uncertainties, directly connected to geological-technical context, are the following:

- type of soil intercepted by the excavation, with highly variable level of cementation and poor geotechnical characteristics;
- presence of an unconfined aquifer at the tunnel level and possibly other deeper aquifers, even in pressure;
- verified presence of man-made cavities in the site, single or complex ones, also of big size (Fig. 3).

The most significant aspect indirectly connected to the geological-geotechnical context is the presence of many buildings along or facing the line of the work.

It is therefore clear that the full knowledge of the geological-technical context is an indispensable prerequisite for the design. This is not only for normative reasons or design completeness (as often required today), but also for the management and mitigation of the risks during construction.

This is especially effective if performed since the very first steps of a project, that is since the Preliminary Design, when specific studies and geotechnical exploration can be successfully used to reduce uncertainties while work's structural designing can be directed at best.

This process will ensure the most effective definition of:

- risks connected to the construction, with reference to the design;
- functional level provided by the line;
- resulting economical and financial schedule.

The value of this approach can further increase once extended to the construction phase by a constant monitoring of the excavation parameters and by the analysis of the work's actual conditions (PAT Method: Protocol for Advancement of Tunnel excavation, Grasso et al. 2002a,b). These are strategic activities for the risk management and its mitigation, as they ensure a

real-time comparison between the design scenario and that encountered during construction.

The B-line extension of Rome subway, designed with a deep awareness of the above described philosophy, well illustrates the Geodata's methodological approach.

3 THE METHODOLOGICAL APPROACH

The methodological approach followed for the design of the B-line extension is based on a well defined succession of phases; each phase was established on the results of the previous one. In this way a sequential "cascade" process was introduced, by which the activities of every single phase proved to be efficiently rationalised (in terms of quantity, typology and costs) as systematically addressed by the issues of the prior phase (Fig. 4).

The process, by favouring a constant comparison with the Owner, benefited from the contributions of the whole project management team, thus permitting a better definition and management of risks.

In the following pages the method outline will be described and subsequently account will be given of the level of knowledge that has been reached by its application.

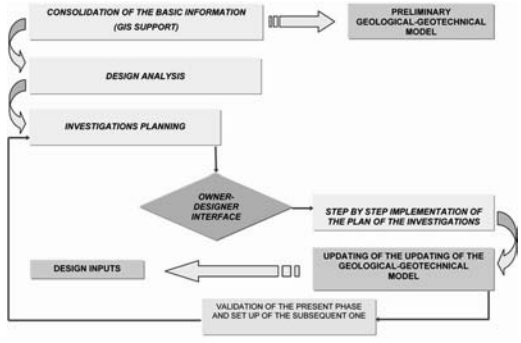

Figure 4. Methodological process flow-chart.

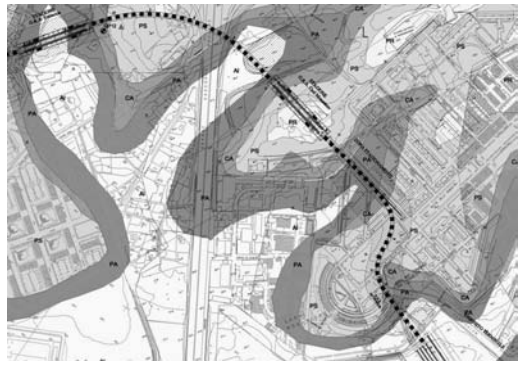

Figure 5. Extract of the Geological Map: actual alluvial deposit (hatched bright zone) and volcanic sequence (hatched grey-scale zone).

3.1 *Consolidation of basic information and preliminary geological-geotechnical model*

The first phase of the process is the collection of all the information and data concerning the geological-geotechnical context, that were available since the Preliminary Design started off. They are: general bibliography, available stratigraphic evidences, technical studies and previous design documentation (in particular, Feasibility Design). This first phase proved to be a strategic one, because it led to an immediate awareness of the context in a very short time.

Technical and reconnaissance surveys were also performed, so that the gathered information could be set in its proper context and the knowledge of the "geo" scenario could be further investigated in a rational way, minimizing the impact on the urban activities and reducing time-cost for the geotechnical exploration.

A platform of GIS (Geographic Information System) was prepared for ground data filing, consultation and real-time updating.

It should be noted that in complex areas, such as Rome, with buried channels and erosion forms, complex lateral eterophies between alluvial and volcanic sediments, etc. reliance must be placed on engineering geological interpretation of available information, prediction on the basis of known geological relationships and careful interpolation and extrapolation of data.

For this reason inside the investigations for the design of Line B the value of the geological surveying phase and the presence in the geological and geotechnical design team of specialist in Structural Geology and Sedimentology were emphasized: also in urban areas, with limited rock and soil outcrops the "geological survey" (improved in this environment with trenches, shafts and other indirect data) made it possible a correct interpretation of the results obtained from the deep investigations. At the end of the first phase a preliminary geological-technical model was defined, substantially represented by a geological map (Fig. 5) and by the corresponding profile along the axis of the work.

3.2 *The project and the plan of site investigation*

After the "geo" context was defined, even if preliminary, the design phase started off; its development took into account the potential risks that had emerged in the previous stage. The hypothesis of the project was since the beginning aimed at reducing risks of the construction phase.

In parallel, once the uncertainty margins of the "geo" context were determined, a specific investigation plan was developed and validated by the Owner; it included different steps: geophysical (Stage I) and geotechnical ones (stages II and III).

3.3 *Update of the geological-geotechnical model*

Once the investigation steps I and II were performed, a first update of the geological-technical model followed, based on which significant design indications to manage risks were given.

4 PRELIMINARY GEOLOGICAL-GEOTECHNICAL MODEL

In the following paragraphs the results of consolidation of the basic information will be showed, with reference to the geological-technical investigations. The analysis of every ambit of study ended up with the characterization of the difficulties connected to the construction, on which the subsequent investigation steps was planned.

4.1 *The geological scenario*

The area of interest is located inside the Thyrrhenian margin of Apennines. Its complex geomorphic, stratigraphic and structural elements can be traced back to the geodynamic evolutionary characters of the Apennines chain of the late Pliocenic-Quaternary period (Ventriglia, 2000).

Above the oldest carbonate levels, not relevant for the design, terrigenous sandy-clayey sediments of Pliocene can systematically be found (Argille di Monte Vaticano, Marne Vaticane, Argille azzurre). These units act as substrate of reference for the subsequent elements. Over them, pre-volcanic alluvial deposits occur (Unità di Santa Cecilia), consisting of gravel, clay and sand, organized in complex stratigraphic relationship.

The pyroclastic sequence that follows is of a later age and is linked to the past explosive volcanic activities, which are characterized by old altered tuffs (from Unità di Tor de Cenci to Successione di Sacrofano), pozzolane (Pozzolane Rosse) and lithoid tuff (Tufo Lionato). Finally one can find the actual alluvial sediment and the more recent man-made filling, often remarkably thick.

Considering the complexity of the stratigraphic features, a geophysical and geotechnical investigation was necessary to reorganize the geological elements concerning the project.

4.2 *Geomorphology and underground cavities*

The area is characterized by the presence of river Aniene's right tributaries, which flow in relatively deep

Figure 6. Cavities found along the line with buildings above (Pietralata area).

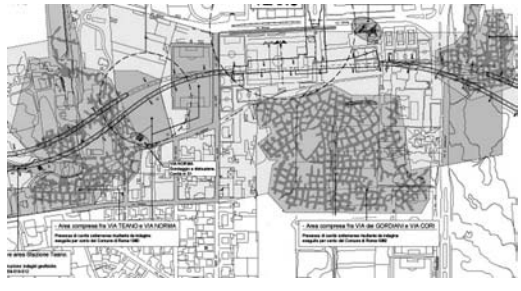

Figure 7. Map of cavities surveyed (hatched grey zone) and risk of being intercepted.

flat valleys, whose sides have often been changed by extraction activities. Old or current instability phenomena are not visible, neither along vertical caves faces, because of the good technical characteristics of the volcanic soils.

In the concerned area underground cavities can occur; they can be caused by the extraction of lithoid tuff (Tufo Lionato) and Pozzolane Rosse, especially in the areas of S. Basilio and Casal Monastero, where the great thickness of the volcanic units favoured the extractions (Fig. 6).

Single and isolated cavities can also be found everywhere, especially inside the pyroclastic sequence; they were generally excavated to function as a well or water storage tank.

Since the beginning, the identification and mapping of man-made cavities proved to be a necessary step, both for technical (difficult realization of support works and excavations) and for safety reasons (buildings near the excavation areas, underground utilities networks, etc.). This activity was performed through surveys, within the planned site investigations, systematically integrated with the GIS platform (Fig. 7).

4.3 *Geotechnical and hydrogeological issues*

The involved lithologies show a high degree of heterogeneity in terms of mechanical characteristics and cementation, in particular:

- pre-volcanic alluvial sediments show prevalent silty granulometry, low density and high water content; occasionally cemented levels. Generally they present poor mechanical characteristics (both resistance and deformability);
- pyroclastic sequence shows a stratified aspect, with alternation of altered (incoherent, mechanically poor) and competent (lithoid tuff) levels;
- actual alluvial deposits show clayey-silty granulometry, good plasticity and high deformability;
- man-made fills present a highly variable granulometry, with incoherent behaviour.

Some potential, major, construction consequences derive from this complexity: for example, the presence of lithoid levels makes difficult the excavation with traditional tools, as well as the possible escape of bentonite-slurry used for the excavation of retaining walls.

A detailed geotechnical investigation was therefore necessary, in order to examine every encountered lythology, both in situ and in laboratory.

The potential hydrogeological problems can be related to underground water at the level of the design (interference with excavations and supporting works, dam effect, hydraulic overpressure); possible deterioration of the setting by underground cavities.

To manage risks at best, all the drillings were provided with stand-pipe and Casagrande type piezometers, for a continuous monitoring of piezometric levels.

5 THE SITE INVESTIGATIONS

5.1 *Step I – The geophysical investigations*

The first step of investigation was performed by combining geophysical surveys of georadar and geoelectrical methods, developed along work's longitudinal axis; the results were reciprocally merged for a better resolution. Site calibration by the selected methods was conducted, accomplished by two field-tests focused on searching for man-made cavity.

Geoelectrical tomography (multi-electrod with spacing <3 m) highlighted resistivity values of 50–200 Ωm for the top layers (pyroclastic sequence) and lower values for the deeper layers, 5–50 Ωm (prevolcanic alluvial deposit, completely saturated). No significant cavity was detected.

Two resistivity anomalies were identified in the prevolcanic alluvial layer (400–600 Ωm): subsequently tested with boreholes, they turned out to be portions of a very loose soil, partially washed out by groundwater flow (Fig. 8).

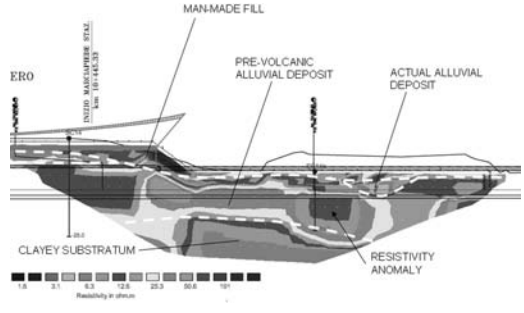

Figure 8. Geophysical section with resistivity anomaly identified, subsequently investigated with test boring.

A multi-array georadar survey was then carried out, for a multiple frequency scanning of the underground context. At first, frequencies at 100–200–600 MHz were adopted, with a lower penetration but higher resolution. Later, an ultra-low frequency antenna was used (25 MHz) for not build-up area only, where no disturbance-factors should be present for the radio signal. Its maximum penetration reached 10 m.

On the whole, the georadar survey has highlighted a complex network of underground utilities as well as the stratification of the upper portion of the pyroclastic sequence.

5.2 *Step II – Geotechnical investigaion*

According to the findings of the previous step, a first geotechnical investigation was conducted, with core borings and laboratory tests: geophysical anomalies was directly explored as well as the most interesting areas.

In total, 27 test boreholes were drilled, all of which provided with piezometers (open stand-pipe or Casagrande stand-pipe, occasionally coupled in the same borehole, for simultaneous logs of different aquifers).

SPTs, Lefranc, Lugeon and pressiometer tests were systematically performed in the boreholes, for a better definition of the geological and hydrogeological context.

5 piezocone tests (CPTUs) were carried out on the alluvial deposits.

Ultimately, for archaeological reasons, 9 additional borings were drilled around the presumed-ancient building of Casal Monastero.

6 UPDATING OF THE GEOLOGICAL-TECHNICAL MODEL OF REFERENCE

At the end of the process the preliminary geological-technical context (Fig. 9) was updated (Fig. 10).

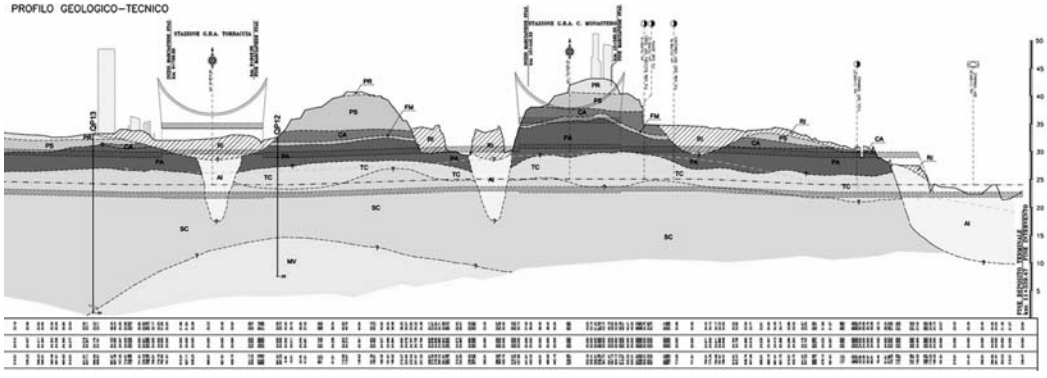

Figure 9. Profile of the preliminary geological-technical model.

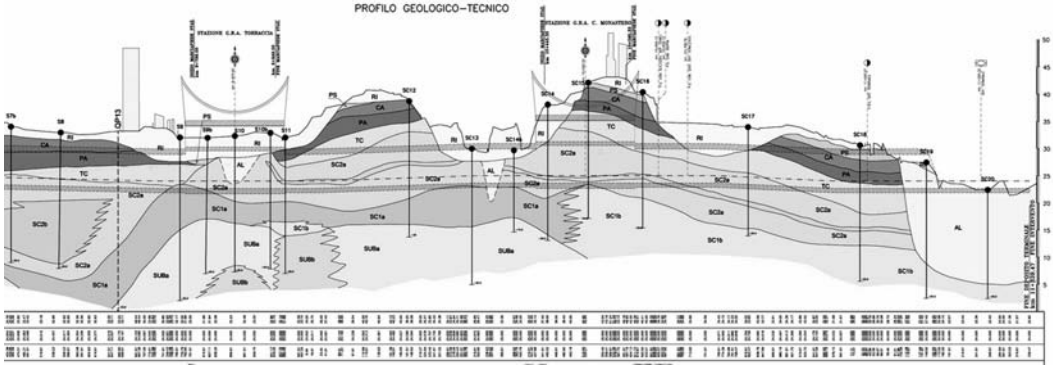

Figure 10. Profile of the updated geological-technical model.

The higher level of details permitted a considerable reduction of the uncertainty margin as well as risks associated with the construction of the subway extension.

In parallel, the GIS archive was kept up to date, with a final reconstruction of the geological-technical model, through 3D rendering.

7 CONCLUSIONS

The proposed method has shown how a rigorous protocol of study, rationally developed, could permit a timely identification of the critical aspects for the design, the further studies and management of these critical aspects in the design process, till the selection of the most appropriate typological solutions for minimizing the connected risks. This has been implemented step by step, with an easy-to-follow-again methodology, both by the Owner and by the Designer.

The whole process was followed by the continuous development of the geological-geotechnical model in GIS environment. This activity will proceed in the further design stages and will be completely accomplished in the construction phase, with the implementation of the PAT protocol that will en-sure the management of risks and any unforeseen situations through the most efficient counter-measures, predefined in the design stage.

Ontologies, thesauruses and information systems for tunnels

N. Faure
SOLEM France, Archamps, France

ABSTRACT: Usefulness of glossaries has not to be proven in the tunnel conception environment. However, glossaries are limited to simple lexical information; semantical information could be interesting to add for multiple uses.

Ontologies allow this addition, along with reuse and easy implementation in a computer system. This paper aims at showing what is an ontology and how it could be built for the tunnelling community. By the tunnelling community, too, for one of the main backdrafts of "classical" information systems ontologies are their high level of technicity. Some ways of avoiding this problem are proposed.

As an illustration, ontology-driven projects are presented with their application and first results. One of the most promising of these projects, more precisely described, combines rule-based knowledge representation and ontology to allow expert-supervised and semi-automatic compliance of a tunnel project to a set of norms or recommendations.

1 INTRODUCTION

This paper deals with some considerations about knowledge management for tunnels. It features at first some elements about terminological knowledge and existing tools, as it is true that "knowledge representation begins with words" (Sowa, 2001), then it unfolds some considerations about the adaptation to other tools (ontologies) for the tunneling community.

What is presented here is a point of view built from the early experience given by various existing or under development projects of knowledge representation and management for the tunneling community. These projects are intended to give tunneling experts and specialists assistance during the course of a tunnel-related work (types of said works varying with individual projects). They are mainly computer systems conceived to be complementary with existing computer tools (which deal mainly with graphics and mechanical calculus).

2 A VARIETY OF TOOLS

When it comes to collecting words, one think to indexes (a collection of words) or glossaries (an index, associated with definitions). But there are more tools than just indexes and glossaries. Let's have a quick look at them:

– a **taxonomy** is some kind of index, organised along some hierarchical guidelines. Taxonomies are often built along the specialisation/generalisation guideline (specialisation: from rock to metamorphic rock to granite; generalisation: the other way – from granite to rock). This induces some limited semantics, even if this can be constrained to the terminological field with the hyponymy/hyperonymy relations (narrower/broader term). Taxonomies can vary, however: they have often one type of relation only, but may also feature other relations – meronymy (part-of relations) is often chosen. In our example, Rock has a narrower term, Granite, which has some components (Quartz, Mica, Feldspar).
– taxonomy introduces some semantics, but do not take well into account the alternative uses for some words (polysemia). This is where the **thesaurus** intervenes, which features, as in a glossary, definitions, and as in a taxonomy, hierarchical relations; but also similarity relations ("see also", "related terms") – which can be used for figuring polysemia, but for other information retrieval goals as well (e.g. finding Music from Rock).
– thesaurus deal not only with terminology (defined here as the collection of terms and their meaning), but dabble also with semantics (defined here as the relationships between various meaning of one word – or group of words). The step beyond is **ontology**. Originally borrowed from philosophy (where the term stands for "the study of what is in being"), ontology has been used in the information systems field from the early nineties. To most people, ontologies are gigantic thesauruses, and indeed they are, but they are more systematic than thesauruses: they depict the knowledge domain,

while the thesaurus is limited to information retrieval.

The next part of this paper expands this last point and describes ontologies, in their diversity and in their uses.

3 ELEMENTS ABOUT ONTOLOGIES

A quick explanation of what is an ontology could be its most famous definition, given by Gruber (1993):

"An ontology is the specification of a conceptualization".

In other words, and at greater length, ontologies rise from another problematic entirely than thesauruses: the matter with ontologies is: "how to describe synthetically the knowledge about things?" The second thought behind this one being, of course: "and use this knowledge for some computer-assisted task". So, conceptualization is a set of objects and constraints between these objects which represent what is known about the field these objects belong to. But, as the whole thing is about knowledge, and knowledge does not belong to the physical world, but is rather applied to it for understanding, these objects are concepts. And as concepts are fundamentally ideas, something of the mind, they are expressed by words. (There is need here for a lot more theoretical explanation, but this should be quite off-topic).

It explains, then, why thesauruses and ontologies look strangely familiar: they are both made of words and relations; it explains also why they are essentially different.

But then, there is the specification part.

3.1 *Models and concepts*

Building a structure for concepts, terminological considerations being irrelevant, is another matter entirely than building some reference structure for general ideas (although this is a quite arduous task, either). This is where models come.

Models are, simply put, some "strategy of irrelevance", which means that it is the result of a choice of objects and relations relevant in a given context, and the deliberate exclusion of every other.

This way, models are everywhere. The "simple" glossary begins with a simple model, for it has a theme, it concentrates on a set of words relevant for a domain; and our geotechnical thesaurus can be rid of the junction between Rock and Music, and Music itself – as Music is irrelevant in a geotechnical context. This is called a "domain", a field of knowledge. The ontologies we discuss here are domain ontologies (some ontologies are deemed global, but their use and "tuning" is very uneasy).

Conceptualization, then, is also a modeling, and as such do not differ greatly from the simple models except that it is formally specified (although this is sometimes discussed). Which means that a simple, natural-language definition of a concept is not sufficient for this concept to be formal: it needs more depth, a definition relatively to other concepts, and a sign (say, a word) exclusively attached to it.

As a result, the concept appears as a category: the set of all things in being that matches its definition. This definition being itself a set of attributes, which are, in turn, concepts of their own right elsewhere in the ontology. This is an old logical approach, but it works quite well with the object-oriented languages of computer science and their logical counterparts (currently, the OWL language is becoming popular for building web-based ontologies).

What does all this imply for tunneling?

3.2 *An ontology of tunnelling*

From what have been said about ontologies, we can conclude rightly that an ontology is essentially context-dependent, or at least model-dependent.

Research has recently evolved towards a multi-modeling conception of ontologies, which means that multiple models can co-exist in an ontology. This is done, more or less, with what can be called "point of view" approaches: for example, one point of view sees the road as a surface where traffic evolves according various parameters, another sees the same road as a concrete layer upon a compacted patch of soil, in which water infiltration has to be minimal. For the same concept "road", attributes and distribution of these attributes is different – modeling is different.

This could be an interesting way of building ontologies in such a diversified field as tunnels-related activities (even considering narrower ontologies such as tunnel construction, tunnel maintenance, safety in tunnels, etc…).

However, much of these point of view approaches still depend on a broader model – extremely arduous and painstaking to obtain in the case of geotechnics, as it needs a broad consensus and a formal definition of every item (which, due to the probabilistic nature of everything soil-related, is quite impossible to obtain).

It should therefore be interesting to build a specific model for each tunnel case, from a knowledge base or another kind of existing data, but without relying on a previous, global model.

That is the point of the RAMCESH project and affiliate projects, led by the SOLEM France society.

3.3 *Induction rather than deduction*

More in line with case-based reasoning (CBR), a new approach for building ontologies is considered: a global formal model is not the starting point, but the end of ontology building, resulting from the

combination of various specific, rather incomplete, models.

These incomplete models ("pieces" of models) are fairly common in the geotechnical literature: observations of some precise material behavior, general consideration about a technical implementation, etc…

These pieces of models, represented in some proper formalism (which should be quite simple and manageable by other than computer scientists), are then combined according to some project considerations in a broader piece of model, and so on until a coherent and rather exhaustive model is attained.

Of course, this type of combinational model has the risk of being not so exhaustive, for every piece of the ideal project model does not exist in the literature, or rather in the knowledge base built from the literature.

But remember: this is a computer-assisted system that we discuss here, not a computer-based tunnel project builder. This approach needs domain specialists and experts for more than supervision, but also for exploitation of the results. And better for them to "fill the blanks" in a model than to build this model from scratch.

In the RAMCESH project, those pieces of models are named "knowledge grains" and use informal concepts; the concepts gaining increased formality by being combined with other grains.

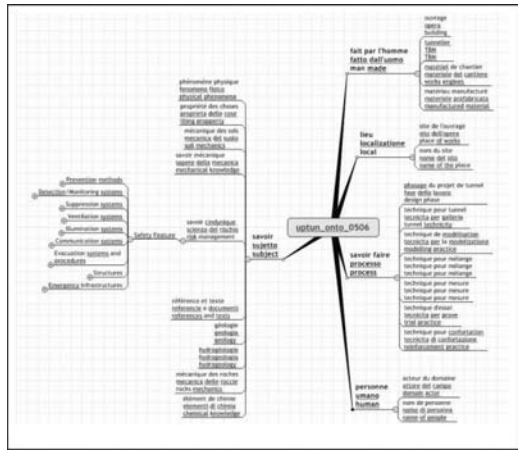

Figure 1. An overview of top-level UPTUN-Onto concetualization.

4 ONTOLOGY: TUNNEL-RELATED USES

The general use for ontologies is communication (Uschold & Gruninger, 1996): communication between people, systems and/or organizations.

For example, ontologies are at the center of what is called the Semantic Web, which aim is to allow "intelligent research" among the Internet – or more specialized networks. The ontologies used or planned in the tunneling community have this same aim.

The CONFEC7 project, for example, is aimed at building an ontology from the normative knowledge contained in the Eurocode 7 (the new European norm about geotechnical calculus); from this point on, every geotechnical project (expressed in an appropriate formalism) can be easily reviewed according to this knowledge, and estimated compliant or not to the norm.

UPTUN is an European Community project focused on the upgrading of safety in tunnels. One of its parts uses an ontology, which describes the various security systems and the way they interact. According to some user-provided data (through various forms describing intended safety modifications), it describes the way safety evolves in a tunnel.

Aforementioned RAMCESH project (from which CONFEC7 project is derived) focus is to give specialists the opportunity to develop their tunneling projects according to some literature-supported specific theories, then to automatically compare the way they have conceived the project with other projects, stored in memory or conceived by other specialists.

Other uses considered in these projects and others include tendering (roughly, estimating prices and delays from the description of a tunneling project) or day-to-day survey of field works and panel of optimized choices according to the results. More documents-oriented applications are possible, too, as the automated indexation of documents (this is a direct semantic web application), but they only indirectly imply tunnels.

One subject of difficulty when building such tunneling ontologies is that it is quite time-consuming for experts to build ontologies. And as tunnel experts are required to build tunnels and not ontologies, this is a major problem. To address it, the general choice made in the tunnels-related ontologies projects mentioned before has been to develop network solutions and sequential procedures to allow various experts to implement the system easily, and not necessarily during long working sessions.

This choice is also related with some conclusions drawn from the expert systems experience for tunneling activities of the eighties-nineties: the implication of the domain experts in the implementation of such knowledge-based systems must be maximal (Magnan, 1992). Formulation and, foremost, use of knowledge must be an expert domain prerogative: the reasoning process of such systems must be expert-driven, not computer-driven (hence, the computer-assisted bias mentioned in chapter 3.3).

This leads to such approaches as UPTUN-Onto or the RAMCESH ontology construction system,

oriented to increased user-friendliness, for the ontology user and builder is the tunnel expert.

One more important point about ontologies when oriented toward such a large and international community is that they have an edge regarding multilingual possibilities. Being conceptually modeled, ontologies are virtually language-independent, i.e. concepts and their relations are the same, only their designation change. This point is discussed in the case of cultural facts, but for the main part, tunneling ontology (featuring physical concepts) should be culturally independent.

Computer-wise, ontologies are fairly portable, as they rely on current and easily accessible technologies, mainly XML and XML-related languages and formalisms (RDF, RDFS, . . .). Therefore, it should not be a technical burden to any organization's computer division to deploy such systems.

5 CONCLUSION

The few applied experiments – that we know of – of ontology development for tunneling uses have shown some merits and drawbacks. Merits concern the very nature of ontologies: terminological and conceptual models in a same portable system, high adaptability to network and distributed contributions, modularity in modeling process. Drawbacks are often directed to the computer-system dimension of ontologies: languages and logical approaches far too uncommon for the tunneling engineer and high degree of formalism required where it is not always possible.

However, these drawbacks can be dealt with, as illustrated in this paper with some current projects and theories.

In fine, ontologies are quite adaptable to the tunneling environment and community; regarding the past trials of glossaries and indexes for the domain, it would certainly be profitable to build such reusable models, for both terminological and conceptual motives.

Building the underground infrastructure of Lausanne's new m2 metro line

F. Gaj & M. Badoux
Métro Lausanne – Ouchy SA

ABSTRACT: A new subway line is under construction in the city of Lausanne, on the shores of Lake Geneva in Western Switzerland. Called "*projet m2*", it is designed for an annual capacity of 25 millions passengers and is scheduled to open in late 2008. It will offer a new "urban elevator" to a city characterized by its steep slopes. The trains of the new fully automatic "driverless" transportation system will feature rubber tires allowing them to climb slopes averaging 6% and reaching up to 12%. It will be the first automatic metro to cope with such steep gradients. About half of the 450 mios Euro project budget will be spent on the 6 km long new infrastructure. It includes approximately 2.9 km of new tunnels, 2 km of new cut-and-cover tunnels, 0.5 km of old tunnels to be renovated and 14 stations. The construction of six separate tunnels in parallel was required to respect the very tight construction schedule and to respond to the varying geological conditions. The engineers and contractors face difficult technical and logistical challenges as these tunnels are excavated at low depth in a dense urban environment. This article will give an overview of the complexity of the project, including different excavation techniques, as well as the point of view of the Client regarding its role in the project managing process.

1 SUSTAINABLE DEVELOPMENT

A new subway line of Switzerland is being built in Lausanne, Switzerland. With a population of about 250'000, Lausanne is a relatively small city for a fully automatic subway system. The ambitious project, named *projet m2* aims at boosting public transportation in a city characterized by a difficult topography and a growing traffic problem. The project received broad public support in November 2002, when the local state population accepted the proposed project funding (overall budget of 450 mio €). Construction work started in spring 2004 and commercial service is scheduled for the second half of 2008. Key project data are presented in table 1.

Covering a distance of approx. 6 km (fig. 3), the m2 line will link the Geneva Lake shore at 373 m.a.s.l. with the suburb of Eplinges at 711 m.a.s.l. (i.e. 338 m higher, which explains the origin of the "urban elevator" expression). Fourteen stations will be distributed along the alignment.

6 km in 20 minutes
1 train every 3 minutes in the central portion
6,600 persons per hour
25 millions persons per year
37,000 jobs at less than 300 m from any metro station
6,000 cars "removed" from the city center

Figure 1. *projet m2* performances.

2 TUNNELLING CHALLENGES

From the "tunneling" point of view, the *projet m*^{2} has been characterized by some challenges requiring the engineers and contractors best performance.

Although most of the m^2 tunnels are at a "standard" low depth of 15–25 m in a relatively good rock (the swiss "molasse", composed by an alternance of sandstone and marls), some segments are very shallow and, sometimes, in weak water saturated soils (sands and gravels).

The most interesting examples are:

- Saint-Laurent tunnel: excavation beneath the traditional masonry bridge "Grand-Pont" (fig. 2).
- Langallerie tunnel: excavation through sands, gravels and silts, 3–4 m under the foundations of Rue Langallerie buildings (fig. 4).
- Viret tunnel: excavation at less than 1m beneath the foundations of the Rue Madeleine buildings (fig. 5).
- Bugnon tunnel: excavation through sands, gravels and silts, less then 1 m beneath an existing tunnel connecting two buildings of a large hospital.

Two others objects are worth mentioning.

The first one is the construction of a new bridge (Pont St-Martin) through the piles and abutments of an existing century old masonry and steel bridge (Pont Bessières, fig. 6).

Due to topography of the city, a bridge was necessary to connect two areas separated by a deep valley.

Figure 2. Saint-Laurent tunnel. Note the passage under the 19th century "Grand-Pont" masonry bridge.

Instead of creating a completely new bridge that would have difficulty to integrate in the urban environment, the designers chose boldly to place the new bridge just below an existing one (fig. 6). The technique adopted to excavate through the piles of the existing bridge (with no interruption of bridge traffic) is a mix of structural engineering and underground technology consisting in:

1. reinforcement of the piles by longitudinal and transversal pre-stressed cables and passive anchors in order to bring confinement to the remaining pile material around the void to be created;
2. umbrella forepoling to reinforce and protect the crown of the void to be created;
3. excavation of the masonry by hydraulic hammer through;
4. construction of a reinforced concrete frame.

Another interesting object is the retrofit of the existing LO tunnel. This ancient masonry tunnel was built in the 19th century for Europe's first cablecar which linked the Geneva Lake with the city center. In order to adapt this tunnel to the new metro alignment, the foundation of the tunnel needed to be lowered 5 m with respect to the original level. Obviously, this had to be done without damaging the tunnel structure and the above-standing buildings.

The solution chosen by the engineers is (fig. 7):

1. execution of a triple curtain of sub-vertical jet-grouting columns on both sides of the tunnel to provide vertical underpinning of the foundations;
2. first 2 m high excavation;
3. execution of 45° inclined jet-grouting reinforced "anchor-columns", in order to improve the adjacent ground and to provide horizontal support;
4. repetition of steps 2 and 3 down to the bottom;
5. casting of the new foundation and walls and installation of horizontal metallic props at mid-height.

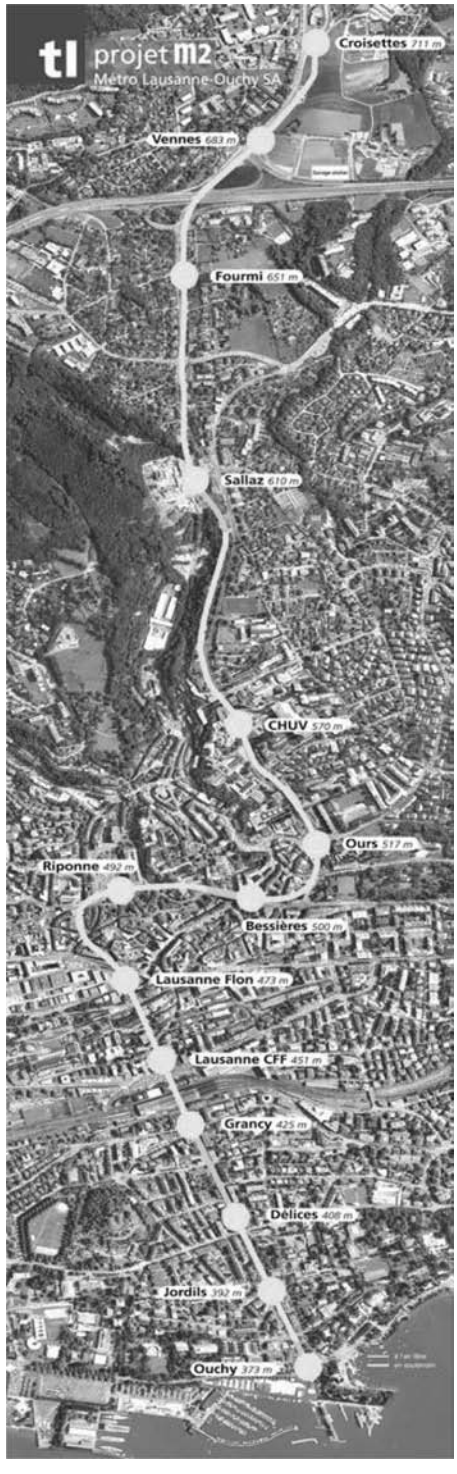

Figure 3. *projet m2*.

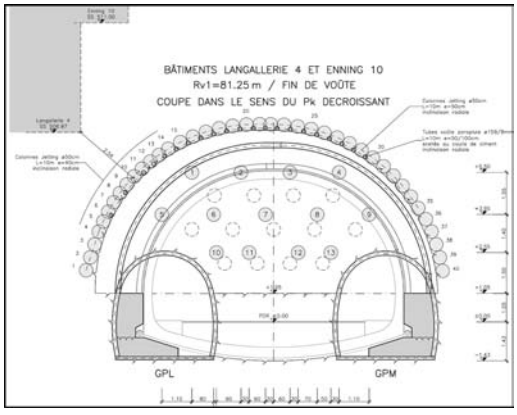

Figure 4. Transversal section of Langallerie tunnel. Note the jet-grouting columns, the side drifts and the proximity to buildings foundations.

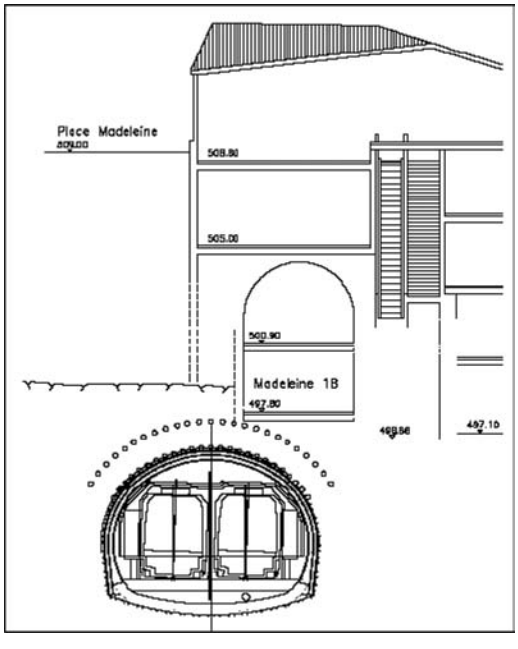

Figure 5. Transversal section of Viret tunnel. Note the umbrella forepoling and the proximity to building foundations.

Different consolidation techniques were used in order to ensure structural safety and settlement control during the construction of tunnels. They include:

– Umbrella forepoling for tunnel crown pre-reinforcement;
– Fiberglass nailing of the tunnel front;
– Jet-grouting, both subvertical and subhorizontal;

Figure 6. Construction of the Pont St-Martin below the Pont Bessières.

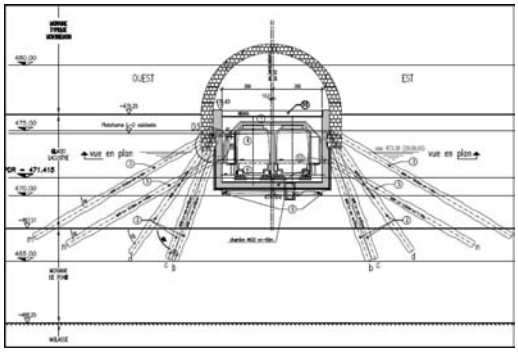

Figure 7. Transversal section of the LO tunnel. Note the existing masonry structure and the jet-grouting columns for underpinning and consolidation.

– Cement grout injections by means of "tubes a manchettes" (non-return valves fitted tubes) for ground improvement.

2.1 *The Saint-Laurent tunnel accident*

The project was unfortunately marred by a serious construction accident.

Late afternoon on February 22, 2005, the front of the Saint-Laurent tunnel collapsed. A large volume (approx. 1500 m^3) of mud flowed into the tunnel, when an unexpected pocket of water saturated sands and gravels was encountered, thus creating a sinkhole that reached the surface 15 m above.

The sinkhole formed under a main square of Lausanne's downtown historic shopping district (Place St-Laurent) and partially under the foundations of a multi-story building (fig. 8). Thanks to Santa Barbara nobody was hurt and the accident only caused material damage.

Figure 8. View of Place Saint-Laurent after the Saint-Laurent tunnel accident. Note the large sinkhole, which extends partially under the building.

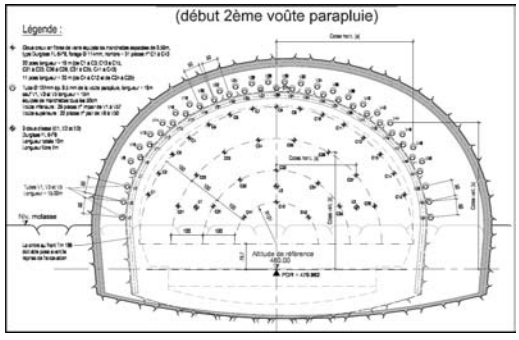

Figure 9. Consolidation measures throughout the critical zone of the St-Laurent tunnel. Note the large number of boreholes for umbrella and injections.

At the moment of writing this article, two inquiries are on-going to determine the causes and responsibilities of the accident, thus no comments on this subject can be made.

The response to the accident required prompt and decisive action by all the parties involved (Besides the engineer and contractor, this includes the Owner and the local political authorities and administrations).

Within two days, countermeasures were taken to stabilize the situation and avoid the progression of the sinkhole which threatened to cause the collapse of adjacent buildings. These measures include:

- Stabilization of the sinkhole walls with shotcrete.
- Further stabilization of the sinkhole with sprayed liquid nitrogen applied in order to freeze the soil at the bottom of the sinkhole and reduce the erosion induced by water circulation.
- Creation of a wall of piles bored from the surface into the tunnel. This wall acted as a "plug" by blocking the flow of material from the sinkhole into the tunnel.
- Filling of the sinkhole with porous material.

Ten days after the accident, the sinkhole was completely filled and the crisis was over. Further measures were taken in the following weeks and months in order to finish the tunnel on time in spite of the accident. Despite its strong emotional impact, the accident did not stop or delay the construction project.

(In retrospect, it is noteworthy for the profession to note that the successful management of the crisis contributed very significantly to reduce the damage to the credibility and image of the *projet m2* resulting from the accident).

After the accident, it was determined that a 35 m long zone of soft and partially disturbed soil between the collapsed tunnel front and a molasse rock formation required special excavation techniques. It was decided to open a new excavation front from the northern adit in order to excavate this critical zone "from the rear".

The following measures were implemented for the excavation of this critical passage (fig. 9):

- Crown pre-reinforcement by means of a double umbrella heavy forepoling, made by metallic tubes and grout injections through singles "manchettes"
- Front pre-reinforcement by means of fiberglass nails coupled with grout injections through singles "manchettes".

The consolidation works and the excavation of the critical zone lasted 7 months. More than 500 m^3 of cement grout were injected (pressure between 3 and 5 bars) into the soil to improve its geotechnical characteristics.

3 PROJECT CHALLENGES

From the Owner's point of view, the challenges of the project include technical and non-technical issues, such as:

- Being a subway project, *projet m2* is mostly built underground. Project optimization measures brought the portion of the new line which is underground to 90%. This implies much construction work at low depth in an urban environment and the associated level of uncertainty and potential for "bad surprises". Planning and managing underground excavation and civil works always entails a certain level of risks. (The *projet m2* is no exception, as it suffered by the serious tunnel accident described above).

  Managing this "underground risk" is a classic application of modern risk management thinking. Since "risk zero" is – unfortunately – an unreasonable objective, the stakeholders of underground construction project must be ready to work on measures to limit the probability of negative events and

on measures to reduce their consequences if they occur.

– The civil engineering infrastructure of the project is built by 8 consortia of construction companies working simultaneously on 10 to 12 worksites with 4 sets of engineering firms (fig. 11). The Owner must be in position to manage and coordinate different companies and contracts. Strong presence is required to counter the natural tendency of each individual structure project to "take its own" technical or planning course.
– Because the worksites are located in the urban environment of the city center, special care and emphasis are required on the relationship with the neighbors, public and city services. More than 200 mios € shall be spent in 3 years and a half on the construction side of the project. With such a high rate of worksite production in a relatively small city, it is crucial to control the project impact on the surroundings and the city.

4 THE CLIENT'S TEAM ROLE

The overall project management is provided by the Métro Lausanne–Ouchy SA, a company managed by the public transport authority of Lausanne. Although the engineering services are delegated, as usual, to different consultant companies, the Client has put in place a team specifically assembled to manage the project.

(This section presents "lessons learned" of Owner's representatives on the role of the Owner's team. The authors are fully aware that these comments are nothing new and/or that their relevance to projects conducted in different conditions and context is uncertain).

The client's team is not there to substitute the resident engineers, but to aid and support them in dealing with the strategic issues and specific problems. The tasks of the Client representatives include:

– to support, back up and control the resident engineer in his design and management tasks;
– to coordinate the different lots in order to have consistent application of the generic performance requirements across the project;
– to keep a constant pressure on the resident engineers and contractors, in order to reduce the risk of cost overrun and delays;
– to support the resident engineers for contractors' claims management;
– to centralize information and defend/promote the project toward the public and authorities.

In the end, the primary role of the Client's team is to ensure that the planning and the budget are respected and without compromising on the safety and quality requirements.

Figure 11. Overview of *projet m2* engineers and contractors JV.

Since the beginning of construction, the Owner's team has tried to pursue with the Engineers and Contractors a sustained search for solutions in terms of technique, planning and budget. It is clear to all that on a large public construction project, the Owner has to do more then record decisions and events and process payments. He has a central role to play in assisting and guiding the project partners in this optimization effort. He is best positioned to arbitrate between conflicting demands.

Without interfering with safety aspects of the projects for which the specialist engineers and contractors are responsible, he can foster a project culture in which design, problem-solving and decision making explicitly happen in the quality-planning-costs triangle (fig. 10).

One-dimensional problems are the exception; it is usually beneficial to try to explicitly address problems in the three-dimensional. Optimization is about having the best combination of all three. Identifying and evaluating possible trade-offs is difficult, but it is often the key to finding the "best" solution, i.e. to optimization.

Owners' representatives have to be pragmatic and remind themselves and their partners the simple message that: "*The people who finance the whole project does not want the best technical solution at an unreasonable price and unacceptable delay. The people want a reasonable solution at the lowest possible price and in the shortest possible time*".

This is illustrated in fig. 10 with a triangle bringing together the three key elements of project management. Meeting technical requirements (in terms of quality, performance et durability), controlling costs and respecting schedules cannot be dissociated. It is not enough to "have one or the other". Of course, safety considerations must be treated differently because they include non-negotiable elements. But if safety requirements are clearly identified, there is usually a range of solutions to a given problem which respect them and optimization in the quality-planning-costs triangle still applies.

5 SUMMARY AND CONCLUDING REMARKS

Two and half years after beginning of civil works, the construction of the *projet m2* new infrastructure generally progresses according to plan. In spite of a serious tunneling accident described above, the construction project is on time. At this point:

- eight new tunnels have been broken through;
- two 19th century tunnels have been retrofitted;
- more than 1 km of new cut-and-cover trenches have been built;
- two new bridges have been completed.

As any large infrastructure project in an urban environment, especially when underground work is required, the *projet m2* presented interesting and unique technical challenges. Two examples involving the retrofitting of traditional existing structures of traditional masonry construction are described above:

- the construction of a new reinforced concrete bridge through the masonry piles of an existing bridge;
- The underpinning of the lining foundations of a 19th century old tunnel in order to lower its ground slab.

But technical successes are not enough. Unlike scientists who can often focus on technical aspects of their work, our task as engineers has to integrate a broad, and sometimes contradictory, set of requirements and considerations. In particular, the successful completion of large projects – such as *projet m2* – requires the project partners to constantly think and optimize in the quality-planning-costs triangle. In the eyes of an Owner's representative, this approach is as important as meeting the technical challenges. The Owner must therefore foster a project culture and environment where this optimization can happen. Most engineers know that this is part of their responsibility toward the entities they serve and respond well to this challenge.

Metro Santiago – Building an urban tunneling industry from the ground up

Alexandre R.A. Gomes & Martin Böfer
Geoconsult Latinoamerica Ltda., Santiago, Chile

Pablo Muñoz
Metro de Santiago, Santiago, Chile

ABSTRACT: Santiago's Metro construction started in the early 70s with the use of extensive cut-&-cover tunnel methods. This type of construction was further used in the 80s, causing major disruptions in the urban surface and strong public opposition. This situation and Metro S.A. key decision to seek for fastest, more efficient and less disruptive construction alternatives, lead to the first mined tunnel experiment under a public Park in 1994. That successful trial tunnel demonstrated the feasibility and benefits of mined tunneling and bestowed Metro S.A. the required confidence to give priority to mined construction in its future projects. Following this decision, and boosted by the continuous and massive array of new subway projects developed in the following decade, a brand-new urban tunneling culture and industry surged in Santiago de Chile. This paper presents this historical evolution, addressing the most relevant landmarks along this way so far.

1 INTRODUCTION

In the early year 2000, the Santiago's subway network was comprised of not more than 40 km and 46 stations with only about half percent of its network being of underground construction, mainly with cut & cover boxes. Nowadays, with the additional 17.5 km of new line extensions planned to be completed in 2009, the subway network will have shown a considerable expansion reaching a total length of 104.5 km and 108 stations, with over 60 km of mined tunnels and more than 70 underground stations.

This lapse of time has seen not only the subway network increase more than twofold but also the establishment, from the ground up, of a whole new urban tunneling industry in Chile. Matter of fact, previously to this period, mined tunneling proficiency in Chile was mainly coming from the construction of rock tunnels for the energy and mining sectors and there was no expertise at all in urban tunneling and soft ground.

Relying mainly on local contractors and designers, fed by a continuous know-how transfer from international tunneling consultants, a remarkably rapid evolution occurred in various aspects of tunnel design and construction, enabling in a short period the development of technical- and very cost-effective solutions for urban mined tunneling in the mostly favorable ground conditions of Santiago de Chile.

Figure 1. Metro system map.

2 SANTIAGO'S SUBWAY HISTORICAL EVOLUTION

2.1 *The early years – 70s and 80s*

Santiago's subway construction began in the early 70s with Lines 1 and 2. Construction was mainly of

Figure 2. Metro construction in the 70–80s – C&C method.

cut- & -cover type with some sections at grade. Cut & cover boxes were built either within sloped or braced excavations. Braced diaphragm walls were also applied at some sections.

This method was further used in the 80s. However, aside from the massive utilities relocation work required, the large construction periods and traffic and surface disruptions, these methods became slowly unacceptable to the community expectations, requiring Metro S.A. to search for less disruptive construction methods (Mercado, C. et al, 2004).

2.2 *The first mined tunnel trial*

In 1994, Metro S.A. ventured to carry out the first mined tunnel experiment, under the public Baquedano Park, during the construction of the first L5 extension. Excavation of the single-tube, double track running tunnel was carried out with full face and the provision of a large central supporting core. Equipment were standard back-hoe excavators.

Design was carried out by local consultant joint venture Ingendesa/ARA. The tunnel presented a horseshoe shape without invert and was excavated in sequential rounds of 0.8 m–1.0 m with a timely differed installation of a double shotcrete lining, 55 cm thick, reinforced with wire-mesh and lattice girders. It is relevant to mention that, at this time, shotcrete technology was poorly known in Chile and only the dry method basics were know from the mining sector experience.

During the construction of this tunnel, monitoring of deformations was carried out only in specific locations and the guarantee of tunnel stability was provided only by the thick shotcrete lining. Ground conditions were favorable, with the typical Santiago's subsoil consisting in quaternary sediments of gravel from the Mapocho and Maipo river basins, the so called "Ripio de Santiago", which presents excellent geomechanical characteristics and are very suitable for tunneling

Figure 3. View excavation and support – First mined tunnel.

(average values at tunnel springline: $\gamma = 22\,\mathrm{kN/m^3}$; $c' = 40$ Kpa; $\phi' = 45°$; $E' = 300$ Mpa; $ko' = 0.3$). The ground water table is variable, but in general is located well below the tunnels at a depth of 70–80 m.

2.3 *Mined tunnels go downtown*

The 2.8 km second line 5 extension to the west was planned to run through a densely built up area in the city center, passing below busy avenues and adjacent to Santiago's old Cathedral and other important historic building. For this endeavor, which would be decisive for the future of mined construction in Santiago, Metro S.A. requested local assigned consultant Cade-Idepe to get support from foreign tunneling experts. For this, Geoconsult of Austria was called in to help with the design of running mined tunnels.

A comprehensive and robust tunnel design was developed by Geoconsult/Cade Idepe with basis on the principles of the NATM (New Austrian Tunneling Method). Soil conditions were the typical Ripio de Santiago, with presence of local ground water infiltration. Tunnel cover was typical with round surface about 10–11 m above the crown. In view of the lack of previous relevant experience, the noviceship of contractors and the sensitivity of the surrounding buildings and structures, running tunnels were intentionally designed as conventional NATM for soft ground conditions.

The tunnel transversal section was ovoidal with an area of about 65 $\mathrm{m^2}$. Tunnel support comprised of a primary shotcrete lining of 200–250 mm, installed immediately after each round, followed by a secondary in situ reinforced watertight concrete lining, with a thickness of 40–45 cm, cast to the invert and arches in a later stage. Excavation was carried out in 0.8–1.4 m rounds with the closed invert no more than 7 rounds behind the top heading. In some sections, micro-piles curtains were installed next to relevant buildings to control deformations.

Stations were constructed as open cuts, but incorporated for the first time the use of ground anchors to

support the piles and soil nailing, avoiding the need for the disturbing internal bracing. Even so, very large ground settlements and adjacent building damage was registered within the area of influence of these excavations.

Tunnel construction was carried out from 1997 to 2000 with the incorporation of systematic monitoring of deformations and stresses in tunnel and surrounding ground. Results from this monitoring program showed that ground behavior was very favorable with low convergences and ground surface deformations, mostly in the range of 4–8 mm.

2.4 *Mined tunnels get established – The first mined stations*

In view of the favorable results obtained in the line 5 and the practically inexistent impact on the urban surface and structures, Metro S.A. decided to apply extensive mined tunneling methods on the following subways expansions.

Therefore, for the new Line 2 and 5 extensions, with a total length of more than 6 km, mined methods were applied not only for the running tunnels but also for station tunnels. Construction was carried out from 2001 to 2003. Design and site supervision work was carried out by 3 different JVs of local with international consultants, namely Cade-Idepe with Geoconsult Austria, Ingendesa-ARA with Dr Sauer Co. from USA and Arcadis-Geotecnica with Bureau de projetos from Brazil.

These new extensions marked the return of the use of shotcrete for both primary and secondary tunnel linings. The tunnel lining concept was based on the consideration of a double and monolithic tunnel lining, where both linings would work together to provide the long term tunnel support and service conditions. This was possible basically due to the favorable ground conditions of the Ripio de Santiago, the inexistence of significant ground water and application of state-of-the-art shotcrete technology, including low dosages of alkali-free accelerators, additives, meticulous shotcrete installation, curing and use of steel fibers to increase quality of the secondary lining.

For the running tunnel sections, horse-shoe tunnels (without invert) were extensively applied and the thickness of the primary lining was reduced to only 15 cm. Tunnels with structural ring closure were applied only at singular sections, such as intersections or heavily loaded sectors.

Stations were typically constituted by one or two lateral shafts, located in a place as to not interfere in public roadways and require extensive utilities relocation, and associated access tunnels, placed mainly in a direction transversal to the main line alignment so that it crosses in a perpendicular way with the main station tunnel.

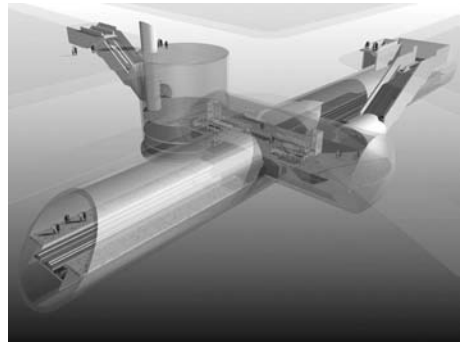

Figure 4. View of a mined station tunnels.

Figure 5. Excavation of access tunnel under pipe roof.

Station tunnel cross sections varied from 100 m^2 at intermediate stations to up to 180 m^2 at terminal or multi-modal stations. With rail levels at a depth of 17–18 m, the crown of cross sections up to 17 m wide were only 6–7 m below the ground surface.

Access tunnels were constructed under the protection of a pipe roof umbrella, as to control ground deformations and allow full-face exaction of the top heading section, which was completely excavated and supported, including a temporary invert, before carrying out the excavation of the bench and invert headings.

After the access tunnel excavation was finished, the break-out for the excavation of the main station tunnel was done. The station tunnel was constructed subdividing the section in 3 or 2 separated headings with the provision of temporary lateral walls, demolished as the excavation stages advanced. No pipe roof or forepoling was installed for these sections. Significant lessons regarding design and construction aspects were drawn from the construction of these two extensions. The most relevant are listed below:

– ground conditions response to the excavation of large dimension tunnels were favorable and safe (max. settlements were in the order of 2 cm);

Figure 6. View of access station tunnel end wall.

Figure 7. View of a mined station tunnel excavation.

- stresses on the linings were below those foreseen in the design, allowing the further optimization of tunnel support;
- The control of shotcrete technology and installation was proven critic to ensure the required lining quality;
- Efforts should be made to reduce the amount of reinforcement in shotcrete linings, as there was a clear limit to get rebars fully embedded and obtain good quality linings, avoiding the need to carry out extensive repair works by post-injection;
- It was not possible to obtain watertight linings with the use of shotcrete (the installation of a sprayable waterproofing membrane between the two linings was proposed in the design but not applied during construction);
- The provision of a qualified and expert engineering team (Site Supervision) on site is of most relevance for tunneling works, providing vital control and solutions to guarantee safety, construction schedule and the specified quality.

2.5 *Tunneling under tunnels and old bridges*

Another line 2 extension's landmark was the construction of a tunnel section below the bottom slab of the six-lane cut & cover highway tunnel "Costanera Norte" and of a large subway mined tunnel section directly under the abutment foundation of an old bridge for vehicular traffic across the Mapocho River, in the centre of the city (Gomes, A., Boefer, M. & Cruz, J.H. 2004).

Figure 8. Interior view of a finished mined station in shotcrete.

Whereas the passage below the cut & cover tunnel constituted no major challenge, the crossing below the bridge abutment required special construction methods and additional auxiliary measures to allow tunnel construction and prevent damages to the bridge. These included the underpinning of the bridge abutment, the installation of an active jacking system, the use of a subdivided excavation face and the implementation of a comprehensive and continuous monitoring system of loads and deformations, designed specifically for this project.

2.6 *New grounds and wet shotcrete*

With the new line 4, constructed from 2003 to 2005, Metro S.A, started one of its more impressive investments in the subway network. The new line encompassed app. 32–33 km, with 12 km of mined tunnels, 14 km at grade and 7 km of elevated rail.

Since its construction overlapped with the construction of the Line 2 and 5 extensions, there was a market peak, which generated a certain overstrain in the local construction industry. Nevertheless, this also helped to create the right scenario for major improvements in technology and a doorway for new local and foreign contractors and companies.

Metro S.A. used the line 4 to foster the use of more advanced techniques for tunnel construction. Therefore, the JV Geoconsult-Cade Idepe was hired to carry out a comprehensive feasibility study on the use of mechanized tunneling (TBM). By using the typical NATM design as a baseline, a comparative study was carried out for different TBM alternatives. This study

Figure 9. Tunneling below the Fray Andresito bridge.

concluded that the NATM approach was the most appropriated approach for the line 4 underground works, as it was less expensive, generated more benefits to the local industry and posed fewer risks for the project schedule.

Another important decision taken by Metro S.A. at the new line 4 was the specification of state-of-the art wet shotcrete for tunnel support, allowing the further development of this technology in Santiago.

The construction of the line 4 also marked the first tunnel excavation in soft ground and the harshest handling of ground water at the Station Puente Alto (Gomes, A. & Boefer, M. 2005). Actually, a large part of the alignment crossed sediments deposited by erosive streams from the Andean Cordillera, consisting mainly of clay and silt with low to moderate plasticity and sand lenses with different thickness. In Puente Alto, even tough the ground was the typical and favorable Ripio de Santiago, the presence of water inflow (up to 15 l/s) from water bearing layers, associated with the contractor inexperience caused important construction problems and program delay. Problems of ground water were also found in other sections of the line 4, without causing many difficulties.

Design concepts were kept basically similar to those used for previous lines. However, some new construction methods were applied, such as the design of the Plaza Egaña station with the use of a composite geometry with double cell and a central pillar, as to reduce excavation area, avoid sinking of rail level and limit deformations to acceptable values. Besides, some sectors presented local instability problems required the establishment of a comprehensive and monitored excavation procedure to control local ground collapse and reduce the risk of global cave-ins. This was managed by the provision of geologists at the face, under the supervision of the site Engineer and in close work with the contractor. Another change was the consideration of an in situ inner concrete lining for the Station Puente Alto due to the presence of ground water.

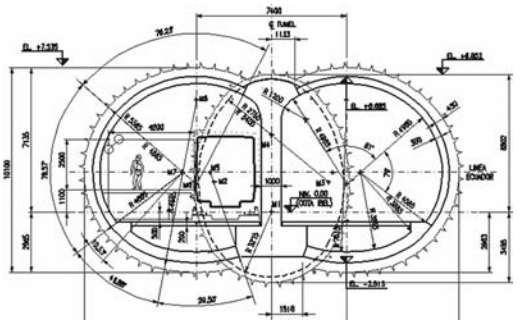

Figure 10. View of station tunnel with central pillar solution.

2.7 *More soft grounds and further expansion*

In the 13 km new line 2 extension to the North, constructed in 2004–2005, aside from typical Ripio de Santiago conditions, tunnels were also excavated in soft alluvial ground (clay, silt and sand layers, intercalated with sand lenses and gravels). Similarly to the experienced in the line 4, local instability problems required the establishment of a comprehensive and monitored excavation procedure.

For this extension, a significant optimization of the lining design was achieved, reducing both thickness and amount of reinforcement in station tunnel crossings.

2.8 *The latest expansions*

With construction start planned for the beginning of 2007, the new extensions of Line 1 to the East and Line 5 to Maipu (West): 17.5 km, will also shown some novelties and new challenges to designers and contractors. At the line 1, ground conditions are the typical Ripio de Santiago. Aside for some tunnel crossing and other singular situations, no significant novelty is expected. However, at the Line 5 to Maipu, tunnels will cross not only the typical fluvial deposits of gravel but also other ground conditions where there is no previous tunneling experience.

The most challenging will be the sectors with raveling gravel, which may require special pretreatment of the excavated surfaces, prior to installation of the shotcrete lining. There will also be sectors running through fine silt-sands deposits of volcanic origin with low cementation, the sol-called "Pumicita", and mixed soft ground conditions with the presence of clay, silt, sand and gravel layers. Additionally, a tunnel sector may experience relevant ground water inflow, requiring proper water control. At the time of preparing this paper, the design was still being carried out. However, even tough not all particularities are defined yet, it can be anticipated that the design of these new structures will incorporate many lessons learned in the past, providing even more optimized solutions, such as the flexibilization of invert installation to account for the different ground conditions.

3 PROCUREMENT AND FINANCING

3.1 *Procurement*

The typical approach to design and construction is based on the development of basic and detail designs by consultants hired by Metro S.A. and bid and build contracts. Bidders are pre-qualified contractors and contracts are awarded to the lowest technically complying bid. Contracts are administrated by Metro S.A. managers, together with a dedicated site Inspection, also provided by local consultants. Additionally, the site engineering supervision, which oversees the overall tunnel construction, is granted to consultants together and as an extension of the detail design works carry out for each contract.

3.2 *Financing*

Since 1990 Metro S.A. is an independent government-owned institutions that own, operate and maintain the subway system. In general, costs of civil works are borne by the National budget through funds granted by the Ministry of Finance. M&E and rolling stock costs are generally financed directly by Metro S.A. itself by means of loans lent by the international banking system. Regarding operation costs, those are totally covered by Metro S.A. own revenues.

4 COSTRUCTION COSTS, PRODUCTIVITY

During this decade of development, construction costs have decrease and productivity increased significantly for the Metro de Santiago underground works. During the first years of tunneling, average advance rate of running tunnel excavation was inferior to or maximum 1.0 m daily. Nowadays, average advance rate reaches up to 2.5 m daily.

Costs have also decreased substantially. Initial ruining tunnel costs per lineal meter were in the range of U$15.000–20.000. Currently, these costs lay typically in the range of U$7.000–8.000. Another important cost reduction aspect was the continuous optimization of the monitoring program, as more knowledge of the ground behavior became available. This effort allowed a reduction from the initial cost of U$1million/km to the current figures, which are lower than U$250.000/km.

5 CONCLUSIONS

On the basis of a successive array of investments in new subway projects and a strong compromise to pursue low disturbance, cost-effective and pragmatic technical solutions, Metro S.A. has managed to develop in a short period of time a remarkable, safe and efficient subway network, which shall still continue to expand in the future.

In this quest, Metro S.A. has also helped to forge a new tunneling industry with qualified and competent tunneling contractors, consultants, suppliers and workers, able to respond to Metro S.A. needs to further develop its subway network, which constitutes the backbone of the integrated Urban Transportation Plan of Santiago (UTPS).

The Slivenec Tunnel on the Prague City Ring Road

O. Hasik & K. Závora
METROPROJEKT Praha, Prague, The Czech Republic

ABSTRACT: A motorway-type ring road is being developed to reduce traffic in Prague. The southern section is currently under construction. The route in this section traverses the Vltava and Berounka valley, to which it descends from a quite steeply rising hilly country along both river banks. In addition, there is a protected landscape area there. For this reason, the authors of the design have proposed underground sections for this locality (construction lots no. 513 Lahovice-Vestec and no. 514 Lahovice-Slivenec). These sections consist of uni-directional tunnels, with two lanes in descending sections and three lanes in ascending ones. In addition, given the steep 4% gradient, the ascending sections are provided with a slow lane for trucks. The tunnel safety equipment is on the top worldwide level. In order to verify the geological conditions thoroughly, an exploration gallery has been designed to pass through the entire three-lane tunnel section. The position and shape of this gallery have been selected in such a way that the gallery will substitute the initial tunnel excavation sequence, the top heading. The gallery bottom will be identical with the floor of the tunnel top heading. The exploration gallery situated in this way will not only serve its primary exploration purpose. The site facility built for the works will even be utilised for the future tunnel excavation. The concept and the technical design of the tunnel sections meet the latest EU safety regulations. The Slivenec tunnel is 1,610 m long in total.

1 THE ABSENCE OF A RING ROAD AROUND PRAGUE AND ITS CONSEQUENCES

The number of vehicles significantly grew in recent years in the Czech Republic. The high traffic volume, unusual in the past, is obvious everywhere. If you look at a road map of the Czech Republic, you will see the apparent centralism in the layout of main roads and motorways; the majority is heading to Prague.

Today's Prague, however, has changed for many drivers from a target city to a transit city. This fact can be related to the political change of the formerly closed socialist state to a state with a democratic system, which is open for the whole Europe. The current large proportion of international transit is one of the effects. International transit routes cross the Czech Republic from Germany in the southwest or northwest to Poland and Slovakia in the east, from Austria in the southeast to Germany in the northwest, etc. The vehicles only passing through Prague put an unnecessary burden on Prague streets and municipal roads. In rush hours, this situation is often unbearable. A ring road around Prague is being badly missed.

The main task of the ring road will be to reduce the traffic volume within the network of Prague streets and local roads, and interconnect all motorways and fast highways before entering Prague, thus to allow the transit transportation to switch fluently between all long-distance radial routes leading from Prague. Considering the location of our republic in the centre of Europe and with respect to the planned cancellation of borders (incorporation of the Czech Republic into the union of Schengen countries), and owing to the actual process of completing the basic network of our motorways, a considerable volume of transit through our territory can be expected in the years to come. The increase in the proportion of truck transit which was recorded after the accession of the Czech Republic to the EU in May 2004 has confirmed the anticipation that all of this traffic will prefer the PRAGUE CITY RING ROAD to the problematic and slow passage through the centre of Prague.

This fact has become clear to members of parliament, mayors, directors of big companies, investors, designers, contractors and all other people who would like to promote the development of the ring road. They have founded the Prague City Ring Road Development Association, which has been creating space for dialogue and, lately, has been helping to accelerate the work on the design and construction of the ring road.

2 THE PRAGUE CITY RING ROAD HISTORY

The first ideas of the Prague ring road project are dated the 1920s. This period even saw first efforts for development of a general plan of the traffic solution for Prague.

Other proposals for the development of a ring road around Prague emerged before World War II. They were based on a contention that "the city of this magnitude cannot cope without a project like this". The ring road, as a basic principle of diverting transit transportation to bypass the centre of the city and to interconnect city centres found in the outskirts was the subject of numerous studies carried out in Prague.

However, the construction of the ring road was approved as late as 1963, and the implementation of the PRAGUE CITY RING ROAD started in the 1980s. The decision that the ring road will be only of the fast highway type instead of the motorway type was made in 1987. This decision also meant the end of discussions about the number this motorway was to be assigned (the D1 motorway had already existed then).

3 THE DESIGN OF THE HORIZONTAL ALIGNMENT AND CONSTRUCTION OF THE SOUTHWESTERN PART OF THE PRAGUE CITY RING ROAD

The process of designing the alignment of each of the segments of the Prague ring road has always risen lots of questions and problems, which were solved and analysed in studies and designs carried out in the particular period. The pressing character of the task to solve the problem became fully obvious only in the 1990s, in the context of the social changes after 1989 and the enormous increase in the vehicular traffic volume associated with this process. Today, there are two parts of the PRAGUE CITY RING ROAD in operation, namely the Slivenec – Ruzyně section (construction lots No. 515, 516 and 517) on the west edge of the capital, and the Satalice – Běchovice section (construction lot No. 510) on the eastern edge.

The most pressing traffic situation is currently on the Barrandov Bridge, where traffic jams even last over 12 hours in a day. The entire length of the Southern Connection Road, which is part of the inner City Circle Road, is filled with standing vehicles. Each driver can experience there the passage through a big city lacking a road loop. The traffic volume on this road, which is today one of the roads most loaded by traffic, should be reduced by the south-western part of the ring road consisting of the construction lots No. 513, 514 and 516, which together form a road link between the D1 motorway for Brno and the D5 motorway for Plzeň. The alignment of the southern part of the Prague City Ring Road crosses the valley formed jointly by the Vltava and Berounka Rivers. It falls to the valley from a relatively steeply rising hilly area lining the river banks. For this reason, and also because of the fact that it passes through protected areas, the alignment of the sections of the construction lot No. 513, Lahovice – Vestec, and construction lot No. 514, Lahovice – Slivenec, is designed to pass through tunnels. The right-hand tunnel tubes are offset from the centre line of the route by means of radii slightly differing from the radii of the route so that an optimum distance between the tubes is achieved.

4 VERTICAL ALIGNMENT AND DIFFERENCES IN THE CONFIGURATION OF TRAFFIC LANES

The revised norm currently valid for road tunnels recommends gradients up to 3.0%; tunnels with steeper gradients need an assessment to be performed whether additional safety measures are necessary. The 4% gradient at the lengths over 1.5 km means, in our specific case, that an additional a traffic lane for slow moving vehicles and trucks is necessary.

Traffic engineering measurements showed that freight traffic makes up a 40% proportion of the total traffic volume, while a 15% proportion had been assumed before the measurements. From this viewpoint, the addition of one traffic lane at an uphill section is obviously necessary even for a smaller gradient. For this reason, three-lane tunnels are designed for the tubes carrying the traffic ascending from the confluence of the rivers up the plateaus. The solution of the question whether the capacity of the 4% uphill gradient three-lane roads is sufficient will remain to be answered in the future. The descending tunnel tubes have two traffic lanes.

The width of the right traffic lanes of 3.75 m, which is increased compared with the standard width of 3.50 m, was designed with respect to the significant proportion of truck traffic. The widths of the roadway were binding for the designer.

5 ARCHITECTURAL DESIGN OF THE PORTALS

Tunnel portals are nearly always difficult items of any tunnel construction. Even the choice of their location depends on many factors, mainly on the terrain configuration, the horizontal and vertical alignment of the route, geological conditions in the particular location, proper incorporation of the structure into the landscape and other factors. All of the above circumstances also apply to the portals of the tunnels built on the Prague ring road. The Lochkov portal of the construction lot No. 514 belongs among the most difficult. It is located on a steep slope above Radotín, where the nappe (gravelly soils) is over 10 m thick. In this case, the portal of the mined tunnel is properly shifted as deep to the rock massif as possible, to a point where at least the bottom part of the tunnel will be excavated in rock conditions. When you walk in this area you can see nothing exceptional. The terrain above the future tunnel, a meadow with naturally seeded trees and brushes, looks

subdued. Unfortunately, there is a biological protected zone located just in the place most suitable for the portal. It means that the initial section of the tunnel must be shifted to a place where, simply put, the conditions for tunnelling are the most difficult. The design of the construction trenches for the portals of the mined tunnels comprises mighty vertical piles keyed in the bedrock, with the steep slopes stabilized by shotcrete, anchors and needles. The trenches will be used for the construction of both the cut-and-cover tunnel sections and the architectural concrete portals. The C25/30 reinforced concrete lining of the cut-and-cover tunnels is 600 mm thick at the vault. The waterproofing system applied to the cut-and-cover tunnels consists of a membrane installed on the outer surface, which is protected on both sides by non-woven geotextile. The cut-and-cover tunnels are founded on strip footings; the invert will be built at the portal.

All portals are designed as cast-in-situ reinforced concrete structures. The elliptic front ends of the portals of the construction lot No. 514 are provided with "ribbed canopies", which improve the architectural impression of the portals and help to incorporate them into the landscape.

This architectural design is used for tunnels designed in our country for the first time and, as you can judge by yourselves, it certainly will make the passage along this section of the route brighter. The finish of the terrain around the portals will be created by the backfill of the adjacent cut-and-cover tunnels, and by a part of portals inclined approximately at 1:1.75. The side slopes of the portals are terminated by retaining walls and service buildings, which are incorporated into the walls.

The chimney of the ventilation structure is also designed as an architectural feature.

6 MINED TUNNELS, CROSS SECTIONS THROUGH TUNNEL TUBES AND CROSS PASSAGES

Mined structures (tunnels, cross passages etc.) form a substantial proportion of the construction lots No. 513 and 514 of the road ring. In terms of the structure, all of the tunnel structures are similar, consisting of reinforced C 20/25 sprayed concrete primary lining, cast-in-situ C 25/30 concrete final lining and intermediate waterproofing layer. The vaults of both liners are circular. All of the tunnels will be driven using the New Austrian Tunnelling Method with a horizontal excavation sequence. The excavated cross-section areas of the double-lane tunnel and three-lane tunnel will be 95 m^2 and 130 m^2 respectively. The internal profiles of the tunnel tubes are vaulted, uniform along the entire lengths, irrespective of the construction technique.

Walkways 1.0 m wide are provided on both sides of the roadway. The height clearance is 4.80 m; higher vehicles could pass through the tunnel exceptionally if they ride under the middle of the vault.

7 SAFETY IN TUNNELS – TUNNEL EQUIPMENT

The scope of safety equipment of road tunnels is wider than that of railway tunnels because of the fact that much more subjects (vehicles) move in a road tunnel, the freedom of their movement is much higher, thus the chance that a dangerous situation will occur during the operation is much greater.

The safety equipment meets the ČSN 73 7507 norm and is designed in compliance with the Directive of the European Parliament and of the Council on minimum

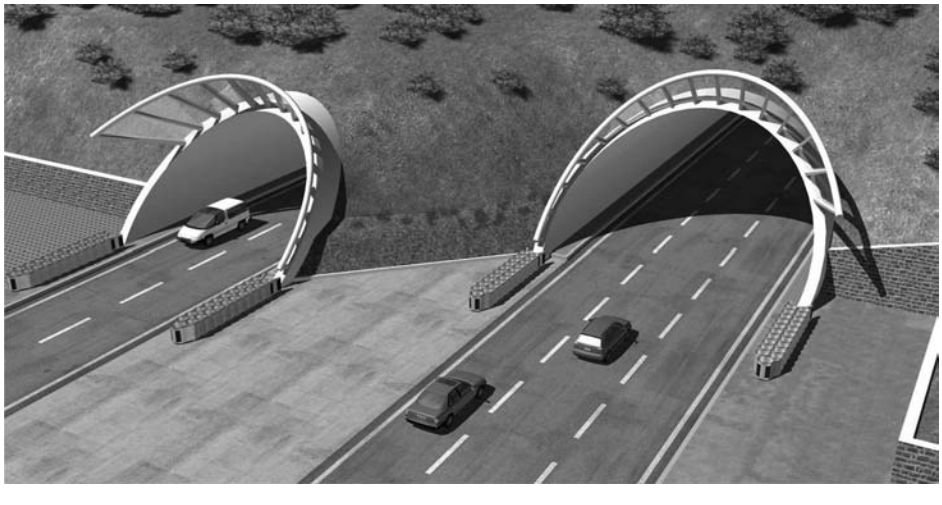

Figure 1. Architectural image of the portals.

safety requirements for tunnels in the Trans – European road network.

The recent conflagrations in European tunnels have shown us that the possibility of escaping from the tunnel is the most important factor of safety in a tunnel. This possibility is provided by construction of the above-mentioned cross passages, which are always equipped with fire resisting doors and separate ventilation systems. In addition, there is an emergency lay-by in each double-lane tunnel to be used for stopping and parking immobile vehicles; the lay-bys also facilitate contingent exiting of trucks from the cross passages passable for vehicles to the double-lane tunnels.

SOS boxes are installed every 150 m. They contain telephones, fire extinguishers and other equipment. A fire main with big hydrants, which is intended for the use only by firemen, is installed in each tunnel.

Of course, tunnel illumination with threshold and transition zones at portals, where the gradual reduction/increase in the lighting intensity provides gradual darkening/lightening and driver eyes can accommodate at the tunnel entry/exit, are a design standard. Stand-by lighting to be used in the case of an accident or fire is also installed in each tunnel.

The traffic control will be possible by variable traffic signs installed both inside the tunnels and on the open road before the tunnels. The tunnel control system is connected to the Traffic Information System and the data is transferred to control centres in Rudná and Prague, where the traffic data collected from the route is assessed. The processes in the tunnel will be observed by video cameras.

The tunnels are ventilated by jet fans installed under the tunnel crown at intervals about 200 m. In the basic regime, they are operated in the direction of traffic movement. The position and output of the fans is designed with respect to a fire emergency. The ventilation will be started during a fire after roughly 6 minutes to 8 minutes, when the cooling of smoke under the tunnel arch causes destratification of the smoke, which starts to threaten the passengers. The hot smoke keeps under the arch till that time and the escape of passengers is possible. The fans in the neighbouring smoke-free tunnel tube will be started in the same direction as those in the tunnel with the fire so that the smoke and other pollutants are not sucked to the clean tunnel via the portals. A ventilation plant for an exhaust ventilation system is designed, which will provide the required dispersion of pollutants in the right-hand (ascending) tunnel tube and partially at the beginning of the left tube.

The power consumption of all of the above-mentioned facilities is very high.

A transformer station and distribution substations are installed in single-storey buildings located in front of the portals; points where the electrical installations in the tunnels can be disconnected are available every 400 m. The power supply is backed up in case of a power failure.

Even the roadway drainage is designed with safety taken into consideration. Inverted siphons preventing a fire caused by an accident from spreading interrupt the drainage ducts installed along the curbs every 50 metres.

8 GEOLOGICAL CONDITIONS

The tunnels of the construction lot No. 514 will be driven through Ordovician and Silurian rocks, which are tectonically faulted and have pervasive faults and folds. Heavy fracturing of the rock occurs along the

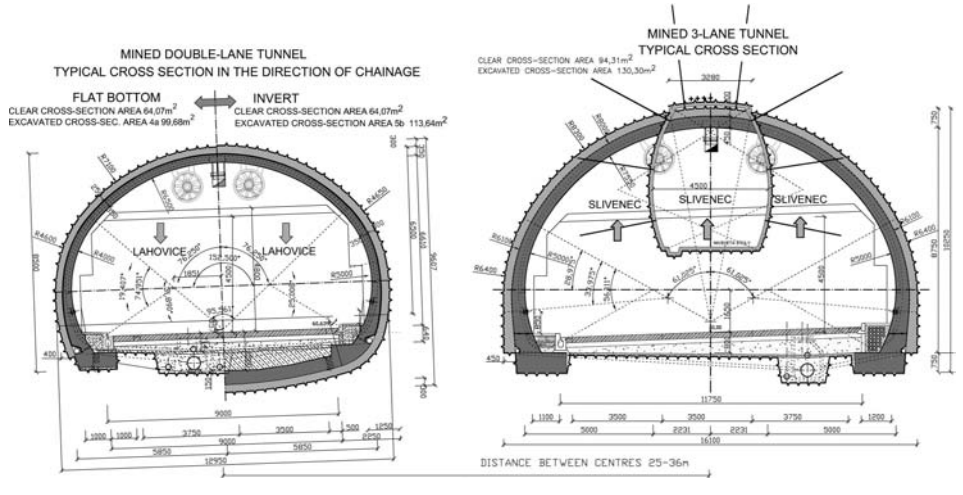

Figure 2. Cross sections.

faults. The shales, which are crushed by remoulding, are slickensided. Fissures are frequently open or partially filled with crushed rock and water. The numerous faults vary in their trends; the NE – SW trend dipping 45° to 60° to northwest can be considered prevailing. However, even transverse down-faults sub-parallel with the route are frequent. The filling of the down-faults consists of breccias of a character of shale fragments or clay. The information about quantity and quality of the faults was refined by an exploration gallery, which was driven along the central line of the top heading of the three-lane tunnel tube.

The hydrogeological conditions are relatively favourable for the excavation despite the fact that nearly the entire length of the mined tunnels passes under the water table lowered by the drainage effect of the exploration gallery. The aquifer existing in the area of the mined tunnels is bound to a fissure-type collector in the weathered zones of the bedrock. The water table copies to a certain extent the ground surface. The yield of the inflows at the excavation face may reach tenths of litres per second, in the case of quartzite or diabase it may grow to roughly 1 l/s, and in the case of water bearing faults up to 3 l/s.

9 THE EXPLORATION GALLERY – A PRE-CONSTRUCTION ELEMENT IN THE AREA

Geological conditions anticipated according to a geological survey can be verified during the planning phase of larger projects by excavation of an exploration gallery.

The exploration gallery, however, is always a matter of discussion in terms of the tunnel excavation; pros and cons of exploration drifts are relatively well known.

Today we would like to draw attention to a little bit different aspect. In addition to the exploration of the geology proper, the exploration gallery will test, on a smaller scale, even other relationships, and will "teach" the inhabitants and the entire region how to coexist with the future construction activities. In practice, it means that the condition survey of the affected buildings must be carried out and the blasting permit must be obtained; truck traffic to the construction site will start, thus the haul routes will be tested. Some utility networks will have to be relocated, the land for the site facility will have to be obtained, selected areas paved, power, water and sewerage services built etc. The inhabitants will feel all of these activities similarly as they will feel them during the future tunnel construction, only to a smaller extent. This process will help to forecast their future attitudes and requirements.

The results obtained by the exploration will be available to the designer and the contractor, who will use them in the process of optimisation of the construction procedures and selection of adequate tunnelling equipment.

10 TECHNICALLY SUITABLE SETTING OF THE EXPLORATION GALLERY

Till now, small cross-section exploration galleries have usually been designed with the aim of minimising the cost. Geological conditions have lately ceased to be the main factor in the design of the alignment passing through a more densely populated area. The final alignment is the result of strenuous searching for a "practicable" corridor.

The extent of tunnel projects, their exactingness and cost demands, the requirement for quick and economic excavation using up-to-date high-performance equipment, require broad knowledge of geology as well as knowledge of the rock response to excavation by heavy equipment. For this reason, "hand excavation" of minimum cross-section galleries with imperfect temporary support is today unsuitable.

The utilisation of heavy equipment requires the exploration gallery cross section to be enlarged; the enlargement requires the setting of the gallery to be selected which is optimal with respect to the subsequent tunnelling work so that the in advance excavated exploration gallery interferes with the excavation of the future tunnel as little as possible, and, on the other hand, contributes to facilitation and acceleration of the work.

The issue of the size and setting of the exploration gallery has been step by step solved for tunnels on the Prague City Ring Road.

The first gallery was designed as a traditional small horseshoe shaped profile gallery with the cross section of 13.8 m^2, set in the centre of the top heading of a three-lane tunnel. The aim of this design probably was to prevent the rock disturbance effects from reaching the surface of the future tunnel excavation. Such the setting will influence the further progress of the excavation of the tunnel tubes in a minimum extent, although, it can contribute to the facilitation of the future tunnel excavation also in a minimum extent if we consider the fact that the floor of the gallery is at least 1 m above the expected bottom of the top heading.

Metroprojekt Praha a.s. negotiated with the client a change in the cross section and setting of the exploration gallery when the work on the final design for the tunnels of the construction lots 513 and 514 was commencing. They incorporated a new setting and an enlarged cross section of 25.6 m^2 into the design; the floor of the gallery was designed at the level of the future tunnel. The height of the gallery is an optimum for utilization of high-performance equipment and for its radius of handling at the excavation face. The

Figure 3. A passing bay in the exploration gallery.

passing bays even represent complete top headings of the tunnel.

The setting and shape of the exploration gallery were selected so that the crown of the primary lining of the gallery extended into the primary lining of the future tunnel and became its part; later, because of the lapse of time between the gallery construction and the tunnel excavation, the gallery arch lining was shifted above the tunnel lining. Owing to this setting, the exploration gallery will create the first partial excavation (sequence) of the top heading of the three-lane tunnel. The primary lining of the gallery will act as a mighty anchor during the course of the top heading excavation. At the same time, it will significantly reduce the excavation face, which will become stable even without any additional measure. This gallery will not deteriorate the conditions for the excavation of the three-lane tunnel proper; just opposite, it will significantly contribute to the tunnel excavation safety.

Apart from its exploratory purpose, the completed exploration gallery, in its new setting, will become an important ventilation adit, escape route and access adit for rescue services in case of an emergency, even an optional supply route. It will allow gravitational drainage of the excavation during the downhill excavation of the large tunnels. The ideal opportunity of installing anchors in the crown of the vault in advance of the tunnel excavation and implementing in advance extraordinary or required measures in locations of weakness zones or other extraordinary conditions identified by the exploration gallery must not remain unmentioned. As a last resort in case of unfavourable rock conditions, a segment of the primary lining of the tunnel can be cast in the crown of the gallery (at a width equal to the width of the gallery) reinforced sufficiently to be capable of acting as a stiff longitudinal beam significantly reducing deformations in the rock mass and surface settlement during the work on the enlargement of the top heading and installation of the excavation support.

11 CONCLUSION

Today, the excavation of the exploration galleries for the 514 and 513 tunnels and the refining the information on geological conditions have been completed. The information and experience gained from the excavation of the exploration galleries have been incorporated into the detailed designs for both tunnels. The excavation of the tunnel 514 has commenced.

Portals – The architecture visible in cities and landscape

O. Hasik
METROPROJEKT Praha, Prague, The Czech Republic

P. Sourek
SATRA, Prague, The Czech Republic

ABSTRACT: Tunnels are civil engineering works where emphasis is mostly laid on their technical and economic design. The public usually view them as very important, even though unsightly rather than nice; as a structure that only serves its purpose and is no aesthetic complement or enhancement of the landscape in which it is located. In the past, tunnel portals were integrated with the ambience without affecting the ambience significantly, in a somewhat uniform style and often intentionally overshadowed by other structures. With the new upswing of the tunnelling industry in the Czech Republic over the last ten years, even tunnel designers dared involve capable architects, whose task was to complete this technical work so that it not only serves its purpose but its appearance also completes the architecture of the territory, and thus underlines the clear meaning of this large investment. The new approach has even made some of the current portals landmarks of the respective territories. The paper illustrates and describes the architectural concept of the tunnel portals being currently under construction or in the preparations phase, and brings back to mind the most important historic portals in Prague.

1 INTRODUCTION

The focus of this paper is on picturing tunnel portals. Photographs of structures built in the past or visualisation of projects being prepared are provided with brief descriptions.

Figure 1. Rudolph's Gallery, the year 1593.

2 SMALL TUNNELS

2.1 *Rudolph's gallery*

It is an underground gallery leading between the embankment of the river Vltava and Kralovska Obora (Royal Deer Park), which is the oldest tunnel in Prague. This historic monument was built in the years 1581–1593 to supply water to a pond in the deer park. The about 1000 m long gallery was excavated simultaneously from both ends and additional five shafts. The dimensions of the cross section are approximately 3.5 m × 2.2 m. The shafts and the gallery were supported only with round timber, which was replaced by masonry during the 18th century. This remarkable piece of technical work has been preserved up to the present time.

2.2 *The tunnel under the Prasny Bridge embankment*

A possibility of interconnecting both parts of Jeleni Prikop (Deer Moat) divided by a road embankment was under consideration from 1990. The tunnel has opened the access to another part of Prague Castle. The shape of the new tunnel and portals as well as the whole construction were sensitively designed by

Figure 2. The tunnel under the Prasny Bridge, 1990.

an architect. The route of the passage is identical with a former Theresian gallery allowing Brusnice stream to pass through the embankment.

The new egg-shaped tunnel is 84 m long. Three basic materials were used for the construction: concrete, hard-burnt brick cladding and, for pavements and the stream channel, natural stone.

3 ROAD TUNNELS

3.1 *The tunnel under Vysehrad*

The 34 m long × 9 m wide tunnel was opened to traffic on 11th December 1904.

The tunnel was considered necessary for vehicular and pedestrian traffic, which was a condition for further development of Prague districts of Podoli, Branik and Hodkovicky (villages on the outskirts then). The ambience around Vysehrad, which is a significant, nearly mythical historic monument, has always a romantic air. This was probably why the authors used crenelation and turrets for the portal decoration, which enhances this romantic character.

3.2 *The Letna tunnel*

The first real road tunnel was the Letna tunnel built in 1949–1953. It is 426 m long × 10.3 m wide × 6.5 m high. The gradient of the S-shaped alignment is uniform at 5.4%.

The tunnel links the area of Letna with the centre of Prague. It was excavated using the Modified Austrian Tunnelling Method.

3.3 *The Strahov tunnel*

The Strahov tunnel route connects the areas of Brevnov and Dejvice with the area of Smichov. The history of this connection can be followed in proposals developed

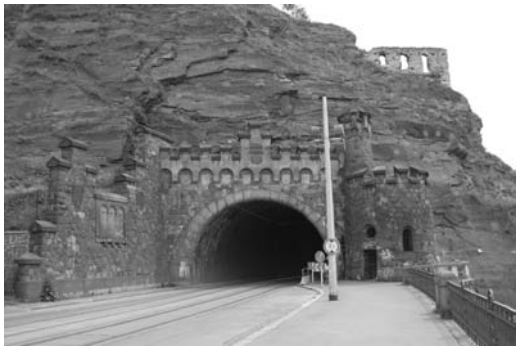

Figure 3. The tunnel under Vysehrad decorated with crenelation; 1904.

Figure 4. The Letna tunnel, 1953.

Figure 5. The Strahov tunnel, 1990.

as long ago as 1847 and 1937. The Strahov tunnel was inaugurated in 1997 as a part of the inner circle road.

The tunnel was driven using the side-drift method, which was probably a little bit archaic at that time.

3.4 *The Mrazovka tunnel*

The Mrazovka tunnel on the City Circle Road in Prague was built recently. The portals have been

Figure 6. The Mrazovka tunnel, 2004.

Figure 7. South-East Portal of The Mrazovka tunnel, 2004.

properly incorporated into the surroundings, from both architectural and town planning viewpoints.

The construction of the Mrazovka tunnel started in the autumn of 1998. It was opened to traffic in August 2004. The tunnel is 1300 m long; three traffic lanes are provided in the major part of its length. The excavated cross-section areas in the three-lane section and in bifurcation chambers were 165 m^2 and up to 340 m^2 respectively. The excavation of the tunnel passing under the relatively densely developed area was carried out by the New Austrian Tunnelling Method.

The northern portal is nearly directly connected to the southern portal of the Strahov tunnel. A cascade of greenery troughs suspended above the portal ends in a park on the top of Mrazovka Hill. The southeastern portal is provided with a staircase leading to a lookout located on the hillside.

3.5 *The Blanka tunnel*

The further development of the City Circle Road in Prague will comprise the Czech Republic's longest road tunnel at a total length of 5.5 km. The construction is planned to begin in 2007.

Figure 8. Troja axonometry – visualisation.

Figure 9. Portals of the Prague City Ring Road – visualisation.

The Blanka tunnel starts at the Malovanka grade-separated intersection, at the northern portal of the Strahov tunnel. In strict sense, the only real portal is the Troja portal.

3.6 *A portal and ventilation shaft of a tunnel on the Prague City Ring Road*

The construction lot 514 of the Prague City (outer) Ring Road project comprises tunnel tubes with "ribbed canopies" skirting the elliptic crowns of the portal ends. This architectural design will certainly relieve the dullness of the passage along this section of the route.

3.7 *The Pisarky tunnel in Brno*

The Pisarky tunnel is the first motorway tunnel completed in the Czech Republic and the first tunnel excavated using the observational method. The variant consisting of a tunnel with relatively long cut-and-cover sections was chosen as the most considerate towards the surroundings.

Figure 10. The Pisarky tunnel, 1998.

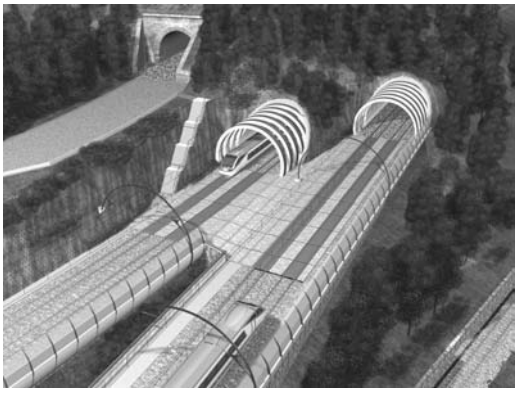

Figure 11. The new connection – visualization of the portal built in the centre of the city.

The tunnel is connected to a bridge over Certik stream on one side and to a bridge over the river Svratka on the other side.

4 RAILWAY TUNNELS

4.1 *The new connection in Prague*

Based on the EIA developed in 1996, it was decided that the railway lines from the Prague Libeň station and Prague Hlavni Nadrazi station and from Prague to Turnov would be led under Vitkov Hill, through a pair of double-rail tunnels. The reason for this solution was the effort to minimise the impact of railway traffic on inhabitants. Both 2400 m long double-rail tunnels were driven using the NATM.

Figure 12. The Vinohrady railway tunnels, 1944.

4.2 *The Vinohrady tunnels*

The year 1866 saw the commencement of the construction of the Franz Joseph's single-track railway line. As a part of this construction, the Vinohrady I single-rail tunnel construction started. The tunnel was later reconstructed and converted to a double-rail tunnel. The growth in the transportation outputs after the foundation of Czechoslovakia and the poor structural condition of the Vinohrady I tunnel resulted in the decision that a second double-rail tunnel (Vinohrady II) be built in 1940.

The recent reconstruction of the Prague railway junction which was carried out around the year 1985 required the addition of the Vinohrady III tunnel. It was driven using the ring method.

The Hlavni Nadrazi portal is located directly in the contact with the historic centre of Prague. We can say that it has become part of the unmistakable local colour of this area.

Study of the ship lift structure at the Slapy Dam

M. Jakoubek & J. Kuňák
Metroprojekt Praha, Prague, The Czech Republic

P. Uher
Pöyry, Prague, The Czech Republic

ABSTRACT: The paper deals with the design of the driven structures of the ship lift at the Slapy Dam, which is some 35 km upstream from Prague on the River Vltava. The dam profile is the main reason why the water route from Prague to České Budějovice is not navigable for ships of tonnage up to 300 tons. At present studies deal with several variants of the ship lift structure. Despite the fact that none of the variants has been chosen for further stages of the project preparation, the text describes in detail only one of the planned variants – the lock with high lift, which is the most interesting one from the point of view of tunnelling. This design of the ship lift uses to the maximum extent the newly built underground structures and at the same time it requires minimum work on the right bank. The excavation of the shaft and the driving will take place in the nearest surroundings of the dam and the hydraulic power plant which will require that extra safety and anti-vibration measures should be taken.

1 INTRODUCTION

The Vltava water route from Prague upstream ends at present below the Slapy Dam. The Slapy Dam is the only structure of the Vltava Cascade where the structure of the ship locking system is not finished. In 1955 the hydraulic structure was put into operation without the locking system and this situation still lasts.

Figure 1. View of the dam downstream side. In the left-hand bottom corner you can see the diversion tunnel outlet.

When the Slapy hydraulic structure was under development, its first studies already planned that the locking system should be constructed. This goal was not met due to the lack of time, high building costs and technological difficulties in connection with the filling of the reservoir. Only the building part of the navigation lock on the right bank in the upstream pool was built.

The original project planned the ship lift structure for ships of tonnage up to 300 tons. A vertical ship lift in a reinforced-concrete tower structure on the right bank below the dam was planned, situated out-side the dam body. The structure should have been connected to the diversion tunnel, which was used during the construction activities for the purpose of diverting water from the dam construction site.

2 STRUCTURE HISTORY

2.1 *Dam*

The decision to build the Slapy Dam was made as early as 1933. The gorge in the place once called Midsummer Streams (Svatojánské proudy) was chosen as the most suitable one for the dam. The structure was approved in 1949. In the same year the work on the diversion tunnel and auxiliary structures was commenced. It was the first big structure of the Vltava Cascade after the World War II. The dam was built

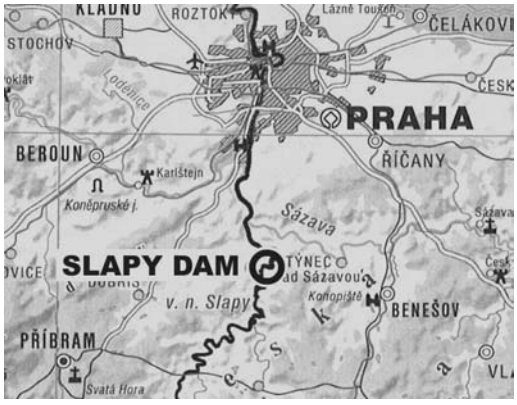

Figure 2. Map plotting.

in a dry pit, protected by fill dams on the upstream and downstream sides of the dam foundation surface. The dam was completed in 1955. The dam crest is 65 m above the bottom; the level difference is 54.6 m. The hydraulic power plant is situated in the concrete dam body. Water runs through four spillways with crest gates built above the hydraulic power plant.

2.2 *Diversion tunnel*

The diversion tunnel 10.0×12.0 m was built to allow rafts and vessels to navigate through while the construction activities were under way and most of all to divert water away from the construction site. The tunnel, 321 m long, was driven in a sound rock on the right bank and it is provided with concrete walling only in short sections by portals. The tunnel longitudinal slope is 0.15%. The diversion tunnel was closed shortly before the dam crest concreting. A concrete plug was constructed at the tunnel upstream end. It rested on cone-shaped pockets created in the wall and grouted with vertical holes, at the length of 30 m. Then, in April 1954, the filling of the reservoir was commenced. In July 1954 a vast flood came (a fifty-year one with the flow of 2200 $m^3.s^{-1}$), however the dam under construction withstood it. A positive result in favour of the capital of Prague downstream was the considerable transformation of the flood wave filling the empty reservoir.

At present the unsupported length of the tunnel is 291 m. The tunnel is accessible from the downstream water level (Fig. 3). The disposition of the tunnel and especially its length on the downstream side of the dam were designed from the beginning so that it could later be used as a navigation canal by the entrance to the locking system. The condition of the diversion tunnel was checked in detail some 20 years ago within trial blasting in connection with the shaft of the locking system. At that time the tunnel condition was quite good, only in a few places the rock under the vault toe.

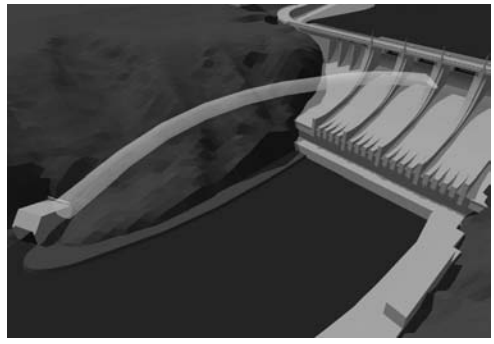

Figure 3. Existing diversion tunnel.

3 GEOLOGIC SITUATION

3.1 *Geologic conditions*

The Slapy hydraulic structure is situated in an area with monotonous occurrence of amphibolites of the argillaceous zone. The amphibolites are of the character of a fine-grained, solid, dark grey-green rock with high unconfined compression strength of up to 300 MPa. Occasionally in complete sections of amphibolites there is the so-called cushion lava forming longitudinally oval-shaped compressed schistose bodies, approx. 1.0×0.8 m. Amphibolites are very tough and resistant to chemical weathering, their faults are caused by slope movements of rock blocks and tectonic movements resulting from intensive compression of the argillaceous zone which is evident in schistose formations.

3.2 *Hydrogeologic conditions*

Groundwater absorbed in the rock base does not form a continuous horizon, its yield is small and the groundwater circulates in fissures without any relations. Apart from the surface sections, the fissures are close, frequently healed with calcite and almost water impermeable. The rock ambience permeability had been tested within research, before work on the dam was started, in holes by means of water-pressure tests and grouting tests. The value of the specific water loss was from 0.001 to 0.014 $l.s^{-1}.m^{-1}$ at the water pressure from 0.4 to 1.0 MPa. The dam profile was sealed with a grouted curtain during the construction activities. Since the dam was completed, the effect of the fissure systems pressure after afflux in the reservoir has not been tested.

4 SHIP LIFT CONCEPTION

4.1 *Original designs*

The heated discussions among experts in the Czech Republic, focused on the locking system structure at

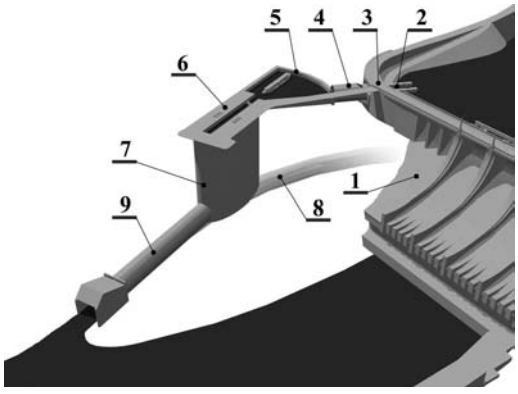

Figure 4. Design diagram. 1. Slapy dam, 2. Existing navigation lock, 3. Existing bridging, 4. New tunnel on the upstream water, 5. Passing bay, 6. Navigation lock platform, 7. Lock with high lift, 8. Closed part of the existing diversion tunnel, 9. Lower navigation tunnel, straightening the existing diversion tunnel.

Slapy, have lasted for more than 50 years. Up to the present several technological conceptions have been prepared (a lock with a high lift, a vertical ship lift in a shaft and a sloping ship lift). There were considered also alternatives of a navigation lock with s reversible pumps, a navigation lock with spare basins, a navigation lock with an ejection effect or a vertical ship lift with a complete balancing. Another proposal was an innovative design of a revolving ship lift when the ship channel moves along one carrying rail the shape of a helix Záruba (1960). Another original solution protected with a patent is a ship lift with pushed chains Záruba (1987).

4.2 *The existing state of project preparation*

The solution is designed in accordance with currently valid parameters of Water Routes European Classification Class I as regards ships of tonnage up to 300 tons. The ship lift must be able to lock a ship of effective dimensions 45.0×6.0 m. The navigation lock construction brings about a number of problems both hydraulic, nautical and static.

The last expert study (Uher and team 2006) contained three variants of the ship lift design: a shaft ship lift with a complete balancing, a lock with high lift with spare basins and a sloping ship lift.

The first and second variants have in essence the same layout, which is also used in all the previous designs. It uses as much as possible the existing navigation lock in the upstream water and part of the existing diversion tunnel for ships arriving to the lift on the downstream water.

The next part of the paper describes the most interesting variant from the point of view of tunnelling – the lock with high lift (Fig. 4). One of the problems of this design is the arrangement of structures with respect to ensuring optimum entry and exit conditions from upstream and downstream pools. In order that a ship enters and leaves on the downstream water it is necessary that this manoeuvre on a straight line. For this reason it is necessary to straighten the existing diversion tunnel in the point of the connection of the vertical shaft. The sudden change of the course of a ship which is necessary with respect to the above specified disposition will take place when the ship stops in the passing bay on the upstream water.

5 LOCKING SYSTEM STRUCTURAL DESIGN

5.1 *Upper navigation canal*

An upper navigation canal will be driven from the existing navigation lock, running partly through an open cut and partly through a short navigation tunnel. The new profile will be driven by means of NRTM (New Austrian Tunnelling Method) with a primary support of the excavation with a sprayed concrete layer and a system anchorage. Final walling will be of cast-in-situ reinforced concrete. On both sides of the tunnel will be (escape) footbridges, their vertical parts will be, within the fluctuation of water level of 1.50 m, used as guard rails.

The navigation tunnel will end in the passing bay tank of trapezoidal layout. The passing bay will be situated in an excavated pit, slopes of the cuttings will be supported with permanent anchors and protected with a sprayed concrete layer. The passing bay tank structure will be made of cast-in-situ reinforced concrete for water structures. The foundation surface of the passing bay bearing structure will be permanently drained with a drain system connected to the downstream water because of the pressure effects on the structure. The passing bay will have two mobile binding systems. With the systems it will be possible to turn the ships if they avoid each other in the passing bay.

In the downstream direction the passing bay tank is connected to the lock with high lift.

5.2 *Lock with high lift*

The navigation lock will be situated in a shaft of an elliptic layout 60.0×25.0 m, cross-section area is approx. 1300 m^2 and depth 60.0 m. The clearance of the lock is 45.0×6.0 m, the intermediate space will be used for spare basins (Fig. 6).

The shaft will be excavated gradually from the surface, it will be secured with primary walling of sprayed concrete with a system anchorage. To prevent the effect of shocks on the structures of the dam and the operated hydraulic power plant, before the excavation is commenced a secured perimeter nick will be

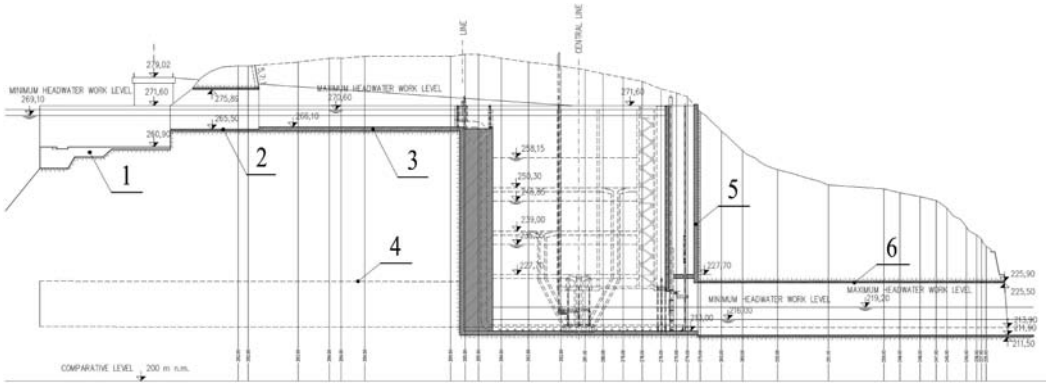

Figure 5. Longitudinal profile. 1. Existing navigation lock, 2. New tunnel on upstream water, 3. Passing bay, 4. Closed part of the existing diversion tunnel, 5. Lock with high lift, 6. Lower navigation tunnel, straightening the existing diversion tunnel.

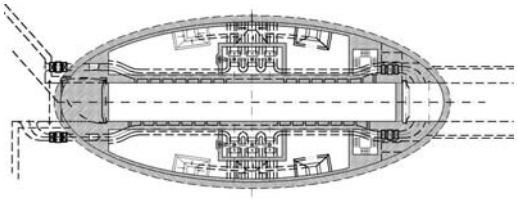

Figure 6. Plane section of lock with high lift.

made by means of a hydro cutter along the height of the shaft. The trench, 0.6 m wide, will be filled with bentonite mud. The final (secondary) walling will be of cast-in-situ reinforced concrete. Waterproofing with a permanent drain system connected to the downstream water will be inserted between the primary and secondary walling. This will eliminate effects of possible hydrostatic pressure from fissure systems on the final shaft structures. The inner clearance of the shaft enclosure will be approx. 60.0×25.0 m.

The shaft inner structures that will be used as spare basins are designed to transfer different hydrostatic pressures during regular water level fluctuation while the navigation lock is being filled and discharged. The lock will be filled and discharged by means of long bypasses closed with check gates. Bypass inlets on the upstream water will be on side walls between the tank and the lock. Check gates will be controlled with hydraulic face jacks. Shafts of bypass closures will be up to the level of the lock platform. In the downstream head the hydraulic face jacks of check gates of bypasses will be situated above the level of maximum downstream water. The navigation lock platform will be at 271.60 meters above sea level and the minimum water depth in the lock will be 3.0 m, the bottom at 213.00 meters above sea level. On the walls of the navigation lock will be installed floating binding elements for big and small ships and ladders. The lock platform will be lit.

The lock will have three twos of spare basins, interconnected with filling and discharging channels in the middle of the lock length with long bypasses. Particular channels will be closed with check gates controlled by hydraulic face jacks installed in the dry shaft integrated into the layout of spare basins. For the purposes of installing technology and its operation the shaft will be accessible from the lock platform. In the section of the channels between the check gates and the lock will be slots of box dam and the space will be filled with air. Particular levels of the spare basins will be connected to the atmosphere through the aeration pipe.

The head gate will be of boards with a vertical axis of rotation controlled by a hydraulic face jack. The gate sill with surface at 266.10 meters above sea level will be of minimum length, thus a ship hull will be prevented from sinking to the bottom when the water level drops while the lock is being emptied. In front of the gate will be the slot of the box dam for filled tube stop logs.

The tail gate situated outside the navigation lock layout will consist of a lift gate controlled by a hydraulic face jack installed in the dry shaft. The shaft floor will be at 227.70 meters above sea level, a box dam board will be permanently installed in the slots against downstream water. Access allowing technology installation and its operation will be possible from the lock platform top. The gate sill will be at 213.00 meters above sea level. The long bypasses will be emptied into the downstream water in the profile between the tail gate and the box dam.

For the purposes of operation and maintenance of the navigation lock and the spare basins there will be two dry access shafts with a staircase and a central

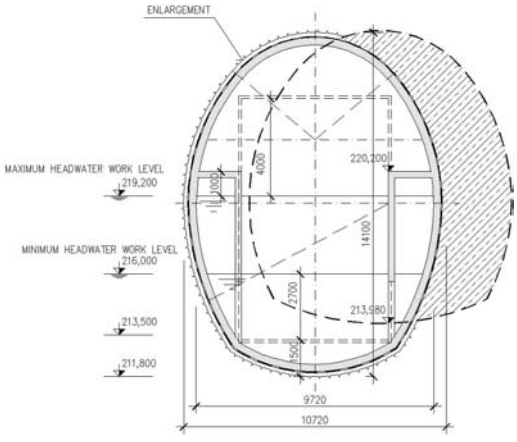

Figure 7. Cross-section of the lower navigation tunnel. Extension of the existing profile of excavation in the place of connection to the shaft.

space for material and equipment transport. Particular landings of the staircase will allow access to the floor of the machine room of tail gate closures, the machine rooms of closures of filling and discharging channels of spare basins and pressure covers provide access to particular spare basins. A small passenger lift will be designed to transport people.

5.3 *Lower navigation canal*

The lower navigation canal will consist of a tunnel running right in the direction of the longitudinal axis of the lock with high lift, connected to the straight end section of the diversion tunnel. The existing tunnel will have to be profiled anew (while using principles of NRTM with the primary support of the excavation with a sprayed concrete layer and a system anchorage). Final walling will be of cast-in-situ reinforced concrete (Fig. 7).

The remaining part of the diversion tunnel, approx. 130 m long, will be used for the fill of muck which will be subsequently grouted and the tunnel profile will be closed. When the operating level in the channel is at 216.00 meters above sea level, the minimum water depth will be 2.70 m (2.20 ship draught and 0.50 m margin). The tunnel bottom at the depth of 2.70 m will be min. 213.30 meters above sea level. Maximum level will be at 219.20 meters above sea level. On both sides of the tunnel will be (escape) footbridges with the top at 220.20 meters above sea level, their vertical parts will be, within the fluctuation of water level of 3.20 m, used as guard rails. The tunnel will be lit.

While the lower navigation tunnel is being driven and equipped, a pit will be excavated outside the tunnel portal in the River Vltava bed.

6 SAFETY ISSUES

6.1 *Safety measures taken during construction activities*

According to the task the work on the construction should be carried out while the hydraulic power plant works full out and the water level in the reservoir must not get lower.

The vertical shaft, some 60 m deep and some 1300 m^2 of excavated area, is a mining work of extraordinary dimensions. Excavation and driving will take place in relatively complicated hydrogeologic conditions (extremely hard amphibolites with compression strength of 300 MPa, broken into blocks with fissure groundwater under the pressure of up to 50 m of water column). Work will be carried out in the nearest surroundings of the dam and the hydraulic power plant, in the nearest place the shaft is 100 m away from the dam body. The establishment of the perimeter nick along the entire height of the shaft before the excavation is commenced is an extensive anti-shock measure taken for the purpose of separating the blasting operations from the outdoor environment. The said designs will be worked out in detail in the following stages of the project documentation.

6.2 *Safety measures during the ship lift operation*

As similar structure is found neither in the Czech Republic nor even abroad, the proposal of safety measures will be based on structures of a similar character, that means navigation locks with a big gradient.

If an accident of a ship in the lock occurs, the advantage of this variant is that it is possible to fill or discharge the lock as an emergency and thus the ship can be relatively quickly moved to one of utmost positions. For purposes of inspections and access of rescue teams there will be a section with ladders along the entire height of the navigation lock.

It is possible to anticipate that despite all the safety measures there will be a group of people that will refuse this way of transporting. In this instance these tourists will be transported by minibuses.

7 INCORPORATING THE WORK IN THE LANDSCAPE

7.1 *Effects on the environment*

The variant of the lock with high lift is to the maximum possible extent situated in the underground so that its adverse effect on the landscape is minimal (Fig. 8). In comparison with the other variants this one offers the slightest impact on the surroundings.

The lock with high lift construction is designed to meet the strictest ecological requirements as it is

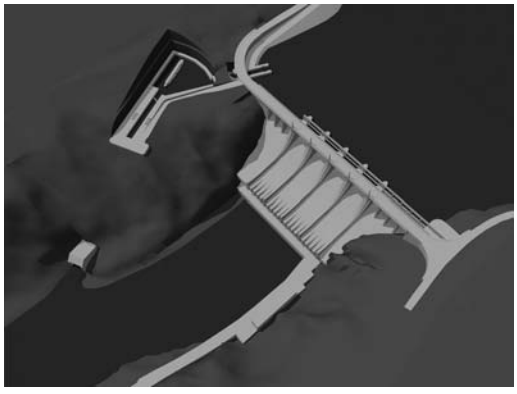

Figure 8. Perspective – bird's eye view.

situated in a beautiful landscape of the River Vltava valley, used as a holiday area by inhabitants of the capital which is some 35 km away.

7.2 *Ship lift as a draw for tourist*

It is expected that the entire ship lift system will be accessible tot the public. The variant of the lock with high lift is probably the least attractive from among the assessed variants if compared with the sloping ship lift when the ship is on the ground level all the time and thus the passengers can watch the valley. In order that the peace of mind of passengers is preserved the navigation lock and the lower navigation tunnel will be lit on walls. Within the reach of the work will be founded a centre to be visited by both ship passengers and the people who will only come to see the work. It is anticipated that the public will be interested in the work as it will be, owing to its extraordinary parameters and its design, a popular destination of tourists. This is also taken into account when the return on the investment is considered.

8 CONCLUSION

It is possible to say that the presented design prepared as a study is feasible on the basis of current conditions.

Safety risks in connection with the construction and operation of the locking system do not exceed common risks associated with the use of water routes and therefore they do not represent any obstacles to the construction.

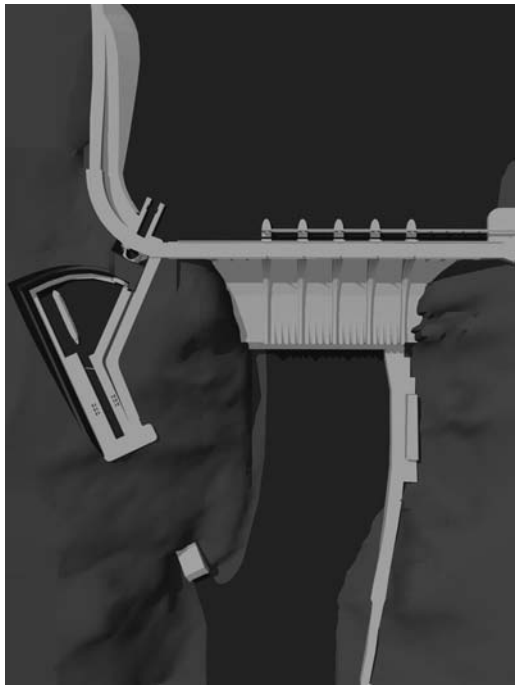

Figure 9. Incorporating the work in the landscape.

Design of the District Heating Tunnel in Copenhagen

T. Kasper, C. Edvardsen & M. Faurschou
COWI A/S, Kongens Lyngby, Denmark

ABSTRACT: The 3.9 km long District Heating Tunnel in Copenhagen is intended to supply the inner city of Copenhagen with district heating. Starting from a 37 m deep access shaft at the power plant on the island Amager, the tunnel is bored by an EPB shield machine and passes under the city to a 44 m deep shaft at Adelgade and a 30 m deep end shaft at Fredensgade. The tunnel has an internal diameter of 4.2 m and will carry 2 steam pipes, 2 hot water pipes and 2 condensation pipes. Under operation with 12 hours ventilation per day, the inside of the tunnel will heat up to a temperature of approx. 50 degrees. With its axis between 25 and 38 m below the ground surface, the tunnel is located at its full length within the Copenhagen limestone. The lining for this tunnel is designed with steel fibre reinforced concrete (SFRC) segments without conventional steel bar reinforcement based on the German SFRC design guideline. Apart from a general overview on the project, this paper is concerned with the methods and calculations applied in the structural design of the tunnel lining including the special aspect of the heating of the tunnel. Further attention is paid to the durability design, laboratory tests and experiences during construction.

1 INTRODUCTION

To upgrade the production and supply of district heating in Copenhagen it has been decided to move the current production from the two older plants Svanemølleværket and HC Ørestedsværket to the completely renovated block 1 at the Amager Power Plant (Amagerværket). In order to minimise the disturbance at the surface in the Copenhagen city it was decided to place the pipelines in a tunnel (Figure 1). The tunnel starts with a straight 2.4 km long stretch between the access shaft at the Amager Power Plant and the shaft at Adelgade, turns about 56° northwards and continues in a straight 1.5 km long stretch to the end shaft at

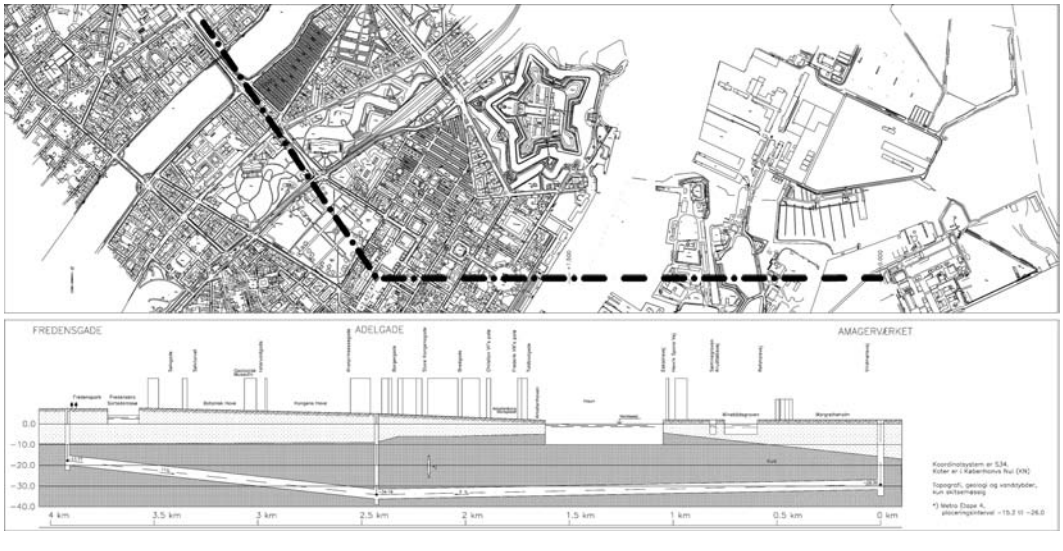

Figure 1. Layout of the District Heating Tunnel in Copenhagen.

Fredensgade. The tunnel is located at a depth between 25 and 38 m. The alignment is governed partly by the wish to excavate the tunnel primarily in the middle Copenhagen limestone and partly by minimum inclinations needed to deal with condensates in the steam pipes during operation. The heating tunnel passes below the future metro tunnel on the first stretch to the shaft at Adelgade. The geology along the alignment is characterized by quarternary layers of fill, clay and sand tills and melt water units down to depths between 14 and 18 m below the surface and Copenhagen limestone underneath (Knudsen et al. 1995, Hansen & Foged 2002, Jackson et al. 2004).

The shafts for the tunnel are constructed with secant pile walls in the upper part and are temporarily lined with shotcrete in the lower part. Permanent concrete linings with membranes at the outer faces will be constructed after the tunnel works are finished. The shaft at the Amager plant is the largest one. It has an oval cross-section with final internal diameters of 25/15 m and an excavation depth of 37 m.

The tunnel is excavated with an EPB shield machine. This type of TBM was also successfully applied in the Copenhagen metro project (Nymann & Taylor 2003). For the installation, launch, turning and arrival of the TBM, NATM caverns with temporary shotcrete linings are excavated from the three shafts. As the shafts, these caverns will also be lined with permanent concrete linings.

Although passing under densely built inner city areas with historical buildings and sensitive infrastructure, no surface settlement problems need to be investigated compared to shallow tunnels in soft soils (Kasper & Meschke 2006a, b) due to the deep location of the tunnel in the intact limestone rock mass. This conclusion is further supported by a comprehensive investigation of settlements experienced during construction of the Copenhagen metro phase 1 + 2A.

The District Heating Tunnel is lined with steel fibre reinforced concrete (SFRC) segments without conventional steel bar reinforcement (Figure 2). Although the properties, design and possible application of SFRC have been a topic of research for a longer period (see e.g. Maidl 1995) only relatively few applications for precast segmental tunnel linings have been reported so far. To the authors' knowledge, the first large-scale test application of SFRC segmental linings without steel bar reinforcement was in 140 m of a pressurized water tunnel in the Lesotho Highlands Water Project in South Africa (Wallis 1995). Further application examples are the baggage handling tunnel at London Heathrow Airport (Moyson 1995) and, on a large scale, about 20 km twin-tube sections of the Channel Tunnel Rail Link (Davis et al. 2006). Design guidelines for SFRC have been worked out in various countries. However, no standards are available yet. The lining design for the

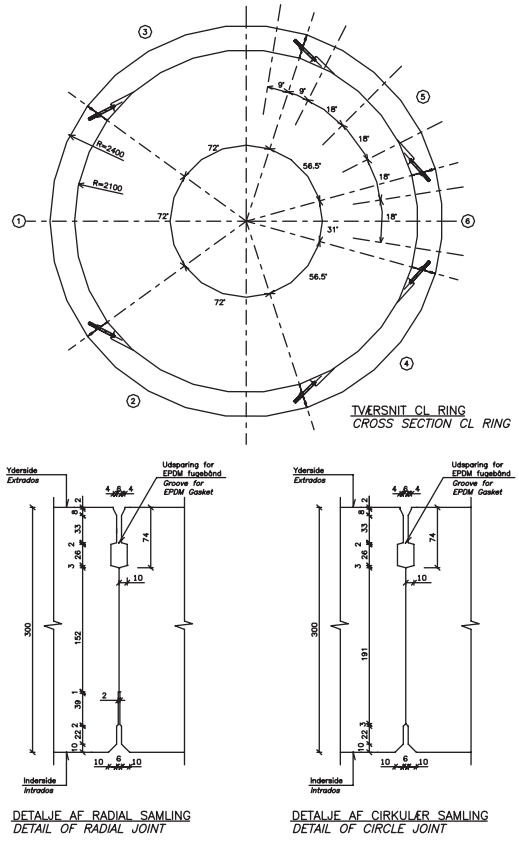

Figure 2. Layout of the segmental lining.

District Heating Tunnel is based on the German SFRC design guideline (DBBV 2001).

The annular gap around the lining is injected with a two-component grout (cement, bentonite, water and stabilizer as component A, water glass and water as component B), which is characterised by short gelling and setting time. This ensures a quick stabilization of the tunnel lining, avoids uplift of the rings and shear displacements between the segments.

The operation of the heating system has been optimized (Matlock et al. 2005). The tunnel is assumed ventilated 12 hours each day during night time leading to a predicted uniform temperature elevation along the circumference to max 54°C on the inside of the lining and to max 50°C on the outside of the lining.

The design and construction of the tunnel is performed based on a partnering model (late partnering) between the involved parties. The design work started in October 2004, the excavation works for the shafts started in September 2005 and the tunnel is due for operation of the pipelines end of March 2009. The total costs of the project are estimated to be DKK

750 million incl. the piping works tendered for in late 2006. The use of steel fibres was included as an option in the tender documents. Apart from direct commercial benefits to the contractor, it is anticipated that the client will gain from the use of SFRC by reduced operation and maintenance costs during the life time of the tunnel.

2 STRUCTURAL DESIGN OF THE SEGMENTAL TUNNEL LINING

The lining has a thickness of 30 cm (Figure 2). The concrete is C50/60 and contains 35 kg/m^3 fibres of type DUOLOC 47/0.80. According to its bending strength characteristics (cp. Figure 5), the SFRC is classified as fibre class 1.4/0.6. The lining has flat concrete-to-concrete radial joints and flat longitudinal joints with 0.9 mm thick bituminous packers. It is equipped with EPDM gaskets. The segments are designed to form tapered rings with a width of 1.50 m and a taper of 2 cm consisting of 3 standard segments, 2 counter key segments and 1 key segment. The final loading situation of the circular tunnel lining in the limestone rock mass is characterised by predominant compression with only small bending moments. Steel fibres in the concrete lining improve the resistance against spalling of corners and edges, introduce a ductile post-cracking behaviour, eliminate corrosion problems and therefore increase the durability. However, special care is required during segment production, transport and construction in the tunnel, as SFRC segments cannot compete with the bending capacity of conventionally reinforced segments. The segments are erected with a vacuum pad erector in combination with a shear key of 110 mm diameter in the centre of the segments. The segments are bolted together with straight bolts in bolt pockets. The bolts are removed after construction.

The sectional forces in the lining for the loading situation without heating of the tunnel have been determined by two-dimensional numerical models using the finite difference code FLAC (Figure 3). The model considers the different soil layers and the grout by continuum elements and the tunnel lining by beam elements. A fine grid is used in the vicinity of the tunnel. The lining is modelled in a simplified way as a continuous ring without consideration of the radial joints. This is a conservative approach leading to the largest possible bending moments while the normal forces in the ring are not affected by this assumption. Table 1 contains the material parameters applied in the analyses. Both an upper and a lower bound estimate of the limestone stiffness are investigated.

The calculated sectional forces contain a circle shape tolerance of the ring of 25 mm and lipping of 15 mm. The load bearing capacity of the lining is verified based on the stress-strain relationship shown in

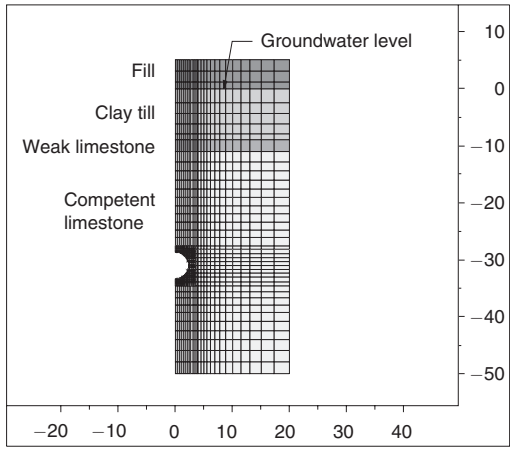

Figure 3. Numerical model for the determination of sectional forces without heating of the tunnel, shown for the deepest section.

Table 1. Geotechnical parameters of the different soil layers.

Material	γ (kN/m^3)	E (MPa)	ν –	ϕ' (°)	c' (kPa)	K_0 –
Fill	22	10	0.3	30	0	0.5
Clay till	23	150	0.3	34	10	0.44
Limestone crushed zone	22	1000	0.25	45	50	0.29
Competent limestone	22	1500 (min) 10000 (max)	0.25	45	100	0.29

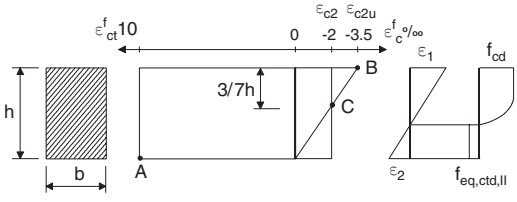

Figure 4. Rectangular SFRC cross-section: Definition of admissible strain ranges and assumed, simplified stress-strain relationship for the verification of the bearing capacity.

Figure 4. A parabolic-rectangular compressive stress block is assumed for the concrete and a simplified (conservative) rectangular tensile stress block is assumed for the cracked concrete. The actual tensile stress-strain relationship of the SFRC determined from bending tests is shown schematically in Figure 5. The resulting failure envelope in the M-N interaction diagram is shown in Figure 6 and Figure 7 together with the calculated sectional forces for the two limit cases

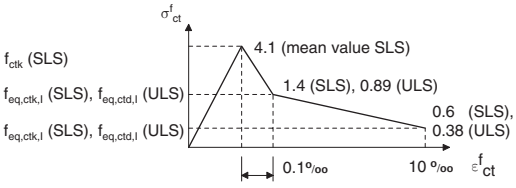

Figure 5. Tensile stress-strain relationship of the SFRC according to laboratory 4-point bending tests.

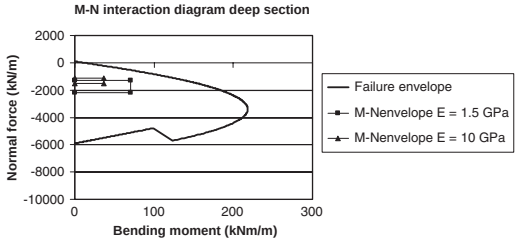

Figure 6. Failure envelope and envelope of the sectional forces for the deepest tunnel section without heating, for the upper and lower bound estimate of the limestone stiffness.

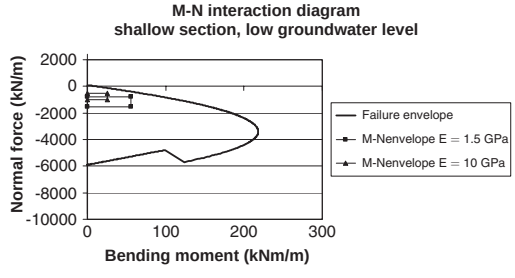

Figure 7. Failure envelope and envelope of the sectional forces for the shallowest tunnel section with low groundwater level, without heating, for the upper and lower bound estimate of the limestone stiffness.

of the deepest and the shallowest section of the tunnel. The ranges of the sectional forces are shown as rectangles, bounded by the lines min N, max N, min M = 0 and max M. The discontinuity of the failure envelope is due to the required higher safety factor of 1.8 for failure of uncracked cross-sections compared to the normal safety factor of 1.5 for failure of cracked cross-sections. It can be observed that without heating of the tunnel the smallest safety margin for the bearing capacity is obtained for the shallowest section with low groundwater level.

The heating of the tunnel leads to an axisymmetric temperature and, consequently, thermally induced strain and stress distribution and has therefore been analysed with an axisymmetric thermo-mechanical numerical model. The model contains the lining, the

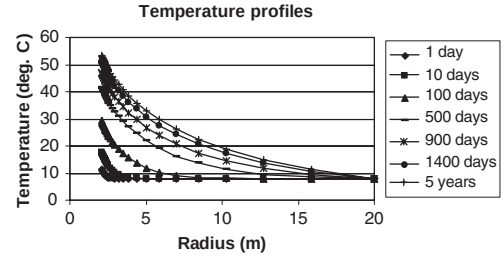

Figure 8. Computed axisymmetric temperature profiles in the lining, grout and limestone at different points in time. The steady state is reached after approximately 5 years.

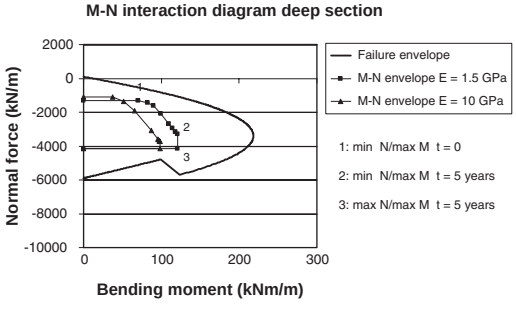

Figure 9. Failure envelope and envelope of the sectional forces for the deepest tunnel section including heating, for the upper and lower bound estimate of the limestone stiffness.

grout and the limestone and considers a constant heat flux on the inside of the lining of 19.7 W/m^2 in the SLS (totally 261 W/m, cp. Matlok et al. 2005). The initial temperature is assumed to be 8 °C in all materials and is assumed to remain unchanged at a distance of 20 m. For the mechanical plane-strain analysis, the displacements are fixed at a distance of 20 m. Figure 8 shows the evolution of the temperatures due to heating of the tunnel. The steady state is reached after approximately 5 years with a temperature of 53.3 °C on the inside of the lining and 49.4 °C on the outside of the lining. For the verification of the bearing capacity of the lining (ULS), a heat flux of $1.35 \times 19.7 = 26.6$ W/m^2 is applied resulting in steady-state temperatures of 66.1°C on the inside and 60.8°C on the outside of the lining.

The temperature induced sectional forces in the lining are obtained by integration of the computed tangential stresses and are added to the sectional forces without heating of the tunnel. The result is shown for the deepest section of the tunnel in Figure 9. The temperature increase causes a considerable increase of the normal force in the lining ring. Due to the temperature gradient over the lining thickness and the lipping tolerance the bending moment increases as well. Only the deepest section is shown as it is obvious that this gives the most critical sectional forces after heating.

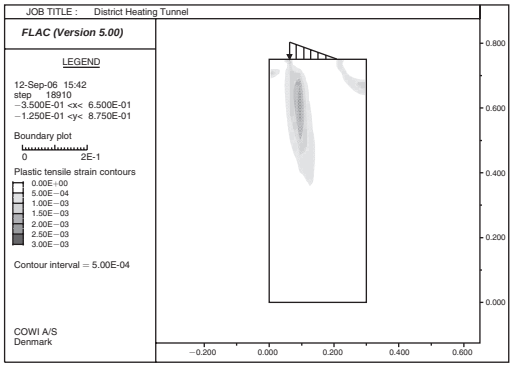

Figure 10. Computed plastic tensile strains (cracking) at the radial joints based on $f_{eq,ctd,I} = 0.89$ MPa (ULS).

The concentrated transfer of the sectional forces at the radial joints through the 152 mm wide contact area (cp. Figure 2) leads to bursting stresses in the vicinity of the joints. The most onerous sectional forces (M = 121 kNm/m and N = 4141 kN/m (ULS) and M = 90 kNm/m and N = 3074 kN/m (SLS)) have been transformed into an equivalent triangular contact pressure distribution and have been applied in a 2D-plane strain numerical model as shown in Figure 10.

Although the formation of a larger crack is observed in the ULS the predicted strain level in the crack of about 2 ‰ is small (cp. Figure 5). It is concluded that the cracks do not represent a critical failure state and that the integrity of the structure can be maintained by the steel fibres. In an SLS computation, no cracking is predicted as the bursting stresses remain below the mean characteristic tensile strength of 4.1 MPa.

3 DURABILITY DESIGN OF THE SEGMENTAL TUNNEL LINING

The client has required that the tunnel shall be designed to satisfy a service life of 100 years, where the structure should not require major maintenance and repair. The elevated temperature in combination with the aggressiveness of the environmental exposure requires special attention. The tunnel is located in salty water, mainly close to the harbour with chloride contents of 1–1.5%. Due to this, the most critical deterioration process in case of traditionally reinforced segments would be chloride induced reinforcement corrosion which, for structures in marine environment, would require special measures to guarantee a service life of 100 years (end of service life is usually defined by the start of reinforcement corrosion). In the present case, the situation is even more serious due to the increased temperature, as the temperature level is decisive for the rate of transporting aggressive substances such as chlorides into and within the concrete. All chemical and electro-chemical reactions are accelerated by an increase in temperature. According to a simple rule of thumb an increase in temperature by 10°C causes a doubling of the rate of reaction. In the present case the temperature is approx. 40°C higher than in usual, bored tunnels with approx. 10°C, which will lead to a $4 \times 2 = 8$ times faster ingress of chlorides in the heating tunnel compared to the ingress rate in normal, bored tunnels. In addition, the corrosion process may be accelerated due to the risk of accumulation of chlorides on the internal tunnel surfaces due to evaporative effects. These factors would make it very difficult to design the heating tunnel for a 100 years corrosion free service life when trusting alone on the traditional durability measures such as sufficiently large and sufficiently dense concrete layers. In the present case, the traditional design would require covers of approx. 70-80 mm. These covers would induce a high risk of spalling during handling and installation of the segments (ram thrust forces etc.).

Several research investigations (Raupach et al. 2004, Weydert et al. 1998) have shown a favourable behaviour of steel fibre reinforced concrete with respect to durability. This is due to the fact that the critical chloride content of steel fibre reinforced concrete (so-called threshold value) is much higher than that of normal steel reinforcement, although identical steel compositions are used. Further, the corrosion activity of steel fibre reinforced concrete is limited to surface rusting of some protruding single fibres. Although rust spots near the surface are expected to occur, corrosion will not penetrate deeply as a result of the following reasons in case of uncracked concrete:

- Continuous corrosion between individual fibres is not possible because each fibre is individually embedded in and thus protected by the concrete. Therefore, no electrical conduction occurs which would result in a continuous process (no macrocell corrosion possible).
- Corrosion of fibres will not cause the concrete to spall. The stresses caused by the expansion of the fibre diameter are negligible and do not lead to more damage.

In summary, steel fibre reinforcement instead of steel bar reinforcement has been found to be the best solution to ensure the required durability of the District Heating Tunnel.

4 LABORATORY TESTS AND EXPERIENCES DURING CONSTRUCTION

The following material tests are made:

- Petrography analyses on plan-sections of extracted cores to investigate the distribution of the fibres in

the hardened concrete. In the beginning, the distribution of the fibres was not always as homogenous as desirable with some higher amounts of fibres in the lower part of the cores. This concrete test has proven to be very useful and almost indispensable, at least during the pre-testing and starting phase of the production.
- Wash-out tests of fresh concrete to determine the amount of fibres. The intention was to find a simple test method which gives a second control of the actual fibre amount in addition to the automatic weighing determination at the mixing plant.
- 4-point bending tests to ensure the required strength properties.
- Splitting tests (Brazilian tests) as additional tensile strength tests.
- Unconfined compressive strength tests to ensure the specified C50/60 concrete class.

About 300 rings have been built so far. The design, the segment production and the construction works appear to be satisfactory as segment damages are limited to 15 visible cracks with wet spots and some irrelevant spalled edges at the bolt pockets and erector cone recesses. Most of the cracks have occurred at the corners of key segments. Only a small number of further minor water leakages have been detected.

5 CONCLUSIONS

The construction works for the District Heating Tunnel in Copenhagen comprise the excavation of three deep shafts, short NATM caverns and 3.9 km of TBM tunnelling in the Copenhagen limestone. Following previous applications in some tunnel projects, the lining for the bored tunnel is made of SFRC segments without conventional steel bar reinforcement. This eliminates the problem of corrosion, ensures the required durability and helps to achieve a cost-efficient segment production as well as an efficient construction with low segment damage rates.

Excavation connecting the underground ventilation station and the underground expressway tunnels

Yoshihito Konishi & Isao Kamegaya
Metropolitan Expressway Company Limited, Tokyo, Japan

Akio Ueda & Yasutaka Imanaka
Obayashi Corporation, Tokyo, Japan

ABSTRACT: Construction of the Nakaochiai Ventilation Station requires the underground connection of the shaft structure and the tunnels. Due to schedule constraints, the entire 50 m-section is to be opened up at the same time, so several countermeasures, such as heavy soldier piles, wedge concrete and soil struts, are adopted for construction. The construction sequence is thoroughly examined and instrumentation of the structures is planned. This paper introduces one successful example of underground ventilation station construction, focusing particularly on the connection between the ventilation station and the tunnels.

1 INTRODUCTION

In recent years, traffic congestion in urban areas has become a major problem as the Japanese population becomes more and more concentrated in large cities. To alleviate traffic congestion, expressways have been constructed in the large cities. The construction of the expressway system in the Tokyo metropolitan area began in the 1960s, but the construction of circular expressways lags far behind the construction of radial expressways, as shown in Fig. 1. When expressway construction started in the 1960s, elevated expressways over the public right-of-way were built to expedite the construction schedule and to minimize the construction cost. However, due to environmental problems and overcrowded ground-level space, plans were made to construct the first underground expressway in Tokyo.

The Central Circular Shinjuku Route is an 11 km-long western section of the Central Circular Route and the first underground expressway in Tokyo, as shown in Fig. 2. The Shinjuku Route is designed as a tunnel structure under the Ring Road No.6, which has an average daily traffic of 18,000 vehicles. One of the problems of underground expressways is the ventilation of exhaust gas. Ventilation stations are being constructed at approximately every 1,500 m. Most of the tunnel sections are built using the shield method, but the ventilation stations are built using a cut-and-cover method above the tunnels. Therefore, connections are made underground between ventilation stations and expressway tunnels, and new techniques will be developed to accommodate underground construction of expressways, such as underground tunnel enlargement and diversion.

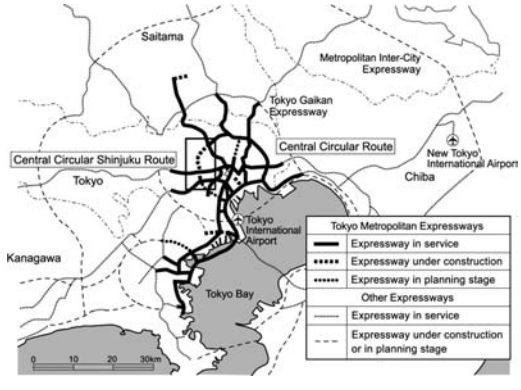

Figure 1. Greater Tokyo Expressway network.

2 DESIGN AND DETAILS OF THE NAKAOCHIAI VENTILATION STATION

The Nakaochiai Ventilation Station is 230 m long, 35 m wide and 22 m deep. The expressway road was built under the ventilation station using the shield method, so the excavation for connecting the ventilation station and the expressway roads reaches a depth of 36 m. Our contract concerns the southern 130 m of

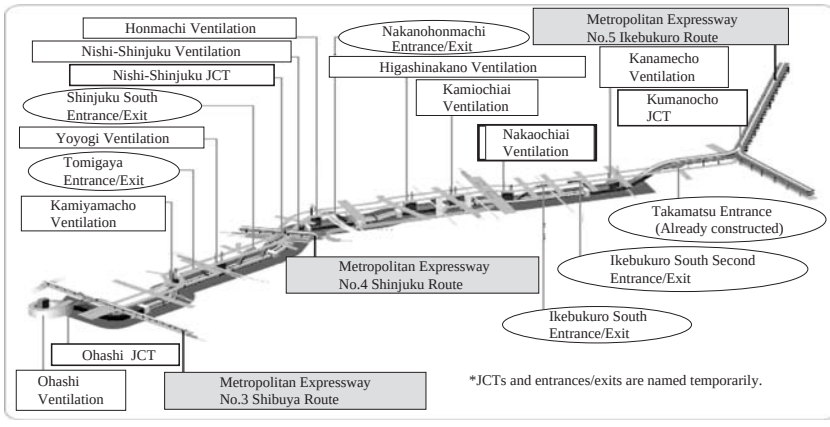

Figure 2. Over view of the Central Circular shinjuku.

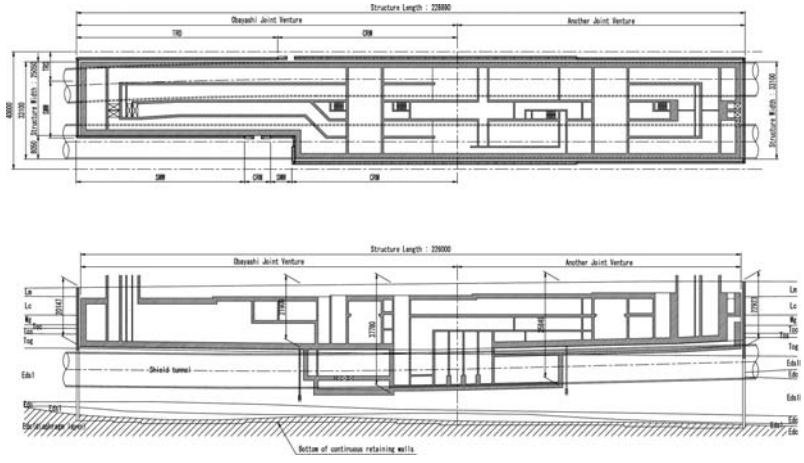

Figure 3. Plan view and longitudinal view of the ventilation station.

the station structure construction. The shaft, which will provide a connection to the tunnels, is 8.1 m wide, 50 m long and between 35 m to 37 m below the ground.

The ventilation station is built in stable diluvial strata. There is a layer of Kanto loam and clay from the surface to a depth of 10 m, followed by a layer of Musashino gravel and Tokyo gravel to a depth of 22 m. The ground underneath the Tokyo gravel layer is the 1st Edogawa sand layer, which is stable diluvial sand, and its N value is more than 100. The 1st Edogawa clay layer lies under the 1st Edogawa sand layer.

The underground water level is about 10m from the surface, which is approximately at the top of the Musashino gravel layer. The Tokyo gravel layer and the 1st Edogawa sand layer both have artesian ground water. When an earth retaining system was designed for the Nakaochiai Ventilation Station, a continuous retaining wall was adopted to prevent adverse effects on the surrounding area by dewatering. Therefore, the retaining wall extends to the 1st Edogawa clay layer, which is about 46 m below the surface.

The wall in the standard section consists of H-488×300 steel piles at 600 mm spacing. In the section where excavation is 36 m deep for connection to the tunnels, H-900×300 steel piles were used at 450 mm spacing, because no ground resistance was expected where the section between the two tunnels was excavated. The plan view and the longitudinal view of the ventilation station are shown in Fig. 3. The cross-sections are shown in Figs. 4 and 5. The Continuous Walls Using Recycled Mud (CRM) method, a kind of slurry wall method in which a horizontal multi-axis

cutting wheel excavator is used, was adopted for a slurry wall where H-900 × 300 steel piles were used. The size of the element, which is 1,100 mm wide and 3,200 mm long, is the same as for a conventional slurry wall. The quantities of the major work items are shown in Table 1.

3 FORESEEABLE DIFFICULTIES AND CONSTRUCTION SEQUENCE OF THE VENTILATION STATION

3.1 *Foreseeable problems with the ventilation station construction*

Due to schedule constraints, the entire ventilation station structure could not be completed before the shields came through, so the ventilation shaft and the connection work could begin only after the shields passed through the station area. The completion of the expressway has long been awaited and the opening date for the public has been set. Accordingly, every effort to expedite the construction schedule had to be implemented. The construction sequence was planned in order to minimize the work remaining after the shields passed through, and all necessary preparation work was planned as well as possible before the shields came through. Only excavation and concrete placement of the shaft and the connection area were planned after the shields passed through, and the ventilation station structure, shaft construction, and connection had to be conducted concurrently. Connection is usually performed by dividing the entire area into several sections and completing the excavation and concreting of each section before moving on to the next section. However, due to the schedule constraints, the entire length of the connection section between the shaft and the tunnels had to be excavated at the same time.

3.2 *Planned construction sequence*

The following measures were planned to expedite the completion of the entire project.

(1) The slurry wall was extended to the impermeable clay layer so that all shaft and connection work could be done in dry conditions.
(2) Heavy H piles (H900 × 300 × 16/28@450 mm) were used for soldier piles so that the retaining wall was strong enough to be supported between the base slab of the ventilation station structure and the ground underneath the tunnels. These heavy soldier piles were adopted so that no passive earth pressure inside the soldier piles between the base slab of the station structure and the ground under the tunnels was measured.
(3) The ground underneath the tunnels had to be consolidated by jet grouting to form soil struts.
(4) When the shaft was excavated to the top of the tunnels, the upper arches of the tunnels were secured at the top to prevent lateral movement of the tunnels and to secure the ground between tunnels and the base slab of the ventilation station structure.
(5) The shaft structure was concreted before excavation between the shaft and tunnels began.

(6) Though the segmental rings at the ventilation openings were cut, the main beams were not cut as long as possible. The connection of the segments and the shaft structure was designed as a pin connection. Stiffeners and gusset plates were welded to the main beams where they come into contact with the concrete to secure the bearing capacity, and the axial loads of the segmental rings were transferred to the shaft structure. The details of the connection are shown in Fig. 6.

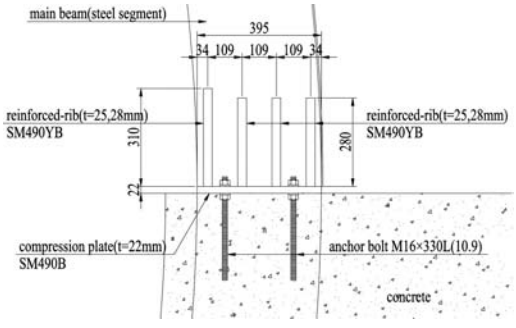

Figure 6. Details of the connection of the segment.

3.3 *The construction sequence*

The construction sequence is shown in Fig. 7.

Step 1: The struts for reinforcement of the tunnel linings were installed in the tunnels by tunnel contractors. The shaft was excavated approximately to the spring line of the tunnels and the pipe roofing was put into place. Steel pipes 87.6 mm and 114.3 mm in diameter were used for the pipe roofing. Then, the ground between

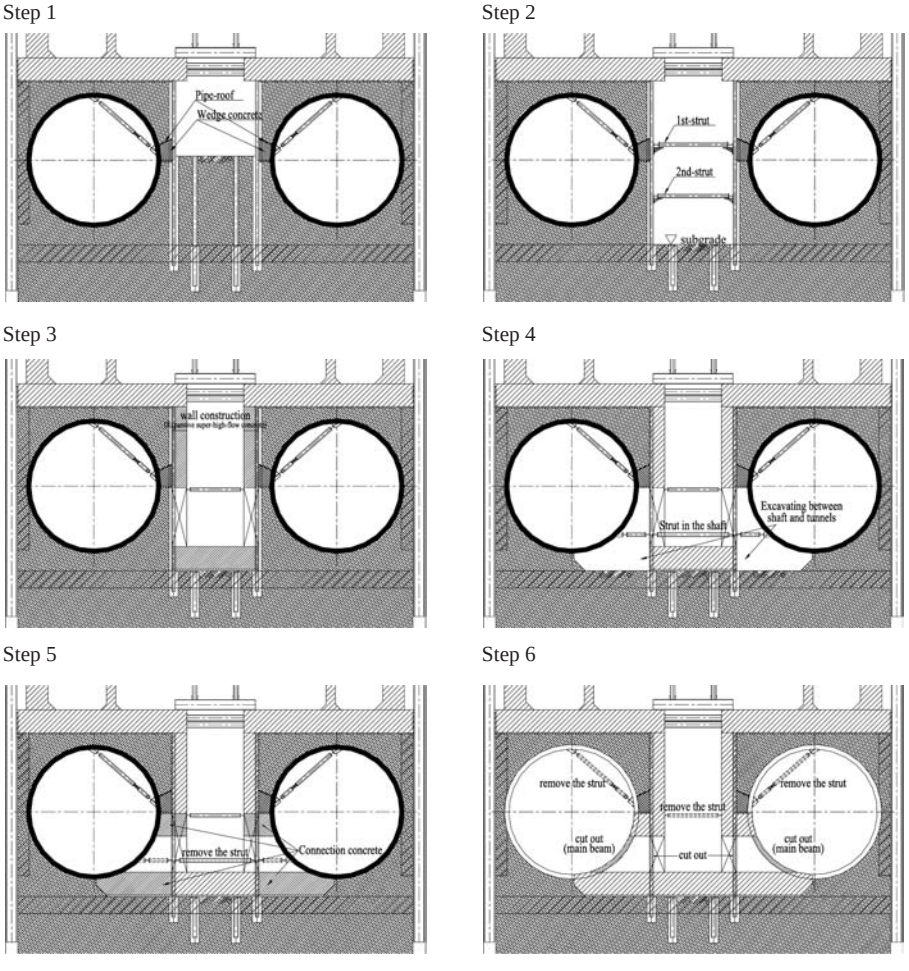

Figure 7. Construction sequence.

the shaft and the tunnels was excavated and the opening was filled with structural concrete, which prevented the lateral movement of the tunnels and secured the ground between the base slab of the station structure and the tunnels.

Step 2: The shaft was excavated to the bottom. Deformation of the soldier piles in the outside retaining wall was monitored by inclinometers, and the load cells were installed on the struts in the shaft excavation to monitor the axial loads.

Step 3: To secure the rigidity of the shaft structure, the concrete of the shaft structure was placed before the ground between the shaft and the tunnels was excavated.

Step 4: The ground between the shaft and the tunnels was excavated, while deformation and displacement of the tunnels and loads on the struts in the shaft was carefully monitored.

Step 5: When excavation was complete and the tunnels were exposed, the skin of the segments was cut out. The ribs and main beams were kept intact until the connection concrete was complete. The base slab of the connection was poured and then rest of the connection structure was completed. Bearing plates and gusset plates were welded to the main beams of the segments and embedded into the concrete.

Step 6: The main beams of the segments were cut out and struts inside the tunnels and the shaft were removed.

Since a wide area was open at the same time on both tunnels, deformation of the tunnels and stress of the shaft concrete and struts were measured. The following measurements were taken while the shaft and connection work was being conducted.

(1) Measurements of the tunnel's inner diameter
(2) Movement of the segmental lining
(3) Strain on the segmental lining
(4) Stress on the reinforcing bars of the connection structure
(5) Load on the struts inside the shaft

4 CONSTRUCTION RESULTS

4.1 *Installation of the pipe roof and placing the support concrete (wedge concrete)*

The pipe roof had to be put into place via the shaft, which was only 8 m wide, and excavation to the tunnels had to be performed by hand because of limited space.

Photo 1. Construction of wedge concrete.

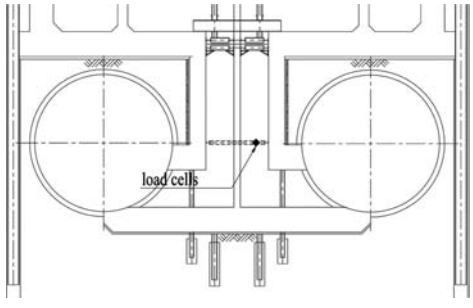

Figure 8. Location of the load cells on the struts.

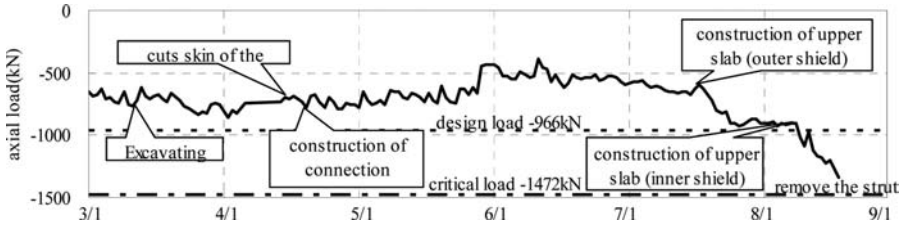
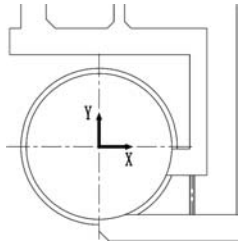
The ground was hard, so the work was very time consuming and tough, as shown in Photo 1. However, this wedge concrete contributed significantly to the stability of the ground between the base slab of the station and the tunnels and to the stability of the segmental linings against lateral displacement. No detrimental movement was detected during the shaft construction, even though the entire 50 m-section was opened at the same time.

4.2 *Measurement of the load on the struts in the shaft*

After the shaft concrete was placed, the struts for the shaft excavation were replaced with new ones in the shaft structure and the axial load was monitored by load cells. The locations of the load cells are shown in Fig.8. Judging from the measurement results, which are shown in Fig.9, little change in the axial load on the struts was detected until the upper slab of the connection section was poured. It is believed that the expansion pressure of the non-shrink concrete, which was used on the upper slab due to its workability, may have caused the increase in axial load. The axial load far exceeds the design value, but it is still less than the maximum capacity of the concrete, and no major cracks were detected in the concrete either.





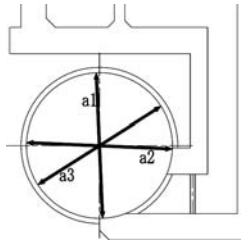


Figure 9. Measurement records of the load cells on the struts.

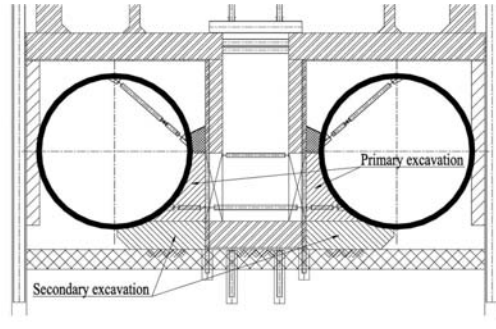
a) Measurement of displacement



b) Measurement of deformation

Figure 10. Displacement and deformation measuring.

Table 2. Maximum displacement and deformation of the segmental linings.

Construction step	X (mm)	Y (mm)	a1 (mm)	a2 (mm)	a3 (mm)
Primary excavating	7	−3	−14	18	5
Secondary excavating	7	−13	−20	9	5

4.3 *Displacement and deformation of the segmental lining*

Once a day during excavation and once a week when concrete work was being conducted, the movement of the segments was measured using an automatic theodolite, while the deformation of the segmental lining was measured by an inner diameter-measuring device that uses lasers. The measurement locations are shown in Fig.10. The maximum deformation values in each stage are tabularized in Table 2. When the first stage of the excavation was completed, lateral movement was shown to have occurred, but the vertical movement was small because the bottom area of the segments had not been excavated. At the second stage of the excavation, the ground under the segments was excavated and 13 mm of settlement was recorded.

Photo 2. Excavation at the base slab of connection by a small backhoe.

Photo 3. Hand excavation under the segment.

Photo 4. Cutting out the skin of the segment.

As for the inside diameter of the segmental linings, the vertical diameter became smaller and the horizontal diameter grew larger as the excavation between the shaft and the tunnels proceeded. This tendency and the magnitude were within the expected range and no ill-effects were observed on the permanent structures.

Photos 2, 3 and 4 show the connection construction.

5 CONCLUSION

Due to the great challenge posed by the tight schedule, additional measures, such as installation of the wedge concrete and soil struts, were implemented. This was the first attempt to construct the entire 50 m section of the connection between the shields and the shaft at the same time. The field work was conducted carefully while measurements of the instrumentation were evaluated to ensure that the construction process proceeded as designed. Because the working area was relatively confined, work had to be performed by hand in many places, which could have resulted in schedule delays if it had not been planned in advance. The entire work of the shaft and the connection construction was completed as scheduled and without any major problems.

Construction plans vary according local geology and conditions, so foreseeable problems need to be investigated as much as possible in advance and necessary countermeasures must be prepared before construction starts.

Since underground connection work will become increasingly required in the future, this paper may help to assist in the planning of such work.

Prague – Beroun, new railway connection

D. Krása, J. Růžička & O. Hasík
METROPROJEKT Praha, Prague, The Czech Republic

ABSTRACT: A large investment, the modernisation of railway corridors, has been under way in the Czech Republic for approximately 10 years. The preparation of the modernisation of the Third Railway Corridor, leading from Prague through Plzen and Cheb to Germany, has progressed to an advanced stage. This corridor also includes the Prague – Beroun section. The existing route, which is 39 km long, currently leads through the valley of river Berounka. The design documentation for the reconstruction of this route following the existing route was prepared first. However, given the parameters required to be met by a design for a modernised railway corridor, the horizontal alignment of this route is very problematic in terms of the track speed, the direct interference with the Protected Landscape Area of Ceský Kras, and the problems stemming from the route passage through a densely populated area. This route modernisation would require large investment without achieving the expected improvement of the track parameters. This gave rise to the idea of a qualitatively different option of delineation of the route from Prague to Beroun. A new Prague – Beroun railway connection will be built to meet the high-speed track parameters, with the speed up to 300 km/h. Given the character of the landscape, the new route, with the total length of 28 km, mostly leads through a tunnel, approximately 24,7 km long, with the longitudinal gradients about 5‰.

1 THE EXISTING CONDITION

The route of the western part of the Transit Corridor III from Prague to Beroun, which is the route heading toward Plzeň and the border with Germany, leads along the densely developed Berounka River valley, and directly touches the Protected Landscape Area of Český Kras (Bohemian Karst).

The horizontal alignment contains sections with maximum design speed of 80 km/h. It was proven during the work on the draft design for the optimisation of this section that modification of the existing alignment was virtually unfeasible and, in addition, the investment would not result in the expected improvement of the parameters of the track. For those reasons the decision was made to seek a new solution that would follow parameters required for a high-speed railway track.

2 THE NEW DESIGN

A new solution to the western part of the Railway Transit Corridor III, the section Prague – Plzeň – state border, was approved by the Government in July 2005. This section is considered as a priority for it is part of the Corridor IV of the European network of main railway lines (AG-TC – C40), (AGTC – E40) Lvov – Čierná nad Tisou – Žilina – Ostrava – Olomouc – Prague – Plzeň – Frankfurt – Paris.

Given the terrain configuration, the newly designed route is 28 km-long, with a major part of its length (approximately 24.7 km) passing through a tunnel to be driven on a minimum longitudinal gradient of 5‰, under an overburden higher than 100 m. Obviously, given the anticipated length of the tunnels, the choice of dimensions of the tunnel clearance will also play an important role.

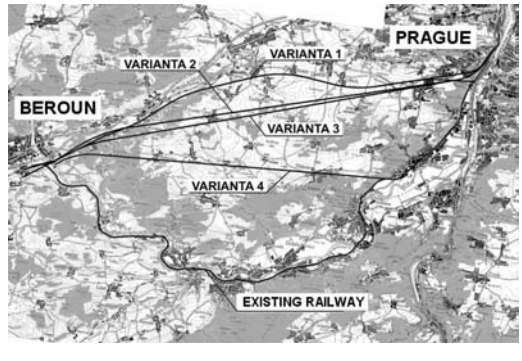

Figure 1. Variants of the route.

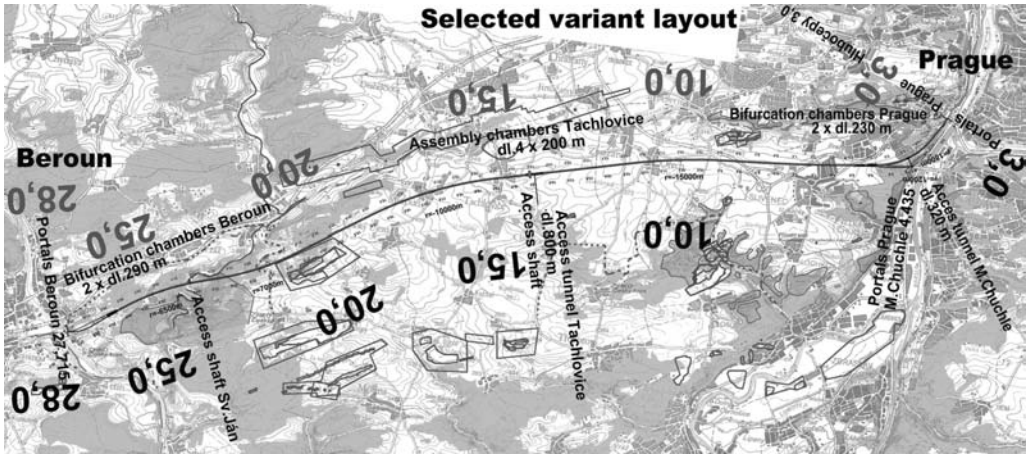

Figure 2. Selected variant layout.

The existing route, leading through the Berounka River valley, will remain without modernisation, only subjected to common maintenance, to serve the dense commuter traffic and as a by-pass route.

The studies which were submitted were assessed on the basis of a risk analysis. The most suitable solution was used as a basis for preparation of the design documentation for issuance of the zoning and planning decision, which is currently underway.

3 THE RISK ANALYSIS AND THE DOCUMENTED SELECTION OF VARIANTS

The risk analysis was carried out in the initial phase of the designing process. Naturally, it did not bring surprising results because the hazards defined at the beginning of the analysed progressions of segments of sources and concurrences are easily foreseeable even without any analysis. However, the risk analysis provides a consistent image of the entire design, not only of isolated parts. The particular risks, including their assessment, were processed in a tabular form.

The result of the risk analysis is a source of recommendations for the owner, designer and others, which are aimed at minimising the design risks. The recommendations cover the risk management, insurance, bank guarantees, dispute prevention and contract procurement.

As required by the order, the designer developed several variants of the possible design approach to the new railway link to be assessed. They consisted primarily of various variants of the alignment and variants of cross sections with various sizes and configurations. The route started at the Prague-Smíchov railway station, and ended in the Berounka River valley, on the edge of Beroun. The variants of the alignment differed in the end section found on the edge of Prague, in the location of the Prague portals, and in the vertical arrangement.

The alignment and configuration of the cross section which were selected on the basis of the risk analysis should meet the highest of all the requirements for basic design parameters, feasibility, safety and overall economy.

The most differing variants of the alignment are shown in Fig. 1; the selected variant is marked with No. 1. The following aspects were taken into consideration in the process of selection: the location of tunnel portals in relation to residential areas; conflicts of interest; passage through conservation areas; outlets to the surface in conservation areas; the possibility of achieving the design speed of 300 km/h; separation of the new high-speed railway line from the existing track; a necessity for modification of the existing track; a possibility for gradeseparated crossings of the two opposing traffic directions in the case of branching off; geotechnical conditions along the route in relation to the construction technique; problems associated with alteration of rock types; occurrence of karst phenomena and caverns during the course of the excavation; passage through a deposit area or its reservation; existing buildings above the tunnel; requirements for ventilation during the excavation and operation; feasibility of establishing site facilities; feasibility of the construction in terms of time; possibility of rail haulage of spoil; road haulage; spoil disposal; the tunnel length-cost relationship.

4 THE MAIN DESIGN PRINCIPLES

Apart from the basic order to connect Prague with Beroun by a double-rail line, the following main principles were sat out to be met:

4.1 *Feasibility*

The railway line will run through a pair of single-track tunnels, each 24.7 km long, according to the map No. 2 enclosed. The alignment must allow the travel at the speed of 300 km/h in the future.

The track will carry freight traffic and passenger traffic. For that reason the track must be split into two directions in Prague: passenger traffic to lead to the Smíchov station and freight traffic to the Krč station.

On the Beroun side, the possibility for the high-speed line to continue past the city as well as to branch off to the station in the city must be maintained. However, only the tunnels to the Beroun station will be built.

The horizontal alignment conditions do not allow branching off in the open-air track, the only branching possible is that in the tunnel.

The longitudinal gradient of the tunnel is 5‰ uphill from the portals to the mid point of the tunnel. The gradient changes at the grade-separated intersections.

The open-air route adjacent to the portals has not been designed to pass through residential areas so that the process of construction approval is not threatened by negotiations with the public, and a possibility of a conflict of interest with owners of existing properties is minimised. The areas for temporary site facilities were designed with the same attitude. The access to the tunnel is at chainages km 4.5 and 14.5 via two access adits and at chainages km 14.5 and 24.0 via two shafts.

The originally designed short at-grade section of the track near the village of Sv. Jan pod Skalou, which is also found in a conservation area, was also located underground as a result of forewarning of problems with the negotiation.

The tunnel will be driven by a TBM, with the sections between the portal and the branching off points excavated using traditional tunnelling methods. The profile of the tunnels is enlarged at the branching off locations and at the access adits connection points.

4.2 *Safety aspects*

The pair of single-track tunnels with separate portals is the basis of the safety concept. The tunnels are interconnected by cross passages every 400 m. This is how safe escape of persons from any point of the tunnel is ensured.

Dangerous contra-flow travels at the branching-off points have been eliminated by designing grade-separated intersections.

Access to the technical services centres are possible from the surface, therefore closing of the line in the tunnel to traffic is not necessary.

The ventilation system has been designed with respect to the needs for maintenance, contingent emergencies and a fire.

State-of-the-art equipment, which provides safety at the world's highest level, has been designed for the tunnels.

4.3 *Service life*

The structure has been designed for a minimum service life of 100 years. It will be solved so that optimum conditions for a long service life of the tunnel and equipment is secured in the way of which we have experience from Prague Metro. The tunnels and equipment rooms will be dry, ventilated and with relatively constant temperature.

4.4 *Environmental aspects*

The in the past completed tunnel structures have persuaded us that a continuous aquifer exists even in the relatively impervious Ordovician shales of the Prague Basin, up to the level of the tunnel at a depth of 100 m. Similarly, it was determined by measurements that the water table returned back nearly to the original level when the construction of a perfectly watertight tunnel had been finished. For that reason a waterproof lining around the entire circumference, the so-called 'submarine' type, has been designed for the tunnels on the new railway link between Prague and Beroun. This design, which does not require removal of groundwater by underground drains, eliminates permanent decline of water table and origination of dead wells or dry woods. It is very environmentally friendly a solution, which guarantees that the natural water regime will be restored.

5 ECONOMIC TUNNEL CROSS-SECTION AND SINGLE-TRACK TUNNELS THROUGHOUT THE ROUTE

The completed studies took into consideration variants with variously differing cross section sizes. The difference between the economic cross-section area and the large area which is assumed in German Railways' regulations amounts to 25%, which means a difference of about 6.5 billion CZK in terms of the cost.

The opposing traffic flows have been thoroughly segregated owing to the grade-separated design of crossings with the branching off tracks. The unfavourable effect of the pressure wave on passengers in common trains travelling in opposing directions will not, therefore, be experienced. The internal space of high-speed trains is sealed so that passengers are protected against these unfavourable effects.

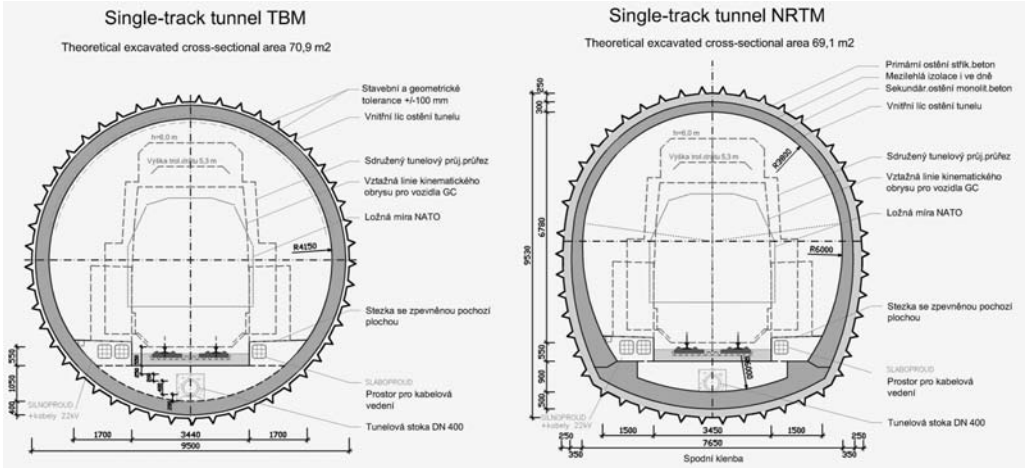

Figure 3. The typical driven tunnel cross-sections.

The above-mentioned measure allowed the owner to choose the economic cross-section. At the same time, the owner decided that the two tunnel tubes would be constructed simultaneously. The fact that a complete double-track railway line will be operated from the very beginning is a great benefit for quality and safety of the traffic. Regarding the environmental impact, the construction site surroundings will be inconvenienced for as short time as possible. Naturally, the total project cost is lowest when the construction programme is not divided into stages.

6 GEOLOGICAL CONDITIONS

Geological conditions are one of the main factors in terms of selection of the alignment. The tunnel route keeps clear of areas with mineral deposits and undermined areas.

The railway line passes through the Early Palaeozoic area forming the central part of the Barrandiene Member. The Palaeozoic rock layers rest unconformably on the basement formed by Proterozoic rock, which was folded during the Cadomian orogeny. The overall knowledge of this area is high, but, for example, a state-of-the-art survey of the tectonic pattern is missing and information from great depths is scarce.

The core of the Barrandiene Basin in Prague consists of a sequence of strata of Ordovician and Devonian sediments and volcanites. The rocks were folded during the Varisan orogeny and disturbed by transverse and longitudinal fault tectonics.

The western part of the tunnel passes through Ordovician rock, i.e. silty shale, siltstone and through quartzite of the Kosov Member, and Silurian rock types. The Silurian rock types are represented by graptolitic shale and marl slate. Shale and claystone prevail and frequent diabase intercalations occur in the lower part of the Silurian strata. The Upper Silurian rock mass contains larger proportion of limestone. It is characterised by a high degree of facies variability, frequent alternation of shale, various types of limestone and volcanic products disturbed by thrust faults.

The carbonate evolution following from the Silurian basement prevails in the Devonian strata in the eastern part of the tunnel. The Lochkov Member contains the Radotín and Kotýz limestone facies. A limestone sequence (Loděnice, Slivenec, Řeporyje, Koněprusy) can be distinguished in the Prague Member. The Zlíchov Member consists of grey, bedded limestone with hornstone. Significant karstification must be expected in the Devonian limestone. The current degree of knowledge obtained by surveys allows us to determine the border of possible karstification in the map with an accuracy of about 100 m. This border runs from the southern edge of Prague-Radlice through Ořech, past the southern edge of Tachlovice to Sv. Jan pod Skalou. According to the results of an information search based on long-term karstological surveys of the Bohemian Karst, it is impossible to determine the depth of a zone which would be beyond the karstification reach. Conversely, manifestations of karstification are expectable throughout the depth of the limestone bodies, which are affected by folding to the depth of about 100 m. It has been ascertained that the occurrence of karst phenomena, tapping of karst cavities, water irruptions etc. are a source of serious risks and threats for mechanical excavation using TBMs.

North of this border, the possibility of occurrence of karst cavities can be completely excluded. The Dalejské Valley Shale is characterised by prevalence of greenish, in higher levels even reddish colour. The Srbsko Member consists of siltstone and shale. The thickness may exceed 250 m in synclines.

7 THE EXCAVATION METHOD

7.1 *TBM drives*

A major part of the tunnel, from the bifurcation chambers in Prague to Beroun, will be driven by a large-profile TBM. Most long tunnels in the world have been driven by TBMs. It is so for the following reasons:

Faster advance rate compared to traditional methods. The shorter construction time means less uncertainties for the owner and the tunnel is cheaper.

The equipment is ever more perfect after the numbers of tunnels driven mechanically in the world. They are capable of coping with mixed geological conditions.

Mechanical excavation is safer; workers do not get into contact with rock and cannot be injured by collapsing rock mass.

Mechanical excavation allows accurate control over the excavated volume; at the same time, it does not disturb the surroundings of the excavation by blasting operations, thus overexcavation is avoided, cavities do not originate behind the lining and settlement of the surface is minimised. This is advantageous when residential areas are being passed under.

The circular profile of the tunnel is the most advantageous in terms of structural analysis, thus the safest at an adequate cost.

With respect to the anticipation that stretches with relatively low hardness of the rock mass will be passed through, the TBM type which has been chosen is not equipped with grippers. This means that the TBM-driven tunnel will have a single-shell segmental lining consisting of reinforced concrete segments, which will provide support to the thrust cylinders propelling the TBM. The lining segments will be made of water retaining concrete; they will be provided with sealing gaskets on all sides, thus the lining will be waterproof.

7.2 *Traditional NATM excavation*

The NATM will be utilised for the excavation of the single-track tunnels which starting at the Prague portals in Hlubočepy and Malá Chuchle and continue up to the bifurcation chambers, for the bifurcation chambers at Prague and Beroun, the access adits and shafts, assembly chambers, cross passages and equipment rooms. There are the following explicit reasons for this decision:

Frequent changes in the shape of the cross section (each of the above-mentioned openings has a different shape).

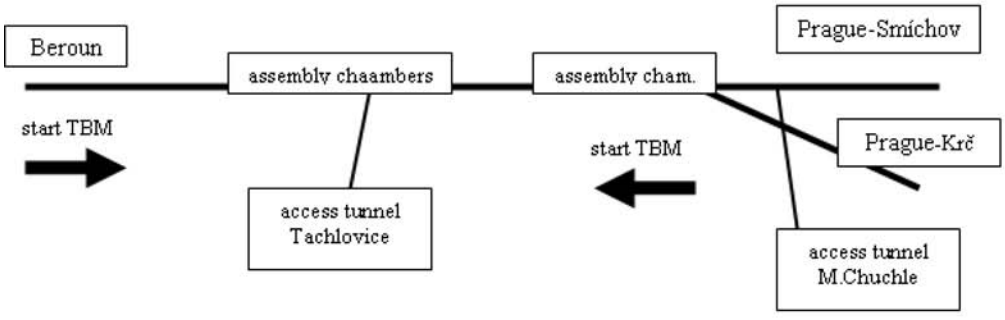
The NATM-excavated parts are enabling works for preparation of the TBM sets and access adits and shafts.

The majority of karst phenomena which will be encountered in the Prague area are much easier for the NATM to overcome. The access adit in Malá Chuchle or other works may even be utilised for geological exploration purposes.

The NATM excavated works, e.g. the access adits and assembly chambers, can be carried out in advance of the TBM excavation or concurrently with it; it will result in reduction of the construction time.

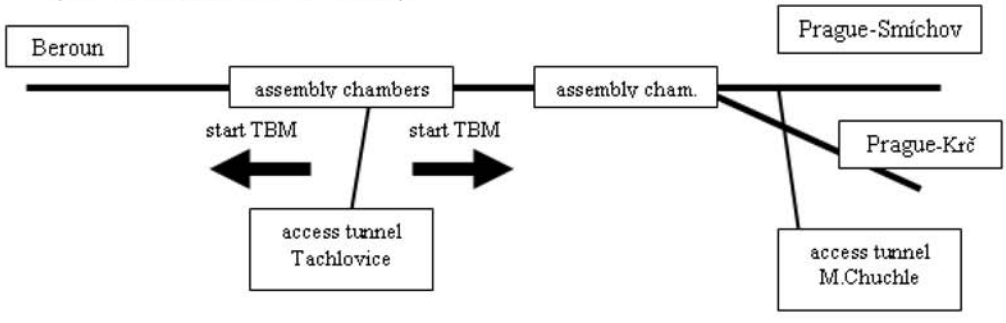
The NATM-excavated tunnel lining structure will consist of a sprayed concrete primary liner, intermediate waterproofing and cast-in-situ concrete secondary liner. The waterproofing will be of the 'submarine' closed type, covering the entire circumference including the bottom. The secondary lining will have an invert structure throughout the NATM-excavated tunnel length to resist the hydrostatic pressure.

8 THE CONSTRUCTION PROCEDURE AND LOGISTICS



A single TBM would need approximately seven years to drive the about 22 km-long tunnel. This is a too distant horizon. Tunnel cost analyses have shown that over a half of the total cost consists of components dependent on time. The total construction time is therefore a deciding factor. For that reason, two TBMs must work concurrently on the drive of one single-track tunnel tube.

Problems may be encountered during the course of the simultaneous excavation by two TBMs when geological weakness zones are being passed through, which may result in suspension of the drive so that measures improving the rock mass can be implemented. In such a case, the work is much simpler and faster if an auxiliary adit can be driven from one tunnel to the other and the operation be carried out from this adit. Such the situation has already taken place in the world and examples of solutions are known. This is the reason why simultaneous drives of both single-track tunnels must be recommended. This recommendation is supported by the results of the risk analysis.



The excavation procedures possible are presented in the following chart. The duration of the tunnel drives is, according to the programme, about 4 years, the total construction time is 6.5 years.

In the case of volumes of material transfer during excavation of tunnels of so great length there

1. **heading from both portals simultaneously** (logistics cannot be provided on the Prague side)

2. **heading to both sides from the access adit connecting in the middle of the tunnel** (one construction site for TBMs)

3. **heading from the portal and from the access adit in the middle of the tunnel**, in the identical direction

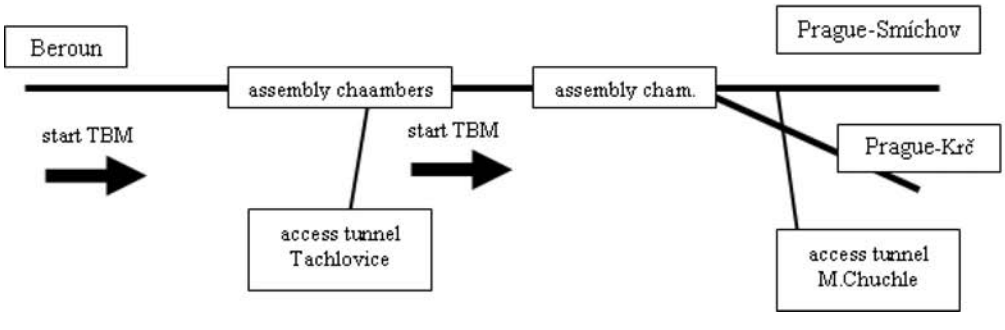


Figure 4. TBM excavation procedures.

is a significant problem associated with logistics, prefabrication and transport of the lining segments, and, primarily, haulage of muck. The design of the areas in front of the access adits and tunnel portals which are necessary for intermediate stockpiles of muck and intermediate storage of the segments allows for the needs; it has been proven that the project is feasible.

Underground high-speed railway – The phenomenon of urbanistic development in Prague

E. Kyllar
METROPROJEKT Praha, Prague, The Czech Republic

ABSTRACT: The Prague subway clearly demonstrates how important the utilization of the underground is for city life. A survey of the development of views about how to organize the basic pillar of the public transportation system. Realization of individual lines and subway stations in the historic section of Prague, in the central city, in the surrounding quarters and in the new suburbs. The transformation of conceptions concerning urban planning from the dominance of automobile traffic to the preference of walk-only zones in city centres. The subway in Prague is one of the crucial factors of urban life and development.

1 INTRODUCTION

After more than thirty years of operation of subway in Prague, we can consider as proven that the underground high-speed railway has besides the basic transport effect also urbanistic significance – city-making. I am going to prove this thesis on an example of several subway stations. Prague has unique specifications in the terrain configuration, geological conditions, but mainly in cultural and historical value of its historical centre, whose total area is almost 900 ha. It has been declared by UNESCO organization as the world cultural heritage for its thousand year's continuity, exceptional well-preservance and integrity and quality of monument sets. This heritage binds for systematic caution and modesty when executing any construction activity and therefore its makers have to deal not only with technical problems.

2 DEVELOPMENT OF OPINIONS ON THE CONCEPTION OF HIGH-SPEED RAILWAY

At the end of 19th century requirements on the transport were increasing with the development of housing. An extensive clearance of the Old Town and Josefov – the Jewish town was carried out, as well as the construction of infrastructure, embankment streets and walls regulating the flow of the Vltava River. Omnipresent construction activity inspired in 1898 Ladislav Rott to propose to use the wide trenches and demolitions for the construction of underground railway (Fig. 1).

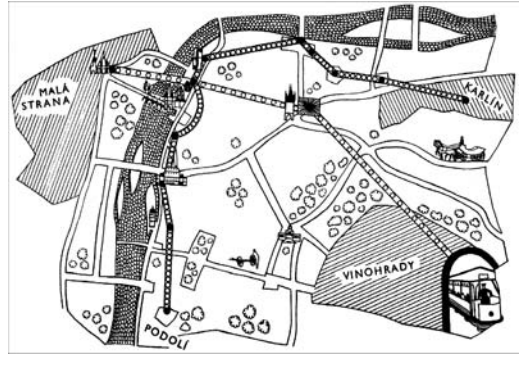

Figure 1. The scheme of Ladislav Rott proposal from 1898.

City technical officer Bohuslav Vondráček proposed in 1912 underground tram railway between Jindřišská str. to the Wenceslas square to Kaprova street. The number of citizens was close to 700 000 after the creation of Czechoslovakia in 1918 and Big Prague in 1922. Jiří Hruša published a proposal in July 1926 to solve the underground high-speed railway by placing it to deeply based tunnels with 3 diametrical lines through the city centre (Fig. 2).

First technically elaborated and complex proposal for the subway system in Prague was a study proposed by *Vladimír List* and *Bohumil Belada* from December 1926, which counted with 4 underground lines (Fig. 3).

A *competition* was announced for the solution of transport in the Big Prague in the year 1930. Results of this competition proved the necessity to introduce

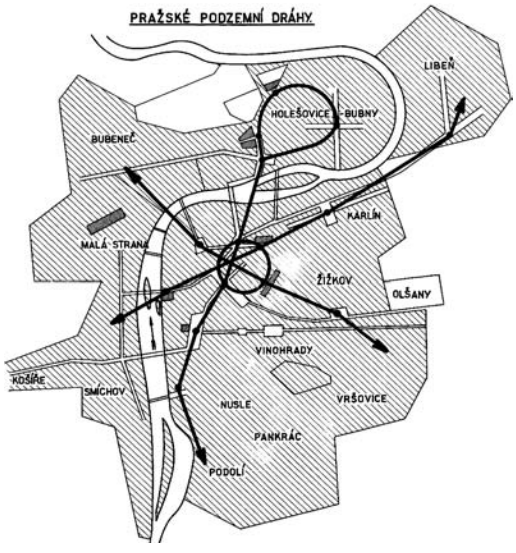

Figure 2. The proposal of Jiří Hruša from 1925.

Figure 3. The proposal of Vladimír List and Bohumil Belada from 1926.

a bearing element into the public transport into the underground.

The study department of municipal Electric companies elaborated in 1938 so called *Project D*, according to which the lines of dominant transport directions through the city centre were supposed to be carried out by cut-and-covered tunnels (Fig. 4).

Project D was rejected and *Konsorcium* of all considered partners for the construction was created. They proposed in 1941 the *Project M* of a classical subway underground railway. They supposed a system with 3 underground lines carried mainly shallowly under the ground with an exception of overcoming the Vltava River. Stations were supposed to be also cut-and-covered with lateral or insular platforms, underground halls and underpasses (Fig. 5).

It was even supposed after the Liberation in years 1946–1947 that it would be possible to begin with the

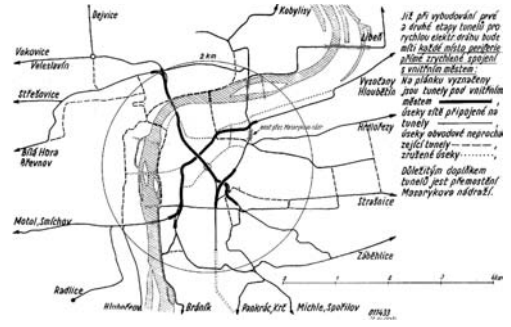

Figure 4. Project "D" from 1939.

Figure 5. Project "M" from 1941.

subway construction in Prague according to the Project M, but it was not possible.

In 50's when the number of inhabitants exceeded 1 million, were elaborated several proposals of territorial plans and also several studies on the solution of subway situation, but they have not succeeded to pass the *Directional master plan* until 1964, whose part was also the solution of public transport with a system of 3 underground lines in the city centre. The system called *Underground tram* (*PPT*). It required extensive groundwork in confined conditions of medieval streets, demolition of historical monument buildings, which evoked big conflicts with city infrastructure. The construction of PPT begun in January 1967 in Opletalova Street, close to the Central Railway Station (Fig. 6).

International expertise rejected project PPT in 1967 and the government then decided that a *classical subway* is going to be constructed in Prague. Projects were reelaborated and the construction was without interruption reoriented from the cut-and- covered tunnels to the bigger proportion of driven works.

3 CURRENT SITUATION IN THE SUBWAY NETWORK IN PRAGUE

There is a majority of railway tunnels between the stations with single or twin-track with stations in the

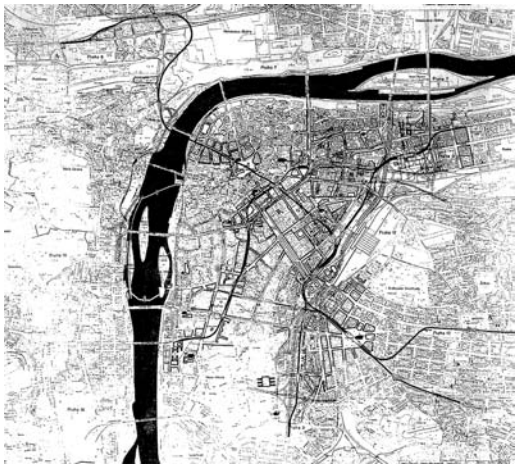

Figure 6. Project of the underground tram from 1964.

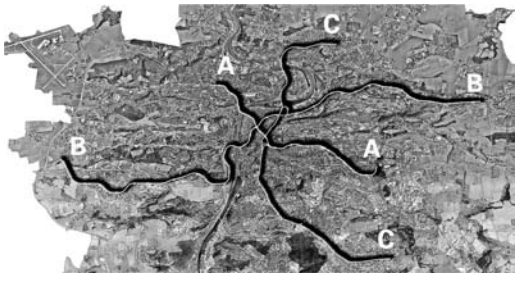

Figure 7. Current situation of Prague subway network.

historical centre and inner town driven and in the outer town cut-and-covered from the surface. All stations except for one are cut-and-covered or surface on the line C (Fig. 7).

An overview of Prague subway network.

Line	Construction length	Stations			
		Driven	c. and c.	Surface	Total
A	10,79	9	3	1	13
B	26,399	13	8	3	24
C	18,77	1	15	1	17
Total	55,959*	23	26	5	54
%		45,6	48,1	9,3	

*from which: 41,5 km driven tunnels = 74%,
13,5 km cut-and-covered tunnels = 24,1%,
1,6 km surface track = 1,9%.

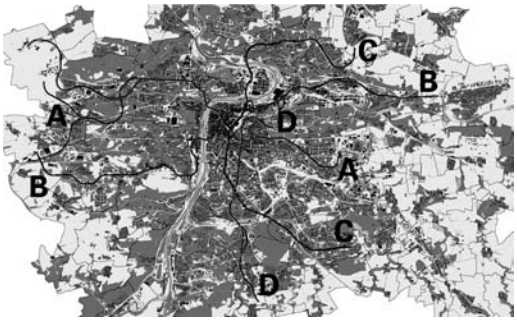

Figure 8. Prague subway network with development intentions.

4 DEVELOPMENT OF SUBWAY NETWORK IN PRAGUE

Subway in Prague is considered as a priority in solving the complete transport problems, because it currently realizes up to 40 % of all transport requirements for the public transport. This proportion is going to even increase by broadening the network. Strengthening the performance of subway is for Prague one of the most effective weapons against clogging of the city areas by car transport and against restricting pedestrian transport mainly in the city centre.

On the *northern end of C line* begun construction of 3 new stations, which are going to be opened in 2008. The construction of *a new 4th line D* is being prepared, from the Central Railway Station through Vršovice, Nusle, Pankrác to Krč, Lhotka and Písnice with the change to all three lines and with extension to the west to Žižkov.

The *extension of line A* westwards should be another extension to the subway network from Dejvice through Veleslavín, Petřiny to the hospital in Motol, to Bílá hora and from here to the airport Ruzyne and with a branch to Řepy and Zličín.

There is prepared turning of the branch on the East from the station Strašnická to Zahradní město and Hostivař and a branch from the station Skalka further on to the industrial area can be executed also (Fig. 8).

The system of Prague subway is fully opened and it allows anywhere and anytime to connect to the current system and to increase the quality of transport service in the city.

5 PRAGUE SUBWAY IN THE HISTORICAL CENTRE

The centre of Prague had a determining influence on the arrangement of subway network and its space solution. Saving majority of railway, stational and escalator parts of tunnels to the underground enables to limit

the intervention to the medieval city only to entrance halls and underpasses. In the area of historical centre is altogether 10 stations, 8 of which are driven and 2 cut-and-covered and 14 shallowly based halls.

Both shallowly based stations on C line, Hlavní nádraží and Muzeum were built in 1974 including their halls on unfinished buildings according to the PPT project.

Hlavní nádraží station – integral part of underground foreground of central railway station, initialized its reconstruction and its finishing to its current appearance (Fig. 9).

A component of the station *Muzeum* on C and A lines is a wide underpass, which provides not only the entrance to both the crossroad station on C and A lines, but also an important connection for the city between Wenceslas square and the area of Vinohrady with the National Museum (Fig. 10).

Figure 9. The central railway station with subway station under the hall in the park.

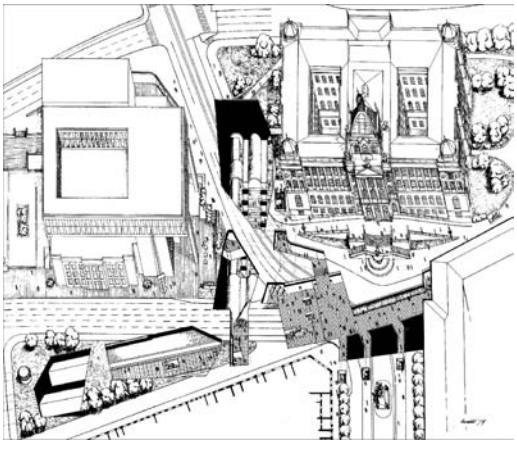

Figure 10. Axonometry of the change point by National Museum.

Malostranská station on A line is the foreground of unique area of Malá Strana with beautiful palaces, gardens and town houses in the area under the Prague Castle. Space solution with deeply based platform limited negative intervention to the valuable organism of the city on several temporary constructions. A surface entrance pavilion and atrium with a garden are a substitute for them. Their surroundings cultivated and brought new quality by enriching the historical heritage (Fig. 11).

Realization of the two stations *Můstek* with changes to line A and B was one of the most demanding in the network of Prague subway (Fig. 12). Station on line A was finished in 1978 and its part is also the underpass to Můstek. Nowadays it is a certain anachronism, but was adequate to the requirements of the times, during

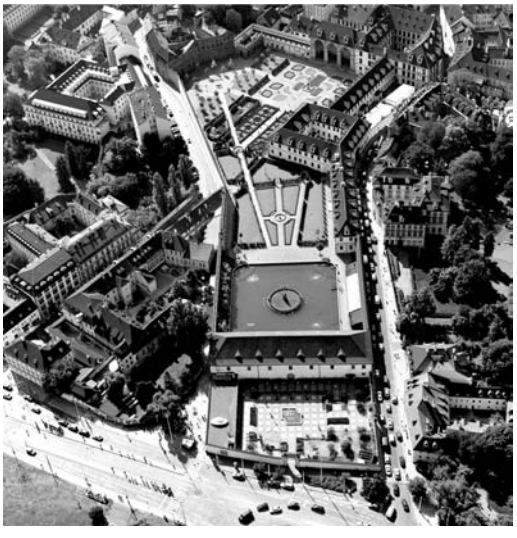

Figure 11. Malostranská station is a part of historical construction.

Figure 12. The diagram of the change point arrangement on Můstek station.

which it was constructed. A huge underground hall and the exit with the underpass to Jungmannovo square was also constructed together with finishing the station on B line in 1985. Shortly before its opening was decided that tram transport here is going to be cancelled and that car traffic is going to be significantly limited and that there is going to be a pedestrian zone. Both underpass areas are used as commercial zones (Fig. 13).

The construction of *Náměstí Republiky* station with deeply based platforms and two escalator tunnels was in the area concentrated on the western hall with the underpass under own square and to eastern hall with underpass to the Masarykovo railway station Free areas were used for their construction without demanding demolitions. Modifications of the parter on the square and foreground of the station were executed together with the construction.

Releasing once unsightly street V Celnici originated conditions for construction of new important hotels and multifunctional buildings in their surrounding, which created new urban cultural area. There is currently a construction of a big multifunctional complex Palladium in the area of former barracks and underpass will become the entrance area to the commercial area (Fig. 14).

Figure 13. Pedestrian zone under the underpass on Můstek station from 1989.

Figure 14. The area over the western hall of Náměstí Republiky station.

6 PRAGUE SUBWAY IN THE INNER CITY

Line C goes from the historical city centre to Pankrác terrace in the tunnel of the Nuselský bridge. On its southern foreground originated unique station Vyšehrad. The bridge was constructed together with the subway construction in 70's of the last century and became a connection of new city areas to the Pankrác plain with the central area. Thanks to this station once deserted place started to change its surroundings to new spacious city dominant with huge composition of Congress centre, hotels, office buildings and houses (Fig. 15).

A new centre grew by the station *Budějovická*. Projects on its construction originated simultaneously with subway projects and became mutually coordinated. The station was originally located on the free area, but a department store and sale gallery were established already during the subway construction. They were able to maintain fixed urbanistic conception for the creation of the centre of Budějovické square up to now and the square with the surrounding sets of offices, commercial buildings and houses is almost complete. This example of usefulness of good planning and coordination deserves to be followed (Fig. 16).

From many localities, where the subway initiated the reconstruction and development of the area, can be presented on the first place the new urban centre Smíchov and surroundings of *Anděl* station. There was still in eighties of the last century a big and old factory in the middle of Smíchov. Unattractive, mixed housing site remained in its surroundings. They managed to substitute in 1985 part of this housing site by surface pavilion of the northern hall together with realization of the subway station. The base of the new centre Smíchov became the Palác Zlatý Anděl, which was creating the new square along the Nádražní Street and originated

Figure 15. The bridgehead of Nuselský bridge with Vyšehrad station.

Figure 16. The Budějovické square with the subway station in the underground.

Figure 17. Centrum Smíchov over the subway station Anděl.

over the reconstructed northern hall (Fig. 17). The Southern hall of the station is placed in the area, around which is being prepared a new construction of urban sets on the currently problematically used areas. In the surroundings of Zlatý anděl gradually originated the centre of commerce, culture, accommodation, alimentation, housing, offices, garages and clubs even in more distant surroundings. Smíchov was really transformed into a modern city and the subway plays a major role.

Figure 18. A commerce centre grew over the subway station Chodov.

Figure 19. A new centre is growing by the hall of Roztyly station.

7 PRAGUE SUBWAY IN THE OUTER CITY

There were two stations on the II. part of C line – realized in almost free area. Both these stations evoked in the end of nineties a huge construction works in the surroundings of business, services, culture, sports and accommodation centres, administration and housing. A huge international technological park and commercial centre Centrum Chodov originated by the Chodov station, which is supposed to be the biggest in the Czech Republic (Fig. 18).

Station *Roztyly*, which was formerly called as the station for rabbits from surrounding forests, is nowadays important terminal for suburban and long-distance bus transport lines, a T-mobile centre was also created here and a big department store. A construction of the centre of a big travel agency, hotel and other buildings is prepared (Fig. 19).

Stations *Stodůlky*, *Luka*, *Lužiny*, *Hůrka* and *Nové Butovice* originated as natural local centres of housing sets on the South-western part of Prague. The preparation of the construction of this outer city began in the area, when it was already decided about the realization of subway in Prague. Authors could therefore create a conception of real *high-speed railway city*, which

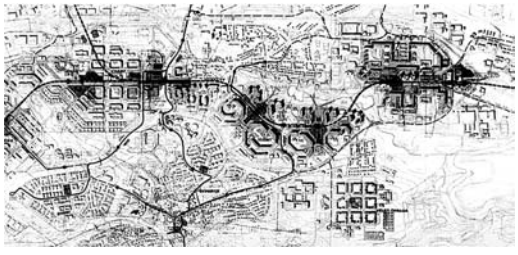

Figure 20. The plan of South-western City with a subway station.

does not have many parallels in the world (Fig. 20). They were successful to coordinate projects of the new residence area with projects for the preparation of subway construction so that a symbiosis of both buildings was created here. The construction of *South-western City* was quicker than the realization of the subway, but areas and corridors in determined localities were prepared for further construction of subway stations and track tunnels. Around stations in all localities were created natural centres for the life of inhabitants of housing complexes. The whole territory of South-western city is thanks to its transport availability in the interest of different, often multinational developers, so that 13. Prague district is the area, where many building of all kinds, importance and size, are constructed. A valuable and attractive city part was created from originally stark block of flats. Subway helped this development to a great extent (Fig. 21).

Rajská zahrada station and its original architectonic solution is inspiration for future. It is not exceptional in terms of traffic, but it is a modern investment to the values, according to which Prague is regarded as a beautiful city (Fig. 22).

Figure 21. South-western City from the East in 2003.

Figure 22. Station Rajská zahrada is an innovation in solution of stations.

Subway in an old town, such as Prague, represents a phenomenon, which helps the city in creation of the environment for its inhabitants, in the development of city's equipment, in using the historical centre and in its protection and preservation and broadening cultural heritage.

Railway line Prague centre – Ruzyně airport

J. Martinec & P. Zobal
METROPROJEKT Praha a.s., Prague, The Czech Republic

ABSTRACT: Prague, the capital of the Czech Republic, still does not have sufficient railway transport capacity serving the city centre and Ruzyně, the international airport in Prague. This should be changed by some 20 km of a new railway line which considerably uses the existing single-track line from Prague to the city of Kladno. In addition to the quick and reliable rail connection between the airport and the capital centre the modernised line will be accompanied with development of architectural and urban centres and important interchanges in the territory. The project comprises several tunnels which cover some 10% of the total length of the line.

1 BASIC IMPORTANCE OF THE RAIL CONNECTION

At present there is not quick, comfortable and especially reliable connection of sufficient capacity between the capital centre and Ruzyně, the international airport in Prague, provided by public transport. The existing bus transport is insufficient and with respect to the expected rise in the air transport volume (at present it is some 11 million passengers a year) it will be inefficient in the future.

From the point of view of a systemic nature it is definitely more suitable for the traffic channels of the airport if the railway transport is used as it removes the disadvantages of the bus transport with its limited capacity and poor travelling standard in general. Major airports in Europe and other countries all over the world are served by railway transport.

It is an advantage that it is possible to use the existing Prague – Kladno railway line, running through stations in Praha Dejvice and Praha Ruzyně. By modernising this line, its current substandard condition will be improved, incl. negative effects elimination such as noise, vibrations and the barrier effect (tunnels and elevated sections, grade-separated intersections). Despite the widening of the line (especially for the reason of doubling of the track) no acquisition of land of greater extent will take place. The new development of the line from Ruzyně station to the end station of Ruzyně Airport runs mostly in the existing traffic corridor (along the Prague ring road).

