For my wife, Jennifer
my sons,
Matthew and Tristan

Eppur si muove
(And yet, it does move)
Galileo Galilei after recanting Copernican beliefs

Preface

So here it is, most of the way through 2015, 8 years after my last effort on this topic, and I am writing yet another preface to yet another edition on evaporites. Once again, my aim is to give you, the reader, a timely overview of our current understanding of all matters evaporitic. That is why the reference list is now the length of a novella and I have added three new chapter topics compared to the 2006 incarnation. And, to massage my ego, I have included the word compendium in the title.

For the first time, the publishers have allowed me to compile an all-colour version, rather than grey-scale. As the use of paper copy for scientific publishing recedes, publishers are finally moving into the digital world, sometimes scratching and screaming. Then again, copyright and intellectual property issues related to information and intellectual property on the internet will be an earner for the legal profession for decades to come. A digital base to any scientific compilation allows a breadth of coverage in the topics and an accessibility to information that is unprecedented, as in all other scientific fields. You can see this evolution in information access in the page lengths in each of my four books on evaporites. The first, in 1989, was a few hundred pages long; the second in 1999, was over 500 pages; the penultimate effort, published in 2006 was over 1,000 pages long; and this current effort runs to more than 1,800 A4 pages.

Yet I now store and access the hi-res digital version of the complete volume, along with numerous other volumes, as a side issue of the use of my smart-phone. On the same device I can link to, search, review and download copies of all related digital information anywhere in the world I can access the net. Needless to say, this is one old-fart scientist who is impressed by this technology. It is a far cry from the 128k Mac that in the mid-1980s I lugged to a house on the coast of Denmark, along with three shipping cases of photocopied references in order to write the first book. On the downside, open internet access has led to a plethora of cacography, prattle and unsubstantiated opinion given as fact.

In this volume I make much more use of online sources, outside the various libraries and subscribed publishing websites. This makes many of the issues and data compilations discussed in this book, both more current and perhaps more relevant but also more readily dated and updatable at the same time. As I sift through much of the unscientific chaff that is presented as fact on the internet, I am very aware of both the strengths and current weaknesses of science conducted on the internet. Outside of the mainstream literature from subscribed publishers and some democratic government bodies, much online material is opinionated and/or uploaded with minimal peer review. As with much educational policy in the Western world these days, the internet approach is by its nature multicultural, largely non-judgemental, non-authoritarian and unfortunately, in terms of science, often phrased in terms of political correctness.

As a rationalist and a non-theist, I welcome the vast increase in freely available knowledge the internet brings. But I worry that logic and rationalism, which underpin all valid science is being lost in many places of education across the developed world. It is swamped in a tsunami of opinionated quasi-superstitious information. In science, not all points of view are equally valid, there are testable hypotheses and then there is opinionated bumpf. One expects the latter from politicians and religious zealots, unfortunately it has entered

matters that should be science-based, such as much of the current climate change discussion, as well as environmental discussions related, for example, to aforesaid climate change, hydrofracing in shale gas exploration, and other low-cost energy-recovery methodologies, as well as the relative merits of vaccinating children and the use of genetically modified crops. It says something about one's intellectual approach to a scientific problem if you tend to use the term skeptic as a pejorative.

Besides the scientific effort involved in writing this book, in order to give the volume broad utility and consistency, a good proportion of the blood, sweat and tears that I put into this volume involved preparing numerous colour illustrations and tables. I hope I have given improved value to the various authors listed, in my converting, compiling and revamping what were mostly their grey-scale and line drawings into Bezier-based colour outputs (all scaled figures with north to top, unless denoted otherwise). For this, thanks also to Saltwork Consultancy Pte Ltd for giving me permission to publish aspects of their evaporite GIS datasets as figures in this volume. In the digital form of this volume, figures should be extractable through any PDF reader and I hope will make a useful teaching and research resource for presentations and writings for anyone interested in matters evaporitic.

I would like to thank the various companies: Chevron Thailand, PDO, PTTEP, SaltWork Consultants Pte Ltd; Shell Brunei, Shell Oman and Statoil, who for the last 20 years have paid my salary allowing me to work as a company-sponsored academic in universities in interesting regions of the world where academic bureaucracy is subjugated to the peoples' thirst for education. So thanks as well, to my host universities of the past two decades: Universiti Brunei Darussalam, Sultan Qaboos University of Oman and Chulalongkorn University, Bangkok. This support has meant my academic teaching for the past 20 years has been based in developing world, in various places where you can be a full-time academic, publish and do research without being involved in the petty bureaucratic politics and political correctness that today plagues the efficiency of most federally and state-funded universities of the Western world.

Most importantly and most completely, my thanks to my wife Jennifer, who even after more than 40 years of marriage still manages to live with her at times abstracted other half.

Bangkok, Thailand John K. Warren

Contents

1 Interpreting Evaporite Textures 1
What is an Evaporite? 1
Solar-Heated Brine Concentration 1
Cryogenic and Other Non-solar Saline Mechanisms 2
Burial and Hydrothermal Salts 5
So, What Exactly Is an Evaporite? 8
Primary Evaporitic Carbonates 12
Carbonate Laminites (Subaqueous?) 13
Strandzone Associations: Microbialites, Pisolites and Tepees 14
Vadose Pisolites, Ooids and Coated Grains 32
Tepees 35
Carbonates: Present and Past 37
Primary Evaporite Salts 39
Gypsum Beds 39
Halite Beds (Chevrons and Crusts) 44
Pedogenic and Wind Reworked Salts 48
Laminites from Settling of Pelagic Salts 54
Salt Reefs, Are They Real? 58
Secondary (Diagenetic) Evaporites 60
Intrasediment Salts 60
Syndepositional Karst in Crusts 62
Shallow Mineralogic Re-equilibration 65
Burial of Sulphate Evaporites 69
Evaporites as Uplift Indicators (Tertiary Evaporites) 74
Fibrous Gypsum and Halite (Satinspar) 76
Anhydrite Rehydration at the Microscale 79
Saline Clay Authigenesis 80
Textural Synthesis 83

2 Depositional Chemistry and Hydrology 85
Quaternary Deserts and Evaporite Assumptions 85
Quaternary Evaporites in a Köppen Climatic Framework 92
Local Variations in Climate 98
Chemical Evolution of Surface and Nearsurface Brines 103
Marine Brines 103
Nonmarine Brines 112
Separating Marine from Nonmarine 120
Back Reactions 121
Marine Aerosols and Continental Gypsum 123
Acid Groundwater in Continental Saline Systems 127

Indicators of Brine Parenthood 132
Bromine Profiles – Parentage or Stability? 132
Sulphur and Oxygen Isotopes 135
Boron Isotopes 138
Chlorine Isotopes 140
Fluid Inclusions and Brine Temperatures 144
Seawater Evolution 147
A Phanerozoic Dilemma: Marine Versus Nonmarine Potash? 147

Interpreting Evaporite Textures

1

What is an Evaporite?

I define an evaporite as a salt rock that was originally precipitated from a saturated surface or nearsurface brine in hydrologies driven by solar evaporation (Fig. 1.1a). This simple definition encompasses a wide range of chemically precipitated salts and includes alkali earth carbonates (Table 1.1). Some workers restrict the term evaporite to salts formed at the earth's surface via solar evaporation of hypersaline waters. To underscore the highly reactive nature of evaporites in the sedimentary realm I think of such evaporites as primary, that is, precipitated from a standing body of surface brine and retaining crystallographic evidence of the depositional/hydrological process set where they formed (e.g. bottom-nucleated or current-derived textures). Outside of a few Neogene examples, there are few ancient evaporite beds with textures that are wholly and completely "primary." Most in the subsurface exhibit "secondary" (burial-related) textures, while remnants that have be uplifted back to the surface show "tertiary" (exhumation-related) overprints (Figs. 1.2 and 1.9).

We can contrast the solar-driven set of precipitative processes with other surface and subsurface water-loss mechanisms that can form bodies and beds of mineral salts, with the same chemical compositions as rocks typically called evaporites as listed in Table 1.1. And yet, if applying the term evaporite in its strictest form (i.e., a response to solar-driven evaporation), this second group of mineral salts/sediments are not "true" evaporites; rather, they are mineral salts that crystallized in response to various cryogenic, hydrothermal and burial processes.

Solar-Heated Brine Concentration

In its broadest definition, evaporation is the process by which molecules in a liquid (water) spontaneously become gaseous (water vapour) and escape the liquid state, while evaporites are the resultant mineral precipitates accumulating in and around an increasingly saline residual brine that has reached a state of supersaturation with respect to a particular mineral salt or salts. Water molecules in the liquid phase are in continuous motion and so will collide. As they collide, they transfer energy to each other in varying degrees, based on how they collide. Evaporation, then, is a simple matter of solution kinetics in this milieu of molecular motion and is a response to varying degrees of heat absorption at the molecular scale.

On average, water molecules within a standing at-surface brine lake or in near-surface pore spaces, near a watertable and its associated capillary zone, do not have enough kinetic energy to escape the liquid phase and so cross the surface tension barrier. Otherwise, liquid water would turn to vapour spontaneously, any at-surface liquid phase would spontaneously disappear, while recharge to an underlying watertable would be an impossibility. Every so often, the level of solar energy transfer (heat absorption) at the molecular collision site is sufficient to give a water molecule (near the water-air interface) the heat energy necessary to pass into the vapour phase and so exit the liquid water mass (Fig. 1.1a). That is, for a water molecule to escape into the vapour phase it must absorb heat energy, be located near the liquid surface, be moving in the proper direction and have sufficient energy to overcome liquid phase intermolecular forces and pass through the surface tension interface. As the concentration of the residual brine increases the specific heat capacity decreases and the density increases (Fig. 1.1b, c). Specific heat is a measure of how much heat is required to raise the temperature of the brine by 1 °C.

In the absence of air movement, water vapour so created resides within the region immediately above the air-brine interface, or in the vapour phase in the gaseous portion near the top of the capillary zone, immediately below the land surface and above the watertable. Typically, the rate of evaporation atop a standing brine body, or in the uppermost few centimetres of a sabkha mudflat, increases with increasing temperature and decreases with increasing salinity (Bonython 1966). It also increases with the passage of dry winds over

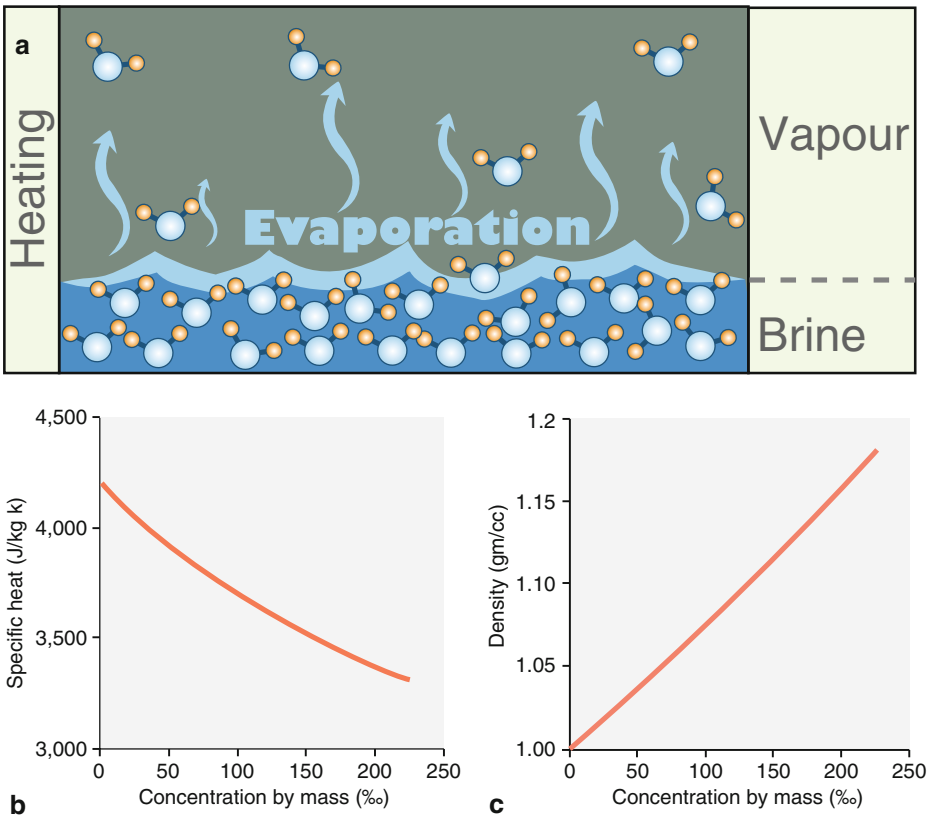

Fig. 1.1 Brine formation by loss of liquid water volume and can occur at any liquid water surface, either at the surface of a standing water body or in a pore. (**a**) Evaporation: the rate of evaporation and consequent rate of brine formation is controlled by rate of molecular passage of H_2O across the vapour – liquid interface. (**b**) Decrease in specific heat with increase in concentration of NaCl solution. (**c**) Increase in density with increase in concentration of NaCl concentration

the brine lake or mudflat as this removes the overlying mass of an otherwise static water vapour cloud. If the water vapour layer is not blown away, it becomes increasingly saturated (humid) and so slows the rate of evaporation, even as the salinity of the underlying water mass increases (Chap. 2). In contrast, if the temperature atop the air-brine interface decreases, the vapour phase can pass back into the liquid phase via condensation. This explains the moisture droplets that form overnight in many saline arid settings and coat rock and salt crust surfaces in the early mornings in most coastal sabkhas. Condensation (not rainfall) explains many of the microkarst runnels that decorate the surfaces in intercrystal vadose contacts of subaerial halite crusts, so obvious in salars in the Andes and in the salt crusts that make up the Devil's Golf Course in Death Valley, California.

Cryogenic and Other Non-solar Saline Mechanisms

In contrast to the formation of evaporite minerals by solar-driven evaporation (heating) of surface and nearsurface waters in hot arid and semi-arid climatic settings, cryogenic brines and associated salts require temperatures at or below the freezing point of the liquid phase. Cryogenic salts, such as hydrohalite, mirabilite, antarcticite and epsomite, can then accumulate. They crystallize in a cold, near-freezing, residual brine as it concentrates via the loss of its liquid phase, which is converting/solidifying to ice (Fig. 1.3a). As brine concentration increases, the freezing temperature deceases (Fig. 1.3b). Hydrohalite is a stable precipitate in a freezing brine only when the water temperature is below 0 °C (Fig. 1.4a).

Hydrohalite ($NaCl{\cdot}2H_2O$) crystals have pseudo-hexagonal cross sections and are found in a number of modern cold saline lakes. Craig et al. (1974) collected hydrohalite from the lake bottom in saline Lake Bonney in Antarctica, where bottom water temperatures vary between +2.0 and −2.0 °C. Nikolaevsky (1938) observed hydrohalite forming in winter in the Baskunchak salt lake, northwest of the Caspian Sea (48°N latitude). It was seen to form on two occasions when formative brine temperatures were between −3 and −23 °C, while in summer halite precipitates. Hydrohalite also occurs in bottom sediments in salt-saturated cryogenic lakes in Saskatchewan, at about 51°N latitude, and has been observed in nearby saline springs sediments of the Northern Great Plains (Last 1989a). Hydrohalite pseudomorphs occur as halite crystals with hexagonal cross sections in cores some 100–140 m deep, in Death Valley, California, indicating NaCl cryogenesis has occurred in the Pleistocene Death Valley Lake from brines with temperatures that were less than 0 °C (Roberts et al. 1997). The climatic significance

Table 1.1 Major evaporite minerals: less saline alkaline earth carbonates or evaporitic carbonates are indicated by **, the remainder are the more saline evaporite salts

Mineral	Formula	Mineral	Formula
Anhydrite	$CaSO_4$	Leonhardtite	$MgSO_4{\cdot}4H_2O$
Antarcticite	$CaCl_2{\cdot}6H_2O$	Leonite	$MgSO_4{\cdot}K_2SO_4{\cdot}4H_2O$
Aphthitalite (glaserite)	$K_2SO_4{\cdot}(Na,K)SO_4$	Loewite	$2MgSO_4{\cdot}2Na_2SO4{\cdot}5H_2O$
Aragonite**	$CaCO_3$	Mg-calcite**	$(Mg_xCa_{1-x})CO_3$
Bassanite	$CaSO_4{\cdot}1/2H_2O$	Magnesite**	$MgCO_3$
Bischofite	$MgCl_2{\cdot}6H_2O$	Meyerhoffite	$Ca_2B_5O_{11}{\cdot}7H_2O$
Bloedite (astrakanite)	$Na_2SO_4{\cdot}MgSO_4{\cdot}4H_2O$	Mirabilite	$Na_2SO_4{\cdot}10H_2O$
Borax (tincal)	$Na_2B_4O_7{\cdot}10H_2O$	Nahcolite	$NaHCO_3$
Boracite	$Mg_3B_7O_{13}{\cdot}Cl$	Natron	$Na_2CO_3{\cdot}10H_2O$
Burkeite	$Na_2CO_3{\cdot}2Na_2SO_4$	Nitratite (soda nitre)	$NaNO_3$
Calcite**	$CaCO_3$	Nitre (salt petre)	KNO_3
Carnallite	$MgCl_2{\cdot}KCl{\cdot}6H_2O$	Pentahydrite	$MgSO_4{\cdot}5H_2O$
Colemanite	$Ca_2B_5O_{11}{\cdot}5H_2O$	Pirssonite	$CaCO_3{\cdot}Na_2CO_3{\cdot}2H_2O$
Darapskite	$NaSO_4{\cdot}NaNO_3{\cdot}H_2O$	Polyhalite	$2CaSO_4{\cdot}MgSO_4{\cdot}K_2SO_4{\cdot}H_2O$
Dolomite**	$Ca_{(1+x)}Mg_{(1-x)}(CO_3)_2$	Proberite	$NaCaB_5O_9{\cdot}5H_2O$
Epsomite	$MgSO_4{\cdot}7H_2O$	Priceite (pandermite)	$CaB_4O_{10}{\cdot}7H_2O$
Ferronatrite	$3NaSO_4{\cdot}Fe_2(SO_4)_3{\cdot}6H_2O$	Rinneite	$FeCl_2{\cdot}NaCl{\cdot}3KCl$
Gaylussite	$CaCO_3{\cdot}Na_2CO_3{\cdot}5H_2O$	Sanderite	$MgSO_4{\cdot}2H_2O$
Glauberite	$CaSO_4{\cdot}Na_2SO_4$	Schoenite (picromerite)	$MgSO_4{\cdot}K_2SO_4{\cdot}6H_2O$
Gypsum	$CaSO_4{\cdot}2H_2O$	Shortite	$2CaCO_3{\cdot}Na_2CO_3$
Halite	NaCl	Sylvite	KCl
Hanksite	$9Na_2SO_4{\cdot}2Na_2CO_3{\cdot}KCl$	Syngenite	$CaSO_4{\cdot}K_2SO_4{\cdot}H_2O$
Hexahydrite	$MgSO_4{\cdot}6H_2O$	Tachyhydrite	$CaCl_2{\cdot}2MgCl_2{\cdot}12H_2O$
Howlite	$H_5Ca_2SiB_5O_{14}$	Thernadite	Na_2SO_4
Ikaite**	$CaCO_3{\cdot}6H_2O$	Thermonatrite	$NaCO_3{\cdot}H_2O$
Inyoite	$Ca_2B_6O_{11}{\cdot}13H_2O$	Tincalconite	$Na_2B_4O_7{\cdot}5H_2O$
Kainite	$4MgSO_4{\cdot}4KCl{\cdot}11H_2O$	Trona	$NaHCO_3{\cdot}Na_2CO_3$
Kernite	$Na_2B_4O_7{\cdot}4H_2O$	Tychite	$2MgCO_3{\cdot}2NaCO_3{\cdot}Na_2SO_4$
Kieserite	$MgSO_4{\cdot}H_2O$	Ulexite	$NaCaB_5O_9{\cdot}5H_2O$
Langbeinite	$2MgSO_4{\cdot}K_2SO_4$	Vanthoffite	$MgSO_4{\cdot}3Na_2SO_4$

Documented dolomite composition ranges from $Ca_{1.16}Mg_{0.84}(CO_3)_2$ to $Ca_{0.96}Mg_{1.04}(CO_3)_2$. Less common evaporite minerals, such as borates, iodates, nitrates and zeolites are not listed here, but are discussed in detail in Chap. 12

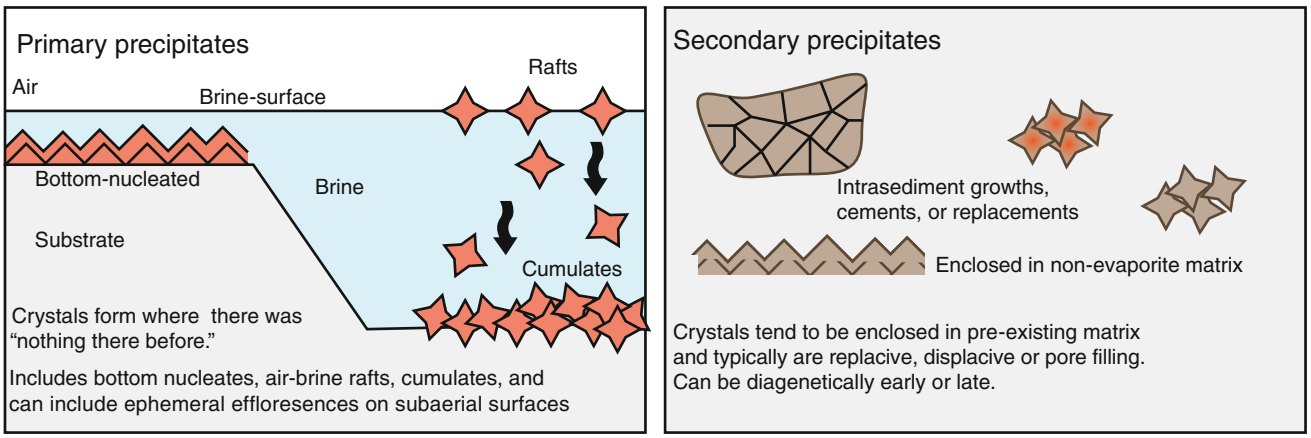

Fig. 1.2 What are primary and secondary precipitates?

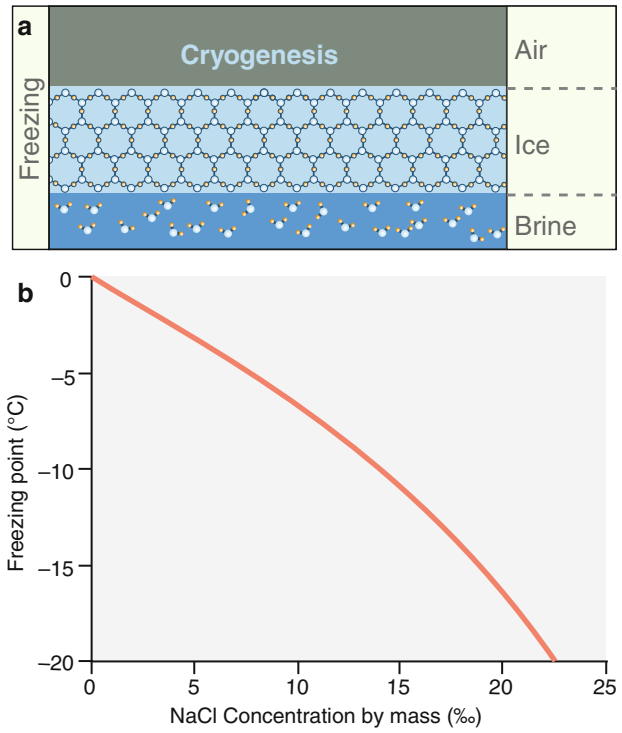

Fig. 1.3 Cryogenesis: (**a**) Brine is formed and concentrated as cations and anions are excluded from the lattice structure of ice (pure water) as it solidifies. (**b**) Brine freezing temperature falls as the NaCl concentration increases

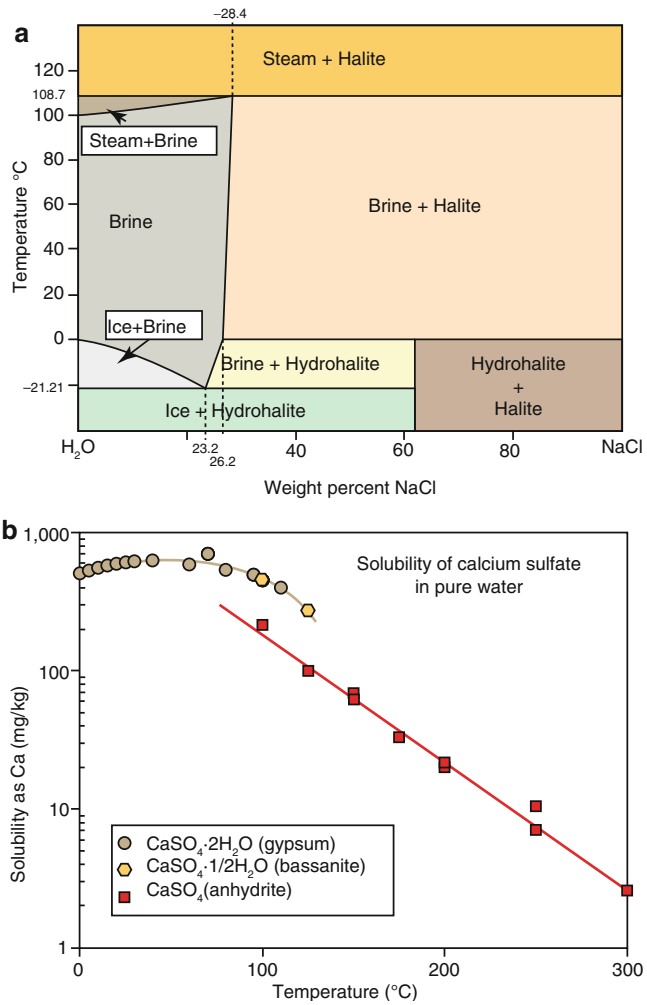

Fig. 1.4 Temperature dependence of (**a**) hydrohalite and, (**b**) $CaSO_4$ (After Cohen 1989)

of such cryogenic salt is discussed in Chap. 2, while economic deposits of cryogenic lacustrine mirabilite are discussed in detail in Chap. 12.

When polar seawaters freeze on Earth, hydrohalite and mirabilite ($Na_2SO_4{\cdot}10H_2O$) precipitate from the residual marine brines and accumulate in ice sheet fissures, or in load-induced fractures in the ice understory wherever an increasingly saline brine sinks into rocks fractures beneath ice sheets. For example, there are numerous mirabilite beds on the ice floes of the Ross Ice Shelf near Black Island. Likewise, there are dense residual saline brines in interstitial waters extracted from deep cores in sediments of McMurdo Sound (Brady and Batts 1981; Frank et al. 2010). It seems that when ice sheets retreat, the at-surface cryogenic salts dissolve in the freshened at-surface hydrology, but the dense hypersaline brines remain behind in deep fissures, held and preserved in the rock fractures (Starinsky and Katz 2003). In the extreme setting of at-surface brine freezing in small saline depressions in the Dry Valleys of Antarctica, a solid form of calcium chloride, antarcticite, grows cryogenically in what is probably the most saline perennial natural water mass in the world (47 % salinity in Don Juan Pond, Antarctica; Horita 2009).

Extraterrestrially, cryogenesis explains sulphate salt phases that typify ice crack fissures crisscrossing the surface of Europa (a moon of Jupiter) and growing seasonally in soils of Mar. Widespread gypsum is also forming via ice ablation in the circumpolar Martian dunefield (McCord et al. 1998; Wentworth et al. 2005; Masse et al. 2012). On Earth, as ground temperatures increase, cryogenic salts tend to deliquesce or convert to their high temperature daughter salts (thenardite, glauberite and halite). Worldwide, in appropriate cold climatic settings, there are also numerous examples of cryogenic hydrated calcite (ikaite-glendonite after $CaCO_3{\cdot}6H_2O$ – see James et al. 2005).

Silica is not normally considered an evaporite salt, but some forms of chert (finely crystalline silica) do accumulate as primary chemical/biochemical precipitates in evaporitic settings. For example, there are hypersaline chert-filled vugs in magnesite crusts in some of the hypersaline alkaline lakes of the Coorong region, Australia (Peterson and Von der Borch 1965) and there are abundant chert co-precipitates (early diagenetic) in Miocene lacustrine beds in the Ebro Basin, Spain (Orti et al. 2007). Then there are thermalitic opal-A cherts associated with hot springs about the edges of

many saline lakes, exemplified by the hot spring precipitates of the East African rift lakes (Owen et al. 2008). These likely-biomediated carbonate and silica terrestrial precipitates crystallize as mineral salts in somewhat saline settings, but unlike other evaporitic mineral salts, these syndepositional calcite and silica cements are not considered a possible variation on an evaporitic theme by the majority of the sedimentological scientific community.

I will leave it up to the purists to decide which of the various "heated" and "freeze-dried" salts, carbonates and silica cements that form at or near the earth's surface, in environments influenced by variations in solar radiation, are "true evaporites."

I am quite happy to call them all variations on the evaporite/mineral salt/brine theme. If not, then the classic thick widespread Quaternary-age cryogenically-formed mirabilites that evolved into the glauberite beds that underlie and typify Karabogaz Gol, and the extensive mirabilite bed in the shallow subsurface of Great Salt Lake, Utah, in two of what are considered by many to be better-known evaporite systems of the Quaternary, are not "true' evaporites. Nor are the mirabilites forming today on the floors and in the mudflats of modern salt lakes across the Canadian Plains.

Burial and Hydrothermal Salts

Substantial volumes of mineral salts, with compositions typically considered evaporite mineralogies, such as anhydrite and even halite, can precipitate in the deep subsurface of the earth in response to heating, cooling, or to increases in pore fluid salinity. None of these process sets, which can typify large parts of the crustal subsurface, are directly solar-driven. Perhaps the resulting mineral precipitates are best classified as hydrothermal or burial salts rather than "true" evaporites. In the sabkha chapter we shall see how retrograde solubility of anhydrite may drive its precipitation as modern sabkha thermalites; the same retrograde precipitation mechanism also drives the formation of burial anhydrites.

The term burial salt is a general descriptor (as defined by Warren 1999, 2006) that encompasses a set of mineral salts created by diagenetic and metamorphic processes that can precipitate mineral salts in the vicinity of a dissolving and altering subsurface salt mass (salt beds, diapirs and allochthons). This is especially so in zones where two brines mix, which premixing had different salinities and chemical constituent proportions. In the sabkha chapter we shall see how retrograde solubility of anhydrite may drive its precipitation as modern sabkha thermalites; the same retrograde precipitation mechanism also drives the formation of burial anhydrites different salinities and chemical constituent proportions. In the subsurface, such burial salts tend to form pore or fracture fills, located wherever the most permeable subsurface conduits were at the time of brine mixing and precipitation. A burial salt is not a true evaporite in that it is not formed by solar evaporation but, the fact that its ionic constituents are typically derived by the dissolution/alteration of a nearby evaporite, means most geologists consider burial salts in sedimentary basins to be evaporites. The precipitative processes driving formation of burial salts are typically heating, cooling or mixing of basinal waters of two salinities, typically derived by the dissolution of subsurface salt masses or relict hypersaline pore brines (see Chap. 2 for detailed discussion of the relevant literature).

The most common burial salt forming within or near a mass of buried evaporites is a sparry poikilotopic anhydrite, as typifies porosity-occluding cements in many reservoir sands in the North Sea (Sullivan et al. 1994). Halite cements can also be burial salts and both minerals are derived by the subsurface flushing of the nearby evaporites, as in carbonate-sliver reservoirs encased in Infracambrian Ara Salt in the South Oman Salt basin (Schoenherr et al. 2009). Timing of the onset of such subsurface dissolution and reprecipitation as burial salts can be late or early (e.g. Schoenherr et al. 2009; McNeil et al. 1998; Kendall 2000).

Hydrothermal salt is a broader descriptor than burial salt and encompasses a higher temperature range for mineral precipitates than the diagenetic realm, Such salts typically formed in heated subsurface fractures or at seafloor vents where hydrothermal waters are escaping, mixing, degassing heating and cooling. Hydrothermal anhydrite crystallizes due to anhydrite's retrograde solubility, whereby $CaSO_4$ becomes less soluble with increasing temperature (Fig. 1.4b). This is why, in the vicinity of active basaltic ridges on the deep seafloor, anhydrite is the dominant component of "white smokers" and is commonplace in other hydrothermal vent mounds; it is also why anhydrite is a major early component of many VHMS seafloor mounds (e.g. TAG Mound where it can constitute more than 50 % of the rock mass; Chap. 16). Hydrothermal anhydrite precipitates in response to the heating of seawater in regions where magmatically-driven hydrothermal fluids are escaping onto the seafloor. In contrast, baryte, another marine hydrothermal precipitate, has prograde solubility and precipitates when an escaping barium-bearing brine is cooled by interacting and mixing with seawater (accordingly the S and Sr isotope signatures in the two precipitates reflect their origins – Paytan and Kastner 2002).

Hovland et al. (2006a, b) and Hovland and Rueslatten (2009) introduced the concept of substantial volumes of hydrothermal halite precipitating from subsurface brines at supercritical temperatures, especially in deeply buried rift-related sedimentary basins. The model relies on heated subsurface waters becoming supercritical and so transforming to a fluid that does not dissolve but precipitates salt (within specific temperature and pressure ranges). A supercritical fluid

is defined as any substance at a temperature and pressure above its critical point; in such a state it can effuse through solids like a gas, and dissolve materials like a liquid. In addition, close to the critical point, small changes in pressure or temperature result in large changes in density. The critical point (CP), also called a critical state, specifies the conditions (temperature, pressure and sometimes composition) at which a phase boundary ceases to exist. Under certain pressure/temperature conditions, supercritical water is unable to dissolve/retain common sea salts in solution (Josephson 1982; Simoneit 1994; Hovland et al. 2006a).

When seawater brines are heated in pressure cells in the laboratory they pass into the supercritical region at a temperature of 405 °C and 300 bar pressure (the CP of seawater). A particulate 'cloud' then forms via the onset of 'shock crystallization' of NaCl and Na_2SO_4 (Fig. 1.5a). The sudden phase transition occurs as the solubility of the previously dissolved salts declines to near-zero, across a temperature range of only a few degrees, and is associated with a substantial lowering of density (Fig. 1.5b). The resulting solids in the "cloud" consist of amorphous microscopic NaCl particles with sizes between 10 and 100 mm. The resultant "salting out" can lead to the precipitation of large volumes of subsurface salts, as well as the ability to carry high volumes of hydrothermal hydrocarbons prior to the onset of supercritical conditions (Josephson 1982; Fig. 1.5c). Supercritical water has enhanced solvent capacity for organic compounds and reduced solvation properties for ionic species due to its loss of aqueous hydrogen bonding (Simoneit 1994).

Hovland et al. (2006a, b) predict that some of the large volumes of deep subsurface salt found in the Red Sea, in the Mediterranean Sea and the Danakil depression, formed via the forced magmatically-driven hydrothermal circulation of seawater down to depths where it became supercritical. This salt, they argue, was precipitated deep under-ground via "shock crystallisation" from a supercritical effusive phase

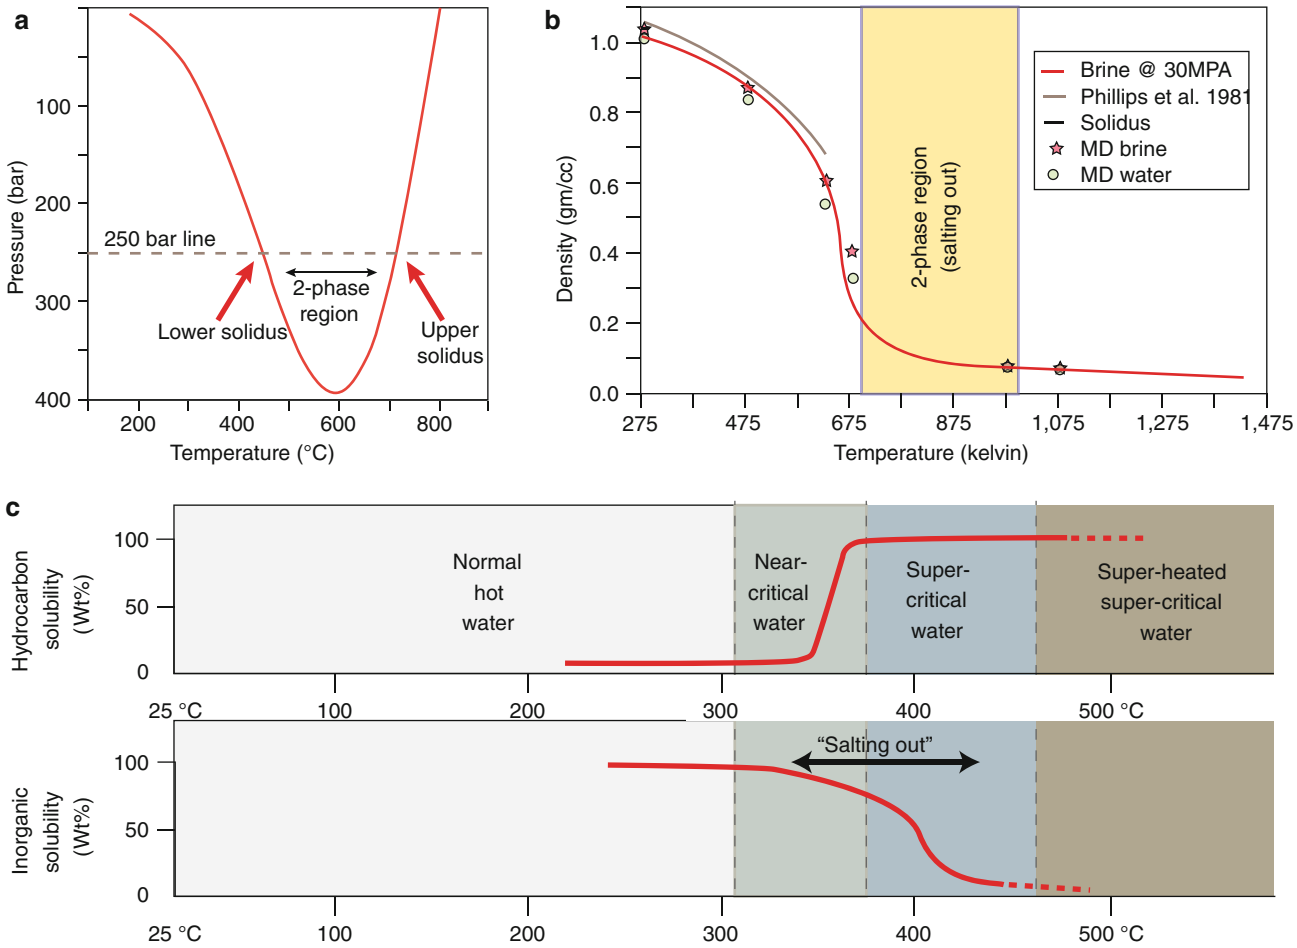

Fig. 1.5 Hydrothermal halite derived from supercritical seawater. (**a**) P-T projection of the monovariant solid-liquid-vapour saturation curve (solidus) for the NaCl-water system. *Arrows* indicate the two points of intersection with the section at 250 bar (defining the lower and upper solidus boundaries). (**b**) Density of water and brine as a function of temperature along the 300 bar isobar. The two-phase region (or "out- salting region") is indicated by the shaded region with onset indicated by a drastic fall in density over a narrow temperature range. (**c**) Ionic and hydrocarbon solubility in heated water at pressures of 200–300 bars (**a**–**b** After Hovland et al. 2006a, b; **c** after Josephson 1982; Simoneit 1994)

and so formed massive accumulations (mostly halite) typically in crustal fractures that facilitated the deep circulation. NaCl then flowed upwards in solution in dense, hot hydrothermal brine plumes, precipitating more solid salt beds upon cooling nearer or on the surface/seafloor. To date, the Hovland et al. model of hydrothermal sourcing for widespread halite from a supercritical brine source (in active magmatic settings) has not been widely accepted by the geological community (Talbot 2008).

Another source of chlorine-rich hydrothermal fluid in the deep subsurface is the recycling of deeply buried sedimentary salt into the greenschist realm and beyond (Yardley and Graham 2002). In the metamorphic realm (T>200 °C) the derived fluids do not precipitate halite, but a series of meta-evaporite indicator minerals (Chap. 14). Lewis and Holness (1996) demonstrated that buried salt bodies, subjected to high pressures and elevated temperatures, can acquire a permeability comparable to that of a sand. This is because the crystalline structure of deeply buried salt (halite) attains dihedral angles between salt crystals of less than 60° and so creates an permeable polyhedral meshwork. Such conditions probably begin at the onset of greenschist P-T conditions, whereby highly saline hot brines form continuous brine stringers around all such altered and recrystallizing salt crystals (Fig. 1.6; Chap. 14). This polyhedral permeability meshwork allows hot dense brines or hydrocarbons to migrate through salt and so ultimately dissolve the salt host, releasing a pulse of sodic- and chloride-rich fluid into the metamorphic realm (Chap. 14). It is why little or no evidence of masses of metamorphosed halite is found in subsurface meta-evaporitic settings where temperatures have exceeded 250–300 °C, even though the melting point of halite is 800 °C. Given the right subsurface conditions these halite-derived metamorphic brines may evolve into supercritical waters.

One of the most visually spectacular examples of hydrothermal precipitation is in the Naica mine, Chihuahua, Mexico (Fig. 1.7a). There several natural caverns, such as Cave of Swords (Cueva de la Espades) and Cave of Crystals (Cueva de los Cristales), which contain giant, faceted, and transparent single crystals of gypsum as long as 11 m (García-Ruiz et al. 2007; Garofalo et al. 2010). Crystals in Cueva de los Cristales are the largest documented gypsum crystals worldwide. These huge crystals grew slowly at very low supersaturation levels from thermal waters near the gypsum-anhydrite boundary. Gypsum is currently precipitating on modern mine walls.

Fluid inclusion analyses show that the giant crystals came from low-salinity solutions at temperatures ≈54 °C, slightly below the temperature at which the solubility of anhydrite equals that of gypsum (Fig. 1.7b). According to García-Ruiz et al. 2007, the sulphur and oxygen isotopic compositions of these gypsum crystals are compatible with growth from solutions resulting from dissolution of anhydrite, which was previously precipitated during late hydrothermal mineralization in a volcanogenic matrix. The chemistry suggests that these megacrystals formed via a self-feeding mechanism, driven by a solution-mediated, anhydrite-gypsum phase transition. Nucleation kinetics calculations based on laboratory data show that this mechanism can account for the formation of these giant crystals, yet only when operating within a very narrow range of temperature of a few degrees, as identified by the fluid inclusion values. According to the paper's authors, these singular conditions create a mineral wonderland, a site of scientific interest, and an extraordinary phenomenon worthy of preservation.

Garofalo et al. (2010), accept the need for a limited temperature range during precipitation, but argue the precipitating solutions were in part meteorically influenced. Their work focused on Cueva de las Espadas. As for most other hypogenic caves, prior to their analytical work they assumed that caves of the Naica region lacked a direct connection with the land surface and so gypsum precipitation would be

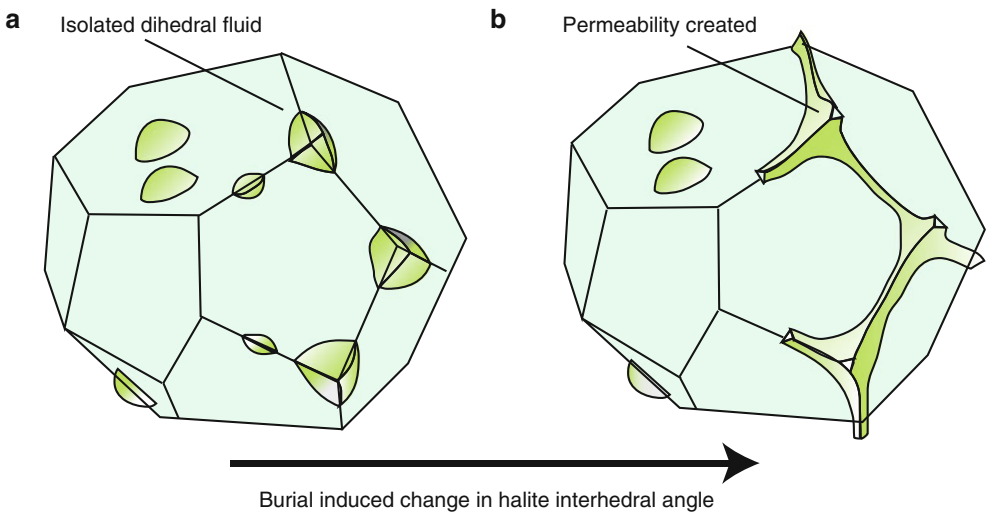

Fig. 1.6 Effect of dihedral angle on pore connectivity in texturally equilibrated monomineralic and isotopic polycrystalline mosaic halite. Shading shows position of dihedral fluid phase within the polyhedral intercrystalline porosity. (**a**) Isolated porosity for dihedral angle >60°. (**b**) Connected polyhedral porosity for dihedral angle <60° (After Lewis and Holness 1996)

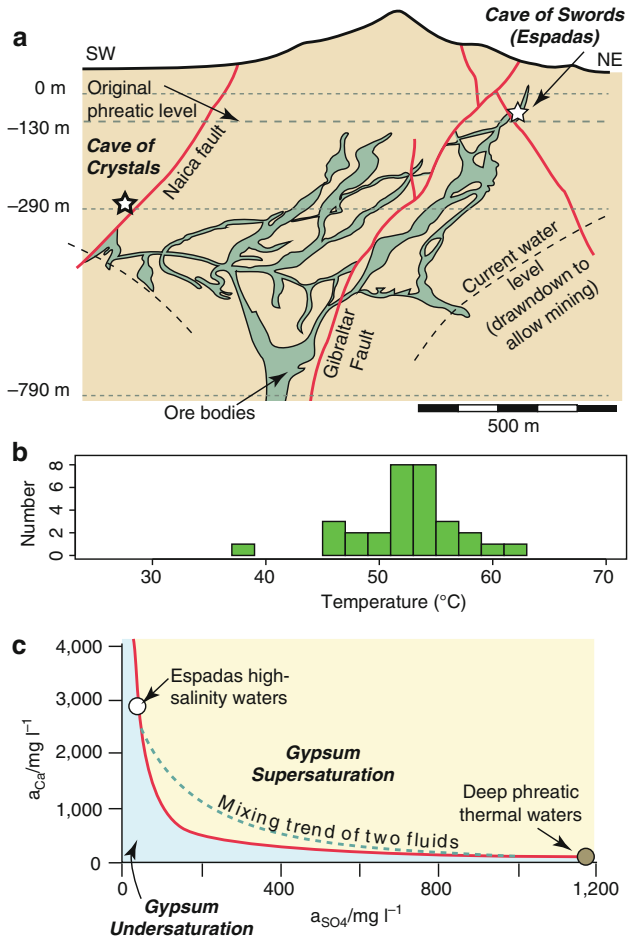

Fig. 1.7 Naica Mine, Mexico. (**a**) Cross section of Naica mine. Mine exploits a hydrothermal Pb-Zn-Ag deposit with irregular manto and pipe morphologies entirely enclosed in subhorizontally dipping carbonates. Cavities of gypsum crystals are located in carbonates close to main and secondary faults. Galleries have been excavated down to –760 m, requiring average pumping rate of 55 m^3/min to depress groundwater to –580 m with respect to phreatic level located at –120 m; Naica and Gibraltar faults act as main drains. (**b**) Homogenization temperatures of 31 fluid inclusions showing actual temperature of growth. (**c**) Solubility of gypsum calculated at 55 °C and 105 Pa and measured activities of shallow and deep cave fluids from fluid inclusion data. Mixing at equilibrium between these two fluids in any proportion generates a fluid with a composition would consistently supersaturated with respect to gypsum, as shown by the position of the mixing curve, indicated by a *dashed line*, in the gypsum supersaturation field (After García-Ruiz et al. 2007; Garofalo et al. 2010)

unrelated to climate variation, Yet, utilising a combination of fluid inclusion and pollen spectra data from cave and mine gypsum, they concluded climatic changes occurring at Naica exerted and influence on fluid composition in the Naica caves, and hence on crystal precipitation and growth.

Microthermometry and LA-ICP-Mass Spectrometry of fluid inclusions in the gypsum indicate that brine source was a shallow, chemically peculiar, saline fluid (up to 7.7 eq. wt.% NaCl) in the Cueva de las Espadas and that it could have formed via evaporation, during an earlier dry and hot climatic period. In contrast, the fluid of the deeper caves (Cristales) was of lower salinity (≈3.5 eq. wt.% NaCl) and chemically homogeneous, and likely was little affected by evaporation processes. Garofalo et al. (2010) propose that mixing of these two fluids, generated at different depths of the Naica drainage basin, determined the stable supersaturation conditions needed for the gigantic gypsum crystals to grow (Fig. 1.7c). The hydraulic communication between Cueva de las Espadas and the other deep Naica caves controlled fluid mixing. Mixing must have taken place during alternating cycles of warm-dry and fresh-wet climatic periods, which are known to have occurred in the region. Pollen grains from 35 ka-old gypsum crystals from the Cave of Crystals indicates a fairly homogenous catchment basin dominated by a mixed broadleaf wet forest. This suggests precipitation during a fresh-wet climatic period, the debate continues.

So, What Exactly Is an Evaporite?

Now that we have discussed some possible complexities in interpretation created by the widespread occurrence of non-solar mineral salts, the remainder of this chapter deals with controls on distribution of "true" sedimentary modern and ancient evaporites (formed at or nearsurface by solar-driven brine concentration). My working definition for an evaporite is, as the name suggests, a sedimentary rock formed at sedimentary surface temperatures (>50–70 °C) and is typically precipitated by solar concentration (heating) of a nearsurface or at-surface brine to where the salinity of residual brine becomes saturated with respect to a particular set of mineral salts, which then drop out of the solution as a series of predictable crystallites, subject to nearsurface and later alteration, replacement and dissolution (Figs. 1.8 and 1.9).

So, what are the basic requirements to form and preserve an evaporite? We need; (1) a surface or nearsurface brine body that is saline enough to precipitate and preserve salt, this typically means an arid to semi-arid climatic setting with a drawdown hydrology capable of maintaining substantial volumes of saltsaturated brine at or near the landsurface, (2) accommodation space in a sedimentary depression that is not completely filled by other sediment, and (3) a burial environment that does not allow sufficient undersaturated porewater throughflow to completely dissolve the buried salts.

Depositional Setting and Texture

Primary evaporites precipitate with distinct textures in a number of hydrologically-contrasted settings, contingent on brine stability and rates of temperature and salinity change in the mother liquor. Primary evaporite textures are direct indicators of the hydrology at the time of precipitation and

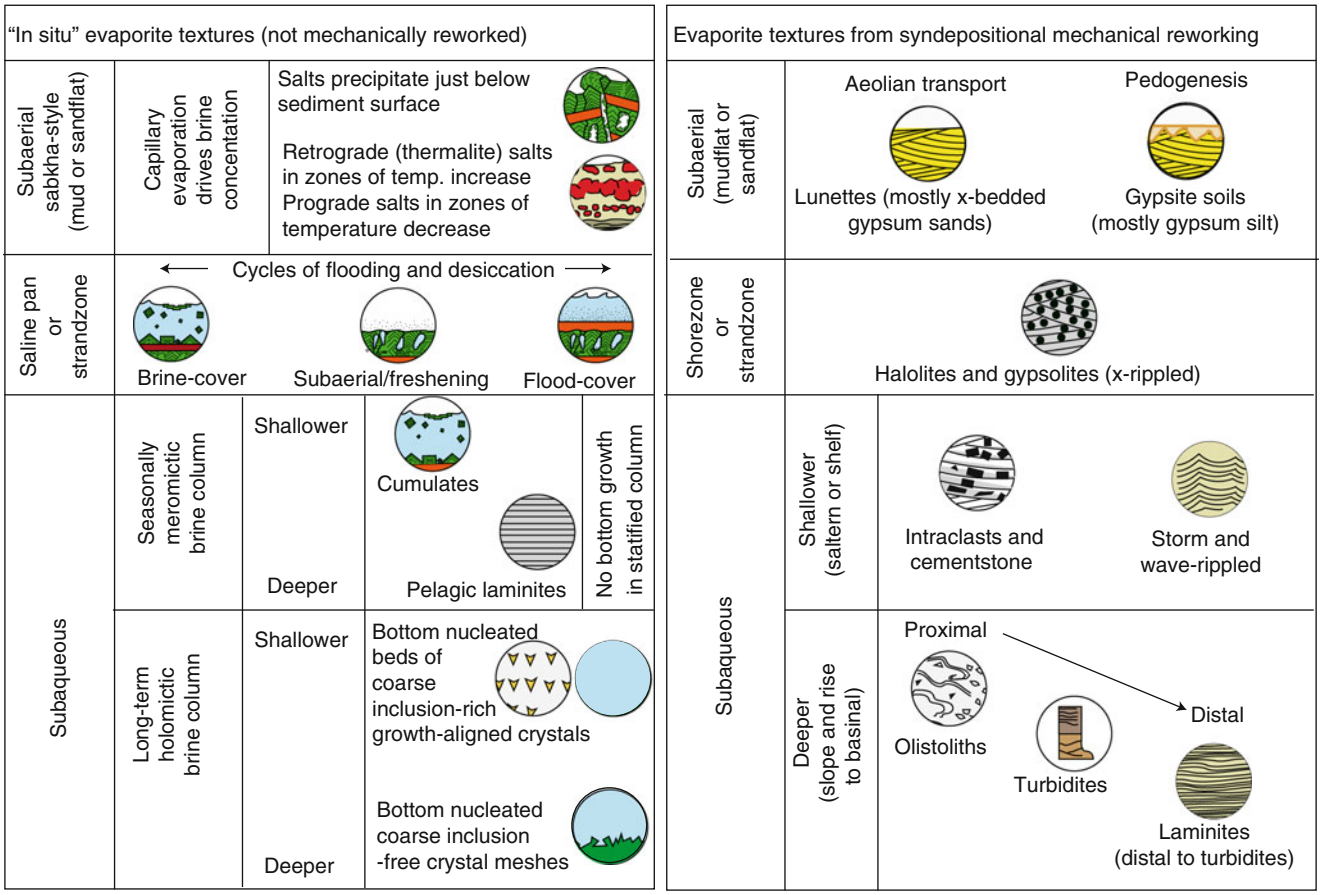

Fig. 1.8 Significance of primary evaporite depositional textures as indicators of brine hydrology

accumulation (Fig. 1.8). Sometimes crystals remain where they precipitate, other times they are mechanically or geochemically reworked, or undergo partial degrees of dissolution and fractional recrystallization.

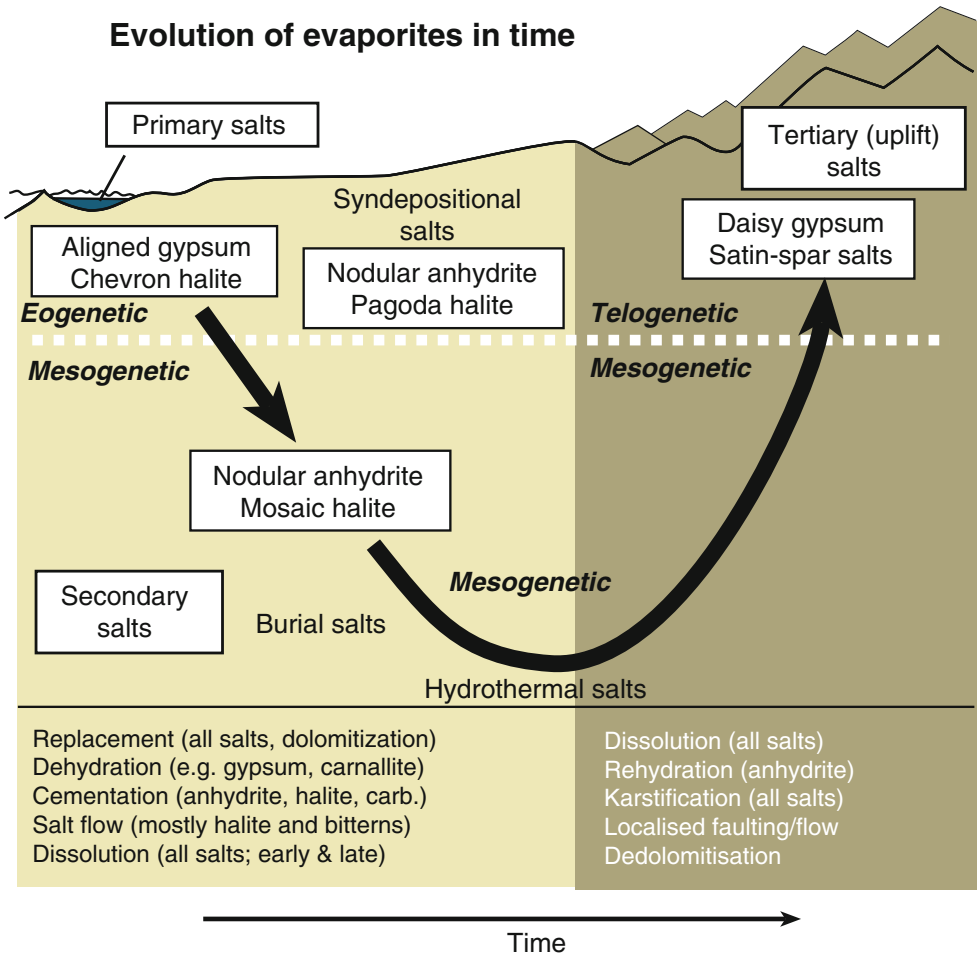
Crystals may first precipitate at the air-brine interface in rafted crystal clusters that then sink to form cumulate beds, or can be blown to the strandzone (e.g., halite rafts crystallizing at the air-brine interface in Lake Guilietti in Ethiopia). Then again, immediately after they crystallize, precipitates can sink from the uppermost water mass to ultimately collect as pelagic accumulations (cumulates) on the shallow or deep brine floor "rain from heaven" deposits. Seasonal or longer term changes in the chemistry and salinity in the upper water column means many such pelagic deposits are mm-scale laminates made up of mineral doublet or triplet layers. In a holomictic shallow water mass, coarse cm-dm scale crystals can form as bottom-nucleated inclusion-entraining precipitates, typically at the base of a water column that is tens of centimetres to metres deep. Such crystals, be they gypsum swallowtails or halite chevrons, tend to be composed of alternating inclusion-rich and inclusion-poor laminae and micro-laminae, reflecting rapid changes in chemistry or temperature of the overlying shallow holomictic water mass (Fig. 1.8).

If a brine column remains both supersaturated and holomictic to greater depths, then evaporites can accumulate at the deepwater base of a brine column that is hundreds of metres deep. This is the case today in the North Basin of the Dead Sea in the Middle East, where a salt bed, made up of a meshwork of inclusion-free, randomly-aligned cm-scale halite crystals, is accumulating and has been doing so since the North Basin brine column became holomictic in February, 1978. Prior to 1978 and for at least the preceding 400 years the brine column of North Basin (>370 m water depth) was a meromictic density-stratified hypersaline system, with pelagic mm-scale laminites accumulating on the same deep bottom, composed of alternating calcite and aragonite lamina, along with minor cm-scale gypsum crystal clusters or rosettes. The lack of inclusions in the halite mesh on the present-day deep bottom reflects the greater stability of chemical conditions on the bottom. The corollary is that growth-aligned evaporite crystals, rich in entrained inclusions of brine (e.g. chevron halite in Death Valley, California, or carbonate pellets encased in swallowtail gypsum in Marion Lake, Australia) indicate precipitation in much shallower water depths (decimetre to metre depths). That is, inclusion-rich aligned bottom-growth

Fig. 1.9 Classification of evaporite formation in the depositional-diagenetic realms emphasizing ongoing postdepositional evolution of mineralogy and texture

		Type	Precipitation process	Temp (°C)	Hydrological process

Crusts, bottom nucleates & pelagic crystals accumulate on brine pool floor.	0–60 °C	Gravity and density effects at surface or in zone of active phreatic flow (brine reflux	Saturation driven by solar evaporation
		"Secondary" evaporites (include sabkha nodules and the bulk of ancient evaporite beds)	An evaporite salt formed in the shallow subsurface in the zone of active prheatic flow. The concentration process of the brine and the associated gravitational reflux is driven by solar evaporation. May form displacive, replacive or cement textures.			
			A burial diagenetic evaporite phase that replaces earlier evaporite beds. Salt precipitation is driven by fluid mixing or saturation mechanisms driven by burial diagenetic processes. Forms replacive and cement textures.	60–200 °C	Burial effects compactional and thermobaric flow	Brine saturation not driven directly by solar evaporation
		Burial salts	Subsurface precipitation of evaporite as cements and replacements in non-evaporite matrix from a saturated brine derived form the dissolution of adjacent evaporite beds or zones of brine mixing.			
	No primary texture	"Tertiary" evaporites	An evaporite formed by brine saturation related to partial bed dissolution via re-entry into the zone of active phreatic circulation. Often driven by basin uplift and reosion.	0–60 °C	Stagnant to active phreatic flow	
? ?		Hydrothermal salts	Salts (anhydrite – retrograde; halite -supercritical) precipitated by heating of seawater or subsurface brines.	>150 °C	Hydrothermal circulation	



textures form in well-mixed brines that are shallow enough to experience short term changes in saturation and growth rate, coupled to short term changes in water temperature or salinity.

If currents and waves rework the bottom crystals, then ripple structures and dune forms can be the dominant texture in the accumulating evaporite bed. The presence of evaporite equivalents of carbonate ooids, namely gypsolites and halolites, indicate oscillating bottom currents at the time the crystals grew. Brine floor instability, related to seismic events, halokinesis or tectonism, can also lead to the formation of slumps, brine escape and debris flow textures (seismites) in a salt bed deposited at any water depth (El Taki and Pratt 2010). The lowering of suprasalt brine column salinity or the lowering of the regional watertable can create karst cones and breccias in an evaporite bed. For more detail on the significance of the various evaporite textures the reader is referred to (Lowenstein and Hardie 1985; Orti et al. 2010).

Evaporite salts can crystallize as early diagenetic precipitates in the shallow subsurface some mm to cm below the sediment surface, as occurs today in the capillary zones of many marine coastal and continental mudflats and sabkhas (where displacive and poikilotopic crystals, nodules and efflorescent crusts are typical). Some initial crystals precipitates can be dissolved and recycled through the nearsurface sediment column, especially in arid and semi-arid settings, to create pedogenic profiles; as in the gypsite soils atop gypsum lunettes in southern Australia or in the nitrate-rich salt solid of the hyperarid Atacama Desert.

So, as for depositional textural associations in carbonate and siliciclastic sediments, a depositional model based on evaporite textures can encompass a spectrum of formative sites ranging from the pedogenic, to saline mudflats, to shallow and deep subaqueous brine settings. However, because evaporite salts are orders of magnitude more soluble than carbonate or siliciclastic sediments, they require particular postdepositional tectonics and hydrologies in order for large volumes of salts to be buried and textures preserved or no more than partially modified. This high degree of solubility and mobility at the time of precipitation and in their subsequent subsurface evolution is key to understanding deposition and diagenesis in both modern and ancient evaporite settings.

Secondary and Tertiary Evaporites

As soon as an evaporite bed is formed it is subject to alteration, which continues at varying levels of intensity throughout the sedimentary history of the rock (Fig. 1.9). In a Pre-Quaternary, or certainly pre-Neogene evaporite, many textures are secondary; the rock has been diagenetically altered, frequently showing fabrics indicating early recrystallisation and perhaps some later crossflow of basinal waters. Under this definition of a primary versus secondary salt, even the nodules in Holocene mudflats are secondary salts, including those in the various modern mudflats of the Arabian (Persian) Gulf, which is the type area for a sabkha. The nodules are a porewater overprint superimposed on a primary matrix of mud and sand. Ancient bedded anhydrites are typically dominated by secondary textures, although beds may still retain "ghosts" or partial relicts of primary textures such as indistinct laminae or aligned nodules after growth-aligned gypsum. In a halite bed there may be remnant patches of aligned halite chevrons floating in a matrix of mosaic halite spar. Even when evaporite beds are extensively recrystallised, most retain coarse stratiform layering made up of impurities that once defined primary depositional discontinuities.

What distinguishes evaporites, especially NaCl beds, from other types of sediment in the subsurface is their ability to flow via pressure-driven recrystallisation, even as they backreact or dissolve. Even earlier secondary textures can be syndepositional precipitates, formed as cements and replacements, while primary matrix accumulated around them. Early replacement sometimes preserves remnants of the original depositional texture, such as gypsum ghosts in nodular anhydrite or aligned halite chevrons outlined by secondary anhydrite. Nodular anhydrite ghosting of lenticular gypsum was recognised in Permian mudflats in the early 1960s by Kerr and Thomson (1963), they interpreted it as a subaqueous saline pan indicator. Unfortunately, for the next two decades their results were overlooked by workers in the Permian Basin who incorrectly applied supratidal capillary analogs to thick massive subaqueous anhydrite beds.

Early diagenetic overprints and effects of later compactiondriven flow and pressure solution can destroy much of the depositional evidence in an ancient evaporite bed. This means retention of primary crystal textures is at best patchy in both halite and anhydrite beds. Many ancient bedded halites are dominated by coarsely crystalline halite spar. Much of it was deposited in multiple episodes of early diagenetic (syndepositional) cementation, leaving less than 10–15 % of the bed as primary growth-aligned chevrons within a few metres to tens of meters below of the depositional surface. This syndepositional coarse sparry halite formed in multiple dissolution-precipitation events in microkarst pits and was precipitated between successive depositional episodes of chevron halite crust formation (Chap. 3). Other coarsely crystalline halite spar, especially in halokinetic beds, shows pervasive and multiple flow-aligned textures created by pressure-solution. Textures are driven by numerous salt creep and recrystallisation episodes, which occur millennia to millions of years postdeposition, and after hundred to thousands of metres of burial (Chap. 6).

Secondary evaporite textures form in subsurface settings equivalent to the eogenetic[1] and mesogenetic porosity realms, as defined for carbonates by Choquette and Pray (1970). Tertiary evaporite textures tend to form in the telogenetic realm (Fig. 1.9). And, as in carbonate diagenesis, the most pervasive alteration of evaporites is either early in the burial history (eodiagenesis) or it occurs much later during uplift (telo-diagenesis). Both the eogenetic and telogenetic settings are characterised by relatively permeable evaporites and hydrologies capable of high volumes of pore fluid cross-flow. Alteration of a salt mass in the mesogenetic realm consists largely of recrystallisation overprints within a flowing salt mass, but with substantial alteration and dissolution possible about the edge of a bed or a flowing salt mass. In carbonates, the mesogenetic overprint tends to be pervasive throughout the bed (Choquette and Pray 1970). In evaporites units, the pervasive early loss of porosity and permeability in the shallow diagenetic/eogenetic realm means that deep burial (mesogenetic) alteration, prior to halokinesis, tends to be first concentrated about the edges of a buried salt body (see discussion of dissolving salt "block of ice" model in Chaps. 7 and 8). Unlike carbonates and siliciclastics, the core of a subsurface bedded halite unit (nonhalokinetic) can be largely unaffected by fluid flow-driven processes of burial alteration due to its early loss of effective porosity via cementation. Preservation of the unaltered core of the salt unit is why viable Permian halobacteria can be cultured from brine inclusions in remnant chevrons in Permian salt beds from West Texas (Vreeland et al. 2000).

Unlike quartzose and aluminosilicate sediments, buried evaporite beds can flow as ductile masses from the surface down to 8–10 km of burial and even into the metamorphic realm. At the same time their dissolving edges supply ions to adjacent nonevaporitic sediments. Salt flow can be: (a) early diagenetic, coinciding with syndepositional fractionation, reflux or dissolution; (b) later diagenetic, associated with complex burial-stage bed dissolution or reprecipitation and driven by subsurface fluid flow in the zone of free convection below the zone of overpressure; (c) widespread and pervasive, as occurs during halokinesis (salt tectonics); and (d) postdiagenetic and extending well into the metamorphic realm where daughter minerals, such as scapolite and tourmaline, can act as a source of volatiles and lubricants long after the precursor salts have gone.

Exhumed or uplifted evaporite beds also undergo pervasive alteration, dissolution and replacement as they re-enter the zone of active phreatic flow (telogenesis) and regain permeability along internodular nd inter crystalline boundaries. Once again, alteration tends to occur from the edges inward. Soluble components from the altering and dissolving bed can be reprecipitated in adjacent shales as alabastrine and satinspar gypsum or fibrous halite veins. Exhumed evaporite textures are termed tertiary (Fig. 1.9) and are varying combinations of competitive crystal alignment and geopetal void fills. The resulting fabrics can duplicate "primary" crystal alignments, especially when parts of a cavern fill can only be studied at a limited scale, as in core or a mine face. Not recognising a telogenetic overprint typically misidentifies tertiary evaporite textures as primary and so creates interpretive confusion (Chap. 7). This is why interpretations of depositional setting are not reliable if based on observations in an evaporite outcrop where that unit is the remnant of a once more massive and thick primary unit that has passed through the mill of burial and uplift. Adjacent nonevaporitic sandstones, shales and limestones also undergo diagenetic reactions when flushed by evolving pore fluids, but the diagenetic rock/fluid framework is slower to respond and requires years to millennia to overprint an original depositional texture. But, given enough time, the textures of many other sediments evolve during burial, just at much slower rates (Table 1.2).

Primary Evaporitic Carbonates

The simplest subdivision of evaporite minerals is into evaporitic alkaline earth carbonates – aragonite, dolomite, low-Mg calcite and high-Mg calcite – and evaporite salts – gypsum, anhydrite, halite, trona, carnallite, etc. (Table 1.1). Primary evaporitic carbonates tend to form in the initial stages of brine concentration, whereas the other primary evaporite salts are precipitated in the more saline stages of concentration (Chap. 2). Evaporitic carbonates can contain and preserve elevated levels of organic matter that subsequently generate hydrocarbons or act as reductants for base metal sulphides (Chap. 9).

Evaporitic alkaline earth carbonates are the first evaporite minerals to precipitate from a concentrating hypersaline surface water and are usually composed of aragonite, high- and lowMg-calcite, magnesite or even primary dolomite. The essential hydrology of any evaporite depositional setting is that evaporative outflow exceeds inflow. This results in two characteristics of the carbonate depositional system, which hold also for the more saline evaporite salts. First, rapid

[1] In their original definitions Choquette and Pray (1970) focused their studies on carbonate sediments. Throughout this book I have expanded and slightly modified their original definitions (*as noted in italics*). So the modified definitions of eogenetic, mesogenetic and telogenetic are as follows: Eogenetic zone extends from surface of newly deposited sediment (*not just carbonates*) to depths where processes genetically related to surface become ineffective. Telogenetic zone extends from erosion surface to depths at which major surface-related erosional processes become ineffective. Below a subaerial erosion surface, the practical lower limit of telogenesis is at or near watertable (*and the related surface driven zone of phreatic meteoric water movement and includes both unconfined and confined aquifers*). Mesogenetic zone lies below major influences of processes operating at surface. The three terms also apply to time, processes, or features developed in respective zones.

Table 1.2 Characteristics of siliciclastic and carbonate depositional systems

	Siliciclastic: (continental, fluviodeltaic, shelf, submarine)	Carbonate: humid-oceanic/marine tropical/subtropical	Carbonate-evaporite: arid, land-locked subtropical/temperate
Early marine cementation	Rare	Local occurrence	Pervasive (especially in mesohaline platform)
Dolomitisation	Rare	Locally in mixing zones (?)	Pervasive (brine reflux and burial)
Leaching	Uncommon, mostly related to freshwater leaching, rare in burial diagenesis	Common, related to subaerial exposure and karstification	Intensive, related to hypersaline brines
Calcite cementation	Uncommon, locally common (mostly related to burial)	Common	Rare to local occurrence (mostly burial)
Anhydrite-halite	Uncommon	Rare to absent	Common to pervasive
Porosity types	Intergranular	(1) Mouldic, vuggy and chalky microporosity (common) (2) Fracture and intercrystalline porosity (local occurrence)	(1) Intergranular, mouldic, vuggy, and intercrystalline (dolomitic) porosity (very common) (2) Fracture and chalky microporosity (locally common)
Controls on reservoir quality	(1) Stratigraphic position (2) Depositional facies	(1) Stratigraphic position (2) Depositional facies (3) Karst in zones on meteoric influx	(1) Depositional facies (2) Accessibility of sulphate- and chloride-bearing and later corrosive fluids (karstic or deep)
Geometry	Layered	Layered	(1) Carbonate-basinwide evaporite: Massive, irregular, halokinetic (2) Carbonate-saltern-mudflat evaporite: layered
Reservoir distribution	High energy shoreline or channel fills with position related to lowstand, transgressive and highstand system tract	Highstand reef or bank carbonate immediately beneath subaerial unconformity	(1) Carbonate-basinwide evaporite: near faults and fractures where late corrosion is most intensive (2) Carbonate saltern-mudflat evaporite (a) Within grain-supported facies where primary porosity is preserved or mouldic porosity was created through leaching (b) Within coarsely crystalline dolomite (c) Within highly fractured limestone

In part after Sun and Esteban (1994)

changes in water level are possible, especially in the more marginward facies, leading to interlayering of strandzone and subaqueous units. Under such a regime any subaqueously precipitated sediment is liable to subaerial exposure and syndepositional subaerial diagenesis. Second, the solute content, especially the Mg/Ca ratio, of shallow hypersaline water fluctuates as the salinity fluctuates. For example, the Ca content of any freshened water is depleted by the early precipitation of calcite or low-Mg calcite. Subsequent carbonate precipitates drop out of increasingly saline waters that will have a higher Mg/Ca ratio and so saline carbonate precipitates tend to be dominated by high-Mg calcite, aragonite, magnesite, or even dolomite.

Carbonate Laminites (Subaqueous?)

Mm-scale lamination is volumetrically the dominant sedimentary texture in modern and ancient evaporitic carbonates as well as in higher salinity salts, but its origins are varied and complex (Fig. 1.10). Sometimes it is an inorganic cumulate, other times it is biologically structured (biolaminite – see next section). Beds dominated by finely laminated, regular alterations of two or more sediment types are called laminites or rhythmites. Many evaporitic carbonate laminites form couplets or even triplets by the regular superposition of micrite with siliciclastic clay, organic matter or evaporite salts. Such couplets and triplets are frequently referred to as varves, yet are not necessarily "true" varves in that the layers may not define annual couplets.

As an example of a contemporary carbonate laminite, consider deep bottom pelagic sediments deposited prior to 1979 in the Northern Basin in the Dead Sea, Israel (Fig. 4.51). They are made up of alternating light and dark mm laminae that accumulated beneath a density-stratified brine column more than 350 m deep. The whitish laminae are composed of stellate clusters of aragonite needles (5–10 μm diameter), which precipitated each summer at the air-brine interface and then sank. The darker laminae consist of clay minerals, quartz grains, detrital calcite and dolomite that washed in as suspended sediment from the surrounding highlands during occasional storm floods (Garber et al. 1987). Thus laminites in the Dead Sea are not annual layers, but indicate flood events that occur every 3–10 years.

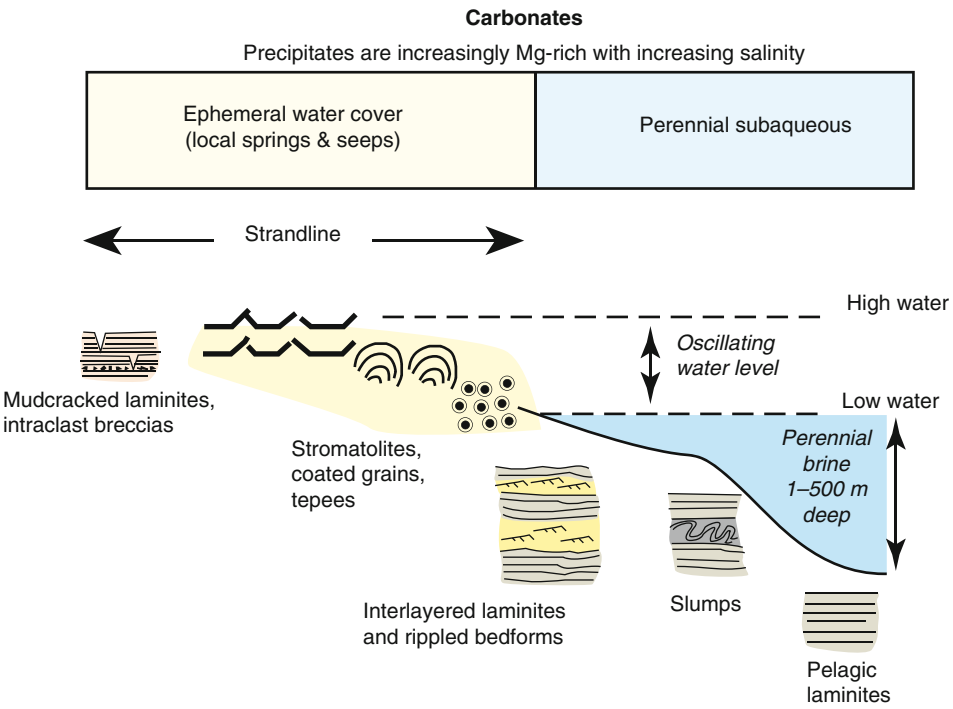


Fig. 1.10 Depositional significance of evaporitic carbonate textures. Note the distinction between subaqueous and strandline (ephemeral water) indicators

Permanent water column stratification, with periodic halotolerant alga blooms at the surface, characterises the current waters of Lake Tanganyika. Deep bottom pelagic laminites (seasonal varves) containing between 7 and 11 % total organic carbon (TOC) accumulate as modern lake bottom sediments where waters are anoxic waters and more than 250 m deep (Cohen 1989). Or consider the shallow lacustrine laminites of the more saline Holocene Coorong Lakes, Australia (Warren 1988, 1990). Coorong laminites make up more than 80 % of the Holocene sediment volume in the Coorong Lakes and are composed of alternating dark-grey organic-rich and light-grey organicpoor laminae. Depending on the salinity of the mother brine, matrix mineralogies range from hydromagnesite to aragonite to Mg-calcite to dolomite and organic levels can be as high as 16 % TOC. As in the Dead Sea, the Coorong laminites formed subaqueously on the floor of a chemically stratified lake. Unlike the 250+ metres depths of the Dead Sea and Lake Tanganyika, Coorong laminites accumulated as microbially entrained pelletal wackestone/mudstones beneath seasonally stratified perennial lake waters, less than 1–5 m deep (Fig. 4.6a, b). Once on the bottom these pellets can be eroded and redeposited as wave-driven bedload, this reworking means the resulting laminite layering is not a varve and can be eroded as it constructs wave ripples.

Laminites can also be preserved under conditions of ephemeral subaerial exposure. Algal-bound laminites (algal mats or biola minites) crosscut by mudcracks characterise the algal channel and strandzone facies in many modern and ancient evaporitic carbonates such as the sabkhas of the Arabian Gulf (Fig. 3.5e). Modern and ancient laterally extensive carbonate laminites, without evidence of subaerial exposure, indicate subaqueous deposition under fluctuating surface water chemistries. They indicate water depths that may have ranged from a few decimetres to hundreds of metres and are not necessarily associated with deepwater conditions or microbial binding (Warren 1985; Kendall 1992). They do indicate a lack of burrowing metazoans in saline carbonate sediments deposited across this wide range of water depths.

Strandzone Associations: Microbialites, Pisolites and Tepees

The strandzone in many evaporitic carbonate systems is characterised by an association of stromatolites, mudcracked cryptalgalaminites (biolaminites), pisolites, ooids, intraclasts, cemented crusts and tepees (Fig. 1.10). Strandzones typify deposition associated with fluctuating shorelines about the edge of a more permanent brine lake or seaway and form in areas of groundwater springs, mudflats and ponds. Rapid fluctuations of strandlines (wet and dry cycles) and associated high rates of capillary crossflow mean this facies association is syndepositionally cemented as it aggrades into stacked layers of intraclast breccia, biolaminites, pisolites and tepees, typically separated by salt beds or their dissolution breccias. Biofilms and mats, in otherwise muddy and granular matrices of any uncemented strandzone sediment, give a leathery depositional strength to this

sediment that encourages the preservation of rip-ups, tears and overfolds due to storm-induced erosion. Biostabilization also tends to encourage the preservation of fenestrae and gas-filled cyanobacterial domes in the surface crusts of many modern strandzones of saltflats and playas.

Microbialites and Stromatolites

Microbialites are "…organosedimentary deposits that have accreted as a result of a benthic microbial community trapping and binding detrital sediment and/or forming the locus of mineral precipitation" (Burne and Moore 1987). They are biogenic structures, the mineralised result of the metabolic activities of microphytic algae, cyanobacteria or archaebacteria (Figs. 1.11, 1.12, and 1.13a; Riding 2000; Brasier 2011). Some possess an internal clotted texture (thrombolites), others are laminar (stromatolites), or combinations with varying degrees of inorganic precipitates and external sediments. Microbialitic structures are commonplace sediments in evaporitic Holocene strandzones (Table 1.3). Textures range from biolaminites (≈cryptal-

galaminites) and stromatolites (matrix-supported agglutinated microbial reefs) through tufa/travertine (cement-supported) reefs to thrombolites (agglutinated reef). Stromatolites and cyptalgalaminates are the most easily recognised microbialites in ancient evaporitic settings. Quaternary tufas and travertines tend to characterise the humid hydrological stages of saline lakes when water levels tend to be higher and surface water less saline. Such mounds tend to define subaqueous groundwater outflow zones on the lake floor, as in Searles Lake and Mono Lake, California

Table 1.3 Selected examples of well documented Holocene microbialites, stromatolites and thrombolites

Brine style	Location, climate and hydrology	Characteristics	References
Marine (*subsealevel or sea margin lagoon*)			
Open-marine, normal salinity, subtidal	Subtidal and intertidal areas of Highbourne Cay, Lee Stocking Island, Bahamas Köppen: Aw (seafloor)	Coarse-grained agglutinated indurated aragonite and Mg-calcite structures, composed of ooid and skeletal sand; they form in normal marine salinities but stressed intertidal and subtidal environments, exposed to high wave energy and strong tidal currents. Precipitation of aragonitic needles associated with the activity of sulphate- reducing bacteria is a key feature in carbonate precipitation, while periodic sediment cover and erosion controls biotal makeup of stromatolites.	Bowlin et al. (2012), Visscher et al. (2000)
Marine-edge Mesohaline and schizohaline, intertidal to subtidal	Domes with synoptic relief along southern intertidal edge of Hamelin Pool, Shark Bay, West Australia Restricted embayment, limited hydrographic connection due to seagrass banks. Köppen: BSh (restricted sea edge lagoon)	Coarse-grained agglutinated indurated aragonite and Mg-calcite structures, composed of skeletal sand; they form in marine mesohaline (up to 65‰) marine waters, subtidal (thrombolitic) and intertidal, occasionally exposed to high wave energy. Formed by combination of (1) microbial trapping and binding and, (2) microbial precipitation. Both processes are important in the intertidal zone, forming coarse-grained sandy stromatolites. Microbial precipitation is the primary accretionary mechanism in the subtidal zone, forming muddy, micritic thrombolitic stromatolites. Induration is tied to uncoupling of sulphate reduction and carbon fixation in the microbial communities, as in Bahamas. Depositional setting is backed by extensive Holocene coquina beach ridges.	Allen et al. (2009), Reid et al. (2003), Jahnert et al. (2012)
Marine-edge Mesohaline and schizohaline intertidal	Biolaminites, no synoptic relief, on lagoon edge, south of Khor al Bazam, Abu Dhabi. Periodically covered by marine mesohaline lagoon waters Köppen: BWh (restricted sea edge lagoon)	Leathery fine-grained laminar mats composed of aragonitic micrite with Mg-calcite. Form on the protected intertidal and supratidal flats of a highly saline lagoon. From the high-water mark seaward these are: (1) Flat zone; (2) Crinkle zone; (3) Polygonal zone (4) Cinder or warty zone. A diagenetic lenticular gypsum overprint is seen in the more landward hypersaline parts of mat.	Kendall and Skipwith (1968a), Park (1977)
Lacustrine saline (*includes continental interior and coastal marine seepage*)			
Hypersaline marine-seepage lacustrine	Laterally linked mm-laminated lakemargin stromatolites, Marion Lake, coastal region southern Yorke Peninsula, South Australia Marine seepage salina, subsealevel depression (−1.5 m) hydrographic isolation. Mesohaline edge Köppen: Csb (−0.5 m)	A variety of finely laminated, subfossil, indurated aragonitic stromatolites and oncolites occur on a regressive marginal flat surrounding Marion Lake, South Australia. Internal lamination is characterized by an extremely fine sub-millimetric alternation of porous and dense laminae, light-grey and dark-grey, respectively. These microbial forms overlie a substrate of coarse, highly porous, mouldic aragonitic limestone and gypsum. These fine-grained stromatolites retain very well preserved mineralized bacterialike biota.	Von der Borch et al. (1977), Perri and Spadafora (2011), Perri et al. (2012)
Marine coastal interior, mesohaline continental seeps	North and South Stromatolite lakes, Coorong coastal region, South Australia. Schizohaline and mesohaline continental carbonate salinas. Supra-sealevel (+1–2 m). Hydrographic isolation from marine. Köppen: Aw (1 m)	Three morphological forms of subaqueous mm-laminar bio-eroded lake-edge hydromagnesite-aragonite stromatolites in ephemeral mesohaline lakes (25–110‰), No equivalents in the nearby less saline Coorong Lagoon or in other lakes. The three forms are stratiform, globular, and crenulate. Each is built by cyanophytes, the first two by near monospecific mats (respectively *Microcoleus chthonoplastes* and *Schizothrix splendida*) and the third by a variable association dominated by *Schizothrix gracilis* and *Calothrix crustacea*.	Walter et al. (1973), Warren (1990)
Continental interior, mesohaline	Stromatolites and hardgrounds, Lake Manito, Saskatchewan, Canada. Schizohaline and mesohaline continental carbonate-evaporite lake (salinity ≈50‰). Köppen: Dfb (583 m)	The salinity has increased from 10‰ to about 50‰TDS in the last 2,000 years. The associated decrease in water level has exposed large areas of nearshore microbialites. These organogenic domes range in size from several cm to over a meter in relief and can coalesce into large bioherms several meters high. Most of the larger microbialites formed between about 2,300 and 1,000 cal BP, whereas the hardgrounds, cements, and laminated crusts formed about 1,000–500 cal BP. Bacterial dolomite.	Last et al. (2010)

Table 1.3 (continued)

Brine style	Location, climate and hydrology	Characteristics	References
Continental interior, mesohaline	Thrombolitic stromatolites, Great Salt Lake Margin, Utah USA Köppen: Cfa (1,283 m) Similar and even larger tufa mounds also typify the now-exposed lake floors of Mono Lake and Searles Lake (Guo and Chafetz 2012)	Holocene aragonite and Mg-calcite stromatolites covered a 280 km ^{2} area when mapped in 1933 when the lake elevation was 1,279.5 m. Bioherms confined to shallow, nearshore areas where wave activity and water circulation was strong. Occur at depths from 5 cm to 3.7 m and formed isolated 20–30-cm-diameter circular mounds to coalesced bioherms 9 m in diameter. Relief above the sediment surface ranged between 15 and 90 cm. In 1933, some 50 % of the bioherm surfaces covered by brown to pink unicellular cyanobacteria *Aphanothece packardii*. The surfaces of these mounds were highly irregular ("nodose"), with many small protuberances. Internally, the mounds were structureless to crudely banded.	Eardley (1938), Halley (1976), Pedone and Folk (1996), Pedone and Dickson (2000)
Continental interior, mesohaline	Laguna Socompa, leathery domal fringe facies in high altitude lake, 3,560 m asl, Andean Puna, Argentina Köppen: ET (3,563 m)	Stromatolites in In small high altitude lake and made up of broad, rounded, low-dome, up to 24 cm high, and 80 cm wide, leathery diatomaceous bioherms, composed of laminated aragonitic muds with bioeroded edges (mound morphology is very similar to North Stromatolite Lake, Coorong region, South Australia).	Farias (2011)
Lacustrine Brackish (*Supra-sealevel Continental, some Marine coastal*)			
Marine coastal interior	Thrombolitic stromatolite edges, Storr's Lake, San Salvador. Suprasealevel (1–2 m) coastal with hydrographic isolation from ocean Köppen: Aw (0–1 m)	Microbialites around the lake margin are made up of alternating stromatolite and thrombolite layers. They are exposed annually above temporary water levels for intervals of many weeks or months. This alternation of exposure and water coverage is triggered by lake-level fluctuations and associated turbidity variability. This mechanism results in a succession of phototrophic-dominated (stromatolites) to heterotrophic dominated communities (thrombolites) as surface communities.	Mann and Nelson (1989)
Marine coastal interior freshwater marsh	Algal pans and marshes, Andros Island, Bahamas Köppen: Aw (0–2 m)	Laminated leathery freshwater cyanobacterial mats in shallow lakes of Andros Island show similarities to ancient hybrid stromatolites, with fine-grained incipiently lithified cyanobacterial mat layers alternating with laminar fenestrae and elongate open voids	Black (1933), Monty (1976)
Marine coastal interior, mesohaline and schizohaline (30–80‰)	Thrombolitic stromatolite edges in Lake Clifton and Lake Thetis, West Australia, and Sleaford Mere, South Australia. Continental carbonate seepage salinas. Supra-sealevel (+1–2 m) coastal with hydrographic isolation from ocean Köppen: Csa (0–1 m)	Lake-margin indurated domes and biscuits with synoptic relief of up to 1 m, periodically exposed and growing in mesohaline to brackish water about lake edges in zones of meteoric spring outflow. Lithified thrombolitic stromatolites comprised mainly of aragonite with patches of living coccoid cyanobacterial mat characterizing their knobbly dome surfaces in the littoral lake area. In contrast a thick flocculent mat composed of phototrophic prokaryotes (principally purple sulphur bacteria) and diatoms accumulates in the central perennial lake basin area. Are distinguished from other nearby coastal salinas by the presence of the flocculent diatomaceous mat and the juxtaposition of this microbial community to the marginal lithified thrombolitic stromatolites.	Burne and Moore (1993), Grey et al. (1990), Warren (1982a), Timms (2009), Burne et al. (2014)
Continental interior, perennial saline lake (depth ≈ 45 m, salinity ≈ 50–90‰)	Tufa mounds and thrombolites, Mono Lake, California Köppen: BSk (1,208 m)	Calcite tufa mounds up to 5 m high and 2–5 m across as lake fringe buildups and also along linear at-surface fault trends. The identification of modern ikaite forming in present day lake waters each winter and its conversion to calcite with spring warming suggests that both Pleistocene and Holocene tufa mounds in the Mono basin originally formed as ikaite in subaqueous spring outflow zones. Similar genesis to Pyramid Lake mounds.	Council and Bennett (1993), Whiticar and Suess (1998)

Freshwater lacustrine (*perennial*)			
Continental interior, perennial ponds and springs in playa host	Cuatro Cienegas Pozas, system of several hundred springs, pools and streams as fresh to brackish dissolution ponds in a gypsum playa in the high-relief Chihuahuan desert of Coahuila, Northern Mexico Köppen: BSh (726 m)	The freshwater pools of Cuatro Ciénegas exhibit the lowest phosphorus content reported in continental waters. Microbialites (diatomaceous calcitic stromatolites) thrive because nutrient constraints prevent snails and other eukaryotes from effectively grazing microbialites. Key microbial groups include cyanobacteria, aerobic heterotrophic bacteria, sulphate-reducing bacteria, sulphide-oxidizing bacteria and fermentative bacteria. Stromatolites construct offset, horizontally oriented, outwardly projecting ledges dominated by calcifying cyanobacterium *Homoeothrix balearica*, in conjunction with the uncalcified cyanobacterium *Schizothrix lacustris*.	Breitbart et al. (2009), Visscher and Stolz (2005), Winsborough et al. (1994)
Continental interior, perennial ponds and springs in karst cenotes hosted in Cenozoic limestone	Giant Holocene freshwater microbialite domes, Laguna Bacalar, Quintana Roo, Mexico Köppen: Aw (0–1 m)	The 10 km of total length, make this one the world's largest modern freshwater microbialite occurrences. Microbialites include domes, ledges and oncolites. Domal forms can grow to diameters and heights of 3 m. Microbialites are composed of low magnesium calcite, mostly precipitated by metabolic activity of the cyanobacteria, *Homeothrix* and *Leptolyngbya*, and associated diatoms. Photosynthesis removes carbon dioxide and triggers carbonate precipitation.	Gischler et al. (2008)
Continent interior perennial lake	Pavilion Lake, British Columbia, Canada, freshwater lake up to 65 m deep in a steep-walled limestone valley (pH ≈ 8.5) Köppen: Dfc (806 m)	Calcite microbialite tufa mounds, which can display dendrolitic microstructures similar to *Epiphyton* and *Girvanella*. The morphologies vary with depth, with dendritic microstructures best developed in the deeper water (>30 m) mounds indicate that they may be modern analogs for the ancient calcareous structures.	Laval et al. (2000)
Large continental interior perennial lake	Lake Van, Turkey. Third largest closed lake on Earth. (pH up to 9.7) Köppen: Dfb (1,647 m)	Tufa spires, pinnacles and domes up to 40 m tall growing on lake floor. Perennial lake is up to 450 deep Microbial growth is by mats of coccoid cyanobacteria (*Pleurocapsa* group) permineralizing in situ with aragonite and by inorganically precipitated calcite. Lake water are highly alkaline.	Reimer et al. (2009), Kempe et al. (1991)

Köppen climate determinations based on centroid overlays on Köppen base published by Kottek et al. (2006); see Chap. 2 for full discussion of this climate classification

and preserve microbially-mediated textures (Guo and Chafetz 2012). Internally, microbial textures can be stromatolitic (fine planar-undulating to wavy-crenulated lamination), oncolitic (concentrically laminated), thrombolitic (with mesoscale clotted textures, not to be confused with clotted or grumous microfabrics, which occur in both thrombolites or stromatolites) or cryptic without obvious internal structure (Figs. 1.12 and 1.13a; Manzo et al. 2012).

Microbialites are typically classified according to the dominant internal or external microfabrics (Fig. 1.12), but all microbial categories are intergradational (Fig. 1.13a). In addition to domes/mounds, the overall shape of a microbial construct can encompass varying regions made up of columns, layers, and irregular masses (Riding 2011). A complication in applying a consistent classification is that stromatolite, leiolite and macrofabrics are defined by features that can be intergradational within a single buildup (inset in Fig. 1.11a). A stromatolite is internally layered from the mm to cm scale, while a leiolite is internally composed of aphanitic micrite. At the outcrop scale leiolite appears massive or homogenous and lacks internal lamination. In the type area in the Messinian carbonates of the Sorbas Basin, Spain, leiolite domes are always found in association with stromatolites and dendrolites (Braga et al. 1995).

In contrast to the internal structures defining stromatolites and leiolites, thrombolite and dendrolite macrofabrics are defined by the external shape of individual masses of microbial carbonate, such as clots or small shrub-like masses. Thrombolitic stromatolite, typified by external parts of some Shark Bay columns (Fig. 1.11a), can be internally weakly clotted and crudely laminated, while others are laminated. It is essentially an agglutinated composite, in contrast to Neoproterozoic and early Palaeozoic thrombolites with their calcified microbial microfabrics. In the latter, the clots may be prostrate and irregular, and also vertically extended into amalgamated elongate branches (e.g., *Favosamaceria*).

Biology of Stromatolites and Microbial Layers

Stromatolites to some researchers are a specific layered type of microbialite, often defined as laminated organosedimentary structures with positive relief away from a point or limited surface of attachment (Fig. 1.12; Burne and Moore 1987). In this sense stromatolites are equivalent to agglutinated microbial reefs in the terminology of Riding (2002). To others, stromatolites are not necessarily a biological construct. Microbes and biofilms may be present at the time chemical sediments accumulate, but they play a passive role in textural style during the deposition of this type of stromatolite. Researchers with this view of stromatolites like to add the phrase "it may or may not be of biological origin" to any definition of an ancient stromatolite. This distinction becomes important as we shall see in a later discussion of pre-Mesozoic evaporitic stromatolites, but reliably defining the contribution of a biofilm to rock texture in ancient evaporitic carbonates is at times near impossible.

This difficulty is separating biologic from abiogenic constructs is in part a reflection of how a stromatolite grows and accretes and that stromatolite micro- and macrofabrics commonly intergrade with those of dendrolites and thrombolites (Fig. 1.13a). Stromatolite accretion can involve three main processes: microbial precipitation, inorganic precipitation, and grain trapping (Fig. 1.13b). These main types represent respectively lithified microbial mat, sparry crust, and combinations of these are termed "hybrid stromatolites" by Riding (2011) (Fig. 1.14).

Internal layers of most modern marine-edge stromatolites define the successive positions of agglutinating bioplexi (algal/bacterial community), with each accreting layer produced by trapping and binding of sand to mud-sized sediment (Figs. 1.11 and 1.13b) In some settings, agglutination occurs in conjunction with direct carbonate precipitation onto (surficial) or within (biomineralisation) the mucilaginous sheaths of cyanobacterial trichomes. Both precipitative processes are driven by changes in ambient pCO_2 and variations in the intensity of sulphate-reduction (Table 1.3). Modern saline lacustrine stromatolites tend to encompass precipitative biochemical structures, while modern marine-margin stromatolites, such as Shark Bay, tend to be largely agglutinated structures; both possess surface microbial communities that evolve as the stromatolites prograde (Duane and Al-Zamel 1999).

Many coarser-grained stromatolites in the modern marine and marine margin realms, as in Lee stocking Island and Shark Bay, are poorly layered agglutinated forms and are transitional into thrombolitic structures (Fig. 1.11a; Table 1.3). Fine-grained mm-laminated stromatolites tend to form best in or near seepage zones in modern hypersaline lakes, such as Marion Lake in South Australia, Gotomeer in the Nederlands Antilles and the Dead Sea in the Middle East, rather than in the open marine realm (Warren 1982a; Kobluk and Crawford 1990; Druckman 1981). Recent work on the biomineralisation process, as preserved in Marion Lake, South Australia shows that, over time frame of a few thousand years, the biomineralisation in a stromatolite can evolve into the inorganic precipitative.

The internal lamination of subfossil indurated stromatolites (3,780 ± 110 years) in Marion Lake is characterised by a submillimetric alternation of porous and dense laminae (Von der Borch et al. 1977; Warren 1982a – see Chap. 4 for depositional detail). The microfabric of the laminae is ubiquitously composed of a fine (10–20 μm) peloidal texture, with many thinner aphanitic layers. Aggregates of very fine, low-Mg calcite and aragonite constitute both peloidal and aphanitic micrite, which is coated, respectively, by spherulitic and fringing acicular microspar (Perri and Spadafora 2011; Perri et al. 2012). Micrite, with a high organic matter content, is formed of coalescing nanospheres grading into small polyhedrons, probably composed mainly of aragonite, with less calcite, and is enriched in Mg, Sr, Na and S. Bacteria-like microfossils and relics of extracellular polymeric substance (EPS) occur abundantly within this micritic framework. The former consist of empty moulds and mineralised bodies of coccoid forms, whereas EPS relics consist of sheet-like or filamentous structures that appear both mineralised and more often still preserved as a C-enriched dehydrated substance that represents the main organic matter component of the deposit. Acicular crystals, which show a prismatic elongate shape, are composed of Mg-depleted aragonite that lacks fossils or organic relicts. Degrading EPS and micro-organisms appear gradually to be replaced and entombed by the nanospherical precipitates, implying the existence of processes of organomineralisation within an original syn-sedimentary microbial community. Succeeding micron-scale crystals merge to form isolated or connected micritic aggregates (the peloids), followed by the gradual formation of the acicular crystals as purely inorganic precipitates. That is the diagenetic driver for the mineralisation pass from biogenic to abiogenic.

At the worldscale, dominant members of modern microbial plexi range from archaea to eubacteria to cyanobacteria to algae, with the proportions and species changing with

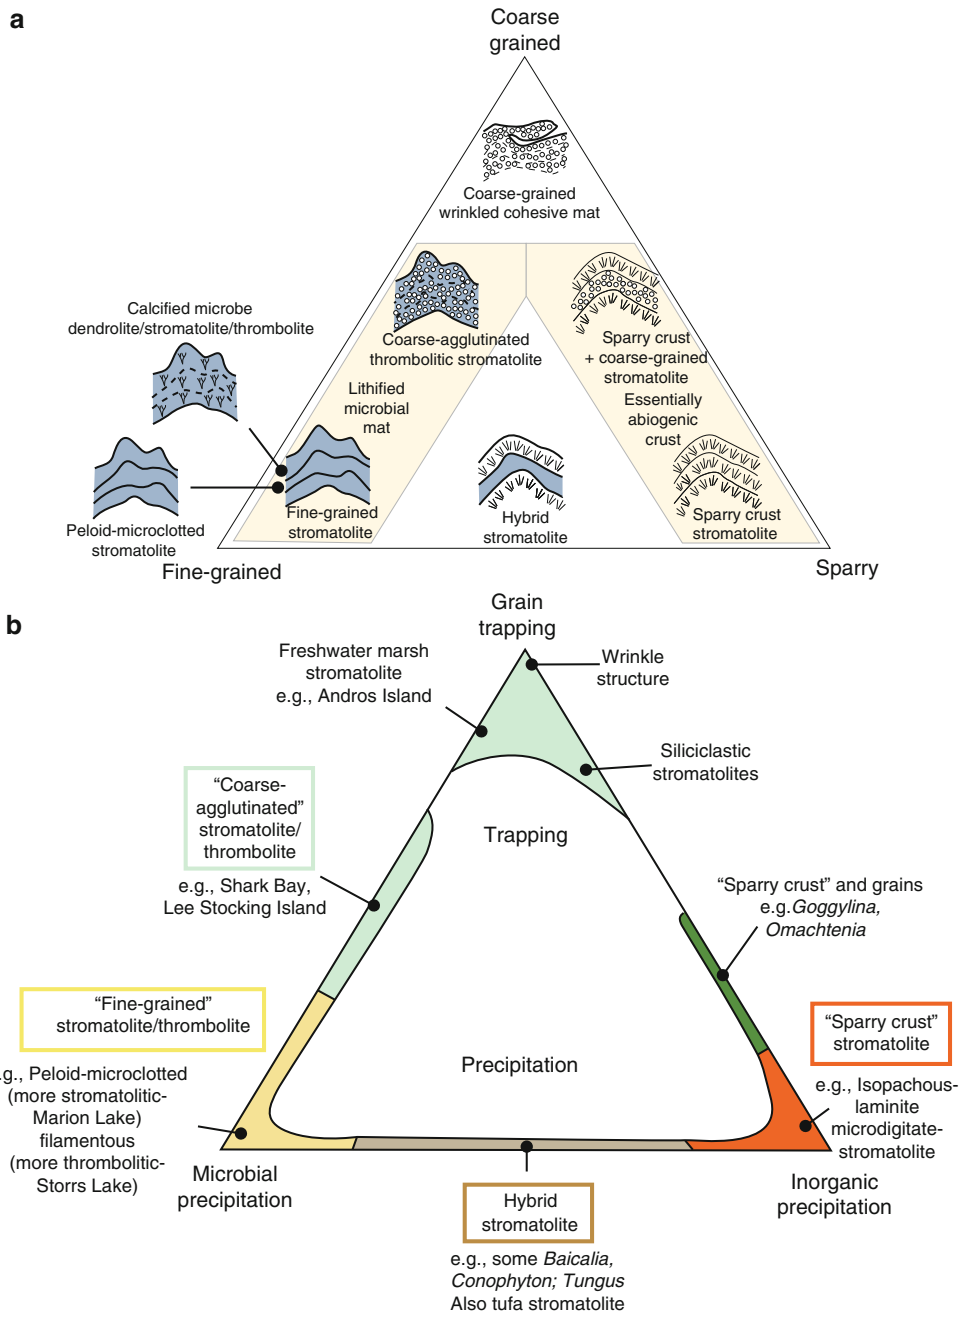

Fig. 1.14 Classification of microbialites (After Riding 2011). (**a**) Classification of stromatolites and thrombolites based on micro/macrofabric. All, except wrinkled cohesive mats, are synsedimentarily lithified by microbial and/or abiogenic processes. Fine-grained varieties include two distinctive types: (i) stromatolites with peloidal-microclotted microfabrics and (ii) dendrolites and thrombolites with abundant filamentous and other calcified microbial microfossils. (**b**) Classification of stromatolitic and thrombolitic carbonates related to grain trapping, and synsedimentary microbial and inorganic precipitation. Principal categories are coarse agglutinated, fine-grained, hybrid and sparry crust. Those dominated by microbial precipitation and/or grain trapping are microbial mats. Sparry crusts are essentially abiogenic precipitates. Hybrid stromatolites are combinations of lithified microbial mat and sparry crust. Fine-grained varieties include filamentous (also termed porostromate, skeletal, and calcimicrobial) which is more thrombolitic and peloidal-microclotted (also termed spongiostromate) which is more stromatolitic. Microbial mats dominated by trapping, but with relatively minor early lithification include freshwater marsh stromatolites and wrinkle marks mainly in siliciclastic sands and silts. For secular distributions see Figs. 1.13c and 1.18

depth in the sediment and salinity of the water column (Chap. 9). The most common biotal constituents of well-preserved stromatolitic bioherms in Phanerozoic evaporitic settings are filamentous and coccoid cyanobacteria, with lesser halobacterias (Figs. 1.13c and 1.14a, b). Species components not only change with water depth and brine salinity but have changed over the course of geological evolution. Modern cyanobacteria typically extrude a mucilaginous sheath that protects the contributing biota from UV radiation. The gooey mucilage also captures sediment particles creating further UV screening, but too thick a sediment layer can cut the necessary exposure to light and so slow photosynthesis. Large amounts of water are held in the mucous sheath and so it also serves as a buffer against osmotic stress in fluctuating salinities.

Modern mesohaline stromatolites exhibit regular occurrences of the halotolerant cyanobacterial species *Microcoleus chthonoplastes*, *Lyngbya* sp., *Entophysalis* sp., *Phormidium* sp. and *Synechococcus* sp. (Gerdes et al. 2000a). *Microcoleus* is one of a number of cosmopolitan cyanobacteria that form ensheathed filamentous cellular bundles in most growing biolaminites. It grows best in the salinity range 80–160‰ but is present as living filaments in salinities as high as 300‰ (Chap. 9). Fibrillar cyanobacteria are able to glide up

and down through nearsurface sediment in order to position themselves in optimal light conditions so that its position below the surface, and the oxygen halo it generates, changes from night to day (Fig. 1.15). This is done by hormogonia, a part of a filament of a photosynthetic cyanobacterium that detaches and grows by cell division into a new filament. Hormogonia are motile and respond phototactically so that, if too much sediment accretes to the mat, or if a deepening brine cover, or the transition from day to night, reduces the light reaching the filaments, they move upwards to where they accumulate on or just below the sediment surface. It is this periodic repositioning that creates the internal laminated structure and phototropic thickening seen in modern stromatolites and algal mats. Left behind in the sediment matrix of an aggrading stromatolite are the abandoned sheaths, immotile filaments, cells and mucilage remnants that, after passing through the decomposer community, become buried organic matter or protokerogen (Fig. 1.15).

Coccoids in modern biolaminites tend to create slime-ensheathed pustules and individual cells grow by binary fission (Gerdes et al. 2000a). *Aphanothece*, *Gloeothece* and *Synechococcus* are three of a number of such coccoid cyanobacteria that make up the other major component of a cyanobacterial plexi. These organisms increase their slime or mucilage content in order to deal with phototoxicity and tend to dominate exposed surfaces of algal mats and stromatolites, as in the algal mats of the Abu Dhabi and Saudi sabkhas (Kendall and Skipwith 1969). Coccoids tend to occur in zones about edges of water-covered biolaminites flourishing on the floors of tidal channels (Chap. 3).

Pleurocapsalian cyanobacteria are a cosmopolitan type of coccoid bacteria, which dominate modern pustular and pinnacle mats. The typical internal structure in a pustule is colonial, with individual nodules showing discontinuous but more or less concentric layers. Slime production is stimulated by an increase in light intensity, salinity or temperature. This creates sediment with a yoghurt-like consistency made up of polysaccharides interwoven with sediment matrix. The slime coat not only protects the coccoids, but also insulates the other species of the mat community from the lethal effects of increasing light, salinity and temperature. Microbial metabolism associated with such slime coats facilitates or even drives the precipitation of primary dolomite in many evaporitic carbonates (van Lith et al. 2002).

It is the alternation between mm-scale layers dominated by the filamentous forms and layers enriched in the coccoids that creates the biolamination of modern marine and marine

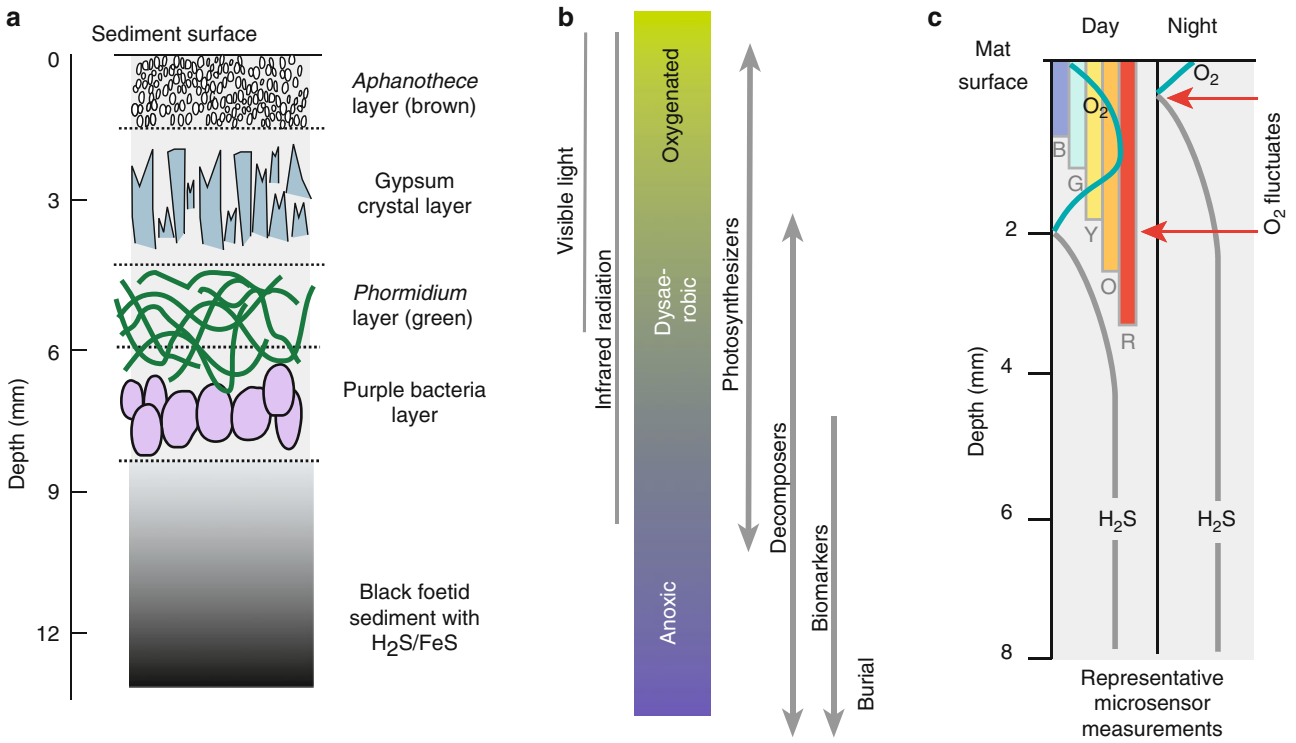

Fig. 1.15 Layering and metabolism in microbial mats. (**a**) Typical microbial community in an evaporitic laminite in a modern coastal salina with salinity in the range 130–200‰ (After Caumette 1993). (**b**) Biogeochemical cycles operating within the mat versus depth. (**c**) Interrelationships between microbes and the oxygen, carbon and sulphur cycles in the uppermost 5–10 mm of a microbial mat. The oxic-anoxic transition shifts lower in the mat in the daytime and higher in the mat at night when photosynthesis has stopped (After Warren 2011 and references therein)

margin stromatolites (Reid et al. 2001; Bowlin et al. 2012). Aggradation in modern marine-edge stromatolite communities represents a dynamic balance between sedimentation and intermittent lithification within the cyanobacterial mat. Periods of rapid sediment accretion, during which stromatolite surfaces are dominated by pioneer communities of gliding filamentous cyanobacteria, alternate with hiatal intervals. Microscale discontinuities in sedimentation are characterized by development of surface films of exopolymer and subsequent heterotrophic bacterial decomposition, which forms thin crusts of microcrystalline carbonate. During prolonged hiatii, climax communities develop, which include endolithic coccoid cyanobacteria. These coccoids modify the sediment micro-environment to create thicker lithified laminae. Subsequence preservation of lithified layers at depth creates the millimetre-scale biolamination that characterises modern and ancient stromatolites.

At the broader scale, successive layers in modern biolaminites can indicate seasonal changes. *Microcoleus*-dominated layers (often associated with diatoms) accumulate in the winter, while coccoid-dominated layers typify the more saline summer growth layers. Alternations of coccoid and filamentous layers in a mat can create lamination, even in the absence of agglutinated sediment. Preservation potential of such organic-only layers is low, unless deposited on the anoxic floor of a perennial stratified brine lake (Chap. 9).

Non-stromatolitic Lacustrine Microbialites

Stromatolites are one part of a much wider group of variably layered microbialites growing in a wide range of saline marine and nonmarine settings (Table 1.3; Riding 2000, 2011; Brasier 2011; Manzo et al. 2012). According to Riding, sediment trapping by filamentous plexi in a modern biolaminite results in an agglutinated stromatolite reef, which is characterised by a particulate microstructure that preserves few, if any, details of the original size, shape or orientation of the biotal plexi responsible for capturing sediment (Fig. 1.13a).

On the other hand, biomineralized deposits, such as thrombolite/tufa/travertine cement reefs described by Riding (2002), retain considerable palaeontological detail about the constituent organisms preserved as skeletal microfossils. Mineralisation is especially important in nonmarine microbialites, as in the lacustrine tufa cement reefs that define the water-covered margins of the less saline high-water stages of many Quaternary salt lakes, as in Great Salt Lake and Walker Lake, USA (Table 1.3). These tufa cement reefs are porous, unbedded or only poorly bedded, and are created by cyanobacteria, algae, grasses, and reeds thriving in brackish to fresh, lake and river waters and groundwater seeps along the landward side of the saline pan or lake edge. Rapid $CaCO_3$ precipitation veneers living plants with cement rinds that would otherwise be masses of soft vegetation (Riding 2000; Pedley et al. 2003; Manzo et al. 2012). Relief on a tufa buildup can be high, with commonplace steep to overhanging, locally cavernous, cemented masses. Tufas tend to occur where inorganic $CaCO_3$ precipitation is enhanced by CO_2 degassing of venting spring waters.

Likewise travertines, which tend to form layered deposits of $CaCO_3$ near the outflow points of groundwater and thermal springs, can preserve details of the contributing microbes. Travertine cement reefs are layered microbialites with dendrolite "shrub" and crystalline fabrics associated with nonskeletal organisms, as in Pavilion Lake, British Columbia (Fig. 1.12; Table 1.3). Deposits tend to form steep-sided mounds, with elevated rimmed pools, normally developed atop and about the mounds (Riding 2002). Smoothly banded crystalline crusts construct horizontal, sloping, vertical or overhanging sheets with pisoids typically developing at the bottom of water-filled pools and polygonal saucers. Folk (1993, 1999) and Chafetz and Folk (1984), along with many others working in travertines, document microbialite microtextures such as spheroidal dolomite, dumb-bell shaped crystals, fine diurnal-layered dendrites and bushes, all of which indicate a strong bacterial contribution to travertine precipitation (Reid et al. 2001). Reeds and grasses can be preserved as moulds within bacterial travertines, but most macroorganisms are excluded by the elevated temperatures and high levels of dissolved minerals (salinity) that typify travertine carbonates. Most travertines are only a few kilometers in lateral extent and, as in tufa cement reefs, subaerial surfaces are common, as are gradations into adjacent marsh and fluvial environments (Manzo et al. 2012; Kosun 2012).

CO_2 degassing, in combination with evaporation and rapid microbial growth, can drive extreme carbon isotope enrichment in the organic matter and co-precipitates in many CO_2 -limited organic-enriched sediments, including evaporitic marls, tufas and travertines (Schouten et al. 2001). Enriched $\delta^{13}C$ values of up to +13‰ in calcite and −10‰ in organic matter were measured in calcite tufas accumulating in well-oxygenated carbonate saturated waters in El Peinado and San Francisco lakes, both high altitude saline lakes in the southern Andean Altiplano, northwestern Argentina (Fig. 1.16). Valero-Garces et al. (1999) argue that the large enrichments of the heavier carbon isotopes in the algally bound sediments indicate nonequilibrium gas-transfer fractionation of the carbon isotopes during CO_2 degassing. Parent waters were derived from thermal springs and subject to subsequent evaporative concentration. In general most ions in lacustrine tufas in volcanic settings ultimately come from geothermal and volcanic CO_2 sources. Physical fractionation, rather than biological enrichment in these settings, may have a greater significance than credited in the commonly accepted biological metabolism arguments typically used to explain carbon isotope records in evaporitic carbonates

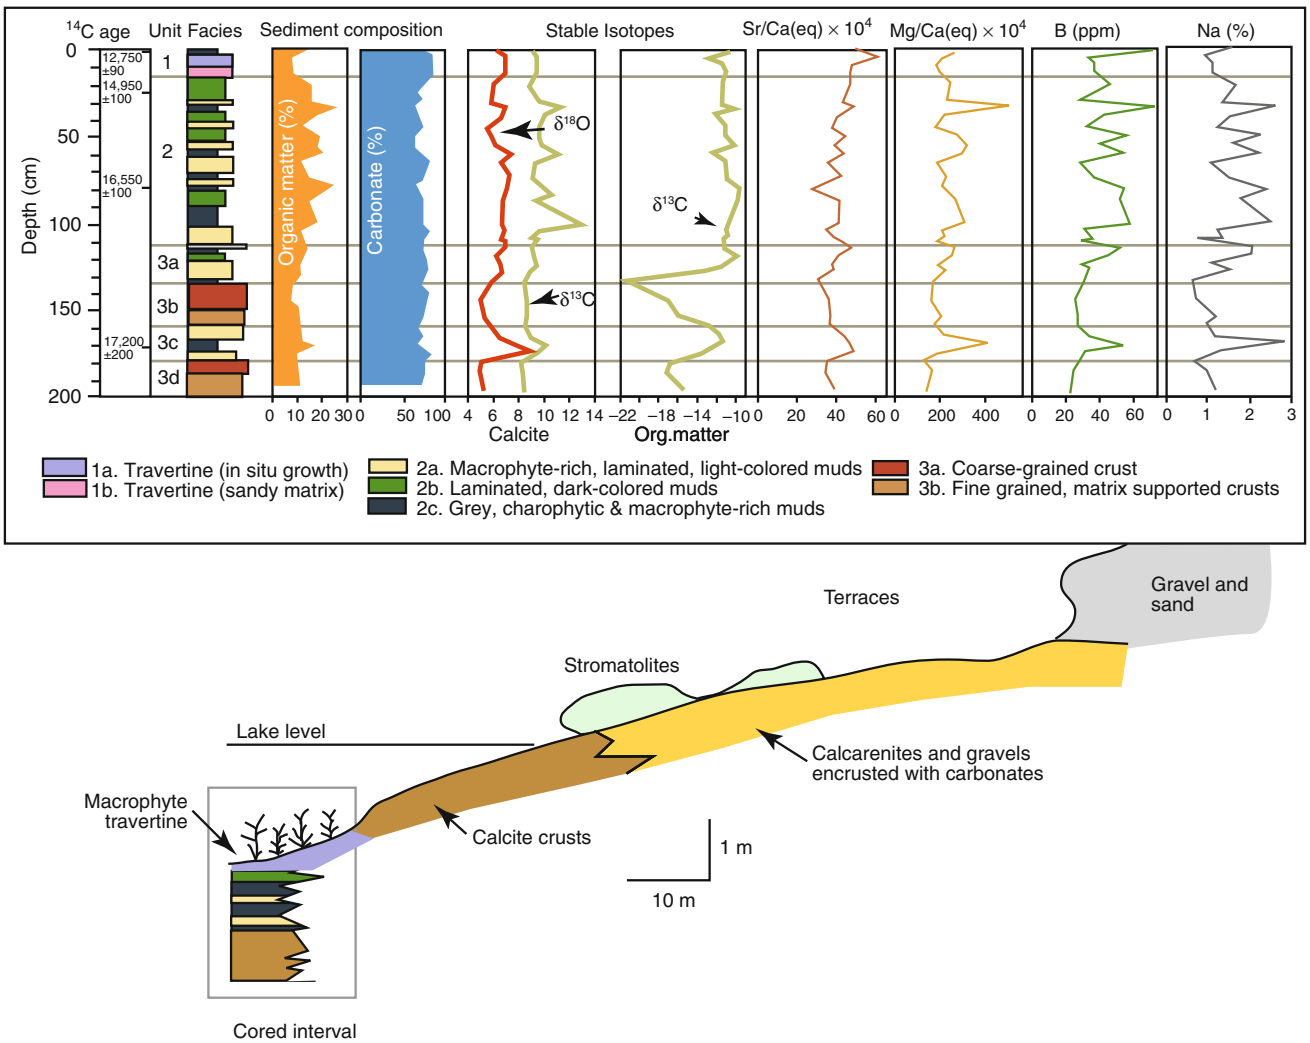

Fig. 1.16 Sedimentary facies, sediment composition, stable isotopes and geochemistry of the Lake El Peinado core, Andean Altiplano. Core was collected in the perennially subaqueous carbonate margin of the lake (After Valero-Garces et al. 1999, 2001). Macrophytes are the current active carbonate binders. Stromatolites today are not active, but grew at an earlier time of more saline water when conditions did not favour macrophytes. Dates are uncorrected AMS 14C ages (years BP). All isotopic measurements are reported as δ values vs. the PDB standard

(see Schouten et al. 2001 for opposing argument). Likewise, the dilution of the isotopic signature by C-14-free CO_2 from volcanogenic sources may hinder accurate C-14 chronologies of lake sedimentation when based on samples of lacustrine organic matter and other aquatic plants.

Microbial plexi can also flourish in a gypsum or siliciclastic host. Meter-sized gypsiferous thrombolites coated by well-developed zonally-differentiated microbial mats have been found growing in the shallow water rim (<1 m deep) of a restricted hypersaline lagoon, Laguna Pirata on the Archipelago Los Roques in Venezuela (Petrash et al. 2012). While within the deeper parts of the same lagoon there are several decimetres of organic-rich material containing gypsum granules and lacking carbonate cementation. The biolithification of the thrombolites is thought to have proceeded as follows: (1) Extracellular polymeric substances (EPS) comprising the microbial mat concentrate Ca^{2+} and other metal cations by adsorption from the hypersaline waters. (2) Some of these bound cations then serve as nucleation sites for primary calcium carbonate precipitation. (3) While carbonate phases are forming in some zones of the mat, in other zones they are being re-dissolved due to the acidity generated through the metabolism of sulphide-oxidizing bacteria. (4) As the dissolved sulphide is oxidized into sulphate, the porewater become saturated with respect to gypsum. (5) As primary gypsum precipitates within the structures, endolithic sulphate-reducing bacteria metabolize the sulphate moiety in the mineral phase, while simultaneously oxidizing the EPS trapped during accretion. (6) As microbial EPS degradation proceeds, the anaerobic oxidation of specific protein fractions

of the EPS matrix leads to increased alkalinity, the partial dissolution of gypsum, supersaturation with respect to calcium carbonate, and ultimately pseudomorphic aragonite replacement; this differs from secondary calcite cements in being enriched in ^{12}C, and depleted in minor and trace metals initially associated with the EPS.

Microbial plexi in a siliciclastic host are typically referred to as wrinkle mats or wrinkle structures and are a common feature in Precambrian sediments. The lack of carbonate minerals and sulphate-reducers makes for a minimum of penecontemporaneous metabolism-related carbonate cementation and they are typically interpreted as dominated by grain trapping processes (Fig. 1.14b). Microbial mats can also occur in a gypsiferous clastic host. This type of saline sedimentary structures, related to mat growth, belong to the group of "mat expansion structures" known as "petees" (Krumbein et al. 1994; Vogel et al. 2009). The name petee is not exclusive as it has also been applied to inorganic pressure expansion ridges and polygons in halite crusts (Bouougri et al. 2007). Petees, as defined by Krumbein et al. (1994) in reference to evaporitic clastic sediment surfaces with biofilms, tend to deform the upper, cohesive part of any gypsum-rich microbial mat into bulges and domes, thus enlarging the mat surface. Sometimes, laterally interacting bulges may be arranged in a polygonal pattern. If petees are filled by combinations of chemical sediment and muds rising up from below, a petee surface may be preserved, such ancient examples have been named "petee ridges" (Schieber 2004; Lokier 2012).

Study of biofilms in the lower portions of gypsum crusts in the gypsum salterns (pre-halite concentrators) at Guerrero Negro has shown they play a role in determining the gypsum saturation state for both the inner regions of precipitation-dominated deposits and biofilm supported surfaces (Vogel et al. 2009) Specifically, biofilms are present where gypsum dissolution has occurred in the interior regions of stacked gypsum bed surfaces. At lower salinities, biofilms apparently facilitated gypsum precipitation within the biofilm-supported surfaces. Both of these processes (dissolution and precipitation) are reflected in fabrics, textures, and mineral morphologies in the crusts. The dissolution zone is important because it becomes a lacunal boundary between the gypsum and the underlying sediment, which is often sulphidic, with much lower gypsum volumes. Significant volumes of gas, containing up to 30 % methane, can occur in sediments beneath gypsum precipitation surfaces in a saltern (Don Bebout, pers. com.). The dissolution zone provides accommodation space for this gas facilitating domal forms and so creating a morphology that may be preserved upon burial (Vogel et al. 2009).

Microbialite Sedimentology in Saline Lakes

Mineralisation associated with biofilm metabolism in hypersaline lacustrine settings is much more important than simple agglutination capture that occurs in many Holocene lacustrine microbialites (Table 1.3). Niches occupied by stromatolites and tufa/travertine cement reefs in saline lacustrine settings circumscribe a much wider range of salinities and water conditions than evidenced by modern marine thrombolites and stromatolites; for example, some modern coastal lacustrine thrombolites in Venezuela are gypsiferous (Petrash et al. 2012). Isopachous biomineralized subaqueous stromatolite reefs, texturally identi cal to their ancient mm-laminated counterparts, still grow in the mesohaline carbonate-saturated seepage waters of some modern marine-fed gypsum lakes (von der Borch et al. 1977; Warren 1982a). The coarse-layered sandy agglutinated forms of Shark Bay and the mud-cracked supratidal algal mudstones of the Abu Dhabi sabkha have fewer ancient evaporitic counterparts.

Similarly, healthy carbonate-precipitating microbialite communities in the upper parts of less-saline carbonate-rich littoral and slope breaks about many prograding lacustrine margins in modern temperate and tropical carbonate lakes, can be used as analogs for microbial growth in the high water stages of some ancient saline basins (Table 1.3; Dean and Fouch 1983). For example, modern thrombolites, tufas and stromatolites occur in littoral waters (10–60 m deep) about the edges of Lake Tanganyika (Cohen and Thouin 1987) and Salda Gölü in Turkey (Braithwaite and Zedef 1996). Near identical fresh to brackish water stromatolites, along with oncoids, travertines and tufas, occur in Plio-Pleistocene sediments of the East African Rift Valley lakes (Casanova 1986). Similar marginward microbial tufa cement reefs (bioherms) reached thicknesses of 7 m, with diameters of 15 m, in the Oligocene Ries Basin (Riding 1979; Arp 1995). Freshwater to mesohaline stromatolites characterise Oligocene lake margins in France (Casanova and Nury 1989) and the 1–10 m deep freshwater-filled evaporite karst pond fills (posas) in a modern gypsiferous playa, Cuatro Cienegas in Coahuila, Mexico (Fig. 1.11b; Minckley 1969; Winsborough et al. 1994). Other examples of ancient lacustrine counterparts include the Tertiary of southern France (Truc 1978) and the Eocene Green River Formation of the USA (Seard et al. 2013).

Widespread mm-laminated fine-grained evaporitic stromatolites tend to accumulate in more saline lacustrine settings, settings where surface brines are waters supersaturated with respect to a carbonate phase, typically aragonite. In these settings the role of biology is less obvious in the laminates. Biofilms of archaea, eubacteria and algae can be passive agglutinators rather than active participants during the formation of domal to massive laminar stromatolites. It is in this group of structures that the phase "may or may not be of biological origin" comes into play. Modern examples of such enigmas include manganiferous aragonitic stromatolites that define the northwestern strandplain margin of the Northern Basin of the Dead Sea (see Druckman 1981 vs. Garber and Friedman 1983). Texturally identical evaporite-associated

biomineralized stromatolites and biolaminites have characterised the mudflat and strandzone margins of saline and alkaline playa lakes and marine evaporite basins throughout much of the Phanerozoic, especially at times or in regions of transition into or out of episodes of basinwide evaporite precipitation.

Mineralogy in most modern saline lacustrine stromatolites is dependent on what carbonate phase is precipitating in the ambient lake water. This is true even when biotal metabolism plays a significant role in driving carbonate precipitation. Stromatolites and microbial bioherms are aragonitic in many modern saline lakes (e.g. Great Salt Lake, Eardley 1938; Marion lake, South Australia, von der Borch et al. 1977) and the precipitation process is often facilitated by the metabolic activities of bacteria. As part of this carbonate saturated spectrum, brine-shrimp egg cases are replaced by aragonite in the growth cavities of modern stromatolites in Great Salt Lake, Utah (Pedone and Folk 1996). Hydromagnesite-aragonite mm-laminated stromatolite domes and mats dominate in the schizohaline ephemeral waters of North and South Stromatolite Lakes in the Coorong region of South Australia (Table 1.3; Chap. 4), while poorly preserved hydromagnesite-magnesite stromatolites characterise many present-day playa surfaces across the Caribou Plateau in Canada (Renaut 1993a). Similar stromatolite domes characterise the highly alkaline (pH>9) fresh to brackish waters of Salda Golu (Lake) in Turkey where lake margin subaqueous stromatolites are composed mostly of hydromagnesite, along with entrapped diatom tests (Fig. 1.17 and Chap. 4; Braithwaite and Zedef 1994, 1996).

At the basin scale, Quaternary calcitic and aragonitic algal tufa and travertine reefs form atop spring vents in groundwater outflow zones, where they can construct substantial spring mounds (Habermehl 1988). Tufa annual growth rates can be impressive in these vent-associated features; Rosen et al. (2004) documented aggradation rates of 30 cm/year in the modern subaqueous tufas of Big Soda Lake in Nevada. In contrast, the annual layers preserved in lacustrine stromatolites are much thinner. When layers in Holocene stromatolites from Walker Lake, Nevada (United States) were dated using high-resolution ^{14}C dating techniques the lamina accretion rate for the 5 cm thick stromatolite layer was low and varied over the period the stromatolite grew from 500 to 3,000 years BP (Petryshyn et al. 2012). At the base of the structure, the laminae formed with a period of 5.6 ± 1.6 years/lamination, in the middle at 1.6–2.8 ± 1.9 years/lamination, and 4.5 ± 0.8 years/lamination at the top of the laminated portion. The predominant 4–6 years periodicity implies that lamination formation is likely more closely related to regional climate forcing (e.g., El Nino-Southern Oscillation) versus the typical diurnal or seasonal changes traditionally assumed for most ancient stromatolites. Some of the impressive thinolitic tufa reef mounds in cool -water temperate and high-altitude saline lakes were originally constructed of an unusual but interesting variety of low temperature calcite called ikaite (Chap. 4). This hexahydrate form of calcite is found today forming ephemeral precipitates in near freezing brines around spring vents of CO_2 -rich waters in Mono Lake and in Quaternary sediments of the Lohanton Basin (Pyramid Lake), Nevada. Similar spectacular tufa mounds occur in groundwater outflow zones on the subaqueous floor of Lake Van, Turkey (Kempe et al. 1991).

Once the water temperature about a spring mound rises above 3–4 °C the ikaite dehydrates to calcite, but the calcite can preserve the characteristic lenticular and twinned outline of its precursor. But a lenticular to lozenge shape in a calcite pseudomorph is easily confused with other evaporite minerals, such as gypsum and gaylussite, which also are readily pseudomorphed by calcite (Chap. 7). Ikaite pseudomorphs can have little to do with an evaporite precursor, and occur in modern marine shelf sediments of the Antarctic and in modern and

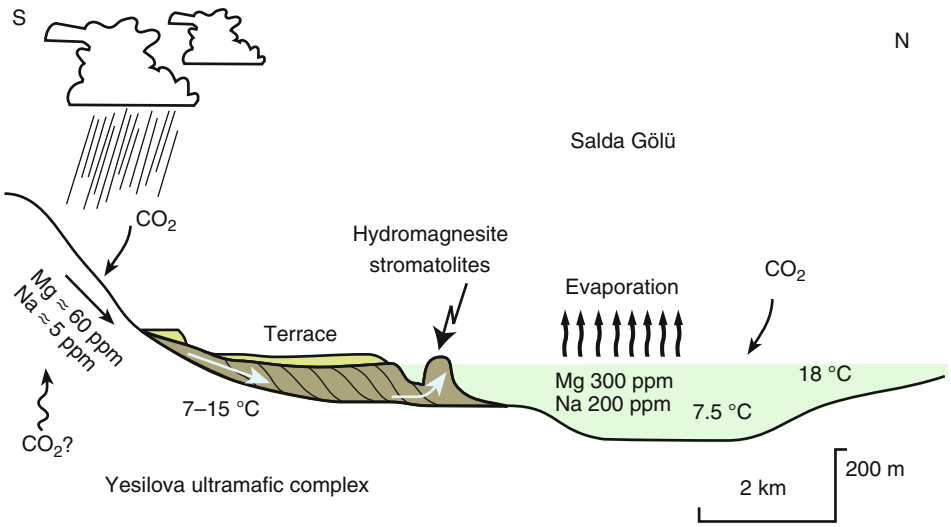

Fig. 1.17 Schematic cross section of Salda Gölü showing hydromagnesite stromatolites growing subaqueously in front of the carbonate tufa terrace (After Russell et al. 1999)

ancient glacial outwash fans from around the world (Shearman and Smith 1985; Larsen 1994; Riccioni et al. 1996).

The perennial, cold, biologically-stressed freshwaters of glacially-fed freshwaters of Lake Untersee in Antarctica provide an interesting setting for conical stromatolite growth (Andersen et al. 2011). Lake Untersee is one of the largest (11.4 km^2) and deepest (>160 m) freshwater lakes in East Antarctica. Located at 71°S the lake has a perennial ice cover, a water column that, with the exception of a small anoxic basin in the southwest of the lake, is well mixed, supersaturated with dissolved oxygen, alkaline (pH 10.4) and exceedingly clear. The floor of the lake is covered with photosynthetic microbial mats to depths of at least 100 m. These mats are primarily composed of filamentous cyanophytes and form two distinct macroscopic structures, one of which – cm-scale cuspate pinnacles dominated by *Leptolyngbya spp*. – is common in other freshwater lake in Antarctica, but the second – laminated, conical stromatolites that rise up to 0.5 m above the lake floor, dominated by *Phormidium spp*. – has not previously been reported in any modern environment, but are analogous to the ancient stromatolite known as *Conophyton*.

The laminae that form the conical stromatolites are 0.2–0.8 mm in thickness consisting of fine glacial clays and organic material; carbon dating implies that laminations may occur on near decadal timescales. The uniformly steep sides (59.6° ± 2.5°) and the regular laminar structure of the cones suggest that they may provide a modern analogue for growth of some of the oldest well-described Archaean stromatolites. Mechanisms underlying the formation of these stromatolites are as yet unclear, but their growth is distinct from that of the cuspate pinnacles. The sympatric occurrence of pinnacles and cones related to microbial communities with distinct cyanobacterial compositions suggest that specific microbial behaviours underpin the morphological differences in the structures across fresh to saline lacustrine settings (Andersen et al. 2011).

Microbialite Sedimentology in Marine Settings

Unlike modern stromatolites and microbialites, which tend to construct significant rock masses in salinity or temperature stressed environments, Precambrian stromatolites were environmentally diverse and abundant across hypersaline, normal marine and nonmarine settings. They first appeared around 3.45 Ga and dominated biogenic sedimentation from 2,800 to 1,000 Ma (Fig. 1.18; Riding 2011). The beginning of their Proterozoic decline and environmental restriction, variously identified at 2,000, 1,000 and 675 Ma, has been attributed to reduced marine cementation or to eukaryote competition. The former was perhaps tied to higher CO_2 concentrations in the atmosphere and higher calcium concentrations in Precambrian oceans compared to oceans of today (Laval et al. 2000), while biogenic competition related to the evolution of shelly exoskeletons and the gastropod radula (Garrett 1970a). The previously enigmatic lack of calcified cyanobacteria filaments in stromatolite-bearing Precambrian sequences is now explained as a likely result of high concentrations of dissolved inorganic carbon in the Precambrian ocean (Arp et al. 2001) or by the postulate that a high proportion of many Archaean stromatolites were the result of inorganic precipitates and the resultant isopachous cement layering (Pope et al. 2000).

Precambrian stromatolites were not confined to the more arid peritidal marine or marginward lacustrine seep situations that characterise most Phanerozoic stromatolites. Such high stress environments (hypersalinity/exposure) tend to exclude many metazoan marine grazers that otherwise browse and destroy algal mats. Modern areas of thick extensive marine-margin stromatolites/cryptalgal laminites are located at the edge of the cropping range of marine grazers. Examples of gastropod restriction include the seaward side of the algal facies of the Arabian Gulf (Kendall and Skipwith 1969), the hypersaline intertidal flats of Shark Bay, Western Australia (Logan 1987) and bio-eroded edges of lacustrine stromatolites in the Coorong Region (Warren 1990).

Various thrombolites and dendrolites, mainly formed by calcified cyanobacteria, became important marine microbialites early in the Palaeozoic and reappeared in the Late Devonian, as marine stromatolite populations declined. Microbial marine carbonates retained their importance through much of the Mesozoic, they became scarcer in marine environments in the Cenozoic, but locally re-emerged as large agglutinated domes, possibly reflecting increased algal involvement in sediment binding and cementation.

There are still a few modern normal-marine settings where metre-scale stromatolites flourish. Holocene columnar stromatolites grow as part of a thrombolite-stromatolite association on the floor of modern tidal channels off Lee Stocking Island, Exuma Cays. These bio-columns show three associations of internal sedimentary structures: (1) prokaryotic stromatolites comprised of alternating layers of coarse-grained ooids and peloids, and fine micrite that are formed exclusively by microbial activity; (2) eukaryotic stromatolites comprised of microbially-induced micritic layers alternating with detrital layers bound and cemented by eukaryotic algae; and (3) thrombolites displaying irregular, clotted fabrics and formed by communities of microbes, algae, and metazoans (Fig. 1.19a; Feldmann and McKenzie 1998).

Onshore in San Salvador in shallow turbid water, beneath the modern mesohaline waters of Storr's Lake, marine-influenced thrombolite layers alternate with stromatolite layers to create mushroom shaped mounds. This alternating layering perhaps reflects changes in salinity and light penetration (Fig. 1.19b; Mann and Nelson 1989). Formation of many modern marine thrombolites has been attributed to

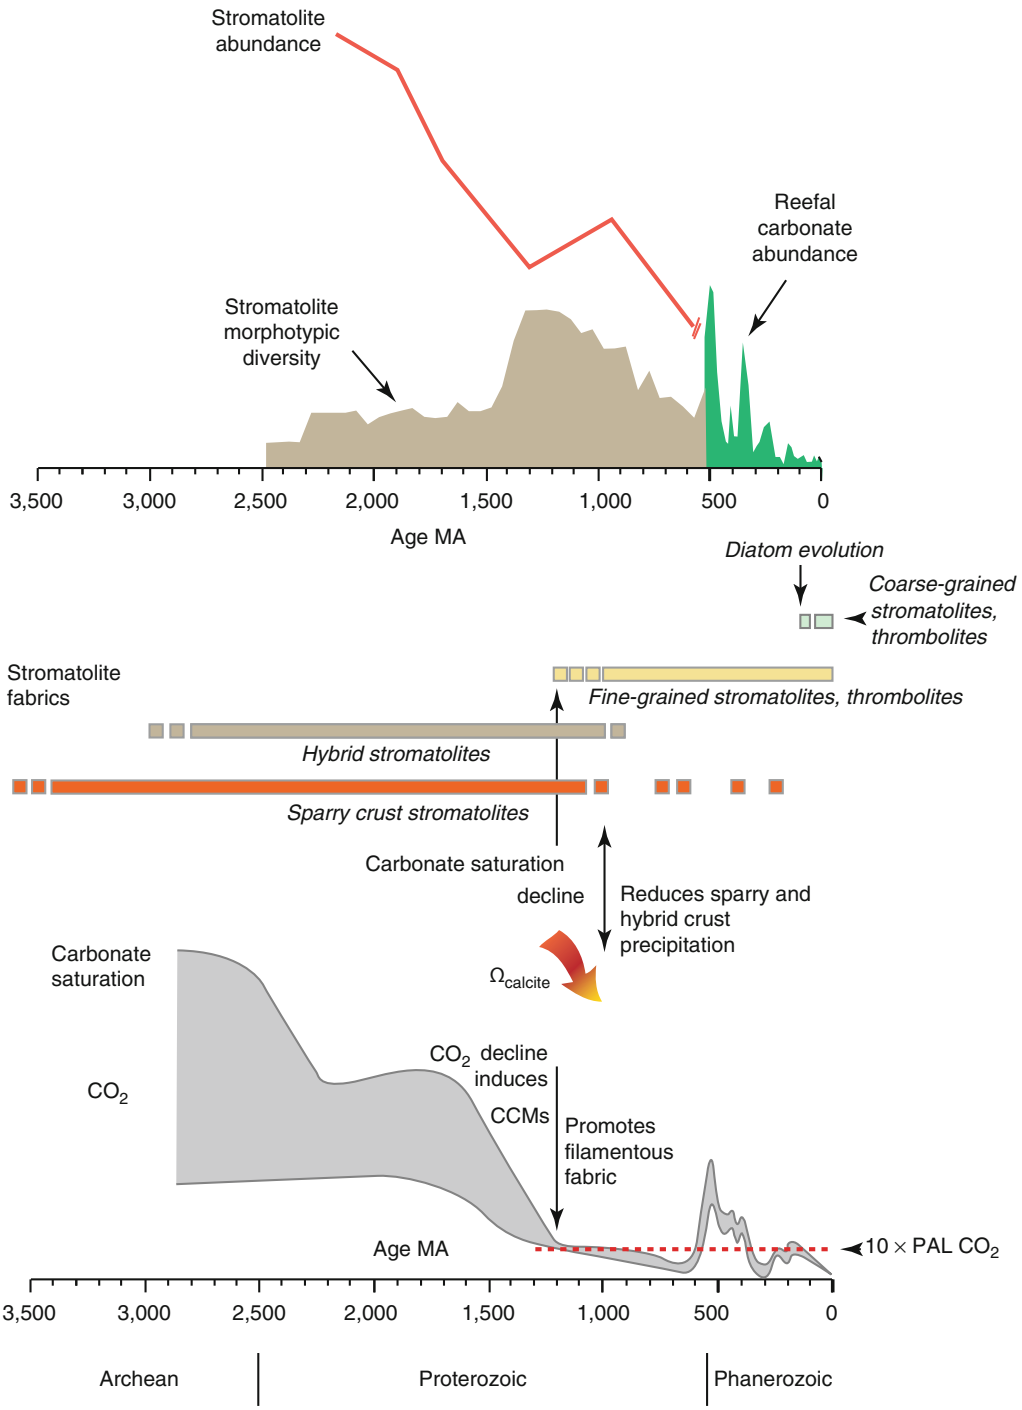

Fig. 1.18 Secular trends and possible controls on microbial carbonate developments across time as compiled by Riding (2011) and references therein. It includes Proterozoic stromatolite abundance (Grotzinger 1990) and morphotypic diversity (Awramik and Sprinkle 1999), together with Phanerozoic reefal microbial carbonate abundance (Kiessling et al. 2003). These suggest overall long-term decline for at least the past 1,000 Ma. Reduction in both Sparry Crust and Hybrid stromatolites 1,000 Ma ago may reflect decline in seawater carbonate saturation (Grotzinger 1990). Stromatolite-like sparry crust occurs sporadically in the Phanerozoic, particularly in evaporite basins (Pope et al. 2000). Increases in thrombolites 1,200–1,000 Ma ago could reflect development of cyanobacterial sheath calcification, reflecting inception of CO_2-concentrating mechanisms (CCMs) as CO_2 levels declined to 10 times present atmospheric level (PAL). Late Neogene inception of coarse agglutinated stromatolites and thrombolite could in part reflect incorporation of diatoms into microbial mats and also generally low values of seawater carbonate saturation

carbonate precipitation driven in large part by sciaphile (dark-loving) bacteria, which flourish under low sedimentation rates, low water energies and higher turbidity, hence the preservation of a clotted fabric and lack of lamination (Dupraz et al. 2009; Dupraz and Strasser 1999; Riding 1991). Phanerozoic marine thrombolites, in contrast, are mostly interpreted as non-laminated microbialites (not stromatolites) constructed by cyanobacteria and are not usually interpreted as sciaphiles.

According to Feldmann and Mckenzie (op. cit.) the contemporaneous formation of prokaryotic stromatolites, eukaryotic stromatolites, and thrombolites under identical conditions within the present marine environment is unlikely. They suggest that the prokaryotic stromatolites in the Lee Stocking bioherms represent microbial forms that began to develop in an environmentally-stressed intertidal setting during the early Holocene flooding of the Great Bahama Bank. In contrast, thrombolites began to form under the present,

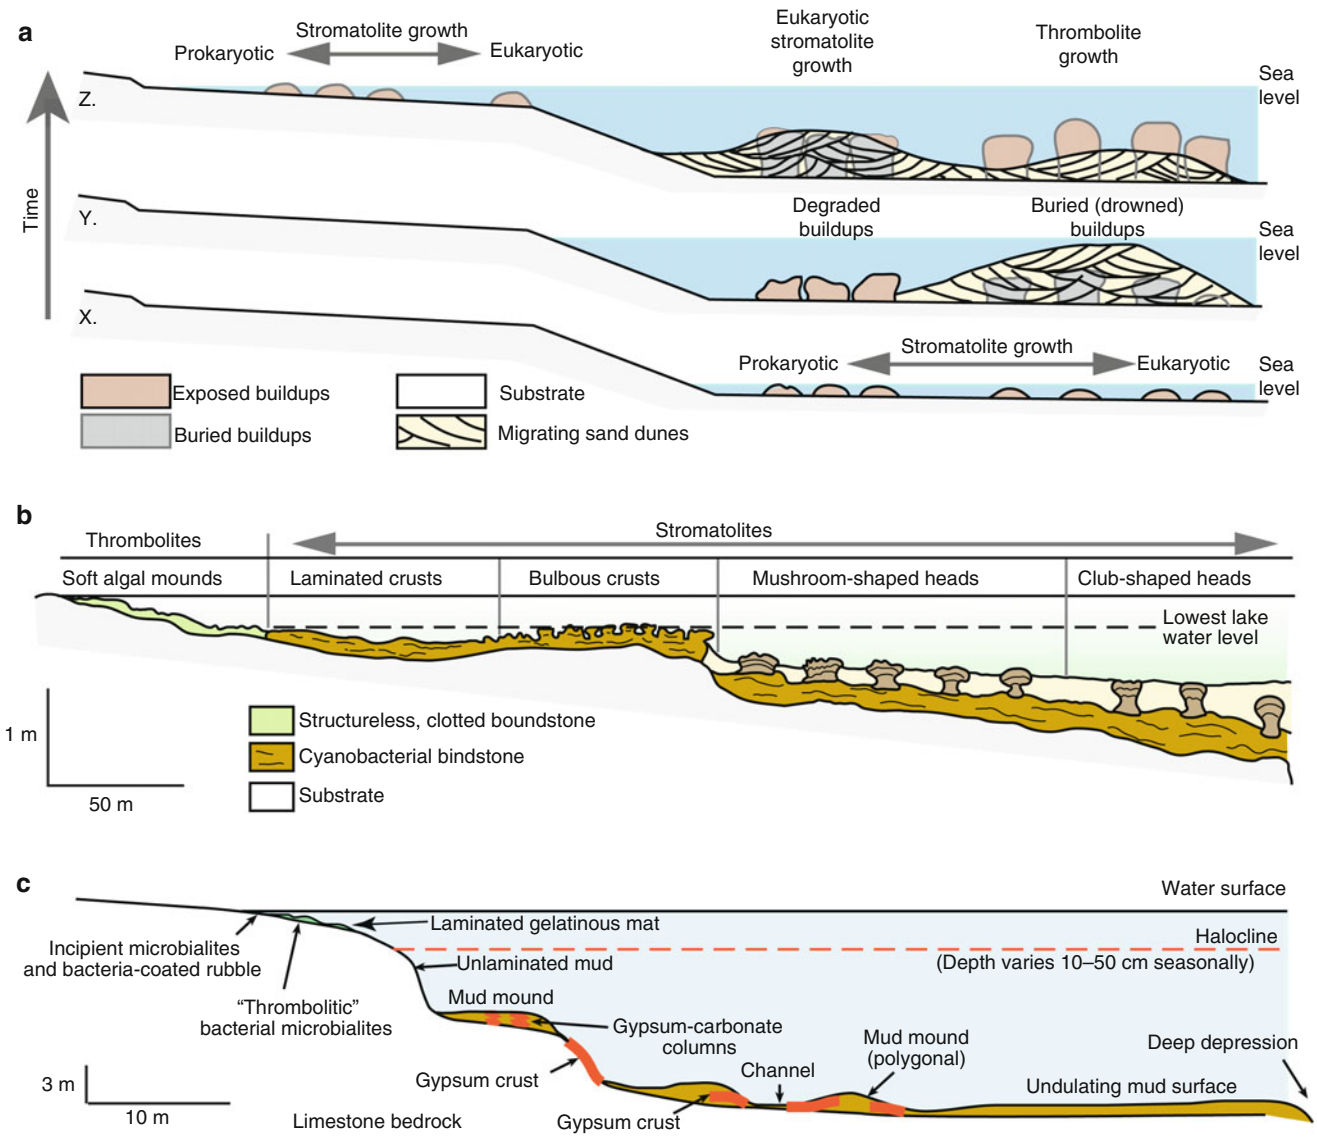

Fig. 1.19 Thrombolites in mesohaline to marine settings. (**a**) Evolution of microbialites during a rise in sea level from time X to time Z in the formation of marine subtidal stromatolites in Lee Stocking Island in the Bahamas (After Feldmann and Mckenzie 1998). (**b**) Distribution of algal/thrombolitic structures in mesohaline aragonite muds of Storr's Lake, San Salvador (After Neumann et al. 1988; Mann and Nelson 1989). (**c**) Thrombolites (aragonitic) passing into gypsiferous mud mounds below the halocline at the southern end of the channel in Gotomeer, Bonaire (After Kobluk and Crawford 1990)

normal-marine subtidal conditions (Fig. 1.19a). The eukaryotic stromatolites represent intermediate forms between prokaryotic stromatolites and thrombolites, with a gradual change from stromatolite to thrombolite reefs tied to rising sealevel. With the deepening, there would have been a decrease in salinity, an increase in energy, and possibly an increase in nutrient supply; all factors that favour thrombolite growth.

Unfortunately, most environmental and depositional models for Phanerozoic stromatolites tend to draw heavily on Holocene peritidal marine-margin analogs, such as Shark Bay, a hypersaline setting where sand grain trapping (agglutination), rather than micrite precipitation, is the dominant mode of sediment accretion. Accordingly, using modern analogs, many sedimentologists assume that well-preserved Phanerozoic stromatolites must have formed in intertidal to supratidal marine settings. As we shall see in Chap. 5, a marine-connected basin is not the best way to model evaporitic carbonates associated with thick evaporites. Microbes living in ancient saline systems constructed a far more diverse and wide ranging biotal association in evaporitic settings than simplistic Shark Bay analogs imply (Chap. 9).

Microbialites Typify Marine to Evaporite and Evaporite to Marine Transitions

Throughout the rock record, Pope et al. (2000) noted that a transition between a carbonate platform or an isolated carbonate buildup and the overlying evaporites is commonly defined by assemblages of stromatolites or interlaminated carbonates and evaporites (Table 1.4). Stromatolites display lamination textures that vary from peloidal and discontinuous on a scale of a millimetre to a few centimetres, to isopachous and continuously laminated on a scale of a centimetre to a few metres. Isopachous lamination may be composed of either: (1) micrite or radial-fibrous calcite, or (2) dolomite. Isopachous laminae are remarkably uniform, varying little in thickness over a given lateral distance, whereas stromatolites formed of peloidal laminae, tend to show marked variations in thickness over an equivalent lateral distance (phototactic thickening). They observe that isopachous textures are uncommon on most open-marine carbonate platforms and apparently developed in transitional carbonate-to-evaporite settings because of basin isolation and drawdown leading to increasing temperature, salinity, and anoxia related to water stratification and saturation with respect to the precipitated carbonate (Table 1.4; Fig. 1.20a). The resulting ecologic restriction created an opportunity for isopachous stromatolite growth.

Stromatolites with isopachous lamination are interpreted to form via in situ precipitation of sea-floor-encrusting calcite and possibly dolomite, whereas the stromatolites composed of peloidal, discontinuous lamination are inferred to have formed by trapping and binding of loose carbonate sediment in microbial mats and can be unrelated to the onset of basinwide evaporite restriction and drawdown. According to Pope et al. (2000), isopachous stromatolites may have accumulated by chemogenic precipitation in the absence of microbial mats, while peloidal stromatolites grew by agglutination in the presence of microbial mats and since the onset

Table 1.4 Selected examples of unique evaporitic carbonate fabrics in basinwide transition facies passing from carbonate through mesohaline to hypersaline deposition

Location	Units	Carbonate fabrics	Composition
Great Slave Lake, Canada, Palaeoproterozoic (1.8–1.9 Ga)	Perthei Grp. (c) Stark Fm. (e)	Tufa, isopachously laminated stromatolite at contact in shallow water; Fibrous marine cements throughout platform	Basinwide evaporite, Halite >> gypsum (no anhydrite)
Oman, Vendian (570–543 Ma)	Buah Fm. (c) Ara Fm. (e)	Fibrous marine cements throughout platform and isolated thrombolitic bioherms; Isopachously laminated stromatolites at contact; tufa-like crusts in carbonates within evaporates	Basinwide evaporite, Halite >> gypsum
Michigan Basin, Silurian (≈400 Ma)	Guelph Fm. (c) Salina Fm. (e)	Fibrous marine cements within pinnacle reefs; Isopachously laminated stromatolites (travertine-like coatings) cap marine reefs; Calcite laminites in interpinnacle reef areas	Basinwide evaporite, Halite >> anhydrite, potash salts
Western North America; Middle Devonian (≈385 Ma)	Winnepegosis (c)	Stromatolites cap marine reefs, fibrous marine cements in reefs and carbonate-evaporite laminites between reefs in deeper-water settings	Basinwide evaporite, Halite >> anhydrite
Sverdrup Basin, Carboniferous, Arctic Canada	Nansen (c) Otto Fiord (e)	Carbonate-evaporite laminites in basinal setting, fibrous marine cements throughout shelf-margin reefs and buildups	Halite ≈ anhydrite
Zechstein Basin, England, Late Permian (≈260 Ma)	Middle Magnesian Limestone (c) Hartlepool Anhydrite (e)	Fibrous marine cements throughout reef complex; Isopachously laminated stromatolites (Crinkly Beds) in bioherm capping marine reef complex; Laminar coatings within bioherm, neptunian dykes and cavities; Laminites in basinal setting between buildups	Basinwide evaporite, Halite >> anhydrite Locally on platform: Anhydrite >> halite
Mediterranean Messinian (Middle Miocene)	Terminal Carbonate Complex (c)	Thinly laminated stromatolites at transition from marine carbonate to evaporite; fibrous marine cements within reefs underlying stromatolites	Basinwide evaporite, Halite >> gypsum
Abu Shaar Complex, Egypt; Messinian (Middle Miocene)	Ruidais Fm. (c) Kareem Fm. (e)	Fibrous marine cements throughout marine reef complex; Thinly laminated stromatolites with fibrous cements on toe of slope; Unique pisoids with distinctive fibrous fabric	Basinwide evaporite, Anhydrite > gypsum > halite

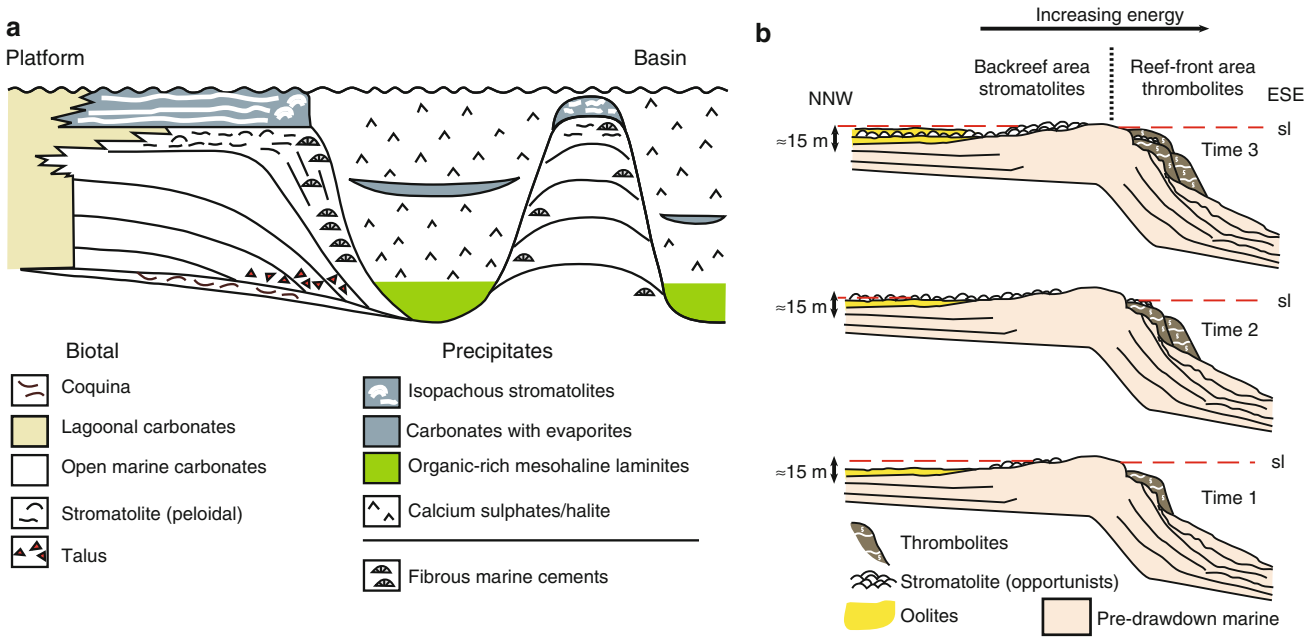

Fig. 1.20 Schematics of marine carbonate to evaporite transitions. (**a**) Typical transitions, showing relative positions in the basin stratigraphy of precipitated isopachous stromatolites and the precipitated carbonate fabrics that typify sediments accumulating mesohaline carbonates immediately prior to complete basin isolation and drawdown that defines the onset of basinwide calcium sulphate and/or halite evaporite deposition (After Pope et al. 2000). (**b**) Platform edge distribution of stromatolites and thrombolites relative to cyclic sea-level changes during the Intra-Messinian flooding event in a marginal Mediterranean sub-basin. (Time 1) Relative high sea-level stand with thrombolite growth in the subtidal zone at the front reef, oolite deposition in the deeper parts of the back-reef area, and stromatolite growth in the intertidal zone of the back-reef area. (Time 2) Relative low sea-level stand promoting thrombolite growth in the basinward migrated subtidal zone at the front reef and opportunist stromatolite growth in the intertidal zone on both the previously deposited ooid sands and thrombolites. (Time 3) Relative high sea-level stand with thrombolites growing over the preceding stromatolites in the subtidal zone at the front reef, opportunist stromatolite growth in the intertidal zone of the back-reef area, and sand deposition in the deeper water of the back-reef area (After Feldmann and McKenzie 1997)

of the Phanerozoic have been largely restricted to environmentally stressed biogenic sediment. The isopachous stromatolites dominated by cementstone textures plot in the sparry stromatolite portion of the classification plot for modern and ancient stromatolites (Fig. 1.14). I would not exclude biofilms from such isopachous stromatolites, it is just that high inorganic precipitation rates, especially in hypersaline settings, can swamp phototactic effects used to interpret ancient biofilms.

Pope et al. (2000) went on to note that when compared to pre-Mesozoic occurrences, stromatolites with thin, isopachous lamination and radial-fibrous textures, though present, are rare to absent in transition facies in Jurassic and younger evaporite basins, such as the Messinian of the Mediterranean region. Instead, the isopachous precipitative facies have been replaced by stromatolites with peloidal, clastic phototropic textures and by mesohaline mudstones with a low-diversity diatomaceous and coccolith biota. These stromatolites are sometimes in terlayered with thrombolites (as in Storr's Lake, Caribbean). They interpret the shift away from chemogenic stromatolites to agglutinated stromatolites as a change in seawater chemistry tied to the evolution of the nannoplankton.

Since the mid-Mesozoic, the accumulation of the biogenic planktonic mudstones beneath deeper ocean waters had three important effects: (1) Increased production of coccolith tests in the world's oceans (chalks) helped extract calcium carbonate from seawater, thus lowering the growth potential for inorganic precipitation of sea-floor-encrusting stromatolites. (2) Settling of both coccoliths and diatoms would have created a sediment flux to the sea floor, which would have served to impede growth of chemically precipitated stromatolites because of ongoing smothering of any growing seafloor crystals. (3) An increase in the Mg/Ca ratio in ocean waters, with consequent effects on the chemistry of marine bittern salts (Chap. 2).

Post-Mesozoic peloidal stromatolites (bio-agglutinates) and thrombolites tend to characterise transitions into and out of episodes of basinwide evaporite deposition. One of the best-preserved transitions of this style of stromatolite/thrombolite occurrence comes from the Late Miocene of SE Spain in cyclic stromatolitic carbonates deposited during and at the termination of the Messinian salinity crisis (Fig. 1.20b; Chap. 5). For example, large microbial carbonate domes (both stromatolites and thrombolites) defined the margins of the Sorbas and Alboran Basin during the uppermost Messinian. They

occur in a unit overlying the Messinian evaporite succession and were deposited in a variety of environments, including strandzones on fan deltas (Martin et al. 1993b; Braga et al. 1995), beaches, and oolitic shoals (Riding et al. 1991).

Their abundance and continuity in the transitional marine setting is comparable in many respects to their omnipresence as transitional forms in the Precambrian. There is, however, an important difference in some parts of the Messinian sequences. Although major unconformities separate normal marine reefs from the carbonates of the "terminal complex complex (TCC)," an impoverished and depauperate, normal-marine biota of Late Miocene corals (*Porites*), coralline algae, serpulids, bivalves, and encrusting foraminifers at times lived alongside the stromatolitic microbes while the TCC was accumulating (Martin et al. 1993b; Braga et al. 1995). The intimate association of stromatolites with a stressed, but stenohaline, marine biota rules out the possibility of continually elevated salinities at the onset of TCC deposition, as suggested by several earlier authors to account for the occurrence and proliferation of widespread microbial structures in the Messinian strata (Esteban 1980; Rouchy and Saint-Martin 1992). The most plausible explanation for this transition into and out of hypersaline into normal marine waters is that microbes acted as opportunistic biota and, for a time, outcompeted other organisms, settling and growing successfully in most of the available and rapidly expanding marine niches (Pope et al. 2000; Feldmann and McKenzie 1997). This happened during the initial stages of marine recolonization of the Mediterranean Sea, after drawdown and deposition of either the lower or upper evaporite sequences.

Thus, the development of microbial structures during the Messinian seems to be related, although indirectly, to the end of each "salinity crisis" and the creation of unoccupied marine ecologic niches as seawater encroached on drawdown unconformities. Earlier but ecologically comparable vacant niche scenarios are found atop Phanerozoic platform carbonates at the onset of basinwide evaporite stages (Table 1.4); examples include the Silurian of Michigan Basin (Sears and Lucia 1979) and the Permian of the Zechstein Basin (Paul 1980). In all these examples an abundance of stromatolites and thrombolites in normal marine environments in the aftermath of a mass extinction of the pre-existing marine benthic biota via drawdown can been explained by the stromatolite and thrombolite communities acting as opportunistic disaster forms taking advantage of vacant ecologic niches (Schubert and Bottjer 1992).

Vadose Pisolites, Ooids and Coated Grains

Fenestral carbonates, sometimes intercalated with grainstones, are frequently interpreted as peritidal sediments (Shinn 1983). Many evaporitic grainstones facies are dominated by coated grains, including oolites, and those with a wave-agitated mechanical genesis are indicated by well preserved crossbed sets. A marine conception is indicated by nuclei of marine shell fragments and intercalation with packstones and wackestones containing marine fossils. More typically in evaporitic settings these metre-thick beds of coated grains lack obvious crossbeds or marine fossils and are intercalated with biolaminites and sharp crosscutting truncation surfaces. Units tend to be inverse graded and coarsen upward into pisolitic rudstones, they are commonly interlayered with evaporite solution breccias (Figs. 1.21 and 1.22a). Pisolitic beds show many textural features, such as bridged coats and polygonal fitting of pisoids, that imply they formed "in situ", under conditions of little or no wave-induced agitation. Individual pisolites, now composed of calcite or dolomite, can show nonconcentric internal truncation surfaces and brick-like crystal terminations indicative of exposure and an aragonite parent (Fig. 1.22b, c; Assereto and Folk 1976).

Pisolite rudstones tend to be caught up in tepee structures or other saline strandzone layers and beds that retain internal

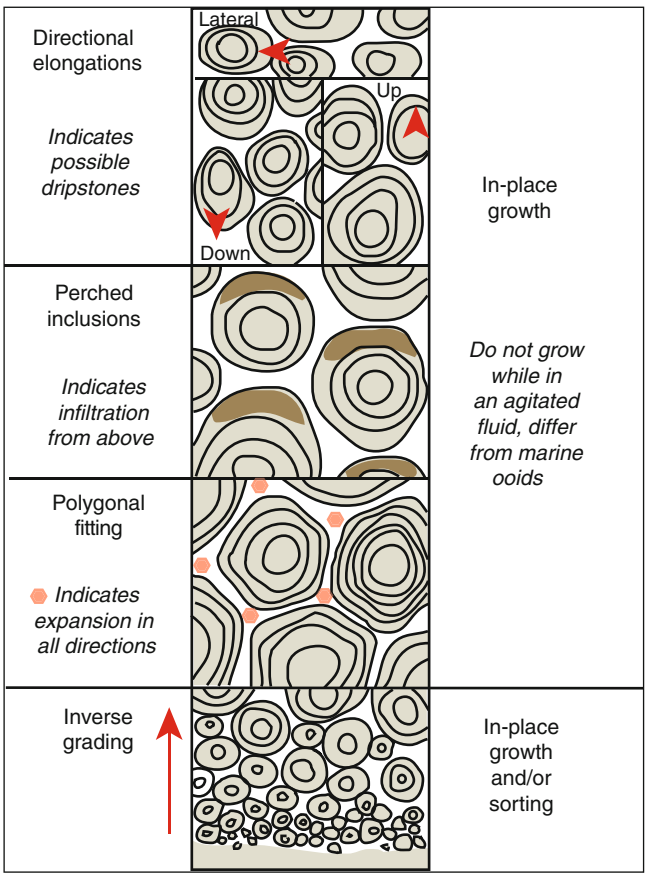

Fig. 1.21 Fabrics of pisoids created by in-place processes. Although all these features have been interpreted as requiring vadose pore conditions, only downward directional elongation (micro-stalactite) require such an interstitial condition (After Esteban and Pray 1983)

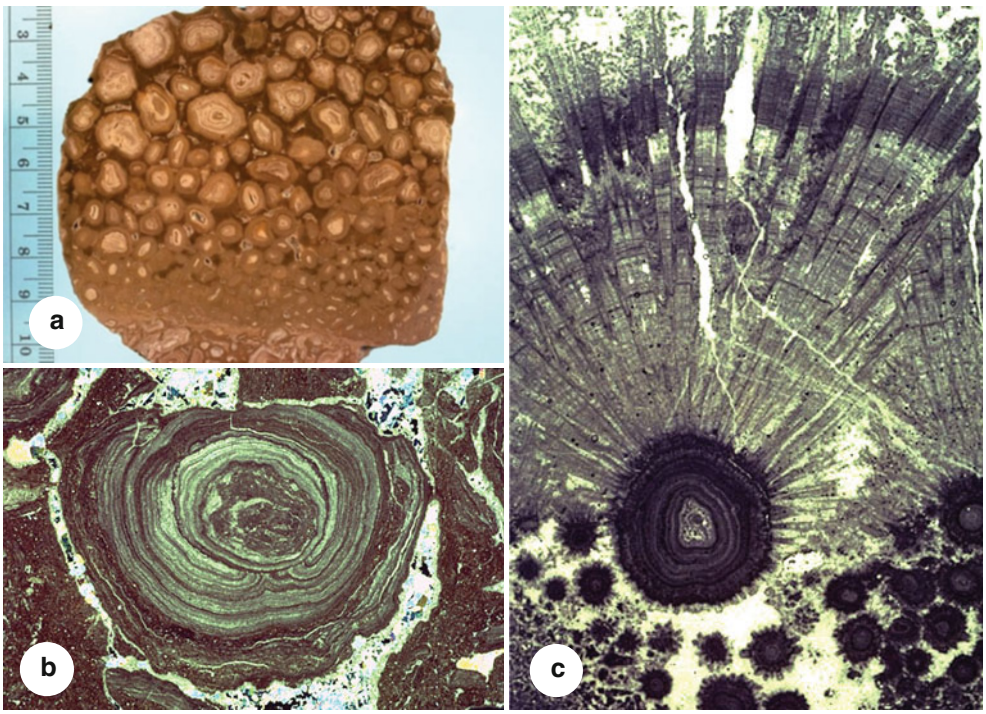

Fig. 1.22 Pisolites from Permian of West Texas. (**a**) Polished slab of pisolitic dolomite from the uppermost Yates Formation. Note reverse grading of grains, and "fitted fabric" in which grains have interlocked boundaries produced by compromise growth of outer coatings. Sample from roadside outcrop at "hairpin turn" on New Mexico Highway 7 in Carlsbad Caverns National Park, Eddy Co., NM. (**b**) Thin-section photomicrograph (cross-polarized light) of a pisoid from the Yates Formation. Note irregular, lumpy, partially concentric coatings; fracturing ("autobrecciation") of micritic- peloidal matrix; and evaporite plugging of remnant intergranular porosity. Sample is from 1,708.1 ft depth in Gulf/Chevron PDB-04 well on Northwestern Shelf of Delaware basin, 30 km ENE of Carlsbad, Eddy Co., NM. Long axis of photo = 14.5 mm. (**c**) Thin-section photomicrograph (plane-polarized light) of a marine-cemented pisolitic dolomite showing transition from pisoid to botryoidal cement crust. Note that the extremely elongate rays of cement which extend from upper surface of the pisoid show squared crystal terminations. This is used as evidence for an originally aragonitic composition for the cement. Sample from 1,739.3 ft depth in Gulf/Chevron PDB04 well on Northwestern Shelf of Delaware basin, 30 km ENE of Carlsbad, Eddy Co., NM. Long axis of photo = 16 mm (Images and descriptions courtesy of P. Scholle)

structures and cements indicative of alternating vadose and phreatic conditions. Such features include; perched inclusions, inverse graded pisolite beds, and pendulous circumgranular cements (Fig. 1.21; Dunham 1972; Esteban and Pray 1983; Handford et al. 1984; Husinec and Read 2006). They indicate a depositional setting that was part of a strandzone, typified by the "to and fro" of the strandline edge of a brine lake or seaway in a zone of groundwater seepage. The associated watertable rose and fell as, pore water conditions alternated between vadose and phreatic.

Pisolite crust cements formed in a strandzone retain infiltrated micrite and pendulous grain underhangs that indicate the sediment spent at least a part of its time above the watertable. The term vadose pisolite is sometimes used to distinguish these evaporitic pisolites from permanently subaqueous isopachous "marine" pisolites or the pedogenically formed calcrete pisolites. The prefix marine is a little misleading when describing isopachous pisolite crusts. Modern examples of isopachous pisolites, along with fitted, pisolith crusts define $CaCO_3$ saturated peripheral marine seepage areas on the strandplain of evaporite-filled coastal lakes in western and southern Australia (Warren 1982a, 1983a; Handford et al. 1984) and the thermal spring-fed margins of large halite-filled continental salars in the Andean Altiplano (Risacher and Eugster 1979; Jones and Renaut 1994). Both settings lack a surface connection to marine waters. The term seepage should perhaps replace the term marine when describing strandzone pisolites.

Ancient pisolites may be marine-fed or continental; all accumulated in $CaCO_3$ saturated waters. Seepage pisolites are part of a sedimentological association where pisolite crusts are forming mainly as accretionary chemogenic particles in areas of cooling, degassing and concentrating resurgent groundwater (in both marine and nonmarine fed hydrologies). Many are coated with microbial communities, which through their photosynthetic activity help drive the process of carbonate supersaturation. Seepage pisolites occur within confined saline groundwater seepage areas that are located on, or adjacent to, extensive carbonate mudflats about saline waterways, even when the waters rarely reach

$CaSO_4$ saturation (Husinec and Read 2006). However, it is emphasised that pisolites (and tepees) are not restricted to marine seepage settings, but also form about the strandzone margins of continental saline lakes and salars.

Esteban and Pray (1983) argue vadose (seepage) pisolites characterise the Permian island shoal and sandflat facies of West Texas (Fig. 1.23). There pisolitic crusts were thicker and most obvious within the central depressions of decametre-diameter saucers in what was an extensive tepee-overprinted megapolygonal terrain. Warren (1983a) argued the same pisolite zones were part of a marine seepage facies about the edge of a widespread saltern/mudflat depression that covered the platform interior and rather that being the high were likely situated behind a sandy island shoal. Nominal "marine" pisolites are characterised by isopachous rim cements, little or no grain fitting and few vadose textures. They are commonplace in normal marine Precambrian carbonates compared with the Phanerozoic marine (Swett and Knoll 1989). Their greater abundance reflects a more carbonate-saturated marine chemistry in Precambrian seas (see below). But, throughout geological time, an isopachous pisolite texture has also been a boiler-plate feature of the carbonate-saturated hypersaline lacustrine realm.

Work by Gerdes et al. (1994) has shown that in addition to "seepage" pisolites other carbon ate grains, such as ooids and peloids, typically thought of as indicators of marine conditions and mechanical agitation, can precipitate *in situ* in $CaCO_3$ -saturated evaporitic settings. They grow within modern microbial mats in hypersaline settings and require no wave-agitated or pelagic phase to precipitate concentric laminar grain coats. Laboratory experiments with unconsolidated muds, and comparisons with fenestral and grainstone textures in evaporitic Guadalupian backreef strata in West Texas by Mazzullo and Birdwell (1989), demonstrated that intense *in situ* hypersaline alteration of fenestral mudstones can create peloidal grainstones. They go on to argue that such diagenetic grainstones may be the precursors of some forms of pisolitic rudstone.

Wave-agitated shore-parallel crossbedded ooid sand belts, very similar to their modern marine look-alikes, can accumulate in a lacustrine strandzone. For example, cross-stratified oolitic lacustrine grainstones and packstones typify wave-agitated strandzone or lake margin sediments of contemporary Great Salt Lake, Utah (Eardley 1938), the Upper Cretaceous to Eocene lacustrine strandzone of Green River Formation of the Uinta Basin, Utah, USA (Williamson and Picard 1974) and the high energy, lake-shoreline carbonates of the Upper Triassic Mercia Mudstone Group of southern Britain (Milroy and Wright 2000). Texturally these hypersaline ooids show a radial texture that contrasts with the more typical tangential structure of modern marine ooids. Eardley (1938) noted that ooid sand bodies in Great Salt Lake are concentrated along relatively narrow, wind-swept coasts, adjacent to steep basement promontories and in waters that are less than 2 m deep (Chap. 4). In contrast, strandzone algal bioherms are typically, although not exclusively, associated with wider, less exposed and more gradually inclined shorelines distal to basement uplands. Work by Halley (1977) on ooids from the Great Salt Lake showed that in an agitated setting radial ooids are structurally weaker than comparable tangential marine ooids (Chap. 4). He argued that a statistically significantly proportion (>1 %) of syndepositionally broken ooids is a reliable indication of radial aragonite ooids associated with hypersaline shorelines (see also, Husinec and Read 2006).

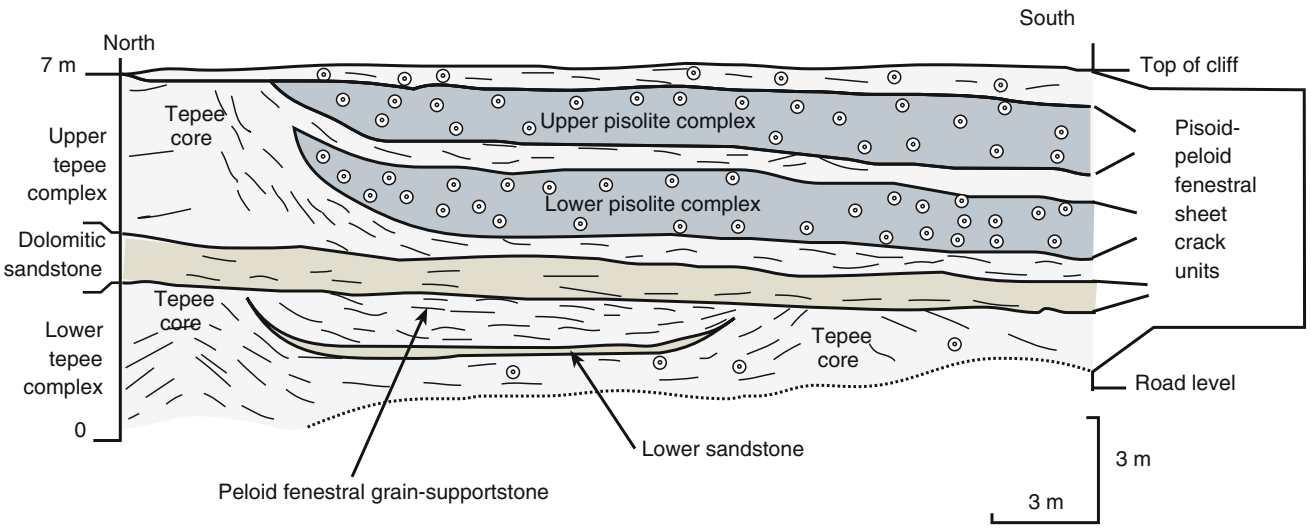

Fig. 1.23 Cross section of a field locality of the Permian Tansill Formation at Hairpin Curve in Guadalupe National Park, West Texas. Note the prominent development of pisolites in intertepee depressions within the upper tepee complex and the erosional surfaces that truncate the tepee complexes (After Esteban and Pray 1983)

Tepees

Tepees are the buckled and broken margins of saucer-like megapolygons in limestone or dolomite crusts that appear as an inverted "V" in vertical two-dimensional exposures (Figs. 1.23 and 1.24a, b; Adams and Frenzel 1950). Tepees are commonplace strandzone features in both modern and ancient settings (Assereto and Kendall 1977; Warren 1982a, b, 1983a; Esteban and Pray 1983; Kendall and Warren 1987; Logan 1987; Kendall 1989; Smoot and Lowenstein 1991; Last 1992; Jones and Renaut 1994; Mutti 1994; Armstrong 1995; lokier and Steuber 2009; Verwer et al. 2009). Some authors have extended the use of the term tepee to pressure ridges in crusts of gypsum or halite. I prefer to restrict usage of the term tepee to overthrust ridges in carbonate crusts and to use the term pressure ridge for overthrust ridges in halite or gypsum crusts. That is, although I use the term tepee non-genetically, I restrict its usage to carbonate crusts and add a prefix to describe its genesis, e.g. groundwater/seepage tepee, seafloor tepee, sabkha tepee, caliche tepee (Kendall and Warren; 1987).

However, not all tepees are tied to sheet expansion via carbonate cements precipitated from supersaturated saline waters, some may be related to microbial growth (Chow and George 2004) and yet others to seismic disturbance and associated thixotropy (Pratt 2002) or saturation in overpressured

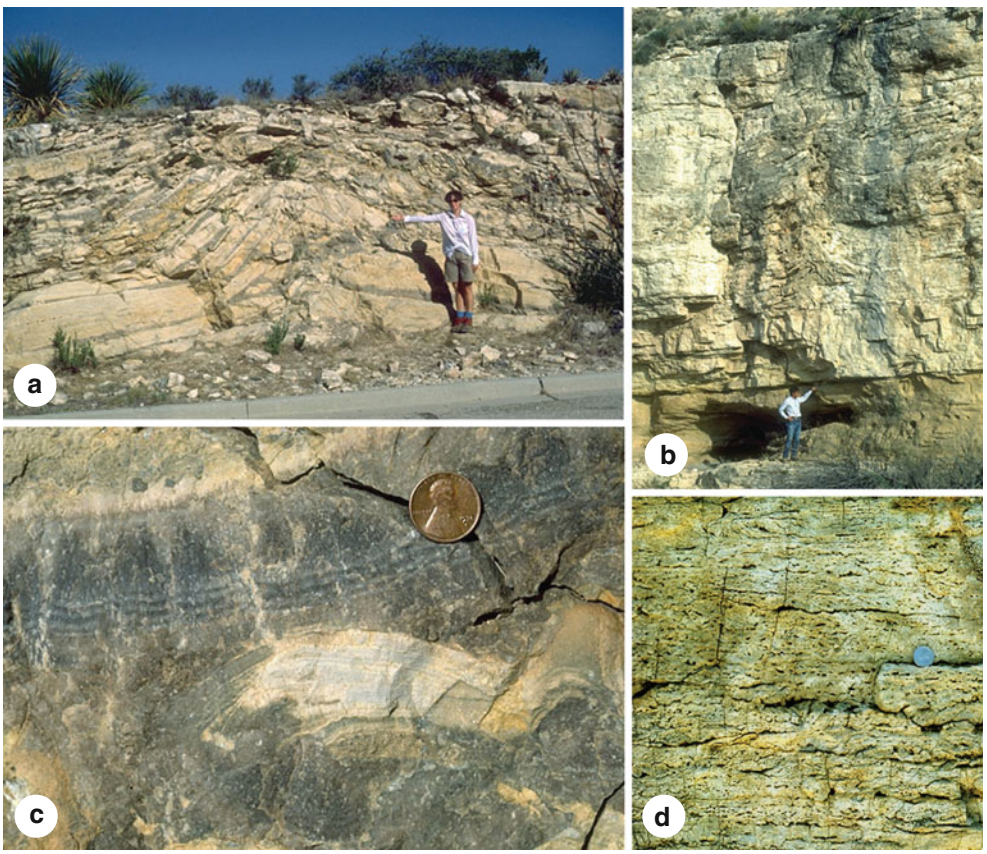

Fig. 1.24 Tepee Structures, Permian Basin, West Texas. (**a**) Tepee structure in Tansill Formation. Note that if the upturned margins of the structure were returned to a horizontal position, they could not be accommodated on a flat bedding plane; this shows that these are expansion polygons. Light yellow layers are dolomitised pisolitic and fenestral sediment; darker, gray layers are zones of sheet spar (aragonitic cement crusts). Interstitial growth of aragonite (in marine or coastal spring settings) was the most likely cause of sediment expansion and buckling. Outcrop at southwest end of parking lot at Carlsbad Caverns visitor's centre, Carlsbad Caverns National Park, Eddy Co., NM. (**b**) Stacked sequence of tepees, associated with fenestral and pisolitic dolomites, in the basal part of the Tansill Formation. A 1.8 m thick sandstone at the base of the exposure (at level of man) has truncated tepee stacks in the underlying Yates Formation and possibly acted as an aquifer for the resurging brines that precipitated these tepees. The sandstone sheets, which thin to a feather edge toward the shelf margin, have been interpreted as sabkha sandflats formed by eolian processes during sea-level lowstands. Roadside outcrop on Dark Canyon road approximately 2 km west of the canyon mouth, Eddy Co., New Mexico. (**c**) Close-up of sheet spar (aragonite cement) crust from within a tepee structure. Note growth of banded cements from top as well as bottom of cavity and incorporation of fragments of matrix sediment. Roadside outcrop at hairpin turn on New Mexico Highway 7 in Carlsbad Caverns National Park, Eddy Co, NM. (**d**) Peloidal and skeletal grainstones with fenestral fabric in the near-back-reef Tansill Formation. These strata were probably deposited on a relatively high-energy mudflat. Outcrop on south side of Dark Canyon, less than 1 km west of the canyon mouth, Eddy Co., NM. Coin is 2.4 cm in diameter (Images and descriptions courtesy of P. Scholle, see http://geoinfo.nmt.edu/staff/scholle/guadalupe.html; accessed May 5, 2014 for more details on this region of New Mexico)

sediments (Gammon et al. 2012). Some workers restrict the use of the term tepee to inorganic overthrust structures (carbonate and salt hosts) and use the term petee to describe overfolded to overthrust ridges in what were originally biogenically-bound surface layers. Petees can occur in layers and crusts composed of both evaporitic carbonates and more saline salts, the ridge crest need not be fractured, but can be a series of polygonally linked folds. See Gavish et al. (1985) for the original definition of petee and Noffke et al. (2003) for a comprehensive discussion of petees and other microbially induced sedimentary structures that are commonplace in evaporitic settings. Microbial petees typically have synoptic relief measured in centimetres, but range up to a metre high in the lagoonal strata of the Devonian Lennard Shelf in the Canning Basin of northwest Australia (Chow and George 2004).

Saline-tepees, along with vadose pisolites are characteristic features of cemented carbonate crusts in areas of a strandplain that experience wetting and drying cycles, $CaCO_3$ -saturated groundwater seepage, fluctuating salinity conditions, and marked diurnal changes in surface and nearsurface temperatures (Fig. 1.24c). Successive episodes of tepee development often stack one bed atop another, with the tepee-overprinted units separated by erosion surfaces, breccias or carbonate-cemented quartz sands (Figs. 1.23 and 1.24d). Pisoids in the Permian strata of West Texas appear to accumulate best within intertepee depressions or saucers (Fig. 1.23; Esteban and Pray 1983). Subsequent expansion episodes, along with local buckling, may rework beds formed in these pisoid-rich depressions into new tepees. When the pace of resurgence was strengthened during times of increased groundwater outflow, tepee crests were capped by domal stromatolites (Warren 1982a; Kendall and Warren 1987).

Many ancient tepee-influenced horizons in saline settings are interbedded with evaporite solution collapse breccias. This characteristic intercalation reflects the to and fro of a brine sheet edge over the strandzone carbonate facies, typically at times when the platform was isolated from a surface connection to the ocean and brine levels were fluctuating in response to the vagaries of evaporitic drawdown (Chap. 5). Some evaporite solution collapse may postdate the depositional hydrology of the cycle that formed the tepee, but, based on modern analogs such as Marion Lake and Lake Macleod, the schizohaline brine hydrology that forms the marginward saline seeps, where tepees flourish, is dominated by pore waters that are undersaturated with respect to halite and gypsum. Resurging groundwaters dissolve nearby evaporite beds as they form the tepee/pisolite beds (Warren 1982a). Because many tepee and seepage pisolite studies are done in the outcrop area of the basin of interest, the significance of thin evaporite residue layers that outcrop as thin layers in a thick stacked sequence is either missed or ignored. Such outcrop features are seen as shortterm exposure surfaces by workers who do not realise these thin residua/breccia bed indicate the former presence of metres to tens of metres-thick evaporite bed. When the unaltered equivalents of these "hiatii" are seen in core they are typically saltern anhydrites. This effect of the telogenetic passage of the platform margin into outcrop should be distinguished from syndepositional evaporite dissolution which can go handin-hand with the formation of stacked and brecciated tepee beds.

The typical result of ongoing early evaporite dissolution (≈eogenetic) is the disturbance or collapse of the tepee-affected strata. Any subsequent prograding of the seepage margin into the edge of an evaporite basin means the tepee zone is cannibalised from below and along its landward margin by its own groundwaters. All that may be preserved as widespread evidence of a prograding tepee hydrology within an ancient platform cycle is a terra rosa profile mixed with remnant breccias composed of fragments of tepee crusts, stromatolite breccias and other residues of the strandplain (Burri et al. 1973; Assereto and Kendall 1977; Bogoch et al. 1994; Mutti 1994).

Evaporite horizons, so typical of sump environments that are located downdip and intercalated with tepee horizons, typically dissolve. Dissolution can very early and effect the depositional landscape or in the mesogenetic or telogenetic realms. These evaporite beds and rarely make it back to the surface as outcrop other than as thin residua horizons. Yet outcrop is where Lidar based studies are done in order to better interpret perceived palaeo-elevations end associated tepee facies inter-relationships, (Verwer et al. 2009). The high probability of syndepositional or early burial evaporite dissolution and its influence of ambient topography is not understood or largely ignored in such studies. So, the tepee--island shoal facies are interpreted as the topographically highest position in the landscape at the time of deposition. Locally, this may be so in regions of strong artesian outflow (as about the pisolitic edges of most drawdown and many endorheic arid lacustrine basins), but much less likely in pisolite zone accumulating in what are interpreted as a open-marine platform edge or ramp setting. These systems, with their inferred surface (hydrographic)[2] connection to the open marine cannot possess the hydrological head required to drive such a pisolite-tepee system (see Chap. 2).

In plan view, tepee ridges define the upturned edges of megapolygonal saucers, typically tens ot metres across (Fig. 1.25). As such they indicate upwelling water-saturated very-shallow watertable conditions where crust volume is

[2]I define brine bodies that are connected to the world's oceans via an at-surface water body as having a hydrographic connection. I do this to contrast the connection hydrology in drawndown water bodies, which require a subsurface or seepage connection. This marine-seepage conduit may be either an open phreatic (no overlying aquitard or aquiclude) or artesian connection.

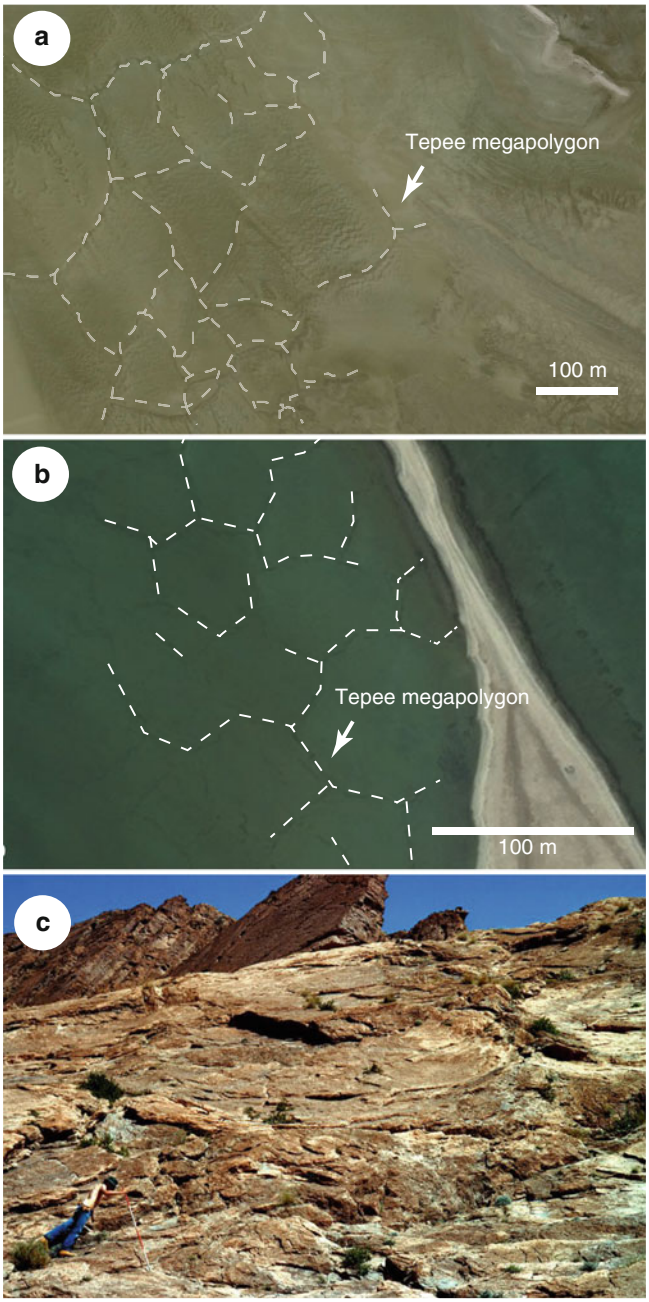

Fig. 1.25 Tepee ridge megapolygons. (**a**) Modern ridge polygons in the water covered lagoon floor at the southern end of Khor Al Bazam, UAE (see Lokier and Steuber 2009). (**b**) Modern ridge polygons in the water covered lagoon floor at Ras Alzabna, near Ra's al Qurayyah at the southern end of Half Moon Bay, Saudi Arabia (see also Fig. 3.17d). (**c**) Tepee megapolygons exposed on a dip surface in Jurassic dolomites in the valley of Todgha, Morocco (see Assereto and Kendall 1977)

being added to form the compressional ridges (Kendall and Warren 1987). This contrasts with the arid hydrological setting where extension-related megapolygonal desiccation features are forming at the same scale. These features are giant, often sediment-filled fissures or open mud cracks that are created by drawdown of the watertable. Such longterm lowering of the watertable can drive formation of huge desiccation polygons and fissures, as are seen today about the edges of the Panamint and Eureka playas, California (Fig. 2.59; Messina et al. 2005). The arid seepage hydrologies inherent to the formation of tepee megapolygons are very different to those required to form desiccation megapolygons and the two should not be confused by the use of the prefix megapolygon when describing either feature.

At a broader scale, the occurrence of a substantial tepee-rich unit in a saline-platform carbonate succession indicates an episode of exposure and watertable drawdown. For example, in the Italian Alps the principal tepee-dominant unit is interpreted as a sequence boundary and forms a regional marker in the highly cyclic Latemar (Triassic) platform interior (Hardie et al. 1986). This 300 m thick tepee facies separates the lower cyclic facies and the upper cyclic facies of the Schlern Formation in the Latemar platform (Christ et al. 2012; Egenhoff et al. 1999; Mutti 1994). It is characterized by 79 tepee zones (0.2–13 m thick) alternating with intervals of thinning-upward, caliche-capped mudstone to packstone cycles. In West Texas the tepee-rich zones of the Late Permian Yates and Tansill formations have been used to pin the highest points in the Permian landscape in what was a laterally-evolving high frequency stratigraphy. For the first time in the history of studies in the Guadalupe Mountains this study quantified the penecontemporaneous nature of downdip high-angle faulting, extension and Permian shelf collapse (Rush and Kerans 2010).