With respect to the prospective volume of transport when it is possible to expect that as at 2015 some 20,000 passengers will be transported in 24 hours in one direction (METROPROJEKT Praha a.s. 2002–2006), the railway transport is the optimum system as regards capacity.

At the same time the railway system provides a higher travelling standard, preferring seating room, luggage hold, allowing seat booking, etc. – in general it gets closer to the air transport standard. In addition to this the connection between the airport and the capital centre will be quick, regular and reliable.

The modernised railway line will also improve the standard of traffic channels of the biggest city of Central Bohemia and its region. This will be a through train connection without any need to change and therefore it will be competitive in comparison with individual car transport.

2 COMPLEX TRANSPORT RELATIONS, IMPACTS ON THE TERRITORY

The railway transport connection to Praha Ruzyně Airport creates conditions for its natural integration into the PID system and is fully in harmony with the policy of development of the traffic channels of the capital of Prague. The railway connection to the airport is of a radial and central character, the railway line ends right in the city centre, its historical core, Praha Masaryk Station. A possible connection of the airport to the long-distance transport can be dealt with in the future through further development of railway lines in the area of the airport.

The route runs through a highly urbanised area providing good conditions for being directly served and conditions for establishing relations with transports of other types. Nine railway stations and stops will be major traffic junctions and the most important

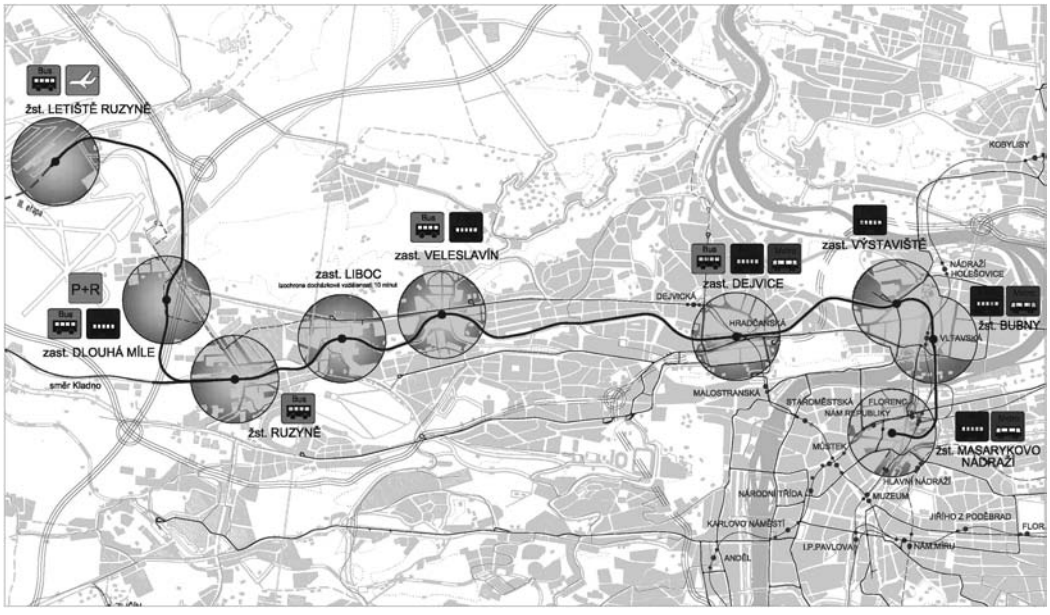

Figure 1. General layout of railway line.

ones – Masaryk Station, Bubny – Vltavská, Dejvice – Hradčanská and Dlouhá Míle – will also be natural architectural and urban centres of the particular locality. This transport connection will also provide an attractive change of all routes of Prague Metro (route A – Hradčanská station, route B – Náměstí Republiky station, route C – Vltavská station). Modernisation of the line will also eliminate all level crossings with the existing road network and thus improve the provision of transport services in the area in general.

3 PARTICULAR STATIONS AND STOPS

The starting point of the route, Praha Masaryk railway station, is situated in the very capital centre, allowing the possibility of changing to the metro route B and tram lines. The station is directly linked to the adjoining area which is important especially as regards accessibility of services and job opportunities (shopping and office centres, major accommodation capacities, etc.). The development of the line and its terminus in the premises of Masaryk station will also considerably contribute to the improvement of the devastated northern part of the station where extensive conversions are planned in connection with the introduction of the line.

The newly planned Bubny – Vltavská station is part of the development area of Holešovice – Zátory and is of an important potential as an interchange point and a destination of trips in relation to the newly planned urbanisation of this area. It is expected that the adjoining area will meet residential and servicing purposes. A new northern hall of the route C Vltavská metro station will be built there and a tram stop will be near.

The new overhead Výstaviště stop will be of its greatest importance especially as regards access to the premises of Výstaviště (Exhibition Ground) and the Stromovka Park (especially as regards services, leisure time activities, culture and sports). At the same time the particular area should be improved from architectural and urban point of view. There will be a direct connection to the tram transportation.

Dejvice – Hradčanská underground stop will provide a short connection to Hradčanská station of the metro route A. At the same time a construction of the metro station western hall is planned. It will also be possible to change to trams and busses. Next future intensive urban development of the area between Hradčanská metro station, the existing Praha Dejvice railway station and Prašný most (Powder Bridge). The station will thus be important as regards availability of services and residential zones. The fact that the station will be underground will improve availability of Prague 6 to pedestrians and in general it will allow its urbanisation.

The partly underground Veleslavín stop moved to the north will be close to Evropská avenue and will make changing to trams or busses possible. Close to the station should be built a new multipurpose building. The station will thus serve also the adjoining area.

The new Liboc stop will both serve the adjoining area (especially residential areas) and allow indirect pedestrian connections to Evropská avenue and the holiday areas of Divoká Šárka and Džbán.

Ruzyně station, moved in the western direction, will be in a space contact with the new grade-separated intersection with Drnovská street, where a bus stop could be established. The station could be important also as regards accessibility of adjoining storage premises. It also creates conditions for urbanisation of the surroundings and allows its direct servicing. Behind the station the line branches off, one branch runs to the airport and one to Kladno, passengers coming from Kladno can change for the airport (until the development of the direct line from Kladno to the airport).

The new Dlouhá Míle stop is an important terminal in the north-western part of the capital where all bus services coming from this direction should end. At the terminal it will be possible to change to the public busses as well as to the trams whose stop will be built in the future. Part of the part of the junction will also be a capacity car part of the P + R system for the purposes of the individual car transport, close to the ring road. Dlouhá Míle terminal is thus the basic junction in this part of the capital owing to which it is possible to reduce the non-railway transport (BUS, individual car transport) in the territory of Prague 6.

The new Ruzyně Airport end station, in the premises of the international airport of Prague, is directly connected to the existing and new terminal and other structures within the airport halls. At the same time it is possible to change to busses here and it is also the required element of integration of the air transport with the PID capital transport system of a corresponding functional and quality standard.

4 BASIC DATA

- Length: 20.3 km, with 5.6 km newly built section Praha Ruzyně railway station – Praha Ruzyně Airport railway station.
- Total number of stations (stops) 9; it is completely a double-line railway.
- Design speed: 80 km/hour.
- Min. curve radius R = 325 m, max. gradient 25‰.
- Traffic completely as electric traction (direct-current, 3000 V).
- Regular shuttle service of the airport and Kladno trains, the interval corresponding to the demand and the chosen transport standard. The peak interval for airport: 10min., for Kladno: 20min.
- Journey time from Praha Ruzyně airport to Masaryk station: 26.5min (stopping train).
- Journey time from Kladno – Masaryk station 40min (stopping train).

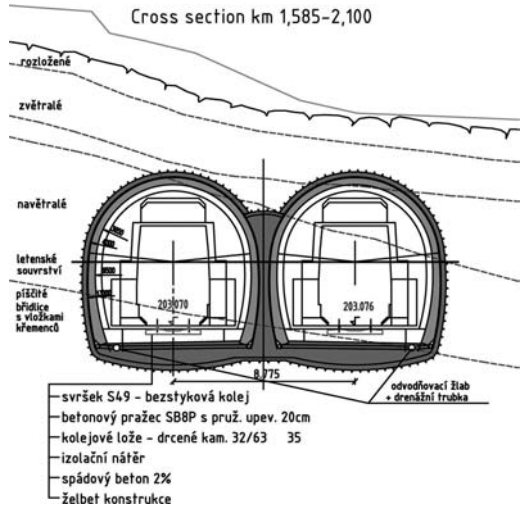

Figure 2. Cross section km 1,585–2,100.

5 UNDERGROUND STRUCTURES ON THE ROUTE

It is not possible to build a structure of this extent within the capital without underground sections of which there will be a great number.

5.1 *Tunnels in the area of Stromovka Park*

If proceeding in the direction from the capital centre, the first tunnels are designed in the Stromovka Park in length of 800 m. They are designed here to minimise negative effects of the new route on the environment. Stromovka is listed as a cultural monument and it is a nature park. The section of tunnels starts with a portal right outside the vaulted overbridge adjoining Kamenická street. The portal is situated next to the overbridge so that the overbridge will be preserved. Tunnels of the double-track line pass partly under the park and partly under the development adjoining the park and are designed on principle as single-track tunnels with a common supporting pillar. This solution with a minimum axial distance of rails allows minimisation of the impact on the outside environment, whether it covers the width of the influenced zone as regards the development area and valuable park area or also overlying rock drifts and surface drops.

Another section is the subway under the existing bridge in Korunovační street. In this place one tunnel tube runs under the existing line and under the right pier of the bridge. If full operation of the bridge is to be maintained, it will be necessary to underpin both its piers of the bridge and secure its right support for the driven subway. Both the tunnel tubes will be gradually

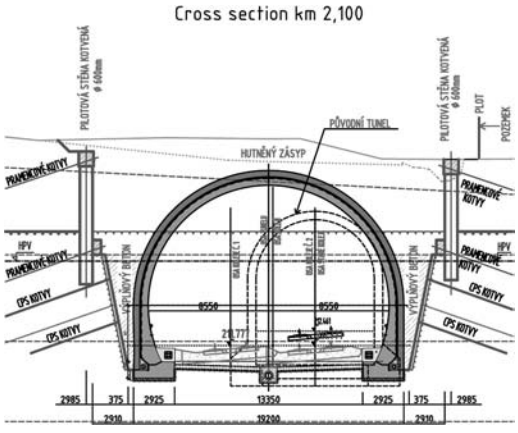

Figure 3. Cross Section km 2,100 – another variant.

inserted, along the bridge subway, under the railway cut so that 1.5 to 2.0 m of rock remain above the top section. In this section the driving of the left tunnel tube will be combined with the development of the right tunnel tube under the protection of the concrete ceiling which will be supported, in the area of the common intermediate pillar, with a number of root piles, which will become part of the common intermediate pillar of the primary lining of both tunnel tubes.

Tunnels will be driven in layers of shale of Letná. The tunnelling and the primary supporting of the tunnel tubes or the intermediate adit is to be performed in accordance with the principles of the New Austrian Tunnelling Method.

Another discussed variant of this passage through Stromovka is a mere doubling of the track of the existing line and its partial covering. This solution requires the necessity of reconstructing the existing single-track Dejvice tunnel, approx. 100 m long, which is a listed structure (the oldest railway tunnel in the Czech Republic). This tunnel had been built in a cut and then covered. The new tunnel of the required arched shape would have to be built also cut-and-cover with pile walls shoring of the building pit. On the basis of experience of similar structures the vaulted, arch structure of an excavated tunnel is built by means of formwork formed from inside with a formwork vehicle and from outside with a system formwork or with auxiliary primary lining.

This variant also requires a complete reconstruction of the bridge in Korunovační street with necessary stoppage of traffic on the bridge.

5.2 *Cut-and-cover section in Letná*

This section is adjoined by a 640 m-long section of a cut-and-cover double-track tunnel in Letná, situated right under the surface. It runs as far as the underground Praha Dejvice-Hradčanská station. It is a cast-in-situ reinforced concrete one-nave frame in an open cut. This solution allows a grade-separated intersection with several cross streets outside the station. The tunnel structure is close to the structure of the exit ramp of the tunnels of the City Ring Road (Ramp 1 – Letná City Ring Road) and the progress of both the building activities will have to be coordinated with respect to the course of time of both the structures.

5.3 *Praha Dejvice – Hradčanská station*

The new Praha Dejvice – Hradčanská underground station will be situated between Milady Horákové avenue, Dejvická street, the existing ČD Praha Dejvice station and Bubenečská street in direct relation to the existing hall of the metro station. The space around Hradčanská metro station and the new station is one of the most complex places on the route. The development of the new underground cut-and-cover station is in close contact with the planned development of road tunnels of the City Ring Road.

It will be connected to the metro station on the level of the existing subway of the metro station from which it will be possible to get into the middle of the railway platform. From the north-western end of the platform of the new station it will be possible to change to metro or leave for Dejvice through the newly planned western metro vestibule. The perimeter walls of the station are diaphragm walls, which will also shore the foundation pit. They are strutted with the foundation plate of the station, on the upper level partly with concrete floor structure, partly anchored with permanent anchors and partly strutted within the final glazed steel structure of the ceiling above the platform.

5.4 *Cut-and-cover tunnels behind Praha Ruzyně station*

In the section between Praha Ruzyně station and Praha Ruzyně Airport end station there are planned several sections of cut-and-cover tunnels where it is not possible to run the route on the surface for the reason of crossing the road beds and protecting airport systems (impact of electric traction on the radio beacon, protection of the route under the planned runway) on this edge of the city. There are altogether five sections of the total length of 1250 m.

Tunnels are designed as cast-in-situ reinforced concrete frame which is not closed in the lower part, longitudinal strip foundations are interconnected transversely only with ribs of max. distance of 8 m. Inside dimensions were determined on the basis of the maximum moving dimensions and requirements for drainage of roadbed. They will be built in an open pit either sloped or shored by Stent Walls.

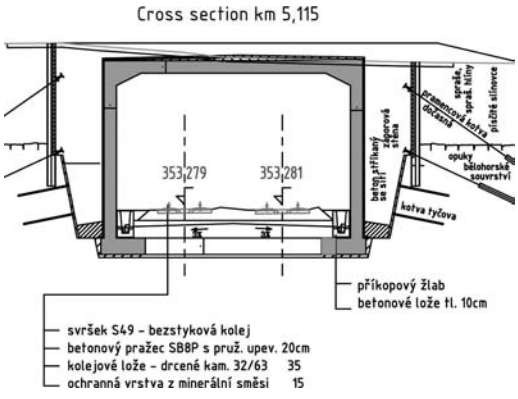

Figure 4. Cross Section km 5,115.

5.5 *Praha Ruzyně Airport station*

This end station with an intermediate platform is situated in the area between air terminals along the elevated roads. The station is the underground one, the bearing structure is a closed cast-in-situ reinforced concrete frame. The station area will be, in addition to the direct exit leading to the surface, also interconnected with the airport buildings with two underground connecting corridors – the eastern one connecting the station with the original terminal and the western one connecting the station with Sever 2, the recently completed new terminal. For the purposes of this corridor, in connection with the construction of the new terminal there was built an underground advanced structure which will allow completion of the corridor without any impact on the surface.

The station will be built in a cut-and-cover system. It will be necessary to anchor gradually the piers of the parallel elevated road. The elevated road was founded so that it would be possible to excavate the pit for the station structure.

6 CONCLUSION

At present the project documentation is being discussed at the stage for planning proceedings and number of additional studies are being completed.

The Trans Hudson Express (THE) Tunnel

Nasri Munfah

Arthur D. Silber
NJ TRANSIT, Newark, NJ, USA

ABSTRACT: Meeting New York Metropolitan area mobility needs is critical to keep pace with growing demand, to achieve the forecasted economic growth, and to maintain midtown Manhattan as a centre of regional, national and global importance. The possibility of insufficient access to midtown Manhattan was recognized as a significant problem, leading to this project major goal of doubling trans-Hudson rail capacity. With a budget of over six billions dollars (2005) and a completion plan by 2016, the Trans Hudson Express (THE) Tunnel project will fulfil these needs. The project faces many technical, environmental, and regulatory challenges including tunnelling under the Hudson River in soft silts and with limited cover; tunnelling through mixed ground in the New Jersey shore; crossing under existing historic bulkhead; tunnelling under high rise buildings in one of the most congested region; constructing a six-track cavern station under 34th Street, one of Manhattan's busiest cross-town thoroughfare; underpinning and supporting existing facilities; maintaining NJ Transit, Amtrak, Long Island Rail Road and New York City Transit operations during construction; and developing the design concepts to meet environmental requirements and regulatory constraints. This paper presents the planning process of the project, the environmental and engineering challenges, and measures taken to address them.

1 GENERAL

The New York/New Jersey metropolitan area is one of the most densely developed areas in the United States. Within the trans-Hudson Midtown corridor, almost 300,000 people commute into Manhattan each weekday on various modes from counties west of the Hudson River. This demand has grown to exceed available capacity on the trans-Hudson transportation network which includes roadways, buses, ferries, PATH trains, and commuter rail to Penn Station New York (PSNY), the existing trans-Hudson rail tunnels, and within PSNY itself. The consequence is that NJ TRANSIT's (NJT) options to provide additional rail service into midtown Manhattan during peak hours have been exhausted without major new infrastructure. Compounding the situation is that demand for additional public transportation solutions are certain to increase, as population and employment across the region grow. Recent projections for commercial development in Manhattan estimate more than 200,000 additional office-sector jobs will be created over the next two decades. Furthermore, maintaining a safe and secure rail system is the highest priority of rail operators. The post 9/11 attack security environment demands rail redundancy across the trans-Hudson Midtown corridor, where one incident can quickly impact hundreds of thousands of commuters, to be critical.

Presently, NJT operates 23 trains per hour during the morning and evening peak periods to and from Penn Station carrying about 42,000 passengers each way during the peak period and about 140,000 passengers per day each way. By 2025, ridership is expected to increase by about 70% to more than 200,000 passengers per day. The Trans Hudson Express (THE) Tunnel project, formerly known as the Access to the Region's Core (ARC) project is vital to accommodate the increased ridership. THE Tunnel will support the New York/New Jersey metropolitan area's future economic well-being by improving trans-Hudson mobility, maintaining a safe and secure transit system, maintaining and enhancing the economic viability of the region, improving the quality of life for transit passengers, and preserving and protecting the environment.

2 PROJECT DESCRIPTION

The project consists of providing additional tracks in New Jersey along the North East Corridor (NEC), new tunnels across the Palisades and the Hudson River,

new tunnels in Manhattan, and a new cavern station under 34th Street. See Figure 1. In New Jersey the project consist of the construction of loop tracks connecting the Main/Bergen/Pascack Valley lines to the NEC near the Secaucus Junction Station, to provide a one-seat ride to and from midtown Manhattan from northern New Jersey, and from Orange and Rockland Counties in New York; a new rail yard in Kearny to accommodate 45 to 50 train sets; and improvements along the NEC to increase its capacity. New tunnels under the Palisades in New Jersey and the Hudson River will connect to a new 34th Street Station in New York and the existing PSNY. The new station will be connected to the existing PSNY, and the Sixth, Seventh, and Eighth avenues, and Broadway Subway lines. With a budget of $6.1 billion (2005) and anticipated completion date of 2016 the project will provide infrastructures, facilities, and rolling stocks to accommodate a total of 48 trains per hour to New York carrying more than 86,000 riders each way during the morning peak period. In addition, NJT is implementing, independently from this project, improvements in PSNY to accommodate the increase in capacity and ridership. These improvements include platform extensions, vertical circulation elements, track modifications and additional storage capacity.

Figure 1. Alignment in New Jersey.

Figure 2. Alignment in New York.

2.1 *Project alignment*

The project extends from just east of the Hackensack River on the NEC to West 34th Street and Sixth Avenue in New York City and includes a new rail yard in Kearny. The alignment includes new loop tracks (Secaucus Loop) from the outer tracks of the existing Main Line on the lower level that connect with the upper level NEC tracks west of Secaucus Junction Station. The new loop tracks will utilize the former Boonton Line right-of-way, and allow Main-Bergen/Pascack Valley Line trains to continue to PSNY or the proposed 34th Street Station through either the existing North River tunnels or the new tunnels. This arrangement will create a direct, one-seat ride for passengers from Northern New Jersey to New York City.

East of the Hackensack River, the alignment includes a new bypass track that would split off to the northern side of the NEC, creating four tracks along the NEC from the Hackensack River to the new tunnel portals. This would allow express service along the NEC in either direction. Two tracks would connect to the existing North River tunnels, and two tracks would connect to the new proposed tunnels, descending and turning southward under the Palisades through Union City and Hoboken. Interlocking configurations along the NEC are developed to provide full flexibility between the existing tunnels and the new tunnels to facilitate emergency operations or periodic closures of the tunnels for maintenance. See figure 1.

Near the Hudson River in Hoboken, the new tunnels will turn eastward to cross the river. At the eastern shore of the river in New York, the alignment will begin to ascend in grade, and turn in a northeast direction, passing under the Hudson River bulkhead. Connections to PSNY will split from the main tracks after passing the bulkhead. The PSNY connector tracks will continue to ascend, before turning east to tie into existing PSNY tracks. Beyond the point where the PSNY connector tracks will split off, the main tracks leading to a new 34th Street Station will descend, and split to four trackways, arranged two-over-two. At West 34th Street, the alignment will turn eastward to match the street grid. Each tunnel level will split into four platform tracks serving two island platforms in a two-cavern station. See figure 2.

3 PROJECT GEOLOGY

The New Jersey portion of the project area is located within the Piedmont physiographic province broad

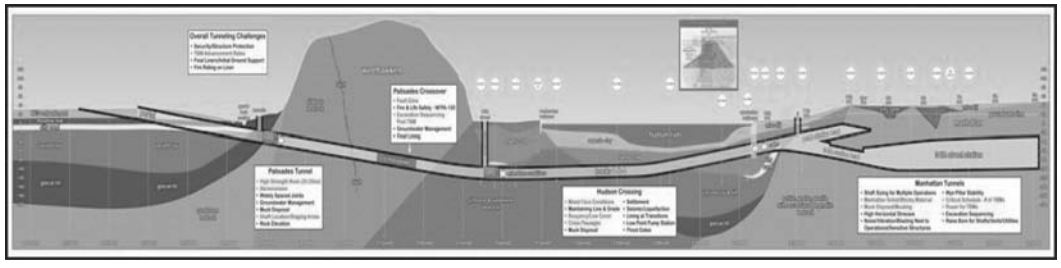

Figure 3. Geological profile.

lowland interrupted by long, northeast-trending ridges and uplands. The most prominent physiographic feature in the eastern part of the province is the Palisades, a striking north-south topographic ridge near the Hudson River that rises above the surrounding lowlands of the Meadowlands. Most of the project area in New Jersey is underlain by rocks of the Newark Basin, a northeast-trending late Triassic – early Jurassic rift basin filled with a thick sequence of sedimentary rocks and intrusive and extrusive igneous rocks. The topography of the bedrock surface shows two narrow, deep, glacially scoured troughs, one on either side of the NJ Meadowlands. Metamorphic rocks in the project area occur only along the Hudson River waterfront in Hoboken and Jersey City. The Hartland Formation consists of gray, interbedded schist, granulite, and amphibolite.

Thickness of surficial materials in the project area in NJ varies from one meter to greater than 75 m (250 feet) at a glacially eroded bedrock trough in the vicinity of the New Jersey Turnpike east of Kearny. Surficial materials consist of deposits of glacial, eolian, alluvial, and marsh/estuarine origin. The Rahway till is a surficial unit directly overlying bedrock. It is a nonstratified, compact deposit with pebbles, cobbles, and boulders in a reddish-brown matrix of sand, silt, and clay. Its thickness is generally less than 10 m (30 ft). Overlying the till are glacial deposits along the west flank of the Palisades ridge, at scattered locations near the Hudson River, and near the Passaic River. The unit includes both deltaic deposits of sand, sand and gravel, and silty sand and lake-bottom deposits of fine sand, silt, and clay. Thickness ranges from about 8 m (25 feet) to over 30 m (100 feet) in the Meadowlands east of Kearny. Passaic terrace deposits, consisting of moderately sorted sand and gravel, are present along the Passaic River in the vicinity of Newark and Harrison. Light brown eolian deposits of very fine to medium sand occur locally near Laurel Hill and just west of Penhorn Creek. A large percentage of soils in the project area have been altered by excavation or filling. Earth and manmade materials that have been placed as fill include gravel, sand, silt, clay, trash, cinders, ash, and construction debris. In the cut and cover section in New Jersey the soil stratigraphy from the ground surface consists of 2.5 to 3 m (8 to 10 ft) of marsh deposits, underlain by about 1.5 m (5 ft) of alluvial sand, underlain by about 6 to 12 m (20 to 40 ft) of hard blue clay deposits of glacial Lake Hackensack, which are in turn underlain by 15 to 24 m (50 to 80 ft) of hard red to brown clay deposits of glacial Lake Bayonne. In the centre of the trough, bedrock is overlain by a glacial deposit of till or hard sand and clay about 15 m (50 ft) thick.

The Hudson River portion of the project area is located between the Piedmont physiographic province on the west and the Manhattan Prong of the New England Upland physiographic province on the east. The topography of bedrock surface underlying the Hudson River shows a narrow, deep, glacially scoured trough that extends to more than 100 m (300 ft) below sea level. Depth to rock is about 40 m (125 ft) below mean low water at the New York bulkhead line and about 55 m (180 ft) below mean low water at the New Jersey bulkhead line in Hoboken. The maximum total thickness of surficial materials overlying bedrock of the Hudson River in the project area is about 100 m (300 ft), with a complex stratigraphy of glacial, fluvial, lacustrine, and estuarine deposits. It is anticipated that the soil materials through which the Hudson River tunnel would be constructed would be primarily estuarine deposits of organic clayey silt and fine sand, with sand or glacial till possible near the New Jersey waterfront and sand or organic clay near the New York waterfront. Gas pockets due to natural methane have been reported in the estuarine silts, mostly at shallow depths. It is also anticipated that hidden offshore obstructions within soil materials, such as boulders, piles, wrecks, or miscellaneous fill exist on both sides of the Hudson River.

The New York portion of the project area is located within the Manhattan Prong of the New England Upland physiographic province. Within the Hartland Formation, granitic intrusions are present near the Hudson River. A large granitic sill has been mapped between Ninth and Twelfth Avenues, and between West 34th Street and West 40th Street. Serpentinite associated with the Hartland Formation has been reported

between Tenth and Eleventh Avenues, at the northern part of the project area, and at scattered locations as far south as West 26th Street. Thickness of surficial materials is variable and they generally have been altered by excavation, filling, or paving for various developments. The entire length of the Hudson River waterfront in the project area is reclaimed beyond the original mid-19th Century shoreline. Filled for urban development, these areas are typically former bays or tidal marshes with organic deposits beneath the fill. Most of the Manhattan tunnels east of Eleventh Avenue, are expected to be excavated primarily in schist of the Hartland Formation, including some granite or pegmatite and possibly serpentinite. Rock along the proposed alignment in this section is likely to be moderately weathered and of fair to good quality within the first 1.5 m (5 ft). Below this zone, weathering is likely to be slight, with good to excellent rock quality. The schist is typically of intermediate strength, with unconfined compressive strength generally ranging from about 28 to 100 MPa (4,000 to 15,000 psi). It may contain significant percentages of abrasive accessory minerals such as garnet or sillimanite, as well as thin veins of quartz. The granite or pegmatite is likely to be of high strength, with unconfined compressive strength from about 100 MPa (15,000 psi) to greater than 170 MPa (25,000 psi) and it is likely to contain a very high percentage of abrasive minerals, mostly quartz. Groundwater levels are within the overburden about 3 m (10 ft) of the ground surface and generally parallel to the bedrock surface. Rock mass permeability is relatively low but with higher permeability and greater water inflow along weathered joints or fault zones.

4 34TH STREET STATION CAVERN

The proposed station concept incorporates a potential four-over-four track configuration in two caverns with two tracks and an island platform over two tracks and an island platform in each. Initially six tracks with three island platforms will be provided. A mid-level mezzanine would be provided in each cavern to provide for circulation and pedestrian distribution. The two caverns will be connected to each other with cross passages and will be connected to PSNY through the 33rd Street LIRR concourse. See figure 4. Street entrances along 34th Street between Eighth and Sixth Avenues will be provided.

The conceptual design incorporates belowground connections to the Broadway, Sixth, Seventh, and Eighth avenues subway lines. The station caverns will be approximately 20 m (60 ft) wide by 23 m (70 ft) high and would be placed about 35 m (110 ft) below street surface at the mid-level mezzanine elevation. The southerly cavern will be located under 34th Street, and

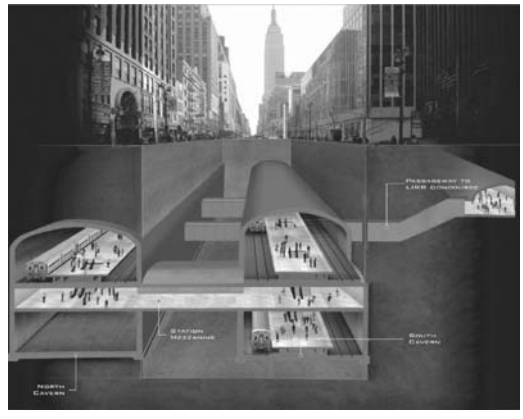

Figure 4. 34th Street station concept.

the northerly cavern will be located under properties along the northern side of 34th Street. The caverns crown will be located approximately 17 m (50 ft) below the top of rock to provide suitable rock cover.

5 TUNNELING CHALLENGES

Building the Trans Hudson Express project will involve construction of a number of tunnels using a variety of construction methods. Selection of an appropriate tunnelling method for each section of the alignment will have a major impact on the successful completion of the project. The project faces many technical challenges:

- Selecting an alignment to meet the transportation needs and minimize environmental issues, while meeting tunnelling method technical challenges.
- Developing a versatile, yet economical and constructible tunnel cross section capable of meeting present and future equipment, and accommodating the required utilities and ventilation.
- Developing track vertical alignments that meet the required design grade to provide connectivity to the existing PSNY and to provide sufficient cover over the tunnel under the Hudson River.
- Utilizing suitable construction techniques in soft silts of the Hudson River with a limited cover.
- Constructing a new cavern station in New York City with access to the existing PSNY, and the existing transportation systems in New York, while minimizing impact on the surface, businesses, and the public.
- Identifying locations for construction staging especially in Manhattan and meeting the needs of other projects in the area.
- Identifying provision for emergency egress and ventilation with minimal impact on land use.

- Minimizing impact on the Hudson River, the Hudson River Park, future developments and existing and future facilities along the alignment.
- Tunnelling in mixed face conditions under the Hudson River.

5.1 *Tunnelling methods*

The construction of the alignment in New Jersey along the NEC would mostly be constructed using the existing or an enlarged embankment, viaduct structures, retained fill, and cut-and-cover tunnels. As the alignment diverges from the NEC and dives under the embankment the construction would be done either by cut and cover, tunnel jacking, or by using sequential excavation or NATM. Cut and cover method will be used to construct other underground segments of the New Jersey alignment to the tunnel shaft west of the Palisades. The cut and cover construction will use slurry walls for support of excavation and water cut off. Staging, rerouting, and decking will be provided to maintain traffic across the excavation. The Palisades tunnels will be constructed using rock TBM starting in a shaft located near Route 1&9. The shaft will be used for access, material delivery, and mucking. Upon completion of the construction it will be converted to a ventilation shaft where a ventilation facility will be located. The tunnels are located about 120 m (350 ft) below surface in the Palisades diabase, with argillite and hornfels of the Lockatong formation for short lengths on either side of the diabase. A cross-over will be constructed between the two tunnels using controlled drill and blast method utilizing the previously excavated tunnels. Crossing the Hudson would be done by a pressurized face soft ground TBM using either Earth Pressure Balance (EPB) TBM or slurry TBM. The TBM will be lowered in a shaft in North Hoboken and would mine the tunnels toward Manhattan under the Hudson River. The tunnels will be lined using one pass gasketed and bolted precast segmental liner. As the alignment approach Manhattan, the cover over the tunnels is limited and special measures would be needed as discussed later. The TBM will be retrieved via a cofferdam constructed in the river at the edge of the bulkhead. Cross passages would be required under the Hudson River that will be constructed using NATM with localized ground freezing. Crossing the river bulkhead, the Hudson River Park, and 12th Avenue in Manhattan would be done using either the cut and cover method with decking and staging to maintain vehicular and pedestrian traffic or alternatively soft ground NATM can be used to construct the crossing with jet grouting and/or ground freezing for ground improvement. The Hudson River TBM can then continue through the previously constructed NATM tunnels and retrieved on land.

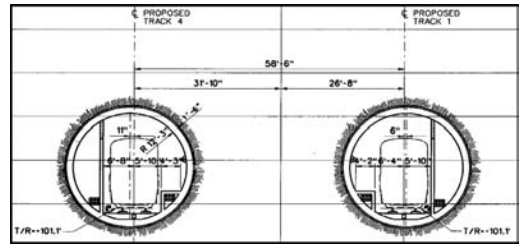

Figure 5. Tunnel cross section.

Tunnelling in Manhattan is challenging in term of access and staging. It is planned that most of the tunnelling in Manhattan would be done from a staging site at 11th Avenue. Two rock TBMs would be used to excavate four tunnels along the alignment through the station caverns. After the initial two runs, the TBMs will be retracted through the tunnels to the 10th Avenue interlocking caverns where they will be re-launched again to excavate the second pairs of tunnels. Subsequently the caverns will be excavated by sequential excavation using controlled drill and blast method from the mined tunnels to create the complex underground track configurations as the tunnels split to serve potential eight-track station. Access and mucking will be through the previously excavated tunnels. The initial liner in the rock tunnels will consist of rock bolts, lattice girders and shotcrete and the final liner will be cast in place concrete liner over a drained waterproofing system.

5.2 *Tunnel cross section*

The tunnel size was established to allow all available vehicles through the tunnel. Its size was based on the Amtrak Super-liner locomotive, with a 4.928 m (16′-2″) vehicle height. The inside tunnel diameter was established to be 7.47 m (24′-6″) to accommodate in addition to the largest equipment, the catenary power requirements, a suitable emergency walkway, and the required systems and utilities. See figure 5. This size tunnel allows the use of the available space for a ventilation plenum created within the bored tunnels to meet NFPA 130. The plenum would be equipped on the top side with motor operated dampers at certain intervals to be used to exhaust smoke in case of fire. In the event of an incident, the dampers in the immediate vicinity would be opened to extract the smoke and hot gases from the trainway. The tunnels will be spaced 17.8 m (58′-6″) on centre to allow sufficient pillar between them especially in the soft silts under the Hudson River.

5.3 *Limited cover over the Hudson Tunnel*

There are several challenges that constrained the design of the connection to existing PSNY. The

engineering alignment underwent many alternative designs to address these challenges. The connection to PSNY was only possible south of the existing North River Tunnel due to the LIRR yard access tracks north of the tunnels and NJT's use of the southern half of PSNY. The operational analysis indicated that 2.0% is the maximum allowable effective grade for locomotive-hauled trains; however with such grade the cover over the tunnels under the Hudson River is inadequate. In an attempt to address this issue two possible solutions were evaluated: an increase in the grade to 3% for approximately 600 m (1800 ft) or artificially increasing the effective cover over tunnel by providing suitable ground improvement. A maximum grade of 3% may be permitted on the PSNY connection if equipment is limited to EMU train sets with multiple-powered coaches. However this will limit the operational flexibility of the railroad. On the other hand, intervention in the Hudson River would trigger environmental and permitting issues. For an effective grade of 2.5% the cover over the tunnel will be about 5 m (15 ft). In this case grouting a canopy over the tunnel from within the TBM can be provided to stabilize the ground and to protect the tunnel face against stability and buoyancy. The TBM would then advance under the protection of the grouted canopy without impact on the Hudson River.

5.4 *Crossing the Hudson River bulkhead*

The Hudson River Bulkhead is constructed of sheet pile walls with stone façade and timber relieving platform and supported by timber piles 18 to 30 m (50 to 90 ft) deep spaced about 1 m (3 ft) apart. The bulkhead is part of the Hudson River Park and is considered a historical structure. Therefore, it is important to preserve and protect it to the maximum extent possible. The piles will intercept the tunnel profile and are expected to be at variable spacing at the tunnel level. Three different methods have been conceptually evaluated for intercepting the Hudson River bulkhead and for constructing the tunnels in the Hudson River Park: continuation of the Hudson River Tunnel Boring Machine through the timber piles with special measures if needed, extraction of the piles, cut-and-cover construction, or excavation using the NATM method with ground improvement.

5.5 *Connection to existing Penn Station*

In order to connect to existing tracks in Penn Station, the track alignment in Manhattan at 12th Avenue diverge to four tracks. The inner tracks descend toward the new station at 34th Street while the outer tracks ascend to meet the existing tracks at the approaches to Penn Station. The track connections to PSNY pass under the Long Island Rail Road (LIRR) storage yard and the LIRR maintenance shop at 10th Avenue in close proximity to their foundations. These tunnels will be constructed using the cut and cover method or NATM. Special measures will be used to minimize the impact on the yard and the shop operations. The yard tracks and the shop will be underpinned prior to the excavation of the tunnels. Underpinning and pre-treatment of the ground will be done at night and on weekends to minimize impact. Conventional tunnelling will be done beneath the yard and the shop with extensive monitoring.

6 CONSTRUCTION COST AND SCHEDULE

At a budget of $6.1B (2005) construction is expected to begin in 2009 and to be completed with revenue operation by late 2016. The peak construction is expected to be in 2011. In order to establish a reliable construction schedule and cost estimate an initial construction packaging plan was established. The plan identified sixteen different contracts ranging in sizes and durations. The packaging plan took into consideration the type of construction, size of the contracts, and their durations and dependency on each other. The Manhattan segment with the TBM tunnels, the 34th Street Station caverns, and subsequently the railroad system work and the station finishes are on the project critical path.

7 CONCLUSION

The Trans Hudson Express (THE) Project is the largest transportation project ever undertaken by NJ TRANSIT. It will improve the overall New York metropolitan area transportation system, will stimulate economic growth, and will maintain midtown Manhattan as a centre of regional, national and global importance. The project has been planned using state-of-the-art design concepts, latest construction techniques and approaches, and with careful attention to environmental issues and concerns.

CTA Block 37 Tunnel Connection in downtown Chicago

V. Nasri & P. Razgha
STV Incorporated, NY

ABSTRACT: Block 37 Station Tunnel Connection project will include construction of two short tunnels to connect the existing subway tunnels (Red and Blue lines) in the northern loop area of downtown Chicago through a new station. The Southeast Tunnel will connect the Red Line to the new station below the intersection of State and Washington Streets and the Northwest Tunnel will connect the Blue Line to the new station below the intersection of Dearborn and Randolph Streets. The connection tunnels are located in a very dense urban area of downtown Chicago and under several important historical buildings. Both tunnels are curved at the intersections and located at a depth of about 7.5 m below ground surface in saturated soft clay with an average undrained shear strength of approximately 25 kPa. The design calls for minimizing surface disruption and ground displacement while maintaining normal operation of the existing subways during the construction of the connections tunnels.

1 INTRODUCTION

To create an express train service linking O'Hare International and Midway Airports, the Chicago Transit Authority (CTA) decided to build two short tunnels to connect the Blue and Red transit lines in Chicago. The connection will be at Block 37, located between State and Dearborn Streets, and will link the two subways through a new station (Figure 1). The new Block 37 station structure will be constructed as part of the Block 37 development project using slurry wall construction and a top down technique. The new connection tunnels will be constructed using mining methods. Mining operations will originate from access shafts to be built within Block 37. The project will also include modifications to the continuous platforms at the existing State Street and Dearborn Street subway tunnels to accommodate the new connections. This project will be accomplished under a complex and tight schedule and must be completed with minimal disruptions to the non-stop subway service. The anticipated subsurface conditions and the stringent project settlement criteria create difficult conditions for the design and construction of the tunnels.

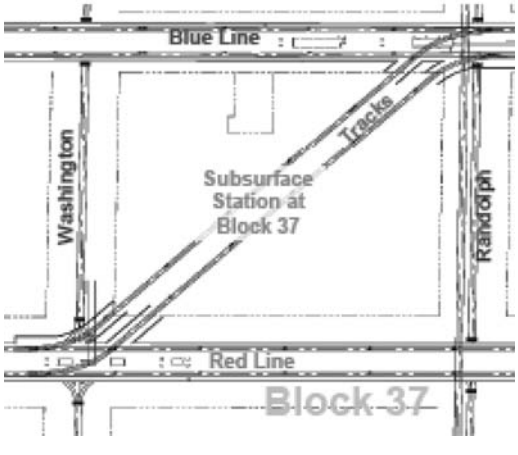

Figure 1. Plan view of project site.

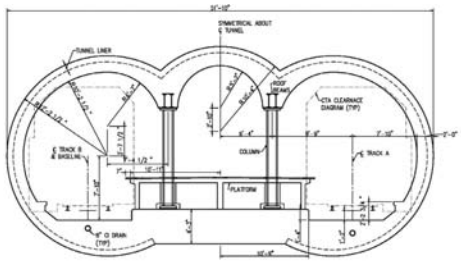
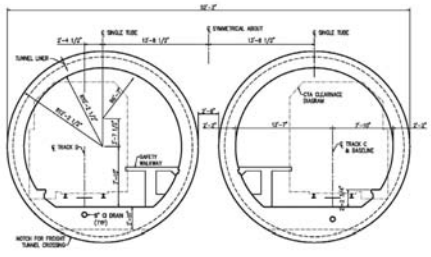


The soft deposits at the project site with their low shear strength can experience large deformations during tunneling. Application of a pre-support interlocking pipe arch method and fiberglass face reinforcement technique ahead of the advancing tunnel face are proposed to limit the ground deformation.

Continuous and swift excavation and support installation combined with an appropriate staging and support system is necessary to minimize short and long-term deformations. The tunnels will be constructed using fiber reinforced shotcrete and lattice girders as an initial support lining. The final lining will be installed using a composite system of steel fiber reinforced shotcrete and lattice girders.



For the connection of the new short tunnels to the existing subway tunnels, a new larger span tunnel will be constructed using the interlocking pipe arch

technique which will be parallel to the existing Tunnel. The new expanded tunnels will transfer the imposed loads to the column line of the existing tunnels. To facilitate the construction of the new expanded tunnels, two cross adits will be constructed perpendicular to the existing tunnels. These cross adits will originate from within Block 37 and extend below State and Dearborn Streets and above the existing Track B and Track C. This construction approach allows all tunneling work, including excavation, temporary and final lining work, to take place outside of the existing tunnel envelopes. Revenue operation can continue practically uninterrupted until the final breakthrough of the existing tunnels is required.

Structural modification and reinforcement of the existing tunnels must take place prior to the excavation of the new tunnels. These structural modifications and reinforcement consist of platform demolitions, erection of new tunnel roof structural support systems and installation of permanent tie down anchors. Removal of some of the existing columns and longitudinal beams will take place after construction of the new tunnels and breakthrough of the sidewall of the existing tunnels. Most of these construction activities will be performed using enclosures separating the work areas from the revenue operations.

b) Tunnel cross section (circular arch)

c) Existing subway station (triple arch)

Figure 2. Existing tunnels.

2 EXISTING SUBWAY TUNNELS

The initial subway system of Chicago included two routes, State Street Route and Dearborn Street Route. The tunnel portion consisted of 7.7 miles of double tube and station sections. All the tunnels were entirely constructed in Chicago clay. The bottom of the tunnels is located at a depth of about 15 m below the street surface.

For constructing the tunnels two different methods were used: the liner plate method and the shield method. In the liner plate method the pressure which acts on the roof of the tunnel is carried by steel ribs which transfer the load onto the footings. In order to use this method the clay located beneath the bottom of the tunnel must be stiff enough to withstand the downward pressure exerted by the footings. This condition was satisfied north of the river, where liner plate method was used. On the other hand, the clay at the south of the river was too soft to support the heavily loaded footings. Inadequate support of the footings of the arch ribs in a liner plate tunnel could cause not only tunnel roof failure but also adjacent buildings collapse. Therefore, in the loop district, shield method was employed in spite of the higher construction cost. Figure 2 shows cross sections of the existing station and tunnels built in 1940's. The outside diameter of the individual tubes is about 7.5 m and the minimum horizontal distance between them at the mid-height of the tunnels is about 2′–8″ (Figure 2).

3 SUBSURFACE INVESTIGATION

The subsurface investigation for this project consisted of performing geotechnical borings with standard penetration tests and cone penetration tests with shear wave velocity measurements. Laboratory tests were also conducted on representative and undisturbed

samples of soils which consisted of index tests, unconsolidated-undrained triaxial tests, consolidated-undrained compression and extension triaxial tests in conjunction with laboratory shear wave velocity measurements.

The subsurface soils consist of an upper layer of miscellaneous sandy fill underlain by layers of glacial deposits above the limestone bedrock. The glacial deposits are Blodgett, Deerfield, Park Ridge, Tinely and Valparaiso. The three layers of Blodgett, Deerfield, and Park Ridge are predominantly clay ranging in strength from soft to stiff. The top of the clay is located at a depth of about 4.5 m below the street surface, approximately at the level of the Lake Michigan. The existing tunnels and the proposed construction are predominantly in Blodgett layer.

Blodgett stratum is characterized as very soft to soft silty clay with trace of fine sand and gravel and shale and mostly shows a variable distribution of water content. Red and Blue line subways were constructed in this layer and the proposed connection at Block 37 is expected to be constructed entirely in this stratum. The upper part of the Blodgett layer to a depth of about 1.5 m is desiccated clay crust and much stiffer than the underlying soft clay. However, the clay crust is very variable in thickness and strength and therefore, the entire stratum was considered as Blodgett layer with softer clay characteristics. The groundwater table is approximately at the top of the Blodgett stratum.

4 DESIGN CONSIDERATIONS

Minimum surface settlement, minimum disturbance to the street traffic and minimum impact on the operation of the existing tracks were the main requirements for the design. The critical design criteria consisted of strict limitation of surface subsidence due to tunneling at the location of existing building foundations. Based on these criteria the angular distortion at these locations can not exceed 1/1000, and no surface point shall subside more than 12 mm below its pre-construction location. Presence of important high rise historical buildings supported on shallow spread footings in the zone of mining influence dictated such strict settlement criteria.

The state of the art geotechnical testing and interpretation program has been carried out by Northwestern University to define the behavior of different Chicago clays at the project site. The type of ground in which the tunnels will be mined is classified as soft clay with very low strength characteristics. Different ground improvement techniques and various pre-support methods were considered in initial phases of design. Ground improvement approaches such as jet grouting and ground freezing were excluded due to their unsatisfactory performance in similar geological settings and also their incompatibility with the densely distributed utilities and other site constraints.

Use of forepoling and interlocking pipe arch techniques as pre-support methods were studied in detail. The interlocking pipe arch concept was selected for the final design to achieve the above described surface settlement criteria. An interlocking pipe installation technology was recommended to minimize installation induced soil disturbance, excess pore water pressure and surface settlement. This technique combines drilling with continuous controlled jacking and auguring.

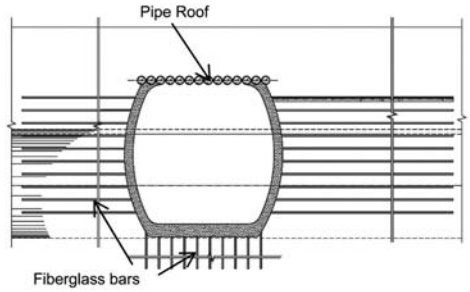
To limit the face extrusion and its resulting ground deformation and to increase the excavation stand up time, fiberglass face reinforcement bars were designed as an element of the pre-support system. The reinforced core in the excavation face reduces ground deformations including extrusion, convergence and pre-convergence components. The design provides either interlocking pipe support or fiberglass reinforcement in all the exposed excavation surfaces including crown, sidewalls, invert and face of all excavations.

The sequential excavation method has been selected as a means of progressively excavating and supporting the ground. The longitudinal tunnels and cross adits are to be excavated with two headings in accordance with the specified sequences designed to stabilize the ground in limited excavation rounds. The excavation sequences of specified round lengths consist of application of steel fiber-reinforced flashcrete to newly exposed surfaces, installation of lattice girders at predetermined intervals, and application of fiber reinforced shotcrete support with variable thicknesses depending upon final opening dimensions.

Due to its particular geometry, the State Street tunnel BD is to be excavated full face. The proposed steel fiber reinforced shotcrete of initial and final liners are combined and the lattice girder is not used as a support element. For shorter connections in State and Dearborn streets a horizontal secant concrete cylinders concept is used as pre-support system. The design of State Street tunnel BD and the longitudinal tunnel were adapted to accommodate the presence of the paid transfer tunnel and the abandoned freight tunnel. The design of the longitudinal tunnel at Dearborn Street was modified to account for the presence of the active and abandoned freight tunnels in Randolph Street.

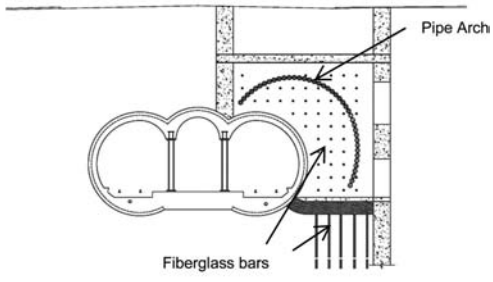
The final tunnel lining will be designed to carry the combination of full overburden and hydrostatic groundwater loads as well as surcharge loads. Due to the varying tunnel shapes and short tunnel lengths, it is proposed to use high quality shotcrete for the permanent tunnel support lining.

Because of very low assumed permeability of the ground and small expected water head, combination of relatively thick shotcrete initial and final liner with



appropriate mix design is considered sufficient to provide acceptable watertightness for the new tunnels. Fuko grouting hoses at construction joints and intersections can be used for repairing the possible leaks.

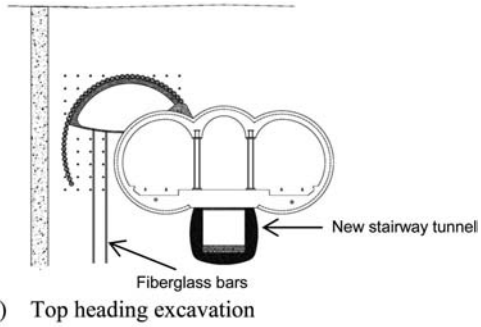
Monitoring of surface movements will be conducted with series of surface settlement points installed in a series of arrays perpendicular to tunnel centerline across the expected settlement trough. In addition, inclinometers, extensometers and piezometers will be installed to detect horizontal and vertical subsurface movements and ground water level. Total station technology will be used to determine buildings deformation in the zone of influence of tunneling operation. Monitoring points and tiltmeters will be installed to observe any building movement. In-tunnel monitoring will primarily comprise convergence monitoring of the new and existing tunnels and deformation and stress measurement of liner using strain gauges and concrete and soil pressure cells.



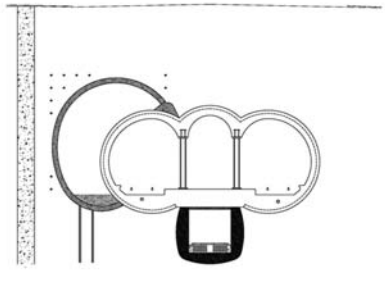
5 CONSTRUCTION ELEMENTS

The construction elements and the corresponding sequences are as follows:

- Building a stairway tunnel under the center arch of the existing tunnel (Figure 4),
- Reinforcement of existing tunnels by erecting new columns, beams and temporary columns (shoring) and installing tie down anchors for both existing Red and Blue line tunnels,
- Installation of 0.6 m diameter interlocked steel pipe roof system and filling them with cement grout (Figure 3),
- Construction of two cross adits under State and Dearborn Streets based on prescribed excavation sequence and support of face, side walls and invert by steel fiber reinforced shotcrete and fiberglass bars (Figure 3),
- Construction of the new expanded tunnel based on prescribed excavation sequence and installation of initial steel fiber reinforced shotcrete and lattice girder support (Figure 4),
- Completing final support system consisting of a combination of cast in place reinforced concrete framing and steel fiber reinforced shotcrete and lattice girder allowing for opening arches at breakthrough points,
- Construction of Tunnel BD at State Street side using interlocking steel pipe arch and fiberglass face reinforcement techniques based on prescribed excavation sequence together with steel fiber reinforced shotcrete as the final liner,
- Connection of track BD at Dearborn Street to the new expanded tunnel at the cross adit location using a short reinforced concrete box structure,



a) Longitudinal section



b) Transverse section.

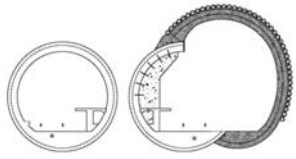
a) Top heading excavation



b) Completed initial liner

Figure 4. New expanded tunnel (during construction).

a) Cross section at triple-arch tunnel

b) Cross section at circular-arch tunnel

Figure 5. New expanded tunnel (after construction).

- Connection of Track AC at State Street and Dearborn street with two new expanded tunnels at intersection points using horizontal secant concrete cylinders pre-support system and steel fiber reinforced shotcrete and lattice girder as the final liner,
- Backfilling both cross adits based on prescribed backfilling schedule,
- Breakthrough sidewalls of existing tunnel (Figure 5),
- Transferring the loads of removed beams and columns of existing tunnels to new framing systems by means of jacking.

The excavation of both expanded new tunnels will be performed in two stages of top heading and bench. Maximum distance between faces of top heading and bench will be 9 m. The more desirable full face excavation cannot be applied due to constructability constraints which would require hand mining or the use of a movable platform for mechanical excavation. The Tunnel BD at State Street side will be excavated full face in one stage.

6 NUMERICAL ANALYSES AND MODELLING

The three layers of Blodgett, Deerfield, and Park Ridge along with the miscellaneous fill were modeled in the finite element analysis. The Hardening Soil (H-S) model (Schanz, 1999) was used for modeling Blodgett, Deerfield and Park Ridge strata. H-S model is an advanced model with stress-dependant soil stiffness using the following three different input stiffnesses: the triaxial loading stiffness (E_{50}), the triaxial unloading stiffness (E_{ur}) and the oedometer loading stiffness (E_{oed}). The limiting states of stress are defined by the friction angle (ϕ), cohesion (c) and dilatancy angle (Ψ). The relatively simple Mohr-Coulomb model tends to overestimate soil dilatancy. For miscellaneous fill, Mohr-Coulomb soil model was used in the analysis. Material properties used for analysis of Block 37 tunnel connections were obtained from Geotechnical Baseline Report (Patrick Engineering, Inc., 2005) and hardening soil parameters developed for this project at Northwestern University (Finno, 2005).

The excavation and support of various elements of the project such as the extended stairway tunnel, cross adits, expanded tunnels and tunnel BD have been modeled according to the construction stages of the existing and new tunnels using PLAXIS software (Brinkgreve, 2002). As an example, the stages used to model the construction of expanded tunnels are as follows:

1. Initialization of stresses. In this stage the soil layers and ground water table are defined and vertical and horizontal stresses are generated before the construction of existing tunnel.
2. Construction of existing tunnels (initial liner). Construction of existing tunnels, which took place in 1940's, was modeled by creating their geometry as closely as possible and then modeling the excavation using undrained analysis. The initial liner consisting of a steel segmental liner was installed in this stage. This liner was modeled using a structural beam element. The beam element section properties were obtained from the existing drawings. To model the effect of compressed air used during the construction of these tunnels, the groundwater pressure inside the excavated tunnel was kept active, since the pressure of air was originally designed to compensate the existing groundwater pressure during the excavation of these tunnels. Moreover since the concrete final liner was installed at a considerable distance from the face of excavation, 100% of excavation induced stresses are released at this stage. A uniform surcharge of 12.5 kPa was applied at ground surface at this stage representing traffic live load. This surcharge was kept active during the following stages.
3. Construction of existing tunnels (final liner). In this stage, the concrete final liner for the existing tunnels was installed and the groundwater pressure inside the tunnels was deactivated to model the removal of compressed air.
4. Consolidation for 65 years. This stage was added to create the existing state of stress in soil layers, as closely as possible, before the new construction for Block 37.
5. Pre-construction support. Prior to new construction, the existing tunnels were supported by installation of tie-down rock anchors. The displacements

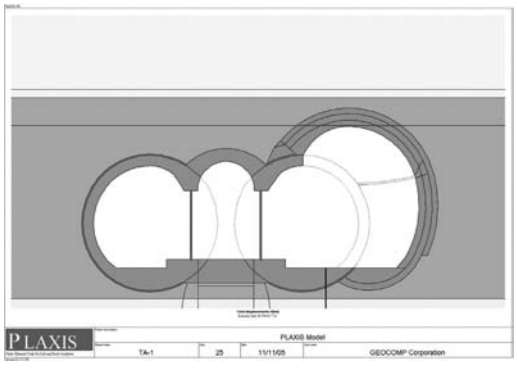


Figure 6. PLAXIS model used in the analysis.

from previous stage were set to zero at this stage, which marks the start of Block 37 construction. Undrained analysis was used for this stage.

6. Construction of new arch (top heading-1). In this stage the top heading of the expanded tunnel was excavated after activating the longitudinal pipes of the pipe arch. It is assumed that 50% of the excavation induced initial stresses are released in this stage. Undrained analysis was used for this stage.
7. Construction of new arch (top heading-2). In this phase, top heading initial liner was activated (shotcrete and vertical fiberglass bars in invert) and 100% of the initial stresses at the excavation boundary were released. Undrained analysis was used for this stage.
8. Construction of new arch (bench-1). The bench of the expanded tunnel was excavated and 50% of the initial stresses were released. Undrained analysis was used for this stage.
9. Construction of new arch (bench-2). In this phase, bench initial liner was activated and 100% of the initial stresses at the excavation boundary were released. Undrained analysis was used for this stage.
10. Cutting the existing tunnel liner. At this stage final liner was installed and part of the existing tunnel liner was cut.
11. Consolidation for 100 years. A 100-year consolidation was performed to calculate long-term ground movements and stresses in surrounding soil and liner.

The tensile stresses in the existing tunnel liner were checked against the rupture modulus of concrete after applying the appropriate load and resistance factors. The analysis indicates that the surface settlement and angular distortion were within the acceptable limits (Figure 6).

7 CONCLUSIONS

A brief history of tunnel construction in Chicago area in the past century including the complexities and challenges involved was presented followed by an overview of construction activities for development of Block 37 in downtown Chicago. A comprehensive geotechnical investigation has been carried out to identify soil parameters required for the design of the connection tunnels at Block 37.

The methodology applied for selection of optimum construction techniques and their complexities were discussed. The construction method included application of fiberglass bars for face reinforcement and interlocking pipe roof technique to minimize the surface settlement induced by tunneling work.

To verify the efficiency of the applied construction technique, series of finite element analyses were performed to investigate: (a) the initial state of stress in soil due to construction of the existing tunnels, (b) the soil-structure interaction during various stages of construction, and (c) the structural response of the existing tunnels.

Construction of a large underground station under a station in operation

T. Niibori, Y. Seki, T. Sato & T. Yamada
East Japan Railway Company Tokyo Construction Office, Tokyo, Japan

T. Fujiwara
East Japan Railway Company Construction Engineering Center, Tokyo, Japan

ABSTRACT: A four- and five-tier box-shaped underground station, measuring 25 m in width and 420 m in length, was constructed by East Japan Railway Company at a depth of about 25 m immediately under Yokohama Station through which about 2.3 million passengers pass each day, to link the Minatomirai Line with the Tokyu Toyoko Line. The construction work faced various challenges, including excavation through special geology, the high level of groundwater, tunneling for a railroad immediately under a large terminal station, and severe restrictions on construction due to live flows of passengers. These obstacles were overcome by meticulous engineering studies and technical development, as a result of which the underground station was finally completed two months ahead of schedule.

1 OUTLINE OF THE PROJECT

Operated by the Yokohama Minatomirai Railway Company and initiated under the Minatomirai 21 Plan, one of Yokohama City's urban plans, the Minatomirai Line is a new 4.1-km line connecting Yokohama Station with Motomachi-Chukagai Station. The Minatomirai Line directly connects with the 2-km line between Higashi-hakuraku Station on the Tokyu Toyoko Line and Yokohama Station, which was also recently built underground. This Project has reduced the time taken to travel from Shibuya Station, Tokyo, to Motomachi-Chukagai Station to a minimum of 37 minutes. East Japan Railway Company (JR) constructed an underground station immediately under the present Yokohama Station under a contract with the operator (Fig. 1).

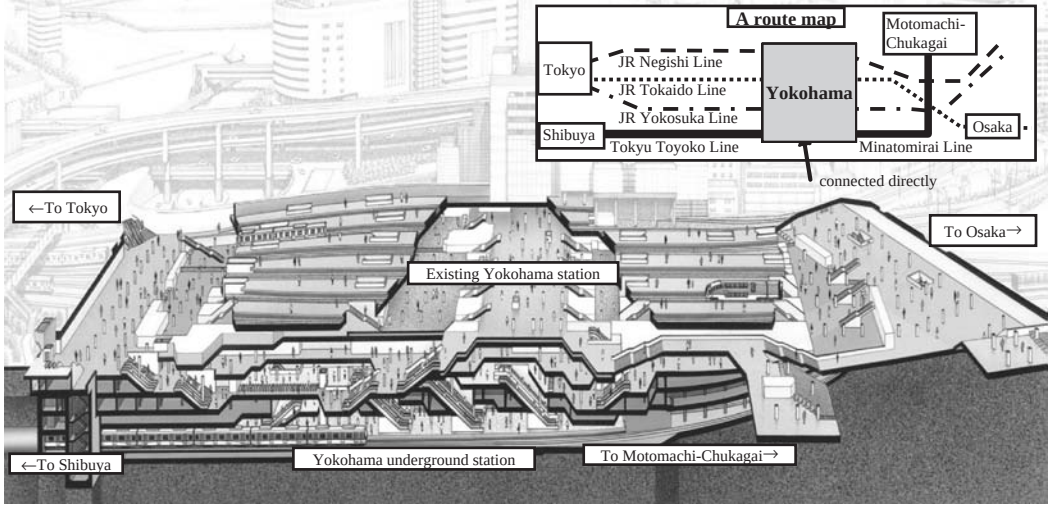

Figure 1. As-built of Yokohama underground station and a route map.

Yokohama Station is used by about 2.3 million passengers every day, serving JR's Negishi Line, Tokaido Line, and Yokosuka Line, the Tokyu Toyoko Line, the Keihin Kyuko Line, the Sotetsu Line and the Yokohama municipal subway through various structures, viaducts and underground tunnels. Yokohama Station is surrounded by station buildings to the east and west, as well as the Aratama River and Katabira River that run north to south.

With no vacant space available above ground, the connecting point of the Minatomirai Line and the Tokyu Toyoko Line was set at about 25 m under the JR Yokosuka Line and the Tokyu Toyoko Line, and a four- to five-tier box-shaped underground station measuring 25 m in width and 418 m in length including the crossing part was constructed.

This paper reports mainly the challenges in terms of geological conditions, working space, available working hours and many other restrictions that were met while constructing this large underground station under a busy, large terminal railway station.

2 AREA SURROUNDING YOKOHAMA UNDERGROUND STATION

2.1 *Geology and underground conditions*

The geology of the ground is very different between the Tokyo side of Yokohama Station and the Kobe side in terms of the depth of bearing stratum, status of geological stratification, and other geological parameters. The Tokyo side ground has good geological conditions, with the Kazusa Group lying between a depth of about 15 m and the ground surface and having an N-value of over 50, whereas the Kobe side ground has a cohesive geological condition down to a depth of greater than 40 m from the ground surface, with an N-value of less than 2. It was a major design and engineering challenge to construct the underground station in such complicated ground.

In addition, a high level of groundwater and the presence of confined groundwater over the entire construction site posed further difficulties for the construction work, including the potential lifting of the underground station structure. Therefore, meticulous design and engineering studies had to be conducted (Fig. 2).

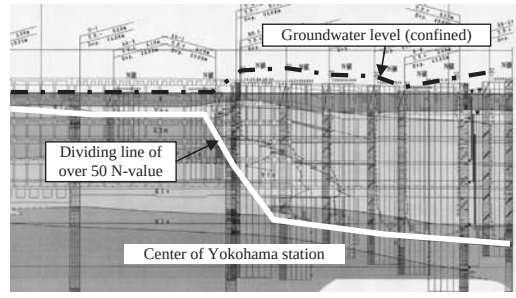

Figure 2. Schematic diagram of Yokohama underground station, geology and groundwater.

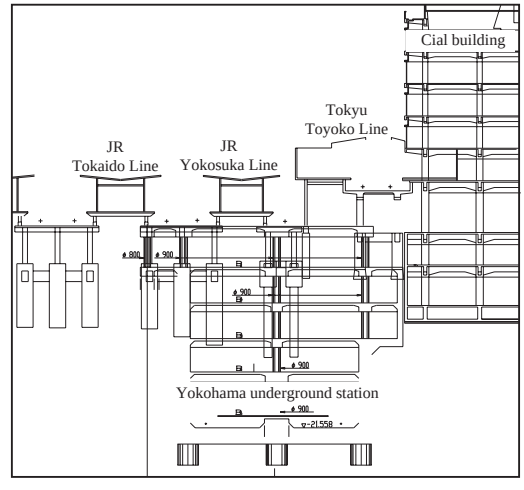

Figure 3. Main body of station – standard section.

2.2 *Structural outline of the underground station*

The Yokohama underground station for the Minatomirai Line and the Tokyu Toyoko Line is a box-shaped structure measuring about 418 m in length, 25 m in maximum width, and 25 m in height. The dimensional details include 24 m for a vertical shaft, 209 m for the structural shell of the station, and 185 m for the crossing under the JR tracks. The structural shell of the station is located immediately under the track of the Yokosuka Line and the viaduct of the Tokyu Toyoko Line. The underground station is thus composed of five layers: one aboveground level that is integrated with the existing JR Line viaduct and four underground levels, as well as two spans (Fig. 3).

In view of the fact that a building is planned to be constructed on the ground above the underground station, specifically a 85-m section from the starting point of the station shell, the steel reinforced concrete construction is adopted for the 85-m section to ensure architectural consistency with the specifications of the future building. The remaining 124-m section was constructed using two different types of construction to reduce the construction period of the underground station although the original plan was to use reinforced concrete construction only. To be specific, steel construction was adopted for the beams and columns of the aboveground part (B0F) and part of the underground level (B1F and B2F), while reinforced concrete construction was used for levels from B3F to B5F.

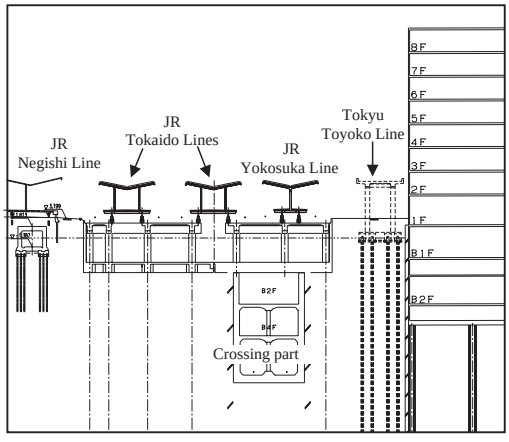

Figure 4. Crossing part – standard section.

The crossing section, which is near the end of the underground station, is a 185-m tunnel that crosses sideways immediately under the existing eight JR lines and connects the main body of the station to the shield-excavated tunnel near Motomachi-Chukagai station.

The structural shell of the crossing section is a reinforced concrete box rigid-frame tunnel, measuring about 14 to 18 m in total width and about 18 to 20 m in height, and with the number of levels and spans varying from 4 and 2 for the station proper to 3 and 1 for the shield-excavated tunnel (Fig. 4).

2.3 *Construction of the underground station*

2.3.1 *Restrictions on work*

Yokohama Station is a large terminal station with some 2.3 million passengers daily, and also operates cargo trains running on a tight schedule. Construction of the underground station faced various restrictions, including that no trains of the existing lines should be forced to reduce speed during excavation. A subway station is generally constructed perpendicular to the direction of the existing track to minimize the influence on the track, but the Yokohama underground station had to be built parallel with the existing tracks since the station buildings and their basements already stand along the existing tracks. Therefore, temporary girders to support train loads had to be built for about 2.4 km in total (283 spans in total). Further restrictions included very short night-time working hours of 3 hours minimum and about 4 hours on average between the last train and the first train.

2.3.2 *Construction procedure*

The Yokohama underground station was constructed as follows, as illustrated in Figure 5.

The existing Yokohama Station, before commencement of the underground station work, had train tracks both on viaducts and embankments. Before excavating

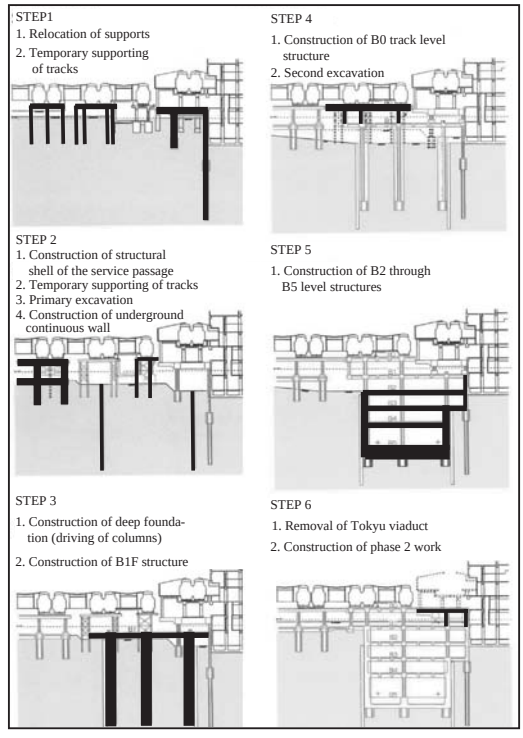

Figure 5. Construction procedure of Yokohama underground station.

the ground, the JR line tracks and the Tokyu Toyoko Line tracks had to be temporarily supported to ensure their structural stability.

[Step 1]
A tentative viaduct was constructed by JR East Japan to support the JR line tracks, while the Toyoko line tracks were temporarily supported by the underpinning method by Tokyu Railroad Company.

[Step 2]
The ground was excavated down to the B1F level of the underground station to create a working space immediately under the existing railroad tracks. Then, the cast-in-situ diaphragm walls were constructed as earth retaining walls to allow further excavation down to the B5F level.

[Step 3]
The ground was excavated down from the B1F level to the B5F level by means of the deep foundation method, and steel pipe columns were constructed from down to up. Then, the structural shell of the B1F was constructed.

[Step 4]
The viaduct to support the JR line tracks was constructed and replaced the temporary viaduct, which was then demolished and removed.

[Step 5]
During construction of the viaduct for the JR line tracks and demolition of the temporary viaduct, the process of excavation and construction of structural shells was repeated to construct the underground station, using the inverted lining method as the main construction method.

The underground station was opened on January 31, 2004, which was the timing when Step 5 was completed.

[Step 6]
From February, the Tokyu Toyoko Line was relocated to a newly constructed tunnel under Yokohama Station, and the former viaduct was demolished. Ongoing construction of the ground level structure of the underground station is the last step, completion of which will mean the completion of the Yokohama underground station.

3 NEWLY INTRODUCED OR DEVELOPED TECHNOLOGIES

The staff repeatedly studied various ways to complete the project within the schedule, and a number of technologies were improved and newly developed to meet the challenge and cope with various restrictions posed by the surrounding conditions and associated engineering difficulties.

3.1 *Development of screwed rotational jack steel piles*

Temporary piles for work girders had to be driven to a depth of about 30 m because of the soft ground and the deep bearing stratum, but as there was only a 2.5-m clearance due to the feeder lines, 17 parts had to be connected to form a single pile. In addition, each pile had to be constructed during just a two- to three-hour period at night when the trains were not running. The screwed steel joint technique was therefore developed and used, as shown in Figure 6. This technique successfully increased the amount of work done each night and reduced the pile construction time. In detail, the conventional method requires 90 minutes to construct a welded joint pile, whereas the screwed steel joint technique can accomplish a single pile in 20 minutes. With the conventional welding joint technique, it would have taken 5 or 6 years to complete all the piles, while the new technique could finish it in almost half the time, or about 3 years.

3.2 *Development of attachable pile cap joint*

Steel pile caps needed to be quickly, neatly and precisely treated to construct lateral girders of temporary viaducts. With the conventional welding connection,

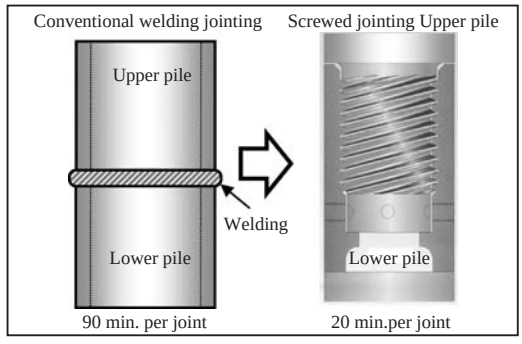

Figure 6. Schematic diagram of screwed steel pipe joint technique.

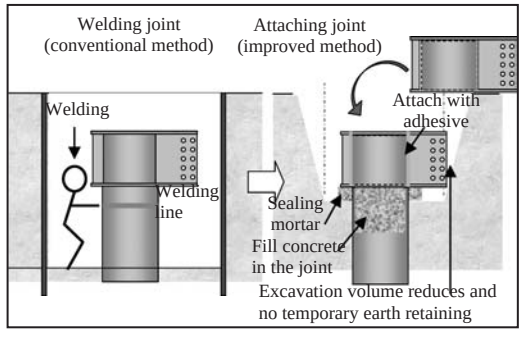

Figure 7. Schematic diagram of attachable pile cap joint technique.

not all the procedures for pile cap treatment could have been completed in just three hours at night. With the screwed technique, however, sufficient precision in the connecting joint was not possible, so a new technique, as shown in Figure 7, was developed. In the new technique, a connecting joint is put over a steel pile head like a cap, the cap-like joint is connected to the steel pile with acrylic resin adhesive filled into the space between the joint and the pile top, and concrete is filled inside the joint to ensure integration. This technique reduced the work load and the volume of excavation, eventually finishing the pile cap treatment work in a single night, down from two nights.

3.3 *Development of the mechanical deep foundation construction technique*

It was necessary to construct main posts for the underground station (2.6 m in diameter and about 30.0 m in length) under limited working conditions with a short overhead space immediately below the existing railroad tracks, and so a deep foundation had to be constructed. However, the conventional approach could not have completed the necessary work safely and smoothly because of the poor working conditions

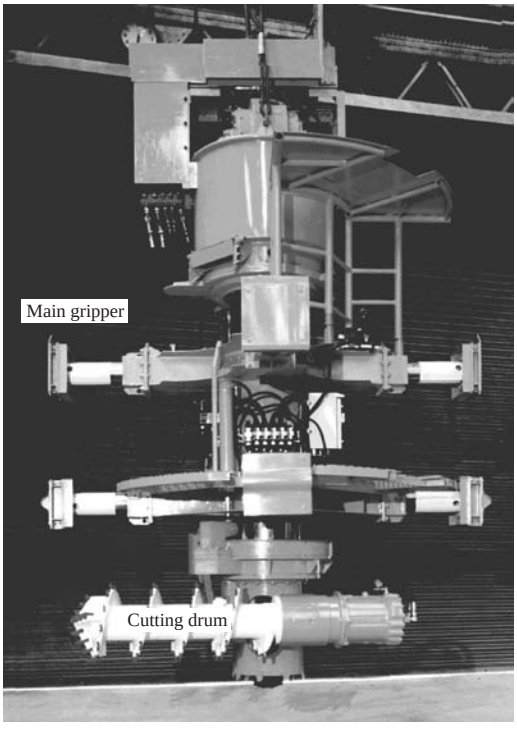

Figure 8. Deep foundation construction machine.

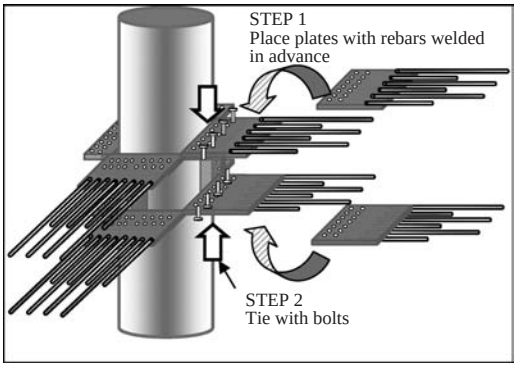

Figure 9. Illustration of connection.

and small number of experienced workers. Therefore, an automatic machine designed to excavate and install liner plates was developed, as shown in Figure 8. This machine successfully allowed safe and smooth construction of a deep foundation in small working spaces.

3.4 *Development of a new technique to connect steel pipes and RC beams*

Steel pipe columns were used for the main columns of the underground station to shorten the construtionperiod, while reinforced concrete beams were used for those connecting the columns to improve economic efficiency. Since there were about 400 places where steel pipes had to be connected to RC beams, a simple connecting technique was needed. A new technique was developed involving an integrated structure in which diaphragm plates at the connection of the steel pipe columns are tied by bolts to plates with mechanical joint rebars welded in advance. The application of this type of precasting technique to the connections of steel pipes and RC beams successfully reduced the field working hours and greatly shortened the total working period (Fig. 9). Before being put to practice, this new technique was proven to be effective by conducting a scale-model experiment and three-dimensional FEM analysis.

3.5 *Development of the steel element continuous wall*

For excavation for the external part of the western side continuous wall (referred to as "extended part") of the main part of the station, and construction of the structural shell, the original plan was to first construct the main body of the station under B2F, without which no extended part could be constructed in terms of structural stability. However, we were requested by the client to bring the start-up timing forward by two months, so we had to shorten the construction period. We drove angular steel pipes called JES (jointed element structure) vertically while manually excavating the ground, and filled the inside of the pipes with concrete. This work eliminated the need to construct the main structure of the station and allowed construction of the main walls that also serve as temporary earth retaining walls without affecting the structural stability of the underground station. Eventually, this technique shortened the original schedule by three months, and it was applied over an area of some 500 m^2. JES are generally applied horizontally in the construction of a tunnel crossing under a railroad track, but for this project they were used vertically (Fig. 10).

4 CONCLUSION

The Tokyu Toyoko Line tracks were relocated to the underground tracks on January 31, 2004, which allowed use of the Yokohama underground station. Then, the Minatomirai Line was opened on February 1, 2004. The work faced a number of challenges, including various restrictions posed by operation of train services, fluctuating loads of station users and special geological conditions immediately under the existing large terminal station. Strenuous efforts were made to study the conditions and develop new engineering ideas, and the project was successfully completed

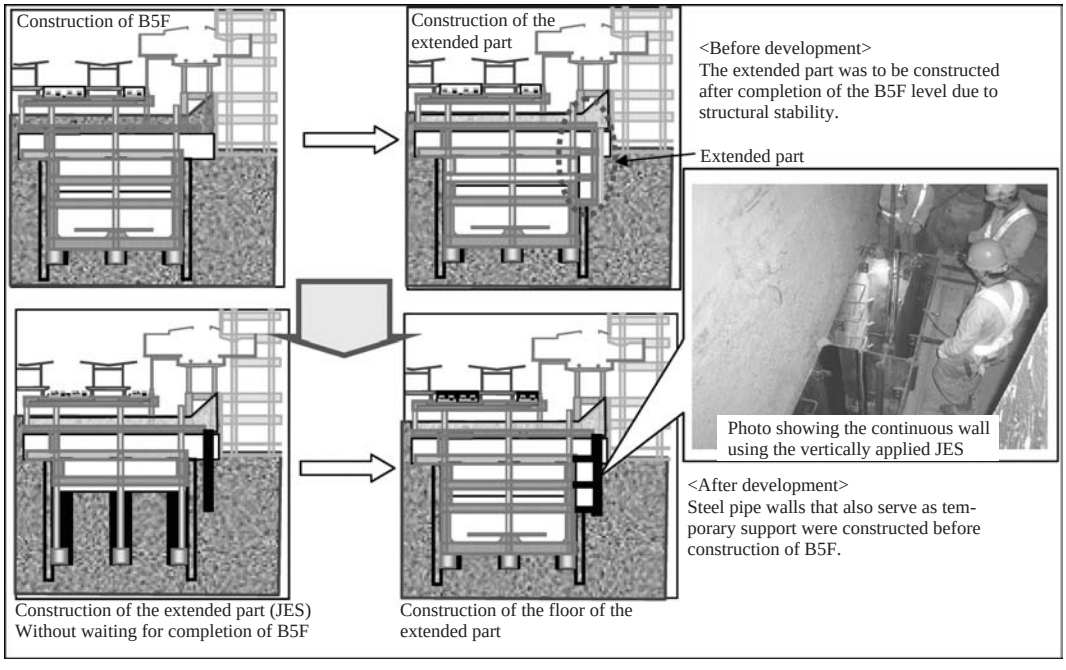

Figure 10. Schedule reduction by construction of continuous diaphragm walls.

about two months earlier than originally planned (March 2004).

The Minatomirai Line has started operation, but some work remains to be done, including deconstruction of the former Tokyu Toyoko Line viaduct and associated construction of the second phase of the underground station. The authors hope that this report may be of help to similar projects in future. Finally, the authors would like to thank all the people involved in this project.

ABSTRACT: This paper attempts to see into the future of subaqueous tunneling and look at some exciting technologies that are beginning to come together to make possible the efficient underwater transportation of people and cargo over heretofore unheard of distances. Further this paper identifies some of the unique environmental benefits of the Submerged Floating Tunnel concept when combined with underground and commercial and municipal facilities. stations, shops and any other suitable activity needing space.

1 INTRODUCTION

At the beginning of the 20th century the only known ways to construct a tunnel under a waterway were by simple digging, sometimes under air pressure and by a new "high tech" method, just emerging initially referred to as "Sunken Tube Tunnel". During the 20th century over 150 tunnels were constructed by this Immersed Tunneling(IT) method. These tunnels were used for many purposes including rail and highway transport, material transport, and the subaqueous crossing for various utilities such as water, sewer, petroleum etc. The Immersed Tunnels are prefabricated in sections 100–200 m. long, sealed by bulkheads at the ends, floated to the tunnel site and lowered into a trench whereby they are joined hydraulically and later backfilled.

Another idea for underwater tunnels had been around for nearly 150 years but was never seriously considered until recently. The idea of a tunnel with a vertical alignment above the bottom of the waterway and either floating with some form of stabilizing support, or simply supported on underwater piers in the form of an underwater bridge. This is what is termed the Submerged Floating Tunnel (SFT). This idea was originally proposed in 1865 for an underwater bridge crossing the English Channel, by a British Naval Engineer, Sir Edward James Reed.

In the 1980's and 90's several crossings of this kind were seriously considered and preliminary designs were developed, notably in Norway (Hogsfjord), Sicily (Strait of Messina), Italy (Lake Lugano) and others in Japan.

As a result of the increasing use of the immersed tunnels for underwater crossings all over the world and the new found interest in the SFT Concept, in 1987 at the World Congress in Manchester, UK, ITA established Working Group 11 "Immersed and Floating Tunnels" to foster these tunneling technologies internationally.

Since then WG 11 has presented many technical papers and has also published two editions and most recently an on-line version of the "Immersed and Floating Tunnels State of the Art Report".

This paper is now intended to take these existing technologies for underwater tunnels and suggest means by which they can be extended perhaps by a factor of 100 or more to serve the developments in long distance transportation in MAGLEV.

We name these extended tunnels "VLT", (Very Long Tunnels)

An extension of VLT is very briefly mentioned at the end of this paper, the Trans Ocean Tunnel (TOT) The combination of land based tunnels and submerged floating tunnels facilitate the use of underground space for a long list of purposes, such as underground parking, service stations, shops and any other suitable activity needing space.

2 EXISTING TECHNOLGY

2.1 *The immersed tunnel*

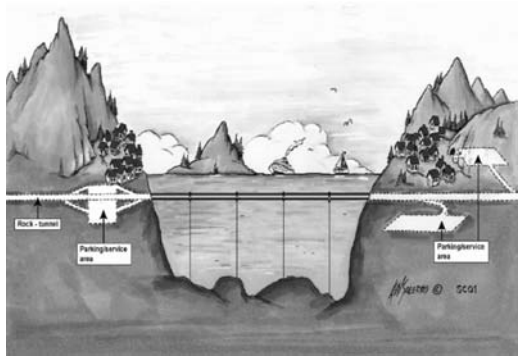
The immersed tunnel method is a well developed technology of great versatility. None of the existing tunnels

are alike. Each is designed to serve a set of specific requirements for interior space, type of throughput, environmental conditions, construction constraints, ventilation, structural strength, seismic loads, accidental loads, etc. Because of this, there exists a wide range of available design and construction experience on which to draw in moving to the development of the as yet untried SFT.

There are, for example, a few basic structural configurations used in immersed tunnels. The most prevalent, particularly for vehicular traffic, is the rectangular concrete box section. This has been widely used in Europe and other parts of the world. In the United States where the technology started however, various forms of single and double steel shell structurally composite sections largely became the norm. In these sections, the steel shell both acts as a structural composite medium with an interior concrete load carrying lining and as a waterproof enclosure..

The construction of these tunnels is a shipyard operation with steel shell elements being assembled from prefabricated modules into long single or double tubes. Bulkheads are fitted to the ends and the element can either be end or side launched or it can be floated out if assembled in a drydock. The interior concrete structure is then largely constructed while the element floats at a jetty. The foregoing methodology is particularly well suited to the development of the SFT.

2.2 *The Submerged Floating Tunnel*



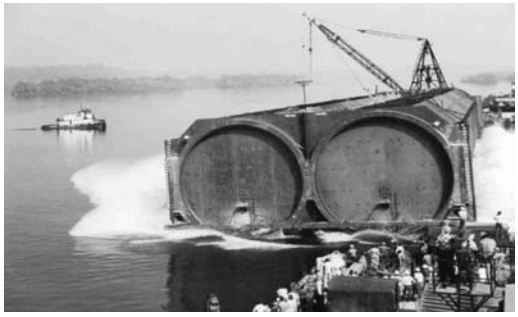
It is now time to describe the SFT as this is the bridge between the immersed tunnel and the Very Long Tunnel (VLT) the subject of this paper. The SFT takes the immersed tunnel and raises it out of the mud, so to speak. The immersed tunnel has an important advantage over the excavated tunnel in that its depth need only be a few meters below the bottom of the waterway. A shield driven tunnel, for example, must be at least a diameter below the stable bottom putting it perhaps ten meters deeper or more. For a rail tunnel with flat gradients of say 0.015 this will increase the total length of the tunnel by $(10/.015)2 = 1{,}333$ m.

Take the example of a crossing under a fjord where the depth might be 500 m. Given the same navigation depth requirements as for the previous example, the SFT would only be as long as the immersed tunnel, but in this case the immersed tunnel would be outside of the range of feasibility for IT's and a bored tunnel would be say $(530/.015)2 = 71$ km longer!

At such a depth to cross, it could be anchored directly by steel tethers attached to bottom anchors spaced along the tunnel alignment.

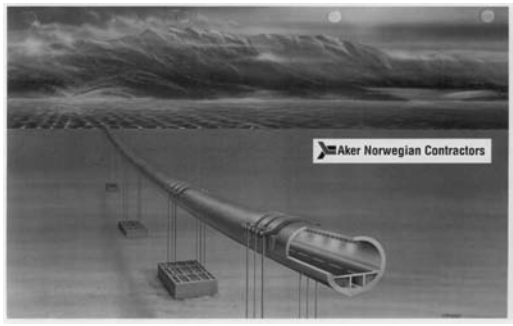
2.3 *Design of the SFT*

As for the IT, almost any configuration can be adapted for the SFT. The structure can be solely concrete, solely steel, or a steel/concrete composite. It can be multilane or multi-track. It can be rectangular or it can be circular. Whatever the configuration, as the depth is made greater the structure increasingly favors a circular cross section for efficient design. Tethered SFTs must float with sufficient positive buoyancy to maintain stable tension in the tethers under all loading conditions. At greater depths, the concrete becomes too much of a dead load so that steel alone may be used. Exterior flotation material may be used to augment positive buoyancy.



Dynamic loads caused by waves, swell, wave drift forces, vortex shedding or varying currents can cause trouble if these forces are not well understood and properly accounted for. Often physical modelling can be helpful directly or can be used to calibrate and verify software for appropriate modelling of such phenomena. Such model testing and evaluation of the test results with particular emphasis on the slowly-varying motions have been done in the Høgsjord project. Based on the present state of the art, circular cross-sections are favoured also from a hydrodynamic point of view.

The terminal ends of the SFT where the tunnel enters the rock or the ground will require special design to limit the motion without focusing load, especially if seismic forces must be taken. Potential lateral, vertical, and longitudinal motions must be taken into account.



2.4 *Construction of the "unsinkable" SFT*

As this discussion will eventually lead us to the next step, the VLT, let us say that we are going to build a tethered, steel shell SFT to cross a 2000 m wide waterway 400 m deep at the center. This SFT will carry three tracks for electric trains. The signal system will be operated so that no more than one train can be in the tunnel on two of the tracks at any one time. Further the tunnel will be designed so that it will not sink and self-destruct if it is breached and filled with water.

The bottom of the water channel is soft and has a low bearing capacity so it must be improved by piling or simply gravel replacement of the soft strata. Large gravity anchors will be used. The elements will be

Example of immersed tunnel of steel.

An approved alternative for SFT and possible anchoring system for (VLT).

200 m long and the anchors and double tethers (on each side) will have a longitudinal spacing of 50 m or four sets per element located so that they miss the joint areas.

Each of the ten elements is constructed on side launching shipways and all are straight as drainage will all be toward one end. A 2 meter thick layer of syntactic foam (made of glass microballoons that will not crush or deteriorate in water pressure) covers the circumference of the tunnel except at the joint areas providing reserve flotation capable of supporting the tunnel if the interior floods. For the SFT to be unsinkable it must have sufficient flotation capacity to allow the entire running tunnel tubes to flooded while maintaining a nominal tension in the tethers.

The joints are designed and the elements are connected very much using the well-proven method used for immersed tunnels. in that an initial seal is first made to seal the joint area so that the water pressure can be released and the full hydrostatic force at the other end of the element being placed can compress the gasket (GINA) and permit a full structural connection to be made.

2.5 *Tethers and anchorages, offshore Technology*

Over the last few decades offshore platforms have been constructed and operated in deep waters, such as in the Gulf of Mexico, the North Sea and off Brasil.

Vast experience has been gained regarding forces exerted on offshore structures by waves and current, the motions induced by these forces and on the hydroelastic interaction between the forces and the motions. Better understanding of phenomena and sources for slow-varying motions has been acquired. This understanding is of vital importance for the safe design and configuration of an SFT with its anchorages.

The Tension Leg Platform (TLP) with its tethered connections to the sea bottom has in particular paved the way for the use of this technology also for structures like the SFT. This applies both to the design and installation of the tethers and their anchoring elements on the sea floor.

For relatively shallow SFT's with depths in the order of 100 m. cable or pipe tethers may be suitable but as the depth gets deeper, the tethers themselves must be more sophisticated. The offshore oil industry has led the way in this respect in the design of tethers for their Tension Leg Platforms (TLP's). Special pile anchorages and floating hollow tethers have been used offshore. This technology is well developed and should be adaptable and suitable for use for SFT's and VLT's.

2.6 *Tunnel saddles*

The method used to connect and fine tune the tethers to the tunnel structure is an area that still requires a great deal of study. The configuration of the tethers themselves and how they attach to the tunnel and transfer huge loads requires special attention in the structural design of the tunnel itself.

A limitation on the use of the SFT is the depth of water. At some point the tethers become too long and laterally flexible allowing unacceptable deflections. It is doubtful that a completely stable SFT can be built in more that 1000 m. of water depth. Unless measures as described to provide enough flotation in the SFT to prevent its destruction in the event of accidental flooding, such a tunnel would be high insurance risk.

For Høgsfjord it was found that, where the tunnel would arch between the abutments, it would be too vulnerable to slowly-varying wave/current forces, and concluded that tethers with sufficient high lateral stiffness was preferable.

2.7 *Stability of tethers:*

The tethers can be unstable due to varying tether forces (so-called Mathieu-instability) also for relatively short tether lengths. The key thing here is to configure a tether system with high enough stiffness both vertically and horizontally. A combination of inclined and

vertical tethers every second pair of tethers might be one interesting possibility.

3 THE VLT

3.1 *The very long SFT + MAGLEV + Vacuum = the VLT*

Say you want to cross the Irish Sea between England and Ireland. It is some 100 km wide and less than 200 m deep. How would one do this. Vehicles are out, but trains maybe. . .

One concept that has been given some attention recently, is the building of a long tunnel and keeping it at a full or partial vacuum. By using frictionless MAGLEV propulsion, theoretically, trains could travel a very high speeds of say 1000 km/hr or faster in such a vacuum and make the 100 km crossing in ten minutes or less allowing some time for acceleration and deceleration.

MAGLEV or Magnetic Levitation of course is the technology now being used to propel trains at great speed by magnetically raising them above what in effect is the stator part of an alternating current motor. By so doing there is only air resistance to overcome. By removing most or all of the air, the train can operate at very high speeds with little energy usage. Most of the energy used is due to resistance losses in the MAGLEV "rails".

So if we take the SFT example we developed above, build the special termini with airlocks and vacuum pumping stations, provided MAGLEV trains equipped with self-contained breathable air/oxygen and assured a very stable precisely aligned leak-proof tunnel, a new international travel system will have been created.

3.2 *Things to consider*

Of course it is not quite as simple as it sounds. For these tunnels to operate safely and comfortably, their alignment must be maintained to precise tolerances. This is not easy to do in open ocean conditions with storms, waves, currents, varying water densities and the weight of the trains themselves acting to displace the tunnel. This favors the idea of going deeper to stay away from the turbulent surface conditions that may prevail. But going deeper requires more structural strength and more weight. Leakage is not an option as any water entering the tunnel will flash into vapor in the tunnel and provide a local pressure that might buffet the train besides that salt would be deposited everywhere and salt is an enemy of electrical equipment.

A long list of problems will have to be solved, among these the amount of electrical power needed, how to produce it and transport it.

The construction and maintenance of the MAGLEV system, the vacuum system, the air-locked train stations and switching yards would be costly and complicated but certainly doable.

For intermediate access and exit to and from the VLT one can imagine intermediate (tethered) submerged stations provided with shafts to a platform above the wavezone. Very much like the existing Tension Leg Platforms. These stations can initially serve for the construction of the tunnel, later for maintenance and for emergency evacuation.

3.3 *Construction time and cost*

Continuing with our 100 km crossing example what will the components of the system be and how long will it take to construct them? At 200 m. per element, there would be 500 elements to construct.

These units would likely be built in shipyards or specially equipped fabrication sites. For easy installation and hookup, most of the electrical mechanical "guts" of each element would be in place when connected into the tunnel so that only the work in the joint would be required.

It is likely then that the fastest any element could be constructed would be 3–6 months. Based on the present day industrial practice for steel tunnels at shipyards, we assume a learning curve for each shipyard so that the average production speed would be 4 months per element, 500 elements would require 2000 shipyard months. To complete the production in say 10 years would take $2000/120 = 17$ shipyards working continuously.

The cost of such a structure would be high compared with the cost of present day tunnels, however these tunnels may be a possibility to help solving future transport problems.

3.4 *Safety*

3.4.1 *Collision from vessel*

While the chances of such a collision should be very low since the SFT and the VLT are essentially exposed to the danger of a ship sinking or a submarine collision, it may not be possible to design a tunnel to absorb such an impact. However small ships would not be a problem given the mass and strength of the tunnel. It is noted that the current practice in designing immersed tunnels provide for accidental loads by sunken ships that could easily be carried by the VLT. Especially if constructed to be unsinkable. Furthermore, it is entirely possible to replace a damaged or destroyed section of tunnel underwater given that the design has provided for a stable flooded tunnel.

If an SFT/VLT is not capable of floating in a flooded condition it will of course then be lost by collapsing to the ocean floor.

3.4.2 *Terrorism*

For bored or immersed tunnels the danger of terrorism is from the inside. For SFT or VLT the outside is also

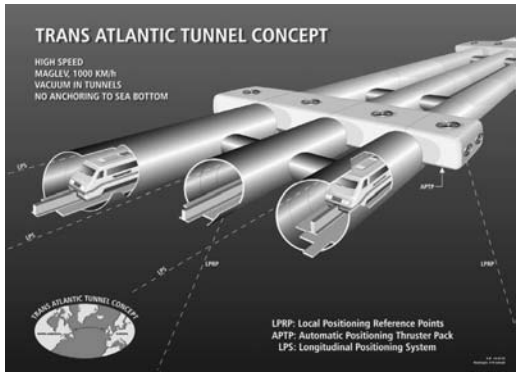
exposed. The danger of terrorist is always present, any underwater tunnel could be a target with the larger, longer tunnel being a bigger "statement" . As the case of airlines, security will be the first countermeasure. However the use of interior foam for flotation can also be designed to absorb explosive energy so that even though a car and train be destroyed, there may be a way to design and prevent the breaching of a SFT or VLT tunnel.

4 ADVANTAGES OF THE SFT/VLT

The SFT can be environmentally attractive as they put roads or railroads out of sight. This is especially beneficial in areas of natural beauty where congested roads or noisy railroads along lake shorelines can be a real blight.

In certain cases, since the roads entering shoreline towns are entirely hidden underground, they might be connected to parking garages and shopping malls also underground and hidden.

These tunnels save fuel/energy by keeping tunnel alignments flat. Steep grades in conventional tunnels require heavy fuel consumption, especially for cargo trucks.



Of course, the proposed combining fast transport with very long tunnels has many potential benefits. While these benefits and technical breakthroughs are very attractive, in the end their costs must be justified by the traffic they will carry.

4.1 *Preliminary conclusion for Submerged Floating Tunnel*

The SFT is a viable environmentally friendly alternative method for underwater transport both vehicular and rail as well as other pipeline, conveyor, or services that might be desired. It is an extension of the immersed tunnel technology with new aspects and engineering problems to solve. No SFT has yet been constructed. This may be because all the SFT's put forward so far are vulnerable to collapse if flooded, but as indicated above, SFT may be made unsinkable. SFT's are more costly on a unit basis of cost per kilometer than tunnels that are excavated but may make up for that by shortening the tunnel significantly.

4.2 *Preliminary conclusion for Very Long Tunnels*

The VLT is an extension to the SFT. The idea of a high speed MAGLEV railroad within a vacuum tunnel seems very novel and interesting. It would only seem to justify itself for significant distances of say more than 50km. Such a tunnel would seem to take many years to amortize its cost and the energy involved in its construction. However with the industrial base in place to produce such tunnels and efforts to standardize components, it might well turn into a wave of the future

A futuristic example of a Trans Ocean Tunnel

with longer and longer subsea tunnels eventually transitioning from VLT's to Trans ocean -Tunnels (TOT's)

40 years ago when containerized cargo began to appear in ports, who could have visualized the huge ships carrying 10–15,000 standardized containers of present day?

4.3 *Some thoughts on Trans Ocean Tunnels (TOT)*

Connection between continents may be called for in future for reducing the use of energy in transport of people and goods.

Combination of all kinds of tunnels and tunneling technology would be required, soil and rock tunnels, immersed and submerged floating tunnels and completely new technologies and solutions.

This would be one of the big challenges of the future in the tunneling industry and preliminary investigations and research should start now.

5 HISTORY AND BACKGROUND

5.1 *Brief history*

In 1865, Sir Edward James Reed, MP for Cardiff put forward the idea of crossing the English Channel in a tunnel suspended on top of caissons. The concept did not win much support, as members of Parliament feared this to be a possible route for invasion of the British Isles.

Recently , a number of studies have been carried in Italy, Japan and Norway. One of these studies, for the Høgsfjord Project in Norway was taken as far as being approved for final engineering design by the Public Roads Administration. This project brought forward four separate concepts, three as concrete tunnels and one alternative in steel as the main construction material. The anchoring methods were by pontoons on the surface or as tethers to caissons on the sea bed.

5.2 *Publications and Conferences*

The following is a summary of recent SFT publications, project studies and conferences , this list is by no means complete, but will illustrate the interest this special structure has received .In addition to this list a large number of presentations have taken place in conferences and seminars over the last 20 years or so.

1973 Vallavik-Bu, Norwegian Public Roads Administration (NPRA), reports
1984 Messina Strait
1989 AIOM Congress , Napoli, Italy
1990 Wegen naar de toekomst (Roads to the future) Robbert and Rudolf Daas, publ.Tirion, Baarn, NL
1996 First International Conference on SFT, under the auspices of the NPRA
1996 FEHRL Report on Analysis of SFT concept
1997 ITA, Working Group no.11, State of The Art Report
1999 Strait Crossings Working Group, ITA, NPRA
2000 Seminar Varenna, Italy, Ponte di Archimede, NPRA
2002 First US workshop on SFT, AUCA
2003 The elevated immersed tunnel James Felch, WCT, Amsterdam, 2003
2004 Discovery Channel, Extreme Engineering, Program: “Trans-Atlantic Tunnel”

Some examples of Project studies known to the authors, there are likely other studies not recorded below:

Vallavik-Bu, NPRA, Norway
Høgsfjord Project, NPRA, Norway
Strait of Messina, Italy
Lake Lugano, Switzerland
Funka Bay, Hokkaido, Japan
Lake Mjøsa Crossing, NPRA, Norway
The Storfjorden Crossing, NPRA, Norway
Lake Washington, Washington State , USA
Lago di Como and Magiore, Italy

6 OVERALL CONCLUSIONS

SFT, VLT and possibly TOT will be challenging future opportunities for cooperation within the whole tunneling industry. ITA may be the most important forum for these exciting possibilities.

Planning and construction of major infrastructure works in Croatia

J. Radic
Faculty of Civil Engineering, University of Zagreb, Zagreb, Croatia

P. Djukan
Civil Engineering Institute of Croatia, Zagreb, Croatia

Z. Zderic
Konstruktor-inzenjering, Split, Croatia

ABSTRACT: The paper presents recent accomplishments in tunnel construction in Croatia, which was part of a much bigger undertaking – development of national motorway network. Over the last decades Croatia made large investments in order to construct the planned 1500-km of motorways. The total length of motorways and semi-motorways currently operated in Croatia amounts to 1020 km, half of which were constructed over the past 5 years. Further works comprise extension of motorway network, as well as rehabilitation of older sections. Development of highway network required construction of a large number of motorway structures. Overall 55 tunnels will in the end provide for little over 86 km of Croatian motorways, including two longest tunnel structures in Croatia: Sveti Rok tunnel (5670 m) and Mala Kapela tunnel (5780 m) completed in 2003 and 2005, respectively.

1 INTRODUCTION

The last decade is marked by extreme growth of construction in Croatia, mainly in terms of intensive development of motorway network. Numerous structures were build to carry motorways across wide rivers, large valleys or deep gorges, cut through mountains, or simply provide facilities for safe and comfortable transport.

Motorway network construction is currently the most important development project in the country. After gaining its independence in 1991, Croatia was faced with insufficiently developed road network.

The strategic significance of the construction of motorways for the Republic of Croatia was soon recognized (Radic et al. 1999) with the long-term development programme of the Croatian road network outlined in Road Network Development Strategy (Banjad et al. 1996) adopted by Croatian Government in 1996 and Croatian Parliament in 1999 (Fig. 1).

Subsequently the construction gained speed and currently the total length of motorways operated in Croatia amounts to 1020 km (www.huka.hr), half of which have been constructed over the past five years. It is planned to construct the total of 1501 km of motorways, and the works are advancing as scheduled (www.hac.hr). Figure 2 indicates the current stage of completion of Croatian motorway network.

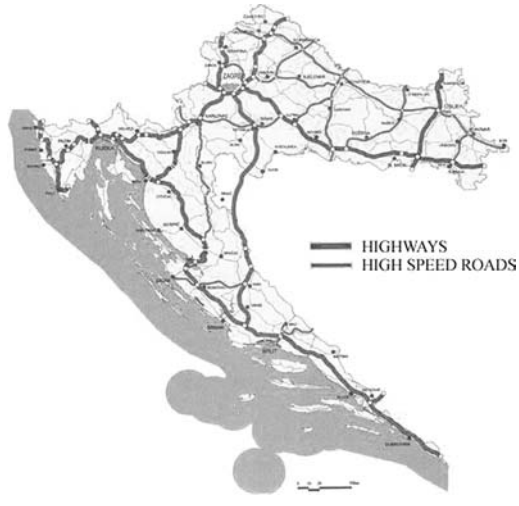

Figure 1. Road network development strategy.

The Croatian motorway network may not seem long, but it is worth mentioning that Croatia already has more kilometres of motorways per 100 000 citizens than UK, Ireland, Greece or Italy.

Development of motorway network required construction of a large number of motorway structures

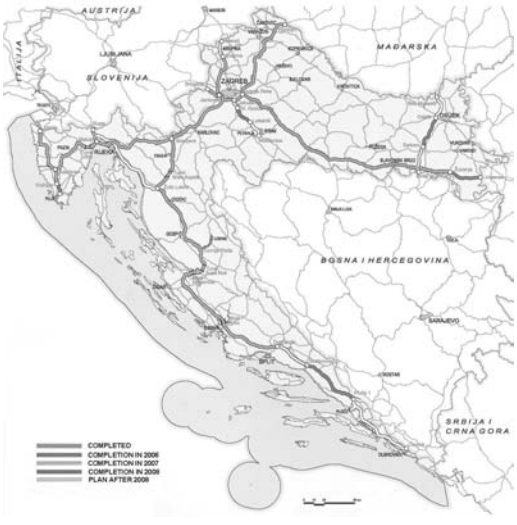

Figure 2. Motorway network in croatia (2005).

(Radic et al. 2006): tunnels, bridges, viaducts, overpasses, underpasses, wildlife crossings etc. For instance, 292 motorway structures account for 19% of the 380-km long Zagreb to Split motorway route. Large-span bridges and long tunnels are the most complex and most expensive part of the network.

2 TUNNELS

2.1 *General*

Overall 55 tunnels (refer to Table 1) will in the end provide for little over 86 km of a total of 1501 km long Croatian motorway network. Two structures stand out – Sveti Rok Tunnel, with total length of 5670 m and Mala Kapela Tunnel with total length of 5780 m, which is the longest tunnel in Croatia, and these shall be described in more detail.

Figure 3. Bisko tunnel.

2.2 *Current works*

Currently, work is in progress on several tunnel structures on Zagreb to Rijeka motorway, Zagreb-Macelj motorway, as well as on motorway sections in the most southern parts of Croatia, which provide for the motorway extension from Split to Dubrovnik.

Most of the structures are constructed as twin-tube tunnels, except on the Rijeka to Zagreb motorway where the current works comprise addition of the second tube to already existing two-way traffic single tubes.

We shall mention only two tunnels among many structures currently under construction: Bisko Tunnel and Strazina Tunnel.

Bisko Tunnel shown in Figure 3 is a twin-tube tunnel with the total length of the left-hand side tunnel tube of 493.5 m and the right hand side tunnel tube of 500.9 m.

Tunnel tubes are spaced at a minimum distance of 35.0 m. The eastern tunnel portal is located at 392.3 m above the sea level, and the western tunnel portal is at 400.2 m above the sea level, resulting in difference of 7.9 m.

Grade in the longitudinal direction is approximately 1.5%. Each of the four portal structures is 12 m long.

Tunnel tube accommodates two-lane roadway (3.75 m + 3.60 m) with the overall width of 7.35 m. Transversal slope of the roadway varies from 2.5% to 3.5%.

Clear cross-sectional area of the tunnel is 56.17 m^2, but the excavation area is in the range of 71.86 m^2 to 86.26 m.

Overburden is approximately 50 m. Total of 76 400 m^3 of material was excavated.

The minimum thickness of the concrete lining is 30 cm. It is constructed of C 25/30 concrete class and total of 9 432 m^3 of concrete was used.

Construction of the tunnel has started in August 2004.

Figure 4. Strazina tunnel.

The entire section between Dugopolje and Bisko of Zagreb-Split-Dubrovnik motorway is scheduled for opening to traffic in 2007.

Strazina Tunnel shown in Figure 4 is another twin-tunnel tube further to the south along the same motorway route. It is somewhat longer than the Bisko Tunnel, with 565.4 m long left-hand side tube and 587.2 m long right-hand side tunnel tube.

Construction of the tunnel started in June 2005 with the opening to traffic scheduled in 2007.

Tunnel tubes are spaced at a minimum distance of 25.0 m. Averaged overburden amounts to 50 m. Eastern and western tunnel portals are located at 282.5 m and 278.7 m above the sea level, respectively. The longitudinal grade in the tunnel is 0.6%.

The roadway in the tunnel is 7.70 m wide, providing for two traffic lanes of 3.85 m. Transversal slope of the roadway is 2.5%.

Cross-sectional area of the tunnel is the same as that of the Bisko tunnel (56.17 m^2), while the excavation are between 70.60 m^2 and 84.05 m^2. Total of 85 800 m^3 material was excavated for this tunnel, and the amount of concrete needed for the construction amounts to 11 800 m^3.

Each of the four portal structures is 12.0 m long, and there is a cut & cover section in the left-hand side tunnel tube in the length of 24.0 m. Secondary tunnel lining is made of concrete class C 25/30, and is 30 cm thick.

2.3 *Sv. Rok Tunnel*

At the time of its construction the Sv. Rok Tunnel was the longest tunnel ever to be constructed in Croatia. It cuts through the Velebit Mountain (Fig. 5), in a total length of 5680 m.

Prior to the completion of the Sv. Rok Tunnel, the longest tunnel in Croatia was Ucka Tunnel near Rijeka, with a total length of 5062 m, which was opened to service back in 1981 (Fig. 6). But, while the Ucka Tunnel is a single-tube tunnel, two separate tunnel tubes were excavated for the Sv. Rok Tunnel.

Figure 5. Sv. Rok tunnel through Velebit mountain.

Figure 6. Ucka tunnel dating back to 1981.

Sv. Rok Tunnel is located on Zagreb to Split motorway, on section between Sv. Rok Interchange and Maslenica.

The preparation work for the construction including clearing the site of landmines started back in 1996, but the excavation itself began in 1997 and was completed in 1999. The tunnel was opened to traffic in 2003.

Two tunnel tubes are spaced at a distance of approximately 35 m.

At the northern entrance located at 561 m above the sea level the slope of the grade line is 0.40%, and at the southern portal located at 511 m above the sea level the slope is 1.5%.

The clear cross-sectional area of a single tube of the Sv. Rok Tunnel is 58.90 m^2. The area of excavation ranges from 70.90 m^2 to 82.30 m^2.

Figure 7. Inside of the Sv. Rok Tunnel.

Table 2. General data on Sv. Rok tunnel.

	Unit	Value
Northern portal	(m above MSL)	561
Southern portal	(m above MSL)	511
Upward slope beginning of tunnel	(%)	1.5
Downward slope end of tunnel	(%)	0.4
Cross-sectional area	(m^2)	58/tube

The roadway in the tunnel is 7.7 m wide (2×3.85 m; refer to Figure 7) with a slope in transverse direction varying from 1.5% to 2.5%.

Tunnel tubes were excavated using New Austrian Tunnelling Method (NATM), which is the only excavation technique that can be used in the region where tunnel passes through all types of soil.

The excavation of twin-tube tunnel was carried out in two stages.

The first stage included excavation of the entire right-hand side tube and 2700 m of the left-hand side tube (almost 50% of its length).

The lining of the right tube is already executed when the second stage of excavation on the remaining portion of the left tube of the Sv. Rok Tunnel takes place. Blasting induces energy in a form of movement and impact on surrounding soil. The distance between two tubes is not large enough to ignore the effect of blasting.

Thus, the design of the concrete lining of the right-hand side tube had to take into account an additional loading due to blasting in the adjacent tunnel tube (Tkalcic et al. 2002).

Finite element analysis was used for this purpose. Data on velocity of the impact were obtained by on-site testing. Movement of the rock mass was measured in the right-hand side tube were the lining had not yet been constructed. The results provided relation between rock movement speed and time.

Figure 8. Twin-tube Mala Kapela tunnel; currently only one tube is opened for two-way traffic.

The main objective of this investigation was to determine excavation step length at which the existing lining in the right-hand tube can remain without reinforcement. It was concluded that from the economical point of view this goal cannot be achieved.

It would be neccesary to make blasting steps so small that it would be more reasonable economicaly to put some reinforcement in the lining.

The second intention was to keep lining reinforcement at the minimum level which would comply with the requirements of Croatian standards.

Since more than 3000 m of the left-hand tube were not excavated at the first stage, placing reinforcement in the existing lining at that length represents a substantial increase in tunnel cost.

This was the main reason that reinforcement in existing tunnel lining was to be kept at the minimum level.

Only the right-hand side tube of the Sv. Rok Tunnel is opened to traffic, while the other one serves as a service tunnel and escape route, refer to Figure 8.

Completion and opening to traffic of the second tube is anticipated when the traffic intensity requires it.

This tunnel tube contains 4 turning points, 12 stopping lay-bys and 14 cross-passages for pedestrian use.

2.4 *Mala Kapela Tunnel*

Mala Kapela Tunnel is located on Zagreb to Split motorway, on section III between Bosiljevo interchange and Sv. Rok.

The tunnel runs through both Mala Kapela and Velika Kapela massif.

It was opened to traffic in June 2005, together with the final 33 km long motorway section between Vrpolje and Pirovac, thus completing motorway connection between the two largest Croatian cities.

Table 3. General data on Mala Kapela Tunnel.

	Unit	Value
Northern portal	(m above MSL)	562
Southern portal	(m above MSL)	573
Upward slope beginning of tunnel	(%)	1.5
Downward slope end of tunnel	(%)	1.2
Cross-sectional area	(m^2)	56/tube

The initial design of the Mala Kapela Tunnel envisaged right-hand side tunnel tube of 5680 m in length, and left-hand side tunnel tube of 5683.2 m in length.

According to these, Mala Kapela Tunnel would have surpassed Sv. Rok Tunnel as then the longest tunnel structure in Croatia by approximately 10 m.

The length of the tunnel was later changed to facilitate the construction of the adjacent Jezerane viaduct. Thus, the completed structure consists of the 5760-m long right tube, and the 5761.7-m long left tube.

Two-tube tunnel was designed, with one-way traffic in both tubes. From the point of view of safety, a twin-tube system with two separate tunnels has a clear advantage over a single tube tunnel. In a case of fire or some other accident, the other tube serves as an escape route.

Longitudinal ventilation of the tunnel also contributes to fire safety in the tunnel as in the case of fire smoke is driven in the direction of travel.

Additionally, one-way traffic in tube provides for traffic safety, as frontal vehicle collisions are excluded.

The clear cross-sectional area of a Mala Kapela Tunnel tube is 56.17 m^2, thus fulfilling all the requirements of both Croatian and Austrian safety standards.

Austrian regulations and recommendations concerning safety in road tunnels were used to supplement the Croatian standards, which date back to 1973. This was only natural, as the tunnel was excavated using New Austrian Tunnelling Method (NATM).

The tunnel is designed for the speed of 100 km/h. Two parallel tubes of the Mala Kapela Tunnel are spaced at a distance of 25 m.

Tunnel grade at the northern entrance (Josipdol) is 0.82%, and at the southern portal (Jezerane) is 1.466%.

The northern portal is located at 562 m above the sea level, while the south tunnel portal is located at 573 m above the sea level, resulting in the difference of 11 meters. The highest point of the tunnel is located at 604 m above the sea level.

The roadway in the tunnel is 7.7 m wide consisting of two 3.5-m wide traffic lanes with 0.35 m wide edge strips on both sides. 90 cm wide sidewalks are elevated 15 cm, and accommodate utility ducts.

Figure 9. Twin-tube Mala Kapela tunnel; currently only one tube is opened for two-way traffic.

Figure 10. Inside of the Mala Kapela Tunnel.

The slope of the roadway in transverse direction is 2.5% directed towards the outer side of the tunnel tube.

Closed drainage system collects the water from the roadway and transfers it to a separate treatment facility.

Construction works started in 2002, and were successfully completed with excavation of both tunnel tubes.

The excavation rate depended naturally on the geology, but on occasions it reached 50 m a day i.e. 200 m a week.

Both tunnel tubes were excavated simultaneously, but at the moment only the right-hand side tunnel tube is opened to two-way traffic, as shown in Figures 9-10, while the other one serves as a service tunnel and escape route.

Completion and opening to traffic of the second tube is anticipated when the traffic intensity requires it. Tunnel tube serving the traffic has 12 emergency and stopping lay-bys.

Additionally, 6 turning points for traffic redirection (spaced at 840 m) were constructed and equipped with sliding fireproof doors providing cross-passage to the

Figure 11. Portal structure on the southern entrance to the Mala Kapela Tunnel.

second tube. There are a total of 14 inches provided in between these cross-passages, spaced at 280 m.

The tunnel is equipped with highly sophisticated traffic surveillance systems which provide 24-hour-a-day surveillance by experts at road maintenance and traffic control centres.

The minimum thickness of the concrete lining is 30 cm. It is constructed of C 25/30 concrete class.

Generally, there is no reinforcement in the concrete lining, except at the location of inches and cross-passages, sections where the large ventilations fans are installed, as well as in the first and last tunnel sections.

Waterproofing layer is installed between the primary and secondary lining.

The primary lining of each tunnel tube contains 19 000 m^3 of shotcrete, while the tunnel tube itself comprises approximately 55 000 m^3 of concrete.

Figure 12 illustrates the construction of the Mala Kapela Tunnel.

3 CONCLUSIONS

Over the last 15 years Croatia made large effort and investments in order to construct motorway network which would integrate the most distant parts of the country and provide for quick, easy and comfortable transportation of people, goods and services.

Several sections of new motorways cut through mountainous regions, thus construction workers were challenged to excavate a substantial number of tunnels, under very tight deadlines and unusually dangerous circumstances posed by landmines left over from the recent War for independence.

Many extraordinary structures have been constructed using the most modern technologies, and the record of the longest tunnel ever built in Croatia was surpassed on two tunnels.

Figure 12. Construction of the Mala Kapela Tunnel.

Most of the tunnels on new Croatian motorways are built as twin-tube structures. The vast majority of those tunnels which were initially constructed as a single-tube structure, are currently being added a second one. Two longest tunnels in Croatia – the Mala Kapela and Sv. Rok tunnels have both been constructed as twin-tube tunnels, but for the time being only one tube is serving two-way traffic as the present traffic volume does not justify the huge cost of equipping the second tube.

In addition to structural safety, much attention and resources were assigned to ensuring traffic and fire safety in tunnel structures. This was confirmed by European Tunnel Assessment Programme which put one of Croatian tunnels – Plasina tunnel on Zagreb to Split motorway – on very high second place while testing tunnels all across Europe with respect to tunnel system, lighting and power supply, communication, escape and rescue routes, fire protection, ventilation and emergency management.

The Dulles Corridor Metrorail Project – Tunneling aspects of the Metrorail extension to Washington, DC Dulles International Airport Phase I and Phase II

J. Rudolf
Bechtel Infrastructure Corporation, Vienna, Virginia, USA

V. Gall & K. Zeidler
Gall Zeidler Consultants, LLC, Ashburn, Virginia, USA

ABSTRACT: The Virginia Department of Rail and Public Transportation (DRPT) is currently undertaking the extension of Washington Metropolitan Area Transit Authority's Metrorail service to Washington Dulles International Airport. The 37 kilometers long Metrorail alignment is scheduled for completion in 2015. The project features two single-track, 700 meter long NATM tunnels at shallow depths in soft ground. At Dulles Airport two 3.3 kilometer long, single-track tunnels will be bored by TBM in siltstone rock. A 25-meter deep station will be constructed using NATM techniques. The total cost of the Metrorail project is estimated to be approximately US $4.0 billion (2006 dollars). Upon completion of preliminary engineering in early 2007 the design build contractor, a joint venture of Bechtel and Washington Group International and referred to as Dulles Transit Partners (DTP) will submit a negotiated, firm, fixed price to DRPT and the project will be implemented under a public private partnership agreement.

1 INTRODUCTION

The Dulles Metrorail project will extend WMATA's rail services from the Metrorail Orange Line in Fairfax County, Virginia to Route 772 near Ashburn in eastern Loudoun County, Virginia. This corridor encompasses several activity centers including Tysons Corner, Reston, Herndon, and International Airport Dulles (IAD) as well as emerging activity centers in eastern Loudoun County. The project alignment within the Dulles Corridor is displayed in Figure 1.

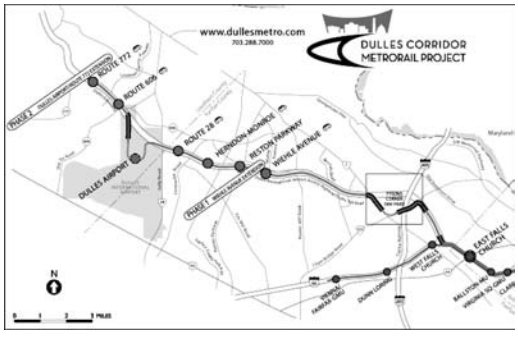

Figure 1. Dulles Corridor Metrorail project.

Rapid Transit for the Dulles Corridor was initially explored in the 1950's as part of the planning process for Dulles Airport. At that time it was decided to reserve the median of the Dulles Airport Access Highway for future transit access to the airport. Preservation of this median allows the alignment to be at grade for most of its length within the corridor. Since the initial planning the need for transit in the Dulles Corridor had been studied and although rail transit in the corridor was not part of WMATA's originally adopted rapid transit system, rapid transit service for the corridor remained a local and regional goal (Schrag, 2006).

The strong growth of the activity centers within the corridor in particular during the1990's and recent 2000's that continues today has led to inception of Metrorail in the Dulles Corridor. Current and projected, future regional growth data exemplify the need for rapid transit and its timely implementation (Dulles Transit Partners, 2006):

- Tysons Corner is the largest employment center in Virginia with 115,000 jobs and close to 4 million square meters of commercial space.
- Reston/Herndon is home of 70,000 jobs and 2.7 million square meters of commercial space.
- In Fairfax County employment is expected to increase 63 percent in the next 20 years.

– Loudoun County grew by 49 percent in the last 5 years and is currently the fastest growing county in the US.
– In the last nine years traffic on the Toll Road in Loudoun County has increased from 50,000 to 90,000 cars per day.
– Dulles International Airport employs more than 18,000 people and serves 23 million passengers per year and presently is being expanded and modernized. Modernization includes a new underground automated people mover system with multiple stations at main and mid terminals.

Regional growth and progress result however in urban and social challenges:

– Washington, DC region has the 3rd worst congestion in the US.
– The annual delay amounts to 69 hours per traveler resulting in a "congestion cost" of US $2.5 billion per year.
– 5 of 8 main roads in the corridor will be gridlocked by 2010.

The much-needed implementation of the project began with Preliminary Engineering in 2004 under a public private partnership agreement between DRPT and DTP. Other funding partners in financing the preliminary engineering effort are the Federal Transit Administration (FTA), the Metropolitan Washington Airports Authority (MWAA), WMATA, County of Fairfax, Loudoun County, and the towns of Reston and Herndon.

This extension to be known as the Silverline once completed will significantly extend the existing Metrorail system. The original system as conceptualized in the 1960's included 103 miles (166 kilometers) and was designed and built between 1969 and 2001. Additions including the Largo Line were accomplished between 2001 and 2004 extending the total system length to about 171 kilometers. The planned extension to the Airport will therefore constitute an addition of some 23% in length.

2 WMATA METRORAIL SYSTEM – COMPONENTS AND TUNNELING EXPERIENCE

A summary of the existing WMATA Metrorail system components is provided in Table 1 followed by a summary of WMATA's tunneling experience of the three decades between the early 1970's through late 1990's.

WMATA's over 80 Kilometers of subway construction provides many examples of tunneling methods and types of tunnel construction and displays a continuous development of tunnel design and construction methodology spanning some 30 years.

Table 1. Current Metrorail system.

Systemwide	Double track length (Km)	Stations (Number)
Subway Includes cut-and-cover construction	80.55	47
Surface	70.41	32
Aerial	14.84	7
Metro System (Total in 2001) Without Largo segment	**165.79**	84
By Jurisdiction		
District of Columbia	61.64	40
Maryland	61.55	24
Virginia	47.43	20
Total Metro System With Largo segment added in 2004	**170.62**	86

In the 1970's WMATA had employed tunneling methods nowadays considered an "old-standard." In soft ground methods involved mandatory dewatering for tunneling with open face digger shields, breasting and temporary support by steel ribs and lagging. These soft ground tunnels were designed for loading conditions assuming a load equivalent to full overburden. Consequently, the final tunnel lining was a rigid, heavily reinforced cast-in-place concrete structure with PVC waterstops in contraction joints as the only means of positive waterproofing. Such construction was used on the Inner City A-Redline, D-Orangeline, and Outer G-Blueline. During that time there are examples of utilizing cast iron bolted segmental lining with lead waterproofed joints between the liner segments. Cast iron linings were used for the Potomac River tunnel crossing on the Orangeline and the Waterfront Tunnel on the F-Greenline. Immersed ("sunken") tube construction was used across the Washington Channel (L-Yellowline).

For tunneling in rock drill-and-blast methods were used for excavation with steel ribs and cribbing as temporary support followed by cast-in-place reinforced concrete for final tunnel support. During this period WMATA already used a modern, gripper-type rock TBM when good bedrock conditions were present, with cast-in-place reinforced concrete lining as final tunnel support. An example is a section on the A-Redline. For the construction of large, approximately 20 meters wide mined station vaults pilot tunnels followed by multiple drift mining were employed. These openings were supported by heavy rock bolting and massive steel ribs embedded in shotcrete for both temporary and permanent support. The final structure was established as an independent architectural precast concrete structure within the mined vault. For the design of the permanent support in rock some arching

effect was considered. Tunnel construction on the A-Redline under Connecticut and Wisconsin Avenues is an example for such rock tunneling.

In the 1980's soft ground tunneling was accomplished using sophisticated Earth Pressure Balance Machines (EPBM) and a single pass segmental, pre-cast concrete lining with gaskets fabricated with tight tolerances. The tunneling was performed under the Anacostia River in adverse ground conditions with 3 bar hydrostatic pressure. It resulted in a very successful waterproofing largely as a result of well-designed and tight tolerances that were required for segment construction and gasket fabrication. This EPBM tunneling was used on two different sections under M Street namely Sections F3a and F3c on the Greenline. Successful installation of bolted segments depended on contact grouting within the time specified. On other sections an open face TBM was utilized. On a section with a low hydrostatic pressure compressed air was employed to control ground water. On another section with an open face TBM systematic dewatering was performed. Both open face TBM drives utilized a one-pass segmental, gasketed, pre-cast concrete lining which was successfully installed.

Also, in the 1980's WMATA allowed new, at that time progressive tunneling and waterproofing approaches. Consequently, in 1984 WMATA accepted the use of NATM rock tunneling proposed by the contractor. This was the first application of a dual lining NATM with PVC waterproofing in the US. It was utilized for running tunnel and station construction on the B-Redline to Wheaton, MD. The design considered arching of the surrounding ground and interaction between ground and the initial lining. Un-reinforced, thin, cast-in-place concrete lining was used for final support. Tunnel and station waterproofing was by an "umbrella type" PVC membrane with fully immersed sidewall drains on both sides of the vault. This resulted in completely dry tunnels in contrast to the A-Redline tunnels experiencing persistent leaks. At the end of the 1980's and at the beginning of the 1990's NATM tunneling was used again, but this time in soft ground for running tunnels and complicated, split station vault construction. The station was built using five different drifts. The first center drift was excavated for installation of a column line located in the middle of the station platform. Both, station and running tunnels were fully encased by a PVC membrane (Fort-Totten Station on the E-Greenline).

In the mid 1990's the NATM was used again for soft ground tunneling by employing dewatering from inside the tunnel and a grouted pipe arch as a crown pre-support to control surface settlement. The grouted pipes were installed by "directional drilling" methods under the Rock Creek Cemetery from a shaft at New Hampshire Avenue. This section was part of the Mid-City E-Greenline.

Also in the 1990's WMATA adopted a "two-pass" lining system for the circular soft ground tunnels excavated by the open face digger shield method (Outer E-Greenline tunnels; Sections E6e and E8a). Besides the need for dewatering this method also required the use of ground modification techniques such as chemical grouting systematically applied from the surface prior to tunneling (Mid-City E-Greenline tunnels; the Under/Over tunnels at Park Road & 14th Street Tunnels). The two-pass tunnel in soft ground with an initial pre-cast concrete liner usually considered as "throw-away" temporary lining was accounted for in the design of the final lining support system. The premise for this assumption was that solid, closed concrete rings were used for the initial support by not allowing any wooden wedges between segments. Rather, the pre-cast lining was required to be fully stabilized before the final concrete lining was cast. The combined liners for final support were designed considering flexibility of the initial lining and soil-structure interaction for "Short Term Loading" and all WMATA loading combinations including full hydrostatic pressure acting on the final lining for "Long Term Loading." Using these assumptions the initial pre-cast and the final cast-in-place linings share the loading combination. This allowed the use of an un-reinforced, cast-in-place final concrete lining. For the initial liner segments installed as expanded rings, success depended upon chemical pre-grouting, dewatering, immediate expansion by jacking the segments against the ground.

Depending on the nature of the soils, ground water level and difficulty in dewatering, such as from aquifers of artesian nature, it was necessary to use EPBM technology again but with the initial liners of non-expansion type but bolted segments similar to those in single-pass installations but with temporary gaskets. This installation was followed by an un-reinforced cast-in-place concrete lining and referred to as "Modified Two-Pass" with a PVC waterproofing membrane between initial and final linings. Such systems were used on the Outer F-Greenline, Sections F6a and F6c, Suitland Parkway to Branch Avenue. Here, the two-pass lining system was used for the first time with the EPBM tunneling method on the WMATA system. In this application the usual rings of four (4) reinforced concrete segments with added key segment forming rings are lightly bolted in the longitudinal joints. The gaskets in joints and the initial liner are designed for temporary hydrostatic pressure as the final waterproofing is achieved by the PVC membrane installed around the entire lining circumference. This system obviously is more costly, but it was necessary to overcome the most adverse ground and water condition where dewatering was not allowed due to environmental concerns. For the initial liner the segments were installed as bolted rings, and success depended upon water control, proper erection scheme and

accomplishing contact grouting immediately behind a sealed tail of the TBM shield (Rudolf, 1997).

3 DULLES CORRIDOR METRORAIL PROJECT DESCRIPTION

The project description concentrates on the tunneling aspects of the work at Tysons Corner (Phase I) and at Dulles Airport (Phase II). The preliminary engineering of Phase I essentially followed the general plans of the Locally Preferred Alternative (LPA) selected by WMATA out of many alternate alignments studied including a tunnel at Tysons Corner. The LPA as portrayed in the approved Final Environmental Impact Statement (FEIS) is designed mainly as an aerial guideway with short tunnels through Tysons Corner.

Late in the preliminary engineering of Phase I WMATA in conjunction with a Spanish contractor and an Austrian design group strongly supported by a local developer proposed an all-underground option for the roughly 6.0 kilometers long segment at Tysons Corner. The envisioned tunnel would have been a large bore, 12 m-diameter TBM driven tunnel to accommodate two over/under tracks and stacked station platforms. It was based on a deep tunneling experience gained at the Barcelona Light Rail system recently constructed (Della Valle, 2002 and 2005). Despite strong support of an underground option by all parties involved, its realization was found to cost from US $250 to $800 million more, based on various estimates, than the mostly elevated and partially at-grade alignment. Furthermore the tunnel option would have significantly deviated from the NEPA selected and approved alignment as portrayed in the preliminary engineering documents. This new tunnel concept would have involved another environmental approval process, and additional geotechnical studies to be followed by a new preliminary engineering. This in turn would have resulted in a project delay of some 2 1/2 to 3 years. The additional projected cost for the tunnel alternative would have practically led to the loss of funding by the Federal Transit Administration (FTA). Due to these factors and the fact that delaying the relief of every-day traffic congestion in Tysons Corner by another up to 3 years, the option was found unacceptable and therefore not pursued further.

3.1 *Phase I tunneling*

The mined tunnel segment includes twin single track NATM tunnels at a length of 700 meters each and an emergency cross-passage. Short cut-and-cover sections will be utilized at the portals. These tunnels will be constructed in soft ground and will be located adjacent to existing structures and utilities that are sensitive to ground movements.

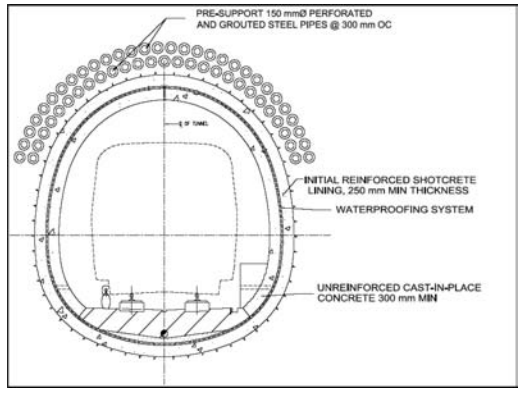

Figure 2. NATM tunnel with pipe arch pre-support.

The soils include mainly residual soils and soil like, completely decomposed rock. The residual soils encountered along the alignment are the result of in-place weathering of the underlying bedrock and are typically fine sandy silts and clays, and silty fine sands. Ground water at portal locations is generally at invert elevation, in mid-point of the tunnel alignment it rises up to the tunnel spring line.

Prominent building and infrastructure elements located in the tunnel's vicinity include an underground parking garage at a distance of some 8 meters from the outbound tunnel wall and bridge piers of the Route 123/Route 7 overpass, at a clear distance of approximately 15 meters from the inbound tunnel, as well as International Drive, a six-lane divided highway located about 4.5 meters above the future tunnel crowns. Deepest overburden cover exists at about mid-point of the alignment with nearly 12 meters. At the west portal and in the center of Route 7 the overburden cover is just 4 meters.

Because of the shallow depth, the prevailing soft ground conditions, the relatively short tunnel length, and the need to control settlements the NATM has been chosen as the preferred tunneling method. To enhance stand-up time of the soils and minimize settlements a single row of a grouted pipe arch umbrella will be utilized for the entire length of the tunnels. This will be sufficient for pre-support where the overburden is greater and surface structures are less sensitive. An additional row of pipe arch umbrellas, using closely spaced 150 mm diameter sleeved steel pipes (tube-a-manchette) will be used on the first 100 m length at the portals where tunneling is shallow with less overburden under International Drive. Figure 2 displays the double row pipe arch umbrella above a typical single track NATM tunnel with shotcrete initial lining, closed PVC membrane waterproofing system and a cast-in-place concrete final lining.

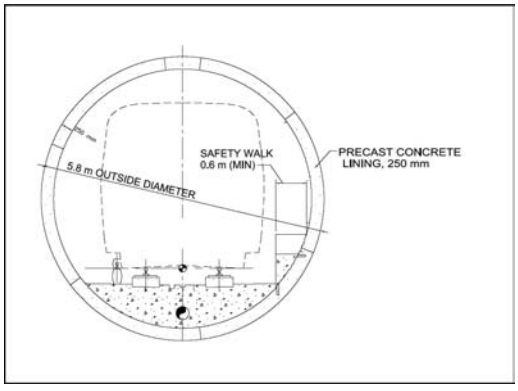

Figure 3. Typical TBM tunnel section.

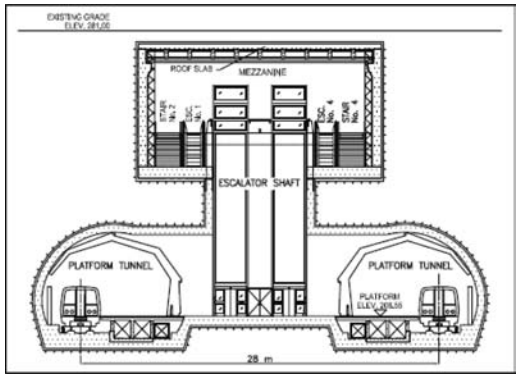

Figure 4. Station typical structural cross section.

3.2 *Phase II tunneling*

The underground segment of Phase II lies within Dulles International Airport property with the metro station referred to as Dulles Airport Station in front of the main terminal. The main terminal has considerable traffic and existing infrastructure with much of the project area having a high concentration of existing utilities. The underground structures include twin single-track TBM tunnels, emergency cross passages, shafts and mined caverns for the Dulles Airport underground station. These structures will be constructed in bedrock and will be located below existing structures and utilities that are sensitive to ground movements. The host geologic formation for tunneling will be generally competent siltstone bedrock whereas the over burden includes fill, residual soils, and decomposed rock.

The TBM tunnels have an approximately 6 meter outside diameter and are about 3.31 kilometers long each. The tunnels will be constructed by either a shielded rock TBM using a single pass, pre-cast concrete, gasketed lining or a rock gripper type TBM with an initial rock support followed by installation of a PVC membrane waterproofing and a final cast-in-place concrete lining. Figure 3 displays a typical, single pass lining cross section for the TBM tunneling.

The mined portions of Dulles Airport Station will be constructed using NATM techniques in sedimentary, typically siltstone bedrock. Excavation will be by road headers. Initial support will consist of rock reinforcement and shotcrete lining. All mined station and associated structures will be waterproofed using an open, "umbrella type" waterproofing system with sidewall drain pipes. Figure 4 displays a typical station tunnel configuration at the central cross passage with 5.2 meters wide platforms. The station platform is about 25 meters below the ground surface.

Figure 5. Station tunnel rendering (by diDo menico + Partners, Architectural Design Consultant).

To allow for a twin station tunnel configuration, where there are two parallel station vaults, the centerline track-to-track distance is 28 meters. Both station platform tunnels are 183 meters (600 feet) long and unobstructed by vertical circulation. The station platforms are connected with cross-passages between the station tunnels. Access to the platforms is provided by a central access structure located between the two station vaults. Architectural rendering for the station tunnel configuration is shown in Figure 5.

All station construction will be mined except for the mezzanine and ancillary rooms, which will be constructed using cut-and-cover techniques. Mined station construction has been selected to minimize disruption to airport activities. Surface disruptions will therefore generally be limited to Mezzanine and ancillary room construction using cut-and-cover excavation while maintaining airport pedestrian circulation above, except for the time period when the mezzanine box will be connected to an existing pedestrian tunnel "Node" that will provide Metrorail Station access.

4 IMPLEMENTATION

4.1 *Public Private Partnership (PPP)*

The project is being implemented in a Public-Private-Partnership under the Public Private Transportation Act (PPTA) an innovative project delivery framework as established by the Virginia Department of Transportation (VDOT) in 1995. Its implementation is in accordance with the guidelines as amended by the General Assembly in 2005 (The Commonwealth of Virginia, 2005). The essential goals of the PPTA are to encourage investment in the Commonwealth by creating a more stable investment climate and increasing transparency and public involvement in the procurement process. According to the guidelines the private entity charged with project implementation is required to provide certain commitments or guarantees and enters into a mandatory risk sharing.

4.2 *Design and construction*

The project is being realized under a design-build contract. The design-builder, Dulles Transit Partners (DTP) is required to initially develop preliminary engineering for the rail project. The cost for the preliminary engineering is shared between the design-builder and the project partners, DRPT, FTA, MWAA and the counties of Fairfax and Loudoun. The preliminary engineering then forms the basis to develop a fixed firm price by the design-builder. To maintain previously established budget limits this results in design challenges and the need to optimize design and construction methods to build to budget. Consequently, many design iterations are required during preliminary engineering. The design and construction team constantly weighs the benefits of underground space to keep everyday routines undisrupted versus its increased cost when compared to at grade and above ground construction.

Value Planning (VP) and Value Engineering (VE) exercises are a central activity of the design development in pursuit of the most economical approach with least impact on the surroundings. In Phase I these exercises led to a series of transformations of the underground segment at Tysons Corner. This alignment was initially envisioned as deep, 1.6-kilometer long twin TBM tunnels and a roughly 24 meter deep underground station constructed by cut-and-cover methods within Route 7, a busy traffic artery. Analysis of construction cost however favored the implementation of the short NATM tunnels with a quasi at-grade station within the median of Route 7 at a cost saving of roughly US $200 million. In Phase II the VP exercises led to selection of a deep TBM tunneling and NATM station construction in rock instead of a cut-and-cover excavation for station and running tunnel construction originally depicted in the FEIS. Since the rock formation at the Airport is close to the surface this selection resulted in considerable cost and schedule savings. This construction will also considerably reduce impacts on the Airport operation. VE exercises, which are to follow, will search for further cost reductions; if successful these will become the basis for construction.

Experience from architectural design and build of the underground space

P. Šafránek
Architektonický a Projekční Ateliér, Prague, The Czech Republic

ABSTRACT: The paper presents meditations, examples and visual prompts of architectural design concerning some Prague metro stations and their incorporation into the city organism and road tunnels of the Prague road ring. There are mentioned also portals of tunnels and their connection with neighbouring bridge – two engineering works, which are applied in close co-operation of architects.

1 GENERAL THOUGHTS ABOUT ARCHITECTURAL DESIGN OF TUNNELS AND UNDERGROUND SPACES

The architectural solution of underground spaces and tunnel interiors is a special discipline, where the arguments of the static and construction needs seem to have the priority. The cooperation of statics and tunnel engineers with architects is sometimes on the edge of common interest, but still needed and contributional. Underestimating of architectonic and aesthetic qualities of such a work can be dangerous. Even a useful and well-functioning technical work can be devaluated in eyes of public this way.

As an introduction, let us spend a while with several ideas of our big theoretist of aesthetic, arts and architecture, professor Mukarovsky:

While thinking of architecture, we come to a need to define an aesthetic norm; By professor Mukarovsky has an aesthetic norm the characteristic of a rule, which is but not fixed, static, but which is changable in time. Rule with dynamic validity. For example, Fechner's so-called experimental aesthetic was based on experimentally detected and further appointed basic aesthetic

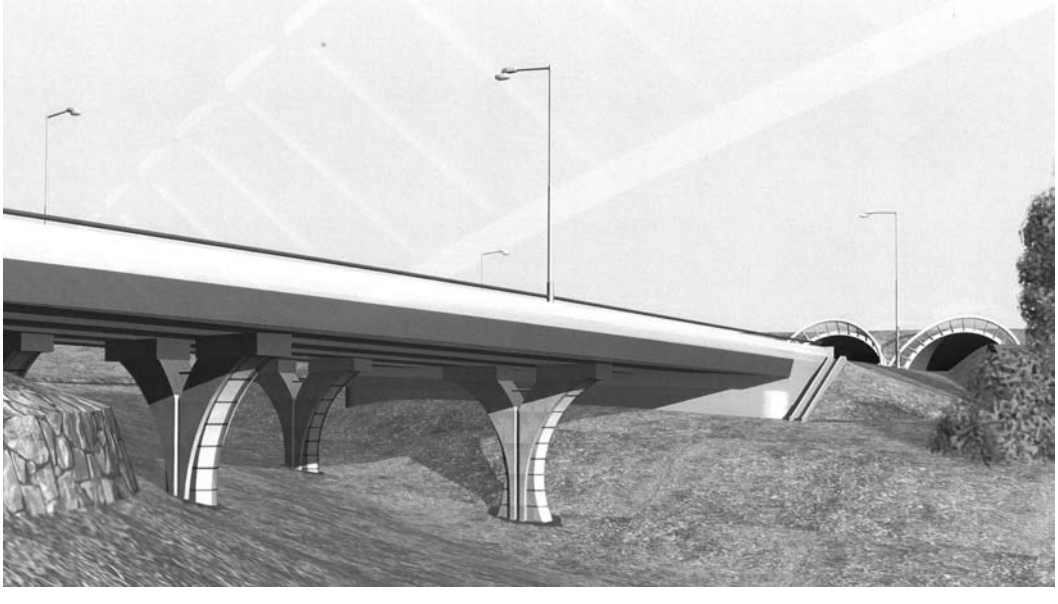

Figure 1. The cooperation of statics and tunnel engineers with architects.

norms. But their further simple applications failed to represent the ideal aesthetic sample.

My personal conviction in a best way represents Mukarovsky's quotation:

If we look at the history of art and architecture from the position of the aesthetic norm, then we see the history of revolts against rulling norms.

This introduction has an ambition to show, that rating and judging the architecture as an art discipline can be problematic and we should keep in mind, that our judgements and objections are rather of subjective and relative character.

The statement about the changebility und unpredictability of the aesthetic norms we should not forget. Therefore more than trying to appoint flatly fitting criterions, we should learn how to be tolerant and pluralist. Because tolerance and pluralism lead to richness, variability and spectacularity of the creative works around us. This means freedom of choice and so plurality as a feedback returns from our society.

Upon the positive influence of aesthetic function in arcitecture on the society agree a big amount of philosophers and theoretists from the times of Aristotel to our days. Professor Mukarovsky comments it: With the means of aesthetic value appeals the art work directly on the man's thinking process and behavior. In comparison, the science or the philosophy needs to pass through the man's willing and thinking process to be able to touch him and influence.

Therefore the aesthetic function means much more than only "the spume on the surface".

At the underground works, tunnels and engineer works, the function, safety, constructive and technical demands are widely pointed out, while the architectonic solution and aesthetic function can be considered to be "the spume on the surface". This attitude is often to be seen as an argument for the financial-costs cut. This attitude represents the narrow minded opinion, that on something, which is not quite important, such as an architecture, the expenses can be radically lowered. These pressures can be very dangerous. Because the simplyfied thinking is tempting.

This article above all refers to some underground stations, highway tunnels and their portals.

2 THE ARCHITECTONIC CONCEPTIONS AND ALTERNATIVES TO THE SOLUTION OF UNDERGROUND STATIONS

Interesting is how the architectural concept of subway stations is approached in different cities:

For example, in Stockholm's subway, the sweedish architects created so-called Cave architecture by using

Figure 2. Design of interior is binded with circle construction of the tunnel.

a local 2 miliards years old granit in a station's interior. In Marseille the mayor at the time, monsieur Gaston Defferce, enforced the idea of specifying each underground station with the local symbols. In the station Sainte-Marguerite was placed a composition reminding the watter-mills on the river Huveanne, which belonged to this fertile land in history.

In Buffalo, USA was organized exhibition, where the public voted for the most favorite art works and conceptions to be used for local subway's design.

Interesting principle was used in Vienna's: At the striked underground stations especially, the dominating idea lies in the division of platform space and railway space. By the highlighting the middle arc's edge, where it penetrates the side arc and placing the light-source on this edge, where the platform is ending, is clearly shown, which space is dedicated to the public and is ment to be pleasant and bright and which space serves as a tunnel-route for the train. That one is left in a rough condition and is rather dark. This difference factor functions as a warning: here the safety of platform is ending. The artistic principle of this extreme contrast further creates a particular tension – dynamism and let the interior talk itself. On the other side stands the conception of the Prague's metro, where even the wall behind the railway is worked out with the surface materials and is intensivelly delighted.

However contradictory these two attitudes are, both seem to have certain reason and bring the contribution to the interior design.

Mr. Liebaerse, president of the comittee for art for the Brusel's metro says:

"The people don't travel by metro for their pleasure, they have to face the stressful atmosphere, closed in a train moving through the dark tunnel. Therefore we try to lead our artists to create bright interiors, which will humanize this oppressive clima."

The fact, that these architectural works are fully under the ground and there are no fascades, which a man can perceive and overview, can be deprivating for a human beeing. This kind of architecture doesn't have an outter volume and can't join the common environment and that can be frustrating.

On the other side in the underground stations is extremelly visible the original characteristic, which differentiates architecture from the other visual-arts such as painting, sculpturing: the possibility to visit and perceive it from inside.

In any case the underground architecture works function as a vital spring for the city organism. The presence of underground traffic net improves the city functions, urbanistic development and architectural design of the buildings in a close neighbourhood.

Such architectural works bring advantages to many people, more than most of other public buildings and that's where lies their strength, competency and reliability.

3 LIGHT AND COLOUR

Very important part of architectural design is colour and ilumination of the surfaces. The undeground spaces, above all the artificial delighted ones, seem to tolerate brighter and richer colours, than the surfaces reflecting the day-light.

Rich encouraging colorcode and sufficient amount of light can ballance the oppressive atmosphere under the ground.

Using the colours in highway tunnels can provide better orientation and safety of moving traffic: In the Radotin tunnel on the Prague road ring are used two tones of blue as a basic colour together with the light gray colour of concrete. As we are approaching the emergency zones, the blue is alternated first by dark and as we come closer , by light yellow colour. This change of colour signs the existence of emergency exits or the end of the tunnel. In front of each portal, the light yellow changes instantlly in a light gray tone of concrete. Therefore the leaving the tunnel is decent.

Figure 3. Expressive colourfulness in the underground of the Hloubetin station.

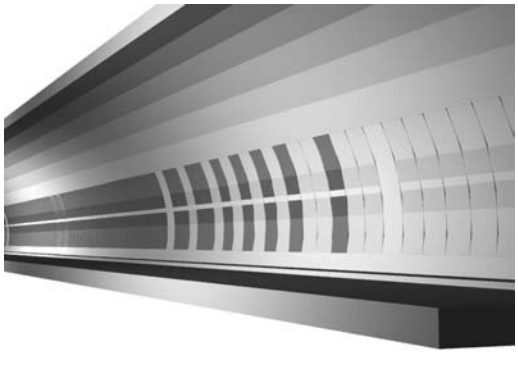

Figure 4. Coloured solution of the road tunnels Radotin.

Figure 5. Tunnel portal Radotín – authoritative element.

The light yellow, already delighted surfacecould feel agressive in contrast with the outter green.

This basic colourcode is symptomatic for the whole Radotin segment of the Prague road ring, where the functions of the colours are: informative, architectonic and safety.

4 TUNNEL PORTALS

The tunnel portals sign the beginning and the end of the underground route and at the same time mark the hidden underground part and therefore should have the representative character.

The function of the portals is not to radically disturb the environment, respect the landscape and show to the approaching in advance, that they are entering the undeground route.

The tunnel portals on the Prague road ring have the appearance of a fan bowing over the cutted arch-segment of the tunnel profile. This shape is a result of an effort to create a shield protecting the entry against falling rocks and the authoritative element serving as an important orientation point for the higway travellers.

At the portal of the railway tunnel in Brezno, the main motto was to connect the surrounding rough terrain with the entry by the natural materials. Therefore the system of supporting walls made of gabions was used to shape the portal.

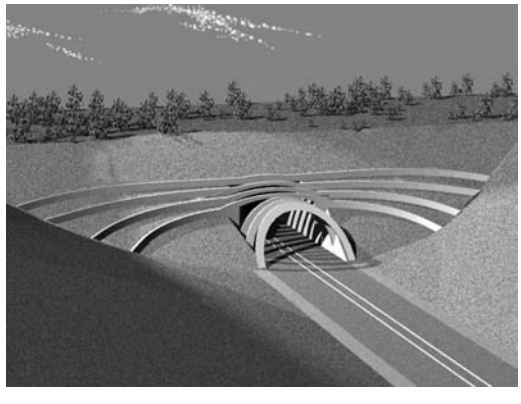

Figure 6. Railway tunnel portal Brezno.

5 THE MUTUAL INSPIRATION OF CONSTRUCTION AND ARCHITECTURAL DESIGN

The construction of tunnel works can expressivelly influence its interior appearance and also engineer works in its neighbourhood.

The west portals of the higway tunnel on the Prague road ring at Lochkov are in the close neighbourhood of the bridge over the Nightingale valley. This locality touches the protected area of natural reservation, therefore the designing process of the both works was

Figure 7. Tunnel portal Slivenec – authoritative element.

accompanished with increased attention and sensibility. For the both objects the common base idea was used and the mutual influence on each other's design is visible: The specific architecture of the fan-portals appeared also on the bridge's soft arch-shaped piers.

6 JUDGING THE ARCHITECTURAL AND ARTISTIC DESIGN OF UNDERGROUND SPACES

While we pass a judgement on the aesthetics of underground spaces (but also other architectural works), we have to admit, that all instructions how to set our rates are very problematic and relative.

Although we should stay watchful and resistant against the absolute judgements, still we can learn: Especially the cooperation of an architect and static – tunnel engineer is contributional, because the contradictory professions can enrich each other and in this cooperation the next impulse and inspiration for the creative work can be founded and cause, that the new aesthetic (or the common) norms are born. And their validity grows upon the norms which are passing over.

Study on underground space planning of Shanghai Expo 2010

H.H. Zhu, P. Li, X. Wang, F.L. Peng & Y.S. Li
Research Center for Underground Space of Tongji University, Shanghai, China

ABSTRACT: The World Expo 2010 will be held in Shanghai, which theme is "BETTER CITY BETTER LIFE". According to the program, large-scale underground space constructions will be built in the Expo Park. For their features that huge investments and non-disassembly, it needs more complex study and planning to satisfy various demand both during and after the Expo. This paper mainly focus on the following aspects: The logical scope of underground space constructions in Expo Park; the Expo Park's underground planning; Re-use of the underground infrastructure facilities by post expo. In conclusion it will be shown that: put the ecological infrastructure facilities underground can not only form a positive cycle of energy utilization, but also a effective way to make the Park ecology, compact and sustainable development. The World Expo underground urban complexes will be connected together to form regional public transit transferring hub and commercial center by post Expo.

1 INTRODUCTION

The World Exposition 2010 will be held in Shanghai in year 2010. Its theme is so called "BETTER CITY, BETTER LIFE". For the first time in the history using *city* as the theme, expresses the desire of all mankind seeking a better life in the future. The philosophies of building up a World Expo are such concepts as constructing a greenwood city, ecological city, digital city, gardening city, co-existing living city, information city and intelligent city. Meanwhile through comprehensive exchange among different points of views and among inter-acting sciences, the new concept and new knowledge as well as new technology of urban development will be enriched, and the urban function will be upgraded, the urban space enhanced. As a result, Shanghai's urbanization will be promoted.

From the figure 1 it can be seen that the Park site was confirmed in the city center, composed of Puxi and Pudong two sections, include the Huangpu River which is the Mother River of Shanghai as a part and the total length of 8.3 km alongside the River. The Park's fencing area (the area with ticket entrance) occupies an area of 3.1 km^2 , parking area is 0.6 km^2, World Expo Village 0.3 km^2, backup land as well as municipal engineering and other facility land plus land reserved land for city resident's use totally consumes 1.4 km^2. The total area of the World Expo Park within the programmed limit is 5.7 km^2 (excluding Huangpu River area), among which there are 1.44 km^2 for Puxi area (West Shanghai) and 4.26 km^2 for Pudong Area (East Shanghai).

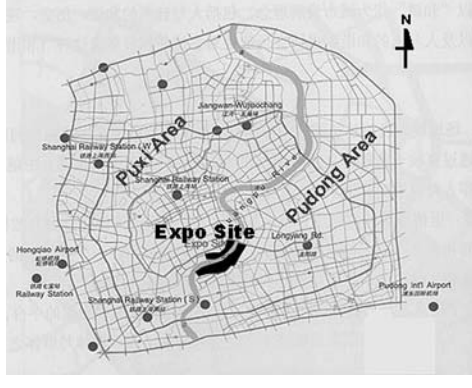

Figure 1. The location of the World Expo Park.

2 THE NECESSITY OF DEVELOPING AND CONSTRUCTING THE UNDERGROUND SPACE IN THE WORLD EXPO PARK

For the purpose of enabling the World Expo Park's construction to fully manifest the main theme of the World Expo and the city life's concept in the 21st century, it is necessary to, based on the features of the World Expo Park is located in the center of the city, make full use of the land development and utilization potential so as to meet the following demands.

2.1 *Demand for fully utilizing the land resources*

Since programmed World Expo Park's halls and pavilions are located in Shanghai city center area, the

control on index of land occupied rate is rather strict, thus it is necessary to study carefully on land resources utilization value and, on this basis reasonable planning and layout of ground and underground space, through the development and utilization of underground space to meet the requirements land occupied rate.

2.2 *Demand for building up ecological and sustainable development World Expo Park*

In the course of the constructing the World Expo Park, enlarging Park's greenwood area and open area are vital to energy saving, environmental protection, Expo Park's climate enhancement as well as improving ability of handling emergency accident, etc. With a view to constructing an ecological and sustainable development World Expo Park, it is a must to develop and utilize the underground space resources, some areas such as man-less space, space where mankind activity consumes little time and Park's municipal engineering infrastructures will be built down to underground area so as to enlarge Park's greenwood area to the most extent to construct ecological gardening World Expo Park, to reveal the theme of "BETTER CITY BETTER LIFE" and reveal urban development trend in the 21st century.

2.3 *Demand for Building up urban traffic system with high efficiency, speedy convenience and safety*

As a comprehensive exposition, the World Expo Park during the expo will receive 70∼80 million person-time visitors from the nation and the world, with averagely 400,000 per day and 800,000 per day in ultimate peak time, thus will create a World Expo record. As a result, huge pressure will be imposed to traffic status.

Therefore it is necessary to build up an underground traffic system with multi-layer both underground and on the surface ground, with multi functions and with information technology. This said underground space will integrate all patterns of traffic facilities and provide reasonable layout so as to form a closely interacted and functionally supplemented tangible space and bring entire effect of the facilities into full play. Meanwhile, it will also reasonably arrange and distribute all types of traffic movement based on resources of space and time. It imposes balance and coordination for the traffic direction layout and time and space layout under the principle of highly effective network operation, and though information technology it reasonably allocates the occupation of tangible space by all types of traffic pattern. Generally speaking, it is an organic combination for all types traffic facilities to play scale effect into full play.

2.4 *Demand for building up modern municipal engineering facility system for the Park*

The municipal engineering facilities are the basis and safeguards that a city relies on for survival and development, they are the nerve and blood vessel to enable the city to normally play its function and enable the people to enjoy peaceful and comfortable life.

For the World Expo Park's being put to show it is need Large quantity of municipal pipelines which will consume tremendous amount of land resources. Thus it is necessary to fully use underground space for those pipelines' planning and construction, so that the valuable land resources can be saved.

2.5 *To establish basis for the Park's post Expo use*

Since the construction of the World Expo Park will definitely impose important impact on city's structure and pattern, and according to the World Expo's features, the roads inside the World Expo Park play different roles between the period during the Expo and post Expo in terms of the road's function. Therefore the utilization of the World Expo Park shall consider the post Expo use. For this purpose, the World Expo Park needs to be included into comprehensive consideration of Shanghai city's organic system. To utilize underground space resources to reduce, to an utmost extent, the negative impact on city of Shanghai due to World Expo Park's construction, and to enable the Park's pattern and structure to meet requirements by post Expo use.

3 PLANNING OF THE UNDERGROUND SPACE

The World Expo Park's underground space development mainly focus on buildings' underground space, the underground commercial facility, the underground walk space, the underground opening space and so on to construct by stages. In Pudong area, the Park's underground space utilization will bring the comprehensive construction of permanent buildings (shown in figure 2, points A, B, C and D denote four permanent buildings respectively), Metro stations, transport hubs into consideration. While in Puxi area of the Park, as the region with the tunnels and Metro lines installed more intensive, and there is a larger surface area of the historical buildings, the remainder underground space is limited. And it can not be connected to form an overall economic even if the limited space is used. Therefore, no more underground space will be developed in Puxi area of the Park.

3.1 *Underground transport facilities*

The Park's underground transport facilities mainly including the Metro lines, cross river tunnels, underground walking space and underground parking lots.

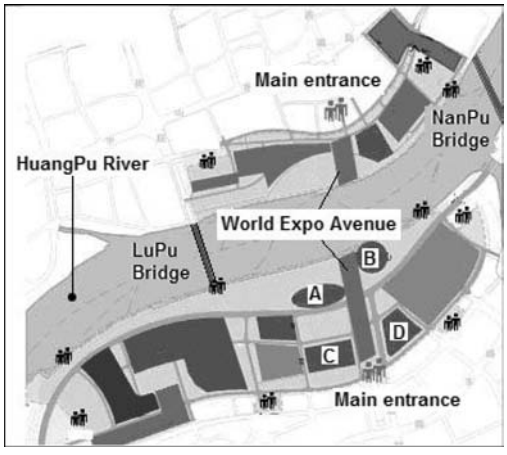

Figure 2. General ground layout in The World Expo Park.

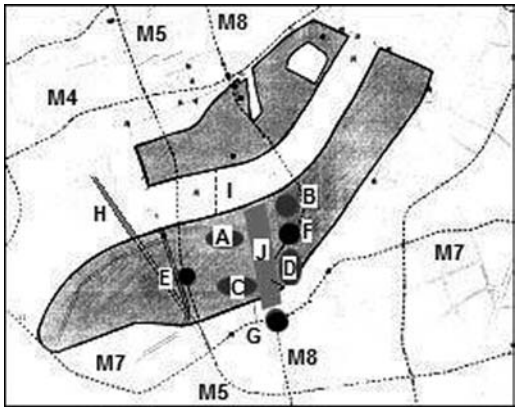

Figure 3. Main underground facilities around The World Expo Park.

3.1.1 *Metro*

In figure 3 it can be seen that there are four Metro lines going through the World Expo Park, namely, M5 and M8 penetrate center of World Expo Park in S-N direction, while M4 and M7 respectively come from Pudong and Puxi going through periphery of World Expo Park in E-W direction. M5 and M8 have set up Metro stations in the World Expo Park's Pudong area (shown in figure 3, point E denote M5's station, Point F denote M8's station). But in considering the convenience for transport organization and ticket – checking, this two stations will be closed during the Expo and re-opened after the Expo.

3.1.2 *Cross river tunnel*

In consideration for cross river transport between Pudong and Puxi Park area, a new cross river tunnel (shown in figure 3, broken line I) will be constructed in the core area of the World Expo Park under Huangpu River. This new tunnel, together with a existed tunnel (shown in figure 3, line H), will be a part of the ring road for public bus.

3.1.3 *Underground walking space*

Between two main entrances of the World Expo Park, a aerial Plaza (called "World Expo Avenue", shown in figure 2) will be built in S-N direction. The World Expo Avenue's width is 80 m and the elevation is +10 m. It is the most important landscape axis of the World Expo Park, is the main place for celebration activities.

A parking lot on the ground is built beneath the World Expo Avenue (shown in figure 4). And a underground walking system (called "World Expo Underground Street" in this paper. shown in figure 3, rectangle J) whose width is equal to that of the World Expo Avenue will be built beneath the parking lot. The World Expo Underground Street extend from the transit transferring station (shown in figure 3, point G) of M7 & M8 to the bank of the Huangpu River in Pudong side in S-N direction. It will be connected with the basements of the permanent buildings that around it (shown in figure 3, points A, B, C and D denote the basements of permanent buildings).

During Expo, the World Expo Underground Street will play the role of the underground walking hub, and the corresponding commercial, leisure facilities will be set in it. Tourist can chose the visit route on the ground or underground.

3.1.4 *Underground parking lots*

In the Park, a certain scale of underground parking lots will be set up under the permanent buildings, and connect them with motorway underground. These underground parking lots are for the use of public bus, tourism passenger bus, VIP vehicles, logistic lorries and fire engine during the Expo, while they will be for the use of cars serving for the Park's internal business or leisure and entertainment by post Expo.

3.2 *Underground municipal engineering facilities*

The World Expo Park may accommodate approx 170 exhibition spaces, large quantity of facilities of electricity, telecommunication, gas, water and dewater are requested to ensure all sorts of requirement during the Expo.

3.2.1 *"Point" layout pattern*

What facilities included in the "point" municipal engineering layout pattern are water treatment plan, pressure pump station, pump station for rain and drainage, gas pressure station, Pressure regulating station, high voltage substation, switch station, rubbish collection

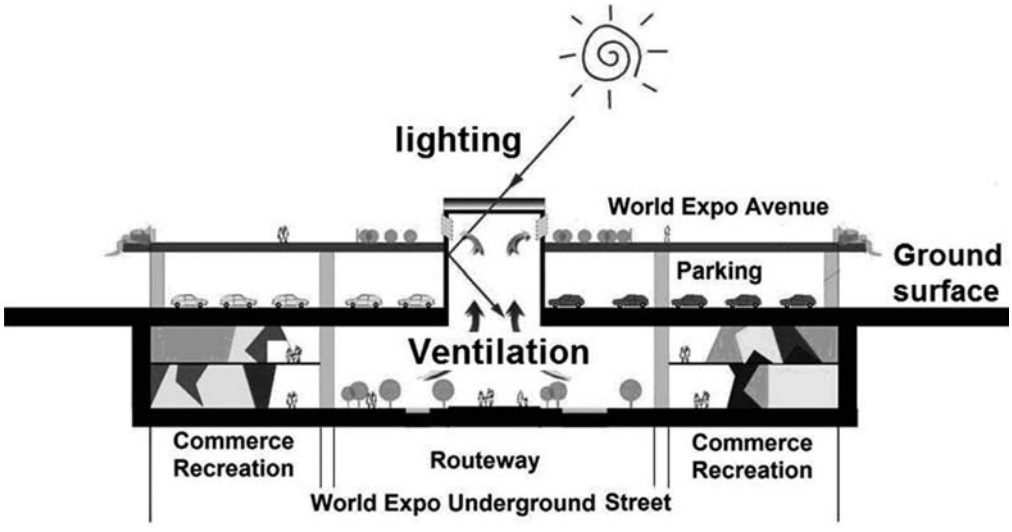

Figure 4. Cross-sectional view of the World Expo Avenue.

station and regional energy station, etc. These facilities have the feature of consuming large area above the ground and causing contradiction to ambient environment, meanwhile bring about negative impact to the development and utilization of the surrounding areas.

With a view to the said features, the layout pattern of these municipal engineering facilities will be set up alongside the areas around the World Expo Park. While in terms of the structure, it shall be best to construct them underground or semi underground.

3.2.2 *"Linear" layout pattern*

The municipal engineering facilities of the "Linear" layout pattern includes running water pipelines, waste water pipelines, rain water pipelines, gas pipelines, concentration heating or cooling pipelines, rubbish collecting pipelines, electricity pipelines and telecommunication pipelines, etc. These municipal engineering pipelines could be laid put based on need underneath trunk road or less important roads with an advantage of lowering cost and being convenient to lay out. But this could also cause repeat cutting and covering the road due to pipelines burying or maintenance. Plus, the pipelines' life time will be shortened by corrosion because of touching the soil and underground water, and this is not good for re-construction or expansion in the future.

Therefore, to pave the main road in & around the Park with so called protection shell, under which the main line comprehensive pipelines tunnel containing all sorts of municipal engineering supply pipelines will be installed.

3.3 *Underground urban complex*

The underground passenger volume during the World Expo will be intensively huge. There will be wide range of service items and concentrated peak time. The traffic volume's peak time coverage during a day will be very distinct according to different ticket-pricing system. Normally the time when evening peak hour comes before closing the Park is the time when the day's most extreme peak time is seen. Therefore the planning of the underground urban complex of the World Expo Park shall play the function to mitigate and disperse the crowded stream of people.

In the Park, large scale compound underground urban complexes will be constructed at the underground railway hub and comprehensively developed and constructed in connection to metro interchange and underground public utility. The World Expo Underground Street will be the main body of the underground urban complexes. These underground urban complexes will play the function to mitigate and disperse the crowded stream of people during Expo, while, the function to mitigate underground traffic congestion will be somewhat weaken and the commercial function of the underground urban complexes will be strengthen by post Expo.

From figure 4 it can be seen that, in the underground urban complexes, light & ventilation wells will be created in order to lead nature light and air into, thereby saving energy sources maximized.

Meanwhile, such landscapes as plant, water, sculpture and so on are settled in the underground urban complexes (shown in figure 5) to create the environment similar to the feeling that on the ground in order

Figure 5. Conceptual scheme of the World Expo Park's underground complex.

to provide a safe and comfortable walking, leisure and shopping space for tourist.

4 RE-USE OF THE UNDERGROUND INFRASTRUCTURE FACILITIES BY POST-EXPO

According to the overall urban planning of Shanghai, the waterfront of two sides across Huangpu River will be the landscape axis, the important ecological corridor, and urban public gathering areas of the city in the future. The World Expo Park's construction will be integrated with the magnificent overall development projects alongside the two banks of Huangpu River by fully utilizing river side's features and the location advantages to build a batch of large service facilities for cultural activity, conference, exhibition, residence, leisure and entertainment as well as commercial service. Therefore in the post Expo stage, the World Expo Park's development positioning is to become important cultural exhibition center, luxury business district and featured river side residence area in Shanghai.

Under this background, those underground traffic and municipal facilities built for the World Expo need to extend further to satisfies the local development demand. The World Expo underground street will be with peripheral underground urban complex, the basement of buildings and Metro stations to become regional public transit transferring hub. Meanwhile, as an important component of the regional commercial network, the underground complex unites the decentralized shops together as an organic body to form regional commercial center. Fat commercial profit will attract the investment to develop underground space to compensate deficient income of the underground transport facilities. This function will also provide convenient and comfortable shopping, F & B, rest and entertainment services to the passengers who use the underground walking system and underground railway hub.

5 CONCLUSION

It is necessary to implement underground space project in order to better manifest the BETTER CITY BETTER LIFE theme of the World Expo 2010. The Park's construction shall consider underground space resources, and try best effort to include the expressway and municipal public facilities down to underground to leave more greenwood space on the ground so as to let Shanghai become ecological city. Meanwhile, put the garbage disposal system, as well as the green energy system and so on the ecological infrastructure underground can not only form a positive cycle of energy utilization, but also a effective way to make the Expo Park ecology, compact and sustainable development. Moreover, in the underground space, constructing the ecology & humanities landscape and carrying on the reasonable layout to them, can promote the quality of the Expo Park, make the underground constructions attractive.

From the context mentioned above it can be seen that large-scale underground space constructions will be constructed in the World Expo Park. For their features that huge investments and non-disassembly, it need to accord with the long-term urban planning to

satisfy various demand both during and after the Expo. Having the largest scale among all underground facilities that would be constructed in the World Expo Park, the underground urban complex will become regional public transit transferring hub. Its principal function is transportation, meanwhile, commercial, cultural, entertainment and other services will be provided in it to both enjoy the local residents & tourists and gradually reclaim the construction costs of underground space, thereby achieving sustainable economic development.

The impact of puncturing support on the expansion of seismic effects during blasting activities in tunnels

Hrvoje Antičević
Croatian road authorities, Širolina, Zagreb, Croatia

Zvonimir Ester & Mario Dobrilović
Department of Mining and Geotehnical Engineering, Faculty of Mining, Geology and Petroleum Engineering

ABSTRACT: This paper outlines the research of the impact of puncturing support during blasting activities in tunnels. The puncturing support, whose main purpose is to bypass unexcavated section in poorer ground categories that is to prevent the material fall from the tunnel calotte after the completion of excavation, has additional functions aimed at decreasing negative impacts caused by blasting. By drilling and placement of puncturing support the rock will get perforated and thus by means of the shielded zone the rock mass will get separated from the excavation area which will prevent excessive loosening of the rock mass and diminish the expansion of seismic effects.

1 INTRODUCTION

As a part of the future motorway Bregana – Zagreb – Dubrovnik, section Žuta Lokva – Ličko Lešće there is a tunnel Brezik with approximate length of 400 m (Figure 1). Tunnel is located in western suburban area of the town Otočac, at an altitude of 450 m. Maximum overburden was 38 m. Tunnel excavation has been performed in full profile, with 2 driving lanes, one for each driving direction. Excavation works began at south portal in midst of April 2003, and both tunnel pipes have been broken through at the beginning of year 2004. Average advance rate was 1.5 m per day for each pipe. Average excavated cross section varied from 74.3 to 85.6 m^2, which depended on rock mass category.

Figure 1. Portal of tunnel Brezik.

Tunnel construction has been performed by N.A.T.M., by drilling and blasting. In better rock mass category, excavation has been performed entirely by drilling and blasting operations; while in worse rock mass category there was a combination of drilling and blasting with excavator operation. Solely excavator method was applied in critical areas.

2 GEOLOGICAL ROCK MASS STRUCTURES

Rock mass through which tunnel is passing is built from carbonate rocks of Jurassic, cretaceous and Paleocene time. Paleocene and Jurassic limestone make up a karsted and broken stratum, upon which limestone Jelar breccias left sediments. These Jelar breccias and breccias conglomerates occupy rather a large area. As in other areas with Jelar type layers it is also obvious here that the contact zone with ground rocks is characterized by significant tectonically disturbances (Figure 2).

Predominant part of Jelar is characterized by fine grains (very rarely bigger than 1 cm, occasionally there are some grains with diameter of few cm). Size of upper Jurassic grains became significantly enlarged from ground rocks.

Generally the boundary between layers in the lower bed is karsted, very uneven, and very often

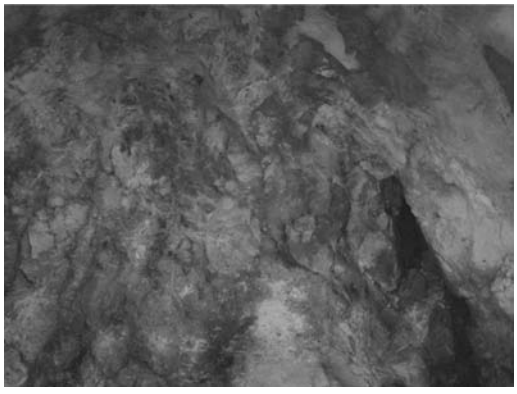

Figure 2. Geological structure – excavation face.

Table 1. Rock mass geotechnical parameters.

	σ_c (MPa)	ρ (kg/dm^3)	E (GPa)
Limestone	70–100	2.64–2.65	35–50
Limestone Jelar breccias	60–110	2.57–2.69	31–60

exceptionally karsted, cavernous dolomitized and recrystallized.

According to hydro geological characteristics rock mass is classified mostly as watertight sediments. Today, flow dynamics of underground water depends on rock fabric, tectonic and level of karst modification on rock. Significant impact on flow dynamics has top cover made from clay sediments.

Condition of surface and underground waters in above mentioned area is partly connected to hydro geological relations in wider area of river Gacka basin. Seepage waters in the tunnel excavation area with regard to small basin area and small overburden are of limited range. Table 1 show Rock mass geotechnical parameters.

3 IMPACT OF DETONATION ON THE ROCK MASS

By the initiation of explosive charge in a blast hole, high-speed chemical reaction occurs whereby large amount of energy and detonation products are being released. Released energy causes occurrence of shock waves in the explosive, which are further transmitted to surrounding rock. Released energy is transmitted in to surrounding rock mass in the form of shock wave and expanded gasses.

Shock wave energy causes primary rock brakeage, meaning rock destruction. The strength of shock wave depends on density of explosive charge and detonation velocity. Further progress of shock wave in the area, where destruction stops, causes generation of radial cracks.

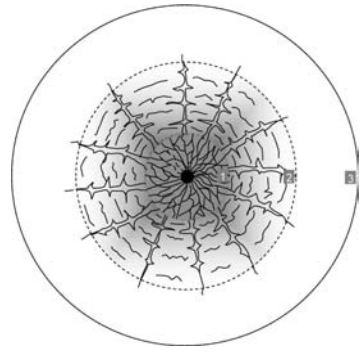

Figure 3. Zone of detonation activity in the rock.

Expansion gasses energy or thrust energy under the impact of expansion gasses with high pressure and high temperature continues process of widening of radial cracks generated by shock wave.

Quantity portion of shock energy is smaller but more far-reaching then gas energy rate, because rock breaking and widening of radial cracks causes release of space around blast hole and fast decrease of pressure.

By increasing the distance from center of explosion, stresses caused by shock wave decrease until they are smaller then tension strength of rock and generating of radial cracks is stopped. Shock wave is continuously spreading as an elastic wave and causes ground oscillations (Figure 3).

Elastic wave could cause undesirable effects on wider surrounding during its traveling route. There are three determinate zones in rock: 1. Zone of plastic deformations (crushing), 2. Zone of generated radial cracks, 3. Zone of elastic deformations (ground particle oscillation).

4 CRITERIA FOR CRITICAL VELOCITY OF DETONATION

Amount of explosive charge which does not cause damage of the rock and supporting system is estimated upon:

- predicted oscillation intensity as a function of the amount of explosive charge per level of ignition,
- Distance between blasting field and supporting system,
- Attenuation of seismic waves as a consequence of geological characteristics of a rock,
- Maximum allowed level of ground oscillation.

Connection between maximum oscillation velocity at a measuring point, amount of explosive charge per level of ignition and a distance from a blasting point

to a measuring point is given by empiric formula after M. A. Sadovski (Krsnik 1989)

$$v = k\left(\frac{\sqrt[3]{Q}}{R}\right)^{n} \text{ (cm/s)} \quad (1)$$

where
v ground oscillation velocity (cm/s), Q amount of explosive charge used for detonation (kg), R distance between measuring point and blasting field (m), k and n constants depend on the geological characteristics of a rock.

Based on the results of measuring of the oscillation velocities and consequential damages of rock mass in surroundings of the blast hole, a ground oscillation velocity was estimated for Swedish gneiss and granite which causes increase in rock deformations (Holmberg 1979). Damage was noticed up to 32 m away from the blasting point by velocity $v = 700$ mm/s.

Langefors and Kihlström suggested the level of $v = 300$ mm/s for unsupported tunnels constructed in rocks like granite.

I.D. Isaac suggested level of $v = 450$ mm/s based on measurements taken by construction of underground engine room of the power plant Dinorwic (Isaac et al. 1981).

T.R. Yu and S. Vongpaisal suggested the criterion for estimation of allowed ground oscillation velocity for underground constructions (Yu et al. 1998) given by blast damage index:

$$\text{BDI} = \frac{vdC}{K_t T} \quad (2)$$

where BDI (Blast Damage Index), v ground oscillation velocity (m/s), d rock density (g/cm^3), C compressive pulse velocity in a rock (km/s), K_1 constant of rock quality, T dynamic compressive consistency of rock (MPa). Value of BDI index varies between 0.125, with no damage occurring, and 2 when great damage occurs related to ground oscillation velocity $v = 85$ mm/s (no damage) and $v = 1750$ mm/s (rock collapse).

A.K. Chakraborty had applied the suggested criterion by construction of underground chambers in basalt rock and found out that the level of possible damages $v = 85$ mm/s is far too low (Chakraborty et al. 1998).

For the orientation about possible support structure damage, standard DIN 4150 is applied.

Table 2; subsection 1, under DIN 4150-3-1999-02, gives values of oscillation velocity for support structures, like armour-concret columns, massive foundations and other.

4.1 *Hopkinson's effect theory*

Based on the observation data we conclude that the ground oscillation velocities reached, at least at one detonation level, values above allowed velocities according to standards for industrial objects. Possible deformations increase in the rock on which measuring was done, can be defined upon analysis of cores before and after blasting or by seismic tomography.

Table 2. DIN 4150-3 1999-02, part 3.

	Maximum oscillation velocity V_{max} (mm/s)			
Frequency (Hz)	1–10	10–50	50–100	over 100
Support structures	40	40–80	80–100	min. 100

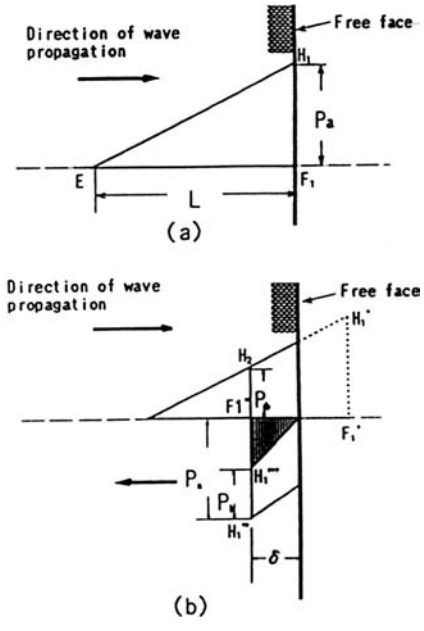

Figure 4. Theory of Hopkinson's effect.

Nearly each blast triggered exfoliation of rock along the lower left side of the right tunnel pipe. This phenomenon, known as Hopkinson's effect, was noticed by Johansson et al. (1970) as an effect of cylindrical explosive charge on metal plate 15 cm thick.

Later on, influence of Hopkinson's effect on rock samples was tested in a laboratory (McCarter et al. 1993, Katsuyama et al. 1993).

Figure 4 explains the simplified influence of Hopkinson's effect which appears as a consequence of interference of pressure shock pulse H1 F1 (triggered by detonation) and a reflected compressive strain pulse of free surface H1" F1". The amount of strain is a sum of strains (Pa-Pb) of a compressive pulse and a reflected compressive pulse, and δ is a thickness of blasted rock.

In case of sufficient kinetic energy exfoliation of rock occurs on a free surface. It is assumed that

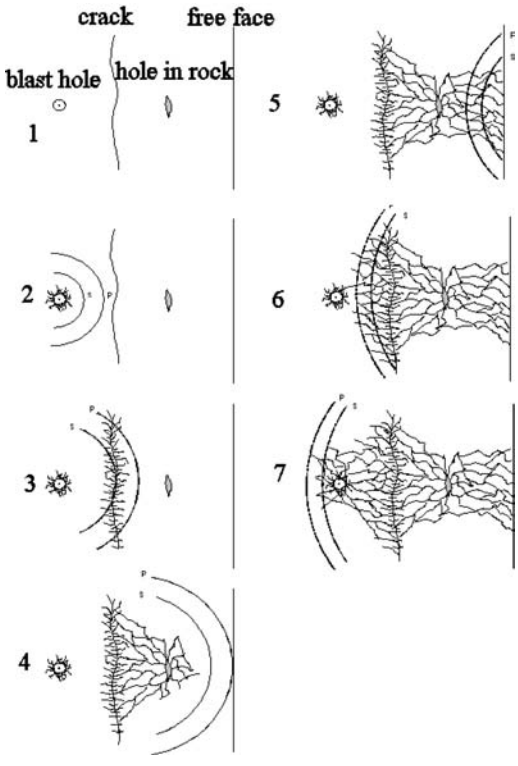

Figure 5. Schematic view of theory of core or shock wave.

velocity of free surface movement above 8.0 cm/s causes exfoliation of rock on the tunnel side.

4.2 *Theory of core or shock wave/cracks*

This theory is based on tests developed in materials, which characterize geological conditions in the rock mass.

Authors of this theory started with examinations on homogeneous materials and from these results they have derived basic assumptions and certain regularities that were later proven on samples as a defined geological structure of rock mass (Figure 5). Other authors continued further investigations on this theory, whereby tests have been performed in actual surrounding, i.e. with respect to rock mass.

Passing of P and S waves through material containing cracks and voids generates new system of cracks around old ones, in the larger scope than in the area without voids. Reason is that they represent area of rock weakening through which waves are spreading. (1–4). When a P wave reaches a free surface it is reflected backwards in form of a shear wave, it collides with a S wave and interference occurs. This interference causes further spreading of existing and generating of new cracks. (5 and 6). After reflection from free surface or crack, new wave system occurs (PP, PS, SP, SS, PP, and S, PS, and S) that causes additional spreading and generating of new cracks.

5 IMPACT VALUES ON BLASTING RESULT

There is a chain of values that have influence on final blasting results and they could be divided in 2 groups.

The first group contains values to which we do not have any influence and they define blasting environment. Those values are: tectonics, mineralogical-petrologic composition, physical and mechanical characteristics, crack system, type of fill, primary condition of stress, subsurface water level, climate conditions (seepage waters) etc.

At inhomogeneous anisotropy rocks with very complex structure, special attention should be paid to cracks system and its fill, that have crucial impact on blasting results.

The second group contains values to which we do have influence, and they are divided into 3 subgroups: drilling, loading and blasting with accompanying elements. These elements should be adjusted to geologic structure of blasting location in a way to perform test blastings and define characteristics of environment in order to perform corrections on existing blasting design.

6 MEASURING AND INSPECTIONS

Excavation area was $P = 80\,m^2$. Drilling depth was from 1,2 to 3,0 m, and total number of holes was from 103 to 132 holes (Picture 4-1 and 4-3) with explosive consumption of 174 to 329 kg explosive per round. For creation of a new free face, a double V cut was applied with drilling patterns shown on Picture 5-3. Daily progress on 2 faces amounts to 3 to 4.5 m. A reason for such poor progress was poor rock category (IV and V), which determines a short “step” per blasting cycle.

Measurements were performed with three-compound seismographs White Digital Seismograph Mini-Seis II and INSTATEL Blast Mate III.

These instruments have the possibility to measure frequency, displacement, acceleration and ground particle velocity. Value of particle velocity is a standardized value for evaluation of possible damages and it is incorporated in the majority of international standards (DIN 4150, OSMRE, B.S. 7385, G.F.E.E.). None of these standards defines limit value for ground particle velocity for tunnels and roads.

6.1 *Blasting without puncturing support*

In total, tree measurements have been performed, whereby each measuring was performed in different conditions. Each measurement was carried out on 2

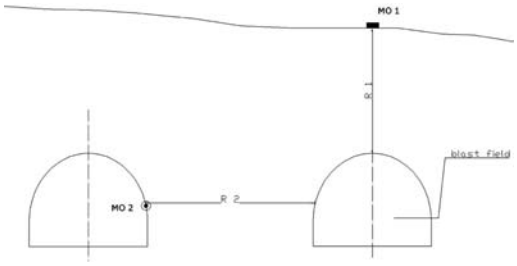

Figure 6. Measurement points positions.

Figure 7. Measurement point no. 2.

monitoring points whereas the first monitoring point was vertical to the terrain, above the blasting point in the tunnel and the second monitoring point was on the concrete lining of the second tunnel tube as it is shown in Figure 6.

The first measurement was performed in the condition without puncturing support (deformed reinforcing steel bars), (Figure 7). The total of 107 holes have been drilled. The depth of holes was from 1.2 to 1.5 m with explosive consumption of 174 kg. Maximum quantity of explosive per delay was 18.30 kg. In measurement point No.1, 28 m away from the blasting location (R 1), ppv reading was 62 mm/s, whereas on the primary support of the adjacent tunnel tube, in measurement point No. 2 (Figure 7), 19 m away from blasting location, ppv reading was maximum 85 mm/s.

6.2 *Blasting under the puncturing support*

Different from above at this measurement a puncturing support (reinforcing steel bars) was drilled and installed before blasting above last lattice girder next to the face. Design of puncturing support, i.e. of deformed reinforcing steel bars contains rebar (RA 400/500–2), diameter 25 mm, length 4 m installed in to calotte with spacing of 0.30 m as it is shown in the Figures 8 and 9.

Figure 8. Tunnel face with blasting field and the puncturing support.

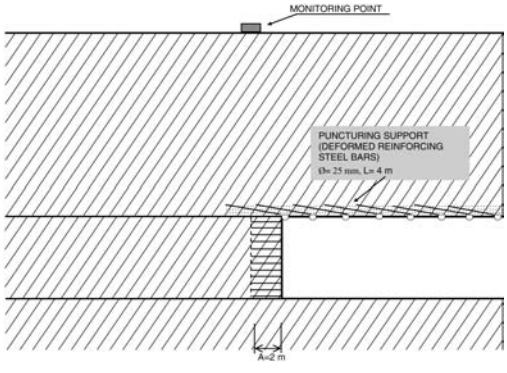

Figure 9. Schematic view of puncturing support.

Although this support system element is considered a beam, which will stop falling of unconsolidated strata in poor categories of rock from calotte after blasting, the significance of puncturing support is ambiguous.

Apart from the above stated, the perforation of rock in calotte along the excavation line will be achieved by drilling and installing of deformed reinforcing steel bars. In that manner excessive squander of surrounding rock mass and lowering of bearing capacity of rock will be avoided. Rock is considered a main support element and it is presumption that ground oscillation above blasting location will be lowered.

In the first measurement below puncturing support drilling the depth was increased to 2.5 m. In total 132 holes were drilled and 275 kg of explosive was spent. Maximum quantity of explosive per delay amounted to 22.6 kg. Distance from the first monitoring point to blasting location was 26 m, and recorded maximum ppv was 71.5 mm/s. The second monitoring point on primary support of adjacent tunnel tube was 26 m away, and ppv was double as high, i.e. 142.7 mm/s.

Table 3. Results of measurements.

No.	Drilling lenght (m)	Hole no. (Pcs.)	Total explosive quantity (kg)	Max. explosive quantity per delay (kg)
1.	1.2–1.5	107	174	18.3
2.	2.5	132	275	22.6
3.	2.0	119	202	18.6
No.	factor (kg/m^3)	Puncturing support	PPV-M.P.1 (distance) mm/s (m)	PPV-M.P.2 (distance) mm/s (m)
1.	1.61	–	62 (28)	85(19)
2.	1.8	yes	71.5 (26)	142.7 (26)
3.	1.26	yes	35 (15)	168 (26)

The second measurement was performed at the drilling depth of 2 m (119 holes) with total explosive consumption of 202 kg. In the first monitoring point (M.P.1) ppv up to 35.5 mm/s at 15 m distance from the blasting location were recorded. Ppv in the second tunnel pipe (M.P.2) amounted to 168.1 mm/s at the distance of 26 m.

7 ANALYSIS OF TEST RESULTS

In Table 3 are the results of measurement with blasting patterns with and without puncturing support. The first test was performed without puncturing support and it serves as a stub, i.e. as a standard for the remaining two measurements. From the other 2 measurements it is obvious that from the monitoring point MO1 above the tunnel calotte, particle velocities are lower than when applying the puncturing support system opposite to the measurement without it.

During testing the quality of tunnel contour has been monitored and recorded. In the places without puncturing support there was an over break along the whole contour of the tunnel. During the excavation below puncturing support the contour quality depended on 3 group of parameters; blasting method, installation of puncturing support and geological excavation structure. In order to achieve proper installation of puncturing support (deformed reinforcing steel bars), the ratio between loading concentration of contour hole and spacing between holes and deformed reinforcing steel bars must be determined. Collar of deformed reinforcing steel bar must have contact and should be covered with shortcrete. Beside that, the diameter of deformed reinforcing steel bar (25 mm) is not strong enough and should be at least 32 mm large; used on the semi motorway project Karlovac-Rijeka, and it was proved very efficient. Proper installation of puncturing support is shown on Figure 10. Improper installation of puncturing support is shown on Figure 11.

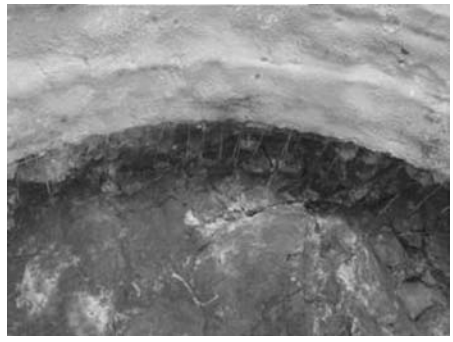

Figure 10. Proper installation of puncturing support.

Figure 11. Improper installation of puncturing support.

8 CONCLUSION

Based on the principle of New Austrian Tunneling Method, stating that the rock is primary a support element, it is necessary to preserve primary strength of rock during the excavation as much as possible. In rock mass next to the tunnel opening there occurs squander of ring-like support structures, which range of disturbance zone depends on the quality of applied blasting method. Implementation of puncturing support has larger significance than beam supporting of calotte material itself. During drilling of puncturing support (4 m) by monitoring of drilling fluid it could be defined what type of material can be expected, and with this knowledge blasting method could be adjusted to forthcoming conditions. Drilling and installing of rebar Ø 25 mm on each 30 cm in tunnel calotte generates broken perimeter arch (shielded zone) that attenuates ground vibrations along the monitoring point and in such a manner prevents unwanted squander of rock mass. Puncturing support (4 m) was installed on each 2 m of excavation, which meant that the overlap was each 2 m, so even two attenuating zone existed. Concluding from all the above stated facts, the puncturing

support has proven to be a useful and multi-valued support element, which only deficiency is a diameter that should be at least Ø 32 mm, because on former projects this diameter has been proven more appropriate.

Two different concepts of geotechnical survey and monitoring in exploration galleries for tunnels in Prague – Lahovská exploration gallery and Blanka exploration gallery

R. Chmelař & B. Březina
PUDIS a.s, Prague, The Czech Republic

ABSTRACT: In the article, two different concepts of geotechnical survey adopted in newly realized exploration galleries in Prague are discussed. The first of them is the Blanka exploration gallery with cross section 10 m^2, in which the geological and geotechnical conditions have been verified especially by means of a series of pressuremetric tests and large scaled in-situ tests performed on rock blocks. Rather different concept was adopted in the Lahovská gallery, where both in-situ geotechnical measurements (pressuremetric tests) and measurements of geotechnical monitoring (especially convergence and extensometric measuring) were concentrated into turnout areas, which were driven with cross section 64 m^2, corresponding to that of top heading of the proposed three lane tunnel.

1 INTRODUCTION

At present, two important underground constructions on different road circuits are performed in Prague, the capital of the Czech Republic. Together with radial connecting roads, these two circuits – the inner City Circle Road (CCR) and the outer Prague City Ring Road (CRR) – are expected to create an up-to-date global traffic system in Prague.

In order to verify the geological and geotechnical circumstances, two exploration galleries have been carried out beforehand for two already finished tunnels – the Strahov Tunnel (built during 1985–1997) and the Mrázovka Tunnel (1998–2004), both forming a part of the CCR.

Currently, the above mentioned exploration galleries are followed by third one, namely the Blanka gallery (2002–2005), performed in the route of the next part of the CCR between Špejchar and Pelc Tyrolka.

At the CRR, two parallel driven tunnels are proposed to become a part of the construction lot No. 514 from Slivenec to Lahovice. Before starting their construction at the end of 2006, the Lahovská exploration gallery has been performed (2004).

As to their general concepts, both above mentioned galleries are reasonably different. In the following text, the differences of the conception of geotechnical survey and monitoring in both exploration galleries are discussed.

2 THE BLANKA GALLERY

2.1 *Purpose of exploration gallery*

Geotechnical survey during tunnelling the gallery was aimed to verification of geotechnical conditions along the difficult parts of the tunnels proposed, especially below the Vltava River and in the area of the Stromovka Natural Park, where the tunnels will be driven immediately below highly water-bearing terrace sediments.

For this purpose, both the total length (1950 m in the left tunnel tube) and the section area (10,5 m^2, or 18,7 m^2 at turnouts) have been adapted. The gallery was driven from its entrance shaft located in Troja (city quarter on the right Vltava bank), and shot firing together with track transport were applied for its driving.

2.2 *Geological conditions*

In the total length of the gallery, its driving was performed in the rock massif consisting of Lower Palaeozoic Ordovician sediments covered with highly water-bearing terrace fluvial sediments.

Along the gallery, the geotechnical character of Ordovician sediments varies extremely, from the softest clay shales (Libeň strata group) and sandy shales (Dobrotiv) with medium strength up to very hard

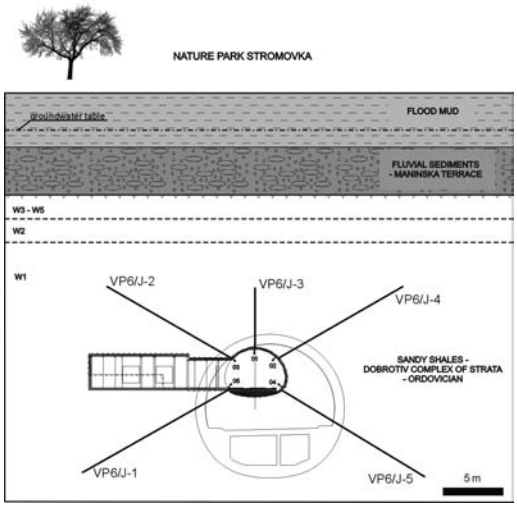

Figure 1. Cross section in turnout of the BLANKA exploration gallery with lateral testing drift for in-situ geotechnical tests.

quartzites (Řevnice and Skalka substrata). All these rocks were formed within Varisan orogeny and locally they display tectonic failures of various degree.

Geotechnical survey has been aimed not only to geological documentation of particular geological types, but also to the verification of their geotechnical properties. As well, great importance was put on hydrogeological conditions of the rock massif and waterflows into the body of the gallery.

As well, the level of underground water in terrace sediments has been monitored, especially in the Stromovka natural park area.

2.3 *Geotechnical tests*

Geotechnical properties of rocks have been determined both by means of laboratory tests (especially strength of the rock mass itself) and in-situ tests. The latter were represented by two main types – pressuremetric tests, performed in 14 bore flappers, each consisted 4–5 radially oriented bores, and large scale strength and deformation tests of rock blocks, situated in two short testing drifts of the gallery. A scheme of the pressuremetric flapper and the testing drift is shown on Figure 1.

In two testing shafts, the following types of large-scaled in-situ tests have been performed: uniaxial and triaxial strength tests on the rock blocks of 50×50 cm cross section and 100 cm height (Fig. 2), shear strength

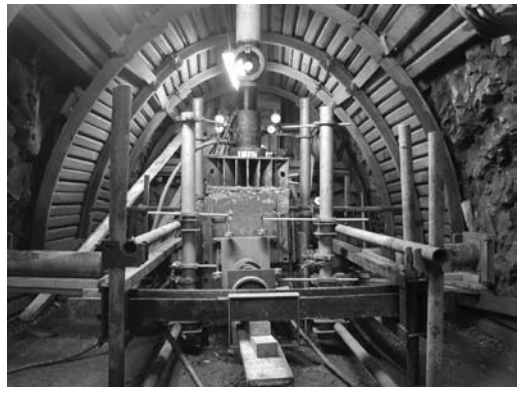

Figure 2. Assembly of large scale in-situ triaxial strength test.

Figure 3. Assembly of in-situ shear strength test with predetermined plane of disturbance.

test with pre-determined plane of disturbance (located along stratification, along fissuration or into tectonic zones, respectively – Fig. 3) and plate load tests (both in horizontal and vertical direction). Thus it was possible both to observe and measure the properties of the rock massif (including the discontinuities) on the rock blocks in the testing drifts and to verify the deformation parameters around the exploration gallery by means of pressuremetric tests performed in bore flappers. As the result, the laboratory and in-situ tests performed gave the opportunity to collect reasonable quantity of geotechnical information not only along the exploration gallery, but also in the environs (and especially the overburden) of the tunnel proposed.

Development of intact rock strength and of pressuremetric modulus along the Blanka gallery and the diagram of shear strength as derived from the results on large-scale rock blocks in the testing drift are shown on Figures 4–5.

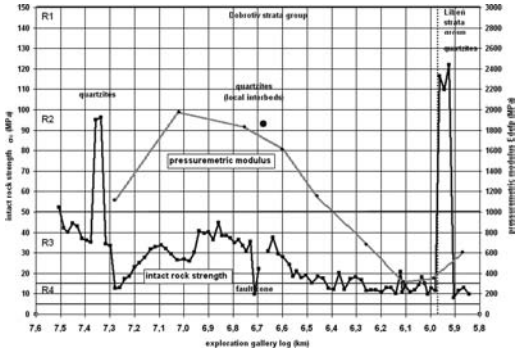

Figure 4. Development of intact rock strength and pressuremetric modulus of deformation in along the Blanka gallery.

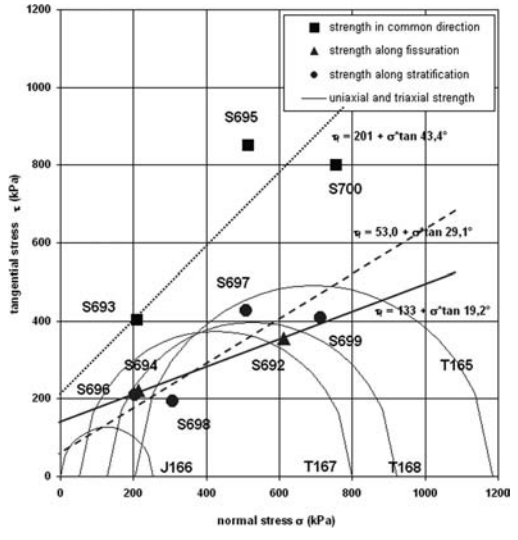

Figure 5. Diagram of shear strength as derived from the results on large-scale rock blocks in a testing drift.

2.4 *Geotechnical monitoring*

As the components of the geotechnical monitoring, especially the convergence measurements, the ground surface deformation measurements and the primary lining pressure measurements have been performed. In the critical tunnel sections with minimum rock overburden, also the extensometric measurements were carried out, with a rod extensometer located above longitudinal axis of the tunnel. All measurements gave the information on the deformation behaviour of the primary lining and the rock massif (and in some case also on the development of a depression basin) invoked from advancing the 10.5 m^2 cross section gallery (18,7 m^2 in turnouts). Even if very valuable, the data of the deformation response obtained during the tunnelling of the gallery should not be overestimated when applied for future tunnels with the cross section over 100 m^2, and some additional prediction method (e.g. pregnant parametric study by means of the mathematical modelling) is definitely needed. Anyway, driving the large cross section tunnels in complicated geological circumstances (as e.g. nearby the end of the Blanka gallery, with only 3 m of rock overburden and under highly waterbearing terrace sediments of the Vltava River) remains always less or more risky and unsafe, and thus most demanding for maximum engineering experience as well as safety precautions applied.

3 THE LAHOVSKÁ GALLERY

3.1 *Purpose of exploration gallery*

Geotechnical survey in the Lahovská exploration gallery was aimed to the verification of geological and geotechnical conditions in route of the tunnels proposed, the driving of which is planned with a minimum delay after finishing the gallery. Therefore, the gallery has been driven from two opposite ends of the future tunnels, i.e. from the Radotín and from the Lochkov portals. The gallery with total length 1313 m has been adapted for wheel traffic and thus its cross section was reasonably larger than in the Blanka gallery (24.5 m^2 against 10,5 m^2). Moreover, all turnouts have been driven in full profile of the tunnel top heading, thus reaching almost 64 m^2 (18.7 m^2 in Blanka). The gallery has been driven by means of shot firing.

3.2 *Geological conditions*

Within its total length, the gallery has been driven in rock massif, consisting of Lower Palaeozoic Silurian and Ordovician sediments, with Quarternary deluvial sediments in overburden. The rock massif was formed during Varisan orogeny, with local tectonic failures of various degree.

In the following text, the dip-advanced half of the gallery (performed from the Lochkov portal) is introduced as an example. In this part, the gallery has been driven exclusively in the Silurian rocks, nevertheless highly heterogeneous. Generally, both strata groups occurred (i.e. the Motol and Kopaniny strata) consist of clay shales with interbedded limestones. Besides Palaeozoic rocks, some basaltic effusive rocks (diabases and basaltic tuffes) also occurred here and there.

3.3 *Geotechnical tests*

Geotechnical survey within tunnelling the gallery included the routine measurements and activities, i.e. geotechnical observation and documentation of

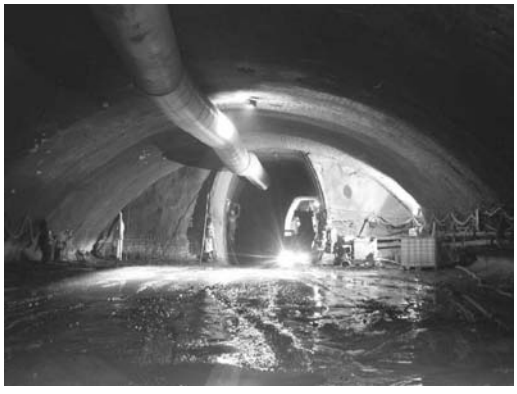

Figure 6. View into the monitored turnout extended into full size of the top heading of a three-lane tunnel in Lahovská exploration gallery.

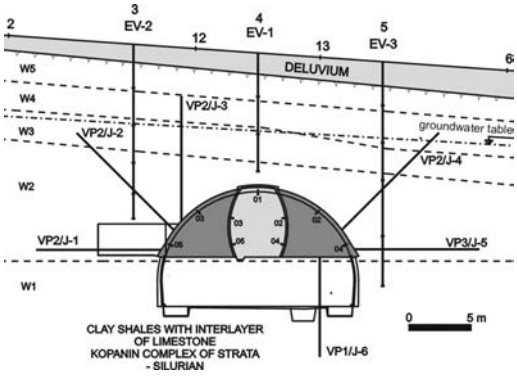

Figure 7. Complex solution of geotechnical survey and monitoring in associated profile situated at the turnout extended into full size of the top heading of a three-lane tunnel in Lahovská exploration gallery.

W1	degree of weathering by ČSN 72 1001 standard

gallery faces, laboratory tests on rock samples (including abrasivity and disintegration tests) as well as geotechnical in-situ tests.

In the original concept of the field tests, two testing drifts for in-situ tests on large-scale rock blocks were proposed. However, with regard to the rapid advance of the tunnelling and the decision of extending the section area in all turnouts, the scheme of in-situ tests has been revised – the original concept of testing drifts has been abandoned and replaced by a series of pressuremetric measurings with the particular tests located in bore flappers consisting of 4–5 radially oriented boreholes, i.e. similarly as in the Blanka gallery. The bore flappers were located into all extended turnouts (top headings) and one of them also nearby the future Lochkov portal.

In first turnout, a series of pressuremetric tests have been executed also in the extensometric bores from the ground surface, in order to determine the deformation properties of the rock massif when under primary stress conditions, i.e. not influenced by the driving. Later, the results collected have could be compared with those from the underground bore flapper situated in the same cross section.

3.4 *Geotechnical monitoring*

After extending the gallery turnouts into full section of the top heading of the three-lane tunnel (Fig. 6), it has been possible to monitor a real response of the rock massif, which is already comparable with that of the driving of the tunnel itself. An example of the associated measuring profile for geotechnical survey and monitoring in the extended first gallery turnout near the Lochkov portal is shown on Figure 7. From such a measuring profile, a great volume of the most important information for designing the future tunnels can be obtained.

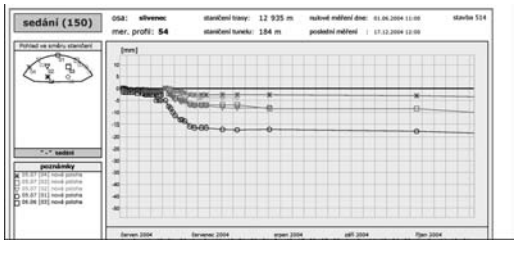

Figure 8. Results of convergence measuring from the monitored turnout displaying vertical deformations of lining – gradually from driving the gallery and then from driving the top heading of a three-lane tunnel.

Unlike the two further turnouts, the first turnout (including the above mentioned associated profile) has been driven gradually. At first, the exploration gallery has been tunnelled in this section, which has been successively extended into full width of the top heading, and geotechnical monitoring has been designed in such a way that could enable the observation of deformations evolved both from driving the gallery itself and from the extended tunnel top heading.

Similar development of vertical deformations from driving the gallery and, successively, the top heading, is evident both from the results of the convergence measurements of the primary lining (Fig. 8) and from a three-stage rod extensometer, situated above the longitudinal axis of the tunnel.

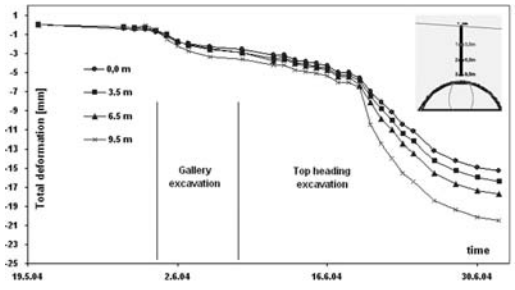

Figure 9. Extensometric measuring – development of vertical deformations of the rock massif in overburden from tunnelling the gallery and successively from extended top heading.

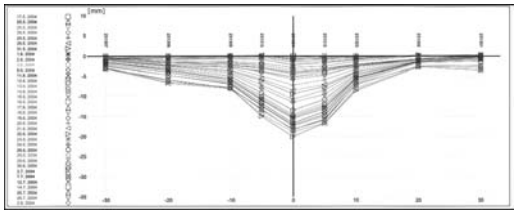

Figure 10. Development of a terrain depression basin from tunnelling the gallery and successively from extended top heading.

From the results of this extensometer, if has been confirmed that a decreased stress zone around the tunnel stope remains relatively narrow – it has been indicated only at the last (lowest) measuring level of extensometers. As well, it has been repeatedly proved that the extensometres are more suitable to be installed from the ground surface, thus obtaining the possibility of measuring the vertical deformations even before the gallery/tunnel face reaches the profile of measuring.

The influence of driving the gallery (and then the top heading) on the development of vertical deformations in the tunnel overburden as detected by the extensometric assembly is shown at Figure 9. Such values are already directly applicable for the design of the tunnel.

Besides the overburden and the lining deformations, also the development of the transverse depression of the ground surface can be observed when the gallery is being extended into the full tunnel top heading. As the result, the limits of the depression basin during the driving of the tunnel itself can be predicted much more precisely. The development of the depression basin above the top heading-sized turnout nearby the Lochkov portal is shown at Figure 10.

4 COMPARISON OF BOTH CONCEPTIONS

Both conceptions of the geotechnical survey the monitoring, as applied in the Blanka and Lahovská exploration galleries, are well-founded. For the sake of the tunnel design, the latter concept seems to be evidently more advantageous and sophisticated, for several reasons: wheel traffic has been applied similarly as for the future tunnels, the turnouts have been extended into the full width of the tunnel top heading, which enabled to monitor the impact of tunnelling on the tunnel overburden and the ground surface intensively, as well as to determine the deformations of the primary lining in the top heading area. Thus, with the geotechnical parameters of the rock massif collected from the in-situ tests carried out, a complex set of information on the properties of the rock massif and its behaviour during driving the top heading of three-line tunnels can be obtained. However, the possibility of application of the above characterized modern survey conception may sometimes be limited, since the exploration gallery with its turnouts extended into full top heading can be proposed only for the tunnels with their horizontal and vertical position finally fixed; otherwise it can hardly be applied. On the other hand, the galleries with smaller cross section area (as e.g. the Blanka gallery) can be used even if the final location of future tunnels is not yet exactly determined, and greater accent is put on the survey activities here. For example, besides pressuremetric in-situ tests, also large-scale tests on rock blocks can be executed under such conditions, in order to compensate the fact that the results of geotechnical monitoring in the smaller-sized galleries are much less comparable with those of the tunnel itself. In similar circumstances, some supporting prediction method, e.g. a parametric study with the application of mathematical modelling is definitely needed.

5 CONCLUSION

Generally, especially the concept of geotechnical survey and monitoring as applied in the Lahovská exploration gallery is evidently perspective. Besides the positives on the field of geotechnical survey, its most important aspect consists in application of the same type of excavation technology and transport as for the tunnels proposed. Moreover, the gallery turnouts extended into the full profile of the tunnel top heading becomes a full-value and in-advance-finished part of the tunnel, thus having an undisputable technological and economical importance for the successive driving of the tunnel itself.

Inverse analysis on measurements realized during a tunnel excavation

S. Eclaircy-Caudron, D. Dias & R. Kastner
URGC Géotechnique, INSA de Lyon, Villeurbanne, France

ABSTRACT: One of the major difficulties for geotechnical engineers during project phase is to estimate in a reliable way the mechanical parameters values of the adopted constitutive model. In project phase, they can be evaluated by laboratory and in situ tests. But, these tests lead to uncertainties due to the soil reworking and to local character of the test which is not representative of the soil mass. Moreover for in situ tests interpretation difficulties exist due to the non homogeneous character of the strain and stress fields applied to the soil mass. In order to reduce these uncertainties, geotechnical engineers can use inverse analysis processes during construction. This article shows the application of two of these processes on convergence leveling measurements realized during the excavation of the Bois de Peu tunnel (France).Two inverse analysis method have been tested (an optimization method and an evolutionary algorithm), coupled with the finite element software CESAR-LCPC to identify soil parameters.

1 INTRODUCTION

The purpose of inverse analysis processes is the identification of parameters using tests results or/and experimental measurement carried out during works. Various methods exist. Hicher (2002) distinguishes three kinds: analytical methods, correlation and optimization methods. Optimization methods are applied when model parameters are not appropriate to be used in a direct approach by graphic construction or in an analytical approach. By this method, the inverse problem is solved using an algorithm which minimizes a function depending on all parameters. This function is generally called "cost function" and corresponds to the difference between numerical and experimental measurements. The experimental results can come from various origins: laboratory tests, in situ tests or work measurement data. Two types of optimization methods are distinguished: deterministic and probabilistic methods. The deterministic methods include gradient, Newton, Gauss-Newton or Levenberg Marquardt optimization algorithms. Several researches aiming at parameter identifications based on deterministic methods were carried out in the last years. Zentar (2001) tried to identify some mechanical parameters of the Saint-Herblain clay using the results of pressuremeter tests and the optimization software SiDoLo. He considered an elastoplastic model with or without hardening. In spite of the identification methods development, a few of them were applied to real cases like tunnels or deep excavations (Finno et al. 2005).

The deterministic methods present some advantages. The iteration number required to achieve the optimization process is relatively low. But, if the cost function presents several local minima, the deterministic methods can converge towards the first found minimum. This major drawback explains why these methods are seldom used for complex problems. For such problems probabilistic methods are preferred. Probabilistic methods include evolutionary algorithms such as genetic algorithms and evolution strategies. Evolutionary algorithms reproduce the natural evolution of the species in biological systems and they can be used as a robust global optimization tool. The major principles of genetic algorithms were developed by Goldberg (1991). Evolution strategies (Schwefel, 1985) start searching from an initial population (a set of points) and transition rules between generations are deterministic. The search of new points is based on mutation and recombination operators. Recent researches applying genetic algorithms to soil parameters identification for a constitutive model have been undertaken in geotechnics (Levasseur et al. 2005). Evolution strategies were also recently applied to problems in many domains (Costa et al. 2001).

First, this paper presents briefly the used optimization software, SiDoLo and the used evolutionary algorithm. Then the numerical modelling of the tunnel and the followed approach are detailed. Finally, results obtained by the two processes are compared.

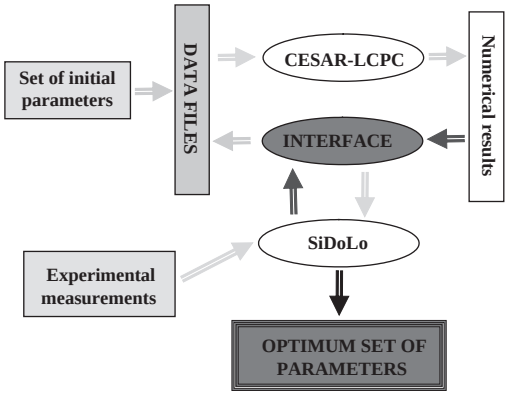

Figure 1. Principle of the coupling.

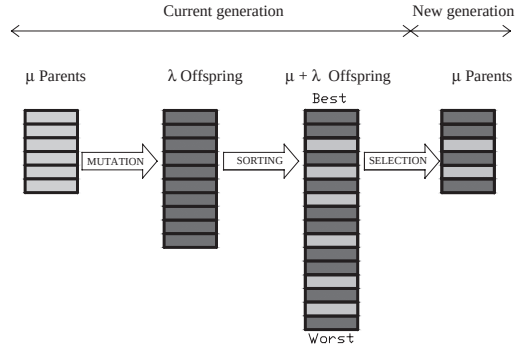

Figure 2. Principle of the $(\mu/\rho+\lambda)$ evolution strategies (Costa et al. 2001).

2 PRESENTATION OF THE OPTIMIZATION METHODS USED

2.1 *The optimization software, SiDoLo*

SiDoLo is coupled with the finite elements code CESAR-LCPC. The coupling principle is illustrated in figure 1.

Though this coupling, SiDoLo compares numerical results with experimental measurements, in order to calculate the cost function. When the cost function is lower than a fixed value, then the optimization process stops. The cost function L(A) is expressed by the following finite sum:

$$L(A) = \sum_{n=1}^{N} \frac{1}{M_n} \sum_{i=1}^{M_n} {}^{T}[Z_s(A,t_i) - Z_s^*(t_i)].D_n.[Z_s(A,t_i) - Z_s^*(t_i)]$$

where A are the model parameters, N is the number of experimental measurements; $[Z_s(A,t_i) - Z_s^*(t_i)]$ is the difference between numerical and experimental results evaluated only at M_n steps of observation t_i and D_n is the weighting matrix of the nth test. Measurements accuracy is taken into account by weighting coefficients.

SiDoLo uses a hybrid optimization algorithm, which combines two typical minimization methods: the gradient method and a variant of the Lavenberg-Marquardt method to accelerate the convergence when the solution is close. More details on the SiDoLo approach can be found in Eclaircy-Caudron et al. (2006).

2.2 *The algorithm based on evolution strategies*

The algorithm used was developed by Costa (Costa and al. 2001). This algorithm was adapted to the problem studied in this paper, and as for SiDoLo, requires to create an interface with Cesar-LCPC. The population individuals are vectors of real coded decision variables that are potential optimal solutions. An initial population is generated and then each following generation, λ offspring are generated from μ progenitors by mutation and recombination. Then the best individuals are selected for next generation among the $\mu+\lambda$ members according to their cost function value. Finally, the μ best of all the $\mu+\lambda$ members become the parents of the next generations. Important features of evolution strategies are the self adaptation of step sizes for mutation during the search and the recombination of individuals that is performed between ρ individuals. This algorithm, named generally $(\mu/\rho+\lambda)$ algorithm, is illustrated in figure 2.

The algorithm stops when one of the following conditions is verified:

- The maximum number of generations is reached
- The difference between the two extremes values of the cost functions is lower than 10^{-5}
- This difference divided by the average of the cost functions values is lower then 10^{-5}

3 THE FOLLOWED APPROACH

3.1 *Presentation of the tunnel*

The Bois de Peu tunnel is situated near Besançon in France. It is composed of two tubes. The excavation length is about 520 meters per tube for a cover height which varies between 8 meters and 140 meters. Four kinds of supports were foreseen in the project phase for the four types of materials: limestones, marls, interbeding of marls and limestones and clays. The studied section is located near one of the two tunnel portals where interbeding of marls and limestones were expected. A face levelling of this section is showed in figure 3. The lining support set up in this area is composed of a mixed support of the tunnel walls by shotcrete with a thickness of 0.2 m and steel ribs. The tunnel is dug with a constant step of 1.5 m. The height

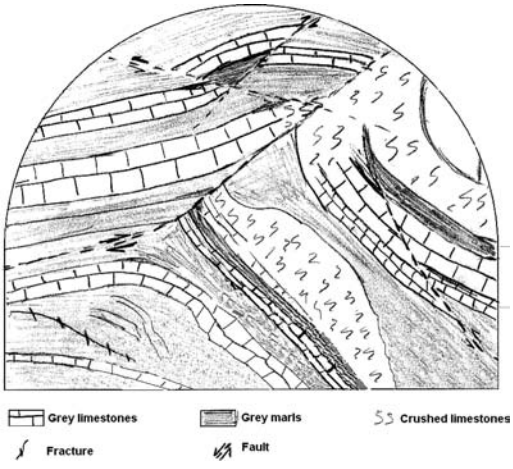

Figure 3. Face levelling.

Table 1. Design characteristics.

Parameters	γ (kN/m^3)	E (MPa)	C (MPa)	ϕ (°)	ν –
Probable	24.8	1600	0.70	40	0.3
Exceptional	24.0	750	0.21	36	0.3

of cover is equal to twenty six meters. At the end of site investigations, two kinds of design characteristics were defined: probable and exceptional. They are resumed in table 1.

3.2 *Numerical model*

Due to time consuming of three dimensional calculations, tunnel excavations are often taken into account by two dimensional modelling. We adopted a transverse plane strain model, taking into account the real geometry, the excavation and tunnel support being modelled by an unconfinement coefficient (Panet, 1995). Only a half section is represented because a symmetrical deformation of the section is assumed. The grid dimensions are 75 m (= 6D) in the two directions in order to avoid the influence of the boundaries. The grid (figure 4) contains around 3900 nodes and 1850 elements with quadratic interpolation (Six nodes triangles and 8 nodes quadrangles). The initial stress field is anisotropic. An earth pressure ratio of 0.7 is adopted. This value was obtained by means of in situ tests. Steel ribs and sprayed concrete are simulated by a homogeneous support with equivalent characteristics. This support is assumed to have a linear elastic behaviour. A linear elastic perfectly plastic model with a Mohr Coulomb failure criterion and non associate flow rule is considered to represent the soil mass.

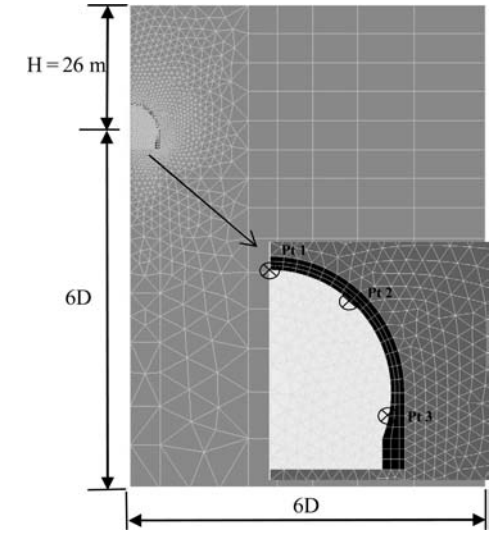

Figure 4. The grid and its dimensions.

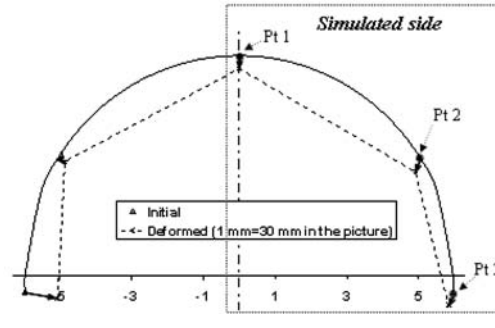

Figure 5. The observations points and deformed section.

Three computing phases are defined. First the initial stress field is applied. After, the tunnel is excavated. In this phase the unconfinement ratio at the time of the support installation is applied. Finally the homogeneous support with a 0.238 m width is activated. A total unconfinement is applied.

3.3 *Experimental results*

Figures 4 and 5 locate the three experimental measurements points used for optimization. Five measurements are observed for these three points: leveling for these three points and horizontal displacements for the points 2 and 3. They correspond to convergence and leveling measurements of the tunnel wall in a given cross section (point 1 to 3 in figures 4 and 5). The convergence and levelling measurements of this section are reported in figures 6 and 7. These measurements permit to deduce the horizontal and

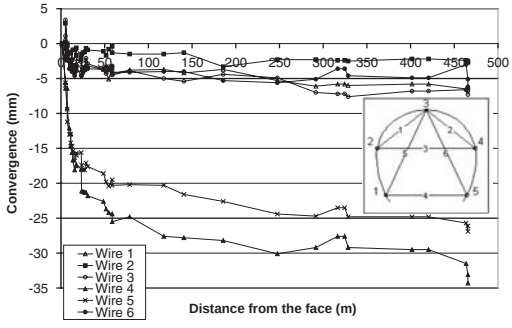

Figure 6. Convergence measurements.

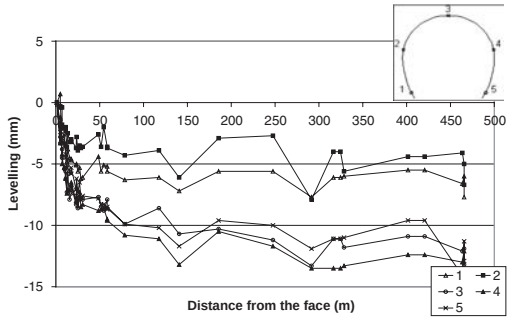

Figure 7. Leveling measurements.

vertical displacements of each point. The convergence is maximal for wires 4 and 5. It reaches 30 mm for wire 4. Moreover levelling is more important for targets 3, 4 and 5 than for the others. It reaches 13 mm. So, these measurements showed a dissymmetrical deformation of the section. In optimization process average displacements measured at equilibrium are used. The dissymmetry is confirmed by the section deformation presented in figure 5 where the crown displacement is assumed purely vertical. The experimental results considered in the optimization process correspond to the average displacements observed at the two sides.

3.4 *Unknown parameters*

In the frame of plane strain calculation, the introduced unconfinement ratio λ at the time of support installation might be calculated by the convergence-confinement method (Panet, 1995) if the constitutive model parameters were well known. But in this study, it is considered as an additional parameter to identify. Before using inverse analysis, a sensibility study was performed. The Poisson ratio and the dilatancy angle are parameters which have low influence on the observed variables. So, these parameters could not be identified with these measurements. Only parameters λ, C, E and ϕ, might be evaluated.

Validation studies (Eclaircy-Caudron et al. 2006) were performed with SiDoLo on this numerical model in order to define which parameters might be identified according to the available experimental measurements. These studies showed that with convergence and levelling measurements no more than two parameters could be identified. But SiDoLo always succeeded to identify ϕ and λ even if they were unknown with other parameters because they have more influence on the convergence and levelling measurements than the others. In order to verify the provided solution an evolution strategies algorithm is used in complement of the software SiDoLo.

4 RESULTS

Several identification attempts were performed with SiDoLo, confirming that SiDoLo provides approximately the same values of ϕ and λ in all cases.. They also showed that the friction angle was lower than the project value (between 10 and 20°).

Two examples of identification are presented here, where three vertical and two horizontal displacements are used in the optimization process. For each identification several initial values (referred as a, b and c) of unknown parameters are tested in order to show the influence of the initial value.

In the first example, the four parameters E, C, λ and ϕ are identified. Table 2 gives the obtained values and the enabled respective ranges in SiDoLo. Several solutions are found by the optimization process according to the introduced initial values but provided values of ϕ and λ are similar. ϕ varies between 12.2 and 15.6° and λ between 0.7 and 0.75. Figure 8 compares the displacements obtained with the optimized values provided by first identifications to the measurements. Displacements computed with the design characteristics (probables or exceptionals) are also reported in this figure. They are very low compared to the measurements. The displacements computed after optimization for points 2 and 3 are close to the measured displacements. The vertical displacements computed at point 1 are lower than the one measured. The iteration number required to achieve the optimization process varies between 16 and 52 according to the initial value. These results highlight the fact that the optimization problem has not a single solution when more than two parameters are unknown. The major drawback of the probabilistic optimization methods is that they can converge to local minima.

In the second identification only the Young modulus E and the cohesion C are identified. λ and ϕ are fixed respectively to the average of values provided by the first identification. A friction angle of 14° and an unconfinement ratio of 0.717 are adopted. The enabled ranges in SiDoLo are the same. Table 3 gives the obtained values. Several solutions are also found by

Table 2. The first identifications results realized with SiDoLo.

Set	E (MPa)	C (MPa)	ϕ (°)	λ –
a	202.3	0.12	15.6	0.7

a	217	0.13
b	100	0.19
c	102	0.19

the optimization process according to the introduced initial values. SiDoLo does not succeed to find the best couple. It provides local minima. Displacements computed after identifications 2 are similar to those obtained after identifications 1. The vertical displacement measured at the tunnel crown appears difficult to reproduce in the numerical model. Although the face levelling showed in figure 3 highlights a disturbed geology with folds and faults a homogeneous medium is considered in the model. A more complex model seems to be required to simulate the real behaviour of the tunnel crown.

In order to avoid local minima, the evolution strategies algorithm is used. The same identifications than those previously presented are realized. These identifications allow to verify the solutions found by SiDoLo. The same ranges are enabled for parameters. The number of generations is limited to 50 in order to keep acceptable computation times. The parent population size is 10 and the offspring population size is 20. For two identifications the evolution strategies algorithm

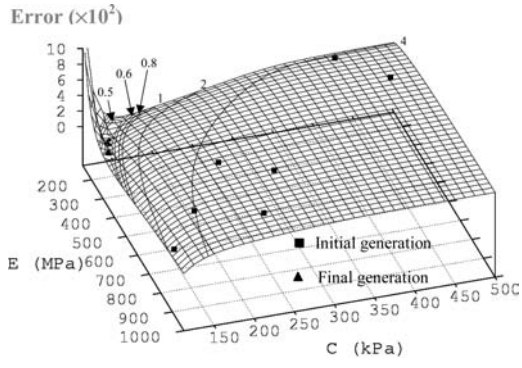

Figure 9. Evolution of the cost function for tests 2. Representation of initial and final generation's parents.

stopped when the maximum number of generations is reached, the cost function being still relatively important and the stop criteria on this function cannot be reached. So the problem seems to be badly formulated. The design characteristics, the best member provided by the Evolution Strategies algorithm (ES) and solutions provided by SiDoLo are resumed in table 4.

For the first identification where four parameters are unknown the evolution strategies algorithm provided a solution different from those provided by SiDoLo. This solution corresponds to a global minimum.

Figure 9 presents the evolution of the cost function in the case of two unknown parameters E and C while λ and ϕ are introduced as input parameters (identifications 2). The cost function is not convex and shows a valley. A decrease of parameter E is counterbalanced by an increase of C in a small variation domain. So it is difficult to identify these two parameters with only convergence and levelling measurements. Moreover the value of the cost function is important, confirming that the numerical model should be improved. Figure 9 shows also the parents at initial and final generations. At initial generation parents are dispersed in all research space. At later generation they are located in the valley and are close to each other. Figure 10 locates the three couples found by SiDoLo and the best

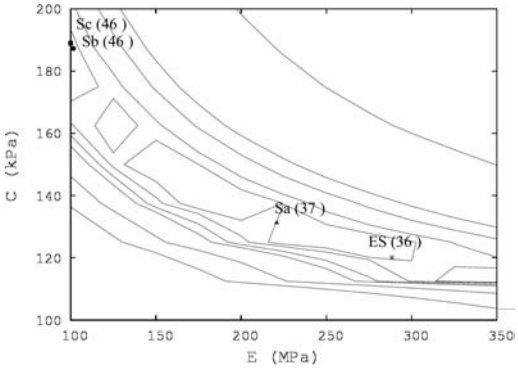

Figure 10. Location of the solution found by SiDoLo (Sa, Sb and Sc) and the best member found by the evolution strategies algorithm (ES) during tests 2.

member found by the evolution strategies algorithm after identifications 2. The error function value is also reported. Solutions found by SiDoLo are situated in the valley and correspond to local minima. The evolution strategies algorithm provides a global minimum.

5 CONCLUSIONS

The use of inverse analysis on in situ measurements carried out during the construction of a real work is rare. This might be due to the difficulty met to apply inverse analysis on real work. In a tunnel case the numerical model required many simplifications in order to obtain acceptable computation times. Moreover, boundaries conditions should be representative. The adopted constitutive model should not be too sophisticated with many parameters but should properly simulate the soil behaviour.

The use of a deterministic method in two steps permits to obtain local minima. The probabilistic method based on evolution strategies makes it possible to find the global minimum. But this method required more important computation time: more than 2 days for the 50 generations against 1h30 for SiDoLo per identification and for the three initial values. Here with two unknown parameters the cost function is not convex and presents a valley. Moreover the error values are important. Thus the problem is more difficult to solve.

In this study a linear elastic perfectly plastic model with a Mohr Coulomb failure criterion is considered to represent the soil mass. In order to improve results a non linear elasticity and a Young modulus which varies with depth could be introduced. Maybe the evaluation of the earth pressure ratio by means of in situ tests needs to be more investigated. This ratio might be considered as a supplementary parameter to identify. Moreover uncertainties exist on the lining stiffness. Due to the face levelling showed in figure 3 and to the section deformed in figure 8 the studied section is not homogeneous. So it could be interesting to realize two optimizations by considering each side. Optimizations could be realized by considering only points 1 and 2 where dissymmetry is less visible.

In order to improve the results provided by the two optimization methods tested in this paper other measurements have to be used like stress measurements in steel ribs or displacements measured along extensometers. Moreover, two numerical models could be coupled in the optimization process. So the optimization could be realized at the same time on displacements measured during the exploration gallery excavation in a zone near the studied section and on convergence measured in tunnel.

Prediction of the ground conditions ahead the TBM face in the tunnels of Guadarrama (Spain), using geophysical methods and in situ testing

José Miguel Galera
Geocontrol S.A. Universidad Politécnica de Madrid

Salvador Pescador, Ángel Rodríguez & Manuel Torres
In Situ Testing S.L.

ABSTRACT: The tunnels of Guadarrama are new twin tunneles crossing the Central Range between Madrid and Segovia, as part of the new High Speed Railway Line to the NW of Spain. Their length is 28,3 km with a maximum overburden of 900 m. The geology consists mainly of crystalline rocks, gneiss and granites, with a main graven in the Lozoya valley where poor quality sedimentary rocks from the Cretaceous are crossed. Nevertheless several faults have also been detected with mylonites and water. The tunnels have been done using four double-shield TBMs, all of them with an excavation diameter of 9,5 m. In order to predict in detail the ground conditions ahead the TBM face, a review of the geological features has been done. This has consisted in detailed geological mapping with a precise photogeological study and systematic Electrical Resistivity Tomography (ERT) profiles along the axis of both tunnels. Also several geophysical investigation methods have been applied, in order to allow a good knowledge of the rock mass. In situ geotechnical tests have been also carried out, yielding ground geomechanical parameters. They can divide as follows:- Surface tests, carried out from the South Portal, previous to the TBM – Surface tests, carried out from the North Portal, previous to the TBM – La Umbría Fault, where various methods have been applied at the surface, in borehole, surface to borehole or borehole to borehole. This paper describes the field campaigns and shows the most significant results of the geophysical investigation in Guadarrama tunnel. In the main faults inclined boreholes were drilled in order to perform dilatometer and permeability in situ test. With all these data it was decided in advance if the double-shield was going to work in a single or double mode. A type of expert system have being used to interpret the data coming from TBM after crossing the expected faults, so allowing a feedback to the entire process.

1 INTRODUCTION

The Tunnels of Guadarrama are new twin tunnels crossing the "Sistema Central" (Central Range) of the Iberian Peninsula, between Madrid and Segovia, for the new High Speed Railway Link Madrid-Valladolid, to the NW of Spain.

Figure 1 shows the location of these tunnels.

The length of each tunnel is 28,3 km with a maximum overburden of 900 m.

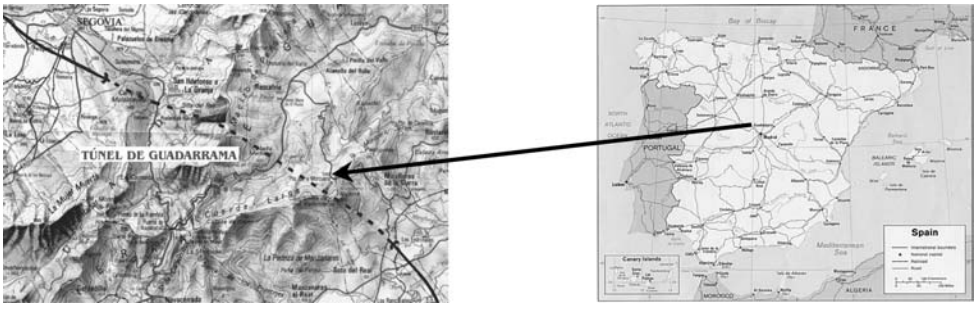

Figure 1. Location of Guadarrama's tunnels.

The tunnels have been excavated using four double-shield TBMs; all of them with an excavation diameter of 9,5 m.

2 MAIN GEOLOGICAL FEATURES

The geological conditions consist of crystalline rocks, gneiss and granites crossed by several types of dykes. A main graben in the Lozoya valley where poor quality sedimentary rocks from the Cretaceous, including loose sands under water table, were crossed is the most problematic section of both tunnels. Nevertheless several faults and dykes have also been detected in the site characterization jobs, inside the crystalline bodies with different mylonites and water conditions.

In the Figure 2 a longitudinal geological section of the tunnel is shown. It can be appreciated, the two main faults encountered that have been intensively investigated in advance using geophysical methods.

There two faults corresponds to Valparaiso and to La Umbría fault areas.

3 METHODOLOGY USED FOR THE PREDITION OF GROUND CONDITIONS AHEAD THE TBM FACE

Since the beginning of the excavation, the major importance of having a prediction of the ground conditions ahead the TBM face has been demonstrated, in order to take the decision to advance in a single or in a double-shield way or if it is necessary to make a ground improvement ahead the face of the tunnel.

For this purspuse a review of the main geological features has been done.

This review has consisted of a detailed (1:1000 scaled) geological mapping with a precise photogeological study.

Following this geological mapping an intensive geophysical survey of both tunnels was done. This survey has consists in the following works:

- Geophysical methods applied from surface.
- Geophysical methods applied between boreholes or between borehole and surface.

In Figure 3 it is shown a block-diagram showing the relationships between the different technologies used (Capote, 2005).

As a prediction tool a systematic Electrical Resistivity Tomography (ERT) profiling along the axis of both tunnels has been carried out.

In the main faults and accidents further inclined boreholes were drilled in order to perform dilatometer and permeability in situ tests, as well as to make some geophysical logging.

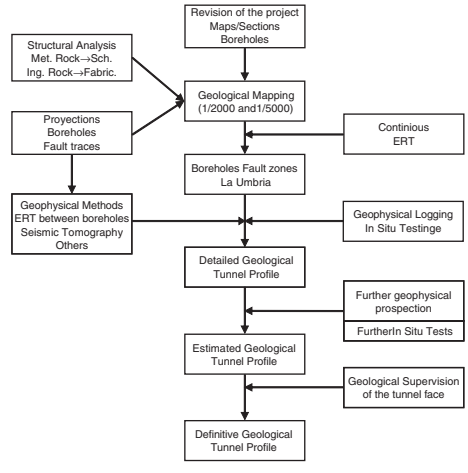

Figure 3. Methodology used for the prediction of the ground conditions ahead the TBM face (modified from Capote, 2005).

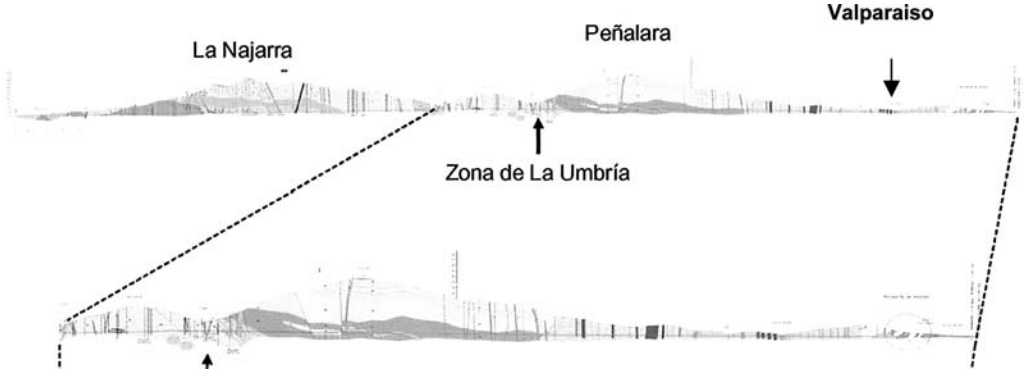

Figure 2. Geological profile of the tunnels of Guadarrama.

This methodology has proven to be effective and very precise down to an overburden around 150 m.

A special remark was done in relation with La Umbría Fault were several geophysical methods have been applied.

In this area most of the geophysical and in situ tests methodologies were used, to precise the structural position of the creataceous loose sands, as well as the position of the main gouge faults zones. It was encountered that the tectonized zones were located in the northern part of the valley.

3.1 *Electrical resistivity tomography (ERT)*

The use of Electrical Resistivity Tomography (ERT) for the detection of faults has already been used since faults usually give low values of resistivity because of the presence of day minerals and high water contents.

The method is based in the measurement of the potential drop between two electrodes (MN), obtaining the resistance of the ground to a current flow (AB).

The multi-electrods mode used has been an axial dipole-dipole, as this is the best mode for the detection of vertical resistivity anomalies.

After several trials a unit electrode spacing of 10,0 m has been used for low overburden, obtaining a constant depth of investigation of about 60 m.

Two parallel profiles along both axis of the tunnels have been done. With this geometry, a good correlation is assured in the strike and dip of the resistivity anomalies.

For the definition of the characteristic of the faults, a very detailed interpretation process has been used.

It has the following steps:

- The apparent resistivity pseudosection is measured.
- Secondly the resistivity is calculated from the resistance value.
- Thirdly, an iterative inversion process is done, minimizing the error between the measurement and the calculated values of resistivity. This accordance is given by the value of RMS error expressed as a percentage.

Finally, as is shown in the Figure 4, the model is corrected to allow for the real topography.

For the final interpretation it is very significative to analyze the chargeability section. This analysis has provided data for the prediction of water inflow into the tunnel.

Since the beginning of the excavation from the North Portal of the tunnels, more than 1.1980 ml of ERT profiles have been done, while the excavated length is 13.500 m for each tunnel (Tunnels 3 and 4).

The prediction system has proven to give satisfactory results. Figure 5 shows the correlation between the geological and the resistivity sections in one of the main faults encountered.

3.2 *3D interpretation of ERT*

In La Umbría fault 4.600 m of ERT profiles from surfaces were done, as well as 5 electrical tomography

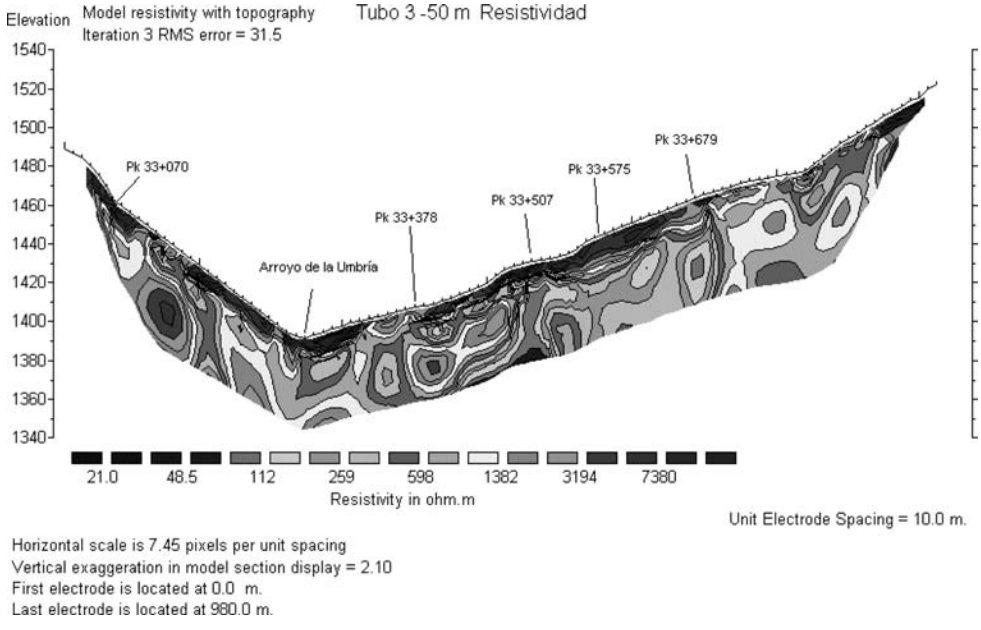

Figure 4. Final section with real topography.

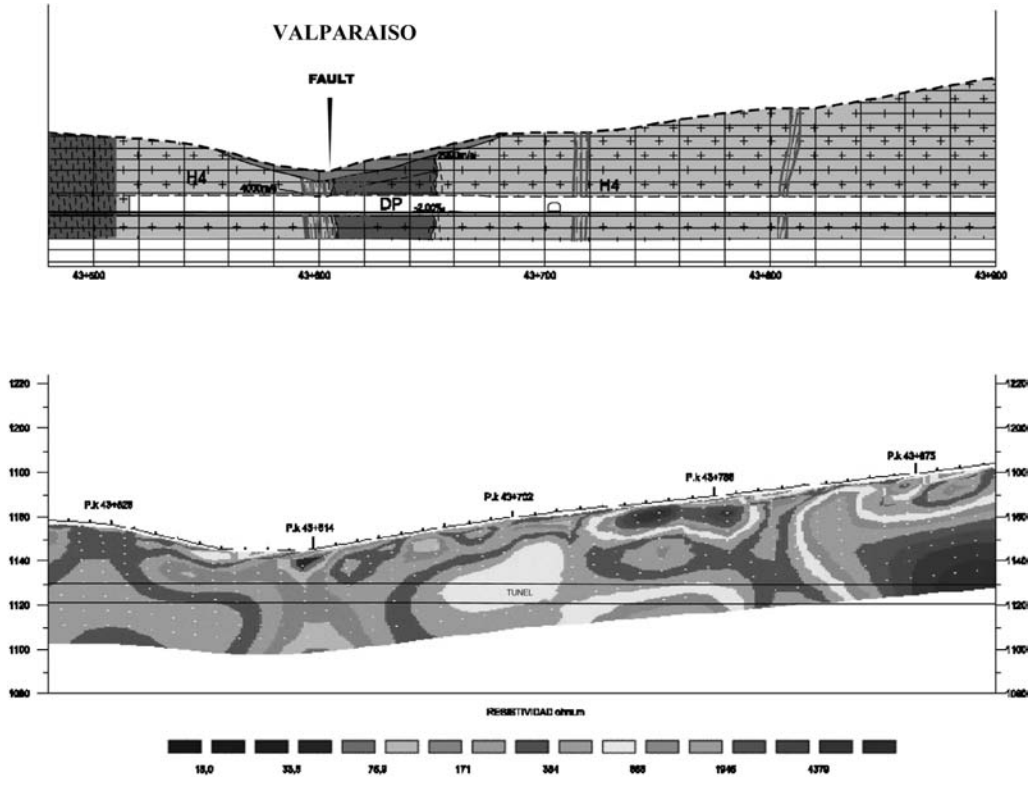

Figure 5. Example of the correlation between the resistivity and the geological profiles. (Valparaiso Fault).

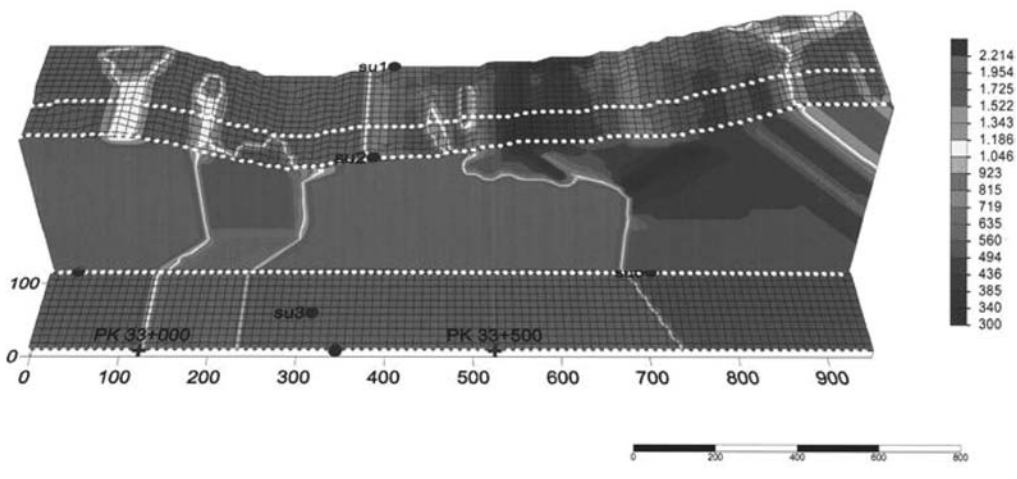

Figure 6. Resistivity 3D model of La Umbria Fault zone. (In the horizontal plane, both tunnel axis have been marked).

borehole-borehole and 6 ERT borehole-surface. This has allow to make a complicate 3D interpretation of the fault.

Figure 6 shows a tridimensional section of Tunnel 3, in which the two low resistivity main faults can be appreciated.

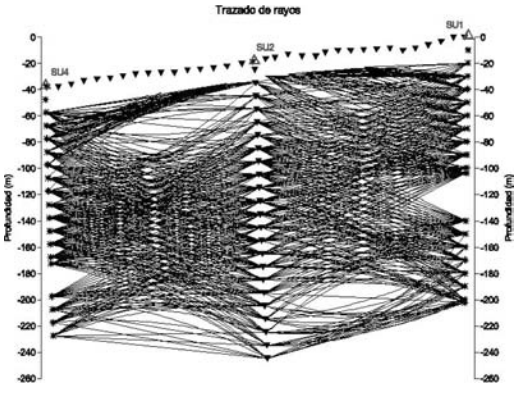

Figure 7. The raypaths of one of the sections measured with seismic tomography in La Umbria Fault zone.

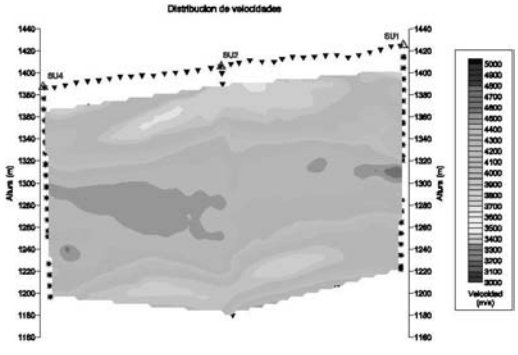

Figure 8. Results of the interpretation, of seismic tomography in La Umbria Fault zone.

As it has been said, these two zones are located in the northern part of the valley.

3.3 Seismic crosshole tomography

The seismic tomography is based on the elastic waves propagation to obtain a spacial distribution of the velocities inside a volume of rock mass.

Once the data acquisition is done, it is calculated the velocities between all the nots of the mesh.

In La Umbria Fault it was done a seismic survey between boreholes.

Considering:

- The distance between boreholes: As bigger this distance is lesser is the accuracy.
- The distance between geophones an shot points.
- The accuracy in the knowledge of the position of emissor and receptors.

Figure 7 shows the raypath, of one of the sections measured. While Figure 8 show the results of the interpretation carried out.

MOUNT SOPRIS	Caliper Acoustic Televiewer Full wave sonic Temperature Gamma Ray Conductivity Resistivity SP

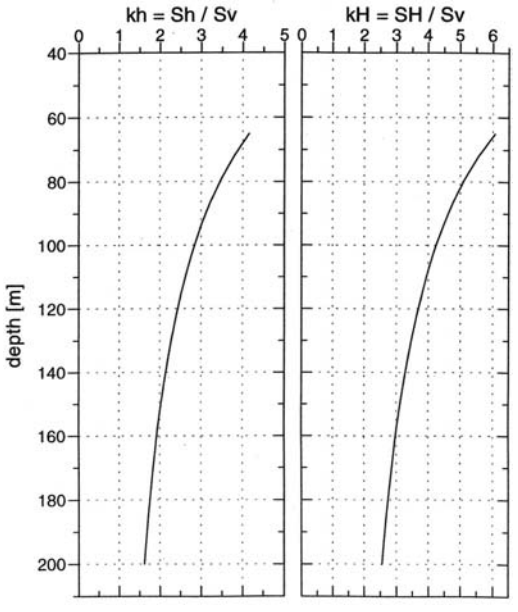

Figure 9. Result of the Hidrofract tests carried out in one borehole, showing high horizontal stresses.

3.4 *In situ testing*

The following techniques have been used:

- Geophysical logging (see Table 1).
- Hidrofract tests (see Figure 9).
- Dilatometer Tests.

These tests have been very useful for geotechnical site characterisation of La Umbria fault, as well as for other tectonical features.

The geophysical logging and in situ test carried out inside the drilled boreholes, have provided a very valuable information concerning:

- structural data.
- natural stress field (with a high ratio k_0, between horizontal and vertical stresses).
- rock mass deformability, specially in the sedimentary rocks of the Cretaceous, including loose sands.

4 DISCUSSION AND CONCLUSIONS

The geophysical surveys and in situ tests carried out, have contribute to define the geological and geomechanical profile of Guadarrama tunnels.

This methodology has allow to predict in advance, the constructive difficulties of the rock mass to be excavated by the 4 TBMs.

The figures of these measurements are the following:

- 3.501 ml seismic profiles.
- 24.870 ml surface ERT.
- 3.860 ml of VLF.
- 11.019 ml of geophysical logging.
- 5 ut. ERT borehole-borehole.
- 6 ut. ERT borehole surface.
- 18 ut. Seismic Tomography borehole-borehole.
- 25 ut. Dilatometric tests.

The ERT has proven to be an efficient system for the prediction of faults and dykes ahead the TBM face in the gneiss and granites of Guadarrama Tunnels.

The use of the chargeability profiles is very interesting for the prediction of water inflow conditions.

The interpretation is very difficult when the strike of the resistivity anomaly is parallel to the axis of the tunnel.

Using the resistivity profile it has been decided in advance, if the TBM has to work in a single or in a double shield way.

For an overburden higher than 250 m, Najarra and Peñalara massifs, no geophysical survey has been used, as all the tests done didn't give enough reliability and accuracy in the interpretation.

For the Umbria Fault, the electrical and seismic tomographies, have contribute to define the position of cretaceous loose sands.

The in situ tests have contributed, in conjuction with the geotechnical logging of the drilled boreholes and the last test to the mechanical characterization of the rock mass.

Risk analysis of soil transition in tunnel works

Q.F. Hu
Shanghai Institute of Disaster Prevention and Relief, Tongji University, Shanghai, China

H.W. Huang
Department of Geotechnical Engineering, Tongji University, Shanghai, China

ABSTRACT: Recent years the demands for systematic risk analysis of soil transition for tunnel works are more and more increasing to minimize the construction accidents. The probabilistic geologic prediction model based on Markov process is being established to characterize the probabilistic form of ground uncertainty. This paper studied how to modify 1D (one dimension) Markov process, and then improved to establish a new method of the conditional Markov Process, which can uses all available ground class information. For analyzing the spatial soil transition, the 2D (two dimension) conditional Markov process is also proposed and discussed. The modified 2D conditional Markov process can predict the soil transition and get the probabilistic risk index by Monte Carlo simulation. Finally a case study of Shanghai Yangtze River Tunnel, the biggest diameter and longer shield tunnel now in the world, showed that the predicted data using the proposed method has very good agreements with the real borehole data.

1 INTRODUCTION

Before the construction of tunnels and underground works is started, engineers should make the site investigation based on the character of the soil, and analyze the random distribution of soil combined with geological borehole samples to create the geological soil transition along the tunnel profile. Due to the information of limited number of boreholes are not enough, which are just discrete point information of the deterministic area around the borehole locations, the soil transition process between the boreholes is a big random uncertainty. The conventional methods of boreholes driven for a tunnel construction are linear interpolation and engineering experience, which can not reflect the soil random distribution. Therefore it has become a critical problem and a challenging task for the tunnel and underground working engineers that how to reduce the random uncertainty between boreholes, and to establish a precise soil transition along the tunnel profile.

At present, the internationally geological researchers (Einstein H.H. 1984; Whitman, R.V. 1984, Isaaks, E.H. 1989) are using the random field theory to study the soil random transition, and therefore analyze the characters of soil random distribution in tunnel and underground works. They use stochastic technology to establish some models to obtain the tunnel profile, which are quantitative, dimension-extendable and faithful to the known borehole information, and establish spatial distribution of soil random field for forecasting the soil character in the tunnel site. Based on Markov Random Field Model (MRFM), and combined with the engineering geological borehole data, the paper studied how to modify the 1D Markov process, and to establish a new method of the conditional Markov Process. This method can use all available ground class information. Then the 2D conditional Markov process is also purposed and discussed for analyzing the spatial soil transition. The modified 2D conditional Markov process can predict the soil transition and get the probabilistic risk index by Monte Carlo simulation. And finally a case stubby about the Yangtze River Tunnel is shown in the end.

2 RISK ANALYSIS OF SOIL TRANSITION BASED ON MARKOV MODEL

In tunnel works, the vertical boreholes only show the soil types that are available in the borehole location. The soil profiles between different boreholes are uncertain. It could be analyzed and defined as an obscure Markov Chain by adopting the model of Markov Process. Currently, many scholars (Likhitruangsilp, 2003; Ioannou, 2003) make use of the method of the Markov chain to study the soil transition and establish the soil profile at engineering site. But they only focused on studying the soil order of the

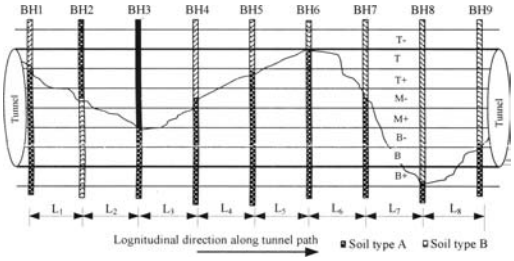

Figure 1. The longitudinal soil profile and transition along tunnel.

perpendicular direction. So their methods could not be used for analyzing the soil transition at two deferment direction like horizontal and vertical direction, and their result was physically poor for reflect the obscure soil random fields. In order to improve the current methods, a 2D modified conditional Markov Process was established to predict the soil transition between the boreholes along the tunnel alignment base on the geological statistics methods (Hou jinyu, 1998; Liu Zhenfeng, 2004).

2.1 *Model hypothesis*

One-demission Markov Model could be mainly used to study the geologic strata deposition and obtain the soil type form at vertical direction. The character of soil deposition sequence is actually hidden in the ground (see Figure 1). And great deals of site investigation data were proved the soil sequence distribution (Ruwanpura A., 2004) and the soil statistic relation in a historical way (Schwarzacher, 1984). So the character and condition of soil transition could be described by the model of Markov Process on the supposition that:

(1) Each soil layer types appear randomly inside the construction site. And all different soil types are district and random distribution, their spread distance is also discrete;
(2) The different boreholes are absolute, and each borehole can only provide the local soil random information around borehole location of construction site;
(3) The condition of soil transition is a homogeneous and smooth Markov Process

Based on the above model hypothesis, Markov Random Field Model (MRFM) was established to study the soil transition and to quantify the risk of soil uncertainty.

It is well known, the key parameters of MRFM are soil tally matrix or soil probability matrix which reflects the soil transition condition (see Figure 2). It is established through dividing the soil sequence

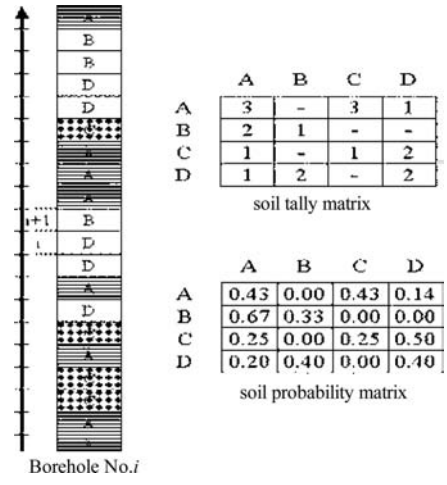

Figure 2. Soil tally matrix or soil probability matrix of borehole data.

of borehole into different soil interval length. Then the soil tally matrix is easily obtained from the borehole data. Generally, the soil interval length is difficult to determine than the soil type through borehole data, so the probability of soil transition is also difficult to calculate. There are two kinds of methods which can establish the soil tally matrix as follows.

(1) Divide the borehole length by the fixed distance. That is the same distance which is equal to the minimal thickness of soil in borehole.
(2) Divide the borehole length by different soil types. That is the same soil type whose thickness is equal to the soil distance.

Different dividing methods have different advantage. The second method is suitable for studying the soil type of borehole, and is non-useful for predict the soil transition condition. Comparatively, the first method is suitable for studying the soil distribution and get soil thickness. In order to get the soil transition for predicting soil profile along tunnel alignment, the first method is used here and the probability of soil transition is calculated by the fixed distance along the borehole.

2.2 *The model of 2D Markov process*

2D Markov model could be established on 1D Markov model. If the method of fixed distance in borehole is used, the probability of soil transition condition of two different directions can be calculated (see Figure 3). It is assumed that the soil transition of up-side and left-side are known, the space of soil transition condition is $S\{s_k \in S, k = 1, 2, \cdots, n\}$, and the probability $P^{(h)}, P^{(v)}$

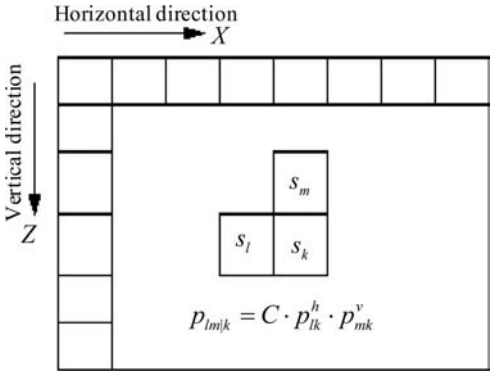

Figure 3. 2D model of Markov Process.

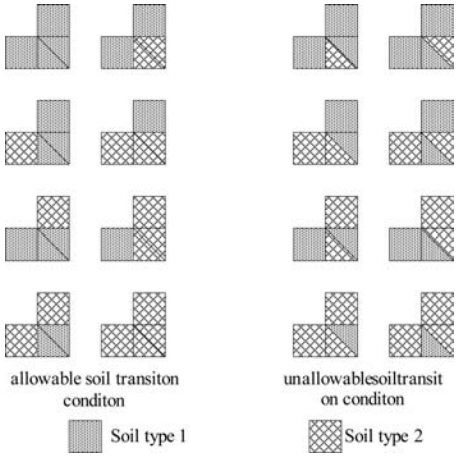

Figure 4. Soil transition condition of two different soil types.

of horizontal and vertical direction, then the probability of certain location, which is soil type k in the space, is defined as:

$$\begin{aligned} p_{lm|k} &= P_r\{X_{i+1} = s_k, Z_{j+1} = s_k \mid X_i = s_l, Z_j = s_m\} \\ &= C \cdot P_r\{X_{i+1} = s_k \mid X_i = s_l\} \cdot P_r\{Z_{j+1} = s_k \mid Z_j = s_m\} \\ &= C \cdot p^h_{lk} \cdot p^v_{mk} \end{aligned} \quad (1)$$

$$C = (\sum_f p^x_{lf} \cdot p^z_{mf})^{-1}, f = 1, 2, \cdots, n \quad (2)$$

Where, C is a unitary parameter, which is defined as Figure 4.

Based on the theory of 2D Markov Process, the soil condition which is two type of soil in the same location by the method of fixed distance does not exist there (see Figure 4). Therefore, the unitary parameter of C is defined as formula (2).

Figure 5. Conditional 1D Markov Process.

Similarly, considering the 3D of soil transition in tunnel construction site, the space of soil transition condition is $S\{s_k \in S, k = 1, 2, \cdots, n\}$, the probability of certain location with soil type k in the space is defined based on the 3D model of Markov Process:

$$\begin{aligned} p_{lmq|k} &= P_r\{X_{i+1} = s_k, Y_{j+1} = s_k, Z_{r+1} \\ &= s_k \mid X_i = s_l, Y_j = s_m, Z_r = s_q\} \\ &= C \cdot P_r\{X_{i+1} = s_k \mid X_i = s_l\} \cdot P_r\{Y_{j+1} \\ &= s_k \mid Y_j = s_m\} \cdot P_r\{Z_{r+1} = s_k \mid Z_r = s_q\} \\ &= C \cdot p^x_{lk} \cdot p^y_{mk} \cdot p^z_{qk} \end{aligned} \quad (3)$$

$$C = (\sum_f p^x_{lf} \cdot p^y_{mf} \cdot p^y_{qf})^{-1}, f = 1, 2, \cdots, n \quad (4)$$

Therefore, if the soil boundary and borehole data are available by site investigation, the soil transition condition can be calculated by modified the 1D Markov Process into Multi-dimension Markov Process, and the uncertainty between different borehole is reduced to build the soil profile along tunnel alignment.

2.3 *The model of 1D conditional Markov Process*

It is known that the soil boreholes only provide the soil transition condition in vertical direction. It is difficult to get the information of soil transition in horizontal direction between two neighborhood boreholes. In order to solve the problem and improve the prediction veracity of soil transition, the 1D model of Markov Process is modified into conditional Markov Process.

Assuming the modified 1D model of Markov Model like Figure 5, the space of soil transition is $S_k, k = 1, 2, 3, \cdots N$, the white fields of soil transition means that the soil type in the certain location is clear, and grey fields are unknown to be determinated by the Markov Model. Therefore, the probability in grey location of soil type S_i is calculated as follows:

$$P_r(X_i = S_i \mid X_{i-1} = S_{i-1}, X_N = S_N) \quad (5)$$

$$\begin{aligned} &P_r(X_i = S_i \mid X_{i-1} = S_{i-1}, X_N = S_N) \\ &= \frac{P_r(X_{i-1} = S_{i-1}, X_i = S_i, X_N = S_N)}{P_r(X_{i-1} = S_{i-1}, X_N = S_N)} \end{aligned} \quad (6)$$

The formula (6) can be changed as through the theory of C-K equation in Markov Process.

$$\begin{aligned} &P_r(X_i = S_i \mid X_{i-1} = S_{i-1}, X_N = S_N) \\ &= \frac{P_r(X_N = S_N \mid X_i = S_i, X_{i-1} = S_{i-1}) \cdot P_r(X_{i-1} = S_{i-1}, X_i = S}{P_r(X_{i-1} = S_{i-1}, X_N = S_N)} \end{aligned} \quad (7)$$

Because the Markov Process is without aftereffect, then the formula (7) was changed to:

$$P_r(X_i = S_i \mid X_{i-1} = S_{i-1}, X_N = S_N) = \frac{P_r(X_N = S_N \mid X_i = S_i) \cdot P_r(X_{i-1} = S_{i-1}, X_i = S_i)}{P_r(X_{i-1} = S_{i-1}, X_N = S_N)} \quad (8)$$

Similarly, based on the theory of C-K equation and the character without aftereffect, the formula (8) can be simplified as:

$$P_r(X_i = S_i \mid X_{i-1} = S_{i-1}, X_N = S_N) = \frac{P_r(X_N = S_N \mid X_i = S_i) \cdot P_r(X_i = S_i \mid X_{i-1} = S_{i-1}) \cdot P_r(X_{i-1} = S_{i-1})}{P_r(X_N = S_N \mid X_{i-1} = S_{i-1}) \cdot P_r(X_{i-1} = S_{i-1})} \quad (9)$$

By the same way, the end calculation formula is got:

$$P_r(X_i = S_i \mid X_{i-1} = S_{i-1}, X_N = S_N) = \frac{p_{i,N}^{(N-i)} \cdot p_{(i-1),i}}{p_{(i-1),N}^{(N-i+1)}} \quad (10)$$

In the end, the probability of soil transition condition is calculated as:

$$p_{i-1,i|N} = \frac{p_{i,N}^{(N-i)} \cdot p_{(i-1),i}}{p_{(i-1),N}^{(N-i+1)}} \quad (11)$$

2.4 *The model of 2D conditional Markov model*

The vertical information of soil transition was explored by many borehole data of site investigation. The soil type of ground surface is also known through some geological survey. Therefore, the soil boundary condition in local field of construction site is clear. A new modeling algorithm to predict the soil transition between the boreholes along tunnel alignment can be established based on the above 2D model and 1D conditional model of Markov Process.

Assuming that the soil transition condition is 2D Markov Process, and the left-side, right-side and surface-side soil information is known after site investigation (see Figure 6), the space of soil transition is $S, \{s_k \in S, k = 1, 2, \cdots, n\}$, then the probability of soil type s_k in a certain location (i, j) between the boreholes can be calculated as follows:

$$\begin{aligned} p_{l,m\to k|q} &= P_r\{Z_{i,j} = s_k \mid Z_{i-1,j} = s_l, Z_{i,j-1} \\ &= s_m, Z_{N_x,j} = s_q\} = C' \cdot P_r\{Z_{i,j} = s_k \mid Z_{i-1,j} = s_l, Z_{N_x,j} = s_q\} \cdot \\ P_r\{Z_{i,j} &= s_k \mid Z_{i,j-1} = s_m\} = C' \cdot p_{lk|q}^x \cdot p_{mk}^z \end{aligned} \quad (12)$$

Where, C' is a unitary parameter, which is defined as:

$$C' = [\sum_f (p_{lf|q}^x \cdot p_{mf}^z)]^{-1}, f = 1, 2, \cdots, n \quad (13)$$

By using of the model of 1D conditional Markov process Model, the formula (14) can be established after the formula (10) is inputted in the formula (12).

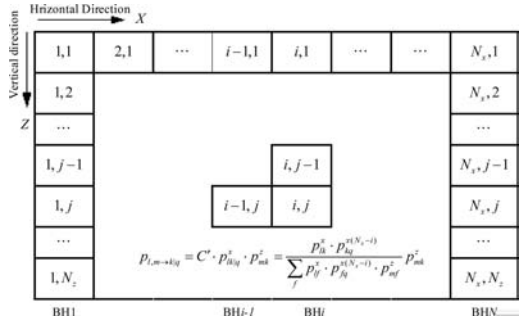

Figure 6. 2D conditional model of Markov Process.

$$p_{lk|q}^x = p_{i-1,i|N_x}^x = \frac{p_{kq}^{x(N_x-i)} \cdot p_{lk}^x}{p_{lq}^{x(N_x-i+1)}} \quad (14)$$

Therefore, the formula (15) is obtained based on the formula (13) and (14).

$$p_{l,m\to k|q} = C' \cdot p_{lk|q}^x \cdot p_{mk}^z = \frac{p_{lk}^x \cdot p_{kq}^{x(N_x-i)}}{\sum_f p_{lf}^x \cdot p_{fq}^{x(N_x-i)} \cdot p_{mf}^z} p_{mk}^z \quad (15)$$

$f = 1, 2, \cdots, n; k = 1, 2, \cdots, n$

In the end 2D conditional model of Markov Process is established to predict soil transition. It shows that the proposed new model can make use of all available borehole data and improve the precise of soil distribution prediction by adding more borehole data.

Three key probability matrixes, vertical soil transition matrix, horizontal soil transition matrix and surface soil transition matrix, are supported in the prediction of soil transition condition by using 2D conditional model of Markov Process. These three soil matrixes could be established by borehole data from site investigation (Qunfang Hu, 2006).

2.5 *The prediction and risk analysis of soil transition*

The 2D conditional model of Markov Process for predicting the soil type in tunneling is carried out by computer. The modeling algorithms were based on the method of Monte-Carlo (Huang Kezhong, Mao Shanpei, 1987).

Assuming that there were three different soil types in the site field, like soil type 1, soil type 2 and soil type 3. Firstly the key three soil transition matrixes is calculated, and the probabilities p_1, p_2, p_3 of those three different soil types in a certain location could

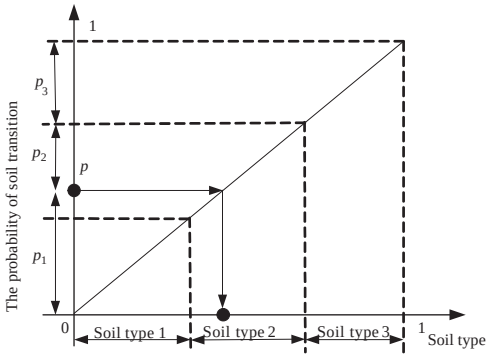

Figure 7. The simulation method based on the method of Monte-Carlo.

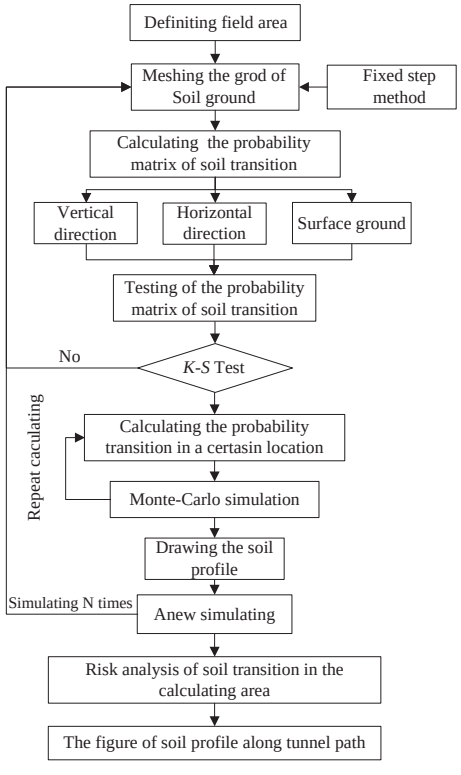

Figure 8. The simulation flow and calculation method for predicting soil transition condition.

be obtained by the 2D conditional model of Markov Process. Then three uniform numbers are produced by the method of Monte-Carlo. It can be seen that those different uniform numbers are represented by different soil type. Therefore the soil type in the certain location is decided (see Figure 7).

Up to now, the simulation method and calculation flow can be given as follows based on the 2D conditional model of Markov Process and the method of Monte-Carlo (see Figure 8).

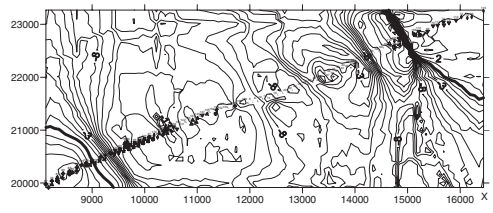

Figure 9. Borehole feature of Shanghai Yangtze River tunnel.

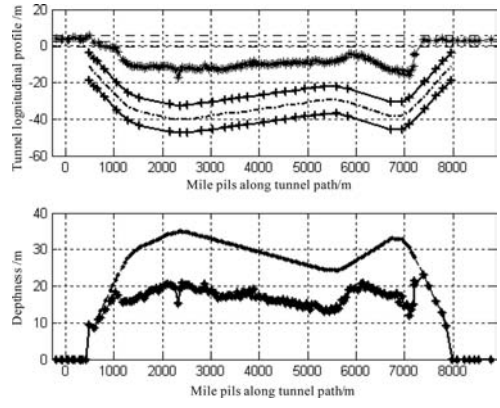

Figure 10. The depth and overburden thickness of Shanghai Yangtze River tunnel.

The simulation method was programmed by the software Matlab2006a (Yin Zheming, 2002). By using the 2D conditional model of Markov Process, the soil transition condition could be clear for drawing the soil profile along the tunnel alignment. The uncertainty between different boreholes is reduced for tunneling. Furthermore, if there are more new borehole data, the prediction precision can be easily increased by adding the new borehole information. So the new prediction model of soil transition is a good way for risk analysis the soil transition.

3 CASE STUDY

Yangtze River tunnel is the south crossing way from Pudong to Changxing island in Shanghai. This tunnel has a 7.5 km in length and 15 m in outside diameter. At present there are 164 geological drilling holes. The specific information of each hole along the axis is shown in Figure 9.

Based on the geological investigation information of Yangtze River tunnel and its longitudinal axis design, the vertical layout of the entire tunnel is shown in Figure 10. The up figure is the depth layout

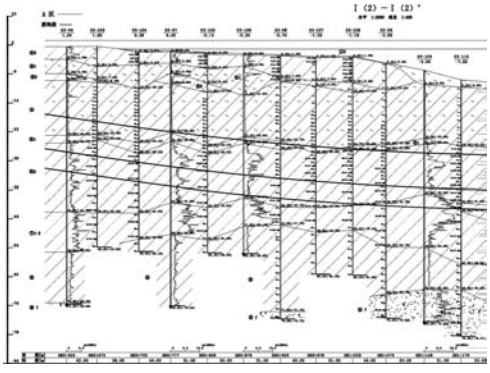

Figure 11. XK0 + 633∼XK1+179 soil layers probabilistic distribution by the method of linear interpolation and experience.

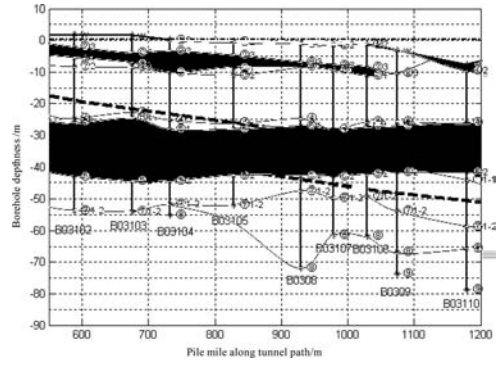

Figure 12. XK0+585∼XK1+180 soil layers probabilistic distribution by the 2D conditional Markov Model.

and the below one is the overburden thickness of tunnel.

Because the Yangtze River tunnel is very long, it is hard to have a one-time simulation. Here, we focus on the critical area using the conclusion of regional soil transition process analysis.

According to geological survey data, the authors draw the stratigraphic profile using linear interpolation in Figure 11. From this figure, we know the shield tunnel transverse ④, ⑤$_1$ and ⑤$_2$ layers in the local area and the soil types are complex comparatively. Especially in the XK0 + 800∼XK1+180 segments, the shield construction will transverse some composite soil layers. The ⑤$_1$ layer is grey clay with thin powder and a little shell chipping and has high compressibility, so the shield construction gesture control is difficult. As the shield launching, the cover soil layer is very thin and the least thickness is only about 8.69 m. Therefore, the construction risk is severely.

After adopting the 2D conditional Markov chain model process, the soil layers distribution from the numerical modeling is shown in Figure 12. Comparing Figure 11 with Figure 12, the soil layers distribution using model predicting is the same with that from the linear interpolation basically except the interlayer ⑤$_1$. However, the soil layer probabilistic distribution token by the stratigraphic profile is more in series and reliable than the general method.

4 CONCLUSIONS

Tunneling works are characterized by high degree of uncertainty. The geologic uncertain factor, here means soil transition condition, may have greater impaction on tunneling. Furthermore, because the boreholes driven for a tunnel construction project only can provide a handful of deterministic information at discrete locations either in the tunnel alignment itself or adjacent to the tunnel, it is necessary to establish a new method to improve the soil predication for tunnel engineering. Some conclusions were drawn in the paper.

(1) It is very essential to consider the uncertainty of soil transition condition which could lead to risk in tunneling work.
(2) The 2D conditional model of Markov Process is established based on the geostatistic theory and Markov Process, and this model can predict the soil transition.
(3) The case study shows the proposed prediction method of soil transition can reflect the adverse soil conditions for risk analysis.

ACKNOWLEDGEMENTS

This study was funded by the Program for New Century Excellent Talents in University under Education Ministry of China and Shanghai Municipal Science and Technology Commission (No.04dz12021), here great thanks should be given to them.

Feasible Boulder treatment methods for soft ground shielded TBM

Warren Wangryul Jee & Sang-Gui Ha
Daehan Consultant, Co. Ltd., Seoul, South Korea

ABSTRACT: Boulder detection methods, treatments and its compensations are discussed with the geotechnical consideration of the boulder conditions in soft ground tunneling by shielded TBM. The prior objective of this topic is to overcome the existing problems to excavate the boulder rich deposits by the EPB shield, or slurry shield in downtown areas. There are three phases of this research work including the boulder detection technology during the design and construction stages of the tunneling projects, secondly developing the appropriate boulder treatment methods at the tunnel site depending on the geological and hydro geological conditions including with dimension issues, and compensation for boulder obstruction removal or weight is not practical for most tunneling situation, but compensation by crew time, is probably for the optimal design modification of the existing EPB shield, and slurry shield TBM to minimize the boulder cutting problems in soft ground. If boulders are anticipated on tunnel project at the design stage, boulder removal plan must be considered with proper equipment selection to handle it easy way.

1 INTRODUCTION

As the number of urban tunneling projects are increased within a soft ground, more and more of difficulties lies to overcome the boulder treatments during the tunnel excavation. This paper covers the major considerations to detect the boulders and existing treatment methods that influence the design and construction of soft ground tunnels which could be excavated by mechanized tunneling machine like EPB shielded TBM or slurry shielded TBM. The objective of this paper is to establish an knowledge of boulders and study the boulder detection technologies and its optimal treatment methods to suggest the developing requirements of the strong shielded TBM to excavate the tunnels in the complex geological conditions.

There are three phases of this research work including the boulder detection technology during the design and construction stages of the tunneling projects, secondly developing the appropriate boulder treatment methods at the tunnel site depending on the geological and hydro geological conditions including with dimension issues, and compensation for boulder obstruction removal or weight is not practical for most tunneling situation, but compensation by crew time, is probably for the optimal design modification of the existing EPB shield, and slurry shield TBM to minimize the boulder cutting problems in soft ground. If boulders are anticipated on tunnel project at the design stage, boulder removal plan must be considered with proper equipment selection to handle it easy way.

Boulders are justified as big dimensional rocks compared with the cobbles, and the gravels, but its real scales are much smaller than the bed rocks which are developed at the construction sites. Therefore, it is not easy to find them along the given alignment of roadway, and railroads during the design and construction stages through the direct boulder detection. However, if the designers find some information related to the possible existence of boulders in a certain geological layers, then, they could better to perform the geophysical exploration and doing the face mapping focusing on the boulder detection during the tunneling works.

2 BOULDER DETECTION TECHNOLOGY

2.1 *Origins of boulders*

In general, boulders are defined as solid objects larger than 300 mm (one foot), which is defined significantly stronger than the surrounding ground. Boulders are typically a part of rock blocks of various origins and sometimes carried to the site by stream works, or natural falls from the mountain sides, or frequently transported by glaciers, and often they including the man-made solid materials, too.

Boulders are commonly found in river beds, glacial tills, and at the bottom of slopes. Another source of boulders is the bedrock itself as a core stones. For example, Doublin boulder clay is a glacial till which overlies the bedrocks.

Figure 1. Boulders collected during the geotechnical investigations.

Figure 2. Full face shielded TBM.

In practice, the hard boulder would neither break up nor pass through spoil holes on either side of the discs, which forced loose boulders to slip sideways off the edge of the head where they encouraged over-break and made the machine difficult to maneuver. Removing calibration bars from across the spoil holes eased the problem. In addition, plans are being considered to grout from the surface and further bouldered areas along the route to hold the boulders firm so that improved cutters can break them down.

2.2 *Geotechnical investigations of boulder detections*

Normally, the aim of geological and geotechnical investigations is to characterize the natural environment in which an underground structure is intended to be built. The results of such studies form the basis for decisions concerning the general construction method, the specific design of the underground structure as well as for numerical analysis. By means of borehole drilling, the excavation of test pits, geophysical probing and other field methods to geological situation in the project area is classified.

All characteristics which will be encountered during tunnel construction have to be identified, including their spatial relation and the extent of geological boundaries. Furthermore, field or laboratory tests have to be applied to determine the geotechnical properties of the rock or soils. For tunneling projects the following parameters are needed (Table. 1).

Where the soft ground tunnels in urban area will be excavated with a shielded TBM , then, the mineral content and the abrasively of the penetrated soil and rock

Table 1. Required geotechnical parameters for the tunneling project.

Materials	Geotechnical parameters
Rock & Soil	Specific weight Poisson number Permeability Stiffness parameters (Deformation modulus, elasticity) Strength parameters (Friction angle, Cohesion)
Rocks	Mineral content Abrasivity Hardness
Soils	Grain size distribution Water content Plasticity Density
Ground water	Chemistry Flow direction & Velocity

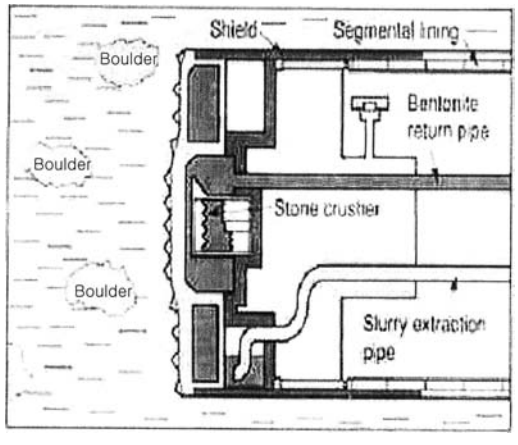

Figure 3. Problems of boulders at the tunnel face.

layers are very important. General site geotechnical investigations are:

– Core drilling (Sampling)
– Geophysics
– General geological pictures
– Geophone (Sonar or seismic systems)

The Geological character of boulder deposits and probability of encountering boulders should be assessed. Hunter and Angulo, 1999 suggested six boulder occurrence characteristics that should be investigated by a subsurface investigation.

– Frequency
– Distribution
– Sizes
– Shapes
– Rock composition
– Matrix soil composition

2.3 *Problems of existing geotechnical investigations*

Due to the small drilling diameter (NX: 76 mm) and the flushing method it is impossible to define the exact composition of boulder, gravel, and cobble layers. The problems are in particular with respect to the choice and operation of the shielded TBM should be considered. Also the other question, whether the jet grouting technique is applicable largely depends on the exact composition of sand / gravel / cobble / boulder layers for the effective pre-reinforcement to increase the face stability. Every soft ground tunnel projects have a crucial question which is whether boulders have to be expected during tunnel excavation or not. When the boulders spread in sedimentary layers, however, are difficult detect by drilling. Due to its implications on shielded TBM design and operation the position is of special interest.

Seismic tomography and seismic sounding from the surface are definitely good method to trace the bedrock boundary, in particular since there seems to be a distinct physical contrast between the sound bedrock and its cover.

2.4 *Boulder detection at the design stages*

For soft ground tunnels, key investigations are focused on the boulder distributions and the groundwater conditions along the designed alignment.

If the boulders are presented in the soft soils, and rocks,

1. Boulders can be the resistive target around the electrically conductive conditions.
2. Elastically, boulders can be the locally high velocity anomaly in the low velocity zones.
3. Response to the radar waves, boulders have a different electromagnetic property like as electric conductivity, magnetic susceptibility, dielectric constant, etc., with the surrounding materials, and boulders have a unique reflection to the radar waves.

Figure 4. Geologger-3 is a multi-purpose field data logger.

It is supposed to be able to use the electrical resistant exploration, the seismic exploration, and the ground penetration radar (GPR) methods to detect the boulders. Some of the possible methods are suggested the electric resistivity tomography (ERT), surface seismic reflection survey, and GPR methods in practice.

But, the depth of exploration target is deeper, the ERT and seismic survey have a difficult by the shortage of analysis limits, and the GPR has a low detect ability by way of reduction of penetration energy.

Therefore, ERT and seismic surveys are available in the target depth range between 20 and 30 m. However, GPR method has accuracy from 5 to 10 m range of the target depth.

Normally, ERT and seismic refraction methods along the alignment are carried out to detect the boulders in the massive hard rocks, after they get the results of analysis to classify the geological layers like soils/ soft rocks, then they can do the more accurate survey at the suspicious area by the 3-D exploration, geotomography, or core drill works. Geotomography can be achieved by the seismic wave, electrical resistance, and Geo-radar.

2.5 *Boulder detection at the construction stages*

2.5.1 *Seismic reflection methods in tunnels*

Seismic reflection method in tunnel TRT method by NSA in Colorado, HSP, and TSP method by Amberg in Switzerland are famous commercial code for this survey ways in underground space during tunneling to take the source by the small blasting or noise generated by rock breaker through the tunnel excavation. Through the source which is generated by the tunnel excavation, and collect the reflect signals from the

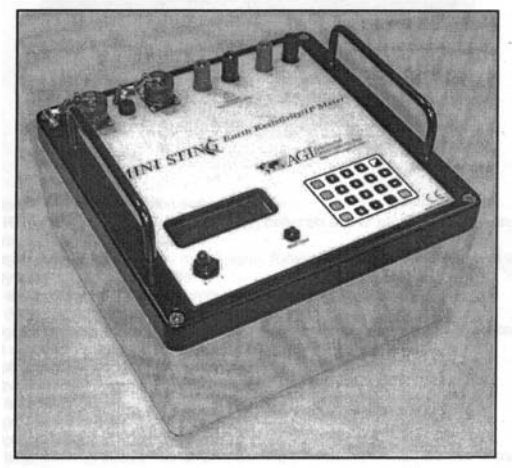

Figure 5. New geophysical electrical resistivity instrument.

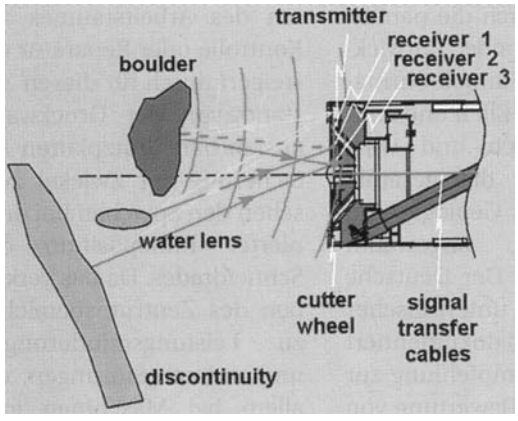

Figure 6. Boulder detection by sonic system.

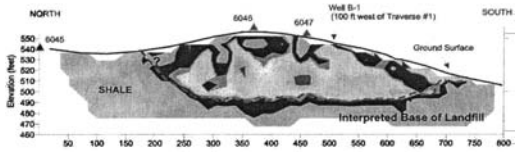

Figure 7. The results of geophysical resistivity and its images.

front face discontinuities like faults, fracture zones, cavity, and boulders, to detect the position of those through the analysis of the reflected data. However, the accuracy of this method is measured very low, because of the data receiving system in the underground conditions, because of the shortage coverage of the cross-hole tomography.

Especially, boulders have a very small scaled anomaly compared with its wave length, which acts the very small reflection signals, therefore, this method only have a possibility to find the boulders in the 5 m distance from the working faces.

2.5.2 *GPR survey*

In general, GPR survey has a limited survey range in soil layers less 5 m distance, but this method is very simple and cheap method, they can use it every tunneling working face to guess the frontal geological conditions at the working face. However, it can not cover the above area of the working face, only possible to discover the just parallel front area from the working site, sometimes, with this survey system mistake to search the boulders above the working faces cause the fatal dangers.

2.5.3 *Pilot core drilling method*

This is the reasonable method to check the existence of boulders by the parallel core drill works in the expected boulder reserved area.

2.5.4 *Special geophysical probe system*

The variation of soil materials will be much easier to predict with a forward looking geophysical technique. A possible method is seismic prospection in soft ground which is currently used in EPB and slurry shield machines. The description of a system, which has been used with success, is presented below:

The sonic soft ground probing system continuously monitors the soil formation ahead of the tunnel face. It is permanently installed in the cutter wheel of the shield machine. This device serves to perform the following.

- To classify soft ground in terms of strength, homogeneity and other physical characteristics.
- To localize and define planar discontinuities ahead of the cutting wheel. Planar discontinuities can be distinct changes between geological formations, for instance from soil to rock, or fault zones.
- To detect and localize irregular bodies and obstacles within a range of about 50 m ahead of the tunnel face.

This sonic system provides the results immediately after the measurement, such that appropriate tunnel construction measures can be adopted before zones of potential problems are excavated.

3 BOULDER TREATMENT METHODS

3.1 *Possible removal methods*

Boulders might be handled during tunneling by one or more of the following methods.

- Removal boulders from the outside of shielded TBM

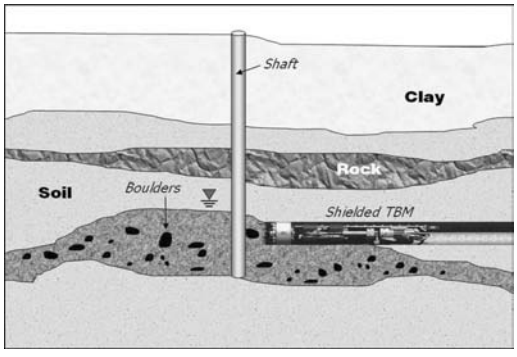

Figure 8. TBM pushing the boulder into a temporary access shaft.

– Piece removal boulders through shielded TBM after fracturing
– Intact removal through shielded TBM
– Pushing aside by shielded TBM

3.2 *Removal boulders from outside shielded TBM*

When a boulder obstruction is encountered with a microtunnelling TBM that is not equipped with rock cutters and boulder is too large for crushers, the obstruction has to be removed from outside of the TBM. The following options might be considered.

– Removal from a temporary access shaft or cross passage tunnel
– Pushing into a drilled hole
– Drilling & Blast

If the boulder is within a granular aquifer, dewatering or grouting will likely be required to maintain stability. After boulder removal, tunneling can resume without trouble.

3.3 *Piece removal boulders through shielded TBM after fracturing*

Boulders can be fractured and ingested by one of three methods.

– Crushing within the plenum
– Cutter fracturing at the heading
– Mechanical splitting through openings

3.4 *Intact removal through shielded TBM*

Boulders can be ingested intact or mostly intact when the openings at the heading are large enough for boulders to pass through. The boulder size that may pass through the heading openings depends on the size and shape of both the boulder and openings. Smooth, spherical boulders will generally pass through cutting wheel openings more readily than oblong and angular boulders. Oblong and angular boulders are more likely to become stuck in an opening or roll around in front of the heading until fractured. Most rotary cutting wheel TBMs are able to ingest boulders with sizes smaller than 15 to 30 percent of the excavated diameter.

3.5 *Pushing aside by shielded TBM*

Boulder might be pushed aside before being fractured or ingested. To be pushed aside, requires mining with a partially closed face TBM through soil that is sufficiently soft or loose to allow boulder penetration into the soil in response to the forces being applied to the heading. Boulders encountered within weak or loose soil that are not pushed aside and are too big to be ingested are likely to roll around in front of the cutters or to become lodged in a cutting wheel door.

4 COMPENSATION METHODS FOR BOULDER OBSTRUCTION

4.1 *Compensation by boulder number encountered*

A simple method of boulder obstruction compensation is payment at a unit rate per obstruction that is bid. This method would provide the same payment for removal of small boulder obstructions that might be split with one blast taking 15 minutes of time as a big boulder obstruction requiring several blasts and over an hour of time. It would also pay the same whether or not the boulder is within a wet sand matrix that must be dewatered or grouted for stability as within a stable cemented granular soil or stiff cohesive soil. Uncertainties such as these will likely lead to contingencies in the bid price.

4.2 *Compensation by boulder size*

Payment based on boulder size may be a more equitable method but requires size measurement. Size measurement is often difficult as previously discussed. The measurement method should be carefully defined to avoid disputes.

One use of payment by size is to avoid payment for boulders anticipated to be small enough to pass through the cutting wheel doors and mucking system. This size might be defined as 20 percent of the excavated tunnel diameter or smaller.

Another option is categorize boulders into two or three size ranges and to pay at bid rates for quantities of each size encountered. This approach may be more equitable and reduce contingencies needed to cover the potential cost of removing very large boulders.

4.3 *Compensation by boulder volume*

The volume method of compensation is not considered viable with most tunneling methods, particularly those where boulders are fractured with cutters or split through cutting wheel doors. It may be a viable method when tunneling with a shield or digger shield where

whole boulders or fragments may be readily removed from the tunnel and sorted for measurement. However, determining boulder volume accurately is not easy. Boulders have irregular shapes that allow only an approximate boulder volume to be calculated based on dimensions. Perhaps the only accurate method of measurement would be to suspend boulders into a tank of water and computed their volume base on increased height of the water.

4.4 *Compensation by boulder weight*

Boulder obstruction removal compensation by weight of boulders removed has been used on some projects and should be easier to measure than volume. The payment item could be limited to boulders greater than a selected weight or size. Bids could also be taken for ranges of weights to allow contractors to bid more for removal of large boulders.

With this method, the contractor must segregate and stockpile boulders and qualifying boulder fragments. However, separating, stockpiling and weighing qualifying boulders is additional work that may not be practical for many projects, particularly where most boulders will be fractured rather than excavated whole or in large pieces.

4.5 *Compensation by crew time to remove boulders*

Payment for boulder obstruction removal by TBM crew hours should be an equitable method of compensation, provided that an obstruction event and qualifying removal work are clearly defined. Mason, Berry & Hatem, 1999 provide a thorough discussion of issues associated with payment for obstruction removal by crew hours. Key aspects of the method include:

- The contract should indicate the various anticipated potential obstructions and anticipated obstruction locations.
- Obstructions to tunneling progress might be defined with a time limit.
- The contractor should be required to provide immediate notification to the resident engineer when an obstruction event has occurred.
- The means and methods of boulder removal not be specified, but left to the contractor.
- Crew hours for obstruction removal should be estimated, baselined and included as a bid item quantity.
- The contract should indicate that crew time unit prices will apply to quantities within a range such as ± 25 percent.
- Mason, Berry & Hatem, 1999 recommend not allowing obstruction removal time to impact the schedule unless the time exceeds 125 percent of the baselined removal time.

5 CONCLUSIONS

1. The GPR method is not possible to be equipped with TBM, and pilot boring system requires to install the special equipment to work on the TBM at the site. Seismic reflection method inside the tunnel will not disturb the TBM operation, but it will take long times to the installation of the measuring system at the site, and also requires to ask the expensive analysis cost with the involvement of specialist.
2. With the present status of arts, there are no confidential survey methods for the boulder detection with reasonable cost, and it is hard to guess that the reasonable boulder detection could not be able to be developed in a near future.
3. The modified pilot boring system like LIM system will be more attractive to develop the boulder detection systems during the tunnel excavation for the tunnel contractor to increase the better operation rate of TBM machines.
4. Compensation for boulder obstruction removal by crew time is probably the most equitable method of those considered.
5. When boulders are spread at the tunnel face, tunnel advance should be halt, and creating very expensive delays, and result in the construction claims. Cutters need to break the boulders too large to fit into the machine mucking system. It is necessary that tunnel engineer try to find the general boulder cutters extremely effective to treat boulder cut.

Reasons of swelling of Miocene clays near Třebovice in Bohemia

F. Kresta
Stavební geologie – Geotechnika a.s., branch Ostrava

ABSTRACT: Track section Třebovice – Rudoltice on the border between Bohemia and Moravia and European watershed is one of the most complicated sections in Czech republic. Main difficulties in that area result from expansive clays with high plasticity. Swelling of these clays caused destruction of the Třebovice tunnel built in 1842–1845. This tunnel was restored after great difficulties in 1932. Reasons of swelling were not completely known just at the beginning of construction works on the re-alignment in 2004. Detailed mineralogical analysis has confirmed a hypothesis that swelling of Miocene is caused mainly by the dispersed coal matter content. Organic matter initialises the swelling.

1 INTRODUCTION

Track section Třebovice – Rudoltice on the border between Bohemia and Moravia and European watershed is one of the most complicated sections in Czech republic. Main difficulties in that area result from expansive clays with high plasticity. Swelling of these clays caused destruction of the Třebovice tunnel built in 1842–1845.

The Třebovice tunnel was built in 1842–1845. Constructors in that time had no experiences with tunnelling in expansive plastic clays. Therefore Negrelli, main designer of railways in Austria, proposed to build open cut instead of a tunnel or to build cut-and-cover tunnel. Austrian railways did not accept these proposals and the first tunnel in Bohemia was built by German coring method. Tunnel was finished in 1845 after great difficulties resulting from expansive clays with high plasticity and water coming from saturated sand lenses inside the clay mass and saturated sand layers above clays. Expected costs (188000 guldens) increased more than six times over 1 mil. guldens. Swelling of these clays caused destruction of the lining and in 1866 tunnel was closed.

In 1866 a new track was built that followed the surface, however, with worse track gradient (9.5‰). That was the reason for reconstruction of the closed tunnel. Tunnel was restored after great difficulties in 1932 (advance in digging per round was only 5–30 mm). New lining from granite blocks was placed to the old one from sandstone. Restored tunnel has been operated since that time till 6.4.2005 when the last train came through it.

Modernisation of railway track in that area was solved by re-alignment of existing tracks. Crossing through the soils with the worst mechanical properties (highly plastic expansive clays) was designed as double-track tunnel built by diaphragm walls with invert. However, contractor in tender proposal suggested to build an open cut and proclaimed significant reduction of costs (approx. 10 MEUR). This solution was accepted and constructed. One-track operation started in 2.8.2005, track No. 2 was opened in 18.10.2005.

2 GEOLOGICAL SITUATION, LITHOLOGY AND LITHOFACIES OF MIOCENE SEDIMENTS

The area is located in the Miocene fill of the Ústí – Česká Třebová trench near the elevation of the Třebovice walls and the Hřebeč edge where it is crosses with the transversal trench Třebovice – Damníkov that communicated with the Lanškroun trench (existing watershed). Miocene sediments in the Ústí – Česká Třebová trench near Třebovice are formed by the Lower Baden clays that are overlapped on the Lower Turonian marls, Ca-spiculites and sandstones. The Upper Cretaceous rocks formed the Třebovice walls and the Hřebeč edge.

Thickness of the Miocene fill reaches up to 170 m. A part of Miocene sediments was eroded (approx. 100+/−30 m). Miocene sediments are formed by marine clays (highly plastic clays stiff to very stiff). In the Eastern part of the area they contain intercalations of sands with terrigenous clasts and re-deposited wooden material. This indicates communication with the Lanškroun trench with fresh and brackish sedimentation with typical coarse-grained sediments. The right stratigraphic position of the Miocene sediments within the Lower Baden complex is not known due to

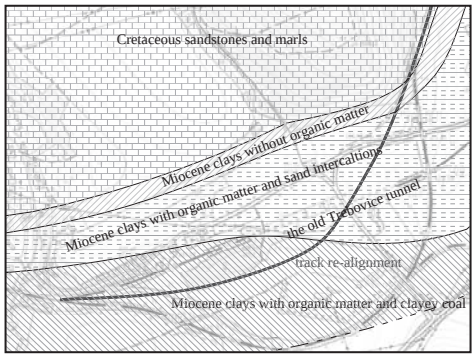

Figure 1. Lithofacies of the Miocene sediments above the level of 420 m above the sea level.

a lack of detailed paleontological data. Lithofacies of the Miocene sediments above the level of 420 m above the sea level are presented in figure 1.

From the geotechnical point of view the most important area contains clays with organic matter. The second factor influencing mechanical properties of clays is the Quaternary weathering crust (a zone of the hypergenous alteration). The depth of the alteration depends on the paleorelief, the erosion history and profile lithology. It however reflects in rock composition (removing off calcite), susceptibility to swelling, etc.

2.1 *Petrography and mineralogy of Miocene clays*

Clays are grey-green, highly plastic, in dry conditions lightly green-grey, very stiff just with conchoidal fracture and contract cracks. They contain variable amount of sand and organic matter. Matrix is clayey (illit-kaolinitic, with variable amount of authigenous montmorillonite). Clasts are formed by sandy grains under 1 mm.

Allochtonous, detritic coal matter represents also a clay component Presence of lens shape clayey sands in clay complex allow us to define this sedimentary milieu as distal proto deltas sediments (in sense Einsele 1992).

2.2 *Clay matter in clays and sands*

Flaky clay particles forming the matrix have not got stable mineralogical composition. A core of primary detritic mica flake is formed by very argillised mica (1.0 nm), continually it is originated a cover from authigenous illite (1 nm), eventually illite-Ca-montmorillonite. Terrigenous clay mineral is represented by kaolinite.

Clay matter in fraction 0.063–0.005 mm as it is presented in grain size tests and in electron microscope snaps (see fig. 2) is formed by agglomerates of particles bounded by cement and authigenous clay

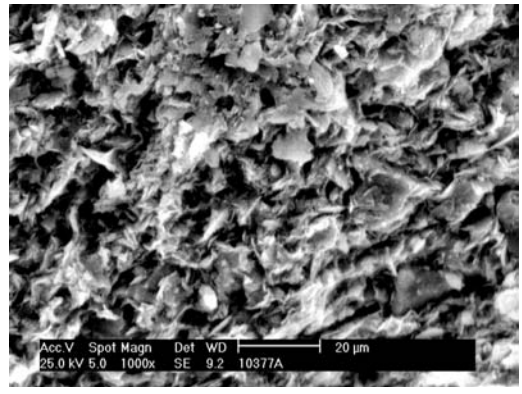

Figure 2. Light grey-greenish clay (illitic type) (borehole VI-1, depth of 11.8–12.0 m). Chaotic flakes of clay matter (illite predominates) and very small angular clasts compose clay matrix. SCAN, metal coated, enlargement on scale (20 µm).

matter and soft clasts. They represent 20–30% of total volume. The rest is formed by clay matter with particles under 0.005 mm.

Dominant mineralogical associations in clays are as follows:

- a clast part is formed by quartz, feldspar and clast muscovite
- cement is formed by authigenous carbonate – calcite. A carbonate content increases with depth under the erosion boundary Quaternary – Miocene
- clay matter is represented by association: (**illite + mica 1.0 nm $\gg$ kaolinite $>$chlorite $\pm$ Ca- smectite (montmorillonite or chlorite 1.38 nm)**, in temperature of 550°C :**(illite + mica) − chlorite − smectite (?).**)

2.3 *Organic matter and humic material in clays*

Coal matter is re-deposited and detritic, washed especially to the foreland of the distal fan of terrigenous floating sediments to the trench formed by clays and sands. Coal matter is formed by unsorted wooden and plant detrite with carbonisation corresponding to lignite. Although coal matter sedimented in marine water milieu it contains high share of extracted humic materials that in interaction and through authigenous clay matter influence local clay properties.

It is not allochtonous sediment (i.e. peat bog), however allochtonous coal matter that was more or less transformed by transport (oxidation, sorption) and more carbonised to the lignite stage in place of sedimentation. Humic materials were not changed. Their partial oxidation is not possible exclude. A transformation of coal matter during the transport was supported either by infrared spectra, either by the presence of oxidized resin of the amber type – valchovite in coal.

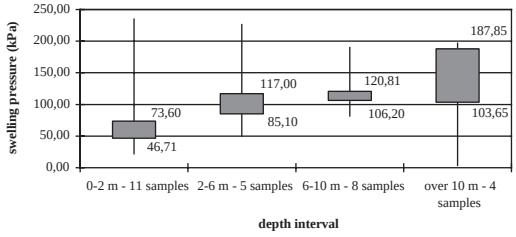

Figure 3. Robust analysis – dependence of swelling pressure on the depth of samples (distance from Quaternary – Miocene boundary).

Ca-humite complexes originated on the contact of the clay and organic matters.

3 GEOTECHNICAL PROPERTIES OF MIOCENE CLAYS

Miocene clays with high plasticity (CV, CE) represent the most important geotechnical hazard. Expansive clays caused great difficulties during construction of existing tunnel in 19th century and they complicated its reconstruction in 20th century too.

Miocene clays were tested by the wide set of laboratory tests (Kresta – Sekyra 2002), Kresta 2003a, Kresta 2003b).

Swelling of Miocene clays was solved individually. Statistical analysis used also results of previous laboratory tests (Pavlík 1998, Tomášek et al. 1998, Dudík 2001).

Detail observation of swelling process showed that start of volume changes begins firstly on the contact of clay matter and cola matter accumulation, i.e. in places with Ca-complexes of humic matter.

Linear swelling of Miocene clays achieve values up to 25% (median from 45 samples was 5%); the maximum value of swelling pressure was 276 kPa (median from 28 samples was 111 kPa.). Robust statistic analysis was used to identify any dependence of linear swelling and swelling pressures on the depth of sampling. The depth was taken as the distance of sample from the boundary between Quaternary and Miocene soils. Results are presented in figure 3 by box-and-whiskers diagrams.

In case of linear swelling no significant dependence of the distance of samples from the Quaternary – Miocene boundary was proven. Values of swelling pressure increase with distance from boundary of Quaternary sediments and Miocene clays. Correlation coefficient of linear regression is 0.57.

Swelling of clays is a long-term process as it is evident from laboratory tests of volume changes in time. Shape of all curves is similar and resembles de-consolidation curve, however stabilisation of deformations is very slow (see fig. 4).

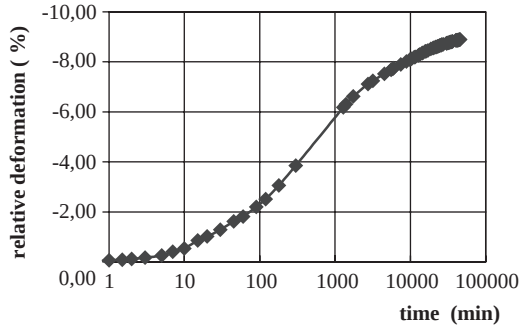

Figure 4. Relative deformations of Miocene clays depending on time (J207, depth 11.7–11.9 m).

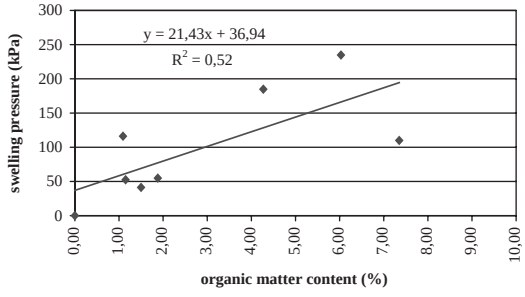

Figure 5. Dependence of values of swelling pressure on the content of organic matter.

It is mainly organic matter dispersed inside the clay matrix that causes swelling of them. The organic matter content is 4–7%, maximally 12%. Values of swelling pressure increase with increasing content of organic matter (see fig. 5) although the correlation coefficient is only 0.52.

4 CONCLUSIONS

The old Třebovice tunnel damaged by swelling of Miocene clays was in 6.4.2005 closed. In the area of its crossing with the track re-alignment it was filled by the fly-ash-cement mixture. The rest of the tunnel will be filled by soils excavated from the construction place. Unique construction documenting the fight between man and nature that was after many problems successful finished its existence.

A track re-alignment leads in deep cuts and short cut-and-cover tunnel. Cut and tunnel walls were protected by diaphragm walls with invert.

During construction of the track re-alignment great size monitoring were carried out. Fortunately, no deformations caused by volume changes of Miocene clays under the bottom of tunnel and in lower parts of cuts were observed (Kresta – Sloboda 2005).

The presence of humic matter bounded as Ca-humic complexes of organic matter is a principal reason of Miocene clays swelling.

Construction of track re-alignment coming through the area with complicated geotechnical conditions was finished in 18.10.2005. I hope that its destiny will not be so dramatic as in case of the old and now liquidated Třebovice tunnel.

Geophysics method used to recognize the boundary between different deposits

R. Kuszyk & M. Superczyńska
Warsaw Uniwersity of Technology, Warsaw, Poland

ABSTRACT: The Warsaw underground line is situated in glacial and pliocen deposits which have quite different geotechnical parameters. Additionally some of those deposits were extrenally distributed during quaternary glaciations. In spite of underground tunnel construction, deep dewatering and possible surface displacements it is very important to clearly specify how proceed the boundary between two different kinds of soil. In some cases the geophysical research is very helpful to recognize this blurred boundary in Warsaw. The authors would like to present one of the example of such research and present also general soil parameters used to design tunnel construction in Warsaw.

1 INTRODUCTION

Geophysics method was used on north part of first Warsaw underground line to localize the boundary between two different kinds of deposits – tertiary clay formation and quaternary sandy river valley. The target was to localize the slope of pliocen clay elevation which strongly subside in the direction of local, deep interglacial period sandy valley full of underground water. It was important because of decision where should finish diaphragm wall tunnel and start shield tunnel. The geophysical research also discovered potencial areas of soil pads in pliocene clay characterize by different geotechnical parameters.

2 GEOLOGY AND GEOTECHNICS

2.1 *Tertiary clay*

In central Poland, in region of Warsaw and its surrounding the Poznań Formation has developed as a clay – soil strongly overconsolidated in a result of complicated geological history. These clay often appears as a soil foundation for high buildings and underground construction. Soil shows the anisotropy features resulting of anisotropy of structure or anisotropy of state tension features. It is the effect of sedimentation as well as geotechnical processes, which soil was subjected in its geological history.

The sedimentation of clay began 13 millions years ago, in central Miocene, and it lasted 9 millions years. The processes of soil erosion connected with forming the river net as well as glacitectonic effects on this region appeared afterwards. It led to coming into existence folding and dislocations in mass of clay. The decompression, erosion and weathering processes followed.

Warsaw area clays lie under Quaternary deposits. The thickness of Pliocen Formation in Warsaw is in range for several metres to 150, however its original thickness is 100–140 m.

Piocen formation include compact clay and sandy clay with fine sand and dusty sand formed lenses inside clay.

In many places in Warsaw the clay formation exists on the surface of the tarraine. This situation take place in the edge of the Vistula valley slope on the left side of the river or under thin cover of quaternary deposit.

There are numerous depressions and elevation on NNW-SSE direction in tertiary clay formation (after glacitectonics and erosion processes). The average thickness of tertiary deposits is 50 meters, and its differences reach 100 m. The biggest and the highest is downtown elevation of altitude about 100–113 m over see level. In elevation the roof of pliocen deposits is secondarly uplifted by glacitectonic process. Original, sedimented surface of the pliocen roof reached the altitude 60–80 m over see level. Present roof surface of the pliocen formation was formed by glacitectonic process during three glaciations and next cut by rivers during three interglacial periods. Major dislocations are connected with Warta glaciation.

Particularly important for clays is the history of loads. The glaciers covered the terrain of Poland three times. The maximum thickness of ice during the earliest glaciation was about 800–1000 meters. Poznań Formation clay is expansive kind of soil, strongly swell. In spite of its geological history there are a lot of

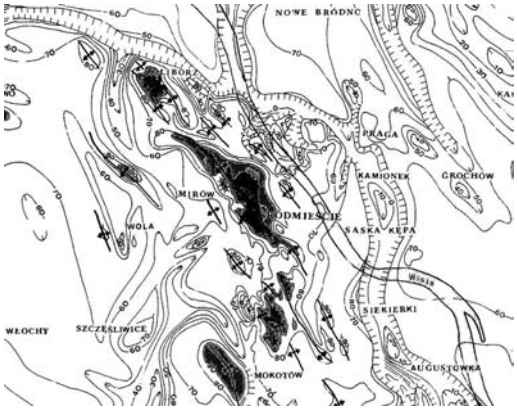

Figure 1. Downtown elevation of tertiary clay and site of geophysical tests.

cracks, dissections, interbeddings and also sand lenses including water under high pressure. Because of it this is important to precisely recognize the roof of those deposits.

Figure 1 presents all the downtown elevations of tertiary clay deposits and their directions and also site of geophysics test. Figure 2 presents those elements in focuse.

2.2 *Geology of the site*

Geology of the investigated site was presented on the cross-section on figure 3. In the base there are the following series of soil:

- Tertiary deposits
  Pliocen Clay – clay and sandy clay, Sandy lenses in Pliocen Clay – medium and thick sand, gravel;
- Quaternary deposits
  Glacial Till – bouldary clay, silty clay, sandy silt, River Sand – interglacial period deposits – medium and thick sand, gravel;
- Contemporary deposits
  Embankment – mixed soil and foundations fragments (mainly war remainders).

2.3 *Geotechnical parameters*

Soil recognition on the site was made by series in situ test verificated by laboratory test.

During in situ test there were done many exploratory drilling, CPT tests made by Borros equipment with Memocone end and Marchetti dilatomiter tests.

On the base of the in situ tests there were determined geotechnical parameters. All the basic parameters are shown in the table 1 and additional parametres in table 2 below.

As it is shown on geological cross-section of this region on figure 3, there are two main formations – clay and sand which have quite different history of sedimentation and geotechnical parameters. In spite of this it is important to have a good knowledge how proceed the border to design economically and safety new construction.

Table 1.

Soil	γ [kN/m^2]	ϕ' [^{0}]	c′ [kPa]	E [MPa]
Embankment	–	–	–	–
River sand	19.0	40.0	0.0	70.0
Glacial till	22.5	23.0	30.0	42.0
Pliocen clay	20.5	15.0	20.0	11.5

Table 2.

Soil	OCR [–]	Ko [–]	I_L [–]	I_D [–]
Embankment	–	–	–	–
River sand	NC	0.40	–	0.80
Glacial till	1.3	0.70	0.10	–
Pliocen clay	2.0	0.80	0.05	–

3 GEOPHYSICAL TESTS

The target of geophysical tests was to define morfology of tertiary deposits roof – pliocen clay in the region of planed underground line. Between Wloscianska street and Armii Krajowej street were designed three section measurement – two along underground line and one perpendicular to it.

The principal difficulty during tests was developed technical infrastructure of terrain. On the ground – marketplaces and subterranean – electro-power industry lines, collectors, canals and deep foundation of bridge pillars.

Geophysical tests were carry throught by ARS-200 equipment – electro-resistance probing method SGE, electro-resistance tomography method in Wenner-Schlumberger configuration. Length of measurement spacing took out 220 m on A-A and B-B profile. Those spacing gave about 30 m of the penetration depth. On the C-C profile length of measurement spacing took out about 130 m what gave less than 25 m of the penetration depth. Spacing between measurement electrodes took out 5 m.

Figure 4 presents one of the geophysical cross-sections in B-B profile.

For the Warsaw soil conditions there are characteristic range of the specific resistance given below:

dry sand – over dozens Ω m,
sand with water – over 20 Ω m,
bouldary clay – over 20 Ω m,
clay – 0–18 Ω m.

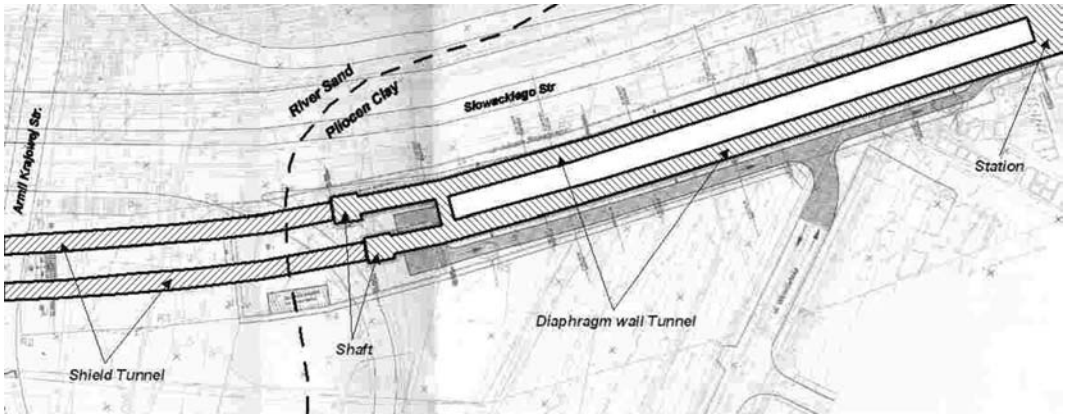

Figure 2. Site of tests.

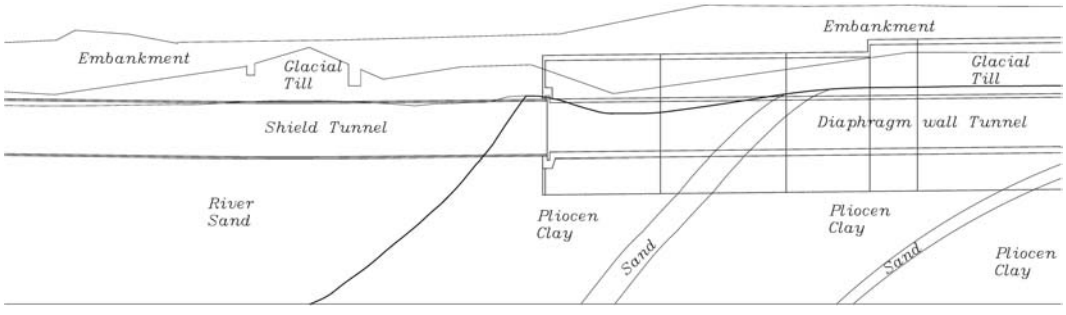

Figure 3. Geological cross-section.

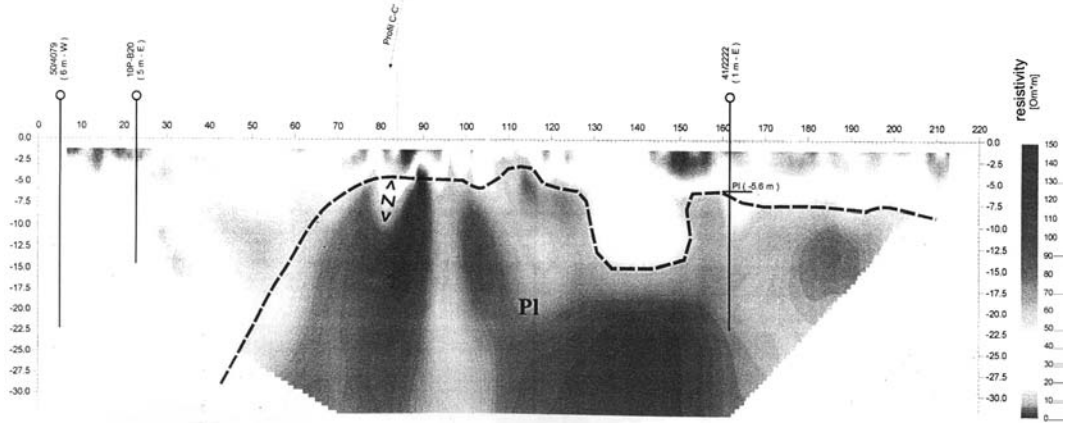

Figure 4. Geophysical cross-section B-B.

On the geophysical cross-sections there is visible high-resistance zone just below surface of the terrain. This zone reach several meters deep and is connected with embankment layer and developed technical infrastructure of subterranean.

Generally low resistance indicates pliocen clay layers but high-resistance zones within the precincts of the clay are connected with sandy dissections in its roof. Generally the roof of pliocen formation sharply subside to the north direction where is the border between river sand and pliocen clay.

4 CONCLUSIONS

In spite of the underground tunnel construction, deep dewatering and possible surface displacements it is very important to clearly specify how proceed the boundary between two different soil formation. In some cases the geophysical research is very helpful to recognize this blurred boundary in Warsaw.

In presented example important element is that pliocen roof fall in very steeply and it is hard to specify its course only by the exploratory drilling. Well known course of the border between this two formation is required because of different designe parameters and especially of pliocen clay expanding property. In spite of this it is important to decide which method of tunnel construction will be apply. Finally the section of the tunnel located in pliocen clay formation was designed as diaphragm wall tunnel and the section located in river sand was designed as shield tunnel.

Geotechnical exploration for the Dobrovského tunnel in Brno

J. Pavlík, D. Rupp & L.Klímek
GEOtest Brno, a.s., The Czech republic

ABSTRACT: Object of the exploration – Tunnel Dobrovského, as part of the constructed Large City Ring Road in Brno, consists of two route tubes which essential length fall on the mined part. Commission for the exploration estimated the excavation of three exploratory galleries with approximately triangular cross section in the area of tunnel tubes at the bases of their vaults, which will be used during the future construction of the tunnel structure. Design of the exploratory works consisted of extensive complex of works, mostly focused on analysis of the behavior of tertiary clays, within which predominant part of the future tunnel tubes will be excavated. Main parts of the exploration are geological observation and documentation during the construction, open-trench works at the surface, laboratory analysis of rock mechanics and chemical tests of waters, geophysical measurement, hydrogeological measurement, field geotechnical tests and measurements in test galleries – loading and shear tests, measurement of massif stress. Article evaluates results of the complex geotechnical exploration works in relation to the future tunnel construction what to be started this year. Exploratory and monitoring activity proved the possibility of realization of the designed tunnel structure and set the conditions for the design intent to be accomplished.

1 INTRODUCTION

Constantly unacceptable high density of traffic in Brno urgently requires relief in terms of large traffic structures. As part of the constructed Large City Ring Road in Brno, the cut-and cover Husovický tunnel and mined Pisárecký tunnel on the highway feeder Prague Radial Road already been constructed. Preparation of the third structure – Dobrovského tunnel has markedly advanced.

Thanks to the support of investment bodies represented by the Brno municipality and the Directorate of roads and motorways in the CR, the process of the investment and preparation was launched in form of exploratory galleries, which represent underground exploratory works constructed using the mining method that cost 300 mil. CZK. A consortium of company Štoly Dobrovského was delegated to be the general contractor of the geotechnical exploration. It consisted of GEOtest Brno, a.s. – leader of the consortium guarantee ling the exploration results, and three construction companies Metrostav, a.s., Subterra, a.s. and ŽS Brno a.s. responsible for excavation of the galleries and connected engineering works.

Three exploratory galleries were completed in August 2003, whose purpose was to find an optimal technology of excavation as well as total design solution of the construction. General designer Amberg Engineering Brno, a.s. considers realization of the tunnel structure using the technique of vertically and horizontally segmented excavation. Shape and location of the exploratory galleries, which will become permanent part of the full tunnel profiles, have been conformed to this technology.

The purpose of realization of the exploratory galleries and connected exploratory works was to:

- Analyze engineering-geological and hydrogeological conditions in the tunnel area;
- Verify the proposed excavation technology and remove potential problems during excavation;
- Determine the maximum range of impact of excavation on the urban area;
- Excavate app. 20% of the total tunnel volume.

2 OBJECT AND CONCEPT OF THE EXPLORATION

Object of the exploration was the tunnel route of two tubes in lengths of 1237 m (northern – designated as tunnel I) and 1258 (southern – designated as tunnel II), from which 1019 m and 1060 m fall on the mined part. Commission for the exploratory galleries with approximately triangular section in the area of tubes at the bases of their vault, which will be used during the future construction of the tunnel structure. Total length of the exploratory galleries reaches something over 2 km (IIA 831 m, IIB 831 m and IB 365 m). Due to technological reasons the galleries did not pursue the entire length of the designed tunnel tubes (Fig. 1).

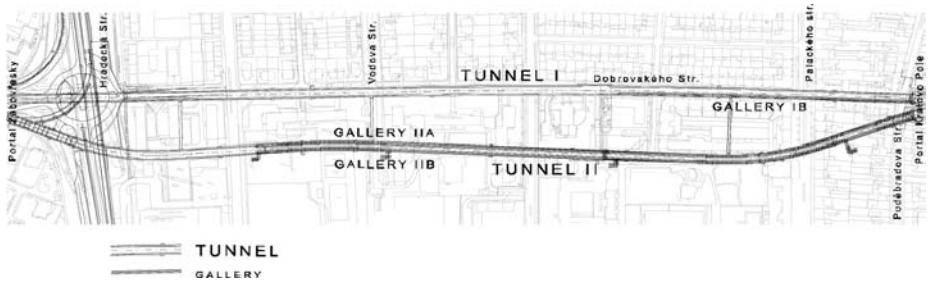

Figure 1. Exposure of galleries and designed tunnels in urban area of Brno.

Proposal of the exploratory works respected requirements laid forth by general designer of the work. It consisted of extensive complex of works, mostly focused on analysis of the behavior of tertiary clays, within which predominant part of the future tunnel tubes will be excavated:

- Factual evaluation of the Brno clays.
- Geological observation and documentation during the construction – constant geological monitoring, documentation of the faces, collection of soil samples, measurement of structure.
- Open-trench works at the surface – engineering-geological core-bores, structure bores, monitoring hydrogeological, geotechnical bores and penetration probes.
- Laboratory tests of rock mechanics, mineralogical and x-ray analyses, chemical analyses of waters.
- Geophysical measurements – vertical electric probing and shallow refraction seismic survey, seismic documentation in the galleries for determination of the massif anisotropy, determination of the Poisson's ratio from measurements of velocity of axial and lateral waves, seismic radiation between the bore and surface and between the galleries using seismic tomography, measurement of corrosiveness and stray currents.
- Passportization of water resources and regime hydro geological measurement – regular complex observation of excavation on water resources as well as their quality and quantity.
- Field geotechnical tests and measurements in test galleries – loading tests for determination of deformation statistics, shear tests with predestined area of faulting, measurement of massif tension using convergence method in a circular cross section during the excavation of test galleries, measurement of clay contraction and in situ permeability.
- Geotechnical tests and measurements in the boreholes – measurement of deformation attributes and trial stress measurements.
- Geotechnical monitoring realized both at the surface and inside the exploratory galleries – it is presented in the special article in the section 4.

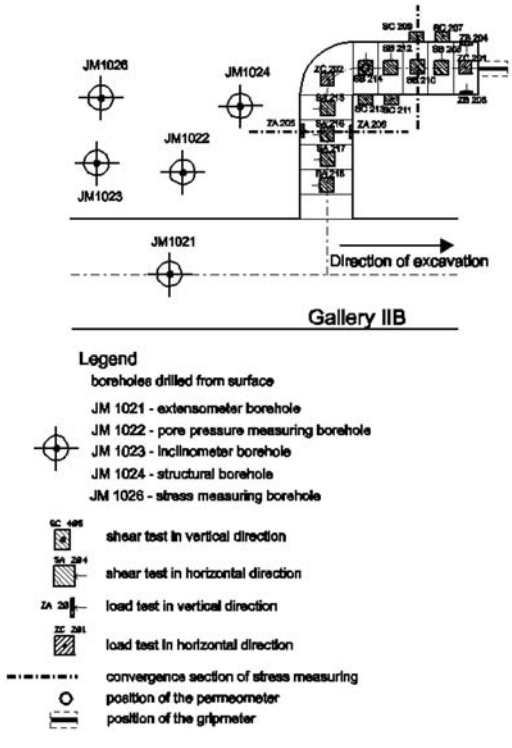

Figure 2. Layout of geotechnical works in places of concentrated investigation.

- Physical modeling using equivalent materials, determination of deformations after gallery excavation and also during the sectional excavation of tunnel for separate phases of the excavation.

For this purpose, 4 bent tests galleries of circular cross section Ø 1900 mm were designed for location of the special field tests. Their floor was bend in ground plan elevated by 0,5 m against level of floor of axial corridor of the IIB gallery, from whose left-side wall the tests galleries were started The tests galleries were part of the so-called places of concentrated exploration, which brought together all main exploratory

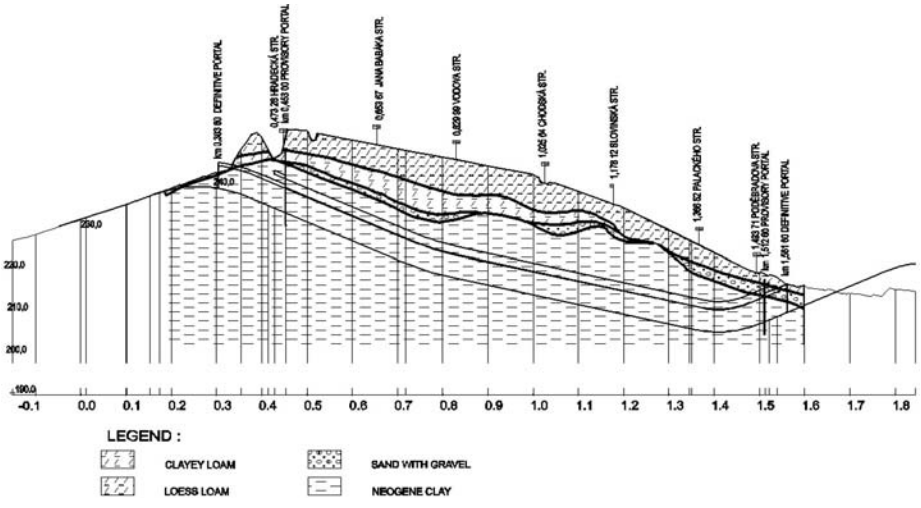

Figure 3. Geological longitudinal section through the axis of the tunnel.

and testing methods of geotechnical exploration as well as monitoring. These places further contained a total of 5 bores, carried out from the surface (see Fig. 2).

The concept of engineering-geological exploration was selected so that exploratory works realized from the surface would be coordinated with the activities underground. A total of 22 core bores was bored in the line of these designed tunnels. Bore depths ranged between 8 and 20 meters. These bores were designed to reliably uncover cross-section of the tunnel overburden and at the same time not interfere with free area of the future tunnels. Selected bores were equipped for observation of groundwater level oscillation. The mentioned places of concentrated exploration consisted of four 60 m deep bores for determination of the geological profile in the estimated zone of impact of the tunnel structure on state of stress in the massif.

3 THE PROCESS OF EXCAVATION

First, the provisory portal Královo Pole was realized by framework with fixed 18 m deep diaphragm wall, into which, following uncovering of the front section, openings were cut using special diamond devices in the shape of consequently excavated galleries with width of the floor 4,75 m and max. height of the niche 4,03 m Prior to the own excavation, which proceed from Královo Pole towards Žabovřesky, 16 m long classic micropile umbrellas were created around the gallery periphery. Lining of the galleries consisted of bearing frames from rolled mining reinforcement K24 with spacing and 10 cm thick B20 shotcrete reinforced with KARI net.

Immediately after the excavation started, the most complicated geological conditions of the track with occurrence of Quaternary watered gravels were encountered in first 60 m. Unfavorable geology in the initial gallery section was further complicated by extensive groundwater inflows, by low overburden and recent reconstruction of the multi-storey houses. Special technical measures had to be adopted in order to provide for stability of the gallery excavation as well as urban area in the overburden of this initial section. These were represented by realization of five rows of 12 m long micropile fans with a four-meter cover, bored from the underground along periphery of all three exploratory galleries. Although it was supposed to be complicated and excavation-retarding measure, it proves effective.

4 ENGINEERING-GEOLOGICAL AND HYDROGEOLOGICAL CONDITION IN THE LOCALITY

The area of the designed tunnel Dobrovského belongs to the expanded pelagic Neogene of Carpathian foretrough, which in this case reaches several hundred meters deep. Sediments lay directly on rock of the Brno massif.

Significant area of the target for exploration is urbanized; predominant part of free areas is covered with fills, or eventually with road structure layers. Terrain surface, which is slightly aligned in uniform gradient in the entire overburden of the exploratory galleries, is in the western part formed by mostly road-type structures, namely cloverleaf crossroad.

Natural cover of the terrain surface is represented by loess loams, sedimented by eolic activity during

Pleistocene. This layer experiences several decimeters thick dark-brown layers representing fossil horizons. Bases of the Quarternary cover is represented by gravel sediments, very often full of loam and clay. Their occurrence is not continuous. The largest thickness of the gravel strata was documented below the municipal bathing pool. In this place, the tunnel overburden will have only 1,5–2,5 m of Neogene clays, yet the gravel layer should not be encountered.

Prequarternary underlay is in the entire given area formed by rock of Neogene (Miocene) lower Badenian age. From the engineering-geological point of view it is limely, largely silty clay. Considering the risk of deformation there is the most vital presence of expanding clayey minerals due to their ability to swell and contract. Newer rock has a greenish-gray color, near the surface it is colored yellow to reddish-brown. Exploratory works revealed that the clays are heavily tectonically faulted, locally in zones up to several tens of meters thick. More significant tectonics areas are rubbed, grooved in the direction of movement and highly undulated.

Groundwater in the given area is mostly bound to the occurrence of Quarternary fluvial sediments in the form of gravel to sand-gravel sediments, which create very good conditions for the origin, transport and accumulation of groundwater. Neverthless, the water collectors are not continuous, and therefore the groundwater is of mostly static resource character.

5 GEOTECHNICAL ATTRIBUTES OF ROCK AND ROCK MASSIF

Attributes of the rock massif, in which tubes of the Dobrovského tunnel are designed, as well as attributes of soils that form this massif were determined based on evaluation of results of several laboratory tests of samples, collected from bores and underground openings, and field tests, realized mainly underground, in lower scale also at the surface in bores. Analysis of the geotechnical attributes proceeded in the mentioned four locations of concentrated explorations that characterized corresponded quasi-homogenous units. Attributes of the covering formations were further explored outside these locations of concentrated exploration using samples collected from bores located along the entire length of both tunnel tubes.

Laboratory tests analyzed the attributes of materials formed the rock massif, among those common index attributes on disturbed samples, on undisturbed samples volume weight in the original condition and after drying-out also permeability, density of the solid particles, total and effective parameters of shear strength, constrained modules, swelling, swelling pressures and contractibility. With regards to the fact, that each location of the concentrated exploration included one 60 m deep bore, it vas possible to observe the process of

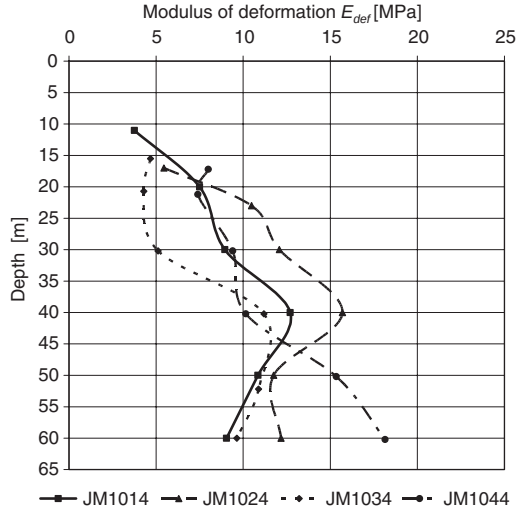

Figure 4. Relation of the modules of deformation into depth.

modification of attributes in the clay massif not only along the gallery length, but also in vertical direction. Figure 4 graphically illustrates the influence of depth on the modules of deformation of clays evaluated from the measured constrained modules.

Field tests were focused on analysis of the Neogene clay massive. Based on their purpose, they were divided into five groups: tests of massif deformability, strength tests, tests of the massif stress, tests of massif permeability and technological tests. Moreover, results and evaluation of the penetration probes were assorted with field determination of geotechnical attributes.

The first group includes mostly loading tests, which were located into test galleries in locations of the concentrated exploration. Determination of a total 6 deformation modules was realized in each test gallery, always in all mutually perpendicular directions. The tests were realized using tough 0,5 m square loading plates, gradually loaded up to the maximum average contact load 0,5 MPa and subsequently relieved to zero in two phases.

Measurement of deformability also proceeded in bores that were carried out from surface using pressiometer up to depth of 40 m below surface. These measurements were realized by employees of SG-Geotechnika Praha. Based on these results of this activity, pressiometric modules and their course of the depth were determined.

The second group is represented by shear tests with predetermined area of faulting under influence of tangential (shear) force in similar directions as for the loading tests – parallel with axis of the IIB gallery, in perpendicular horizontal and vertical direction. The tests were performed on $50 \times 50 \times 30$ cm block, which

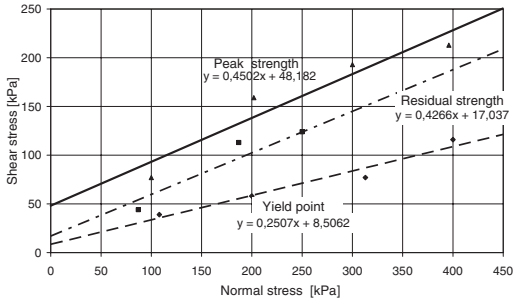

Figure 5. Strength lines of Neogene clays in vertical plane measured in the test gallery 2.

had been prepared pressing steel frames into tested environment and by gradual removal of the surrounding material. Four block formed one set, in which each block was loaded with a different combination of normal and tangential load up to disconnection of the block by shearing of its basis. From measured deformations during loading of the blocks were evaluated lines of the yield point, peak and residual strength of clay massif (see Mohr's diagram in Fig. 5). Altogether, 34 tests were performed.

Measurement of the massif stress (third group) represents the most complicated and least mastered part of rock mechanics, especially in the conditions of underground openings. Magnitudes and direction of principal stresses that occur in the massif of Neogene clays were measured by three methods, none of which had been applied in similar rock environment. Therefore, the stress measurement had a rather experimental nature. For this purpose were used three methods: the Hydrofrac, which measures horizontal stress by a probe inside of a bore that is expanded into its faulted walls by pressure of a liquid medium, the method of stress determination based on measurement of convergence of the circular opening during its excavation and finally the stress measurement by probe inside of bores that observed contracting effect of plastic clays (called method of Svěrometr).

The Hydrofrac method was developed for stress measurement of massif with solid rock, in this locality was used for the first time in a clay massif. This measurement was applied by Institute of Geonics by ČAV Ostrava in three bores. This method, however, proved unsuitable for use in a clay massif.

On the contrary, very good results were achieved by stress measurement using convergence method, although this is an indirect method that determines magnitudes and direction main stresses by calculation from measured values of other factor – deformations of the circular opening during its excavation. This method was used in all tests galleries in their both parts – in parts perpendicular to a axis of the IIB gallery and those curved, which had been excavated

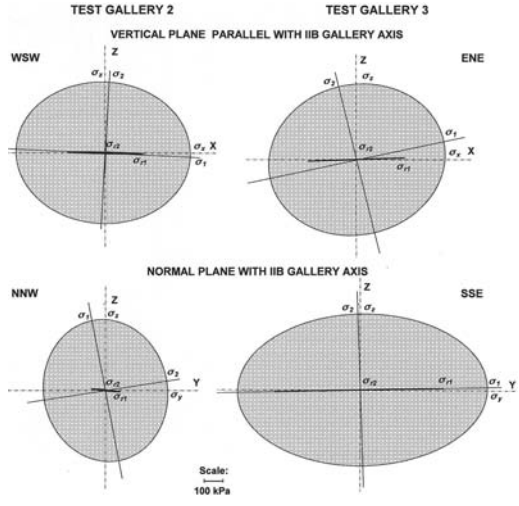

Figure 6. Ellipses of stress of rock massif in the central part of tunnel evaluated of the convergence measurement in the test galleries 2 and 3.

in parallel direction with this axes. This measurement submitted the magnitudes of normal and shear stresses in vertical and horizontal direction in planes perpendicular to axes of the cut, from its were calculated magnitudes and direction main stresses actuates in this plane and finally the residual stresses existing in the massif before excavation of the underground openings obtained by subtraction of the stresses evoked by weight of the overburden. The measurement showed that there is a horizontal residual stress, which is, in perpendicular direction to the tunnel axis, almost constant at 80 kPa with the exception of one short section below Vodova Street, where an enormous five-fold increase of value of this stress was discovered. In the axial direction, the residual stress in end section was measured with slightly reduced values (60 kPa), which increased three-fold in the middle sections. Existence of the residual stress can be attributed to preconsolidation of clays by originally high, now denudated overburden (reaching up to 80 m above the current surface); its elevation in the middle section probably to an existence of faulting line. For magnitudes of stresses measured in middle section of the explored area see ellipses of stress on Figure 6.

The method of stress measurement using contractionmeter probe is a direct method, which uses geological attributes of clays that become expressed in contraction of bored holes. It is a generally simple test, yet a very demanding one, and therefore due to time reasons the measurement could be realized only on two test galleries. The measuring device was developed for measurement in this locality, and therefore had an experimental nature. Nevertheless, achieved results

proved that use of this method of stress measurement can be considered as successful. This method can determine stress in planes perpendicular to axis of trial bore as well as magnitudes and directions of residual stresses in the same way as with convergence method. Moreover, this method enables measurements in different levels based on length of trial bores.

Four group of the field tests measurement included measurement of permeability of the rock massif by infiltration method using the Horn permeability-meter, which proceeded in all test galleries, into whose permeability-meter located. The method uses principle of measurement according to Maag, the Horn's device removes disadvantages of using the original method by its application in low permeable soils. The measurements proceeded for a long period of time, which also allowed contemplating possibilities of modification of the clay massif permeability based on the duration of the open excavation in the floor. These measurements showed permeability higher by two orders than laboratory results and slight reduction in permeability based on the time of excavation opening.

Fifth group – technological tests include only pulling tests of anchors, which had been realized in two trial fields in the trench near IB gallery portal.

The aim of these tests was to analyze effectiveness and attributes of rod anchors in the environment of Neogene clays. The task was solved in two phases – The supplier of anchoring CarboTech Bohemia installed a total 12 anchors in the first phase (4 anchors of SN type, 2 glass-fibre and 4 self-boring anchors TITAN. In the second phase following completion of the pulling tests, GEOtest Brno, a.s. installed 2 anchors of SN type and 2 anchors TITAN. After testing of the second phase anchors it was possible evaluate the self-boring anchors TITAN as the most suitable for subsequent construction of the underground work.

Penetration probes analyzed attributes of overburden of the never realized gallery IA in lower part of Veleslavínova Street – near the provisory portal of the tunnel tube I. They were carried out as dynamic enabling determination of the value of deformation module as well as parameters of the shear strength from the number of hits of the ram needed for driving the measuring pike in given depth interval and from toque at the string of rods. They were focused on exploration of the Quaternary rock and surface zone of Neogene clay massif.

6 CONCLUSIONS

As results of the realized exploratory activity showed, the tunnel structure will be realized in an environment of over-consolidated Neogene clays with specific attributes that need to be respected during the design of its dimensions as well as during the technology of realization. This environment is marked by relatively low strength, high contraction, slow creep and volume modifications due to changing water amount.

There is a very positive factor for the excavation in very low permeability of the clay massif, and therefore running groundwater will be unfavorably affecting the excavation only in section to the exit portal, where the cut penetrates into Quaternary rocks.

Exploration proved that there are relatively high horizontal residual stresses in the clay massif. As for excavation of the tunnel tubes by which horizontal directions outweigh the vertical ones, occurrence of higher horizontal stress will be an advantage.

Geotechnical conditions thus require for the excavation to be realized in shortest time possible and immediately equipped with non-permeable lining the entire periphery. Moreover, organization of works will have to be adjusted to these geotechnical conditions – it will be necessary to select such technological procedures that would only minimally interrupt otherwise continuous excavation.

Finally, along with the excavation, it will be necessary to monitor behavior of the rock massif, lining of the excavation and deformations of surface and especially the impact of underground works in urban area in the settlement trough in order to immediately evaluate the acquired data for potential guidance of realization of the tunnel structure.

Design and construction of a large underground cavern in Atlanta, Georgia, USA

T.W. Pennington, R.F. Cook & D.P. Richards
Parsons Brinckerhoff, Portland, Oregon, USA

G. Barnes
City of Atlanta, Department of Watershed Management, Atlanta, Georgia, USA

ABSTRACT: The Southern Piedmont Geologic Province in the state of Georgia (USA) consists primarily of moderate to high-grade metamorphic rock that lends itself well to underground development, particularly within the Atlanta metro area. The Custer Avenue Storage Facility was designed and constructed within this massive, high quality metamorphic rock of the Piedmont. Design of the ground support originally consisted of three types of patterned rock bolts with shotcrete and incorporated a combination of widely accepted empirical design methods for underground excavations in rock. During construction, contract requirements directed the contractor to excavate a 20-feet (6.1 meters) wide pilot drift at the top heading of the cavern excavation to confirm rock mass conditions along the length of the cavern and to serve as the initial drift of the cavern excavation. Where zones of weakness or less favorable conditions were identified in the pilot drift, the ground support was modified based on the in-situ rock Q-values. Ultimately, the pilot drift provided valuable data on the geologic conditions encountered prior to enlargement of the cavern and allowed flexibility in the design of the ground support for the final cavern.

1 BACKGROUND

Under federal mandate by the federal Environmental Protection Agency (EPA), the City of Atlanta was required to implement long-term planning and combined sewer overflow (CSO) controls throughout the city's combined sewer areas. Originally, a 1-mile (1.6 kilometer) storage and transport tunnel was considered to provide CSO control for the East Area Combined Sewer Basin. Following a value engineering study, the tunnel was replaced with an above ground CSO storage tank with an estimated cost savings of $150 million ($US). During preliminary design, a review of operational hydraulics; available property; protection of the mature, stately trees in the area; impacts of construction and future operation to the area residents; and cost, led to the consideration of options to provide the required additional CSO storage in an underground configuration. The selected option was a 60-feet (18.3 meters) wide, 600-feet (183 meters) long underground cavern with a storage capacity of 10 million gallons (3.8 million liters) excavated into the massive granite bedrock. Favorable bedrock conditions were subsequently confirmed at the site following a detailed site investigation. Ultimately, the cavern proposal reduced cost and only came to the surface at the mining shaft, minimizing the impact to the neighboring community. Furthermore, the Custer Avenue Storage Facility only required the acquisition of one property.

2 GEOLOGIC SETTING

2.1 *Southern Piedmont*

The Custer Avenue site is located within the Midland Georgia Subsection of the Southern Piedmont Physiographic Region of Georgia. The Piedmont is a region of moderate to high-grade Precambrian and Paleozoic metamorphic rocks such as schist, quartzite, amphibolite and gneiss, as well as various igneous rocks. Peak metamorphism occurred 365 million years ago in the Devonian Period with igneous intrusions dating to the late Paleozoic Period. The Piedmont Province has undergone several periods of intense deformation resulting in a great deal of folding, faulting and thrusting.

The deformation and recrystallization of the Piedmont metamorphic rocks produced parallel planar structures, schistosity and banding with a general structure that has a northeasterly strike and an accompanying southeasterly dip. The structure is reflected in rock foliation, fold axes and orientation of major thrust faults, as well as joints that developed in the

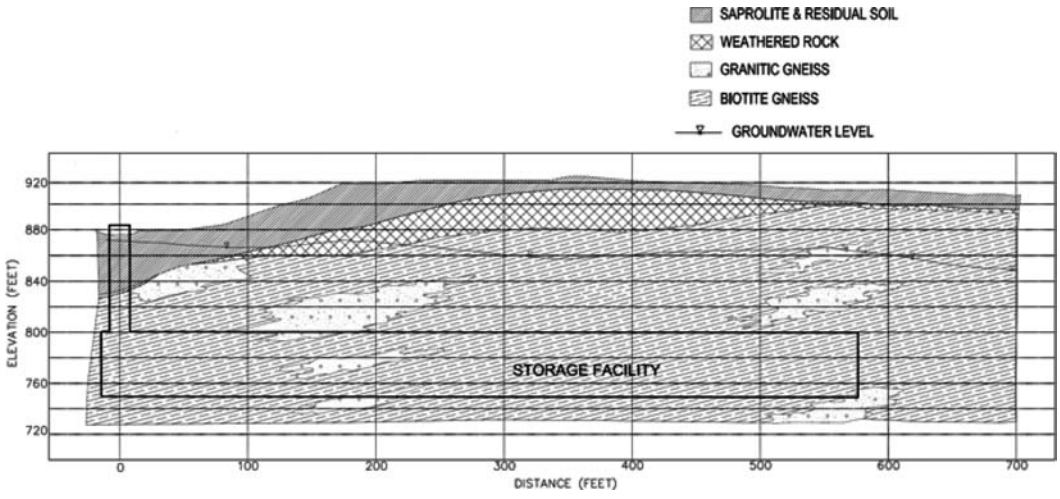

Figure 1. Storage facility geologic profile.

rock due to volume changes caused by slow cooling of the rock mass. Joints in the metamorphic rocks can assume many orientations but it is common to have one orientation parallel to the rock foliation strike and another that is perpendicular to the strike direction.

2.2 *Geologic units*

Along the Storage Facility alignment, the bedrock consisted primarily of biotite gneiss with lesser amounts of granitic gneiss (Figure 1). Local geologic mapping indicated that the project area was underlain by granitic gneiss, but borings drilled during geotechnical site investigation penetrated predominantly biotite gneiss. Quartz veins (up to four feet thick) were encountered in nearby borings drilled for the adjacent Intrenchment Creek Tunnel at the northern terminus of the proposed facility alignment.

2.3 *Weathering profile*

Following uplift and erosion of the Piedmont, the exposed bedrock was subject to deep chemical weathering that has resulted in a weathering profile that is irregular, with gradational contacts between weathering zones. The boundary between soil and rock is a transition zone, grading with increasing depth from residual soil to fresh unweathered rock. Since weathering is facilitated by fractures, joints and the presence of less weathered material, the weathering profile was expected to be highly variable and the contact with the underlying fresh rock irregular and erratic. For the Storage Facility, the following criteria were established for characterization of the weathering profile:

A. Residual zone (residual soil and saprolite with N-values < 100 blows/foot)
B. Partly weathered zone (weathered rock with N-values > 100 blows/foot)
C. Bedrock Zone (Unaltered, unweathered, or slightly weathered rock)

The boundaries between weathering zones in the Piedmont are generally not horizontal. Weathering is often deeper and more advanced adjacent to fractures that transmit water and in mineral bands that are more susceptible to decomposition (as found in foliated gneiss). Vertical foliation in the bedrock also enhances weathering resulting in deep saprolite deposits. Weathering in the highly foliated rock proceeds inward from joints through less resistant rock producing deep soft seams alternating with seams of hard, relatively unweathered rock.

2.4 *Structural geology*

The sub-parallel foliation within the rock mass was identified as the primary joint set (and potential plane of weakness during cavern excavation). Infrequent high angled joints and shear zones up to five feet thick were also identified in three of the borings drilled along the alignment as follows.

2.4.1 *Foliation and schistosity*

The biotite gneiss encountered during subsurface explorations contained abundant biotite mica that produces a strong foliation. The granitic gneiss contained less mica and thus shows less foliation. Since the majority of the cavern would be located within biotite gneiss, foliation orientation would influence the overbreak and stability of the resulting excavation. Foliation within the biotite gneiss and granitic gneiss consisted of thin laminations of contrasting mineralogy; however, large-scale foliation would be present.

Laminations generally dipped from 0° to 60° from horizontal, but the average dip of the majority of the foliation was less than 30° from horizontal.

2.4.2 *Jointing*

Bedding planes, foliation, and jointing were confirmed within cores obtained from subsurface explorations. A minimum of three joint sets were assumed along the proposed Storage Facility. Based on the history of metamorphasism in the Piedmont, joint frequency was expected to decrease with depth below top of rock. Average fracture frequencies for individual core runs varied from about one to 20 fractures per 10 feet (3.0 meters). Measured dip angles (measured from the horizontal) on the vertical drill core were estimated to vary from 0 to 45 degrees. In the deeper portions of the Storage Facility, joints were expected to become tight and in most cases to have no apertures or openings. Occasional localized joints containing small amounts of clayey gouge material (indicating minor shear or altered zones) were expected at depth.

2.4.3 *Groundwater*

In the Atlanta area, the main source of groundwater is infiltration from the ground surface into the overlying soil zone. The soil zone acts as a reservoir consistently recharged by the substantial precipitation in Georgia. The saprolite and weathered rock have significant storage capacity within abundant open fractures and small voids and act as a conduit for groundwater transmitted into the underlying bedrock. Groundwater in the underlying bedrock is present in irregularly distributed, highly localized, discontinuous water-bearing zones. Groundwater is typically conveyed along foliation planes, fractures, joints, boundaries between different rock types, veins, and other geologic features that have been enhanced by differential weathering. Within the bedrock units themselves, permeability is largely controlled by secondary porosity, i.e. open joints, fractures and shear zones, rather than through the porosity of the crystalline rock material.

2.4.4 *In-situ stresses*

In-situ horizontal stress in the Atlanta area has been reported to vary from 800 to 2,500 psi (5.6 to 17.1 MPa) (Lindner and Halpern, 1978), with maximum principal stress direction approximately perpendicular to the fold axes in the area. At the planned depth of the Storage Facility, these stress levels were not expected to introduce any stress related modes of instability. However, stress levels ere considered high enough to either hold in or force out blocks depending upon the geometric details of the block with respect to the excavation, and depending upon the shear strength properties of the controlling discontinuity surfaces.

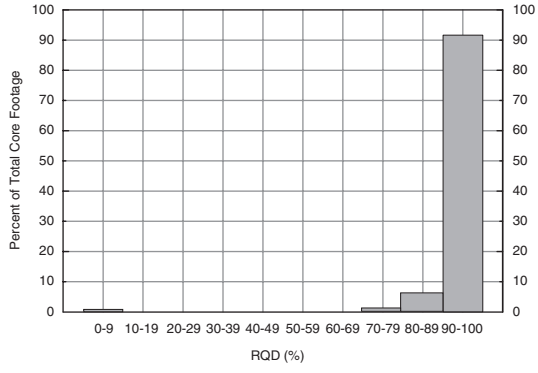

Figure 2. Distribution of RQD.

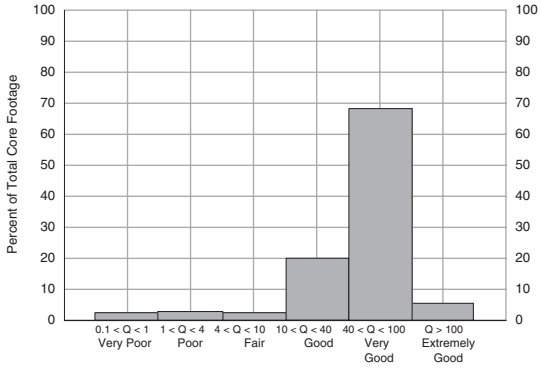

Figure 3. Distribution of Q-values.

3 ROCK MASS PROPERTIES

3.1 *Rock quality*

The rock mass within the Storage Facility excavation was relatively unweathered (moderately weathered to fresh) except for localized weathered zones and a few potential shear zones. Rock Quality Designation (RQD) values in the granitic gneiss and biotite gneiss ranged from six to 100 percent, with a median value of 95 percent. Distribution of RQD values are provided in Figure 2.

The Norwegian Geotechnical Institute (NGI) Q system (Barton, 1988) was used to characterize the rock mass and to assist in establishing and sizing the permanent ground support. Q-values were estimated along the Storage Facility alignment at the approximate depth of excavation by interpretation of rock discontinuity data for core runs within the Storage Facility envelope (defined as 30 feet, (9.1 meters) above the Storage Facility crown and 30 feet below the invert). Distribution of Q-values is provided in Figure 3. NGI parameters assumed along the Storage Facility are summarized in Table 1. Q-values were anticipated to

Table 1. NGI parameters selected for Q-values.

NGI parameter	Selected value
J_n – Joint Set	3.0
J_r – Joint Roughness	1.0 to 3
J_a – Joint Alteration	0.75 to 8
J_w – Joint Water Reduction Factor	1.0
SRF – Stress Reduction Factor	1.0 to 5.0

Table 2. Summary of point load test strength and UCS.

	$I_{S(50)}$	UCS (psi)
Axial point load test	0.66–1.82	15,840–43,680
Diametrical point load test	0.38–1.14	9,120–27,360
UCS	–	6,700–12,270

span a range of support categories from very poor ($Q < 1$) to extremely good ($Q > 100$).

3.2 *Rock strength*

Unconfined Compressive Strength (UCS) tests and Point Load Strength Index tests were performed on representative core samples. UCS values obtained during laboratory testing ranged from 6,700 to 12,270 psi (46 to 85 MPa). Review of the photos of failed test specimens indicated that many of the samples appeared to have failed prematurely as they did not exhibit a traditional shear failure. These results were assumed to underestimate the intact rock compressive strength.

Point load tests were used augment rock strength data and to estimate rock strength anisotropy (due to foliation and variation in crystal structure) present in the rock mass. Test results were correlated to UCS using compressive strengths estimated from the Point Load Index values, $I_{S(50)}$. As shown in Table 2, compressive strength from the axial and diametrical Point Load Strength Index tests indicated that strength along the foliation was approximately 60% of strength perpendicular to foliation.

3.3 *Anticipated ground behavior*

Results of the Point Load Strength Index and UCS tests, as well as foliation observed in core samples obtained during the subsurface investigation program, suggested foliation would influence excavation of the cavern, particularly when excavated by drill and blast techniques. Influence of foliation would be more pronounced where excavating through the strongly foliated biotite gneiss. Excavation in the crown would break along foliation planes and discontinuities, resulting in localized areas of overbreak and a corbelled surface across the crown. Additional rock breaking across the roof to remove protrusions was also anticipated.

Excavation of the sidewalls would also result in breakage along foliation planes, as well as joint sets subparallel to the walls, again requiring removal of protrusions and resulting in excessive overbreak. It was anticipated the breakage pattern across the crown and sidewalls would not be fully controlled by means of smooth-wall blasting. The excessive overbreak over the crown of the excavation would require application of shotcrete to provide a final lining over the crown to meet the final lining shape.

Where zones of blocky rock were anticipated, blocks formed by intersecting joint surfaces would be prone to fallout when they are oriented adversely relative to the excavation orientation, open, or contain mineral coatings or gouge material. The probability for fallout was judged to be high where closely to moderately spaced persistent joints, especially in fractured zones, would be encountered. Unless promptly supported during excavation, the blocks would tend to fall out of the crown and sidewalls due to the interaction between foliation, potential shear zones and joints oriented across foliation.

The main types of block fallouts from the crown, sidewalls and the face of the excavation are as follows:

Wedge-shaped fallout – characterized by blocks bounded by three or more intersecting joints. In general, these would occur due to the presence of steeply dipping joints intersecting the cavern excavation combined with shallow dipping foliation joints. Such instabilities would occur both during pilot drift excavation and cavern excavation.

Slab fallout – occurring at intersections of discontinuity planes, such as altered, shear, or weathered zones. Slab fallout would also occur due to the presence of a combination of closely spaced shallow foliation joints or shear zones and one or more moderately to widely spaced steeply dipping joints.

4 GROUND SUPPORT

Three ground support types were specified for construction based on expected rock mass conditions, as well as Q-values and RQD values along the cavern alignment. Typical details of each support type are provided in Figure 4. Ground support for Type I and Type II consisted of patterned rock bolts ranging from 10 to 20 feet (3.0 to 6.1 meters) in length, with alternating offset patterns ranging from four to 8 feet (1.2 to 2.4 meters). This support category corresponded to “good” to “extremely good” rock conditions in accordance with the NGI classification. Ground support for Type III consisted of lattice girders spaced at 4 feet (1.2 meter) with 20 feet (6.1 meter) long rock bolts spaced at 8 feet (2.4 meters) to support the crown. Sidewall support was provided by 10 and 20 feet (3.0 to 6.1 meter) rock bolts. This support category corresponded to “poor” to

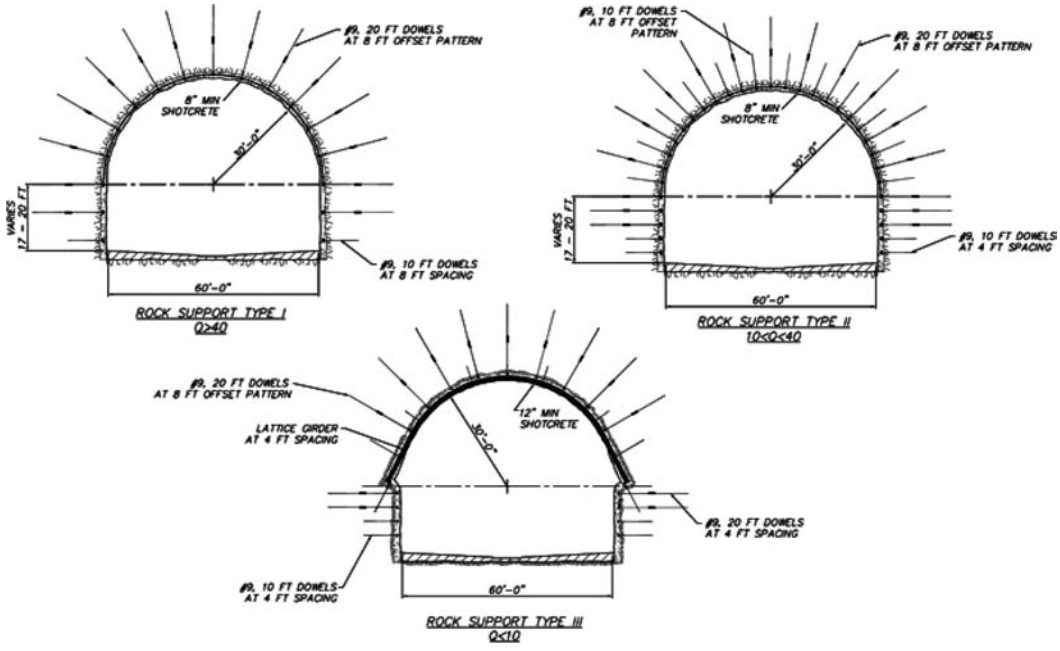

Figure 4. Ground support details.

Table 3. Ground support criteria.

Type	Q-Values	RQD (%)	Cavern Length (%)
I	>40	>95	60
II	10–40	75–95	35
III	<10	<75	5

"fair" rock in accordance with NGI classification and was intended for zones within the cavern where weathering or alteration of the massive rock was expected.

All ground support types also required a minimum of 8 to 12 inches (20 to 30 cm) of shotcrete following installation. The distribution of each ground support type along the cavern alignment is shown in Table 3.

4.1 *Pilot drift excavation*

Excavation of the pilot drift extended along the length of the cavern alignment prior to enlargement of the cavern. Approximate dimensions of the excavated drift were 25 feet (7.6 meters) wide by 20 feet (6.1 meters) high. Advance rates ranged from nine to 20 feet (2.7 to 6.1 meters) per day. Geologic mapping provided along the pilot drift indicated better than anticipated rock mass conditions than assumed during design. Based on the ground support criteria defined during the design stage (Table 3), 80% of pilot drift length, or 480 feet (146 meters) required Type I ground support, with calculated Q-values greater than 50 and frequently exceeding 100. Approximately 20% of the pilot drift length, or 120 feet (37 meters) required Type II ground support, with Q-values ranging from 17 to 36.

Discontinuities encountered along the pilot drift consisted of wide to very widely spaced healed shears and pegmatite veins with near vertical orientation, as well as wide to very widely spaced steeply dipping joints (>70 degrees). Few shear zones and joints oriented parallel to the sub-horizontal foliation were encountered. The shear zones observed ranged in thickness from 0.25 to 10 inches (0.6 to 25 cm) in thickness, with occasional clay coating. Where these discontinuities intersected the near vertical joints, potential rock wedges were identified and supplemental rock bolts were installed. No extensive zones of weakness or significantly altered zones requiring Type III ground support were observed along the length of the pilot drift excavation.

The pilot drift was primarily dry during excavation. Localized groundwater inflows were encountered primarily from the sub-parallel shear zones and foliation joints and maximum seepage rates were less than 25 gallon per minute (75 liters per minute).

4.2 *Cavern excavation*

Enlargement of the cavern excavation encountered conditions similar to those encountered during the pilot drift excavation. Rock mass conditions and rock quality were comparable to those mapped in the

Figure 5. View of fully excavated cavern.

pilot drift and similar ground support types were utilitized. Overbreak along foliation was encountered and required localized milling and shotcrete infilling to provide a relatively smooth excavated surface.

Potential rock wedges were evaluated as the cavern was enlarged and supplement rock support in the form of spot and patterned rock bolts were provided. No slab-type fallouts were encountered due to wide to very wide spacing of discontinuities.

Similar to the pilot drift excavation, minimal groundwater control was required during enlargement of the cavern excavation.

5 CONCLUSIONS

The Custer Avenue Storage Facility successfully utilized the massive, high quality metamorphic rock to provide a cost effective underground solution to providing CSO control for the City of Atlanta. Project designers were able to rely on excellent rock quality, as well as documented local construction experience, to develop a successful and cost effective solution for the project owner. At 60 feet (18.3 meters) in width, the Custer Avenue Storage Facility is among the largest underground spans in the Atlanta area.

Characterization of the rock mass using the NGI Q-value system, combined with comparison of local construction experience, was imperative to the successful design and construction of the Custer Avenue CSO Storage Facility. Construction of the pilot drift prior to enlargement of the cavern to the design dimensions allowed identification and mapping of potential zones of weakness, as well as development of supplemental ground support.

ABSTRACT: During tunnel construction, ground failures are often reported due to occurrence of weak zones such as faults, joints, and cavities. By using conventional geophysical characterization methods, it is hard to detect detailed weak rock and fault zone which can lead underground structure to fail after excavation and before supporting. In this study, an enhanced detection system of predicting weak zones ahead of tunnel face is developed for making up the problems of the conventional characterization methods. Using the developed system, case studies are performed for detection of a spherical shaped weak zone and an oriented fault. The experimental results show that the presence of weak zones and their sizes, location, and states can be accurately predicted from electrical resistance measurements through a proper inversion process.

1 INSTRUCTION

Rapid urbanization has necessitated the creation of underground spaces such as tunnels and underground structures. Unfortunately, a considerable number of accidents have occurred in such sites, including tunnel collapses. Accidents of this nature mostly occur in areas under construction and around tunnel faces. During tunnel construction, the unexpected occurrence of anomalies ahead of tunnel face, such as weak zones, fault zones, and cavities, may cause mechanical failures and ultimately result in casualties. So, various methods to predict geotechnical ground conditions in advance have been studied while conventional geophysical characterization methods have been relied upon. However, the application of conventional geophysical characterization methods is quite limited because of their failure to yield reliable prediction, especially for weak zones near the tunnel face. For this reason, it is necessary to develop an enhanced geophysical characterization method which allows predicting ground-condition ahead of tunnel face during construction.

The Tunnel Seismic Profiling (TSP) method has been generally used for that purpose. This is suitable for detection of weak zones for hard rock mass in 100 m∼200 m ahead of tunnel face. However, the TSP is not applicable to detection in a near range such as 10 m∼20 m ahead of tunnel face (Sattel et al., 1992; Lee, 2001; Lee et al., 2002). Therefore this study will present an enhanced electrical resistivity prospecting system. This method overcomes shortcoming of elastic wave and performs more precise analysis than other conventional resistivity-based geophysical characterization methods.

2 ELECTRIC FIELD ANALYSIS IN ROCK MASS

2.1 *Homogeneous intact rock*

The electric field analysis in intact rock can be done in a semi-infinite medium that is homogeneous and ideal. Let us consider that two spherical electrodes are placed at a certain distance in an ideal infinite medium. An electric field at any point can be expressed using Coulomb and Gauss' laws, so that intact rock resistance (ρ_{IR}) can be expressed as follows:

$$R_{IR} = \rho_{IR} \frac{1}{\pi a} \tag{1}$$

where ρ_{IR} ($=1/\sigma_{IR}$) is the electrical resistivity of intact rock, σ_{IR} is the conductivity of intact rock, and a is the electrode radius.

2.2 *Jointed rock mass*

In electric field analysis, joints in a rock mass are assumed to be saturated with water (e.q., most underground sites are below the groundwater table). Figure 1 shows a configuration of two electrodes (radius = a) on the face of the rock mass (x-y plane) having joint sets in x, y, and z directions. The origin for the rectangular coordinate system is at the center of the left electrode. The direction of excavation is on the z-axis. The width of each joint is 't' and the distance between joints is 'd'. The electric field at the joint surfaces (E_J) and intact rock (E_{IR}) can be expressed as follows:

$$E_J = \frac{Q}{2\pi\varepsilon_J}\frac{L/2}{\left[(L/2)^2 + y^2 + z^2\right]^{3/2}}\cdot\hat{r} \tag{2}$$

$$E_{IR} = \frac{Q}{2\pi\varepsilon_{IR}}\frac{L/2}{\left[(L/2)^2 + y^2 + z^2\right]^{3/2}}\cdot\hat{r} \tag{3}$$

where ε_J and ε_{IR} are the dielectric permittivity in joint and intact rock, respectively. The electric current of the rock mass along the y-z plane (I_{RM}) can be expressed by the summation of the electric current of joints parallel to x-z plane (I_{xz}), the electric current of joints parallel to x-y plane (I_{xy}) and the electric current of intact rock (I_{IR}) as follows:

$$I_{RM} = I_{xz} + I_{xy} + I_{IR} \tag{4}$$

where

$$I_{xz} = \frac{1}{2}\sum_{k=-\infty}^{\infty}\int_{-\infty}^{\infty}\int_{k(d_y+t_y)-t_y/2}^{k(d_y+t_y)+t_y/2}\sigma_J E_J dy dz = \frac{\sigma_J Q}{\pi\varepsilon_J}\cdot\alpha_{xz} \tag{5}$$

$$I_{xy} = \frac{1}{2}\sum_{l=-\infty}^{\infty}\int_{l(d_z+t_z)-t_z/2}^{l(d_z+t_z)+t_z/2}\int_{-\infty}^{\infty}\sigma_J E_J dy dz = \frac{\sigma_J Q}{\pi\varepsilon_J}\cdot\alpha_{xy} \tag{6}$$

$$I_{IR} = \frac{1}{2}\sum_{l=-\infty}^{\infty}\sum_{k=-\infty}^{\infty}\int_{l(d_z+t_z)-t_z/2}^{l(d_z+t_z)+t_z/2+d_z}\int_{k(d_y+t_y)-t_y/2}^{k(d_y+t_y)+t_y/2+d_y}\sigma_{IR}E_{IR}dy dz = \frac{\sigma_{IR}Q}{2\pi\varepsilon_{IR}}\cdot\beta \tag{7}$$

$$\alpha_{xz} = \sum_{k=-\infty}^{\infty}\left[\sin\left(\tan^{-1}\left(2k\left(\frac{d_y}{L}+\frac{t_y}{L}\right)+\frac{t_y}{L}\right)\right) - \sin\left(\tan^{-1}\left(2k\left(\frac{d_y}{L}+\frac{t_y}{L}\right)-\frac{t_y}{L}\right)\right)\right] \tag{8}$$

$$\alpha_{xy} = \sum_{l=-\infty}^{\infty}\left[\sin\left(\tan^{-1}\left(2l\left(\frac{d_z}{L}+\frac{t_z}{L}\right)+\frac{t_z}{L}\right)\right) - \sin\left(\tan^{-1}\left(2l\left(\frac{d_z}{L}+\frac{t_z}{L}\right)-\frac{t_z}{L}\right)\right)\right] \tag{9}$$

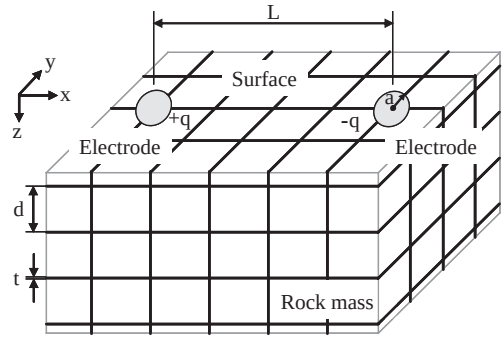

Figure 1. Rock mass with joint set.

$$\beta = \sum_{l=-\infty}^{\infty}\sum_{k=-\infty}^{\infty}\int_{l(d_z+t_z)+t_z/2}^{l(d_z+t_z)+t_z/2+d_z}\frac{2/L}{1+4(z/L)^2}\left[\sin\left(\tan^{-1}\left(\frac{2k\left(\frac{d_y}{L}+\frac{t_y}{L}\right)+\frac{t_y}{L}}{\sqrt{1+(z/L)^2}}\right)\right) - \sin\left(\tan^{-1}\left(\frac{2k\left(\frac{d_y}{L}+\frac{t_y}{L}\right)-\frac{t_y}{L}}{\sqrt{1+(z/L)^2}}\right)\right)\right]dz \tag{10}$$

where σ_J is the electric conductivity of a joint, d_y and d_z are the distance between joints along the y- and z-axis, respectively, t_y and t_z are the joint thickness along the y- and z-axis, respectively, k and l are integers and L is the distance between electrodes. If $d_y = d_z$ and $t_y = t_z$, which is a specific case, $I_{xz} = I_{xy}$.

Finally, using Eq. (4) through Eq. (7), electrical resistance (R_{RM}) and resistivity in rock mass (ρ_{RM}) where joints are included can be written as follows:

$$R_{RM} = \frac{1}{a}\cdot\frac{1}{\left[2\sigma_J\left[\alpha_{xz}+\alpha_{xy}\right]+\sigma_{IR}\beta\right]} \tag{11}$$

$$\rho_{RM} = \frac{\pi}{\left[2\sigma_J\left[\alpha_{xz}+\alpha_{xy}\right]+\sigma_{IR}\beta\right]} \tag{12}$$

3 ELECTRIC FIELD ANALYSIS IN ROCK MASS WITH A SPHERICAL WEAK ZONE

Consider that a weak zone is ahead of tunnel face. The shape of the weak zone is assumed to be a spherical shape.

Figure 2 shows electric field variation in spherical. The electric field of a weak zone (E_w) can be expressed

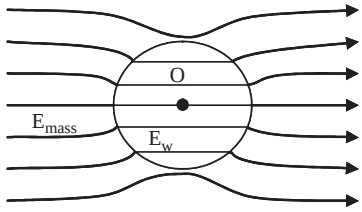

Figure 2. Electric field variation in spherical.

in terms of relative permittivity (K) and the electric field of rock mass (E_{mass}) (Reitz et al., 1993):

$$E_w = \frac{3}{K+2} E_{mass} \tag{13}$$

where K = the ratio of the permittivity of rock mass to the permittivity of weak rock mass ($=\varepsilon_w/\varepsilon_{mass}$).

Using the configuration shown in Figure 3, the current of rock mass with a spherical weak zone can be calculated as follows:

$$I = \int_0^{l-r} \sigma_{mass} \overline{E}_{mass} \cdot \pi l dl + \int_{l-r}^{l+r} \sigma_w \overline{E}_w \cdot \alpha l dl + \int_{l-r}^{l+r} \sigma_{mass} \overline{E}_{mass} \cdot (\pi - \alpha) l dl + \int_{l+r}^{\infty} \sigma_{mass} \overline{E}_{mass} \cdot \pi l dl \tag{14}$$

where $\alpha = \sin^{-1}(r/l)$, r = the radius of weak zone, l = the distance between the center of electrode and that of weak zone, σ_w = the conductivity of weak zone and σ_{mass} = the conductivity of rock mass. After substituting Eq. (13) for Eq. (14), the resistance of total rock mass with a weak zone is

$$R = \frac{1}{\left[\pi \sigma_{mass} A + \left[\frac{3\sin^{-1}(r/l)\cdot\sigma_w}{K+2} + \left[\pi - \sin^{-1}(r/l)\right]\sigma_{mass}\right] \cdot B\right] \cdot \frac{a}{2}} \tag{15}$$

where

$$A = 2 + \cos\left(\tan^{-1}\frac{l+r}{x}\right) + \cos\left(\tan^{-1}\frac{l+r}{L-x}\right) - \cos\left(\tan^{-1}\frac{l-r}{x}\right) - \cos\left(\tan^{-1}\frac{l-r}{L-x}\right) \tag{16}$$

$$B = \cos\left(\tan^{-1}\frac{l-r}{x}\right) + \cos\left(\tan^{-1}\frac{l-r}{L-x}\right) - \cos\left(\tan^{-1}\frac{l+r}{x}\right) - \cos\left(\tan^{-1}\frac{l+r}{L-x}\right) \tag{17}$$

where x = the distance from electrode $+q$ to the point, meeting perpendicularly the line passing the center of spherical weak rock mass with the line passing the center of two electrodes simultaneously, and L = the distance between two electrodes.

In practice, multiple sensors are installed on the tunnel face. Although the electric current (or resistance) can be measured only between two sensors at a time, each resistance measured is dependent upon each

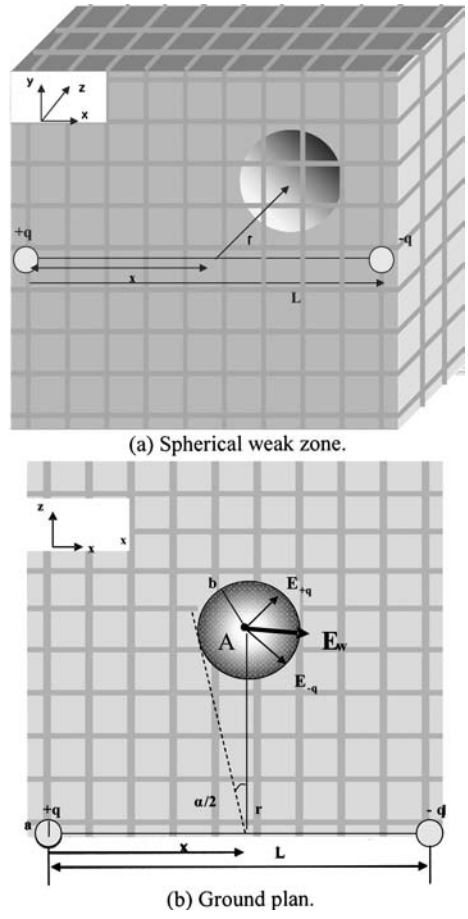

Figure 3. Electric field analysis of weak zone in a semi-infinite medium.

sensor configuration. For changing three-dimension to two-dimension, the parameters L, l, x must be changed. Figure 4 shows a spherical weak zone in three-dimension. ⓐ coordinate is ($x1$,$y1$,0), while ⓑ coordinate is ($x2$,$y2$,0). Each parameter is obtained as follows:

$$L = \sqrt{(x2-x1)^2 + (y2-y1)^2} \tag{18}$$

$$l = \sqrt{g^2 + e^2} = \sqrt{\left(\frac{\left|x3(y2-y1) - y3(x2-x1) - x1(y2-y1) + y1(x2-x1)\right|}{\sqrt{(y2-y1)^2 + (x2-x1)^2}}\right)^2 + z^2} \tag{19}$$

$$x = \sqrt{(x3-x1)^2 + (y3-y1)^2 + z^2 - l^2} \tag{20}$$

Substituting Eq. (18) through Eq. (20) for Eq. (15), it is possible to obtain a resistance for any arbitrary sensor configuration.

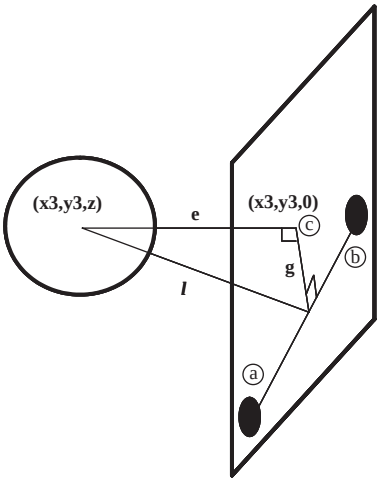

Figure 4. Spherical weak zone in three-dimension.

4 ELECTRIC FIELD ANALYSIS IN ROCK MASS WITH A FAULT ZONE

Consider that a fault zone is ahead of tunnel face. The shape of the fault zone is assumed to be a rectangular shape. If no a fault zone exists ahead of tunnel face, the equation is as follows:

$$I = \iiint \sigma_{mass} E \cdot dxdydz \tag{21}$$

A fault zone is considered as a plane (Figure 5). If a fault zone exists ahead of tunnel face, the equation is as follows:

$$I = \iiint \sigma_{mass} E \cdot dxdydz + \iint\int_{Z}^{Z'} (\sigma_f - \sigma_{mass}) E \cdot dzdxdy \tag{22}$$

$$Z = \frac{-AX - BY + D}{C} \tag{23}$$

$$AX + BY + C(Z' - t) = D \tag{24}$$

$$Z' = \frac{-AX - BY + Ct + D}{C} \tag{25}$$

where Z is the equation of the fault zone front, Z' is the equation of the fault zone back (i.e., the equation that Z plane moves toward z-axis by an extent of the fault zone's thickness, t), σ_f is the conductivity of the fault zone and A, B, C, D are constant values.

As shown in Figure 6, the electric field can be expressed as follows:

$$E = \frac{Q}{4\pi\varepsilon_0}\left(\left(\frac{1}{k^2}\times\cos\theta 1\right)+\left(\frac{1}{q^2}\times\cos\theta 2\right)\right)i$$
$$= \frac{Q}{4\pi\varepsilon_0}\left(\left(\frac{1}{k^2}\times\frac{\sqrt{k^2-l^2}}{k}\right)+\left(\frac{1}{q^2}\times\frac{\sqrt{q^2-l^2}}{q}\right)\right) \tag{26}$$

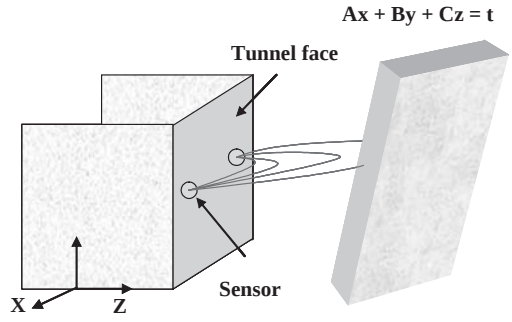

Figure 5. Fault zone.

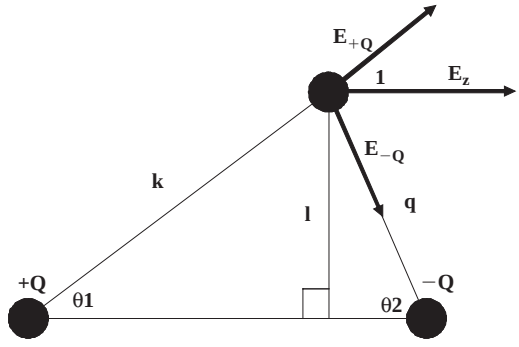

Figure 6. Electric field, E

$$k = \sqrt{(x-x1)^2 + (y-y1)^2 + z^2}$$
$$q = \sqrt{(x-x2)^2 + (y-y2)^2 + z^2} \tag{27}$$

where $x1$, $y2$, $x2$, $y2$ are coordinates of sensors. L is expressed in Eq. (19). So using Eq. (21) through Eq. (25), the current can be expressed as follows:

$$I = \int_{\infty}\int_{\infty}\int_{\infty} \frac{dV\sigma_{mass}}{2}\left(\frac{\sqrt{k^2-l^2}}{k^3}+\frac{\sqrt{q^2-l^2}}{q^3}\right)dzdxdy$$
$$+\int_{\infty}\int_{\infty}\int_{\frac{AX-BY+D}{C}}^{\frac{-AX-BY+D}{C}} \frac{dV(\sigma_f-\sigma_{mass})}{2K}\left(\frac{\sqrt{k^2-l^2}}{k^3}+\frac{\sqrt{q^2-l^2}}{q^3}\right)dzdxdy \tag{28}$$

where V is the voltage. As a result, if a fault zone exists ahead of tunnel face, the resistance can be obtained as follows:

$$R = 1/\left(\int_{\infty}\int_{\infty}\int_{\infty} \frac{d\sigma_{mass}}{2}\left(\frac{\sqrt{k^2-l^2}}{k^3}+\frac{\sqrt{q^2-l^2}}{q^3}\right)dzdxdy + \right.$$
$$\left.\int_{\infty}\int_{\infty}\int_{\frac{AX-BY+D}{C}}^{\frac{-AX-BY+D}{C}} \frac{d(\sigma_f-\sigma_{mass})}{2K}\left(\frac{\sqrt{k^2-l^2}}{k^3}+\frac{\sqrt{q^2-l^2}}{q^3}\right)dzdxdy\right) \tag{29}$$

Figure 7. Model test setup.

Figure 8. Sensor configuration on a tunnel face.

5 DEVELOPMENT OF PROGRAMS

Using the derived equations, an inversion method is developed for predicting weak zones and fault zones ahead of tunnel face from in-situ resistance measurements. Inversion methods are composed of loop forms. Comparing the measured resistances with the calculated resistances through loop forms, the unknown parameters can be determined at the smallest error.

An integrated program with the inversion process is developed, composed of two other programs. One is a program which can be utilized when a fault zone exists ahead of tunnel face. The other is a program which can be utilized when a weak zone exists ahead of tunnel face. Given that resistances measured for each sensor configuration, the location of sensors and the conductivity of the rock mass, the unknown parameters such as the size of the anomaly, the conductivity of the anomaly and the location of the anomaly can be obtained using the developed program.

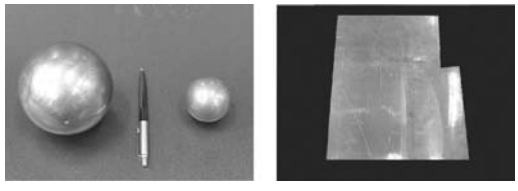

Figure 9. Materials used for simulation of weak zones and fault zones.

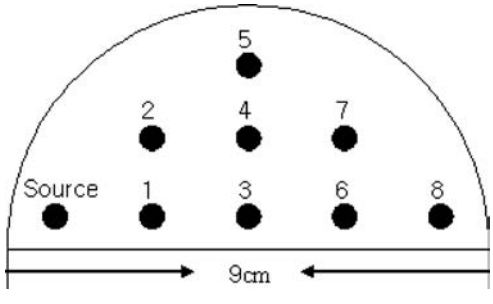

Figure 10. The location of sensors.

6 EXPERIMENTAL TESTS

Laboratory experimental tests are performed to verify the derived equations, inversion methods and developed programs. Figure 7 shows a model test setup that simulates a tunnel under the ground, Figure 8 shows sensor configurations on a tunnel face, Figure 9 shows the materials simulating weak zones and fault zones, and Figure 10 shows the location of sensors. Table 1 shows the measured resistances for different sensor locations when weak zones and faults zones exist ahead of tunnel face. Table 2 shows the comparison of the real values such as the location, size, and conductivity of a weak zone and the predicted values for the case of a weak zone. Table 3 shows the comparison of the real values such as an equation of plane, the thickness, and conductivity of a fault zone and the predicted values for the case of a fault zone. The results show that the predicted values are in good agreement with the real values. Thus, the detection system developed in this study can be used for predicting a weak zone and a fault zone ahead of tunnel face effectively.

7 CONCLUSIONS

This study presents an enhanced electrical resistivity-based detection system for predicting a weak zone and a fault zone ahead of tunnel face. The electric field analyses are based on Coulomb's law and Gauss' law considering electrical characteristics of rock mass properties. The equations for resistance are derived for the presence of a weak zone and a fault zone ahead of

tunnel face. The developed algorithms and programs are verified through laboratory experimental tests. The experimental results suggest that the presence of weak zones and their sizes, location and states can be effectively predicted from electrical resistance measurements through a proper inversion process. This method would benefit from verification using more elaborate field measurements.

A modified design of a large section tunnel as an auxiliary spillway along large faults

Y.W. Shin, I.K. Lee, T.S. Park, H.S. Choi & S.C. Park
Tunnel & Geotech. Div., Hakyong Eng. Co., Korea

J.K. Kim, M.S. Lee, K.H. Shin & B.H. Han
Division of Civil Works, Samsung Corporation, Korea

ABSTRACT: An auxiliary spillway tunnel of 18 ~ 15 m height and 24 ~ 15 m width is planed for increasing flood control capacity of the Soyang river dam in South Korea. It is composed of two parallel tunnels, T1 and T2. Some faults unexpected in design stages are revealed in transition section of entrance. Two times of roof falls are caused by those faults. Additional vertical borings at ground surface and horizontal borings at tunnel side wall are executed. Some alternative reinforcement methods based on additional borings are carefully investigated. Roof falls were occurred in entrance section of T1 and T2 tunnel. Steel pipes are inserted and cement mortar is filled temporarily. The results of additional geological investigation indicate that T1 tunnel are planned parallel to faults of maximum width 20 m. Four faults are intersected with T2 tunnel. Extremely poor mica gneiss is widely distributed and stability of tunnel face is not guaranteed. It is concluded that original support system is deficient and alternative support system is needed. Several alternative methods such as cut and cover tunnel, double support system and steel pipe insertion method are profoundly investigated considering ground and construction conditions. Double support system is selected as the most suitable alternative. Numerical analyses considering field ground condition and dimension of tunnel cross section manifest the tunnel stability.

1 INTRODUCTION

A localized heavy rain is often caused by a worldwide unusual change of weather. The magnitude of flood disaster is gradually increased. Therefore, an auxiliary spillway has been constructed in order to improve the safety of existing dams in Korea. For the purpose of this, a large section spillway tunnel of the Soyang river dam is constructing of 25 m width and 18 m height. And this spillway tunnel is the first case in Korea. It is composed of two parallel tunnels, T1 and T2. Some faults unexpected in design stages are revealed in transition section of upper entrance tunnel through additional ground investigation. Two times of roof falls are caused by those faults. In addition, the spillway tunnel should be obliged to construct through a large fault of 20 m width. Therefore, an alternative method for excavation and reinforcement is needed to guarantee the stability of the spillway tunnel. Double support system is selected as the most suitable alternative in very poor ground with large faults.

2 PROJECT OUTLINE

2.1 *Design status*

This spillway tunnel for increasing of flood control capacity is composed of two parallel tunnels of T1 and T2 and two domains of upper and lower. Tunnel length is about 1,300 m respectively. The large inlet part of 155 m length with horseshoe-shaped section in upper domain is transition section for smooth inflow of overflow water. From that point, tunnel section narrow more and more, and become most safe circular section by hydraulics in lower domain Incline of upper tunnel section is steep slope of 14.036°. The whole status of auxiliary spillway tunnel is shown in Figure 1.

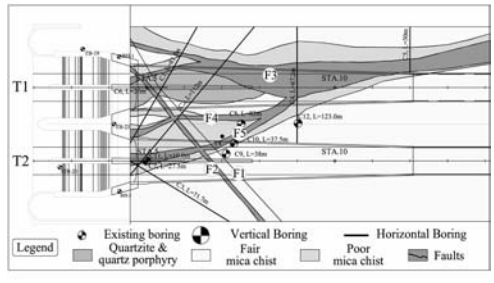
2.2 *Construction status*

Upper tunnel was excavated upward toward inlet. Roof fall of T1 tunnel was caused directly after 47 m advance during upper section excavation. Mucks were accumulated and reinforcement was executed in the

rear of roof fall area. Roof fall of T2 tunnel was caused immediately after 130 m advance of pilot tunnel and excavation of left and right parts of upper section. Mucks were stacked up and face shotcrete was shot in the roof fall area of T2 tunnel. Also, cement mortar was filled up in the roof cavity. The status of construction and roof fall are shown in Figure 2.

2.3 *Geological conditions*

On the excavation of the spillway tunnel, the unexpected large faults were appeared and an additional geological investigation on the ground will be excavated was needed. Borings and an outcrop investigation were preferred than physical investigation such as electrical resistivity survey. Geological characteristics were reevaluated by additional investigation. Results of additional geological investigation are shown in Figure 3. C1∼C7 are horizontal boring and C8∼C10, C12 are vertical boring.



5 faults of F1∼F5 in the construction area were investigated by additional borings. Considering the fault width and distribution range, an original support is not insufficient. It was estimated that roof falls during excavation were caused by many faults. Geological condition of the roof falling section and transition section are shown in Figure 4. Analyzing roof falling status and results of an additional detailed geological investigation, probable reinforcement methods were examined.

F4	2.2 ~ 6.0m	disturbance structure
F5	2.5 ~ 5.4m	large scale shear zone

Figure 3. Results of additional borings.

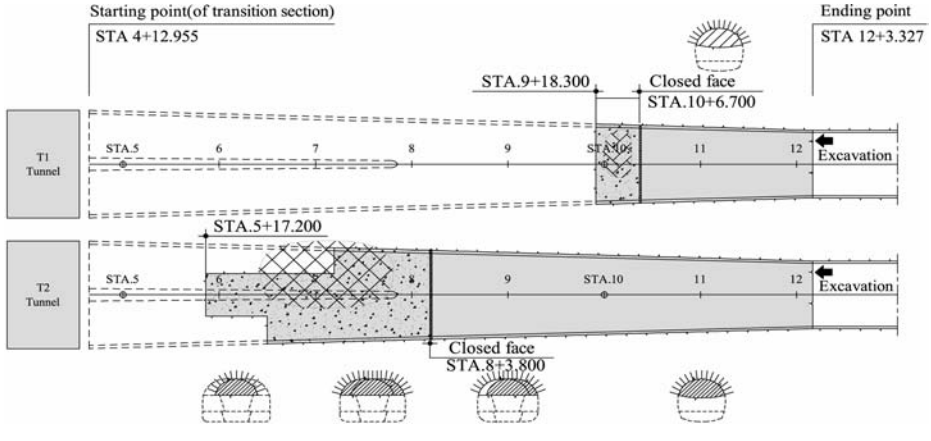

Figure 2. Construction status.

3 ALTERNATIVE EXAMINATION

For successful construction of the auxiliary spillway tunnel, possible alternatives were investigated considering construction status and new-revealed geological condition. First of all, the design and construction cases of large tunnel like the inlet cross section of spillway tunnel and those of constructed in very poor ground condition were investigated. Geological survey technology, reinforcement method and numerical analysis method were investigated. Probable alternatives to solve this problem were NATM, cur and cover tunnel, and pipe insertion method. The first alternative of NATM is more economic than the others and continuous with section constructed in former times. However, various support patterns are needed due to uncertainty of ground condition.

The second alternative, cut and cover tunnel can eliminate the possibility of roof fall at faults area and reduce uncertainty of ground condition. But application to whole section is impossible and uneconomic in comparison with NATM because of large excavation and temporary retaining wall.

The third alternative is the pipe insertion method of inserting a large diameter pipe into the ground prior to excavation. The benefit of this method is the increasing of tunnel stability and foresight of fore ground condition. However, construction cost is very expensive and its application cases are scarce.

Results of giving careful consideration to geological condition and stratum show that NATM with additional reinforcement is more suitable method than the others from a economical point of view and considering the construction convenience. Cut and cover tunnel method is applicable to the entrance section of 30∼50 m length, but the impossibility of temporary heaping of blasted rocks and a widespread damage of mountains and forests. Finally, NATM is chosen as the most suitable alternative considering the results of construction, construction cost and construction period.

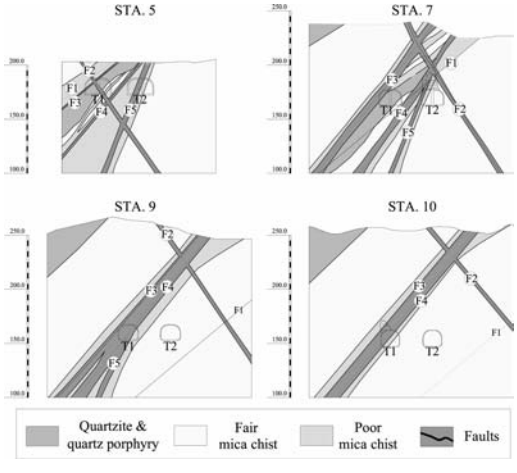

Figure 4. Faults condition.

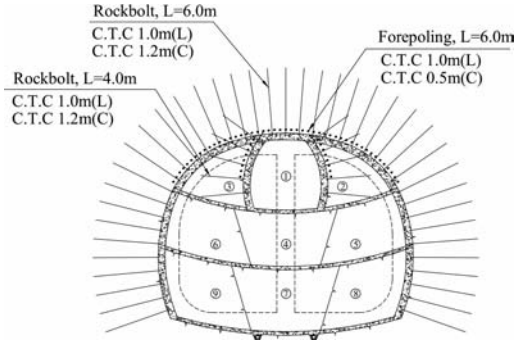

Figure 5. NATM.

4 MODIFIED DESIGN

Detailed excavation and reinforcement method of NATM concluded as the most suitable alternative were investigated.

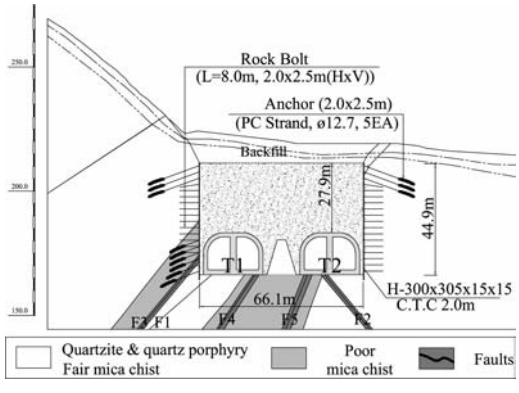

Figure 6. Cut and cover tunnel.

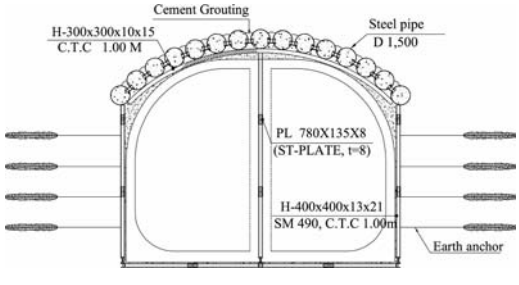

Figure 7. Pipe insertion method.

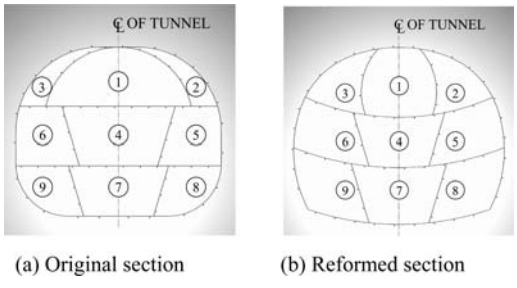

Figure 8. Improvement of cross section.

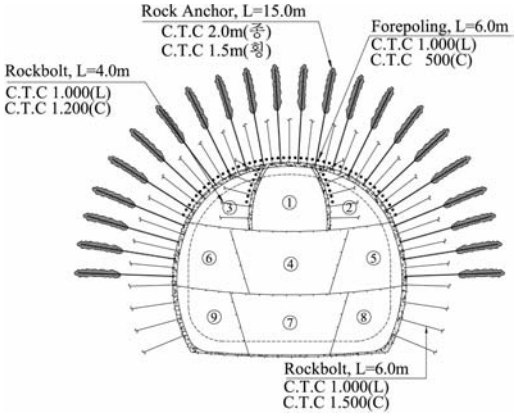

Figure 9. Anchor system.

4.1 *Improvement of tunnel cross section*

Cross section of an original design is unfavorable to support rock loads because crown and side wall of cross section are flat. Obtaining the supporting capacity by arching effects is probably difficult in the section of poor ground condition. Therefore, the shape of excavation cross section is converted into arch shape although excavation area is more or less increased.

4.2 *Supporting pattern*

Section of roof fall is located in very poor ground condition. Reinforcement of supporting system is needed because the maximum width of fault is about 20 m and overburden of 100 m height is very excessive. First of all, numerical analysis for original supporting system is carried out in the changed ground condition. Countermeasure reducing or supporting ground stress is needed because engineering properties of faults are very poor and ground stress induced by overburden is very excessive. Accordingly, anchor system that can reduce the ground stress and double support system that can uphold rock loads are evaluated as suitable countermeasure for the mechanical stability and construction convenience.

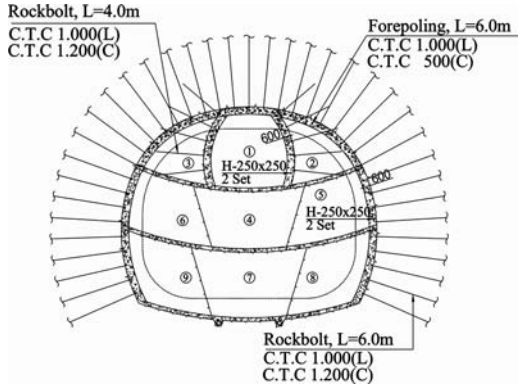

Figure 10. Double support system (Double steel-rib support).

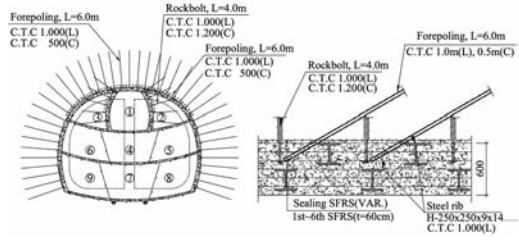

Figure 11. Outline of double support system.

Investigation results show that both two systems guarantee the tunnel stability. Double support system is chosen as an alternative method for faulted ground because it is more preferable than anchor system considering construction convenience, economical efficiency and construction period. The first steel rib of the double support system make ground permit some deformation for extremely rock loads and swelling pressure. Behind the first support release the rock loads, the second steel rib is installed to secure the stability of general support system. Some successful application cases has been reported in Japan that overall ground condition is poor. Tunnel cross section and construction sequence of double support system chosen as an alternative are shown in figure 11 and figure 12.

4.3 *An auxiliary reinforcement method*

An auxiliary reinforcement method is needed because self-supporting time of the face is insufficient even if the face is excavated into 8 m width separately. Therefore, forepoling, face bolt, face shotcrete, temporary invert, and umbrella arch method are chosen as an auxiliary reinforcement method to insure the stability of tunnel crown and face.

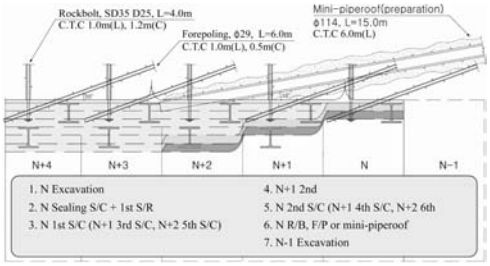

Figure 12. Construction sequence of double support system.

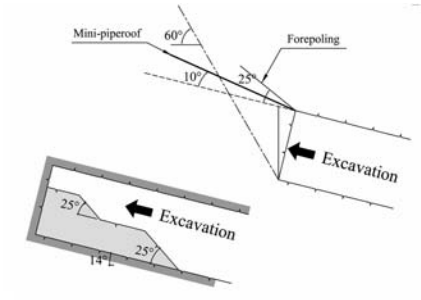
4.4 *Excavation direction*

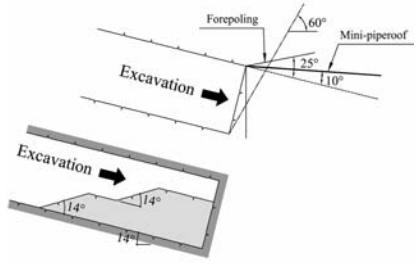
Considering a longitudinal steep inclination with 14° and very poor ground condition, an original upward excavation is profitable to drain of itself. However, when the upper, middle and lower part of tunnel section is excavated separately, construction is very difficult because the maximum longitudinal inclination of mount road is 14°. On the contrary, when tunnel is excavated downward, a pumping drainage is needed because groundwater is collected at the face. When the upper, middle and lower part of tunnel section is excavated separately, the longitudinal inclination of mount road is less than 14°. Accordingly, the downward excavation is very profitable because the upper, middle and lower part of tunnel section can be excavated simultaneously. In addition, downward excavation is more profitable than upward excavation, because the reinforcement effect of mini-piperoof of excavating downward is more preferable than the other. In conclusion, the downward excavation is selected for the face stability.