Some authors have suggested a Milankovitch cyclicity may be preserved in thickness variations within the saline platform interior sediments of the Latemar (Hinnov and Goldhammer 1991). If so, the highly altered, overprinted and collapsed origin of at least some of the tepee intervals, probably means individual eustatic parasequences are no longer recognisable within the tepee facies. The predominance of tepees in the Latemar platform also suggests periodic evaporative drawdown in the platform interior. Seepage hydrology needed to form pisolites and tepees implies an exposed and somewhat elevated edge to a platform rim at the time the tepees of the interior were active. In contrast, the thicknesses of the transgressive systems tracts (subtidal successions) also preserved in the platform interior indicate flooding and are more likely to retain finer-scale eustatically/climatically distinctive thicknesses.

Carbonates: Present and Past

Phanerozoic evaporitic carbonates accumulate in $CaCO_3$ -saturated waters. Consequent aragonite/dolomite muds and cements are distinctive and readily separated from open marine shelly carbonate shelf textures. The separation between marine and hypersaline settings is much less

distinctive in Proterozoic or older strata. In fact, the best modern textural analogs for many Precambrian marine carbonates are to be found in Holocene evaporitic carbonates and not in modern normal marine carbonates. The dichotomy reflects two major events in earth history: (1) the evolution of an increasingly bicarbonate-depleted and sulphate-enriched ocean by the Proterozoic, and (2) the rise of a shelly marine macrofauna at the Cambrian-Precambrian boundary.

During much of the Precambrian, $CaCO_3$ was extracted from seawater by a combination of inorganic and microbial processes, the same two sets of processes that dominate in modern evaporitic carbonate settings. Archaean carbonate sediments entrain numerous and prolific giant botryoids of aragonite that can be up to 1 m in radius, as well as widespread Mg-calcite precipitates (Grotzinger and Read 1983; Grotzinger and Kasting 1993; Grotzinger and Knoll 1995; Sumner and Grotzinger 2004; Reitner and Thiel 2011). These beds sometimes formed cementstone sheets several metres thick, with strike lengths of more than 100 km, with no modern counterparts in normal marine carbonates (Figs. 1.18 and 1.26).

By the Palaeoproterozoic, marine carbonates entrained less spectacular masses of aragonite and calcite, although cementstone crusts and microdigitate stromatolites in tidal flats remained a characteristic style of carbonate platform aggradation, as did the widespread presence of molar-tooth structures in the Mesoproterozoic (Shields 2002). In contrast, the late Meso- through Neoproterozoic carbonate sedimentation saw a progressive decline in the precipitation of massive widespread carbonate cements and an increase in widespread precipitation of micritic whitings. Throughout the Precambrian, periodic high-energy events ripped up and transported fragments of these cementstone crusts and whiting beds to redeposit them as intercalated intraclast conglomerates and breccias. The secular decrease in the volume of seafloor precipitates reflects a change in the chemical state of the ocean. The much lower sulphate concentrations and much higher bicarbonate to calcium ratios reflect the elevated levels of CO_2 in the Archaean atmosphere and its long-term decrease since then (Fig. 1.18; Chap. 2; Grotzinger and Kasting 1993; Riding 2011; Bose et al. 2012).

The change in the earth's atmosphere and ocean chemistry from the Archaean to the present is reflected in the evolving nature of microbialites (Fig. 1.18; Grotzinger and Knoll 1999; Riding and Liang 2005). During the Archaean and early Proterozoic, when CO_2 levels were much higher than today, stromatolites formed by "in situ" precipitation of laminae and conoform stromatolites were commonplace. But younger Proterozoic marine stromatolites grew largely through the accretion of carbonate sediments, mostly through the physical process of microbial trapping and binding (agglutination). Conoform stromatolites had by then largely disappeared from the world's oceans (Sumner and Grotzinger 1996) and today are found only as tufas in hypersaline lakes

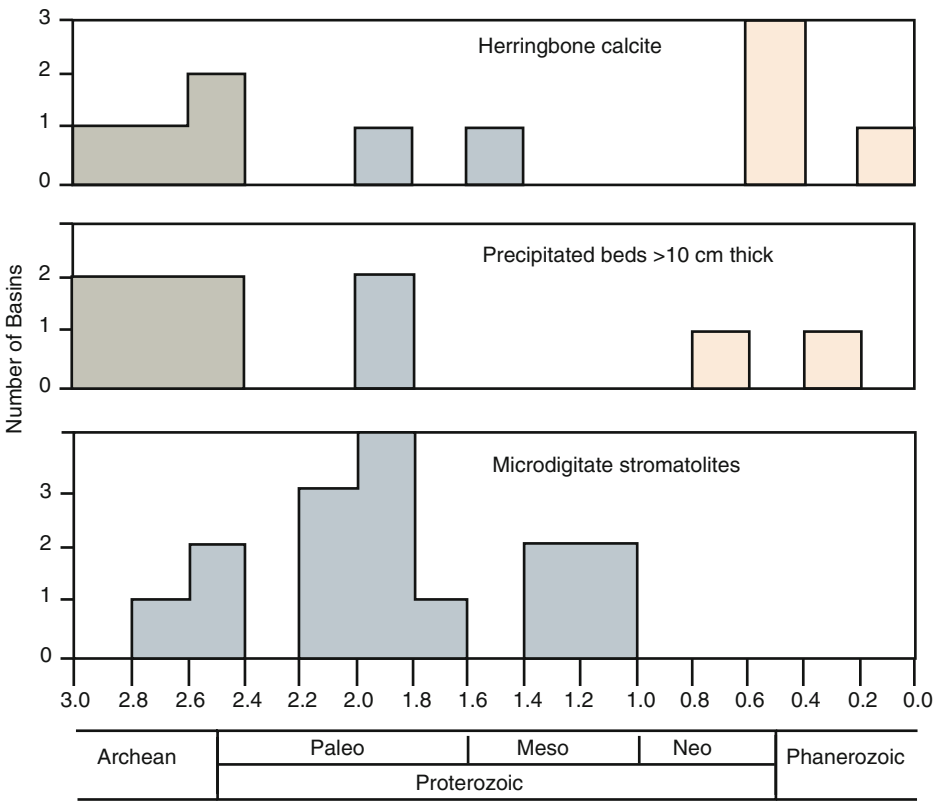

Fig. 1.26 Carbonate precipitation from seawater through time. *Brown fill* represents basins where the textures are abundant across a range depositional settings. *Grey fill* represents basins where the textures are present in a limited number of depositional settings. *Pink fill* indicates textures and minor components with limited extents (After Sumner and Grotzinger 1996)

(Warren 1982a). Marine abundance data across the Phanerozoic Eon show that microbial carbonates episodically declined during the past 545 Myr, from a peak 500 Myr ago (Riding and Liang 2005). The Phanerozoic abundance trend is generally the inverse to that of marine metazoan taxonomic diversity, supporting the view that metazoan competition has progressively limited the formation of microbial carbonates. The Precambrian evolution of the ocean saturation state, and the passage at various times into marine cementstones, was paralleled by times when marine tepees were more commonplace, as in the Marinoan cap carbonates of the Neoproterozoic when marine cold-seep tepees were common (Fig. 1.26; Corsetti and Lorentz 2006; Gammon et al. 2005). Carbonate supersaturation in Archaean seawater has led some to question the biogenicity of the 3.43 Ga isopachous stro matolites at North Pole, Australia – historically interpreted as the world's oldest biological fossils (Grotzinger and Rothman 1996 vs Allwood et al. 2007).

The dramatic rise of a skeleton-secreting and sediment ingesting macrofauna at the beginning of the Phanerozoic changed the nature of marine shelf sedimentation. The proportion of chemically precipitated open-marine mud and cement decreased and new sedimentary particles, such as abundant shell fragments, faecal pellets and biologically derived muds, came to dominate the marine carbonate realm. The formation of widespread cementstone sheets on the seafloor had ceased several hundred million years before the rise of the shelly macrofauna. It was only in widespread hypersaline settings that carbonate supersaturation persisted throughout the Phanerozoic, such as the Permian cementstones that crop out along the edge of the Delaware Basin, Texas. In such settings, isopachous stromatolites and other halotolerant microbialites continued to flourish in the absence of bioturbation and gastropod grazing.

Primary Evaporite Salts

Evaporite salts are deposited in a brine pan or seaway after the brine has precipitated the alkaline earth carbonates. The salts, dominantly $CaSO_4$ or halite, show a range of crystal textures that indicate relative stability, depth and permanence of the precipitating brine (Fig. 1.27a). Variations in key interpretive textures occur in a framework of stratified (meromictic) and non-stratified (holomictic) brine column hydrologies that will be discussed in detail in Chap. 2 (Fig. 1.27b).

Simple monomineralic carbonate, sulphate or halite layers and laminae, as well as beds composed of complex interlayered mixtures, dominate subaqueous deposits of many saline lakes and seaways. Laminae created by chemical settling are a typical subaqueous stratification style at the onset of primary salt accumulation. Some laminae outline underlying crystal morphologies, others are flat-planar and can be correlated for long distances across the basin. Biolaminae, including microbial bedding and accretionary tufa and travertine deposits described previously, are common intercalations and indicate less saline intervals in the same brine body. Mechanically reworked laminae (ripples, dunes and slumps) are less common in subaqueous evaporites than in their carbonate or siliciclastic counterparts. This is due to the predominance of chemical sedimentary processes operating in the brine bodies at the salt precipitating stage whereby early crystal precipitates interlock and cement as they evolve into growth-aligned crystals.

Widespread layers or crusts composed of cm-dm sized aligned bottom-nucleated crystals are one of the most widely recognised shoalwater textures. Depending on the salinity of the precipitating brine this bottom-nucleated unit is typically composed of halite chevrons or aligned gypsum crystals. Beneath deeper waters, crystals may accumulate on the bottom as a silt-sized "rain from heaven" pelagic deposit or as a mass of coarsely crystalline monomineralogic bottom meshworks (Fig. 1.27a). A range of slope deposits, dominated by reworked shoal water crystals, typifies the subaqueous region separating the shallow from the basinal (Chap. 5).

Over time, decimetre-to-metre thick evaporite beds can stack one atop the other to form evaporite units that can be hundreds of metres thick. When conditions are suitable, huge thicknesses of shoalwater evaporite can accumulate in very short time frames. For example, a more than 1-km-thick sequence of interbedded halite and clay has accumulated in less than 10,000 years in the Danakil Depression of the Ethiopian rift (Chap. 11). No other type of sediment, carbonate or siliciclastic, can aggrade as rapidly as a subaqueous evaporite bed (Warren 1991).

Gypsum Beds

A few thousand years ago subaqueous crystals of gypsum, up to 1 m tall, grew in stable bottom waters of shallow (<10 m deep) Holocene brine pans of southern Yorke Peninsula, South Australia (Chap. 4; Warren 1982b). The crystals coalesced into crusts and beds dominated by swallowtail and palmate gypsum crystals. Similar giant growth-aligned subaqueous gypsum with single crystals up to several metres tall have been documented in the Middle Miocene (Badenian) evaporites in the Carpathians (Babel 2007) and the various Late Miocene Messinian sub-basins of the Mediterranean (Lugli et al. 2010). Growth cycles in these subaqueous gypsum deposits range from mm couplets to decametre beds to brining cycles that are tens of metres thick (Fig. 1.28a, b).

Large aligned gypsum crystals that make up the bottom-grown beds typically entrain curved growth faces interspersed among parallel-sided prisms. Very few natural

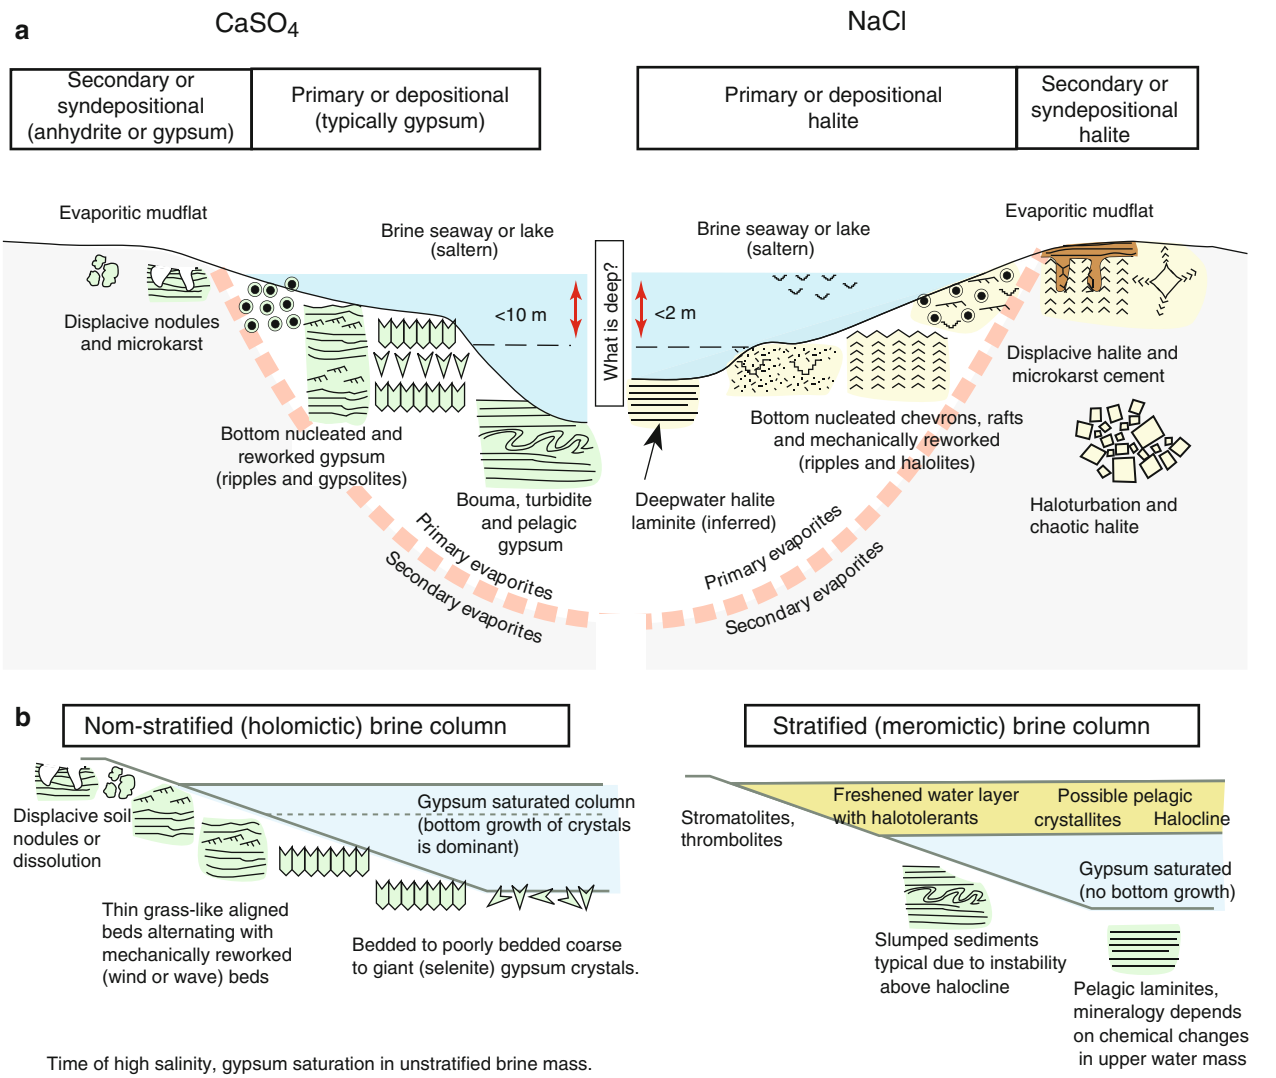

Fig. 1.27 Signatures of primary evaporite textures and syndepositional secondary evaporites for $CaSO_4$ and NaCl salts. (**a**) Depositional spectrum for both gypsum and halite. Secondary textures related to burial are discussed later in this chapter. (**b**) Hydrological end members (non-stratified and stratified waters) and the gypsum textures that illustrate this hydrology

gypsum beds are made up of growth-aligned crystals that first formed as aggregates of upward-oriented simple twins. That is, natural crusts and bed of growth oriented gypsums are not conjoins of the simple prisms shown in Fig. 1.29a. In fact, the crystal forms illustrated in Fig. 1.29a, and given in many mineralogy texts as typical gypsum morphologies, are the least common forms of sedimentary gypsum in beds accumulating in natural subaqueous systems.

Where a curved face encapsulates a crystal, a single lenticular crystal forms (Fig. 1.29b). The term "bird-beak" gypsum is sometimes used to describe its distinctive lenticular shape. The characteristic hooked termination can be used with pseudomorphs to help separate gypsum from the truncated lenticular "axe-head and keg barrel" forms of diagenetic anhydrite. Individual lenticular gypsum crystals range from sand-size to boulder-size. Lenticular sand-sized forms make up the uppermost lake sediments and the gypsum lunettes about the saltflat edges of many coastal and continental salt lakes in Australia (Chap. 4; Warren 1982b). Holocene lenticular gypsum crystals are intimately associated with algal

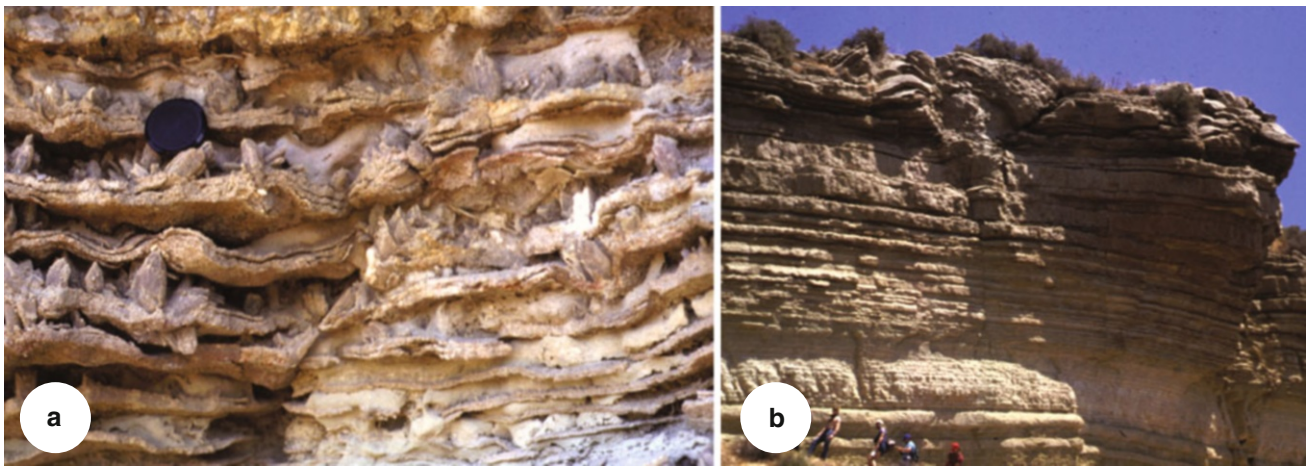

Fig. 1.28 Subaqueous gypsum from the late Miocene of Sicily. (**a**) Stacks of layers of aligned cm-scale gypsum crystals, each layer indicates growth competition from a marly gypsarenite base (lens cap for scale). (**b**) Metre-scale layers showing a larger subaqueous growth cycle from a finely laminated marly base through coarsely-bedded aligned gypsum to a series of domal mounds capping the cycle (people for scale)

sediments in marine-seepage-fed Ras el Shetan mudflats in the Gulf of Aqaba, Egypt (Aref 1998a).

Bedded gypsum growing on the shallow bottom of a perennially subaqueous lake or seaway typically precipitates as masses of large parallel-sided megacrystals that show varying levels of expression of the curved faced (Fig. 1.29c). Individual growth-aligned crystals are decimetres to metres long in gypsum beds in marine seepage fed Holocene salina such as Marion Lake and Lake Asal, while ancient counterparts in the Middle Miocene of the Carpathians can be up to several metres long and variations in their crystal form can be used to define differing styles of brine stability and associated crystal growth (Fig. 1.27b; Babel 2007).

Varying degrees of face curvature lead to the growth of distinctive gypsum twins with acute (narrow) to obtuse (wide) angles along the twin plane. Doug Shearman described this form of overlapping curvature along the twin plane as "arms of Siva" gypsum. Strong vertical development of the upper half of some twins creates beds of upward aligned gypsum crystals showing strong curvature of the intercrystalline faces. Such forms are sometimes called palmate gypsum. Some purists would argue that most of these natural forms of growth-aligned gypsum are not true twins (Babel 1990). The varying degrees of curvature entrained in the crystal generate changes in the apparent twin angle, even in a single crystal. This breaks the rule of constancy of twin angle, leading some to refer to them as pseudo-twins (e.g. Schreiber 1988). Whatever the crystallographic semantics, these large aligned crystals only grow on the gypsum-saturated bottoms of shallow subaqueous brine lakes and seaways.

The reason why the curved face comes to dominate some gypsum crystals (e.g. lensoidal crystals and displacive rosettes) is not well understood. On the basis of a number of laboratory-based growth experiments using brine columns separated by gel growth media, Cody and Cody (1988) argued the lenticular shape of displacive gypsum (intrasediment sediment growth) reflects influence of temperature and the presence of humic compounds in the parent brine (Fig. 1.30). Two temperature dependent trends were obvious in the precipitates. At low temperatures the hemipyramidal habit, dominated by the {111} faces dominate. At higher temperatures the lenticular {$\bar{1}$03} is obvious in all crystals. They concluded that elongate prisms grow best at low temperatures and in the absence of habit-modifying organics.

They found that the modifying influence of temperature on morphology was swamped by the presence of low levels of organics in all the growth experiments. With increasing polytannate concentrations (analog for terrestrial humics), crystals become less elongate and penetration twinning along the {100} develops. This is followed by secondary complex nucleation near twin faces as rosette and rosette-like aggregates form (aka desert roses). The changes in morphology are interpreted as the result of a high degree of adsorption of organic compounds on the $\bar{1}$03 and $\bar{1}$11 faces that inhibits their growth and consequently minimizing growth parallel to the crystallographic c-axis (Cody 1976). This absorption is thought to reflect the peculiar surface structure of the face, which unlike the other faces of gypsum is almost entirely composed of Ca^{++} ions and these Ca^{++} ions bond readily with organics Aref (1998a). In the subaqueous gypsum pools and sabkhas or Guerrero Negro, Mexico, Vogel et al. (2009, 2010) describe equant and distorted gypsum crystal morphologies that were unique to biofilm-supported samples.

Warren (1982b) found that masses of sand-sized lenticular gypsum crystals dominate in near surface beds, deposited

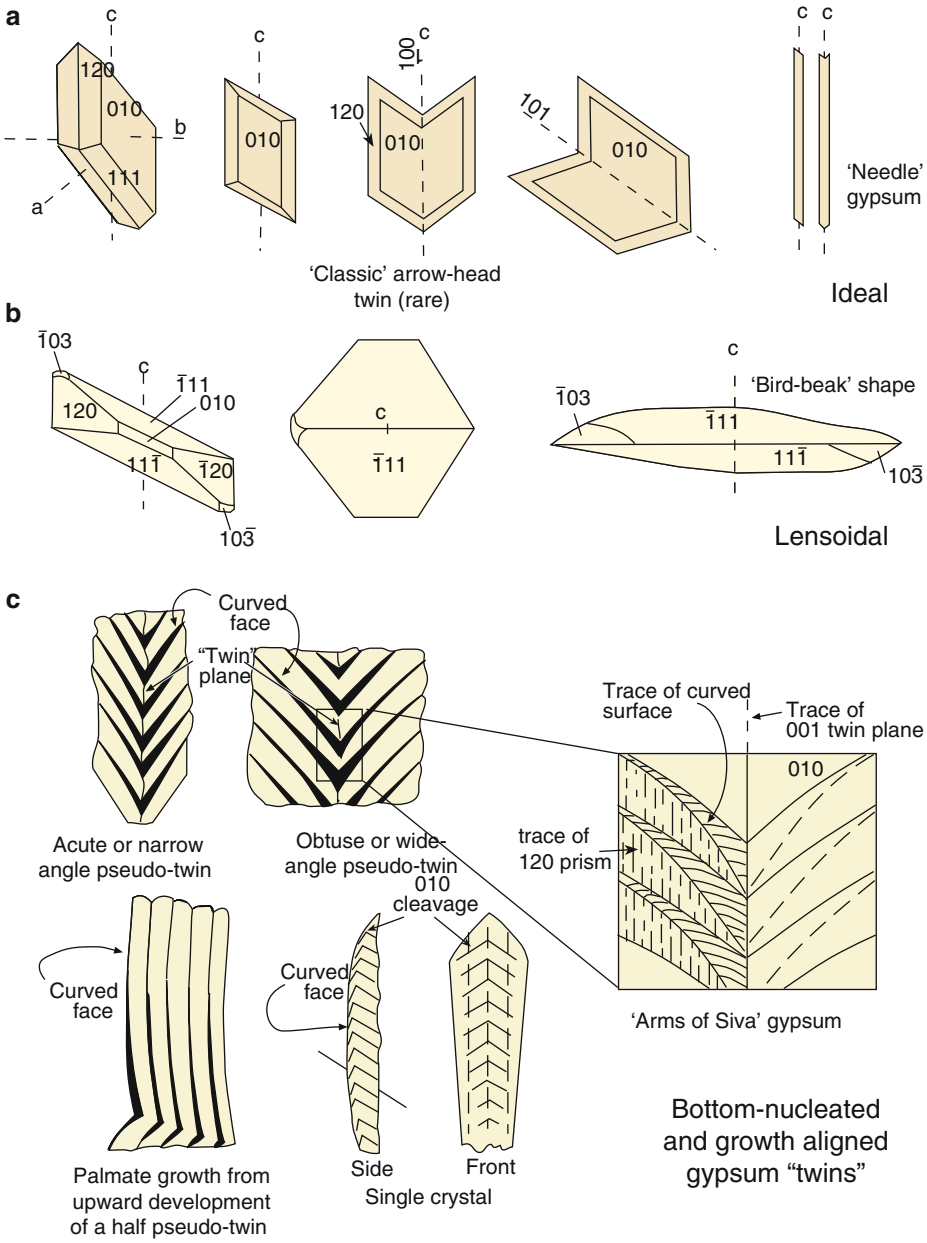

Fig. 1.29 Gypsum. (**a**) Prismatic forms of gypsum parallel to (010) with *arrow head* twins along (100) or (101) and extreme acicular forms of prism and twin on the right. (**b**) Lenticular form of gypsum. Note how the lenticular form (*on right*) is dominated by the curved faces that are much less important on a typical prism as seen in the side and top views of a crystal (*on left*). (**c**) Various forms of typical subaqueous "zig-zag" gypsum growth as described in text (After Shearman 1978; Orti Cabo and Shearman 1977; Rouchy et al. 1994)

in seasonally vadose settings across numerous coastal salinas in southern Australia. He argued the lenticular shape tends to form best in the upper seasonally vadose parts of the brine pan fill, where crystals are subject to periodic short-term dissolution and regeneration. The pristine parallel-sided gypsarenite prisms that constitute the underlying thick beds of gypsarenite or growth-aligned laminar selenite were not present at this upper level in the lake stratigraphy. However, the vadose gypsum in these salinas grows in surface and near-surface pore waters that are more influenced by surface runoff from nearby vegetation-covered calcareous dunes and so entrain higher tannic acid levels.

Growth-aligned coarse-grained gypsum beds form in Holocene coastal lakes of Southern Australia, beneath the waters of perennial subaqueous brine pans that are density stratified for more than 6–8 months of the annual depositional cycle. In the early stages of infill of the salina, the perennial bottom brine was always saturated with respect to gypsum (Fig. 1.27b). Salinity conditions were stable and allowed the upper euhedral surface of the aggrading crystal bed to preserve the upper outlines of crystals in each growth stage. If gypsum precipitating today in Lake Inneston, South Australia, is indicative of the subaqueous growth style, then throughout much of their growth, any large upward facing gypsum crystals are covered by a microbial mat or film that captures aragonite pellets and can be considered a type of gypsum stromatolite (Chap. 4). Similar subaqueous gypsum mounds, coated with cyanobacteria, line the southern end of

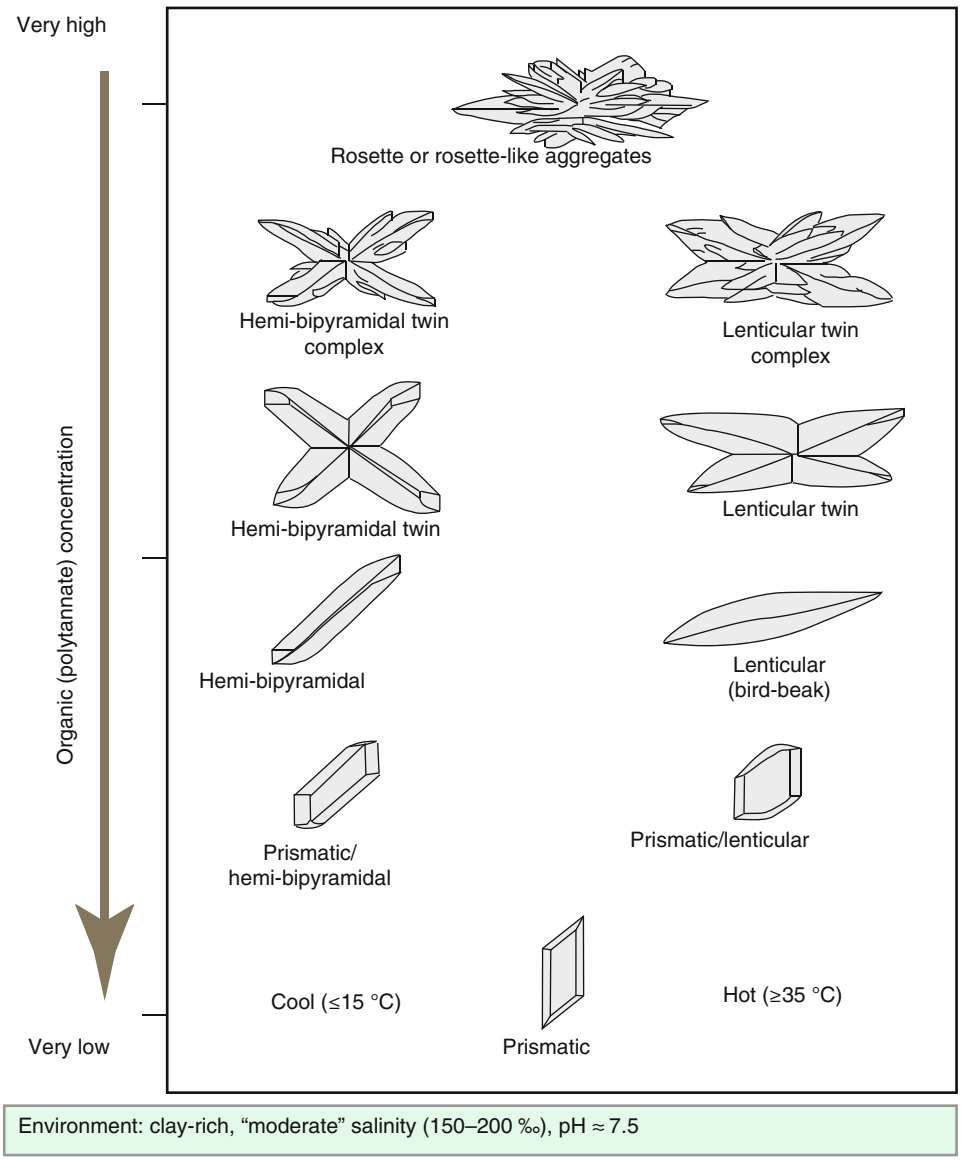

Fig. 1.30 Laboratory based changes in gypsum growing in a muddy (bentonite) sediment matrix at moderate salinity and neutral pH in environments characterized by increasing temperatures and dissolved polytannate concentrations. Polytannate is considered to be an analog for terrestrial humic material. c-axis vertical in all examples (After Cody and Cody 1988)

the brine channel leading into Gotomeer in the Nederlands Antilles and pass into laminated aragonitic microbialites beneath shallower waters along the channel edge (Fig. 1.19c; Kobluk and Crawford 1990).

Beds of growth-aligned crystal beds about the edges of the Danakil Depression, Ethiopia, define an earlier Holocene-Late Pleistocene perennial lake level that was a few metres higher and somewhat fresher than the current saline halite pan level (Fig. 1.31). About the saline lacustrine edge these subaqueous beds alternate with pedogenic beds dominated by nodular gypsum.

Rapid widespread bottom growth of aligned-gypsum occurs when stratification of the brine column is lost via seasonal concentration of any upper fresher surface water body. When it reaches the same salinity as the dense gypsum-saturated bottom waters the two waters mix (Fig. 1.27b). Once this happens the whole water column is supersaturated

Fig. 1.31 Stack beds of alternating growth-aligned gypsum (thickest bed 30 cm) and marly gypsum in the Late Pleistocene-early Holocene gypsum-fringe in the Danakil Depression, Ethiopia

with respect to gypsum and crystal bottom growth begins anew on a metres-deep brine pool floor. As the aggrading euhedral gypsum bed surface encloses $CaCO_3$ impurities, it encapsulates and preserves smooth to ir regular laminae within the bed, so creating textures indicative of brine column stability and oxygenation (Chap. 2).

Aragonite pellets that mantle the re-entrant laminae in the salina gypsum are a combination of a pelagic "rain from heaven" and faecal pellets excreted by a grazing biota cropping the biofilm that covers the gypsum. In the Australian coastal seep salinas, metazoan life flourishes during the freshened salina stage when a less saline surface water body (≈50 cm thick) floats atop the lower brine mass (from spring to early summer). Pellets in Lake Inneston and Deep Lake salinas signify the feeding activities of ubiquitous ostracods and the Southern Hemisphere brine shrimp (*Parartemia zietziana*). When salinities in the surface waters are suitable, this halotolerant pelagic biota spreads through surface waters over the whole brine lake (Chap. 9). When surface salinities later increase to levels that can no longer support a metazoan population, mass mortality occurs. Soon after, the upper and lower brine masses equilibrate/mix and lakewide gypsum precipitation begins again. Even so, small living populations of brine shrimp and ostracods remain in refugia about seawater-fed seeps in the inflow zones supply the tepee and mound-spring dominated salina strandzones.

Over millennia, the depositional surface of the salinas aggraded as successive gypsum layers infilled the centre of the brine lake depression (Warren 1982b). As the top of the salina gypsum bed aggraded, it reached a level where even the dense bottom water mass was seasonally freshened. Then the perennial bottom waters, as well as surface waters, were undersaturated with respect to gypsum for a number of months each year. At that time the upper gypsum surface dissolved each winter to form a flat planation surface. Now the seasonal growth of the aggrading bed surface enclosed $CaCO_3$ pellets laying atop this dissolution surface to form a flat mm-laminated gypsum bed (see Chaps. 2 and 4 for more detail on this typical brine column hydrology).

Halite Beds (Chevrons and Crusts)

Crystals in halite crusts first precipitated on the floors of shallow hypersaline brine pools as upward-growing chevrons, cubes and cornet-shaped crystals (Fig. 1.32a, b). Chevron structures, which preserve the outlines of successive crystal growth edges, are defined by layers of enclosed brine inclusions. Remnants of aligned chevrons are the most commonplace primary texture preserved in ancient halites. Abundant inclusions impart a cloudy or milky appearance to layers rich in chevron crystals. Even without a hand-lens,

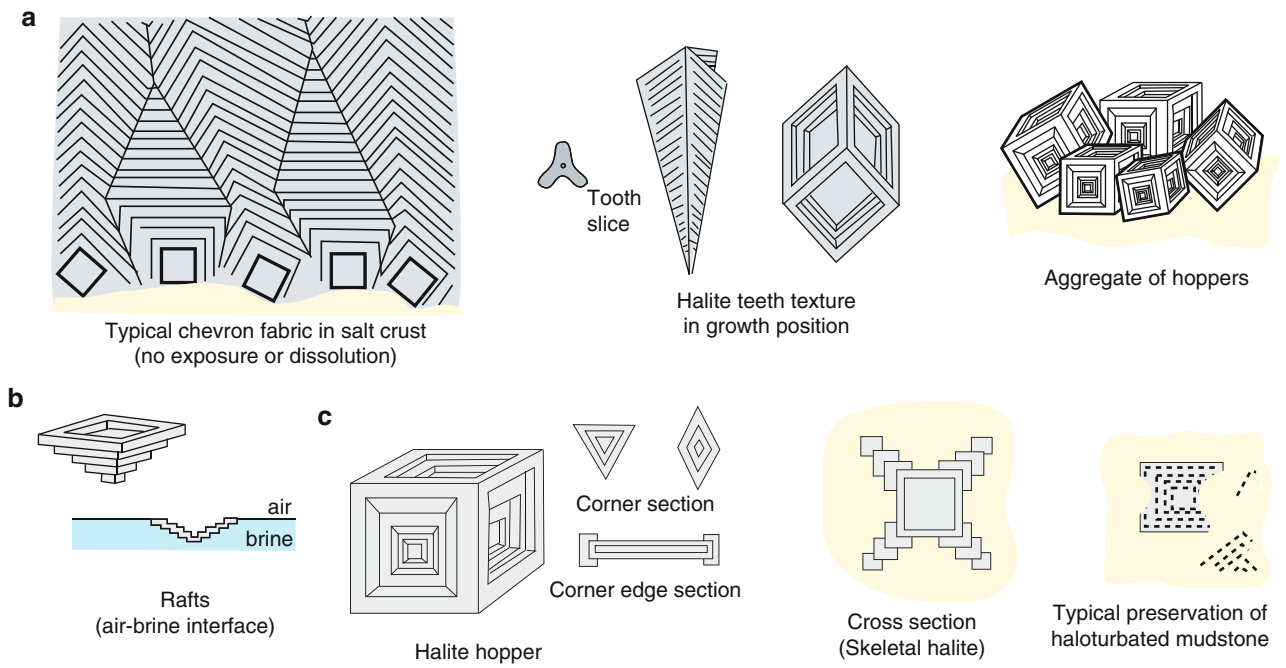

Fig. 1.32 Halite. (**a**) Growth-aligned forms of subaqueous halite and typical chevron growth fabric outlined by inclusions in the crystals. Those crystallite cubes with upward-aligned edges, rather than faces, come to dominate the growth fabric as a series of merged chevron crystals. Other bottom growth forms include upward-growing halite teeth and aggregates of hoppers on the bottom that were created by overgrowths on sunken rafts. (**b**) Halite raft growth, where crystals hang from the air-brine interface. (**c**) Various forms of skeletal or intrasediment halite hoppers. Notice how the outline of the halite shape or its pseudomorph can vary from rectangular to triangular depending on the plane of intersection of the viewing horizon with the crystal hopper (In part after Shearman 1970; Rouchy et al. 1994)

this is a feature that can be used in ancient counterparts to distinguish primary halite from clear or spar-like crystals of secondary or diagenetic halite. Milky inclusion-rich crystals can accumulate as successive layers of growth-aligned prisms or can form as syntaxial overgrowths on floundered rafts and other cumulate crystals that have settled to the pan floor.

As for all isotropic crystals growing in crowded conditions, the crystal edges of halite cubes that point upward into the brine grow more rapidly than crystals with upward-pointing crystal faces. The upward pointing "V's" of the edges quickly dominate and so creates an aligned chevron texture that characterises many subaqueous halite crusts (Fig. 1.33a). Less common are thin crusts and beds composed of upward-facing cornets and plates. There the crystals grew by the upward aggradation of the horizontally aligned faces, and perhaps indicate less crowded conditions of bottom growth (Handford 1990, 1991).

Such halite crystals accumulations form the lower parts of halite beds up to 5 m thick in Lake Macleod, Western Australia where the beds are composed of stacked decametre-thick crusts dominated by bottom-nucleated aligned chevrons. Brine sheets that precipitated the halite were always less than a few metres deep and usually less than 0.5 m deep (Logan 1987). Similar units of stacked crusts, but with obvious truncation surfaces and pervasive capillary overprints, characterise saline pans in Salar Uyuni and other pans worldwide (Fig. 3.43; Bobst et al. 2001). Patchy remnants of chevron halite crusts, deposited in shallow to ephemeral brines, are also preserved in ancient thick halite beds such as the Ordovician-Silurian Mallowa Salt of the Canning Basin (Cathro et al. 1992) and the Permian San Andres Formation of West Texas (Hovorka 1987).

However, there is a sampling bias when Holocene halite pan textures are used as direct deposit-frequency analogs for ancient bedded evaporites. This is related to three factors; (1) Access, (2) Rapidity of subaqueous fill and, (3) Scaling of modern analogs to ancient depositional systems. This true for all evaporite mineralogies and textures, not just halite, we shall discuss analogue scaling problems in detail in Chap. 5. For now let's just consider the implications of access and rapidity of fill. Most of our observations of primary textures forming in natural halite deposits that have been made in the last 100 years comes from areas adjacent to where there was easy foot ot vehicular access. So, we have excellent studies of pan and capillary halites forming in a number of modern salars and playa lakes in South and North America, respectively (e.g. Bobst et al. 2001). We also have well documented examples of halite pan textures in coastal saline pans and anthropogenic saltworks in Mexico and elsewhere (Shearman 1970).

The problem is that these samplings of halite tend to be from areas where we can get out of a vehicle, walk a short distance into the saline system and sample. This creates an immediate sampling bias in that we tend not to sample textures forming in permanently somewhat deeper brine-covered areas, which are highly uncomfortable to access. So, in Holocene studies we tend to sample halites from areas subject to cycles of flooding and drying. We do have drill core samples of some subaqueous versus capillary textures in South American salars, but the key question is how relevant is an endorheic 2,000-m plus-elevation continental lake hydrology to the hydrologies in ancient subsealevel marine-fed megahalite basins for which there are no modern same scale analogs (Warren 2010). In addition, active permanently brine-covered areas where subaqueous halite deposition is

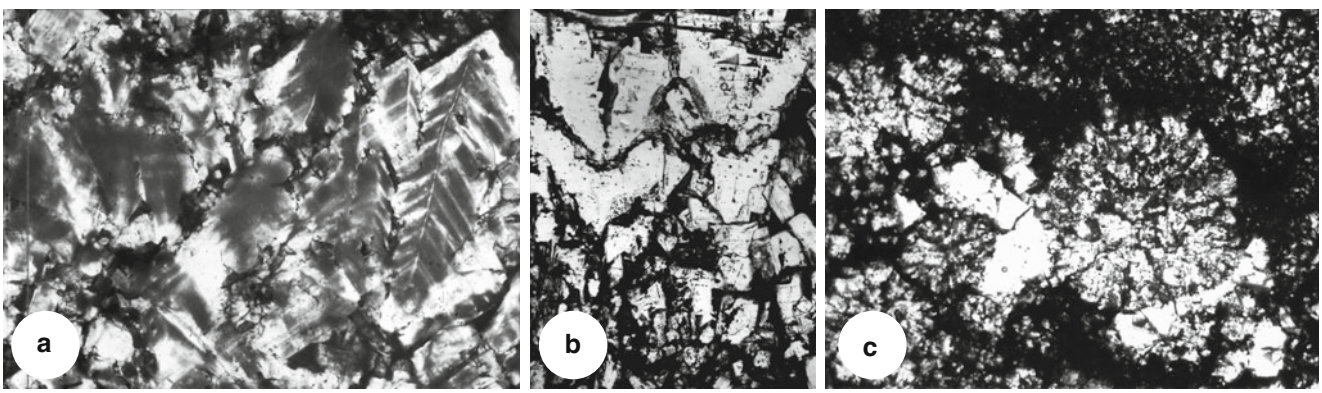

Fig. 1.33 Subaqueous halite (**a**) Thin section photomicrograph of halite from perennial saline lake interval, Death Valley core, depth of 8.1 m. Halite chevrons with dense fluid inclusion banding (dark) and vertical, competitive growth fabrics. Horizontal field of view is 4 mm. (**b**) Thin section photomicrograph of halite from perennial saline lake interval, Death Valley core, depth of 15.8 m. Bottom-grown halite crystals with vertical growth fabric. Note that halite crystals widen upward and contain faint fluid inclusion banding. Some mud (dark patches) is trapped within or between crystals. Horizontal field of view is 4 mm. (**c**) Thin section photomicrograph of halite from perennial saline lake interval, Death Valley core, depth of 8.6 m. Halite pisoids, 2–5 mm in diameter and with faint radial fabric, from the upper shallow saline lake interval. Note mud drape (*black*) and fine-grained halite cumulates above the largest pisoid. Horizontal field of view is 10 mm (Images and descriptions courtesy of Tim Lowenstein)

occurring beneath brines more than a few tens of centimetres deep are relatively rare on the world's surface of today. The best documented current example of a deeper water halite setting comes from samples recovered in piston cores released into the present day deep floor of the Northern Basin of the Dead Sea where halite is accumulating at the base of a 350 m+ brine column. This deep-brine halite started to form in February 1979 when the Dead Sea brine mass changed from perennially stratified to holomictic (Chap. 4).

A paucity of relevant analogs is related to the fact that the present is a limited key to the past in terms of evaporite deposition (the scaling problem) and that when deeper subaqueous halite systems are active in the Holocene they very rapidly aggrade from a permanently subaqueous brine saturated setting to the current hydrological equilibrium surface which is typified by alternating episodes of wetting and drying (Warren 2010).

This limitation in access and rapidity of fill is seen in the most recent episode of halite infill in a large evaporite basin we have available for study, namely the Late Quaternary salt fill in the Danakil Depression, Ethiopia. Cores in halite down to 200 m below the current pan surface show an abundance of pristine primary subaqueous textures (Fig. 1.34a–d). But the system today is in near hydrological equilibrium and

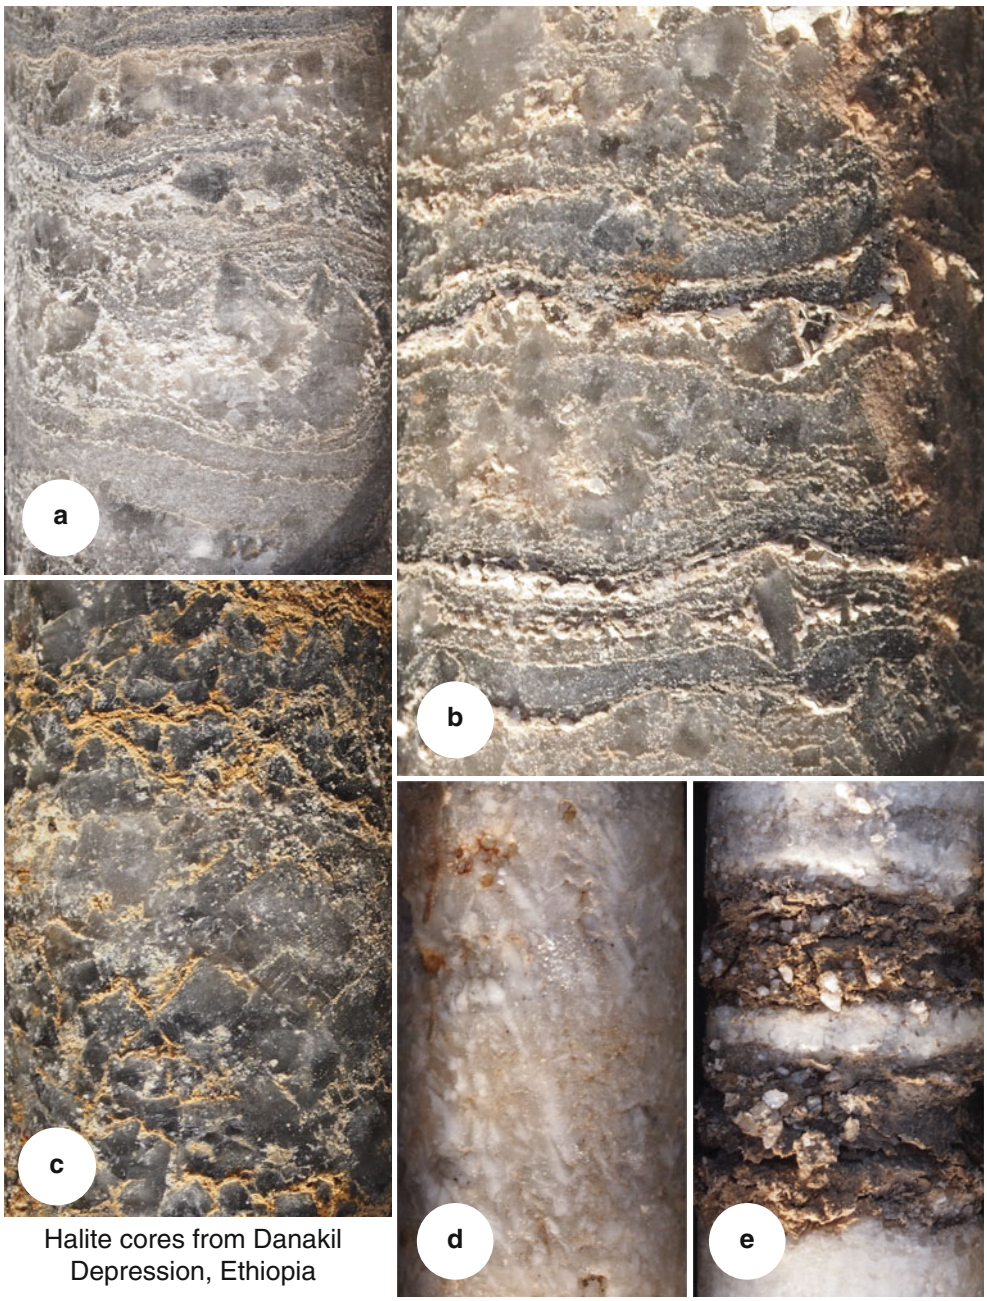

Fig. 1.34 Cores sampling various Pleistocene halite textures in the Danakil Depression, Ethiopia. (**a**, **b**) Primary growth-aligned inclusion-rich halite indicating a periodically stratified shallow subaqueous halite seaway/lake with aligned halites subject to periodic freshening and $CaSO_4$ mantling – similar $CaSO_4$ -encased textures probably misinterpreted as syndepositional brine-reflux secondary by Hovorka (1992) in the Permian of West Texas. (**c**) Stable holomictic pond textures with $CaSO_4$ drapes on upward aligned chevrons. (**d**) growth-aligned milky halite in stacked halite crusts. (**e**) Halite crust alternating with clay influxes (subaqueous settling for clay floods as no obvious capillary textures in salt crusts)

tends to accumulate halite crusts textures interlayered with clays (Fig. 1.34e). Yet in terms of total halite fill these clayey textures are much less important than the subaqueous textures, which dominate the Late Quaternary halite/potash fill in the evaporite sumps across this part of the Afar Depression (Chap. 11).

Capillary and freshwater flood textures forming across the current Danakil surface are similar to what is documented at the surface in Death Valley, Guerrero Negro and the South American salars. Such systems tend to show a strong secondary overprint related to flooding and drying cycles creating evaporite units deposited from markedly schizohaline surface and nearsurface pore waters, which cause the lake surface in areas of such halite nuclei facies to currently aggrade at rates up to 3 cm per year (Fig. 1.35a; Ruch et al. 2012). Most current depositional surfaces in a natural (non-anthropogenic) salt pan setting tend to be near the hydrological equilibrium stage in the basin's fill history and this surface is what we can access for samples of halite texture. But it is a biased sample and as such tends to be unrepresentative of textures in the greater volume of halite fill. This volumetric unrepresentativeness is due the rapid way in which subaqueous basins fill to the equilibrium level, as we shall see in the various proportions of subaqueous versus capillary fill in Holocene marine-fed deposits documented in Chap. 4.

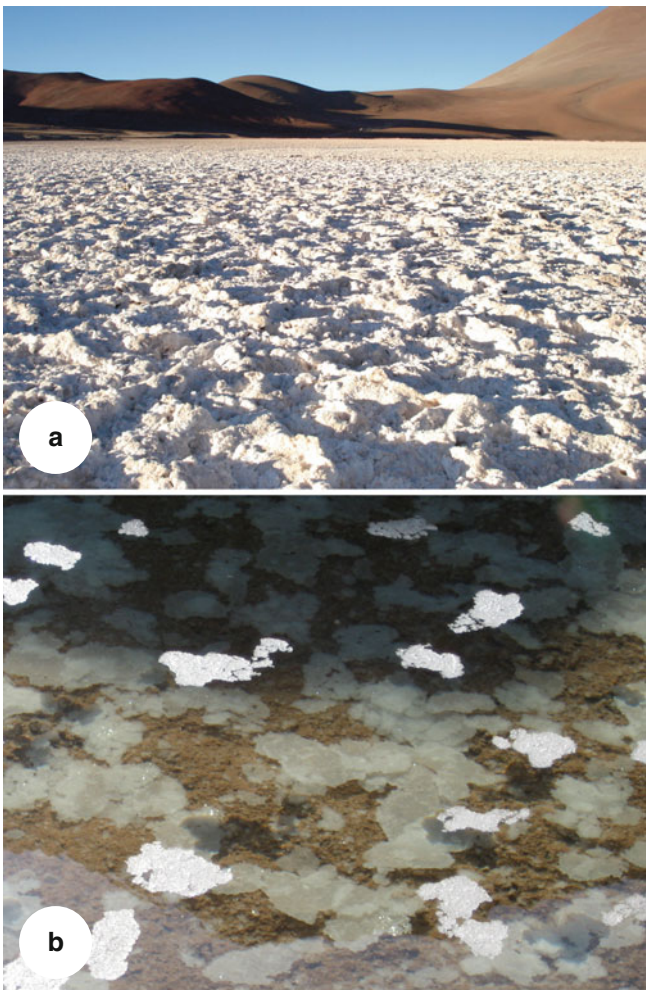

Fig. 1.35 Modern halite textures. (**a**) Halite nucleus (capillary halite) in Salar de Agua Amarga, Andes (photo courtesy of Tom Carpenter). (**b**) Halite rafts (up to 35 cm across) floating on brine pool surface with foundered raft beginning to stack up as "cumulate" layer on bottom of a pond, Kum region, Iran

In extremely hypersaline brines the precipitation behaviour of halite and the resulting textures can respond to elevated cell densities in halobacteria (Gerdes et al. 2000a, b). Proteinaceous compounds coating the surface of the growing halites encourage the growth of dendritic crystals rather than chevrons. Crystals forming in organic-enriched brines contain more and larger brine inclusions than crystals growing at the same salinities from sterile brines. Cells are smaller and much more numerous in the organic-enriched brines and the cells are thought to create templates for halite nucleites.

Halite Cumulates, Rafts and Coated Grains

Crystallites grow in the uppermost part of a standing body of brine where water is rapidly lost by evaporation and salinities are at their highest (Fig. 1.1a). Silt and sand-sized crystals settling to the bottom of the brine pool then form layers and beds of cumulate crystals ("salt and pepper" halite and massive gypsi-siltites). Periodic influxes of freshened surface waters, followed by evaporative concentration, can produce mm-scale lamina in bottom cumulates. Such "rain-from-heaven" laminites are typically composed of alternating carbonate-sulphate and sulphate-halite couplets and triplets.

When surface water salinities are suitable and surface waters are undisturbed by wind and waves, crystals can continue to grow as rafts held by surface tension at the air-brine interface (Figs. 1.32b and 1.35b). Rafts float and grow until the crystal mass becomes so heavy that it exceeds the holding ability of the interfacial surface tension and sinks to the bottom. Halite rafts in quiescent waters can be centimetres to decimetres across before they sink to the bottom. Eventually, increasing wind and wave action breaks up the rafts, usually while rafts are out in the brine lake and still well away from the strandzone. These remnants then sink to mix with the smaller crystals and so make up part of the texture of the cumulate beds of the brine lake floor. Later, when the lake shallows and further desiccates, these cumulate beds are covered by crusts and beds of bottom-nucleated chevron halite or swallowtail gypsum. This upward transition from cumulates to crusts is commonplace in modern crusts.

Rafts and other cumulate crystals in very shallow to ephemeral brine pans may be blown across the brine surface or carried by bottom currents into the strandzone to accumulate as subaerially exposed masses of strandzone crystals.

Such deposits characterise surface carnallite/halite shores about the brine pan edge of Lake Qarhan in China and trona cumulates about the edges of Lake Natron and Lake Magadi (Chaps. 11 and 12). Whenever the adjacent lake water body freshens and expands, the dissolution of the strandzone salts generates dense brine plumes that cement underlying sediment (Casas et al. 1992; Hovorka 1992; Schubel and Lowenstein 1997).

Ancient cumulate crystal beds, when not quickly covered by bottom-nucleated crusts, were sometimes mechanically reworked by storm and wave-induced bottom currents into crossbeds and ripples. This tended to happen on the bottoms of ancient perennial brine seaways and lakes that were above wavebase and covered by brines that were less than 5–10 m deep (Fig. 1.27). In even shallower nearshore positions, which were subject to higher wave-energies, fine-grained cumulate crystals formed the nuclei to concentric ooids composed of gypsum and halite (gypsolite and halolite respectively). Today, such coated grain textures are precipitating immediately basinward of the strandzone of Lake Asal in the African Rift Valley, Tuz Golu in Turkey, and along the southern end in the Dead Sea (Tekin et al. 2007; Castanier et al. 1992, 1999), they are also preserved in perennial brine halites in Death Valley California (Fig. 1.32c). Both Tekin et al. (2007) and Perthuisot and Castanier (2000) have argued that the process of halolite formation is bacterially (biofilm) mediated. The significance of bacterial activity in precipitating evaporitic oolites is widely debated. It is much like the unresolved debate on the importance of bacteria in marine ooid formation that has gone on for decades amongst carbonate sedimentologists.

At the broader scale, Lopez-Cortes et al. (1994) and Gerdes et al. (2000b) have argued that elevated cell densities of halophilic microorganisms in a hypersaline brine can change the crystal growth rate and crystal habit of the precipitating halite. Salt crystals deposited from brines with such dense microbial communities generally contain more and larger fluid inclusions than crystals formed in sterile salt solutions (Norton and Grant 1988). They suggested that the halophilic cells may serve as templates for halite formation, resulting in a larger number of cubic crystals of smaller size than those formed in sterile control solutions. The proteinaceous envelope, called an S-layer, of the archaeal cells may serve as template in the nucleation of halite crystal formation, thereby modifying the halite crystal structure (see Chap. 9).

Pedogenic and Wind Reworked Salts

Many arid to semi-arid desert soils are gypsiferous in areas surrounding the perennial saline lakes, the brine pan depressions and their dune margins. Where gypsum dominates the pedogenic profiles, the soils are typically described as gypcretes, gypsites, gypsicretes, *croûte de nappe* or *croûte gypseuse zonée*. Currently, something like 2×10^6 km^2 of gypsum-entraining soils cover the world landscape (Nettleton 1991). Gypsum crusts have been reported from all the continents, including Antarctica (El-Sayed 1993). They typify soils in arid areas where mean monthly evaporation exceeds mean monthly precipitation, Watson (1985) notes a close association of gypsum soils with areas receiving less than 250 mm annual rainfall.

Use of the term gypcrete often has a connotation of gypsum being the dominant hardpan cement, while the term gypsite implies a finegrained (silt-sized) powdery soil. According to Aref (2003) gypsum crusts and soils are surficial and penesurficial accumulations that have the following specifications: (1) a minimum thickness of 0.1 m; (2) a minimum gypsum content of about 15 % by weight; and (3) a gypsum content at least 5 % greater than the underlying rocks. If the soil contains less than 15 % gypsum it is classified as a gypsiferous soil. Watson (1985) also grouped the consolidated gypsum, together with weakly cemented and powdery gypsum accumulations, under the term gypsum crust.

Four mechanisms or processes precipitate most gypsum soils and crusts worldwide: (1) In-situ pedogenic weathering of existing gypsiferous or volcanogenic (ash) parent material; (2) eolian or fluvial transport of gypsum or SO_4-rich sediment; (3) an oceanic aerosol source, creating in sulphate-enriched rainfall that evaporatively concentrates within the regolith (4) in-situ oxidation of sulphide minerals. The first two sources are direct evaporite associations, while the third is typically associated with salt lakes, sabkhas and playas in semi-arid or desert settings within 500–1,000 km of the coast. Many gypsic soil horizons are combinations of both pedogenically precipitated and detrital wind- reworked gypsum.

Soils with gypsic horizons form in various parent materials such as alluvium, eolian sediments and weathered geologic formations, many in regions of pre-existing gypsiferous sediments (Taimeh 1992). For example, differentiated gypsum soils 0.5–1.5 m thick, largely formed by capillary evaporation, cover much of the area east of the Fayum depression (chott) in the north central part of Egypt (Fig. 1.36; Aref 2003). These pedogenic gypsum crusts only cap Middle Eocene carbonate rocks that are interbedded with thick gypsiferous shale beds and the soils are mostly a result of the hydrological reworking of this Eocene source. The soils show a three-part layering from top to bottom of: (1) massive powdery gypsite/gypcrete, (2) massive indurated gypcrete, and (3) massive mottled gypcrete. All layers are composed of variable amounts of microcrystalline gypsite, fine to coarse lenticular gypsum, as well as porphyroblastic, prismatic and fibrous gypsum. Precipitation of the various types of gypsum is driven by capillary evaporation of $CaSO_4$ -enriched meteoric waters, so most of the gypsum occurs as vadose surficial crusts dominated by displacive gypsum growth. In the lower

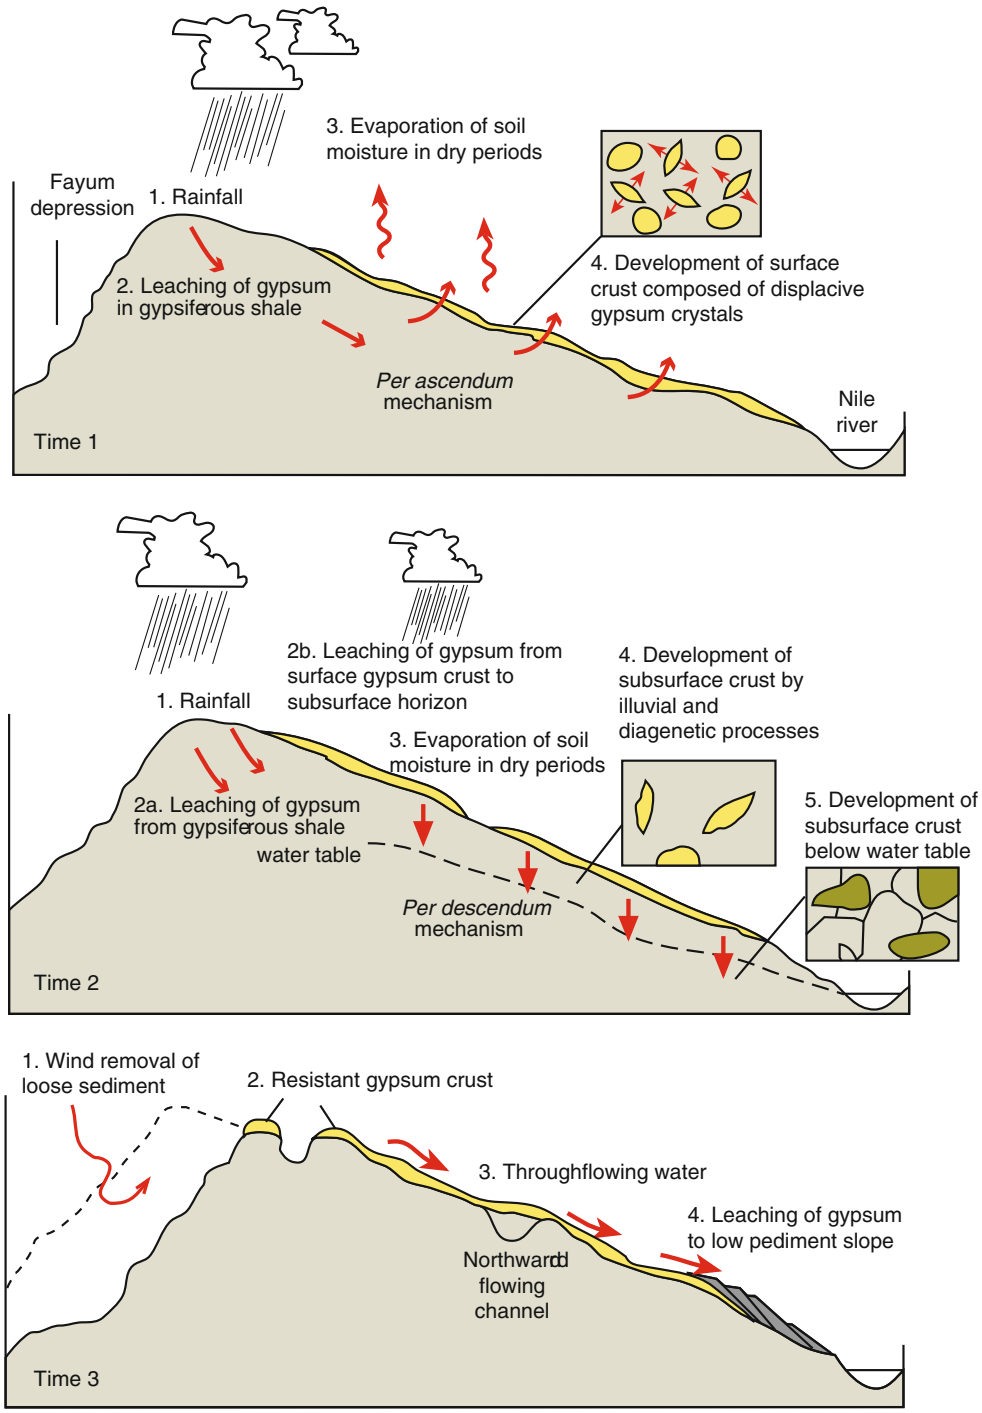

Fig. 1.36 Formation of pedogenic gypsum crusts at the eastern side of the Fayum depression Egypt (After Aref 2003). During dry periods, the gypsum-rich meteoric waters are drawn to the surface by capillarity (*per ascensum*), which leads to gypsum crystallization and crust accretion on the lower slope. During a subsequent wetter period, the surface gypsum crust is partially dissolved by meteoric water that moves downward (*per descendum*) and is mixed with laterally moving gypsum-rich meteoric water from the gypsiferous beds, which leads to deposition of subsurface gypsic crust. During subsequent weathering of the landscape the gypsum crusts can preserve residual landforms from subsequent erosion and weathering

vadose zone, gypsum accumulates by illuviation, interspersed with hydromorphic (sparry) accretion when watertable levels are higher (Aref 2003). The resulting gypsum carapace, although susceptible to dissolution, tends to preserve the residual landforms from severe erosion or weathering and so form gypsum-capped mesas.

Elsewhere, marine aerosols are focused into playa sinks and then reworked by eolian processes, as in much of the Namibian Desert and in soils about the arid salt lakes areas of southwestern and southeastern Australia. Other evaporite salts, with their inherently higher solubilities, tend to dissolve too rapidly in most vadose situations to form soil crusts and so do not form thick preservable accumulations in most of the world's deserts. Impressive exceptions to this generalisation can be found in the hyperarid Atacama Desert of South America. There

pedogenic accumulations of nitrates and iodates, along with halite and gypsum, are accumulating in the desert regolith; and have been doing so since the mid Miocene, when uplift of the Andes first created desert conditions (Chap. 12). For the same reason, namely hyperaridity in the Atacama, small parabolic dunes of halite (0.7–1.3 m in width and length) are today blowing across the saline pan floor of Salar de Uyuni (Svendsen 2003).

Pedogenic gypsum horizons can sometimes stack to substantial thicknesses. This is especially so in arid, subsiding groundwater-basins where ancient evaporite beds exposed by diapirism or uplift about the basin edge are being recycled by karstification. For example, there is a 25 m thick gypcrete hosted in Miocene alluvial fan sediments in the Calama Basin of northern Chile. The gypcrete is a single horizon in the alluvial bajada and it surrounds an ancient endorheic basin. It formed in the Miocene, via stacking of gypsum-cemented soil horizons (Hartley and May 1998). It was probably preserved, despite its high susceptibility to meteoric recycling, by its 9.5 Ma carapace of ignimbrite. This relatively impervious volcaniclastic ashfall isolated it from downward-percolating meteoric waters.

Gypsum dunes, stabilised by gypsite-soil caps, form wind-reworked vadose deposits around the margins of many Holocene and Quaternary brine lakes throughout the world (Table 1.5). For example, gypsum dunes line the salt pan edges of undisturbed continental salt lakes and coastal salinas in southern and western Australia. Lesser accumulations of eolian gypsum can create nabkha fields about the salt pan edge (Fig. 3.19d). Today all lakes are in the penultimate stages of their Holocene brine pan fill; hydrologies are characterised by ephemeral surface waters interspersed with long periods of deflation. In the coastal zone these are the same pans that precipitated large bottom-aligned gypsum crystals in the earlier perennial brine stages of their Holocene infill. But now, with the aggradation of the gypsum fill to near sealevel elevations, the lake surface is at hydro logical equilibrium with current sealevel and can aggrade no further (Warren 1982b). Surface brine sheets in these flood settings come to saturation quickly and all have dried up by late spring. Rapid multiple nucleation of gypsum crystallites takes place across the floor of the brine

Table 1.5 Some of the arid to semi-arid regions where gypsum dune fields (and lunettes) are associated with the deflation of saline lake (playa) sediment

Locality (Köppen)	Style	Reference
Bonneville Salt Flats, Utah (BSk)	Small gypsum dune field along the edge of an active continental sabkha (Bonneville Salt Flat) formed atop a now deflated perennial saline lake, Made up of two shore parallel dune ridges up to 9 m (30 ft high).	Jones (1953), Eardley (1962)
White Sands dune field, Tularosa Basin, New Mexico (BSk)	Dunefield area of 500 km^2 is one of largest gypsum dunefields in the world and consists of a core of crescentic dunes flanked to the north, east and south by fields of parabolic dunes. Gypsum dunes created by active deflation of gypsiferous sediments of Pleistocene Lake Otero around 7,000 years BP.	Langford (2003), Kocurek et al. (2007), Szynkiewicz et al. (2010), Chavdarian and Sumner (2011)
Salt Flat Playa, Guadalupe dune field, Trans-Pecos Basin, Texas and New Mexico (BWk)	Gypsum dunes cover an area ≈100 km^2 and are primarily parabolic in morphology, and reach up to 15 m in height. Occur along the edges of an active continental sabkha at the western foot of Guadalupe Peak, forming atop a former perennial saline lake. Gypsum is deflated from a former large perennial gypsum lake, Lake King, that occupied the closed Trans-Pecos basin during the late Pleistocene.	Hussain and Warren (1989), Wilkins and Currey (1999), Szynkiewicz et al. (2010)
Estancia dune field, Estancia Basin, New Mexico (BSk)	Gypsum dunes cover 120 km^2. Isolated domal bedforms and crescentic ridges occur in the centre of the basin and are derived from the initial deflationary events. Numerous lunettes on margins of isolated deflationary basins were initiated during the last deflationary event. Dunes sands contain about 60–70 % gypsum, within a loose matrix of clay and minor carbonates. Deflation of the gypsum from the former perennial Lake Estancia began with the passage into dryer conditions around 7,000 years BP.	Allen and Anderson (2000), Szynkiewicz et al. (2010)
Laguna Ojo de Liebre area of Baja California (BWh)	Gypsum dunes along the mudflat edges of coastal lagoons.	Kinsman (1969), Holser et al. (1981)
Cuatrociénegas dune field; Cuatrociénegas Basin, Coahuila, Northern Mexico (BSh)	Overall the saline lacustrine environment of Laguna Grande appears to have remained relatively stable through the late Pleistocene and increased in aridity during the Holocene, with associated deflation and gypsum dune formation. Dunes are near pure gypsum in some areas	Forti et al. (2004), Minckley (1969, 1992), Minckley and Cole (1968)
Continental playas or salt lakes of inland Australia (BSk)	Gypsum lunettes in most salt lakes located in zones of continental seepage outflow in the interior of Australia including; Lake Eyre, Lake Frome, Lake Fowler, Lake Malata-Greenly, Lake Amadeus, Cooke Plains, Prungle Lakes, Lake Lefroy and Lake Cowan. Other less saline pans are lined by lunettes of pelleted clay or sand. Dune forms are typically parabolic (lunette) and tied too downwind edge of lake, tend to not coalesce into large dune fields.	Bowler (1983), Chen et al. (1990), Dutkiewicz et al. (2002), Magee (1991), Zheng et al. (2002)

Table 1.5 (continued)

Locality (Köppen)	Style	Reference
Salinas of coastal western and Southern Australia (Csb)	Gypsum dunes formed by late Holocene deflation of lacustrine gypsarenites in a marine seepage lake that is currently filled to within a few cm of sea level (e.g. Lake Macdonnell, Marion Lake, Streaky Bay Lakes, Hutt Lagoon). Dune forms are typically parabolic, some are tied to downwind edge of lake, others still blowing across lake. Tend to not coalesce into large dune fields.	Arakel (1980), Warren (1982b)
Dunes in chotts in South-central Tunisia (BWh)	Small gypsum dunes (≈70 % gypsum) are derived by the subaerial break-up and deflation of older gypsum crusts that cover much of the seepage areas in the chott depressions (as in Chott Fedjaj and Chott el Djerid). This is followed by eolian gypsum transport, deposition and possible recementation into a new crust.	Mainguet and Jacqueminet (1984), White and Drake (1993)

Köppen climate zones are explained in Chap. 2

sheet as beds of sand-sized gypsum (gypsarenite) accumulate, only to be subject to later desiccation and deflation into lunettes that line the edges of the saline depressions.

Thus, each summer, as undisturbed coastal and inland salinas exsiccate, the watertable falls and the upper part of any newly formed gypsarenite layer leaves the capillary zone and is blown into dunes that line the margins of the lake (lunettes). Capillary zone deflation forms the characteristic truncation or Stokes surfaces in regions sourcing eolian sediments worldwide (Table 2.15). When dune growth ceases, a stabilised and vegetated gypsum dune is subject to the ongoing set of pedogenic processes that form gypsite and gypcrete carapaces. Gypsum rhizoliths and bioturbation structures, as well as bioturbated gypsum soils (gypsites) form atop eolian crossbeds (Fig. 4.6g). Both the gypsite soils and the fresh lake flats develop polygonal crack networks similar to the features describe from desiccated dunefields in White Sands, New Mexico (Chavdarian and Sumner 2011). In regions where the watertable is relatively shallow, such cracks are not typical V-shaped mud cracks created by simple drying, rather they form via ongoing cycles of capillary evaporation and gypsum cementation.

Gypsum and pelleted clay dunes (lunettes) line the edges of many salt lakes and playas in southeastern, southern and southwestern Australia; Prungle Lakes and Lake Fowler (gypsum lunettes), Lake Tyrell (clay lunette) and Lake Mungo (quartz sand lunette; Fig. 1.37; Table 1.5). These lunettes are relicts from the Late Pleistocene deflationary period, when the lacustrine hydrology changed from perennial water-filled lakes to desiccated mudflats. Likewise, there are gypsum dunes in deflationary depressions in Salt Flat Playa and the Bonneville/Great Salt Lake region of Utah (Table 1.5). Internal sedimentary structures in many of these lake-edge gypsum dunes or lunettes show tabular cross beds with consistent bedform orientation. Many lack abundant trough or festoon cross beds, suggesting consistent wind directions (Fig. 1.38a; Jones 1953; Bowler 1973, 1983). Grain constituents clearly indicate deflation of former lake sediments, which were mostly vadose prior to deflation and passage into the dunes (Fig. 1.38b).

Gypsum dunes are part of a much broader lake-edge eolian sandflat association with the lakes often supplying large volumes of eolian quartzose sediment into adjacent sand seas or ergs (Chap. 2). Dunes described as 'lunettes' have a characteristic crescentic shape, other lake edge dunes may show more linear or longitudinal outlines (Fig. 1.37; Bowler 1973, 1986). Lunette sediments range in composition from quartz-rich, sandy clay, through gypseous clay to nearly pure gypsum. Pure quartz dunes formed under lake-full conditions and are distinct from that of the clay and gypsum-rich varieties, which formed by flocculation and deflation from adjacent subaerially exposed lake floors. In arid to semi-arid zones throughout the Quaternary the interplay between salinity of lake waters and groundwater levels is critical in lunette growth and the mineralogy of the lunette (Bowler, *op cit*).

Although body fossils are rare in most evaporite beds, many gypsum soils, some subaqueous beds, and associated redbeds which are deposited in and about fluctuating to ephemeral saline water bodies, can preserve abundant trace fossils that, in addition to track and trails, also include rhizoliths and other pedotubules (Chap. 9). Burrows and trackways tend to be more abundant when the pans and playa waters are freshened and ponded, and typified by halotolerant insects and crustacea burrows and feeding traces, along with bird tracks in the Tertiary and desert dinosaur tracks in the Pre-Tertiary (Melchor et al. 2012; Konrad et al. 2010; Minter et al. 2007; Gibert and Ekdale 1999; Brogley et al. 1998). There are even 5,000 year old human footprints preserved in dolomitic carbonate "soupstones" about the edges of coastal salinas in Fowlers Bay, central southern Australia (Belperio and Fotheringham 1990). Rhizoliths in a gypsiferous lacustrine system, tend to indicate periodic wetting/freshening followed by subaerial exposure and colonisation by terrestrial plants with roots growing in the gypsiferous sediments. These plants, if they can tap sufficient fresh-brackish water, can grow into substantial structures. Halite beds tend to be too saline to host plant-root systems and are typified by microbial traces of the shallow soil biota.

Rodríguez-Aranda and Calvo (1998) identified six associations of trace fossils in subaerially exposed evaporitic

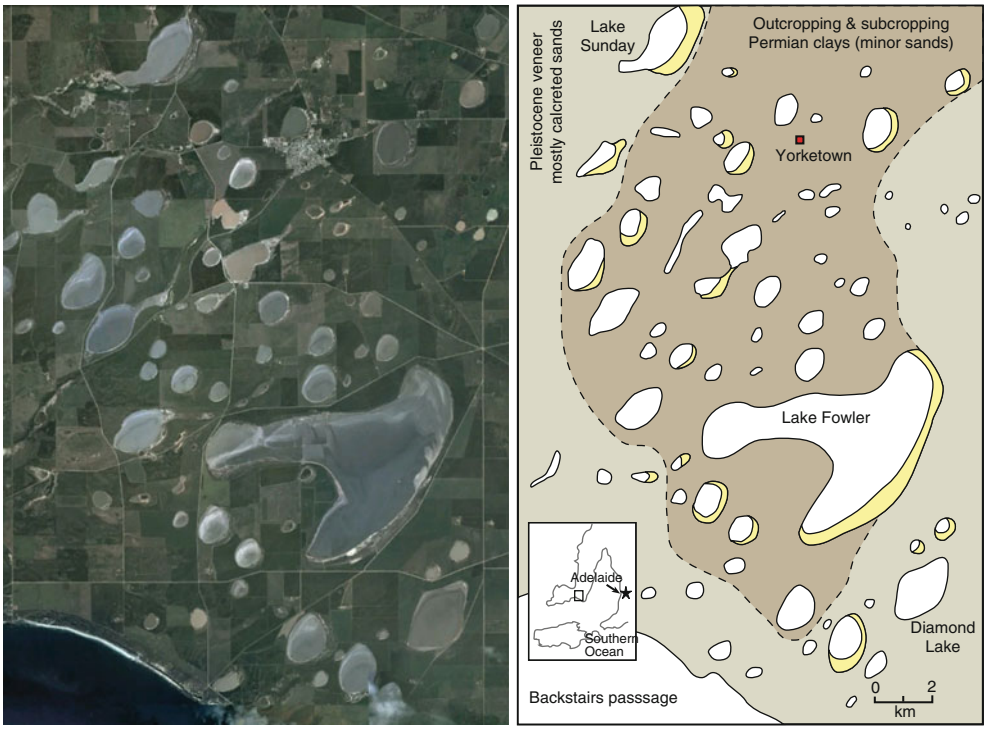

Fig. 1.37 Late Pleistocene lunettes in saline pans (salt lakes) in semi-arid southern Australia near the town of Yorketown showing gypsum lunettes at the edges of some of the wind-oriented lakes at the southeastern end of Yorke Peninsula. The largest is a gypsum lunette some 2 km long 100 m wide and 30 m thick at the southeastern strandline of Lake Fowler, the large T-shaped lake with a long axis ≈6 km (see Warren 1982b for description of gypsum in the lunette). It was extensively quarried in the early part of last century. Larger gypsum dunes (lunettes) are shaded yellow in the geological map (Google image)

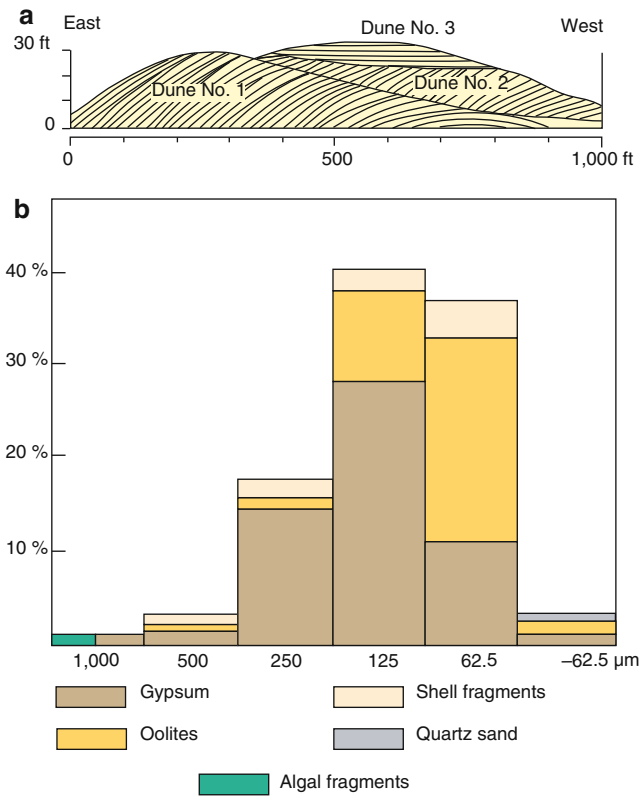

Fig. 1.38 Eolian gypsum in the Bonneville saltflats, Utah. (**a**) Cross section through the dune complex near Knolls, Utah. (**b**) Grain size distribution and mineralogy of the sands showing it is the result of deflation of sediments laid down in highstand conditions in the Bonneville/Great Salt Lake Basin (After Jones 1953; Eardley 1962). See Chap. 4 for a discussion of Great Salt Lake

sediments of the continental Tertiary basins of Spain: (1) networks of small rhizoliths; (2) large rhizoliths; (3) tangle-patterned small burrows; (4) isolated large burrows; (5) L-shaped traces; and (6) vertebrate tracks (Fig. 1.39a). The rhizoliths occur both in the marginal areas of hypersaline lakes and across lakes characterised by ephemeral but moderately high salinity waters (Fig. 1.39b). In either setting, pedoturbation indicates colonization by grasses and bushes and so indicates vadose conditions at the sediment surface that were tied to a drying of the lake and a lowering of the watertable.

According to Rodríguez-Aranda and Calvo (1998) burrowing invertebrates were especially active in those Spanish evaporite lakes where gypsum was the main mineral phase, not the more saline salts. They define a separate, sometimes pedogenic, facies in these lakes they called a "bioturbated gypsum deposit." It is typified by tangle-patterned small burrows and minor isolated large burrows; they are interpreted as burrows of insect larvae, probably chironomids, coleopterans and annelids. Similar organisms typify modern lake environments with water concentrations averaging 100–150 g/l, they flourish in lake areas subject to frequent drying and terrestrial encroachment (Chap. 9).

What is interesting about the bioturbation of these Miocene gypsum lakes in Spain is that the mm-scale layers rich in faecal pellets and associated with this bioturbation can be composed of gypsum and not the aragonite typically seen in Holocene coastal salinas (Fig. 1.39b). For example, the gypsum-pellet-rich Libros Gypsum was deposited in the

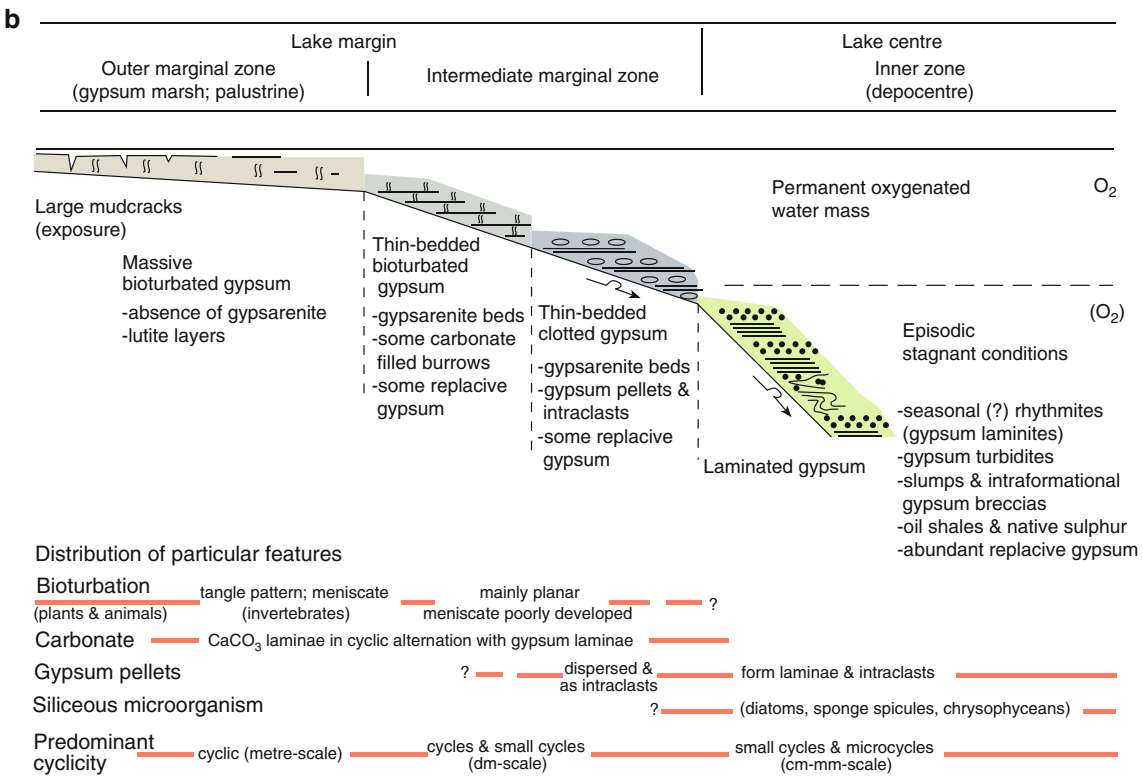

Fig. 1.39 Summary of trace fossil and rhizolith types in continental evaporite beds in Spanish Miocene Lacustrine Basins. (**a**) Spectrum of bioturbation structures, mostly from plants and animals in the lake margin facies (After Rodríguez-Aranda and Calvo 1998). (**b**) Distribution of bioturbation structures in relation to lacustrine gypsum textures and water depths (After Orti et al. 2003)

southern Teruel Basin (NE Spain) during the Miocene (Orti et al. 2003). It accumulated in a deep saline lake in which the water stratification became unstable with progressive shoaling. In the basin depocentre, a continuum of lacustrine evaporite lithofacies was influenced by the activity of organisms. Rhythmites, composed of laminae of pelletal gypsum and laminae of very fine lenticular gypsum crystals mixed with siliceous microorganisms, formed in addition to gypsum turbidites, intraformational gypsum breccias and slump structures.

The pelletal laminae originated from the faecal activity of animals (crustaceans?) ingesting gypsum crystallites in the lake water during episodes of maximum evaporation, whereas the laminae of very fine lenticular gypsum mixed with microorganisms accumulated during episodes of relative dilution. In the wide marginal zones of the basin, the Libros Gypsum unit consists of massive to thin-bedded bioturbated gypsum and thin-bedded clotted gypsum, which formed in intermediate to very shallow (palustrine) water depths. The bioturbated gypsum lithofacies were produced by the action of diverse organisms, presumably worms and coleopterans, and chironomid larvae to a lesser extent; the massive lithofacies precipitated in very shallow water; and the thin-bedded lithofacies formed in shallow to deeper settings. The thin-bedded clotted gypsum is a relatively deep facies that may have diverse origins (e.g. bioturbation, compaction, disruption of soft sediments and early diagenesis). There is a well-developed metre-scale cyclicity in the marginal lake sequences, which is not observed in the inner lake deposits. This suggests a depth change in the various lacustrine subenvironments is needed to record cyclic evaporitic processes. The isotopic composition of the pelletal gypsum indicates early sulphate-reducing bacterial activity in the bottom of the lake (Orti et al. 2003).

Biological metabolism drives substantial fluctuations in pedogenic pore pressures and salinity in gypsiferous and magnesitic soils in many lake margins and vegetated areas of coastal sabkhas. This is especially so in the immediate vicinity of plant roots, where evapotranspiration can precipitate $CaSO_4$ nodules around the plant roots. Such anhydrite and gypsum nodules are growing centripetally about halophyte roots in the modern gypsiferous supratidal sabkha succession of the Al-Khiran sabkha of Kuwait (Gunatilaka et al. 1980) and in the current lacustrine margin facies of the Danakil depression (Fig. 1.40). Anhydrite nodules in pedogenic horizons in the bedded Miocene magnesites of the lacustrine Calatayud Basin in Spain evolved into vertically aligned textures that today resemble gypsum ghosts (Sanz-Rubio et al. 1999). Early stages of this nodule growth were associated with typical pedogenic features such as rhizoliths and clotted to peloidal textures. The consequent anhydrite nodules, which replaced dissolving gypsum during very shallow burial, developed a strong vertical orientation as

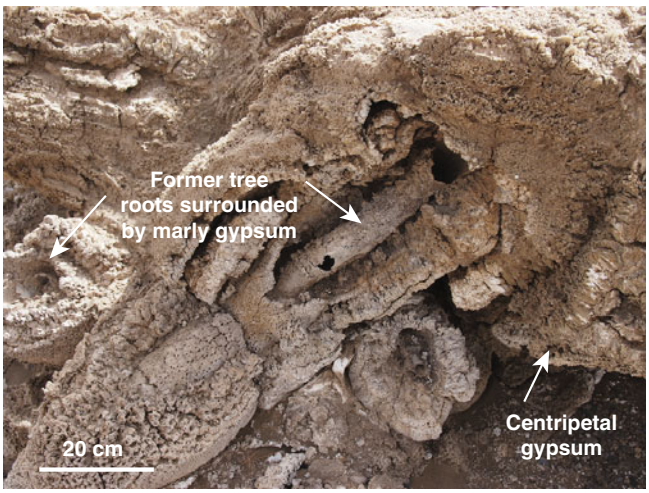

Fig. 1.40 Marly gypsiferous tufa (rhizoconcentionary core), surrounded by centripetal gypsum crystals in saline spring zone on southwestern edge of Danakil depression, Ethiopia

nodules precipitated along what were mostly vertical soil fissures. It is this nodular texture, mimicking a ped structure, that still dominates most clayey soils in the region. Much of the soil fissuring reflects expansion and contraction driven by root metabolism and a changing soil moisture profile.

Laminites from Settling of Pelagic Salts

At the other end of the mechanically-reworked evaporite spectrum from lunettes and soils are the continuously subaqueous basin-centre "rain-from-heaven" accumulations, typically composed of laminar couplets of sand- and silt-sized evaporite crystals. Crystals now on the deep bottom were originally precipitated at the air-brine interface or within the upper few metres below the brine surface (Fig. 1.27b). Less often, pelagic crystals may have precipitated at the mixing interface in a stratified brine (Raup 1982). The resulting finely-layered and laminated bottom cumulates typify many ancient "deepwater" evaporite-laminites. Such deposits tend to occur in basinal positions located well away from the evaporite platform margin.

In some ancient basinal settings, such as in the Castile Formation, which is a widespread Permian laminite in West Texas, water depths in the drawndown seaway bottom were probably sub-wavebase and the sediment-brine interface lay beneath anoxic gypsum-saturated bottom waters. Repetitive layering in laminites is resolvable at two scales; (1) at the scale of individual 1.5–2.0 mm laminar couplets of calcite and anhydrite with calcite making up about 6 % of a typical couplet, and (2) at the coarser scale of millennial brining upward parasequences ≈4 m thick (Figs. 1.41a and 1.42a). The mm-couplets in the Castile are remarkably regular in

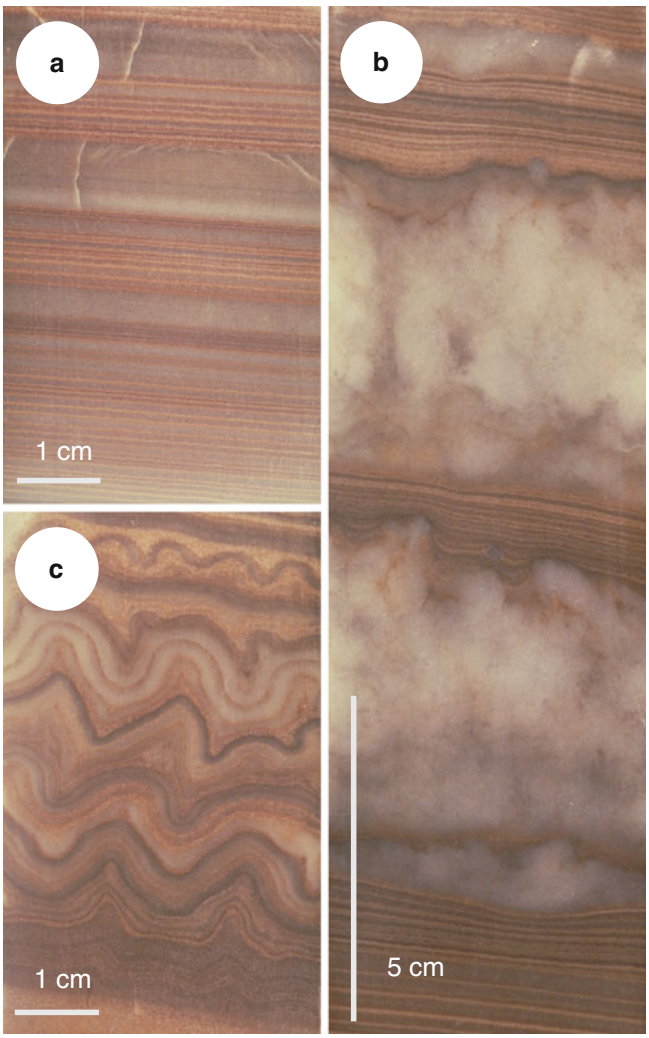

Fig. 1.41 Typical textures in cores from Castile formation, New Mexico. (**a**) Fine mm scale laminae of alternating calcite and anhydrite. (**b**) Beds of gypsum ghosts hosted in laminites. (**c**) Folded laminites possibly related to slumping into cavities created by dissolution of intra-Castile halite beds (Images courtesy of Sue Hovorka)

thickness, and are commonly repeated thousands of times vertically, without interruption in the textural style (Kirkland et al. 2000). The evaporitic sediments that formed these anhydrite-calcite couplets were pelagic cumulates. Crystallites formed at the brine surface or in the upper part of the brine column and "rained" onto the basin floor. Thickness variations of anhydrite laminae in parts of cores dominated by alternating laminae of calcite and anhydrite have been correlated from well to well over distances of up to 113 km (Anderson et al. 1972; Dean and Anderson 1982). Many laminar groupings can be correlated throughout the entire basin to within a fraction of a millimetre (Kirkland et al. 2000).

Spacing variations indicate cyclicity due to Milankovitch fluctuations in solar intensity and so are often interpreted as true varves (Dean and Anderson 1982). If so, it means the broader scale brining upward cycles were deposited in something like 1,800–3,000 years per cycle, with an average of 2,700 years and something like 175,000 years to deposit the Castile Formation (Kirkland et al. 2000). A cycle typically begins with couplets of calcite-anhydrite in which the anhydrite lamina are thin, and calcite may form as much as 80–99 wt% of the couplet. Above the basal carbonate-rich portion, anhydrite laminae increase in thickness, forming the calcite-banded anhydrite typical of the bulk of the Castile where calcite constitutes 10–15 wt% (Fig. 1.42a). Upward within a cycle, anhydrite laminae become thicker, with calcite laminae constituting about 5 wt%. Farther upward within these thick anhydrite laminae are nodules of anhydrite.

But some beds in the Castile Fm., typically up to 1 m thick, are made up of nodular anhydrite mosaics and, like the laminite sections, can be correlated across the basin (Fig. 1.41b; Leslie et al. 1997). Sporadically associated with these beds of nodular mosaic anhydrite are centimetre-size, anhydrite pseudomorphs perhaps after upward-growing gypsum crystals (Fig. 1.42b; Hovorka 1989). These aligned bottom textures suggest that at times the basin was not as "deep" as many have postulated from the laterally extensive laminites. Leslie et al. (1997) argue they represent time intervals when the basin brines became sufficiently shallow (<40–50 m) to allow supersaturated surface brines to come into contact with the basin floor (Kendall and Harwood 1989). Alternatively, and in my mind offering a more hydrologically feasible option, is that the aligned gypsum "ghosts" indicate times when the whole brine column was increasingly drawdown and associated with the loss of the upper freshened water mass (via evaporation without significant refreshing inflow). The brine column became holomictic, so facilitating an episode of basinwide gypsum bottom-growth. In either scenario, gypsum-supersaturated brines on the basin floor drove aligned crystal growth and also precipitated displacive lenticular gypsum in the upper few decimetres of the aggrading sediment column. In about one in ten cycles, nodular mosaic anhydrite is overlain by anhydrite-banded halite where the halite is coarsely crystalline and recrystallised. Although the contact with the halite is abrupt, deposition was regular and uninterrupted and perhaps tied to even more intense drawdown episodes that first changed the depositional style from laminites to bottom-nucleated gypsum (Chap. 5).

Leslie et al. (1996) interpreted some of the abundant structureless interbeds of coarse nodular mosaic anhydrite, which are up to 10 m thick in Castile Formation cores from the Union 4 University 37 borehole, as resedimented beds and not aligned nodules after bottom-growth gypsum (Fig. 1.42b). Based on what we now know about the modern Dead Sea sediments (Chap. 4), they may also be the altered remnants of a former bed made up of a massive inclusion-free gypsum meshwork deposited on the floor of the Castile Basin when the overlying brine column was still deep, but

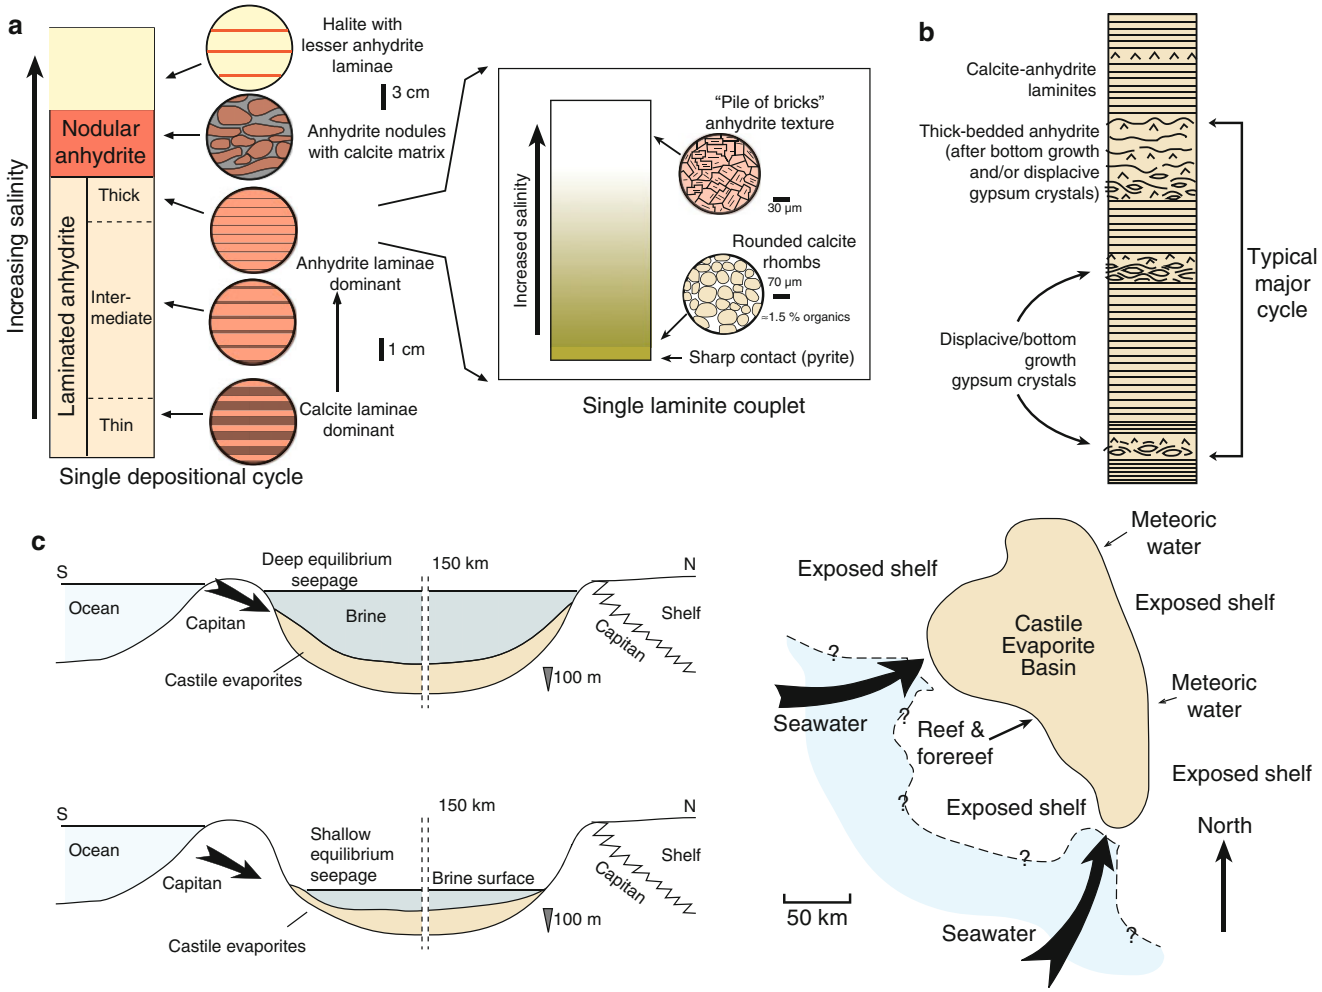

Fig. 1.42 Castile Formation, Delaware Basin, West Texas. (**a**) Representative section of a millennial cycle in the Permian Castile Formation of West Texas with a typical thickness of 1.4 m. Inset shows a typical calcite-anhydrite couplet with typical thickness of 1.5–2.0 mm (After Kirkland et al. 2000). (**b**) Typical sedimentary cycle within the Anhydrite 1 Member, it is capped by thick-bedded anhydrite after displacive and bottom-growth gypsum. Laminae at the base of most cycles are thinner with less anhydrite and more calcite. This cycle is overlain by a layer of laminated anhydrite with less calcite. The top of the Anhydrite 1 Member (which is made up of 5 cycles) is overlain by the Halite 1 Member (After Leslie et al. 1997). (**c**) Alternate models for Castile deposition, both based on a closed-basin, deep-marine-brine model. Brine drawdown either came to drawdown-seepage equilibrium when the brine depth was hundreds of metres or when the brine depth was tens of metres. Seawater seeped into the isolated basin along one or more segments of the reef front. These seepage areas were possibly most active near location of the what were former open marine surface channels through which seawater had entered the Delaware Basin during Guadalupian time (In part after Kirkland et al. 2000)

holomictic. Whatever their origin, these intervals do not exhibit the mm-scale laminae that typify the majority of the Castile anhydrite. Leslie et al. (op. cit.) argued the nodular beds were reworked from a sulphate platform that defined the eastern margin of the Delaware Basin. They noted that thick turbiditic units are less common nearer the centre of the basin, as seen in cores from the PDB-03 research well, where laminites dominate.

Differences in the interpretation of brine depth during deposition of the Castile remain unresolved, especially in some wells where there is evidence of later structuration and folding of lamina, related to collapse-driven filling of accommodation space created by exhumation and dissolution of halite intrabeds (Fig. 1.41c; Chap. 7). However, most agree that the stacked laminites intervals in the Castile Formation accumulated in brines somewhat deeper than the adjacent sulphate platform and that when the laminites formed the water body was density stratified (Fig. 1.42c; Hovorka et al. 2007).

In my mind, it was a hydrology much like that of the Dead Sea prior to 1979. The most significant difference was that there is a detrital supply of calcite to the Dead Sea laminites, while in the Castile basin there was no fluvial- or wadi-supplied detritus, only minor eolian transport of siliciclastics to the basin centre. The Castile evaporites accumulated on the deep subaqueous floor of drawndown carbonate-hosted marine seepage depression. There was no periodic flood of

sand sized detritus and so the bottom sediments are direct indicators of the salinity state of the surface water mass.

Slumped and current-reworked deepwater anhydrite laminites and turbidites have been recognised in slope and rise areas near platform margins in many other ancient evaporites, e.g. Zechstein basinal evaporites in NW Europe (Schlager and Bolz 1977), the Triassic lacustrine slope deposits of Northern Chile (Bell 1997) and the Middle Miocene (Belayim Formation) evaporites of the Red Sea Rift (Rouchy et al. 1995a, b). These deepwater reworked sequences are defined by entrained turbidite textures and Bouma cycles sandwiched in anhydritic mm-laminites. The source for the reworked anhydrite was either clastic $CaSO_4$ crystals eroded from the adjacent, but much shallower, platforms or from the sinking of "pelagic" salts. Deepwater sequences are discussed again in the basin focus of Chap. 5.

Deepwater ancient halites are rarely documented, even less so than in anhydrite-dominated basins, perhaps because beds composed of pure cumulate halite are more liable to recrystallisation and flow. By analogy to ancient anhydrite laminites "deep" water halite, historically has been thought to be thin bedded and intercalated with anhydritic laminites, but documented examples are not forthcoming. Primary textures that are patchily preserved and recognised in most ancient bedded halite are aligned chevrons. The likely deep brine texture, based on comparisons with "deep water" halite accumulating on the bottom of the modern Dead Sea, is a massive meshwork of poorly-aligned clear coarsely-crystalline halite prisms, far different from the commonly accepted notion of a "deep water laminite" as listed in Schreiber and El Tabakh (2000).

One of the few documented examples of an ancient "deep water" halite mass flow comes from the lower Miocene Vorotyshcha Suite in the Ukrainian part of the Carpathian foreland basin (Peryt and Kovalevich 1997). These halite breccias have traditionally been interpreted as tectonically deformed units related to the overthrust nappes of the Carpathians. Most clasts in the breccia consist of intrabasinal sandstone, marlstone, halite, and anhydrite, but exotic clasts consisting of rocks that are characteristic of the Carpathian flysch rocks are also present. Breccia beds are intercalated with salt layers containing chevron crystals and cubic hopper crystals, and some layers are composed of detrital salt. These salt layers rarely display graded bedding or cross-lamination, and continue over great distances. There are also slump structures associated with the bedded salts, where "deep water" halite breccias are interlayered with beds of potash. Deposition versus deformation is an ongoing debate in the interpretation of these sediments.

Can Growth-Aligned Evaporite Crystals, Interlayered with Laminites, Be Deep?

Textural interlayering of beds of cm-scale nodules with beds of laminites, like those of the Castile Fm., underline a broader interpretation problem in our current notions of what constitutes a deepwater evaporite signature. Can layers of coarse bottom crystals, intercalated with laminites, ever have accumulated on the bottom of a deepwater brine lake or seaway? The high degree of supersaturation required for primary crystal growth means that brine depths are generally shallow during crust growth in all modern examples. Maximum brine depths are measured in metres atop gypsum laminites in modern coastal salinas and decimetres to centimetres for halite crusts in saline pans. Halite chevrons and aligned laminated gypsum prisms retain intracrystal evidence of successive growth pulses as either thin layers of less saline salts or varying densities of entrained brine inclusions. This style of microlaminated intracrystal layering reflects changes in crystal precipitation rates induced by short-term changes (daily to monthly) in salinity on the subaqueous floor of the shallow to ephemeral brine pan (Warren 1982b; Handford 1991).

One inference made from modern evaporite textures is that laminated beds separating "in situ" bottom-growth-aligned crystals do not necessarily form in deep (>2 m) water in the salinas of Australia, the Red Sea and Sicily (Chap. 4). This has had significant implications in water depth interpretations of the Castile and other "deep water" laminite formations. Bottom brines in deep stratified brine columns are probably too dense and too stable to change with the rapidity required to form the mm-scale intracrystal discontinuities or layers seen in modern coarsely crystalline beds. Hence, laminated bottom-nucleated coarsely-crystalline growth-aligned textures do not form widespread bottom precipitates in modern deeper water settings (Chap. 4).

Rather, the bottom waters of a deep stratified brine system reach saturation and accumulate coarse salts only if the total brine column is at saturation all the way up to the air brine interface. This deposits monomineralic deep bottom beds made up of meshworks of poorly-oriented coarse crystal meshworks like those forming halite beds on the present-day deep bottom of the holomictic Dead Sea and the mirabilite beds on the bottoms of decametre deep saline lakes in western Canada (Fig. 1.43). Typically, they are interlayered with pelagic laminites formed when the brine column was stratified.

Thus, a modern analogy doesn't exclude a notion of deepwater halite or gypsum laminates interlayered with coarsely crystalline deepwater beds. But it does exclude the notion of coarsely crystalline beds (be they halite or gypsum) entraining regular discontinuities or fine mm-scale intrabed layers in growth-aligned crystal crusts. Otherwise one must ask, what mechanism could act over the floor of an ancient brine seaway, which was up to hundreds of metres deep and hundreds of kilometres across, to rapidly displace or cool dense halite- or gypsum-saturated bottom waters with short-lived pulses of less-dense freshened or cooler water, which would then pulse the rate of bottom crystal growth?

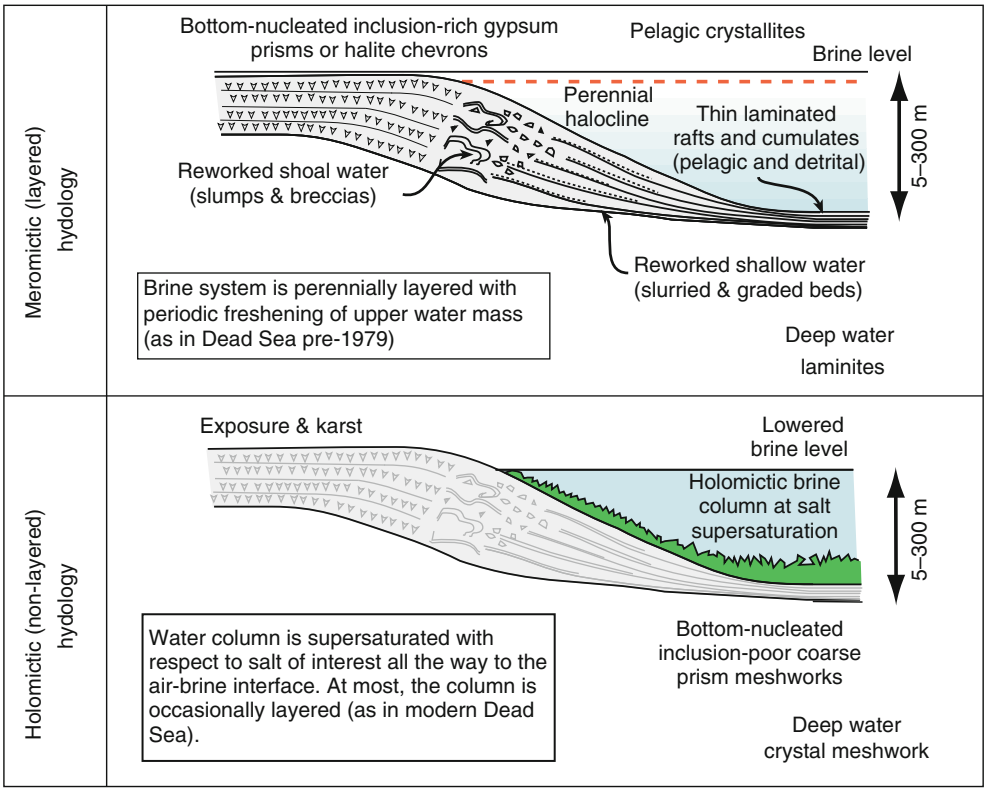

Fig. 1.43 Inclusion-free bottom-nucleated coarse crystal mesh textures can form in deep water when the water mass is holomictic, pelagic laminites form when the brine column is density stratified (meromictic)

Freshened water will always float atop a dense brine. The volume of less dense water required to displace and dilute a brine column hundreds of metres deep, or the time required for complete mixing to the bottom, excludes a deepwater "in situ" origin for fine layering in coarsely crystalline bottom-nucleated fabrics. But it does not prevent "rain from heaven" carbonate laminates accumulating in deep brines (Fig. 1.43), as happened in the Dead Sea when it was a stratified water mass for at least 400 years prior to February 1979 (Chap. 4).

As more studies are completed on modern deepwater evaporites, it is increasingly obvious that laminated beds alternating with coarse crystal beds can be a typical signature of a deep subwave-base evaporite. But the coarse beds sandwiched in among laminite layers do not show evidence of inclusion-rich layers outlining ghosts of growth-aligned swallowtail gypsum or beds of chevron halite. Brine saturations cannot change rapidly enough for these textures to form at the base of deep brine column. If the anhydrite nodules in the Castile and other deepwater evaporites are after coarse gypsum then they were deep bottom crystal meshworks that indicate times of holomictic brines in a hydrographically isolated seaway. Then, when the brine column returned to more typical meromictic (density stratified) conditions, it became a seaway where laminites accumulated on the deep sea floor. This explains the correlatable lamina spacings over distances of more than 100 km in Castile Fm. laminite beds.

As in many evaporite interpretation quandaries, part of the problem lies in the pervasive diagenetic overprinting of primary gypsum texture by a mosaic of overprints that were driven by ongoing compaction and flow. The other part of the interpretation quandary lies in the observation that the present icehouse climate mode limits the range of modern marine-fed evaporite basins available for study (Chap. 5). If a crystal crust is growing near a deepwater hydrothermal spring, there is also the possibility of pulsing crystal growth in the bottom waters due to temperature fluctuations or changes in the rate and saturation of the spring outflow. This last scenario is not volumetrically important in terms of widespread beds of ancient growth-aligned evaporite textures.

Salt Reefs, Are They Real?

Halite in modern pans and salinas typically constructs beds made up of stacked subaqueous crusts, which may locally entrain recrystallised cumulates and have been periodically subaerial. Beds tend to be dominated by flat layers with synoptic relief of no more than decimetres related to the formation of pressure ridges. However, mushroom-shaped halite buildups or reefs, with steep near vertical sides and a relief measured in metres, are currently forming in artificial solar ponds on the southern margin of the Dead Sea (Chap. 11). Halite reefs began to form in the 1970s and 1980s, after

dykes were built to enclose most of the southern basin of the Dead Sea (>200 km^2) and so create two sets of solar evaporation ponds on either side of the Truce Line Channel (Talbot et al. 1996). At that time the reefs were attributed to salting-out via common-ion mixing between natural Dead Sea brines and end-brines from the first potash plant (Chap. 2). However, tens of thousands of new salt reefs continued to grow in the enclosed salt ponds long after the pans were re-engineered and end-brines from both plants were channelled directly back to the depths of the northern Dead Sea basin (Charrach 1986; Ram et al. 1988).

The reefs grow in metres-deep perennial halite saturated brine pans as large isolated vegetable-like shapes that merge to form networks of polygonal salt walls (Fig. 1.44; Talbot et al. 1996). The walls subdivide large salt concentrator ponds into thousands of small compartments that resist brine throughflow. This is contrary to the engineer's plan of large subaqueous pans filled with brines that were easily homogenized by wind. Instead of following a designed flow path of homogenisation and downstream fractionation, brines in the compartments between the halite reef walls stratify, ultimately allowing unrecoverable carnallite precipitation in depressions between the walls.

In the inter-reef polygons is an evaporatively-maintained supersaturated 10-cm-thick surficial layer floating atop brines that are halite saturated all the way down to a cumulate covered floor (Fig. 1.44). Epitaxial halite overgrowths expand along the supersaturated uppermost brine layer and the salt reefs develop botryoidal overhangs. Salt projections can merge into a hollow platform, roofing over a cell of encased brine. Reefs and their overhangs prolong the crystallization season in the halite-saturated pans by breaking up the continuity of brine throughflow to the carnallite pans. Depositionally, they replace the planned cumulates with brine compartments walled by expanding overhangs. Salt-crusted shallows on bridged-over reef platforms and around the pan strandlines are typically made up of thin flat salt beds with vertical palisade and chevron textures that characterise ephemeral brine pans everywhere (Fig. 1.44).

In the 1980s, in order to destabilise the problematic salt reefs, brine levels in the compartments were allowed to draw down by lowering the rate of supply of pumped brine. But, rather than diminishing the evaporation area available for reef growth, the damp emergent salt reefs seemed to act as giant transpirative pumps. This further accelerated salt crystallization rates in the remaining brine compartments, which

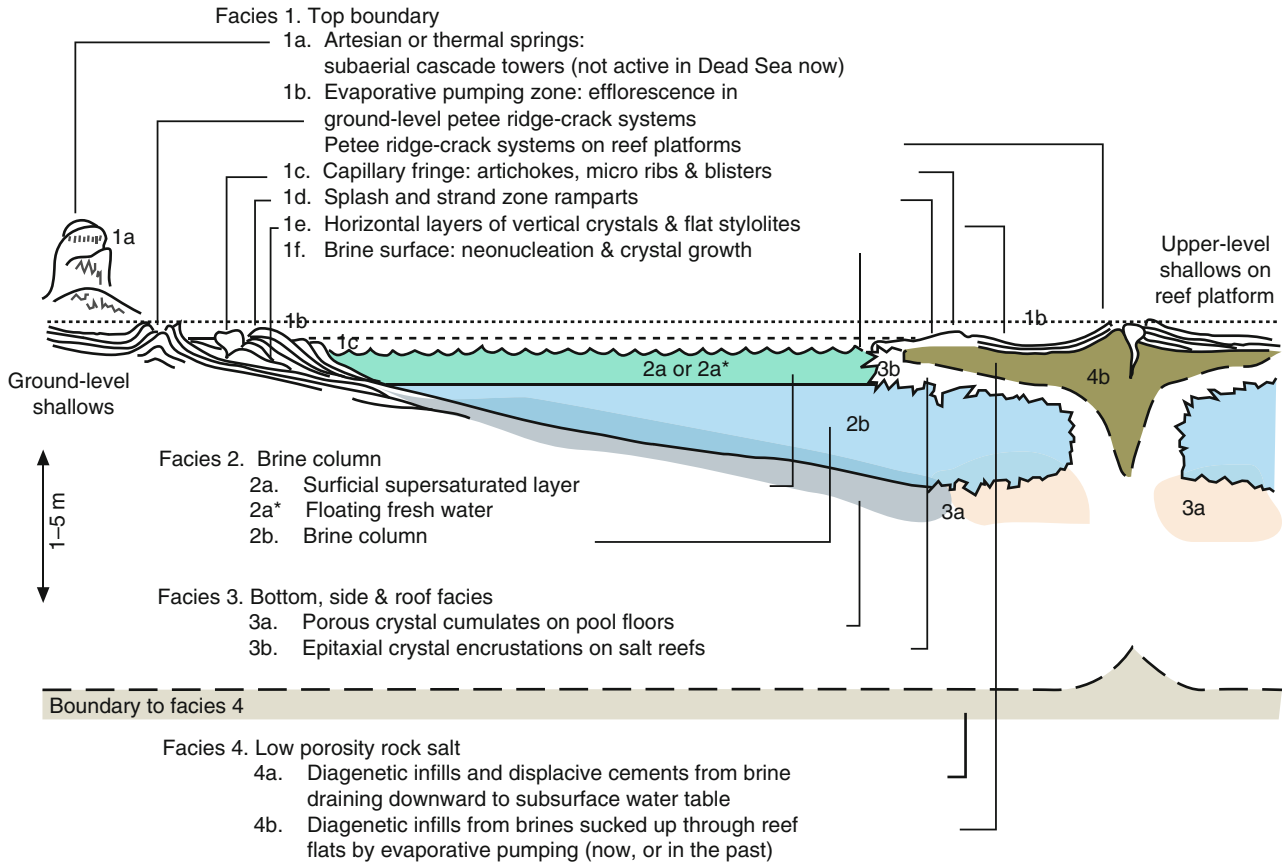

Fig. 1.44 Subdivision of the mushroom-shaped salt reefs of the southern Dead Sea is related to the permanency and salinity of stratification in the perennial pond brines in the inter-reef areas (After Talbot et al. 1996)

continued to reconfigure the evaporation ponds into smaller and smaller areas. Even today the problem is not solved and once an inter-reef area is isolated from brine throughflow, waters caught up in reef-walled depressions concentrate to bittern saturation. Bottom-nucleated carnallite drops out before reaching the target crystallizer pans. Thus, pervasive salt reefs lessen the volume of suitable brine product reaching the final fractionation pans. The solution to this problem is not subtle, reefs in both the Israeli and Jordanian saltworks are periodically removed by a combination of dredging and blasting.

The densest halite reef complex occurs in a broad band that crosses both the Israeli and the Jordanian salt ponds (and their pre-enclosure depth contours), despite each suite of ponds being different distances from the northern basin (Fig. 11.25b). The most vigorous salt reefs within this band nucleated on an old road incorporated into the Jordanian ponds. The natural end of salt reef formation is probably when shallow brines on hollow reef platforms become ephemeral on solid salt flats. But if pans in the saltworks are allowed to evolve and fill to this stage, they are no longer suitable brine concentrators for the continuous feed bittern crystallisers further down the fractionation string.

Reefs seem to evolve from cracks along pressure-ridged salt crusts, and once supersaturated surface brine layers form, grow rapidly outward and upward via epitaxis. Compared to natural saline pans, brine depths in the pans of the Dead Sea saltworks are maintained at artificially deep levels by pumping Dead Sea brine into the pans. Zones of new salt reefs grow alongside recently flooded pan shores and quickly become unrecognizable as former pressure ridges once the brines deepen. Salt reefs are not seen in modern natural brine pans and salars as the water depths where stacked salt crusts accumulate are always too shallow or ephemeral for pervasive reef growth. Talbot et al. (1996) argued epitaxis in supersaturated surface brine layers helps account for the rapid deposition of modern thick beds in the Dead Sea prior to the building of the salt works. He argues that similar structures probably formed in marine-fed regions of pure salt accumulation on the floors of ancient rifts that periodically opened to the ocean.

Domal gypsum reefs occur in modern salinas and in the Messinian of the Sorbas Basin, Spain (Fig. 4.6d), but as yet no ancient halite reefs have been documented. They should be distinguishable as being outlined by botryoidal layers of nonvertically-aligned chevron crystals, which would tend to follow a megapolygonal pattern between saucers of recrystallised cumulates. Part of the problem of recognition lies in the scale of outcrop exposure needed to recognise such a salt reef. Bedded gypsum outcrops entraining reefs and domes are commonplace, but nonhalokinetic ancient halite never makes it to the surface. Halite reef textures would be next to impossible to document in cores, but should be visible in mine walls in the same way that ancient halite megapolygon and pressure ridges are, but would easily be misinterpreted as mesoscale syndepositional karst features. Another part of the problem is a lack of expectation of halite reef structures, which are not a commonly listed texture in sedimentology textbooks. And yet another problem is that rapid infill means metres-deep perennial halite-saturated brine bodies are not found in modern salt lakes, only in anthropogenic ponds as in Israel and in quarried coastal pans in Saudi Arabia (Fig. 3.17). But, as will be seen in Chap. 5, there are many ancient saline seaways where salt reefs were possible in halite-saturated brine bodies with depths measured in metres to tens of metres.

Secondary (Diagenetic) Evaporites

Most ancient evaporites show strong evidence of secondary or diagenetic textural overprints. Providing brine is saturated with respect to a particular evaporite mineral it has the potential to precipitate that mineral. This potential exists both at the surface and in the subsurface. So far, we have discussed the primary processes of evaporite precipitation in the context of single-phase primary evaporite crystals deposited on the floor, or about the margins, of brine pans, lakes, salterns or saline seaways. However, evaporites also precipitate as intrasediment crystal growths and replacements, or as cements in pre-existing evaporite and nonevaporite hosts.

Processes of secondary evaporite formation are reflected in crystals and textures that indicate displacive growth, recrystallisation, back reactions and replacement. Such events indicate a superimposed brine chemistry that differs in terms of chemical composition, or salinity, or temperature from the brine chemistry that formed the primary or pre-existing evaporitic sediments (see Chap. 2).

Intrasediment Salts

The well-studied nodular anhydrites and gypsums of the Abu Dhabi sabkha in the Arabian Gulf are probably the most widely recognised examples of syndepositional intrasediment evaporites (Fig. 3.5). The nodules form displacively and replacively from concentrated pore fluids in the capillary and upper phreatic zones beneath the sabkha surface (Fig. 1.45a). In the type area these intrasediment crystal growths precipitate in a matrix of upper intertidal and supratidal sediments. But in addition to anhydrite capillary salts, gypsum and halite also precipitate displacively in numerous continental and pedogenic settings. Salts and their crusts may come and go, driven by the vagaries of groundwater resurgence, surface flooding and reconcentration, so that all that may be left as indicators of their former presence are

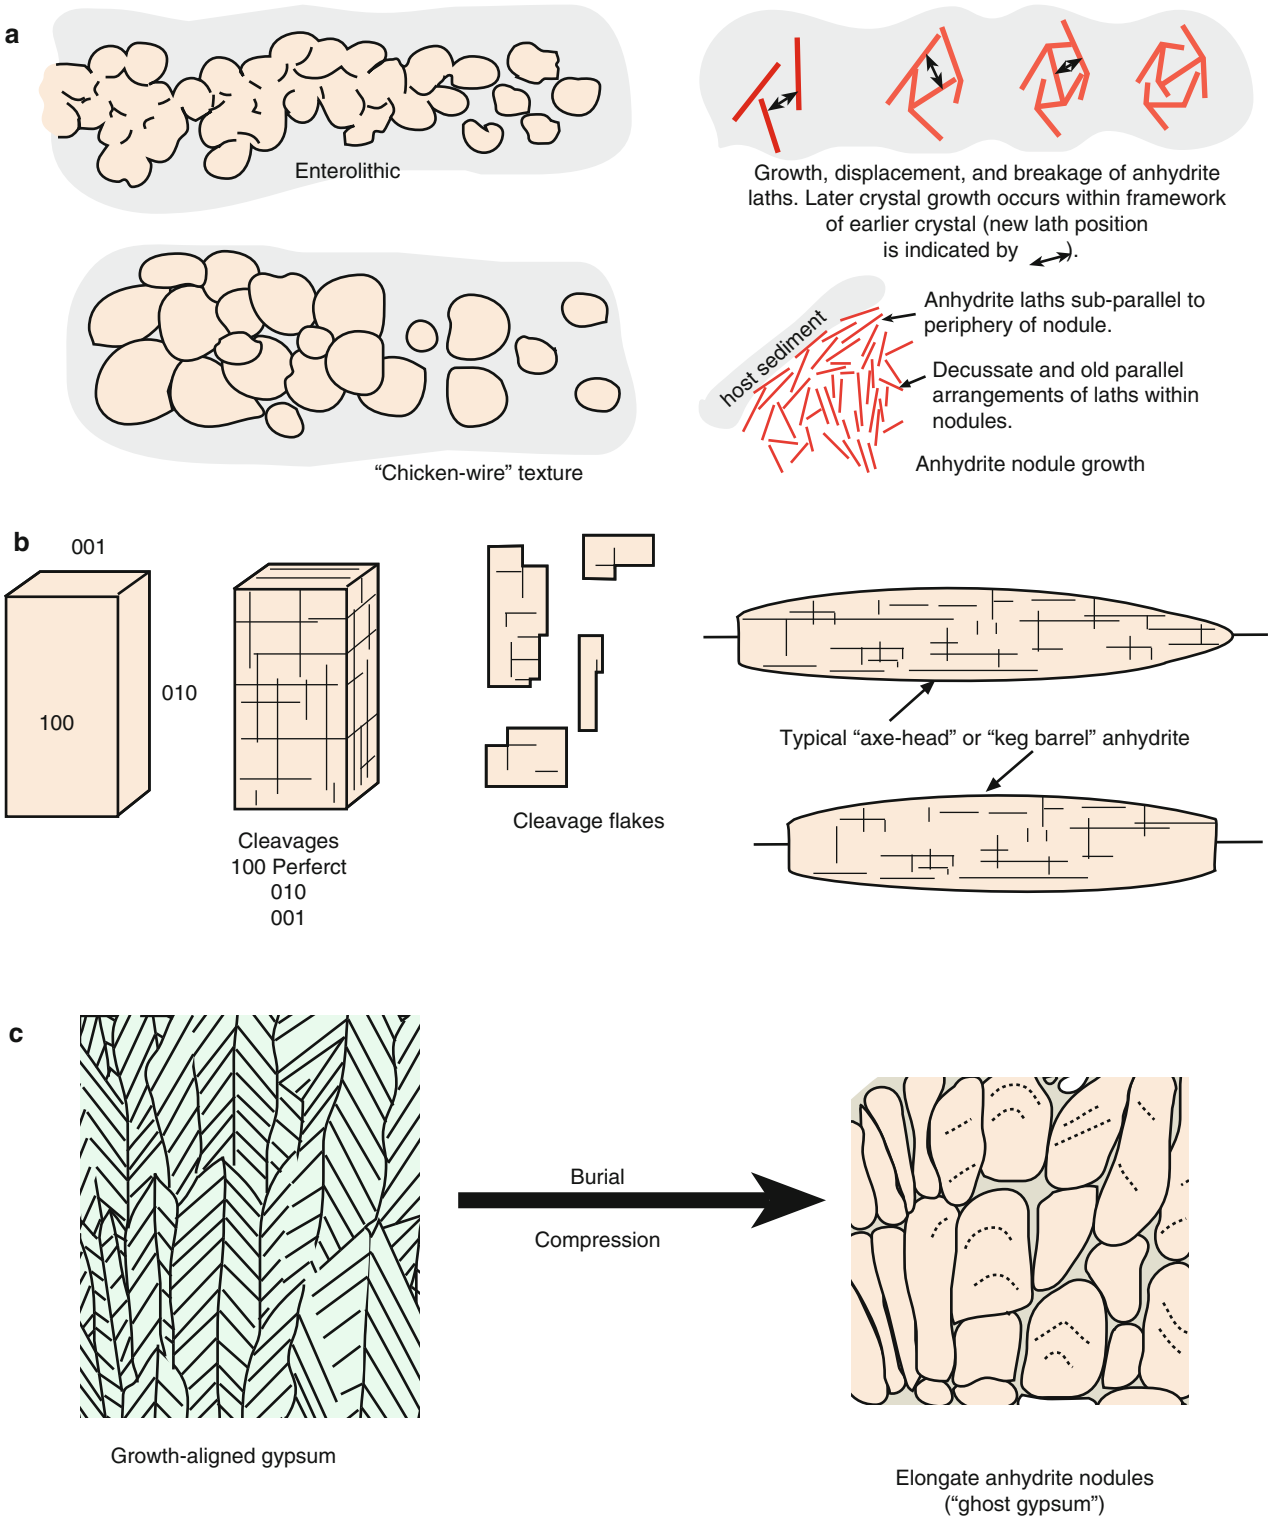

Fig. 1.45 Anhydrite characteristics. (**a**) Anhydrite nodule growth into chicken wire and enterolithic anhydrite. Also shows how successive new anhydrite laths break and rotate earlier formed laths. The end result is a nodule with a margin composed of laths aligned subparallel to the its edge. Many nodule interiors preserve clusters of subparallel laths showing large nodules grow by accretion of smaller nodules. (**b**) Crystallographic characteristics of anhydrite laths showing well developed orthorhombic cleavage. Large isolated anhydrite spar crystals in mudstones sometimes have a lenticular form. It or its pseudomorphs can be distinguished from lenticular gypsum by a typical "axe-head" and "beer-keg morphology" with well developed cleavages at one or both ends of the lens. (**c**) Preservation of gypsum ghosts as elongate anhydrite nodules created during burial (After Shearman and Fuller 1969; Warren and Kendall 1985)

highly disturbed sediments with a few halite or gypsum pseudomorphs.

The amount and variety of intrasediment salt is highly variable. Some mudstones contain scattered crystals and nodules that make up less than 1 % of the rock volume. Others are made up of approximately equal volumes of host matrix and evaporite salts, while yet others are characterised by layers composed almost entirely of intrasediment salts. The thickness of the layer over which intrasediment salts can precipitate is controlled by the style of brine supply. If the salts are precipitating by capillary evaporation beneath a subaerially exposed mudflat then the thickness is controlled by the pore throat size of the host sediment. Capillary zones can be metres thick in fine clays, while they are only centimetres thick in sands. If the intrasediment salts are precipitating by the downward percolation of dense cooling brines from a subaqueous water body then the thickness is dependent on the rate of diffusion or reflux into the underlying clay. Handford (1991) estimates intrasediment halite can precipitate in brine-saturated soft muds down to depths of 1–2 m below the sediment-brine interface.

Sabkha Nodules and Crystals

As gypsum and anhydrite nodules grow and coalesce in highly saturated pore waters of the capillary zone, they form enterolithic, contorted fold (ptygmatic) and chickenwire textures, which typify the supratidal portion of a coastal sabkha sequence. New laths of anhydrite form between older laths as such anhydrite nodules grow "from the inside out" (Shearman and Fuller 1969). Successive laths crystallise, displace, rotate and perhaps break the older laths, while the expanding nodule pushes aside the adjacent host matrix. Figure 1.45a illustrates this process and the position of each successive new lath is indicated by a double-ended arrow in the figure. The end result of this "inside-out" growth is a near pure anhydrite nodule, with laths about the edge of the nodule rotated into a subparallel alignment to the nodule margin. Many nodules are constructed of a number of subsets of this subparallel arrangement, implying large nodules grow by accretion of smaller nodules.

Capillary halite crystals typically show an incomplete development of the cube face, and in soft muds with supersaturated pore brines there is intense development of the cube edges at the expense of the cube faces to create dendritic or pagoda-like morphologies. Rapid crystal growth often entrains some of the mud matrix within the halite, usually parallel to the cube faces. Such rapid growth is thought to indicate a rapidly attained and high degree of supersaturation with respect to halite (Arthurton 1973; Southgate 1982) or perhaps growth in organic-rich brines (Gerdes et al. 2000a, b).

Displacive halite grows by capillary evaporation of supersaturated pore waters in soft brine-soaked mudflat or sabkha sediments (Fig. 1.32c). Such hoppers are found growing in carbonate muds along the western shore of the Dead Sea (Gornitz and Schreiber 1981). Similar halite crystals are found actively growing as much as metres below the surface of present day mudflats in Bristol Dry Lake in California (Handford 1991). Growing about the edges of the same lake are unusual capillary pavements of growth-aligned seepage gypsum (Rosen and Warren 1990). Dendritic or pagoda forms of halite cannot easily grow in deeper burial environments where rates of salinity fluctuation and kinetics of reactions are much slower. The surrounding matrix is more likely to be indurated, so secondary crystals formed at depth tend to be fracture or mould fills.

Syndepositional Karst in Crusts

Crusts and beds dominated by primary subaqueous textures (chevrons and palmate/zig-zag structures) can be partially dissolved by more dilute surface brines or by subaerial exposure. Freshening can be via a rise in the brine-pool level associated with rainfall and sheetflooding, by seawater flooding, or by morning dew dissolution associated with the complete drying of the brine pan. The resultant dilution creates a truncating dissolution surface that crosscuts crystal faces in both subaerial and freshened subaqueous settings (Fig. 1.46). In a subaerially exposed halite crust numerous cm-dm-scale vertical to subhorizontal karst cavities typically form beneath an upper crystal-truncating exposure surface. Cavities subsequently fill with clear evaporite cement sometimes atop a cavity-lining rind of detrital mud and clay (Fig. 3.33). In chevron halite beds these cavities are often filled with a clear inclusion-poor halite spar cement. Void infill is often related to the depositional event that precipitated an immediately overlying chevron halite or swallowtail gypsum layer (Handford 1991; Warren 1982a). Using bromine signatures, Cathro et al. (1992) found the Silurian brines that precipitated the cloudy primary halite in the Mallowa Salt of the Canning Basin were indistinguishable from the signatures in the secondary spar-like halite that filled voids in the primary halite, implying an early origin from the same depositional/syndepositional brine. This is a depositional signature still preserved in these beds more than 400 million years later.

Intensity and frequency of dissolution overprints in salt crusts are largely determined by brine depth, frequency of dilute water floods and the permanency of the brine body. Most modern and ancient halite salt pan crusts preserve evidence of syndepositional dissolution in the form of dissolution surfaces and halite-spar-filled cavities. Lowenstein and Hardie (1985) emphasised that the presence of such features in a halite bed is the unequivocal signature of ephemeral surface waters. The texture reflects dissolution events that accompany subaerial exposure of any salt crust and the periodic flooding of the halite pan by fresh to brackish meteoric

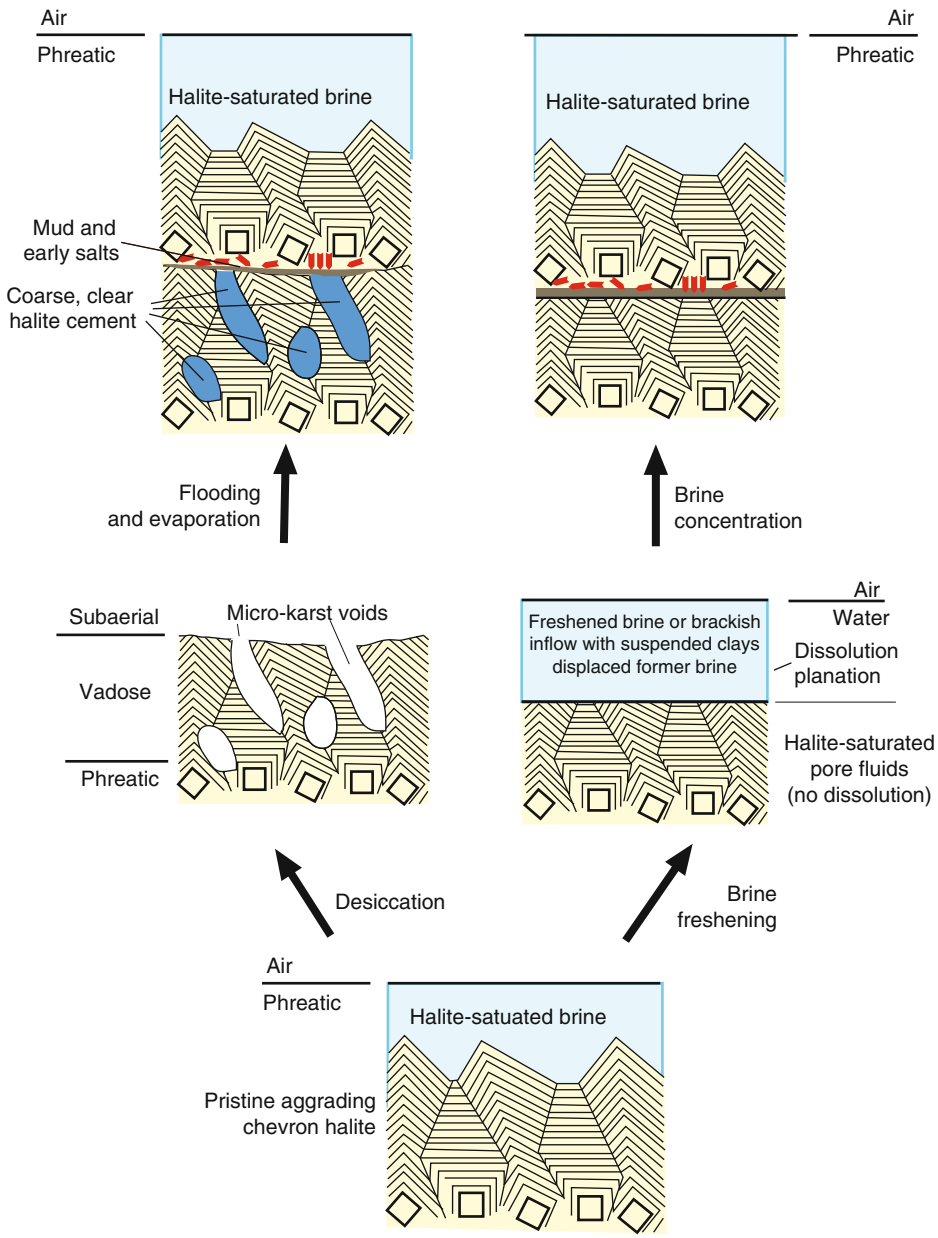

Fig. 1.46 Syndepositional overprints on chevron halite. The textural evolution illustrated on the left shows the formation of vadose microkarst, while that on the right illustrates the effect of bottom freshening on the floor of a perennial brine pool and the formation of a planation surface with no vadose karst development

water (Fig. 3.33). Dissolution cavities are less likely to occur in bottom-nucleated beds deposited in evaporite basins covered by deeper perennial brine bodies. Freshened inflow waters tend to float atop the denser halite-saturated brine body at least until its density equalises that of the underlying brine. If brine freshening does occur in a perennial brine situation then a planation surface without vadose cavities is the likely result (Fig. 1.46).

Nearsurface Crystal and Crust Dissolution

The following section focuses on small-scale syndepositional features indicative of the groundwater cycling of salt crystals and crusts, Chap. 7 looks broader and deeper in a discussion of dissolution mechanisms creating "the salt that was."

Coming and Going of Salt Crusts

Salt crusts and isolated crystals on many modern saline mudflats are ephemeral; they are not preserved in the final sediment matrix, yet their growth and subsequent dissolution on or within nearsurface sediments can alter sedimentary structures and textures to such an extent that it is difficult to identify the original texture. Areas dominated by this set of processes occupy large schizohaline areas of modern salt flats in SE Arabia such as Sabkhat Rumadan in Saudi Arabia, Sabkhat Matti and the At Taf coastal region, both in the Emirate of Abu Dhabi, and the Umm as Samim region in Oman (Goodall et al. 2000; Lokier 2012).

These salt flats are affected by varying combinations of tidal-marine, alluvial and eolian depositional processes and

the resulting sediments include both clastic- and carbonate-dominated successions. The efflorescent and precipitated salt crusts in these areas can be grouped into two main types: (1) thick crusts, with high relief (>10 cm) and a polygonal or blocky morphology; or (2) thin crusts, with low relief (<10 cm) and a polygonal or blister-like appearance. The thin crusts may assume the surface morphology of underlying features, such as ripples or biogenic mats (petees).

A variety of small-scale textures resulting from the interaction of detrital sediments with the salt crusts were observed by Goodall et al. (2000), they include: pustular growths, hair-like spikes and irregular wrinkles. Evolution of crusts over time creates a variety of distinctive sedimentary fabrics by salt-growth sediment deformation, salt-solution sediment collapse, sediment aggradation and compound mixtures of these processes. Preservation ranges from completely preserved crusts to highly disturbed siliciclastics where only suggestions of former salt crusts remain (haloturbation).

When a subaerial sabkha surface is marked by a salt crust with pressure ridges, the lee side of a ridge acts as a trap to cross-drifting sands that become enmeshed and cemented by further salt growth. Eolian-dominated sabkhas accrete via a set of processes that begin with a sandstorm, followed by a new salt ridge episode, followed by another sandstorm (Fig. 1.47a). The resulting sediment is an irregularly layered sandy mud, disturbed by ongoing intrasediment salt and carbonate growth and solution (Fryberger et al. 1984; Goodall et al. 2000). In other words haloturbation, rather than obvious crust preservation, is the dominant texture in many eolian sabkhas.

Salt-crust processes can produce features that may be confused with eolian adhesion structures. For example, distinctive wavy-laminated facies in the Lower Triassic Ormskirk Sandstone Formation in the Morecambe Field of the Irish Sea Basin had previously been interpreted as the product of fluvial sheetfloods modified by soft-sediment deformation and bioturbation. Close inspection of laminations in core revealed many of the same sedimentary fabrics seen in Sabkha Matti (Goodall et al. 2000). This facies is the product of salt growth on eolian sediment and is not of fluvial origin.

Lenticular Mudcracks

Evaporites growing in association with drying muddy sediments and eolian sands can also produce mudcracks that may be confused with syneresis cracks. There are numerous mud cracks in irregular arrays and often showing lenticular outlines in the Orcadian (Devonian) laminites of Scotland. They are considered one of the type examples of syneresis cracking and were used as evidence that these sediments were

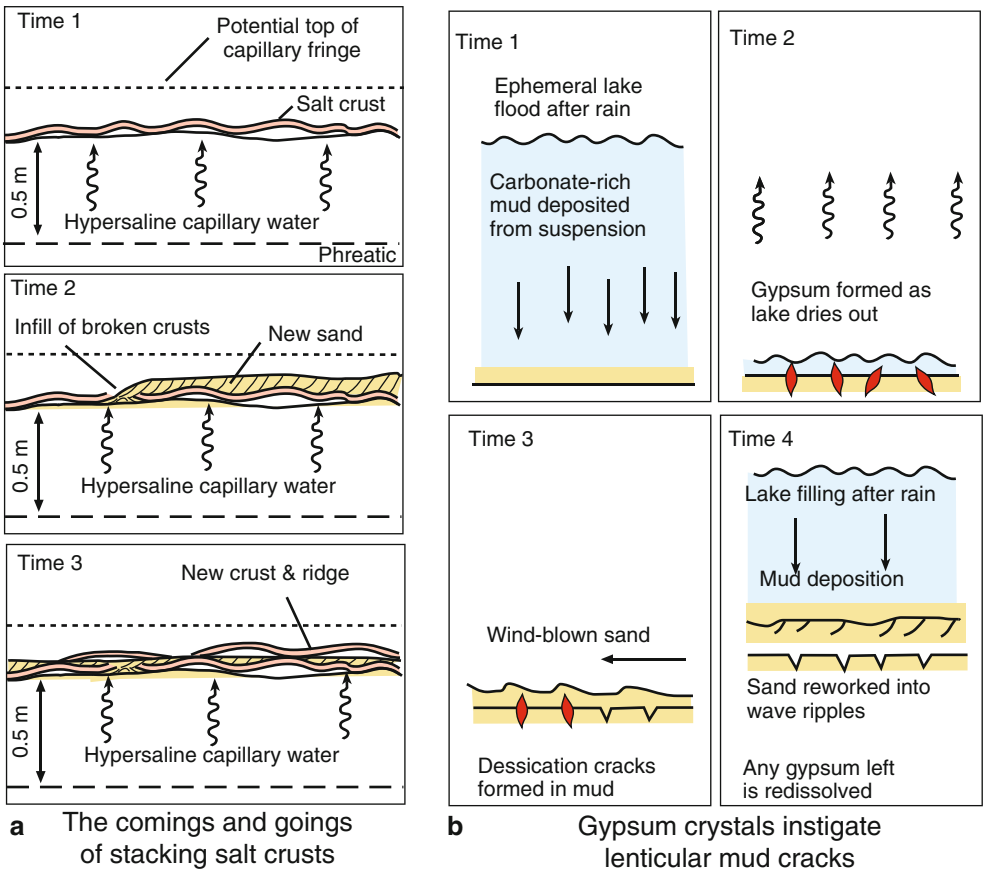

Fig. 1.47 Residual evaporite textures indicating syndepositional precipitation and dissolution. (**a**) Salt crust accretion mechanism. (Time 1) Development of salt crust at top of capillary zone. (Time 2) Covering of crust by windblown sand. (Time 3) Incorporation of crust and salt cover by capillary wicking, portions of the old crust may dissolve and collapse (After Fryberger et al. 1984). (**b**) Instigation of lenticular mud cracks (syneresis mimics) by early gypsum growth and dissolution in an ephemeral mudflat/saline pan (After Astin and Rogers 1991)

deposited in a shallow (<30 m) lacustrine environment. Yet, lenticular shaped features seem to initiate many of the mudcracks. Rather than a subaqueous origin, these mudcracks are equally characteristic of the incipient stages of subaerial shrinkage with what appear to be gypsum pseudomorphs in some of the straight cracks (Astin and Rogers 1991).

Cracks are abundant and irregularly clustered because early gypsum crystals acted as nuclei for cracking and controlled crack morphology (Fig. 1.47b). The majority of the lenticular cracked surfaces formed as the ephemeral lakes waters dried up and deposited lenticular or bird-beak gypsum. The crystals were modified to varying degrees before being covered by wind blown sand laminae and buried. Subsequently the gypsum, along with minor halite, dissolved to leave the characteristic cracks in the lake sediments. In a review of other documented examples of subaqueous syneresis cracks, Astin and Rogers (op. cit.) argue that many can be reinterpreted as the result of gypsum instigation, followed by desiccating cracks centred on the crystals and then burial. They go on to conclude that syneresis cracks, although well documented in the laboratory, are rare and insignificant in nature and that evaporites growing in mudcracks are commonplace. For example, King had noted carnallite-filled mudcracks in the salt clays of the Permian Salado Fm., West Texas, as early as 1946.

Haloturbated and Chaotic Halite

Percolation of capillary waters periodically saturated and undersaturated with a particular evaporite salt can also create textural havoc in a nonsalt matrix. For example, displacement halite grows via capillary evaporation during the supersaturated phase of pore flushing of the saline mudflat facies surrounding many brine pans. The growth of this halite disturbs and rotates primary mechanical structures in the original sediment matrix (laminae, ripples, mudcracks, etc.). But with each flooding of the brine pan there is a freshening of surface waters and nearsurface pore fluids, driven by sheet flood runoff followed by seepage down to a depressed watertable. Near surface pore waters become undersaturated with respect to halite and the displacement halite dissolves. Sediment matrix then collapses into the voids so formed, further disrupting any primary structures in the sediment matrix. As the pore fluids are again concentrated by capillary evaporation, intrasediment halite and gypsum begin to grow once more, further displacing and disrupting existing textures. This process of alternate wetting and drying with the associated destruction of primary stratification in the matrix is known as haloturbation (Smith 1971). If the sediment is preserved with halite still present, it is termed chaotic halite. If the halite is completely dissolved, all that may be left is a haloturbated massive mudstone.

Because it is largely a syndepositional process that occurs prior to induction of the clayey matrix, one of the effects of haloturbation is to create highly deformed intraclasts within the haloturbated or chaotic-halite bed. Powers and Holt (2000) use the term "smeared intraclasts" to describe this form of salt-related mudflat texture. It can be used to recognise a hypersaline capillary mudflat unit, even if the original displacive salt is leached. Smeared intraclasts are typically 2–5 cm across, are made up of the same lithology as the surround matrix and show distorted or smeared internal thin beds or laminae (Fig. 1.48). The facies transition layered and undisturbed mudflat to haloturbated mudflat to chaotic halite indicates increasing proximity to a perennial saltpan (Chap. 3).

Shallow Mineralogic Re-equilibration

Dense saturated bottom brines percolating down through a shallowly buried primary evaporite unit can create diagenetic havoc within the original texture. For example, saturated bottom brines percolating through a buried cumulate halite

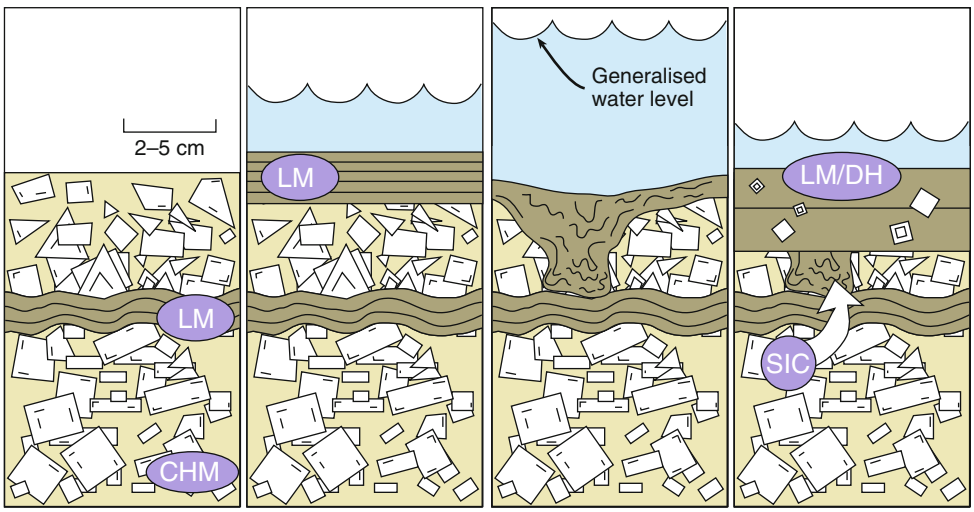

Fig. 1.48 Evolution of smeared intraclasts by collapse of lacustrine mudstone into void space created by dissolution of halite crystals during the freshened stage of a wet-dry cycle in an evaporitic mudflat. *LM* lacustrine mudstone, *CHM* chaotic halite mudstone, *SIC* smeared intraclast, *DH* displacive halite (After Powers and Holt 2000)

deposit can convert it into a tightly-cemented coarsely-crystalline halite mosaic retaining little evidence of the primary texture (Smoot and Lowenstein 1991; Cathro et al. 1992). Dense halite-saturated brines flushing down through shallowly buried subaqueous gypsum beds that are dominated by bottom-nucleated gypsum crystals can set up diagenetic conditions where the gypsum is replaced by halite/anhydrite pseudomorphs of the original aligned gypsum. In Permian evaporites of West Texas the replacement mimics the crystal shapes in beds composed of bottom-nucleated gypsum precursor, as well replacing internal layering within crystals. This tends to happen early and be driven by reflux of halite-saturated brines into gypsum beds. Ambient high temperatures and salinities mean much of the finer grained gypsum matrix has already converted to nodular anhydrite. Reflux in ancient brine platforms drove a process of gypsum dissolution and halite replacement a few metres beneath the brine-covered sediment surface in ancient brine seaways (Figs. 1.49 and 2.64; Hovorka 1992).

In a similar fashion, changes in the near surface hydrology within the modern saline mudflats of Salt Flat playa in West Texas, have "sabkha-ized" a subaqueous laminated lacustrine gypsum bed (Hussain and Warren 1989). The process was driven by the superposition of a Holocene capillary hydrology onto subaqueous gypsiferous laminites originally laid down in a Pleistocene salt lake. This capillary zone overprint precipitated nodular displacive gypsum within a matrix of laminated gyp-sum/dolomite. The change in hydrology indicates a change in climate from more humid Late Pleistocene to more arid Holocene conditions. It also set up shallow subsurface pore chemistries, whereby lenticular gypsum crystals were pseudomorphed and replaced by halite spar.

Owing to the mixing of waters of two salinities, reflux dolomitisation beneath a platform evaporite can take place concomitantly with $CaCO_3$ dissolution (Sun 1992). Relative rate of limestone solution compared to dolomite growth is a likely control on porosity levels during the later stages of the reflux dolomitisation process (Sun 1995). If the rate of dolomite growth keeps pace with the rate of $CaCO_3$ dissolution, then the mimetic replacement of micrite matrix and micritised grains occurs with little change in porosity levels, as in many ancient evaporitic peritidal dolomites. If the rate of reflux dissolution exceeds the rate of dolomite replacement, as in open marine platform carbonates beneath the seaward edge of a platform evaporite, then there is large scale skeletal aragonite dissolution, along with an increase in effective porosity in the dolomitised interval compared to precursor limestone. During shallow subsurface brine reflux in the Permian in the Palo Duro Basin, Texas, the flow of such refluxing waters dissolved marine carbonate to form anhydrite-filled moulds (Bein and Land 1983), while in the Levelland-Slaughter interval it enhanced reservoir porosity (Fig. 10.27; Elliott and Warren 1989).

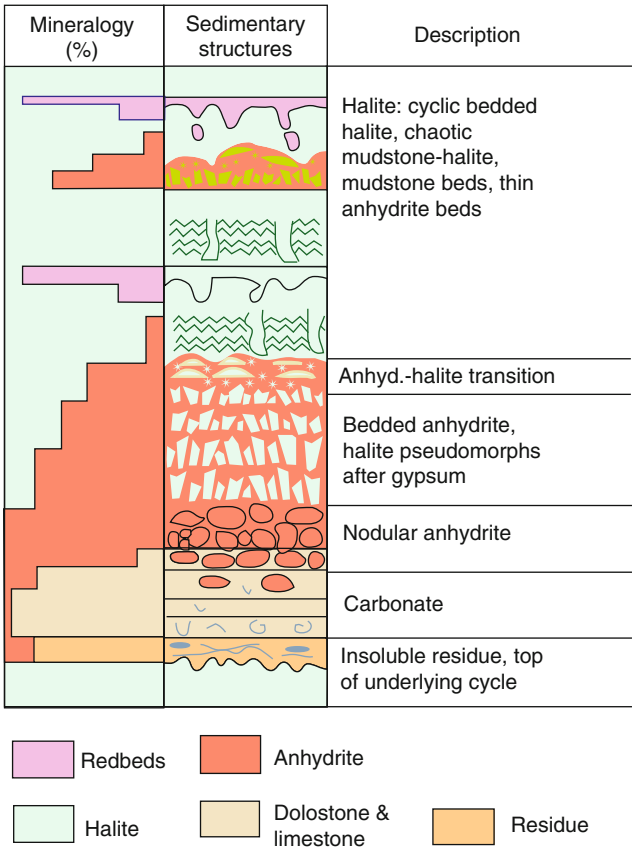

Fig. 1.49 Typical depositional cycle in the Permian evaporites of the Texas Panhandle where gypsum (rather than anhydrite) was the dominant sulphate precipitated, even at salinities near halite saturation. Large gypsum crystals grew vertically on floors of brine pools, surrounded by a matrix of autochthonous trans-ported gypsum sand and silt. Most or all of the primary gypsum was altered to anhydrite or leached and replaced by halite in the very shallow (<2 m) burial environment under the influence of halite-saturated diagenetic brines (After Hovorka 1992)

Porosity Loss

Syndepositional alteration, cementation and porosity loss, in a halite bed continues into the shallow subsurface until the bed can no longer support fluid flushing. This occurs once all effective porosity is occluded by compaction and secondary evaporite cementation. In halite-dominated continental sequences this loss of effective porosity is typically early and shallow (Fig. 1.50). Casas and Lowenstein (1989) showed that Quaternary halite layers only 10 m below the land surface have typical porosities of <10 % and that layers at depths below 45 m are tightly cemented without visible porosity. By 100 m of burial, almost all the halite units were tight and impervious. Diagenetic porosity occlusion by surface-driven hydrology in these halite beds was essentially over. No further porosity change can occur until beds start to dissolve deep in the mesogenetic realm or even in the metamorphic realm as the dihedral intercrystalline angle of halite begins to change as the beds approach greenschist conditions (Lewis and Holness 1996).

From a few hundred metres burial until it reaches the zone of metamorphism, a halite unit maintains permeabilities that are measured in no more than microdarcies or nanodarcies. Thus halite beds and allochthonous sheets provide a highly effective seal to sediments beneath. To move closer to the surface, trapped basinal fluids must either flow laterally around such a salt barrier or dissolve it. If the trapped pore fluids are hydrocarbons then no dissolution can occur as halite is virtually insoluble in gas and oil. Retention of pore fluids below a salt barrier means porosity in the host sediment is maintained to a much greater depth and that sediments below a salt barrier in an actively subsiding basin are typically overpressured.

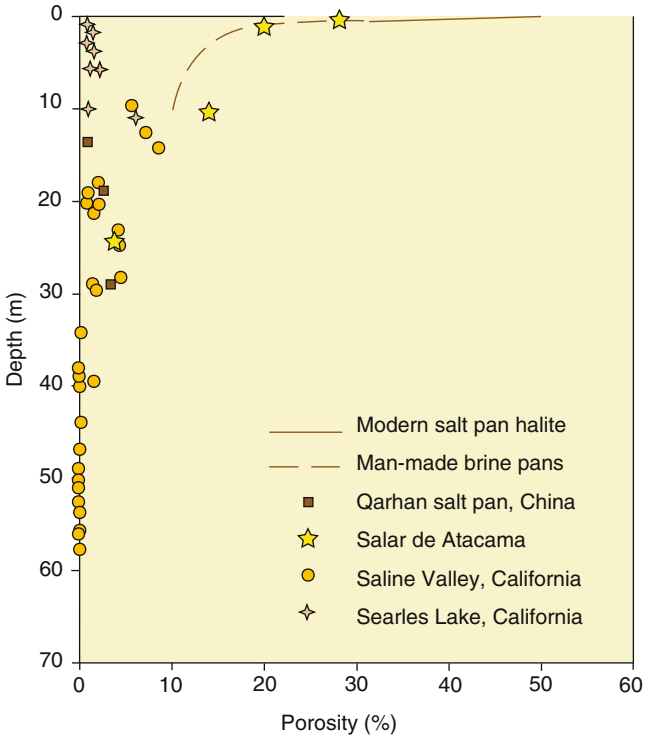

Fig. 1.50 Porosity in Quaternary halite beds versus depth (After Casas and Lowenstein 1989). All effective porosity is lost by 70 m burial

The pervasive early loss of porosity from more than 50 % near the surface to zero by 100 m burial also has important implications for textural and geochemical studies of ancient bedded halite. Casas and Lowenstein (1989) showed that this porosity loss was entirely due to early post depositional diagenetic cementation by clear halite. Other mechanisms of porosity loss by chemical or mechanical compaction were dismissed for lack of evidence. There were no strained or broken crystals, pressure solution boundaries nor stylolites, and patches of chevrons preserved in among the mosaic halite spar were all undeformed.

Many Phanerozoic halite beds that have not undergone halokinetic deformation also contain patches of relict depositional and early diagenetic textures, which have remained unchanged for hundreds of millions of years. For example, the Ordovician-Silurian Mallowa Salt (formerly Carribuddy Formation) in the Canning Basin, West Australia, retains aligned halite chevrons crosscut by syndepositional karst and an overprint of coarse mosaic recrystallised halite (Fig. 1.51a; Cathro et al. 1992). Such textures are thought to be syndepositional, yet are not dominated by large volumes of pristine chevron halite. Rather, they preserve evidence of early porosity loss brought on by numerous syndepositional cycles of dissolution and recementation. Lowenstein and Hardie (1985) showed that patchy remnants of chevrons and cornets in a dominantly coarse-grained mosaic of halite spar are not necessarily a burial fabric. All "mature" saltpan halites have this fabric within tens of metres of the depositional surface.

The mechanisms that allow a shallow brine to become super-saturated with respect to halite and to precipitate intercrystal-line cements/replacements are still not well understood. One possible mechanism is brine mixing. When compositionally distinct brines mix in the subsurface a new

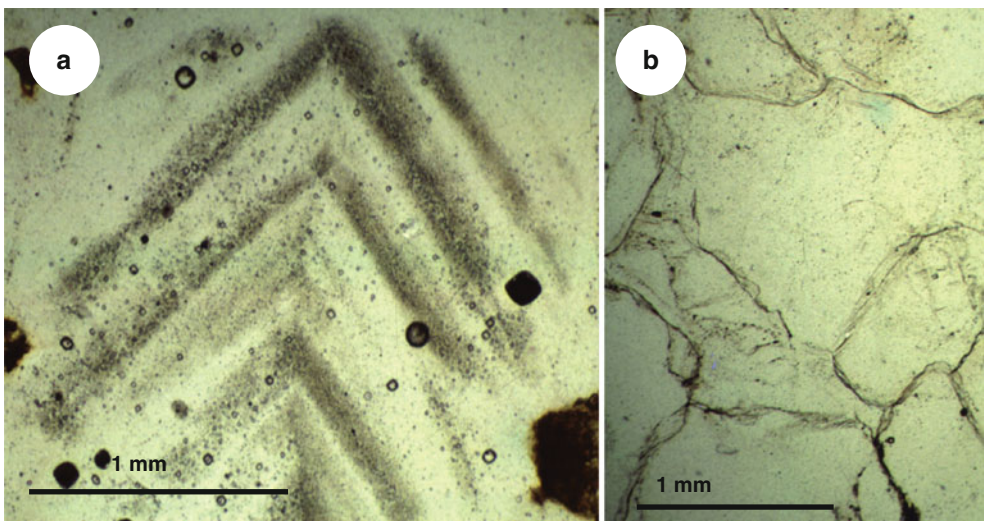

Fig. 1.51 Halite textures in the Silurian Mallowa Salt, Canning Basin. (**a**) Preserved halite chevron in growth position with erosionally truncated crest implying periodic bottom freshening and hence fairly shallow brine. (**b**) Recrystallised mosaic halite, an enigmatic texture that dominated most of the crust textures in the unit (After Cathro et al. 1992)

halite-saturated brine may result. This is the case when $MgCl_2$ brines are mixed with $CaCl_2$ -rich brines (Raup 1970). Casas and Lowenstein (1989) have questioned whether this is the dominant mechanism that forms pervasive halite cements in most shallowly buried playa sediments. Rather, they suggest a simple temperature drop is the dominant control. Brines in halite-forming surface waters can be heated to temperatures in excess of 60–70 °C, while groundwater brines typically have temperatures of 15–30 °C. They suggest that the cooling associated with the downward reflux of a surface water is all that is required to saturate a brine and so precipitate widespread halite cements.

Deeper Burial – Mosaic Halite?

Formation of pervasive mosaic halite spar early in the burial history of a salt bed creates a problem in recognising those parts of a halite unit that have been subjected to later burial recrystallisation as a deeper burial environment is also thought to form mosaic halite spar. Diagenetic textures in most ancient bedded halite units are dominated by sutured mosaic textures, where grain boundaries suture in the same fashion as neomorphic pseudosparite in calcite (Spencer and Lowenstein 1990). Individual crystals display curved boundaries that tend to meet at triple junctions with angles approaching 120°, and interstitial impurities concentrate along the crystal boundaries (Fig. 1.51b).

Mosaic texture is comparable to the polygonal equigranular mosaic texture that forms in annealing metals, where cooling grains tend to optimise their size, shape and orientation in order to minimise energy. The same mosaic texture can also be found in a soap foam as bubble boundaries with 120° triple junctions. The exact mechanism that controls the formation of mosaic textures in halite is still not well understood. It forms either early during brine reflux cementation or later during burial driven compaction and pressure-solution recrystallisation. During burial, flowing halite can create a pervasive overprint whereby pressure solution and recrystallisation moves fluid inclusions to new crystal edges. Crystals tend to flatten in the direction of maximum stress and this flattening can be used to distinguish salt that has flowed from other forms of mosaic halite (Fig. 6.16a; Rahimpour-Bonab and Kalantarzadeh 2005).

Limpid Dolomite in Mosaic Halite

The term limpid dolomite is describes a crystal form of dolomite composed of clear sparry rhombs, which in thin section appears largely free of internal impurities. As such it is a nongenetic term, limpid dolomites can form in a range of environments ranging from mixing zones to refluxing brines moving through recently deposited halite beds (Warren 2000a). Limpid dolomite in mosaic halite was documented as a late, ordered, stoichiometric, euhedral to subhedral set of dolomite crystals along the contact between bedded halites and interbedded mudstones in the platform evaporites of the Clear Fork and San Andres formations of the Palo Duro Basin, Texas (Fig. 1.52; Naiman et al. 1983; Gao et al. 1990). There it is interpreted as an outcome of focused burial diagenesis in a halite-mudstone succession. In these Permian examples, the limpid dolomite is characterised by a low Sr content and depleted $\delta^{13}C$ and $\delta^{18}O$ signatures (Fig. 1.52a). This C-O plot field is interpreted as indicating meteoric or structural waters held in adjacent deeply buried mudstones, and acting as the source of ions for the limpid dolomite that typifies the mudstone-halite contact.

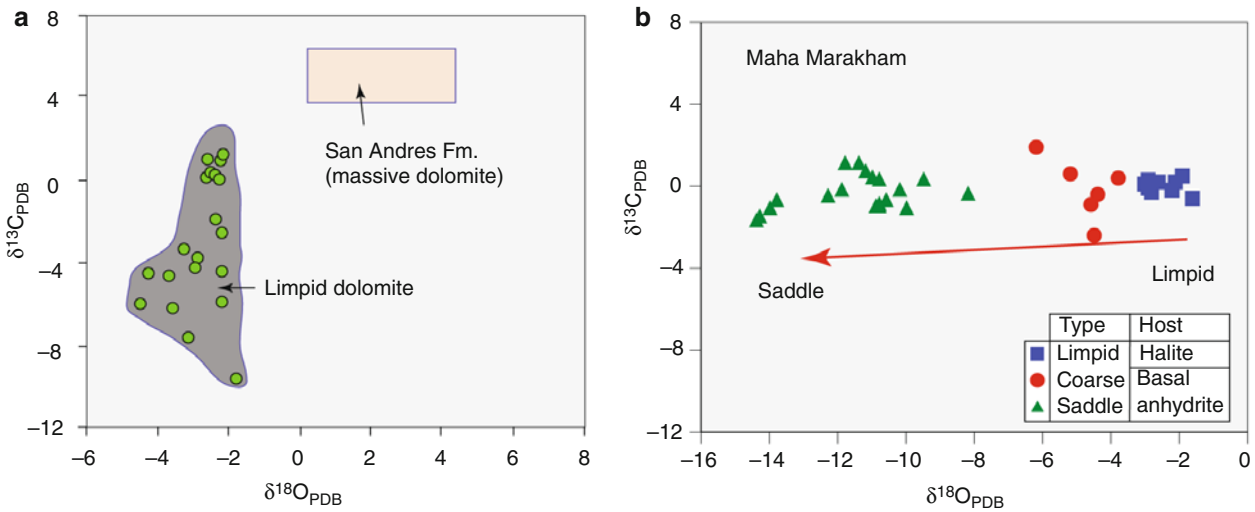

Fig. 1.52 Limpid dolomite in Mosaic halite, (**a**) In halite of San Andres Fm. Palo Duro Basin. Limpid dolomites are depleted in carbon-13 and oxygen-18, compared to typical isotopic signatures in the massive (reflux) dolomite of the San Andres Fm (After Gao et al. 1990). (**b**) Limpid dolomite in a halite host and its isotopic evolution and recrystallization when subject to an ongoing crossflow of escaping basinal waters at the base of the Cretaceous Maha Sarakham evaporites (Replotted form El Tabakh et al. 2003)

According to Gao et al. (1990) limpid dolomite in the San Andres is not the product of reflux brines, which created the pervasive massive mimetic dolomite in the interlayered San Andres platform carbonates. Limpid dolomite in the San Andres crystallised locally under favourable sulphate-reduction conditions during burial compaction and salt dissolution. Compaction mixed the waters, released from the dewatering mudstones, with brines derived by the dissolution or recrystallisation of adjacent impervious halite beds. Limpid dolomite spar precipitated along halite-shale contacts where escaping shale waters caused the halite to dissolve and recrystallize as mosaic spar.

The mode of dolomite formation from escaping structural waters, as indicated by the isotopic cluster in Fig. 1.52a, is part of a larger set of evaporite-focussed fluid flow processes that precipitate sparry or limpid burial dolomites at the contact between a dissolving salt bed and crossflowing basinal waters. The broader context of limpid dolomite is illustrated by the dissolving lower contact of the halite mass that is the Cretaceous Maha Sarakham Fm. of NE Thailand (Fig. 1.52b; El Tabakh et al. 2003). Limpid crystals of dolomite occur in the polyhedral sutures of mosaic halite that has undergone varying intensities of salt flow. In addition to the halite-hosted occurrences, there are two other forms of limpid dolomite crystals, which occur in the Basal anhydrite (a diagenetic unit discussed in Chap. 7) that defines the dissolving underside of the salt mass. These forms of limpid dolomite (coarse and saddle) show increasingly negative oxygen values, related to ongoing dolomite crystal growth in an anhydrite host, while flushed by warmer escaping basinal fluids (Fig. 1.52b). The burial evolution is also seen in the $^{87}Sr/^{86}Sr$ evolution of the various dolomites.

Burial of Sulphate Evaporites

Due to water release, gypsum and other bedded evaporite units made up of hydrated salts with entrained structural water show an inherently more complicated textural response to burial than the simple mosaic overprint of halite beds (Fig. 1.53; Warren 1991). Gypsum releases structural water as it converts with burial to nodular mosaic anhydrite. Carnallite ($KCl{\cdot}MgCl_2{\cdot}6H_2O$) releases Mg and water as it converts to sylvite (KCl) by incongruent dissolution associ-

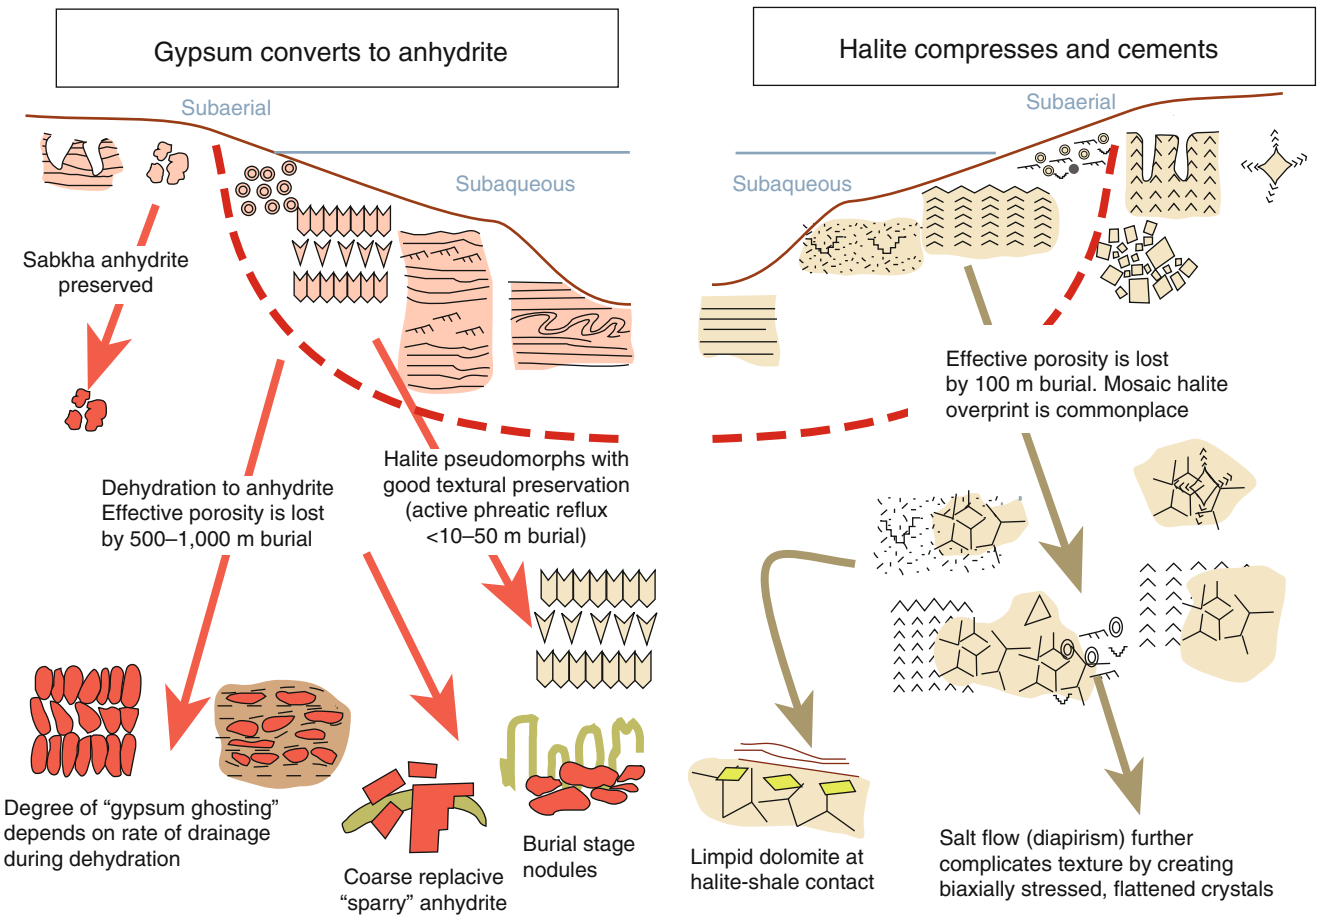

Fig. 1.53 Evaporite diagenesis showing evolution of burial-related secondary evaporite textures (includes burial salts)

ated with burial diagenesis or phreatic flushing by meteoric waters. Loss of structural water during burial dehydration means syndepositional textures in the converting bed are modified by this flush of escaping water.

The following discussion focuses on the conversion of a gypsum unit into anhydrite (anhydritisation) within the same mass of solid $CaSO_4$. There is an associated set of diagenetic fluid processes related to this conversion, namely the escape of $CaSO_4$ -saturated waters that can create sparry anhydrite burial cements in adjacent non-evaporite units. This set of subsurface processes is mentioned again later in this chapter, but textures and outcomes will be discussed in more detail in Chaps. 2 and 8. There is an additional set of anhydritisation processes where the precursor being converted to anhydrite is not gypsum, but a limestone or a dolomite. This set of processes and outcomes is also discussed in detail in later chapters.

Nodular Anhydrite and Water Loss

Gypsum, rather than anhydrite, is the most common form of sedimentary $CaSO_4$ at earth surface temperatures. Intense solar heating in very arid regions can dehydrate gypsum to form bassanite/anhydrite at the surface. Bassanite is also the precursor to gypsum in many depositional settings (Van Driessche et al. 2012). Natural gypsum forms via a three-stage process: (i) homogeneous precipitation of nanocrystalline hemihydrate bassanite crystallites below its predicted solubility, followed by (ii) self-assembly of bassanite into elongated aggregates co-oriented along their c axis, and then (iii) transformation into dihydrate gypsum.

Gypsum can convert to anhydrite in the capillary zones of sabkhas and evaporitic mudflats where gypsum is bathed in highly saline NaCl brines. But thick anhydrite beds deposited in ancient saline giants were first laid down as gypsum on the subaqueous floors of perennial brine lakes and seaways, as were most nodules and capillary layers in ancient mudflats. Prior to anhydritisation, beds of primary saltern gypsum extended across tens of thousands of square kilometres. Such beds compacted and converted by burial dehydration to nodular anhydrite during early burial, so releasing large volumes of structural water (Warren 1991).

As gypsum is buried and ambient temperature rises above 50–60 °C, it converts to nodular anhydrite. The depth of transformation is between a few metres to more than a kilometre. The exact depth in any region will depend on lithostatic pressure, local geothermal gradient and pore brine salinity. For example, in Miocene Lower Fars evaporites of the United Arab Emirates, with its relatively saline pore brines, the conversion depth ranges from 60 to 245 m across a zone some 10 m thick (Billo 1986). In the Salton Sea region with its high geothermal gradients, the conversion from gypsum to anhydrite occurs at 80–105 °C and at depths of less than 200–250 m (Osborn 1989). Similar anhydrite conversion was noted at 150–200 m depth in cores from the Pleistocene evaporites in nearby Bristol Dry Lake, California; but here the isotopic evidence suggests sulphate-reducing bacteria also play a role in the conversion (Fig. 1.54; Rosen and Warren 1990).

If the nearsurface pore-fluid salinity approaches halite saturation, the conversion from gypsum to anhydrite can occur at shallower depths and much lower temperatures ≈35–45 °C. Such temperatures occur as shallow as 1–2 m below the depositional surface of a halite-saturated brine pool where sediments reside in the zone of active phreatic flow or brine reflux. At such depths the buried gypsum bed retains well-developed intercrystalline porosity and inherently high permeabilities. This facilitates the leaching of the gypsum crystals and their infill by clear halite spar, which pseudomorphs the various forms of the precursor gypsum (e.g. Fig. 1.49).

With less saline brines in the pores of a buried $CaSO_4$ bed, the conversion of gypsum to anhydrite may not occur until burial depths of hundreds of metres (Fig. 8.37). By such

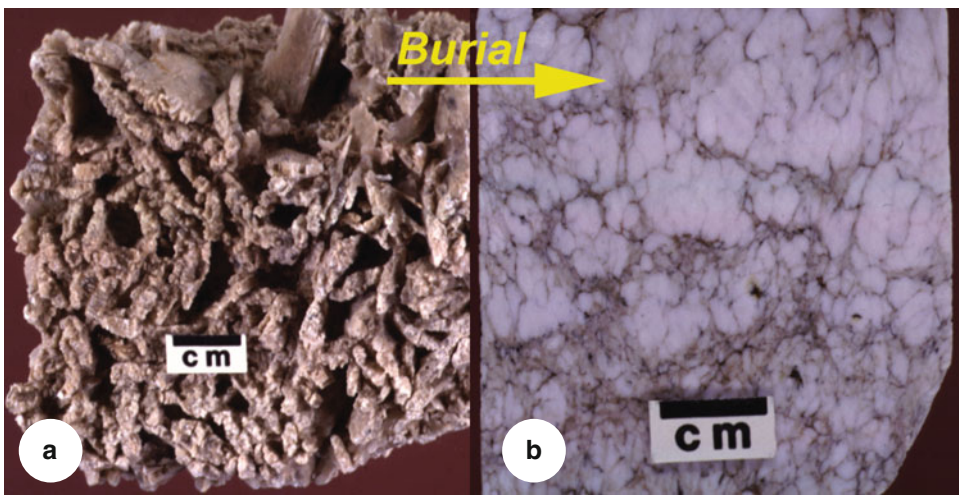

Fig. 1.54 Gypsum converts to burial anhydrite in Bristol Dry Lake, California. (**a**) Lenticular gypsum meshwork from a lake floor sediment sample a metre below the lake surface. (**b**) Nodular anhydrite still retaining the outline of the gypsum precursor. Sample from a lake core some 140 m below the lake surface

depths, natural compaction has greatly depleted intercrystalline porosity in the gypsum bed. Release of water from already compressed and cemented gypsum will create 40 % water-filled porosity in an otherwise impervious anhydrite unit. Over the long term this water is not retained but escapes into the subjacent sediments. A likely effect within the converting $CaSO_4$ bed is a decrease in its inherent strength; and in compressive situations, an increased ability to act as a lubricating horizon or décollement, even if no halite is present. If the water cannot drain freely from the dewatering gypsum, the bed may convert to a quicksand-like consistency. This explains some of the intense deformation and enterolithic textures with flow orientations that are commonplace even in flat-lying and otherwise undeformed ancient bedded anhydrites.

As it converts, the more deeply buried and compressed $CaSO_4$ unit loses almost all of its original texture. Rare indistinct elongate, and partially flow-aligned, nodular "ghosts" may be all that remain of the primary bottom-nucleated textures in many ancient anhydrite beds (Fig. 1.45c). Loss of water of crystallisation also affects units subjacent to the dehydrating gypsum/anhydrite. The escaping water is saturated with respect to $CaSO_4$, but undersaturated with respect to other evaporite minerals, including any nearby carbonates, as well as halite and the bittern salts. The onset of anhydritisation will be effected by the salinity and temperature of pore waters and the volume of pore water throughflow.

Such a complex anhydritisation history is well documented in the varying onset of anhydritisation in calcium sulphate sediments of the Middle Miocene Badenian evaporite basin in the Polish Carpathians. Three distinct, now anhydritised, facies associations record a range of depositional environments from nearshore to deeper basinal settings (Fig. 1.55; Kasprzyk 2003). Coarsely crystalline platform sulphates were deposited in subaerial and shallow-marine environments (shoreline and inner platform-lagoon system) mainly as autochthonous selenitic gypsum. These were reworked and redistributed into deeper waters (outer platform-lagoon, slope and the proximal basin floor system) to form resedimented facies composed mostly of allochthonous clastic gypsum and minor anhydrite. In contrast small gypsum prisms tend to accumulate in water characterised by rapidly fluctuating bottom brine conditions. The prisms were often mechanically reworked into rippled and ooid-like accumulations or captured in algal mats. These laminites were deposited in brine depths ranging down to hundreds of metres, but most accumulate in shallow brines less than a metre or two deep or as pelagics in the deeper part of the basin. It is the rapid salinity fluctuations associated with very shallow waters that favour rapid crystallite formation and multiple nucleation.

Subsequent anhydritization was superimposed on depositional gypsum facies. It was the result of interactions between concentrated seawater, meteoric runoff and highly saline, residual pore fluids. And so two different anhydrite styles overprinted the original Badenian sulphates (Kasprzyk 2003): (1) synsedimentary anhydritisation of gypsum deposits driven by highly concentrated brines and elevated temperatures (mostly in the lower member), (2) successive phases of anhydrite formation (syndepositional de novo growth, early diagenetic to late diagenetic replacement of former gypsum) during progressive burial (mostly took place in the upper member). In the basin the anhydrite started to grow in a fine-grained bottom host under very early, probably synsedimentary conditions and formed a displacive micronodular laminated lithofacies. Likewise the onset of anhydritisation was very early in clastic gypsum of the strandline. It formed abundant displacive anhydrite with intense synsedimentary deformation structures related to nodule growth. This environment was subject to early exposure, high temperatures and high salinities. Later, a deeper burial anhydrite phase spread through the coarsely crystalline gypsum of the shelf. This created replacive nodular anhydrite in sediment hosts so that primary crystal textures are well preserved.

Porosity loss in these units is essentially complete by burial depths of 500 m. After this, these anhydrous units, like halite at even shallower depths, are essentially impervious and act as aquitards and pressure seals to any crossflow of pore water, hydrocarbons or metals. Evaporite salt beds below 500–1,000 m typically respond to further burial by flowage and edge-focused dissolution.

In a variation on the same theme of burial alteration of gypsum (bioturbated bedded) are meganodules of secondary gypsum (after anhydrite) that former in buried Miocene gypsum in the Ebro Basin, Spain (OrtÍ et al. 2012). These outcropping and sub-cropping meganodules and masses are mostly made of crystalline and alabastrine gypsum, which has replaced the original burial anhydrite (relic anhydite is still present in the meganodules, but not in the host gypsum beds). The isotopic composition (11.1–17.4‰ for $\delta^{18}O_{SMOW}$; 10.7–15.3‰ for $\delta^{34}S_{CDT}$) of secondary gypsum in this meganodular facies indicates that the precursor anhydrite derived from in situ replacement of an initial primary gypsum. Anhydritisation was a result of ascending circulation of deep regional fluid flows through the Miocene gypsum units near the basin margins (Fig. 1.56) as primary gypsum was partly altered to anhydrite within burial conditions from shallow to moderate depths (from some metres to a few hundred metres?). At such depths, the temperatures and solute contents of these regional flows exceeded those of the ground water today. These palaeoflows became anhydritizing solutions and partly altered the subsiding gypsum units before they became totally transformed by deep burial anhydritization. The characteristics of the meganodular anhydritization (for example, size and geometry of the meganodules and irregular masses, spatial arrangement, relations with the associated lithologies and the depositional cycles, presence of an enterolithic vein complex and palaeogeographic

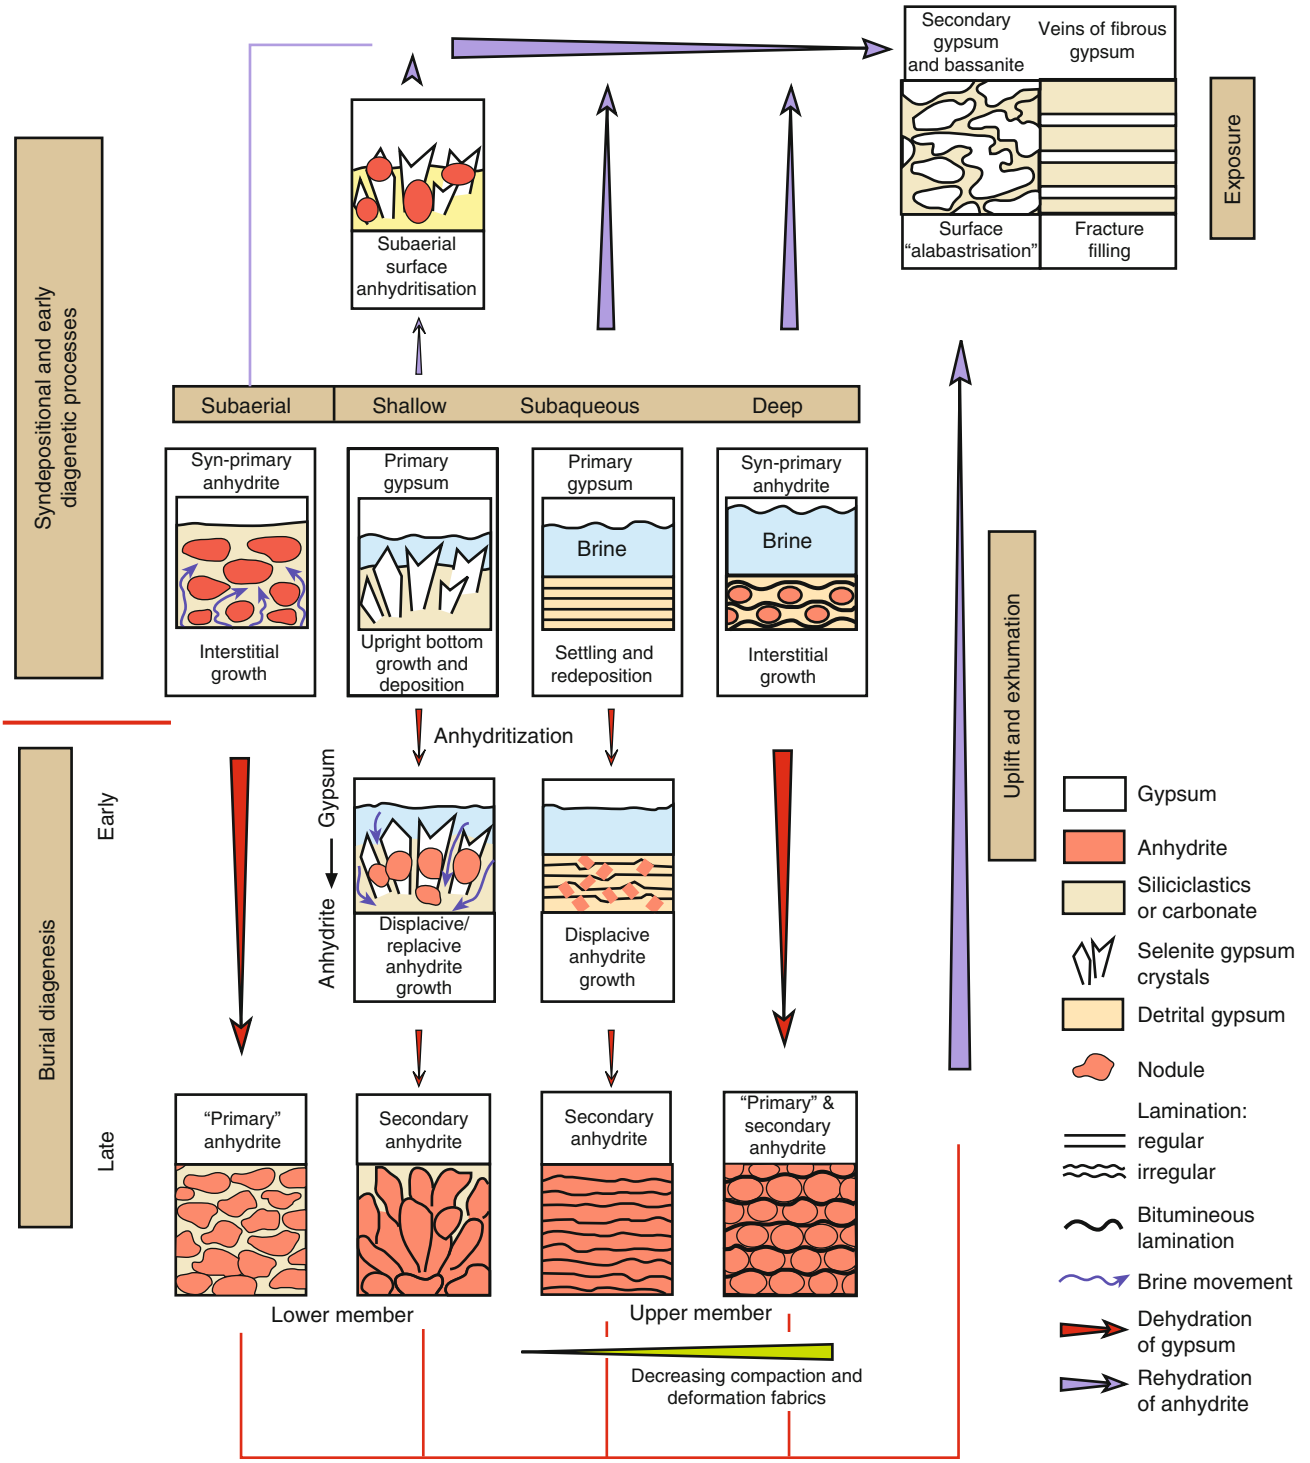

Fig. 1.55 Sulphate textural evolution is clearly seen in Middle Miocene sulphates in the Carpathians (After Kasprzyk 2003). Platform sulphates were deposited in subaerial (sabkha) and shallow-marine environments (shoreline and inner platform-lagoon), mainly as autochthonous coarse-grained aligned (selenitic) gypsum. This platform sediment was reworked and redistributed into deeper waters (outer platform-lagoon, slope and the proximal basin floor system) to form resedimented facies composed mostly of allochthonous clastic gypsum and minor anhydrite. Burial and the conversion to anhydrite subjected these sulphates (mostly gypsum) to two different hydrological styles: (1) synsedimentary anhydritisation of gypsum deposits by highly concentrated brines or elevated temperatures in surficial to shallow-burial environments (mostly in the lower member of these Badenian sulphates), and (2) successive phases of anhydrite formation (syndepositional de novo growth, early diagenetic to late diagenetic replacement of former gypsum), which occurred during progressive burial (mostly in the upper member). Finally, the succession was uplifted and re-entered the active meteoric realm where various fibrous and alabastrine textures formed

distribution) are different to sabkha anhydrites or sparry anhydrites formed under or under deeper burial conditions. The most distinctive feature is the large size of the meganodules (up to 5 m across) and the fact that nodules are devoid of internal textural zoning. In combination, both features suggest anhydrite growth was slow and continuous, which is consistent with the circulation of deep regional aquifers acting as anhydritizing flows. The process affected the subsiding, marginal gypsum units, prior to their complete lithification (Fig. 1.56).