4.5 *Numerical analysis*



Numerical analysis is performed to investigate the stability of double support system using FLAC of Itasca consulting group. In Korea, the support capacity of steel rib is not considered conservatively in numerical analysis because steel rib is regarded as temporary support till shotcrete hardening.

A role of steel rib is great in very poor ground with fault. For that reason, the supporting capacity of steel ribs of double support system is reflected to analyze the tunnel stability.



Equivalent elastic modulus(E_0) and equivalent moment of inertia(I_0) are Eq. (1) and Eq.(2). Bending moment is only supported by steel ribs.

$$E_o = \frac{E_c A_c + E_s A_s}{A_c + A_s} \quad (1)$$

$$I_o = \frac{I_s E_s}{E_o} \quad (2)$$

(a) Upward excavation

(b) Downward excavation

Figure 13. Excavation direction.

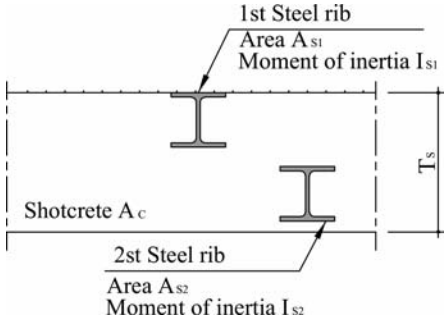


Figure 14. Structural properties of shotcrete and steel ribs.

where, Ec : elastic modulus of shotcrete, Es : elastic modulus of steel rib

Numerical analysis shows that the maximum crown settlement is 124.0 mm and the maximum convergence is 43.19 mm. The maximum compression stress of shotcrete is 4.59 MPa and that of steel rib is 269.43 MPa. All are lower than allowable criterion.

5 CONCLUSIONS

A large section spillway tunnel of large dam is constructing of 25 m width and 18 m height. It is composed of two parallel tunnels, T1 and T2. Some faults

unexpected in design stages are revealed in transition section of the inlet of upper tunnel. Two times of roof falls are caused by those faults. The countermeasure based on an additional geological survey was investigated as follows.

NATM, cut and cover tunnel, and pipe insertion method are investigated considering the ground condition and construction status for the purpose of choosing an countermeasure. NATM is chosen as the most suitable alternative considering the results of construction, construction cost and construction period.

Double support system is chosen as an alternative method for faulted ground because it is more preferable than anchor system considering construction convenience, economical efficiency and construction period.

Geotechnical control during the excavation of the tunnel of Guadarrama

Isidoro Tardáguila, Benjamín Celada & José Miguel Galera
Geocontrol S.A.

ABSTRACT: The tunnels of Guadarrama are new twin tunnels crossing the Central Range between Madrid and Segovia, as part of the new High Speed Railway Line to the NW of Spain. Their length is 28.3 km with a maximum overburden of 900 m. The geology consists mainly of crystalline rocks, gneiss and granites, with a main graven in the Lozoya valley where poor quality sedimentary rocks from the Cretaceous are crossed. Nevertheless several faults have also been detected with mylonites and water. The tunnels have been done using four double-shield TBMs, all of them with an excavation diameter of 9.5 m. The information that can be accessed from the face during its excavation with a Double-Shield TBM is generally limited. Nevertheless during Guadarrama tunnels excavation a close control of the excavated ground has been carried out, in order to allow the prediction of ground conditions ahead the TBMs. The applied methodology consists in: – geotechnical face characterization – inspection of the excavated chips – analysis of TBM drilling parameters. In relation with face characterization, conventional mapping of the face has been done as well as short boreholes (<1 m) through the lining segments. These cores have provided samples for laboratory conventional tests (UCS, PLT, Vp,…). The inspection of the waste chips has consisted not only in the weight in the belt but also in the size and shape of the waste. Finally, the drilling parameters controlled were: – rate of advance – time of excavation – weight of material in the belt – thrust – rotation speed – torque. These basic drilling parametes have been used to obtain the drilling specific energy, that has shown to be a very powerful index to predict ground conditions in the face. By means of this analysis the prediction of ground conditions ahead the TBM face was successfully done, specifying discontinuities spacing and condition.

1 INTRODUCTION

The construction of a tunnel using a TBM requires an accurate knowledge of the rock mass as the face is almost inaccessible and therefore the information that can be obtained from it is limited. Also because the TBMs are very sensible to the rock mass characteristics and its possibilities to adaptation to other conditions not foreseen is quite difficult.

In Guadarrama tunnels one of the tunnels (In the North Portal, the eastern one) goes always ahead the other. This circumstance makes very interesting to make a precise supervision in the first one, in order to:

- Foreseen the ground behaviour in relation with the TBM performance.
- Extrapolate the TBM behaviour from one tunnel to the parallel one.

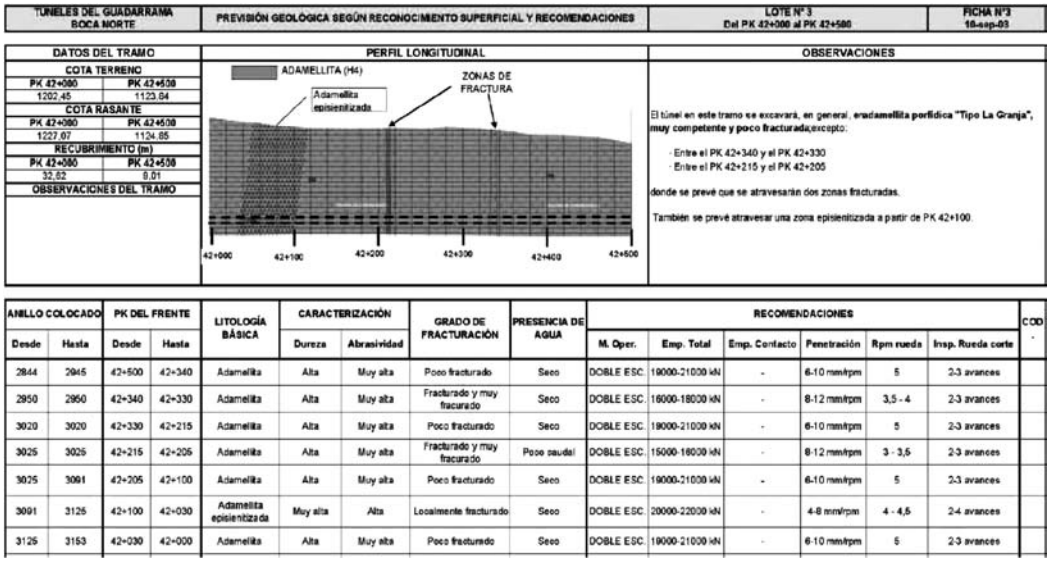
The methodology set up includes the following activities:

- Geological and geomechanical prediction.
- Information collected from the tunnels excavation.
- Data storage and exploitation.

2 GEOLOGICAL AND GEOMECHANICAL PREDICTION

The main objective of this activity is to have a prediction of the ground conditions ahead the TBM face.

In Galera *et al.* (2006) it has been explained the importance of geological mapping as well as geophysical prospecting and in situ testing, for this purpose.



Following that methodology for the each 500 m of tunnel that roughly correspond to a month of advance a prediction sheet was done. Figure 1 shows an example of this prediction sheet.

It can be observed that this prediction sheet includes the following information:

- Geological profile and description.
- Lithology.
- Discontinuity spacing.
- Hardness and abrasivity.
- Water presence.

Also in the right hand side it includes the recommendations for the TBM, as follows:

- Working mode (Double or Single Shield TBM).

– Time for inspection of the cutter wheels (TBM head).

3 INFORMATION COLLECTED FROM THE TUNNEL EXCAVATION

3.1 *Tunnel face*

The access to the tunnel face in a Double-Shield TBM is very restricted. Nevertheless in some maintenance gaps,…, it is possible to access to it. Usually this access is done through the windows included in the TBM head (cutter-wheels, bucklets or man windows).

The information collected from the face is shown in the sheet included in Figure 2, that contains the following:

– Face scheme, mapping lithologies and geological structures.
– UCS estimation, using point load tests (I_{S50}).
– RMR determination (Bieniawski, 2003).
– Discontinuities (strike, dip, spacing, roughness, filling).
– Photos.

Figures 3, 4 and 5 include photos taken on the tunnel face.

These photos have been systematically taken from the three different available windows at the TBM head.

Exceptionally it has been possible to visit the face of the tunnel while some maintenance stops. Figure 6 shows the aspect of the face in one of these occasions.

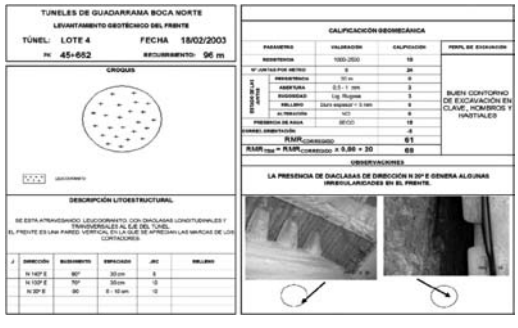

Figure 2. Example of the geotechnical information obtained from the mapping of the face.

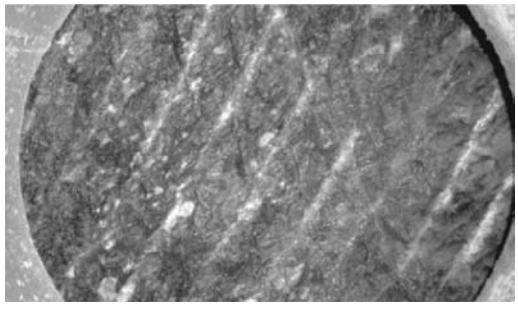

Figure 3. Face view taken through the man window in the TBM head.

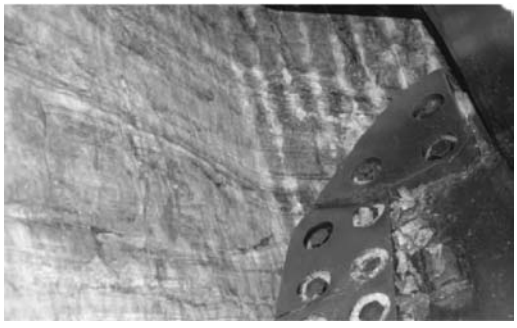

Figure 4. Face view taken though the bucklet window in the TBM head.

Figure 5. Face view taken through the cutter-wheel window in the TBM head.

Figure 6. Face of the tunnel taken during one maintenance stop.

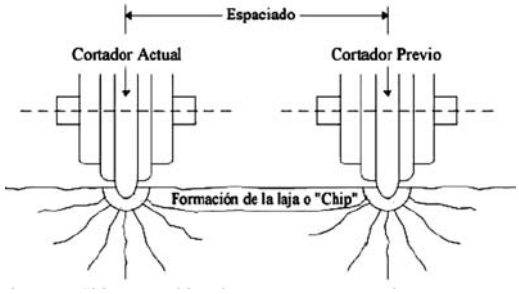

Figure 7. Chip created in a homogeneous ground.

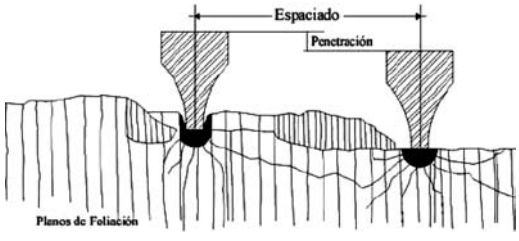

Figure 8. Chip created in a ground foliated longitudinally.

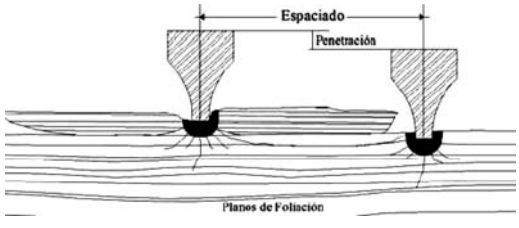

Figure 9. Chip created in a ground foliated perpendicularly.

3.2 *Chip inspection*

The most usual way to analyse the ground condition in a tunnel excavated using a TBM, is following the chips coming from the TBM head.

Figures 7, 8 and 9 shows the way in which the cutter wheel creates different types of chips, depending on the kind of ground.

Figures 10, 11 and 12 include photos showing the type of chips coming from a homogeneous face, fractured face and faulted-gouge.

3.3 *TBM drilling parameters*

The following TBM drilling parameters have been systematically recorded:

- Advance rate (ARA)
- Time of excavation
- Weigh of the debris in the belt
- Thrust (total/contact) (F)

– Rotation speed (N)
– Torque (T)

Two different interpretations can be done:

– Qualitative
– Quantitative

In the first type the following circumstances have been noticed:

– A significant increase in the rate of advance with an decrease in the geomechanical ground quality.

Figure 10. Chips coming from a homogeneous ground.

Figure 11. Chips coming from a fractured face.

Figure 12. Chips coming from a faulted face.

– An increase in the debris weight with a face instability.
– Instantaneous torque increase with a face instability.
– The difference between the applied and the contact thrust is equivalent to the TBM friction. If this value increase the TBM can get stucked.

In relation with a quantitative interpretation, the following values have been considered:

– Penetration rate (p)

$$p\,(mm/r) = \frac{V\,(mm/m)}{N\,(rpm)} \tag{1}$$

that gives the ground resistance to be excavated.

– Penetration index (I_p)

$$I_p = \frac{F_c\,(kN)}{p} \tag{2}$$

that proportionates the thrust per cutter to penetrate 1 mm per revolution.

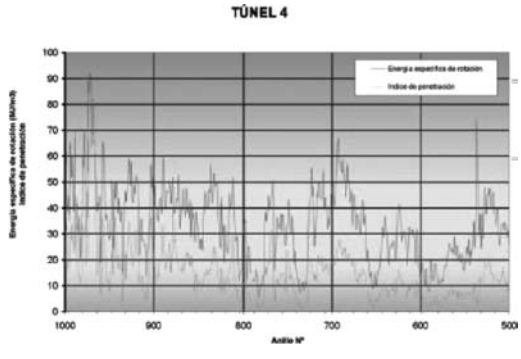

Figure 13. Relationship between I_p and E_{sr} for 500 segments rings.

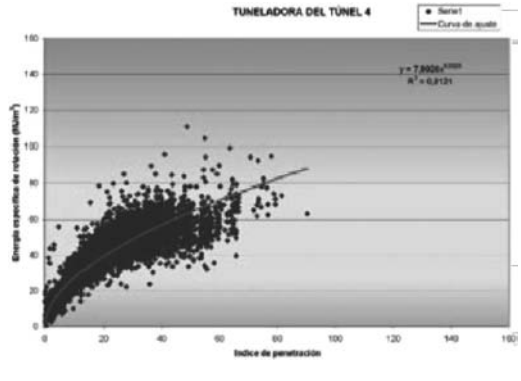

Figure 14. Correlation between E_{sr} and I_p ($E_{sr} = 8 \cdot I_p^{0.52}$).

– Specific energy of excavation (E_s)

$$E_s\ (kJ/m_3) = \frac{F}{A} + \frac{2\pi \cdot N \cdot T}{A \cdot ARA}\ \text{(Teale, 1965)} \qquad (3)$$

where E_s = specific energy of excavation (kJ/m^3), F = total cutterhead thrust (kN), A = excavated face area (m^2), N = cutterhead rotation speed (rps), T = applied torque (kN·m) and ARA = average rate of advance (m/s).

As it can be observed there are two addends, the first one corresponds to the thrust energy (E_{st}) while the second one corresponds to the rotation energy (E_{sr}).

– Correlation between I_p *vs.* E_{sr}.

Figures 13 and 14 shows the existing relation between the penetration index and the specific rotation energy of excavation.

In the first one it can be observed the direct relation between both parameters considering 500 segment units. From this relation it can be concluded that the specific energy depends on the geomechanical quality of the rock mass as the penetration index does.

Table 1. Rock mass classification, considering discontinuities spacing (NTNU, 1994).

Rock mass classification	Discontinuities spacing (cm)
0	Massive
0–I	160
I	80
I–II	40
II	20
III	10
IV	5

Table 2. Criteria to establish the rock mass spacing discontinuities at the excavation face, considering different criteria.

Rock mass type	Spacing (cm)	Joints/m	I_p	E_{sr} (kJ/m^3)	Debris
I	>40	4	20–30	40–60	chips
II	20	4–8	10–15	20–30	chips and occasional blocks
III	10	8–15	4–7	10–15	cm and dm blocks
IV	5	15–30	1	5	heterometrical blocks (dm, cm, fines)
V	<5	>30	>0	<5	sand and fines

3.4 *Discontinuities at the excavation face*

The Norges Lekmsk-naturritenskapllige Universitet (NTNU, 1994) made a classification (see Table 1).

In the Guadarrama tunnels the discontinuities spacing has been determined:

– Directly from the mapping of the face.
– Indirectly from the debri type at the belt.
– Indirectly from the TBM drilling parameters.

In Table 2 it is shown the relation between them.

3.5 *Rock sampling*

The aim of this activity was to obtain information about basic rock mechanics properties of the excavated rock mass.

Each 125 m of tunnels a small borehole (70 cm aprox.) was drilled, obtaining samples to carry out the following tests: density, sonic velocity, UCS, brazilian, point load test, petrographical analysis, DRI and Cerchar abrasivity.

In Table 3 it is shown the average parameter obtained for the different lithologies excavated in the tunnels of Guadarrama.

Table 3. Geomechanical properties of the Guadarrama lithologies.

Lithology	Density (gr/cm^3)	UCS (N/mm^2)	Is50	σ_t (N/mm^2)	V_p (m/s)	Qz (%)	Quartz equivalent (%)	DRI	CLI	Cerchar

4 CONCLUSIONS

The methodology followed during the excavation of the tunnel of Guadarrama for its geotechnical control, has consisted on:

- Mapping of the tunnel face.
- Chips inspection.
- TBM drilling parameters record.
- Discontinuities spacing at the excavation face.
- Rock sampling.

This methodology has proved to be efficient for the geological and geomechanical prediction of the rock mass to be excavated.

Assessment of rock mass properties using machine performance data from roadheaders

K. Tsukamoto, H. Hamada & S. Ebisu
Okumura Corporation Technical Research Institute, Tsukuba, Japan

ABSTRACT: The authors have developed and continue to refine a rock mass assessment system, which is based on machine performance data from roadheaders. This assessment system utilizes measured data on thrust force by the roadheader, electrical energy consumed, machine vibration and excavation rate and it evaluates in-situ rock mass conditions objectively and quantitatively. It is shown that the estimated rock strength and elastic wave velocity of rock mass are in accordance with data from rock mass investigations, Point Load tests, and elastic wave exploration and it is effective in assessing rock mass conditions and rock strength at the tunnel face on real time basis.

1 INTRODUCTION

It is important to determine economic considerations as well as appropriate support systems on the basis of accurate assessment of rock mass properties during the construction of mountain tunnels. The tunnel face evaluation method is widely used in Japan for quantitative evaluation of stability by experienced engineers. However, the conclusions derived from evaluation of rock mass conditions and stability, using this method, differ from person to person even though the engineers are all very experienced. Therefore, these evaluations are somewhat subjective and require some improvements. The Japan Highway Public Corporation (JH) introduced a new tunnel face evaluation method. The JH system is a rock mass rating system, which relies primarily upon the following four general observation data related to rock mass strength: "compressive strength", "weathering", "spacing of joints" and "condition of joints" (Akagi et al., 2002). In this method, simple in-situ tests are performed on the rock obtained from the tunnel face to get a better grasp of the mechanical characteristics of the rock. A typical in-situ test may include one or more intrusive examinations, such as the Point Load test, Rock Schmidt Hammer test, etc. The compressive strength of the rock is estimated based upon historical data. Moreover, seismic explorations and core borings might be performed at the tunnel face, if deemed necessary. However, these tests may require interrupting tunneling work, while the tests are performed. Generally, the testing can be limited to small scale test instruments, in which case this process can be accomplished comparatively quickly. But, these tests cannot be performed when the rock mass at the tunnel face is fractured, due to the danger of falling rocks or collapse of the tunnel face. If the evaluation method used to determine rock properties is based upon real time data taken from roadheader operations, objective and quantitative rock mass conditions can be determined without interruption of the tunneling work. In view of this, the authors have developed a rock mass assessment system, which is based on machine performance data taken from roadheaders (Tsukamoto et al., 2002).

Excavation experiments were performed on mortar material to investigate the effects of machine performance data. In addition, the assessment system, which relies upon machine performance data from roadheaders, was applied to two tunnel sites. In this paper, the practicable effectiveness of this system is presented.

2 LABORATORY EXCAVATION EXPERIMENTS

2.1 *Overview of excavation experiments*

To clarify the relationship between machine performance data from roadheaders and rock mass strength, experiments were performed on mortar specimens with different compressive strengths. A roadheader with a milling cutting head with an electrical power rating of 65 kW and total weight of 22 tons was used for the experiment.

2.2 *Mortar specimens*

The size of the mortar specimens were 2 m (width), 2 m (height), and 1 m (depth). Table 1 shows the properties

Table 1. Properties of the mortar specimens.

Specimen no	Mass density (t/m^3)	Unconfined compressive strength (MPa)	Elastic modulus (GPa)
1	2.0	12.8	12.9
2	2.1	38.5	20.4
3	2.3	63.3	27.6
4*	2.3	63.3	27.6

*Contains 9 slits, which are 9 mm (thickness), 1.2 m (width), 0.8 m (depth).

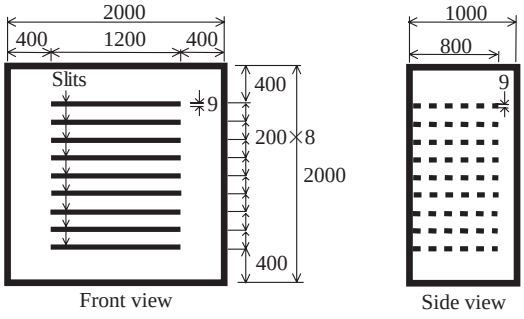

Figure 1. Overview of specimen No. 4 (Unit: mm).

of the mortar specimens. Specimen No.4 had the same unconfined compressive strength (63.3 MPa) as specimen No.3, but to simulate the effects of joint in the rock mass, nine slits were cut into the face of this specimen (see Figure 1).

2.3 *Procedure of the experiments*

The specimens were fastened to the reaction wall and floor by steel H-beams and steel rods (see Figure 2). Because the boom extension was limited to only 0.4 m, the experiments had to be performed in two steps. In the first step, the cutter performed its cutting operation until the boom was fully extended, whereupon the boom was retracted and the roadheader was advanced and the cutting operation continued to completion.

Measurements were taken for the cutter head motor current, penetration, thrust force and cutter boom acceleration. An accelerometer was attached to the boom casing and was used to monitor accelerations transmitted from the cutter head to the boom. The Root-Mean-Square (RMS) value was calculated by using boom acceleration data from the sampling frequency of 1 kHz.

2.4 *The results of the experiments*

The mean values, such as thrust force, electrical power consumption for cutting, boom vibration and

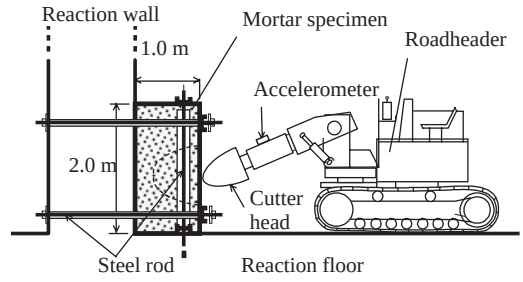

Figure 2. Overall view of excavation experiments.

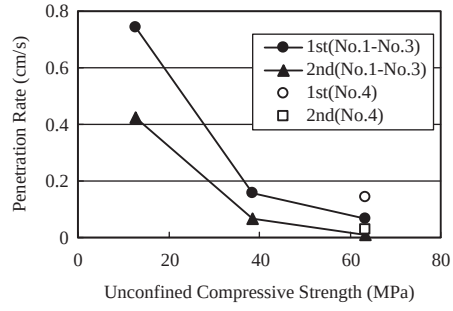

Figure 3. Relationship between penetration rate and unconfined compressive strength.

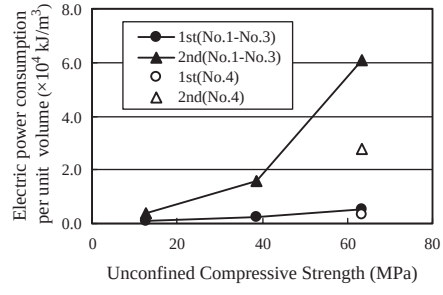

Figure 4. Relationship between electric power consumption and unconfined compressive strength.

penetration rate were calculated from measured data from the roadheader during cutting operations.

Figure 3 shows that there is an inverse relationship between penetration rate and unconfined compressive strength. Penetration rate decreases rapidly when compressive strength increases, because cutting time, per unit volume, is lengthened.

Figure 4 shows the relation between electrical power consumption for cutting, per unit volume, and unconfined compressive strength. Similarly, electrical power consumption tends to increase rapidly, when compressive strength is increased. Perhaps, specimen No.3, which had the highest compressive strength of the

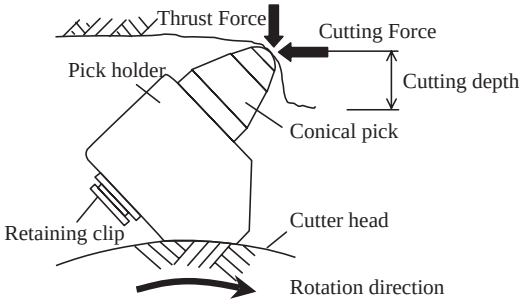

Figure 5. Bit of a cutter head cutting a specimen.

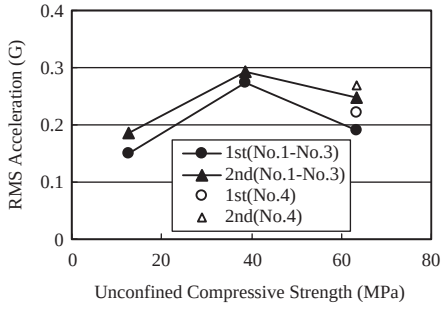

Figure 6. Relationship between RMS acceleration and unconfined compressive strength.

specimens, may have been at the strength limit for the roadheader's cutting ability.

Figure 5 shows the bit of a cutter head cutting a specimen. During normal cutting, the penetration rate is proportional to the cutting depth of the bit. And, it is a given that the cutting depth is related to thrust force and cutting force (Hurt et al., 1979). Cutting depth is inversely proportional to the compressive strength of the specimens, so that the cutting bit depth is deeper for lower compressive strength specimens (No.1 and No.2) and more shallow for higher compressive strength specimens (No.3 and No.4). In the latter case, since the output of the cutting motor was not consumed in cutting, the current decreased. However, the electrical power consumption per unit was increased, because the overall cutting time was lengthened, with very little cutting progress accomplished.

Figure 6 shows the relationship between the measured RMS acceleration of the boom vibration during cutting and the unconfined compressive strength of the specimens. From the results of cutting specimens No.1 and No.2, it is evident that RMS acceleration during cutting is proportional to increased compressive strength. However, RMS acceleration is inversely proportional to compressive strength for specimens No.3 and No.4, with higher strengths.

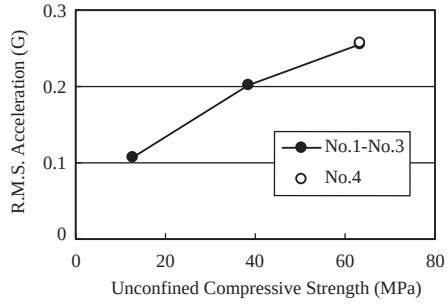

Figure 7. Relationship between RMS Acceleration and Unconfined Compressive Strength for a Penetration Depth of 10 cm.

Figure 7 shows that RMS acceleration is proportional to unconfined compressive strength given a constant cutting depth of 10 cm. It seems evident that it is not practical to continue excavation under conditions which result in shallow cutting depths. It is anticipated that RMS acceleration would be further increased for specimens No.3 and No.4 than for specimen No.2, where a very large thrust force was applied by the roadheader. The RMS acceleration and penetration rate for specimen No.4 was only slightly higher than for specimen No.3, even though slits in its face were present.

From the above results, it is evident that there is a correlation between RMS acceleration of the boom, penetration rate, and electrical power consumption per unit volume and unconfined compressive strength.

3 ASSESSMENT SYSTEM OF ROADHEADERS

The assessment system consists of the following three subsystems (See Figure 8).

1. A "Measurement subsystem" that automatically measures machine performance data with a measurement device installed on the roadheader. Various sensors that measure the current of the cutting head, thrust force, boom acceleration, etc., are installed on the roadheader. Control sequence devices are programmed to take measurements in the range of 1 kHz (for boom acceleration) to 10 Hz (for other items to be measured). The device can transmit the averaged measurement data at intervals of one second, wirelessly. At the same time, the data is saved to hard disk on a notebook computer. It automatically starts saving data, when the current value on the cutting motor exceeds a threshold level and continues to record data until the current falls below the threshold level for a fixed period of time (e.g., 20 minutes).
2. A "Face observation subsystem" that inputs the results of geological data, face observations and in-situ tests. Face rating values, which are determined

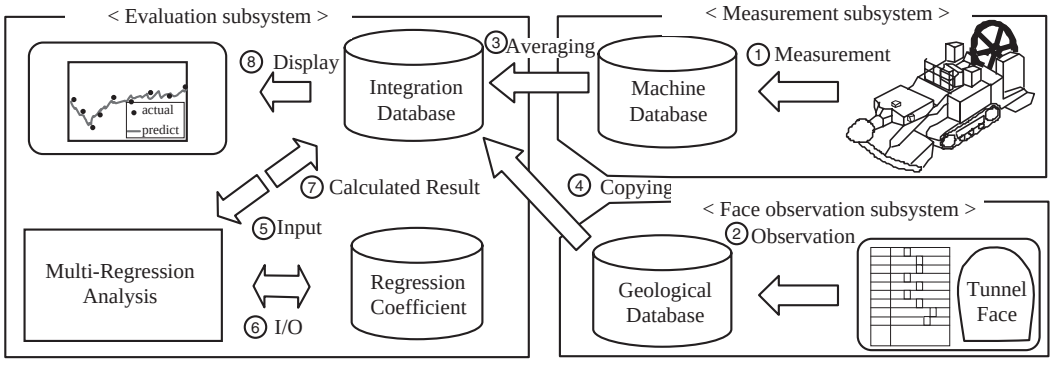

Figure 8. Assessment system of for a roadheader.

by tunnel engineers in the field, unconfined compressive strength estimated from Point Load tests or Rock Schmidt Hammer tests, after excavation, are inputted into the computer and stored in a geological database.

3. An "Evaluation subsystem" that evaluates geological conditions. The mean of the machine performance data from roadheaders, for each excavation cycle, is calculated for each item to be measured. The face rating and unconfined compressive strength are predicted by substituting the above noted mean value in the regression equation obtained through multiple regression analysis in advance. The regression coefficients, are adjusted to correspond to the amount of data accumulated in an early stage of the application. The face rating, unconfined compressive strength and elastic wave velocity of rock are calculated using the following equation.

$$y = a \times X_1 + b \times X_2 + c \times X_3 + d \times X_4 + e \qquad (1)$$

Where, y = face rating, unconfined compressive strength, elastic wave velocity; a, b, c, d, & e = regression coefficients, X_1 = electric power consumption to excavate a unit volume of rock; X_2 = thrust force of the cutter head; X_3 = RMS acceleration of the boom; and X_4 = excavation rate (cutting volume per hour).

Table 2. The contribution rate by multiple regression analysis.

4 SYSTEM PERFORMANCE EVALUATION

4.1 *Overview of application tunnels*

The JH system, which utilizes the measured data from roadheaders, was applied to the Takahara tunnel and the Yanbe tunnel, where the new face observation method had been adopted. The rock units of this site consisted mainly of rhyolitic tuff and rhyolite of Neogene Miocene epoch. Due to hydrothermal alteration and weathering, the tuff was in a softened condition. A boom-type roadheader with a cutting head power rating of 240 kW and total weight of 54 tons was brought to these sites. Moreover, the Point Load tests were examined by using the rock taken from the tunnel face, where deemed appropriate.

4.2 *Selection of independent variables*

Cutting electric power consumption, excavation rate, boom acceleration and thrust force were selected as independent variables, based on the results of excavation experiments. All possible regression methods were applied, and the case where the contribution rate, of the combination of the four independent variables was maximum, was calculated. The results of the contribution rate calculations for the Takahara tunnel and the Yanbe tunnel are shown in Table 2.

Because the contribution rate is maximum, when all the independent variables are used, the expression

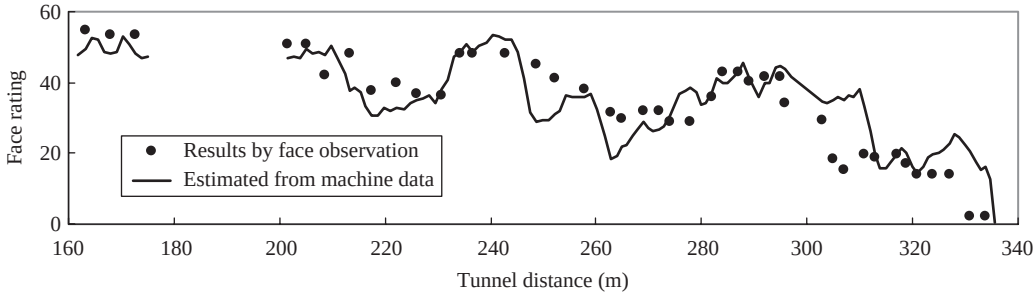

Figure 9. Comparison with face rating by face observation and estimated from machine data.

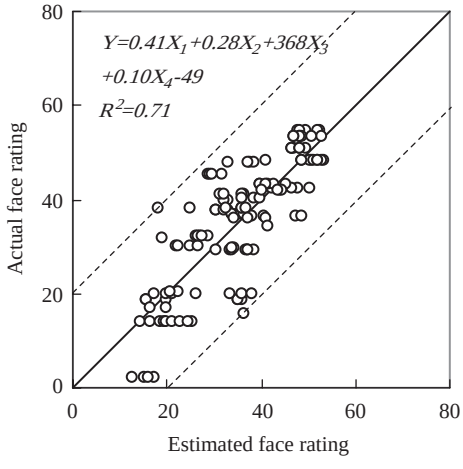

Figure 10. Estimated face rating from machine data and face rating by face observation.

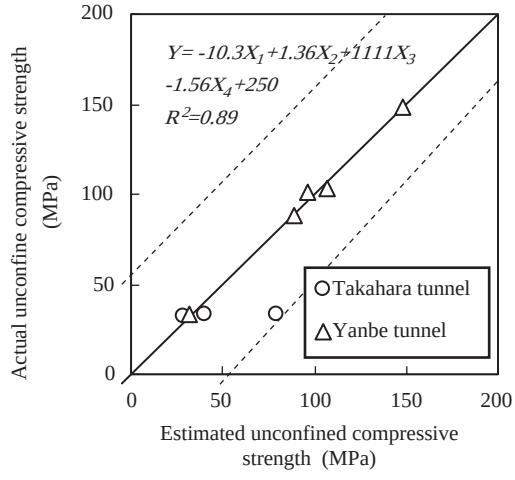

Figure 11. Estimated unconfined compressive strength from machine data and unconfined compressive strength by Point Load test.

shown in equation (1) is used for the regression analysis.

4.3 *Predictive performance of face rating calculated from roadheader machine performance data*

Figure 9 shows that estimated values from methods using machine data and from face observations were both in the upper 40's for the 165 to 175 m, 202 to 247 m, 286 to 289 m, and 293 to 296 m ranges. In addition, both methods showed a minimum value at about 335 m, indicating that these methods were in good agreement. Also, note that a higher face rating indicates a more competent rock mass.

Figure 10 shows the correlation between face rating values evaluated by the JH system and estimated face rating values calculated from roadheader machine data taken from the Takahara tunnel. We can see that contribution rate of regression is high (0.71) and the estimated face ratings are within the error range 2.5 Standard Error. This indicates that the predictive performance of the assessment system developed is reliable and practical.

4.4 *Predictive performance of unconfined compressive strength and elastic wave velocity*

Although there were relatively few samples, the assessment system may be verified by using the results of in-situ tests. More specifically, a multiple regression analysis can be performed, with unconfined compressive strength and elastic wave velocity as dependant variables, and the four machine data values in equation (1) as independent variables.

At the locations selected on the Takahara and the Yanbe tunnels, Point Load tests were performed on rock obtained from the face and the unconfined compressive strength was estimated using the failure load of the rock. Since, the contribution of regression was large (0.89), it was determined that it reliably predicted unconfined compressive strength based upon machine data from roadheaders (Figure 11).

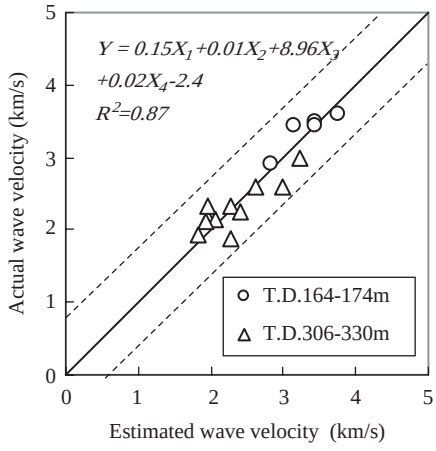

Figure 12. Estimated wave velocity from machine data and wave velocity by seismic exploration.

Seismic explorations were performed at two locations in the Takahara tunnel, primarily due to the presence of hard tuff, from 164 m to 174 m, as well as the presence of weathered, very soft tuff from 306 m to 330 m. The elastic wave velocity of hard tuff is 1.8 km/s to 3.0 km/s and that of very soft tuff is 2.8 km/s to 3.8 km/s. A multiple regression analysis was done based upon machine data measured at the same locations as the seismic explorations. The contribution of regression was high (0.87) and its estimation reliability was found to be in good agreement with the elastic wave velocity (See Figure 12). The contribution rate of unconfined compressive strength and elastic wave velocity are higher than the contribution rate of face rating. And, the data shown in Figures No.11 and No.12 show less scattering than those in Fig. 10. This indicates that the results of unconfined compressive strength and elastic wave velocity provide an objective assessment of the properties of the in-situ rock. In contrast, face ratings, which involve error by face observers, are a less reliable means of assessment. Therefore, the use of objective information obtained from roadheader machine data is more effective for the reliable evaluation of tunnel face ground conditions.

5 CONCLUSIONS

This rock mass assessment system, was developed to analyze real time data from roadheaders, which are commonly used in tunnel excavation, to accurately predict rock mass conditions at the tunnel face, without interrupting the progress of work during construction. It was confirmed that this system has sufficient accuracy to be effectively and reliably used to evaluate in-situ conditions during construction. Furthermore, this system may be further developed to be used for the assessment of rock mass properties. The following conclusions can be drawn from the results obtained in this study:

1. Boom acceleration is increased with increased compressive strength of rock at tunnel face. However, when the cutting performance of the roadheader is inadequate, boom acceleration is reduced.
2. It was confirmed that this assessment system can reliably predict rock mass properties at tunnel face from the results of multiple linear regression analysis using four independent variables for machine data taken during one excavation cycle of tunneling work.
3. It was demonstrated that the predictive reliability of this assessment system, which uses unconfined compressive strength from Point Load tests and the elastic wave velocity from seismic explorations, exceed the reliability of other assessment systems, which rely upon determining face ratings from evaluation of observations of the tunnel face.
4. It was also demonstrated that the application of this assessment system, based upon objective machine data was effective and reliable as compared to a face rating assessment system, which is subject to personal and estimation errors by tunnel engineers.
5. The operation of the system begins by determining a correlation coefficient for the roadheader from historical data collected at an earlier stage of tunnel construction. However, the same correlation coefficient cannot be applied to different types of roadheaders. Subsequently, it is necessary to assess the correlation coefficient and confirm the presumption accuracy.

Deep tunnelling in hardrock with large diameter TBM: What's up? An experience from the Gotthard Base Tunnel

I. Vicenzi, S. Pedrazzini, A. Ferrari & G. Gubler
Lombardi Consulting Engineers Ltd., Minusio, Switzerland

O. Böckli
Implenia Ltd., Aarau, Switzerland

ABSTRACT: In the driving of underground openings, two main factors are to be borne in mind. First, the existence of failed rock and second, the control of displacements. The general problem devolves into questions of excavation geometry, sequence and support specification while adverse performance of the rock mass in the post-excavation stress field may be caused by either failure of the medium or slip on the weakness planes. During the excavation of the southern section of the Gotthard Base Tunnel, the rock mass response to TBM tunneling activities described unusual magnitudes of displacements in so far as the thrust of the machine couldn't overcome the shield's frictional forces. A smooth-blasting technique was implemented so that pressures on it went back to a sustainable magnitude. This paper describes how appropriate design and contractual approach are critical in assuring both efficient geomechanical and economic performance of hardrock tunnelling by large diameter TBM.

1 INTRODUCTION

1.1 *The new Gotthard Base Tunnel Project*

By constructing the New Rail Link through the Alps, Switzerland is integrating itself into the growing European high-speed network. AlpTransit Gotthard Ltd. – a completely state owned subsidiary of Swiss Federal Railways charged with the overall planning and supervision of the construction works of the New Rail Link on the Gotthard axis – is creating a flat rail link for future travel through the Alps.

At the heart of the new transalpine rail route is the world's longest tunnel – the 57 km Gotthard Base Tunnel – whose highest elevation at 550 meters above sea level is much lower than the highest point of the existing route through the mountains at 1,150 meters, so that gradients will be no steeper accordingly to those of a modern high performance rail link making freight transportation more productive, while passenger traffic benefits from massively shorter journey times.

In 1995, after intensive political, financial and technical studies of several options the Swiss Federal Council approved the plan for the Gotthard Base Tunnel and spoke in favor of a tunnel system with two single-track tunnels. The two rail tunnels are about 40 meters apart and joined approximately every 3,125 meters by connecting galleries. Two double crossovers allow trains to change from one tunnel to the other – which may be necessary to allow maintenance work if an accident occurs. Trains can switch tunnels in the multifunction stations which also house ventilation and technical equipment, safety and signaling systems, as well as two emergency stop stations which are directly linked by separate access tunnels.

Other then the two portals, intermediate headings provide additional accesses to the tunnel from above (shafts) and from the sides (adits), shortening also the construction time and dividing the tunnel into five sections: this paper focuses on the southern section of Bodio.

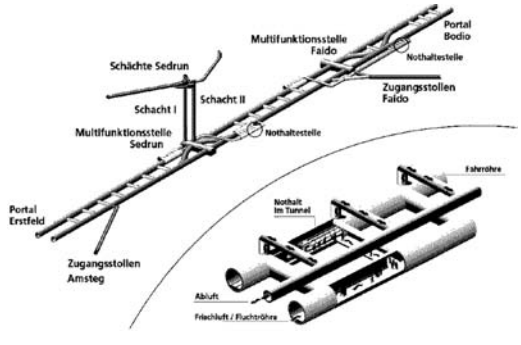

Figure 1. Gotthard Base Tunnel. Tunnel systems with shafts and adits.

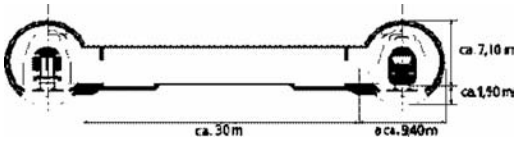

Figure 2. Typical cross section of the two twin tube tunnel in the section of Bodio.

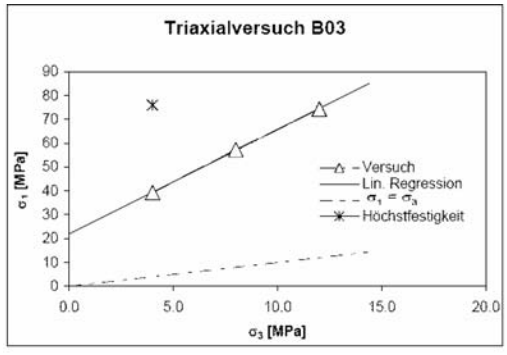

1.2 *Site description*

The section of Bodio is located in Southern Switzerland (Ticino) at the southern portal of the tunnel. This section is the longest one of the Gotthard Base Tunnel. To allow faster construction of the underground assembly caverns for the TBM, a bypass tunnel was driven out round the site of the portal. From the assembly caverns, two 400 m long – complete driving unit with backup train – open gripper TBMs with a diameter of 8.9 m started driving north towards the next section of Faido in 2003: the length of the TBM driven tunnels reaches 13.4 km in the eastern tube respectively 14.1 km in the western tube, the headings facing steadily an uphill gradient of 7‰. The Breakthrough is expected in the "multifunction station" 16 km from portal.

1.3 *The event at chainage 13,692 EST W*

The sensitivity of large diameter TBM to adverse rock mass conditions has been a major issue since the very beginning of the design and tendering stages of the Gotthard Base Project; in view of the crossing of zones allocated to the poorest excavation classes accordingly to the contract specifications, the owner commissioned TBMs with reaming equipment by pull-out cutters fitting the driven diameter up to 30 cm over the standard one. The sensitivity of the TBMs was particularly well highlighted by the event occurred in the western tube at ch. 13,692 (2006, March 3rd), where unusual large displacements brought – even without evidence of major failure of the surrounding rock mass – one of the two TBM – the so called West TBM – to be overcome by the frictional forces acting on the short front shield while the second one could pass throughout the same ground unit without getting blocked as well.

This paper presents an attempt to quantify and understand both the records and the limitations in poor ground related to the response of the managing TBM's operator – as well as the importance of reaming opportunities – by driving through low quality rock masses on the basis of the experience of the above-mentioned event; moreover, the importance of both appropriate design and contractual approach for achieving efficiency in geomechanical and economic performance by TBM tunnelling is showed by the same case study.

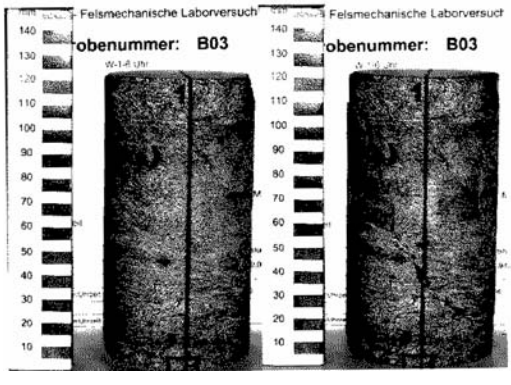

Figure 3. Core sample recovered in the near field of the jammed West TBM before (left) and after (right) lab test.

2 GEOLOGY AND POTENTIAL MODES OF OPENING BOUNDARY FAILURE

2.1 *General geological and geomechanical data*

The section of Bodio lies in the hard rock formations of the Penninique gneiss, which are typical of southern Switzerland. The geological longitudinal section shows at the location mentioned in 1.3 a biotite rich gneiss with prominent sub-horizontal weakness planes with relatively low shear strength compared to that of the intact rock; the overburden at the same location slightly exceeds the km mark.

Average geotechnical parameters of intact rock were determined by a large series of triaxial compressive tests carried out by the lab of the Federal Institute of Technology in Zurich on core samples recovered in the near field of the jammed West TBM: Young's modulus ranging around 10 GPa, uniaxial strength ranging from 5 MPa to 35 MPa. The mechanical properties of the weakness planes of the intact rock were also assumed on the basis of the same lab tests, i.e. cohesion $C' = 1{,}200$ kN/m^2 and friction angle $\phi' = 32°$.

Volumen [m³]	<0.001
Höhe [m]	<0.5
Gewicht [to]	
KS	225-057 /0-85
K I+ II	150(320) /89
K IV	045-070 /80-85
K III + V	220-230(050) /80-85

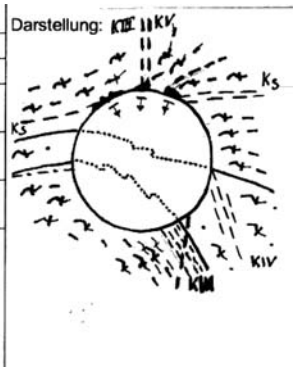

Figure 4. Tunnel mapping and potential modes of boundary failure reported for the western tube from ch. 13,569 to ch. 13,743.

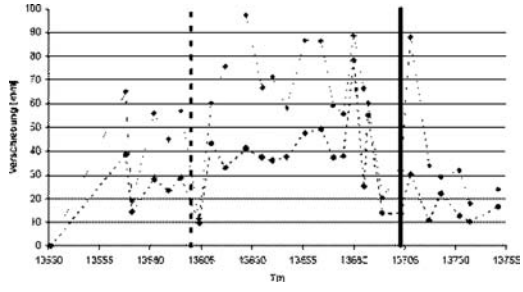

Figure 5. Total measured convergences of the opening between ch. 13,530 and ch. 13,755. Zero measure was taken 4 m from the heading. Rock support already set. The figure shows largest (max. 10 cm) and medium (max. 8 cm) displacements lines, i.e. from 5 points.

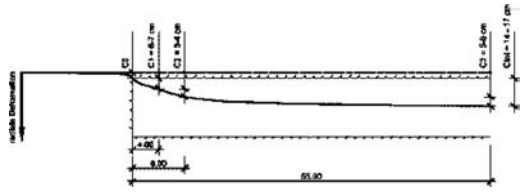

Figure 6. Schematic representation of the progression and extension of the roof displacements between ca. ch. 13,600 and ca. ch. 13,700: ca. 7 cm (40% of the whole displacement) at 4 m from heading, ca. 10 cm (60%) at 8 m from heading and finally ca. 17 cm at 55 m from heading.

2.2 *Potential modes of rock mass failure*

Following the two main factors mentioned in the abstract for designing the rock supports, particular attention has been given to ensure that large, uncontrolled displacements of excavation peripheral rock couldn't occur in order to satisfy the tunnel duty requirements, such as minimum dimensions required both for excavating equipment as well as for the minimum clearance of the mined section. The first main factor – major boundary failure – could be neglected due to the fact, that around chainage 13,692 no one was reported; nevertheless, the effect of any major discontinuities which will transgress the excavation has been examined by consideration of both the general effect of the structural features on boundary stresses and local stability problems in the vicinity of the discontinuity/ boundary intersection. These considerations educed support design adjustments to achieve simultaneous satisfaction of local and general stability conditions for the excavated perimeter near chainage 13,692.

The potential mode of boundary failure is depicted in Figure 4, where the banding (i.e. K_s) running with sub-horizontal banding is showed. Local phenomena of minor parting or slabbing couldn't be excluded if two or more families of joints (i.e. K_I to K_V) come to intersect each other.

The mapping of the tunnel sets forth the bent of that geological unit to large displacements; this feature has been then confirmed by monitoring the behavior of the rock mass surrounding the tunnel; in fact, the largest displacements were measured between chainage 13,595 and chainage 13,695 (Figures 5 and 6, western tube).

It is important to note that, the possibility to comfort the opening with rock support is not given before the end of the short TBM shield, i.e. at 4 m from the heading, where over 40% of the total displacement has already took place. In other words, the pre-mining stress field came to be disturbed in a quite large extent before any opportunity to control it by rock support were given.

2.3 *Rock support*

The adverse performance of the opening boundaries in the post-excavation stress field illustrated in the previous chapter were mainly caused by slipping on the pervasive weakness planes while a few sloughing due to induced tensile stress exceeding the strength of the rock occurred.

The opening reinforcement was defined in the attempt to reach as soon as possible a stable equilibrium between the rock mass and rock supports by placing the reinforcement close to the TBM short shield soon after excavation. Heavy rock support consisting of blocked steel sets (TH 29 each meter, all around) combined with a wire mesh and two layers of shotcrete (first layer of 9 cm, second layer of 5 cm, both sprayed on 260°) were installed for a maximum stiffness of the reinforcement.

Although heavy rock supports were installed, evidence of suffering from the disadvantage of a poor stiffness by the blocking points of the steel arches, where overlapping of two neighboring elements often

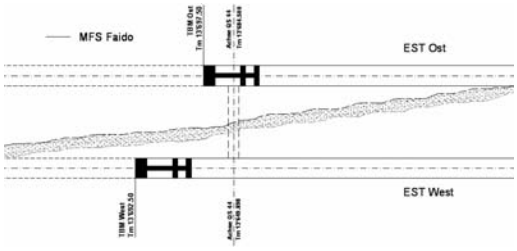

Figure 7. Layout of the heading progress of both TBMs on 2006, March 3rd.

happened, as well as from failure by sideways buckling were reported.

3 TBM JAM AT CHAINAGE 13,692, WESTERN TUBE

3.1 *TBMs working progress*

On 2006, March 3rd the western TBM reached chainage 13,692 before getting blocked by the rock mass pressure acting on the short TBM shield; in fact, the machine was no more able to overcome the frictional forces solely with its own thrust. By that time the eastern TBM was progressing at chainage 13,698. The actual distance between the advance headings came to 40 meters (ch. 0 milestones slightly differ each other, of exactly 34,612 m); nevertheless, no mechanical interaction between the openings could be evidenced confirming thus the general rule saying that the zone of influence of one opening lies outside one another's when the distance between their centers is $D_{I,II} \geq 6r$ where r is the opening's radius (ideal case, hydrostatic stress field).

A fault striking the tunnels with an acute angle and dipping almost vertical was intercepted coming from east and going straight westwards was feared to influence the behavior of the tunnel system in addition, of course, to those to the single tubes. The fault, consisting of a strong weathered, loose material with a thickness of in the m range, hit the two tubes in a distance of about 300 m.

Accordingly to a back analysis carried out by a 2D-model using both a FLAC code and the characteristic curve method, the influence of that fault would have significantly affected the pre-mining stresses field around the western tube so far as the fault location reached the centerline between the two tubes. One can take also reference to Figure 5 again, where the left vertical line points out the chainage – respectively the displacements – by which the fault was located at 3 m away from the tunnel sidewall while the right one do the same for the fault location in the middle

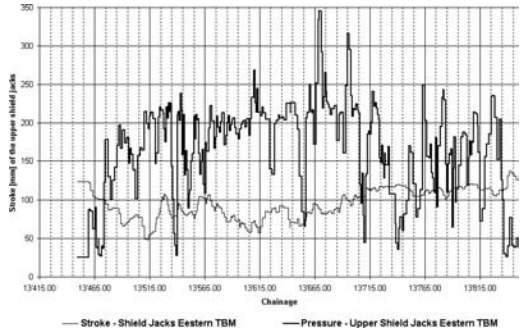

Figure 8a. Stroke vs. pressure in the upper shield jacks of the eastern TBM.

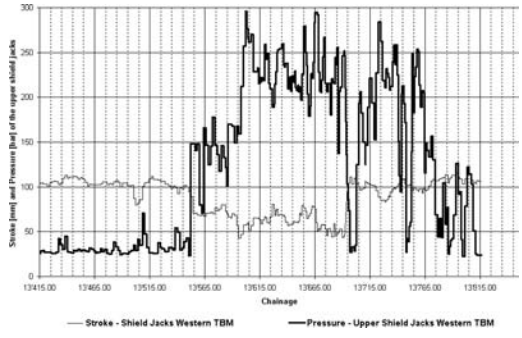

Figure 8b. Stroke vs. pressure in the upper shield jacks of the western TBM.

distance between the tubes: from this location on, the displacements clearly decrease due to the fact, that the influence of the fault is vanishing.

3.2 *TBMs crossing of the zone with large displacements*

Both TBMs are equipped with automatic data log instrumentation recording a wide range of operating parameters, mostly of which are directly related to the steering system of the TBM: of particular interest are then the data of the thrust cylinders and that of the shield jacks which supply informations about the advance of the TBM as well as the encountered rock mass pressures. Such data are recorded online by the contractor and delivered to the site engineer in real time.

The site engineer disposes of a code named SISO, which first selects the useful ones and in a second stage processes them; as a result, the whole operation's track is stored in a data bank and ready for the rendering as graphs or in tables.

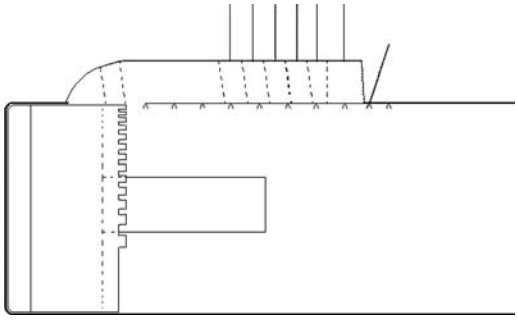

Figure 9. TBM recovery.

By comparing several data coming from the TBM, the stroke's progression of the jacks moving the upper part of the TBM shield in function of the time delivered the most feasible explanation for the jamming occurred only to the western TBM at chainage 13,692 while the eastern one could successfully manage the similar bad conditions, this with although reported damages of the jacks of the shield ant of the shield itself.

The TBM guidance on the vertical and horizontal planes basically results from the control of two sets of elements: the grippers and the shield. By adjusting them the operator can drive the TBM accordingly to the given alignment as well as reacts in case of troubles, that's for instance when the ground collapses underneath the gripper or soft rock formations let the cutting head to depart from the horizontal plane.

Seemingly, the western machine entered the difficult zone, characterized by unusual large displacements, with the strokes of the shield jacks being more or less just half way extended (ca. 70 mm out of 150 mm of the total stroke). By the sudden increase of the rock mass pressure – topping 300 bar on the shield jack gauge – the only way let to the operator in order to shift away from such a zone is to lower the upper part of the shield and release then the frictional forces on it. This procedure is usual successful in the short period but not if the extent of the zone is important; in fact, the stop line of the jack is quickly reached. From this point on – if a natural release of the rock mass pressure does not take place – one has to overcome then by other methods.

3.3 *Western TBM recovery*

Contractor, designer and the site engineer agreed to recover the jammed TBM by taking back the rock pressure to a sustainable magnitude. The implemented technique was based on firing shotholes in short sequences in the upper part of the TBM (smooth blasting). The recovery lasted about 10 days.

4 DISCUSSION

4.1 *The importance of the contract*

The contract governing the project is a fixed price one, ruled also accordingly to Swiss construction standards such SIA 118 and 198.

The contractor accepted with its tender the risks for stipulated sum or rates nominated in its bid. However, provisions for adjustments have been included; in particular, the risk of a diverting, unexpected geology and delays caused by the owner are compensated to the contractor.

Provisional items, which also are a part of the contract, allow to cover works for which complete details were not known at the time of tendering without creating new ones. Time related costs are covered by separated items offered by the contractor with its bid, so that unexpected variations of order could easily, upon agreement, be integrated in the contract.

That's to say, the unexpected additional works caused by the recovery of the TBM could be well managed by the existing contract in case of agreement on the liabilities.

4.2 *The importance of the TBM data logs*

More attention should be paid to the interpretation of the TBM parameters in real time. This should be true at any level of the operation's management and should be achieved by a more intensive education of the involved technicians.

Contractor and site engineer should take more advantage of the possible fine tuning of the TBM operations, especially in adverse conditions, accordingly to the long learning curve which long lasting, well monitored projects allow.

4.3 *What about reaming?*

Reaming has been a major issue from the very beginning of this project; in fact, the contract specifications included the opportunity to shift the cutting head of the TBM for 15 cm in radius – on short sections going through the mapped faults for some 200 m in accordance to the contract – for overcoming adverse rock mass conditions requiring a thicker reinforcement and enough comfort for controlled displacements. Accordingly to the literature, no successfully reaming hasn't yet been carried out in crystalline hard rock.

Actually, any attempt to reaming up to 30 cm in diameter on the section of Bodio failed since the beginning of the operations because of technical problems. Those problems were considered to be insuperable from both the technical and the contractual point of view. As a result, the contractual parties agreed to close any dispute: the owner abandoned the request accepting an equitable technical proposal for replacing

reaming – shift of 10 cm in diameter – along with a fair price adjustment.

5 CONCLUSION

The accident occurred to the western TBM driving the longest section of the Gotthard Base Tunnel would cause delay and extra costs due to the compulsory stop of the operations.

It is not the goal of the authors to argue hereby on the liabilities of the contractual parties.

The goal of the paper is to incentive the discussion on the way to improve TBM operations in deep, long tunnels taking benefits from the experiences learned on the Bodio site and, last but not least, to generally question the ones involved in full face, mechanized tunnelling: still reaming a challenging issue for hardrock TBM manufacturers or is just a designer's chimera?

ACKNOWLEDGMENT

The authors cordially thank Mr. Stefan Flury, head of the AlpTransit Gotthard Ltd. for the section of Bodio, for his appreciated cooperation and review of the paper as well as AlpTransit Gotthard Ltd. in Lucerne for giving us the permission to publish it.

Laboratory tests for EPB tunnelling soil conditioning

R. Vinai, D. Peila, C. Oggeri & S. Pelizza
Tunnelling and Underground Space Center – Dept. of Land, Environment and Geotechnology, Politecnico di Torino. Italy

ABSTRACT: The screw conveyor system plays a fundamental role during the EPB tunnelling operations for the tunnel face pressure control. On the other hand, the use of additives such chemical foams is even more applied in order to extend the EPB technology to the cohesionless soils. Despite the extensive use of the EPB technique in urban environment, little knowledge exists in the understanding of the behavior of such conditioned soil during the excavation operations. At the Turin University of Technology the Tunnelling and Underground Space Centre, in the mainframe of a wider research on soil conditioning, has developed an experimental apparatus that simulates the extraction phase with screw conveyor from a pressurized tank. In this paper the apparatus is presented and the results of a first series of tests carried out on sand are discussed.

1 INTRODUCTION

EPB tunnelling in the last years has experienced a great increase in the number of applications and it can be considered the most used technology of mechanized tunnelling in urban area, challenging the primate of slurry shield both for size and field of applicability. This has been possible from one side thanks to the mechanical development that brings even more power on the TBM, from the other thanks to the more effective use of additives (foams, polymers, bentonite, fillers) injected in the soil and in the bulk chamber, following the practise that is currently named "soil conditioning".

Since the application of such conditioning agents is relatively recent, a little experience on the use of them is achieved, particularly from the research point of view. In fact there have been a few studies concerning on this issue: Peron & Marcheselli (1994) report the first case of foam injection in Europe with the Milan Passante Ferroviario project in Italy; Maidl (1995) in Germany and Quebaud (1996) in France exploit this subject giving the first quantification of the effect of the foam when mixed with soil. Other interesting contributions can be found in Bezuijen et al. (1999), Herrenknecht & Maidl (1995), Jancsecz et al. (1999). Milligan (2000) gives the mainframe in which all the researches on the soil conditioning are organized and reports the state of the art. EFNARC (2005) also provides some guidelines for the use of conditioning products and their characterization. More recently, Mair et al. (2003) carried out studies on the effect of foam and polymers on the London Clay using a special experimental apparatus that simulates the extraction of material from a pressurized tank by means of a screw conveyor. An apparatus with the same features has been used by Peña (2003) at the Oxford University for the assessment of foam effects on fine and medium sand.

In this frame a research on the effects of conditioning on soils, developing a screw conveyor experimental apparatus able to apply relatively high pressure in the chamber, to better simulate the effects which are present ahead of a EPB machine was developed (Vinai, 2006; Gallina, 2006; Vinai et al., 2006). The description of the built up device and the used test procedures are described to explain their vantages and disadvantages and the results obtained from tests carried out on a medium sized sand are analyzed and discussed in the following sections to focus the applicability of the proposed test procedure for the choice of the optimum conditioning when EPB tunneling in cohesion-less soil.

2 DESCRIPTION OF THE EXPERIMENTAL DEVICE

2.1 *Screw conveyor system description*

Starting from the experimental system and procedure developed in Oxford as well as in Cambridge (Mair et al., 2003; Peña, 2003) it is clear that only a test able to simulate the complex EPB operation that involves both the conditioning of the soil but also the interaction with

Table 1. Transducer description.

Number	Description	Type	Range
1	Displacement wire transducer	Potentometric	0–1000 mm
2, 3	Pressure cell	De-aired liquid pressure	0–500 kPa
4, 5, 6	Pressure cell	Load cell	0–500 kPa
7	Torque meter	Slip ring contacts	0–500 Nm
8	Scale	load cell	0–50 kg

machine-member for the extraction operation would be really significant for the mix (soil + conditioning agents) behavior understanding.

It has also been observed that, in order to extend the tests on gravely soils and to try to obtain a relationship between the test results and real size excavation data, it would have been necessary to construct a large-sized system, follow the real geometry of the screw position and measure the same data recorded on a real scale EPB.

The apparatus has been designed and constructed to fulfill these goals: it consists of a iron tank 800 mm height with an outer diameter of 600 mm, on which an aluminum plate 40 mm thick fits. The plate is then connected to a hydraulic cylinder, with a stroke of 500 mm, driven by a hydraulic pump with a maximum pressure capacity of 400 bars.

The 1500 mm long screw conveyor is coupled with the tank with an inclination of 30° on the horizontal line. The inner diameter of the screw case is 162 mm, the flights have a pitch of 100 mm, and the screw shaft is 60 mm diameter. Following safety considerations, in order to avoid the possibility for the operator to be injured by accidental plate movement while working around the charging point of the tank, a metal grid has been placed around the tank, which interrupts via a micro-switch the power supply of the hydraulic pump is the hydraulic cylinder is started before rising it up to protect the connection between the plate and the tank. The screw is equipped with a three-phase motor with an installed power of 1.1 kW, coupled with a mechanical gear that gives screw rotation speeds between 6 and 15 rpm.

2.2 *Data acquisition system description*

In order to monitor the test parameter the sensors described on Table 1 were installed on the device while figure 1 shows the complete system and the sensor positions.

The transducers are connected with a pc-driven data logger. Signal conditioning, real time visualization, sampling and data memorization steps are executed through a specific software, supplied by the data logger constructor.

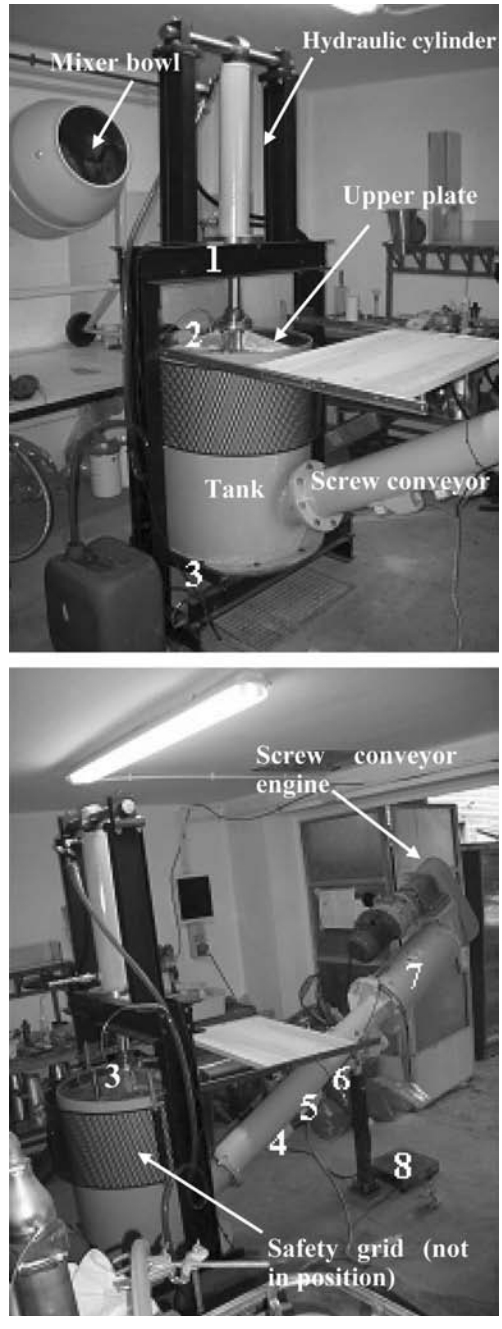

Figure 1. Experimental apparatus views where the numbers refer to the installed transducers.

2.3 *Foam generator system description*

The foam is obtained from an industrial generator redesigned for lab purposes. The generation unit

allows the control of the liquid flow (maximum flow 15 l/min) and air flow (maximum air flow 150 n.l/min), as well as the electronic control of the foaming agent concentration. The required expansion ratio can be achieved by the regulation of both fluid flows. The system is completed with an air compressor and a collector tank (Figure 2).

3 CARRIED OUT TESTS AND RESULTS

3.1 *Procedure description*

The tests are carried out following this procedure: a certain quantity of sand (approx. 25 kg), with defined moisture, is placed into a concrete mixer and the required amount of foam is added into the mixer bowl. As soon as the mix is ready (according to the operator check) it is poured into the tank and this operation is repeated until the tank is full (about 330 kg of sand required for each test). Subsequently the plate is positioned and pushed down by the hydraulic cylinder until the test pressure in the tank is reached. The screw conveyor is then started and the material is collected at the discharging point of the screw where it is weighted. The test is stopped when the hydraulic cylinder reaches its maximum stroke. Slump tests on the material coming out from the screw as well as on soil sampled in the tank at the end of the test are carried out in order to check the final plasticity of the material. The duration of each test, saving the loading phase, is about 15–20 min.

3.2 *Test operative conditions*

In order to assess the effects of foam on a medium graded sand with the grain size distribution shown in Figure 3, several tests have been carried out with different values of moisture, Foam Injection Ratio (FIR – as defined for example in Milligan, 2000) and pressure applied in the tank. The used conditioning agent was a commercial foam agent.

Here the results coming from six tests, respectively three on saturated sand without additives and three on conditioned sand, are presented and discussed. The conditioning parameters were defined after a specific study carried out by means of slump tests and mixing tests, varying systematically the water content (w) and the FIR. This test campaign allowed defining the optimum conditioning settings. Therefore the tests with the screw conveyor apparatus were carried out to compare the best conditioning with nil to focus the advantages of the additivation.

The following parameters were used in this set of tests: $FIR = 40\%$, $w = 10\%$ while the screw conveyor was set for a rotation speed of 6 rpm which is close to the one normally used in the EPB machines.

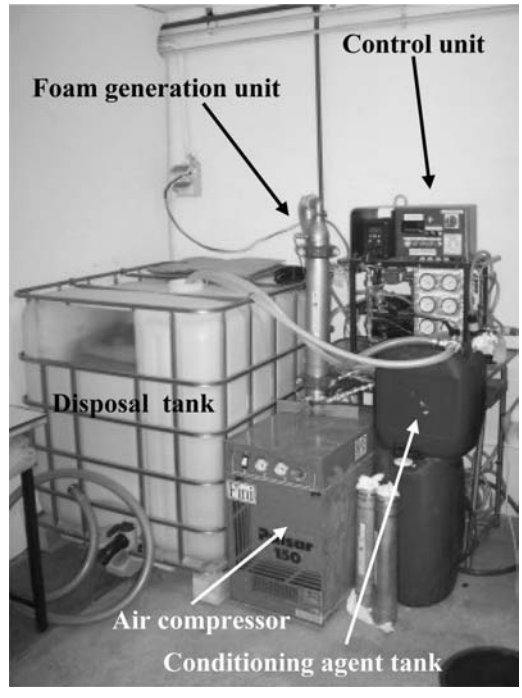

Figure 2. Foam generator equipment.

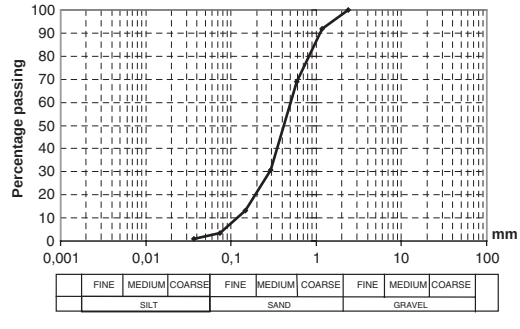

Figure 3. Grain size distribution of the sand used for the tests.

3.3 *Results and comments*

The efficiency of the conditioning can be verified through the analysis of several monitored parameters in the screw conveyor apparatus:

- the pressure distribution into the tank,
- the required torque,
- the displacement gradient,
- the discharged weight gradient
- the trend of the pressure along the screw conveyor.

The obtained results are summarized in Table 2.

The analysis of the pressure transmission in the tank indicates that in case of conditioned soil the material

Table 2. Summary of the results obtained from the tests on saturated and conditioned sand.

Test #	Theoretical pressure [kPa]		Measured pressure [kPa]		Torque [Nm]	∂disp. [mm/s]	∂weight [kg/s]	Cell 1 [kPa]	Cell 2 [kPa]	Cell 3 [kPa]
	Top	Bottom	Top	Bottom						
S1 saturated	60	75	N.A.	N.A.	35–45	0,299	0,159	6–8	4–6	2–4
S2 satuarated	90	105	150–230	110–120	30–40	0,327	0,137	4–8	4–6	2–4
S3 saturated	90	105	90–150	75–85	35–40	0,283	0,145	4–6	7–9	2–4
C1 conditioned	30	45	35–40	45–50	6–8	0,517	0,215	15–20	12–15	4–6
C2 conditioned	90	105	80–95	90–100	6–10	0,546	0,183	20–23	12–14	4–6
C3 conditioned	90	105	60–80	60–80	8–10	N.A. (0,431)	0,193	23–28	12–17	4–7

Key: Theoretical pressure = pressure in the tank derived from the pressure in the cylinder. Top and Bottom cells should differ, for the weight of the material acting on the bottom one, by about 15 kPa; Measured pressure = pressure measured by the cells located respectively on the top and on the bottom of the tank; Torque = torque acting on the shaft of the screw conveyor; ∂disp. = gradient of displacement of the plate; ∂weight = gradient of the weight recorded by the scale; Cell X = pressure cell on the screw case (cells numeration goes from the closest to the most far from the tank).

is far more homogeneous and plastic, whereas in case of saturated sand the material is too stiff and is not able to transmit properly the stresses in the tank (Figure 4).

In the latter case the top pressure is higher than the bottom one, and it is even higher than the maximum theoretical one.

This might be due to the partial reduction of the contact area between plate and sand from the theoretical section, because the material doesn't flow homogeneously under the plate and the sensor encounters a stiffer area. The torque is dramatically reduced in case of conditioning. The value in stationary conditions falls between one fourth to one fifth of the value recorded for the saturated sand. It is also to be pointed out that the diagram becomes smoother for the conditioned sand, whereas for the saturated sand periodic peaks, related to the screw rotation speed, are visible (Figure 5). The displacement gradient shows a higher speed for the downward movement of the plate in the case of conditioned sand: this means that the screw conveyor increases its efficiency, since more material is extracted during the same time interval.

This aspect is less evident analyzing the extracted material weight gradient, because the saturated sand is heavier than the conditioned sand, therefore less quantity of material gives similar weight.

Finally, the analysis of the pressures along the screw case shows clearly that the conditioned material is more able to transmit pressure, as well as that the screw is completely filled with material: the value recorded by the cell closest to the tank is of the same magnitude of the pressure in the tank and it is clearly visible the pressure fall along the screw (Figure 6). The same is not observable for the saturated sand case, where the pressures are low and similar along the entire case and periodic peaks, due to the effect of the screw flights on the cells, are evident.

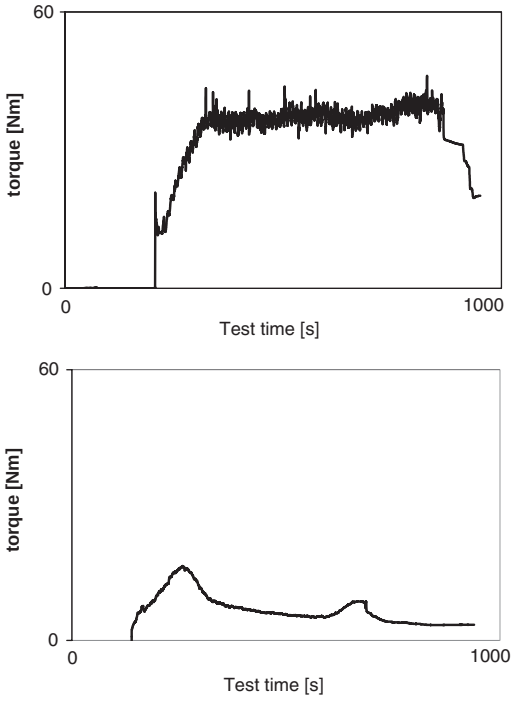

Figure 5. Torque required for the screw conveyor. Upper diagram: saturated sand. Lower diagram: conditioned sand.

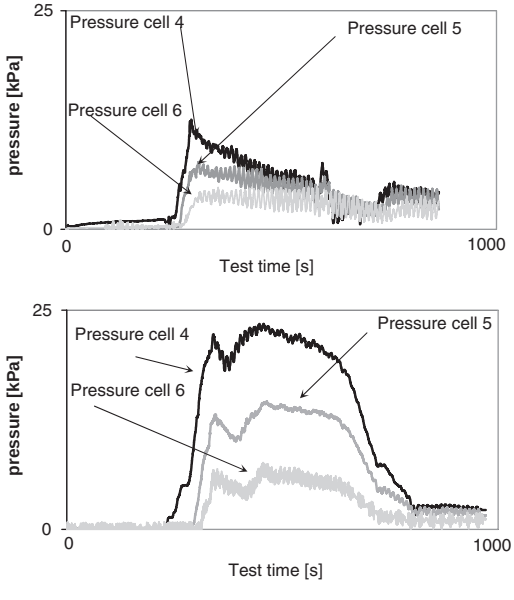

Figure 6. Pressures measured along the screw case. Upper diagram: saturated sand. Lower diagram: conditioned sand.

4 CONCLUSIONS

The soil conditioning is nowadays a crucial task for EPB tunneling application, because of the huge diffusion of this method even soils previously thought not suitable are now excavated using EPB machines with a systematic soil conditioning with foam and polymers. It is therefore very important to define some feasible and reliable laboratory test procedures able to improve the understanding in the design stage of the conditioned soil behavior rather than slump test only, which is one of the most used test.

A reliable test procedure, that might be used for this goal, foresees the extraction of conditioned soil from a pressure chamber with a screw driver thus allowing the measurements of many parameters which are very close to the real behavior of an EPB machine.

A device with a screw conveyor device that simulates the extraction phase from a pressurized chamber has been designed and constructed to study the effect of conditioning on cohesion-less soil. The obtained results, from a tests campaign carried out on a medium sized sand, show that this device is efficient to study the effects of foam conditioning of the soil. Particularly some monitored parameters, like the pressure distribution into the tank, the required torque, the displacement gradient, the discharged weight gradient and the trend of the pressure along the screw conveyor, are good markers for the definition of the conditioning quality, since differences are evident between conditioned and non-conditioned sand tests.

3D geo-modeling for spillway tunnel construction in the complex fault region

W.S. Yoon & U. Jeong
NEXGEO Inc., Seoul, Korea

B.H. Han, K.H. Shin, S.S. Lee & Y.K. Kim
Samsung Corporration, Sungnam-Si, Korea

ABSTRACT: Existence of main fault zone is one of main hazardous factors of tunnel construction. In this case, a part of fault zone was exposed on the spillway tunnel face. The fault zone with graphite triggered some failures of the tunnel. According to the result of face mapping to an adjacent slope, the fault zone estimated a complex thick fault system consisted with sub-parallel faults in meta-sedimentary rocks. Detail geological survey including concentrated vertical and horizontal drillings was carried out in order to evaluate geometry and engineering properties of the fault system. We could construct a 3D Geo-Model of the unexcavated tunnel ground using the results of detail geological survey. The 3D Geo-model consisted with 3 rock units (quartz-schist, fair mica-schist and poor mica-schist) and fault zone unit. Individual units were characterized by core condition with RMR values and lab/field test properties. This 3D Geo-Model provided useful information about spatial and engineering relationship between the complex fault system and the tunnel to re-design excavation and supporting method for the unexcavated tunnel ground.

1 INTRODUCTION

Engineering Geological Model is a representation of the geology for engineering practice in a particular location. The form of the model can vary widely and include written descriptions, section or plans, block diagram, or be slated towards some particular aspect such as groundwater or geomorphological process, rock structure and so on (Fookes, 1997). Classification and reconstruction of geological units are very important in order to engineering geological modeling. Figure 1 shows elements of engineering geological modeling.

This process of engineering geological is just ground investigation and characterization. We classify geo-materials and define their engineering properties and distribution under surface. Figure 2 shows relationship between ground investigation and geological modeling. Engineering geological model is upgraded and detailed during the process (Dearman, 1991).

This case is an engineering geological modeling for construction stage of a spillway tunnel in Korea. The Geological maps and sections of the design stage were used to pre-construct engineering geological model of this tunnel site. In the maps and sections of design stage, some fault zones developed across the spillway tunnel. These fault zones were sub parallel with the tunnel. Some borehole logging sheets showed that graphite materials are in the fault zones.

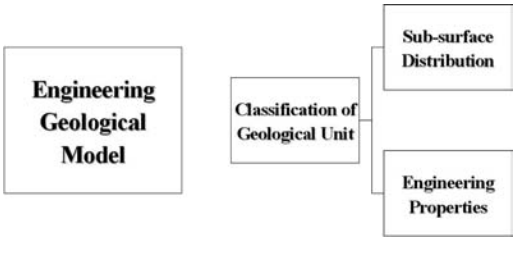

Figure 1. Elements of engineering geological modeling.

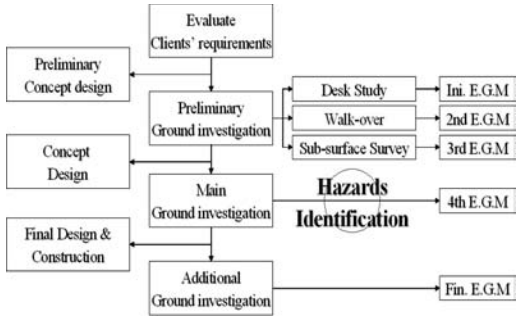

Figure 2. Process of engineering geological modeling.

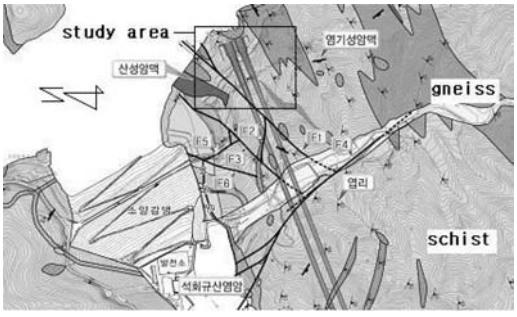

Figure 3. Geological map drown in design stage.

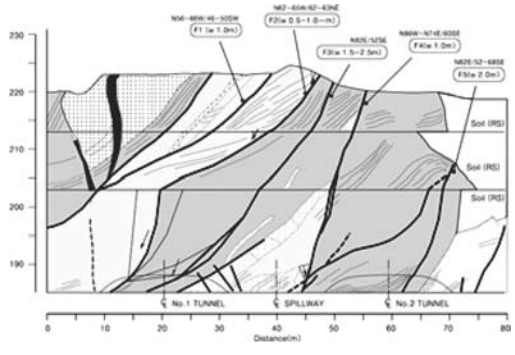

Figure 4. Geological map of tunnel slope.

A part of fault zone was exposed on the spillway tunnel face. The fault zone with graphite triggered some failures of the tunnel. Tunnel excavation was stopped and additional geological survey was planed in order to detailed engineering geological modeling for safety of tunneling. LYNX S/W (Geosystems, 2004) was used for 3D computational modeling.

2 GROUND INVESTIGATION

2.1 *General geology*

Pre-Cambrian metamorphic rocks are in the tunnel site. Schist group is consisted with mica-schist, quartz-schist and calc-silicate rocks. Some main faults cross the tunnel sun parallel or normally (Figure 3).

Some failures occurred in the study area of figure 3. Fault material like graphite was estimated main factor of these failures.

2.2 *Slope and tunnel face mapping*

Detailed geological mapping was carried at tunnel slope and faces. Figure 4 was a geological map of tunnel slope.

Figure 4 shows five faults with 1∼5 m thickness in slope face. Five faults have complex shape and various fault materials. Some faults have thick graphite zone and sub parallel direction against tunnel axis. These faults were occupied at tunnel face around failures. Distance between slope and tunnel faces is about 50 m. Table 1 shows characteristics of faults in the slope face.

Table 1. Characteristics of faults in the slope face.

Fault	Orientation		Matrial type	Fault zone thickness
	Strike	Dip		
F1	N60W	50SW	clay	∼1.0 m
F2	N60W	60NE	clay	∼1.0 m
F3	N80E	50SE	graphite	∼3.0 m
F4	EW	60SE	graphite	∼2.0 m
F5	N80E	60SE	graphite	∼2.0 m

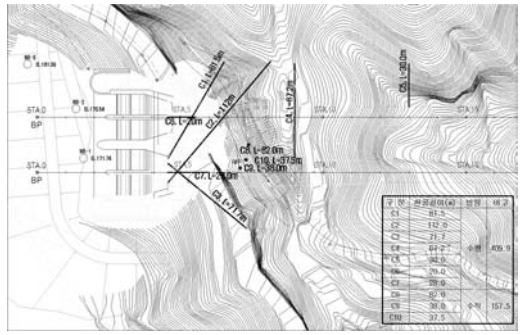

Figure 5. Location of boreholes in the under tunneling region.

2.3 *Drilling and logging*

In order to characterize geological condition including faults, drilling survey is planned in the region under tunnel excavation. Seven horizontal and inclined boreholes and five vertical boreholes were drilled. Figure 5 indicates location of boreholes.

Detailed geological logging of all cores was carried out. Engineering geological parameters based on ISRM standards (ISRM, 1981a,b) were decrypted and RMR (Beiniawski, 1989), Q value (Barton, 1974) and GSI (Hoek, 1995) were rated.

3 3D GEOLOGICAL MODELLING

3.1 *Classification of engineering geological units*

Engineering geological condition were classified five geological units of quarts-schist (QS), fair mica-schist (FMS), poor mica-schist (PMS) and fault zone (FZ) based on above mentioned geological survey. Individual units have characteristics in Table 2.

Table 2. Characteristics of faults in the slope face.

Units	QS	FMS	PMS	FZ
Class	Good	Fair	Poor	Very Poor
RMR	38–74	30–47	16–39	8–21
Q	15.813	2.156	0.869	0.027
GSI	32–88	30–57	22–49	11–34
Em (Gpa)	15,000	6,000	2,500	400
C (Mpa)	1.95	0.69	0.24	0.05
Friction A.	42	38	35	25

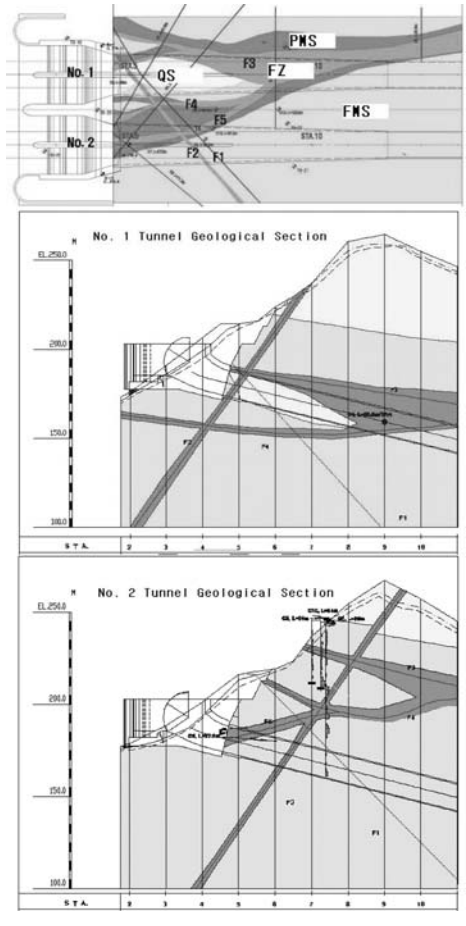

Figure 6. Geological map and section of No. 1&2 tunnels.

Engineering properties of units were evaluated through field and Lab. tests. These results were summarized in Table 2.

3.2 *Construction of plan and sections*

Geological plan and longitudinal geological sections of No. 1 and 2 tunnels were drawn (Figure 6).

Figure 7. Representaion of geological survey results.

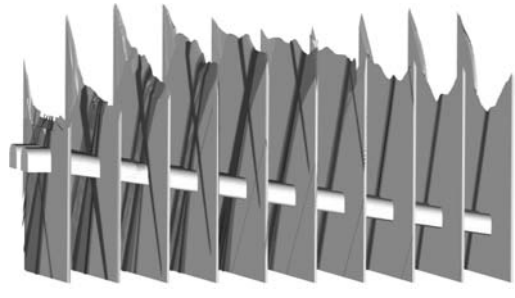

Figure 8. Geological cross sections using 3D geo-model.

Fault Zone (FZ) and Poor Mica Schst (PMS) units have very complex shape. Occupied failures located at fault zone across No. 1 and 2 tunnels in longitudinal sections.

3.3 *Reconstruction of 3D geo model*

In the site, tunnel is inclied and geological structures are complex shapes and spatial relationships. In order to fully understanding relationship between tunnel and geological structures, 3D geological model was constructed.

Figure 7 summaries all geological survey results, i.e. tunnel face mapping and core logging and etc.

3.4 *Use of 3D geo model*

Reconstructed 3D geological model can provide useful information for understanding geological condition and making concept of engineering practice.

Figure 8 shows geological cross sections using the geo-model. If 3D computational geological model is constructed, engineers can get any geological section with any direction and shape.

Additionally, engineers can easily recognize the relationship between structure and geological units.

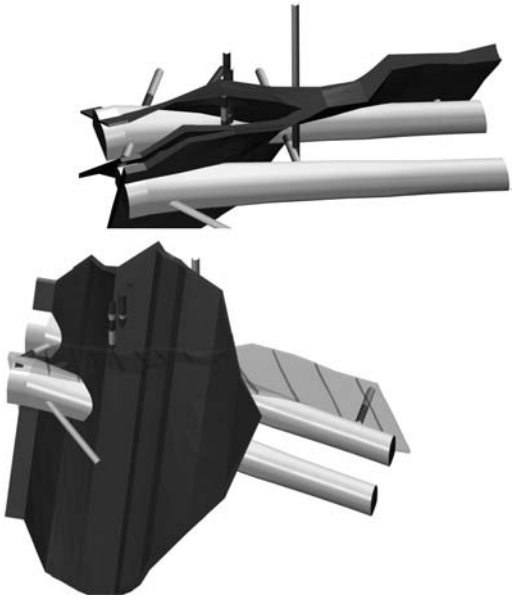

Figure 9. Spatial relationship between tunnels and zone.

Figure 9 shows spatial relationship between No. 1, 2 tunnels and fault zone.

In this work, No. 1 and 2 tunnels under excavation were successfully redesigned using 3D geo-model

4 CONCLUSION

3D Geo-Model of the unexcavated tunnel was constructed using the results of detail geological survey. Redesign of tunnels was carried out based on the 3D Geo-model with four engineering geological units, quartz-schist, fair mica-schist, poor mica-schist and fault zone unit. This 3D Geo-Model provided useful information about spatial and engineering relationship between the complex fault system and the tunnel to re-design excavation and supporting method for the unexcavated tunnel ground.

Dilatometer tests in deep boreholes in investigation for Brenner base tunnel

M. Zalesky & Ch. Bühler
Solexperts AG, Mönchaltorf, Switzerland

U. Burger
BBT SE, Innsbruck/Bolzano, Austria/Italy

M. John
John Tunnel Consultant, Innsbruck, Austria

ABSTRACT: Results from more than one-year of in-situ deep borehole dilatometer testing and data evaluation for the Brenner base tunnel geotechnical investigation project are presented. The principle of dilatometer measurements is explained. Dilatometer measurements describe deformation properties of rock massif. Deformation modulus and modulus of elasticity are determined in relationship to applied pressure. Equipment for testing in deep boreholes with diameters ranging from 96 to 158 mm is described. Information needed prior to measurements, testing procedures as well as evaluation of recorded data are discussed. Examples of in-situ dilatometer measurements are presented. Range of use of gained results is discussed and conclusions are drawn.

1 INTRODUCTION

The Brenner base tunnel will be a significant part of European railway axis Berlin – Napoli – Palermo. The 55.6 km long tunnel route will be built from Austrian Innsbruck to Italian Franzensfeste (Fortezza). Numerous deep boreholes up to 1351 m depth were simultaneously drilled during the second phase of geological exploration in 2004–2005. Depth of the boreholes required drilling in several sections with decreasing diameter. Other reason for various borehole diameters was that six different drilling companies participated in the project. To comply with the proposed procedure of "drilling – logging – measuring", Solexperts AG was obliged to perform tests in boreholes with diameters ranging from 96 mm to 158 mm.

Several types of borehole measurements were performed: geophysical logging, packer tests, stress measurements using hydraulic fracturing and dilatometer measurements. In this paper we focus on in-situ determination of deformation properties of rock massif using Solexperts dilatometer.

2 SOLEXPERTS DILATOMETER SYSTEM

The dilatometer probe developed by Solexperts AG has been successfully used for more than 30 years (Thut 1977). Determination of the mechanical properties of the rock mass is based on real-time measurement of the applied pressure and the resulting deformation – the change of the borehole diameter.

The dilatometer probe consists of a metal core, which holds three potentiometeric displacement transducers placed in the centre of the core, Figure 1. The axes of the transducers are oriented 120° to each other and vertical distance between the transducers is 75 mm. The borehole wall is loaded by means of a reinforced packer sleeve fixed to the core of the probe at its both ends. The packer can be expanded by compressed nitrogen or air via a high-pressure hose connected to either nitrogen bottles or a compressor. The dilatation of the borehole wall is directly measured by the transducers, which contact the borehole wall through steel pins with spherical heads. The applied pressure is measured at the surface using a pressure sensor. The electronic signals of the displacement transducers are transmitted to the dilatometer logger through a coaxial cable within the high pressure-hose. The probe can be additionally equipped with a compass for oriented strain measurement or with two pressure sensors: one measuring the formation pressure underneath the probe and the other measuring the pressure inside the packer. To simplify installation and minimize risk of damage when retrieving the probe from the borehole a steel cone is attached to the lower end

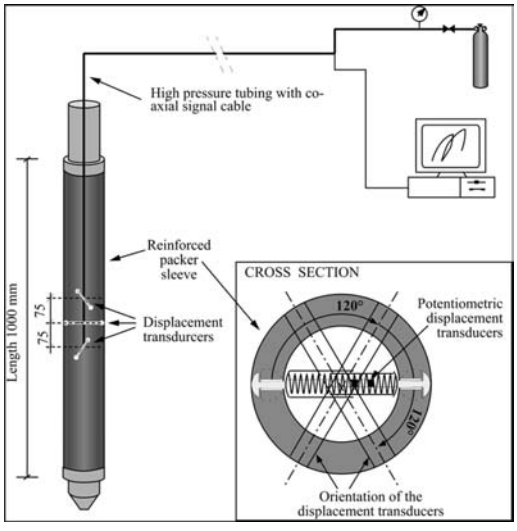

Figure 1. Scheme of the Solexperts dilatometer.

Table 1. Diameters of Solexperts dilatometer.

Diameter		
Unexpanded probe mm	Borehole – minimum mm	Sign
92	96	HQ
95	101	
118	122	PQ
142	146	
148	152	

of the probe and an open type bailer, called sedimentation tube, to its upper end in order to prevent blocking the probe by loose material falling down the drill hole.

The maximum measurement range of the displacement transducers is 25 mm, also due to their high accuracy of 0.001 mm. The packer is designed for this range of strain too. To perform tests in boreholes with diameters ranging from 96 mm to 158 mm there had to be either a single probe for each diameter or one type of probe, where the packer element and transducer extension pins could be easily changed. Solexperts has developed a dilatometer probe body (core), which can be equipped by packer elements of different diameters. A set of corresponding sedimentation tubes and calibration tubes have also been provided, Table 1. The probe is installed with so called hydro-frac tubing of 1″ using a drilling rig.

The high-pressure hose containing signal cable is wound on a winch on the surface. The hose/cable was manufactured in sections of 200 m with the appropriate connectors. Connecting multiple sections, made it possible to perform measurements up to 1400 m in depth. One or more 200 m sections of the hose/cable can be replaced, if needed.

The inflation pressure is manually regulated and automatically measured at the control panel with a pressure sensor. Additionally it can be observed together with the pressure in the system and the rest pressure in the nitrogen bottle (or compressor) with mechanical pressure gauge in the control panel. For special long-term dilatometer experiments a fully automated monitoring system (the Solexperts GeoMonitor II) can be used. In this case however, the dilatometer system is pressurized with silicon oil.

The pressure sensor and the signal cable from the probe are connected to special dilatometer data acquisition system, which is controlled by a computer via the software program DilatoII developed by Solexperts. This program provides data acquisition, testing control, graphical and numerical real-time data presentations, as well as test analysis and reporting.

3 DILATOMETER TESTS

3.1 *Planning and preliminary information*

To comply with a “drilling – logging – measuring” procedure requires a significant planning, decision making and preparation is necessary prior to execution of each series of tests.

In-situ testing i.e. dilatometer measurements or hydraulic tests using a double packer system can be done during the drilling phase or after the entire length of the borehole has been drilled. Performing measurements according to the state of drilling progress may be difficult to manage especially when several boreholes are being drilled simultaneously, as it was for the Brenner exploration project.

In most cases however, measurement campaigns are carried out after the drilling has been successfully finished. The geologist in charge usually overviews the entire borehole and specifies the borehole sections of interest. Results of tests might be affected by “borehole history effect” (especially affecting the hydraulic tests results). Another problem to be considered for testing after drilling is the stability of the borehole. Especially, investigation of faults and shear zones is of interest for the design of planned excavation. In cases of poor borehole stability only the “measurement-while-drilling” approach can be applied.

The approach chosen for the geotechnical and hydrogeological investigation for the Brenner base tunnel was a compromise of the presented possibilities: a series of test measurements was done after a first section of the borehole with one diameter was drilled.

Borehole logging and geophysical measurements were carried out at the beginning of a testing campaign.

The logs were used to decide about the subsequent testing strategy and number of tests. For the dilatometer tests the most important information was:

- nominal borehole diameter,
- test depths,
- type of rock / inspection of borehole cores,
- dipping of shistosity,
- calliper log for actual borehole diameter or
- borehole scan for geologic structure and
- ground water table / hydrostatic pressure at each test depth.

The calliper log and/or the borehole scan provided information about the true borehole diameter as well as the possible existence of caverns, discontinuities, large cracks and fractures of the massif. Uneven borehole walls result in higher risk of packer damage and, in the extreme case, the possible blockage of the borehole by an irretrievable probe. Additionally, to high artesian water pressure (determined by the hydrogeological tests) can cause difficulties during the tests.

3.2 *Test procedure*

The dilatometer probe must be calibrated prior to testing. The calibration is done by inflating the probe inside a steel tube of known diameter. The DilatoII software then records the data from each displacement transducer and calculates offsets so that a "zero reading" corresponds to the known inner diameter of the tube. The actual borehole diameter can then be precisely determined. It is needed for control of the probe expansion state during the test and for test analysis.

The test sequence usually begins at the lowest test position in the borehole. During installation into deep boreholes the probe must be partially inflated in order to counterbalance the acting hydrostatic pressure. After lowering the probe to the depth given by the geologist, the dilatometer measurement can start. The actual borehole diameter can be determined with the dilatometer probe in cases where the calliper log shows significant variations in borehole diameter along the borehole section selected to be the test position, or the borehole cores showed discontinuities, but especially if no core could be retrieved. The actual diameter can be determined by inflating the probe just enough to overcome the hydrostatic pressure and the stiffness of the packer. Then the packer is in contact with the borehole wall. Under low inflation pressure there is no danger for the probe even if a cavern or fracture exists at this borehole section. The risk of damaging the equipment can be minimized by selecting a test position with an appropriate diameter after measuring the borehole diameter at several locations along the test zone using the described procedure.

The dilatometer tests for Brenner base tunnel project were performed with four loading cycles. At first, the probe was inflated to a base pressure, which was about 0.5 MPa higher than the hydrostatic pressure at the test position in order to establish a good contact between the packer and the borehole wall. The first cycle consisted of initial loading and subsequent unloading to the base pressure. The following cycles consisted of reloading up to the maximum pressure of the previous load cycle, initial loading to a higher level and then unloading to the base pressure level.

The maximum level of loading pressure has to be chosen with respect to the rock type, its assumed compressibility and the aim of the test. In case of measurements for a future base tunnel, the applied pressure should reach the same order as the horizontal pressure at rest in the mountain massif. One of the aims of a good dilatometer test is to describe the ratio of plastic and elastic deformations together with general behaviour of the rock, which can be also mostly elastic or plastic. The range of applied pressures should be chosen so, that the maximum of elastic deformation phase of the rock is used, but causing massive plastification or fracture of the rock is to be avoided if possible.

After the test is finished, the probe is unloaded under the level of acting hydrostatic pressure and raised to the next higher measurement zone.

3.3 *Evaluation of dilatometer test*

The moduli are calculated based on Lamé's equation for a tube with infinite wall thickness (1):

$$E = \frac{\Delta p * d * (1 + \nu)}{\Delta d} \tag{1}$$

where Δp = pressure difference; d = borehole diameter; Δd = change of borehole diameter; ν = Poisson's ratio. In case where no results of laboratory tests are available for the tested rock formation, we assume the Poisson's ratio of 0.33 with respect to rock quality.

The deformation modulus (V) is calculated based on data of initial loading from each load cycle. The modulus is computed using a linear regression along the corresponding section of the curve. The deformation modulus from reloading phase of each cycle is calculated in a similar manner.

The modulus of elasticity (E_1) is calculated from the slope of a secant connecting the first and the last point of the unloading phase, which corresponds to the initial loading range for each cycle. However in cases of very step slopes which correspond to very small elastic deformation of the borehole wall and thus to very high moduli, it appears to be more appropriate to calculate E_2 (Fig. 2) from the entire unloading curve for each load cycle.

The averaged displacement measurements of the all three transducers are mainly used for the calculation

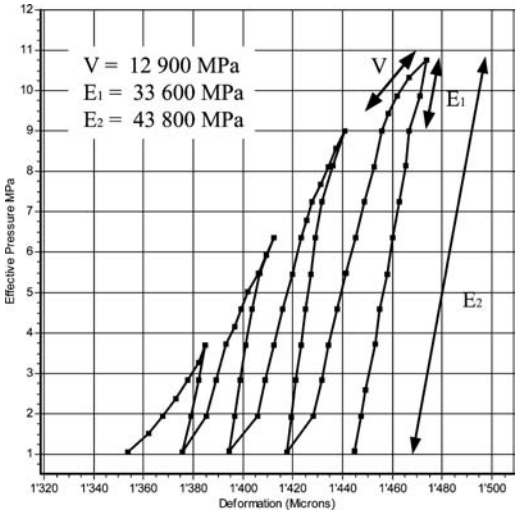

Figure 2. Dilatometer test in borehole Va-B-03/04s, 986.5 m depth, chlorite schists. Graphical representation from the DilatoII software program: average from deformation measurements of all three extensometers.

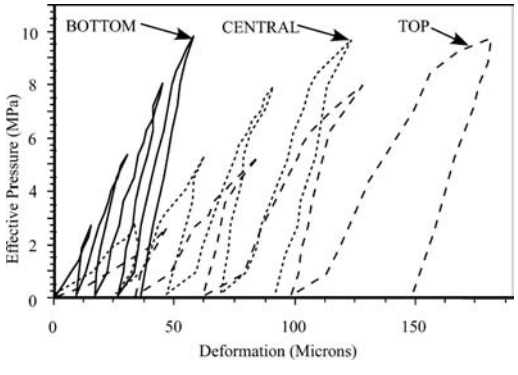

Figure 3. Dilatometer test in borehole Va-B-03/04s, depth 986.5 m. Comparison of pressure/deformation graphs for three extensometers.

of the moduli. Based on comparison of all three pressure / deformation graphs, conclusions on elastic or plastic behaviour of the rock massif can be drawn and estimates of anisotropy can be made. Figures 2 and 3 show a dilatometer test in chlorite schists at 986.5 m depth. The borehole Va-B-03/04s is inclined 30° from vertical.

The method of analysis described above allows assessing one dilatometer test at a time. The stiffness of the examined rock can be classified according to the values of deformation and elasticity modulus from the last loading cycle. For this purpose we use the classification based on E-modulus values, which was proposed by AFTES (1993).

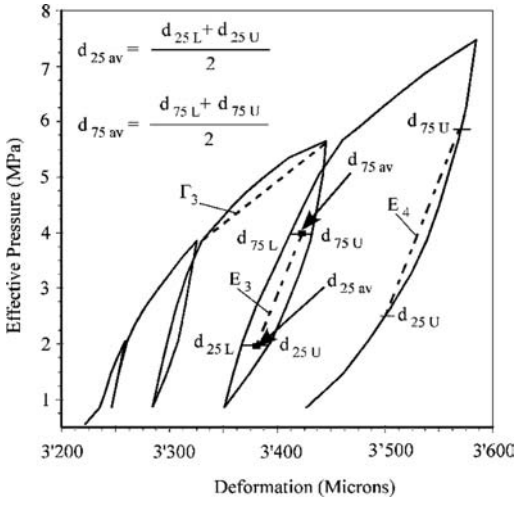

Figure 4. Schema for computation of E and Γ for Schneider's criterion. Graph: Test in borehole Pf-B-03/05, depth 39 m, quartzphyllite. Average from deformation measurements of all three extensometers.

Another approach, Schneider's criterion (1967), also uses the Lamé's equation, but allows interpretation and comparison of series of dilatometer tests from a wide range of rocks. Development of the deformation properties can be evaluated with respect to acting pressure. Measurements with four loading cycles are required for the Schneider's criterion, which describes the relationship of a factor of permanent deformation C_p (2) to a ratio of elasticity modulus E to deformation modulus Γ (3):

$$C_p = \frac{d_p}{p_{max}} \quad (2)$$

$$\frac{E}{\Gamma} \quad (3)$$

where d_p = permanent deformation after a complete loading cycle; and p_{max} = maximum loading pressure applied with this cycle. The factor of permanent deformation is calculated for each loading cycle.

The modulus of elasticity E is defined as a slope of a straight line, which connects points $d_{25\ av}$ and $d_{75\ av}$. These points represent average deformation from unloading ($d_{25\ U}$, $d_{75\ U}$) and reloading ($d_{25\ L}$, $d_{75\ L}$) phase of the corresponding load cycle (see Fig. 4). Values of d_{25} and d_{75} are determined at pressure levels of 25% and 75% from the maximum pressure applied in the loading cycle. The E moduli are calculated for the first to the third load cycle. The calculation of E-modulus from the last (fourth) cycle is based on data from the unloading phase only. These calculations

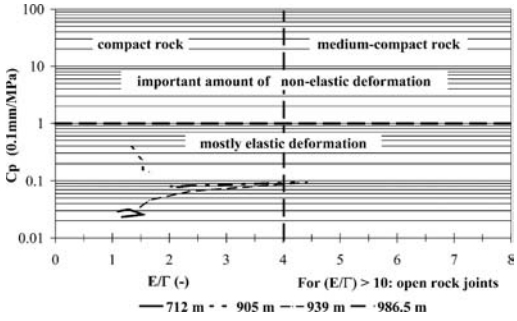

Figure 5. Schneider's criterion, after Schneider (1967). Graph: dilatometer tests in shales, borehole Va-B-03/04s.

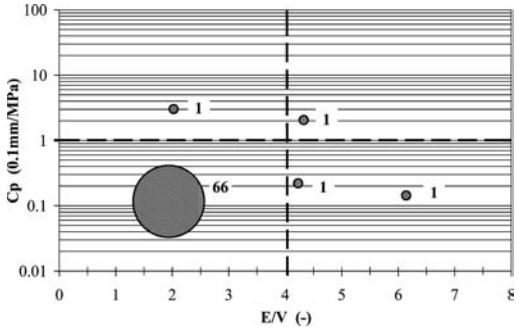

Figure 6. Modified Schneider's criterion. Distribution of 70 test results. The position of the points corresponds with average of E/V and C_p for each presented rock class. The size of points relatively depicts the number of tests.

can be done by interpolation between the data points recorded during the measurement (see Figure 2) or estimated in the chart. The analysis data presented in this article were interpolated. The deformation modulus Γ is determined as the slope of a secant, which connects the first and last point of an initial loading phase of a load cycle, Figure 4.

The resulting data is plotted in a semi-logarithmic graph, which is also used for rock classification, after Schneider (1967), Figure 5. All four data sets presented in this example indicate compact rocks with mainly elastic deformation behaviour.

Data analysis for Schneider's criterion is not integrated into the analysis part of DilatoII program. Therefore the analysis was made with a spreadsheet program, which is rather time consuming. Further, presentation of a large number of tests in a diagram according to Schneider can become confusing. For these reasons we propose a modified version of Schneider's criterion based on the values from the last (fourth) loading cycle only. The results of a complete dilatometer test are reduced to only one point in the Schneider's graph, instead of a polygon line in the original Schneider's criterion. This method allows a quick comparison of rock properties in a large set of dilatometer tests. This procedure does not depict the development of the moduli and the amount of plastic deformation with respect to pressure changes during the test but makes evaluation of the distribution of measured moduli much easier.

We use the data of V (deformation modulus calculated as regression) and E (elasticity modulus) computed by the DilatoII program in the modified Schneider's analysis. The E_2 modulus calculated from the entire unloading phase of the fourth loading cycle was chosen, because it is closer to the original Schneider's criterion than the E_1 value determined from the upper part of the corresponding unloading phase only, Figure 2. This simplifies determination of coefficient E/V (instead of original E/Γ), whereas the coefficient C_p remains unchanged. All results are then displayed in Schneider's graph. To get a better overview of the distribution of test results, the average is calculated for each rock class. Seventy dilatometer tests executed during the exploration campaign for Brenner base tunnel project are shown in Figure 6.

The proposed analysis and graphic presentation gives an overview of the deformation properties along the whole project. Based on the modified Schneider's criterion, it is obvious, that that about 95% of the tests indicate a compact rock, of mainly elastic behaviour in the range of applied pressures. Only four tests (roughly 5%) represent rock with partly plastic deformation behaviour. In the next step, these tests should be reviewed in detail and further investigation might be considered if these results appear to be critical for the project.

This approach might be helpful for decision making in the early stages of geological and geotechnical survey. The knowledge gained from the modified Schneider's criterion may be used:

- as another point of view for preliminary characteristics the rock mass,
- to find areas, where further investigation may be required,
- to obtain an overview of the deformation properties of the rock mass and
- to estimate suitable tunnelling techniques and the type of primary tunnelling supports.

4 APPLICATION OF RESULTS

For the determination of the stiffness parameters of the rock mass at the Brenner base tunnel various formulas given in the literature such as Hoek et al 2002 have been used. Results obtained revealed a considerable scatter. The results of the dilatometer tests have been used to verify calculated results. Due to the fact

that dilatometer tests represent the deformability of sections of rock mass of less than 1 m, whereas during excavation stress redistributions affect sections of up to 10 m results of dilatometer tests have been regarded as an upper limit taking into consideration the scale effect.

5 CONCLUSIONS

Results of dilatometer in-situ measurements describe deformation properties of rock mass. A large number of tests were performed during the second phase of geological exploration for the Brenner base tunnel in 2004–2005. The borehole diameters were ranging from 96 to 158 mm and the boreholes were reaching to depths of more than 1300 m. The results from the provided dilatometer tests were used to verify calculated stiffness parameters of the rock mass at the Brenner base tunnel. Based on our experience with test analysis and interpretation, a modification of Schneider's analysis of dilatometer tests has been created in order to allow quick overview and comparison of numerous dilatometer tests. The most important modifications are: moduli calculated only from the last loading cycle are directly used. Each dilatometer test is then represented by only a single point in the Schneider's graphical classification. Even large series of tests covering the whole explored area of interest can be assessed. Evaluation of the distribution of points in the resulting graph allows characterization of the major type of rock mass deformability. The rock classes where few tests occur can indicate areas to be reviewed or further investigated.

ACKNOWLEDGEMENTS

The authors would like to thank BBT SE for the permission to publish results from the 2004/2005 exploration campaign.

The dimensioning of tunnel face reinforcement

G. Anagnostou & K. Serafeimidis
ETH Zurich, Switzerland

ABSTRACT: Ground reinforcement using fiberglass or steel bolts is a very efficient measure for stabilizing the face in conventional tunneling. The reinforcement needs a careful design in order to optimize the construction process. This paper presents a computational method which is based upon limit equilibrium considerations and which can be applied to heterogeneous, layered ground as well as to arbitrary reinforcement layouts in terms of the spacing, length, longitudinal overlapping and installation sequence of the bolts. Additionally, design nomograms are presented for the assessment of tunnel face stability in the special case of a homogeneous ground with uniform reinforcement.

1 INTRODUCTION

The most serious risks in tunneling through weak ground are associated with a collapse of the tunnel heading. In shallow tunnels the instability may propagate towards the surface, thereby creating a crater on the ground surface. In mechanized tunneling through soft ground, closed shields are applied for stabilizing the face. In conventional tunneling, ground reinforcement using face bolts is a very efficient measure besides partial excavation or ground improvement through grouting or artificial freezing.

The face reinforcement needs a careful design because it slows down construction progress considerably as it is carried out ahead of the face intermittently with the excavation. Besides experience and engineering judgment, calculations are indispensable. Basic considerations for the stabilizing action of face reinforcement may be found elsewhere (Anagnostou 1999). In the following pages, a dimensioning method as well as design nomograms will be presented.

2 COMPUTATIONAL METHOD

2.1 *Failure mechanism*

As in past contributions (Horn 1961, Anagnostou & Kovári 1994), the computational method is based upon the limit equilibrium of a failure mechanism that consists of a wedge and the overlying prism (Fig. 1). Mohr-Coulomb failure condition will be assumed for the ground. Cohesion c and angle of internal friction ϕ may vary over the face (layered ground). Both the inclination ω of the slip plane and the elevation z_f of the wedge foot are in general unknown at the start. Their

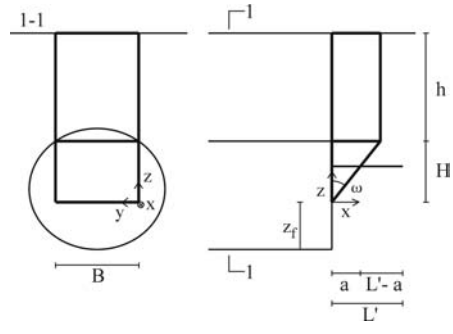

Figure 1. Failure mechanism.

critical values, i.e. the values that maximize support requirements, depend on the shear strength and on the stratigraphy of the ground and they will be determined iteratively.

2.2 *Effect of reinforcement*

During ongoing excavation (without anchorage plates), the supporting effect of the face bolts relies solely on the strength of the bond between grout and soil. The support force of one bolt depends thus on its tensile strength F_z, on the diameter d of the grouted borehole, on the shear strength τ_m of the soil – grout interface, on the bond length a inside the wedge as well as on the bond length $(L' - a)$ in the ground ahead of the inclined slip surface, where L' denotes the actual bolt length (Fig. 1).

If anchorage plates are present (e.g. during an excavation standstill) and the bond length a inside the wedge is insufficient, the bolt force will be transmitted to the ground through the plates being thus limited by

the bearing capacity F_p of the anchorage system at the face (bolt plates and soil).

In general, the support pressure s offered by the face reinforcement is given by

$$s = n \cdot min[F_z, max(\pi d \tau_m a, F_p), \pi d \tau_m (L'-a)], \quad (1)$$

where n denotes the reinforcement density, i.e. the number of bolts per sqm.

Note that the bond lengths a and $(L' - a)$ vary over the height of the wedge and, moreover, they depend also on the specific mechanism considered, i.e. on the angle ω and on the elevation of the wedge foot z_f. Consequently, the support force offered by the reinforcement will not be uniformly distributed even in the case of constant bolt spacing (Fig. 2a).

Depending on the initial lengths of the bolts and on the longitudinal overlapping of the successive installation stages, bolts of different lengths may be present at the same time. It is interesting to note that the same total quantity of bolts (linear meters bolts installed per linear meters tunnel) may lead to different support pressures, depending on the installation sequence (Fig. 2b and 2c).

2.3 *Equilibrium assessment*

The wedge is loaded by the overlying prism. The bearing capacity of the wedge depends on the shear resistance of the ground and on the support force offered by the bolts.

The shear resistance of the two lateral, vertical slip surfaces of the wedge contributes to stability considerably. The frictional part of the shear stress depends, however, on the respective normal stress (i.e. on the horizontal stress σ_x), which cannot be derived from the equilibrium conditions. Following Anagnostou & Kovári (1994), the horizontal stresses will be derived here by assuming that their ratio to the vertical stresses σ_z is constant and equal to $\lambda = 0.8$. The vertical stress σ_z will be obtained by considering the equilibrium of a horizontal, infinitesimal slice of the wedge (Fig. 3). Walz and Prager (1978) first proposed such an approach for the stability assessment of slurry walls (so called "method of slices"). It is very similar to the one of silo theory, eliminating the need for an *a priori* assumption of the distribution of the vertical stress σ_z and offering the possibility of analyzing a layered ground with an arbitrary distribution of reinforcement.

The infinitesimal slice is acted upon the following forces (Fig. 3): its weight dG; the "supporting" force $V(z)$ exerted by the underlying ground; the "loading" force $V(z) + dV$ exerted by the overlying ground; the forces dN and dT at the inclined slip surface; the shear force dT_s at the vertical slip surfaces; and the supporting force dS of the reinforcement (i.e. $s(z) \cdot B \cdot dz$, where B is the width of the wedge and dz the thickness of the slice).

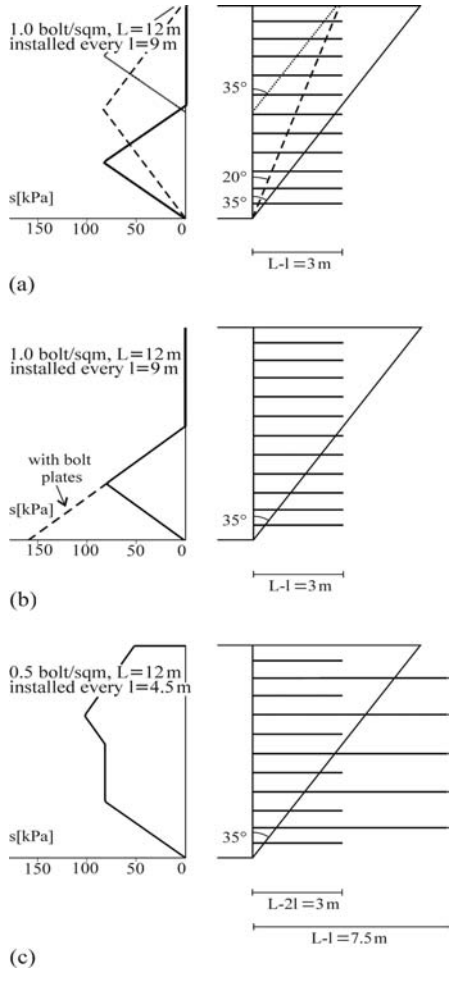

Figure 2. Support pressure distribution for different reinforcement densities and installation sequences.

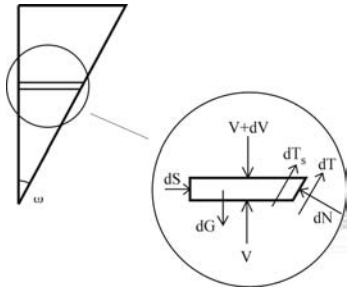

Figure 3. Forces acting upon infinitesimal slice.

The equilibrium conditions parallel and perpendicular to the sliding direction, i.e.

$$dT_s + dT + S \sin\omega = (dV + dG) \cos\omega \quad (2)$$

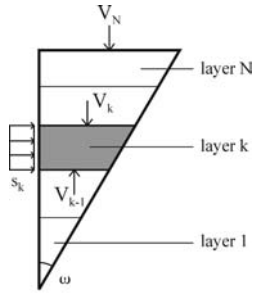

Figure 4. Division of wedge in layers.

and

$$dN = (dV + dG)\sin\omega + dS\cos\omega \quad , \tag{3}$$

lead to the following differential equation for the vertical force $V(z)$:

$$dV/dz - A(z)\,V = \Gamma(z)\,z + \Delta(z) \, , \tag{4}$$

where the coefficients $A(z)$, $\Gamma(z)$ and $\Delta(z)$ depend on the shear strength constants $c(z)$ and $\phi(z)$, on the soil unit weight $\gamma(z)$, on the ratio λ of horizontal to vertical stress, on the wedge width B, on the support pressure $s(z)$ and on the angle ω.

For the solution of Eq. (4), the wedge is divided into an arbitrary number N of finite thickness layers (Fig. 4). Each layer k is homogeneous (constants c_k, ϕ_k and γ_k) and is supported by a uniform pressure s_k, i.e. the irregularly distributed support pressure $s(z)$ (Fig. 2) is approximated by a piecewise constant pressure. The support pressure s_k of each layer is calculated based upon its reinforcement density n_k and by taking into account the average bond length (at mid-height of the layer). Under these conditions the coefficients A, Γ and Δ are constant within each layer and Eq. (4) can easily be integrated layer-wise.

As a result one obtains the following equation for the k.th layer:

$$V_k = C_{sk}\,s_k + C_{Vk}\,V_{k-1} + C_{ck}\,c_k - C_{\gamma k}\,\gamma_k \, , \tag{5}$$

where

$$C_{vk} = e^{A_\kappa\cdot(z_\kappa - z_{\kappa-1})} \, , \tag{6}$$

$$C_{sk} = \frac{(C_{v\kappa}-1)\cdot B\cdot\tan(\omega+\varphi_\kappa)}{A_\kappa} \, , \tag{7}$$

$$C_{ck} = \frac{(C_{v\kappa}-1)\cdot B\cdot A_\kappa + 2\cdot F_\kappa\cdot\sin\omega}{A_\kappa^2\cdot\cos^2\omega\cdot(1-\tan\omega\cdot\tan\varphi_\kappa)} \, , \tag{8}$$

$$C_{\gamma k} = \frac{F_\kappa\cdot\tan\omega\cdot B}{A_\kappa^2} \, , \tag{9}$$

$$A_k = \frac{2\cdot\lambda\cdot\tan\varphi_\kappa}{B\cdot\cos\omega\cdot(1-\tan\omega\cdot\tan\varphi_\kappa)} \, , \tag{10}$$

$$F_k = C_{v\kappa}\cdot\left(1+A_\kappa\cdot z_{\kappa-1}\right) - 1 - A_\kappa\cdot z_\kappa \, , \tag{11}$$

and z_k denotes the elevation of the upper layer boundary. Eq. (5) expresses the "loading" force V_k acting at the upper boundary of the k.th layer as a function of the "supporting" force V_{k-1} acting on its bottom boundary (Fig. 4). The forces V_k are calculated by applying Eq. (5) successively from down to top starting with $V_0 = 0$.V_k represents the force that can be sustained by a wedge consisting of the layers 1, 2, . . . k. A negative value of V_k (tensile force) means that the wedge must be hanged in order to remain stable, thus indicating a collapse of the face up to layer k. So the following constraint has to be fulfilled by the chosen reinforcement:

$$V_k \geq 0 \;(k = 1, 2, 3, \ldots N). \tag{12}$$

V_N represents the bearing capacity of the entire wedge up to the overlying prism: In order that the face remains stable, V_N must be higher than the load V_S exerted by the prism. The latter is calculated based upon silo theory. At limit equilibrium,

$$V_N = V_S \tag{13}$$

applies. The iterative solution of this equation together with the constraints according to Eq. (12) yields the required reinforcement densities for the specific mechanism considered (i.e. for a given inclination ω and wedge foot elevation z_f). The critical mechanism, i.e. the one necessitating the maximum support quantities, is found by repetitive application of the procedure outlined above. In general, a multi-parametric optimization problem has to be solved because any layer may have another bolt density. A unique solution can be obtained, however, by specifying the bolt distribution (e.g., uniform distribution).

2.4 *Homogeneous ground, uniform reinforcement*

In this special case, one can readily verify, by inspecting Eqs. (5) and (1), that the required bolt density n depends linearly on the ground cohesion c, and can, therefore, be expressed in the following way:

$$n = n_o\,(1\text{-}c/c_{crit}) \, , \tag{14}$$

where n_o is the necessary reinforcement density in the case of cohesionless ground ($c = 0$) and c_{crit} denotes the minimum cohesion required in order that the face remains stable without support ($n = 0$). A dimensional analysis shows, furthermore, that the following dimensionless dependencies exist:

$$\bar{c}_{crit} = c_{crit}/\gamma H = f(\phi,\, B/H,\, h/H,\, \lambda) \, , \tag{15}$$

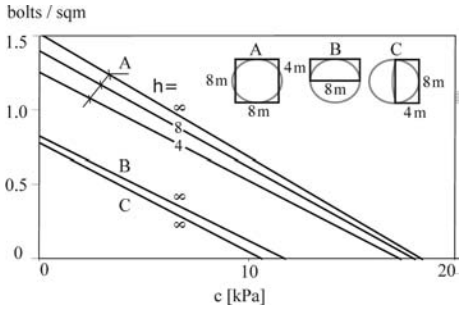

Figure 5. Numerical example on the influence of shape and of depth of cover h ($L = 12$ m long bolts installed every $l = 9$ m).

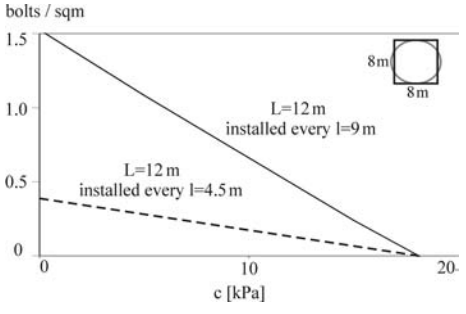

Figure 6. Numerical example on the influence of installation sequence.

$$\bar{n}_0 = n_o\, d\tau_m/\gamma = f(\phi,\ B/H,\ (L\text{-}l)/H,\ l/L,\ h/H,\ \lambda)\ , \quad (16)$$

where L denotes the initial bolt length (at installation), l the distance between the successive installation stages and L-l the longitudinal overlapping of the bolts (see Fig. 7).

Eq. (16) does not take into account the tensile strength of the bolts and the bearing capacity of the plates. This is a reasonable simplification as experience shows that shear failure at the grout-soil interface is the most critical mechanism, at least for soft ground.

The effect of depth of cover (h/H) is negligible as can be seen from the computational results of Figure 5 (lines A). The shape of the wedge (expressed by the width-height ratio B/H) is, however, an important parameter (see Fig. 5, lines for $h = \infty$). The smaller the width, the more pronounced becomes the stabilizing effect of the shear resistance at the vertical slip surfaces of the wedge. So, for example, case C of Figure 5 needs about the same bolt quantity as case B, in spite of the greater height of the wedge.

The reinforcement installation sequence (expressed by the parameters l and L) is also important. In the example of Figure 6, up to 1.5 bolts/sqm are needed if installed every 9 m (upper line). In the case of frequent installation (every 4.5 m, see lower line), only

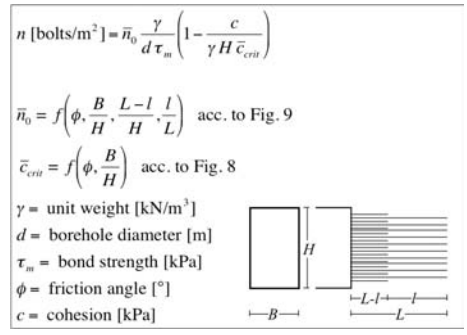

Figure 7. Synopis of equations for using the nomograms.

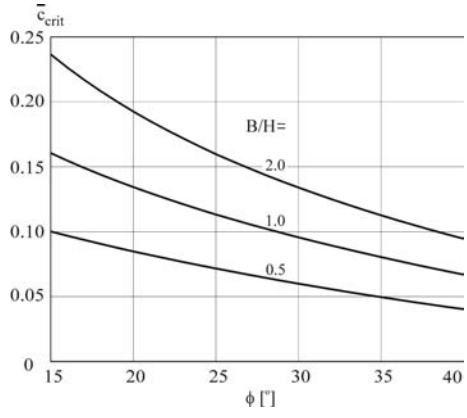

Figure 8. Dimensionless critical cohesion $\bar{c}_{crit}$ as a function of friction angle ϕ and of shape factor B/H.

0.4 bolts/sqm must be installed. The total quantity of bolts (meter bolts installed per linear meter tunnel) is given by $n{\cdot}B{\cdot}H{\cdot}L/l$ and amounts up to 130 m/m in the first case, and up to 65 m/m in the case of frequent installation. This considerable saving is due to the more favorable pressure distribution (cf. Fig. 2a and 2b). A frequent installation of bolts interferes, nevertheless, with the excavation works and may therefore be advantageous only if the reinforcement quantities are large.

2.5 *Design nomograms*

Based upon these considerations, design nomograms have been prepared. Figures 8 and 9 show the dimensionless critical cohesion $c_{crit}/\gamma H$ and the dimensionless reinforcement density $n_o d\tau_m/\gamma$, respectively, as a function of the friction angle ϕ for cross section shapes $B/H = 0.5$ to 2, $h/H = \infty$ and $\lambda = 0.8$ (cf. Eqs. 15 and 16). The solid lines in the nomograms of Figure 9 concern the common case of short overlapping lengths (L-$l < L/2$). The dashed lines apply to the case

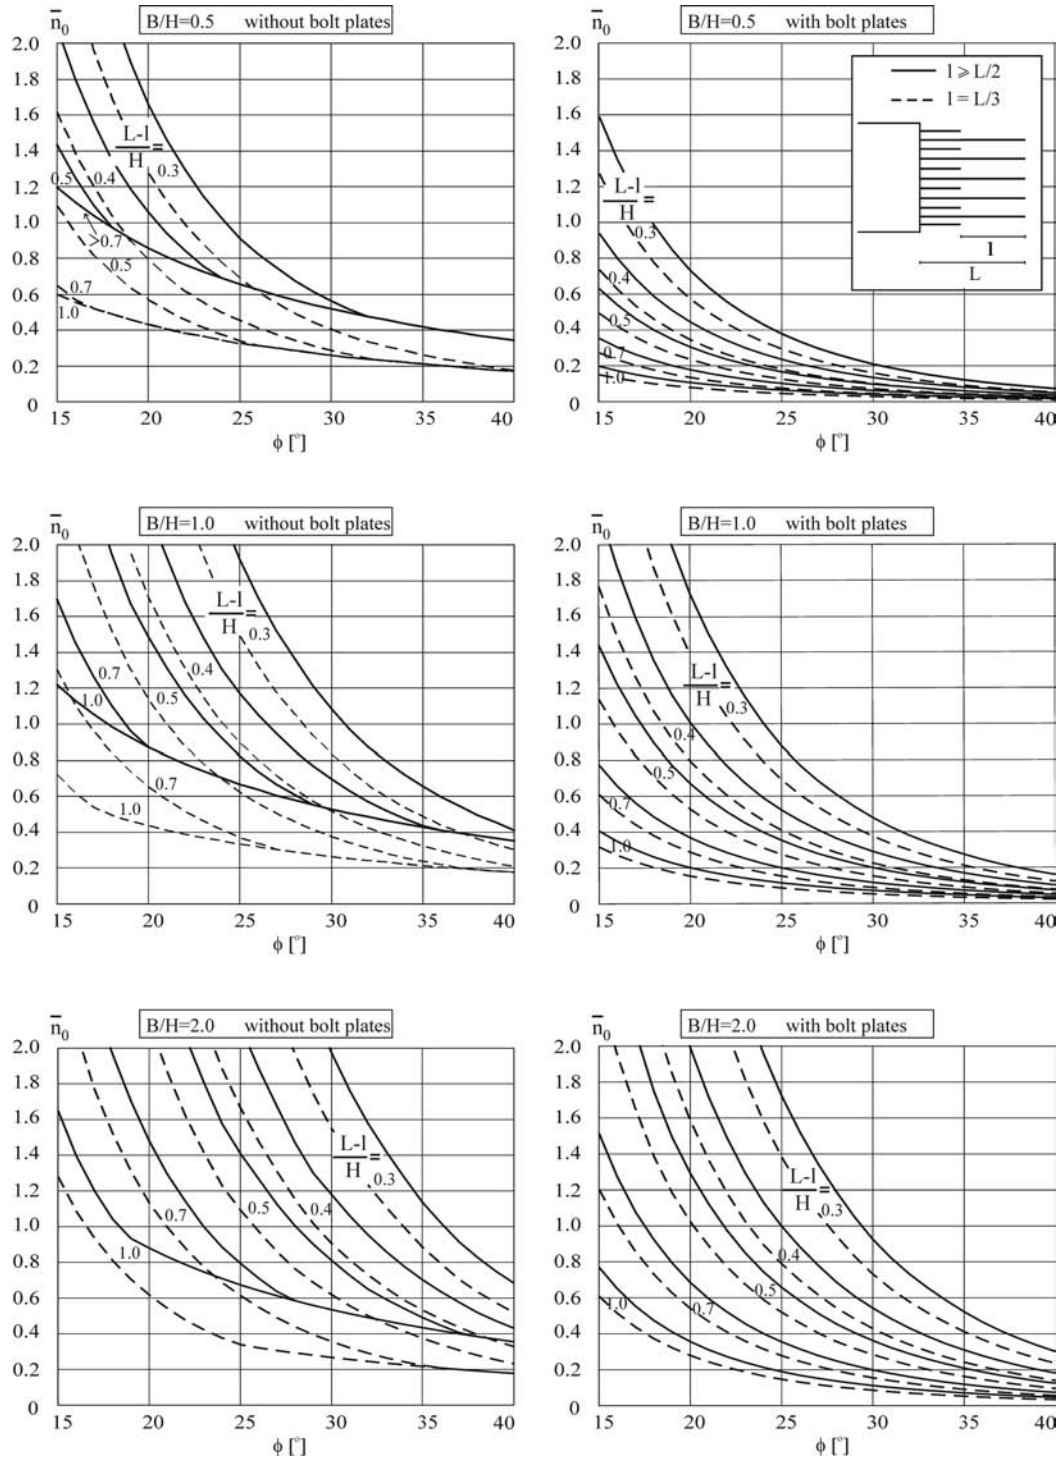

Figure 9. Dimensionless reinforcement density $\bar{n}_0$ as a function of friction angle ϕ.

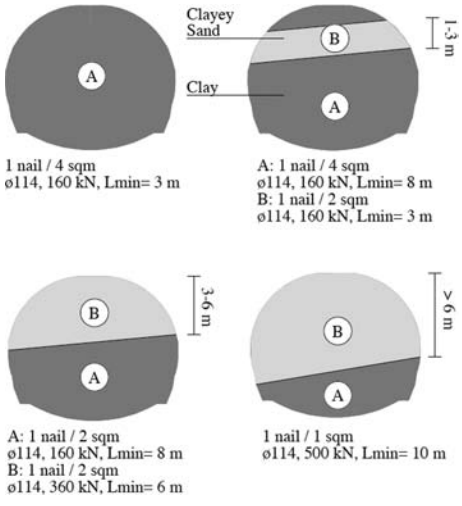

Figure 10. Example of face stabilization according to stratigraphy (after Anagnostou 2001).

$l = L/3$, i.e. to frequent reinforcement installations. All diagrams have been calculated for a safety factor of 1.0. A safety factor ν can easily be taken into account through an appropriate reduction in the shear strength parameters (c/ν, $tan\phi/\nu$ and τ_m/ν).

3 CLOSING REMARKS

The presented nomograms cover a wide range of conditions and represent a very useful design aid for conventional tunneling through soft ground. One should, nevertheless, keep in mind the underlying assumptions and their limitations. Besides a global instability of the tunnel heading, local failures may also occur and endanger safety on the work site. For example, the nomograms suggest that a cohesionless ground can be stabilized by bolts. Without a minimum cohesion, however, the ground will fail between the bolts particularly in the presence of water. On the other hand, according to Figure 8 the face should remain stable without any measures if the cohesion is higher than a threshold value of about $0.2\gamma H$, i.e. 40–50 kPa for common cross-sections of traffic tunnels. This conclusion oversimplifies reality, because failures such as detachment of wedges along wet slickenslides, may occur even in a stiff clay. Heterogeneous ground is particularly demanding (Fig. 10). Design calculations in that case provide only rough guidelines for decision-making during construction.

Cost-effective pre-injection with rapid hardening microcement and colloidal silica for water ingress reduction and stabilisation of adverse conditions in a headrace tunnel

A.K. Bahadur
Uttaranchal Water and Power Department, Dehradoun, India

K.G. Holter
BASF UGC Europe, Zürich, Switzerland

A. Pengelly
BASF Construction Chemicals, Delhi, India

ABSTRACT: During the drill-and-blast excavation of the headrace tunnel, difficult rock conditions were encountered in a zone caused by a regional fault. Tunnelling through the zone was initially done without pre-treatment of the ground, resulting in severe difficulties and a lengthy delay. Therefore it was decided to excavate a bypass tunnel utilizing pre-excavation grouting from the tunnel face. A two-stage pre-injection scheme was laid out in order to achieve the desired penetration of grout into the ground. First stage grouting was done with rapid hardening microcement, in which a limited grout take was achieved. The second stage of grouting was done with liquid colloidal silica, thus achieving penetration into the finest discontinuities. The result was an acceptably fast advance, excellent ground stability and virtually dry ground conditions. This enabled the safe installation of rock support with steel sets combined with sprayed concrete.

1 BACKGROUND

1.1 *The project*

During the drill-and-blast excavation of the 16 km long headrace tunnel of 4×76 MW Maneri Bhali Hydro Electric Project, difficult ground conditions were encountered in the stretch passing below a stream. The ground cover mostly consists of river born material (RBM).

Tunneling through this section was initially done without any pre-treatment of the ground, resulting in the puncturing of the small rock cover over the tunnel crown, causing severe leakages from the water saturated RBM zone and chimney formations. The difficulties caused lengthy delays, so much so that a 56 m long problem zone in the tunnel took nine months to excavate.

Moreover, due to problems faced in negotiating this sitaution, the tunnel could not be excavated to full required cross section. As a result the designers of the tunnel lining advised the reduction of the tunnel section and the installation of steel lining.

The work on the project was stopped in early nineties. When it was resumed in 2002, the project management did not feel comfortable with the idea of having a reduced tunnel section with steel lining in this portion due to the of extra time required for the steel lining, as well as the increased friction losses associated with this arrangement.

1.2 *Geological conditions*

The challenge in this situation was to 'again' cross this fault zone in the bypass tunnel, without ground collapse and in dry conditions, thereby allowing lining construction in dry and stable conditions. The rock mass consisted of heavily jointed quartzites and metabasics on each side of a regional fault zone.

A river valley at surface followed the fault zone alignment with subsequent thick deposits of river born materials over lying the quartzite and metabasics. The fault zone exhibited highly crushed material with associated high water seepages that resulted in significantly reduced stability of the excavated rock-mass. Joint fillings consisted of fine grained quartzite material of clay and silt fractions.

1.3 *The problem*

During the initial phase of the project, the tunnel was excavated through this zone without any pre-treatment

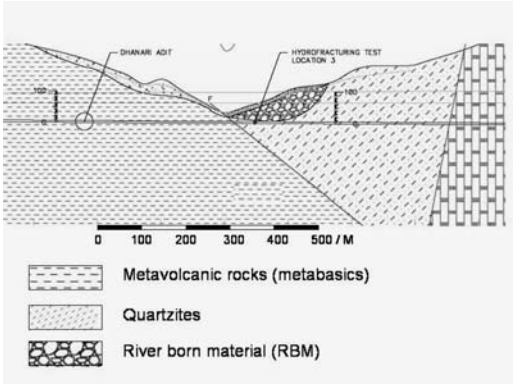

Figure 1. Longitudinal geological section with the tunnel alignment passing under the weak zone. Note that the rock overburden is indicated as uncertain. The vertical lines indicate exploratory holes.

of rock mass. Large water ingress and cave-ins were experienced. A very irregular tunnel contour with less than required excavation diameter was the result. The tunnel was supported with steel sets and bakfill concrete. The tunnel has suffered from major seepages in this section since the excavation in the eighties.

After the work was restarted in 2002, it was decided to reconsider the design of the tunnel lining in this section, with a intent of reducing the lining construction time and friction losses. The first option was to re-excavate this part of tunnel to the fully required cross section. This was not implemented since this would have caused stoppage of all excavation/lining activities further downstream.

Moreover, with the rate of water seepage being observed it was considered uncertain if a structurally sufficient support of the tunnel could be achieved in the already excavated tunnel. For these reasons, it was decided to excavate a by-pass tunnel around the problem area. Pre-treatment ahead of the excavation was decided in order to improve the properties of the ground as well reduce water ingress to a minimum.

The by-pass tunnel was located at approximately 25 meters distance running parallel to old Head Race Tunnel alignment. Limited relief in the form of already happening seepage in the original Head Race Tunnel alignment was anticipated, though it could not be considered adequate to create desirable dry excavation conditions.

When excavating through the zones, the exploratory holes drilled ahead of the tunnel phase always showed a significant amount of water seepage. Hence, a pre-injection scheme was considered necessary, to consolidate the ground and reduce the seepage to a minimum.

2 PRE-INJECTION SCHEME

2.1 *Required results of the pre-injections*

The main goal of the pre-injection works was to achieve penetration of the ground with a grout with a significant mechanical strength. The extent of the penetration had to be sufficient in order to reduce the water seepage to a virtually dry rock mass.

The densely fractured competent quartzitic schist which was the rock mass to be encountered, would require an improvement of the joint characteristics in order to achieve a general improvement of the rock mass. General weathering of the rock mass or voids in the rock were not encountered. Hence, the pre-injection scheme was a pure issue of achieving good penetration into fine joints with fillings of in-situ crushed rock material.

2.2 *Pre-injection strategy*

The first attempts with pre-injections with ordinary Portland cement (OPC) were not convincing. Penetration of the ground was not achieved. In most cases, one only achieved filling of the drill holes with the grout. It was therefore obvious that one had to employ a more sophisticated injection system, including a well laid out method in order to achieve the desired result.
The strategy for the injection works consisted of the following main elements:

a) Injection with pressure up to 60 bars to achieve sufficient penetration
b) Injection rounds up to 15 m ahead of the tunnel face, covering the full tunnel circumference
c) A method for the establishment of drill holes to desired length in the fractured rock
d) Injection materials which would penetrate into the rock mass to the necessary extent to provide the desired improvement result
e) A second stage of injections (if necessary) with low viscous grout
f) A simple method to verify the achieved result of the injections, and hence, decide further advance of the tunnel face

2.3 *Method considerations*

After the initial attempts with injection with OPC as well as microcements, it was obvious that a two-stage injection scheme would be required. Basically this consisted of a first stage injection with microcements with a limit to the injection pressure.

Following the first stage of microcement injections, one drilled a few holes ahead of the tunnel face to verify the achieved water seepage reduction and improved properties of the rock mass (by drillability). In the case the result were unsatisfactory, one would decide the second stage injection.

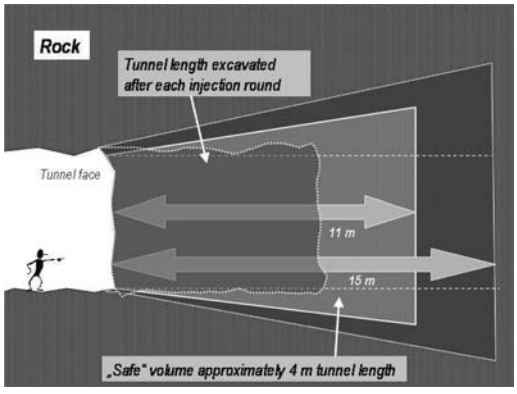

Figure 2. Principal sketch showing coverage of the two injection stages ahead of the tunnel face. The dark area indicates the coverage of the first stage with microcement injections. The lighter area shows the second stage with colloidal silica injections.

The second stage of injections was designed as an inner injection fan which was entirely covered by the rock mass volume treated under the first stage of injections. Figure 2 shows the layout of the two stages of injections.

With this method it was possible to advance the tunnel face approximately 7–8 m before a new injection cycle had to be undertaken. This provided a 'safe' volume of treated ground of minimum 3–4 m ahead of the tunnel face which had been injected during both injection stages.

The jointing of the rock mass imposed a limit to the feasible drilling length with normal percussive drilling. In untreated rock the holes would partially collapse and create difficulties with the retracting of the drilling rods. It was also difficult to achieve good and tight placements of the injection packers in open drill holes under such high extent of jointing and unstable rock.

For this reason it was decided to establish the drillholes through grouted steel pipes. Furthermore, the drilling and injection through the steel pipes was done in advancing steps with lengths of approximately 3 m. Hence, one would re-drill and inject through the same steel pipe several times, advancing longer for each time. In this way one would be re-drilling through a stabilized length and hence, one could drill further into un-treated rock. This method allows making long holes but limiting the drilling length in untreated ground to sections of 2–5 m.

This particular method was applied for injections in adverse ground with rapid hardening microcements during the construction of the Bjoröy subsea road tunnel in Norway in 1994. A controlled improvement of the ground was achieved and safe drill-and-blast excavation through the zone could be realized. (Holter et al. 1995, Holter et al. 1996)

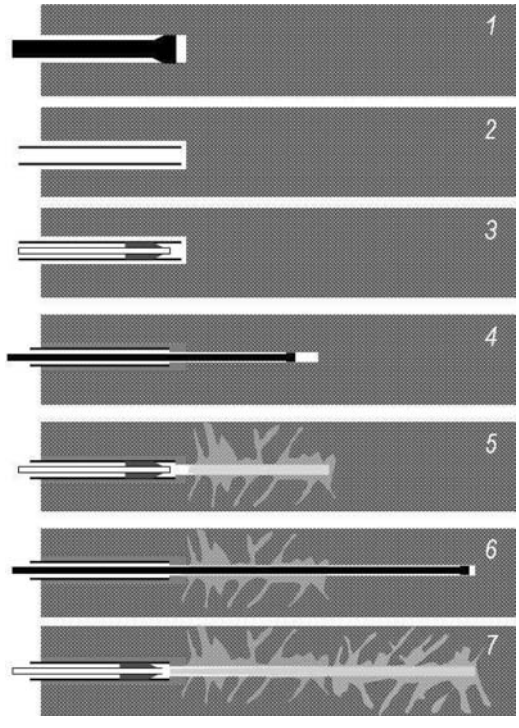

Figure 3. Sketch showing the main steps in the method of establishing drillholes through steel pipes for injection in difficult rock. Repeated drilling and stepwise advance through grouted steel pipes.

The method of stepwise advancing repeated drilling and injection through grouted steel pipes was one of the key issues to achieve any success with pre-injections under these ground conditions. This method is therefore explained in detail below. Figure 3 below illustrates the method graphically.

- *Step 1:* Drilling of 65–70 mm diameter hole to 3 m length
- *Step 2:* Installation of a steel pipe with internal diameter 50 mm (or diameter to fit the expandable packers)
- *Step 3:* Placement of packer (diameter 48 mm) at the very end of the steel pipe and injection of a stiff (very viscous) cement based grout which fills the annular space between the rock and the steel pipe. Hardening for approximately 12 hours
- *Step 4:* When the grout is hardened, drilling through the steel pipe to feasible length (approximately 3 m beyond the steel pipe)
- *Step 5:* Placement of packer and pressure injection with microcement grout for penetration into the rock mass in the drilled length of the hole.

Termination criteria for the injection set to 60 bars injection pressure, or 300 kg injected cement per meter drillhole

- *Step 6:* After hardening of the injected grout, re-drilling through the pipe and injected area to approximately 3 m beyond last drilled length
- *Step 7:* Placement of the packer in the pipe and inject (repetition of step 5)

The length of the drilling steps was adjusted to the encountered rock conditions.

Normally it was possible to advance the drilling to a depth 4–5 m beyond the preceding injection depth. The same method was used when injecting the liquid colloidal silica. However, drilling lengths were normally 5–6 m in untreated rock due to the improvement effect in the rock of the preceding microcement injections.

2.4 *Injection materials*

Bearing in mind the relatively low rock cover and the poor ground, it was necessary to inject with moderate pressures. In order to achieve penetration of the different joint features with moderate injection pressures, one recognized the need for two different grouts. One grout was designed to penetrate into the largest fissures and the other grout type to penetrate into the fine joint features which were partially filled with the in-situ crushed rock material (silt and clay fractions).

2.4.1 *Microcement grout*

In order to achieve the best possible penetration in the first stage of injection, a microcement with particularly good penetrability properties was chosen. Furthermore the chosen microcement had rapid hardening properties. Initial set of the grout mix took place after approximately one hour with water/cement ratio 1:1 at 20°C (typical temperature in the tunnel). The grain size characteristics of the microcement was a d_{95} of 16 μm.

The standard utilized mix design of the microcement grout had a water/cement ratio 1:1 with the dosage of a special dispersing agent. This gave an exceptionally good stability combined with low viscosity of the grout (Marsh cone time 32 sec) which was considered essential for the penetrability properties. The rapid hardening properties of the microcement grout enabled the continuous work without any delay between the different steps in the injection operation. For the microcement a maximum injection pressure of 60 bars was experimentally established, based on when hydrofracturing with a grout would with water/cement ratio 1:1 would occur. Furthermore, at 60 bars injection pressure with this mix a relatively limited grout take was experienced. Hence, a risk of a significant pressure build-up in the ground fed by an injected volume of grout could be neglected.

2.4.2 *Colloidal silica grout*

For the second stage injection an injection gel based on liquid colloid silica was chosen. The reason for this was the penetrability properties that this gel offered. The chosen gel had a viscosity of 5 mPas in liquid state (during injection) and a particle size of 0.016 μm. This allowed for extremely good penetration under difficult ground conditions.

The workability properties of this grout were exceptionally favourable under these conditions. One could easily utilize the same injection equipment for the microcement and the colloidal silica grout, a cement injection plant with a high pressure single component plunger pump.

The open time of the colloidal silica grout could be easily and precisely controlled from approximately 10 minutes up to 2 ½ hours.

Colloidal silica is a pure mineral grout. The gelling process takes place by a physical reaction between particles of silica (SiO_2). The accelerator for this grout is a solution of sodium chloride. Hence, this grout is very user and environmentally friendly, imposing no health risks due to chemical reactivity or toxicity during the injection works.

Furthermore, colloidal silica offers long term chemical stability and durability (resistance to washout or leaching). For this reason colloidal silica was preferred to silicate (waterglass) based gels.

3 ACHIEVED RESULTS

During injection it was necessary to limit the maximum injection pressure to approximately 60 bars. The reasons for this were occurrence of backflow of grout into the tunnel and sliding of the packers in the steel pipes.

The first stage injections with rapid hardening microcement showed a relatively limited grout take of only 100–150 kg per m drillhole when the termination pressure of 60 bars was reached. Bearing in mind the seepage which was encountered in the drillholes one would expect a higher grout take.

The reason for the relatively low grout take was joint fillings which consisted of the silt and clay particles, which in turn limited the penetration of the grout created by filtration.

The first stage injection fan with microcement was always completed in the full circumference of the tunnel before the secondary fan was attempted. The reason for this was that the first stage injection provided penetration of grout into the joints with the largest apertures. Hence, the second injection stage with an extremely low viscous grout could be targeted for the finer joints and the joints which were partially filled with clay and silt.

Figure 4. A typical situation during ongoing injection works. The steel pipes for injection are seen along the perimeter of the tunnel face.

Figure 5. Tunnel under excavation through successfully treated ground in the weakness zone. Litterally dry and stable conditions at the tunnel face, as well as a favorable shape of the tunnel contour have been achieved.

The secondary fan was drilled and injected with liquid colloidal silica with a termination pressure of 25 bars, or approximately 100 kg per m drillhole length.

Injection beyond a pressure of 25 bars usually showed signs of hydrofracturing. The control of the achieved result was done in two ways. Firstly, the water seepage situation after the injection of the two stages was controlled in drillholes. Secondly, the result was observed in the tunnel contour after the excavation of the first round starting from the injection location. In this way the detailed criteria for termination of the injection were fine tuned and continuously adjusted.

The result was a literally dry and stable tunnel contour. No excessive breakouts of rock or cave-ins occurred during excavation through the weakness zone. (Figure 5).

4 CONCLUDING REMARKS

This proactive approach to pre-grouting fault zones ahead of the excavation face resulted in the tunnel being excavated without a single incidence of collapse and with virtually dry conditions. The effects could be directly compared to the poor conditions and heavy water flows observed in the adjacent tunnel where pre-injections were not used. A direct comparison of the effectiveness of microfine cements and colloidal silica gels versus OPC was also clearly evident.

This exercise also showed that a proactive approach to drilling and grouting with a clearly defined method statement and utilizing materials with the proper penetration, viscosity and rapid hardening characteristics can significantly reduce the construction time through such highly faulted and unstable zones (6 months in by-pass tunnel versus 18 months in original tunnel). The low cost of pre-injection in comparison with post-injection techniques can also be clearly seen. The cost for materials on this project came to a material cost of approximately Euro 1,200/m versus a similar condition in another tunnel in India where polyurethane post-injections were utilized at a cost of approximately Euro 12,000/m and currently almost 2 years behind schedule.

The post-injection then cost about 10 times more just in materials. Considering that materials are mostly less than 10% of the total cost, post-injection as a method may easily cost 20 to 30 times more than pre-excavation injection. (Stenstad, 1998)

ABSTRACT: Backfill grouting is an important technique to decrease stratum deformation in shield tunnel construction. After backfill grouting completed, grout gradually convert from liquid to solid due to the grout draining and consolidating. Grout volume shrinkage has an important influence on stresses and deformation of soil around tunnel. An element model apparatus was used to test grout deformation under various grout pressures and groundwater pressures. In sand soil, grout deformation time is short; high grout pressure can accelerate drainage and consolidation; high groundwater can slower the grout deformation rate, and minimize the final grout deformation.

1 INTRODUCTION

With the fast development of economy in China, there is a huge demand for the development of underground space in large and medium cities (Qian Qihu 1998). Nowadays shield tunneling technology has widely applied to the construction projects of subway and cross-river tunnels, such as Nanjing subway and the South-to-North Water Transfers Middle Route Cross Yellow River Tunnel. The stratum disturbance would be induced more or less in process of shield tunneling, then cause ground settlement. So predicting ground settlement and decrease the settlement caused by tunnel excavation is a major engineering challenge (Qu et al., 1995 & Bernat et al., 1998). The stratum displacement can be mostly induced by two aspects: the supporting pressures in chamber cannot balance the earth pressure and groundwater pressure ahead of working face, and induce the working face instability; the tail void closure and backfill grout shrinkage induce periphery soil deformation. It is shown in Figure 1 that mostly ground settlement occurs in excavation stage and tail void grouting stage (Hwang et al., 1995 & Kuwahara et al., 1997).

Apart from control working face stability strictly during shield tunnel excavation, the tail void backfilled by grout is an active measure to reduce stress release of soil and soil deformation. After backfill grouting completed, grout convert from liquid to solid under grout pressure during the action with soil and liner (Bezuijen et al., 2004, Hashimoto et al., 2004 & Zhou Xiaowen et al., 2001). So the grout mechanical properties and grout volume shrinkage vary with time is relevant to

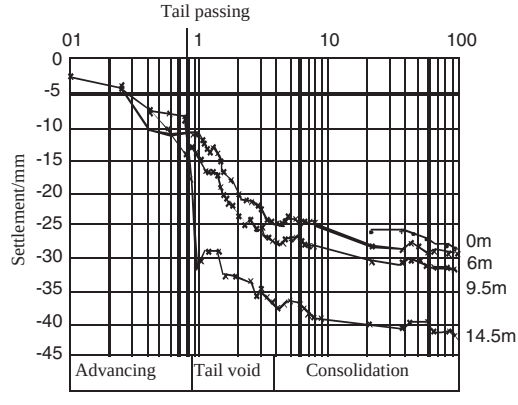

Figure 1. Settlement of shield tunnel construction in Taibei.

grout pressures, surround soil parameters, groundwater level and grout material properties(Snuparek et al., 2000).

With the proceeding of backfill grouting, tail void gradually backfilled, the water content drained slowly from grout to soil under grout pressure. Then grout volume shrunk, grout pressure dissipated, grout become hardened. Many numerical calculation methods have taken into the function of backfill grouting. The hardening of the grout materials with the process of shield excavation were simulated by varying parameters such as the stiffness, the internal friction angle and cohesion at different construction stages (Bernat et al., 1999). But the parameters of grout are defined based on presupposition, especially at the stage of state

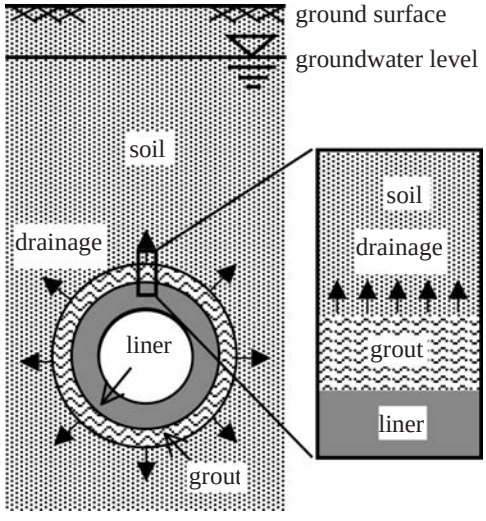

Figure 2. Sketh of consolidating grout around tunnel liner.

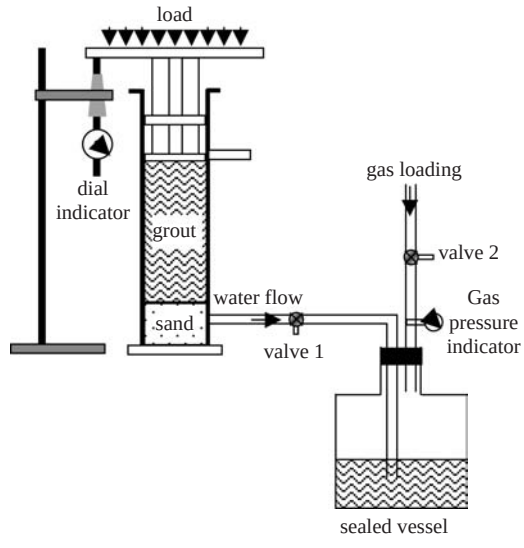

Figure 3. Experimental setup of grout volume shrinkage.

conversion from liquid to solid. So the changes of the grout parameters are very important to predict the ground settlement.

2 TEST SCHEME

2.1 *Test introduction*

After backfill grouting completing, grout formed an annular layer between liner and surrounding soil. The sketch is shown in Figure 2. An element is taken out from tunnel crown. The element model includes soil, grout and liner. Liner is considered impervious. Water content penetrates through soil from grout under grout pressure. Based on the element model, experimental setup was designed, see Figure 3.

Test sample is chosen from the medium and fine sand stratum of South-to-North Water Transfers Cross-Yellow River Tunnel. Sand particle size distribution curve see Figure 4. Sand mechanical parameters see Table 1. Grout is hard grout, and mixture ratios see Table 2.

2.2 *Test procedure*

Sand must be saturated by air extraction before test. Close valve 1, the sealed vessel must be inflated up to preset gas pressure to simulate groundwater pressure, then inject the grout and load weights up to plunger to preset grout pressure. Open the valve 1, the data of dial indicator be recorded simultaneously.

Complete trial scheme adopted, grout pressures are 150 kPa, 200 kPa, 250 kPa, 300 kPa respectively, groundwater pressures are 0 kPa, 50 kPa, 100 kPa respectively.

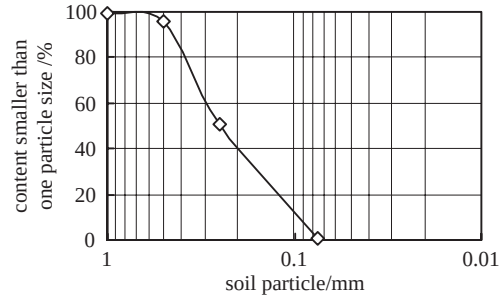

Figure 4. Particle size distribution curve of sand.

Table 1. Mechanical parameters of sand.

	γ/kN/m^3	c/kPa	ϕ/^{o}	E/MPa	ν	K/cm/s
sand	17.21	10	38	34	0.3	1.16E−3

3 TEST RESULTS AND ANALYSES

1. Figure 5 to Figure 7 present comparisons of grout deformation vary with time between different grout pressures (Pg) under same groundwater pressure (Pw). With the increase of grout pressure, the grout volume shrinkage rate is accelerated, the final deformation is large, and the deformation stabilization time is short. It is obvious that high grout pressure accelerates the rate of permeation of grout-water to soil, then promotes the grout harden rate. It is advantageous to tunnel early stage stability.

Table 2. Mixture ratio of backfill grouting material.

material	cement	Flyash	bentonite	sand	water	water reducing agent
percentage ratio	1.0	1.67	0.21	4.10	2.0	0.02
content /kg/m^3	195	325	40	800	390	4.5

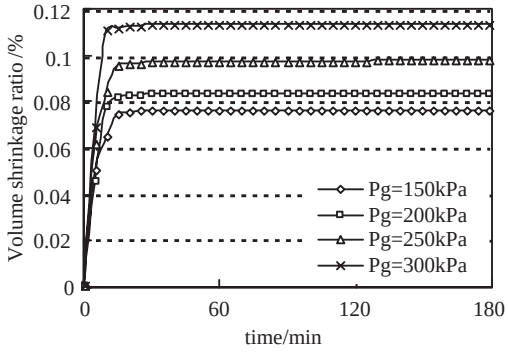

Figure 5. Shrinkage ratio curves versus time under different grout pressure Pg and groundwater pressure Pw = 0 kPa.

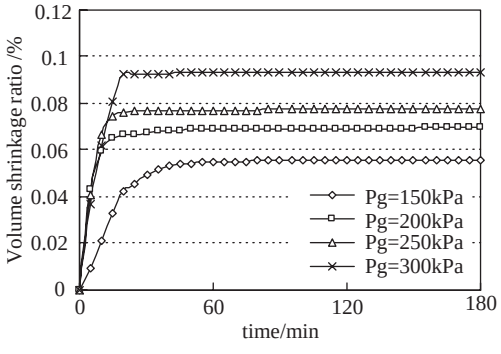

Figure 6. Shrinkage ratio curves versus time under different grout pressure Pg and groundwater pressure Pw = 50 kPa.

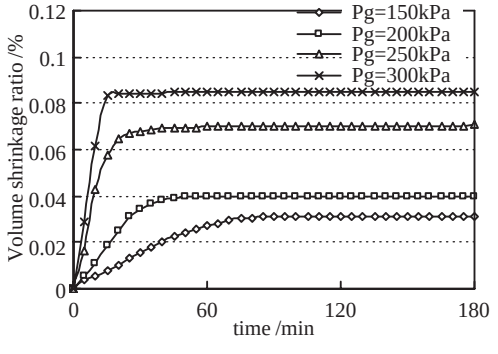

Figure 7. Shrinkage ratio curves versus time under different grout pressure Pg and groundwater pressure Pw = 100 kPa.

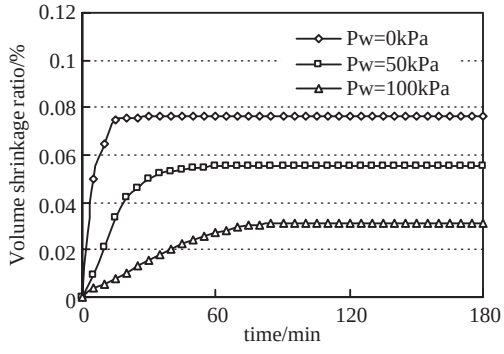

Figure 8. Shrinkage ratio curves versus time under different groundwater pressure Pw and grout pressure Pg = 150 kPa.

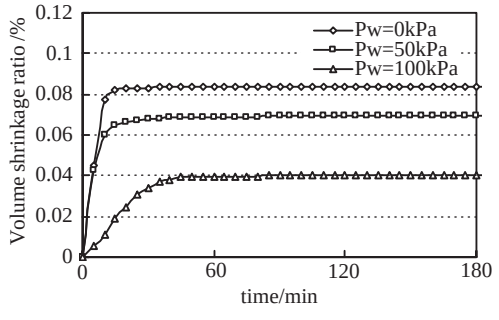

Figure 9. Shrinkage ratio curves versus time under different groundwater pressure Pw and grout pressure Pg = 200 kPa.

2. Figure 8 to Figure 11 present comparisons of grout deformation vary with time between different groundwater pressures (Pw) under same grout pressure (Pg). With the increase of groundwater pressure, the grout volume shrinkage rate is slower, the final deformation is small, and grout deformation stabilization time is longer. It is obvious that the main function of groundwater is to slow down the rate of permeation of grout-water, then influence on the grout harden rate.
3. Figure 5 to Figure 11 show the major change of deformation complete within about 1 hour, and the final deformation is not exceed 12%. The grout pressure compare with groundwater pressure is higher, the curves of deformation is more steeply. The groundwater pressure has big effect on grout

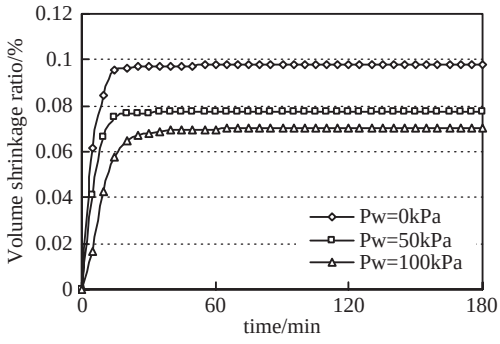

Figure 10. Shrinkage ratio curves versus time under different groundwater pressure Pw and grout pressure Pg = 250 kPa.

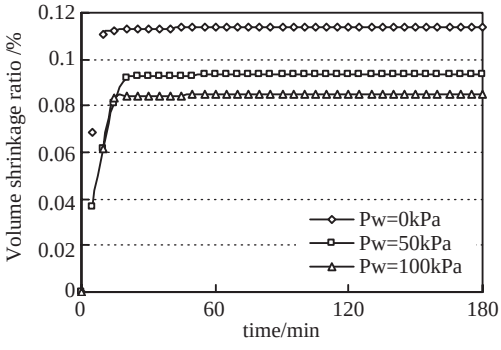

Figure 11. Shrinkage ratio curves versus time under different groundwater pressure Pw and grout pressure Pg = 300kPa.

deformation rate under relatively minor grout pressure. Grout volume shrinkage occurs during the stage of grout drainage and consolidation due to the big permeability of sand.

4 CONCLUSIONS

The grout is injected in a fluid state with a high value for the water content. As the tunnel is located under the water table, the grout mechanical properties variation is a very complicated process. The grout deformation characteristic has studied by element model apparatus. The following conclusions can be drawn:

1. High grout pressure is advantageous to accelerate the permeation of grout-water, then short the time of grout deformation time.
2. The main function of groundwater pressure is slow down the rate of grout-water drainage, and reduces the final grout deformation.
3. Due to the high permeation rate of sand, grout consolidated drained time is short, grout deformation rate is fast.

Advances in synthetic injection technology, do they improve tunnel construction productivity?

Thomas Yang
General Manager – Hydroseal Enterprise Co Ltd

ABSTRACT: As tunnelling in urban areas continues to expand problems of sink holes and traffic disruption become less acceptable. Delays in the construction process become costly and can lead to subsequent claims from follow on contracts such as track laying, lighting and others. Build Own Operate companies want the tunnel in use on the time and with minimum maintenance. Chemical injection resins have been available in crude forms for many years. The available materials in the 1970 to 1985 were often highly toxic and carcinogenic and could injure the operatives as well as pollute the ground. Polyurethane technology was normally single component water reactive often with brittle open cell foams. Problems of running sands, silts and high water pressure need a variety of solutions. Material set times and pot life has to adjust from seconds to minutes and often need some structural strength. Modified and new equipment coupled with advance chemical resins have provided solutions to solve some of these problems. Case histories will outline how contractors were able to speed up tunnel excavation and solve unstable soil conditions. The new generation resins have their long properties listed opening up new possibilities for solving problems. Costs are examined showing often the overall saving in the contract by spending relatively small amounts of money in critical areas.

1 INTRODUCTION

Injection techniques using cements, modified cements and resins as means of solving problems in the tunnelling industry have been available for many years. Materials technology has advanced rapidly over the last two decades and due to this some manufacturers no longer use the historic generic names as they are no longer specific enough to describe their actual use and application. As more and more structures move underground and often nearer to other underground structures new methods of injection have been developed. Today methodology is the key word, that is not just material but also equipment, trained experienced applicators and technique.

1.1 *Materials*

The early injection resins consisted of cements, later these were modified with supplementary materials such as bentonite, fly ash and other pozzolans. Often there was a need for acceleration of the set time and this was achieved by the use of silicate and similar materials. These materials are still in use today and are cost effective and a practical solution to many ground and water ingress problems.

Marotta & Peach. 2006. High Pressure …
Bossard & Mattar.2005. How the Zimmerbert…

In the early seventies water based chemical grouts appeared in the market. Compared to epoxy and polyurethane resins in 1970–1975 they had much lower viscosity were flexible and apparently easier to use. However many of them were carcogenic and not environmentally acceptable. However the ability to adjust set times from seconds to minutes plus ultra low viscosity opened up new methods of sealing structures against water ingress.

Developments in epoxy and polyurethane resins continued and by the late 80s and into 1990 had became less viscous and capable of exhibiting properties from flexible to rigid depending on the formulation. Micro cement technology was improving allowing penetrations into soils and other substrates that was previously impossible.

The twenty-first century has seen even more accelerated progress and Tables I. Highlight some areas of application needed in injection materials. Table II. Look at specific injection properties.

1.2 *Equipment*

With the constant advancement of materials in both viscosity and gel time change in the pump and packer technology was inevitable.

To use injection resins with set times from 10 seconds to 3 minutes require the use of twin line pumps where the resin is mixed at the point of application in a specially designed mix head. Twin line pump technology is not new and in epoxy injection was used in the mid 1970 for epoxy crack injection. What has changed is the understanding of the methods of mixing resins in the mix head.

Early mix heads had brushes or inserts of a fixed length so no change in mixing shear could be introduced. This could lead to resins of different viscosity or chemistry not being mixed properly and thus not developing full performance. We have developed mix head technology that varies the shear energy in the mix head thus ensuring all mechanical properties of the resin we achieved.

Other developments in equipment include very high volume pumps up to 60 litres per minute. Diagram A illustrates a modern twin line pump and correct mix head technology.

To place injection resins in the right place requires a packer. Standard packer is available from many sources but in out experience custom designed packers are often needed. Diagram B illustrates a specific packer developed for a tunnel injection.

1.3 *Case histories – Singapore MRT circle line*

A suburban MRT Station was being built underground where the ground conditions were variable. The construction method was to build a secant pile diaphragm wall and then excavate and strut. As in most situations some leakage at the pile joints is inevitable. In good clay or rock this is never an issue but in sandy soils it can have disastrous consequences.

In this particular project and advance plan was made to counteract this situation should it arise. The first line of defence was sandbags on the site near the area of excavation. The second line of defence was to keep on site specialised twin line pumps and quantities of hydro-structure resin. This meant in emergency mobilisation would be fast and effective.

Table II. Injection resin properties.

	Viscosity CPS	Set time	Strength N/mm^2	Resistant to water pressure wash out	Relative cost index

Cost of site downtime S$	15,000/day	15,000/day
Time to grout	1–3 days	1–4 hours

The hydro-structure resin has ultra low viscosity and an ability to vary the gel time between 8 seconds to three minutes. The twin line pump has a mix head near the point of injection and built in water flush.

This technique of injection was used on a number of occasions and proved totally successful. The sketches below show the sequence of work.

1.3.1 *Cost benefit*

Cost savings are difficult to quantify due to a large number of variables however Table III shows a cost estimate. The cement grout is disrupted by the water flow and this is why the grouting time is longer.

The water pressure and flow are not having the same effect on the resin injections as compared to cement grout. If the volume flow is too high then the cement grout will always be washed out and will not be able to seal the leaks. The skill and experience of the specialist applicator is critical in ensuring the resin injection is cost effective.

1.4 *SMART tunnel Malaysia*

One of the largest tunnels in Asia is being constructed using slurry shield Tunnel Boring Machines. When cutter heads need to be replaced or other essential maintenance is required it is critical to be able to stabilise the air pressure.

Table IV. Case benefits – KMRT C01 LUO04 shield machine arrival.

Item	Injection water Glass-cement grout	Injection MC-Injekt GL 93/95 Acrylic Gel
Volume	26 m^3 × NT$25,000/$m^3$ = NT $650,000	105,690 kg × NT$280/kg = NT $2,959,320
Length Progress	2.4 (Not finished)	7.2 (Arrival End)
Time	60 days	7 days
Time Cost	Shield Machine Operations Cost 60 days × NT $100,000 = NT $6,000,000	Shield Machine Operations Cost 7 days × NT $100,000 = NT $700,000
Time Delay	55 days	Normal
Problem	Not solvent	Solvent
Payment cost	NT $6,650,000	NT $3,659,320

Hydro structure resins have been adopted as a means of ensuring this pressure can be maintained.

This is not a new technique – it was used in Singapore on Contract T05 for the Deep Tunnel Sewage System and in Holland on the Westerschladen Tunnel.

We have however due to experience and better resin technology been able to substantially reduce costs. Hydro structure resins can be both retarded and accelerated to ensure the optimum reaction time.

This means that we can pump less resin as the setting time to some degree dictates the flow pattern. Packer spacing can then be optimised which again saves time and costs. Typically at the SMART project we are using some 60%–70% less material than on other projects with a downtime of hours rather than days.

1.5 *Taiwan MRT*

The breakthrough of a TBM into the station box can be difficult or easy depending on ground conditions. Where a high water table sandy soils and moving water is expected hydro structure resins can be an economic solutions.

The choice of using Portland cement injections or resin injection is often made on the basis of comparative cost of a litre of material. However in areas of high water flow it is often impossible to prevent cement grout wash out.

The accelerators used in cement grouts are often stiffness or gelling agent not true set admixtures and depending on flow/pressure of the water they do not have the physical properties to stop the water.

In Table IV we summarise the actual costs involved in a tunnel break through with a high water table and sandy substrate.

2 CONCLUSION

In every part of our lives technology changes are forever increasing. In construction this is also true and it is difficult to keep up with all these changes. We are not suggesting that all traditional materials be abandoned but rather that there is an awareness of the new technologies. To be able to create resins with strengths greater than 60 N/mm^2 in 12 seconds creates problem solving system which previously were non existent. New applications are being discovered and the technology changes continue. Cost comparisons are important and if traditional materials are the correct technical answer then it would be foolish to use alternatives. However it is important that a total evaluation including down time, project delay costs and other parameters are included.

Injection techniques used at the old workings and karst voids abandonment under the built-up residential areas in the Urals

A.B. Kondratov
State Specialized Research & Production Operations "Geoinjection", Perm State Technical University, Russia

ABSTRACT: Results of a special injection technique development and application for the old underground workings and karst voids abandonment under the built-up residential areas are examined. Field and analytical studies data and specific examples of the technique practical application to provide for surface structures and facilities safety are presented.

1 INTRODUCTION

Many cities, medium-size and small towns in the Urals (Perm, N. Taghyl, Kungur, etc.) are located in karst terrain as well as in the areas undermined in the 17–18th centuries. To date no surveying records are retained. These underground openings of hundreds to thousands cubic meters volume are located at a depth of a few tens of meters from the surface presenting a real hazard to the surface structures, facilities and services.

Ensured protection of the municipal structures in the areas specified is provided for by the injection techniques developed in the Specialized Research & Production Operations "Geoinjection". These techniques are based on:

- geophysical methods of voids detection (seismic survey, electrical prospecting, ultrasonic location, teleinspection, etc.) with further verification through core drilling and core recovery;
- geomechanical analysis of surface movement through parameters before and after abandonment works;
- design of injection technique parameters and procedures in terms of the preliminary studies and geomechanical analysis;
- monitoring of rock mass injection treatment quality by means of submersible TV and ultrasonic equipment;
- geodetic monitoring of protected surface structures carried out by conventional means as well as GPS satellite geodetic control.

2 FIELD SURVEYING OF STRUCTURES

One of the typical structures located in the area of karsting is a brick 87 apartment house in Kungur, a small town in Perm Province. The building was constructed over pile foundation of 9 m depth. Geologic section of the foundation is presented by filled soil (0–3 m), loam with peat partings (3–6 m), loamy sand (6–10 m), loam (10–17.5 m), gravel and sand (17.5–22 m), limestone debris (22–28.5 m). It is underlain by thick hypsoanhydrite formation.

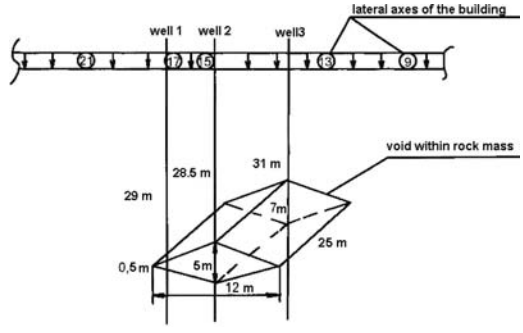

Figure 1. Configuration of the karst void in the formation under the building.

Deformations of the building have occurred right away on construction completion. In order to find the cause of this phenomenon the earth foundation study has been carried out by means of low-depth seismic survey of high resolution, core drilling and core recovery, ultrasonic echo-location and bore teleinspection. The building settling geodetic monitoring station has been deployed.

Studies enabled to establish that an extensive channel like solution cavity of volume about 900 m^3 is located under central part of the building at a depth of 28.5 m–33.5 m, 31 m and 38 m in the formation of hypsoanhydrite. The cavity is oriented perpendicular to longitudinal axis of the building. Configuration of the cavity of interest is illustrated in Figure 1.

Table 1. Filling material size distribution.

Sieve diameter, mm								
>10	10–5	5–2	2–1	1–0.5	0.5–0.25	0.25–0.10	<0.10	Total, %
Percentage								
25.01	22.89	14.60	9.55	8.96	11.47	5.87	1.65	100

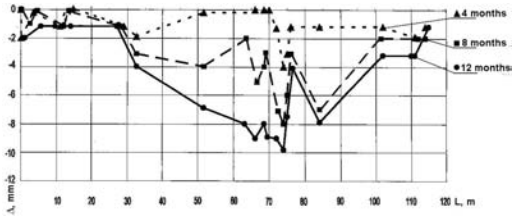

Figure 2. The building annual settling dynamics.

Underground void is filled with water and aggregate composed of chippings, gravel and sand. Aggregate grain size distribution is presented in Table 1.

Dynamics of the building annual settling is illustrated in Figure 2.

Comparing Figures 1 & 2 we may see that maximal settling of the building is observed directly over the solution cavity. In order to choose the measures preventing the building from further settling respective geomechanical analysis has been made.

3 GEOMECHANICAL ANALYSIS

A concept of safe mining depth can be found in various regulations on buildings and facilities protection against underground workings adverse effect on them. According to [1] safe mining depth may be calculated from the formulae:

$$H_s = \sqrt{Rk \cdot m} \quad \text{or} \quad H_s = 25K_l\sqrt{\frac{D \cdot m}{\varepsilon}} \tag{1}$$

where
R – the minimum allowable design radius of curvature, km;
k – proportionality factor;
m – height of a mine goaf;
K_l – a factor related to an angle of a seam dip;
D – the minimum size of a goaf, m;
ε – the maximum allowable relative lateral strain, mm/m.

The formula enabling to calculate the minimum depth of mining that manifests itself in surface

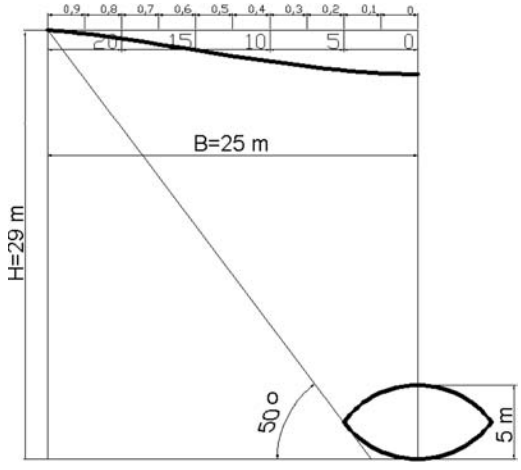

Figure 3. Counting circuit to estimate the surface subsidences and strains.

subsidence is given in the document [2]:

$$H_s = \frac{D}{0.15} \tag{2}$$

where

$$D = \sqrt{L_1 \cdot L_2}$$

L_1 and L_2 – dimensions of a goaf in two normal directions.

Taking the values of K, ε, k, k_α as it is recommended in the document [3], we have found the values of H_s from the formulae presented above. Respective values are 121 m, 220 m and 67 m, i.e. these three values exceed the goaf location depth therefore rock movement process will manifest itself in surface subsidence.

Proceeding from stated above we made analysis to find expected and design values of surface subsidences and strains for service life of the structure located in Commune Str., 45 with the goaf features being accounted for. Structural model is given in Figure 3.

The following assumptions have been made: $H = 29$ m, $B = 25$ m, $L_1 = 10$ m, $L_2 = 10$ m, $m = 5$ m.

Maximum expected subsidences as of the end of ground movement process are estimated by the formula:

$$\eta_0 = 0.9 \cdot f_0 \cdot m \cdot \omega \tag{3}$$

where:
f_0 – a factor accounting for effect of goaf and mining depth on maximum subsidence value is a function of

$$\chi = \frac{D}{H} = \frac{\sqrt{L_1} \cdot L_2}{H}, \tag{4}$$

$$\chi = \frac{\sqrt{10 \cdot 10}}{29} = 0.345 < 1.4 \qquad \text{therefore}$$

Table 2. Expected surface subsidences and strains per life of a building located over packed goaf.

Points of trough principal sections	Expected surface subsidences and strains per life of a building located over a packed goaf				
	Subsidences, m	Inclination, $i_0 \times 10^{-3}$	Curvature, $k_0 \times 10^{-4}$, l/m	Lateral strains, $\alpha_0 \times 10^{-3}$	Radius of curvature, R_0, km
0	0.130	0	0	0	∞
0.1	0.122	2.60	−6.35	−1.52	−1.575
0.2	0.108	4.88	−5.67	−1.36	−1.763
0.3	0.085	6.50	0	0	∞
0.4	0.059	5.69	3.81	0.91	2.626
0.5	0.039	4.06	4.65	1.12	2.148
0.6	0.026	2.76	2.37	0.57	4.220
0.7	0.016	1.95	1.69	0.41	5.908
0.8	0.009	1.46	1.27	0.31	7.877
0.9	0.004	0.98	0.85	0.20	11.815
1.0	0	0	0	0	∞

$f_0 = \beta\left[\beta_1\left(\beta_0\chi^{\alpha_0} - 1\right) - \chi\right]$ where β, β_1 β_0 and α_0 – variables of approximation, $\beta = 0.5953$ $\beta_1 = 3.7678$ $\beta_0 = 1.6708$, $\alpha_0 = 0.25$;

$f_0 = 0.5953[3.7678 \cdot (1.6708 \cdot 0.345^{0.25} - 1) - 0.345] = 0.422$

$\eta_0 = 0.9 \cdot 0.422 \cdot 5 \cdot 1 = 1.9$ m.

Predicted maximum subsidence value for residual service life of the structure (50 years) is calculated by the formula:

$$\eta_m = k_t \cdot \eta_0 \tag{5}$$

where η_m – time factor specifying $\frac{\eta_m}{\eta_0}$ ratio variation with time:

$$k_t = \beta_z \cdot \eta_t^{\alpha_z},\ \eta_t = \frac{t}{100} = \frac{50}{100} = 0.5,\ \beta_z = 0.385,$$

$$\alpha_z = 0.807, \eta_m = k_t \cdot \eta_0 = 0.385 \cdot 0.5^{0.807} \cdot 1.9 = 0.418\,m$$

Length of the ground movement trough margin in view of small size of the goaf is calculated by the formula:

$$L = H \cdot ctg\delta_0 = 29ctg50 = 24.33 \tag{6}$$

Expected values of surface subsidences and strains in the points of the trough principal sections within time in question are calculated by the formulae:

Subsidence $$\eta(z_i)_t = \eta_m S(z)_i \tag{7}$$

Inclination $$i(z_i)_t = \frac{\eta_m S'(z)_i \cdot q_i}{L} \tag{8}$$

Curvature $$K(z_i)_t = \frac{\eta_m S''(z)_i \cdot q_k}{L^2} \tag{9}$$

Curvature radius $$R(z_i)_t = \frac{1}{K(z_i)} \tag{10}$$

Rock strains $$\varepsilon(z_i)_t = m_e \cdot K(z_i)_t \cdot L,\ mm/m \tag{11}$$

where z_i – dimensionless coordinate of a point in the ground movement trough margin;

$S(z_i)$, $S'(z_i)$, $S''(z_i)$ – dimensionless functions of distribution in subsidence, inclination and curvature.

In view of the subsidence trough margin low length the following values have been adopted: $q_i = 0.5$, $q_k = 0.7$;

m_e – curvature – lateral strains transfer factor;

$$m_e = \beta_e \times \beta_k \tag{12}$$

where $\beta_e = 0.05, \beta_k = 1.0$ at $\lambda_{ok} = \frac{\eta_m \cdot S''(z_i)}{1 \cdot 10^{-4} \cdot L^2} < 1$

Let's make similar analysis for a case of a packed goaf with the filling factor making A = 0.8. Maximum subsidence as of the end of ground movement process can be found by the formula:

$$\eta_0 = 0.9 \cdot f_0 \cdot m \cdot \omega \cdot (1 - A(1 - B)) \tag{13}$$

$B = 0.18;\ \eta_0 = 0.9 \cdot 0.422 \cdot 5 \cdot 1 \cdot 0.34 = 0.646m$

At a filling factor A = 0.9 maximum subsidence as of the end of ground movement process will make

$\eta_0 = 0.9 \cdot 0.422 \cdot 5 \cdot 1 \cdot 0.242 = 0.130$

To estimate the undermining-induced loads at designing of a structure to be located on the undermined area design strains have to be calculated through multiplication of expected strain values by respective overload factors, o [4]: $o_l = 1.1$; $o = 1.2$; $o_k = 1.4$; $o_e = 1.2$.

The estimates are presented in Tables 2 & 3.

Table 3. Design surface subsidences and strains per life of a building located over packed goaf.

Points of trough principal sections	Design surface subsidences and strains per life of a building located over a packed goaf				
	Subsidences, m	Inclination, $i_0 \times 10^{-3}$	Curvature, $k_0 \times 10^{-4}$, l/m	Lateral strains, $\alpha_0 \times 10^{-3}$	Radius of curvature, R_0, km
0	0.143	0	0	0	∞
0.1	0.134	3.12	−8.89	−1.83	−1.125
0.2	0.119	5.85	−7.94	−1.63	−1.260
0.3	0.093	7.80	0	0	∞
0.4	0.064	6.83	5.33	1.10	1.875
0.5	0.043	4.88	6.52	1.34	1.534
0.6	0.029	3.32	3.32	0.68	3.014
0.7	0.017	2.34	2.37	0.49	4.220
0.8	0.010	1.76	1.78	0.37	5.626
0.9	0.004	1.17	1.18	0.24	8.440
1.0	0	0	0	0	∞

The estimates enabled to come to the following conclusions and make the following recommendations:

- solution cavities are located at a depth that is less than its safe value, therefore in case of their caving the process of ground movement will actively manifest itself in surface subsidence and strains with the latter many times exceeding allowable values ($i_g \leq 3.0 \times 10^{-3}$; $R_g \geq 20$ km; $\varepsilon_g < 1.0 \times 10^{-3}$); in particular, maximal surface subsidence will make 1.9 m and failure of the building will be catastrophic;
- in case of a cavity being filled with sand grout 90% full strain values in some points of the ground movement trough principal sections will also exceed allowable values, therefore the solution cavities have to be filled 100% full with further pressure testing to be carried out by polymer mortar injection.

4 PRACTICAL DESIGN IMPLEMENTATION

In terms of studies and analysis made the building foundation soil stabilizing has been carried out by injection technique. The activities included cementation and resin injection stabilizing of weak loose ground underlying the pile foundation base as well as abandonment of the solution cavity located in rock mass under the building. For this purpose cement-water slurries, urea resins and sand grouts have been used. Sulfate-resisting Portland cement amount made up 320 t, KF-MT urea resin amount made up 68 t. At present works on the solution cavity abandonment are still in progress.

The situation now is under control. The taken measures resulted in stabilization of the building settlement and deformation. All works have been carried out without evacuation of the tenants.

The next objective is to furnish the "problem" building and similar structures (only in Kungur their number exceeds 40) with a GPS satellite geodetic control station equipped with "Trimble" complex. Our experience of work in cooperation with the Institute of Mining of the Ural Branch of the Russian Academy of Science, Ekaterinburg, has shown that proposed technique provides for sufficient accuracy of measurements (1–2 mm), their continuity and gives an opportunity of simultaneous data transmission to personal computers of various services to rectify a situation in due time.

Instabilities at the Messochora tunnel, Greece: ground improvement and safety evaluation based on observational data

V. Kontogianni
Geodesy Lab., Dept of Civil Engineering, Patras University, Greece

Y. Thanopoulos
Public Power Corporation, Messochora Hydroelectric project, Messochora, Greece

ABSTRACT: The Messochora road tunnel, central Greece, 1100 m long and 10 m diameter, aims to serve transportation after flooding of the nearby Messochora reservoir. The tunnel opened through medium to poor flysch was excavated at the heading level with no significant deformations but during the bench excavation, high distortion of the steel sets and fractures along the shotcrete shell were observed at a 36 m long 'failure zone'. To stabilize strains and avoid a generalized failure, the bench was re-filled and additional support was installed at the affected zone. During these works systematic monitoring, based on geodetic techniques and rock extensometers was performed to confirm effectiveness of ground improvement and evaluate tunnel safety. Detailed analysis of recorded deformation revealed strains at the '*failure zone*' and other nearby stable locations immediately after the failure, generated from stresses re-distribution within the rock. Furthermore, careful analysis of the monitoring data indicated that post-failure strains correspond to a clearly time-dependent effect, with strains in the '*failure zone*' and adjacent sections accumulating for several days, until reinforcement works were fully completed. Strains stabilization permitted the bench re-excavation a few months later; minor displacements recorded during this last stage of construction suggest that the restoration works carried out indeed improved the rock mass and reinstated stability of the tunnel.

1 INTRODUCTION

Seventy years ago, Karl Terzaghi first methodized continuous recording of ground surface and tunnel walls displacements to evaluate the Chicago Subway excavation procedure and maintain safety and stability during construction (Terzaghi 1942). This innovative technique, i.e. to judge about the effectiveness of the excavation technique and support measures and need for construction modifications in tunnelling based on the detailed recording of ground-support interaction, revolutionized a new methodological approach for underground excavation, later named the '*observational method*' (Peck 1969). The '*observational method*', widely spread to all kind of underground projects, remains till today the most essential tool for construction of safe and low-cost underground structures.

In the last years, though, the evolution of electronics made possible to obtain, store and process great amounts of observational data even in real time and opened up new possibilities to tunnelling works optimization by providing early detection of potential failures in unstable ground conditions, a study particularly important for project economy and critical for overall safety of construction. In modern tunnels both geodetic techniques and geotechnical instrumentation are utilized: (i) to record the ground response to excavation-induced stresses, by extensometers, load cells etc. and (ii) to describe the subsequent reduction of the excavated opening, by surveying the support shell distortion (Kontogianni & Stiros 2003; Kavvadas 2005). These records, planned to control tunnel behaviour at various ground conditions, are particularly valuable in failure cases, where special supporting and modifications in construction are crucial for future stability.

In this study, the planning of restoration of the Messochora tunnel, immediately after instabilities affected a 36 m long part of the tunnel in Aug. 2005, based on geodetic techniques and extensometers data, are presented. Aim of the study is to describe the post-failure kinematics of the ground-support system based on the collected measurements at the 'failure zone' and at its neighboring locations during and after the ground improvement works.

2 THE MESSOCHORA PROJECT

Messochora hydroelectric project, a part of the Acheloos River diversion project owned by the Public Power Corporation of Greece, is planned to provide hydroelectric power to the national grid, with a 2×80 MW installed capacity (Fig. 1). The formation of an artificial lake upstream of Messochora Dam for water storage will cause inundation of the existing road network. A new road, aiming to serve local traffic across the lake is currently under construction, as part of the Trikala – Arta main road, including the 1099 m long Messochora tunnel.

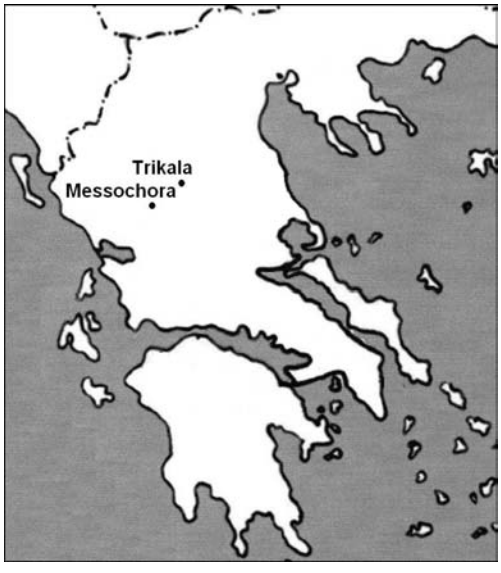

Figure 1. Location map.

3 THE MESSOCHORA ROAD TUNNEL

The Messochora tunnel, 10 m in diameter, is excavated through a flysch complex, widespread in the Pindos Mt. range, at a maximum overburden height of ~150 m. The tunnel cuts through ~500 m of cretaceous limestone before entering a claystone formation, of medium to poor quality, representing a 'transitional zone' to the neighboring flysch formation. This zone is composed of limestone mixed with claystone and clay materials at increasing ratio near the surface. At the NE portal, shear zones, substantially deteriorate geotechnical conditions of the ground. A geological section of the tunnel with 'transitional zone' divided in two different zones representing material with different mechanical characteristics is shown in Figure 2.

The tunnel was constructed at the framework of two different contracts. The first, 1997–1998, involved the excavation of 48 m at the NE portal of the tunnel, which proved extremely difficult due to low strength rock masses met and high risk of triggering a landslide. The second, 2004–2006, involves the excavation of the rest 1051 m, at the limestone and the transitional zones, with severe damages and high convergence along a 36 m zone of the tunnel, and restoration and safe completion of the tunnel.

3.1 *Tunnel excavation and failure*

3.1.1 *Excavation from the NE tunnel portal – ch.1 + 495 m to ch.1 + 447 m*

Excavation of the N-E portal of the tunnel from 1997 to 1998 at highly weathered rock proceeded in full

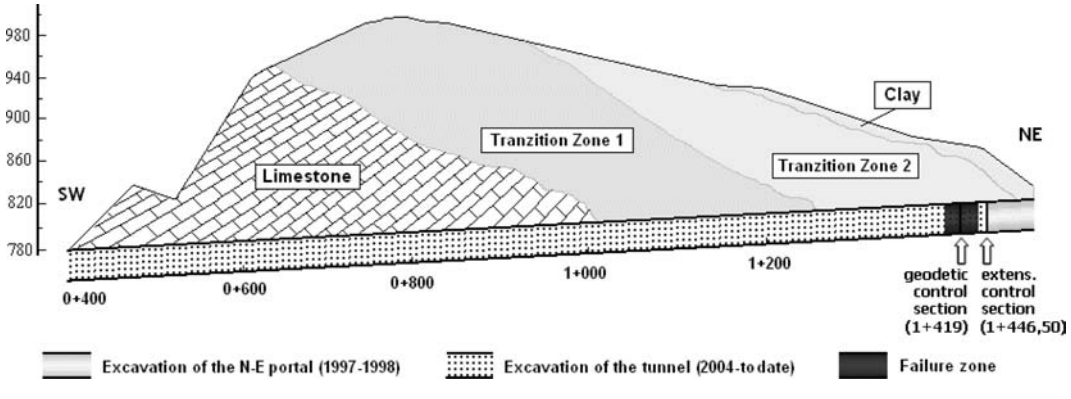

Figure 2. Geologic cross section of the Messochora tunnel. The tunnel cuts through Limestone and a 'Transiotional Zone' divided in two separate sections: 'Transition Zone 1' with medium and 'Transition Zone 2' with poor geomechanical characteristics. Segments of the tunnel excavated at the first and the second contract are shown. The 'failure zone' and the two control sections (at ch.1 + 419 m and ch.1 + 446.50 m) where displacements associated with stress and strain re-distribution in the ground were recorded are also indicated.

face in steps of ∼1.0 to 2.0 m. A basic requirement of construction was the immediate installation of stiff support measures (steel ribs HEB140 and 180 and shotcrete) with full closure at steps of 1.0–1.5 m, to prevent ground displacements that might induce instability of the slope. In addition, 12 m long Forepoling tubes were installed, to minimize ground movements until ring closure, following closely the tunnel front (1.0 to 2.0 m). Displacements, measured with geodetic techniques and rock extensometers, did not exceed safety levels and proved that the excavation technique adopted was successful (Thanopoulos et al. 1998).

3.1.2 *Excavation from the SW portal – ch.0 + 395 m to ch.1 + 447 m*

Messochora tunnel was excavated from the SW portal from 2004 to 2006 in two phases including: *first*, excavation of the heading with installation of steel sets (IPB 120), rock bolts at the lining footings and 15 cm of shotcrete and *second*, bench excavation with rock bolts and shotcrete. The excavation, however, did not follow the predefined steps given at the technical specifications for Rock Class IV, i.e. face advance 1.0 to 2.0 m and ring closure maximum at 12 m, for rock mass properties were overestimated during excavation. The whole tunnel was excavated at the heading level with no stability problems. However, a few weeks after the bench excavation a failure suddenly occurred at the weathered 'transition zone'. At ch.1 + 401 m to ch.1 + 437 m, high distortion of the steel sets and fractures along the shotcrete were observed, on August 29th, 2005, indicating extremely 'weak' rock conditions at the 36 m long tunnel segment ('failure zone'; Fig. 2).

3.2 *Tunnel restoration*

A restoration program was developed after the failure. Its purpose was to maintain tunnel stability both immediately after the failure and in the long-term permitting installation of the final lining. Tunnel restoration involved two phases:

(1) Immediate measures. They aimed to prevent further instabilities and stop all movements in the tunnel and involved re-filling of the bench area and additional self-drilling, injection boring bolts; 9 m long bolts were installed at the crown and 12 m at the tunnel springline (Fig. 3).
(2) Full section restoration. After all movements were stabilized a few months later, the bench was re-excavated following small steps (1–1.5 m). A new lining, including 2 rows of 6 m-long self-drilling, injection boring bolts at each of the bench sidewalls and a layer of 30 cm shotcrete, was installed at each excavation cycle. Removal of the bench filling was definitely the most difficult part of restoration since the already yielded rock at the 'failure zone' would be loaded again.

To evaluate stability during the above stages of restoration, a monitoring system including a geodetic and an extensometer control section was established (see Fig. 2). Geodetic data permitted the estimation of the absolute displacements of the support shell while the extensometer records permitted to assess rock reaction at the vicinity of the 'failure zone' during restoration. Yet, these data offered the possibility:

(i) to control post-failure ground movements at the 'failure zone' and neighbor sections, confirm effectiveness of the immediate measures and plan full restoration when all strains are stabilized and
(ii) to evaluate stability at the 'failure zone' and neighbor sections during the full section restoration.

Collected monitoring data and post-failure tunnel behavior are analyzed below.

3.3 *Monitoring data and analysis*

Seven geodetic control sections were initially installed along the tunnel between ch.0 + 480 m and

Figure 3. Left: Injection boring bolts installation for immediate support of the Messochora tunnel. Right: A photo from the Messochora tunnel taken on August 30th, 2005, shortly after re-filling of the bench area. A several meters long and a few cm wide crack of the lining are visible in this photo.

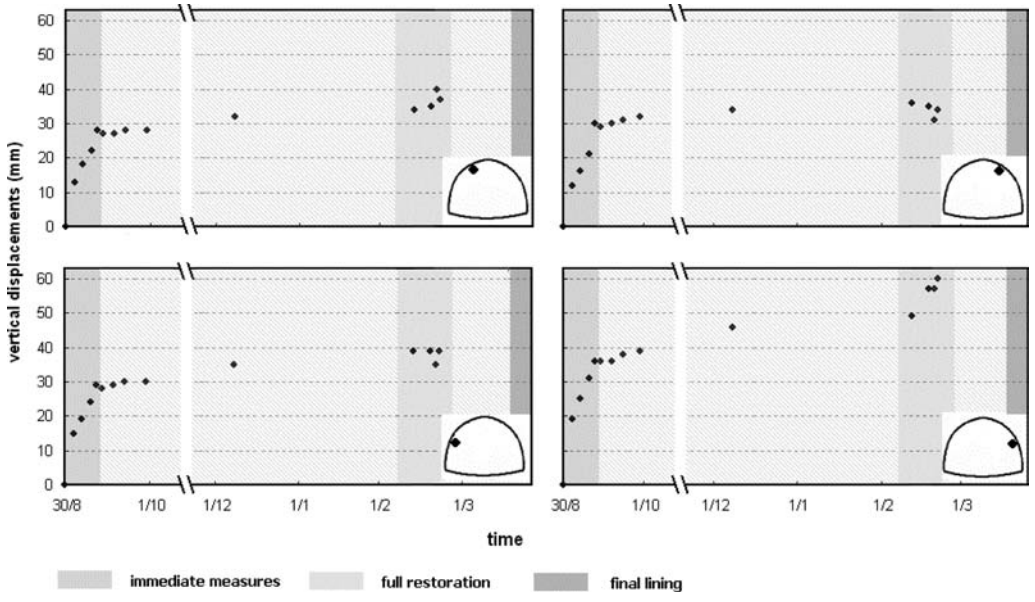

Figure 4. Time-history of vertical displacements geodetically measured at ch.1 + 419 m, immediately after the failure. It is evident that movements accumulated till Sept. 10th, when ground improvement and re-filling of the bench was completed. Afterwards, all movements tended to stabilize. On Feb. 2006 when bench was re-excavated minor displacements were detected.

ch.1 + 319 m shortly after heading excavation. Recordings at six of these revealed minor displacements and only at ch.0 + 979 m, at maximum overburden, displacements reached 60 mm but did not affect tunnel stability. However, instabilities at the 36 m long 'failure zone' on August 29th, led to the installation of an eighth control section in the middle of the 'failure zone' (ch.1 + 419 m) on August 30th. Continuous measurements for over a month revealed post-failure displacements accumulating till Sept. 10th when immediate reinforcement works, i.e. refilling of the bench area and ground improvement at the 'failure zone', were completed. After Sept. 10th only slow-rate creep strains were recorded for several months testifying to ground stresses were fully compensated. Recordings of all four targets of control section at ch.1 + 419 m are shown in Figure 4.

Additionally, two sets of 3 extensometers (Fig. 5a) were initially installed at ch.0 + 949 m and ch.1 + 051 m and one set of 4 extensometers (Fig. 5b) was installed at ch.1 + 446.50 m close to the breakthrough point of the tunnel (ch. 1 + 447 m). Records at ch.0 + 949 m and ch.1 + 051 m did not exceed ±6 mm at any of the extensometers sensors, indicating minor stress distribution and subsequent deformation within ground volume. At ch.1 + 446.50 m, only 9.5 m far from the 'weak' zone (distance <D), minor displacements were recorded after installation of the instruments on August 1st, but on August 29th, the day failure appeared at the 'failure zone', records at two

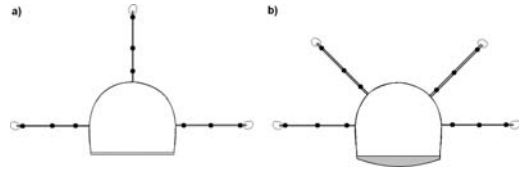

Figure 5. Positions of rock extensometers installed at the Messochora tunnel: (a) at ch.0 + 949 m and ch.1 + 051 m and (b) at ch.1 + 449.50 m, which recorded later strains after the nearby failure.

of the extensometers revealed movements within the rock (Fig. 6). Displacements continued to accumulate for several days and stabilized on Sept. 10th. Afterwards, only slow creep deformations were recorded for several months.

4 DISCUSSION

Messochora tunnel sections excavated from the SW portal at the heading level were stabilized a few weeks after excavation, with geostatic stresses on the lining fully compensated. However, on Aug. 29th, 2005, a few weeks after the bench excavation, an entirely sudden, episodic failure, characterized by high closures and failure of the lining, affected a 36 m long segment of the tunnel. Failure and disablement of the lining to accommodate additional loadings led to post-failure

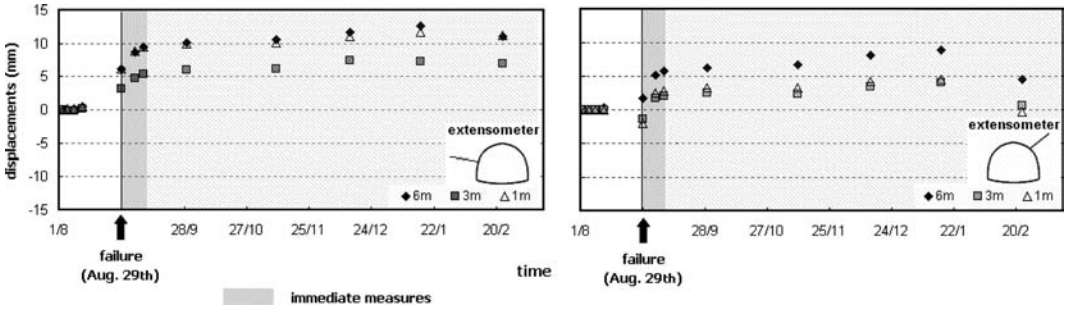

Figure 6. Time-history of displacements of all sensors (at 1 m, 3 m and 6 m from the tunnel wall) of two extensometers installed at ch.1 + 446.50 m. Extensometers were installed at the heading excavation on Aug. 1st, 2005 and practically no movements were recorded. Suddenly on Aug. 29th, the day failure appeared at the 'failure zone', rock displacements were detected and accumulated till Sept. 10th when movements at the 'failure zone' were also stabilized. Afterwards, only slow creep movements were recorded.

deformations at the 'failure zone' which continued accumulating for several days after, till installation of the immediate measures was completed (Sept. 10th). However, these measurements, did not alarm site engineers for strain rates were kept at low levels (they did not exceed 8 mm/day) and strain curves had a clear tendency to stabilization (Fig. 4).

Though, a similar time history of displacements was observed at the ch.1 + 446.50 m extensometers control section showing additional unforeseen ground displacements of up to 8 mm (as shown in diagrams of Figure 6). The fact that this new phase of deformation started on the day failure initiated at the 'failure zone' and stabilized with strain stabilization at the latter is far from coincidental and suggests that strains, originated from 'failure zone' induced further deformation at stable sections at short distances (∼1-2D) outside it, as is schematically shown in Figure 7.

This conclusion clearly suggests that failure actually affected a wider area with strains from the 'failure zone' transferred at distance >D from the edge of the 'failure zone' – an effect related to stresses distribution at the vicinity of the tunnel sections, analogous to the face advance effect – though with no apparent signs, as lining cracking or high deformation. Furthermore, analysis of monitoring data proved this strain transfer to be a clearly time-dependent effect; deformation at the 'weak' zone and the adjacent sections continued for 12 days since initial damage (Aug. 29th to Sept. 10th) and both stabilized only when ground improvement was fully completed at the 'weak' zone.

Stabilization of the 'failure zone' and adjacent areas for several months after allowed the full restoration of the 'failure zone' sections on February 2006. Displacements were recorded at the geodetic control section (ch.1 + 419 m) during the bench re-excavation, carried out on Feb. 7th to Feb. 27st, 2006. Records indicated only minor displacements at the heading area (Fig. 4) and permitted installation of the final

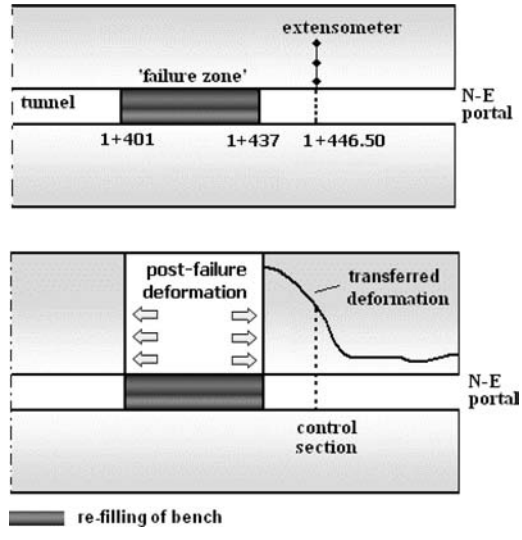

Figure 7. An ideal sketch showing the transfer of ground deformation from the 'failure zone' to adjacent stable areas of the Messochora tunnel due to stresses re-distribution at the vicinity of the 'failure zone'.

lining one month later (Mar. 2006). Interestingly, no movements were detected at the extensometers control section during that period, which revealed that the ground-support system at the failure zone was adequately strong to accommodate all the stresses generated after bench re-excavation. This effect suggests that despite the extremely weak rock conditions and rock yielding, ground improvement carried out contributed to the development of the physical bearing capacity of the rock around the excavation; a process characterizing response of ground around successful tunnels (i.e. 'arch effect'; Lunardi, 2000).

5 CONCLUSIONS

A detailed monitoring system established to evaluate stability during restoration of the Messochora tunnel, recorded post-failure strains at the 'failure zone' and other sections at short distances (∼1D) apparently testifying to stresses and strains transfer along the tunnel. Such transfer of strains could possibly trigger high closures or even more generalized failures propagated even at distant areas; an effect detected in many other tunnels in the past leading to costly failures and great project delays (Kontogianni & Stiros 2006). However, immediate development of ground improvement and section reinforcement obviously interrupted a possible uncontrolled propagation of strains along the tunnel.

Besides, this study made clear that appropriate ground improvement and support installation, planned on the basis of systematic ground monitoring, may help even yielded rock masses around failed tunnel sections to recover their bearing capacity and eventually maintain tunnel stability.

ABSTRACT: Rock bolts play a crucial role in the reinforcement of Single-shell tunnels and rock slopes as rock bolts become a main support system. Numerical and experimental studies are performed to evaluate the integrity of rock bolts encapsulated by grouting paste using a transmission method of ultrasonic guided waves. Numerical simulation shows that the optimal frequency range is 20∼70 kHz in the first longitudinal L(1) mode for the rock bolt NDT system. Analytical and experimental results represent the velocities of the ultrasonic guided wave increase with increase in the defect ratio. This study demonstrates that the transmission method of ultrasonic guided waves may be a valuable tool for the evaluation of the rock bolt integrity.

1 INTRODUCTION

For the construction of tunnels by using a conventional method, NATM, rock bolts with shotcrete are widely used as a subsidiary tunnel support system. Furthermore, rock bolts play a crucial role in a Single-shell tunnelling method and rock slope reinforcement as rock bolts become a main support system.

Generally, to install the rock bolt on the rock mass, a 38 mm diameter grouting hole is drilled, cement-mortar grouting is pumped into the hole, and a 25.4 mm diameter steel bar is inserted. After the grouting is cured, the steel bar and rock work as a composite material. Rock bolts are commonly installed in a whole section of the tunnel: from sidewall to crown. When rock bolts are installed on the crown, the cement-mortar grouting is easily running out due to the gravity. Thus, the grouting may be poorly or partially plugged in the tip of rock bolt. This phenomenon is a typical example of defects in rock bolt systems. The defect of rock bolts on the ceiling may result in falling of rock mass during and/or after tunnel construction. Therefore, the evaluation of rock bolt quality is essential to the safety and reliability of tunnels.

The traditional methods of inspecting rock bolt integrity are the destructive pull-out tests or the over-coring methods. As these methods are generally expensive and time-consuming, a new method is required. Therefore, nondestructive evaluation may be an alternative.

A number of nondestructive evaluation techniques have been conducted for the inspection of the slenderness material including rock bolts surrounded by rock mass, steel bars in a concrete block, steel tendons in a bridge deck, and even concrete piles in soil and rock mass. The techniques included numerical, analytical, and experimental methods. The experimental methods covered the reflection (impact-echo) and transmission of waves. The waves used for the integrity evaluation of the slenderness material were ultrasonic guided waves including flexural, longitudinal, and lamb waves.

Thurner (1988) introduced the non-destructive testing using the reflection method "Boltometer", which compares the amplitude of the reflected ultrasonic guided waves. However, it should be noted that the amplitude of the reflected guided waves is dependent on not only rock bolt conditions but also the length of the rock bolt, rock condition and even coupling conditions of the transducers.

The delamination of the steel bar from concrete mass using ultrasonic guided waves was investigated by Na et al. (2002). They used flexural, longitudinal, and lamb waves. Furthermore, the dispersion curve, which shows the relationship between the phase velocity and the frequency, was used. Hassan & Nagy (1999) measured the change of the velocity of copper

wire (1.0 mm in diameter and 500 mm in length) with frequency in fluid. The intensive analysis of the dispersion curve shows that the velocity of ultrasonic guided waves changes with frequency in the slenderness material due to the different modes (Beard et al. 2003). Beard et al. (2003) also did experimental studies by using reflected ultrasonic guided waves in the longitudinal mode.

Madgena et al. (2006) investigated the effect of the curing time and testing frequency on the ultrasonic guided wave velocity. Zhang et al. (2006) showed the numeral simulation solution and experimental data. The velocity and amplitude were compared with frequency.

The purpose of this paper is to extend the application of ultrasonic waves to evaluate the integrity of rock bolts encapsulated by grouting paste. A transmission method rather than the reflection method is adopted for simplicity in analysis. This paper includes numerical studies for the dispersion analyses of ultrasonic guided waves in rock bolt systems, experimental studies for both embedded in the concrete block and non-embedded conditions, and simple analytical solutions.

2 DISPERSION OF GUIDED WAVES IN ROCK BOLT SYSTEM

2.1 *Guided wave and dispersion*

Equation of motion in an elastic medium is:

$$\rho \frac{\partial^2 \mathbf{u}}{\partial t^2} = (\lambda + \mu)\nabla(\nabla \cdot \mathbf{u}) + \mu \nabla^2 \mathbf{u} \tag{1}$$

where body forces such as gravity are absent, ρ is a mass density of an elastic medium, **u** is the displacement vector in a specified direction with a Cartesian coordinate system, λ and μ are Lame's constants, and t is time.

Using Helmholtz decomposition, the displacement field **u** can be expressed with a scalar potential ϕ and a vector potential **H** (Kolsky 1963, Graff 1975):

$$\mathbf{u} = \nabla\phi + \nabla \times \mathbf{H}. \tag{2}$$

Hence, substituting Equation 2 into Equation 1 yields:

$$c_1^2 \nabla^2 \phi = \partial^2 \phi / \partial t^2 \tag{3}$$

$$c_2^2 \nabla^2 \mathbf{H} = \partial^2 \mathbf{H} / \partial t^2 \tag{4}$$

where c_1 and c_2 can be represented as follows,

$$c_1 = \left[(\lambda + 2\mu)/\rho\right]^{0.5} \tag{5}$$

$$c_2 = \left[\mu/\rho\right]^{0.5}. \tag{6}$$

Table 1. The material properties used for the analysis.

Layers	Steel	Grouting	Rock
Young's modulus [GPa]	206	10	20
Poisson' ratio	0.30	0.27	0.25
Density [g/cm^3]	7.90	2.10	2.40
Thickness [mm]	12.5	6.50	infinite
Remarks	D25	cement mortar	

If a wave propagates in cylindrical elastic system, which is axially symmetric and infinitely long, the constants c_1 and c_2 are real valued, and equal to the longitudinal and shear bulk wave velocities respectively. In a cylindrically embedded rock bolt system composed of arbitrary several layers, the characteristic equation for wave propagation may be described, which satisfies the boundary conditions of stresses and displacements for each interface.

The solution of the characteristic equation can be expressed by several types of graphs, what are called "dispersion curves", which are series of roots of the equation, for example, frequency versus phase velocity and/or group velocity etc. In other words, characteristic properties including dispersion, changes of wave modes and attenuation can be determined through the dispersion curves.

2.2 *Analysis of dispersion*

The selection of the nondestructive test equipment can be acquired by the inspection of wave propagation. When ultrasonic guided waves propagate through the steel bar in the rock bolt system, the energy leakage occurs from the steel bar into surrounding layers including grouting paste and rock mass. Note the energy leakage includes geometrical spreading, material losses, and apparent attenuation due to partial transmission and scattering. Apparent attenuation and geometrical spreading are the main sources on the decay of the wave amplitude in the rock bolt system. Furthermore, as the frequency increases, the change of velocities such as phase and group velocities is accompanied during ultrasonic guided wave propagation.

For the purpose of finding dispersion in the rock bolt system, the numerical code "DISPERSE", developed in Imperial College, UK, has been used (Beard et al. 2003, Pavlakovic & Lowe 2003). The material properties taken in this study are listed in Table 1, and a schematic diagram, which models the embedded rock bolt system, is shown in Figure 1. Figure 1 describes the system consisting of a steel bar, cement-mortar grouting materials and surrounding rock mass.

The predicted energy velocities are plotted versus frequency for the non-embedded, free end rock bolts and the embedded rock bolts in Figures 2 and 3. The

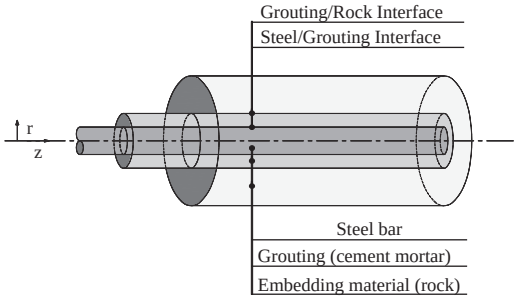

Figure 1. Schematic diagram of the rock bolt system.

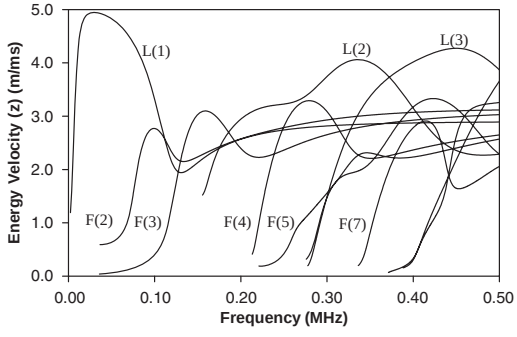

Figure 2. Energy velocity dispersion curves in the non-embedded, free end rock bolt. L and F mean longitudinal and flexural modes respectively. Number in parentheses is a mode number counted with increasing frequency.

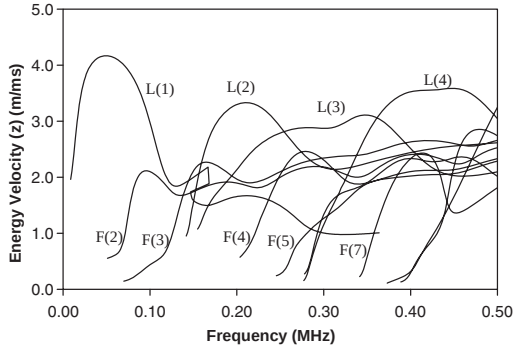

Figure 3. Energy velocity dispersion curves in the embedded rock bolt. L and F mean longitudinal and flexural modes respectively. Number in parentheses is a mode number counted with increasing frequency.

velocity range is 0∼5000 m/sec and the frequency range is 0∼0.5 MHz.

The dispersion curves represent that the maximum energy velocities appear at the first longitudinal mode L(1) with the frequency range 20∼70 kHz for the non-embedded, free end bolt and the embedded rock bolt. Note L(2) and L(3) show the second and/or third maximum energy velocity. However their frequency depends on the embedded condition. In addition, the flexural mode shows the lower energy velocity with the higher attenuation. Therefore, the L(1) mode is used for the attenuation analyses.

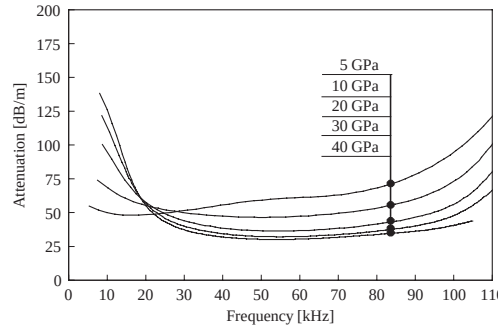

Figure 4. The effects of the Young's modulus of rock mass on attenuation for L(1) mode in the embedded condition. Number in figure denotes the Young's modulus.

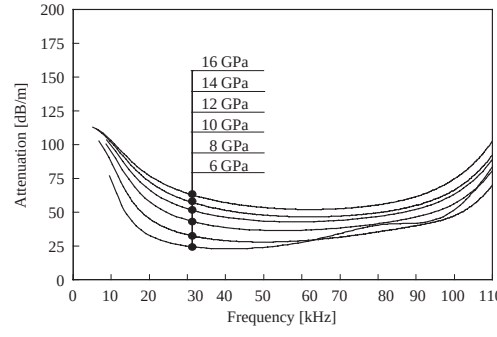

Figure 5. The effects of the Young's modulus of grouting materials on attenuation for L(1) mode in the embedded condition. Number in figure denotes the Young's modulus.

The effects of the modulus of rock mass, which surrounds grouting and a steel bar, is shown in Figure 4 in terms of attenuation for the L(1) mode. The attenuation of the L(1) mode is not affected by the rock modulus at about 20 kHz. The attenuation of the L(1) mode increases with decrease in rock modulus if the frequency is ranged about 30∼110 kHz. Figure 4 shows that the optimal frequency is about 20∼70 kHz for the L(1) mode.

The modulus of the grouting material between a steel bar and rock mass is easily affected by the ground water condition and the water-cement ratio. The effect of the modulus of the grouting material is plotted in Figure 5. Figure 5 shows the attenuation increase with increasing grouting modulus. The attenuation is about 25∼70 dB/m at 30∼100 kHz in frequency.

3 EXPERIMENTAL STUDIES

The numerical studies by using "DISPERSE" suggest that the appropriate frequency range is about 20∼100 kHz in the L(1) mode for the integrity test in the rock bolt system. Therefore, the system for experimental study is prepared in accordance with the numerical study. For the simplicity, the transmission method is used in this study.

3.1 *Specimen preparation*

Experimental studies are carried out by using 3.1 m in length and 25.4 mm in diameter steel bars encapsulated with grouting paste. The grouting material is mixed with cement, fine grain sand and water in a weight ratio of 1:1:0.4. The external diameter of grouting, which encapsulates the steel bar, is fixed at about 38 mm. However, the length of grouting L_G changes from zero meter to the full length of the steel bar L_S in accordance with the intended defect ratio DR (see Figure 6):

$$DR(\%) = \left(\frac{L_S - L_G}{L_S}\right) \times 100 . \tag{7}$$

The specimen with 0% in DR is prepared for the non-embedded, free end rock bolt condition. After nondestructive test is carried out by using the non-defect specimen (0% in DR), the grouting of this specimen is gradually taken out to increase the defect ratio. The increment of the defect ratio is about 10%. For the application of the same technique in the embedded rock bolt, five specimens with different defect ratio are prepared in the non-embedded, free end rock bolt condition: 0, 25, 50, 75, 100% in DR. Five specimens are carefully installed in the concrete block as shown in Figure 7. Note the non-grouted area is maintained in the concrete block. The dimension of the concrete block is 3.0 m in length, 0.8 m in height and 0.9 m in width.

3.2 *Experimental device*

The piezo ceramic elements (PZT elements) are used for the generation of ultrasonic waves (see Figure 7).

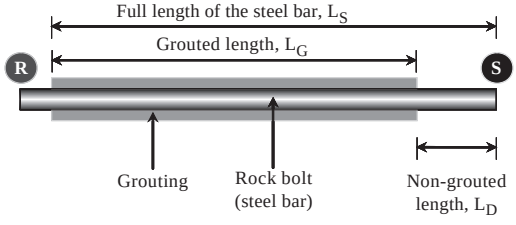

Figure 6. Schematic diagram of the rock bolt partially encapsulated with grouting. Non-embedded, free end condition. S: PZT element (source). R: AE transducer (receiver).

The piezo ceramic element is attached by using the epoxy resin at the end of the rock bolt (see Figure 6). The dimension of element is 14mm in ceramic diameter, 20 mm in element diameter and 0.45 mm in thickness.

The single square signal was delivered from the signal generator (Agilient A3441) to the element. The ultrasonic guided waves, which is emitted from the source elements and traveled through the rock bolt system, was captured and transformed into the electrical signal in the receiver. The receiver used in this study is an acoustic emission sensor (Physical Acoustics A3). Note a typical accelerometer is not applicable due to the operating frequency range. The electrical signal was fed through a pre-amplifier and post-amplifier. The amplified signal was digitized through oscilloscope. Note the 500∼1000 signals were averaged to remove the high frequency uncorrelated noise.

3.3 *Experimental results*

Measured signals in non-embedded, free end condition are plotted in Figure 8. Figure 8 shows that the amplitude of the signal increases and first arrival time decreases with defect ratio.

The calculation of the velocity of ultrasonic guided waves is based on the steel bar length and travel time. The evolution of the ultrasonic wave velocity is plotted versus the defect ratio in Figure 9. Figure 9 shows the wave velocity increases with increase in the defect ratio. When the ultrasonic waves propagate through the mixture composed of the steel bar and grouting, the mixture condition affects the travel time. In other words, the velocity reflects the property of the composite material. The equivalent velocity of the composite material may be simply expressed as follows.

$$V_{eq} = \sqrt{\frac{E_{eq}}{\rho_{eq}}} = \sqrt{\frac{A_s \rho_s V_s^2 + A_c \rho_c V_c^2}{A_s \rho_s + A_c \rho_c}} \tag{8}$$

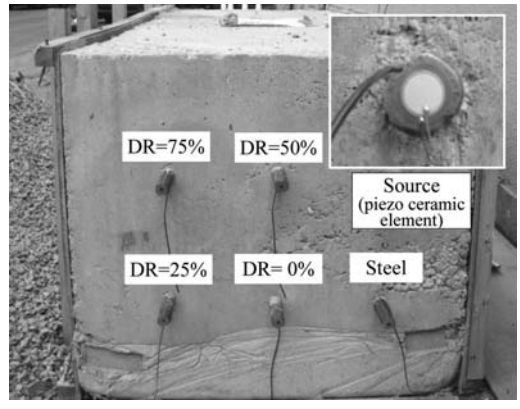

Figure 7. Picture of the concrete block with rock bolt specimens for the embedded condition.

where E is elastic modulus, A is cross-sectional area, ρ is a mass density, and subscripts eq, s, c are equivalent, steel bar and cement-mortar, respectively.

The calculated velocity by equation 8 is plotted versus the defect ratio in Figure 9. Figure 9 shows the relatively good agreement between the simple analytical solution and experimental results in non-embedded, free end condition. Thus, the defect ratio can be evaluated by measuring the ultrasonic wave velocity of installed rock bolts.

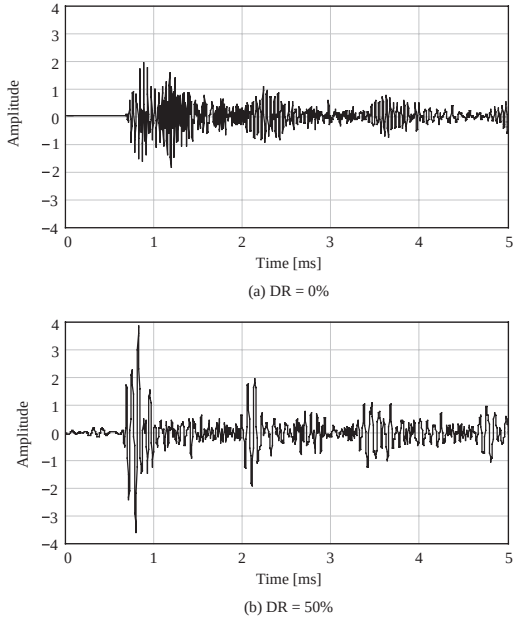

Figure 8. Ultrasonic wave velocity versus defect ratio (DR) in non-embedded, free end condition.

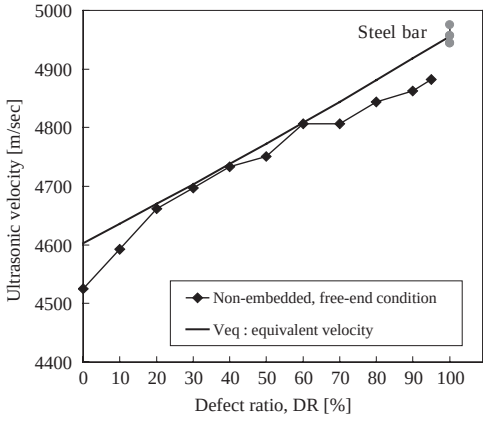

Figure 9. Ultrasonic wave velocity versus defect ratio (DR) in non-embedded, free end condition.

Responses of the embedded rock bolt into the concrete block are plotted in Figure 10. Figure 10 shows that the amplitude of the signal increases and first arrival time decreases with defect ratio. The calculated velocities are plotted in Figure 11.

The test result shows that the velocities increase with increase in the defect ratio in both embedded and non-embedded conditions. However, the velocities are slower in the embedded rock bolt than in

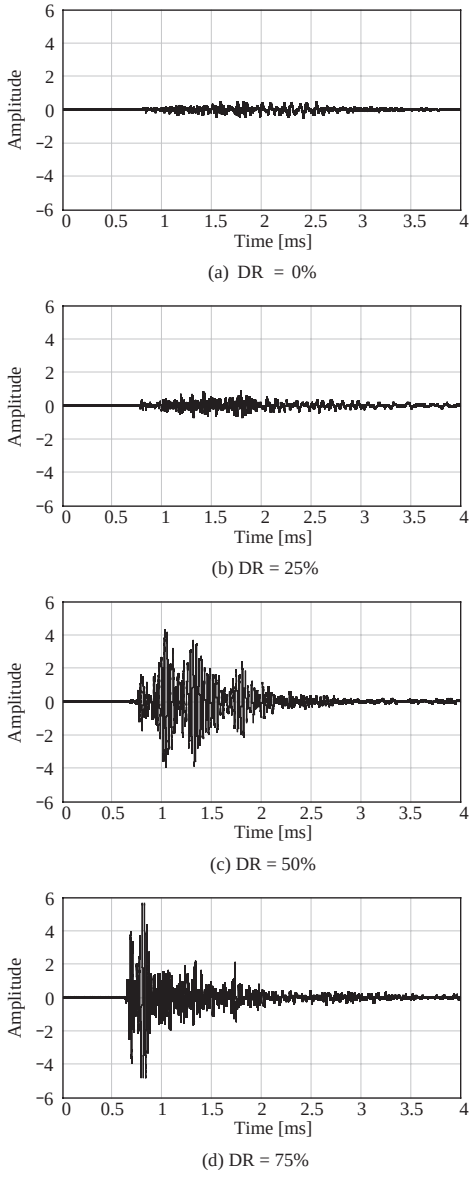

Figure 10. Responses of AE sensor for the embedded rock bolt with 3.1m long in the concrete block specimen.

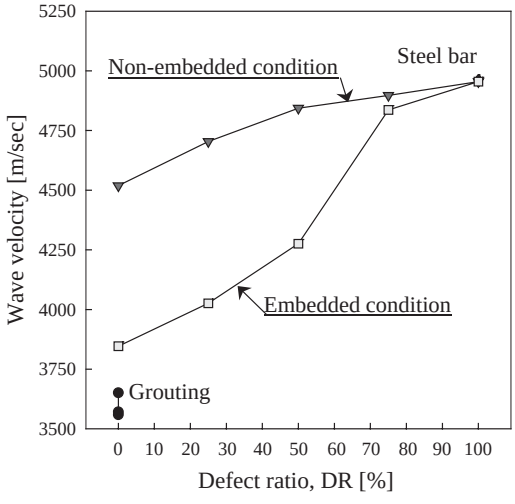

Figure 11. Ultrasonic wave velocity versus defect ratio(DR) in non-embedded condition.

the non-embedded rock bolt. The slower velocity in the embedded rock bolt results from the increase of the affected zone, where the guided wave travels (see Figure 11).

4 CONCLUSION

Numerical and experimental methods using ultrasonic guided waves have been implemented to evaluate the integrity of rock bolts encapsulated by the cement-mortar grouting in both embedded and non-embedded condition. The numerical code "DISPERSE" is used to identify the dispersion characteristics in ultrasonic guided waves in the cylindrical geometry. The numerical code shows that the maximum energy velocity is expected at the frequency range 20∼70 kHz on the first longitudinal mode L(1) for the grouted rock bolt system.

Experimental studies were carried out with different defect ratios in both of the non-embedded and embedded conditions. The measured ultrasonic wave velocities increase with increase in the defect ratio for the embedded condition as well as the non-embedded condition. The simple analytical solution, which is based on the volume fraction, shows a good agreement with measured velocities in the non-embedded rock bolt. Note velocities of the embedded rock bolt are lower than those of the non-embedded rock bolt at the lower defect ratio due to the increased affected zone.

The numerical simulations, experimental studies, and the analytical solution suggest that the integrity of rock bolts can be easily evaluated by the transmission method of ultrasonic guided waves.

Jet-grouting in underground construction

A.G. Malinin & P.A. Malinin
EPC close corporation, Perm, Russia

ABSTRACT: Recently jet-grouting technology becomes more popular at solution of different tasks of underground construction in Russia. Developed calculation method of deformation mode of one- and two-row cofferdams from jet-grouting columns is realized in the application software, which allows to get jet-grouting cofferdam parameters.

The main point of the jet-grouting technology is using of high-pressure grout jet for destruction and simultaneous mixing of soil with cement grout. As a result columns from new material – soil-concrete are formed in the ground. The new material has high strength and antifiltering characteristics. Depending on the technology the diameter of pile is 600–2000 mm.

The most significant application of jet-grouting is soft ground consolidation. There is no doubt that in this case the jet-grouting technology has advantages over historically preceding, simpler, but practically uncontrolled technology of injection ground strengthening, where cement grouts or mixtures on the basis of liquid glass or artificial resins are used.

For example, at the construction of highway tunnel in Ufa, plastic clays in walls and roof of one of the technological adits were reinforced using jet-grouting technology. The works were made from the ground surface at a depth of 30 m.

Another interesting task is stabilization of clays at subway tunnel crossing with one of the auxiliary underground course. In order to do this work a small drill rig was installed in the course, so 9 m long protective circular shield was made towards forthcoming TBM 5.6 m in diameter.

On the territory of one of the metallurgical plants two 20 m deep technological pits were constructed in watered sandy ground using jet-grouting technology. So with the help of intersecting piles vertical cofferdam and horizontal curtain grouting were made.

Meanwhile the jet-grouting technology allows also to solve the other, in our opinion, more complicated problems of underground construction.

Among them first of all there is a construction of deep foundation pits in difficult geological conditions. Importance of such problem has increased recently because of appeared and annually rising demand for the underground multilevel parking construction, located under the dwelling houses. It is well-demonstrated in such megalopolis as Moscow, where at the construction of practically each building in center underground parking is planned. That makes such project very attractive for investors.

Application of jet-grouting technology in this case has the following advantages:

- absence of negative influence on the nearby buildings foundations in the process of cofferdam making from jet-grouting piles;
- providing of cofferdam water impermeability from intersecting piles;
- possibility of safe horizontal waterproofing membrane performance in the foundation pit bottom, artificial aquifuge layer.

Reinforcement of jet-grouting piles is usually made using centrally located pipes 89–219 mm in diameter or single reinforcement bar. For such schemes of reinforcement authors got formulas which allow to calculate limit moment of pile section.

When natural aquifuge layer occurs at a big depth, jet-grouting technology allows to form in watered ground massif horizontal waterproofing membrane – layer of artificial aquifuge from intersecting jet-grouting piles.

1 STRENGTH ANALYSIS OF JET-GROUTING COFFERDAMS

Strength analysis of jet-grouting cofferdam and reliability assessment of construction is the main stage of design and decision-making. In this process the most important cofferdam characteristics are taken, such as – diameter, positional relationship and depth of columns, type and parameters of columns reinforcement.

Strength analysis of jet-grouting cofferdam is made by determination of maximum bending moment. Analysis of longitudinal bending stresses is made taking into consideration soil-concrete deterioration in terms of stretching longitudinal strains and comparing obtained maximum stresses values in soil-concrete and reinforcement with allowed values.

In this paper a method of jet-grouting cofferdams strength analysis is presented. This method can be used for different types of cofferdams: one-row, two-row.

2 PROBLEM DEFINITION FOR ONE-ROW JET-GROUTING COLUMN COFFERDAM

In problem of cofferdam mode of deformation the following suggestions are made:

- in cofferdam mode of deformation and strength analysis we consider longitudinal component of stress tensor only;
- soil-concrete doesn't resist stretching;
- hypothesis of plane sections in design section of jet-grouting cofferdam.

Strength analysis of jet-grouting cofferdam is made in section with maximum value of bending moment. Stresses in section are obtained from equilibrium equations for external forces.

Among the external forces are:

- normal and tangent forces, which act on the column from the soil side, R = resultant of forces of normal pressure; S = resultant of tangent force;
- gravity force, G = resultant force;
- reaction, acting from the side of jet-grouting column, which is situated below the design section, p = distribution of normal forces for section, T = resultant of intersecting forces.

To make equilibrium equations the external forces are given in the point O – figure 1. At parallel translation of R and S forces in the point O we add a couple of force with moment $M_o(R+S)$, equal to bending moment in section from soil pressure on the cofferdam. Reaction of the lower jet-grouting column part in design section is resulted in two components of main vector T and $N(p)$ and main moment $M_o(p)$. Neglecting the bending column deformation, the gravity force G is transferred along the line of action to the point O, reduced forces are shown on the figure 1, forces R and S are marked as R' and S'.

For the reduced forces we will write two statistical equilibrium equations:

$$N(p)-G-S=0 \tag{1}$$

$$M_o(p)+M_o(R+S)=0 \tag{2}$$

where distribution of normal forces p is unknown.

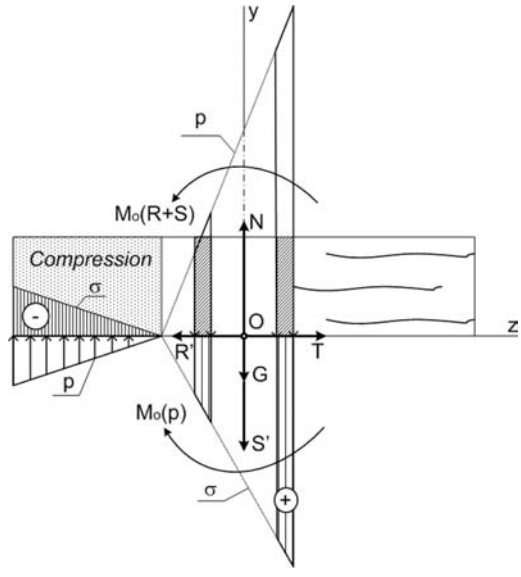

Figure 1. System of balanced forces.

In order to make a closed set of equations we will use the following:

- Koshi correlations, according to which $p_y = -\sigma_y$, where p_y = projection of force p on the axis oy; σ_y = longitudinal component of stress tensor;
- hypothesis of plane sections. Its application gives the following formula for the bending deformation:

$$\varepsilon(z)=\frac{\delta+z}{\rho} \tag{3}$$

- Hooke's law, which connects longitudinal bending deformation with longitudinal stresses.

For reinforcement material:

$$\sigma(z)=E_s\varepsilon(z) \tag{4}$$

For jet-grouting column:

$$\varepsilon(z)<0 \Rightarrow \sigma(z)=E_b\varepsilon(z),\quad \varepsilon(z)\geq 0 \Rightarrow \sigma(z)=0 \tag{5}$$

where ρ = curvature radius of neutral line in the design section, δ = distance from column axis to neutral line in the design section.

Let's consider the variant of intersecting jet-grouting columns. Calculation of separate columns is a particular case of intersecting columns calculation.

There are two variants of neutral line position:

1. Neutral line is out of the columns crossing area. For this case the area of compression and tension in soil-concrete is shown on the figure 2.

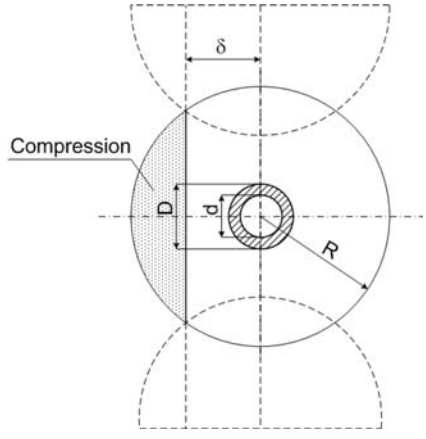

Figure 2. Neutral line is out of the intersecting columns crossing area.

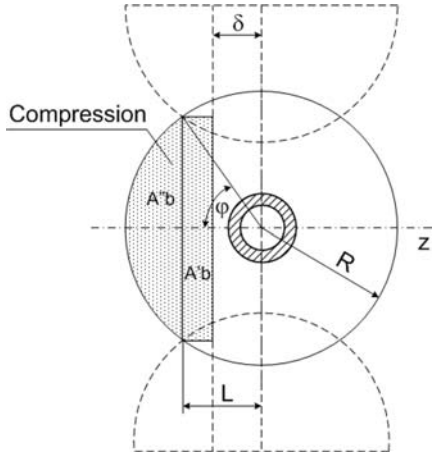

Figure 3. Neutral line goes through the crossing area of intersecting columns.

2. Neutral line goes through the crossing area of columns sections – figure 3.

For the second case $\delta \le L$ we will calculate integrals of the main vector and main moment from forces *p*.

$$N(p)=-\int_{A_b}\sigma_y dA_b-\int_{A_s}\sigma_y dA_s=$$
$$=-\int_{A_b'}E_b\frac{\delta+z}{\rho}dA_b'-\int_{A_b''}E_b\frac{\delta+z}{\rho}dA_b''-\int_{A_s}E_s\frac{\delta+z}{\rho}dA_s \quad (6)$$

$$\int_{A_b'}E_b\frac{\delta+z}{\rho}dA_b'=\frac{bE_b}{\rho}\left(-\frac{1}{2}\delta^2+L\delta-\frac{1}{2}L^2\right) \quad (7)$$

$$\int_{A_b''}E_b\frac{\delta+z}{\rho}dA_b''=\delta\frac{E_bA_b''}{\rho}-\frac{b^3E_b}{12\rho},$$
$$A_b''=\frac{1}{2}R^2(2\varphi-\sin 2\varphi),\quad b=2R\sin\varphi \quad (8)$$

$$\int_{A_s}E_s\frac{\delta+z}{\rho}dA_s=E_s\frac{\delta}{\rho}A_s=E_s\frac{\delta}{\rho}\frac{\pi}{4}(D^2-d^2) \quad (9)$$

$$M_o(p)=-\int_{A_b}\sigma_y zdA_b-\int_{A_s}\sigma_y zdA_s=$$
$$=-\int_{A_b'}E_b\frac{\delta+z}{\rho}zdA_b'-\int_{A_b''}E_b\frac{\delta+z}{\rho}zdA_b''-\int_{A_s}E_s\frac{\delta+z}{\rho}zdA_s \quad (10)$$

$$\int_{A_b'}E_b\frac{\delta+z}{\rho}zdA_b'=\frac{bE_b}{\rho}\left[\frac{(L^3-\delta^3)}{3}-\frac{\delta(L^2-\delta^2)}{2}\right] \quad (11)$$

$$\int_{A_b''}E_b\frac{\delta+z}{\rho}zdA_b''=-\frac{\delta b^3E_b}{12\rho}+$$
$$+\frac{E_b}{4\rho}\left[R^4\left(\varphi+\frac{\sin 2\varphi}{2}\right)-2L^4tg\varphi\right] \quad (12)$$

$$\int_{A_s}E_s\frac{\delta+z}{\rho}zdA_s=\frac{\pi E_s}{64\rho}\left(D^4-d^4\right) \quad (13)$$

Substitution of integrals (6)–(13) in the equilibrium equations (1) and (2) results in set of two nonlinear algebraic equations relative to δ and ρ.

3 PROBLEM DEFINITION FOR TWO-ROW COLUMNS COFFERDAM

Calculation of mode of deformation is made for cofferdam part, width *b*, situated above the design section (Fig. 4).

Let's consider the case when $-\delta < L$.

$$N(p)=-\int_{A_b}\sigma_y dA_b-\int_{A_s}\sigma_y dA_s=$$
$$=-\int_{A_b'}E_b\frac{\delta+z}{\rho}dA_b'-\int_{A_b''}E_b\frac{\delta+z}{\rho}dA_b''-$$
$$-\int_{A_{s1}}E_s\frac{\delta+z}{\rho}dA_{s1}-\int_{A_{s2}}E_s\frac{\delta+z}{\rho}dA_{s2} \quad (14)$$

$$M_o(p)=-\int_{A_b}\sigma_y zdA_b-\int_{A_s}\sigma_y zdA_s=$$
$$=-\int_{A_b'}E_b\frac{\delta+z}{\rho}zdA_b'-\int_{A_b''}E_b\frac{\delta+z}{\rho}zdA_b''-$$
$$-\int_{A_{s1}}E_s\frac{\delta+z}{\rho}zdA_{s1}-\int_{A_{s2}}E_s\frac{\delta+z}{\rho}zdA_{s2} \quad (15)$$

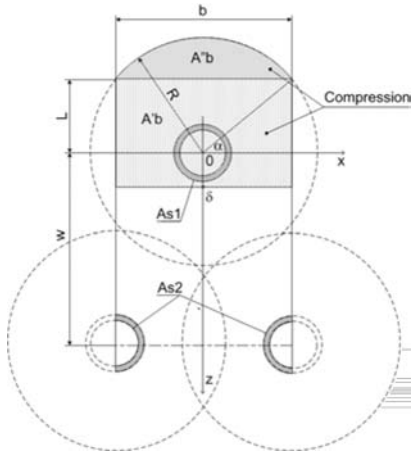

Figure 4. Design section for two-row columns cofferdam.

In case $-\delta \geq L$ there are no integrals in area A_b' in forms (14) and (15).

Substitution of integrals (14), (15) in the equilibrium equations (1) and (2) results in set of two nonlinear equations relative to ρ and α parameters.

We summarize suggested method of calculation in case of reinforcement over one or two columns. For example, in case of each second column reinforcement, the main vector and main moment of longitudinal forces for reinforcement is multiplied by reinforcement ratio equal to 0.5.

4 STRENGTH ANALYSIS OF JET-GROUTING COFFERDAMS

Solution of nonlinear equations set (1), (2) relative to ρ and α parameters, or ρ and δ, is made using Newton-Rafson method. In the process of parameters value iteration a set of equations was selected depending on neutral line position.

Developed calculation method of deformation mode of one- and two-row jet-grouting columns cofferdams was realized in the application software. The following example will show its work.

One-row cofferdam is made from columns 900 mm in diameter, located with interval $b = 900$ mm and reinforced with steel pipe 159×9 mm. Stress-strain properties of soil-concrete: deformation module $E_b = 1000$ MPa, compressive strength $R_b = 5$ MPa. Stress-strain properties of steel: modulus of elasticity $E_s = 20,000$ MPa, tensile strength $R_b = 250$ MPa. Bending moment from external forces $M_o(R+S) = 166$ kN/rm, specific weight of soil-concrete is 20 kN/m^3.

So the task solution relative to desired quantities is found: $\delta = 47$ mm, $\rho = 104,708$ mm. The maximum stresses in jet-grouting columns are $\sigma_b = 3.85$ MPa, maximum reinforcement stress is $\sigma_b = -242.1$ MPa.

5 SUMMARY

The choice of cofferdams construction from jet-grouting columns is based exclusively on the calculation results of cofferdams strength and reliability. Lack of developed methods of jet-grouting cofferdams strength analysis, development of new designing approaches and its practical application is still an actual problem.

In this paper the calculation method of one- and two-row cofferdams from jet-grouting columns, based on the numerical solution of bending beam equilibrium equations with longitudinal compression is suggested. This method is realized in the application software, which allows to get jet-grouting cofferdam parameters.

Modelling of ground freezing in tunnelling

E. Pimentel, A. Sres & G. Anagnostou
ETH Zurich, Switzerland

ABSTRACT: Depending on the prevailing soil, the project location and the environmental requirements, the artificial ground freezing may be advantageous or even the only technically feasible method for strengthening, stiffening and sealing the ground. The potential problems of this method are associated with high groundwater seepage velocities (which hinder the development of a frozen body) and surface heaves (due to the expansion of the frozen soil) or settlements (due to the consolidation in the thawing phase). To avoid such problems careful analysis and design of the freezing operation is necessary. A new numerical model has been developed and implemented in order to simulate the time-dependent, three-dimensional growth of the ice body, taking into account the complex thermal and seepage flow interactions. For the verification of the numerical model a large scale laboratory model was conceived and constructed. The tests performed show the high quality of the laboratory measurements. The respective simulations with the numerical model agree very well with the measurements.

1 INTRODUCTION

Due to the ever increasing extent of underground space utilization, urban construction projects are realized ever more frequently in very difficult conditions. Construction methods in shallow soft ground tunneling beneath the water table must ensure control of the ground at the tunnel heading and, additionally, prevent seepage flow towards the working face. For these reasons, tunnel construction in saturated soils is being carried out ever more frequently with closed shields, which provide support to the tunnel face continuously during excavation. Slurry and EPB-shield tunneling has been successfully applied worldwide in recent years. Under extremely unfavorable geological conditions, however, face instabilities may occur. Furthermore, stability of the tunnel face must also be ensured during maintenance works on the cutter head or other activities at the face (e.g. removal of large blocks, tree trunks etc.). Finally, for special underground works (crossovers, caverns, adits etc.) only conventional tunneling methods can be applied. In all these cases, auxiliary ground improvement measures are still indispensable for maintaining face stability and preventing groundwater drainage.

The ground can be strengthened and sealed either by grouting or by artificial freezing. Grouting is in most cases the first choice due to economic and technological considerations. Its applicability may be limited, however, by the grain size distribution of the soil as well as by environmental constraints. In such cases artificial ground freezing is an alternative. The potential problems of this method are associated with surface heaves (due to the expansion of the frozen soil) or settlements (due to the consolidation in the thawing phase). Furthermore, high groundwater seepage velocities may prevent the closure of the freezing body. Systematic experimental investigations hardly exist for these topics. Jessberger (1996) outlines for the development of the freezing body a critical velocity for seepage flow of more than 2 m/d. Based on Darcy's law and thermodynamic considerations, Sanger & Sayles (1979) developed an equation for the critical seepage flow, which is useful for preliminary design.

In order to evaluate the above-mentioned problems from case to case and to plan appropriate measures, the temperature distribution of flowing groundwater as well as the deformations of the ground over time have to be known. With the aim of being able to plan this construction method for the threshold cases more safely and thus more economically, numerical 3D models that can simulate thermal and hydraulic (TH model) processes as well as the mechanical ones coupled to them (THM model) on the basis of the FE-method were implemented. In the present contribution the TH model and its experimental verification is described. With this model it is possible to simulate the distribution of the temperature in the frozen body, the required freezing-time and the energy demand. The creep behaviour of frozen soil is not part of our research, since other authors are investigating this (Cudmani 2006, Orth 1986).

2 MATHEMATICAL MODEL

The time-dependent temperature distribution of the soil in flowing groundwater during the application of the ground freezing method may be prognosticated realistically only by means of thermo-hydraulic models (TH-model). An overview of the state of the art of numerical models for the ground freezing method taking into account seepage flow and frost heaves is shown in Sres et al. (2006). At the present the known models have been developed for simulations in 2D only and are, thus, not suitable for the modeling of complex geometries and soil stratification. Thus, when planning this construction method for the threshold cases, the uncertainties associated with not having an adequate model have to be compensated by costly over-dimensioning of the freezing operation (refrigeration capacity, number of the freezing pipes) as well as by additional auxiliary measures such as grouting or ground densification.

In a first stage of the ongoing research project a TH-model in 3D was formulated. Here, a temperature field T and a piezometric height H were coupled. This is defined as:

$$H = \frac{p}{\rho^w g} + z \tag{1}$$

where p is the pore water pressure, p^w the water density, g the gravity acceleration and z the geodetic height. The field temperature is governed by the equation of heat transport:

$$C^s \dot{T} - \partial_k(\lambda \partial_k T) + C^w v_k \partial_k T = 0 \tag{2}$$

where λ is the thermal conductivity, C^w the volumetric heat capacity of the water and C^s the so-called effective heat capacity of the saturated soil. C^s includes the latent heat that occurs during phase change. Darcy's law gives the velocity v^k

$$v_k = -k \cdot \partial_k H \tag{3}$$

where k denotes the hydraulic conductivity. The velocity field fulfils the equation of continuity, which for a quasi steady-state seepage process is reduced to

$$\partial_k v_k = 0 \tag{4}$$

The equation 4 of continuity and the equation 2 of heat transport are coupled by the Darcy velocity v_k and the temperature dependency of the hydraulic conductivity k.

The equations 1 and 2 are solved numerically by the FE-method in a given 3D domain. With the increasing size of the model, 3D calculations rapidly consume more memory and computing time. Therefore for the numerical implementation special attention was paid to simple and efficient algorithms. The spatial discretization is accomplished by means of the Garlekin method. Integration over time is managed by a single-step, non-iterative backward Euler scheme (Reddy & Gartling 2001). In order to save computer memory space, the fields H and T are calculated one after another in each time-step, namely each with the actual value of the other. Furthermore and in order to increase computational efficiency isoparametric hexahedral elements with biquadratic shape functions were chosen. Since all elements have the same shape but different dimensions, the Jacobi matrix and its determinant become very simple, depending thus only on the side length of a cube.

3 EXPERIMENTAL TESTS

The verification of the numerical model was carried out in a multi-stage approach on the basis of laboratory tests results. In the literature, there is a lack of well-documented tests with seepage flow. Only the experiments of Beggren (1979) are well documented and allow some verification calculations.

In the first stage, the Beggren-tests have been numerically modeled. The TH-model shows a good agreement with the measurements (Sres et al. 2006). Nevertheless, the apparatus of Beggren showed some restrictions on comprehensive verification, e.g. small dimensions ($H \times L \times W = 0.5 \times 0.5 \times 1.3\,m^3$), low hydraulic gradients ($i < 0.1$ m/m) and seepage velocities ($v < 1$ m/d). A new testing program was therefore developed, consisting of an element test without seepage flow and a large-scale laboratory test with seepage flow. The element test is composed of a cooling system, a barrel with a diameter of 0.5 m and thermal isolation. The test and the verification results are described in Pimentel et al. (2006). The calculations showed a very good agreement with the measurements. Later, the large-scale laboratory test with seepage flow will be described.

The laboratory model includes a watertight box with effective dimensions $H \times L \times W = 1.2 \times 1.3 \times 1.0\ m^3$ (Figure 1), assembled from 2 cm thick PVC plates. The dimensions and components of the model have been designed so as to achieve a large degree of flexibility in defining the test conditions and for obtaining comprehensive information on soil behavior. Depending on the boundary conditions, the position and alignment of a row with three frozen pipes can be varied. For the verification of the TH-model a vertical alignment of the pipes has been chosen. In the next stage of the laboratory test program, i.e. tests for the verification of the THM-model, a horizontal alignment of the pipes is intended in order to simulate the formation of ice lenses and the associated soil deformations.

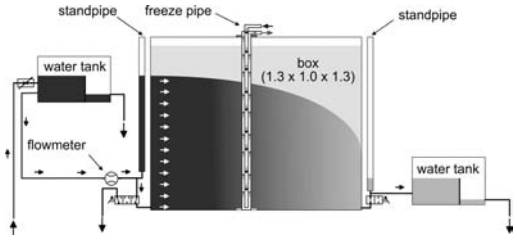

Figure 1. Plan of the large-scale laboratory model.

The freezing pipes consist a PVC down pipe with an inner diameter of 21 mm and a copper pipe with an outer diameter of 41 mm. The head and foot of the frozen pipe is made from PVC. The brine hoses were insulated with neoprene.

The box has an all-around thermal insulation of at least 18 cm of foam. The box was placed on a layer pallet and a layer of wood beams with a total thickness of 36 cm. All the spaces in the pallets and beams were filled with foam. The tests are performed in an air-conditioned room with a constant temperature. Using the insulation described above, it was possible to achieve controlled thermal boundary conditions.

In order to simulate ground freezing with seepage flow the box has a water inlet and outlet at the bottom of the two frontal faces. They were connected to water tanks with spill (Figure 1). Standpipes control the hydraulic gradient. The amount of water, which inflows the model is being recorded over time with a flow meter.

The cooling system consists of an electronically controlled cooling machine with an electrical power of 1.6 kW. The cooling machine and the other components were designed for a temperature range down to $-30°C$. The cooling liquid used is brine (water: glycol 1:1). The temperature at the inlet and outlet of the machine is being electronically registered as well as the amount of cooling liquid pumped through the system.

The monitoring of the tests includes sensors distributed in the model for measurement of temperature and pore water pressure, i.e. 40 temperature sensors PT100 and 8 miniature tensiometers (Figure 2 and 3). The data logging was done with a conventional PC (Figure 4).

Several tests with different seepage flow velocities were performed. The average flow velocity measured at the location of the frozen pipe was varied between $v = 0$ and $v = 3$ m/d. By each test the water tanks were positioned at a given level. After having achieved stationary conditions all over, i.e. no changes over time of the water table and temperature in the model, the cooling phase was started. The cooling phase was stopped either when the frozen body closed (no seepage flow) or when approximately steady state conditions were achieved (no drop of temperature in the model). The experimental results are presented later in Section 5, together with the results of the respective computer simulations.

* for T = 15°C.

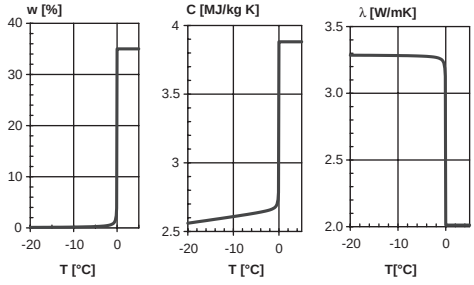

Figure 5. Thermodynamic parameters against temperature. From left to right: water content, heat capacity and heat conductivity.

4 MATERIAL PARAMETERS

For the laboratory tests a medium sand with maximum grain size of $D_{max} = 1$ mm was used. The hydraulic conductivity was determined with a big permeameter and the specific weight with a pyknometer. The box was filled with dry sand in layers of 10 cm. The filled material was weighted continuously and each layer was compacted locally by hand, so that the density of the sand in the box could be calculated. In Table 1 the geotechnical parameters were listed.

The thermodynamic parameters were also determined experimentally. The specific heat of the sand was determined calorimetrically. For the other parameters in addition to temperature sensors, a Time-Domain-Reflectometer (TDR) system for measuring the water content, a Non-Steady-State-Probe sensor for measuring the heat conductivity and an environmental chamber were used. The chamber has effective dimensions of $H \times L \times W = 0.25 \times 0.25 \times 1.0\,m^3$. The temperature is controlled by a thermostat down to −30°C. Dry sand was filled in a watertight PVC cylinder with a diameter of 150 mm and a height of 450 mm. After positioning the above-mentioned sensors in the sample this was saturated and placed in the chamber. The temperature in the chamber was dropped gradually until the whole pore water was frozen. In Figure 5 the temperature dependence of the thermodynamic parameters is shown. The heat conductivity was calculated using the equation of Johansen & Frivik (1980).

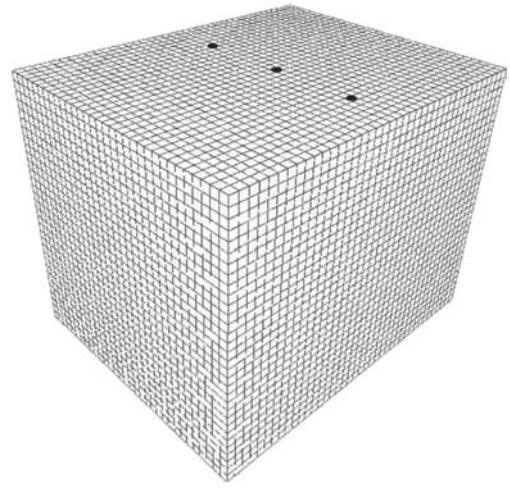

Figure 6. Perspective view of the FE mesh. The three dark elements in the center represent the freeze pipes.

Table 2. Closing time of the frozen body.

Test	v [m/d]	t_c_{bottom} [h]	t_c_{middle} [h]	t_c_{top} [h]
v0	0	11.50	12.54	15.08
v1	1	39.92	44.27	73.02
v2	2	–	–	–

5 NUMERICAL SIMULATIONS

Figure 6 shows the 3D mesh. As mentioned above isoparametric hexahedral elements were used. The laboratory test was modeled with $H \times L \times W = 32 \times 40 \times 32 = 40{,}960$ elements.

Three selected laboratory tests were calculated, namely for the conditions without water flow (v = 0), with high flow velocity but with a closed frozen body (v = 1 m/d) and with excessively high flow velocity, i.e. no closed frozen body (v = 2 m/d). The closing times of the frozen body at the bottom, middle and top of the water table are listed in Table 2.

The measurements (points) and their respective calculations (lines) along two lines located on a horizontal plane at half of the height of the model are shown in the Figures 8 to 13. Line 1 runs from the center of the frontal plate (inlet) to the center of the back plate (outlet) and line 2 runs perpendicular to this from the freeze pipe in the middle to the center of the side plate on the right (Figure 7 and 3).

The measurements of the test v0 shows, as expected, a symmetrical temperature distribution along line 1 and between the freeze pipes in line 2. This symmetrical distribution could also be observed during the tests

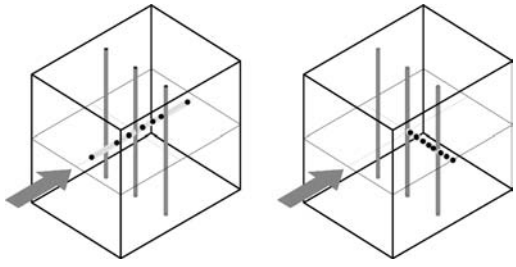

Figure 7. Line 1 (left) and 2 (right) of measurements.

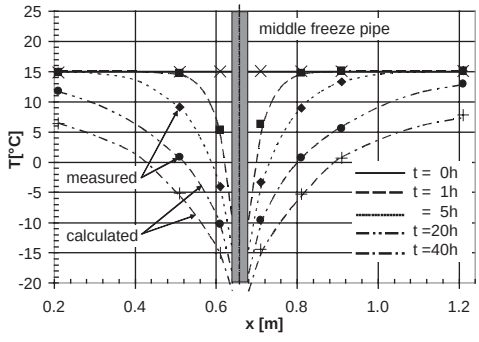

Figure 8. Measurements and calculations. Test v0 – line 1.

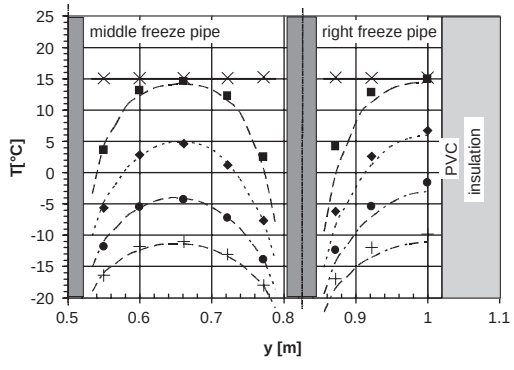

Figure 9. Measurements and calculations. Test v0 – line 2.

with seepage flow along line 2. The distribution along line 1 for these cases is plausible, since the water in the inlet is warmer than in the outlet due to the cooling work of the pipe. These measurements provide evidence of the high quality of the laboratory tests. Their results are therefore appropriate for verification purposes.

The calculated values show a very good agreement with the measurements all over, including the cases with high seepage flow velocities.

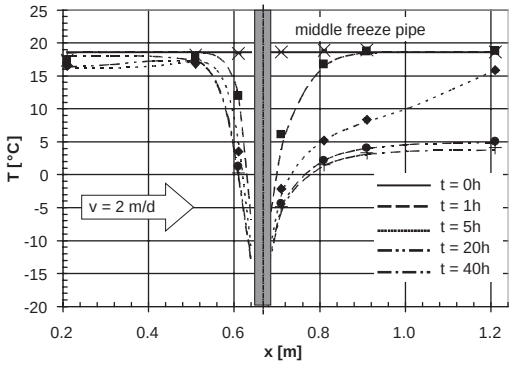

Figure 12. Measurements and calculations. Test v2 – line 1.

6 CONCLUSIONS

A new TH-model in 3D with optimized algorithm has been successfully implemented. The verification of the model on the basis of external tests published in the literature and particularly on the basis of our own large scale tests covering a wide range of seepage

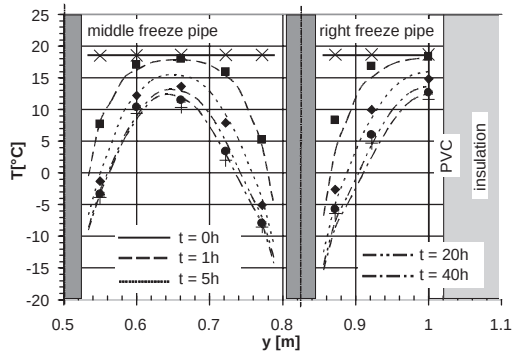

Figure 13. Measurements and calculations. Test v2 – line 2.

flow conditions shows a very good agreement with the measurements. The large-scale laboratory model conceived and constructed has shown itself to be adequate for the purposes of verifying tests involving complex boundary conditions.

Our research work includes the following additional tasks:

- analysis and variation of relevant design parameters for the ground freezing method with seepage flow
- enhancement of the model with a coupled mechanical component (THM-model) in order to simulate the formation of ice lenses
- element tests with ice lense formation
- numerical simulation of the element tests
- large scale test with ice lense formation
- numerical simulation of the large scale test
- analysis and variation of relevant design parameters for the ground freezing method in grounds susceptible to ice lense formation

Performance evaluation of ground improvement by electrical resistivity tomography

T. Shimizu, K. Narumoto & S. Ebisu
Okumura Corporation, Technical Research Institute, Tsukuba City, Ibaraki Prefecture, Japan

ABSTRACT: Electrical resistivity tomography was carried out in order to identify the chemical grouting range in ground improvement. Experiments were conducted on imitated ground and imitated improved ground prepared using sand and mortar, respectively. The results confirmed that it was possible to accurately grasp the range for imitated improved ground by designing the appropriate electrode array.

1 INTRODUCTION

The procedures for initial excavation in general shield tunneling are as follows: 1: Seepage control work and ground reinforcement around the starting shaft, as shown in Figure 1, are carried out using ground improvement methods such as chemical grouting; 2: Improved ground of the excavation part is exposed; and 3: Shield propulsion starts.

Moreover, an impervious zone is constructed at the face in cases where diluvium soil below groundwater level is excavated by mountain tunneling method without lowering the groundwater level. Similar seepage control work and ground reinforcement methods are used when constructing a tunnel in soft ground in urban areas. However, in actual practice, the thickness of the improved ground layer is designed on the safe side, since the technique for accurately predicting and evaluating improvement performance is not yet sufficiently established. Therefore, it is expected that the technique will enable accurate evaluation of the impervious performance of improved ground for enhanced reliability and cost reduction in tunnel construction.

We applied multiple geophysical exploration such as electrical resistivity tomography, acoustic tomography, and ground temperature distribution measurement for the purpose of accurately visualizing the imitated improved ground and detecting artificially generated water leakage for wall-like imitated improved ground prepared in the imitated ground. This paper reports the results of examining the applicability of electrical resistivity tomography applied in order to specify the shape of the improvement range.

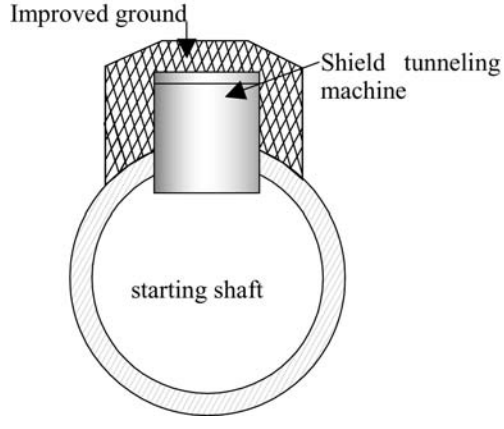

Figure 1. Ground improvement around the starting shaft in shield tunneling method.

2 OUTLINE OF THE EXPERIMENT

2.1 *Specifications for the imitated improved ground*

The imitated improved ground used in the experiments was composed of 20 cm-thick mortar and was constructed so as to bisect the excavation in the east-west direction. First, a 9.5 m area around the excavation was dug to a 2.5 m depth as shown in Figure 2. An impervious rubber sheet was laid between the peripheral ground and imitated ground in order to cut off any effects from the peripheral ground and to easily control the groundwater level in the imitated ground. River sand was used to fill the area on both sides of

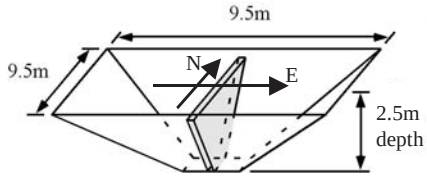

Figure 2. Schema of imitated ground and imitated improved ground.

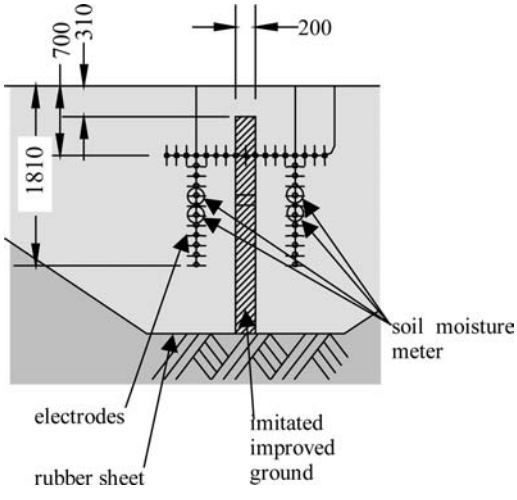

Figure 3. Position of electrodes and surrounding conditions.

the imitated improved ground, and with equal pressure. The resistivity of the mortar was 26.2 Ωm and that of the river sand in a saturation state was about 70 Ωm. For the groundwater conditions, multiple cases were created. For example, the water level of both sides was changed, and water leakage was intentionally generated by drilling the imitated improved ground.

2.2 *Measurement*

The electrodes used for measuring resistivity were placed at 10 cm intervals, forming a 'π' in left-right symmetry, around the imitated improved ground, as shown in Figure 3. Sensitivity seemed to improve by placing electrodes at all four corners of the rectangle as the exploration object within the three boundaries of the π. However, considering that such an arrangement would be difficult in practical use, the above-mentioned arrangement was used. Since contact resistance is lowered, a copper disk with 10 cm outer diameter and 3.2 cm inner diameter was used for the electrode. Each electrode was connected by polyvinyl chloride pipe.

It was difficult to establish an infinite electrode because it was measured in a closed region electrically isolated by the impervious sheet for the peripheral ground. Therefore, the four-electrode method was used in the measurement.

3 COMPARISON OF THE ELECTRODE ARRAY PATTERN

3.1 *Electrode array*

The two-dimensional electrical resistivity method, which is nearly established, seems to obtain inversion analysis results for resolution corresponding to the quantity of data, if the data has been acquired in the correct manner. However, it is important to accurately grasp the position of the boundary in the improved and unimproved area in order to estimate the improvement range from the resistivity distribution. Therefore, resolution beyond the conventional electrical resistivity method is necessary. Since the resolution is closely related to the stability of the inversion analysis solution, it is important to examine the boundary-value problem described next in order to stabilize the solution of the inversion analysis (Wang 2003).

i. Stability and uniqueness of the inversion analysis solution are improved if the survey point is placed within the boundary surrounding the region to be investigated, if possible, even if not all data space is proven.
ii. The best possible estimation is given for a boundary where data is lacking, using all known information, when above survey point placing cannot be achieved.
iii. Useless estimated calculation is not carried out for subspace of the model, which cannot be controlled in known data.

In this study, the arrangement of the survey point described in i was observed; that is, the selection of the electrode array was examined, and efforts were made to enhance the estimation accuracy of the improvement range. The basic pattern (a, b, c, d, e) of the electrode array applied in this study is shown in Figure 4.

Pattern-a was created by combining a Wenner electrode array with a dipole-dipole array. Pattern-b was devised by predicting that a clear image of the improved ground would be obtained by putting the imitated improved ground between two current electrodes. Pattern-c was thinned out from all available combinations except for Pattern-a and Pattern-b. Pattern-d and -e were made similar to a two-electrode array by fixing the positions of one current electrode and potential electrode as shown in Figure 4, and applying the other current electrode and potential electrode to all combinations considered.

3.2 *Quantitative evaluation of the tomogram*

Quantitative evaluation was performed on the tomogram obtained from measured data using the inverse

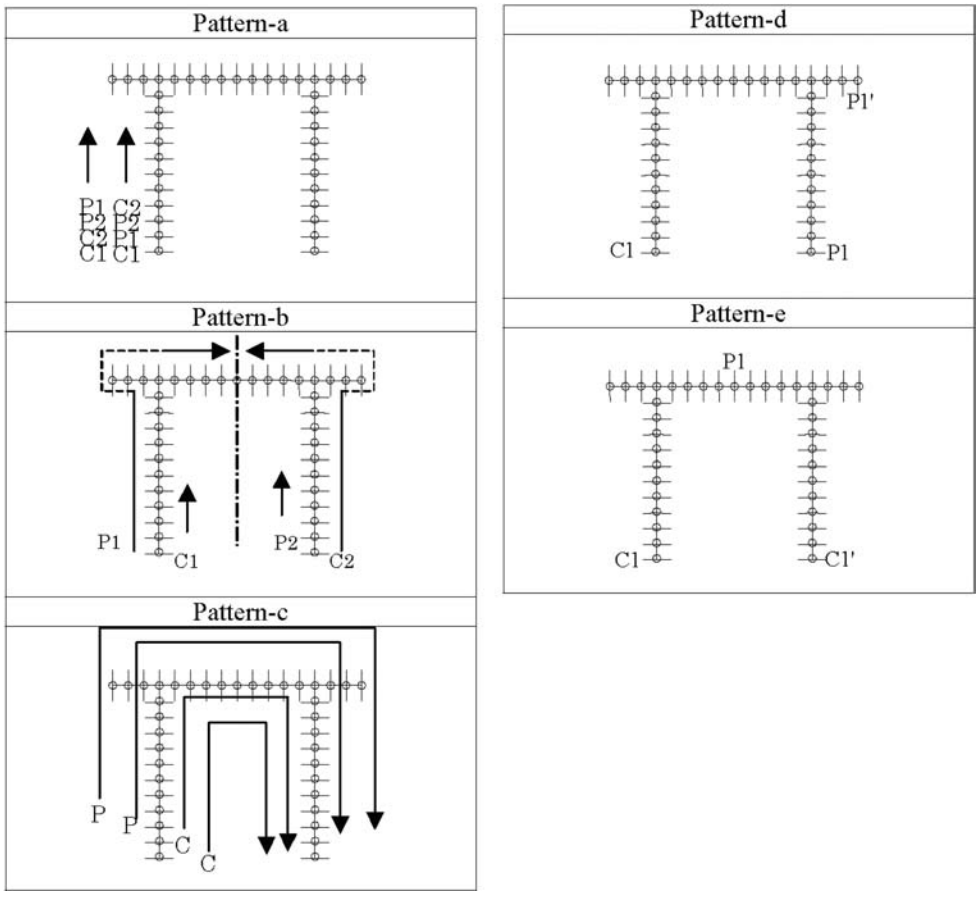

Figure 4. Basic pattern of the electrode array. C1, C2: Current electrode. P1, P2: Potential electrode. Pattern-a: Combining Wenner electrode array with dipole-dipole array. Pattern-b: C1 and P1 were selected from only the left side, and C2 and P2 were selected from only the right side. analysis method. In this study, resistivity distribution based on known information is assumed for the true model, because the position of the boundary and the resistivity of sand and mortar are known. Then, the degree of difference between the true model and the tomogram was used as an index for the evaluation. That is, the least mean squared error (*LMS*) was calculated using the following equations. The objective range is one surrounded by three measurement lines of electrodes.

$$LMS = \sum_i \varepsilon_i^2 \tag{1}$$

$$\varepsilon_i = y - y' \tag{2}$$

$$y = \frac{Y - Y_{ave}}{\sigma_Y} \tag{3}$$

$$y' = \frac{Y' - Y'_{ave}}{\sigma_{Y'}} \tag{4}$$

where Y = resistivity of true model; Y_{ave} = average of Y; σ_Y = standard deviation of Y; Y' = resistivity calculated by inversion; Y'_{ave} = average of Y'; $\sigma_{Y'}$ = standard deviation of Y'.

The effect of the exception value (noise) was strongly received, as the *LMS* increased linearly in the inversion analysis results separate from the true model. On the other hand, the *LMS* can catch sharply even slight signal in the inversion analysis results obtained from data with low noise. Then, it is considered that the

electrode layout pattern with smaller *LMS* has better performance to specify the shape of the improvement range in this study.

Still, the observed resistivity of sand and mortar for the true model was 73 Ωm and 26.2 Ωm, respectively. The finite element method was utilized in forward analysis, and the constrained least squares method was used in inversion analysis. In the inversion analysis, the convolution in which a minimum residual is reached in 20 times iterations was adopted. Because it was predicted that 20 times iterations were sufficient to reach minimum residual empirically.

3.3 *Patterns to compare the perfomance of electrode array pattern*

In measuring the resistivity, 21 composite electrode array patterns, as shown in Table 1, which combined the above-mentioned 5 basic patterns, were used to examine the estimation accuracy. And, considering its potential importance as a parameter affecting the performance evaluation of the electrode array, the constraint of inversion analysis was also parametrically examined. Examination was conducted on the 9 patterns of constraint shown at Table 2, making a sum total of 189 cases. These are all combinations able to examine within limitation of the computer soft for inversion calculation.

Still, this paper reports the results of examination at a groundwater level of 40 cm beneath the surface on both sides of the imitated improved ground.

Table 2. Constraint of inversion analysis.

No.	Constraint	Horizontal continuity*

5	C	0.5
6	D	0.0
7	D	0.5
8	E	0.0
9	E	0.5

* Degree of continuity in horizontal direction.
A : Initial model is not significantly different.
B : Minimize the difference between resistivity of neighboring elements.
C : Minimize the curvature of resistivity distribution.
D : Minimize the difference between resistivity modification of neighboring elements.
E : Minimize the curvature of distribution of resistivity modification.

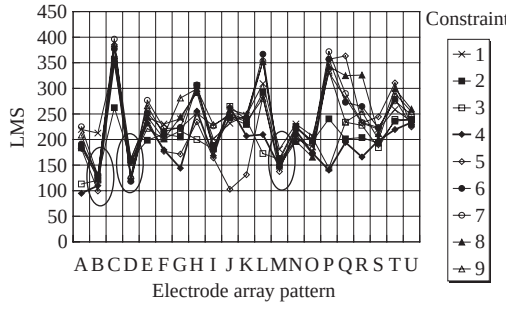

Figure 5. Value of *LMS* in each case.

3.4 *Results of the examination*

The *LMS* of each case is shown in Figure 5. The *LMS* seems to be more dependent on the electrode array than on the constraint, because all plot lines in each constraint gather together. The value is small for the *LMS* of pattern B, D, and M (= B + D) in most constraints. The *LMS* of pattern A is also small only in the case of constraint 4 and 5. Tomograms of case B5, in which the *LMS* is small, and of case E4, in which the *LMS* is medium, are shown in Figures 6 & 7 as examples. Two length lines in the center of the figure show the width of the imitated improved ground. The form of π shows the line of electrodes. The *LMS* of cases B5 and E4 are 99 and 232, respectively. The shape of the imitated improved ground is clearly recognized in Figure 6, but not in Figure 7. From these results, it was proven that the *LMS* could be used as an index for the accuracy of the tomogram, because the shape of the

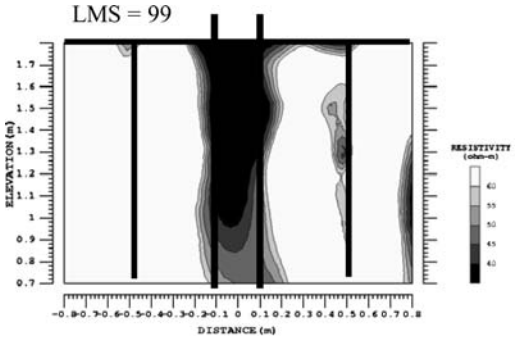

Figure 6. Tomogram for case B5.

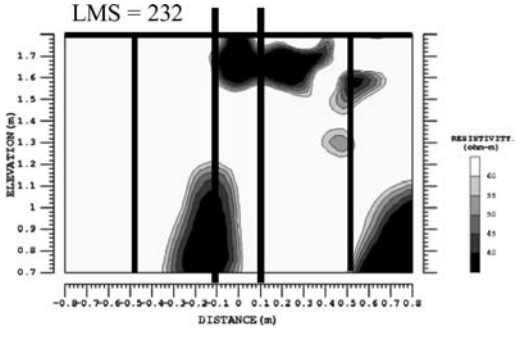

Figure 7. Tomogram for case E4.

imitated improved ground was accurately recognized, as the *LMS* is smaller.

Pattern B, in which the *LMS* is averagely small, is distinguished by the many arrangements for the position where current electrodes and potential electrodes respectively hold the imitated improved ground. Moreover, it is also a characteristic of pattern B that there are many measurement frequencies compared to the other pattern in the lower half of the π form in which the measurement density is low. The cause-and-effect relationship has not yet been clarified. The accuracy should have improved with the increase of information. However, the results were not good for the combined patterns used in this study.

On the other hand, Wenner Method or Dipole-Dipole Method, which are contained in Pattern-a, are usually used in four-electrode resistivity tomography as standard method. But the *LMS* of them takes not only small value but also medium value, though the LMS of Pattern-b mostly takes small value.

4 APPLICABILITY IN DIFFERENT MEASUREMENT CONDITIONS

The examination described in the previous chapter revealed which electrode array pattern should be selected to accurately visualize the imitated improved ground in the disposition of measurement line in this study. This chapter presents the results of inversion analysis based on data measured adopting the electrode array pattern of case B5 and changing the measurement conditions to ground water conditions.

Table 3. Measurement conditions.

	Imitated water-leaking holes	Ground water conditions
Stage 1	not exist	Saturated on both sides
Stage 2	not exist	E*: saturated; W*: unsaturated
Stage 3	exist	E*: saturated; W*: unsaturated

* E: east side W: west side.

Table 3 shows the measurement conditions. At first, the ground on both sides was saturated up to the ground surface by injecting water (Stage 1). This stage is the same as in the examination of electrode array patterns. After that, the water level on the west side (left side on paper) was lowered to the level at the lower end of the imitated ground by pumping up ground water. In other words, the ground on the east side was saturated, and that on the west side unsaturated (Stage 2). The imitated improved ground was sound up to this point.

Next, holes forming a horizontal line were made in the imitated improved ground at 250 mm intervals and at half its depth. This imitated the condition of water leakage. The same ground water conditions as in Stage 2 were created by pumping up ground water on the west side (Stage 3). The difference in water head between the two sides caused a steady water leak in Stage 3, which was maintained by pumping the water leaking from the west side and returning it to the east side.

The ground water conditions and the tomogram of the electrical resistivity at each stage are shown in Figures. 8–10. The form that is taller than broad in the figure for the ground water conditions shows the imitated improved ground, and the π form shows the line of electrodes. The tomogram is enlarged to show the resistivity distribution in and around it

The tomogram of the electrical resistivity at every stage shows the shape of the imitated improved ground clearly. The change in ground water conditions is also reflected to a certain degree. That is to say, while the resistivity of the ground on both sides ranges from 60 to 100 Ωm in Stage 1, the resistivity on the west side ranges from 140 to 290 Ωm for the most part in Stage 2. This reflects the increase in resistivity due to the decrease in water content by volume after pumping up the ground water on the west side.

In this experiment, soil moisture meters were buried at the locations shown in Figure 3 in order to grasp the water content by volume, automatically taking measurements once every hour. According to the results,

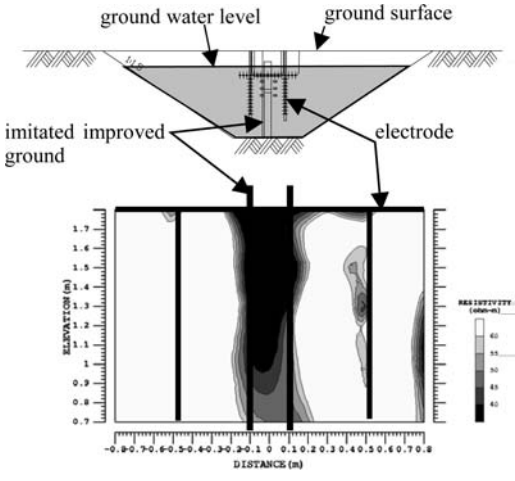

Figure 8. Ground water conditions and tomogram of electrical resistivity in Stage 1.

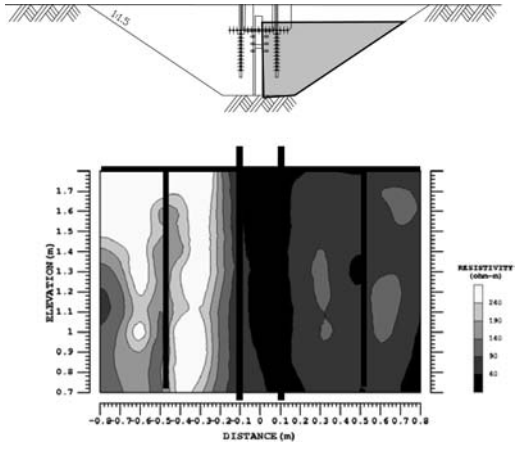

Figure 9. Ground water conditions and tomogram of electrical resistivity in Stage 2.

the change in water content by volume on both sides ranged from 46 to 50% in Stage 1. In Stage 2, the change ranged from 13 to 15% on the west side, and from 47 to 50% on the east side.

On the other hand, the relationship between the water content by volume and the resistivity was examined for the sand used for the imitated ground by a laboratory test. Figure 11 shows the relationship between the water content by volume and the electrical conductivity, which is a reciprocal of the electrical resistivity. Correlate coefficient between them was 0.998. So they were related with hard linear relationship.

Figure 12 shows the relationship between the water content by volume and the resistivity. When the resistivity shown in the above-mentioned tomogram and

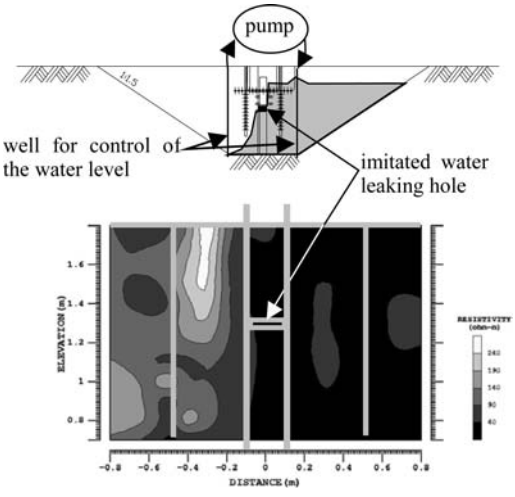

Figure 10. Ground water conditions and tomogram of electrical resistivity in Stage 3.

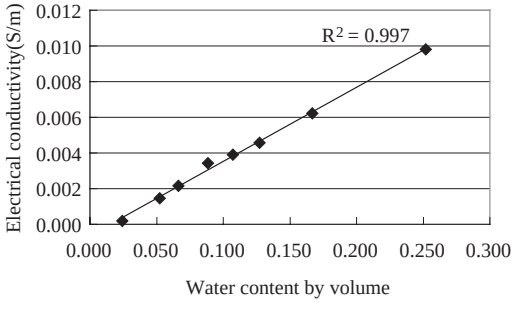

Figure 11. The relation between the water content by volume and the electrical conductivity.

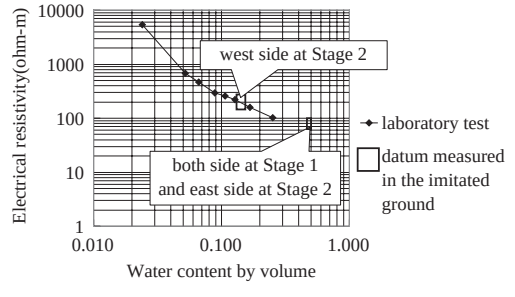

Figure 12. Relationship between water content by volume and resistivity.

the water content by volume measured by the moisture meter are plotted in the figure, the plotted points agree with the relationship or its extrapolation. Therefore, the validity of the absolute value is ascertained.

The resistivity in the lower half area on the west side is somewhat lower in Stage 3 compared to Stage 2. It seems that the condition of water leaking from the imitated holes wet the lower area, reflected by the water leakage caused in Stage 3.

5 CONCLUSIONS

The following conclusions were obtained in this experiment:

i. Pattern-b, the electrode array pattern that emphasized the low, center area where the measurement density is thin, enabled to visualize the shape of the imitated improved ground clearly, and the ground water distribution to a certain degree.
ii. Although the measurement conditions changed using Pattern-b, the imitated improved ground and the change of water table were visualized regardless of the difference in measurement conditions.
iii. From the above, it is considered that an estimate of the range of improved ground by electrical resistivity tomography can be sufficiently practical by Pattern-b.

After this, we would examine reproductiveness of this result besides improvement of accuracy. Moreover, we hope to examine the required technique for detecting water leakage in addition to this method, and suggest a system to detect water leakage for improved ground using a combination of techniques.

ABSTRACT: One of the most popular pre-reinforcement methods of tunnel heading in cohesionless soil would be the fore-polling of grouted pipes. This technique allows safe excavation even in poor ground condition by creating longitudinal arch parallel to the tunnel axis as the tunnel advances. Some previous studies on the reinforcing effects have been performed using numerical methods and/or laboratory-based small scale model tests. The complexity of boundary conditions imposes difficulties in representing the tunneling procedure in laboratory tests and theoretical approaches Full-scale study to identify reinforcing mechanism of the tunnel heading has rarely been carried out. In this study, a large scale model testing for a tunnel in granular soils was performed. Reinforcing patterns considered are non-reinforced, crown-reinforced, and crown & face-reinforced. The behavior of ground and pipes were fully measured as the tunnel advanced. The influence of reinforcing pattern, pipe length, and face reinforcement were investigated in terms of stress and and displacement, It is revealed that the pipe reinforcement of heading increases longitudinal arching sufficiently along the tunnel axis, consequently decrease settlement sufficiently at the heading, and improves the face stability significantly.

1 INTRODUCTION

Generally tunneling in granular soils is performed with the protection of a shield providing to support the excavated perimeter and to, when necessary, support the tunnel face until the initial/final supporting system can be erected. One common and economical alternative for the case would be the pre-reinforcement of tunnel heading. One of the most popular pre-reinforcement methods id the fore-polling of grouted pipes above the tunnel crown. This technique allows safe excavation even in poor ground conditions by developing longitudinal arching parallel to the tunnel axis as the tunnel advances. Lunardi(2000) identified the advantages of heading reinforcement based on field instrumentation. It is clear that the pre-reinforcement reduces plastic strains in the tunnel heading, decreases in lining loads, increases face stability and prevents damages from structures nearby.

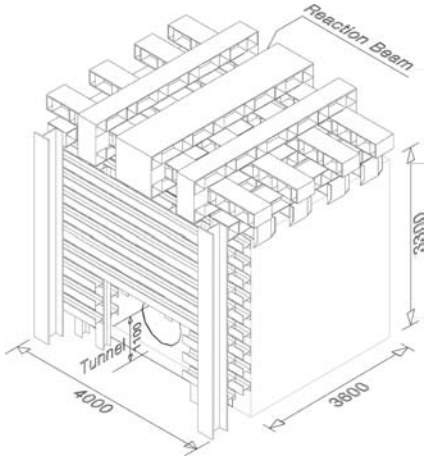
The method is initially developed in 1970s(Barisone, 1982; Pelia, 1994) and has been used increasingly with the improvement of grouting equipments. Figure 1 shows arching effect at the tunnel face (Gnilsen, 1989) and design factors. Although some previous studies on the reinforcing effects have been performed, the complexity of boundary conditions imposed difficulties in representing the procedure in laboratories and theory. Therefore, full scale research to identify reinforcing mechanism quantitatively has rarely been carried out. In this study a large scale model testing was performed to evaluate and improve the design method of the heading reinforcement

2 LABORATORY TESTS PREPARATION AND PROCEDURE

The tunnel was excavation in a test tank of which length is 3.6 m long, width is 4.0 m and depth is 3.3 m as shown in Fig 1. Steel structures were used for the frame of the soil tank. The floor and lateral sides and a back-end of the tank were built of reinforced concrete of which thickness is 30 cm. The floor and lateral sides and a back-end of the tank were built of reinforced concrete of which thickness is 30 cm The front wall was made of steel plate with the thickness of 10 mm. Inner sides of the concrete and steel wall were covered with thin clay layer to reduce friction between the soil and the wall. The tunnel was 1.1 m in diameter and 1.0 m in cover depth.

To identify full effect of reinforcement, it would be appropriate to consider all design factors.

Total 8 cases of tests were considered. To explore the effect of reinforcement, firstly an unsupported model was considered, two different pipe lengths were considered to investigate the effect of pipe length and finally the effect of face-reinforcement was examined by modeling face reinforcement with different length of pipes. All Test cases considered are summarized in Table 1.



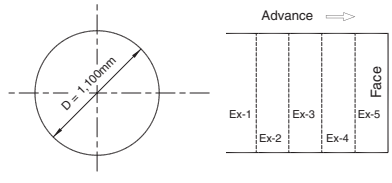


Figure 1. Layout of the model.

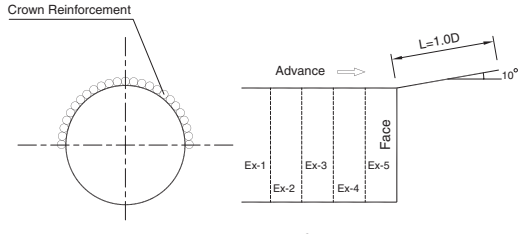
2.1 *Model ground*



Model ground was prepared by falling sand from a certain height of the tank and compacting it in every 30 cm layer with constant energy. The soil properties are summarized in Table 2.

2.2 *Install pipe and grouting*

Grout pipe with external diameter of 25 mm and thickness of 3 mm were used. Grouting was performed to

determine appropriate grouting pressure and the diameter of the grout. Cement mortar of 200% W/C ratio was used as grout material. At the far-end of pipes, the required diameter of grout was 90 mm which was obtained under the pressure of 1.2 kgf/cm^2. The lining was made of steel plates of which shape is circular shape. Each lining segment has 30 cm in width and is assembled with epoxy resin.

(c) Crown-force reinforced (c1.5F0.5)

(d) Face reinforced (F1.5)

Figure 3. Schematic diagram of the reinforced type.

Figure 4. Strain gage install process.

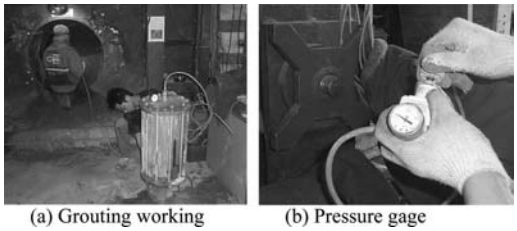

Figure 5. Grouting using pressure apparatus in the FRP pipe.

2.3 *Tunnel excavation*

Model testing was performed sequentially as shown. The lining was made of steel plates of which shape is circular shape. Each lining segment has 30 cm in width and is assembled with epoxy resin as shown in Fig 6.

2.4 *Surcharging*

After completion of excavation to the desired location, surcharge is given to induce sufficient displacement and stress, and failure behavior of tunnel heading is investigated. Surcharge was applied to a stress-controlled boundary at the top of the model ground surface. Surcharge is loaded in six steps;

2.5 *Instrumentation*

To monitor the ground behavior, settlement gages earth pressure cells were pre-installed. Behavior of pipes was also instrumented by measuring axial forces and bending moments in the pipes using strain gages. The

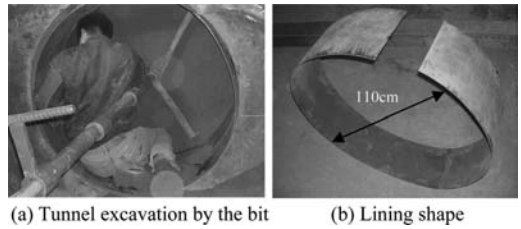

Figure 6. Inserting a steel ring after excavation.

Figure 7. Strain gage attached on the steel bar.

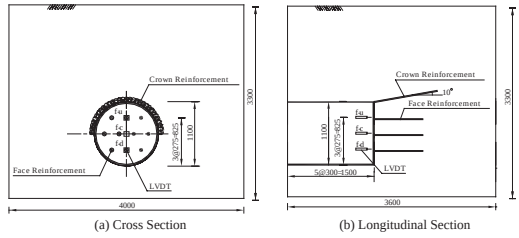

Figure 8. Horizontal displacement instrumentation(LVDT).

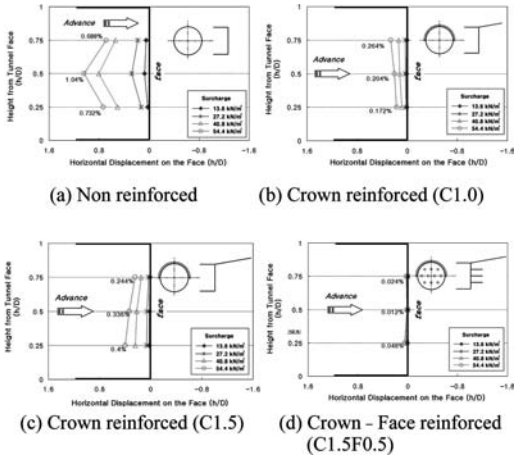
horizontal movements of face were measured at three point; crown (f-u), center (f-c) and invert (f-d).

2.6 *Summary of testing procedures*



The testing procedures mainly consists of three steps: firstly boreholes are drilled at the tunnel face, then FRP pipes are inserted and finally grouts are injected. The testing procedure is as following:

a) Test ground are prepared by falling sand from the soil tank and relative density of 56%.

(a) Crown reinforced (b) Face reinforced

Figure 9. The umbrella shapes of field model tests.

(a) Non reinforced (b) Crown reinforced (C1.0)

(c) Crown reinforced (C1.5) (d) Crown – Face reinforced (C1.5F0.5)

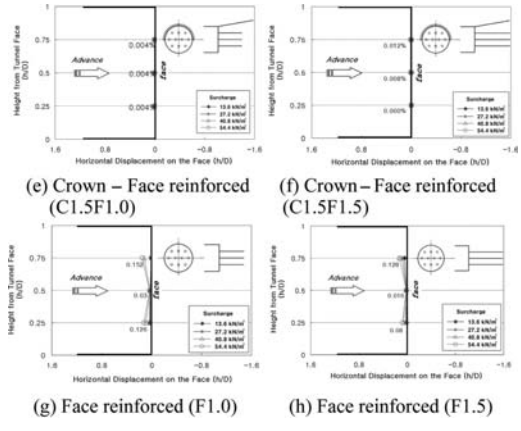


Figure 10. Face displacement due to surcharge (Continue).

b) While preparing model ground, measuring devices are installed at the predetermined locations and connected them to data loggers, and the PVC pipes of 32 mm diameter were pre-installed at the desired locations of FRP pipes.
c) Remove steel plate-tunnel face at the front and excavate a tunnel with a specially devised mechanical excavator.
d) For every excavation of 30 cm, steel plate lining is installed. The excavation process is repeated until the desired location has been reached.
e) After completing excavation, extract the PVC pipes and insert FRP pipes. Grout the pipes with cement milk under the pressure of 1.2 kgf/cm^2.
f) Surcharge is loaded on the surface of model ground.

3 TEST RESULTS

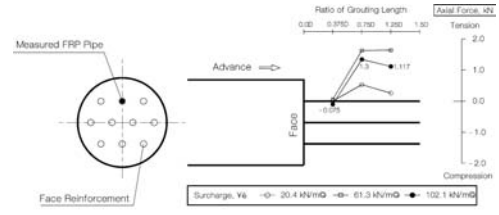
(d) Crown - Face reinforced (C1.5F1.0)



(e) Crown - Face reinforced (C1.5F1.5)

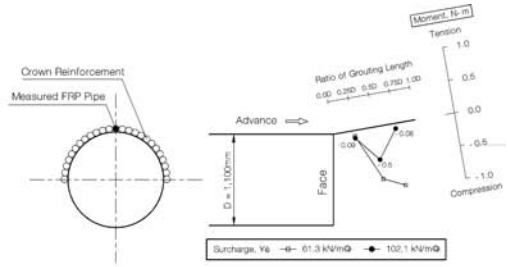
(f) Face reinforced (F1.0)

Figure 12. Comparison of increments of axial force in the FRP pipe due to the surcharge (continues).

(g) Face reinforced (F1.5)

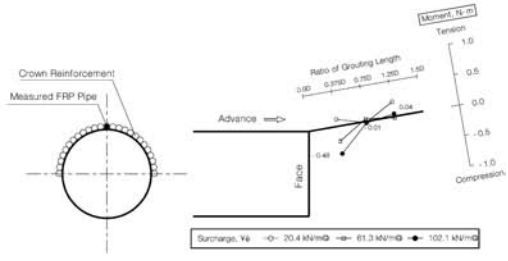
Figure 13. Comparison of increments of axial force in the FRP pipe due to the surcharge.

3.2 *Horizontal displacement shape of the face*



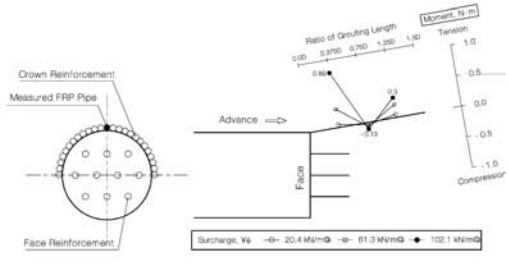
Surcharging after completion of excavation is also useful in investigating the failure mechanism of the face. The influence of face reinforcement on stability can also be investigated by comparing test in Figure 10. The horizontal movement is negligibly small for the test of face reinforcement. The Average Horizontal displacement ratio at tunnel face has decreased from 0.01 to 0.327. Increase in pipe length reduced displacement slightly at the tunnel crown from 0.264 to 0.244(Table 3). It is shown that the face reinforcement, particularly combined with crown reinforcement is considerably beneficial in securing face stability.

3.3 *Behavior of grouted pipes*

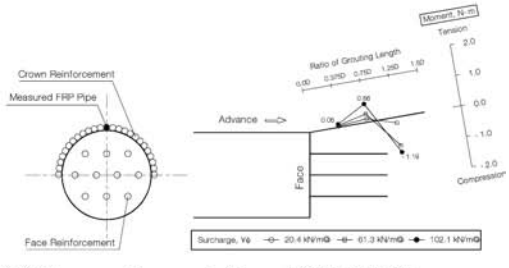


Figures 11 & 12 presents axial forces and bending moments in the grouted-pipes for the tests result. High tension load and bending moments were obtained in the pipes installed at the tunnel crown. The behavior indicates that the deformed shapes for the pipes are downward concave. At initial stage maximum axial loads and bending moments were observed at the middle of pipes. However, the location of maximum loads and bending moments moved towards tunnel face with an increase of sur-charge. Measured results indicate that the grouted-pipes resist effectively against face collapse mechanism which is being developed close to tunnel face. Pipes installed at the face showed less axial forces and moments in comparison with those in the pipes at the crown.

4 CONCLUSIONS



A series of large scale model test were carried out to investigate the behaviour of tunnel heading in granular soils reinforced by pipe grouting. It is revealed that the pipe grouting of heading is an efficient measure in reducing settlement, consequently preventing damages from surface structures



(a) Crown reinforced (C1.0)

(g) Face reinforced (F1.5)

Figure 15. Comparison of bending moment in the FRP pipe due to the surcharge.

and increasing face stability. Results are summarized below.

(a) surcharge increduce may not be significantly reduced before failure because the straining of pipes is counteracted after considerable sur-charge.

(b) Face reinforcement combined with crown reinforcement improves face stability significantly during excavation. Shorter pipes length can be employed at the face than at the crown.

(c) The grouted-pipes resist effectively against face collapse mechanism.

ABSTRACT: This paper deals with investigation and testing of targeted properties on the basis of laboratory research of geo-composites, which are prepared form rocks and chemical grouts including their rheological and chemo-rheological study (particularly epoxy material, which is not in common use in domestic grouting practice). The paper presents some testing methods and procedures for research of both clean grouting media and composites with the grouted discontinuity, which enables to optimize a choice of grouting media for affecting the properties of rock mass.

1 INTRODUCTIONS

Discontinuities affect significantly stress and deformation phenomena in rock mass. Moreover, they affect its cohesion and therefore, they affect negatively the stability and the construction of underground structures and reduce occupational safety at construction works. The worsened stability occur primarily at shallow depths and in rock mass with de-stressed areas where structurally controlled failures may be the prime concern in the underground constructions and excavation design (Brady 1993).

In the cases when discontinuities of rock mass complicate the construction, it is possible to improve its quality with targeted geo-technical steps in rock mass. One of the options of application of such geo-technical procedures is the grouting technology with utilization of progressive chemical grouts. With application of chemical grouts into discontinuities, it is possible to affect properties of rock mass.

With application of chemical grouts, primarily on the basis of polymers, new geo-composite materials come into existence in the grouting process. The important factors, which affect a choice of grouting media and at the same time, the effectiveness of grouting technology, are resulting properties of geo-composites. Generally geo-composites are materials that are produced in the process of pressure grouting on the basis of rocks as a skeleton and grouts s as a binding agent. With stabilizing grouting of petrean types of rocks, the grouts are grouted into the void of discontinuities in rock mass. A new composite material comes into existence consisting of the system of rock-cured grouts-rock, the so called "geo-composites with the grouted discontinuity".

In present grouting practice, epoxy resins are not currently used despite their high target strength and adhesion parameters. Therefore, we have examined the possibilities of available epoxy materials utilizable in grouting practice, primarily in the field of rehabilitation of fissures in petrean rocks.

The presented material deals with the knowledge in the field of targeted treatment of properties of rock mass for geotechnical purposes gained from laboratory research. At the same time, there are described some general procedures for the research and assessment of properties of pure chemical grouts in the liquid and cured condition relating both to grouting process and to properties of geo-composites with the grouted discontinuity.

The achieved results and procedures described in this paper are based on the results from the completed Grant Project GA AVČR No.B3086907 and project aimed research carried out by the Academy of Sciences of the Czech Republic No. S3086351.

2 MATERIALS USED

Polymer systems based on epoxy resins cured with aliphatic amines have been used for the purpose of rehabilitation of discontinuities. There are three epoxy-amine systems identified as Epoxy A, Epoxy B and Epoxy C cured with the usual hardener T used in dry conditions, and/or hardened with the hardener T1 for application in humid conditions. All the epoxy

Table 1. Basic properties of epoxy resins.

	Epoxy A	Epoxy B	Epoxy C
Properties of non-cured resins

Bending strength (MPa)	> 40	> 85	> 90

systems have been chosen also with respect to the application at lower temperatures than is, for example, the temperature of the Carboniferous massif, i.e. at least 8°C. Originally, these epoxy systems have been intended for preparation of the putties with mineral fillers, polymer-mortar and polymer-concrete composites. The following table shows some general properties of these epoxy systems taken over from material sheets of the company Spolchemie (Table 1).

For comparison, the three types of chemical grouting resins, that are currently used today, have been used in the laboratory research; there are grouting polyurethane materials Bevedan – Bevedol S and WF (BBS and BBWF) and the organic-mineral material Bevedan – Bevedol OM.

The drill cores with the diameter of 48 mm, of prevailingly light grey medium-grain carboniferous sandstone, with a slight content of mica, non-calcareous, well sorted out, with uniform grain size with massive texture – fresh rock have been used for preparation of geo-composites.

3 USED CHEMICAL GROUTS PROPERTIES

Several experimental methodologies have been used for the comparison and assessment of the applicability of chemical grouting polymer systems in the liquid and/or hardened condition on the basis of the following criteria:

- Viscosity of reactive mixture – affecting directly the flow itself (velocity, pressure gradient in the grouts, etc.) of grouting media in rock environment; the higher viscosity of grouting mixture requires higher pressures under the comparable conditions;
- Velocity of hardening reaction (the period of gel formation) determining the workability of reactive mixture, the time of grouting process and the reach of grouting process;
- Mechanical properties of hardened grouting material – modulus of elasticity (at room temperature, and/or at increased temperature in rubber-like condition), strength, ductility, etc;
- Thermal stability of permanency of form (temperature of glass transition T_g);

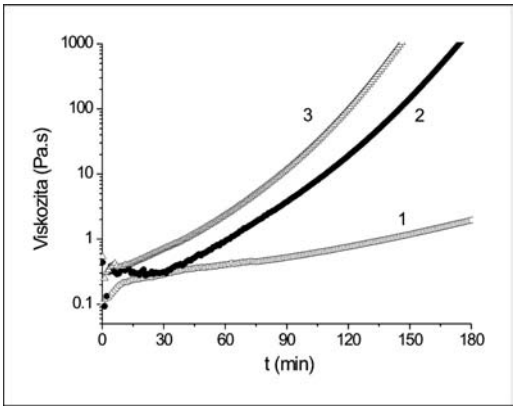

Figure 1. Growth of viscosity in the course of hardening of epoxy systems at temperature of 30°C, 1 Epoxy A-T, 2 Epoxy B-T, 3 Epoxy C-T.

- Thermo-oxidation stability against degradation and combustion resistance.

3.1 *Dynamic-mechanical analysis (DMA)*

3.1.1 *Chemorheology*

Chemo-rheology as part of DMA is the methodology determining rheological changes of reactive mixture in the course of curing, i.e. the growth of viscosity and modulus of elasticity. This methodology is used for determination of initial viscosity of reactive system, the course of hardening at the given temperature, gelation and/or system vitrification. A very important parameter is primarily the dynamic viscosity and the time of workability of the mixture, which depends on the speed of curing process. This period can be determined as reactive time in which the reacting system reaches a certain defined value of dynamic viscosity. The point of gelation corresponds with the utmost limit of workability of reactive mixture. However, the mixture viscosity considered as workable depends on the technological method of preparation of mixture, grouting method and on the physical condition of discontinuities in rock environment.

The Epoxy A-T (see Figure 1) shows the lowest initial viscosity of polymer mixture (i.e. 100 mPa.s). The speed of formation of a net was characterized by determination of the times of gelation t_g (at 20°C) that are outlined in the following table (see Table 2). From this table and the following figure (see Figure 1) it results that the fastest growth of polymer structure occurs in the case of the Epoxy C-T. It can be stated, from the development of viscosity values in the graph in this table that the more favorable rheological properties, from the viewpoint of grouting process (the lower values of viscosity, i.e. better grouting through the less opened fissures, the lower grouting pressure and higher reach of grouting medium) have the Epoxy A

Table 2. Gelation time, thermo-mechanical and strength characteristics of epoxy systems cure at temperature of 20°C.

	t_g (min)	η (Pa.s)	T_g (°C)	$G'_{120°C}$ (MPa)	$G'_{25°C}$ (MPa)
Epoxy A-T	540/2160*	0,1	30/20*	5,0/0,8*	600/100*
Epoxy B-T	250/1200*	0,3	51/29*	8,0/0,9*	880/200*
Epoxy C-T	190/900*	0,3	87/40*	8,8/3,0*	920/760*

	σ_b (MPa)	σ_k (MPa)	ε_b (%)	ε_k (%)
Epoxy A-T	31 ± 2	36 ± 2	$5{,}8 \pm 2$	4 ± 1
Epoxy B-T		49 ± 7		$1{,}8 \pm 0{,}5$
Epoxy C-T		62 ± 3		$2{,}8 \pm 1{,}5$

T_g – Temperature of glass transition; η- initial viscosity; $G'_{25°C}$, $G'_{120°C}$ – Dynamic conservative shear modulus at temperature of 25°C and 120°C; σ_b, ε_b – stress and/or relative, longitudinal deformation at breakage; σ_k, ε_k – stress and/or relative longitudinal deformation at tensile strength; * – values of parameters stated for reaction temperature 8°C.

and B roughly in the first 30 minutes of reaction. It was found out that hardening of reactive mixtures of Epoxy B and C was significantly faster in comparison with Epoxy A. In the case of Epoxy B and C, the systems gelate in the period of approx. 3–4 hours, while the system based on Epoxy A gelates in approx. 9 hours.

3.1.2 *Temperature dependence of dynamic module (DMA)*

DMA gives the information about the modulus of elasticity in the glass-like and rubber-like condition and at the temperature of glass transition T_g, characterizing the thermal stability of material permanency of shape (See Table 2).

3.2 *Strength characteristics*

The determination of strength characteristics (strength, ductility, toughness) by means of a tensile or pressure test is one of general criteria of material quality (see Table 1, 2). In the case of foaming grouting systems, it is appropriate and desirable to determine their mechanical properties according to their degree of foaming (Snuparek 2000).

3.3 *Thermo-gravimetric analysis – (TGA), thermo-oxidation stability and combustion resistance*

The TGA analysis informs about thermal stability of material and resistance against oxidation degradation and combustion. The methodology gives the information about the loss of material mass when the temperature rises. Samples have been heated in air atmosphere with velocity of 10°C/min. The values $T_{5\%}$ a $T_{50\%}$ have been chosen for characterization

Table 3. Thermo-oxidation stability of epoxy, PUR and OMR materials.

	$T_{5\%}$ (°C)	$T_{50\%}$ (°C)	Char (at 700°C) (%)
Epoxy A-T	234	381	0
Epoxy B-T	331	385	0
Epoxy C-T	304	360	0
BBOM	91	409	27
BBS	311	452	0
BBWF	314	422	1

of hardened materials corresponding to temperatures when a 5% and 50%, respectively, of mass loss occurs. While the parameter $T_{5\%}$ characterizes the thermo-oxidation stability, $T_{50\%}$ can be considered for a degree of resistance of material against the general degradation and combustion. An important parameter is also non-burnt residual mass (Char) at very high temperatures, which characterizes the resistance of material against combustion as well as (see Table 3).

4 SOME KNOWLEDGE CONCERNING THE USED EPOXY RESINS

It can be stated, on the basis of the carried out investigations by means of the above-mentioned experimental procedures, that due to vitrification of the system, the course of hardening depends very much on the reaction temperature. At the low temperature, the reactive mixture vitrifies early at lower conversion, which affects the next course of reaction, its resulting mechanical properties and thermal stability of permanency of shape characterized by the value of glass transition T_g. Therefore, we have observed the effect of reactive temperature and compared the course of reaction and properties of the systems hardened at the temperature of $T = 8°C$ and $T = 20°C$ (see Table 2). If the temperature of hardened mixture approaches the value T_g, the grouting material will be capable of more deformable behavior, for instance, during the tensile tests – the occurrence of residual strength behind the tensile strength (see Epoxy A in Table 2 – temperature of tests of approx. 24°C). The quantity (volume) of reactive mixture affects also the mechanical properties. For example, in the case of Epoxy A, the thermo-mechanical behavior is almost independent on the quantity of reactive mixture. In this case the reaction is slow, the originating reactive heat is efficiently dissipated and the reactive mixture is not heated even in a thick layer. On the contrary, in the case of the fast reacting Epoxy C, there was an apparent rise of T_g at reaction in a thick layer almost by 50°C; $T_g(\text{weak}) = 48°C$, $T_g(\text{thick}) = 87°C$. It is apparent that with Eoxy C-T, the exothermic reaction heats up the

sample in the event of the sufficiently great quantity of reactive mixture. Due to the increased reactive temperature, the system vitrifies, characterized by the condition of $T_g = T_{react}$ and the reaction takes place in a higher conversion. Therefore, this sample shows a higher T_g and the modulus of elasticity G′. The effect of the quantity of the reactive mixture Epoxide on resulting properties of the hardened system is important, because it shows that the material hardened in a narrow gap will show the worsened properties in comparison with the epoxy system, which has reacted in a thick layer (Kroutilová 2006).

Polyurethane materials show significantly a greater resistance against the total thermal degradation of material and combustion in comparison with epoxy materials. The relatively small resistance against degradation (characterized by the parameter $T_{50\%}$) has been observed in Epoxy A-T and the high resistance has been observed in Epoxy B-T and C-T, which relates apparently to a greater net thickness of these systems. The hybrid organic-inorganic mixture is resistant against flammability due to a high content of non-combustible inorganic component (char). However, it contains a considerable quantity of thermo-oxidation instable low-molecular components and a quite significant loss of material occurs early at the temperature below 100°C.

5 STRENGTH PARAMETERS OF GEO-COMPOSITES WITH THE GROUTED DISCONTINUITY

The adhesion of chemical grouts to rock surface is of a crucial importance on strength parameters of geo-composites with the grouted discontinuity. A limiting factor for assessment of the quality of geo-composite system "rock – cured grouts – rock" is its capability to resist tensile and shear stress. Principles and procedures of tests of geo-composites with the grouted discontinuity have been similar as for tests of rocks; however, with the difference that, in the preparation phase of test bodies, the discontinuity has been formed on the tested samples and afterwards this discontinuity was glued with the tested grouts, so as its orientation corresponded to the tested type of loading (tension, shear). Tests with geo-composites with the grouted discontinuity based on the selected grouts have been carried out in dependency on quality of their surfaces (natural – by breaking or artificially created – by cutting) and humidity of surfaces of discontinuities (i.e. the rocks glued in dry or wet conditions after they have been taken out from a water bath; the time of submersion in water bath for approx. 24 hours).

5.1 *The used testing methods*

The types of tests have been chosen with regard to the desired requirements for curing grouts in practice. This

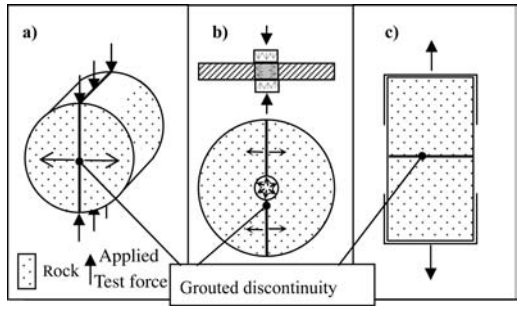

Figure 2. Scheme of used tensile tests a) Brazilian test and, b) tensile strength test by coaxial punches in axiator, c) direct tensile test

is the mobilization of capabilities of discontinuities to transfer tensile stress (which is almost zero or very low before the grouting process itself), the improved capability to transfer shear (shearing) loads on fissures, especially at zero or very low normal stress. To assess the quality of bonding the rocks with selected grouts, the three types of tests have been used. There are tensile, shear c and pressure tests (the so called "bond strength test" (ref.). In the first type of test, the adhesion of tested grouting resins to rocks is tested; in the second type of tests, the shear strength of the grouted discontinuity is measured. As in the tensile tests of geo-composites with the grouted discontinuity the strength parameters are ascertained, which are directly affected by adhesive bonds of tested grouted medium to the surface of rocks, the bonds are identified as "tensile adhesive strength (TAS)".

5.1.1 *Tensile tests*

Originally, the three types of tensile tests have been used for testing of capability of bonded discontinuities to transfer the tensile stress. One test was a direct test and two types of tests were indirect tests:

- Simple tensile test
- Transversal tensile test (Brazil test)
- Tensile strength test with the coaxial punches in the axiator.

Figure no. 2 shows schematically the used types of tests. With respect to the description of results achieved from tests, the method of disintegration of test bodies and demanding character of their preparation, the direct tensile test was mainly used in the research, because this test describes better the values of adhesive tensile strength of geo-composites with the grouted discontinuity in comparison with the indirect tests that are more appropriate only for comparison of the quality of reinforcement of rock mass by means of various types of grouting resins.

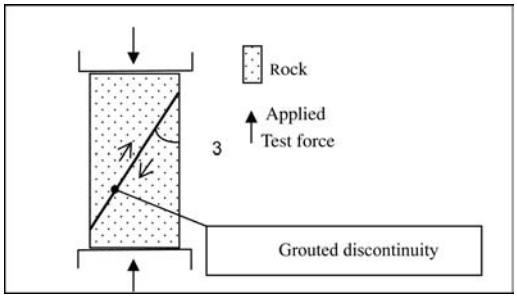

Figure 3. Scheme of Bond strength test

5.1.2 *Bond strength test*

In principle, the bond strength test is a pressure test. Originally, this test was carried out on cylindrical concrete test bodies with the slenderness ratio 2 (diameter of test body 76 mm) with the glued discontinuity inclined at 30 degrees from the longitudinal axis of the sample (see Figure 3). This type of test is used to assess and compare the capability of different types of the bonding agents to glue the surfaces of discontinuities. In our case, the test bodies consisted of sandstone with medium grain size and with the diameter of 48 mm and with the slenderness ratio 2. The result of this test is expressed in a percentage share of uniaxial compression strength of specimen with the bonded discontinuity pressure to the compression strength of undisturbed cylindrical body without discontinuity (PPG). In this test, the area of failure is not pre-determined with the design of testing equipment as in the case of shear cut tests, but with the total state of stress in the specimen. Therefore, in this test, we can differentiate three general types of failures in test bodies.

5.2 *Discussion of the achieved results*

5.2.1 *Tensile adhesion strength (TAS)*

In the majority of cases, the simple tensile test was used for the measurement of values of TAS. From the reason of non-homogeneity and generally low simple tensile strength of rocks, good adhesion of resins to the used rocks, the TAS was not always measured, but often the tensile strength on unconventional test bodies was measured.

With test bodies of geo-composites based on the tested epoxy systems with a dry discontinuity formed with a cut, the values of TAS exceeded the tensile strength of sandstone used, i.e. c. 6 MPa. With test bodies with discontinuities glued in humid conditions, the situation was different.

On all the test bodies, the failure occurred in the glued discontinuity, so the TAS of the observed epoxy systems was measured. The lowest values of tensile adhesion strengths have been recorded in the system Epoxy A-T1 (c. 1,3 MPa); the highest values have been recorded in the system Epoxy C-T1 (c. 3 MPa). In the case of the system Epoxy B-T1, the values of TAS were measured slightly lower than in the system Epoxy C-T1 (c. 2.7 MPa).

TAS decrease significantly with the increased humidity of grouted discontinuities and vary below the limit of 1 MPa for all the three compared and commonly used grouting systems (BBS, BBWF and BBOM). In all cases in these tests, the failure was in area of the glued fissure too.

The quality of grouted discontinuities surfaces affects the values of TAS. The majority of tests carried out on the samples with discontinuity caused by a fracture (a higher roughness of the fissure surface) show higher values of such adhesion strengths in comparison with the samples with a fissure created by cutting. In these tests it is not possible to define a precise value of TAS due to the failure of PUR and OMR geo-composites outside the glued discontinuity; however, it can be certainly stated that these values of adhesion were greater than 3 MPa.

From comparison of TAS in the case of polyurethane resins in simple tension it is apparent that the samples grouted with resin with a smaller capability to create foam in dry environment show slightly higher values of adhesion i.e. BBWF. In the conditions with a dry discontinuity formed by cutting, the values of tensile adhesion strength showed in this resin approx. 2,8 MPa (in the conditions with wet discontinuity of c. 0,4 MPa) in comparison with the values measured with the grouting system BBS, i.e. c. 2,5 and 0,3 MPa, respectively. Under the same conditions, with the grouts BBOM the TAS were approx. 4 MPa and 0,2 MPa, respectively. In the wet condition of discontinuity surfaces, the values of such TAS are very low and approximately on the same level.

5.2.2 *Bond strength test*

As it has been already mentioned, one of potential assessments of this test is the expression of a share of uniaxial compression strength (UCS) of geo-composite with the glued discontinuity and original rock material expressed in percentage (PPG). The results of individual tests for the particular systems are shown in the following table (see Table 4). The average value UCS of the used rock in was 43 ± 5 MPa. The PUR and OMR systems show prevailingly a smaller capability to bond the rock used (discontinuity in the dry condition) in comparison with epoxy systems (see Table 4).

The test bodies of geo-composites based on the grouting system BBOM with the discontinuity bonded both in the dry and wet condition have shown approx. $2 \times$ higher pressure strengths in comparison with geo-composites based on BBS and BBWF. From the comparison of results of compression strengths on geo-composites with the glued discontinuity by means of epoxy systems it is apparent that Epoxy A is less

Table 4. Strength parameters - "Bond Strength Test"

Chemical grouts	Dry condition		Wet condition	
	UCS (MPa)	PPG (%)	UCS (MPa)	PPG (%)
BBS	9 ± 2	21	4 ± 2	9
BBWF	7 ± 3	16	6 ± 2	14
BBOM	23 ± 4	53	10 ± 5	23
Epoxy A-T(T1)	31 ± 5	72	7 ± 1	16
Epoxy B-T(T1)	47 ± 4	109	44 ± 8	102
Epoxy C-T(T1)	43 ± 2	100	43 ± 7	100

capable to bond the used rock both in the dry and wet condition (see Table 3). The compression strength of test bodies of geo-composites with Epoxy B and C vary on the limit of strength of the used rock, and/or they exceed it slightly, which is caused by non-homogeneity of the used rock, higher adhesion bonds and strength parameters of Epoxy B and C in the hardened condition (see Table 1,2).

In these tests, the three types of failure of test bodies have been diagnosed. The first type presents a fragile failure in diagonal bonded discontinuity with the immediate drop of pressure force. This group includes the BBOM based geo-composite (the discontinuity glued in the wet and dry condition) and Epoxy A-T1 (the discontinuity glued in the dry condition). The second type of failure represents also a failure in the glued discontinuity, but there does not occur a fragile disintegration of a test body. The slippage occurs only in the diagonal discontinuity and on the deformation graph, there is apparent a significant residual strength beyond the ultimate strength in uniaxial compression. This category includes the geo-composite based on BBWF and BBS (the discontinuity glued in the wet and dry condition) and Epoxy A-T1 (the discontinuity glued in wet condition). In the group of geo-composites with the glued discontinuity based on the epoxy resin Epoxy B and C, the situation is different from the viewpoint of the manner of failure of test bodies. With these geo-composites with the glued discontinuity (in the dry and wet condition), the test bodies were disturbed primarily outside the glued discontinuity and disintegrated into more parts outside the glued discontinuity. The character and manner of failure of test bodies of these geo-composites was characteristics for failure of compact rock test bodies in uniaxial compression. At failure of test bodies of geo-composites based on these two epoxy systems, the compression strength of the used rock was a constraining factor.

6 CONCLUSIONS

From the results of research of the properties of geo-composites with the grouted discontinuity it can be stated that by means of tested chemical grouting systems it is possible to reinforce the rock mass significantly. The degree of reinforcement will depend both on used grout and on the roughness of rehabilitated discontinuities surface and their humidity.

A higher level of reinforcement can be achieved by means of epoxy systems, eventually, with organic-mineral system in comparison with the polyurethane grouts. The epoxy resins Epoxy B and C have shown the most favorable results even under the conditions of wet discontinuities. TAS achieved c. 3 MPa in comparison with polyurethane, and/or organic-mineral grouts, where these TAS did not exceed the limit of 1 MPa. Tensile and compression strength was a constraining factor at test bodies failure of geo-composites based on Epoxy B and C in the both discussed tests (the discontinuity was glued in the dry condition and formed by a cut).

Cohesion of test bodies beyond the ultimate strength was found out at the certain kinds of geo-composites. This behavior was observed primarily with geo-composites based on BBS and BBWF, which is probably caused by different deformation properties of grouting systems. BBS and BBWF show foaming during chemical reaction on the contrary with the BBOM, which behaves more fragile. In the case of the Epoxy A, this behavior can be affected by a low temperature of its glass transition (c. 30°C) and low temperature difference (i.e. c. 5°C) during geo-composites testing.

The described general methodologies and procedures enable to optimize a choice of grouting medium for affecting the properties of rock mass and to gain the necessary information on the degree, quality of reinforcement and rehabilitation of discontinuities in rock mass.

From the results of research into chemo-rheological behavior of epoxy systems in the course of reaction it is apparent that the tested resins will be probably more applicable in rock mass with a higher temperature. There is potential problem with vitrification of epoxy systems in the course of reaction at low temperature. Tests of thermo-mechanical properties have shown that the Epoxy B and C are more favorable in the conditions with higher temperature too. They show higher temperature of glass transition.

Deformation computation based on numerical modelling for urban NATM tunnelling

M. Zaki Abd Elrehim
Civil Engineering Department, Minia University, Minia, Egypt

ABSTRACT: In this paper, numerical studies in the context of plane-strain Finite Element analyses are presented, comparing the effect of different parameters on deformations' values. Height of overburden, stiffness of the ground, underground water level and size of a tunnel among others are influential factors in the developed deformations. A special cell mesh generation is presented to reduce the effort and calculation time needed for repeated calculations and parametric studies. Based on the calculated results it would become necessary to modify or change the used construction method even during the planning and design stages. On the basis of the numerical results, a definition for the critical deformation related to a certain tunnel project can be defined. Hence, the original design/construction method can be modified and the optimal method of soil reinforcement can be determined. It is the aim of this paper to help the geotechnical engineer to decide which deformation limits can be allowed to achieve a safe and economical tunnel design that meets all construction and operational requirements.

1 INTRODUCTION

NATM (the New Austrian Tunnelling Method) has become one of the main tunnelling concepts. It has originally been developed for rock conditions in the Alps. As a matter of fact, soft ground tunnelling with NATM has a shorter history than NATM tunnelling through rock. Currently, an increasing number of tunnels in urban areas is excavated according to the principles of NATM. During construction, the main aim is to preserve and improve the potential of the ground to support itself as far as possible by making use of an arching effect in the ground around the tunnel. Too large deformations should be avoided otherwise loosening in the ground will take place which significantly reduces the potential of the ground to support itself. This results in an increase of load on the tunnel lining which may cause critical situations for tunnelling safety.

An essential part when planning urban tunnels is to indicate the expected deformations. Surface deformation is important to ensure the stability and safety of surface structures and utilities (Sozio 1998, Mair 1998, Netzel & Kaalberg 2000) whereas deformation within the tunnel is important to ensure the safety of tunnelling procedure and construction technique. The task of the geotechnical engineer is to decide which deformations can be allowed to achieve a safe and economical design that meets all operational requirements. Efficient numerical methods could provide the geotechnical engineer with an additional tool for getting better insight into the behaviour of the ground. Consequently, a numerical model for predicting possible deformation behaviour of the ground could support the engineer and avoid dangerous situations during tunnelling.

In order to achieve more efficient control for the ground deformation, the load-carrying capacity of soil surrounding the tunnel may be improved by means of many techniques. Grouting techniques, soil freezing, pipe-roofing, jet-grout arch, micro-piles, grouted-fiber glass or re-bar nails…etc are examples of soil reinforcement techniques (Guatteri et al. 1994, Fitl 1997, Liebsch and Haberland 1998, Gioda and Locatelli 1999, Tan and Ranjith 2003). The engineer needs a helpful tool to select the optimum technique that will reduce the deformation to the required levels. So, there is an increasing demand to firstly know the deformation limits of the natural soils in the planning stage and hence deciding the optimum reinforcement technique.

Compared with shield tunnelling methods, there is currently no NATM design method that has been established for urban areas (Ishibashi et al. 2004), and there are some reports of ground settlement being greater than expected and cost and time overruns occurring because of the use of various reinforcement methods.

2 MODELLING OF URBAN NATM TUNNELS

The urban NATM tunnelling is usually characterized by the sub-division of the tunnel cross section in multiple stages. The subdivision can be on the form of a top heading, bench and invert sequence, the side-wall drifting procedure or the use of advance pilot tunnels. All these sequences are based on the principle that ground deformations are practically proportional to the size of the tunnel cross section.

Finite Element Method (FEM) in usual soft-ground tunnelling design practice is one of the main tools to simulate complicated three-dimensional stress distribution in the tunnel vicinity in both cases of using three or two dimensional calculations. It is very important to carefully simulate the construction sequences to analyse the expected loading conditions. Despite the merits of three dimensional analyses in realistic modelling of tunnel face, 92% of the published tunnel analyses are still performed in two dimensions, using plane strain models and mostly elastic-perfectly plastic ground behaviour (Farias et al. 2004).

As a result of FEM calculation there is a stress and strain distribution related to each loading condition. The most important two cases that characterize the final deformational behaviour of the ground are:

1. Deformations due to stress relieve (after considering the initial stress condition) which take place just before excavation in every cross section.
2. Deformations after excavation and after developing final strength of the initial shotcrete lining.

In the present analyses, a 2D plane strain elastoplastic soil model based on Mohr-Coulomb failure criterion has been used. The excavation of each part of the tunnel is simulated in two steps according to the stiffness reduction method (Swoboda 1990). In the first step (called loosening), the stiffness of the soil inside the tunnel part is reduced to the value corresponding to the z-location along the tunnel axis where temporary support is installed. In the second step (support), the excavated soil is removed and its primary stresses are eliminated simultaneously with the installation of the secondary shotcrete lining with its fresh state. The lining helps in controlling further deformation of the soil. In multi-stage excavation, the above two steps are repeated for each excavation stage. This simulation can achieve the three-dimensional effect near the tunnel face. Figure 1 illustrates the basic investigated load conditions for top heading and bench excavation sequence. With respect to deformation consideration, these loading cases correspond not only with the three dimensional modelling requirement, but also with the practical feasibility of measurement possibilities at the face.

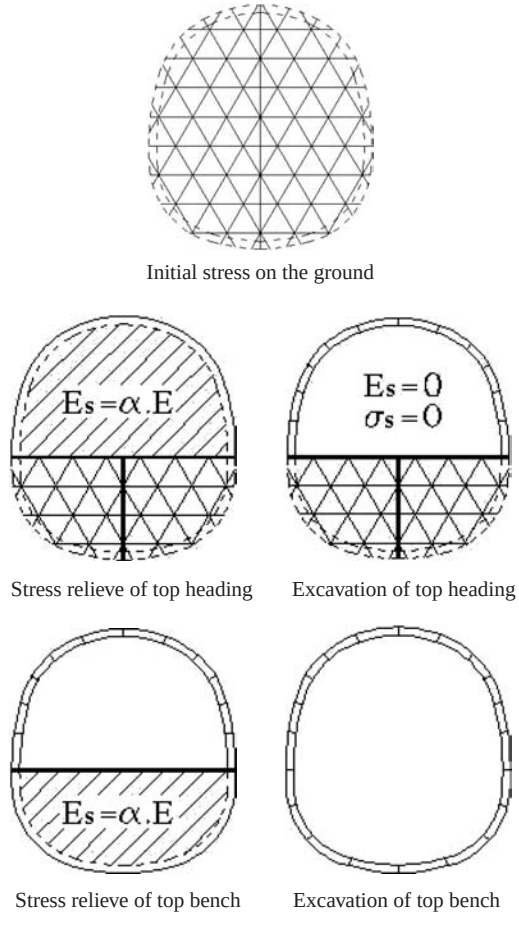

Figure 1. Loading conditions related to construction sequences.

Modern geomechanical measurements methods have been developed to measure very accurately deformations caused by stress relieve (loosening) as well as by excavated and initially lined tunnels. Comparing both types of measurements leads to better values for the stiffness reduction factor.

It is important to check, whether the calculated deformations correspond with the associated measured deformations or not especially before the installation of the final lining. Therefore, the calculated stress relieve deformation has to be compared with the measured one to check whether the analysis corresponds satisfactorily with the construction or not. Numerical models are continually updated by back analyses of the observed behaviour (Sakurai et al. 2003) to update the most critical ground parameters used in the model.

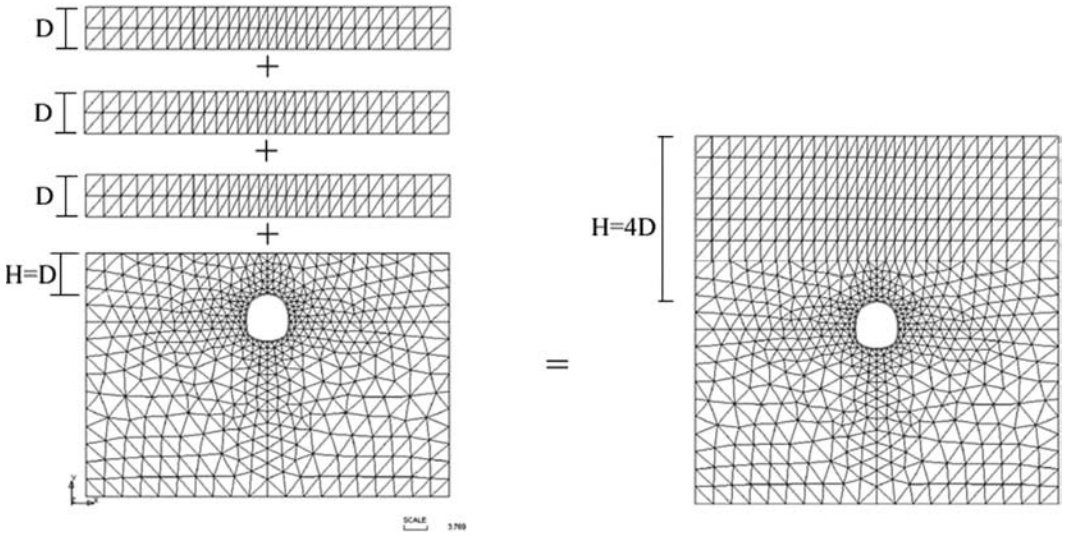

Figure 2. Mesh-generation cell technique.

3 CRITICAL SECTIONS AND CRITICAL DEFORMATIONS

The determination of the most critical sections along a tunnel route is mainly based on, among other factors, the following parameters:

1. The depth of the tunnel.
2. The mechanical parameters of the soil layers.
3. The ground water pressure exerted on lining.
4. The surface loading.

For large tunnel projects with several kilometers of excavation and various cross sections, it is impractical to analyse all sections along the tunnel route. It will be more helpful to have a round figure about the deformation limits along the route and then to determine the most critical sections for detailed analysis. The deformation limits can be used to define the critical deformations along the tunnel route. If these critical deformations are acceptable, the design process continues to the next detailed step otherwise modifications for the construction sequence and/or tunnel alignment, especially for the depth factor, are to be considered.

At this preliminary stage, the first parameter for the tunnel depth can be considered more effective especially if the variation in ground condition is not too much. Many calculations are to be made according to the variations on tunnel depth to have a more clear idea about the deformations. With the help of numerical techniques a lot of work for meshing and deformation calculation within the context of FEM can be saved.

It should be noted that each tunnelling project must be treated on its own characteristics, the issues discussed in this paper should be given due consideration for the proper modelling and analysis of the construction sequences.

3.1 *Mesh-generation cell technique*

Relating the studied varied height of overburden above tunnel cross section with the maximum diameter (D) of the tunnel, leads to very tidy mesh layout in the zone beyond the tunnel and near the ground surface. In order to save the time needed to generate many repeated larger meshes, a mesh-generation cell technique was developed. Using this technique a mesh for a regular cell representing the required varied height is first generated. The basic mesh containing the tunnel is generated in the usual way. Then, the entire mesh is generated with the required number of cells using a cell mesh-generation program. The process is performed numerically and without regeneration of the mesh again every time we change the height of overburden (D). Figure 2 shows three cells of height equals (D) each and the whole FE mesh with a total overburden of ($4D$) above the tunnel.

Finite element meshes for models with regularly varied height are generated by a mesh generation cell method. These meshes are composed of Linearly Strain Triangular (LST) elements. To meet the requirement of accuracy of the calculation, the meshes of triangular elements near the tunnel axis should be suitably dense.

The calculation and results of deformation development presented in this paper are performed using general FE package, FINAL package (Swoboda 2001).

The mesh generation-cell technique is coded, linked and used with the main FINAL package.

The procedure of mesh-generation cell can be described as follows:

- Define the cell geometry. This includes the depth (D) and the width (W).
- Generate a mesh for the defined cell.
- Transform the mesh to FINAL input file.
- Generate an original mesh for the tunnel with the minimum depth.
- Transform the original mesh to FINAL input file.
- Use the cell program to merge both generated files with any number of repeated cells and check for nodes/support compatibility and connectivity.
- Run FINAL to get the required results for deformations, stresses...etc for the larger meshes.

The procedure was firstly checked for small examples and then generalized for tunnels meshes. The method is found to be useful and time saving for repeated calculations and parametric studies. The precondition to be carefully noted during the application of the method is that cells must be regular in rows and ranks. With the increasing of total mesh height, attention should be paid to total mesh width (aspect ratio) to have reasonable far field and support conditions at the mesh boundary.

4 ANALYSIS OF A TYPICAL EXAMPLE

A typical cross section of a shallow single-track railroad tunnel has been modeled. The geotechnical soil parameters are excluded from the investigation report of Cairo Metro line III phase II (NAT documents 2003). The soil at this phase is characterized by the existence of uniform sand and clay layers without ground water within the tunnelling zone which more encouraging the use of NATM technique. Thus, it is expected that the most important factors for deformation calculation along the tunnel route is the height of overburden and the construction technique.

The initial overburden over the tunnel crown was chosen to be roughly equal to the tunnel diameter. The analysed domain has horizontal fixations at both sides of the mesh whereas the bottom nodes of the mesh are vertically fixed. The used FE mesh is illustrated in Figure 2 for the basic mesh and the extended ones for the overburden variations. The loading conditions related to the chosen method of construction are illustrated in Figure 1 for a top heading excavation followed by a bench excavation.

Results regarding deformations and critical deformations as will be made here are strictly related to shallow tunnels under soft ground or mixed face conditions. It is assumed that whatever construction concept will be used the ring closer time is short and is about one diameter from the face. This precaution will minimize the effect of face stability on the developed deformation in two dimensional analyses.

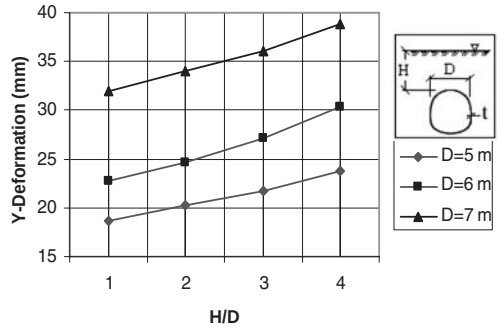

Figure 3. Surface settlement (t = D/30).

A series of FE calculations is performed for different tunnel diameters each having different height of overburden and for different lining thicknesses. The height of overburden and the lining thicknesses are chosen as a function of tunnel diameter (D) and within the practical engineering values.

Based on structural calculations, the relation between lining thickness and tunnel diameter is in the range of (1/30). Two other values (1/15 and 1/40) can be considered as the upper and lower limits of lining thickness of shallow tunnels under soft ground conditions. However, it is possible to interpolate any other different relation between lining thickness and tunnel diameter between these two limits.

A lot of curves and relations may be resulted from the FE calculations. As an example, the effect of NATM tunnelling on surface settlement for different tunnel's diameter and different values of overburden is illustrated in Figure 3 for a lining thickness of ($D/30$). The thickness is thus ranging between 15 cm and 25 cm which agree well with the engineering experience.

Figure 3 dictates that surface settlement is directly proportional to the height of overburden. The variations in settlement values are nearly within *25%* for the indicated range of H/D for each diameter. It can also be noticed that the settlement increases with the increase of tunnel diameter for the same H/D value.

The settlement values at the tunnel crown for different H/D values and for different tunnels diameters are shown in Figure 4. The same trends noticed in Figure 3 can also be noticed here but with more effect for the height of overburden. The settlement values nearly doubled for the indicated range of H/D for each tunnel diameter.

Both Figures 3 and 4 can be used to investigate the optimal diameter for the specified construction method. Studying the intervals between the curves of different diameters shows a larger interval beyond

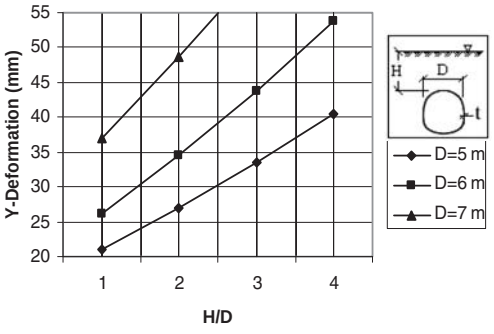

Figure 4. Crown settlement (t = D/30).

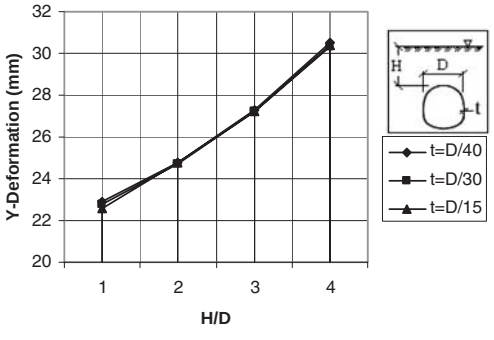

Figure 5. Effect of lining thickness on surface settlement (D = 6 m).

a diameter of 6 m. This indicates that the optimal acceptable limit for a top heading bench sequence of construction in the specified soil is up to 6 m. For a diameter of 7 m, a modification in the construction sequence by more tunnel section subdivision or by introducing a soil reinforcement technique is recommended if a reasonable level of deformation is required.

The effect of lining thickness on reducing surface settlements for NATM tunnels in the specified conditions of the considered example is not significant, Figure 5.

Many FE calculations was performed and used to define the critical deformation in a simple and usable way, Figure 6. The recommended value of critical deformation can be found by using the data of the tunnel diameter, the height of overburden and simple interpolation between the indicated curves. The curves help to define the critical deformation in the early design stage to decide if the construction method is appropriate or some modifications should be considered for the tunnelling process, tunnel

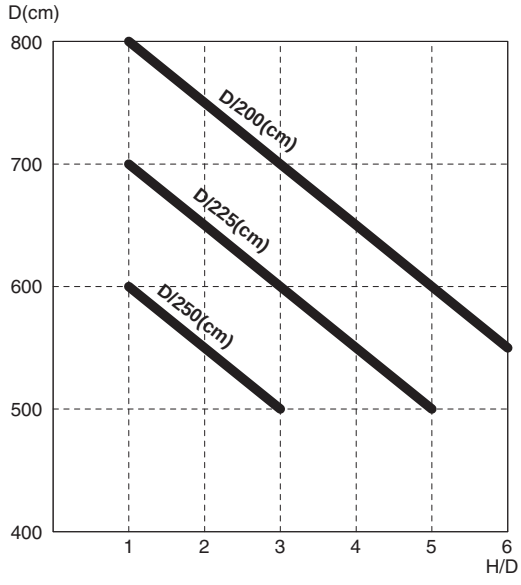

Figure 6. Critical surface deformation of the considered typical example.

alignment (especially tunnel depth) and/or soil reinforcement. The principle ideas in the curves of Figure 6 can be extended systematically and developed in design tables and charts easy to use by engineers for the studying of the deformational behaviour of different soil/structure interaction problems.

5 CONCLUSION

An essential part when planning urban NATM tunnels is to indicate the expected deformations. The ideas presented in the paper help the geotechnical engineer to decide which deformations can be allowed to achieve a safe and economical design that meets all operational requirements. A criterion for defining the critical sections along the tunnel route was pointed out. A mesh-generation cell technique was developed, coded and linked to a FEM package to facilitate and save the time needed for repeated calculations and parametric studies. A typical cross section of a shallow single-track railroad tunnel has been analysed and used to clarify the main ideas of deformation analysis. A set of characteristic curves for deformation was given and from which a simple definition for the critical deformation is indicated. The principle ideas as presented in the curves can be extended systematically and developed in simple design tables and charts easy to use by engineers. Although the tunnel engineers understand that each NATM case must be treated on its

own characteristics, the issues discussed in this paper should be given due consideration for the studying of deformational behaviour in the early design stage.

Numerical analysis of TBM road tunnels under Suez Canal at Port Said

Ashraf Abu-Krisha
National Authority for Tunnels (NAT), Cairo, Egypt

ABSTRACT: Due to the construction of the international littoral road, the road tunnels at Port Said under the Suez Canal are required and studied. This road consists of two identical tunnels (twin tunnels) with inner diameter 10.8 m that run parallel to each other with length of about 2.30 km. The two tunnels will be constructed by Tunnel Boring Machine (TBM). These tunnels are analyzed using a two-dimensional (2D) numerical simulation by FEM, with allowance for three-dimensional (3D) effects. Several 2D numerical models, based on the finite element technique, were generated in plane strain analysis at different depths to simulate TBM process and to investigate the effect of ground movements due to tunneling. The soil mass were modeled as a non-linear perfect elastic-plastic, based on the proper constitutive laws according to the soil layers type. The long-term ground response is contributed to simulating the second tunnel.

This paper presents the results of the numerical studies performed to investigate the effect of different conditions on the predicted ground behavior and tunnel lining. Also, the results of these analyses are compared with the laboratory scale model.

1 INTRODUCTION

Egypt has a rapidly expanding economy, which consequently requires the construction of the necessary transport infrastructure. As part of this infrastructure it is proposed to construct twin road tunnels to form a permanent and durable road link between Port Said city in the west and Sinai Peninsula in the east. This project will link the international coastal express highway from the North Africa to Asia via Sallume – Alexandria – Port Said and going to Sinai Peninsula – Ghaza under the Suez Canal. The tunnels are to be located at Kp 19.15 of the Suez Canal south of Port Said while the Mubark Al-Salam Bridge is far from south of Port Said by 48.5 Km. So, the project will save approximately 100 Km from the international coastal express highway.

The road tunnel shall have two tunnels, each one have two lanes in each direction with minimum clear lane width of 3.75 m and clear height of 5.5 m minimum vertical clearance. Figure 1 shows the cross section of the proposed road tunnel. Each tunnel has four ventilation shafts, two at the sides of the canal bank by distance 100 m, the others at the entrance and exit of the TBM. The total length of each tunnel is approximately 2300 m. The tunnel will be protected by a fire barrier system.

The present Suez Canal is 214 m width at level – 11.0 m and 22.5 m depth at the location of the project. The project will take into account the forecast of the Suez Canal for the depth and the width. The future depth is 27.0 m and the future width is 270 m at level – 11.0 of the Suez Canal. Figure 2 shows the proposed longitudinal section of the project.

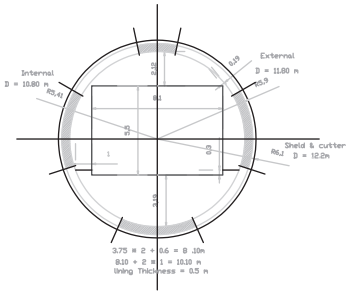

Figure 1. The proposed cross section of road tunnels under Suez Canal.

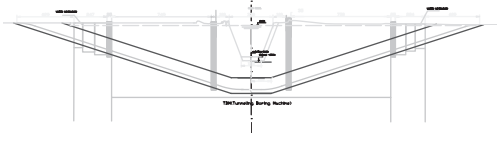

Figure 2. The proposed longitudinal section of road tunnels under Suez Canal.

Numerical simulation of the interaction between ground and structure using the Finite Element Method (FEM) as implemented with Plaxis software (2002) is performed. The behavior of soft soils is complicated

Table 1. Layers and geotechnical parameters.

Soil layer	Depth (m)	γ	E MPa	ν	ϕ	C
Fill	0–2	17.0	20	0.2	24	0
Silty clay	−2–35	16.0	10–45	0.40	22	5
Sand (1)	−35–45	18.5	70	0.35	36	0
Sand (2)	−45–70	20.0	100	0.3	38	0

and hardly accurately modeled, even with the most elaborate constitutive models; moreover, parameters such as soil deformation modulus, which are essential to output of numerical analysis, can hardly be estimated with sufficient accuracy with exist testing techniques. The more recent advances related to FE techniques were further analyzed by Mair and Taylor (1997), Leca and Mestat (1999) and Abu-Krisha (2002). FE modeling can be considered as a powerful means of analysis, because it allows the main parameters involved in the tunneling process and construction sequence.

2 GEOLOGY AND GEOHYDROLOGY

The geological knowledge of the site collected from the extensive studies on the basis of deep drillings, surface surveys and analysis of geostructural surveys. The subsoil consists mainly of, medium dense to dense sandy gravel, covered with a top layer of silty clay and fill. During soil surveys a 34 to 36 m thick layer of stiff to very stiff silty clay was encountered. The lab results from the oedometer tests show a large bandwidth of stiffness, which is an important design parameter for bored tunnel. The sand layers which were encountered at depths below 46 m displayed refusal N values in field STP tests, indicating very dense conditions.

According to the geotechnical reports by NAT 2004 the recommended design parameters for the four main soil deposits are given in Table 1. The ground water depth stabilized inside the open boreholes at 1.5 m to 2.0 m. The ground water level will be taken −2.00 m from the ground level as a critical case in the FE analysis. The results of the chemical tests indicate to high concentrations of chlorides, sulphates and total dissolved salts (TDS).

3 MODELS SIMULATION STUDIES

3.1 *Structural properties*

Two identical 10.8 m diameter TBM tunnels will be used for installing a concrete lining as it advances. The diameter of the cutter head of TBM is 12.2 m. One tunnel is constructed with two way and then- in future- it will be with one-way direction. The second tunnel will be construed in future with one-way direction.

Table 2. Material properties of the tunnel lining (beam).

Parameter	Name	value	Value in long term	Unit
Type of behavior	*Material type*	Elastic	Elastic	
Normal stiffness	*EA*	0.75E7	0.5E7	KN/m
Flexural rigidity	*EI*	1.5E5	1.0E5	KNm2/m
Thickness	*t*	0.5	0.5	m
Weight	*w*	12.5	12.5	KN/m/m
Poisson's ratio	*v*	0.2	0.2	

Each tunnel having four ventilation shafts, two at the sides of the canal bank by distance 100 m, the others at the entrance and exit of the TBM. The lining thickness is 0.5 m and the gap between the soil and liner associated with the over cutting is 0.2 m. The material properties suggested for the tunnel lining are listed in table 2.

3.2 *Analysis model*

In the present analysis, the straining actions acting on the tunnel lining resulting from the soil and groundwater pressure is evaluated along the TBM route. The 2D finite element method code Plaxis was adopted in this numerical study. Full-face excavations in two stages of the Twin bored tunnel with lining is supporting the tunnels immediately after the excavation were modeled to allow of 3D effects. Three particular and representative sections are chosen for the analysis in order to get a realistic range of values of the deformations, the stresses and the internal forces in the lining that could be developed under tunneling process. These sections are a plane strain non-linear elastic plastic model that resembles the soil by 4th order 15-node isotropic Strain Triangular elements. The lining is modeled with the help of beam element as a linear. This beam element with interface was used to perform realistic analysis of geotechnical structure. The volume loss is simulated by applying a contraction to the tunnel lining. The range of contraction values are 1.5% – 2% according to the depths. Three sections were chosen for analyses:

- Section 1(lowest one): case of the maximum normal force and located just at the canal axis where tunnels are included into sands. The maximum water pressure is 40 m. the minimum soil cover is 13 m (13 m after 3 m dredging).
- Section 2 (middle): case of the maximum bending moment. The maximum soil cover is, 33 m corresponding water pressure 31 m.
- Section 3 (shallow): The soil cover is, 11 m corresponding water pressure 9 m.

The analysis cases are included the long-term effects of the construction of the second tunnel. Also, the horizontal distance between the two tunnels was

Table 3. Internal Forces and Displacement for three sections.

	Displacement. mm	35.5	45	72.8

performed for investigation. The results of these FE analyses are compared with the results of tests to investigate the techniques that should be applied to obtain reliable solution to this type of project. Also, the water uplift stability is studied in the present analysis.

4 RESULTS AND DISCUSSION

The analysis results of the internal forces that developed in the tunnel lining for the three sections according to the construction stages and the conditions of every section are compared in table 3. The tunnel lining displacement obtained from the analysis included the tunnels movements due to soil deformation beside the lining distortion are shown in table 3. Table 3 showed the results of internal forces and displacement for the first tunnel in long term. The excavation of the second tunnel beside the first one lead to significant increase in bending moment in the lining of the first tunnel according to the volume loss.

Figure 3 shows the plastic zones distributed around the tunnels obtained from the analysis of section 2. The thickness of the plastic zones sideward from the tunnel lining was limited. These plastic zones lead to increase the internal forces in lining of the second tunnel compared to the first one.

The contours of the total deformation of the mesh for the section 1 are illustrated in figure 4 for the soil mass. The surface settlement for the section 3 is illustrated in Figure 5. The contours of the vertical effective stress at the final loading step for the two tunnels at sections 2&3 are shown in Figure 6. The stresses obtained at the region between the two tunnels were out the limits of ultimate strength of that soil layers.

5 RESULTS COMPARISON WITH PHYSICAL MODEL TESTS

The results presented here are limited to the comparison between the results of test PS3 given by Kim (1996,

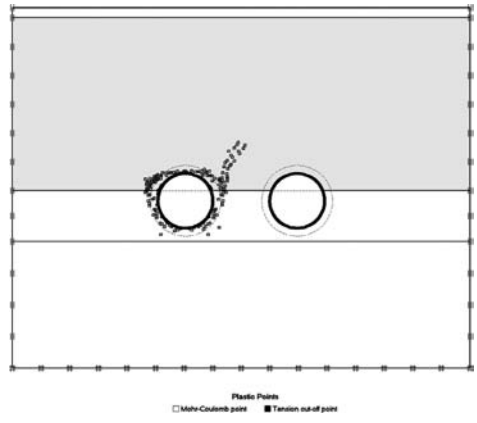

Figure 3. Plastic zones distributed around the tunnels obtained from the analysis of section 2.

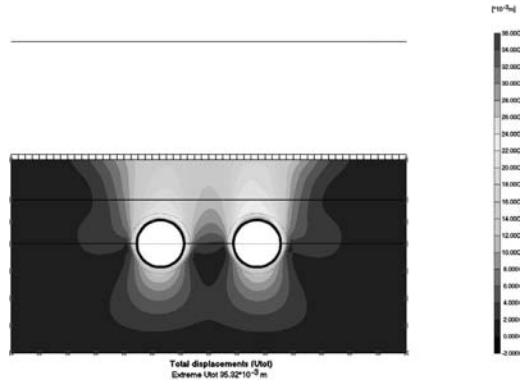

Figure 4. The total deformation of the mesh for the section 1.

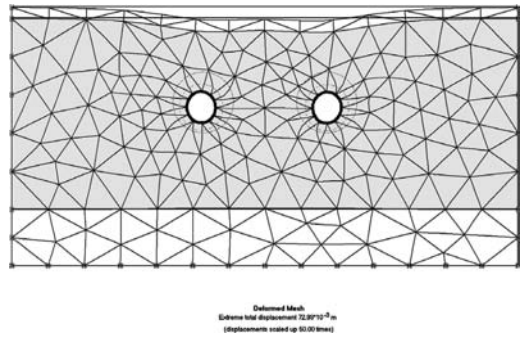

Figure 5. The surface settlement of the mesh for the section 3.

2004) and the corresponding FE analysis of section 3 where the tunnel is located in silty clay layer. The diameter changes of the first tunnel immediately after the

construction of the second one. Figure 7 indicates good agreement between the physical and numerical results of the deformation for the four main points. Figure 8 shows the incremental Bending moments induced in the instrumented lining due to the installation of the second tunnel. These results indicate that the numerical and the model test data are well agreed. Figure 9 shows typical results of total displacements of the lining.

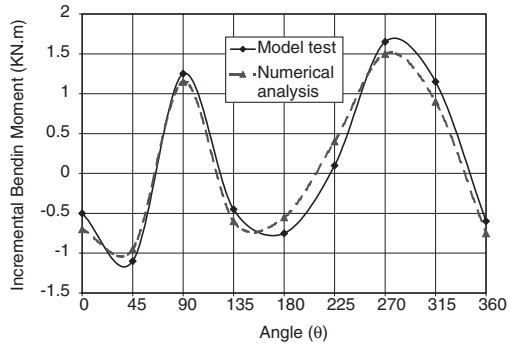

Figure 8. Incremental Bending Moments against tunnel test PS3.

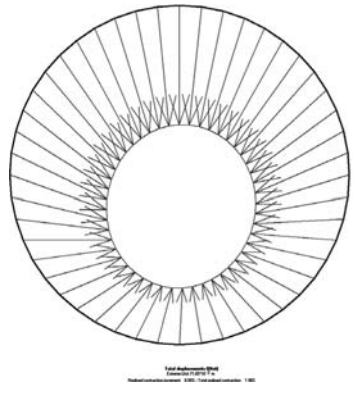

Figure 9. Total displacements in lining of section 3.

6 OVERALL STABILITY OF THE TUNNELS

One of the important aspects of the water uplift stability is developed in the present analysis. The water level in the area of construction is too high and the weight of the structure shall overcome the water uplift forces. The stability is ensured for the critical section located under Suez Canal where the soil cover is minimum 13 m after dredging. Any resisting forces due to soil friction are neglecting.

7 CONCLUSIONS

One of the major advantages of the numerical studies is to allow the very complex soil structure interactions involved in the tunneling process to be accurately investigated. The technique has been developed to include 3D effect in 2D analysis was succeed.

The straining actions acting on the tunnel liner resulting from the soil and groundwater pressure is evaluated along the TBM Tunnel route through the three sections considering in the analysis.

Based on the results of the analysis providing to the stresses and the plastic zones, it can be shown that the interaction between two tunnels is unlikely to be significant unless the spacing between them centers is more than about two tunnel diameters.

The non-linear FE analysis with a hydrostatic procedure gives results that appear to be in good agreement with the results of the physical model tests for the internal forces and deformations.

The stability is ensured for the tunnels against the uplift pressure with safety factor of 1.5. The soil cover that must remain on the tunnels should be at least about 6 m.

The results obtained from this study are believed to be useful for design of the project and to facilitate the interpretation of the monitoring results. Also, it is benefit for the back analysis that can be achieved privilege during the construction of project.

Numerical modeling of face stability for TBM tunneling

Ashraf ABU-KRISHA
National Authority for Tunnels (NAT), Cairo, Egypt

ABSTRACT: Several approaches have been developed to analyze the face stability for TBM tunneling in soft ground. The face stability for TBM is a three-dimensional (3D) problem. As a consequence of the TBM procedure, 3D analyses are the most realistic, especially the modeling of the face stability. In the present numerical examples, the effects of face supports at the front of the shield have been considered in the analyses. Incremental stage-by-stage analysis simulating excavation scheme is used.

In this study, the face stability in underwater tunnels was evaluated by simultaneously considering the effective stress acting on tunnel face and the seepage force. The effect of permeability anisotropy on the seepage force acting on the tunnel face was also assessed by conducting a coupled analysis. This presented model is namely a four-dimensional (4D) numerical model. The support pressures calculated by the analytical methods taking seepage forces into account were compared with the results of the coupled finite element analysis.

Keywords: Numerical Analysis, TBM Tunnelling, Face stability, four-dimensional.

1 INTRODUCTION

Advances in computer systems have allowed complex conditions to be accurately modeled by means of numerical methods, thus providing new approaches for characterizing the face stability of TBM tunnels constructed in soft soils. Front stability is usually maintained by bentonite slurry or pressure balance shields. Recently, several studies are developed to deal with the face stability of the TBM tunnels. Many approaches can be applied to tunnel subject to seepage forces during tunnel construction which are located under the ground water level. The upper bound solution by modifying the failure mechanism was provided by Leca and Dormieux (1990). The wedge stability model that taking full account of the three-dimensional geometry at the tunnel face, was proposed by Anagnostou and Kovari (1996–1997), using limit equilibrium principles. This model is not valid when different soils are present within the tunnel face, and those soils have different angles of internal friction and cohesion. Also, there is no straightforward way to approximate or average the soil properties to obtain the correct support pressure. Two slice methods are proposed according to the shape of sliding surface, In-Mo Lee and Seok-Woo Nam (2004). The first sliding surface is employed to be a logarithmic spiral while the second sliding surface is assumed to be a straight line. The critical support pressure at the tunnel face can be determined by iteratively altering the inclination angle between the sliding surface and the horizontal. Figure 1 shows the critical surfaces for the methods of the analysis of tunnel face in longitudinal section.

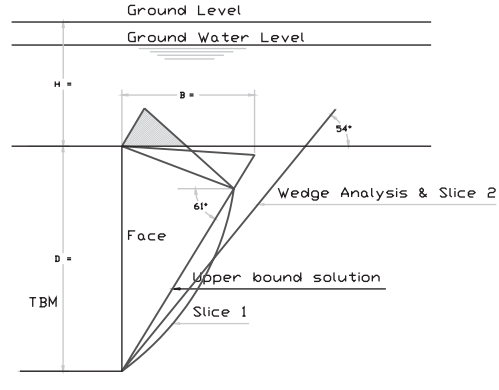

Figure 1. Critical surface of the analysis of TBM tunnel face.

In the TBM tunneling, the penetration of the support medium into the soft soils simultaneously with the removal of soils at the face is taken into account. This infiltration may in turn leads to excess pore pressures in the front of the TBM as well as a reduction of the effective support force. The penetration distance is governed not only by the filtration velocity but also by the advance rate. Thus, the support pressure is then transported onto the soil skeleton over this infiltration length. Consequently, there are three cases of the slurry infiltration; formation of filter cake only,

pure penetration without filtration, and combination of filtration and penetration.

In a soil problem with the consideration of water flow, there are two methods to analyze the forces that acting on an element. One is to use boundary water forces along with the total weights and the other is to use seepage forces along with the submerged weights. The two methods give approximately the same results exactly. The support pressure that is calculated by latter one in wedged analysis is used in this study. In this paper, 3D FEM model that include face pressure is performed describing time-dependent in longitudinal section deformations. These types of model are known as a four-dimensional (4D) model analysis.

The 4D face stability model was derived from the twin tunnel of El-Azhar road tunnels, Cairo, Egypt. Each tunnel is 2.7 km long and has inside diameter of 8.35 m with 0.4 m lining thickness. Construction used a TBM with bentonite slurry shield. A system of monitoring was installed for the project. This system at considering north tunnel section consists of surface settlement points, deep extensometer with 4 points, inclinometer and contraction section. Face pressure transducers have been inserted in ring 171 of the northern tunnel beneath the monitoring section. This instrumented ring was monitored during excavation and construction and after lining installation, NAT Monitoring Documents (1999).

2 DATA ANALYSIS AROUND MONITORING SECTION

The monitoring results around ring 171 of north tunnel have been analyzed in details. Surface settlement versus time was plotted as settlement versus TBM position, NAT Monitoring Documents (1999). For a uniform tunnel boring posses these plots should show the influence of face stability pressure and TBM volume loss. Surface settlement at ring number can be compared with face pressure at ring number x-10 in figure 2. Also, the ground displacements are given as a function of time from the deep extensometer and inclinometer. The extensometer is located at the tunnel centerline by 6.6 m near the ring 171. Heave was mainly found during boring of TBM for ring numbers 150 through 200. This heave is limited to the zone directly above the tunnel. Figure 3 shows the monitoring results of the face stability pressure and vertical settlement at the considering section versus the time. From the above mentioned, it is evident that tunnel boring from rings 130 to 210 has not been constant.

3 GEOLOGY AND GEOTECHNICS

The geological formations along El-Azhar road tunnels project are typical Cairo Nile Alluvial deposits.

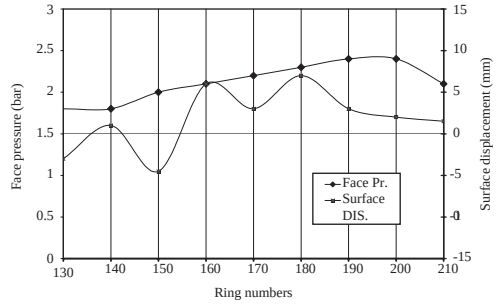

Figure 2. Face stability pressure at crown and surface settlement versus ring numbers.

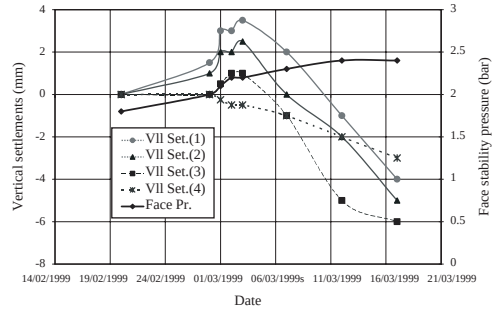

Figure 3. Vertical displacement extensometer at 4 points and face pressure as a function of time.

Table 1. Layers and geotechnical parameters.

Soil Layer	Depth (m)	γ KN/m^3	E Mpa	v	K_0	ϕ	C Kpa
Fill	0–6	18.0	10	0.4	1.0	26	15
Sand (1)	−6–9	20.0	40	0.35	0.37	37	0
Clay (1)	−9–12	18.5	13	0.4	1.0	0	90
Sand (2)	−12–15	20.0	50	0.3	0.4	38	0
Clay (2)	−15–25	18.5	14	0.4	1.0	0	100
Sand (2)	−25–60	20.0	50	0.3	0.45	39	0

The tunnels are mostly bored in slightly silty sand. Soil parameters were derived from in situ and laboratory tests. Geotechnical parameters that used for the analysis are given in Table 1. Water table is −8 m from the ground level, NAT soil report (1998).

4 NUMERICAL MODEL

Half north tunnel is modeled with standard boundary conditions for soil and lining using FINAL code (1998) for coupled analysis, as shown in figure 3. In coupled

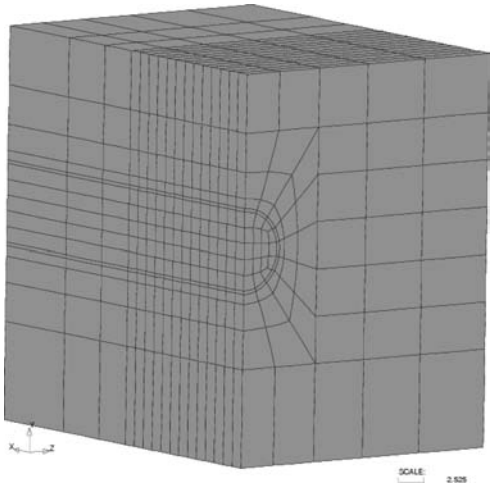

Figure 4. 3D finite element model.

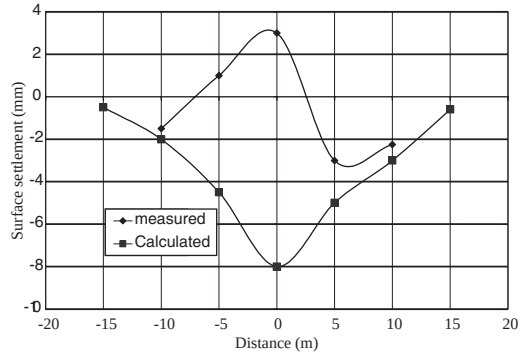

Figure 5. The comparison between the calculated and measured transverse surface settlement.

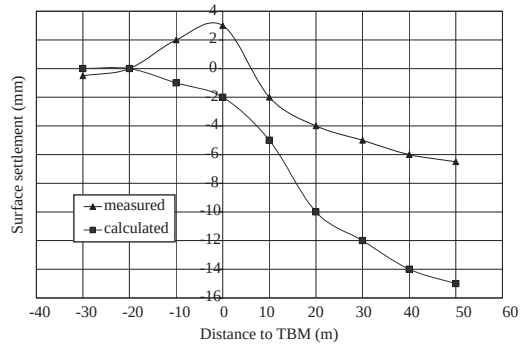

Figure 6. The comparison between the calculated and measured longitudinal surface settlement.

analysis, the hydraulic boundary conditions must be defined. These conditions are identical to those that used in seepage analysis. The model is divided in longitudinal direction according to the one tunnel ring that is 1.5 m to simulate the phase's construction. The number of stages will cover a constant bending moment at some distance from both TBM and model boundaries. The total length and width of the model are 120 m and 40 m respectively. The upper part section of the tunnel is in sand and the remaining lower section is in plastic to very plastic clay. The tunnel axis is 8 m below the water table level. The coefficient of horizontal permeability to the coefficient of vertical permeability (K_h/K_v) is 10 time.

The soil has been modeled using the hardening soil model. This model implements soil behavior under the unloading-reloading conditions governing the tunnel construction. The TBM and Tunnel lining are modeled by shell elements. TBM face pressure is modeled by applying slurry pressure at the crown and the pressure gradient of 20 KN/m^2/m. This face support pressure is modeled as external forces and not linked to the TBM. The tunnel boring process has been modeled by incremental stage-by-stage analysis construction calculation; where there is approximately 30 stages, one ring per stage is bored.

The summation value of the slurry pressure at the face of TBM (slurry confining pressure) consists of the hydrostatic pressure, over-burden pressure and factor of safety pressure. At any section the hydrostatic pressure and over-burden pressure are constant while the factor of safety pressure will be changed according to the allowable settlement and soil parameters.

5 RESULTS OF 4D FEM ANALYSIS

The results of the analyses have been compared with monitoring soil deformations. Some of the calculations have been conducted in order to determine the model's sensitivity to the face stability pressure.

The results show that the maximum of the calculated final surface settlement is about 8 mm. Figures 5 & 6 show the comparison between the calculation under the effect of measured face slurry pressure and measured surface settlement in the transverse and longitudinal direction respectively. The final deformation at surface level measured at the monitoring section is varied between approximately 6 mm heave and 5 mm settlement. Hence the 4D model with best estimate parameters calculates the maximum of measured settlements. The calculated transverse through is symmetric, while the measured one is not. The deformations measured by inclinometer and the calculated horizontal displacements are plotted in figure 7. The calculated curve is closely matches these measured. It is found that magnitude of horizontal components of the displacement vectors is much larger than that of

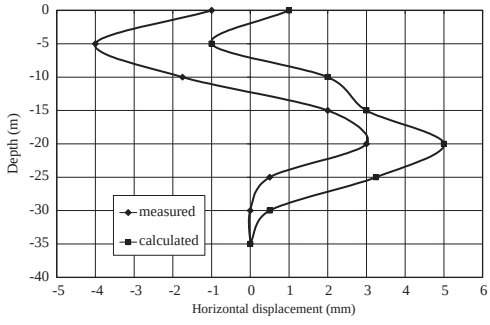

Figure 7. The comparison between the calculated and measured horizontal displacement.

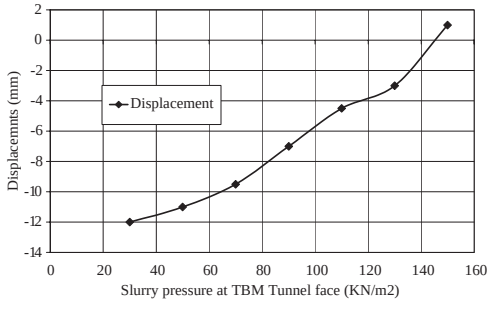

Figure 8. Slurry pressure versus horizontal displacement at tunnel face.

vertical components with small slurry face pressure and depends on the seepage flow vectors.

The horizontal displacements at center node of the tunnel face are plotted against the slurry pressures as shown in figure 8. The support pressure estimated was compatible with the wedge stability method using limit equilibrium principles.

The effects of permeability anisotropy on support pressure for face stability are illustrated in figure 9. It can be noted from this figure that the higher horizontal permeability compared with the vertical one (k_h/k_v) has a favorable effect on the TBM face stability. This result was the same trend as that obtained by Buhan et al. (1999). The critical failure surface might vary due to the permeability anisotropy of the soil. So, the critical failure surface can be determined by iteratively changing of the slurry face stability pressures in the coupled analysis until matching with one of suggested calculation method.

6 CONCLUSIONS

The face stability of TBM tunnel was studied in this paper and the methods of calculate the slurry pressures required for the face stability were reviewed. The coupled numerical analysis was performed for the slurry

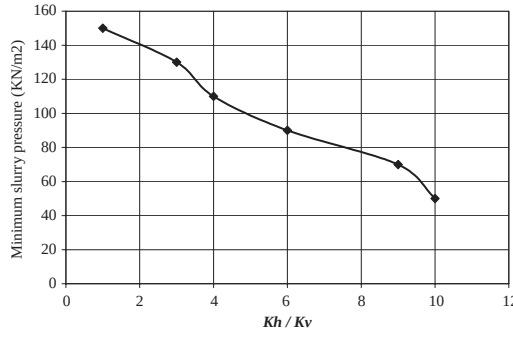

Figure 9. Slurry pressure as a function of permeability anisotropy.

pressure of face stability and checked with estimation methods.

The presented results show that the FEM for face stability combined with the practical experience currently available it is feasible to model TBM with 4D approach. The monitoring data show that the boring process has not been constant at the section used for the history match with the FE model.

The stability model that deals with layered soils, especially at the tunnel face, is clearly needed. The existence of ground water may seriously affect the face stability.

Impact of the face anchoring on the stability of underground working

J.Aldorf, E. Hrubesova & L. Duris
VSB –Technical University Ostrava, Ostrava-Poruba, The Czech Republic

ABSTRACT: Underground working stability depends on many objective and subjective factors. One of the important condition participant in the underground working stability is the face stabilization. These condition resulted from the fact, that after excavation the primary state of plane -deformation on working face and ahead of it changes into complex spatial (3-D) stress–deformational characteristics. The area ahead of face get deformed in the transverse plane as well as in longitudinal axis of the working. Without the adoption of appropriate stabilisation measures at the face (e.g. anchoring) , this qualitative change of stress-strain state can lead to loss of face stability and, eventually, may lead to the loss of stability of the whole section of the underground working. The paper is concerned with the mechanism of the face stability, with the stabilization effect of face anchoring, including the possibilities for the determination of optimum anchoring parameters.

1 FACTORS DETERMINING FACE STABILITY OF UNDERGROUND WORKING

Leaving aside the factors like shape and dimension of the tunnel, depth, characteristics of rock mass (deformational, strength, structural) and hydro-geological conditions of the rock environment in which the tunnel is being realized, among the basic factors, which determine the face stability and loading of the support, belong the technological factor of tunnelling and supporting of the tunnel, particularly the system of division of the face of the excavation and the length of the unsupported part behind the face. From this point of view, it is necessary to evaluate the time factor of supporting of the tunnel from two viewpoints, one is with regard to the influence on face stability and the other is with regard to its influence on loading of the support. Increased time lag between the stoppage of excavation and it's supporting may indicate increase in stability problems in transverse as well as in longitudinal direction. On the contrary, however, from the view point of loading of the support, the optimum time lag in supporting may contribute to the reduction of loading of rock mass on the support. Effective utilisation of co-acting of system "rock-support", for attaining minimum loading of the support while maintaining the stability and allowable deformation of rock mass (in transverse as well as in longitudinal direction), assumes, among others, objective determination of manifestation of deformation in the rock mass, not only in the part behind the face but also ahead of it, with the objective to determine that part of the total deformation which is not brought on the support. Stress–deformational manifestations of the rock mass are, however, influenced as well by the stabilisation measures at the face. For the purpose of stabilisation, it is possible to use different types of anchors and bolts, whose purpose is not only to anchor the potential unstable area around the face, but also to increase parameters of deformational and strength properties in the anchored part ahead of the face.

2 MODELLING OF FACE STABILITY AND IT'S INFLUENCE ON THE LOADING OF THE SUPPORT

Problem of face stability and the problem of determination of loading of the support are, therefore, mutually closely interconnected. Different types of physical models (Broms and Bennermark, 1967, Chambon and Corté, 1994) and simplified models based on evaluation of working–deformational characteristics of rocks and supports (Lombardi and Amberg, 1979) have contributed towards the understanding of the mechanism of stress-deformational behaviours around the face and towards the quantification of stability conditions at the face. These models, however, due to their simplification cannot take into account the influence of all the determining factors mentioned

earlier. Numerical methods of spatial (3D) modelling have wider possibilities for more reliable and objective solution of stability in tunnel and in determining the loading of the support.

A tunnel lying at a depth of 30 m below the surface has been modelled by using the program system 3D Tunnel, which works on the basis of finite elements method, developed by the Dutch company Plaxis. Dimensions of the model are $60 \times 60 \times 100$ m. The tunnel has arched transverse cross-section. Height of the tunnel is 5,5 m and the width, as measured along the floor, is 7 m. In this model case, the drivage has been considered as undivided face, the concrete support (E = 20000 MPa) of thickness 25 cm has been initiated in the model at a distance of 1 m behind the face. The spatial (3D) model works with homogeneous, isotropic environment. Behaviour of this environment has been described on the one hand by means of an elastic model and on the other hand by an elastic – plastic Mohr – Coulomb material model. The rock environment is characterised by the following parameters: Weight per unit volume $\gamma = 22$ kN/m^{3,} modulus of elasticity Ed = 50 MPa, cohesiveness c = 100 kPa, angle of internal friction $\varphi = 17°$.

Simulation of face stabilisation has been conducted within the framework of the model by means of fibreglass anchors (length 5 m and diameter of rod 25 mm) located in the direction of the longitudinal axis of the model. The influence of the anchor density has been investigated on the following variants: density 1 m × 1 m/anchor (representing 27 anchors at the face); density 1 m × 1,5 m/anchor (representing 14 anchors at the face);density 1.5 m × 1.5 m/anchor (represents 14 anchors at the face). Influence of anchoring of the face on the change of deformational and strength parameters of rock environment in the surrounding of the face has been considered in the model by modifying the value of modulus of elasticity and cohesiveness. Simplified assumption has been adopted that the increased values of deformational and strength properties, which are, among others, functions of number of anchors at the face, are constant in the whole anchored part ahead of the face. Percentage increase of modulus of elasticity stems from the parametric studies conducted by using finite elements method. Value of increased cohesiveness "c" comes from the relationship.

$$c' = \frac{1+\sin\varphi}{2\cdot\cos\varphi}\cdot\frac{P}{F} \qquad (1)$$

where P is the load – bearing capacity of the anchor, F is the area of transverse cross-section of the face coming under one anchor.

The following increased values of the mentioned parameters have been considered (table 1).

Table 1. Increasing parameters depending on anchor density.

	Increase of parameters	
Anchor density	Modulus E %	Cohesion c %
27	30	197
22	25	98
14	20	32

3 RESULTS OF MATHEMATICAL MODELLING

Parametric computations have been conducted for the stated variants of anchor density utilising the mentioned program 3D – Tunnel and the stress – deformation and stability state in the rock environment around the tunnel (inclusive of the face) has been determined as well as the internal forces and deformation in supports of the tunnel and fibreglass anchors have been evaluated. Some of the results of 3 D – modelling have been presented in figures 1 to 7. Evaluation of the results of parametric computations is possible to summarise as follows:

- final maximum value of the vertical displacement of the roof of the excavation (15 mm) has been achieved at a distance of approximately 50 m behind the face (approximately seven times the width of the excavation as measured along the floor), this remains valid not only in the case of an elastic model but also in the case of an elasto-plastic model and is not dependant on the anchor density at the face
- the influence of stress release in the rock mass, as a consequence of realisation of the tunnel, has been observed at a distance of 50 m ahead of the face and has been manifested by vertical displacement of the roof (0,3 mm to 0,5 mm) in connection with the chosen constitutive relationship and the density of anchoring of the face
- the character of the graphs of vertical displacement at the face and in the immediate surroundings differs in relation with the chosen type of behaviour of the rock environment. Realized computations have shown substantial quantitative and qualitative differences between the results of computation of displacement on the assumption of elastic behaviour of the rock environment and on the assumption of elastic – plastic behaviour of the medium (figure 1 and 2).
- in case of elastic model, approximately 36% of final vertical deformation of the roof has occurred ahead of the face in case of unanchored face, while in the case of anchored face the final vertical deformation of the roof has been reported to be only 30% (influence of anchor density has not been almost

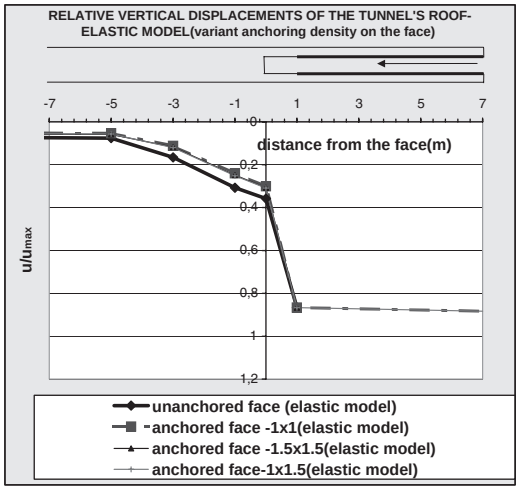

Figure 1. Vertical displacements in the roof (elastic model).

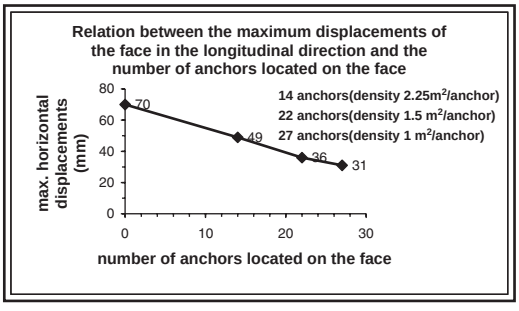

Figure 4. Relationship of the maximal longitudinal displacements on the number of anchors at the face.

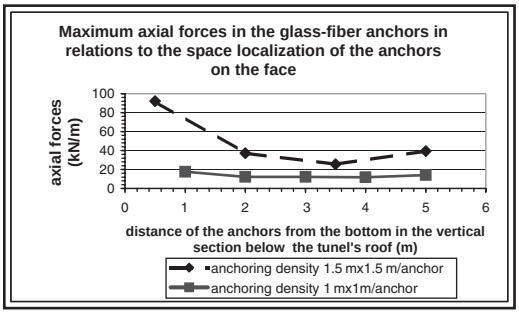

Figure 5. Relationship of the maximal axial forces in the fibreglass.

manifested in that model). In case of unanchored face, 100% of the vertical deformation of the roof has occurred ahead of the face on the assumption of plastic behaviour of the rock environment, which implies probably from the effects resulting forming the longitudinal arches. With the increase of anchor density, this share of vertical roof displacements which have already occurred ahead of the face gradually decreases within the boundary of 69% to 21% of the total vertical displacements. The share of total displacements changes proportionally (directly proportional) to the degree of face stabilisation, which corresponds to the unsupported metres behind the face (66% for maximum considered anchor density, 19% for minimum considered anchor density). The influence of anchor density at the face on the value of vertical displacements of the roof, which is brought on to the tunell support does not demonstrate practically.

– in case of the elastic model with the unsupported face, the results of computation show higher percentage of the total vertical displacements of the roof, which is brought on the support in comparison with the elasto-plastic model. In case of anchored face, the loading of the support increases as a result of stabilisation, subject to the the assumption of elasto-plastic deformation. The used numerical

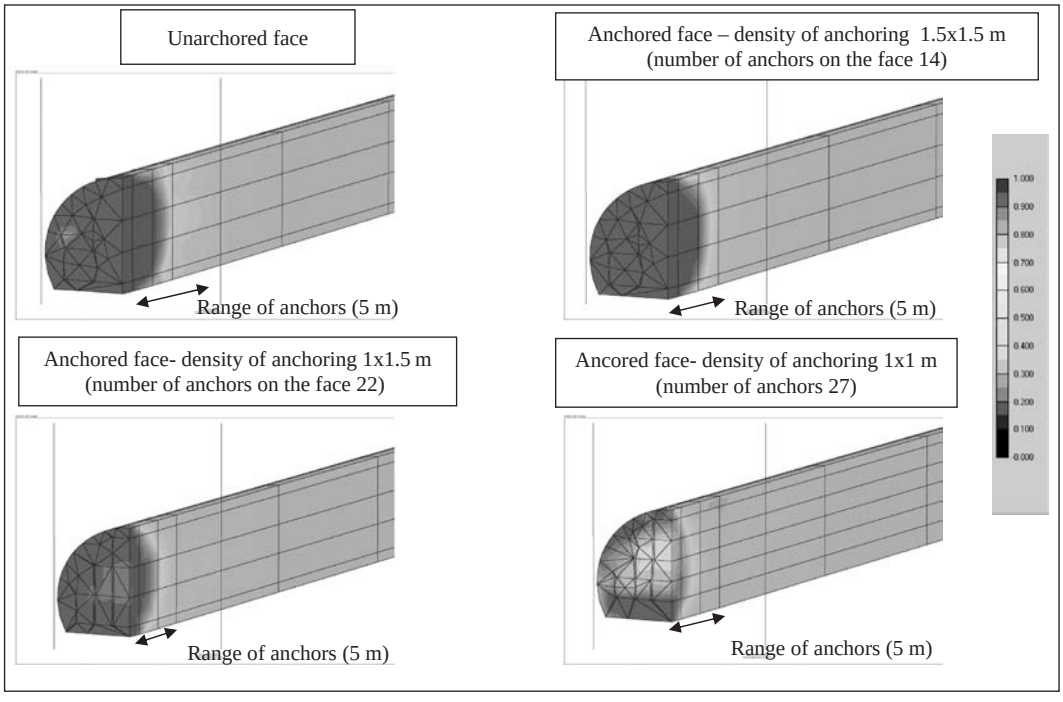

Figure 6. Strength factor on the face and it‘s forefield.

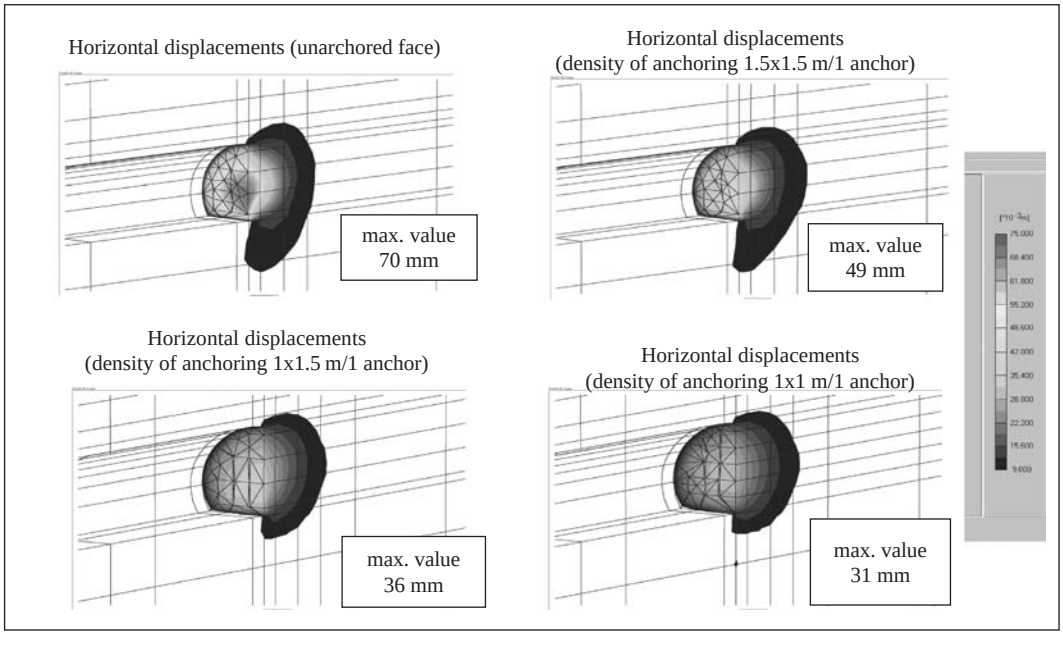

Figure 7. Horizontal displacements in the longitudinal direction.

model, however, in this case did not prove the influence of anchor density on the magnitude of that part of the support loading, which implies from the shifting of vertical displacements to the supports.
– graphs in figure 3 and fig. 6 illustrate increase in drawing of strength with the reduction of anchor density at the face and further show the indirectly proportional relationship of the range of the zone of fracturing on the number of anchors at the face. Extent of the area of fracturing, corresponding to drawing of strength in the range of 0,8–1 varies in the interval of 3,5 m (unanchored face) to 1,2 m (anchor density 1 m^2/anchor). Face stability is increased with the increase of anchor density.
– horizontal displacements in the direction of longitudinal axis of the excavation are inversely proportional to the anchor density at the face. It varies in the range of 70 mm (unanchored face) to 31 mm in the case of anchor density of 1 m^2/anchor (graph in fig 4 and fig 7).
– from the evaluation of axial forces in the anchors, whose heads are localised in the vertical section passing through the centre of the transverse cross - section of the excavation, it appears that in case of lowest considered anchor-density (2,25 m^2/anchor), the highest axial forces are located closest to the floor (92 kN/m). The axial forces are lowest (25 kN/m) in the middle part of the transverse section of the face. Axial forces in anchors are gradually decreased with the increase of anchor density at the face and their values then practically do not depend on the distance of the anchor from the floor (graph in fig. 5).

4 RECOMMENDATIONS IMPLIED FROM THE RESULTS OF THE MODEL

– from the viewpoint of the evaluated extent of fracturing ahead of the face, the minimum length of the bolts should be 0,5 times the width of the excavation.
– anchor density with area higher than 2 m^2/anchor do not any further markedly influence the stability state. Therefore, the recommended anchor density at the face is 1,5 m^2/anchor.
– due to the determined not very high values of the axial forces in the anchors (maximum 92 kN/m), the requirements regarding the load bearing characteristics of the anchors are quite little.

5 CONCLUSION

Results of the parametric computations show, except others, mutual close relationship between face stabilisation and loading of the support, particularly in the case of elasto-plastic model of behaviour of the rock environment. Optimisation of this mutual state is not possible to carry out in an objective and reliable manner without the realisation of the respective spatial (3 D) mathematical model which enables to take into account the complicated spatial (3D) character of the stress – deformation state ahead of the face. The paper also points towards the quantitative and qualitative differences of results of modelling in relation to the accepted model of behaviour of the rock environment (elastic model, elasto – plastic model). This reality has, in case of low strength rocks where it is possible to assume the creation of zone of plastic deformation, great consequence not only for the effective stabilisation of face but also for more objective determination of loading of the support.

Bentonite and grout flow around a TBM

A. Bezuijen
GeoDelft, Delft, The Netherlands

ABSTRACT: The flow of grout and bentonite around a slurry shield TBM is investigated, using a 1-dimensional calculation model. The results show that the shield of the TBM is only partly in contact with the surrounding soil and that for a large extent it is in contact with the liquid grout and, depending on the amount of over cutting, also in contact with the bentonite that is injected at the tunnel face. These liquids also determine the forces on the TBM shield. The calculation model presents the pressure distribution on the shield and shows the influence of the soil properties, the overcutting and the properties of the grout and the bentonite.

1 INTRODUCTION

The cutting wheel of a TBM is in most cases a bit larger than the TBM itself. There is only a small difference (a few centimeters on a TBM with a diameter of 10 meters or more), but this difference is significant. It means that for a slurry shield bentonite can flow from the tunnel face back to the grout used to fill up the tail void. However, it is also possible that grout can flow from the tail void to the tunnel face. It is important to quantify the flow of both the bentonite and the grout because these flows determine the quality of the tail void grouting and in non-cohesive soils these flows have to be controlled to avoid erosion of the soil around the TBM. Furthermore these flows determine the pressure distribution on the TBM shield that is important in both the design of the TBM and to calculate the soil settlement that is caused by the TBM tunnelling. Lack of knowledge on the pressure distribution on the TBM led to deformations of the TBM during tunnelling (Barends, 2005).

A 1-dimensional model is developed to get information on the order of magnitudes of the flow of the grout and the betonite, the pressure distribution and the soil deformation around the TBM shield. The model assumes a given pressure distribution at the tunnel face (the face pressure) and at the tail of the TBM (the grout pressure) and incorporates the yield strength of both the grout and the bentonite. It takes into account the over cutting of the cutting wheel and the conical construction of the TBM (with a bit smaller diameter at the tail compared to the front). Linear elastic soil behaviour is assumed. This last assumption is justified to a certain extent by the observation that only small deformations will occur during TBM tunnelling under normal operation.

Finite element calculations (Hoefsloot & Verweij, 2005; Kasper & Meschke, 2006) have shown that the calculated settlement trough is too deep when it is assumed that the TBM shield is in contact with the soil all over the TBM. The model described in this paper presents a framework that quantifies the amount of contact between the soil and the TBM and indicates what volume loss can be expected depending on the face pressure and the grout pressure.

2 GEOMETRY OF A TBM

A TBM shield seems to be a tube with a constant diameter, sketched in a way as in Figure 1.

However, looking more in detail the shield is part of a cone. The diameter at the front is larger than at the tail. The difference is only small, normally around 0.4% of the diameter of the TBM. For a TBM shield

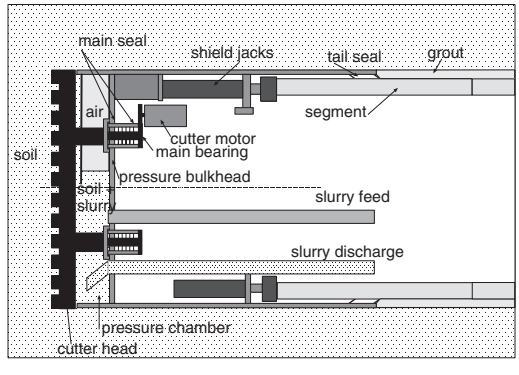

Figure 1. Sketch of a slurry shield TBM.

with a diameter of 10 m, this means that the diameter of the shield is 4 cm smaller at the tail compared with the diameter just after the cutter head. This small difference in diameter allows the TBM to maneuver in the soil.

3 GROUT FLOW AROUND A TBM

3.1 *Theory*

Assume a TBM with a small change in diameter (a diameter decrease from front to back). The TBM is boring in soil that is assumed linear elastic with a shear modulus G.

Assume that the soil flows around the shield and the soil is in contact with the shield. This leads to a decrease in stresses in the soil around the TBM going from the tunnel face to the tail. A simple approach is to neglect the influence of gravity and assume a tunnel that is positioned perfectly symmetric in the bore hole. In such a situation the relation between deformation and stress reduction can be written as:

$$\Delta\sigma = 2\frac{\Delta r}{r}G \tag{1}$$

Where $\Delta\sigma$ is the change in pressure, Δr the change in radius, r the radius of the tunnel and the grout and G the shear modulus of the soil around the tunnel. The interaction between soil and grout was also described with this formula in Bezuijen & Talmon. (2003) and proved to be useful in that research.

Calculating the pressure from front to tail of the TBM, without the influence of grout, will lead to an ongoing pressure reduction. However, grout is injected at the tail of the TBM. If this is injected with a pressure higher than the pressure calculated with Equation (1) the soil will be pushed from the TBM and the situation sketched in Figure 2 will occur. The grout will flow in the joint between the soil and the TBM. Flowing into this joint will lead to a pressure drop in the grout. The pressure is the highest in the tail and decreases going to the tunnel face of the TBM. This pressure drop is determined by the yield stress in the grout and the width of the joint. Assuming that most flow induced friction will develop between the soil and the grout, the pressure drop can be written as:

$$\Delta P = \frac{\Delta x}{s}\tau_\gamma \tag{2}$$

Where ΔP is the change in pressure due to the flow, Δx a length increment along the TBM, s the joint width between the tunnel and the soil and τ_γ the shear stress of the grout around the TBM. In this formula we neglect viscous forces. This is allowed due to the low flow velocities that can be expected. With these equations and the known shape of the tunnel it is possible to calculate what joint width can be expected and for how far the grout in the tunnel flows over the TBM shield.

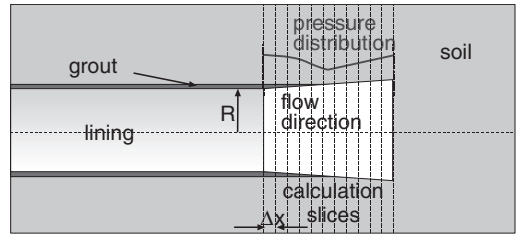

Figure 2. Idealized sketch of a TBM and lining in grout (picture not to scale).

Table 1. Parameters used in calculation.

Length TBM	5	m
Diameter	10	m
diameter reduction	0.2	%
1 or 2 side (1 with non-symm. TBM)	1 or 2	
Grain stress	200	kPa
Grout pressure drilling	500	kPa
Pore pressure	200	kPa
Shear modulus (G)	90	Mpa
Yield stress grout with soil	0.8	kPa

The following calculation procedure is used. The soil around the tunnel is assumed to behave as independent slices with a thickness Δx, see Figure 2. Knowing the geometry of the tunnel, the grouting pressure, the soil pressure and the elastic properties of the soil, the joint width at the tail of the TBM can be calculated using Equation (1). That joint width can be used to calculate the pressure drop due to the flow of the grout to the front of the TBM over the distance Δx with Equation (2). The resulting pressure (the original grouting pressure minus the pressure drop) is used to calculate the deformation and joint width of the next slice and so on. For each calculation it is checked if the calculated joint width is still positive. If this is not the case then the soil is in contact with the TBM and the pressure is calculated from Equation (1) using the actual diameter of the TBM for that slice.

3.2 *Calculation*

The diameter of the TBM at the front face is 10 m, the diameter at the tail is 20 mm less. All values used in this calculation are mentioned in Table 1 are used. 1 or 2 side is mentioned in this table. “2 side” assumes a symmetric situation as shown in Figure 2. “1 side” indicates the asymmetric situation in which the tunnel is on one side in close contact with the soil and as a result the joint on the other side is wider.

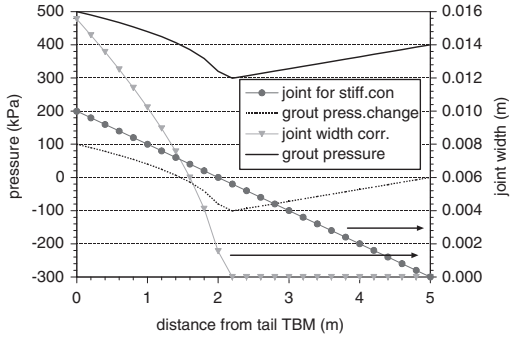

Figure 3. Calculated pressures at the tail of a TBM and the resulting joint width. Symmetric situation (lines with markers refer to the right vertical axis, the others to the left), see also text.

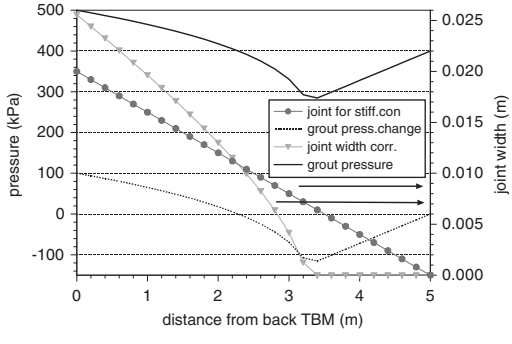

Figure 4. Calculated pressures at the tail of a TBM and the resulting joint width. Asymmetric situation (lines with markers refer to the right vertical axis, the other to the left), see also text.

The calculation shows that there is a considerable amount of the shield, which is not supported by soil but is in the grout (2.2 m from the back of the TBM is in the grout).

In these figures the line with the round dots represents the joint width that would occur if the tunnel is boring trough a completely rigid soil. In that situation the diameter of the hole in the soil would be constant and the diameter of the TBM shield decreases (going from the tunnel face to the tail. This line is simply the difference between these 2 values. The line with the triangles is the correction due to elastic deformation in the soil caused by the diameter differences in the TBM and the grout pressures. The solid line presents the grout pressures along the TBM, and the broken line the grout pressure minus the static soil pressure.