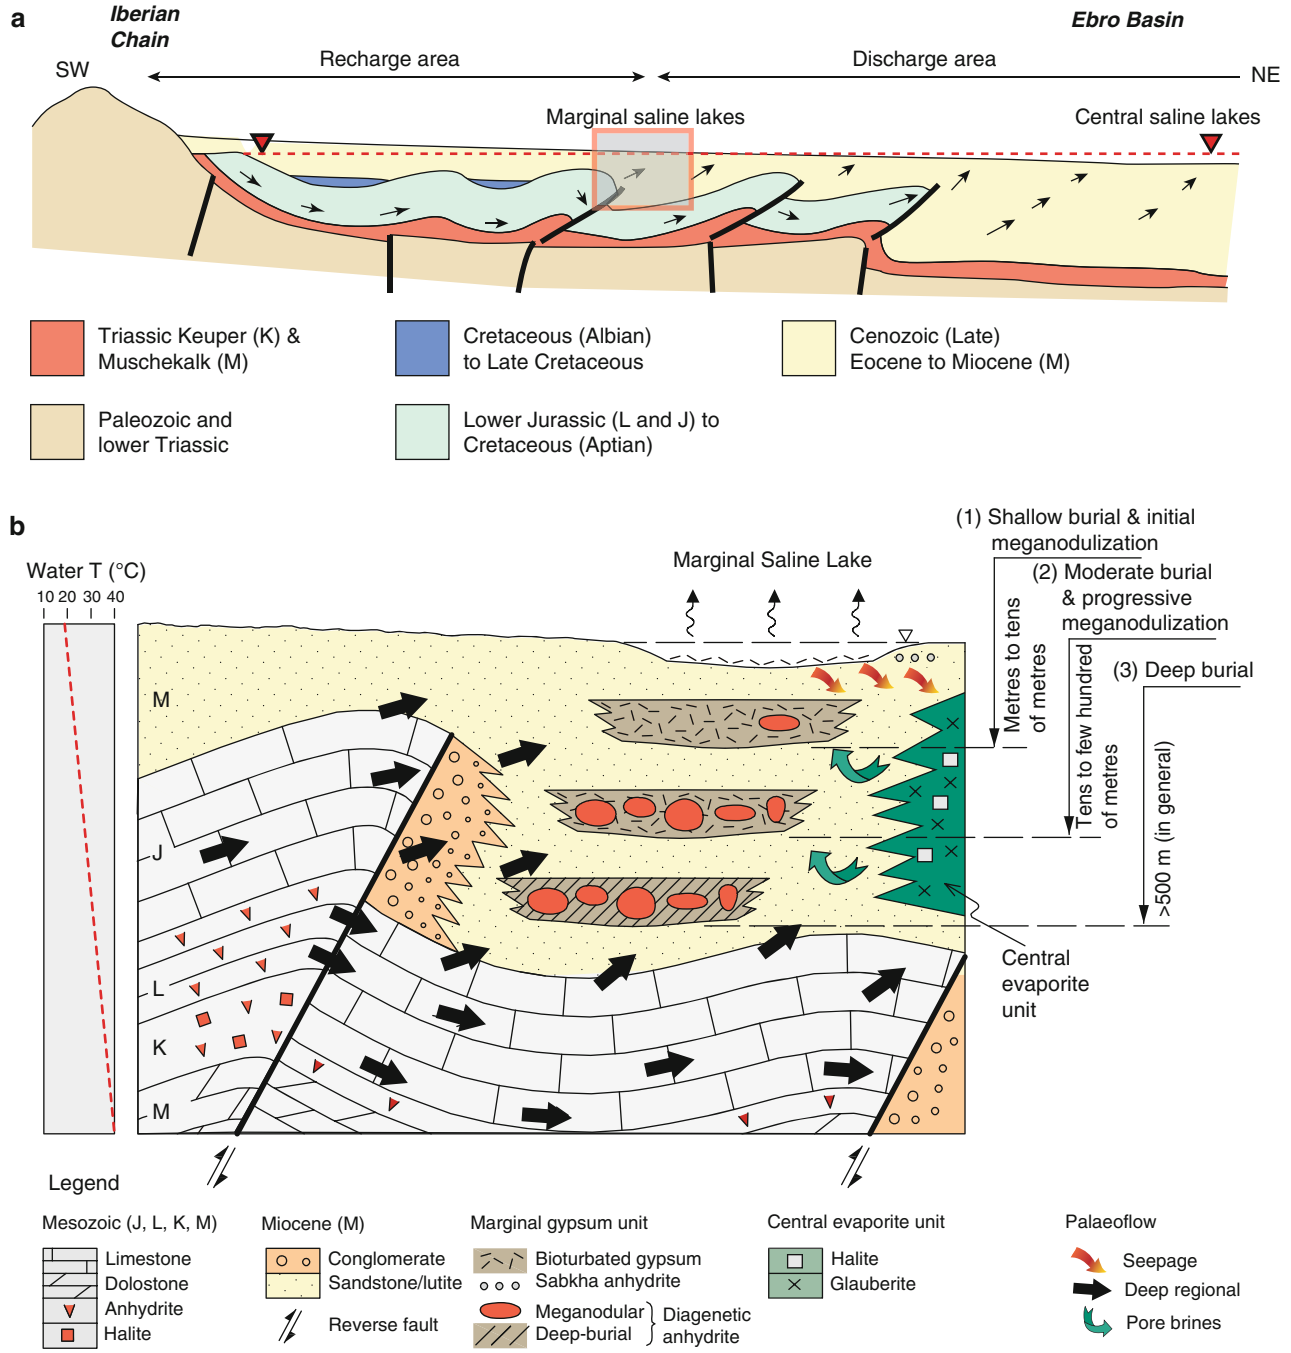

Fig. 1.56 Meganodular anhydritization in the marginal gypsum units of the Ebro Basin during the Miocene (After Ortí et al. 2012). (**a**) Geological cross-section normal to the basin margin at the end of the Miocene (before partial erosion of the basin-fill), Illustrating the palaeohydrological discharge and the downslope transition from marginal saline lakes to perennial saline lakes in the basin sump. (**b**) The process (growth of displacive/replacive meganodules and irregular masses of anhydrite) occurs progressively during shallow to moderate burial (Stages 1 and 2). Under deeper burial conditions the preserved primary gypsum hosting the anhydritized portions is also converted to anhydrite (Stage 3). The anticline structures roughly correspond to those represented in *shaded box* in Fig. 1.56a

One of the most impressive examples of the possible retention of the primary gypsum mineralogy comes from the Lower Cretaceous Ferry Lake Anhydrite in the Mississippi Interior Salt Basin, USA (Amadi et al. 2012). The gypsum remains as cores of anhydrite nodules at depths of more than 3,900 m or 13,000 ft. The gypsum retention is perhaps related no fluid access due to early and ongoing encasement in evaporites, as argued by Amadi et al. (2012). In my mind, if this is the mechanism, we should see similar widespread gypsum retention in the cores of other salt-sealed anhydite nodules and we do not. Another possibility is that anhydrite rehydration has occurred in the core trays in storage, as the documented examples are from decades old wells. Another perhaps more likely possibility is that the gypsum is the result of thermal sulphate reduction waters and the subsequent mesogenetic dehydration of the gypsum (that is, the gypsum formed as a type of burial salt and is not primary).

Burial Salts: Nodules and Stylolites

Subsurface sulphate-rich waters derived from deeply buried dissolving evaporites can precipitate anhydrite nodules in adjacent nonevaporitic strata. Such nodules are a form of burial salt fed by saline compactional and thermobaric waters and are a distinct style from anhydrites formed as part of the burial related conversion of gypsum to anhydrite discussed earlier. Superficially these nodules can resemble those of a sabkha anhydrite, but there are a number of distinguishing features (Machel 1993, 2013; Machel and Burton 1991; Warren 1991). Most obvious is that the burial nodules precipitate in porosity zones that are not depositionally defined. They can occur within or adjacent to faults, or within open marine shelf carbonates, which are not intertidal/supratidal units. They often occur within, or juxtaposed to, dark, bituminous argillaceous seams and pockets, or within zones of anastomose bituminous veinlets and carbonaceous haloes, all of which are the result of pressure solution and stylolitisation. They typically replace the host rock and can crosscut stylolite boundaries in the carbonate matrix. Thus, they enclose material generated during burial diagenesis, such as authigenic pyrite and saddle dolomite, and show little evidence of mechanical compaction. They are often associated with coarsely crystalline, late-stage poikilotopic and pore-filling anhydrite spar cements.

In a study of burial anhydrites in the Devonian Nisku carbonate, Canada, Machel (2013) concluded that most anhydrites (more than 90 %) are replacive and that they are syn or postdate dolomitisation. The six textural types he defines did not form at the same time, some were early burial, some later and some formed during or after oil migration in the Late Cretaceous to Early Tertiary.

Stylolites hosted in a limestone or dolomite matrix are widely recognised pressure solution features thought to indicate burial depths in excess of 0.5–1.0 km (Bathurst 1980). Stylolites in evaporite beds are not common and may not necessarily form by such deep burial. Some have argued that anhydrite and halite cannot exist at the pressure necessary to form stylolites without pervasive recrystallisation. But stylolite horizons do occur in the Gorleben Zechstein salt dome in the Bänderanhydrit located near the top of the Zechstein Hauptanhydrit (Bäuerle et al. 2000). Intra-evaporite stylolites were also noted by Peryt et al. (1993) in the Werra Anhydrit (Zechstein 1) of western Poland and by El Tabakh et al. (1998a) in the Basal Anhydrite of the Cretaceous Maha Sarakham of Thailand. The latter can be related to differential salt solution during burial flushing (Fig. 7.45).

Bäuerle et al. (2000) tied the pressure-solution seams in the Hauptanhydrit to the presence of thin magnesite-clay interlayers and distinguished five principal stylolite morphologies (Fig. 1.57a). The orientation of the sutured seams is generally bedding-parallel with the stylolite axes vertical to the bedding surface. Some seams have been deformed by salt flow and the anhydrite beds with bedding parallel stylolites are now steeply inclined to the horizontal. There is no relation between stylolite formation and pressures created by the modern salt dome crest. Solution rates of up to 26 % were calculated by measuring maximum stylolite amplitudes in core.

The bedding-parallel occurrence of the Hauptanhydrit stylolites, in combination with the observation that the stylolite seams are crosscut by anhydrite pseudomorphs after gypsum, argues that the stylolites formed before the dehydration of gypsum to anhydrite was complete. The lower parts of the Hauptanhydrit were excluded from the stylolitisation process as they had already been converted to anhydrite by ascending compaction fluids of the underlying Zechstein 2 Salt (Fig. 1.57b; Bäurle et al. 2000). Porosity and permeability loss that is an integral part of the conversion process prevents the formation of stylolites once any interval had converted to anhydrite. The transition depth in the Zechstein was around 125 m. Pervasive dehydration of gypsum to anhydrite in the Hauptanhydrit was probably complete before the end of Zechstein sedimentation. The arguments of Bäurle et al. (2000) imply that the formation of stylolites occurs in gypsum, not anhydrite, and is a relatively shallow burial process (≈100–150 m).

Evaporites as Uplift Indicators (Tertiary Evaporites)

At the other extreme of the burial cycle is the conversion of exhumed and uplifted evaporite beds entering the telogenetic realm. Most common is the conversion of anhydrite into diagenetically regenerated gypsum (Fig. 1.58). Uplifted halite beds first undergo differential dissolution to leave behind layers of residual nodular anhydrite, which are then dissolved by ongoing meteoric flushing. Two commonplace

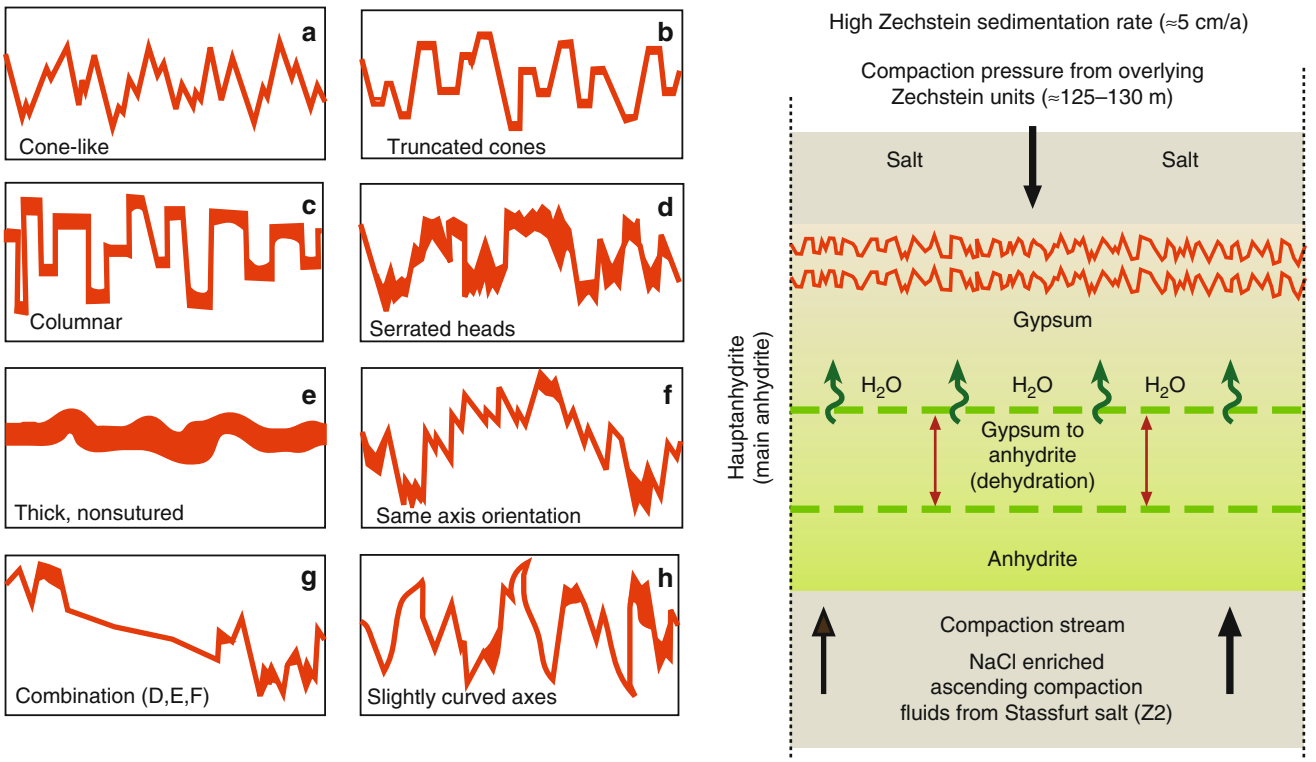

Fig. 1.57 Stylolites in anhydrite beds. (**a**) Types of stylolite seams or sutures hosted in the Hauptanhydrit (Zechstein) of the Gorleben salt dome, Germany. (**b**) Model for the development of stylolites in the upper part of the Hauptanhydrit during deposition of the younger Zechstein beds. Stylolitisation is restricted to a gypsum matrix (pre-anhydritisation) and occurred less than 150 m below the sedimentation surface (After Bäuerle et al. 2000)

gypsum fabrics are the result of exhumation: coarse porphyroblastic gypsum and fine-grained alabastrine gypsum (Holliday 1970; Warren et al. 1990; Arzaghi et al. 2012; OrtÍ et al. 2012). Porphyroblastic gypsum rosettes, especially in the lower parts of the telogenetic realm, can retain dispersed relics of the precursor anhydrite in the core of the nodule. The radiate crystal texture means it is sometimes described as gypsum "daisies" or "daisywheel gypsum." Crystal forms are coarse, up to two cm across, and can be euhedral or anhedral, thin and acicular or thick and stubby (Fig. 1.58). Porphyroblasts typically aggregate into cm-scale layers, rosettes or blebs with acicular gypsum rinds.

Daisy gypsum is a response to rehydration under the relatively homogenous conditions of uplift hydrology in a massive nodular anhydrite unit entering the lowermost parts of the telogenetic zone. Rates of fluid crossflow are low, so chemical dissolution is slow and dissolution fronts tend to be focused about the bed contacts between aquifers and the anhydrite (gypsum is not stable at such depths). As an anhydrite bed is uplifted into the telogenetic zone it once again comes into contact with low salinity, low temperature waters. In many uplift situations there is also an artesian flow system established so that both karstification and rehydration to gypsum tends to at first be focused on the edge of the bed where satinspar gypsum tends to dominate. As rehydration to gypsum becomes more pervasive within a bed, it tends to penetrate first along the impurity-rich more permeable edges of anhydrite nodules. Sparry aligned gypsum crystals grow toward the centre of the nodules to form daisy-wheel gypsum (Warren et al. 1990). As the rehydration proceeds through the bed, some of the gypsum then dissolves to give greater access to undersaturated waters to the gypsum bed to create caverns. Because of the destructive nature of porphyroblastic overprinting, interpreting original depositional environment is next to impossible in nearsurface and outcropping $CaSO_4$ units, they are composed almost entirely of diagenetically regenerated gypsum.

Alabaster is the other form of telogenetic gypsum and is created where anhydrite pervasively rewaters to gypsum in the zone of active phreatic flow. Individual gypsum grains are typically less than 50 μm, with grain boundaries that range from poorly defined to equidimensional granuloblastic. The change from porphyroblastic to alabastrine may be depth-related (Warren et al. 1990). Porphyroblastic gypsum defines the re-emergence of nodular anhydrite from the stagnant phreatic into the deep portion of the zone of active phreatic flow. Alabastrine gypsum forms in the zone of more diffuse active phreatic flow. This re-emergence is also associated with the formation of gypsum karst and the formation of evaporite-dissolution breccias (Chap. 7).

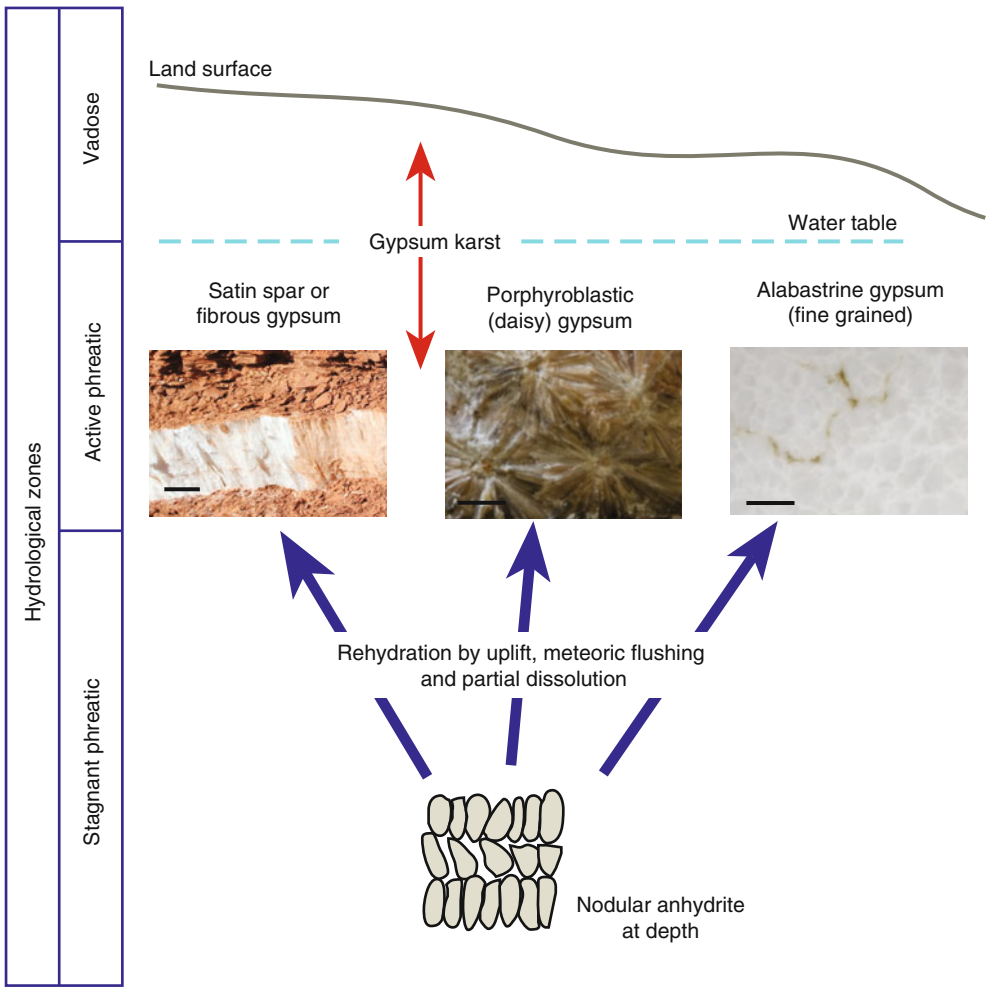

Fig. 1.58 Rehydration fabrics in calcium sulphate from uplift, meteoric flushing and dissolution. Scale bar is 1 cm long. These textures are the tertiary evaporites of Fig. 1.9

Excess amounts of trace elements, especially strontium and boron, are released from some bedded anhydrites as they reconvert to gypsum. The released elements may precipitate in the regenerating alabastrine gypsum as celestite or boron-bearing minerals, such as proberite, ulexite, tyreskite and priceite.

Fibrous Gypsum and Halite (Satinspar)

Veins and fractures filled with fibrous satinspar $CaSO_4$ (typically gypsum) or halite are widespread in the mudstones and shales adjacent to bedded evaporite units undergoing dissolution. Fractures may be subhorizontal and lie roughly parallel to the contact with the bedded evaporite unit or may form as conjugates. The fractures form and fill with fibrous cements in response to stresses set up in the bed by the formation of nearby stratiform cavities (Fig. 1.59). The fracture filling is usually zoned and made up of two or more parallel layers of either fibrous $CaSO_4$ or fibrous halite. Fracture-fill crystals are oriented with their long axes perpendicular to the fracture walls. Coarse calcite crystals can occasionally fill the centre of the fracture. Most fracture fills are monomineralic and gypsum is the dominant mineral in most nearsurface fracture systems. Internal fracture zonation is pronounced and reflects episodic and ongoing opening and filling of the fractures. Some fibrous fills are sigmoidally deformed showing fracture fill was ongoing as adjacent blocks slid and rotated in response to changes in nearby dissolution cavities (El Tabakh et al. 1998b).

Fibrous halite and satinspar formation are linked to fracture and cavity formation in active hydrological systems. Fractures filled with satinspar are linked to uplift and either the generation of open fractures induced by subsidence associated with salt dissolution and uplift (Fig. 1.60; Gustavson et al. 1994) or to hydraulic fracturing associated with the conversion of anhydrite to gypsum (Cosgrove 2001; Philipp 2008). Thus fracture-filling satin-spar may be a passive process in open fractures or a more active process with fractures forced open by overpressured $CaSO_4$ -saturated artesian waters.

Superimposed on these processes may be the force of crystallisation of gypsum. Shearman et al. (1972) suggested that displacive satinspar veining is a feature of anhydrite

hydration, which may have been due to hydrofracturing by overpressured confined groundwater as exhumed anhydrite reconverted to gypsum. Shearman et al. (1972) pointed out that if all the calcium sulphate is retained within the system, the hydration of anhydrite to gypsum should result in an increase in volume of 63 %. They noted that in many secondary gypsum rocks, former anhydrite is replaced on a volume-for-volume basis, and the additional volume of gypsum appears as fibrous or satinspar veins that cut the associated rock. Gypsum grew in the water-filled fractures, whenever the overburden was supported by pressurised water.

Fig. 1.59 Meshwork of satinspar gypsum veins created by dissolution of an adjacent anhydrite bed in the Permian of eastern Saudi Arabia (car key for scale)

Progressive sediment fracturing (hydrofracturing?) is thought to be a response to unroofing. Unloading and release of overburden weight drives the formation of near surface fractures parallel to the earth's surface. Fibrous halite and satinspar $CaSO_4$ are commonly associated with, but not exclusive to, zones of exhuming evaporites (Fig. 1.58). It is not known if satinspar-filled fractures can also form at greater depths (1000s of metres) in mesogenetic realms associated with overpressuring and compactional or thermobaric waters.

Cosgrove (2001) and Philipp (2008) describe networks of satinspar-filled hydraulic fractures preserved only in the exhumed evaporite horizons of the Mercia Mudstones of the Bristol Channel Basin of southwest England. Like Shearman et al. (op. cit.), they conclude satinspar preservation relates to

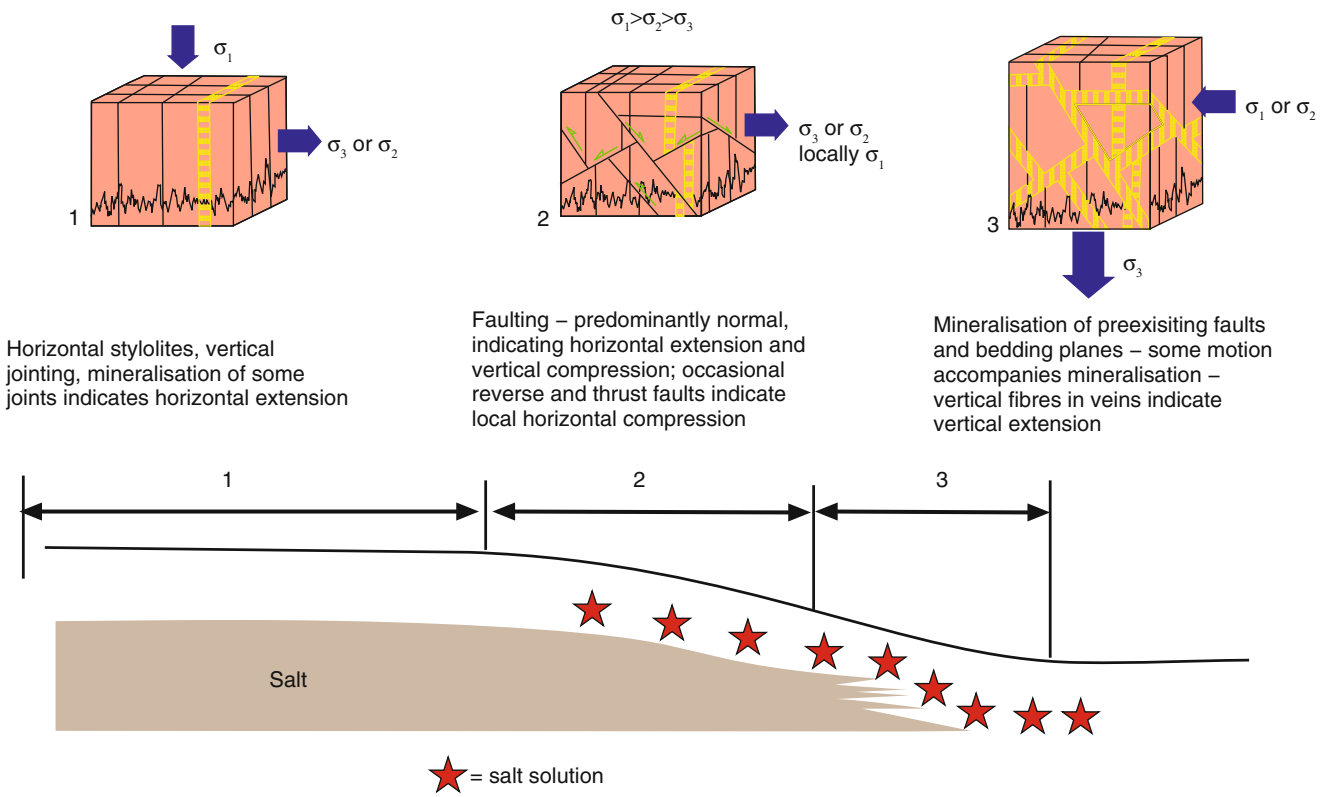

Fig. 1.60 Conceptual model of deformation above salt dissolution zone showing structural sequence and proposed location relative to dissolution front. Stage 1 occurs prior to salt dissolution and is characterised by jointing resulting from normal burial. Late stage 1 and stage 2 occur as salt dissolution begins. Early stage 2 is characterised by a few vertical gypsum veins with horizontal fibres. Later stage 2 is characterised by normal faults and uncommon reverse faults. In stage 2 layer parallel extension results from the onset of dissolution and subsidence. Stage 3 is characterised by gypsum veining of bedding planes and faults. In stage 3 vertical extension results from widespread dissolution and collapse of underlying evaporites (After Gustavson et al. 1994)

the volume changes associated with the hydration of anhydrite to gypsum, which occurred as the rock mass was exhumed and the relatively low temperature and pressure conditions necessary for the formation of gypsum were encountered (e.g., Jowett et al. 1993; Philipp 2008). Hydration in the Mercia Mudstones occurred during the tectonic inversion of the basin as basin sediments experienced tectonic compression during Tertiary exhumation. This caused an increase in fluid pressure and facilitated the formation of hydraulic fractures that then fill with satinspar. Cosgrove goes on to argue that hydraulic fractures also formed in the muddy evaporite-free horizons. But the fractures reclosed and healed as soon as the fluids had passed through them and pressure had dropped as the appropriate brine required for their preservation as satinspar veins was not present within the nonevaporite sections.

The mechanism of creating satinspar filled fractures, as documented by Gustavson et al. (1994), is a much more passive process. They note that most satinspar veins occur in highly fractured or brecciated strata that overlie or are associated with exhumed bedded halite, anhydrite and gypsum. There are often saline springs in the vicinity of a satinspar occurrence indicating active halite dissolution. In this scenario satinspar is a response to several hydrologically driven processes (Fig. 1.60). Cavernous porosity is created as halite is dissolved by crossflows of low salinity active-phreatic waters down to depths of 200–750 m. Extensional fractures form in the strata above these dissolution zones and anhydrite is rehydrated to gypsum either via a dissolution-precipitation interface or though a bassanite intermediary (Holliday 1970). The deeply circulated groundwater is now saturated with respect to gypsum and any further anhydrite hydration results in supersaturation. Excess $CaSO_4$ now carried in solution by groundwaters flowing out of the dissolution zones precipitates gypsum in open high permeability fractures created during overburden collapse.

It may well be that the satinspar and the associated fracturing are a response to both active and passive modes of formation. Perhaps active hydrofracturing, as envisaged by Shearman et al. (1972), is more significant in driving satinspar fracture fill at greater depths where the dissolving evaporites and adjacent beds are still relatively tight and are first entering the telogenetic realm (via the zone of stagnant phreatic circulation). As exhumation and dissolution continues the fracture and fill process evolves into a more passive set of collapse induced features. This occurs once beds are shallower and have become more permeable. They have moved into the zone of active phreatic circulation and are closer to the landsurface (see Chap. 7 for more hydrological detail on the effects of telogenetic alteration).

Isotopically, the effects of dissolution and brine recycling in fracture-filling fibrous gypsum cements of various ages in a formations burial evolution can define the sequential evolution of the unit (Fig. 1.61; Moragas et al. 2013). The upper Burdigalian Vilobí Gypsum Unit, located in the Vallès Penedès half-graben (NE Spain), consists of a 60-m thick succession of laminated-to-banded secondary and primary gypsum variably affected by Neogene extension in the western part of Mediterranean Sea. Tertiary extensional events are recorded in the evaporitic unit as six fracture sets (faults

(**b**) $\delta^{34}S$ versus $^{87}Sr/^{86}Sr$ cross-plot for host gypsum, sigmoidal fibres and macrocrystalline cement samples. *Shaded areas* indicate plot fields for Tertiary marine evaporites (After Moragas et al. 2013)

and joints), which can be linked with basin-scale deformation stages utilising fracture cement fills. All fractures are totally or partially infilled by four types of gypsum precipitates showing diverse textures and microstructures. Combined structural, petrological and isotopic study of the unit establishes a chronology of fracture formation and infilling, from oldest to youngest as: (i) S1 and S2 normal faults sets with formation and precipitation of sigmoidal gypsum fibres; (ii) S3 joint sets with perpendicular fibres; (iii) S4 inverse fault sets, infilled by oblique gypsum fibres and associated with deformation of the previous fillings; and (iv) S5 and S6 joint sets tied to later dissolution processes and infilled by macrocrystalline gypsum cements. The fractures provided ongoing pathways for focused fluid circulation within the Vilobí Unit. The oxygen, sulphur and strontium isotope compositions of the original host rock and the various precipitates in the fractures imply ongoing convective recycling processes across the host-sulphates to the fracture infillings, as recorded by a general enrichment trend toward heavier S–O isotopes, from the oldest precipitates (sigmoidal fibres) to the youngest (macrocrystalline cements) and to the preservation of the strontium signals in the various infillings (Fig. 1.61).

Anhydrite Rehydration at the Microscale

At the microscale a range of related $CaSO_4$ textures indicate a common set of nearsurface diagenetic (telogenetic) mechanisms and processes, which through multiple dissolution and reprecipitation cycles create ever increasing proportions of purer gypsum and every decreasing amounts of residual anhydrite. Anhydrite at outcrop, where it constitutes more than 5–10 % of the calcium sulphate in a sample, is typically present as scattered, variably-etched, oriented to non-oriented prismatic crystals and laths that are surrounded by more coarsely crystalline poikiloblastic gypsum (Fig. 1.62a–c). No uplifted outcrop is ever composed of pure anhydrite and typically calcium sulphate outcrops with anhydrite present are dominated by gypsum as either finely crystalline alabaster or coarsely crystalline (selenitic gypsum).

Coarsely crystalline (selenitic) gypsum: Outcrop samples with the higher proportions of relic anhydrite typically have anhydrite present as felted aligned to less-aligned masses of lathes encased in coarsely crystalline gypsum and typically adjacent to other coarser gypsum crystals that contain few to minor anhydrite relics (Fig. 1.62a–c). In the literature these larger gypsum crystals are termed porphyroblasts and the texture is typically described as poikiloblastic (Holliday 1970; Artieda 2013). This coarsely crystalline texture, dominated by transparent crystals, is also described as selenitic. Coarsely -crystalline gypsum tends to show open porosity between crystals (intercrystal-line polyhedral porosity; Fig. 1.62a, b). It typically has relatively inclusion-free gypsum pore linings adjacent to the open pores implying a possible mesoscale replacement front is involved in its formation. That is, porosity is created by dissolution of its precursor (gypsum + anhydrite) is followed by precipitation of gypsum in the resulting pore space. This gives the appearance of a clear gypsum rim to some crystals but it is actually a dissolution front moving through the crystal and precipitating pure gypsum (Fig. 1.62c).

Alabastrine gypsum: Alabastrine gypsum tends to contain lesser amounts of anhydrite in gypsum crystal than selenitic gypsum, typically in the range 0–2 %. Gypsum textures tend toward equigranular and interlocking, with growth-sutured crystal edges (Fig. 1.62d). This texture is often described in the literature as granoblastic (Holliday 1970). Granoblastic textures indicate grain boundary equilibration in the solid state. This texture is also seen in metamorphic rocks, such as when limestone converts to marble. It consists of an isotropic aggregate of polygonal grains of more or less similar size, perhaps within an order of magnitude. Samples of alabastrine equigranular gypsum tend to lack significant amounts of polyhedral porosity. Rather the gypsum crystals form an interlocking meshwork, sometimes with local preferred directions of crystal growth elongation. Compared to relic anhydrite crystals in the coarser (selenitic) gypsum the anhydrite residuals in equigranular granoblastic gypsum tend to show more evidence of etching (Fig. 1.62e, f).

Satin-spar gypsum: This style of gypsum is made up of growth-aligned, fibrous elongate crystals that infill veins or fractures (Fig. 1.62g, h). Most satin spar samples lack significant amounts of inter crystalline porosity, although some veins do show geopetal accumulations of anhydrite or dolomite on the lower sides of the fractures. Such geopetalled fractures were likely created via fractional dissolution of precursor $CaSO_4$, leaving behind a residuum of less soluble materials (anhydrite, dolomite).

The relative timing of porphyroblastic versus alabastrine gyp-sum during telogenesis is difficult to determine. A review of the literature suggests porphyroblastic gypsum tends to precede alabastrine gypsum in the uplift realm (when associated with anhydrite telogenesis) and that satin spar forms in fractures created by the dissolution and volume loss associated with meteoric flushing and uplift of a former anhydrite bed (Holliday 1970; Gustavson et al. 1994; Warren et al. 1990). But alabaster and selenitic textures can be intimately intermixed at outcrop and differences in gypsum style may be more related to the degree of gypsum supersaturation during anhydrite dissolution. In this scenario porphyroblastic gypsum is favoured by sluggish water crossflows, slower crystal growth rates and less saturated pore fluids (with respect to gypsum), while granoblastic gypsum is favour by supersaturation, multiple crystallisation nuclei, faster crystal growth rates and Ostwald crystal ripening.

The growth of granoblastic and porphyroblastic textures from an anhydrite precursor, which in turn was often formed

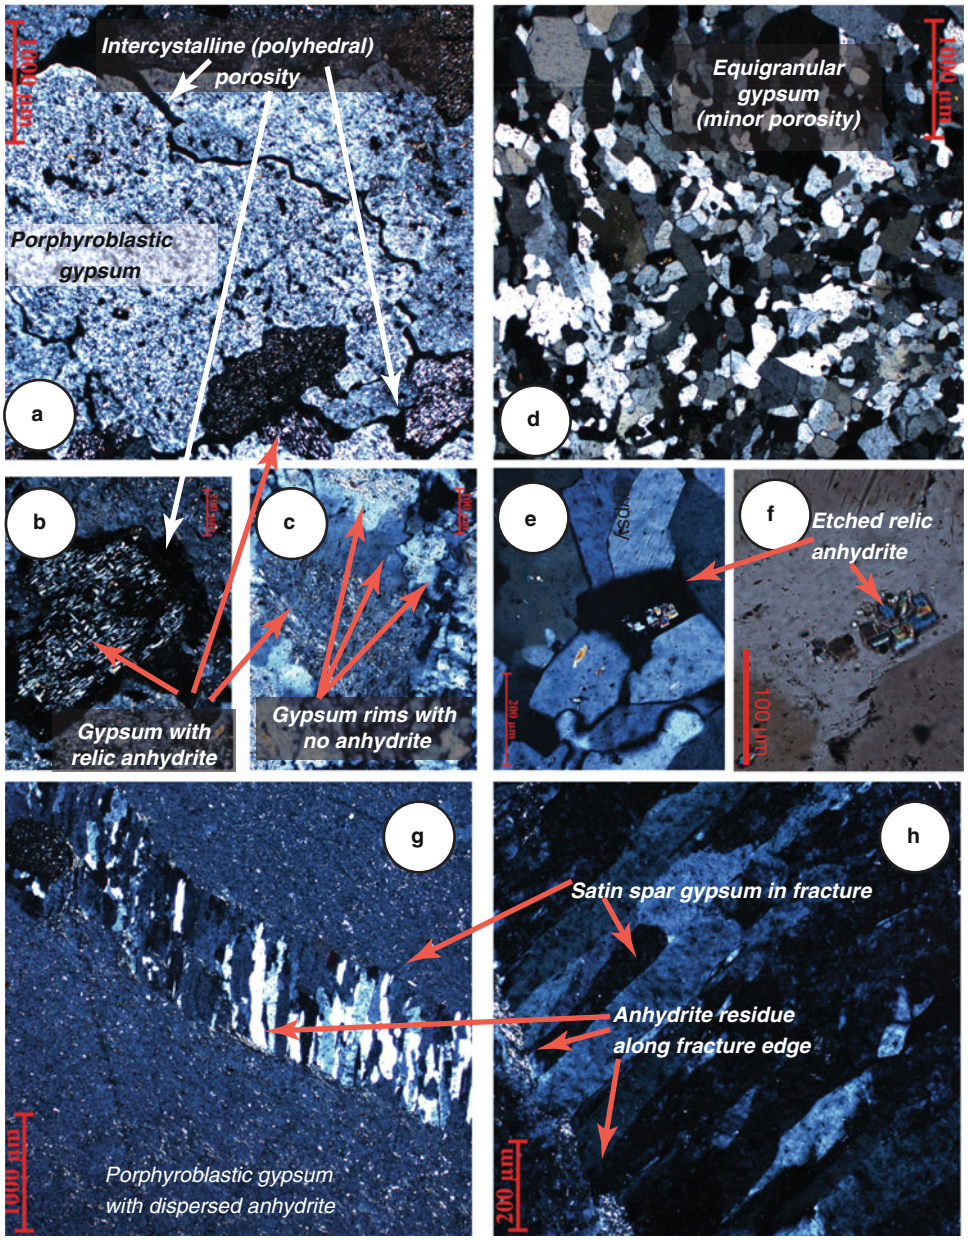

Fig. 1.62 Gypsification microtextures, all photomicrographs are taken in polarised light. (**a**) Porphyroblastic coarsely crystalline (selenitic gypsum with intercrystalline porosity (partially polyhedral). (**b**) Gypsum porphyroblast (in extinction) showing a felted anhydrite relic which it encloses. (**c**) Gypsum porphyroblast with relic gypsum adjacent to newly precipitated rinds with polyhedral contact between the rinds. (**d**) Equigranular (granoblastic) gypsum. (**e**) Equigranular (granoblastic) gypsum enclosing etched anhydrite. (**f**) Close up of etched anhydrite in (e). (**g**) Satin-spar gypsum infilling vein/fracture in porphyroblastic gypsum, with anhydrite residue along lower vein margin. (**h**) Close-up of vein margin (All samples from Laurent Gindre and come from Namibian anhydrite/gypsum residual/caps to the Cretaceous Loeme Fm., see Gindre-Chanu et al. 2014 for detail)

by fractionated removal of halite (see Chap. 7), means that all the textures seen at the micro and mesoscale in gypsum outcrops are indicative of telogenetic processes. There is little or no possibility of these uplifted-related reprecipitation and recrystallisation $CaSO_4$ textures preserving primary depositional relics.

Saline Clay Authigenesis

So far we have focused on the formation and alteration of the various evaporite salts, but the same evolving saline hydrologies can also drive the formation and alteration of clays (Table 1.6). Many authigenic clay minerals formed in hypersaline settings are enriched in magnesium (Fisher 1988), but authigenic clays do not make up the greater volumes of clay in modern or ancient salt lakes. Most of the clays in salt lakes and playas are detrital and reflect compositions of older argillaceous formations in the palaeodrainage areas. Illite, kaolinite, chlorite, dioctahedral smectite and a number of mixed-layers clays are commonplace detrital clay minerals in saline formations (Calvo et al. 1999). Widespread flocculation of clays is an effective sedimenter of suspended clay wherever freshwater runoff and streams flood an area of standing saline water. Thus the composition of initial clay sediments in a playa largely reflects that of the minerals carried as suspended load into the lacustrine depression.

The magnitude of detrital clastic input is thought to be a significant factor in the relative volume of authigenic clay. Regions with rapid deposition of clays, tied to high detrital inputs, tend to be areas where the authigenic clay component is swamped by the high detrital input. Clay authigenesis in evaporitic basins is favoured in marginal playa areas where rates of detrital clay input are low (Fig. 1.63). This encompasses interdunal depressions, peripheral sandflats and muddy carbonate flats. In these low sedimentation areas the transformation of precursor clays is more effective, driven by episode surface inflow and groundwater discharge (Calvo et al. 1999). Highly reactive nearsurface and surface conditions are favoured by inherently large variations in pore water salinity, pH and pCO_2 levels.

Clay authigenesis in many saline depressions is driven by pedogenesis, especially in the marginal areas where sedimentation rates are low and subaerial exposure dominates at the sedimentation surface. Below the surface episodic wet-dry cycles means neoformed clays are the byproduct of complex reactions between Na and Mg-rich interstitial brines and detrital silicates. Pedogenic processes account for the formation of widespread lake margin palygorskite and sepiolite, typically in association with the creation of calcretes, dolocretes and silcretes. In cases where palygorskite dominates the soil profile, they are sometimes described as palycretes. Zeolites can also form from saline groundwaters in saline lake-margin pedogenic settings (Fig. 12.71). Artesian and phreatic groundwater discharge through springs into the lake margin areas also plays a significant role in the formation of

Table 1.6 Main authigenic clay minerals occurring in continental evaporitic environments

	Structural formula	Mg/Si	Al/Si
Saponite	$(Ca, Na)_{0.3}(Mg{\cdot}Fe)_3(Si,Al)_4O_{10}(OH)_2(OH)_2{\cdot}4H_2O$	0.76–0.87	0.07–0.18
Kerolite	$Mg_3Si_4O_{10}(OH)_2{\cdot}H_2O$	0.75	0.0
Stevensite	$Na_{0.15}Mg_3Si_4O_{10}(OH)_4$	0.75	0.0
Hectorite	$Na_{0.3}(Mg,Li)_3Si_4O_{10}(F{\cdot}OH)_2$	0.67	0.0
Sepiolite	$Mg_4Si_6O_{15}(OH)_2{\cdot}6H_2O$	0.67	0.0
Palygorskite	$(Mg{\cdot}Al)_2Si_4O_{10}(OH){\cdot}4H_2O$	0.17–0.49	0.02–0.31

After Calvo et al. (1999)

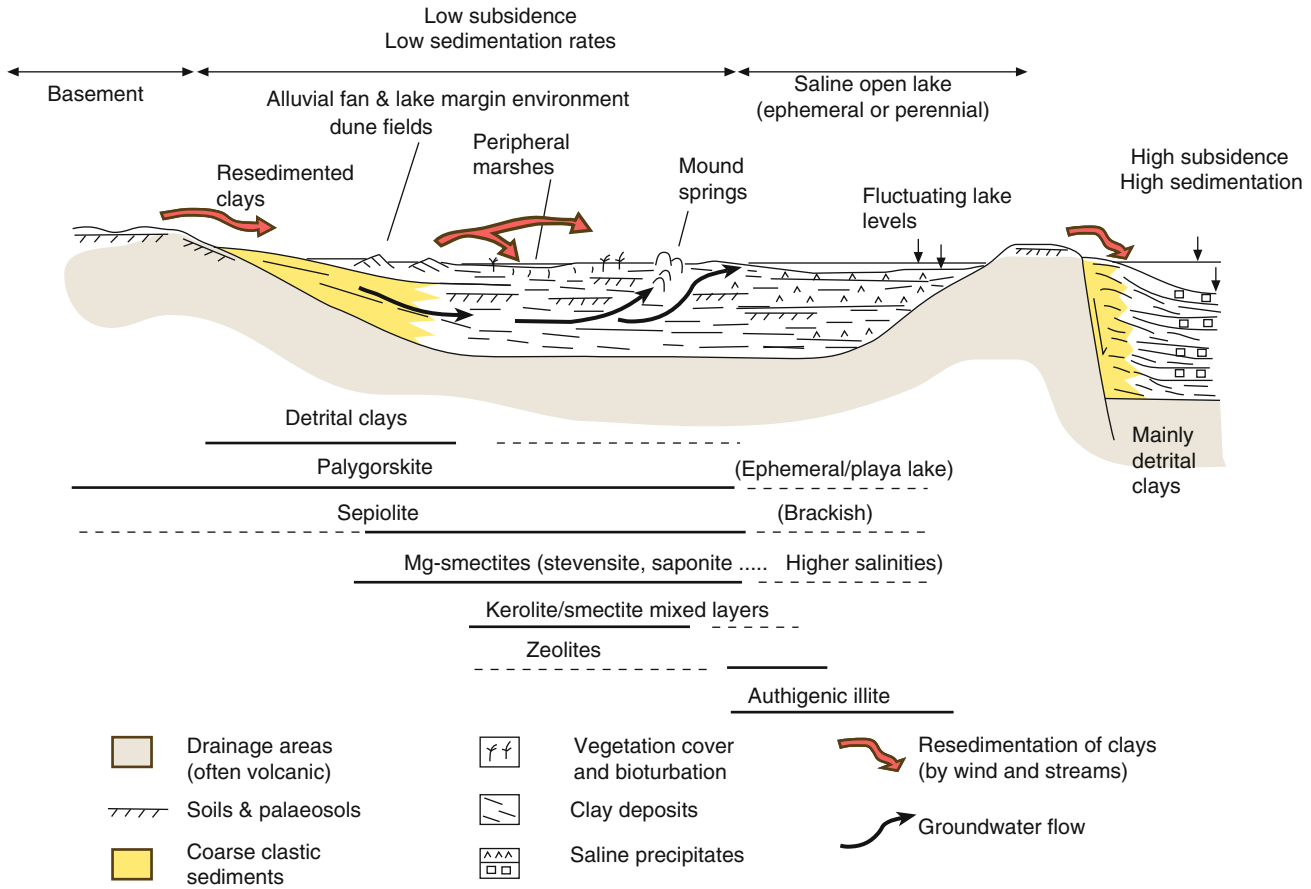

Fig. 1.63 Commonly observed distribution of authigenic clays in saline continental environments, emphasising the differences between basins undergoing slow versus rapid subsidence. Authigenic clays form mostly in saline lake-margin environments. Formation of authigenic clays in open-lake environments is dependent on the degree of schizohalinity (After Calvo et al. 1999)

other authigenic clays, as in saline lakes at the foot of Mt Kilimanjaro, in Tanzania and Kenya (Hay et al. 1995).

Hypersaline brines in modern, marine-edge evaporite basins can also enhance clay authigenesis even in settings where thermal and saline stresses keep both organic and inorganic carbon concentrations in the sediments unusually low relative to coastal marine environments with lower salinities (Martini et al. 2002). This is the case in Salina Ometepec where sediment pore waters exhibit little microbial sulphate reduction, and dissolved inorganic C contents are also very low. Instead of carbonate alteration (dolomitisation) in the Mg brine, authigenic K-rich Mg-smectite (saponite) formation is occurring, driven by the concurrent processes of brine concentration, selective dissolution of K- and Mg-bearing salts, and dissolution of detrital aluminosilicates. Salina Ometepec pore waters at a depth of 1 m have $^{87}Sr/^{86}Sr$ ratios that require input of Sr that is less radiogenic than that of Gulf of California seawater. This Sr is likely derived from weathering and leaching of detrital aluminosilicates from nearby volcaniclastic sources. Although rare in Holocene successions, similar Mg-rich authigenic clay assemblages are well documented in Palaeozoic evaporite basins (Bodine 1983; Janks et al. 1992; Andreason 1992).

Once precipitated in an evaporite basin, authigenic clays can be retransported further out into the saline depression and in more humid climatic stages may even end up on the floor of freshwater lakes (Fig. 1.63). This situation is seen in lacustrine sequences from the Miocene formations of the Madrid Basin (Bellanca et al. 1992) where significant amounts of palygorskite and sepiolite occur as either mud chips or clay aggregates in the basal part of a fresher water lacustrine unit. Eolian transport of saltating clay pellets or dust suspensions may also contribute to the transport of authigenic clays from marginal to more central areas. This sometimes leads to problems of interpretation of detrital versus authigenic in ancient lacustrine successions subject to oscillations in climate, especially when detrital clays are partially or fully inherited from arid soils.

Sepiolite, interstratified Mg-Smectite and palygorskite form authigenic phases in the Quaternary sediments of the Double Lakes Formation, Texas (Webster and Jones 1994). The dominance of each of these minerals in separate horizons represents evaporative shifts in salinity at the time they precipitated. Sepiolite is thought to indicate a brackish lake, while Mg-smectite indicates more saline conditions. Palygorskite is interpreted as a saline pore water precipitate in the arid soils of the playa stage. Likewise Jones (1986) interpreted authigenic Mg-smectites (e.g. stevensite) as requiring higher salinity than sepiolite. Mg-silicates also define saline lake clays in Great Salt Lake (Spencer 1983) and some Bolivian salars (Badaut and Risacher 1983). In Bolivia, the authigenic Mg-smectite replaces the biogenic silica in diatom frustules and requires a pH in excess of 8.2. Authigenic stevensite occurs in unconsolidated muds underlying saline crusts in the interdunal depressions of northern Lake Chad and as small aragonite-associated oolites on the lake floor (Gac 1980; Darragi and Tardy 1987). Similar stevensite oolites have been found in the Eocene Green River lacustrine basin. Stevensite is also an early authigenic phase in the modern carbonate thrombolites in the hyposaline Lake Clifton, Australia (Burne et al. 2014). Authigenic sepiolite associated with calcite, gypsum and dolomite occurs about the margin of Saline Valley Playa, California and the edges of saline pans in the Kalahari of southern Africa (Hardie 1968; Kautz and Porada 1976). Palygorskite, sepiolite and authigenic smectite are commonplace precipitates in calcretes of groundwater discharge playas in inland Australia (Arakel et al. 1990).

Clearly, palygorskite and sepiolite (both two-chain structure fibrous clays) occur worldwide as authigenic phases in the soils and palaeosols of arid and semi-arid regions, but the mode of precipitation is still not well understood (Singer 1979). Both minerals are common in environments with elevated levels of magnesium and silica. Hence they form in alkaline lakes and caliche, as well as in deep sea sediments and hydrothermal alteration products; Folk and Rasbury (2007) argue there may also be a microbial association to their formation, at least in some Texan caliches. Jones (1986) concluded sepiolite in the calcic soils of southwest Nevada required percolation of high salinity groundwaters. Magnesium and silica solutes were sup-plied by the weathering of nearby pyroclastics and carbonates. Sepiolite has replaced magnesite pebbles, from the edges in, during freshened highstand intervals in Miocene Lake Eskisehir in Turkey (Ece 1998). Palygorskite in calcic soils is thought to be the result of incongruent dissolution of pre-existing clays (Jones and Galán 1988). Fibrous clays degrade when climate becomes more humid and alter to smectite. Paquet and Millot (1972) conclude that the transformation takes place when mean rainfall exceeds 300 mm and Calvo et al. (1999) suggested the transformation can be used as a palaeoclimatic indicator.

Alunite ($KAl_3(SO_4)_2(OH)_6$) is a common clay product in acid saline lacustrine settings, but can also form diagenetically in regions where sulphate reduction is occurring. It is thought to be derived by the reaction of clay minerals with sulphuric acid created by oxidation of sulphides or H_2S at a redox boundary. It is a common product where clays are present in zones of sulphate reduction and examples have been documented in the Middle Miocene gypsums of the Gulf of Suez (Rouchy et al. 1995a, b) and the Upper Miocene gypsums of the Lorca Basin in Spain (Rouchy et al. 1998).

Even the smectite to illite transformation, which is used as an indicator of diagenetic intensity and clay transformations occurring at higher temperatures may be influenced by salinity. This makes illite crystallinity a less reliable indicator

of diagenetic stage in environments with saline pore fluids (Honty et al. 2004). Turner and Fishman (1991) found illite-smectite mixed layer clays having a range of expandabilities in altered tuff beds in a Jurassic lake in the Morrison Formation (Eastern Colorado Plateau, USA). The observed clays did not experience deep burial, and did not undergo hydrothermal alteration. The illite content generally increases from the lake margin (100–70 % smectite) to the lake centre (30–0 % smectite) and follows a lateral hydrogeochemical gradient, which was characterized by increasing salinity and alkalinity (Fig. 12.74). It seems that in a saline depositional setting, solution chemistry is a principal factor controlling the smectite to illite proportion. Illite-smectite can form from smectite at low temperatures in several ways (see Honty et al. 2004), but forms best in saline environments subject to wetting and drying cycles, which is a hydrology exemplified in salt lakes and playas. In the presence of K^+ ions, alternating wetting and drying leads to irreversible fixation of K and the formation of illite layers. Illite-smectite clays forming at elevated pH may not even require wetting and drying cycles.

Textural Synthesis

Evaporitic settings can accumulate evaporitic carbonates as well as more saline salts dominated by gypsum and halite beds. Evaporitic carbonates accumulate across the whole range of brine depths from ephemeral to shallow perennial to deep. Carbonate laminites tend to dominate in the deeper brine areas, while a whole range of textures and features, including laminites, form in the shallow and strandzone settings. Strandzone regions are often characterised by pisolites and algal structures of various types, ranging from cryptalgalaminites to stromatolites and tufas. The ephemeral water and groundwater seepage systems that characterise strandzones facilitate the cementation and ongoing growth of carbonate crusts. Over time, these marginward carbonate crusts can grow and deform into overthrust V-shaped carbonate ridges called tepees.

The typical evaporite accumulating on the floor of a stable shallow brine pool or a shallow epeiric shelf is composed of upward or growth-aligned crystals. Depending on the stability, salinity, and permanence of the overlying bottom brine, various mineralogical and dissolution surfaces can be superimposed on the upward growing prisms. When the overlying brine column is not subject to marked salinity fluctuations, then pristine crystal outlines are made up of stacked halite chevrons or zig-zag gypsums, with varying degrees of face curvature. When the overlying brine column is deep and holomictic then beds composed of coarse inclusion-free meshworks can form.

When an overlying perennial but shallow brine body mixes and freshens, subaqueous crystal truncation surfaces can form. Similar surfaces can form where the brine body dries up. Desiccation-related dissolution surfaces are distinguished from subaqueous truncation surfaces by an inherent abundance of vadose, karst and geopetal features. These three are all features that form during complete drying and falling of the watertable into the evaporite bed.

But evaporites do not just form on the bottom of a brine lake or seaway. They can also form where porewaters attain supersaturation in a pre-existing nonevaporite matrix (secondary evaporites). Probably the best-documented textures of this type are sabkha nodules composed of anhydrite and gypsum in the supratidal sediments of the Arabian Gulf. Large crystals of displacive halite form in a similar fashion beneath the mudflats of the Arabian Gulf, where the capillary pore fluids are at halite supersaturation. Dense brines, created during the formation of primary and early secondary salts, can sink into the underlying sediments where they can facilitate backreaction and alteration processes in the now buried evaporite beds.

At greater depths of burial, evaporite salts can reprecipitate as pore-filling cements and burial salts. Many primary and early secondary textures are overprinted at this stage by dewatering and recrystallisation processes associated with compactional dewatering and thermobaric alteration. Brines created by the subsurface dissolution of evaporites may also reprecipitate as burial salts in nearby nonevaporite beds.

If evaporites beds survive the rigours of deeper burial, they can be uplifted and re-enter the active phreatic zone where they are once again subject to dissolution and recrystallisation. Satinspar fractures and alabastrine textures are common indicators of this style of alteration. Such evaporites can be classified as tertiary evaporites. All of the textural and re-equilibration processes outlined in this chapter reflect the ongoing evolution of the brines that bathe the beds throughout their formation, burial and dissolution. Brine hydrology and its evolution is the fundamental control on evaporites. For example, work by Aleali et al. (2013), on the range of depositional and burial textures preserved in anhydritic core has integrated the various types of textures in the Triassic Kangan Formation of the Persian Gulf (South Pars Gas Field) into an inter-related textural classification, tied to the hosting depositional setting. Such an approach should find application in other anhydritic successions. In the next chapter we look at how brine evolution controls evaporites from the time they precipitated until the time they are completely dissolved.

Depositional Chemistry and Hydrology

2

In Chap. 1, an evaporite is defined as a salt rock originally precipitated from a saturated surface or nearsurface brine by hydrologies driven by solar evaporation. There is no assumption as to the origin of the parent brine; it may be marine (thalassic), nonmarine (athalassic) or a hybrid. By implication, there is a need for aridity and for water loss to exceed inflow. This means deposition and diagenesis in evaporites is more climate dependent than in either siliciclastic or carbonate sediments; reaction rates and reversibility are an order of magnitude faster. Suites of precipitated salts follow the geochemical make-up of the parent brine, while primary textures indicate hydrological stability and energy levels of the time of precipitation.

All evaporite salts are ionic salts, containing the major ions Na, Ca, Mg, K, Cl, SO_4, CO_3 in varying proportions along with other less common ionic constituents, such as B, Ba, Sr, Br and I and varying amounts of structural water (Table 1.1). The mineralogy and order of precipitates in any brine pool is controlled by the ionic make up of the parent brine. This, in turn, reflects the chemical composition of lithologies contributing dissolved ions to the parent water on its way to the site of precipitation. Because of consistent ionic proportions in seawater worldwide, the modern marine evaporite series is predictable and tied to increasing salinity. With nonmarine brines, proportions vary according to source terrain and levels of hydrothermal input. Hence, the proportions of minerals and sequence of precipitation is more variable. In addition, we now know that the ionic proportions in seawater were not constant through time and that the modern evaporite series is not necessarily a one-for-one analogue for past marine-fed precipitates.

Quaternary Deserts and Evaporite Assumptions

Modern continental evaporites typically accumulate within groundwater discharge regions in semi-arid to hyperarid deserts[1] (Fig. 2.1a; Table 2.1). Marine-fed coastal evaporites can occur at the oceanic edge of the same deserts, typically in coastal depressions fed by marine seeps or by rising groundwaters along coast-parallel mudflats. Evaporites also form lake precipitates and efflorescences in cold polar deserts in Antarctica, but the volumes of salt in these cryogenic regions pale to insignificance compared to arid settings closer to the equator. Brine freezing and mixing (cryogenesis), rather than direct solar concentration, plays a much more important role in the crystallisation of most cold climate salts, not just in Antarctica but also in the interior plains of Russia and Canada and high alpine deserts of the Andes and Tibet (Carlson et al. 1990; Marion et al. 1999).

Salt-accumulating continental depressions typically define the discharge areas of endorheic (internal drainage) basins; these are areas where more water is leaving the via evaporation than entering as rainfall, snowmelt, surface, or subsurface inflow (Table 2.1). They are found in: (1) tectonic basins, which include fault-defined intermontane basins and intracratonic structural sags, (2) interdune or inter-draa depressions

[1]Semi-arid deserts have a mean annual precipitation of between 250 and 500 mm. Arid deserts have less than 250 mm of annual rainfall. Extremely arid or hyperarid deserts have at least 12 consecutive months without rainfall. Worldwide, some 4 % of the earth surface is hyperarid, 15 % arid, and 23 % semi-arid.

Inset gives proportion of each continent that is arid or semiarid. (**c**) Longitudinal cross section through the earth's atmosphere showing major circulation cells, including jet streams. *ITCZ* intertropical convergence zone. Belts of cool dry descending air at 30° N and S of the equator create the main arid zones of the world

about the edges of sand seas or ergs, (3) wind-deflation hollows, (4) abandoned fluvial valleys (5) bolide-impact or volcanic craters, or (6) interior drainage depressions created by a combination of the preceding. The greatest volumes of desert salts today accumulate within arid to hyperarid depressions in continental rifts, compressional sags and transforms.

Climate drives evaporite deposition in modern deserts at scales ranging from broad latitudinal belts (100 s km) down to microclimatic niches (cms; Table 2.2). At the broadest scale, evaporites that occur in deserts are the result of large-scale atmospheric circulation. Modern deserts cover more than 25 % of the world's landsurface, mostly within two belts lying 15–45° north and south of the equator (Fig. 2.1b).

Global-scale atmospheric circulation is driven by varying intensities of solar irradiation, which is most intense directly above the equator and lessens toward the poles (Fig. 2.1c). Hence, the equatorial belt experiences greater insolation than the adjacent temperate latitudes. Equatorial air warms as it rises, creating a tropical belt of low pressure. As it rises it cools, losing most of the water vapour as rainfall to the tropical jungles and rainforests below. This now moisture-depleted air moves up and away from the equator and further cools and compresses. Finally, it sinks back to the earth's surface at around 30° latitude north and south of the equator. The cool descending dry air is reheated as it returns to the lower atmosphere, garnering an enhanced potential to absorb moisture (Fig. 2.1c).

Table 2.1 Quaternary examples of evaporite accumulations in various deserts

	Region	Location and setting	Notable evaporite features
Africa	East	Continental	Continental evaporites. In addition to large volumes of halite and $CaSO_4$, potash salts and trona are important salts in particular lakes with mineral evolution dependent on inflow chemistry.
		Danakil Depression, Lake Magadi, Lake Natron, Lake Kivu, Lake Tanganyika, Lake Turkana, Lake Urmia	
	North	Continental	Sodium carbonate is the dominant primary mineral in Lake Chad, while sodium sulphate and sodium chloride occur in subordinate amounts. Potassium and magnesium salts occur in near negligible amounts.
		Saharan ergs, Lake Chad, chotts of northern Africa	
		Coastal	Coastal sabkhas and salinas dominated by gypsum and anhydrite, along with halite and sometimes small volumes of potash, as in modern chotts and sabkhas of Tunisia.
		Coastal sabkhas and salinas of Algeria, Tunisia Libya, Morocco, the Nile delta and the Red Sea	
	Southern	Continental	Thousands of small wind-aligned salt pans, often with downwind lunettes, dot the arid landsurface. They form preferentially on a clayey substrate that is made up of the Ecca and Dwyka Shales in South Africa, the Karoo in Namibia and the Kalahari Beds in Botswana.
		Pretoria, Otjiwalundo and other salt pans, interdunal sabkhas of Namibia	
	Middle East	Continental	Dead Sea naturally accumulates pan halite in the shallow southern basin, along with carbonate laminites and massive halite in the deepwater northern basin.
		Rub al Khali ergs, Dead Sea evaporites	
		Coastal	Nodular calcium sulphate with minor halite in classic coastal sabkha successions of Abu Dhabi, Saudi Arabia and Kuwait.
		Coastal sabkhas and salinas of the Arabian Gulf	
Antarctica		Continental	Cryogenic evaporites (brine freezing). Aragonite in the Taylor Valley and the Vestfold Hills. Sulphate minerals predominant in the Wright Valley. Halite and mirabilite are widespread. Trona and thermonatrite in the East Taylor Valley, and soda nitre, bloedite, and darapskite in the Wright Valley. Antarcticite ($CaCl_2 \cdot 6H_2O$) in Don Juan Pond.
		Lake Bonney, Taylor Valley; Lake Vanda, Wright Valley, Organic Lake, Deep Lake and Ekho Lake in the Vestfold Hills.	
Asia	Central	Continental	Potash salts (especially carnallite) are accumulating as karstic fills in bedded halite in perennial lakes and playas of the Qaidam Basin. Other lakes in with a range of other salts. Borates occur in Lake Inder. Sodium sulphate (cryogenic) dominant in Korabogazgol.
		Qaidam Basin, Gulf of Kara Bogaz, Lake Inder	
	Southern	Continental	Iranian playas show complex facies interactions with rising salt diapirs with localised potash and even tachyhydrite present. Turkish lakes are accumulating large volumes of magnesium carbonate and dolomite.
		Iranian playas; Van Golü, Salda Golü and Tuz Golü, Turkey; Didwana Lake and other playas of Thar desert	
		Coastal	Gypsum and halite sabkhas, widespread fluidization textures from earthquakes.
		Coastal sabkhas of Ranns of Kutch, India	

(continued)

Table 2.1 (continued)

	Region	Location and setting	Notable evaporite features
Australia	Eastern	Continental	Continental salt lakes (playas), some with gypsum/clay lunettes that rim brine pans; others, especially in volcanic maars, are characterised by Mg-rich carbonate sediments and crusts.
		Lake Tyrell, Lake George, Maar Lakes, Lake Victoria	
	Central	Continental	Continental salt lakes (playas), typically with gypsum lunettes that rim the various brine pans. Many lunettes were more active in the Late Pleistocene. Many pans form as groundwater sumps in paleochannels. Salt crusts are now largely recycling through the lakes, with no massive accumulations.
		Lake Amadeus (Karinga Creek lakes), Lake Eyre, Lake Frome, Lake Torrens Simpson and Victoria deserts	There are fresher artesian aquifers beneath many of the larger continental lakes. Mostly halite and gypsum accumulate in the lakes, minor thernadite/mirabilite accumulating as ephemeral salts in the Karinga Creek area.
		Coastal	Coastal lakes or salinas are classic Holocene areas for coarse-grained bottom growth and reworked gypsum beds up to 10–15 m thick, pisolite seepage pavements, modern tepees, mm-laminated domal stromatolites.
		Marion Lake complex, Lake Macdonnell, Streaky Bay Lakes, Fisherman Point sabkhas	
	Western	Continental	Continental playa lakes within elongate and sinuous Tertiary palaeodrainages on the Yilgarn Craton. Evaporitic fill in the lakes is up to 10 m thick and mostly gypsum with lesser halite. Wind and wave-driven currents rework sediments that are then deflated by the wind to be redeposited in marginal gypsum dunes (lunettes).
		Lake Lefroy, Lake Cowan, Lake Dundas, Lake Ballard, Lake Carey, Lake Raeside	
		Coastal	Coastal lakes or salinas with gypsum and halite in beds up to 10–15 m thick in Lake McLeod.
		Lake Mcleod, Hutt Lagoon, Leeman Lagoon	
Europe	Spain	Continental	Glauberite and other sodium sulphates accumulating in modern playas.
		Playas of Los Monegros and Bajo Aragon, Laguna de Tirez in La Mancha	
Americas	Central Canada	Continental	Salt pan and perennial subaqueous evaporites (mostly cryogenic) containing mirabilite, thenardite, and bloedite. Some lakes, such as Freefight and Deadmoose, are accumulating salts in perennial "deep" waters (10–30 m), as well as bacteriogenic carbonates.
		Ceylon Lake, Freefight Lake, Deadmoose Lake, Little Manitou Lake and many other saline lakes and playas on the Great Plain of central Canada	
	Northern USA	Continental	Salt pans containing sodium sulphate salts, as in Central Canada.
		Saline lakes and interdunal sabkhas, Nebraska and North Dakota. Draas of the southwest USA	
	Southern USA	Continental	Pleistocene continental lacustrine accumulations of mostly gypsum ± halite, now deflated and overprinted by Holocene sabkha signatures.
		Salt Flat playa, West Texas; playas in Rio Grande Rift	
		Coastal	Coastal mudflats with displacive gypsum.
		Laguna Madre	
	Western USA	Continental (Basin and Range) Death Valley, Saline Valley, Deep Springs lake, Searles Lake, Bristol Dry Lake, Great Salt Lake, Owens Lake, Salton Sea	Quaternary continental lakes with diverse range of salts including thick halites, lesser anhydrite, trona, glauberite and other salts depending on chemistry of inflow waters. Holocene is a time of saline mudflats, at other times in the Pleistocene the depressions lay beneath the waters of saline/brackish (glacial) lakes.
	South Americas	Continental	Large volumes of continental evaporites accumulated within the central Andes during Neogene uplift of the Altiplano-Puna plateau with associated development of the Andean volcanic arc. Halite and gypsum are dominant minerals, along with local and economically important borates, nitrates and potash salts.
		Salar de Atacama, Salar Uyuni, Salar Coipasa, Pastos Grandes, Laguna Salinas, Salar de Pintados	
		Coastal	Large volumes of marine-fed estuarine evaporites in a drowned river valley.
		Bocana de Virrilá, Peru	

Table 2.2 Causes of modern deserts

		High pressure belts	Continentality	Adiabatic or rain shadow	Upwelling (cool sea surface)
		Beneath the descending limbs of Hadley cells (centred 20–30° north and south of the equator) or under stagnant air masses.	Regions within the continental interior. Locations isolated by distance from moisture sources, principally the oceans.	Regions located in the lee of topographic barriers where airmass subsides as it warms and dries and flows inland.	Amount of moisture evaporated from the ocean surface is less, so yielding drier air when sea air moves overland and warms.

See Fig. 2.1a for locations, typically more than one factor drives desertification

Belts of aridity sit beneath cold dry descending air masses of the Hadley Cells, which define high-pressure belts known as the subtropical Trade-Wind Belts or Horse Latitudes. The trade winds form the equatorward limb of the Hadley circulation in each hemisphere Such areas are seldom subjected to moisture-bearing disturbances or pressure depressions (lows), either from the Intertropical Convergence Zone (ITCZ) of the tropics or from the belt of mid-latitude depressions associated with the circumpolar westerlies. The trade winds that blow across these zones are evaporating winds, and, because of the trade-wind inversion, they tend to be areas of atmospheric subsidence and stability. That is, subtropical high-pressure belts are the major cause of aridity, though deserts are not always continuous around the earth at 30 N. For instance, the Asian monsoon supplies large quantities of rain over northern India, and elsewhere the high-pressure cells are disrupted into a series of local cells, notably over the oceans, where air moving clockwise around the equatorial side of the cell brings moisture-laden air to the eastern margins of the continents.

The earth-scale distribution of Holocene desert belts reflects broad-scale atmospheric dynamics. When icecaps expand the atmospheric circulation belts are pushed and compressed toward the equator and they have done so numerous times in glacial maxima of the current icehouse climate mode. Equatorward compression increases the intensity of atmospheric circulation and alters the latitudinal distribution of climate belts. This has a marked effect on climate in Quaternary deserts, so that almost all modern continental playas in the Horse Latitudes have experienced numerous water-full versus dry stages in the last few hundred thousand years, what follows are examples from different continents to underline this fluctuation.

Strontium-isotopic composition of preserved gypsum in Lake Frome, a large discharge playa in South Australia, records periods of high rainfall at 3–6, 12–15, and >17 Ka,

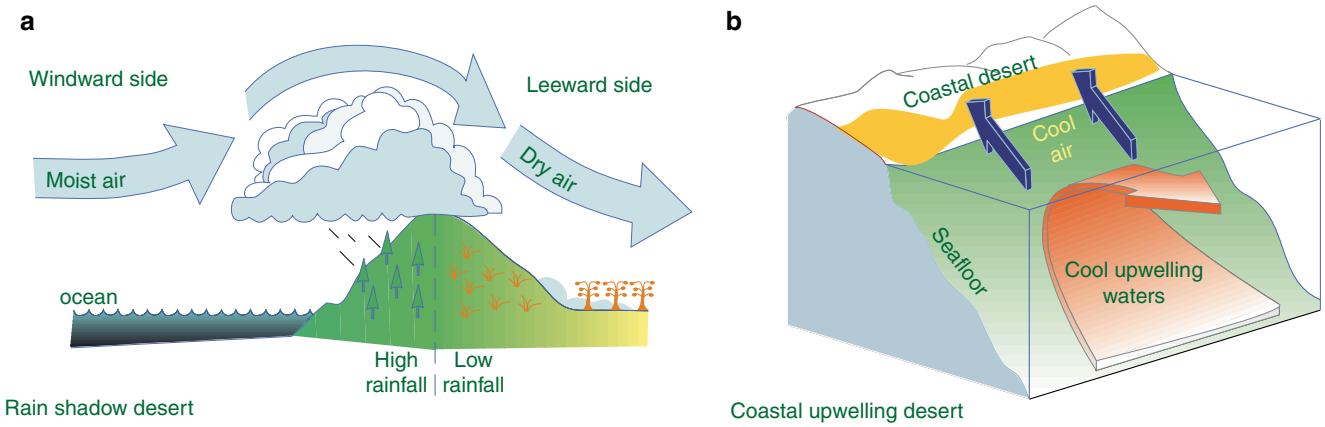

Fig. 2.2 Local controls on deserts. (**a**) Adiabatic or rain shadow desert where rain tends to fall on the seaward side of the mountains. (**b**) Coastal deserts form in response to cool upwelling ocean waters and the cool dry onshore winds warming as they pass overland (After Warren 2008)

and drier periods at ≈10 and ≈17 Ka (Ullman and Collerson 1994). In the last interglacial (early in oxygen isotope stage 5) a nearby and much enlarged Lake Eyre maintained a perennial freshened water body up to 25 m deep (Magee et al. 1995; Cohen et al. 2012). Subsequently, as climate deteriorated into glacial mode, there were a number of dry periods separating successively less effective wet phases, culminating in the deposition of a substantial halite salt crust around the time of the last glacial maximum. Lake Eyre only attained its present saline mudflat/ephemeral playa status some 3–4 Ka. The drying trend over the last hundred thousand years in Lake Eyre corresponds to a longterm lessening of monsoon intensity in the northern part of Australia, which is the main source area for waters flowing into the lake depression.

In Death Valley, USA, there were dry mudflats, characterised by abundant glauberite, gypsum and minor calcite from 0–10 to 60–100 Ka (Li et al. 1997). In contrast, the wet period from 10 to 60 Ka was typified by halite and mud layers, with relatively abundant calcite. This wetter period encompasses sediments deposited 10–35 Ka, when Death Valley contained a perennial halite lake. These millenial-scale oscillations define a predominately Na–Ca spring-fed inflow hydrology during dry climatic periods and increased volumes of bicarbonate-rich river waters in the wetter periods.

Likewise sediments of the inland sabkhat of the Tayma playa (Saudi Arabia) illustrate a change from a relatively humid Holocene period (10–8 ka) to the hyperarid conditions of today (Ginau et al. 2012). During the humid period, a perennial lake defined the playa depression with a characteristic suite of carbonate-dominant sediment, including ostracod valves and foraminifer shells, all adapted to salinity fluctuations. At the same time, phases of lake contraction and high salinity were responsible for the formation of open water evaporitic carbonates, such as aragonite needles, ooids and magnesite in the surrounding mudflats (much as in the Coorong region and in Great Salt Lake, Utah). Dilution occurred during rain events and the flooding of the playa is indicated by clastic layers in the lake sediments, which were often deposited in graded fining-upward sequences indicative of sheet flooding. With time, lake sedimentation became increasingly arid and sabkharized. Today, the lake hydrology is dominated by the precipitation of capillary salts in varying combinations of halite, gypsum, anhydrite and bassanite.

Saline playas and midlatitude deserts of central Asia and central Australia are in part a product of their isolation from the nearest ocean. Continentality is the term that describes the geographic isolation of a desert by its large distance from the ocean. It explains why the highly continental Takla Makan Desert of central China is a hyperarid desert at 50°N latitude, well north of the world's subtropical high pressure belts. Another factor helping form this type of desert is the rain shadow effect.

Rain shadow deserts, also known as adiabatic deserts, form where air masses move up and over mountain ranges (Fig. 2.2a). As air rises over a mountain range it cools, moisture develops into clouds and falls as rain on the side of the mountain range facing into the prevailing wind. Subsiding air on the other side of the range is dry and its moisture-bearing capacity increases further as it sinks and warms. For example, the deserts of Patagonia lie on the lee side of the Andes, while the deserts of Nevada and Utah are in the rain shadow of the Sierra Nevada. The Dasht-i-Lut in Iran is in the rain shadow of the Alborz and Zagros Mountains and its maximum surface temperatures at 70.7 °C (measured in sand) make it one of the hottest deserts in the world. Adiabatic deserts can also be found behind the Himalayas, the Ethiopian uplands and Eastern Highlands of Australia. Extreme examples include the Dead Sea rift and the Afar depression, both areas are subsealevel depressions surrounded by high mountain ranges of the rift rim. Rain shadow effects increase where the region inland of the mountains lacks relief.

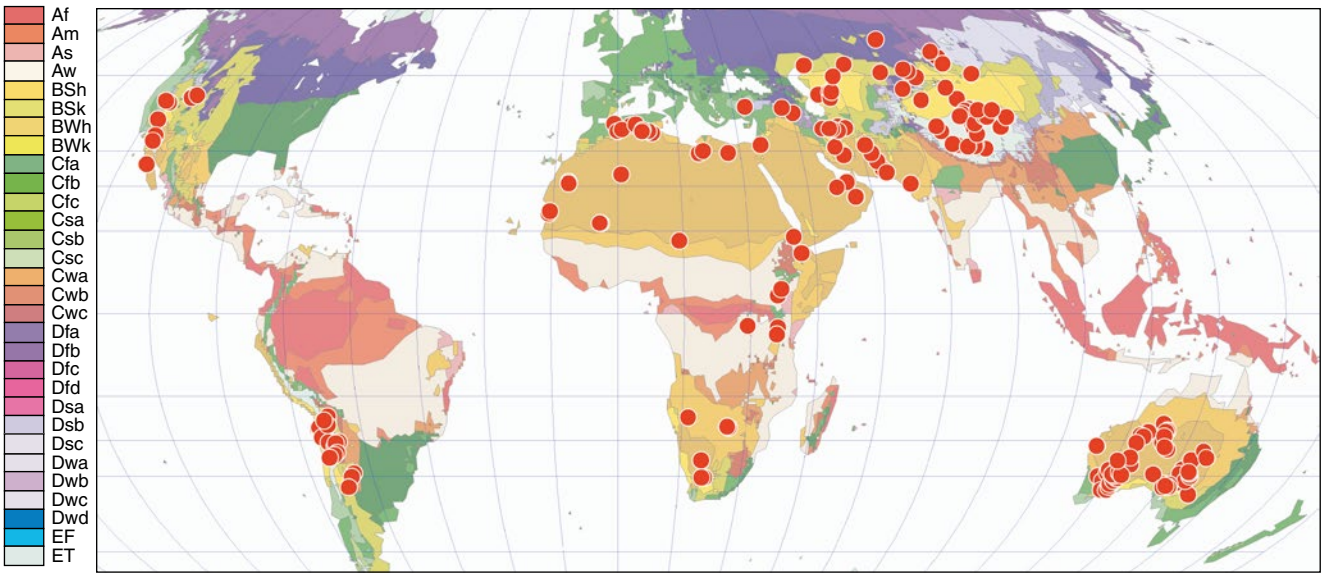

Fig. 2.3 Quaternary evaporites with areas >250 km^2 and climate setting. Centroids plotted on the earth surface where an evaporite depositional setting (sabkha, salina, playa, saline lake, saline soil) extends across an area of more than 250 km^2. This plot set is overlain on a Köppen climate base (After Kottek et al. 2006). *Main Climates*: *A* tropical, *B* arid, *C* warm temperate, *D* snow, *E* polar. *Precipitation*: *W* desert, *S* steppe, *f* fully humid, *s* summer dry, *w* winter dry, *m* monsoonal. *Temperature*: *h* hot arid, *k* cold arid, *a* hot summer, *b* warm summer, *c* cool summer, d extremely continental, *F* polar frost, *T* polar tundra

Rainshadow deserts and bedded evaporites are often part of a longer term tectonic association between sedimentation and climate in both extensional and compressional settings and are a climatic response independent of whether the earth is in greenhouse or icehouse climate mode (Hay 1996). Over millions of years, the rifting of continental blocks involves broad upwarping, followed by subsidence of a central valley and uplift of marginal shoulders. The result is an evolving regional climate-sediment association that is repeated many times in the Phanerozoic: first a vapour-trapping arch with centripetal fluvial drainage forms. This is followed by a rift valley, first with fresh-water lakes, culminating in an arid subsealevel evaporitic rift bordered by mountains intercepting incoming precipitation (adiabatic desert).

Convergence tectonics also affect climate at the broad scale. A rising mountain range is a barrier to atmospheric circulation, especially if perpendicular to the incoming circulation. The uplift of the Tibetan Plateau in the Late Tertiary created an easterly subtropical jet stream, which now flows from Tibet across the Arabian Peninsula toward Somalia. This stream of cool dry air accentuated the existing aridity and created an adiabatic desert that lies almost on the Equator (Fig. 2.3). In the past both extensional sag and compressional tectonism have helped induce hyperaridity atop large subsea-level seepage depressions, which were capable of accumulating thick halite and gypsum successions (Fig. 5.32).

Upwelling ocean waters off continental landmasses in the trade wind belts favour coastal deserts. Cold upwelling ocean water creates a belt of coast-parallel cool water. And, as evaporation is a function of heating, cold offshore oceans provide less moisture and less cloud to the adjacent land. The cool air above creates relatively dry onshore winds. As this colder air moves across the land it is heated, so developing an increased capacity to absorb rather than shed moisture (Fig. 2.2b). Offshore, these cool strips of water are frequently engulfed in winter sea fogs, created by a blanket of warmer air atop cold seawater. Such cold upwelling ocean currents account for the deserts of Baja California and the Namib of southwest Africa (Benguela Current). The Peru Current, as it upwells along the west coast of South America, helps maintain hyperaridity in the Atacama Desert of Chile, which receives around 1 mm of rain every 5–20 years making it the driest desert in the world.

Fog, rather than rain, is the main supplier of moisture to coastal deserts in such areas and it also moderates the coastal air temperature. An array of unusual desert plants and animals have evolved behaviours and physical adaptations to make maximum use of this foggy water. For example, in the early morning some Namibian desert insects with water-capturing fluted carapaces stand on the coastal dunes with sails-high to collect condensation from foggy onshore morning breezes.

The present western edges of most tropical or Trade Wind deserts are washed by cool ocean currents driven by large scale ocean gyres, which rotate anticlockwise in the Southern Hemisphere and clockwise in the Northern Hemisphere. Throughout much of the Phanerozoic, coastal deserts in

ancient trade wind belts, indicated by eolian dunes and evaporites, have characterised the western sides of continents in the horse latitudes (Hay 1996).

Quaternary Evaporites in a Köppen Climatic Framework

In much of the geological literature, Quaternary evaporite occurrences are stated as being directly related to the distribution of the world's hot arid deserts, and in a general way this is true but, as Warren (2010) showed, it is an oversimplification. Hot arid desert does not necessarily equate to laterally extensive bedded evaporite occurrences; there must also be a significant long term brine source, it may be meteoric, marine, a hybrid and perhaps fed brines from dissolution of earlier formed salts in the drainage basin (including diapiric salt).

There are different ways of defining a desert and by implication its associated evaporites. One accepted approach is to define a desert as a land area receiving less that 250 mm of annual precipitation. Using this definition some 26.2 % of the world's landsurface is desert. But, in terms of evaporite distribution and their economics, this climatic generalization of evaporites related to annual rainfall conceals three significant hydrological truisms needed to accumulate thick sequences of bedded salts (Warren 2010): (1) For any substantial volume of evaporite to precipitate and be preserved, there must be a sufficient volume of cations and anions in the inflow waters to allow thick sequences of salts to form; (2) The depositional setting and its climate must be located within a longer term basin hydrology that favours preservation of the bedded salt, so it may pass into the burial realm, and/or it must favour the ongoing creation of a suitable saline brine feed to a solar-evaporation fed chemical sump. (3) There must be a negative water balance with the potential for more water to leave the system than enter. The significance of these simple hydrological statements and the consequences, as to where bedded evaporites accumulate, is lost in the generalization that "evaporites form in the world's deserts."

For evaporite studies it is preferable to define and plot saline hydrologies within a climatic framework where deserts are given the same hydrological consideration that is required for evaporite salts to form. That is, a desert is an area of land where annual precipitation is less than potential evapotranspiration. This definition of a desert is the one used by Köppen (1900). With slight modifications, his climatological scheme is still in widespread use today to breakout the various climatic zones across the world's landsurface (Kottek et al. 2006). Using a Köppen climate base, Fig. 2.3 plots worldwide occurrences of modern saline depositional systems with areas greater than 250 km^2. Table 2.3 compares characteristics of some of the larger Quaternary bedded evaporite settings in marine edge and continental interiors. These regions contain evaporite salts accumulating in saline soils, sabkhas, salinas, saline lakes, playas and salt flats, with textural forms ranging from; isolated crystals and nodules in a terrigenous matrix, to salt crusts, to stacked beds of salts more than 10 m thick. The majority of the saline areas are in arid areas, as defined by Köppen (Zone B), but not all such areas of widespread salts are in deserts (as defined by Köppen) and not all are in hot climates.

Before we get further into a discussion of climatic associations across modern continental and marine-fed evaporite occurrences, a few words are needed to explain the groups and subgroups that make up the Köppen climate classification (see Kottek et al. 2006 for more detail). In terms of evaporite occurrences, the most important is Köppen Group B (arid or semiarid); it defines climate areas on the continents where annual precipitation is less than potential evapotranspiration. Group B climates cover 12.2 % of the world's land surface, much less than the 26.2 % desert area when defined purely by rainfall (Fig. 2.4). Group B is further divided into desert (BW) zones, where annual precipitation is low, and steppe or semiarid (BS) areas where precipitation is somewhat higher relative to evapotranspiration. Kottek et al. 2006, discusses the equations used to define these and other Köppen climate boundaries and how the climate data plot, shown in Fig. 2.3, is generated.

A third letter is added to a Köppen classification of deserts to indicate temperature, for example, h indicates hot and k indicates cold in the BW group. Definitions vary on what is the actual thermal boundary between h and k; in the classification followed in this book Köppen's original separation of average annual temperature being more or less than 18 °C is used. Common practice in the USA today is to assign k if there is one month or more in a year when the average monthly temperature is below zero (°C).

Group A encompasses tropical (megathermal) climates, it is assigned to regions that have year-round monthly temperature averages above 18 °C. The tropics are further subdivided in Af for rainforest, Am for monsoonal, while seasonally variable tropical climates are called savannah. As denotes a tropical savannah zone with a dry summer, and Aw indicates tropical savannah with a dry winter. The savannah group encompasses most tropical setting where bedded evaporites can occur (e.g., Aw characterizes many saline African rift lakes and salt pans on the leeward of some oceanic islands, such as Inagua in the Caribbean, while an As climate typifies the climate over anthropogenic salt pans near Macau in central Brazil (see Chap. 11 for discussion of anthropogenic coastal salt factories).

Group C is the temperate (mesothermal) climate group and includes the dry summer subtropical or Mediterranean climate (Csa, Csb) zones showing marked seasonal separation between hotter drier summers and cooler wetter winters. This climate setting facilitates seasonal salt harvesting in many solar salt farms and pans about the Mediterranean and southeastern Australia (Chap. 11). There is also a humid sub-

Table 2.3 Area, elevation (with respect to msl) and climate in selected natural endorheic saline depressions in marine-margin versus continental-interior positions, with and without salt diapirs in the drainage

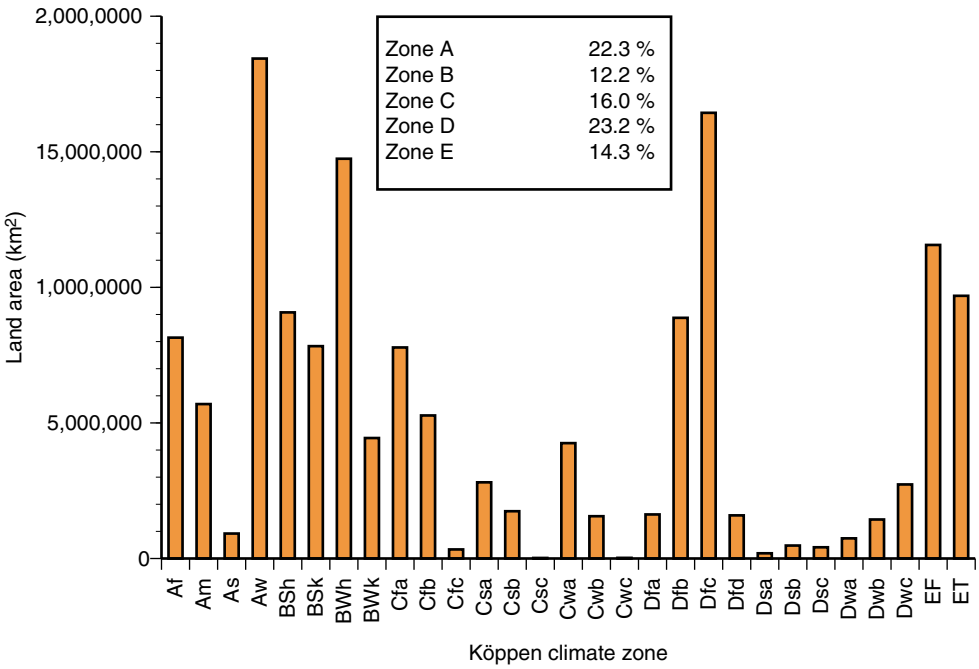

Fig. 2.4 Land areas of the various Köppen climate zones (Extracted and plotted from Kottek et al. 2006). The earth's total land area is 148,940,000 km^2

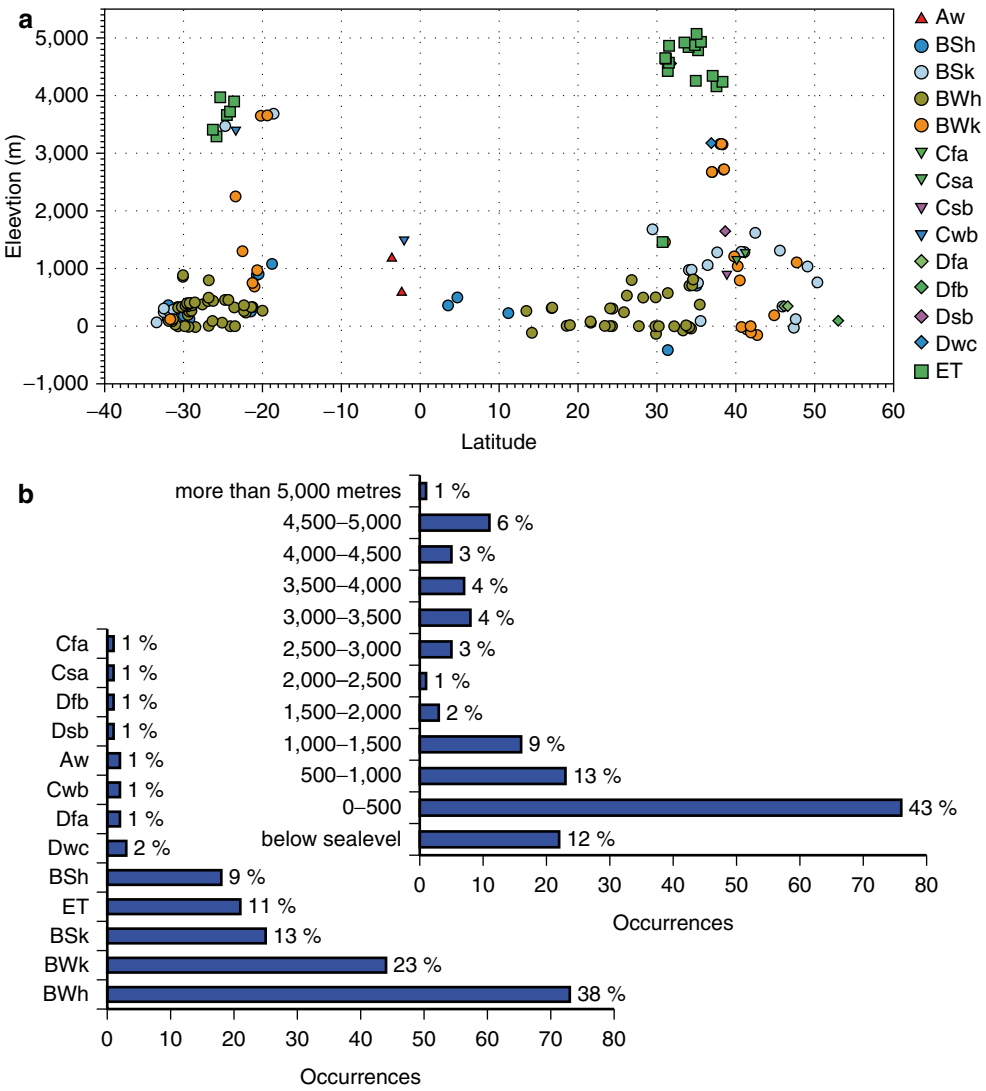

Fig. 2.5 Large saline areas (>250 km^2) on the earth's landsurface in terms of Köppen climate zones. (**a**) Plot of locations in terms of climate versus latitude and elevation. (**b**) Count of occurrences (>250 km^2) as bar charts showing percentage occurrences in climate zone and elevation ranges (metres sea level)

tropical group (Cfa and Cwa) that tends to occupy temperate continental interiors. Maritime or oceanic temperate climate zones (Cfb, Cwb, Cfc) have milder summers and winters; they tend to occur on western sides of continents, polewards of the Mediterranean climate zones of the world (Fig. 2.3). Then there are the temperate climate zones with dry winters and cool summers (Cwb) and the Maritime subarctic climates (Cfc), typically located poleward to the maritime temperate zones. Group D encompasses continental climate regimes, sometimes called the snow climates, which tend be located within continents and subject to greater temperature extremes compared to the maritime zones. They are subdivided into continental regions with hot summers (Dfa, Dwa, Dsa), continental regions with warm summers, also called hemiboreal (Dfb, Dwb, Dsb) and a third grouping that is subarctic or boreal (Taiga) and termed Dfc, Dwc and Dsc. Cryogenic evaporites are not uncommon in regions covered by this D climatic group.

Finally, there are the polar climates of Group E, characterized year round by monthly average temperatures below 10 °C. Group E is further divided into icecap or frost climate (EF) and tundra (ET) which includes alpine or high-altitude climates and encompasses many natural accumulations of borate and low temperature sodium sulphate salts and along with lithium brines in the adiabatic high-altitude deserts of the Andes and the Himalayas (Chap. 11). Above 4,000 m most of these saline ET accumulations are relatively small deposits (<10 km^2).

Continental-Interior Settings

When >250 km^2 evaporite occurrences are plotted against latitude, climate and elevation, the range of large (>250 km^2)

saline systems in the world's landscape is seen to be more climatically diverse than just evaporite occurrences within hot arid deserts (BWh), although such associations do constitute some 38 % of occurrences (Fig. 2.5a; Table 2.3). Cold arid deserts (BWk) host 23 % of large saline occurrences, making a combined total of 61 % for large evaporite accumulation (area >250 km^2) occurrences in modern arid deserts (BW group), while the arid steppes (BSh and BSk) host another 22 %. In total the world's arid climatic zones host 83 % of today's larger evaporite occurrences (Fig. 2.5b).

This leaves another substantial, but not widely recognized, climate zone where Quaternary evaporites accumulate, this is the polar tundra (ET), an environment where some 11 % of large evaporite areas occur. It is typified by arid high altitude belts, mostly in the Horse Latitudes, not in polar positions. As a depositional type it is typified by the lakes and pans of the high plateaus of the Andes (Altiplano) and the Himalayas (Tibetan Plateau). In this zone H_2O may be commonplace, but is there mostly as ice, and cryogenic salts are commonplace. The remaining region (some 6 % of the total of large saline occurrences) is a group defined by continental interior snow climates (group D), some with hot dry summers or dry winters favouring the possible accumulation of cryogenic salts.

Another interesting aspect of the Quaternary salt distribution seen in the latitude plot (Fig. 2.5a) is that in the Northern Hemisphere the occurrence of large evaporite systems within arid deserts and steppe climates (BW and BS settings) extends much further south toward the equator and much further poleward (from 5 to 55°N) than the narrower range of large evaporite occurrences and associated climates in the southern hemisphere. In large part this is a response to world-scale adiabatic effects associated with the growth of the Himalayas. This Cenozoic mountain range diverts world-scale atmospheric air flows from a more north-south trajectory, usually associated with Hadley Cell circulation. For example, the Kunlun Mountains, formed some 5.3 Ma, prevented moisture from the Indian Monsoon reaching much of the adjacent Tibet Plateau. Its adiabatic rain shadow creates the Taklamakan desert, the second largest active sand desert in the world (BWk).

The uplift of the Himalayas also created a dry easterly jet stream, moving arid cool air across the Tibet Plateau, around the northern side of the Himalayas, and then equatorward across the Arabian Peninsula toward Somalia where it descends and gains heat. This stream of cool southward-flowing dry air warms as it moves across the Eastern Mediterranean land areas and so accentuates existing aridity. It helps create an adiabatic desert zone that extends across Arabia and northern Africa almost to the Equator (Figs. 2.1a and 2.5a).

In the southern hemisphere, the uplift of the Andes has formed high intermontane depressions and the associated adiabatic aridity has created Salar de Atacama (with a sediment fill composed of more that 900 m of interlayered salt and clay) and Salar de Uyuni (with more than 120 m of interbedded salt and clay infill) with areas of 3,064 km^2 and 9,654 km^2 respectively. These are the two largest examples of Quaternary bedded halite accumulation, worldwide. Yet neither resides in hot arid desert settings (BWh), both are located in cold arid deserts (BWk) and in actively subsiding, high altitude (>2,500 m) intermontane (high relief) endorheic depressions.

Worldwide, distribution of most larger (>250 km^2) Quaternary evaporite settings in hot arid (BWh) desert settings is tied either to endorheic river terminations along desert margins, especially adjacent to mountain belts (e.g., circum Saharan chotts, playas and sabkhas adjacent to Atlas mountains – Fig. 2.6 and the southern Africa pans), or to ancient inherited paleodrainage depressions (as in the majority of the interior salt lakes of Australia – Fig. 2.3). Another BWh evaporite association is along the termination outflow rims of deep artesian systems, as in Lake Eyre North, Australia (8,528 km^2, with an ephemeral halite crust up to 2 m thick in its southern portion). Similar deeply-circulating meteoric hydrologies explain the distribution of chotts in the BWh zone of NE Africa. Unlike Atacama and Uyuni in the Andes, none of these BWh artesian systems are accumulating stacked decametre-thick salt beds. Rather, the most extensive style of BWh salt in meteoric-fed artesian outflow zones is as dispersed crystals of gypsum and halite in a terrigenous redbed matrix or as visually impressive large ephemeral saline flats and pans covered by metre-scale salt crusts that dissolve and reform with the occasional decadal freshwater flood (Chap. 3). Sediments of such continental groundwater outflow zones are typically reworked by eolian processes and, due to a lack of long term watertable stability, the longterm sediment fill is matrix-rich and evaporite-poor, with the Quaternary sediment column typified by episodes of deflation, driven by 10,000–100,000 year cycles of glacial-interglacial climate changes.

It seems that to form and preserve laterally-extensive decametre-thick stacked beds of halite in a Quaternary timeframework requires an actively subsiding tectonic depression in a cooler high-altitude continental desert, where temperatures and evaporation rates are lower than in BWh settings, allowing brine to pond and remain at or near the surface for longer periods (Fig. 2.7). But perhaps more importantly all of the larger regions of the Quaternary world, where thick stacked bedded (not dispersed) evaporites are accumulating, are located in continental regions with drainage hinterlands where dissolution of older halokinetic

Fig. 2.6 Köppen climate zones across North Africa showing centripetal distribution of saline lakes and chotts (*small blue areas*) about the perimeter of the Saharan Desert (mostly BWh). Clearly show the importance of a fluvial (*blue lines*) or groundwater supply to create an area of saline lake/salt deposits. That is, no brine at or near landsurface means no evaporites can form. For detail on Köppen climate refer to Fig. 2.3. The resolution in this image is better suited to the digital version of this book (Output overlays courtesy of SaltWork Database Version 1.6)

marine-fed salt masses are actively supplying substantial volumes of brine to the near surface hydrology. This halokinetic-supplied set of deposits includes, Salar de Uyuni and Salar de Atacama in the Andean Altiplano, the Kavir salt lakes of Iran, the Qaidam depression of China and the Dead Sea (Table 2.3).

Marine-Margin Settings

Thick sequences of stacked Quaternary evaporite beds with a marine brine feed are far less common and far smaller than meteoric/halokinetic continental evaporite occurrences. Relatively few marine-fed evaporite regions exist today with areas in excess of 250 km^2 (Table 2.3). The largest deposit of this group is Lake Macleod on the west coast of Australia, with an area of 2,067 km^2 and containing a 10 m-thick Holocene gypsum/halite bed. It hosts a saltworks producing some 1,500,000 t/year from lake brines in a BWh setting (Chap. 11). A smaller marine seepage example, with a similar Quaternary coastal carbonate dune-hosted seepage hydrology, is Lake Macdonnell near the head of the Great Australia Bight. It has an area of 451 km^2, a 10 m-thick fill of Holocene bedded gypsum and is located in a milder BSk setting, compared to Lake Macleod. Even so, annually, the Lake Macdonnell operation is quarrying more than 1.4 Mt of Holocene coarsely-crystalline near-pure gypsum and producing more that 35,000 t of salt via by pan evaporation of lake brines. Interestingly, when the climatic settings of Holocene coastal salinas of southern and western Australia are compared, all of which show similar interdunal depression seepage hydrologies, it is clear that gypsum forms from marine brines in BSk and lower precipitation regions Csb, settings. Halite dominates the marine-fed fills in BWh coastal settings, while Coorong-style meteoric-fed carbonates dominate in similar interdunal coastal seepage depressions in the more the humid Csb settings of the Coorong region (Chap. 4)

One of the most visually impressive marine seep systems in the world is Lake Asal, immediately inland of the coast of Djibouti, with an area of only 54 km^2 it is much smaller than the 250 km^2 cutoff used for this discussion. It is located in a BWh climate, similar to that of the Danakil depression, contains subaqueous textured gypsum and pan halites, and lies at the bottom of a hydrographically-isolated basalt-floored depression with a brine lake surface some 115 m below sea-level (see Chap. 4 for geological detail). This difference in elevation between the sea and the lake floor drives a marine seep hydrology, so that seawater-derived groundwater escapes as springs along the lake margin. Most of the cations and anions in the seawater feed, that ultimately accumulate as salts in the subsealevel Asal sump, move lakeward via gravitational seepage along fractures in the a basaltic ridge aquifer separating the Red Sea from the brine lake, in what is an actively extending continental rift that will shortly become and arm of the Red Sea.

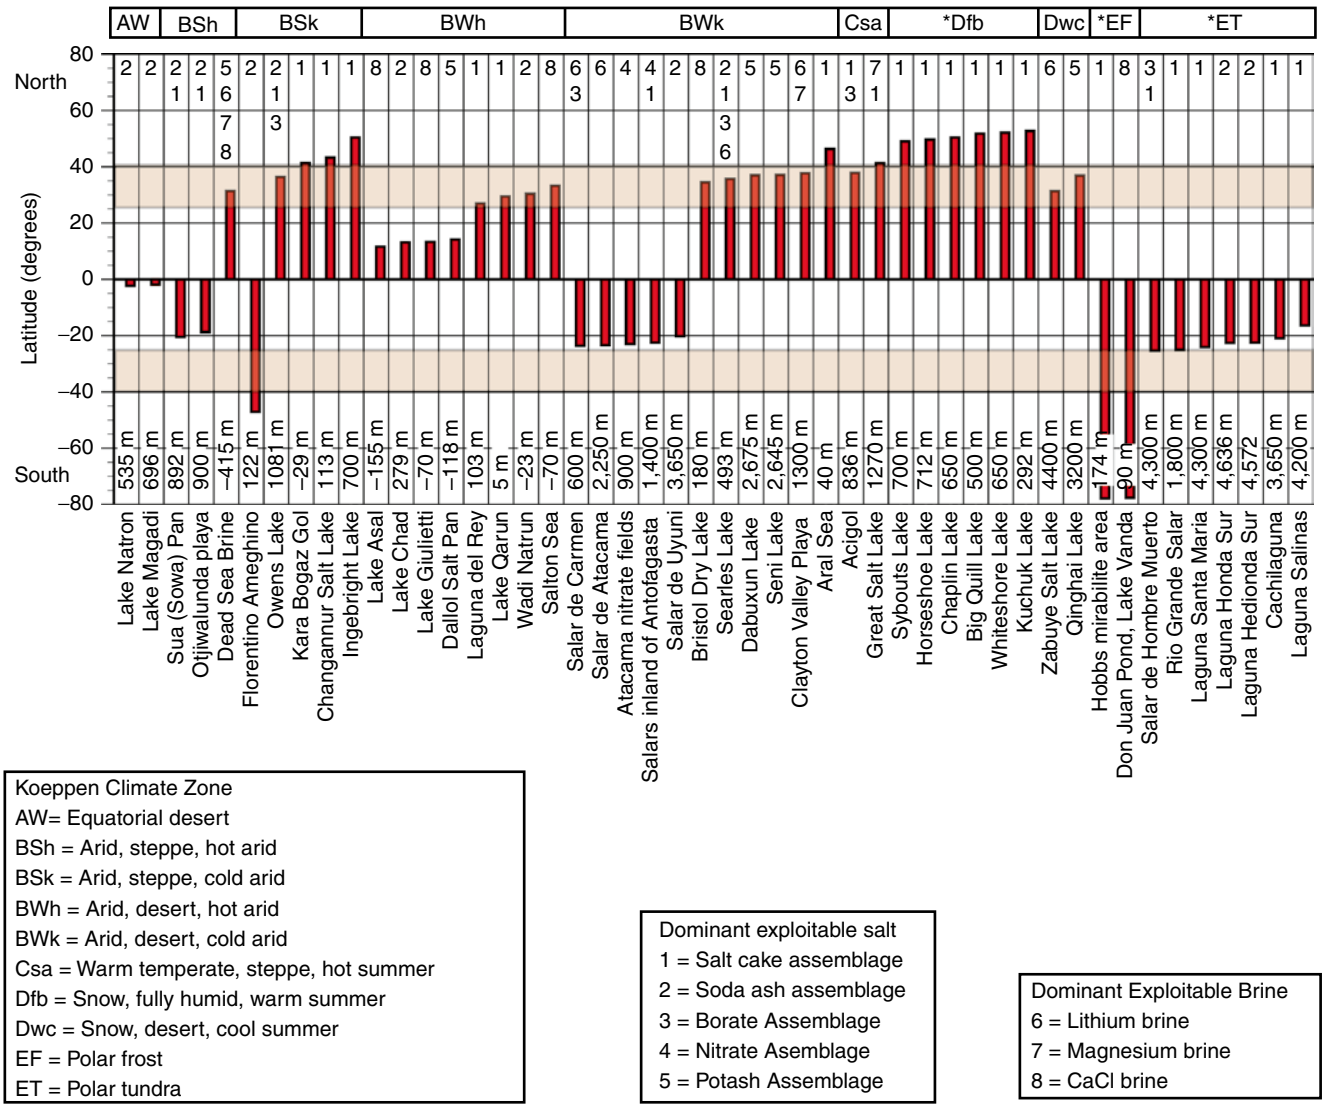

Fig. 2.7 Quaternary continental lacustrine saline deposits plotted against their latitude and Köppen climate zone (see Fig. 2.3). The brown shade indicates "horse latitude" belts situated some 25–40° north and south of the equator. Exploited or exploitable commodities are listed as a set of numeric keys for each deposit, in some lakes the exploited deposits underlie or form about the margins of the current lake/playa and indicate earlier (Pleistocene) or marginward increases in salinity (see Chaps. 11 and 12 for details). Asterisk indicates settings where cryogenic salts dominate the natural precipitates, i.e., saline lakes within the D and E climate settings (After Warren 2010)

That there are very few large marine-fed bedded Quaternary evaporite systems is illustrated by summing the total area of large active continental-fed evaporite areas (>250 km^2) listed in Fig. 2.3, which gives a total surface area worldwide in excess of 360,000 km^2. In contrast, the total area of large modern marine-fed systems, at slightly less 10,000 km^2, is more than an order of magnitude smaller. This low value for large coastal marine-fed evaporite occurrences is in part because many classic coastal sabkhas, with characteristic dispersed evaporites in their supratidal sediments and long considered to be archetypal marine-fed groundwater evaporite system, are now seen as mostly continental brine-fed hydrologies.

For example, the modern Abu Dhabi sabkha system (1,658 km^2; BWh) has been shown by Wood et al. (2005), to be a continental groundwater outflow area, where most of ions precipitating as salts in the supratidal zone are supplied by upwelling of deeply-circulated meteoric waters, not seawater flooding (Chap. 3). Similar continental hydrologies resurging into the coastal zone supply much of the salt accumulating in the suprasealevel sabkhas near Khobar in Saudi Arabia (BWh), Rann of Kutch in India (28,000 km^2, BWh), Sabkha Matti (2,955 km^2, BWh) in the Emirates, and Sabkha de Ndrhamcha (634 km^2, BWh) in Mauritania. And yet today all of these large sabkha occurrences are located just inland of modern coastal zones and so without hydrological knowl-

edge are easily interpreted as marine. This distinction between a water budget and a salt supply budget emphasizes a general observation in Holocene evaporite systems that, in order to define the main fluid carrier for the salt volume in any supratidal part of an evaporitic depression, it is important to understand and quantify the nature of the groundwater feed, be it by marine or nonmarine, in both continental-interior and marine-margin settings. It also means that surface runoff and seawater washovers, while at times visually impressive, typically do not supply the greater volume of preserved salts in a coastal sabkha system.

Due to the highly impervious nature of muddy sabkha sediment, an occasional seawater storm flood into a coastal margin mudflat does not mean the pooled seawater ever penetrates the underlying sabkha. Most of its solute load is deposited as an ephemeral surface crust of halite that is a few centimetres thick atop the sabkha muds (Wood et al. 2005). Based on Wood's and other hydrological studies of modern coastal sabkhas in BWh settings (see Chap. 3) it seems that the salt supply to most modern coastal sabkha depressions is still not at hydrological equilibrium with the present sealevel, which was reached at the beginning of the Holocene some 6,000–8,000 years ago. That is, modern zones of continental groundwater outflow along an arid coast have watertables that are up to a metre of two above sealevel and a strongly influenced by the resurgence of seaward-flowing deeply circulating, continental groundwaters (it is axiomatic that surface runoff and local meteoric recharge tend to be limited in BWh settings). In this situation resurging waters in the sabkha tend to have a dominantly continental ionic supply for their preserved salts.

Lastly, in terms of the climatic and hydrological prerequisites for the accumulations of thick bedded Holocene salt deposits, one must recognize that marine-margin sabkha mudflats do not have the same geohydrology as a near-coastal, hydrographically-isolated seepage-fed sub-sealevel salina depression. A BWh or BSk near-coastal salina is slowly but continually resupplied ions via springs fed by the effusion of seawater, moving under a gravity drive (evaporative drawdown), through an aquifer that is the barrier separating the salina depression from the adjacent ocean. Until the depositional surface reaches hydrological equilibrium, it draws continually on the near limitless supply of ions in the adjacent salty reservoir that is the world's ocean. Salts growing displacively in the supratidal parts of a sabkha cannot call on a drawdown hydrology and can only be supplied marine salts from salt spray as it is blown inland or from waters washed over the sabkha by the occasional storm driven wash-over and breakout (Warren and Kendall 1985).

So, if we based our ideas of where ancient evaporites formed on a strictly uniformitarian approach using Quaternary analogs, then the study of where bedded salts have formed best in the world over the last two million years leads to a conclusion that they are not marine fed. Rather, thick bedded salts form best in tectonically active, subsiding hypersaline groundwater sumps located in cold arid deserts. These depressions are hydrographically closed, with the purer, most voluminous, examples of 100 m-thick evaporite successions located in tectonically active piggy-back depressions with lake floors and hydrologies that are more than 2,000 m above sea level. Their hydrologies are endorheic and strongly influenced by deeply circulating meteoric waters. In addition, the best examples of thick stacked bedded salts are supplied ions via the dissolution of older marine halokinetic salts in the surrounding drainage basin.

Yet, anyone working in ancient evaporites knows from simple arguments of salt volumetrics versus brine sources, and the nature of the enclosing sediments, that they are part of a dominantly marine basin fill. All the larger examples of ancient evaporites are interbedded with or immediately underlain or overlain by marine sediments, with chemistries and mineralogies that can be directly related to the concentration of seawater. They occur in ancient continent margin or intracratonic subsealevel tectonic depressions, which were supplied large volumes of saline waters via seepage of seawater into hydrographically isolated depressions. Such deposits are known as saline giants, megahalites and megasulphates, all with areas well in excess of 10,000 km^2 (Warren 2010). These marine-associated systems have no same-scale Quaternary analogs. We shall return to the tectonic and hydrologic significance of this schism between marine and nonmarine evaporites in Chap. 5.

Local Variations in Climate

At finer climatic scales within a groundwater sump in a desert depression, local variations in effective evaporation rates influence salinity of a brine body, or pore waters in nearby mudflats/sandflats. This in turn influences mineralogy and the preservation potential of precipitated salts. Water vapour pressure over a free-standing brine decreases with increasing salinity and increases with increasing temperature (Fig. 2.8a; Bonython 1966; Calder and Neal 1984). Saturated water vapour pressure over any salt solution is always lower than the vapour pressure of pure water at a given temperature. This is due to the binding of water molecules into hydration sheaths about the various charged ions dissolved in the brine. As the concentration of a surface brine increases, the water vapour pressure decreases in the overlying air mass, reaching its lowest value when the brine is saturated (Kinsman 1976). At very high salinities the pressure difference between the brine and the air immediately above the brine can become so small that evaporation effectively shuts down and the higher salinities necessary to precipitate the bittern salts may not be reached (Fig. 2.8b; Laborde 1983).

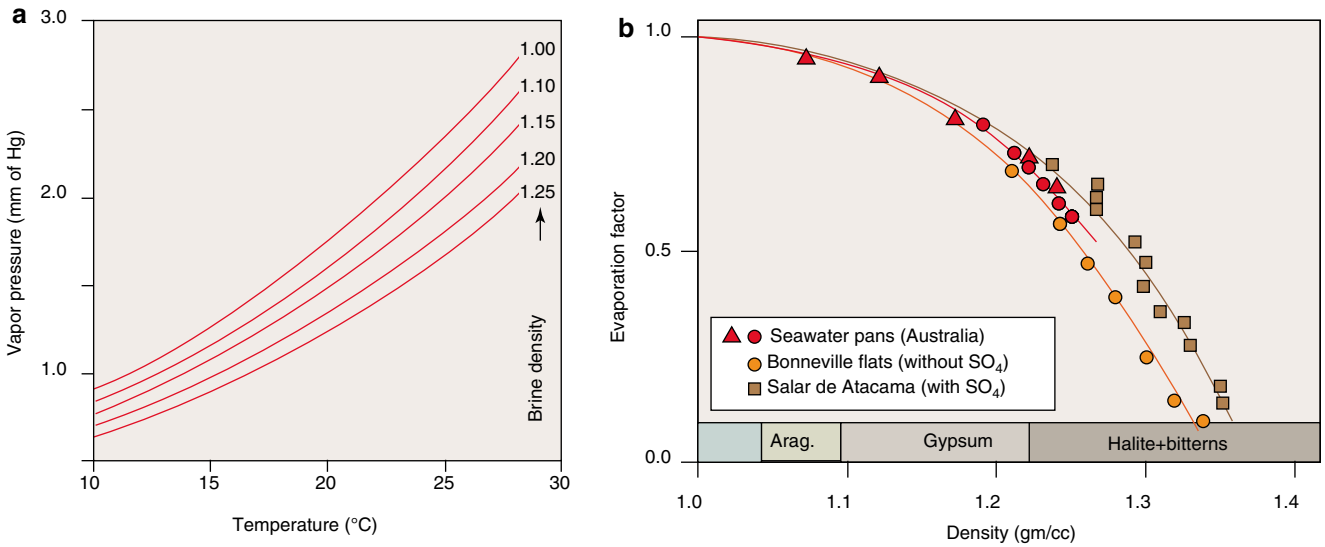

Fig. 2.8 Factors influencing evaporation rates from brine surfaces. (**a**) Salinity (brine density versus vapour pressure above a standing brine replotted from Bonython 1966). (**b**) Evaporation factor (freshwater is 1) decreases as salinity/density of the brine increases. Evaporation factor is applied to measured pan evaporation to attain a more realistic estimate. For example, a seawater brine with a salinity around 200 ‰ has an actual evaporation rate that is only 85 % (0.85) of the measured pan evaporation rate (After Myers and Bonython 1958; Laborde 1983)

Aerodynamically, the evaporation rate of a surface brine is the product of wind velocity and the difference in water vapour pressure between the main air mass and the air above the surface of the evaporating brine. Complete humidity-induced shutdowns of evaporite precipitation are rare as the air above an evaporating brine body is usually in continual motion, driven by adiabatic, catabaric and onshore breezes. Salinity of a freestanding brine is a function of wind speed, surface roughness and atmospheric stability in the air above the brine (Fig. 2.8a; Myers and Bonython 1958; Bonython 1966).

Elevated above-brine humidity and limited lateral extent (tens of kilometres) create a natural buffer to evaporation above modern coastal lakes or sabkhas. Lower salinity evaporite minerals, gypsum and halite, are the dominant precipitates in modern coastal lakes beneath humid marine air, such as the coastal pans of the Saudi Gulf coast and the coastal salinas of southern and western Australia. Gypsum with minor anhydrite is the dominant salt in both the capillary zone and the phreatic zone of most modern arid coastal hydrologies such as the sabkhas of Abu Dhabi (Kinsman 1976). Any efflorescences or crusts of bittern salts do not last long, and are recycled or washed away by occasional rainstorms and sheet floods.

The potential for humidity-induced evaporitic shutdown will have an interesting effect on the currently falling water level of the Dead Sea basin. Asmar and Ergenzinger (1999) conclude that the actual evaporation rate of the surface brines in the Dead Sea will become zero at a salinity of 483–486 g/l. As water loss can then no longer be driven by evaporation, the currently falling Dead Sea level should stabilise when currently increasing salinities reach this level (Fig. 2.9a). The evaporation rate data were calculated using a modified Penman method and were fitted as a function of salinity, where salinity (S) is in g/l and evaporation rate (E) is in mm/year. The relationship is $E = 1{,}826.1 - 1.6405S + 0.0116S^2 - 3 \times 10^{-5}S^3$ Asmar and Ergenzinger emphasize that this equation is an estimate and should be used with caution.

Intrabasin variations in temperature and effective evaporation influence the volume and mineralogy of precipitated sediments and there is often a feedback between these various factors. For example, there is a decrease in the efficiency of capillary evaporation wherever a white salt crust covers the surface of a saline mudflat. The decrease is not just related to a humidity increase in the air above the mudflat, but also to the increased albedo (reflectance) created by the white surface of the salt crust. The amount of short-wave radiation absorbed by any soil surface is largely a function of its albedo (a measure of the amount of light reflected). It varies from 0.2 (20 %) for a water saturated soil surface to 0.75 (75 %) for a salt-encrusted surface (Malek et al. 1990). A salt-encrusted mudflat on a clear calm sunny day makes use of only a quarter of the incoming energy (drives evaporation) compared to a damp crust-free seepage mudflat. For the same reason, sediment below a white salt crust will stay moister for longer in the absence of ongoing inflow/seepage.

To quantify the effects of salt crust formation on evaporation rate, Newson and Fahey (2003) conducted a series of laboratory evaporation experiments using artificial soils saturated by water with various NaCl contents ranging from freshwater to concentrations of 23 % (mass salt/mass solution).

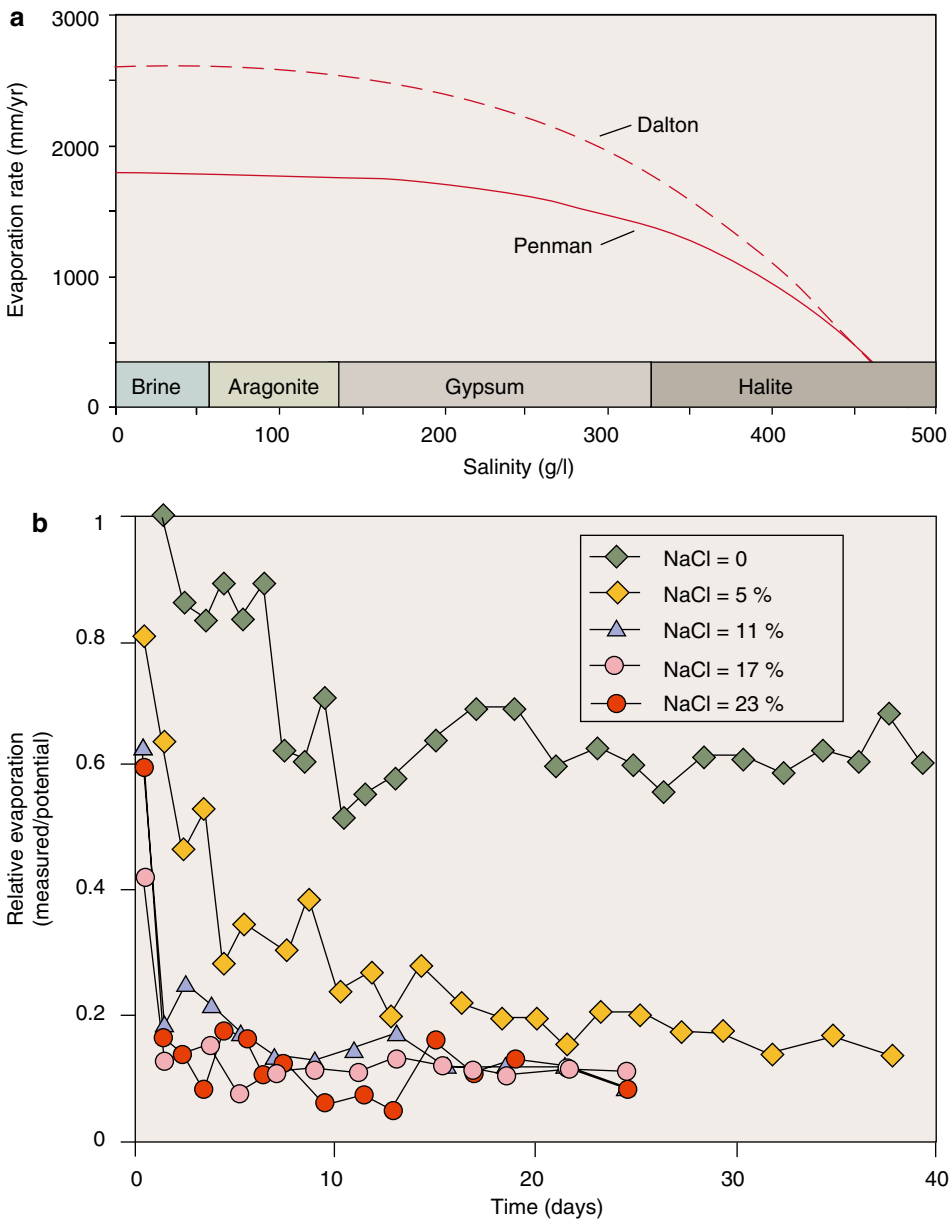

Fig. 2.9 Evaporation and salinity. (**a**) Effect of salinity on evaporation rates in the Dead Sea using the predictive formulae of Penman or Dalton (After Asmar and Ergenzinger 1999). (**b**) Effect of salt crust formation on the relative evaporation (measured evaporation rate/potential pan evaporation) with waters of variable concentration lying beneath the subaerial crust (After Newson and Fahey 2003)

Their aim was to develop an understanding of salt crust formation in order to increase the efficiency of desiccation in mine tailing dams and so improve remediation efficiency. But their results are pertinent to the hydrology of any salt-crusted mudflat. Relative evaporation (ratio of actual to pan evaporation) for the freshwater system fell to about 0.6 after about 10 days, and then remained near constant (this indicates capillary equilibrium with fresh water in pores = no salt crust). However, for all other experimental runs using saline water of varying initial concentrations, the relative evaporation ratio was much lower, and once the salt crusts had formed consistently reached values around 0.1–0.2 of potential freshwater evaporation rates (Fig. 2.9b). For the high concentration pore waters the reduction occurred almost immediately, and somewhat more slowly for the starting solution with the lowest NaCl concentration (C = 5 %). Their results indicate that even a moderate amount of salinity in any feed brine in a semi-arid to arid setting will quickly form a salt crust that severely reduces the relative evaporation rate above the crust.

Their experimental data compares well with observations made for salt-encrusted surfaces on playas and salt lakes around the world. Natural salt encrusted mudflats typically display relative evaporations of the order of 0.03–0.2, for potential evaporation rates of 1.5–3.5 m/year (Malek et al. 1990). For example, the measured effective evaporation rates above salt-free mudflats in Lake Frome, Australia range from 90 to 230 mm/year and average 170 mm/year (Allison and Barnes 1985). In areas in the same lake covered by white salt crusts the effective evaporation rate falls to 5–30 mm/year (equivalent to relative evaporation of 0.03–0.18; Ullman 1995).

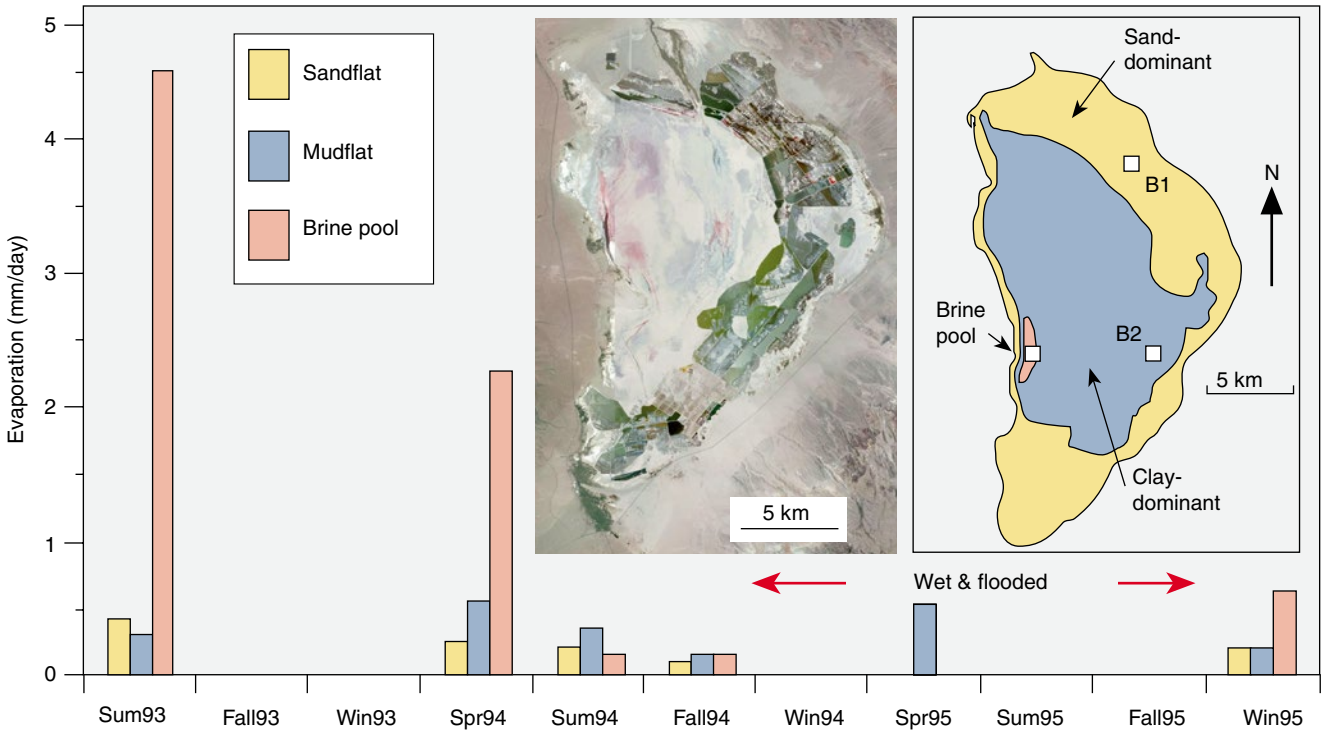

Fig. 2.10 Seasonally measured evaporation from the three dominant types of surface sediment in Owens Lake, California. Squares in the inset map show monitored sites (After Tyler et al. 1997)

Newly formed salt crusts are porous, variably buckled layers (pressure ridges and petees) that lack direct contact with the underlying sediment over at least 50 % of the crust base (Newson and Fahey 2003). Air-filled cavities reduce areas beneath the crust where capillary moisture can be transferred in a liquid phase through the salt crust to the air during evaporation. Coupled with this, the high porosity and broader pore throats in newly-formed salt crust, drastically reduces the rate of capillary rise of water compared to a clay or mud and so further reduces the liquid phase continuity to the crust/air interface. Once a crust forms, the only widespread effective mechanism for moisture transfer from the underlying mud to the overlying air mass is by diffusion in the vapour phase. This means mechanisms involved in reduction of the effective evaporation rate from any salt-encrusted mudflat are varying combinations of; (1) an increase in albedo, (2) resistance to moisture transfer and, (3) a decrease in the saturation vapour pressure of the pore fluid.

In a brine pool-entraining modern playa there is substantial cross-playa variation in effective evaporation rate depending on sediment type, proximity of the watertable to the landsurface, the presence or absence of salt crusts and the permanence of surface brine sheets. An excellent set of data illustrating this complexity was collected during 1993–1996 in Owens Lake, California using monitored lysimeters and evaporation pans (Fig. 2.10; Tyler et al. 1997). Measurements were not made during the period autumn (fall) 1994 to winter 1995 due to playa-wide flooding that marked the end of a long drought period. Rain preceded each summer and autumn measurement period in 1993 and 1994 by at least 15 days and was not significant (1 mm or less). Spring measurements may have been influenced by prior rainfall, with 3 mm falling 1 day before the 1994 measurements and 19 mm falling 21 days before the 1995 measurements.

Figure 2.10 plots the averaged daily evaporation rate as a function of season of measurement from the three study areas in Owens Lake (sandflat, mudflat and free surface brine; Tyler et al. 1997). Evaporation from the sandflat appears to steadily decline from initial measurements in summer 1993 to autumn (fall) 94 and may reflect the prolonged drought and subsequent decline of the watertable in this area. In contrast, evaporation from the salt-crusted mudflat shows similar summer rates in 1993 and 1994. The insensitivity to drought in these saline clayey soils may be related to the continued high water contents maintained by capillary rise to elevations well above the watertable. The mudflat site also shows highest evaporation rates during spring periods (0.5 mm day^{-1}), when near-surface soil moisture is at its highest level. During these periods, the overlying salt crust is less desiccated and so may also maintain better hydraulic contact with the underlying sediments.

Malek et al. (1990) postulated that loss of hydraulic contact between lake sediment and an overlying salt crust impedes capillary evaporation loss by effectively forming the equivalent to

a mulch layer over the clayey substrate. During both spring measurement periods in Owens Lake, no decline in evaporation rate was observed throughout the period of measurement, suggesting that rain before the measurement dates had little influence on the evaporation rates. Winter evaporation rates were slightly higher than those recorded during the autumn months, although they are similar. The winter measurement period was characterized by warmer than average daytime temperatures, which may have slightly increased the evaporation rates. However, wind conditions were uncharacteristically calm, with maximum daily wind speeds rarely exceeding 1 m s^{-1}, which may have reduced the evaporative flux.

Rates measured in the brine pool in spring 1994 were below those in the previous summer, owing to lower temperatures and decreased net radiation (Tyler et al. 1997). However, evaporation in the brine pool area in the following summer and autumn of 94 were much lower than expected for a free-standing saline water body. The dramatic reduction in evaporation in 1994 was due to a thin (less than 2 mm) floating crust of halite rafts that covered the entire extent of the brine pool. Both periods of measurements in the brine pool were characterized by calm conditions, which allowed the crust to remain intact and effectively cut off evaporation. Winter evaporation rates over the raft-covered brine pool averaged 0.6 mm day^{-1}, almost an order of magnitude below that measured during the raft-free summer of 1993. Rafted crusts are a part of the evaporation setting of most halite-saturated brine pools/sheets and are another reason why brine sheets remain for extended periods in some salt lakes. Surface water sheets in nearby less saline raft-free lakes tend to dry much more quickly. Rafts generally break up and sink or are washed to the lake shore during windy periods.

Yearly estimates of groundwater evaporation from the three dominant surface areas in Owens Lake (sandflat, mudflat, brine pool) were calculated by Tyler et al. (1997) using the data shown in Fig. 2.10. Yearly average evaporation was taken as the arithmetic average of the four seasonal rates for each area. For both the sandflat and mudflat areas, autumn rates were well below those measured in the spring, implying that evaporation is more strongly controlled by groundwater conditions rather than potential evaporation rates above the sedimentation surface. Groundwater levels tend to decline in late summer and autumn, owing to evaporative demand, and therefore it is conceivable that winter rates, when the water-table is nearer the lake floor, may actually exceed autumn rates. The coincidence of a prolonged drought (1993 to fall 1994) with the main measurement period appears to have affected evaporative flux in both the sandflat area and the brine pool. Consecutive summer measurement of evaporation at both these sites showed a considerable decrease owing to drought conditions. For this reason, summer evaporation rates from 1993 were considered more representative and used to estimate the yearly evaporation from the sandflat to produce a more representative average annual evaporation. At the brine pool site, autumn rates were assumed to be equal to those measured in spring 1994, when open raft-free water was extensive. Using this approach, the seasonally adjusted annual evaporation rate from the sand-dominated areas was $\approx 88 \pm 22$ mm $year^{-1}$. Clay–salt crust-dominated (sabkha) regions in Owens Lake have an evaporation rate $\approx 104 \pm 26$ mm $year^{-1}$. Yearly evaporation from the brine pool surface was $\approx 872 \pm 218$ mm $year^{-1}$ although this is substantially less whenever a cover of salt rafts floats at the air-brine interface. The crust lowers the actual evaporation rate so much that the halite-precipitating brine pool remains as a perennial feature in the lake's sump (Groeneveld et al. 2010).

In a similar study Kampf et al. (2005) estimated the level of evaporation in across the central halite nucleus of Salar de Atacama, Chile. They found measured values of net all-wave radiation were highest at vegetated and rough halite crust sites and lowest over smooth, highly reflective salt crusts (greater albedo). Over most of the Salar de Atacama, net radiation was dissipated by means of soil and sensible heat fluxes.[2] Dry salt crusts tended to heat and cool very quickly, whereas soil heating and cooling occurred more gradually at wetter vegetated sites. Sensible heating was strongly linked to wind patterns, with highest sensible heat fluxes occurring on summer days with strong afternoon winds. Very little energy available at the land surface was used to evaporate water. Eddy covariance measurements could only constrain evaporation rates to within 0.1 mm/day, and some measured evaporation rates in the halite nucleus were less than this margin of uncertainty (Fig. 2.11). Evaporation rates ranged from 0.1 to 1.1 mm/day in smooth salt crusts around the margin of the salar and from 0.4 to 2.8 mm/day in vegetated areas. No evaporation was detected from the rugged halite salt crust (halite nucleus) that covers the interior of the salar, even though the depth to groundwater across this zone is less than 1 m in this area. These crusts therefore represent a previously unrecorded end member condition in a hypersaline groundwater sump in which the salt crusts form a practically impermeable barrier to evaporation (Fig. 2.11). The significance of this hydrology to the various textures seen in the crusts is discussed further in Chap. 3.

The combination of all local climatic effects, as discussed in this section, helps explains why high salinities needed to precipitate primary bittern salts are unlikely in most modern marine-fed and continental interior hypersaline settings. To produce and accumulate primary bittern salts, like carnallite, sylvite and kieserite, to where they constitute a bed rather than an efflorescent crust, requires a degree of aridity so extreme that it is difficult to envision it forming in the relatively humid climatic coastal conditions in any modern

[2]Sensible heat flux is the heat energy is transferred from the Earth's surface to the atmosphere by conduction and convection.

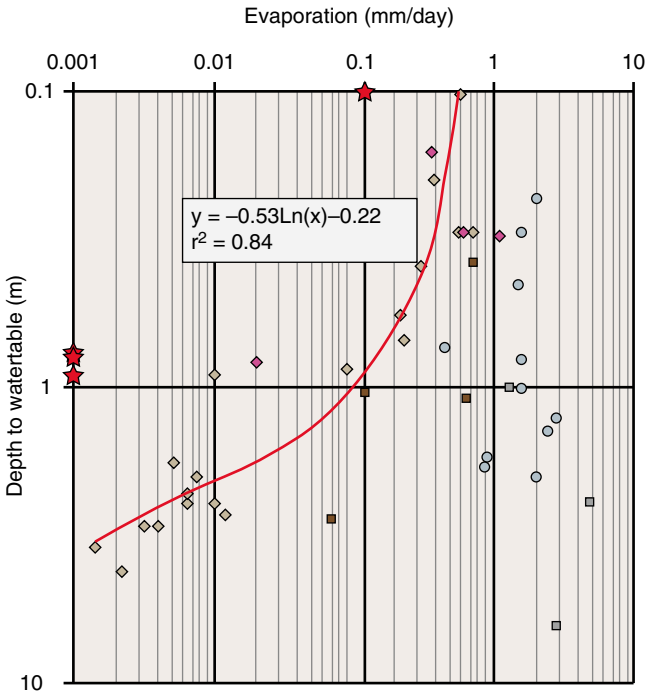

Fig. 2.11 Evaporation vs. depth to watertable for Salar de Atacama, Chile, compared with measurements at other salt flats and from bare soils (After Kampf et al. 2005). *Diamonds* and *red circles* represent playas or salt flats and saline lakes; *squares* represent vegetated areas, *grey circles* represent bare agricultural soils. *Red stars* represent data from Salar de Atacama, *stars* are plotted along 0.001 mm/day axis to conform to the logarithmic scale, but were actually were so low as to be not measurable. Likewise, the *star* plotted as point on 0.1 m depth axis (logarithmic scale) actually corresponds to 0 m depth (watertable at surface). The *red line* represents a logarithmic fit (with equation) for the playa data

marine-fed arid setting and even contemporary continental instances are rare. Carnallitite is a precipitate in saltwork pans of the Dead Sea where it is the end result of anthropogenic management of fractionated brines (Fig. 11.25). The only substantial natural Holocene potash accumulation in the world today is a syndepositional karst fill in bedded halites of the Qaidam Basin of western China, located some 1,500 km from the nearest ocean. Even there, the potash ultimately comes from reworked basinal brines that flush subcropping Plio-Miocene potash evaporites (Chap. 11). One must go to pre-Quaternary megahalite settings to understand how a widespread potash bed can accumulate with a lateral extent measured in tens to hundreds of kilometres and thicknesses measured in metres (Chaps. 5 and 11).

Chemical Evolution of Surface and Nearsurface Brines

Until recently, most geologists assumed ancient marine evaporites were precipitated from seawater brines with chemical make-ups very similar to that of today. Now, there is a growing body of evidence that the ionic make-up of Phanerozoic seawater has varied to where magnesium sulphate was not always a dominant bittern precipitate. In modern seawater bitterns, it is. As well, varying intensities of evaporite dissolution, dolomite precipitation and hydrothermal flushing contributed varying ionic proportions to the brine feed of ancient salt systems (Hardie 1984, 1991). This leads to a dilemma in deciding what is marine, what is nonmarine and what is a hybrid brine, based on mineralogical suites found in ancient bedded evaporites.

Marine Brines

Today the chemical make-up and the proportions of the major ions in seawater are near constant in all the world's oceans. Seawater is dominated by Na and Cl, with lesser amounts of SO_4, Mg, Ca, K, CO_3 and HCO_3. Using the brine classification of Eugster and Hardie (1978), modern seawater is a Na–(Mg)–Cl–(SO_4) water, with a density of 1.03 g/cc and a salinity of 35 ± 2‰. When seawater evaporates, a predictable suite of primary evaporite salts crystallise from increasingly concentrated hypersaline waters (Fig. 2.12; Table 2.4). The sequence of marine precipitates was first documented by Usiglio (1849), while later work by Carpenter (1978) and McCaffrey et al. (1987) focused on the details of the evolving chemistry of the residual bitterns as the various supersaline salts precipitate (Fig. 2.12a).

As seawater concentrates, the first mineral to precipitate is $CaCO_3$, usually as aragonite. This begins in mesohaline waters where the brine reaches twice the concentration of seawater (40–60‰) and achieves a density ≈1.10 g/cc. As the brine continues to concentrate and approaches four to five times the concentration of seawater, that is 130–160‰, gypsum precipitates from penesaline waters with densities around 1.13 g/cc (Figs. 2.12b and 2.13a, b). At 10–12 times the original seawater concentration (340–360‰) and densities around 1.22 g/cc, halite drops out of supersaline marine waters. After halite, the bittern salts (potassium or magnesium sulphates/chlorides) precipitate from supersaline waters at concentrations that are more than 70–90 times that of the original seawater. Carnallite and epsomite are the dominant bittern precipitates from modern marine brines (Fig. 2.12c). Brine density by this stage of concentration is in excess of 1.30 g/cc and brine viscosity and feel approach that of olive oil (Fig. 2.13b).

Modern coastal lagoonal systems do not naturally attain high salinities until the surface (hydrographic) connection to the ocean is lost and they evolve into marine-seepage groundwater sinks (Fig. 4.8). Brines then evolve into mesohaline to penesaline waters with seawater-like (thalassic) ionic proportions (Table 2.5).

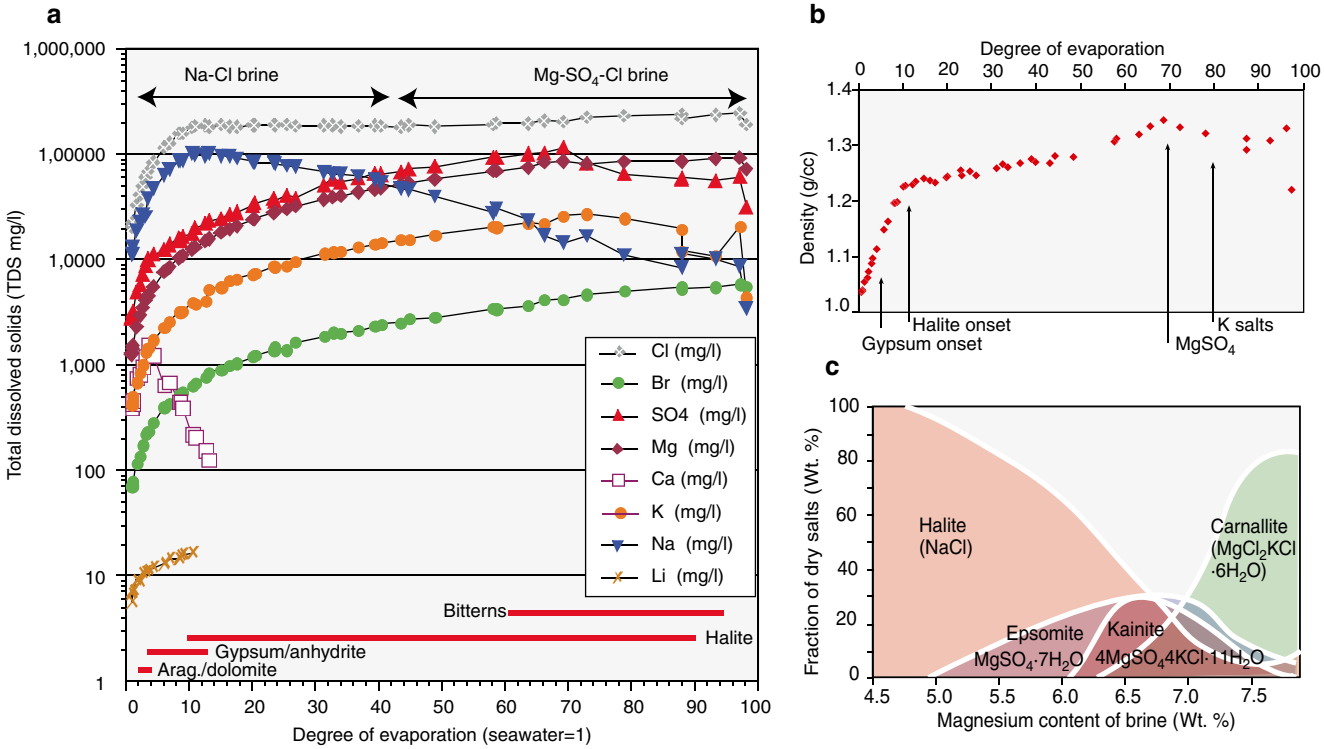

Fig. 2.12 Marine hydrogeochemistry. (**a**) Changes in ionic proportions due to sequential precipitation of aragonite, gypsum, halite and bittern salts as modern seawater is evaporated to 100 times its original concentration (in part After McCaffrey et al. 1987). (**b**) Evaporation pathway of modern seawater showing how density increases and the proportions of various ions in solution change as the brine concentration increases (Recompiled from data in appendices in McCaffrey et al. 1987). (**c**) Sequential precipitation of potash bitterns from modern seawater plotted against increasing Mg content in bittern (After Garrett 1970a)

Table 2.4 Salinity based classification of mineral paragenesis and brine properties based on concentrated seawater

	Brine stage	Mineral precipitate	Salinity (‰)	Degree evap.	Water loss (%)	Density (g/cc)
Sea	Normal marine or euhaline	Skeletal carbonate	35–37	1×	0	1.040
Hypersaline	Mesohaline or vitahaline	Alkaline earth carbonates	3–40	1–4×	0–75	1.040–1.100
	Penesaline	$CaSO_4$ (gypsum/anhydrite) $CaSO_4 \pm$ Halite	140–250 250–350	4–7 7–11×	75–85 85–90	1.10–1.214 1.214–1.126
	Supersaline	Halite (NaCl) Bittern salts (K-Mg salts)	>350 Extreme and variable	>11× >60×	>90 ≈99	>1.126 >1.290

Hypersaline is defined as >35‰. Biologists working in saline waters use a somewhat different classification of; fresh water (less than 1‰), subsaline (1–3‰), hyposaline (3–20‰), mesosaline (20–50‰), and hypersaline (greater than 50‰). Geohydrologists tend to refer to fresh water as less than 1‰, brackish water as 1–10‰, saline water as 10–100‰, and brine as greater than 100‰

Ongoing evaporation of seawater produces two types of high density, high viscosity brine: Na-Cl brines and Mg-Cl-SO_4 brines. Na-Cl brines dominate in the salinity range 35–330‰. Brines become progressively dominated by Mg-Cl-SO_4 at higher salinities, indicating preferential removal of Na by halite precipitation. At first, Mg is the dominant cation in the bittern brines, but as the various $MgSO_4$ bitterns crystallise its place is taken by K. Chlorine remains the dominant anion throughout the evaporation sequence (Fig. 2.12a).

Much of the field and laboratory work done on evaporating water has been done in closed conditions. Usiglio (1849) simply took a container of seawater and monitored its progress as he evaporated it to complete dryness. McCaffrey et al. (1987) studied the evolution of seawater in a series of man-made salt ponds in the Bahamas and supplemented this with laboratory work at higher salinities and densities not found in the ponds, as did Laborde (1983). Ideally, after depositing gypsum and halite, supersaline seawater evaporated to complete dryness

deposits a predictable suite of Mg and K sulphate minerals, with the majority of the salt volume dominated by halite (Fig. 2.13a; Usiglio 1849). The most problematic endgame in this evolving marine brine system is predicting what will be the bittern salt sequence (Fig. 2.12c). This is especially obvious when one tries to compare the suite of bittern salts seen in ancient marine evaporites to modern bittern; there are obvious discrepancies related to brine leakage, backreaction and evolving Phanerozoic seawater chemistries. As we shall see in the following discussion, these problems can be addressed at varying levels of chemical, hydrological and chronological complexity. In the end, many of the discrepancies can be related to the simple statement, "In nature, there is no such thing as a totally closed, static system."

Chemical Composition and Phase Chemistry

One of the first to attempt to deal with the chemical discrepancies between a modern seawater precipitation suite and the

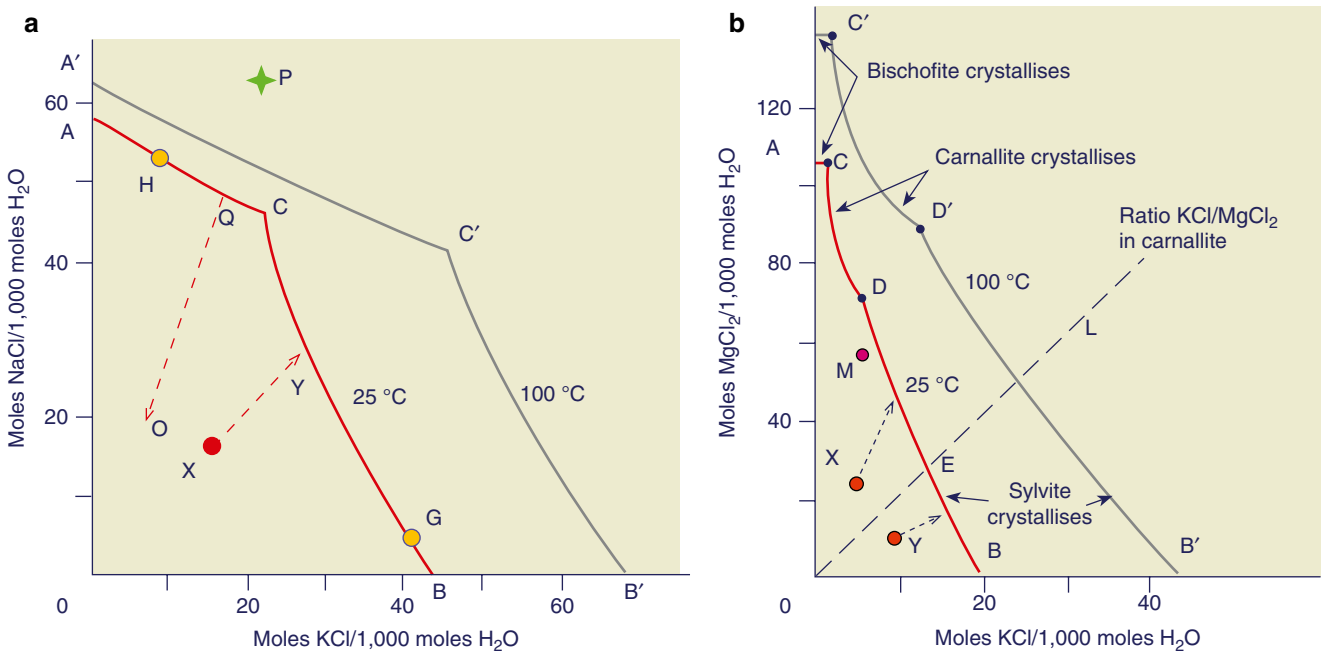

Fig. 2.14 Van't Hoff plots. (**a**) Crystallisation of solutions containing NaCl and KCl at 25° and 100 °C. (**b**) Crystallisation of solutions containing $MgCl_2$ and KCl at 25° and 100 °C

bittern suite, as seen in the Permian Zechstein salts of the Stassfurt β, was Van't Hoff, a nineteenth century German chemist. He reasoned that the best way to study evaporites was to start with a simple solution of two salts and add components one by one, studying the behaviour of the various mixtures at each stage of the experiment. From this work he formulated a series of rules of behaviour for salts in concentrated brines.

- If two salts are in solution, precipitation depends on the relative solubilities of the salts and their concentrations.
- If two salts have a common ion, the solubility of each in a solution of the other is less than in pure water.
- If two salts do not have a common ion, the solubility of each in the other is greater than in pure water.
- Solubility is markedly influenced by increases in temperature, much less so by pressure.

When studying bittern evolution the phase diagrams Van't Hoff developed experimentally are still useful today. Consider a KCl-NaCl system at 25 °C and 100 °C, this is an example of a salt pairs with a common ion (Fig. 2.14a; Borchert and Muir 1964). Points A and B represent solubilities in pure water at 25 °C. Points G and H represent the solubilities in 1:10 NaCl-KCl solution and 10:1 NaCl-KCl solutions, respectively. Point C represents the point at which the mixture is saturated with respect to both NaCl and KCl salts. Any point below line ACB is undersaturated at 25 °C, above it is saturated with the solid salt. Let's now consider the effects of crystallisation and dissolution in this simple system. With concentration, a solution of composition X moves away from the origin until reaching the line ACB at Y, where KCl precipitates (Fig. 2.14a). The ratio of NaCl/KCl increases as the solution composition moves along line Y-C (less water, less KCl in brine as NaCl increases). At C, both salts precipitate until dryness. With dissolution, a mixed salt of composition F remains solid until sufficient water has been added to begin its dissolution. At that point both KCl and NaCl begin to dissolve (point C). When all KCl has dissolved some NaCl remains and the composition shifts along C-Q as NaCl continues to dissolve. At Q the final NaCl dissolves and continued dilution moves the composition of the solution toward the origin along line Q-O.

Figure 2.14b is the Van't Hoff plot of the KCl-$MgCl_2$ system, an example of a salt pair with a common ion forming a double salt. In addition to the two end members (bischofite and sylvite) it has an intermediate double salt $KCl{\cdot}MgCl_2{\cdot}6H_2O$ (carnallite). Points A and B represent saturation with $MgCl_2{\cdot}6H_2O$ (bischofite) and KCl (sylvite) respectively. The dashed line 0-L shows the ratio of KCl to MgCl in carnallite. When a dilute solution of composition X is evaporated its composition shifts directly away from the origin until encountering line ACB. At the intersection point sylvite begins to crystallize and continues to crystallize as the composition of the solution shifts along line B-D, well below the composition of the double salt. Only when the solution has reached composition D does carnallite appear. At this point the composition of the solution remains fixed as carnallite

crystallizes, both directly out of solution and by partial reaction of dissolved ions with some of the previously precipitated KCl. The resulting solid is a mixture of carnallite and sylvite.

Or with a more KCl-rich initial solution of composition Y, as it concentrates it moves away from the origin until it intersects line ACB where sylvite once again begins to crystallize. It continues to crystallize as the composition of the solution moves up along B-D. At D, carnallite begins to crystallize as the sylvite is used up. If evaporation continues, the composition of the solution now moves along line D-C until it reaches point C, where bischofite crystallizes, along with carnallite. The composition of the solution now remains constant until evaporation is complete.

We can also use this Van' Hoff plot to visualise how carnallite dissolves in this simple system. We begin with carnallite, which has an initial composition D. Since this solution is much richer in $MgCl_2$ it is preferentially dissolved (it lies to the left of the dashed line EL) Once all the carnallite has dissolved, the net result is a solid residue of KCl (sylvite) (incongruent dissolution). Further solution of the residual will move composition of the solution down along line D-B. When it reaches E, the last of the sylvite is dissolved, and further dilution shifts the composition along line E-0 (origin).

So, we can describe the section of the saturation line B-D as the 'sylvite region', since here KCl alone is in equilibrium with saturated solutions; CD is the 'carnallite region', and CA the 'bischofite region'. Point C represents the composition of a saturated solution in equilibrium with both bischofite and carnallite, point D the composition in equilibrium with both carnallite and sylvite. Note that point D differs from point C in that during evaporation it can be approached from only one side, the KCl side, whereas C can be approached from either the carnallite or bischofite side. In other words the bittern precipitation sequence sylvite followed by carnallite, carnallite followed by a bischofite-carnallite mixture, or bischofite followed by a bischofite-carnallite mixture are possible, but never carnallite followed by sylvite.

If two salt pairs do not have a common ion they form a reciprocal salt pair such as a KCl-$MgSO_4$ system. In an evolved seawater brine it is possible to have four end members plus any number of intermediate double salts. Rather than depicting such a system as this on a simple Van't Hoff binary plot, it becomes necessary to use a ternary diagram. A ternary plot of reciprocal salts is handy, as fixing the relative concentration of three of the four ions also fixes the fourth, providing the system is at equilibrium. This is the basis for seawater ionic reconstructions in many micro-inclusion studies in halite. The most commonly used type of ternary plot in evaporite bittern studies is a Jänecke Diagram (Fig. 2.15). In many respects it is analogous to the ternary diagrams used in igneous and metamorphic petrology where plotting of two components fixes the relative proportion of the third component and it is very useful in the interpretation of brine inclusion chemistry (Zimmermann 2001).

Evaporation on a Jänecke plot is represented by the reciprocal salt pair $MgCl_2$-K_2SO_4. The solution remains saturated with NaCl at all times and thus this ubiquitous component can be ignored.

The corners of the diagram are represented by:

- Mg^{2+} = 100 % bischofite ($MgCl_2 \cdot 6H_2O$)
- K_2^{2+} = 100 % sylvite (KCl)
- SO_4^{2-} = 100 % thenardite (Na_2SO_4)

Points along the triangle edges are pure salts with only two end members:

- c = carnallite $KCl.MgCl_2 \cdot 6H_2O$
- ks = kieserite $MgSO_4 \cdot H_2O$
- hx = hexahydrite $MgSO_4 \cdot 6H_2O$
- bl = bloedite $Na_2Mg(SO_4)_2 \cdot 4H_2O$
- gl = glaserite $K_3\ Na(SO_4)_2$
- e = epsomite $MgSO_4 \cdot 7H_2O$

Points within the triangle contain end members such as:

- k = kainite $KMgClSO_4 \cdot 11/4H_2O$
- p c = picromerite $K_2Mg(SO_4)_2 \cdot 6H_2O$

If the bulk composition lies within the field, the fields represent the composition of the first salt to precipitate. However, the point representing the actual salt composition often lies outside the field where the ideal salt would precipitate. This is analogous to the previous binary Van't Hoff plots in which point F (carnallite composition) lay far outside the "carnallite region."

In the evaporation of seawater, the average seawater composition is represented by point A on Fig. 2.15. This point lies in the bloedite field. Thus, bloedite is the first bittern mineral to crystallize. As bloedite crystallizes the composition moves away from point A along a line, which is a projection of the bloedite compositional point projected through point A. At B (seen in the expanded part of the plot) there are two possible pathways:

(i) If bloedite has settled out and does not react further, epsomite begins to crystallize and the composition of the salt solution migrates across the epsomite field to point C, the path of migration from point B to C is a projection through B to the epsomite point on the triangle edge. Or (ii) if bloedite is free to backreact with the solution, then crystallisation takes a different path. The composition of the solution shifts along line B-D with bloedite being consumed as epsomite forms. At D, the last of the bloedite

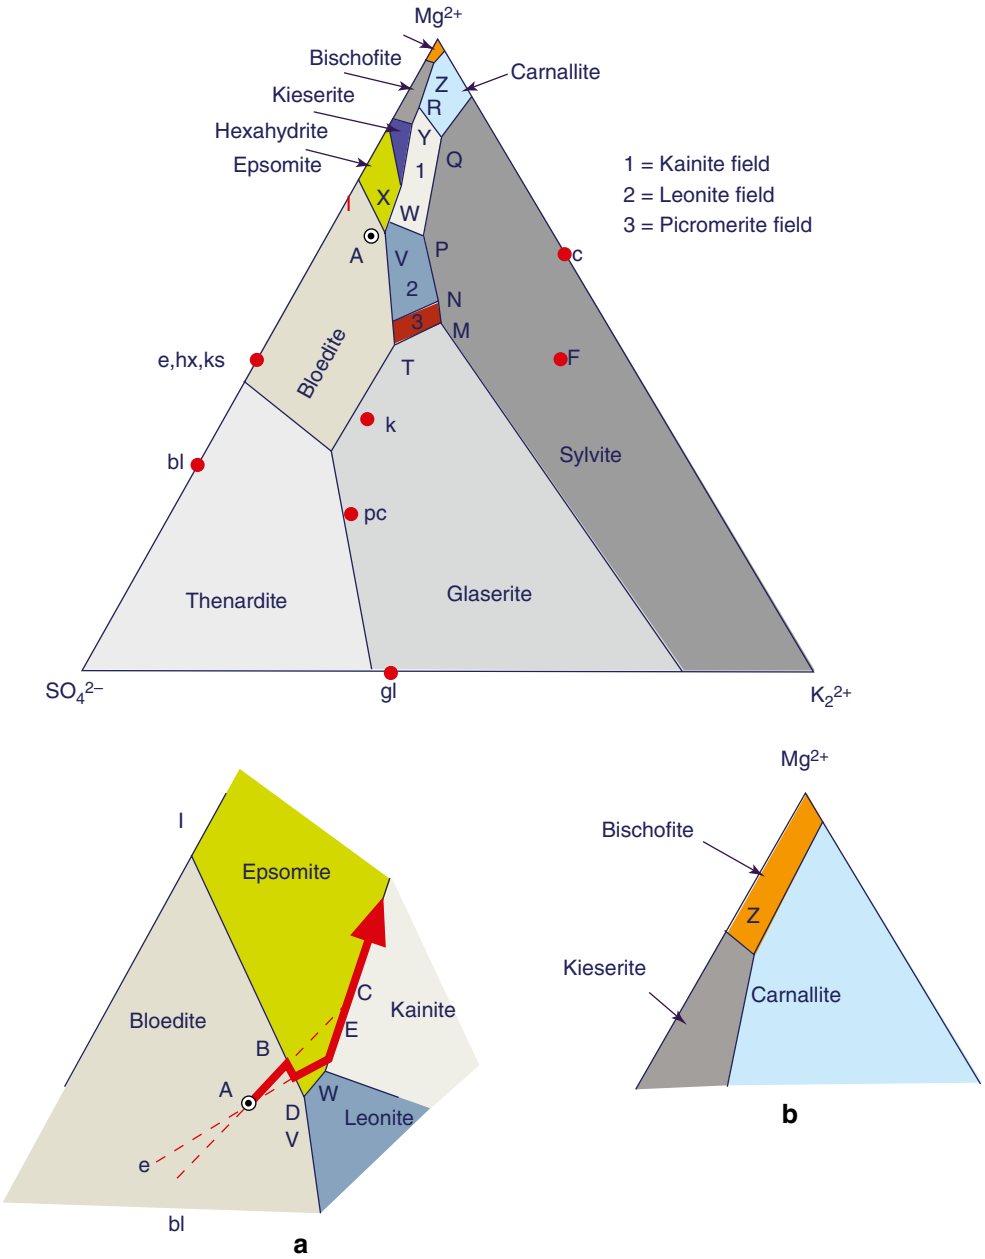

Fig. 2.15 Jänecke diagram for system $NaCl{\cdot}MgCl_2{\cdot}Na_2SO_4{\cdot}H_2O$ at 25 °C. Salt points: *c* carnallite, *bl* bloedite, *gl* glaserite, *e* epsomite, *hx* hexahydrite, *ks* kieserite, *k* kainite, *pc* picromerite. Point A defines the composition of seawater. (**a**) enlargement near I to show part of the crystallisation path of seawater; (**b**) shows detail of the Mg corner

disappears. At this point the composition of the solution is free to migrate through the epsomite field to point E, which is a projection from the epsomite compositional point at the edge of the triangle through D.

At either point C or E kainite begins to crystallize with epsomite (two-phase boundary) and the composition of the solution moves along the kainite – epsomite boundary. At X, epsomite becomes unstable with respect to hexahydrite. It reacts in the same way, consuming earlier precipitates or not, depending on how isolated precipitates are from the evolving brine. With further evaporation the composition of the solution moves along the kainite-hexahydrite boundary and both crystallize simultaneously. At Y, hexahydrite becomes unstable with respect to kieserite. At R, kainite becomes unstable with respect to carnallite. Thus, we have kainite and kieserite remaining when we leave point R. If concentration continues (we are now well into the bittern field) we move to Z, where we reach a three-phase boundary. Bischofite begins to crystallize with carnallite and kieserite. The solution remains at this point until dryness.

If equilibrium is maintained so that earlier salts are reabsorbed (backreacted) during ongoing crystallisation, the final product should be only three salts (bischofite, carnallite and kieserite), plus halite, plus small amounts of some calcium salts. If equilibrium had not been maintained other salts

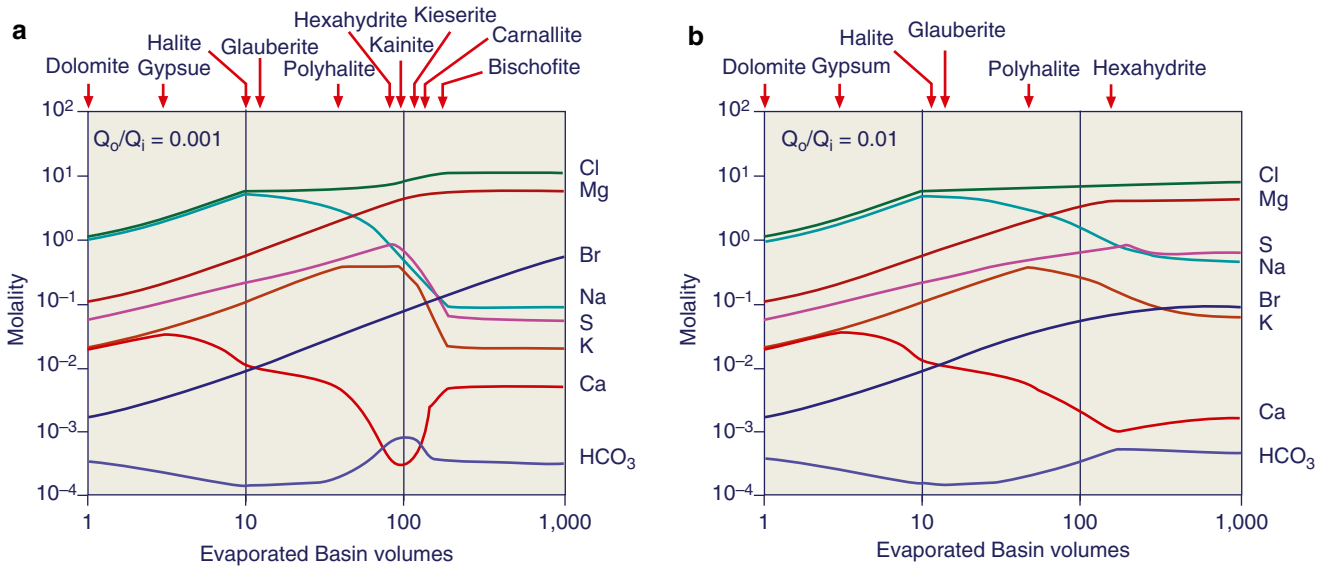

Fig. 2.16 Effects of varying levels of basin leakage on ionic proportions and the precipitated mineral suite with a seawater parent brine and measured as a function of the number of evaporated basin volumes (After Sanford and Wood 1991). (**a**) Leakage ratio of 0.001 (≈ closed basin) shows bittern precipitation. (**b**) Leakage ratio of 0.01, the system never reaches the upper end of the bittern field

could be present, but they should be layered in a vertical sequence predicted by the crystallisation path.

The problem with all this nineteenth-century laboratory-based bittern phase chemistry is that the prediction rarely matched the reality. For example, polyhalite is an abundant component in the Stassfurt Salt of the Permian Zechstein. This was the salt bed that formed the test case for much of Van Hoff's and Jänecke's work, yet polyhalite did not appear in Jänecke's plot. One reason for its absence is our inability to precipitate polyhalite from seawater in the laboratory at earth surface temperatures. Little was known about the stability of polyhalite. Where we do find it in the Holocene is as a replacement of gypsum in zones of mixing between marine brines and continental groundwaters (as in the shallow subsurface of the Ojo de Liebre saltflats, Baja California, Mexico, Pierre 1985). According to the marine brine evolution predicted by the Jänecke plot of seawater, kainite should be absent, or present only in the lower portion of the Stassfurt Salt. Yet, in reality it occurs near the top of the Stassfurt bed and is the dominant primary marine bittern in the Danakil, Ethiopia. Unusual salts, such as loeweite, picromerite, vanthoffite and langbeinite, should not be present at all, yet they are not uncommon in the Stassfurt. A sylvite-kieserite assemblage is forbidden by the phase diagram, but is present in the Stassfurt.

In order to explain some of these problems Van't Hoff suggested that the temperature at the time of salt formation in the Zechstein Basin was as high as 83 °C. This explained some of the unusual mineralogies and the sylvite-kieserite association. If the temperature drops to 55 °C near the end of the deposition, it allows kainite to be present near the top of the Stassfurt. Geologists found his suggestion of temperatures close to boiling in surface evaporite environments, cooling to 55 °C at the end of a cycle, a little unlikely. Jänecke proposed that the high temperatures suggested by Van't Hoff were diagenetic and had developed during burial (Borchert and Muir 1964). He proposed that the problematic polyhalite had formed by secondary alteration as calcium-bearing brines reacted with kainite (addition of calcium, subtraction of chlorine) and that most sylvite formed by incongruent solution of carnallite (loss of magnesium). The more unusual salts, he argued, represented high temperature burial metamorphism. Harvie et al. (1980) recalculated the order of onset for the marine bittern salts in the Zechstein as: glauberite, polyhalite, epsomite, hexahydrite, kieserite, carnallite, bischofite (Fig. 2.16a). They concluded that the type of bittern salt and the salinity at which it precipitates varied according to temperature and levels of impurities in the residual brines.

In reality, hydrology of the system is more significant than idealised chemistry in controlling bittern evolution. Brine leakage, mixing with freshened recharge about the basin's margin and the influence of humid air layers lingering above the brine body mean a standing body of modern seawater-derived brine liquor rarely moves to the bittern stage in a single primary desiccation cycle. Sanford and Wood (1991) modelled the changes in fluid composition and the sequence of primary salts that would precipitate under a leaky brine hydrology where bottom brine slowly discharges through underlying sediments (leakage via brine reflux). They found that the leakage ratio (ratio of water outflow to inflow) has a profound effect on both the evaporite mineral

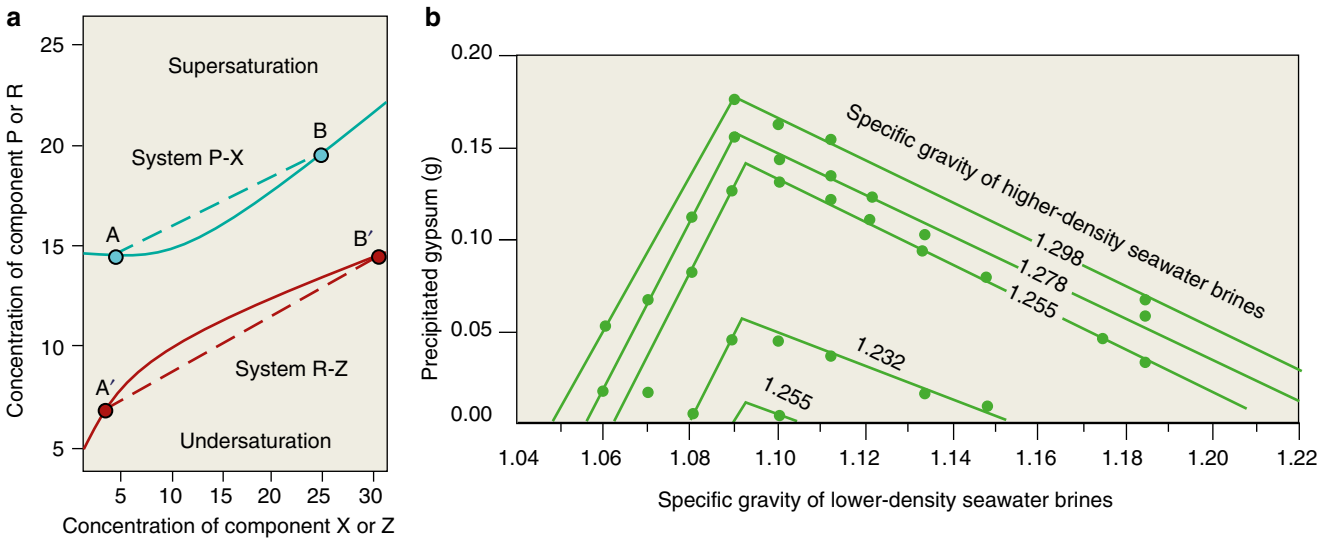

Fig. 2.17 Brine mixing. (**a**) Schematic showing effects of brine mixing on supersaturation in two styles of saturation curves – component system P-X and component system R-Z. Solid lines shows equilibrium saturation curve for their respective systems, while the dashed lines are the mixing lines. When solutions A and B mix in system P-X, the resulting solution is supersaturated and liable to precipitate. When solutions A′ and B′ mix, the resulting solution is undersaturated and liable to drive dissolution of the component of interest. (**b**) Amount of gypsum (in grams) precipitated by mixing of 50 ml each of two seawater brines in various concentrations at 25 °C (After Raup 1982)

suites precipitated and the thickness (or volume) of a deposit (Fig. 2.16). A system with a leakage ratio of 0.001 (that is, a 1× volume of water escapes from the basin for every 1,000× volumes of inflow), the resulting salt evolution sequence is near identical to that of a completely closed system, as first documented by Usiglio (1849). However, with leakier systems there are significant reductions in the maximum salinities that the surface brines can attain and it is increasingly difficult to reach salinities sufficient to precipitate upper-end bittern salts. With a leakage ratio of 0.01 the final brine composition, reached after about 600 basin volumes have evaporated, has higher Na, K and SO_4 compositions and the four most soluble salts, kainite, kieserite, carnallite and bischofite, are not present (Fig. 2.16b). This is reflected in the geological reality that textures in most natural bittern salts, such as carnallite and sylvite, indicate near surface brine cooling or back reactions drive their crystallisation.

There is another problem with much chemical/mineralogic modelling of ancient salts. It is predicated on an assumption that the major ion proportions of seawater do not change with time. But were the ionic proportions of Phanerozoic seawater constant? Ionic proportions and the precipitation order of ancient seawater bitterns may have changed according to variations in the flux rates of river inflow relative to flux rates through mid-ocean ridges or the volumes of magnesium carbonate accumulating in the world's oceans (i.e., the "zip and split" of supercontinents) may have changed through time. Variations in either mechanism would have changed the proportions of major ions in seawater (Fig. 2.45).

Brine Mixing Drives Precipitation or Dissolution

Van't Hoff's work also showed that salts can precipitate at a brine interface. All that is needed is mixing of waters of two saturation states with respect to the mineral of interest (Fig. 2.17a). When two waters that are saturated with a particular phase are mixed, the resulting solution may be undersaturated or supersaturated with respect to that particular phase (two salt problem discussed earlier). The saturation state during mixing depends on the solubility curve of the mineral phase of interest and the parameter of interest (ion concentration, temperature, salinity, etc.). The only requirement is that the solubility curve for that particular component is nonlinear. Raup (1970, 1982) in a number of experiments showed how halite and gypsum can be precipitated by the mixing of two seawater brines of differing salinity and densities. Figure 2.17b plots experimental results for the mixing of various low and high-density seawater brines and the resulting amount of gypsum precipitated (Raup 1982). A similar plot can be drawn for the mixing of more saline seawater brines, where halite is the precipitate (Raup 1970). For similar reasons, gypsum can precipitate in mixing zones in coastal aquifers when seawater first intrudes and displaces freshwater (Gomis-Yagues et al. 2000).

Mixing brines with different temperatures or salinities can be an important salting mechanism in the calcium sulphate (gypsum/anhydrite) salt system as it follows a nonlinear solubility trend, as does the halite-$MgCl_2$ bittern system (Raup 1970, 1982). Figure 2.18a shows the solubility curves

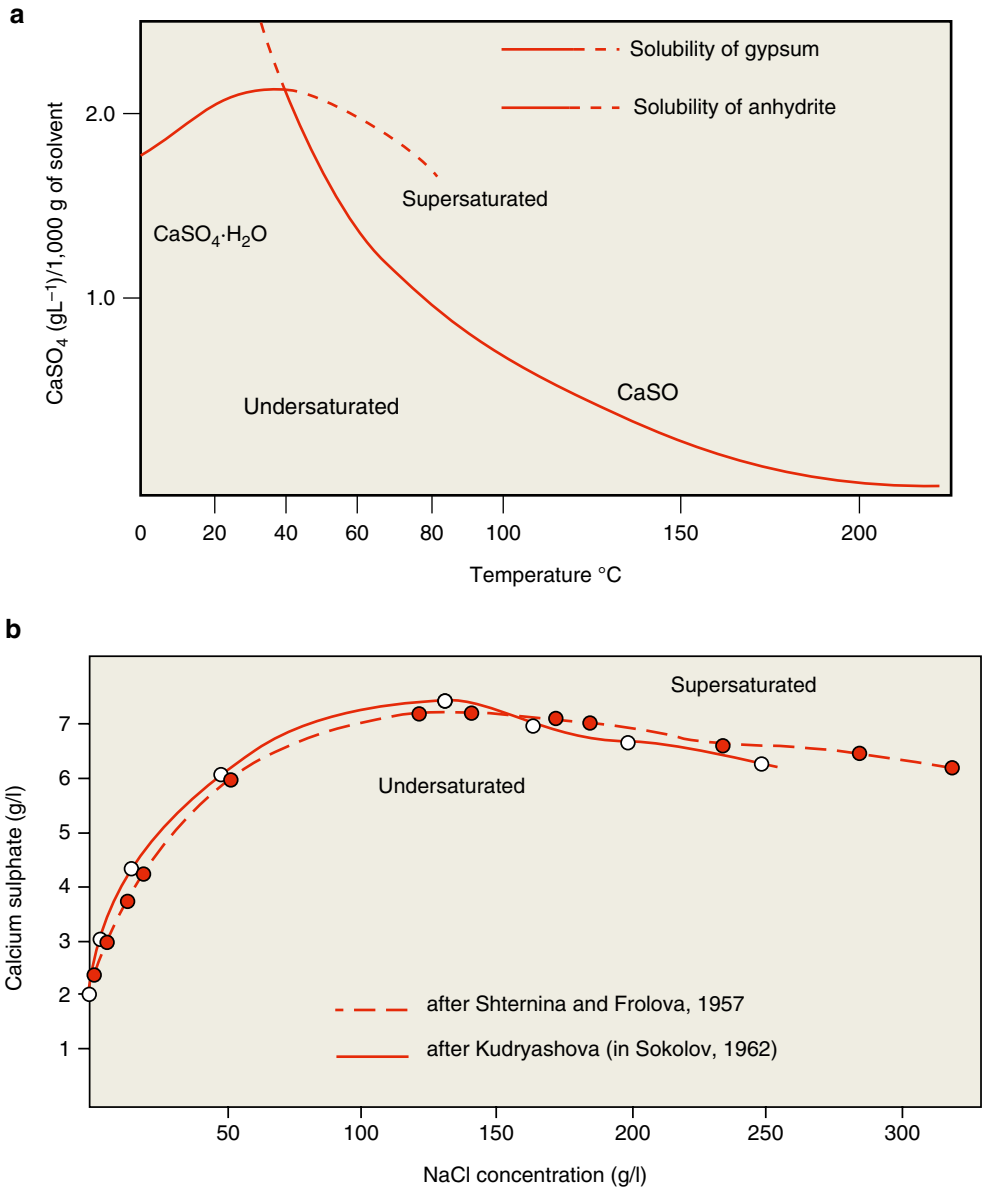

Fig. 2.18 Calcium sulphate solubility. (**a**) Idealised gypsum and anhydrite solubility with respect to temperature (After Zverev 1967). (**b**) Anhydrite solubility first increases then decreases slightly with respect to increasing NaCl content at temperatures of >100 °C (After Hryniv and Peryt 2003)

of gypsum and anhydrite with respect to increasing temperature in pure water. For gypsum, it clearly shows that when two gypsum-saturated waters of different temperature mix then the resulting solution is undersaturated and gypsum tends to dissolve. It also shows that gypsum follows a prograde solubility curve, whereby in the temperature range where gypsum is the stable $CaSO_4$ phase (<40 °C) it is increasingly soluble with increasing temperature. In contrast, at higher temperatures (>40–50 °C) anhydrite and gypsum follow a retrograde solubility curve whereby they are less soluble with increasing temperature. Thus, when two anhydrite-saturated waters of different temperatures mix the result is supersaturated brine with a propensity to precipitate anhydrite. This helps to explain why anhydrite is a commonplace hydrothermal precipitate in many mid-oceanic ridges and smoker chimneys (see Chap. 16). On land, beneath the surface of the Abu Dhabi sabkha, the heating of desert waters rising through the capillary zone to temperatures above 30 °C drives the precipitation of $CaSO_4$ (Fig. 3.15; "thermalites").

Anhydritic systems drive complex diagenetic effects when $CaSO_4$-saturated brines are diluted via dispersion into adjacent less saline waters (Fig. 2.18b). This happens in brine reflux systems where dense $CaSO_4$-saturated brine plumes, derived at the surface at halite saturation, sink into, and interact with less saline brines held in underlying or adjacent anhydritic carbonates. If temperature remains near constant the tendency in this zone of dispersion or mixing is to dissolve anhydrite cements, creating vugular porosity in the interval below or adjacent to a thick salt sequence. If temperature decreases and the brine plume cools, with little change in ionic proportions due to mixing, then the tendency is to precipitate anhydrite. It is not a simple system, with temperature

and mixing processes pulling the brine chemistry in opposite directions. It is of economic interest as brine reflux in ancient evaporitic carbonate platforms created diagenetic conditions suitable for the formation of potential hydrocarbon reservoirs via extensive dolomitisation (Fig. 10.29).

Later in the history of a calcium sulphate bed, during its uplift and dissolution (telogenesis), the mixing of sulphate-enriched waters with waters in adjacent aquifers drives dedolomitisation. This is a process that can also create extensive karst in the absence of soil-derived carbonic acid and is doing so today in the Lake Banyoles region of northeast Spain (Bischoff et al. 1994). Lake Banyoles is a karst lake fed by sublacustrine springs, where dedolomitisation-driven karstic collapse drives ongoing subsidence in the immediate vicinity of the lake. The lake lies within the outcrop area of the middle Eocene Banyoles Fm.; a marine marl and mudstone that is organic-rich and pyritiferous. The marls are underlain by the 200–300 m thick massive gypsum of the Eocene Beuda Formation, which is in turn underlain by the 100–200 m thick dolostones of the Perafita Fm.

Gypsum dissolution drives the local precipitation of calcite, both in the lake and in the aquifer (dedolomitisation), thus consuming ions released by dissolving dolomite and facilitating further dissolution in the aquifer (see Chap. 7 for details).

$$\mathrm{MgCa(CO_3)_2 + CaSO_4 \cdot 2H_2O \rightarrow 2CaCO_3 + Mg^{2+} + SO4^{2-} + 2H_2O}$$

Lake waters reflect this process; they are dominated by Mg-Ca and SO_4-HCO_3 and are supersaturated with calcite, which is actively accumulating in lake sediments at a rate of 38 $mg \cdot cm^{-2} \cdot year^{-1}$. Modelling of the regional hydrology based on the chemistry of lake and aquifer waters, along with measures of the annual water flow through the lake, shows that artesian waters create $\approx$9,500 m^3 of subsurface void space per year, enough to create the present karst depression of Lake Banyoles in 1,800 years (Bischoff et al. 1994). One could argue that gypsum dissolution alone can account for 55 % of the lake volume. However, when coupled with the ionic removal from the dedolomitisation process, gypsum solubility is enhanced by a factor of 1.56, as presumably is the rate of dissolution. Bischoff et al. (1994) go on to argue that gypsum-driven dedolomitisation may be responsible for extensive limestone karst in other exhumed $CaSO_4$ terrains in semiarid to arid settings, heretofore attributed solely to soil-generated carbonic acid.

Nonmarine Brines

Unlike marine-derived brines, evaporating continental waters do not draw on the near isochemical reservoir of an ocean. A more diverse, less predictable, suite of evaporite minerals precipitates during evaporation of continental waters. In nonmarine settings, rivers and groundwaters are the source of most of the ions that are ultimately deposited as evaporite salts. In a closed hydrological system the composition of nonmarine brines depends on the lithologies that are leached in the drainage basin surrounding a salt lake (Eugster and Hardie 1978; Eugster 1980a). Flow through limestone aquifers in hydrologically-closed basins produces inflow waters rich in Ca and HCO_3, dolomite dissolution generates Mg, igneous and metamorphic matrices yield silica-rich Ca–Na–HCO_3 waters. Pyritic shales and other sulphide-rich sediments will contribute sulphate ions, whereas basic and ultrabasic rocks tend to produce alkaline Mg–HCO_3 waters.

In all, Eugster and Hardie (1978) distinguished five major water types in what they termed "hydrologically closed" continental evaporite basins (Fig. 2.19; Table 2.6):

1. Ca–Mg–Na–(K)–Cl
2. Na–(Ca)–SO_4–Cl
3. Mg–Na–(Ca)–SO_4–Cl
4. Na–CO_3–Cl
5. Na–CO_3–SO_4–Cl waters

As any one of these waters concentrates within a particular evaporite basin, it deposits a characteristic suite of evaporite minerals. First precipitates are the alkaline earth carbonates: low-magnesian calcite, high-magnesian calcite, aragonite, and dolomite. The mineralogy of this initial precipitate depends on the Mg/Ca ratio of the parent brine. The subsequent evaporation pathway of a basin brine is determined by the proportions of calcium, magnesium, and bicarbonate ions in the brackish inflow waters. It sets up geochemical divides early in the evolution of a lake brine, these divides define the subsequent geochemical and mineralogical evolution of a lake basin.

If the lake waters are enriched in HCO_3 compared to Mg and Ca (i.e., $HCO_3 \gg Ca + Mg$), then the brine follows path I (Fig. 2.19). Ca and Mg are depleted during the initial precipitation of alkaline earth carbonates, leaving excess HCO_3 in the brine. As HCO_3 is the next most abundant ion in these waters it combines with Na in the next stage of concentration. Sodium carbonate minerals, such as trona, natron and nahcolite, precipitate. Little or no gypsum can form from pathway-I brines as Ca is completely used up during the preceding alkaline earth carbonate stage. In contrast, during the evaporation of modern seawater, all the HCO_3 is depleted in the initial alkaline earth precipitates (mostly as aragonite and Mg-calcite). The excess Ca then combines with SO_4 to form gypsum. It is chemically impossible for sodium carbonate to form by evaporation of modern seawater. The assumption that the proportions of calcium to bicarbonate in seawater have not changed much in the last 600–800 Ma implies that trona salts or their pseudomorphs

Brine type	Saline mineral	
Ca-Mg-Na-(K)-Cl	Antarcticite	$CaCl_2 \cdot 6H_2O$
	Bischofite	$MgCl_2 \cdot 6H_2O$
	Carnallite	$MgCl_2 \cdot KCl \cdot 6H_2O$
	Halite	NaCl
	Sylvite	KCl
Na-(Ca)-SO_4-Cl	Tachyhydrite	$CaCl_2 \cdot 2MgCl_2 \cdot 12H_2O$
	Glauberite	$CaSO_4 \cdot Na_2SO_4$
	Gypsum	$CaSO_4 \cdot 2H_2O$
	Halite	NaCl
	Mirabilite	$Na_2SO_4 \cdot 10H_2O$
	Thenardite	Na_2SO_4
Mg-Na-(Ca)-SO_4-Cl	Bischofite	$MgCl_2 \cdot 6H_2O$
	Bloedite	$Na_2SO_4 \cdot MgSO_4 \cdot 4H_2O$
	Epsomite	$MgSO_4 \cdot 7H_2O$
	Glauberite	$CaSO_4 \cdot Na_2SO_4$
	Gypsum	$CaSO_4 \cdot 2H_2O$
	Halite	NaCl
	Hexahydrite	$MgSO_4 \cdot 6H_2O$
	Kieserite	$MgSO_4 \cdot H_2O$
	Mirabilite	$Na_2SO_4 \cdot 10H_2O$
	Thernadite	Na_2SO_4
Na-CO_3-Cl	Halite	NaCl
	Nahcolite	$NaHCO_3$
	Natron	$Na_2CO_3 \cdot 10H_2O$
	Thermonatrite	$NaCO_3 \cdot H_2O$
	Trona	$NaHCO_3 \cdot Na_2CO_3$
Na-CO_3-SO_4-Cl	Burkeite	$Na_2CO_3 \cdot 2Na_2SO_4$
	Halite	NaCl
	Mirabilite	$Na_2SO_4 \cdot 10H_2O$
	Nahcolite	$NaHCO_3$
	Natron	$Na_2CO_3 \cdot 10H_2O$
	Thernadite	Na_2SO_4
	Thermonatrite	$NaCO_3 \cdot H_2O$

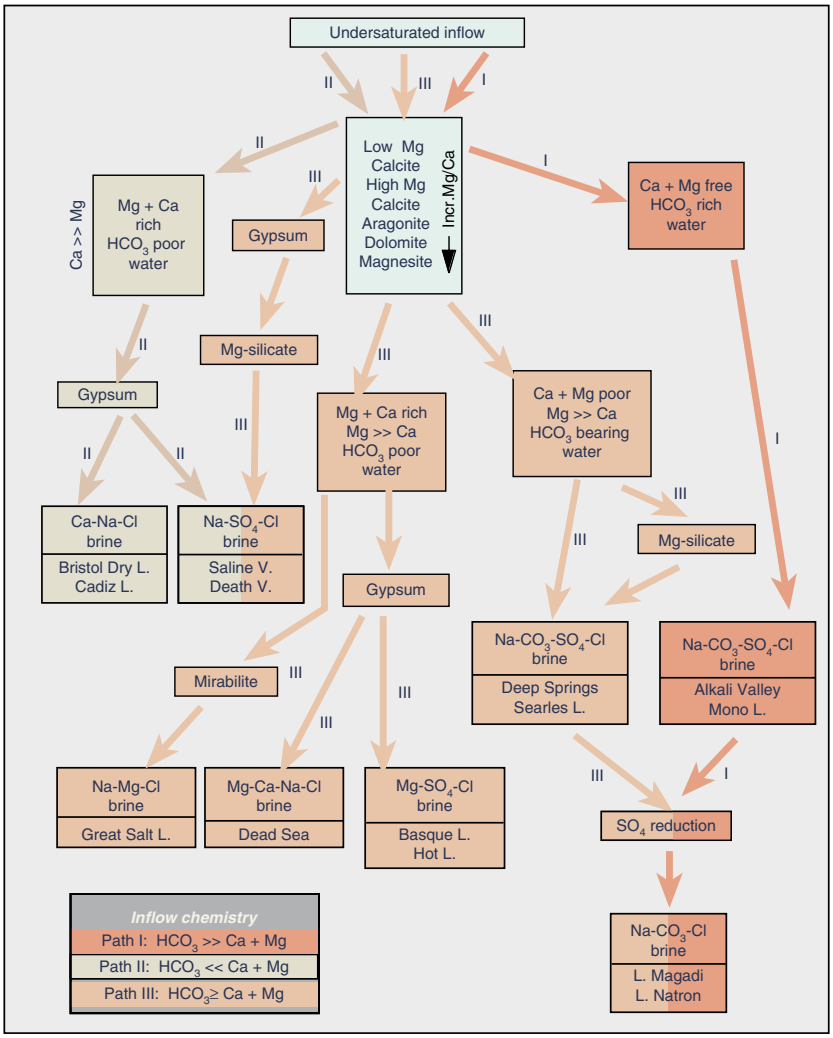

Fig. 2.19 Hydrologic classification and brine evolution pathways of concentrating nonmarine waters and a listing of major evaporite minerals associated with the different brine types (After Eugster and Hardie 1978). *L* lake, *V* valley

Table 2.6 Mineral occurrences and parent brines

Brine composition and source	Major saline minerals	Key minerals
Na-K-CO_3 -Cl-SO_4 Non-marine waters or possibly early Archaean seawater	Alkaline earth carbonates, mirabilite, thenardite, trona, nahcolite, natron, thermonatrite, shortite, halite.	Na_2CO_3 minerals
Na-K-Mg-SO_4 -Cl Seawater, non-marine water or hybrids	Alkaline earth carbonates, gypsum, anhydrite, mirabilite, thenardite, glauberite, polyhalite, epsomite, bloedite, kainite, halite, carnallite, sylvite, bischofite.	$MgSO_4$ and Na_2SO_4 minerals
Na-K-Mg-Ca-Cl Non-marine waters (hydrothermal and basinal brines or seawater with different ionic proportions from today)	Alkaline earth carbonates, gypsum, anhydrite, sylvite, carnallite, bischofite, tachyhydrite, antarcticite.	$KCl \pm CaCl_2$ minerals in the absence of Na_2SO_4 and $MgSO_4$ minerals

After Hardie (1991)

indicate nonmarine settings throughout the Phanerozoic and much of the Neoproterozoic.

If initial inflow waters have $(Ca+Mg) \gg HCO_3$ then, after the initial evaporitic carbonate precipitates, the brines become enriched in the alkaline earths but depleted in HCO_3 and CO_3. If the relative volume of HCO_3 is low, little carbonate can precipitate with further concentration. Brine evolution follows path II, whereby excess alkaline earths (Ca, Mg) left after depletion of carbonate combine with sulphate ions to precipitate large volumes of sulphates (gypsum and/or

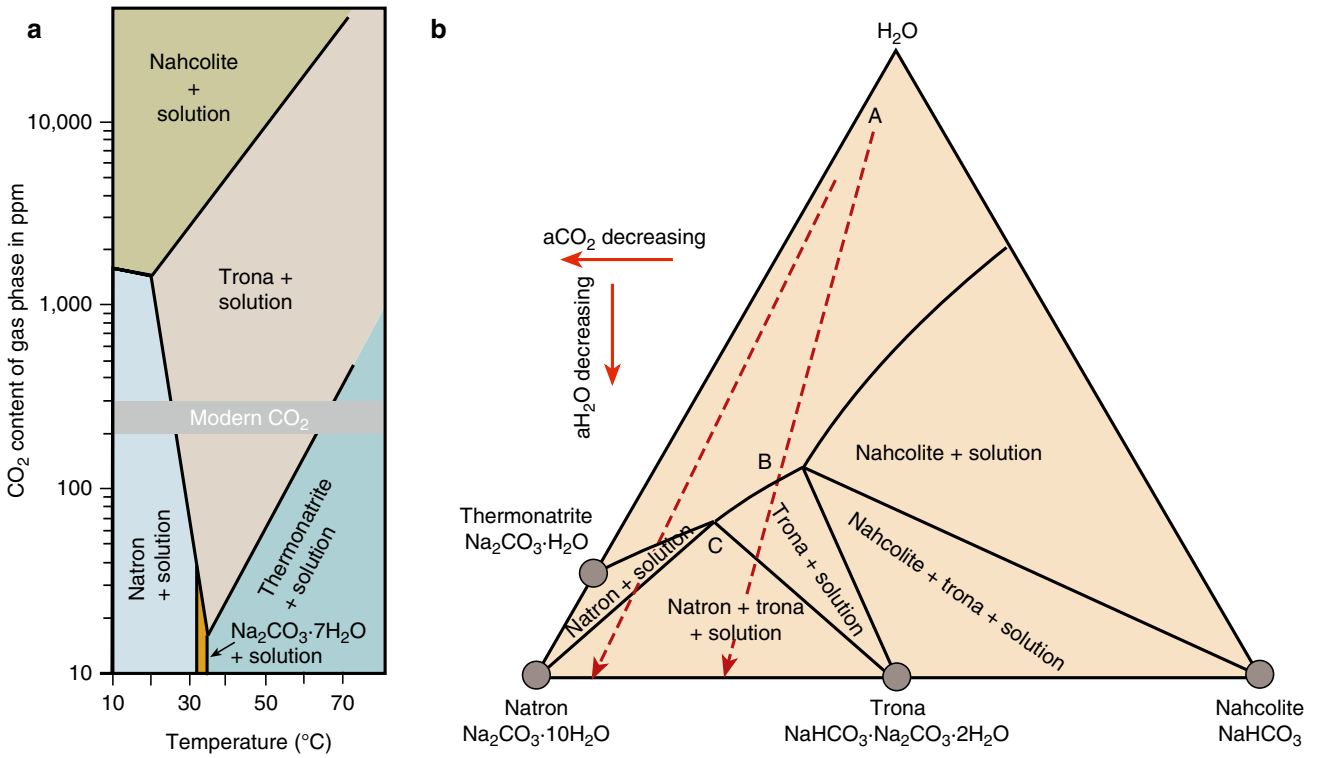

Fig. 2.20 Phase chemistry of sodium carbonate salts. (**a**) Sodium carbonate phases in equilibrium with a saturated solution as a function of CO_2 content of the gas phase and temperature. CO_2 content of today's atmosphere is plotted as a grey band (in part after Eugster 1971a). (**b**) Phase diagram for the sodium carbonate, sodium bicarbonate, water system at 25 °C. Trona saturation occurs at **b** where the brine trajectory *arrow* passes into boundary of trona stability field (After Eugster 1971a)

epsomite). Path II precipitates a suite of continental salts and bitterns similar to that derived from modern seawater. If the ratio of $(Ca+Mg)/HCO_3$ is near unity (path III) carbonate precipitation can be extensive and voluminous. As Ca is progressively removed there is a progressive increase in the Mg/Ca ratio of the residual brine until large volumes of high-Mg calcites, dolomites and even magnesites precipitate.

But such theoretical separations can be difficult to determine in continental lacustrine systems where there is a mixture of groundwater sources and carbonate detrital inputs. For example, across the northern Great Plains of western Canada, there are literally millions of lakes and wetlands of variable salinities and hydrologies (Last and Last 2012). Although typically characterized as a saline, Na-SO_4 system, in fact the wide range of water chemistries exhibited by the lakes results in an unusually large diversity of sediment composition. About 30 species of carbonate minerals have been reported from the modern and Holocene sediment in about 50 lacustrine basins in the region. The ubiquity of detrital calcite and dolomite in most is a legacy of the carbonate bedrock and a carbonate-rich glacial sediment feed to the lakes. Elevated salinities of the lakes, together with high alkalinities, productivity, and pH values, act in concert to create thermodynamically saturated or supersaturated conditions with respect to many carbonate minerals. The most common non-detrital components are Mg-calcite, aragonite and non-stoichiometric dolomite. Many of the basins whose brines have very high Mg/Ca ratios also contain hydromagnesite, magnesite, and nesquehonite. This suggests that extended periods of high salinity and elevated Mg/Ca and alkalinity levels persisted in the basin before climatic and hydrologic changes brought about less saline conditions during the late Holocene. Although not common, sodium carbonates, including trona, natron and nahcolite, also occur in some of these hypersaline lakes. So far, the often-difficult task of distinguishing endogenic lacustrine carbonates from allogenic and authigenic minerals in the lakes has limited the use of carbonate stratigraphy in deciphering the hydrological evolution of region (Last and Last 2012).

Trona-Nahcolite-Shortite Chemistry (Path I Brine)

Clearly, path I brines cannot be derived by solar evaporation of waters with the ionic proportions of modern seawater. An occurrence of primary trona or its pseudomorphs in Phanerozoic evaporites is evidence of a nonmarine brine with an excess of bicarbonate (Fig. 2.20). The three better-known trona deposits in the world are the Pleistocene and

Holocene sediments of Lake Magadi, Searles Lake and the Eocene Green River Formation (Chap. 12). All regions show the appropriate bicarbonate excess in their inflow waters that differentiates them from seawater brine. But, as we shall see later in this chapter, there is increasing evidence that early Archaean marine evaporites are most likely represented in the rock record by silica replacements of widespread nahcolite or trona, as well as halite. So, it's worth considering in more detail what is the phase chemistry of a sodium bicarbonate system.

By definition, there must always be an excess concentration of bicarbonate ions in an inflow water to force it into a path I composition (Fig. 2.19). This means trona-forming brine is always an alkaline solution, typically with a pH above 9, and so is seen in all modern soda lake waters[3] (Eugster 1971a, b; Eugster and Jones 1978). Alkalinity is the result of the required solution's inherent chemistry. Trona cannot form in acidic waters, it is a matter of basic chemistry. Any carbonate ion in any aqueous solution tends to bump into and react with whatever ionic species are around. When there is not much free hydrogen around, carbonate in effect steals a hydrogen ion from a water molecule, leaving a hydroxyl ion behind and so, *ipso facto*, produces an alkaline solution. Because sodium is usually the dominant cation in the world's saline lakes, some make an anionic distinction in their classification, referring to lakes containing predominantly sulphate as bitter lakes and those containing predominantly carbonate as alkaline or soda lakes.

A number of conditions must be present to create natural Path I brines and so produce trona beds: (1) an underfilled tectonic basin in which downwarping exceeds the rate of sedimentation, (2) a closed hydrographic basin in which evaporation exceeds outflow, (3) evolution of solutes in the lake waters that lead to high Na/(Ca + Mg) and ($HCO_3 + CO_3$)/(SO_4 + Cl) ratios, that is alkaline brines, (4) a more-or-less permanent body of nutrient-rich water, (5) a warm climate favouring high primary productivity by microbes and algae, and (6) a high rate of bacterial sulphate reduction. Given the presence of these requisite conditions, varying intensity of photosynthesis, temperature and changes in the amount or volume of degassing spring waters then control the CO_2 content of the sodium bicarbonate precipitating brines and hence the mineralogy of the sodium bicarbonate precipitates (Fig. 2.20a).

Trona evaporites in Lake Magadi accumulate as the surface brine is losing (degassing) a substantial portion of its CO_2 to the atmosphere. As that happens the increasingly concentrated brine follows a path similar to the dashed line moving away from point A (Fig. 2.20b; Eugster 1970, Eugster 1980a, b). Trona precipitation then occurs at ambient equilibrium (point B). Natron rather than trona is likely to form when ambient temperature is below 25 °C (left hand dashed line). Once native trona deposition in Lake Magadi has begun, the CO_2 resupply from the atmosphere is too slow to allow ongoing equilibrium between atmospheric CO_2 levels and levels of CO_2 in the brine. The deposition of the later salts, along with the observed HCO_3 depletion in increasingly saline brines (levels not buffered by CO_2), suggested to Hardie (op. cit.) that fractional crystallisation likely controls trona deposition in Lake Magadi. Thermonatrite/halite can sometimes precipitate in the later stages of evaporative concentration in Lake Magadi. At higher temperatures, earlier formed natron and trona can be replaced by thermonatrite.

Kinetic effects, especially those governing equilibration between dissolved and atmospheric CO_2, are extremely important in determining the final mineralogy of sodium carbonate precipitates (Eugster 1970; Whittig et al. 1982). Evaporative concentrations under conditions of equilibrium with atmospheric CO_2 at 25 °C follow path AB in Fig. 2.20b and at B, trona begins to crystallize. Crystallisation of trona, together with further evaporation, results in the solution composition moving towards C, i.e., it causes a decrease in the HCO_3/CO_3 ratio because this ratio in trona is greater than that in the solution. However, if equilibrium with atmospheric CO_2 is maintained, this ratio should be buffered, and only trona is produced because addition of atmospheric CO_2 stabilizes (buffers) the HCO_3/CO_3 ratio via the following reaction:

$$CO_3^- + H_2O + CO_2 = 2HCO_3^-$$

Under conditions where atmospheric disequilibrium is promoted, i.e., where the HCO_3/CO_3 ratio is not buffered, path BC is followed, producing thermonatrite and trona at C. The removal of HCO_3 along path BC under these conditions also causes a marked rise in the pH (alkalinity), as the solution compensates for HCO_3 removal by the reaction,

$$CO_3^- + H_2O = HCO_3^- + OH^-$$

In spite of this compensation, the HCO_3/CO_3 ratio in lake Magadi brines falls well below that of atmospheric equilibrium, especially in nutrient-rich waters with a flourishing photosynthesising microbial community (Fig. 2.20a).

[3]The term "soda lake" defines a class of saline lakes with water/brine chemistries having an excess in total alkalinity ($\approx [HCO_{3-}] + 2[CO_3^{2}]$, i.e., the sum of the charges of the bicarbonate ion plus carbonate ion) is in excess over the charges of the alkaline earth ions, magnesium and calcium: $[HCO_3^-] + 2[CO_2^-] > 2[Mg^{2+}] + 2[Ca^{2+}]$ when such lake waters concentrate the high CO_2 level causes a rise in pH and eventually, if evaporation proceeds, various sodium carbonate minerals precipitate. The largest soda lake in the world is Lake Van in Turkey. Many soda lakes are located on or near plate tectonic boundaries within continental land masses (rifts and collision zones). About a third of the soda lakes in the world are located in a high-altitude collision belt, stretching from Tibet, through Qinghai Province to the Inner Mongolia Autonomous Region. Precipitation of salts in most of these soda lakes is cryogenically driven.

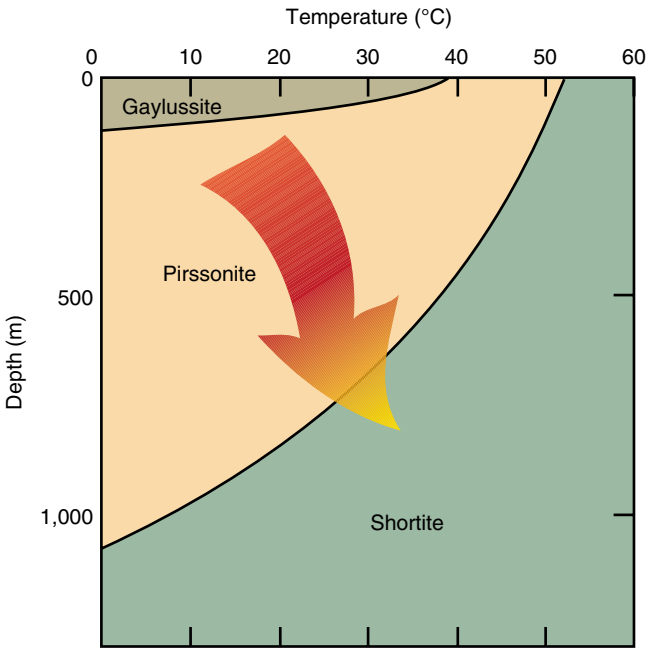

Fig. 2.21 Stability of gaylussite, pirssonite and shortite with inferred burial depth/temperature (°C). The temperature for the gaylussite/pirssonite transition is ≈ 40 °C. The illustrated pirssonite–shortite boundary temperature of 52 °C is the lower temperature stability limit of shortite (Jagniecki et al. 2013)

The grey shaded interval in Fig. 2.20a shows the range of CO_2 values typically present in brines in equilibrium with present-day atmospheric CO_2. Trona is the stable phase in the 25–60 °C temperature range typical of most modern surface brines in modern soda lakes where sodium bicarbonate minerals are precipitating. CO_2 values were higher (10–200 times; Kaufman and Xiao 2003) in the Archaean atmosphere (as were CH_4 levels), favouring the widespread co-occurrence of nahcolite with trona along with halite, not gypsum, in marine evaporites of the time (Fig. 2.49).

Shortite does not form at earth surface temperatures, but its occurrence can also be used to track burial temperature. Based on experimental work, Bradley and Eugster (1969) concluded the reaction, whereby pirssonite converts to shortite:

$$Na_2Ca(CO_3)_2 \cdot 2H_2O + CaCO_3 = Na_2Ca_2(CO_3)_2 + \text{brine}$$

only occurs at temperatures around 100 °C ± 25 °C at 2 kbar pressure. The precursor to pirssonite is gaylussite and the conversion occurs around 40 °C at normal surface conditions (Fig. 2.21) Subsequent experiments on shortite stability by Jagniecki et al. (2013) found that shortite forms via the above reaction at a temperature of 55 °C at standard conditions and in presence of an NaCl brine its temperature stability field is slightly lower (≈52 °C). It seems the temperature at which shortite forms from a pirssonite precursor does not vary significantly with brine chemistry or aH_2O. These results suggest that shortite is not found in modern saline lake environments because the surface temperatures are too low, but also explains why it is a common diagenetic/burial product in path 1 brine settings.

For example, shortite is abundant in the Wilkins Peak Member (WPM) of the Eocene Green River Formation, Green River Basin, Wyoming, USA (≈78 Mt/km^2), where it occurs as diagenetic displacive crystals, fracture fills, and pseudomorphous replacements of a precursor Na-Ca-carbonate (Jagniecki et al. 2013). The large area over which shortite occurs in the WPM indicates that saline type 1 pore fluids once existed in the buried lacustrine sediments, and thus, at times, large Na-CO_3-rich saline alkaline lakes or laterally extensive saline groundwaters existed in the Green River Basin during WPM time with extents greater than those outlined by trona beds, which are also economic (Chap. 12). The thermal stability of shortite, together with vitrinite reflectance data and inferred regional geothermal gradients, establish that the shortite-bearing intervals of the WPM were buried to maximum depths of ≈ 1,000 m in the Green River Basin, and since experienced ≈ 800 m of erosional exhumation (Jagniecki et al. 2013).

Are Continental Salt Lakes Hydrologically Closed?

Hydrogeochemical studies do not always draw the distinction between hydrographic closure (endorheic basin) and hydrological closure (no leakage). The former situation is commonplace in evaporite basins, while the latter is rare. Studies of the nonmarine hydrogeochemistry of low-relief desert terranes detailed in this section show that varying degrees of brine leakage, rather than hydrological closure, characterise large-scale endorheic lakes and playas located well into the continental interior. Even in modern near-coastal settings the hydrology tends to be open and leaky rather than a closed cumulative systems. For example, evolved path III continental brines, in combination with varying degrees of brine leakage, explain the diversity of evaporitic carbonate mineralogies in the lakes of the Coorong, South Australia (Warren 2000a). Individual lakes, less than 1 km apart and with sediment surfaces above sea-level, are filled with up to 6 m of Holocene carbonate and show mineralogies that range from low Mg-calcite to high Mg-calcite to calcian dolomite to magnesian dolomite ± magnesite to aragonite ± hydro-magnesite to aragonite + gypsum (Fig. 4.5). Calcites and calcian dolomites tend to dominate in lakes with lower average annual salinities, while the magnesian carbonate phases, along with aragonite/gypsum, tend to dominate lakes with higher average salinities (Warren 1990). During the desiccated stage of the late summer, halite-$MgSO_4$ efflorescences form atop carbonate mudflats in many

Coorong lakes, but are flushed from the system by winter rains. Mineral variation in the Coorong lakes illustrates the importance of relative rates of brine loss (residence time and leakage) in controlling mineralogy in this hydrologically-open continental system. Average brine residence times in the different lakes ultimately control mineralogic assemblage. Those lakes with leakier basements allow a more rapid throughflush of waters and so show lower longterm salinities and so accumulate less saline precipitates.

Yet in the literature, many of our ideas on the nature and evolution of continental evaporite brines and the resulting salts are based on hydrochemical analysis of high topography, "closed-basin" (effectively non-leaking), rain shadow lacustrine systems such as the Basin and Range province of the southwest USA and the continental lakes of the African Rift system. Uplifted bedrock lithologies surrounding these lakes tend to contain abundant labiles in their tectonically-active high-relief catchments. Bedrock alteration with rapid weathering is a major contributing factor to variations in ionic proportions of the final lake brine (Fig. 2.19). In contrast, saline groundwaters in playas and salt lakes of low-relief tectonically-stable deeply leached regions such as the interiors of Australia and southern Africa tend to have salt lakes with seawater-like Na-Cl dominated brines (Type II or thalassic brines). Many Australian playas are hydrologically open; the outcropping parts of mixed local and deeply circulating regional discharge systems (Chap. 3). Aridity and deeply weathered soil profiles have characterised these areas since the early to mid Tertiary. Ionic proportions and chemical constituents of surface waters and brines vary little, even across regions of variable bedrock lithologies (Table 2.7). Gypsum, with lesser volumes of halite, are common precipitates in some, and all lake floors show varying degrees of brine leakage.

Jankowski and Jacobson (1989, 1990) and Jacobson and Jankowski (1989) showed that in such deeply weathered and leached systems the amount of rainfall in a given part of a catchment area is a more important determinant of the chemical composition of the final playa brine, rather than bedrock lithology. In the Lake Amadeus – Spring Lake region of central Australia, higher rainfall regions of the catchment generate playa inflow waters that are bicarbonate-dominated, while lighter rainfall regions generate chloride-dominated inflow waters. Differences in brine chemistry can be related to the rate of cycling of pedogenic carbonate within the catchment profile, not to differences in basement lithology. More carbonate is dissolved in the nearsurface when rainfall is relatively high, and so contributes a greater proportion to the brine composition. Higher rainfall regions also flush greater volumes of water through the same profile in a given time and so are characterised by shorter residence periods per given water volume for rock/fluid interaction. In low rainfall regions chloride tends to remain mobile in the catchment profile, while bicarbonate is more likely to remain fixed as carbonate minerals in the soil profile (Fig. 2.22).

The buildup of more soluble salts as pedogenic residuals in low rainfall regions can be impressive. Salt-rich soil profiles near Lake Eyre, South Australia sit atop a widespread flat-lying and deeply weathered pyritic Cretaceous Bulldog Shale. Deep leaching has created a pedogenic unit of epsomite, with a thickness measured in metres and an area measured in thousands of square kilometres (Lock 1986). Pedogenic nitrates in the hyperarid Atacama Desert have a similar pedogenesis (Fig. 12.62).

Hydrological leakage varies over time through a brine-covered lake floor situated in the lowest parts of an endorheic basin and does so in response to climate changes driving rising and falling watertables. Variation occurs across time frames of hundreds to thousands of years, and periodic deflation is typically part of the sedimentary history of these playas. Variations can create regional disconformities in the upper few metres of lacustrine sediment. This hydrological

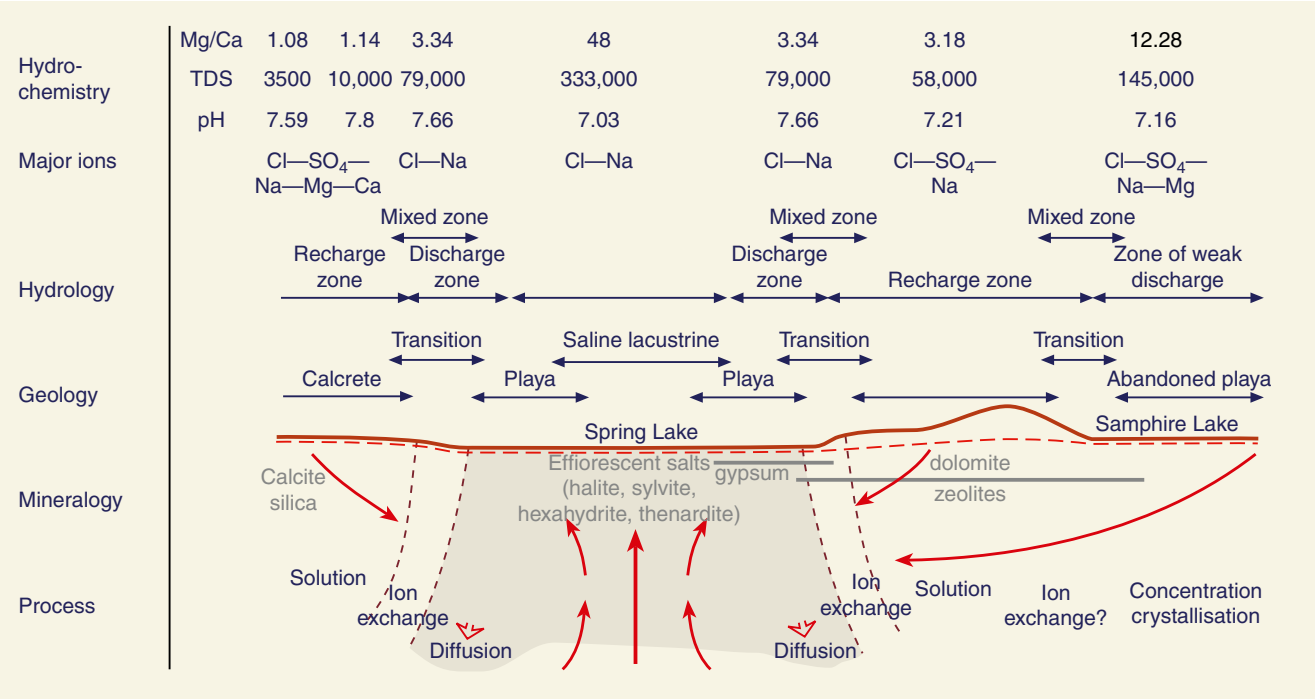

Fig. 2.22 Schematic of hydrochemical processes in a groundwater discharge playa complex, Spring Lake, Curtin Springs, Central Australia (After Jacobson et al. 1989). See also Fig. 2.54

regime begs the question, how useful are the major ions proportions in the present surface waters in understanding the mineralogical evolution of the preserved lake precipitates? In other words, how valid is the assumption, typically made in "closed lake" settings, that the chemistry of the concentrating surface waters gives an understanding of the hydrogeochemical parentage of the preserved sediments?

Studies by Dutkiewicz et al. (2000) underline the significance of varying rates of phreatic leakage (both upwelling and downwelling/reflux) in controlling the mineralogy of lacustrine sediments in more hydrologically open playas. Using a steady-state isotopic model of lacustrine carbonates they concluded that present-day leakage in the Malata-Greenly playa complex in South Australia is 75–90 % of regional inflow. Mineralogy of nearsurface sediment beneath all the lakes in the Greenly-Malata system is relatively simple, dominated by alternating layers of chemically-precipitated gypsarenite and carbonate muds, which are either dolomites or calcites, all with relatively minor amounts of transported calcareous sand (Fig. 2.23a; Dutkiewicz and von der Borch 1995). Under present conditions of high leakage, only low magnesian calcite precipitates are preserved along with gypsum. Compared to more arid times in the past when dolomite accumulated, current lake waters experience somewhat reduced effects of evaporation, gas and vapour exchange and, consequently, reduced isotopic and chemical enrichment.

Using regional groundwater values, Dutkiewicz et al. (2000) calculate that any precipitated carbonate in a salt lake in the region will be calcite, which becomes increasingly Mg-rich as brine concentration continues, until the brine reaches a chemistry favourable for dolomitisation. Thus dolomite intervals preserved in the cores, but not forming in the present climate, probably reflect more arid climate or times of slower leakage of brine from the lake. Their modelling predictions are confirmed by isotopic measurements over the length of a 2.5 m core taken in the dolomitised carbonates of the lake complex, where the $\delta^{18}O$ and $\delta^{13}C$ of the lacustrine carbonates show excursions on the order of 5‰ (Fig. 2.23a).

At one end of the hydrological spectrum are past times of throughflow-dominated leaky conditions, when low-Mg calcite accumulated (with characteristic depleted $\delta^{18}O$ and $\delta^{13}C$ levels). These were times defined by a high watertable, perennial waters and a humid climate (Fig. 2.23b) with relatively short residence times in the pore brines. Then there were times of decreased leakage and higher rates of evaporation. These more arid climatic episodes were characterised by the accumulation of high Mg-calcite/dolomite (relatively enriched in $\delta^{18}O$ and $\delta^{13}C$ (Fig. 2.23a). Dolomite precipitation dominated in Lake Greenly when leakage was reduced to some 55–70 % of present inflow.

Then there is the climatic situation where deflation or a lowering of the regional watertable causes the water level to sink into the lake sediment column to become a watertable. The system is then driven by capillary evaporation, the formation of widespread erosional surfaces (disconformities) and net loss of sediment (via deflation) from the lake. This creates breaks or disconformities in the sedimentation history

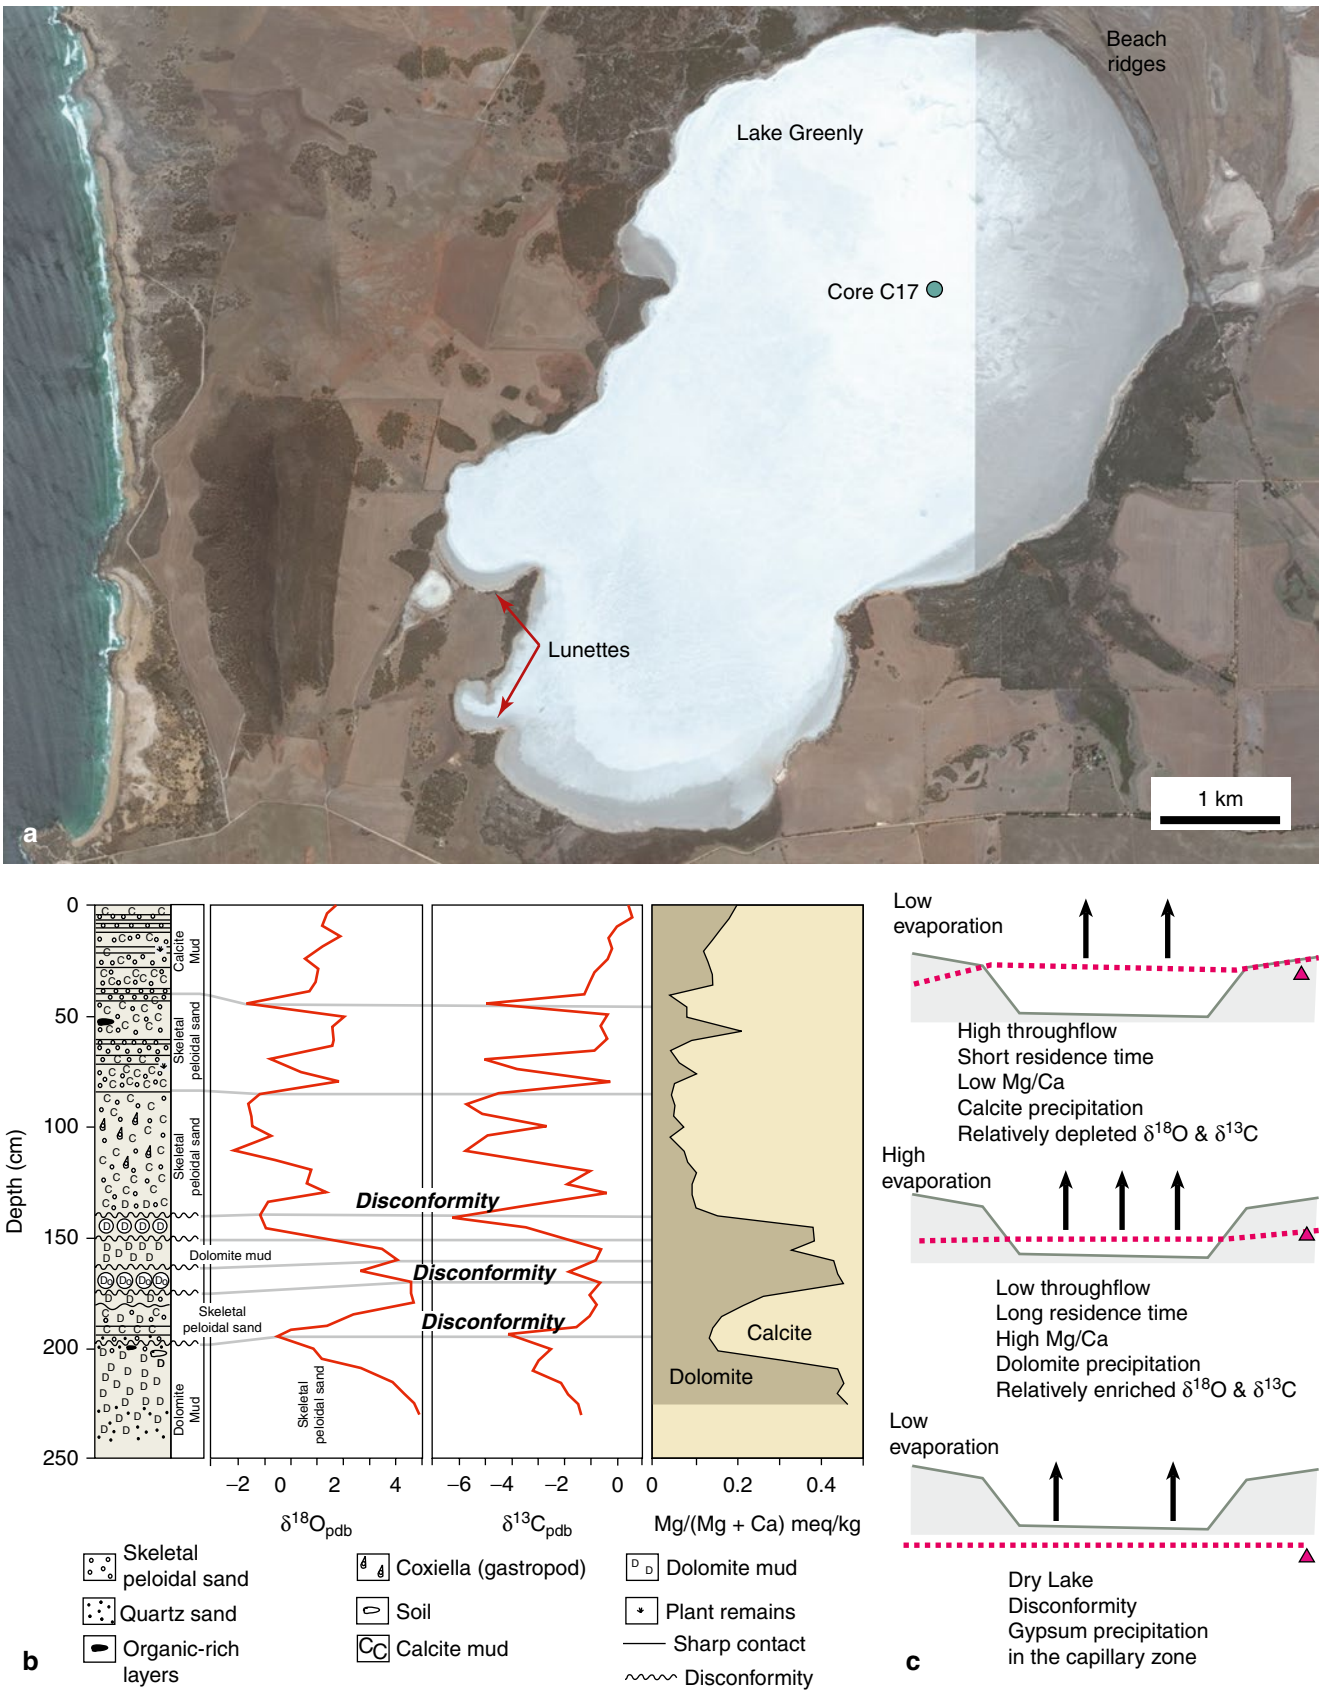

Fig. 2.23 Lake Greenly complex, South Australia. (**a**) Satellite image (Bing® image mounted in MapInfo®). (**b**) Stable isotopes and Mg/(Mg+Ca) ratios plotted against depth and sedimentology of core C17 in Lake Greenly. (**c**) Schematic of the three playa hydrological stages with varying watertables indicated by dashed lines (After Dutkiewicz et al. 2000)

and it can effect both dolomite and calcite successions. It tends to occur more frequently during dolomite depositing episodes, as these were times of greater aridity. Using the modern isotopic signatures of the regional groundwaters as a baseline, signatures in the preserved lake sediments indicate variable, but high, rates of throughflow or leakage throughout the Late Quaternary (55–90 % of today's).

Yet, when mass balance calculations are done using the surface water chemistry in the lake and an assumption that Cl and Br are conservative, there is apparent hydrochemical closure in surface waters of the lake system (ionic proportions indicate <1 % leakage of waters from the lake). Clearly, the surface brine chemistry does not match the leakage history shown by isotopic signatures of the preserved sediments beneath the lake floor (Dutkiewicz et al. 2000). Surface waters reflect the ongoing cycling of a seasonal halite crust, which redissolves each winter. The crust formed during the previous summer under conditions dominated by evaporative discharge into the lake. Circulation of surface waters and the periodic creation of secondary surface brines by halite leaching takes place above a separate widespread mixing zone where older lake brines interact with regional groundwater inflow. Thus the annual solute cycles of surface waters and the halite crusts are decoupled from the subsurface water cycle which are what tends to preserved in the carbonates of the playa sediments (not the uppermost halite level). This decoupling is true of many inland playas across Australia, where reflux and mixing of the lake brines into the regional outflow hydrology prevents the accumulation of thick sequences of bedded gypsum or halite (Fig. 3.59).

Decoupling also explains a general observation that in many Quaternary salt lakes around the world, the relative abundance of preserved authigenic minerals in the sediment column is different from that predicted by conventional solute mass balance calculations using surface brine compositions. Conventional hydrogeochemical mass balance models assume that chloride (and bromine) behave conservatively over long periods of time. Such models of ionic evolution fail to take into account the role of diffusion, deflation and fractional crystallisation/dissolution of salts. That is, not all water exchange in a saline system is closed and so can be tied to a simple relationship between runoff and evaporation; in reality all salt lakes will reflux, seep and leak brine to varying degrees.

This decoupled hydrogeochemistry illustrates a general observation on evaporite deposition, underlined by Sanford and Wood (1991) and Rosen (1994), namely, there are very few truly "closed" hydrological systems in evaporite basins in either marine or nonmarine settings. All natural groundwater systems in salt-accumulating areas leak to varying degrees. Geological evidence for leakage through the floor of an evaporite basin includes the formation of reflux dolomite, the longterm stability of brine plumes beneath lakes that are accumulating thick salt sequences, the loss of halite porosity by 30 m burial, the near surface dissolution of marginward portions of salt beds, the diverse suite of early burial alterations and backreactions, and the formation of burial salts in brine curtains beneath saline depositional systems.

As for seawater bitterns (Fig. 2.12), the geochemical divides defining the evolution of Type I through III nonmarine brines are perhaps more dependent on the ratio of leakage to inflow rather than the lithology of the surrounding basin. Only in high-relief reactive catchments with very low basin floor leak-age (near-closed) hydrologies will surface brine chemistry and crust mineralogy correlate with the suite of minerals and salts accumulating as the lacustrine fill. There the rapid rates of subsidence in the lacustrine sink mean the accumulated salts largely reflect catchment lithologies.

In more hydrologically open systems, with slower rates of lacustrine subsidence and sediment accumulation, the rate of solute input from precipitation and meteoric outflow via pedogenic leakage in the surrounding low-relief deeply weathered and flushed catchment is often more significant in controlling inflow chemistry than the rate of labile bedrock weathering. Hydrogeochemical proportions of ions in waters throughout the continental groundwater profile are then controlled by a combination of rates of leakage and the ionic composition of the precipitation entering the system. Solutes from the shallowest portions of the groundwater profile are recycled through the seasonal formation and dissolution of salt crusts on the lowest parts of the playa floor and so are typically decoupled from the mineralogy in the immediately underlying lacustrine sediments. The proportion of leakage of solutes into the sediment below the cycling crust is controlled by longer term climate change and the interactions between tectonism, subsidence and deflation.

Separating Marine from Nonmarine

Hydrological requirements needed to accumulate large-scale thick salt deposits complicates our ability to separate marine from nonmarine water sources in ancient evaporites. A high degree of isolation or "continentality" is required for stable longterm evaporative drawdown, which is always needed to accumulate a thick sequence of bedded salts (see Chap. 5 for detail). That is, a marine evaporite basin may have been supplied seawater by marine seepage or occasional surface seawater breakthrough via narrow ephemeral surface inlets, but, if the basin is to accumulate thick salt beds, it must be a longterm topographically-isolated regional low. The inherent hydrological requirement of isolation from any continuous surface connection to the ocean means it is by definition a subsealevel basin surrounded by land with a marine-phreatic groundwater feed. The salt accumulating area is

Table 2.8 Examples of diagenetic (secondary) evaporites that form easily below 30 °C

Secondary mineral phase	Syndepositional origin (<30 °C)
Anhydrite $CaSO_4$	Dehydration of early formed gypsum as a_{H2O} of evaporating brine decreases.
Bloedite Na_2 SO_4 $MgSO_4{\cdot}4H_2O$	Back-reaction between previously precipitated epsomite and concentrating brine.
Gaylussite $CaCO_3{\cdot}Na_2CO_3{\cdot}5H_2O$	Back-reaction of evaporating alkaline brine with early formed aragonite or calcite.
Glauberite $CaSO_4{\cdot}Na_2SO_4$	Back-reaction of evaporating Na_2SO_4-brine with early formed gypsum or halite.
Kieserite $MgSO_4{\cdot}H_2O$	Dehydration of early formed hexahydrite as a_{H2O} of evaporating brine decreases.
Polyhalite $2CaSO_4{\cdot}MgSO_4{\cdot}K_2SO_4{\cdot}2H_2O$	Back-reaction of evaporating K-Mg-SO_4 brine with early formed gypsum, anhydrite or glauberite.
Sylvite KCl	Incongruent dissolution of carnallite in undersaturated waters.

After Hardie (1990), Sanchez-Moral et al. (1998)

either surrounded by continental sediments and hydrologies or is a depression within or behind a subaerially exposed carbonate platform. Invariably in some parts of the basin, marine chemistries are overprinted by deeply circulated meteoric waters, thalassic surface waters can be diluted by occasional rainstorms and by the effects of pulses of highly labile volcanic ash. This next section is an attempt to present some of the possible complexities that characterise ancient hybrid (mixed marine/continental) brine systems.

Back Reactions

Backreactions complicate the interpretation of brine parentage in ancient evaporite salt sequences. At the start of the last century they were recognised as significant controls on mineralogy by van Hoff and others (Figs. 2.14 and 2.15). Backreactions can occur both at the sediment-brine interface and within shallow subsurface brine plumes that displace and mix with less dense underlying pore brines. Pseudomorphs and reaction rims are common indicators of this process, as are relict mineral cores encased in the mineral that replaced it. Documented examples include pseudomorphs of halite after subaqueous gypsum, reaction rims of polyhalite and glauberite around earlier gypsum or anhydrite, bloedite after epsomite, relicts of carnallite in secondary sylvite, and pseudomorphs of sylvite plus kieserite after earlier langbeinite (Table 2.8).

Backreaction means relevant bittern chemistry and associated brine evolution is poorly modelled by studying brine evolution in man-made seawater ponds. In such salt works the evolved brines are separated from earlier precipitated mineral species by sluice gates and pumps. The aim of the saltwork engineer is to create harvestable monomineralic or bimineralic salts and brines in the various fractionating pans. Backreaction either does not occur or is kept to a minimum.

Many secondary (replacive and displacive) salts in natural systems, such as sylvite, glauberite and polyhalite, form syndepositionally via interaction between highly evolved near-surface brines and earlier formed minerals (Fig. 2.24; Table 2.8). For example, during the equilibrium evaporation of seawater at 25 °C, glauberite and polyhalite form by

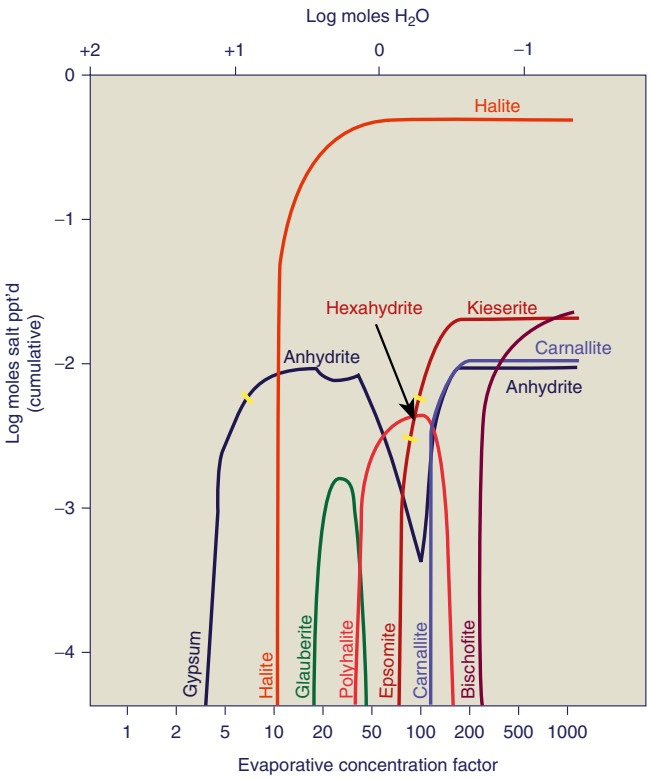

Fig. 2.24 Evaporative concentration of modern seawater simulated using the computer program of Harvie et al. (1980) showing cumulative masses of minerals precipitated and resorbed by backreaction as evaporation proceeds. Initial seawater has a concentration factor of 1, with an initial mass of 1 kg of H_2O (After Hardie 1991)

backreaction of the brine with earlier formed anhydrite and gypsum. Harvie et al. (1980) modelled much of the variability present in the bittern salts of the Permian Zechstein deposits in Germany via a combination of equilibrium batch evaporation interspersed with times of fractionation and backreaction. As seawater concentrates to slightly below halite saturation, anhydrite replaces gypsum.

As evaporation continues, anhydrite is partially replaced by glauberite. Glauberite in turn is replaced by polyhalite and levels of anhydrite are further reduced. These replacements change the residual brine composition so that kainite

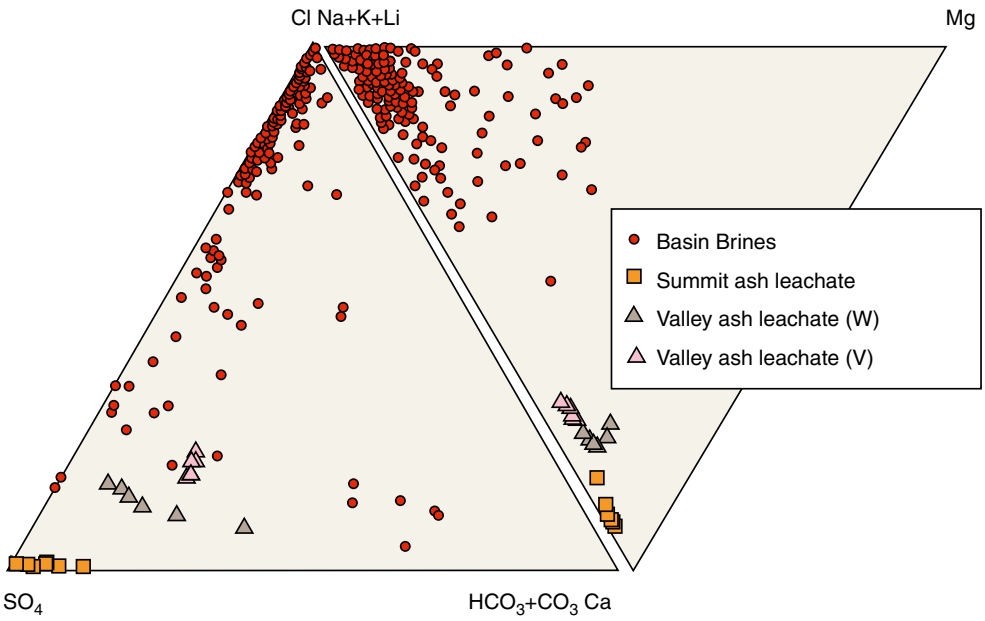

Fig. 2.25 Ionic composition of ash leachate from Lascar volcano summit and Talabre Valley floor (*V* valley floor, *W* valley on west side of volcano) compared with basinal brines of northern Chile (After Risacher and Alonso 2001)

does not supersaturate, a problem that plagued earlier geochemical models of marine-derived potash precipitation in the Zechstein Series. The Harvie et al. (1980) model not only explained the absence of primary kainite in the Zechstein deposits, but also explained the pseudomorphic replacement of gypsum and anhydrite by glauberite or polyhalite and the replacement of glauberite by polyhalite. Previous authors had attributed these replacements in the Stassfurt Salt to burial-stage thermal and solution metamorphism (Borchert and Muir 1964).

Likewise, textures in beds of polyhalite in the Lower Werra Anhydrite (Zechstein – Upper Permian) of northern Poland show they are a very early replacement of anhydrite formed within platform sulphates by diagenetic backreaction with a highly evolved marine brine (Peryt et al. 1998). Formation of polyhalite was preceded by the anhydritisation of the original gypsum. Anhydritisation of primary platform and slope gypsum was an early subsurface alteration driven by syndepositional brine plumes, with ghosts of the primary gypsum texture still visible. Later brines, which were potassium and magnesium rich and nearly saturated with respect to halite, were created by ongoing reflux during more hypersaline conditions on the platform. These more highly evolved brines reacted with anhydrite to precipitate polyhalite along the slopes of the Zdrada Platform. The oxygen and sulphur isotopic compositions of sulphate evaporites indicate that marine solutions were the only source of sulphate ions supplied to the drawndown Zechstein Basin.

Hypersaline groundwaters can also react with adjacent nonevaporite minerals to form indicator clays and authigenic phases. For example, in reactive volcanogenic margins associated with many rift-valley evaporites there are suites of authigenic zeolites and clays (Fig. 12.71). Many formed by the diagenetic reaction of nearsurface saline pore waters with metastable clays derived by weathering and alteration of labile volcanics. The best studied authigenic phases are the sodium silicates, such as magadiite; the borosilicates, such as searlesite; and the zeolites of the alkaline saline lakes, such as clinoptilolite, erionite and analcime. Sepiolite (meerschaum) clays form beds and nodules in saline lake deposits in the Miocene Eskisehir Lake of Turkey. These Mg-rich clays were deposited by direct precipitation out of silica-saturated saline and alkaline lake waters (Ece and Coban 1994). The rather unusual inflow water was derived by the weathering of a Cretaceous ophiolite complex that contained abundant serpentinite and magnesite. Many of the saline lakes in this region of Turkey also contain widespread evaporitic micrites dominated by primary magnesite.

Volcanogenic ash and debris can be a substantial component in the drainage basins of salt lakes and playas in active rift and collision belts. For example, in the Central Andes various volcanic formations overlie Cenozoic evaporites and the longterm meteoric recycling of salts from these labile carapaces into the present endorheic basins is a well-documented process. But, pulsed short term recycling of fractionated ions into the salar hydrology following a volcanic eruption is another widespread, yet less well-documented phenomena (Risacher and Alonso 2001).

During a recent eruption of the Lascar Volcano in northern Chile around 10^9 metric tonnes of air-fall tephra was deposited over the surrounding endorheic basins. Leachate experiments on this ash near the volcano summit and the nearby Talabre Valley produced fluids that were almost pure $CaSO_4$ and near neutral on the summit ashes, while leachates of valley floor ashes were alkaline (pH as

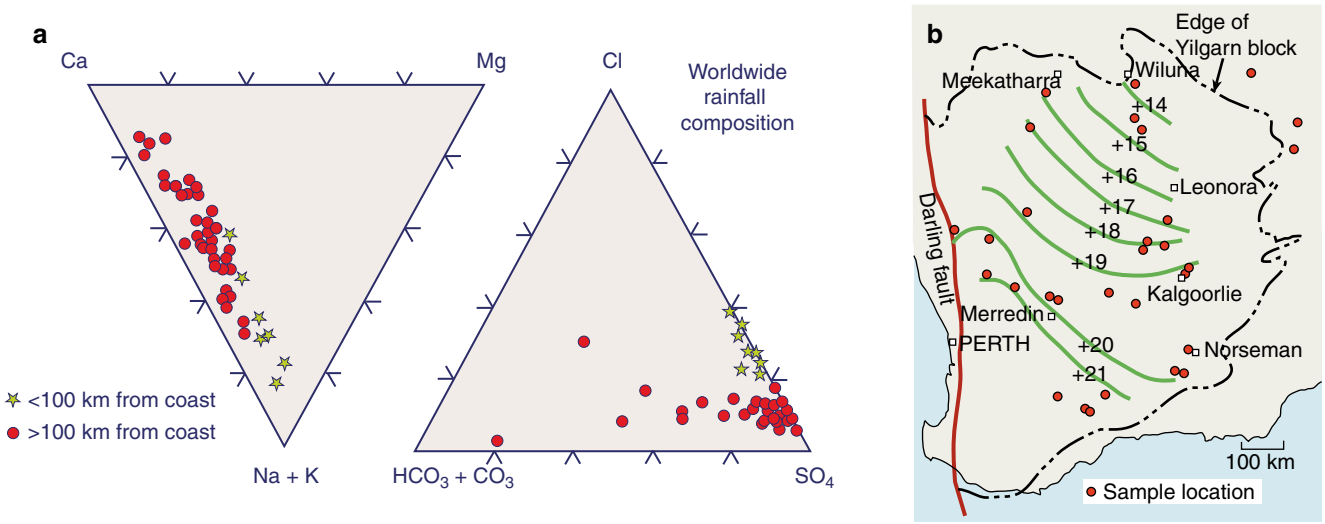

Fig. 2.26 Marine aerosols can supply ions in solution to inland playas and lakes in low relief landscapes. (**a**) Major ion content of worldwide rainfall in relation to distance from coastline, compiled from various sources listed in text. (**b**) Changes in sulphur isotope values (mostly gypsum, occasionally from alunite; After Chivas et al. 1991)

high as 10.5) and more enriched in minor components compared to the $CaSO_4$ leachate of summit ashes (Fig. 2.25; Risacher and Alonso 2001). Sulphur isotope compositions of leached sulphate are consistent with volcanogenic recycling from Tertiary gypsum that underlies the volcanic cordillera. Risacher and Alonso (op.cit.) estimate that 700,000 t of easily soluble $CaSO_4$ were added to nearby endorheic basins by 3 days of eruption. The high pH of the valley floor leachates indicates hydration of alkali and alkali-earth metal-oxides via pyrolysis of vegetation during ash fall. Efflorescent salts encrusted on plants and dissolution of volcanic glass also provided some of the minor leachate components.

The almost pure $CaSO_4$ composition of summit leach waters is compositionally distinct from any present inflow waters in the central Andes. Addition of volcanogenically cycled $CaSO_4$ may explain some of the differences between the observed brine compositions and those predicted by computed simulations of the evaporation series based on the chemistry of longer-term inflows. Rapid recycling of sedimentary gypsum and short-term pulses of salts from labile ashfall is probably not restricted to Lascar volcano. The recycling of ancient salts, and possibly the pyrolysis of vegetation, may have been crucial processes in controlling the ionic proportions of closed basins during episodes of intense volcanic activity in the Tertiary. Some of the anomalies in salt mineralogies in ancient salts may reflect pulses of volcanism rather than variations in short term climate or the degree of leakage. Lascar brine chemistry is an example of a decoupled hydrogeochemical brine system where short term brine chemistries are decoupled from longterm chemistries in the drainage basin.

Marine Aerosols and Continental Gypsum

Brine sources in ancient settings are usually inferred by a study of the regional palaeogeography and a definition of drawdown, seepage and hydrothermal brine supply using outcrop or seismic interpretation. Seepage drawdown or periodic storm floods are thought to be the predominant mechanisms for supplying substantial volumes of marine ions to larger ancient basins. But aerosols are a viable ionic supply mechanism in the hydrochemistry of modern continental arid-zone systems up to a thousand kilometres from the coast. There is even a modern aerosol-defined marine versus nonmarine salt-line in the saline depressions of the Vestfold Hills of Antarctica (Gore et al. 1996).

Aerosols

Modern aerosol supply routes are best seen in isotopic signatures of the resulting salt, but this leads to a circular argument if marine aerosols are invoked as brine sources for ancient evaporites in continental settings (i.e., I assume a portion of the input is marine therefore a proportion is marine), underpinning once more the numerous difficulties involved in separating marine and nonmarine brine sources for ancient salts.

Aerosalts from salt spray can supply substantial quantities of ions to precipitative hydrologies in modern continental salt lake depressions located hundreds of kilometres from the continental margin (Fig. 2.26a). For example, the Murray Basin, in southeast Australia, contains a 500 m thick sequence of Palaeocene to Recent sediments deposited in fluvial to marine settings (Jones et al. 1994). The upper 100 m in the central part of the basin now entrains large vol-

umes of subsurface brines with salinities in excess of 100,000 mg/l. These brines feed many of the discharge playas in the region. They are type II brines with major solute compositions and proportions very much like that of evaporated marine waters (thalassic groundwater). Their isotopic composition, however, is that of evaporated meteoric water. This led Jones et al. (1994) to the conclusion that the brines have been derived by the longterm accumulation of salt from marine aerosols, mixed with continental waters. The marine salts are blown into the basin either as dry salt suspensions or arrived as rainfall. Evapotranspiration in this semi-arid basin greatly exceeds rainfall and so solutes accumulate as brackish near surface waters. These shallow waters are further concentrated via capillary evaporation before escaping into saline discharge lakes. Regionally, the shallow groundwater flow regime is sluggish and not capable of dispelling these brines, so they infiltrate and accumulate above a regional aquitard.

Likewise, the $\delta^{34}S$ values of gypsum accumulating in modern playa lakes in the ancient landscape of southwestern Australia show little relationship with underlying bedrock types or the $\delta^{34}S$ values of any nearby bedrock sulphur (Chivas et al. 1991). Analysis of $\delta^{34}S$ from surficial lacustrine and pedogenic gypsum on a regional scale, in both Western Australia (Yilgarn Block) and South Australia, shows distance-related dispersal patterns over distances of 500–1,000 km from the coast. The highest values (≈21‰) occur near coastlines decreasing to $\delta^{34}S$ values of≈ 14‰ further inland (Fig. 2.26b). Marine sulphate is the dominant source of sulphur to the lakes investigated, with the proportion decreasing from approximately 100 % near coastlines to around 55 % further inland. For tens of kilometres inland of the modern coast, one can argue for a seepage origin of gypsum in many subsealevel lows (salinas) with active seawater seeps and appropriate drawdown surfaces. Further inland the gypsum in the various salt lakes reside in depressions that intersect a regional continental watertable. This watertable is metres or more above sealevel and it slopes seaward, so phreatic seawater seepage is not viable, yet the gypsum still has a marine isotope signature.

In some of the more interior Australian salt lakes, there can be a significant weathered bedrock component to the ionic components in the salt lake waters, especially where the bedrock contains abundant soluble sulphur and high levels of iron. Lake Cadibarrawirracanna (inland South Australia), for example, receives approximately 10 % of its sulphur from weathering of the pyritic Bulldog Shale (Cretaceous); brine in nearby Lake Amadeus receives up to one-third of its sulphate from leaching of evaporites from the Neoproterozoic Bitter Springs Formation.

Like much of arid inland Australia situated up to a thousand kilometres from the coast, the Namib Desert, which hosts one of Africa's most extensive accumulations of modern pedogenic and playa gypsum, is largely supplied by a variable combination of regolith runoff and marine aerosols (Fig. 2.27a; Eckardt and Spiro 1999; Eckardt et al. 2001). An extensive pedogenic gypsum accumulation forms a 50–70 km wide band parallel to the shore in the Central Namib Desert between the Kuiseb and Omaruru rivers. $\delta^{34}S$ analysis of calcium sulphate in this belt and the associated brines, along with an analysis of the brine chemistry shows marine aerosols are a major ion contributor to the gypsum budget (Fig. 2.27b). Marine aerosol sulphates are stored within widespread terrestrial gypsum deposits on the hyperarid gravel plain and are traceable as groundwater precipitates, including gypsum, in near coastal sabkhas and inland playas.

$\delta^{34}S$ values for the gypsum crusts are between +13.0 and +18.8‰, with lower values ($\delta^{34}S$ = +3.1–3.4‰) in crusts near local bedrock sulphur sources, which are typically metal sulphide bodies. These Damaran bedrock sulphides show a wide $\delta^{34}S$ range from −4.1 to +13.8‰ but are significant sulphur sources only on a local scale. Dissolved sulphate in playa, sabkha, spring, borehole and ephemeral river waters have an overall $\delta^{34}S$ range between +9.8 and +20.8‰ but, unlike Australia, do not show a systematic geographical trend tied to distance from the coast. Even so, marine aerosols are the only viable supply mechanism for pedogenic sulphate over such a large arid near coastal area. Further south, in the Holocene Yzerfontein and Zwartwater pans of South Africa, which are some 15 km from the coast, Mauger and Compton (2011) use a combination of stable isotope and radiogenic Sr data to illustrate that marine aerosols are the dominant source of Ca in the bacteriogenic dolomites currently forming in the pans.

Atmospheric sulphates in the Namib are carried landward as marine aerosols, with a large proportion ultimately derived from decomposition of the dimethyl sulphide of phytoplankton. The plankton are an integral part of high levels of primary production driven by the upwelling of the cool Benguela current, the same oceanic system that creates the onshore aridity. The Central Namib Desert lies onshore from the thickest organic-rich sediment accumulations on the Namibian Shelf (Fig. 2.27). This suggests that some of the sulphate component in Namib gypsum is derived from marine H_2S during the anaerobic decomposition of this organic-rich sediment. The gas is probably carried into the desert by frequent advective fogs. Sea salt, decompositional marine biogenic and local bedrock sulphide sources, once invoked as the main sulphate source in these widespread gypsum accumulations in the Namib Desert, cannot account for the volumes of calcium sulphate unless the substantial dimethyl sulphide from plankton is also included in the sulphur supply cycle (Eckardt and Spiro 1999).

That is, most of the marine aerosol that drives extensive onshore gypsum accumulation is a mixture of marine sources

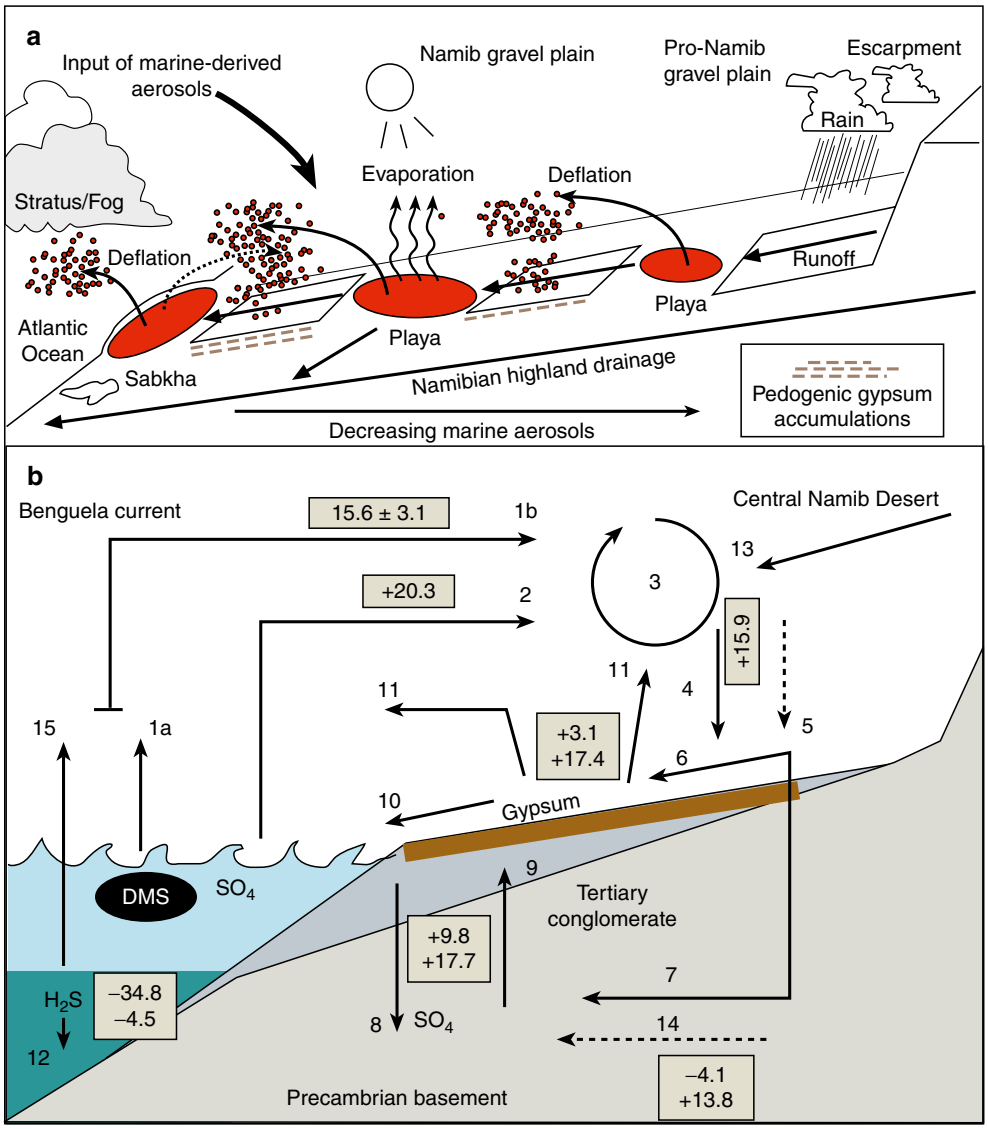

Fig. 2.27 Pedogenic gypsum and the origin of sulphate in waters and sediments of the Namib Desert. (**a**) Model of pedogenic gypsum formation for the Namib Desert where marine-derived dry aerosols are dissolved and mobilized through moisture provided by fog and rain water. Primary gypsum formation takes places in playas and is subjected to eolian and fluvial dispersal. Pedogenic gypsum accumulations increase towards the coast as the volume of marine supplied aerosol increases. (**b**) Schematic representation of hydrogeochemical sulphur cycle along the Atlantic – Namib Desert interface (After Eckardt and Spiro 1999). *Solid arrows* show sulphur pathways, potential sulphur pathways are indicated by dashed arrows. Range of $\delta^{34}S$ composition is indicated in boxed numbers. *1a* dimethyl sulphide (DMS) released from phytoplankton, *1b* Non-sea-(NSS) sulphur, *2* SO_4 release in sea spray, *3* mixing of aerosols in the atmosphere, *4* dry aerosol deposition, *5* – wet aerosol deposition, *6* runoff and gypsum formation, *7* infiltration and groundwater flow, *8* capillary rise and gypsum precipitation, *9* gypsum dissolution and infiltration, *10* gypsum dissolution and runoff, *11* eolian gypsum dust dispersal, *12* in situ sulphide and sulphate formation in Benguela sediments, *13* subcontinental dust input, *14* sulphide oxidation by groundwater, *15* H_2S release to atmosphere (After Eckardt et al. 2001)

of sea spray and atmospheric non-sea-salt (NSS) sulphate, largely supplied by oxidation of biogenic sulphur compounds – dimethyl sulphide, CH_3SCH_3 (DMS). Many organisms, including plankton and seaweeds, rid their bodies of sulphur (a biochemical waste product) by attaching it to various methyl compounds. They do the same with mercury, antimony and arsenic and other toxins. Such compounds are much more volatile than the original and so readily escape from cellular cytoplasm. Hence, a substantial portion of the sulphur isotope signature of pedogenic gypsum in the Namibian Desert reflects a biogenic marine source for the sulphur. The Benguela Current has been a major upwelling system dating back to the Late Miocene (10 Ma) and is likely to have generated DMS for a significant amount of that time (Fig. 2.27a).

Likewise, much of the gypsum in Atacama Desert soils below 1,200 m and within 90 km of the coast receive a portion of their sulphate from coastal fogs locally known as

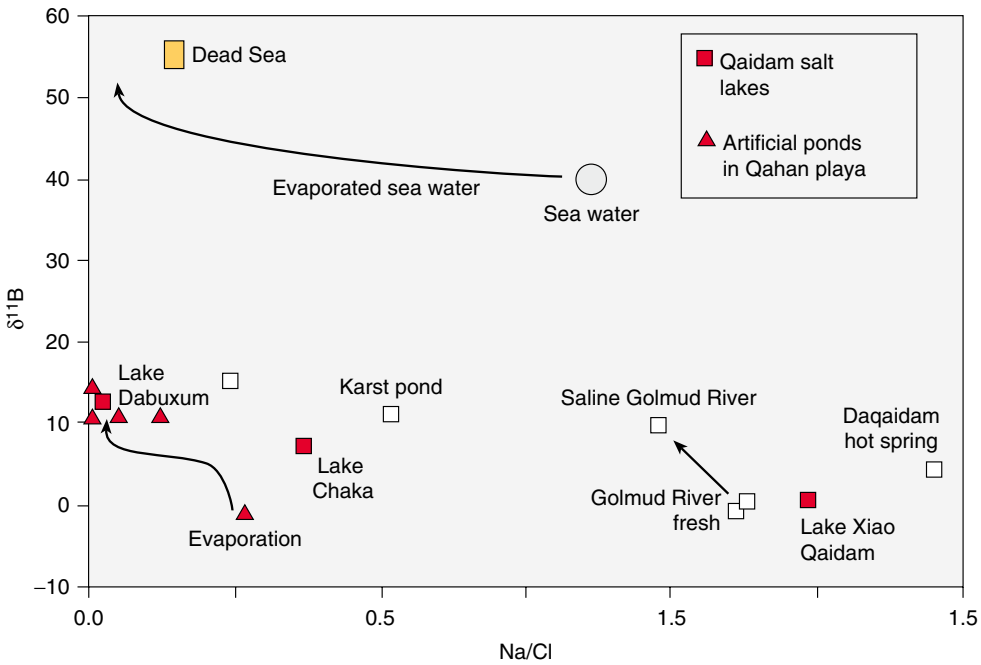

Fig. 2.28 Boron isotopic and Na/Cl ratios of waters and brines in the Qaidam Basin, China (After Vengosh et al. 1995). See Fig. 11.10 for locations

camanchaca. Soils within 50 km of the Pacific Coast and below 800 m elevation, receive 50 % of their calcium and sulphur from marine aerosols (Rech et al. 2003). Interestingly, in this hyperarid region the $\delta^{13}C_{PDB}$ values in the moister area are as negative as −7.2‰ in the soil carbonates, reflecting the metabolic activities of the soil biota, especially in coastal fog oases. In contrast $\delta^{13}C_{PDB}$ values in the drier higher elevation regions, below the puna rainfall belt, have positive values up to 7.2‰, indicating mostly abiogenic precipitation of the soil carbonates (Quade et al. 2007). This same coastal fog system sources much of the economic accumulations of sodium nitrates in the coast-parallel Atacama soils (Böhlke et al. 1997; Chap. 11)

Evaporite Bedrock

Difficulties in distinguishing marine versus nonmarine sources are further complicated by ongoing dissolution of older exhumed evaporites, which can act as chemical feeds into purely continental hydrographically-closed basins. In areas too continental for significant contributions from marine aerosols, this can still create marine-like signatures in the ionic proportions (Na-K-Mg-SO_4 -Cl brines). For example, carnallite-sylvite-halite is a modern lake precipitate in Qaidam Basin, northern Qinghai-Xizang on the Tibet Plateau, China (Fig. 11.10). This basin lies within a large, tectonically active region that is totally isolated from the effects of the ocean and is filled with Neogene clastics and evaporites. Its modern at-surface discharge playas are subject to intense evaporation and are characterised by ephemeral hypersaline brines as well as halite, potash and borate crusts and layers.

The chemical composition and Na/Cl ratios of the dissolved solutes in the modern brines and waters in the salt lakes of Qaidam Basin reveals three main sources (Vengosh et al. 1995): (1) Inflow of hot springs enriched in sodium, sulphate and boron. Evaporation of these waters leads to a high Na/Cl ratio (>1), a Na-Cl-SO_4 brine and an evaporite mineral assemblage of halite-mirabilite-borate (e.g., Lakes Daqaidam and Xiaoqaidam). (2) Inflow surface river waters, which are modified by preferential dissolution of older halite and potassium and magnesium salts. Evaporation of such waters creates Na-(Mg)-Cl brines with low Na/Cl (<1) and low Br/Cl, Li/Cl and B/Cl ratios. (3) Ca-Cl subsurface brines with chemistries controlled by both salt dissolution and dolomitisation processes. Evaporation and salt crystallisation from mixtures of brines (2) and (3) leads to a "marine-like" Na-Mg-Cl brine with Na/Cl ratios $\ll 1$. Although more than 1,000 km from the nearest ocean the precipitated sequence of salts in these lakes is similar to that predicted for progressive evaporation of seawater. Lake Dabuxum and Qarhan playa today contain halite-sylvite-carnallite-bischofite successions.

The lower $\delta^{11}B$ values of the Qaidam basin brines and halites compared to seawater ($\delta^{11}B \approx 40$‰) indicate that the boron within these salt lakes is nonmarine (Fig. 2.28; Vengosh et al. 1995). The $\delta^{11}B$ values of the dilute inflow waters to the Qaidam Basin range from −0.7 to +10.9‰, while brines in the various salt lakes range from +0.5 to +15.0‰ (Vengosh et al. 1995). Both groups overlap and are similar to those of associated granitic rocks ($\delta^{11}B = -2.12$ to +3.7‰) and hence indicate the nonmarine origin of these fluids.

In contrast to the Qaidam playas, the boron isotopic composition of brines, groundwaters and sediments of modern inland salt lakes located nearer the coast across southern

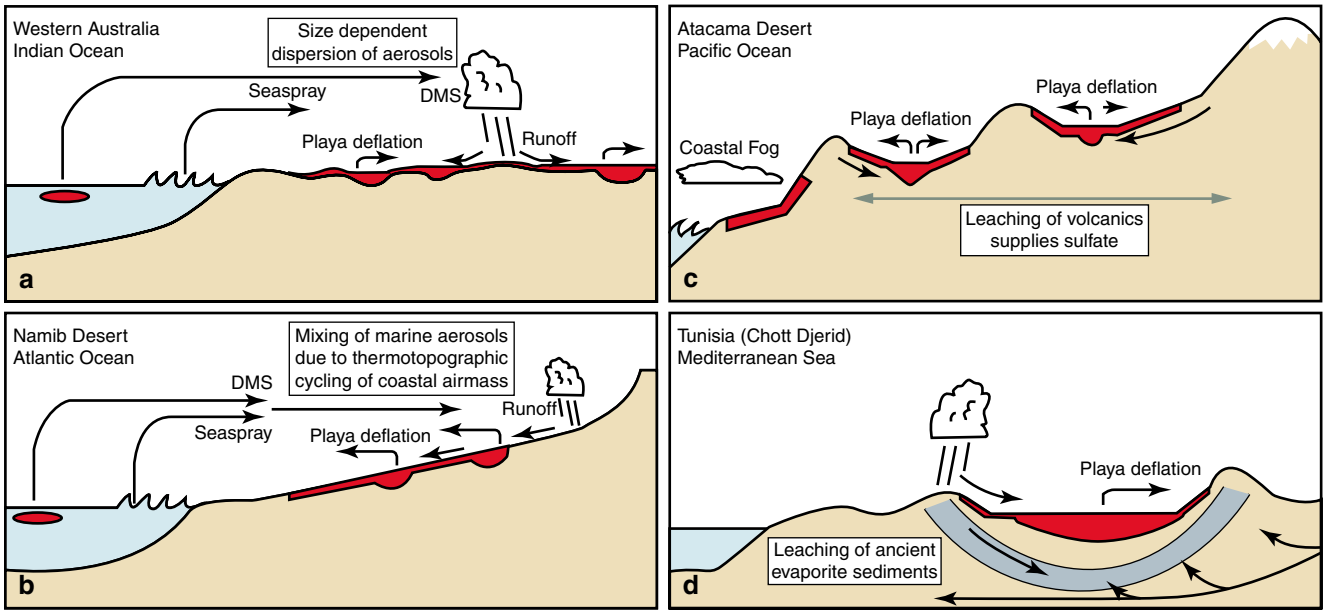

Fig. 2.29 Various atmospheric and groundwater transport mechanisms supplying sulphate to modern continental saline lakes and pedogenic gypcretes in; (**a**) Southwestern Australia, (**b**) Namibian Desert, (**c**) Atacama Desert, (**d**) Chott Djerid. (After Drake et al. 2004)

Australia have a marine component, probably from aerosols (Vengosh et al. 1991). $\delta^{11}B$ values of brines in these salt lakes are 25–48‰, with values up to 54–59‰ in volcanic maar lakes in the higher rainfall areas near coastal region of southeastern Australia. Modern seawater has a $\delta^{11}B$ of 39‰ (Fig. 2.28).

Across much of northern Tunisia, centred on the Chott Djerid region, there is an extensive gypcrete bed up to 7 m thick and sometimes covered by later eolian and fluvial clastics. It is probably the most aerially extensive gypsum bed in northern Africa (Drake 1997; Drake et al. 2004). Sulphur isotope analysis ($\delta^{34}S$) of bedrock samples, groundwater, playa brines, playa sediments, and gypsiferous crusts indicate the ultimate source of sulphate now residing in this regional gypsum unit was not marine aerosols, but weathering and leaching of the subcropping Triassic, Cretaceous, Eocene and Mio-Pliocene marine salts. That is, Drake et al. (2004) conclude that recycling of ancient $CaSO_4$ is the source of the sulphate in the modern groundwater that ultimately deposits the modern playa sediments and crusts of northern Tunisia. The low $\delta^{34}S$ values found in Eocene and Mio-Pliocene gypsum imply that this groundwater recycling of sulphate has been going on for much of the Tertiary. When Tunisian bedrock sources are compared with transport and precipitative processes actively forming continental lacustrine and pedogenic gypsums in Australia, the Atacama and Namibia, it is obvious that, although the source of the sulphur varies from bedrock reworking to marine and local aerosols to eolian reworking, the final pedogenic textures in all areas are derived from a similar set of capillary and eolian precipitative processes (Fig. 2.29).

In summary, the occurrence of modern continental evaporites, especially sulphates, exhibiting largely marine-like (thalassic) brine ionic chemistries and isotopic signatures, is in part due to marine aerosol input and in part due to regionally open or leaky meteoric hydrologies. Mineralogies of preserved evaporitic sediments in low relief depressions on stable cratons can be largely uncoupled from the surface lake chemistries and salt crusts. A leaky hydrology, in a landscape dominated by deep weathering, deep regionally circulating groundwaters, with variable reflux intensity (leakage) can drive the evolution of seawater-like ionic proportions in the subsurface pore waters. It is common set of processes to many modern, low-latitude, tectonically stable desert areas and differs from the less aerially extensive but better documented, highly-endorheic hydrologies of the Basin and Range and East African rift valleys. Perhaps the hydrologically open setting is the more relevant hydrochemical analogue for the continental hydrologies of ancient interior redbed deserts of ancient continents. If so, models based on assumptions of evaporite mineralogies in desert redbeds as being indicators of various "closed basin" hydrologies are largely irrelevant. If so, it makes the hydrochemical distinction between marine and nonmarine evaporites in the geological record even more difficult.

Acid Groundwater in Continental Saline Systems

Many playas atop the deeply weathered ancient regolith in central and southern Australia have elevated iron and sulphur

contents. Salt lakes with more elongate shapes outline Tertiary palaeovalley fills in palimpsest landforms that were created under a different climate than that of today (Fig. 11.34; Clarke 1994). From the mid-Eocene, the climate in Australia became progressively drier until, by the Miocene, much of central Australia was dominated by perennial alkaline lakes (Alley 1998). The subtropical style of weathering that prevailed in the Early Eocene slowly changed with the passage into the Neogene, resulting in the development of a more arid siliceous and ferruginous regolith. The present elevated iron and sulphur levels in the modern Australian landscape ("the Red Centre") were derived, to a large extent, from earlier deep weathering profiles and even today these relicts of a more tropical time are still cycling through the now-arid Australian regolith. Passage into drier conditions allowed the buildup of minerals such as alunite and gypsum in the weathered profiles. The resulting low relief, gently undulating landsurfaces formed partial etchplains with topography controlled largely by the elevation of the paleoweathering front and associated erosional topography of an incised Tertiary-age palaeodrainage and duricrusts. Hilltops may today be composed of fresher rock, while valley slopes, pediments and pediplains are typically composed of fresh to saprolitic rock, along with residual ferricretes that form low mesas.

Palaeodrainage fills can locally be more than 100–200 m thick, with many palaeodrainage networks currently occupied by elongate playa lakes, often with lunette margins and separated by wide areas of desert soils and dune sands. Formation of the weathered regolith largely predated the incision of the palaeodrainage which, in its deepest parts, has cut through to fresh rock (Clarke 1994). Older relict saprolite in the current landscape dates back to the Late Permian-Middle Jurassic. Stripping of this regolith occurred in the Middle Jurassic-Early Eocene during the formation of the seaward-sloping palaeodrainage system. For example, about 400 m of material was denuded from the Yilgarn Craton, to infill the Perth, Eucla and Great Australian Bight Basins. Ongoing deep weathering occurred concurrently with erosion as increasing aridity led to disorganization of the drainage to form numerous chains of lakes, which by the Pliocene had evolved into saline lakes. Some of these palaeovalleys today contain economic capillary uranium (calcrete) deposits.

The great age of the Australia landscape and the buildup of remobilised iron in the modern regolith has led to natural acid brine systems feeding into many inland playas such as Lake Tyrell in Victoria and Lake Yaninee in South Australia. The salt lakes are recharge depressions, which supply free-convecting dense saline brine (Na-Cl-SO_4 reflux brines) to their underlying aquifers.

For example, Lake Tyrell, with an area of 185 km^2, is the largest of three salt lakes in the Tyrell Basin, a structural downwarp located some 10 km east of the N-S trending Tyrell Fault in the riverine plain of the Murray river in semi-arid northwestern Victoria (Fig. 2.30; Macumber 1992). It is a well-studied example of a lunette-fringed lake where deflation plays a major role in controlling morphology and sediment thickness. It evolved into a dry lake some 32 ka, but is today water-covered for up to 3 months in the winter and early spring (Teller et al. 1982). Despite ongoing deflation, up to 5 m of lacustrine sediment is found in the lake centre and consists of varying proportions of clay, silt and sand, covered by an ephemeral halite crust up to 30 cm thick. The lakebeds are underlain by the Parilla Sand, a regional sulphate-rich aquifer.

Lake Tyrell is part of the outcropping expression of a regional oxidised acidic groundwater mass with characteristically low pH of 2–4 and salinities between 35 and 115‰ (Petrides et al. 2006). In contrast to the regional acidic system, the reflux brine plume beneath the lake is neutral (pH ≈ 7) but with salinities around 240‰. Direct rainfall in the winter months provides the bulk of the surface water currently entering the lake, whereas regional discharge and evaporation of westward-flowing Parilla groundwaters contributes most of the salt load. Faulting to the west of the lake uplifts the Parilla Sand aquifer and effectively closes the basin to ongoing throughflow or outward seepage and augments groundwater discharge by halving the saturated thickness of the aquifer. An additional groundwater divide separates the shallower parts of the hydrology of Lake Tyrell from that of Lake Wahpool (Fig. 2.30).

As the regional Fe and S-rich acidic groundwaters resurge into the spring zone about the saline lake edge they precipitate varying proportions of characteristic lacustrine mineral suites made up of varying proportions of alunite, jarosite, halite, gypsum, opaline silica and iron oxyhydroxides. All these mineral phases are rich in Al, Fe and SO_4 giving the oxidised portions of the spring-zone sediments a classic "red bed" appearance (McArthur et al. 1989, 1991; Long et al. 1992a, b; Alpers et al. 1992; Macumber 1992; Benison and Goldstein 2002).

Hemley et al. (1969) showed by experiment that a high H_2SO_4 concentration is needed to form alunite ($KAl_3(SO_4)_2(OH)_6$) and jarosite ($KFe_3\ (SO_4)_2\ (OH)_6$) in any low pH lacustrine environment. Associated acid minerals in the alunite–jarosite family include; natroalunite, alunogen, jurbanite, basaluminite, and rostite (all in the system Al_2O_3-SO4-H_2O), along with natrojarosite, schwertmannite, halotrichite, melanterite, and copiapite (all in the system Fe_2O_3-SO_4-H_2O; Nordstrom 1982a, b; Van Breemen 1982; Bigham and Nordstrom 2000). Once formed in acid settings, these acid minerals may undergo further reactions, breaking down into more stable forms of iron oxides (i.e., goethite or hematite; Bigham and Nordstrom 2000), sulphates (i.e., gypsum or anhydrite; Van Breemen 1982), and aluminosilicates (i.e., microcline or albite; Long et al. 1992a).

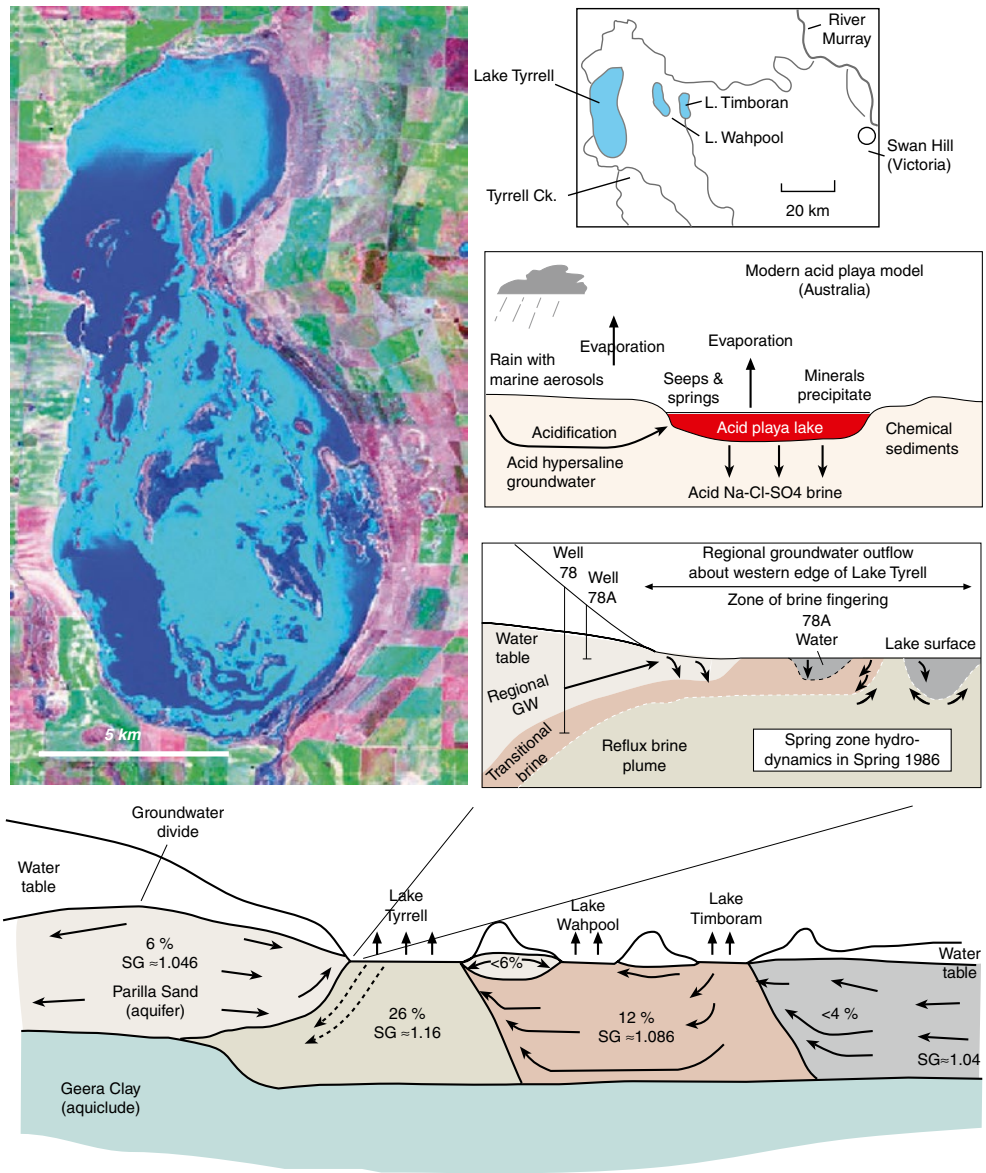

Fig. 2.30 Acid lake formation based on modern natural acid lake and groundwater systems centred on Lake Tyrell in southern Australia (After Macumber 1992; Lyons et al. 1995). These redbed siliciclastic sediments of the Parilla sand aquifer host sulphuric-acid rich saline lakes and groundwaters (pHs of 2–4) which precipitate alunite, jarosite, halite, gypsum, opaline silica, and possibly iron oxyhydroxides. Acidification may occur in the groundwater by processes such as oxidation of pyrite, ferrolysis, and microbial reduction of iron oxyhydroxides. Brine fingering typifies the mixing zone between regional groundwater outflow and the brine reflux prism beneath Lake Tyrell (Landsat image courtesy of NASA)

What make Lake Tyrell sediments interesting is that these lacustrine redbeds indicate the influence of groundwaters carrying elevated levels of sulphuric acid (the pH in the modern groundwater systems of SE Australia is typically in the range 2–4) interacting with the neutral hypersaline waters of the lake itself. These regional naturally acid waters of the regolith are very different brines to the alkaline waters of well documented continental soda lakes and the marine-fed groundwaters of coastal salinas. Acid groundwaters in arid to semi-arid Australia indicate a landscape that has undergone a transition from tropical to arid conditions, perhaps related in part to Australia's northward drift, but more controlled by climate deterioration created by the transition from greenhouse to icehouse climate mode (Chap. 5).

The spring seep region in the Lake Tyrell outflow zone was one of the first wet playas documented with sinking brine plume fingers in the axial saucers of polygons of convective upwelling groundwater across the zone of phreatic mixing about the lake edge (Fig. 2.30; Lyons et al. 1995). As upwelling regional groundwater reaches the Lake Tyrell depression, it evaporates and concentrates and so becomes denser. It then sinks to mix into the regional groundwater crossflow atop the Geera Clay aquiclude. Rather than sinking as a homogenous front these descending waters sink as denser brine fingers surrounded by upward flowing polygonal cells of fresher resurging groundwater that continually resupply the evaporating water surface (Fig. 2.30). This convective counterflow creates large variations in fluid composition in short horizontal distances. Migration of the fingers over time creates numerous laterally migrating redox and salinity interfaces where diagenetic minerals can backreact and precipitate. This patchy diagenesis further complicates simple models for the distribution

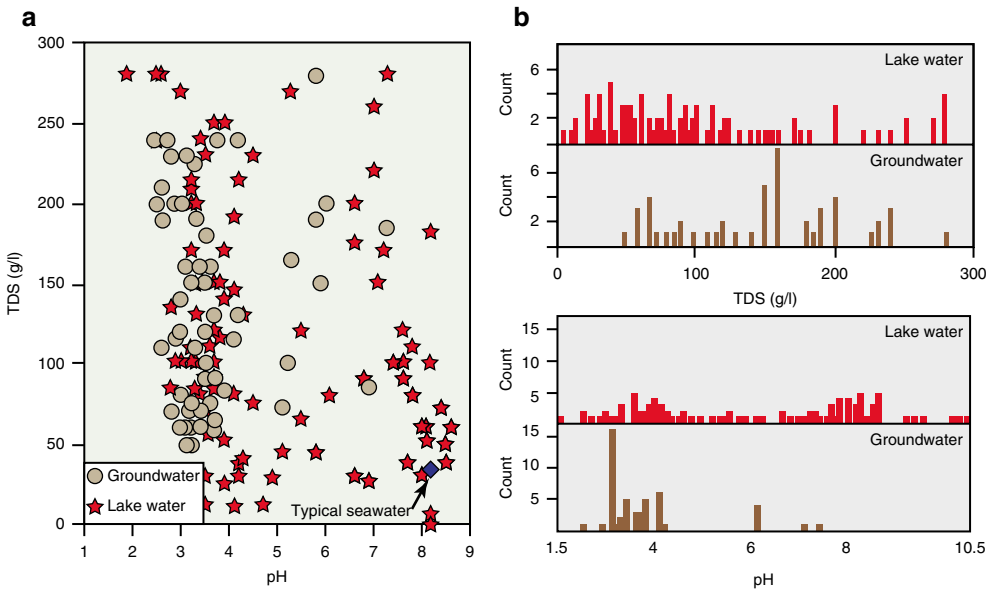

Fig. 2.31 Field pH and salinity (total dissolved solids (TDS) in g/L) data for all West Australian lake and groundwaters (After Bowen and Benison 2009). (**a**) Range of all pH and salinity. Value of typical seawater included. (**b**) Histograms showing the count of all measured lake waters and groundwaters with various salinity and pH values, respectively

of the original "red-bed" precipitates and explains the complex counterplays of salinity indicators seen in ancient spring-seep strandzones (Chap. 1).

Based upon theoretical and experimental evidence, Wooding (1960) and Tyler and Wooding (1991) postulated that near the evaporating water surface, the downward movement of dense brine is confined to fingers or plumes of dense fluids, surrounded by an upward flow of fresher water supplying the evaporating surface. Similar convective polygons can also occur in freestanding zones of mixing near the strandzone edges of coastal salinas and saltworks. Tyler and Wooding (1991) showed that the conditions necessary for the onset of fingered polygonal convection beneath an evaporative wet playa surface are characterized by a modified Rayleigh number, R_c of the form:

$$Rc = \left(kg\Delta\rho\tilde{n}\right)/\left(\mu\varepsilon\right)$$

where k is the intrinsic permeability (in cm^2), $\Delta\rho$ is the difference in density between the evaporated brine and the regional groundwater (in g/cc), μ is the dynamic viscosity, ε is the evaporation rate and g is the acceleration due to gravity.

For a playa groundwater system to exhibit brine fingering, Tyler and Wooding (1991) and Ferguson et al. (1992) suggested that the Rayleigh criteria (R_c) must be around ten or higher. Controlling factors leading to brine instability and convective fingering are sediment permeability, density contrast between the brine and regional groundwater outflow, and the evaporation rate. Using typical playa parameters of $\Delta\rho = 0.3\ g \cdot cm^{-3}$ and $\varepsilon = 30\ cm \cdot year^{-1}$, then the sediment permeability must be $10^{-9}\ cm^2$ (100 md) or higher for the playa groundwater system to begin to convect as polygonally distributed circulation cells. This level of permeability lies between that of unconsolidated clay and sand in the lake sediments, suggesting that spring zones in sandy or permeable carbonate sediments, such as those typically found near playa and marine strandzone margins, are likely to exhibit brine fingering and laterally migrating redox and salinity interfaces. Perhaps some of the megapolygonal patterns seen in domal stromatolites and tepees about the strandzone of Marion lake and other modern coastal salinas are the result of stable convective polygons in a resurgent brine hydrology (Fig. 4.6b, c).

Acid regolith/playa systems dominate also the ephemeral lake hydrologies in paleochannels of the Yilgarn Craton, West Australia (Figs. 2.31 and 2.32; Bowen and Benison 2009; Jagniecki and Benison 2010; Benison and Bowen 2013). Approximately 40 % of the lakes sampled and 84 % of the measured groundwaters in West Australia are extremely acidic (pH <4) with some pHs as low as 1.7. The salinity of lake waters and groundwaters ranges from relatively rare freshwater to common saline water and brine with total dissolved solids >28 %. The fluids are typically Na-Cl to Na-Mg-Cl-SO_4 brines with variable yet locally high amounts of Ca, K, Al, Fe, Si, and Br, especially in more acid waters (Fig. 2.31). The acid brine fluid compositions are unusual in terms of comparison with seawater and most other continental groundwater compositions. For example, in some fluids the amount of Al≫Ca, the amount of Br>K, and comparison of total S to values suggest the presence of uncommon S-bearing species.

Trends in $\delta^{18}O$ and $\delta^{2}H$ illustrate a separation between surface lake water and shallow groundwaters (as in Lake Malata, Eyre Peninsula), and indicate the strong contribution of evaporatively evolved meteoric waters to the lakes. The chemical and isotopic compositions of these fluids indicate a spatially and temporally dynamic, yet regionally consistent, history of brine evolution that is fundamentally different from most other terrestrial closed basin brines. Most importantly, like Lake Tyrell, the West Australian saline lake brines do not evolve from surface evaporation of dilute inflow waters, but rather are fed by highly evolved regionally acid saline groundwaters. This is also true for two small acid

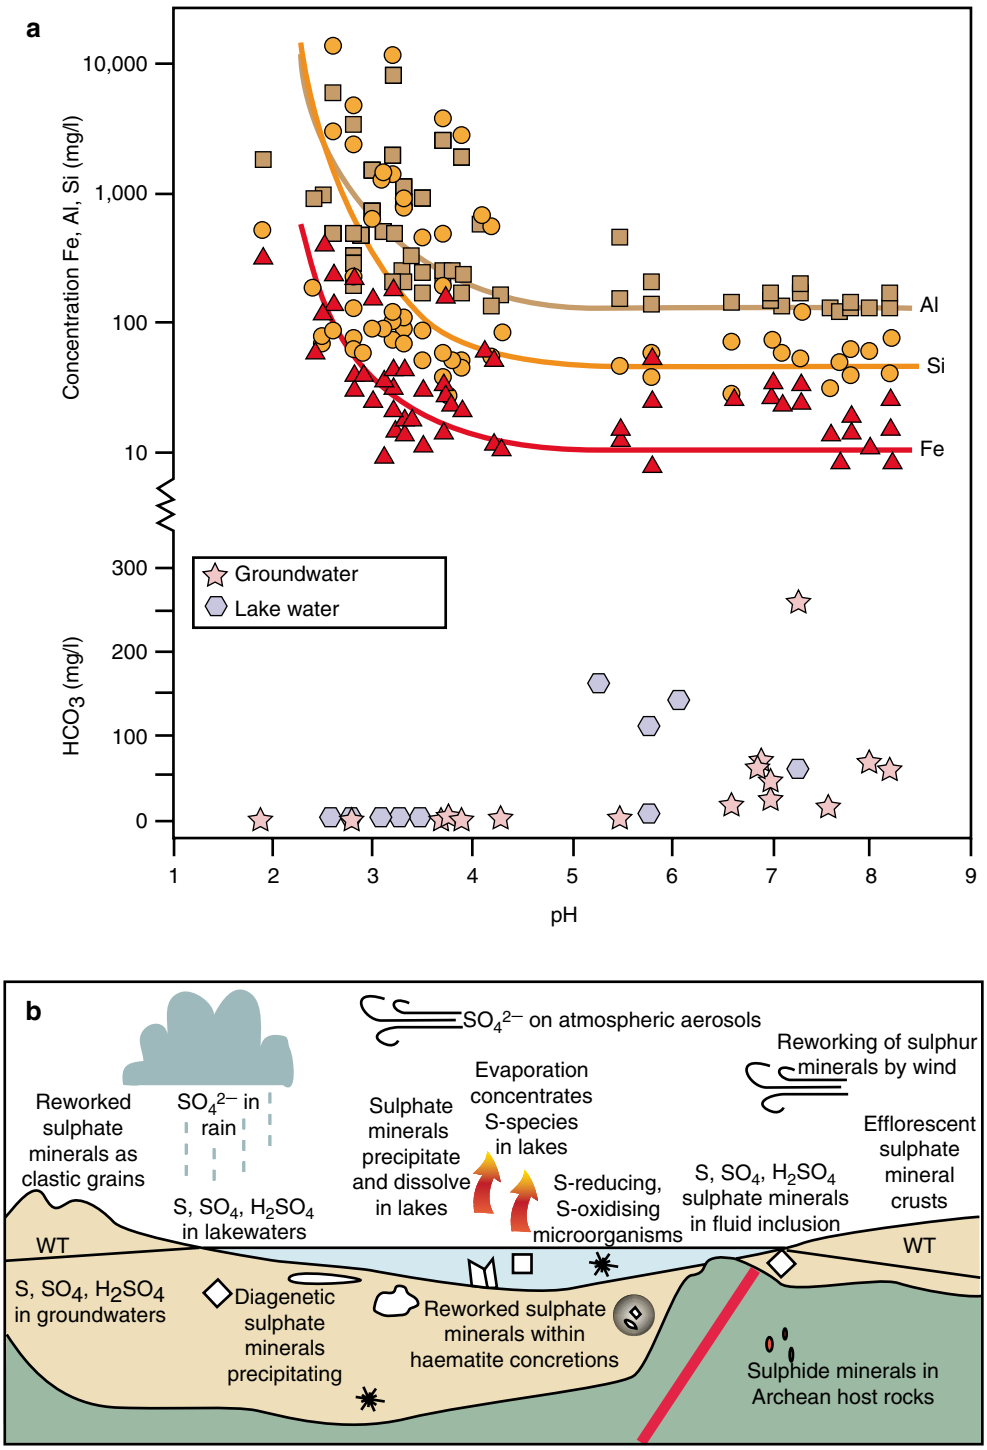

Fig. 2.32 Acid saline lake water chemistry, Yilgarn, Australia. (**a**) Relative concentrations of Fe, Al, and Si in West Australian lake waters and groundwaters versus pH, all three ions increase in concentration with decreasing pH Lower portion shows HCO_3 concentrations in both lake waters and groundwaters tend to increase in more alkaline waters (After Bowen and Benison 2009). (**b**) Schematic of Western Australian acid saline lake system, showing multiple products and processes driving sulphur cycling (After Benison and Bowen 2013)

saline salars in the High Andes of Chile – the Gorbea (3,950 msl) and Ignorado (4,250 m) salars. There the acidity is a direct reflection of the active hydrothermal alteration driven by the andesitic volcanism and the high sulphur content that typifies the region (Risacher et al. 2002). This acidity is localised (2 out of 84 lakes sampled) and is nothing like the more sedimentologically relevant climatic transition that created the acidity in the modern saline waters of southwestern and southeastern Australia.

Rainwaters, which have previously been suggested as a source of sea spray aerosol SO_4 to the lake systems, yielded 7–8 ppm SO_4. Sulphur isotope analysis shows that $\delta^{34}S$ for lake waters is 17.0–19.1‰, for groundwaters is 17.0–18.6‰, for gypsum is 20.2–20.4‰, and for alunite is 18.9‰. These values are consistent with a combination of S sources and sinks. Sulphur cycling processes include sulphide oxidation, evapoconcentration, mineral precipitation, mineral dissolution, and bacterial reduction and oxidation. Field, petro-

graphic, and molecular analyses of microorganisms in these acid saline environments suggest that some are S-oxidizing and S-reducing bacteria. Sulphur-bearing minerals in the area include both sulphides and sulphates (Fig. 2.32b). Sulphides, including pyrite, have been observed in veins and disseminated in surface exposures and shallow cores of Archaean igneous and metamorphic host rocks, as well as in overlying sediments. Sedimentary sulphate minerals include gypsum, bassanite, anhydrite, and rozenite that grow directly from lake waters, and gypsum, anhydrite, jarosite, natrojarosite, alunite, basaluminite, hydrobasaluminite, langbeinite, and rozenite that grow diagenetically from shallow groundwaters.

These sedimentary minerals are subjected to physical reworking and chemical dissolution and re-precipitation. Sulphur cycling among the lithosphere, hydrosphere, biosphere, and atmosphere in acid saline environments is dynamic. Driving forces are rock weathering, weather, and climate, which ultimately influence the water chemistry. Flooding, evapoconcentration and desiccation cycles accelerate short-term local and regional sulphur cycling. The combination of low pH, highly saline waters, and dynamic changes in environment make sulphur arguably the most important element in these environments (Fig. 2.32b; Benison and Bowen 2013).

Similar climate-controlled acid hydrologies probably characterised the continental interior of the USA in the Permian in saline redbeds of both the Opeche Shale and Nippewalla Group halites. Although large volume terrestrial analogs for these deposits are not widespread in the Quaternary, Benison and Goldstein, (2002) argue acidic saline deposits are commonplace in the rock record, whenever continental conditions were saline and subject to transitions from tropical humid to arid. If so they are largely unrecognised. That paper, along with Jagniecki and Benison (2010), propose the following as criteria for wider recognition of ancient acid saline lakes and arid-zone groundwater deposits: (1) high HSO_4 in fluid inclusions in depositional and early diagenetic often red-hued halite (or other evaporite minerals); (2) elevated concentrations of Al, as well as Fe and Si, in the same fluid inclusions; (3) identified remains of acidophilic bacteria or other acidophilic microbes; (4) acid minerals such as alunite or jarosite (or, more likely, the diagenetic products of acid minerals, such as gypsum or anhydrite); (5) presence of continental red beds; and (6) lack of widespread carbonate minerals. They go on to argue that many ancient red bedhosted evaporite saline-pan and saline-lake deposits, which lack widespread bedded carbonates, are likely arid-zone outputs from ancient acidic hydrologies, not just on Earth, but also on Mars (Benison 2006).

Indicators of Brine Parenthood

Chemical and isotopic studies of various evaporite salts have been used for more than four decades in an attempt to define brine parentage. Bromine concentration and chlorine isotopes values have been used in this way to separate marine from nonmarine evaporite source brines, but are perhaps better indicators of salinities and stabilities of the parent brine. Sulphur isotopes can be used to indicate parentage, while the boron isotopic signature from brine inclusions in chevron halite is perhaps the best currently used tool for separating a marine from a nonmarine brine source. The lack of fractionation even with alteration and the creation of new indicator minerals well into the metamorphic realm means a boron isotopic signature in meta-evaporitic tourmalinites is still a reliable separator (Peng et al. 1998). Brine inclusions in unaltered sedimentary halites are also useful indicators of both temperature and salinity, especially when microanalytic techniques are used to interpret the original brine chemistry. In the last two decades the microanalysis of brine inclusions in marine halites has led to paradigm shifts in our notion of the ionic stability of Phanerozoic seawater.

Bromine Profiles – Parentage or Stability?

Trace element concentrations in halite and other salts can sometimes help support an interpretation of a marine origin of the mother brine, especially if microanalytic techniques are used to determine fluid inclusion contents within the salts of interest and the sampled crystals retain primary sedimentary textures, such as bottom-aligned chevrons in halite. Bromine is fourth in anion abundance in seawater anions after Cl, SO_4 and HCO_3 (0.0671 g/1,000 g seawater). With an ionic radius of 1.96 Å it easily substitutes for chlorine (1.81 Å) in the halite crystal lattice as well as in the other chloride salts. Numerous experiments and case studies have found halite's Br-concentration increases in tandem with the bromide concentration of the parent brine, its level in a halite crystal also increases with increases in parent brine temperature and in the speed of crystallisation (Table 2.9; Wardlaw and Schwerdtner 1966; Raup and Hite 1978; Küster et al. 2009).

Fixation of Br in the halite lattice is also dependent on the level of other ionic species present in the solution. Cl is strongly preferentially partitioned over Br into Na, K and Mg halogen salts during their precipitation and Br preferentially remains behind in solution (Fig. 2.12). Br content decreases with increasing $MgCl_2$ content in the mother brine and with any increase in the degree of secondary recrystallisation (Dean 1978). Its conservative behaviour in marine brines means that it has commonly been used as a salinity indicator in ancient halites and other chloride minerals.

The distribution of bromine between a halite crystal and the coexisting solution is described by its partition coefficient (D):

$$D = \left(Br_{mineral}/Cl_{mineral}\right)/\left(Br_{solution}/Cl_{solution}\right)$$

During initial evaporation of seawater, both Br and Cl increase in concentration in the residual brine, and the Br/Cl content of these waters does not vary (Fig. 2.12). When halite saturation is reached, Cl is preferentially removed over Br from the brine. A small fraction of the Br is also partitioned out into the halite,

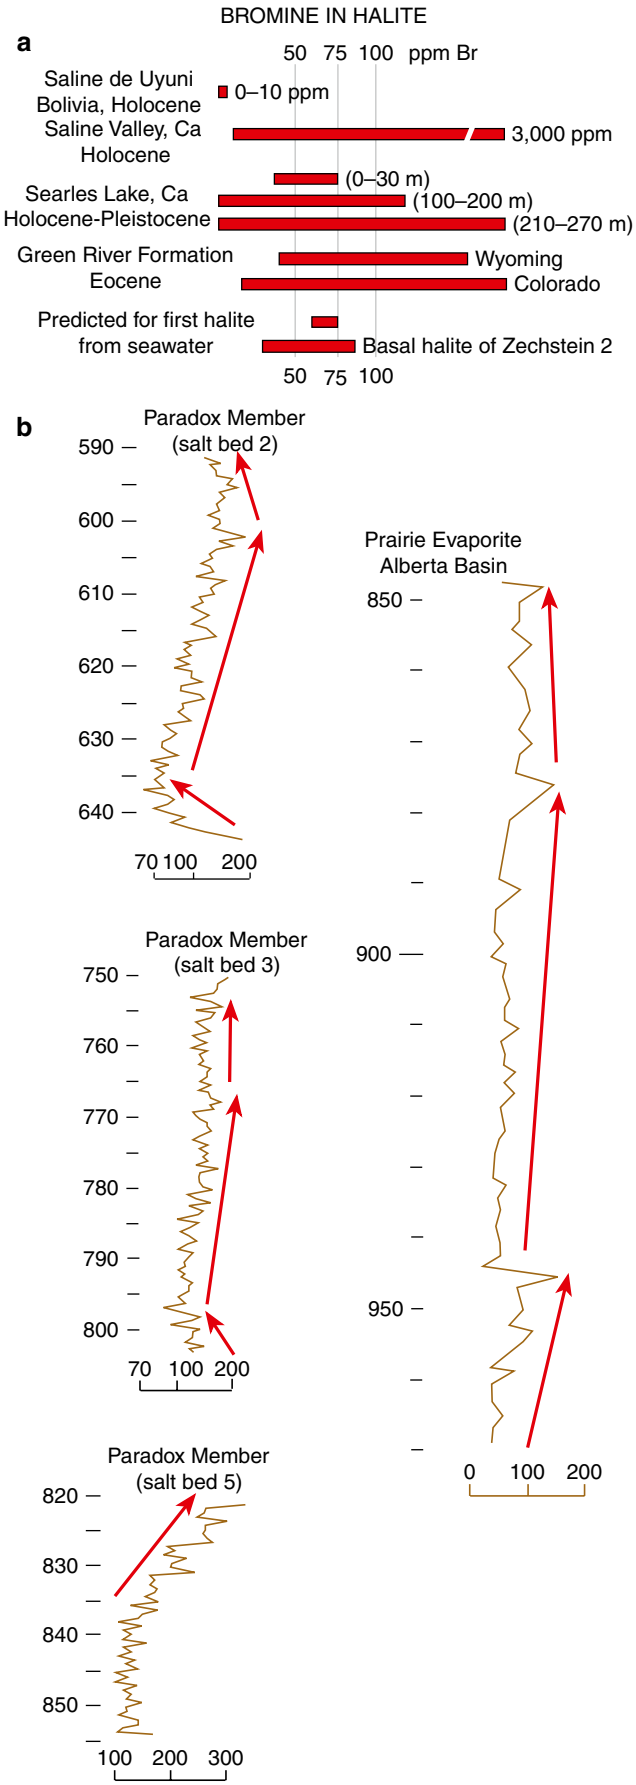
Table 2.9 Some examples of the use of Br content to interpret depositional setting of the halite

Unit	Location	Observation	Reference
Sedom Fm halite, Pliocene, Sedom diapir	Dead Sea, Israel	Br contents in inclusion in chevron halite crystals (52–191 ppm) are within the range of halite precipitated from marine water, and the highest value (191 ppm) occurs in a general upward increasing, but fluctuating, salting-upward trend is close to those expected for halite associated with potash salts	García-Veigas et al. (2009)
Halokinetic halite of the Upper Red Formation, Middle to Late Miocene	Iran	High bromide content in halites sampled suggests their marine origin (BR ranges up to 226 ppm used to suggest salinities sufficient to precipitate primary marine sylvite were never reached and to confirm the absence of the extensive meteoric alteration or subsequent bromine depletions.	Rahimpour-Bonab and Kalantarzadeh (2005)
Zaragoza Gypsum, Lower Miocene, Ebro Basin	Spain	Br contents in halites with primary textures (hoppers and chevrons) were below the standard for lowest marine Br concentration (<13 ppm). Tis and inclusion microchemistry are interpreted as indicating non-marine halite precipitation or recycling of marine halite in nonmarine waters. Also imply that conditions for co-precipitation of halite and glauberite, or for precipitation of Na-sulphates (mirabilite, thenardite) were never fulfilled in the saline lake system of the Ebro basin at this time	Salvany et al. (2007)
Rot Halite, Lower Triassic in Rockensussra 2/83 borehole	Northern Germany	Br content in fluid inclusions in chevron halite is 78–107 ppm, indicating a marine origin of the halite. Brines of primary gas-liquid inclusions are thus representative samples of trapped evaporate water and they may be used for the reconstruction of the composition of Early Triassic seawater.	Kovalevych et al. (2009)
Z2 in Upper Permian Zechstein of Polish Basin	SW Poland	Br content in halite (49–77 ppm) associated with sylvite daughter crystals in chevron halite indicated that these salts had a marine origin with recycling of earlier salts and were deposited at an elevated temperature, from concentrated seawater with a high potassium content, that favoured precipitation of primary sylvite.	Vovnyuk and Czapowski (2007)
PZ2 and PZ3 in Upper Permian Zechstein of Polish Basin	Poland	Combined use of bromine concentration in halite, isotopic composition of anhydrite, and major-ion composition of brine inclusions in primary halite crystals used to interpret episodes of overturn in Zechstein brine mass	Garcia-Veigas et al. (2011a)
Zechstein 2 rock salts in the Southern Permian Basin, Upper Permian	Germany	Br profile of the bedded and layered salt is characterized by a continuous upward increase in the bromide contents from base to top, indicating progressive evaporation of seawater. This same profile shape is retained in halokinetic salt layers in the studied salt diapirs. Br contents can be redistributed and homogenised via recrystallization processes of halokinesis.	Küster et al. (2009)
Ara Salt and carbonate stringers, Neoproterozoic to Earliest Cambrian, South Oman salt basin	Oman	Br geochemistry revealed significantly higher bromine contents (up to 280 ppm) in the early halite compared with the late halite (173 ppm). The distribution patterns and the (high) bromine contents of early halite are consistent with precipitation caused by seepage reflux of highly saturated brines in carbonate stringers during deposition of the overlying rock salt interval.	Schoenherr et al. (2009)
Early Cambrian Salt Basins of Siberia	Russia	Br content is 60–280 ppm in Usolye halite, 58–203 ppm in Belsk rock salt, and 60–261 ppm in Angara rock salt. Value ranges imply a primary marine source for these halites, a lack of meteoric dilution or subsequent mobilisation indicative of pervasive recrystallization.	Petrychenko et al. (2005)

but most remains behind in the brine. As saturation with the bitterns (K-Mg-Cl) salts is reached, the slope of the Br-Cl curve flattens out as these minerals discriminate somewhat less in terms of Br incorporation (higher partition coefficients).

In earlier studies Br content of ancient rock salt was used to separate marine from nonmarine precipitates (Dean 1978; Holser 1979; Wilgus and Holser 1984). Fresh seawater contains around 65 ppm bromine and reaches 500 ppm by the onset of halite precipitation (Fig. 2.12). Halite from a normal marine feed purportedly contains 50–100 ppm bromide and it should increase up to a maximum of around 270 ppm at the onset of bittern precipitation (Valyashko 1956, p. 578; Herrmann et al. 1973). Halite that has been recrystallised in a second cycle of solution and reprecipitation in a brine of lower Br content than the original brine should have a bromide content of 20 ppm or less, especially if the recycling waters were nonmarine. But variations in salinity and the dilution by shallow to ephemeral residual brines, along with ongoing halite recrystallisation and backreaction, all influence the final Br content of any halite crystal in both marine and nonmarine settings (Fig. 2.33a). Hardie (1984) discussed the limitations of using whole rock Br content as a depositional indicator and clearly showed the possible confusion that results if Br levels in wholerock halite samples are used in an attempt to separate marine from nonmarine halite.

Even if Br content of halite is not always a reliable indicator of the source of the mother brine, perhaps it can tell us something about brine stability at the time a salt was precipitated. Figure 2.33b plots bromide profiles from halites in two saline giants, the Paradox and the Prairie evaporites where values change in a predictable upsection fashion. Increasing upward trends indicate an increase in average annual brine salinity, while decreases indicate freshening (shown by arrows in Fig. 2.33b). The trend to very high values



(Br >250 ppm) near the upper part of salt member 5 of the Hermosa Formation in the Paradox occurs beneath a potash bed and indicates higher salinities needed for the precipitation and preservation of bittern salts. The upward trends for the Prairie evaporite, although sampled at a somewhat coarser spacing than the Hermosa, show similar brining upward profiles beneath potash beds. In a similar fashion Bein et al. (1991) used Br variations in brine inclusions in halite to define a southerly brine source for Permian San Andres halite in the Palo Duro Basin, Texas.

Halokinesis drives pervasive halite recrystallisation and migration of primary fluid inclusions to the polyhedral boundaries of newly formed flow-aligned crystals (Chap. 6). Recognition of this pervasive alteration in crystal textures has led some authors to question the reliability of Br profiles as depositional indicators in halokinetic salt (Bornemann et al. 2000). In a study of Zechstein salt in variably flow-overprinted profiles, Küster et al. (2009) found characteristic trends in depositional bromide profile were generally preserved in both the bedded and the more intensely deformed domal salt layers. However, they also concluded that ongoing pervasive deformation and recrystallisation will ultimately homogenise Br profiles in intensively deformed salt. They went on to argue that preservation of the characteristic depositional salting upward trend in the bromide profiles, in all salt dome layering they studied, indicates that large-scale brecciation, folding processes or circulating bromide-rich fluids played only a minor role during the formation of the salt domes.

The relative bromine content with respect to chlorine in a saline aquifer in the vicinity of dissolving salt structures has been used to define the parentage of the saline pore fluid. Figure 2.34 illustrates the Br/Cl content of produced water in the vicinity of a salt structure in offshore Louisiana (Steen et al. 2011). Most of the produced waters plot well below the typical bromine trajectory of evaporated modern seawater (McCaffrey et al. 1987). The Br depletion indicates elevated concentrations of chloride in the pore fluids, it is likely produced by the dissolution of halite rather than by evaporation of marine waters.

Contents of most other trace elements in marine evaporite salts are typically very low and not diagnostic of brine source. Iodine has very low partition coefficients in halite, sylvite, carnallite and the other bitterns, so they contain very little iodine. Its relatively large ionic radius impedes its replacement of chlorine ions in the respective lattices, so any residual liquor (marine or nonmarine) is strongly enriched. Iodate salts form pedogenic phases in the hyperarid Atacama

Fig. 2.33 Bromide in halite. (**a**) Bromine levels in halite in marine and nonmarine settings clearly showing that Br levels have a degree of spread that does not support the assumption that nonmarine or recycled halite will always show values less than first cycle precipitates (in part after Hardie 1984). (**b**) Br profiles from the Paradox Member, Hermosa Formation in the Paradox Basin and the Prairie Evaporite in the Alberta Basin. All wells drawn to the same depth scale (After Holser 1966, 1979)

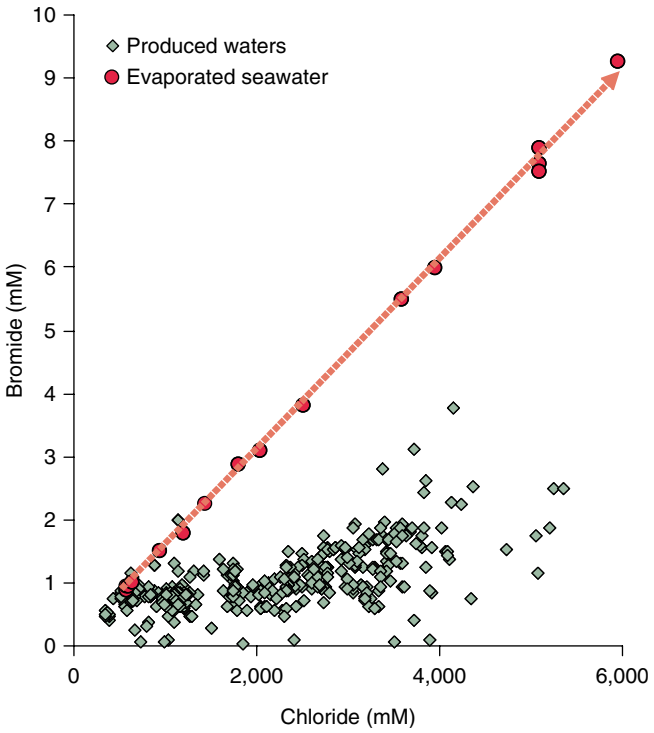


Fig. 2.34 Dissolved bromide–chloride relations for produced waters from the reservoirs in the vicinity of a dissolving salt structure in offshore Louisiana. Most waters plot well below the trend for evaporated seawater (McCaffrey et al. 1987), reflecting elevated concentrations of chloride produced by the dissolution of halite rather than by evaporation of marine waters. The extremely low Br/Cl ratios of a few waters may reflect dissolution of low-Br recrystallized halite (After Steen et al. 2011)

desert (Chap. 11). Fluorine minerals occur principally in sulphate deposits and salt clays that possibly have been influenced by hydrothermal inflows, although some Russian authors have argued for a marine evaporite association (Fig. 7.92). There is no published data on fluorine behaviour during seawater concentration. However, if fluorine concentrates at the same rate as Cl during evaporation, then seawater should have a fluorine concentration around 10 mg/l at the onset of halite saturation. Rubidium and ammonium substitute for potassium in crystal lattices of the bittern chlorides (e.g., sylvite, carnallite). Caesium does not occur in halite, and lithium in water-soluble form is only found in concentrations up to 0.2 ppm. The colouring of halite often feigns higher amounts of heavy metals. Only 2 ppb of trivalent iron can give halite a yellow colour, while a few more parts per billion can turn salt red (Sonnenfeld 1995).

Sulphur and Oxygen Isotopes

Modern seawater sulphate has a homogeneous and well-defined isotopic composition for both sulphur and oxygen:

$$^{34}SSO_4 = +20 \pm 0.5 \quad CDT$$

$$^{18}OSO_4 = +9.5 \pm 0.5 \quad SMOW$$

Likewise, the fractionation of sulphur and oxygen, which occurs during the transition from aqueous to solid state of sulphate is also near constant at earth surface temperatures. For gypsum, the mean values of the isotope enrichment factor are (Pierre 1988):

$$\varepsilon^{34}S_{gypsum-SO4} = 1.65‰$$

and,

$$\varepsilon^{18}O_{gypsum—SO4} = 3.5‰$$

Thus the $\delta^{34}S$ and $\delta^{18}O$ values of sulphate evaporites are directly related to the state of the aqueous sulphate reservoir where precipitation occurred. A plot of ancient marine $CaSO_4$ evaporites shows the sulphur curve for seawater has varied across time from +30‰ in the Cambrian, to around +10‰ in the Permian and the it increased irregularly in to Mesozoic to its present value of +20‰. Oxygen values show much less variability (Fig. 2.35a). Variations are reflected in all major marine evaporites and were most likely controlled by major input or removal of sulphides from the oceanic reservoirs during changes in tectonic activity and weathering rates. Historically, simple removal of oceanic sulphate (increase in evaporite formation) was thought not be accompanied by dramatic isotopic effects.

Rather, variations within the global sulphur cycle were thought to be controlled by a redox balance, which linked to the carbon cycle and the atmospheric oxygen budget. The oxidative part of the global sulphur cycle is governed by continental weathering (especially of marine black shale), riverine transport and evaporite deposition, while the reduced part is controlled by levels of fixation of reduced sulphur-bearing compounds in the sediment column, mostly as pyrite via bacterial sulphate reduction (Fig. 2.35b). The latter process will preferentially remove isotopically light sulphur from seawater and so increase its $\delta^{34}S$ value in the ocean and any subsequent marine evaporite salt.

However more recent work questions aspects of this older sulphur cycle model. As just discussed, variations in $\delta^{34}S_{sulphate}$ across the Phanerozoic are traditionally interpreted to reflect changes in the total amount of sulphur buried in ocean sediments as pyrite—a parameter referred to as f_{pyr} and defined as (Hurtgen 2012);

$$f_{pyr} = \left[\left(\text{pyrite S burial}\right)/\left(\text{pyrite S burial} + \text{evaporite S burial}\right)\right].$$

However, Wortmann and Paytan (2012) conclude that the 5‰ negative $\delta^{34}S_{sulphate}$ shift in ~120-million-year-old rocks was caused by massive seawater sulphate removal, which accompanied large-scale evaporite deposition during the opening of the South Atlantic Ocean (Fig. 2.35). Evaporite formation does not directly cause sulphur isotope fractionation; in their model, the negative $\delta^{34}S_{sulphate}$ shift is driven by lower pyrite burial rates resulting from substantially reduced marine sulphate levels.

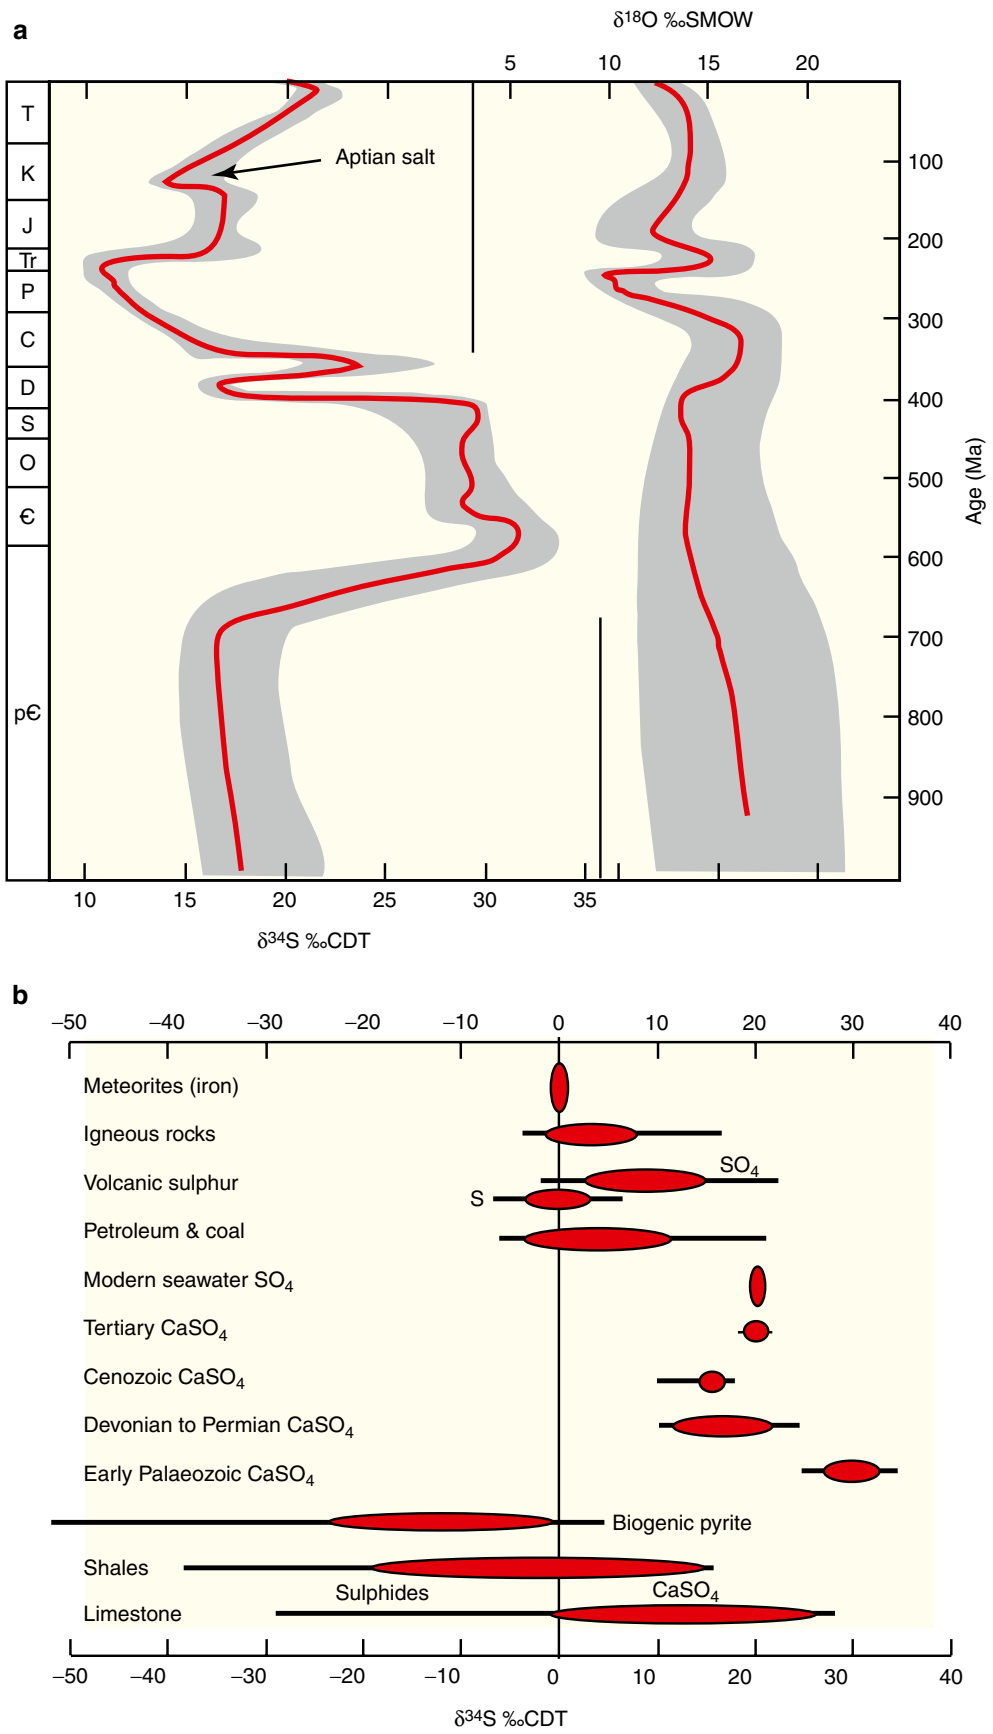

Fig. 2.35 Sulphur and oxygen isotopes. (**a**) Sulphur and oxygen isotope age curves for marine sulphate evaporites. The heavy lines are the best estimates of $\delta^{34}S$ and $\delta^{18}O$ values of calcium sulphate minerals in equilibrium with world ocean sulphate at that time. Shaded areas are estimated uncertainty envelopes of these curves. (**b**) Isotope range of various systems and selected seawater sulphate (After Pierre 1988; Veizer et al. 2000)

The authors attribute a 5‰ positive $\delta^{34}S_{sulphate}$ shift in the world's oceans about 50 Ma ago to an abrupt increase in marine sulphate concentrations as a result of large-scale dissolution of freshly exposed evaporites; they argue that the higher sulphate concentrations in the ocean led to more pyrite burial.

Likewise, Halevy et al. (2012) studied past sulphur fluxes to and from the ocean, but over a longer time-frame (the Phanerozoic). They quantified sulphate evaporite burial rates through time, then scaled these rates to obtain a global estimate of variation in sulphur flux. Their results indicate that sulphate burial rates were higher than previously estimated, but also greatly variable. When Halevy et al. (2012) integrated these improved evaporite burial fluxes with seawater sulphate concentration estimates and sulphur isotope constraints their calculations implied that Phanerozoic f_{pyr} values (f_{pyr}=fraction of sulphur removed from the oceans as pyrite) were ~100 % higher on average than previously recognized. These surprisingly high and constant pyrite burial outputs must have been balanced by equally high and constant inputs of sulphate to the ocean via sulphide oxidation (weathering). These relatively high and constant rates of pyrite weathering and burial over the Phanerozoic, as identified by Halevy et al. (2012), suggest that the consumption and production of oxygen via these processes played a larger role in regulating Phanerozoic atmospheric oxygen levels than previously recognized – perhaps by as much as 50 %.

Both studies recognize the importance of episodic evaporite burial on the sulphur cycle, while Wortmann and Paytan (2012) clearly show that large-scale deposition and dissolution of sulphate evaporites over relatively short geologic time scales can have an enormous impact on marine sulphate concentrations, pyrite burial rates, and the carbon cycle and probably have a more important role than previously recognised in regulating the chemistry of the ocean atmosphere system.

The ^{18}O content in seawater sulphate fluctuates less than sulphur values over geologic time. The isotopic composition of sulphate minerals varied only slightly from the Neoproterozoic to the Palaeozoic decreasing from +17 to +14‰ (Fig. 2.35a). Values then rose during the Devonian to reach +17‰ during the Early Carboniferous (Mississippian). Values then fell to=+10‰ during the Permian, mimicked by a similar decline in sulphur values in the Late Permian to Early Triassic. Since a rise to +15‰ in Early Triassic values of marine sulphate minerals have remained close to +14‰ (add 3.5‰ to mineral determined value to give ambient seawater value). Overall, oxygen values show little correlation with marine sulphate variation and are perhaps controlled by sulphide weathering reactions that contribute sulphate to seawater and the dissolution of sulphate evaporites.

Further discussion on global controls of isotope chemistry lies outside the evaporite focus of this book. What is significant is that, given the now well established sulphur isotope age curve, a comparison of a measured $\delta^{34}S$ value from an anhydrite or gypsum of known geological age to the curve allows an interpretation of a possible marine origin to the salt. A value which differs from the marine signature does not necessarily mean a nonmarine origin, but at the least it does mean diagenetic reworking or, more likely, a groundwater-induced recycling of sulphate ions into a nonmarine saline lake (Pierre 1988). Such oxygen and sulphur isotopic crossplots have been used to establish the continental (nonmarine) origin of the Eocene gypsum of the Paris Basin and the upper Miocene gypsum of the Granada basin, with sulphate derived from weathering of uplifted Mesozoic marine evaporites (Fontes and Letolle 1976; Rouchy and Pierre 1979; Pierre 1982). Sulphur in evaporitic sulphate can come from a number of sources other than reworked marine evaporites, likely isotopic ranges of possible sources are given in Fig. 2.35b.

Crossplots of oxygen with carbon or deuterium isotopes are useful in defining the origin of evaporitic carbonates. If these carbonates are interlayered with gypsum or anhydrite at the mm scale, then their signatures are very useful in determining the origin of the waters precipitating both the carbonates and the sulphates. This was the rationale used by Bellanca and Neri (1986) in a study of the origin of gypsum and associated carbonates in the Messinian of Sicily. The oxygen and hydrogen isotope compositions of crystal water from the laminar gypsum indicate primary precipitation of the sulphate from marine waters concentrated by evaporation (Fig. 2.36a). The isotopic data also show compositional changes due to periodic influx of continental waters into the depositional basin seen by the clustering of the laminar gypsum values along the SMOW concentration-dilution line with a regression coefficient of 0.98. The massive gypsum signature indicates rehydration by meteoric waters (probably modern). Open-marine-water incursions probably led to the deposition of carbonate layers overlying the laminar gypsum. These contain abundant aragonite with textural features and isotopic compositions suggesting precipitation in shallow and quiet marine waters slightly enriched in ^{18}O by evaporation (Fig. 2.36b).

Sulphur is largely resistant to isotopic fractionation during burial alteration and transformation (Worden et al. 1997). Primary marine stratigraphic sulphur isotope variation is preserved in anhydrites of the Permian Khuff Formation, despite subsequent dehydration to anhydrite during burial (≈1,000 m) and initial precipitation as gypsum from Permian and Triassic seawater. Gypsum dehydration to anhydrite did not involve significant isotopic fractionation or diagenetic redistribution of material in the subsurface. At depths greater than 4,300 m, the same sulphur isotope variation across the Permian-Triassic boundary is still present in elemental sulphur and H_2S, both products of the reaction of anhydrite with hydrocarbons via thermochemical sulphate reduction (Fig. 9.65). Clearly, thermochemical sulphate reduction did not lead to isotope fractionation. Worden et al. also argues that significant mass transfer has not occurred in the system, at least in the vicinity of the Permian-Triassic boundary, even though elemental sulphur and H_2S are both fluid phases at depths greater than 4,300 m. Primary differences in sulphur isotopes have been preserved in the rocks and fluids, despite two major diagenetic overprints that converted the sulphur in the original gypsum into elemental sulphur and H_2S by 4,300 m burial and the potentially

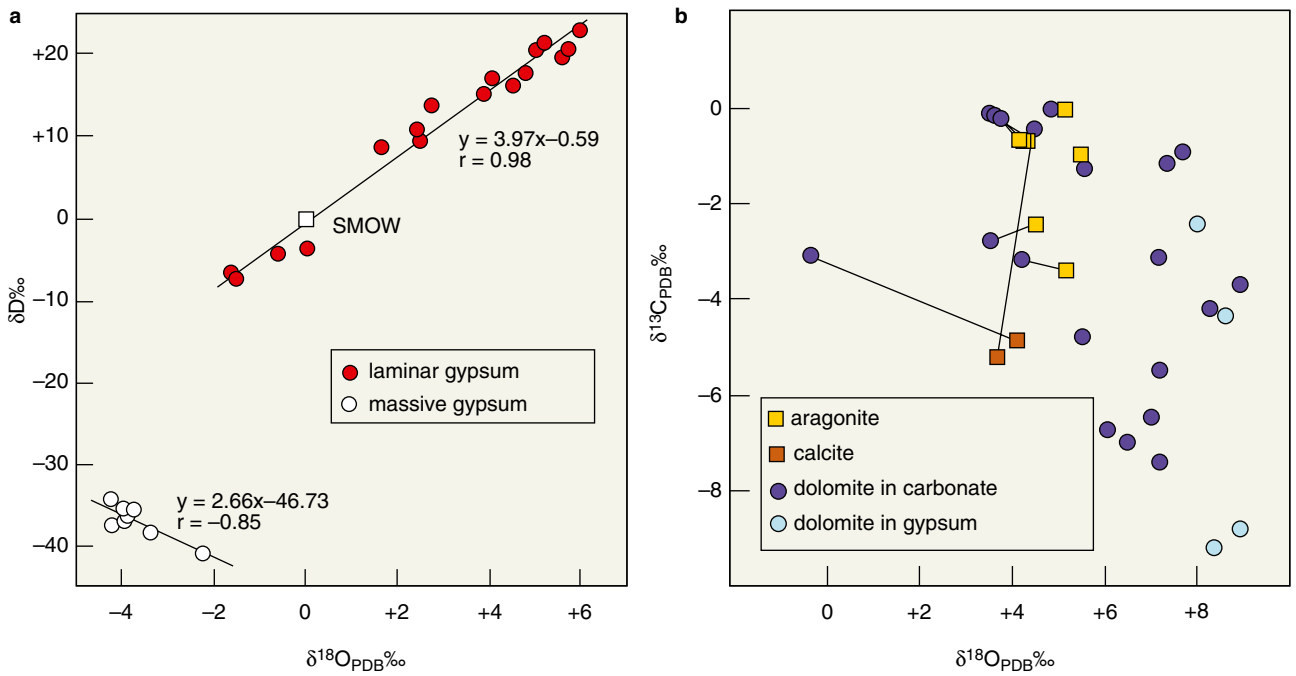

Fig. 2.36 Isotope crossplots in Messinian evaporites, Sicily. (**a**) Isotopic associations (carbon and oxygen) in water of crystallisation. (**b**) Deuterium- carbon relationships in carbonate layers in the same units (After Bellanca and Neri 1986)

mobile nature of some of the reaction products. That is, all reactions must have occurred in situ; there was no significant sulphur isotope fractionation, and only negligible sulphur was added, subtracted, or moved internally within the system.

The resistance to fractionation of sulphur isotopes in subsurface pore waters can also be utilised to determine the origin of saline thermal pore waters. In a study of sulphur isotopic compositions of waters in saline thermal springs, Risacher et al. (2011) came to the interesting conclusion that dissolution of continental sedimentary gypsum from the Tertiary-age Salt Cordillera was the dominant supplier of sulphate (Fig. 2.36). The sulphate in the springs was not supplied by the reworking of volcanic sulphur in this active volcanic terrain. $\delta^{34}S$ values from 3 to 11‰ in continental gypsum and this also encompasses the range of $\delta^{34}S$ in pedogenic gypsum (5–8‰) and in most surface waters (3.4–7.4‰) including salt lakes (Rech et al. 2003). Frutos and Cisternas (2003) found isotope ratios ranging from 1.5 to 10.8‰ in five native sulphur samples. Figure 2.37 presents the sulphur isotope ratio of dissolved sulphate in thermal waters sampled by Risacher et al. (2011) and references therein. The $\delta^{34}S$ of sulphate in northern thermal springs is within the range of salt lakes waters and continental gypsum. In an earlier paper Risacher et al. (2003) showed that salar brines leak through bottom sediments and are recycled in the hydrologic system. Deep circulating thermal waters are dissolving continental gypsum in sedimentary layers below the volcanics associated with the present day salars. The exception to this observation is the sulphur in Tatio springs where Cortecci et al. (2005) proposed a deep-seated source for the sulphate, related to magma degassing (Fig. 2.37).

Boron Isotopes

Boron is a relatively light element in nature, with the atomic number of 5. Boron has two stable isotopes, ^{10}B and ^{11}B, which make up approximately 19.82 and 80.18 % of total boron, respectively. Boron isotope ratios are given in the delta notation with $\delta^{11}B$ (‰) defined as deviation from standard NIST-SRM 951 (Xiao et al. 2013):

$$\delta^{11}B\,(‰) = \left[\left({}^{11}B/{}^{10}B\right)_{sample} \Big/ \left({}^{11}B/{}^{10}B_{NIST-SRM-951} - 1\right)\right] * 1000$$

The large relative mass difference between ^{10}B and ^{11}B leads to significant boron isotopic fractionation in nature. In addition, boron is highly soluble in aqueous environments and has high geochemical reactivity. Thus, $\delta^{11}B$ values in different environments are diverse. In nature, the measured $\delta^{11}B$ values vary between –70 ‰ and +75 ‰. Negative $\delta^{11}B$ values are usual found in nonmarine borate minerals and tourmalines, while positive $\delta^{11}B$ values are found in brines of salt lakes and evaporated seawater. Dead Sea brines, for example, have values from +35 to 60 ‰, while values for the various salts precipitating from the brines are much more negative (Fig. 2.38).

Hence, boron isotope determinations from halite, borate salts, tourmalinites and brines are all capable of distinguishing between marine and nonmarine sources (Fig. 2.38; Xiao et al. 2013; Vengosh et al. 1992; Swihart et al. 1986). Marine evaporite salts are characterised by distinctly higher $\delta^{11}B$ values (+18.2 to +31.7‰) than nonmarine evaporites (–30.1 to +7.0‰; Swihart et al. 1986). The latter span the range typical of the boron isotope signatures of most other rock types (Palmer and

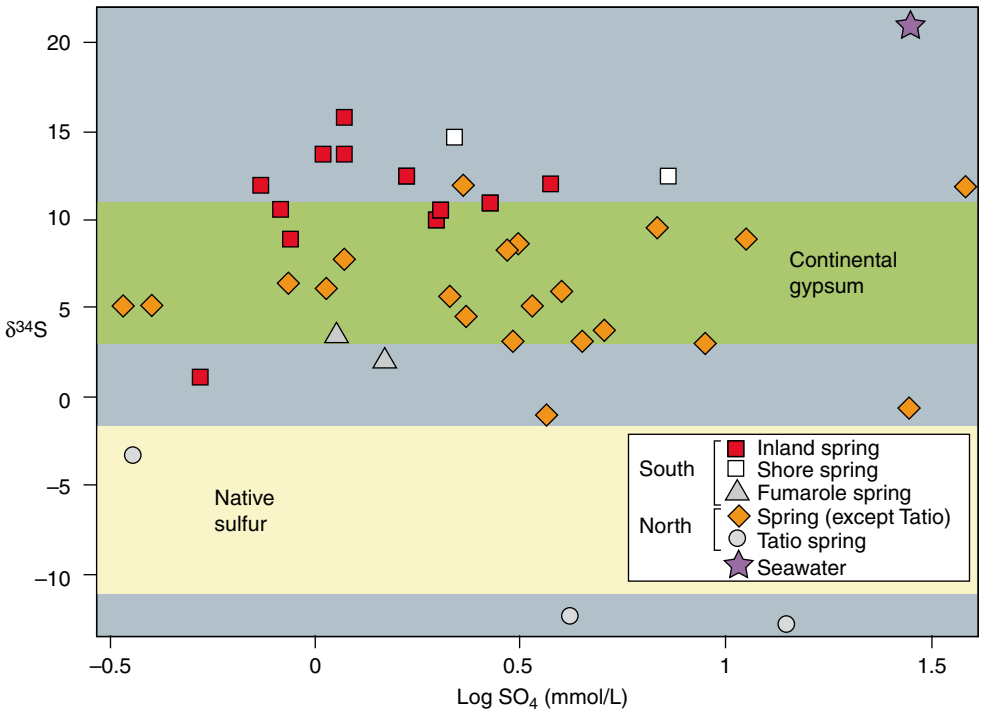

Fig. 2.37 Sulphur isotope ratios in sulphate of Chilean thermal waters, mostly collected from active springs in the salars of northern and southern Chile (After Risacher et al. 2011)

Helvaci 1997). Likewise, there is a clear isotopic separation between marine and nonmarine brines (Fig. 2.39a, c).

The separation reflects the enrichment of the ^{11}B isotope in seawater compared with both oceanic crust and continental crust. Differences are due to the original isotopic fractionation that occurred when boron was extracted from seawater into detrital clays, weathered basalts and carbonate minerals. Continental evaporite brines are derived from the weathering of these various lithologies, while the boron in seawater salts comes straight from the concentration of seawater. Much of the boron signature that is measured when whole rock halites and other salts are analysed comes from the fluid inclusions and not from boron in the lattice structure. The low level of fractionation between the brine and its precipitate at the time of halite deposition means boron isotope analysis can reliably distinguish nonmarine and marine brine parents in modern salts, even in complex multisource systems such as Lake Qaidam (Liu et al. 2000). However, the boron isotope signature of seawater is not a constant (Paris et al. 2010). It has increased by +10‰ over the past 40 my, to its present value of +39.9‰. This is likely in response to more intense continent-continent collision, the Himalayan uplift and an associated increase in erosional input of continental clastics into the world's oceans.

Beyond the halite precipitation field $\delta^{11}B$ values tend to increase with increasing concentration in both brine and the associated bittern precipitates. In all fields the $\delta^{11}B$ values and boron contents are higher in brine than in its precipitated halite suite (Fig. 2.39b; Vengosh et al. 1992). However the boron is not behaving in an absolutely conservative fashion and there is a deficiency of boron in the increasingly saline brines and a concurrent increase in the boron content of the associated salts (Table 2.10; Liu et al. 2000). The highest $\delta^{11}B$ values in the Qaidam Basin are associated with fluids with low B/Li ratios, indicating selective removal of elemental boron and ^{10}B by adsorption onto clay minerals along the flow path into the basin (Table 2.10; Liu et al. 2000). The magnitude of ^{11}B enrichment due to adsorption differs by 15–20‰ from the supply, and thus nonmarine brines are still distinguished from marine-derived evaporitic brines, which have much higher $\delta^{11}B$ signatures in the range +39 to +59‰ (Figs. 2.39a, d).

Palmer and Helvaci (1997) found that the isotopic values of the main borate minerals in the major Turkish borate deposits are largely controlled by their mineralogy and the pH of the brines from which they precipitated. For example, the differences in the $\delta^{11}B$ values of the three main borate minerals at Kirka (colemanite, ulexite and borax) are greater than would be expected if they had precipitated in equilibrium with one another from a solution with the same $\delta^{11}B$ value and pH (Fig. 2.39c). The data are consistent with all three minerals being primary precipitates from a concentrated brine, with colemanite precipitating from a brine of lower pH than ulexite, and borax precipitating from a brine of higher pH than ulexite. The only other Turkish deposit in which there are significant amounts of coexisting primary borate minerals is at Bigadic, which contains coexisting ulexite and colemanite (Fig. 12.6). There the average $\delta^{11}B$ value of ulexite is −6.8‰, this is 3.6‰ higher than that of colemanite −10.4‰ (Fig. 2.39c). This difference suggests that colemanite precipitated at a lower pH than ulexite (Palmer and Helvaci 1995).

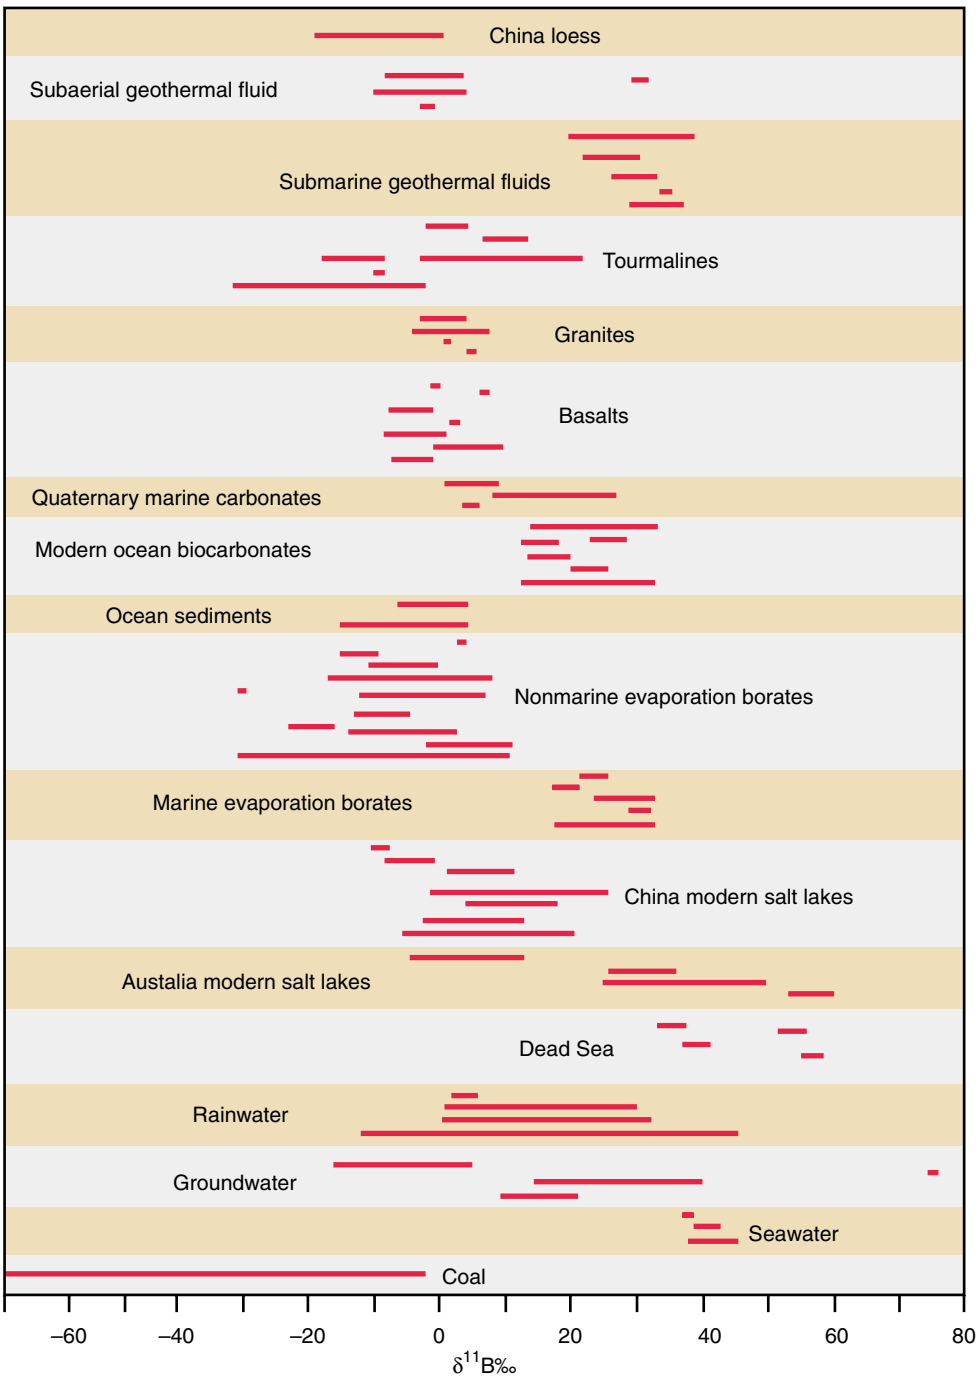

Fig. 2.38 Worldwide ranges of boron isotopes (After Xiao et al. 2013)

Chlorine Isotopes

Unlike the stable isotopes of boron and sulphur, which can be used as indicators of parent brine type, ^{37}Cl interpretation is more problematic due to its inherently low levels of fractionation during evaporation. Prior to the early 1980s, this meant analytical methods lacked the precision needed to detect small variations in chlorine isotopes levels that occur in nature. Measurements have now improved to where even small fractions in natural halites can be reliably and accurately determined (Long et al. 1993). Earlier work also suffered from a poor understanding of evaporitic fractionation mechanism and it was only in the mid 1990s that our understanding of ^{37}Cl determinations evolved into a useful environmental tool in an evaporite basins (Eggenkamp et al. 1995). Ongoing impermeability and a lack of reactivity away from the edge of a halite mass means that depositional isotope values will persist, even in tectonised evaporites or in evaporites that have undergone recrystallisation (Eastoe and Peryt 1999; Eastoe et al. 2007).

Eggenkamp et al. (1995) determined a fractionation of $0.26 \pm 0.07‰$ between halite and a NaCl solution at 25 °C. Halite crystallising from a 0.00‰ NaCl solution will therefore have an initial value of 0.2–0.3‰. Variations in δ

After Liu et al. (2000)

^{37}Cl in modern seawater are minimal and the oceans appear well mixed, so that a value of 0.00‰ is widely accepted, although the upper current layer in the Bosphorus is unusual as it has a value of 0.4‰ (Eastoe et al. 2007). Halites precipitated from seawater brines show decreasing values from 0.2‰ at the onset of halite precipitation to –0.5‰ by the hexahydrite precipitation stage (Eastoe et al. 1999). Using seawater, Eggenkamp et al. (1995) showed that the $\delta^{37}Cl$ value decreases in the halite stage from 0.0 to –0.45‰. During the subsequent kainite and carnallite stages the fractionation factor is close to unity and the $\delta^{37}Cl$ of the brine is only 0.04‰. In the subsequent bischofite stage the fractionation factor is <1 and $\delta^{37}Cl$ increases during the final stages of evaporation. The $\delta^{37}Cl$ values of precipitates in the halite stage decreases from 0.26 to –0.19‰ (Fig. 2.40). In the kainite stage, the precipitate (a mixture of salts) has a $\delta^{37}Cl$ that decreases to –0.34‰ and then to –0.47‰ in the carnallite stage. However in the last stage, typified by the precipitation of bischofite in the mix, the $\delta^{37}Cl$ value increases from –0.55‰ back into positive values in the very latest stages of evaporation before complete dryness. Error ranges in determinations increases after the end of the halite stage. Because $\delta^{37}Cl$ values decrease monotonically with concentration in the halite stage, it is possible to use $\delta^{37}Cl$ values in unaltered halites (chevron halite) to estimate

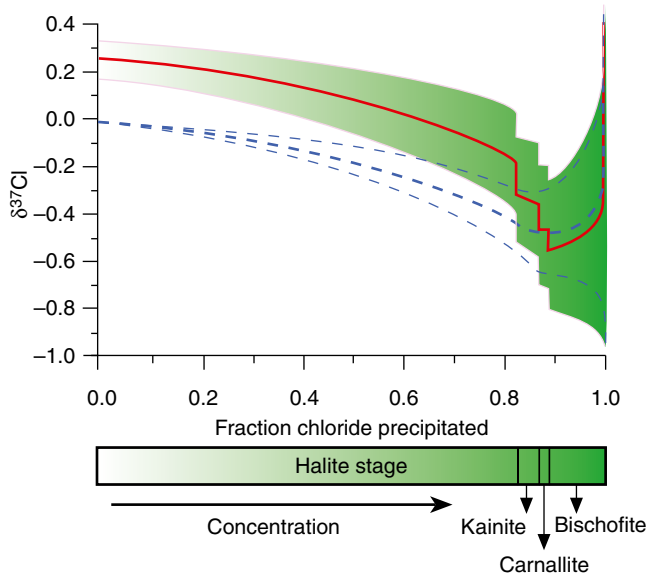

Fig. 2.40 Calculated $\delta^{37}Cl$ values of the precipitate and residual brine during seawater concentration. The *shaded area* indicates the error range for the precipitates (*solid line*), while the area between the *dashed lines* is the error range for the residual brine. Note the discontinuities in the curve for the precipitates (After Eggenkamp et al. 1995)

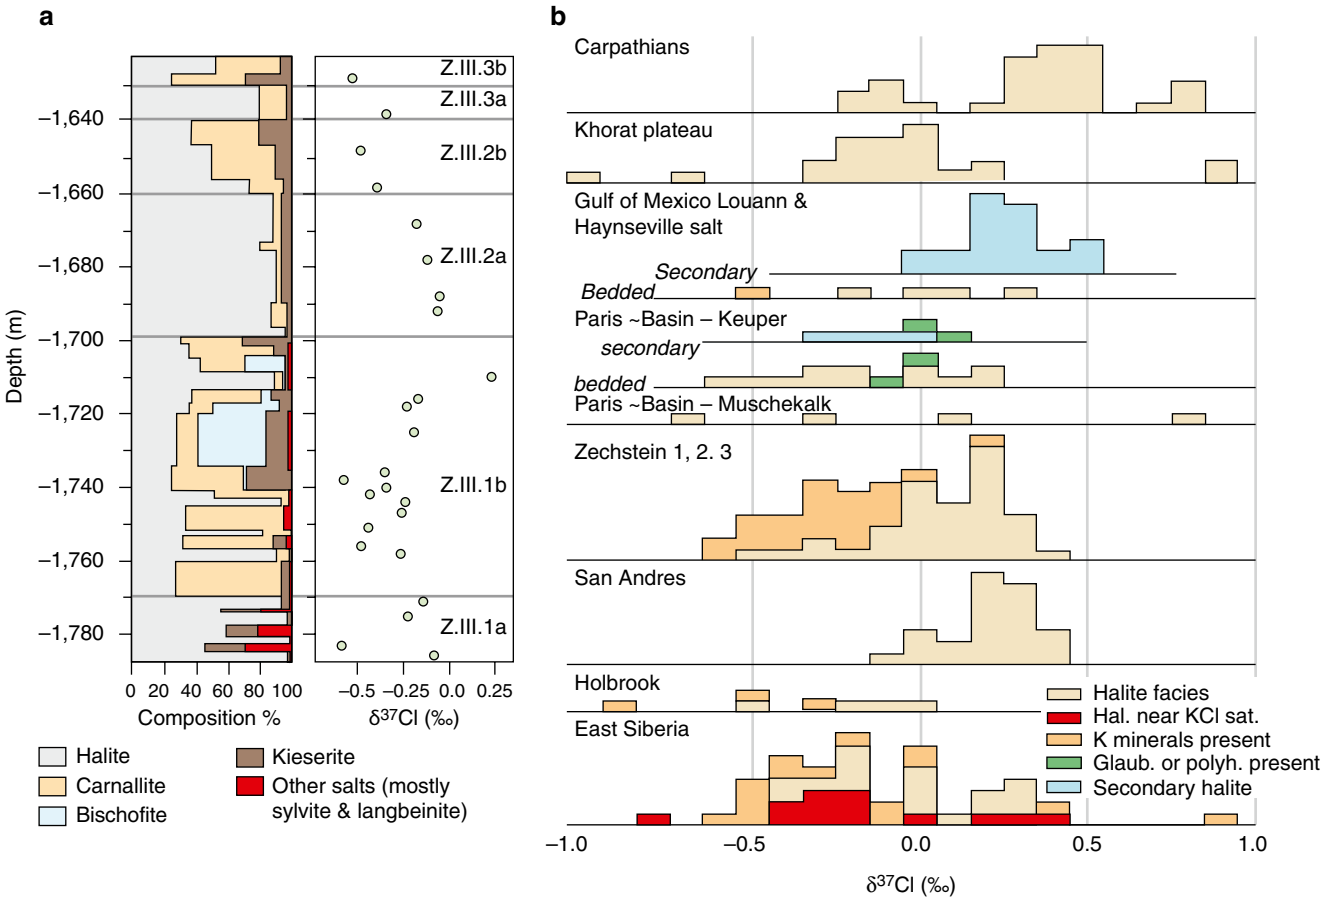
the concentration stage at the time of precipitation of an ancient halite (palaeosalinity determination). At later bittern stages this methodology is less effective and more subject to ambiguities (Eggenkamp et al. 1995).

That this methodology works is clearly seen in a study of the $\delta^{37}Cl$ signatures of the ZIII interval of the Permian Zechstein salts in the TR-2 well in the Netherlands (Fig. 2.41a). The interval is a combination of halite and bittern stage salts. The halite-dominated interval (Z.III.2a) has a simple salt chemistry with minor amounts of carnallite, bischofite and kieserite. $\delta^{37}Cl$ values tend to decrease upward into the overlying carnallite-kieserite interval at 1,660 m, implying increasing salinities as the unit passes up into the bittern-dominated succession. Samples in the bittern-dominated intervals (Z.III.1b and Z.III.2b) show high levels of carnallite, kieserite and bischofite and values that tend to be toward the lower end of the $\delta^{37}Cl$ value scale, consistent with higher supersaline salinities needed to precipitate these salts, sylvite ore brines show a similar highly negative signature.

Other ancient bedded halites also lie in the marine supersaline range. For example, bedded Permian halites in the Palo Duro basin, situated immediately above and below a halite



bed preserving chevrons, show primary $\delta^{37}Cl$ values of 0.4 to around 0.0‰ (Fig. 2.41b). Waters driving the recrystallisation cannot have been generated by later meteoric dissolution and recrystallisation. Rather, these recrystallised halites preserve their Permian depositional signatures (Eastoe et al. 1999). This conclusion supports the notion that subsurface salt beds intercalated with remnant chevrons are largely impervious closed systems that dissolve from the edges inward. It means any temperature and salinity values measured in brines in micro-inclusions in the chevron halite will indicate ambient conditions at the time of halite precipitation (e.g., Fig. 2.42). It is also why viable Permian haloarchaea can be cultured from such inclusions (Vreeland et al. 2000).

In contrast, nonmarine chloride contributions to a basinal brine precipitate halite with a more positive $\delta^{37}Cl$ value. Carpathian (Middle Miocene) halokinetic halite has $\delta^{37}Cl$ values greater than 0.4‰, as do some halites in the Gulf of Mexico, the North Sea and the Paris Basin (Fig. 2.41b). Such positive values cannot arise solely from seawater evaporation and require a considerable input of nonmarine chloride, either from a continental meteoric or igneous/hydrothermal source (Eastoe and Peryt 1999).

The contrast between halite with a hydrothermal signature and that preserving original syndepositional values is clear in Jurassic halite in the Gulf Coast Basin (Eastoe et al. 2001, 2007). Halite has a $\delta^{37}Cl$ range of −0.5–0.3‰ in most

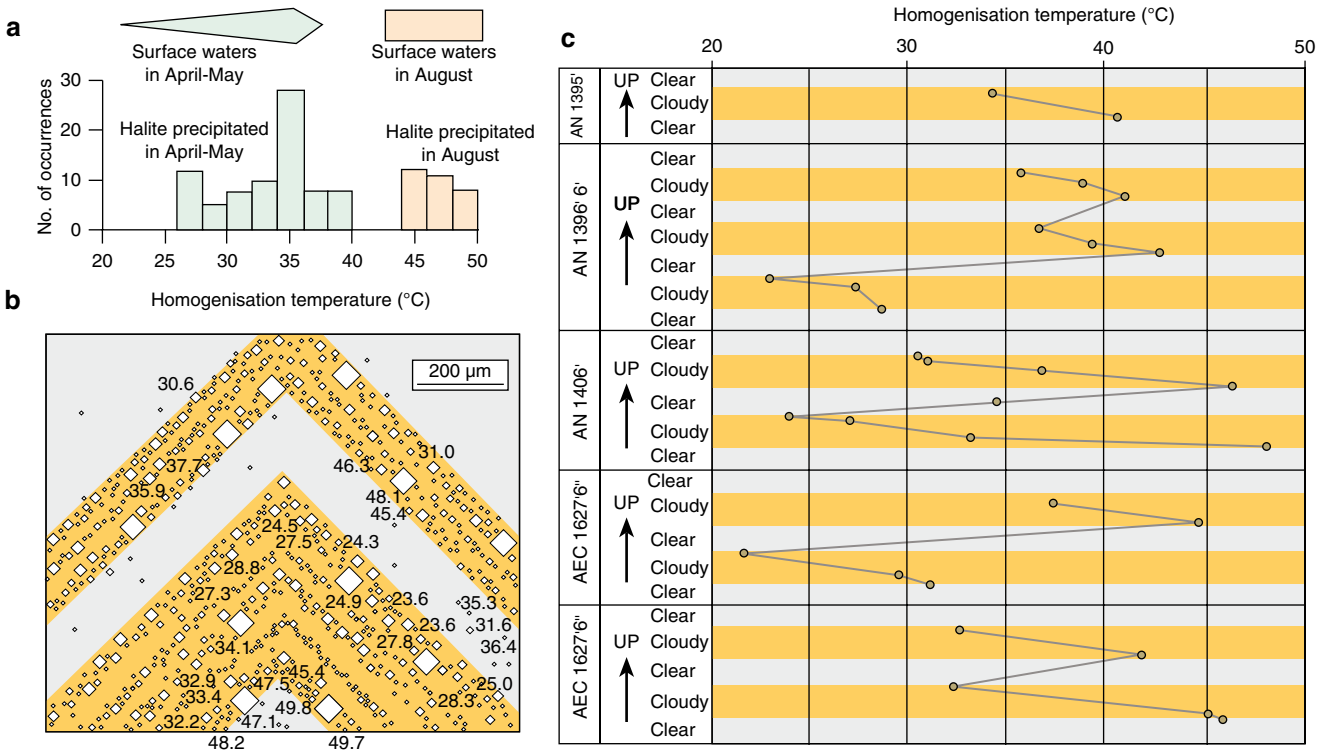


Fig. 2.42 Inclusions in chevron halite. (**a**) Histogram of homogenization temperatures measured by the 'cooling nucleation' method in initially all-liquid primary fluid inclusions from halite in modern pans of Death Valley. Plotted above the *histogram* are the temperature ranges of the brines from which these halite crystals grew (After Roberts and Spencer 1995). (**b**) Representation of chevron bands in a halite crystal from the Anadarko Davis No. 1 core (1,406 ft depth). Note homogenization temperatures in relation to bands; although homogenization temperatures are consistent within individual fluid inclusion assemblages thin, high frequency growth bands, they decrease from base to top of chevrons (After Benison and Goldstein 1999). (**c**) Graphic representation of homogenization temperature trends within and among cloudy, inclusion-rich and clear, inclusion-poor growth bands in five chevron halite crystals from the Nippewalla Group. *Circles* mark average homogenization temperatures within thicker chevron growth bands. Lines connecting *black circles* are extrapolated temperature trends. Upward decrease in homogenization temperatures from base to top of individual cloudy chevron bands probably reflect daily fluctuations in surface water temperatures perhaps related to evening cooling (After Benison and Goldstein 1999)

Fig. 2.41 $\delta^{37}Cl$ isotope as an environmental indicator. (**a**) Isotopic and mineralogic composition of Zechstein III showing that in these marine salts the $\delta^{37}Cl$ isotopic values are typically higher in the halite layers than in carnallite and bischofite layers (After Eggenkamp et al. 1995). (**b**) Isotopic values of selected halites of various ages showing marine values are typically less than 0.4‰ and centred on 0.0‰, with bitterns tending to show more negative values than less saline halite phases, while secondary halite tends to show slightly more positive values (After Eastoe et al. 2007). Secondary salt is diapiric salt in the Gulf of Mexico Basin, and open-space filling salt in the Keuper. *Glaub* glauberite, *polyh* polyhalite

bedded salt and 0.0–0.5‰ in diapiric salt. The values for bedded salt are consistent with a $\delta^{37}Cl$ value of 0.0‰ for Jurassic seawater chloride, as in modern oceans. The slightly higher values for diapiric salt are possibly caused by incongruent solution of halite (Fig. 8.43).

Chloride isotopes in subsurface waters can indicate their provenance and show a $\delta^{37}Cl$ range of −1.9 to 0.7‰ (Eastoe et al. 2001, 2007). Formation waters in the Gulf of Mexico with $\delta^{37}Cl < -0.6$‰ are confined to geopressured Eocene to Miocene strata at depths of 2,500 m or greater. Strongly negative values do not occur in Plio-Pleistocene strata, which retain the values of seawater (connate brines), nor do they occur in Mesozoic strata, which are marine carbonates. It seems that the strongly divergent values come from chloride in waters released from shales undergoing the smectite-illite transformation in the zone of geopressure.

Low $\delta^{37}Cl$ values in such waters are related to low m_{Cl}/m_{Na} (a parameter indicating dewatering) but show no general relationship to Cl/Br ratios (Eastoe et al. 2001). They are consistent with diffusion of chloride from allochthonous brine. Diffusion can generate domains of water with negative $\delta^{37}Cl$ on a scale of hundreds of metres in 10^4–10^6 years, and may also generate positive $\delta^{37}Cl$ chloride in residual source brine. The expulsion of such brines into an evaporite basin may account for most non-0‰ chloride sources in evaporite basins.

The experiments of Eggenkamp et al. (1995; Fig. 2.40) were limited to a single seawater evaporation cycle, but evaporites accumulating in shallow pans in marine and continental settings are subjected to multiple cycles of dissolution and partial reprecipitation before their burial. This can bring about measurable changes in $\delta^{37}Cl$, but also leaves little residual halite within the total halite mass.

Fluid Inclusions and Brine Temperatures

When halite and other salts are precipitated, they can capture and enclose inclusions of ambient brine. Such inclusions form the cloudy lamina that outline milky halite chevron and cornet textures and are used to indicate primary growth orientations of crystals in ancient salt beds (Fig. 1.33). Inclusion-rich bands indicate episodes of rapid growth, while clearer bands indicate slower growth rates (Shlichta 1968; Goldstein 2001).

Chevron banding typically indicates diurnal temperature changes in a shallow brine pan, with rapid growth spurts encouraged by the cooling of brine each evening.

Halite's high solubility and potential for deformation sometimes raises doubts about longterm preservation of the integrity of fluid inclusions. Even ancient halite that still retains abundant growth-aligned textures, if exposed to even moderate heating it may contain fluid inclusions that have leaked. Halite's propensity to flow also means its fluid inclusions are more vulnerable to stretching, leaking, and necking-down compared to most other minerals. But Petrichenko (1979) and Roedder (1984a, b) have shown that even when deformation has occurred, only the outer portions of halite crystals tend to be affected, the centres of crystals typically remain unaltered. Alteration textures in ancient bedded halites with crystals suitable for microinclusion analysis are thus defined by altered, clear, outer rims and unaltered, cloudy, primary inclusion-rich cores that retain meaningful inclusion data (Petrichenko 1979; Roedder 1984a, b). The problems of defining inclusion leakage, coupled with the possibility of bedded and halokinetic salt being used as repository sites for radioactive waste, has generated valuable research on the validity of fluid inclusion data in halite (Chap. 12).

Lowenstein and Spencer (1990) obtained some of the first reliable and consistent estimates of ancient syndepositional brine temperature estimates using solid-liquid homogenization temperatures of sylvite daughter crystals in halite from the Devonian Prairie Formation. They show Devonian brine temperatures were similar to those in Quaternary continental equivalents and that many ancient potash deposits still retained evidence of very early diagenetic features, created by the cooling of syndepositional reflux brines. Since then there have been numerous studies that illustrate the utility of inclusion-based studies of chevron halite (Table 2.11).

Even so, many geologists have maintained a healthy scepticism toward fluid inclusion data derived from evaporites, especially from non-chevron halite (Roedder and Skinner 1968; Kovalevich 1975, 1976; Petrichenko 1979; Roedder and Bassett 1981). Work by Roberts and Spencer (1995) and by Benison and Goldstein (1999) has shown how petrographically controlled microthermometric testing can define and avoid zones of inclusion alteration in ancient halite. If the tests suggested by these authors show that primary fluid inclusions have not been altered since entrapment, then fluid inclusions from the unaltered portions of a salt bed may be considered representative of evaporative parent waters and can even be used to define palaeotemperatures of the mother brine (Fig. 2.42). This is now a widely used approach for determining surface water palaeotemperatures from ancient halites whose fluid inclusions lack daughter crystals (Benison and Goldstein (1999)).

An all-liquid primary inclusion in halite at room temperature indicates mineral growth below approximately 50 °C (Kovalevich 1975; Petrichenko 1979). Vapour bubbles can be nucleated artificially in some all-liquid inclusions by placing samples in a freezing chamber so that homogenization temperatures below 50 °C can be measured. Roberts and Spencer (1995) found that when primary fluid inclusions in newly precipitated halite in ephemeral-lake saltpans in Death Valley, California, were cooled (in order to nucleate vapour bubbles) and homogenization temperature

were measured, the resulting temperature ranges were equivalent to the measured temperatures of the shallow brine sheets from which the halite had precipitated (Fig. 2.42a).

Likewise detailed inclusion analysis, centred on chevrons and cornets in unaltered portions of halite beds in the Permian Nippewalla (uppermost Leonardian – Kungurian) Group of

Table 2.11 Selection of outcomes illustrating the utility of inclusion studies in chevron halite

Unit	Location	Observation	Reference
Sinian Halite, Ediacarian, Neoproterozoic	China	Used to quantify ambient ocean temperatures and influence on multicellular evolution in late Precambrian within a long-term ocean cooling trend from nearly 70 °C at ~3,500 Ma to around 20 °C at ~800 Ma. Showed seawater temperatures when these halites formed were highly similar to tropical Phanerozoic seawater temperature estimates. The authors infer the Proterozoic decline in sea temperatures and the reduction of salinity, along with the sequestration of salt in massive Neoproterozoic halite deposits allowed more dissolved oxygen in oceans, so facilitating evolutionary innovation of complex multicellularity.	Meng et al. (2011)
Hisarkic Fm. borates, Miocene, Emet Basin,	Turkey	Fluid inclusion compositions in halite show that the free-brines in the saline lake corresponded to the Na-K-Cl-SO_4 type remaining very impoverished in Ca and Mg. High K concentrations were present in the final salt-forming brines (borates), which did not reach saturation with respect to K-bearing evaporites.	Garcia-Vegas et al. (2011b)
PZ2 (Stassfurt) halite, Permian, Polish sector European Southern Permian Basin.	Poland	Major ion concentrations in primary fluid inclusions in halite, along with sulphur and oxygen isotopes, show that the change to sulphate-depleted (calcium-rich) brines that occurred during halite deposition of the PZ2 (Stassfurt) cycle is related to the overturn of anoxic sulphidic deep-waters from the Panthalassa stratified superocean and coincides with the Permian-Triassic mass extinction event.	Garcia-Vegas et al. (2011a)
Modern acid and neutral saline lakes, Yilgarn Craton	Western Australia	Acid fluid inclusion freezing/melting behaviours include characteristics that differ from neutral fluid inclusion behaviours, such as lower eutectic temperatures, higher and wider temperature range of hydrohalite rims with a definable fuzzy border and more complex metastable phases.	Jagniecki and Benison (2010)
Salt IV sylvite beds, Oligocene Mulhouse Basin	South France	Small "growth band" scale variations in the K concentration in halite chevrons near potash layers, suggests very sensitive processes within the brine with potential environmental changes (i.e., seasonal variations, day-night temperature fluctuations cycles) leading towards precipitation of a sylvite layer.	Cendón et al. (2010)
Halite from several Cretaceous Basins	Angola, Congo, Brazil, Laos, Thailand	Cretaceous seawater was enriched several fold in Ca^{2+}, depleted in, Na^{+}, and Mg^{2+}, and had lower Na^{+}/Cl^{-}, Mg^{2+}/Ca^{2+}, and Mg^{2+}/K^{+} ratios compared to modern seawater. Elevated Ca^{2+} concentrations, with $Ca^{2+} > SO_4^{2-}$ at the point of gypsum saturation, allowed Cretaceous seawater to evolve into Mg^{2+}–Ca^{2+}–Na^{+}–K^{+}–Cl^{-} brines lacking measurable SO_4^{2-}. Cretaceous (Aptian) seawater has the lowest Mg^{2+}/Ca^{2+} ratios so far documented. Suggests a link between seawater chemistry and midocean ridge hydrothermal brine flux.	Timofeeff et al. (2006)

Th homogenisation temperature, *AVG* average, *MAX* maximum, *MIN* minimum

Kansas gave cooling-induced homogenisation temperatures representative of the temperature range of the original mother liquor (Fig. 2.42b, c). What was even more interesting was the intimate and consistent relationship between temperature and position in the inclusion rich layer in the chevron bands in this Permian halite (Fig. 2.42b, c). It probably preserves daily temperature changes and shows the propensity of inclusion-rich bands to precipitate when the overlying halite saturated brine cools each evening or with the passage of a cold front.

If the inclusion data in the Nippewalla Group halites are reliable indicators of syndepositional not burial temperatures, then the temperature regime at times was far in excess of any seen in today's deserts (Zambito and Benison 2013). Extremely high temperatures, to 73 °C, are evidenced in the lower Nippewalla Group halite chevrons, as are large diurnal temperature ranges of more than 25–30 °C (Table 2.12). The inclusions suggest conditions were at times more extreme than anywhere on Earth today. In contrast, the

upper Nippewalla Group halites were cooler; maximum temperature was 43 °C and diurnal temperature ranges were smaller, similar to modern extremely hot environments such as Death Valley and the Danakil Depression (Fig. 2.42b, c).

The fact that halite can retain such intimate precipitational detail supports the notion that growth-aligned chevrons are subsurface survivors. This means microanalysis of the chemical make-up of a brine inclusion in an unaltered halite chevron or cornet is indicative of the chemical composition of the water that precipitated the crystals (Timofeeff et al. 2001). This gives an ability to map temporal changes in the ionic proportions of seawater and once again also suggests why Permian halobacteria can be cultured from brine inclusions in Permian salt (Vreeland et al. 2000; Lowenstein et al. 2010).

Seawater Evolution

So far in this chapter three things are clear: (1) it is difficult to separate marine and nonmarine parent brines based on mineralogy; (2) isotopes and micro-inclusions can sometimes separate brine parentage; (3) it is increasingly obvious that the proportions of major ions in seawater are probably not constant across geological time. The significance of various indicators of chemical evolution of seawater over time is now considered in two parts. First, in the Phanerozoic where actual salts are available for sampling and analysis. Second, in the Precambrian, where much of the evidence of brine composition comes from pseudomorphs of evaporite salts.

A Phanerozoic Dilemma: Marine Versus Nonmarine Potash?

Phanerozoic potash evaporites fall into two categories: (1) potash deposits with $MgSO_4$ salts, such as polyhalite, kieserite and kainite; and (2) potash deposits with halite, sylvite and carnallite, and entirely free or very poor in the magnesium-sulphate salts. This latter group makes up more than 60 % of ancient potash deposits (Hardie 1990). The former group may well be marine-derived as they contain the bittern suite predicted by the evaporation and backreaction of modern marine brines, but the latter group must have precipitated from Na-Ca-Mg-K-Cl brines with ionic proportions quite different from that of concentrated modern seawater which have a bittern suite dominated by the $MgSO_4$ salt suite (Fig. 2.12).

$MgSO_4$-depleted potash evaporites have been explained by some as modified marine evaporites thought to result from backreactions during burial diagenesis of normal marine evaporites (Borchert 1977; Dean 1978; Wilson and Long 1993). If so, then they were derived from an ancient seawater source with modern ionic proportions that were altered via; (a) dolomitisation, (b) sulphate reducing bacterial action, (c) mixing of brines with calcium bicarbonate-rich river water, or (d) rock-fluid interaction during deep burial diagenesis.

Alternatively, Hardie (1990) suggested that $MgSO_4$ depleted potash evaporites formed from sulphate-depleted inflow waters seeping into an evaporite basin via springs and faults. Springs were fed either by $CaCl_2$-rich hot hydrothermal brines or by cooling resurging deep basinal brines. Such fault-fed deeply-circulating evaporite brines occur today in springs in the Dead Sea, Qaidam Basin, Salton Sea and the Danakil Depression. The upwelling of the brines in these regions is driven either by thermally induced density instabilities related to magma emplacement, or by the creation of topographic gradients that force deeply-circulated basinal brines to the surface. Ayora et al. (1994) demonstrated that such a continental Ca–Cl system operated during deposition of sylvite and carnallite in the upper Eocene basin of Navarra, southern Pyrenees, Spain (Fig. 8.12).

Thirdly, and more widely accepted as an explanation for Phanerozoic evaporites, is that there is the high likelihood that seawater chemistry has evolved throughout the Phanerozoic and that changing ionic proportions in seawater define whether or not $MgSO_4$ salts were typical marine evaporites. Work by Kovalevich et al. (1998) on inclusions in primary-bedded halite from many evaporite formations of northern Pangaea, and subsequent work using microanalyses of fluid inclusions in numerous chevron halites (Lowenstein et al. 2001, 2003), shows that during the Phanerozoic the chemical composition of marine brines has oscillated between Na-K-Mg-Ca-Cl and Na-K-Mg-Cl-SO_4 types. The former does not precipitate $MgSO_4$ salts when concentrated, the latter does.

The background chemistry of this marine potash dichotomy ($MgSO_4$ -depleted bitterns versus $MgSO_4$ -enriched bitterns) is simple, and can be related to brine evolution observations published by Hardie more than 30 years ago (Hardie 1984).

The chemical makeup of the bittern stages of any marine brine is largely controlled by its chemical constituent proportions in its early stages of concentration. These ionic proportions will control how it passes through the $CaCO_3$ and gypsum divides (Fig. 2.43). That is, a marine brine's evolutionary pathways are determined by the ionic proportion chemistry during the precipitation of relatively insoluble evaporitic carbonates (aragonite, high-magnesium calcite, or low-magnesium calcite) and then by its constituent chemistry as it attains gypsum saturation. These two stages define the $CaCO_3$ and gypsum divides.

The Mg/Ca ratio in any ambient seawater controls whether the first-formed carbonate is aragonite (Mg/Ca >5)

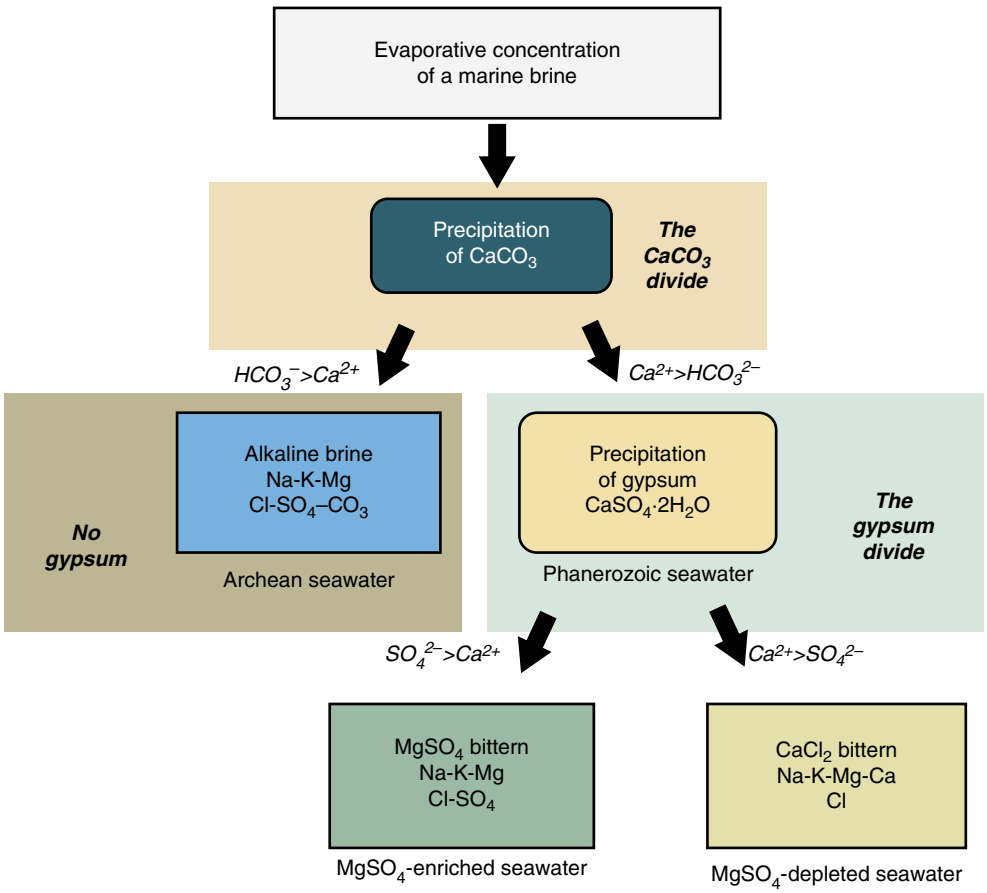

Fig. 2.43 Chemical divides and the evolution of three major brine types (in part after Hardie 1984)

or high-magnesium calcite (2>Mg/Ca>5), or low-Mg calcite (Mg/Ca >2). The latter is not relevant to Phanerozoic seawater. As seawater concentrates and calcium carbonate mineral(s) precipitate, either Ca is used up, or the HCO_3 is used up. If the Ca is used up, an alkaline brine (pH >10) forms, with residual CO_3, along with Na, K, SO_4, and Cl but no remaining Ca. With ongoing concentration this brine chemistry will then form sodium bicarbonate minerals, it cannot form gypsum as all the Ca is already used up. Such a ionic proportion chemistry may have defined oceanic waters in the Archaean but is not relevant to seawater evolution in the Proterozoic and Phanerozoic as gypsum or its pseudomorphs are well documented. At very high concentrations, these brines (aka Type 1 waters) can produce halite and sylvite bitterns but no gypsum or anhydrite (Fig. 2.43).

If, on the other hand, the HCO_3 is used up during the initial formation of evaporitic carbonates, the water will become enriched in Ca and Mg, and a neutral brine, very depleted in carbonate, is formed. The next chemical divide reached by a water depleted in HCO_3 occurs when gypsum precipitates ($CaSO_4.2H_2O$). As gypsum is precipitated, either the Ca in the brine is used up, or the SO_4 in the brine is used up. If the Ca is depleted, a calcium-free brine rich in Na, K, Mg, Cl, and SO_4 will be the final product and the diagnostic bittern minerals will include magnesium sulphate minerals. This is the pathway followed by modern seawater bitterns.

If, however, the sulphate is used up, the final brine will be rich in Na, K, Mg, Ca, and Cl. Such a calcium chloride brine will produce diagnostic potassium chloride and calcium chloride minerals such as sylvite, tachyhydrite, and antarcticite, but no sulphate minerals. Although the theory of chemical divides is important in understanding bittern chemistry, a few problems complicate its direct application to saline-mineral deposition. Problems arise from the thermodynamics, kinetics and hydrodynamics of the precipitation process: (1) whether or not the evolving brine backreacts with previously formed minerals (i.e., whether fractional crystallization prevails or not); and (2) whether or not metastable phases precipitate out of the evolving brine; and (3) Variations of rates of brine loss in a unclosed hydrologies as the basin fills with salts. In natural systems, dense evaporated brines can leak out as dense underflows or as refluxing groundwaters.

A detailed analysis of the ionic make-up of Silurian seawater using micro-inclusion analysis of more than 100 samples of chevron halite from various Silurian deposits around the world was published by Brennan and Lowenstein (2002), and clearly supports the notion that ionic proportions in the

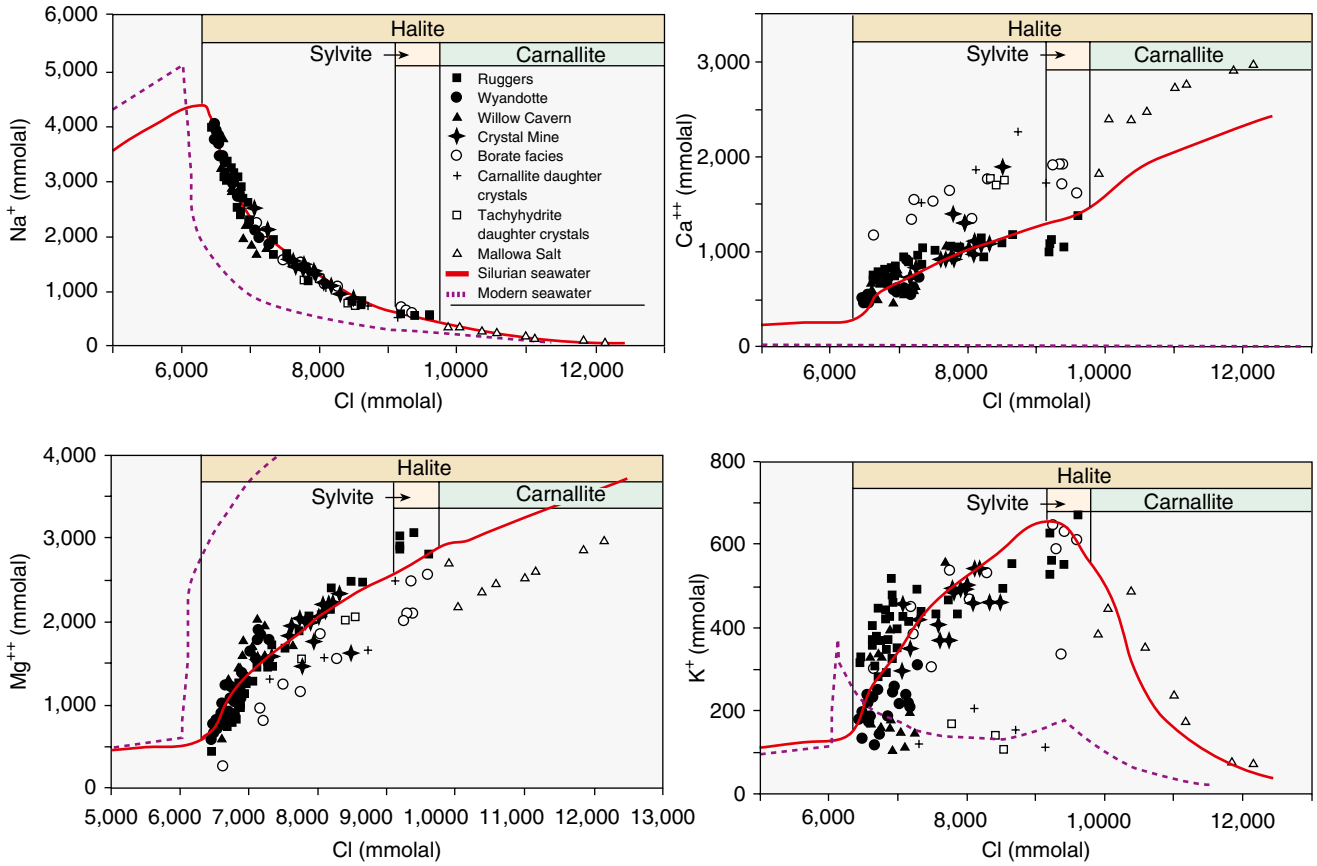

Fig. 2.44 Plots of the major-ion concentrations of the fluid inclusions versus chloride concentrations in Silurian salt with preserved primary structures (After Brennan and Lowenstein 2002). *Closed symbols* represent fluid inclusions from pristine marine halites, *open symbols* represent suspect fluid inclusions from halites associated with potash mineralization or high degrees of evaporation. Only the *closed symbols* were considered for determining Silurian seawater. The evaporation pathway of modern seawater is shown with a *dashed line*, and the best-fit evaporation pathway for the Silurian data is shown with a *solid line*. All the plots show that the evaporation pathways defined by Silurian fluid inclusions are different from the modern seawater pathways. The Silurian fluid inclusions all have an excess of calcium, and no measurable sulphate. Modern seawater evaporated to halite saturation has abundant sulphate, and negligible amounts of calcium. Salts expected to precipitate at given Cl concentrations in evaporated "best-fit" Silurian seawater are indicated along the top of each plot. Sylvite is a primary precipitate from concentrated seawater with these ionic proportions

world's Silurian oceans were different from those of today (Fig. 2.44). Samples were from three formations in the Late Silurian Michigan Basin, the A-1, A-2, and B Evaporites of the Salina Group, and the Early Silurian in the Canning Basin (Australia) in the Mallowa Salt of the Carribuddy Group. The Silurian ocean had lower concentrations of Mg^{2+}, Na^{+}, and SO_4^{2-}, and much higher concentrations of Ca^{2+} relative to the ocean's present-day composition. Furthermore, Silurian seawater had Ca^{2+} in excess of SO_4^{2-}. Bittern stage evaporation of Silurian seawater produced KCl-type potash minerals that lack the $MgSO_4$ -type late stage salts formed during the evaporation of present-day seawater and allowed sylvite as a primary precipitate.

There is now convincing evidence that the chemistry of seawater has varied across the Phanerozoic, what is not so well understood are the processes driving this change (Fig. 2.45). Spencer and Hardie (1990) and Hardie (1996) have argued that the level of Mg in the Phanerozoic oceans has been relatively constant, but changes in the rate of seafloor spreading have changed the levels of Ca in seawater. The postulate was also supported in publications by Lowenstein et al. (2001, 2003). Timing of the increase in the amount of Ca in the world's oceans was synchronous with a decrease in the SO_4 ion concentration, which at times was as much as three times lower than the present concentration of that ion in seawater.

Through its interaction with seawater, ocean crust is a sink for Mg and a source of Ca, predominantly via the formation of smectite, chlorite, and saponite due to alteration of pillow basalts, sheeted dykes, and gabbros (Müller et al. 2013). Additional removal of Mg and Ca occurs during the formation of vein and vesicle-filling carbonate and carbonate-cemented breccias in basalt from low-temperature fluids. Hence changing rates of seafloor spreading likely influenced ionic proportions in the Phanerozoic ocean.

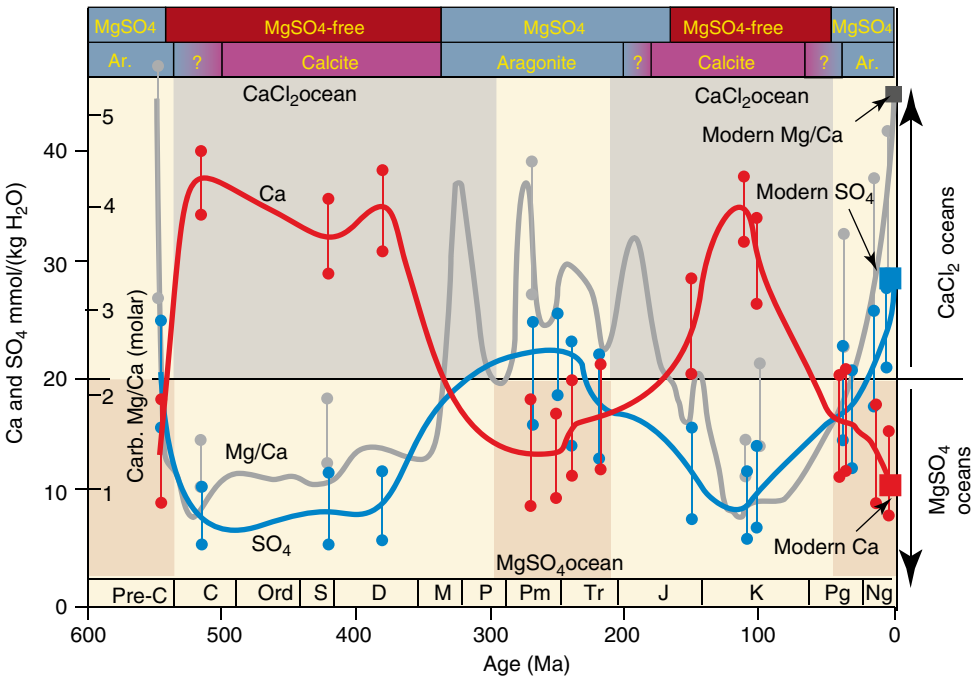

Fig. 2.45 Secular variation in the amounts of Ca and SO_4 in seawater for the last 600 Ma estimated from fluid inclusions in marine halites (*vertical bars*), compared to predicted seawater secular variations. The *horizontal line* around 20 mml/kgH_2O is the approximate divide between $CaCl_2$ and $MgSO_4$ seas. Also plotted are the temporal distributions in the primary mineralogies of Phanerozoic nonskeletal carbonates (calcite and aragonite) and periods of $MgSO_4$-free and $MgSO_4$ bitterns. For Mg/Ca, the grey plot bars are from halite inclusions measurements but the Mg/Ca curve is from marine carbonate data (After Lowenstein et al. 2001, 2003; with Paleozoic $MgSO_4$ boundary change after Holt et al. 2014)

Table 2.13 Predicted composition of seawater (meq l^{-1}) as a function of variations in the ratio of mid-ocean ridge hydrothermal brine flux compared to river water flux into the ocean, and the saline mineral paragenesis of the resulting seawater

Flux ratio	Na	K	Ca	Mg	Cl	SO_4	HCO_3	Order of appearance of saline minerals during evaporative concentration of seawater
0.96	490	3.7	4.8	111	548	59.0	2.7	$CaCO_3$ – gypsum – anhydrite – glauberite – halite – polyhalite – epsomite – hexahydrite – kieserite – kainite – carnallite – bischofite
1.00	470	10.2	20.3	106	548	53.9	0.6	$CaCO_3$ – gypsum – anhydrite – glauberite – halite – polyhalite – epsomite – hexahydrite – kieserite – carnallite – bischofite
1.05	448	17.6	36.2	101	548	53.8	0.6	$CaCO_3$ – gypsum – anhydrite – halite – polyhalite – sylvite – carnallite – kieserite – bischofite
1.10	427	24.3	51.8	97	548	51.4	0.4	$CaCO_3$ – gypsum – anhydrite – halite – sylvite – carnallite – bischofite – tachyhydrite
1.25	376	41.2	91.4	85	548	45.3	0.3	$CaCO_3$ – gypsum – anhydrite – halite – sylvite – carnallite – antarcticite – tachyhydrite

After Spencer and Hardie (1990). Only the first appearance of each mineral is listed (see Fig. 2.24 for backreaction effects)

Simple mixing models show that changes in the flux rate of mid-oceanic hydrothermal brines can generate significant changes in the Mg/Ca, Na/K and SO_4/Cl ratios in seawater (Table 2.13). Such changes of molal ratios in seawater would have generated significant changes in the type and order of potash minerals at the bittern stage. For example, Spencer and Hardie's model predicts that an increase of only 10 % in the flux of mid-ocean ridge hydrothermal brine over today's value would create a marine bittern that would precipitate sylvite and calcium-chloride salts instead of the Mg-sulphate minerals expected during bittern evaporation of modern seawater. This Ca-Cl ocean corresponds to times of "calcite oceans" and contrast with the lower calcium, higher magnesium "aragonite oceans" of the Permo-Triassic and the Neogene (Fig. 2.45; Hardie 1996; Demicco et al. 2005).