In this first example it was assumed that the TBM was perfectly symmetric in the soil. However, it is likely that this is not true. The tail of the TBM weights less than its front and if this tail is embedded into the grout, it is likely that buoyancy forces lift the tail. The lifting will be counteracted by the yield stress of the grout. Therefore the second calculation is made for the situation that the TBM is as asymmetric as possible. One side of the TBM is in contact with the soil over the full length the other side has a joint that is twice the joint in the symmetric situation. The symmetry was used to calculate the soil deformation and therefore this solution is strictly spoken not valid. However, this solution can be used to get an indication on the possible pressure distribution.

In both cases the grout pressure at the end of the TBM is higher than the soil pressure. As a result the soil is pushed away from the TBM. The corrected width of the joint between the tail of the TBM (the line with the triangles) and the soil is therefore bigger at the end of the TBM than it would be by the cutting of the TBM only (the line with the round dots). The difference is small, only 6 mm, but significant compared with the original joint width of 10 or 20 mm. Going from the back of the TBM along the shield to the front, the joint width decreases and the corrected joint width becomes smaller than the original. At 2 respectively 3.5 m from the back of the TBM the corrected width of the joint between the soil and the TBM becomes zero. The soil pressure is at that location 100 kPa less than the original value. Going further to the front of the TBM the soil pressure increases because the diameter of the TBM increases.

4 INFLUENCE OF BENTONITE FROM THE TUNNEL FACE

The calculations presented in the section above have some simplifications. The over cutting that occurs at the tunnel face by the cutting wheel was not taken into account neither the influence of the bentonite that is present at the tunnel face at a certain pressure (the face pressure). In this section these two effects are incorporated.

In normal operation a TBM has an over cutting of 10 to 30 mm (depending on the state of the teeth at the cutting wheel) with respect to the TBM itself. This will result in a larger joint between the TBM and the soil. The joint at the tunnel face is not zero as was assumed in the section above, but the value imposed by the over cutting. Bentonite will now flow to the tail of the TBM and grout will flow to the face. Somewhere in the middle around the TBM these flows will meet. Calculating the pressure distribution is now complicated by the fact that the direction of the flow is of importance. Both grout and bentonite are usually described as Bingham liquids. This means that a certain pressure gradient is needed to start a flow. Therefore there are 3 possible flow situations, see also Figure 5.

1 Grout flows from the tail to the tunnel face and bentonite flows from the tunnel face to the tail this

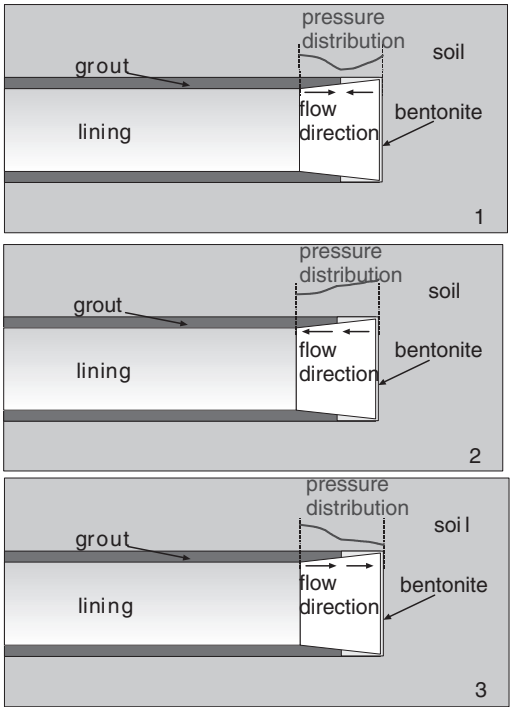

Figure 5. Possible flow directions and sketched pressure distributions along the TBM. The 3rd situation is worked out quantitatively, see Figure 6.

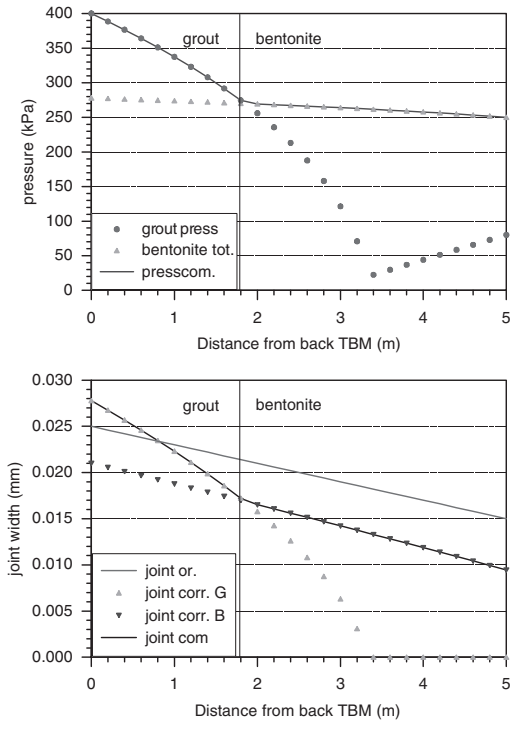

Figure 6. Pressures and joint width along a TBM. Grout pressures and bentonite pressures. Parameters see Table 2. Plots show pressures and joint width for the bentonite and grout pressure separately and the combined result.

situation can only occur when there is some volume loss in the joint between the TBM and the soil for example due to bleeding of the grout or penetration of the bentonite into the soil. For this situation the lowest pressure will be present there where the bentonite and the grout meet.

2 Bentonite is flowing backwards to the tail and pushing the grout out of the joint between the TBM and the soil. The pressure will be the highest at the tunnel face and will decrease when going to the tail. This cannot be a continuous situation, but can occur temporally.

3 Grout is flowing to the tunnel face and pushes the bentonite to the tunnel face. The pressure is highest at the tail close to the injection points of the grout and will decrease going to tunnel face.

The model developed can in principle cope with all these 3 options. However, for simplicity in this paper we will only deal with the 3rd option because this is the most realistic situation for most of the drilling process. Starting with a certain grout pressure at the tail void, this pressure will decrease due to the flow from the grout into the joint between the TBM and the soil. This pressure decrease will depend on the viscosity of the grout and the joint width. The joint width depends on the pressure at that location as is explained in Section 3. This grout flow is completely comparable to the calculation of that section. The pressure at the tunnel face will be the bentonite pressure. Since the bentonite is pushed forward from the tail to the tunnel face, the bentonite pressure will be highest at the tail and lower at the face. It is assumed that there is no mixing from the bentonite with the grout. In such a situation the grout pressure and the bentonite pressure can be calculated. When the grout pressure is higher than the bentonite pressure, there will be grout in the void and if the bentonite pressure is higher there will be bentonite. The result of such a calculation is shown in Figure 6.

The upper plot of this figure shows the pressures and joint widths that would occur if there were only grout (G) or only bentonite (B) in dots and in lines the combined joint width and pressure. In this calculation the grout penetrates between the shield and the soil up to 1.3 m from the tail. The remaining part of the joint between the TBM and the soil is filled with bentonite. The amount of penetration varies with the pressures and shear strength that are chosen. The parameters used in this calculation are shown in Table 3. Although there is an open connection between the face and tail of

Table 2. Input parameters used in calculation with bentonite and over cutting.

Length TBM shield	5	m
Diameter	10	m
Diameter reduction	0.2	%
over cutting	0.015	m

Shear strength bentonite 2 sided friction assumed	0.08	kPa

the TBM (See the lower plot of Figure 6, the joint width of the combined calculation is never zero), there is still a stable boundary between the grout en the bentonite. Since both liquids behave as a Bingham liquid there can be some decrease in the grout pressure and still the position of the grout-bentonite front will be the same.

According to the results, the tail of the TBM is never in contact with the soil. In reality there can be some contact due to forces not taken into account in this calculation (vertical loading from the lining, moments induced by the hydraulic jacks). However, it is clear that tapering of the shield does not necessarily lead to a certain volume loss, as is suggested by Kaspar & Meske (2006). The calculation results presented here are also in line with the TBM data, which normally show that more grout have to be pumped into the tail void than the original tail void. The grout that flows into the joint between the soil and the TBM is not an extra volume, because it is a constant volume during tunnelling, but the grout volume increases because the grout pressure makes a wider joint.

5 EXAMPLE CALCULATIONS

The calculation method can now be used to test the influence of various parameters. In a set of example calculations the length of the TBM has been changed (the length used up to now is with 5 m a bit short compared to the usual TBMs) and/or the grout pressure or the soil properties. In all example calculations Table 2 is used as a reference and the parameter changed is mentioned.

Assuming the same amount of tapering but a longer tunnel leads to a comparable distance over which grout flowed over the tail of the TBM (approximately 2 m). Most of the shield is in that situation covered with bentonite, increasing the face pressure to 370 kPa results in a joint completely filled with bentonite. But then the assumptions of the 3rd picture in Figure 5 are not valid

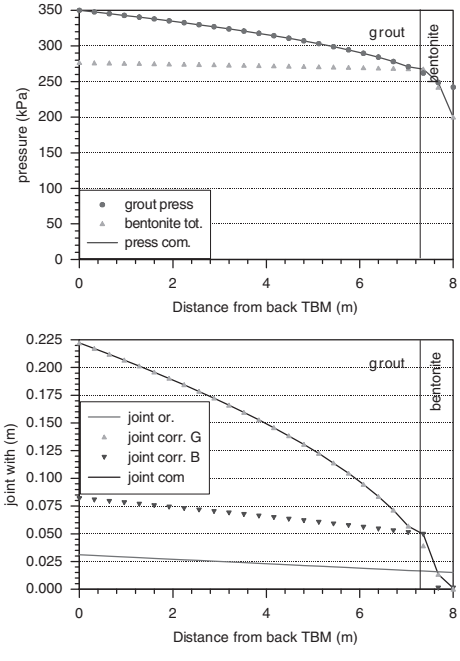

Figure 7. Pressures and joint width along a TBM for a TBM drilling in clay. Grout pressures and bentonite pressures. Parameters see Table 3. Plots show pressures and joint width for the bentonite and grout pressure and the combined result.

anymore, because there it was assumed that the grout pushed the bentonite in the direction of the face during drilling. This is obvious not the case when no grout is present at all anymore in the joint. In this situation (thus with a shield of 10 m length and the other parameters taken from Table 2) the grout pressure can be increased until 750 kPa before the bentonite flows through the joint between the TBM and the soil into the pressure chamber. Assuming that the minimum grout pressure

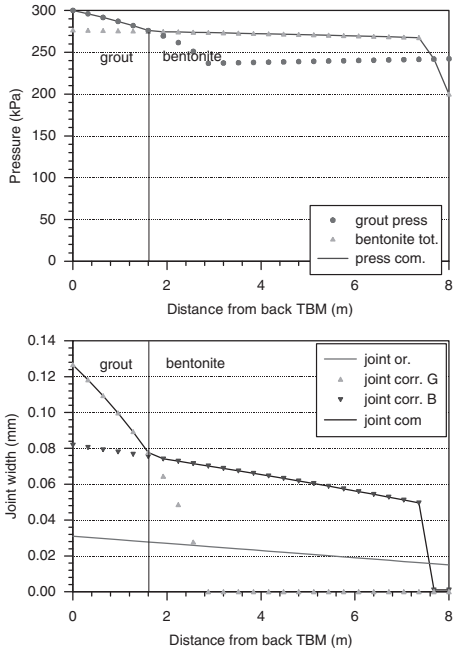

Figure 8. Pressures and joint width along a TBM for a TBM drilling in clay. Grout pressures and bentonite pressures. Parameters see Table 3 but grout pressure lowered until 300 kPa. Plots show pressures and joint width for the bentonite and grout pressure and the combined result.

is somewhat higher than the total stress (350 kPa in this situation), this result indicates that quite a variation in grout injection pressure is possible before the grout really reaches the pressure chamber.

Interesting is to investigate the influence when the TBM drilled through holocende clay layers as will be the case in the Netherlands for the RandstadRail project, (Pachen et al. 2005) and also possibly in future projects. Clay has a much lower shear modulus. Pachen et al. (2005) assumed an average value of 1.7 Mpa at the centre of the tunnel. A first calculation was run with the parameters of Table 3. In this calculation the assumed geometrical parameters for the RandstadRail tunnel are used, the (face and grout) pressures are set on a level that is usual for boring a tunnel in sand, but the shear modulus of the clay is used (1.7 MPa).

The results of such a calculation are shown in Figure 7. The results show that the applied grout pressure will lead to a considerable joint width above the shield of 0.225 m. This means that this joint width is wider than the original designed tail void, which will be 0.15 m and this would also have enormous consequences for the amount of grout used, which will more than double. This problem can be overcome by reducing the grout pressure. In a second calculation the grout pressure was reduced to 300 kPa and for this situation the joint width reduces until approximately 0.125 m (Figure 7). Still considerable but only halve the value of the original calculation. This model therefore shows that when drilling in soft clay the grouting process is even more critical than during drilling in sand. Considerable changes in joint width above the TBM shield and therefore also considerable changes in volume loss (or gain) can be achieved by only limited changes in the grout pressure.

6 CONCLUSIONS

1-dimensional calculations showed that it is very likely that the tail of the TBM is to a large extent supported with bentonite and grout and not with soil. Therefore there is no direct relation between the tapering of the TBM and the volume loss, as is sometimes suggested. There is, however, in this model a direct relation between the grouting pressure and the volume loss. 4-D FEM calculations performed for COB in The Netherlands (Hoefsloot et al., 2005) are in agreement with these results.

The model shows that a good pressure control is essential when tunneling in soft soil (holocene clay).

ACKNOWLEDGEMENT

The author wants to thank Dr. K.J. Bakker from Plaxis B.V. and Dr. Ulrich Rehm from Herrenknecht for stimulating discussion.

Volume changes in grout used to fill up the tail void

A. Bezuijen & W.H. van der Zon
GeoDelft, Delft, The Netherlands

ABSTRACT: Volume changes in grout to be applied in the tail void of a tunnel were measured in the laboratory. Two different mechanisms that lead to volume changes have been distinguished: Bleeding of the grout, which is the dominant mechanism when a tunnel is constructed in a permeable soil; and volume changes during the hardening process. The last volume changes are the only volume changes that occur when a tunnel is constructed in an impermeable soil. Two test set-ups have been developed to test these two different causes of volume changes. It appeared that the volume changes caused by bleeding varied between 3 and 8%. Volume changes during the hardening process were less than 3% for a two component grout that was tested. A 2-component grout mixture with air appeared to have a certain elasticity also after hardening of the grout. As a result small volume changes did not result in large pressure changes, which will lead to smaller loading on the lining compared with grout without air.

1 INTRODUCTION

The tail void between the lining and the soil in a tunnel is filled with grout during the construction of a tunnel. This tail void grouting appears to be an important process in tunnelling. This process appears to have an important influence on the resulting settlement trough and on the loading on the lining. Volume changes in the grout after its application in the tail void will lead to surface settlements above the tunnel and/or will change the loading on the lining. Two different mechanisms can lead to volume changes:

1. Bleeding of the grout. The water in the grout is expelled to the surrounding soil when applied in a permeable soil. The amount of bleeding depends on the permeability of the grout, the consolidation properties and the hardening properties.
2. The hardening of the grout. Even when there is no bleeding, as will be the case when the tunnel is bored in nearly impermeable soil as rock or clay, volume changes can occur during the hardening of the grout.

Two test set-ups have been developed to measure the volume changes during bleeding and hardening of grout.

This paper presents detailed information on the set-ups and the results of various tests. Results will be compared with small scale tests on samples with a thickness of 0.02 m. Consequences for tunnelling will be discussed.

2 SET-UP OF TESTS

2.1 *Types of tests*

Two different set-ups were used to test the volume change caused by the two mechanisms mentioned above for four different types of grout.

The first setup was a consolidation cell with a diameter of 0.3 m in which a grout layer of 0.2 m thickness was tested. The 0.2 m is comparable with the thickness of a grout layer around a tunnel. This is important because the ratio between hardening time and consolidation time determines the bleeding. When the hardening time is much less than the consolidation time (for a layer of grout of a certain thickness) the bleeding loss will be small. During a test the pressure was kept constant and volume change was measured continuously.

The second set-up was again a cell with a diameter of 0.3 m and 0.2 m thickness. However, in this cell there was no bleeding of the grout. The set-up was designed to measure volume changes accurately. The set-up was developed to see how a grout behaves that is injected between the lining and the soil in the case the surrounding soil is impermeable.

2.2 *Bleeding tests*

Tests have been performed to investigate the hardening and bleeding of conventional grout, see Figure 1 and Figure 2. In this test a grout layer of 0.2 m is

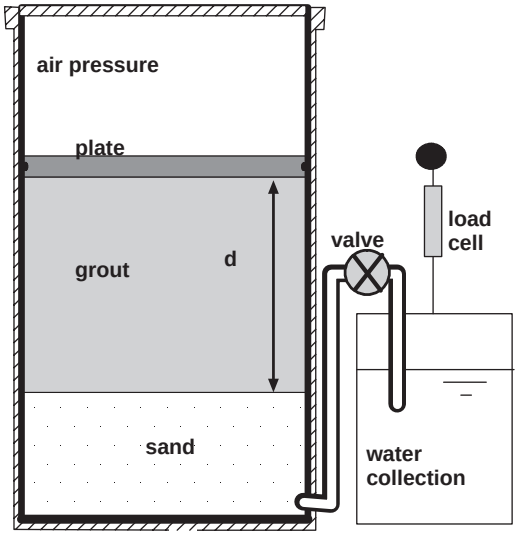

Figure 1. Measurement principle.

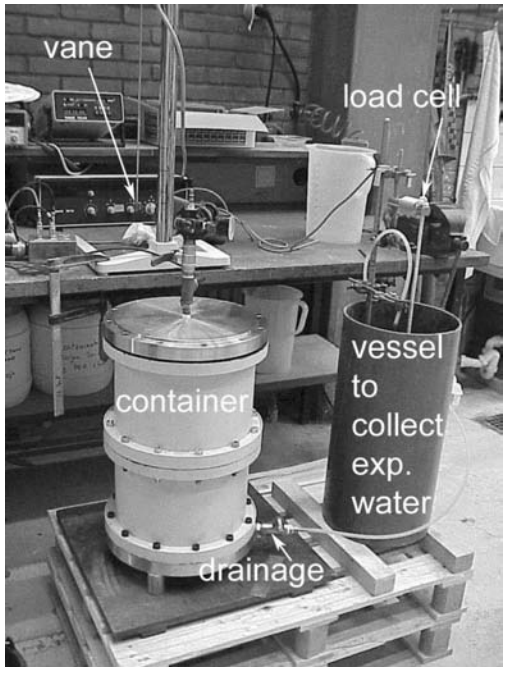

Figure 2. Experimental setup.

loaded mechanically with a constant load of 1–3 bar. The expelled water is a measure of the consolidation of the grout. After several minutes of consolidation the sample was unloaded and the shear strength of the grout was measured at different locations in the grout. An example of results of such a test is shown

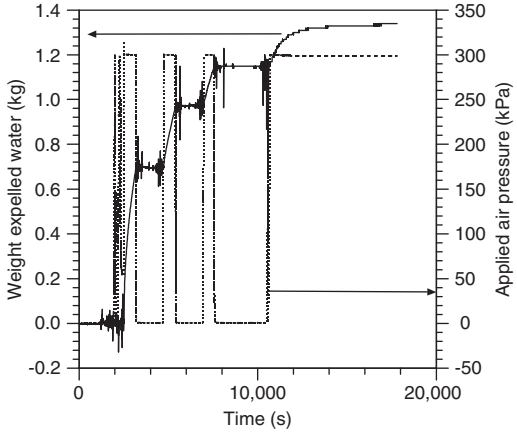

Figure 3. Test result expelled water as a function of time and applied pressure.

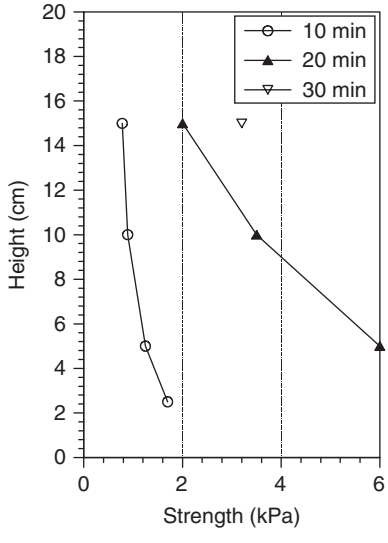

Figure 4. Strength development as measured with a vane.

in Figure 3 and Figure 4. Figure 4 shows the amount of expelled pore water as a function of time and the applied pressure. In this test a pressure of 300 kPa was applied. Pressure was relieved several times to be able to take the vane tests. Figure 4 shows the measured shear strength after various times that pressure was applied. In this test it was focused on the lower values of the shear strength. Therefore only shear strengths up to 6 kPa were measured and presented in the plot.

The type of grout tested here was tested before at atmospheric pressure (Bezuijen *et. al. 2002*). In that test it appeared that the measured shear strength remained more or less constant until 5.5 hours and after that time the hardening of the grout started.

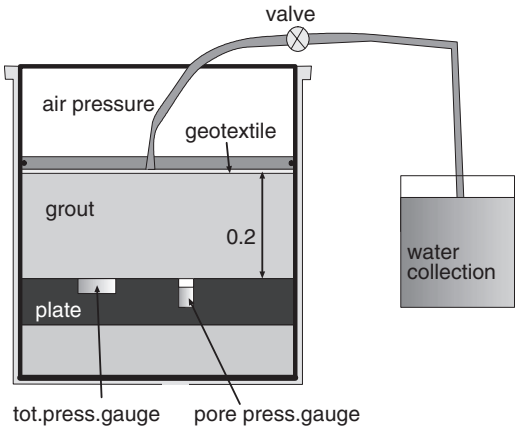

Figure 5. Modified test set-up to measure the bleeding of grout.

Comparing the result from the test at atmospheric pressure with the results of the tests at 1–3 bar over pressure it became clear that the increase in strength in the over pressure case is caused by consolidation of the grout and not by the hardening of the grout. To understand the grout properties just after injection in the tail void it is therefore necessary to understand consolidation. If the grout layer is consolidated it will have certain strength to act as a foundation for the tunnel lining, even before hardening of the grout commences. If it is not consolidated, it is possible that the shear strength is too low to counterbalance the buoyancy forces of the tunnel. Another important consequence of consolidation is an increase of flow resistance, which directly affects the pressure distribution behind the TBM when drilling.

The vane test as shown in this Figure 4 was only possible in case a grout was used with a relatively long hardening and consolidation time. For tests performed with two-component grout or grout without cement, the strength development was not measured. For later tests the set-up was changed, to avoid the preparation of the sand sample and to be able to measure the pore pressure and total pressure in the grout. The set-up for these later tests is shown in Figure 5. The principle is the same, but the drainage is in a different direction to the top of the grout sample.

The test where evaluated using the theory developed by Bolton & Mckinley (1997). There formulation written in porosity changes in stead of void ratio (as in the original paper) reads:

$$x = \sqrt{2k \frac{1-n_i}{n_i - n_e} \Delta\phi \, t} \qquad (1)$$

Where x is the thickness of the consolidated layer, n_i the initial porosity, n_e the porosity after consolidation, k the permeability of the consolidated layer, $\Delta\phi$ the difference in piezometric head over the column and t the time.

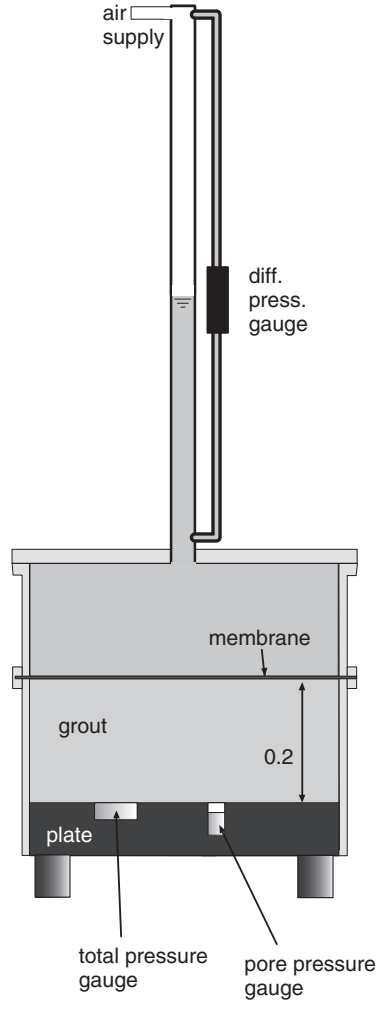

Figure 6. Sketch test set-up, grout tests for rock applications.

2.3 *Measuring the volume changes in the grout without bleeding*

The test set-up for these tests is sketched in Figure 6. The test set-up was designed to be able to exert a constant pressure on the grout and to measure volume changes accurately during hardening of the grout. The pressure was kept constant by applying a constant pressure at the air supply on top of the set-up. An excess pressure of 1 bar was used during the tests. Volume changes were measured by measuring volume changes in the water cylinder on top of the container.

Table 1. Properties of the grout samples used.

Parameter	CG	2CG	NCG	Dim.
Density	2109	1225	1840	Kg/m^3
water content.	16	225	36.3	%
D_{15}	–	–	0.0043	mm
D_{50}	–	–	0.017	mm
D_{85}	–	–	0.095	mm
Conf. pressure	300	100	100	kPa
Volume loss	8	3.5	4.5	%
Permeability cake	4.10^{-8}	$1.3.10^{-8}$	$1.6.10^{-7}$	m/s

A differential pressure gauge is attached to this cylinder and a change in water level leads to a change in differential pressure. Changes in the water level also lead to pressure variations in the grout, but these variations will be relatively small compared with the applied excess pressure of 1 bar. The container with the grout has an inside diameter of 0.284 m, the cylinder on top a diameter of 0.03 m. The height of the tube was 1 m.

3 TESTS PERFORMED

3.1 *Bleeding tests*

Three different types of grout were tested. A 'traditional' cement based grout (CG), a 2-component grout (2CG) and a grout mixture without cement (NCG) that gets the desired properties by choosing the right grain size distribution of the granular material in the grout. The properties of the grouts selected and the volume strains that were found in the consolidation tests are summarized in Table 1. It should be noted that the volume strain of the CG grout is higher than of the other 2 but that this was also measured with a higher confining stress. For the same confining stress the difference will be smaller.

As examples the results of the bleeding tests for 2CG and NCG are shown in Figure 7 and Figure 8. These materials were tested with the set-up of Figure 5. The pressures are measured with the pressure transducers in the plate below the grout. The vane tests were not performed in these tests.

Although the 2 component grout has a certain strength within a very short time (seconds) the volume decrease due to bleeding continues until 5 hours after the beginning of the test. In the hardening process that starts after approximately 5 hours the pore pressure decreases sharply until −100 kPa because the water is bounded by the chemical reaction that leads to hardening.

With the pressure applied (100 kPa) the bleeding of the NCG grout is only present for a period of approximately 0.5 hour. Since there is no chemical hardening reaction with the water the pore pressure decreases until 0 kPa, but negative pressures are not found. The

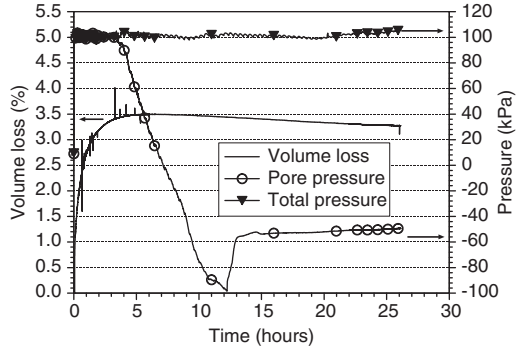

Figure 7. Result Bleeding test for the grout 2CG.

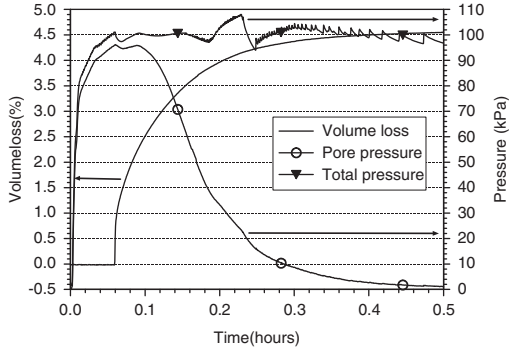

Figure 8. Result Bleeding test for the grout NCG.

measured pore pressure is not in agreement with the theory of Bolton & McKinley (1997). According to that theory the pore pressure should remain constant at 100 kPa until all material is consolidated. During the test it appears that the pore pressure at the bottom of the sample already starts to decrease before the end of consolidation, showing that the theory is only an approximation of the real process.

The 2-component grout was also tested on bleeding properties using a standard oedometer test with a sample height of 0.02 m. In such a test the consolidation times are theoretically 100 times shorter than in a sample with a thickness of 0.2 m. Therefore the influence of the hardening of the sample on the result will be less. This resulted in a much larger volume loss of around 30%. This result shows that for grouts where the hardening component is significant, the bleeding has to be tested using a layer with a comparable thickness as is expected in the application, thus for tail void grouts this has to be the actual thickness of the tail void.

3.2 *Results tests without bleeding*

The tests without bleeding, with the set-up shown in Figure 6, were only performed on grout type 2CG. One

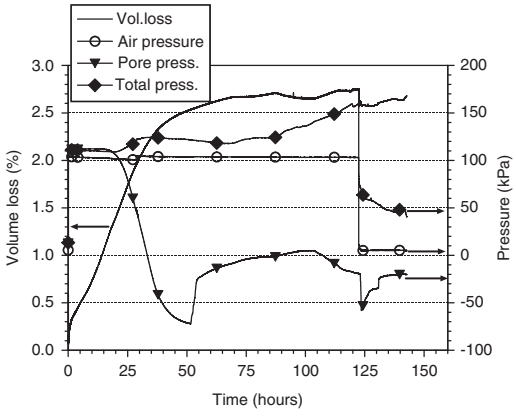

Figure 9. Test volume change during hardening. 2CG without air.

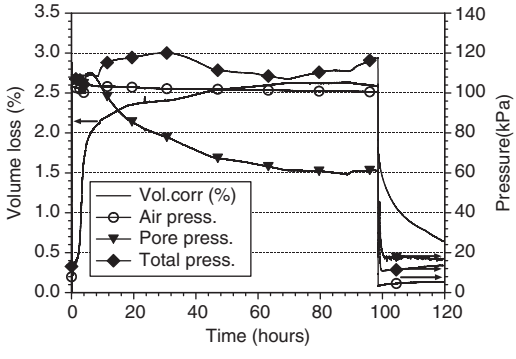

Figure 10. Test volume change during hardening. 2CG with air.

sample with only 2CG and one sample where air was mixed into the grout. Results are shown in Figure 10 and Figure 9.

Figure 9 shows the result without air. There is a constant rate of volume loss until approximately 50 hours. After 50 hours the rate of volume loss decreases, but even after 125 hours of testing the volume is still not constant. The volume loss is then around 2.8%. The experiment is stopped after 125 hours and the pressure is released. This leads to a small decrease in the volume loss. The results from the pore pressure gauge showed again that during hardening of the grout all water is used, leading to a very low pore water pressure.

The result with air, as shown in Figure 10, is different. Now the pore water pressure remains positive. It is likely that this is caused by the elastic storage that is brought into the sample by the air. It appears that even after 100 hours the grout has still some elasticity, as can be seen when after nearly 100 hours of testing the pressure is released resulting in a decrease of the volume loss from 2.6 to 0.6%.

4 DISCUSSION ON THE RESULTS

The grout mixtures tested all appeared to have some volume loss. This is caused by bleeding of the grout, but also in the case bleeding is not possible during the test there is a few percent of volume loss. The volume loss will lead to a decrease in the pressure loading on the lining in case the lining is placed in sand (Bezuijen & Talmon, 2003). This means that the original stress distribution in the sand is of no importance any more when the tunnel is made, because this stress distribution changes during the tunnel process itself (Bezuijen, 2006) and during the grouting process. Calculation methods that use the original stress distribution will over predict the loading on the tunnel, as was proven by Hashimoto et al. (2002).

The 2CG was tested for the situation without bleeding. This is the situation that can occur when the grout is used in a rock tunnel or for a tunnel made in soft clay. The 2.7 % volume loss will have not significant influence on the pressure distribution of the soil around the tunnel when this is soft clay, but may lead to considerable pressure changes in case the tunnel is made in rock, because both lining and surrounding (the rock) will react very stiff. A situation where there is some elasticity in the grout itself, as was the case for the second test where the grout had 17% air, seems to be advantageous. However, this will depend heavily on the quality of the mixture, which is more difficult to control when air is applied. Another advantage from the air is that the density of the grout decreases, which lead to a reduction in the buoyancy forces on the lining (Bezuijen et al. 2005).

5 CONCLUSIONS

Bleeding characteristics of different grout mixtures have been tested. Pressurizing these mixtures with a constant pressure of 100 to 300 kPa led to a volume loss of 3 to 8%. It was shown that these bleeding characteristics can only be tested accurately in a setup where the thickness of the grout layer is comparable to the thickness of the layer that will be applied during tunneling. Although in literature (see for example, Bolton and McKinley, 1997) the bleeding process is described as a kind of consolidation process only, it is a consolidation process that is influenced by the hardening of the grout. The time scale for consolidation is proportional with the square of the thickness, but the hardening time is independent from the dimensions.

The hardening leads to a large decrease in the pore pressure in the grout. This can result in negative pressures (relative to the atmospheric pressure).

In the tests without bleeding the presence of air appears to have a remarkable influence on the results. The grout mixture tested appeared to have an elastic

behaviour even after 120 hours when the hardening of the material is finished.

Laboratory tests on compensation grouting, the influence of grout bleeding

ABSTRACT: The process of compensation grouting has been investigated by a series of laboratory tests. In previous test series all tests resulted in an injection body of grout that had an irregular shape relatively close to the injection point. Shape of the fractures and necessary injection pressure indicate that the process was more comparable to compaction grouting than to fracture grouting. It was assumed that this was caused by bleeding of the grout mortar. Therefore a new test series was performed with larger variations in permeabilities and amounts of solid material between the injection fluids of different tests. Here it appeared that the injected 'grout' sometimes created fractures. Calculation models are described to calculate the interaction between soil and the injection fluid and a conceptual model what parameters determine the shape of the injected volume.

1 INTRODUCTION

Compensation grouting or fracture grouting has been successfully applied in several projects to compensate for surface settlements induced by for example tunnelling. Fracture grouting is planned to compensate possible settlements of buildings in Amsterdam during the construction of the tunnels for the North/South Metro Line.

Fracture grouting uses hydraulic fracturing to get a heave that can compensate the settlement. Hydraulic fracturing of competent material has been studied extensively in the oil industry where it is used successfully to enhance the capacity of oil wells. Hydraulic fracturing can also be an unwanted phenomenon in tunnelling or horizontal drilling when high pressures can cause a blow-out that starts with a hydraulic fracture (Bezuijen & Brassinga 2001).

The area where heave can be expected is determined by the shape of the fracture. Some pictures taken near Antwerp Station and a theoretical model by Te Grotenhuis (2004) showed thin fractures propagating over a large distance. However, experiments on fracture grouting in sand performed by Gafar & Soga (2006) and experiments reported by Kleinlugtenbelt (Kleinlugtenbelt 2005 and Kleinlugtenbelt et al. 2006) showed no fractures but a shape that looks as a perfect ball or an irregular ball with something that looked like the beginning of a fracture, see Figure 1.

Figure 1. Grout body formed in sand during a compensation grouting test.

That sand can be fractured was proven by experiments with different fracture materials (Khodaverdian & McElfresh 2000, Pater & Bohloli, 2003 and Bezuijen, 2003iii).

This paper starts with a conceptual idea how fracturing of sand can occur. This idea shows what parameters are of importance to determine the shape of the fracture. It describes briefly the set-up and the results of the model tests on fracturing that has been performed and the tests to characterize the injection material and will end up with conclusions.

2 CONCEPTUAL MODEL

2.1 *Fracturing*

When a grout is injected into an opening of sand, as is done by compensation grouting, there will be an elastic deformation of the opening, the opening will increase. Assuming the injection fluid (the grout) forms a plastering layer we can describe this first deformation with cavity expansion theory. The radial stress will increase and the tangential stress will decrease. This will go on until, according to the Mohr-Coulomb criterion for cohesionless soil, the stress ratio (σ_r/σ_θ) in the sand at the boundary of the injection hole fulfils the relation:

$$\frac{\sigma_r}{\sigma_\theta} = \frac{1+\sin\phi}{1-\sin\phi} \qquad (1)$$

Where ϕ is the friction angle of the sand. For sand with a friction angle of for example 35 degrees this ratio is 3.7. If the radial stress increases further, the stress ratio will remain constant and plastic deformation will occur.

Classical cavity expansion theory assumes that there will be a radial expansion, which is uniform in all directions. However, in reality the sand is never perfectly homogeneous. Looking at the scale of the grains at the boundary of the opening there will be some grains that are in closer contact and some between which there is some space, see Figure 2.

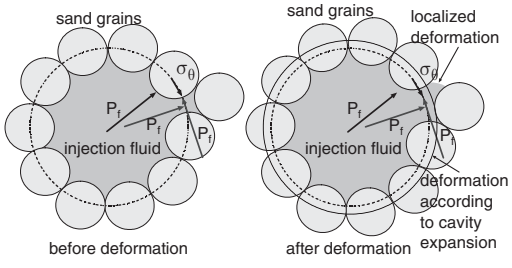

Figure 2. Sketch with possible deformation modes of the injection hole.

If the radial pressure is exerted by the injection fluid, the pressure in the fluid will be the same in all directions. As a result the pressure working on two grains on the boundary of the opening, which are not in direct contact will lead to a tangential stress that wants to remove the grains form each other and that is higher than the opposing tangential stress from the soil. As a result the grains will be pushed apart. A micro mechanical calculation has shown that this situation, in which 2 grains are pushed apart, is stable in case the soil has a plastering function and most forces work on the grains at the boundary of the opening. From hereon this process can go further and more grains can be pushed apart by the injection fluid until a full fracture occurs.

The model as described above, explains why the injection pressure is difficult to predict. There is no clear boundary where a fracture starts. The injection pressure must be high enough to create plastic deformation in the sand, but it is always possible that some plastic deformation occurs before a fracture starts. Literature presents the injection pressure in most cases as a ratio of the vertical stress on the soil sample (Bezuijen et al. (2003i). It appears from our tests and literature that this ratio can vary between 3 and 20. However, the highest values do not produce real fractures. The reason for that is, that there will always be cavity expansion in case pressures are high enough. Fracturing is an additional failure mechanism that can only occur at a lower injection pressure than cavity expansion.

The conceptual model described above also explains why the properties of the injection fluid are of importance. The injection pressure has to work close to the boundary. When there is too much plastering than the injection pressure is not applied on the sand, but on the plaster, see Figure 3. In that case the tangential force that is exerted on the grains at the boundary of the opening is much less and depends on the mechanical properties of the plastered material.

The mechanism described here for injecting in loose granular material is different for cohesive soils and

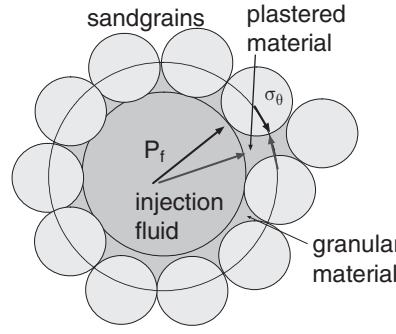

Figure 3. Influence of plastering.

rock where tension cracks can occur. In sand there will never be tension, because there is no cohesion in the material and therefore plastic deformation will occur in the material before tension stresses develop.

2.2 *Injection fluid*

The injection fluid used in compensation grouting is a mixture of water, bentonite and cement. Plastering can occur by 2 different mechanisms:

1. Bleeding of the injection fluid, as described by Bolton and McKinley (1997). The amount of bleeding depends on the injection pressure, the duration and the permeability of the plastered material.
2. Leak-off of the injection fluid. This phenomenon occurred when most of the particles in the fluid are very small. In that case the injection fluid will penetrate into the sand. In the situation that there are also larger particles, these will not penetrate, but will end up at the boundary between the fluid and the soil, see Figure 4.

The injection fluid for compensation grouting has 3 different components. Looking at the particle size only, the cement particles will not penetrate into the sand, but the very small bentonite particles will. However, from literature (Mitchell, 1976) it is known that these particles cannot be dealt with separately. The calcium in the cement leads to flocculation of the bentonite, which results effectively in larger particles and therefore in a larger permeability of the cake. Due to this the bleeding will increase but the leak-off will decrease.

3 MODEL EXPERIMENTS

3.1 *Test set-up*

A circular container with a diameter of 0.9 m was used for the tests (see Figure 1). This container was filled with saturated sand up to 0.84 m height. A PVC plate was placed on top of the sand sample. There was an air tight connection between the plate and the container by means of a rubber ring. It was therefore possible to pressurize the sand sample, using air pressure, simulating sand at a larger depth. The injection nozzle is comparable to the system developed for compensation grouting. A pipe with a rubber sleeve has been used (see Figure 2). The sleeve will only allow outflow of the grout when the grout pressure is higher than the soil pressure. The injection nozzle was located 0.37 m above the bottom of the tank.

Tests were performed with Baskarp sand ($d_{50} = 130\,\mu m$). The sand was wet pluviated into water in the container. The loose sand was densified by dropping the whole container over a few centimetres several times depending on to the required density. The sand was 'pre-stressed' by applying a high vertical pressure before the test to achieve a higher K_0. This pre-stressing was only partly successful. The K_0 achieved with this procedure was around 1. During grout injection K_0 rises rapidly to values well above 1 and even to 4.5 in the case of dense sand. Pore pressure transducers and total stress transducers were installed at various locations in the container, see Figure 7.

Special attention was paid to the measurement of the volumes. The increase in volume of the sample due to the injection and the drainage of pore water was measured continuously during the tests, more details

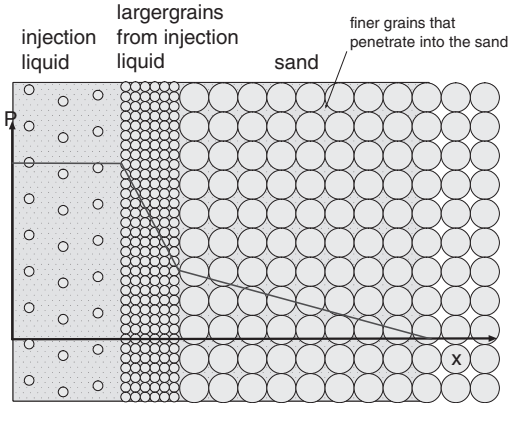

Figure 4. Plastering that can occur during leak off due to larger grains in the liquid that cannot penetrate into the sand and sketch of the pressure distribution over the injection liquid.

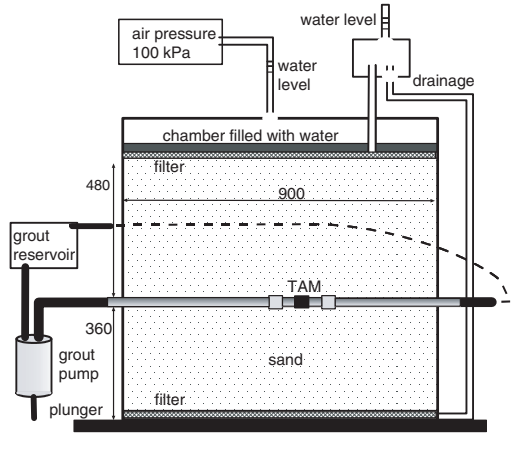

Figure 5. Set-up of the experiments. Note that changes in pore volume and sand volume can be measured as changes in the water levels.

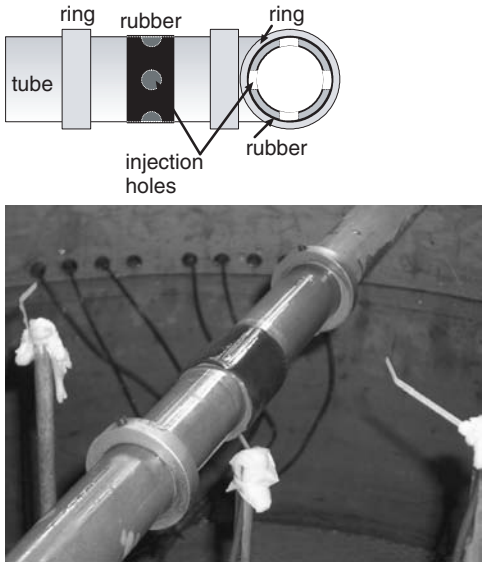

Figure 6. Injection system with rubber sleeve. The steel rings were placed on the tube to prevent grout flow along the tube.

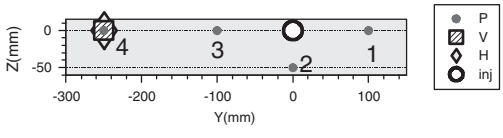

Figure 7. Position of the instruments with respect to the injection tube (inj). P are the pore pressure gauges, V measures the vertical pressure and H the horizontal.

on the measurements of the volume can be found in (Kleinlugtenbelt, 2005).

Grout was injected by means of a plunger pump. This pump pumped water and by means of a bladder the grout was pumped into the system (the sketch in Figure 5 does not show the bladder). The bladder system was installed to avoid damage to the pump by the granular particles in the grout. The maximum injection pressure of the injection pump was 25 bars.

The grout was allowed to harden for one day after the test before the sand was washed away and the shape of the injected grout became visible. There was no hardening of the grout in the test without cement. After these tests the capillary forces in the sand were used to see the shape of the fracture.

3.2 *Classification experiments*

The properties of the injection fluids were determined for each test. Viscosity and yield point were determined using a Fann V.G. viscometer that was operated at 300 and 600 rpm. Leak-off and bleeding

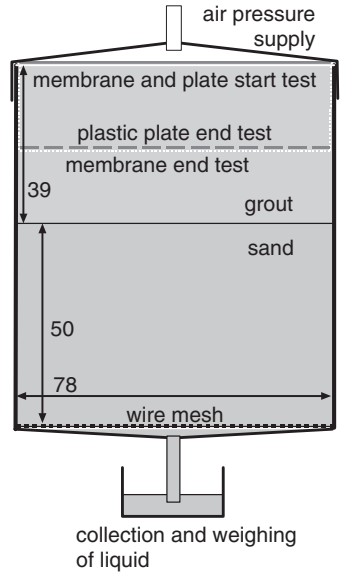

Figure 8. Sketch of the apparatus used for the bleeding tests, see also text (dimensions in mm).

were determined using a modified consolidation test, see Figure 8.

A cylindrical pressure vessel with an inward diameter of 78 mm and a height of 89 mm can be pressurized on one side and has drainage capabilities on the other side. A fine wire mesh allows water to flow through, but prevents sand particles to pass. In an experiment 50 mm of medium fine sand (d_{50} = 130 μm) is applied on the wire mesh and densified until the maximum density. 39 mm of injection fluid was applied and the pressure vessel was sealed off with a rubber membrane and a plastic plate. The latter is to achieve an even settlement of the grout. An air pressure of 4 bar is applied on top of the membrane and the amount of liquid expelled is continuously measured with a balance. The membrane and plastic plate will settle as is indicated in the figure during the experiment. The experiment is continued until the amount of expelled water remains constant.

The result of the test depends on the type of injection fluid. For a grout without any leak- off the amount of expelled water is proportional with the square root of time, as in agreement with the findings of Bolton and McKinley (1997) and can be described with the formula:

$$x = \sqrt{2k\frac{n_i - n_e}{1 - n_i}\Delta\phi\, t} \qquad (2)$$

Where x is the thickness of the consolidated layer, n_i the initial porosity, n_e the porosity after consolidation,

Table 1. Parameters of tests performed.

No	Yield stress (Pa)	Visc (Pas)	σ_v peak (kPa)	σ_h peak (kPa)	Perm. $\times 10^{-12}$ (m/s)	Peak press. (kPa)	Frac.
1	39	7.5	145	250	211	1600	No
2	35	17	150	270	17	1200	No
3-1	98	11	195	300	35	1200	No
3-2	39	7.5	210	400	470	1060	No
4	n.d.	n.d.	160	225	5.6	750	Yes
5	8	9	150	170	6	1200	Yes
6	51	21	170	200	50	1700	Yes

Notes: Yield stress = the yield stress of the grout, Visc = the viscosity of the grout, σ_v = the vertical total stress, σ_h = the horizontal total stress, Perm = the permeability of the grout filter cake, peak pressure = the maximum pressure measured and Frac = the fracturing of the sand. n.d = not determined.

Table 2. Additives injection fluid.

No	Bentonite (%)	Cement (%)	Silica flower (%)	Fly ash (%)	Retarder (%)
1	7	-	-	33.3	5.3
2	7	-	33.3	-	5.3
3-1	12	-	0.5	33.3	5.5
3-2	7	-	0.5	33.3	5.3
4	-	-	0.5	-	-
5	6.2		0.5	-	-
6	6.2	0.5	-	-	-
7	6.2	5	-		-

Note: All values are related to the real water content of the grout mortar.

k the permeability of the consolidated layer, $\Delta\phi$ the difference in piezometric head over the column and t the time. The formula was used to describe bleeding tests on tail void grout and appeared to describe the bleeding process quite well (Bezuijen & Talmon, 2003ii).

In case there is leak-off, there is a quick discharge in the first few seconds when leak-off is dominant, after that the curve follows again the curve that is expected from the bleeding.

3.3 *Tests results*

The typical conditions of the tests performed with the set-up of Figure 5 are listed in Table 1. The idea for this test series was that the grout properties are determining the result of the test, more than variations in other parameters (changing the sand into silt of clay will also have an influence, but the aim was to create compensation grouting in sand). For that reason most parameters were kept constant but a wide variety of

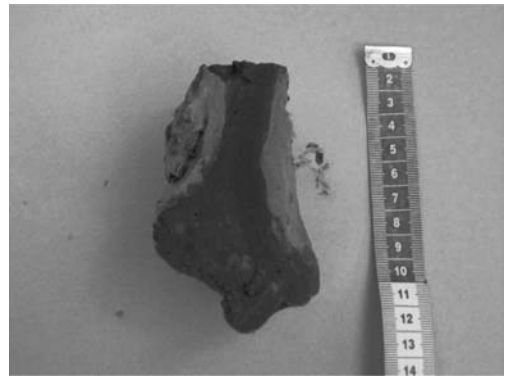

Figure 9. Injection results test 3.

'grout mixtures' was used in the tests as an injection fluid. To compare with other results, injection fluids without cement were used and in one case we used X-linked gel, a fracture fluid that is used in the oil industry to create fractures.

The injection rate in all tests was 167 ml/s. All tests were run with a relative density of the sand sample of around 65%. The confining stress on the sand was 100 kPa on all tests and the pore pressure in the sand was only a few kPa.

The first two tests resulted from the conclusions of the test series described before (Kleinlugtenbelt et al. 2006). A very impermeable grout mortar was used, but this did not lead to fractures, probably due to the relative high percentage of solids in the injection fluids. Even with a limited amount of leak-off this leads already to a plastering layer that prevents fractures, see also the discussion section.

Two injections were performed with the sand model of test 3. It appeared that the second injection was capable to fracture the grout body that was formed by the first injection, but was not able to fracture the sand any further, see Figure 9.

The fourth test was performed with X-linked gel. This test was performed to test the model set-up. X-linked gel produces fractures in a comparable model set-up (De Pater & Bohloli, 2003). We also found fractures in our test set-up for this injection fluid, see Figure 10.

The last two tests also resulted in fractures, but only to a limited extent, because in both cases there was a considerable leak-off, see Figure 11.

4 DISCUSSION

The results of these tests, together with the results of Kleinlugtenbelt et al. (2006) and De Pater & Bohloli (2003) show that it is not easy to get long hydraulic fractures in sand. Fractures as predicted by the model

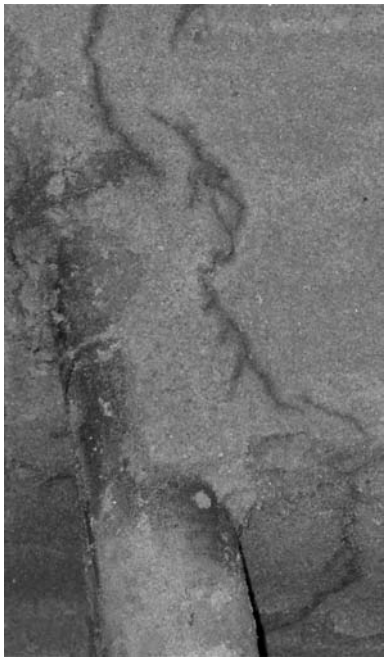

Figure 10. Fractures obtained using X-linked gel.

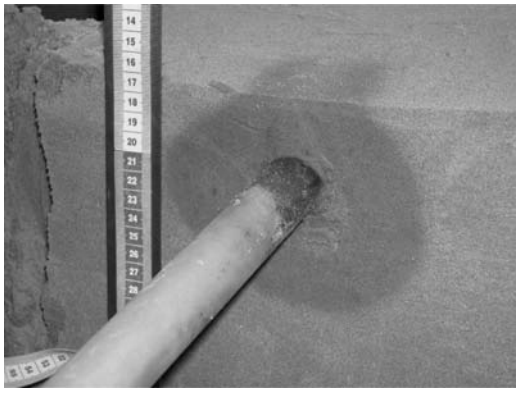

Figure 11. Results test 6 with some fractures and a considerable leak-off.

of Grotenhuis (2004) could not be produced in the tests using mixtures of bentonite slurry and cement or silica flour.

The reason is that the traditional grout mixtures (5% bentonite and a WCR of 3 or less) are too permeable, when pressurized the consolidated material will form a cake, which will prevent a fracture as described in Section 2. This can be shown by using Equation (2) that is plotted in Figure 12. Calculations were run for

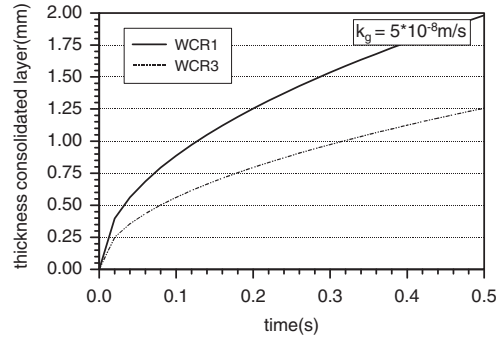

Figure 12. Plot of equation (1) for relevant permeabilities and injection times. Results show that with WCR 3 a filter cake of several tenths of mm is formed with one second.

0.5 s, approximately the time necessary to pressurize the injection hole. It can be seen that in this period the consolidated layer is already significant compared with the grain size diameter (d_{50} = 130 μm).

The mixture in test 1 and 2 did not fracture because of the leak-off. This leak-off causes the fly ash and the silica flour to gather at the interface between the injection fluid and the sand. The leak-off after the test was approximately 10 mm. The ratio (with respect to the weight) between water and fly ash or silica flour was 3. Neglecting the weight of the bentonite (only 7%) the ratio in volume for silica flour is 3*2650/1000 = 7.95 (the correction for the difference in density), for fly ash this is 3*2900/1000 = 8.70. Assuming that the porosity of the silica flour after sedimentation is roughly comparable to the porosity of the sand this means that a leak-off of 10 mm into the soil will result in a layer of silica flour of 1.3 mm, which is again much more than the grain size of the sand. Leak-off itself does not hamper fractures, as long as no filter cake is formed, but leads to less fluid that can contribute to the fractures. This is shown from the results from Test 5 and 6.

The results show that fracture grouting in clean sand will be more an exception than the normal result of a compensation grouting process. Projects where, according to the contractor, settlement in sand is corrected by fracture grouting will in most cases be examples of compaction grouting, unless there is cohesion in the soil or the soil is much more impermeable than the soil tested here (with a permeability of 10^{-4} m/s). Since compensation grouting projects are executed deep under the soil surface it is seldom known what is created, only in few cases where there was the opportunity to investigate the fracture afterwards because some soil has to be removed. Some projects report high injection pressures, which indicate that there is a kind of compaction due to cavity expansion.

How compensation is achieved, is of importance for the field situation, because it indicates how localized the compensation will be. Fracture grouting will result in heave over a wider area than compaction grouting.

5 CONCLUSIONS

From the tests performed we came to the following conclusions:

1. The grout as used in practice formed a dehydrated cake between the injection fluid and the sand where through a fracture could not propagate.
2. More cement in the grout mortar results in a thicker and more permeable filter cake.
3. Tests implemented with a low amount of particles and impermeable filter cake gave small fractures. From this we concluded that the dry mass entity of the hydraulic fracture fluid also has a major influence on the mechanism of fracturing.
4. Too much leak-off decreases the amount of injection fluid that can really contribute to the fracturing, where through the fracture stays small. (Cement can counteract the leak-off through the acting reactions of calcium.)

Software solutions for sensitivity studies in design of tunnels

E. Bieth
Centre d'Etudes des tunnels, Lyon, France

L. Chantron
BG Bonnard & Gardel Ingénieurs-conseils, Lyon, France

P. Roure
Itech, Paris, France

ABSTRACT: The design of a tunnel is characterized by certain degrees of uncertainty, particularly in regard to the characteristics of the rock mass. As a result, in the design of tunnels a certain level of risk is not completely avoidable and therefore, sensitivity studies are highly recommended. The design and sizing studies of tunnels require different calculation methods providing connected information. Many cases require a finite element method analysis. Yet, during the initial study phases for ordinary tunnel designs, the geometry of the excavation and structures stems from a systemization of standard profiles commonly employed. A complete software (C-Tunnel) dedicated to tunnel design has been developed by CETU (The "Centre d'Etudes des Tunnels" is the French tunneling study Center which is part of the French transports Ministry) and the producer of computation software ITECH. This software includes a finite elements tool (Plane strain Module), a convergence-confinement tool and many other state of the art tools dedicated to design. It allows to create automatically a calculation note and offers the possibility of a fast sensitivity study of the involved parameters.

1 DEALING WITH UNCERTAINTY

Dealing with uncertainty, caused by material parameters varying in a wide range or simply by a lack of knowledge, is one of the important issues in geotechnical analyses. In underground construction, it often leads to design and construction conservatism and hence to inflated costs. Nevertheless, different ways to take uncertainty into account exist. On the one hand, there are deterministic methods associated with sensitivity studies, and on the other hand there are probabilistic ones.

1.1 *Probabilistic modelling*

The mathematical representation of uncertainty has started with the concept of probability theory. Re-cent developments made in computational modelling have established various probabilistic related methods such as stochastic finite element analysis or random set finite element method. Despite the fact that they can give a more formal consideration of uncertainties, the use of such method is not common practice. The most difficult task is to characterize input parameters with density distribution function in view of having insufficient data available for a particular project, especially in the very preliminary design steps.

1.2 *Deterministic modelling with sensitivity studies*

This is the classic engineering analysis. One runs deterministic sensitivity analyses which means varying each variable at a time while keeping all others constant. The range of variation is usually either the range between the extremes or the standard deviation.

Since using probabilistic analyses is more complex than doing deterministic ones, it is advisable to only include parameters (variables) in the probabilistic analysis which have a major effect on the out-come. For this purpose, those two approaches are complementary.

The software solution presented in this article was developed with that concern: giving a user friendly tool dedicated to tunneling design and able to assist and facilitate such sensitivity studies.

2 TUNNELING DESIGN METHODS

2.1 *Most commonly used tunneling design methods*

Calculation – or rather the justification – of underground works is a relatively recent science. It is the know-how of the engineer which prevails because

designing tunnel support was for many years considered too complex for strict engineering analysis and remained an empirical art repeating techniques that had proven satisfactory under similar conditions in the past. This similarity approach is principally based on various geotechnical classification systems (Bieniawski's RMR, Barton's Q system,. . .).

In addition to that approach, the design and sizing studies of tunnels require different calculation methods providing connected information. We can first quote the convergence-confinement method. Recent advances made in computational modelling have extended the use of numerical methods. Because of the huge of time required by a full three dimensional analysis, the most commonly used numerical methods in current design are the followings:

– plane strain analysis
– axisymmetric

2.2 *Provide connected information*

As it was said, there is not only one method to compute a tunnel support, and even less only one solution. According to the geological and geotechnical configuration, as well as the geometry and the environment of the work, a technique will be more suitable than another to provide the wanted result. And very often, the only choice of the kind of result conditions the choice of the method !

As illustration, let us take the case of a not-circular tunnel, dug at strong depth in a homogene-ous and isotropic ground. The particular geometry of the excavation section makes one choose a plane strain finite-element computation. To determine the confinement-loss value at the installation of support, required for the phased-computation, it will be nec-essary to use the convergence-confinement method principles or better, to carry out an axisymmetric computation with an « equivalent » circular tunnel. A data-processing tool making it possible to handle all these methods at the same time, while passing from the one to the other and preserving the under-ground « state of the art », thus constitutes a price-less saving of time.

3 SOFTWARE SOLUTION

3.1 *Purpose*

The reports established in the preceding paragraphs underline the complexity and the complementarity of calculations for tunnel design. The main characteristic is the permanent interaction ground-structure.

The studies carried out by CETU (The "Centre d'Etudes des Tunnels" is the French tunneling study Center which is part of the French transports Ministry) and a professional of FEM calculations and producer of computation software ITECH deal with the design of support and lining structures for tunnels and the subsequent development of a complete software (C-Tunnel) which makes it possible to lead huge sensitivity studies starting from the most elaborate methods of calculation.

It was also developed to responds to two main issues:

– the pre-design of tunnels may require the analysis of a great number of alternative scenarios
– the large majority of preliminary studies can be performed on a restricted number of standard geometries

3.2 *Many tools dedicated to design*

The functionalities proposed are based on the state that most of tunnel calculation reports mainly use simultaneously the three methods described just before. Furthermore, a pre-design study also requires the practitioners to estimate some of the parameters and in the previous steps of a project, engineers do not spend lot of time on various calculations. Therefore, they need help to build the numerical model and practical tools to analyze the results.

In order to respond to these demands, the software would be articulated around three methods of calculation:

– The analytical convergence-confinement method analysis
– FEM analysis: plane strain FEM analysis and axisymmetric FEM analysis (axisymmetric analysis is not available yet)

The other main characteristic is that the model would be only defined by project parameters (geometry, soil properties) and the results automatically extracted on pre-selected sections and summered in an automatic report.

In fact, most of the steps of the model generation process can be automated, from the definition of the tunnel geometry to the publishing of the report. The usual modelling steps specific to the finite element method such as meshing, definition of the boundary conditions and application of the loads are here fully automated according to finite element best-practice.

Finally, the software works as it is presented in figure 1.

The different tools are presented in detail just bellow.

3.2.1 *Analytical convergence-confinement tool*

This tool allows to carry out studies for pre-design of tunnels according to the convergence-confinement method.

Several configurations are proposed:

1 The convergence curve of soil is defined selecting one of the four following material behaviors:
– Mohr-Coulomb,
– Mohr-Coulomb with softening,

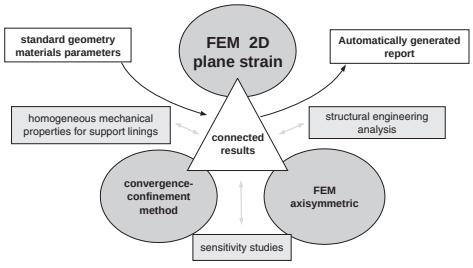

Figure 1. Software architecture.

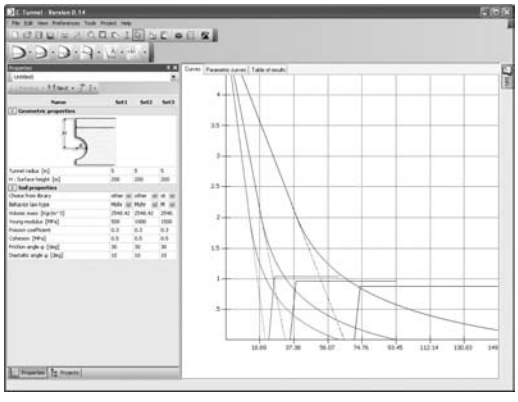

Figure 2. Parametric study with the convergence-confinement tool.

– Hoek and Brown,
– Hoek and Brown with softening.

2 The displacement curve at lining setup is defined from one of the two following methods:
– Elastic method (AFTES)
– Similarity principle

Using an input in grids, the convergence-confinement tool enables to vary very simply parameters in order to test their sensitivity (Fig. 2).

It displays simultaneously the results of all the studies, allowing a graphic visualization of the influence of a parameter.

The user can also visualize curves of variation of a result according to a parameter.

An automatic report will synthesize the results.

3.2.2 *FEM tool*

C-tunnel implements the finite element method for two-dimensional calculations in plane strain. It uses for these calculations solver CESAR-LCPC designed by the LCPC (Laboratoire Central des Ponts et Chaussées, France). The steps of the user are as follows:

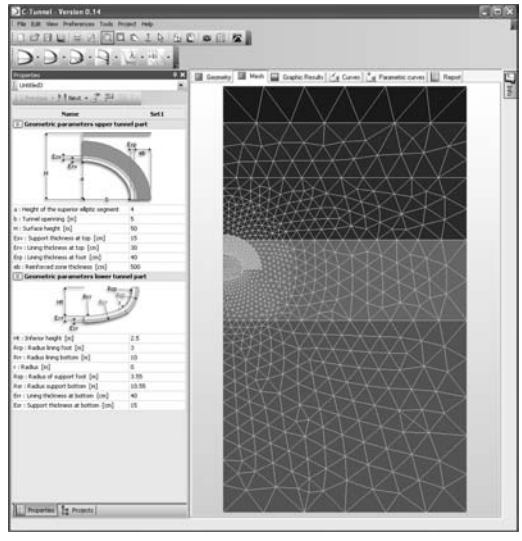

Figure 3. FEM tool: automatic creation of the mesh from geometrical parameters.

– Description of typical section (from many current sections)

  Model is defined from geometrical parameters; Finite Element mesh used by solver CESAR is automatically generated. Yet, during the initial study phases for ordinary tunnel designs, the geometry of the excavation and structures stems from a systemization of standard profiles commonly employed.
– Input of material properties: Soil layers, reinforced soil, lining, support, lateral pressure coefficient, long-term effects coefficient, ground water level,. . .
– Input of confinement loss coefficient: (Manual definition or use of convergence-confinement tool)
– Choice of the method of tunnel excavation: excavation in full section or half-section, that determines the phases of calculation.

All the steps dedicated to finite elements modelization are automatically managed by the software: creation of the mesh, definition of the boundary conditions. . . That enables to be freed from the modelization errors and gives once again the possibility of testing the influence of parameters.

The results are graphically exploited and synthesized via a report generator, selecting, phase per phase, required results for design.

The choice is offered to simulate full face or half section excavation.

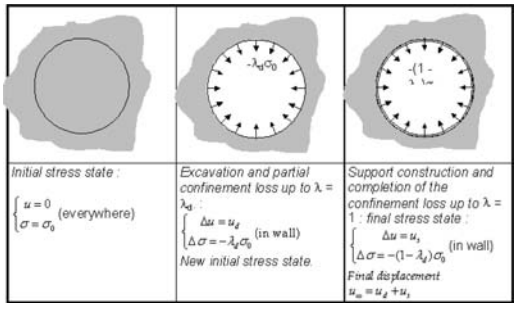

Figure 4. Modelling steps for full face advance.

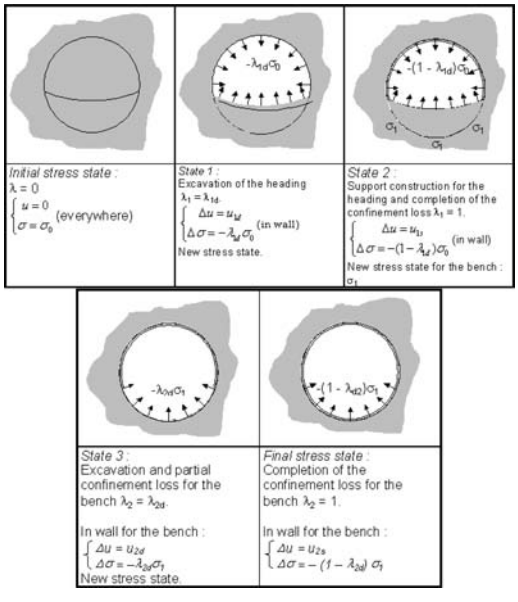

Figure 5. Modelling steps for top heading and bench excavation.

– For full face excavation, the tunnel advance is simulated by a single confinement loss (Fig. 4).
– For top heading and bench excavation, two confinement loss are needed (Fig. 5).

3.2.3 *The additional wizard*

Using the direct characteristics of projects, the wizards bring their technical "appreciation" around the software C-Tunnel.

The wizard for Bolting: It allows, starting from the mechanical characteristics of the bolts, to deter-mine the increase of the cohesion in the reinforcement area.

The wizard for mixed Supports: it makes it possible to calculate, starting from the properties of the concrete and of the steel arches, the homogeneous characteristics of the supports. It also enables

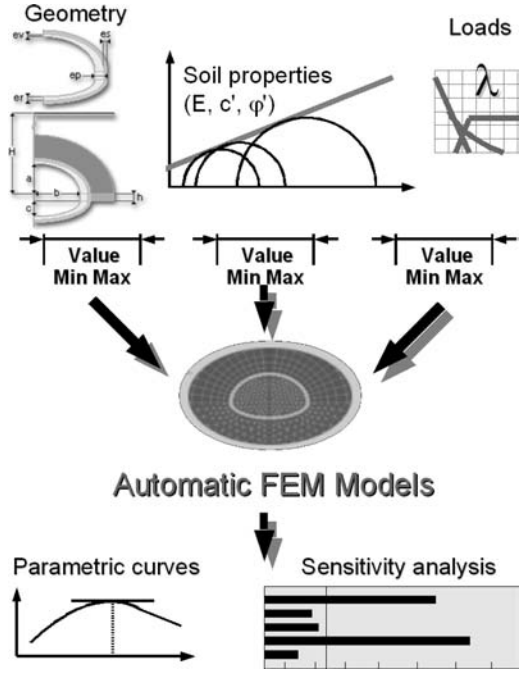

Figure 6. Sensitivity studies principles.

to calculate the distribution of the efforts within the concrete and the arches.

In addition, each module of calculation or wizard uses material libraries which are managed like true data bases by the user.

3.3 *Leading sensitivity studies easily*

In tunneling design, the advantages of numerical modelling have been appreciated by practitioners. Therefore, it seems to be logical to combine numerical modeling with concepts for sensitivity studies.

Then, each tool is developed to encourage those studies. The user only have to choose one or more project parameter and define min and max values. The software will automatically compute models and propose parametric curves for the selected parameters (Fig. 6).

4 CONCLUSIONS

Tunneling design studies are hard work especially for an engineering structure due to uncertainty in geotechnical properties. Therefore, sensitivity studies are highly recommended for the pre-design studies. In order to encourage taking that uncertainty into account, a new software has been developed, based on the FEM code CESAR LCPC. It allows the use of various connected calculation methods and structural

tools and offers help to make fast and easy sensitivity studies.

It is thus beneficial to make use of "trade"-specific tools, as a complement to the geotechnical computation codes for more specialized interfaces; such tools apply this systematization by automatically conducting both a numerical model and the standardized interpretation of results.

Safety problems of underground structures in the design

N. Bulychev & N. Fotieva
Tula State University, Tula, Russia

A. Levchenko
Department of City-Planning Policy Development and Reconstruction of Moscow, Russia

ABSTRACT: A high degree of safety of underground structures such as lining and support in the design is provided by a strength computation. Design methods of underground structures are very difficult in comparison with other structure types because of the interaction between the structures and the surrounding rock mass. That is why the first problem of the safety provision of the underground structures consists in choosing the design method is that which faithfully valid physical essence of the lining – rock mass interaction.

The second problem lies in the authentic input data securing for computation or modeling the underground structures. Obligatory input data are the following: characteristics of the intact rock mass stress state (magnitudes and directions of principal stresses) as well as deformation characteristics of rock mass in the position taking into account the scale effect. The fact is that the concrete lining is loaded at the same time when the shuttering demoulds.

1 INTRODUCTION

1.1 *Fundamentals*

Safety of underground structures contacted with the rock mass such as a lining or support is provided in the design by strength computation. The basic principle in modern theory of underground structures design is that of joint contact interaction of the rock mass and the lining. In accordance with that principle the lining and the rock mass are elements of a united deformable "rock-support" system subjected to external loads and actions (Bulychev 1994, Bulychev & Fotieva 1999, 2001). According to the theory it has been established that the rock pressure or, more precisely, contact stresses on the interface between rock mass and support, is not fixed but depends from both technology and support stiffness. Due to that peculiarity underground structures methods have been recognised as not having analogies among other engineering structures in respect to the design.

That is why the first problem of the high degree of safety of underground structures during the process of the structures design resides in proper choosing the design method for them.

The next problems depend from the chosen design method and lay in determination of input data for the design method.

Obligatory input data are the following:

- characteristics of the intact rock mass stress state (magnitudes and directions of principal stresses),
- deformation characteristics (modulus and Poisson ratio) of rock mass in the position taking into account the scale effect,
- strength and deformation characteristics of tunnel lining materials,
- characteristics of tunnel (shaft) lining erection technology especially lining lag behind tunnel face advancing.

2 BRIEF REVIEW OF TUNNEL LINING DESIGN METHOD

2.1 *Methods of fixed loading*

The first attack the problem of the tunnel lining design was application of the ordinary design methods considering underground structure as ordinary one. The design method was discussed as consisting of two steps: design (calculation, as such) and loads (rock pressure) determination. It was proposed that the rock pressure is conditioned only by rock mass properties.

The next step of the underground structures design evolution was a model of ring beam on elastic

(Winkler) base (rock mass). It should be pointed out that the design scheme of bedded ring beam and the corresponding widely spread method of tunnel lining design was developed by Russian engineers-designers when the Moscow Underground construction has been started (Bodrov & Matery 1936).

The rock mass model (the elastic Winkler foundation) is not loaded in relation to lining because of that the bedded ring beam method involves fixed "active loads" taking into account a "passive loads" due to the reaction of the elastic base.

At the present time the traditional calculation methods of both fixed and fixed active loads as well as a century-long efforts to understanding the rock pressure independently of the tunnel lining characteristics are not correct in general. That is proved today. In spite of that those methods are discussed and practically currently recommended for use (IBSM 1995, Japan Society 1996, ISSMGE ERTC 9 1997, ITA 2000).

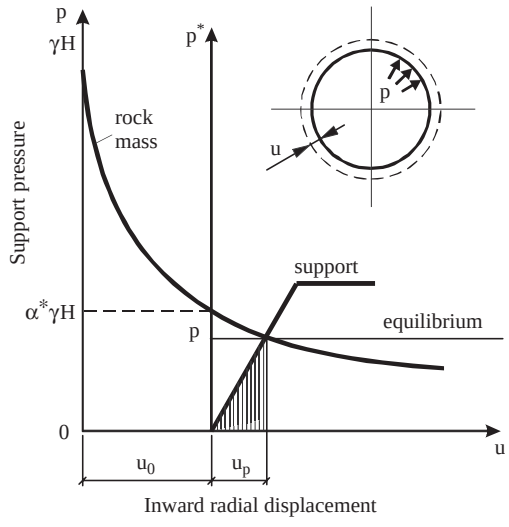

Figure 1. Scheme of interaction between rock mass and tunnel lining (u_0 is initial displacement before the lining is installed, u_p is joint displacement of rock mass and lining as result of their interaction).

2.2 *Methods of interactions between lining and rock mass*

Notions about tunnel lining function were sufficiently changed by Fenner (1938) and Ruppeneyt (1954). They have given us insight into the mechanism of the rock mass and lining (support) interaction. The curve in Figure 1 illustrates response of lining to tunnel walls displacements resulting in establishment of equilibrium. Owing to them a great step has been made towards the theory.

Thanks to that investigations it has been found the principal peculiarity of underground structure, namely, the interaction between a structure and surrounding rock mass. It has been established that the rock pressure or, more precisely, contact stresses on the interface between the rock mass and support, is not fixed but depends from both technology (u_0) and support stiffness (u_p). Due to that peculiarity underground structures methods have been recognised as not having analogies among other engineering structures in respect to the design.

One may distinguish three directions of the following development of the underground structure design methods taking into account the principle of rock-support interactions:

- New Austrian Tunnelling Method (NATM)
- physical equivalent material (sand and plaster) modeling
- numerical modeling (FEM)
- analytical design method.

The NATM is the first that found a practical implementation of Fenner-Ruppeneyt investigation. It is well known that generally recognised NATM is based on the philosophy of following relations represented at the Figure 1 (Rabcewicz 1973, Muller 1990). The concept of the NATM is to construct a tunnel on the basis of scientifically established principles and ideas which have been proved in practice, the main idea being that by mobilising the bearing capacity of the rock mass. The NATM philosophy is the use of instrumentation to monitor the deformation of the excavation and the build-up of load in the support or reinforcing elements. In this manner the NATM is not design method. It is empirical method of underground support constructing.

The analytical methods of underground structures design are developed according to the modern theory "Underground Structures Mechanics". The theory consists in applying rigorous analytical solutions of the elasticity theory contact problems simulating interaction between rock mass and different types of supports and linings when the rock-support system is subjected to all kinds of loads and actions including a seismic effects.

The mathematical elasticity theory developed in the classical works by Muskhelishvily, Sherman, Lekhnitsky and others may be used to solve the problems of underground structures design. The analytical methods allow to obtain both direct and inverse solutions (back analysis) and optimal solution too. The analytical methods of underground structures design are developed by Savin (1947), Muir Wood (1975) as well as Fotieva, Bulychev and others.

As to numerical methods such as FEM we would like to note that numerical methods are modeling ones (not design) and they are approximate. Because of that they need to be checked for accuracy. Analytical

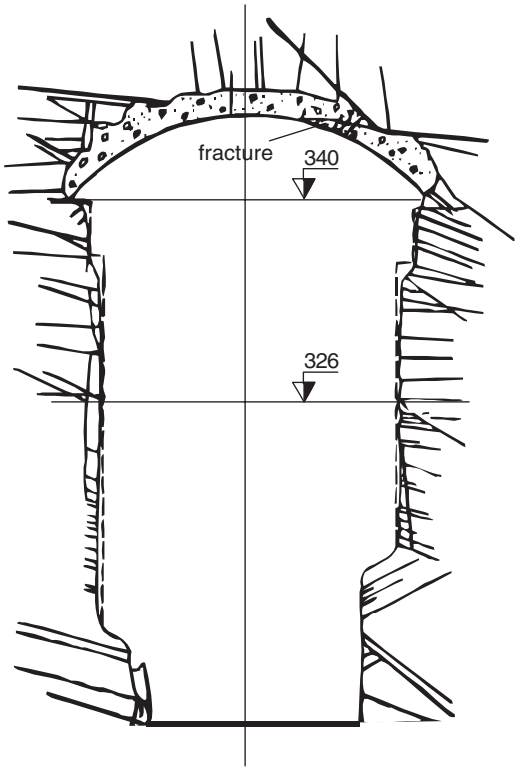

Figure 2. Scheme of fracture in the vault of Kolymskaya. Power station chamber. After Mostkov.

solutions are the only to check for accuracy numerical methods. By the way comparing results of analytical underground structures design with numerical (FEM) and physical (equivalent materials) modeling we discovered to our surprise that the result obtained by physical modeling most closely corresponds.

2.3 *Case history*

Case history is a failure of the reinforced concrete vault of Kolymskaya Power House in Siberia (Fig. 2) during the process of construction at a depth of 60–70 m (Mostkov et al 1993). The powerhouse was constructed in jointed and fractured granite with fractures filled by ice. Span of the arch was 24.7 m. According to field measurements horizontal stresses in the intact rock mass were 3.3–4.9 MPa consequently the lateral pressure coefficient represented about 2.5.

These rock mass intact stress state characteristics were ignored and the vault was worked out the design for a prescribed vertical pressure. But vault facture was caused by convergence of the chamber walls. A fracture appeared in the arch. Somewhere along the fracture the concrete was spalled and reinforcing bars were uncovered. As the chamber was constructed that fracture extended along the arch of the chamber up to 84 m length. Then the new spalling of the concrete protective layer appeared and reinforcing bars experienced buckling. The fracture in reinforced vault has the aspect of shear. In specific places the fracture is through.

According to further field measurements the convergence of the arch skewbacks comprises from 20 up to 70 mm within 7 years. The rate of the convergence at the beginning period ranges up to 7.6 mm per month.

It cannot be doubted that the reason of the vault fracture is not expected compressive stress due to convergence of the chamber walls as the powerhouse was constructed. Consequently the design methods not correlate with physical essence of the vault and rock mass interaction.

3 ROCK MASS CHARACTERISTICS

3.1 *Intact rock mass stress state*

The very important problem of the high degree safety provision of underground structures in the design consists in plausible input data securing. Among the obligatory input data are characteristics of the intact rock mass stress state.

In gravitational stress field that take place in sedimentary rocks the main characteristic of the intact stress state is only the lateral pressure coefficient. But different matter is in magnetic or metamorphic rocks especially in tectonic and seismic areas. In these cases the intact rock mass stress state characteristics represent magnitudes and directions of three principal stresses in a region of underground construction. It allows presenting those characteristics in statistic form.

The design intact rock mass stress state may be not only natural but also man-made due to technology of underground construction. These situations take place when applied frozen technique of construction (Bulychev 2005).

Let us consider the following instance preparing a shaft sinking. Rock mass – mergel at depth of 300 m, the deformation modulus is 4000 MPa, the Poisson's ratio is 0.3, the moisture transformed into ice is 6%. Natural intact horizontal stress in the rock mass is 3.2 MPa. Additional horizontal stress produced by the action of freezing is in the range of 5.9 MPa. Influence of rock freezing is obvious.

Similar situation take place when press concrete tunnel lining method is applied (Bulychev at al 2003). Pressing the stiff concrete behind a sliding shutter using the shield jacks under pressure 1–2 MPa carries out the concreting of the tunnel lining. The concrete sets and hardens under that pressure. One has to consider this pressure as a design initial soil stress state especially for shallow tunnels.

A sewer tunnel of 4 m diameter has been constructed in the center of Moscow with use the press concrete technology. Engineering geological condition was complicated: weak water bearing ground at depth up to 30 m. Operating pressure on concrete mix was 1.3–1.5 MPa what was about two times as great than vertical stress in the ground mass. According to surveying of a subsidence of buildings positioned over the tunnel the subsidence along the whole alignment of the tunnel was effectively zero.

3.2 *Deformation characteristics of rock mass*

Tunnel lining stress-strain state sufficiently depends on deformation characteristics of the rock mass namely on deformation modulus and Poisson's ratio.

At the present time there are mistakes in determination of these characteristics especially the deformation modulus. For instance real deformation modulus of clay obtained as a result of geotechnical monitoring in the course of underground tunnel construction in Saint Petersburg (Kulagin et al 2004) appears to be more than 10 times in comparison with official input data.

Similar case takes place when drainage adit in Tomsk City was driving. In this instance the difference comprises almost 100 times.

The fallacies in these instances are that the ground mass characteristics were obtained as results of specimens laboratory test. To eliminate the trouble it needs to execute of ground mass testing in the immediate occurrence of a place of tunnel driving.

4 CHARACTERISTICS OF LINING MATERIAL

4.1 *Characteristics of monolithic concrete*

Cast-in situ concrete is erected behind shuttering. The concrete mix is compressed between shuttering and rock walls due to the rock walls displacements and is hardening sometimes. Then according to the sequence diagram of the work organization the shuttering is ripped from the concrete lining.

The concrete is remoulding and because of that radial stresses that have been before at the inner surface of concrete lining are reliefed and the lining is loaded. So the lining is loaded in early age of the concrete mix hardening. Under these conditions monolithic concrete lining is subjected to twice simultaneously acting factors: hardening concrete in early age and the lining loading due to rock mass deformation.

The first accidents and concrete shaft lining failure were established on Tashtagol iron ore deposit in Siberia at the depth more than 400 m in jointed and faulted sienites and carbonate-chlorite shales. According to results of investigations the distinguished feature of the rock mass is a tectonic intact stress state: sub horizontal normal stresses are 2–3 times as much as vertical ones.

The reason of the accidents was deficient the shaft lining bearing capacity because loading in early age of concrete hardening together with increased horizontal stresses in rock mass.

Because of that the following characteristics of concrete are necessary for the tunnel (shaft) lining design taking into account the early age hardening of it: deformation modulus and compressive strength for the moment of the concrete demould. The concrete lining is to be designed for the above moment and the second design has to be executed for operating period.

4.2 *Case history*

Combined shaft sinking method is characterized that cast-in situ concrete is erected immediately above the shaft face. After rock blasting the shaft face advance and the concrete mix is compressed behind shuttering. After taking away the crushed rock the shuttering is ripped from the concrete lining and lowered to the face.

According to shaft sinking experience (Mindely et al 1970) the period of the concrete mix hardening time may range between 10 and 20 hours. In the process of rapid shaft sinking technique the hardening time may be reduced up to 3–4 hours.

It happened in 1984 at chromite ores deposit in Kazakhstan. In the Central Mine, a 8.8 m diameter cage shaft, 766 m deep, was been sinking. Inner diameter is 8 m. Rock mass consists of jointed and faulted serpentinits with cracks filled by talc. Compressive strength of the rock mass as whole is 15–20 MPa, the angle of the internal friction is 18–20° (due to talc). In addition to that intact stress state of the rock mass is characterized as tectonically with heightened normal horizontal stresses. The lateral pressure coefficient is from 1.0 up to 1.5. Because of that the rock mass may be estimated as instability. In the process of the shaft sinking unsupported rocks in shaft walls were crushed and failure.

The situation on the eve accident is the following. The face of the shaft was at the depth 765 m. Holes were drilled and blasted; the shuttering was put down on crushed rock. At that time rock failure occurs behind shuttering and part of before installed lining was fractured. To prevent further failure of rock and lining 117 rock bolts were installed and 50 m^3 of concrete mix was placed against shuttering. In spite of that cracks occur above in the lining in the range of depth 737–743 m. Work in the shaft was stopped but next day increasing fracture of shaft lining started. A total of near 200 m of the shaft lining above the face including three shaft insets was crushed.

Cause of the accident is deficient the shaft lining bearing capacity because loading in early age of concrete hardening. We emphasize that deficient the lining bearing capacity took place on 200 m part of the shaft during near two month.

It needs to be noted that the above-mentioned press concrete lining was loaded in early age of concrete hardening but the tunnel was constructed with increased requirements to the concrete quality and lining technique were made

- average length of advance of the press concrete operation was 0.33 m
- concrete mix pressing cycle took 2.5 hours
- the class of concrete strength was B60
- the strength of high-early-strength concrete mix after 5 hours was 5.0 MPa and after 7.5 hours was 11 MPa
- the brand of watertight was W16.

5 CONCLUSIONS

A high degree of safety of lining in the design is provided by a strength computation.

The first problem consists in proper choosing the design method correlate with physical essence of the lining-rock mass interaction. The next problems lay in obtaining obligatory reliable input data for the design method.

Stability and deformations in large-scale underground constructions

A. Butovic
Satra spol. s r.o.

ABSTRACT: As the tunnel construction under the town develops, also technical demands of their implementation increase. The underground location of factories, hydropower stations, road networks etc. lead to a demand for construction of large-scale underground works. Modern technology allows for the development of incredible feats of engineering, which could not be even dreamt of by our predecessors. But, of course, even today there are certain limits. The article analyses the stress and deformation response to the excavation process. Possible solutions of constructing in such loose rock have been calculated from mathematical modeling using the final element method (FEM). The choice face are sequencing and influence of anchoring from the point of view of the stress and deformations influence on the rock. Examples are shown on completed constructions in different geotechnical conditions in the Czech Republic. The article compares and provides quantity assessment of the influence of individual measures and sets possible limits for some particular cases.

1 LARGE-SCALE UNDERGROUND CONSTRUCTIONS IN THE CZECH REPUBLIC

1.1 *Introduction*

Geomorphology of the terrain in the Czech Republic does not call for the construction of a high number of the tunnels. In most cases it is beneficial to find cheaper, non-tunnel solutions for the direction of the road and railway routes. In spite of this, many interesting underground constructions have been built over the last century. As a reference we can show almost 60 km of the Prague's metro underground network plus the new Mrazovka tunnel.

A significant chapter of the Czech underground architecture is the construction of the large – scale underground structures. Except for the military construction it is possible to mention at least:

- Pumped storage "Dlouhe strane"
- Excavated tunnel forks of the Mrazovka tunnel
- The Kobylisy excavated one-vault metro station
- The "Blanka tunnel" ventilation machinery room

Basic information about the above examples is adduced in the following paragraphs.

1.2 *Pumped storage "Dlouhe strane"*

The construction of the pumped storage "Dlouhe strane" is one of the most technically unique constructions in the Czech Republic. It is located in the Northeast part of the Czech Republic in Jeseniky Mountains. It was built in a period from 04.1978 to 12.1996 and in the time of its construction it was one of the world's top structures. The extended time of a construction was due to different non-technical reasons, which are not pertinent from underground construction point of view.

Main construction parameters :

Storage cavern	$87 \times 25.5 \times 50$ m (l, w, h)
Transformer station cavern	$115 \times 16 \times 21.7$ m
Declivity	534.3 m
Supply tunnels	d. 3.6 m, l. 1547 m (1499 m)
Waste tunnels	d. 5.2 m, l. 354 m (390 m)
Volume of the excavated space	290.000 m^3

All construction was built into the stable rock, which represent gneiss.

The excavation site of the caverns was reinforced by steel rock bolts and by a primary lining from the shot crete. A final lining was constructed from reinforced concrete and the supply tunnels were lined with steel.

A point of interest: Two Francis turbines were installed with a total performance 2×325 MW. During electricity production there are 68 m^3/s traversing there, by reverse it pumps up to the height 534.3 m 55 m^3/s.

Figure 1. "Dlouhe strane" cavern.

Figure 2. East tunnel fork excavation.

Figure 3. East tunnel fork – current state.

1.3 *Excavated tunnel forks of the Mrazovka tunnel*

The Mrazovka tunnel is about 1.1 km long tunnel, which is a part of Prague city ring, and its construction was completed in 2004. Complicated motoring solution requested implementation of two excavated tunnel forks. This concerned those parts of the tunnel where three-lane tunnels, with the area of excavation of 165 m^2, gradually broaden and are divided into independent two-lane (122 m^2) and one-lane (85 m^2) tunnels. Vertical sequencing was chosen for excavating by experience from previous excavated parts and math modelling by final element method (FEM).

Main construction parameters:

Total length	53.7 m	(21.1 m)
Excavated cross section	322.0 m^2	(335.1 m^2)
Excavation clearance	16.0 m	(16.6 m)
Excavating width	23.8 m	(24.2 m)
Volume of the excavated space	13.090 m^3	(12.790 m^3)

The excavation proceeded in bad clay-dust shales (E_{def} = 100–200.000 Mpa, ν = 0,31–0,29, φ = 31–35°, c = 35–60 kPa) with the total overburden depth of 19–24 m (20–35 m). There were many houses and engineer networks in the area. The performed excavation was protected by hydraulic rock bolts 6–8 m in length and by primary lining from shot-crete with the width up to 700 mm reinforced by steel frames and meshes.

1.4 *The Kobylisy excavated one-vault metro station*

The Kobylisy Station of the Prague metro route 4.C is the first station, which was constructed as one-vault. It was installed in rock of Ordovician age, which represents clay-dust shales (E_{def} = 100–350.000 Mpa, ν = 0,3–0,27, φ = 30–34°, c = 40–100 kPa) and crushingly roughed quartzites. There were blocked sandstones in overburden. There were many houses and engineer networks on the surface of this area corresponding with Mrazovka tunnel fork.

Main construction parameters:

Total length	148 m
Excavated cross section	220 m^2
Excavation clearance	13.8 m
Excavating width	21.2 m
Volume of the excavated space	32.560 m^3
Sequencing	combined

Figure 4. The Kobylisy metro station excavation.

Figure 5. The Kobylisy metro station – current state.

A combination of the vertical and horizontal sequencing was chosen for excavation. The excavation site was reinforced by hydraulic rock bolts 6 m in length and by shot-crete, reinforced by steel frames and meshes.

Maximal surface settlement did not exceed 75 mm, the deformation of the primary lining reached in maximum 60 mm.

1.5 *The "Blanka" tunnel ventilation machinery room*

Currently next large scale underground construction is being prepared. It will be the construction of the excavated ventilation room designed as a part of the continuation Prague city ring.

Main construction parameters:

Total length	123.3 m
Excavated cross section	298.8 m^2
Excavation clearance	18.3 m
Excavating width	20.2 m
Volume of the excavated space	36.850 m^3
Sequencing	vertical

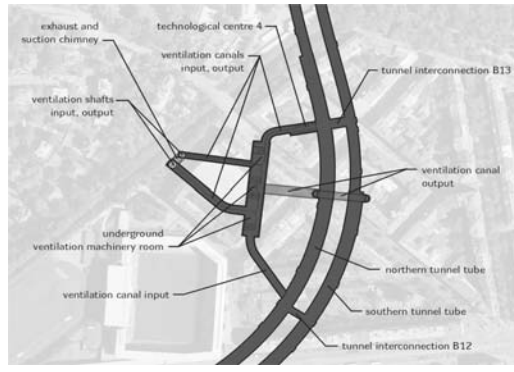

Figure 6. The ventilation machinery room – situation.

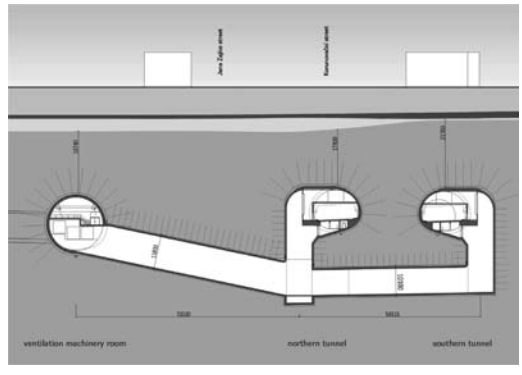

Figure 7. The ventilation machinery room – cross section.

It will be constructed in good sandy shales ($E_{def} = 200–600.000$ Mpa, $\nu = 0{,}27–0{,}24$, $\varphi = 34–37°$, $c = 45–150$ kPa) with total overburden depth 32–33 m. There are many buildings on the surface.

The ventilation machinery room excavation is not main problem, there are five another big tunnel profiles (about 120 square meters), which cross it.

This tunnel will be under construction at the end of year 2007.

2 DEFORMATIONAL – TENSENSESS ANALYSIS

The above constructions have one thing in common; the size of the excavation complicates their performance from two main reasons:

1. Technological – available mechanical mechanization is not able to work in a heights transcend 7 m (except TBM)
2. Deformational-tenseness – depending on quality of the rock condition, overburden height etc. it is necessary to choose suitable performing procedure and

completion of unsupported excavation. Except for cases when the underground construction is carried out in carefully chosen conditions it is the deformaltensensess that plays the most important role.

Different variants of the excavation approach were solved based on the example of the East Mrazovka tunnel fork by mathematical modeling by Final element method (FEM):

1. Full profile excavation without rock bolting
2. Horizontal sequencing (top heading and invert) without rock bolting
3. Vertical sequencing without rock bolting
4. Full profile excavation with 8 m long hydraulic rock bolts
5. Horizontal sequencing (top heading and invert) with 8 m long rock bolts
6. Vertical sequencing with 8 m long rock bolts
7. Full profile excavation with 12 m long hydraulic rock bolts
8. Horizontal sequencing (top heading and invert) with 12 m long rock bolts
9. Vertical sequencing with 12 m long rock bolts

Number 6 variant has been used for tunnel fork excavation.

Annotation: The calculations of the full profile excavations without rock bolting have not been finished.

Program that was used is Tunnel by RIB Stavební software Company, version no.12. The rock condition has been modelled as homogeneous isotropic material considering Mohr – Coulomb material law, with an assumption of strain plain.

The influence of the rock bolting was implemented into the model as a change of material characteristics of the rock bolted area elements by (5).

The calculations have been executed just for one particular example of the rock condition.

Variant number 6 was chosen as a base for percentage results comparing; it represents the real excavation of the Mrazovka tunnel forks.

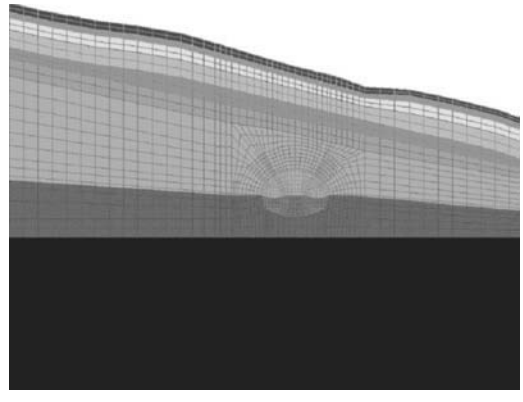

Figure 8. Model geometry.

Where: Lining deformation – vertical element of the lining displacement in an arch crown; Surface settlement – vertical element of surface settlement above tunnel geometrical axis; N – Axial force in a lining in an arch crown; M – Bending moment in a lining in an arch crown; Stress – main stress in rock conditions on left side of the excavation.

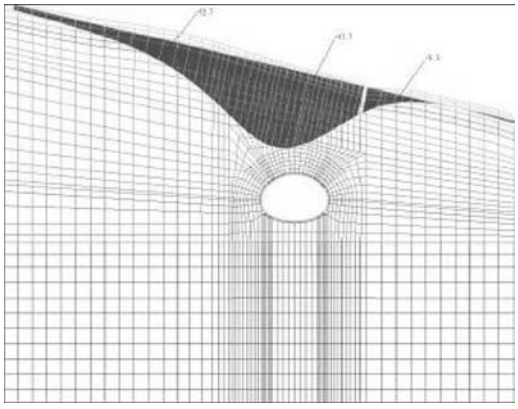

Figure 9. Model results – settlement of the surface.

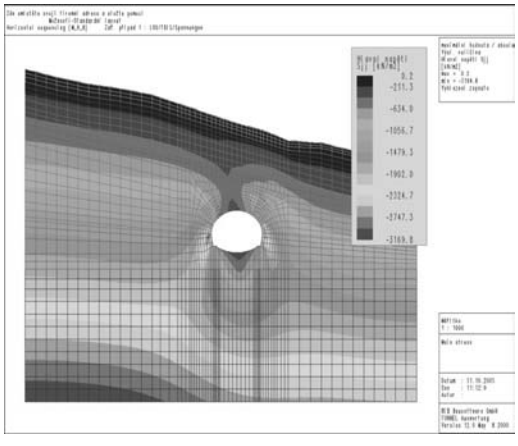

Figure 10. Vertical stresses – horizontal sequencing.

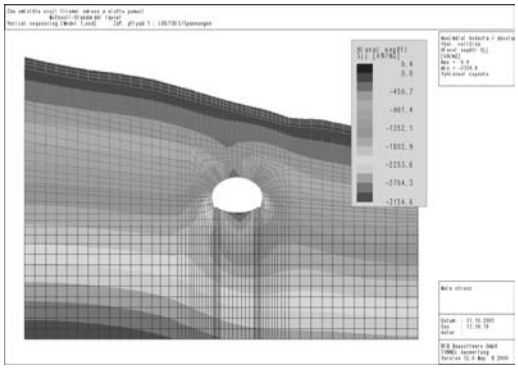

Figure 11. Vertical stresses – vertical sequencing.

3 CONCLUSION

1. The calculation simulating the tunnel fork full profile excavation without influence of rock bolting was not successfully finished. The results considering the influence of the rock bolting show unreal values. The above mentioned indicates that full profile tunnel fork excavation is according to the deformal – tensensess analysis unreal.
2. The choice of the sequencing has fundamental influence on the values of the displacements of the primary lining, rock conditions and surface settlement. In this case the displacements of the primary lining with horizontal sequencing are about 140% higher than at vertical sequencing. The similar result was registered at surface settlement where calculated difference is 70%.
3. The values of the axial forces in the primary lining are similar in both cases; the type of sequencing has no influence on it.
4. Large influence has been registered at bending moment (top of the arch), which in the case of the horizontal sequencing increased about 230%. This result is real and is related to a different history of rock massif loading and different span of the arch (the influence of the side wall tunnels).
5. The vertical sequencing is distinctively more "careful" to the rock massif, which can be seen from the side rock massif stress comparing, see pict.10, 11.
6. The rock bolting influence is certainly in all cases positive, particularly in the case of the horizontal sequencing. I expect its influence to be larger, calculated values probably relate with the implementation of the rock bolts to the mathematical model.

Particular design for nuclear long term interim storage

N. Dias & J. Triclot
Scetauroute DTTS, Pringy, France

H. Lagrave & E. Breton
CEA, Valrho, France

ABSTRACT: The third research topic of the 1991 French nuclear waste management act covers long-term interim storage. Two options are being investigated for waste packages: surface and subsurface storage. The object of this article is to describe the particular designs of the subsurface storage, which are based on a network of shafts and tunnels. In this study, we propose the organisation methodology of civil engineering construction for two kinds of waste: high-level waste and intermediate-level waste.

1 INTRODUCTION

The French Atomic Energy Commission (CEA) has carried out a major R&D programme on underground interim storage for spent fuel and nuclear waste (CEA., 2005). The programme concerns the design of storage facilities, durability and functional performance demonstrations.

The R&D aspect conducted by the CEA includes the demonstration of the long-term performance of concrete structures subjected to thermal and mechanical stresses.

The CEA asked SCETAUTOUTE DTTS to carry out the civil engineering construction design and the associated organisation methodology. It should be emphasised that many earlier studies were carried out in order to finalise these particular designs.

In this study, the organisation methodology of Civil Engineering construction is described for two kinds of long-term interim storage:

1 High-Level long-lived Waste Storage (this entire process will be referred to as "HLWS" as follows) and spent fuel storage.
2 Intermediate-Level long-lived Waste Storage. (referred to as "ILWS").

The storage design of these two wastes is different due to their thermal and mechanical characteristics: the high-level wastes are exothermic. The required design conditions are that, the subsurface facilities must have a target 300 years life, where the first 100 years should be without major repairs.

After a description of each kind of subsurface storage design, this article focuses on excavation processes for underground works, different logistic ways to link with milestones, and construction costs for the options considered are presented.

2 PROJECT DESCRIPTION

2.1 *Location*

The subsurface storage for the two facilities is located between 50 m and 100 m below ground level on the hillside, above the water table. This geometrical situation allows water to drain by gravity.

2.2 *Geological and geotechnical conditions*

At present, the real construction site has not been identified, so this research is based on a "generic" site represented by limestone rock with enhanced geotechnical parameters. The rock mass fracturation is considered to be moderate. (Fig. 1)

The main 150 m thick geological layer of is composed of good quality limestone called F1. Layer F1 is situated between two geological layers called F2 and F3 represented by marling limestone. The site is

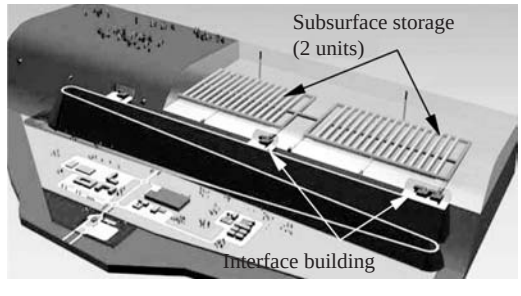

Figure 1. Geological location of subsurface facilities.

intersected by two major geological faults (ZF1 and ZF2). (AFTES GT1).

The geotechnical parameters are represented in table 1. (AFTES GT7).

According to the rock mass classification published by Bieniawski (Barton & al. 1974b), (Bienawski, 1984), the RMR value for each layer is as shown in table 2.

2.3 *High level waste storage (HLWS)*

The design of the HLWS is composed of several units, for instance, the spent fuel is made up of six units.

Each unit is composed of 6 parallel galleries divided into two levels, and linked to each other by vertical shafts. In these shafts the waste packages are stocked. The dimensions of each underground unit are approximately 800 m long by 160 m wide. The number of shafts depends on the kind of waste, varying between 600 and 720 per unit (100 or 120 per gallery). The access for each unit is provided by a single interface building, situated in the hillside. Figure 2 presents the scheme of one unit.

Seven types of gallery are distinguished. As an example, table 3 describes different gallery types for spent fuel.

The distance between the upper ventilation galleries is 26 m. The distance between vertical storage shafts is 3.70 m.

Two packages of HLWS waste are set down in each vertical shaft. The package loading is carried out by a special handling vehicle, which accesses through the upper ventilation gallery (Fig. 3).

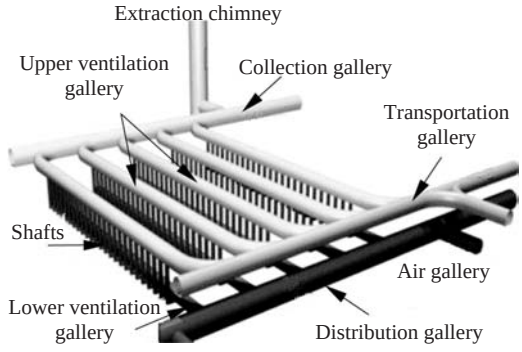

Figure 2. Scheme of one unit (HLWS).

Table 3. Gallery characteristics in terms of length and section.

Gallery name	Length m	Excavated section m^2 (Profile N2)
Transportation and handling gallery	182	108
Upper ventilation gallery	4620	60
Lower ventilation gallery	3782	46
Storage shaft (720 per unit)	12384	13
Distribution gallery	156	97
Collection gallery	156	108
Chimney	65	89

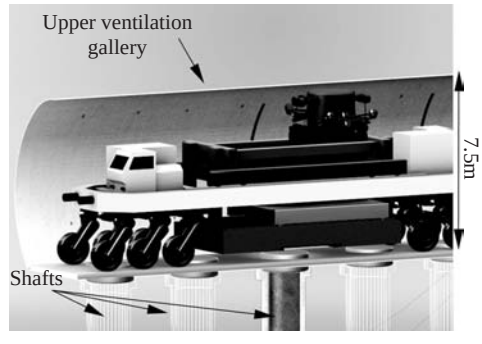

Figure 3. Handling in the upper ventilation gallery.

The HLWS design takes into account the waste temperature effects in the underground structure (with a maximum temperature of about 80° C). (Lagrave & al. 2006).

The ventilation concept plays an important role in the storage of exothermic HLWS waste packages.

The cooling air arrives by the distribution gallery from outside in order to supply the lower ventilation gallery. As a result, the packages are cooled by natural

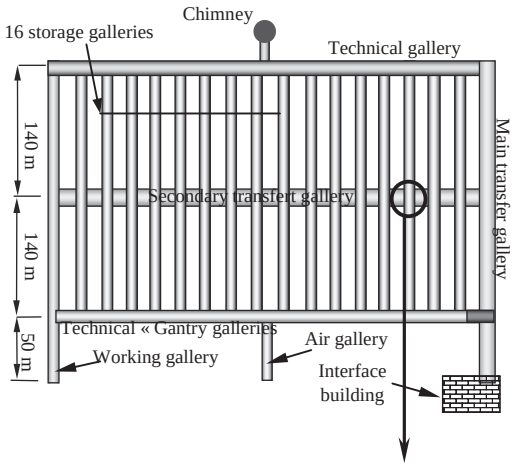

Figure 4. Scheme of ILWS unit.

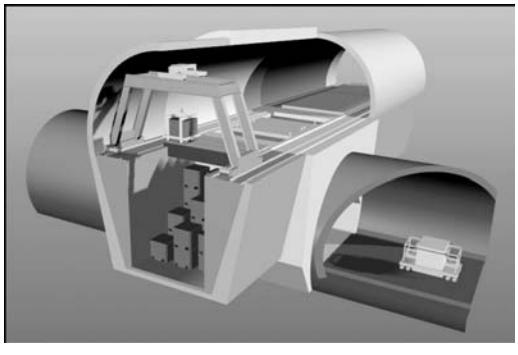

Figure 5. Crossing between the secondary transfer gallery and the storage gallery.

ventilation due to the temperature difference between outside and inside which draws air into the collection gallery and then towards the extraction chimney. (Lagrave & al. 2005).

2.4 *Intermediate-level waste storage (ILWS)*

The conception of intermediate-level waste storage (ILWS) is different due to the absence of waste exothermic effects. Consequently the design contains only one level. Three units compose the ILWS storage. Each unit comprises sixteen parallel galleries (15 storage galleries + 1 empty gallery). Finally, the complete facility consists of 48 galleries (45 storage galleries + 3 empty galleries). The access to each unit is ensured by an interface building. The storage gallery is 280 m wide by 520 m long (Figs 4–5).

Every unit comprises 9 types of gallery (Table 4).

The crossing between 16 storage galleries and the secondary transfer gallery is perpendicular and

Table 4. Gallery characteristics in term of length and section.

Name of gallery	Length m	Excavated section m^2 (Profile N°2)
Working gallery	340	64
Air entrance/exit gallery	50	20
Chimney	50	23
Technical gallery ≪gantry≫	460	99
Technical gallery	525	72
Assembly gallery	61	81
Main transfer gallery	345	108
Secondary transfer gallery	465	108
Storage gallery (16 per unit)	4480	147

halfway up the level. This configuration ensures complete insulation of the storage galleries from a ventilation point of view as well as providing protection against radiation.

The principle of waste storage is as follows: the handling vehicle takes the main transfer gallery, then the secondary transfer gallery, and stores the waste packages at each storage gallery.

The travelling gantry crane is situated in the upper part of the technical "gantry" gallery and plays an important role in the waste package handling. The gantry crane accesses every storage gallery via the technical "gantry" gallery and moves the packages along from the crossing to each storage gallery.

The functions of the gantry crane are as follows: handling the waste packages from secondary transfer gallery to the storage gallery by means of the hatch.

Even if the waste of the ILWS is not exothermic, the ventilation is important to evacuate the hydrogen, which is given off by some packages, the humidity in galleries and to reduce the impact of water streaming.

3 CHOICE OF EXCAVATION METHOD

The choice of tunnel excavation method must be adapted to the rock masses encountered, to the cross-sections and it has to be effective, speedy and safe (AFTES GT29).

Taking into account non-circular gallery sections, short lengths and differing cross sections, the excavation by means of TBM is not suitable.

In this study phase, the excavation by roadheader cannot be adopted because of its operational limit, which is related to ground geotechnical features, particularly the compressive strength Rc and the rock mass abrasivety.

The most adapted excavation method for this complex network of shafts and tunnels seems to be the conventional method known as the "drill and blast method". This method permits the excavation of the

rock mass under very difficult and variable geological conditions.

The shafts for the HLWS facility will be excavated by the "raise drill" method.

4 TUNNELING SUPPORTS

In this design stage, three kinds of tunnel support have been chosen. The lighter support is for very good bearing rock mass quality and the heavy support is for poor bearing rock mass quality. (AFTES GT29).

Profile N°1: very good quality limestone (RMR > 80).

- Occasional rock bolts in crown : 1 bolt/4 m^2, Ø25, L = 2.5 to 4 m;
- Shotcrete 0.05 m in crown.

Profile N°2: good quality rock (60 < RMR < 80).

- Systematic rock bolts: 1 bolt/4 m^2, Ø25, L = 2.5 to 4 m;
- shotcrete 0.1 m.

Profile N° 3: poor quality rock and fault zones ZF1 et ZF2 (20 < RMR < 30).

- Colliery arches 0.18 m H sections at 1 m centres;
- Shotcrete, concrete fill, concrete facing;
- Concrete strip footings reinforced with four 0.25 m diameter high tensile bars;
- Self-drilling bolts if necessary 1 bolt /2 m^2.

5 TUNNEL EQUIPMENT

Another major condition for design of this kind of facility is the reduced maintenance due to the 300 year design life objective of the waste storage where there should be no major repairs for the first 100 year. Consequently, a strict minimum of mechanical and electrical equipment will be used in the galleries.

6 ORGANISATION OF UNDERGROUND WORK

6.1 *HLWS*

6.1.1 *Access and in-situ installation*

In the scheduled programme of underground work for high-level waste storage, we considered two principal attacks per level, which represent four principal attacks with four construction installations (Figure 6).

Upper level:

1 Attack N°1 corresponds to an uphill drive and comprises the main underground site in the transport gallery entrance. The access building will be situated at the end of the underground works.

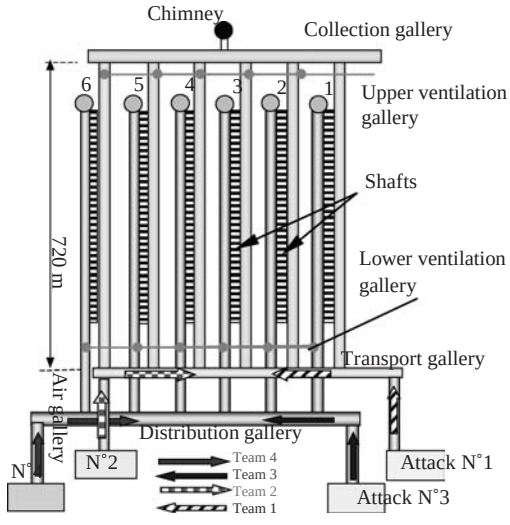

Figure 6. Scheme of on-site installation and excavation phase.

2 Attack N°2 corresponds to a second uphill drive and is situated along the temporary work gallery, which will be closed afterwards.

Lower level:

The lower level is located about 10 to 17 m lower than the upper level. The two attacks are separate. They are linked to each other by a site access haul road.

3 Attack N°3 is located at the front of the air gallery.
4 Attack N°4 is at the face of the second air gallery.

6.1.2 *Excavation phases*

6.1.2.1 Phase 1

For the workers' security, during the whole underground excavation it is vital to ensure ventilation at all times (CRAM). The drilled air chimney will allow natural ventilation in the upper level. Additionally, six temporary ventilation shafts will be drilled between the two levels in order to ensure natural site ventilation.

The first excavation phase starts with four main parallel attacks. The whole face is excavated by the "drill and blast" method:

- Attacks N°1 and N°2 (upper level) correspond to excavation of the transport gallery from two galleries, which are perpendicular to the transport gallery.
- Attacks N°3 and N°4 (lower level) correspond to the excavation of the distribution gallery from two air entrance galleries.

6.1.2.2 Phase 2 – Excavation phases of ventilation galleries.

Upper level:

Two attacks (N°1 and N°2) are used to excavate the first upper ventilation gallery. After finishing the excavation of the upper ventilation gallery, construction team N°1 continues to excavate the collection gallery as far as the air chimney. Once the extraction chimney is accessible, the boring of the pilot hole can begin (0.3 m). After boring the first hole, the raise-drill reams a hole of 3 to 4 meters in diameter. The final diameter (about 12 m) of this chimney is obtained by the "drill and blast" method.

Attack N°2 excavates the upper ventilation galleries N°2, N°4 and N°6. Attack N°1 excavates galleries N°1, N°3 and N°5.

Lower level:

The lower level excavation is carried out by construction teams N°3 and N°4. The underground work for the lower level is carried out after the upper level, thus avoiding a stress concentration in the rock mass.

Attack N°3 drills the upper ventilation galleries N°1, 3 and 5. Attack N°4 excavates the upper ventilation galleries N° 2, 4 and 6 (Fig. 6).

The drilling of the access to the storage shafts requires particular attention for many reasons (Fig. 3). On the one hand, the excavation must not penalise the deadline of the gallery excavation. On the other hand, the cost (per meter) of their accesses is about twice that of the gallery.

6.1.2.3 Phase N°3 – Shaft drilling

The storage shafts (600 or 720 per unit) will be drilled by the "raise-drill" method with specific boring machines adapted for industrial drilling.

This drilling phase will be carried out by four construction teams after the tunnel lining phase in the upper ventilation galleries.

6.1.3 *Tunnel lining phase*

All the underground galleries, except the transport gallery and the air entrance gallery, will be lined but not waterproofed.

The lining operation is carried out with non-reinforced in-situ concrete of 0.35 to 0.5 m thickness, depending on the profile. The reinforced concrete will probably be applied in the gallery where the concrete is subjected to high temperatures (80°C), notably in the upper ventilation gallery. The 3D numerical modelling carried out by CEA, shows that a weak section is situated at the crossing between the bottom and the side wall of the upper gallery.

6.1.4 *Scheduling aspects*

The expected average rate of advance by "drill and bast" used in this study is presented in table 5. The work assumptions take into account 24 hour working five days per week.

Table 5. Expected average rates.

Tunnel support	Rates
Profile N°1	5 m/day
Profile N°2	4 m/day
Profile N°3	1.5 m/day
Lining	
All 3 Profiles	10 m/day

The construction period for one HLWS unit was estimated at 5 years and 4 months. Consequently, for six units of spent fuel, the total construction period is 32 years and 4 months.

6.1.5 *Cost of the HLSW unit*

Here we present the cost for the reference profile, N°2. The construction cost (for year 2005) of one unit of spent fuel is estimated at 132 M€ exc. tax, so for 6 units the total costs is 792 M€ exc. tax.

6.2 *ILWS*

6.2.1 *Access and in-situ installation*

In the operating phase of the ILWS unit, two principal in situ installations are provided (Attacks N°1 and N°3) as well as one secondary in-situ installation (attack N°2).

Attack N°3 is situated along the working gallery. In the operating phase, this working gallery will be used for access, but afterwards, in the maintenance phase, it will be closed.

6.2.2 *Excavation phases*

6.2.2.1 Phase 1 – Ventilation during the construction phase.

As noted previously, ventilation of the underground space is necessary during construction for the workers' security. (CRAM). Consequently, the first excavation phase will start on the perimeter unit in order to drill the air chimney to ensure natural air ventilation. An additional air supply is also used during excavation.

Excavation starts with two main parallel attacks, N°1 and N°3. The first attack drills the main transfer gallery, half of technical gallery and after the access to the air chimney. Attack N°3 excavates the working gallery and half of technical gallery (Fig. 7).

The drilling of the air chimney is carried out by the "raise-drill" method.

After the perimeter excavation, both construction teams will be used for boring attack N°3, first the air entrance gallery and after the upper part of "Gantry" gallery. The lower part of the "Gantry" gallery will be excavated later.

6.2.2.2 Excavation of 16 storage galleries

In order to optimise the deadline, a third construction team is used, altogether representing 3 parallel attacks.

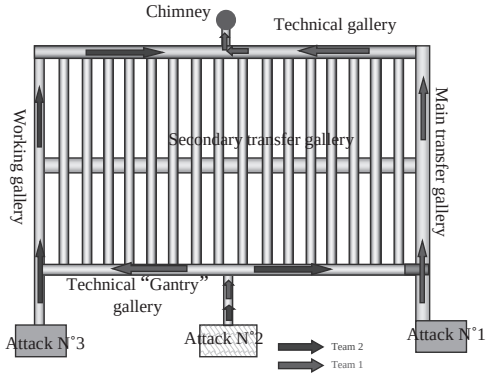

Figure 7. Scheme of excavation phases.

The storage gallery excavation will be carried out in two successive stages:

1 Upper part of the gallery (handling zone).
2 Lower part of the gallery (storage zone).

6.2.2.3 Excavation phase of secondary transfer gallery

After finishing the upper part of the storage galleries, construction team N°1 starts the excavation of the secondary transfer gallery. These two galleries have different levels, the secondary transfer gallery being lower (Figure 5). Their connection points are very delicate, there are 16 per unit.

At the same time, attacks N°2 and N°3 will excavate the lower part of the storage galleries by vertical boring.

6.2.2.4 Excavation of the lower part of the storage gallery

When the excavation of the secondary transfer gallery is finished, the phase "Blast and muck removal" of the lower part of storage gallery commences. It was decided to first excavate the secondary transfer gallery in order to use this gallery as an optimal means to evacuate the muck for all lower parts.

6.3 *Scheduling aspects*

The assumptions are the same as for HLWS (§6.1.4). The construction period for one ILWS unit is 4 years and 9 months, thus the total construction period for 3 units is estimated at 14 years and 7 months.

The construction of one access building will take over 5 years.

6.4 *Cost of ILSW unit*

The construction cost for the ILWS unit for profile N°2 is estimated at 141 M€ exc. tax, so for 3 units the costs is 423 M€ exc. tax.

7 CONCLUSIONS

In this paper we have described two particular designs for two kinds of waste storage (HLWS and ILWS) and we have proposed the organisation methodology for each facility. This network composed of shafts and tunnels is non-typical and complex to design and to manage. We have then givensome of the main considerations.

According to the scheduling aspects, the maximum total construction period for the HLWS waste storage (spent fuel) is 32 years and 4 months. For the ILWS it is 14 years and 7 months. It is necessary to note that this construction schedule is not penalised by the storage waste process, which lasts 50 years.

In terms of muck removal, the excavation volume mass for one HLWS unit is estimated at 960 000 m^3, so the maximum total volume of spent fuel is 5 760 000 m^3. For one ILWS unit, the excavation volume mass is estimated at 1 116 000 m^3, so the total volume for 3 units is 3 348 000 m^3.

It is important to emphasise that, in today's economical context with sustainable development it is necessary to identify how to enhance the value of this enormous volume of excavated rock mass.

Design and construction of a tunnel using the technology for controlling muck flow in the cutting chamber of an earth pressure balance shield of large cross section

H. Dobashi & M. Matsuda
Metropolitan Expressway Co., Ltd.

K. Matsubara & A. Kitayama
Obayashi Corporation

ABSTRACT: Of the Metropolitan Expressway Central Circular Shinjuku Route, which is being constructed by the Metropolitan Expressway Public Corporation, tunnels of the SJ51 to SJ53 Sections were decided to be excavated using a world-largest earth pressure balanced shield, which has an outer diameter of 12.02 m. In the conventional earth pressure balanced shield method, plastic flow of excavated soil within the cutter chamber, which is indispensable for stable excavation, has never been analyzed, and the method has been little used to excavate tunnels of over 10 m in diameters. In this project, a system for visualizing the flow of soil inside the chamber was decided to be developed and introduced. This paper describes an overview of the system and results of its application.

1 INTRODUCTION

Metropolitan Expressway Company Limited is now constructing the Central Circular Route of the Metropolitan Expressway with a total length of approximately 47 km outside the Inner Circular Route, approximately 8 km in radius from the city center. The goal is to alleviate traffic congestion by diverting or dispersing traffic passing through the city center and thereby form a well-balanced circular traffic network. Sections of approximately 26 km, about 60%, of the Central Circular Route have been completed and are currently in service. The remaining 20-km sections consist of the Shinjuku Route on the west side and the Shinagawa Route on the south side. In the Shinjuku Route with a length of approximately 11 km, construction is being carried out rapidly mainly with the shield tunneling method to perform construction work smoothly under heavily congested roads and minimize adverse effects of construction on residents in surrounding areas. Shields of large cross section with a diameter of more than 10 m are used in all of the eight sections where shield tunneling takes place. Figure 1 provides an outline of the project.

As shields of large cross section with a diameter of more than 10 m, slurry shields have frequently been employed because they facilitated the stabilization of the face. In this project (work sections SJ51 to SJ53 (clockwise route) of a highway tunnel), an earth pressure balance shield of cross section with an outer diameter of 12.02 m, largest in the world at the time of receipt of the order, was adopted because the construction base was narrow, so no space could be secured for installing equipment required for a slurry shield and because effects of leaking slurry on the ground surface or surrounding structures in sections with shallow depth of overburden during the operation of a slurry shield was of concern. Figure 2 gives a geological profile at the construction site.

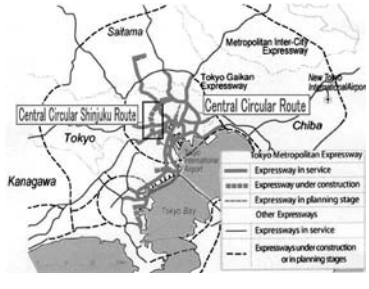

Figure 1. Project outline.

In the earth pressure balance shield, establishment of plastic flow of excavated material in the cutting chamber is important to the stabilization of the face and smooth removal of excavated material through the screw conveyor. In the earth pressure balance shield of large cross section, it has been unknown whether

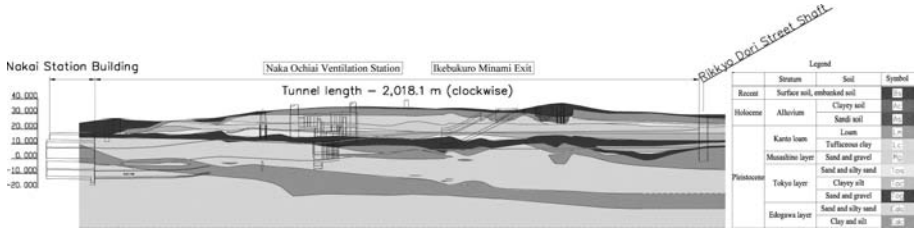

Figure 2. Geological profile.

appropriate agitation is possible to ensure the plastic flow of slurry or not, which has been preventing the earth pressure balance shield from being applied to tunnels of large cross section. The problem has yet to be solved because no method has been established for quantitatively grasping the establishment of plastic flow.

In this project, technology for controlling muck flow in the cutting chamber of an earth pressure balance shield was developed and applied to maintain face stability and ensure safe excavation solving problems involved in the use of an earth pressure balance shield of large cross section. The technology enabled the contractor to quantitatively grasp the plastic flow of excavated material in the cutting chamber and to carry out the following work.

(i) Quantitative excavation control by evaluating the plastic flow of the muck in the chamber
(ii) Appropriate system design for agitation and muck removal in the chamber

This paper outlines the technology developed, describes the results of its application to actual construction and presents case studies of design of an agitation and muck removal system.

2 OUTLINE OF MUCK FLOW CONTROL TECHNOLOGY

"Plastic flow" is essential to the stabilization of the face and smooth removal of excavated material through the screw conveyor. Where there exits plastic flow, excavated material starts flowing at a deformation rate (shear strain occurs) when the shear stress in the material exceeds a certain yield value (Figure 3). In the case where the plastic flow of the excavated material in the cutting chamber is in a good condition, the rotation of the cutter face causes the excavated material to flow and be mixed with additives for excavation and agitated. As a result, the excavated material flows at a deformation rate. When the chamber is clogged, the velocity of the material is high and deformation rate is low (Figure 4). Where the excavated material is blowing from the screw conveyor, velocity is low and deformation rate is high.

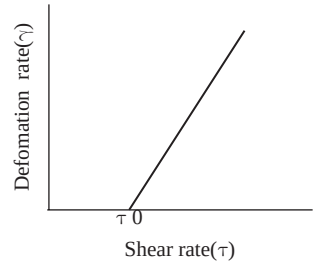

Figure 3. Plastic flow of excavated material.

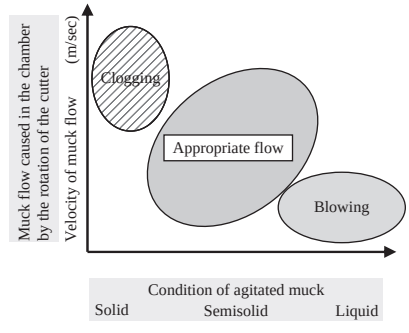

Figure 4. Muck flow velocity and deformation rate.

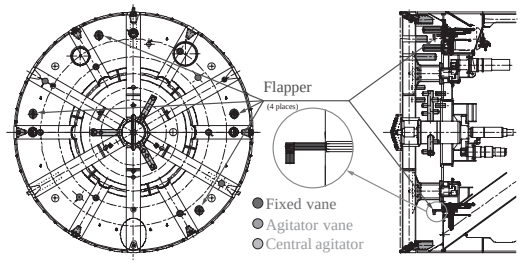
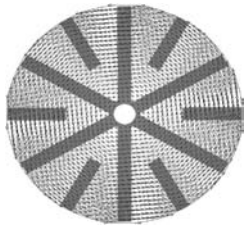
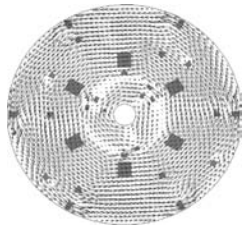
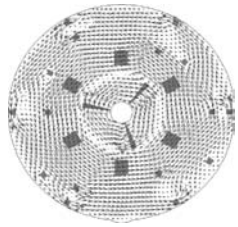
The technology we have developed involves the making of a three-dimensional model of the inside of the cutting chamber in the shield for analyzing muck flow, calculation of velocity and deformation rate in the chamber and evaluation of plastic flow. To reflect the actual condition in the chamber in analysis, a flapper (Photograph 1) was developed and four flappers were installed on the bulkhead in the chamber (Figure 5). Flaps were rotated with electric motors during excavation to measure the variations of torque due to muck flow. The flapper was also modeled for analysis. In the case where analysis results were in good agreement with measurements, it was determined that the calculated velocity and deformation rate were actually found in the chamber. The muck flow control technology enables visual display of velocity and deformation rate in the chamber based on analysis results. Then, quantitative control of

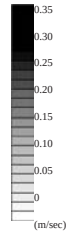
Photo 1. Flapper.

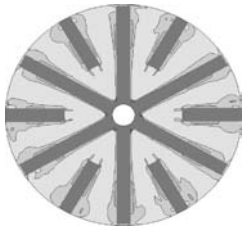


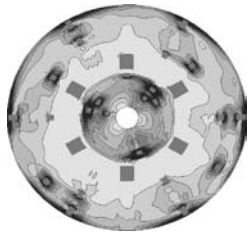












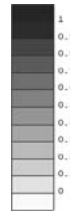


Figure 5. Positions of flappers.

Table 1. Inside the chamber during smooth excavation.

	Near the cutter face	At the middle of the chamber	Near the bulkhead	Legend
Velocity (m/sec)				
Deformation rate (1/sec)				

injection of additives for excavation becomes possible. For example, additives are injected exclusively at points where no appropriate plastic flow seems to have been established.The condition in the chamber can also be grasped real-time by controlling the variation of torque of the flapper during excavation. Thus, actions can be taken promptly in response to changes in property of the muck in the chamber. The technology therefore contributes to safe excavation. The technology also enables quantitative design of an agitation system beneficial to the establishment of plastic flow based on the results of analysis using an arbitrary model of the agitation system in the chamber.

3 APPLICATION IN ACTUAL CONSTRUCTION PROJECTS

3.1 *Condition in the chamber during smooth excavation*

In the actual construction project, muck was removed smoothly through the screw conveyor without any blowing throughout the tunnel alignment along which shield tunneling took place. It was then assumed that there was plastic flow of the muck in the chamber and that the face remained stable.

Results of analysis of plastic flow in the chamber are listed in Table 1.

Table 1 shows distributions of velocities and deformation rates in the chamber in three cross sections: near the cutter face ($z = 1.7$ m, where z represents the distance from the bulkhead), at the middle of chamber ($z = 0.9$ m) and near the bulkhead ($z = 0.45$ m) (Figure 6). Velocity is a vector quantity. The directions and lengths of arrows indicate the directions and levels of velocities.

Deformation rate, a scalar quantity, is expressed by brightness. Analysis results show that distributions of velocities and deformation rates are not uniform transversely but are different in the cutter peripheral area, cutter support area and agitator area. In the longitudinal direction, distributions of velocities and deformation rates are different in the three cross sections between the cutter face to the bulkhead.

Figure 7 shows logarithms of velocities (m/sec) plotted along the vertical axis and logarithms of deformation rate (l/sec) along the horizontal axis in the areas shown in Figure 6. The plotted points move toward the center of the graph in the agitator and cutter peripheral areas as the cross section move from the cutter face to the bulkhead. Plastic flow of the muck is therefore assumed in these areas. In the cutter support area on the other hand, the movement toward the center of the graph is not so outstanding. Velocity is available owing to the rotation of cutter supports, but no mixing and agitation takes place. Plastic flow is therefore unlikely to be established. In the project, excavation could be carried out while maintaining face stability. As a result of analysis, however, plastic flow was found unlikely to start at some points. Then, additives for excavation were injected also at such points shown in Figure 8.

3.2 *Condition in the chamber during muck blowing from the screw conveyor*

At the time of blowing, excavated material pressurized in the chamber moves through the screw conveyor remaining in the form of a liquid and the pressure is not reduced to air pressure at the outlet, and the volume of muck can no longer be controlled by adjusting the speed of rotation of the screw conveyor. When muck is being removed smoothly, the pressure of the muck pressurized in the chamber is reduced to air pressure owing to resistance in the screw conveyor by the time the muck reaches the outlet, and the volume of muck can be controlled by adjusting the speed of rotation of the screw conveyor.

In this project, excavation was carried out smoothly while maintaining face stability owing to smooth muck removal throughout the tunnel alignment along which the shield tunneling method was adopted. The condition in the chamber at the time of blowing of the muck from the screw conveyor was therefore not measured. The muck flow control technology was used to calculate the pressure in the chamber through the outlet of the screw conveyor in analysis. Figure 9 shows the pressure in the screw conveyor during smooth excavation and at the time of muck blowing. The pressure acting on the muck in the chamber was reduced in the screw conveyor and no longer acted at the outlet of the screw conveyor during smooth excavation. At the time of blowing of the muck, pressure was not reduced at the outlet.

Table 2 shows the condition in the chamber when an analysis was made at the time of muck blowing (Figure 9). Figure 10 presents mean velocities and deformation rates during smooth excavation and at the time of muck blowing for comparison.

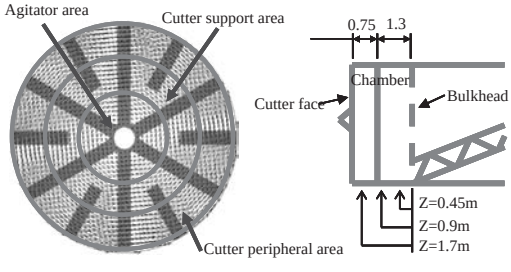

Figure 6. Points of evaluation.

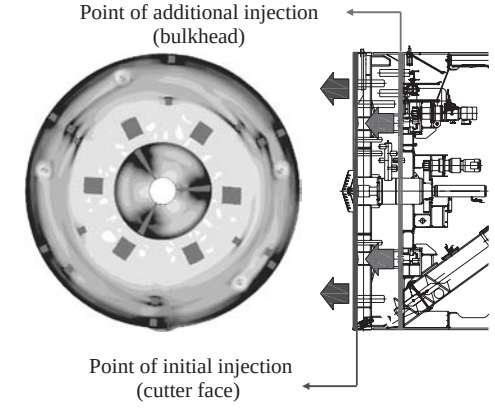

Figure 8. Points of additive injection.

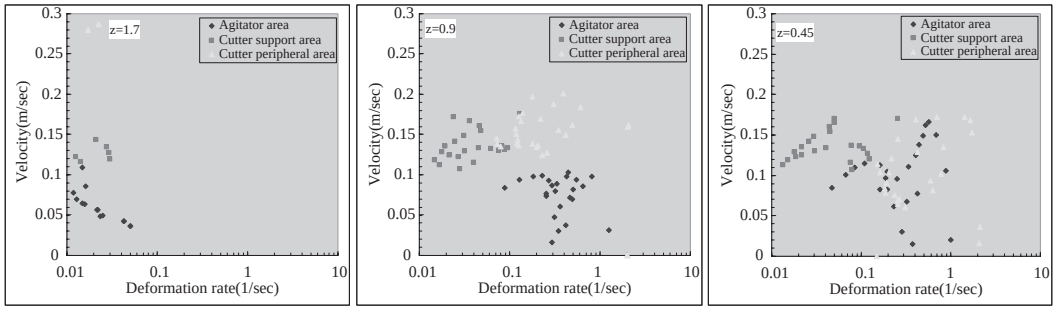

Figure 7. Velocity and deformation rate in each cross section.

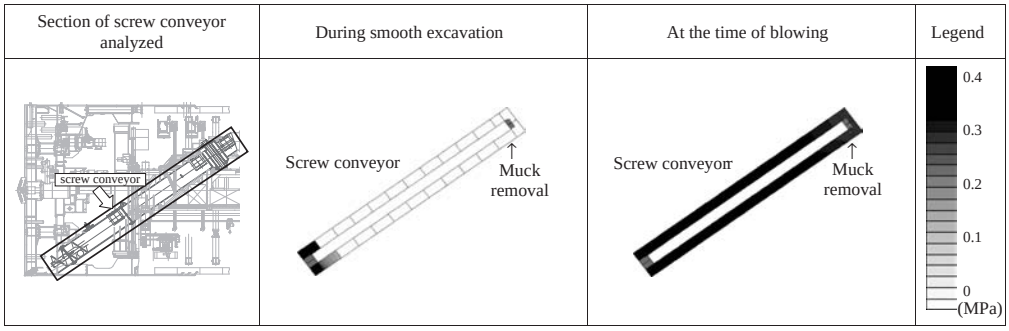

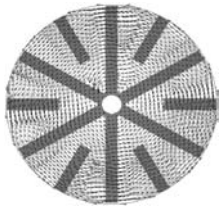

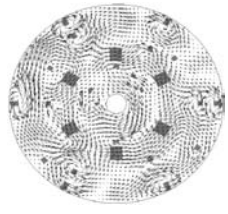

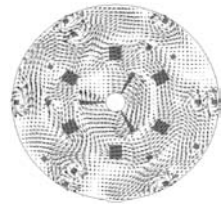

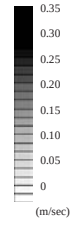

Figure 9. Pressure in the screw conveyor.

Table 2. Condition in the chamber at the time of muck blowing.

	Near the cutter face	At the middle of the chamber	Near the bulkhead	Legend
Velocity (m/sec)				
Deformation rate (1/sec)				

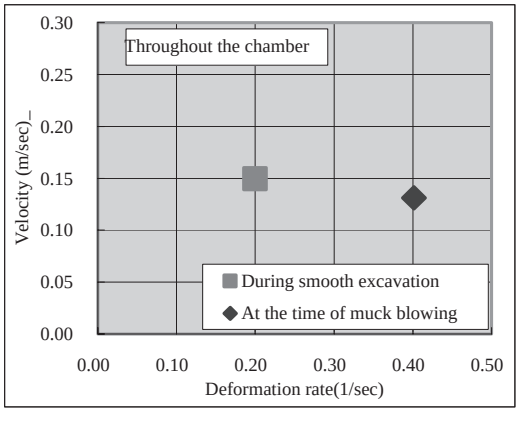

Figure 10. Velocity and deformation rate during smooth excavation and at the time of much blowing.

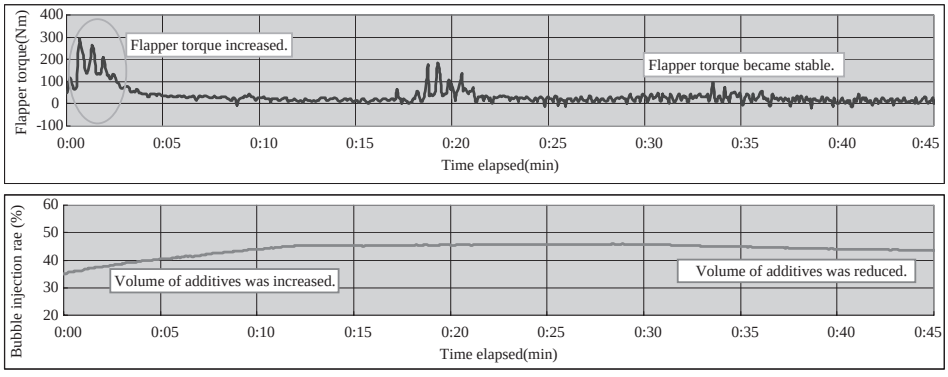
Velocity at the time of muck blowing was similar to that during smooth excavation. Deformation rate was higher at the time of muck blowing. Deformation rate was in the area of muck blowing shown in Figure 4. In the case where the condition shown in Table 2 is found during tunnel construction similar to this project, measures should be taken promptly such as those for modifying the property of the muck.

3.3 *Excavation control based on the variation of flapper torque*

To establish plastic flow of excavated materials in the chamber, the property of the muck removed through the screw conveyor has conventionally been evaluated by visual inspection or slump tests. Where and how much additives for excavation should be injected were adjusted based on the evaluation results. In this project,



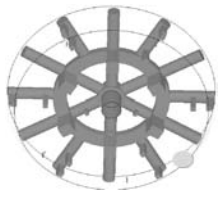


Figure 11. Excavation control using flappers.

Table 3. Model of agitation system designed.

CASE 1 Cutter	CASE 2 Cutter and agitation vane	CASE 3 Cutter, agitation vane and fixed vane	CASE 4 Cutter, agitation vane, fixed vane and agitator
			

injection of additives was controlled also using the muck flow control technology.

Additives for excavation were injected not only on the front face of the cutter but also at points where plastic flow was found unlikely to be established based on the distributions of velocities and deformation rates identified in analysis. The volume of additives was adjusted according to the variations of flapper torque. Figure 11 shows an example of control of additive injection in the project.

In the excavation work shown in Figure 11, the torque of the flapper increased rapidly, so more additives were injected. When the flapper torque became stable, the volume of additives was reduced. Flapper torque changes earlier than the change in property of the excavated material that is removed through the screw conveyor. Actions therefore can be taken quickly in response to the change in plastic flow in the chamber by controlling the volume of additives according to the flapper torque. Thus, safe excavation can be carried out.

In this project, the tunnel was excavated over a length of 2020 m and the geology varied from cohesive soil to grave layers. The muck flow control technology helped complete excavation smoothly without any adverse effects on the ground surface or on adjacent structures including railway tracks and land bridge foundations.

4 OPTIMAL DESIGN OF AGITATION AND MIXING SYSTEM IN THE CHAMBER

The muck flow control technology involves the modeling of the system of agitation and mixing in the chamber for controlling muck flow. Making an arbitrary model of agitation and mixing system and making analysis under one and the same conditions enable optimal design of an agitation and mixing system beneficial to the establishment of plastic flow of excavated material based on the results of comparison in calculated velocity and deformation rate. In this study, agitation and mixing systems were designed in four cases for analysis (Table 3). Figure 12 shows mean velocities and deformation rates in the chamber in respective cases.

As a result of analysis, it was found that velocities were more or less the same in all cases. Deformation

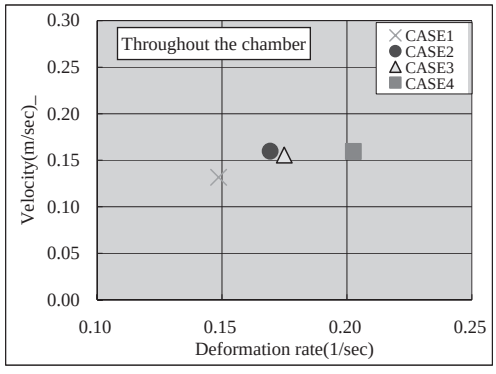

Figure 12. Velocity and deformation rate.

rate in the chamber was highest in case 4. This was considered the optimal agitation system that is capable of establishing the plastic flow of the muck.

As discussed above, it has been confirmed that the muck flow control technology provided for the evaluation of the effects of agitation and mixing systems quantitatively for the first time. Thus, the technology enables smooth mixing of muck with additives in the chamber and the design of an agitation system effective for establishing plastic flow of the muck.

5 CLOSING REMARK

The “technology for controlling muck flow in the cutting chamber of an earth pressure balance shield” enables tunnel excavation based on the results of evaluation of the plastic flow of the muck in the chamber. Thus, greater face stability can be ensured.

The shield tunneling method has been playing a leading role in urban tunnel construction and is expected to play a greater role. In big cities in particular, tunnel construction is expected to be more demanding for such reasons as the shortage of construction sites, need of construction adjacent to important structures, construction at great depths and requirements for cost reduction. Earth pressure balance shields need to play a greater role to solve these problems. The “technology for controlling muck flow in the cutting chamber of an earth pressure balance shield of large cross section” will help increase the cross section of an earth pressure balance shield and apply earth pressure shields in an increasing number of projects.

Estimation of front-end stability using field displacement

R.M. Faure
Centre d'études des Tunnels, France

J.F. Thimus, F. Desmoulin & S. Delvaux
Université catholique de Louvain, Génie civil et environnemental, Belgium

ABSTRACT: The stability of a front-end of a bored tunnel is for safer works a crucial estimation. It depends of soil reinforcement or slurry pressure following the means of boring. Based on a 3D analysis, we propose in this paper a new approach of safety estimation that can be summarized through the following steps. Determination of 3D failure surfaces by an automatic process and estimation of stresses on these surfaces. This estimation is based on Mohr circle analysis. Determination of 3D fields displacement, in a parametric approach, at each vertices of a spatial net, which allows 3D interpolation. Determination of behaviour laws (stress – displacement laws) for any soils and inclusions. Using homothetic fields of displacement we can so compute the equilibrium and define a kind of distance to failure, that is an estimation of safety. It is very easy to change any parameters like soil nails and so, to optimize the design.

1 INTRODUCTION

Lot of methods try to assess the front face stability using failure schemas and soil failure equations. Among these methods we can notice the Terzaghi method, taking into account some vault effects for determining the vertical load. The resistance is the integration of shear stress along chosen failure surfaces. Except DEM, no method is able to take into account the displacement of blocks of soils moving relatively to each others.

With the possibilities of computer it is now possible to check 3D failure surfaces and obtain a more realistic result.

If safety is not checked, the two main way for reinforcing the stability is the slurry pressure in case of TBM or nailing in case of traditional boring.

This paper presents a new method that can determine the efficiency of the two reinforcement systems already mentioned. This method can be summarized in three steps.

2 SOLVED PROBLEM

As to define the given problem, we use the name of the different data screens we can find using the computer code available on the net.

2.1 *Tunnel geometry*

The tunnel section is circular and the axe of the tunnel is horizontal. The ground is defined by two layers, and the interface of the two layers is parallel to the tunnel axe, but can be inclined in the transverse direction. (Figure 1)

2.2 *Failure surface*

The failure surface is determined using parametric curves defined by only two points, one at the vertical of the front face, the second at a given distance from the front face, on a horizontal line at the top of the front face. (Figure 2)

2.3 *Reinforcement system*

2.3.1 *Pressure*

If boring is done by a TBM a pressure transmitted by air or slurry can be applied to the front face. In the equilibrium of the instable soil mass, the pressure is

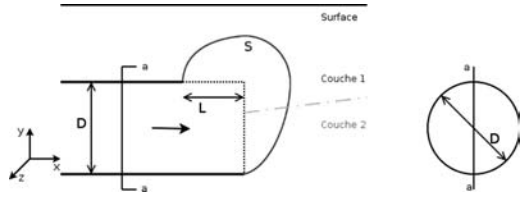

Figure 1. Tunnel geometry.

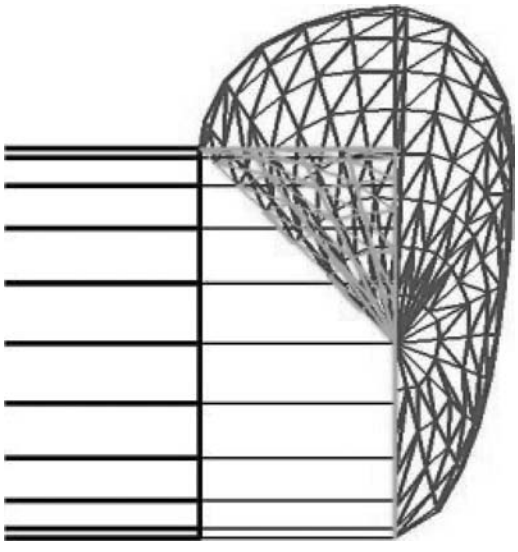

Figure 2. Example of 3D surface failure (see annex 1).

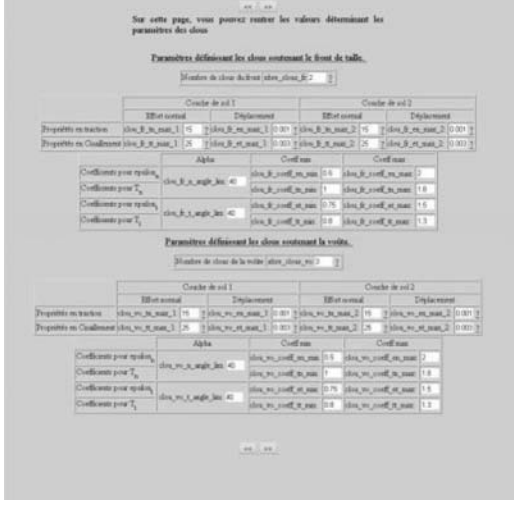

Figure 3. Data for nails definition.

equivalent to a non uniform force on the front face depending the altitude of each facet.

2.3.2 *Nails*

The definition of nails takes lot of values. So, usual nails are stored as tables. Figure 3 is an example of nail data sheet.

Data are numerous because the behavior of the nail is given in terms of displacements. This model was obtained after numerous giant shear box tests with nails inside.

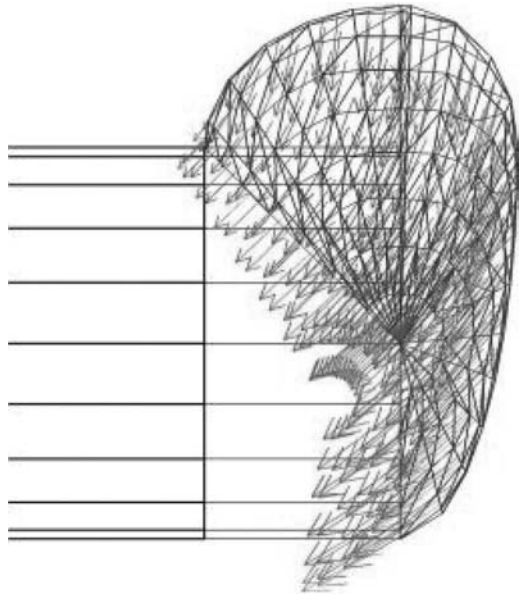

Figure 4. Example of displacement field.

2.4 *Given displacements*

A displacement field is compulsory for the calculation. This field that represents the maximum of displacement on the failure surface will be divided into ten steps and equilibrium is computed at each step. With this approach it is possible to have an approximation of the displacement leading to stabilization when the balance of forces is satisfied. The field is a combination of translational and rotational movements, as shown on figure 4.

2.5 *Water table*

Taking into account the water table is important and the water table is defined by a level.

3 CALCULUS

3.1 *Stresses determination*

3.1.1 *Static : the perturbation method*

Before taking into account displacements a static calculus is done using the perturbation method. This method was developed for 3D slope stability evaluation.(Faure et al, 1998) The main advantage of the perturbation method is in the realistic determination of stresses on the surface failure. The analysis is done using the Mohr circle criterion, respecting the failure criteria of the soil. Starting with this accurate value of stresses on the failure surface, extensions with nails or displacement are easier because all used values are limited and stay in range.

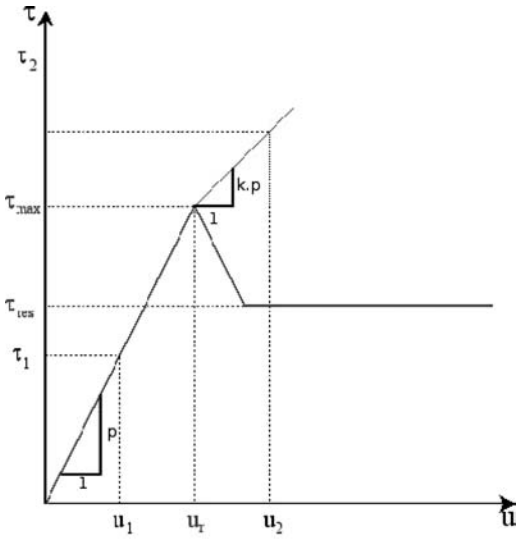

Figure 5. Behavior of soils.

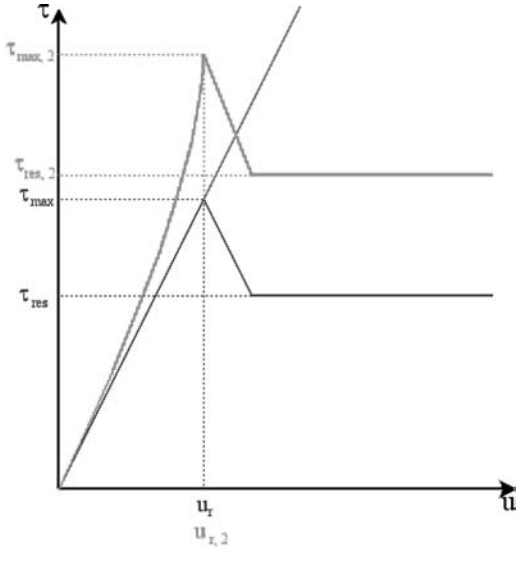

Figure 6. Modified soil behavior when pressure.

3.2 *With displacement*

The two displacement models are the soil model and the nail model.

In the soil the parameters c, ϕ, ε_r, R_f defined the curve on figure 5 and in case of external pressure this curve is modified following figure 6.

In this model, τ_{max} is computed by the Coulomb law using the realistic value of σ given by the perturbation method. u_r (or ε_r) is a given value in correspondence

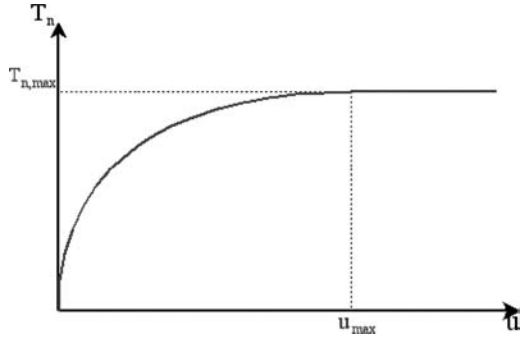

Figure 7. Axial effort in the nail.

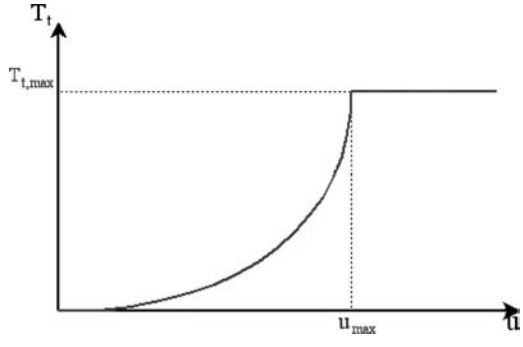

Figure 8. Transverse effort in the nail.

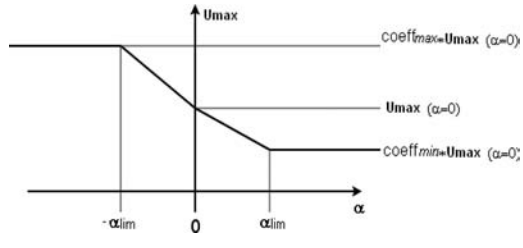

Figure 9. Influence of α.

with the maximum displacement of the field displacement, and R_f define τ_{res} following $\tau_{res} = R_f * \tau_{max}$.

With nails it is more complex; the displacement model is obtained following giant shear box trials with nails included in the shear box. One of the important parameter is the inclination of the nail on the failure surface. For all the nails given as a family this inclination is computed, and allows the determination of ratios that modify the value of nail strength when they are perpendicular to the shear surface. Figures 7 and 8 show the variation of axial and tangential forces in the nail following the shear displacement on the failure surface.

Figure 9 gives the ratio function depending of inclination of the nail on the failure surface. All the

parameters describing these curves are defined on the data sheet corresponding to each kind of nail.

4 RESULTS

With the use of displacements we can't have a unique safety factor because at each point on the failure surface, the displacement is not the same (the sliding mass is not a block and have deformations) and we have to define new parameters that can represent the safety level of the front face with its reinforcements for a given displacement.

So we define that we call "safety margin" that is an expression infinite when no displacement and going to 1 when the large displacement put all element on residual failure. At each point the difference between failure shear stress and shear stress evaluated using the displacement is computed. Integration of all these stress reserve gives, when normalized, the 'safety margin'.

In another approach, we can define the "global safety factor" that is an integral of local safety factors, that is zero when no displacement and going to a limit value when large displacements occur.

These two ratios give a good idea of front face stability. But this approach is more efficient when we compare two solutions of reinforcement, because we can make a choice between the two (or more) solutions in terms of displacement, that very important at the front face.

5 CONCLUSION

This method seems complex because lot of concepts must be used together. But it is simple because all concepts are easy to understand, and the computer manages all of them. This code is now available on the web site of Solem or UCL supporting the DIDACTU learning system. We hope that with this code any student can understand the challenge of front face reinforcement for minimizing front face displacement.

Influence of soil grouting on the shallow tunnel linings stress state in urban areas

N. Fotieva, N. Bulychev, S. Antziferov, A. Sammal & P. Deev
Tula State University, Tula, Russia

ABSTRACT: An analytical method for determining the stress state of multiple shallow circular tunnel linings constructed with the application of grouting in build up areas is proposed based on consideration of interaction of underground structures and the surrounding soil mass as elements of a united deformable system and on the new analytical solutions of corresponding plane problems of elasticity theory with approximate taking the 3-D character of surface loads into account.

1 INTRODUCTION

In tunnels being constructed in complicated hydrogeological conditions special techniques such as grouting (cementation) the surrounding soil mass are applied. Strengthening by grouting allows anisotropy of soils around a tunnel to be reduced and their deformation modulus to be raised. In this case a soil zone around the opening the mechanical properties of which are different from those of the rest massif is being created. This circumstance resulting in a redistribution of the "lining – soil mass" system stress state, may exert a substantial influence on the lining bearing capacity and it is necessary to be taken that influence into account in the lining design.

At present there are methods by Fotieva & Sammal (1986) and by Fotieva, Bulychev & Sammal (1993) for the design of deep tunnel linings of an arbitrary cross-section shape under the actions of the soil's own weight and external water pressure taking the influence of grouted zone into account, based on analytical solutions of the corresponding plane problems for a single double-layer non-circular ring in a linearly deformable medium. Similar methods for the design of shallow non-circular tunnel linings constructed with the application of grouting are described in the paper by Fotieva, Bulychev & Deev (2006).

There is also a method for designing multiple shallow circular tunnel linings in grouted soils developed by Fotieva, Bulychev & Antziferov (2003) allowing the linings stress state under the actions of the soil own weight and the weight of a building or structure both existing before the tunnels driving and erected nearly to the already constructed tunnels to be determined. Some improvements giving the possibility of this method application for the design of tunnels constructed in built-up areas are described in the paper presented.

2 THE DESIGN METHOD

The method proposed is based on analytical solutions of the corresponding plane problems of elasticity theory for a weighty linearly deformable semi-infinite medium simulating the soil or rock mass, weakened by a finite number of arbitrarily located circular openings of different radii supported by double-layer rings (the internal layers simulate the tunnel linings, the external ones simulate the soil zones around openings strengthened by grouting). The general design scheme is given in Figure 1.

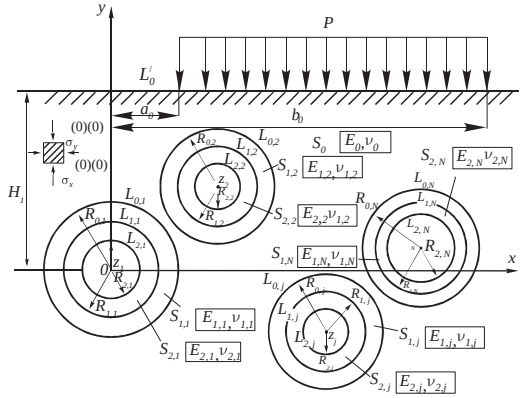

Figure 1. The design scheme.

Here a heavy semi-infinite linearly deformable medium S_0 the mechanical properties of which are characterized by the deformation modulus E_0 and the Poisson's ratio ν_0, simulates the soil or rock mass. The layers of double-layer rings $S_{m,j}$ ($m = 1, 2$; $j = 1, \ldots, N$) from materials possessing the deformation characteristics $E_{m,j}$, $\nu_{m,j}$ ($m = 1, 2$; $j = 1, \ldots, N$) simulate correspondingly soil zones strengthened by grouting ($m = 1$) and tunnel linings ($m = 2$), located on depths H_j ($j = 1, \ldots, N$), counted off from centers having complex coordinates $z_j = x_j + iy_j$ ($j = 1, \ldots, N$).

The medium S_0 and layers of rings $S_{m,j}$ ($m = 1,2$; $j = 1, \ldots, N$) undergo deformation together i.e. conditions of continuity of vectors of displacements and complete stresses are satisfied on the contact lines $L_{m,j}$ ($m = 0,1$; $j = 1, \ldots, N$). The internal outlines $L_{2,j}$ ($j = 1, \ldots, N$) of the rings are free from loads.

The action of the soil own weight is simulated by a presence of initial stresses in the medium S_0 and layers $S_{1,j}$ ($j = 1, \ldots, N$) determined by formulae:

$$\sigma_y^{(m)(0)} = -\gamma(H_1 - y),\ \sigma_x^{(m)(0)} = -\lambda\gamma(H_1 - y), \qquad (1)$$

where γ = soil unit weight, λ = lateral pressure coefficient in an intact soil mass.

The weight of a building or structure on the surface is simulated by a vertical load of the P intensity uniformly distributed along the part $a_0 \le x \le b_0$ of the straight boundary L'_0 of the semi-plane.

There are two cases under consideration – when a new building is erected near the already existing tunnels and when the building was erected before the tunnels driving. In the latter case the ground displacements appearing before the tunnels construction are excluded from the boundary conditions connected the displacements.

The described problems have been solved with the application of the complex variable analytic functions theory (Muskhelishvili 1966), analytical continuation of complex potentials regular in the lover semi-plane out of the openings into the upper semi-plane (Aramanovich 1955) and the method of solving problems for an infinite medium weakened by a finite number of supported circular openings (Fotieva & Kozlov 1992). Such an approach allowed to reduce the problems considered to the iteration process (Fotieva, Bulychev & Sammal 1996) in every approximation of which the solution of the problem for a single double-layer ring supporting an opening in a whole plane is applied at the boundary conditions including some additional items reflecting the influence of the straight boundary of the semi-plane and the other openings. These items are represented in the form of the Laurent series the unknown coefficients of which assumed to be equal to zero in the first approximation then are specified on each step of iterations.

For approximate account of the influence of the distances $l_j (j = 1, \ldots, N)$ between the lining constructed in every tunnel and the tunnel face the correcting coefficients are introduced into the results of the lining design under the action of the soil own weight and weight of buildings existing before the tunnel driving. These coefficients are determined by empirical formulae obtained on the basis of 3-D numerical modeling (Bulychev 2002):

$$\alpha_j^* = 0.6\exp(-1.38\ l_j / R_{1,j}) \quad (j = 1,..., N). \qquad (2)$$

The sequence of the tunnels construction may be taken into account in the same way as described in the work by Fotieva & Kozlov (1992) by means of consequent consideration of all stages of the tunnel complex construction applying the above correcting coefficients.

For approximate taking the limited size of the surface load in the direction along the tunnel axis into account in the work by Fotieva, Bulychev & Antziferov (2003) the correcting multiplier k was introduced in to the results of calculations obtained as the relation between maximal vertical stress appearing in a solid semi-plane on the level of the tunnel arch due to the action of the load of a limited width and due to an infinite load corresponding to the conditions of the plane strain. However formula for determining this coefficient needed to be improved because it did not take the length b of the load into account and gave no possibility to take into account a presence of several buildings located on some distances to one another along the tunnel axis. This is why an improved technique is offered for an approximate account of the 3-D character of problems caused by limited sizes of buildings in the direction along the tunnel axis and by their 3-D locations with respect to the tunnel.

The technique is based on a hypothesis that the relation k between stresses in the ring simulating the tunnel lining obtained from the solution of a 3-D problem, to the ones given by a 2-D problem, is approximately the same as a similar relation between vertical stresses appearing in the point of a solid half-space (without tunnel) corresponding to the center of the tunnel cross-section considered. The coefficient k may be determined in way described in publication by V.B, Shvetz et al. (1987).

The above hypothesis has been confirmed to a certain degree by comparison of results obtained in this way for a single tunnel, with the data from physical modelling on the equivalent materials published in the paper by Fotieva et al. (2005) and from 3-D linear and non-linear numerical modeling carried out by J. Aldorf, E. Hrubesova & K. Voitasik in the framework of joint project supported by the INTAS grant No01-0647. Some examples of compared results are given below.

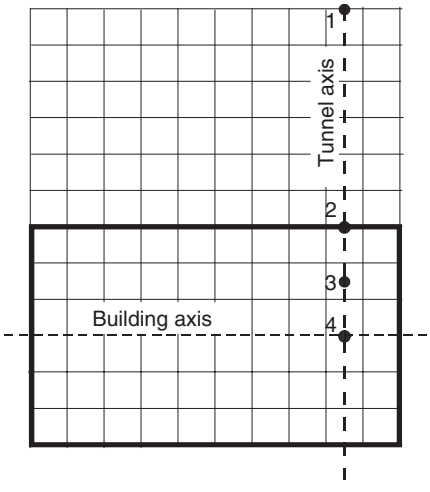

Figure 2. Plan of the building location.

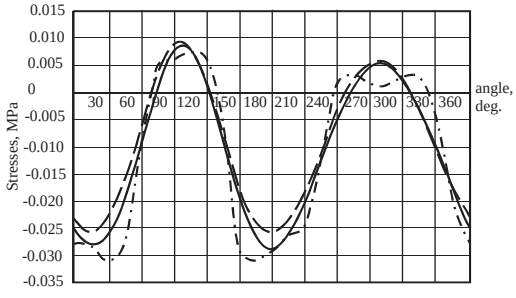

Figure 3. Comparative diagrams of stresses along the internal outline of the lining cross-sections 1.

A circular tunnel located on the depth $H = 18$ m in the rock mass with the deformation characteristics $E_0 = 5000$ MPa, $\nu_0 = 0.3$ has been considered. The lining of radii $R_0 = 3.0$ m, $R_1 = 2.7$ m is produced from concrete with characteristics $E_1 = 23000$ MPa, $\nu_1 = 0.2$. The load $P = 0{,}075$ MPa simulates the weight of the building of sizes $b = 10$ m, $l = 6$ m, erected nearly to the already existing tunnel. The plan of the building location with respect to the tunnel axis is shown in Figure 2 (one grid side corresponds to 1×1 m). Non-linear 3-D numerical modelling has been carried out taking the plastic deformations of rocks with $C = 5$ KPa and $\varphi = 30^\circ$ into account. The stresses have been determined in the lining cross-sections 1, 2, 3, 4.

Diagrams (in involute) of circumferential stresses $\sigma_\theta^{(in)}$, MPa along the internal lining outline obtained with the aim of the approximate technique proposed, are shown in Figures 3–6 by solid lines. The same stresses determined from 3-D linear and non-linear

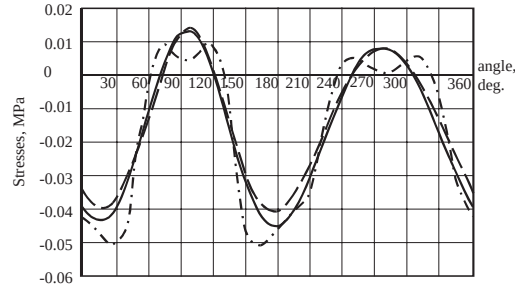

Figure 4. Comparative diagrams of stresses along the internal outline of the lining cross-sections 2.

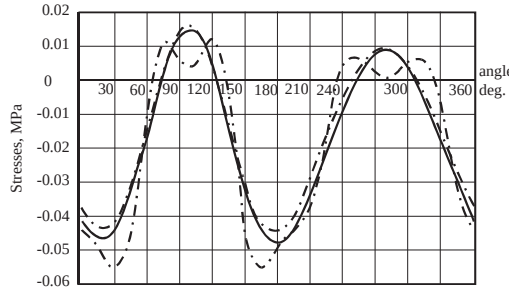

Figure 5. Comparative diagrams of stresses along the internal outline of the lining cross-sections 2.

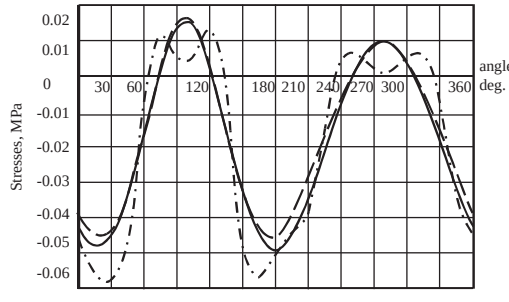

Figure 6. Comparative diagrams of stresses along the internal outline of the lining cross-sections 4.

numerical modeling are given for comparison by dotted and dot-and-dash lines correspondingly.

One can see from Figures 3–6 that the compared results of approximate analytical approach and 3-D linear modelling are in wholly satisfactory agreement. A similar conclusion has been drawn from physical modeling on equivalent materials described in papers by Fotieva, Sammal et al. (2004) and by Fotieva, Bulychev et al. (2005).

There are some differences with the data from non-linear 3-D modeling showing the increase of maximal compressive stresses and the decrease of maximal tensile stresses in the lining up to 18–20% due to the

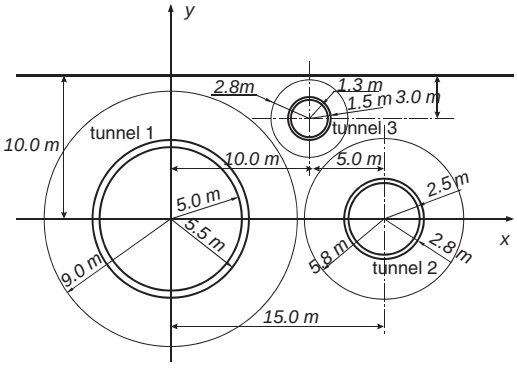

Figure 7. Tunnels cross-section.

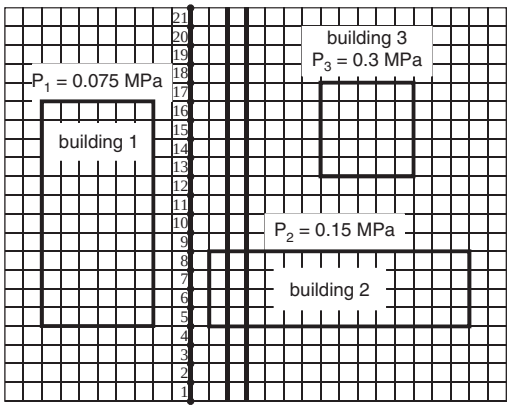

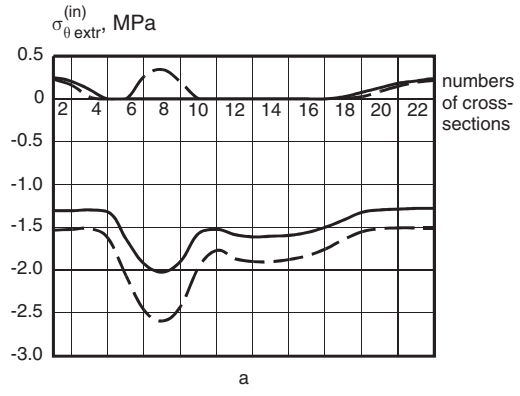

Figure 8. Plan of buildings locations.

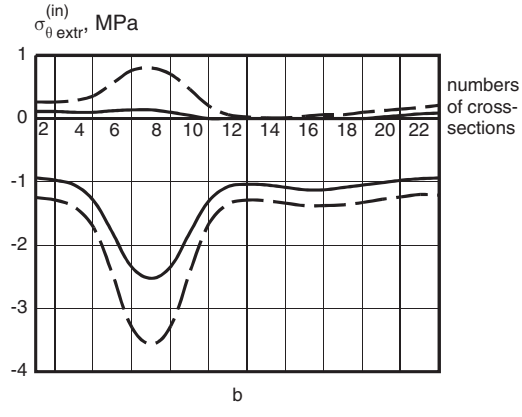

influence of plastic soil deformations. Since the tensile stresses are substantially more dangerous for the lining than the compressive ones, it is save to say that applying the linear model of soils lays only some additional margin of the lining safety.

3 EXAMPLES OF THE DESIGN

The example of the design of concrete linings of three parallel tunnels is given below. The input data are the following: $E_0 = 300$ MPa, $\nu_0 = 0.35$, $E_{1,1} = E_{1,2} = E_{1,3} = 900$ MPa, $\nu_{1,1} = \nu_{1,2} = \nu_{1,3} = 0.35$, $E_{2,1} = E_{2,2} = E_{2,3} = 30000$ MPa, $\nu_{2,1} = \nu_{2,2} = \nu_{2,3} = 0.2$, $\gamma = 0.022\,MN/m^3$, $\lambda = 0.54$, $l_1 = l_2 = l_3 = 1$ m. A cross-section of the tunnels is given in Figure 7.

Tunnel linings are subjected to the actions of soil own weight and the weight of three buildings erected close to already existing tunnels. The plan of the buildings locations is given in Figure 8.

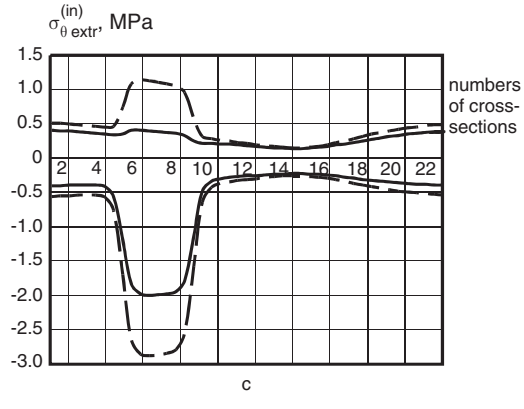

Figure 9. Distributions of maximal tensile and compressive stresses along the tunnel axes: a – tunnel 1; b – tunnel 2; c – tunnel 3.

One mesh on the plan has corresponds actual size 5 m × 5 m.

Distributions of maximal tensile (positive) and compressive (negative) stresses along the tunnel axes

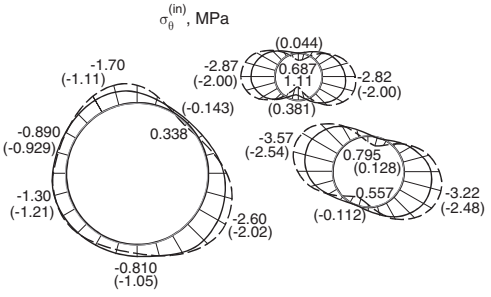

Figure 10. Circumferential stresses along the internal linings outlines in the cross-section 7.

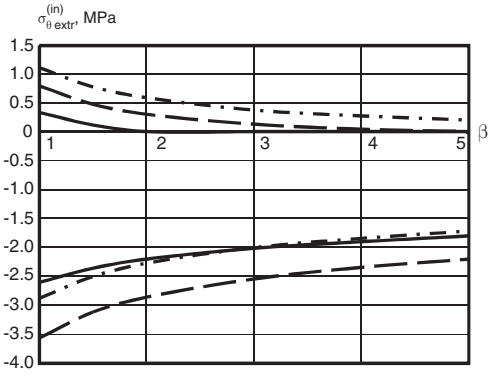

Figure 11. Dependencies of extreme stresses in the linings on the degree of strengthening.

are shown in Figures 9a, b, c by solid lines. Dotted lines correspond to the case when the tunnels are constructed without grouting.

One can see from figures 9 a, b, c that section 7 is the most dangerous for tunnels 1 and 2 and section 6 is the most dangerous for tunnel 3.

Diagrams of circumferential stresses along the internal linings outlines in the cross-section 7 are represented in Figure 10.

From Figure 10 one can see that the applying of grouting significantly reduce total stresses in tunnel linings. For example, maximal compressive stresses in tunnel linings fall by 22. . .30%, maximal tensile stresses disappear in the lining of tunnel 1 and drop by 38% and 84% in the linings of tunnels 2 and 3 correspondingly.

Dependencies of extreme (maximal compressive and maximal tensile) circumferential stresses $\sigma_{\theta\,extr}^{(in)}$ on the degree of strengthening $\beta = E_1/E_0$ are shown in Figure 11. Solid, dotted, dash-and-dot lines corresponds to stresses in the linings of tunnels 1, 2, 3.

On can see from Fig. 11 that the rise of the degree of strengthening leads to the decrease of extreme stresses in all three tunnels.

4 CONCLUSIONS

A new analytical method and the corresponding software for the design of multiple shallow circular tunnel linings including the ones constructed with the application of soil grouting in build-up areas has been developed. The method allows the influence of the distance between the lining been installed in every tunnel and the tunnel face and the sequence of tunnel complex construction as well as the 3D character of problems connected with surface loads caused by the weight of nearly located buildings to be approximately taken into account. This give a practical possibility to evaluate the linings stress state and their bearing capacity depending of thickness of zones strengthened by grouting and on the degree of strengthening by multi-variant calculations of a high accuracy requiting a few time.

Analyses of underground structures crossing an active fault in Coronado, California

T. Gregor & B. Garrod
Hatch Mott MacDonald, Mississauga, Ontario, Canada

D. Young
Hatch Mott MacDonald, Pleasanton, California, USA

ABSTRACT: The City of Coronado, California, has initiated the design for the State Route 75/282 Transportation Corridor Project. This project includes the design of approximately 5700 feet (1740 m) long twin road tunnels. The shallow, 32′–6″(9.9 m) finished diameter, tunnels will be crossing the seismically active Coronado Fault. A cut-and-cover box structure or twin bored tunnels lined with precast segmental concrete linings, have been considered as options in the area of the fault crossing. Assessment of the structural behaviour of these options during fault rupture consisted of the development of finite difference (bored tunnels) and finite element (cut-and-cover boxes) analytical models. Both types of models reflected non-linear stress-strain ground behaviour. The results of the design analyses have shown that it is possible to assess the structural behaviour of underground structures under severe ground displacement conditions using numerical analysis and to develop structural solutions.

1 INTRODUCTION

The City of Coronado has initiated the State Route 75/282 Transportation Corridor Project to improve traffic flow between the San Diego-Coronado Bay Bridge and the Naval Air Station North Island, a distance of approximately 1.4 miles (Figure 1). The project is in the Project Report / Environmental Document (PR/ED) phase. Several alternative alignments and associated construction methods are under consideration, including both cut-and-cover and twin bored tunnel options.

The tunnel length is approximately 5700 feet (1740 m). For the twin bored tunnels alternative, pressurized face tunnel boring machines (TBMs) will be used to install a single-pass lining system consisting of gasketed, precast concrete segmental rings concurrent with TBM advance. These rings are referred to as a Precast Concrete Tunnel Lining (PCTL) system. PCTL systems have been extensively used in seismically active locations in the United States and around the world (Dean, et. al. 2006).

In order to complete the PR/ED phase of the project, preliminary designs are required as a basis for estimating, and feasibility of designing fault crossings must be confirmed.

Figure 1. Project area.

2 GEOTECHNCIAL AND SEISMIC CONDITIONS

The excavations will be in soils, consisting of interbedded clays and sands of the Quaternary-age Bay Point Formation overlain by younger deposits of dune sand and fill. Bed thickness in the Bay Point Formation typically varies from a few inches to tens of feet. The natural water contents for these materials are

Table 1. Design ground motion levels.

Designation	FEE	SEE
Return period	150 years	Not applicable
PGA	0.17 g	0.57 g
PPV	7.8–8.3 inches/second	26.3 inches/second
Free field shear strain	0.04%	0.28%

Notes: PGA: Peak Ground Acceleration, PPV: Peak Particle Velocity, 1 inch = 25.4 mm

typically at or near the plastic limit, and the over consolidation ratio of these materials is typically in the range of 2.5 to 2.9.

The Bay Point Formation sands are medium dense to very dense, with an effective friction angle typcally ranging from 33 to 38 degrees.

Groundwater exists 10 to 15 feet (3.0 to 4.5 m) below ground surface, and depth to invert varies from 40 feet (12 m) for the cut-and-cover option to 100 feet (30 m) for the bored tunnel option.

Site seismicity and geologic hazards were assessed by Kleinfelder (2006). Three faults, the Coronado, Silver Strand, and Spanish Bight Faults, have been identified in and around the project area but only the Coronado fault crosses the proposed tunnel structures, as shown on Figure 1.

The project is being designed for a Functional Evaluation Earthquake (FEE) event and a Safety Evaluation Earthquake (SEE) event. As the anticipated lifetime of the project is on the order of 100 years, the FEE will conform to the 150-year return period event. The SEE event is similar to the maximum credible earthquake. The maximum moment magnitude for the SEE is 7.0. A summary of proposed design seismic ground motion levels for the SR75/282 Project is provided on Table 1. Return period and peak ground acceleration (PGA) values are provided in the table as well as peak particle velocity (PPV) and free field shear strains that consider near source effects.

3 CORONADO FAULT

The fault is only expected to rupture in the SEE event. It will rupture through the soil to the ground surface in an oblique sense of movement, with displacement spread over a fault zone thickness of 2 feet (600 mm). Displacement values for design are described in terms of vector components along strike and down dip.

The primary fault rupture occurs along the 2 foot (600 mm) wide zone that can occur anywhere within a 70 foot (20 m) wide zone along the alignment. In addition to primary rupture, secondary fault rupture would occur within a zone 50 feet (15 m) in each direction outside of the primary zone.

Table 2. Maximum fault rupture design parameters in the main zone.

Scenario	Lateral (Along Strike) Displacement (1 inch = 25.4 mm)	Sub-vertical (Along Dip) displacement
Right lateral	22 inches	11.75 inches
Left lateral	14 inches	11.75 inches

Table 3. Maximum displacements in secondary zone – footwall (hanging wall similar).

Scenario	Lateral (Along Strike) displacement	Sub-vertical (Along Dip) displacement
Right lateral	11 inches	5.9 inches
Left lateral	7 inches	5.9 inches

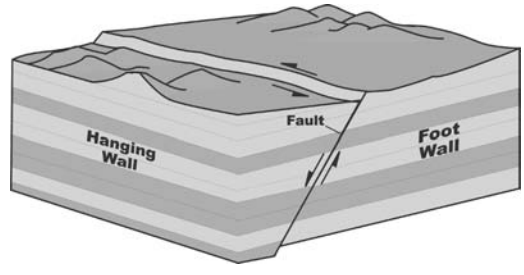

Figure 2. Hanging wall and Foot wall.

The lateral design offsets were estimated by deterministic methods. The two fault rupture lateral and vertical displacements for the SEE are outlined on Table 2 below for the main zone and in Table 3 for the secondary zones. A graphic depicting a hanging wall and foot wall is shown on Figure 2.

Lateral displacements occur in the same direction as the strike of the fault which intersects the tunnel at an angle of 78 degrees. The dip of the Coronado Fault was observed to be 70 degrees. (Kleinfelder, 2006).

4 BORED TUNNELS

4.1 *Tunnel structure properties and geometry*

Geometry of the planned tunnels and assumptions that were built into the analytical models were as follows:

- External tunnel diameter: 36.5 feet (11.12 m)
- Lining thickness: 1.5 feet (457 mm)
- Ring length 5 feet (1.52 m)
- Number of segments in a ring: 6 + a key
- Spacing between the twin tunnels 62.5 feet (19.05 m) center-to-center
- Lining modulus of elasticity 4354 ksi (30000 MPa) (uncracked concrete)

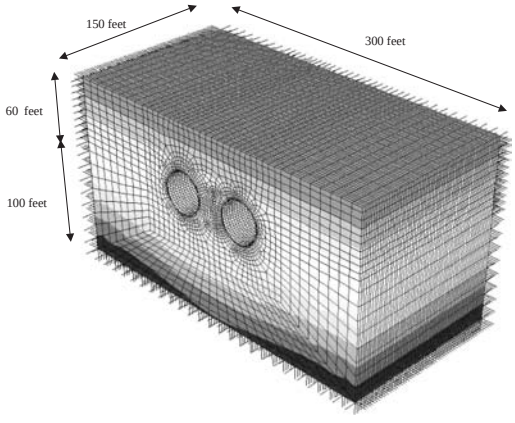

Figure 3. FLAC^{3D} model.

- Closure of the convergence gap between the extrados of the lining and the soil was assumed to be 0.25″ (6 mm) before grouting.
- The friction angle between the extrados of the lining and soil/grout was assumed to be 15°, reflecting the smooth surface of the extrados and presence of the tail seal grease from the TBM.

4.2 *FLAC^{3D} model size*

The block of ground represented in the models is 300 feet (91.4 m) wide 150 feet (45.7 m) long and 160 feet (48.8 m) deep with the tunnels located with their horizontal axis 60 feet (18.3 m) below the ground surface. See Figure 3.

Only the primary slip zone displacements were modeled for the bored tunnels, since the gradient of displacement is much more severe in the primary rupture zone in comparison to the secondary zone and it seems to be reasonable to assume that if the structure can withstand the primary zone displacement it can withstand the secondary zone displacements at the same time.

4.3 *Lining ring stiffness*

The precast lining is a segmental lining therefore its flexural stiffness in the hoop direction will be less than that of a solid tube. Muir Wood (1975) proposed that the stiffness of the segmental lining can be approximated by:

$$I_e = I_j + \left(\frac{4}{n}\right)^2 I \qquad (1)$$

With $I_e \leq I, n > 4$

Where I_e is equivalent moment of inertia, I_j is the moment of inertia of the joint (assumed 0 in this case) and n is the number of radial joints and I is the moment of inertia of the solid section of the lining. The formula has been derived under the assumption that the radial joints are uniformly distributed along the ring circumference. Typically, with the key segment being much smaller than the rest of the segments the radial joints adjacent to the key are much closely spaced than the rest of the radial joints and thus the two joints adjacent to the key were conservatively considered as one joint.

In order to preserve the true axial load stiffness of the lining the following calculations had to be performed where t_m is the lining thickness in the model, t is the actual thickness of the lining, E_m is the modulus of elasticity of the lining in the model, E is the actual modulus elasticity of the lining and A is the actual lining area per unit length:

$$I_e = \frac{t^3}{12}\left(\frac{4}{6}\right)^2, A = t, I_j = 0, n = 6 \qquad (2)$$

$$t_m = \left(\frac{12 I_e}{A}\right)^2 \text{ and } E_m = \frac{EA}{t_m} \qquad (3)$$

4.4 *Lining ring connectivity*

Precast rings are connected along the circumferential joints by bolts or dowels. In addition, the thrust of the TBM on the lining during the tunnel construction results in locked in compression along the circumferential joint interface between adjacent rings. Therefore, the relative displacement (slip) between adjacent rings is difficult to estimate. To capture the limits of behaviour we have assumed three extreme cases:

Case 1. Adjacent rings cannot slip relatively to each other along the circumferential joints but the joint can open and only compression force can be transmitted across the joint.

Case 2. Adjacent rings behave independently of each other, where no force (axial or shear) is transferred from ring to ring across the circumferential joint.

Case 3. Adjacent rings are fully connected to each other, the tunnel is a continuous structure. This would approximate a structure with special provisions to prevent joint opening and transfer forces across the joint.

4.5 *Modeling process*

- In-situ stresses including pore pressures from the water table were generated in the soil block.
- Soil in the tunnel void was removed and a stress free linear elastic lining, was installed. A 0.25″ (6 mm) gap (corresponding to the 0.23% volume loss) was left between the lining and the soil.
- The gap was pressurized to the level of the water table head.

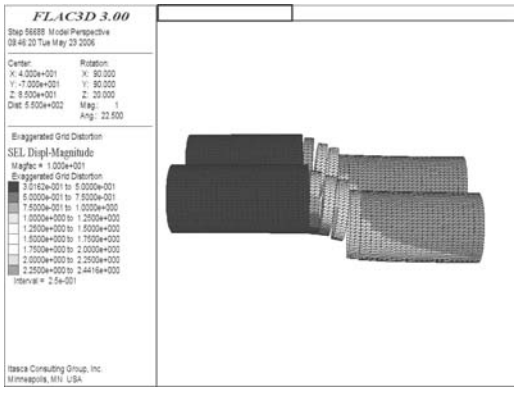

Figure 4. Case 2 tunnel ring displacements (x10).

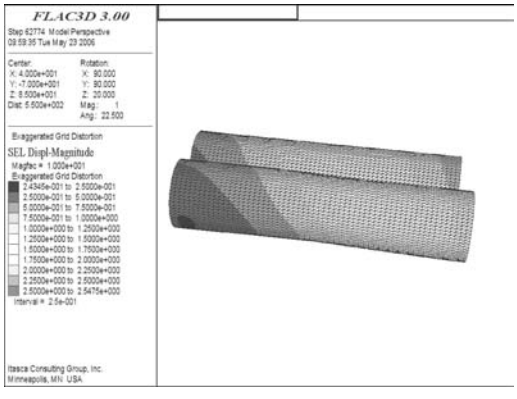

Figure 5. Case 3 tunnel ring displacements (x10).

- The system was brought to equilibrium, while the gap was allowed to close.
- In the next phase, the fault offset displacement pressures have been gradually applied to the boundaries of the model while concurrent solving of the model towards equilibrium was performed. Once the prescribed displacements at the model boundaries were reached the model was brought into the final equilibrium.
- A similar gradual loading process was applied to model the SEE shaking. A free field strain of 0.34% was applied gradually along the boundaries of the model, perpendicularly to the tunnel direction thus imposing ovaling deformations.
- Non-linear material simulation of the concrete lining was performed.

4.6 *Observations from the analyses*

Figure 4 shows that for ***Case 2*** the tunnel displacements follow the ground displacements. Figure 5 shows that for ***Case 3***, however, the tunnel

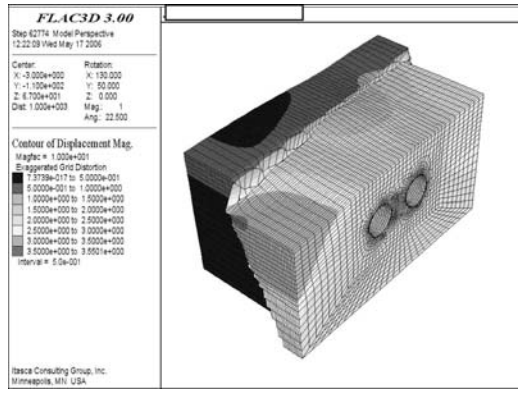

Figure 6. Case 3 soil block displacements (x10).

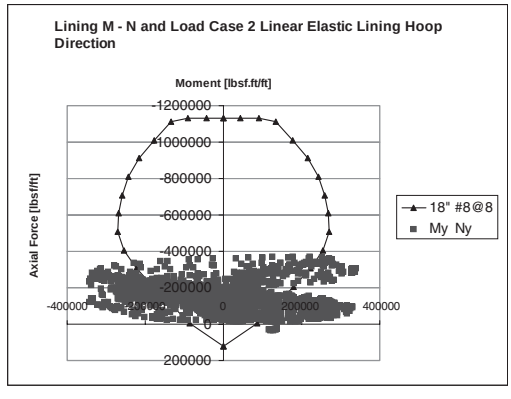

Figure 7. Capacity and loads, linear elastic lining hoop direction, case 2.

displacement is gradual, extending beyond the model limits and smoothes out the abrupt ground displacement. ***Case 1*** results were intermediate between these two extremes.

4.6.1 *Post processing*

A moment-axial force interaction curve was developed for the precast lining assuming the reinforcement of about 1% in each direction. Values of axial loads and corresponding moments were read from all elements representing the tunnel lining in the model and plotted against the capacity curves.

4.6.2 *Lining as linear elastic material*

As the first step in the evaluation, the lining rings were conservatively assumed to be a linear elastic material. This would correspond to uncracked lining. Figure 7 shows the critical curve for ***Case 2*** connectivity assumption.

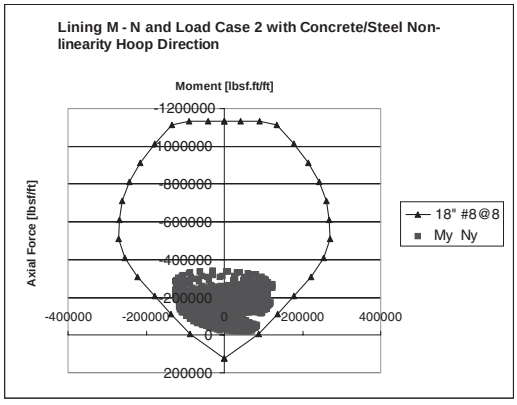

Figure 8. Capacity and loads, non-linear lining hoop direction case 2.

As it can be seen, the lining capacity appears to be insufficient in the hoop flexure for ***Case 2*** when the lining is considered to be linear elastic material.

4.6.3 *Lining as non-linear material*

The loading on the lining rings has been applied by prescribed ground displacements rather than by applied forces, which would remain constant throughout the loading process. If the flexibility of the structure increases (say by cracking) the forces in the lining will decrease. The key is to ensure that there is a sufficient ductility in the lining ring structure and that with additional small displacements the internal forces in the structure decrease.

The reinforced concrete material has been simulated using a HMM developed FISH function (FLAC^{3D} internal programming language). The method takes each lining model element and divides it into 10 layers. Strain in each layer is evaluated. Based on a parabolic and no-tension stress-strain relationship for concrete and elasto-plastic relationship for rebars, stresses in each layer are calculated. Stresses are summed into sectional forces and added into the equilibrium equations which are rebalanced in the solving process.

Figure 8 shows the lining capacity curves for the same case and direction as in Figure 7 but with the lining as non-linear material. Strains in the rebars in no case exceed 6%, the typical rebar rupture limit. The results clearly show that the lining strength is sufficient once the non-linearity of the lining is considered. This was true for all configuration cases.

5 CUT AND COVER BOXES

5.1 *Boxes properties and geometry*

A 3-D model of the cut-and-cover box was built using StaadPro software. The model represented a 294 feet (89.6 m) long section of the concrete box. The box geometry is outlined in Figure 9. The box is assembled from rectangular linear elastic plate elements.

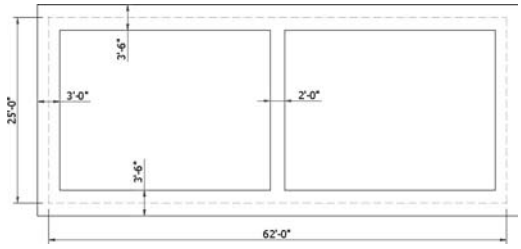

Figure 9. Box geometry.

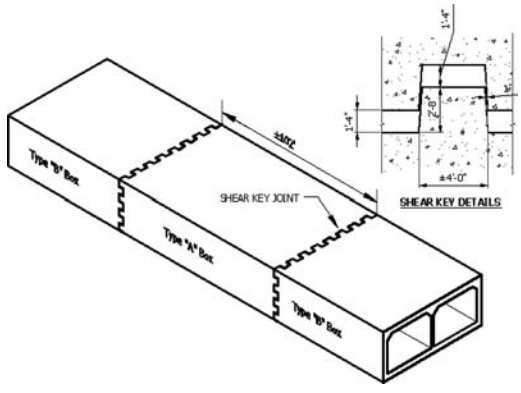

Figure 10. Box layout.

The soil was represented by compression-only springs that were placed at every exposed model node of the structure. The springs act perpendicularly to the corresponding face of the box and are capable of transmitting axial compression only. These springs have variable stiffness and are defined by multi-linear curves.

In order to simulate the long tunnel, elastic springs were assumed at both ends of the box. In trial runs we found that a seamless continuous box would produce very high compressive and tensile forces along the box length that required heavy reinforcing. For that reason shear key joints were introduced in the structure so that axial stresses are relieved during fault rupture event. A conceptual sketch of shear key joint is presented in Figure 10. Box A is the box crossing the main rupture zone, boxes type B are adjacent boxes. In the model these joints are simple hinges that are only capable of carrying in-plane shear forces only along the joint edges. The two shear key joints were placed 102 feet (31.1 m) apart so that fault rupture plane is at equal distance from each joint.

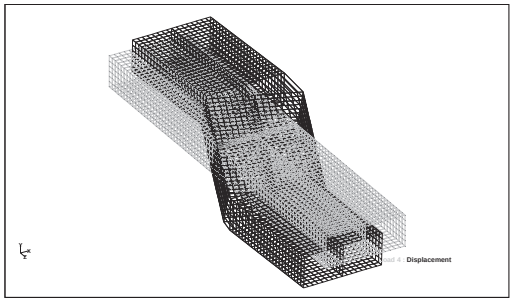

Figure 11. Box displacements.

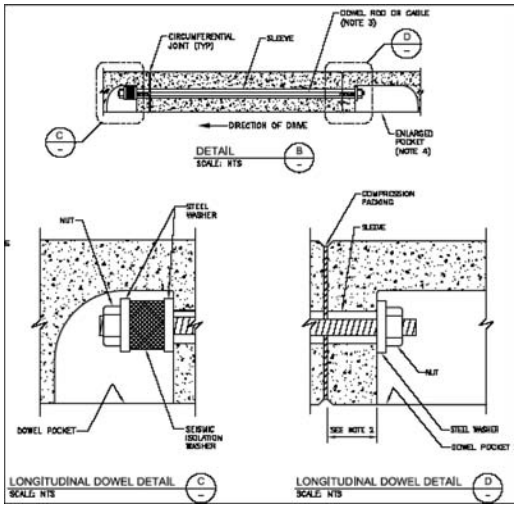

Figure 12. Circumferential joint opening control.

5.2 *Modeling sequence in StaadPro*

A two stage modeling sequence was used to circumvent some of the StaadPro loading modeling limitations.

Soil shear strains causes by ground shaking were applied as an additional, racking, displacement derived from the calculated soil shear strain and the ratio of the ground and structure stiffness.

Consideration has been given to using compressible material around the box structure to reduce the forces on the structure due to ground movements.

5.3 *Analyses results*

Figure 11 shows the resulting box displacement. The results also showed that with providing the special joints the effect of the fault rupture was actually secondary to the effects of the ground shaking.

6 CONCLUSIONS

From application of numerical analyses tools to assess the effects of a rupture of the Coronado fault on underground structures crossing the fault it can be concluded that:

- It is feasible to design a structure crossing the fault that would withstand the SEE and rupture event without a structural collapse.
- Both bored tunnels and cut-and-cover boxes can be used for this purpose.
- Both structures would show some degree of post-rupture damage (concrete cracks, large deformations).
- Bored tunnels constructed using segmental lining are more prone to inundation by water and soil during and after the fault rupture event. However, providing longitudinal ties connecting the rings and/or soil treatment around the tunnels over the tunnel length affected by the fault rupture could mitigate this issue. Some type of circumferential joint opening control is required, an example of which is shown in Figure 12.

Numerical modeling of tunnel excavation and lining under high initial stresses and high underground water pressures at Jinping Mountain

Wei Chen & Huai-Ning Ruan
Institute of Geotechnical Engineering, Hohai University, Jiangsu Province, China

ABSTRACT: The Jinping underground hydroelectric power plant is one of major hydropower projects in China. Four high-pressure tunnels at about 2000 m depth below JinPing Mountain surface act as waterway towards the power plant. The phreatic water table is located at about 900 m above the tunnels. This paper presents the tunnel excavation and lining procedures under high initial stresses and high underground water pressures at Jinping Mountain. Coupled hydro-mechanical (HM) behavior of fractured rock during tunnel excavation is analyzed. A three-dimensional stochastic continuum model that accounts for the heterogeneity of the permeability has been developed to simulate the excavation and lining processes. The random permeability field is generated using sequential indicator simulations, which is then mapped into the finite element mesh. The concrete lining is modeled by shell elements and assumed impervious. Truss elements embedded in a set of three dimensional solid elements are used to model anchors with the embedded element technique. Some simulation results are discussed in details in this paper.

1 INTRODUCTION

The Jinping hydroelectric power generation plant with a maximum generating capacity of 4400 MW is one of the major hydropower projects in China. The pressure tunnels, which act as waterway towards the power plant, have an excavated span of 12 m and are approximately located at 2000 m depth below the Jinping Mountain surface. The water table is at about 900 m above tunnels. An understanding of the mechanical behavior of the support system and the hydro-mechanical (HM) processes of fractured rock are major challenges when assessing the performance of pressure tunnels under high initial stresses and high water pressures.

Natural spatial variability in hydraulic and mechanical variability can play an important role in the hydro-mechanical processes in fractured rock (Hudson et al, 2001). In this paper a three-dimensional stochastic continuum model that accounts for the heterogeneity of the hydraulic properties of fractured rock has been developed by using a non-parameter geostatistical technique. The results are then imported into a finite element model that resolves the HM behavior in detail. The tunnels are excavated in full-section and supported with rock anchors and concrete lining after excavation. The compliant joint model (CJM) (Chen, 1991) has been employed to perform mechanical calculations; both drained and undrained conditions are discussed in our numerical model. Coupled HM simulations were implemented with the commercial code ABAQUS 6.6 (ABAQUS, 2005).

2 MATHEMATICAL FRAMEWORK

2.1 *Fluid mass balance equations*

The final form of mass balance equation of flow in a deformable porous medium is expressed as:

$$\phi\frac{\partial(S_w\rho_w)}{\partial t}+S_w\rho_w\left[\frac{\partial\varepsilon_v}{\partial t}+\frac{(1-\phi)}{\rho_s}\frac{\partial\rho_s}{\partial t}\right]=-\nabla\cdot(\mathbf{q_w}) \quad (1)$$

where ϕ is the porosity, S_w is the saturation, ρ_s and ρ_w are the density of the solid and the fluid respectively, ε_v is the skeleton volume strain, and $\mathbf{q_w}$ is the mass flux. The rate of change of fluid mass is caused by changes in saturation, fluid density, volume strain of solid skeleton and grain volume (Lewis, 1987).

The mass flux, $\mathbf{q_w}$, can be written as

$$\mathbf{q}_w=-\rho_w\frac{\mathbf{k}}{\gamma_w}(\nabla P_w-\rho_w\mathbf{g}\nabla z) \quad (2)$$

where $\mathbf{k}$ is the hydraulic conductivity, P_w is the pore pressure. The permeability is assumed constant and heterogeneous in our numerical model.

2.2 *Mechanical constitutive relations*

The compliant joint model is used for modeling the mechanical behaviour. The CJM provides a simple, continuum model for materials containing a high density of parallel joint surfaces in different orientations. It can model joint opening/closing and the plastic behaviour of a joints system, which is defined as:

$$f_a = \tau_a - P_a \tan \beta_a - d_a \tag{3}$$

where f_a is the failure surface, τ_a is the magnitude of the shear stress resolved onto the joint surface, P_a is the normal pressure stress acting across the joint, β_a is the friction angle for the joint system a, and d_a is the cohesion for system a.