Yet many sources have argued, including earlier work by Hardie, that bittern salts lacking $MgSO_4$ components indicate a nonmarine CaCl source. The strong possibility of temporal changes in Phanerozoic seawater chemistry from a $MgSO_4$ to a KCl ocean confuses a mineralogical distinction between marine and nonmarine brine sources. It can be used to argue that many extensive ancient evaporites, such as the Devonian Prairie Evaporite Fm. of Canada and the Cretaceous Maha Sarakham salts of Thailand are in fact marine and formed by the evaporation of a $CaCl_2$ ocean (Timofeeff et al. 2006). A recent paper by Holt et al. (2014), focusing on

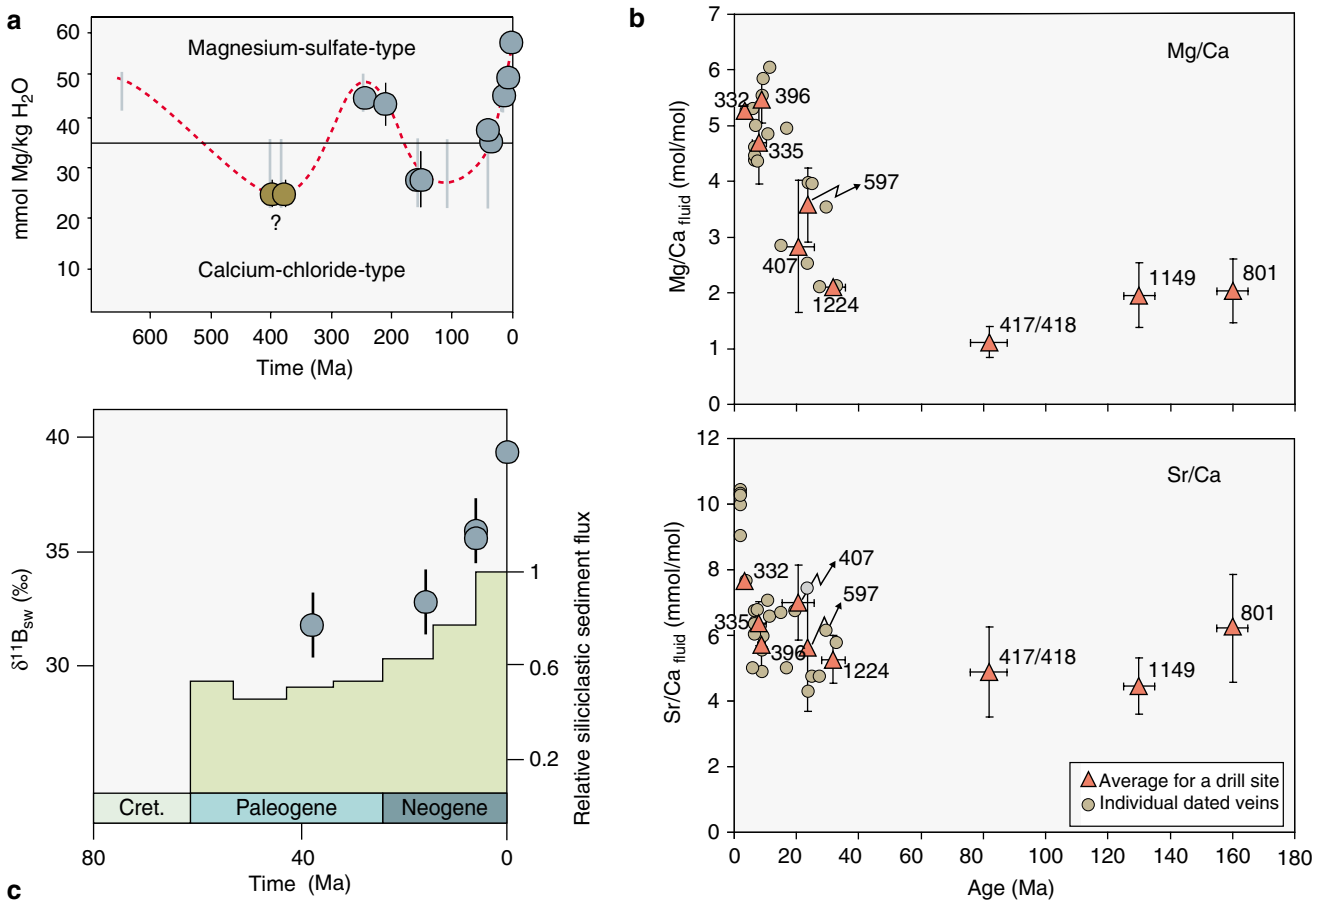

Fig. 2.46 Seawater evolution. (**a**) Secular changes in seawater chemistry based on microanalysis of fluid inclusions in marine halites and tied to levels of shelf dolomite (after Zimmermann 2000a). (**b**) Reconstructed Mg/Ca and Sr/Ca ratios of past seawater, based on calcium carbonate veins from the ocean crust (After Rausch et al. 2013). *Triangles with error bars* are averages for different drill sites. For sites in basement older than 38 Ma, dating of the carbonate veins was not possible and no individual analyses are depicted (**c**) Evolution of boron isotope values in Tertiary-age seawater, based on brine inclusions in chevron halite and plotted against relative siliciclastic input to oceans (After Paris et al. 2010)

chevron halite inclusions from various Carboniferous evaporite basins, further refined the transition from the Paleozoic $CaCl_2$ sea into a $MgSO_4$ -enriched aragonite ocean, so showing $CaCl_2$ oceanic chemistry (and sylvite bitterns) extend even further across the Paleozoic than previously thought (Fig. 2.45).

Holland et al. (1996), while agreeing that there are changes in ionic proportion of Phanerozoic seawater and that halite microinclusions preserve evidence of these changes, recalculated the effects of changing seafloor spreading rates on global seawater chemistry used by Hardie and others. They concluded changes in ionic proportions from such changes in seafloor spreading rate were modest. Instead, they pointed out that the composition of seawater can be seriously affected by secular changes in the proportion of platform carbonate dolomitised during evaporative concentration, without the need to invoke major changes in global seawater composition. In a later paper Holland and Zimmermann (2000), suggest changes in the level of Mg in seawater were such that the molar Mg/Ca ratio of Palaeozoic global seawater (based on dolomite volume) was twice the present value of 5.

Using micro-inclusion studies of halites of varying ages, Zimmermann (2000a, b) has proposed that the evolving chemistry of the Phanerozoic ocean is more indicative of changing volumes of dolomite than it is of changes in the rates of seafloor spreading (Fig. 2.46a). Using halite inclusions she showed that the level of Mg in seawater has increased from ≈ 38 mmol/kg H_2O to 55 mmol/kg H_2O in the past 40 Ma. This increase is accompanied by an equimolar increase in the level of oceanic sulphate. Over the longer time frame of the Palaeozoic to the present the decrease in Mg/Ca ratio corresponds to a shift in the locus of major marine calcium carbonate deposition from Palaeozoic shelves to the deep oceans, a change tied to the evolution of the nannoplankton. Prior to the evolution of foraminifera and coccoliths, some 150 Ma, the amount of calcium carbonate accumulating in the open ocean was minimal. Since then, a

progressively larger portion of calcium carbonate has been deposited on the floor of the deep ocean. Dolomitization of these deepwater carbonates has been minor.

Reasons for the increase in Mg in the past 40 Ma are still not clear. In a study of $CaCO_3$ veins in ocean basement, utilising 10 cored and documented drilled sites, Rausch et al. (2013) found for the period from 165 to 30 Ma the Mg/Ca and the Sr/Ca ratios were relatively constant (1.22–2.03 mol/mol and 4.46–6.62 mmol/mol respectively (Fig. 2.46b). From 30 to 2.3 Ma there was a steady increase in the Mg/Ca ratio by a factor of 3, mimicking the brine inclusion results in chevron halite. The authors suggest that variations in hydrothermal fluxes and riverine input are likely causes driving the seawater compositional changes. They go on to note that additional forcing may be involved in explaining the timing and magnitude of changes. A plausible scenario is intensified carbonate production due to increased alkalinity input to the oceans from silicate weathering, which in turn is a result of subduction-zone recycling of CO_2 from pelagic carbonate formed after the Cretaceous slow-down in ocean crust production rate.

Ayora et al. (2001) called for caution in applying general models of secular changes in seawater chemistry based on assumptions of worldwide sulphate depletion at various times in the past. They reconstructed the chemical evolution of several European Mesozoic and Tertiary marine evaporite basins using mineral associations, primary fluid-inclusion analyses, and numerical simulations of evaporation scenarios. The solute proportion recorded in the fluid inclusions in all basins could be explained using the evaporation of present-day seawater as a major recharge. Sulphate depletion in the brines was responsible for the type of potash deposit formed, namely potassium-magnesium sulphates or sylvite. But this sulphate depletion was due either to dolomitisation or to the addition of a $CaCl_2$-rich solution to the basin. Sulphate depletion occurred in varying intensity in basins of the same age, as well as throughout the evolution of the same basin negating the notion of changes in seafloor spreading. They concluded changes in potash mineralogy and sulphate depletion based on fluid inclusions are not conclusive arguments in favour of secular variations in the composition of the ocean.

Bots et al. (2011) further develop the notion of the importance of sulphate levels in controlling Phanerozoic chemistry. Rather than variations in Mg/Ca ratio in seawater being the prime driver of the aragonite versus calcite ocean chemistries across the Phanerozoic, they conclude sulphate levels are the most important control. They demonstrate that an increase in dissolved SO_4 decreases the Mg/Ca ratio at which calcite is destabilised and aragonite becomes the dominant $CaCO_3$ polymorph. If so, then the Mg/Ca and SO_4 thresholds for formation of calcite seas are mutually dependent and significantly lower than previously estimated.

In a study of boron isotopes in inclusions in chevron halite Paris et al. (2010), mapped out the changes in marine boron isotope compositions over the past 40 Ma (Fig. 2.46c). They propose that the correlation between $\delta^{11}B_{SW}$ and Mg/Ca reflects the influence of riverine fluxes on the Cenozoic evolution of oceanic chemical composition. Himalayan uplift is a major tectonic set of events that probably led to a 2.5 times increase of sediment delivery by rivers to the ocean over the past 40 Ma. They argue that chemical weathering fluxes and mechanical erosion fluxes are coupled so that the formation of the Himalaya favoured chemical weathering and hence CO_2 consumption. The increased siliciclastic flux and associated weathering products led to a concomitant increase in the influx levels of Mg and Ca into the oceans. However the levels of Ca in the world's ocean are largely biologically limited (mostly by calcareous nannoplankton and plankton), so leading to an increase in the Mg/Ca ratio in the Neogene ocean.

As well as changes in Mg/Ca and SO_4, the salinity of the Phanerozoic oceans shows a fluctuating but overall general decrease from the earliest Cambrian to the Present (Fig. 2.47; Hay et al. 2006). The greatest falls in salinity are related to major extractions of NaCl into young ocean (extensional continent-continent proximity) or foreland (compressional continent-continent proximity) ocean basins (Chap. 5). Phanerozoic seas were at their freshest in the Late Cretaceous, some 80 Ma, not today. This is because a substantial part of the Mesozoic salt mass, deposited in the megahalites of the circum-Atlantic and circum-Tethyan basins, has since been recycled back into today's ocean via a combination of dissolution and halokinesis. Periods characterised by marked decreases in salinity (Fig. 2.47) define times of mega-evaporite precipitation, while periods of somewhat more gradual increases in salinity define times when portions of this salt were recycled back into the oceans (Chap. 5).

The last major extractions of salt from the ocean occurred during the late Miocene in the various Mediterranean Messinian basins created by the collision of Eurasia with North Africa. This was shortly after a large-scale extraction of ocean water from the ocean to the ice cap of Antarctica and the deposition of the Middle Miocene (Badenian) Red Sea rift evaporites. Accordingly, salinities in the early Miocene oceans were between 37 and 39‰ compared to the 35‰ of today (Fig. 2.47). The preceding Mesozoic period was a time of generally declining salinity associated with the salt extractions in the opening North Atlantic and Gulf of Mexico (Middle to Late Jurassic) and South Atlantic (Early Cretaceous) and the earliest Cambrian oceans also had some of the highest salinities in the Phanerozoic. Recently, work by Blättler and Higgins (2014) utilising Ca isotopes studies of selected Phanerozoic evaporites has confirmed the dichotomous nature of Phanerozoic ocean chemistry that was previously defined by micro-inclusion studies of chevron halite (Fig. 2.45).

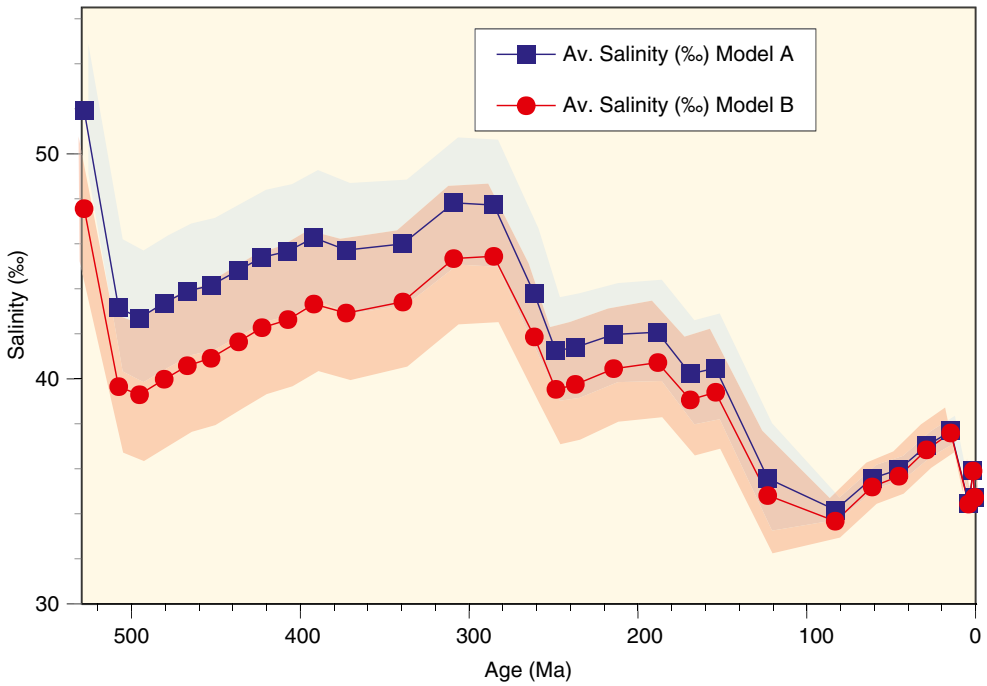

Fig. 2.47 Oceanic salinity changes for the last 500 my (After Hay et al. 2006)

In summary, based on a growing database of worldwide synchronous changes in brine chemistry in fluid inclusions in chevron halite, and Ca isotope variations, most evaporite workers would now agree that there were secular changes in Phanerozoic seawater chemistry and salinity. Ocean chemistries ranged from $MgSO_4$-enriched to $MgSO_4$-depleted oceans, which in turn drove the two potash endmembers (see Chap. 11). What is not yet clear is what is the dominant plate-scale driving mechanism (seafloor spreading versus dolomitisation versus uplift/weathering) that is driving these changes.

Precambrian Oceanic Chemistry

Given that ionic proportions of major ions in seawater and oceanic salinity have changed through the Phanerozoic, forces the question, how constant was the chemistry of the world's oceans since the early Archaean? For example, does the evaporite evidence support the possibility of a primordial reducing atmosphere and/or higher levels of bicarbonate in an ancient ocean?

Some authors postulate that there have been no significant changes in the major ion proportions in seawater for the past 4 Ga (Morse and Mackenzie 1998). Others assert that the Archaean was dominantly a time of little or no atmospheric oxygen and that ocean waters were reducing fluids (Krupp et al. 1994). Yet others propose that the bicarbonate to calcium ratio was so high in Archaean and Palaeoproterozoic seawater compared to today that all the calcium was used up in widespread abiotic marine aragonite and Mg-calcite precipitates (Sumner and Grotzinger 2000). In this case trona or nahcolite are likely marine evaporites in the early Archaean bitterns. Still others have theorised cyclic changes in oceanic chemistry occurred in much of the Precambrian similar to those of the Phanerozoic. Such changes were related to changes in styles and rates of sea floor spreading-hydrothermal circulation in midoceanic ridges (Channer et al. 1997) and the development of tonalitic continents (Knauth 1998).

In the Phanerozoic, seawater was dominantly a Na-K-Mg-Ca-Cl (Ca-rich) type that changed periodically to a Na-K-Mg-Cl-SO_4 (SO_4 -rich) type. Do similar oscillations in ocean chemistry extend back into the Precambrian? Given that the oldest halites are those of the Bitter Springs Formation in the Amadeus Basin and deposited some 840 Ma, we can only extend a halite inclusion based study of ocean chemistry back to that time. Recrystallised halite from the uppermost Neoproterozoic Salt Range Formation (ca. 545 Ma) in Pakistan, contains solitary inclusions indicating SO4-rich brines (Kovalevych et al. 2006b). This supports a similar ocean chemistry derived from primary fluid inclusions from the Neoproterozoic Ara Formation of Oman; that is SO_4-rich seawater existed during latest Neoproterozoic time (ca. 545 Ma). In contrast, Kovalevych et al. (2006b) determined samples of recrystallised halite from the Bitter Springs Formation (840–830 Ma) in Australia contain inclusion brines that are entirely Ca-rich, indicating that basin brines and seawater were Ca-rich during deposition of central Australian evaporites. These combined data, supported by the timing of aragonite and calcite seas, suggest that during the Neoproterozoic, significant oscillations of the chemi-

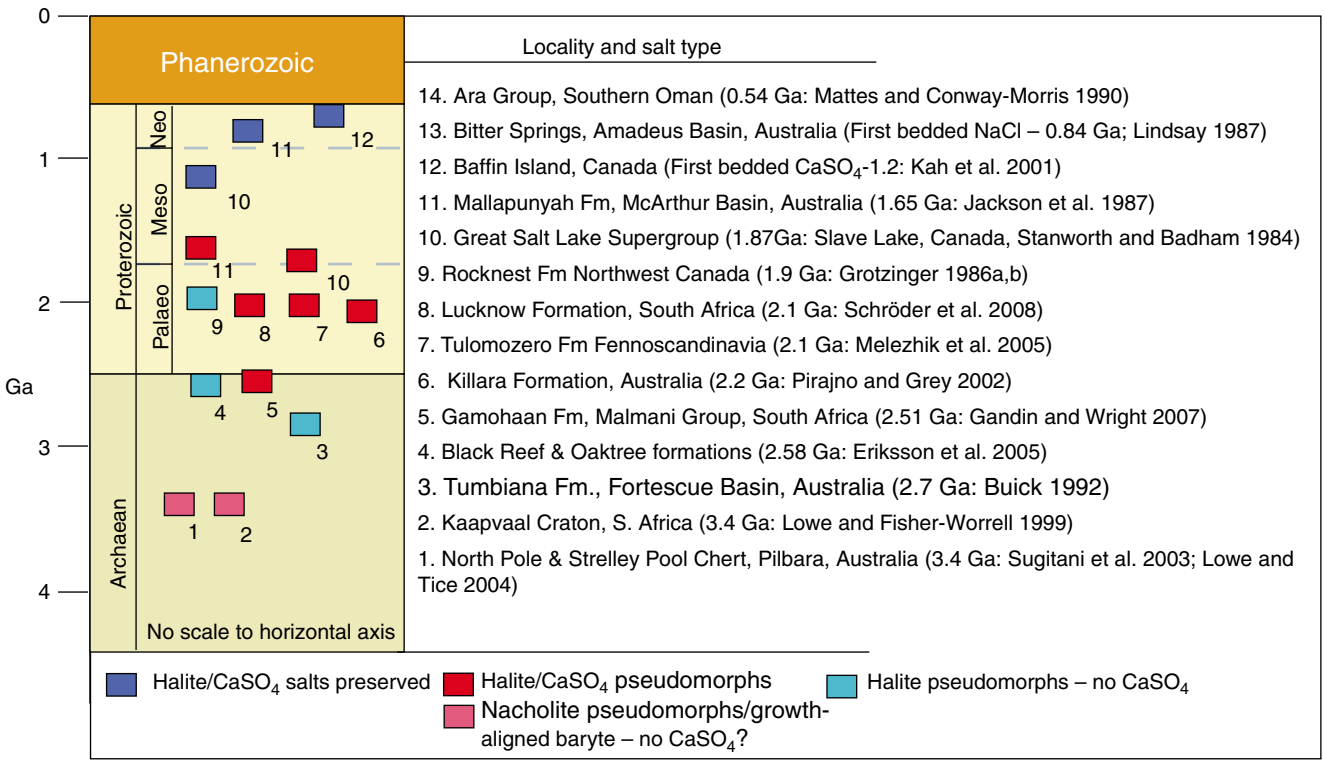

Fig. 2.48 Precambrian evaporite occurrences and mineralogies (compiled from listed sources)

cal composition of marine brines, and seawater, occurred, and were similar to those of the Phanerozoic. It seems that Ca-rich seawater dominated for a substantial period of Late Precambrian time (more than 200 Ma) from 850 Ma, until some 650 Ma, this was replaced by SO_4-rich seawater, returning to Ca-rich seawater at 530 Ma (Fig. 2.45).

The detail for much of the Precambrian is far less than when modelling inclusion chemistries in actual halites. The oldest documented chevron halite is 850 Ma and the oldest bedded anhydrite is 1.2 Ga, beyond that only evaporite pseudomorphs are available to study. So, beyond the 850 Ma record established by halite inclusions, can other Precambrian evaporites especially the calcium sulphates with a record that extends back patchily to the Mesoproterozoic, give indirect clues as to a chemical scenario for the world's paleo-oceans and brine?

Pseudomorphs, especially of halite hoppers, occur in marine rocks as old as Archaean, but are far more common, as are the actual salts, in Proterozoic strata (Fig. 2.48). Halite or its pseudomorphs characterise areas of widespread marine chemical sedimentation from the Archaean to the present. $CaSO_4$ pseudomorph distribution is more enigmatic. In the 1980s and 1990s, the oldest documented $CaSO_4$ pseudomorphs were thought to cm-sized growth-aligned barytes and cherts in 3.45 Ga metasediments in the Pilbara/North Pole region of Western Australia. They were interpreted as replacing primary bottom-nucleated gypsum (Fig. 7.98; Barley et al. 1979; Clemmey and Badham 1982; Lowe 1983; Buick and Dunlop 1990). They occur in volcaniclastics in association with what are possibly the world's oldest stromatolites (Hofmann et al. 1999; Allwood et al. 2007). Similar growth-aligned baryte crystals, which were also interpreted as likely primary gypsum pseudomorphs, occur in the Nondweni greenstones in South Africa, some 3.4 Ga (Wilson and Versfeld 1994).

Sequences in both regions are now completely silicified or barytised. At the time they were first documented, the recognition of what were considered shallow-water Early Archaean gypsum pseudomorphs at North Pole, Pilbara Craton, caused a re-evaluation of models of a totally reducing Archaean atmosphere (Dimroth and Kimberley 1975; Clayton and Thorpe 1982). The presence of free sulphate in surface brines of the Archaean world was thought to imply an at least locally oxygenated hydrosphere. Gypsum precipitating in Archaean ocean waters also meant calcium levels in the ocean waters were in excess of bicarbonate, as is in the modern oceans (Fig. 2.12). The presence of free-standing gypsum on the seafloor is incompatible with any model of the Early Archaean ocean as a "soda lake."

However, in both the Pilbara and the South African sequences there are no actual calcium sulphate evaporites preserved, only growth-aligned crystal textures now preserved as baryte or chert. Textures in baryte ore from Frasnian sediments in Chaudfontaine, Belgium, are near identical to

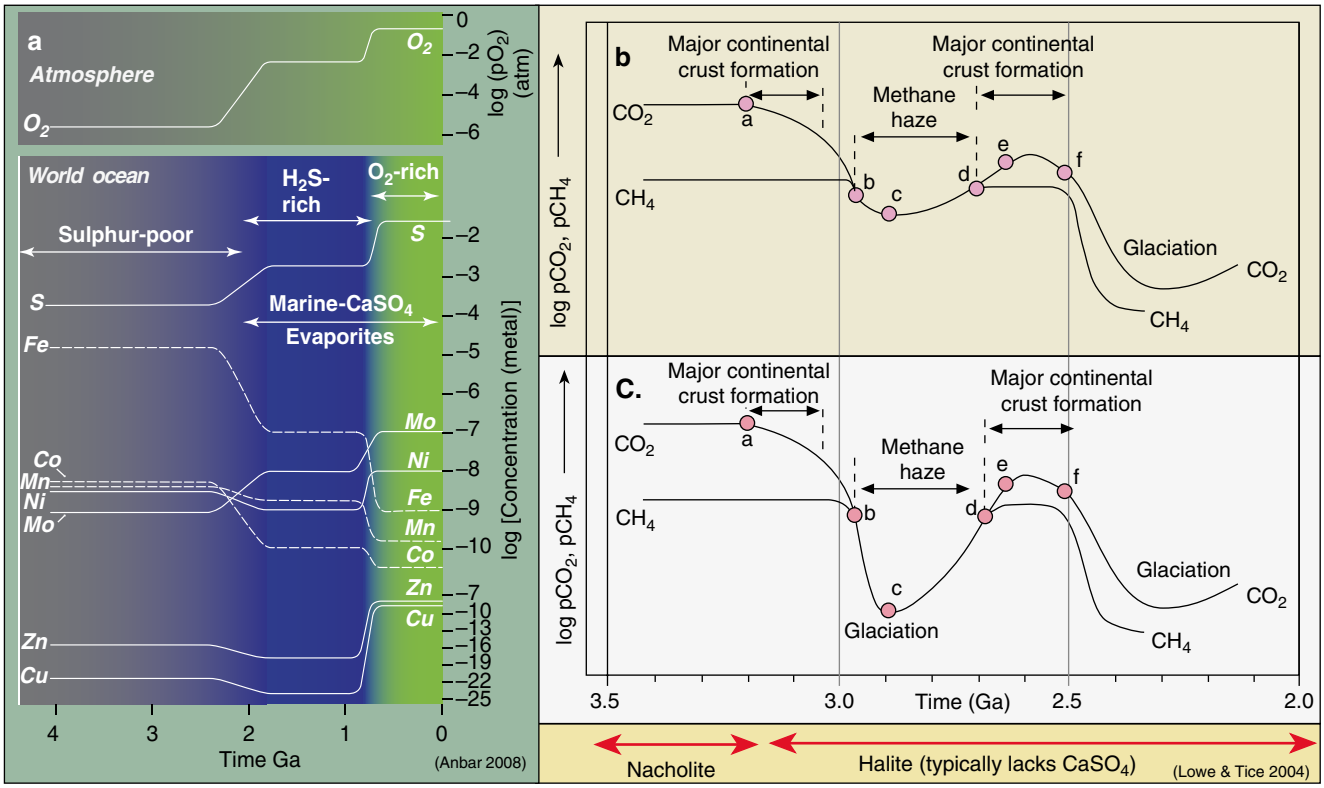

Fig. 2.49 Schematic diagrams showing proposed Earth's oceanic and atmospheric evolution. (**a**) Oxygen, sulphur and metal levels in the world oceans across time. The Archaean ocean was sulphur-poor, an expansion in H_2S-rich oceanic regions occurred around 2.4 billion years, which then gave away to fully oxygenated oceans around 800 Ma ago. That is, marine-derived sulphate evaporites formed both from mother brines that were sourced in H_2S-rich oceans from 2.4 to 0.8 Ga and from O_2-enriched since 0.8 Ga (in part after Anbar 2008) (**b**) and (**c**) pCH_4 and pCO_2 evolution during Archaean and earliest Proterozoic, 3.5–2.2 Ga (After Lowe and Tice 2004). *Diagrams* show atmospheric evolution (**b**) without and (**c**) with glaciation at 2.9 Ga. High surface temperatures, 70 ± 15 °C, were maintained from before 3.5 to at least 3.2 Ga by mixed CO_2 and CH_4 atmospheric greenhouse with $CH_4/CO_2 \ll 1$. Starting ca. 3.2 Ga (point a), enhanced weathering associated with continent formation began to deplete atmospheric CO_2, leading eventually to $CH_4/CO_2 \approx 1$ some. 2.9 Ga (point b) and formation of organic haze, which began to reduce pCH_4 along a path defined by $CH_4/CO_2 \approx 1$. Declining pCO_2 and pCH_4 at 2.9–2.7 Ga resulted in global cooling and possibly glaciation (point c in *lower diagram*). Reduced weathering and continued tectonic recycling 2.7–2.6 Ga led to increasing pCO_2 (line c-d-e), allowing a coupled increase in pCH_4 while maintaining $CH_4/CO_2 \approx 1$. When upper limit of CH_4 production was reached (point d), CH_4/CO_2 became <1 and methane haze formation ceased. Enhanced weathering ca. 2.6 Ga (point e) associated with continent building at 2.7–2.5 Ga once again initiated rapid depletion of atmospheric CO_2 and decline in surface temperatures. Increased O_2 production—associated with latest Archaean spread of oxygenic photosynthetic microbes onto large, shallow-water, continental shelves developed on older (pre–3.0 Ga) blocks of continental crust (point f)—concurrently lowered pCH_4, maintaining CH_4/CO_2 <1 and preventing the formation of organic haze. Oxygen in this period did not approach levels comparable with the Phanerozoic. Widespread glaciation at 2.4–2.2 Ga resulted from decreasing pCO_2 due to weathering and declining pCH_4 due to oxidation

those observed at North Pole, Australia. The Belgian barytes are primary sea-bottom precipitates with no precursor mineral phase (Dejonghe 1990). Some workers in the Pilbara feel that the growth-aligned baryte in this region is also a primary precipitate, formed in the vicinity of hydrothermal vents (Vearncombe et al. 1995; Nijman et al. 1999; Runnegar et al. 2001). As such, it is not secondary after gypsum. A similar hydrothermal discharge model has been developed for aligned barytes in the Barberton Greenstone belt (De Ronde et al. 1994; De Ronde and Ebbesen 1996).

Levels of Archaean sulphate in the world ocean were probably less than a few percent of the current levels and probably remained so until the evolution of an oxygen-producing biota into the Proterozoic (Figs. 2.49a and 2.50; Habicht and Canfield 1996; Kah et al. 2004). Barium sulphate is highly insoluble in modern oxygenated seawater. To carry large volumes of barium or sulphur (as sulphide) in seawater solution to the precipitation site requires anoxic conditions. If the aligned baryte crystals are primary, their formation still requires sulphate to be locally present on the seafloor, at least in the vicinity of the depositional site. A possible source for local sulphate production in the shallow waters that characterised the North Pole site was shortwave ultraviolet photoxidation of volcanic SO_2, indicating an inorganic association (Runnegar et al. 2001). Within barytes in the same 3.47-Ga-old barytes there are microscopic sul-

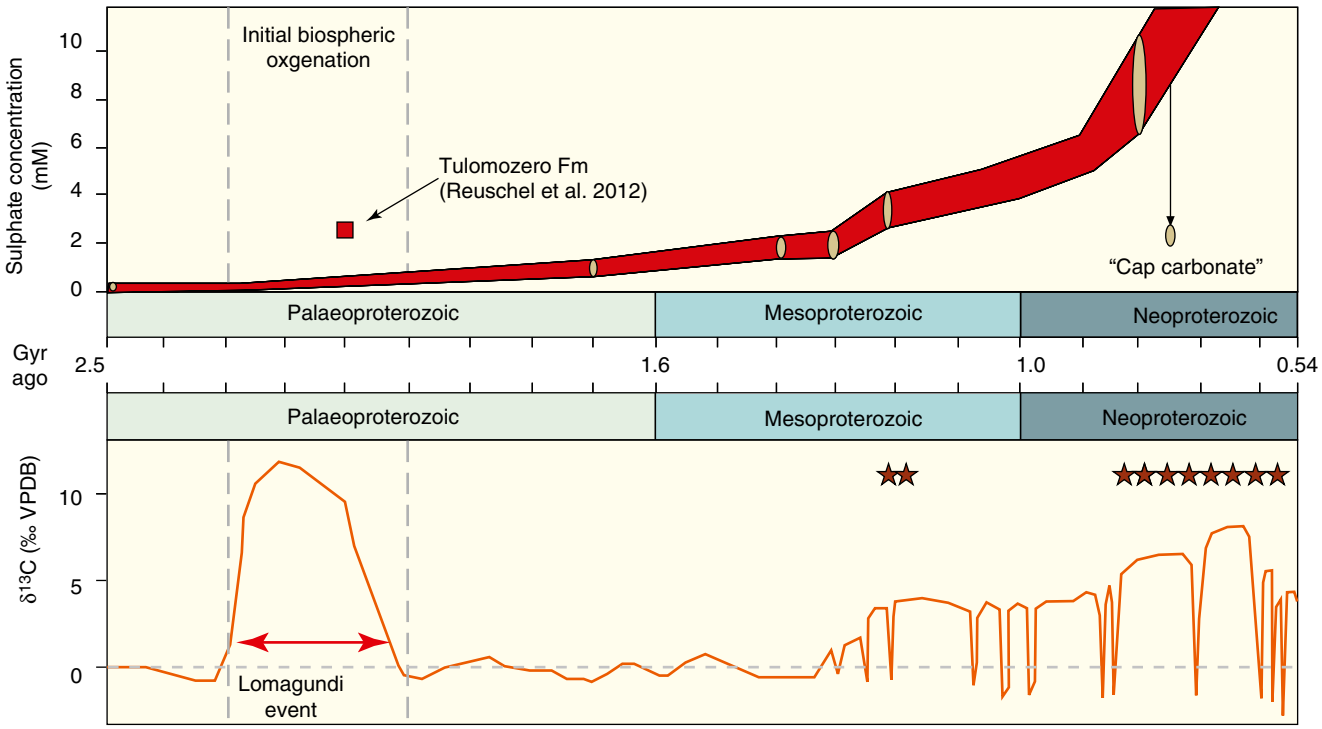

Fig. 2.50 Proterozoic marine sulphate concentrations. Filled ovals mark data determinations (in part after Kah et al. 2004). Marine sulphate concentrations probably remained mostly below 2 mM until about 1.3 Gyr ago (except in the Lomagundi event), rose to, 4.5 mM by 1.2 Gyr ago, and possibly as high as 7–10 mM by the mid-Neoproterozoic, although near-complete reduction of oceanic sulphate may have occurred during Neoproterozoic glacial intervals (*arrow*). Increased sulphate concentrations coincide with changes in marine $\delta^{13}C$ associated with biospheric oxygenation and are marked by the appearance of bedded gypsum (*stars*) in the late Mesoproterozoic and more frequent gypsum deposition in the last two-thirds of the Neoproterozoic

phides. These sulphide inclusions show a $\delta^{34}S$ of 11.6‰, possibly indicating microbial sulphate reduction with H_2 as electron donor (Canfield et al. 2004; Shen et al. 2009).

According to Nijman et al. (1999) the occurrence of the North Pole baryte in sedimentary mounds atop growth faults meant sulphate was locally derived via boiling of escaping hydrothermal vent waters enriched in Ba, Si and sulphide. As these hydrothermal waters vented beneath waters perhaps 50 m deep, they boiled or violently degassed. Consequent mixing with normally stratified seawater, caused instantaneous oxidization of sulphide into sulphate that then, on cooling, combined with the Ba to precipitate as growth-aligned baryte crystals on the seafloor. Conflicting notions (replaced gypsum versus primary baryte) mean that at this stage of our understanding, the bedded baryte evidence cannot be reliably used to support an evaporite paragenesis of gypsum and so infer an Archaean ocean with ionic proportions similar to those of today.

Archaean and Proterozoic distributions of gypsum have been further complicated by the misidentification of primary aragonite splays and pinolitic siderite marbles as gypsum replacements Warren (1999); Chap. 8). When these misidentifications are removed from the record it is obvious that calcium sulphate precipitating directly from Archaean seawater to form widespread beds did not occur, and that precipitation of aragonite as thick crusts on the sea floor was significantly more abundant than during any subsequent time in earth history. In contrast to gypsum, halite pseudomorphs are found throughout the Precambrian (e.g., Boulter and Glover 1986; Fig. 2.48).

Grotzinger and Kasting (1993) argue that high levels of atmospheric CO_2 meant HCO_3/Ca ratios were much higher in the Archaean and the Palaeoproterozoic oceans than today. All the calcium in seawater was deposited as marine cementstones and other alkaline earth precipitates well before bicarbonate was depleted and there was no Ca left over to precipitate as gypsum. The early Archaean ocean was perhaps a Na–Cl–HCO_3 sea, and not the Na–Cl ocean of today (Kempe and Degens 1985; Maisonneuve 1982). This early Archaean hydrosphere had a chemistry similar to that found in modern soda lakes like Lake Magadi and Lake Natron (pathway I brines in Figs. 2.19 and 2.20) and hence the term "soda-lake oceans." This rather different marine brine chemistry would have precipitated halite and trona/nahcolite, not halite/gypsum. It probably meant that if gypsum did ever precipitate from Archaean seawater it did so only in minor amounts well after the onset of halite precipitation. Excessive sodium in the ocean may help explain the ubiquity of stratiform albitites in much of the Archaean. They would have

formed throughout the marine realm as early diagenetic replacements of labile volcaniclastics/zeolites in volcanogenic/greenstone terranes (See Chap. 11, zeolite).

A case for nahcolite ($NaHCO_3$) as a primary evaporite, along with halite, in the 3.42 Ga rocks of the Barberton greenstone belt was documented by Lowe and Fisher-Worrell (Lowe and Worrell 1999). Sugitani et al. (2003) reported silicified nahcolite (the high CO_2 form of sodium carbonate salts; see Fig. 2.20a) in ≈3.2 Ga rocks in the northern part of the Eastern Pilbara block, Western Australia. Coarse, upward-radiating, silicified evaporite crystals in the ca. 3.47–3.46 Ga Strelley Pool Chert (Lowe 1983) show the same habit, geometry, and environmental setting as nahcolite in the Barberton belt and also probably represent silicified $NaHCO_3$ precipitates (Lowe and Tice 2004).

Marine nahcolite in the 3.5–3.2 Ga sedimentary record is thought to be evidence of surface temperatures around 70 ± 15 °C (Figs. 2.20a and 2.49b, c; Lowe and Tice 2004). Contemporary early Archaean nahcolite ($NaHCO_3$) as a primary evaporitic mineral in a very aggressive weathering regime, in the absence of land vegetation, is best explained by a mixed CH_4 and CO_2 atmospheric greenhouse. CH_4/CO_2 ratios were $\ll 1$ and pCO_2 was at least 100–1,000 times the present value, perhaps as high as several bars (Kaufman and Xiao 2003). The formation of large areas of continental crust at 3.2–3.0 Ga, including the Kaapvaal and Pilbara cratons, resulted in the gradual depletion of atmospheric CO_2 through weathering and a lack of marine nahcolite since the early Archaean. By 2.9–2.7 Ga, declining pCO_2 was associated with climatic cooling and siderite-free soils.

Transitory CH_4/CO_2 ratios of ~1 may have resulted in the sporadic formation of organic haze from atmospheric CH_4, and are reflected in one or more isotopic excursions involving global deposition of abnormally ^{13}C-depleted organic carbon in sediments of this age. Surface temperatures of <60 °C after 2.9 Ga may have allowed an increase in the distribution and productivity of oxygenic photosynthetic microbes (and a decrease in sulphur dependent thermophiles). Eventual lowering of newly formed continental blocks by erosion, reduced loss of atmospheric CO_2 due to weathering, and continued longterm tectonic recycling of CO_2 resulted in rising pCO_2 and decreasing CH_4/CO_2 ratios in the later Archaean and eventual re-establishment of a mainly CO_2 greenhouse. Similar events may have been repeated in the latest Archaean and earliest Proterozoic, but gradually rising production of O_2 effectively kept CH_4/CO_2 ratios to $\ll 1$.

By 2.2–2.0 Ga and perhaps as early as 2.5 Ga, reliable examples of pseudomorphs after primary marine-sourced calcium sulphate first appear in the rock record, but aside from the Karelian beds associated with the Lomagundi Event (LE), widespread stratiform sulphate beds of anhydrite do not appear until 1.2 Ga (Figs. 2.48 and 2.49a). Undeniable $CaSO_4$ nodular and lenticular pseudomorphs are widespread in latest NeoArchaean of South Africa and Palaeoproterozoic to Mesoproterozoic sediments of the McArthur Basin, Northern Territory, Australia, and in rocks of Great Slave Lake in northern Canada. For example, in the Malapunyah Formation (1.65 Ga) of the Northern Territory, Australia, the outer portions of numerous decimetre to metre-diameter silicified anhydrite nodules still retain outlines of felted anhydrite laths (pers. obs). The oldest reliable sulphate pseudomorphs after anhydrite and gypsum in Australia come from Palaeoproterozoic cherts in the 2.0–2.2 Ga Bartle Member of the Killara Formation, western Australia (Pirajno and Grey 2002). These cherts locally retain small amounts of anhydrite (verified by XRD, as well as appearing as highly birefringent flecks in thin sections). Other widespread but younger sulphate pseudomorphs occur in the 1.2 Ga Amundsen Basin in the Canadian Arctic Archipelago. Actual $CaSO_4$ beds outcrop in the 1.2 Ga Society Cliff Formation in Baffin and Bylot Islands of the Canadian Archipelago (Kah et al. 2001, 2004). Sulphate evaporite pseudomophs and nodules in all these Neoproterozoic basins are hosted in sedimentary layers up to tens of metres thick and with lateral extents measured in hundreds of square kilometres. All were laid down in shallow marine, coastal, and alluvial environments under an increasingly oxygenated Meso- to Neoproterozoic atmosphere (Jackson et al. 1987; Walker et al., 1977a, b). After passing from the Archaean, by the Mesoproterozoic the hydrosphere contained free sulphate and Ca/HCO_3 ratios were lower, leading to a decrease in molar tooth and other structures indicative of widespread inorganic calcium carbonate saturation in shallow oceanic waters (Fig. 1.26). However, oceanic mother brines for these now-widespread calcium-sulphate evaporites were largely H_2S rich with only moderate levels of oxygen in the atmosphere until some 800 Ma (Fig. 2.49a)

The work of Kah et al. (2004) shows that prior to 2.2 Ga, when oxygen began to accumulate in the Earth's atmosphere, sulphate concentrations in the world's oceans were low, <1 mM and possibly <200 μM (Fig. 2.50). By 0.8 Ga, oxygen and thus sulphate levels had risen significantly. Sulphate levels were between 1.5 and 4.5 mM, or 5–15 % of modern values, for more than a billion years after initial oxygenation of the Earth's biosphere some 2.2–2.4 Ga and mid -ocean depth waters were anoxic for most of that time (Brocks et al. 2005). Marine sulphate concentrations probably remained low, no more than 35 % of modern values, for nearly the entire Proterozoic. A significant rise in biospheric oxygen, and thus oceanic sulphate, may not have occurred until the latest Neoproterozoic (0.54 Ga), just before the Cambrian explosion, when sulphate levels may have reached 20.5 mM, or 75 % of present day levels. This is a time when thick sulphate platforms first characterised the salt basins of Oman, prior to that most actual calcium sulphate is in the form of nodules or relatively thin beds.

In a refinement of the sulphate model, Bekker and Holland (2012) note that free sulphate evaporites and not just its pseudomorphs were present during the Lomagundi Event (2.22–2.06 Ga), and then became relatively scarce once more until some 1.2 Ga. For example, there is a 200 m thick stratigraphic interval of sulphate evaporites of Lomagundi-age, preserved in a shallow-water open-marine siliciclastic and carbonate succession (Lower Jatuli informal group) of Karelia, Russia (Morozov et al. 2010). The Lomagundi Event defines the most extreme and longest lasting isotope excursion of carbon in the world's marine carbonate record. Bedded gypsum pseudomorphs in the Malmani Group some 2.5 Ga (Gandin and Wright 2007) implies that elevated oceanic sulphate levels that typify the Lomagundi Event may have extended a little further back in time, at least locally (Fig. 2.50).

At the same time as the Lomagundi event, the average ferric iron to total iron (expressed as $Fe_2O_3/\Sigma Fe_{|Fe2O3|}$) ratio of shales increased dramatically. At the end of the Lomagundi Event (LE), the first economic sedimentary phosphorites were deposited, and the carbon isotope values of marine carbonates returned to $\approx 0.0‰_{VPDB}$ (Fig. 2.50). Thereafter marine sulphate evaporites and phosphorites again became scarce, while the average $Fe_2O_3/\Sigma Fe_{|Fe2O3|}$ ratio of shales decreased to values intermediate between those of the Archaean and Lomagundiage shales.

In support of this notion of an "oxygen overshoot," sulphur isotope work by Reuschel et al. (2012) on the 2.1 Ga dolomitic Tulomozero Fm, which entrains abundant $CaSO_4$ pseudomorphs, concluded that there was a minimum level of 2.5 mM sulphate in the world ocean at that time (Fig. 2.50).

Bekker and Holland (2012) argue the short appearance of sulphate evaporites in Logamundi and the other associated events can be regarded as a ca. 200 Ma "glitch" in the gradual oxidation of the atmosphere–ocean system. It was driven by a positive feedback between the rise in atmospheric O_2, the oxidation of pyrite in rocks undergoing weathering, a decrease in the pH of soil and ground water, and an increase in the phosphate flux to the oceans. This sequence led to a major increase in the rate of organic matter burial, a rise in atmospheric oxygen, a large increase in the $\delta^{13}C$ value for marine carbonates, the deposition of marine evaporites containing gypsum and anhydrite, and the formation of the first commercially important phosphorites. The end of the LE was probably brought about by the weathering of sediments deposited during the LE.

In yet another proposal of hydrosphere-atmosphere evolution, Huston and Logan (2004) argue that the presence of relatively abundant bedded sulphate deposits before 3.2 Ga (as baryte) and after 1.8 Ga (as $CaSO_4$ salts), and the peak in banded iron formation abundance between 3.2 and 1.8 Ga, and the aqueous geochemistry of sulphur and iron, when taken together suggest that the redox state and the abundances of sulphur and iron in the hydrosphere varied widely during the Archaean and Proterozoic. They propose a layered hydrosphere prior to 3.2 Ga in which sulphate was enriched in an upper oceanic layer, whereas the underlying layer was reduced and sulphur-poor. The sulphate was produced by atmospheric photolytic reactions with volcanic gases in a reducing atmosphere. Mixing of the upper and lower water masses allowed the banded barytes to form prior to 3.2 Ga and created an ocean chemistry where nahcolite was a marine evaporite. Between 3.2 and 2.4 Ga, decreasing volcanogenesis and sulphate reduction removed sulphate from the upper layer, producing broadly uniform, sulphur-poor and iron-rich oceans.

As a result of increasing atmospheric oxygenation around 2.2–2.4 Ga, the flux of sulphate into the hydrosphere by oxidative weathering was greatly enhanced, producing layered oceans, with sulphate-enriched, iron-poor surface waters and reduced, sulphur-poor and iron-rich bottom waters. Gypsum evaporites were increasingly likely as marine precipitates. The rate at which this process proceeded varied between basins depending on the size and local environment of the basin. By 1.8 Ga, the hydrosphere was relatively sulphate-rich and iron-poor throughout. Gypsum was now a widespread marine evaporite. Variations in sulphur and iron abundances suggest that the redox state of the oceans was buffered by iron before 2.4 Ga and by sulphur after 1.6–1.8 Ga.

Gypsum in combination with halite was the marine evaporite association from then until now. Seawater was predominantly a Na-Cl-SO_4 ocean. Neoproterozoic stratiform sulphates along with widespread halokinetic halite, occur in the Bitter Springs Formation of the Amadeus basin, central Australia (0.8 Ga), its equivalents in the Officer Basin, the Callana beds of the Flinders Ranges and the younger Infracambrian salt basins of the Arabian (Persian) Gulf (≈0.545 Ga; Wells 1980; Cooper 1991; Mattes and Conway-Morris 1990; Edgell 1991).

The transition to calcium sulphate textures in evaporite pseudomorphs mirrors a marked change in the style of marine carbonates that began around 2.2–2.3 Ga when herringbone calcite and precipitated carbonate beds become much less common and the precipitation mode shifted from the seafloor to the water column (Fig. 1.26; Saunders and Thomas 1996). The boundary also corresponds to the "rusting" of the oceans when oxygen levels became high enough to precipitate widespread banded iron deposits on the seafloor. Microdigitate stromatolites cross this boundary with little effect, suggesting the marked decrease in dissolved iron exerted little influence on them.

The relative scarcity of actual Pre-Phanerozoic salts, not pseudomorphs, especially in the Archaean has been used by some to argue that conditions were less favourable for

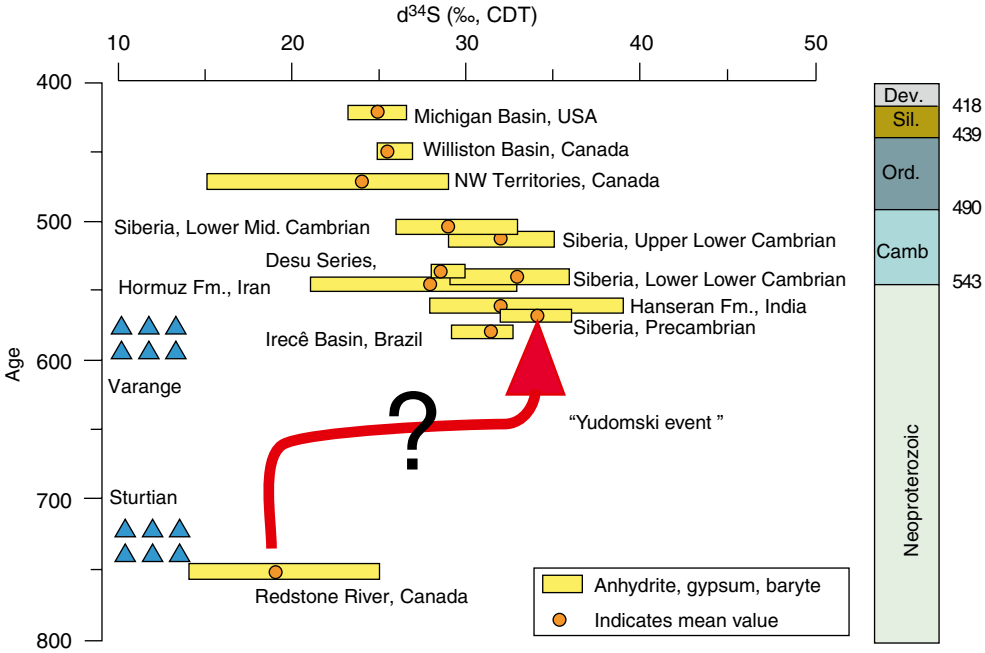

Fig. 2.51 Temporal evolution of $\delta^{34}S$ from marine chemical sediments (anhydrite, gypsum, baryte during the terminal Neoproterozoic and early Palaeozoic. Blue triangles indicate the Sturtian and Varanger glaciations (After Strauss et al. 2001 and references therein)

widespread evaporite deposition in the early Precambrian (Cloud 1972). Others, myself included, feel that the relative scarcity of preserved evaporites in older sequences reflects the greater likelihood of fluid flushing, evaporite dissolution and metasomatism in progressively older rocks. It is likely that oceanic calcium-sulphate evaporites were less common in the Archaean, and that sodium carbonates mixed with halite were dominant evaporite salts in the seawater-fed saline giants in appropriate tectonic seepage depressions of the Early Archaean. But widespread evaporite deposition from sodium-dominated brines did occur throughout the Archaean in large drawdown basins isolated from a surface connection with the ocean. A paucity of preserved bedded evaporite salts in the Precambrian reflects an increased probability of partial or complete evaporite dissolution, remobilization and metasomatism with increasing geological age (see meta-evaporite).

In what is an inclusion study of oldest actual halite, Spear et al. (2014), characterised marine brine chemistry using brine inclusions in the 830 Ma salt of the Browne Formation, Officer Basin, Australia. It seems that concentrations of the major ions in these inclusions, except K^+ and possibly SO_4^{2-}, fall within the known range of Phanerozoic seawaters. This analysis suggests that mid-Neoproterozoic marine sulphate concentrations were lower (≈90 %) than modern values. By the terminal Neoproterozoic, fluid inclusions in halite and evaporite mineralogy from the Browne Formation in Western Australia and the Ara salt in Oman indicate seawater sulphate levels had risen significantly, to 50–80 % of modern concentrations, which parallels increases in atmospheric and oceanic oxygen.

Precambrian-Cambrian Transition

Through much of the Neoproterozoic marine sulphates are preserved as actual chemical precipitates (anhydrite, gypsum, baryte). Their impermeable nature means their isotopic signatures are useful supplements to more widespread marine carbon and sulphide records in defining the transition from the Terminal Neoproterozoic into the early Palaeozoic. Holser (1977, 1984) was the first to address the specific conditions required to produce the rapid rise in $\delta^{34}S$ of seawater sulphate during the terminal Neoproterozoic which he termed the "Yudomski event" after the regional stratigraphy preserved in SE Siberian evaporites. His model of stratification-stagnation and subsequent ventilation of the deep ocean and mixing of different sulphur isotope signatures for dissolved marine sulphate between surface and deep water was reinforced by subsequent workers (Goodfellow and Jonasson 1984; Logan et al. 1995). Recently it has been placed in the contextual framework of a possible "Snowball Earth" and the oxidation of the Ediacaran Ocean (Fig. 2.51; Strauss et al. 2001; Fike et al. 2006). The enrichment in $\delta^{34}S$ signature of chemical sediments across the Precambrian-Cambrian boundary is real, but its ultimate cause is still a matter of debate.

Holser (1977) favoured brine generation and density/salinity stratification of the late Neoproterozoic ocean to explain the "Yudomski event." Alternatively Hoffman et al. (1998), proposed extreme climatic conditions and coverage of the global ocean with sea ice (Snowball Earth) followed by a rapid termination of glacial conditions as a consequence of the build-up of large quantities of volcanogenic CO_2 in the deeper ocean. Subsequent mixing of water masses triggered

the precipitation of large quantities of cap carbonates following the glacial horizons. This scenario (sometimes called "freeze then fry") results in a major reorganisation of the biogeochemistry for the entire water column and is interpreted by some to be documented in the extreme fluctuations of the carbon isotopic composition that occur at that time and likely reflect major changes in the makeup of the world's carbon cycle as we move across the boundary, with related changes in carbonate saturation (Chap. 5).

The Precambrian to Cambrian sulphur cycle, as preserved in marine sulphate evaporites, is intimately linked to the carbon cycle (Holser et al. 1988a, b). This is expressed through a negative correlation of their isotopic compositions i.e., carbonate carbon and sulphate sulphur, reflecting the biological aspects of the exogenic cycle (Figs. 2.35 and 2.51; Strauss et al. 2001). The temporal record of the carbon isotopic composition displays intervals of strongly ^{13}C-enriched values preceding the Neoproterozoic glacials, a decline in $\delta^{13}C$ immediately prior to the glacial horizons, and low $\delta^{13}C$ values in the cap carbonates followed by an evolution back to more ^{13}C-enriched values (Figs. 2.50 and 2.51).

If the Snowball Earth model is real, this may reflect severe changes in primary productivity associated with varying sea ice coverage. Hand in hand with evolving anoxic conditions in the water column under sea ice, heterotrophic recycling of organic matter by sulphate-reducing microbes would have become an important process in the water column, leading to ^{34}S-enriched seawater sulphate. This is clearly documented in the isotopic composition of resulting sedimentary sulphides (e.g., Strauss 1997). Deglaciation and rapid ocean turnover then transferred ^{34}S-enriched water on to the shelf, where marine-fed sulphate evaporites record this isotopic signature.

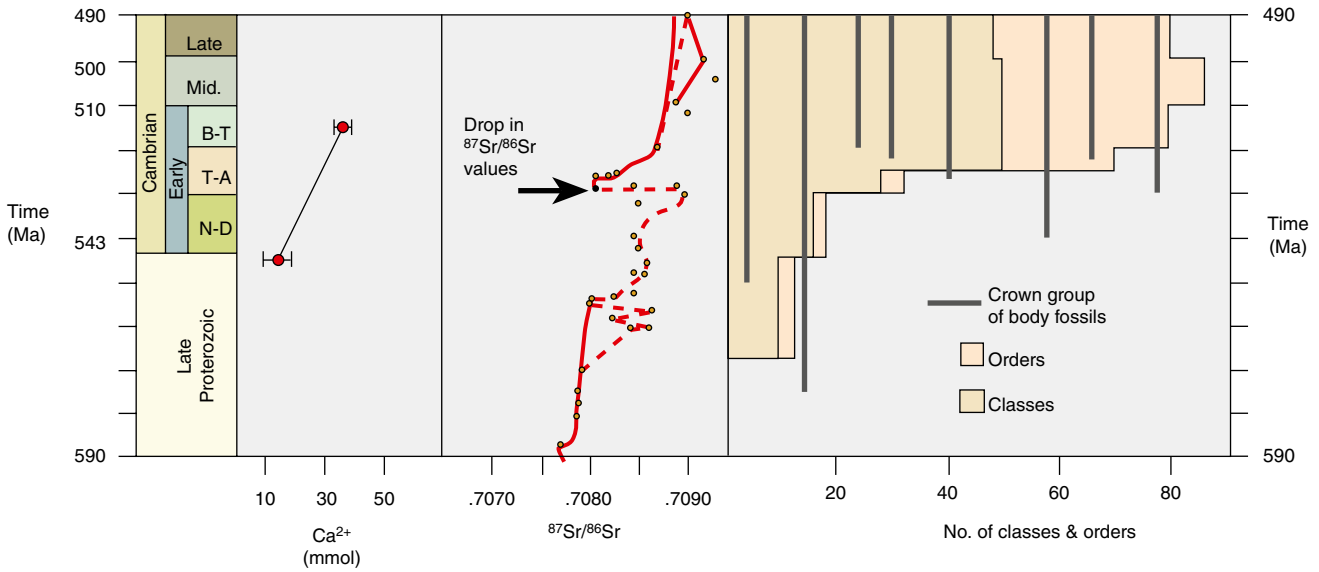
Next in the geological history of Precambrian seawater, after the "Yudomski event," as preserved in evaporite chemistry, comes what is, at least from an anthropocentric viewpoint, the most significant time in the evolution of life. It is when metazoans evolved mineralised hardparts and there was the concurrent evolution of the phylum Chordata (animals with backbones and our distant ancestors). Comparisons of chemical compositions of primary fluid inclusions in marine halite chevrons from terminal Proterozoic Ara Salt (≈544 Ma) and Early Cambrian (Toyonian) Angarskaya Formation of eastern Siberia (≈515 Ma) indicate that Ca concentrations in seawater increased approximately threefold across the Precambrian-Cambrian boundary and into the Early Cambrian (Fig. 2.52; Brennan et al. 2004). That is, the concentrations of Ca in seawater rose precipitously from the Neoproterozoic to reach a Phanerozoic high in the earliest Cambrian (Peters and Gaines 2012). Much of this increase is attributable to enhanced chemical weathering of continental crust during the Sauk transgression, also known as the "Great Unconformity", which since the time of Darwin has defined the Cambrian-Precambrian boundary.

The timing of this marked increase in Ca in seawater broadly coincides with the Cambrian explosion in life, as well as a brief drop in marine $^{87}Sr/^{86}Sr$ values, and an increase in tectonic activity at mid ocean ridges (see earlier in this chapter for discussion of how midoceanic spreading rates may link to oceanic chemistry). Their coincidence suggests a link between the advent of biocalcification, increased hydrothermal midocean-ridge brine production, and the changed composition of seawater (Fig. 2.52).

Brennan et al. (2004) suggest that the evolution of widespread biomineralization might be a metabolic detoxification process induced by large increases in intracellular Ca^{2+} as identified by increases in Ca levels in halite inclusions. During the Early Cambrian, the ambient oceanic calcium level may have risen to such a degree that cells could no longer effectively exclude or expel Ca^{2+} ions, causing intracellular Ca^{2+} in certain marine organisms to reach toxic levels (Simkiss 1977, 1989; Kempe and Kazmierczak 1994). Furthermore, high phosphate levels in Early Cambrian seawater may have amplified the uptake of Ca^{2+} by organisms (Kempe and Kazmierczak 1994). Opportunistic organisms may have modified their existing cellular waste-removal systems by binding Ca^{2+} as relatively insoluble minerals (calcium carbonate or calcium phosphate).

Yet another factor that favoured the evolution to multicellular life toward the end of the Precambrian was the transition of atmospheric temperatures into more temperate ranges (Fig. 2.53; Meng et al. 2011). Seawater temperatures throughout Earth's history illustrate a long-term cooling trend from nearly 70 °C at ~3,500 Ma to around 20 °C at ≈800 Ma. The terminal Neo proterozoic prior to the "Cambrian explosion" is a key interval in evolutionary history, as complex multicellularity appeared with the advent of the Ediacara fauna. These organisms were likely the first that required higher levels of atmospheric and dissolved marine oxygen for their sustainability. Most modern macroinvertebrates are intolerant of temperatures in excess of 45 °C. Perhaps more importantly, these high seawater temperatures limit the potential of dissolved oxygen, and therefore become an integral part of this evolutionary story.

Most of our understanding of seawater temperature during the terminal Neoproterozoic comes from $^{18}O/^{16}O$ and $^{30}Si/^{28}Si$ ratios a from a limited number of cherts. Isotopic ratio methods for assessing seawater temperatures are inherently indirect and have a wide range. However, maximum homogenization temperatures (T_{hmax}) of primary fluid inclusions in halite are a direct means of assessing brine temperature, and as seen earlier in this chapter have been shown to correlate well with average maximum air temperatures. Some of the oldest chevron halites date to the Neoproterozoic-lower Palaeozoic (≈700–500 Ma), and Ediacaran representatives occur in Sichuan Province, China. Meng et al. (2011) used chevron halite samples from the Changning-2 well, correlative to the Dengying Formation (551–542 Ma), to give a



Inferred ion compositions in ancient seawater (chevron halite)

Major Ion	Terminal Prot. (≈ 544 Ma)	Early Cambrian (≈ 515 Ma)	Modern
Na	479	450	485
K	11	9	11
Ca	11 (9.5–18.5)	37 (33.5–40)	11
Mg	52	44	55
Cl	581	605	565
SO_4	20.5 (16–25)	8 (4.5–11)	29
Mg/Ca	≈4	≈1	5

Ca and SO_4 values represent averages of possible end-member concentrations (in parentheses). All concentrations are mmol (millimoles/kg of H_2O)

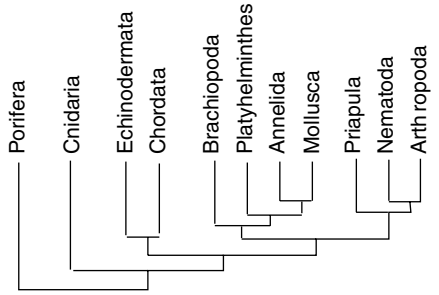


Fig. 2.52 Geological and biological changes in oceanic realm during terminal Proterozoic and Cambrian (After Brennan et al. 2004 and references therein). Stages in Early Cambrian are Nemakit-Daldynian (N-D), Tommotian–Atdabanian (T–A), and Botomian–Toyonian (B–T); Middle (M) and Late (L) Cambrian are also shown. There was dramatic increase in diversity of animal classes and orders starting in Tommotian time. Phylogeny and corresponding crown group first appearances (time line) show diversification of animal clades from the earliest Cambrian. Crown groups are the last common ancestor of all living members of a clade plus all its descendants. Decrease in marine $^{87}Sr/^{86}Sr$ ratios ≈530 Ma during an otherwise increasing trend in $^{87}Sr/^{86}Sr$ ratios likely indicates increase in mid-ocean-ridge spreading rates. Bars indicate possible ranges of oceanic Ca^{2+} determined from inclusions in chevron halite; open circles represent average values with measured ranges shown in parentheses in inset table of computed values of seawater composition for the terminal Proterozoic and Early Cambrian with the composition of modern seawater listed for comparison

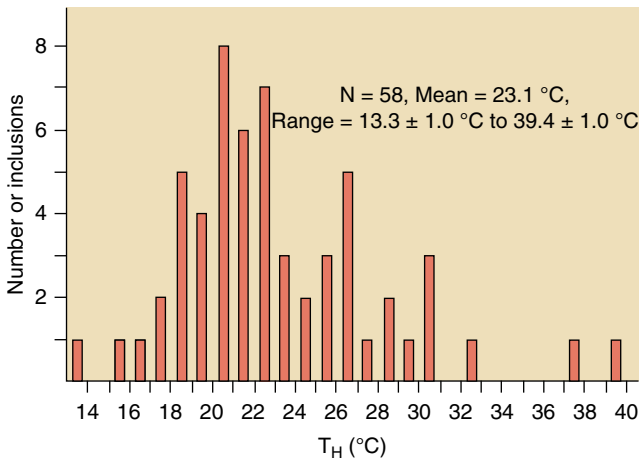

Fig. 2.53 Temperature-frequency distribution of measured homogenization temperatures from inclusions in chevron halite from the Dengying Formation in the Changning well (After Meng et al. 2011)

direct assessment of terminal Neoproterozoic seawater temperature (Fig. 2.53). Their measurements indicate marine-fed brine temperatures similar to those seen in tropical Phanerozoic halites. They argue that the decline in seawater temperatures over the course of the Proterozoic, accompanied by the reduction of seawater salinity with the sequestration of salt in massive halite deposits in the Neoproterozoic, allowed the ocean system to accumulate more dissolved oxygen, and potentially paved the way for the evolutionary innovation of complex multicellularity. These transitions in calcium and O_2 in oceanic chemistry, preserved in halite inclusions, could have been the starting point of the complex process that led to exo- and endo-skeletons (and us!).

Based on the preceding discussion we can state categorically that evaporites and associated isotopic evidence document secular changes in the Earth's atmosphere, hydrosphere and biosphere across the past 4 Ga. In a broader evidential paper

Eriksson et al. 2013 (15 co-authors with Precambrian expertise) noted the following secular changes from the Hadean, across the Precambrian into the Phanerozoic. The documented changes encompassed and were driven by: (1) time related variations in mantle heat, rates of plate drift and of continental crustal growth, the gravitational effects of the Moon, and in rates of weathering, erosion, transport, deposition and diagenesis; (2) a decreasing planetary rotation rate over time; (3) no higher vegetation in the Precambrian, but prolific microbial mats, with the opposite pertaining to the Phanerozoic; (4) the long-term evolution of the hydrosphere-atmosphere-biosphere system. A relatively abrupt and sharp turning point was reached in the Neoarchaean, with spikes in mantle plume flux and tectonothermal activity and possibly concomitant onset of the supercontinent cycle. Substantial and irreversible change occurred subsequently in the Palaeoproterozoic, whereby the dramatic change from reducing to oxidizing volcanic gases ushered in change to an oxic environment, to be followed at ≈2.4–2.3 Ga by the "Great Oxidation Event" (GOE); rise in atmospheric oxygen was accompanied by expansion of oxygenic photosynthesis in the cyanobacteria.

A possible global tectono-thermal slowdown from ≈2.45–2.2 Ga may have separated a preceding plate regime which interacted with a higher energy mantle from a ≈2.2–2.0 Ga Phanerozoic-style plate tectonic regime; the slowdown period also encompassed the first known global-scale glaciation and overlapped with the GOE. While large palaeodeserts emerged from ≈2.0–1.8 Ga, possibly associated with the evolution of the supercontinent cycle, widespread euxinia by 1.85 Ga ushered in the "boring billion" year period. A second time of significant and irreversible change, in the Neoproterozoic, saw a second major oxidation event and several low palaeolatitude Cryogenian (740–630 Ma) glaciations. With the veracity of the "Snowball Earth" model for Neoproterozoic glaciation still under dispute, genesis of Pre-Ediacaran low-palaeolatitude glaciation remains enigmatic. Ediacaran (635–542 Ma) glaciation with a wide palaeolatitudinal range contrasts with the circum-polar nature of Phanerozoic glaciation. The observed change from low latitude to circum-polar glaciation parallels the advent and diversification of the Metazoa and the Neoproterozoic oxygenation (ca. 580 Ma), and was succeeded by the Ediacaran-Cambrian transition which ushered in biomineralization, with all its implications for the chemical sedimentary record.

Hydrology Is Depositional Style

Grains in siliciclastic sediments indicate sediment source or provenance, grains in a carbonate setting indicate biological parentage, mineralogy and textures in an evaporite indicate the nature of the hydrology that created them. During deposition, the hydrologic framework of an evaporite basin consists of surface and near subsurface waters flowing into and out of the areas accumulating salts. It is the upper part of a larger geohydrology made up of several regimes: (1) the active phreatic/vadose, (2) the compactional, (3) the thermobaric, and (4) the active-phreatic-exhumation/uplift regime (Figs. 1.9 and 2.54a). Boundaries are typically indistinct and transitional. The remainder of this chapter concentrates on syndepositional hydrologies of the active phreatic regime, where fluid circulation is driven by solar evaporation and gravity (eogenesis and mesogenesis). Chapter 8 takes this discussion deeper into the subsurface of evaporite basins in thermobaric, compactional and uplift regimes (mesogenesis and telogenesis). In the deep subsurface, where ancient salt masses have spent most of their time, rates of brine flow are slower, alteration events are longer term and driven by a combination of temperature, pressure and density differentials.

Brines and meteoric waters in the zone of active phreatic flow move under the influence of density/salinity or temperature gradients at rates controlled by the permeability of the aquifer. Where areas of strong topographic relief define the basin margin, as in a continental rift valley or in a transtensional basin-and-range setting, unconfined and confined meteoric water typically discharge into the edges of a brine-saturated depression. Further out, beneath the more central and topographically lowest parts of the depression, density-induced brine reflux, and not meteoric throughput, is the dominant process driving shallow subsurface flow (Fig. 2.54a). In a large evaporite drawdown basin, such as in the Mediterranean in the Late Miocene, the level of the discharge zone and the water surface of the perennial brine discharge lake was at times thousands of metres below sea level. Gravity seepage then moved huge volumes of marine/meteoric waters into the depression.

Active Phreatic/Vadose Regime

All primary and syndepositional evaporites first precipitate from brines outcropping at the top of the active phreatic zone or its capillary fringe. This setting is capable of maintaining the density or gravity heads necessary to drive, pond and concentrate large volumes of brines needed to deposit and preserve thick salt beds. An active phreatic flow regime encompasses the zones of seepage outflow, brine ponding, brine reflux and meteoric flow (Fig. 2.54a). The surface of a perennial brine lake or seaway is the outcropping expression of the regional watertable. In the surrounds, where the regional watertable comes near the landsurface, the top of a capillary fringe may be the outcrop expression of the same regional watertable and evaporitic mudflats dominate. Solar evaporation drives water loss at the surface of both settings to form bottom nucleated and pelagic salts in a standing water body and capillary salts in a mudflat. Depressions with

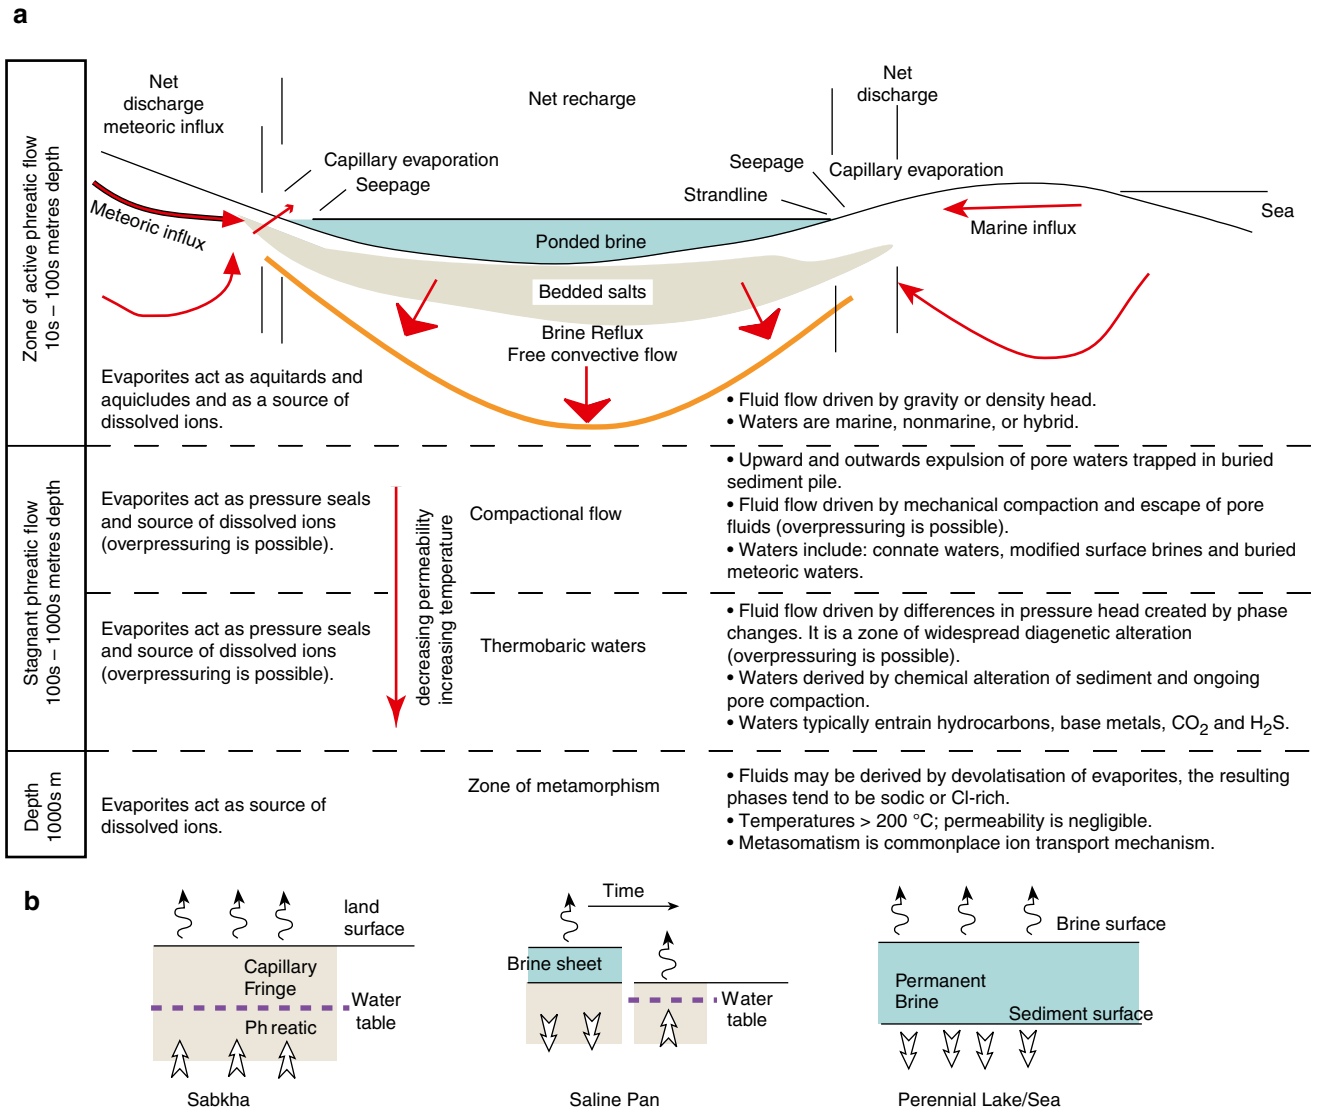

Fig. 2.54 Hydrological regimes and processes in evaporitic systems. (**a**) Depth related mechanisms and processes influencing evaporites. (**b**) Simplified hydrology of the three depositional settings that accumulate evaporites

surface and nearsurface brines in arid settings indicate groundwater discharge zones and their ongoing desiccation creates discharge playas and ancient evaporite seaways. Water lost is replaced by water seeping in from the surrounds creating a replenishment hydrology sometimes described as evaporative drawdown. The replacement water can be continental or marine, and can be supplied via unconfined nearsurface aquifers or via deeply circulating artesian systems.

Hydrologies in Saline Basins

Hydrologies that precipitate salts can be divided into two end members (Fig. 2.54b), (1) a perennial brine lake or seaway (saltern) that at times is density stratified and (2) an evaporitic mudflat (sabkha) with a landsurface defined by deflation at the top of the capillary fringe. A common intermediary stage is an evaporitic mudflat occasionally covered by thin sluggish brine sheets (salt pan). Before discussing the significance of hydrology to evaporitic sedimentation, we first must define some general hydrological principles (Fig. 2.55).

The hydrology of an evaporitic saline mudflat and its landward surrounds (dry mudflat or sandflat) is controlled by the position of the watertable in the sediments (Fig. 2.55a). Pores below the watertable are filled by water of variable salinity and constitute the phreatic or saturated zone where the water volume saturation is total (equals 1 or 100 %). The phreatic zone is the region where gravity-driven groundwaters seep down the potentiometric slope toward discharge

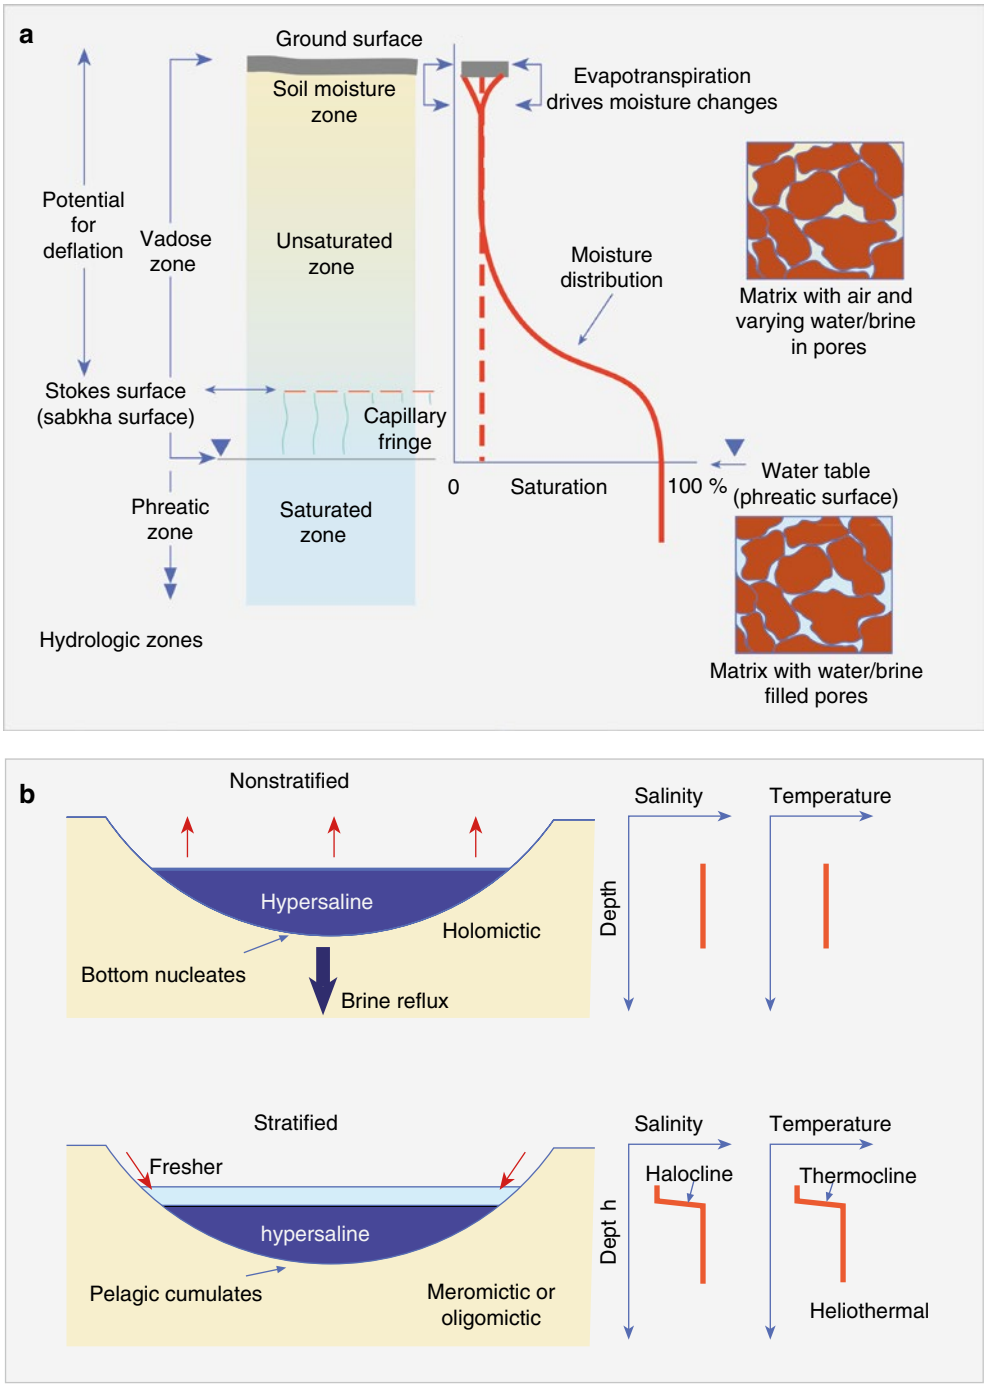

Fig. 2.55 Hydrological classification in saline settings. (**a**) Hydrological zonation in the mudflat and its landward surrounds. (**b**) Water mass zonation in a perennial brine lake or seaway

zones (forced-convection) and dense free-convecting brines, which are created by the evaporation of free surface waters, sink into underlying strata (brine reflux).

Above the watertable is the vadose zone, where pores are filled by a combination of soil air and varying levels of water and brine, water volume saturation is less than one. The vadose zone in dry mudflats or sandflats contains an uppermost interval known as the soil moisture zone where the water content can vary considerably over short time frames. Light rains typically penetrate the soil moisture zone but are not sufficient to saturate the whole vadose zone. Pore water returns to the atmosphere, via evapotranspiration, without ever replenishing the watertable. Fluctuating evapotranspiration levels in this zone vary widely between storms, reflected in variable metabolic activities of the soil biota, variable mean moisture contents, and varying O_2 and CO_2 levels. Pedogenic carbonates and more soluble salts are typically precipitated as surface crusts and near surface cements as a result of these fluctuations. With the next heavy rain the less soluble carbonate precipitates remain, while any more

Table 2.14 Representative thickness of the capillary zone in various host sediments

Sediments	Capillary rise (cm)
Fine silt	750
Coarse silt	300
Very fine sand	100
Fine sand	50
Medium sand	25
Coarse sand	15
Very coarse sand	4
Fine gravel	1.5

soluble salts tend to be flushed back into the subsurface, through a now saturated vadose profile, to re-enter the phreatic water mass.

The process of flushing surface waters to the phreatic zone is known as infiltration. In a homogeneous medium it requires the whole vadose profile to be water saturated. In an inhomogeneous medium, such as a karstic or a fractured and fissured evaporitic landscape, replenishment to the watertable can be more focused. Once the more soluble ions are back in the phreatic mass they continue to flow as dissolved load down the potentiometric gradient and ultimately into the discharge depression where, driven by solar concentration, emerging waters once again can precipitate salts in sabkhas, pans, brine lakes and seaways.

The lower part of the vadose zone beneath a dry mudflat is made up of the capillary fringe (aka tension-saturated or wetting zone). In a saline mudflat the capillary fringe extends all the way to the landsurface. The diameter of pore throats in the capillary zone controls the thickness of the capillary zone; the smaller the throat, the thicker the capillary zone. It is a few mm thick in sands and metres thick in fine clays (Table 2.14). Pores in the capillary fringe are not completely filled with water until its lowermost regions, there 100 % water/brine saturation defines the top of the phreatic zone and the position of the watertable (Fig. 2.55a). Water film and gas phases coexist in the interstitial pore space of much of the capillary zone. The relative humidity of the gas phase (saturated vapour pressure) is, however, equal to the thermodynamic activity of water, and so no evaporative concentration can occur in the capillary zone unless it is very close to the landsurface. Loss of pore water from the capillary fringe in a mudflat typically only occurs in its uppermost few centimetres.

There are some simple principles of soil physics associated with capillary fringes in groundwater discharge zones (sabkhas) that at times have been ignored in sedimentological models of sabkha deposition. First, if the capillary fringe is relatively thick, say 0.5–1.0 m, then host sediments must (by definition) have small pore throats and so must have low permeabilities. A sabkha, by definition, is a zone characterised by the growth of displacive and replacive capillary salts. Salinity of pore water in this capillary fringe is elevated (indicated by the preservation of gypsum, anhydrite, halite etc.). This low permeability means that high rates of transient short-term rapid lateral or vertical flow through a sabkha capillary fringe is impossible. When a sheet flood covers the 0.5–1.0 m thick saline capillary fringe of a sabkha with a sheet of fresher surface water (rainwater or seawater) this water does not begin to infiltrate until its density exceeds that of water in the underlying capillary pores. Then, even when densities do exceed that of the underlying waters, the low permeability of the narrow pore throats means the rate of recharge is slow.

To accumulate salts in the capillary fringe the overall solute-carrying water flow vector over time must be upward, not downward. It also means that almost all of the water in occasional fresher water sheets covering a sabkha are lost to the atmosphere. Low permeabilities mean a sabkha is not capable of maintaining longterm downward reflux flow of water or solute to the phreatic mass. This is true in all evaporitic mudflats. This notion of *per ascendum* rather than *per descendum* hydrologies is correctly accommodated in water flow models for most continental sabkhas and mudflats. This was less so in some sedimentological models of modern marine margin sabkhas, or at least this was so until the last decade when detailed hydrological data sets were collected, and coastal sabkha hydrologies quantified, rather than assumed.

As Wood et al. (2002) has clearly shown in the Abu Dhabi sabkha (Fig. 3.13) and Dutkiewicz et al. (2000) demonstrated in Lake Greenly mudflats and pans (Fig. 2.23), solute flux in the capillary fringe of saline mudflats is largely decoupled from the effects of water cycling in ephemeral sheets of surface water and their salt crusts. Most of the solute load precipitated as salts in a sabkha comes from rising, sometimes deeply circulating groundwater. It does not come from recharge by occasional surface floods atop the sabkha. Floods (marine or meteoric) in a sabkha tend to do little more than redissolve and reprecipitate surface salt crusts and flush the dissolved contents to the sea or the basin pan. Floods of surface waters to a sabkha flat tend to evaporate, not infiltrate. We shall return to this discussion in more detail in Chap. 3, for now we will just note that any secondary salts actively accumulating in a sabkha or evaporitic mudflat at depths of more than a few centimetres below the landsurface are precipitated by physical and chemical changes in ascending, not descending, pore waters.

Quantified hydrological observations in the capillary zone of Owens Lake mudflats by Tyler et al. (1997) underline some other significant general characteristics of the hydrology of evaporitic mudflats (Fig. 2.56):

1. Effective evaporation rates are higher over brine pools than evaporitic mudflats, especially those mudflats covered by a salt crust.

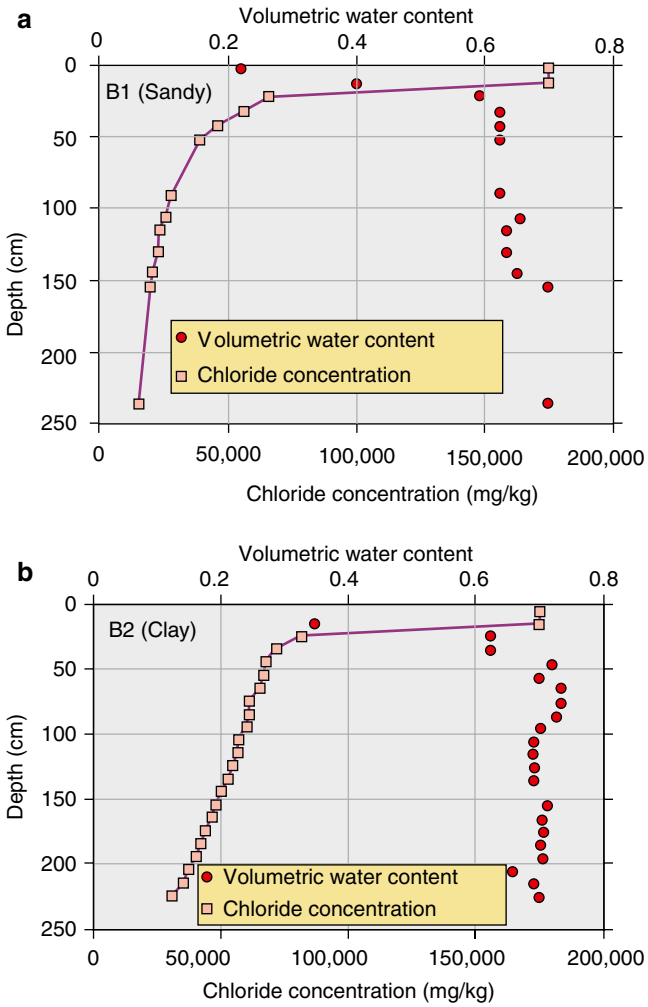

Fig. 2.56 Measured moisture and chloride profiles in the vadose zone of two monitored boreholes in the salt-crusted clay-dominated saline mudflats in Owens Lake, California. Measurements were made in summer of 1994 and 67 days after last recorded rain in the region (After Tyler et al. 1997). A water saturated profile would have a volumetric water content or saturation of 1 or 100 %. See Fig. 2.10 for location, both boreholes are from the saline mudflat sites, one is more clay-rich the other sandier

2. Depth to the watertable in a mudflat is a significant control on the volume of capillary salt precipitated in an evaporitic mudflat or saline pan. That is, much higher volumes of salt accumulate in regions where the saline watertable resides closer to the sediment surface for longer periods of time.
3. Because winter and spring watertables are higher (typically cooler with more precipitation) than summer watertables, the rate of capillary salt accumulation in some mudflats can be greater than in the hottest and driest part of a year, when watertables are lower.

The top of the capillary fringe is the landsurface in those parts of an evaporitic mudflat (sabkha) that are actively accumulating surface salt crusts. Heating of pore waters moves liquid water into vapour that leaks into the atmosphere only in the uppermost few centimetres of the capillary zone, immediately beneath the landsurface. The salinity of the residual brines in this uppermost zone increases to where various salts precipitate (Fig. 2.56). Lost waters are replaced by the rise of capillary waters from below in the process known as capillary rise.

There is another general principal of soil physics in operation here that many sedimentologists working in sabkhas have ignored. To concentrate a brine to where water is lost in large amounts happens largely in the uppermost parts of the capillary fringe, not throughout its whole extent. This is why in every capillary fringe in every discharging sabkha in every modern example, the most saline pore waters (and the most saline salts, sometimes including bitterns) occur in the uppermost portion of the capillary fringe or in the efflorescent crusts at its surface (Fig. 2.56). The underlying capillary waters show upward-increasing salinities, but never attain the salinities of this uppermost few centimetres where salts can evaporatively precipitate (Fig. 2.56).

And yet, from the displacive evaporite textures seen in the capillary fringe of most sabkhas and evaporitic mudflats it is obvious that sabkha salts do not only precipitate as surface and uppermost nearsurface efflorescences and crusts (Figs. 3.6g and 3.7). This leads to the conclusion that preserved calcium sulphate salts in the classic Abu Dhabi sabkha and probably many other sabkhas are a type of retrograde evaporite precipitate known as thermalite salts (Wood et al. 2005). Such salts form passively and displacively in the bulk of the capillary fringe, below the uppermost interval of ephemeral evaporative halite and bitterns. The precipitation mechanism is heating of a rising capillary pore water solution that is dominated by a retrograde phase (anhydrite, gypsum) to temperatures above 25–30 °C (see Chap. 3 for details). Sabkha salts in a capillary zone are "true" evaporites in that the overall precipitation hydrology is driven by solar evaporation, but the local precipitation mechanism in the bulk of the capillary zone is more a response to temperature change than to evaporative concentration.

In contrast, the hydrology that preserves modern bitterns (carnallite) in the bedded halites of Qaidam Basin is not that of a capillary fringe in a sabkha about the lake edge. By definition, sabkha pore waters are rising and heating. Rather, the precipitation mechanism in Qahan salt flats is one of sinking and cooling dense brines precipitating prograde salts, following an episode of halite karstification (Fig. 11.13c). Modern carnallite precipitation is a passive pore filling process that takes place *per descendum*, beneath a freestanding and concentrating holomictic brine sheet, which is feeding a dense descending brine plume (brine reflux). It is a recharge mechanism and not a capillary rise process.

Surface waters within freestanding perennial brine lakes or seaways routinely fluctuate between stratified and

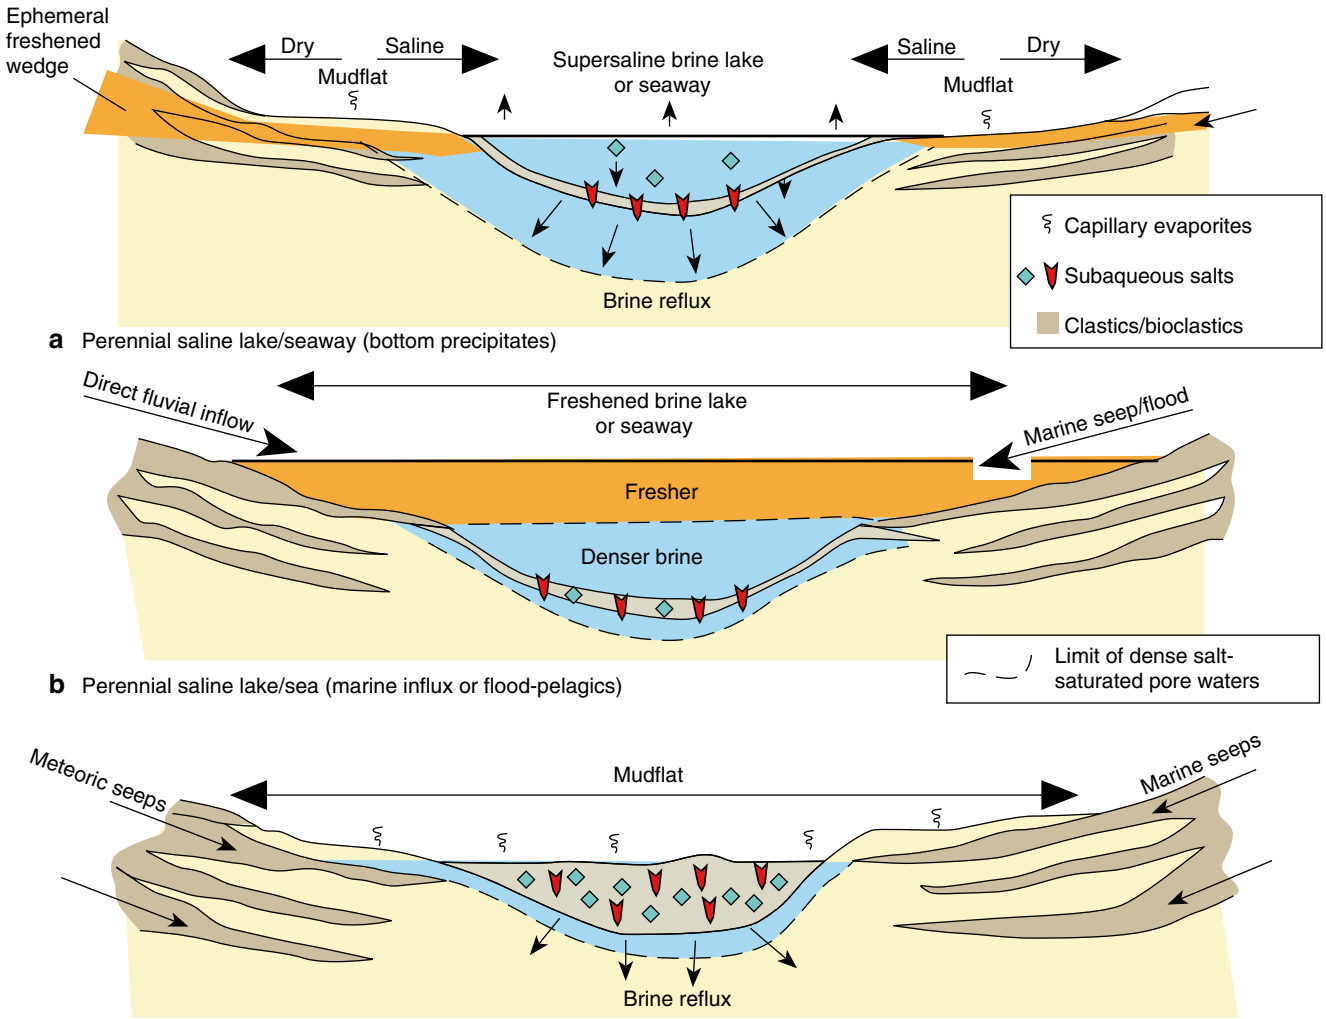

Fig. 2.57 Cross sections showing hydrological stages in the active phreatic zone in an evaporitic seaway or a continental lake. (**a**) Perennial saline lake accumulating widespread subaqueous evaporites from a nonstratified brine body. Capillary evaporation of fresher water lenses about the lake margin. (**b**) Perennial saline lake or water full stage with subaqueous brine lens isolated from solar evaporation processes by a layer of surface water. This shuts down widespread crystallisation in lower brine body and slows brine reflux. (**c**) Playa stage where ongoing evaporite fill, or lowering of regional water level, means the sediment surface is mostly subaerial and in capillary equilibrium with saline lake watertable. This is a classic evaporitic mudflat or sabkha hydrology. No fresh water lens exists until after the next flood event

nonstratified conditions. In the stratified system an upper fresher (less dense) water mass sits atop a more saline (denser) lower water mass (Fig. 2.57b). The narrow zone of transition between the two masses in the brine column is called the halocline. Often a stratified saline lacustrine system is also thermally stratified, with warmer waters in the lower water mass and a zone of transition is called the thermocline. Its position is typically identical in the column to that of the halocline. Thermal stratification with a cool top and a hot base is opposite to that found seasonally in many temperate freshwater lakes and so is sometimes called reverse stratification and also described as heliothermal layering. The term meromictic is used to describe a permanently stratified water mass where surface layers may mix, but the bottom layer does not disappear. The upper water mass that periodically mixes is the mixolimnion, the lower permanent mass is the monimolimnion. Oligomictic is used to describe stratified water masses that mix or homogenise for short irregular periods every few years.

Mixing in a saline water mass is controlled by the evaporation and concentration of the upper water mass until it reaches a density equivalent to the lower water mass. Then mixing or overturn occurs. Substantial density differences between the upper and lower masses in most density stratified systems means diffusive mixing across the halocline is insignificant. A stratified system is a stable system, so that

when a hypersaline water mass is density stratified there is little bottom precipitation of salts. Sedimentation is mainly by a pelagic rain of crystallites, which first formed either in the uppermost part of the upper water mass or by brine mixing at the halocline. Whenever the upper and lower water masses equilibrate and homogenise, bottom nucleation of salts is possible even at the base of deep brine columns, as is occurring in the Dead Sea today (Chap. 4). Whenever a homogenised water mass restratifies, the rate of brine reflux in to sediments below the sediment brine interface slows and ultimately stops, for there is no ongoing mechanism to resupply brines denser than pore waters in the substrate.

Refluxing brine plumes beneath homogenized surface water masses sink and at the same time start to spread laterally toward the basin fringes where they mix with incoming forced-convection waters of the seaway or playa margin. Ultimately plume waters can return to the surface in a diluted form as a component of spring or seep waters or they can be lost to the regional hydrological flow. Reflux-driven convective flow is an effective way of moving salt load through large volumes of basin sediments in modern saline depressions (e.g., Lake Tyrell, Australia: Fig. 2.30) and also explains the distribution of salts, pseudomorphs and dolomites in ancient sediments that underlay or were adjacent to areas accumulating bedded salts.

Mudflat Aggradation Mirrors Watertable Change

Unconfined meteoric and marine groundwaters seeping and discharging into the edges of an evaporitic depression have a potentiometric head defined by the position of the regional watertable. The unconfined meteoric watertable surrounding a modern coastal marine-seepage lake is typically a few centimetres higher than sea level. In a continental saline lake or an ancient drawdown saline giant, the watertable about the basin margin is higher than the brine level within the evaporite-accumulating depression (Fig. 2.57a). Once meteoric/marine groundwater seeps into discharge zones within the salt-accumulating region of the central depression, it comes into contact with more saline and denser surface and pore brines. On average, the throughflowing waters beneath a mudflat or bajada margin are less dense (fresher) than hypersaline waters in the brine-saturated lowermost parts the saline depression. After a heavy rainstorm or a flood, a shallow fresher groundwater layer forms along the strandline edge of the permanent brine lake or seaway as freshwater floats atop a wedge of denser hypersaline pore waters (Fig. 2.57a, b).

Shallow meteoric sheets and groundwater lenses are typically transient mudflat features, so without ongoing recharge, these freshened groundwater outflows within the mudflat dissipate via capillary evaporation and are replenished by more saline pore waters. Alkaline earth carbonates and lower salinity salts can precipitate as surface crusts or nearsurface pedogenic nodules and crystals in the vadose portions of the basin edge. During prolonged dry spells, capillary evaporation continues to lower the saline mudflat watertable until flow directions may be reversed. Brines in aquifers from the basin centre and more deeply circulating region groundwaters begin to seep into the margin to replace the lost capillary fluids. Increasingly saline pore waters in a saline mudflat, mean salts, which crystallised earlier, can now evolve into more saline precipitates via backreaction and replacement (Fig. 2.57c).

With the next inflush of freshened recharge the watertable rises once more in the marginward vadose zone of the saline depression. At the same time a thin sheet of fresh rainwater or seawater can cover the surface of the saline mudflat. This redissolves highly soluble salts of the uppermost capillary zone, along with any of the more soluble surface efflorescences (Fig. 2.57b). A wedge of freshened water now floats above a stable body of dense brine, both atop pore waters of the saline mudflat and atop a dense lower brine mass the central density-stratified perennial brine lake. This blanket of freshened water shuts down evaporation of saturated waters and prevents further accumulation of salts, both in the uppermost parts of the capillary mudflat and in the salt brine covered regions of the perennial lake or seaway. The style of surface sedimentation at this time is sheet flood sands followed by accumulation of suspended load clays.

Then, as the depression begins to dry out, the brine sheet shrinks until it only covers the lowermost parts of the lake depression, the zone of perennial lake waters. Once the saline mudflats are re-exposed, capillary evaporation begins once more. At some point in this desiccation stage, surface water becomes saturated and crystallites formed at brine surface sink through the brine column to the lake/seaway floor (pelagic sedimentation of carbonate and gypsum). Bottom nucleation and intrasediment prograde precipitation of reflux salts beneath a standing brine lake recommence when the rising salinity (density) of the upper water mass comes to equal that of the lower brine mass. The two water bodies then mix and precipitation of bottom salt begins anew (Figs. 2.55a and 2.57b).

Near surface sediments in saline mudflat margins experience the effects of schizohaline pore waters. Salinities in sediments beneath perennial (meromictic) brine-covered depressions tend to be more stable, although a body of freshened surface water comes and goes. Textures in schizohaline salt beds are dominated by ongoing re-equilibration reactions, backreactions, dissolution-reprecipitation and haloturbation, while textures in beds deposited in perennial brine seaways and lakes tend to be more stable and dominated by large growth-oriented crystal beds and brine reflux re-equilibration textures below.

Table 2.15 Some examples of modern capillary deflation surfaces or Stoke's surfaces

As an evaporite basin aggrades toward its hydrological equilibrium level (Fig. 2.57c) the depositional surface aggrades into ephemeral brine sheet (pans) and ultimately mudflats (filled accommodation space). The progression brine lake to a mudflat induces schizohaline textures in the uppermost parts of each shallowing upward hydrological cycle. If there is no rise in regional watertable, the same textural shoaling occurs across the whole discharge zone.

Indicators of Fluctuating Watertables

Because evaporites form by the evaporation of discharging and ponding waters, any longterm water fluctuations in an evaporite basin influence sedimentation style and mineralogy on scales coarser than the stacked gypsum and tepee truncation layers and parasequences described in Chaps. 1, 3 and 4. Longterm aggrading watertables (or regional subsidence) in an evaporite basin enable the capture of formerly vadose sediment by the damp, sticky to wet conditions that characterise the capillary and phreatic zones and so facilitate the preservation of formerly vadose and nonevaporite sediment in the depositional system – sediment that would otherwise be blown away (e.g., Newell 2001). It is aggrading saline watertables that ultimately preserve almost all ancient sabkha, brine lake and dune sediments.

Falling watertables enable entry of vadose conditions into former capillary and phreatic sediments. This leads to the dissolution of salt beds, to eolian deflation and to the formation of residual sediment layers that come to lie at or just above the regional watertable. Episodes of active deflation in the Late Quaternary have periodically fed the extensive quartzose and gypsum sand dunes that abut numerous playas in Australia, Saudi Arabia and the southwest USA. Deflation to the top of the capillary fringe creates the characteristic flat surfaces of many modern playas, sabkhas and interdunal depressions. The hydrological process has been called watertable bevelling as it is tied to the erosional top of the capillary zone (Bowler 1986; Warren and Kendall 1985). The capillary surface erosionally truncating underlying sedimentary structures is termed a Stokes surface.

Stokes Surfaces

Stokes surfaces accompany changes in the base level of erosion/deflation and are commonplace in eolian sand seas or ergs abutting ancient evaporite beds. At the local scale a Stokes surface defines the top of the sedimentation surface in a degrading wet interdunal depression (Table 2.15; Stokes 1968). A succession of such truncation surfaces can be preserved atop a number of depositional cycles as successive packages of sediments aggrade and stack, driven by longterm watertable rise. Changes in watertable level may indicate climatic change or episodic basin floor subsidence. At the regional scale an extensive truncation surface in an ancient desert succession, which passes through various arid lithofacies, is called a super-surface or a super-bounding surface by sequence stratigraphers, but it is really a glorified Stokes surface.

Stokes surfaces create sharp planation surfaces in eolian crossbeds, sometimes outlined by a thin veneer of lag sediment (Fryberger et al. 1983, 1984). Watertable control on their creation is clearly seen in the Umm Said portion of the Qatar coast south of Doha where large transverse and barchan dunes still migrate into the sea (Fig. 2.58a). This eolian-fed progradation of the shoreline and the creation of the associated Stokes surface has been taking place since the early Holocene sea first intersected the sand sheet (Fig. 2.58b, c). The Stokes surface is the surface of uppermost eolian preservation and it migrates seaward as the dunes build out into the Arabian Gulf. In all modern coastal dune successions the Stokes surface is the top of the capillary zone and it approximates sealevel.

Erosion surfaces, defined by the top of the capillary zone also truncate anhydrite nodules or enterolithic folds in the upper parts of the coastal sabkhas of the United Arab Emirates (Fig. 3.5g). In the fine-grained matrices of a sabkha the erosional truncation of an evaporite is typically up to a

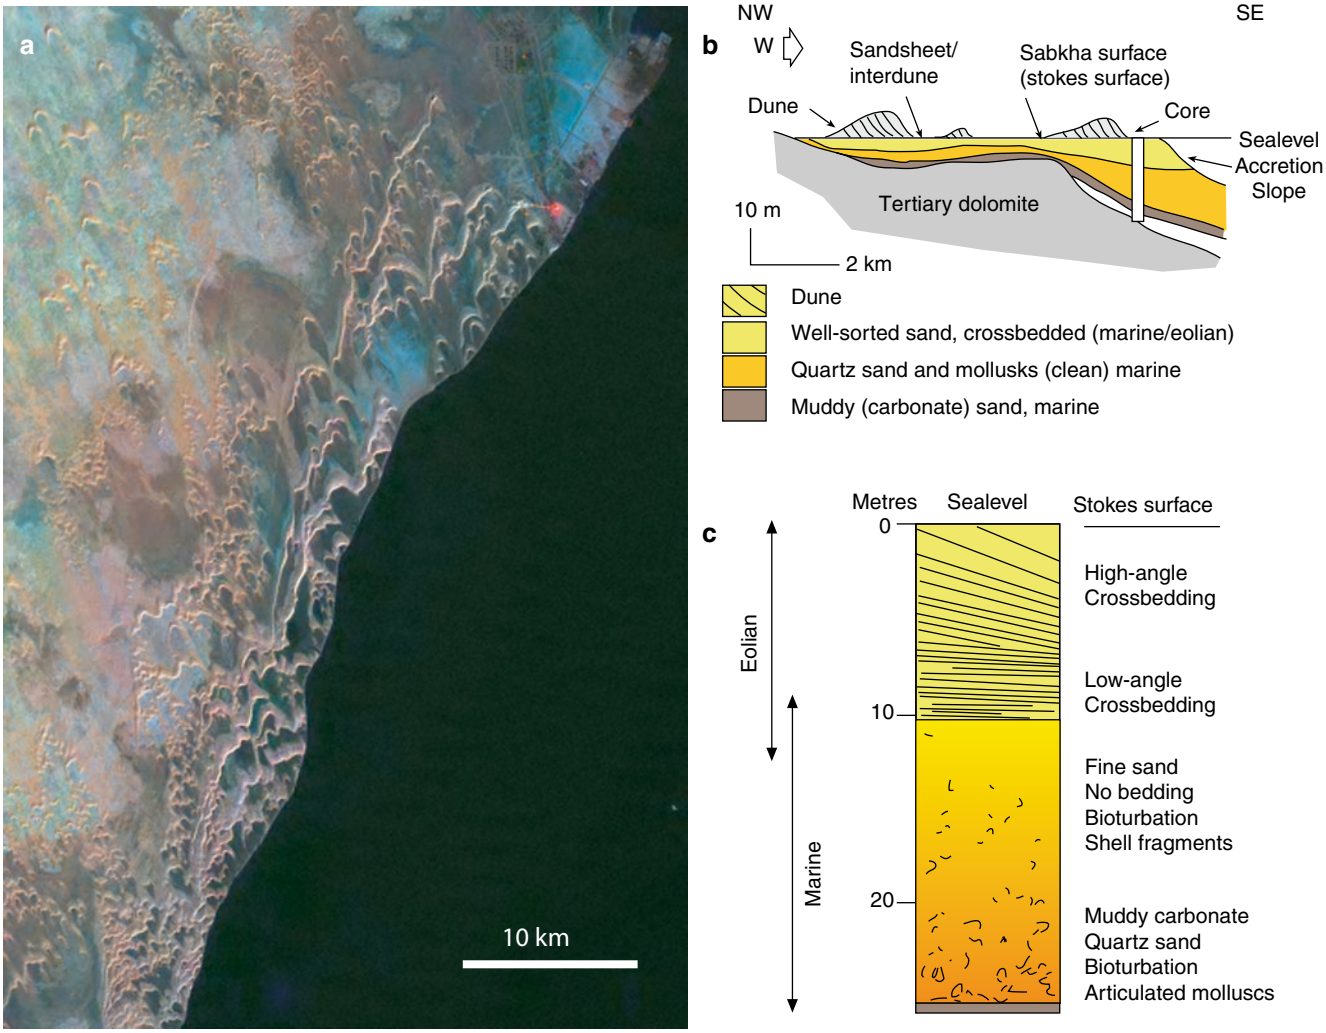

Fig. 2.58 Umm Said Sabkhat, Qatar. (**a**) Transverse and barchan dune moving seaward atop sandflat and coastal sabkha (Image courtesy of NASA). (**b**) Cross section and core from an Umm Said sabkha in coastal Qatar showing how the deflation surface that defines sealevel and the top of modern coastal sabkhas is also a Stokes equilibrium surface (indicates the top of the capillary zone). (**c**) Schematic core taken in position shown in **b**. (**b**, **c** After Shinn 1973)

metre above the watertable. Stokes surfaces are an integral part of the capillary hydrology of a sabkha and are very useful in distinguishing ancient mudflats from subaqueous evaporites (Warren and Kendall 1985).

Aggrading watertables in discharge depressions in sand-rich eolian environments can promote the passive precipitation of pore cements in the uppermost part of the capillary zone. In modern dunes and sandflats these aggrading salt-cemented intervals are sometimes called salcretes, the evaporite equivalent of capillary calcretes. They are made up of passive pore-filling cements (gypsum or halite), not the active displacive nodules and crystals that typify sabkhas. Schenk and Fryberger (1988) noted such massive phreatic-gypsum cemented zones act as a lower limit to any subsequent eolian deflation in the gypsum dunes of the White Sands dune field, New Mexico. They create a cemented near-horizontal base level to erosion, now seen as a widespread Stokes surface in the interdunal corridors. Aggrading salcretes, tied to a rising watertable, can help preserve capillary and eolian sedimentary structures. Salcretes were the main reason why dune topography is preserved in some transgressive settings where ancient ergs are overlain by evaporite beds (e.g., Entrada-Todilto and Rotliegende-Zechstein formations).

Megapolygonal desiccation cracks are another expression of the hydrology associated with a Stokes surface and form in deflating mudflat or playa sediments in conjunction with a regionally falling watertable (Fig. 2.59). Megapolygons can be up to 300 m wide and separated by fissures up to 5 m deep, they characterise the modern surfaces of a number of Basin and Range playas in Oregon,

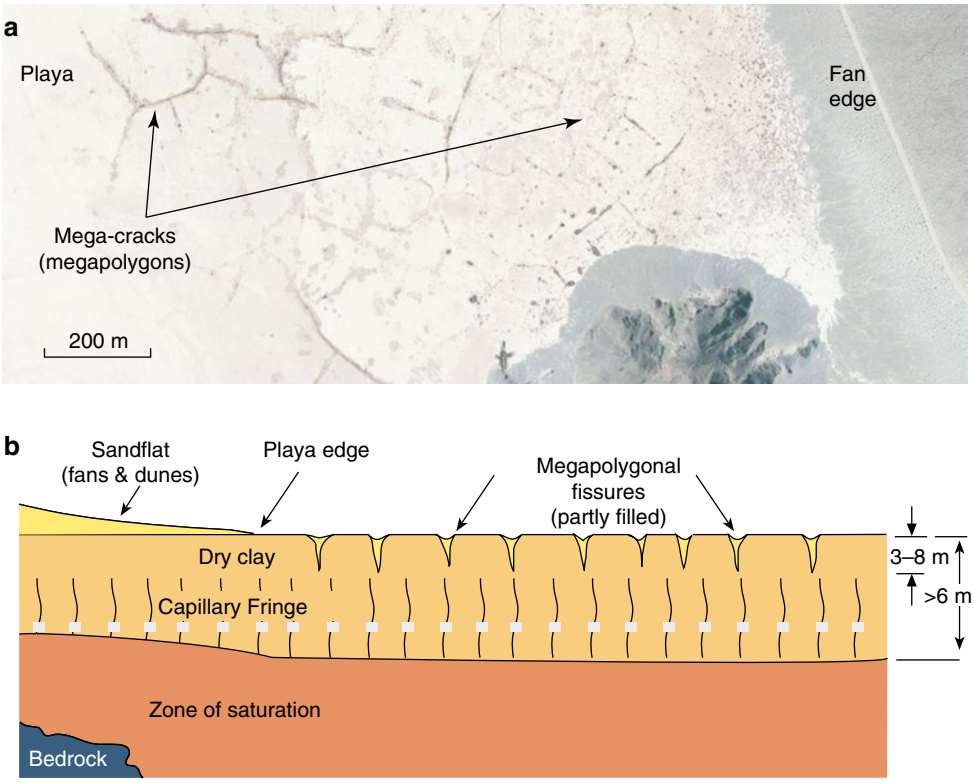

Fig. 2.59 Megapolygonal desiccation cracks. (**a**) Megacracks at the northern end of the Panamint Valley playa. (**b**) Formation and preservation. Vertical section shows megacracks partly filled with sand, captured as it saltated across the deflationary playa surface. Fissures were formed during a lowering of the regional watertable and the associated shrinkage during drying of lacustrine clays (After Neal et al. 1968)

Nevada, California, Arizona and New Mexico (Neal et al. 1968). Fissures are hosted in fine-grained playa sediments rich in clays and carbonate minerals. The fissures, which are up to 1 m wide, are routinely filled or partly filled with wind blown sands (mixture of quartz and gypsum). Individual fissures tend to be discontinuous across the playa surface and often display en-echelon patterns. Antrett et al. (2012) argue that ancient counterparts to these various-scaled megacracks influenced gas production from Permian Rotliegend sediments in northwest Germany, by compartmentalising the reservoir.

Megapolygons are the result of shrinkage in fine-grained lake sediments and indicate water loss following a fall in the piezo-metric head. In some cases the watertable lies 3–20 m below the megapolygonal surface. As pore waters evaporate from the upper part of the newly created vadose zone, tensile stresses accumulate in the muds until they eventually rupture into the polygonal fissure network. Neal et al. (1968) interpret the fissures as indicating vigorous desiccation over a number of years. Some playa fissures may be related to over-exploitation of the local groundwater resources in the last 50–100 years, most indicate the rigorous climatic transformation that occurred during the Pleistocene-Holocene transition. Identical sand-filled fissures, up to 18 cm wide and 5.7 m deep, have been documented in the Pennsylvanian Hermosa Formation of southeastern Utah (Loope and Haverland 1988).

Stokes Surfaces and Palaeohydrology

Recognition of Stokes surfaces, associated interdunal sabkhas and wet mudflats/interdunes has broader scale implications in terms of regional hydrological evolution over time frames measured in thousands of years and to permeability models. Most modern Stokes surfaces either are a coastal groundwater response to progradation since the last rise in sea level some 6,000 years ago, or are a hydrological response related to marked climatic changes in deserts from the Late Pleistocene to the present, usually toward increasing aridity (Table 2.15).

Changes in the level of ancient regional watertables and aggradation of base level (creation of accommodation space) is often preserved in ergs (sand seas) abutting the edges of evaporite basins in the USA and elsewhere (Mountney and Thompson 2002). For example, Havholm and Kocurek (1994) used the presence of regional discontinuities in the erg succession to interpret the depositional history of the Jurassic Page Sandstone of the Colorado Plateau, USA (Fig. 2.60). The Page Sandstone was deposited in a coastal erg where there was a constant rise and fall of the strandzone of the adjacent epeiric seaway. These eolian sediments encompass a number of regional erosion surfaces known as super bounding surfaces or supersurfaces. Sometimes the interdunal portions of these supersurfaces preserve giant (5 m high) stromatolites indicating flooding and longterm at-surface brines in the interdunal corridors (Eisenberg 2003).

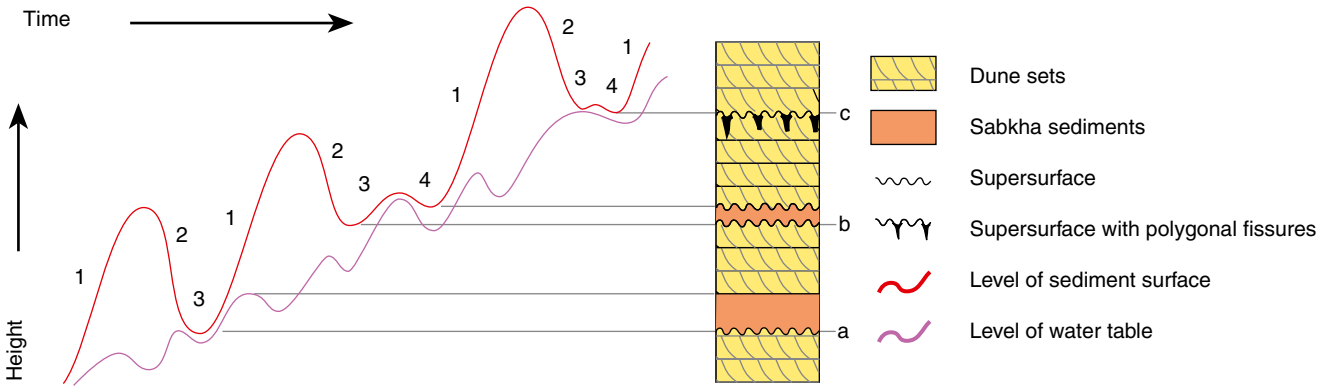

Fig. 2.60 Accommodation space for Jurassic Page Sandstone (30–50 m thick) sedimentation was controlled by interaction during subsidence between deflation (*upper curve*) and changes in the level of the watertable (*lower curve*). Surface a is over-lain by sabkha sediments that were not eroded, surface b is overlain by partly eroded sediments, and surface c is an erosional surface with polygonal fissures. Numbers 1–4 on sedimentation curve indicate type of activity: (*1*) dune accumulation, (*2*) deflation, (*3*) sabkha formation or formation of polygonal fissures, (*4*) deflation of surface features (From Havholm and Kocurek 1994)

Correlation of super-surfaces between outcrops defined inter-relationships between the dune sands and the interlayered sabkha and interdunal successions (Fig. 2.60; Havholm and Kocurek 1994). Sand accumulation in the Page was episodic and punctuated by the formation of supersurfaces tied to substantial lowerings of the regional watertable. This created both Stokes surfaces and megapolygonal fissures. Sabkhas and interdunes aggraded as the watertable rose until sedimentation surfaces sat above the top of the capillary zone. Then vadose sedimentation, typically eolian crossbedded dunes sands, dominated once more. Thus the Page Sandstone is a collection of desert dune-interdune successions preserved in accommodation space created by an overall rise in the watertable (basin subsidence). The smaller scale sequence packaging (dune alternating with wet interdune) reflects periodic rises in the watertable, tied to shorter-term variations in climate, tectonics (subsidence) and changes in the strandline positions of nearby seaways or lakes.

The Jurassic Entrada Formation shows a similar watertable control with its sea-marginal setting, promoting numerous internal truncation surfaces tied to deflation to the top of the capillary fringe (Crabaugh and Kocurek 1993). Sediments deposited in the passage of the Entrada Fm. into the overlying evaporitic Todilto Fm. are unusual for an eolian system. The upper part of the Entrada is characterised by mass flow deposits and preserved eolian dune palaeotopographies beneath sandy subaqueous strata, rather than the more typical erosional top with the eolian unit passing up into continental deposits (Fig. 2.61a; Benan and Kocurek 2000). Preserved dune remnants have relief of up to 35 m and are buried by onlapping, subaqueous, largely structureless sandstones. The latter are derived by mass wasting of the upper portions of the dunes as regional water levels rose. Eolian sands were redeposited as sediment-gravity flows, which infilled depressions between the dunes. Preservation of dune palaeotopography beneath mass-flow deposits argues that flooding of the Entrada dune field was geologically rapid and energetically gentle.

Flooding heralded the onset of a restricted density-stratified brine lake/seaway, which deposited the evaporitic Todilto Formation. This seaway was a marine-seepage fed drawdown depression within what was the lowest part of the erg. This type of seepage encroachment converting the erg to a lake meant there was no transgression of a high-energy marine coastline across the top of the sand sea (Fig. 2.61b). Rather, aggradation of the saline watertable was a relatively gentle process, with preservation of dune topography beneath lacustrine laminites perhaps aided by the formation of ephemeral capillary-fed salcretes. Salcretes precipitate where the capillary zone intersects the eolian landscape in any arid zone transition from an erg to a brine lake. A similar preserved dune palaeotopography, also with ephemeral salcretes, formed atop the Permian Rotliegende/Wiessliegend sands of the North Sea and heralded the onset of evaporite deposition in the saline giant that deposited the Zechstein salts (Glennie and Buller 1983; Glennie and Hurst 2007).

The position of the watertable in many ancient sand seas controlled the depositional style and facies continuity of various windblown sand units (Fig. 2.62). Less permeable lenses of salcrete-cemented, damp and wet interdune strata and interdunal sabkhas exhibit an intertonguing, transitional relationship to the toe-sets of adjacent and overlying eolian dune units (Mountney and Thompson 2002). Intercalation signifies vadose dune migration (eolian cross beds) was contemporaneous with watertable-controlled accumulation in adjacent interdunes. Eolian crossbedding can only form in the vadose zone. Downwind changes in the geometry and facies of the interdune units indicate periodic expansion and contraction of the interdunes in response to changes in the

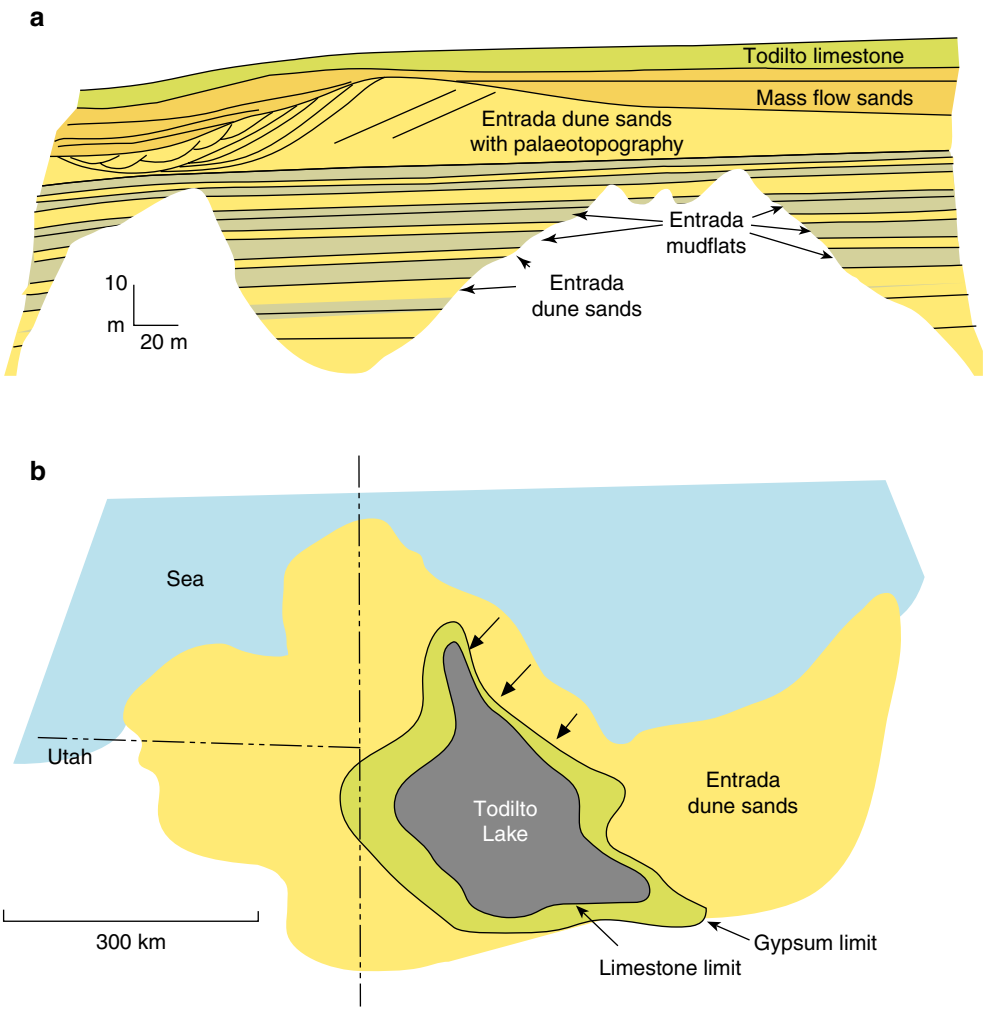

Fig. 2.61 (**a**) Outcrop drawing showing preserved dune palaeorelief with onlapping structureless sandstones and overlying limestones of the Todilto Formation. The Entrada Sandstone underlying the preserved relief consists of interbedded dune sets and evaporitic mudflat (sabkha) deposits (After Benan and Kocurek 2000). (**b**) Approximate Late Callovian–Oxfordian (?) palaeogeography of the four corners area after partial marine transgression of the Entrada. Extent of the Todilto formation shown with concentric limits of limestone and gypsum within the unit, with surrounding eolian units (After Lucas and Anderson 1994)

elevation of the ground-watertable with respect to the land-surface. Changes in geometries and extents of the various vadose, capillary and lacustrine units in an erg are a response to climatic change, subsidence and episodic flooding.

Understanding that hydrology (depth to watertable) creates permeability layering during deposition of ancient dune sand succession adds another level of reality to previous dry erg models for fluid flow in eolian reservoir sands deposited below evaporite seals. Older engineering models guiding hydrocarbon recovery from oil and gas fields from eolian sands below evaporite seals typically assumed that the spectrum of internal flow discontinuities in the eolian sands were largely defined by 1st- through 4th-order bounding surfaces, that is, the primary sedimentary structures control permeability. At the reservoir scale the sands were assumed to respond as largely homogenous flow units during hydrocarbon extraction, with permeability variation tied to grainsize variation. This is after all what is seen in the impressive Quaternary ergs of the Sahara, Arabia and Mongolia.

But these analogs are all purely continental settings, located a long way from the ocean and from any other permanent body of surface water with a hydrology capable of depositing a widespread evaporite seal over the top of the erg.

The reality is that homogenous eolian sand reservoirs are not all that commonly associated with bedded evaporite seals that overlie windblown sediments. Typically, thick homogenous dune sand units are not preserved at or immediately beneath the contact with a encroaching evaporite seal. The encroaching hydrology associated with the passage from an eolian system to an evaporite system simply does not allow widespread vadose conditions during the transition. Rising watertables feed capillary salts that patchily cement the reservoir sands during passage into deposition of an evaporite seal. Reservoir quality in these systems is typically a reflection of intergranular cement intensity (anhydrite or halite) and is not a direct reflection of primary depositional geometries or primary sedimentary structures. By the time an evaporite seal covers a unit dominated by windblown sands any loose sands have already blown on and away into the interior, as is the case in the central Arabian Peninsula, or have been dispersed into the shoreface, as in the southeastern Qatari and northeastern Saudi coastal zones (Fig. 3.68b).

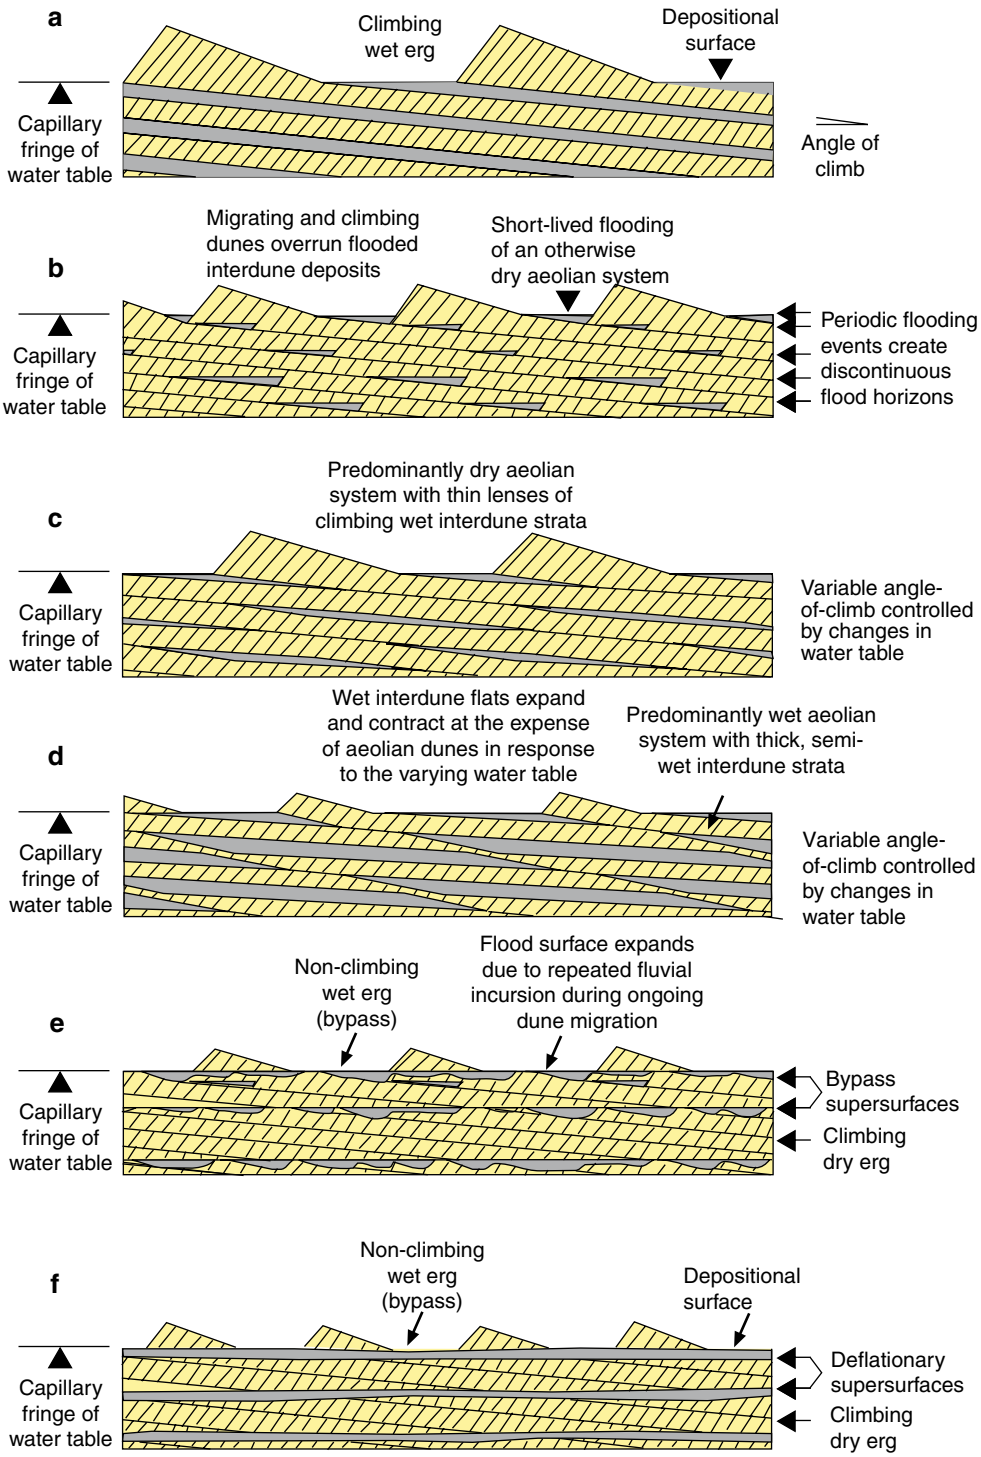

Fig. 2.62 Spectrum of interdune geometries generated by variations in the frequency and magnitude of watertable change, the rate of dune migration and the net eolian sediment budget. (**a**) Entrada Sandstone, (**b**) Navajo Sandstone, (**c**) and (**d**) Helsby Sandstone Formation, (**e**) Cedar Mesa Sandstone, (**f**) White Sands (After Mountney and Thompson 2002 and references therein)

Preserved sandflats about the edges of most aggrading and transgressive evaporite seaways are tied to deflation controlled capillary fringes and aggrading marine watertables. Such a hydrology must deposit evaporite cements wherever the capillary fringe intersects the land surface and reflux cements where brine plumes sink into the underlying sands beneath brine-filled interdunal corridors. In this hydrological setting the sabkhas, mudflats and salcretes that characterise the transition to the seal facies create low permeability cement patches within any underlying eolian sediment sheet. Thick piles of more homogenous vadose crossbedded dune sand that may have once been present in the region prior to the encroachment of the evaporite precipitating hydrology now lie deeper in the succession, and so are of less interest in terms of modelling hydrocarbon production from sediment beneath the evaporite seal.

Reservoir models for flow response in eolian sandflats sealed by evaporites should not assume intraformational continuity in the sands beneath the seal. Instead, a competing model with two end-members is more appropriate. At one end of the depositional spectrum are damp/wet interdune strata in wet eolian sandflats with shallow watertables. At the other end of the depositional spectrum are dry dunes with deep watertables that are flooded by the rapid entry of seawater into the continental depression. Inputs to the model can be quantified by the relative proportion of dry eolian version versus wet interdune structures seen in core or core-calibrated FMI imagery. Scaling of reservoir geometries can be done using analogs for the various styles of watertable encroachment on coastal dunes as seen in modern marine and lacustrine settings (Fig. 3.67).

A climbing dune model (relevant for much of the Entrada Sandstone, in Utah) requires moderate–high sediment supply in balance with a relatively deep watertable. It has a relatively low potential for widespread capillary salcretes and fine-grained interdunal sediments (Fig. 2.62a). The non-climbing dune model at the other end of the hydrological spectrum is characterised by widespread episodes of non-accumulation or hiatii (relevant for climatically controlled supersurfaces as in the coastal zone of modern NE Saudi Arabia, Sabkha Matti in the UAE, the White Sands of New Mexico, the Late Quaternary sandflats surrounding Lake Eyre and their Pre-Khuff counterparts in the subsurface of Saudi Arabia). It requires periodically low rates of sediment supply, high rates of deflation and longterm low rates of creation of watertable controlled preservation space for the sand sheets. It has a much higher potential for large areas of the system to be deflationary, for large areas of the sedimentation surface to intersect the capillary fringe and for the preservation of widespread capillary salcretes (Fig. 2.62f).

Defining which of the various intervening styles of sediment accumulation in the eolian succession under study is important in modelling porosity and permeability extents and in correlating lateral extents of high permeability zones in ancient sand bodies (Mountney and Thompson 2002; Fig. 2.62b–e). Textures indicative of dry or wet eolian systems and interdunal sabkhas are discussed in the next chapter. Wet interdune textures are described in detail by Goodall et al. (2000).

Degrading Hydrology and Playa Capture

Aside from Stokes surfaces, the effects of a degrading (falling) hydrology and associated deflation are seen in sediment and drainage patterns in many Late Quaternary playas, including those in Central Australia located in and around Lake Amadeus and Curtin Springs (Fig. 2.63a; Jacobson et al. 1989). Longterm reduction in groundwater levels associated with increasing aridity at the end of the Pleistocene led to a change in the status of some inland playas from discharge playas to recharge playas (with solution fissures and karst holes) via a process known as playa capture. It occurs when a fall in the level of regional groundwater, perhaps driven by the deflationary deepening of one playa floor leads to the removal of one or more adjacent playas from the discharge level of regional groundwater outflow (Fig. 2.63b; Jacobson and Jankowski 1989). Groundwater head in the Curtin Springs area has decayed over the last several thousand years and so changed the nature of playa sedimentation. A few thousand years ago Samphire Lake was a discharge playa and it still retains thick deposits of groundwater-derived lacustrine gypsum from that time (Fig. 2.63b).

Today the discharge system is no longer active in the lake as the regional watertable lies metres below the playa floor. Samphire Lake has evolved into a vegetation-covered recharge playa and regional discharge is focused into nearby Spring Lake and Glauberite Lake. This has rendered the Samphire Lake surface sediment susceptible to eolian deflation, karstification and vegetation coverage. Over time Glauberite Lake will become the primary focus of groundwater activity in this region and will ultimately form a regional groundwater sump where bedded salts will accumulate.

Falls in local hydrological base level can be driven by changes in climate, uplift or tectonic isolation. It drives local processes such a karstification and carnallite precipitation in bedded halites in the Quaternary playas of Qaidam Basin, China and in Lake Asal, Djibouti. An impressive example of the effects of a local lowering of the saline base level on karst intensity is seen in evaporite-cemented sediments that increasingly exposed about the margins of the Dead Sea in the Middle East. Lake water level has been falling since the 1940s and the rate of fall has accelerated since the 1960s with increasing anthropogenic extraction of fresh water (Figs. 4.45 and 4.46). This fall in water level drags with it the brackish groundwater lens that floats atop dense lake brines about the lake edge (Fig. 2.64a; Salameh and El-Naser 2000; Frumkin et al. 2011). With the encroachment of brackish to fresh pore waters, sediments, which were evaporite-cemented and mineralogically stable when bathed by hypersaline lake brines, become subject to dissolution and collapse. The process of dissolution is especially obvious at the contact between the less permeable Lisan Formation and the overlying salt-cemented gravels. This interface focuses the flow of fresher water at the top of the salt and base of the salt/gravel unit (Fig. 2.64b). The marked fall in the Dead Sea water level in the past few decades has accelerated the rate of sinkhole creation (Nof et al. 2013). The first documented sinkholes along the Dead Sea coast appeared in the 1960s. The occurrence rate has accelerated significantly since then, from less than 50 new sinkholes per year prior to 1999 to more than 380 per year since 2003.

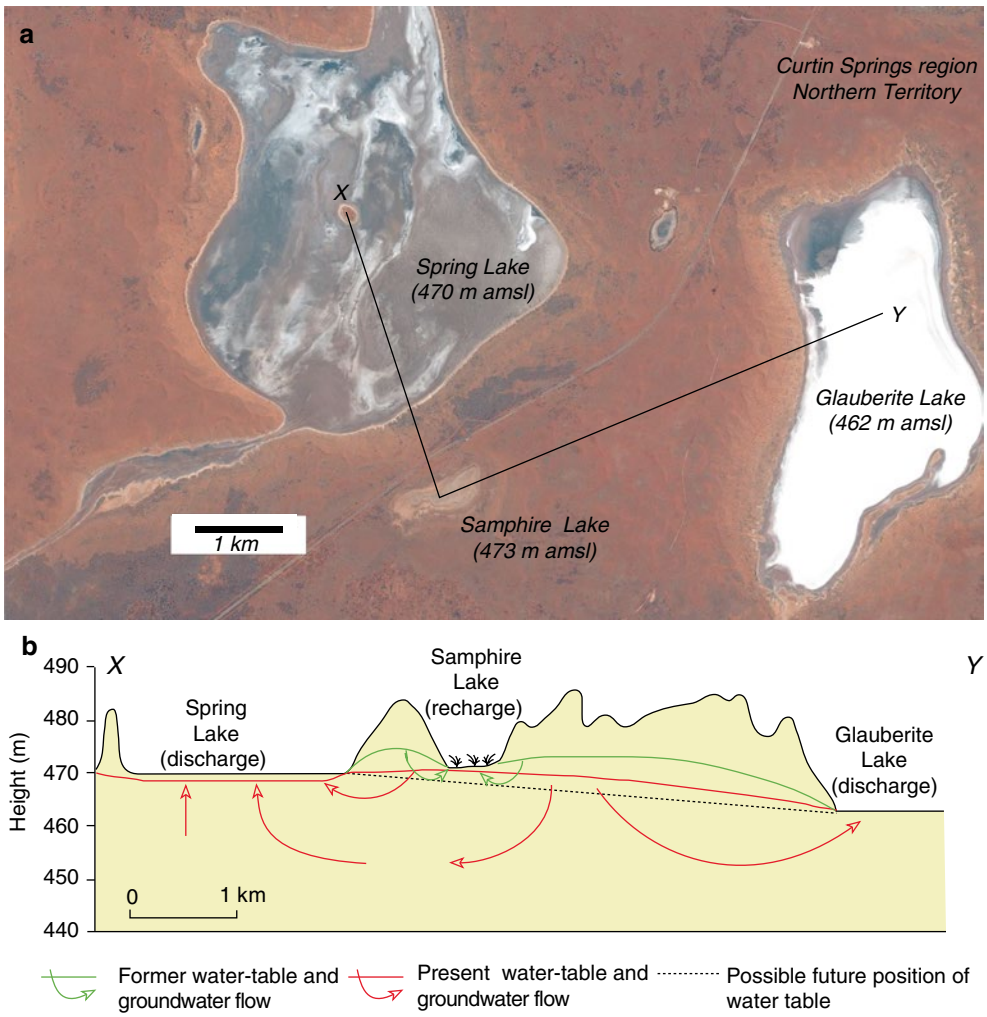

Fig. 2.63 Salt lakes in the Curtin Springs are, Northern Territory. (**a**) Plan view showing elevation above mean sealevel of Spring Lake, Samphire Lake and Glauberite Lake. (**b**) Schematic of playa capture or abandonment via decay of groundwater head. Samphire Lake was once a discharge playa (*green line* indicates former watertable) that was accumulating gypsum, but it was converted to a recharge playa as Glauberite Lake progressively captured the regional groundwater flow system (After Jacobson and Jankowski 1989)

Away from the pervasive collapse dolines tied to the retreating shoreline, other areas of reactivated subsidence in the Dead Sea depression are tied to fault intersections and radial uplift fractures atop and about areas of active diapir uplift in the Lisan Straits (Closson 2005; Closson and Abou Karaki 2009). Groundwater preferentially flows along faults, joints and fractures so that chemical and physical erosion of saline sediments takes place along such weaker zones. Underground voids then appear, creating growing cavities, which come up to the surface after successive roof collapses (Chap. 12). For example, the falling water levels of the Dead Sea lake has created problems for the salt works in the Southern Basin with newly-formed solution collapse structures weakening some of the dykes enclosing the evaporation ponds. Between 2000 and 2002, the Arab Potash Company (APC) lost two salt evaporation ponds due to solution-breaching of dykes resulting in a loss of $70 million. The breached zones show a strong structural control tied to regional lineaments. The southern Dead Sea is by far the most affected by sinkholes and decametric to kilometric subsidence phenomena. In this scenario the sinkholes are the surface manifestations of active neotectonic faults that may serve as conduits for under-saturated groundwater, enabling its access across aquiclude layers.

At first this tectonic hypothesis seems to conflict with models that consider the salt-edge dissolution front as the major site control of sinkhole formation. Recent seismic work by Ezersky and Frumkin (2013) has shown that the thicker shallow buried salt mass largely terminates along the active neotectonic faults that are now covered by recent sediment. That is, the majority of the Dead Sea sinkholes form in a narrow strip (60–100 m wide) along a paleo-shoreline (perhaps 10,500 years old) which was constrained by faults and alluvial fans and this subsurface boundary today determines the edge of the main salt layer dissolution edge. This scenario reconciles the two major competing frameworks (salt edge versus neotectonic lineament) for sinkhole formation in the Dead Sea rim.

At a broader scale, longterm watertable falls in any saline basin drive a redistribution of salt sinks within large isolated drawndown sedimentary basins. Drawdown changes the distribution of marginal versus basin-centre evaporite

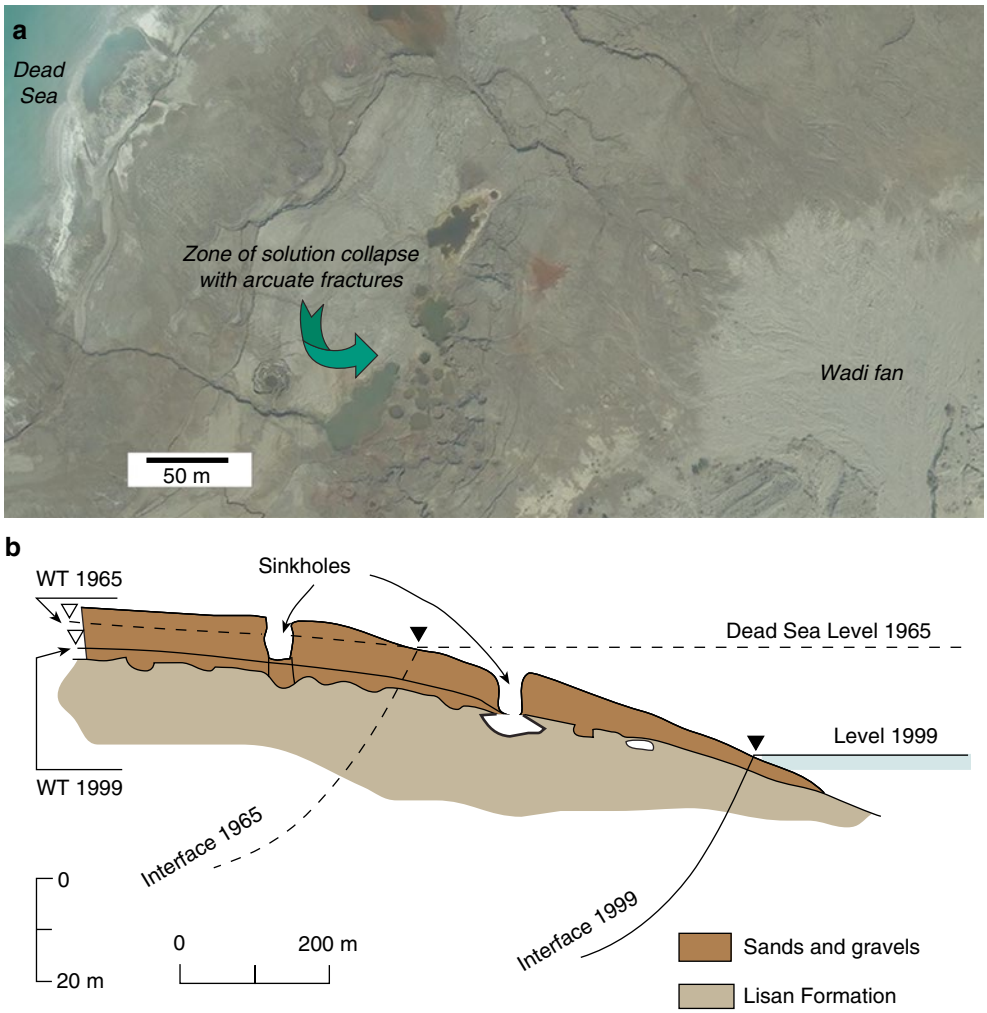

Fig. 2.64 Karstification along the newly exposed margin of the Dead Sea. (**a**) Plan view showing zone of karstic collapse zones near a wadi outflow fan on the eastern margin of the Dead sea (31.333265 N, 35.542658E). (**b**) Collapse process is related to dissolution and removal of salts due to lowering of Dead Sea water level and the associated flow of freshwater along the interface of the sandy gravels and the salty Lisan Formation deposits at the Dead Sea margin. This drives the accompanying cavity, collapse, and sinkhole formation in the at-surface gravel carapace (After Salameh and El-Naser 2000)

accumulations (Fig. 2.64). It can create regional mega-surfaces or unconformities, which are recognisable on seismic sections and can cross continental and marginal marine sequences (e.g., the Messinian M-horizon of the Mediterranean). These surfaces are sometimes described as mega-bounding surfaces by sequence stratigraphers. If they are incorrectly interpreted as eustatically induced contacts, rather than watertable or climatic responses to subaerial exposure in a continental settings, they can greatly complicated any attempt at age fitting a sealevel curve to the seismic sequence stratigraphic signature (Chap. 5).

Remote Sensing of Saline Hydrologies

The preceding discussion shows there are two end member styles in any saline hydrology; (1) Aggrading or accreting systems typified by ongoing accumulations of evaporite beds and an accompanying rise in the saline hydrology/watertable in the depositional sump, (2) Degrading or deflating systems where salts and sediments are being lost by a combination of dissolution and deflations with an accompanying lowering of the watertable. What is interesting is that some of these hydrologies can be identified remotely using satellite monitoring.

This has been accomplished in an investigation of the spatiotemporal evolution of three salars in the Altiplano of the central Andes by defining a deformation time series retrieved from satellite radar interferometry in the time from 2003 to 2008 (Fig. 2.65; Ruch et al. 2012). Located in an arid to hyperarid region, with an average elevation of 3,750 m and annual rainfall less than a centimetre, the Altiplano Puna comprises broad, internally-drained endoreic depocentres with intervening north-south-oriented volcanic mountain ranges, often between 5,000 and 6,000 m elevation, primarily bounded by high-angle reverse faults (Fig. 2.65b, c; Strecker et al. 2007). Sedimentary basins in the Puna-Altiplano contain 3–5 km thick successions composed of varying proportions of continental evaporites, volcanics and clastics. The high elevations of the Altiplano salars mean that in terms of the Köppen climate classification many (including the three salars in this study) reside in the alpine

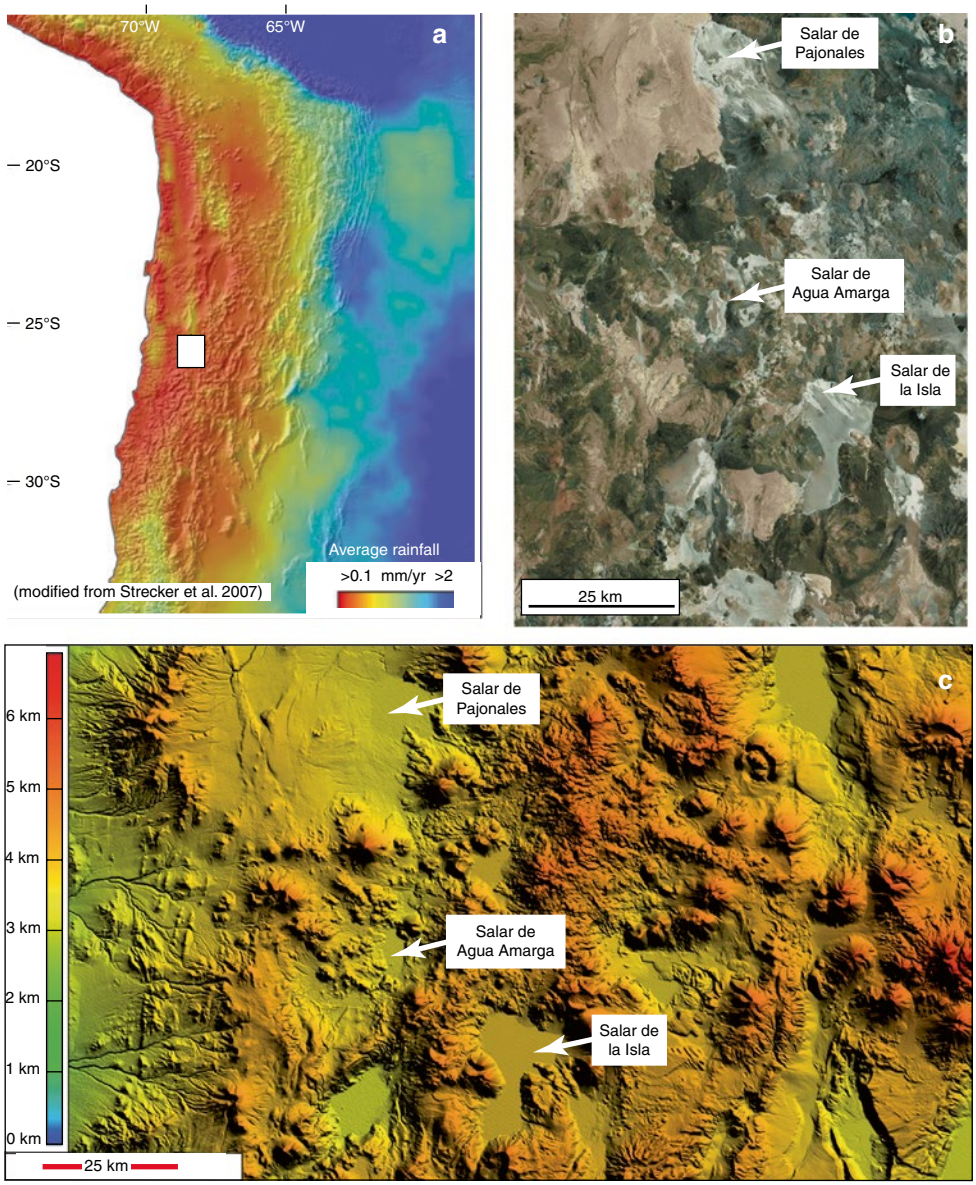

Fig. 2.65 Location, climate and elevation of the salars (After Ruch et al. 2012). (**a**) Topographic map of the central Andes overlain by annual rainfall (Modified from Strecker et al. 2007); the *white rectangle* indicates the position of the salars. (**b**) Image of the South Puna Plateau with salar locations, The *dark area* surrounding the salars are relatively impervious volcanics the *brown regions* are dominated by alluvial sediments (porous). (**c**) DEM overlay showing elevations of the drainage around the three salars. Note that Salar de la Isla is surrounded by volcanogenics in its drainage catchment, Salar de Pajonales lies at the eastern end of a broad bajada (porous), while Salar de Agua Amarga has some alluvials in its drainage basin

tundra (ET) climate belt. Others, such as Salar de Atacama and Salar de Uyuni, lie in the adjacent cold-arid dry winter desert Köppen belts (Bwk).

The Altiplano Puna plateau underwent rapid regional climatic change during the Mid-Holocene period, shifting from vegetated areas subject to frequent rainfall to a more inhospitable desertic environment (Betancourt et al. 2000; Núñez et al. 2002). From 8 to 3 ky BP, in response to the desertification, lake levels decreased and many former perennial lakes desiccated into salars. The term salar (salares) describes salt-encrusted flats formed by the evaporation of at-surface or shallow subsurface groundwater discharge in hydrographically closed (endoreic) desert depressions (Fig. 2.65b, c). A noted earlier, hydrographic closure is not the same as total hydrologic closure; bottom sediments in all modern Andean salars probably leak brine and solutes to varying degrees (with leakage more likely in salars underlain by alluvium rather than lavas and volcanogenics). There is also a strong possibility that the groundwater regime supplying many salars, considered to be surrounded by "fossil" groundwater, are still actively supplying longterm water inflows into the salar sump. The inflow system is driven, at least in part, by the ongoing drainage of groundwater heads and potentiometric surfaces still in a decay-mode response to elevated meteoric inflows from earlier Holocene pluvial periods (Houston and Hart 2004).

The term salar describes a groundwater sump where the sediments are typically subaerial and halite-rich, with intrasediment salt-growth textures driven by capillary evaporation of near-surface hypersaline groundwaters Within a salar, there are a number of typical sedimentary sub-environments tied to inherent hydrological characteristics and responses to

Fig. 2.66 Surface geology. (**a**) Regional view from the northern end of Salar de Agua Amarga showing the white efflorescence-encrusted surface of the marginal facies association and the slightly more elevated, brown irregular surface of the halite nucleus facies association (25°29′43.87″S, 68°49′57.96″W). (**b**) Irregular surface of the halite nucleus facies in Salar de Agua Amarga (25°31′06.16″S, 68°50′50.93″W). (**c**) Flat surface of marginal facies in south of Salar de Agua Amarga, partially covered by frozen brine and passing north across the saline pan into the slightly elevated, dust-cover irregular surface of the halite nucleus facies association. the evaporation of shallow near-surface and surface waters (Ruch et al. 2012). At the broadest scale, the salar sediment system consists of two parts: a halite nucleus and a marginal zone (Fig. 2.66a) with respective proportions varying from one salar to another. Compared to the marginal zone, the halite nucleus surface is typically a zone of somewhat higher elevation in the salar plain compared to the more marginal facies (Fig. 2.66a–c). The salty surface of the halite nucleus facies association is composed of mm-scale sugary inclusion-poor halite crystals and eolian silts. Surfaces of the adjacent marginal facies are varying combinations of silty mudflats, saline pan crusts, brine ponds and salty efflorescences (Fig. 2.66c and Chap. 3). Sheet flood and alluvial processes supply much of the terrigenous mud and silt sediment found in the fringe zone. Spring-fed lakes and brine pools (lagunas) are typically interspersed within the marginal facies

association in most Andean salars (Fig. 2.66d). Evidence of former subaqueous gypsum beds precipitated during higher saline lake levels are indicated by rims of gypsum crusts. These crusts are still subject to ongoing gypsum growth indicated by the tumuli ("igloo") structures that typify outcrops of these older less-saline evaporites (Fig. 2.66e). Table 2.16 summarises the geological and hydrological characteristics of the various facies in the salars.

There is a clear relationship between sediment facies and regions of salar surface accretion versus degradation when SAR surface observation and local geology are compared utilising profiles sampled across the InSAR dataset overlain by optical images acquired by the LANDSAT satellite (Fig. 2.67; Ruch et al. 2012). Band 7 (mid-IR), which is sensitive to soil moisture, provides contrasted information about the ground intensity, often critical to definition of salt-rich areas. Areas with a weaker InSAR uplift signal (see ISLA2, Fig. 2.67a) correspond in LANDSAT to higher ground intensity values (close to white). This geologically matches with the marginal facies, where much of its flat surface is covered by ephemeral white halite (chevron-dominant) crusts. In contrast areas with larger uplift signals (see ISLA1, Fig. 2.67) have lower ground intensity values, these correspond to the halite nucleus regions, where salt typically precipitates by capillarity from shallow groundwater bodies. A ground intensity of zero corresponds to free water, all the light being absorbed and in lower water times defines regions of spring inflow or water-filled solution dolines and pits within the salar.

On the ground it is clear that the nucleus surface is somewhat elevated compared to the lower more-frequently-flooded and dissolved halite pan crusts of the marginal facies. The halite nucleus surface is typically red to grey-red as it retains a hummocky carapace coloured by entrained eolian silt (Fig. 2.66a–c). Profiles across both InSAR velocity maps and LANDSAT ground intensity images show that radar and optic signals have comparable shapes (Fig. 2.67), where the maximum uplift agrees with halite-rich nuclei regions prone to salt accretion. Localized peaks in the ground intensity values that tend to zero correspond to perennial lake locations. The intensity signal in areas prone to subsidence typically correspond to water-saturated grounds.

To analyse the temporal evolution of the salar surface, Ruch et al. (2012) compiled displacement time series on selected areas from 2003 to 2008 (Fig. 2.67d, e). ISLA1 (atop halite nucleus facies) and ISLA2 (atop marginal facies) are both located at the northern end of Salar de la Isla (Fig. 2.67a). The compilations show different cumulative displacements sampled on two clearly-delimited facies zones, with mean values of 2 and 6.5 cm, respectively, implying aggradation of both the marginal facies and the halite nucleus facies in this salar, with aggradation rates greater atop the halite nucleus facies association. Moreover, cyclic displacement changes (mini uplifts) approximately from September to March each year, are best expressed on the halite nucleus at Isla (ISLA1). PAJ1 is located in the northern part of the Salar de Pajonales (Fig. 2.67b) and shows a comparable displacement trend with respect to ISLA2, with a cumulative displacement of 2 cm in almost 5 years. Likewise the AMA profile in Salar de Amarga shows a similar growth profile related to nucleus versus marginal facies, the indicated accretionary rates are less than in Salar de la Isla (Fig. 2.67b).

In contrast, in Salar de Pagonles, the PAJ2 profile, which was collected atop a zone characterised by sedimentary features indicative of local salt dissolution (marginal facies separated by numerous water filled dolines and spring pools and ponds), shows a clear signal subject to a rapid negative displacement along the LOS direction during the first trimester of 2004, for a duration of almost 1 year (Fig. 2.67c). After 2006, the signal follows again a similar ground displacement comparable with areas of PAJ1 and AMA, the latter being located on the Salar de Amarga, 50 km distant, southeast from Pajonales (Fig. 2.67d, e). Clearly, that sediment facies can be related to InSAR-determined surface deformation (velocity profiles and time series analysis), implying an underlying hydrologic/sedimentologic control.

To confirm likely hydrological drivers to the varying rates of ground displacement within and between salars phenomena, the sedimentological and InSAR results were compared to chemical analysis of surface waters, from both water inflow and laguna locations, which were systematically sampled across the Andes in 1991 (Risacher and Fritz 2009). Although there are no pore water samples in the nucleus facies in the salars under study, hydrogeochemistry samples from the salar edges confirm that the salar with the highest ground displacement rate of all salars observed, Salar de la Isla, also contains surface waters with the highest salinity in this section of the central Andes. Its maximum salinity is 330 g/l, significantly more than at Pajonales (247 g/l) and at Agua Amarga (197 g/l), hence, it is more prone to salt precipitation and associated ground displacement, explaining the higher deformation rate observed.

Ruch et al. (2012) show that all salar surfaces they observed are uplifting and at rates directly related to ground compositions. There is a strong intra- and inter-salar association between saline facies distribution and rates of rise or fall of the salar surface. Ground displacement in the salars is directly related to levels of salt precipitation and salt crust thickening at the surface. Salt crust thickening is likely responsible for the revealed ground uplift signal. In this case, based on the stability of InSAR coherence, thickening probably occurs best in zones beneath the upper salt crust levels in the salt nucleus and are driven by capillary evaporation of highly saline brine.

Table 2.16 Summary of geological facies related to hydrology in a South American salar

Major facies association	Halite Nucleus (HN)	Marginal facies (MF) – subaerial portions are covered by thin white ephemeral efflorescent veneer of halite and/or gypsum (in salars with no halite nucleus, such as Pajonales, equivalents (MFE) of this association dominate the whole salar surface)				
Subenvironments	Rugose halite capillary crusts (Subaerial)	Saline pans and mudflats (subaerial most of time)				Moat facies (subaqueous)
Dominant constituent in setting	Halite	Halite	Gypsum	Carbonate	Silty mudflat (terrigenous sediments	Brine pools, channels and lagoons
Hydrologic/ sedimentologic character	Upper zone is up to tens of cm thick, composed of mm scale sugary inclusion-poor halite, with interstitial mud. Worm-eaten appearance of this upper zone is due to periodic dissolution. Remnants of megapolygonal pressure ridges recognisable in less overprinted zones. Below this upper zone the association is metres or more thick and is dominated by large cm-scale interlocking meshworks of halite with minor interstitial mud. Crystals mostly clear (inclusion-free) due to slow shallow diagenetic growth from halite-saturated brines. Some clear crystals grew as cavity fills. This is a polycyclic set of ground water overprints, driven by ongoing capillary evaporation and preserved in the halite textures, so unit retains little or no primary texture.	Zone up to a metre or so thick made up of stacked mostly flat layered salt crusts dominated at deposition by inclusion-rich halite chevrons. Current at-surface crusts show varying development of polygonal and megapolygonal pressure ridges. Initially, this halite precipitates as growth-aligned crystal layers from ephemeral brine sheets. With ongoing desiccation, primary-textured crusts are over printed to varying degrees by capillary salts, efflorescences and karst cavities. Many zones of stacked crusts in the Marginal Facies association are subject to partial to completed is solution in occasional sheet flood events. Dominant formative process is from a desiccating at-surface brine sheet. With time, in a halite-saturated setting, a resurgent hypersaline ground water overprint can alter this unit into a nucleus facies association.	Gypsum crusts have an irregular buckled and blistered surface with locally developed polygonal pressure ridges. Constituent gypsum crystals are mm-scale lenticular to and sugary meshworks. In shallow subsurface can create cross sections of discontinuous bowl shaped, concave upward saucer-shaped layers that are 10s of cm in diameter. This salar gypsum facies association is distinct from supra-strandzone bedded gypsum units (showing coarse selenitic bottom nucleated growth-aligned growth textures) that out crop about some salar margins and formed during earlier, somewhat less saline, hydrological events. This unit can be deformed into tumuli (igloo-like mounds) via ongoing capillary precipitation.	Micritic precipitates (mostly aragonite/ calcite) as cm-scale crusts with varying degrees of induration. Preserved in subsurface as gray-green mud layers.	Subenvironment proportions are variable and include; ephemeral streams, sandsheets, mudflats, eolian dunes, spring-fed vegetated marshes and pools (vegas). Each preserves a characteristic suite of sedimentary structures (crossbeds, conglomerates, caliche, pedotubules, etc.). Silty mudflat sediment scan host lenticular shaped gypsum, fibrous vein gypsum, gypsum cemented thin sandy bands and rare cm scale displacive halite. Also host mm-scale carbonate nodules and rhodoliths.	Variable bottom accumulations and precipitates indicative of ambient salinities. Calcite laminates, tufas and crusts (≈5 cm thick) are typical of fresher/ brackish pools. Gypsum bottom cumulates and aligned cm-scale crystals construct stacked beds away from spring inflow. Rippled surfaces, underlain by carbonates and gravel can form via erosion of surface crusts along the strandzone. Pisolite textures and tepees locally possible, especially in zones of aragonite saturated groundwater resurgence. Ponds typically indicated zones of dissolution of former halite units.
Depth to watertable	Within tens of cm of surface	Within a few cm of the surface	Within a few cm of the surface	Within a few cm of the surface	More than tens of cm to metres below	Crops out as perennial water surface

This classification only considers salars with surface facies dominated by halite, it does not encompass perennial lacustrine gypsiferous, calcitic/terrigenous facies which underlie or are lateral to halite-rich salar facies. These non-halite facies were deposited in humid, less saline periods in the same intermontane lacustrine depression and have modern analogs in some other perennial fresher-water Andean lakes.

However the observations were taken over a short period of time (about 5 years) in the salars' depositional histories (Fig. 2.67d, e). If a constant ground displacement (aggradation) rate of >1 cm/year (as observed at Salar de la Isla) had continued over a century or more, the ongoing precipitation of halite in the nucleus facies should induce a height differential of around 1 m/century, compared to the aggradation rate of the marginal facies. This is not the case, field observation at Isla and at other salars across the Altiplano indicate that only few tens of centimetres separate the surfaces of the halite nucleus and the margin facies associations, indicating likely variation in the hydrological dynamics in the recent past. Transient strong rain or snowfall events on time scales greater than the few years of observation must influence the heights of differentials across the various salar surfaces (Ortlieb 1995). Alternatively, the regional diminution of the permafrost elevation observed over decades in the Andes (Trombotto and Borzotta 2009; Trombotto 2000; Romanovsky et al. 2007) may have contribute to increase the annual incoming groundwater. In the long-term, this may increase the salar watertable elevation and induce faster salt precipitation in the ground water sumps.

The degree of solute cycling in both the nucleus halite and marginal facies over the longer time frames associated with the halite infill of a drainage sump in an endorheic salar depression, as observed by Ruch et al. (2012) has significant implications in terms of: (1) Recognition of hydrologic stability/climatic variability preserved in the infill beds as variable salt signatures. (2) Identification of regions of likely concentration of particular solute components in salar pore brines, such as lithium and boron (Chap. 12). The fact that salar surfaces are aggrading at different rates, both within and between salars, has direct geohydrologic and indirect long-term climatic implications. (3) Development of remote techniques for recognition of movable nearsurface water in extraterrestial settings (Fig. 2.68).

Earlier studies of South American salars have suggested tectonically or fault-related ground motion can drive elevation changes in the salars (Reutter et al. 2006), while others propose an uplift and subsidence related to unloading, or the reduction of the water column (Bills et al. 1994), while yet others attribute in-salar elevation changes it to climate change and/or ice lens development in elevated saline lakes (Hurlbert and Chang 1988). Historically, all these earlier studies failed to match the hydrological style indicated by the evaporite distribution within the salar to the specific regions where different rates of ground elevation change are occurring. For example, if tectonic uplift was driving changes in elevation across a salar surface, elevation changes would not match the presence or absence and the undulating edges of the halite nucleus in all imaged parts of the salar. Rather, changes would relate to fault position and regional tilting and shifting of the active saline sump within the salar depression. This was not seen in the three studied salars At the millennial scale, tectonic tilting can change the regional salar hydrology, as seen in the changes in the salt sump position being driven by tilting in Salar de Atacama (Bobst et al. 2001; Jordan et al. 2002) but it does not explain the cm/year scale of accretion observed in the imaged salars.

It has been proposed that ice heave in these high elevation BSk and ET climatic locations may have controlled intrasalar elevation changes (Hurlbert and Chang 1988). If so, ice sheets would have to be a dominant feature within the halite nucleus area, where the InSAR analysis shows most of the elevation changes occur. However, the halite nuclei in all Andean salars lack evidence of pervasive intrasediment ice sheets. If an ice sheet ever did form in the halite nucleus area, it could only form atop or very near to the nucleus surface (freezing water is less dense than a halite saturated pore brine). No such feature has ever been documented in any Andean halite nucleus. If any cryogenically precipitated salts ever formed substantial salt masses within a halite nucleus, they would leave behind widespread characteristic mineral fingerprints; such as, cold season hydrohalite, mirabilite, thernardite, glauberite, and epsomite (Warren 2010). None of these cryogenic indicator salts is commonplace in the halite nucleus of any Andean salar.

Another possible alternative to capillary evaporation driving aggradation is a variable distribution of hygroscopic material (i.e., clays or hydroscopic salts) in the salar depression, which may induce local ground swelling and thus ground displacement in response to periodic water influx to the salar system (Gabriel et al. 1989). However the better tie of the InSAR rates to the at-surface expressions of evaporite hydrology (halite nucleus versus margin flat versus salt karst) suggests the relative rates of rise of the various salar evaporite surfaces are more responses to a hydrologically, not hydroscopically, driven set of arid-zone processes. The predominant salt texture present in the halite nucleus is medium to coarsely crystalline halite aggregates and clusters. When halite acts best as a hydroscopic salt it tends to be fine grained with the resulting increased surface area greatly aiding its hydroscopic capacity. Other highly deliquescent salts (such as the calcium chloride salts or the potash salts) are not pres-

Fig. 2.67 Deformation maps acquired by InSAR during the period from 2003 to 2008 on a DEM overlay at (**a**) Salar de la Isla, (**b**) Salar de Agua Amarga and (**c**) salar de Pajonales (Chile). Profiles across the salar surface deformation show a clear transition with the surroundings volcanic basement, indicated by *light grey* at either end of *transect lines*). Fig. 2.68 Summary illustrating facies associations and rates of surface deformation in the surface geology are direct responses to the volumes of solute/brine accumulating in the three salar depressions and related to a combination of evaporation and the degree of hydrographic and hydrologic closure that typifies each salar depression

ent in sufficient volumes to explain the elevated rates of aggradation in the nucleus. If hydroscopic clay is the main driver, then the highest rates of aggradation would not be confined to the halite nucleus.

When the three salar settings are compared, the rate of accretion or degradation can be related to the sedimentological, hydrological setting of the three salars (Fig. 2.68). Across the 5-year time frame of the observations, the hydrogeochemical budget in both Salar de la Isla and Salar de Aqua Amarga is positive, with a gain in salt volume over the period of observation. These two salars are clearly acting as sumps for regional groundwater. In contrast, Salar de Pajonales shows a split response in its hydrogeochemical budget. The northern and eastern portions of the salar are groundwater sumps and gaining in salt volume. In contrast, the hydrogeochemical budget in the central and southern end of this salar is negative as soluble sediment material is being lost (the salar surface is lowering). This implies this part of the salar is a region of more open groundwater flux where pore or surface waters carrying the dissolved salt is escaping, possibly related to proximity to the adjacent bajada aquifer. Use of InSAR monitoring of salar surfaces may help define water budgets within and between salar depressions. Drilling through a salar infill and the monitoring of the sedimentological changes in the nature of the recovered core and cuttings can be used to document longterm climatic evolution in the salar depression (e.g., Bobst et al. 2001).

Ions such as lithium and boron tend to be enriched in late-stage magmatic fluids and also become increasingly concentrated in salar pore brines at higher salinities

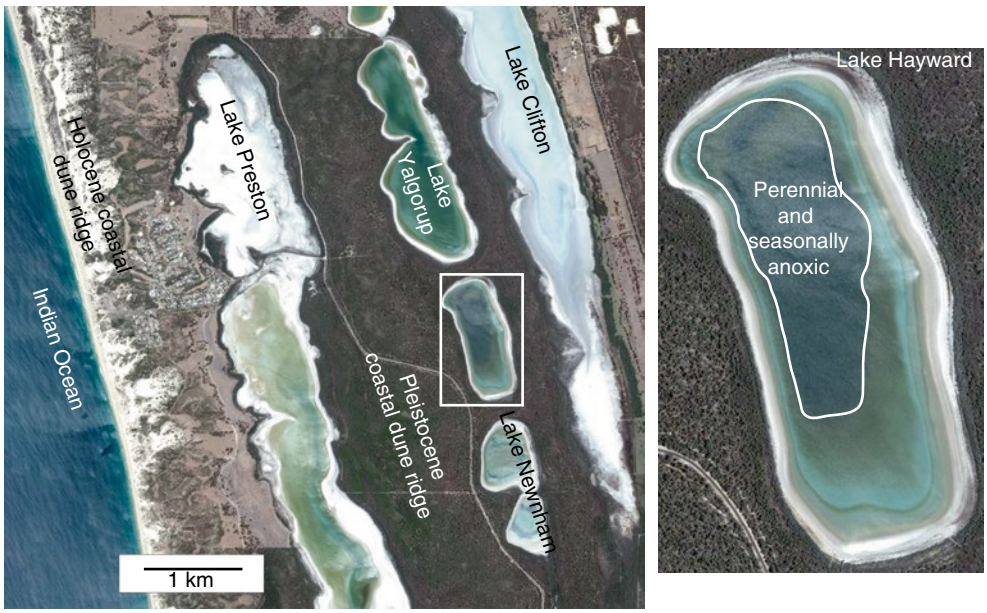

Fig. 2.69 Lake Hayward, West Australia

(Garrett 1998, 2004). Chapter 12 lists and discussed known potential and producing Li and B regions with saline associations worldwide. Interestingly, the two active lithium carbonate brine plants in salars of the Altiplano region (Salar de Atacama and Salar del Hombre Muerto) both produce from brines sources within halite-nucleus dominated sumps and are regionally located in high relief endoreic depressions. Other Andean salars associated with substantial stacked flat-bedded chevron-halite pan fills (equivalent to marginal facies) in high relief endoreic depressions, such as Salar de Uyuni (which is the largest Quaternary halite deposit in the world), have yet to be commercially exploited due to lower concentrations of Li in the salar pore brines. A predominance of stacked beds of the halite nucleus facies association rather than subaqueous sheet crusts, and a predominance of halite nucleus facies associations at the salar surface, probably indicate salars with a longterm hydrology that is more likely to retain high salinity brines over longer time frames. An association with an appropriate source of hydrothermal lithium, either in the drainage hinterland or in springs about the salar margin, indicates a high potential for accumulations of Li and B at economic levels in these nucleus-facies dominated salar pore brines.

Salinity Stratification Controls Texture

The occasional surface input of freshened waters into the central discharge depressions of evaporitic seaways (salterns) or perennial saline lakes tends to create stratified surface water bodies with less-dense lower-salinity waters floating atop more-dense saline bottom brines (Fig. 2.55b). If there are large salinity contrasts between the two water masses, they tend not to mix until their densities equilibrate. The emplacement of a freshwater body atop a lower dense brine slows and stops the concentration process in the lower brine body that drives brine reflux. It can start up again once the freshwater body has concentrated to where it mixes with the underlying brine. This ongoing stop-start mechanism probably explains the finer scale layering seen in the many anhydrite cements and replacement dolomites created by reflux hydrologies.

Brine stratification occurs today in marine-fed coastal salinas in Australia, in perennial saline lakes in the African Rift Valley and in the Dead Sea, Israel (Chap. 4). Lake Hayward, a coastal salina in Western Australia, typifies such a stratified brine system and has ionic proportions in the bottom brines similar to that of seawater. Carbonate muds are accumulating on the microbially bound floor of its small perennial brine pool (2–3 m deep) under a limnology that is density and thermally stratified for much of the year (Figs. 2.69 and 2.70; Rosen et al. 1995). Meteoric inflow creates a well-defined longterm mixolimnion; this upper, less dense and cooler water mass has salinities ranging from 50,000 to 210,000 ppm. It exists from late autumn to early summer (May to February) as it floats atop a lower denser and warmer water mass (monimolimnion) with salinities in the range 150,000–210,000 ppm (Fig. 2.70).

Stratification disappears for a few months each year from mid-summer to mid-to-late-autumn (Fig. 2.70a). During summer the waters of the upper water mass evaporate and concentrate as their bicarbonate content steadily increases. From the onset of stratification in late autumn, across mid winter and on into to early summer the temperature trends of the two water masses are parallel. They form a heliothermic system where the lower water mass is some 15–20 °C hotter

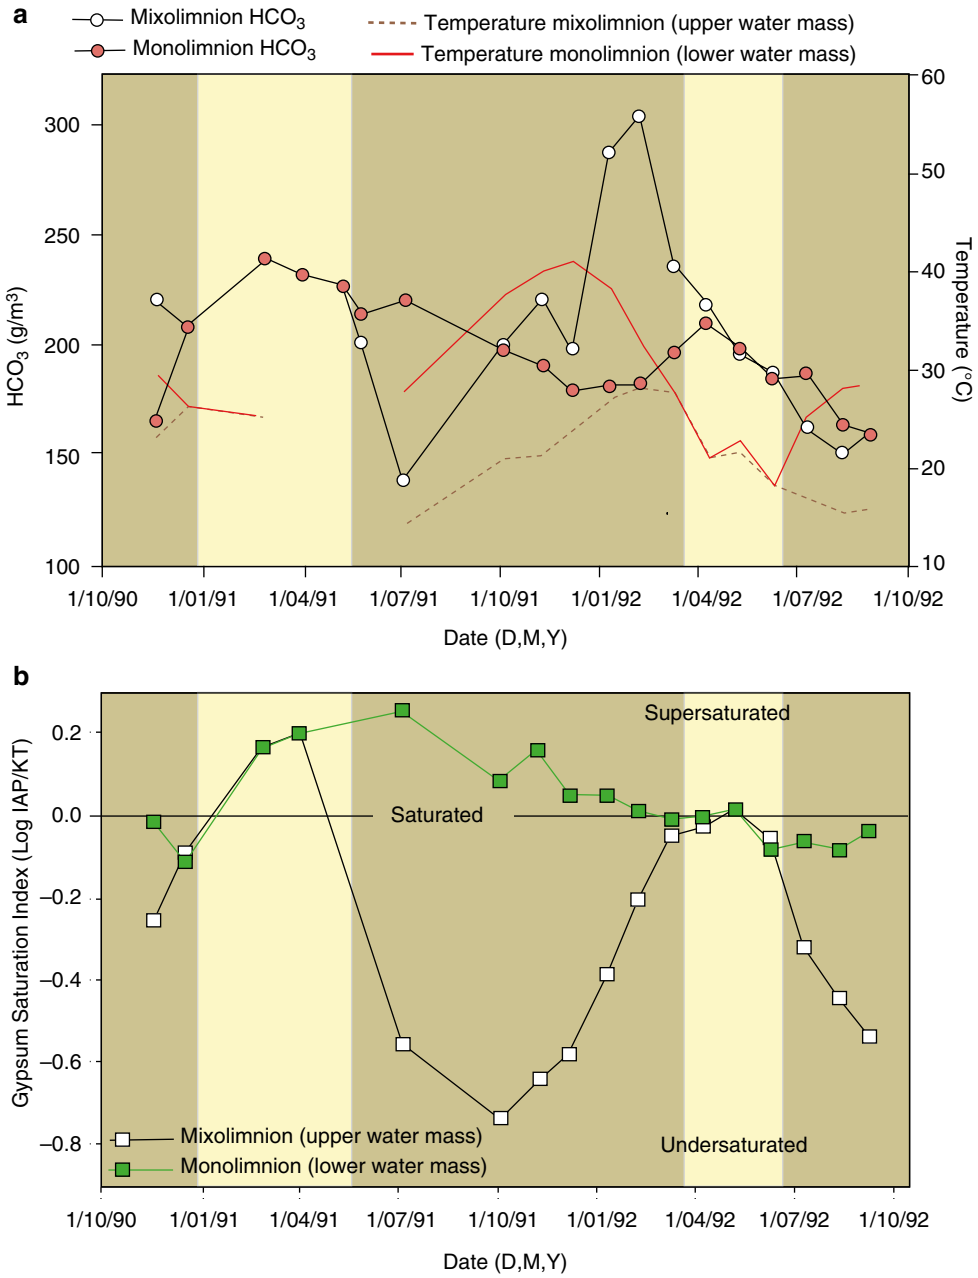

Fig. 2.70 Hydrogeochemistry of Lake Hayward waters, Western Australia. (**a**) Plot of temperature regime in upper (mixolimnion) and lower (monimolimnion) water masses and bicarbonate content. As the lake mixes, the thermal and density stratification disappears. Immediately prior to mixing the bicarbonate concentration decreases suggesting precipitation of calcium carbonate (aragonite) (After Rosen et al. 1995). (**b**) Saturation state with respect to gypsum. The monimolimnion was saturated with respect to gypsum from summer 1991 to autumn 1992 and was again near saturation at the start of summer 1992–1993. The mixolimnion was only saturated when the lake water column was homogeneous (After Rosen et al. 1996)

than the upper water mass. By mid summer (e.g., January 1992) lower water mass begins to cool, while the temperature of the upper water mass continues to rise. Once the temperatures (and densities) of the two water masses equalise they mix as the lake overturns. Waters of the lower water mass (the monimolimnion) now come into contact with the atmosphere once more. While the water masses are stratified, the chemocline and the thermocline are sharply defined across a 10 cm interface with a salinity contrast that may be as much as 135,000–140,000 ppm and a temperature difference of up to 19 °C.

The time of mixing is immediately preceded by a sharp fall in the level of bicarbonate in the mixolimnion, suggesting the precipitation of calcium carbonate (mostly aragonite) occurs in the upper water mass from late summer to autumn (Fig. 2.70a; Rosen et al. 1995). The lower water mass in Lake Hayward was supersaturated with respect to gypsum and anhydrite from late 1990 to February 1992 (Fig. 2.70b; Rosen et al. 1996). When the lake mixed from January 1991 to May 1991 and from March 1992 until early May 1992, the entire water body was at gypsum saturation, but slightly undersaturated with respect to anhydrite. A 'whiting' (a cloudy white appearance to the water body) was observed in the lake in March 92, just at the time of first mixing of the lake. Analysis by scanning electron microscopy (SEM) of the collected filtrate indicated that the 'whiting' was

composed of gypsum and diatom tests, At that time, there was also a thin (10–20 mm) crust of gypsum on the lake floor. After the 'whiting', when the water was unstratified, both the monimolimnion and mixolimnion were near saturation with respect to gypsum.

After mixing, the stratification begins to reform with the next influx of meteoric waters onto the lake surface. In the early stages of setup leading into the longterm stratification it appears stratification is not stable and the water bodies may remix before stable stratification sets in by mid winter (e.g., May–June 1992; Fig. 2.70). Lake Hayward illustrates an aspect of pelagic evaporite precipitation that is probably more generalised in many "deep-water" density-stratified settings. Namely, that evaporite crystals grow on the bottom only when the water column is unstratified. This is so even when the lower water mass is at saturation almost year round (Fig. 2.70b versus Fig. 9.48).

Another well-documented heliothermal brine lake is Solar Lake, a small monomictic hypersaline lake located on the Sinai coast of the Gulf of Aqaba (Cytryn et al. 2000). The lake is separated from the ocean by a narrow sand bar (Fig. 4.12). Water is supplied via seawater seepage through the sand bar and occasional winter precipitation. Brine depth fluctuates between 4 and 6 m, driven by seasonal changes in the intensities of evaporation and the related levels of seawater seepage and brine reflux. High evaporation and aridity in the summer months raises the lake salinity to 200‰. At that time the brine column is completely mixed (holomictic) and the entire water column is oxygenated (Fig. 2.71a). Temperature/salinity vary little throughout the brine column and sulphide/methane concentrations are very low.

By autumn, the water column is stratified with a newly introduced seawater brine (50‰) layer overlying residual, highly saline bottom water (180–200‰). A well-defined density gradient (halocline or pycnocline) now separates an upper oxygenated cooler (16 °C) brine mass (epilimnion) from the lower hotter (45–55 °C) anoxic sulphide-rich brine mass (hypolimnion; Fig. 2.71b). High sulphide concentrations develop in anoxic waters below the halocline from the activities of sulphate-reducing bacteria, both in the water column and in the underlying cyanobacterial mats. Crossing the halocline into the lower brine there is a rapid downward increase in sulphide concentration, which reaches a maximal value of 1,240 μM proximal to the sediment brine contact (Cytryn et al. 2000). At the same time a peak in methane concentration develops directly below the halocline, where a maximum value of 6.5 μM was measured in the December 1997 profile and was in part a reflection of the decomposer activities of the methanogenic haloarchaea (Chap. 9).

As winter passes into spring, a gradual heating and increase in the salinity of the upper water mass degrades the halocline. The data shown in Fig. 2.71c was collected in June 1997 and portray a transitional state between late stratification and the beginning of holomixis. Salinity and temperature gradients across the halocline are more gradual and deeper in the water column than those observed in the December 1997 profile. The deepening halocline allows oxygen to penetrate much deeper than in the earlier stages of stratification, and the chemocline is now located 3.25 m below the water surface. The oxygen concentration in the upper water mass reaches a maximum value of 300 μM at a depth of 1 m below the water surface. These supersaturated values of oxygen imply intense photosynthetic activity at these depths. Below the chemocline, a sharp rise in sulphide concentration occurs, reaching a maximum value of 2,150 μM at the water-sediment interface (Cytryn et al. 2000). Methane concentration increases linearly from the surface and reaches a maximum value of 17 μM adjacent to the lake bottom, implying methane, like the bacterially derived H_2S, is escaping from the sediments. Subsequent increasing evaporation rates further disrupt the stratification and ultimately lead to summer holomixis identical to that in the September 1997 profile.

Thick cyanobacterial mats carpet the Solar Lake sediment surface and contain a highly diverse microbial community of cyanobacteria and haloarchaea. Their metabolic activities, along with the lake's planktonic microbes greatly affect the hydro-geochemistry of the lake waters by exporting oxygen, sulphide, and methane into the brine column. Biological interactions with evaporite sediments and brine columns are discussed in detail in Chaps. 4 and 9.

Although the daily temperature/stratification records of Lake Hayward and Solar Lake are probably the best documented examples of the hydrology of a naturally stratified brine column, both regions have a number of inherent limitations when attempting to use them as direct analogs for the hydrology of ancient stratified brine seaways. Unfortunately, neither are saline enough nor isolated enough from their seawater feeds to accumulate substantial thicknesses of halite. Neither are hydrological analogs for bottom-nucleated salt beds, such as gypsum or halite units that dominate the central portions of ancient evaporite seaways and lakes. They also suffer from the scale limitations that enfeeble all modern marine-associated evaporite analogs (Fig. 5.4). Their small aerial extent ($\leq$0.6 km^2) prohibits a direct hydrological comparison with bedded salt accumulations in ancient saline giants (areas >10^6 km^2). Their centripetal unconfined meteoric inflow hydrologies, driven by winter rains and a lowering of evaporation intensity, means they cannot be directly compared to ancient brine seaways where strandlines moved up to hundreds of kilometres in a wet-dry cycle and where unfractionated meteoric waters or seawaters were insignificant in the freshening process in the subaqueous basin centre.

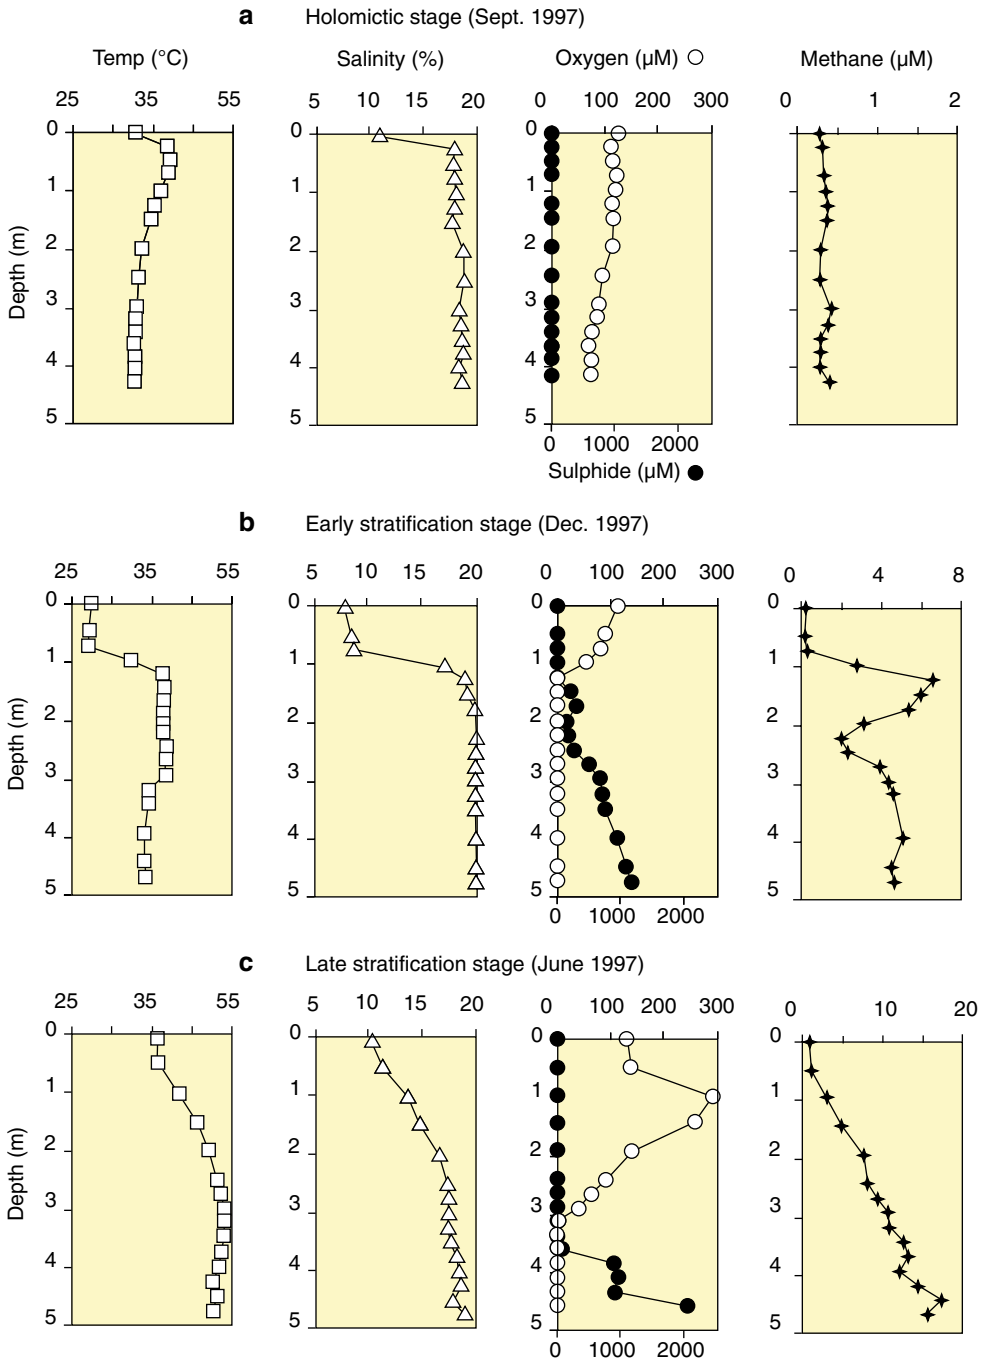

Fig. 2.71 Effects of the seasonal development of heliothermic stratification in Solar Lake, Middle East (After Cytryn et al. 2000). *Open circles* O_2, *filled circles* sulphide

Brine Stability and Evaporite Textures

In ancient evaporitic seaways and lakes the style and permanency of brine stratification is best interpreted from the preserved depositional textures (Lowenstein and Hardie 1985; Warren and Kendall 1985). But there are some physical principles common to modern and ancient brine hydrologies. If a stratified brine column forms above a growing crystallisation surface, solar driven crystal growth of gypsum or halite in the bottom waters first slows then stops (Figs. 2.55b and 2.72). Once a water body is stratified, no solar mechanism is available to further concentrate the bottom waters. Subaqueous crystallisation can only continue in a stratified system in zones of brine mixing or bottom temperature change near subaqueous spring seeps. Once the freshened inflow ceased, ongoing evaporation concentrates the upper brine body until its density matches that of the lower brine body. The two water bodies then mix (holomixis) and crystal growth on the bottom can begin anew (Fig. 2.72). This type of holomictic bottom crystal precipitation, where the crystallisation surface

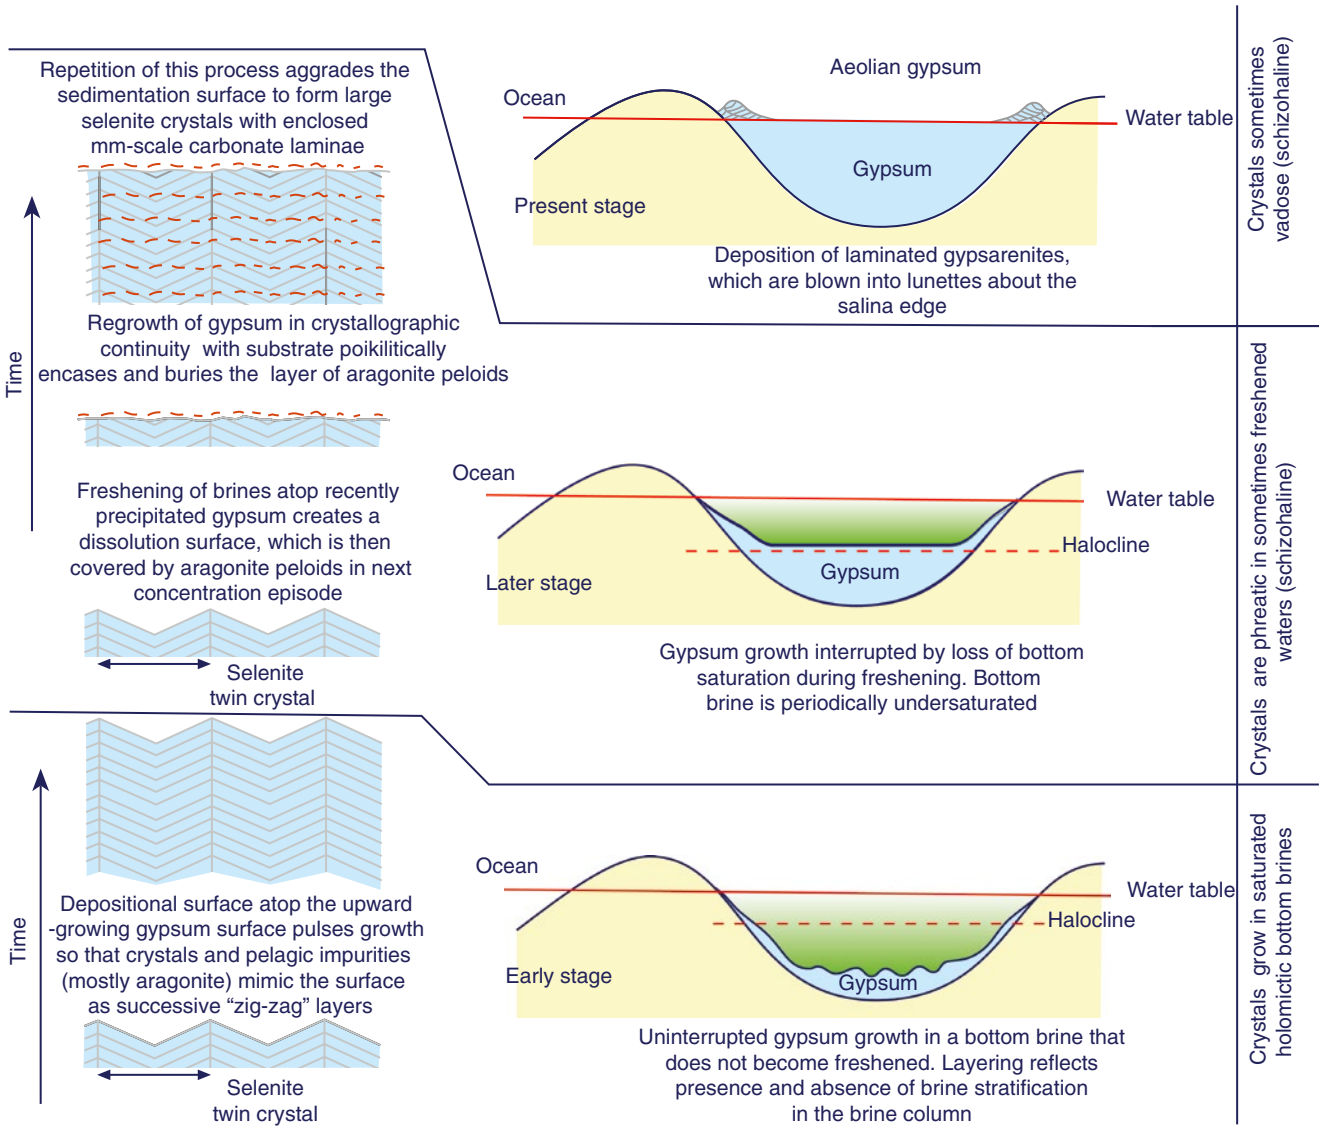

Fig. 2.72 Growth-aligned gypsum shows internal textures are controlled by the gypsum growth surface interacting with the stability and salinity of bottom brines. In the early stage of fill, when the brine lake is deeper, the bottom brines are stable and salinities do not ever decrease to where they become undersaturated with respect to gypsum. "Zig-zag" textures result. When the sediment surface aggrades to where bottom brines freshen, then the periodic dissolution of the upper part of the growth surface dissolves and mm-laminated textures form. The present stage of sediment fill is where the brine lake has been filled to equilibrium with the local watertable, eolian reworking of seasonal gypsarenite precipitates is the dominant mode of deposition (After Warren 1982b)

is never in contact with undersaturated bottom water, deposits layered euhedral growth-aligned crystal beds on the brine floor (e.g., chevron halite or aligned swallowtail gypsum; Fig. 2.72).

If, on the other hand, the freshened upper water body does come into contact with the crystallisation surface of the salt bed then subaqueous horizontal planation surfaces develop. Subhorizontal planation occurs both in saline basins subject to complete desiccation and in those parts of evaporite seaways covered by perennial brine sheets (tens of cm deep) that were subject to periodic freshening. A desiccation stage, followed by a freshened water flood, creates a near horizontal planation surface with intercrystalline karst, which marks a time when the watertable was lowered into the salt bed immediately prior to a subsequent freshening event (Fig. 1.46). In contrast, freshening of perennial bottom brine creates a horizontal planation surface atop the salt bed with little or no intercrystalline karsting (laminated coarse-grained gypsum in Marion Lake; Figs. 2.72, 4.6f).

In both cases the freshened surface water sheet only dissolves the uppermost portion of the salt bed, it does not displace the much denser pore brines that saturated the bulk of the underlying salt bed. A planation surface defines the top of saturated pore brines. Vadose karst in a desiccated salt pan

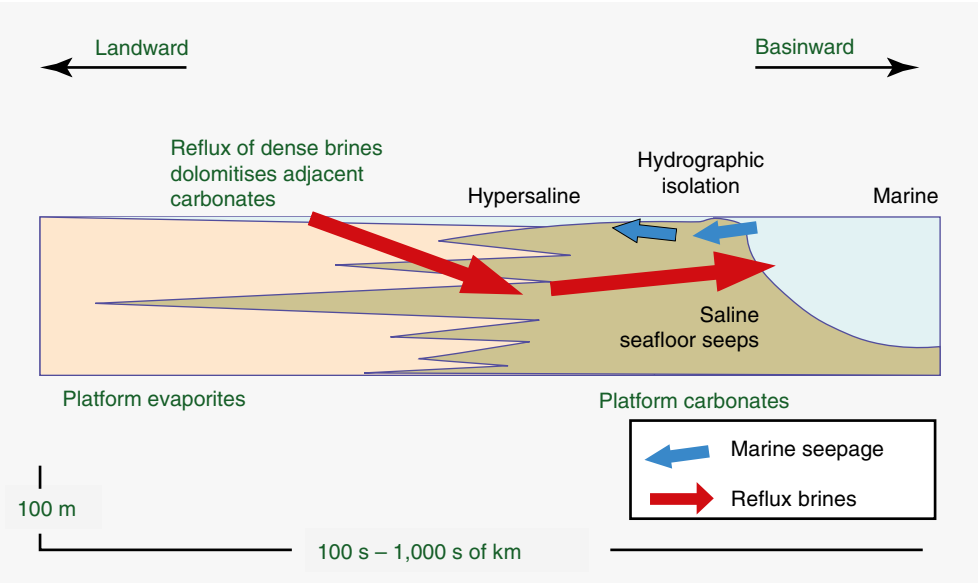

Fig. 2.73 Schematic illustrating the process of brine reflux creating secondary dolomite in a carbonate platform (After Warren 1991)

Table 2.17 Features associated with reflux dolomites

Evaporite unit proximity, geometry and position	Close spatial relationship of dolomite to evaporite sequences that can reasonably be deduced as being subaqueous in origin. Reflux dolomitised units should exhibit dolomitisation gradients, with increasing volumes of dolomite toward the source of refluxing brines. The stratigraphic, tectonic, and eustatic setting of the associated evaporites must be appropriate for the development of a barred base or lagoon.
Textures and hydrological preparation	The dolomitised reflux receptor units must have had high porosity-permeability, and suitable hydrologic continuity at the time of dolomitisation. Reflux dolomite crystal size are generally coarser than those found associated with sabkha sequences, because coarse receptor beds dictate fewer nucleation sites.
Geochemical gradient	While geochemical information relating reflux dolomite to evaporative pore fluids might be lost by recrystallization, gross vertical geochemical gradients, such as increasing Sr, Na trace elements, and stable isotopes enriched in ^{18}O toward the evaporative brine source might be preserved.

After (Moore 2001)

can only extend down to the top of this dense pore brine layer. Below it the pore brines are saturated, above it the waters are undersaturated or nonexistent.

These flat, laterally extensive dissolution surfaces typically truncate the tops of previously growing crystals, be they trona, halite, gypsum or any other bottom nucleating salt (Fig. 2.72). As the freshened water body begins to concentrate it may precipitate a less saline mineral phase, which settles onto the planation surface. It may also be the time when clays, formerly suspended in the floodwaters or blown in by the wind, begin to flocculate and sink through increasingly saline surface waters. As the freshened water body continues to concentrate into salinities that precipitate the dominant salt phase the aggrading crystals that underlie the planation surface can now poikilitically enclose the less saline precipitates (e.g., laminae of aragonite pellets in laminated coarse-grained gypsum; Fig. 2.72).

Brine Reflux Drives Substrate Alteration

Brine reflux occurs when ponded or concentrating holomictic brines atop the floor of an evaporitic seaway or lake become dense enough to displace underlying pore fluids and so percolate into the underlying succession so creating a brine curtain (Fig. 2.73). Descending brines can have chemistries that are supersaturated with different mineral phases to the matrix through which they are flowing and so drive various alteration processes such as dolomitisation, backreactions and pseudomorphing. It may also drive the precipitation of widespread authigenic K-feldspars in siliciclastic hosts at burial depths that are much shallower, and in authigenic stages much earlier than those of equivalent precipitates in non-evaporitic siliciclastics (Sandler et al. 2004).

One of the most widely recognized effects of brine reflux is the formation of dolomite in units underlying and adjacent to a thick evaporite sequence (Table 2.17). When evaporitic

carbonate or gypsum precipitates in hypersaline areas on such platforms, the surface brine densities are in the range 1.1–1.2 g/cc (Fig. 2.12b). Concurrent Mg/Ca ratios of the remaining brines rise compared with their seawater seep feed, and so dense Mg-enriched solutions sink through the underlying platform sediments. They displace connate pore fluids with densities around 1.03 g/cc and slowly seep basinward through underlying platform limestone aquifers. In this way large volumes of Mg-rich brine pass through previously deposited shelf limestones, precipitating dolomite both as a pore fill and as a replacement in the former shelf limestones (Fig. 10.29). The first evaporite-generated brine reflux model for ancient dolomites was by Adams and Rhodes (1960). Their model explained the dolomitisation of the Permian Capitan reef complex of West Texas; whereby backreef, shelf and lagoonal carbonates are intensely dolomitised, while the shelf edge and slope carbonates are not. They envisioned reflux dolomitisation through porous sediments to depths of several hundred metres below the brine source.

By the mid 1960s, seepage reflux dolomitisation as proposed by Adams and Rhodes had gained a large number of proponents working in ancient evaporite-associated dolomites (Hsu and Siegenthaler 1969) but needed, under the dictates of strict geological uniformitarianism prevailing at the time, to be verified in the Holocene (Warren 2000a). In 1965 Deffeyes et al. reported modern Mg-rich brines in a marine spring-fed gypsum salina (Pekelmeer Lagoon) on Bonaire in the Netherlands Antilles in the Southern Caribbean. From the water chemistry, they predicted that concentrated lagoonal brines should be sinking and forming reflux dolomite in underlying sediments. They observed micritic dolomite in Holocene lagoon muds beneath gypsum crusts but, with only a soft-sediment coring device to work with, could not penetrate the cemented Pleistocene base. Outcropping on the opposite end of the island, well away from the present lagoon, they located a dolomite replacing what they interpreted as Pleistocene lime-stone and inferred that this had formed during an earlier episode of brine reflux.

Lucia (1968) subsequently drilled beneath the Pekelmeer Lagoon and found no widespread dolomites in the underlying Pleistocene carbonates. He also found that porewaters were of normal marine salinity in areas where brine was predicted by a seepage reflux model. A thin clayey ash layer of generally low permeability was found forming a hydroseal that separated sediments below with normal salinity from lagoonal sediments with elevated salinity. Thus, reflux dolomitisation was not occurring beneath the lagoon. Springs supplying seawater to the salina were in areas where the ash bed was broken or missing and formed the terminations of flow pathways in the underlying Pleistocene/Pliocene (Murray 1969). For most of the year seawater seeps into the Pekelmeer springs driven by evaporative drawdown. However, during a short period in the late summer, the springs are inactive and the hydrostatic pressure on the landward side is greater than that on the seaward side. Murray concluded that return flow or reflux could occur at such times, but did not appear to do so with sufficient volumes of brine crossflow to form replacement dolomite.

The claim that the Pekelmeer was forming extensive seep-age reflux dolomites beneath an evaporite lagoon was further challenged when Sibley (1980) concluded that the solutions responsible for extensive dolomitisation in Tertiary sediments on Bonaire (dolomites that were earlier used as evidence for reflux dolomite) were probably fresh to brackish meteoric waters mixed with seawater, and were not derived by reflux of the modern Pekelmeer hydrology. Later work by Fouke et al. (1996) on dolomite in the Seroe Domi (Miocene), a unit more than 20 m thick that extends 115 km across the Nederlands Antilles, has reinforced Sibley's conclusions. However, Lucia and Major (1994) continue to argue for a significant input of marine/hypersaline waters during Neogene dolomitisation in the region.

There are, nevertheless, other islands in the tropics where localized brine reflux, associated with hypersaline conditions, is apparently forming local-scale Holocene dolomites. Müller and Teitz (1971) documented brine-reflux dolomite replacing earlier carbonate cement in skeletal grain-stones on the shoreline in Fuerteventura in the Canary Islands. Kocurko (1979) found brine-reflux dolomite a few metres above the high tide line, in the spray-zone pools of the shoreline of San Andres, Columbia. Aharon et al. (1977) described small volumes of reflux dolomite forming in Holocene sediments of Solar Lake. Thin, localized brine-reflux dolomites can also be found about the present-day edges of Ras Mohammed on the Sinai Peninsula (Chap. 3). It seems small-scale examples of brine reflux dolomites exist, but pale in comparison to obvious and extensive reflux dolomites of the past.

Hydrological modelling of ancient reflux systems by Shields and Brady (1995), using very conservative assumptions of brine head and drawdown, show that reflux can explain platform dolomites within geologically realistic time frames of burial (Fig. 2.74). Their flow model used flow lengths varying from 1 to 1,000 km and the relative densities of seawater and brines of two end member compositions (Fig. 2.74a): brine 1 is anhydrite-saturated (density $\rho = 1{,}120$ kg/m^3) and brine 2 is halite-saturated ($\rho = 1{,}200$ kg/m^3). Brine 1 is approximately 9.3 % denser than seawater ($\rho_{seawater} = 1{,}024.5$ kg/m^3), and brine 2 is 17.1 % denser. Using a 100 m tall and 1 m wide flow cell (Fig. 2.74b), brine 1 has approximately 9.3 m more hydraulic head than a comparable column of seawater, while brine 2 has a differential hydraulic head of 17.1 m. Shields and Brady (1995) assume a pure calcite precursor and a final product that is 100 % dolomite with 7 % porosity; this requires 350 kg/m^3 of magnesium. The results (Fig. 2.74c) show that reflux flow could circulate the

a

Flow length (km)	Volume of slice (m^3)	Required Mg (kg)	Required volume (m^3)	
			Brine 1	Brine 2
① 1	1×10^5	3.5×10^6	5.19×10^6	2.59×10^6
② 10	1×10^6	3.5×10^7	5.19×10^7	2.59×10^7
③ 100	1×10^7	3.5×10^8	5.19×10^8	2.59×10^8
④ 1000	1×10^8	3.5×10^9	5.19×10^9	2.59×10^9

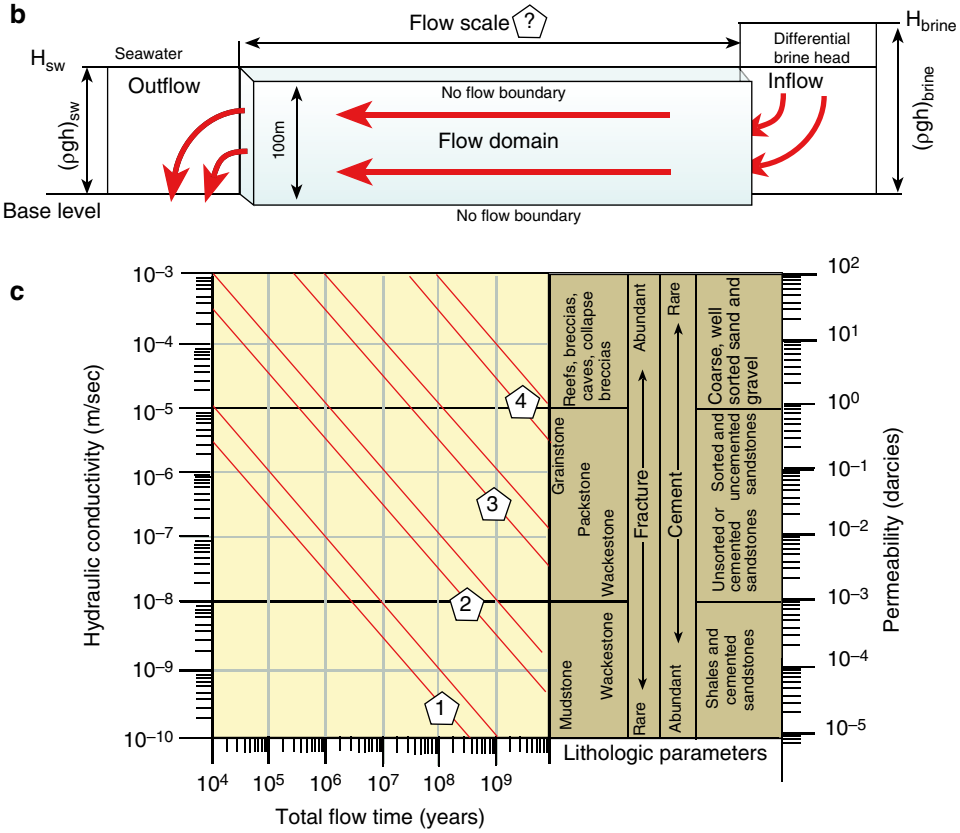

Fig. 2.74 Dimensional analysis of seepage reflux (After Shields and Brady 1995). (**a**) Table of brine properties and amount of Mg required to covert calcite to a dolomite with 7 % porosity. (**b**) Dimension of slice model used in their calculations. Slices are similar except that flow length varies from 1 to 1,000 km. Base level is 100 m in all cases and head drops are 9.3 m for anhydrite saturated brine 1 and 17.1 m for halite saturated brine 2. (**c**) Dimensional analysis of Darcy's Law for a regional brine reflux system with 100 m base level. *Diagram* illustrates the time necessary for the minimum volume of dolomitizing brine to flow through a rectangular slice. All slices are 100 m thick and 1 m wide with varying flow lengths (1–4). It is assumed 350 kg/m^3 of Mg are required to dolomitise the block. The *lower curve* for each flow path represents brine at halite saturation with a Mg exchange efficiency of 47 %. The *upper curve* represents brine at anhydrite saturation with a Mg exchange efficiency of 36 %. Permeability conversions assume an average brine density of 1,160 Kg/m^3 and a viscosity of 8.904×10^{-3} kg/(m/s) and a temperature of 40 °C

Mg necessary to completely dolomitise carbonate platforms with radii of a few tens of km in a few million years. Shelves with shoreline to basin distances of the same order can be completely replaced in a similar period. Larger platforms require more time or that the evaporite recharge areas migrate with time. Carbonate platforms tens to several hundred kilometres across could be dolomitised by such epeiric hydrologies.

The relative abilities of rocks to transmit brine will control where the bulk of the fluid flux occurs within platform limestones of any age. It is unrealistic to think of reflux dolomitisation as a homogenous process uniformly overprinting all platform lime-stones. The inherent permeabilities of the various precursors clearly play an important role in dolomite intensity. The most permeable lithologies beneath the evaporite lagoon will focus the bulk of flow as the brine seeps seaward. Whatever unit acts as the aquifer at the time of reflux will also be the subject of the most intense dolomitisation. High permeability units within flow paths of tens to hundreds of kilometres can channel the volume of necessary brine in time frames ≈1 Ma. Such high permeability units also have the potential to be dolomitised in regions well removed from the brine source.

Jones et al. (2002) has shown that the effects of a single 100,000 year platform evaporite episode can generate a reflux plume that persists for as long as 10 Ma in underlying carbonates before it is once again displaced by geothermally driven brines (Fig. 2.75). They call this long term effect "latent reflux," it documents a hydrological situation where the effects of a sinking reflux brine persist long after the at-surface

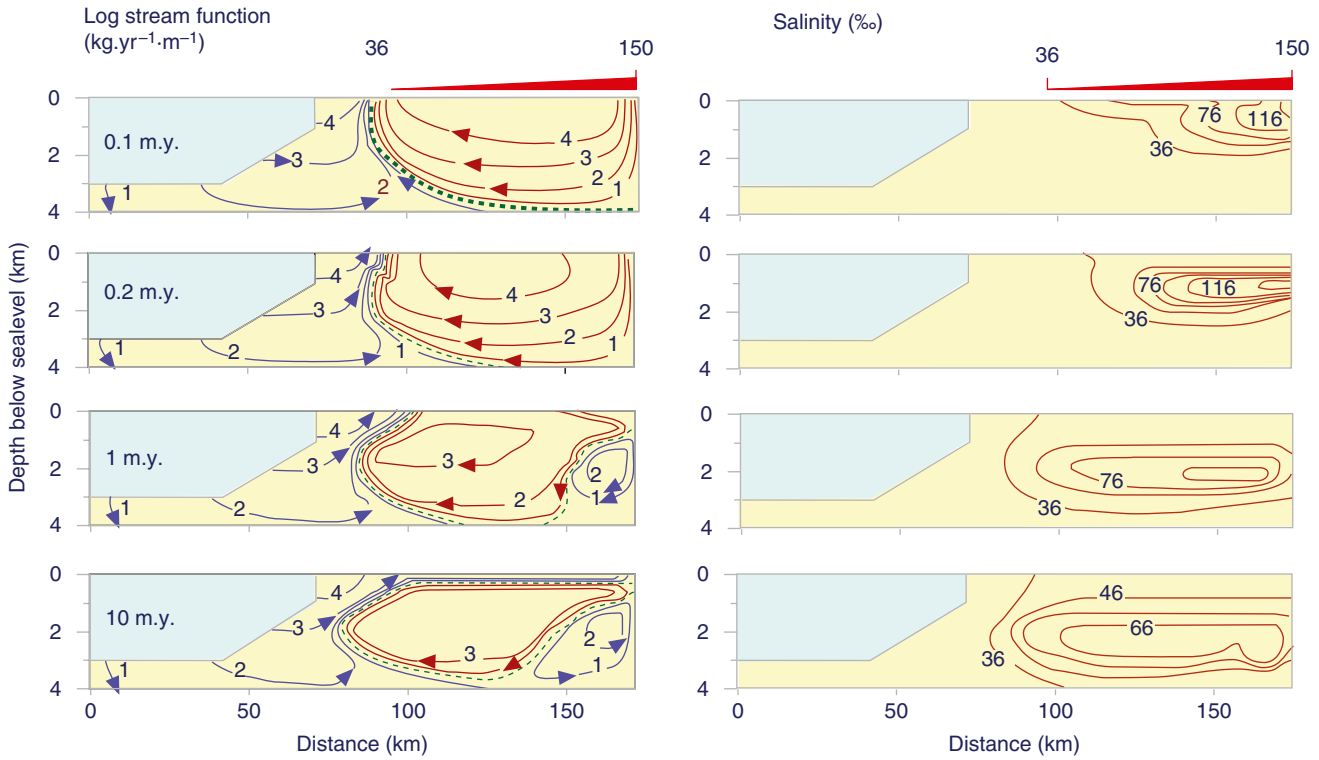

Fig. 2.75 Evolution of groundwater circulation and salinity persists for as much as 10 Ma. after a single reflux event at gypsum saturation which lasted 0.1 Ma. *Dashed line* in the stream-function plots represents interface between geothermal and reflux and latent reflux. Only the upper 4 km of platform is plotted; vertical exaggeration = 9 (After Jones et al. 2002)

brine lake or seaway has disappeared. The modelling utilised a single depositional episode and a surface brine at gypsum saturation (150‰). They went on to note that higher salinity waters and longer episodes of evaporite precipitation would generate more widespread and longer acting brine plumes in the underlying sediments (Jones and Xiao 2005). In this context it is interesting that dolomite is forming today in the slope sediments of southern Australia from marine-derived reflux brines with elevated salinities (Rivers et al. 2012).

Detailed mapping of dolomite distribution across the Permian Capitan shelf, the type area for the brine reflux model, clearly shows reflux works in ancient evaporitic platforms (Melim and Scholle 2002). Dolomite extent is greatest beneath and adjacent to the drawndown lagoon facies. In contrast, dolomite distribution through the Capitan reef and into the forereef outlines the distribution of those brine aquifers that were more active at the time of brine reflux, namely fractures and fore reef debris aprons. Aquifers carrying the descending brines out into the adjacent basin were dolomitised, while tighter aragonite-cemented intervals between aquifers were largely isolated from the flushing brines and so remained undolomitised. Garber et al. (1990) used a similar model of reflux but called upon bittern brines, derived from the very saline Salado Formation, to explain magnesite, not dolomite, distribution in the same basin. They argued that when a brine has a Mg/Ca ratio >40 it will precipitate a magnesite replacement rather than the more commonly observed dolomite. Similar reflux processes, driven by the deposition of Zechstein evaporites, may have precipitated authigenic magnesite cements in siliciclastic dune sands of Rotliegende reservoirs in the North Sea (Purvis 1989).

Reflux dolomitisation in a platform setting can often be distinctive, even in core, as the intensity of total dolomitisation decreases the further down core or laterally one moves from the evaporite-carbonate contact (Fig. 2.76). If not completely re-equilibrated during later burial dolomitisation, the oxygen isotope signatures in platform dolomites formed by reflux typically follow a lightening trend away from the evaporite unit; that is, the further one moves from the contact, the less was the sediment's isotopic signature influenced by the heavier reflux-derived brines. If the sediments are not extensively recrystallised by later burial dolomitisation, trace elements, along with strati-graphic position, can give another clue to a reflux association. In a study of dolomite from Neogene to Permian age, Sass and Bein (1988) found that evaporative dolomites associated with gypsum/anhydrite tend to show 50–57 % $CaCO_3$ and the highest levels of sodium (up to 2,700 ppm). Marine nonevaporitic subtidal dolomites have a similar range of compositions, but sodium concentrations of only 150–350 ppm.

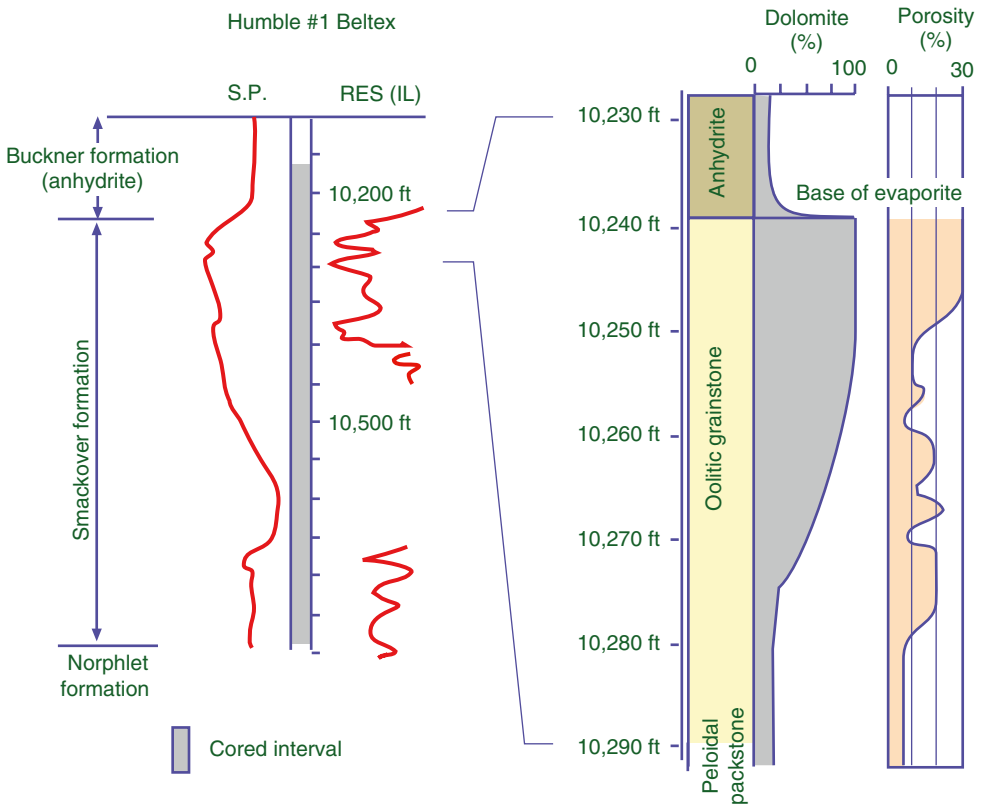

Fig. 2.76 Wireline signature and the interpreted core description of the Humble #1 Beltex Well, Bowie County, Texas. Shows a close relationship between Buckner anhydrite and dolomitisation in the underlying Smackover Formation. Note changes in proportion of dolomite and porosity in terms of proximity to evaporite contact (After Moore et al. 1988)

The present may be the key to the past, but it is simply not a good time to document depositional or diagenetic analogs for ancient platform and basinwide evaporites, nor their associated reflux hydrologies. There are no modern depositional counterparts to most types of ancient marine-platform and basinwide evaporites, hence there are no modern counterparts to brine-reflux dolomites (Chap. 5). Holocene evaporites are accumulating within an "icehouse" climatic phase. The current "icehouse" mode, typified by waxing and waning polar icesheets, has dominated the earth's climate for the last 12 Ma. "Icehouse" times, with their high frequency sealevel oscillations, are not conducive to the formation of thick platform evaporites. In contrast, "greenhouse" time, with their inherent lack of polar ice sheets and low amplitude sealevel changes, favour the formation of platform evaporites and hence widespread reflux dolomitisation of platform carbonates. Basinwide evaporites and their associated dolomites form via tectonic controls on basin isolation that are independent of "icehouse versus greenhouse" sealevel scenarios.

Most brine reflux models published to date utilise a platform evaporite setting typically tied to saltern anhydrites. Examples include: the Cambrian Ouldburra Formation in the Officer Basin, Australia (Kamali et al. 1995); the Devonian Birdbear (Nisku) Formation of Canada (Whittaker and Mountjoy 1996); Pennsylvanian platform carbonates of West Texas (Dickson et al. 2001); the Lower Permian Abo-Tubb (Hartig et al. 2011); Permian San Andres Formation, USA (Leary and Vogt 1986; Ruppel and Cander 1988; Elliott and Warren 1989); the Permian Tansill and Yates Formations of the Central Basin Platform, USA (Andreason 1992; Garber et al. 1990); the Upper Permian Changxing Formation and the Lower Triassic Feixianguan Formation of the NE Sichuan Basin, China (Jiang et al. 2013); the Jurassic Smackover and Haynesville Formations of the Gulf of Mexico (Moore et al. 1988); the Lower Cretaceous Edwards Formation of Texas (Fisher and Rodda 1969) and the Middle Palaeocene Beda Formation, of the Sirt Basin, Libya (Garea and Braithwaite 1996). Hydrological geometries of reflux dolomite associated with drawdown basinwide settings are different and are discussed in Chap. 5 after the various styles of saline giant are presented, while a number of oil field examples are discussed in detail in Chap. 10.

As well as long term effects in underlying carbonates, reflux also has significant syndepositional effects on nearsurface salt beds. Sinking supersaturated brines force backreactions and replacement processes in salt beds immediately beneath an evolving brine body. Hovorka (1992) recognised reflux of halite-saturated brines through gypsum beds as the dominant control in the formation of halite pseudomorphs of subaqueous gypsum (Figs. 1.49 and 2.77). The replacement process is driven by the fact that gypsum precipitation is favoured by low temperatures and low salinities, while anhydrite precipitation is favoured by higher temperatures and higher salinities. At the warm temperatures that typify

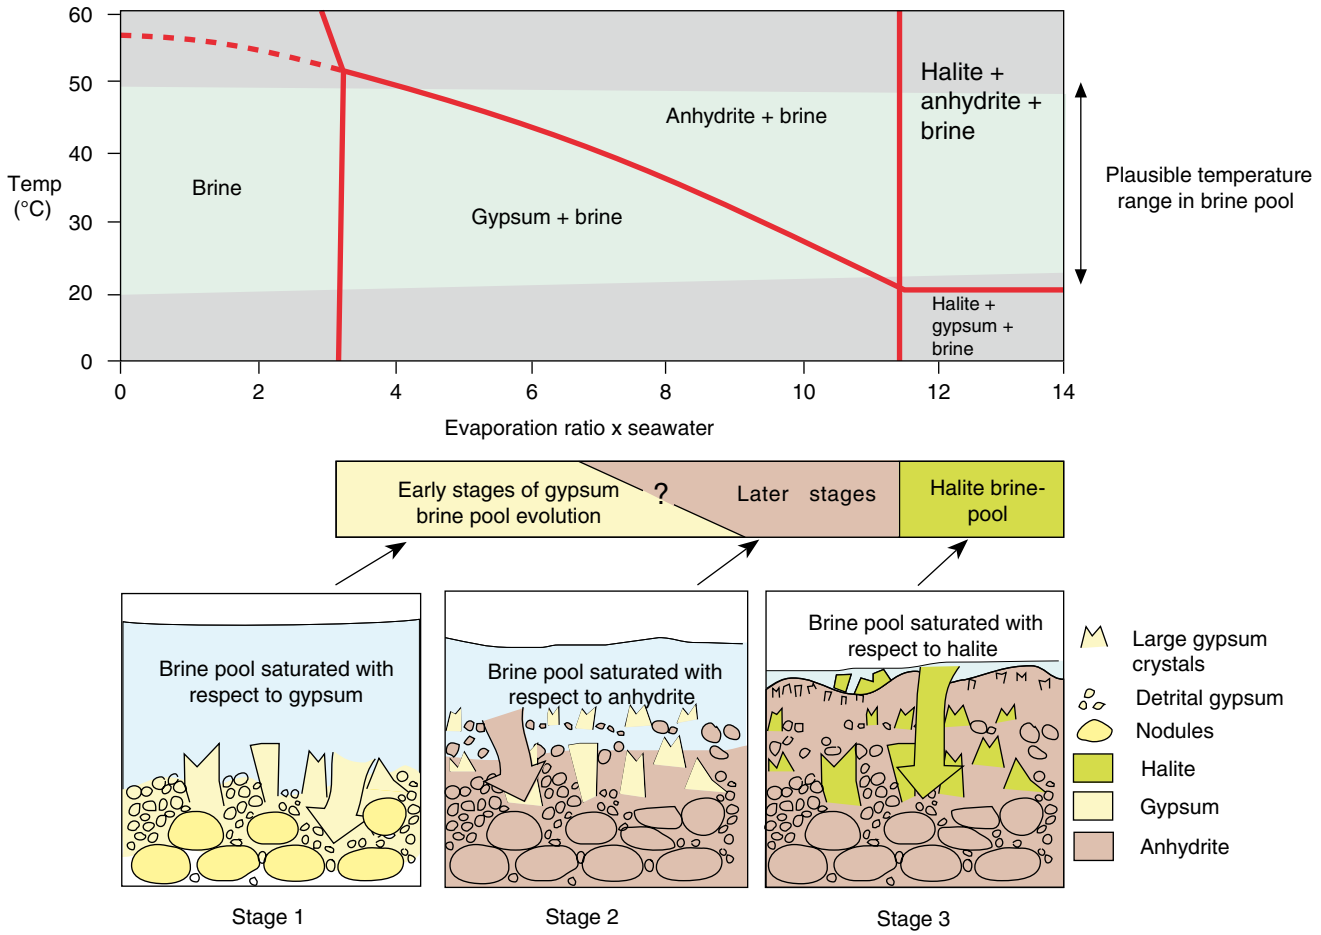

Fig. 2.77 Gypsum replacement by halite during brine reflux. *Upper part* shows phase relationships between gypsum and anhydrite in NaCl brine. *Lower part* shows how the alteration and replacement is dependent on the evolution of the overlying brine supplying waters that are refluxing through the gypsum bed. *Stage 1*: Large gypsum crystals grow vertically from the floor of the brine pool, and gypsarenite accumulates between the crystals. Gypsum is stable in diagenetic fluids concentrated three to approximately six times seawater concentration: alteration to form nodules occurs in shallow subsurface environments. *Stage 2*: As salinity increases from six to ten times seawater concentration, gypsum continues to precipitate metastably, but is dehydrated to thermodynamically stable anhydrite in the shallow diagenetic environment. *Stage 3*: When the brine pool evolves to concentrations about ten times seawater concentration, halite begins to precipitate. Halite-saturated brines introduced into the shallow burial environment dissolve any remaining gypsum and replace it with halite (After Hovorka 1992)

modern low-latitude brine pools (25–50 °C), the gypsum-to-anhydrite transition is predicted to occur somewhere between the initial precipitation of gypsum and initial precipitation of halite. In contrast, brines at halite saturation are undersaturated with respect to gypsum, while saturated with respect to halite. Textural relationships in such settings, where bottom-aligned gypsum is replaced by halite, are shown to be controlled by nearsurface diagenesis and related to brine pool evolution (Hovorka 1992).

During Stage 1 the perennial brine body is four to six times the concentration of seawater and is at gypsum saturation (Fig. 2.77). In stage 2 brines are at the upper end of the calcium sulphate field (6–10× seawater) and are in the anhydrite stability field. Metastable gypsum continues to precipitate on the brine pool floor, but reflux of this brine converts gypsum to nodular anhydrite. By stage 3 the surface brines lie in the halite saturation field (>10–11× seawater) so that halite is precipitating on the floor of the brine pool. The refluxing brine is now undersaturated with respect to gypsum so that it is dissolved in the shallow subsurface and the resulting voids are filled by halite cements. This replacement process is thought to take place in the first few metres of burial, but like reflux dolomite has yet to be documented as more than a localised process in a Holocene gypsum deposit. As thick halite beds are tightly cemented by 100 m of burial, surface-driven brine reflux and associated backreactions in ancient salt beds are most intense in the first few tens of metres of burial.

In a related paper Schreiber and Walker (1992) argue that pseudomorphous replacement of gypsum by halite at the transition between bedded sulphate and chloride documented by Hovorka (op. cit.) in cyclic evaporite sequences of

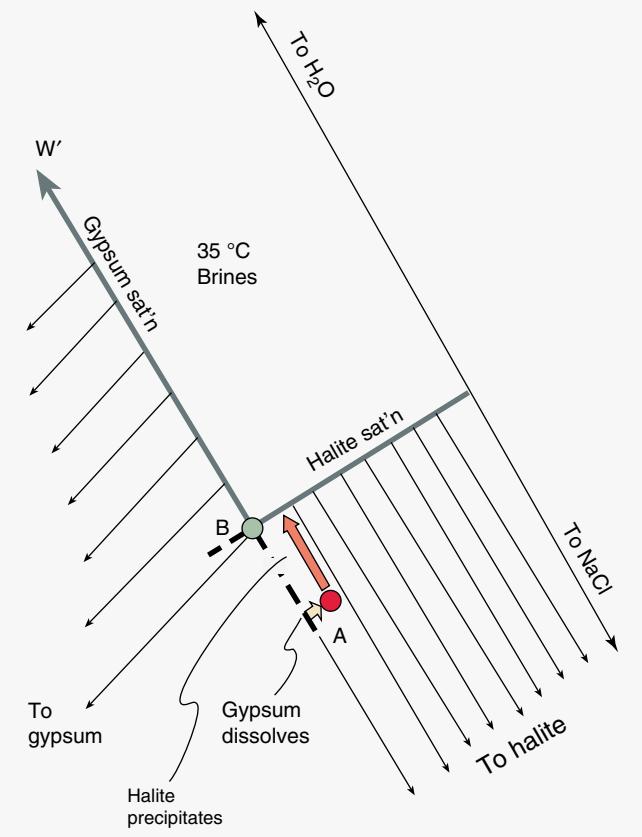

Fig. 2.78 Salient features of the metastable gypsum-halite phase curves at 35 °C (After Schreiber and Walker 1992). A co-saturated brine, as plotted at A from 50 °C when entering the 35 °C environment will be out of equilibrium. Gypsum must dissolve and halite must precipitate in order to move brine A composition to equilibrium at B

Permian age is an early diagenetic reflux process. But they argue it is a thermal disequilibrium process and cannot be directly tied to simultaneous conversion of gypsum to anhydrite (Fig. 2.78). They argue that in solar salt ponds, hot brines at halite saturation are undersaturated in gypsum and oversaturated in halite with respect to the cooler, previously accumulated gypsum substrate. This is what causes the halite to replace gypsum when suitably hot brine is in contact with the substrate. If this is the mechanism driving replacement it too would take place at or very close to the sediment brine interface.

Solar heating of the brines and production of porosity within the gypsum crystals, both of which are key features of the replacement mechanism suggested by Schreiber and Walker (1992), are materially aided by red pigments from halophilic activity (see Chap. 9). If this is the mechanism driving replacement then it cannot be related to the large-scale transition of gypsum to anhydrite (as argued by Hovorka 1992). Diluted brines created by the replacement of gypsum by anhydrite would corrode halite rather than precipitate it. Modern examples of a thermally driven replacement process are rare, perhaps because the appropriate brines are decanted for commercial collection of halite and are not allowed to backreact.

Can Reflux Really Work?

Some have argued that brine reflux cannot be a geologically significant process because we do not see modern marine brines capable of displacing substantial volumes of pore waters at sufficiently rapid rates to drive brine reflux. Rather the deposition of bedded salt creates a "hydroseal" (discussed in Chap. 5). I have just stated and will argue in detail in Chaps. 5 and 10, that marine-fed reflux dolomite is not a widespread process in today's marine platforms but is a significant process in ancient evaporitic settings.

Today's carbonate platforms are characterised by laterally discontinuous buildup geometries. They are a response to high-amplitude high-frequency eustatic signals of the current icehouse climate mode whereby continuous reef rims and shoals do not form. Subsealevel marine seepage inflows into an isolated platform lagoon, and consequent reflux of dense brine is impossible in the hydrologies of icehouse mode carbonate shelves. Likewise, there is nowhere on the world's surface today where large subsealevel marine basin floors are hydrographically isolated from the ocean, so no basinwide evaporites and reflux dolomites are accumulating in modern examples of this setting. But the viability of reflux hydrology and its ability to quickly drive brine descent into underlying strata can be seen in modern continental systems where man has interfered with natural hydrologies and created saline hydrologies in regions where there were none before. This is perhaps our best set of hydrological analogs to characterise modern counterparts of the hydrologies of ancient platform and basinwide evaporite systems.

One of the best examples comes from Owens Lake, California, where the water needs of the City of Los Angeles converted a moderately saline perennial lake (salinity ≈90‰) into a hypersaline pan accumulating bedded halite and trona. Starting in 1913, the streams that fed the Owens River, which in turn fed Owens Lake, were diverted by Los Angeles Department of Water and Power to feed the Los Angeles Aqueduct. The lake level started to drop quickly and by 1924 the lake had completely dried out. Prior to this the lake was saline, but perennial.

In order to study the Quaternary history of the lake, the US Geological Survey collected a 323 m long core from the lake (Bischoff et al. 1993a). The core encompasses the last 800,000 years of basin fill and was analysed for water content, pore water salinity, sulphate and chloride values (Fig. 2.79). Water content, a measure of compaction, varies erratically down the core, generally decreasing from about 60 wt% at the top to about 20 wt% at 240 m (Bischoff et al. 1993a). Below

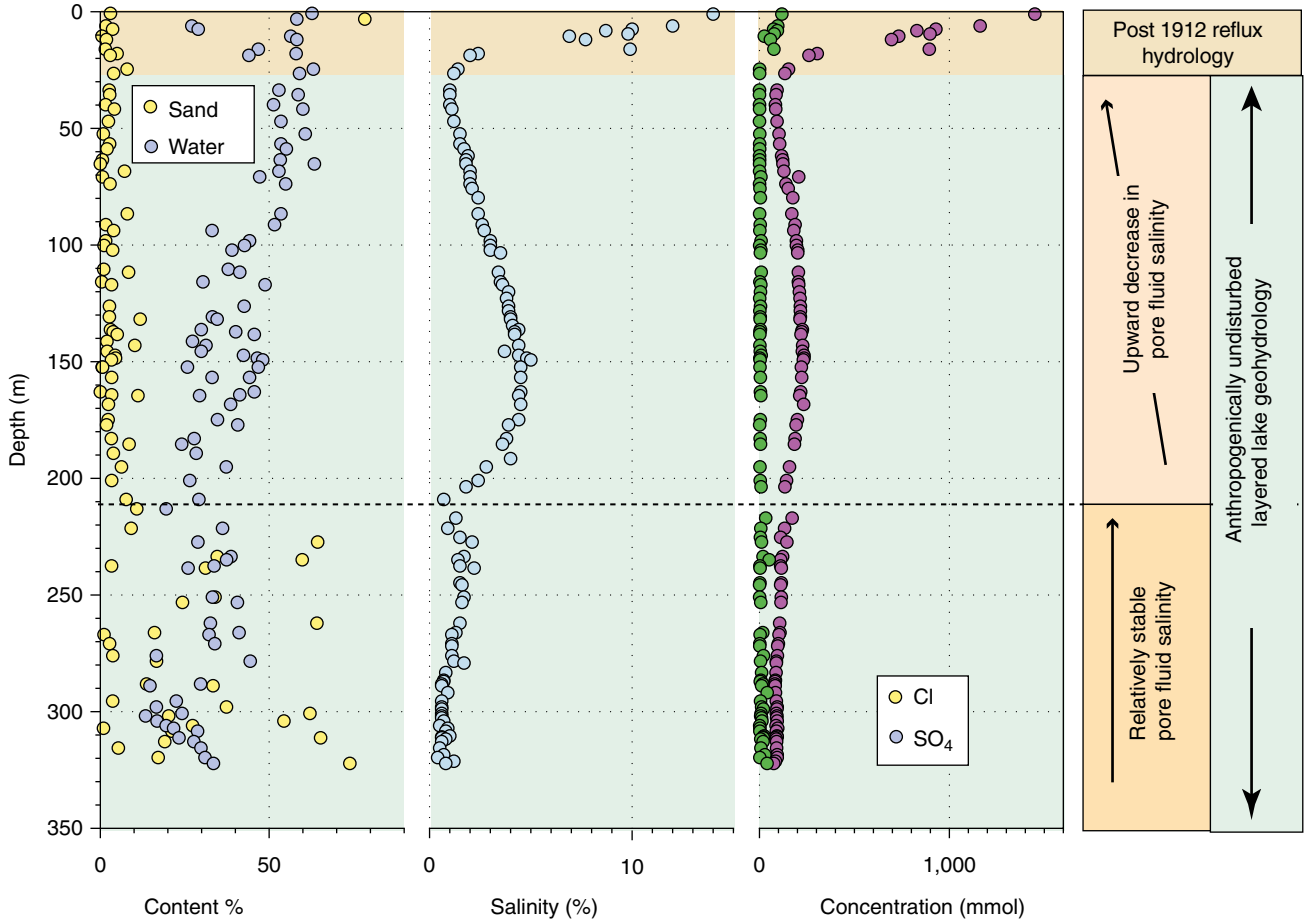

Fig. 2.79 Core OL-92 a 327 m core collected in Owens Lake, California (See also Fig. 2.10). Shows depth plots of sand and water content (%), salinity (%), chloride and sulphate content (mmol) of pore waters squeezed from the core (Replotted from data in Table 1 in Bischoff et al. 1993a)

1,200 m and to the bottom of the core the water content sharply maintains levels of less than 50 % by weight. This zone is characterized by an increasing abundance of sandy units, which are less subject to dewatering-related compression. Salinity varies with depth in a smooth pattern, with a minimum at 30 m, gradually increasing to a single broad maximum at about 150 m depth, and sharply declining thereafter to steady low values at 210 m and below.

The salinity of the modern lake prior to diversion of the Owens River, was about 9 % (Bischoff et al. 1993a). Assuming that similarly elevated salinity characterizes previous interglacial times when Owens Lake was the terminus to the Owens river, and that fresh waters must have characterized the glacial periods of intense overflow, expect about eight salinity oscillations during the past 800 kyr time span of the core. Such cycles are seen in the solid components of the sediments, particularly for carbonate and organic carbon content (Bischoff et al. 1993a) indicating the lake did indeed experience such climate changes. Yet the salinity-depth profile has been drastically smoothed by post-depositional diffusion of dissolved salts. This is not a hydrologically closed system.

Remnant water, a leftover from the last glacial is the likely explanation only for the first salinity minimum seen at 30–40 m depth (Bischoff et al. 1993a). The smooth and gradual increase of salinity in the older sediments below this depth to a maximum at about 150 m is likely the result of diffusional smoothing of waters of older cycles. Diffusion should have had more than sufficient time, therefore, to smooth salinity gradients even lower in the core. The abrupt and erratic decrease of salinity from 150 to 210 m depth, and the erratic and generally low salinities from 210 to the bottom of the hole points to an open throughflow system for the basal pore fluids. The most likely explanation for this pattern is that deeply circulating fresher waters are actively moving through the sandy units below 200 m, diffusionally harvesting solute from the overlying fine-grained sediments in the process. Thus ground water is moving at different velocities in the varyingly permeable sandy units. A diffusional steady state and smoothing of the salinity gradients has not been achieved. This particular depression in the Basin and Range province of the USA, is in the type region for what has been argued are “hydrologically closed” lake systems, clearly is

Fig. 2.80 Relationship between the ratios of the cross-sectional area of a surface inlet (*Ai*) and the surface area of the associated hypersaline basin (*Ao*) plotted against salinity in the basin, with examples from several modern evaporitic depressions. Note that Quaternary examples that are accumulating substantial evaporite beds have no surface connection and are fed either by continental inflow or by marine seepage (Modified from Lucia 1972; Handford 1991)

not. It is leaking waters vertically and laterally at a rate sufficient to smooth any former climatic layering.

But what is most impressive in the lake's hydrology is what has happened in the upper 20 m in the last 80–90 years (Fig. 2.79). The pre-1900 waters of Owens Lake had a salinity less than 9 %, the lake was alkaline and probably had a pH ≈9–10. The extremely high salinity of the top 20 m is not a reflection of the pre-1912 natural lake. Rather, it is a consequence of river diversion and almost complete desiccation of the lake basin since 1924, and the associated downward migration of dense residual-brines (Bischoff et al. 1993a). As the post-1924 lake dried out, Na-carbonate minerals precipitated to form a 1–2 m thick salt bed now covering the lower parts of the lake depression. Residual brines from the salt bed were denser than the underlying 9 % pore water and were also relatively enriched in Cl. Modern brine percolated downward by gravity displacement and ionic diffusion, so that high salinity pore waters now dominate down to about 15–20 m.

Reflux brines derived by the accumulation of 2 m of bedded salt have penetrated some 20 m of relatively fine-grained water-saturated sediment in 80 years. The original now-displaced pore waters had a salinity up to three times that of seawater and so would have been more difficult to displace than seawater brines in an ancient carbonate platform undergoing reflux, which would have had salinities around 3–4 %. Clearly once a holomictic bedded salt system has formed, associated reflux is rapid and ongoing. What is more, the total system leaks water and brine at all levels in the cored hydrology. It possesses an open hydrological base to the lake depression even though the underlying nonevaporite sediments are more than 90 % clay. Reflux rules the upper portions of the hydrology, deeper artesian circulation rules the lower part of the hydrology. It is a small, but temporally impressive, example of the hydrological processes that would be active in ancient drawndown platform or basinwide evaporite settings (Chap. 5).

Importance of Hydrographic Isolation

Modern continental lacustrine evaporites accumulate in underfilled endorheic or hydrographically closed basin hydrologies. Likewise, modern marine-fed evaporite basins like Lake Macleod, Lake Asal and Marion lake require complete hydrographic isolation from the ocean and a subsea-level water surface in order to maintain the required throughput/seepage of brine (Chaps. 3 and 4; Nunn and Harris 2007). In Chap. 5 we shall see that both basinwide and platform evaporites are a response to underfilled marine-seepage hydrologies.

I use the term hydrographic isolation as distinct from the groundwater connection, which dominates in all evaporite-accumulating depressions. Lucia (1972) studied the interrelationship between maximum salinity in a modern evaporite basin and the basin's water balance (water loss versus gain). He showed that for marine-fed halite to precipitate any surface inlet from the ocean must be at least one hundred million times smaller in cross-sectional area than the surface area of the basin; for gypsum it must be at least a million times smaller (Fig. 2.80). That is, any basin accumulating

thick beds of halite effectively lacks a continuous surface connection to the ocean or other standing body of brackish water.

The nature and driving processes that bring about hydrographic isolation are contentious, in the most recent example we have to study, the onset of Messinian salinity crisis in the Mediterranean, most authors would agree it was driven by tectonic uplift creating inflow restriction. The final nail in the coffin that created complete hydrographic isolation was probably eustatic. Possibly, gypsum began to form in the more isolated parts of the circum Mediterranean before the complete cutoff of Atlantic and Tethyan surface inflow, but halite is a response to complete isolation.

In a theoretical consideration of the passage to cutoff in the Mediterranean and loss of exchange with Atlantic waters, Meijer (2012) concluded that the response of Mediterranean basin salinity to strait depth, strait width, and relative thickness of the outflow layer (return of Mediterranean water to the Atlantic) was highly nonlinear. For a strait width on the order of kilometres, an asymptotic rise in basin salinity occurs when the strait depth is on the order of a few tens of metres. Completely blocked outflow takes place when the depth is reduced to metres. The nonlinear nature of the system implies that even a slow gradual reduction in the sill depth leads to an event-like rise in basin salinity. For values of basin salinity approaching gypsum saturation, the response of the basin to changes in the strait depth is significantly delayed in the order of several thousand years. Nunn and Harris (2007) came to similar conclusions in terms of the lack of a need for spillover and the dominance of marine seepage, not hydrographic connection, in the formation of the Aptian salts in the Circum Atlantic and the thick salts of the west Siberian basin.

Maiklem (1971) in a study of evaporative drawdown in the Elk Point Basin of Canada showed that, once it was hydrographically isolated from the ocean, the Devonian Pesqu'ile barrier it did not have sufficient transmissivity to prevent evaporative drawdown, even with permeability of 73 darcies. Kendall (1989) recalculated Maiklem's figures using more realistic values of 0.9–2.7 darcies for permeability in the barrier and concluded that evaporative losses were as much as 200–800 times greater than the rate of supply. Any saline giant precipitating bedded salts is subject to evaporative drawdown and seepage influx of marine-fed phreatic waters. A corollary is that at the time of thick evaporite precipitation there is a correlative unconformity or hiatus forming in the adjacent nonevaporite lithologies that make up the surrounds of the hydrographically isolated depression.

An evaporite basin capable of accumulating thick salt beds is always located in a large isolated depression where at the onset of drawdown more water is being lost by evaporation than entering as seepage inflow and runoff (Nunn and Harris 2007). The water level in the basin is drawn down until the volume of water lost equals the volume of inflow (hydrologic equilibrium). A potentiometric gradient (elevation head) then exists between the level of water in the basin and its surrounds, so that by definition an evaporite basin must be an underfilled basin. Such large deep holes in the landsurface attract not just marine seepage, but also ground and formation water seepage from beneath areas adjacent to the hole. In a drawndown saline-giant basin, with a predominantly marine source, the seawater enters mostly as resurging brines through springs in the basin floor. In a saline lake fed by nonmarine water, the water enters by a combination of occasional storm runoff and rainfall, as well as by groundwater and hydrothermal springs (Chap. 4).

Water ponded in an evaporitic depression must remain at the surface or reside just below the land surface in the realm of capillary evaporation. Otherwise, thick sequences of bedded salt could not accumulate, parent waters would seep away before attaining salinities high enough to precipitate salts. In a hydrological setting where the saline watertable is rising into a previously vadose environment, the first salts typically precipitate as a capillary cement in previously nonevaporitic sediments of the basin floor. This is the typical situation in marine transgressions and it characterises evaporite accumulation in marine-fed Holocene coastal salinas without a hydrographic connection to the ocean. It is also the hydrology of their larger scale counterparts in subsiding rifts and intracratonic sags where rising relative sealevels force a marine-fed seepage hydrology into a previously continental depression. It also characterises Quaternary continental lacustrine transitions from a dry mud-flat or sandflat into a saline pan or perennial saline lake and can be driven by a change to a more humid climate in an arid nonmarine basin.

In a hydrological situation where a previously marine basin becomes a marine-fed depression, the basin waterlevel falls. It is drawdown once the basin-centre or platform lagoon becomes hydrographically isolated from the ocean. Now the water level falls and surface water concentration increases to where dense saline brines begin to sink into the underlying succession. The water level will fall until the volume of water lost from the basin by a combination of evaporation and reflux leakage equals the volume entering by influx seepage of marine and continental waters. Hydrological equilibration in some basins occurs at gypsum saturation, in others at halite saturation. In some basins it occurs when the water level is a water surface and subaqueous evaporites accumulate. In other basins it does not occur until the water level falls below the surface of the sediments and evaporitic mudflat deposition dominates.

Hydrographic isolation drives the formation of marine-fed platform evaporites where a fourth order sealevel fall occurs during a 3rd order rise and it also dominates in basin-wide evaporite deposits formed in soft-collision continent-continent suture belts (Chap. 5). It also occurs in continental

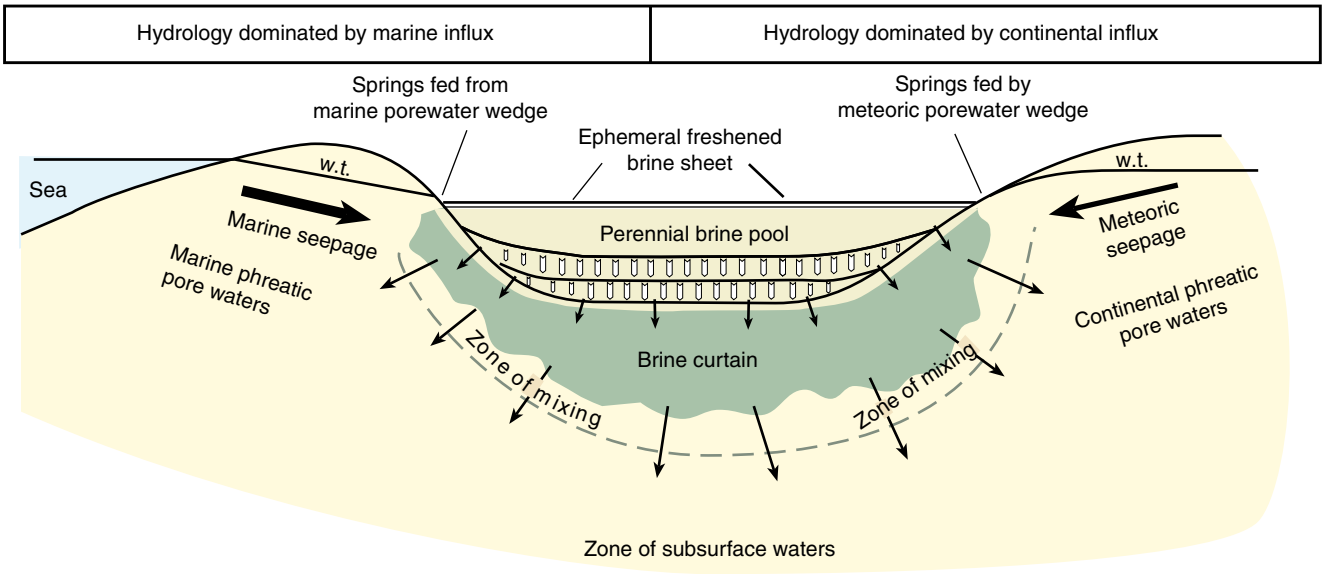

Fig. 2.81 Schematic of a brine curtain in a marine-fed and a meteoric-fed evaporitic setting (V:H ≈ 10:1). Once established the brine curtain is actively maintained by ongoing evaporation and reflux, as well as by the relatively impervious nature of the salt bed (highly effective aquitard). It is difficult to displace the curtain via influx from the margin of less-dense marine or meteoric waters. These tend to float out over the saline watertable atop the denser waters of the curtain and move into the salt-filled depression via groundwater wedges that feed spring seeps about its edges. Short-term high-volume runoff or floods of fresher waters tend to form a floating brine sheet across the brine body, which disappears once it is concentrated to where its salinity and density equals that of the underlying brine body. Focused outflow of confined artesian water can locally displace the brine plume. Longer term fluctuations in the volume of all types of freshened inflow can cause changes in the mineral equilibrium that is depositing salts across the perennial brine covered floor. It can lead either to a freshening or a salinity increase in the waters of the brine curtain. Such longterm changes in flow volume favour dissolution, alteration or backreaction of pre-existing mineral phases, as can complete drying of the brine body, which may follow a longterm lowering of the regional watertable

lakes undergoing a transition from fresher high-waterlevel systems into saline lower-waterlevel lakes. In this purely continental scenario the transition in lake style can be a climatically-driven change from humid to arid, or it can be a tectonically-driven change in the amount of fresh water entering the lake depression (Chap. 4).

In all situations of holomictic subaqueous and salt pan evaporites, the necessary hydrology creates a cone of refluxing brine below the concentrating water mass. This leaky plume of dense brine bathes the accumulating evaporites in saturated and supersaturated water as the plume sinks, spreads and diffuses into the underlying regional hydrology. I call this zone of sinking waters associated with the accumulation of bedded salts the brine curtain (Fig. 2.81). The process is brine reflux, the geometry outlined by salt-saturated pore waters defines the brine curtain. Rates of brine escape or brine residence time within the plume of the brine curtain control many of the backreactions discussed in Chap. 2 (e.g., halite pseudomorphs after subaqueous gypsum – Hovorka 1992; carnallite in Lake Qaidam – Casas 1992; and the mineralogy of the Holocene Coorong Lakes – Warren 1990).

Once the brine curtain (reflux plume) is established and actively cycling hypersaline groundwaters, it is not easily displaced by short-term inflows of less-dense marine or meteoric groundwaters. The curtain creates an autochthonous hydrology of stable hypersaline pore waters where evaporites can continue to accumulate as secondary cements and alteration haloes. It is a plume of dense pore waters with wedgelike margins that force less-saline groundwaters to enter the basin as a series of seeps and springs about the edge of the curtain. Upon burial the evaporite cements associated with the base of the curtain are typically the first part of the evaporite sequence to be dissolved by resurging basinal and compactional waters.

Locally, the brine curtain may be breached atop areas of exceptionally strong upwelling or artesian outflow, which can be situated well out into the salt-saturated parts of the basin.

Where resurging artesian waters break though the brine curtain to the landsurface, as along the fault lines that cut across Lake Frome, they feed prominent lines of spring mounds on the lake floor. In some ancient drawdown basins a localised freshened upflow occurred through zones of exposed pinnacle reefs and were associated with haloes of less saline mineralogies in a sea of halite. Unlike the hydrologies of most ancient basinwide evaporites, the brine curtain in many Quaternary continental lakes in central Australia fades at depths not far below the surface of the lake sediments. In lakes such as Lake Eyre and Lake Amadeus, or the sabkhas of the Abu Dhabi coast, the brine curtain is destroyed

at depths of a few metres by dilution from resurging artesian waters. This brackish to mesohaline upwelling of regional groundwater, coupled with periodic surface floods, continually recycles salts into nearsurface sediments. There they are deflated or washed away, so preventing stacking of thick bedded salts within the playa or sabkha depressions. The only bedded salt to accumulate in such settings is a continually recycling pan crust that is never more than a metre thick. Its hydrogeochemistry is largely decoupled from the mineralogies of the underlying sediments (Chaps. 2 and 3).

Logan (1987) and Kendall (1992) use the term "hydroseal" to describe the lowermost salt layer in any evaporite sequence. They interpret it, and not the formative reflux hydrology, as the fundamental cause of evaporite accumulation and the varying mineralogies in the basin. The notion of a "hydroseal" is not strictly correct, as secondary or capillary salts precipitated in any zone of refluxing brine must be by definition forming in an aquitard and not an aquiclude. It leaks, to varying degrees, across the whole of the salt -covered basin floor. Even when a salt bed becomes cemented it still dissolves from its underside and becomes a supplier of brines to the base of a more deeply buried brine curtain (Chap. 8). As pore waters making up the brine plume slowly seep and sink, they ultimately mix with underlying compactional and basinal crossflows, as well as any more marginward meteoric or marine inflows. This mixing drives diagenetic reactions that include the precipitation of quartz overgrowths and dolomite cements in units located further away from the brine curtain (Ceriani et al. 2002; Morrow et al. 2002).

Thus, the term "seal" is not appropriate to any reflux situation and the notion of the base of an evaporite bed as a total seal, which is not subject to dissolution or alteration, is one of the reasons why the significance of basal anhydrites and other diagenetic deposits, such as some of the Rote/Faule Kupferschiefer ores, were not attributed to an inherent evaporite dissolution hydrology (Chap. 15; Warren 1999, 2000b).

Extraterrestrial Hydrologies, "Freeze-Dried" Salts, and the Meaning of Life

In order to complete this chapter on hydrology and evaporites, with its focus on the interactions between the earth's hydro-sphere, atmosphere and the lithosphere, I would be remiss if I did not include some mention of possible implications for extraterrestrial salts. Are there possible examples of large-scale occurrences of extraterrestial evaporite salts? If so what are the atmospheric implications of extraterrestrial salts, as well as their possible significance as indicators of extraterrestrial life? And lastly, what were the contributions of bolide interactions with earthly evaporites as drivers of extinction events here on Earth?

Partial analogs to the Earth's saline pans and saline lakes may have existed in crater-basins during the early Noachian epoch on the planet Mars (Forsythe and Zimbelman 1995). Evidence includes images of terraced, patterned and channelized ground in crater-basins, which imply ancient ponding of surface water, as well as possible prolonged and evolving erosional base levels. Williams and Zimbelman (1994) argue that White Rock, an enigmatic highly reflective crater interior deposit, measuring 12.5×15 km across, with an eroded thickness of 180–540 m, and a volume of 40 km^3, may be the remnant of a saline lacustrine deposit. They infer the exposed sequence may include deposits similar to those that outline layered rocks and concentric desiccation rings formed during drying of continental salt lakes on earth.

Edgett and Parker (1997), in a discussion of surface imagery of cratered terrain in the Sinus Meridiani region of Mars, recognised a combination of aeolian dunes and polygonally patterned ground. They argued, using a comparison with similar features that form today in saline seepage areas of the present-day Saudi Arabian desert, that Mars once had flowing surface waters and that capillary evaporation hydrologies creating and preserving evaporite sediments in the early history of Mars are a distinct possibility.

Further developing this concept of at-surface waters, Montgomery and Gillespie, 2005 argued that the Martian outflow channels developed via the catastrophic dewatering of evaporite deposits. Layered deposits within Valles Marineris, are interpreted as unconformably underlying Hesperian-age lava flows, which are thought to contain hydrous sulphates. These hydrated salts were heated by an increased geothermal gradient associated with to development of Tharis. Increased temperatures adequate to dehydrate hydrous evaporites would have triggered significant volumetric expansion and catastrophically released tremendous amounts of overpressured water onto the Marian surface.

So, across the last few decades, the discovery on the Martian surface of hydrated salt minerals, including sulphates and chlorides, all interpreted as deriving from the desiccation of preexisting large bodies of water, such as lakes, has been used to conclude there was liquid water activity on the surface of Mars. Consequently, it has reinforced the plausibility of finding relics of life on Mars (Barbieri and Stivaletta 2011). Because evaporites require short-term aqueous processes for their formation, they can trap and preserve over geologic times a biological record made up of halophilic extremophiles—such as microalgae, bacteria, and their remains—that recent research on Earth has shown to be characterized by unexpectedly high biodiversity. Space agencies, such as CNSA, ESA and NASA, have accordingly increased their interests in Earth-bound saline deposits as analogues for the Martian salts.

On the theme of evaporites and water on Mars, and as an alternative to the notion of an early warm wet Mars, Banin

(2002) has proposed a model that attributes the peculiar nature of Mars soil to it being a relatively 'young' weathering product. The model suggests that Mars soil components formed at the microscopic rock/atmosphere interface during recent periods by a process involving chemical neutralization of acidic volcanic aerosols containing soluble S and Cl species. This 'Acid Fog' formation scenario seeks to reconcile conflicting evidence for the presence of very soluble, water-transported sulphate and chloride salt minerals ('evaporites') in the soil with the lack of crystalline secondary iron oxides, clays and carbonates that usually form during weathering in aqueous environments. This emerging new view of Martian hydrology, based on the recent imagery that show water seepage, surface ice-dust interactions and volcanic activity on Mars as recent as the last 10 Ma, adds strength to a model of recently mobile water. A major conclusion from the 'Acid Fog' hypothesis is that the lack of organic matter in Martian soil may be due to low cumulative meteoritic input rather than to exceptionally high oxidizing power of the atmosphere.

Consistent with a non-waterlain theme, Michalski and Niles (2012), in a spectral/morphologic study focused on Valles Marineris, argue that many of the supposedly waterlain layered deposits of Mars are more akin to the layered aeolian-ice deposits with partial analogs in layered ice deposits in Antarctica. They postulate formation of sulphate-rich layered sediments on Mars was governed through time by volcanogenic SO_2 and H_2O emission rates and dust production against a backdrop of obliquity variation under a largely cold and dry climate. That is, layered Martian deposits indicate an atmospheric source, not water transport; volcanogenic acid volatiles were deposited along with snow, ice, and dust during periods of obliquity-driven climate change. If so, intervals when sulphate-bearing layered deposits formed might mirror periods of extremely high volcanic outgassing rates on a planet that was largely cold and dry with no surface water to act as a sink. They do not infer diapir-like associations with the layered sulphates they interpret.

In yet another evaporite-related study of the layered chasma deposits of Mars, Adams et al. 2009 concentrated on the nature of the layering and mineral spectra in Hebes Chasma, a Martian erosional valley located a few degrees north of Valles Marineris. They conclude that the mineralogical spectra (including kieserite), and the erosion/collapse patterns defined by the layering, are indicative of salt diapirism. That is, Hebes Chasma, formed by solution-related saltflow collapse of the Martian megaregolith. Local heating facilitated drainage of ~10 km of brines and so entrained particulates both through fractures in the chasma floor and into a regional aquifer. They argue a mega-regolith, rich in salts and water, is implied by massive, low-gradient allochthonous flows that terminate in deep pits and troughs, marked by emergent diapirs, and by arching of Hebes Mensa. These at-surface dipping structures are consistent with plastic and viscous deformation, but inconsistent with collapse of basalt flows and/or tephra. Spectral measurements confirm that hydrated sulphate salts (including kieserite) are spatially associated with allochthonous flows in the chasma, derived from depth and now indicated by light-toned at-surface deposits. Collapse features and flows are present in many other chasmata in Valles Marineris, suggesting that widespread salt tectonics and dissolution may have shaped the regional landscape, as also interpreted by Montgomery et al. 2009 (Fig. 2.82).

Likewise, Wezel and Baioni (2014) interpret the 1,500 m-thick "Sinus Meridiani complex" as sulphate rich and saltflow-based. It appears to be composed of a superposition of three lithologically similar stratigraphic units, each ending with a residual mesa caprock associated with planation surfaces. The three exposed caprock plains display polygonal fault networks, nodular anydrite/gypsum dykes located along subvertical polygonal fractures, and presumed pipe-like fluid flow structures. Such vertically intrusive fluidized bodies are interpreted as indicative of subsurface evaporite remobilization and injection, which probably occurred near actively rising evaporite diapirs originating from an autochthonous "mother" layer situated underneath the Meridiani region. Renewal of diapirism is inferred to have caused repeated post-depositional cycles of uplift and erosional exhumation during relatively recent times. The differences in interpretation by Adams et al. (2009), Montgomery et al. (2009) Wezel and Baioni (2014) versus Michalski and Niles (2012) are yet to be resolved.

The discovery of halite-siderite-anhydrite-chlorapatite assemblages in interstitial positions in the Nakhla meteorite with halite often being adjacent to or enclosing siderite, strengthens the argument for some form water of Mars (Bridges and Grady 2000). The Nakhla meteorite, recovered in Egypt in 1911, is a fragment of Mars pushed into space by a bolide impact. The nature of the mineral assemblage suggests that its source rocks on Mars were evaporites, which may be common in the craters and flood plains of the Martian southern highlands (Bridges and Grady 1999). Two models can explain the incorporation of evaporitic material into the Nakhla igneous parent. It may have happened as a low-temperature process (<200 °C by crystallisation from an aqueous fluid. An origin at low temperature is compatible with the available experimental data on siderite stability. Alternatively, evaporitic material may have been incorporated into the Nakhla parent while melt was still present and crystallized $\approx$800 °C. The latter model can more readily explain the trace element abundances and also the siderite textures that imply intergrowth with residual interstitial melt. Both high- and low-temperature models are consistent with the presence of sulphate salts (evaporite?) on Mars.

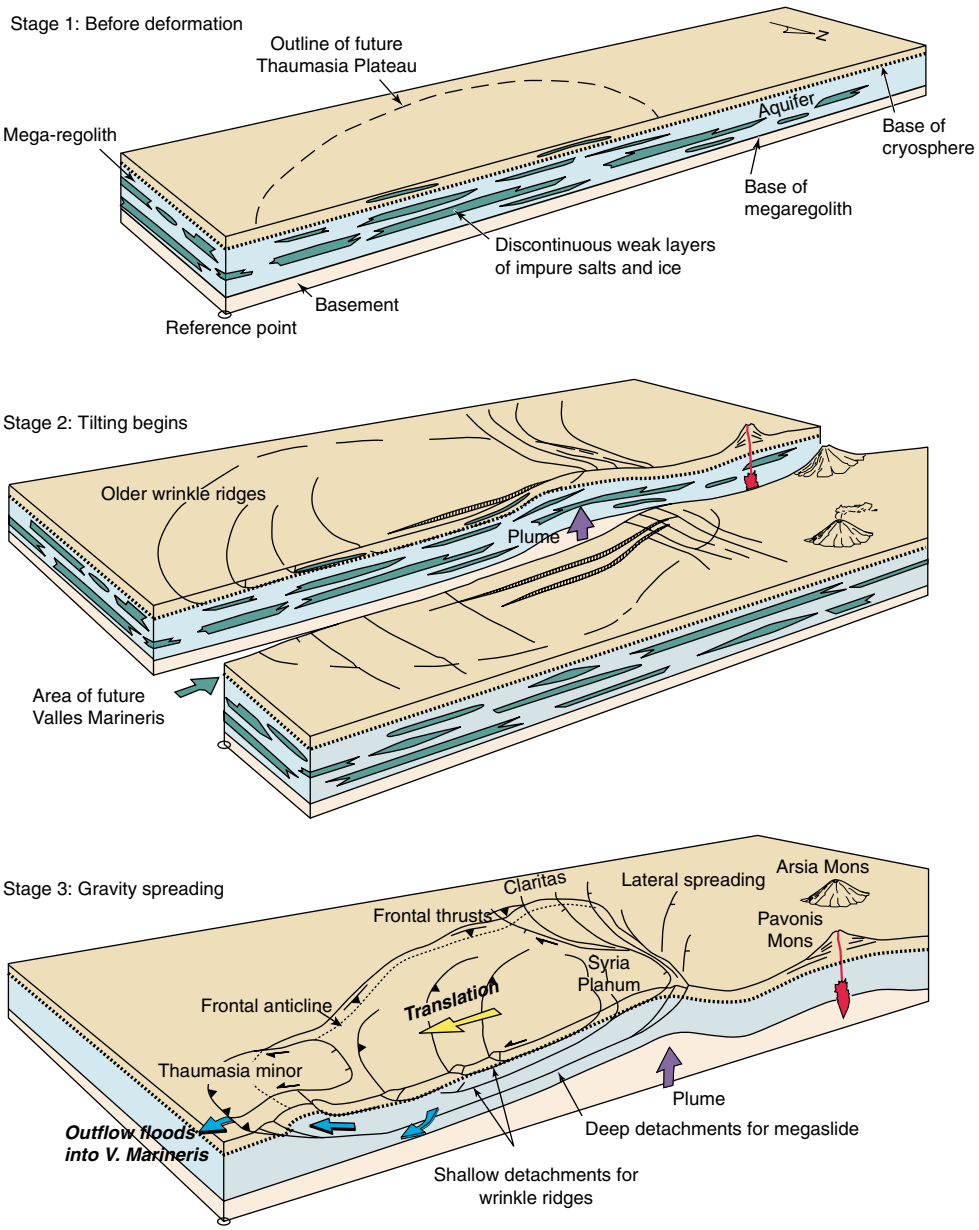

Fig. 2.82 Schematic illustration (not to scale) of the deformation of the Thaumasia Plateau as a "mega-slide" formed by continental-scale salt tectonics (After Montgomery et al. 2009). In *stage 1*, discontinuous layers of salts, ice, and impact breccia accumulate in Noachian time as megaregolith before the growth of Tharsis, perhaps as surface evaporites, or subsurface precipitates during impact-driven generation of the brecciated martian megaregolith. In *stage 2*, the rise of the Tharsis volcanic province and later arching of Syria Planum above a suspected plume increased both the regional heat flux and local topographic slope, loading the region with ash and lava flows and producing radial extension faults that may have penetrated through the regional cryosphere. In *stage 3*, layers of salts, ice, and basaltic debris within the regolith provided multiple detachments for the gravity spreading southeastward, possibly in response to further intrusion under Syria Planum. In addition, the aquifer below the cryosphere found outlets to the surface along the chasmata of Valles Marineris where the basal décollement cuts upward to intersect radial extension cracks projecting from Tharsis. This connection rapidly drained the extensive confined aquifer, which had substantial topographic head within the deforming zone. Drainage then carved the outflow channels

Radar imagery of the surface of Venus has outlined Venusian canali or outflow channels, as well as other associated volcanic deposits (Kargel et al. 1994). Most of these features resemble fluvial landforms much more than they resemble volcanic features on Earth and Mars. Yet surface temperatures on Venus are above 500 °C, and are well above that of the boiling point of water. Some of the canali show meandering habits, crevasse splays and other geomorphic features that are very similar to fluvial channels and flood plains here on Earth. Given the high temperatures on the Venusian surface, these feature must be related to lava landforms, yet they more closely resemble the water-carved outflow channels of Mars and the channelled scablands here on Earth. Likewise, the collapsed terrain at the sources of some Venusian channels resembles chaotic terrain at the meltwater sources of martian outflow channels. There are also Venusian lava deltas with shapes identical to bird's-foot deltas such as the Mississippi delta on Earth.

According to Kargel et al. (1994) these canali features suggest the involvement of an unusual lava and/or extraordinary eruption conditions, which they relate to a carbonatite lava rather than a silicate melt. Venusian nearsurface rocks may contain 4–19 % calcite and anhydrite, this is in part a reflection of the likelihood that Ca-bearing hydrous silicates are unstable on the surface of Venus due to widespread sulphatisation to anhydrite (Zolotov et al. 1997). Unlike silicate lavas, some carbonatites (including carbonate-sulphate-rich liquids) have a more fluid rheology (on earth, carbonatites

can have viscosities that are only 500 times that of water and tend to flow in water-like channels – canali. If these Venusian outflows are carbonatites, they would have a melting point that was only slightly greater than the Venusian surface temperature. Such lavas could flow great distances while retaining high fluidity, significant mechanical erosiveness, and a substantial capacity to transport and deposit entrained sediment.

Such mixtures of crustal salts would melt at temperatures a few tens to a few hundred Kelvins above the Venusian surface temperature; hence, melting may be induced by modest endo-genetic or impact heating (Kargel et al. (1994)). Salts on Venus may play many of the same geologic roles as water and ice do on Mars and Earth. A molten salt (carbonatite) "aquifer" may exist beneath a few hundred metres to several kilometres of solidified salt-rich "permafrost". In this way many geologic features on the Venusian surface can be explained by carbonatite magmatism and impact melting. They include: (1) impact melting of crustal salts to form crater outflows, (2) small, sustained eruptions from molten salt aquifers to create sapping valleys, (3) large, sustained eruptions that form canali and their flood plans, and (4) catastrophic outbursts forming outflow channels and chaotic terrain.

Further out in the solar system on the surface of Europa, a moon of Jupiter, and a celestial body much more distant from the Sun than Mars, there is an even more spectacular and unusual development of salts. Using infrared spectral analysis on images of the cracked and icy surface of Europa, McCord et al. (1998) and Kargel et al. (2000) identified spectra that are best interpreted as hydrated salts dominated by trona and epsomite, rather than clays or other alternate minerals. The salts characterise distorted spectral bands that are only observed in the optically darker areas of Europa. This includes regions along many of the lineaments that crisscross the icy surface.

According to the authors the spectra may represent "evaporite" deposits formed by water, rich in dissolved salts, that reached the surface from a water-rich layer underlying the ice crust. Whether the sub-ice ocean still exists is a matter of speculation. Such a salt precipitating mechanism visualises at-surface freeze drying of the salts. Salts are cryogenically precipitated from liquid water as it escapes via breaches and lineaments to flow and quickly freeze on the extremely cold Europan surface (−160 °C). Such a mechanism means these salts are "freeze-dried" and not true evaporites as defined in Chap. 1. But, as noted by McCord et al., if the spectra are truly those of hydrated salts escaping from a saline liquid ocean beneath the icy cap, then it offers exciting evidence for the possibility of extraterrestrial life on Europa. It suggests that there may be, or once was, active hydrothermal activity on Europa and that water rock interaction has created an ionic solution beneath the icy surface similar to that of the early Archaean bicarbonate ocean. It may well indicate hydrothermal vent conditions on a sub-ice ocean floor similar to those on earth when life first evolved in the early Archaean.

So far, all extraterrestrial evaporites we have discussed (solar or cryogenic) are carried as ions in a water solution; Barnes et al. (2011) and Cordier et al. (2013) note the possibility of a different solute carrier, namely liquid hydrocarbon on Titan. Titan is a moon of Saturn with a surface temperature of −179 °C (Fig. 2.83a). It is the only moon in the solar system with a substantial atmosphere, composed of 98.4 % nitrogen and the other 1.6 % is composed of methane, along with trace amounts of other gases. At that low temperature Titan hosts at-surface lakes of liquid hydrocarbon, mostly methane and ethane. There are other organic molecules in solution in the liquid methane, all derived from ultraviolet photolysis of methane and then carried to and across Titan's surface, dissolved in rain, surface and ground liquids (Fig. 2.83a, b).

The surface temperature is around 92°K and the temperature lapse rate through the troposphere was determined by the Voyager measurements (Fig. 2.83a). A temperature inversion occurs at an altitude of 50 km, allowing the stratospheric temperature to rise to 170° K (−103 °C). The small hydrocarbon molecule composition of the atmosphere, made up principally methane and extended hydrocarbons, is an effective short-wavelength shield with photochemistry inducing the formation of high-molecular-weight hydrocarbons known generally as'tholins'[4] (Fig. 2.83b). A cycle of heating and cooling with convection allows methane to reach its saturated vapour pressure at 1.5 bar to form clouds. The hydrocarbon hydrosphere, called the liposphere (from the Greek lipos meaning 'oil'), here completes the cycle, condensing into lakes and oceans of hydrocarbon, hydrocarbon snow and rain.

Organics in solution can precipitate out of lakes as evaporites when liquid methane pooled on the surface and a methane ocean passes back into the gaseous phase, which dominates in the atmosphere. According to Barnes et al. (2011) these methane lakes are the only known extraterrestrial indicators or an active extant "hydrological"[5] cycle. In the same vein, they note that darkening of Titan's surface

[4]Tholin [after the ancient Greek word θολός (tholós) meaning "not clear"] is a heteropolymer molecule formed by solar ultraviolet irradiation of simple organic compounds such as methane or ethane along with ethylene, acetylene an hydrogen cyanide. Tholins do not form naturally in our modern-day Earth atmosphere, due to the presence of oxygen, but are found in great abundance on the surface of icy bodies in the outer solar system. They usually have a reddish-brown appearance and on the early Archaean or even late Hadean earth may have been the first microbial food for heterotrophic microorganisms before autotrophy evolved.

[5]Barnes et al. (2011) use the word 'hydrological' to refer generally to 'volatilological', i.e., any substance on a planetary surface that undergoes processes physically similar to those of water in the Earth's hydrological cycle passing from a liquid to a gaseous state, and leaving behind solutes. In the case of Titan, the fluids passing from a liquid to a gaseous state are dominated by methane and ethane.

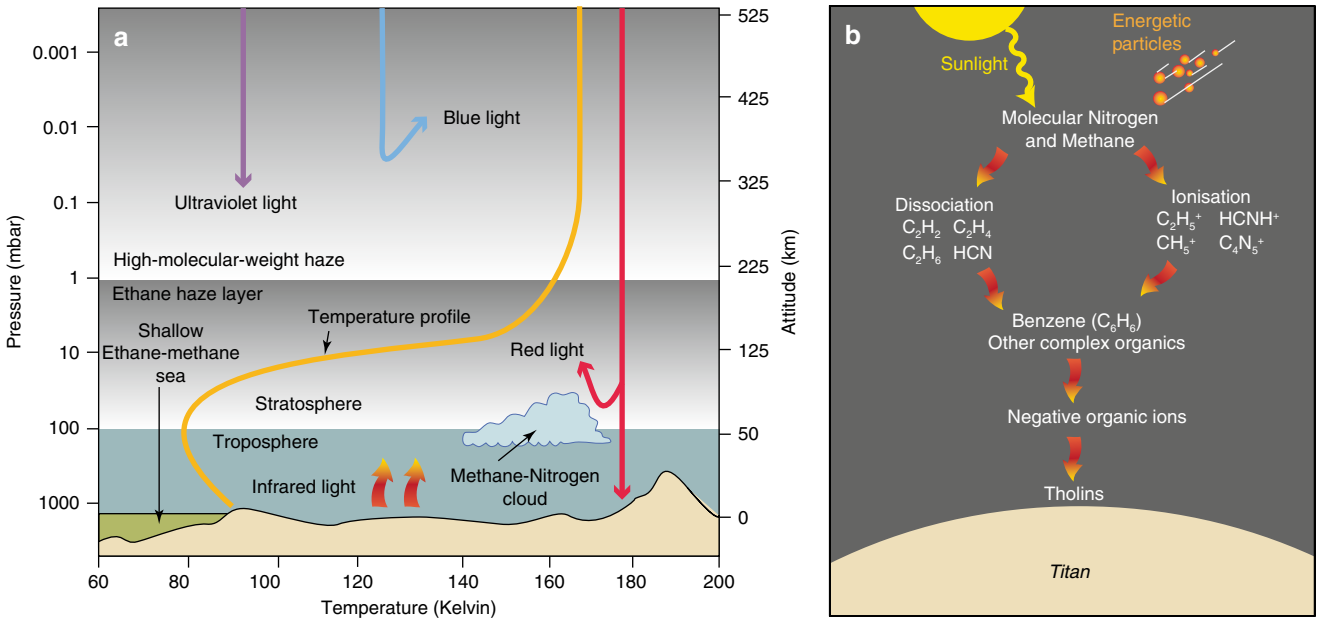

Fig. 2.83 Atmosphere of Titan, (**a**) Stratification and temperature profile. (**b**) Formation of tholins in the atmosphere of Titan (After Barnes et al. 2011)

occurs in the wake of large equatorial storms, empirically demonstrating that rain, composed mostly of liquid methane not water, reaches the surface of Titan. Other monitored surface changes shows that some hydrocarbon lakes appear and disappear with time. For example, near-infrared imaging reveals concentric deposits rimming the south-polar lake Ontario Lacus, much like the layered desiccation patterns found in arid-zone lakes on earth. Multiple images acquired years apart show that south-polar lake Ontario Lacus may be drying up right now. According to Barnes et al. this lake dessication process indicates the formation of evaporite deposits in the floors of dried hydrocarbon lake beds.

Methane and ethane that make up the lakes are nonpolar molecules, hence their solutes and the resulting evaporitic precipitates would be quite different from those of liquid water. Most of these evaporite candidates would be organics and probably be derived from species forming atmospheric haze particles. For example, McKay (1996) shows a solubility upper limit of tholin in liquid methane of 0.03 % by mass, making this a prime candidate for a Titan evaporite. Even this low level of solubility should produce detectable evaporitic deposits, if at least 10 m depth of methane solute were evaporated. Alternatively, more volatile species like CO_2 (McCord et al. 2008) or benzene (Clark et al. 2010), are other evaporite possibilities. Along with the evaporite lakes, vast dune fields are found near Titan's equator, shaped by strong winds blowing east to west. Unlike Earth's sand dunes, Titan's dunes are thought to be composed of organic material that has rained down from its smoggy photochemical skies.

Here on earth evaporites may have played a major role in the end-Cretaceous and end Permian extinction events (Brett 1992; Svensen et al. 2009). At the end of the Cretaceous a large asteroid collided with the earth to create the Chicxulub impact crater in Yucatan, Mexico. This region is underlain by widespread Jurassic anhydrites and their vaporization during the impact added a good deal to the ensuing climatic mayhem. Pope et al. (1994) calculated that $0.4–7.0 \times 10^{17}$ g of sulphur were vaporized by the impact into the anhydrites. A large portion of sulphur was released as SO_2, which, due to the rate-limiting oxidation of SO_2, very slowly converted to aerosol. Their radiative transfer calculations of the effects of this aerosol, when combined with rates of acid production, coagulation and diffusion, show that solar transmission was reduced to 10–20 % of normal for a period of 8–13 years. This reduction in solar transmission produced a climate forcing (cooling) of −300 Wm^2, so producing a decade of freezing and near-freezing temperatures.

The direct modelling of the results of shock vaporisation of anhydrite, when applied to the Chicxulub geology and using bolide diameters of 10 or 20 km across, yield volumes of 0.5×10^{17} g and 2×10^{17} g of degassed sulphur from the impact (Yang and Ahrens 1998). These results add further veracity to the models of Pope et al. (1994). Passage of these volumes of sulphur into the atmosphere (as SO_2 or SO_3) are sufficient to cause global cooling of 10 °C or more. A prolonged impact winter, with a major contribution from the degassing of evaporites, is a major contributing cause to the K/T extinctions.

The end Permian extinction, its tie with the Siberian traps and associated Permian and Cambrian evaporites and volatiles, is detailed in Chap. 16. And who said evaporite studies were esoteric?

Sabkhas, Saline Mudflats and Pans

3

Introduction

This chapter looks at Quaternary depositional styles depositing saline sediments in ephemeral saline waters, focusing on modern evaporitic mudflats (sabkhas) and saline pans. These two settings encompass that part of the hydrological spectrum dominated by capillary and ephemeral at-surface brine hydrologies. Climatically, these settings tend to occur in arid deserts (Köppen zone: BW) in both coastal and continental interior arid settings where saline groundwaters are found with a metre of the landsurface. A saline watertable may sometimes outcrop for a short period and precipitate a layer of pan evaporites with primary textures before drying up once more. With drying the brine surface sinks into the sediment to become a watertable and the evaporite system switches to capillary evaporation with secondary (very early diagenetic) sabkha salts forming in the sediment host. The other modern hydrological setting where salt beds tend to form is that typified by perennial subaqueous brine hydrologies (primary textures) in coastal and continental settings and this will be the focus of the next chapter.

The first sedimentological studies of sabkhas were in the Arabian (Persian) Gulf (e.g. Curtis et al. 1963), but similar arid-zone capillary salts were soon described in sediments along the coast of Baja California, Mexico (Phleger 1969; Shearman 1970), the coast of Sinai (Gavish 1974; Levy 1977a, b), and in various continental playas worldwide (Fig. 3.1; Table 3.1; Moiola and Glover 1965; Surdam and Wolfbauer 1975). Ancient sabkha successions are typically dominated by matrix, with capillary salts occupying less than 30–50 % of a stack of m-scale erosion-capped beds, that also contain biolaminites and microbial peats.

Often forming in depressions in the sabkha flats, modern saline pans accumulate as metre-scale stacked masses of salt crusts, typically retaining patches of chevron halite and variably overprinted by karst and capillary cements (Table 3.1). Ancient saline pans can stack into relatively pure beds of recrystallised halite with remnant patches preserving aligned chevrons, which are crosscut by syndepositional karst (Chap. 1). In contrast, perennial subaqueous sequences tend to be purer and thicker than sabkhas, dominated by remnants of bottom-nucleated textures and, compared to pans and sabkhas, the salt beds are cross cut by far fewer exposure surfaces.

In the minds of some geologists the recognition of anhydrite nodules is sufficient to classify a core or outcrop as a sabkha. The reality is more complex. For example, in the past 10 years the importance of subsurface diagenetic cements composed of anhydrite nodules within ancient evaporitic platform hosts has been increasingly recognised as indicative of a widespread mesogenetic process (Al-Helal et al. 2012). Such nodules grow poikilotopically and replacively in a burial setting, fed by dense surface brines sinking through restricted marine carbonates. Ensuing textures, when seen in limited exposures or core, are similar to the matrix-dominated nodular textures that typify sabkhas. It is likely that a significant proportion of subsurface successions, previously interpreted as ancient sabkhas, are actually stratabound zones of nodular anhydrite burial cements (Chap. 8). Hence, when making a sabkha interpretation, it is important to look beyond the presence of nodular anhydrite. One must also look at the vertical sequence, the presence of stacked erosion surfaces, lateral equivalents and the hydrological setting in order to make a reliable sabkha interpretation.

What Is a Sabkha?

Sabkha is a transliteration of the Arabic *sebkha* describing a salt flat. In the local terminology of the Arabian Gulf region it describes any area of extensive, barren, salt-encrusted, and periodically flooded, coastal or inland mudflats. Geological usage implies intrasediment evaporite growth beneath a flat geomorphic surface, with single-cycle bed thickness dictated by the vertical extent of the capillary fringe (Warren and Kendall 1985). Modern sabkhas in the Arabian Gulf (sabkhat is the correct form of the Arabic plural) are occasionally covered by ephemeral marine and continental floodwaters that, until recently, were thought to be the major suppliers of ions to underlying salts growing displacively in the sabkha matrix (*per descendum* – ions come from above). We know now that this is not the case and that deeply circulated resurging continental groundwater moving into the strandzone is the major supplier (*per ascendum* – ions come from below) of salts to most sabkhas and many saline pans. The mudflat surface is dry and subaerial for most of the time. It is held in place by capillary moisture, fed from a shallow saline water-table lying a few centimetres to a metre or two below the sediment surface.

Occasionally, the term sabkha is used in a narrow sense to describe anhydritic mudflat sediments deposited in a marine coastal or sea-margin sabkha, exemplified by the Arabian Gulf coastal sabkha. But when sabkha is used to imply "salt flat," it should include both coastal and continental sabkhas and encompass displacive growth of other intrasediment capillary salts like halite or glauberite as well as calcium sulphate. Some coastal sabkhas, such as those along the At Taf coastal strip (formerly known as the Trucial Coast), pass laterally in to continental sabkhas (e.g. Sabkha Matti) without any noticeable change in surface morphology (Kinsman 1969; Goodall et al. 2000). The seaward side of a modern coastal sabkha is characterized by a matrix of marine sediments, while the continental portion is characterised by non-marine sediments and continental groundwaters.

Sometimes, the term playa is used as a geological equivalent to continental sabkha. But, as used in the southwest USA, playa is a much wider ranging depositional descriptor than sabkha. In addition to the salt-crusted evaporitic mudflat (sabkha) a playa encompasses other related settings including, distal alluvial fans, sand flats, saline pans and dune fields as well as abandoned or desiccated shorelines[1]. Continental sabkhas may also be encompassed in local usage of other wider ranging terms such as; chott (northern Africa); vloer/pan (southern Africa), salt lake (Australia), rann (India); nor (Mongolia), takir (Russia), kavir (Iran), salar (Chile) and alkali flat/ salada/dry lake/playa (southwest USA). Terms in local usage may not necessarily identify geomorphologically and geologically identical features. Even the original usage of the term playa does not mean salt flat, rather its Spanish usage covers the terms beach, shore, strand or coast. Its usage first came across into English to describe abandoned beaches or strandlines that can be seen on the margins of many inland salt lakes and saline pans. Likewise the word chott comes via French from the Arabic shatt. As originally used in Tunisia, shatt/chott describes the halophyte-covered portion of a saltflat and contrasts with sabkha, which describe the vegetation-free portion of the saline flat. Using sabkha, playa or chott interchangeably is very poor usage of what is already a poorly defined set of terms (see Briere 2000).

In an attempt to clarify the geological usage of the term sabkha so it can be more easily applied to a particular vertical sequence in ancient evaporitic sediments, I define a sabkha as a ground-water driven sedimentary system indicated by syndepositional intrasediment capillary evaporites, which precipitate in both marine and continental saline mudflats (Warren and Kendall 1985; Warren 1989). The hydrology of precipitation, via capillary evaporation, is the same in both

[1] In the original Spanish, playa means beach or shoreline.

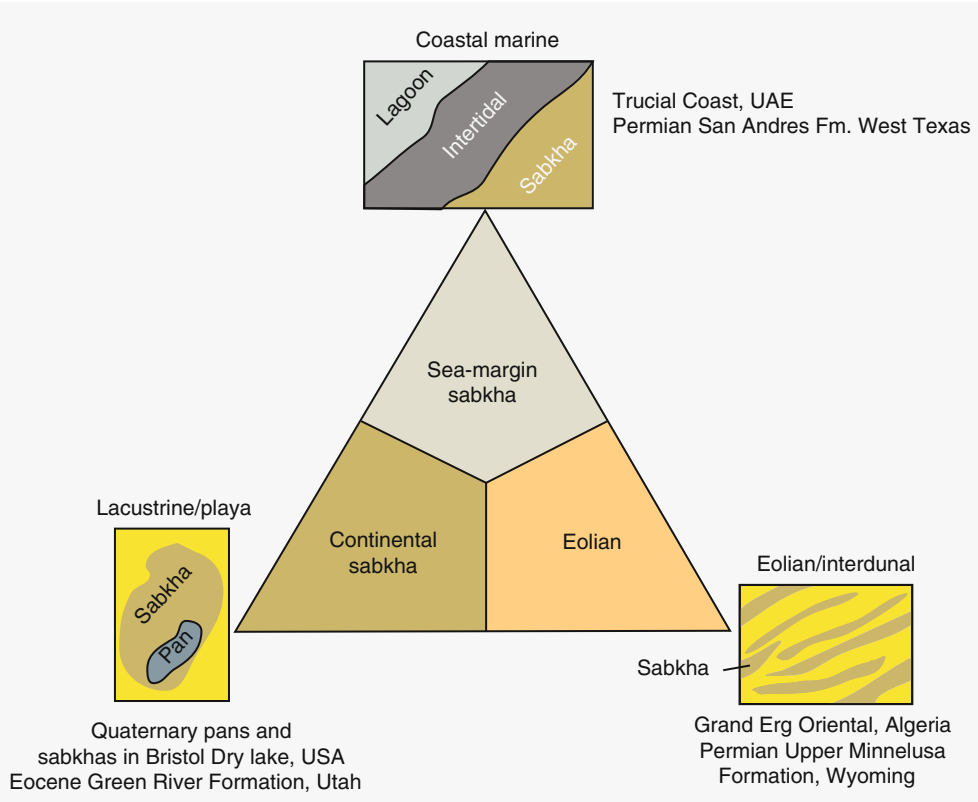

Fig. 3.2 Sabkha classification using regional depositional setting of the matrix material (Modified from Handford 1981a) – see Table 3.1 for examples

marine and continental settings. Even so, the matrix typically shows evidence of its marine or continental pedigree, as can the hydrogeochemistry of the pore waters (Table 3.1). In other words, sabkhas are hydrological settings where resurging groundwaters form displacive and replacive evaporite minerals (gypsum, anhydrite, halite, polyhalite, glauberite, etc.) in the capillary fringe above a saline watertable or in the brine-saturated muds immediately below. By this definition the sabkha sequence or cycle is capped by a deflationary surface, which defines the top of the capillary zone (Stokes surface). The whole capillary sequence is typically made up of more than 50 % non-evaporite matrix (Warren and Kendall 1985). Based on their work in the Qatar coastal sabkhat, and in agreement with the above definition, Jameson et al. (2009, 2010) state;… "A sabkha is a diagenetic overprint, not a depositional system."

The advantage of this definition is its utility in subsurface studies of ancient sediments where it can be applied using sedimentary textures in a single core; the surrounding depositional sequence does not need to be interpreted. The common thread is the growth of intrasediment salts in the capillary zone and in brine-saturated phreatic muds immediately below the watertable, with the whole succession capped by a syndepositional erosion surface. Sabkha hydrology controls the thickness of an evaporite unit, the style of intrasediment crystal (euhedral outlines to nodules) and most importantly generates the characteristic erosional or hydraulic "jack-up" surface that caps a sabkha cycle.

The host matrix, and associated sedimentary structures, in which sabkha salts grow by capillary evaporation, along with the underlying sediments, is the sedimentological basis of most sabkha classification (Fig. 3.2: Handford 1981a; Warren 1991). Matrix in modern and ancient sabkhas is deposited in varying hosts that may grade laterally into each other, namely;

- Marine coastal
- Fluvio-lacustrine
- Eolian

Dominance of one of the three matrix associations gives rise to sea-margin, continental, or eolian sabkhas. Modern coastal sabkhas typically contain gypsum or halite and less often anhydrite, likewise for many inland sabkhas, but these interior settings can also contain more unusual intrasediment salts such as; trona, borax or glauberite.

Marine Coastal Sabkhas

Modern sea-margin sabkhas form as narrow belts along many coastal arid to semi-arid deserts including; the western and southern coasts of the Arabian Gulf, the coast of western and southern Australia, Northern Africa, and the Sinai (Table 3.1; Fig. 3.1). The most complete documentation of modern marine-carbonate sabkhas centres on the southern

coast of the Arabian Gulf (aka Persian Gulf[2]) in the emirate of Abu Dhabi, while siliciclastic sabkhas typify the Saudi Arabian coast between Qatar and Kuwait, and fluvio-deltaic coastal sabkhas are forming atop the Shatt al Arab delta at the northwestern end of the Gulf. Elevated pore water salinities along the various BWh coasts of the Arabian Gulf (aka Persian Gulf), reflect a combination of; frequent winds (mostly blowing from between 315° and 15° – the Shamal), high temperatures (up to 45–50 °C), low precipitation (typically less than 5 cm a year), low fluviatile input (except for the Tigris, Euphrates and Karun rivers in the extreme north of the Gulf) and the restricted silled connection via the Strait of Hormuz between the saline waters of the Arabian Gulf and the normal salinity waters of the Gulf of Oman and the Indian Ocean.

Physiographically, the Arabian Gulf is an almost enclosed sub-rectangular basin that trends northwest-southeast; it is approximately 850 km in length, with a maximum width of 330 km (Fig. 3.3a; Wyn Hughes 1997; Evans 1995, 2010). The basin floor is markedly asymmetrical, forming a ramp that dips gently (35 cm per km) away from the tectonically stable Arabian side (typical depths of 20–40 m), and more steeply (175 cm per km) away from the tectonically active Iranian side (depths of 40 to nearly 100 m). The greatest water depth (100 m) is reached near the entrance to the Gulf at the Straits of Hormuz.

In terms of its regional tectonic setting, the Arabian Gulf is an epicontinental sea within a foreland basin, located between the geologically stable, low-lying, Precambrian Arabian Shield and the high, geologically unstable Tertiary foldbelt of the Zagros Mountains of Iran. The foldbelt is a compressional suture, active since the Early Miocene along the Zagros Thrust Zone and driven by the subduction of the Arabian Plate beneath the Eurasian Plate (Wyn Hughes 1997). The Gulf's bathymetric asymmetry comes from Pliocene to Quaternary tectonic loading on the Iranian side, and tilting of the Arabian Peninsula in the Neogene, during the opening of the Red Sea. The southeastern part of the Arabian Gulf is a very gently sloping ramp. The Qatar Peninsula forms a distinct feature on the near-linear Arabian coastline, and causes anomalous trends in current direction, and possibly of sedimentation, along the southeastern Gulf.

Ramp carbonates, including sabkhas, define the coast along much of the cratonic southern side of the Gulf, while the northern coast is dominated by more-steeply dipping siliciclastic alluvial aprons, passing landward and northward into the Zagros Mountains (Fig. 3.3a). Moving south from the deepest Gulf floor, the bottom changes from deepwater micrites through grainstones and reefs of the Great Pearl Bank into reworked dune and eolianite barrier shorelines into the coastal carbonate sabkhat (the shorelines of the Emirates, Qatar and Saudi Arabia).

Entry of siliciclastic sediment to the present Arabian Gulf is mostly longitudinal via the Shatt Al Arab delta at the northwestern end of the Gulf. The Shatt Al Arab is the confluence of the Tigris, the Euphrates and the Karun rivers. It has constructed a huge wedge of fluviodeltaic sediments, with thin patchy sabkha capstones landward of the shoreline (coasts of Iraq and Kuwait). Siliciclastics enter also from wadis along the northeastern side of the Gulf and from encroaching dunes along parts of the Saudi coast. Eolian transport is driven by the northwesterly Shamal winds (*shamal* is Arabic for northerly) and carries both siliciclastic and carbonate fines well out into gulf waters. Interestingly, detrital dolomite rhombs make up around 15 % of the non-clay component of modern bottom sediments in the northern Arabian Gulf and up to 60 % of the 30–125 μm fraction (Al-Bakri et al. 1984). Morphologically they are near identical to the authigenic sabkha dolomite rhombs that first caused so much interest in sabkhas in the Emirates in the 1960s.

Geologically the Arabian Gulf is unique as it is the only modern example of a modern shallow inland sea in which widespread ramp carbonates are accumulating. This is attributed to its low latitudinal position and relatively clear waters, the result of low terrigenous input, making much of the seafloor suitable to a tropical carbonate-secreting biota (Wyn Hughes 1997). The depth to the base of the photic zone is around 20 m in turbid waters above the muddy sediments along the Abu Dhabi coastline, but increases to 30 m in the clearer deeper waters in the axial parts of the seaway.

Although the Gulf floor is a marine carbonate setting today, 20 ka when sealevel was 120 m below its present level, the whole Gulf was a desiccated basin with active eolian dunes covering much of what is the present seafloor. The Pleistocene-Holocene (Flandrian) transgression covered and reworked much of this dune sand as the gulf waters returned to the present coastline some 7–10 ka. Much of the Holocene marine carbonate section in the southern Gulf is now underlain by these eolian siliciclastics.

Carbonate-Hosted Coastal Sabkhas in the Southern Arabian Gulf

The Arabian Gulf sabkha, centred on Abu Dhabi city, is the eastern part of a sabkha belt known as Sabkhat as Salamíyah that extends along the coast of the United Arab Emirates between Yas Island and Ras Ghanada (Figs. 3.3b and 3.4). Further west, adjoining the eastern base of the Qatar

[2]On almost all maps printed before 1960, and in most modern international treaties, documents and maps, this body of water is known as the "Persian Gulf". This follows similar usage of Persian Gulf by the ancient Greek geographers, Strabo and Ptolemy, who in contrast, used Arabian Gulf to the refer to the Red Sea. With the rise of pan-Arabism and Arab nationalism, the name Arabian Gulf, not the Persian Gulf, become predominant in many Arab countries, initially as an expression of anti-American feeling in the Arab world, because until 1979 and the Iranian Revolution, America supported the of Shah of Iran. Since 1980, the term Arabian Gulf, is increasingly used by many Sunni-dominated Arab Gulf states to counter the rising power of the theocratic (Shia-dominated) Iranian (Persian) Republic.

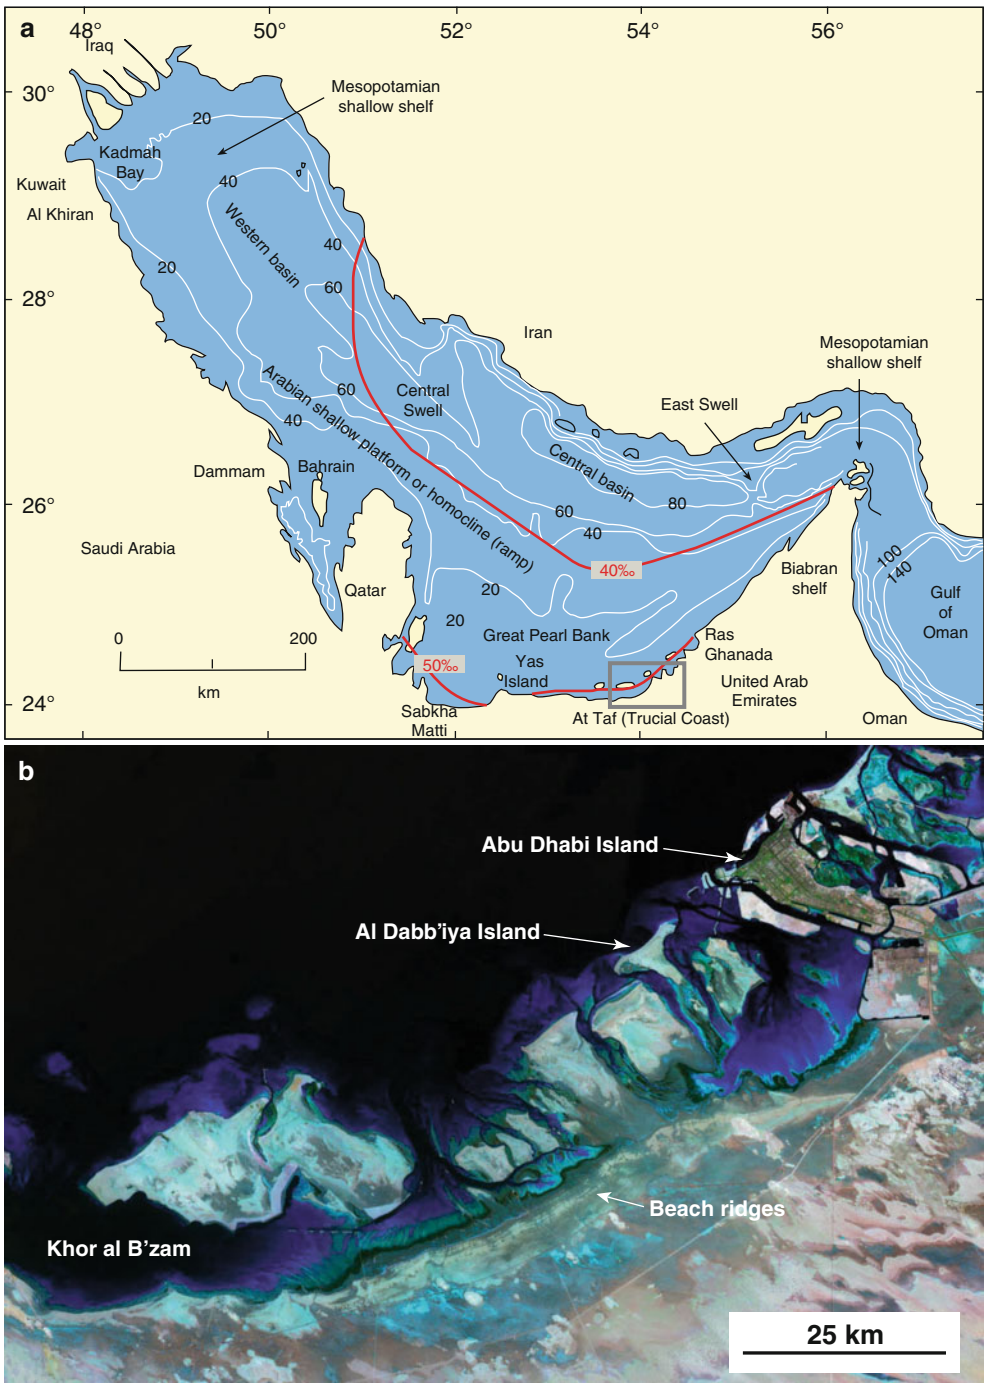

Fig. 3.3 Sabkhas of the Arabian (Persian) Gulf. (**a**) Physiography (m) and salinity (‰) in the Arabian Gulf (After Purser 1973a; Evans 1995; Wyn Hughes 1997). (**b**) General sediment distribution of the Trucial Coast of the United Arab Emirates from the entrance to the Khor al B'azm Lagoon to Abu Dhabi Island, showing the shallow water areas of the lagoon and the oolitic ebb-tidal deltas on the seaward side of the tidal channels between the islands (see Fig. 3.4). The intertidal zone, defined by intertidal algal mats, is clearly visible as zones of dark-coloured sediment. Landward of the intertidal zone is the supratidal zone of the sabkha, which in turn passes into dune sands across the mesa that defines the erosional edge of the Miocene plateau (Landsat image courtesy of NASA)

peninsula is Sabkha Matti, one of the largest tectonically-induced sabkha depressions in the region (see eolian sabkhas). The sabkha-dominated At Taf coastal strip is approximately 320 km (200 miles) long and the coastal sabkha belt is up to 24 km (15 miles) wide; on average it has prograded 1.5 km (1 mile) every 1,000 years. Seaward slopes on the sabkha are low and range from 1:3,000 to 1:4,000, this means whenever water a few centimetres deep arrives on the sabkha, the strandline on the brine sheet will have migrated kilometres.

It was the occurrence of modern nodular anhydrite and dolomite in the sabkhas of Abu Dhabi and Qatar that first attracted the attention of the geological community during the 1960s. The work of Curtis et al. (1963), Illing et al. (1965), Evans et al. (1969), Kinsman (1969), Shearman (1963), Butler (1966, 1969, 1970), and Kendall and Skipwith (1969a, b) provided observational data on which most of our current sabkha models are based. Field-work since the 1960s tended to consider specific sedimentological problems within the sabkha setting, such as hydrological zonation (Patterson 1972; Hsu and Schneider 1973; McKenzie et al. 1980; Patterson and Kinsman 1981), the origin of dolomite (McKenzie 1981; Patterson and Kinsman 1982; Bontognali et al. 2012), or it has reinforced the facies model of earlier

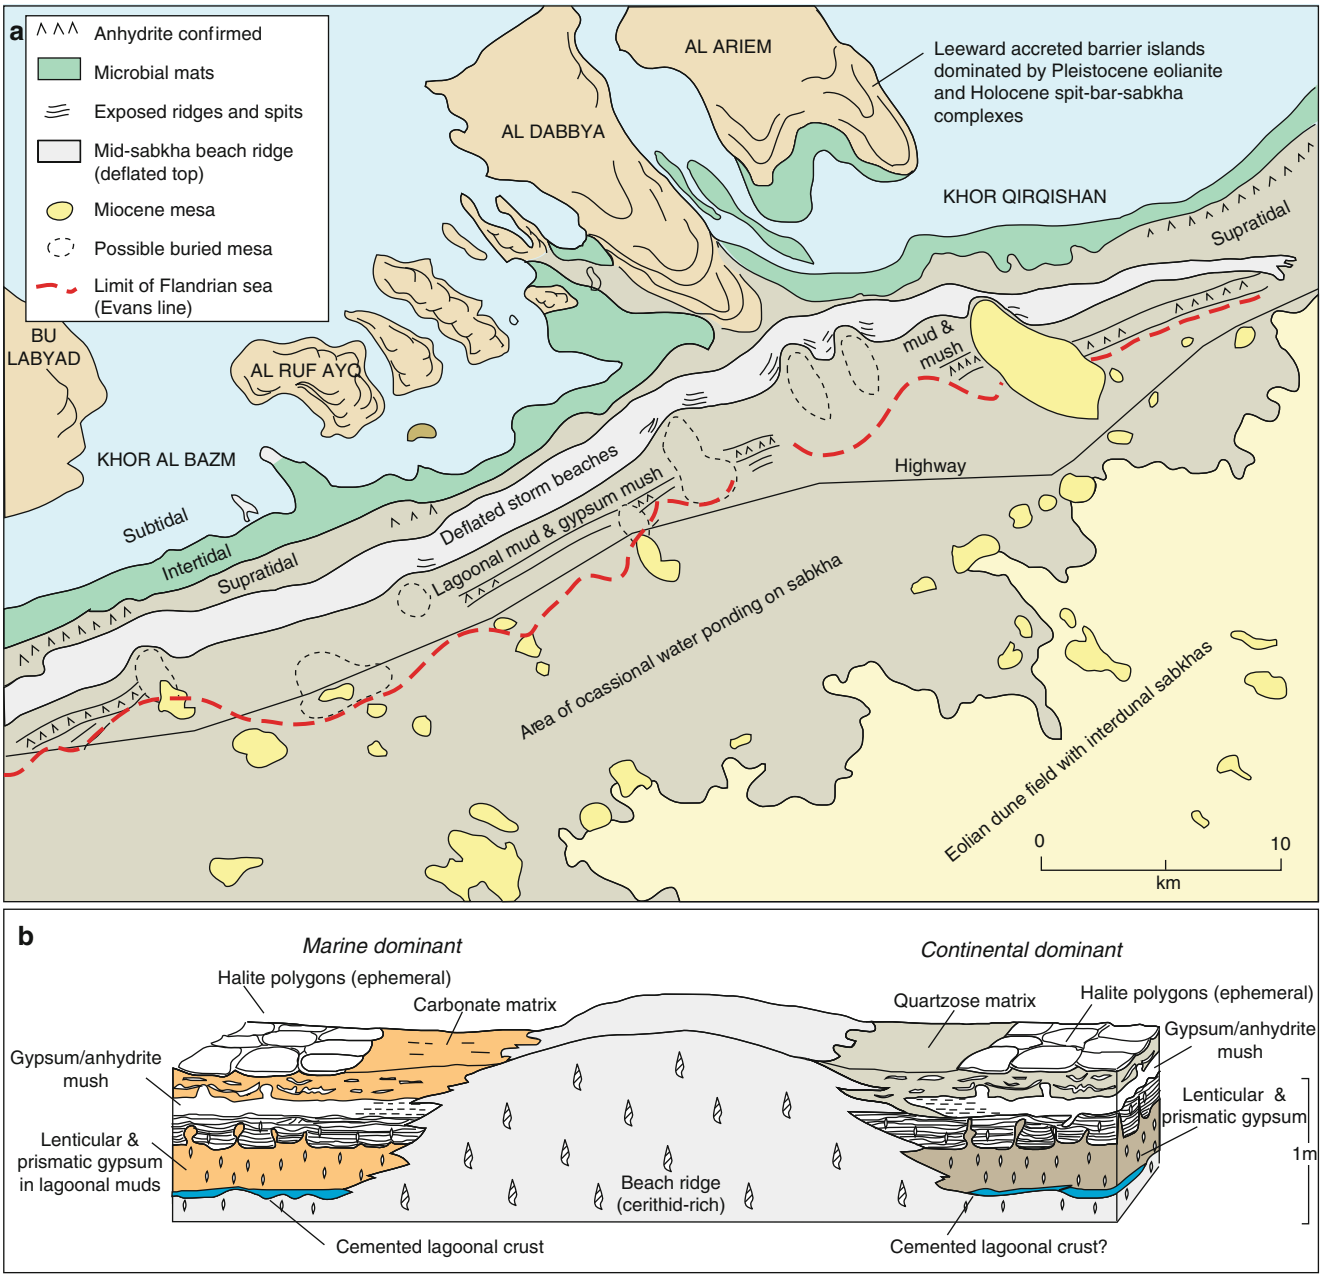

Fig. 3.4 Abu Dhabi sabkha. (**a**) Sabkha facies located to the west of Abu Dhabi showing beach ridges encased in sabkha sediment in the vicinity of Bu Labyad – Al Du'yybaya (After Kirkham 1997). (**b**) Sabkha cross section based on facies present in the vicinity of the beach ridges south of Al Du'yybaya Peninsula and the Mussafah Channel wall (After Warren and Kendall 1985)

workers (Bush 1973; Butler et al. 1982; Kendall and Warren 1988). More recently, Lokier and Steuber (2008, 2009), Lokier (2012) have looked at various polygonal features in the intertidal and supratidal zones. Excellent reviews of the relevant Gulf literature, and some new insights, are given in review papers by Strohmenger et al. 2011; Alsharhan and Kendall (2003), Kirkham (2011), Riegl et al. (2010) and Evans (1995, 2010). Over the past decade or so, the most significant addition to this substantial knowledge base is a drastic revision of our understanding of the dynamics of sabkha hydrology by Wood et al. 2002. It changes our understanding of evaporite capillary salts from one of marine-derived floodwaters to one of solutes precipitated in a Holocene marine matrix, but sourced from resurging basinal waters.

To understand sabkha deposition requires an understanding of the climatic and hydrological factors that create conditions suitable for sabkha progradation into the southern Gulf. The Arabian Gulf is the warmest sea in the world and, like the Red Sea, lies within the most laterally extensive

BWh climate belt in the world (Figs. 2.3 and 3.1). Surface temperatures in the open Gulf range from 20 °C in February to 34 °C in August, with an annual average around 29 °C in waters located offshore from Abu Dhabi. Water temperatures on the open platform in the vicinity of Abu Dhabi Island range from 23 to 34 °C and from 15 to 40 °C in the inner lagoon. Shallow waters in the lagoon can experience daily changes of 10 °C. Air temperatures on the adjacent mudflat can be as low as 5 °C in the winter and as high as 50 °C in summer, with average temperatures ranging from 23 to 33 °C. Sediment surface temperatures on the sabkha are even more variable, with reported values up to 60–80 °C atop dark-coloured microbial mats (Kinsman 1965). Temperatures a few centimetres below the sabkha surface range from 22 to 40 °C. In summer, the sabkha is extremely humid, especially at night, when the humidity reaches 100 %. Salinities in the open Gulf are 3–4‰ above normal open marine salinities. Where coastal islands restrict exchange with the open Gulf, as in the vicinity of Abu Dhabi Island, lagoon salinities range between 54 and 67‰, near double that of the open ocean.

Prevailing onshore winds influence evaporation levels on mud-flats along the southern coast of the Arabian Gulf. In winter the intensity of the onshore winds increases as the Shamal blows seawater and sediment from the lagoon onto the mudflat. At other times offshore winds blow continental dune sand into the back-side of the sabkha. Winter Shamals occur from November through March and tend to follow cold fronts (Riegl et al. 2010). Shamals tend to set in with great abruptness and force, often with wind speeds of 40–50 km/h and gusts up to 100 km/h. Both summer and winter Shamals are known, those in summer being less powerful. This dominant northwest to southeast airflow is a result of orography. Sharply rising mountains lie to the east and north of the Gulf, while gently rising mountains lie to the west and southwest effectively funnelling the low-level airflow. Alsharhan and Kendall (2003) consider the Shamal to be a equally important sedimentological drivers in southern Gulf sedimentation to the Caribbean hurricanes on the Bahamian platform.

The sabkha is furnished with matrix sediment from two sources, carbonates from the lagoon and siliciclastics from the hinterland. Many earlier sabkha models tended to ignore the eolian input, yet some areas of the mainland side of the Abu Dhabi sabkha (e.g. Al Du'yybaya sabkha) have quartz silt and sand as the major matrix material and it is the dominant unconfined aquifer supplying meteoric water to the coastal plain. Rainfall along the sabkha coast averages 70 mm/year and is very irregular, in some years no rainfall is recorded. In the 6-year period from 1958 to 1964 the highest annual reading on the sabkha was 6.73 cm, the lowest 0.33 cm. When rain does fall it can be torrential. Bottomley (1996) notes that in the last 30 years there was at least one 24 h period when more than 200 mm of rain fell on the sabkha. Although infrequent, such desert rains can be torrential, especially in coastal sabkhas near the foot of the Oman Mountains, such as at Rams, where flooded wadis typically carry continental sediments as sheet floods many kilometres into the sabkha (Warren 1991). Rain floodwaters can sometimes cover portions of the sabkha for 1–3 months and so dissolve and recycle surface and nearsurface halite/bittern crusts, as occurred in late 2003 and 2009.

Physiographically, the Abu Dhabi and other sabkhas in the Gulf are characterized by billiard table flatness, a direct reflection of control by capillary wicking, fed from the underlying watertable. The sabkha surface is a Stokes surface (Fig. 3.5a). In general, the watertable control to any sabkha gives them one of the most levelled forms of any arid landscape feature. Below this flat surface the Abu Dhabi sabkha preserves an evaporitic mixed-carbonate-siliciclastic stratigraphy (Evans et al. 1969; Kinsman 1969; Kirkham 1997). Deposition began some 7,000 years ago when a rapid transgression flooded interdunal (eolianite) depressions with a veneer of marine-reworked, predominantly quartzose sediments. About 4,000 years ago the Arabian Gulf shoreline reached its maximum Holocene strandline and the edge of this flooding event is defined by a line of well preserved beach-ridge sediment sometimes called the "Evans line" (Strohmenger et al. 2011) This was followed by pulsed progradation of the sabkha sequence to its present configuration.

Abu Dhabi Facies Associations

The peritidal belt that defines the Abu Dhabi sabkha is divided into three: subtidal, intertidal, and supratidal (Fig. 3.4a). Tidal range is 2–2.5 m along the seaward side of the islands of the southern Gulf, but it can be as little as 1 m in the more restricted lagoonal areas, which are locally known as khors. As the strandzone progrades, the peritidal belts of the lagoon, cyanobacterial mat and sabkha, all located landward of the present barrier island belt, are stacked one atop the other to create an archetypal shallowing-upward sabkha cycle. We will discuss each peritidal belt in detail, but first let's look at a largely ignored part of the southern Arabian Gulf peritidal trilogy, the island shoal and bank facies. This is the unit that protects the muddy lagoons in the vicinity of Abu Dhabi and allows the various coastal sabkhas to form. Facies belts basinward of the island shoal are classic carbonate ramp sediments, while peritidal sediments landward of the island shoal make up the sabkha association.

Island Shoal and Bank Facies

Cemented coastal-beach-dune barriers form the core of a belt of northeast trending carbonate islands that are the easternmost extent of the "Great Pearl Bank" (Wyn Hughes

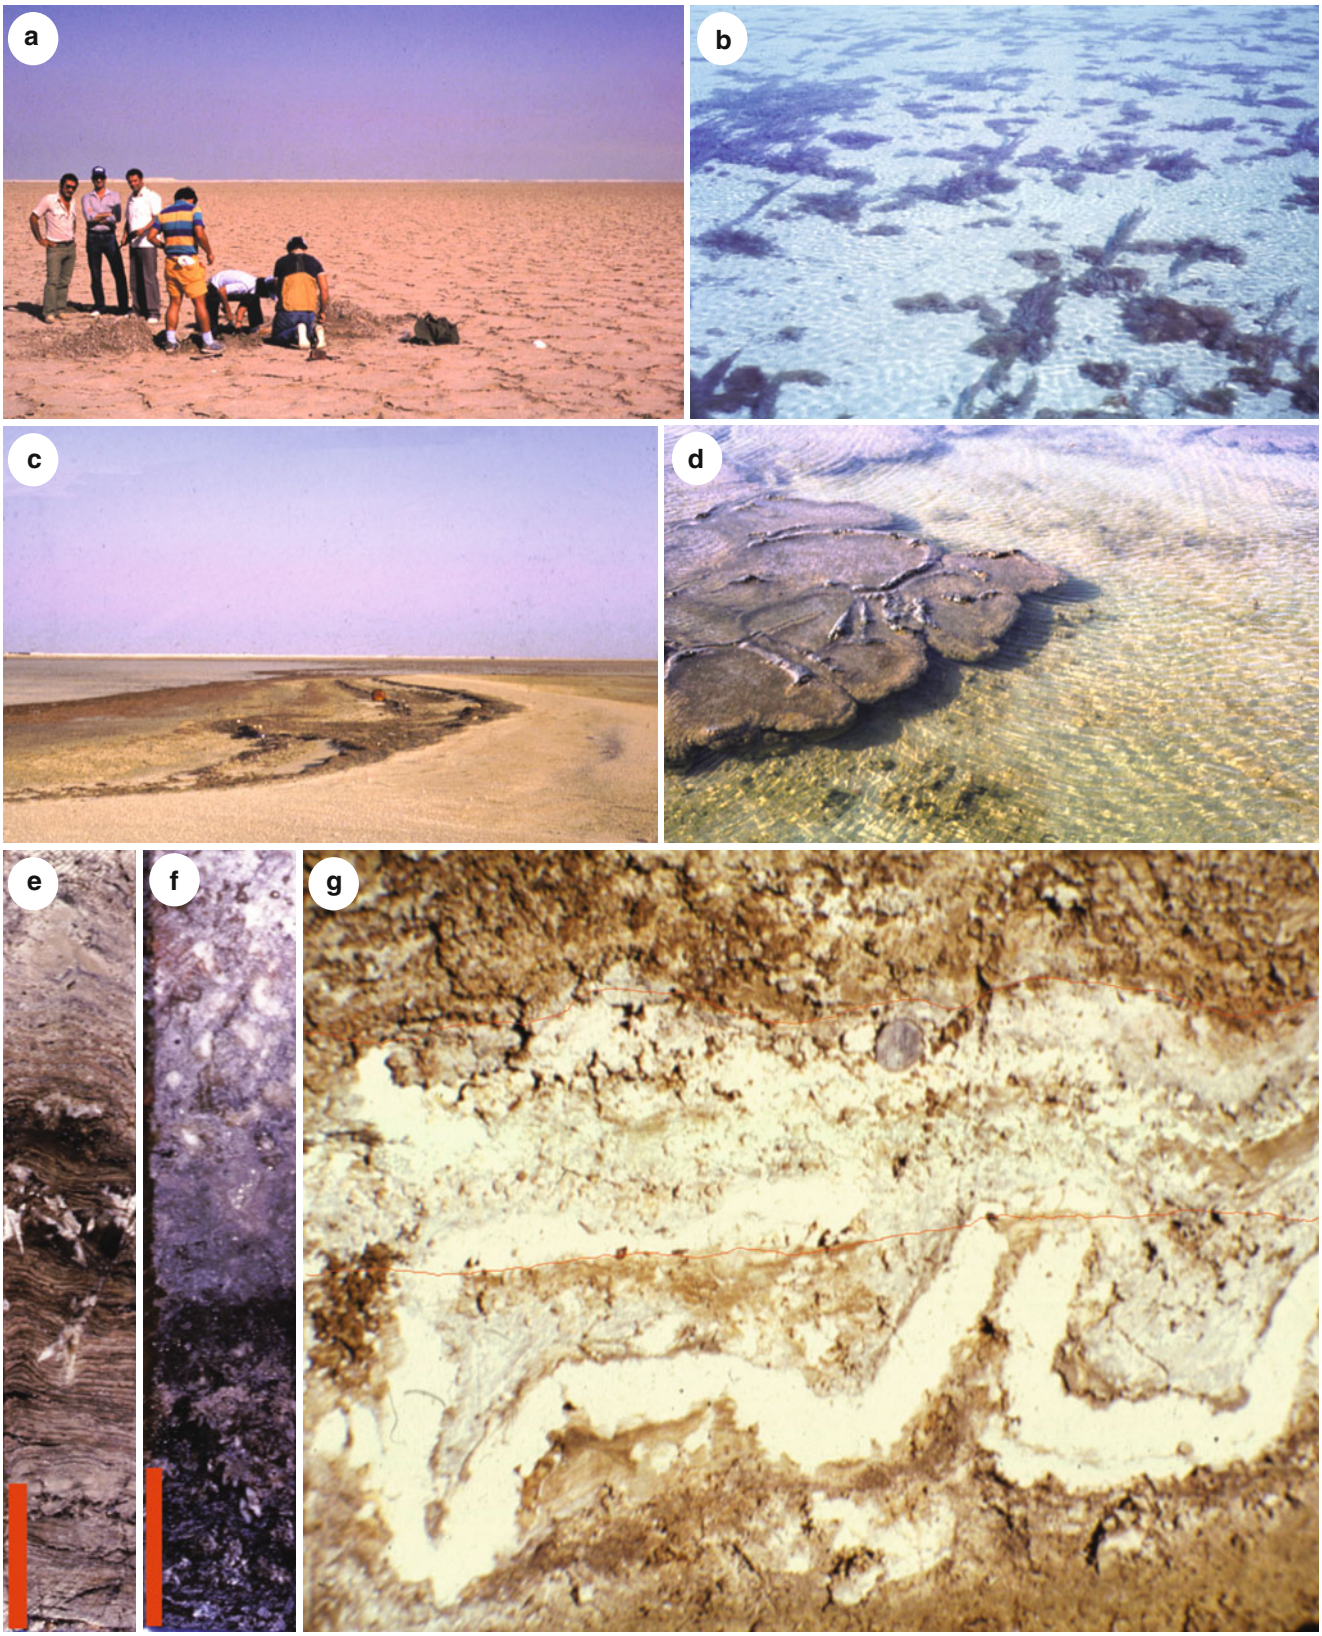

Fig. 3.5 Arabian Gulf sabkha, Abu Dhabi. (**a**) Sabkha surface covered in an ephemeral halite crust; (**b**) Lagoonal sediments of Khor Al B'azm showing peloidal grainstones and packstones with growing clumps of brown algae covered with calcareous epibionts (photo courtesy of Xris Kendall); (**c**) Cuspate, laterally accreting beach ridge on seaward side of Al Du'yybaya sabkha, Abu Dhabi; (**d**) Truncated and grazed edge of laminated polygonal mat at the edge of a tidal pool, southern Khor Al B'azm; (**e**) Core of laminated mat with displacive euhedral gypsum and an overlying unit of supratidal gypsum and anhydrite, sabkha south east of Abu Dhabi City (scale bar = 5 cm); (**f**) Core of cyanobacterial peat (?pustular mat) with lenticular gypsum and an overlying unit of supratidal gypsum and anhydrite, sabkha south east of Abu Dhabi City (scale bar = 5 cm); (**g**) Nodular and enterolithic anhydrite with obvious truncation surface preserved in middle of unit, Al Du'yybaya sabkha

1997). These barriers enclose lagoons or tidal estuarine sequences and in places may directly abut the mainland (Warren 1991). Most of the islands are eolianite-cored shoals, composed of varying proportions of Holocene and Pleistocene ooids, along with skeletal and quartz sands (Teller et al. 2000). Island cores are stationary, fixed in place by carbonate cements, and are separated by active tidal channels up to several kilometres wide and 7–10 m deep (Figs. 3.3b and 3.4a; Purser and Evans 1973; Loreau and Purser 1973). Further up the Gulf coast on the Qatar Peninsula and along parts of the Saudi coast their place is taken by marine-reworked quartzose eolian dune sand shoals, which still have counterparts building directly into the Gulf (see later discussion of eolian sabkhas for details). The coastal barriers and spits along the At Taf coastal strip, which form the depositional frame for the Holocene sabkha, formed in the late Pleistocene via carbonate accretion atop reworked eolian quartzarenites as the desert dunes were inundated during the final phase of Flandrian rise (Purser and Evans 1973; Kirkham 1998; Teller et al. 2000). Up to 9 m of Pleistocene eolian material and 2.7 m of Holocene carbonates overlie Miocene marine carbonates in the vicinity of Abu Dhabi city (Butler et al. 1982). Miocene strata also form mesas and outliers on the landward side of the sabkha (Fig. 3.4a).

Holocene vadose and phreatic cements stabilised the transgressive island shoals at the position of the Pleistocene-Holocene stillstand. Previously, the coastal dune/shoreface had migrated landward in front of the rising late Pleistocene sea. The early Holocene stillstand, in combination with cementation meant the islands evolved into wave-resistive structures fronted by coralgal reefs. This in turn preserved a barrier lagoon, even in the early Holocene when wave-resistive reefs had yet to grow on the seaward side of the now stationary barrier islands. Cemented sands formed a stable substrate for subsequent coralgal reefs and today maintain a relatively fixed focusing grid for wave, longshore and tidal currents.

Island stability in turn maintains the position of numerous active tidal channels as fixed breaches in the cemented eolianite topography. Tidal channels between the islands allow exchange of seawater with the more saline waters of the inner lagoon. The longterm stability of the island shoal facies explains the formation of thick ooid ebb-tidal delta sands on the seaward ends of many channels along the Abu Dhabi coast. Where these ooid sands accumulate above sealevel they are blown into Holocene coastal eolianites, adding volume to the island shoal sediment pile (Fig. 3.3b). If the islands were not cemented stationary structures, then tidal channels and islands would migrate laterally, ebb sands would spread out as much thinner accumulations and form barrier geometries more akin to classic "drumstick" tidal deltas in mesotidal barrier coasts.

Subtidal Facies

Subtidal sedimentation along the Abu Dhabi coastline can be divided into sediments accumulating seaward of the island shoal facies and sediments in the lagoon (Evans 1995):

1. *Open marine sedimentation* occurs along the seaward side of the northeast trending barrier island coast and has largely buried the underlying Pleistocene eolianites and seif dunes (Fig. 3.4a). Seaward terminations of shallow channels draining the lagoon are flanked by tidal ebb deltas composed of oolitic sand. These Holocene lobes form lens-shaped bodies 2–10 km wide and 1–5 m thick. They occur in wave- and tide-agitated areas where ooids are piled into shoals by opposing onshore waves and offshore ebb-tidal currents. The ooid sands (ooid grainstones) are fashioned into various bedforms including break point bars, along with large and small-scale ripples. Skeletal fragments in the shoals indicate a limited macrofauna of molluscs, echinoids and burrowing crustaceans. Broken fragments of this fauna typically form the core or nuclei to individual ooids.

The Gulf lacks many of the algal sediment producers that are found in the Atlantic and Indo-Pacific (like *Halimeda*, *Penicillus*, etc.). Red algae can occur as encrusters primarily associated with other calcareous substrata, such as reef corals, or they can occur in more or less dense growths by themselves (Riegl et al. 2010).

Within the ooid sand pile that define tidal deltas on the seaward end of inter-island channels feeding the lagoons, typical ooid grain size and cortex thickness decreases away from the channel levees. Cemented crusts (aragonite and Mg-calcite) and crust fragments can also be found in the sand pile, much in the same way they occur in the less active portions of Bahamian ooid shoals (Lokier and Steuber 2009). At a water depth of about 2 m on the spillover front of the Abu Dhabi ooid shoals there is an abrupt change into mixed ooid-bioclastic grainstones/packstones. Storms and the wind drive ooid sands onto the island shoal belt and so continue to supply sediment to the barrier islands. High eolian dunes form where active ebb tidal deltas are building out onto the cemented island core. Bedding in these parabolic dunes is inclined landward and retains continental indicators such as occasional rhizoconcretions and insect burrows.

Patch reefs are growing immediately seaward of the Pleistocene-cored islands (island shoal facies) in areas between the ooid shoals. Reefs also extend landward along the sides of some of the more stable open-marine tidal channels, but do not extend far into the more restricted sections of the lagoon. There the waters quickly become too saline for the stenohaline components of the reef to remain healthy (Kinsman 1969) especially during intense temperature and salinity variations induced by Shamal storms (Fig. 3.6; Riegl 2003). Shinn (1976) attributed massive coral die-back in the southern Gulf (Qatar) to a severe Shamal, which caused cooling to 4 °C at sea surface and to 14.1 °C at 18 m

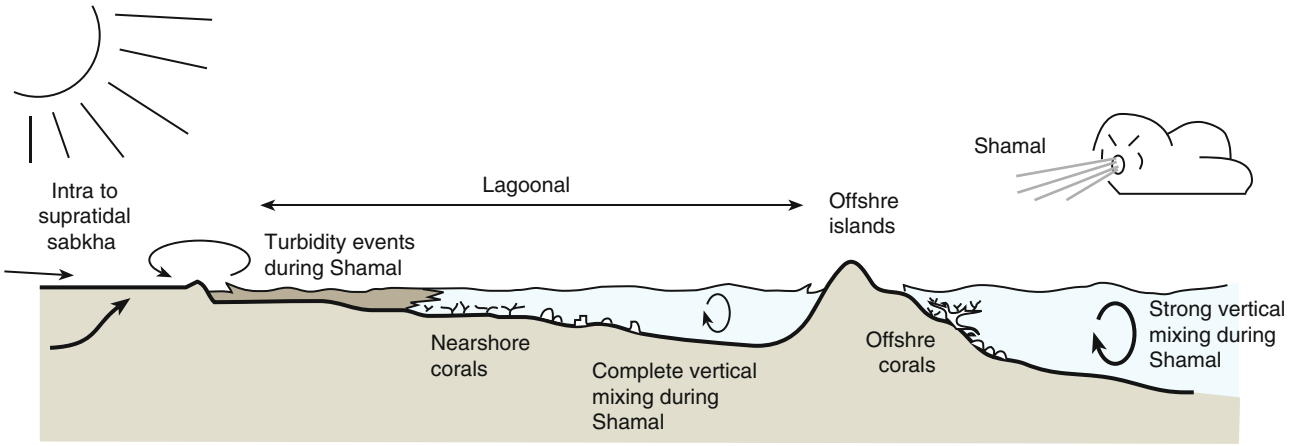

Fig. 3.6 Schematic of hydrodynamics in the near offshore and lagoon/sabkha of the southern Arabian Gulf (After Riegl 2003)

depth. Shamals may generate storm seas of up to 6 m wave height (65 kph winds), driving erosion, turbidity and complete vertical mixing of lagoon waters and partial mixing offshore. Clearly, rapid cooling by Shamals, sometimes coupled with extremely low tides, amplified by negative storm surge, are a significant stress factor causing repeated coral mortality and bleaching throughout the southern Arabian Gulf (Riegl 2003).

Accordingly, when compared to reefs of the open Indian Ocean, the coral fauna of the southern Gulf, even on the open marine side of the islands of the Emirates, is somewhat sparse and restricted but is well adapted to recovery from bleaching events (Burt et al. 2011). Southern Gulf reefs are dominated by genera of *Porites* and *Acropora* along with *Platygyra*, *Cyphastrea*, and *Stylophora, while* binders are dominated by coralline algae (*Lithothamnion*, *Lithophyllum,* and *Goniolithon*.). Regionally, the open marine reefs are dominated by extensive *Acropora* thickets that often extend over many km^2, with a mixed understory assemblage mainly made up of poritids, faviids, siderastreids, and dendrophyliids. In areas of elevated salinity (>45‰), typically in lagoonal habitats, Acropora gives way to Porites dominance.

This is a response to temperature and salinity stresses inherent to the restricted Shamal-prone lagoonal waters of the Arabian Gulf. Salinity and turbidity oscillations mean many of the corals growing along the sides of tidal channels feeding the lagoons appear unhealthy and at times are covered by flourishing coats of green algae, which do better in elevated salinities. Like *Acropora*, echinoids die out in the lagoons although asteroids, and more particularly ophuroids are more salinity tolerant and extend much further into the lagoons.

Seaward of the coral-fronted islands is a broad gently sloping Holocene platform covered by skeletal sands, which pass offshore into progressively deeper and finer-grained carbonate silts and muds of the Gulf centre. This sloping profile is one of our better modern analogs for ancient carbonate ramps (Evans 1995), while the Great Pearl Bank makes and excellent Holocene analogue for Cretaceous rudistid buildups (Wyn Hughes 1997).

2. *Restricted marine (khor) sedimentation* takes place along the landward side of the barrier islands in areas dominated by lagoon and sabkha sediments (Fig. 3.5b). The tidal inlets and khors (*khawrs*) are unique subtidal settings formed behind the grainstones of the island shoals and constitute the protected seaward edge of many sabkhas. They vary in shape and size from large elongate lagoons such as Khor al B'azm and Khor al Baghi (behind Abu Dhabi Island) to the estuarine inlets of Umm Al Qwayn (Warren 1991). Most channels are dendritic (tidal) and lack any permanent surface freshwater inflow on the updip side (Warren 1991). The exceptions are those khors located close to the mountains near the Straits of Hormuz, which can be periodically flushed by meteoric runoff. Today many khors in the Emirates are dredged to form accessible waterways and sheltered harbours. Some deepened channels can now accommodate large dhows and other seagoing vessels, whereas undredged natural tidal channels into the khors are typically less than a metre or two in depth, even at high water.

Tidally- scoured lagoonal channels join the open-marine settings to the restricted-marine lagoons or khors. Channels are floored with skeletal and peloidal sands, which are reworked by tidal and wave action into crossbedded skeletal/peloidal grainstones. Toward their inner parts, in the lagoon proper, the channel floor sediments become sandy muds (peloidal/skeletal packstones and wackestones). Wherever they poke through a thin lag of coarse shell and intraclasts, cemented calcareous eolian sands (eolianite) sometimes crop out on the channels floors.

Extensive shallow-water lagoons, filling with bioturbated packstones and wackestones, occupy the shallower parts of

the khors away from the channels. Because of their higher elevation relative to the lagoonal channel floors, subaqueous areas of khor away from the channel are sometimes described as lagoonal terraces. Terrace sediments entrain a diverse biota made up of many benthic species but relatively few phyla (Kendall and Skipwith 1968b). Molluscan sands and peneroplid foraminifera dominate the more open terrace areas, whereas pelleted carbonate mudstones with a sparse fauna accumulate in the more protected reaches. Cyanobacterial grain coats and biofilms are abundant on the lower-energy terrace sediments and encourage healthy populations of cerithid gastropods, which through their grazing contribute a large proportion of the pellets in the lagoon. Crustaceans and worms also heavily burrow terrace sediments. The somewhat elevated temperatures and salinities on the lagoon floor drive seafloor cementation of these ubiquitous pellets.

In the more marine parts of the terraces various sea grasses and seaweeds (brown algae) form dense carpets on the channel floors, along with healthy epiphyton coats of bryozoans and calcareous algae (Fig. 3.5b). There are four species of seagrass in more open marine parts of the khors and further offshore: *Halodule uninervis, Halophila stipulacea, H. ovalis* and *Syringodium isoetifolium. Halodule uninervis* is the dominant species of seagrass in the southern Gulf and in the UAE is the major food-plant taken by herds of grazing dugongs.

One of the more interesting mega-fossils preserved in the Abu Dhabi sabkha sediments is a cetacean (Stewart et al. 2011). These whale remains (a left and right mandible, scapula, humerus and fragmentary radius and ulna as well as parts of the cranium and rostrum) belong to a humpback whale (*Megaptera cf. novaeangliae*) and were found in excavated edge of the Musaffah Industrial Channel (now backfilled). Sediments encasing the whale bones were age-dated at approximately 5,200 ^{14}C yrs BP and are therefore interpreted to correspond to the late Flandrian sea-level peak, preceding a fall in sea-level which culminated in the supratidal sabkha overprint of the carbonates. Associated with the whale remains is an assemblage of molluscs, foraminifera and ostracods. Together with the inferred presence of sea grass and algae, these facies are interpreted to indicate a very shallow subtidal to intertidal lagoonal environment. Cirripede remains found associated with the skeleton were identified as those of the whale barnacle *Coronula diadema* and hence had their origins with the whale. Significantly, the low species diversity of microfossils associated with the whale remains suggests that higher salinities existed in the mid-Holocene lagoon than are present in its modern counterpart and tied to the onset of continental aridity in Arabia during the mid-Holocene (Stewart et al. 2011).

Due to the saturated state of lagoonal and intertidal waters, isopachous crystalline rinds and micrite crusts, composed of aragonite and Mg-calcite, bind large areas of the lagoon terraces into cemented layers. Ongoing expansion of the layers creates dm-scale tepee structures or megapolygons up to 165 m across, which can also be traced upslope into the base of the intertidal zone and also occur further offshore in fully subaqueous settings (Fig. 1.25a; Shinn 1969; Kendall and Warren 1987; Lokier and Steuber 2009). Tepee-overprinted ridges on the lagoon floor create a stable substrate or holdfast for much of the larger epiflora as well as a healthy population of borers. Seaweeds tend to attach themselves to tepee ridges in preference to the less stable muddy bottom veneer that forms the lagoon bottom away from the tepee crest.

Intertidal Facies (Strandline Sands)

Waves can drive loose terrace sediments shoreward to build narrow sandy beaches and berms of peloidal and skeletal grainstone, typically with landward-directed cross stratification (Figs. 3.3a, b, 3.5c, and 3.7a; Evans 1995; Warren and Kendall 1985). Cerithid gastropods, which populate the more landward parts of most khors, are a major skeletal component of the ridge sands, as are bivalve fragments and benthic forams. In areas more exposed to wave action the beach ridge sediments are coarser, ranging from coarse sands to skeletal gravels (rudstones). Locally, low-relief tidal levees and ridges enclose monospecific mangrove swamps (*Avicennia marina*) where sediments tend to be highly bioturbated muds crosscut by rhizophores. More typically, the narrow beach ridges in a sabkha coast are transitional into the cyanobacterial-dominated intertidal sediments that typify much of the intertidal zone of the inner lagoon (Fig. 3.4a).

I have trenched and cored buried equivalents of these beach ridges within various parts the Abu Dhabi supratidal sabkha succession, they are most obvious in the sabkha to the south and west of the Al Du'yybaya peninsular (Fig. 3.4a). Historically, they have not been well documented as a facies within the Abu Dhabi sabkha as the tops of older ridges landward of the modern strandline are typically deflated and buried beneath a halite crust (Fig. 3.7a). Southeast of Khor al B'azm a line of deflated beach ridges lies behind the currently active area of sabkha sedimentation. It is some 3–4 km inland of the present edge of the lagoon and forms the seaward edge of a 10 km wide belt of older Holocene sabkha sediments (Fig. 3.4). Remnants of an older sequence of beach ridges define the maximum extent of the Flandrian (Holocene) transgression (aka the "Evans Line"), indicating the initiation of the seaward progradation of the Holocene sabkha coastline and the occurrence of supratidal $CaSO_4$ facies. Portions of this ridge system are now buried beneath lagoonal muds. The contact between more oxidised beach-ridge pore waters and the reducing waters of the lagoon muds is typically defined by an iron-stained band of lenticular and prismatic gypsum (Fig. 3.7a).

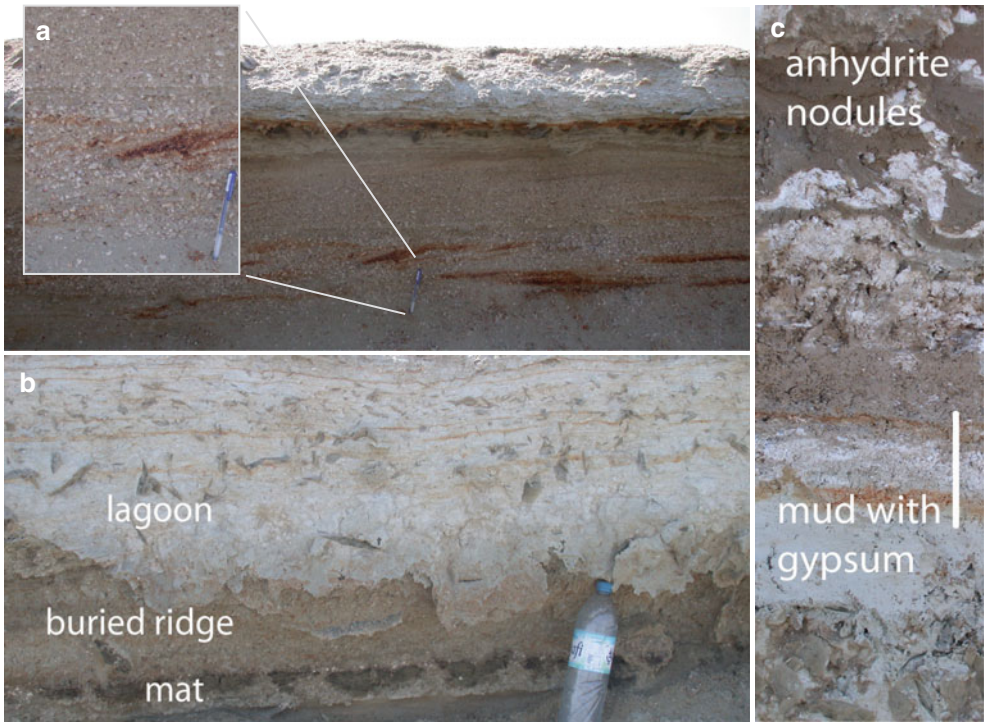

Fig. 3.7 Styles of $CaSO_4$ occurrence exposed in the Mussafah Channel, Abu Dhabi: The trench is actually the wall of a man-made shipping canal cut into the sabkha near the Mussafah Industrial Area. The locality is over 7 km landward of the present-day restricted lagoon and 25 km from the open Arabian Gulf waters. (**a**) Buried beach ridge gastropod rudstone showing landward-directed low-angle accretionary bedding and gypsum at the contact with overlying mud (*inset* shows detail of bedding). (**b**) Buried algal mat (*dark blebs*) overlain by ridge and lagoon sediment, with lenticular gypsum growing in the overlying lagoonal muds. Site is located about 50 m seaward of ridge in (**a**). (**c**) Enterolithic anhydrite in the supratidcal sabkah which is a lateral equivalent of gypsum in 3.6b, the site is located around 200 m northwest of the gypsum in 3.6b. Scale bar is 10 cm long

The presence of Holocene beach ridges along the coast on the seaward side of the present day sabkha supratidal, the presence of older largely buried and deflated Holocene beach ridges in the mid sabkha, and the relicts of early Holocene ridges defining the most landward extent of the Flandrian transgression clearly show Holocene sabkha progradation is not a simple seaward progression of peritidal facies. It is a punctuated and possibly forced regression (Warren and Kendall 1985; Warren 1991; Kirkham 1997; Strohmenger et al. 2011). Similar beach ridges within Holocene sabkhas are described from the northern Emirates by Al-Farraj (2005), from Kuwait by Picha (1978) and from northeast Qatar by Shinn (1973).

Intertidal Facies (Lagoon-Edge Muds)

Away from the active beach ridges, the intertidal zone is divided into upper and lower intertidal facies, although the lower intertidal facies of some workers is equivalent to the lagoonal terrace facies of others. The confusion stems from the presence of a wide cemented flat along the mainland shore of the various khors; a flat that is covered by rippled peloidal sands or muddy sands (peloidal grainstones and packstones) and hosts a dense population of cerithid gastropods. Some authors place this flat in the shallow subtidal as an extension of the lagoonal terrace, while others place the cemented terrace in the lowermost intertidal. The lack of firm definition of its distribution is due to the flat, shallow nature of the southern Gulf sediment surface. This means minor variations in wind direction, speed and the barometric pressure can cause the predicted tides in the khors to remain either "out" or to advance several kilometres further "in" than predicted. Longer term seasonal variations follow a more defined if unusual pattern, with inundation of many otherwise "supratidal" areas, that is large areas of sabkha flat, not occurring until late autumn (post-equinox). Hence, the lateral extent (strandzone) of the intertidal area of sedimentation in the UAE is large, but poorly defined. Even the terms tidal to describe sheets of lagoon water that at times cover more than the uppermost parts of the sabkha "intertidal" is a little misleading as the process driving the sheets further landward is typically the shamal.

Geologically, what defines the muddy intertidal facies is evidence of cyanobacterial (aka algal) mats. Mats first occur as degraded cyanobacterial peats in a transitional 100–200 m-wide zone where the bare lagoonal flats pass landward into a belt of well-preserved laminated mats

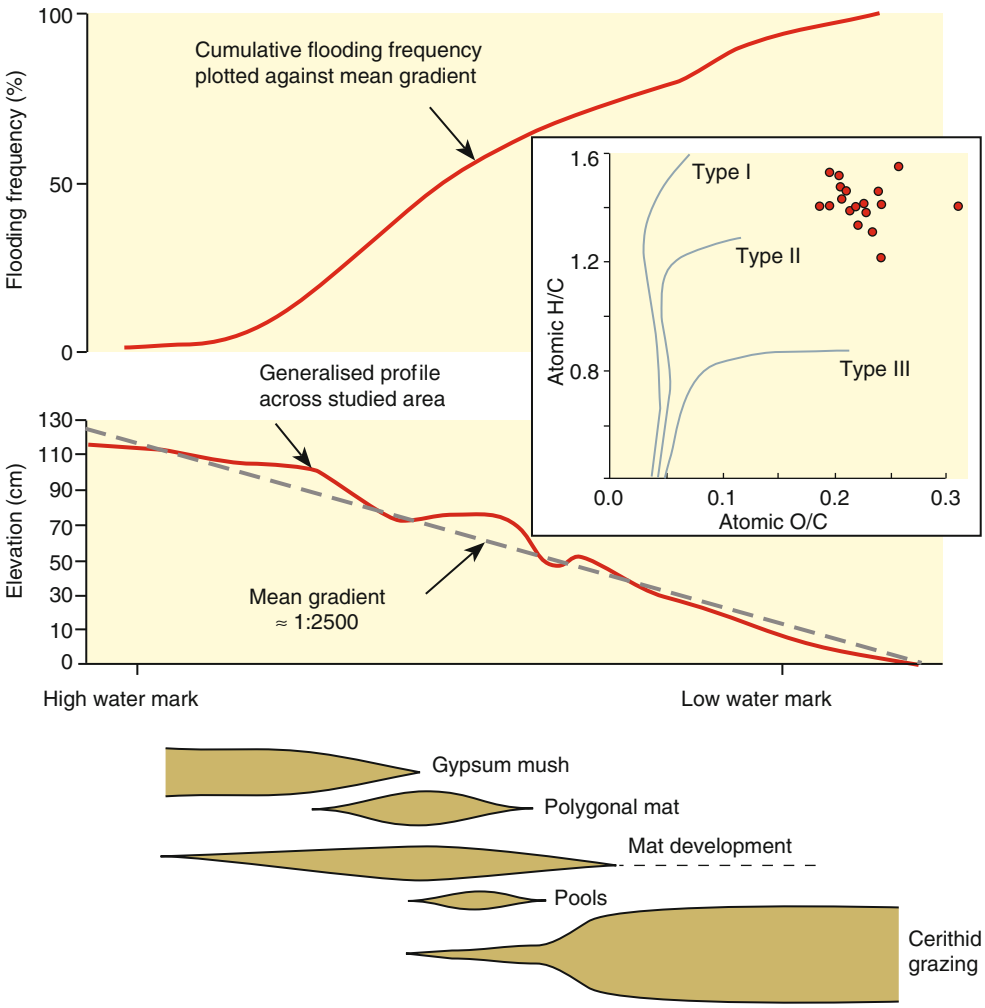

Fig. 3.8 Distribution of cyanobacterial mats in relation to tidal range, flooding frequency and cerithid grazing on the Abu Dhabi coast. *Inset* shows van Krevelen plot of protokerogen type in mat organics (After Park 1977; Alsharhan and Kendall 2003)

(Figs. 3.5e, f and 3.7b; Kendall and Skipwith 1968a; Park 1977). Hence, the lower intertidal is defined by degraded oxidised peats composed of the bioturbated remnants of cyanobacterial mat. The upper intertidal facies is variably defined by laminated microbial mats across an extensive belt up to 1–2 km wide. These biolaminites accumulate in moist intertidal areas where salinities and temperatures are too hostile for cerithid gastropods and the other grazing animals of the lagoon flat (Fig. 3.8). Many mats have sharp edges on their seaward side due to the grazing activities of the cerithids and other salinity-tolerant gastropods (Fig. 3.5d). Sediments in the microbial flat are dominated by mm-laminated mudstones up to 50 cm thick composed of cyanobacterial remnants interlayered with aragonite muds. Periodic exposure means many mats are crosscut by desiccation cracks and are termed polygonal mat. Measured TOC contents of the microbial mats vary between 0.5 and 2.7 %, with hydrogen indices between 510 and 675 in a range of type I-II protokerogens, with a $\delta^{13}C_{PDB}$ range from −8.41 to −10.78‰ (see inset in Fig. 3.8; Kenig et al. 1990; Kenig 2011). The highest TOC contents in the Abu Dhabi sabkha occur in mangrove peats (up to 8.6 %), not in microbial mats. But these mangrove-derived organics contain higher levels of higher plant protokerogen and so would constitute of more gas-prone source of future hydrocarbons.

Most of the literature on the sabkha gives the impression that laminated cyanobacterial mat is the only type of microbial sediment accumulating in the upper intertidal zone. Yet, in almost every area of mat I have visited along the mainland shores of the various khors of the Arabian Gulf, laminated mat tends to occur beneath the floors of shallow channels and pools (waters a few centimetres deep), separated by interchannel areas of rugose or pustular mat. The sedimentary signature of the pustular mat is a poorly layered organic-rich mush or peat, often mixed with patches of lenticular gypsarenite. Thus, the intertidal zone in an ancient equivalent need not be laminated to be microbial in origin.

Many intertidal mats are crosscut by desiccation cracks that contain euhedral or lenticular (diagenetic?) gypsum crystals up to 2 mm long (Figs. 3.5e, f and 3.7b). Gypsum is especially common in areas of pustular mat and along the landward side of the cyanobacterial belt, where it passes into

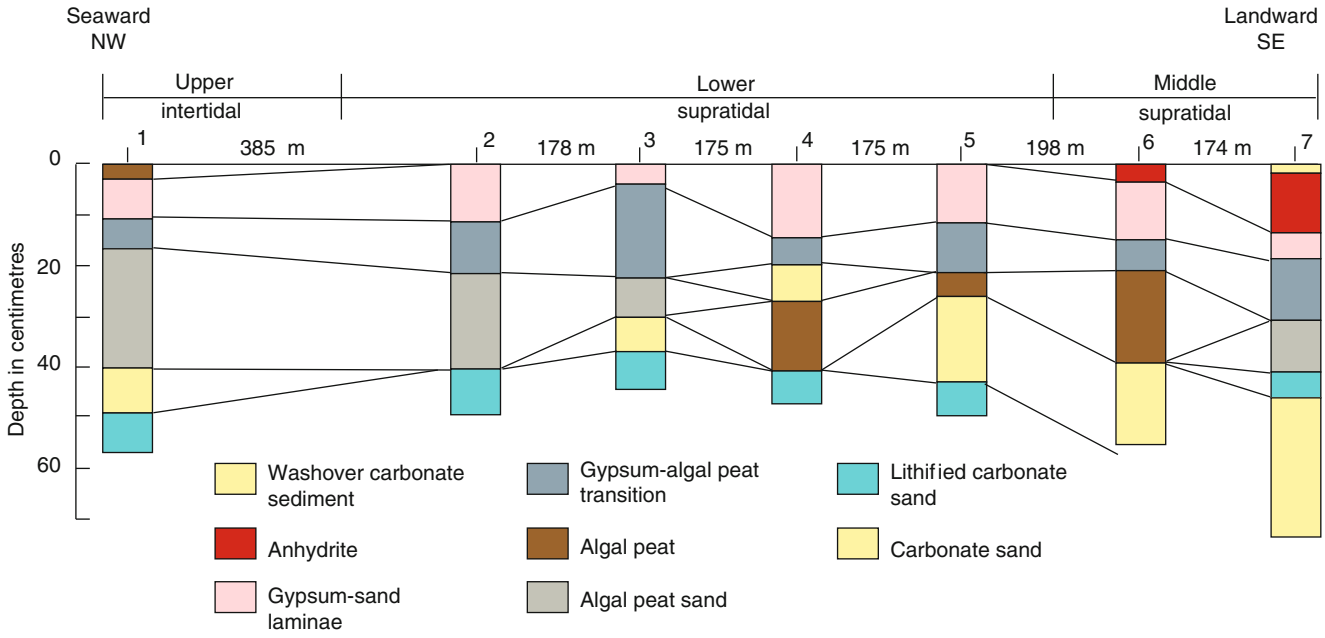

Fig. 3.9 Lithofacies distribution in subsurface across the upper intertidal to middle supratidal along the southern shore of the SW Khor al B'zam south of Al Qanatir Island, western Abu Dhabi (After Alsharhan and Kendall 2003)

the gypsum mush zone. Aragonite, magnesite, and dolomite locally cement surface and shallowly buried sediments of the cyanobacterial flat (Butler et al. 1982).

Arabian Gulf sabkha dolomites were first documented by Wells (1962) and are one of the two or three areas on the world's surface where Holocene dolomites are forming over aerially extensive regions, even if the actual distributions are somewhat thin and patchy (Warren 2000a). Holocene dolomite distribution in the Abu Dhabi sabkha is closely tied to the presence of cyanobacterial mat, suggesting that microbes and sulphate-reduction are involved in the dolomite mineralization process (Bontognali et al. 2010, Bontognali et al. 2012). The 16S rRNA gene sequence of a microbial isolate from the mat revealed a 99.6 % identity (i.e. same species) with *Desulphovibrio brasiliensis*. This is the sulphate-reducing bacterium, previously isolated from Lagoa Vermelha (Brazil), and known for its ability to metabolically precipitate dolomite.

Supratidal Facies

That part of the sabkha landward of the microbial mats and active beach ridges is further subdivided into three subfacies: lower, middle and upper supratidal (Figs. 3.4 and 3.9).

Lower Supratidal Lower supratidal sediment accumulates in a belt just above the high water mark (hwm) in a zone up to 2.5 km wide and flooded perhaps once or twice a month during high spring tides. It is characterized by a mushy gypsum bed, up to 30 cm thick, which passes seaward into cyanobacterial mat. Its lower part is an aragonite mud, crisscrossed by cyanobacterial filaments and isolated gypsum prisms (Fig. 3.4b). The upper part is a near-thixotropic mush of lagoonal mud and small, mostly sand-sized lenticular gypsum, with an occasional 1–1.5 cm long crystal. Much of the mush is thought to grow as displacive gypsum crystals within the capillary zone, from pore waters not saline or hot enough to precipitate anhydrite. If it desiccates, the surface of the mush can alter to white bassanite ($CaSO_4 \cdot 1/2H_2O$), or to anhydrite during longer hotter, dry periods.

Middle Supratidal The middle supratidal is a belt of sediment up to 1.6 km wide covered by lagoonal water at less than monthly intervals. It is characterized by growth of nodular anhydrite or gypsum within the sediment matrix. In the shallow subsurface, well away from the lagoon, there is a lateral transition from gypsum to anhydrite (Fig. 3.9). Subsurface and surface anhydrite nodules can increase in size and number in a landward direction until in some areas they eventually form interlocking polygons. Along the Al Du'yybaya sabkha, pockets of gypsum crystals are mixed with anhydrite nodules and layers, especially on the landward side of this zone, where they are dispersed in a matrix of reworked eolian quartz sand and silt (Wilson et al. 2013). An ephemeral halite crust and thin patches of loose blowing siliciclastic and carbonate sands sometimes cover the middle sabkha surface.

Intrasediment anhydrite tends to grow as nodules above the watertable, while displacive and pore-filling gypsum precipitates in sediments immediately beneath the sabkha watertable (Fig. 3.7c). Crystal growth breaks up and destroys laminar textures in some buried biolaminites (Fig. 3.5e, f). The seaward part of the middle supratidal is also the zone

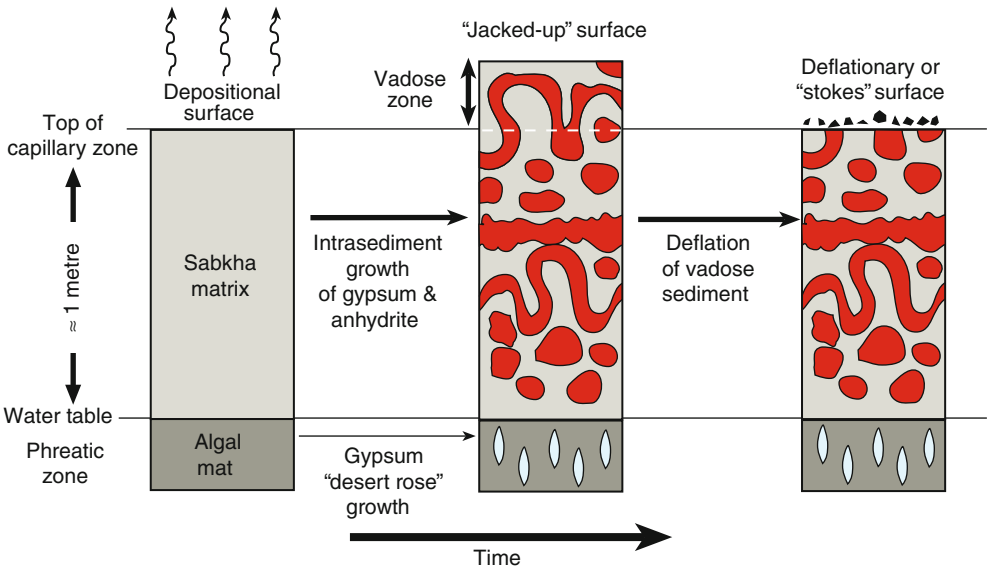

Fig. 3.10 Capillary evaporation in the sabkha precipitates nodules and crystals of gypsum and anhydrite in the capillary zone. This increasing volume lifts the upper part of the sediment column out of the zone of capillary water into the vadose zone where it deflates to leave behind the characteristic erosional surface that caps modern and ancient sabkhas. It is a type of Stokes surface (After Warren 1991)

where dolomite is most common. It grows best as a pore cement in aragonite muds and can replace portions of the lower supratidal and intertidal mud facies (McKenzie et al. 1980; Butler et al. 1982).

Upper Supratidal In the vicinity of Abu Dhabi city the upper supratidal zone is up to 4.8 km wide and is rarely flooded by seawater (less than once every 4–5 years) when there is a fortuitous combination of storm surge and high tide. In this, the most landward zone of the sabkha, the gypsum mush can be completely replaced by coalesced nodules of "chicken-wire" anhydrite to form near pure intervals that are up to 30 cm thick and lie mostly above the watertable, not immediately below the landsurface (Figs. 3.5g and 3.7c). Ongoing growth of irregular anhydrite layers creates "thrust" folds, ptygmatic and enterolithic folds, and diapir-like protuberances. Beneath this zone much of the original cyanobacterial lamination is partially or completely obliterated by the growth of clusters of large prismatic to lenticular gypsum crystals (6–25 cm in diameter, locally known as desert roses). Anhydrite and gypsum also fills the interior of hollow aragonitic shells, especially the former living chambers of cerithid gastropods. Along its most landward extent, the upper supratidal anhydrite layer can contain gypsum after anhydrite, with some nodules constructed of mixtures of both gypsum and anhydrite.

Widespread displacive calcium sulphate growth in the capillary zone sediments raises the sabkha surface out of the capillary zone to form a widespread erosional surface. As the rising sediments enter the vadose zone they dry and are blown away to leave behind the characteristic erosion surface of a sabkha sequence, covered in places by a deflation veneer (Fig. 3.10).

This erosion surface, especially where it truncates enterolithic or ridge anhydrite is one of the most useful indicators of the sabkha hydrology. Like other Stokes surfaces, it defines the top of the capillary fringe (Fig. 3.5g). Its presence in an ancient sabkha clearly distinguishes this style of truncated nodular anhydrite layering as penecontemporaneous and cannot be the result of burial conversion of gypsum to nodular anhydrite.

In times of drought much of the middle and upper sabkha is covered by a pock-marked crust of halite, crosscut by pressure ridges and petees. This crust contains a range of efflorescent bittern and nitrate salts, but is dissolved and the soluble products flushed seaward with the next intense rainstorm or sheet flood. It is an ephemeral crust with a decoupled hydrology much like salt crusts in Australian salt lakes, as described in the previous chapter. Cm-sized displacive halite crystals can grow below these ephemeral salt crusts in the uppermost few centimetres of the upper supratidal sediments, attesting to the infrequency of surface water in this region. The coming and going of the halite crust at the depositional surface of aggrading sections of the Abu Dhabi sabkha strongly influences textures in the remaining "supratidal" sediments (Fig. 1.46a). Although the halite crust is ephemeral there is a strong inheritance in the position of the ridges in the crust each time it reforms; it seems the topography of the underlying sediment surface is the primary controlling factor on halite polygon development. In almost all cases recurrent polygon margins form in association either with low-amplitude mud ridges or with exposed anhydrite mounds (Goodall et al. 2000; Lokier 2012).

Sabkha Hydrology and Hydrogeochemistry

Hydrologically, much historic argument in the Abu Dhabi sabkha has dealt with the ultimate origin of the pore waters precipitating supratidal sulphate, i.e. marine flooding versus continental storm runoff (Fig. 3.11a). Hydrogeochemical

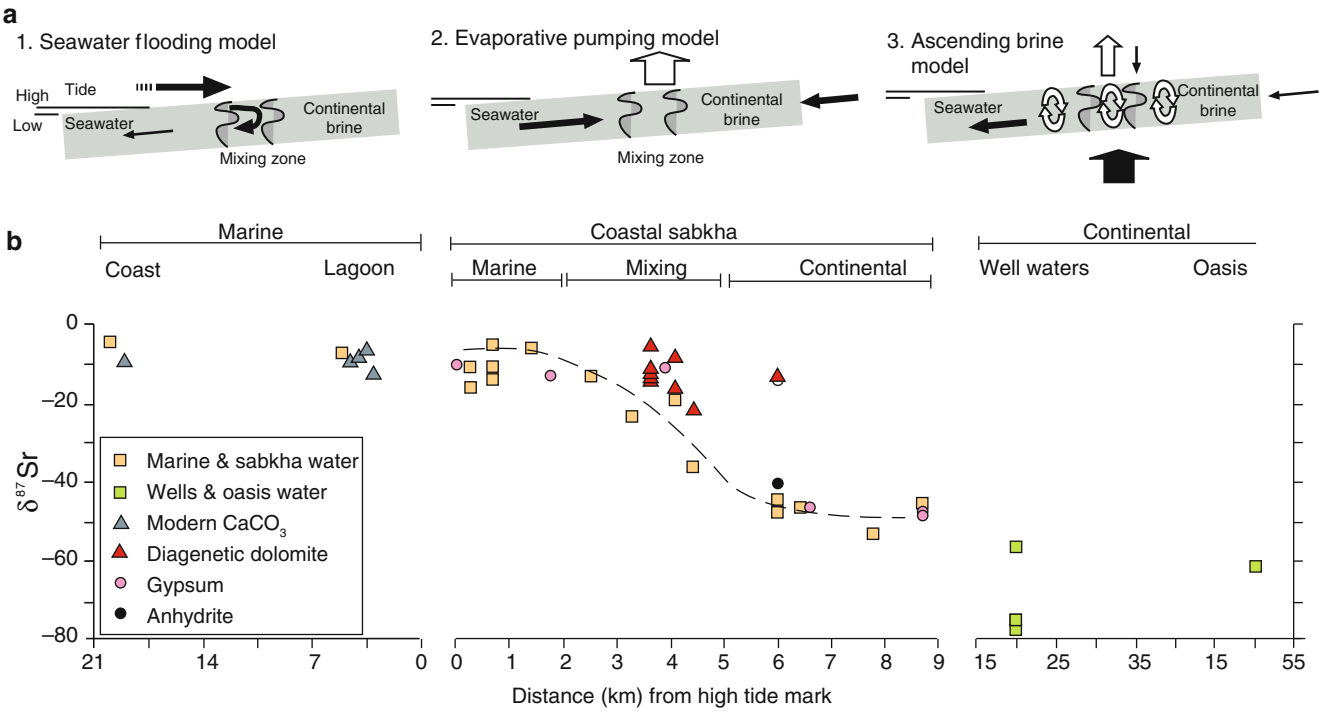

Fig. 3.11 Hydrology of the Abu Dhabi Sabkha. (**a**) Schematic of various models for sources of solutes in the (*1*) seawater-flooding model, (*2*) evaporative-pumping model, and (*3*) ascending-brine model. Open arrows indicate vapour loss, solid arrows represent solutes, and width of arrows indicates relative solute mass (After Wood et al. 2002). (**b**) Analysed $\delta^{87}Sr$ values for water, carbonate and sulphate samples versus distance from the high tide mark. On the basis of these values the sabkha hydrology is divided into marine, mixing and continental zones with the dashed line representing the generalised trend (After Müller et al. 1990)

work in the 1960s and 1970s argued for a largely marine origin of the sabkha brines, which were supplied and replenished by occasional Shamal-driven tidal/storm seawater floods (Kinsman 1969; Butler et al. 1973). The seawater-flooding model was the first to provide a mechanism for cycling ions through capillary sediments and so account for the observed dolomite and calcium sulphate (Fig. 3.11a). An alternate "evaporative-pumping" model was proposed by Hsu and his coworkers (Hsu and Siegenthaler 1969; Hsu and Schneider 1973) and included in the layered seawater flood/upwelling models of McKenzie et al. (1980), which suggested a compartmentalised hydrology made up of aquifers and aquitards and that capillary evaporation from the sabkha induced lateral flow of both seawater and continental groundwater (Fig. 3.11a). All these early models suggested that seawater, either by flood recharge or seepage reflux, was the dominant supplier of ions to the salts precipitating in the coastal plain. Much of the base hydrochemical data for a marine source was ambiguous. And, some measurements such as strontium isotopes suggested the possibility of at least a partial continental source to the ions in the sabkha groundwaters (Fig. 3.11b; Müller et al. 1990). Warren and Kendall (1985) and Warren (1991) noted that much of the matrix hosting the coastal sabkha salts of the Emirates was not marine but was a continental eolian sediment. Warren (op. cit.) also noted that, as the sabkha prograded, pore waters were replaced by continental fluids and that in ancient counterparts marine hydrologies probably only dominated the most lagoonward portions of the coastal sabkha flat.

Much of this earlier work extrapolated longterm hydrological processes over the whole sabkha coast, based on short term observations of the effects of Shamal winds and storm surges covering the sabkha with sheets of water, and on studies of a limited number of shallow trenches and transects. The assumption was that the solutes accumulating in the sabkha were derived and replenished in these occasional marine and wadi sheetfloods. Recent detailed groundwater study of the sabkha has concluded much of this earlier hydrological discussion assuming a marine solute source to the sabkha is largely erroneous or irrelevant (Sanford and Wood 2001; Wood and Sandford 2002; Wood et al. 2002; Wood et al. 2005).

Quantitative hydrological modelling uses longterm (1–2 year) monitoring of changing water levels and chemistries in a continually logged database across the sabkha. It is made up of data from 490 wells drilled to 1–2 m below the sabkha watertable, including a number of piezometer nests (listed as RP wells in Table 3.2) and six deep cased wells to monitor deeper hydrological circulation (listed as GWP wells in Table 3.2). The deep wells were drilled to depths of more

than 100 m into the Tertiary aquifers that underlie the sabkha (Fig. 3.12a, b). These real time measurements, and the resultant realistic hydrologically and geochemically balanced models, show that some 95 % of the solutes precipitated as salts in the capillary zone of a sabkha are derived from ascending deeply-circulating continental brines; only minor amounts of the solutes are derived from rainfall or from lateral groundwater flow entering from nearby areas, including the ocean. Solute load in the capillary salts are largely decoupled from the rainwater cycling in the sabkha as are the salt crusts, which dissolve and reprecipitate with each flood-desiccation cycle. Flood recharge of marine water does not supply ions to the capillary salts of the sabkha, upwelling or ascending continental groundwaters do (Wood and Sandford 2002).

Potential (pan-measured) evaporation rates of fresh surface water on the sabkha are ≈ 3,500 mm/year. But free surface water rates are not the same as actual rates of evaporation of pore waters held in the sabkha capillary zone by pore surface tension (Fig. 2.10). Measured evaporation rates, using a humidity chamber, were around 0.24 mm/day at site 1 and 0.14 mm/day at site 2, with rates of evaporation changing with time of day (Fig. 3.12c, d). These values are 3 % of the pan evaporation rates at both measurement sites and correspond roughly to the mean annual rainfall throughput at both sites (90 mm/year for Abu Dhabi City and 50 mm/year at Sabkha Matti). The estimated rainfall recharge to the sabkha occurs at a rate of 640 m^3/year in the representative volume illustrated in Fig. 3.13. A mean value of 69 mm/year (from humidity chamber values) for evaporation gives a value of 690 m^3/year for the volume of water lost in the sabkha, as shown in Fig. 3.13. This volume of evaporative loss is about 15 times that of upward leakage from the underlying Tertiary aquifer (45 m^3/year), and there is a meteoric-evaporation deficit of ≈ 50 m^3/year. Put simply, the sabkha is taking up Tertiary groundwaters like a sponge.

The humidity chamber measurements also showed that water flux during the night can be reversed at times when the humidity in the air above the sabkha exceeds the activity of water on the surface of the salt crusts, causing night dew and some redissolution of the crusts. Periods of reversal are the times when the sabkha evaporation values are less than zero in Fig. 3.12c.

Ongoing capillary evaporation means water level in the sabkha is typically around 1 m below the sabkha surface (Table 3.2). Pore waters above this level are held in the pore throats by capillary pressure. Measurement of squeezed pore waters shows most salinities in the unsaturated zone are in the gypsum/ anhydrite saturation range, as are waters at and just below the watertable (130–290 mg/l), with brine densities ranging from 1.070 to 1.187. Measured conductivity (permeability) of the sabkha sediment is between 0.3 and

2.0 m/day (≈3–10 md), and is relatively uniform across the sabkha. Using a hydraulic conductivity of 1 m/d, and a density-corrected piezometric gradient of 0.0002, results in a lateral flux of between 7 and 8 cm/year (Wood et al. 2002). Dividing the flux by porosity from an average of the measured porosities (0.38) gives a seepage velocity of 18–21 cm/year. This range in itself negates any notion of lateral marine seepage from the lagoon ever being capable of supplying the volumes of solute needed to precipitate the Holocene evaporites of the sabkha coast. These transmissivity calculations show that solute-carrying water simply cannot seep into the sabkha from its sides in sufficient volume to explain the volumes of capillary salts now in the sabkha. Solute-carrying waters must be coming from below.

Between 47,600 and 55,500 years are required for a molecule of a conservative (i.e., nonreactive) solute to traverse the 10 km width of the sabkha in the considered rectilinear volume (Fig. 3.12). If it is assumed that the average residence time is one-half of the total time required for a conservative solute to traverse the full length (10 km) of the rectilinear volume by horizontal flow, the average steady-state residence time of a conservative solute in this sediment volume is ≈26,000 year. Because the calculated residence time is greater than the age of the sabkha-aquifer system, it is clear that steady state for the solute flux has not been achieved. Capillary salts are still accumulating across the sabkha and it is this mechanism that is driving the jack-up and formation of Stokes surfaces.

In terms of the water cycle (not the solute cycle), direct rainfall onto the sabkha and subsequent groundwater recharge to the underlying aquifer accounts for 90 % of the annual water input to the system; the remaining 10 % comes from both lateral and ascending saline groundwater flow (Wood et al. 2002). Less than 1 m^3/year of pore water enters and exits by lateral groundwater flow into a representative rectilinear volume of sabkha aquifer measuring 1 m wide, 10 m deep, and 10 km long (Fig. 3.13a), Some 45 m^3/year enters by upward vertical leakage, 640 m^3/year enters by recharge of rainfall, while 690 m^3/year is lost to evaporation. But, and this is what earlier work had not expected, the water and solutes in the sabkha are largely from different sources; they are decoupled as they are in the playas and salt lakes of Australia (Chap. 2). The bulk of the solute load precipitated in the Abu Dhabi coastal sabkha comes from the resurgence of deeply circulated groundwater returning to the surface in the coastal plain via Tertiary limestone aquifers. Most of the solutes precipitated as capillary salts are not from seawater or from direct rainfall onto the sabkha. Approximately

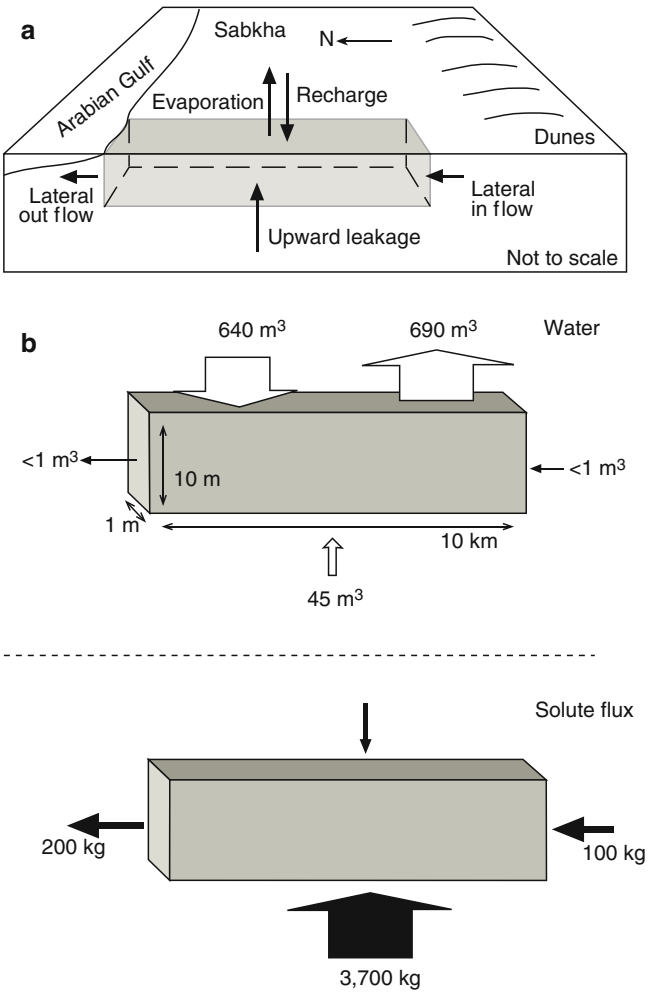

Fig. 3.13 Hydrologic fluxes in the coastal sabkha aquifer of the Abu Dhabi sabkha. (**a**) Schematic of hydrologic processes in the Abu Dhabi sabkha. (**b**) Magnitudes of the various annual water fluxes in a 1 m × 10 m × 10 km control volume (After Wood et al. 2002)

100 kg/year of solute enters from lateral flow; ≈15 kg/year enters by rainfall; and ≈ 3,700 kg/year enters by ascending vertical leakage (Fig. 3.13b). Some 200 kg/year is discharged to the Gulf by lateral flow. Upwelling groundwater originally entered the system in feeder zones in the Oman Mountains some tens to hundreds of kilometres to the east and picked up much of its solute load by water-rock interaction on its way to the coast.

Vertical gradients and hydraulic conductivity suggest that approximately seven pore volumes of water from the underlying Tertiary formations have discharged to the original coastal sabkha-aquifer system in the 7,000 years since deposition of those Holocene formations (Wood et al. 2002). Wood et al. (op. cit.) go on to argue that, if there are no other sources or sinks of solutes, then the concentration of a conservative solute should be approximately seven times the concentration of the input Tertiary brine. Bromine, a conservative element in brines, should have a concentration ratio close to the seven fold predicted by the hydrologic analysis if fed by Tertiary aquifers, and this expectation is realized (Fig. 3.14a).

Loss of halite from the pore water is clearly shown by the low concentration ratios of both sodium and chloride. Sulphate and calcium concentrations are less than seven because of the precipitation of calcite, anhydrite, and gypsum in the unsaturated zone in the sabkha. Magnesium should be generally conservative in this system because there is no significant mass of clay that could act as an ion exchanger or structural sink for the mineral. Magnesium, like bromine, is not being removed by mineral precipitation of chloride bitterns within the aquifer. The current chemical conditions in the majority of the sabkha aquifer do not favour dolomitisation (low concentrations of bicarbonate, low pH, and magnesium/ calcium ratio of ≈ 1:1; Table 3.3; Wood et al. 2002). It means that magnesium in the dolomite observed by previous workers in the sabkha is related to the original volume of trapped seawater and the interaction of these pore waters with microbial metabolisms. Significant masses of magnesium are not lost or gained from sources other than the brine, and the concentration ratio is approximately seven (Fig. 3.14a). Like bromine, it is behaving conservatively.

In solutions without significant concentrations of carbonate species, magnesium hydroxide complexes [$MgOH^+$ and $Mg(OH)_2$] can control the pH (Wood et al. 2002). Observed pH in sabkha brines, which declines with increasing magnesium concentrations is consistent with this hypothesis (Fig. 3.14b). The relative concentrations of calcium and sulphate can also be used to define the source of the solutes. Hydrochemical divides, as conceptualised by Hardie and Eugster 1970, mean that mineral precipitation in a relatively closed system, such as the sabkha, will cause the concentration of one element of a precipitating mineral to approach zero, while the other element or elements will increase in concentration (Fig. 2.19). The initial input concentration of the elements determines which element will be limiting. In the case of seawater, there is a greater equivalent of sulphate compared to calcium; thus, with precipitation of calcite, anhydrite, and gypsum, the thermodynamic activity of calcium will approach zero. In the case of the Tertiary brines and oilfield waters, the average equivalents of calcium are greater than the average equivalents of carbonate and sulphate (Table 3.3). Thus, precipitation of anhydrite and calcite from the concentration of Tertiary brines will result in sulphate and carbonate levels in the brines approaching zero, while calcium increases in concentration. In the Abu Dhabi sabkha system the observed calcium is increasing, and sulphate approaches zero in most cases (Fig. 3.14c), consistent with a Tertiary brine source for the sabkha anhydrite and gypsum. The few analyses in which sulphate is greater than calcium are from the supratidal zone nearest the lagoon. The concentration of sulphate does not go to zero because of hydrated complexes formed with magnesium and calcium;

(**a**) Concentration factor (ratio of existing concentration in the sabkha-aquifer to input concentration of Tertiary brines) in the sabkha aquifer. (**b**) Decline in pH with increasing magnesium in sabkha aquifer. (**c**) Sulphate as a function of calcium in sabkha-aquifer. (**d**) One day temperature record of the surface, at various depths in the capillary zone, and of groundwater at site 1 in the coastal sabkha of the Emirates of Abu Dhabi

however, the thermodynamic activity does approach zero (Wood et al. 2002).

This interpretation of ionic proportions assumes that no other process, such as bacteriogenic sulphate reduction, is removing sulphate from solution. The regional groundwater system is oxidizing, with dissolved oxygen values between 4 and 5 mg/l, except at the distal edge of the sabkha. Therefore, it is not likely that bacterial sulphate reduction is removing a substantial mass of sulphate to significantly alter the Ca/SO_4 ratio as this bacterial process requires anoxic pore waters.

Periodic intense recharge by rainwater in the coastal plain dissolves halite and other soluble minerals on the sabkha surface, causing the surface and near surface waters to become more dense and sink (reflux) to the bottom of the aquifer where it vertically mixes with less dense ascending basinal brines (Wood et al. 2002). With the next drying cycle solutes are once again returned to the surface by capillary forces (a cycle that is largely decoupled from external solute supply). Thus, the system becomes vertically mixed, but there is essentially no horizontal mixing of seawater with groundwater. In the same way bittern salts are flushed from the uppermost parts of the unsaturated sediment column.

Any observed seawater solutes in the undersaturated zone come from interstitial seawater trapped by the rapid progradation of the sediments into the Arabian Gulf or from marine aerosols, they are not refluxed or laterally mixed marine pore brines as was inferred in the previous hydrological models. For example, Müller et al. (1990) observed a seaward gradient in strontium isotope values perpendicular to the coast, which they attributed to lateral mixing of continental brines and seawater within the sabkha (Fig. 3.11b). Wood et al. (2002) reinterpret the significance of this distribution, noting that the inferred lateral mixing is as readily explained as the function of the number of pore volumes of resurging conti-

Sulphur isotope values in PDB
After Wood and Sanford (2002), Wood et al. (2005)

nental brine contributed to a specific area on the sabkha. That is, the distance from the shoreline and the number of pore volumes of Tertiary brine recharged to the sabkha-aquifer system are directly proportional and it is this that controls the Sr isotope values in the Abu Dhabi sabkha, not lateral recharge of seawater. In other words it is not necessary to invoke lateral mixing or transport to obtain the observed strontium isotope distribution.

Wood et al. (op. cit.) go on to note that the area of dolomitisation (as identified by Patterson and Kinsman 1982) is the region closest to the Abu Dhabi shore. This is the zone that retains the largest amount of seawater solutes because it is the area most recently prograded. The mass of dolomite formed on the sabkha is limited to that derived from the magnesium and carbonate concentrations in the initial pore volume of seawater trapped by the prograding sediments. The evaporative geochemical mechanism for regional dolomite formation, as proposed by Patterson and Kinsman (1982) appears to be correct; it is just that there is no ongoing seawater reflux occurring in this dolomitizing system. Arguing that all that is needed is more time to explain extensive dolomite cycles by prograding a set of sabkhas across ancient platforms is not hydrologically viable, syndepositional ancient platform dolomites require a different set of hydrological drives than icehouse sealevel (Chap. 5). In addition, dolomite seeding may require the local presence of organic matter and the appropriate microbial (sulphate-reducing) community.

The hydrological mechanism driving the accumulation of calcium sulphate salts in the sabkha is the rise of deeper circulating groundwater to replace waters lost by evaporation. The process moving capillary waters and their solute load through the unsaturated zone of the sabkha is solar driven and so the calcium sulphate in the sabkha is a true evaporite mineral (Chap. 2). Within this evaporative framework, Wood et al. (2005) argues that brine warming drives calcium-sulphate precipitation in the Abu Dhabi sabkha. That is, gypsum and anhydrite precipitate in the capillary zone because of their retrograde solubility. As well as belonging to the broader family of "true" evaporites, they are also "thermalites." A thermalite is defined by Wood (op. cit.) as a mineral formed by changes in temperature, independent of other processes that alter the thermodynamic properties of the solution. He argues that the capillary zone is critical to the development of the authigenic thermalite salts in any sabkha.

Any capillary fringe is the result of two sets of forces: mutual attraction between water molecules (hydrogen bonding), and molecular attraction between water and the different minerals that form the aquifer. Thus, for any given mineral, the smaller the interstitial pore size, the greater the vertical rise of water (Table 2.14). The zone of capillary rise (also known as the "zone of tension saturation" or the "wetting front") is the saturated zone above the watertable in which the interstitial pore space is completely filled with water, but this water is under less than atmospheric pressure. There can be no evaporation within this zone of tension saturation (no pore water passing into its gas phase) because water completely fills the narrower pore spaces and the atmospheric pressure is negative. If it does not, capillary rise cannot occur. Above the zone of tension saturation in the unsaturated zone is a zone in which the water film and a gas phase coexist in the interstitial pore space. The relative humidity of this gas phase is, however, equal to the thermodynamic activity of water, and no evaporative concentration can occur in this interval as well.