3 GENERATION OF THE HETEROGENEOUS PERMEABILITY FIELDS

The hydraulic conductivity of the rock matrix is ignored because the matrix permeability is several orders of magnitude lower than the fracture permeability. The dimensions of the domain are $700 \times 1000 \times 1100$ m in the x, y, z directions, respectively. The domain is discretized into $5 \times 10 \times 5$-m grids for a total of 3,080,000 elements. The random field generation was performed with the sequential indicator simulation routine SISIM (version 2.9) of the geostatistical library GSLIB (Deutsch and Journel, 1992). The sequential indicator simulation allows users to assign different isotropic or anisotropic correlation scales to different segments of the probability density function. The permeability data used for the creation of the random fields are mainly based on pumping test in Jinping Mountain and the fracture surveys in the drift tunnel. A spherical correlation structure with an isotropic correlation length of 5 m is adopted for permeability values less than $10^{-13.5}$ m. A correlation length of 90 m in the x-direction and the z-direction, and a correlation length of 10 m in the x-direction, both using a spherical correlation structure, are given to permeability values larger than $10^{-13.5}$ m. Figure 1 shows a generation of the permeability field.

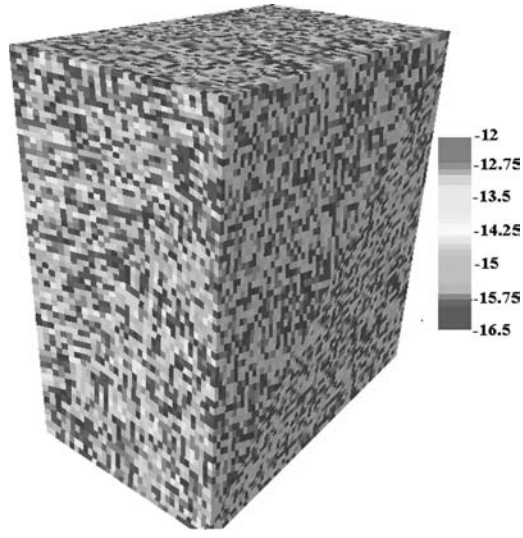

Figure 1. Permeability distribution generated by GSLIB (the legend indicates log10 permeability in m^2.

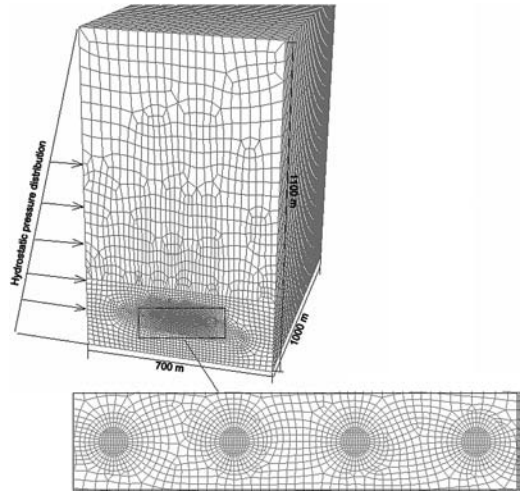

Figure 2. The finite element model (the mesh near tunnels are enlarged).

4 MODELLING OF EXCAVATION AND LINING

4.1 *Model domain geometry and boundary conditions*

It is impractical to model the whole mountain for the coupling calculations. Therefore a 'local model' was developed in our study. The 3D domain chosen for the simulation is 700 m wide (x-direction), 1000 m deep (y-direction) and 1100 m high (z-direction). In order to limit the computational load, a relatively coarse mesh with high resolution grids near the tunnels is used. The finite element mesh is shown in Figure 2. The heterogeneous permeability distribution is interpolated from the previous high-resolution onto this finite element mesh.

The vertical boundaries have a constant hydrostatic pressure, and the top and bottom boundaries have a no flow condition. The initial stress was obtained from the calibrated data based on a regression analysis.

Table 1. Material parameters for coupling analysis.

Material type	Properties		value
Fluid	γ_w, specific weight		10 kN/m^3
	E, Young's modulus		2.5e + 07 kPa
	γ_s, specific weight		27 kN/m^3
	ν, Possion's ratio		0.3
	n, porosity		0.007
Fractured rock	φ, Friction angle	Parameters	35°
	ψ, dilation angle	for joints	15°
	C, cohesion		40 kPa
	φ, friction angle	Druker-Prager	45°
	ψ, dilation angle	parameters for	35°
	C, cohesion	bulk material	1350 kPa
Concrete lining	E, Young's modulus		3.0e + 07 kPa
	ν, Possion's ratio		0.2
	d, thickness		0.5 m
Steel anchors	E, Young's modulus		2.1e + 08 kPa
	ν, Possion's ratio		0.3
	L, length		6 m

4.2 *Numerical analysis steps*

The tunnels are excavated in full-section and are supported by steel anchors and concrete lining after excavation. Steel anchors are modeled by truss elements which are embedded in solid elements. Shell elements are used to represent concrete lining. The details of analysis steps are as follows:

(1) Initial stresses were imported, and lining and anchor elements were deactivated. Geostatic equilibrium was established during this step.
(2) Excavated rock elements were deactivated and nodal forces and fluxes were ramped down to zero in the excavation stage.
(3) Anchor and lining elements were activated. Both drained and undrained conditions during tunnel excavation are included in our model. The properties of rock and fluid are summarized in table 1. The physical deterioration of the components of rocks due to pore water was not considered.

5 RESULTS

5.1 *Displacements*

Figure 3 illustrates the radial displacement of a tunnel section after excavation under undained conditions. The calculated results have indicated inward, non-uniform convergence of the tunnel. The maximum value of radial displacement is 2.2 cm, which occurs at the side walls of the tunnel.

Figure 4 shows the radial displacement of the section under drained condition. It is found that the inward

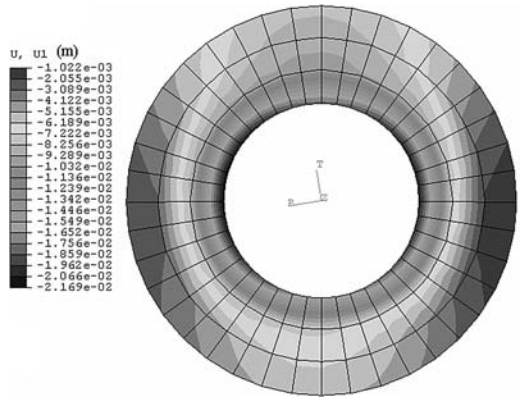

Figure 3. Radial displacement of a tunnel control section under undrained conditions.

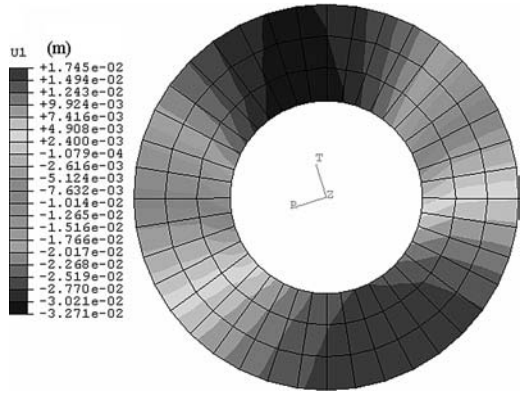

Figure 4. Radial displacement of a tunnel control section under drained conditions.

deformation of the crown is relatively large. The bottom of the tunnel section has an outward deformation. This is caused by drainage-induced consolidation of rock in the vicinity of the tunnel. The pore pressure is much reduced after drainage, which will induce a new non-uniform deformation of the opening.

5.2 *Stresses and moments*

The tangential stresses of rock around the tunnel under drained and undrained conditions are illustrated in Figure 5 and Figure 6, respectively. When the tunnel is assumed undrained, tensile stresses occur in rock, which are not found in the calculated results when assuming full-drainage conditions. A comparison between the two results indicates that drainage conditions have significant effects on mechanical response of rock.

Figure 7 and Figure 8 show the stresses in the steel anchors. It is found that the tensile stresses in anchors under non-drainage conditions are larger than

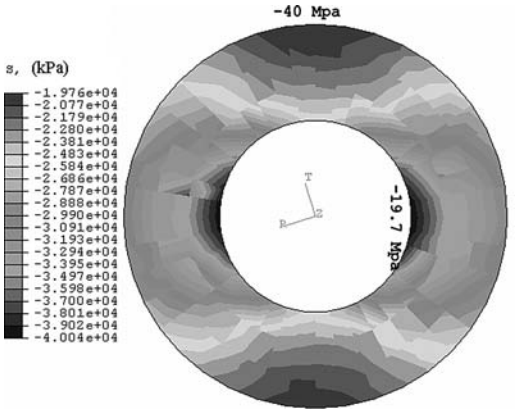

Figure 5. Tangential stresses of a tunnel control section under drained conditions.

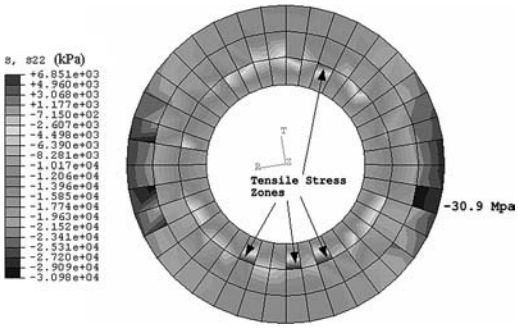

Figure 6. Tangential stresses of a tunnel control section under undrained conditions.

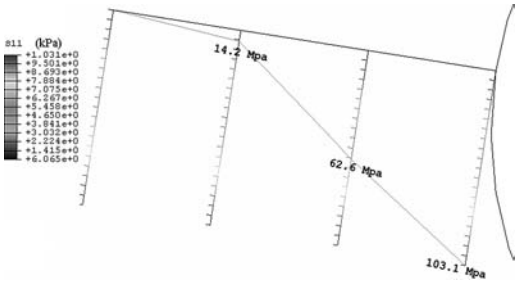

Figure 7. Axis tensile stresses of an anchor under drained conditions.

that under full-drainage conditions. The maximum value of tensile stresses under undrained conditions is 236.4 MPa.

However, the stresses in the concrete lining are not affected by the drainage conditions, which is also presented by Bobet using analytical solutions (2003). The calculated moments in the lining are shown in Figure 9.

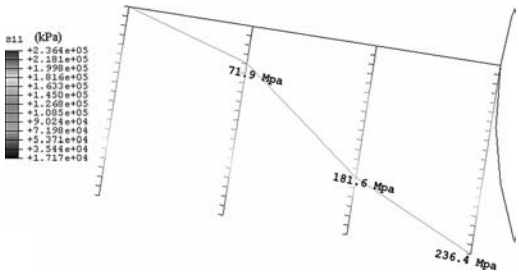

Figure 8. Axis tensile stresses of an anchor under undrained conditions.

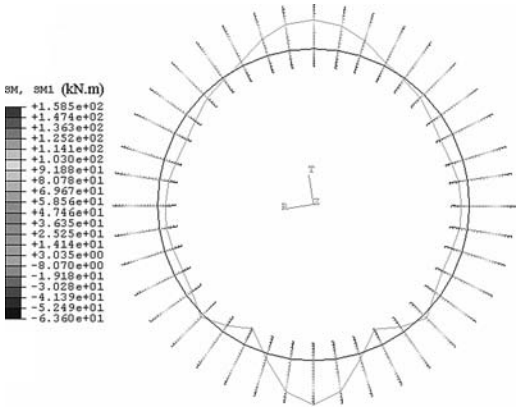

Figure 9. Moments in the lining.

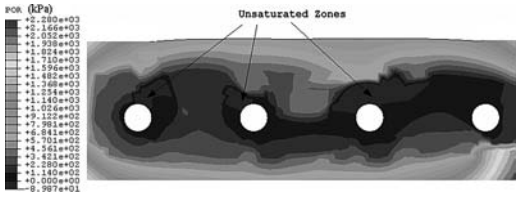

Figure 10. Pore pressure contours at a slice under full-drainage conditions.

The maximum moment occurs in the bottom of the lining, with the value 158.5 kN.m.

5.3 *Pore pressure*

Figure 10 presents the pore pressure results at the slice 400 m from the tunnel access. Negative pore pressures have been predicted near the tunnel after drainage using the heterogeneous permeability field as shown in the contours, which indicates the development of an unsaturated zone. This is the result of highly permeable fractures in the tunnel vicinity. The contours indicate a non-uniform pore pressure distribution, which reflect the heterogeneity of the model area.

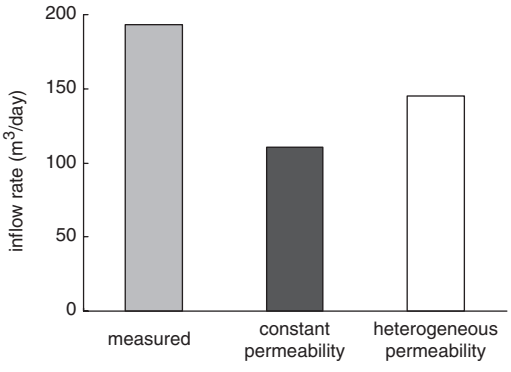

Figure 11. Inflow rates to the tunnel.

5.4 *Inflow rates to the tunnel*

The calculated inflow rates are compared to the measured data in Figure 11. The maximum water inflow rate to the tunnel, in calculations with heterogeneous permeability, is about 145 m^3/day, which is close to the measured value (194 m^3/day). Assuming constant permeability, the result is much smaller (110 m^3/day).

Both simulated results of maximum inflow rate were below the actual measurements, which may be caused by the ignorance of the underground water recharge in our study.

6 CONCLUSIONS

A 3D finite element model with heterogeneous permeability has been developed for simulating coupled hydro-mechanical behavior during tunnel excavation. The calculated results of hydraulic and mechanical response have been discussed in detail.

The results have indicated that the presence of groundwater in rock has a negative effect on the stability during tunnelling as a result of strength reduction due to the reduction of effective confining stress caused by high pore water pressures. Tensile stresses, which are found under non-drainage conditions, are eliminated when assuming full-drainage conditions. The stresses in steel anchors also change significantly from drainage to non-drainage conditions. It can be concluded that with the application of the drainage and removal of pore water and water pressure from fractured rock, tensile forces will be eliminated and rock masses can be strengthened.

The heterogeneous model gives a better prediction of inflow rates compared to the homogeneous model. Due to highly permeable features in the heterogeneous model, unsaturated zones are predicted. The heterogeneity of permeability has a significant effect on the hydraulic behavior of fractured rock during tunnel excavation.

ACKNOWLEDGEMENTS

The authors are grateful to Wouter Karreman at Delft University of Technology, the Netherlands for a careful review of the manuscript and his critical comments.

Simulation of failure around a circular tunnel using a bonded particle model

Dae-Sung Cheon & Chan Park
Korea Institute of Geoscience & Mineral Resources, Korea

Seokwon Jeon
Seoul National University, Korea

Young-Sik Jeong
Sambo Eng. Co. Ltd., Korea

ABSTRACT: To evaluate brittle failure around deep tunnels, true triaxial compression tests were performed, using cement mortar with a circular tunnel. In order to simulate the observed failure zone around the tunnel, the particle flow code (PFC) was applied. The PFC is a distinct element geomechanical modeling program in which rock is represented by an assembly of thousands of round particles bonded together at each contact point. The modeling program reproduced complex macroscopic behavior such as strain softening and dilation by simulating micro-mechanisms without resorting to complex constitutive laws. To determine the micro-mechanical parameters needed in the calibration process of the simulation, laboratory uniaxial tests were performed. Compared to the continuum models with traditional failure criteria, PFC^{3D} simulated the localization behavior of the brittle materials, and the numerical model reproduced the failure zone observed in the physical model test.

1 INTRODUCTION

At low in-situ stress magnitudes, the continuity and distribution of natural fractures in a rock mass control failure processes. However, at highly stressed levels, the failure process is affected and eventually dominated by stress-induced fractures growing preferentially parallel to the excavation boundary. And in these geological environments, brittle failure is the dominant failure mode. Brittle failure results from the growth and accumulation of tensile cracks around tunnels. This failure is usually described as "spalling" or "slabbing," and the shape of the failure zone is commonly called the "breakout" or "V-shaped notch."

To model the observed spalling, numerical simulations were carried out using the Mohr-Coulomb or Hoek-Brown criterion (Read & Martin, 1996). However, none of the suggested modeling simulations predicted a V-shaped failure zone. This is because conventional continuum modeling approaches overlook a fundamental observation of brittle failure, which is that the formation of tensile crack is the first step in the failure process.

In this study to simulate an observed failure zone around a tunnel, the particle flow model (PFC^{3D}), which does not need specific failure criteria, was applied. To determine the micro-mechanical parameters needed in the calibration process of the simulation, laboratory uniaxial tests were performed. And to investigate the effect of particle size on macro-properties, the resolution test was carried out.

The results of PFC^{3D} modeling were verified with the physical model tests, which were performed under true triaxial stress conditions using a cement mortar block with a circular tunnel. Also, the results of the modeling were compared to the continuum modeling.

2 BONDED PARTICLE MODEL

2.1 *Theory*

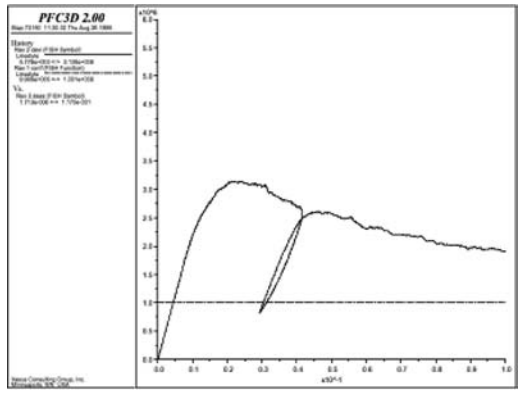
The particle flow code (PFC) is a discontinuum code that represents a rock mass as an assemblage of balls confined by planar walls. The distinct element method is used to model the forces and motions of the particles within an assembly. This method is similar to that used in explicit finite difference analyses and allows information to propagate dynamically through the system.

The particles move independently of one another and interact only at contact points. They are assumed to be rigid (non-deformable), but overlap can occur at the contacts. Contacts are assumed to exist only at a point and not over some finite surface area as would be the case with fully deformable particles. The particles

can be bonded together to simulate a competent rock. The contact bonds can be envisaged as a pair of elastic springs with constant normal stiffness and shear stiffness acting at a point. The values assigned to these stiffnesses influence the macro deformation properties of the rock sample. The contact bonds also have a specified shear and tensile strength. The values assigned to these strengths influence the macro-strength of the sample and the nature of cracking and failure that occurs during loading.

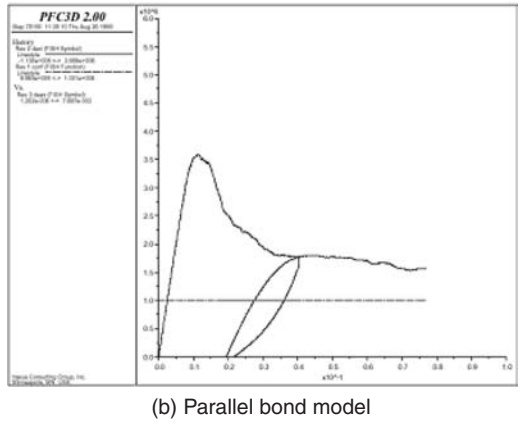
After a bond breaks in PFC, stress is redistributed, and this may then cause more cracks to form nearby. If the rock model is suitably stressed, then these bond breakages will localize into an inclined macro-fracture. Eventually, the macro-fracture will cause sample failure. In this way, deformation and fracture of rocks is modeled directly by allowing micromechanical damage to evolve, instead of indirectly by using constitutive equations, as is the case in most continuum models (Itasca Consulting Group Inc., 1999; Hazzard & Young, 2000).

2.2 *Bonding type*



PFC^{3D} allows particles to be bonded together at contact points. Two bonding models are supported: a contact bond model and a parallel bond model. Both bonds can be envisioned as a kind of glue joining the two particles. The contact-bond glue is of a vanishingly small size that acts only at the contact point, while the parallel-bond glue is of a finite size that acts over a circular cross-section lying between the particles. The contact bond can transmit only a force, while the parallel bond can transmit both a force and a moment.

Both types of bonds may be active at the same time: however, the presence of a contact bond inactivates the slip model. Once a bond is formed at a contact between two particles, that contact continues to exist until the bond is broken. Only particles may be bonded to one another; a particle may not be bonded to a wall.



Two simulations are performed with a contact bond and a parallel bond (Fig. 1). In the unload/reload cycle during the test with the contact bond, there is only minor degradation in the elastic modulus. This reflects the nature of contact bonds, which represent only the drop in the load-carrying ability of a contact, not the change in stiffness. The parallel bond, on the other hand, also models stiffness reduction during failure. A parallel bond is more suitable to materials such as rock. Thus, in this study, parallel bonds are adopted for the simulation.

2.3 *Effect of resolution on macro-properties*

If the PFC is used to predict damage formation surrounding an excavation, then the absolute size of the potential damage region is fixed, and successively finer resolution models can be produced by decreasing

(a) Contact bond model

(b) Parallel bond model

Figure 1. Axial deviatoric stress and confining stress vs. axial strain.

particle size. It is expected that as the resolution continues to increase, the coefficients of variation will converge to specific values. These values should be a true measure of the effect of both packing and strength heterogeneities in the model materials, because the number of particles across the specimen has become large enough to obtain a representative sampling of the material response. A high resolution must be present for the model to resolve and reproduce the failure mechanisms that influence the strength properties.

To evaluate the effect of resolution on macro-properties, six PFC^{3D} materials were produced using the same micro-properties with different values of resolution. In this study, the resolution is defined as the number of particles within the model width. Table 1 shows the tested resolution and run time.

The Young's modulus and peak strength, etc. except for Poisson's ratio, exhibits a dependence on the resolution (Fig. 2). The characterization of the elastic grain-cement micro-properties in terms of the ball-ball contact modulus, parallel bond modulus, ball stiffness

Table 1. Mean radius of particle at each resolution.

Resolution	Mean radius (mm)	Run time (min.)	No. particle
5	5.2	1	298
10	2.6	11	2837
15	1.73	36	8103
20	1.3	94	19098
25	1.04	222	37301
30	0.87	517	63719

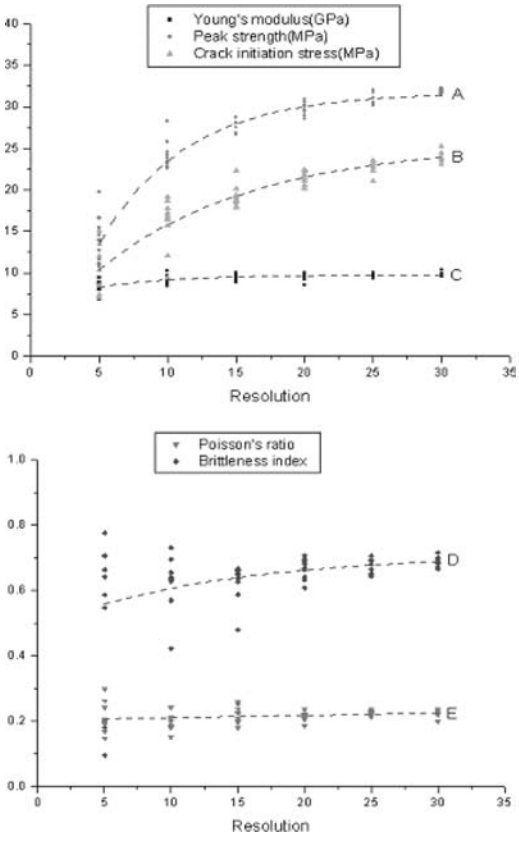


Figure 2. Result of resolution test.

ratio, and parallel bond stiffness ratio provides a size-independent means of specifying the Poisson's ratio of the material, but the Young's modulus exhibits a minor size effect (Potyondy & Cundall, 2004).

PFC^{3D} modeling in high resolution needs a much more efficient computer CPU and run time than PFC^{2D}. And some times the modeling does not run. Thus, in this study a 25 resolution was used to predict failure.

Table 2. Micro-parameters used in modeling.

Parameter	Description	Value
ρ	ball density [kg/m^3]	2,020
Ec	ball-ball contact modulus[GPa]	9.7
k_n/k_s	ball stiffness ratio	2.1
$\overline{\lambda}$	parallel bond radius multiplier	1.0
$\overline{E_c}$	parallel bond modulus	9.7
$\overline{k_n/k_s}$	parallel bond stiffness ratio	2.1
μ	ball friction coefficient	1.5
(mean)	parallel bond normal strength (mean)	35

2.4 *Determination of micro-parameter*

In order to determine the micro-parameter necessary for bonded particle modeling, preliminary analyses with varying micro-parameters were carried out.

The model width for determining the micro-parameter was set to 50 mm as the average diameter of the test samples used in the uniaxial compressive tests. The model height was set to 100 mm in order to satisfy the height/diameter ratio of 2:1. The measurement circles were located in the top, bottom, and middle of a test sample, and in each time step, the stress and stain of a model were calculated by averaging the stress and strain of particles within a measurement circle. The determined micro-parameters are listed in Table 2.

3 PHYSICAL MODEL TESTS

Physical model tests under true triaxial stress conditions were carried out, in order to evaluate brittle failure around deep tunnels.

3.1 *Specimen and test procedure*

The specimen used as substitute rock was cement mortar. This mortar was formed by mixing cement, fine sand, and water in the proportion of 3:6:2 by weight and air curing more 28 days. The size of the specimen was 290 mm × 290 mm × 290 mm. It had a half-excavated circular tunnel of 60 mm in diameter. The specimen width was five times the tunnel diameter to eliminate edge effects.

The physical model tests were carried out using a true triaxial testing system (Cheon et al., 2006). The testing system consists of two main parts: the biaxial loading apparatus and the polyaxial pressure chamber. The test procedure was conducted as follows.

To avoid intrusion of fluid into the specimen during tests, the surfaces of the specimen were coated with a thin film. Also, the entrance of the tunnel was isolated by a tunnel plug to prevent fluid from entering the tunnel.

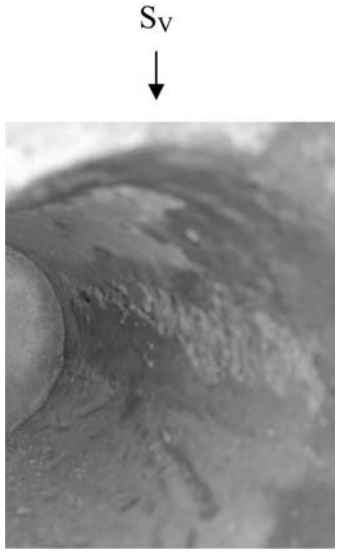

Figure 3. Failure around the tunnel in the physical model test.

The prepared specimens were carefully transferred into the polyaxial chamber. Using a hoist and an electric lift, the chamber was settled into the Interlaken rock testing machine. Next, the two independent stresses (S_V and S_{H2}: perpendicular to the tunnel axis) were applied initially in small amounts (about 1 MPa). And then S_{H1}, which was parallel to the axis of the tunnel axis, was increased to a constant value. After reaching the predetermined level of S_{H1} and S_{H2}, S_V was increased monotonically to a constant level ($S_V > S_{H2} > S_{H1}$). During the tests, acoustic emissions and source locations were detected to determine the S_V level. The tests were performed for 5 to 10 minutes using load control.

3.2 *Test results*

The failure around the tunnel observed in the physical model tests is depicted in Figures 3 and 4. As Figure 3 reveals, spalling occurred parallel to the S_V, and it was V-shaped, as in previous research studies (Martin et al., 1999; Kaiser et al., 2000). Little damage occurred around the tunnel face due to the 3D arching effects. As the distance from the tunnel face increased, the failure zone became wider and deeper.

4 NUMERICAL SIMULATION

The numerical investigation was performed using the PFC^{3D}, and this was compared to the result of physical model test and FLAC^{3D} simulation using the Mohr-Coulomb criterion. In order to simulate the physical model test as reliably as possible, the axial stress (S_v) was monotonically increased until it reached the tested stress level.

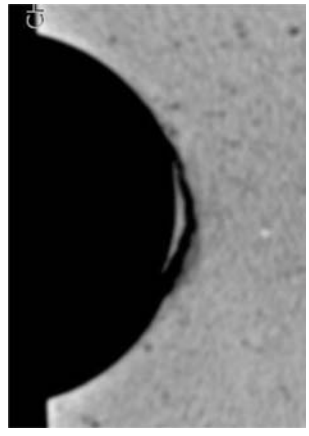

Figure 4. V-shaped notch in CT image.

4.1 *Comparison of PFC^{3D} and FLAC^{3D}*

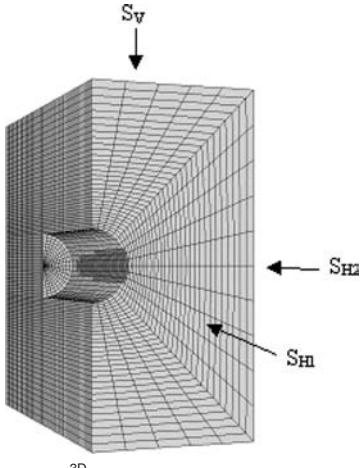

Figure 5 shows the results of PFC^{3D} simulation and FLAC^{3D} simulation. As shown in Figure 5, FLAC^{3D} using the Mohr-Coulomb criterion did not show a V-shaped notch as observed in the physical model test. The continuum modeling using the Mohr-Coulomb criterion seems to be inappropriate for brittle materials, because this criteria ignores material weakening in its constitutive equation, whereas the PFC^{3D} modeling could be simulate the V-shaped notch. However, in 3D simulation it is sometimes difficult to detect the notch formation compared to 2D simulation (Bae, 2005). If the continuum model does not use a specific constitutive equation for brittle material, it would be better to use the particle flow code to simulate brittle failure.

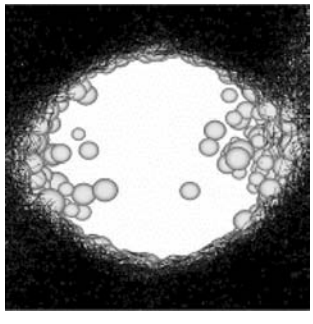
4.2 *Failure characteristic with stress conditions*



Based on the physical model tests, crack initiation stress was considered to be the brittle failure initiation stress level. In this study, crack initiation stress is equal to the stress when the 10% cracks of total cracks were occurred. As the S_{H1} and S_{H2} increased, crack initiation stress also increased (Figure 6). From the multi-variable regression on stress conditions and failure initiation stress, $f(S_v, S_{H1}, S_{H2})$ was proposed as below.

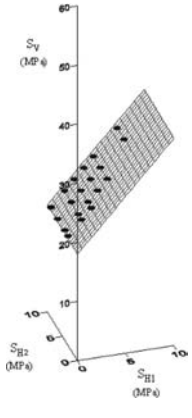
$$f(S_v, S_{H1}, S_{H2}) = -\frac{S_V}{\sigma_c} + 1.700\frac{S_{H1}}{\sigma_c} + 0.930\frac{S_{H2}}{\sigma_c} + 0.452 = 0 \qquad (1)$$

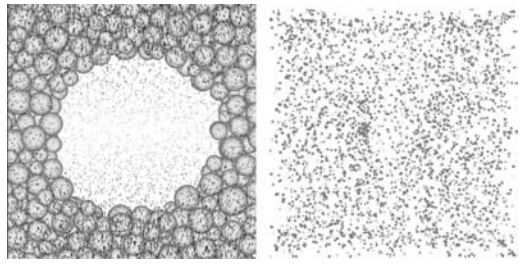
PFC^{3D} can describe spalling as a splitting of particles. Figure 7 shows the failure pattern and displacement

(a) FLAC^{3D} simulation using Mohr-Coulomb model

(b) PFC^{3D} simulation

Figure 5. Comparison of failure shape between PFC^{3D} and FLAC^{3D}.





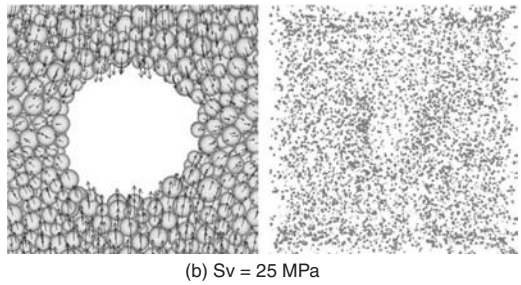


Figure 6. Crack initiation stress from PFC^{3D} modeling with different stress conditions.

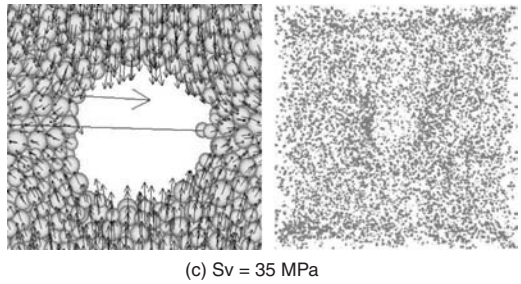

vector around a tunnel with S_V stress conditions (S_v: parallel to the tunnel axis). Figure 7 (a) is the state when S_v is at 20 MPa. There were no significant changes,

(a) Sv = 20 MPa

(b) Sv = 25 MPa

(c) Sv = 35 MPa

Figure 7. Particle displacement, crack distribution with different Sv level.

but as S_v increased, the displacement vector greatly increased and cracks were concentrated at the side-wall parallel to S_v. In particular, when S_v reached 35 MPa, particle splitting was clearly detected with visual observation.

5 CONCLUSIONS

To evaluate brittle failure around a deep tunnel, numerical simulations using PFC code were performed, and the results were compared with the physical model test and the simulation using FLAC. From this study, the following results were obtained:

– The Young's modulus and peak strength and etc. except for Poisson's ratio exhibits a dependence on resolution in PFC simulation. As the resolution continues to increase, the coefficients of variation will converge to specific values.

– The particle flow code (PFC) could simulate a V-shaped notch and describe spalling as a splitting of particles.
– Based on the physical model test, crack initiation stress was considered to be a brittle failure initiation stress. As the applied polyaxial stress increased, crack initiation stress also increased.

Deformation prediction for tunnels at PiccEx junction in London heathrow – An engineering approach

J.Jäger & A.Stärk
Beton-und Monierbau Ges.m.b.H, Innsbruck, Austria

ABSTRACT: The capability of three relatively simple soil models to predict movements in stiff clay are investigated in this study. Calibration of material parameters and theoretical justification for selecting these models are discussed. Finally the predictions are compared with the actually measured deformations and the overall performance of the models discussed.

1 INTRODUCTION

To connect the newly constructed Piccadilly Line Extension tunnels that go to Terminal 5 at London Heathrow with the existing Piccadilly Line tunnels a structure called PiccEx Junction has been built. The structure encloses two turnouts connecting the eastbound and westbound Piccadilly Line Extension to the existing Piccadilly Line tunnels. The two turnouts are enclosed in a combination of sprayed concrete lined (SCL) tunnels and a cut and cover box. Construction and Monitoring of PiccEx Junction is explained in a companion paper (Stärk & Jäger 2007).

This paper deals in particular with the prediction of movement of existing Piccadilly Line tunnels as a result of close by tunnelling operation for the new Piccadilly Line Extension tunnels. The smallest distance between the old segmentally lined tunnels and the new sprayed concrete lined tunnels is only 40 cm.

For carrying out the movement assessment a full 3D finite element model has been chosen. All major construction steps like construction of diaphragm wall of the cut and cover box, plugging of the existing tunnels to control movements, excavation of SCL tunnels using full face excavation according to Laser Shell™ method of construction (Eddie & Neumann 2004) and removal of plug in existing tunnels. As several calculation runs with varying input parameters are required to learn about the sensitivity of the results on modelling assumptions, a numerically efficient model is important for an efficient design process.

Generally soil models taking into account small strain stiffness nonlinearity are recommended for stiff clay. For every days design work a robust model with sound theoretical basis is vital. The mathematical formulation should be such that efficient and robust numerical algorithms can be used. In addition a small number of material parameters should facilitate the model calibration. A further requirement is that the assessment of material parameters should be possible with available test data.

A simple model for predicting short term deformation is considered to be a modified von Mises plasticity model, formulated in total stress space. In order to improve the model performance a nonlinear isotropic and a kinematic hardening law has been added to account for the prefailure nonlinearity.

2 GROUND CONDITIONS

The soil at Heathrow is typical for the greater London area. There is a several meter thick layer of earth and gravel on the surface, which is followed by around 50 m of London Clay and 20 m Lambeth Group. The tunnels at PiccEx Junction are well embedded in London Clay so that there is about a tunnel diameter thick clay cover between the tunnels and the clay/gravel interface. The low permeability of around 10^{-10} m/s and the homogeneity of London Clay make sure that dry conditions prevail during tunnelling.

2.1 K_0-*value*

The heavy overconsolidation of London Clay gives rise to high horizontal effective stresses. In the upper 10 m of the London Clay K_0 varies between 2 and 2.5 and this value tends to decrease with increasing depth, falling to 1.5 at about 30 m depth.

Therefore a typical horizontal in-situ stress at tunnel level is around 1.5 times the vertical stress.

Table 1. Parameters for small strain stiffness model

ε_a	E_u/C_u
$\leq 0.003\%$	5000
0.01%	2800
0.1%	750
1%	150

2.2 *Strength*

The undrained shear strength C_u (in kPa) is depth dependent. The origin of the depth coordinate z (in m) is at the clay/gravel interface.

$$C_u = 37.5 + 6 \cdot z \quad (1)$$

2.3 *Stiffness*

It is well known, that the stress-strain behaviour of soil is highly non-linear and soil stiffness may decay with strain by orders of magnitude.

The mathematical formulation used originally for strain dependent (secant) undrained stiffness Eu is given below (Jardine 1986)

$$\frac{E_u}{C_u} = A + B\cos\left\{\alpha\left[\log_{10}\left(\frac{\varepsilon_a}{C}\right)\right]^{\beta}\right\} \quad (2)$$

In (2) C_u denote undrained shear strength and ε_a is the axial strain of an undrained cylindrical sample. All the other constants A, B, C, α, β are material parameters and must be assessed from tests using curve fitting techniques. Rather than carrying out the curve fitting exercise the strain levels and corresponding stiffness values are given in Table 1.

3 CONSTRUCTION PHASES

The construction phases can be outlined as follows:

- Building diaphragm wall box structure with short ending D-Walls above existing Piccadilly line Tunnels
- Filling foam concrete plug (over a length of 8 m) into existing tunnels to provide sufficient stability and to limit movements of existing tunnels during construction of adjacent tunnels
- Create opening in D-Wall for new Eastbound tunnel and start mining Eastbound Tunnel
- Remove plug from existing Eastbound Tunnel
- Fill plug in existing Westbound Tunnel
- Create opening in D-Wall for new Westbound Tunnel and start mining Westbound Tunnel
- Remove foam concrete plug from existing old tunnels

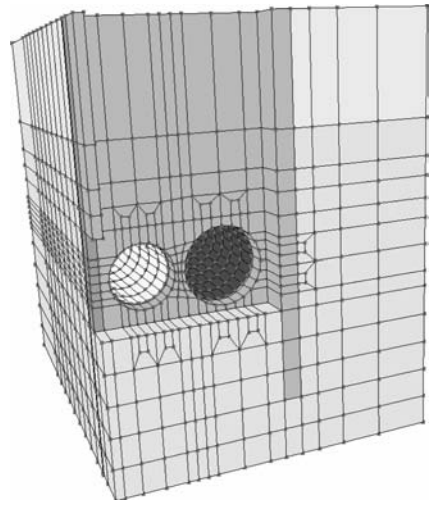

Figure 1. Full 3D model – view from within the box.

4 NUMERICAL MODEL

To take into account the beneficial effect of foam concrete plug and the increasing width of ground pillar with increasing distance from the diaphragm wall a full threedimensional finite element model has been chosen. The finite element program ZSoil v 6.2 (Z_SOIL.PC 2003) has been used. Ground materials (gravel and clay) have been modelled with continuum elements and diaphragm wall and tunnel linings haven been modelled with shell elements. The elastoplastic von Mises material is part of the material library being available in ZSoil. The isotropic hardening and the kinematic hardening model extensions have been added using the interface provided by ZSoil to ad user defined materials.

4.1 *Spatial model*

The model is shown in Figure 1. For greater numerical efficiency symmetry along a vertical plane in the middle between the existing Eastbound and Westbound Tunnels has been taken.

4.2 *Total stress vs effective stress*

As one purpose of this study is to investigate how much sophistication in material modelling is actually required to get a reliable deformation prediction the pros and cons of a total and effective stress analysis shall be discussed. It is well accepted that stress-strain behaviour of soil is correctly described in terms of effective stresses. For some problems involving the deformation of clay, the soil may be idealised as undrained, and for these problems a total stress analysis may be used – provided the following conditions

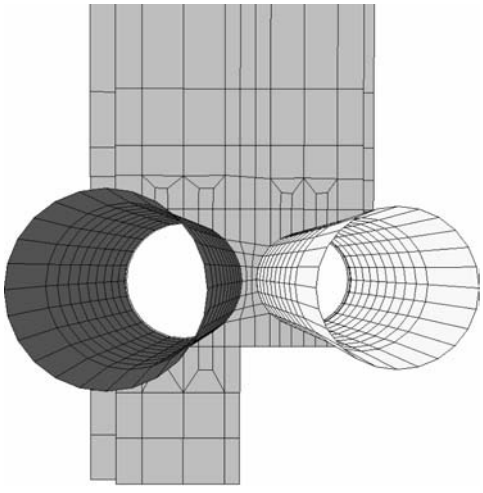

Figure 2. Shell elements for D-Wall, SCL-tunnel (left) and existing segmentally lined tunnel (right) – view from outside the box.

apply. A total stress analysis is only valid in the short term while there is no significant dissipation of the negative pore water pressures induced on clay around the excavation.

4.3 *Material models*

The analysis has been carried out using relatively simple elastoplastic material models adopting total stress approach. The first step was to run the analysis with a simple elastoplastic material selecting an elastic modulus and a corresponding K-value such that they compensate the obvious shortcomings of the existing model. In the next two steps analyses have been run with isotropic and kinematic hardening. A common feature of all three models is that they are based on linearised theory of elastoplasticiy. The linearised strain tensor ε may be decomposed into an elastic part ε^e and a plastic part $\boldsymbol{\varepsilon}^p$

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^e + \boldsymbol{\varepsilon}^p \tag{3}$$

The stress is defined by an isotropic tensor function of the elastic part of the strain tensor following Hooke's law expressed. The elastic parameters are the shear modulus G and the Poisson ratio v.

$$\boldsymbol{\sigma} = 2G\left[\boldsymbol{\varepsilon}^e + \frac{\nu}{1-2\nu} tr\left(\boldsymbol{\varepsilon}^e\right)\mathbf{1}\right] \tag{4}$$

The plastic strain rate is calculated from an associated flow rule.

$$\dot{\boldsymbol{\varepsilon}}^p = \gamma \frac{\partial f}{\partial \boldsymbol{\sigma}} \tag{5}$$

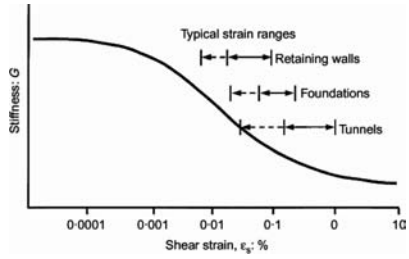

Figure 3. Characteristic stiffness-strain behaviour of soil with typical ranges for laboratory tests and structures (after Mair 1993).

Only stress states inside the yield surface are allowed. This can be the case for purely elastic loading or for strains beyond the elastic limit. The consistency parameter γ ensure that there is no stress state outside the yield surface. Those rules can be expressed mathematically be the Kuhn Tucker complementary conditions. (Simo & Hughues 1998)

$$\gamma \geq 0,\ f \leq 0,\ \gamma \cdot f = 0 \tag{6}$$

4.3.1 *Elastoplastic Model and Parameter Selection*

To compensate for the obvious inability of the elastoplastic model without hardening to simulate small strain stiffness nonlinearity parameters like the elastic modulus and the K-value must be modified.

One possibility to deal with small strain stiffness in a practical way is to take into account the expected strain amplitude in selecting the moduli used. Typical strain ranges for geotechnical structures are those proposed by Mair (Mair 1993).

The proposed strain ranges in Figure 3 are based on stiffness which gave reasonable designs for structures in stiff, overconsolidated clay. A typical characteristic strain in London Clay due to tunnelling has been found to be 0.1%. According to Table 1 this strain corresponds to an undrained stiffness of Eu = 750× Cu.

The von Mises yield surface can be expressed mathematically in the following way

$$f(\boldsymbol{\sigma}) = \|\mathbf{s}\| - \hat{C}_u \tag{7}$$

where **s** is the deviatoric stress tensor and $\hat{C}_u$ is related to the undrained cohesion C_u as shown in (8).

$$\hat{C}_u = 2\sqrt{\frac{2}{3}} C_u \tag{8}$$

It should be mentioned that C_u is depth dependent as defined in (1).

The high K-values near the ground surface are typical for heavily overconsolidated clays. When modelling those initial stress conditions together with low

elastic stiffness material unrealistic movements can be observed. To be able to come up with meaningful analysis results a modified K-value must be introduced. For London Clay it has been found that figures ranging between 0.6 and 1.0 may lead to realistic results. Based on this information the analysis has been carried out with K-value of 1.

4.3.2 *Isotropic hardening model and parameter selection*

The yield surface of the isotropic hardening model is similar to (7)

$$f(\boldsymbol{\sigma}, p) = \|\mathbf{s}\| - \left[\hat{C}_y + \hat{K}(p)\right] \tag{9}$$

The yield limit is expressed by $\hat{C}_y$. To account for nonlinear isotropic hardening with a saturation term an exponential formulation has been chosen, similar to Voce (Voce 1955). The saturation term ensures that there is no stress state beyond undrained shear strength possible. The isotropic hardening modulus is a function of the plastic strain *p*.

$$\hat{K}(p) = \hat{K}_\infty \left(1 - e^{-\delta \cdot p}\right) \tag{10}$$

The rate of plastic strain *p* is defined as

$$\dot{p} = \left\|\dot{\boldsymbol{\varepsilon}}^p\right\| = \gamma \tag{11}$$

Similar to (8) the following relations hold:

$$\hat{C}_y = 2\sqrt{\frac{2}{3}} C_y \,,\; \hat{K}_\infty = 2\sqrt{\frac{2}{3}} K_\infty \tag{12}$$

As the yield limit is given through the yield strain of 0.003% (see Table 1) the yield limit C_y can be calculated from elasticity theory. From undrained shear strength C_u and with C_y the second parameter K_∞ can be computed.

$$C_u = K_\infty + C_y \tag{13}$$

The third parameter δ can be found by curve fitting. For the isotropic hardening model a K-value of 1.5 has been selected for the analysis which is the actually assessed earth pressure coefficient at the elevation of the tunnel axes.

4.3.3 *Kinematic hardening model and parameter selection*

The elastic domain is defined by a von Mises yield function *f* in the stress space

$$f(\boldsymbol{\sigma}, \boldsymbol{\alpha}) = \|\mathbf{s} - \boldsymbol{\alpha}\| - \hat{C}_y \tag{14}$$

where $\hat{C}_y$ again represents the yielding parameter. The evolution equation for the stress type kinematic hardening tensor α is the Armstrong-Frederick evolution equation of the back stress (Armstrong & Frederick 1966).

$$\dot{\boldsymbol{\alpha}} = A \cdot \dot{\boldsymbol{\varepsilon}}^p - B \cdot \dot{p} \cdot \boldsymbol{\alpha} \tag{15}$$

A and B are material parameters and can be assessed considering ultimate state condition. At ultimate state the rate of the back stress is zero and equation (15) can be rewritten.

$$A \cdot \dot{\boldsymbol{\varepsilon}}^p = B \cdot \dot{p} \cdot \boldsymbol{\alpha} \tag{16}$$

Using the definitions for plastic strain rate tensor and plastic strain rate as well as the yield conditions finally leads to the following equation.

$$A \cdot (\mathbf{s} - \boldsymbol{\alpha}) = B \cdot C_y \cdot \boldsymbol{\alpha} \tag{17}$$

From (17) it is evident that the deviatoric stress tensor and the backstress tensor have got the same direction in ultimate state and therefore the ultimate shear strength can be expressed in the following way.

$$\hat{C}_u = \hat{C}_y + \frac{A}{B} \tag{18}$$

From (18) we see that the ratio of A over B determine the undrained shear strength of the model and the absolute values of A and B govern the stiffness between yield initiation and ultimate state. Like for the isotropic hardening model a K-value of 1.5 has been chosen.

4.3.4 *Comparison of models in simple strain path*

To investigate the performance of the three models with regard to their ability to reproduce the required small strain stiffness non-linearity a single element has been subject to a monotonically increasing strain path ranging from 0.001% to 1%. The results thereof are shown in Figure (4).

From Figure 4 it can be seen that for axial strains ε_a greater than 0.1% all three models are close to the required small strain stiffness nonlinearity. For axial strains smaller than 0.1% the deficiencies of elasto-plastic von Mises material become evident. Only the two hardening plasticity models are capable of reproducing the varying secant stiffness at small strains.

5 ANALYSIS RESULTS

Figures 5 to 7 show analysis results and compare predicted horizontal movements along the tunnel alignment (starting at the headwall and ending in 20 m distance from headwall) with actually measured

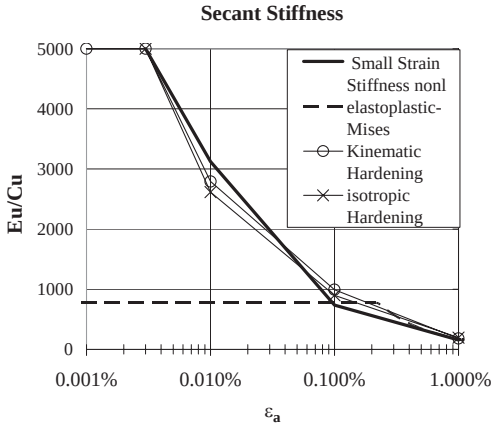

Figure 4. Secant stiffness computed from axisymmetric single element test.

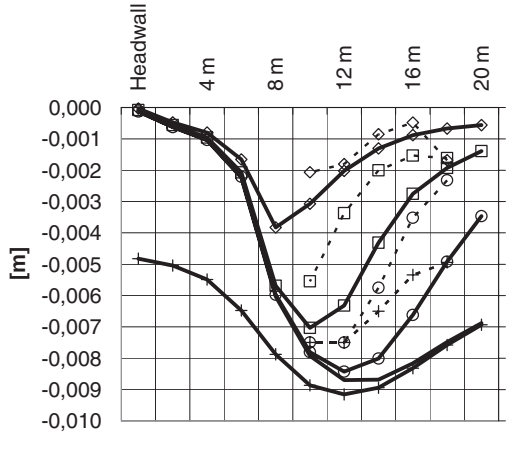

Figure 5. Measured and predicted movements – elastoplastic model.

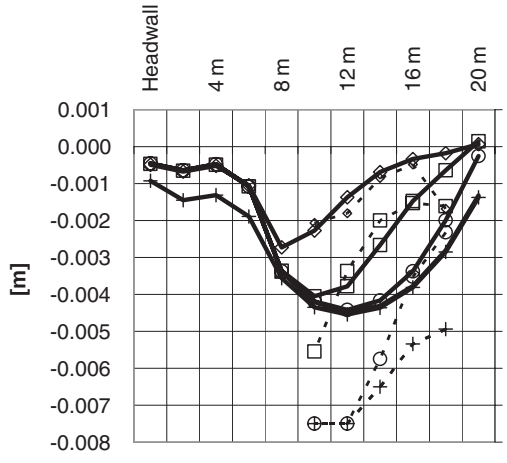

Figure 6. Measured and predicted movements – isotropic hardening model.

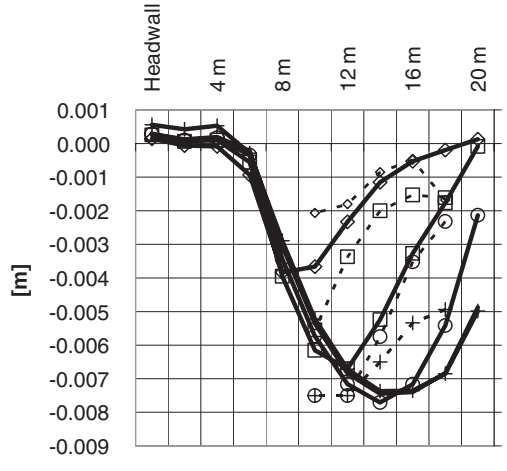

Figure 7. Measured and predicted movements – kinematic hardening model.

movements. The results of five construction stages are shown on the diagrams. For each construction stage there is a separate line for predicted as well as for measured movements. The continuous lines indicate predicted movements and the dotted lines indicate measured movements. The legend in Figure 8 should help to identify each construction stage.

The results shown in Figure 5 suggest that the simple elastoplastic model provides a reasonably conservative prediction of a maximum of 9 mm lateral movement. The maximum measured lateral deformation however is 7.5 mm only. In general there is a more pronounced peak of deformation to be observed in the measured data than in the predicted data. A significant difference between measured data and predicted data is the resilience of the predicted data after removal of the plug. There has been observed no additional movement at all after removing the plug.

The isotropic hardening model in Figure 6 significantly underestimates the lateral deformation predicting a maximum deformation of 4.5 mm only. The resilience after removal of the plug is much smaller than in the elastoplastic model. Looking at the stiffness calculated from monotonic strain path as shown in Figure 4 a better fit with measured data could have been expected. However it seems that the stress reversals taking place in the ground because of the advancing face and the lining installation have got a significant impact on the deformations.

The total deformation predicted by the kinematic hardening model (see Figure 7) is close to 7.5 mm

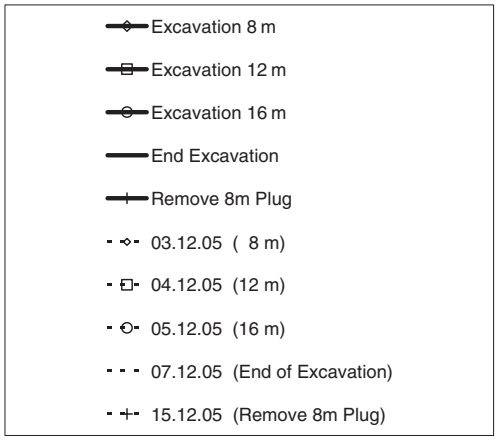

Figure 8. Legend for figures 5 to 7.

which have been measured on site. In general however the locations of peaks of predicted and measured deformation are around 2 m offset. The resilience after plug removal is small, which compares well with actual movements. The strain dependent stiffness in the monotonic strain path is similar for isotropic and kinematic hardening models, however the analysis results from the 3D model with complex loading path show quite significant different performance.

6 CONCLUSIONS

The simple elastoplastic model was relatively successful in predicting the maximum deformations. However it must be noted that some significant assumptions (K-value and stiffness according to 0.1% strain) have been made to end up with realistic results. Those assumptions came from previous experience from tunnelling in London Clay which may not be available elsewhere.

The isotropic and kinematic hardening models on the one hand do not rely on those assumptions, on the other hand however the results are not really better.

To exploit the capability of isotropic and kinematic hardening models more fine tuning of the models based on more complex stress path is necessary. Calibration of models based on monotonic strain path as shown in Figure 4 is probably not sufficient to justify use of more complex models.

Finally it should be mentioned that apart from soil modelling there are some more parameters not addressed in this study (lining stiffness, advance length, actual excavation sequence etc.) which may cause discrepancies between predicted and measured movements.

Improved design method for 2-arch tunnel

Wan Gi Jeon, Kyeong-Han Jeong & Ju Hyoung Lee
Dodam Engineering & Construction CO., LTD, Korea

Hyun-Ho Ahn & Seok-Won Lee
Dept. of Civil and Environmental System Engineering, Konkuk University, Seoul, Korea A.T.

ABSTRACT: Most conventional 2-arch tunnels have been constructed with pilot excavation of center tunnel-utilized 3-step excavation. However, such method has low constructability due to the confined space of the center tunnel and is exposed to various issues, including leakage from the required complex waterproofing-drainage system. Accordingly, this research studied designing an improved 2-stage 2-arch tunnel excavation method in which the proceeding tunnel is constructed after establishing structural stability of preceding tunnel through reinforcement shotcrete or concrete. First, a scaled model test using plaster was conducted to validate the improved 2-arch tunnel construction method. Based on the experimental test results, various parametric studies were conducted through numerical analysis. Findings from those studies yielded a standard cross section with the central support thickness at 40 to 60 cm. The suitable amount of support and a standard supporting pattern were then suggested through converted breadth estimation. Bench cut and/or CD cut excavation sequences were suggested for excavation of the proceeding tunnel.

1 INTRODUCTION

As the number of tunnels with considerably close separation distance increases in consideration for inferior ground conditions, civil complaints, minimization of environmental impact, etc., application of the 2-arch tunnel has recently been on the rise. Most of current 2-arch tunnels are a 2 arch-1 pilot that utilizes supporting function of the central wall. 2 arch-1 pilot tunnels are, however, complex in constructing the central tunnel and inherent with issues such as waterproofing-drainage. To this end, this research aims to present an improved 2-arch tunnel design method capable of attaining safety, constructability, and economic efficiency.

2 2-ARCH TUNNEL CONSTRUCTION METHOD

2.1 *Issues with conventional 2-arch tunnels*

While conventional tunnels are constructed in two mining phases of left and right main tunnels, the standard construction sequence of 2-arch tunnels, as shown in Figure 1, take place in three-phases of central tunnel mining, central pillar, and main tunnel mining. Consequently, the cycle time in 2-arch tunnel construction is longer in comparison to conventional tunnels,

Figure 1. Panoramic view of a conventional 2-arch tunnel construction.

resulting in lowered constructability and economic efficiency.

On the construction front, the narrow central tunnel width makes equipment use difficult and main tunnel blasting and shotcreting causes damage of waterproofing system (Figure 2). Furthermore, protective facilities need to be installed to the central wall unit during blasting.

Maintenance wise, water can leak from the upper sections of the central wall unit and the upper lining joint of the main tunnels to cause road surface freezing. Furthermore, icicles could form on the ceiling to impede vehicle safety and cause additional erosion of the surrounding concrete. These aforementioned

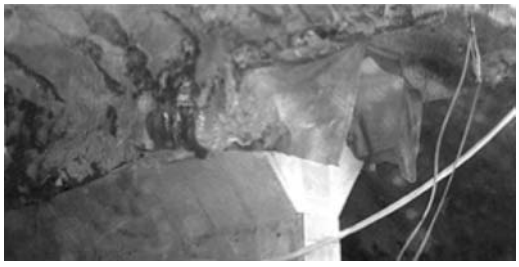

Figure 2. Waterproof sheet damage.

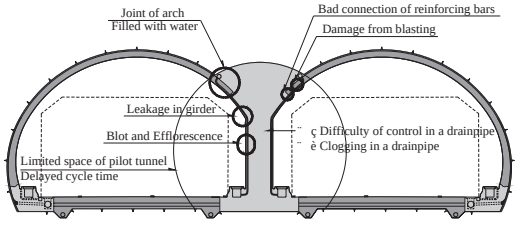

Figure 3. Issues with conventional 2-arch tunnels.

issues with the conventional 2-arch tunnel construction method are summarized in Figure 3.

2.2 *Improved 2-arch tunnel design method*

Improved 2-arch tunnel design method eliminates the preceding excavation of the central tunnel found in the conventional 2-arch tunnel construction method and, like adjacent tunnel construction, excavates the preceding tunnel first and then installs reinforcement shotcrete to gain structural safety first before excavating the proceeding tunnel. The matter of improvement here is that reinforcement shotcrete or concrete are added as substitutes to the central wall unit in preventing stress concentration on the central section between the expected preceding and proceeding tunnels. This effectively controls the displacement and stress generated as per excavation of the proceeding tunnel.

Consequently, previously raised issues of constructability, economic efficiency and waterproofing-drainage issues can be resolved at the source through this improvement.

3 VERIFICATION THROUGH SCALED MODEL TESTS

3.1 *Model material and dimension analysis*

The material used in the scaled model tests must be able to sufficiently reflect the physical properties of the base rock from the research subject site. In this respect, a mixture of sand, plaster, and water was used. The strength of the model required in this research was

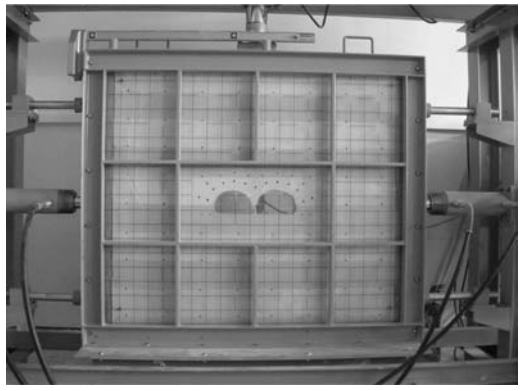

Figure 4. Scaled model testing device.

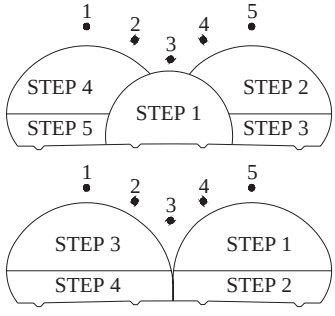
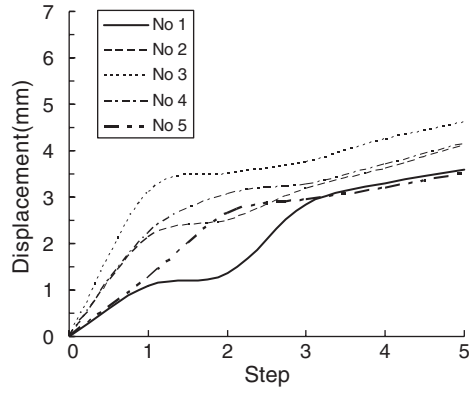
3 kgf/cm^2. Various mixture ratios were experimented with, and it was found that a ratio of 2.8:1.0:1.9 that has been cured over fifteen days yielded the desired strength.



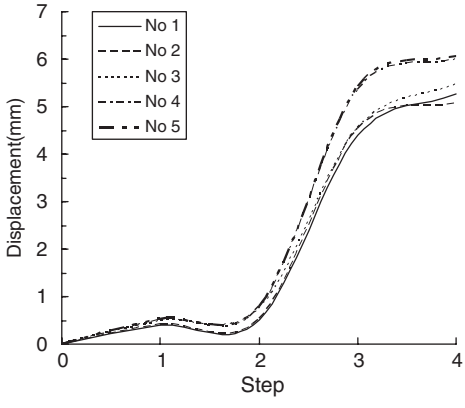
Dimension analysis (Everling, 1964; Hobbs, 1968) between the construction site condition and the reduced model must be conducted so that the site conditions can be sufficiently recreated in the reduced model test. Where the three fundamental dimensions are Length [L], Mass [M], and Time [T], the reduction ratio of the length is calculated first and then the length reduction ratio is used to derive time, density, mass, stress, and strength reduction ratios in that sequence.

The length reduction ratio was set to 1/89.8 after determining the model tunnel width to be 30 cm in consideration for the model's dimensions ($1000 \times 1000 \times 100$ mm) and the onsite tunnel's width of 2,694 cm. The time reduction ratio then became 1/9.48. With the mixture density being 1.75 g/cm^2 and with the in-situ density being 2.141.75 g/cm^2, the density [ML^{-3}] reduction ratio became 1/1.22. Where the length reduction ratio has been set at 1/89.8, the mass reduction ratio became $1/(8.83 \times 10^5)$. Subsequently, the stress, elastic modulus, and strength [ML^{-1}T^{-2}] reduction ratios became 1/109.4.

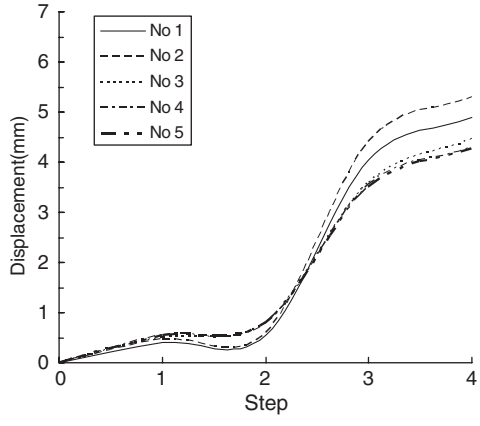


3.2 *Testing method and analysis program*

A model testing device with dimensions of $2290 \times 1930 \times 710$ mm (L × H × W), was fabricated for this research as shown in Figure 4. The lower section is secured with a steel plate, and the front and rear sides are made of acrylic boards. In addition, three pressure devices, one on the top, one on the right side, and one on the left side, were installed.



First, the model was prepared according to the mixture and then cured over fifteen days. Dots were then drawn in specific distances to be used in measuring displacements using PhotoModeler Pro 5. Once the model was prepared, the load was pressurized.



(a) Construction step for 2-arch tunnel.

(b) Result based on the conventional method.

(c) Result based on the improved method without central rein-forcement.

(d) Result based on the improved method with central rein-forcement.

Figure 5. Experimental test results.

Digital pictures were taken at each stage of the load increase and the displacement was analyzed using PhotoModeler.

3.3 *Model testing results*

Figure 5 shows the results from the three model tests conducted in this research. Figure 5(b) is the results based on the conventional 2-arch tunnel construction method. Figure 5(c) is the results based on the improved 2-arch tunnel construction method, but without the reinforcement shotcrete installed to the central section. Figure 5(d), on the other hand, is the results based on the improved 2-arch tunnel construction with reinforcement shotcrete.

As shown in Figure 5(b), the conventional 2-arch tunnel construction produces significant displacement during central tunnel excavation(step 1). In the case of left and right main tunnel excavations, however due to the installation of central pillars, the ratio of increment of displacement showed somewhat of a decrease. Figure 5(c) reveals that the improved 2-arch tunnel construction method without central reinforcement resulted in greatest displacements at the preceding tunnel's crown (No. 5) and the sidewalls (No. 4) and in significant displacement at the proceeding tunnel's crown (No. 1). In the case of the improved 2-arch construction method with central reinforcement shown in Figure 5(d), however, displacements at the preceding tunnel's crown (No. 5) and the sidewalls (No. 4) were significantly reduced, and the greatest displacement took place at the proceeding tunnel's sidewalls (No. 2).

Considering that the tests did not replicate the rockbolt, shotcrete, and other supports, although comparison of the conventional 2-arch tunnel construction technique to the improved version shows similar displacement results from the tests, it is clear that installation of supports such as rockbolt and shotcrete

in actual constructions does support the validity of the improved 2-arch construction method. This validity will be described in following numerical analysis results.

4 IMPROVED 2-ARCH TUNNEL DESIGN THROUGH NUMERICAL ANALYSIS

Through the aforementioned model testing, the improved 2-arch tunnel construction method has been proven to be capable of attaining constructability and economic efficiency through use of suitable supports. Consequently, in this section, the various numerical analyses were conducted to determine the central reinforcement shotcrete thickness, suitable amount of supports and the excavation sequence for the proceeding tunnel. Finally, improved design method for 2-arch tunnel was suggested.

4.1 *Tunnel cross section design*

The improved 2-arch tunnel, as mentioned before, is free of the central tunnel excavation phase. Therefore, it does not require installation of the central wall unit but produces stress concentration at the central section between the preceding and proceeding tunnels. Consequently, reinforcement shotcrete or concrete has to be installed additionally as a substitute to the central wall unit in supporting the stress concentration in order to control the displacement and stress resulting from excavation of the proceeding tunnel. A numerical analysis was conducted to derive the suitable shotcrete thickness as shown in Figure 6. Included in Table 1, Figure 7 and Figure 8 are input properties applied to the analysis, 3D modeling and analysis results, respectively.

As shown in Figure 8, 2D finite difference analysis (FLAC) and 3D finite element analysis (Pentagon-3D) with central reinforcement shotcrete thickness as the parameter showed that the central section's bending compressive stress was stabilized to within the permissible range when the thickness is over 60 cm in the 2D analysis and when over 40 cm in the 3D analysis.

With the results from the analysis of the improved 2-arch tunnel's behavioral characteristics as per the shotcrete thickness as the basis, a standard cross section of 40 cm or thicker central reinforcement thickness as shown in Figure 9 is suggested in this study.

Case Categorization by Support Thickness

- 2D : 40 cm, 50 cm, 60 cm, 70 cm, 80 cm
- 3D : 20 cm, 40 cm, 60 cm, 80 cm

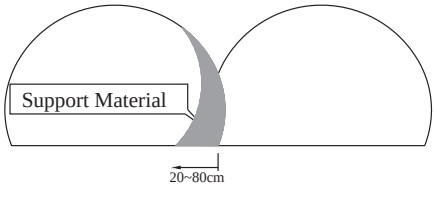


Figure 6. Central reinforcement and analysis case.

Table 1. Base rock and central reinforcement shotcrete properties.

Category	γ_t	E	v	c	ϕ	K_0
Base rock class	2.3	180,000	0.28	60	33	1.0
Shotcrete	1.8	1500,000	0.2	50	40	1.0

4.2 *Calculation of a suitable amount of supports*

The entire 2-arch tunnel breadth is similar to a four-lane tunnel. However, because the central section is supported by central supports and the stress can

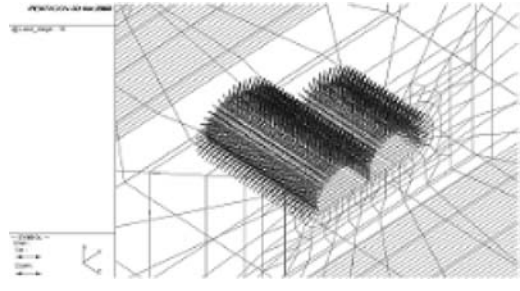

Figure 7. Modeling of 3-D element analysis.

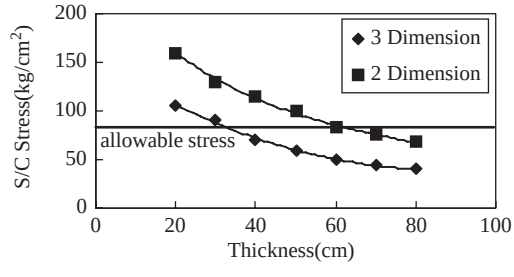

Figure 8. Bending compressive stress of central section.

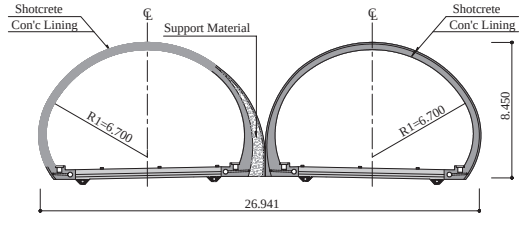

Figure 9. Suggested cross section of the improved 2-arch tunnel.

be reduced through arching effect during main tunnel excavation, designing the 2-arch tunnel with the four-lane breadth can result in an excessive design. Therefore, in reviewing the amount of supports in the improved 2-arch tunnel, 2-, 3-, and 4-land tunnel cross sections and the 2-arch tunnel's displacement were numerically compared and analyzed to determine the converted tunnel width. This width was then applied as the maximum width in calculating the suitable amount of supports.

As shown in Figure 10, the analysis resulted in a 2-arch tunnel's displacement at crown and convergence similar to those of a 2-lane or a 3-lane tunnel, with maximum displacement distributed between 2-lane and 3-lane tunnel values. Consequently, the 3-lane tunnel breadth was applied in determining the support pattern for the improved 2-arch tunnel and then Q-system and RMR were used to derive the suitable amount of supports as shown in Table 2.

4.3 *Excavation sequence of proceeding tunnel*

Excavating the proceeding tunnel after excavating the preceding tunnel and reinforcing the central section results in transference of the preceding tunnel's load over to the proceeding tunnel and greater stress concentration on the proceeding tunnel than the preceding tunnel. To this end, a proceeding tunnel excavation method capable of providing tunnel stability was sought after.

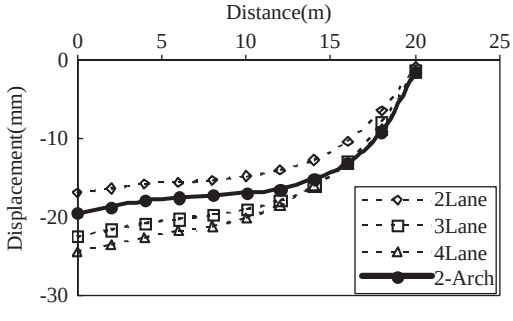

Figure 10. Displacement at crown by excavation distance.

Bench cut and CD cut excavation techniques were selected as four proceeding tunnel excavation cases and then numerically analyzed. After which preceding tunnel, proceeding tunnel, and central support stabilities were reviewed.

Figures 11 and 12 show the analysis cases and modeling, respectively, for which the following analysis criteria were applied :

- Analysis Criteria
  - Program: MIDAS GTS
  - Foundation: Base Rock Class – IV (Table 2)
  - Support Strength: fck = 210 kg/cm^2
  - Support Thickness: 60 cm (Figure 6)

Based on the analysis results, the displacements of preceding and proceeding tunnel were stable to within

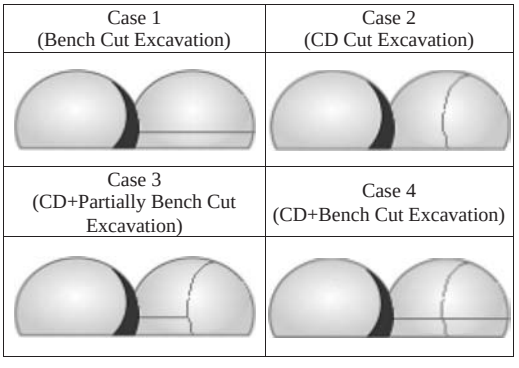

Figure 11. Analysis cases.

Table 2. Calculation of a suitable amount of supports.

Support Class		1	2	3	4	5
Base rock category	Q	Over 40	40 ~ 10	10 ~ 1	1 ~ 0.1	Under 0.1
	RMR	Over 81	80 ~ 61	60 ~ 41	40 ~ 21	Under 20
Shotcrete (cm)		80	80	100	180	200
Rock Bolt	Length (m)	4.0	4.0	4.0	5.0	5.0
	Vertical Distance (m)	3.0	3.0	2.0	1.2	1.0
	Horizontal Distance (m)	3.0	1.5	1.5	1.2	1.0

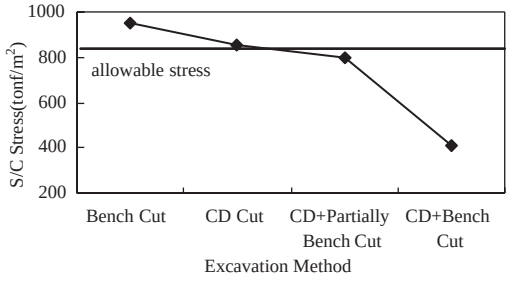

Figure 13. Bending compressive stress of shotcrete by excavation method.

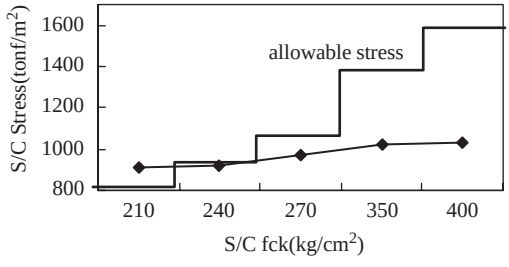

Figure 14. Bending compressive stress of shotcrete by support strength.

11 mm in all cases and, as shown in Figure 13, bending compressive stress of shotcrete satisfied the permitted value in Case 2 (CD cut excavation).

However, because proceeding tunnel's CD cut excavation, which is the only case to satisfy the allowed value, is a constructability lowering cause, the range of possible bench cut excavation with enhanced central support system strength was reviewed. The support strength applied to this was $f_{ck} = 210$, 240, 270, 350, 400 kg/cm^2, and all other input data remained the same. Figure 14 shows stability review results by support strength.

According to the analysis results, bench cut excavation is possible on a foundation of base rock class IV (Table 2) or higher when support strength is $f_{ck} = 240$ kg/cm^2 or greater. For soft ground conditions of base rock class V or lower, portals, and fault zone, it is recommended that application of CD cut excavation or CD + bench cut excavation is safe.

5 CONCLUSIONS

Conventional 2-arch tunnels carry clear areas of improvement, such as construction of a central tunnel and waterproofing/leakage issues, and are not economically efficient due to the need to increased cycle times from installation of a central tunnel and a central wall unit. To this end, this research has presented an improved 2-arch tunnel construction method that eliminates the central tunnel and that involves excavating the preceding tunnel first and then reinforcement shotcreting to gain structural safety first before excavating the proceeding tunnel. Conclusions from the research are:

(1) As the result of reviewing the improved 2-arch tunnel construction method's validity through scaled model tests, it has been found that there is no problem when a suitable support system is installed.
(2) As the result of support system stress review through 2D and 3D numerical analysis, the suitable central shotcrete thickness is found to be 60 cm under 2D analysis and 40 cm under 3D analysis. This is a difference as per the existence of longitudinal arching effect and load distribution rate. Finally, the improved 2-arch tunnel's cross section that has been applied with a 40 to 60 cm reinforcement shotcrete was suggested.
(3) As the result of calculating the converted breadth for calculation of the amount of supports for the improved 2-arch tunnel, the displacement of 2-arch tunnel was found to be similar to that of a 3-land tunnel. Therefore, the amount of supports as per a 3-lane tunnel was calculated and suggested.
(4) As the result of reviewing the excavation sequence of proceeding tunnel, bench cut excavation for foundations of rock base class IV or higher and CD cut excavation for foundations of rock base class V or lower were suggested. It was also found that here the central support system's strength needs to be $f_{ck} = 240$ kg/cm^2 or higher.

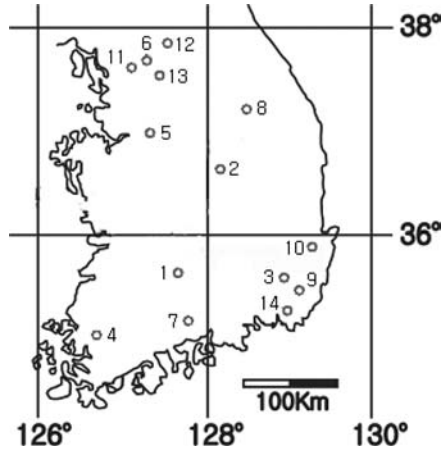
Evaluation of strength parameters for the single shell tunnel in Korea

Kim, Hak Joon
Daejeon University, Dept. of Geological Engineering

Lee, Seong Ho, Shin, Hyu Seong & Bae, Gyu Jin
Korea Institute of Construction Technology

ABSTRACT: Shotcrete is used as a permanent lining in single shell tunnels even though shotcrete has been used as a temporary lining in NATM tunnels. Therefore, the accurate evaluation of strength parameters is very crucial because the reliable estimation of loads acting on the shotcretes is necessary to maintain the stability of tunnels. The evaluation of strength parameters of the ground for the single shell tunnels should be investigated to adapt the method in Korea because the geological condition of Korea is different from those of other countries. Rock classification and strength parameters obtained from 25 tunnel sites were investigated for this study. Support types for the different rock classes are suggested for the single shell tunnels in Korea based on the NMT. The support types in terms of both Q and RMR values are given based on the correlation of Q and RMR values obtained from the case studies.



1 INTRODUCTION

Shotcrete and rockbolts are used as a permanent lining in the single shell tunnel. The method has been widely used in several countries such as Norway, Sweden, and Finland. However, the method was not used in Korea even for very good rock mass conditions because the research for the single shell tunnel was not actively conducted in Korea.

Rock classification and strength parameters obtained from 25 tunnel sites were investigated for the application of single shell tunnels in Korea. The characteristics of rock masses and the values of strength parameters for each rock mass class were obtained from the case studies. Support types for the single shell tunnels were suggested considering the characteristics of rock mass conditions in Korea and support patterns used in the other countries. The support types in terms of both Q and RMR values are given based on the correlation of Q and RMR values obtained from the case studies.

2 CASE HISTORIES OF ROCK MASS CLASSIFICATION IN KOREA

Rock classification system, the RMR system and the Q system, and strength parameters obtained from 25 tunnel sites were investigated for the application of single shell tunnels in Korea. The location of 25 tunnel sites is shown in Figure 1. The following results were obtained from the case studies.

Tunnel Name

Figure 1. Location of case histories used for this study.

2.1 *Correlations between the Q and the RMR*

The correlation between the Q-index and the RMR were given by several authors (e.g. Bieniawski, 1974;

Rutledge & Preston, 1978; Goel et al., 1995). The correlation is not so good because the two systems use different parameters and different weightings to similar parameters. However, the correlation between the two systems is pretty good according to the current study as shown in Figure 2 and the following relationship is applicable:

$$RMR = 7.40 Ln(Q) + 39.5 \quad (r^2 = 0.81) \qquad (1)$$

The correlation between the Q and the RMR systems shown in Equation 1 is very close to the correlation given by Geol et al. (1995).

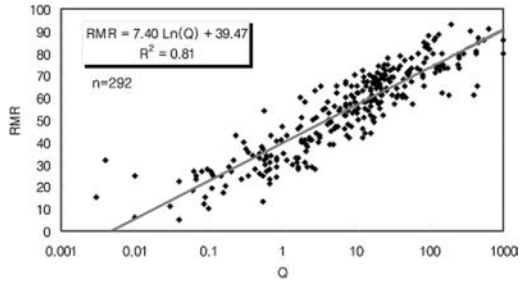

Figure 2. Correlation between RMR and Q in the study area.

2.2 *Values of strength parameters for each rock mass class*

The values of strength parameters used in 25 tunnelling sites were investigated with respect to rock mass classes of the RMR as shown in Figure 3 and summarized in Table 1. The deformation modulus and the cohesion show wide range of values even for the same rock mass class, whereas the friction angle, Poisson's ratio, and unit weights have small range of values within the same rock mass class.

The obtained values of cohesion are generally higher than those given by Bieniawski (1989) but lower than those given by Trueman (1988). The values of friction angles are comparable with those suggested by Bieniawski (1989) except for Classes IV and V, which show higher values than Bieniawski's. Poisson's ratio and unit weight values are generally agreed with those reported in Korea (e.g. Shin et al., 2000).

The strength parameters given in Table 1 are expected to use in the preliminary tunnel design in Korea.

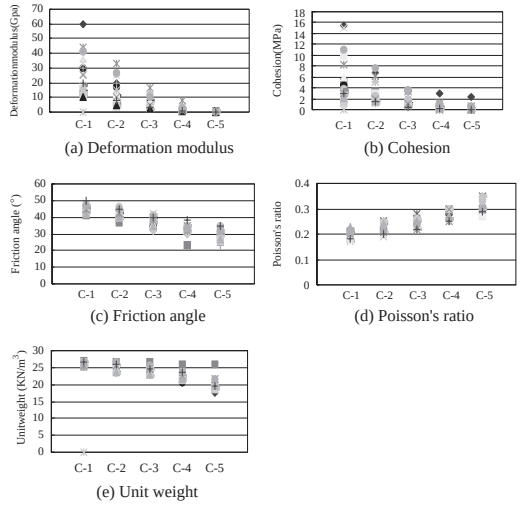

Figure 3. Values of strength parameters with respect to rock mass classes (C).

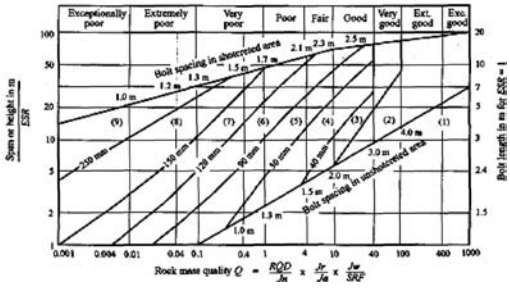
Table 1. Average values of strength parameters for rock mass classes.

Rock mass class	Deformation modulus (MPa)	Cohesion (MPa)	Friction angle (°)	Poisson's ratio	Unit weight (kN/m^3)
I (Very good rock) RMR: 81–100	23.34	5.32	43	0.20	26.1
II (Good rock) RMR: 61–80	12.16	2.88	42	0.22	25.0
III (Fair rock) MR: 41–60	5.49	1.47	38	0.24	23.9
IV (Poor rock) RMR: 21–40	1.71	0.60	33	0.28	22.3
V (Very poor rock) RMR: < 20	0.36	0.26	30	0.30	20.0

3 ROCK MASS CLASSIFICATIONS FOR SINGLE SHELL TUNNELS



3.1 *Rock mass classifications for single shell tunnels in other countries*

Barton et al. (1974) proposed a Q-system on the basis of a large number of case histories of underground excavations. The proposed support system is based on the rock bolts and shotcretes or the rock bolts and wire mesh reinforced shotcretes. Barton et al. (1992) presented the methods, philosophy, and materials of Norwegian Method of Tunnelling (NMT). In essence, NMT combined the use of Q-system characterization, Q-system permanent support design, and the rock bolts and steel fibre reinforced shotcretes.

Grimstad & Barton (1993) updated the original chart of support categories suggested by Barton et al. (1974) to reflect the increasing use of steel fibre reinforced shotcrete in underground excavation as shown in Figure 4.

Geofront (2000) suggested rock mass classifications for the single shell tunnel in Japan. According to Geofront (2000), the NMT cannot be applied directly for the single shell tunnel in Japan because the geological condition of Japan is very much different from that of European countries.

Geofront (2000) considers the rock mass as a soft rock if the uniaxial compressive strength of a rock specimen is lower than 30 MN/m^2 or absorption index of a rock specimen is greater than 5%. Additional support materials for resisting the bending moments or the concrete lining in the invert of a tunnel are recommended to use because the safety of the single shell tunnel cannot be guaranteed for such ground conditions. The contents of steel fibres are determined to be 30 kg/m^3 and 40 kg/m^3 for the amount of water inflow of less than and greater than 50 *l*/min/km, respectively. However, the contents of steel fibres can be increased up to 50 kg/m^3, depending on the site conditions.

1) Unsupported
2) Spot bolting
3) Systematic bolting
4) Systematic bolting with 40-100mm unreinforced shotcrete
5) Fibre reinforced shotcrete, 50-90mm, and bolting
6) Fibre reinforced shotcrete, 90-120mm, and bolting
7) Fibre reinforced shotcrete, 120-150mm, and bolting
8) Fibre reinforced shotcrete, >150mm, with reinforced ribs of shotcrete and bolting
9) Cast concrete lining

Figure 4. Estimated support categories based on Q for NMT. (After Grimstad & Barton, 1993)

The support categories for the single shell tunnels in Japan are based on Figure 4 with some modifications. The thickness of inner layers in single shell tunnels are the same as the thickness of shotcretes in NATM tunnels, whereas the thickness of outer layers in single shell tunnels is determined using the equivalent thickness of the concrete lining in NATM tunnels, considering the high strength of shotcretes in single shell tunnels.

3.2 *Rock mass classifications for single shell tunnels in korea*

Even though new rock mass classification system is proposed for the single shell tunnel in Korea, the verification of the system is difficult due to the lack of case histories of the single shell tunnel in Korea. Therefore, rock mass classification based on the Q-system will be appropriate, considering the wide use of the Q-system in Korea and similarities of rock mass conditions between Korea and Norway.

The Q-system has several advantages over other methods because the system was verified from a large number of case histories. However, the outcrop which is necessary to investigate the rock mass conditions in Korea for the determination of support categories may not be enough compared to that of Scandinavia. Therefore, the credibility of the investigation for the parameters determined in the tunnel face can be questioned. The RMR system, which is widely used in Korea due to its simplicity, is suggested to use in this study with the Q-system for the determination of the support categories of the single shell tunnels in Korea.

It is necessary to limit the application of the single shell tunnels to the good ground conditions because the single shell tunnelling method is very new in Korea. However, various rock mass classes generally occur even in the same tunnel site. The rock mass classes distributed in the 11 tunnel sites are summarized in Table 2. The rock mass classes between I and III from the RMR-system are distributed along the 87% of the tunnel section, whereas the rock mass classes of IV and V are also distributed 13% of the tunnel section. Therefore, the poor ground conditions should be also considered for the application of the single shell method in Korea.

The application of the single shell method for the road and railway tunnels in Korea is recommended to use for the Jw value greater than 0.66 and the Q value greater than 1. The limitation of Jw value is due to the difficulties of the groundwater handling in the single shell tunnel. The limitation of the method to

Table 2. Distribution of rock mass classes along the tunnel section.

Tunnel name	Class (Units: %) I	II	III	IV	V	Total
Jeom-gok	29.1	25.2	24.3	10.9	10.4	100

Wol-mun, Do-gok, Pal-dang	100	48	48
Average	82	73	63

Table 4. Rock mass conditions for tunnels without support requirement.

Rock mass classifications	Rock mass classes
RMR	RMR(No Support) = 22 ln(Equivalent dimension) + 25, Kaiser et al. (1986) ex) For a 12 m wide tunnel RMR ≥ 80 Class I(RMR ≥ 81) : No support required except for occasional spot bolting
Q system	Maximum unsupported span = 2 ESR $Q^{0.4}$ ex) Equivalent dimension 10 m tunnel, Q > 60, Barton et al. (1974) Unsupported span = 2 $Q^{0.66}$, Barton et al. (1980)

the Q value above 1 is related to the lack of experiences making the high strength shotcrete in excess of 360 kN/m^2 and corrosion protected rock bolts. However, support categories should be considered for the Q values lower than 1 because various rock mass classes generally occur together as shown in Table 2. What percentage of the tunnel length along the entire tunnel length should satisfy the above requirements of Jw and Q for the application of the single shell method needs to be determined considering the construction cost. If the construction of the single shell tunnel continues with the accumulation of field measurements, the single shell method can be extended for the more challenging rock mass conditions.

3.3 *Suggested support requirements for the single shell tunnel in korea*

The application of the single shell method for the road and railway tunnels in Korea was recommended to use for the Q value greater than 1 and the Jw value greater than 0.66 as mentioned in the previous section. Table 3 shows the investigated results of 11 case histories for the Q value greater than 1 and/or the Jw value greater than 0.66. Average values of 82% and 73% of the total tunnel length have a Jw value greater than 0.66 and the Q value greater than 1, respectively. An average value of 63% satisfies both Jw and Q requirements at the same time.

Table 4 shows rock mass conditions without support requirements for the construction of a tunnel. Generally no support is required for this kind of rock mass conditions except spot bolting.

The selection of support for the single shell tunnel in Korea is proposed based on Figure 4, Table 4, and the study of Geofront(2000) as shown in Table 5. Table 5 is for a 12m wide tunnel and Figure 4 may be used for the other size tunnel.

Support for the single shell tunnel is given in accordance with the RMR values as well as the Q values using the correlation of the RMR and the Q in order to improve its usability. The correlation between the RMR and the Q for Table 5 is obtained based on the studies of Bieniawski (1974), Rutledge & Preston (1978), and Equation 1 because they have good correlation ratios compared to other suggestions. Conservative RMR values are chosen among the correlative values as shown in Table 6.

Field measurements are necessary to verify the suggested support for the single shell tunnel in Korea even though field monitoring is less used in NMT compared to NATM. More reliable support requirements for different ground conditions can be proposed if field measurements are collected from various case histories.

4 CONCLUSIONS

Rock classification and strength parameters obtained from 25 tunnel sites were investigated for the application of single shell tunnels in Korea. The values of strength parameters for each rock mass class were presented from the case studies.

Table 5. Guidelines for the support of 12 m wide single shell tunnels in Korea. (Modified after Geofront, 2000)

		NATM support	Shotcrets for single shell tunnels

* Note: ( ) is contents of steel fibers in shotcrets in kg/m^3.

Table 6. Correlation between Q and RMR used for the support requirements of single shell tunnels.

Q	RMR (Bieniawski, 1974)	RMR (Rutledge & Preston, 1978)	RMR (Current Study)	RMR (Chosen)
10	65	57	57	65
3	54	49	48	55
1	44	43	40	45
0.3	33	36	31	35
0.1	23	29	22	30
0.01	3	16	5	15

Support types for the different rock mass conditions are suggested for the single shell tunnels in Korea based on the NMT. Support for the single shell tunnel is given in accordance with the RMR values as well as the Q values using the correlation of the RMR and the Q in order to improve its usability.

The application of the single shell methods for the road and railway tunnels in Korea is recommended to use for the Q value greater than 1 and the Jw value greater than 0.66 because the single shell tunneling method is very new in Korea. However, support categories should be considered for the Q values lower than 1 because various rock mass classes generally occur together at the same tunnel site in Korea. What percentage of the tunnel length along the entire tunnel length should satisfy both the Q and Jw requirements for the application of the single shell method needs to be determined considering the construction cost.

Even though support requirements for the single shell tunnel are suggested conservatively, the validation of the proposed support categories cannot be evaluated due to the lack of case histories. More reliable support requirements for the various and challenging rock mass conditions can be proposed if the construction of the single shell tunnel continues with the accumulation of field measurements. The single shell tunnelling method is expected to contribute to the economical construction of tunnels in Korea.

ABSTRACT: This paper presents description of experimental seismic measurements that were performed during construction of underground spaces. Numerous site and source factors influence seismic effects on the surface. Therefore, individual measurements have to be completed by geological and geotechnical parameters. Seismic apparatuses GCR-16, GeoSIG Ltd. were used for our measurements. Their amplitude range is 1, 10 or 100 mm.s-1; recording bandwidth is up to 315 Hz using the sampling rate 1 kHz. Experimental instrumentation of PCM3-EPC type was also used. Generally, the most intensive seismic effects are generated in cases when blasts were used as a part of the technological process. It is usually used timing of blast, therefore wave patterns are short, and they have sharp inputs and very often documented vibrations on high frequencies.

1 INTRODUCTION

Urban tunneling induces not only changes in rock massif (e.g. Rozsypal 2001), but buildings and inhabitants in the nearest surroundings above the tunnel or a mine working can be affected too. Vibrations are one of the most significant effects, especially when blasting operations are used as part of technological process. Seismic load on buildings and constructions can be evaluated with use of maximum velocity amplitude V and prevailing frequencies f in records. There is an effort to compile a universal relation for prediction of the maximum amplitude V. So-called Langerfor's relation (Bongiovani 1991) is often used:

$$V = K.Q^{m}.R^{-a}. \quad (1)$$

There, Q is the total charge or charge fired in one stage, R is distance, K is a coefficient representing physical properties of medium where the waves spread, m and a are empirical constants. Properties of medium (local geological pattern) influence attenuation, refraction and reflection of seismic waves and their modification into different types on boundary; therefore they have significant influence on resulting wave field, e.g. Isaac (1991). Similar empirical relations, which optimally satisfy local geological conditions and conditions for blasts performing, are presented in many other publications. All relations are based on empirical constants that represent studied locality and that can be obtained by parametric measurements. Analyses of wave patterns can be performed for either a whole record or parts of a records representing blast of charge in individual stages (e.g. Pandula & Leššo 2005).

Blasting operations generate seismic waves with a wide spectrum of frequencies. This process depends on type of broken-up rocks, properties of charges and technology of blasting. With increasing distances the components of higher frequencies are absorbed faster in the rock massif than components of lower frequencies. It is documented in publications that frequency spectrum of seismic signals generated by near blasting operation in rock massif can contain frequencies up to 250 Hz. It is also known that shear waves can evoke vibration in soil or rock on defined frequencies (Isaac 1991). Graph of general dependence of frequency content of seismic signal on distance from the point of shot is presented on Figure 1.

2 CONDITIONS DURING URBAN TUNNELING

When studying urban tunneling, distances exceeding 10 m must be taken into account; it means frequency ranges up to several hundred Hz. From the metrology viewpoint, it is a very complicated task, because the wave field of high frequencies of seismic signal is significantly interfered on the surface and an important part of this field is also response of buildings' constructional elements. As an example: if wavelength $\lambda = 10$ m and frequency 200 Hz determine vibration

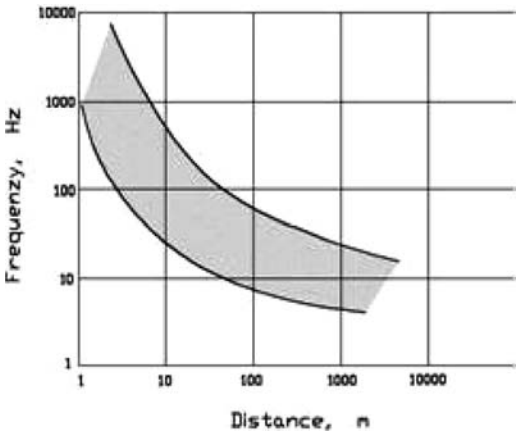

Figure 1. Graph of general dependence of frequency content of seismic signal on distance from the point of shot (according to Rock Blasting Technique).

velocity $v = 2\,\mathrm{km \cdot s^{-1}}$, mechanic constructional elements with n*λ/4 must be to taken into account. Therefore, selection of point for mounting of detecting sensors is very significant in order to obtain measured velocity value, which is fully representative for wide surroundings. Boundary between mediums (rocks) with differential acoustic impedances can generate transform waves; this fact complicates studied wave field even more. Searched predictor dependence of maximum velocity value V on charge Q and distance R can be determined using statistic method only, while it is necessary to check existing values of maximum velocity by an experimental measurement. This conclusion is consequence of influences mentioned above.

Local geological setting, especially shallow sedimentary layers, level of underground water and other factors have significant influence on value of maximum velocity on surface, as described above. Therefore, seismic load on farther construction can be smaller.

3 CONDITIONS FOR PERMANENT MONITORING OF SEISMIC LOADING

Temporary or permanent monitoring system of seismic vibration is suitable for construction in case when seismic loading is expected to last for a long period and/or vibration sensitive apparatuses are installed inside affected objects. Generally, it is necessary to account local conditions and to perform detailed parametric measurement in order to derive basic information about:

- Behavior of seismic noise in a particular region
- Maximum amplitudes and frequency spectra of vibrations
- Type of movement (particle motion)
- Validity of measured values for surroundings.

Detailed parametric measurement must be performed using seismic digital instrument. Obtained data have to provide:

- Analyses in time and frequency domain, especially to determine frequency of wave with maximum amplitude of space vibration component
- Polarization analysis to determine types of recorded parts of wave pattern (e.g., occurring of Rayleigh and Love surface waves and subsequently to define influence of geological pattern)
- Evaluation of character, sources and seismic noise on surface.

Basic parameters from technical point of view are amplitude and frequency range of seismic channel. Usually, the amplitude and frequency ranges of seismic records for monitoring structures on surface are determined in local regulations; frequency range 2–200 Hz is often used. This range was determined from amount of experimental measurements. The frequency range of signals and prevailing frequencies form demands for parameters of sensors and their mounting (concrete pillar, grounding …), needed sampling frequency for digital data and needed storage volume. It is necessary to point on exacting installation of sensors for first quality data with the highest frequencies (e.g. Ground Vibration 2001).

Following significant parameter for preparation of monitoring system is behavior and level of vibration noise in given area. Noise generated by automobile and rail transports and operation of technological instruments can be detected very often in cities. Amount of vibrations induced during mining of underground tunnel and level of common seismic noise on surface establishes the type of recording and preprocessing of measured data.

(a) Level of vibrations induced during mining of underground tunnel significantly exceeds common seismic noise. Apparatuses with triggering regime, which means exceeding of defined vibration level, can be used in such conditions. Generally, short time history that runs over fulfillment of triggering conditions is recorded. Advantage of this type of recording is a small volume of recorded data and, therefore, easy transportation of recorded data to interpretation centre. During preprocessing the technical staff detaches useful signals for further interpretation.

(b) The level of vibrations induced during mining of underground tunnel is practically the same as the level of seismic noise. In this case it is not possible to use monitoring system based on triggering and it is necessary to realize continuous record of situation. Recorded data volume is

very large and therefore telemetric transport (e.g. by modem) from field station without Internet is complicated from both technical and financial viewpoint. For example, three-component record from 16-bit seismic instrument and using sampling frequency of 500 Hz is about 260 MB per day. These data have to be stored on high-volume media and interpretation is then realized off-line. A specialist or a professional technical staff performs preprocessing of these records.

4 EXAMPLE FROM EXPERIMENTAL MEASUREMENT

Presented parametrical measurement was realized in Prague in January 2006. Blast operation was performed as a part of mining technology in terms of preparations for new plumbing. Total charge was 5.95 kg in 17 holes, timing in 10 steps. Mining works were made about 10 m below the surface; working face was contained by slates with mica.

Three seismic apparatuses GCR-16, GeoSIG Ltd. were used for our measurements. Their amplitude range was 1 or 10 mm·s^{-1}; recording bandwidth was up to 315 Hz using the sampling rate 1 kHz. Experimental instrumentation of PCM3-EPC type (Knejzlík & Kaláb 2002) was also used (Figure 2). This apparatus enables semi-continuous records of industrial seismic noise generated by common working activities. Basic problem for seismic measurement in these conditions is good anchorage of sensors as it is not possible to construct special seismic pillars (usually we do not have a place well connected with soil that is needed).

Permanent buildings do not exist in surroundings of preparation of plumbing. Therefore, solid plane areas were utilized for sensor installing (sensors were flatted by rock). Furthest station (instrumented by PCM3-EPC2) was installed about 250 m from source of vibration (station 1). Evaluation of seismic effect in this distance was main reason for this position. By contrast, the nearest station was about 25 m far from source of vibration (station 2). Here two apparatuses GCR-16 with different sampling frequency of digital signal (500 Hz and 1 kHz) were installed. Evaluation of wave patters recorded in the immediate vicinity of source and check of influence of sampling frequency on shapes of records. Last position was about 190 m from source (station 3); see Figure 3.

Duration of seismic effect on station 1 is almost 3 s, maximum recorded velocity amplitude is 0.078 mm·s^{-1} (vertical component), space component is 0.098 mm·s^{-1}($\sqrt{(Z^2+(N-S)^2+(E-W)^2)}$). Wave patterns do not contain sharp inputs except first one because significant damping of inputs generated by subsequent shots, occurring of secondary wave groups and their interferences. Spectral analysis documents frequency range 10–40 Hz.

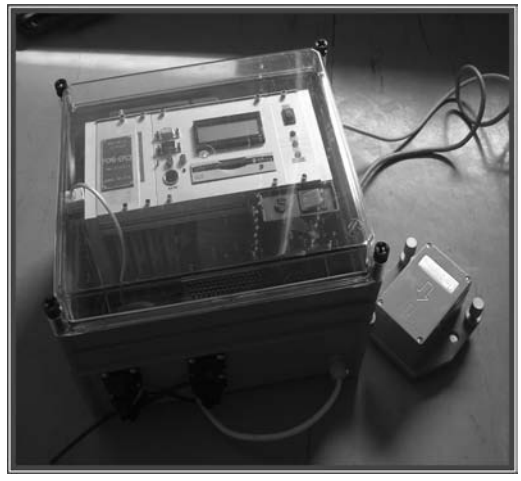

Figure 2. Photo of experimental instrumentation of PCM3-EPC type (developed in Institute of Geonics).

Figure 3. Sketch of position of source of vibrations (star) and seismic stations (St. 1 – St. 3) at experimental measurement.

Records on station 2 are shorter (about 2 to 2.4 s). Maximum recorded velocity amplitude is 1.12 mm·s^{-1} (vertical component); space component is 1.33 mm·s^{-1}. Wave patterns contain clearly recognizable sharp inputs that correspond to individual shots of holes and quick damping of individual seismic wave groups that have character of harmonic wave with different damping. The FFT of records show prevailing frequency range 40–55 Hz.

Records on station 3 represent transient type of records. Their durations are approximately 2.5 s, maximum recorded velocity amplitude do not exceed 0.3 mm·s^{-1}. Prevailing frequency range is up to 40 Hz.

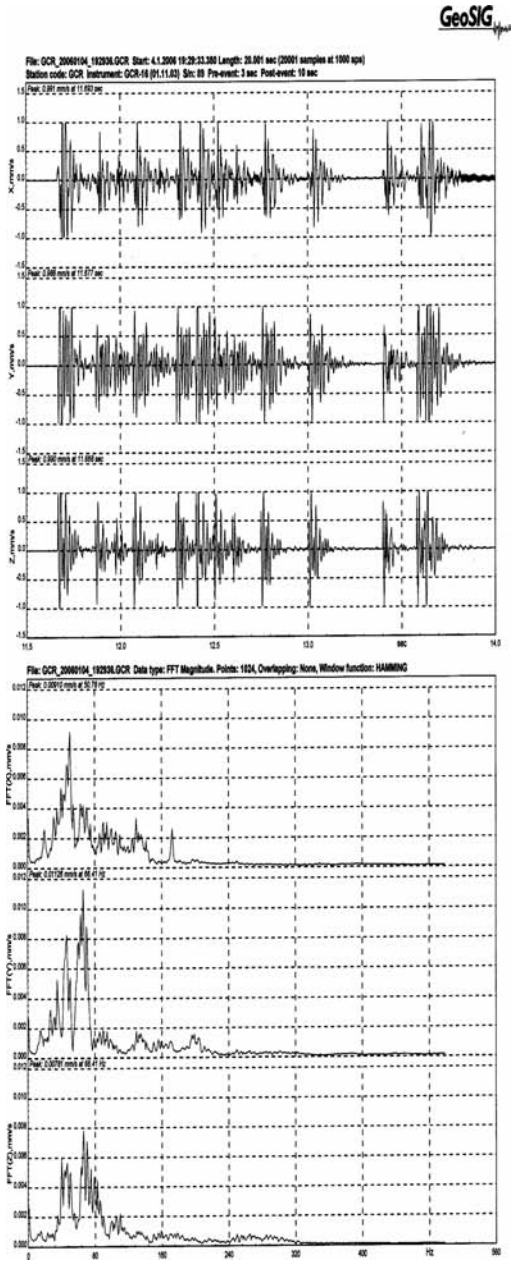

Figure 4. Example of wave pattern of blast, sampling frequency 1 kHz, distance to source about 25 meters.

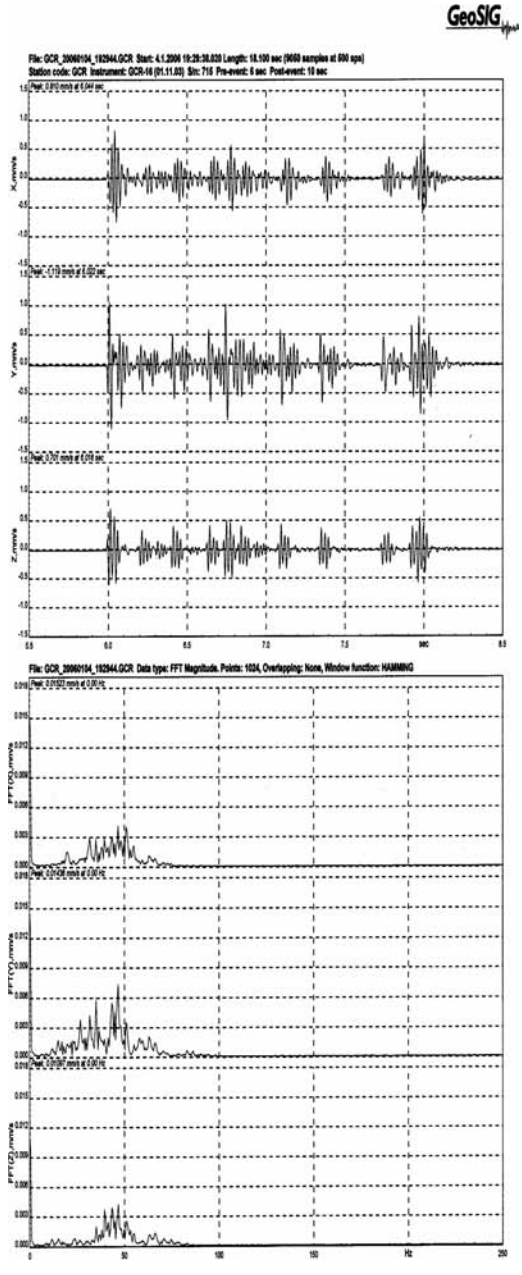

Figure 5. Example of wave pattern of blast, sampling frequency 500 Hz, distance to source about 25 meters.

Figures 4–5 document the changes of shape of recorded wave patterns due different sampling frequency. First figure presents wave pattern (top-down horizontal radial component, horizontal normal component and vertical component) and their spectra (Fast Fourier Transform) using sampling frequency 1 kHz, the second figure presents the same situation but with sampling frequency 500 Hz.

Values of maximum amplitudes of both records are almost the same (differences up to 15%). However,

frequency capacity of recorded signals is different; the 1 kHz record has wider frequency range, especially in higher values.

5 REMARKS RESULTED FROM MEASUREMENT

Obtained knowledge from experimental measurement is possible to summarize as follows:

- In short distances from source of vibration, it is necessary to provide high dynamic range of recorded apparatuses.
- Frequency range of seismic channel (i.e. both sensors and apparatus) should be as wide as possible, especially for higher frequencies.
- To record data of first quality, it is necessary to use high value of sampling frequency of digital signal, optimally 1 kHz or at least 500 Hz.
- Very good contact between sensor and basement is necessary to realize; to best solution is anchor sensors to basement using bolts or suitable additional load (it must not vibrate).
- All demands are possible to reduce adequately if seismic station is located in larger distance.

Behavior of signals, especially sharp inputs of first wave group, gives good conditions for possibility to use apparatuses with trigger regime of data recording. It is true that common seismic noise (other technical seismicity) do not often exceed preset trigger level. This fact is very important in case when medium-term or long-term monitoring is necessary to use.

Generally, the most intensive seismic effects are generated in cases when blasts were used as a part of the technological process. It is usually used timing of blast. Therefore, wave patterns are short, and they have sharp inputs and very often documented vibrations on high frequencies, mainly in short distances between source of vibration and sensor.

6 CONCLUSION

Evaluation of technical seismicity induced during urban tunneling on buildings and structures on surface results from experimental measurements usually. Realization of temporary seismic stations that will operate in suitable buildings during whole period of seismic loading (generally weeks or first months) is supposed. As was mentioned above, vibrations can be produced by different sources. Amount of measurements illustrates that the highest values are induced by blasts of explosives. Damage of buildings within the meaning of limitation on usability is not expected when referential values specified in standards, e.g. Czech Standard CSN 73 0040 or German Standard DIN 4150, are not exceeded (Kiehl & Werfling 2003).

At present, permanent seismic monitoring with automatic data acquisition and primary interpretation of basic parameters is favored in urban regions when significant vibrations are generated. Obtained results are at disposal to civil engineers, firefighters and also to custodians and occupants of influenced buildings. Usually, web application is used with different access authority. This web continuously presents basic parameters and results of seismic monitoring (and other information). Limit and critical values of vibrations for appropriate damages of buildings are determined for evaluated area. These values, of course, depend on technical wear of building and local geological conditions.

Design method considering construction loads during shield tunneling using a three-dimensional FEM analysis model

Kiyoshi Kasuga, Naruhiko Kawada & Akira Shiratori
Metropolitan Expressway Co., Ltd., Japan

Naomitsu Fukai & Masayuki Saitou
Nippon Civic Consulting Engineers Co., Ltd., Japan

ABSTRACT: With recent technological advancements, secondary linings have been eliminated, segmental linings have become thinner and lining rings have become wider to reduce the cost of constructing shield tunnels of large cross section. There have, however, been concerns about the functional deterioration of linings due to the effects of loads during construction, which are difficult to handle in conventional design processes.

In the Shinjuku Route of the Central Circular Route of the Metropolitan Expressway, the effects of loads on tunnels during construction have been analyzed using the data on the control of construction with shields and the measurements of the behavior of segmental linings. No measurements were, however, available to identify the effects of loads during construction, and no detailed studies could be made.

In this study, construction control data and measurements were collected in the Kamiyamacho-Yoyogi shield work section of the Shinjuku Route based on a measurement plan aimed at analyzing the loads during construction. Three-dimensional FEM analysis was made using the measurements. A method for analytically checking the effects of loads on tunnel linings during construction was examined. The concept of the method and problems involved in its future application are described in this paper.

1 INTRODUCTION

A growing number of shield tunnel projects have been implemented for constructing road tunnels with an outer diameter of as large as 11 to 13 m and without any secondary lining. With recent technological advancements, segmental linings have become thinner and lining rings have become wider to reduce construction costs. Then, safety margin against loads during construction, which were difficult to handle quantitatively in conventional design processes, has been reduced and lining damage is more likely to be caused.

Segmental linings of a shield tunnel are subjected to jack thrust, tail seal pressure and backfilling pressure during construction. The surrounding ground is not expected to provide support right after the assembly of segmental linings, so the deformation of segmental linings, joint opening and joint unevenness are likely to occur. Records on past construction show that such effects of loads during construction are found outstanding in curved sections where segmental linings deviates from the direction of shield advance. In the design of a shield tunnel, loads such as jack thrust, tail seal pressure and backfilling pressure are generally examined separately, but they probably combine with one another and damage segmental linings. The authors, with the view to reproducing the behavior of segmental linings, have conducted field measurement of their behavior during construction, and analyzed the behavior of the shield machine and made three-dimensional FEM analysis.

This paper presents the results of evaluation of the effects of construction loads on segmental linings based on the results of measurements of segment linings that were taken in the field.

In this study, the behavior of segmental linings was analyzed using a three-dimensional FEM model of shield tunnel in order to identify the effects of construction loads on segmental linings based on the results of measurement of the behavior of segment linings conducted in the field and on the data on construction with shield machines. The analysis results were compared with field measurements to verify the validity of behavior analysis. Based on the above results, a segmental lining design method was examined that took the effects of construction loads into consideration.

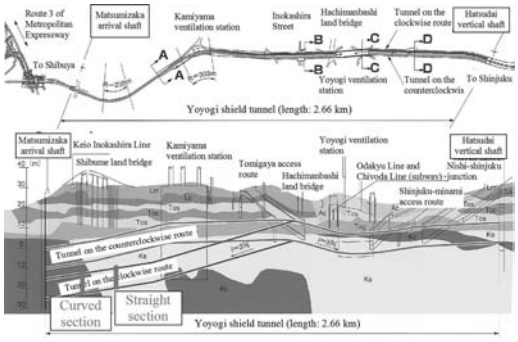

Figure 1. Measurement sections (Kamiyamacho-Yoyogi shield work section).

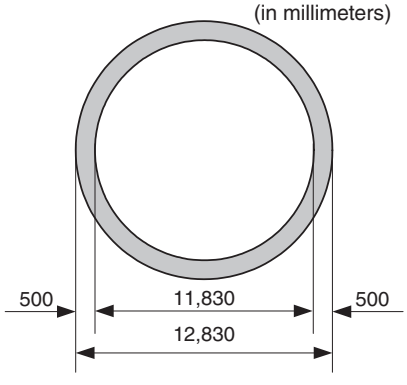

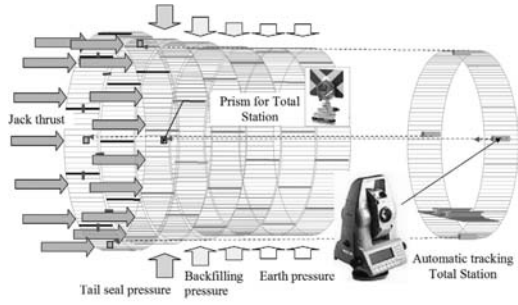

Figure 2. Tunnel cross section (on the clockwise route).

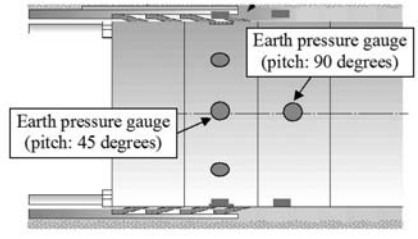
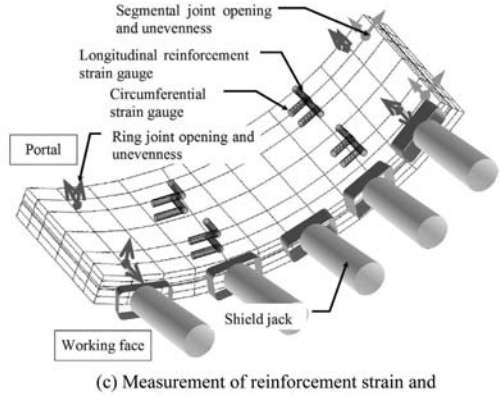
2 FIELD MEASUREMENTS OF LOADS DURING CONSTRUCTION



2.1 *Outline of the site*

Field measurements were taken of the loads during construction in straight and curved (radius: 238 m) sections of varying cross section of the Kamiyamacho-Yoyogi shield tunnel on the Shinjuku Route of the Metropolitan Expressway to evaluate the effects of loads in different types of alignment (Figure 1).



The Kamiyamacho-Yoyogi shield tunnel is constructed using slurry shields over a length of 2,660 m between Hatsudai icchome, Shibuya ward to Aobadai yonchome, Meguro ward under Central Circular Route 6 (Yamatedori Avenue). The tunnel passes through consolidated ground mainly composed of Kazusa formation. The tunnel on the clockwise route has a diameter of 12.83 m and is 3.5 to 9 m away from the other of twin tunnels. The two horizontally parallel tunnels change into vertical parallel ones. Reinforced concrete segmental linings with a thickness of 500 mm are used in the sections where measurements were taken. Segmental rings are divided into nine segments.

(a) Measurement of displacement

(b) Measurement of earth pressure

(c) Measurement of reinforcement strain and joint opening and unevenness

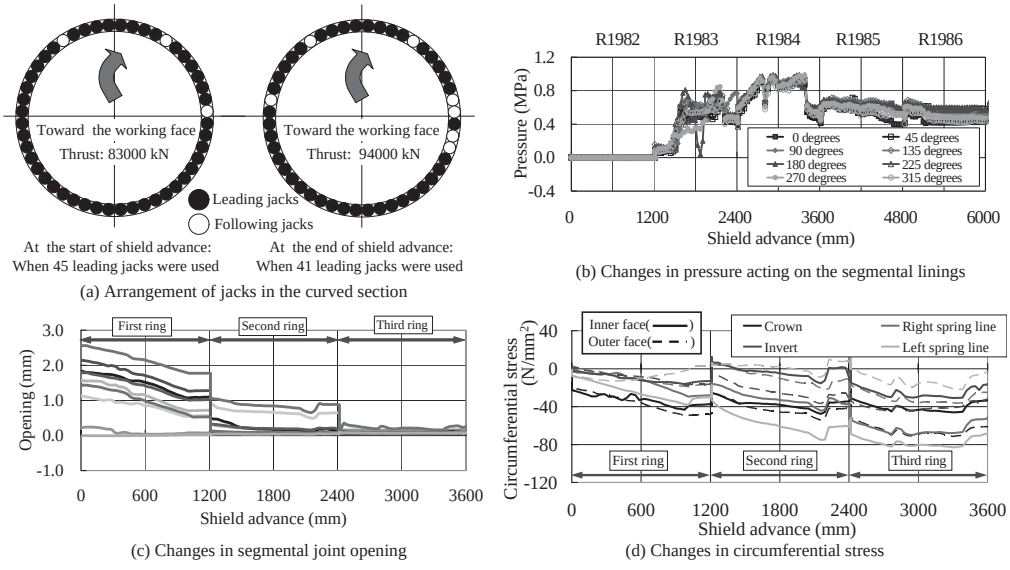


Figure 3. Measurement instruments.

2.2 *Details of measurement*

In the field measurement of loads during construction, displacement, earth pressure, strain of reinforcement, and joint opening and unevenness were measured. In the straight section, only displacement and joint opening were measured (Figure 3).

For displacement measurement, Total Stations were installed at a pitch of 90 degrees to identify the three-dimensional behavior of the tunnel.

Earth pressure gauges were installed in two rings, main and sub rings, to grasp tail seal pressure and backfilling pressure acting on the segmental linings during excavation.

(a) Arrangement of jacks in the curved section

(b) Changes in pressure acting on the segmental linings

(c) Changes in segmental joint opening

(d) Changes in circumferential stress

Figure 4. Results of measurement (in curved section).

Reinforcement strain gauges were used to obtain changes in strain in segmental linings right after assembly and during construction. Gauges were installed at 36 positions in a ring, or at four positions per segment, to measure circumferential and longitudinal strains.

Gauges for measuring joint opening and unevenness were installed at segmental and ring joints at the four corners of a segment. They were used to monitor how the initial joint opening and unevenness right after assembly would vary with shield advance.

2.3 *Results of measurement*

Results of measurement were shown in terms of the arrangement of jacks, and changes in earth pressure with shield advance, in segmental joint opening and in circumferential stress (Figure 4).

The number of jacks was gradually reduced to enable the shield to follow the tunnel alignment in the curved section. Jacks on the concave face of the curve were reduced earlier. The jack thrust was greater at the end of shield advance than at the start. Thrust per jack increased by 24%.

The pressure acting on the circumference of the segmental lining is represented based on the reading of the earth pressure gauge and the stroke of the jack. The segmental ring did not reach the tail seal while the shield was used to assemble the first ring following the ring for measurement. Then, no pressure from areas around the tunnel was acting. While the shield was used to assemble the second ring, the segmental ring was subjected to tail seal pressure and rapid variation of earth pressure was found. The segmental ring was subjected to the highest pressure due to the effect of backfilling pressure while the shield was assembling the third ring because the segmental ring passed the tail of the shield. Little variation of pressure was observed in the fourth and subsequent rings.

Segmental joint opening was approximately 2 mm at the maximum near the key segment right after assembly, but decreased with the advance of the shield. All the joints had an opening of less than 0.2 mm after the excavation in the second ring.

Circumferential stress gradually increased after the start of shield advance, similar to the circumferential pressure and segmental joint opening.

Conventional three-dimensional FEM analysis [4], [5], [6] considered jack thrust (arrangement of jacks) and changes in circumferential pressure acting on the tunnel. In the analysis model adopted in this study, segmental joint opening was also considered. The results of analysis were verified by comparing the stress and deformation with measurements.

3 THREE-DIMENSIONAL FEM ANALYSIS

3.1 *Analysis model*

A three-dimensional FEM analysis model was adopted for analyzing loads during construction (Figure 5). Segments were modeled using solid elements and connected to one another via spring elements. The first three rings were analyzed because variations of circumferential pressure were confirmed in these rings based on the measurements. The tunnel was compressed by jack thrust along the tunnel axis during excavation. To reproduce the behavior, values of springs at the boundary were specified as boundary

conditions for the analysis model based on the relationship between the absolute value of shield tunnel displacement and the jack thrust obtained in field measurement (Figure 6).

Physical property values of segment are listed in Table 1. Concrete was regarded as a perfectly elastic body when the model was made.

Values of springs of segmental and ring joints were specified around the tunnel circumference, along the tunnel radius and along the tunnel axis based on the results of element tests (Figure 7).

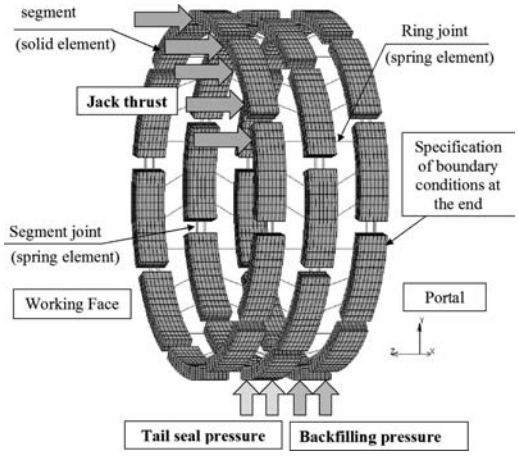
In this study, the curve representing the joint spring passing the origin was shifted based on the changes in segmental joint opening with time shown in Figure 4 to make a model similar to the ring in actual construction.

3.2 *Loading conditions*

For analysis, jack thrust that varied according to the arrangement of jacks and varying pressures acting on the circumference of the tunnel (Figure 4) were adopted as the loads during construction. Circumferential pressure was measured at a pitch of 45 degrees, so it was interpolated linearly around the tunnel circumference for input.

3.3 *Analysis cases*

Analysis was made in a curved section subjected to outstanding effects of loads during construction in four cases (Table 2). The timing of measurement, at the start or end of shield advance where different numbers of jacks were used, and whether there was a segmental joint opening or not were used as parameters.



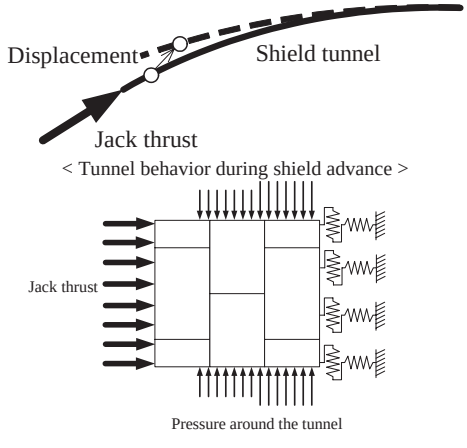


Figure 5. Analysis model.

Type of spring		Characteristics
Longitudinal		Tension (joint spring)/ compression (specified based on measurement)
Transverse		Shear (joint spring)

Figure 6. Specification of boundary conditions.

Table 1. Physical property values of segment [1], [2].

σck (N/mm^2)	E (kN/m^2)	ν	σca (N/mm^2)	ftk (N/mm^2)
48	3.9×10^7	0.17	$18 \times 1.5 = 27$	3

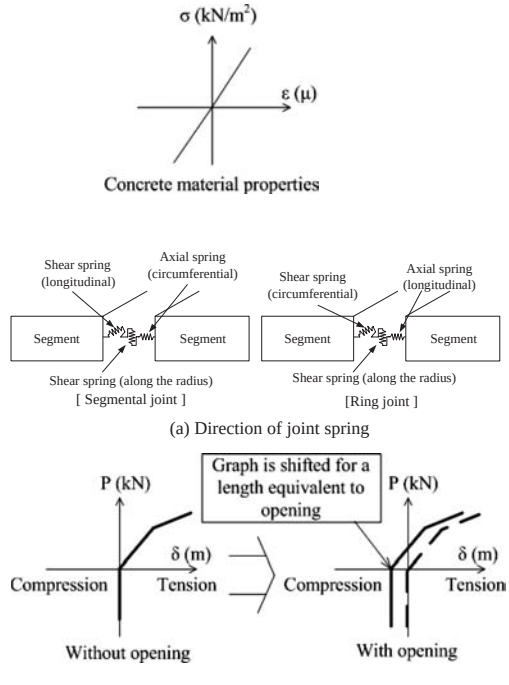

Figure 7. Characteristics of joint spring.

3.4 *Results of analysis*

3.4.1 *Distribution of acting stresses*

Measurements and analysis results for stress are represented by points and solid lines in Figure 8. Analysis results are given only for cases 2 and 4 at the end of shield advance without and with segmental joint opening, respectively.

Where joint opening was considered, circumferential stress varied at segmental joints although the variation was small. In both cases 2 and 4, analysis results were in good agreement with measurements in terms of stress level. No local variance in stress on the outer and inner faces are reproduced in the figure. Local stress varied greatly at different measurement positions. This may have been caused by the rotation of segmental joints (variance in mode of contact between segments), which was not considered in analysis.

It was confirmed based on the longitudinal stress that little axial compression occurred on the inner face of the segmental lining in the second and subsequent rings as shown by the results of measurement where joint opening was considered.

Table 2. Analysis cases.

Measurement section	Case	Construction condition	Segmental joint opening
Curved section	1	At the start of shield advance	Without opening
	2	At the end of shield advance	
	3	At the start of shield advance	With opening
	4	At the end of shield advance	

3.4.2 *Deformation*

Tunnel deformation is shown in Figure 9. Black circles indicate measurements and solid lines indicate analysis results. Analysis results are given only for cases 2 and 4 at the end of shield advance without and with segmental joint opening, respectively as for stresses.

Transverse deformation shows that tunnel cross section was reduced with shield advance when joint opening was taken into consideration as reflected in the measurements.

Longitudinal deformation is more or less the same in cases 2 and 4, and is nearly in agreement with measurements. The boundary conditions of the analysis model specified based on measurements are therefore determined to be appropriate. Longitudinal deformation was partially different in a cross section probably because boundary conditions were specified

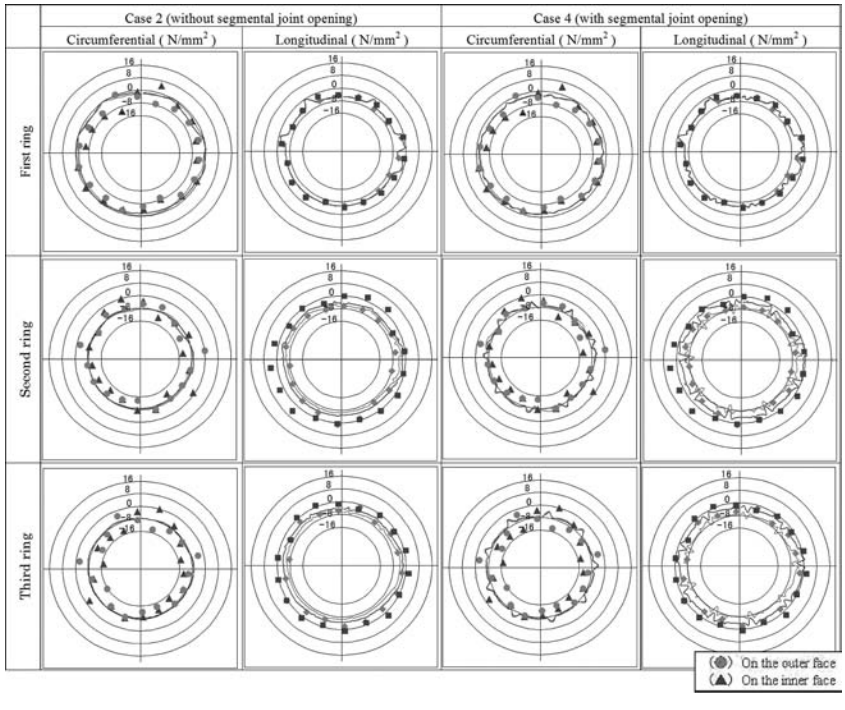

Figure 8. Stress (in N/mm^2).

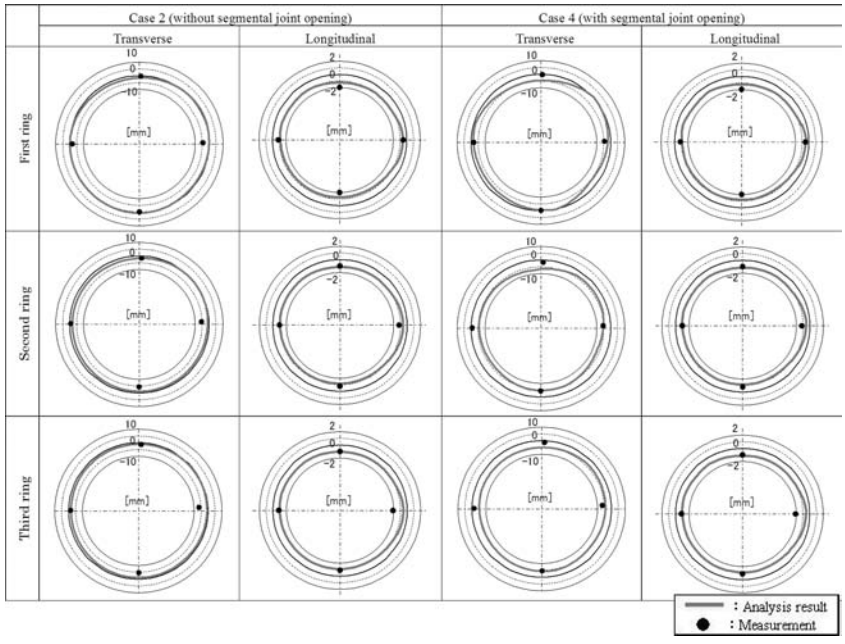

Figure 9. Tunnel deformation.

uniformly in a cross section. More detailed specification of boundary conditions is expected to increase the accuracy of analysis.

4 CONCLUSIONS

In this study, evaluation was made of a method for examining the effects of construction loads on the tunnel based on the field measurements of the behavior of segmental linings during shield advance and using three-dimensional FEM analysis. The results of evaluation and future tasks involved in the application of the method are described below.

It was confirmed that a three-dimensional FEM analysis model could reproduce nearly satisfactorily the behavior of segmental linings that was identified in field measurement if segmental joint opening was considered in addition to jack thrust, pressure along the circumference of segmental linings and boundary conditions obtained based on the absolute displacement of the tunnel.

In the future, variations of stress occurring locally along the circumference will be verified analytically.

Loading conditions and the accuracy of shield assembly are now defined based on measurements. In order to establish a design method, a method should be developed for specifying these parameters quantitatively.

In this study, verification was made in highly consolidated ground with an N-value of more than 50. For application in weak soils, further verifications will be required.

The analysis model proposed in this study is highly complicated, so making analysis frequently with the model in daily design process is difficult. Design methods using two-dimensional models are now being examined based on the knowledge obtained in this study. Simpler design methods will be proposed in the future.

Development of a new center-cut method: SAV-cut (Stage Advance V-cut)

Donghyun Kim, Seunghwan Noh & Sangpil Lee
GS Engineering & Construction Corp., Seoul, Korea

Byungki Park & Seokwon Jeon
Seoul National University, Seoul, Korea

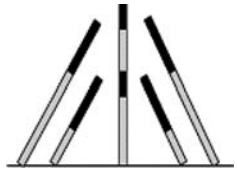
ABSTRACT: In most tunnels in South Korea, blasting has been widely used as an excavation method. The key of blasting method in tunnel is the center-cut, which creates first free surface. This paper introduces new center-cut method named SAV-cut (Stage Advance V-cut) developed on the concept of V-cut. An important factor of SAV-cut is center holes drilled and partly charged for maximizing tensile failure effect and satisfying optimum charge density. Field tests and numerical analysis were carried out to analyze the mechanical behavior and blasting vibration. In the numerical analysis, PFC 2D (Particle Flow Code 2D) was used and two field tests were performed to verify the high performance of SAV-cut. From the results, the newly developed SAV-cut was proved as an effective center-cut method for both increasing blasting efficiency and decreasing blasting vibration.

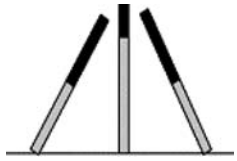
1 INTRODUCTION

In South Korea, the ground is mainly composed of hard rock such as granite and gneiss, but the complex geology generally limits blasting method as a main tunnel excavation method rather than mechanical excavation using TBM or shield method. In tunnel blasting, the center-cut inducing first free surface is very important for enhancing excavation efficiency and reducing vibration caused by exploding.

In general, V-cut and cylinder-cut are commonly used for center-cut. V-cut is a representative type of angle-cut having inclined holes that nearly meet at the bottom. Charging at the bottoms of the holes play a role to pull out the rock mass by the shape of V. Cylinder-cut is a type of parallel cut having 2-4 large empty holes (generally over 102 mm in diameter) drilled at middle of the center-cut. This method is most commonly used for long advance over 2 m.

But there are some problems in applying these methods as center-cut because there may be considerable difficulties in accurate drilling of inclined holes for V-cut and the narrow width (0.2-0.4 cm) of parallel holes makes drilling work difficult for cylinder-cut. Also, due to the regulations in South Korea, cartridge explosives are generally used rather than bulk type explosives. Therefore, tight loading at the bottom of the holes, yielding center-cut blasting, is not always successful.





In this study, a new center-cut method named SAV-cut (Stage Advance V-cut) was developed to overcome these problems on the concept of V-cut. In order to verify the performance of the SAV-cut, field tests and numerical analysis were carried out.

2 CONCEPT OF SAV-CUT

The principle of V-cut is to create the first free surface by wedge failure. For the success of V-cut blasting, accurate drilling and sufficient failure at the bottom of inclined holes are important. The concept of SAV-cut is focused on these two factors. The center hole that is the significant feature of SAV-cut makes the rock mass around bottoms of inclined holes weakened by being ignited at first. As the rock mass constant is diminished, it can be enabled to decrease the amount of charging in the inclined holes. Also, the adverse effect of inaccurate drilling is to be reduced because the bottom spacing between two inclined holes can be more widened due to the center hole.

In the SAV-cut, the angle of inclined holes could be extended to 70 degrees and the spacing between two holes could be increased due to the added center holes. Therefore, SAV-cut is more effective for long hole blasting than V-cut in consideration of drilling work. Cross section and main features of SAV-cut were described in Table 1. Figure 1

Table 1. Cross sections and the main features of SAV-cut.

Classification	Cross section	Features	Application
Pattern for long hole blasting		– Center hole – Baby cut hole – Deck charge of center hole – Ignition sequence: center hole(1) → baby cut hole → center hole(2) → main cut hole	– Advance of 2.0 m or more
Pattern for short hole blasting		– Center hole – Ignition sequence: center hole → main cut hole	– Advance of 2.0 m or less

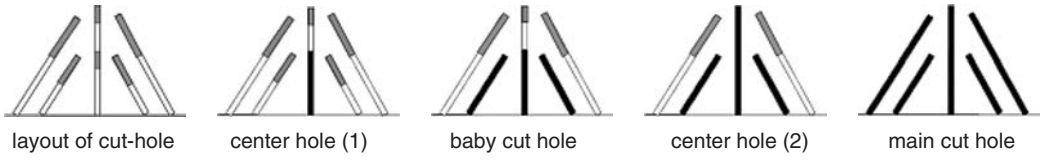


Figure 1. Ignition sequence of SAV-cut (long hole blasting).

shows the ignition sequence of SAV-cut for long hole blasting.

3 NUMERICAL MODELING WITH PARTICLE FLOW CODE

3.1 *Input parameters for numerical modeling*

In PFC2D, particles interact with other particles and walls, through the forces that develop at their contacts. Each contact model may be divided by three models: (1) a contact-stiffness model, (2) a slip and separation model and (3) a bonding model (Itasca, 1999a).

In this study, a linear model as a contact-stiffness model and a contact-bond model as a bonding model was used. Micro-mechanical parameters, which define the contact-bonded material, include ball density, ball-ball contact modulus, ball stiffness ratio, ball friction coefficient, contact-bond normal strength and contact-bond shear strength.

The parameter analysis was carried out to determine the input parameters, i.e., micro-mechanical parameters of the particle assembled model which has similar mechanical behavior of the rock mass based on the macro-mechanical parameters of the rock mass shown in Table 2. In Table 2, the deformation modulus of rock mass E_m and the rock mass strength σ_{cm} were estimated from the uniaxial compressive strength of intact rock σ_{ci} and the geological strength index (GSI) from Equations (1) and (2) (Hoek et al., 2002).

$$E_m(GPa) = \left(1 - \frac{D}{2}\right)\sqrt{\frac{\sigma_{ci}}{100}} \cdot 10^{\frac{GSI-10}{40}} \quad (1)$$

$$\sigma_{cm} = \sigma_{ci} \cdot \frac{\left[m_b + 4s - a\left(m_b - 8s\right)\right]\left(m_b/4 + s\right)^{a-1}}{2\left(1+a\right)\left(2+a\right)} \quad (2)$$

where, D is factor to allow for the effects of blast damage and stress relaxation ($0 \le D \le 1$).

$$m_b = m_i \exp\left(\frac{GSI-100}{28-14D}\right), \quad s = \exp\left(\frac{GSI-100}{9-3D}\right)$$

$$a = \frac{1}{2} + \frac{1}{6}\left(e^{-GSI/15} - e^{-20/3}\right)$$

The micro-mechanical parameters determined by the trial-and-error method through many numerical simulations were summarized in Table 3.

3.2 *Blasting pressure-time history curve*

Sudden release of energy and reaction products at high pressure by rapid chemical reaction in explosive charged in a blast hole gives rise to compression waves

Table 2. Micro-mechanical parameters of the model.

Parameter	Rock mass class I	Rock mass class IV
Modulus of deformation of rock mass	75 GPa	24 GPa
Poisson's ratio	0.20	0.22
Rock mass density	2,700 kg/m^3	2,600 kg/m^3
Rock mass strength	92 MPa	41 MPa

Table 3. Micro-mechanical parameter values used in the PFC2D simulation.

Parameter	Rock mass class I	Rock mass class IV

* SD: Standard deviation.

in the explosive and surrounding rock material. The detonation waves play an important role in the function of the explosive and fragmentation of rock mass (Persson et al, 1994).

Detonation is the first step of fragmentation process. After detonation, components of explosives are immediately converted into high-pressure and high-temperature gases. In general, it is impossible to measure the detonation pressure directly. Many researchers, however, such as Atlas Powder Company (1987) and Liu and Tidman (1995) have proposed equations to calculate the detonation pressure employing the chemical equilibrium equation of explosives and the empirical factor obtained from field tests. In this study, Equation (3) suggested by National Highway Institute (1991) was applied to estimate the detonation pressure.

$$P_D = \frac{4.18\times10^{-7}\times\gamma_e\times D_e^2}{1+0.8\gamma_e} \tag{3}$$

where, P_D is detonation pressure (kbar), γ_e is explosive density (g/cm^3), and D_e is detonation velocity (ft/s).

Time history of dynamic pressure was considered in order to simulate its effect of rock blasting accurately

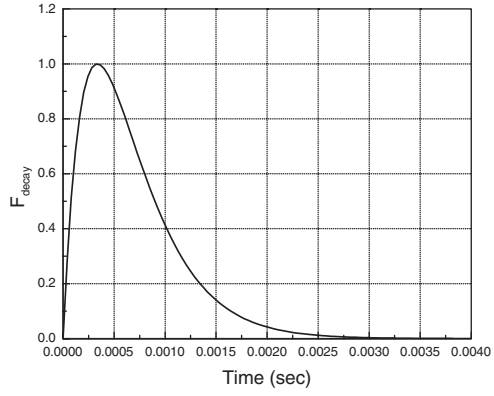

Figure 2. Time history curve for the dynamic pressure acting on the wall of blast hole.

because dynamic pressure acting on the wall of blast hole varies with time. The time history of dynamic pressure can be obtained by using window function proposed by Starfield and Pugliese (1968) as shown in Equation (4).

$$P_D(t) = 4P_B\left[\exp\left(\frac{-Bt}{\sqrt{2}}\right)-\exp\left(-\sqrt{2}Bt\right)\right] \tag{4}$$

where, P_D is detonation pressure, P_B is decoupled detonation pressure, B is loading constant (=16,338 in this study), and t is time.

Also, the decay function, Equation (5), was used to consider the extent of attenuation with time. However, it is difficult to determine the time when the pressure arrives its maximum value.

$$F_{decay} = \exp\left(1-\frac{t}{t_0}\right)\times\frac{t}{t_0} \tag{5}$$

where, F_{decay} is decoupled detonation pressure.

The detonation pressure calculated by Equations (4) and (5) is for the fully coupled holes. In order to take into account the decoupling effect, the borehole pressure is calculated by Equation (6).

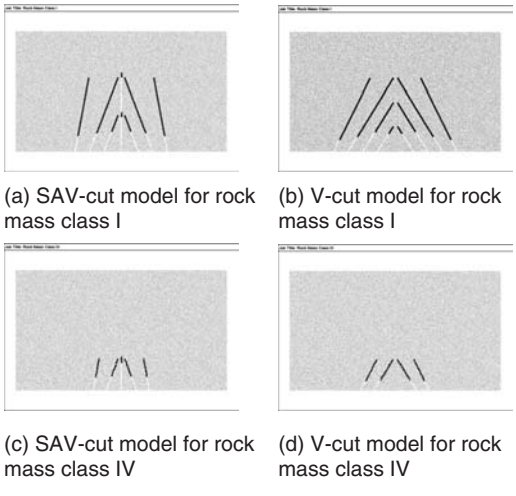
$$P_B = P_D\times\left(\frac{d_c}{d_h}\right)^3 \tag{6}$$

where, P_B is decoupled detonation pressure, P_D is detonation pressure, d_c is charge diameter, and d_h is borehole diameter.

The borehole pressure was simulated to consider the characteristics of decay function using Equation (5) and detonation pressure using Equations (4) and (6). Figure 2 shows the time history curve for dynamic pressure acting on the wall of blast hole.

This study was carried out under following assumptions. (1) The viscous damping effect was neglected in the numerical simulation because its influence on the response of high-velocity explosives was insignificant. (2) The cracks in the numerical simulation were formed as a result of contact-bond breakage between balls. (3) The damage to the rock mass due to the penetration/explosion of the explosive gas into the existing fracture was not considered.

However, numerical results obtained by the past researches suggested that the damage of modeling induced solely by stress wave propagation could give reasonable prediction of rock mass response to blasting load (Hao et al, 2002).



3.3 *Modeling*

The domain of model is 6 m long and 10 m wide and the radius of particle used in the simulation is 0.04 m. A total of 4 cases including two rock mass classes (class I and IV) and two blasting patterns (V-cut and SAV-cut) were considered as shown in figure 3.

3.4 *Results of numerical modeling*

3.4.1 *Blast efficiency in the bottom area of cut holes*

Blast efficiency of each cut blasting pattern was measured by the number of crack generated in the bottom area of cut holes. The boundary of bottom area was defined as 1.0 m ahead from the end of blast hole in rock mass class I, 0.5 m ahead in rock mass class IV. Table 4 shows cut volume, drill length, charge, the number of tensile crack and shear crack in four cases, respectively.

(a) SAV-cut model for rock mass class I

(b) V-cut model for rock mass class I

(c) SAV-cut model for rock mass class IV

(d) V-cut model for rock mass class IV

Figure 3. PFC 2D model for efficiency comparison.

In the case of rock mass class I, total number of tensile cracks and shear cracks by SAV-cut was increased by 41% and 128%, respectively than that of V-cut. In case of class IV, total number of tensile cracks by SAV-cut was increased by 108%, while the number of shear cracks was decreased 19%. The simulation showed that SAV-cut generated more cracks than V-cut in rock mass class I and IV.

The propagation pattern of cracks of each ignition step is shown in Table 5. The rock mass around cut holes is broken by step-by-step blasting within 0.2 sec. In spite of more cracks, the broken rock mass area of SAV-cut was expressed smaller than that of V-cut on the simulation results because the displacement of rock mass occurred by failure was transferred to the center hole in case of SAV-cut by the limitation of 2D numerical analysis.

3.4.2 *Blast vibration attenuation*

In order to measure peak particle velocity, the particle velocity in the x- and y-direction at specific points was measured and peak vector sum was calculated with particle velocities. There are three measuring points located in the vicinity of left boundary as indicated in Figure 4. On the assumption that the center of model domain is the origin, coordinates of each measuring point (A,B,C) are shown in Table 6.

Table 4. Blast efficiency comparison of SAV-cut and V-cut in the bottom of cut holes (PFC 2D).

	Class I		Class IV	
Factors	V-cut	SAV-cut	V-cut	SAV-cut
cut Volume (m^2)	15.22	13.72	4.00	3.8
Drill Length (m)	25.48	24.94	7.2	8.9
Charging (kg)	16.8	13.2	4.00	3.25
Tensile failure crack (Ea)	332	469	136	283
Shear failure crack (Ea)	25	57	422	341

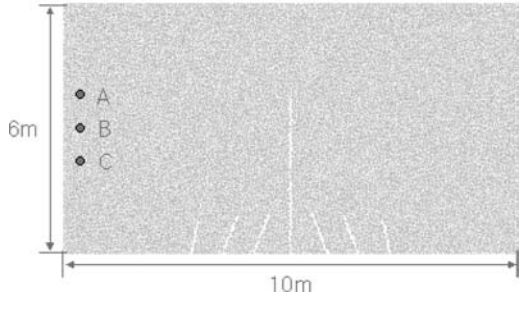


Figure 4. The location of measuring points to monitor peak particle velocity.

The peak particle velocity of SAV-cut was compared to that of V-cut by numerical analysis using PFC 2D as detailed in Table 7. In comparison with V-cut, the peak particle velocity of SAV-cut was reduced by 24∼39% in rock mass class I and 16∼51% in rock mass class IV.

Table 8 shows the peak particle velocity of each ignition step measured at point B.

Table 9 shows the time history of particle velocity in the x-direction, y-direction and vector sum of V-cut and SAV-cut. In case of rock mass class I, the peak particle velocity was occurred at 0.12 sec in SAV-cut and 0.06 sec in V-cut respectively. In case of rock mass class IV, the peak particle velocity was occurred at 0.065 sec in SAV-cut and 0.025 sec in V-cut.

The peak particle velocity of SAV-cut was occurred 0.06 sec later than that of V-cut because the delay time of main inclined holes after center hole ignition was designed to be 40 ms for preventing cementation effect. Due to the delayed time and smaller amount of charging, blast vibration of SAV-cut was lower than that of V-cut.

Table 6. Coordinates of measuring points (A,B,C).

location	A	B	C
x coordinate	−4.7	−4.7	−4.7

4 FIELD TEST RESULTS

The performance of SAV-cut and V-cut was compared by two field tests. Figure 5 shows the cut-hole location of V-cut and SAV-cut marked on the tunnel excavation face.

From test results, the blasting efficiency of SAV-cut was 10 % higher than that of V-cut. Also, the peak particle velocity was decreased as shown in table 10.

5 CONCLUSION

This paper introduced SAV-cut (Stage Advance V-cut) developed to overcome the disadvantage of V-cut and Cylinder-cut. Field tests and numerical analysis were carried out to analyze the mechanical behavior and blasting vibration. The results of studies are summarized as follows.

(1) In numerical analysis, a total of 4 cases including two rock mass classes (class I and IV) and two blasting patterns (V-cut and SAV-cut) were compared using PFC 2D.
(2) In case of rock mass class I, tensile cracks and shear cracks induced by SAV-cut were increased by 41% and 128%, respectively. In case of class IV, tensile cracks of SAV-cut was increased by 108%, while the number of shear cracks was decreased 19%. The simulation showed that SAV-cut generated more cracks than V-cut in both rock mass class I and IV.
(3) The peak particle velocity of SAV-cut was compared to that of V-cut by numerical analysis. In comparison with V-cut, the peak particle velocity of SAV-cut was reduced by 24∼39% in rock mass class I and 16∼51% in rock mass class IV.
(4) The performance of SAV-cut and V-cut was compared by two field tests. The blasting efficiency of SAV-cut was 10 % higher than that of V-cut. Also, the peak particle velocity was decreased.

ABSTRACT: Invert is a kind of the tunnel structure which is applied to weathered rock or poor ground condition. In this study we grasped the efficiency of the plate and invert section by the laboratory model test and numerical analysis for the korea high speed railway's tunnel section and verified that invert is more superior than plate section for the load resistance ability. We analysed tha failure mode of the tunnel peripheral ground for the each test case using the critical shear strain rate among the indicated parameters of the failure mechanism. To control ground deformation in a weathered rock, the invert section is more effective than the plate section. But the invert's shotcrete section force exceeded the allowable limit and this was checked using a numerical analysis. When the invert section is applied, it should be installed permitting a maximum ground deformation in order to prevent failure of supporting system.

1 INSTRUCTIONS

The invert which is installed on the base of the tunnel floor is applied to the tunnels outer wall to resist external pressure from weathered rock or poor ground condition. The invert is stabile solution in soft ground but it is often omitted in fine ground because of economical reasons.

In bad ground conditions, it is more effective to install the invert as soon as possible, but if the invert is installed too early (before settling) supporting capacity can not effectively be controlled, so it should be installed after permitting sufficient rock deformation.

Pre-estimating of the failure mechanism using a model test with different mathmatical modeling and numerical analysis to determine tunnel failure behavior is important process. A laboratory model and centrifuged model test represent the bearing and failure behavior which can be observed with the naked eye. To analyze the ground failure use the numerical analysis on a computer for quicker and more effective conclusions.

In this study the invert section's resistance from external pressure is estimated quantitatively through the 2- axis compression test and numerical analysis. This is for the Korean express train tunnel which has a height of 15.3 m and a width of 11.0 m.

A failure state around the tunnel is estimated from different test results with the critical shear strain and this also provides basic information to set up an effective installation analysis through the invert and plate section's behavior with consideration to the ground conditions.

2 STUDY OF THE TUNNEL MODEL TEST AND NUMERICAL ANALYSIS

2.1 *Equipment of the model test*

When using a downsized scale model test of real site conditions deformation behavior of the tunnels stability can be verified using a reduction rate calculation. The down-scaled model tester using hydraulics has a bearing of 25 ton, $48 \times 48 \times 20$ cm (width $\times$ height $\times$ length) The down sized scale model test is a 2-dimensional space test, the upper side of the tunnel model is fixed with a displacement control bar. A digital camera (type EF 28$\sim$105 mm, 6.5mega pixels) is installed at a distance of 2 m from the down-scaled model. A displacement (error range $\pm$0.1 mm) of the model test is measured by comparing pictures taken at regular intervals with pre-marked measuring points.

2.2 *The down-scaled model test*

The purpose of this study is quantity estimation of resistance capacity against external pressure through

Figure 1. The down-scaled model tester.

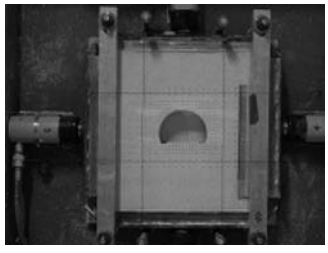

Figure 2. The measuring points are marked.

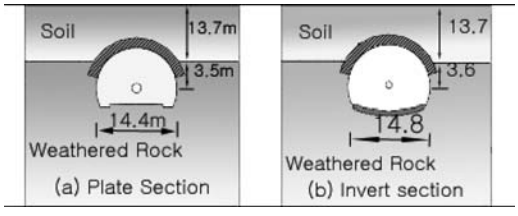

Figure 3. Down-scaled model test section.

a 2-axis compression test and the use of numerical analysis, using a section of the Korea express train tunnel. The area of excavation is about 140 m^2 (width 15.3 m, height 11.0 m).

The model test is performed at tunnel depth G.L −11.0 m, the reinforced space in the crown has a range of approx. 150° of the umbrella roof reinforcement. The materials used in this model test are the same as in real site's engineering properties and test material used in sand, gypsum(or lime), and water.

To get an exact test result, a dimensional analysis is performed. The three physical factors, that is length [L], time [T], and mass [M], are used to assist in the result of the reduction rate. The reduction rate is then applied to the model test as the result of a dimensional analysis. The displacement measured in the invert section and plate section is constantly updated and has a variable pressure, which is measured in hydrostatic pressure (Ko = 1).

Table 1. Material properties.

Classification	Soil	Weathered rock	Hard rock
rt (tf/m^3)	1.9	2.1	2.7
E (tf/m^2)	8×10^3	9×10^4	4×10^6
υ	0.35	0.31	0.2
Cohesion(tf/m^2)	2	10	1,000
Φ	31	35	48
qa (tf/m^2)	25	180	15,000

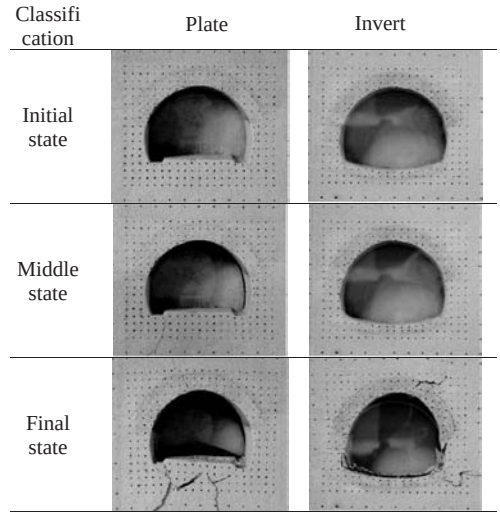

Figure 4. Result of plate & invert section test.

2.3 *The result of down-scaled test*

When 2.2 kgf/cm^2 pressure is applied to the plate section as seen in fig. 4, a crack developed from the left corner of the tunnel and additional failure occurred along the tunnel floor. A big displacement has formed on the tunnel floor and a crack has occurred on the crown of the tunnel in its final stage.

On the other hand, when 2.7 kgf/cm^2 pressure is applied to the invert section in fig. 4, a crack has developed from the upper soil layer and left corner of the tunnel. The right side crown of the tunnel and the bottom side of the tunnel experienced failure in the final stage, but the tunnel has no floor heaving.

2.4 *Numerical analysis – Investigate numerical analysis*

FLAC 2D,2-dimensional finite element Method, is used to analyze more details of the tunnel failure behavior after the model test. The numerical analysis modeling uses the same soil properties and scale as the model test. Load is increased step by step at model boundary.

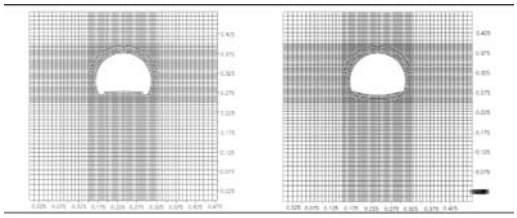

Figure 5. Numerical analysis modeling.

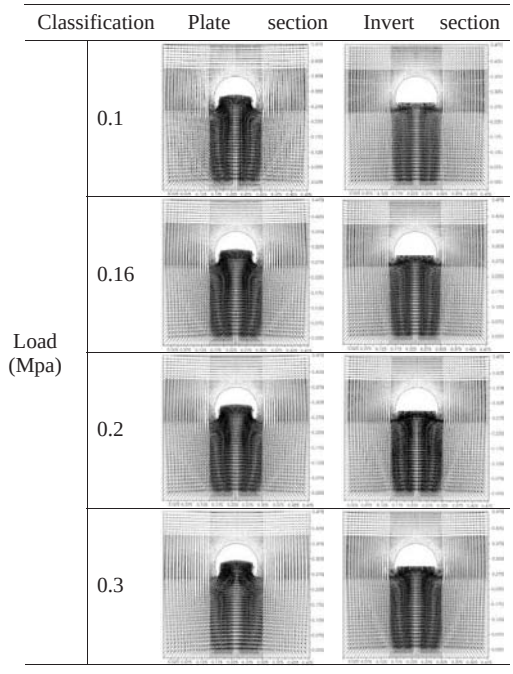

Figure 6. The strain vector depend on load pressure.

In the plate section each analysis section's displacement vector is displayed with fig. 6., the tunnel displacement is increased fundamentally when the load pressure exceeds 1.6 kgf/cm^2 and floor heaving occurs on the tunnel floor when the load pressure exceeds 2.0 kgf/cm^2. But in the invert section, displacement has gradually increased but floor heaving has not occurred when the load pressure is over 3.0 kgf/cm^2. Plasticity area has extended from the bottom edge of the tunnel according to the increase in load pressure, and most of the bottom of the tunnel has failed(fig. 7), this represents for the distribution shape of the plasticity area on loading pressure, but the invert section has smaller plasticity areas compared with the plate section these have no failure on the bottom of the tunnel at 3.0 kgf/cm^2 load pressure. The results are very similar with the model test.

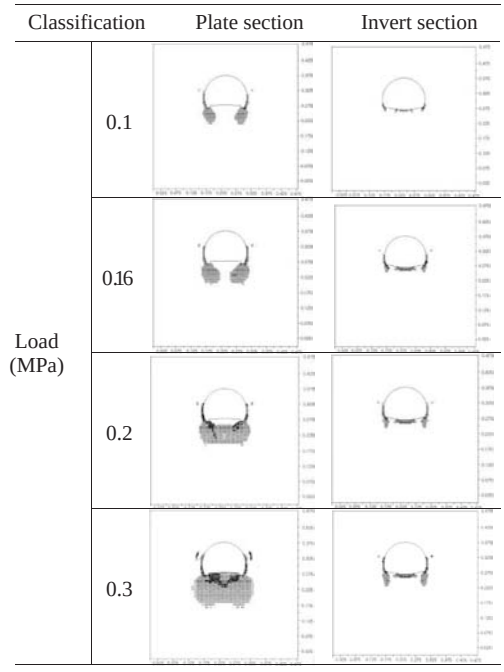

Figure 7. Distribution form of plasticity area depend on loading pressure.

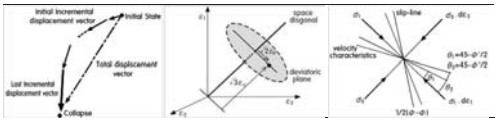

3 ESTIMATES OF EFFECTIVENESS OF INVERT ON ANALYZING OF THE FAILURE MODE

3.1 *Characteristics of failure mechanism around tunnel*

If the plate section permits displacement without support in the weathered rock or bed ground condition, the bottom of the tunnel will have failure by floor heaving. The invert section has fixed condition effect, so that support's stress increase with ground deformation, and support's failure precedes ground failure. To analyze tunnel failure mode by numerical analysis, it is important to consider choice of parameters and how to use these parameters. A pre-estimate of failure mechanism is possible from increment strain vector, shear strain rate, velocity properties but failure mode must be decided by supplemental investigation of new parameters in Shin et al; (2001)

(a) Incremental strain vector
(b) Deviatoric Strain Space
(c) Relation between Velocity Characteristics and Slip Line

Shear deformation, which is one of the indicated parameters, is defined as an exact failure surface when shearing deformation has a narrow and conspicuous direction(Shin et al; 2001). Failure behavior in the

(a) Increment strain vector | (b) Deviatoric Strain Space | (c) Relation Between Velocity Characteristics and Slip Line

Figure 8. A failure mechanism of indicator parameter (Shin et al; 2001).

invert section and plate section is estimated by Mohr-Coulomb, which can be compared to critical shear strain rate. If the area around the tunnel ground adapts a standard failure by Mohr-Coulomb, a formula will be applied to deviator stress.

$$\sigma_1 - \sigma_3 = (\sigma_1 + \sigma_3) \cdot \sin\Phi + 2 \cdot c\cos\Phi \text{ ----------(1)}$$

And deviator strain will be expressed by Hook method as below.

$$\varepsilon_1 - \varepsilon_3 = \frac{1+\upsilon}{E} \cdot (\sigma_1 - \sigma_3) \text{ ---------- (2)}$$

A indicated parameter of the failure ε_1, ε_3 is Max, Min deformation rate, E is elastic modules, and υ is poison rate. The critical shear stress strain will be defined by combination of the two above formulas as below

$$\gamma_c = \varepsilon_1 - \varepsilon_3 = \frac{1+\upsilon}{E} \cdot (\sigma_1 - \sigma_3)\sin\Phi + 2 \cdot \frac{1+\upsilon}{E} c\cos\Phi$$

$$\approx \frac{1+\upsilon}{E} P_o \sin\Phi + \frac{1+\upsilon}{E} c\cos\Phi \text{----------(3)}$$

3.2 *Failure mode analysis of tunnel model test*

Figure 9. shows the tunnel's failure behavior depends on the load condition by shear strain of model tests. In the plate section, ground failure caused the concentration of shear strain rate on both sides of the tunnel bottom when loading pressure exceeded over 1.0 kgf/cm^2, and shearing deformation has extended at the tunnel bottom. But the invert section shows a very stable state compared with the plate section with the same load conditions.

3.3 *The invert section is behavior characteristics in weathered rock*

Maximum Shearing deformation, under weathered rock condition, is about 15,000 kgf/cm^2 based on many test carried out in Korea fig. 10. the purpose of this study is to estimate the invert section's effectiveness and tunnel failure behavior using weathered rock deformation such as 500, 1,000,

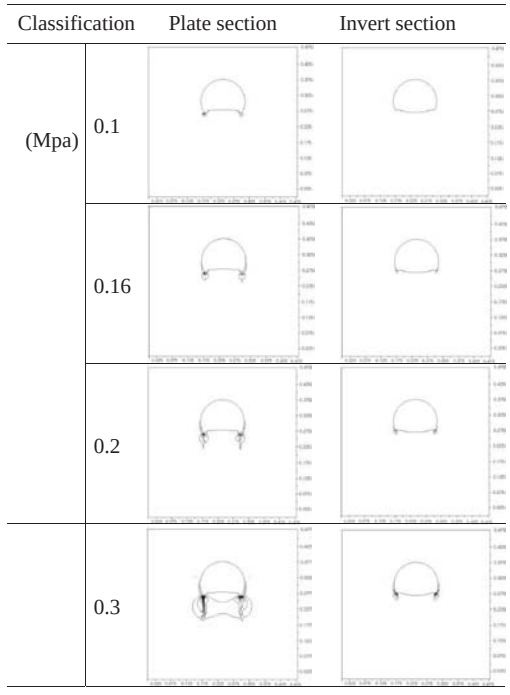

Figure 9. A increasing chart of shearing deformation according to loading pressure.

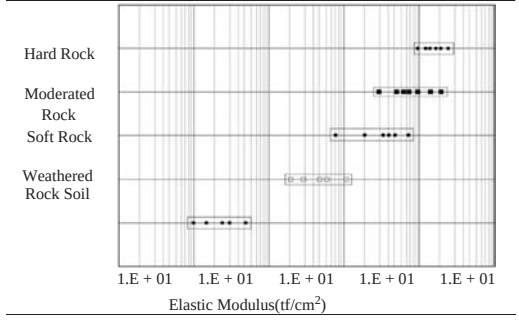

Figure 10. Range of deformation according to ground condition(in Korea).

5,000, 10,000 kgf/cm^2, which correspond with Mohr-Coulomb criteria.

The Korean express train tunnel section is applied to estimate the invert section's effectiveness, in the modeling range was included 1D for depth and over 3D for the left and right side in numerical modeling. A portion of 20% loading was applied before installing supports and 80% after. A result of critical shear strain rate and displacement, is shown in table 2 at formula 3, these are applied to properties in numerical modeling.

Table 2. Critical shear strain (rate) each case.

Classification	Case1	Case2	Case3	Case4
E (tf/m^3)	5,000	10,000	50,000	100,000
C (tf/m^3)	2	4	8	10
Φ ( )	25	28	30	35
Critical shear strain rate	0.0107	0.0061	0.0013	0.0007
Critical shear strain (mm)	161.3	92.7	20.4	11.7

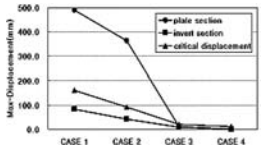

Figure 11. Critical shear strain according to case analysis.

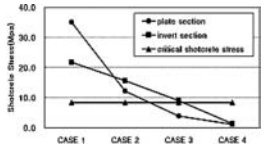

Figure 12. Stress at supporting to case analysis.

In plate section displacement over the critical shear strain in case 1, 2 but in the invert section, a displacement was under a critical shear strain in all cases (fig 11).

In the invert section bending-compressed stress of shotcrete was over the limit bending-compressed stress in case1, 2, 3, but in the plate section bending-compressed stress of shotcrete over the limit bending-compressed stress in case 1, 2 (fig 12).

The plate section is installed under weathered rock condition and soft ground, ground failure started from the bottom of the tunnel when tunnel displacement is in a unconfined condition. But the invert section's support stress is larger than the plate section's support stress, that means invert section's stress is increased because of the fixed condition effectiveness. Therefore, the plate section have more advantages in good ground conditions because displacement of tunnel bottom is smaller than the critical shear strain in good ground conditions. But the invert section have more advantages in bad ground condition because ground will be failed by deformation of tunnel when deformation of tunnel is over the critical stress strain. When the invert section is needed, the invert section should be installed as soon as possible but if it is installed too soon, the inverts supporting stress will be over the allowable stressed. So when the invert section is

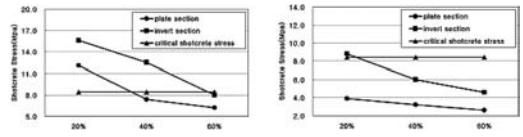

Figure 13. Supporting stress according to allowed displacement.

applied, the invert section should be installed after permitting a maximum of ground deformation within critical shear strain. To verify this, displacement is increased by a portion of load distribution which is applied 20%, 40%, 60% before installing the invert. Figure 13. shows a result of section force in support.

When a distributed loading pressure of 20% is applied, the shotcrete's stress is over the allowable limit as in case 2, 3 but the shotcrete's stress is under the allowable limit when 60% distributed loading pressure as in case 2 and over 40% distributed loading pressure as in case 3, and the support such as shotcrete is installed in inferior ground, it is more effective to install an support after displacement has occurred. That means when the invert section is installed after until the critical shear strain has occurred, it can be prevented from ground failure and an anchor failure.

4 CONCLUSION

The invert section is a very effective structure to control failure influence around the tunnel in a under weathered rock condition. Tunnel down-sized test and numerical analysis is executed for the Korean express tunnel section and the invert section is quantitatively estimated compared with the plate section in a weathered rock condition.

1) These results shows that the invert section is more effective against external pressure compared with the plate section.
   (a) From the result of a laboratory model test, cracks in the plate section started approximately at 20% pressure higher than the plate section.
   (b) Floor heaving and plasticity area is noticeable reduced when the invert section is applied to the tunnel compared with the plate section.
   (c) In the invert section, small floor heaving and plasticity area, which has shown noticeable reduction in the failure area around the tunnel. When the shearing deformation and the critical shear stress strain are used, which is a standard from Mohr-Coulomb.
   (d) Using the indicator parameter of failure mechanism which are incremental strain vector, shear strain rate and velocity property, these are tested individually in the laboratory model test.

2) To analyze the behavior of the invert section in a weathered rock condition, parameter study is carried out to analysis of invert section's behavior properties. Smaller displacement has occurred in the invert section compared with the plate section, but the supporting system showed stress in excess of the allowable stress. That means invert sections of the shotcrete show stress has increased due to ground deformation because of confined conditions. To prevent ground failure and the supporting system concrete failure, the invert section should be installed after ground deformation in the critical shear strain range.

ABSTRACT: The man-made island, created in Dubai, UAE in the shape of a palm tree is known as the 8th Wonder of the World. To the Island it was given a name of Palm Jumeirah Island. The Palm Jumeirah will measure approximately 5 km in length and 5 km in width. The crescent Island surrounding the Palm will measure approximately 11 km in length. Infrastructure construction for this island has comprised amongst others, the construction of several bridges, waste water collection and maintenance systems, storm water drainage system, irrigation and domestic water supply network, pipe-gas system, telecommunications, electrical system, tunnels, marinas facilities and landscaping. Among numerous tasks the service tunnels supplying electricity from the Palm Island to the Crescent is one the most difficult and expensive. This paper describes the design and construction issues for tunnel and shafts sophisticated waterproofing system, which will warranty dry condition during the life time of all underground structures.

1 INTRODUCTION

The man-made island, created in Dubai, UAE in the shape of a palm tree is known as the 8th Wonder of the World.

The complex of the islands that is called "The Palm Jumeirah" was artificially reclaimed of sand in the Arabian Gulf approximately 30 km away from the center of Dubai (Fig. 1).

About 100 million cubic meters of sand have been used to create this island. The height of "The Palm" (i.e. the length of the island) is about 5 km, the distance between the tips of the biggest branches – the Fronds (i.e. the width of the island) is about 5.5 km.

"The Palm" is framed by another man-made island named "The Crescent", which is approximately 1.5 km away from the top branches – the Spine of "The Palm" and was designed in order to protect the coastline from possible storms (like breakwaters).

The project suggests the construction of about 60 high-class fashionable hotels, more than 5000 villas and over 100 residential buildings. Numerous entertaining and cultural leisure centers such as parks, yacht and golf clubs, a delphinarium, restaurants, shopping malls, cinemas and many more will be built.

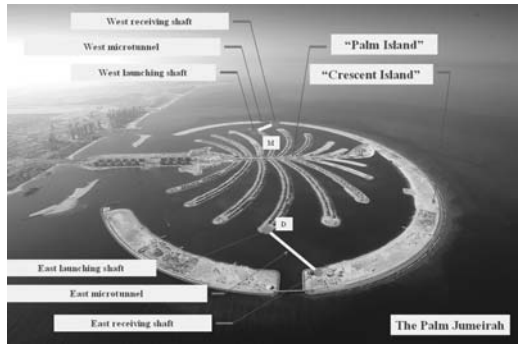

Figure 1. The Palm Jumeirah Island and service shafts location plan view.

"The Crescent" and "The Palm" are linked to each other by a road tunnel and a monorail, the services and communication means will be supplied thanks to 2 microtunnels and 12 Horizontal Directional Drilled (HDD) pipes with the diameter of 0.5 m.

The Eastern and the Western microtunnels are meant to be the energy supply to "The Crescent". Each

of them about 700 m long and has the internal diameter of 2.4 m, they approximately go as deep as to 25 m below the sea level.

One of the largest and well-known Construction Companies of Dubai "Al Naboodah Engineering Services LLC" (ANES) was entitled to an authority to design and construct the service tunnels and HDD on "The Palm".

The construction of the tunnels was carried out thanks to the modern microtunneling method which suggests the usage of the TBM AVN3 manufactured by well-known company "Herrenknecht" and specially designed concrete jacking pipes. The tunnels construction using the afore-named method required the design and the excavation of two launching and two receiving shafts which were supposed to be used afterwards, while functioning, in order to have an access to the tunnel and to accommodate the electric cables and the required electric equipment.

The TBM complex AVN3 was installed one by one on the Fronds "D" and "M" in launching shafts and the feeding of the concrete jacking pipes which were subsequently jacked and served as a tunnel liner. The launching shafts are about 12 m in diameter and with the depth of around 28 m. (Fig. 2).

The receiving shafts located on "The Crescent" are about 9 m in diameter and around 20 m deep.

The main difficulty while designing and constructing all four shafts was the necessity to excavate them in totally unstable and saturated drudged sand, which actually reacted as "quicksand". Only going as deep as to 17 m the reclaimed sand underlined by natural sandstone which was classified as a weak and heavy fractured rock formation.

Existing subsurface geological conditions made it necessary to excavate the shaft using shoring system made of from secant piles.

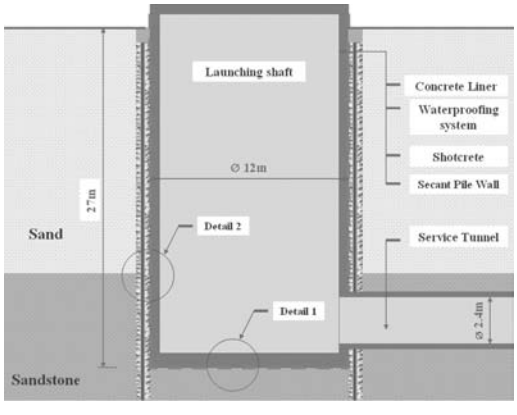

Figure 2. Launching shafts at Frond "M" & "D".

Thus, in general the shafts construction scheme can be described as below:

1) The construction of shafts shoring system made of from secant piles with the diameter of 1.0 m and 30 m deep, the suggested distance between the piles' axes was about 0.85 m;
2) The soil excavation to the project level of approximately −28 m fixing several levels of bracing beams made of pre-cast reinforced concrete;
3) The shafts' walls surface preparation for the installation of a waterproofing system by applying shotcrete around 10 cm thickness;
4) The waterproofing system installation around of 5000 m^2 using PVC membrane;
5) The reinforcement installation at the bottom of the shafts and base slab casting with thickness of 1.0 m;
6) Shafts walls casting with thickness of 0.45 m;
7) The roof pre-cast slabs (the weight of slabs around 90 tons) installation.

Taking into consideration the sever geological conditions, the high level of underground water and the high level of aggression of the seawater towards shafts concrete, the high level demands to the water tightness of the shaft liner while functioning, the major concern was as follows: to develop a waterproofing system that would meet the demands and provide reliability during all shaft operation period as per project specification and international standards has to be not less than 120 years.

2 THE DESIGN SOLUTIONS OF THE SHAFTS WATERPROOFING SYSTEM

The long-term experience in tunneling and in general underground constructions shows that to reach the above-mentioned requirements require quite considerable investments, but make sense from economical point of view as investing once in the future they allow to use the equipment without wasting huge sums to struggle with water-suppression and grand construction overhauls.

To fulfill the mentioned above task considering the accepted construction scheme, the analysis of the building elements' mutual relocations, the climatic conditions, the surrounding environmental factors etc., there has been made a comparative analysis. It analyses the characteristics of various types of membranes which are well known in underground construction, such as highly elastic polyethylene (VFPE), high density pressure polyethylene (HDPE), a polyvinylchloride (PVC) and other alternatives, after which the final decision was made. The PVC membrane has been selected as a basic material of the waterproofing system.

PVC membranes of various manufactured companies, such as "Sika" (Switzerland), "Flag" (Italy), "Alkor Draka Ltd." (UK) and the other companies offering analogous product in the UAE market have been thoroughly and carefully studied paying heed to the comparative characteristics of the materials, suggested technological schemes of the system installation, "the know-how", the technical assistance possibility, the supply terms, the cost and some other factors. Considering all the afore-named factors, the choice has finally been made in favor of the company "Flag-Degussa".

In the process of the collaboration of the experts between the companies "ANES" and "Flag - Degussa" there was developed a basic concept of the shafts waterproofing system installation that is as follows:

The PVC membrane stacking up on a blinding concrete layer of a base slab and a shotcrete layer which evens the secant piles surface. Before fixing the membrane the base surface should be in corresponding conditions: smooth to the utmost extent, with no contain of off and other uneven substances, capable to break the PVC membrane layer subject to the influence of the water's negative effect and reinforced construction weights, the surface. Generally, the admissible radius of unevenness with more than 200 mm or their width relation towards the height more than 5/1 is acceptable. In spite of the fact that the membrane underlying layer course is not directly relevant to the waterproofing system, it importance in terms of it preparation quality shouldn't be neglected.

The layer of Geotextile Drefon S with specific gravity not less than 500 g/m^2 is applied on the prepared base. This layer prevents the PVC-membrane from possible damages under the loading influence from shafts concrete slab and it is a drainage layer as well, in order to direct the water from the walls into the gravel drainage layer installed under the base slab;

The main element of waterproofing system is PVC membrane Flagon BSL (3 mm) for a base slab and Flagon BSL (2 mm) for the walls, which is defined further to the liquid pressure water volume and the conditions of interactivity between the constructions of the base slab and the shoring in the process of functioning;

The additional – Flagon PZ with the thickness of 1.5 mm, which is also used to insure the safety, is fixed onto the main layer of the PVC membrane. Almost all the manufactured companies of PVC and HDPE membranes around the world apply a similar technical solution, which is called Fail-Safe System (the destruction preventing system). This layer does not fulfill the main waterproofing function, but along with the injection tubes it allows the leakage observation and to carry out the repairing structure injection between the two layers of the membranes when needed;

The waterproofing system surface was divided by waterproofing tape Waterstop W4 into compartments not more than 200 m^2, in order to have a precise control over the possible leakage areas, and to save the repairing contents injection as well. The installation site of the waterproofing tape was figured out in a way so that the center of Waterstop would coincide with the center of a concrete construction joint that was also an additional safety element to prevent the shafts from water access.

A protective layer of the Drefon S Geotextile with specific gravity not less than 200 g/m^2 was applied over the PVC membrane in order to protect the main membrane from accidental punctures in the process of the subsequent constructional works including reinforcement installation, the casing and concreting. There was an additional protective layer of a cement screed applied over the Geotextile coating for the base slab.

The design of "shear key" between a base slab and secant piles with expectable water pressure up to 3Bar and the utmost maximum displacement of the structural components was a matter of a major concern. The displacement of the structural elements had a potential danger in terms of the membrane's possible destruction; the concrete finishing construction joints have been paid a certain attention too, as they were critical for the water filtration into the structure. The shear key Waterstop W4 along with the multiple use injection system Masterflex 900 has also been fixed in all similar construction joints, allowing to prevent leaking applying the repairing structure.

Summarizing the aforesaid, there has been developed and later on used a waterproofing system unique for this project. A system, which not only prevents the shafts from water infiltration (PVC membrane) but also repeatedly protects the construction from interior water filtration which may occur due to poor quality welding of a membrane, its unforeseen infringements in the process of work, etc., and making it possible to have a simple repairing of the membrane across the total construction area having the control and the water display elimination throughout the whole period of its usage.

3 THE WATERPROOFING SYSTEM INSTALLATION PROCEDURE

Due to the construction constrains and not-so-beneficial construction of "working scaffolds" from a base slab (−28,00 m) up to the top point of the shafts (+1,00 m) the project management decided to carry out the work on a step-by-step basis capturing the height from 4.0 m up to 8.0 m in accordance with the height of a concrete area.

It is important to mention that this working scheme can be favorable for the general work organization but not for a waterproofing system, i.e. actually while

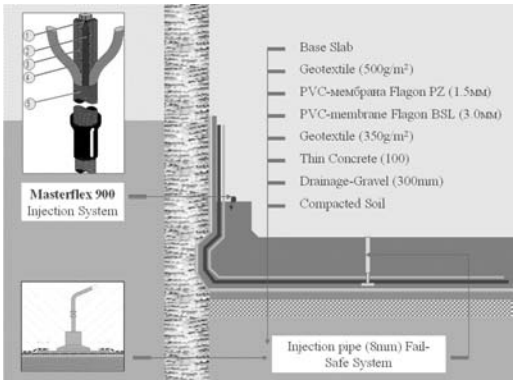

Figure 3. Waterproofing Details at the Base Slab level.

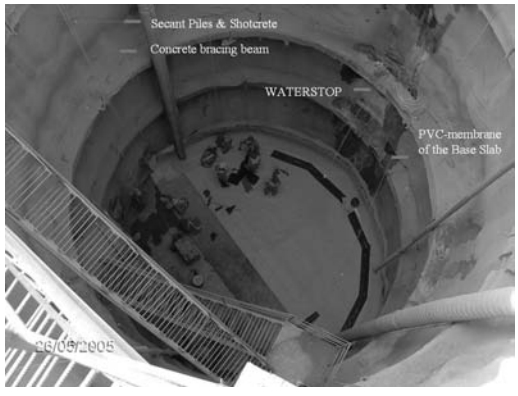

Figure 4. Waterproofing membrane installation.

Figure 5. Waterproofing membrane seam testing.

installing the 20 m high PVC-membrane we are limited to 4 (8) m that has a great impact on membrane installation speed, therefore the cost of the installation works and the most important factor- its quality as there may appear between 3 to 5 additional welded joints overall the shaft perimeter, repeatedly increasing the leakage risk through possible poor quality connections.

Thus the general work scheme can be described as below:

3.1 *Stage 1*

The drainage layer installation and concrete preparation of the shaft base slab with drainage pit for water accumulation and evacuation using the pumps during working time (fig. 3).

3.2 *Stage 2*

The base slab waterproofing system installation stacking the first layer of Drefon Geotextile, the main layer of waterproofing membrane Flagon BSL, fixing the separating element WATERSTOP, a safety layer of Flagon PZ membrane, a protective layer of Drefon S Geotextile (350 g/m^2) and a protective screed of blinding concrete (fig. 4). All the works are listed in a technological order.

A drainage pipe Ø160 mm which had a joint point with a waterproofing membrane due to a special element of waterproofing system Flagon Pipe Collar has been fixed in a pre-cast pit.

The injection tubes Ø18 mm that would allow the application a repairing structure in case of the membrane damage were fixed between the two layers of the PVC membrane Flagon.

Due to the fact that the most critical design loads that effect the PVC membrane thanks to the mutual displacement of the structural components are located in a zone of a base slab joining with the mine non-load-bearing construction the additional injection tubes were installed across the bottom perimeter of a base slab (4 pieces) and in a zone where a base slab is joint with the secant piles (4 pieces).

Works on automatic welding joints of the membrane were implemented using the equipment Leister Twinny S with a nozzle, allowing to carry out the quality test of the membrane welded joint by air pressure through the special test channel with a pressure of 2 Bars. The welded joint is considered to be accepted in case of the pressure drop not more than 20% within 10 minutes (fig. 5).

Manual welding was done applying the equipment Leister Triac S with a 100% quality control by means of a non-destructive method.

During the works on the sites of all the waterproofing system installation works were controlled starting with the quality tests of the supplied materials and their correspondence to the confirmed specification, their storage conditions up to the technological order and quality of the installation works (the membrane welded joints control). All the examination results were daily reported in a special journal that is dedicated to the waterproofing system installation works.

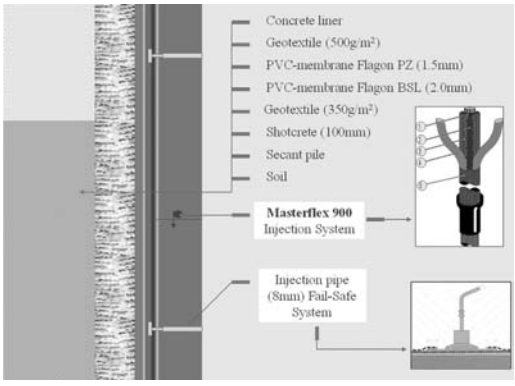

Figure 6. Waterproofing Details on the Walls.

3.3 *Stage 3*

The additional reinforcement and concreting of a base slab.

3.4 *Stage 4*

While installation of the working scaffolds step-by-step, the evening of the secant piles surface by shotcrete, the installation of the two layers of the PVC membrane according to the technology described in a stage 2 and concreting of shafts in-situ concrete liner (fig. 6).

A separating element Waterstop W4 was fixed in each construction joint of the reinforced walls of the shaft and 4 injection tubes were mounted in areas between the construction joints. Every zone of the suggested repairing works did not go beyond 200 m^2.

In addition, each concreting industrial joint was equipped with a multiple use injection system of Masterflex 900 divided along the length into areas 9.0–11.0 meters that became necessary by simplifying of the installation works system and in the future carrying out repair works if required, lessening the injection contents volume.

3.5 *Stage 5*

The separating element Waterstop W4 installation into the reinforced wall of the mine while carrying out the reinforcement works at the level of a return soil coating and the subsequent concreting. The last layer of the waterproofing PVC membrane was welded after dismantling the casing on Waterstop.

3.6 *Stage 6*

The drainage pit elimination, the ability to stop the pumps work and the waterproofing system work reliability control.

There were several local leakage spots defined at this stage both through the injection tubes and in concreting construction joints, that became possible either as a result of the poor-quality welding of a joint or by a membrane puncture during reinforcement installation. However the presence of the two additional protective systems against the leakages allowed their elimination within a short period achieving a 100% result.

4 THE PROSPECTS

Along with the waterproofing system installation for the project “Service Tunnels” the company ANES got orders and has started the works on designing and installation of the analogous systems for the other underground project on the palm islands. In total the capacity of the prospective installation works for the year 2006 has increased from 5000 m^2 in 2005 up to 60,000 m^2 in 2006.

Each new project has its specific features, both in technological solutions and in the companies – the manufacturers of waterproofing membranes, but what they have in common is their unique tendency to switch of from the second safety layer of the membrane as the experience in the construction of this project shows:

1) The cost of the required materials increases 1.5 times;
2) The industrial input therefore the cost of the installation works increases more than twice;
3) The time required for the waterproofing membrane installation almost doubles and this has a negative effect on the object’s work conditions in general;

Considering that the concrete quality and all the works relevant to concrete respond the high standards in the UAE, and selecting the concrete of the right grade in terms of its water tightness and competent calculation of the reinforced concrete structure, we can be confident declaring that one layer of a waterproofing membrane is sufficient making it necessary to use the additional elements related only to the touching areas, joints and similar constructive units.

To make the final decision on this matter it is necessary to have the additional observations over the completed construction done, to analyze all the results as aspiring to create and put into practice the effective waterproofing system that would satisfy the Customer in all respects, it is important to keep in mind the profitability and the terms of construction and all the other way around.

5 CONCLUSION

Despite the fact that the waterproofing of the underground constructions on “The Palm, Jumeirah” using

the PVC materials was the first experience both for the whole island and the company "Al Naboodah Engineering Services LLC" in particular, we can confirm it is a success.

Upon the results of the carried out works the Client received the structure which was completely free from leakages and the possibility of their total control in the future while it's functioning. The repairing works of the PVC membrane can be done at any times if required, without significant labour and material expenses, without creating an obstacle to the operation of the structure.

The correct technical solutions, well trained personnel, a strict fulfillment of all technological processes and the continuous control both internal and from the Client's side made it possible to perform to the utmost extent, the least expenses and within the demanded period.

While designing the shafts not many people were assured in the effectiveness and expediency of waterproofing membranes of this kind, but the successfully gained experience was a proof to all that despite the relatively higher cost of the materials compared to the traditional methods, this direction of underground construction waterproofing is one of the most effective and should be given a priority.

ABSTRACT: T.R.&T (Tubular Roof & Trench) method has been invented for safety and effectiveness on underground construction, then, applied to some projects recently. In this research, the practical site where T.R.&T method was applied is selected and dynamic response was analyzed by 2-dimensional numerical analyses. The behavior of T.R.&T under seismic excitement is important because it is constructed near ground surface normally and composed of various sizes of steel pipes which means enormous differences of stiffness. It may cause tremendous ground amplification and stress concentration at the connection part of steel pipes. Therefore, it is necessary to examine the general behavior and seismic performance of T.R.&T structure under troublesome ground conditions such as fault zone and highway underpass. Stress concentration and displacement occurrence trends are investigated thoroughly in those two cases Consequently, case study on practical sites showed the weak part of T.R.&T structure under dynamic loading and characteristics of seismic behaviors.

1 INSTRUCTIONS

1.1 *T.R.&T (Tubular Roof & Trench) method*

A new excavation method, T.R.&T, has been invented for safety and effectiveness on underground construction, especially for the excavation under the existing road or railway with shallow cover. Several steel pipes have large section($D = 2{,}000$ mm) are injected to the ground for restraining surface settlement and excavated inside the pipes. Smaller pipes connect main pipes transversely to build up stable steel structure. The area between pipes is grouted to prevent water leakage. Concrete slabs and walls are placed after cutting the inner section of whole structure. These procedures offer stability of ground during excavation. That is why this method is broadly applied to the excavation under existing roads, railways, boxes, etc. Figure 1 shows the typical T.R.&T section.

T.R.&T method has advantage on water leakage, erosion and stability during construction. In addition, it is tremendously economical because construction period reduction under the difficult conditions (for example, adjacent excavation or urban tunneling with shallow depth, large sectional tunneling, etc.).

Otherwise, T.R.&T tunnel is normally constructed near the ground surface, earthquake load may cause stability problem. Connecting pipes can be the weak part of the structure, therefore, seismic behavior of T.R.&T structure should be examined.

In this study, 2-dimensional dynamic numerical analysis has been performed in two practical sections, respectively. Stresses and displacement occurrence trends are investigated thoroughly to investigate the behavior of T.R.&T structure.

1.2 *Analysis procedures and conditions*

First of all, static analysis has been performed to simulate in-situ condition of the structure and ground. The input load is applied as artificially composed acceleration time history which has 10 second of duration and 0.154 g of peak acceleration. Peak acceleration and other guidelines for dynamic analysis are determined by the seismic design code of civil structure in S. Korea.

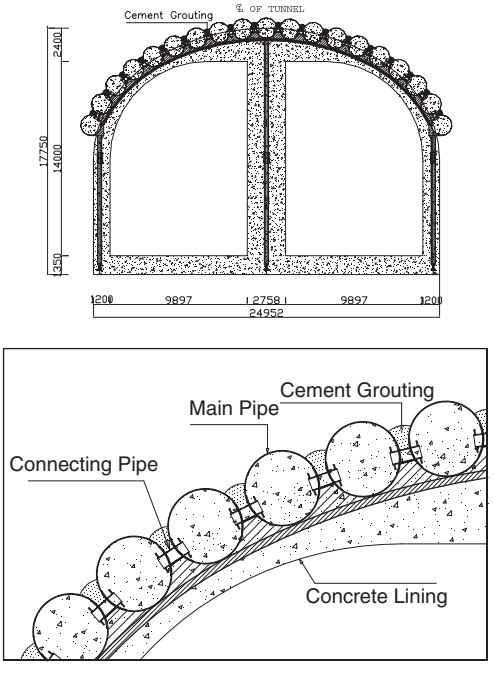

Figure 1. Typical T.R.&T section (arch type).

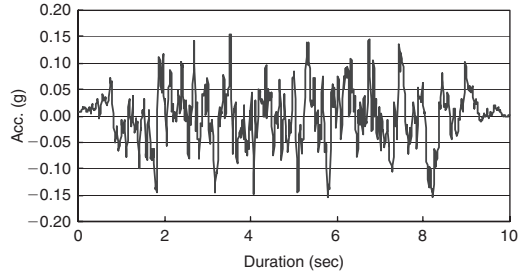

Figure 2. Artificial wave time history.

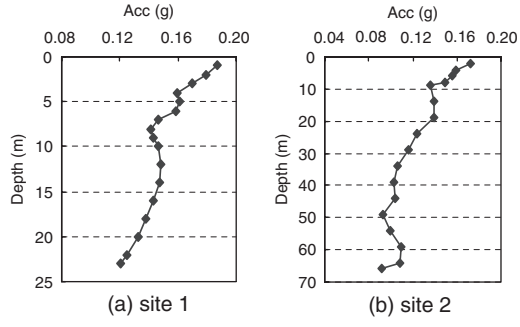

Figure 3. Ground response analysis results.

To find the input motion of wave, one dimensional linear ground response analysis has been performed. As the result of ground response analysis, raw values of artificial acceleration are changed into the base rock motion by deconvolution, then, applied to the base rock. 2-dimensional finite difference method is used to calculated dynamic response of the model.

2 GROUND RESPONSE ANALYSIS

2.1 *Overview*

The mechanism of epicenter, wave propagation through multi-layered soils and other intricate parameters are required to perform ideal ground response analysis. Practically the fracture mechanism of faults and energy propagation are too difficult to obtain precise solution. Therefore, ground response analysis has been performed based on empirical and simplified theory such as 1-dimensional equivalent linear method. SHAKE91, 1-D equivalent linear analysis program has been employed, hereafter.

In the first section, soil layers are composed of weathered soil (thickness = 8 m) and weathered rock from the surface. SPT-N value varies from 6 to 28 in weathered soil. Load of road on the surface are applied on the surface, which may cause the large displacement of surface and large sectional excavation may trigger settlement of the slab and wall.

In the second section, soil layers are composed of weathered soil (thickness = 9 m), weathered rock and soft rock from the surface. SPT-N value varies from 13 to 50 in weathered soil. Large sectional arched tunneling (width = 25 m, height = 18 m) may trigger settlement of the crown and surface ground. Figure 2 shows artificial wave history and Figure 3 shows the results of ground response analysis.

Based on the results, base rock motions have been acquired and displayed in Figure 4.

As the result of ground response analysis, accelerations have been amplified about 55 and 87 per cent in each site. Peak accelerations in the base rock motion are estimated as 0.113 g and 0.092 g at the site 1 and 2, respectively. In both cases, the amplification near the ground surface shows rapid increase, which means the typical tendency of ground excitement.

Time history above will be applied at the lower boundary of FDM mesh as the input loading of dynamic numerical analysis.

3 DYNAMIC ANALYSIS

3.1 *General*

Several methods to estimate the behaviour of civil structures under the dynamic loads have been invented and developed. In order to arrive at rational and correct result, geological investigation of the site and

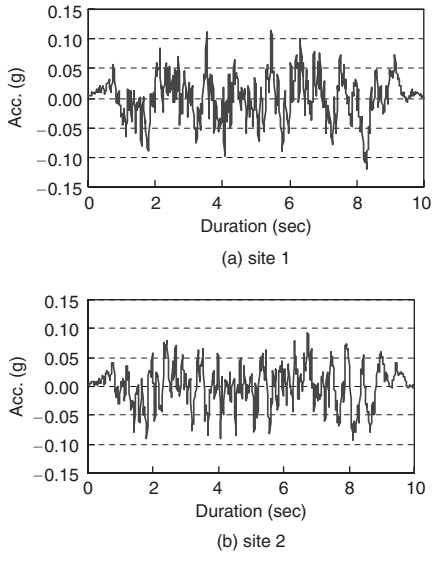

Figure 4. Base rock motion.

appropriate analysis procedures are inevitable. Additionally, elaborate insight into the dynamic analysis method and sufficient understanding of computational tools are also required. In this study, dynamic numerical analysis using the finite different method has been performed to minimize the inaccuracy of other approximate method.

FLAC^{2D}, universal code of numerical analysis using FDM, has been chosen to estimate dynamic response of the structures. It has been utilized in many practical projects in Korea and also verified in previous study. Finite difference method (Explicit method) has several advantages, then, most importantly, no iteration process is necessary when computing stresses from strains in an element. In an implicit method which is normally used in FEM program, several cycles of iteration are necessary before compatibility and equilibrium are obtained.

3.2 *Case-1: Dynamic analysis on the box type*

T.R.&T method is applied to the large sectional underground box structure which has 17 m of width and 7 m of height. Road is passing on the surface. Site section is demonstrated in Figure 5.

Based on the practical site profile, 2-dimensional FDM mesh is built. Static analysis is performed first, then free-field boundary condition and base rock motion are applied to the model. Steel pipes are modeled as consecutive beam element in elastic model and ground as Mohr-Coulomb model. Mesh and vertical stress distribution results are shown in Figures 6 and 7, respectively.

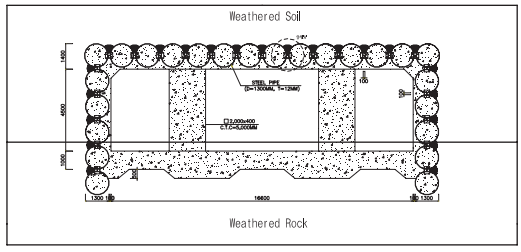

Figure 5. Section (Case-1).

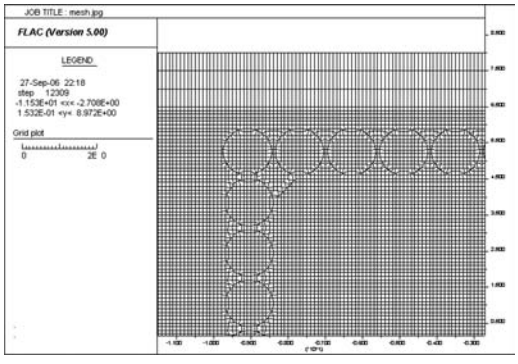

Figure 6. Mesh for 2D analysis (left edge).

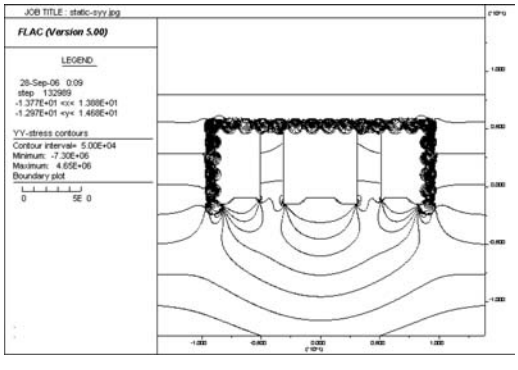

Figure 7. Vertical stress distribution (static analysis).

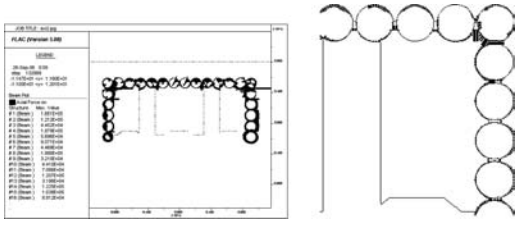

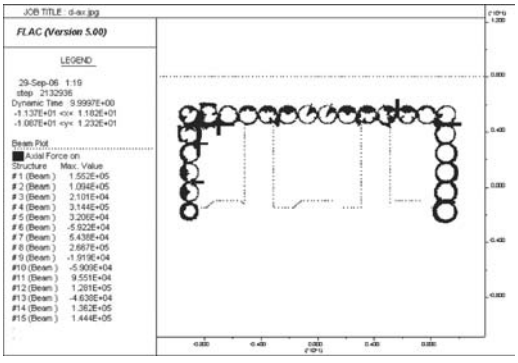

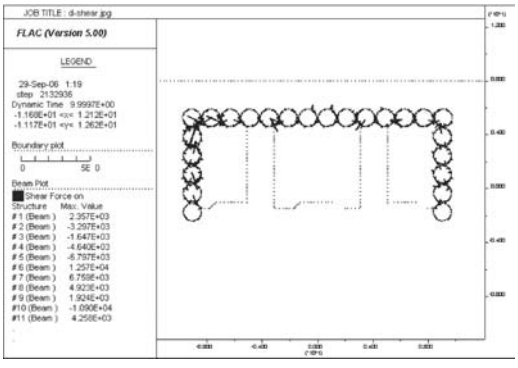

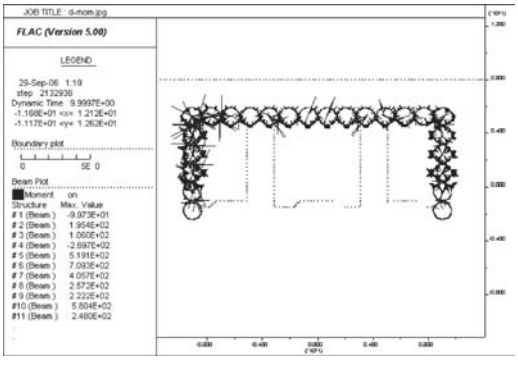

Figure 8. Axial forces of steel pipe elements.

(a) axial forces

(b) shear forces

(c) bending moments

Figure 9. Structural forces (Case-1).

Target values are axial stress, velocity and displacement of steel pipes and displacement, velocity and acceleration of the upper slab.

Maximum axial stress in all steel pipes are estimated 93.17 MPa and presented 45.3% of yield stress in static analysis.

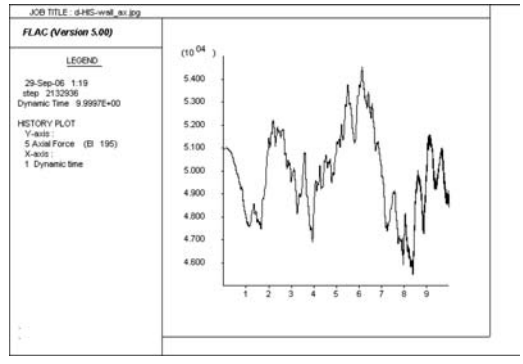

Figure 10. Axial force history at side wall.

Dynamic analysis is performed in addition to the result of static analysis. Free-field boundary condition is applied to side edge and base rock motion history is loaded at the base of mesh. Acceleration in y-direction is set to 0 to preventing rocking along base. Target positions are upper slab between columns and side wall. Maximum axial stress of pipes is 123.44 MPa which occurred at the upper slab edge. Displacement shows quite small value, 8.85 mm at the Figure 9 displayed structural forces and moment.