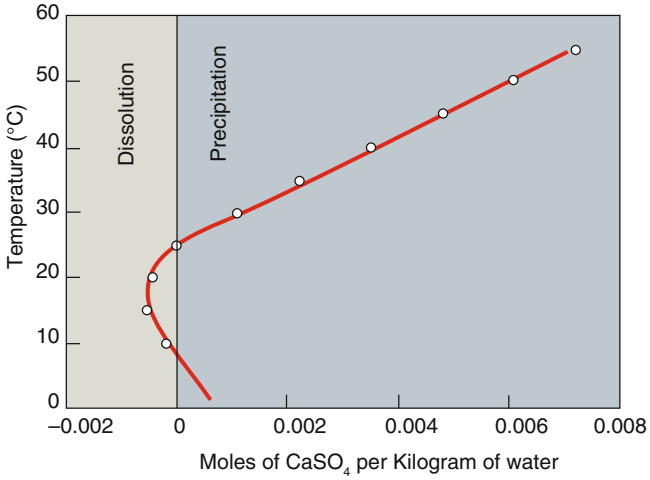

Fig. 3.15 Moles of $CaSO_4$ precipitated per kilogram of water as a function of temperatures for a representative solute sample from the sabkha of the Emirates of Abu Dhabi (After Wood et al. 2005)

The physics of the capillary zone means evaporation in the Abu Dhabi sabkha (or any other sabkha) can only occur at the surface, or in the pore spaces a few cm below, in the interval where the relative humidity of the gas phase is less than the thermodynamic activity of the water. Thus, any minerals precipitated lower in the capillary zone must be thermalites with precipitation driven by the retrograde solubility of calcium sulphate and not by an evaporation driven increase in the salinity of the pore fluids (Fig. 3.15). The notion of thermalites explains the typical occurrence of the bulk of the $CaSO_4$ in the sabkha. Nodules and prisms are most common in the interval about the watertable and toward the base of the capillary fringe, not in the few centimetres immediately below the land-surface. This would be the position of maximum anhydrite growth if evaporation of capillary waters, not their heating, was the dominant process driving $CaSO_4$ precipitation.

Wood (op. cit.) argues this conceptual model of thermalite precipitation applies to mineral deposition in the capillary zones of most coastal sabkhat. Water and solutes are transported upward by capillary forces from the shallow watertable in response to water evaporating at the surface. As water passes into the gas phase and is removed from the uppermost few centimetres it leaves behind evaporatively precipitated salt residues, including bitterns in the uppermost part of the capillary fringe. It is a diverse suite, dominated by halite (NaCl), but encompasses other more saline salts such as carnallite ($KMgCl_3 \cdot 6H_2O$) and antarcticite ($CaCl_2 \cdot 6H_2O$)

as well. Below this uppermost zone, minerals exhibiting retrograde solubility, such as anhydrite ($CaSO_4$), calcite ($CaCO_3$), dolomite ($CaMg(CO_3)_2$), and gypsum ($CaSO_4 \cdot 2H_2O$), are precipitated as thermalites. They are the result of increasing temperature experienced by solute-rich deeply circulated groundwaters as it moves through the capillary zone toward the surface during the summer months.

A representative summer day temperature profile (July 6, 1999) illustrates a positive gradient of approximately 25 °C m^{-1} in the Abu Dhabi sabkha at site 1 (Fig. 3.14d). A reverse thermal gradient (upward cooling) in the winter permits dissolution of some of the previously precipitated retrograde minerals. Because the negative thermal gradient is less in the winter than in the summer with nearly the same water flux, the water does not have the capacity to dissolve all of the mineral mass that was precipitated in the preceding summer. Thus, there is a net accumulation of these retrograde (thermalite) minerals in the capillary zone (Wood et al. 2005). Figure 3.15 illustrates the difference in mass of salts precipitated and dissolved as a function of temperature for anhydrite based on measurements made in the sabkha. It clearly shows the relatively small temperature window in the sabkha (5–25 °C) during which winter dissolution can occur.

Detailed hydrological studies of the coastal sabkhas of the Abu Dhabi region show they are no more than the outcropping expression of outflow zones of regional artesian aquifers. Clearly the ascending brine model of Wood et al. (2002), and his subsequent conclusions of sabkha salts accumulating beneath the halite crust as thermalites, contrast significantly with both the seawater-flooding and evaporative pumping models previously proposed and widely accepted as explaining the source of solutes to the coastal sabkha of the Emirate of Abu Dhabi (Fig. 3.11a). Wood's conclusions show solute cycling in the coastal sabkha setting is decoupled from the water budget and similar to that in continental sabkhas and chotts in many inland deserts with seawater like ionic proportions, as in the Sahara or central Australia (Chap. 2). The phreatic seawater wedge associated with the modern shoreline focuses outflow of deep seepage throughput in the Abu Dhabi coastal sabkha. Sediment matrix in some parts of the sabkha may be marine, but the hydrology and the authigenic overprint (mostly $CaSO_4$) comes largely from ions supplied by a deeply circulating continental aquifer. This new understanding of the large-scale sabkha hydrology has significant implications for the preservation potential of ancient marine-margin sabkhas.

Siliciclastic-Hosted Coastal Sabkhas, Western and Northern Arabian Gulf

An excellent literature base dealing with the sedimentology of the seaward side of the Abu Dhabi sabkhat creates an impression that coastal sabkhas bordering the Arabian Gulf are characterised by capillary salts hosted in marine carbonate matrices. But this is not always the case and many marine-margin capillary salts in the Arabian (Persian) Gulf are hosted in siliciclastics or even in desert loess blown into coastal depressions. Even in the type area, the Abu Dhabi sabkha, at least 50 % of the coastal plain sediments that host capillary evaporites do so in a matrix of mixed carbonate-siliciclastic or pure siliciclastic. Many ancient counterparts to strandzone sabkhas have siliciclastic matrices. Well-documented examples include the Permian sandflats of Europe and much of the Guadalupian lagoonal sediments of the Central Basin Platform in west Texas and New Mexico (Chap. 10). The following section describes some modern coastal sabkhas of the Arabian Gulf with capillary salts growing in mixed siliciclastic/carbonate and pure siliciclastic matrices.

A predominance of siliciclastics in the sabkhas of Kuwait and Saudi Arabia in the northwest of the Gulf versus carbonate in sabkhas along the At Taf coastal strip in the southeast of the Gulf simply reflects sediment transport and coastal dynamics in the Gulf seaway (Fig. 3.3a). The northwestern shore of the Gulf passes from the siliciclastics of the shallow Mesopotamian Shelf to the carbonate shoals of Bahrain, Qatar and the At Taf coastal strip. The northern Gulf is an arid, micro to mesotidal region with tides ranging from 1 to 4 m (Gunatilaka and Mwango 1988). Anticlockwise tidal currents of the northern Gulf and the prevailing northwesterly Shamal winds produce a shore-parallel, largely southeasterly-directed, wind-wave energy system, which supplies a combination of desert sand and loess to this part of the Gulf coastline, with an increasing fluvial contribution toward the northernmost gulf.

From the coast to inland areas along the northwestern Gulf there are three broad depositional environments (Lomando 1999). Along the coast is a near continuous belt of modern mixed carbonate-siliciclastic deposits with a wide range of depositional styles from interdunal to estuarine to barrier coast. To the immediate landward is a discontinuous belt of active and abandoned marine sabkhas, which pass into a broad desert system of continental sabkhas, desert flats, and dune fields. The inland desert system is the flattest area of Kuwait and northern coastal Saudi Arabia and is part of a zone of regional deflation, providing wind-blown sand to the Jafurah Sand Sea and ultimately accumulating in the northern areas of the Rub Al Khali in Saudi Arabia (Fig. 3.63).

Coastal Sabkhas of Eastern Saudi Arabia

Sabkhas of eastern Saudi Arabia are divisible into coastal and inland sabkhat, both are surrounded and underlain by Pleistocene and Holocene dune sands (Fig. 3.16a). Eolian sandflat sediments of the coastal region were documented by Fryberger et al. (1983, 1984) in a study of the Jafurah Sand Sea margin and are discussed in detail toward the end of this chapter. The Eastern Province of Saudi Arabia, south of Dammam, is characterised by a north–south elongated belt

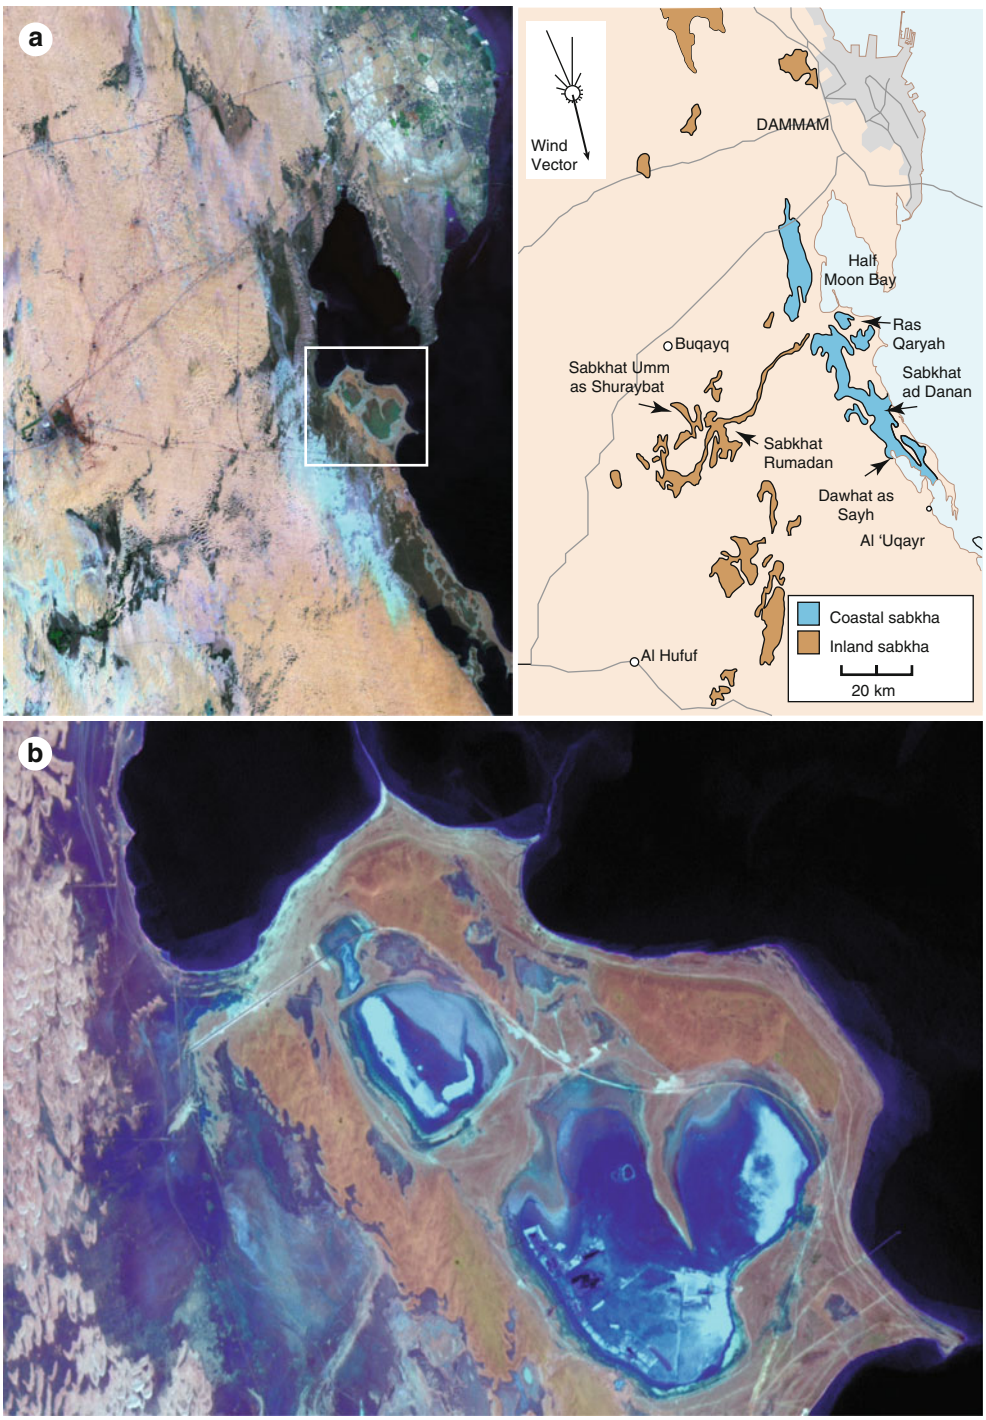

Fig. 3.16 Sabkhas of Saudi Arabia southeast of Dammam. (**a**) Distribution of coastal and interdunal sabkhas in areas of shallow groundwater resurgence along the Dammam coastline. The coastal region defines the modern marine edge of the Jafura sand sea where isolated subsealevel coastal depressions are today filling with capillary salts in a mostly siliciclastic matrix. In the last glacial this sand sea extended well out into the Arabian Gulf (Landsat image courtesy of NASA, wind vector after Fryberger et al. 1984). (**b**) Semi-circular marine seepage sabkhat behind Ras Qaryah and adjacent to the eastern edge of Sabkhat ad Danan

of eolian dune sand, which approaches the coast between Doha Dhalum (Half Moon Bay) and Al-'Uqayr (Fig. 3.16a). To its immediate north are the Tertiary limestone and dolomite highlands that define the outcrop expression of the Dammam dome (cored by a salt diapir). This coastal zone is surrounded by siliciclastic sand sheets, passing upwind into active barchan sand dunes, which are still moving sand into and across the coastal sabkha to create a prograding siliciclastic shoreline. Sand movement is principally towards the south-southeast and sand is driven seaward by the Shamal (Fig. 3.16a). In areas where the watertable approaches the landsurface, sabkha evaporites are growing in sand sheets in both sea-margin coastal sabkhas and in interdunal sabkhas located further inland (Fig. 3.16a, b). At Dahat as Sayh there is a highly restricted saline lagoon at the southern end of the Sabkhat as Danan, with a restricted marine carbonate fauna, somewhat akin to Hamelin Pool, although at a much smaller scale (≈75 km^2; Jones et al. 1978).

The dominant capillary salt is gypsum (Fig. 3.17a–c) in both inland and coastal sabkhas in the Eastern Province on

Fig. 3.17 Coastal sabkhas of the Eastern Province, Saudi Arabia. (**a**) Flat puffy algally-bound (petee) surface of the Sabkhat ad Danan. (**b**) Typical displacement gypsum (desert rose) growing within a half a metre of the sabkha watertable in Sabkhat ad Danan. Crystal is 10 cm across. (**c**) Gypsum lunette showing characteristic eolian cross bedding (outcrop face ≈ 1.5 m high) (**d**) Megapolygonal tepee ridges in marine cemented intertidal lagoon crusts in southern Half Moon Bay (area locally known as "wrong way spit"). (**e**) Pressure ridges in the halite pan facies (lowest point) of the Ras Qaryah sabkha shown in 3.16b in March 2004. The watertable at this time of year is no more than a tens of cm below the sabkha surface. (**f**) Displacive nodular anhydrite growing in the capillary zone in fine detrital clay about the edge of this saline pan facies in the Ras Qaryah sabkha (scale division is in cm)

Saudi Arabia, with small local areas of halite and anhydrite in the most saline parts of both the inland and coastal sabkhas. Some of the large coastal sabkhas, such as Sabkhat ad Danan, have gypsum lunettes along the sabkha edge (Fig. 3.17c). Gypsum is also a widespread pedogenic precipitate in much of the arid landscape of eastern Saudi Arabia. The level of carbonate matrix in the Saudi sabkha increases with proximity to the present coastline with a few wet interdune seeps adjacent to the coast even supporting a healthy mollusc and gastopod population. Coastal margins to the sabkhas show a range of cemented carbonate crusts with some modern lagoonal shorelines showing megapolygons in marine-cemented layers identical to those of the Abu Dhabi lagoonal margin (Fig. 3.17d). The important difference in the sabkha between the two areas is the amount of eolian siliciclastics in the upper intertidal and lower supratidal sediments.

Brine seeps through the sand aquifer to replenish areas depleted via drawdown, driven by capillary evaporation within the lower parts of the sabkha depressions. Gypsum crystals grow in the pore spaces near the watertable, poikilitically enclosing sand grains, to form spectacular crystal clusters or desert roses (Fig. 3.17b). Individual crystals can be up to a metre across, but most are measured in centimetres. The proportion of gypsum in the crystals is more than the porosity of the adjacent loose sand, showing that gypsum is not only growing in the pore spaces, it is also displacing the sand as it grows (Warren 1991).

Gypsum typically grows in a matrix of brown quartz sand and silt, in a capillary zone that can actively precipitate gypsum up to 50 cm above the watertable. Some sabkhas, such as Sabkhat ad Danan are currently deflating so that parts of the surface of the sabkha are paved by isolated prismatic gypsum blades standing up along fracture polygons, while the edge of the adjacent sabkha is lined by a dissected terrain of gypsum lunettes (Fig. 3.17c). Most of the crystals at the surface are weathered white and have split along cleavage planes. Immediately below the sabkha surface the gypsum crystals are still entire. The Stokes surface overprint indicates a fall in the regional watertable or active hydraulic jacking, which moves crystals into the vadose zone. Ongoing deflation may in part be a response to regional uplift driven by the nearby salt diapir-cored Dammam dome, which is currently rising at a rate of 5.5 m per million years (Weijermars 1999). More likely, it indicates the local vagaries of erosion associated with ongoing autocyclic gypsum crystal growth jacking overlying sediment up and out of the capillary zone, where it is subject to intense wind deflation.

In the lowermost parts of the regional sabkha plain there are local depressions a few kilometres across where brines pond and the sediment surface periodically lies below the watertable.

There, marine-seepage fed saltpans are forming and filling with successive crusts of chevron halite, rather than the more typical displacive gypsum of the regional sabkha (Fig. 3.17b, e). Around the high salinity edges of these halite pans are zones of nodular anhydrite rather than the ubiquitous sabkha gypsum (Fig. 3.17f).

Sabkhas of Coastal Kuwait

Modern sea-margin sabkhas in coastal Kuwait are not developed at the same broad scale as those of Abu Dhabi or the Dammam region, but are nonetheless interesting as they illustrate a transition from a fluvio-deltaic to an alluvial fan-fluvial supplied sabkha in Kadmah Bay (aka Kuwait Bay) to a mixed eolian siliciclastic-carbonate matrix sabkha in the Al Khiran region to the south (Fig. 3.3a). Inland, Kuwaiti sabkhas are also widespread in depressions more than 10 km from the coast. Both inland and coastal sabkhas of Kuwait are largely hosted in sheets of reworked medium-grained quartz dune sand, along with variable amounts of eolian reworked authigenic gypsum sand (Al-Hurban and Gharib 2004; Khalaf and Al-Awadhi 2012). Compared to inland sabkhas, the detrital matrices in coastal sabkhas are slightly muddier, contain less gravel and show higher levels of gypsum due to their proximity to marine aerosols and marine seeps (Fig. 3.18).

Sabkhas of Kadmah Bay

To the north of Al Khiran sabkha, the Holocene sediments of Kadmah Bay (Kuwait Bay) represent the western-most limit of the siliciclastic Shatt Al-Arab delta and the southern limit of the alluvial fans of Jal Az-Zor escarpment (Saleh et al. 1999; Al-Sarawi 1988). Most of the sediment matrix in the western part of the Kadmah Bay hypersaline system is deposited at the distal end of large alluvial fans, downdip of the Jal Az-Zor Escarpment (Fig. 3.19a, b). In contrast, sabkha matrix in the northeastern part of the bay is fed substantial volumes of finer-grained sediment by longshore drift of sediment sourced in distributaries of the Shatt el Arab delta sediments. This higher volume of sediment supply means sabkha at the northeastern end of the bay has prograded further into the bay waters (Fig. 3.19a). Today, the bay is about 20 km wide, has a tidal amplitude of almost 2 m and is around two-thirds exposed during very low tide. Although very shallow, the lack of wave energy and the proximity of the muddy Shatt al Arab, means the central bay fill is very muddy and is near impossible to cross on foot at low tide.

Four sedimentary settings define the northwestern Kadmah Bay margin; namely alluvial fans, playas, sabkhas and beaches (Fig. 3.19b; Al-Zamel and Al-Sarawi 1998). Coastal sabkha deposits extend landward to where they interfinger with the distal ends of modern alluvial fans, much

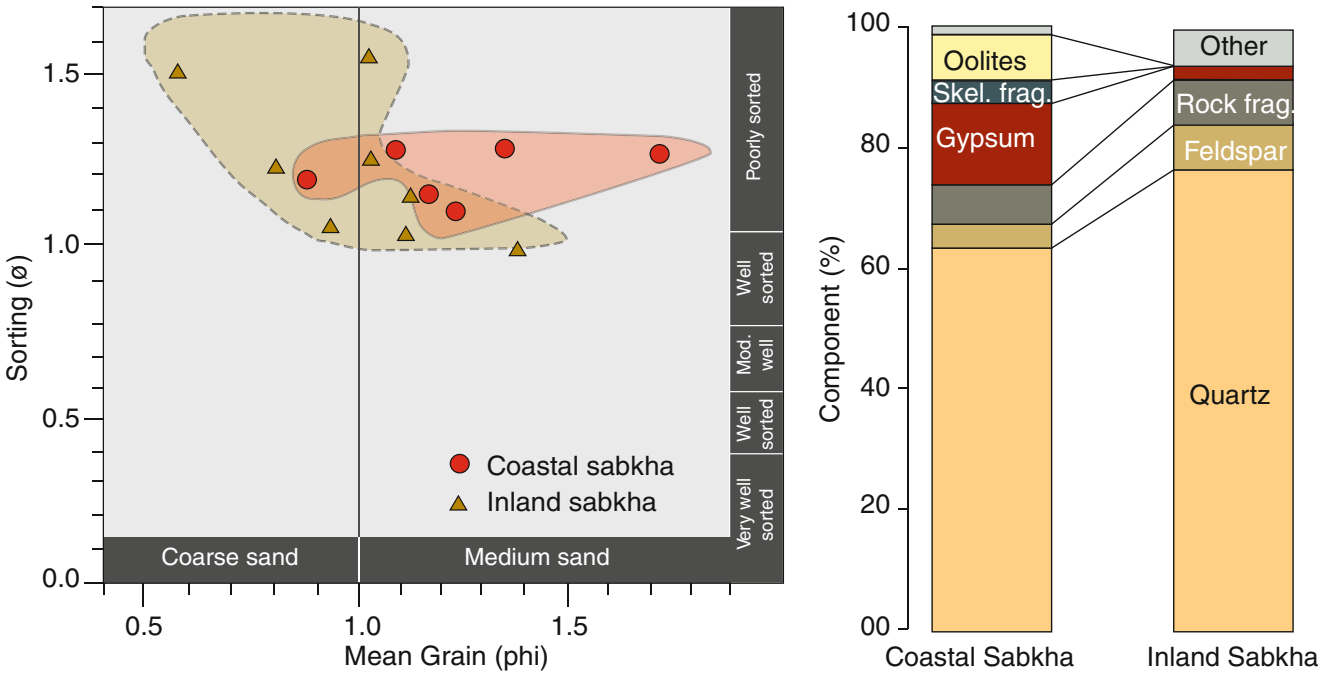

Fig. 3.18 Grain-size and mineralogical comparison between sediments of inland and coastal sabkhas of Kuwait (Replotted from Al-Hurban and Gharib 2004)

like the sabkhas of Ras Al Khaimah at the other end of the Arabian Gulf (Warren 1991). Distal fan sediments are typically plane-laminated sands interlayered with playa lacustrine muds and are often encrusted by a gypcrete carapace. Mid fan sediments are dominated by crossbedded and parallel laminated sands, while proximal fan sediments are poorly sorted imbricated gravels and poorly stratified pebbly sandstones.

Evaporitic Kadmah Bay sabkha sediments can be divided into two subfacies: (1) dark brown silt mixed with very fine sand, rich in prismatic gypsum, gypsum roses and gypsum nodules at the level of the watertable, along with some halite and aragonite and very minor amounts of anhydrite; and (2) light brown silts mixed with local anhydrite nodules in fine sands in the upper parts of the sabkha plain. Gypsiferous sabkhas dominate.

An erosional or deflationary regime now characterizes the sabkha of the coastal plain of Kadmah Bay (Saleh et al. 1999). Maximum marine flooding of the supratidal area is dependent on the coincidence of high water spring and/or storm tides with southeasterly winds and is an uncommon event. This results in a very limited portion of the tidal zone (0.6–0.7 km wide) being subjected to flood recharge during the normal tidal cycles. Away from the immediate bay waters, much of the active Kadmah Bay sabkha is best described as an evaporitic 'wind flat' or sandflat rather than a diurnally flooded carbonate mudflat. The closest comparable modern setting documented in the sedimentological literature is probably the evaporitic mudflat of the Colorado River delta (Shelton et al. 1978). Once again, this is a continental system that just happens to be at the edge of a modern sea and its hydrology is largely continental.

The dominant southeasterly flow of the Shamal wind means coastal sabkhas in Kadmah Bay and on Bubiyan Island are distinct from carbonate-dominated coastal sabkhas further south in the Gulf. The Shamal blows continental sediment south into the bay, so that the sabkhas are the seaward edges of deflation flats with matrices characterized by abundant siliciclastics, not carbonates. The dry windy setting means there is an absence of healthy laminated cyanobacterial mat along much of the intertidal sabkha strandline. It is simply too dry, so laminated cyanobacterial mat is mostly confined to small moister areas on the floor and the immediate vicinity of tidal channels.

However, oncolites can grow in this shallow subtidal to intertidal siliciclastic environment, mostly as syndiagenetic carbonate precipitates (Alshuaibi et al. 2012). The cyanobacterial population in oncolites is closely related to the population found in the subtidal sediments, along with abundant *Dunaliella viridis* (see Chap. 9). The biota forming the binder population are halotolerants, as it is a setting subject to periodically excessive hydraulic energy, extreme salinity (up to 47‰), and high concentrations of organic matter subject to bacterial sulphate reduction and elevated H_2S in the pore fluids.

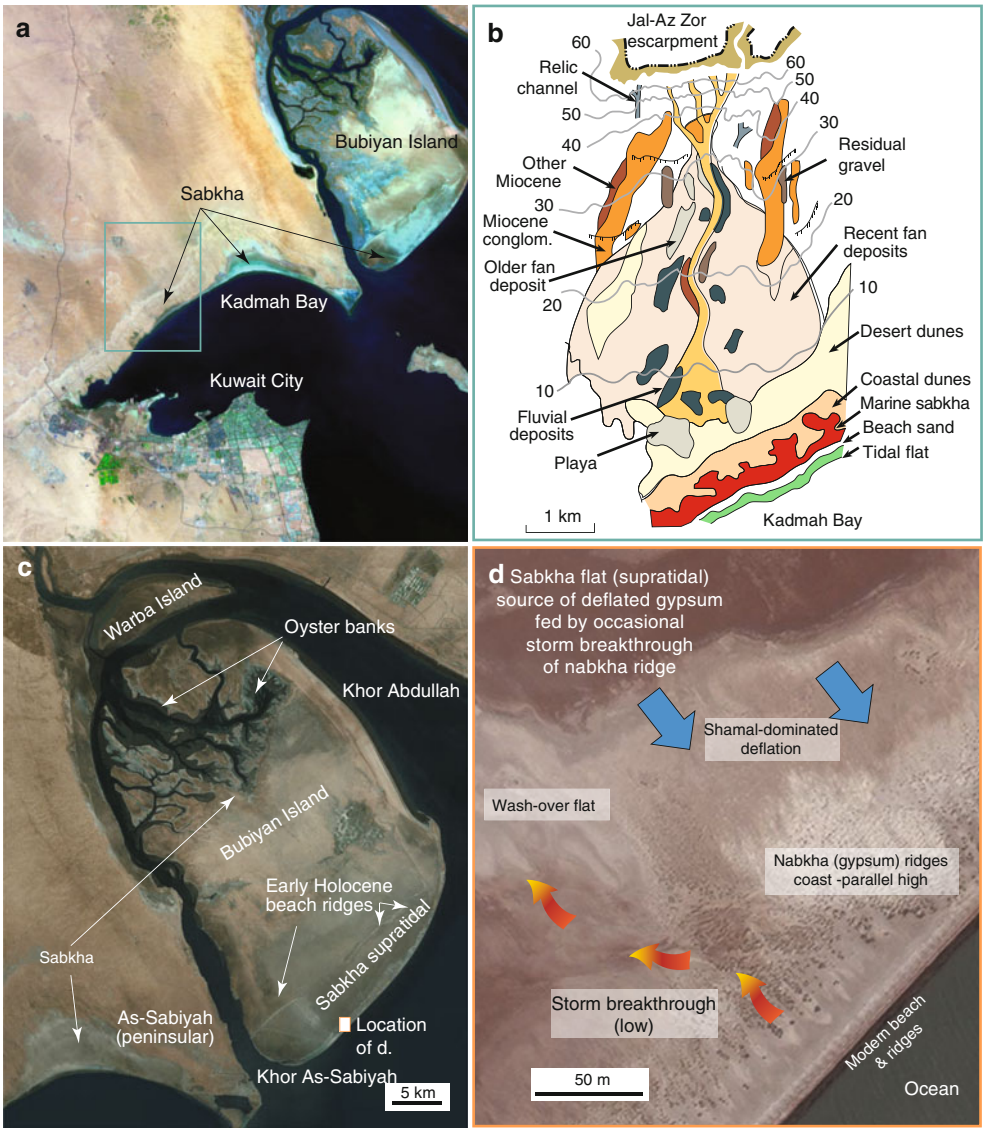

Fig. 3.19 Kadmah or Kuwait Bay (**a**) Shows the development of an extensive but narrow coastal sabkha with a siliciclastic matrix on the northern margin of the bay (Landsat image courtesy of NASA). (**b**) Surface geology of the region where alluvial fans pass south into Kadmah Bay sabkhat, Kuwait (After Al-Sarawi 1988). (**c**) General Holocene geology of Bubiyan Island (After Khalaf and Al-Awadhi 2012). (**d**) Relationship between coastal belt of gypsiferous nabkhas (low lunettes) washover breakouts and the deflationary supratidal sabkha plain

The mud-size fraction in the Kadmah sabkha (≈5 % of sediment volume) is dominated by carbonate minerals, but this carbonate is detritus from weathering carbonate strata to the north, not diagenetic or marine supplied material from the bay to the south (Saleh et al. 1999; Al-Bakri et al. 1984). Much of it is low-Mg calcite washed in from the surrounding plain where capillary calcretes (*gatch*) are commonplace. Similarly, almost all of the dolomite in the northern Arabian Gulf, including that on the floor of Kadmah Bay is detrital and derived either from longshore transport from the Shatt el Arab delta or is blown in by the Shamal as it scours the desert plains of Iraq (Al-Bakri et al. 1984). Numerous primary sheet flood and eolian structures are preserved beneath the prograding supratidal flat, with only minor disruption to these structures caused by local growth of intra-sedimentary gypsum. Gypsum and other capillary salts never dominate mineral proportions in the supratidal zone of Kadmah Bay (Fig. 3.18).

The windblown and deltaic siliciclastic coastline of Kadmah Bay has been prograding into the bay for 3,000 years at a rate of 1.5–2 km per 1,000 years. More landward, the preceding "Early Holocene" transgressive coastal sediments are made up of patchily distributed, autochthonous carbonates (aragonitic oolites, pellets and micrite), similar to the early Holocene beach ridge carbonates of the At Taf coastal strip. The Mid-Holocene transition to a siliciclastic matrix along the north coast of Kadmah Bay indicates the time when longshore currents flooded the northern bay with reworked muddy fluviodeltaics from the prograding Bubiyan channel.

Along the prograding southern coastal zone of Bubiyan Island the Shamal deflates gypsum from the coast-parallel

sabkha belt and so constructs a downwind coast-parallel nabkha belt (Fig. 3.19c, d; Khalaf and Al-Awadhi 2012). A nabkha[3] is defined as a vegetation-stabilised aeolian landform, which usually develops as result of the depositional capture of wind-driven sediments around desert shrubs in arid and semi-arid regions (Cooke et al. 1993). Typically they occur in the vicinity of dune fields where the dominant eolian component is quartz sand and other siliciclastics along with minor gypsum. Khalaf and Al-Awadhi (2012) make the point that the term "gypsiferous" is used for sediments containing gypsum (i.e., gypsum occurs in small amounts), while the term "gypseous" is used for sediments having gypsum as the main component, and go on to note the coastal nabkhas on Bubiyan Island are gypseous with well developed gypsite or gypcrete crusts.

In my opinion, the coast-parallel gypsum nabkhas of Bubiyan Island are an excellent example of a deflationary process set that dominates the sabkha edges in most saline depressions across the world. It is a response to the formation of the Stokes surface that caps all sabkhas (Table 2.15). I have seen similar gypsum nabkha rims to those of Bubiyan Island in the coastal and inland sabkhas in Saudi Arabia and the UAE. Nabkhas also line saline paleochannels and inland saline lakes in Australia and the southwest of the USA and atop the gypsum rim to the Dallol depression in Ethiopia. In all cases they are a response to flooding followed by desiccation and deflation (Fig. 3.19d). On Bubiyan Island the flood occurs via combinations of storm surge and high tides. In the various inland playas the flood is sourced in rainstorms and the resultant sheet flooding of the sabkha/playa depression. Gypseous nabkhas form best on the dominant downwind parts of a saline sump. In cases where substantial volumes of gypsum are deflated from the sump, they can evolve into downwind gypsum dunes or lunettes, as in White Sands in New Mexico, or Lake Eyre and Lake Frome in South Australia (Table 1.5). The distinction between a saline sump with a dispersed downwind gypseous nabkha rim, versus a more lake-edge defined gypseous lunette rim, probably indicates a hydrological contrast in the two depression styles, with nebkhas indicative of a more arid setting.

Al-Khiran Sabkha

To the south, near the Kuwaiti border with Saudi Arabia, Late Pleistocene and Holocene sediments are exposed in and about the sea-margin sabkhas in the Al-Khiran area (Fig. 3.20; Lomando 1999; Duane et al. 2004). The Al-Khiran sabkha is one of three carbonate-hosted lagoonal/coastal sabkha systems, some 120 km^2 in area. The Al Khiran sabkha, the best documented of the three sabkhas has much of its original depositional geometry now disturbed or destroyed by development of a resort city. All three sabkhas lie behind chenier belts of oolitic beach-dune ridges where large parts of the inter-ridge sabkha depressions are no longer subject to marine flooding (Fig. 3.20). In the Al Khiran sabkha the oldest and most landward exposed beach ridge is older than the Flandrian transgression. The four younger, accreted ridges, as mapped by Al-Sarawi et al. (1993), are dated at 6,800, 5,800, 3,000 and 2,000 years BP.

Sabkha flats in the various inter-ridge depressions were formed by sedimentary offlap, driven by the relative fall in sea level since the last Holocene transgressive maximum, approximately 4.5–4.7 ka. Sabkha evaporites (gypsum and anhydrite) in the inter-ridge depressions are hosted by aragonite-rich pellet muds, which also entrain significant amounts of comminuted marine shell material. Thin layers of blowing sand now cover portions of the sabkha to varying thicknesses, depending on depth to the top of the capillary fringe. Some of the anhydrite in the Al Khiran sabkha is unusual compared to the Abu Dhabi sabkha in that it first nucleates in zones of moisture stress around plant roots and so is an evaporitic form of dikaka or rhizoconcretion often related to vegetation-bound nabkhas (Gunatilaka et al. 1980).

At the regional scale, each of the three structurally controlled headlands has major modern shoal complexes several kilometres in length extending from their tips to the northeast along the structural axis of underlying folded successions (Fig. 3.20). Large bars within the shoal complexes are oriented roughly northwest-southeast, parallel to the longshore drift direction. At Ras Al-Qulay'ah, a bar complex extends seaward from the point of the spit, with an overall arcuate shape. Patch reefs grow along the windward northwestern flank of the bathymetric nose. Sediments from the nearshore to beachface are composed of fine- to medium-grained ooids with lesser amounts of quartz sand, intraclasts, and skeletal grains. At Ras Al-Zour (Fig. 3.20), the headland shoal and spit complex has the same overall geometry as Ras Al-Qulay'ah, and has begun to build above sea-level to form a small island. Headland spit extension is likely a response to anticlockwise eddy currents.

Sabkha development at each headland is related to the progressive cutoff of a marine lagoon, which formed in a sag located southeast of the sea-covered anticlinal high, where the carbonate sediment factories are flourishing in the shallows. Longshore transport is driven by the nigh-on coast-parallel direction of the prevailing winds (Shamal). As the entrance to a lagoon is choked, marine inflow becomes more restricted and sabkha evaporites start to precipitate in its marine sediment matrix. Khor Iskander illustrates the open stage of inflow hydrology (Fig. 3.21).

Today, during an annual sediment cycle in the Al Khiran sabkha, modern marine water diurnal inflows are confined to

[3]In original Arabic, nabkha (nebkha) translates as "small sandy hillock".

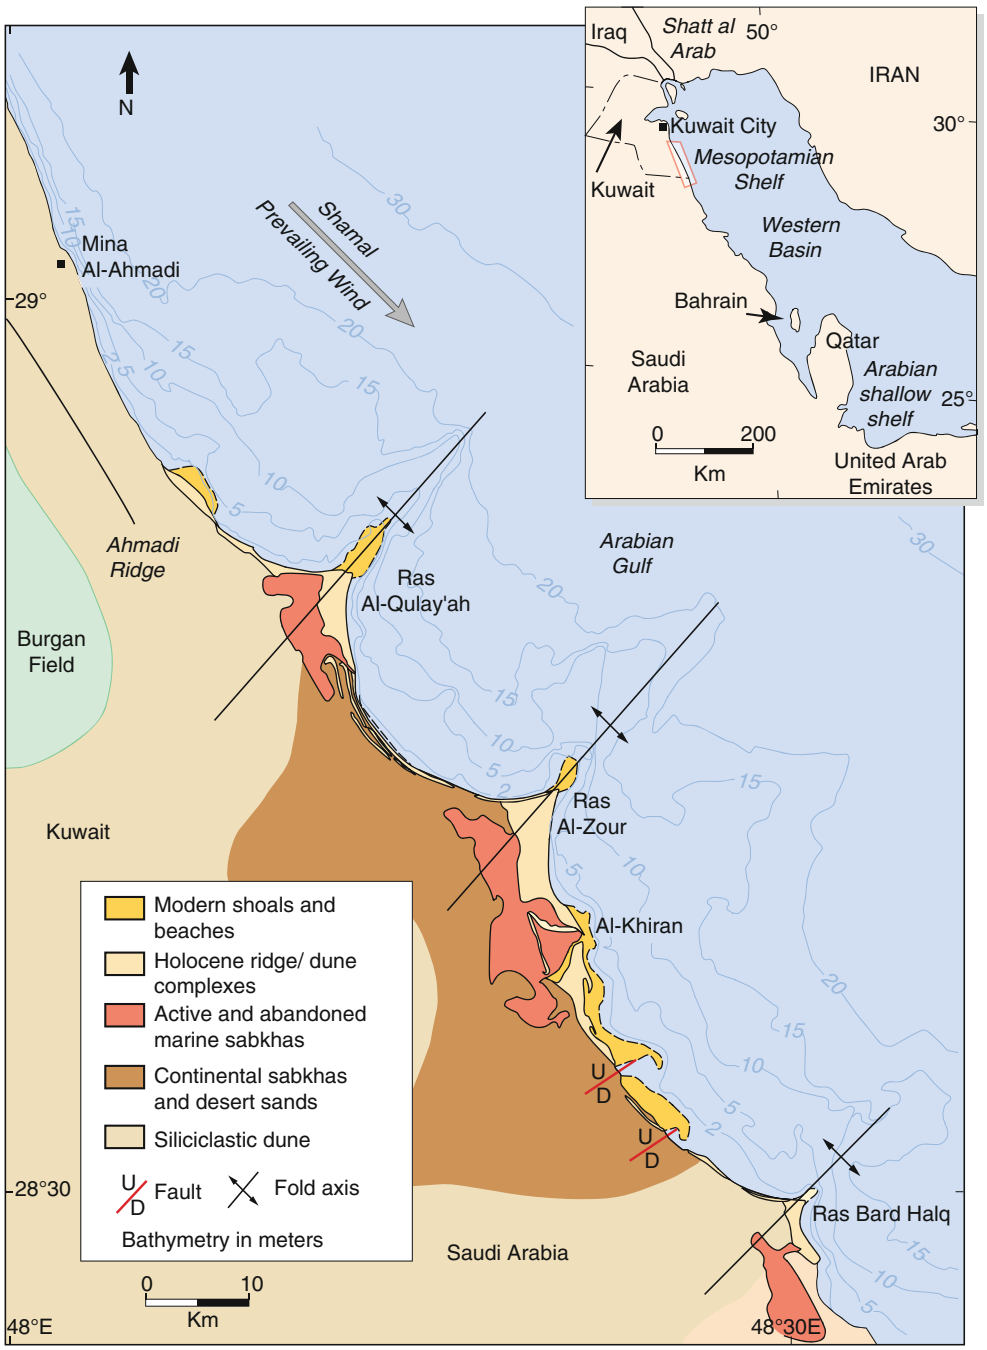

Fig. 3.20 Location map showing the major coastal deposits and offshore bathymetry along the Kuwait- Saudi Arabian coast. Prevailing wind direction (Shamal) is from the northwest. General facies distribution patterns are associated with folds and are repetitive across each of the three-fold related headlands. Siliciclastic dune fields are best developed in the intervening sags between the headland folds while the sabkhas form in the protected lee of the carbonate sediment buildups that typify the three structurally-controlled headlands (After Lomando 1999)

two tidal creeks cutting the Al-Khiran sabkha (Fig. 3.21; Gunatilaka et al. 1987). Occasionally, perhaps a few times in a year, a narrow strip, up to a 100 m wide adjacent to the creeks, is covered by tidal waters, brought there by exceptionally high spring tides and/or storm surges. An absence of significant marine flooding over the rest of the sabkha means much of the current hydrology and pore chemistry is controlled by influxes of continental groundwater. This topographic-continental hydrologic framework is also reflected in the formation of diagenetic continental dolomite in some depressions on the salt flat, as well as the isotopic make-up of the dolomite, which indicates a continental or nonmarine source, with similarities to the Coorong dolomites.

Major ions show a steady evaporative concentration across the sabkha from inland to the coast, with a "high" chloride plateau in the central parts of the marine sabkha similar to the plateau that occurs in the Abu Dhabi sabkha (Robinson and Gunatilaka 1991). Monitoring of groundwater over a 3-year period indicated that: (a) when the water-table depths are <1.2 m, the sabkhas are in a state of depositional equilibrium; (b) watertable fluctuations (due to

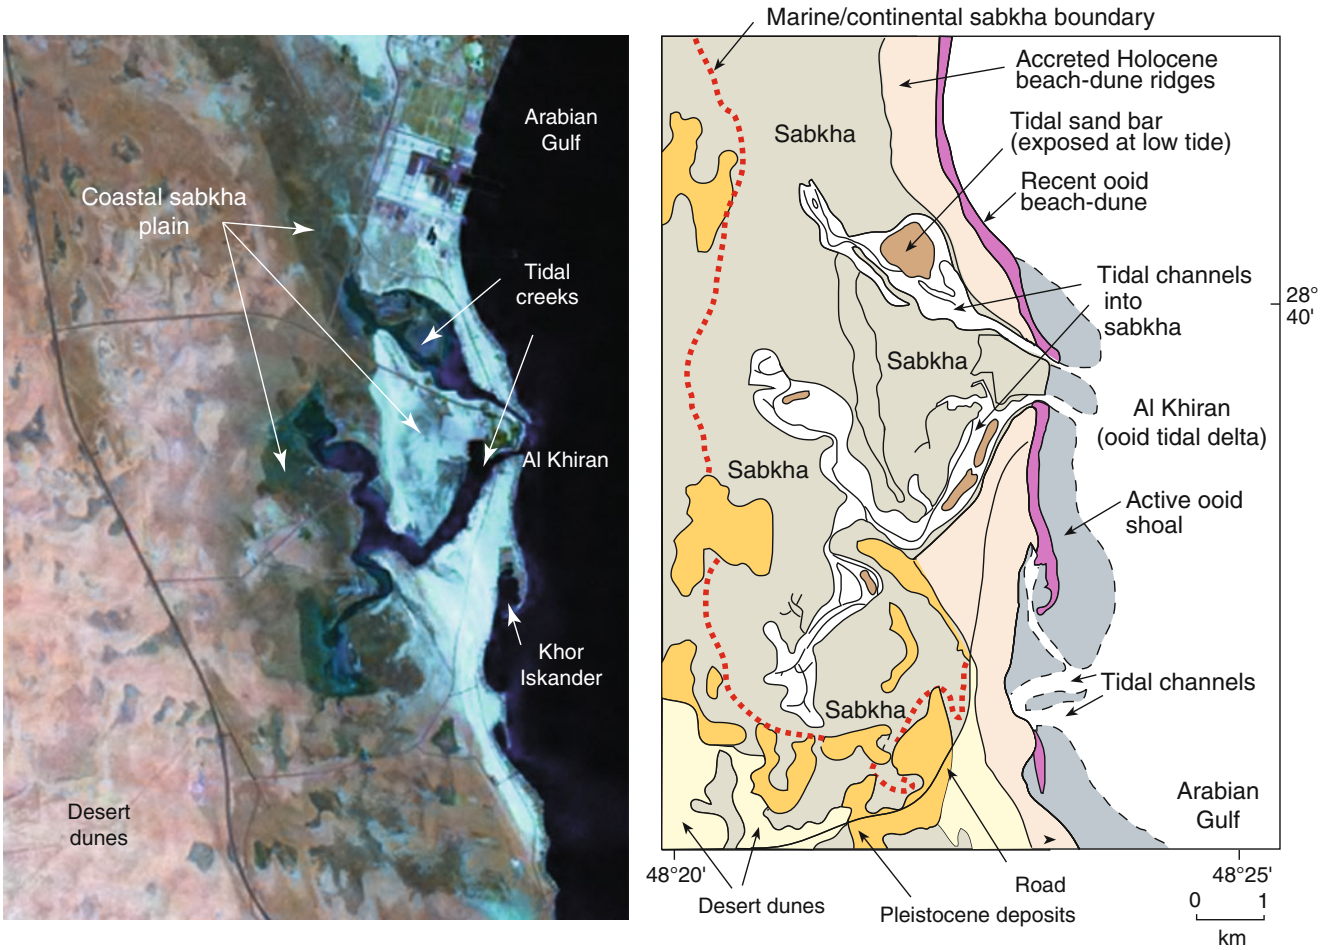

Fig. 3.21 Surface geology of part of the Al-Khiran sabkha, Kuwait, showing the importance of accreted ooid beach ridges in forming the structural framework of the coastal sabkha estuary and the passage into dune sands in the sabkha hinterland. Year 2000 vintage is used as subsequent engineering works have constructed a luxury marina at this site and depositional patterns have been drastically altered (Landsat image courtesy of NASA, surface geology after Gunatilaka et al. 1987)

drawdown or recharge) exceed 0.5 m/year; and (c) calculations based on measured fall in watertable levels, porosities of the sediments, and the volume of anhydrite formed in the sabkha all suggest that over the last 4,700 years, since progradation commenced, only 2–4 cm/year (net) of groundwater is lost from the sabkha surfaces. This is a surprisingly low rate for this arid region and indicates significant replacement by resurging continental groundwaters. This groundwater replenishment maintains longterm stability of the sabkha sequence. Without it, deflation would dominate and most of the older sediment would be planed off to the level of the intertidal/subtidal crust, much like what has occurred on the backside of Kadmah Bay.

Supratidal anhydrite in the Al Khiran sabkha has three distinct morphologies (Gunatilaka 1990): (a) hair-cream anhydrite, which occurs exclusively in association with the halophytic saltbush *Halocnemum strobilaceum*; (b) nodular/laminated cottage cheese anhydrite, which is associated with a bacterial-cyanobacterial mat. This nodular anhydrite forms massive layers up to 4 cm thick with the anhydrite initially pseudomorphing gypsum crystals in the mats. In laminated anhydrites it can form aphanitic layers up to 7 cm thick, made up almost entirely of microcrystalline anhydrite; (c) anhydrite formed by the alteration of prismatic gypsum crystals now exposed in the lowermost parts of some now abandoned and desiccated drainage channels.

With "hair cream" anhydrite, climate and biological influences play a significant role in what is often an annual mineralogical change between gypsum and anhydrite, depending in part on rainfall intensity. On the death of the halophyte, hair-cream anhydrite reverts to microcrystalline alabastrine secondary gypsum and then to a gypcrete. The gypsum-anhydrite transformation is a reversible dissolution-reprecipitation process and there appears to be an intimate relationship between the plant, its "soil water" requirements and the hydrodynamic behaviour of capillary groundwater brines in the vadose zone, which interact to control mineralogy. Compared to "hair cream" anhydrite, type (b) anhydrite

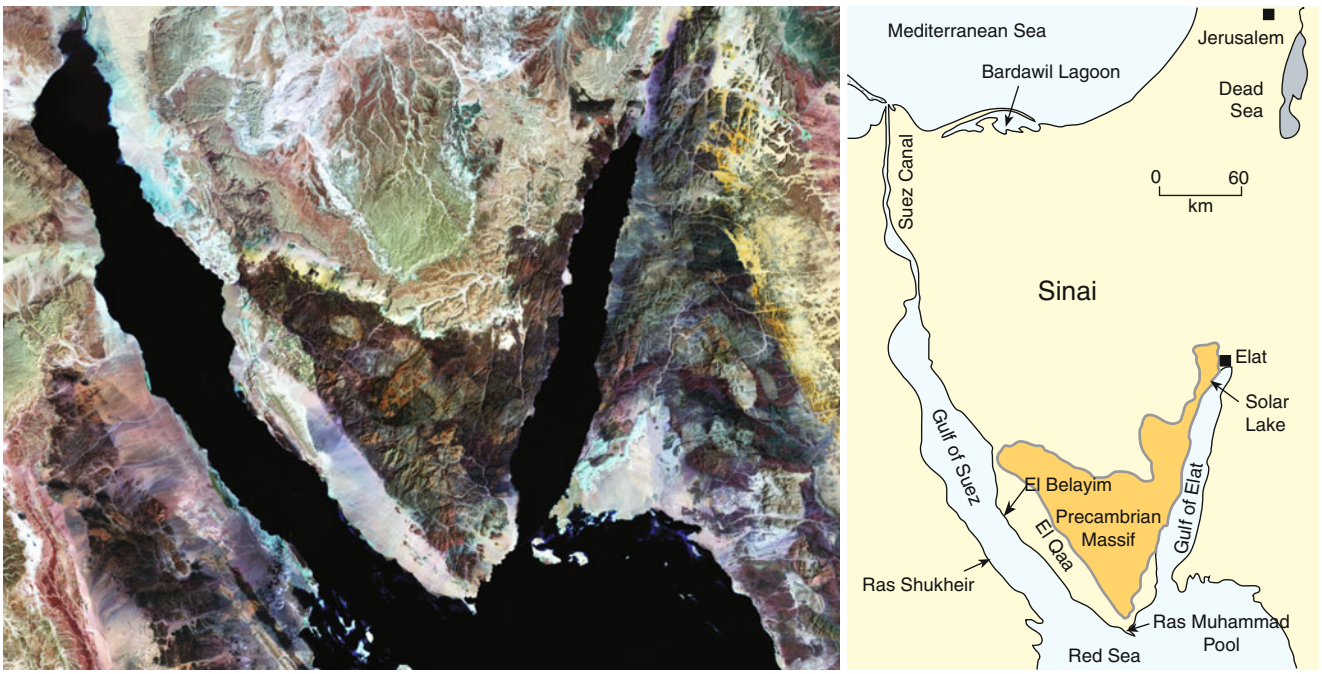

Fig. 3.22 Sinai Peninsula showing distribution of some of the studied Holocene sabkhas and salinas in the Quaternary coastal fringe (Landsat image courtesy of NASA)

is more likely to be preserved as anhydrite, not gypsum, at least into the shallow subsurface above the watertable. Type (c) anhydrite is rare and possibly only forms with complete drying of the channel bottom, it is always susceptible to deflation or rehydration and so has low preservation potential compared to types (a) and (b).

All anhydrite in the Al-Khiran sabkha forms from a gypsum precursor at temperatures >30 °C, with brine chlorinities >4 mol Cl/kg. Al-Khiran is the northernmost occurrence of widespread patches of anhydrite in the coastal belt of the Arabian Gulf (gypsum dominates further north). It also defines a change in lagoonal matrix in the coastal plain to the fluviodeltaic sabkha coast of northern Kuwait and Iraq.

Other Coastal Sabkhas

Outside of the southern coast of the Arabian Gulf there are many other coastal deserts where evaporation of a combination of marine and continental waters precipitates capillary salts in a matrix of marine-reworked sediment.

Gulf of Suez

Sea-margin sabkhas occur along both sides of the Gulf of Suez. Small sabkhas are patchily developed along the seaward edge of the El-Qaa, in a coastal strip that runs from Abu Rudeiz to Ras Muhammad (Fig. 3.22; Gavish 1974, 1980). The El Qaa is a near-flat alluvial plain, mostly composed of alluvial silicate minerals weathered from Precambrian metasediments and granitic massifs to the east. The El Qaa area experiences some of the hottest and driest conditions in the Sinai, yet it lacks substantial accumulations of sabkha anhydrite or other salts. Capillary evaporites where they do occur are mostly scattered patches of interstitial gypsiferous cements within a few hundred metres of the coast (Fig. 3.23). Nowhere in the Sinai coast are sabkha salts as extensive as in the Arabian Gulf sabkha, indicative of a lack of shallow groundwater to source capillary precipitates (Gavish 1974). Gypsiferous capillary cements in marine-reworked siliciclastic matrices, are also patchily developed in a narrow coastal strip on the opposite (African) side of the Gulf of Suez (Keheila et al. 1989). At Ras Shukheir the sabkha is unique in that it is developed atop and around one of the world's few examples of a Late Pleistocene coastal salina, which was once filled with laminated subaqueous gypsum, although now the succession is heavily eroded (Fig. 4.16).

The sabkha fringe to the Gulf of Suez coastal plain typically extends from the marine shoreline to the seaward base of an alluvial fan apron or bajada, which lines a faulted escarpment located up to a kilometre or more in the hinterland. The sabkha itself usually occupies the first few hundred metres immediately landward of the shoreline where the bajada watertable approaches the landsurface in what is typically a fan delta coast (Fig. 3.23a). Matrix sediments are mixtures of clastic fine-sands, derived from alluvials, and marine carbonate washover sands composed of skeletal

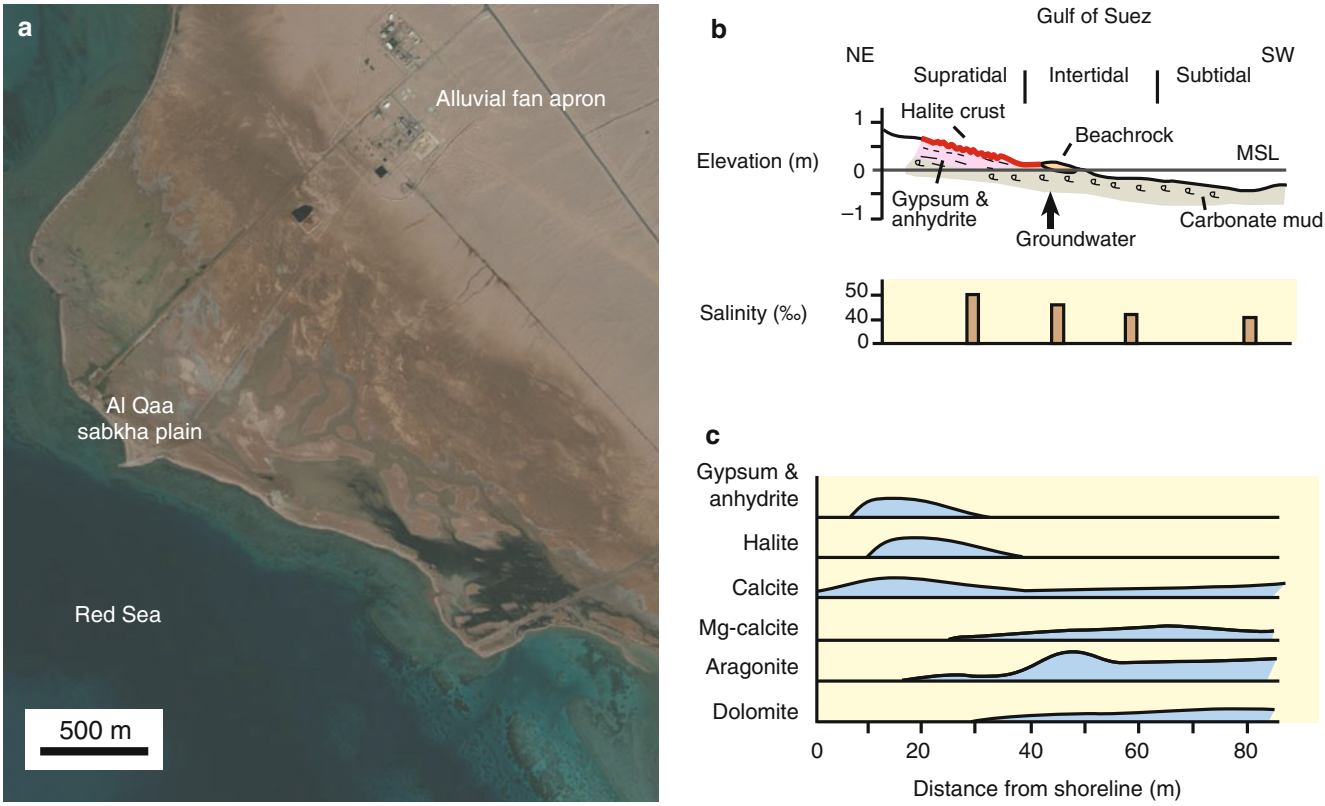

Fig. 3.23 Gulf of Suez sabkhas. (**a**) Geological overview of the Al Qaa region, Red Sea (Bing® image scaled and mounted in MapInfo®). (**b**) Generalised cross section through sabkhas of the coastal zone of the Al Qaa region, Gulf of Suez and typical pore water salinities (After Gavish 1980). (**c**) Idealised distribution of various mineral phases in terms of distance landward from the marine shoreline in Al Qaa region. Gypsum, anhydrite and halite are the main evaporite minerals (After Gavish 1980)

fragments, pellets, ooids, and some intraclasts (Sellwood and Netherwood 1984). Finer-grained marine carbonates typically occupy the seaward side and coarser-grained alluvial clastics occur on the landward side, so that the proportion of carbonate decreases upward in a prograding sabkha cycle. In many places there is an elevated sandy berm or a strip of pebbly beachrock defining the upper limit of the intertidal zone and a sabkha flat is developed behind the berm (Fig. 3.23b). The supratidal zone generally extends a few hundred metres inland, its width being dependent on the regional slope. Further landward the top of the capillary fringe passes below the landsurface. Storm surge waters occasionally cover portions of the supratidal flat and a thin ephemeral crust of pressure-ridged chevron halite may form a cm-thick cap to the sabkha as the surface waters disappear. The crust too disappears in the next flood or rainstorm. Once again, it is highly likely the hydrology of the crust is decoupled from that of the underlying sabkha.

Evaporite mineral distribution in a typical Gulf of Suez sabkha is very similar to the mineral suite in an Arabian Gulf sabkha but the volumes of capillary salts and their lateral extents are far less. Sabkha depositional belts are much narrower due the greater slopes as they occur mostly on the seaward edges of alluvial fan aprons advancing into the Gulf of Suez. Like the Arabian Gulf, the Gulf of Suez sabkhas precipitate evaporites mostly as displacive crystals within the supratidal zone (Fig. 3.23c). Capillary driven concentration precipitates salt in a matrix-rich supratidal evaporite unit, which is no more than 60–80 cm thick – the thickness of the capillary fringe. Most of the gypsum is precipitated as passive pore cements immediately above the watertable. Gavish (1974, 1980) attributes most of the ion supply to landward seepage of seawater, driven by capillary evaporation, as per the model of Hsu and Schneider (1973). The hydrology of the Gulf of Suez sabkhat has not been re-assessed since the work by Wood et al. (2002) on sabkhas of the At Taf coastal strip.

One of the most obvious differences between the Gulf of Suez sabkhas and the Arabian Gulf sabkhas is the distribution of the two calcium sulphate phases (Gavish 1974). In the Gulf of Suez, gypsum is the dominant sabkha mineral in all active parts of the sabkha. Only very minor traces of anhydrite are found and only in the older more elevated portions of the sabkha where it has locally recrystallised or replaced a gypsum precursor.

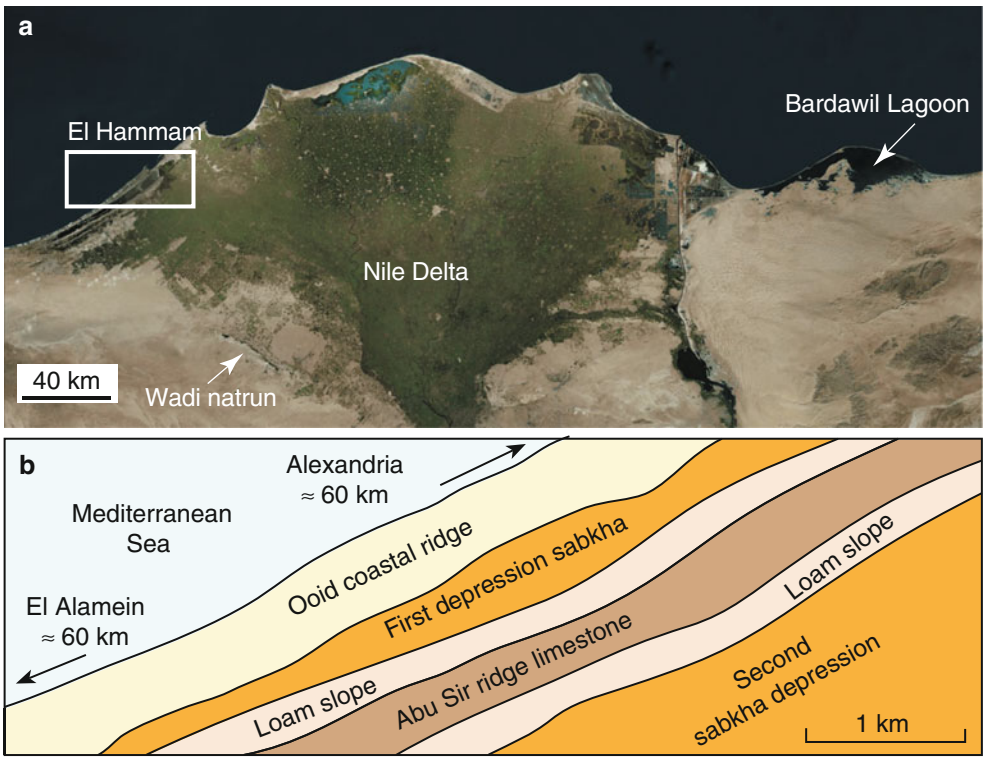

Fig. 3.24 Nile Delta. (**a**) Egyptian coast centred on the Nile Delta. Interdunal coastal sabkhas occur on the eastern end of the vegetated Nile cone (rectangular inset, while Sabkhat Yathal Yam occur on the southern side of Bardawil Lagoon beyond the eastern end of the Nile delta (Bing® Image mounted in Mapinfo®). (**b**) Surface geology of El Hammam sabkhat in interdunal depressions (After West et al. 1979)

Beach-Dune and Fluvial Sabkhat on Deltas

Modern sea-margin settings where large river systems are building deltas into the marine realm in arid settings are areas that set up shallow watertables and so can host local near-coastal sabkha systems. They form where the capillary fringe intersects the land surface and so tend to be preserved either in more protected subsealevel depressions behind coastal beach ridges (Nile Delta) or as fringes to coastal lagoons fed by occasional storm surges and marine floods (Bardawil Lagoon).

Western Nile Delta Coast, Mediterranean, Egypt

Interdunal sabkhas of the Nile delta are forming today along the Mediterranean coast near El Hammam, a region halfway between Alexandria and El Alamein (Fig. 3.24; Bellah and Hassouba 1995). There the coastal zone consists of nine or more Quaternary shore-parallel carbonate beach-dune ridges. All the ridges are cemented with a hard caliche cap, except the most recent dune known as the "coastal ridge." Lagoonal and desert loess sediments fill large swaths of the elongate depressions between the ridges and act as host matrices to the sabkha precipitates.

The first sabkha depression is situated immediately behind the "coastal ridge" of oolitic sand and is more than 8 km long and a few 100 m wide (Fig. 3.24b; Ali and West 1983; West et al. 1979). Displacive nodular gypsum (with minor palygorskite/attapulgite) is growing in the capillary zone of the carbonate-rich desert loess that has filled this most seaward interdunal depression. Landward and to the south, beyond the Abu Sir limestone ridge (Pleistocene), there are other interdunal sabkhas forming about and within various halite-encrusted, cyanobacterial-mat-fringed lakes.

Sediment behind the third ridge back from the coast is very interesting in that it contains a laminated gypsum fill, which is possibly the preserved remnant of a Pleistocene subaqueous deposit (pers. obs). The beds there are extensively quarried and well exposed, but as yet its geology is poorly documented and it is not known if it formed as a marine-fed salina or as a continental chott. The fact that this laminar gypsum fill alternates with thin limestone layers preserving articulated shells of *Cardium sp.* argues perhaps for a marine seepage origin.

All the sabkhas in the inter-ridge depressions are characterised by gypsiferous capillary zone units up to 60 cm thick made up of a combination of lenticular to prismatic gypsum crystals, and small spherical to elliptical nodules 1–4 cm wide composed of silt-sized gypsum. There is no anhydrite growing in the capillary fringe. Matrix sediment is a mostly brown, laminated, very fine quartzose silt and carbonate sand. It was deposited as desert loess and is occasionally reworked by sheet floods shed from the adjacent ridges. Nodules grow most efficiently in Zone III and IV of the inter-ridge sabkha, with more saline pore waters above and less saline waters below (Fig. 3.25). Nodules in zone IV and the uppermost part of Zone II are soft, very friable, uncemented and still maintain high intranodule porosity and permeability. Zones of coalesced nodules can create local upward-bulging enterolithic structures. Nodules made of

After Ali and West (1983)

small gypsum crystals typically overlie nodules composed of larger crystals. The relationship between crystal size and distance from the sabkha surface shows that nodules are precipitating in the active capillary zone and do not form by replacement of an anhydrite precursor. As capillary gypsum crystals continue to grow, the nodule expands by pushing aside and deforming adjacent sediment laminae. The fine-grained nature of the hosting loess encourages displacive growth rather than passive interparticle poikilotopic growth. Minor amounts of authigenic calcite and dolomite are also precipitated.

A marine-seepage origin for the gypsum nodules was inferred by Ali and West (1983), based on the seawater-like proportions of the interstitial brines and periodic gypsum saturation in waters of zones III and IV in the waters of the first inter-ridge depression (Fig. 3.25; Table 3.4). But as we saw in Chap. 2 seawater-like proportions in a groundwater do not necessarily mean a seawater origin in continental areas with caliche. Salinities of phreatic groundwaters in Zone II vary from 40 to 80‰, with a mean of 59‰, which is almost twice as concentrated as seawater. Na, Mg and Cl are present in thalassic proportions; Sr is somewhat in excess, as are Ca and SO_4, an association that probably indicates ongoing dissolution of gypsum. Above Zone II, salinities increase upward in zones III and IV. Zone IV, with a predominance of growing gypsum nodules has an average pore water salinity of 148‰ (Fig. 3.25). The uppermost part of the sabkha interval has the highest salinity pore waters, averaging 327‰, a salinity value that is five times that of zone II. Na and Cl maintain their relative proportions, tied to brine concentration in Zones II through V (five-fold increase from Zone II to V). K rises nine-fold over the same interval and Mg about

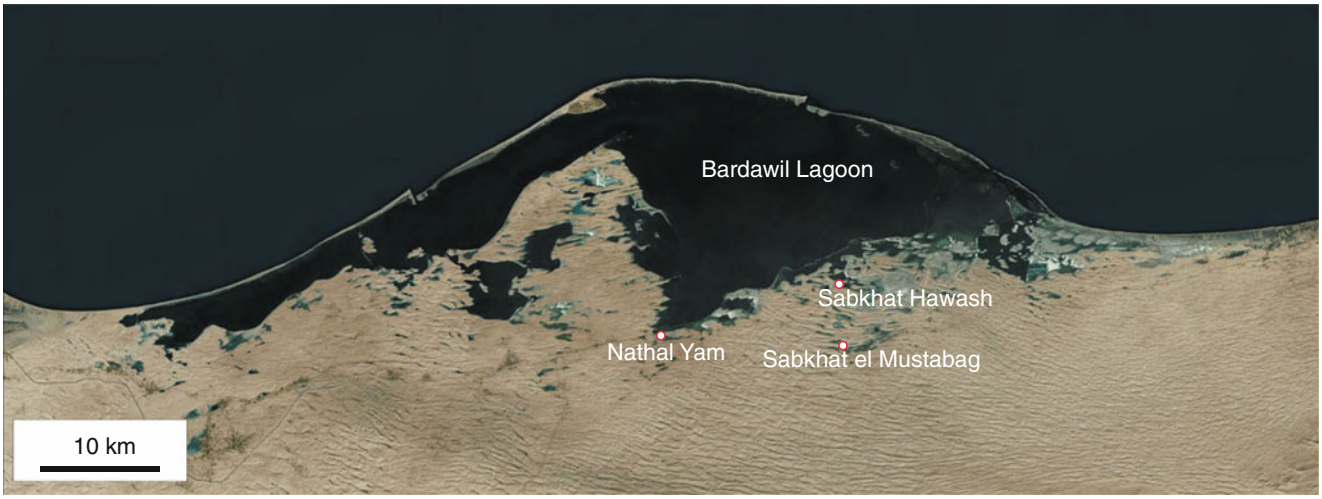

Fig. 3.26 Southern coast of Bardawil lagoon, northern Sinai, Egypt, shows beach-lagoon and interdunal sabkhas within the coastal portion of a sand sea dominated by longitudinal (seif) dunes. Sabkha deposition was a response to a rise in the regional watertable driven by the end-Pleistocene rise in sea level to its present position some 6 ka (Image courtesy of NASA)

eleven-fold. In contrast the Ca content is almost constant in zones II through IV and drops sharply in zone V, showing that gypsum is actively precipitating in zones III and IV. Sr shows a similar trend to Ca, although it does not decrease as sharply in Zone V. SO_4 increases upward to a concentration in Zone V that is a six-fold increase over its levels in the groundwaters of Zone II.

Ali and West (1981) utilised the measured hydrogeochemistry of the interstitial waters to argue for gypsum precipitation by capillary evaporation of thalassic seepage waters via "per ascendum" rather than a "per descendum" model, although at the time they published their work the latter was the prevailing interpretation for a sabkha hydrology.

This series of Egyptian coastal sabkhas is of interest as it is an active sabkha plain in the low-fluvial-supply (desert loess) coastal portion of the prograding Nile delta. It also shows that extremely arid conditions are not a requirement for evaporite nodule growth; it only needs the appropriate seepage hydrology where the capillary fringe intersects the land surface and there is an excess of evaporation over inflow. These sabkhas are actively accumulating gypsum in a region where annual rainfall is ≈ 18 cm.

Once again, like the At Taf sabkha, it demonstrates the lack of preservation potential of any salts precipitated in the seepage hydrology of all modern coastal sabkhas. Once the gypsum nodules are buried into Zone II they are seen to dissolve in rising phreatic brines, which are undersaturated with respect to gypsum (Fig. 3.25). Gypsum is being recycled through the upper parts of a subsiding profile and its preservation potential is low (implications of this typical saltflat hydrology are discussed further later in this chapter).

Eastern Mediterranean Coast of the Nile Delta and Northern Sinai

On the other side of the Nile delta, the northern Sinai coast is bordered for about two-thirds of its length by the Bardawil Lagoon (Figs. 3.24 and 3.26; Levy 1977a, b, 1980). It is a broad marine lagoon with smaller evaporitic sabkha/lagoons in interdunal depressions along its southern coastal interface. The southern part of the Bardawil also defines the coastal desert edge of an extensive sand sea or erg dominated by longitudinal or seif dunes. Regional climate is arid, evaporation rates are high (≈2 m/year) and precipitation is low (≈100 mm/year). Marine-influenced sabkhas on the southern side of the lagoon occur wherever the capillary fringe intersects the landsurface and are of two types: (1) Coastal sabkhas (also called lagoon-beach sabkhas-see Warren 1991), which are at present connected to the lagoon and flooded occasionally by seawater – examples include the inner lagoons and Nahal Yam, and (2) Near-coastal interdunal sabkha depressions, which are now cut off from the lagoon by sand dunes – examples include Sabkhat Mahzin and Sabkhat Hafiordim (Figs. 3.26 and 3.27a). Both types of sabkha formed as a rising marine watertable, created by the Late Pleistocene-Holocene transgression, encroached upon the erg. There is also a third type of sabkha in the region; it is typified by large inland eolian sabkhas such as Sabkhat el Mustabag and Sabkhat Bir Kasiba. This group of sabkhas is carbonate rich and formed under a Late Pleistocene paludal hydrology, which was active at the edges of this desert sand sea in more humid climatic periods. Eolian-lacustrine sabkhas are discussed in more detail toward the end of this chapter.

The largest documented coastal-beach sabkha, Sabkhat Nathal Yam, is about 7 km long and extends about 1 km

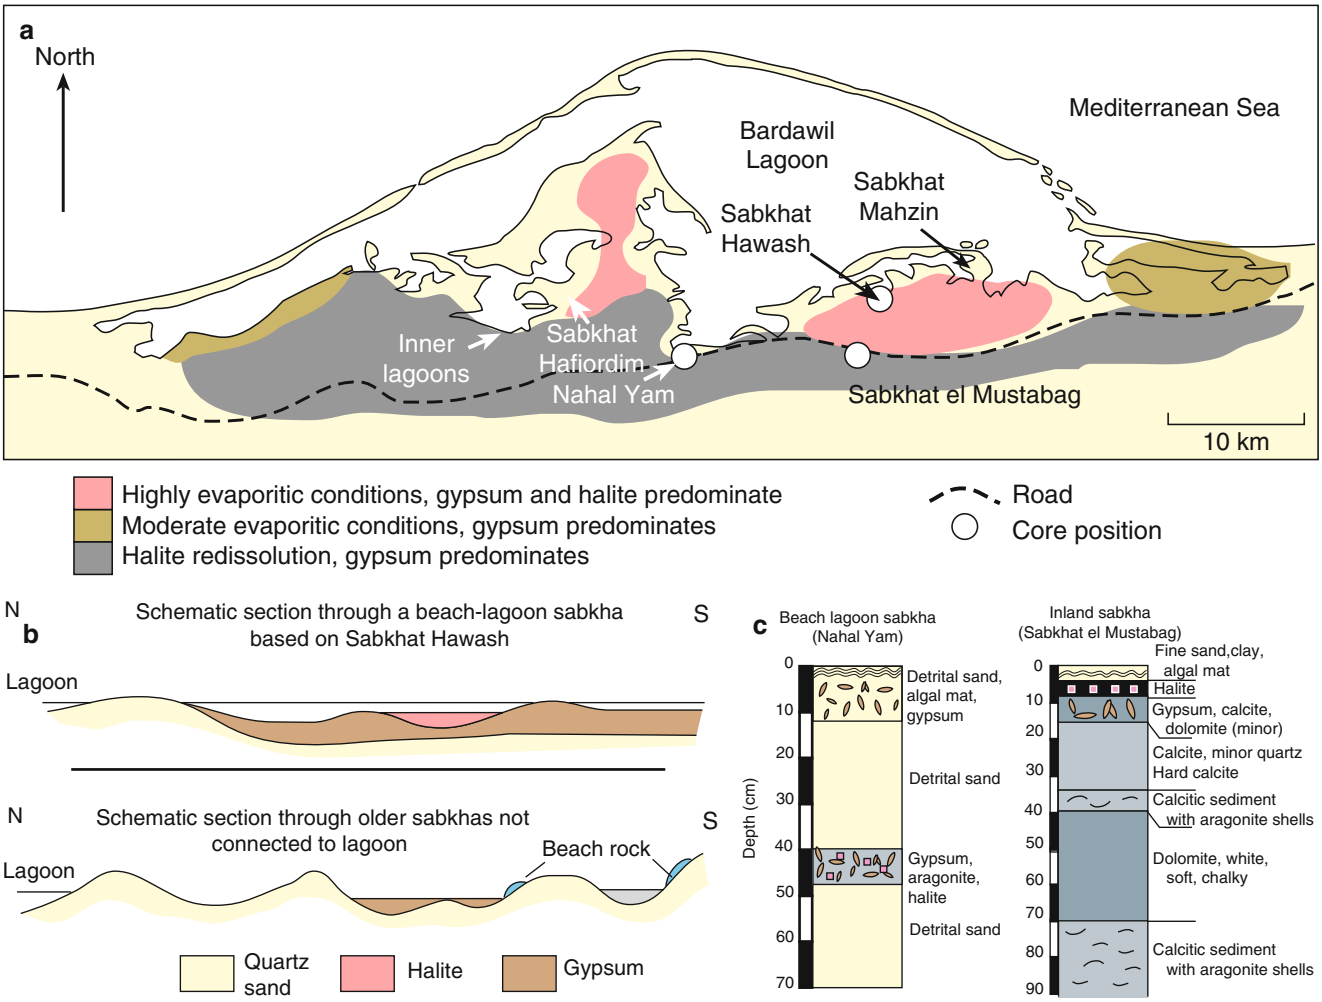

Fig. 3.27 Sabkhas of the Bardawil lagoon, Mediterranean Coast, northern Sinai (After Levy 1977a, b; see Fig. 3.22 for locality). (**a**) Distribution and mineralogy of sabkha salts south of the Bardawil Lagoon. (**b**) Schematic cross section through a beach-lagoon sabkha based on Sabkhat Hawash, showing differences in lateral scale with older inter-ridge sabkhas. (**c**) Composite vertical section in a beach-lagoon sabkha based at Nathal Yam, it is based on cores taken at 20, 500 and 700 m from the beach line

inland. To the south of the lagoon beach sabkhas, coastal interdunal sabkhas extend inland to a distance of about 1–4 km and are accumulating capillary salts from hypersaline capillary water lenses surrounded and underlain by slightly less saline continental phreatic wedges. These "inland" eolian sabkhas tend to be a few kilometres long and less that a kilometre wide (Fig. 3.27a). They define a coast-parallel hydrological transition from marine seepage into continental groundwaters carried in the unconfined aquifers of the regional sand sea or erg.

Both types of sabkha are typified by siliciclastic matrices, with displacive gypsum occurring within supratidal evaporitic units up to 60 cm thick (Figs. 3.27b, c). The intertidal zone in the beach-lagoon sabkha of Nathal Yam is 200–300 m wide and is regularly flooded by tidal waters of the lagoon. The intertidal is characterised by cyanobacterial mats, interlayered with low Mg-calcite muds and containing marine gastropod and lamellibranch shells derived from the lagoon. Lenticular and prismatic gypsum crystals are growing in the cyanobacterial mat layer in the more landward parts of this zone; it is very similar to the gypsum mush zone of the At Taf coastal strip. Landward of the intertidal zone is a 100 m-wide outer flood recharge zone, it experiences no more than an occasional marine flood (a few times a year) during a fortuitous combination of storms and high tide. There, the cyanobacterial mat is covered by a thin layer of detrital quartz sand and otherwise lies atop the same basic sequence of sediments found in the intertidal zone. Landward, still at the southern end, is a 500 m-wide supratidal zone. This area is not currently flooded by lagoon waters, even during storms and defines the interval where the capillary zone intersects the land surface. Under an ephemeral halite crust it hosts displacive gypsum lenses and prisms in a matrix that is otherwise identical to its more seaward counterparts.

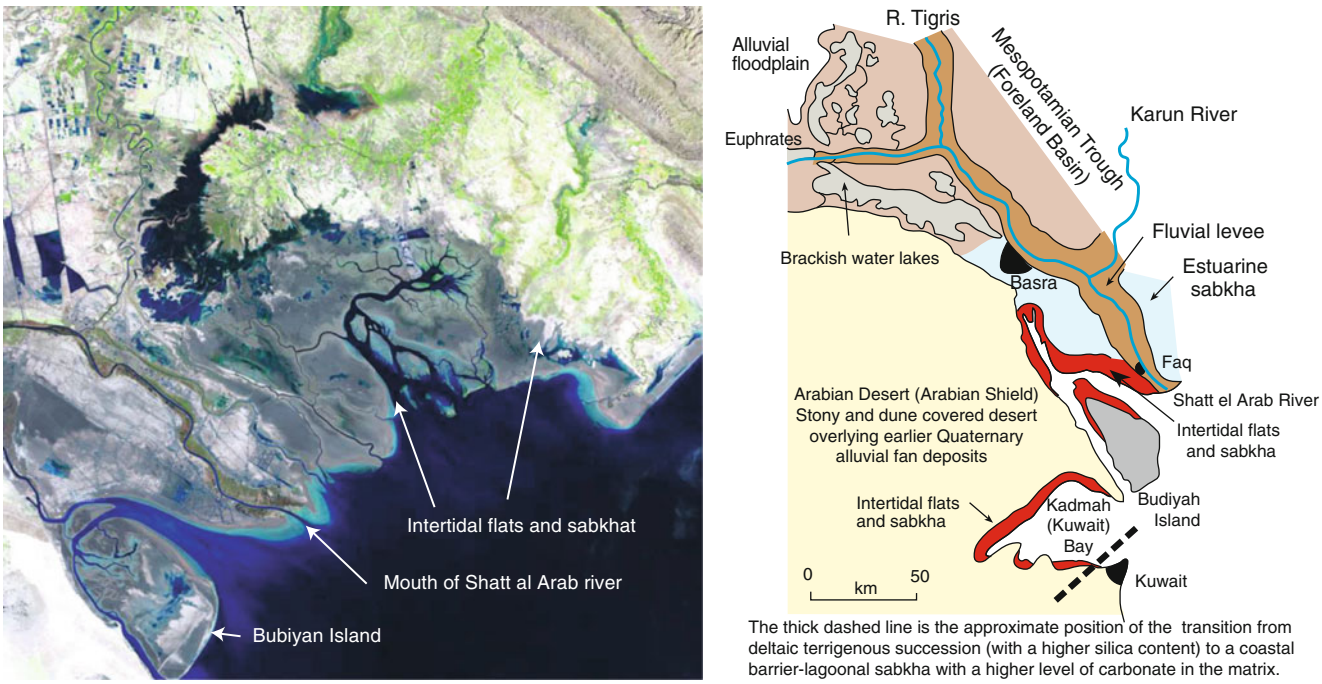

Fig. 3.28 Distribution of fluvial related facies including estuarine sabkha with a siliciclastic matrix along the lower length of the Shatt el Arab River. Note Kuwait Bay in lower centre of geology map (Landsat image courtesy of NASA, surface geology after Evans 1995)

Unconfined continental groundwater, moving north toward the shoreline, periodically seeps into the supratidal zones of all the beach lagoonal and near coast "inland" sabkhas along the southern side of Bardawil Lagoon. Rising water levels occur after heavy winter rains and create ponds of surface water that rapidly evaporate to precipitate thin halite crusts and efflorescences. In fact, most of the present freshened inflow into the supratidal zones both beach-lagoon and coastal interdunal sabkhas comes from a winter groundwater flood from the nearby dunes and not from any influx of storm-derived seawater. This rising watertable dissolves most surface halite crusts, as well as some of the gypsum precipitated in the more isolated parts of all sabkhas in the previous summer. The inherent fractionation explains why ephemeral halite crusts are typically found in depressions located seaward of the gypsum-dominated inland sabkhas.

The calcium sulphate mineral in both styles of near-coastal sabkha is a gypsum pore cement, it is not anhydrite. The groundwater setting is not saline enough, nor hot enough, to favour the preservation of anhydrite. Groundwater floods in the winter means most crystals of capillary gypsum are periodically flushed by meteoric waters and so show internal layering and lenticular shapes indicative of alternating stages of precipitation and dissolution. Mg-calcite, dolomite and halite are minor authigenic components in some near-coastal sabkhas.

Large inland sabkhas, such as Sabkhat el Mustabag, were possibly once connected to the Bardawil Lagoon, although dunes now cut off all the inland sabkha depressions from the sea (Figs. 3.26 and 3.27b). More likely, they formed in the Late Pleistocene in an earlier paludal phase at the seepage edge of the Sinai sand sea, when the seacoast was tens of kilometres further out on the exposed shelf. Soft chalky-white calcian dolomite (layer up to 20–30 cm thick) caps the upper portions of the sediment fill in some of the larger inland sabkhas (Fig. 3.27c). The age of the carbonate precipitates in these older sabkhas is not well constrained. Beneath the dolomitic carapace are well preserved aragonitic gastropod shells, typically embedded in a muddy calcitic groundmass. Radiocarbon dating shows that the dolomite and the underlying unit is older than 35,000 years (Fig. 3.27c). It is a lacustral continental sabkha, possibly deposited in a Pleistocene pluvial, with little tie to the present largely vadose hydrology of the inland sabkhas along the landward edge of the Bardawil coastal prism.

Shatt el Arab Estuarine Sabkha Iraq

The Shatt el Arab delta lies at the northwestern end of the Arabian Gulf, immediately northeast of Kuwait (Kadmah) Bay. It is an area where three rivers (Tigris, Euphrates, Karun) merge to form the Shatt el Arab delta (Fig. 3.28). It is an unusual region in that it is one of a few modern examples of a large modern river delta feeding into an enclosed saline sea and where the amount of eolian sediment in the delta (via the northwesterly Shamal wind) may equal the volume of water-borne fluvial sediment (Evans 1995).

The Shatt el Arab is fed by a broad funnel-shaped estuarine channel with wide levees on either side. Spreading out from the levees are dense surrounding marshes of reed beds (locally known as *ahwar*). The region was drained

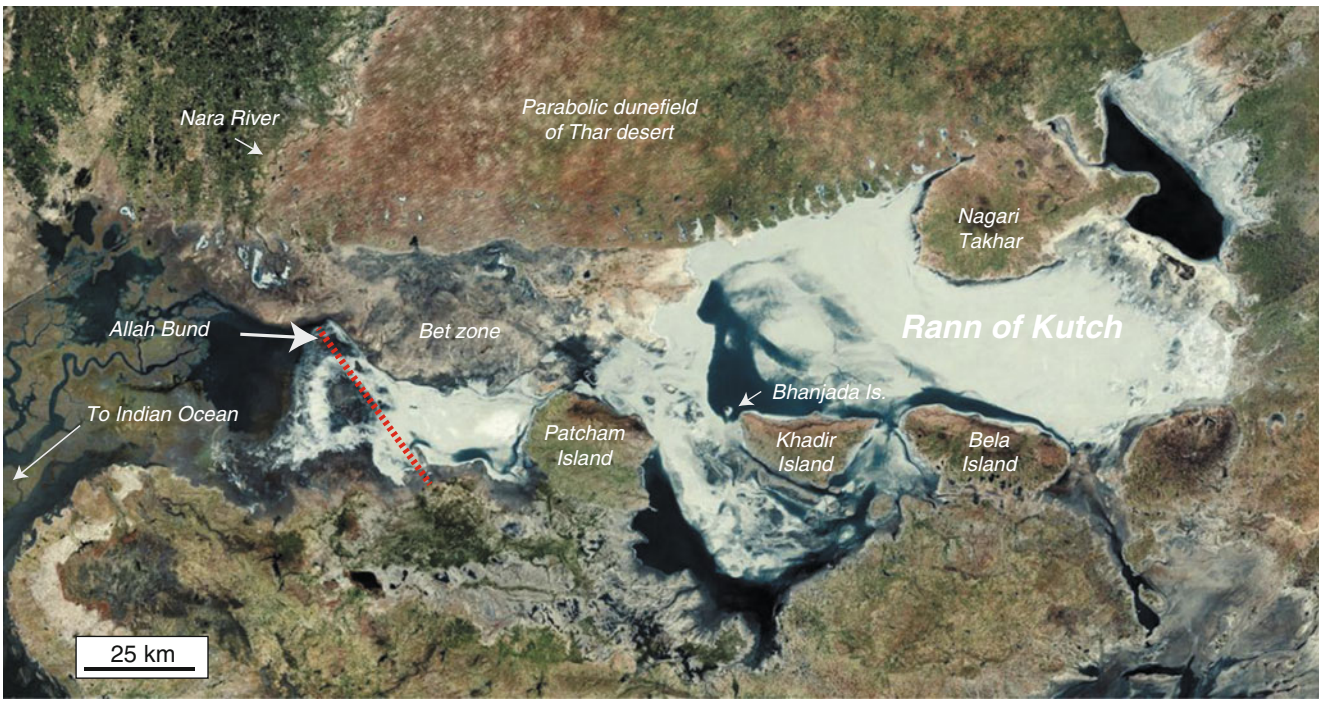

Fig. 3.29 The Rann of Kutch, see text for discussion of noted features

under the genocidal policies of Saddam Hussain, but has now been re-engineered to return the reedbed system to its natural state. These areas are flooded each spring and early summer by waters fed from snowmelt in the river headwaters. Large crevasse splays spread into interchannel areas, which in the lower deltaic plain are dominated by brackish to freshwater lakes and dense surrounding reed-bed marshes (Aqrawi and Evans 1994; Banat et al. 2006). Lakes are floored by bioturbated sandy silts and clayey silts, which preserve abundant meshworks of plant roots and a brackish shelly fauna. Crevasse sediments feeding the lakes are well-stratified sandy silts and muds. At its most seaward extent and across Bubiyan island an extensive plain of estuarine sabkha takes the place of the reedbed.

Matrix in both the sabkha and the ahwar regions is similar. It is rich in detrital carbonates as well as quartz, reflecting the large volumes of outcropping carbonate in the hinterland. What separates the two settings is the lack of higher plants on the estuarine sabkha (instead of root meshworks there are widespread cyanobacterial mats and some local mangroves) and the widespread authigenic precipitation of high-Mg-calcite, calcite, calcian-dolomite, gypsum and perhaps pyrite as capillary salts in the sabkha matrix. Palygorskite is present in the sabkha as both authigenic and allochthonous phases (Aqrawi and Evans 1994).

The extremely low wave energy attacking the front of the Shatt el Arab delta separates it from other arid-zone deltas, such as the Indus, which show similar 2–3 m tidal ranges. Due to this low wave energy (limited fetch), only narrow beaches and small coastal dune systems form along the leading edge of this arid zone delta. Rapid progradation of fines forms widespread saline mudflats and sandbars across much of the seaward part of the delta plain, also dissected by tidal channels along the delta front. Saltpans and gypsiferous sabkhas form behind low relief beach ridges and chenier ridges wherever surface seawater is trapped after very high tides and storm floods. The resulting evaporitic zones are characterised by crusts of halite and capillary precipitates of gypsum. Anhydrite after gypsum occurs in the most exposed and saline portions of this system.

The seaward extent of the evaporite-capped volume of deltaic sediment is not well established, but is significant as the delta lobe probably extends some 100 km from the modern shore (Fig. 3.3a; Evans 1995). Away from the active fluvial-fed portions of the delta lobe, quartzose sands are reworked into a shoalwater complex of elongate tidal bars that passes seaward in prodeltaic marls, which in turn enclose the reef capped Kharg Island off the Iranian coast.

Sabkha sediments, passing updip into dense reed beds, show affinities to similar facies on the Nile Delta. In both, the increasing distance from the active part of the delta explains the change from a quartzose matrix in the delta sabkhas to a more carbonate-rich barrier-lagoon style of sabkha (e.g. Fig. 3.28 – dashed line southeast of Kadmah Bay).

Rann of Kutch

The Great Rann of Kutch (Kachchh) is a marine-influenced evaporitic sump some 300 km long and 80–100 km wide on the margin of the Thar Desert in arid western India (Fig. 3.29; Glennie and Evans 1976; Tyagi et al. 2012). Its intra-plate

position, south of the Himalayan suture, creates a unique arid capillary salt landscape inundated during the monsoon by wind-driven marine storm surges, sourced on its seaward side, and continental fluvial influxes from the landward (Glennie and Evans 1976). The Kutch depression is bound by the Nagar Parker Fault (NPF) on the north and Kachchh Mainland Fault (KMF) on the south. Capillary evaporitic sedimentation in the Great Rann occurs in a siliciclastic matrix with deposition controlled by an interplay between tectonic, continental and marine processes.

Glennie and Evans (1976) concluded that the Great Rann was probably occupied in the Early Holocene by shallow marine gulfs following the rise in sea level after the last glacial epoch, whereas continental sediment influx dominated during the transgressive phase. According to them, the clay mineral matrix assemblages is dominated by illite, kaolinite, chlorite and montmorillonite, with little or no carbonate, suggesting the dominant influence of the Indus River drainage system on the matrix mineralogy. They argued that most of the matrix was derived from the combined Indus and Nara Rivers, which extended southwards towards the present Indus delta, with some of its waters escaping into the Arabian Sea via Kori Creek. There is also the possibility that a former mighty river, called the Saraswati, received water and sediment from the Himalaya and once flowed into the Great Rann of Kutch.

The sabkha-capped Western Great Rann is also known for its tectonic instability, this has created numerous episodes of liquefaction and seismite overprint in the sediments of the Rann as evidenced in the 2001 earthquake (Rastogi 2004; Rajendran et al. 2001). As well as causing severe structural damage, this 7.7 magnitude event killed more than 13,000 people, caused collapse or severe damage to over a million houses and an economic loss in the region of US$10 billion. Paleoseismological investigations in the vicinity of the earlier 1819 Allah Bund earthquake indicate the occurrence of an even older earthquake around 800–1,000 years ago, both relate to the surface expression of a growth anticline atop an active (but hidden) thrust fault (Rajendran and Rajendran 2001).

The various documented seismic effects on sedimentation (summarised in Tyagi et al. 2012) strongly support the notion that the present Rann is the uplifted floor of a former Holocene marine gulf. Studies of the occurrence of raised notches and abraded platforms on the margins of Bela, Khadir and Bhanjada islands, suggests uplift of the Rann Gulf occurred less than 2,000 years ago and that marine ports were once active in what is now the Rann (Chowksey et al. 2010; Khonde et al. 2011). The most recent seismic event driving a substantial rise in portions of the Rann floor was the 1819 Allah Bund (*Dam of God*) earthquake. It created a 6 m tall, 6 km-wide, natural dam across the Puran or Nara River. This NE–SW trending scarp not only dams river inflow, on its seaward side it controls the distribution of modern tidal influence (Fig. 3.29).

Today, interactions of marine and fluvial processes continue essentially unchanged (Glennie and Evans 1976). The annual flooding by the sea, driven by the Southwest Monsoon, still brings fine sediment into the Ranns. The streams draining the borders of the Ranns transport coarser material from the hills during this season and deposit it where they debouch into the Ranns. The finer material is carried further out onto the Ranns to mingle with the marine derived silt and clay. Small waves rework the outwash plains around the edges of the Rann at these high-water stages and sometimes cut cliffs in the outwash plains.

As the water recedes, evaporation proceeds and halite crystallizes out to form the extensive surface crust. The interstitial waters become concentrated and gypsum crystals grow within the sediment. Waters enriched in magnesium ions, as a result of precipitation of other salts, react with the sparse carbonate present in the sediment to form dolomite.

The outwash material is reworked by the wind and some sand, very rich in gypsum, has been blown into low dunes (lunettes) along the edges of the Rann. Some of the crystallized halite and gypsum is blown even further landwards into the Thar (Rajasthan) Desert. Similarly, considerable dust is probably blown back onto the Rann from the surrounding arid areas during times of wind reversal in other seasons (e.g. northeast winds of the ‘Little Monsoon’).

Much of the halite crust is recycled each year via flooding by marine waters and so does not attain any great thickness in the sediment column. Halite layers with thicknesses of 90–120 cm were, however, described by Oldham (1893) from near Sindree. The lenticular gypsum that has grown within the sediment will probably remain and may gradually increase in percentage with time to preserve a displacive salt sabkha signature in the more evaporitic sediments.

Although the total proportion of the Holocene sediment volume in the Rann of Kutch that is made up of capillary gypsum is less than 5–10 % it is an interesting marine-associated evaporitic example for a number of reasons. It has a sedimentary system with tidally-influenced marine clastics as the primary signature in the matrix (mostly tidal flat heterolithics with some tidal channel sands). At the time the matrix of the Rann of Kutch saline flat was deposited there were no evaporite salts. The transition to a capillary evaporite hydrology, came about some 1,000–2,000 years ago, as a diagenetic evolution driven by tectonics and the formation a hydrographic barrier tied to the early stages of the Allah Bund high. This makes it an interesting example of a Holocene marine sabkha created by tectonics, not eustasy. The other question generated by its current sedimentological scenario is how would we recognise an ancient counterpart? The pervasive seismically-induced liquefaction that occurs in the Kutch sediments with each significant seismic event

(every hundred or so years) probably means little or no primary matrix structure (tidal sedimentation) will be preserved in ancient counterparts. What would be preserved is likely a few anhydrite nodules (after gypsum) floating in a relatively structureless or intensely seismite overprinted matrix.

Interpretive Limitations of Holocene Sabkha Models

Capillary salts and surface crusts precipitated in Holocene marine-margin sabkhas and many continental sabkhas have low preservation potential. They precipitate in a hydrological fringe underlain by undersaturated waters and below a land surface subject to periodic freshening and flooding. Whether capillary salts form by cooling (thermalites) or pore brine evaporation is irrelevant in terms of their ultimate preservation potential. To pass into the rock record any sequence must, by definition, subside. As it does so, the sabkha nodules, crystals and crusts at the edge of a body of brine of normal seawater salinity must pass back into waters undersaturated with respect to the minerals precipitated in the capillary fringe. At best, what will be preserved of the original salts in the prevailing hydrology at the edge of a normal marine water body will be partially dissolved remnants of the salts and nodules. More likely, the capillary fringe precipitates will become a thin interval of haloturbation textures and dissolution collapse. If, on the other hand, a sabkha succession sits on the edge of a hypersaline saline pan (as in some modern continental sabkhas) or on the edge of an ancient saltern or seaway, then the capillary salts pass into a saturated brine curtain or into the edge of a reflux plume, and so preservation of the original capillary textures is more likely.

There are other implications of the sabkha signature always forming in a capillary fringe. A typical sediment distribution model for an ancient sabkha, based on the Abu Dhabi Holocene, looks something like that presented in Fig. 3.30. Such models typically do not consider hydrology, bed thickness, lateral extent or structural controls when compiling the sabkha units; they merely use Walther's Law[4] to stack the various peritidal sequences into a vertical

[4]Walther's Law of Facies states that the vertical succession of facies reflects lateral changes in environment. Conversely, it states that when a depositional environment "migrates" laterally, sediments of one depositional environment come to lie on top of another.

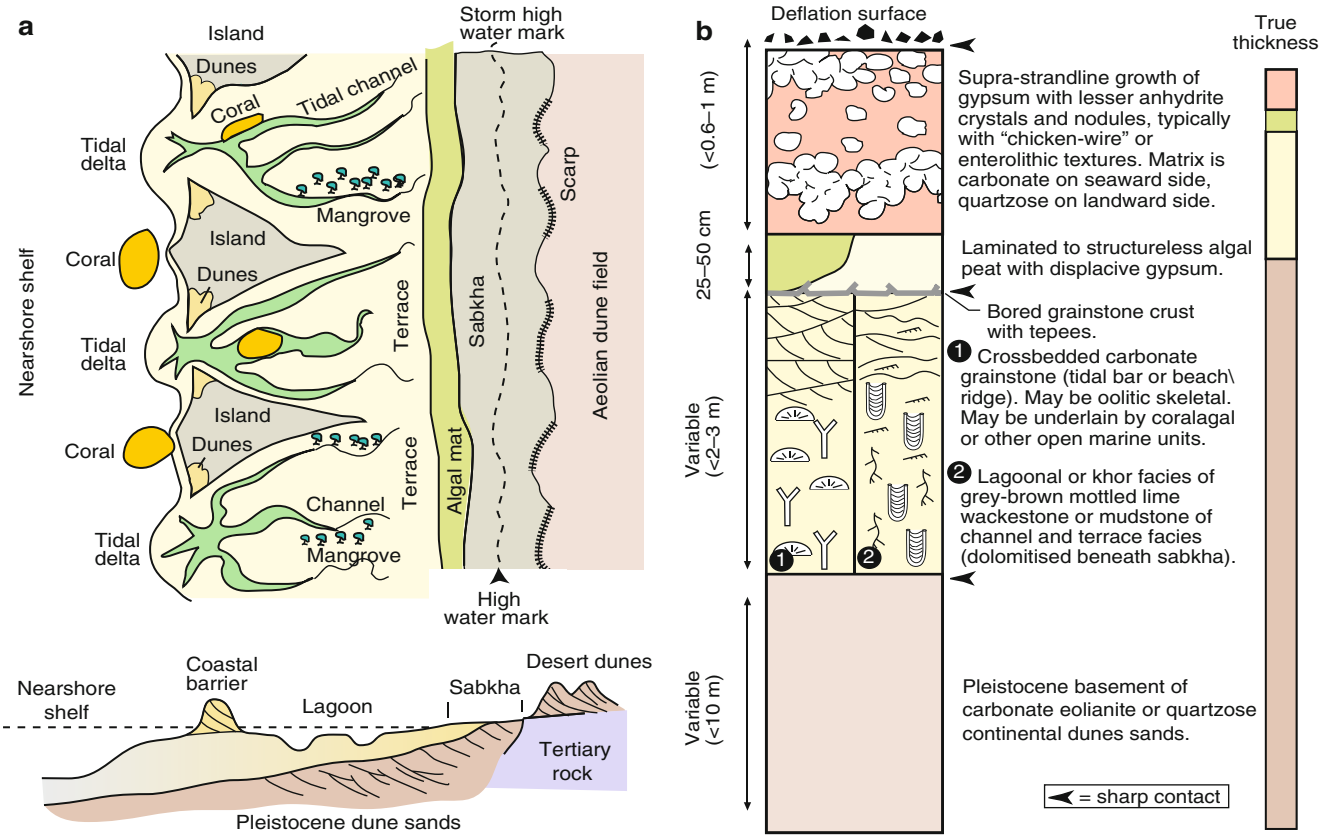

Fig. 3.30 Generalised geological model. (**a**) Based on the distribution of the main carbonate facies belts in Abu Dhabi – Khor al B'azm region (in part after Evans 1995). (**b**) Characteristic vertical succession of sea-margin carbonate sabkha showing typical thickness for each unit, *right column* shows true relative thickness (in part after Warren 1991)

succession. Because of this, the Abu Dhabi sabkha analogy is sometimes used to interpret ancient evaporitic platform successions composed of marine carbonate beds interlayered with nodular anhydrites (platform evaporites), without a full understanding of the implications of the requisite sabkha hydrology.

An Arabian Gulf carbonate-hosted sabkha is part of a prograding Holocene ramp where the total succession is composed of subtidal, intertidal, and supratidal sediments. It is capped by a Stokes surface and typically backed by a siliciclastic sand sheet/dune association. The complete Holocene section is no more than 3 m thick and in the type area centred on the Abu Dhabi region the Holocene sequence is composed predominantly of subtidal lagoonal carbonates. The evaporitic intertidal and supratidal cap is up to a metre thick and always reflects the thickness of the capillary fringe.

Underlying Pleistocene sediments are up to 12 m thick in the vicinity of Abu Dhabi Island; they are permeable Pleistocene dune sands that directly overlie the Miocene carbonate aquifer supplying solutes to the sabkha (Fig. 3.30a). In terms of sediment volume, scaling and perhaps even geometries of accommodated sediment, much of the Abu Dhabi sabkha is best considered to be an eolian sabkha with a watertable closer to the landsurface because of proximity to the ocean (eolian sabkhas are discussed in more detail at the end of this chapter).

In its strictest sense, based on relative unit thicknesses, an Abu Dhabi sabkha should only be used as an analogue for ancient successions made up a transgressive subtidal lagoonal carbonate (1–3 m thick) with a 0.5 m thick matrix-rich cap containing capillary salts, which is in turn capped by an erosional surface (Fig. 3.30b). The whole succession should have been deposited atop a much thicker marine-flooded eolian dune aquifer system (Achauer 1985). In most Holocene-based analogs for ancient evaporite systems, we modify notions of Holocene thickness and stacking to accommodate great changes in scale and thickness needed to typify ancient epeiric settings. Sometimes this is done without considering inherent hydrological limitations and the laws of fluid physics are unknowingly ignored (see Chap. 2 for hydrological details of various saline hydrologies).

For example, many thick, ancient sequences of pure nodular anhydrite have been interpreted as sabkhat deposited under conditions of slowly rising sea level (transgressive systems tract). There are hydrological and preservation restrictions associated with this hypothesis that are not considered in many sabkha reconstructions. The thickness of nodular anhydrite in any supratidal unit is limited by the thickness of the capillary fringe. Any evaporite sediment lying above the top of the capillary zone is blown away or dissolved (Fig. 3.30b). Aside from the preservation issues mentioned earlier, this means that the supratidal evaporite phase in a single sabkha cycle (stillstand) can be no more than 0.5–1 m thick and by definition it is matrix dominated (Warren and Kendall 1985). Matrix must exist before capillary salts can grow. Hence, the inherent difficulty in explaining metres-thick pure nodular anhydrite as a thick sabkha without any encapsulated erosion surfaces. If in an ancient succession a nodular anhydrite is relatively pure and lacks internal erosion surfaces it cannot be a sabkha, it is some sort of subaqueous succession or subsurface replacement front.

The only exception to ancient sabkha sequences being dominated by non-evaporite matrix is when the matrix is composed of mechanically deposited sulphate or halite, perhaps derived by storm or eolian transport from a nearby saltern or saline pan. If such a succession was buried, the result would be a nearly pure sulphate or halite unit composed of sabkha cycles, each 1–2 m thick, interlayered with saltern or saline pan units many metres thick. No modern examples of this style of evaporite deposition exist outside of the stacked saline pan halites in the South American salars discussed in the next part of this chapter. Modern sulphate equivalents are unknown, although they can be commonplace in stacked saltern-dominated marine-fed platform successions such as the Cretaceous Ferry Lake Anhydrite of the Gulf of Mexico and the Permian Werra Anhydrite of the Zechstein (Chap. 5).

The need to stack sabkhas into hypersaline, not marine, groundwaters also means that wherever matrix-rich beds of nodular anhydrite are metres to tens of metres thick with no intrabed erosional surfaces (Stokes surfaces) then the sequence is probably not a sabkha. It may be a reflux-cemented marine platform carbonate, or an interval overprinted by burial cements. In my experience many ancient normal marine platforms overprinted by later patchy diagenetic anhydrite nodules and axe-head anhydrite cements are often misinterpreted as sabkha indicators. In many sequence stratigraphic reconstructions this leads to such intervals being misinterpreted as being formed in times of lowered sealevel. This is especially so in studies by stratigraphers looking for evidence of times of sealevel lowering in platform successions. They tend to ignore the possibility of diagenetic evaporites or the marked differences in eustatic amplitude and frequency that characterise icehouse and greenhouse climate modes (Chap. 5). The presence of a few anhydrite nodules in a core or an FMI image, floating in a matrix of carbonate or siliciclastics, is not sufficient evidence to interpret the sequence as an ancient sabkha.

In the modern sabkha, the evaporites of the sabkha supratidal zone overlie restricted lagoonal sediments; they never overlie open-shelf carbonates. Yet in ancient platform evaporites, many beds of nodular anhydrites have been interpreted as sabkha. Such units typically seal dolomitised open-marine shelf carbonates. Perhaps insufficient time has elapsed in the Holocene for sabkha progradation to form a geologically

realistic sabkha cap atop marine platform carbonates. Or perhaps ancient nodular anhydrite beds were deposited in a subaqueous saltern at a time when the platform was an isolated drawdown lagoon.

In a few millennia in the Abu Dhabi region, and only if the At Taf coastal strip undergoes suitable subsidence, the succession of sabkha evaporites, and its formative hydrology, may prograde over the Holocene carbonates of the oolite shoals and the open shelf. And yet, the modern sabkha progrades across the inshore lagoon in response to the protecting action of the offshore oolite-reef shoal. The barrier islands screen the soft sabkha muds and evaporites from the erosive forces of the open gulf waves and the Shamal storms. Once the sabkha has infilled the lagoon behind this buffer, it is unlikely the sabkha will prograde much further seaward without the deposition of another sand shoal or reef a little further offshore.

Yet the sabkha "Trilogy" used by many to interpret ancient nodular anhydrite is supposedly composed of three laterally continuous facies belts with subtidal overlain by intertidal overlain by supratidal sediments, all merrily marching out into a subsiding basin without a change in facies. In reality, sabkha progradation, using an Arabian Gulf analogue, must be a punctuated process over geologically significant time scales with the original evaporite capillary salts unlikely to be preserved (Warren and Kendall 1985). A sabkha succession cannot be a simple continuous seaward movement of the 'Trilogy", never broken up by coquinas, barrier islands, ooid shoals, beach ridges or reefs.

Lastly, models used to interpret ancient sabkhas typically regard the Arabian Gulf as a carbonate province with the siliciclastic components ignored, or mentioned only in passing. This should not be the case. In almost all coastal areas along the southern Arabian Gulf the most landward portion of the sabkha is a sediment belt 2–6 km wide with gypsiferous evaporites accumulating in an eolian derived siliciclastic matrix. This zone passes seaward into a predominantly carbonate matrix. There are, in fact, numerous modern siliciclastic continental sabkhas both in the Arabian Gulf and elsewhere, all of which show lateral extents more akin to larger scale ancient counterparts than do any modern carbonate-hosted coastal sabkhas (see eolian sabkha section at the end of this chapter).

Lacustrine Sabkhas and Pans

So far this chapter has focused on sabkhas and evaporitic mud-flats in modern sea-margin settings. But at the 10,000-year-scale these are aerially-limited and ephemeral hydrologic systems, tied to the Holocene coastal highstand, with inherently poor preservation potentials. To study sabkhas that can stack to greater thicknesses and have sizes and volumes comparable to some of the smaller ancient evaporite systems we must move to Quaternary continental lacustrine settings in regions of intermontane subsidence and include hydrology of the saline pan in our modelling of preservation potential.

Modern continental sabkhas contribute to salt deposits with thicknesses of more than a hundred metres and areas measured in thousands of square kilometres. Evaporites in continental sabkhas grow by displacive crystal growth in the capillary zone or in immediately underlying brine-saturated muds. Ongoing growth of capillary salts above the watertable pushes the sabkha surface up out of the capillary zone into the vadose zone. This raised and dried continental sediment deflates to create the characteristic erosion/truncation surface. As in models based on modern marine-margin sabkhas, the presence of a Stokes surface is a key feature in recognising an ancient continental sabkha succession. Brine concentration in the saline mudflat is driven by the intensity of capillary evaporation and occurs adjacent to areas of saline pan and even adjacent to perennial subaqueous salt beds. Pans and holomictic brine lakes are needed to generate stable brine plumes or brine reflux curtains that preserve a stacked sequence of salt beds. The presence of a pan or perennial lake next to a sabkha defines the hydrology needed to preserve subsiding sabkha sequences. Their longterm absence is why Quaternary marine-margin sabkhas have little or no preservation potential.

Depositional Characteristics

A continental sabkha is the part of a playa mudflat complex where the capillary fringe intersects the landscape. It sits within a sedimentary transition from the basin margin to the lowest parts of the brine-saturated basin floor (Fig. 3.31; Eugster and Hardie; 1978):

alluvial fan / ephemeral stream / floodplain → sand flat → dry mudflat → saline mudflat → saline pan

The more landward parts of this depositional association are composed of terrigenous alluvial sediments and their reworked eolian residues in the dry sand flat (Fig. 3.32a). The watertable is usually deep within these alluvials and so sediments do not retain the more saline capillary salts, which are the focus of this discussion. They can contain caliche horizons formed by soil moisture fluctuations and perched capillary evaporation. We will come back to these less saline

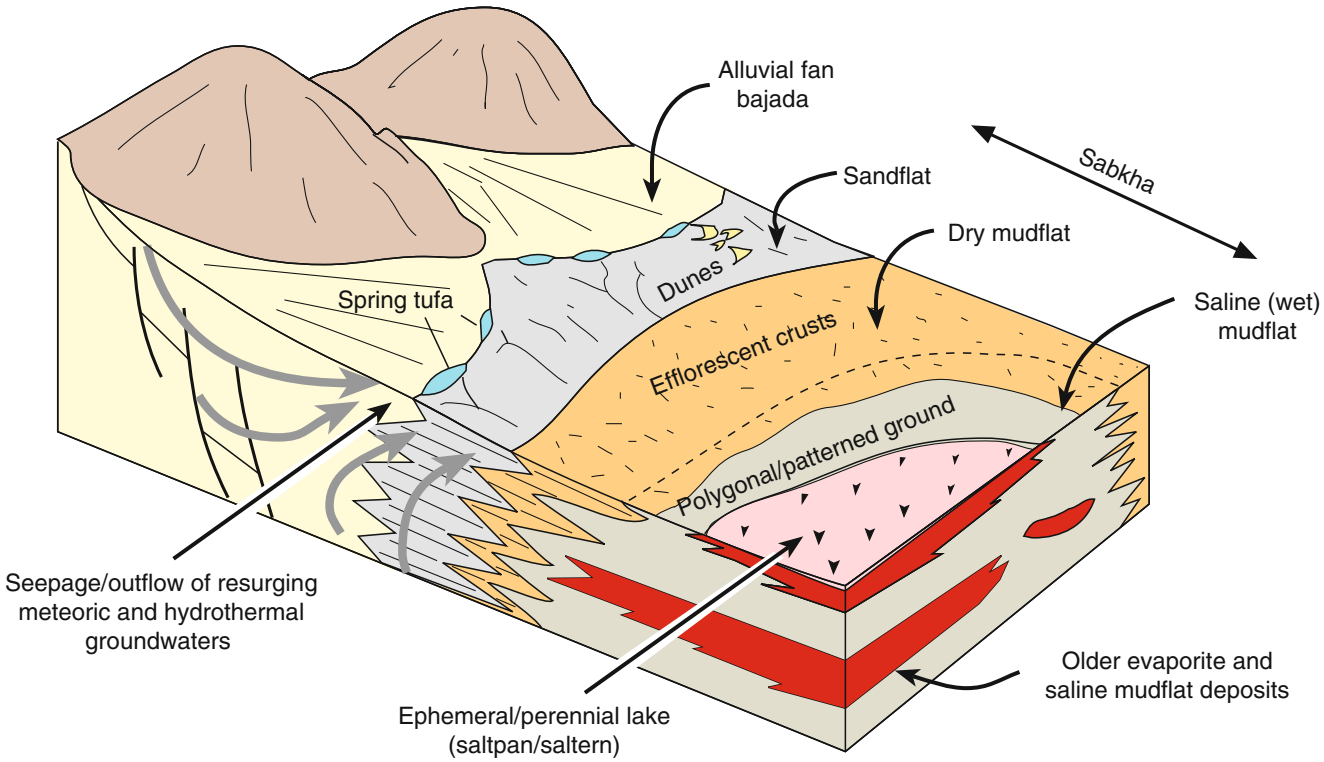

Fig. 3.31 Continental sabkha/playa showing various facies belts and processes of solute supply that include surface runoff, meteoric and hydrothermal groundwaters (in part after Kendall 1992; Eugster and Hardie 1978)

margins settings in our discussion of various specific examples of modern continental sabkhas. For now, we will focus on those parts of the playa system that do preserve substantial volumes of the evaporite salts, namely, the saline mudflat and the outer edge of the saline pan.

Saline Mudflat

The saline mudflat, along with the haloturbated parts of the dry mudflat, define the sabkha belt of a continental sabkha and together make up what is also often called the ephemeral saline lake belt (Figs. 3.31 and 3.32a; Eugster and Hardie 1978). The sabkha passes basinward into beds of the saline pan, which are made up of stacks of predominantly subaqueous and recrystallised salt crusts, and landward into dry mudflats, sandflats and alluvial fans. Additional sedimentary facies may be found within the sabkha tract at any of several positions depending on short and longterm changes in the basin hydrology. They include dunefields and lunettes, which are composed of terrigenous sands, mud pellets, or evaporite grains; travertine springs or tufa mounds; and shoreline/strandline features such as sheet deltas, beach ridges, or spits.

Continental saline mudflats (sabkhas) are extensive vegetation-free flatlands composed of fine-grained sediments with displacive intrasediment precipitates of halite, gypsum and anhydrite or, less often, of more exotic salts such as glauberite, mirabilite and trona. Displacive salts may grow randomly in the capillary fringe as crystals and nodules or be concentrated in dm-thick layers (Fig. 3.32b). Backreactions, periodic freshening and progradation may drive alteration, leaching and replacement of salts in this zone and mineral precipitation is sometimes aided by bacterial processes (Rosen and Warren 1990).

Dry mudflats, with their requirement of a somewhat deeper watertable, typically lie closer to the landward edge of a playa and form the rim to saline mudflats and saline pans. Sediments are mostly fine-grained, characterised by primary structures formed under alternating upper and lower flow regime conditions, such as sand-rich layers deposited by sheetflood, along with palaeosol horizons indicating periods of landscape stability. Dry mudflats do not retain evaporite salts, but may show disrupted to massive textures created by earlier intrasediment evaporite growth and dissolution (haloturbation), related to earlier times of higher watertables. Occurrences of actual salts on modern dry mudflats are limited to puffy surface efflorescences related to humidity fluctuations in the soil moisture zone and are destroyed/dissolved with the next light rain or fog.

A feature common to many dry mudflats is a pervasively cracked surface with crack diameters ranging from centimetres to giant polygons tens of metres across. Giant polygons or megapolygons indicate a longterm drawdown of the

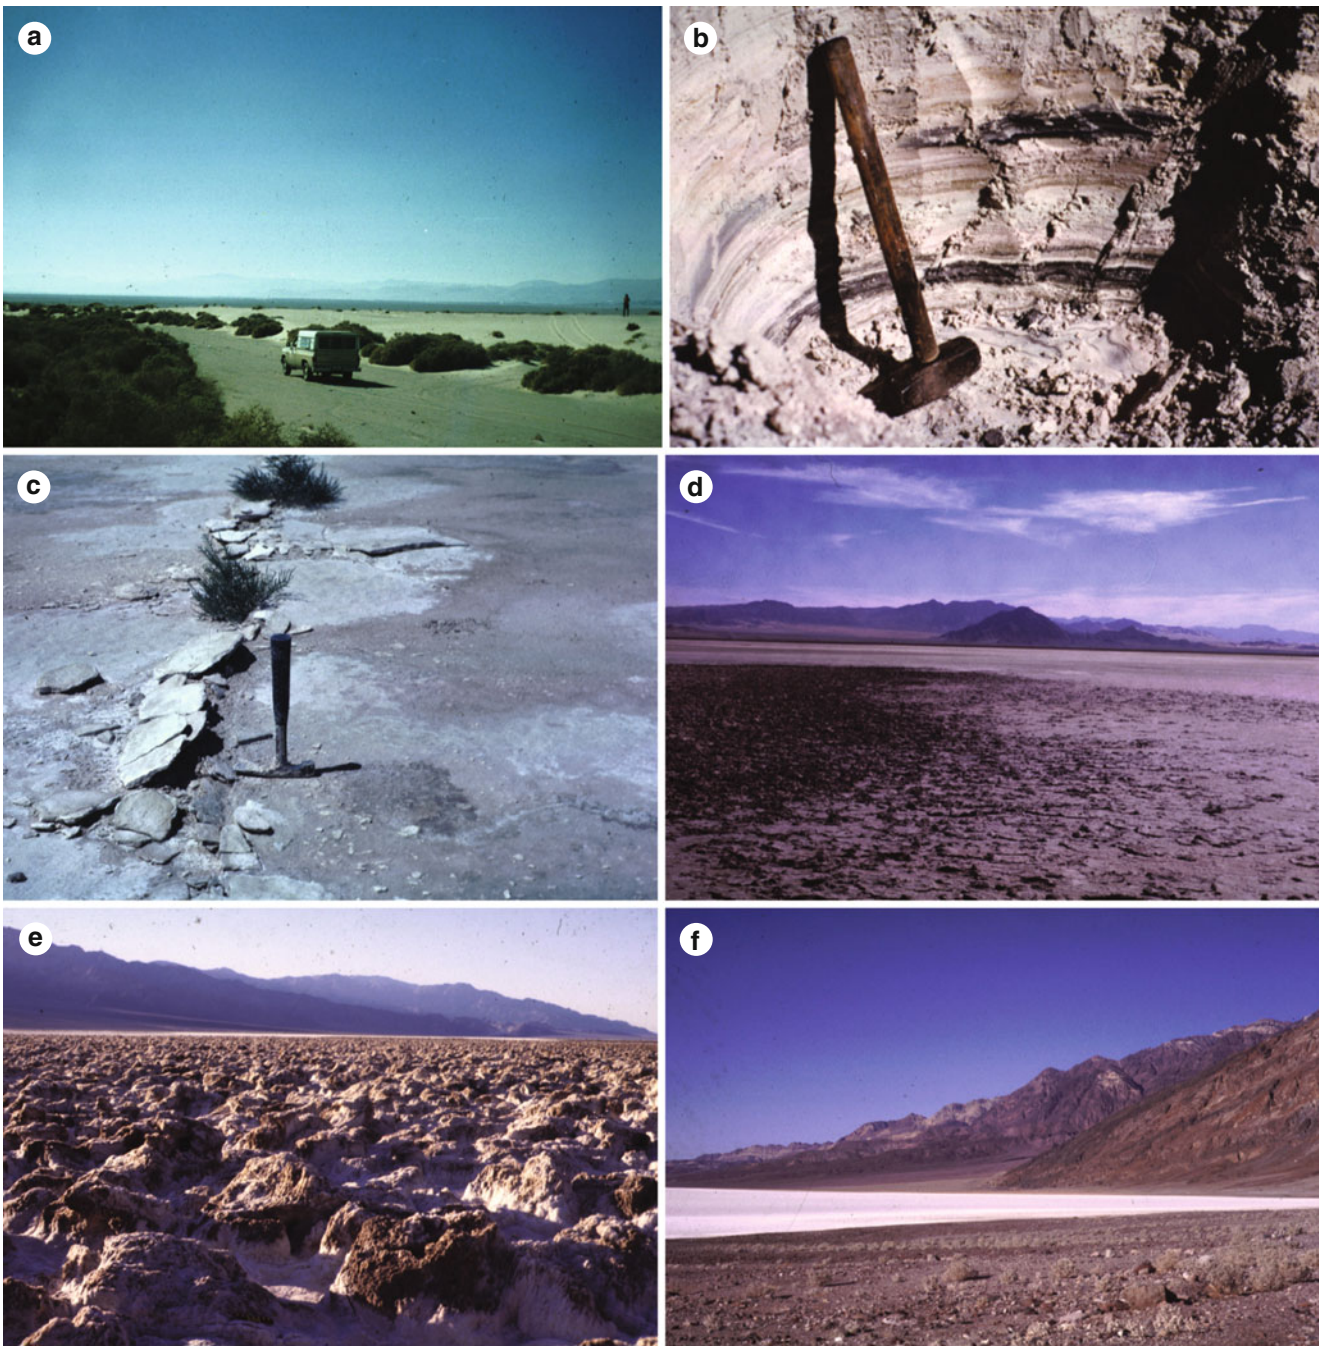

Fig. 3.32 Continental sabkhas. (**a**) Dry mudflat with local eolian dunes and nebkhas on the edge of Owens Lake, California. (**b**) Laminated dolomite-gypsum sediment where capillary gypsum is growing above the water-table, the hosting matrix is made up of former perennial lake sediments with dark organic rich layers, Salt Basin Playa, west Texas. (**f**) Panorama of Death Valley showing juxtaposition of alluvial fan with sabkha/saline pan facies due to steepness of valley walls

regional watertable associated with longer-term climatic change (Fig. 2.59; Neal et al. 1968). Cracks may not be a simple V, but may step across layers, show evidence of multiple stages of growth and be filled by a variety of sediments ranging from sands to muds.

Groundwater Transport and Fractionation in Saline Mud-Flats

Sheet floods in ephemeral lakes are relatively rare, most salts move about the lake flats as soluble load in shallow groundwaters, not as mechanically reworked sediment.

Surface water and groundwater always flows to the lowermost point on the playa surface. Groundwater on this journey can come near or to the playa surface a number of times in zones defined by capillary salts and ephemeral efflorescent crusts. Crusts and salt assemblages in early stages of their formation can contain metastable high salinity salts such as epsomite and thenardite, which can even occur at the surface of the most landward parts of a mudflat. But when subjected to fluctuating humidities or light rains the less stable (more soluble) salts are quickly leached back into the dissolved load of the groundwaters and continue their journey basinward down the potentiometric gradient. Brines derived from the partial dissolution of efflorescent crusts are usually simple chemical solutions dominated by one or two major solute species (e.g., NaCl, Na_2SO_4, Na_2CO_3). The less-soluble mineral fraction is then left behind, in the more landward parts of the saline mudflat where it forms a carbonate crust, such as the dolomitic crusts of Salt Flat Playa, west Texas. There, the ongoing accumulation of capillary carbonate has forced the surface crust to buckle and crack into lacustrine mudflat tepees (Fig. 3.32c; Hussain and Warren 1988).

Farther out into a salt basin, ongoing capillary evaporation precipitates new salts as efflorescences on the lake surface or as intrasediment nodules and the process of fractionation can begin all over again. Ongoing repetition of this process means shallow sabkha groundwaters become increasingly saline as they seep toward the lowest part of the lake floor – so saline that even the more soluble salts become stable and can accumulate as intrasediment precipitates (e.g. displacive halite, glauberite, thenardite). Only the most soluble salts are carried into the lowermost portions of the lake basin, so that crusts deposited in saltpans define mineralogically simple bull's-eye patterns with the most soluble salts accumulating only in the lowermost portions of the ephemeral lake floor. Such concentric or "bull's-eye" fractionation patterns are often assumed for salts making up ancient sabkhas and pans, with the most soluble salts indicating the deepest part of the basin. But this simple pattern can be complicated by periodic near-unidirectional flooding fed from a single inflow channel, as seen today in some of the sabkhas in the salt lakes of central Australia (e.g. the Warburton Channel into Lake Eyre; Fig. 3.55).

Saline Pan

Saline pans in modern continental salt lakes are closely tied to the formation of saline mudflats and dry mudflats (Fig. 3.33; Lowenstein and Hardie 1985). They define zones on the salt lake floor where surface brines pond and concentrate long enough to stack into layers and beds composed of aggrading salt crusts (Fig. 3.33; Stage II). Pans typically form in drainage sinks situated in the lowest parts of the playa surface. A pan is typically surrounded by a saline mudflat and is frequently underlain by older bedded or layered salt units (Figs. 3.31 and 3.32d). In Lake Magadi, for example, the pan is defined by a trona bed 40 m thick, while in Bristol Dry lake the saline pan facies can be found intercalated with saline mudflat facies throughout the 400 m of core recovered from the basin centre.

Pans range in size from small features a few km across to gigantic continental salt sinks as in Salar di Uyuni where the pan area is more than 9,000 km^2 (Rettig et al. 1980). Textures in the stacked salt layers are a combination of subaqueous aligned features (e.g. chevrons and swallowtails) and exposure overprints (e.g. microkarst pits, subhorizontal erosional bevels and salt-filled polygons) that formed each time pan dried and its surface was exposed (Fig. 3.32e). Stacked crusts are usually dominated by halite, but other minerals such as gypsum, mirabilite and trona can be important.

When the pan dries eolian dust is trapped by capillary adhesion on its moist, rough surface or filters down cracks and fissures in the salt crust. Storm waters cover the pan after the next lake flood and the upper part of the salt crust dissolves, while flocculating muds settle onto the solution surface and sink into intercrystalline karst cavities (Fig. 3.33, Stage I; Shearman 1970). Ongoing evaporation then creates a new subaqueous salt crust atop the dissolution surface. The knobbly surface seen on some playa salt crusts is the result of continual precipitation and fretting of a subaerial salt layer, fed brine by "capillary wicking."

The halite in the initial crust is often composed of upward-pointing subaqueous halite chevrons (Fig. 3.33; Stage II). The freshening episodes plane off the upper part of the chevrons as undersaturated waters eat into the crust along the inter-chevron boundaries and form brine-filled pores (Chap. 1). Capillary evaporation and brine reflux then fills the porosity with clear halite cement. Continued dissolution and reprecipitation of halite and other soluble salts in the vadose and capillary portions of the crust can destroy much of the initial aligned chevron texture. The end result of alternating freshening and drying episodes is a bedded stack of salt crusts with pores filled by halite spar, occasional relict zones of aligned chevrons and numerous internal truncation surfaces (Fig. 3.33; Stage III).

At the broader scale, the continual addition of new salt crystals from evaporating pore waters causes an increase in the volume of the surface crust, which, once the pan desiccates, lies at the top of the capillary zone. Thickness of the capillary fringe limits any continued vertical growth of the crust and focuses precipitation into the uppermost parts of the crust, so the crust attempts to expand horizontally. The force of crystallisation creates a biaxial stress in the crust that ultimately forms cracks that grow into overthrust salt polygons or pressure ridges. Freshly exposed thin halite and gypsum crusts in modern pans and sabkhas around the world show this style of polygonal ridging and crestal cracking.

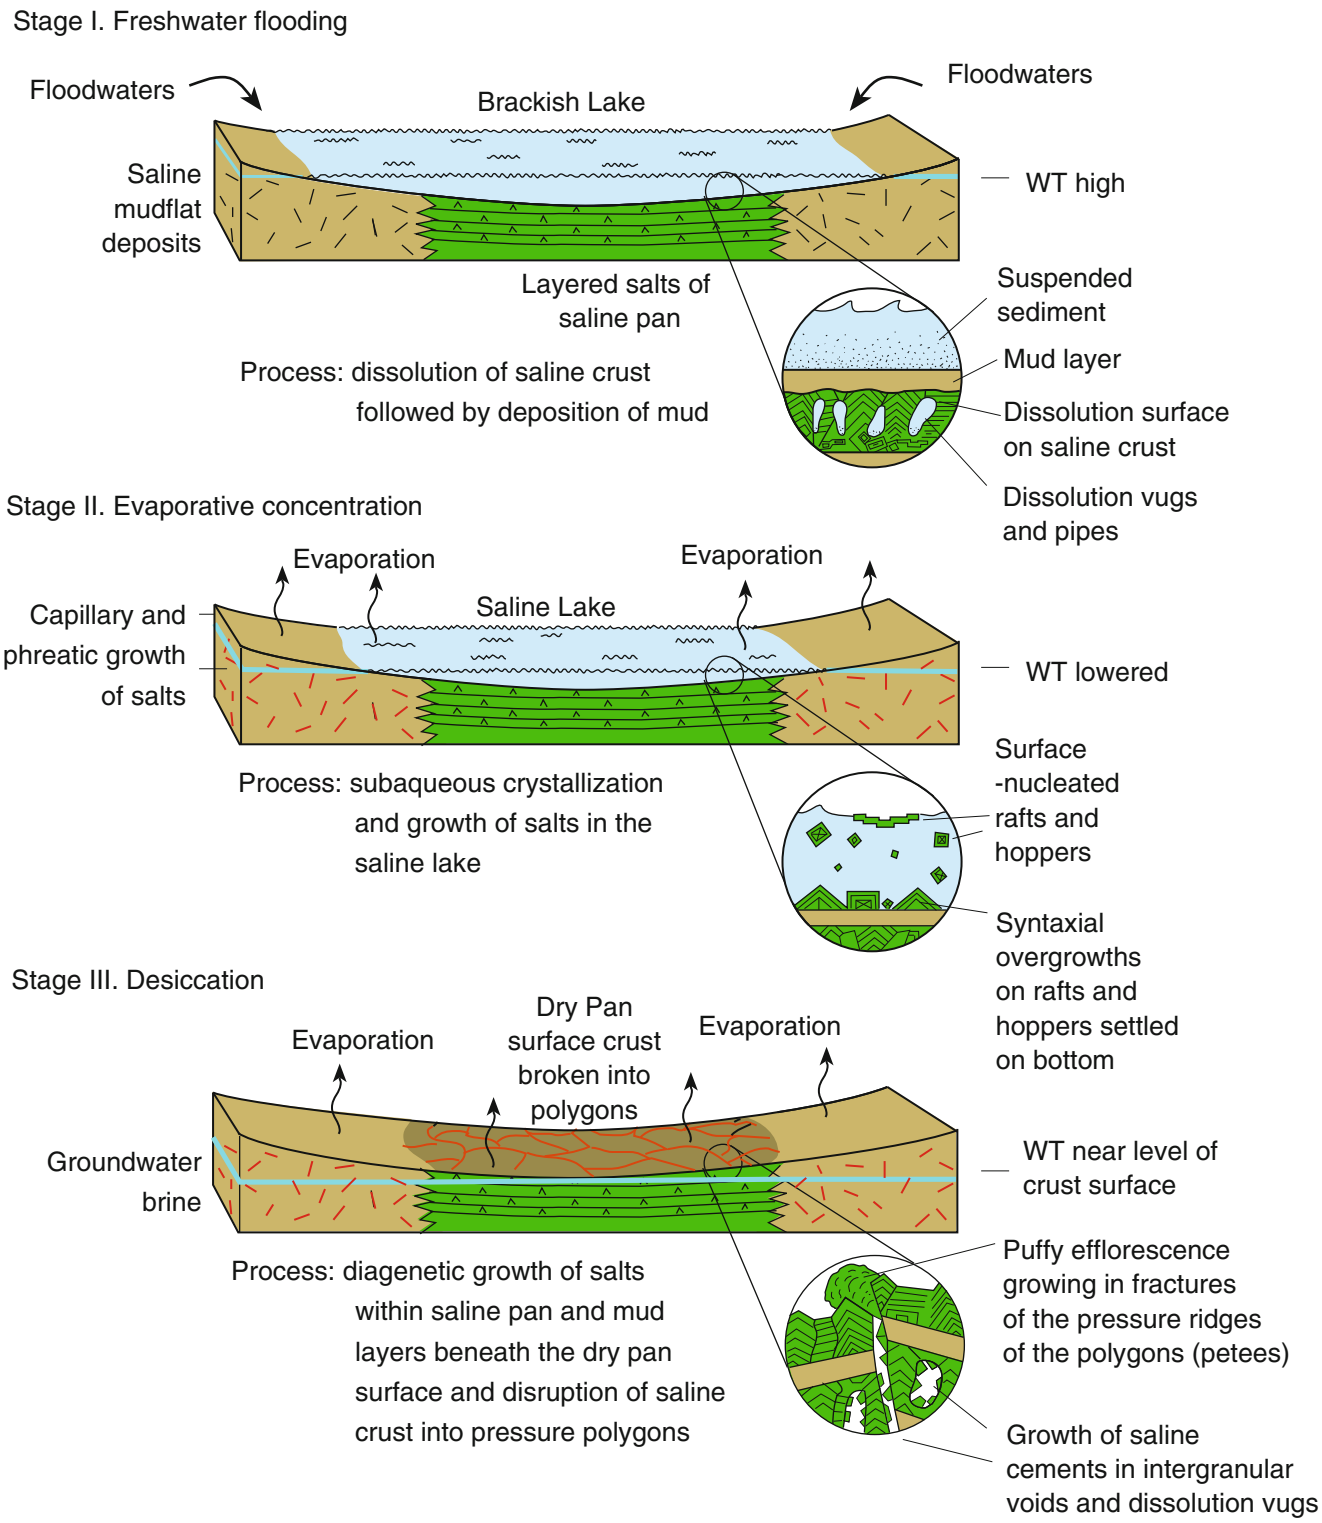

Fig. 3.33 Evolution of a depositional cycle in a saline pan setting (After Lowenstein and Hardie 1985)

But the mechanism creating mature metre-thick pressure-ridged beds is not crust expansion driven solely via the force of crystal growth. There is also the addition of detrital sediment to the crust via infill and cementation in newly formed fissures. Wind-blown detrital sediment fills fissures with successive linings that are cemented into the crust.

Ongoing capillary precipitation means pressure ridges rarely retain the simple inverted V cross section of the infill

formed in the initial break in the salt crust. Ongoing salt growth, fissuring and dissolution, along with infiltration of eolian silt and sand into cracks and fissures, deforms and anneals the crust into a variety of knobs, ridges, and pinnacles with a relief of up to a metre above the adjacent mudflat floor (Fig. 3.32e). Underlying clays often heave up and out through the axis of the megapolygon suture. Ancient counterparts to salt hosted pressure ridges and megapolygons have been recognised in the Messinian salts of Sicily (Lugli et al. 1999) and the Triassic salts of Cheshire, UK (Tucker 1981), where they are used as indicators of times of exposure in thick halite sequences. Fissure fills in these ancient counterparts can cut up to 6 m vertically across stacked halite beds.

Each salt layer in a thick saltpan unit, is in large part derived from the recycling of older salt layers. Layers are separated and crosscut by mud partings composed of detrital material carried in by floodwaters or eolian detritus blowing across the emergent salt surface. The final buried sediment is a thick bedded-salt composed of randomly aligned recrystallised evaporites. Saline pans form relatively pure salt units, which are metres thick, layered, and crosscut by fissures filled with eolian or detrital impurities. This type of bedded salt, which has been subjected to ongoing exposure and capillary evaporation, contains randomly aligned and overprinted crystals precipitated from a brine hydrology characterised by crystallisation, dissolution and recrystallisation. It contrasts with bedded salt deposited in the relatively stable perennial brine hydrologies of a more-or-less continually subaqueous saline lake where, even after burial, the crystals in the stacked crusts still retain a growth-aligned fabric of upward pointing large gypsum crystals, chevron halites, or trona prisms (see perennial lake discussion in the next chapter).

Styles of Continental Sabkhas

Mudflats, sabkhas and saline pans occur as parts of three saline lacustrine settings, with or without a saline pan in the depositional sump (Hardie et al. 1978);

- Alluvial fan–ephemeral saline lake
- Ephemeral stream floodplain–dune field–ephemeral saline lake
- Perennial stream floodplain–perennial saline lake

Settings are not static and changes in tectonics or climate can cause one setting to evolve into another. Texture of the capillary precipitates are similar in all three, but differences in lacustrine hydrology means continental sabkhas are more widespread in ephemeral lake systems than in perennial lake systems, which seem to require steeper sided basins (Table 4.7).

Alluvial Fan–Ephemeral Saline Lake

The alluvial fan–ephemeral saline lake depositional complex typifies fault-bounded, orogenic basins in tectonically-active arid areas. Tectonism generates topography and increased contrast in thermal gradients, so that water volumes seeping into the evaporitic mudflat (continental sabkha) and adjacent saline pan can be quite high, fed predominantly from groundwater and occasional storm runoff. Such arid intermontane lows can be covered by extensive continental sabkhas, with areas of saline pans in the lowermost positions on the playa floor (Fig. 3.31). Modern examples range across various tectonic settings and include intermontane playas in the Basin and Range of North America, salars of the Central Andes, some East African rift valleys, saline valleys at the southern end of the Dead Sea transform, and playas on the Tibetan Plateau and Mongolia. Of the two ephemeral lake settings, this is the one where thick sequences of evaporitic salts are more likely to be preserved due to rapid subsidence. Ancient counterparts of this style of deposit include the saline mudflat and pan facies in the Wilkins Peak Member of the Eocene Green River Formation, Utah, the Tertiary borate deposits of Turkey and Cambrian Lake Parakeelya of the Officer Basin, South Australia (Fischer and Roberts 1991; Helvaci 1995; Southgate et al. 1989). Let us now look in more detail at the geology of few Quaternary examples.

Sabkha Yotvata, Israel

Sabkha Yotvata is a continental sabkha with an aerial extent of 45 km^2; it infills the entire 10 km width of the southern Arava Valley (Fig. 3.34a; Amiel and Friedman 1971). It is located some 45 km north of the Red Sea and 110 km south of the Dead Sea in the Great Rift Valley, the transform depression separating the Jordanian and Palestinian plates. The Yotvata valley floor is only 75 m above sea level. To the east and west the sabkha is bordered by steep-sided valley margins; to the east the valley wall rises up to 1,300 m above the valley floor while to the west it rises up to 600 m. Differences in relief are a response to current movement on the Avrona Fault zone (Sarti et al. 2003). Some 1 km wide and 35 km long, the Avrona Fault extends in a NNE direction from the western margin of the northern coast of the Gulf of Elat across the Avrona Playa and up along the steep eastern side of the Yotvata Playa (Amit et al. 1999). North of the Yotvata Playa it dies and merges with the prominent strike-slip fault that trends north to become the Dead Sea Fault.

Steep valley walls have led to the development of an extensive bajada, which interfingers with the evaporitic sediments of the sabkha. In the valley to the north of the sabkha is an extensive dune field extending some 40 km up the valley. To the south is another smaller dune field, which partially covers the south-ernmost sediments of the sabkha.

Matrix sediments are moved in to the sabkha by sheetfloods and a series of short ephemeral anastomose streams

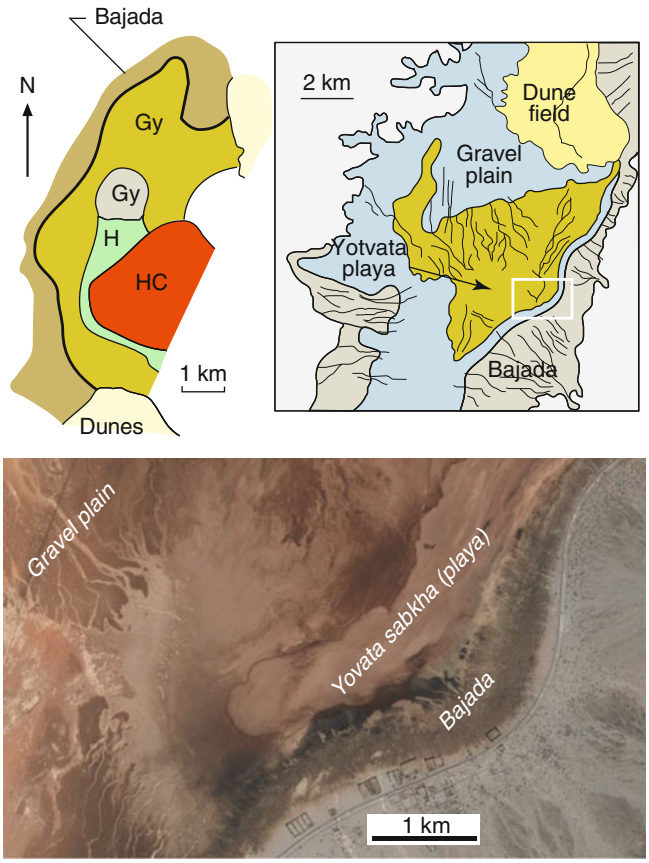

Fig. 3.34 Surficial geology of Sabkha Yotvata, Israel, showing centripetal hydrology created by the bajada rim (Amiel and Friedman 1971; Amit et al. 1999). *Gy* gypsum, *H* halite, *HC* halite crust

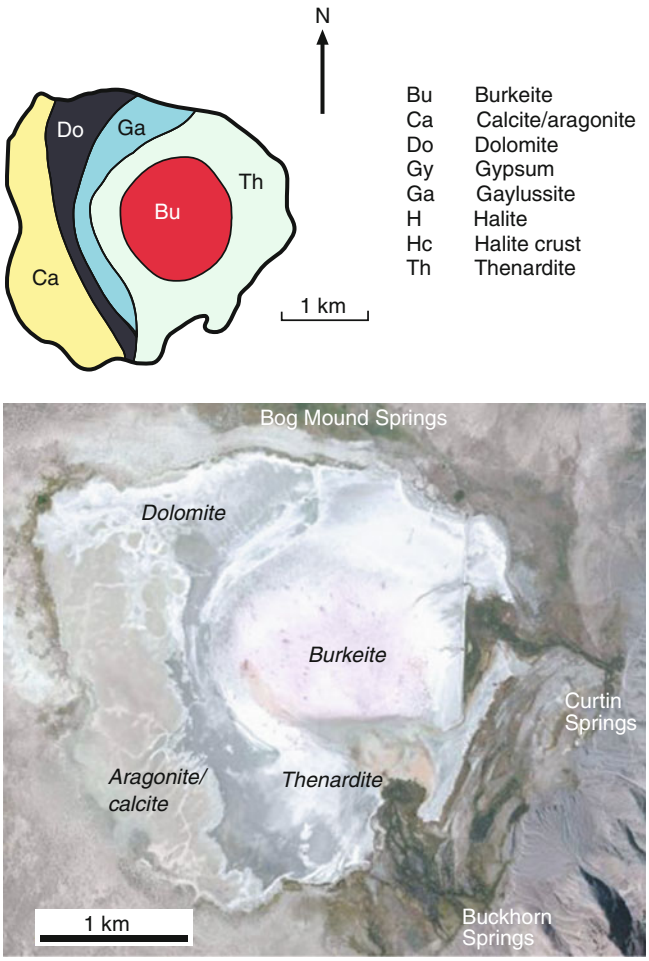

Fig. 3.35 Deep Spring Playa, California (Eugster and Hardie 1978). Note the off-centre bull's-eye pattern in the distribution saline salts indicating nearsurface seepage fractionation and the accumulation of the most saline salts in the lowermost part of the playa floor

(wadis) on the bajada, while fine silts and sands are blown into the sabkha by northerly winds from the dunes. Matrix grain size in the sabkha shows a bull's-eye pattern of distribution with fine to coarse sands and pebbles about the margin and silty to sandy clays in the central sump. North and south the grain-size bull's-eye is complicated by the presence of dune sands. The displacive evaporite salts of the sabkha grow in the capillary and phreatic zones and also follow a bull's-eye pattern related to efflorescent/capillary fractionation of the groundwater; gypsum dominates the periphery and halite the lowermost central portion of the sabkha. The watertable is as deep as 4 m about the bajada periphery and shallower than 1 m beneath the sabkha. Puffy ground and dissected halite crusts form the ephemeral saline pan facies in the lowest part of the valley, whereas displacive nearsurface gypsum grows in the capillary zone of the adjacent saline mudflat.

Basin and Range Playas, USA

Saline lakes with extensive mudflats and smaller areas of saline pans, both surrounded by extensive alluvial aprons (bajada) characterise many of the depressions in the arid zone of the southwestern USA. These saline systems are locally known as playas. Tectonically, the depressions hosting the sabkhas are a response to extension and transform faulting.

Deep Springs Lake, California

Deep Springs Lake is a small 5-km wide playa at an elevation of 1,500 m asl in Deep Springs Valley in eastern California, just east of Owens Valley (Fig. 3.35; Jones 1965). The valley was an eastward draining fresh water-filled lake during the last glaciation (Jones 1965; Meister et al. 2011), but modern Deep Springs Lake only covers an area of 4 km^2. About 1 km^2 of the depression is water saturated and largely water covered throughout the year. The water depth varies in the central sump of the lake between ≈30 cm during the wet season and a few centimetres in the dry season, but its extent is strongly subject to sporadic rainfall in the area. Lake water is constantly supplied from different springs around the lake (Fig. 3.35). Jones (1965) mentioned the inflow of water from

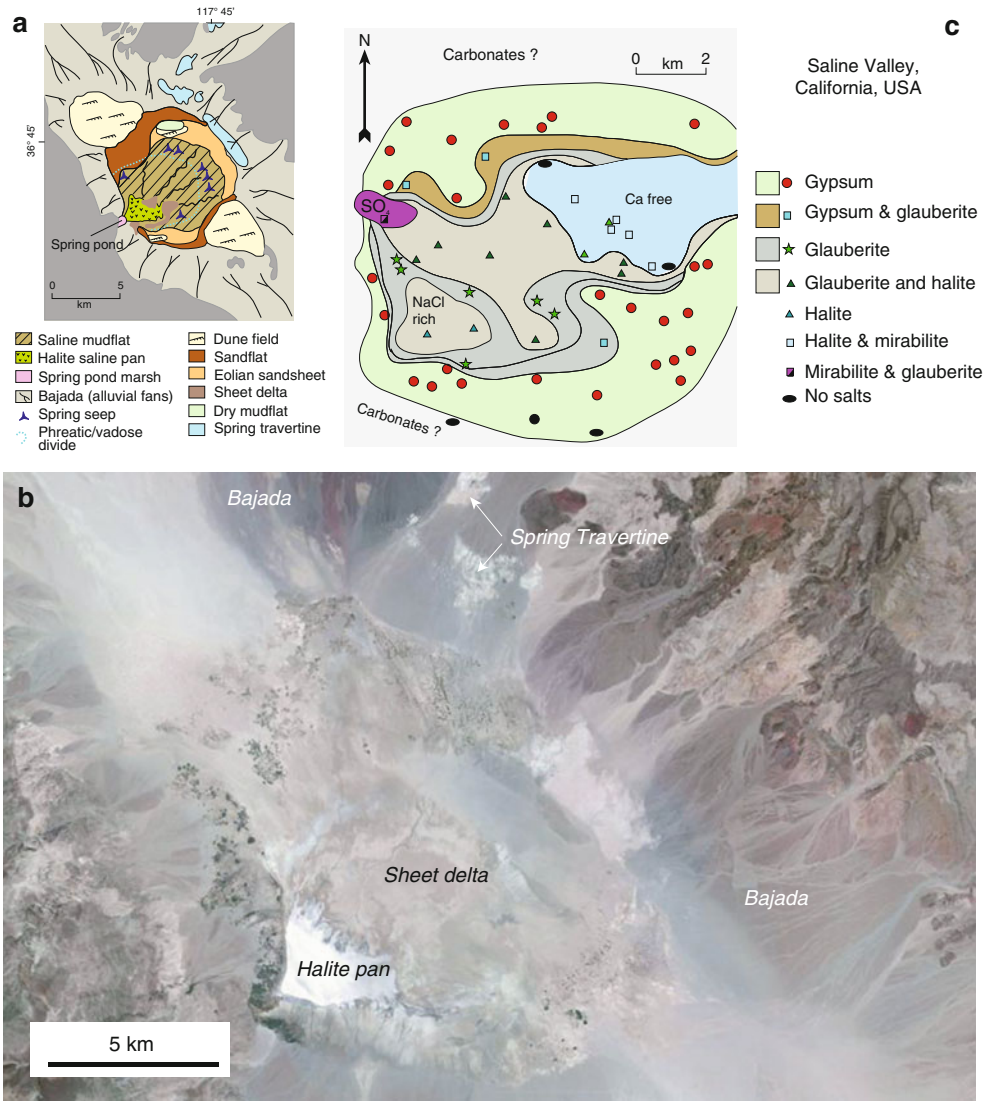

Fig. 3.36 Saline Valley Playa, California. (**a**) Regional sediment distribution (After Hardie et al. 1978). (**b**) Landsat image of the valley showing the off-centre saline sump surrounded by bajada apron. (**c**) Distribution of intrasediment evaporite salts in the saline mudflat (sabkha) part of the playa. The concentric of "bull's-eye" pattern with the more soluble salts in the lowest parts of the area indicates fractionation and progressive concentration of groundwater seepage (After Hardie 1968 and Smoot and Lowenstein 1991)

river drainage; however, today this source is almost completely exhausted due to artificial water collection. The central playa depression is fed by a series of tufa springs with waters that have been in contact with igneous and metasedimentary rocks. The pan in the lowest part of the playa floor is occupied by soluble, mainly Na-rich salts –thenardite, burkeite, trona and halite– deposited as a bedded crust deformed into overthrust pressure ridges.

Dolomite is present across the playa, but elevated levels typify mudflat sediments in the more peripheral, less saline pan areas. Isotopically, there are two types of dolomite; Type A and Type B, very similar to the two types defined in the Coorong lakes of South Australia (Meister et al. 2011; Peterson et al. 1963). Type A precipitates in hypersaline surface brines while Type B is more common in subsurface crusts and cements, under the influence of meteoric waters. The playa is surrounded by the distal sediments of a series of alluvial fans with carbonate-cemented tufa springs at their feet. Volumetrically the capillary and pan salts are a minor portion of the valley-fill, which is dominated by alluvial fan and sand flat (distal fan) facies.

Saline Valley Playa, California

Saline Valley playa is a small continental sabkha-salt pan playa in a fault-bound graben located east of Owens Lake across the Inyo Mountains. Amalgamated alluvial fans (bajada), fed from adjacent mountains, are dominated by debris flow deposits; their slopes are short and steep with little sandflat development around their bases (Hardie 1968; Hardie et al. 1978). In contrast, fans at the NW and SE ends of the depression are more longitudinal to the basin axis and so show lower gradients allowing eolian sand sheets and dunes to accumulate adjacent to wind-reworked fan toes (Fig. 3.36). Pleistocene travertines and active spring mounds mark zones of groundwater seepage.

Sabkhas (saline mudflats) cover a large portion of the basin floor and are dissected by sinuous seepage channels,

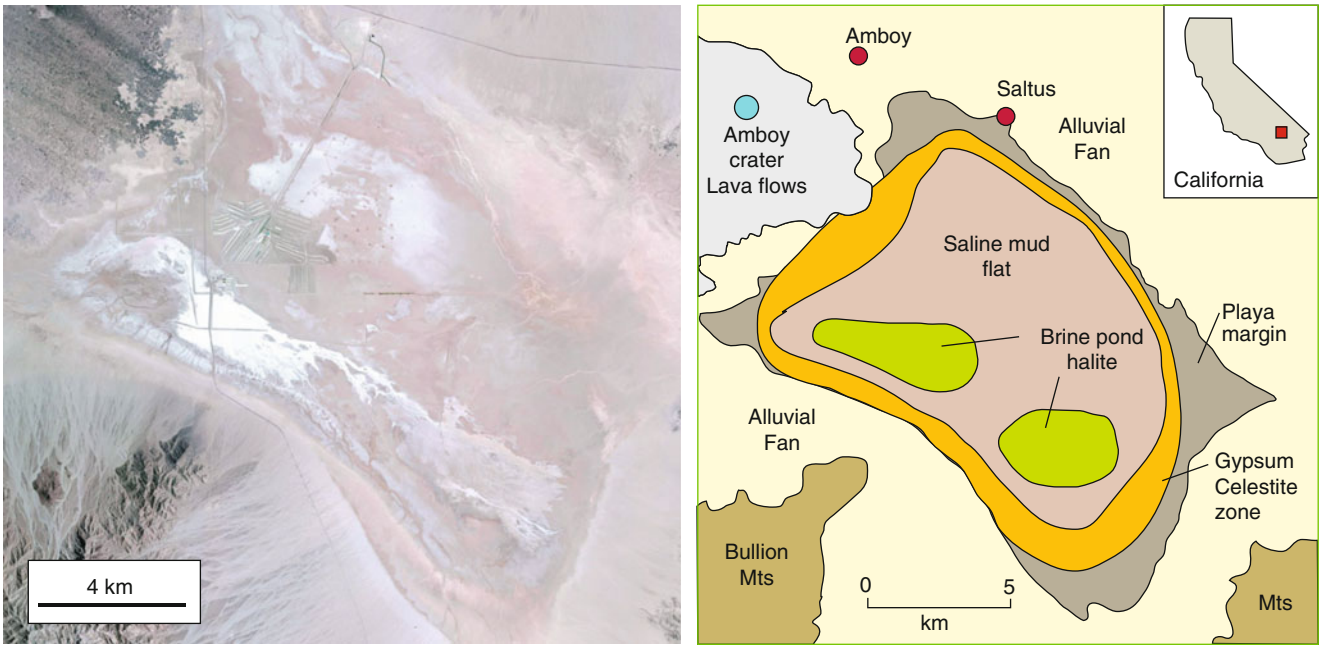

Fig. 3.37 Bristol Dry Lake, California. The continental sabkha facies shows concentric pattern of intrasediment salt growth with an outer gypsum capillary pavement and an inner halite saline mudflat, the halite pan facies is slightly offset from the centre and occurs in the lowest parts of the lake in the southern part of the depression (Bing® image scaled and mounted in MapInfo, surface geology after Rosen and Warren 1990)

while a halite-floored saline pan defines the lowest part of the playa. Pan facies are made up of dm-thick halite beds separated by mud layers with abundant intrasediment crystals of halite, glauberite and thenardite (Fig. 3.36). Glauberite crystals and moulds of mirabilite, now filled with glauberite, are common in the sabkha or saline mudflat. Along the southern zone of the saline mudflat is a belt of layered aligned gypsum that probably formed by intense capillary fringe evaporation like the texturally identical capillary gypsum crusts defining the sabkha edge of Bristol Dry lake (Rosen and Warren 1990). The sulphate-rich northwest corner of the mudflat is tied to ponding and evaporation of seepage waters from a nearby spring.

Bristol Dry Lake, California

At the surface, the Bristol Dry Lake basin in the Basin and Range province of California exhibits what appears to be a slightly off centre bull's-eye distribution of surface and near surface salts (Fig. 3.37; Handford 1982; Rosen 1991). Low-gradient alluvial fans ring the 10-km wide playa, while extensive calcretes and pedogenic calcites, associated with halophyte plants, cement mid-to-distal fan gravels and sands. There is a 62 km^2, ≈2 m thick, roughly circular and level black basaltic lava flow atop the playa surface along the west and northwest edges of the lake depression. It originated at the same time as the Amboy Crater and is likely a Holocene feature. It indicates ongoing hydrothermal circulation, so explaining the $CaCl_2$ brines that typify lake porewaters and the natural, but highly unusual occurrences of antarcticite precipitates in the lake trenches (see Chap. 12).

Basinward of the distal fans, in the playa margin facies, is a centripetal gypsiferous sabkha some 300 m wide where celestite precipitation forms large decimetre-size nodules that can coalesce into metre-size patches. The gypsum unit is characterised by a growth-aligned fabric created by competitive alignment of gypsum prisms in a zone of capillary wicking (Fig. 3.38; Rosen and Warren 1990). Once these gypsum crystals are buried and converted to aligned anhydrite nodules it would be next to impossible to distinguish them from the much more commonplace subaqueous textures. Basinward of the playa margin facies, halite hoppers (up to 0.5 m in diameter) form displacive intrasediment precipitates in brine-saturated muds of the saline mudflat facies. Finally, in the basin-centre depression a 0.2-m thick chevron-halite crust (salt pan) is forming by evaporation of ponded ephemeral waters.

The lateral facies distribution seen at the surface also stacks throughout the entire length of deep cores collected in the playa (Rosen 1991). Saline pan halite beds alternate with halite-saturated siliciclastic muds in a 500-m core from the basin centre. Playa margin cores exhibit alternating beds of playa margin sediments and saline mudflat (sabkha) units for most of their length. Towards the base of the deepest playa-margin core, distal alluvial fan sediments are also present. Rosen (op. cit.) notes that a delicate balance between subsidence and mechanical/chemical deposition of minerals was necessary to maintain a vertically-consistent ephemeral

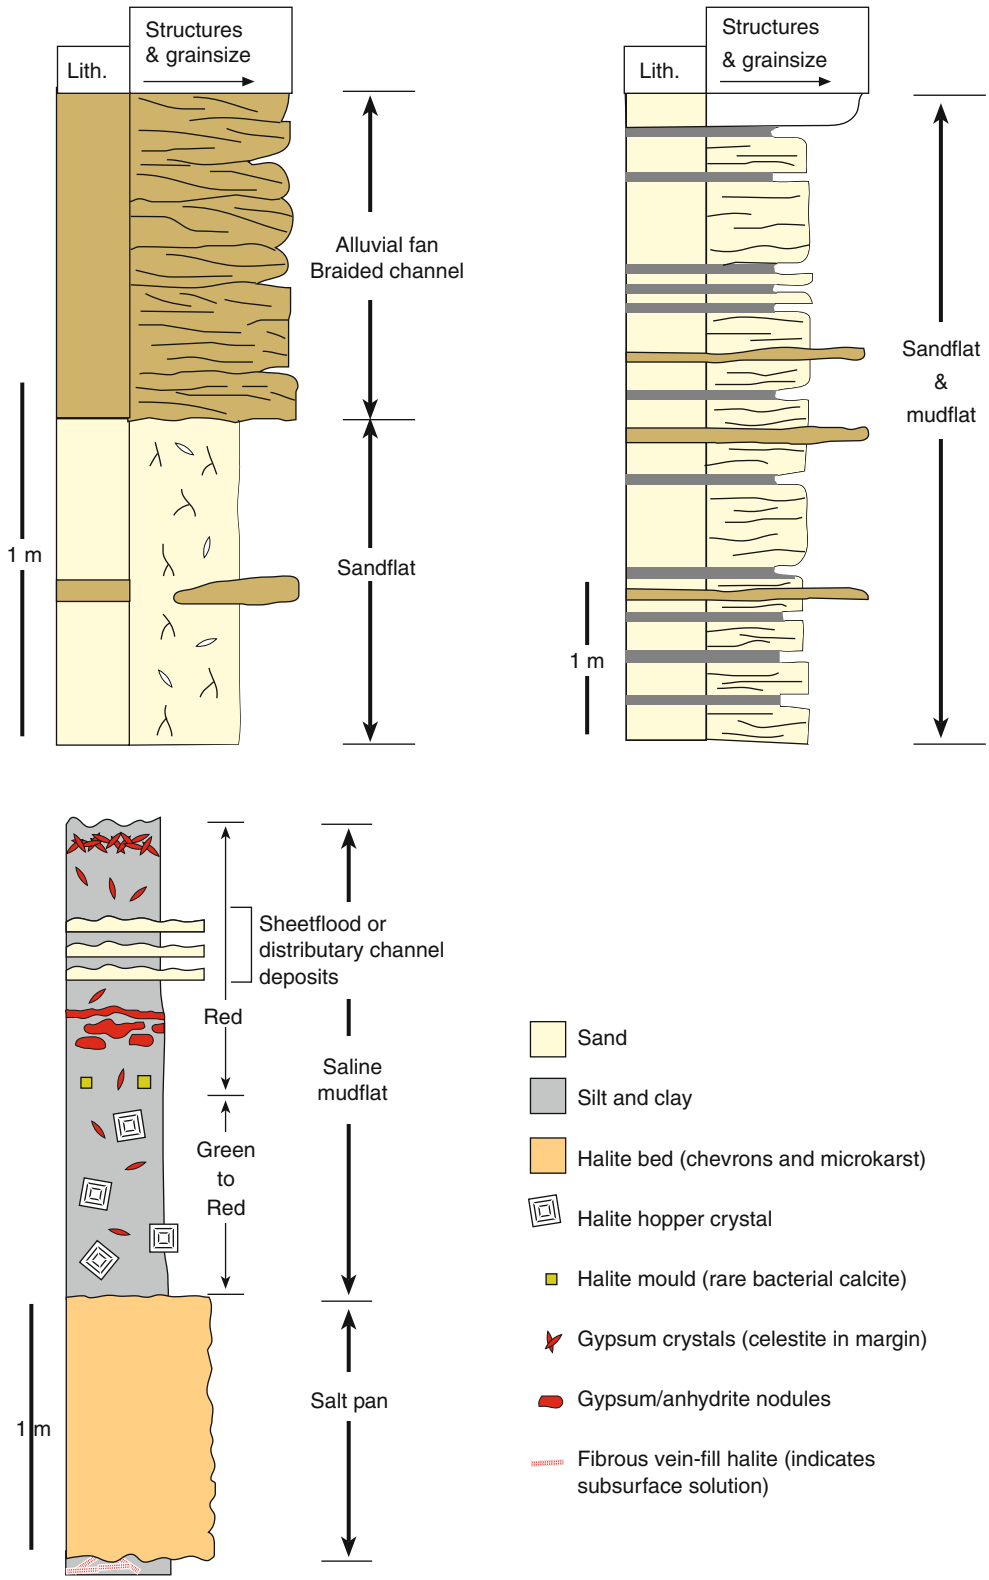

Fig. 3.38 Generalized stratigraphy based on Bristol Dry Lake from the alluvial fan margin into the saltflat saline pan centre (After Handford 1991; Rosen and Warren 1990)

brine environment during the deposition of over 500-m of basin fill.

I would say this is not really an example of some rather unusual delicate balance preserved in the sedimentary signature, so much as it is evidence of a hydrological/deflation forcing mechanism. It is a response to the same Stokes-surface hydrology that drives sedimentation in the sabkha and pan regions of most Quaternary continental playas and sea margin sabkhas. Accommodation space in the Bristol Dry Lake depression is created by subsidence in

a tectonically active region, in what has been a variable but mostly arid climate throughout the basin's Quaternary history. The basin's hydrology dictated the contrast in accumulation styles between the salt rich succession in the basin centre and the coarser siliciclastic dominated basin edge. The volume of sediment accumulating in the basin centre in Bristol Dry Lake can never surpass the ability of the wind to blow any dried sediment out of this depression centre into surrounding areas. That is, the surface of the sedimentation in the basin lowermost parts is maintained by deflation at a position that is always near the watertable. The only types of sediment that can remain in the arid basin centre are in equilibrium with the watertable and the top of the overlying capillary zone. When the watertable was a metre or so below the sedimentation surface, aggrading sediments were held in place by meniscus forces inherent to the capillary fringe and accumulated in saline mudflats as sabkha sediments. When the watertable rose to become a water surface, it created a semipermanent saline brine pan that then deposited and stacked salt pan crusts.

Basin edge sedimentation was not hydrologically forced but built up as volumes of centripetally-supplied sediment accumulated. This is turn facilitated the creation of an aggrading potentiometric head feeding ground and surface waters to the basin centre lows. About the edges of Bristol Dry Lake, where the accumulating clastic sediment is closer to its source, it is coarser grained and less liable to deflation. Clastics are accumulating in sufficient volumes to build facies belts situated well above the regional watertable, hence the accumulations of alluvial fan, dune and sandflat sediments. At times when the subsidence rate exceeds the rate of sediment supply in this area, its hydrology becomes more like that of the basin centre and saline mudflat facies come to dominate over much of the playa floor. Such a hydrologically forced system means that when regions of maximum subsidence in a basin change position, it moves the position of the hydrologically forced sediments into the new lowermost areas on the playa floor. Ultimately, once the rate of subsidence decreases to where the rate of clastic sediment supply exceeds the ability of the wind to deflate, the margin sediments will cover the whole basin and evaporite sedimentation will cease.

Death Valley Playa, California

Death Valley is probably the best known playa of the Basin and Range setting in the USA, yet Death Valley is a very steep sided and unusual lacustrine depression. Its floor is some 24 m below sea level, making it the lowest continental locality in the Western Hemisphere. Its steep sides mean it is likely to become a perennial saline lake with minor changes in climate (Chap. 4). In many areas of Death Valley the coarse-grained debris flows of the alluvial fan directly abut the salt crusts of the sabkha and the saline pan. Sandflats and dry mudflats, so obvious in most Basin and Range playas, are poorly developed or absent in Death Valley. This too reflects the steep valley walls (Fig. 3.32f) and its relatively high watertable in relation to the lake surface. It is a rapidly subsiding saline lacustrine system in which more than 50 % of the Quaternary sediment fill beneath the lowest parts of the lake floor are dominated by saline lake and pan halite rather than matrix-rich evaporitic mudflat (sabkha).

This is clearly seen in a 90-m length of core (DV93-1), which returned an interbedded salt and mud sequence extending back some 200,000 years (Fig. 3.39; Li et al. 1996, 1997; Lowenstein et al. 1999). Minerals intersected in the core include sodium chloride (halite), sulphate minerals (glauberite, gypsum, and thenardite), and carbonate minerals (calcite and dolomite). Glauberite, gypsum, and thenardite occur in mud layers or partings as randomly oriented, mud-incorporative crystals. They are thought to be early diagenetic and to have precipitated from nearsurface ground waters within saline mudflat or sabkha settings. Carbonate minerals calcite and dolomite occur as rhombs to irregularly shaped crystals that are less than 5 μm in diameter. Vertically, there are significant mineral assemblage variations in the core. Abundant glauberite and gypsum, and relatively small amounts of calcite (13–35 % of >1 μm size insoluble fraction) are associated with both sabkha and subordinate saline pan settings. They formed in relatively dry periods from 0 to 10 ka and 60 to 100 ka (0–8 m and 60–90 m depths in the core, respectively). Sabkha sediments (0.25–7 m, 60–78 m, 87–90 m) consist of muddy silts with sand patches and mud cracks and accumulated during long periods of desiccation. They indicate sedimentary accretion via formation and incorporation of efflorescent salt crusts in the accreting sediment matrix. These episodes of sabkha and subordinate saline pan deposition indicate periods when Death Valley was relatively arid and the sedimentation surface was the top of the capillary zone over much of the valley floor, similar to the modern setting.

In contrast, most of the remaining intervals in the core are characterised by sparse $CaSO_4$-bearing minerals and relatively high amounts of calcite (20–50 % of the >1 μm-size insoluble fraction). These are intervals where much of the sediment is halite rather than mud-dominated. It defines a time 10–60 ka (8–60 m) when the basin-floor watertable was above the sedimentation surface for long periods of time, including the 25,000 year wet period when Death Valley contained a perennial halite lake (10–35 ka; 8–18 m) and the 25,000 year period when the floor of Death Valley consisted of saline pan-ephemeral saline lake environments (35–60 ka; 18–60 m; Fig. 3.39). Core intervals through saline pan sediments are composed of interbedded halite, chaotic muddy halite, and mud. The halite contains abundant vertical dissolution pipes, cemented with clear halite, indicating the watertable periodically

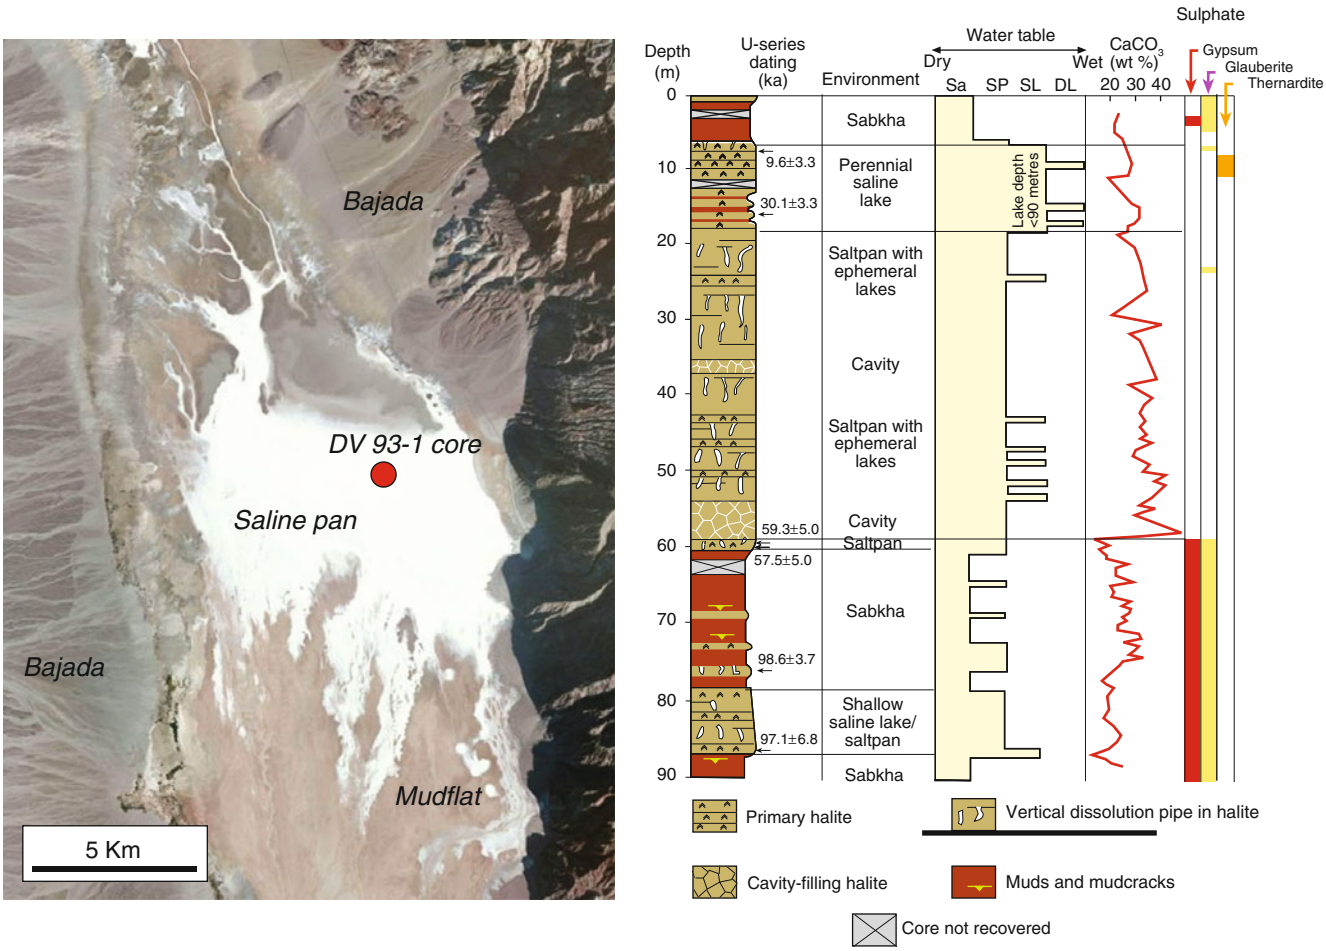

Fig. 3.39 Landsat image of Death Valley, California, showing saline pan in lowest part of sump and the stratigraphic column of upper 90 m of core DV-93-1 from within Death Valley (After Li et al. 1997). Lake levels and watertable fluctuations are shown ranging from driest (sabkha) through saline pan (*SP*) to the wettest lacustrine phases of saline lake (*SL*) and deepest lake (*DL*). The dominant evaporite mineral is halite and the position of the sulphate evaporites in the core, as well as the weight percent $CaCO_3$ in the >1 μm fraction, are also shown

dropped below the surface of the stacking halite crusts. These sediments record repeated flooding by dilute waters, dissolution of subaerially exposed surface salt crusts, deposition of mud from suspension, precipitation of halite during the saline lake phase, and cementation by diagenetic halite (Li et al. 1996). Such deposits document a relatively wet climate with a high ratio of water inflow to evaporation compared to today. Ostracods in mud layers represent the least saline, deepest lake phases when, based on the position of beach deposits in the valley walls, water depths in the deepest part of the lake were as much as 90 m. Halite layers are made of fine-grained cumulates and clear, vertically oriented crystals precipitated during shallower, perennial lake stages. The near complete absence of syndepositional dissolution textures in saline minerals precipitated in the perennial saline lake interval, imply that the accumulating salts were permanently protected from dissolution by an overlying perennially-saline at times holomictic water column (see detailed discussion in Li et al. 1996).

According to Li et al. 1997, the interval with little glauberite and gypsum, and relatively abundant calcite, dated from 10 to 60 ka (8–60 m), corresponds to the last glaciation, i.e., stages 2 and 3 of the marine oxygen isotope record. This was a relatively wet period in Death Valley. The intervals with abundant glauberite and gypsum and relatively low calcite correspond to the Holocene and to stages 4 and 5 of the Quaternary marine record, which were two relatively dry periods in Death Valley. Therefore, mineral assemblages correlate with wet and dry climate cycles in Death Valley (lake versus mudflat), which shows once more that mineral assemblages, depositional style and brine chemistry are all linked to climate changes (Chap. 2).

Salars of South America

The greatest thicknesses and volumes of evaporites currently accumulating anywhere in the world are doing so in the various collision related intermontane depressions and deserts of South America. More than a hundred salt-crusted pans or playas, locally known as salars, characterise

Fig. 3.41 Index of the main salars and salinas and nitrate deposits in the central Andes, South America (After Ericksen 1993)

depressions in the high-relief arid region of the central Andes and constitute salt deposits with areas ranging from more than 9,000 km^2 to less than 1 km^2 (Figs. 3.40 and 3.41). Some have been harvested on a small scale since the mid 19th century for their chloride, nitrate, borate and iodide salts. Huge state-of-the-art brine extraction/processing plants have come to operate in some of these salars in the last two decades and have taken much of the world

market from similar older smaller facilities in North America (Chap. 11).

Salars occur within a tectonically active region of largely interior (endorheic) drainage over an area of more than 400,000 km^2. It extends from the arid to semi-arid deserts of the Andean highland plateau (Altiplano Puna) down to the hyperarid Atacama desert, an area that is so arid that nitrate salts form widespread (and mineable) pedogenic precipitates (Fig. 12.62). Altiplano Puna was uplifted in the Miocene and is characterised by an average elevation greater than 3,000-m and widespread endorheic drainage. Salars of the Puna are either "wet" or "dry" and similar styles of arid deposition have dominated their fills throughout their Neogene histories (Alonso et al. 1991).

Dry salars are characterized by high rates of evaporation and are starved of detrital sediment. Fluvial input is restricted to rare flash floods and groundwater seepage is the dominant source of solutes. Stacked crusts of salar halite are typically in direct contact with basin margin gravels. Desert indicators are abundant in the clastic edge and include, eolian sands, polished clasts, varnished cobble, desert pavements and gypcrete soils. Volcanism, either by ash fall or hydrothermal circulation is the parent to almost all solutes accumulating in the basin. Examples include; Salar de Uyuni, Salar de Atacama, Salar Grande and Salar Arizaro.

In addition to groundwater seepage, wet salars are fed by permanent streams. These salars have perennial brine lakes and evidence of fluvial deposits, especially alluvial fan deposits, is more significant in the fill than in dry salars. Salar fill is typically alternating beds of clastics and evaporites. The slightly wetter (but still arid) environment of deposition is indicated by mud cracks, raindrop prints, bird tracks, ripple marks, desiccation breccias and preserved plant fragments. Modern examples include the Pastos Grande and Hombre Muerto salars.

The hyperaridity of much of this region of South America reflects a confluence of a number of desert-forming conditions. First, it lies in the Horse Latitudes, a region of permanent subtropical highs locally blocking influence of the semi-permanent South Pacific Anticyclone and so limiting the influence of winter storm tracks from the south. Second, offshore upwelling of the cold northward Humbolt current creates an atmospheric temperature inversion (≈1,000 m elevation) that prevents inland penetration of Pacific moisture. And third, the Atacama Desert lies on the western flank of the high Andes and so sits in a rain shadow not subject to tropical/subtropical moisture from the east. The driest part of the Atacama, which is 50 times more arid than Death Valley, California, in effect lies in a "double" rain shadow with the Andes to the east and the Coastal Range to the west (Figs. 3.40 and 3.41).

The region has experienced arid to semi arid climate as far back as the Middle Miocene, when the modern Andes were first uplifted to form a barrier to easterly trade winds. Uplift anchored the South Pacific Anticyclone to the western bend in the South American continent. Uplift of the Andes to its present elevation may have occurred as early as 15–19 Ma, although palaeobotanical evidence suggests the Central Andes were at half their present elevation some 10 Ma (Vandervoot et al. 1995; Gregory-Wodzicki 2000). The Humbolt current has been active since the Early Tertiary, but reached its present intensity either during a major expansion of the Antarctic ice sheet 15 Ma or after the Isthmus of Panama formed some 3.5 Ma (Chap. 5). Onset of Miocene aridity also shut down the meteoric flushing that drove supergene enrichment needed to create the giant porphyry copper deposits of the Southern Atacama (Sillitoe and McKee 1996).

There are four Neogene evaporite domains in the Andean highplain (Fig. 3.42a; Alonso et al. 1991). Deposits change from only travertine in the north, to a mix of travertine, gypsum and minor borate, to completely evolved halite dominated successions in the south, with borate-rich sequences along the eastern Puna. Older halite-rich successions are often caught up in subsequent tectonism and become halokinetic sources to modern salars such as Salar de Uyuni and Salar Atacama. The southward change from travertine to halite is consistent in deposits ranging in age from the Miocene until the present and probably indicates a consistent trend of increasing aridity from north to south since the Andes first arose in the Miocene (Alonso et al. 1991).

Present day rainfall in the Andean Highlands ranges from <50 mm in the vicinity of Salar di Maricunga and nearby areas in Bolivia and Argentina to nearly 300 mm in the area around Lake Titicaca and southern Peru (Fig. 3.44; Ericksen 1993). In contrast, the Atacama Desert lacks an annual rainfall and it may rain as infrequently as once every 10–20 years. Much of the groundwater in the desert is sourced from runoff in the Andean Highlands. Unlike the playas in the southwest of the USA, dry salars are dominated by pan facies rather than mudflats, perhaps reflecting higher relief and lower permeability substrates in this region creating more opportunities for flooding, followed by extended times of brine ponding.

Active continental volcanism is ongoing, with several west-northwest trending volcanic ridges cutting the Puna. This divides the Puna into several stagnant endorheic basins, further subdivided by north–south trending structural blocks creating local sources for alluvial fans and groundwaters. Thus, many of the salars show elevated lithium and boron contents in their surface and interstitial brines, with solutes sourced in abundant highly reactive volcanics, mostly rhyolitic ash-flow tuffs. Ions are redistributed to the salar by runoff and ongoing hydrothermal circulation (Table 3.5; Ericksen 1993). Evaporative concentration of salar brines leads to the depletion of Ca, HCO_3, B_2O_3 and SiO_2, and the enrichment of Li, K and Mg. Ca and SO_4 are removed from

In part after Ericksen (1993)

the concentrating waters as gypsum, while Ca and HCO_3 are removed early in brine evolution as cyanobacterial limestones, ostracode carapaces and inorganic precipitates, mostly travertines (Risacher et al. 2003). Boron precipitates as ulexite (see Chap. 11), while SiO_2 is removed by incorporation into widespread diatom tests in the fresher water lakes and spring pools. The proportions of Li, K and Mg tend to remain constant in a single lake basin, but vary from basin to basin owing to varying proportions of contributing lithologies from one drainage basin to another.

According to Risacher et al. (2003), sea salts and desert dust are blown eastward over the Cordillera, where they can constitute an appreciable fraction of the solute load of very dilute waters feeding the salars (salt content <0.1 g/l). But weathering of volcanic rocks contributes most components to inflow waters with salt content ranging from 0.1 to 0.6 g/l. However, the average salt content of all inflows is much higher, about 3.2 g/l. Chemical composition, Cl/Br ratio, and ^{18}O–^{2}H isotope contents point to the mixing of very dilute meteoric waters with present lake brines for the genesis of most of the saline inflows. Saline lakes and subsurface brines are a steady-state hydrologic regime. The average residence times of conservative brine components ranges from a few years to some thousands of years and indicate permanent leakage of the brines through bottom sediments. The infiltrating brines are recycled in the hydrologic system where

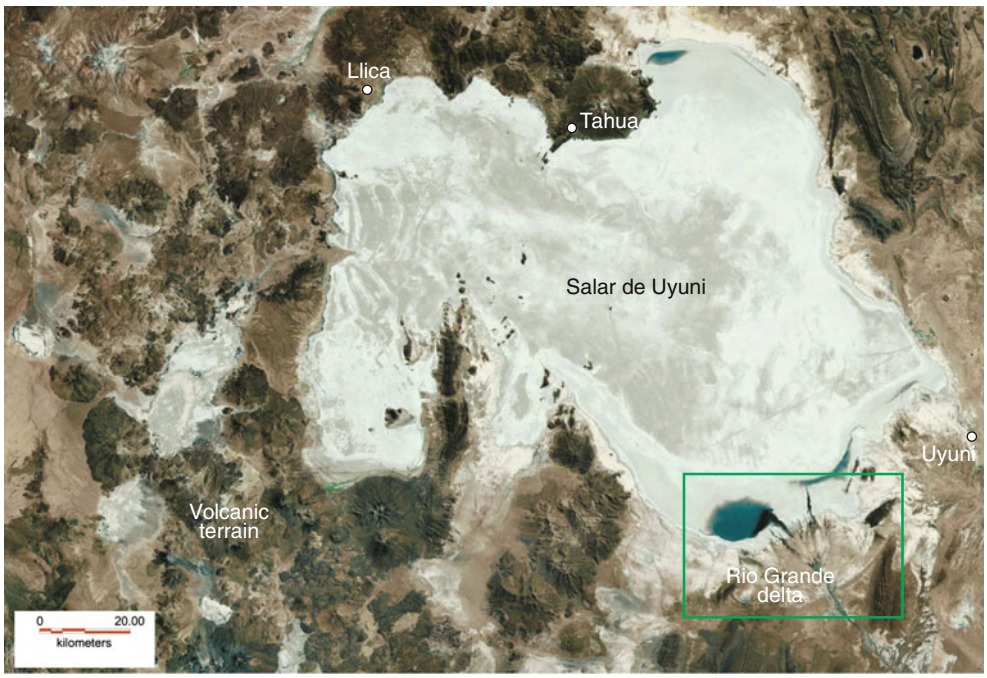

Fig. 3.43 Salar di Uyuni, Central Altiplano, Bolivia, showing salar is dominated by white halite crust with Rio Grande fan delta in southwest (delta region indicated by green rectangle; Bing® image automounted and scaled in MapInfo®)

they mix with dilute meteoric waters. High heat flow is the likely driving force that moves the deep waters in this magmatic arc region. According to Risacher et al. (2003), active Chilean salars cannot be considered as terminal lakes nor, strictly speaking, as truly "closed" basin lakes. They leak (see Chap. 2). Almost all incoming salts ultimately leave the basin and are transported elsewhere. Moreover, the dissolution of fossil salt crusts in some of the active salars also carries away important fluxes of components in percolating brines. In effect, the regionally leaky salar hydrology constitutes a broad scale fractionating system that can accumulate relatively pure salts in each of the large salt basins.

Although there is a longterm north to south trend of increasing salinity, evaporite basins and aridity have migrated eastwards with time, driven by the Miocene evolution of the Andean Range. Consequently, many of the westernmost salars, such as Salar Grande, are presently not regions of internal drainage (Pueyo et al. 2001). Worldwide, this migration of precipitative activity in "piggy-back" salt basins characterises the evolution of many evaporite deposits that accumulate in collision belts. The Central Depression is bounded on the west by the Coastal Range and the Pacific Ocean and to the east by the Andean Pre-Range (Fig. 3.42b). Throughout the Neogene, it acted as a significant drainage basin for pluvial input from the east that flowed into the area without reaching the sea. Its alluvial fan systems reach dimensions of tens of kilometres wide and hundred of metres in thickness. In the more distal parts of the fans, both perennial and ephemeral lakes developed (e.g. Calama-Chiu Chiu, Batea, Quillagua-Soledad, Bellavista-Pintados, Pisagua basins). The topography responsible for this drainage arrangement was generated during the Upper Paleogene, as a result of the Incaic orogenic pulse. From this time to the Pliocene the Central Depression was an endorheic area, and the Coastal Range acted as a barrier to drainage to the sea.

In plan view, sediment patterns in most of the South American salars with salt fills show a central zone, consisting of a relatively thick stack of halite crusts, surrounded by a thin marginal sulphate zone consisting of a variety of sulphate minerals, as well as minor halite and ulexite (Ericksen 1993). The zoning may be symmetrical (bull's-eye pattern) with sulphate surrounding a central halite core, or asymmetrical with the halite zone crowded against one side of the salar. This is the situation in Salar de Atacama where tectonic tilting has displaced the lowest part of the brine sink to the southern end of the playa. Alternating arid and pluvial climatic episodes, since the mid-Miocene, means alternating beds of salt and siliciclastics fill most Andean salars/playas.

Salar de Uyuni, Bolivian Altiplano

The Salar of Uyuni, at an elevation of more than 3,600-m in the central Bolivian Altiplano, is an active ephemeral saline lake (salt-crusted saline pan) where substantial salt thicknesses have accumulated across an area of a little less than 10,000 km^2, making it the world's largest salt-filled saline pan (Figs. 3.43 and 3.44a; Risacher and Fritz 2000). A 121 m deep well, drilled in the central salar, intersected a complex evaporitic sequence made up of 12 saline pan intervals separated by 11 mud layers deposited mostly as saline mudflats or sabkhas (Fig. 3.44b). The thick saline pan beds are composed of stacked salt crusts and alternate with thinner mud units in the lower half of the well. The mud beds show obvi-

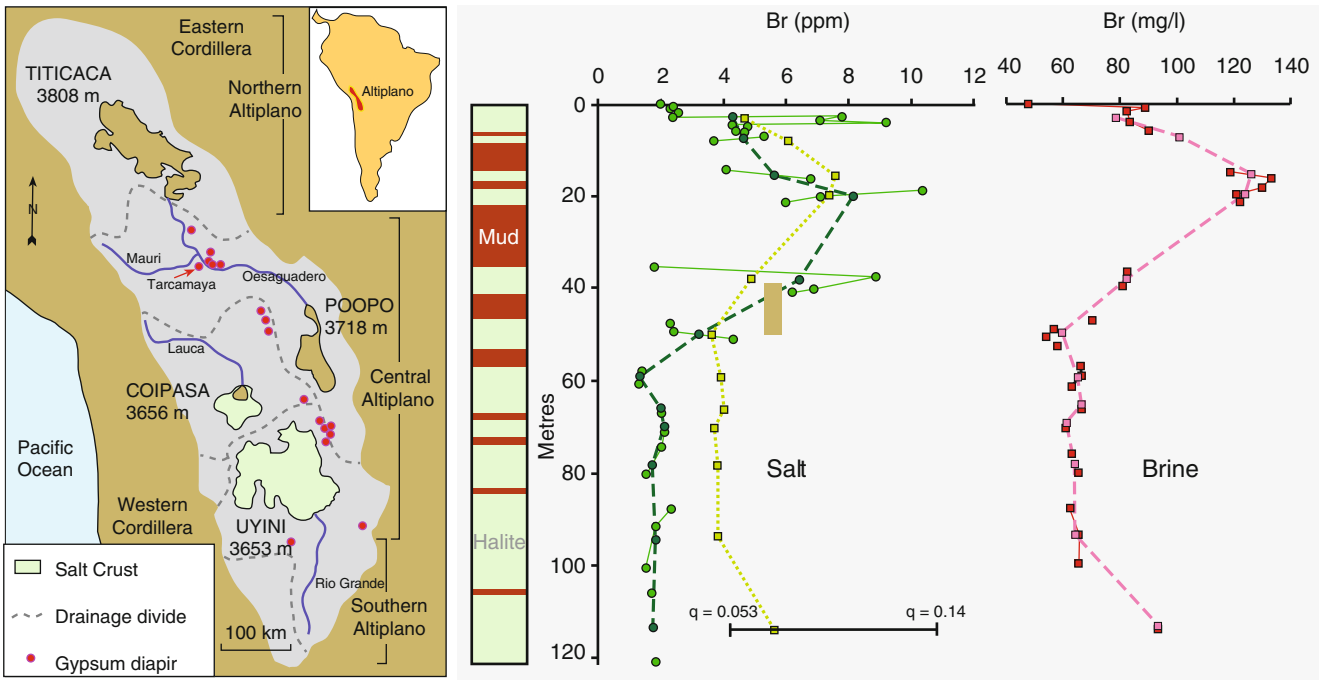

Fig. 3.44 Salar di Uyuni, Andean Altiplano. (**a**) Locality map showing hydrological relations with drainages of other salars and lakes of the Altiplano as well as its proximity to diapirs. The dissolution of diapir salts has sourced much of the salt accumulating in the Salar di Uyuni. (**b**) Lithology and Br profiles from a 121 m well in Salar di Uyuni (After Risacher and Fritz 2000)

ous lacustrine features and thicken upwards as salt beds thin. The well indicates a longterm hydrology where tectonics, as well as climate, controlled the level of the regional watertable.

Bromine contents of the recovered pan halites range from 1.3 to 10.4 mg/kg (Fig. 3.44b). Such low values mean the various halite beds were not precipitated by simple evaporation of meteoric and surface waters. This would be indicated by Br contents of tens of mg/kg in the pan halites (Risacher and Fritz 2000). Rather the brines were created by dissolution of older evaporites, which subcrop in the drainage basin. Halite from one such nearby gypsum-capped diapir has a very low Br content of 2 mg/kg, strongly suggesting that most of the halite deposited at Salar di Uyuni originated from the leaching of similar diapiric salt. The ubiquity of this salt source is indicated by the numerous gypsum-crested diapirs, which still outcrop in the Altiplano (Fig. 3.44a).

The very low and fairly constant Br content (1.6–2.3 mg/kg) of the lower salt beds, along with an abundance of detrital minerals, suggest the deeper and thicker halite beds were deposited as saline pan intervals in ephemeral lakes (Fig. 3.44b). Thereafter, perennial water episodes of increasing duration, flooded the central Altiplano. This change is tied to an increase in the volume of dilute meteoric waters entering the Uyuni drainage basin and in the proportion of mud beds in the salar core. These waters had lower Cl/Br ratios, indicated by an increase in Br to 6–10 mg/l in the pan halite beds between 10 and 40 m depth (Fig. 3.44b). The change may have also coincided with the exhaustion of diapiric halite as a source of ions, perhaps related to a decrease in the intensity of tectonism that was driving diapiric salt to the surface. Paleolake levels in the central Altiplano rose at this time, while those in the northern Altiplano (the Titicaca basin) were simultaneously falling. This reflects progressive fluvial erosion of the threshold between the northern and the central Altiplano, which lowered the levels of the northern lakes and allowed more dilute waters with lower Cl/Br ratio to flood the central Altiplano and so move into Salar di Uyuni. The three uppermost salt crusts show a decrease in bromine content, which may reflect a recent modification to the inflow regime.