Figure 9 designates the critical position of T.R.&T box structure can be the edges between wall and upper slab, especially connecting points under the dynamic loading. Force and moment are concentrates at that position of structure, however, shows quite small values. Moment and shear forces display relatively large values at the side walls due to lateral seismic load.

Figure 10 shows axial force history at the side wall on the inner position. Axial forces are tensional and vary from 54.54 kN (t = 6.14 s) to 46.50 kN (t = 8.39 s).

3.3 *Case-2: Dynamic analysis on the arch type*

T.R.&T method is applied to the large sectional tunnel which has 25 m of width and 18 m of height. Site section is demonstrated in Figure 11.

Procedures are same as Case-1. Mesh and vertical stress distribution results are shown in Figures 12 and 13, respectively.

The smallest length of mesh is only 0.12 m to avoid being distorted. Mesh and vertical stress of the model are demonstrated in Figure 13.

Maximum axial stress in all steel pipes are estimated 133.84 MPa and presented 65% of yield stress. Figure 14 shows axial forces of steel pipe elements.

Dynamic analysis is performed in addition to the result of static analysis. Target positions are crown and shoulders of the tunnel. Results are

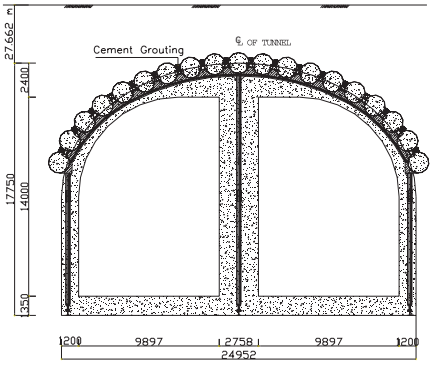

Figure 11. Section (Case-2).

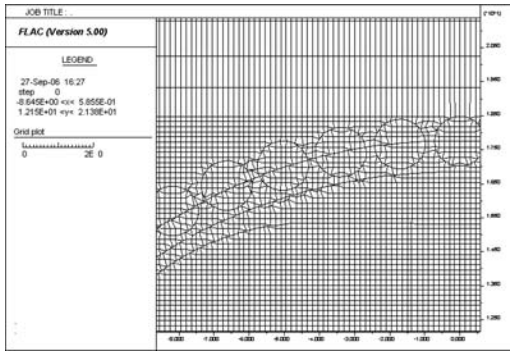

Figure 12. Mesh for 2D analysis.

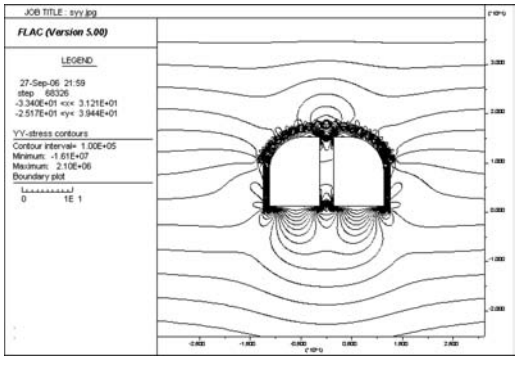

Figure 13. Vertical stress distribution (static analysis).

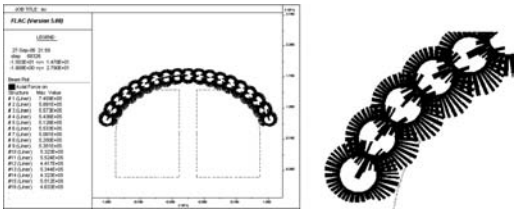
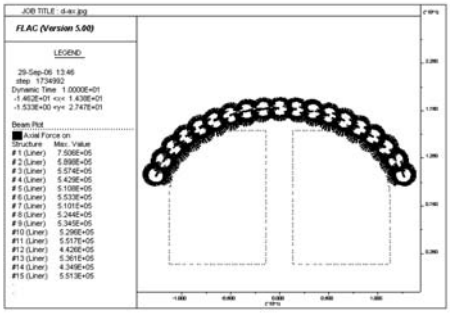
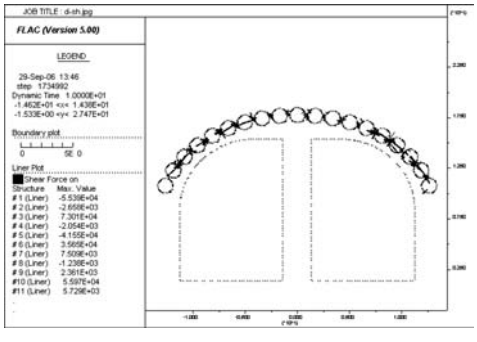
also obtained in time history. Maximum axial stress of pipes is 134.12 MPa which occurred in the shoulders. Figure 15 displayed structural forces and moment.

Figure 15 designates the critical position of T.R.&T tunnel (arch type) which penetrates in weathered rock can be shoulder, especially connecting points under the dynamic loading.







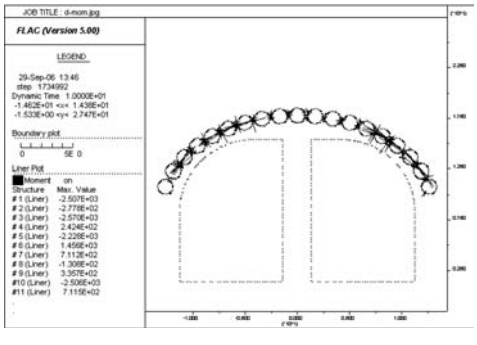


Figure 14. Axial forces of steel pipe elements.

(a) axial forces

(b) shear forces

(c) bending moments

Figure 15. Structural forces (Case-2).

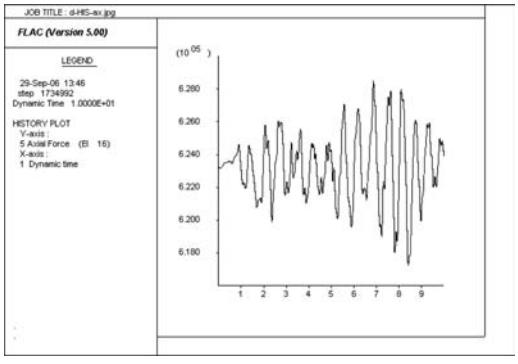

Figure 16. Axial force history at shoulder.

Figure 16 shows axial force history at the side wall on the inner position. Axial forces are compressions and vary from 628 kN (t = 6.86 s) to 617 kN (t = 8.43 s). The range of fluctuation shows large extent comparing to Case-1 due to the depth of structure, however, difference of peak values between static an dynamic is quite small which means the effect of seismic load is not so significant to tunnel.

4 CONCLUSIONS

2-dimensional dynamic numerical analysis has been performed in this study. Some reviews are as follow according to the analysis results.

1. The maximum axial stresses of pipes are increased to 32.5% (93.17 to 123.44 MPa) in Case-1 (box type) and only 0.2% (133.84 to 134.12 MPa) in Case-2 (arch type). Enormous difference is shown between two cases due to the depth from the surface. Ground amplification in deep position is relatively small, therefore, the depth of T.R.&T structure has the key role under dynamic load.
2. The stability of T.R.&T structure is governed by joining position of transversely connecting pipe and main pipes. The stress of structural elements at wall or shoulder displayed larger value than at upper slab or crown. In box type(Case-1), stresses are concentrated to the edge between wall and upper slab. In arch type(Case-2), stresses are concentrated to the shoulders, normally.
3. Axial force history fluctuates according to time. In box type (Case-1), the difference between initial value, i.e the result of static analysis and peak value of axial force is 5.35 kN (11.75%). In arch type (Case-2), the difference between initial value and peak value is 6.00 kN (1%). This result also prove that seismic load amplification is more severe near the ground surface than near the base rock.

A laboratory test for determination of the optimum installation number of face bolts

K.W. Seo & S.W. Lee
Korea Institute of Construction Technology, Republic of Korea

T.Domon & K. Nishimura
Tokyo Metropolitan University, Japan

ABSTRACT: This study dealt with the analysis of behavior of ground and face bolts in a tunnel supported by face bolts by means of laboratory experiments and it mainly focused on the installation number. The followings are conclusions of this study. The support effect increases up to 8 bolts in one section ($N_p = 8$) and the effect of the more face bolts does not increase. Also, the axial force decreases more with the more installation number. The axial force on a face bolt decreases with more installation number and therefore, the number should be determined for 1 face bolt to display maximal axial force.

1 INTRODUCTION

Among various supplementary support methods, the face bolt installation is one of the frequently used methods due to simplicity of work, economical reason and effective control of axial displacement. Its use increases dramatically by introduction of new materials and development of the method in Japan. In more than 70 working site per year, face bolt method is employed in Japan. Active researches are being conducted for investigating the support effect of face bolts and site investigation.

As the study of installation number of face bolts, D.Pelia et al (1996) studied the relationship between the number of face bolts and axial displacement of the face. They reported that more than about 100 bolts in numerical analysis and more than 80 bolts in the site measurement do not have any effect against the face displacement. Yoo (2003) found that support effect by face bolts in his numerical analysis would not increase any more if the installation density is more than 1.1 bolts/m^2. According to the investigation of 33 tunnels in Japan by Ohtsuka (2006), the numbers of bolts have been predominantly determined by experience and the calculation method which uses the axial force of the face, proposed by Murayama (1966).

However, the effect of face bolts depend chiefly on the axial force and, therefore, its support effect is very dependant on the specification of the bolt. Also, every working site has different ground conditions and then it is fairly hard to determine the installation number.

Fig. 1 shows the elastic modulus, one of ground properties, based on the real data from 11 tunnel sites measured by the writers. There seems to have no relationship between the elastic modulus and the installation number of face bolts as shown in the figure. Because most of tunnels where the face bolt method is employed require strong control for the surface subsidence, more than two support methods are used together. Therefore, unless the support effect of the other method or methods employed is determined, the exclusively direct relationship between the modulus and the number cannot be found easily.

The relationship between tunnel depth and installation number of face bolts and Reinforced Protective Umbrella (RPUM) steel pipes is represented in Fig. 2. Both methods are applied in the ground deeper than 40 m often. Despite this, their relation with tunnel depth is vague.

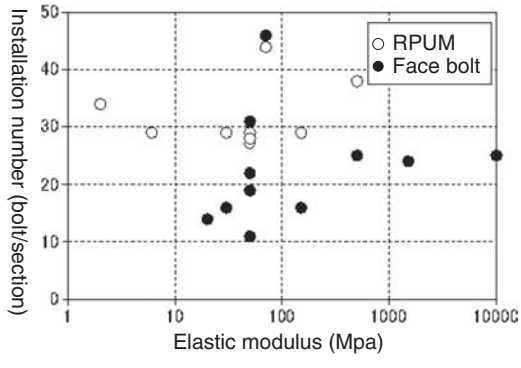

Figure 1. Elastic modulus of ground and the installation number of face bolts and steel pipe.

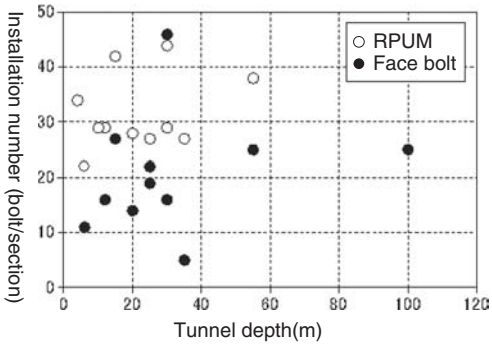

Figure 2. Tunnel depth and the installation number of face bolts and steel pipes.

This is, as mentioned, because the other support methods are employed in many cases and hence the installation number does not increase even under very bad ground condition. Also, the number of RPUM steel pipes is almost fixed but that of face bolts is rather dependent on the working site. RPUM has abundant cumulated data due to frequent use and, in many cases, is designed systematically with installing it in 120° or 180° on the basis of the tunnel axis. Contrarily, face bolt is employed together with the other support method and consequently there is no established design scheme. Thus, the installation number of face bolts has no verified interrelationship with ground properties.

The installation number of face bolts depends on the sites there is no design pattern for it.

In this study, a laboratory test will be conducted to obtain the relationship between the installation number of face bolts and their displacement prevention, and a method to determine the installation number will be introduced.

2 LABORATORY TEST

2.1 *Test procedure*

Ground behavior around and behind the face due to the alternatively repetition of face bolt installation and excavation (cutting) are examined, which is similar as the real installation and excavation process. To model this working process, the laboratory test is planned.

2.1.1 *Material of the ground*

The artificial soil used here is the mixture of copper bead, Vaseline and zincous oxide in the weight ratio of 200:1:0.3 respectively. Although copper bead is not light enough to handle easily and required to be kept in the stable temperature, it could provide some adhesive power, and could be preserved for a long time. The soil is filled 6 times up to totally 30 cm of its thickness and

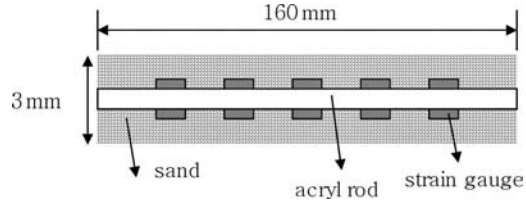

Figure 3. Diagram of a face bolt.

the compaction with 23 gf/cm^2 is done at every time the soil is filled.

The density of copper bead, main material, is 5.4 g/cm^3, and the effective size (D_{10}), uniformity coefficient (U_c) and coefficient of curvature (D_{60}) for the ground are 0.88 mm, 2.18 and 1.92 mm, respectively.

2.1.2 *Test box*

The test box used in this study is an aluminum box of which the width is 0.88 m, the length is 1.08 m and the height is 0.6 m. A removable plate is located on the lower side for the entrance of the model tunnel (see Fig. 5).

2.1.3 *Face bolt*

The face bolt used in this test, of which the section is a 2 mm wide square, is a 1D (160 mm) long acryl rod. On its surface, sand is attached with epoxy and it is 8 pairs of strain gauges are placed on a pipe. And this is installed in the center of the face to measure the axial force (Fig. 3). The bolts are installed by pushing into the face during excavation with hand, and every 20 mm of each pipe is cut at the each step of excavation.

2.1.4 *Excavation method*

The model tunnel is advanced 2 cm(1step) sequentially to 2.8D (44 cm) by hand. This excavation method was successfully carried out by Ishimura (1998).

Fig. 4 shows the complete setup of test box with artificial soil and gauges, and Fig. 6 represents the surface settlement after completion of excavation to 2.8D (44 cm) with $N_p = 3$.

2.2 *Test case*

Test cases are represented in Table 1. The longitudinal pipes are placed 6 times, until the tunnel reaches 2.8D (44 cm) with 0.5D (8 cm) of the overlap length. Because the tunnel model is excavated sequentially and, therefore, its face displacement cannot be measured. Fig. 7 illustrated the laboratory test's case.

3 TEST RESULT AND DISCUSSION

In this study, the axial displacement of the tunnel face could not be measured directly due to the sequential

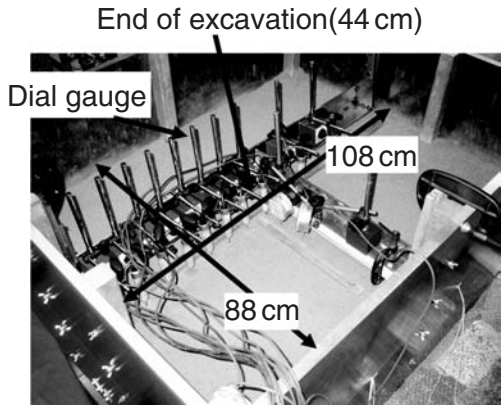

Figure 4. Complete setup of test box.

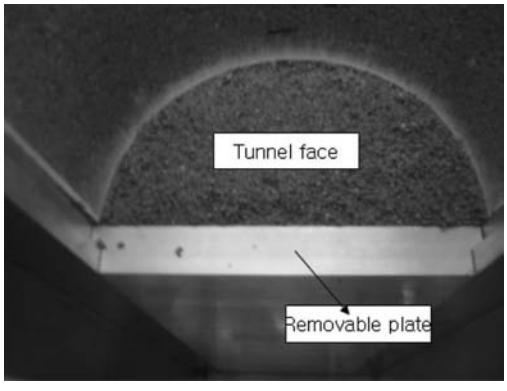

Figure 5. Lower part of the model tunnel (removable plate).

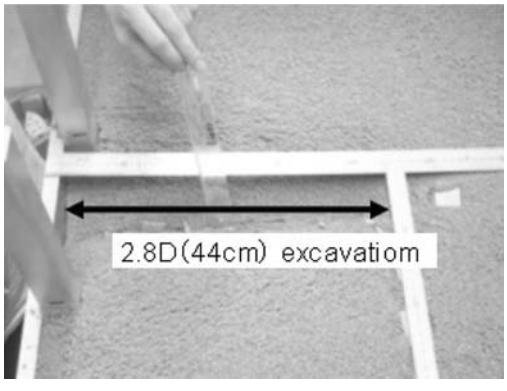

Figure 6. Surface settlement after completion of excavation (2.8D (44 cm) with $N_p = 3$).

excavation. Therefore, only the surface settlement is analyzed.

The surface settlement of axial direction according to the installation number after 2.0D (32 cm) excavation is represented in Fig. 8. It can be found in the figure that the settlement is reduced by the face bolt installation. As the installation number increases up to 8 bolts, the settlement decreases.

The surface settlement at the final excavation position 2.8D (44 cm) is shown in Fig. 9 (see Fig. 4 for the measurement position). The settlement decreases as the installation number increases same as above cases. Comparing $N_p = 6$ and $N_p = 11$, the difference of N_p is almost twice, but the support effect increases only 31% at the face and 32% at 1.9D position. In other words, the growth of the support effect by increasing the installation number has limitation.

Fig. 10 shows the surface settlement in transverse direction of the tunnel after 2.8D (44 cm) excavation

Table 1. Test case.

Test case		Layout of face bolts
	Model	Characteristics of layout
1	$N_p = 0$	No bolt
2	$N_p = 3$	Installed on 1 outer round line
3	$N_p = 6$	Installed on 2 round lines
4	$N_p = 8$	Installed on 2 round lines
5	$N_p = 11$	Installed on 2 round lines

- Tunnel depth (D): 1.4D (22 cm)
- Overlap of bolts: 0.5D (8 cm)
- Total installation shift: 6
- Total excavation length: 2.8D(44 cm)
- Excavation method: hand excavation
- 1 excavation distance: 2 cm (1step)

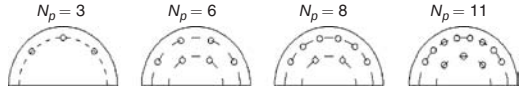

Figure 7. Layout of face bolts.

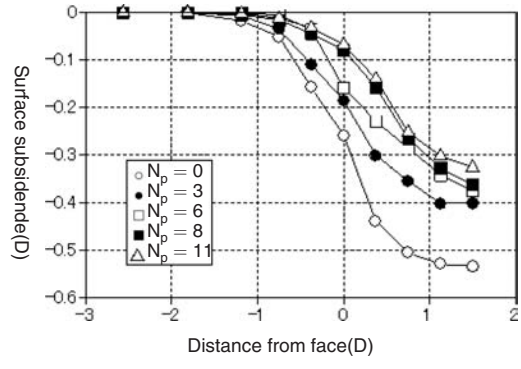

Figure 8. The surface settlement after 2.0D (32 cm) excavation – axial direction.

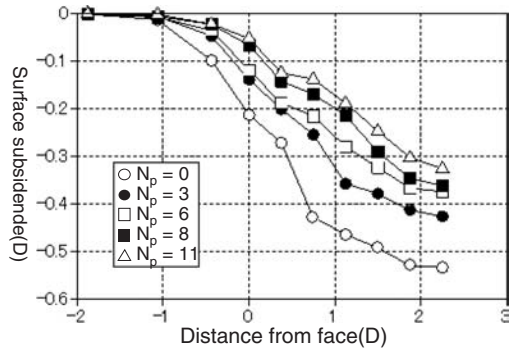

Figure 9. The surface settlement after 2.8D (44 cm) excavation – axial direction.

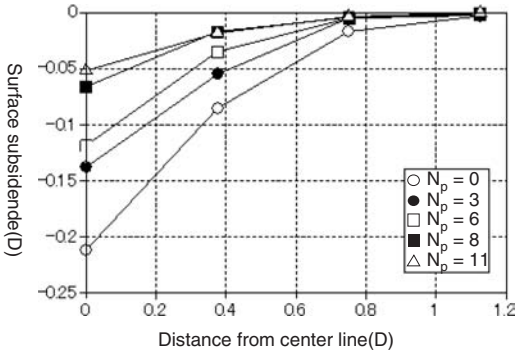

Figure 10. The surface settlement after 2.8D (44 cm) excavation – transverse direction.

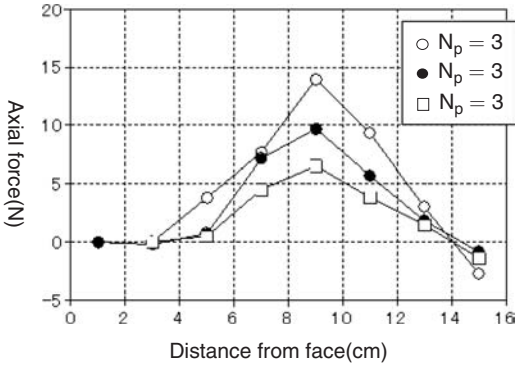

Figure 11. This is a comparison of excavation steps showing the maximal value.

(see Fig. 4 for measuring position). The surface length of settlement part from the tunnel center (x = 0) is about 0.8D without a face bolt ($N_p = 0$). Comparing cases of $N_p = 8$ and $N_p = 11$, the support effect of $N_p = 11$ has only 6% more than that of $N_p = 8$. Therefore, it is thought that $N_p = 8$ is the maximal installation number of face bolts under the conditions of this paper.

The axial force according to the installation number is shown in Fig. 11. The bolt used for measurement is the one in the face center in Fig. 7. Strictly, the actual positions of the bolts for measurement are somewhat different. The forces when $N_p = 3$, 8 and 11 are 14 N, 10 N and 6 N, respectively. That is, the axial force is smaller with more face bolts. Because the axial force of a bolt is a function of relative displacement of a bolt and ground, the force is smaller with smaller displacement.

4 CONCLUSION

In this paper, a basic laboratory test is carried out to introduce a method for determination of the optimum installation of face bolts. From the test, the following conclusions are obtained.

(1) The maximal optimum installation under the condition in this test is 8 ($N_p = 8$). Increase of support effect by more than 8 bolts is too small.
(2) The axial force on a face bolt decreases with more installation number and therefore, the number should be determined for 1 face bolt to display maximal axial force.

The result of this laboratory test has been reported, and the determination method will be introduced by the study using the real data.

Development of tunnel drainage system using drain board

G.P. Lee, H.S. Shin, G.J. Bae & S.W. Lee
Geotechnical Engineering Research Dept., Korea Institute of Construction Technology, Republic of Korea

ABSTRACT: The objective of this study is development of economical drainage system by omission of construction step such as trench, paving stone in trench and set up of drain pipes etc, at the existing drainage system. Pavement is generally make up with sub base, base and pavement and the drain board is constructed at the top of sub base with concrete. The concrete layer is used base and cavity is formed at the lower part of base act as drain line. For this study, numerical analysis and laboratory tests are performed to investigate fatigue behavior by dynamic load and to make pillar shape of drain board. At the result of hydrological model test, drain capacity of rectangular with half circle at both side pillar shape is more superior than the capacity of rectangular and circle pillar shape and distance of pillars for inflow direction affects the drain capacity. And at the result of numerical analysis and investigation of fatigue behavior, structural safety of the concrete layer which is constructed to make drain line for the dynamic load by vehicle is verified.

1 GENERAL INSTRUCTIONS

A drainage system is required in all tunnels to remove water that could accumulate from rainfall, tunnel washing operations, tunnel seepage, vehicle dripping, fire-fighting operations, or any combination of these sources. Drainage of a tunnel can be accomplished either by a gravity flow system or a pumped system. A gravity flow system will suffice for tunnels with continuous grades, provided that the collected water can be properly disposed of at the lower end of the tunnel. It may be necessary to have a pumped system to dispose of collected water when a low point occurs within the tunnel.

The objective of this study is development of economical drainage system by omission of construction step such as trench, paving stone in trench and set up of drain pipes etc, at the existing drainage system. Pavement is generally make up with sub base, base and pavement and the drain board is constructed at the top of sub base with concrete. The concrete layer is used base and cavity is formed at the lower part of base act as drain line. For this study, laboratory tests are performed to investigate to make pillar shape of drain board.

2 TUNNEL DRAINAGE SYSTEM

2.1 *Existing tunnel drainage system*

Existing tunnel drainage system in South Korea is divided in two types such as partially or fully separation system between ground water and contaminated water. Gravity flow system is generally common used in South Korea, standard drainage system is composed longitudinal perforated drain and gravity drain line such as side drain pipe, transverse drain pipe and spiral seam duct(or T.H.P.) etc,.

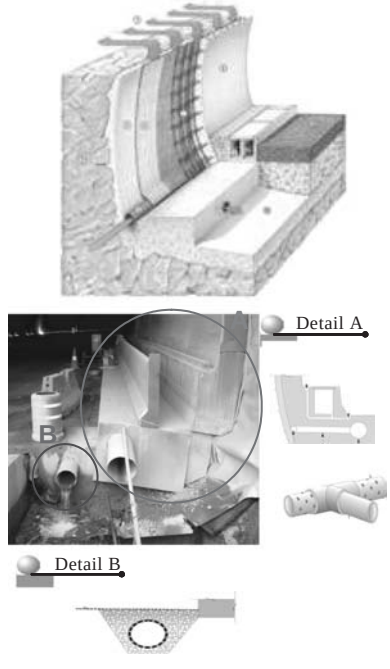

Figure 1. Drainage system using perforated pipe.

(a) upper part

(b) lower part

Figure 2. Drain board sample.

2.2 *Tunnel drainage system using drain board*

As illustrated figure 2∼3, a channel within concrete slab which is constructed by concrete and then aging on drain board installed at invert is formed. Therefore side drain pipe, transverse drain pipe and perforated pipe etc, are omitted in tunnel drainage system using drain board. The slab is used to base in road tunnel and to sub-roadbed in railway tunnel.

3 CORRELATION INVESTIGATION OF DRAIN BOARD PILLAR SHAPE VS. DRAINAGE CAPACITY

Drainage capacity of drain board is affected by pillar shape. But circle or rectangular pillar shape is generally common used without examination of correlation between the shape and drainage capacity to improve the drainage capacity.

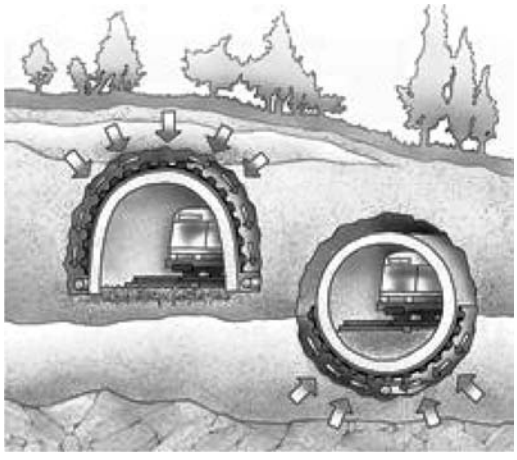

Figure 3. A concept of tunnel drainage system by using drain board.

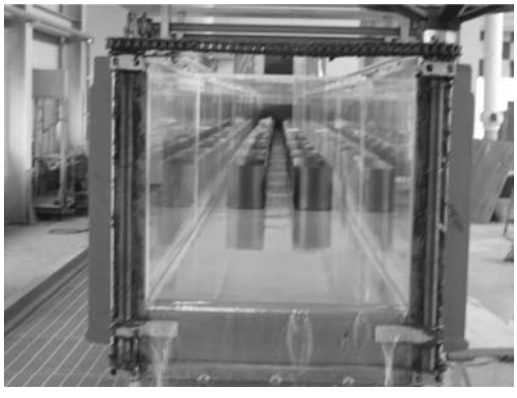
Table 1. Resistance coefficient of flow in river for bridge pillar shape.



Shape	Resistance coefficient
(Rectangular)	0.07
(Circle)	0.04
(Rectangular with half circle at both side)	0.04

As illustrated table 1, resistance coefficient of flow which is determined by pillar shape in case of rectangular pillar shape is 1.75 times higher than circular or rectangular with half-circle at both side pillar shape(standard of bridge design, South Korea, 2003). Therefore, rectangular pillar shape more obstruct water flow than circle or rectangular with half-circle at both side pillar shape. But, different condition between drain board and bridge such as pillars group is not considered in the standard.

To improve the drainage capacity, hydrological model test was performed with conditions of pillar shape(rectangular, circle, rectangular with half-circle at both side) and width for flow direction between pillars.

(a) a general view of channel

(b) cross section of channel

Figure 4. A general view of channel used to hydrological model test.

4 HYDROLOGICAL MODEL TEST

To improve the drainage capacity by determine pillar shape and disposition, analyzed the resistance of flow by water level measurement in hydrological model test for each pillar shape and width for flow direction between pillars.

4.1 *A summary of hydrological model test*

Dimension of the channel used in hydrological model test is 12,000 mm × 400 mm × 400 mm (total length × width × height). To minimize effect of Froude resemblance law, rectangular specimens (width × length = 114 mm × 114 m), circle specimens (ø114 mm) and rectangular with half circle at both side specimens(width × length = 114 mm × 500 mm) which are reproduced from drain board pillar are prepared (figure 4∼5). The channel gradient affecting on flow at open channel is fixed on 0.25%.

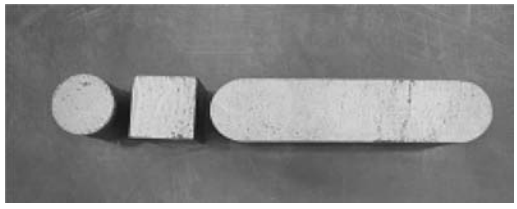


Figure 5. A specimens used to hydrological model test.

Table 2. Amount of flowing water conditions.

	Amount of flowing water
1	0.0045 m^3/sec/m
2	0.0103 m^3/sec/m
3	0.0170 m^3/sec/m

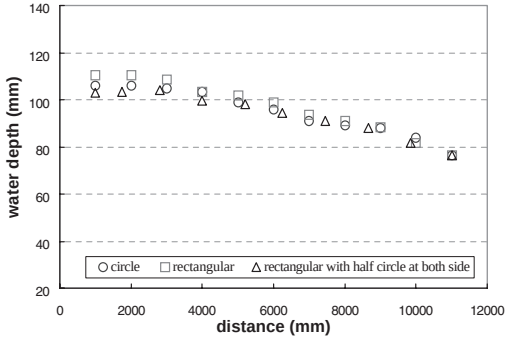

Figure 6. Drainage water level with specimen shape.

The specimens is lined up in a double file, distance between specimens for flow direction is 86 mm to rectangular and circle shape specimens and the distance is 86 mm, 61 mm, 36 mm and 0 mm to rectangular with half circle at both side specimens. The amount of flowing water conditions are follow as table 2.

4.2 *Test results*

The depth of water according to the variation of specimens shape from upper stream to down stream in the channel is plotted at figure 6(at q = 0.0170 m^3/sec/m). The highest water depth is in case of rectangular specimen and water depth is decreased in circle specimen shape, half circle at both side specimen shape sequence.

As a result of measure the depth of water at varied condition of the distance decreased in 86 mm, 61 mm, 36 mm and 0 mm sequence, the highest water depth decreases with decreasing the distance. There is difference of drainage water level between 86 mm, 61 mm and 36 mm, 0 mm(figure 7).

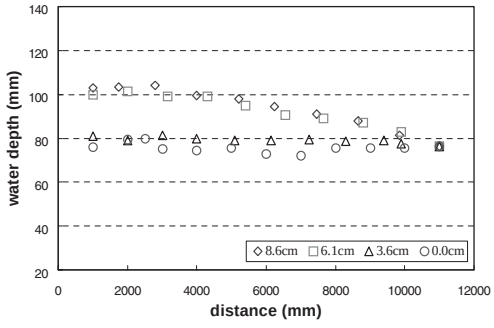

Figure 7. Drainage water level with the distance.

5 CONCLUSIONS

The hydrological model test have been examined, to improve drainage capacity of drain board in tunnel drain system.

From the hydrological model, drainage capacity of rectangular with half circle at both side shape is more effect than the drainage capacity of rectangular or circle shape. And it is of utmost importance to the distance between specimen for flow direction.

There is a correlation between drainage capacity of drain board and the distance, the highest water depth decreases with decreasing the distance. And there is difference of drainage water level between 86 mm, 61 mm and 36 mm, 0 mm according to decrease head loss.

The effects of tunnelling on an adjacent single pile

C.J. Lee, S.H. Jun & N.J. Yoo
Department of Civil Engineering, Kangwon National University, Korea

G.W. Kim
Department of Geology, Kyungpook National University, Korea

ABSTRACT: Three-dimensional numerical analyses have been conducted to study the effects of tunnelling on an adjacent single pile constructed in weathered soil and rock. The study includes ground settlement trough, pile settlement and shear transfer mechanism at the pile-soil interface. In particular, the change of apparent pile capacity associated with the tunnel advancement has been analysed. The computed results show that the ground settlement trough might not be represented by the well-known Gaussian distribution curve. Due to the reductions in vertical soil stress underneath the pile base and settlement of the surrounding ground, pile settlement was induced, thereby changing shear stress distribution along the pile. Some insights into the pile behaviour under the influence of tunnelling obtained from the numerical analyses will be reported and discussed.

1 INTRODUCTION

In recent years, there have been a number of tunnel construction projects in urban areas where the performance of nearby piled foundations might have been affected by the tunnelling activities (Fig. 1, Pang 2006). This might have resulted in increasing pile settlement and changes in the shear stress distribution in the piles. There have recently been several studies on the influence of tunnelling on the behaviour of piles located near a tunnel (Vermeer & Bonnier 1991; Bezuijen & Schrier 1994; Mroueh & Shahrour 2002; Jacobsz 2002; Lee 2005; Selamates et al. 2005; Pang 2006 and others). These were based on field observations, numerical simulations and experimental studies. These studies considered the effects of tunnelling on piles constructed mainly in clayey or sandy ground. Compared to the overseas studies, however, research on this issue is rather limited in Korea (Lee et al. 2006). Moreover, geological condition in Korea is completely different from above-mentioned ground types. Typically the ground in Korea consists mainly of weathered soils, weathered rock and soft rock. These materials might have resulted in different tunnel-pile interaction compared to the overseas studies. Furthermore, the behaviour of piles affected by tunnelling has attracted less attention among engineers.

In this study, three-dimensional (3D) numerical analyses have been performed to study the influence of tunnelling on an adjacent single pile. The analyses have concentrated on the ground settlement trough, pile head settlement, change of apparent pile capacity and shear stress transfer to the pile. It is expected that the current analysis can be used to understand the fundamental mechanism of pile-tunnel interaction caused by tunnelling.

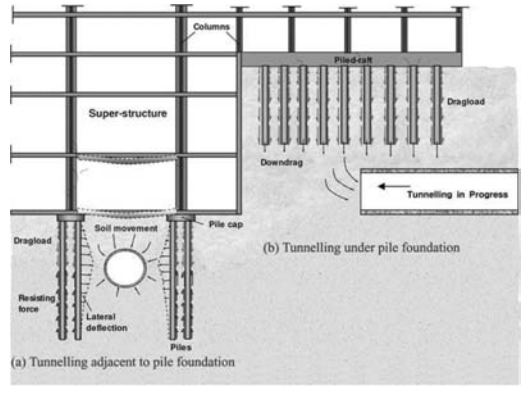

Figure 1. An illustration of pile response caused by tunnelling (Pang 2006).

2 NUMERICAL MODELLING

In the current study, the finite difference analysis package Flac 3D was used in the numerical analyses to study the effects of tunnelling on a single pile located above a tunnel. Totally there numerical analyses have been conducted (i.e., Analysis 1 : pile loading test,

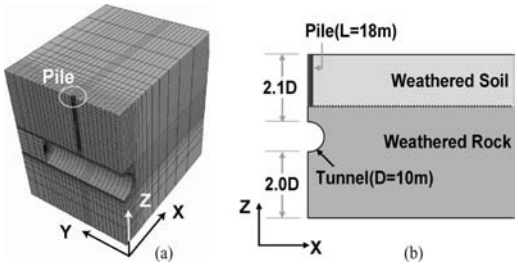

Figure 2. (a) A 3D finite difference grid, (b) Location of pile and tunnel.

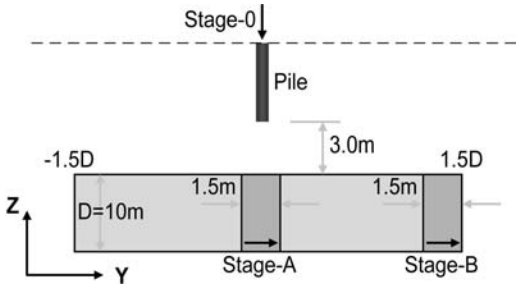

Figure 3. Numerical modelling procedure (not to scale).

Table 1. Material parameters assumed in the numerical analysis.

Analysis	E (MPa)	γ_t (kN/m^3)	ν	c' (kPa)	ϕ' (°)	K_0
Weathered soil	50	20	0.3	20	30	0.5
Weathered rock	100	20	0.3	50	35	0.5
Soft shotcrete	5000	20	0.2	–	–	–
Hard shotcrete	15,000	20	0.2	–	–	–
Pile	20,000	24	0.2	–	–	–

Note: E = Elastic modulus, γ_t = Unit weight, ν = Poisson's ratio, c' = Cohesion, ϕ' = Internal friction angle, K_0 = Earth pressure coefficient.

Analysis 2 : tunnel-pile interaction, Analysis 3 : tunnelling in the green field condition). In analysis 1 pile-soil interaction was studied, while in analyses 2 and 3 tunnelling in the green field condition and pile behaviour under an axial loading excluding tunnelling were simulated respectively. Figs. 2a∼2b show a 3D finite different grid used in the numerical analysis (Analysis 1). A single square concrete pile above the tunnel crown is shown. The pile was 18 m in length L and 0.5 m in size. The pile base was assumed to rest at an elevation of 3 m above the tunnel crown as shown in Fig. 2b. The tunnel diameter is 10 m and the tunnel centreline was located at a depth of 26 m below the surface. Considering the plane of symmetry, only a half of the whole grid was used in Fig. 1a. The ground was divided into two layers, i.e. weathered residual soil above the tunnel and weathered rock below the weathered residual soil. The bottom of the grid was pinned and its lateral boundaries were supported by rollers.

Table 1 summarises the material parameters assumed in the numerical analyses, which are typical design values widely used in Korea. An isotropic elastic model was used for the pile and the shotcrete. A Mohr-Coulomb failure criterion was used for the ground. All the analyses were based on drained analyses, assuming a hydrostatic pore pressure distribution in the ground with the water table located at the surface. In the numerical simulation, interface modelling at the pile-soil interface was not included since the relative displacement between the pile and the soil was expected to be insignificant.

The numerical modelling consisted of three stages, i.e., initial geostatic equilibrium, application of axial pile load under the service condition, followed by tunnel excavation. The analysis stages referred to in the current research are shown in Fig. 3 (Stage 0 : application of axial load, Stage A : tunnel excavation below the pile, Stage B : end of tunnel excavation). Following the initial geostatic stage, an axial load of 1000 kN was applied to the pile head to simulate a service load prior to the tunnel excavation. The axial load was decided based on computed load-settlement relation from analysis 1. The tunnel excavation was then simulated in several stages. In each advancement, the tunnel was excavated in increment of 1.5 m. The simulation of tunnel excavation was performed by using the "Null Element" provided by the Flac 3D programme. At the same time, a shotcrete of 200 mm in thickness was applied on the excavated soil face by specifying material parameters corresponding to soft shotcrete. The elastic modulus of the soft shotcrete was then changed to that of the hard shotcrete (E = 15,000 MPa) during the tunnel excavation in the next excavation stage. The tunnel excavation was simulated from −1.5D to 1.5D in the longitudinal direction (Y direction) as shown in Fig. 3.

Upon completion of the numerical calculation, the axial force on the pile, P_a, was calculated using $[P_a = (\sigma_{zz})_{avg} \times A_p]$, where $(\sigma_{zz})_{avg}$ is the averaged vertical stress component in the pile zones at a certain elevation, A_p is the sectional area of the pile. In addition, the shear stress τ acting on the pile shaft was calculated by using $[\tau = (P_{i+1} - P_i)/A_c \times dz]$, where i and i + 1 are the reference points, A_c is the circumferential area of the pile, dz is the distance between i and i + 1. Finally the volume loss V_l was calculated based on [V_l = amount of ground lost in the region near the tunnel per unit length/sectional area of the tunnel per unit length)].

3 PILE-TUNNEL INTERACTION COMPUTED FROM NUMERICAL ANALYSIS

3.1 *Load-settlement characteristic (Analysis 1)*

Fig. 4 shows load-settlement characteristic of the pile under an axial loading (Analysis 3). It is demonstrated that when the axial loading is more than 2000 kN, a sudden increase in the pile settlement occurred, indicating development of yielding at the pile-soil interface. Similarly when applied the Davisson's method (1972) widely used in Korea to determine pile capacity, the ultimate pile capacity of about 2100 kN can be obtained as shown in the figure. Hence in the current study the pile capacity was assumed to be 2000 kN (Pile head settlement: 7.38 mm) and applying the factor of safety of 2.0 the design pile capacity was 1000 kN. At the design load the pile head settlement was 2.84 mm. The load-settlement curve in Fig. 4 was used to analyse the change of pile behaviour under the influence of adjacent tunnelling. In particular, the change of apparent pile capacity during the tunnelling was studied.

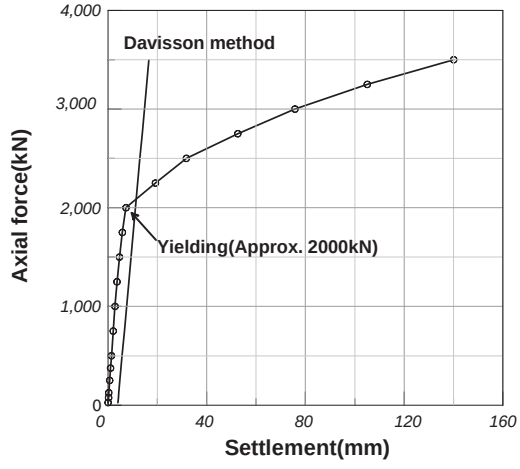

Figure 4. Load-settlement relation (Analysis 1).

3.2 *Pile head settlement (Analyses 1∼2)*

Fig. 5 shows changes in the pile settlement during tunnel excavation. The pile head settlement δ is normalised by the pile head settlement δ_i at analysis stage 0 (prior to the tunnelling). Fig. 5 shows how the pile head settlement increased as the tunnel excavation proceeded. As expected, it is clear that the longer the distance from the tunnel, the smaller the effect of tunnelling on the pile settlement would be. It is noted that the rate of pile settlement increase is at a maximum when the tunnel was excavated underneath the pile (during the analysis stage A). At stages A and B, δ/δ_i of 1.99 and 3.04 was computed, respectively. Upon completion of tunnel excavation, maximum pile settlement of 8.63 mm was computed. This is substantially larger than that computed from analysis 1 (2.84 mm). Hence, when using load-settlement relation in Fig. 4 apparent axial load of about 2100 kN can be deduced. Therefore the apparent pile capacity perhaps reduced substantially with a reduced factor of safety of about 0.95. Similarly, Lee & Ng (2005) reported a reduction in the apparent pile capacity due to tunnelling. This probably affects the serviceability of piled foundation.

The computed results showed that tunnelling might have resulted in a substantial increase in the pile settlement. On the contrary, it was found that pile movements in the lateral and longitudinal direction were insignificant, suggesting that bending moment in the pile might be insignificant. In the current study the majority of deformation developed in the vertical direction. However, when a pile locates near the tunnel horizontally from a tunnel, a significant lateral deflection might be induced in the pile (Lee & Ng 2005).

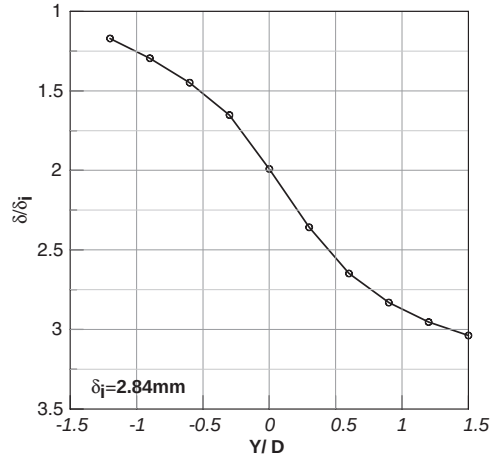

Figure 5. Distribution of pile settlement with tunnel advancement (Analyses 1∼2).

The computed results showed that tunnelling might have resulted in a substantial increase in the pile settlement. On the contrary, it was found that pile movements in the lateral and longitudinal direction were insignificant, suggesting that bending moment in the pile might be insignificant. In the current study the majority of deformation developed in the vertical direction. However, when a pile locates near the tunnel horizontally from a tunnel, a significant lateral deflection might be induced in the pile (Lee & Ng 2005).

3.3 *Distribution of settlement trough (Analyses 2∼3)*

Figs. 6a∼6b show the distribution of the settlement trough in the lateral direction (X direction in Fig. 1)

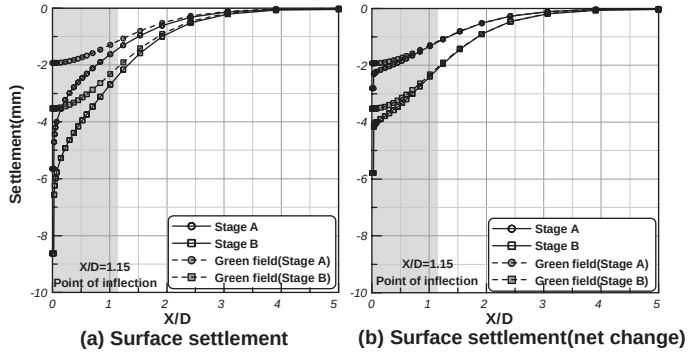

Figure 6. Distribution of surface settlement (Analyses 2∼3).

at the location of the pile for analysis stages A and B. In Fig. 6b, only net changes in the ground settlement purely associated with the tunnel construction are considered. Hence, the ground settlement developed at stage 0 (i.e., axial loading) is not included.

The ground settlement profile for the green field condition in the lateral direction is similar to the well-known Gaussian distribution curve based on $[s_m \times \exp(-0.5(X/i)^2]$, where s_m is the maximum ground settlement at the tunnel centreline, X is the lateral distance from the tunnel centreline, i is the point of deflection in the settlement distribution curve. The computed ground settlement distribution was compared with the Gaussian settlement curve. The point of deflection (i) was about 11.5 (X/D = 1.15) and the trough width parameter, K, was calculated to be about 0.45 ($K = i/Z_C$), where, Z_C, is the vertical distance between the ground surface and the tunnel centre. Mair & Taylor (1997) has reported that K values for clay and sand/gravel ground are 0.5 and 0.25 respectively. The computed K value of about 0.45 was somewhat larger than the typical value for sand/gravel (0.25).

When there is a pile in the ground, settlement trough is not following the Gaussian distribution curve (Analysis 2). In addition, the point of deflection was unable to be decided in the settlement trough. This is perhaps related to the stress concentration of the ground near the pile, thereby leading to large ground settlement near the pile. Hence to express settlement trough other settlement distribution pattern other than the Gaussian curve may probably required. In this case the maximum ground settlement is about 65% larger than that computed in the green field condition [Maximum surface settlement: analysis 2 (5.79 mm), analysis 3 (3.50 mm)]. Hence pile settlement estimation using the green field condition may result in underestimation of pile settlement leading to unsafe design.

Prior to tunnel excavation volume loss of 0.03% was computed at stage 0 due to pile loading. The volume loss deduced from the computed ground settlement trough in the green field condition was 0.07% and 0.13% at stages A and B, respectively. This is substantially smaller than those observed in the tunnelling excavation in London clay (1.0∼2.0%) (Mair & Talyor 1997). This is perhaps related to higher stiffness of weathered soil and rock. When there is a pile in the ground volume loss of 0.08% and 0.14% was calculated at stages A and B (net change only related to tunnelling). This is larger than those in the green field condition perhaps due to an increase in the pile settlement near the tunnel as shown in Fig. 6b.

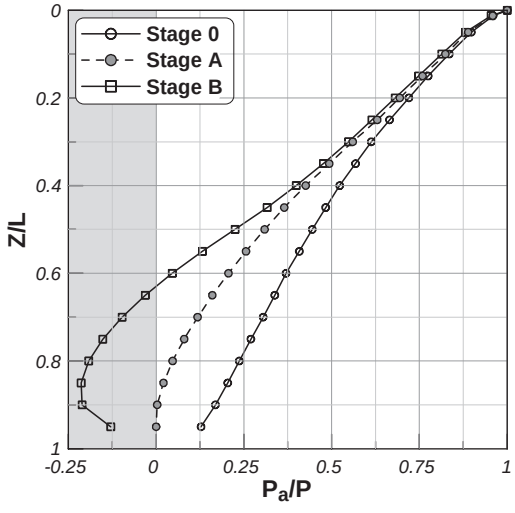

Figure 7. Distribution of axial forces in the pile (Analysis 2).

3.4 *Axial force distribution in the pile (Analysis 2)*

Fig. 7 shows changes of the normalised axial forces on the pile with the normalised pile depth, Z/L. The axial

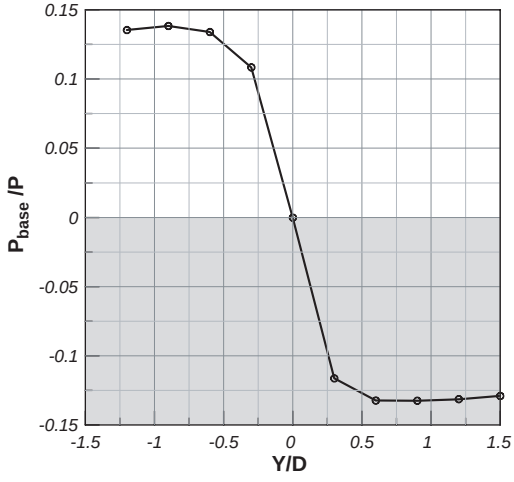

Figure 8. Changes of pile force at the base (Analysis 2).

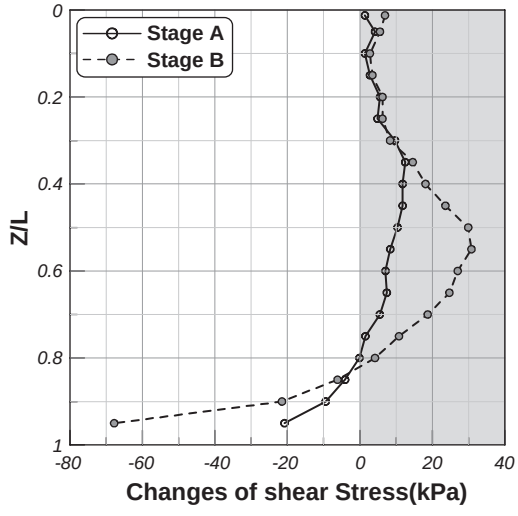

Figure 9. Changes of shear stress along pile (Analysis 2).

force on the pile, P, is normalised by the axial load, P_a, applied on the pile head at stage 0 prior to the tunnel excavation (i.e., Stage 0), most of the axial force is carried by skin friction, implying the pile behaviour is similar to that of a friction pile. Only about 15% of the pile load reached the pile base. This is probably due to insufficient pile head settlement (2.84 mm) to fully mobilise end bearing capacity. It is shown that the axial forces reduced as the tunnel excavation proceeded. Hence, a portion of the axial load carried by the pile base prior to the tunnel excavation was now supported by skin friction as reported by Jacobsz (2002). In particular, the axial force actually reduced to below zero, implying the development of tension near the pile base. A maximum tensile force of 217 kN was calculated, which equals about 11% of the tensile capacity of pile (2000 kN) assuming a tensile concrete strength of 8 MPa. Hence, the probability of a tensile crack developing in the pile therefore appears low.

Fig. 8 shows changes of the tensile forces at the pile base, P_{base}, normalised with the axial force, P, during tunnelling. Prior to the tunnel excavation a compressive force of about 0.135P developed, but as tunnelling proceeded the compressive force decreased gradually. At the end of tunnelling a tensile force of 0.132P developed. It is noted that when tunnelling near or underneath the pile ($Y/D = -0.3 \sim 0.3$) the compressive force reduced rapidly and turned to tensile force indicating the major influence zone maybe about 0.3D (Y direction) measured from the tunnel centre.

3.5 *Shear stress distribution along the pile (Analysis 2)*

Fig. 9 shows distribution of net changes in the shear stress purely due to the tunnel excavation with the normalised pile depth, Z/L, excluding the effect of the axial loading on the pile at stage 0. The shear stresses are deduced from the axial force distribution in the piles. It is shown that the shear stresses at the most part of the pile (from $Z/L = 0.0$ to $0.85 \sim 0.90$) increased at stages A and B, while those near the pile base decreased in a similar pattern. The negative shear stresses near the pile base were large up to 68 kPa, perhaps indicating that the substantial relative displacement between the pile and the surrounding ground might have taken place. This illustrates that the development of the tensile force near the pile base as mentioned previously was related to the downward shear stress component (Pang 2006). The reason for this observation is probably attributed to the soil around the pile base settling less than the soil around the upper parts of the pile shaft due to tunnelling. Depending on the amount of volume loss, this might even result in negative friction on the upper sections of the pile (Jacobsz 2002).

3.6 *Development of plastic yielding in the soil (Analysis 2)*

Changes of stress state of the soil next to the pile prior to tunnel excavation and during the tunnel excavation was studied. At stage 0, the zone of plastic yielding in the soil prior to tunnelling only extended to $Z/L = 0.25$ from the surface. This is probably due to the large relative shear displacement developed at the pile-soil interface near the surface. The extent of plastic yielding during tunnelling increased at stages A and B. The range of plastic yielding increased to $Z/L = 0.45$ at stage A and $Z/L = 0.60$ at stage B. In addition, a plastic zone developed near the pile base ($Z/L = 0.95 \sim 1.0$)

at stage B due to the large shear displacement which developed there. Generally pile behaviour under the service condition can be explained based on the elastic model. However, the computed results indicate that substantial plastic yielding can be developed in the soil near the pile which will in turn affect the performance of the pile significantly.

4 CONCLUSIONS

Parametric numerical analyses have been conducted to study the influence of tunnelling on an adjacent single pile. The following conclusions can be drawn from the present study.

1. Due to tunnelling pile settlement increased and shear stress distribution along the pile changed.
2. The pile settlement increased as the tunnelling proceeded. The computed pile settlement was larger than that computed from the green field condition. Moreover, the ground settlement distribution was severely deviated from the Gaussian settlement distribution. Hence, a relation that can include this phenomenon is perhaps necessary to estimate ground settlement trough. The apparent pile capacity deduced from load-settlement of the pile during tunnelling was reduced. At the end of the tunnel excavation, the apparent pile capacity was reduced to about 50%. Therefore, a significant reduction in the pile capacity is expected affecting serviceability of the piled foundation.
3. Due to development of the relative shear displacement at the pile-soil interface the shear stress distributions along the pile changes, and so is the distribution of axial force of the pile. The analysis showed that axial forces near the pile base reduced while those at the upper part of the pile increased, implying an increase in the shaft resistance of the pile. In addition, tensile forces developed near the pile base up to 13% of the axial load.
4. The extent of plastic soil yielding next to the pile expanded as the tunnelling proceeded and hence when large ground settlement is expected, soil slip at the pile-soil interface very likely to be developed.
5. It may be necessary to study the effects of ground reinforcement on the pile performance where tunnel excavation is to be conducted near the piled foundation to minimise damages of superstructures.

ABSTRACT: Load on the center pillar of two-arch tunnel and behavior of the ground around it under the influence of discontinuity planes were studied. Large scale model tests in the scale of 1/10 were performed in the biaxial loading test apparatus. Tests ground with various angle of discontinuity in 0, 30, 60, and 90 degrees were built, which was 3.3 m in width, 3 m in height, 0.45 m in length. During the construction sequences were pillar loads, deformation of the ground around the two-arch tunnel, liner stress, and the distortion of tunnel measured. Tests results show that pillar load and ground deformation are distinctly depended on the angles of discontinuity. The construction sequences should be considered in the construction of two-arch tunnel in the ground including discontinuity planes.

1 INTRODUCTION

Recently two-arch tunnel has been commonly constructed because it has many advantages such as the minimization of tunnel section, less loading on the environment and easy connection to adjacent roads. But the behavior of two-arch tunnel and ground around it have not been fully clarified because of its complex construction sequences and relaxation history. Effects of the existing discontinuities in the ground and the construction sequences on the behavior of two-arch tunnel, especially loads on the center pillar, are not well known yet.

This research was focused on the analysis of pillar load, liner stress, and deformation of the ground around two-arch tunnel depending on the lateral stress coefficient, the construction sequences, and the inclination of discontinuities.

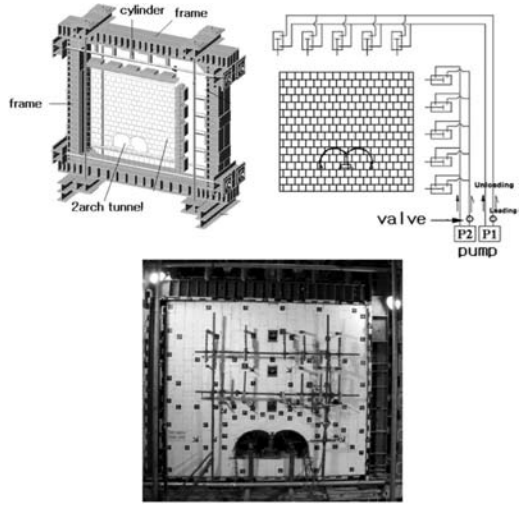

Figure 1. Test equipment and model ground.

2 LARGE SCALE MODEL TEST

2.1 *Development of model test*

Large scale model tests in 1:10 scale were accomplished in the biaxial load test facility which was 5 in width, 5 m in height and 0.8 m in length. Load capacity was 2.50 MN in both vertical and horizontal directions (Fig. 1).

Figure 2 shows a model test ground including various discontinuities, which is 3.3 m in width, 3.0 m in height, and 0.45 m in length. The ground, whose RMR value was about 67, was constructed by using the hexahedral concrete blocks which are 0.2 m in width, 0.15 m in height, and 0.45 m in length. And the discontinuity inclination test ground was in 0, 30, 60, and 90 degrees. The model tunnel in 1:10 scale was 1.2 m in width, 0.6 m in height and 0.45 m in length. The steel liner in 0.4 mm thickness was designed according to the similitude law by Duddeck and Erdmann (1985), to have the same moment of inertia as the standard

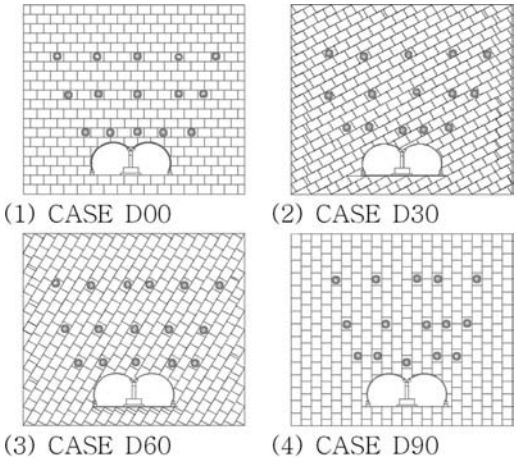

Figure 2. Test ground including discontinuities and displacement measuring points.

supporting type III. Friction at the boundary of test ground was minimized by installing rollers. The center pillar load, ground deformation and tunnel distortion were measured during the construction sequences.

2.2 *Test procedure*

Before tunnel excavation, the test ground was loaded not only vertically but also laterally. Lateral stress coefficient was kept constant as 0.4.

Model tunnel was excavated in the sequence of pilot tunnel, upper right face, upper left face, lower right face, and lower left face. After tunnel construction, horizontal stress was increased to change the lateral stress coefficient in 0.3, 0.325, 0.35, 0.375, 0.5, 1.0, 1.4, 2.0.

3 TEST RESULTS

3.1 *Ground deformation*

Ground deformation around tunnel was measured by using LVDT(Linear Variable Displacement Transformer), and was shown in contours. And maximum displacement was illustrated in construction stages. Results showed that most part of displacements was occurred during the excavation of upper face. Ground deformation was distinctly dependant on the inclination of discontinuity planes.

3.1.1 *CASE D00*

When a two-arch tunnel was excavated in the ground, which had horizontal discontinuity planes, ground deformed symmetrically to the center pillar. Maximum displacement was measured at the ground above pillar.

Displacement history at the location of the maximum displacement during excavation procedure is

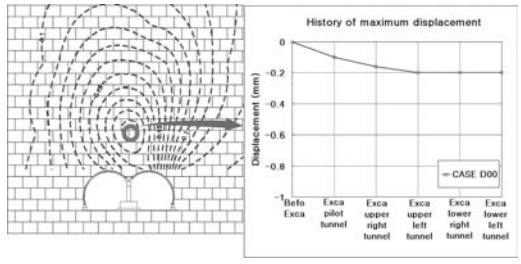

Figure 3. Displacements contour and the history of the maximum displacement in CASE D00.

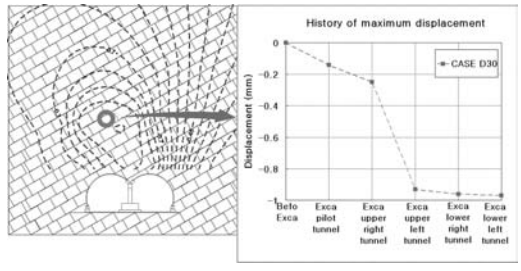

Figure 4. Displacements contour and the history of the maximum displacement in CASE D30.

illustrated in figure 3. Most part of the displacement was measured during the excavation of pilot tunnel and upper face of main tunnel. But almost no displacement was measured during the excavation of lower face of main tunnel.

3.1.2 *CASE D30*

In case of D30, when discontinuity was inclined 30 degrees, most part of the displacement was occurred during the excavation of the upper face of left main tunnel. And maximum displacement was occurred at the ground above the crown of left tunnel.

Maximum displacement due to the excavation of upper left face in CASE D30 was 20 times larger than that in CASE D00. And that due to the excavation of pilot tunnel and upper face of right tunnel in the CASE D30 was 1.5 times larger than that in the CASE D00. Ground was deflected perpendicular to the discontinuity planes and directed to tunnel.

3.1.3 *CASE D60*

In CASE D60, when discontinuity inclined 60 degrees, ground deformed in the very wide area above the crown of left tunnel during the tunnel excavation. But maximum displacement was occurred in the ground direct above the crown of right tunnel.

Displacement due to the excavation of upper face of right tunnel was 3 times larger than that, which happened due to the excavation of any other faces. The angle of discontinuity planes and the lateral stress

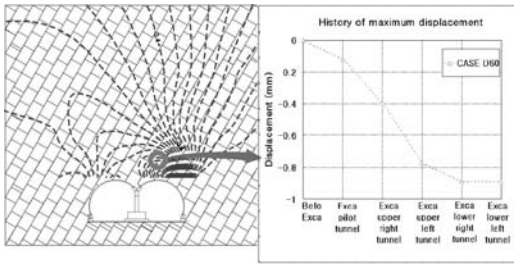

Figure 5. Displacements contour and the history of the maximum displacement in CASE D60.

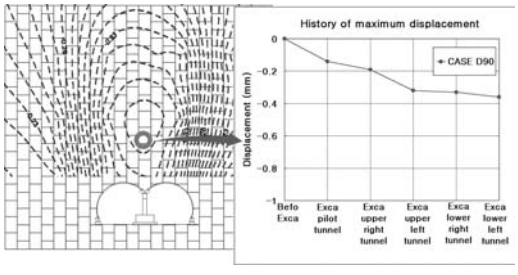

Figure 6. Displacements contour and the history of the maximum displacement in CASE D90.

coefficient were the most important factors for the ground deformation. Displacement due to the excavation of upper face of left tunnel in CASE D60 was greater than that in CASE D00 and D90.

3.1.4 *CASE D90*

In CASE D90, when discontinuity planes were vertical, ground deformed almost symmetrically to the center pillar. Displacement contours showed that ground deformation was concentrated on the upper part of center pillar. The ground above center pillar deformed as if it was sliding into the tunnel (fig. 6).

Displacement at every tunnel excavation stages was almost same amount at every tunnel excavation stages. Maximum displacement in CASE D90 was slightly larger than that in CASE D00.

3.2 *Pillar load*

In the tests, initial stress condition was produced by applying both vertical and horizontal loads at the horizontal and vertical boundary. Lateral stress coefficient was kept constant (K = 0.4).

Firstly, pilot tunnel was excavated and then center pillar was installed. Excavation of main tunnel began with upper face and right tunnel.

During the main tunnel excavation, load on the center pillar at each construction procedure is normalized thru rock mass load by Terzaghi and shown at

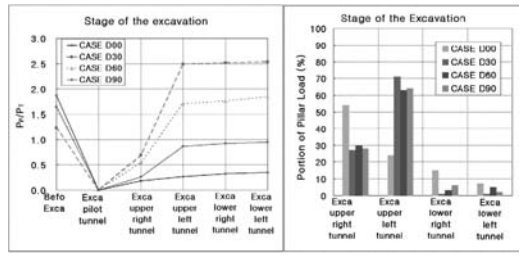

Figure 7. Pillar loads during construction sequences.

Table 1. Pillar loads during construction, P_P/P_T*.

Joint dip	Right upper	Left upper	Right lower	Left lower
0°	0.19	0.27	0.33	0.35
30°	0.70	2.52	2.55	2.57
60°	0.55	1.73	1.78	1.87
90°	0.26	0.87	0.94	0.96

*P_P : Pillar load after lower left tunnel was excavated,
P_T : Rock mass load by Terzaghi

Table 2. Ratio of pillar load to Matsuda and Lee equation.

Joint dip	P_P/P_M	P_P/P_L
0°	0.62	0.77
30°	4.53	5.67
60°	3.3	4.13
90°	1.69	2.11

table 1 and figure 9. It shows that pillar load increases depending on the excavation sequences.

Measured pillar loads were compared with the calculated loads by Matsuda(1997) and Lee(2004), which are for continuous ground. Lee took into consideration the liner stiffness for the calculation of pillar loads.

The calculated loads did not coincide with the measured value. Calculated pillar load was larger than the measured value in case of horizontal discontinuity planes (D00), but much smaller in other cases (D30, D60, D90).

Especially, in CASE D30, measured pillar load P_P was 4.53 times (P_M by Matsuda) and 5.67 times (P_L by Lee) larger than the calculated values.

3.2.1 *CASE D00*

Measured pillar load was smaller than the calculated by Matsuda's equation.

About 53% of the total pillar load was developed during the excavation of upper face of right tunnel, and 25% during upper face of left tunnel. That means about 80% of total pillar load was developed during the upper face excavation.

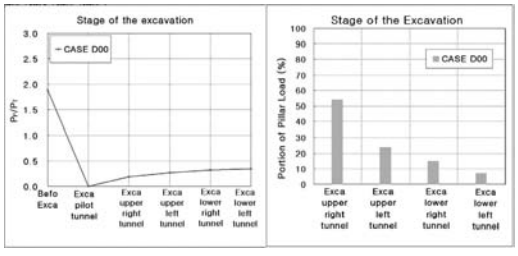

Figure 8. Pillar loads in CASE D00.

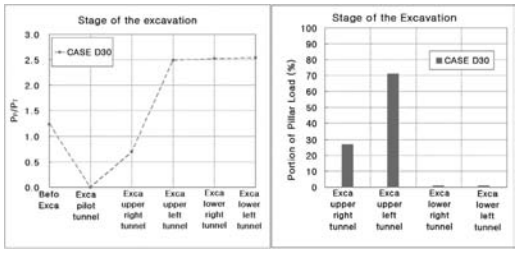

Figure 9. Pillar loads in CASE D30.

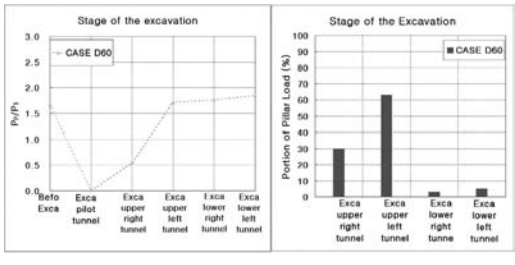

Figure 10. Pillar loads CASE D60.

3.2.2 *CASE D30*

Measured pillar load was 4.53 times larger than P_M.

Measured pillar load at the time of complete excavation in CASE D30 was 7 times larger than that of in CASE D00. But pillar loads due to the excavation of upper right face and upper left face in CASE D30 were 3.75 times and 21.8 times larger than that of D00.

3.2.3 *CASE D60*

After complete excavation in D60, the measured pillar load was 3.3 times larger than that of calculated by Matsuda.

Pillar load due to the excavation sequences showed almost the same trends but was slightly lower value than that in CASE D30. Largest pillar load was measured at the excavation of upper face of left tunnel, and its increment was largest when excavation line was parallel to discontinuities.

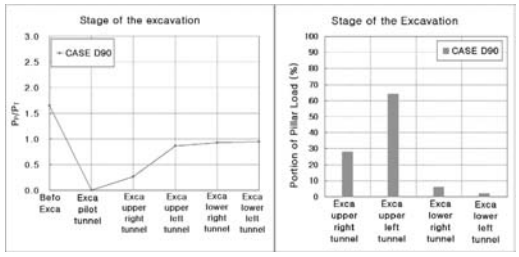

Figure 11. Pillar loads and its development during the excavation stages in CASE D90.

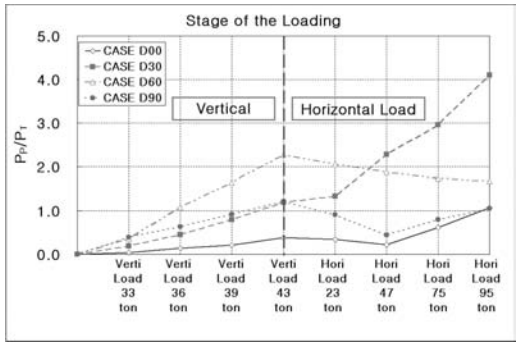

Figure 12. Pillar loads under vertical and horizontal loading.

3.2.4 *CASE D90*

When two-arch tunnel was completely excavated, pillar load in CASE D90 was 2.72 times larger than that in CASE D00. When upper left tunnel was excavated, almost 60% of total pillar load was developed.

3.3 *Vertical and horizontal loading*

Loads at the vertical and horizontal boundary were increased, in order to see the behavior of two-arch tunnel and the ground around it due to the changed loading condition.

Vertical load was increased gradually from initial value 300 kN to 330, 360, 390, 430 kN to change the lateral stress coefficients from 0.4 to 0.375, 0.35, 0.325, and 0.3, respectively. And horizontal load was increased from initial value 140 kN to 230, 470, 650, and 950 kN to change the lateral stress coefficient 0.5, 1.0, 1.4 and 2.0 respectively.

During these loading stages, the pillar load, liner stress, and the deformation of tunnel and ground around the two-arch tunnel was measured.

3.3.1 *Pillar load*

Pillar load due to extra boundary load is shown in figure 12. Pillar load at the time of completion of construction was the largest in CASE D30. Due to the

vertical load, the largest pillar load was developed in CASE D60, and it was more than 4 times larger than that of CASE D00.

On the other hand, due to the horizontal load, pillar load was developed depending on the inclination of discontinuities and the lateral stress coefficient.

In CASE D00 and D90, pillar load was decreased due to horizontal load if lateral stress coefficient was smaller than 1.0 ($K<1.0$). But it was increased in case lateral stress coefficient larger than 1.0 ($K>1.0$).

In CASE D60, due to the horizontal load, pillar load was decreased proportionally to lateral pressure, but in CASE D30, it was increased continuously.

4 CONCLUSION

Conclusion of large scale model tests for two-arch tunnel could be drawn as follows;

1 Largest pillar load due to the excavation of main tunnel was developed in horizontal discontinuity (D00) and then in the order of 0°, 90°, 60° and 30°.
2 Measured pillar load in the ground with horizontal discontinuity was smaller than the calculated values by Matsuda equation (1997) and Lee (2004) for continuous ground. But much larger pillar load was measured in the ground with inclined discontinuity than the calculated for continuous ground.
3 Most part of the pillar load was developed during the excavation of upper face of right tunnel in the ground with horizontal discontinuity(D00), but it was developed during the excavation of upper face of left tunnel in the ground with inclined discontinuity (D30, D60, D90).
4 Due to vertical load, the pillar load was eventually increased irrelevant to the load, pillar load was developed depending on the inclination of discontinuity and the lateral stress coefficient.

A case study of tunnel excavation adjacent to a steep slope

Shen-Chung Lee & Lin-Bin Chiou
Taiwan Area National Expressway Engineering Bureau, Taipei, Taiwan

Gwo-Fong Lin
National Taiwan University, Taipei, Taiwan

ABSTRACT: The Hsintien No.1 tunnel located in the northern section of National Expressway No.3 in Taiwan passes through the toe of a steep slope in parallel manner, due to the unfavorable topographical and geological conditions as well as the onslaughts of torrential rains during the construction, the project was on the brink of total collapse. Assessing the monitoring data and evaluating the failure mode, the engineering layout was changed so that the slope could stop cutting downward; the stability of the slope was enhanced by massive backfilling and heavier tunnel supports. After a series of remedial measures, the stability of the slope and tunnel was reached. Current construction of expressways in Taiwan has expanded to the mountainous terrains; thus a big portion of tunneling works is expected. It is hoped that this case study will shed some light on the future projects of similar nature.

1 INTRODUCTION

The National Expressway No.3 connects both the northern and southern ends of Taiwan. The feasibility study of this expressway commenced in 1983, followed by the planning, design and construction, and was completed for operation in January 2004. The total length of this expressway (Fig. 1), including the main route and branches, is 518 km (TANEEB, 2004). There are 14 tunnels with a total length of 13.6 km in Expressway No.3 of which 12 of them are located in the northern section, thus a tunnel group is formed. Most of these twin-tube three lanes tunnels passing through unfavorable topography and adverse geology; therefore, the tunneling works were always critical during the construction.

The Hsintien No.1 Tunnel is one of the tunnels in the tunnel group that runs through the hilly area at the rim of Taipei Basin. This tunnel cuts through the toe of an 80 m steep slope. There are high-voltage electric towers on the top of the slope and a community with hundreds of residential buildings near the toe, thus the topographical condition around the site is complicated. The rock formations are loosely cemented and low in strength, as well as affected by the thrust fault nearby the site, the geological conditions are unfavorable for constructions. To aggravate the matter, three consecutive torrential typhoon rains invaded the site during the construction and resulted the sliding of the slope. There was tremendous deformation in the tunnel excavated simultaneously with the slope cut.

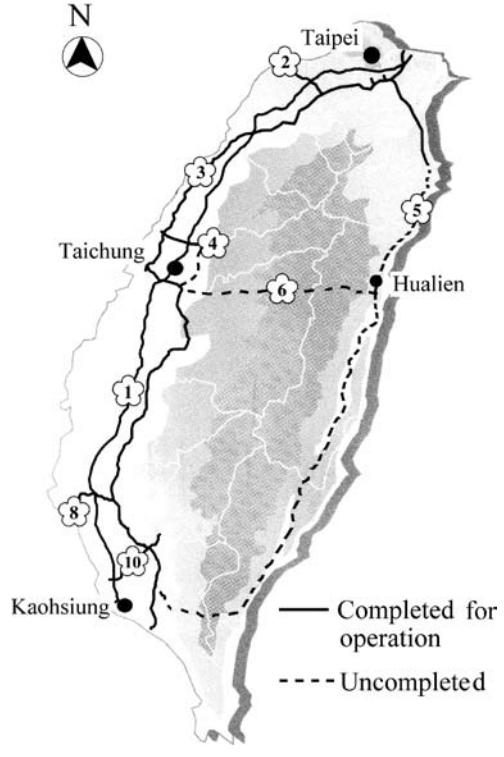

Figure 1. Taiwan National Expressway Network.

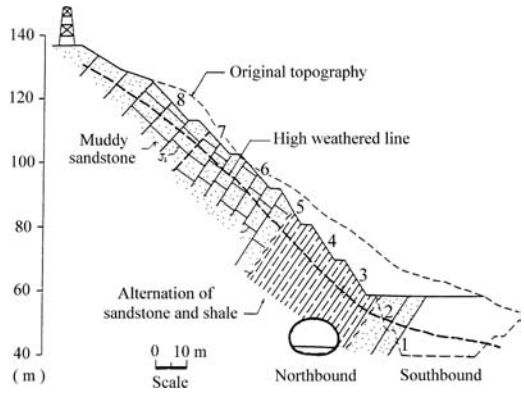

Figure 3. Geological section of Hsintien No.1 Tunnel.

This paper first gives a general description of the project, followed by the construction procedures, the interactive factors that affected the stability of the project, and the remedial measures adopted. Finally, the causes of construction delay were summarized and presented.

2 GENERAL DESCRIPTION OF THE PROJECT

2.1 *Original design*

Due to the topographic restriction, Hsintien Tunnel was constructed by four separated tunnels, namely Hsintien No.1 to Hsintien No.4 Tunnels. These four separated tunnels were connected in the concrete lining installation stage. According to the original design, the northbound of Hsintien No.1 Tunnel was cut through the bottom of the slope by tunneling, while the southbound was designed by open cut in the original design owing to the interchange ramp merge into the main route. The original plane view is shown in Figure 2.

The slope is steep with a height of 80 m in the original design. The slope was designed to cut by 8 benches; each bench is 10 m high with a 3 m berm. The primary supports of the slope are shotcrete, rock bolts and stressed rock anchors.

2.2 *Topography and geology*

The Hsintien No.1 Tunnel is located at the rim of Taipei Basin where the topographic surface is rugged. It runs in parallel manner to the slope, an unbalanced earth pressure thus occurred on the tunneling work. It passes through the Nankang Formation where its geological age is middle Miocene. It is a marine sedimentary sequence. The formation is divided into two parts according to lithological differences: the upper part is mainly composed of thick-bedded muddy sandstone, while the lower part is mainly composed of thin alternation of sandstone and shale. As a result of squeezing effects from the thrust fault nearby the site, shale beds in the sandstone and shale alteration are transformed into clay seams. The bedding planes are often open with smooth surfaces, thus its shear strength is low. The beds are smooth with attitude of N44° E / 55°S. The strike of the beds intersects the tunnel axis and the excavated slopes at a small angle or the two are extending in parallel. They incline into the hill, thus a scarp slope was formed (Cheng et al. 1997). A representative cross-section showing the geologic units is shown in Figure 3.

3 CONSTRUCTION PROCESSES AND REMEDIAL MEASURES

3.1 *Initial remedial measures*

The slope was excavated from June 1992 and when the slope was cut to the fifth bench, the excavation of northbound tunnel at the bottom of the slope was commenced from the south portal (Sta.16 k + 480). When the tunnel was excavated to 16 k + 342 (138 m far from the south portal), the cut slope reached the third bench. During this time, the shotcrete on the slope began to crack and propagated upward toward the top of the slope, the slope toe showed signs of bulging, and a few tendons of rock anchor were broken. After reviewing the monitoring data and evaluating the failure mode, the slope was belief to be in the state of creeping. The northbound tunnel also showed increased convergent displacement; the shotcrete had the phenomena of cracking and stripping, and the steel ribs seriously buckled. If the project were to proceed according to the original design, more slope slides might occurred and the stability of tunnel would than be affected. Based on the long term stability analysis, initial remedial measures were proposed and adopted for the construction:

1. Installation of rock bolts and rock anchors on the completed slope to enhance stability.

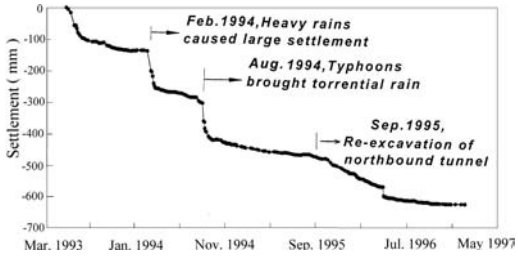

Figure 4. Time-settlement plot measured on the top of the slope.

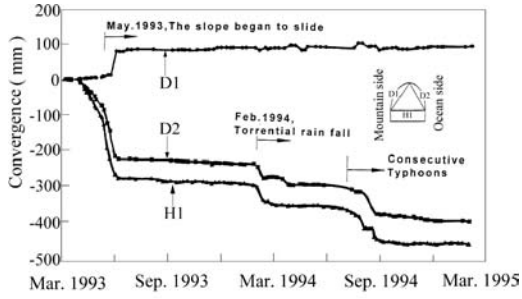

Figure 5. Time-convergence plot measured at sta. 16k + 391 of northbound tube.

2. Construction of 1.0 m diameter by 25 m long bored piles on the slope between Sta. 16 k + 375 to 16 k + 445. The piles are tied back by 50 m long anchors.
3. For the sake of reducing the cut slope area, the north portal of northbound tunnel was extended 40 m, i.e. the station of north portal was moved from 16 k + 272 to 16 k + 232.

After the completion of all the initial remedial measures, the slope resumed excavation downward from the third bench in June 1994. In the mean time, the excavation of the northbound tunnel was stopped to avoid interactive effects between the tunnel and the slope. During the resuming of slope excavation, there were onslaught of three consecutive typhoons which brought heavy rain falls, the remedied slope cracked and deformed again as the rock mass strength was weakened by the water. In that time, the inclinometer on the fifth bench measured a maximum movement of 60 cm; the disc load cell on the fourth bench indicated the tendons had reached 77 tons (design stress was 60 tons), the accumulated settlement of electric tower on the top of the slope was 40 cm (Fig. 4), and the convergence of northbound tunnel at station 16 k + 391 reached 35 cm (Fig. 5). The cracking of the shotcrete and buckling of the steel ribs in the tunnel became worsen. It was obvious that the tunnel suffered tremendous deformation due to the formidable slope sliding. Thus, the entire project was stopped again for the further remedial measures.

3.2 *Subsequent remedial measures*

After reviewing the monitoring data and evaluating the failure mode it was revealed that the slope and the tunnel were at critical state. Further excavations of the slope and the tunnel might trigger a total collapse that would damage the residential buildings at the toe and the electric towers on the top of the slope. The following construction should be performed in such a way that the tunnel must be completed safely without having to perform any more downward excavation on the slope. After a through evaluation and considering

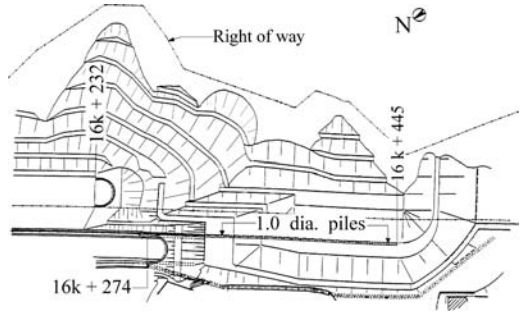

Figure 6. Plane view of the subsequent remedial measures.

the workability, the following remedial measures were adapted (TANEEB, 1998):

1. Installation of more rock anchors on the slope to counter the slope slide.
2. To extend the north end of bored piles from station 16 k+375 to 16 k+270, thus the length of the bored piles was increased to 175 m.
3. Performed massive backfilling at the toe of the slope, in two benches to a height of 20 m with a total volume of 60,000 m^3, to ensure long term slope stability.
4. The southbound was changed from open cut to tunnel excavation. In addition, the southbound tunnel was excavated by both side galleries method.
5. Heavier tunnel supports were adopted in the northbound tunnel thus the rigidity of supports was increased.

The plane and cross-section views for the subsequent remedial measures are shown in Figures 6, 7. After the completion of the subsequent remedial measures, the displacement rates of slope and tunnel work were significantly reduced. Moreover, the contractor and engineers had sufficient understanding of the geological conditions and the failure mechanisms, more effective measures were adopted in the subsequent construction stages.

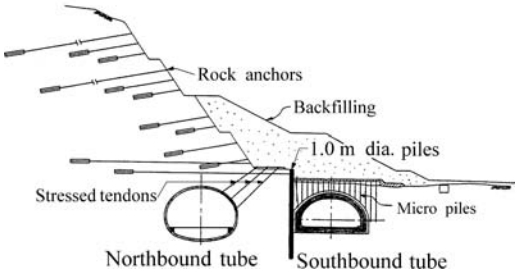

Figure 7. Cross-section view of the subsequent remedial measures.

4 TUNNEL CONSTRUCTION

4.1 *Northbound tunnel*

The northbound tube of Hsintien No.1 Tunnel is a three-lane, one traffic direction tunnel. The original designed station, from 16 k + 272 (north portal) to 16 k + 480 (south portal), was 208 m in length, with a horse-shoe shape cross-section and an excavation area of 157 m^2. The excavation sequence was top-heading first, followed by the bench and invert excavations. In order to avoid vibration caused by explosion to the local inhabitants, the tunnel was excavated by mechanical means such as road-headers or breakers. The rock mass rating (RMR) was the major engineering rock mass classifications used for this tunnel. It was divided into six grades, namely class I to class VI. The tunnel was excavated and supported in rock mass class VI. The thickness of shotcrete is 25 cm, rock bolts diameter (φ) was 29 mm with lengths varied between 6 to 9 m long. After the primary support, the tunnel was lined with 40 cm thickness concrete.

In order to reduce the cutting area of the slope and to avoid the accidents caused by rock falling during operation, the north portal was extended 40 m in the initial remedial measures, thus the length of northbound tunnel was increased to 248 m. In the subsequent remedial measures, the thickness of the shotcrete was increased from 25 cm to 35 cm to restrict the increased convergent displacement. Some additional 40 tons-stressed anchors were installed inside the tunnel. It is noteworthy that the fixed end of some rock anchors installed from the slope surface were exposed during the tunnel excavation, in this situation the exposed tendons were stressed again toward opposite direction from the excavated tunnel, thus both-end-stressed tendons were formed and the rock pillar was reinforced (Fig. 7).

In addition to increase the strength of primary supports, a more rigid concrete lining was also adopted. The thickness of concrete lining was increased from 40 cm to 50 cm; the compressive strength of concrete was also increased from 210 kgf/cm^2 to 350 kgf/cm^2; the reinforcing bars inside the concrete also added.

The monitoring data showed that the rapidest deformation of the tunnel occurred at station 16 k + 420; for the sake of diminishing the deformation by the rigid concrete lining, steel form was transported to the vicinity of station 16 k + 420 and placed the concrete lining by priority herein. It was different from the ordinary operation that the concrete lining was placed consecutively from the portal. Though the "jumping lining" required more construction time, it reduced the tunnel deformation significantly and provided a great help to the tunnel stability.

4.2 Southbound tunnel

In order to prevent further slope movement when the slope was cutting down to the third bench, the proposal of changing the southbound from open road to tunnel excavation had been adopted in the subsequent remedial measures. The southbound tunnel is 206 m long, from 16 k + 274 to 16 k + 480. Owing to the ramp of Hsintien Interchange merge into the main route at the north portal section, there is a 49 m long section near the north portal with 4 traffic lanes with cross-section excavation area of 230 m^2—the biggest cross-section road tunnel in Taiwan. The following 48 m long is the transition section from 4 lanes to 3 lanes, and the other 109 m near the south portal is 3 traffic lanes.

When the southbound was changed from open road to tunnel excavation, the slope had been cut down to the third bench; therefore, the overburden above the tunnel was only 8∼10 m thick. In such situation of big cross-section, shallow overburden and unbalanced earth pressure, the construction encountered extreme perplexities. After investigation, the following measures were adapted for the southbound tunnel:

1. The overburden above the tunnel was reinforced by micro piles: Before the backfilling at the toe of the slope, the shallow overburden was reinforced by vertical micro piles. The construction methods for these micro piles were to drill 4″φ bored holes until the tunnel crown at 1.5 m × 1.5 m c/c. The bored holes were filled with 1:1 cement-sand grouting, and then the piles which composed of four 25 mm φ reinforcing bars with spacer were installed into the bored holes. Finally, all of the top ends of micro piles were placed with a 50 cm thick concrete, similar to the cap slab of foundation piles. After the completion of micro piles, backfilling at the toe of the slope was performed on the cap slab, as shown in Figure 7.
2. Installation of pipe roofing at the portal section: Pipe roofing often used as auxiliary support for the treatment of tunnel disasters such as cave-in, collapse, etc. The portals of Hsintien No.1 Tunnel were sensitive to the disturbance; in case of tunnel collapse, it would cause great damages to the slope and the inhabitants. Therefore, the 4″φ by 25 m long

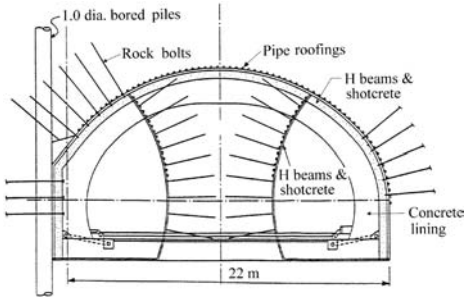

Figure 8. Cross-section view of southbound tunnel.

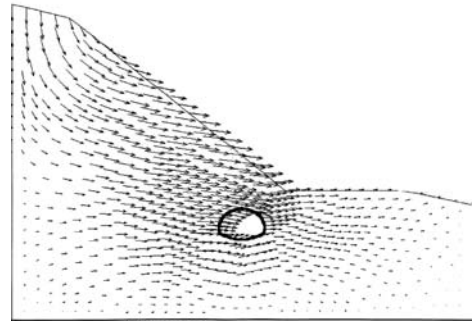

Figure 9. Displacement field after the excavation of slope and northbound tunnel.

pipes were installed adjacent to each other before the portal excavation.

3. Side gallery excavation: Owing to the adverse geology and topography as well as the shallow overburden, the southbound tunnel was designed and constructed by both side galleries method. The construction sequences are (Fig. 8): (i) side galleries excavation (round length 8∼12 m) ,(ii) placing the foundation concrete of side galleries, (iii) excavation of central pillar (round length 8∼12), (iv) placing the foundation concrete of central pillar, (v) erection of steel form, (vi) installation of waterproofing membrane and reinforcing bars, (vii) placing of concrete lining (8 m long), and (viii) curing of concrete lining for 3 days. The thickness of the shotcrete in the primary support is 50 cm, and the inner concrete lining is between 1.2 ∼ 2.0 m thick; therefore, the rigidity of tunnel support was significantly increased. During the construction, the deformation of this tunnel was generally found to be less than 2 cm.
4. Flexibility principle: The tunnel cross-section varies from 4 to 3 traffic lanes at the north portal section. During the installation of concrete lining, the width of steel form has to be modified according the dimensions of the tunnel cross-section. To do this, the contractor separated the original 3-lane steel form, and inserted a transition steel panel at the center part; thus a changeable-dimension steel form was formed and adapted for the variable tunnel cross-sections. Moreover, as the thickness of concrete lining is over 1.2 m, the space was enough for workers to use this steel form as the working truss for the erection of waterproofing membrane and reinforcing bars, it was not only convenient for the construction but also cost and time effective. The both side galleries method resulted a very small deformation during the construction, thus the contractor could changed the construction sequences and support systems with ease, this was also the main reason that the construction time of southbound tunnel could be reduced significantly.

As the contractor was getting familiar with the side galleries excavation, the cycle time (round length was 8 m) could be reduced from 45 days to 23 days. The southbound tunnel was excavated simultaneously from both portals; it was completed in 11 months, 3 months earlier than the anticipate time. After the completion of concrete lining for both tubes and the earth backfilling between the portals of Hsintien No.1 and No.2 tunnels, the entire project of Hsintien Tunnel is in a stable condition, no more disasters happened again.

5 CAUSES OF DELAY

Hsintien No.1 Tunnel was only a short tunnel in the tunnel group, but it took 7 years and 3 months to complete, twice the contract construction time of 3 years and 6 months. Except the Hsuehshan Tunnel (composed of two main tunnels and one pilot tunnel, each is 12.93 km in length) of National Expressway No.5, which was just completed for operation in June 2006, the Hsintien No.1 Tunnel is one of the most formidable construction among all expressway tunnels in Taiwan. The causes of such delay are:

1. Complicated and unfavorable topographic conditions: Expressway No.3 had been planned to pass through Taipei metropolitan area. To avoid large scale demolition of residential buildings and to minimize the environmental impact to schools along the alignment, it was decided to align the expressway along the hilly areas around the Taipei Basin. In terms of topography of Hsintien No.1 Tunnel, the slope is high and steep, and the tunnel runs through and parallel to the toe of the slope. The project was in an unbalance pressure situation, and the displacement was toward to the ocean side, as shown in Figure 9. This situation also can be verified from the convergence measurement. In Figure 5, the diagonal measurements D2 was

convergence, while the D1 was divergence, it is different to the normal situation.

2. Adverse geological condition: The rock formations around the site are mostly of tertiary sedimentary sequences, their lithology, thickness and geologic structure are often vary within even for a short distance, this became the main cause of many design changes and the progress of the project was delayed considerably.
3. Rock mass strength was weakened by water: It was learned from the monitoring data that many rapid displacements occurred after torrential rains; it showed that the failures of the slope and the tunnel were related to the water. The study of rock strength performed by Lin & Hung (1982) shows that: (a) the uniaxial compressive strength of sandstone reduced 50% if moisture content was increased from dry to 75%; (b) the uniaxial compressive strength for shale reduced 56% and the elasticity modulus reduced 25% if the moisture content increased from dry to 75%. Moreover, according to Jeng et al. (1996), the strength of submerged soft sandstone weakened obviously if the soft sandstone was submerged in water for 120 minutes. Its peak uniaxial compressive strength reduced 60%, the shear deformed modulus reduced 60%, and the bulk modulus reduced 70%. From the above studies, if the soft rock submerges in the water or situated in a high moisture content surroundings, its strength will be weakened and deformed significantly.
4. Unfavorable engineering layout: Due to the restriction of route alignment, the northbound tunnel passes through the bottom of the slope by tunnel excavation, while the southbound runs at the toe of the slope by open cut in the original design; thus the interactive effects between the excavation of the slope and the tunnel were sensitive. At the beginning of the slope cut, the slope was stable because the tunnel was not excavated yet. When the slope was cutting down to the third bench, the northbound tunnel was also excavated to the section with the most unbalanced pressure (in the vicinity of station 16 k + 400). During this time, the slide of the slope became serious, and the deformation of tunnel became rapid. After the engineering layout was changed, i.e. the southbound was changed from open road to tunnel excavation, and backfilling was performed at the toe of the slope, the stability of the whole project was fulfilled.

6 CONCLUSIONS

From this case study, the following conclusions can be made:

1. The route selection should be prudent. If the tunnel is designed to excavate through the bottom of a slope in parallel manner, then detailed geological investigations and stability analyses are necessary.
2. The stability issues of scarp slope can not be neglected, especially in the steep slope with adverse geological condition. In the present case, the slope is a scarp slope, but the joints are loosened due to construction operations, topping failure could be easily induced.
3. The strength of rock mass is easily weakened by water. Slope protection measures and drainages facilities can not be overlooked during the design and construction stages.
4. Prevention is always better than remedial measures. Disasters of tunnel and slope are not generated abruptly. By evaluating the monitoring data carefully, many disasters can be prevented in time. A well-planned monitoring system is important for tunneling project.
5. The present project was on the brink of collapse several times during the construction, it was prevented because of the effective remedial measures especially the stoppage of downward excavation of slope and the earth backfilling at the toe contributed the stability greatly on this project.
6. Flexibility is important in tunneling project. Owing to the flexible design and construction of tunneling works, the present project could be completed safely in time.

Subsurface settlement profiles above shallow and deep model tunnels at large ground loss

Yong-Joo Lee
Senior Researcher, Soil-Structure Interaction Group, Steel Structure Research Laboratory, Research Institute of Industrial Science & Technology (RIST), South Korea

Chung-Sik Yoo
Professor, Department of Civil & Environmental Engineering, Sungkyunkwan University, South Korea

ABSTRACT: A major concern in the construction of any tunnel in urban areas is the ground movements that inevitably take place. Geotechnical engineers are responsible for assessing these ground movements in association with tunnel design and have to demonstrate that neighbouring structures will not be subject to excessive differential settlements. The study presented in this paper focuses on the subsurface settlement profiles above shallow and deep tunnels in granular material simulated by aluminium rods. In order to provide theoretical deformation patterns during two-dimensional volume loss, CRISP is used for the finite element analysis. Comparison is then made with idealised laboratory tunnel model tests using close range photogrammetry to measure displacement pattern in a multi sized rod mixture. FEA based on the test results is shown to be in good agreement with the physical model data.

1 INTRODUCTION

The construction of any tunnel will give rise to ground movements in the form shown in Figure 1. Geotechnical engineers are responsible for assessing these ground movements related to the tunnel design and an assessed construction quality, usually expressed as a volume loss (V_L, %). They should demonstrate that neighbouring structures will not be subject to excessive differential settlements.

The pattern and magnitude of ground movements depends on the soil type, the stress history of soil through which tunnel is constructed, the tunnelling methods (open face tunnelling – NATM and closed face tunnelling – slurry shield and EPB) adopted, the geological setting, ground water level, speed of construction and workmanship.

Numerous studies on the tunnelling-induced ground movements in clay soils have been carried out, but few studies have focused on the behaviours of granular soils to date. In particular, there is spare data on the subsurface deformations at the large ground loss.

The study presented in this paper focuses on the subsurface settlement profiles above shallow and deep tunnels in a granular mass. In order to provide theoretical deformation patterns, the CRISP code is used for the finite element analysis. In addition, the close range photogrammetric technique is adopted to generate displacement data from the laboratory two-dimensional tunnel model tests using the multi-sized aluminium rods.

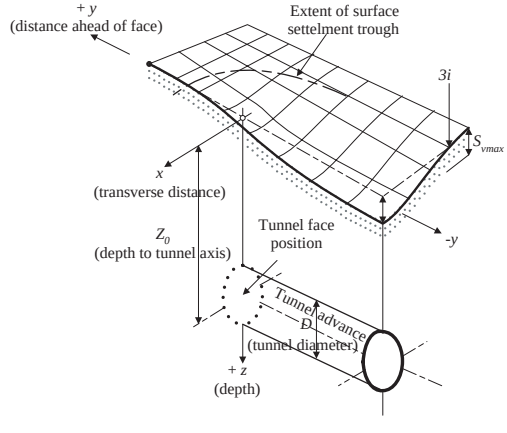

Figure 1. Three dimensional shape of surface settlement above advancing tunnel (Attewell et al., 1986).

Digital image processing has allowed overall deformation patterns of ground movements to be obtained from the analysis of digital images. Detailed patterns of ground movements can be obtained which give a clear insight into deep and shallow tunnelling events and are particularly valuable for validation of numerical analyses.

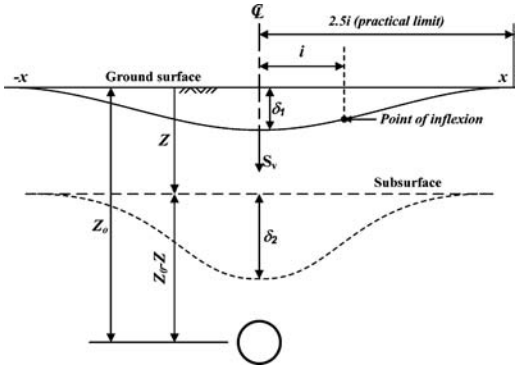

Figure 2. Form of surface and surface settlement profiles (after Mair et al., 1993).

2 SUBSURFACE SETTLEMENT PROFILES

In contrast to the collections of surface settlement measurements, there are relatively few field measurements of subsurface profiles available. It is common to assume that the shapes of subsurface settlement profiles developed during tunnel construction also approximate to a Gaussian distribution, as shown in Fig. 2. However, field and model measurements of subsurface settlements in clay soils indicate that the parameter K does not remain constant but increases with depth, giving proportionally wider settlement profiles closer to the tunnel crown (Mair et al., 1993). For the above subsurface settlement profiles, Mair et al. (1993) proposed a relation between K and the dimensionless subsurface below ground level (Z/Z_0):

$$K = \frac{0.175 + 0.325(1 - Z/Z_0)}{1 - Z/Z_0} \quad (1)$$

where K = trough width parameter; Z = depth of subsurface settlement trough below ground surface; and Z_0 = depth of tunnel axis below ground surface.

3 2D MODEL TEST

3.1 *Deep and shallow tunnel model tests*

Three tunnel model tests were conducted with respect to three tunnel embedment depths, viz. Z_0 = 270 mm; Z_0 = 420 mm; and Z_0 = 470 mm. No surcharge was applied to the surface as all stresses being provided by self-weight of the aluminium rod material.

The tunnel model tests did not precisely reproduce real tunnel construction replicating the method of excavation and support but carefully reduced tunnel diameter to simulate increasing 2D volume loss. The authors investigated the resulting deformation patterns as the tunnel cavity diameter was reduced in a displacement-controlled manner rather than by reducing the support pressure. This method approximates to the condition within a tunnel during excavation where the controlled physical support is provided and limited (i.e. deformation is the aim). The boundary conditions associated with plane-strain conditions are shown in Fig. 3.

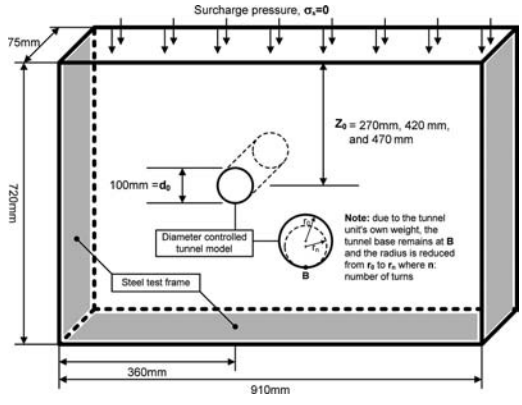

Figure 3. Boundary conditions for two-dimensional tunnel model test (non-scale).

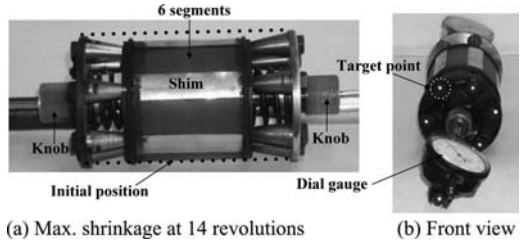

Figure 4. Two-dimensional tunnel device (diameter reduction system).

3.2 *Test equipments*

The model tunnel consists of 6 segments, the two ends of a segment being carved on the tapered cones. Each segment will move inward as the tapers are withdrawn, simulating the two-dimensional volume loss during tunnelling operations. The tunnel diameter is reduced by rotating the two knobs as shown in Fig. 4. The outer diameter of the tunnel is initially 100 mm. The reduction of the tunnel diameter gives directly a 2D volume loss (V_L). This 2D volume loss per revolution is determined from the calibration result (Lee, 2004). The model tunnel itself is a stiff element in the soil but is not fixed in space, so it can move freely during the development of the volume loss.

The aluminium rod mixture consists of six different diameters (viz. 2 mm, 3 mm, 6 mm, 9 mm, 12 mm and 20 mm), which have the same length of 75 mm.

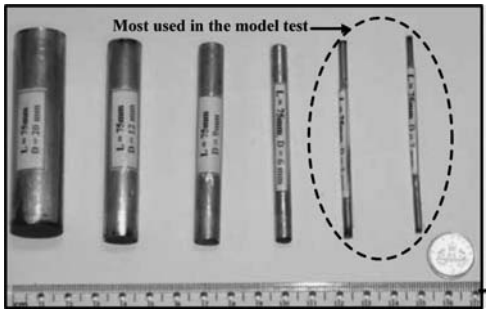

Figure 5. Multi-sized aluminium rod material.

It represents a well graded, idealised two-dimensional granular material, as shown in Fig. 5. The smallest rods (2 mm and 3 mm diameters) were mainly used in the specific area of the model test. However, the biggest rods were only used at boundaries which could not affect the stress-strain behaviour around the tunnel model.

The main features of the modelling of the ground by aluminium rods are as follows: (a) rigid motions such as movement and micro-rotation are visually observed; (b) aluminium rods satisfy plane-strain conditions; (c) as aluminium rods are self-sustaining, there are no side walls. Thus, the aluminium rod models are free from lateral wall friction; (d) the specific gravity of aluminium is comparable to that of sand and gravel. However, the irregular roughness of the shape of soil particles which would normally prevent the rotation of particles is neglected.

The testing time is much quicker than any conventional test using sand or clay. In addition, detailed observation of the side section is easily carried out enabling details of deformation patterns, which are associated with strain fields rather than stress fields, to be determined.

3.3 *Calibration of tunnel model and test procedures*

The tunnel model provided a surface of negligible bending stiffness adjacent to the rod material. The two-dimensional volume loss was determined from the calibration test result, as shown in Fig. 6. The relationship between 2D volume loss and number of revolutions based on the dial gauge was polynomial.

The test procedures are as follows: (a) Preparation of the rod model; (b) Preparation of the test equipment (e.g. model tunnel); (c) Stacking the rod model with the silver reflective markers and insertion of the tunnel at the correct level in the steel test frame; (d) Recording 10 digital images for the initial stage of the photogrammetric measurement; (e) Reduction of the tunnel diameter by the controlled rotation of the knobs at the front and back of the tunnel unit. The following were normally recorded: - 1 revolution

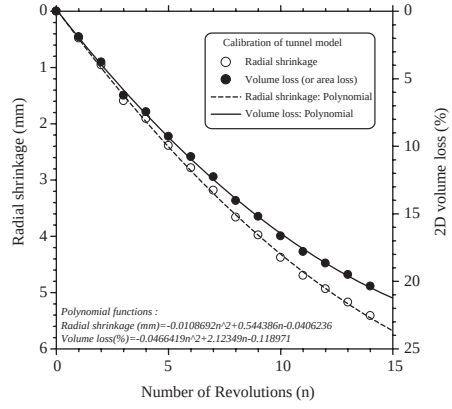

Figure 6. Calibration result of 2D tunnel model.

(V_L = 1.96%), 3 revolutions (V_L = 5.83%), 6 revolutions (V_L = 10.94%), and 9 revolutions (V_L = 15.21%); and; (f) Recording 10 digital images for each chosen stage of (e) above.

The physical position of the tunnel model was not restrained. Care was taken that adjustments made never disturbed the rod material, great care being taken not to apply load or to distort or to twist the unit. The resulting physical location of the tunnel centre during the model test was investigated by using the reflective nodes immediately adjacent to the model tunnel and this actual location was inserted into the finite element analysis (FEA) to mimic the actual physical conditions. The triangular mesh of reflective silver markers used in the Z_0 = 270 mm tunnel model test is shown in Fig. 7. The mesh is comparable with the FE meshes. They are generated by the EngVis program. The horizontal and vertical location of every reflective point is calculated for each 2D volume loss. The incremental displacements and the associated strains within triangular elements were calculated on completion of the whole imaging process.

Specific details of the digital imaging process and strain generation were introduced by Lee and Bassett (2006).

4 NUMERICAL ANALYSIS

4.1 *Numerical simulation*

In order to simulate the "floating" model tunnels in the CRISP FE code, the actual centre point movements of the physical model tunnel were investigated for each of the tunnel depths (Lee and Yoo, 2006). The vertical movements appeared to increase almost in proportion to the volume loss, as shown in Fig. 8. The centre point of the model tunnels moved vertically down while the invert remained at very nearly the same level, which is what would often be the situation in real life, the

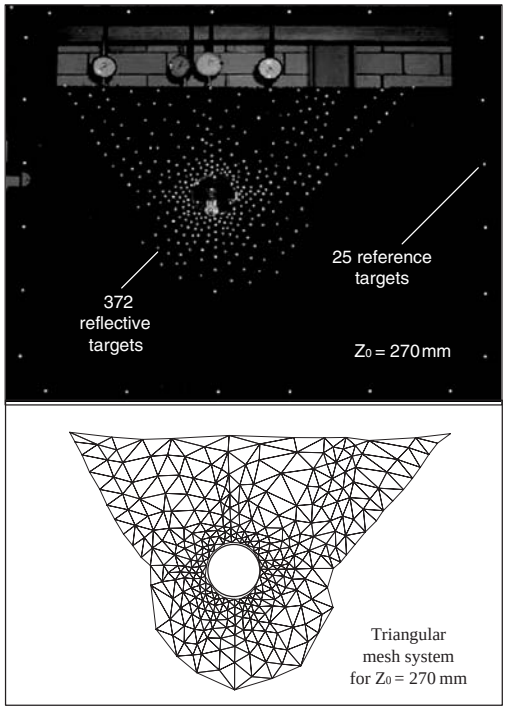

Figure 7. $Z_0 = 270$ tunnel model test and corresponding triangular mesh.

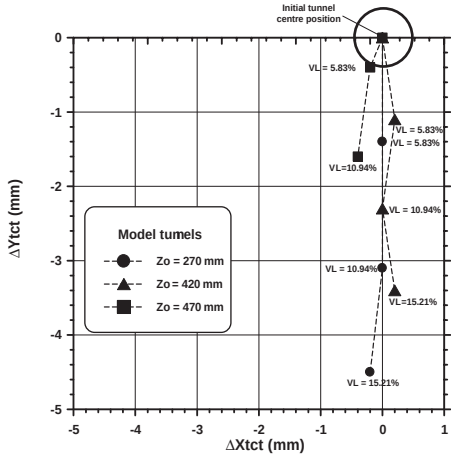

Figure 8. Horizontal and vertical movements (ΔX_{tct}, ΔY_{tct}) of a centre point of a "floating" tunnel model.

level of the invert being the key control. The horizontal movements of the tunnel centre point were assumed to be zero throughout the tests.

The correspondent 2D finite element mesh for the $Z_0 = 270$ mm is shown in Figure 9. It should be noted

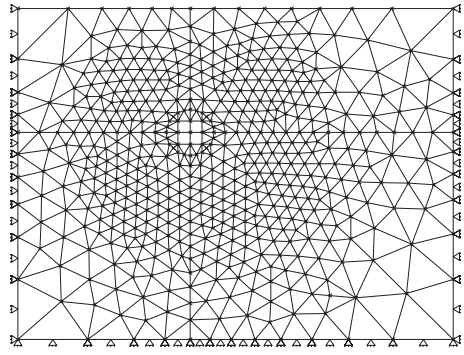

Figure 9. Finite element mesh for $Z_0 = 270$ mm.

Table 1. Soil parameters used in the FEA.

Reference level, Y_0*(m)	0.72

Angle of dilation, ψ (degrees)	15

Note: * at ground surface; ** varying with depth.

that for the finite element mesh shown the FE tunnel centre was not located at the middle line of the mesh. This was because in the physical model the tunnel model was not at the centre of the test equipment. This fact was dictated by a later study of pile-soil-tunnel interaction.

4.2 *Constitutive model and model parameters*

Soil behaviour was assumed to be governed by an elastic-perfectly-plastic constitutive model based on the Mohr-Coulomb failure criterion with a non-associated flow rule. The effective angle of friction (ϕ') and the angle of dilation (ψ) were determined to 23° and 15° for granular material, respectively (based on a best FEA fit of load-settlement relationship for the wall model loading tests, Lee, 2004). The effective cohesion (c′) was assumed to be 0.1 kPa. The variation of E (Young's modulus) was assumed to increase linearly with depth. The soil parameters are summarised in Table 1.

The tunnel support is modelled as two-noded bar element and linear elastic material respectively. The Young's modulus and Poisson's ratio for the tunnel support are assumed to be 15.5 GPa and 0.2. The cross section area of the tunnel support ring is 0.003 m^2.

Numerical FNR (full Newton-Raphson) iterative solution scheme was used with a tolerance of 0.05 and a maximum iteration number of 100. K_0 was applied to the initial in-situ stress conditions and a double

convergence check applied. A total of 250 increments were used.

5 RESULTS

The authors investigated the vertical displacement (S_v) for a half width for the following 2D volume losses, viz. $V_L = 5.83\%$, 10.94% and 15.21% and at the various subsurface levels, as shown in Figs. 10 and 11. The ground deformation data S_v was extracted from the vertical displacement contours provided by the FE runs and by the photo imaging process for the 2D tunnel model tests. For comparative purposes between the numerical and physical models, the authors concentrated the settlement data close to the ground surface (GL.-20 mm) and on a level $1d_0$ above the tunnel axis. It should be noted that the "surface line" of reference markers in the physical models was actually located at GL.-20 mm.

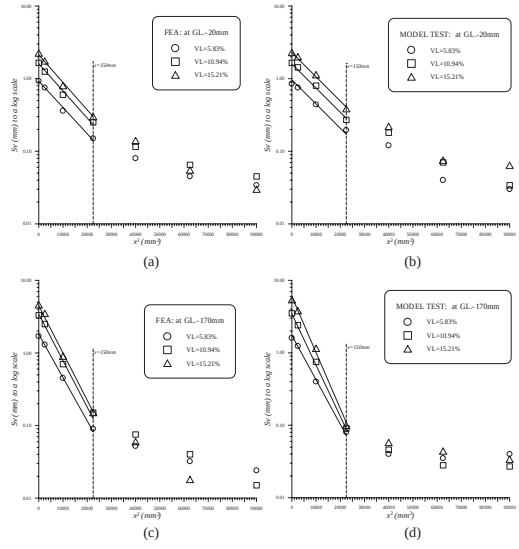

Figure 12. S_v (log scale) – x^2 ($Z_0 = 270$ mm): (a) FE data at *GL.-20 mm*; (b) model data at *GL.-20 mm*; (c) FE data at *GL.-170 mm*; (d) model data at *GL.-170 mm.*

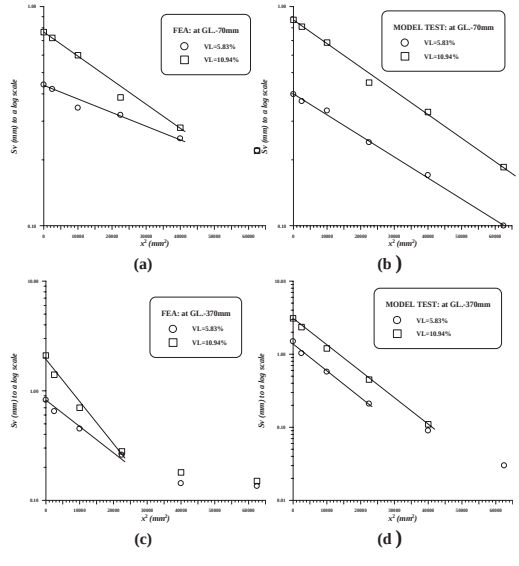

Figure 13. S_v (log scale) – x^2 ($Z_0 = 470$ mm): (a) FE data at *GL.-70 mm*; (b) model data at *GL.-70 mm*; (c) FE data at *GL.-370 mm*; (d) model data at *GL.-370 mm.*

5.1 *Investigation of i values*

In order to investigate whether an inverted Gaussian is an acceptable approximation to both the numerical and the experimental subsurface settlement profiles, all $S_v - x$ data was re-plotted in the form of log scaled settlement to x^2 (Figs. 12 and 13). A true

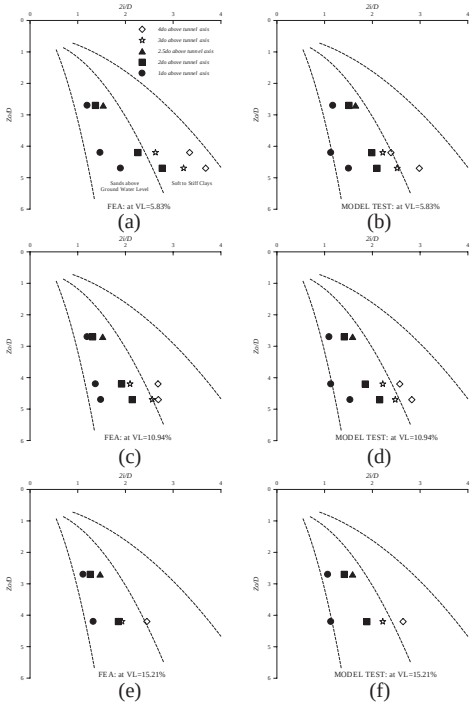

Figure 14. Subsurface settlement profile with tunnel depths: (a) FE ($V_L = 5.83\%$); (b) model ($V_L = 5.83\%$); (c) FE ($V_L = 10.94\%$); (d) model ($V_L = 10.94\%$); (e) FE ($V_L = 15.21\%$); (f) model ($V_L = 15.21\%$).

Gaussian function will provide a straight line on the S_v to a log scale against x^2 plot. The magnitude of i being found at $\underline{S}_v = 0.61 S_{\text{vmax}}$ for which $x^2 = i^2$. The assumed Gaussian error function associated with i values appear to fit both the surface and the subsurface settlement data up to a horizontal distance of 1.5 to 2i in both the FEA and the laboratory model tunnel test (Fig. 12). Beyond that horizontal location, the data does not appear to comply with the same Gaussian function at all. For the deepest case (Z_0 = 470 mm) the model data shown in Fig. 13 the FE analysis shows a similar break at GL.-370 mm but the model data shows subsurface settlement profiles that appear to fit a single Gaussian curve. In the FE case, where the fit does not occur, the authors believe that this is due to the roller boundary conditions applied at the mesh side boundaries which were not remote enough. A fictitious frictional boundary would have been a better assumption or the use of an element to represent the effect of a remote extent of material.

5.2 *The variation of i with depth*

These i values were determined from the data within 200 mm either side of the centre line (i.e. $x^2 < 40{,}000$)

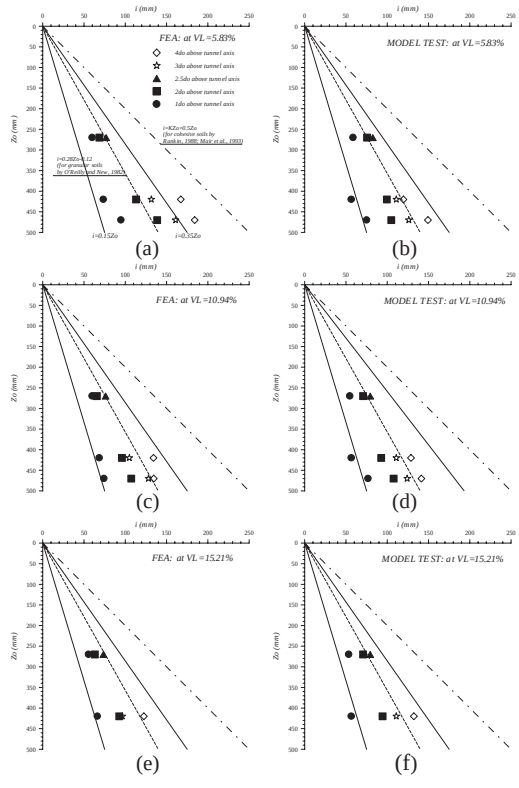

Figure 15. Trough width parameter (i) with tunnel depths: (a) FE ($V_L = 5.83\%$); (b) model ($V_L = 5.83\%$); (c) FE ($V_L = 10.94\%$); (d) model ($V_L = 10.94\%$); (e) FE ($V_L = 15.21\%$); (f) model ($V_L = 15.21\%$).

as discussed above. In Fig. 14, $2i/D$ has been plotted against Z_0/D (D is a tunnel diameter, d_0). As expected, the rods are a dry granular material, the authors' model data all falls in Peck's zone "sand above the water table" (Peck, 1967). The FE data agrees except for the data at small volume loss (Fig. 14 (a)). The physical model values change slightly with increasing 2D volume loss. The FEA values appear to vary quite considerably at high Z_0/D values and different 2D volume loss values. In FEA the zone of influence of a tunnel does not appear to remain consistent throughout its construction. Simple constant spread angle from the centre point or the centre of the invert are not a good representation of the situation throughout the soil depth.

The FE and model data are replotted as i against Z_0 in Fig. 15 and as Z/Z_0 against K in Fig. 16. The settlement trough width parameter (i) for both the FEA and the model tunnel test lie close to O'Reilly and New (1982) for levels 2.5d_0 above the tunnel, but fall to values close to or less than $i = 0.2Z_0$ for levels close to the tunnel crown (i.e. 1d_0 to 2d_0 above the tunnel axis).

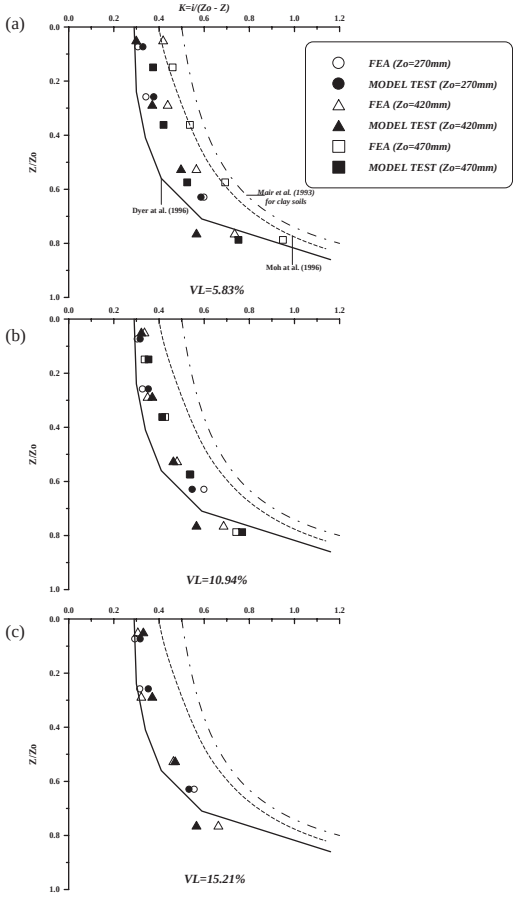

Figure 16. K with tunnel depths for subsurface settlement profiles above FE and model tunnels: (a) $V_L = 5.83\%$; (b) $V_L = 10.94\%$; (c) $V_L = 15.21\%$.

The values of K from both the FEA and the model test lie in a band according to Dyer et al's (1996) field observation as 2D volume loss increased.

6 CONCLUSIONS

In order to provide theoretical deformation patterns associated with shallow and deep tunnels in granular material with increasing 2D volume loss, the CRISP code was used for the finite element analysis and comparisons were made with an idealised laboratory model. Throughout the above comparison the authors reached the following conclusions:

(a) Attention was drawn to a single Gaussian curve, which did not fit well for both the FE and physical model data (Fig. 12), except for the model data for the case of a deep tunnel (Fig. 13).
(b) The i values agreed well with Peck's zone of real field values (Fig. 14) and K values range between 0.15 and 0.35 for dry granular materials (Fig. 15).
(c) The values of K agree very closely with Dyer et al's (1996) field observation data (Fig. 16).

Application of digital image processing in tunnel excavation

Leng Biao*, Qiu Wen-ge, Liu Yang & Wei Hong-chun
School of Civil Engineering, Southwest Jiaotong University, Chengdu,Sichuan, China

ABSTRACT: With the development of civil traffic, more and more roads and railways have been built. Correspondingly, the number of tunnels becomes larger. During tunnel excavation, geological logging and rock mass classification are two major tasks to be concerned, so tunnel face image analysis is essential. Traditional analysis is time-consuming, costly and the effect is different because of different operators. While conventional approaches are limited, graph and image processing and 3D modeling technology are adopted for tunnel face imaging. Tunnel Face Geology Image System (TFGIS) is designed to manipulate tunnel faces. After processing a series of face images which are snapped by tracking tunnel logging, rock edges and rock characteristic information can be acquired, by which rock masses are classified. According to rock corresponding relation between adjacent face images, 3D tunnel model is built up, which can be regarded as reference information on tunneling.

FOREWORD

Traffic–the basis of national economic development– is the prerequisite to social production currency consumption distribution, and it is also very important to ensure national economic persistent healthy development and accelerate national modernization construction.

With the enhancement of national basis construction, roadway net construction will be one of investment emphasis. In many places, tunnel length took up a big proportion of the whole roadway length. In some sections, the proportion came to more than 40–50%. Therefore, tunnel logging and geology detection are very important to totally roadway construction. During tunnel logging, tunnel excavation volume (includes overbreak and underbreak) reckoning geology prediction and tunnel mechanics structure transformation research are often encountered. If those questions can not be well processed, disasters including tunnel collapse and underground water flooding may take place when tunnels are excavated. Traditional observations are manual record face description and photography, which are diverse with different operators. As a result, the data obtained are inconsistent and incomparable. Photos gained from photography have to be rinsed, which can not be digitized and processed in time. The effects of manual analysis are very limited. If the experience and knowledge of analyzers are different, the analysis outcome will be distinct. There is something that can not be touched by manual analysis. For example, in order to know the geology construction of tunnel logged part, tunnel 3D model need to be built, which nearly can not be manually achieved. However, 3D modeling with computer is easier. In 1990's, researchers in Japan applied imaging technology to tunnel faces so as to extract parameters about surrounding rock classification, predict geology structure in front of tunnel faces, observing lining cracks. In 1993 year, QingShui civil construction company developed tunnel face imaging system[1]. In China, software and hardware of under-well drilling vidicon had been systemic designed, which can not only display deep geology structure and play it, but also determine structural plane attitude and joint width[2]. In document [3], the digital photogrammetry was applied into rock mass joint measurement to overcome traditional methods' disadvantage. An interpretation scheme for images of rock mass joints based on digital photogrammetry is put forward. In document [4], the author had studied on rock mass joint measurement based on digital photogrammetry.

Above all, most of study work is still not systemic. However, photogrammetry always includes job site measurement and image interpretation. In this paper, the author systemic analyzes image interpretation. Graph & image processing technology and OpenGL 3D modeling technology are adopted to deal with tunnel face images gained from job site. Rock mass edges are automatically acquired, and manual interference is

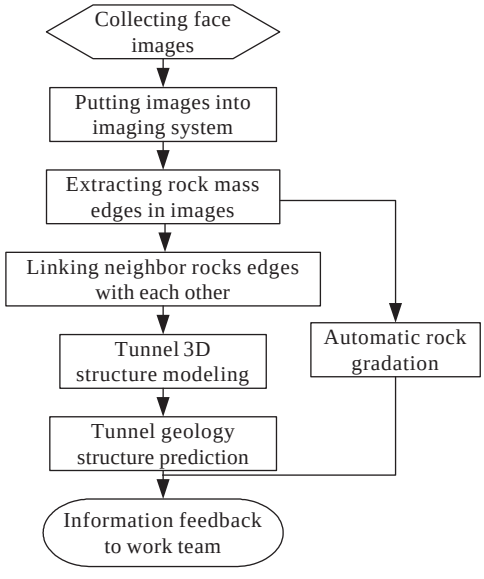

Figure 1. Tunnel face processing flow.

taken as assist step. At last, all rock mass edge information in face images is obtained, then tunnel 3D model is built. According the 3D model tunnel forward geology structure can be predicted.

1 BASIC THINKING

During tunnel logging, tunnel face images are gained by photogrammetry. These face images snapped along with construction schedule are input into imaging system. Every image is processed by digital imaging technology[4]. All rock mass edge information is extracted. After being analyzed by characteristics extraction, rock mass area character parameters are acquired so that rock masses can be classified. At the same time, these corresponding relationships are established between neighboring digital images according rock mass edge information. When all rock mass corresponding relations of all neighboring face images are established, tunnel 3D model then can be set up according edge information. Through this 3D model, tunnel interior geology structure can be observed from all directions. Relevantly, tunnel forward part is predicted from the 3D model. The information is very useful to tunnel construction safety, construction quality and so on. Fig. 1 is the whole flow sheet from photogrammetry to imaging system operation[5].

In the whole procedure, digital image and graph processing pattern recognition and OpenGL 3D modeling technology are needed. Digital image intensification image restoration image segmentation characteristics extraction and so on, which can extract rock mass edges from tunnel face images. Graph processing includes line curve movement distortion and so on, which can edit rock edges. Pattern recognition includes neural network genetic arithmetic vector machine, which can be used to automatically classify surrounding rocks. OpenGL is a 3D graph and model library, which can finish tunnel 3D modeling.

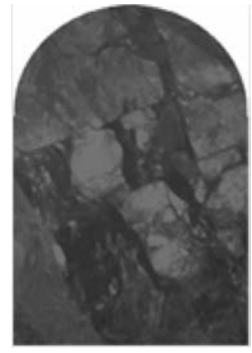

Figure 2. Source image.

2 DIGITAL IMAGE PROCESSING TECHNOLOGY

Digital image[6] and graph processing technology is the base of the whole system. They are complementary to each other. It uses imaging technology to extract rock mass edges of tunnel faces in images. These edges are not always automatically achieved. Therefore, graphing technology is introduced to edit and modify rock mass edges.

Ordinarily, according to processing way, digital image processing includes image preprocessing image segmentation and characteristics extraction.

2.1 *Image preprocessing*

At first, tunnel face images are imported to the imaging system, then these images sorted by shooting time. These images' brightness are often dim. In order that images can be better observed and analyzed, image preprocessing arithmetic is needed. Color equalization processing arithmetic can balance colors distributing among these images, which have a good effect on intensify images. Fig.2 is the source image, and Fig.3 is the result by color equalization processing.

It can be seen from the processing result that the whole brightness and contrast ratio are obviously improved.

2.2 *Image Segmentation*

After preprocessing, the system considers two ways to process images. One way is that edge detection

Figure 3. Color equalization processing result.

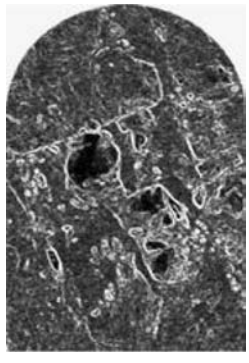

Figure 4. Face image edge detection result.

operators are used to detect image edges. After that, rock mass edges in these images will be more conspicuous. Then these result images are processed to extract edge information. The other preprocessing way is target rock masses segmented directly. From the result, the rock mass edges can also be extracted.

2.2.1 *Edge detection*

The aim of edge detection is that rock mass edges are displayed more clearly. Fig.4 is tunnel face image edge detection result. It can be seen that the edges of rock masses can be well marked using while lines while the none-edge area is darker. The next step is to study how to extract rock edges, then automatic link none-continuous edges.

In practical face images, rock edges and rock mass interior color varies from large range. After being processed binary images, white edges is not always continuous. The result of edge detection is that all edges are detected. Then how to determine which edges are real rock mass edges, and how to link none-continuous edges is difficult. Therefore, it should be considered manual interfere way to link rock edges so that all rock mass edges of rock can be intacted.

Figure 5. Image segmentation result.

2.2.2 *Target segmentation*[7]

Specific arithmetic is used to segment images, and target rocks' internal will become foreground color blocks. Meanwhile, target rocks' external will become background color block. If rocks' internal color block is gained by segmentation, it can be easy to extract these block edges. This can be seen from Fig. 5.

In Fig. 5, white blocks are target rock blocks. From the result of image segmentation, target rock blocks can be well segmented. It will be of great benefit to edge extraction of target rock masses.

Compared to edge detection, target segmentation is more difficult which have to determine whether each area in images belongs to some rock mass target. If target segmentation problem is determined, then it will be easy to find out the boundary of rock target.

2.2.3 *Boundary extraction*

After edge detection and target segmentation, it needs extracting the boundary of rock target blocks in images. From these blocks, rock size can be determined and rock block character parameters can be achieved. According to rock mass block boundary, 3D tunnel model can be rebuilt.

Edge detection is much more difficult than target segmentation when rock mass boundary is extracted automatically. In TFGIS, after rock boundary being extracted from rock mass blocks, the boundary is processed by polygon simulation arithmetic. In Fig. 6, the gray boundary marks are the processing outcome of Fig. 5.

2.3 *Character extraction and pattern recognition*

After rock mass targets are determined, some character parameters can be farther gained from those targets. The purpose of characteristics extraction is that surrounding rock mass level is classified according to character parameters extracted from rock mass. The classification information can be referred to tunnel construction, so that units in charge of construction

Figure 6. Object rocks boundary extraction result.

clearly understand rock level in tunnels and cut down the incidence of emergency accidents.

Characteristics extraction directly analyzes rock mass targets. According to pixel gray level in rock mass target areas, nth moment estimation and texture statistical characters can be acquired. Based on area shape, target long axis short axis round degree and rectangular degree can be acquired. 1D characteristic vector is established with these characters. In some given rule, this vector is compared with all kind of standard rock mass characteristic vectors. If the vector is closer to a standard vector than others, then the rock mass is classified to the standard one. Target rock mass characteristic parameter extracted from some rock mass targets can be seen from Table 1, in which slice number marks different face images, target number names diverse objects in the same face image, gradation is pixels' gray average value in object rocks when separating image color into 256 gray scale, centering coordinate x and y means object's x-axis and y-axis respectively when both face images' length and width are 1 unit.

In general, if the section is different, the geological condition always differs from each other. It is impossible to obtain all standard rock characteristic vector data, so if compared with all standard rock character vector in databases, the actual rock mass characteristic vector data is very different, the actual rock mass image and vector data will be saved in databases so as to provide references for analyzing this kind of rock masses next time.

3 TUNNEL 3D REBUILDING AND 3D PREDICTION

In order to know geology structure of tunnels, it's necessary to rebuild tunnel 3D model. Tunnel geology structures are observed in all directions from the tunnel 3D model.

OpenGL 3D modeling technology was adopted in 3D rebuilding. OpenGL's full name is Open Graphics Library, which is a 3D graph and model library, and it is a new 3D graph industry criterion. OpenGL is not only a graph library, but also an Application Programming Interface.

Table 1. Object rocks character parameter.

Slice No.	Object No.	Gradation average	Center coordinate x	Center coordinate y
1	1	199.179	0.368	0.361
1	2	190.603	0.078	0.687
1	3	192.111	0.839	0.331
1	4	198.727	0.370	0.361

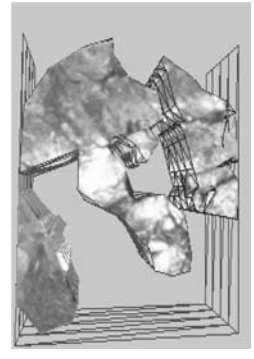

Figure 7. Tunnel 3D model.

3.1 *Tunnel 3D rebuilding*

During tunnel 3D rebuilding, the most important thing is how to link the same rock mass edges in all neighboring face images. Only if the corresponding connections are formed correctly, the 3D model can be exactly restituted. In TFGIS, neighboring image rock mass edges were linked through pattern recognition arithmetic. After that, all face image sequence corresponding relations were constituted. Considering some special construction conditions, rock mass edges can not be linked through pattern recognition arithmetic. Especially when rock dislocation takes place, manual interfere needs to be introduced to modify real corresponding relations between neighboring rock masses. Tunnel 3D model was shown in Fig.7 which was established according to face sequence.

In Fig.7, the outer outline is tunnel profile. The 3D model can be observed in all directions.

3.2 *Tunnel 3D prediction*

According to the 3D model, however, only logged part geology structure can be observed, which is not very useful. The unit in charge of construction always hopes to learn about the geological structure around the

tunnel. This function is offered in TFGIS, by which the structure around the tunnel can be automatically predicted and displayed. Thus the system affords more information, which will be great helpful to tunnel logging and construction units will make much more feasible measures. As a result, construction process will be safer.

4 THE END

Tunnel face image processing and tunnel 3D modeling have been studied for a moment. Yet there is low correlative information that can be found overseas.

(1)There is lots of image processing arithmetic applied in the system, and some new arithmetic is included on the base of real instances. When using this system, operators can process tunnel face with different image processing arithmetic according to different actualities.

(2)When 3D model was built, neighboring face rock corresponding relations were established through pattern recognition arithmetic. Tunnel 3D model was set up according to corresponding relations.

(3)In this system, it is necessary to study much more arithmetic about tunnel overbreak area and excavation volume computing, and it can predict tunnel unlogging geology structure 3D model.

Recent development of tunneling techniques in Taiwan

H.S. Liu, P.C. Hou & C.T. Chang
Sinotech Engineering Consultants, Ltd. Taiwan, ROC

ABSTRACT: Located along the tectonic boundary of the Eurasian Continental Plate and the Philippine Sea Plate, Taiwan is a mountainous island with complicated geological environment. The unfavorable ground conditions pose a severe challenge to tunneling works. Many national development projects such as water transmission lines, railway and highway projects, and hydropower development projects, involve lots of tunneling works. Both of the size and the scale of these tunneling works have been increased significantly from time to time. And the construction techniques have also been improved substantially from project to project. In this paper, the geological environments, which are closely related to tunneling works, are outlined. Then, some technical developments such as support systems etc. are presented. Finally, handling of difficult ground is illustrated. It is hoped that the development of the tunneling techniques can help upgrade the competition capability of Taiwan in international tunneling industries.

1 PREFACE

The current Taiwan tunneling works, including mainly the tunnels of highways, railway, mass rapid transits systems (MRT) and hydropower development projects, are positively pushed forward. However, the future main tunneling works are focusing on the tunnels of urban pipe lines, the extended MRT systems, the island wide highways and railway systems, the hydraulic and hydropower development projects and so forth. It is therefore estimated that approximately 150 tunnels are to be built in the future with total length of more than 400 km.

With the application of the new concepts, new techniques, new construction equipment and new materials as well as the accumulated experiences, Taiwan tunneling works, no matter in quality or quantity, have been achieved with a great development in the current decades. In order to consolidate the results gathered from the previous tunneling experiences in planning, designing and tunneling techniques and to provide as the guidance for the future tunneling works, this paper addresses major subjects of Taiwan tunneling techniques, beginning with a brief description on geological background and geotechnical investigation techniques, following by an overview on the current development of Taiwan tunneling techniques, and a discussion on the concepts and practices to overcome the extremely difficult ground when tunneling. It is hoped that a common consensus among the tunneling industry can be manifested and Taiwan tunneling techniques can be led into a new frontier.

2 GEOLOGICAL BACKGROUND AND EXPLORATION

The island of Taiwan can be geologically divided into four distinct provinces, namely, the Western Coastal Plain, the Western Foothills, the Central Ranges and the Eastern Coast Range, each having different engineering geological characters. The Central Range with precipitous cliff is mainly formed by argillite, slate, meta-sandstone in the Hsuehshan Range and schist, marble, amphibolites and some ultra basic rock in the eastern slope of Central Range. Due to multiphase metamorphism and orogenic process, the rocks in the Central Range are highly contorted and are structurally complicated. Separated by the longitudinal fault with the Central Range, the Coastal Range is formed of a core of Miocene andesite covered with thick andesitic agglomerate, tuffaceous and pyroclastic deposits. Outcropped in the southern section of the Coastal Range is the mélange chaotic with serpentine inclusions. The mélange material in this area is tectonically related with the collision between the Eurasian Plate and Philippine Sea Plate. The Western Foothill Province is formed by Tertiary sedimentary rocks that were folded and faulted during orogenic processes. This imbricate folded and faulted belt system represents

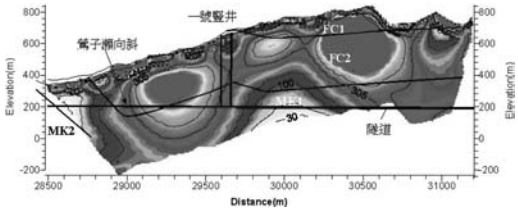

Figure 1. Rip profile showing groundwater distribution along tunnel alignment.

a west-verging deformation front. The Chichi earthquake of 1999 with magnitude of 7.3 can be considered as the outcome of the on-going orogenic process. West of the Foothill area is the Western Coastal Plain mainly composed of unconsolidated material including lateritic gravel tableland, piedmont deposits and recent alluvial deposits.

In the early days the geological investigation was mainly performed by surface mapping supplemented by local subsurface drillings but the drilling depth was highly limited due to technique constrain. In recent years investigation approaches are versatile and more important is that the concept of investigation during construction being part of the overall exploration program is widely accepted in the tunneling industry. The techniques used in explorations include surface mapping, aero-photo or remote sensing interpretation, drilling, geophysical exploration and trench excavation, etc. Among the above-mentioned items, geophysical explorations are widely adopted such as resistivity study, seismic refraction study, tunnel seismic profiling, True Reflective Tomography (TRT). Figure 1 is the results of the resistivity imaging profiling performed along a part of Hsuehshan tunnel of 12.9 km long. For some important project such as at Hsuehshan tunnel project, pilot tunnel parallel to the main tunnels is sometimes adopted for geological exploration purpose. As for the coring technique, drill holes with length more than several hundred meters are very common. Furthermore, horizontal directional drilling technique as shown in Figure 2 was also applied in the undersea exploration for the Circulating Water Discharging System of the Forth Nuclear Power Plant Project in northern Taiwan. The versatile exploration techniques make engineers have a deeper insight into the subsurface geological conditions.

3 RECENT DEVELOPMENT OF TAIWAN TUNNELING TECHNIQUES

3.1 *Portal excavation and slope protection*

Tunnel portal is the critical construction item of the whole tunneling works. In the recent years, due to high rising of environmental protection consciousness, the extent of portal excavation is required as little as

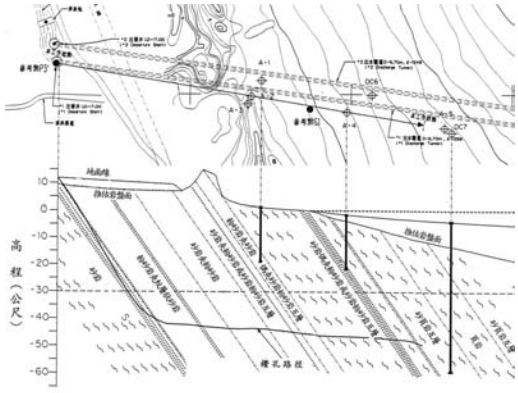

Figure 2. Geological exploration of undersea tunnel project using directional drilling technique.

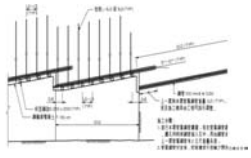

Figure 3. The layout figure of pipe roofing application.

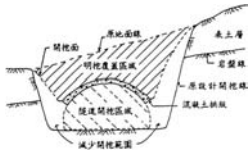

Figure 4. Schematic sketch showing the pre-arch cover method.

possible. In order to comply with such a tendency, most of the tunnel portals are now excavated by the adopting the pipe roofing method to reinforce the stability of portal section. Pipe roofing method is one of the many common methods used in Taiwan for the poor ground sections. The method is carried out by drilling horizontal boreholes on the crown area before inserting steel pipes and then injecting the bonding grout for the ground consolidation, which could build up at the arch of tunnel to form a reinforced umbrella protection ring. Steel pipes used for pipe roofing combined with the rock bolts, steel supports, and the (steel fiber reinforced) shotcrete can create a lattice support system with high support stiffness both in the longitudinal profile and in transversal profile, as Figure 3 indicated. Recent examples in Taiwan are the Lantan Tunnel of Second Freeway, and the Hsinkuanyin Tunnel of North Link Railway, etc.

Alternatively, the false portal section can also be constructed by means of pre-arch cover method as Figure 4 indicated. (Liu et al. 1999) By Pre-arch Cover

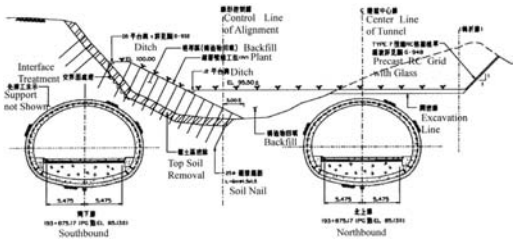

Figure 5. The layout figure of shallow coverage thickened section of Lantan Tunnel.

Method, the portal slope is slightly excavated and cast with the RC cover on the crown before mining in. Depending on ground condition, the feet of the Prearch Cover sometimes need to be pre-reinforced with micro-piles or grouting. The major advantages of the above mentioned methods are to minimize the extent of excavation and the environment impacts. Recent cases in Taiwan are the Lantan Tunnel, the Hsichi Tunnel of Second Freeway Group, etc.

The slope stability of the portal must be assured before mining. Normally, the slope of portal is covered with slope wash or weathered rock. Adequate slope protections are required to avoid slope failure when excavating the portal slope. Factors need to be considered during portal excavation include ground condition, incident angle into the slope, etc. Slope stability analysis should be made with the incorporation of the tunnel portal excavation method. The analysis then can be used as a basis to select an appropriate stabilizing measure, which is constructably, economically, safely and landscape wisely justified. Case examples of measures with ecological approach are the prestressed tendons coordinated with precasted or cast-in-place rebar reinforced concrete grid with plantation for the slope protection or the thickening of the lateral tunnel cover reinforced with grouted rebar, etc. as shown in Figure 5.

3.2 *Support design*

Due to the complexity of ground and the difficulty in the direct application of theoretical mathematic analysis, the design of semi-rigid tunnel support is proceeded in accordance with the experiences of previous design based on the rock mass classification. It must be then examined and verified by means of numerical analysis based upon the estimated parameters of geological investigation and the data of laboratory tests. At the design stage, the ground at the tunneling level must be, in advance, classified into different grades to which adequate support patterns are designed in accordance with the estimated ground conditions. During construction, adequate support system is selected according to the exposed rock conditions. Based on the monitoring data and feedback analyses, it will then be decided whether the support system need to be enhanced or not.

The RMR System of South Africa and Q System of Norway for the rock mass classifications are most popularly used in Taiwan tunneling works today. However, due to the unique geological and geomorphologic characters of Taiwan such as young geological age, drastic change of rock conditions, high cover, on-going orogenic belt, etc., the application of the foreign rock classifications are still not satisfactory based on the monitoring data. In addition, the existing rock classifications are not applicable to the unconsolidated material in western foothill area and western coastal plain of Taiwan. To deal with the young and drastic geological change, the Public Construction Commission of Taiwan establish Taiwan Rock Classification System (PCCR-System) and the tunnel support system which could be more suitable to be used in the local geological conditions and make the design of tunnel support more realistic. The recommended support system for A Rock Mass (uniaxial compressive strength greater than 25 MPa) and B Rock Mass (uniaxial compressive strength between 5–25 MPa) are as Table 1 indicated. (Chang et al. 2004)

3.3 *The excavation methods and construction equipments*

Traditional drill and blast (D&B) method and mechanized tunneling method are widely used in tunneling in Taiwan. In the recent years the drilling machine used in D&B has been advanced to multiple arms Jumbo. As for the explosives, the standard bar type with diameter of 32 mm of 60% to 80% nitroglycerin gelatine dynamite or ammonium nitrate (AN) gelatine dynamite or emulsion gelatine dynamite have been adopted. For the perimeter holes on the excavation face, the detonating cord of containing dynamic at 10 g/m and multiple dynamite bar of half in size collaborated with bamboo spacing filled with the explosive agent or slender bar with external diameter 18 mm contained with 45% to 60% gelatine dynamite is constantly adopted in the recent years as shown in Figure 6. In addition, MS or DS electric delay detonator or nonelectric delay detonator are commonly used in blasting to secure the blasting safety and to improve the construction quality and advance rate.

In addition to the traditional D&B excavation method, mechanized excavation methods such as shield machine, roadheader and TBM are also common in many recent tunneling cases. The shield machine is mostly used in the soft and the weak ground while the roadheader is used in the medium strength rock tunnel. The TBM is merited with average faster speed, less man power required, economic support systems as well as less environmental impact, and

Remark: The shotcrete and the steel support, in the table, all must be based upon the result of individual assessment and to see if it can be replaced by the steel fiber reinforced shotcrete or the lattice girder.

Figure 6. The standard bar type dynamite and the slender type Nitroglycerin gelatine dynamite.

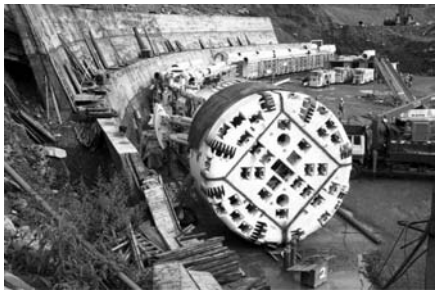

Figure 7. Open type TBM assembled at the outside of portal of Newwuchieh Diversion Tunnel Project.

therefore will be expected to be a major construction method in Taiwan in the future.

The first introduction of rock TBM into Taiwan commenced in the year of 1992 in Hsuehshan tunnel. The performance of the TBM is not as expected mainly due to extremely poor geological condition with large water inflow of the eastern section of the tunnel and lack experience of mechanized construction method. However, many valuable experiences have been accumulated and have been applied to the headrace tunnel of Shihlin Power Project, the diversion tunnel of Newwucheih Project, the circulating water discharging tunnel of Nuclear Power Project No.4, etc. Especially, the Newwuchieh Diversion Tunnel, for instance, had created the fastest monthly advancement record of 659.3 m, as shown in Figure 7.

3.4 *The support materials and the inner lining steel form*

To stabilize the surrounding rock, inner support (permanent support) and outer support (primary support) system are normally required. Since the concept of NATM was introduced into Taiwan, shotcrete, rock bolt, steel support, auxiliary measurement and reinforced concrete lining, etc. have been playing a key role for tunneling support system. The function and the development of main support materials and the inner lining steel form are briefly described as follows:

3.4.1 *Shotcrete*

The main functions of the shotcrete are to seal and fill the rugged surfaces, preventing the ground from stress concentration, and slaking. It will form a thin shell and can contact tightly with the excavated surface. Although the conventional dry-mixed shotcreting are proved to have good capability of compressive resistance, yet the tensile strength, the flexural strength and the ductility performance concerned are relatively poor. However, the mentioned deficiencies can be improved if appropriate amount of steel fiber, superplasticizer, silica fume, etc. can be added into the shotcrete mix. By doing so the advantages include reducing dry shrinkage, preventing the support material from cracking, enhancing the strength of durability, increasing the abrasion resistantability, minimizing the damage caused by collision, increasing the ductility and strengthening the shock resistance. For the application on the design and construction, steel fiber can substitute the wire mesh to save the time of installation for the wire mesh and the thickness of shotcrete. Should the wet-mix shotcrete be used together with robot spray device, not only the rebound ratio but the dust volume can be significantly reduced. With these advantages, the steel fiber reinforced shotcrete can be seen as one of the safe, fast and economic supporting element. The typical steel fiber reinforced shotcrete mix proportion of Lantan Tunnel is as shown in Table 2 (Chang et al. 1998). Similar cases in Taiwan are the Mingtan Pump Storage Power Caverns, the Lantan Tunnel of Second Freeway, etc.

3.4.2 *Rock bolt*

The rock bolts installed in the surrounding rock are designed to assist the surrounding rock to form the rock arch and provide with shearing resistance for potential shear failure in jointed rock. In the early days, the resin rock bolt had been widely used and proved that it can provide with the support function within a short period of time and also provide with anchoring effect when encountered with water seepage. However it needs second corrosion proof grouting, and the resin mix quality can not be easily controlled. With this reasons, the resin rock bolts is currently seldom used in Taiwan. For the moment, the full section grouting type anchor bolt (such as SN anchor bolt) are much widely used. As the system is made of high tensile strength rebar, cement mortar and the fast set accelerator, it is much cheaper than those of other type rock bolts as far as the cost is concerned. Along with drastic progress of the material science, many new type rock bolts have been developed, such as the Swellex bolt, the Hardi bolt, the self drilling rock bolt, the expansion end rock bolt, the glass fiber rock bolt

Table 2. The steel fiber shotcrete mix proportion of Lantan Tunnel. (kg/m^3)

Cement	water	Fine agg.	Coarse agg.	Steel fiber	Silica fume	Accerator	S. p.	Slump
440	207	1,031	566	55	40	8.8	6.6	22 cm

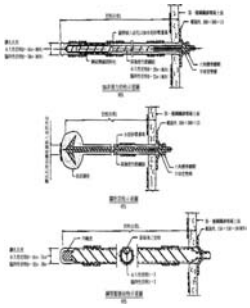

Figure 8. The typical rock bolts.

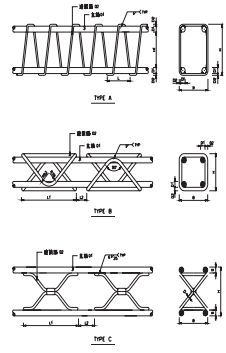

Figure 9. The typical lattice girders.

Figure 10. The needle beam steel form.

and etc., the typical rock bolts as shown in Figure 8. The Swellex bolt, among them, has the advantages of easy installation, quick support effect, suitability to various geological conditions, less environmental contamination, and to meet the requirements of TBM fast advancement. Cases in Taiwan where Swellex rock bolts are used include the tunnel group of Newtenlun Power Project, the tunnel section by TBM of Shihlin Power Project, etc.

3.4.3 *Steel support*

The steel support is designed to share most of rock stress in early age when shotcrete strength is still low and can function as reinforced material for the shotcrete. Furthermore, it can prevent the loose rock from falling down when used with wire mesh. In addition, it can be applied as the template for the subsequent excavation outline. The conventional H beam steel support used in poor ground condition is designed to make use of its wider extensive wing boards which can undertake bigger rock loads. However, the extensive wing boards sometimes hinder the shotcrete from closely contacted with the cut face, which weaking the support performance. To solve the above-mentioned problem, the lattice girder is usually applied to most current projects. The lattice girder usually used was assembled with either 3 or 4 main rebars and spiral hoop rebars (or connection rebars) after the welding. As the space is large enough for the shotcrete to penetrate through, the shotcrete can tightly contact with the rock, and to create with the lattice girder strong rebar reinforced shotcrete structure. The typical lattice girders are shown in Figure 9. The cases where lattice girder were used include the Lantan Tunnel of Second Freeway, most of tunnels of Taiwan High Speed Rail Tunnel Group, etc.

3.4.4 *Inner lining steel form*

To speed up the construction schedule, enhance the construction quality and reduce construction cost, the traditional steel form, with length 8–12 m each are popularly adopted for the most of tunnel inner linings. Nevertheless, it is still limited by the time for the form assembly, the form positioning, the form sealing, the concrete placement, the form maintenance, the form dismantling, the form moving, the form reassembling, etc. , which must be carried out step by step accordingly. Therefore, it causes that the rate of monthly advancement is only about 120 m. In order to overcome the mentioned obstructions, the needle beam steel form and the telescopic steel form, which are provided as the inner lining forms. Normally, all the length of needle beam steel form is not extended over 15 m, as Figure 10 indicated. The telescope steel form

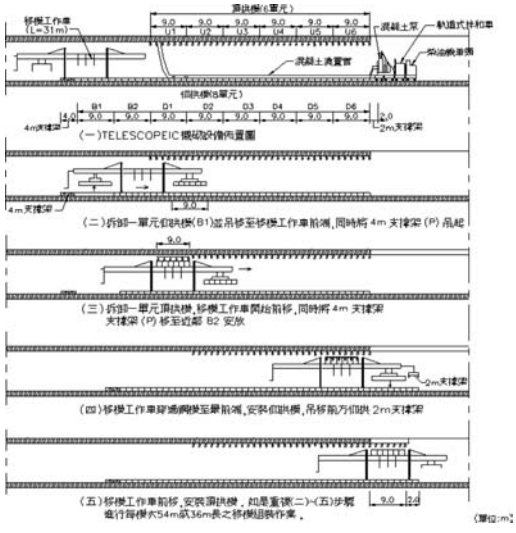

Figure 11. The form moving sequences of telescopic steel form adopted in the headrace tunnel of shihlin power project.

which is used to complete the lining work can be contacted and taken apart, then it must be moved to pass through the steel form at the movement of maintenance and moved to the next work face standing by. Also the steel form must be re-assembled and positioned for the afterward operation of lining works. Thus the steps must be preceded repeatedly until it reaches at the expected terminal position of lining work, so that the telescope steel form can be used for the continuous concrete lining placement. Sequences of telescope steel form moving, as figure 11 indicated (Sinotech 2002). Owing to that the support manner of telescopic steel form is by means of external support with systematic support studs, installed on the outside of steel form and stretched on the excavated rock face (or shotcrete) to against the gravity forces, the buoyant and the lateral forces reacted on the steel form when placing concrete lining. Meantime, owing to that the length of allowable tolerance for support stud adjustment is limited, thus the telescopic steel form is suitably to be used to excavate the tunnel surface which is relatively smooth such as tunnel section by the TBM. The whole set of telescopic steel form is assembled with several sub-forms, generally, with total length of 30–60 m. For the telescopic steel form to carry out its utmost performances, the non-rebar (utmost with re-bar of single layer), the steel fiber of high performance concrete which must be adopted as inner lining materials, thus the form head sealing and the vibration compaction can be eliminated. Meanwhile, the concrete placement can be continuously proceeding. The Headrace Tunnel of Shih Lin Power Project, for instance, the needle beam steel form with the length of 12 m and the monthly average advancement rate 179 m was adopted in the D&B section of upstream while as the telescopic steel form, with length of $9\,\text{m} \times 6$ ones $= 54$ m, and the monthly average advancement rate about 345 m, was adopted in the TBM section of downstream.

4 NEW TECHNIQUES FOR THE DIFFICULT GROUND

The geological structure of Taiwan is very complicated, meantime, the fault zones and the shear zones always cause the tunnel squeezed phenomenon after the tunnel is excavated. Moreover, as Taiwan is located in the subtropical zone with the abundant rainfall, the water inflow is frequently encountered during underground excavation. Obviously, the long and large tunneling works would be faced with big challenges : such as the Hsuehshan Tunnel of Chiangweishui Freeway with total length of 12.9 km (opened to the traffic on June 16, 2006) and etc. In addition to the mentioned fault squeezed zone and the water inflow problem, the high rock pressure, the geo-thermal, the toxic gases, the ventilation, the maintenance, etc. are the major problems need to be solved one by one accordingly. In addition, the tunnel to be cut through the Western Foothills soft and weak sandy clay layers or the gravel strata is really to be faced with big challenge. To overcome such difficult geologies, based upon the present development conditions of domestic and foreign new tunneling techniques, the typical Taiwan Tunneling Methods are developed.

5 CONCLUSION

Tunneling work in Taiwan before 1950 had been carried out by human labors using simple and crude techniques for the excavation of short and small tunnels. However, the conventional long tunnel engineering techniques have been evolved and gradually replaced by machineries today. It fully reflects that Taiwan tunneling techniques has been achieved with a great development. For the coming future, when faced with extremely soft ground and high ground water level in the densely populated metropolitan area, and extremely hard rock and lithological change area in high mountainous area, stringent difficulties could not be avoided. However, the experience gained through previous projects such as Second Freeway Project and Chiangweishui Freeway Project provide us with more confidence to undertake future underground works involved, for example, in cross island freeway systems and many more. In technological improvement, sharing of experience is a very important factor. Taiwan has unique geological conditions for tunneling, and the

local engineers will be glad to share the Taiwan experience with our foreign counterparts. Undoubtedly, international cooperation will contribute to the further upgrading of the technique level of our tunneling industry.

Construction method of connecting tunnel in a shield-driven tunnel

J. Liu
Beijing Municipal Engineering Research Institute, Beijing, China

F. Zhang & H. Kong
Beijing Municipal Engineering Company, Beijing, China

ABSTRACT: According to the design, there should be a connecting tunneling between two shield driven tunnels, the connecting tunnel is often built by NATM in China. In a real project, the geological condition of the ground is typically complex consisting of clayey soil, saturated fine sand, and saturated gravel soil. The soil cover above the crown of connecting tunneling is about 8.0 m, and there are three existing utility pipes passing above the tunnel. Heavy traffic road is directly above the tunnel and there are many old buildings in the same directions as the tunnel center line. Therefore, the construction of this connecting tunnel may take a high risk; moreover, two segments of existing shield-driven tunnels should be removed before this tunnel is dug. Because the location of this connecting tunnel is very sensitive to the surrounding environment, how to construct is a challenge to us, especially, how to remove the two segments is very important in this difficult ground condition. This similar engineering accident has ever appeared in Shanghai. According to the results of numerical simulation, the detailed construction method was constituted to affect the pipelines less and to avoid the large disturbance above the ground, including the remove order of two segments. Besides these, a series of in-situ measurement were carried out during the whole period of construction. After the project was finished, the maximal ground settlement was only 4.1 mm, the whole project was successfully completed without any accident and the surrounding environment was protected very well. At last, the results of numerical simulation were compared with the in-situ measurement, the result indicated that numerical simulation can predict the ground settlement well. It can be said that the experience on this project is valuable to solve similar problems in connecting tunnel between two shield driven tunnels.

1 INTRODUCTION

According to the design, there should be a connecting tunneling between two shield driven tunnels, the connecting tunnel is often built by NATM in China, and the location to be excavated has been designed as two rings of steel segment. The connecting tunnel is located at Dongsi Hutong. Dongsi Hutong is a street, which often has heavy traffic. The soil cover above the crown of connecting tunneling is about 8.0 m, and there are many old buildings directly above this tunnel, especially, there are three existing utility pipes passing above the tunnel: (1) waste pipe, which cross the tunnel, the crown of it is about 2.0 m, the diameter is about 0.5 m; (2) telecom pipe, which is in the same direction of the tunnel, the crown of it is about 1 m; (3) tap water pipe, which is also in the same direction of the tunnel, the crown of it is about 1 m.

According to the report of engineering geologic investigation, the condition of the ground is typically alluvium, consisting of backfill, silty clay, silty-fine sand, medium-coarse sand and gravelly sand, and the groundwater level is about 4 m below the surface. Because of the soft ground and abundant groundwater, the old buildings, utility pipes and road surface are very sensitive to the excavation of the connecting tunnel. Therefore, the construction of this connecting tunnel may take a high risk; moreover, two segments of existing shield-driven tunnels should be removed before this tunnel is dug. It can be seen how to construct is a challenge to us, especially, how to remove the two segments is very important in this difficult ground condition. This similar engineering accident has ever appeared in Shanghai.

In order to solve these problems, numerical simulation was used to study the ground settlement when excavating the tunnel, including the remove order of two segments. Besides these, a series of in-situ measurement were carried out during the whole period of construction. It is well known that the ground settlement may directly affect the surrounding environment, so the most important task is to control the ground settlement.

2 NUMERICAL SIMULATION AND ANALYSIS

2.1 *The calculating model*

The FLAC^{3D} program is performed in this calculation. The calculating model can be found in Figure 1, and the connecting tunnel between two shield-driven tunnels can be found in Figure 2.

The calculating parameters are listed in Table 1.

In this table, material 1 represents segment, material 2 the grouted ground, material 3 the primary support, and material 4 the secondary lining; γ is density, E is elastic modulus, μ poisson's ratio, c cohesion, and ϕ angle of internal friction.

In this calculation, elastoplastic model and Mohr-Coulomb yield criterion are used.

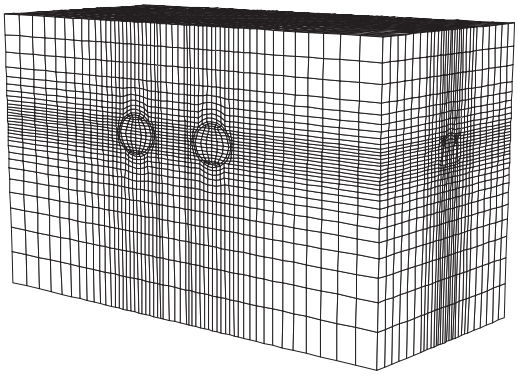

Figure 1. The calculating model.

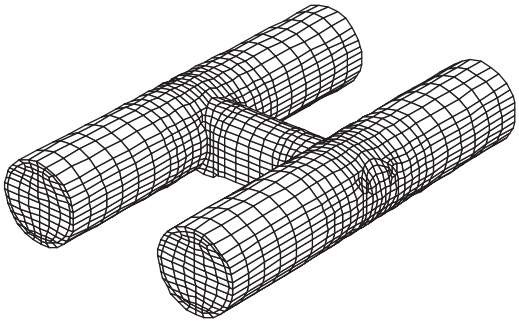

Figure 2. The connecting tunnel model.

Table 1. The calculating parameters used in calculation.

Material	γ (kN/m^3)	E (MPa)	μ	c (kPa)	ϕ (°)
1		34500	0.17		
2	22	30	0.25	75	40
3	25	18	0.2		
4	24	30	0.2		

2.2 *The calculating results*

Through the calculation, the following results are obtained.

(1) The maximal deformation of the crown of the remaining segments is about 9 mm, when the segment is removed and the connecting tunnel is finished (Figure 3).
(2) The convergence of the remaining segments is about 3 mm (Figure 4).
(3) After the segments are removed and the connecting tunnel is finished, the major principal stress of other segments near the excavation face is changed greatly, from compressive stress to tension stress, the value is about 2.77 MPa, but it remains the same opposite the excavation face.
(4) After the two shield-driven tunnels are finished, the maximal settlement of surface is about 15 mm. After the connecting tunnel is finished, the total settlement of surface is about 28 mm, therefore the ground settlement is about 13 mm when excavating the connecting tunnel (Figure 5).

On the basis of theory analysis, the remaining segment will be deformed after the connecting tunnel is

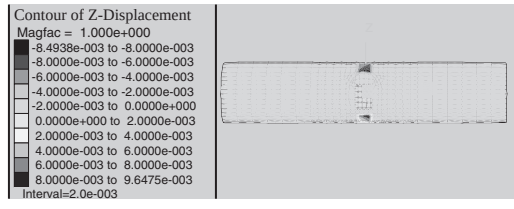

Figure 3. The maximal deformation of the crown of segment.

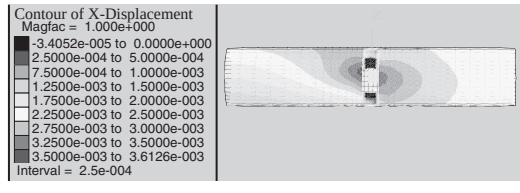

Figure 4. The convergence of the remaining segments.

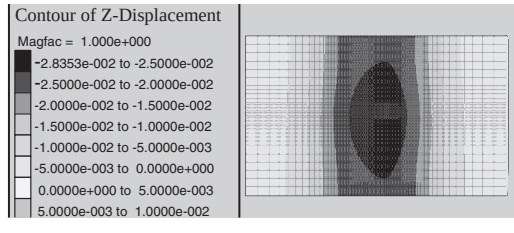

Figure 5. The ground settlement after the connecting tunnel finished.

excavated, and the surface above the connecting tunnel will subside. In order to protect the surrounding environment well, some construction measures should be taken.

3 CONSTRUCTION METHOD

Because of the difficulty ground, the surface above the tunnel may collapse induced by quicksand when removing the segments and excavating the tunnel. Therefore, the ground must be reinforced using cement and soluble glass. The area to be grouted is about 3 m around the tunnel (Figure 6). When grouting, two steps are carried out, that is, the small hole of soil is injected, then the grouted soil is crushed and injected using higher pressure in second step.

Before remove the steel segments in the shield driven tunnel, the remaining segments should be braced temporarily using I-shape steel (Figure 7).

After grouting and bracing, the steel segments of shield-driven tunnel should be removed, and the construction method of connecting tunnel can follow 6 steps as below till the connecting tunnel is finished.

(1) dewater: the remnant groundwater should be drained using small pipe;

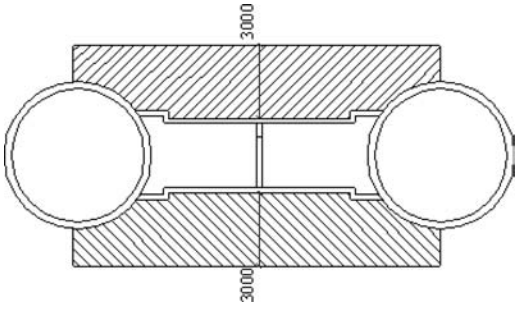

Figure 6. The area to be grouted.

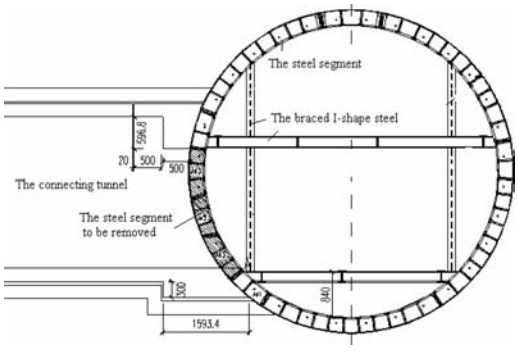

Figure 7. The temporary braced I-shape steel.

(2) removing steel segments: the steel segments should be removed from top to bottom;
(3) excavating: the whole section was divided two steps, and using benching tunneling method. After the upside step was finished, concrete should be sprayed immediately;
(4) install steel frame: three steel frames should be fixed in time;
(5) spray concrete: after steel frame was finished, concrete should be sprayed again;
(6) secondary lining: the primary support could be completed through the steps mentioned above. When the primary support of the whole connecting tunnel was finished, and the deformation of it became stable, the secondary lining should be constructed.

4 IN-SITU MEASUREMENT

In order to ensure the ground settlement and the deformation of segment within the prescribed limit, a series of in-situ measurement were taken out during the period of excavation. For example, the crown settlement of remaining segments, the convergence of remaining segments, the stress of remaining segments, the ground settlement, and the others (Figure 8).

The ground settlement observation points are set along the axis above the connecting tunnel.

As regards the crown settlement of remaining segments, the maximal value occurred (about 6 mm) when the steel segment was removed and upside step of the connecting tunnel excavated into 3 m (Figure 9).

The convergence of remaining segments was about 2.9 mm.

The major principal stress of the segments near the excavation face was about 2.8 MPa, which was tension stress, and opposite the excavation face, the stress was 0.6 MPa, which was compressive stress.

As regards the ground settlement, the maximal value was about 4.1 mm.

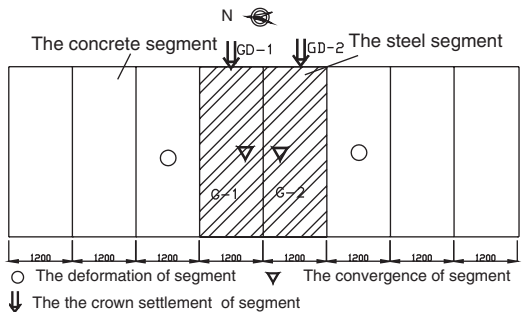

Figure 8. The map of observation points in shield-driven tunnel.

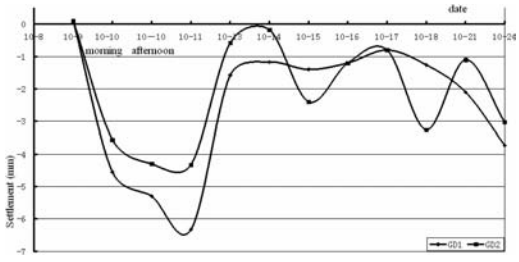

Figure 9. The crown settlement of remaining segment.

5 CONCLUSIONS

Because of the difficult ground and complex surrounding environment, the construction of the connecting tunnel between two shield-driven tunnels may take a high risk, the construction method has been studied in detail. Firstly, the mechanical behavior of the connecting tunnel is simulated using FLAC^{3D}. Then the construction method has been presented, and some measures have been taken, such as grouting the soft soil, using the braced I-shape steel, fixing three steel frame in time, and dewatering in the shield-driven tunnel. The results of in-situ measurements were smaller than that of theory analysis, which indicated that the construction method was suitable for this project, and all values were within the prescribed limit. The pipes and old buildings were protected very well. It is can be said that the experience on this project is valuable for solving similar problems in difficult ground and complicated surrounding environments in urban areas.

Closely constructing influence forecast of hydraulic tunnel under-cross existing railway tunnel

Gong Lun*, Qiu Wen-ge & Wang Fei
School of Civil Engineering, Southwest Jiaotong University, Chengdu, Sichuan, China

ABSTRACT: This paper gives an analysis of the influence which under-cross hydraulic tunnel construction imposed on the existing railway tunnel and discusses the security countermeasure of existing railway tunnel's structure, Using three-dimensional numerical modeling methods associated with the practical situation of Shoupayan Tunnel in the Neijiang - Kunming railway which was under-crossed by Baishuijiang 3-level electric station hydraulic tunnel in Yanjin country of Yunnan province. The results indicate: the hydraulic tunnel construction circle which affects the existing railway tunnel has relation with driving direction. The circle is 2*D* (*D* means the hydraulic tunnel excavation diameter) when adjacence to the existing railway tunnel, while it is 4.5*D* away from; the inflection area of the existing tunnel is 6.5*D* in longitudinal direction and 3*D* in transversal direction. When closely constructing the hydraulic tunnel, the railway tunnel will be occurred deformation such as twist rotation. Monitoring of railway tunnel baseboard settlement, lining distortion, lining transversal/vertical force and vertical vibration velocity at the two tunnels' crossover point in the influence circle of existing railway tunnel must be carried out. In additional, the rail should be reinforced by clasp in order to insure the existing tunnel structure and the train traffic safety.

FOREWORD

With the development of national economy, the building needs were increased constantly for foundation projects in our country[1], the using of underground space was gained developments unparalleled, there were many of closed construction projects which new building structure adjacency existing construction.

At present, there has a certain extent individual research towards appearance underground engineering closed construction in home and overseas: the classification, partition and adjacent degree of underground engineering closed construction; the vibrancy influence of up-down across tunnels[2]; the vibrancy influence of closed blasting towards existing tunnels[3]; the influence of exploiting coal bed to the above highway tunnels[4]; discussing adjacent influence from different position and distance[5]; closed construction influence to each other of overlap and interlace subway interval tunnel when in different distance[6]; the stress redistribution which caused by the new building tunnel driving to the two parallel closed tunnels[7]; the deforming of vertical crossing tunnel in shield construction[8]; surrounding rock stability of the overpass place in up and down run tunnel[9] and so on. in this paper, through the analysis of water tunnel down through railway tunnel in the Yanjin country of Yunnan province, the forecasting and countermeasure research were carried out towards railway tunnel by the construction influence of under-cross water tunnel.

1 ENGINEERING GENERAL

The angle between water tunnel and rail track plane is 82 degree, water tunnel down through railway tunnel, which foundation height mark of plane intersect position is 465.55 m, the water tunnel's top contour is 452.49 m, the clear distance between two tunnels is 13.06 m.

The construction delimitation of Shoubayan tunnel was tunnel limited-2A, macadam track bed, it has cross-section size: clear height 6.55 m, clear width 4.9 m, C20 concrete lining with 40 cm thickness (III degree), grate layer with 20 cm thickness; Water tunnel cross-over the stratum layer of limestone, marlstone rock, sandstone and so on, the circle cross-section with inner diameter 7.0 m, outer diameter 8.1 m, C20 concrete lining with 55 cm thickness.

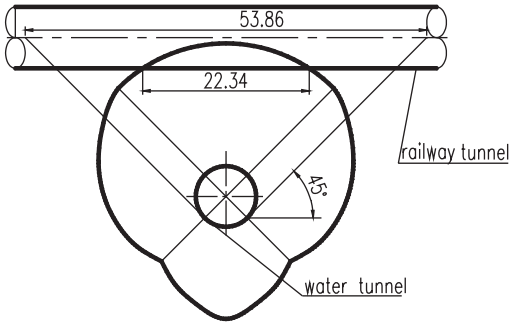

Figure 1. Influence range of railway tunnel by the closed construction of water tunnel (Unit: m).

2 INCIDENCE BY THEORETICAL CALCULATION

For the influence problems of up-down cross closed tunnel construction, longitudinal effect was mainly considered. The existing tunnel which in the weak influence area of new building tunnel was needed to consider longitudinal effect partly; while in the strong influence area was needed to not only consider longitudinal effect but also consider transverse effect partly.

In order to ensure the influence range for which railway tunnel by the closed construction of water tunnel, based on the K. Terzaghi theory, leading-out 45° oblique line as potential break gliding plane, intersect with railway tunnel axial line in order to ensure the longitudinal influence range of railway tunnel, while transverse influence range was determined based on the closed influence partition standard between the two crossing tunnels (Figure 1).

From figure 1: the longitudinal influence range of railway tunnel was 53.86 m (about 6.5D, D was excavation diameter of water tunnel, same as below), transverse influence range was 22.34 m (about 3D).

3 THE INCIDENCE OF NUMERICAL CALCULATION

When using 3D FEM numerical calculation, it could simulate the time and space effect, the mechanics effect of stratum layer and supporting structure during construction, the effect of railway tunnel by the closed construction of water tunnel could be understood generally.

3.1 *Calculation model*

The range of calculation model was consulted to the theoretical calculation result: the left, right and bottom boundary were all adopted 50 m away from the edge of water tunnel, the top boundary has a distance 30 m higher than the existing railway tunnel, the length was adopted 120 m; model constraint: there has horizon constraint of for and after, right and left direction, vertical constraint of bottom plane, top surface was free face; the calculation model was divided to 37008 elements and 38711 nodes totally; using elastic shell element to simulate the linings of railway tunnel and water tunnel, using elastic-plastic entity element to simulate surrounding rock, using Drucker-Prager elastic-plastic nonlinear constitutive model as the constitutive equations of rock and soil[10], calculation model such as figure 2.

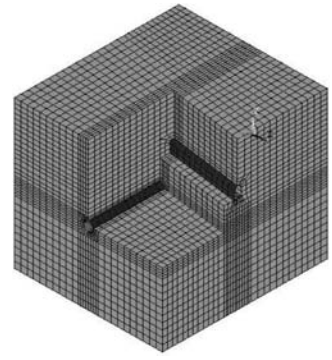

Figure 2. FEM model.

Table 1. Physics mechanics parameter.

Stratum and material	Young's modulus E/GPa	Poisson ratio μ	Bulk density γ/kN/m^3	Cohesion force c/MPa	Internal friction angle f/°
III level wall rock	10.0	0.25	23.0	0.7	39
Lining concrete	28.0	0.18	23.0	—	—

3.2 *Calculation physics mechanics parameter*

The physics mechanics parameter of surrounding rock and lining such as table .1[11]

3.3 *Calculation load and construction process*

The stratum layer's deadweight stress and gravity of concrete lining was mainly considered as calculation load, vertical stress was applied based on the practice depth of burial of tunnel top surface.

Using element kill and alive function which supplied by ANSYS calculation software to implement rock mass's excavation and lining's application during construction, so that it could complete dynamic

simulation of total construction process. The concrete construction process in calculation were: original ground stress field-tunnel excavating and lining applying-the first step excavating and lining applying of water tunnel-· · · · · ·-the last step excavating and lining applying of water tunnel.

3.4 *Calculation result and analysis*

3.4.1 *Water tunnel's construction range which has impact on the railway tunnel*

The relationship curves between settlement which at the cross point of railway tunnel and water tunnel and the horizon distance away from the face of water tunnel as the following figure 3.

The settlement value was 0.005 mm when the face has 15 m distance away from railway tunnel; when the face just at the lower side of railway tunnel, settlement value was not at the most, when the face depart 37 m away from the railway, settlement value at the most (that was 0.102 mm). When the construction of water tunnel in this area, it needed to carry out monitoring for railway tunnel; when out of this area, the settlement impact by the construction of water tunnel to railway tunnel could be ignored.

From the analysis we could know, the construction range of water tunnel which has impact on the railway tunnel was related to the tunneling direction, the distance was 2D when near the railway tunnel, while 4.5D when far away from the railway tunnel.

3.4.2 *The influence that railway tunnel by water tunnel*

1) Deformation analysis

(1) Longitudinal influence range of railway tunnel

The longitudinal settlement canal and its settlement curvature at right side wall basement of railway tunnel such as figure 4 and 5.

A The settlement value was 0.015 mm when the distance was 25.11 m away from the two tunnels' axis cross point left side of the railway tunnel, curvature was $-1.18 \times 10-5$; While at the right side the settlement value was 0.014 mm and the curvature was $1.31 \times 10-5$; The finally settlement value at the cross point was 0.107 mm, so this range was get to the influenced area (length about 50.22 m).

B The Max curvature about longitudinal settlement of railway tunnel was $6.20 \times 10-5$, that was less than the limited value of rail vertical curve $1.0 \times 10-4$, considered the influence of train getting through and blasting vibration in railway tunnel, it needed to make pinch rail for the influenced rail, and make settlement monitor for the ground floor during construction.

C The longitudinal settlement deformation of railway tunnel was similar to the free beam, it needed to carry out checking about longitudinal bend moment and axis force of concrete lining of the tunnel.

(2) The transverse deformation of railway tunnel

The deflection condition of railway tunnel cross section which intersect with the horizon cast shadow of water tunnel at different position of face such as figure 6.

During the whole process of water tunnel down through the railway tunnel, the differential settlement would yield on the cross section.

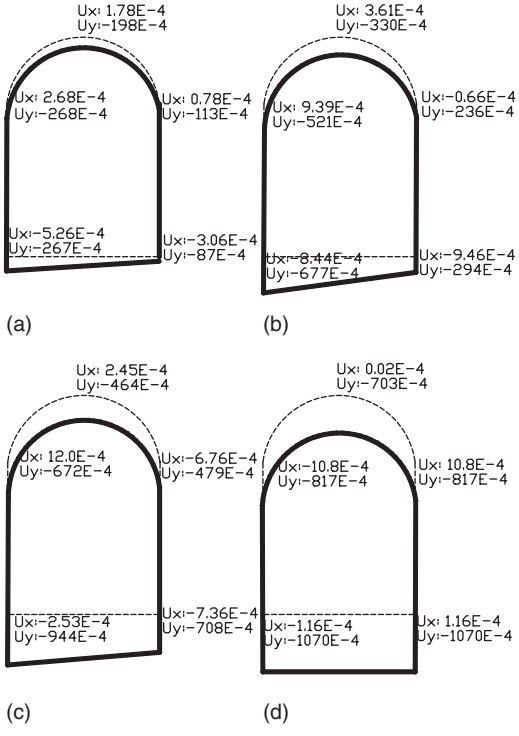

Figure 6. (a) The distance between the face and railway tunnel was 10 m; (b) The face just at the lower position of railway tunnel; (c) The face down through railway tunnel over 10 m; (d) The face over through the influenced area. The cross section displacement of railway tunnel.
Note: Ux: horizon settlement; Uy: vertical settlement.

The face was not at the position of railway, cross section would incline to the face direction, such as figure 6(a); when the face at the just lower position of railway tunnel, the slant value of cross section was reach the Max, such as figure 6(b); since with the driving of the face, the slant value of cross section would release gradually, such as figure 6(c); when the face out of the influenced area, cross section would not incline, getting back standing state, but brook away the original position, there were vertical settlement at each observed points and the horizon settlement with the character of symmetry, such as figure 6(d).

From the deflection process of cross section we could know, the twist rotation deformation would be yielded of railway tunnel by the construction influence of water tunnel. When discussing the structure security of railway tunnel, it needed to carry out inner force examination of bend moment and axis-force about the transverse section of concrete lining.

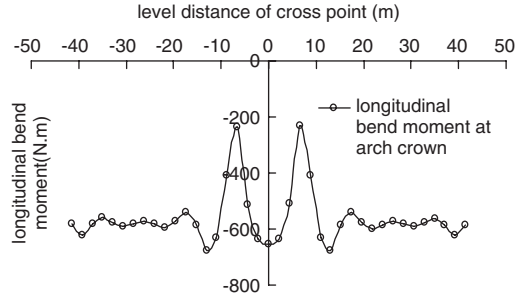

Figure 7. Longitudinal bend moment at the arch crown of railway tunnel.

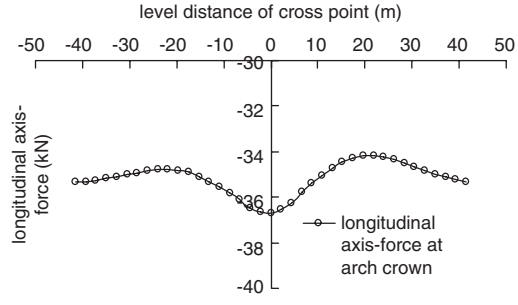

Figure 8. The longitudinal axis-force at arch crown of railway tunnel.

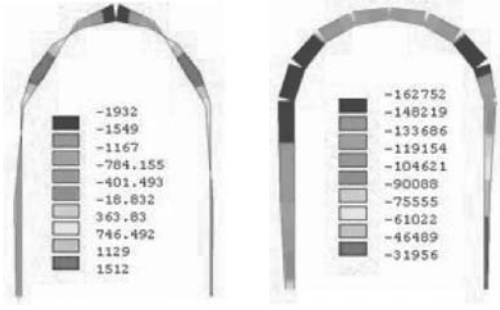
In theory, when symmetry construction was adopted for water tunnel at the both sides of railway tunnel, because the symmetrical characteristic, it could avoid creating twist distortion for the railway tunnel.

2) Stress analysis

(1) Longitudinal stress

The longitudinal bend moment and axis-force at the arch crown of railway tunnel after the water tunnel down through such as figure 7 & 8.

The longitudinal bend moment (678.58 N.m) reach the Max at the cross point $\pm$ 13.10 m away from the railway tunnel; while reach the Min (232.52 N.m) at the point $\pm$ 6.55 m. The longitudinal axis-force at the Max bend moment point was -34735 N. Based on the bending press structure the inner force checking was carried out to the Max bend moment section, the Max longitudinal press stress of concrete lining was $4.39 \times 10 - 3$ MPa, the value was less than the concrete tolerance press stress 11.0 MPa.



(2) Transverse stress

The bend moment and axis-force of cross section such as figure 9.

Known from the longitudinal and transverse direction stress checking of lining concrete of

Table 2. The stress checking table of lining structure.

Check computation part	Concrete grade	M/N.m	N/N	Linear eccentricity e_0/m	Resist compression safe coefficient	Resist extension safe coefficient
Vault	C20	1932	104621	0.018	59.5(>2)	–
Hance	C20	1512	162752	0.009	38.4(>2)	–

(a) bend moment (unit: N · m) (b) axis force (unit: N)

Figure 9. The bend moment and axis force of cross section.

railway tunnel, the lining of railway tunnel could satisfy the safety requirement, it needn't to carry out special reinforcement for lining concrete. Considering the influence of blasting by mining method construction and train getting through in the tunnel, it needed to carry out monitor for longitudinal and transverse direction lining concrete of railway tunnel.

4 INFLUENCE FORECASTING AND COUNTERMEASURE

Based on the calculation analysis above, the countermeasure of railway tunnel by the construction influence of water tunnel and the construction forecasting area of water tunnel which has influenced on the railway tunnel such as below:

(1) The construction area of water tunnel which has influenced on the railway tunnel was related to the driving direction, while the distance was 2D when near the railway tunnel and 4.5D when away from the railway tunnel. When adopting the blasting construction method of water tunnel in this area, it needed to carry out vertical vibration monitor for the cross point of two tunnels in the railway tunnel.
(2) The longitudinal influenced area of railway tunnel was 6.5D, while transverse influenced area was 3D. It needed to carry out buckle rail method for the rail which in the influenced area of railway tunnel, and to carry out monitor for the ground floor of railway tunnel.
(3) By the influence of tunnel construction of down through water tunnel, twist rotation deformation would be occurred of railway tunnel. If using the method of symmetry construction at both sides of railway tunnel for the water tunnel, such deformation would be avoided; If using one-way construction method, it needed to decide deformation value strictly, and to carry out lining deformation monitor of railway tunnel during construction.
(4) The lining concrete could satisfy safety requirement of railway tunnel, it needn't to carry out special reinforcement for lining concrete. Considering the influence of blasting by mining method construction and train getting through in the tunnel, it needed to carry out monitor for longitudinal and transverse direction lining concrete of railway tunnel.

The implement of each influence countermeasure above, the main purpose was to ensure the safety of railway tunnel structure and train operation.

5 THE END

During the construction water tunnel of Baishuijiang three degree hydroelectric station down through Shoubayan tunnel of Neijiang-Kunming railway in Yanjin country Yunnan province, this influenced forecasting result was applied sufficiency. During construction process, the monitoring was carried out for the ground floor settlement, lining deformation and stress and vibration speed when in blasting, and buckle rail method for the rail. At present, the water tunnel was getting through the closed influenced area of two cross tunnels successfully, so it showed the correctable and feasible of this influenced forecasting result.

Monitoring of the state of pipes in sewage networks as an element of adapting such networks to the technical demands of modern, urban subterranean infrastructure

C. Madryas & B. Przybyła
Wrocław University of Technology

ABSTRACT: A strategy for adapting sewer networks to the demands of modern cities is becoming more and more vital. Intensification of the usage of underground space has brought about the need for new research on the operation, modernization and renovation of sewer networks. Leaving this issue unsolved would make the sustainable development of cities impossible. As an element of such a strategy, the monitoring of technical conditions in sewers concentrates on: (1) determining short-term actions leading to an improvement in the operational reliability of a sewage network, (2) predicting the technical condition of a network, in order to optimally plan the financial resources allocated to renovation and improve long-term reliability, (3) optimising, given the existing constraints: the technology used for renovation, the materials used, the range and form of renovation and the modernization of a network (including integrated systems i.e. utility tunnels). This will enable the adaptation of a network to modern methods of utilizing underground space. This paper presents the current issues, guidelines and principles for the monitoring of sewers, together with a discussion on practical aspects.

1 INTRODUCTION

The elements in a sewage network were built in different eras, from various materials with greatly differing properties (stone, brick, concrete, polymer concrete, stone, cast iron, PEHD, PCV, GRP), which leads to problems in maintaining the condition of such systems. Damaged elements in the network cause many negative effects on the surrounding environment.

The location of sewage networks under roads (from 2 to 10 m) and, in particular of gravitational pipes, cause serious problems and sometimes even prevent changing the location of these pipes, in order to build other subterranean installations. These traits are fundamental constraints on the construction of e.g. pedestrian subways or shallow tunnels for road traffic. However, they have become an important incentive for the dynamic development of non-invasive techniques and technologies for renovating and monitoring the technical state of pipes.

A strategy for adapting sewage networks to the needs of cities of the future are particularly necessary. In order to adapt cities to an increased density of subterranean installations, it is above all necessary to undertake research into perfecting the processes of exploiting, modernizing and restructuring sewage networks. The balanced development of urban agglomerations will not be possible without such work. Monitoring the elements in a sewage network is an element of such operations aimed at obtaining the necessary information to assess their technical state and choose the appropriate means of renovation and improving the reliability of the network.

2 MONITORING DURING THE PROCESS OF NETWORK RENOVATION

2.1 *Monitoring as an element of the renovation process*

The process of renovation is conducted for a specific time referred to as the renovation time. This is the length of time from assessing a pipe to be unsuitable until its return to active service and is the sum of the following times:

- monitoring time, determining the location of damage – t_K,
- diagnosis time, determining the cause and scale of the damage – t_D,
- repair time (sum of the following times: for carrying out formal procedures, preparing projects, transporting the required materials and carrying out construction work – t_N,
- for testing after repair – t'_K.

Figure 1 illustrates these elements of the renovation time along the time axis

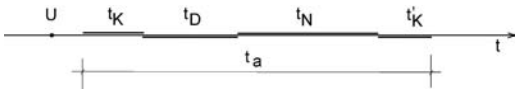

Figure 1. Components of renovation process: U – demage, t_K – monitoring, t_D – diagnosis, t_N – renovation, t'_K – testing after repair.

As can be seen from figure 1, the time at which the damage occurs us not the time at which the renovation of the pipe starts (the time at which the pipe is monitored). This is due to the fact that damage in sewage networks is often not immediately observable and the damage caused depends, to a large extent, on the length of time that passes between inspections. Hence, it is necessary to choose the frequency at which inspections are made, such that the costs caused by undetected faults are less than the costs of inspection.

A fundamental question is the optimization of the renovation time, particularly in cases when a so called by-pass is necessary or (even worse) when invasive renovation, which disturbs the normal functioning of the city, is required. In such cases, the social costs caused by extended renovation times may well be extremely high. Ignoring the renovation time t_N, the most important determinants of the renovation time are the monitoring and diagnosis times. Assuming that diagnosis is in the form of a in-depth inspection of the technical state of a pipe, the sum of the monitoring and diagnosis times to a large extent determines the efficiency of the renovation process. The inspection techniques used, competency of the inspectors and the skill of the diagnosticians play a fundamental role in minimising these times. These and other factors imply the need to continuously search for optimal renovation and diagnostic techniques, as well as inspection timetables and improving formal procedures.

The fundamental task of monitoring and diagnostics is to discover damage and determine the cause, respectively. An inspection may result from the observation or evidence of damage to the network. Such inspection is unplanned and occurs at an unknown rate. Diagnosis and repair of appropriate elements in the network is required. An inspection may also be carried out as part of a monitoring strategy.

In practice, the time required to localise the damage may sometimes exceed the repair time. The inspection/localisation of damage may be carried out by workers either directly observing the pipe or with the aid of remote monitoring devices. In organisational terms, an inspection may by facultative, logical or logical-facultative. It should be noted that sewage pipes (in contrast to the majority of technical installations) may well be able to carry out their function even when damage has been caused to several elements (e.g. leakage at junctions), although from a technical point of view the state of such elements would be deemed to be non-operational. This means that diagnosis must cover the entire section of the network in which a fault may have occurred and must be continued, even when a fault has been found.

If an element is found to be faulty and the fault localised, then the next step is diagnosis. The goal of diagnosis is to determine the cause of a fault and seriousness as quickly as possible. Additional inspections are sometimes needed within the framework of diagnosis. This requires the appropriate procedures and equipment. Such inspections should be carried out by a technical specialist and sometimes require laboratory tests in addition to in situ tests, particularly in order to define the parameters of the construction materials and the degree of the degradation caused by chemical and biological corrosion. It should be stressed that sometimes inspections are commissioned to incompetent individuals or firms, which may result in mistakes and unsuccessful renovation.

The testing time t'_k depends on the type of work carried out, the equipment used and the skill of the inspectors. Standard testing after repair is based on observing the renovated channel using CCTV or by direct inspection from inside large pipes. Due to the complexity and high costs of some repair techniques, there are cases in which testing after renovation requires laboratory testing of the parameters of the construction materials used to renovate a channel. In this case the testing time may be long.

2.2 *Monitoring as an element of a strategy for renovating a network*

Companies involved with the running of a sewage system carry out a planned or quasi-facultative monitoring strategy, which may be classified into the groups described below. These are presently treated as conventional strategies for the technical renovation of a sewage network.

The "Fire Service" Strategy. Such a strategy calls for inspections only in the case when an element has failed (analogous to a fire service which simply puts out fires). Due to the "hidden" nature of subterranean infrastructure (unforeseen faults suddenly appear), such a strategy is very commonly used. However, analysis of previous faults can lead to significant improvements. Sections of networks which have been particularly prone to faults may be systematically monitored. In this way, without carrying out expensive inspection, statistical analysis may be used to attain a higher level of reliability. It should, however, be stated that most unexpected failures have to be repaired using invasive strategies, which create large "social costs" in the functioning of a city. This means that the "fire service" strategy should be replaced by other strategies, which remove negative changes in the network before

they cause a failure, even though the costs of such monitoring schemes are higher.

Strategy of "relieving". Such a strategy does not call for the renovation of old elements in the network, but is based on the building of new elements in order to e.g. relieve the burden placed on older elements. Strictly speaking, this is not a renovation strategy, but rather a system for increasing the reliability of the system. Since they are less burdened, older elements in the system are less often subject to failure, which increases the reliability of the system. This strategy is often used in transport industries, transporting water and gas and less often for sewage networks and supplying heat. It should be stressed that such strategies are associated with costs for predicting the future demand of a good and does not solve the problem of old elements which are subject to gradual decline. Thus, this cannot be treated as the only option for water supply companies.

Strategy of regular replacement (prevention). Elements of the system are replaced by new elements at regular intervals, regardless of whether they are in a poor state or not. Of course, an element is replaced if it fails (hence we can distinguish between profilactic and forced changes). Such a strategy is normally used in systems, whose elements have short operative lives whose variance is small. It is possible to mathematically estimate the optimal time at which an element should be replaced (such a strategy is called a preventative strategy with the optimal replacement time T_{opt}). In practice, due to the multiplicity of factors affecting the operative life of pipes (such elements are designed to have a long operative life, at least 50 years independently of the material used), this strategy is not used in sewage networks, but only for minor elements in the system eg. manhole covers, safety valves, locks.

Strategy of renewal based on monitoring. While the previous systems do not require a system of monitoring a network, in this case renovation comes as a result of inspection and assessment of the state of elements in the system. If, as a result of an inspection, an element is assessed to require repair (its state is in some defined critical set), it is renovated. Such an approach requires the definition of indicators of the state of an elements and the states requiring renovation, based on the level of wear/damage of the element. The methods used for monitoring (inspection) must be specified, i.e. observation of these indicators, time between inspections, the methods for storing and analyzing the results of inspections. The costs involved depend on the strategy adopted and the reliability of the system.

In the case where the results of an inspection are used only to determine which elements should be renovated, the scope of a firm's medium-term planning and records are constrained. In order to eliminate this problem, the results of inspections may be stored and then analyzed in order to obtain prognoses regarding the behaviour of the system in the future. This leads to the final strategy to be considered here:

Strategy of renewal based on monitoring and prediction. A prognosis for the evolution of the wear/aging of elements in a sewage network using long-term monitoring of a system, taking into account all possible constraints, together will the boundary conditions of the functioning and characteristics of the materials used, is the basis of such a strategy.The dates of future inspections and renevations are planned with reference to this prognosis. The prognoses made basically regard the physical process of wear on the elements. Another question is the determination of the so called "moral" level of wear of an element, which is an important factor when a firm plans its budget.

It is easy to see that a strategy of renewal based simply on monitoring can be developed into such a strategy when enough material has been collected to carry out the appropriate statistical analysis.

3 SYSTEMS OF MONITORING

The systematic monitoring of sewage network is carried out in order to observe the state of its elements and the level of corrosion. This is part of a firm's maintenance programme. Moreover, monitoring the network includes inspection of the elements of the network which lie above the surface and detection of collapses along the channels.

The implementation of a strategy of prevention with the optimal replacement time T_{opt} requires information regarding the reliability of the system. Since water companies do not normally have such information, it seems reasonable to start by using a renovation strategy based on monitoring and gradually switching to a renovation strategy based on monitoring and prediction when enough information has been obtained. This is the standard approach to the monitoring of elements in most modern, well-managed firms.

A monitoring system, which is a key element in a renovation strategy, can be defined as an multilevelled inspection system carried out at constant or variable intervals based on criteria indicating the order in which inspections should be made in the various parts of the network. In organisational terms we may distinguish the following types of inspection: routine, detailed and specialist. This classification is based on the exactitude and frequency of inspections. Routine inspections (with the lowest degree of exactitude q_1) are carried out with the most frequency and at regular intervals, Δt, detailed inspections (with a higher degree of exactitude q_2) are carried out at intervals which are multiples of Δt. Specialist controls are only carried out when the results of a routine or detailed inspection are unsatisfactory. Hence, such inspections appear at random intervals and do not have to be

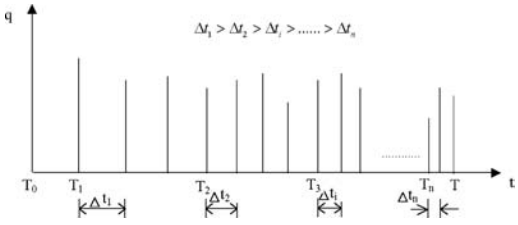

Figure 2. System of sewer inspection (Madryas, 1993) T_i – general overhauls, Δt_i – mean time between inspections, q – coefficient of the exactitude of an inspection.

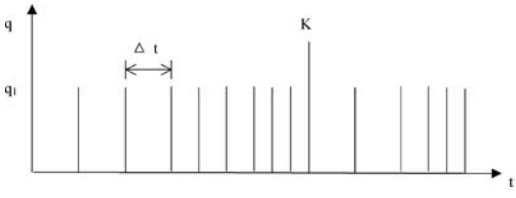

Figure 3. Generalised system for monitoring a sewage network Δt_i – mean time between inspections, which is constant or variable depending on the state of the pipe or the prognosed age/level of wear. q – coefficient of the exactitude of an inspection. K – coefficient of the exactitude of a detailed inspection carried out when planning the renovation of an element or testing after carrying out emergency repair resulting from a fault.

included in the calculations for optimising the costs of routine and detailed inspections.

In order to limit the losses associated with an undetected fault, it is necessary to minimise the length of time between the ocurrence of the fault and the moment of its discovery. Hence, it is necessary to inspect pipes which are more subject to faults than other pipes. Figure 2 illustrates a system which on observing a worsening of the state of a pipe, increases the frequency of inspection, together with an appropriate change in the exactitude of inspection q (Madryas 1993).

The majority of pipes in a sewage network are of large enough diameter to allow inspections by workers from inside the pipe. Hence, it is relatively straightforward to adopt the appropriate exactitude of inspection. In this case, the appropriate recording instruments should be used to analize the state of the system, which is used to determine the time and the exactitude (or at least a bounded interval for the exactitude) of future inspections. However, in the case of smaller pipes a significant increase in the exactitude of inspection requires direct, specialist observation and this requires exposure of the element under observation (invasive work) and normally the element should be isolated from the rest of the network. At the same time, similar methods may be used in pipes of larger diameter. Hence, a generalised system may be proposed for monitoring a sewage network (see figure 3). Such a scheme is adapted to each specific case, according to the goals of each individual inspection, the goals of the whole system of monitoring, as well as the skills and technology available in a given water supply company. In the simplest form of such a system, one may assume that inspections carried out using video cameras are of exactitude q_1, whereas an inspection of exactitude $K > q_1$ enables detailed planning of any repair work to be done.

4 SELECTIVE AND EXHAUSTIVE INSPECTIONS, THE PRIORITY OF INSPECTIONS

4.1 *Exhaustive inspections*

Taking into account the size of an urban sewage network and the constrained funds of water supply companies, the choice of the length of time between inspections should depend on the classifaction of an element, together with the possible consequences of a fault. It is necessary to choose:

– the elements which are to be inspected first,
– a policy for adapting the monitoring strategy according to the results of inspections.