The salt of the uppermost saltpan layer began to accumulate around 10,000 years ago and continues today. The halite shows a bromine distribution that is low in the shallow parts of the bed (≈2 mg/l) but unexpectedly increases with depth to values in excess of 8–10 mg/l (Fig. 3.45a, b). This increase is thought to indicate an episode of exposure and recycling of earlier formed marginward salt crust into the current brines (Fig. 3.45c). As the lake dried some 10,000 years ago, the resulting salt crust was initially distributed over a wider area than the crust of the present pan. It covered the topographic surface of the salar depression up to the level of the lake where halite brines first reached saturation (Fig. 3.45c). Ongoing lowering of the Holocene watertable, and the associated dissolution of the higher parts of the salt crust about the more marginward parts of the pan depression recycled ions (including Br) from crusts about the margins of the lake into the brines feeding the lowered

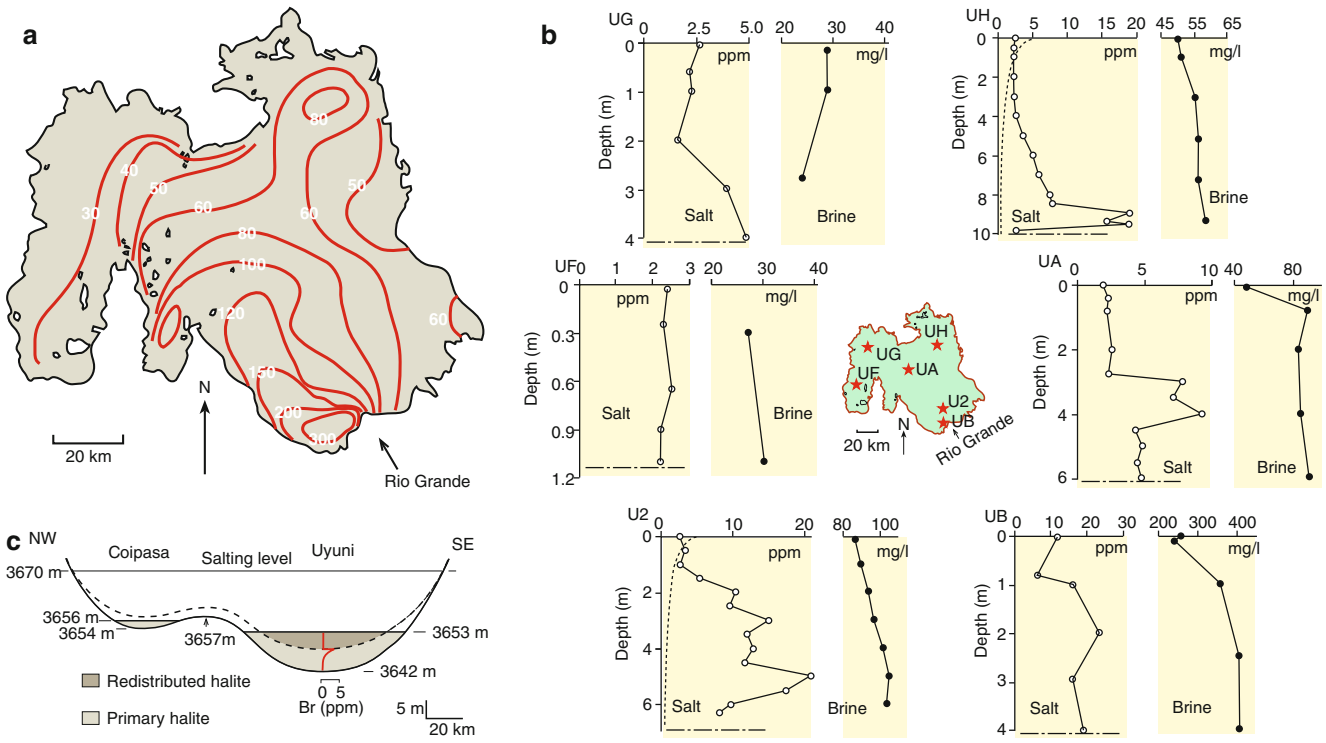

Fig. 3.45 Distribution of Br in shallow saline pan sediments of Salar de Uyuni. (**a**) Distribution of Br in nearsurface brine. (**b**) Br profiles of pan halite and interstitial brines from selected shallow cores. (**c**) Schematic showing how low bromine salt is reworked and redistributed from initial marginward crusts by a lowering of the perennial watertable (After Risacher and Fritz 2000)

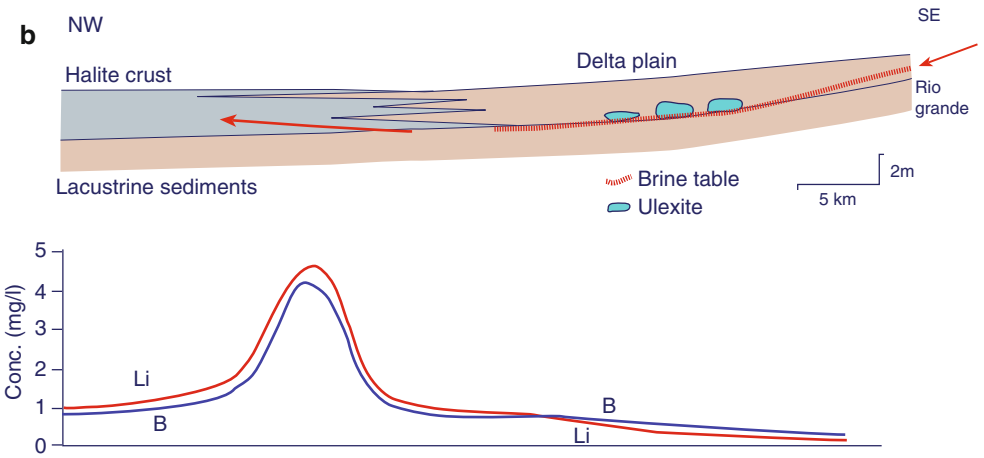
brine levels located further toward the salar centre. Ongoing recycling explains the progressively lowered Br contents in successive pan crusts in the more central parts of the salar. Clearly, the increasing aridity and lowered watertable that typifies the current episode of saline pan aggradation has cannibalised earlier versions of itself as ongoing longterm drying of the lake raised marginward crusts above the salar watertable.

Many parts of the lake surface about the lake edge still show evidence of salt dissolution and crust recycling. Circular holes appear in the lake crust, especially about the salar edge; surface expression of the holes can be a few tens of centimetres wide but they are typically underlain by brine-filled swallow holes opening out in to salt cavities that are metres deep and wide. It makes driving on some parts of the salar edge quite hazardous.

The local name for these small holes at the surface is "Eye of the Devil" (*ojo del diablo*). Local karst development about the edge of a bedded salt mass is an early diagenetic overprint common to many modern and ancient saltpans. It is driven by changes in the lake watertable and the encroachment of regions of less saturated water into the margins of the bedded salt. The associated preferential leaching and fractionation drives the syndepositional formation of many potash and borate accumulations (Chaps. 11 and 12).

The main fluvial feed to the salar is from the Rio Grande, which enters the salar depression in its southwestern part. There it has built up a 300-km^2 delta, characterised by a lens of fresher water and sediment that intertongues with the halite crust unit (Fig. 3.46). The delta itself is a complex of silt and clay with local sand lenses indicating fluvial channel fills. Clays are mostly smectite with some illite and minor kaolinite. Overall, the delta prism is characterised by low porosity and permeability (Risacher and Fritz 1991a, b). Paludal muddy lacustrine sediments underlie both the delta prism and the halite crust facies. The contact between the delta wedge and the halite unit is a brine interface and the watertable of the delta prism today lies close to the surface. It converts much of the delta prism situated some distance from the fluvial channels into an evaporitic mudflat, where capillary evaporation is driving fluid flow. This in turn drives a slow circulation in the underlying mixed waters and so precipitates calcite, gypsum and ulexite ($NaCaB_5O_9.8H_2O$) toward the edge of the delta prism (Fig. 3.46). This has created one of the largest borate accumulations in Bolivia where the ulexite interval in the delta prism has an average thickness of 0.1 m over a 120 km^2 area with a water content of 50 % (Risacher and Fritz 1991b). Total boron reserves in this area are estimated to be around 1.6×10^6 t.

The Salar di Uyuni surrounds also preserve evidence of Upper Pleistocene sedimentation, a time when the Central Altiplano of Bolivia was repeatedly flooded by deeper and extensive saline lakes (Rouchy et al. 1996; Baker et al. 2001a). These freshening episodes in the Salar di Uyuni area



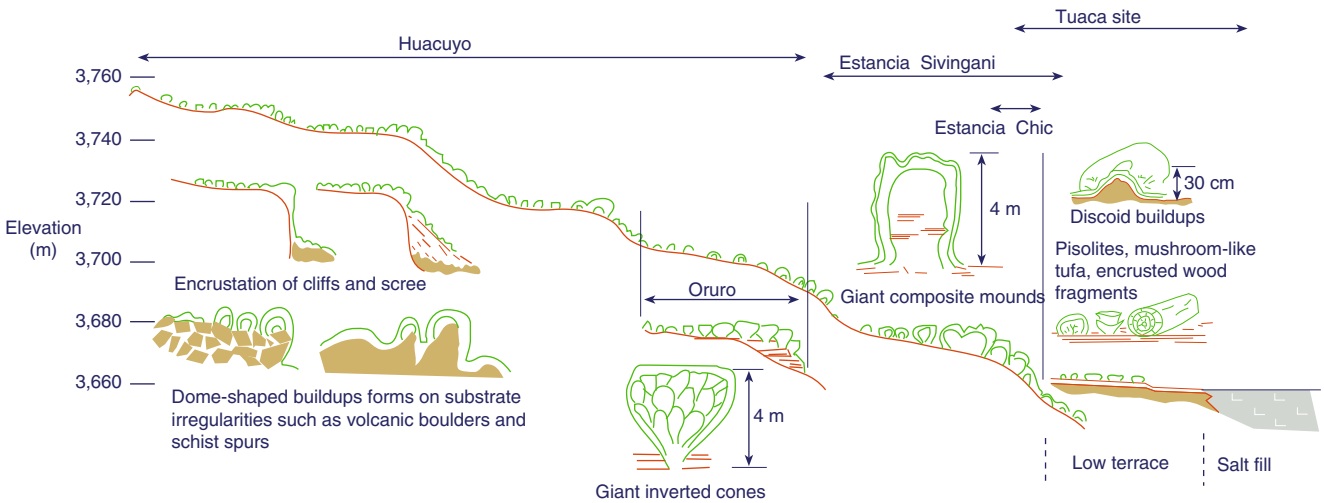


Fig. 3.46 Rio Grande Delta in southern Salar de Uyuni. (**a**) Scaled satellite image downloaded as Bing® image and mounted in MapInfo®. (**b**) Stratigraphic cross section and associated B-Li content of shallow brine in the southwestern portion of Salar di Uyuni in the Rio Grande delta. *Arrows* indicate brine flow, Brine chemistry shows a peak in both B and Li at the chemical interface between halite saturated lake brines and the delta prism, but the ulexite precipitates by capillary evaporation at the brine table interface beneath the delta prism (After Risacher and Fritz 1991a, b). See Fig. 3.43 for location of delta

Fig. 3.47 Schematic of the distribution of various types of algal bioherms within the outcropping as carbonate veneers in the surrounds of Salar di Uyuni. At the time the bioherms were actively accumulating these areas were shoal water portions of a perennial lake (After Rouchy et al. 1996)

are marked by the development of microbial bioherms defining at least three major periods of lacustrine highstand (Fig. 3.47). These calcitic tufas discontinuously cover the 300-km-long and up to 100-km-wide lacustrine slopes and terraces of the surrounds of Uyuni up to an elevation of 100 m above the surface of the modern halite crust. Clearly, Salar di Uyuni was a perennial mega-lake when the bioherms were growing and deepwater diatomaceous siliceous muds were accumulated across the same area where subaerial crusts are accumulating today.

The distribution, size and shape of the bioherms are diverse, reflecting various factors such as the nature and morphology of the substrate and the hydrodynamic conditions that prevailed during bioherm growth (Fig. 3.47; Rouchy et al. 1996). Build-ups on the larger palaeoterraces coalesced to form platform-like carbonate reef mound accumulations. Although the morphologies closely resemble those created by cyanobacterial binding, they were predominantly constructed by other plant communities, largely dominated by green algae. Cyanobacterial communities flourished in association with the plants, but they did not contribute significantly to the architecture of the bioherms; rather they encrusted the plant stems and microbial bushes, or formed thin laminated layers that covered the last stages of build-up growth. Buildups located between 3,660 and 3,680 m elevation show one or more of three growth stages or envelopes: (1) a massive inner core formed before 40 ka during an early Minchin highstand; (2) a large peripheral envelope deposited at about 40 ka (late Minchin) and (3) a thinner outermost crust formed during a late glacial event. Many bioherms show composite growth layering indicating episodes of microbial growth during lake highs separated by times of subaerial exposure and moderate erosion.

Salar de Atacama, Chile

Salar de Atacama is the lowest drainage sink in another endorheic basin in the pre-Andean depression of the Atacama Desert and contains more than a kilometre of interlayered halite and siliciclastics (Jordan et al. 2002; Rech et al. 2002). At an elevation of 2,300 m above sea level with an area of 3,000 km^2, it is the third largest saline pan in the world and an excellent barometer of Pleistocene climate change in the southern hemisphere (Figs. 3.40 and 3.41).

Today the San Pedro River forms an ephemeral stream feed along the western margin of the northern sector of the salar and defines the edge of a saline mudflat dominated by sulphate, carbonate and siliciclastic sediments (Bobst et al. 2001). The mudflat surface is dominated by brown halite-rich crusts and is underlain by silty clays with sand, displacive halite and locally organic-rich mud. A "sulphate marginal zone" dominated by ephemeral streams, eolian dune fields, sand sheets, dry mudflats and spring-fed ponds and marshes, forms the eastern edge of the salar and lies to the east of the saline mudflat (Figs. 3.48 and 3.49a). This northern region captures the majority of the siliciclastics entering Salar de Atacama. In general its watertable is between tens of centimetres and several metres below the deflationary land surface. Uppermost sulphate zone sediments are typically covered by and cemented with efflorescent sugary gypsum and minor halite. When trenched these gypsum crusts form discontinuous bowl-shaped concave-upward layers tens of centimetres in diameter.

In addition, the sulphate-margin flat entrains a number of gypsiferous brine-filled depressions or laguna (Stivaletta 2011). These depressions form separate small brine lakes in the dry season (such as Laguna Cejas, Laguna de la Piedra and Laguna Tebiniquiche), which merge into a connected water mass when the saltflats flood (Fig. 3.48b, c). The water bodies are up to a few metres deep and floored by mamelon-like mounds of halite and gypsum that entrain a halotolerant to halophilic biota.

South of the gypsum flat and its laguna is a thick layer or crust of halite that defines the halite nucleus of modern Salar de Atacama (Bobst et al. 2001). The top 40 cm of this crust is made up of millimetre-scale "sugary" inclusion-poor halite crystals along with interstitial mud. The crystals show a well-developed interlocking polygonal texture. At the broader scale the crust appears "wormy" with numerous subvertical to randomly oriented tubular microkarst voids. The crust surface is broken by metre-scale polygons with typical upturned edges showing up to a metre of relief. Mud typically ponds in the centres of saucers between the megapolygonal salt ridges. This uppermost crust is interpreted as an efflorescent crust formed largely by the capillary evaporation of groundwater brines and contains only a few growth-aligned chevrons.

Below the surficial crust the halites of the saline pan nucleus are massive and mainly composed of cm-sized interlocking crystals separated by mud-filled voids. Most of this halite is clear and inclusion poor indicating slow subsurface growth. Occasional freshwater influx drives dissolution of surface efflorescent halite crusts and creates large voids that then fill with clear cm-scale euhedral halites growing in toward the centre of the void. This dissolution-reprecipitation of halite is an ongoing process with evidence of numerous overprinting episodes destroying most primary chevron structures. Layering is poor to nonexistent.

A deep core (No. 2005) through the halite nucleus facies recovered some 100 m of evaporitic sediment and sampled some 100,000 years of salar sedimentation (Fig. 3.49b; Bobst et al. 2001). Deposition was dominated by arid conditions similar to today, with two significant wetter intervals. From 100 to 62.8 m the core is composed of clear interlocking halite with patches of millimetre-scale sugary halite. These textures are near identical to those forming at the sur-

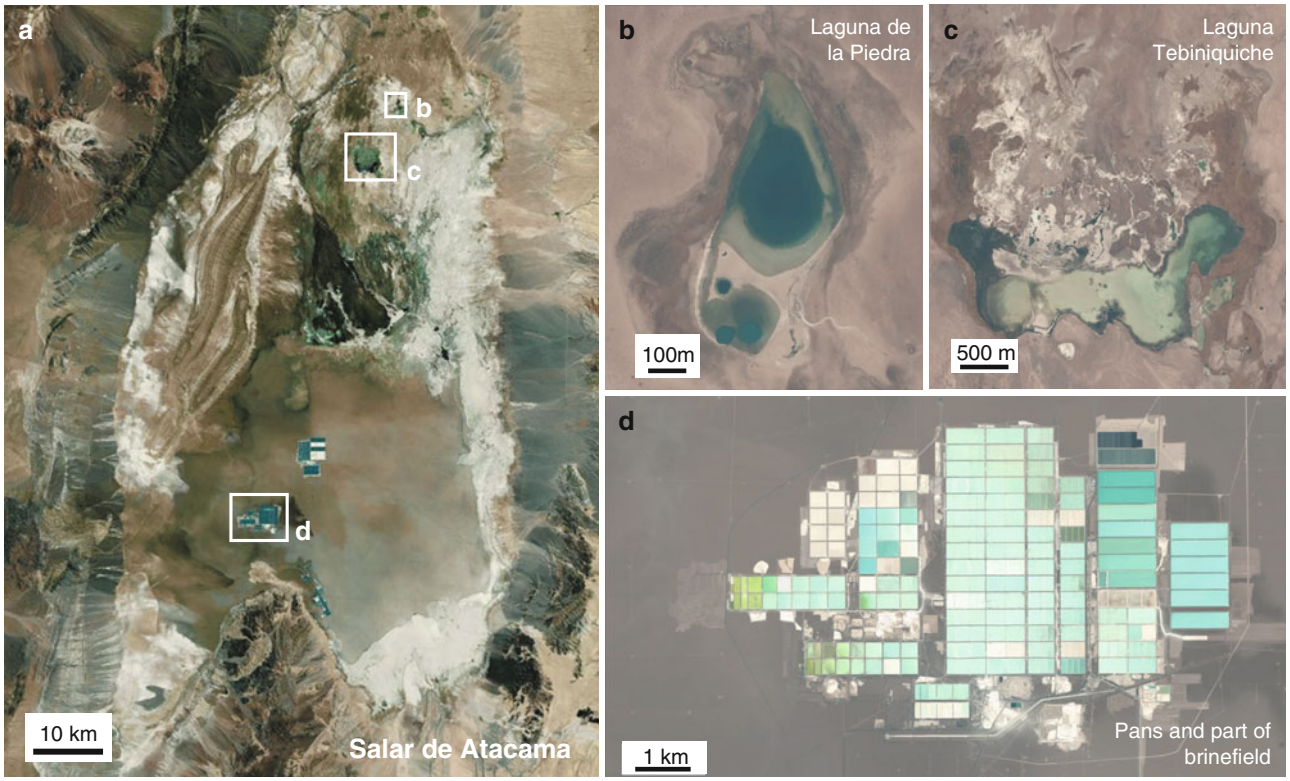

Fig. 3.48 Salar de Atacama, Chile. (**a**) Saline pan facies associated with the influx of the San Pedro River along the northeast side of the salar, the sulphate-rich marginal zone along the east and northeast of the salar and the salt-crusted halite facies dominating the southern portions of the salar. (**b**) Laguna de la Piedra in the Gypsum flat. Shows circular doline features indicating these zones of perennial brine ponding are karst associated. (**c**) Laguna Tebiniquiche, cuspate outline of perennial water body indicates dissolutional karst feature. face today and indicate dry mostly subaerial accumulations. From 62.8 to 47.0 m (75.7–60.7 ka) there is a vertical succession passing from mudflat gypsum to mudflat/shallow pond to subaerial halite and mudflat deposits that represent a progressive increase, then a decrease and finally an increase in water supply to Salar de Atacama. This occurred within what were moderately wetter conditions (saline lakes and saline mudflats) than the subaerial conditions of today (Bobst et al. 2001). A similar somewhat wetter interval occurred from 53.4 to 15.3 ka, with the wettest perennial lake interval from 26.7 to 16.5 ka. Short relatively wet periods (chevron halite) also occurred in the Holocene from 11.4 to 10.2 ka and from 6.2 to 3.5 ka. The remaining sections are dominated by halite textures similar to the subaerial dominated capillary fringe conditions of today.

Seismic collected across Salar de Atacama shows a north-northwest–striking fault system that extends for at least 30 km across the salar and can be seen intersecting the lower part of the halite nucleus (Fig. 3.50a; Jordan et al. 2002). In the southern sector of the salar there is at least 700 m of Pliocene–Quaternary down-to-the-east reverse motion across the fault, but locally the salar fault system deforms the lower halite unit into a monocline with 400 m of structural relief (Fig. 3.50a). Rates of displacement throughout the Quaternary have been on the order of 0.1–2.0 mm/year. And yet, despite these large displacements and large displacement rates so obvious in the seismic, no modern topographic scarp exists in the halite nucleus. Seismically-defined stratal geometries and thicknesses reveal variation between former times when there was a topographic scarp at the deformation zone and times, like today, with no topographic expression. The available borehole data suggest that both the times with and without a topographic scarp were likely dominated by halite accumulation adjacent to the salar fault system (Fig. 3.50b).

Jordan et al. (2002) propose that unique sedimentation processes in a groundwater-fed evaporite environment are responsible for the lack of topographic expression of a major fault system that intersects the salt. During desiccated times, groundwater derived from topographically driven flow on the east side of the salar would have been forced upward by a barrier created at the fault zone, enhancing the supply of solutes to the zone immediately east of the fault (Fig. 3.50c). This mechanism generates a higher rate of accumulation of

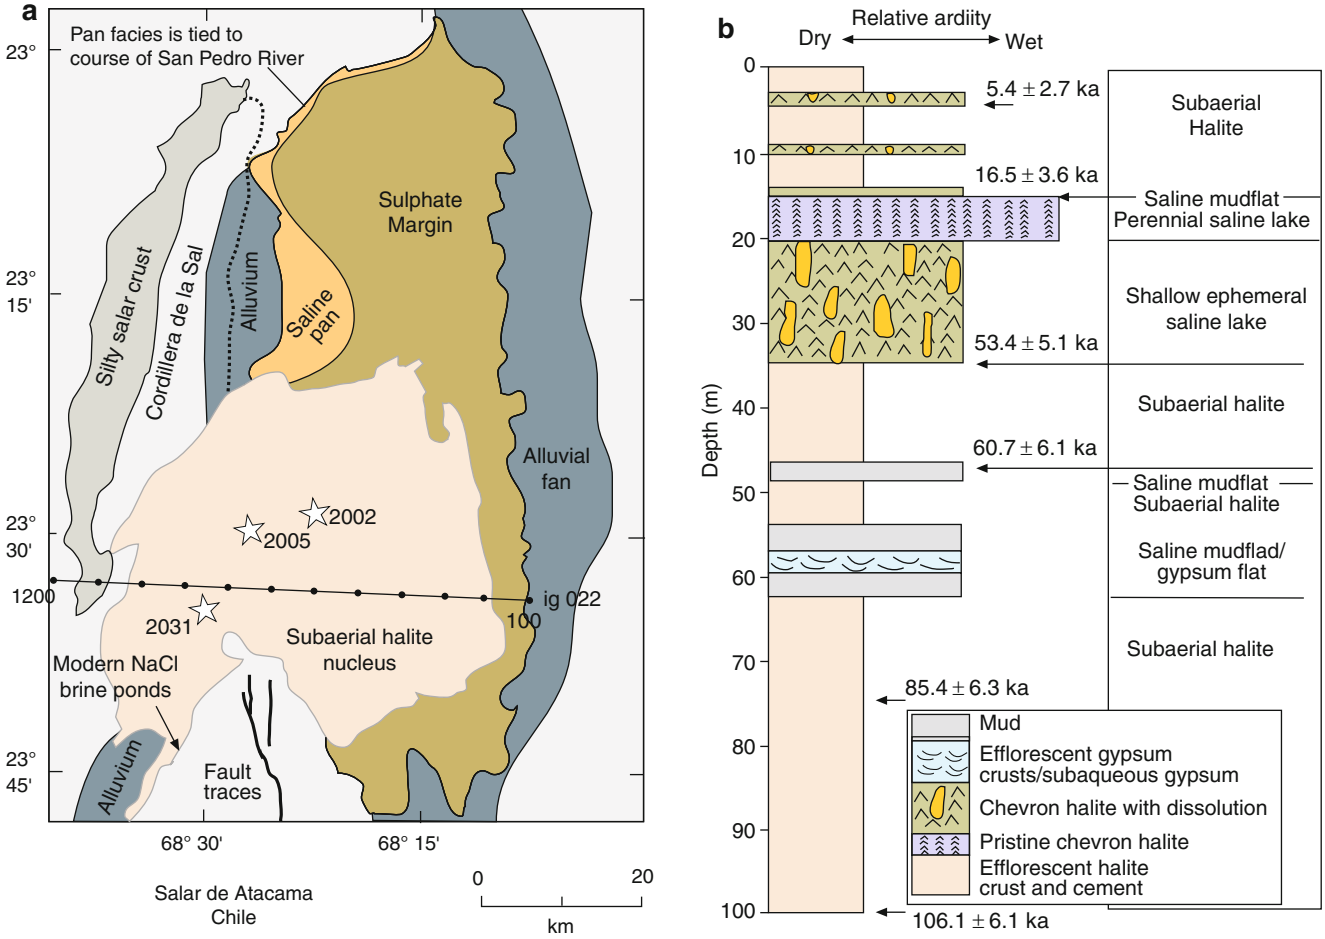

Fig. 3.49 Salar de Atacama, Chile (see Figs. 3.41 and 3.48). (**a**) Surface geology and extent of main salar lithofacies. Also shows onshore position of main salar fault and location of seismic trace ig 022 (with shot point positions). The stars show the position of cores 2002, 2005 and 2031. (**b**) Sedimentology of core 2005 (After Bobst et al. 2001; Jordan et al. 2002)

halite east of the Salar fault system than to its west. The enhanced deposition on the eastern fault block is sufficient to prevent scarp formation during times of moderate displacement by the Salar fault system, though during times of especially high rates of offset, this depositional mechanism was not sufficient to prevent temporary formation of scarps. It is not yet known how common "truly blind" faults are beneath the dry salt pans of other salars, but they are not unique to the Atacama basin. Similar occurrences of blind faults beneath the depositional surface of the ephemeral saline pan facies characterise; Salar de Antofalla and Salar de Hombre Muerto in the Altiplano, along with the Badwater salt flat in Death Valley, California and Great Salt Lake in Utah (Jordan et al. 2002). Like Salar de Atacama, they indicate the rapid deposition/accumulation rates that typify brine-saturated salt accumulating depressions.

Salar Grande, Central Andes of Chile

The Salar Grande is a 45-km-long (N-S axis), 4–5-km-wide, fault-bounded (pull-apart) Neogene forearc evaporitic basin, located in a depression in the Cordillera de la Costa of northern Chile (Fig. 3.51a). The altitude of the Salar Grande salt surface is currently 640–750 m above sealevel and halite deposition is inactive compared with salars to the east (Pueyo et al. 2001). The salar fill is composed almost exclusively of dry massive halite around 100 m thick, with dry salt in the deepest parts more than 160 m thick (Pueyo et al. 2001; Diaz et al. 1999; Ericksen 1993). The salt is very pure, locally 99 % NaCl, with a lakewide average of 95 % over an area of 280 km^2. It has been mined at least since the mid 19th century and today it supplies all of Chile's needs, as well as being exported, mostly to Japan.

Halite is in direct contact with igneous lithologies about the salar edge, while something like 10 m of alluvium separates the bottom of the salt body from its andesitic Mesozoic basement. There is no evidence of a concentric pattern of mineral fractionation in the salar, nor of any significant volume of salts other than halite (Diaz et al. 1999). Only a patchy anhydrite belt, several metres thick, caps portions of the salar edge (Ericksen and Salas 1989). It is made up of

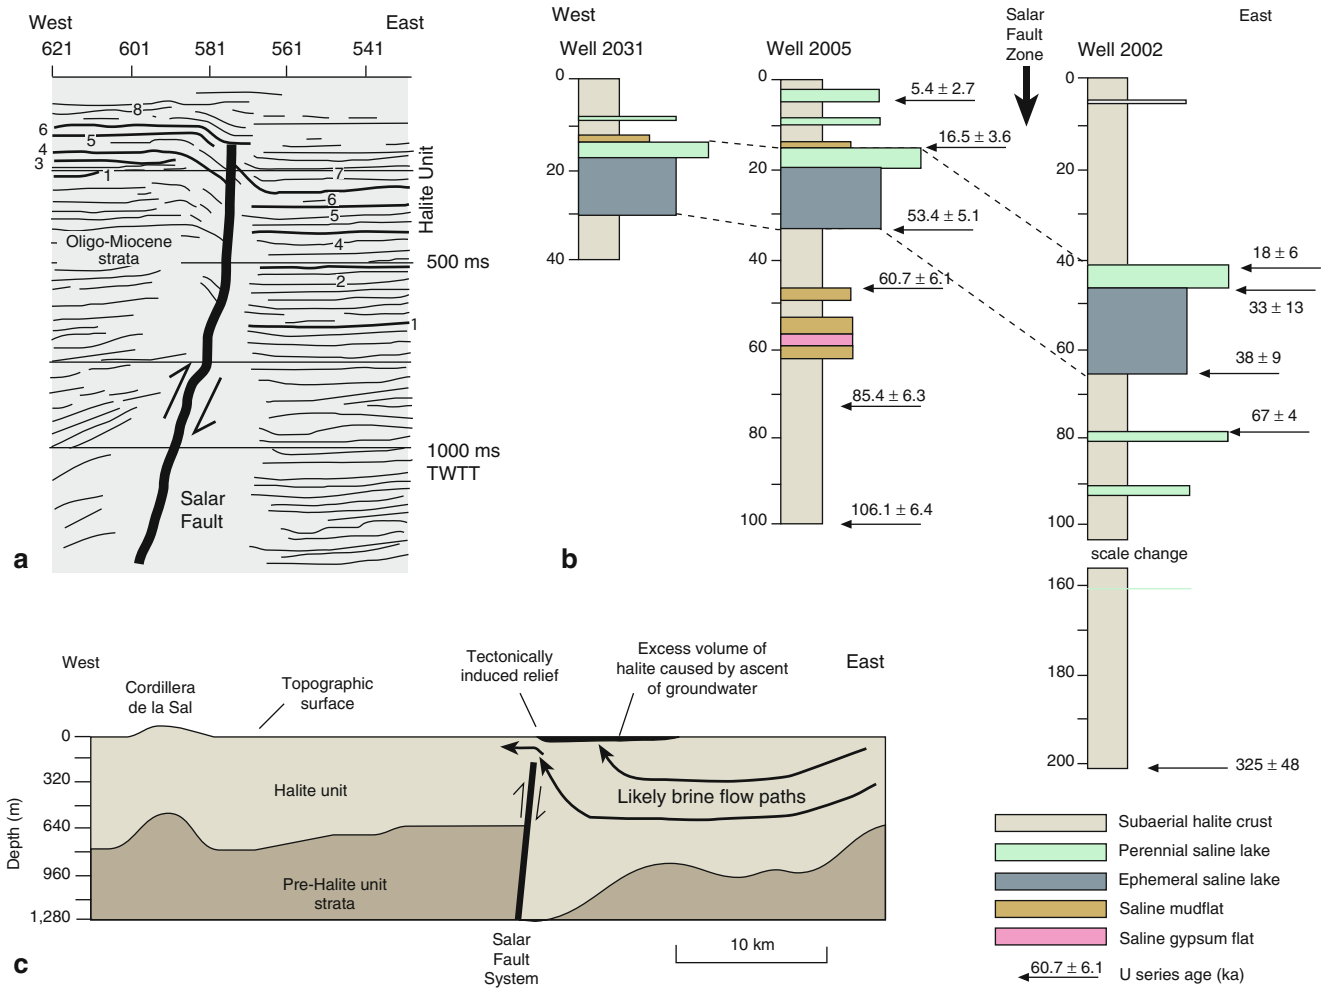

Fig. 3.50 Interactions between the Salar de Atacama fault zone and halite sedimentation (See Fig. 3.49a for location of seismic line and wells; after Jordan et al. 2002). (**a**) Interpreted seismic line ig 022 across the Salar reverse fault showing monoclinal flexure and thickening of beds across the fault. Fault trace dies out before reaching current halite surface. (**b**) Summary of halite facies in sequence 8, documented in SQM cores. Boreholes 2031 and 2005 are located west of the Salar fault system, whereas borehole 2002 is located east of the Salar fault system. U-series dates from boreholes 2005 and 2002 and comparisons of halite depositional environments at the three sites allow temporal correlation among the cores. The top of the perennial saline lake facies, dated as ca. 16.5 ka, is readily identifiable in all three locations. That horizon occurs at similar depths in cores 2005 and 2031, but is vertically displaced ≈ 28 m across the Salar fault system. (**c**) Conceptual model of enhanced halite accumulation east of the Salar fault system, which leads to a horizontal depositional surface across the fault trace. Under the conditions of a desiccated surface environment, halite accumulates because of evaporation of groundwater-fed brines. A drop in permeability at the fault (either due to juxtaposition of lower permeability rocks in the western fault block or due to properties of the fault zone itself) blocks the westward flow of topographically driven groundwater, forcing a high rate of upwelling in the downthrown eastern fault block

saccharoidal $CaSO_4$, which sometimes retains selenite pseudomorphs (dm-diam), as in the SE margin of the salar (Fig. 3.51). This sulphate bed can be traced into the adjacent western Llamara area.

The Neogene depositional history of Salar Grande is closely tied to an adjacent Tertiary lacustrine basin, the Llamara-Quillagua basin to its east (Fig. 3.52a). The Salar Grande basin became hydrologically inactive during the Late Pliocene (Chong Díaz et al. 1999). The present-day, dry, fossil salar consists of thick beds of almost pure halite with scarce sulphate and terrigenous elements (García-Veigas et al. 1996; Chong Díaz et al. 1999). Fogs and occasional rain periodically dissolve the surface halite, down to a maximum of 1 m (Chong Díaz et al. 1999).

During the hydrologically active stage, phreatic waters flowing into the Salar Grande depression from the east (now the Precordillera and Altiplano) were progressively enriched in solutes by interaction with volcanic rocks. These fluids had first drained into the Llamara-Quillagua lacustrine system of the Central Depression to deposit thick sequences of diatomites, carbonates, evaporites and clastic sediments. This lacustrine area eventually filled and dried to where it became a salar filling with anhydrite and halite. During this stage (Late Miocene-Pliocene), the evolved

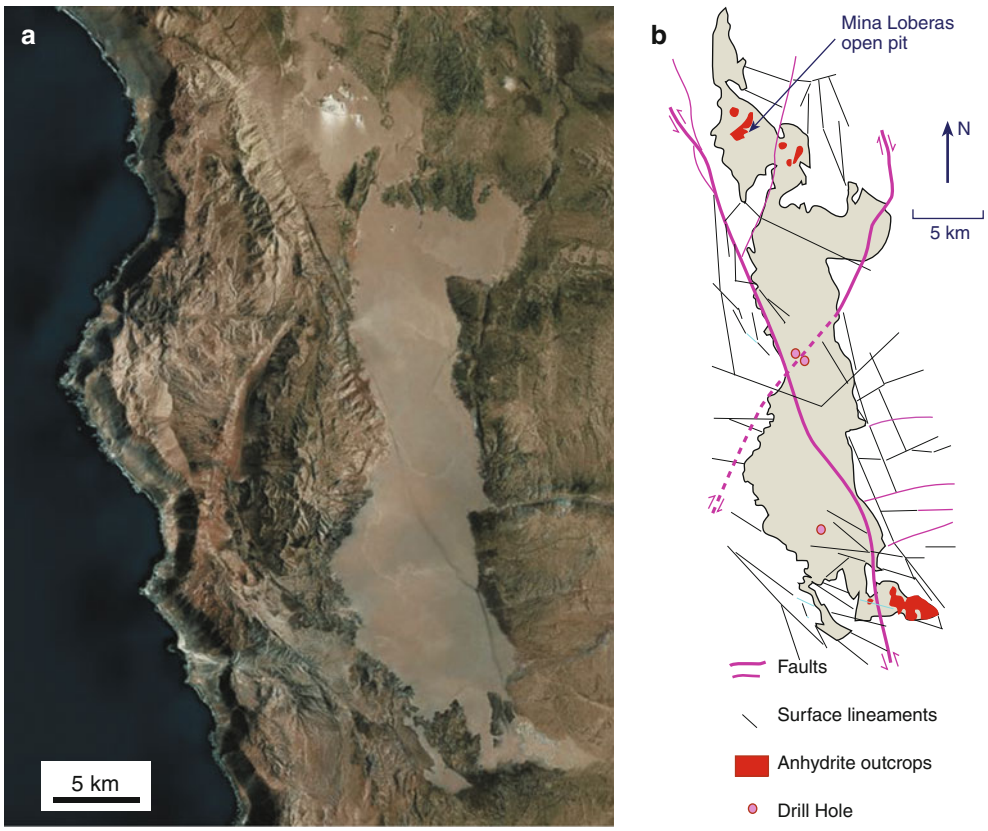

Fig. 3.51 Salar Grande, Northern Chile. (**a**) Satellite image clearly show fault trace cutting across salar floor. (**b**) Geological map shows position of 3 drill holes drilled in the 1920s for potash, which established salt in the central portion of the salt was more than 162 thick and underlain by dry alluvium. Also shows main fault of Atacama fault system trending SE-NW as well as other faults and lineaments in and around the salar (Bing® image mounted and scaled in MapInfo®)

brines of the Llamara-Quillagua area seeped eastwards along structural paths (fractured bedrock?), to reach the Salar Grande basin, which acted as their final sink. Proof of this connection is the anhydrite/selenite bed that overlies the halite in both lakes and links the western Llamara to the southeastern Salar Grande areas via the Montón de Gloria pass (Diaz et al. 1999).

Phreatic brines were subsequently lost from the basin in late Pliocene times when the Loa River canyon reached the sea. This was the beginning of the current exorheic hydrology and the opposite of its previous endorheic hydrology. Drainage into the ocean was reflected in a fall of the regional watertable, the drying of the salt body and the underlying alluvium, and the creation of a hydrologic situation in Salar Grande that still exists today (Ericksen 1993).

Large halite sinkholes, up to 10–20 m deep are best developed on the eastern side of the salar, while others developed along fault lines where they transect and weaken the now dry salt body (Diaz et al. 1999). Some sinkholes are funnel-shaped, while others are cylindrical; all may be connected laterally by a network of caves. Etched profiles in the sinkholes walls indicate they were brine-filled pools prior to the drainage of brine from the salar much like the "eyes of the devil" in Salar di Uyuni.

The regionally extensive Atacama Fault zone, a major tectonic feature in the region, transects the Salar Grande with its position marked on the salt crusted surface by irregular elongate depressions and mounds, low scarps and fractures (Fig. 3.51b). Other active faults, defined by open fracture networks, outline tectonic zones in the adjacent and underlying bedrock. The appearance of the fault trace at the surface of Salar Grande is in marked contrast to Salar de Atacama, which lacks any expression of its active faulting at the surface. That the regional fault intersects the surface of Salar Grande and not the surface of Salar de Atacama shows that the halite accretionary process is today much less active in Salar Grande. Accretion of halite requires a saline watertable within a few decimetres of the lake surface; the watertable of Salar Grande is much deeper.

Dripping fogs (*camanchacos*), in combination with deflation, capillary evaporation and rain, have sculpted a knobbly and pressure-ridged surface to the modern salt crust with relief up to 50–60 cm. At the larger scale some pressure ridges outline megapolygons in the salt with saucer diameters measured in tens to hundreds of metres, as well as smaller polygons measuring several metres between ridges (Ericksen 1993). Ongoing reworking of the upper boundary of the massive salt crust by fog moisture and the incorporation of eolian, detrital and insoluble clays through time has created a dirty brown salar-capping halite crust, up to 1 m thick, atop thicker, drier, purer halite.

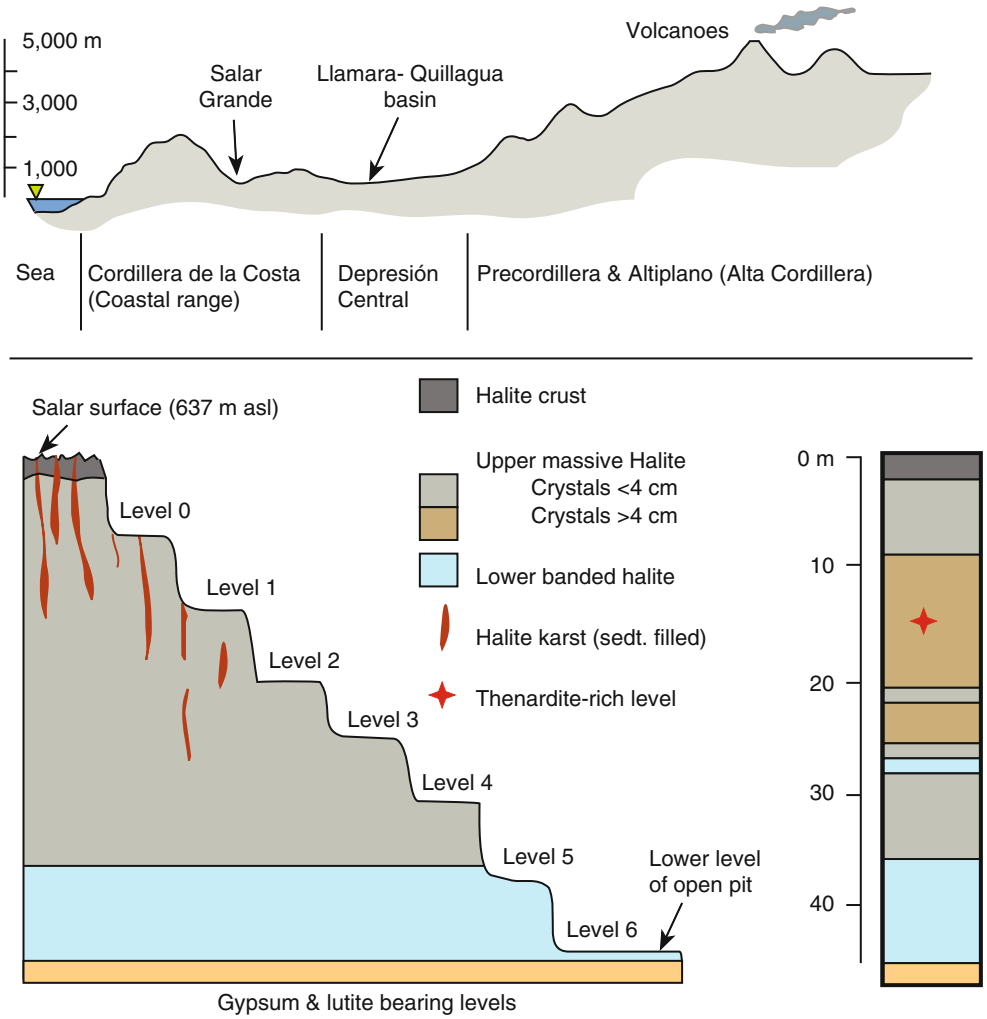

Fig. 3.52 Salar Grande. (**a**) Schematic of main physiographic subdivisions and the relative position of the Llamara-Quillagua Basin. Total section length is about 100 km. (**b**) Section through open pit at Mina Loberas in the northern part of the salar showing stratigraphic arrangement of different lithofacies discussed in text. (After Diaz et al. 1999; Ericksen 1993)

Mining and coring in the northern part of Salar Grande shows the lower 10 m of the salt fill was deposited on the floor of a mostly brine covered saline pan. It is made up of thinly-layered halite composed of cm-mm-sized bands of chevron halite, separated by synsedimentary dissolution surfaces. It is depositionally similar to the shallow saline pan facies of Salar di Uyuni and the saline lake facies of Salar de Atacama (Fig. 3.52b). Minor amounts of sulphate salts (mostly mm-sized glauberite, thenardite and polyhalite) and clay minerals cap each dissolution surface, indicating settle-out and freshening related to periodic flooding of the basin. The overlying Massive Halite was deposited as displacive or intrasediment halite, still in a saline pan but now accumulating in the capillary fringe of a pan that was subject to ongoing desiccation and evaporation, much like the majority of the halite filling Salar de Atacama.

The transition between the Lower Banded Halite and the Upper Massive Halite takes place over an interval several metres thick, which shows alternations of both units. Lower banded halite passes by an increase in crystal size into the Upper Massive Halite, which is made up of two halite crystal classes (<4 cm diam and >4 cm diameter). The random nature of crystal alignment in the massive halite shows its precipitation as multiple overprints of displacive crystal growth from saturated phreatic and capillary waters at a time when the salar surface was mostly subaerial.

Minor thenardite (Na_2SO_4) crystals occur in the Upper Massive Halite at levels 2 and 3 in the Mina Loberas pit where it appears to be an early, perhaps syndepositional, cement between displacive halite crystals (Diaz et al. 1999). Thenardite locally replaces the halite, but typically shows poikilotopic textures with solid inclusions of glauberite, clay and micrite. Polyhalite ($2CaSO_4{\cdot}MgSO_4{\cdot}K_2SO_4{\cdot}H_2O$) is the most abundant sulphate mineral in Salar Grande; it outlines grain boundaries and dissolution surfaces in the Massive Halite.

Pockets of very coarsely crystalline halite (>50 cm diameter) occur in the Massive Halite and in parts of the underlying Banded Halite. They show centripetal or geode-like patterns of halite growth and infill. This very coarse halite is

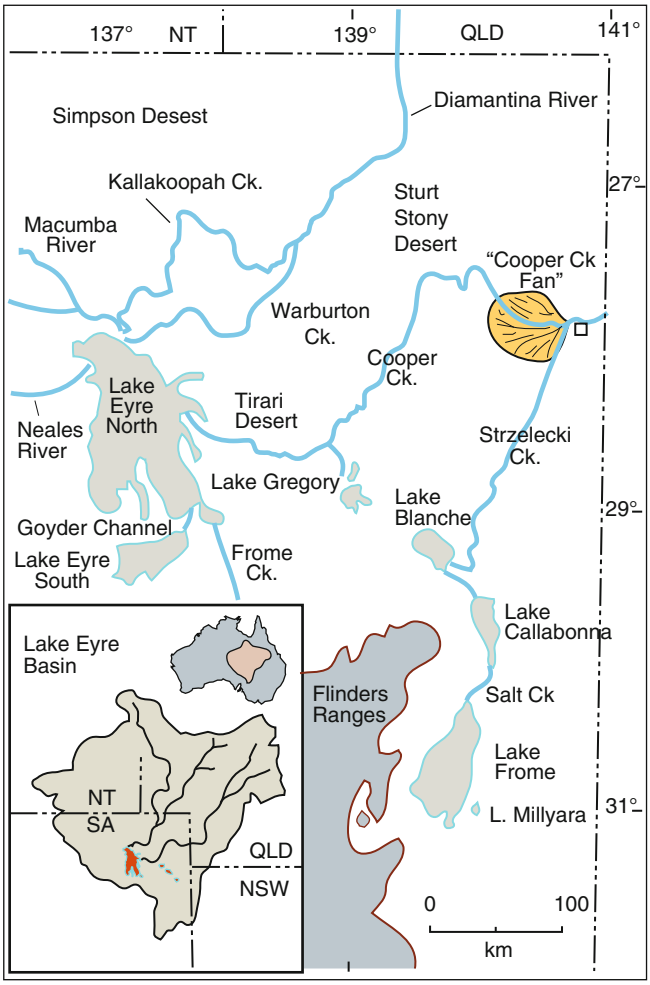

Fig. 3.53 Drainage into and between lakes in the Lake Eyre Basin of South Australia

thought to be an earlier dissolution tube fill precipitated when the watertable was higher. It is a common texture in many other South American salars where it precipitates as halite karst-fill cement in the Ojo de Diablo.

Work on the sedimentology of the halite pans in the South American salars over the last two decades has substantially improved our understanding of the hydrological significance of halite textures. It has added a third group of textures to prior notions of: (1) matrix-dominated displacement halite forming in the capillary fringe of a sabkha sitting in a zone of ascending waters above a less saline phreatic water mass and (2) subaqueous chevrons, overprinted by subaerial microkarst forming in areas of ephemeral waters in saline pans. This third textural style is exemplified by the halite units currently forming in Salar de Atacama and dominating the Massive Halite fill of Salar Grande. It is a form of chaotic displacement halite with little or no non-evaporite matrix and little or no preserved chevron textures. It is porous and forms mostly in the capillary fringe above a groundwater fed halite-saturated brine mass or brine curtain. As it forms it cannibalises itself to such a degree that little or no primary texture is preserved.

Ephemeral Stream Floodplain – Dune Field–Ephemeral Saline Lake

The ephemeral stream floodplain–dune field–ephemeral saline lake complex typifies tectonically-stable low-relief areas usually located within arid-zone subtropical high-pressure belts. Continental saline mudflats (sabkhas) are commonplace in regions of shallow watertables in this lacustrine complex, but low rates of subsidence and high rates of deflation mean evaporites are less likely to be preserved compared to rapidly subsiding alluvial fan–ephemeral saline lake settings. Rather, sediments are composed of varying combinations of saline mud flats or sandflats, with the more saline intervals showing widespread haloturbation, but little or no preserved salts. The latter were recycled as ≈ 1 m thick at-surface crusts, dissolved and reprecipitated after each flood event.

Most of the large ephemeral lakes in this setting occur in regional outflow zones of large artesian hydrologies or regional artesian seeps in low relief terranes. The rise of less saline resurging water inhibits development of a thick brine curtain or reflux plume beneath the pan and the mudflat, a requirement for longterm preservation of salt beds (Chap. 5). Surface inflow is a combination of local storm runoff and long distance ephemeral floods, with intense flood events often spaced years apart. Lake sediments are subject to the vagaries of climatic changes outside the immediate vicinity of the saline lake. These lakes generally lie at the edges of sand seas or ergs. They tend to preserve relatively thin lacustrine sediment piles with numerous truncations that indicate ongoing deflation Wind reworking of vadose lacustrine and fluvial sediment supplies substantial volumes of sediments to these adjacent sand seas.

Ephemeral braided stream floodplains, sheet deltas, dunes and sandflats are the dominant facies in the depositional basin, not bedded evaporites. Lake Eyre (9,500 km^2), Lake Amadeus (1,032 km^2), Lake Frome (2,700 km^2), Lake Gairdner (4,351 km^2), and Lake Torrens (5,745 km^2) in inland Australia are modern well-documented examples of this depositional style (Fig. 3.53; Pell et al. 2000). Major flood events are mostly fed by long distance southward transport from intense monsoonal outbursts in northern Australia.

Likewise, Lake Chad in North Central Africa, another well documented example of this style, is fed via the Chari/Logone river system from monsoon rains that typically fall in June, July and August. The subtropical position of all these examples means vertical sequences retain evidence of Pleistocene fluctuations in monsoonal intensity. Many lake complexes in southern central Australia (Lake Callabonna,

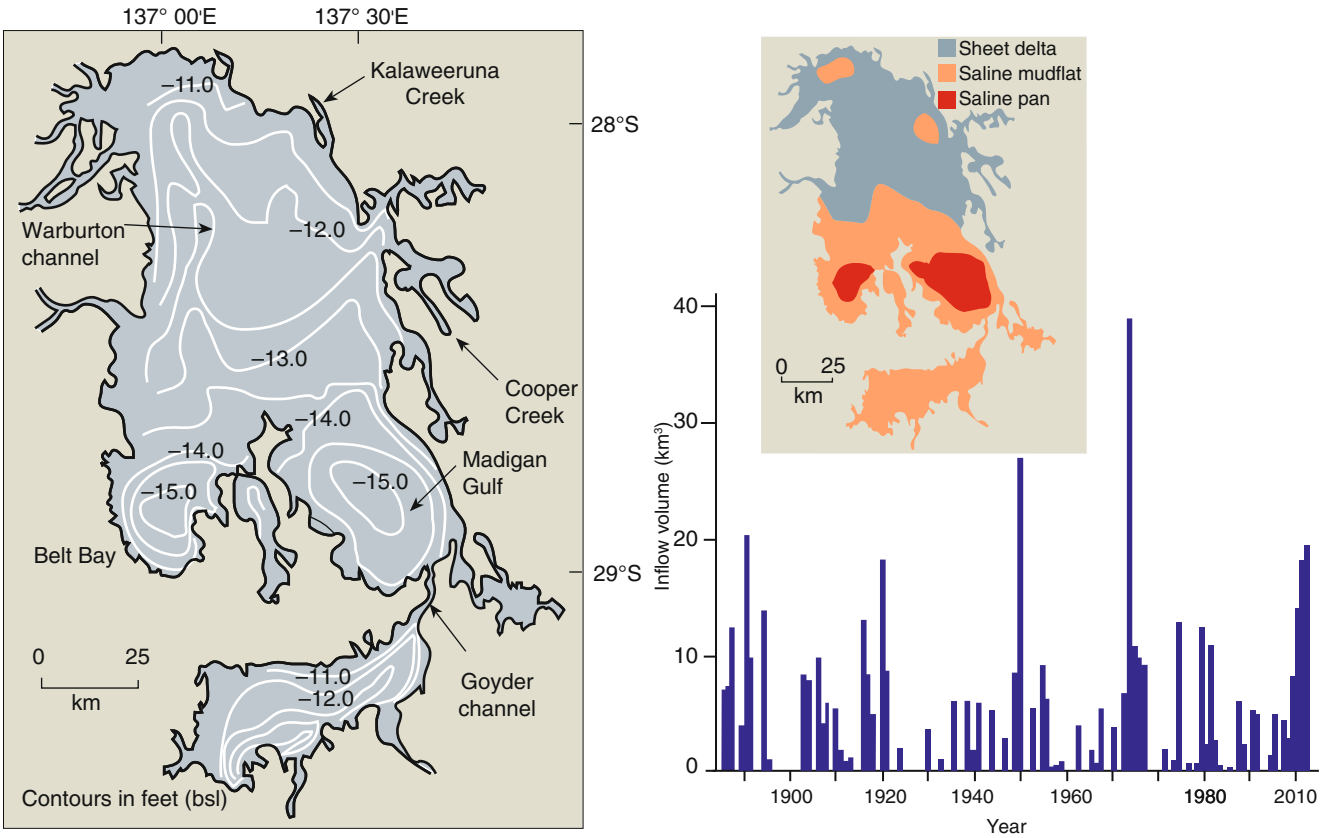

Fig. 3.54 Lake Eyre bathymetry, facies and flooding history compiled from Kotwicki (1986), Kotwicki and Allan (1998) and various references cited in text. Lake floor contours are in metres below sea level. Inflow volumes (1885–2012) replotted from <http://www.k26.com/eyre>, last accessed April 24, 2014

Lake Eyre, Lake Frome, Lake Gairdner, and Lake Torrens) were freshwater to brackish water lakes some 35,000 years ago, yet today are saline mudflats with only short-term episodes of filling. Likewise, Lake Chad has undergone massive fluctuations in size and salinity; at one point during the Pleistocene it extended to the Tibesti Mountains in northwest Chad, at another point it was sufficiently saline to precipitate natron (Eugster and Maglione 1979). Droughts since the 1970s have decreased Lake Chad levels so that it is now extremely shallow and divided into northern and southern pools. This drying is not unusual, the lake has dried up completely a number of times in the last 200 years. What is unusual in the lake's long history is the environmental stress created by too many people attempting to eke out a living in and around the lake.

Ancient counterparts to the ephemeral stream floodplain-dune field-ephemeral saline lake association include portions of the Lower Permian Rotliegende of northern Europe, Permian red beds of the US interior centred on Kansas; the Late Triassic of northwest Europe and the Palaeoproterozoic Whitworth Formation of the Mt Isa Block, Australia (Glennie 1989a, b; Benison and Goldstein 2000; Talbot et al. 1994; Simpson and Eriksson 1993).

Lake Eyre, Australia

Lake Eyre North has an area of some 8,430 km^2 and is 144 km long and 77 km wide. It is joined by the narrow Goyder Channel to Lake Eyre South, which is 64 km long and 24 km wide with an area of 1,260 km^2. The lowest part of Lake Eyre North is the eastern part of Belt Bay with some areas slightly deeper than −15.2 m ahd, making it the lowest point on the Australian continent (Fig. 3.54). The floor of the Lake is very flat with bottom slopes $\approx 2 \times 10^{-5}$, so the definition of the exact location of the deepest point is rather arbitrary. For the same reason, boundaries of its sedimentary facies tend to migrate large distances with little change in the lake water level. In dry times the lower parts of Lake Eyre North in Belt Bay and Madigan Gulf are covered by a bedded halite crust around 0.5 m thick. The 4×10^8 tonnes of salt held in this crust completely dissolves during major floods, so the lake floor actually deepens topographically during a flood (Dulhunty 1977). When the lake is dry, the saline pan crust is surrounded by a saline mudflat facies where gypsum grows displacively in the capillary fringe (Figs. 3.54 and 3.55).

The northern portion of Lake Eyre is where most of its ephemeral streams enter the lake depression. Entry points

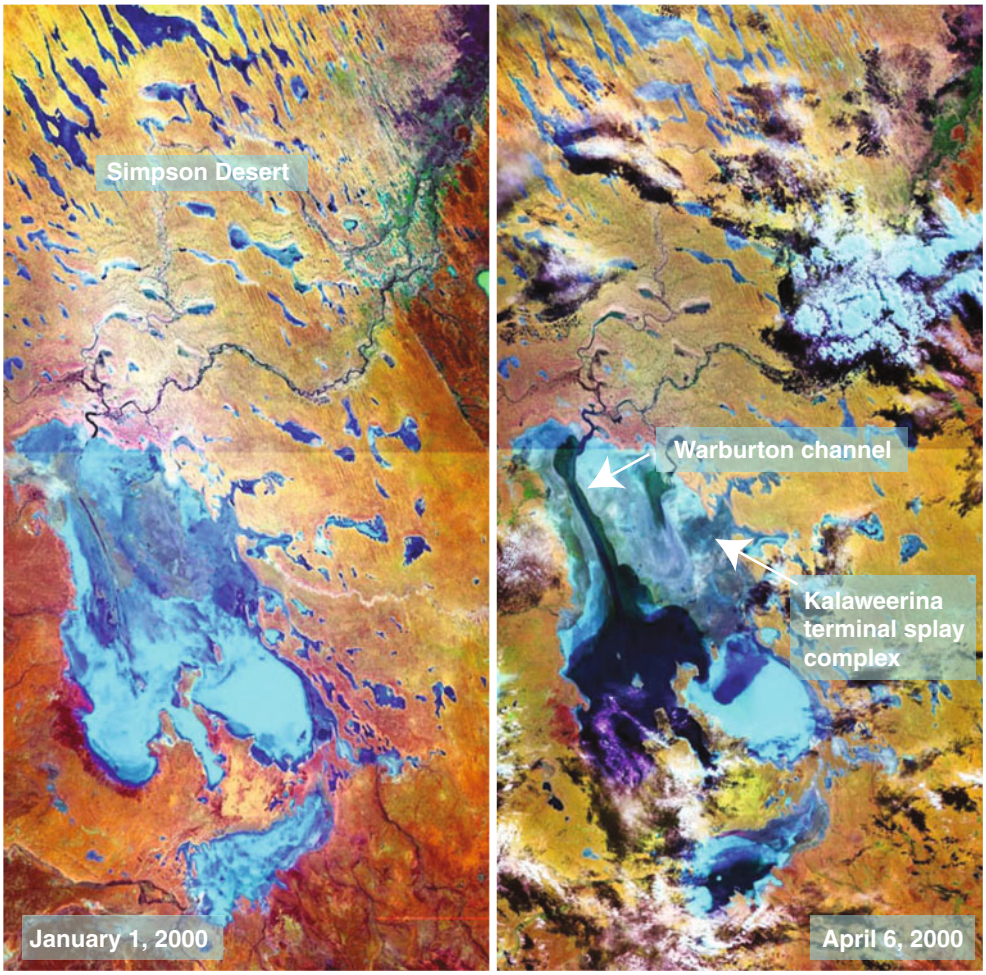

Fig. 3.55 Lake Eyre, South Australia. Image on left taken on January 1, 2000 at a time prior to a major flooding event. Partly cloud-obscured image on right taken on April 6, 2000 after a major monsoon-fed flood influx into lake from northern part of lake. The elongate interdunal sabkhas and pans in the northern part of the image constitute the Kallakoopah Pans. Note the water-filled Warburton Channel transecting the northern lake floor (Landsat 7 satellite images acquired and processed by ACRES)

are defined by a number of low flat amalgamated sheet deltas (aka terminal splay complexes), which are dominated by fine sands and silts.

Sedimentation in these sheet deltas is not the classic fluvial dominated delta topset sand association. Shallow trenches through these terminal splay complexes, such as in the outflow sheet where Kalaweerina Creek exits into Lake Eyre (Fig. 3.55) document paired mud drapes (bundles) on cross-beds, cross-bedding reactivation surfaces, lateral bundle thickness variations, herringbone cross-bedding, flaser, wavy, and lenticular bedding, and desiccation cracks (Ainsworth et al. 2012). Historically, this association of sedimentary structures has been used to indicate marine tidal sediments, yet is forming in Lake Eyre an arid-zone playa, located hundreds of kilometres inland of the ocean. In Lake Eyre these features indicate meteorological tides that are active during the flood stage in the lake and are generated by daily changes in wind direction and velocity, along with weekly to monthly discharge variations in the feeder river/creek system.

Further out in the lake depression the lower part of the coalesced sheet delta facies are cut by low channels, the largest of which is a north–south depression that transects the northern two thirds of the lake and is known locally as the Warburton Channel (Fig. 3.55). When the lakes first floods, these channels quickly drain the floodwaters into the lowest part of the lake and dissolve the salt crust (Fig. 3.54). As more floodwater enter, the lake sump areas expand and these brines are covered by a floating mass of fresher flood water that at peak flood occupies the whole lake depression and sets up stratified water conditions suitable for a mesohaline biotal bloom (Chap. 9).

Lake Eyre is an ephemeral playa-salt lake that lies asymmetrically in the southern portion of one of the largest internal drainage basins in the world (1.14 million km^2) and covers one-sixth of the Australian continent (3.53). Drainage topography is flat, with extensive areas of sandy and stony deserts. There are regions with some relief near the boundaries of the drainage basin, but only 30 % of the area is elevated more than 250 m above sea level. All streams flowing into Lake Eyre are characterised by extreme variations in discharge and flow duration (Fig. 3.54). Mean annual runoff across the basin is 4 km^3, equivalent to a water layer 3.5 mm in depth, the lowest runoff level of any major drainage system in the world. The Lake Eyre Basin is large but dry, its

drainage spans a number of climatic zones, including the tropical monsoon system to the north and the mid-latitude westerly circulation belt to the south. Some 5×10^5 km^2 of the drainage basin receives less than 150 mm of rainfall per year (on average). The highest rainfalls, with annual averages around 400 mm, occur in the northern and eastern margins, where rainfall comes from the edge of the monsoon belt.

The northern end of the Lake Eyre catchment lies barely on the periphery of the planetary monsoon system. The Northern Australian monsoon is erratic both in space and time. Recent lake floods are related to La Nina phases of the El Nino-Southern Oscillation (ENSO)[5] and are out of phase with the Pacific Dry Zone rainfall and El Nino events (Kotwicki and Allan 1998). Changes in the intensity of the monsoon have controlled the frequency and permanency of Lake Eyre waters throughout much of the Quaternary (Magee et al. 1995, 2004).

Monsoonal outbursts supply water to the Lake Eyre via its eastern tributaries; Cooper Creek, Diamantina and Georgina rivers systems. This water takes weeks to reach the lake and floods much of its flow path on the way, as it deposits sediment in a unique set of anastomose arid-zone fluvial deposits, known locally as "the Channel Country" (Gibling et al. 1998). Trustworthy data on the filling of Lake Eyre reports flooding in 1938, 1955, 1963, 1968, 1973, 1974, 1975, 1976, 1984, 1989 and 2012 with exceptional floods occurring every 25–30 years (Fig. 3.54; Kotwicki 1986; Kotwicki and Allan 1998). In 1974, in the largest flood on record, water flowed from Lake Eyre North to Lake Eyre South between March and October when an equilibrium level was obtained. More than 39.3 km^3 of surface runoff flowed into the lake at this time, completely dissolving the salt crust. The crust reformed in the following 2 years as more than 39.5 km^3 of water was evaporated (Dulhunty 1977; Kotwicki 1986). Large quantities of salt, estimated at 30 million tons (7.5 % of Lake Eyre North content), were transferred into Lake Eyre South during this event, creating, in its lowest portion, a salt crust up to 29 cm thick for the first time on record (Dulhunty 1977).

As well as the monsoon feed from the north, significant runoff can originate in the desert west of the basin, where it is drained by the Neales and Macumba creeks. The 1984 filling, with a total volume of 10 km^3, was a relatively minor one but if proved that the western tributaries can fill Lake Eyre in a matter of days. During the 1984 flood, maximum water depths were 5.7 m in Lake Eyre North and 3.7 m in Lake Eyre South. Lake Eyre South this time filled first – an event never previously recorded and considered to be extremely unlikely – and overflowed to Lake Eyre North, reversing the usual flood pattern in the lake (Allan et al. 1986).

Monitoring of the chemistry of the lake brines in the 1984 flood shows the conservative behaviour of all the major ions in Lake Eyre with the exception of Ca, which, relative to the other ions, started to deplete after October 1984 and to sulphate, which flattened its still rising concentration rate. This coincides with the onset of gypsum precipitation around October 1984. Its seawater like brine evolution is typical of most inland waters in Australia (Table 3.6 and Chap. 2).

[5]The El Nino – Southern Oscillation (ENSO) is a global climatic phenomenon marked by see-saw shifts in air pressure between the Indo-Australian and eastern regions of the Tropical Pacific. El Nino and La Nina refer to extreme phases in the 2–7 year cycle. During the warm 'El Nino' phase, the Australian seaboard cools, SE trade winds slacken and extended periods of drought are experienced in the Australian interior. In the cool 'La Nina' phase, the seas around Australia warm, the SE trade winds intensify, and widespread rain and flooding occurs.

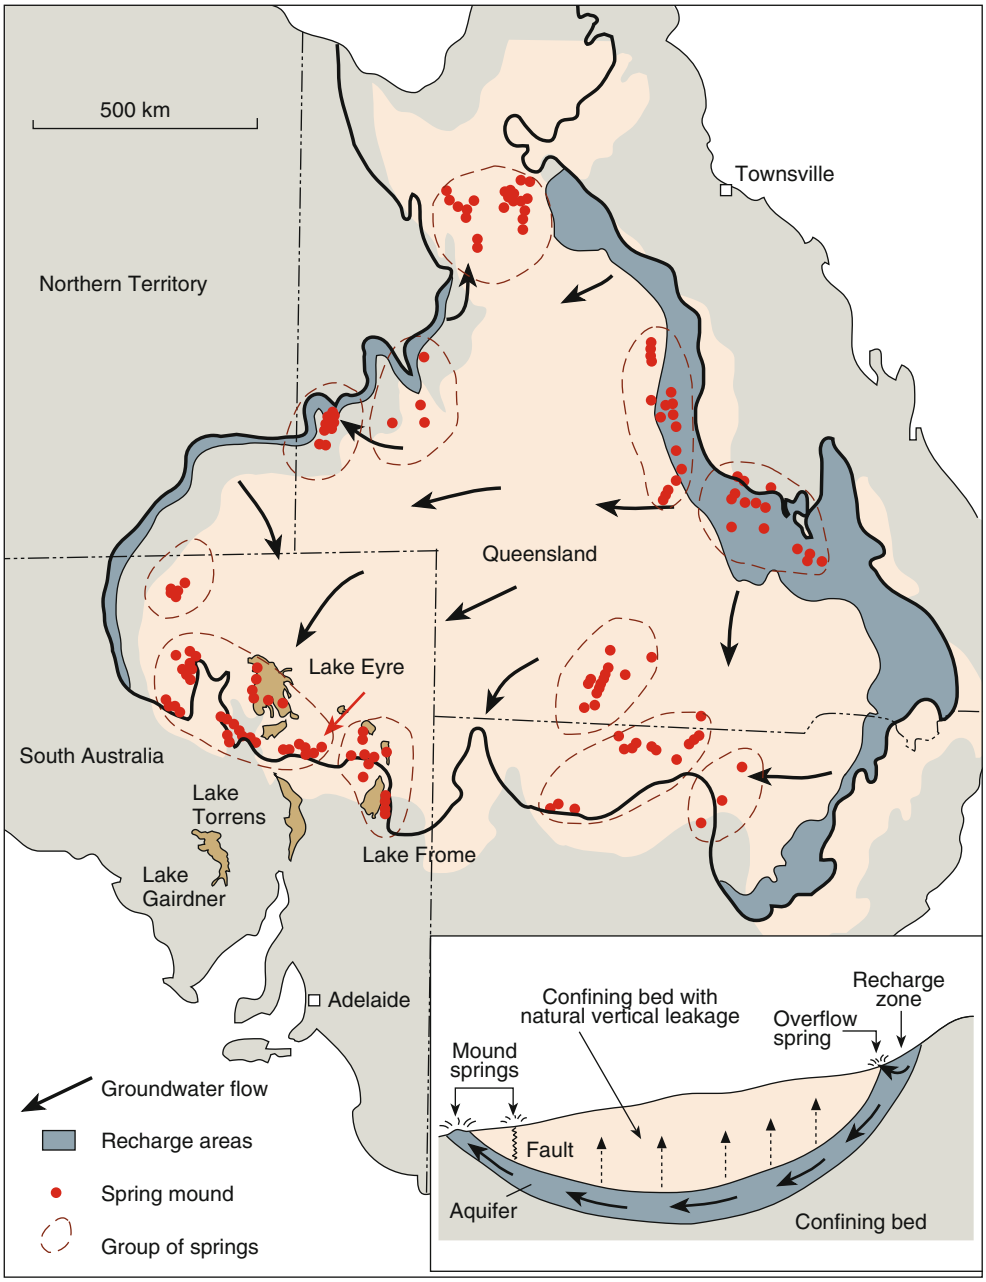

Fig. 3.56 Location of spring mound groups and artesian groundwater flow paths in the Great Artesian Basin, Australia. Shows a high density of mounds in the vicinity of Lake Eyre and Lake Frome (After Habermehl 1982)

In 1989 another western-fed flooding event occurred, coinciding with the filling of Lake Torrens on the other side of the Flinders Ranges. Lake Torrens is the second largest Australian playa after Lake Eyre and in 1989 it filled for the first time since 1878. Short term inflow rates into Lake Eyre during both the 1984 and 1989 flooding events were enormous: for example in 1984 and in 1989 Lake Eyre received some 8 km^3 from western tributaries in three days, which implies discharges of the order of 30,000 m^3/s, or one-sixth that of the Amazon. The 1989 "wet" continued into 1990 when, after some of the most devastating floods of the Channel Country in Australian history, water from the Cooper Creek reached Lake Eyre for the first time since 1974.

As well as the being the regional sink for its surface run-off, Lake Eyre's position also defines the southern outflow or seepage area of the Great Artesian Basin (GAB), which covers an area of 1.7 million km^2 (Fig. 3.56). The GAB consists of several contiguous sedimentary basins with confined aquifers of Triassic, Jurassic and Cretaceous continental quartzose sandstones, underlain by an impervious pre-Jurassic base (Habermehl 1980, 1982, 1996). It forms a large synclinal structure, uplifted and exposed along its eastern margin, leaving the overall basin tilted southwest. Recharge to the GAB occurs primarily along the uplifted eastern margins and also on the western margins where the aquifers are exposed or overlain by sandy sediments. Confined groundwater then

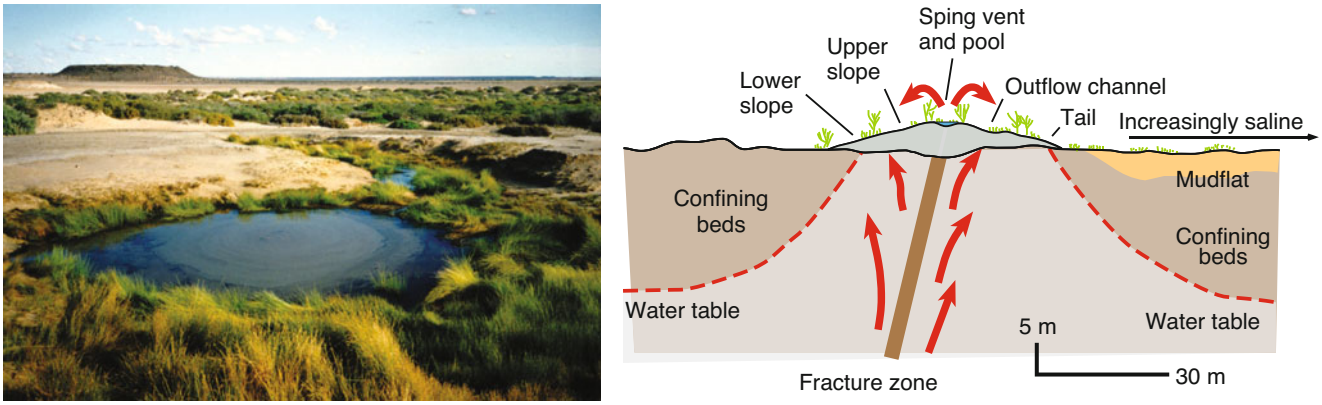

Fig. 3.57 (**a**) Active mound spring in the southern margin of the Great Artesian Basin artesian where water up to 3 million years old returns to the surface. (**b**) Schematic cross section of typical Lake Eyre Basin mound spring

percolates very slowly towards the terminal base level of Lake Eyre and saline lake sumps, reaching the Lake Eyre area after a calculated travel time of up to three million years (Fig. 3.56).

Natural discharge from the GAB comes from two principal processes: (1) diffuse vertical leakage towards the regional watertable and, (2) from focused outflow via 600 springs located in 11 groups along the western and southern boundaries of the Lake Eyre basin (Fig. 3.56). Many spring mounds define linear fault-controlled surface trends. Flow from the mounds totals 0.03 km^3/year and is a minor discharge component of the overall diffuse artesian discharge to the watertable. But it creates distinct carbonate spring mounds with the potential to be preserved (Ponder 1986; Mudd 1998, 2000; Keppel et al. 2011). Measured flows from various springs range from 0.0001 to 0.23 m^3/s totalling around 1 m^3/s. Salinities range from 700 to 800,000 ppm, pH from 7.1 to 8.0 and water temperatures from 30 to 40 °C.

A typical mound consists of a central pool of water, an outer rim of reeds and vegetation, an outflow channel, and successive layers of carbonate (Fig. 3.57). They are constructed of micritic marls, invertebrate remains, microbial thrombolitic tufa, pisolites and micrite-cemented eolian sands and are surrounded by gypsiferous saline mudflats. Spring mounds are especially obvious in the southern part of Lake Eyre (Habermehl, op cit). Active mounds are up to 8 m in height and up to 30 m across. The now extinct Hamilton Hill Spring Mound rises more than 40 m above the surrounding hypersaline playa floor, suggesting that late Pleistocene artesian pressures have been higher (Habermehl, op cit.). Flow rates from Lake Eyre springs are directly proportional to the area of wetland vegetation that the spring supports (Williams and Holmes 1978). Mineralogically, the mound springs are dominantly calcitic and constructed in response to the degassing of emerging Great Artesian groundwaters. Textures are combinations of thrombolitic, microbial and higher plant moulds and linked to the development of extracellular polymeric biofilms (Keppel et al. 2011).

The shores of modern Lake Eyre erode the edges of some now inactive spring mounds and a number of lunette-cored islands within the lake. The southeastern lake coastline, which today consists of eroded dune sand cliffs, is being rapidly cut back, with an erosion rate in the order of 5 m per major flood. The presence of several older strandlines some 0.7, 1.6 and 2.8 m above the 1974 water level, indicate previous unrecorded major flood events. According to Kotwicki (1986), the above levels represent approximate storages of 35, 48 and 67 km^3 respectively. The highest potential available storage in the Lake Eyre depression is more than 200 km^3, i.e. almost seven times greater than the 1974 storage. The terms "full" or "flooded to capacity" should therefore be used cautiously in Lake Eyre in relation to historical flooding events.

The Lake Eyre basin has been an area of lacustral sedimentation since the Mesozoic. The first documented lacustrine sediments are of freshwater Lake Walloon, which occupied central eastern part of the Australian continent some 150 Ma (Middle Jurassic). By the late Cretaceous (85–75 Ma) it had shrunk to become the much smaller 5×10^5 km^2 Lake Winton. By the early Miocene (21 Ma) the freshwater lake had assumed a position closely resembling that of Lake Eyre, it even had an indigenous species of freshwater dolphin. This freshwater system in turn evolved into Lake Dieri, a Pleistocene "greater Lake Eyre or mega-Eyre" which underwent large scale variations in size and salinity from a perennial freshwater lake up to 25 m deep, to a groundwater-controlled playa marked by substantial sediment deflation to enter the Holocene as a dry salt pan subject to occasional flooding (Magee et al. 1995, 2004; Magee and Miller 1998; Cohen et al. 2012). Four Late Pleistocene shorelines have been recognised in those parts of the present Lake Eyre surrounds not located downwind of the depression. They are: a 40 ka shoreline at –10 m AHD (Australian Height Datum),

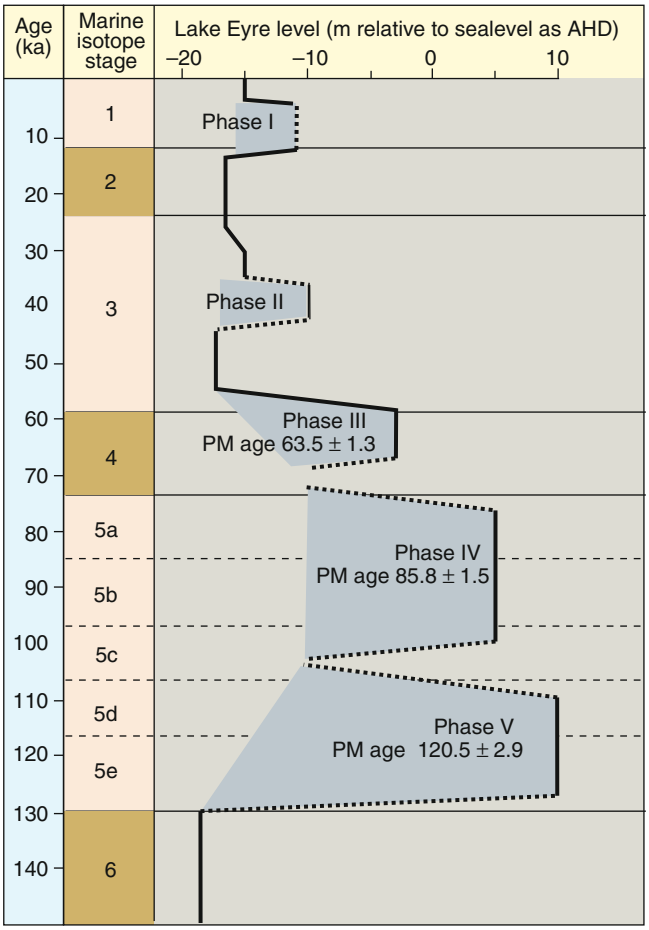

Fig. 3.58 Late Quaternary changes in lake level in Lake Eyre (After Magee et al. 2004)

a 65 ka shoreline at –3.5 m AHD, a 80 ka shoreline at +5 m AHD shoreline and a 125 ka shoreline at +10 m AHD, which corresponds to Stage 5e on the Quaternary eustatic curve (Fig. 3.58; Magee et al. 2004; De Vogel et al. 2004).

Greatest effective aridity in Lake Eyre over the past 150,000 years occurred in marine oxygen isotope stage (MIS) 6, when basin deflation was 4.3 m lower than today (Fig. 3.58). This arid event was followed abruptly by formation of the deepest perennial lake (phase V at +10 m relative to the Australian height datum [AHD—mean sea level]), a level some 10 m above sealevel and some 25 m above the modern playa floor. At least 6 m of finely laminated gypsiferous and calcareous clay were deposited at this time in conditions characterised by salinity stratification and strongly reducing bottom conditions (Magee et al. 2004). At the same meandering inflowing streams deposited thick, lateral-accretion sediments and fluviodeltaic sediment at the stream mouths.

After this acme level, the lake then shallowed and briefly dried at least once, but no evidence is seen of deflation or pedogenesis (Magee et al. 2004); then the lake refilled to +5 m relative to AHD between 100 and 75 ka (Phase IV), when lacustrine deep-water clays, calcareous nearshore and beach sands, and clastic gypsum evaporites were deposited coevally with renewed fluvial aggradation. Fluctuations in lake level and salinity noted by Magee et al. (op cit.) suggest decreasing regularity of inflow and gradual diminution of the monsoon toward the end of Phase IV.

Sediments of Phase IV were pedogenically modified and eventually truncated by deflation when the lake dried at 75–70 ka and disrupted gypsiferous playa sediments were transported downwind. Incision of tributary rivers into previous fluvial and lacustrine sediments, extending down almost to the modern level, documents a transition to significant aridity.

Lacustrine conditions returned at 65–60 ka (phase III), depositing lake sediment and a prominent beach sand, rich in the brackish water gastropod *Coxiellada gilesii* at −3 m relative to AHD; coeval fluvial aggradation and vertical accretion of overbank muds occurred. Though having shallower water and shorter duration than Phases V and IV, Phase III had significantly deeper water and longer duration than the modern ephemeral events and represents the last deep-water perennial lake in the basin and the last influence of moderately effective monsoon precipitation.

A major deflation episode between 60 and 50 ka excavated the present Lake Eyre basin to deposit gypsum- and clay-rich lunettes at a number of sites around the lake edge as well as covering former shorelines on the windward side of the lake. After deflation ceased, a thick secondary gypsum soil profile (gypsite) developed on the dunes early in oxygen-isotope stage 3. Between about 30,000 and 12,000 year. B.P. Lake Eyre was at least as dry as it is today. At many sites a lunette-like, playa-marginal, eolian unit formed from saline mudflat sediments deflated from the playa floor. After 10,000 year B.P. a minor lacustral phase occurred (Phase I) until the modern ephemeral playa regime became established at 3,000–4,000 year B.P.

Given the large volumes of water periodically entering the lake depression, and its long history extending back to the Mesozoic, one would perhaps expect large volumes of salt to have at times accumulated in the lake sediments. Certainly, Lake Eyre (Madigan Gulf) is the only Australian playa to retain buried Pleistocene halite beds (Fig. 3.59; Magee et al. 1995), but both beds are less than a metre thick. The total Pleistocene thickness is only 3 m in this the saltiest part of Lake Eyre North. A lack of preservation/accommodation space, tied to ongoing lake floor deflation, reflects the meteoric/artesian recycling hydrology that also characterises most other large low relief playas of inland Australia (Chap. 2).

Gillespie et al. (1991) interpreted the buried halite in Madigan Gulf as a former salt pan unit, which was partially dissolved during the onset of a minor halite phase in the early Holocene and then preserved by the deposition of the

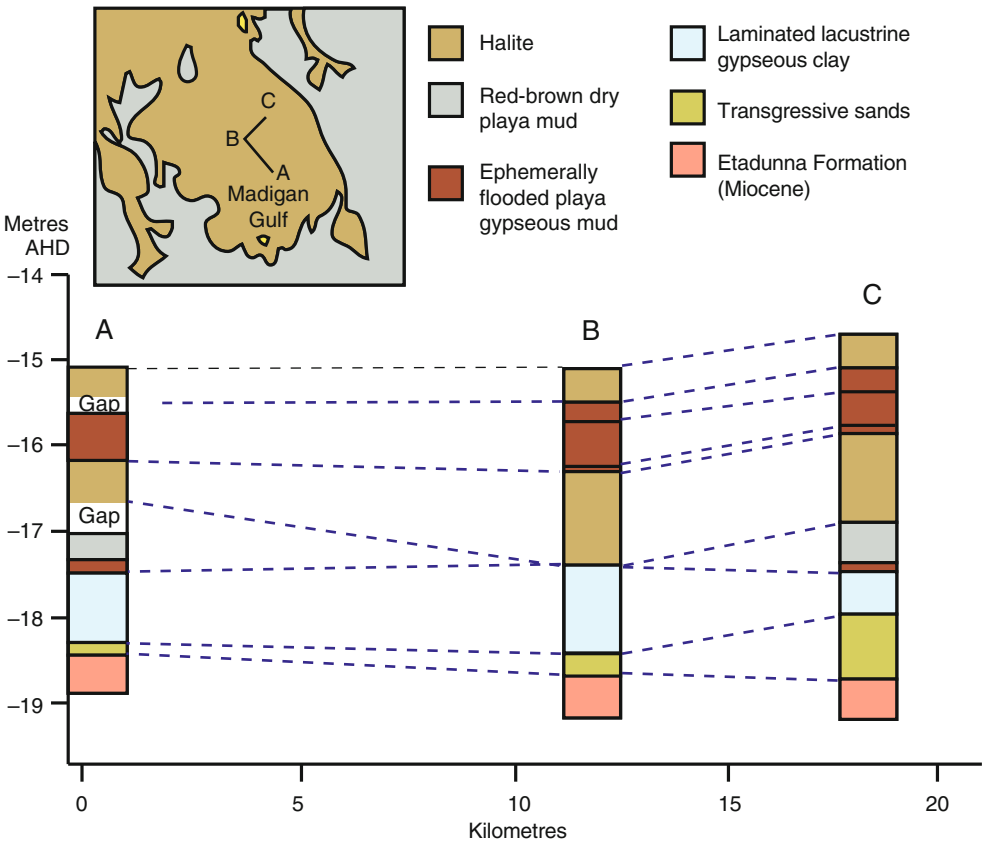

Fig. 3.59 Distribution of buried saline pan halite beds and associated sediments in Madigan Gulf, Lake Eyre North (After Magee et al. 1995)

overlying gypsiferous clays. But with thicknesses of less than a metre for each of the two preserved saline pan beds it is not a geologically significant body of halite. Inherent low relief and artesian hydrologies means the ephemeral stream floodplain – dune field – ephemeral saline lake playas of Australia and elsewhere are unable to accumulate thick sequences of bedded salt in the lowest parts of the drainage basin. It simply blows away. Haloturbation of siliciclastics in continental sabkhas in association with widespread redbed fluvial and eolian deposition is the dominant signature of this style of deposition.

Lake Frome, Australia

Lake Frome, South Australia, is another example of an ephemeral stream floodplain – dune field – ephemeral saline lake complex in the major outflow zone of the Great Artesian Basin (3.53). Lake Frome is approximately 100 km long and 45 km wide with an area of 2,700 km^2 and lies to the south of Lake Eyre (Fig. 3.60). Sediments come mainly from the west via a series of short, relatively steep gradient streams, originating in the Flinders Ranges some 40–50 km away. Overflow waters from Lake Eyre sometimes spill into the north of the lake via Warrawoocara Channel, which also connects lakes Gregory, Blanche and Callabonna. This spillover prevents Lake Eyre water from today rising to a height of more than 12 m above the Australian height datum (AHD).

The lake contains many islands mainly in the south, where the lake floor is at its lowest, some 2 m below mean sea level (Fig. 3.60). These islands are the erosional remnants of earlier now largely deflated Pleistocene sediments and are composed of gypsiferous quartz sands atop a clay surface. Around the edges of the lake there are quartzose spits and bars, beach deposits, and delta fans, as well as Pleistocene transverse and longitudinal desert dunes (Draper and Jensen 1976). As in Lake Eyre, sheet delta fans define the entry points of the larger ephemeral streams and are built by the coalescence of flat lenses of ephemeral stream sediment and dominated by low angle layering. Stream channels are shallow, straight to gently curved features with few point bars. Oxidised organic-rich muds define lowest parts of the channels. Fine-to-coarse sands with minor gravels form the bulk of the sheet delta sediment. Interchannel areas are composed mostly of reworked eolian sands. Marginward evaporitic flats with widespread capillary gypsum form large areas peripheral to, but sometimes, atop the sheet delta sand prisms.

Further out into the lake the channels die out and pass into the sands and muds of the saline mudflat, which dominates the lake basin. The bulk of the mudflat matrix is a quartzose sandy mud or mud with displacive gypsum forming in the capillary fringe and displacive halite in the uppermost 10 cm. Mudflat sediments tend to be massive but can locally show

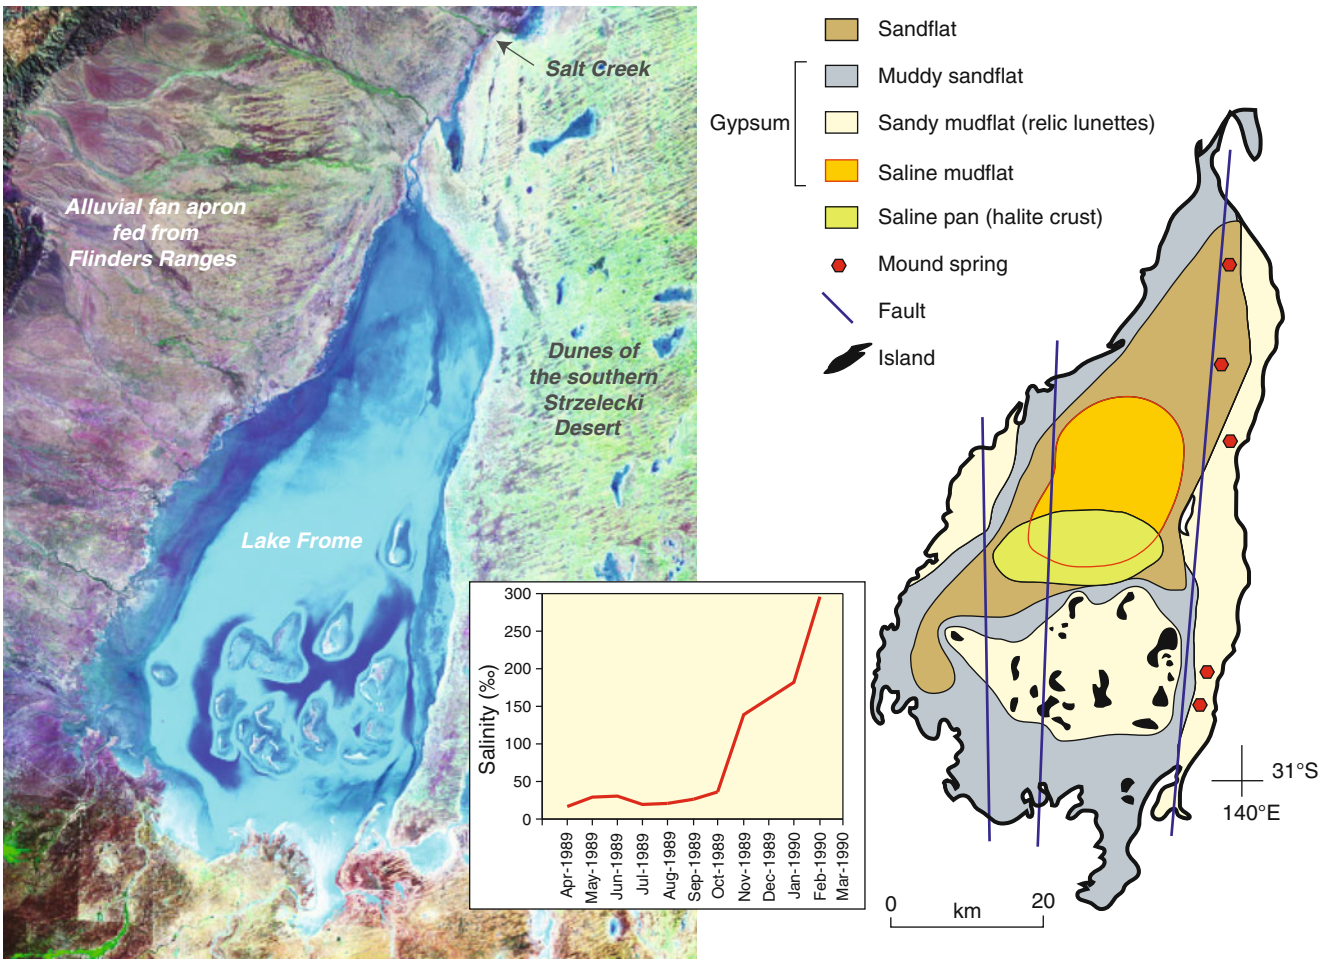

Fig. 3.60 Surface sediments in Lake Frome, South Australia. The Flinders Ranges are visible in the upper northeast corner of Landsat image. Sediments in the lake depression show an off-centre bull's-eye pattern related to the presence of a deflationary high in the southern centre with islands dominated by lunette gypsum. The clastic distribution is also inverted with high proportions of sand in the more central positions of the saline mudflat rather than along the current lake strandline. This unusual matrix position indicates detrital flooding from the north fed by overflow from the Warrawoocara Channel (Salt Creek), which feeds overflow from Lake Eyre into the northern end of the lake. Note also the association of aragonitic spring mounds along the eastern side of the lake with their positions controlled by upwelling along a north–south trending fault. *Inset* shows salinity evolution of surface waters after the April 1989 flood (Landsat Image courtesy of NASA, surface geology in part after Draper and Jensen 1976)

indistinct wispy organic lamination. In the lowest part of the lake floor is the saline pan made up of an ephemeral halite crust up to 20 cm thick and composed of halite rafts and chevrons. The crust completely dissolves during times of flood and is continually underlain by water-saturated muds with large crystals of lenticular and prismatic gypsum.

Like Lake Eyre, the lake also displays large active spring mounds along its eastern side. Mound sediments are made up of varying proportions of detrital sediment and authigenic aragonite, calcite, and dolomite cements forming an microbial tufa bindstone. An apron of gypsite fringes the active mounds. As in Lake Eyre, the mounds indicate fault-focused outflow fed from aquifers of the Great Artesian Basin and line up parallel to the major north–south normal fault system that characterises the area.

The inset in Fig. 3.60 shows the salinity evolution of a brine sheet from April 1989 until complete desiccation 11 months later in March 1990. The rate of salinity change in the brine sheet was climatically controlled. In April 1989 it was a sheet of mesohaline water (<50‰) covering the previously dry lake floor. Much of the salinity in the water sheet soon after flood-ing came from dissolution of the salt crust that had previously occupied the central depression. The brine sheet remained for 6 months through the cool months of winter and spring, with little change in its mesohaline salinity. Then, with passage into the hot summer of the Australian interior, brine sheet salinity rose rapidly. In less than a month it moved from its previous salinity plateau into gypsum saturation and then into the halite saturation field before desiccation 3 months later. By end March-early April,

(**c**) Histogram of summed individual $^{230}Th/^{234}U$ age distributions of speleothem ages at Naracoorte Caves and Kelly Hill Caves, Kangaroo Island, normalized to unit area (low analytical errors give sharply defined age distributions). Multicollector – inductively coupled plasma – mass spectrometry Mairs Cave ages are not included in summed distribution due to differing techniques and are plotted on x-axis; January insolation at 30°S (Berger 1992). (**d**) Sealevel curve. (**e**) Stacked sea surface temperature (SST) record for Southern Ocean. MIS—marine isotope stage

1990 (almost a year after the flood) the lake floor had dried out and its 30 cm-thick salt crust had reformed. This style of salinity increase, with a long plateau of mesohaline waters, is important to life in the lake as it allows sufficient time for a halotolerant macro and microfauna to breed and survive into adulthood. Plateaus in salinity evolution can control the intensity of the "feast or famine" response in many saline water bodies worldwide (Chap. 9).

The gypsum-entraining sediments of Lake Frome, like those of Lake Eyre, preserve a high-resolution record of climatic fluctuations over the last 100,000 years (Fig. 3.61; Cohen et al. 2011). Over the past 20,000 years the climate in the drainage basin has become increasingly arid (Fig. 3.61a). The hydrologic feature known as a "mega-lake" stage indicates a former lake water level that was sufficiently high to merge Lakes Frome, Blanche, Callabonna and Gregory. This Lake Mega-Frome was connected for the last time to adjacent Lake Mega-lake Eyre in the high water period 50–47 ka, this defined the largest remaining interconnected system of paleolakes on the Australian continent at that time. The final disconnection and a progressive drop in the level of Lake Mega-Frome indicates a major climate shift to aridification (gypsum beds) that coincided with the arrival of humans and the final demise of the megafauna in the Lake Eyre Basin.

The elevated supply of moisture to the Australian continent at various times across the Quaternary has been inferred to be to a response to an enhanced monsoon. The Lake Frome data provides reliable quantitative evidence for periods of enhanced tropical and enhanced Southern Ocean sources of water that supplied and filled these lakes at different times during the last full glacial cycle.

Mega-Lakes and Mega-Faunas

Interestingly, for much of the Mid to Late Pleistocene especially in glacial periods, the Lake Eyre catchment was savannah grassland, supporting large numbers of marsupial grazers and predators; this was an megafauna-dominated ecosystem and very different to today (Webb 2006, 2009). At various humid times (times of Megalake Eyre and Megalake Frome) the surrounding grasslands and along-drainage forests supported large numbers of *Diprotodon* and other megafauna.

This included giant 3-m tall kangaroos, giant flightless birds such as *Geryonis* (aka "thunder birds") that stood more than 2 m tall and were much heavier and taller than an ostrich or emu. There were also large lizards, including predatory herds of *Megalania prisca*, a species of predatory lizard that when fully grown was up to 7 m in length and so was larger than the modern Komodo dragon. Its main prey was likely the various species of diprotodontids. As well, there were numerous snakes, including 5 m-long pythons (*Wonambi naracoortensis*), and several species of predatory thylacines (marsupial tigers), including the lion-sized *Thylacoleo carnifex*. At the top of the mega-lake food chain were two species of 5–8 m long crocodilian predators, *Crocodilus porosus* and *Palimnarchos pollens*. During lake-full times these crocodilians occupied almost all of the Lake Eyre catchment waterways.

D*iprotodon* species were grassland marsupial grazers that were a widespread inhabitant of the savannah surrounding the megalakes. The diprotodontid group includes the largest marsupial known to ever exist in Australia (some species were rhinoceros-sized) and as a group were the main prey species for the crocodilians. Crush pits on Diprotodon long bones are up to 10 mm in diameter, showing the enormous crush strength of the jaws of these crocodilian predators. Tapir to rhino-sized Diprotodontids were most vulnerable on steep, muddy banks of rivers feeding into perennial mega-lake Eyre and Frome. A 5–8 m crocodile clamping its jaws over the snout of one of these animals and then rolling would have caused massive injury and instant death if the neck was broken by the roll.

Today, in what was the former water covered areas of Lake Callabonna and Lake Blanche the remains of various large-bodied vertebrates, especially *Diprotodon,* are found in wind-eroded muddy mounds that encase or partially expose fossil carcasses. There are thousands of such mud-covered gypsum-cemented mounds littering the exposed lake floors.

According to Webb (2009), the savannah areas of the paleo-Lake Eyre catchment had a low drought threshold with stream and lacustrine standing water drying out long before main feeder channels. Around 80 kyr the Lake Eyre and Lake Frome regions experienced fluctuating widespread aridity with decreasing maximum lake levels. It is likely that, after 80 ka, mega-faunal populations never again reached the same proportions in the Lake Eyre and Lake Frome drainage, although they did survive in the less arid parts of Australia until as recently as 15 ka, before being hunted into extinction. Climate deterioration drove a slow reduction in the population and species variety, commensurate with deepening aridity throughout central Australia. This pattern gained momentum after 65 kyr. River channels probably provided escape corridors and re-entry for animals at these times as they followed fluctuating water levels.

Remnant animal populations focused on shrinking water bodies along main channels but tethering of groups would have occurred as water holes became isolated; Lake Blanche and Lake Gregory were probably the last two water holes of what was once the megalake system (De Vogel et al. 2004). Increasing bouts of aridity brought food shortages and the concentration of dwindling animal populations at reducing riverine refuges. Increased competition at these places followed as plain dwelling animals fell back on major streams with predators experiencing a short-lived abundance of prey. While some animals may have used northern escape routes, the main exit and supply of species probably came not along riverine corridors but through southerly directed corridors into areas of western, southeastern Australia.

Salina de Ambargasta, Central Argentina

Salina de Ambargasta is a saline depression situated in the mid latitudes in central Argentina (29°S, 64°W). Its Köppen climate setting is BSh, a hot arid setting, but some 20 or so kilometres to the east is a milder Mediterranean-style climate (Cwa) in the lowlands, while to the west are the BSk and ET climates of the Andean cooler rain shadow deserts. As such, Ambargasta straddles a transition in hydrological and climatic environments marked by fluvial and cooler perennial lake deposits to the east and the classic volcanic salars and lagunas evaporitic lakes of the Andes highlands to the west.

Because of its hydrological setting, the Ambargasta saline complex can be subdivided into a closed system "sensu-stricto" (area A) and an "open-like system" (Area B) in the north, characterised by seasonal overflow (Fig. 3.62: Zanor et al. 2012). Its geomorphological and sedimentological features also divide the Ambargasta depression into well-defined western, eastern and northern zones, where aeolian processes, groundwater supply and surface inflow, respectively, define distinctive sedimentary environments and typical processes of deposition within what is a single playa depression. The following depositional settings are seen to follow this topographic subdivision: (1) alluvial fan; (2) sandflat; (3) springs; (4) dunes and palaeo-dune field; (5) dry mudflat; (6) capillary mudflat; (7) ephemeral saline lake (includes saline mudflat and salt pan).

The dry mudflat is present at the highest topographical zone, where the groundwater influence is less important and only intermittent ponds are present. In the capillary mudflat, evaporite sedimentation is limited to the development of efflorescences via evaporative capillary pumping. The ephemeral saline lake system, occupies the lowermost topographical region, as is evidenced by the strong asymmetric distribution of the various lagunas in the Ambargasta

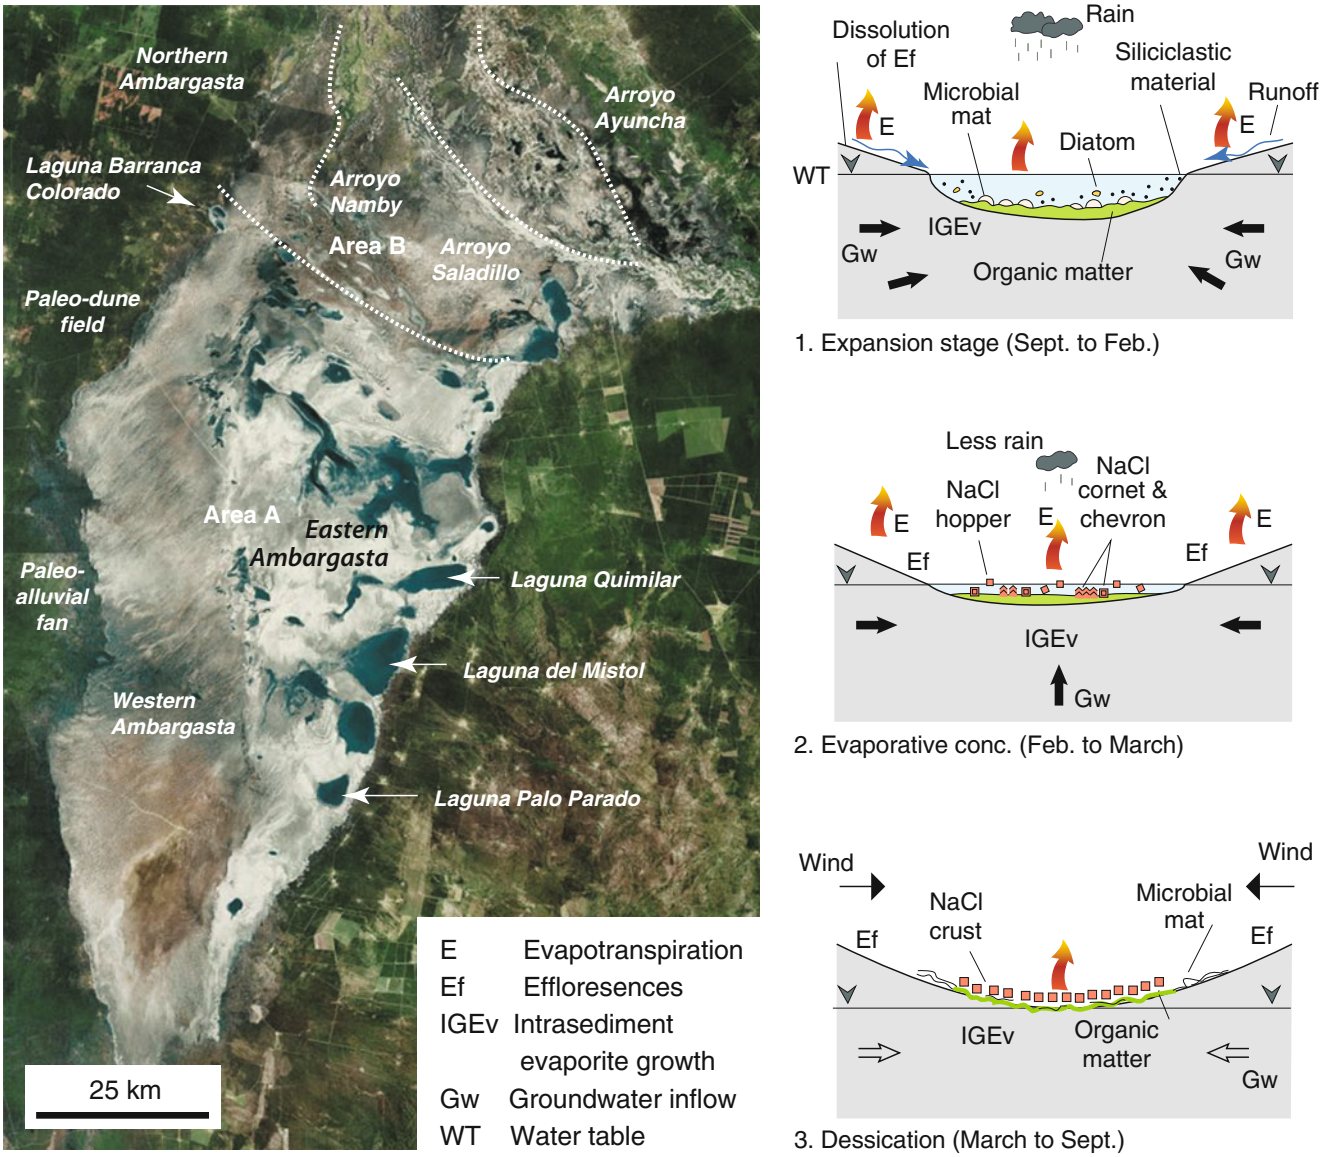

Fig. 3.62 Salina de Ambargasta is made up of Area A, which is a hydrographically closed system and Area B which is a more open hydrology that is drained by Arroyo Saladillo. The boundary between A and B is indicated by a white dashed line. The three geomorphic zones that make up the main topographical levels correspond to western Ambargasta, eastern Ambargasta and northern Ambargasta. Also shown is the seasonal evolution (Stages 1–3) of the salar's hydrology and associated sedimentation systems (After Zanor et al. 2012)

depression. Alternate cycles of lake expansion and contraction in the lagunas and across the depression are responses to inter-annual hydrological variability as well as to seasonal variability (Zanor et al. 2012). Isotopic compositions of surficial and underground waters (^{18}O and ^{2}H) indicate that lake waters become isotopically enriched during summer when evaporation plays a significant role in the saline complex.

Ambagastra's transitional climatic setting means seasonal fluctuations in the hydrological balance throughout the year trigger the flooding and desiccation stages in the lakes and the surrounding depression. After the lakes are flooded by meteoric waters (Stage 1), they begin shrinking due to the intense evaporation during the late austral summer (Stage 2). Whenever the lakes completely dry up, as in the case of Laguna Quimilar, Laguna Mistol, Laguna Palo Parado and Laguna Barranca Colorada, a salt pan forms in the lowest part of the lake area across the austral winter (Stage 3).

In the various Ambargasta salt lakes, the saltpan deposits typically reach no more than 2.5 cm in thickness and are

Table 3.7 Rates of extreme rainfall events that create sheetfloods in the arroyos, ephemeral fans and "channel country" fluvial systems feeding surface waters into saline lakes and pans

Location of event	Date of event	Annual av. (mm)	Storm rainfall (mm/time)
Aozou, Sahara	May, 1934	15	370 mm in 3 days
Tamanrasset, Sahara	Sept., 1950	27	44 mm in 3 h
El Djem, Tunisia	Sept., 1969	275	319 mm in 3 days
Bisra, Algeria	Sept., 1969	148	210 mm in 2 days
Sharja, UAE	1957	107	74 mm in 50 min
Swakopmund, Namibia	1934	15	50 mm
Dead Sea, Middle East	Nov., 1995	90	150 mm in an hour (2.5 mm per minute)
Mt Dare, Australia	March, 1967	126	149 mm in 1 day
Alice Springs, Australia	March, 1988	275	205 mm in 1 day
Innamincka, Australia	Jan., 1974	172	356 mm in 3 days
Balcanoona, Australia	March, 1989	200	341 mm in 2 days
Chicama, Peru	1925	4	394 mm in single storm
Lima, Peru	1925	46	1524 mm (more than 30 times annual)

composed almost exclusively of cubic halite and minor quantities of gypsum, not continuous salt beds. So, instead of forming extensive continuous saltpan layers in the lowest portions of the saline depression, halite precipitates as small crystal bowls of a diameter of 1 m, separated from each other by muddy, relatively halite-free, sediment. Modern and ancient lakes with these mosaic halite distributions were termed "spotted lakes" by Renaut and Long (1989).

Perennial Stream Floodplain–Perennial Saline Lake

Perennial stream floodplain–perennial saline lake depositional complexes, the third saline lacustrine depositional style of Hardie et al. (1978), occur in several high relief tectonic settings and usually lack extensive sabkhas. Any sabkhas that are present tend to be localised muddy embayments about the lake shoreline. Most perennial saline lakes such as the Dead Sea and the Great Salt Lake are characterised by steep slopes surrounding the lake. The steep slope allows saline water to pond in an arid climate and the lack of sabkhas is often the result of the steep basin sides, with the associated lack of an aerially extensive outcropping of the capillary fringe. These perennial lakes are discussed in detail in the next chapter.

Continental Inflow

All the ephemeral saline water systems discussed in this chapter have one very obvious feature in common, that is, all are subject to an unpredictable and variable rate of water inflow. Researchers who have not experienced a heavy desert rainstorm often do not appreciate how much and how quickly moisture can enter the system and move large volumes of poorly consolidated sediment in a desert soil system, which largely lacks a stabilising vegetation carapace. Desert downpours in the drainage hinterland create debris-charged raging torrents in normally dry streambeds, along with crossbedded and rippled sheet sands and vast areas of muddy floodplain. This is especially so when rain falls over barren rock at higher elevations in the drainage. As little as a few millimetres of rain can produce flow in dry desert wadis; the flow tends to emerge suddenly, peak rapidly, but last only a few hours (flash flooding). Less than 100 mm can produce catastrophic floods. In the Tadmait Plateau of the Sahara a rain of approximately 16 mm generated a flood with peak discharge in emergent wadis of about 1,600 m^3/s.

The results can be catastrophic for the people living in these areas. For example, a storm in August 1988 at Khartoum, at the eastern edge of the Sahara, had a daily rainfall of about 200 mm (twice the previous heaviest fall on record in the region). The resulting flash flooding left tens of thousands of homes destroyed and vast areas around the city inundated (Hulme and Trilsbach 1989). An estimated 1.5 million people were made homeless, and there were over 100 deaths and hundreds of injuries. Most of the homeless had nowhere to go; even areas which had not suffered damage were under water and there were few areas dry enough for temporary camps to be erected.

In a day or two such rapid influxes of water can convert a saline pan sump into a lake filled with brackish water and teeming with a halotolerant biota (Chap. 9). Table 3.7 lists extreme rates of rainfall in some of the areas that occasionally can feed huge volumes of surface flow into the saline lake depressions. Once this huge volume of water has moved large volumes of siliciclastic sediment into the lake depression, it dries out within weeks to months and the system then can stay dry for years. With desiccation the newly deposited sediment is subject to the vagaries of deflation and with longer term climatic change and lowering of the regional watertable can evolve into what can be extensive eolian sand and dust sheets.

Eolian-Hosted Sabkhat

So far, this chapter has described and defined sabkha and pan salts hosted in either marine-margin or continental sediments. In both situations the interpretation of ancient counterparts comes from the matrix, not the salts. Put simply, nodular anhydrite accumulating in a marine sabkha is hosted in, and intercalated, with marine (fossiliferous) fine-grained sediment, while continental sabkhas are intercalated with, and hosted in fine-grained nonmarine fluvio-lacustrine matrices. But there is a third sabkha association, that of eolian sabkhas, where nodular anhydrites, gypsums and displacive halites are hosted in muddy eolian matrices (Table 3.1; Fig. 3.2). Eolian-hosted sabkhas can form in either marine margin or continental lacustrine settings. In either setting their depositional proximity to eolian sands means eolian sabkhas tend to be intercalated with potential eolian reservoirs and can form lateral discontinuities (lenses) in the eolian sands (Figs. 2.61 and 2.62). For this reason I have broken out modern occurrences of eolian sabkhas as a separate topic.

I define an eolian-hosted sabkha as being characterised by capillary salts accumulating in any eolian-derived matrix and sitting below a Stokes surface. It may form in interdunal depressions, in sand sheets on the marine or lacustrine edges of ergs, or even in areas of desert loess. By definition, eolian sabkhas, like all sabkhas, require the upper part of the capillary fringe to intersect the landsurface. Fluctuating water levels and watertables will move a sabkha strandline back and forth over the lower parts of an arid drainage so that eolian sabkha sediments are often intercalated with units deposited in either the ephemeral saline pan or in sand sheets. The ratio of siliciclastic matrix to capillary evaporite in an eolian sabkha unit means it can be further classified into: (1) detritally-dominated (wet eolian sabkha) with a capillary succession showing haloturbation but little or no preserved capillary salts (possible hydrocarbon reservoir), and (2) chemically-dominated (saline eolian sabkha) with abundant capillary salts preserved (possible hydrocarbon seal).

Matrix in wet eolian sabkhas has a characteristic association of sedimentary structures associated with ephemeral water and eolian overprints ranging from; subaqueous current and wave ripples, wavy laminae and contorted bedding (wet-surface conditions), through adhesion structures, bioturbation structures, desiccation cracks (damp-surface conditions), megapolygons and Stokes surfaces (falling watertables) to wind-ripple lamination (dry-surface conditions; see Chap. 2; Mountney and Thompson 2002; Goodall et al. 2000). Similar sedimentary structures occur in chemically-dominated eolian sabkhas but they tend to be overprinted and disturbed by pervasive chaotic salts and associated haloturbation.

One of the better modern areas to study the interrelationships between eolian sabkhas and dune systems is the Arabian Peninsula (Fig. 3.63). At least six generations of dunes can be identified on satellite images of the United Arab Emirates and Saudi Arabia (Glennie 1998). Geomorphic relations indicate that older periods of Pleistocene dune formation have been modified by later periods of eolian activity, including modern wind flow patterns. In addition, at least two periods of older eolian sedimentation lie beneath the modern dunes. Some dunes sands have a high content of comminuted marine shells and along with wind-reworked oolites have been cemented into calcareous eolianite, locally known as miliolite. They were sourced in sands blown out of the exposed marine shelf during glacial induced sealevel lows (Fig. 3.63). Thus, the modern eolian sabkhas on the Arabian Peninsula indicate a complex combination of groundwater overprints interlayered into active dunes and palaeodune bedforms. Those dunes cemented into calcareous eolianites (miliolites) tend to be associated with sea margin sabkhas, as in the vicinity of Al Liwa oasis in the UAE, others form in siliciclastic matrices at the edges of ergs in continental interiors, as at Umm as Samim in Oman (Fig. 3.63).

Older literature discussing eolian-hosted sabkhas typically assumes an elongate interdunal geometry, inherited from groundwater-driven infill between the partially preserved topography of the underlying dune ridges (Fig. 3.2; Handford 1981a). But dunes are merely loose sediment blowing around above the watertable, if the dunes blow on, the remaining sediment is held in place by the capillary fringe and so this type of eolian sabkha can stack into a sheet-like geometry. It also means the edges of many active ergs are flat laterally extensive erosional sandflats with deflation limited by the top of the capillary fringe, as in the Tamya sabkha of northwest Saudi Arabia (Ginau et al. 2012). Thus, sheet-like sandflat-hosted styles of eolian sabkha about the edge of a sand sea are likely more commonplace in continental interiors than the more typically cited elongate interdunal sabkha geometries.

Elongate interdunal geometries tend to be most obvious where changing climate or subsidence pushes a rising watertable further into a sand sea. They are typical of low energy desert coastlines preserving lacustrine or Flandrian marine transgressions. In the southern Arabian Gulf the Flandrian event is typically associated with carbonate-rich (miliolite) hosts. Interdunal geometries are typical of rising water levels at lacustrine-dune contacts, for example in Lake Chad or the southeastern coastal portion of Caspian Sea, south of Karabogaz Gol (Fig. 3.64a, b). There rising lake levels in the last 10,000 years and limited fetch in the adjacent lakes push the rising watertable to outcrop in nearby partially reworked dunes. In Lake Chad the rising circum-lake watertable drove the formation of authigenic silicates and sodium bicarbonate salts in the interdunal capillary fringe.

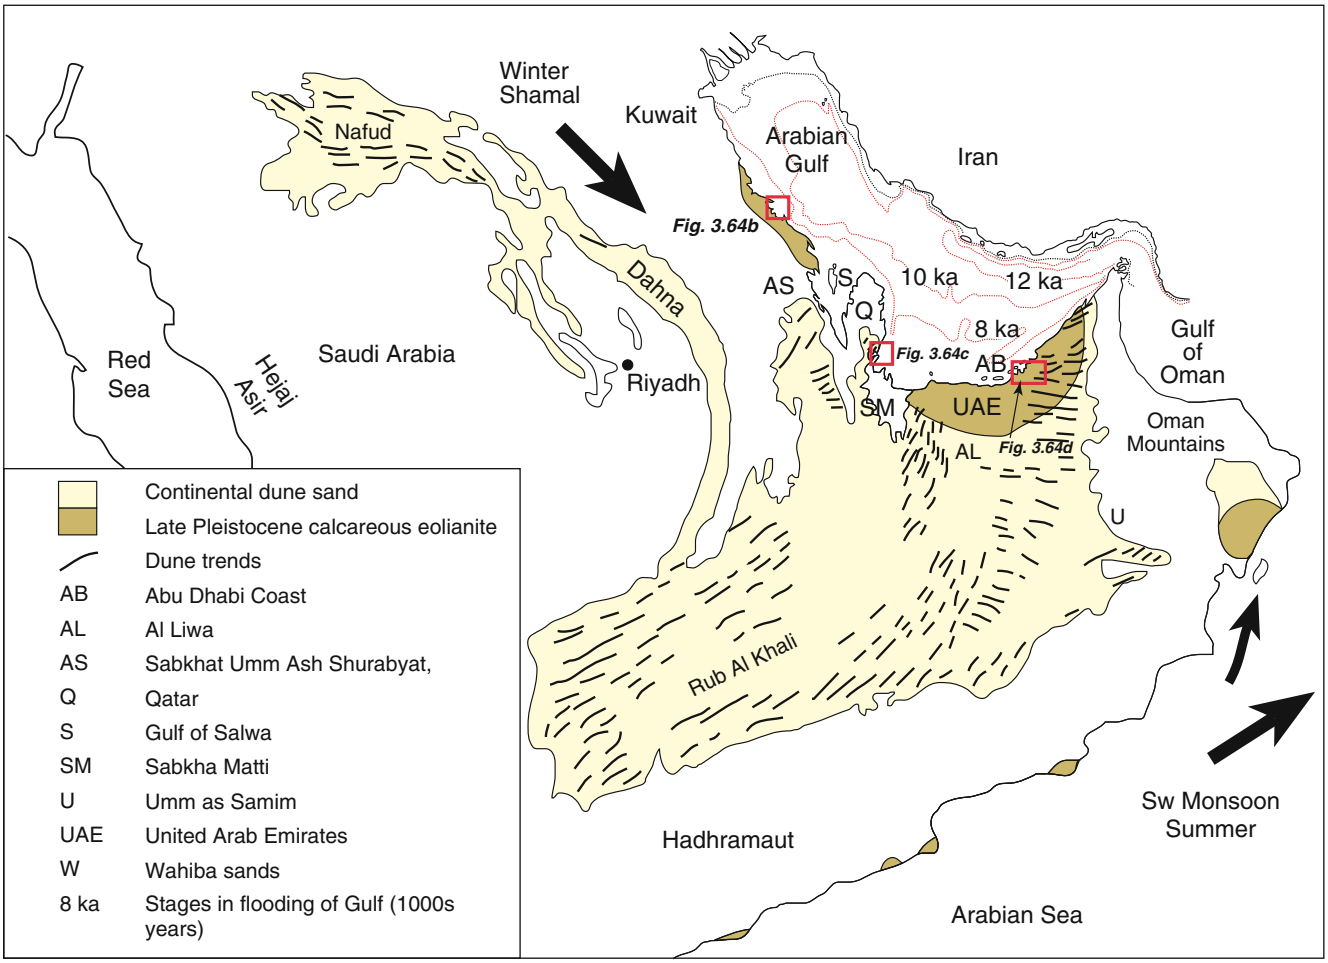

Fig. 3.63 Extent of dunes and orientation of their crests on the Arabian Peninsula and approximate extent of the postglacial marine transgression into the Arabian Gulf basin at 12, 10, and 8 ka (After Glennie 1998; Teller et al. 2000). Dominant modern wind directions are shown by *arrows*. Occurrence of late Pleistocene eolianite (Miliolite) is indicated by a dark brown pattern along coast, especially along southern coast of the Arabian Gulf around the Salwa Gulf and in the United Arab Emirates (*UAE*) where these palaeo-dunes extend as far south as about Liwa Oasis (*AL*), which is just north of the Saudi Arabian border. AB, SM, U and AS show the position of Abu Dhabi coast, Sabkha Matti, Umm as Samim and Sabkhat Umm Ash Shurabyat, all examples that are discussed in this section on eolian sabkhas

Sea-Margin Sabkha Capping Preserved Dune Shape

For an dune geometry to be preserved during a marine transgression requires relatively low energy in the zone of marine encroachment. Otherwise, the encroaching high-energy coastal shoreface will erode and transform the depositional signature to a planar unconformity and largely destroy any sabkha signatures and geometries (Fig. 3.65a). That is, these modern marine interdunal systems tend to occur in coastal zones on the edges of marine gulfs with limited fetch and sediment columns indicating a Pleistocene-Holocene rise in sea level (transgression that defines the end of the last glacial).

Interdraa marine coastal eolian sabkha geometries are obvious along the low energy coast in the region south of Munfah, Saudi Arabia (Fig. 3.64c). There interdunal depressions are dominated by muddy sands with fringes of mm-scale biolaminites and displacive and lenticular gypsum growing at or above the watertable (pers obs). Likewise the landward side of the barrier-lagoon northeast of Abu Dhabi is a somewhat more energetic setting located at the sandflat edge of a large sand sea (erg) in the triangle between Abu Dhabi, Dubai and Al 'Ayn (Figs. 3.63 and 3.64d; Abu-Zeid et al. 2001; Teller et al. 2000; Glennie 1998). Close to the coastal plain these dunes contain a high proportion of marine derived calcareous sand grains (miliolite). The dunes were at their most active in the late Pleistocene glacial maximum when strong winds blew from the west across the Eastern Emirates. Dune surfaces have been subsequently modified by the modern NNW Shamal winds.

At the time they were at their most active the ocean had receded from the Arabian Gulf and the Tigris-Euphrates River reached the sea east of the Strait of Hormuz. Along the At Taf this facilitated transport of exposed shelf sediments

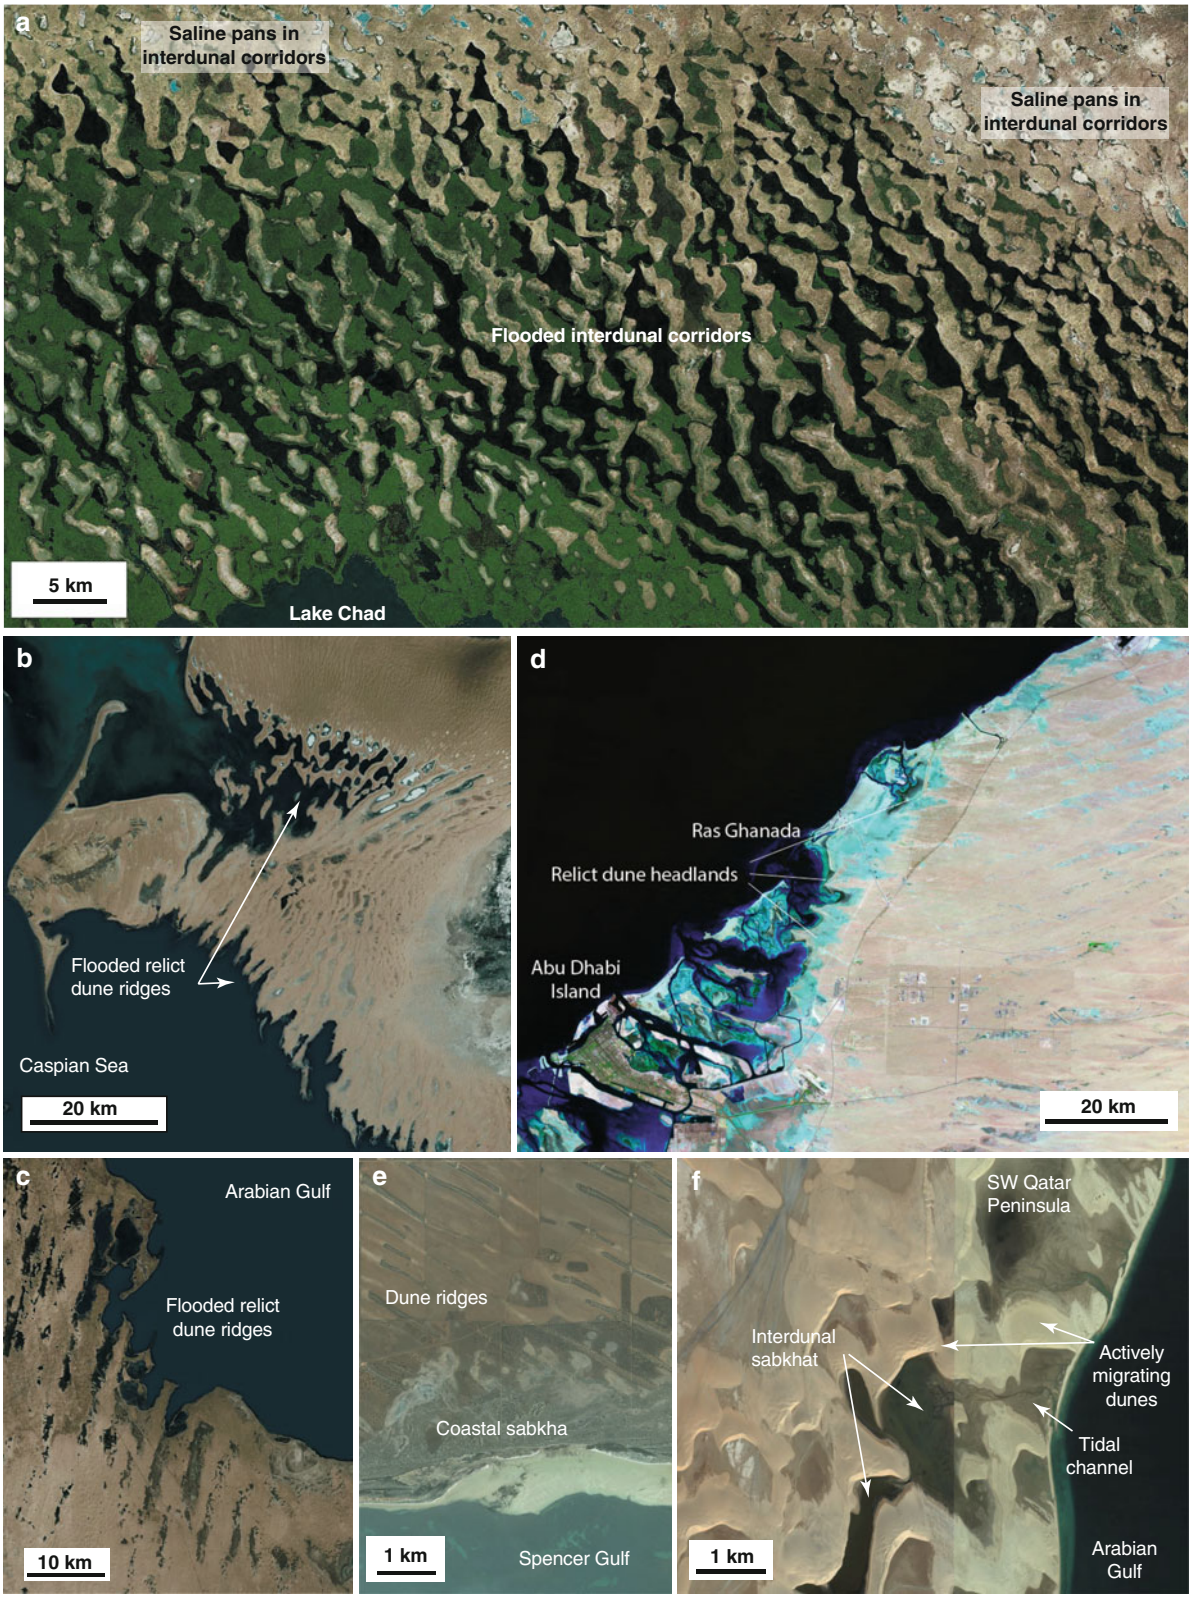

Fig. 3.64 Examples of modern eolian sabkhas created by lacustrine transgression or the Flandrian sea level rise and the encroachment of a groundwater wedge into what were formerly continental interdunal corridors. (**a**) Embayed sabkha pan-lacustrine coastline in the strandzone of north eastern Lake Chad, Chad. (**b**) Embayed sabkha-lacustrine coastline in the coastal zone south of Kora Bogaz Gol, Caspian Sea. (**c**) Embayed interdunal sabkhas in the coast in the Al Khawwari area, south of Munfah, Saudi Arabian coast of the Arabian Gulf. (**d**) Embayed sabkha-lagoonal coastline in the coastal zone between Abu Dhabi and Ras Ghanada, UAE. (**e**) Interdunal seepage sabkhas near Lucky Bay, Spencer Gulf, South Australia. (**f**) Marine-fed interdunal sabkhas in an active Shamal-driven dunefield migrating to the Arabian Gulf in the southeast coastal zone of the Qatari Peninsula (Bing® images mounted and scaled in MapInfo®) See Fig. 3.63 for location of Arabian Gulf examples

into a series of E-W trending seif dunes and draas (Fig. 3.63). Then, between 12 and 6 ka, the sea transgressed more than 1,000 km to fill the formerly subaerial Arabian Gulf and in so doing cut off the supply of eolian sand to the dunes of the At Taf (Trucial Coast). At the same time the rising watertable and the encroachment of the Flandrian seashore converted the present day coastal area from an eolian-dominated system to the Holocene coastal sabkhat documented earlier in this chapter.

Today the lagoon-sabkha system between Abu Dhabi and Ras Ghanada shows broad-scale E-W curvilinear trends that are partially truncated by marine encroachment, so that sabkha-lined dune-cored spits now protrude into the lagoon (Fig. 3.64d). To the south, similar now sabkha-covered dune ridges constitute the core to the elongate trend of the Abu Dhabi and Al Du'yybaya spits. In fact much of the classic sabkha coast of the southern Arabian Gulf shows broad scale thickening patterns in the base of the Holocene section that indicate an initial relatively low energy passive marine encroachment into interdraa depressions that facilitated the partial preservation of the dune form (Warren 1991; Kirkham 1998).

Yet another coastal association of somewhat low-energy marine encroachment onto interdunal ridges is clearly seen on the northwestern coast of Spencer Gulf, South Australia (Fig. 3.64e). In this case the encroachment was more energetic than on the Saudi coast. Many of the coastal sabkhas behind the Lucky Bay shore lie parallel to the coastline in an area immediately in front of relict seif dune ridges. The dunes were last active in the Late Quaternary and subsequently the most seaward quartzose dune sand ridges were reworked into coast-parallel beach ridges. Hence, the most seaward portion of the sabkha flat shows a coast parallel orientation. It changes to a more obvious interdunal orientation a little further back from the coast.

According to Eschner and Kocurek (1988) and Fryberger (1986), the geometry of preservation of an eolian dune system when undergoing transgression and possible encasement by an evaporite seal, is classifiable into inherited, reworked, and/or erosional dune morphologies at the contact with the sabkha evaporite (Fig. 3.65a, b). Reworked dune relief, a preservation style which shows significant destruction of original dune topography, but with remnants preserved, is the most typical situation when an erg experiences marine encroachment or transgression in both the modern and the ancient. Modern examples include relict dunes of coastal Australia and the Arabian Gulf (Fig. 3.64), ancient examples include marine-transgressed parts of the Jurassic Entrada Sandstone of the San Juan basin, and the Pennsylvanian-Permian Minnelusa Formation of Wyoming (Fig. 3.65b; Vincelette and Chittum 1981; Achauer 1982).

Eschner and Kocurek's modelling was done based on Holocene analogs and prior to our current understanding of the hydrological requirements needed to create platform and basinwide evaporite seals. We now know that most laterally extensive marine evaporites are seepage fed systems that form when a basin is hydrographically isolated and that there are no modern same-scale marine analogs for this hydrology (Chap. 5). The corollary is that in any ancient drawdown saline basin filling with subaqueous salts, the system will tend to have strandzones that transgress on adjacent sand seas in the same fashion as occurs in modern lacustrine settings, like Lake Chad and the Caspian Sea, whereby the relief of the dune tends to be preserved (plotfield indicated by rectangular outline in Fig. 3.64c). Transgressing brines in an ancient evaporite basin are an inherently lower-energy system compared to open-ocean facing coastal settings. This is why inherited dune morphologies tend to be preserved below evaporite seals (Weissliegend and Entrada sands beneath Zechstein and Todilto seals, respectively; Figs. 2.61a and 3.65b).

With thicker evaporite seals to the preserved dune morphology, the base of the seal tends to be a sabkha cement, hosted in the dune sands or its reworked equivalent, which in turn passes up into subaqueous evaporitic carbonates and salts of the evaporite proper. Initial cementation in the reworked dune sand carapace is typically due to capillary salts and so is tied to a shallow watertable. Hence, the most intense capillary cementation can be associated with interdunal rather than high dune positions in the landscape. This creates a carbonate/evaporite cemented carapace that is more resistant to erosion than mobile loose sands of the draa crests. Upon transgression, this can create an inverted remnant topography with the cemented carapaces forming higher parts of the beleaguered landscape and corridors of marine embayment preferentially entering and reworking the more easily eroded loose draa sands (Fryberger 1986). Remnants of this style of cementation beneath a platform or basinwide evaporite seal can give strong directionality to permeability and create fluid flow corridors in the upper parts of an eolian reservoir sand beneath the seal.

Whether inherited or somewhat reworked, how much dune relief is preserved in a marine transgression depends on the sand budget of the dunes and the erg, the degree of capillary cementation prior to transgression, and to the level of coastal energy in the transgressive environment (Fig. 3.65b; Eschner and Kocurek 1988; Fryberger 1986). Sand budget refers to the maintenance, gain, or loss of dune sand prior to and during initial transgression. Sand can be conserved and the dune form stabilized by vegetation, early capillary salt cementation, or a wind regime conducive to "sand trapping" by the dune as it is encroached by the sea (Eschner and Kocurek 1988).

Dune building and interdunal cementation can continue during initial transgression by maintenance of sand-drift paths, best accomplished by offshore winds, as seen today along the marine edge of southeastern Qatar (Figs. 2.58 and 3.64e). In contrast, dune forms can be degraded by deflation, a cutoff of the sand supply, and a variety of marine processes as is seen today along the At Taf coastal strip and the

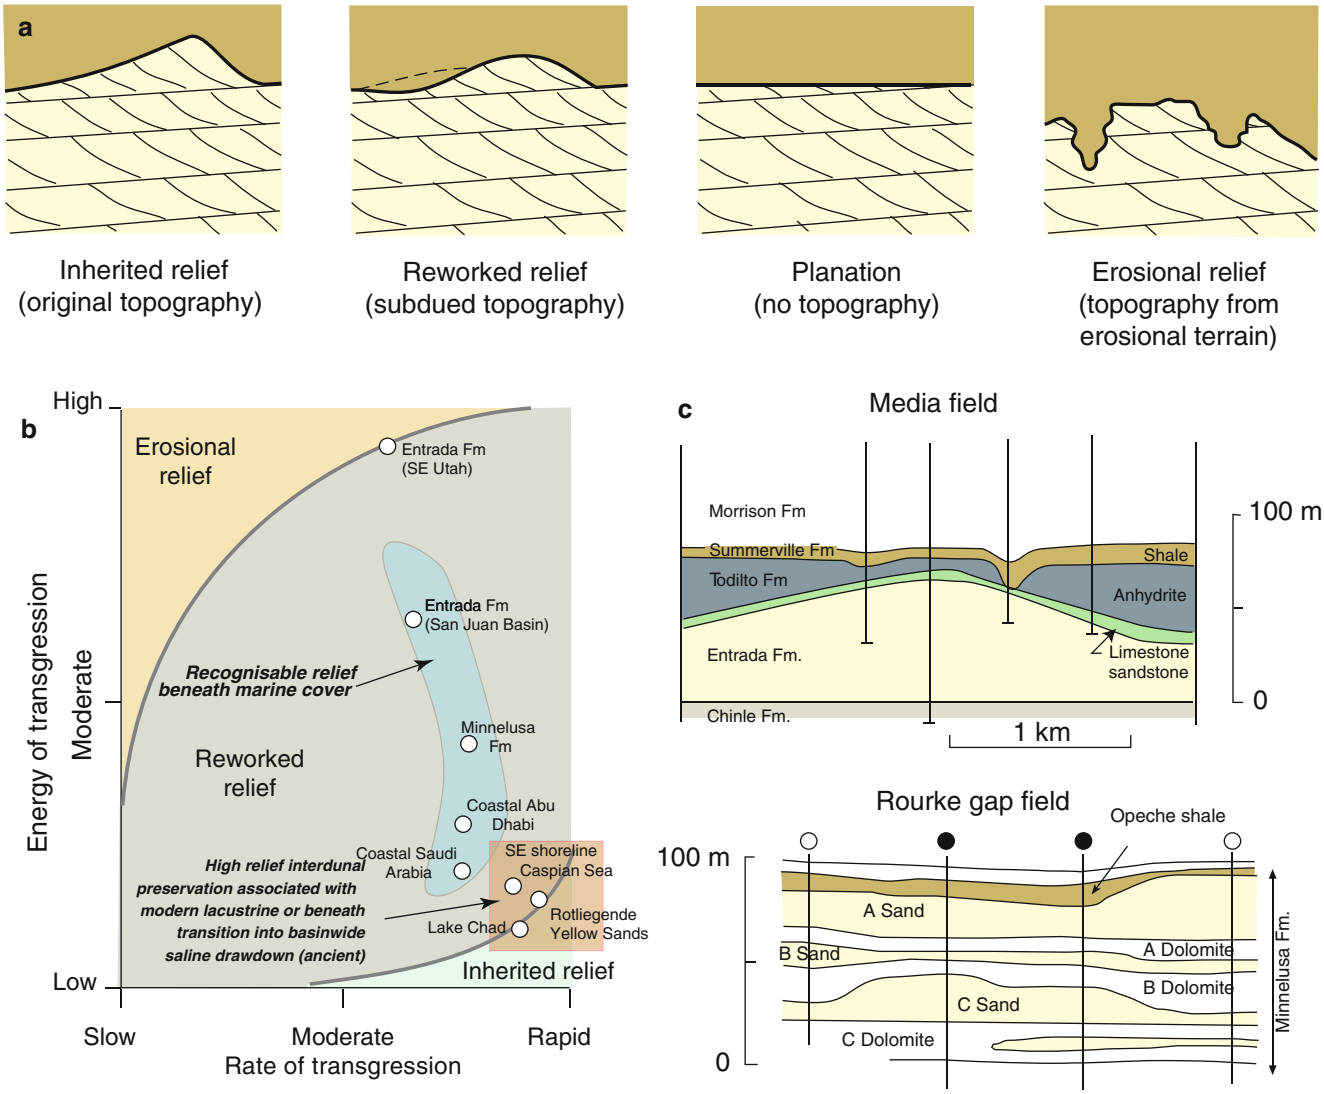

Fig. 3.65 Preservation of marine-margin eolian sabkha geometries. (**a**) Schematic of varying styles dune-sabkha contacts in transgressive marine-margin situations. (**b**) Controls on the preservation of relict dune topography during a marine transgression (**b**, **c**) in part after Eschner and Kocurek 1988). (**c**) Ancient dune-hosted oil field encased by an eolian sabkha seal (After Vincelette and Chittum 1981; Achauer 1982)

northern end of Sabkha Matti. Factors related to the nature of the transgressive environment and ultimate permeability in the reservoir sand include; (1) orientation of the dunes to destructive marine processes, (2) types of processes, (3) energy level, (4) type and rate of sedimentation, and (5) rate of marine encroachment (Eschner and Kocurek 1988).

Preservation of inherited to reworked relief requires that the dunes ridges become stabilized or remain active into the early phases of the transgression. Effects of destructive marine processes are minimized by; (1) resistant, early capillary saline cement in the encroached dunes, (2) an orientation of the dunes such that marine energy is dissipated along a minimum area of the dunes, (3) low-energy, non-wave-dominated transgressive marine environment and (4) rapid transgression that reduces the length of time for reworking, or by high rates of marine or evaporite sedimentation burying dune forms (Fig. 3.65b).

Sheets of Eolian Sabkhat

This style of eolian sabkha is not as widely documented as elongate interdunal sabkhas in modern settings. Yet modern examples characterise numerous continental interior situations where a rising watertable in a deflationary sand sheet creates conditions suitable for the preservation of eolian sabkhas. They tend to be geomorphologically stable areas in that within a yearly sedimentation cycle they experience less erosion or deposition than nearby dunes sheets. In fact, because they lie in a moist hydrological zone below the top of the influence of the shallow watertable, sheets of continental eolian sabkha tend to have much higher preservation

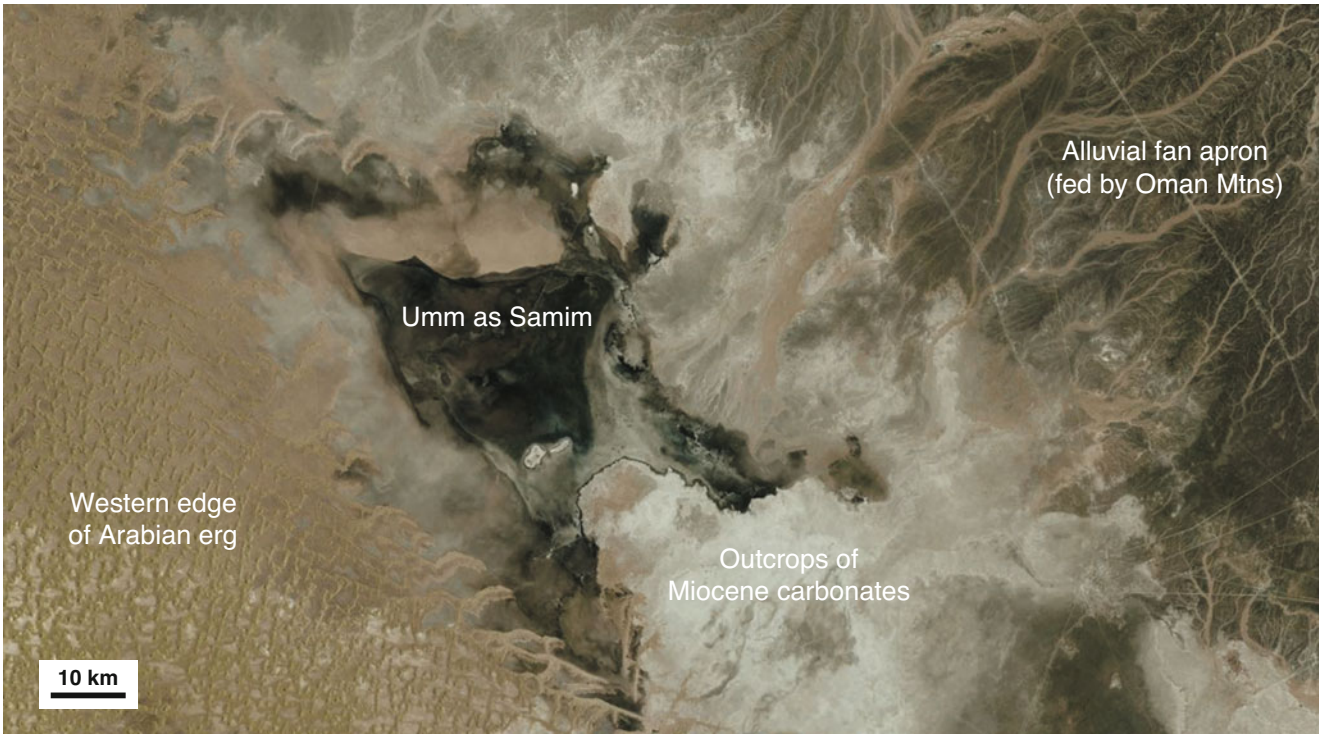

Fig. 3.66 Umm as Samim, occurs in a groundwater sump at the hydrological interface between the alluvial fans of the Oman Mountains to the east and the Arabian Erg to the west. Bing® image mounted and scaled in MapInfo

potential than most of the crossbedded sands of the dunes. The latter sit above the watertable and so have a tendency to blow on through (Fig. 2.62f). Eolian sabkha sheets lie beneath exposed surfaces with high rates of sand cross-drift, a direct result of their saline watertable-induced flat topography and lack of vegetation. That is, in sump regions of shallow desert groundwater the flat bedded eolian sabkha sheets with characteristic capillary salts and Stokes surfaces are preserved more often than cross-bedded eolian sand, which by definition is deposited in a vadose environment and subject to ongoing deflation.

Depending on grain size of sediment in the capillary zone and the time of the year, the surface of a modern eolian sabkha sheet can lie up to a metre above the regional watertable in the driest times of the year. Fluctuations in the regional watertable in ergs can lead to the deflation of gypsiferous inter-draa sabkha and the creation of an eolian gypsum component to the dunes. This is the case in the near coastal region of Saudi Arabia where deflation has formed gypsum lunettes along the deflated pan margin of the gypsum encrusted Sabkhat ad Danan (Fig. 3.16b; Barth and Böer 2002). Similar long term deflation of saline mudflats led to the downwind formation of extensive quartz dune fields as in the Late Pleistocene Chott Rharsa Basin of Tunisia (Blum et al. 1998) and to the growth of Holocene gypsum dunes along the edge of Lake Lucero in White Sands, New Mexico (Langford 2003).

Continental eolian sabkha surfaces can be accretional or deflational, depending on the availability of sand, subsidence rate and whether the watertable is rising or falling. Deflationary eolian sabkhas typically leave behind little more than an evaporite-cemented Stokes surface and so have little preservation potential. Modern deflationary sabkhas are commonplace occurrences at the arid endorheic ends of large areas of monsoon-fed fluvial drainages, as in the Kallakoopah interdunal sabkhas and pans north of Lake Eyre and Lake Frome. Both are examples of the ephemeral stream-dune field-ephemeral saline lake association, discussed earlier in this chapter.

Accretionary eolian sabkha sheets have higher preservation potential and tend to characterise areas where eolian and alluvial sediment is piling up within rising artesian saline groundwater and surface water outflow zones. Such conditions are typically found at the foot of mountain ranges with sands piling up at the base of the fan or in arid continental regions characterised by subsidence (alluvial fan-ephemeral saline lake association). This is the case at Umm as Samim ("Mother of Worries") sabkha in Oman, which is fed sediment from dunes to the west alluvium from the Oman Mountains to the east and groundwater from the limestone aquifers of the Tertiary Umm Er Radhuma Formation to the east and south (Fig. 3.66).

At around 3,000 km^2 in area (55 m elevation, BWh) Umm as Samim is one of the largest sabkhas on the Arabian

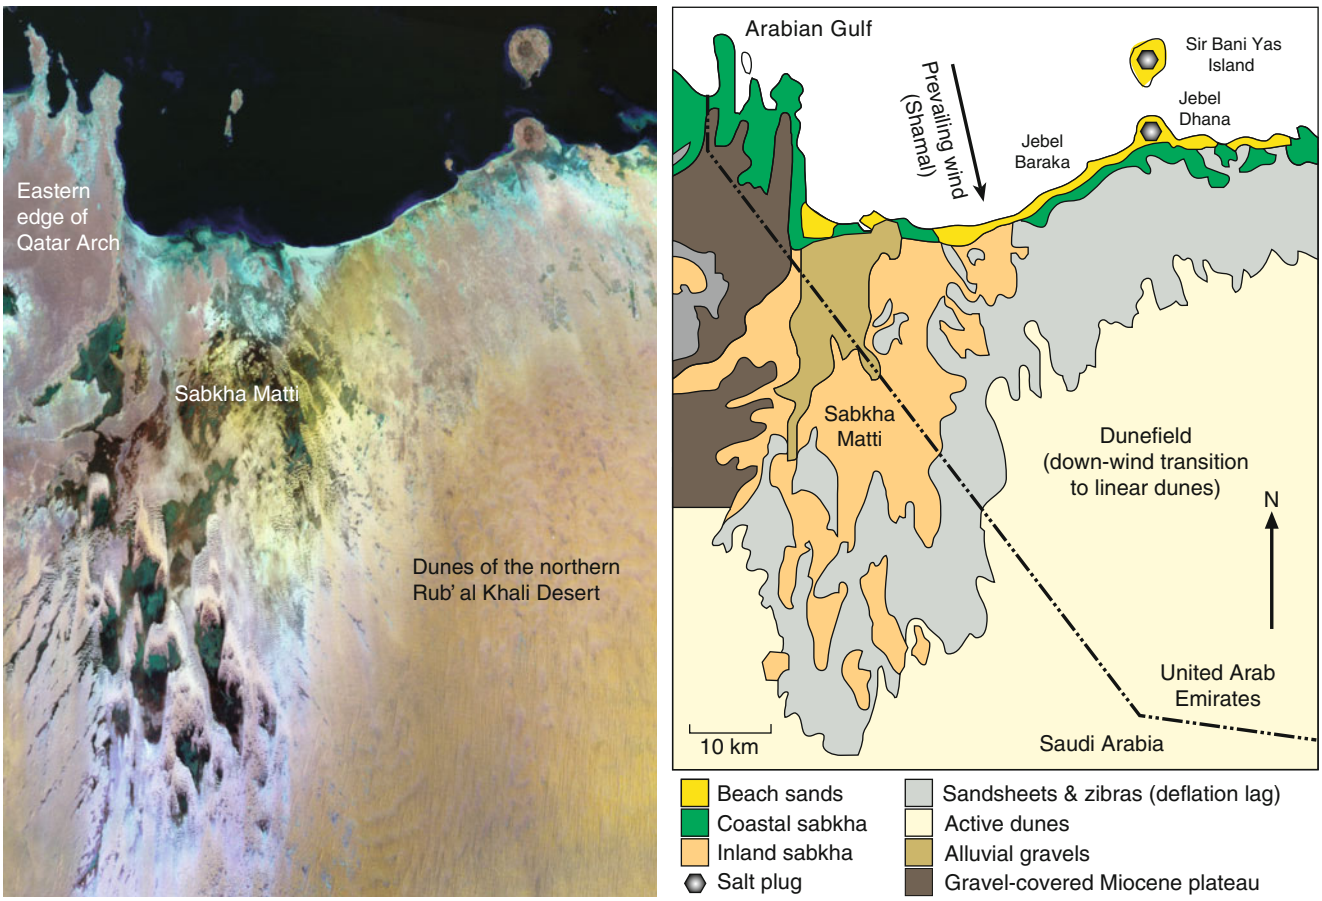

Fig. 3.67 Sedimentary facies in Sabkha Matti, and inland sabkha in the southern central Arabian Gulf (in part after Alsharhan and Kendall 2003; Landsat image courtesy of NASA)

Peninsula. It forms a groundwater sump along the boundary the eastern edge of the Arabian erg and the alluvial fans to the east, with many widyan draining from Al Hajar (Oman Mountains). Wadi Aswad, Wadi Musallim, Wadi Majhul, Wadi Umayri and Wadi Haliban all periodiaclly feed the Umm as Samim sump. Units hosting Holocene capillary salts are typically less than a few metres thick. Today, the water source is dominated by alluvial seeps, but prior to 6,000 years ago it was a much less saline hydrology (Heathcote and King 1998). Then the sump was a perennial lake. The initial closed sabkha depression or playa formed via deflation in the gypsiferous 'Fars Group' sometime prior to 30 ka BP. During the Late Pleistocene, from 30 to 20 ka, this closed depression became a saline lake, and fluvial flow brought in detrital silt and clay. A drier climate prevailed from 20 to 15 ka and the lake changed to a sabkha. Wetter conditions returned towards the end of the Pleistocene, from 15 to 12 ka, and a perennial saline lake was re-established, whereby halite was dissolved but gypsum still remained. In the interval from 12 to 9 ka, sabkha conditions were again established with deposition of displacive gypsum and minor halite in a sandy matrix. During the Early Holocene wet phase, from 10 to 5.5 ka, a saline lake formed again, only to terminate in the arid capillary gypsum/halite conditions from 5.5 ka to the present-day (Heathcote and King 1998).

Likewise, in the region of subsidence that defines Sabkha Matti groundwater sump, capillary salts (gypsum and halite) are growing in inland sabkha zones where shallow water-tables occur across large expanses hosted within deflationary eolian sand sheets (Fig. 3.67; Goodall et al. 2000). Coast-parallel supratidal salt flats of the marine margin sabkha grade southwards into inland flats of the continental eolian sabkha of Sabkha Matti with no distinct break in surface topography. The inland sabkha (BWh), with an area of 2,950 km^2, extends southwards for about 150 km and, in this distance, the land surface rarely rises more than 40–60 m above sea level (Fig. 3.67). There is little information available on rainfall for the inland areas of Sabkhat Matti, but measurements taken on the coast show that average annual rainfall is less than 40 mm and further inland it is less.

Like the Rann of Kutch, Sabkha Matti occupies a former fluvial valley that in the Miocene was a fresh water river system. Goodall (1995) reported OSL/TL ages of 5.9 ± 0.5 and ≈ 208 ka on aeolian sands, and 40 ± 2.7 and 147 ± 12 ka

on fluvial sands that host the sabkha salts of Sabkhat Matti. Today the region of saline mudflats is a groundwater sump to the Qatar Arch and defines the margin to a modern accretionary eolian sabkha sheet and so is adjacent to a set of dry mudflats and sand sheets. This in turn passes downwind into an active sand sea (Rub Al Khali portion of the Arabian Erg) that is ultimately piling up sand at the foot of the Oman Mountains (Fig. 3.63).

Evaporation of occasional ephemeral brine sheets forms and reforms the salt crust, which for most of the year covers large areas of Sabkha Matti. Somewhat thicker salt crusts (1 ± 5 cm), with large megapolygonal pressure ridges characterise the Sabkha Matti surface situated within 5–10 km of the modern coast. Further inland the Sabkha Matti surface is characterised by thinner salt crusts (≈1 cm) and smaller, lower-relief, pressure ridges, along with more numerous blisters and petees interacting with windblown sediments to form characteristic haloturbated structures (Fig. 1.46a; Fryberger et al. 1979; Goodall et al. 2000).

The surface of the sabkha-hosting sand sheet of Sabkha Matti is planed by wind action (Stokes surface). Internally the eolian sabkha sheet consists mostly of low-angle eolian stratification (cm-scale laminae) created by migrating ripples and grainfall that can be altered by ongoing haloturbation. Quartz sand fills the saucers between eroded salt ridges and locally gives the Sabkha Matti surface a "leopard-skin" appearance (Goodall et al. 2000).

This "leopard-skin" terrain is most obvious in the landward sabkha region behind the coastal sabkha. Its slightly reddened appearance is emphasised by a characteristic hummock and hollow relief of up to 1 m (Kirkham 2011). Within 50 cm of the surface, hummocks are typically underlain by concentrations of fibrous halite, gypsum and palygorskite. In some areas selenitic and fibrous gypsum veins protrude onto and crosscut the leopard skin surface. Near the centre of the larger depressions on Sabkha Matti there are artesian gypsum mounds (aka gypsum volcanoes) made up of concentric gypsum cones, some 50–80 cm across, typically with hollow cores to the centripetally aligned crystal rims They are likely artesian features and texturally near-identical to modern gypsum spring mounds that typify the early Holocene margins of the Dallol Depression (pers. obs; Chap. 11).

The end result of ongoing wetting and drying in the sandsheet host is a highly disturbed sheet-like body of sediment entraining a variety of distinctive sedimentary fabrics. Formative processes range across salt-growth sediment deformation, salt-solution sediment collapse, sediment aggradation and compound mixtures of these processes. Salt-crust processes also produce features that may be confused with eolian adhesion structures (Goodall et al. 2000).

Elsewhere in Saudi Arabia, modern accretionary sabkha sheets define groundwater sumps adjacent to zones where eolian dune sediment is accumulating. As in Sabkha Matti and Umm as Samim, these regions tend to be located near zones of alluvial sediment supply (reworked fluvio-lacustrine sediment) and regions where shallow groundwaters abut actively encroaching sand seas, often in association with ephemeral river breakout through the dunes. Unlike Umm as Samim and Sabkha Matti the much smaller Sabkhat Umm Ash Shuraybat (75 km^2; BWh), an hour's drive southwest of Dammam in Saudi Arabia is one of the more accessible areas to study capillary processes in action in dune flats and accretionary eolian sabkhat located at the edge of a sand sea. It defines a zone of aggrading sabkha sedimentation subject to occasional floodwater ponding adjacent to a sand sea and like Samim and Matti it was a region of fresher water ponding in the Late Pleistocene and early Holocene (Figs. 3.16a and 3.68a).

The dunes fields are still active and form a cover to the aggrading outflow zone of a regional artesian aquifer. The dunes also store waters from rare periods of heavy rainfall. Because of this, the watertable intersects the edges of some dunes where oases form. Oases define areas where local fresher water seeps support a halophyte fringe and with evaporation also precipitate the salts of the adjacent sabkha sheet. Spring mounds, cyanobacterial blisters and petees dominate in the seepage zones immediately downstream from the outcropping watertables that define the edge of the dunes (Fig. 3.68b). In places the seepage waters are fresh enough to support a flourishing biota of ostracods and brine shrimp (pers. obs.). Away from the seepage zone the accretionary eolian mudflats (a combination of desert loess and fluvially-supplied sediment) host displacive capillary gypsum, identical in morphology to that described for the coastal sabkhas of Saudi Arabia. Further down the fractionation trend in Sabkhat Umm Ash Shuraybat, the saline waters pond in the lower parts of the depression and have precipitated stacks of saline pan halite crust (Fig. 3.68c). The resulting halite beds are up to 4 m thick and layered at the decametre scale by thin laminae and partings of clay and anhydrite (Collenette and Grainger 1994).

In addition to its currently active eolian sabkha/pan the Umm Ash Shuraybat area preserves evidence of a late Pleistocene-early Holocene river, which flowed into the Gulf but is now largely covered by dunes. Ephemeral streams, which follow remnants of this old channel, still flow into the dunes as periodically water-filled channels before being dammed by the dunes. Ponded water is then lost to the dunes via seepage. Historically, there is no record of the main stream channel breaking through the dunes to the coast in this region, although the satellite imagery suggests this may have happened sometime in the last few thousand years.

Better documented examples of catastrophic breakout of flooded rivers through an erg to the sea can be seen in

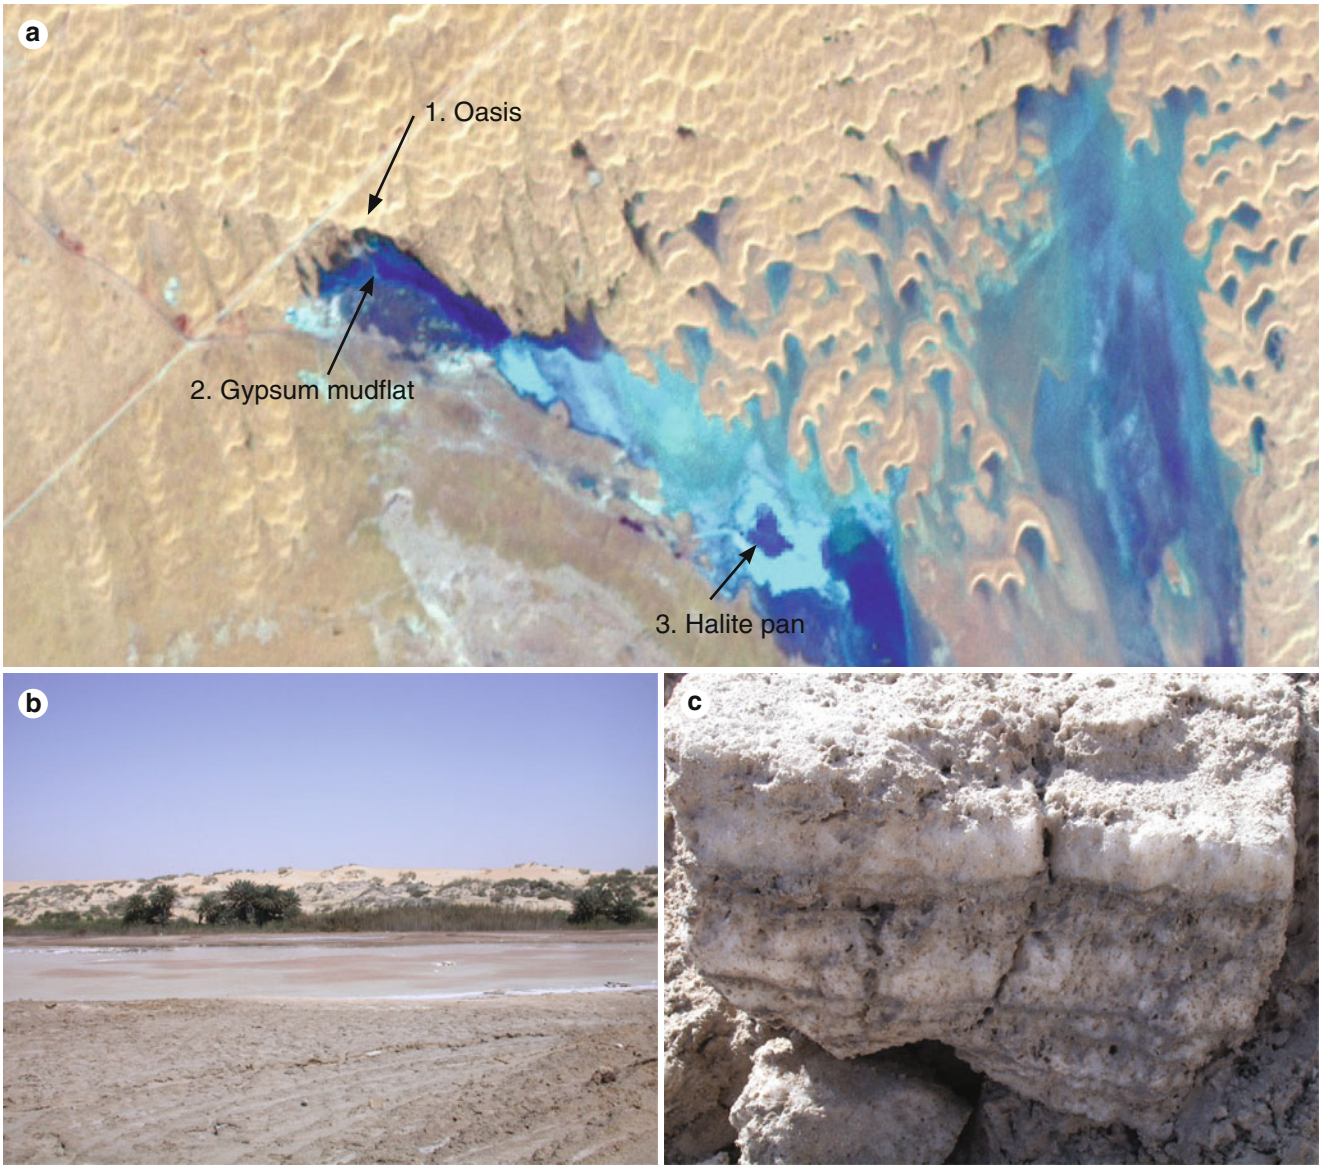

Fig. 3.68 Sabkhat Umm Ash Shurabyat, Saudi Arabia (Fig. 3.16a for location). (**a**) General location of the sabkha at the edge of the dune field clearly shows the position of the intersection between landscape and dune watertable at position 1 where fresh to brackish phreatic water held in the erg seeps into the sand flat margin to create an oasis (position 1 as seen in Fig. 3.67b). (**b**) View from puffy ground atop gypsum mudflat (eolian sabkha) and looking north toward oasis at the edge of the sand sea. (**c**) Stacked saline pan halite facies with eolian silt laminae. Sample was extracted from position 3, each pan halite layer is between 5 and 10 cm thick

Namibian ergs of the Skeleton Coast of southwest Africa (Svendsen et al. 2003). Evidence of periodic flooding, ponding and occasional breakout of a stream channel into any dune field is a number of clayey fluvial lenses in the interdunal corridors, which then act as a host for capillary sabkha salts. Such elongate or interdunal geometries fed by streams and deposited in corridors dominated by interdunal fluvial and carbonate marls (pedogenic), have been documented in the Permian sandstones of Utah and Colorado (Driese 1985) and in Tertiary "oases" in the Namibian desert (Smith and Mason 1998).

It seems that some ancient counterparts of continental eolian sabkha sheets are preserved in regions where little or no crossbedded dune sand is preserved; these sheets do not show the elongate interdunal geometries that much of the literature seems to require for an eolian sabkha interpretation. Rather, they possess a sheet geometry associated with capillary evaporite-cemented and haloturbated muddy sands accumulating in large erosionally-capped flatlands (Figs. 2.62f and 3.65a). Their sheet-like distribution is the sedimentary response to their watertable-capillary zone origins. Such sheet-like eolian sabkha systems typify the flat-topped depo-

sitional geometries of the Permian Yates Formation reservoir sands of west Texas and portions of the reservoir sands of the Rotliegende Formation in the northern Netherlands (Chap. 10). It is also the case for muddy sand sheets in parts of the Lower Triassic Sherwood Sandstone Group of offshore NW England (Cowan 1993; Herries and Cowan 1997) and parts of the Lower Permian Rotliegende Group in the North Sea (Goodall 1995). In the North Sea examples, which are offshore reservoirs for gas, the change in understanding of the origin of these facies from fluvial shoestrings to haloturbated sand sheets has had profound implications in planning for the exploitation of the entrapped gas.

This is not to say all evaporite-cemented intervals in eolian reservoir sands beneath an evaporite seal are preserved eolian sabkha caps. But sabkhas will be a commonplace signature of the transition from a completely isolated continental basin into the outcropping hydrology required for widespread evaporite deposition. The limited fetch of hydrographically isolated evaporite seaways, the widespread capillary cementation in the strandzone and across the basin at the onset of evaporite accumulation, along with the consequent low energy of the transgressing hypersaline water edge, will tend to better preserve dune topography. There will be less high energy coastal reworking of sediment compared to a marine transgression into a sand sea (Fig. 3.65b). Excellent examples are preserved in the transition from the Rotliegende-Weissliegend into Zechstein evaporites in the Permian Basin of NW Europe and in the transition from the Jurassic Entrada into the Todilto evaporites in the San Juan basin of the USA.

In summary, eolian sabkhas are a response to areas of shallow subcropping watertables within or about the edges of continental sand seas (ergs). The matrix for the displacive evaporite growth comes from the sediments of the dunes blown onto the areas of shallow subcropping watertable, or is supplied by fluvial processes periodically cutting through a sand sea. In many cases the geometry of the eolian sabkha is not an elongate shoestring or interdunal trend. Rather the capillary salts accumulate in areas of shallow watertable in aggrading sand/mud sheets. Thus, in the rock record, narrow (1–2 km) elongate interdunal eolian sabkha trends have much lower preservation potential than areas of capillary cementation in eolian sand sheets (>5–10 km wide) accumulating in regions of rising watertables (Chap. 2). A rising watertable can be driven by subsidence, changing climate, or by a rise in the regional hydrological base level driven by sea level rise. In these situations the eolian sabkha is more likely to be deposited as the evaporite-cemented portions of a sand sheet with textures dominated by adhesion ripples and haloturbation rather than by preserved salts. High watertables and high salinities in "wet" or chemically-dominant sabkhas can induce widespread early cementation, which through its retention or dissolution may control lateral variations reservoir quality in ancient counterparts. Episodes of deflation during the aggradation of the eolian sabkha are indicated by "Stokes surfaces," which are often preserved in ancient eolian counterparts (Newell 2001).

Salt-Pans (Marshes) and Diapirs

So far, we have discussed the various pans and sabkhas in a hydrologic framework of endorheic depressions, with the topography doing little more than supply the gradient to an arid groundwater and crating the hydrographic sump. But there are also a few modern deserts where the drainage topography is not passive, rather it is salt-cored and replenished by halokinesis even as the diapiric salt is simultaneously recycled into salt encrusted depressions. Earlier in this chapter in the various South American salars, such as Salar de Uyuni and Salar de Atacama we saw a more passive mode of diapiric supply whereby ions derived from the dissolution of at-surface diapirs supplied significant volumes of ions (along with weathered acid volcanics), to the groundwater as it seeped into saline sumps floored by hardrock basement. But in parts of the Iranian interior, centred on the Kavir and Lut deserts located north of the Zagros Mountains and south of the Alborz Mountains, the role of the diapirs in controlling the drainage and groundwater network is much more active. There the diapirs and their namakiers create the landscape, the drainage patterns and supply ions to various suprasalt groundwater sumps so that recycled diapiric salt (Miocene) accumulates in salt-rich Quaternary playas atop suprasalt rim synclines (Fig. 3.69).

The region is known as the Dasht-e Kavir or great salt desert; it is some 800 km long and 320 km wide, located southeast of the Alborz Mountains in north central Iran. It is a huge saline desert basin with endorheic drainage and named after the large kavirs (salt marshes) that characterise salt-floored depressions in the landscape. The Kavir Buzurg (Great Kavir), some 320 km long and 60 km wide, constitutes the lowest part of the desert depression. It lies in a rain-shadow desert that is almost rainless. Strong surface evaporation in the salt marshes and wet saline mudflats in the lower regions of the kavir sump precipitates stacked crusts of pan and capillary salt with a high proportion of the ions in the crusts coming from the dissolution of nearby diapir crest. The ease of breaking through the surface salt crusts into hot dark saline mush beneath makes travel across the kavirs quite dangerous. The kavir's aridity and hostility means it is almost uninhabited and only partly explored; human settlement is largely restricted to the hills and mountains surrounding the kavir. Extending south from the Dasht-e Kavir is the Dasht-e Lut, which is a more typical sand and stone desert, some 480 km long and 320 km wide. It is dominated by dry mudflats and sandflats with extensive sand dunes and

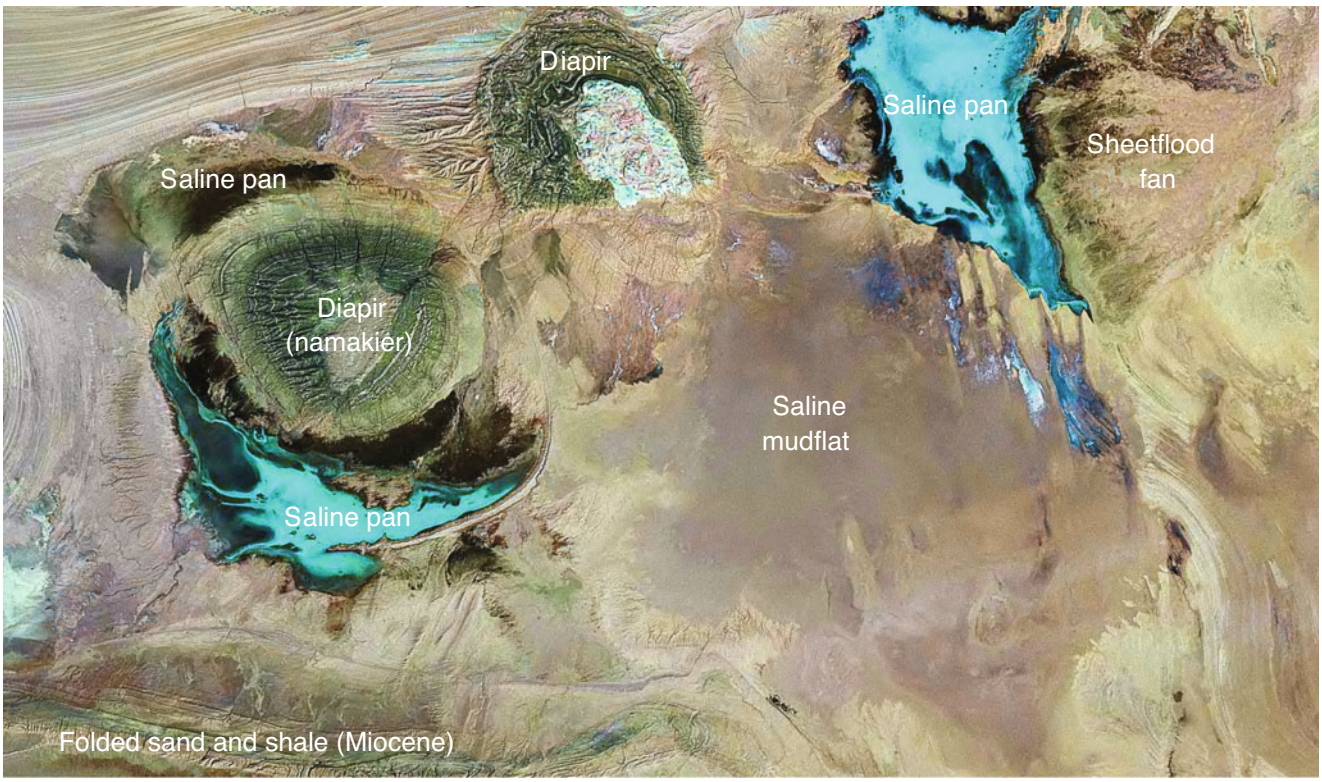

Fig. 3.69 Diapirs composed of Miocene salt pierce the surface of the Great Kavir, Central Plateau of Iran (see also Fig. 6.13). Salt is dissolved from the diapir crest and redeposited in a saline pan facies in the rim synclines created by salt withdrawal adjacent to the diapir crest. (Diapir on the left is diapir No 10 in Jackson et al. 1990; Image courtesy of NASA)

deflationary lag plains. Together the two deserts occupy most of the central Iranian plateau.

Salt in the various active diapirs that have surfaced in the Kavir plateau of Iran is much younger (Lower Oligocene-Miocene) than the Hormuz namakiers of SE Iran (Figs. 6.90 and 6.91). This part of North Central Iran is undergoing north–south shortening between the Alborz mountains in the north and the Zagros mountains in the south (Talbot and Aftabi 2004). Diapirs tend to emerge along releasing bends that have been pulled apart along major dextral transpressive faults in the central plateau of Iran. These structures include the small but mature salt fountain of Kuh-e-namak (mountain of salt in Farsi) near the holy city of Qum. This is probably the salt mountain best known to most Iranians because it dominates the western skyline of Qum, the religious capital of Iran some 140 km SSW of Tehran. It is probably the best described namakier and brief descriptions of Qum Kuh are given in Gansser (1957), Richter-Bernberg (1980), Aghashahi and Zomorodian (1981) and Jackson et al. (1990), with a more detailed analysis by Talbot and Aftabi (2004). Qum Kuh is of economic interest as centimetre to decimetre thick beds of sylvinite (KCl ± NaCl) are interbedded with the halite and repeated by folds in the extrusion.

The shapes of these extrusions of Tertiary salt indicate that they have followed a history similar to that of extrusions of the older Hormuz salt in the Zagros (Fig. 6.87). Gansser (1957) and Jackson et al. (1990) noted that salt deformation in the central Iranian Plateau involves two Tertiary-age salt sequences: a clean white salt at the base of the ductile marls and shales of the Lower Oligocene Lower Red Fm, and a rhythmic sequence of multicoloured salt at the base of the salty marls of the Lower Miocene Upper Red Fm. These two salt sequences are generally separated by limestones of the Qum Formation, which according to Talbot and Aftabi (2004) tend not to surface in emergent salt structures.

Influence of the diapir-induced topography is clearly seen in the position of the various modern saline pan facies, which tend to stack in the lows atop secondary rim synclines adjacent to outcropping salt ridges of the diapir high (Fig. 3.69). The dissolution of this Miocene salt supplies most to the salt accumulating in the depressions. Further away from the diapir crest is the saline mudflat interval, which tend to dominate atop turtle-structure anticlines. Based on the Landsat imagery this mudflat succession is topographically higher than the sump of the saline pan floor, arguing that the zone of maximum salt withdrawal (indicated by maximum subsidence at the landsurface) has migrated progressively closer to the stem from the position of the original primary rim syncline (see Chap. 6 for a discussion of topography associated with diapirs and turtles).

Although as yet poorly documented, the sedimentology of this diapir-cored landscapes offers an excellent modern analogue for syndepositional responses to halokinetic highs such as those that once characterise the salt beds of the Triassic Kueper Fm. in Germany and the Cretaceous Maha Sarakham Fm. of Thailand. (Mohr et al. 2004; Warren 2000c, 2008).

Why and Where of Sabkhas & Pans?

Now that the detail of depositional variability of sabkhas and saline pans has been outlined using documented Quaternary examples, it is useful to go back to examples given in Table 3.1 and Fig. 3.1 and place them in a broad geographic, climatic and latitudinal framework. Figure 3.70a, b plot all the listed examples as climate-coded crossplots of area versus elevation and area versus latitude. Plots of documented sabkhas in their climatic framework lead to the following general conclusions at the world scale.

1. Latitudes tied to Hadley atmospheric cell (15–40°) encompass all of the larger Quaternary sabkhas and pans.
2. Most documented sabkhas, located in BWh climate zones (hot arid deserts), are situated near or below sealevel, including the Rann of Kutch (the largest example). The next most common sabkha climatic grouping is the BWk grouping (hot arid steppe) encompassing a range of areas and elevations
3. With the exception of Tuz Golu in Turkey, all of the sabkhas and pans with areas of more than 200 km are located in hot arid deserts. That is, sabkhas and pans located in desert steppe and Mediterranean climates tend to be smaller.

Subaqueous Salts: Salinas and Perennial Lakes

4

Introduction

Ancient shoalwater platform (saltern) and deepwater (slope and basin) evaporites are dominantly subaqueous precipitates, and, as for the mudflats and pan settings discussed in the previous chapter, when we seek equivalence in the Quaternary record we find our marine-fed choices are limited both in number and scale (Fig. 4.1; Table 4.1). If we consider all nonmarine and marine saline perennial water masses in modern systems as suitable for discussion in this chapter then, as well examples of larger saline perennial lakes, such as Great Salt Lake and Lake Urmia, we must include the feeder-edge brine pools to some larger saline pans and lakes, such as pools or moat facies to lakes Magadi and Natron, and some centripetal depressions to the Turkish lakes such as in Acigolu. In Chap. 12 subaqueous cryogenic continental examples discussed include Karabogazgol and various mirabilite lakes on the Canadian plains. I also arbitrarily split out of this chapter some examples of the larger continental saline pans with feeder pools. This latter group, including most of the South American salars, were discussed in the preceding chapter. Following a similar reasoning, if the bulk of the Holocene column in a lake is dominated by subaqueous textures, then I include it in this chapter, even though Holocene aggradation has moved uppermost part of the Holocene column into a sabkha setting, as in many modern gypsum-filled coastal salinas in southern and western Australia.

Index of localities in this table run from west to east in Fig. 4.1

As explained in Chap. 5, there are two main reasons for the scale dichotomy between examples of marine-fed Quaternary and ancient marine subaqueous evaporites. First, we live on an icehouse earth, characterised by climate-driven high-amplitude high-frequency changes in sea level. In marine settings this glacially-driven eustatic style forms small-scale coastal ponds and mudflats, with limited preservation potential. Widespread marine seepage-fed platform evaporites that dominate portions of the ancient record simply do not form nor could they be preserved in this hydrology. Periplatform evaporites require the hydrological stability associated with much gentler sea level fluctuations that characterises greenhouse earth climates. Second, there are no sizeable areas on the world's surface today where the appropriate combination of tectonics and climate have hydrographically isolated and desiccated whole ocean basins and so turned them into subsealevel seepage-fed marine basins (these platform and basinwide settings are discussed in Chap. 5).

What we are left with today as depositional analogs for ancient marine subaqueous systems (platform and basinwide) are transient, limited-scale sea-margin settings or somewhat larger high-relief continental saline lakes in closed intermontane basins (Table 4.1). Neither setting approaches the scale nor the subsealevel hydrographically-isolated hydrology that defines most ancient marine-fed systems. To form a permanent body of saline water in the Quaternary, with a lateral extent of more than a few tens of kilometres, with salt beds accumulating to thicknesses of more than a 50 m, today requires a high relief tectonically-active continental closed basin. It needs a landscape and a hydrology characterised by subsidence of the lake floor and the maintenance of a longterm brine or reflux plume (brine curtain) within and beneath the accumulating salt beds (Warren 2010).

Until the 1970s most subaqueous evaporite textures had been documented in ancient halite-rich basins (e.g. Dellwig 1955) and very few examples of Holocene subaqueous gypsum or halite deposition had been published. Then Holocene subaqueous gypsum was documented in sea margin settings in Baja California, the Mediterranean, Southern and Western Australia and the Middle East (von der Haar and Gorsline 1977; Aharon et al. 1977; Schreiber and Kinsman 1975; von der Borch et al. 1977; Arakel 1980). This body of work led to a new understanding of the significance of laminar and bedded textures (both sulphate and halite), so that in the last 30 years many ancient evaporites, previously interpreted as sabkhas, have been re-evaluated and found to be combinations of a number of mostly subaqueous settings. In the last 20 years we have also documented the beginnings of a partial Holocene analogue for ancient deepwater evaporites via the ongoing hydrological transformation of the Dead Sea into a halite-accumulating perennial lake. So, let us now look at some modern examples of subaqueous evaporites, first in small coastal subsealevel (sea-margin) settings then in larger Quaternary lacustrine depressions.

Sea-Margin Subaqueous Salts

Modern subaqueous evaporites are forming today in shallow marine-fed coastal lakes or salinas around the edges of the Mediterranean, the Black Sea, the Red Sea and along the southern and western coast of Australia (Fig. 4.1). All these marine-fed coastal salina systems are subsealevel depressions, all lack a permanent surface connection to the sea (hydrographically isolated) and are supplied most of their solutes via seawater seeps or coastal spray. Within the coastal salina grouping, most of the salinas accumulating carbonate minerals (dolomite, hydromagnesite, aragonite) occur in milder Mediterranean or tropical climates, while the larger deposits of gypsum and halite are found in somewhat warmer arid deserts (Table 4.1)

Coastal Salinas of Australia

Holocene salinas occupy isolated depressions within Quaternary calcareous coastal dunes along the southern and western coasts of Australia (Fig. 4.2). Most depressions are filled, or are filling, with bedded subaqueous evaporites; some are filled with evaporitic carbonates (e.g. Coorong dolomite lakes and Sleaford Mere in Southern Australia, Lakes Clifton and Haywood in southwestern Australia), while others are filled by combinations of carbonate, gypsum and halite (Marion Lake, Lake Macdonnell and Lake Macleod complexes). Solutes in all the salinas are supplied by resurging groundwaters, no salina has a surface connection to the sea if subaqueous evaporites are accumulating. Seawater seepage, plus varying amounts of meteoric water, supply coastal salinas filling with gypsum or halite, while carbonate-filled salinas are largely supplied by resurging continental groundwaters. Winter temperatures typically reach 10–20 °C and rarely fall below freezing, summer air temperatures are often in the 30°s but can climb into the 40°s. The $CaSO_4$ phase in coastal Australia is always gypsum, not anhydrite, temperatures are not high enough, nor the basins saline enough, for anhydrite to be stable. Its lack tempts one to propose that primary sedimentary anhydrite only forms as a capillary salt in hot arid mudflats (thermalites?) and never forms as a subaqueous precipitate at the sediment-brine interface in nonhydrothermal waters.

The three salina styles – carbonate versus gypsum versus halite – can be separated using annual rainfall, an indirect measure of the degree of coastal aridity. Carbonate salinas dominate in the higher rainfall parts of the southeastern coast

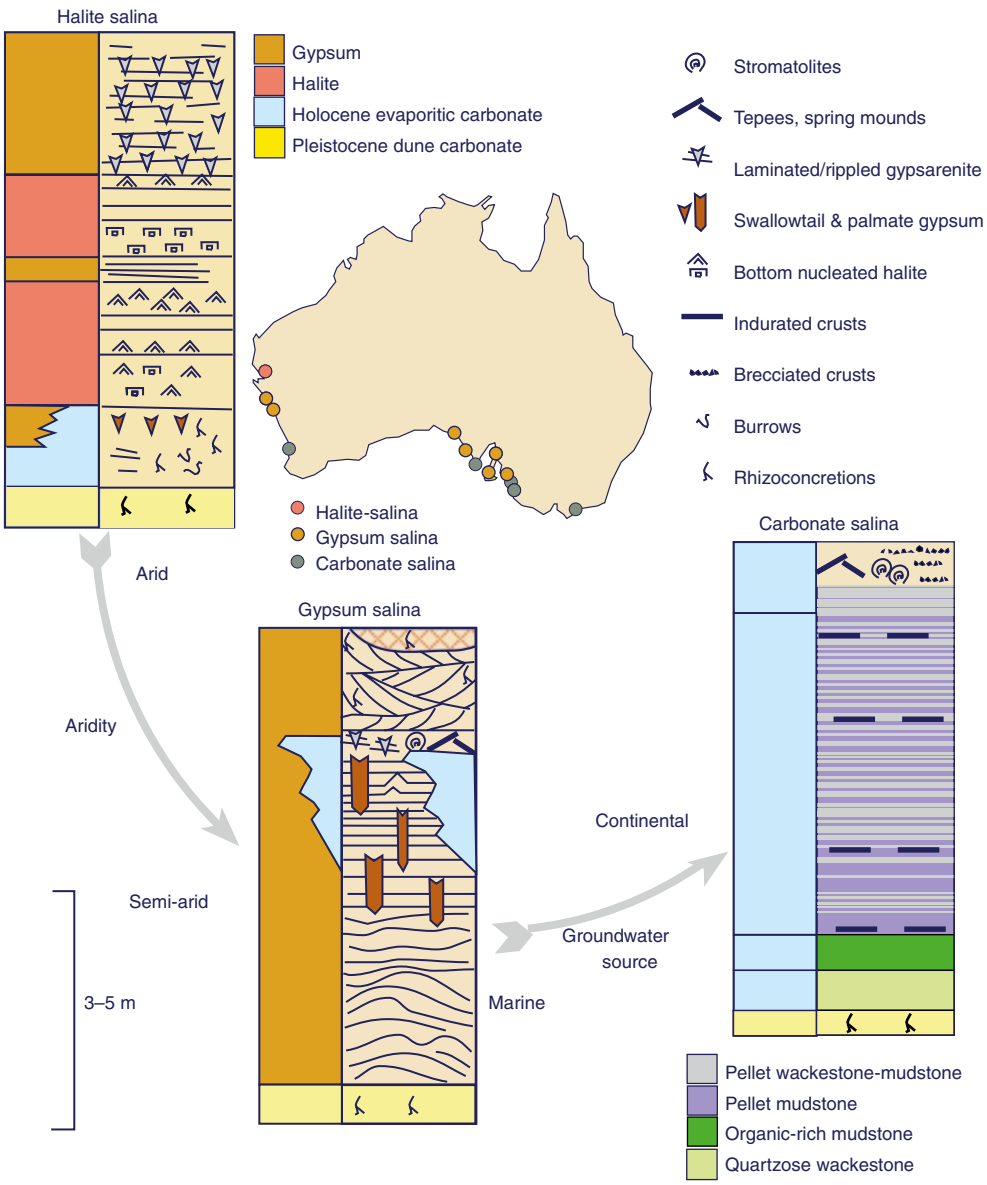

Fig. 4.2 Climatic and groundwater spectrum, textures and mineralogies in the Holocene coastal salinas of southern and western Australia (After Warren 1982a, b, 1990)

of South Australia and the southwestern coast of Western Australia, where annual rainfall is 450–800 mm. Gypsum salinas typically form best along the semi-arid southern Australian coast where annual rainfall is between 300 and 450 mm/year, while the halite-filled salinas such as Lake Macleod form in arid areas of the central western coast of Australia where annual rainfall is less than 300 mm.

Carbonate Salinas

The best documented and most voluminous carbonate fills of Holocene salinas, including some salinas filled with Holocene dolomite, are found in Pleistocene interdunal corridors behind the main Coorong lagoon in South Australia in Csb climate belts (Fig. 4.2). The modern coastal dune ridge (Younghusband Peninsula) and the adjacent Coorong Lagoon are the latest of a number of offlapping highstand beach-dune ridges and lagoons that have typified the slowly uplifting southeastern coastal zone of South Australia since the Pliocene (Fig. 4.4; Schwebel 1983; Warren 1983b). Dolomite and other lacustrine carbonates begin to form in the interdunal sumps, once the lagoons lose a hydrographic connection to the ocean.

There are numerous less well documented examples of Holocene lacustrine carbonates accumulating in coastal salinas in other parts of southern and western Australia, such as Sleaford Mere on Eyre Peninsula, and Lakes Clifton and Haywood in southwest Australia (Fig. 4.2). Actively growing calcite and aragonite tufas dominate the strandlines in these other settings, mostly as indurated reef mounds (thrombolites and tufas). Further out into the tufa-fringed salinas, where water depths can be up to 4–5 m, bottom sediments are laminated ostracodal pellet wackestones and mudstones. Bioherm shapes around the salina edge range from elongate reef terraces to isolated domal and conical mounds, some with *Conophyton*-like shapes. Individual mounds can be 2 m high and extend as reefal terraces for up to 6 km along the

Fig. 4.3 Algal tufas of Sleaford Mere, Southern Eyre Peninsula, Australia. (**a**) Tufa reef mounds define the lake strandline (kangaroo for scale). (**b**) Looking down on the cracked, knobbly and crenulated surface of indurated calcite tufa mounds (coin for scale)

Fig. 4.4 Coorong region in the area centred on the township of Salt Creek, South Australia. Part of the 120 km long barrier island, composed of carbonate sand (Younghusband Peninsula), is visible, backed by the waters of the Coorong Lagoon, which is floored by mm-laminated aragonite muds. Laminated lacustrine carbonates, including dolomites, are accumulating in lakes in isolated interdunal corridors behind the Coorong Lagoon, especially south of Salt Creek – see Fig. 4.5 (Bing® image mounted in MapInfo)

salina strandline (Fig. 4.3; Warren 1982a; Coshell et al. 1998; Konishi et al. 2001). This indurated fringe contrasts with the leathery Holocene cyanobacterial mats and hollow domes that typify most of the Coorong ephemeral lakes.

The Coorong Region was first documented as an area of modern dolomite precipitation by Mawson (1929), but was not studied in any detail until the work of Alderman and Skinner (1957), von der Borch (1965, 1976), von der Borch and Lock (1979), Rosen et al. (1988, 1989), and Warren (1988, 1990), Wacey et al. (2007). Most early work in the region concentrated on salinas that contained dolomite, but there are many salinas, probably the majority, where the fill is dominated by carbonate mineral phases other than dolomite (Warren 1990). Fills include low and high Mg-calcite, magnesite, hydromagnesite, aragonite, and less commonly gypsum (Figs. 4.4 and 4.5). Von der Borch (1976) observed that Holocene dolomite occurs in areas of the coastal plain where rainfall is less than 700 mm, encompassing the area

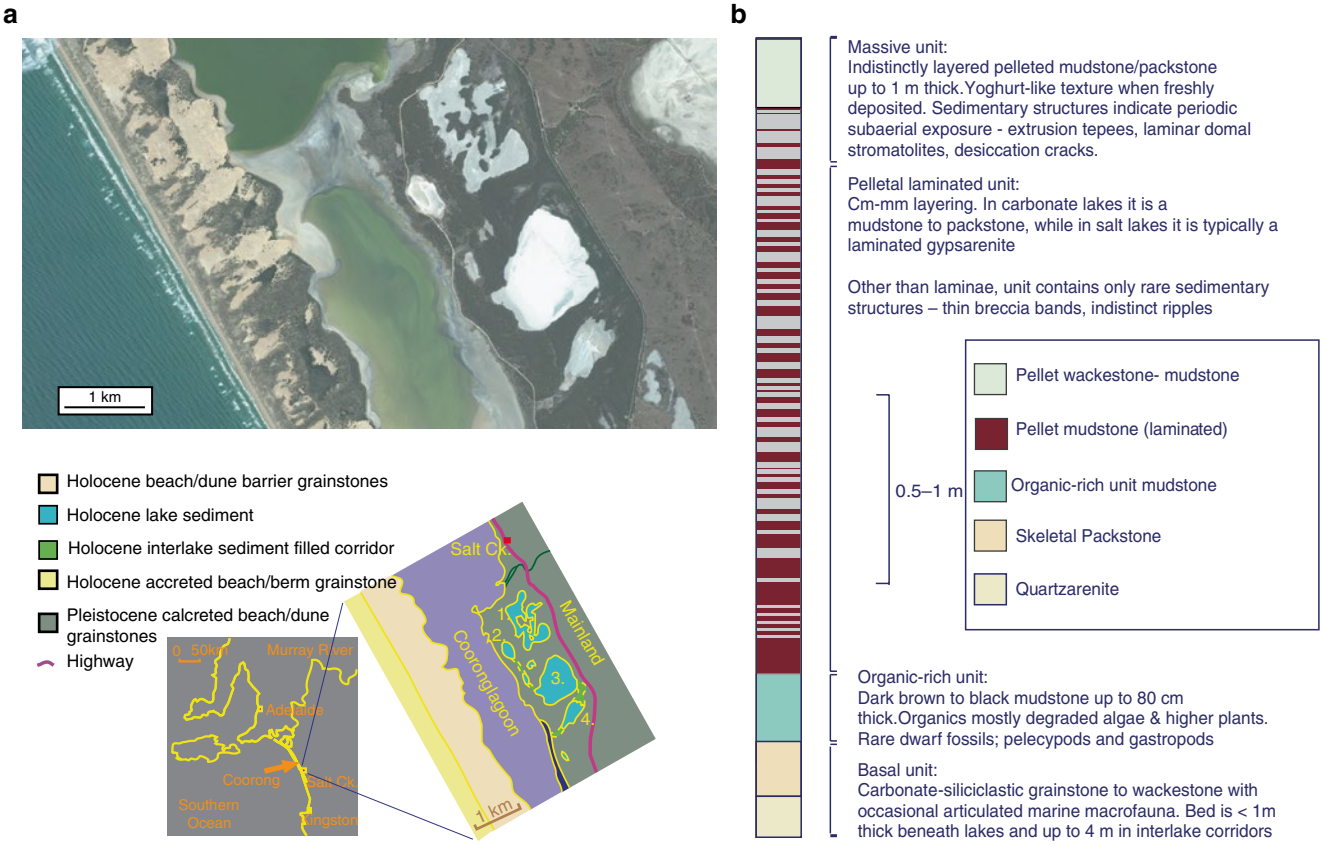

Fig. 4.5 Coorong Lakes, South Australia. (**a**) Locality and map of the Coorong region. Geological plan of the Salt Creek region shows how three of the four major lakes are joined by an interdunal corridor and were connected to the Coorong lagoon earlier in the Holocene. Milne Lake, the best dolomite accumulator in the Coorong coastal plain, never had a surface connection with the Coorong Lagoon. Mineralogies: Lake 1 = Milne Lake (dolomite + magnesite), Lake 2 = Halite Lake (gypsum + aragonite overlain by hydromagnesite + aragonite in massive unit and currently covered by ephemeral halite crust), Lake 3 = Pellet Lake (dolomite + hydromagnesite + aragonite), Lake 4 = North Stromatolite Lake (hydromagnesite + aragonite; minor dolomite in basal unit and about lake edge) (After Warren 1990). (**b**) Typical vertical sequence in Holocene evaporitic lakes of the Coorong coastal plain (After Warren 1990, 2000a)

between Kingston and Salt Creek (Fig. 4.5a). He suggested that south of the 700 mm isohyet, reduced evaporation rates and higher rainfall prevented the concentration of lake waters to salinities where dolomite could precipitate. Regional sampling of lakes across the area tied to climate confirms his postulate and shows that the more magnesian-rich dolomites tend to occur in the more arid northwestern portion of the Coorong coastal plain, centred on lakes in the vicinity of Salt Creek, while Mg-calcite and calcite filled salinas are increasingly common in the cooler moister parts to the southeast (Warren 1988, 1990). More recently, papers detailing the organic constituents of selected Coorong lakes, and their geological significance, have been published (Krull et al. 2009; McKirdy et al. 2010).

Textures in Coorong salinas and pans are largely independent of mineralogy and can be related to salinity, brine depth and permanence (Fig. 4.5b; Warren 1990, 1991). If the salina possessed an early Holocene connection to the marine waters of the Coorong Lagoon, then the lowermost Holocene unit is a marine/estuarine skeletal grainstone/packstone, similar to Holocene units flooring the more saline salinas of the Marion lake Complex and Lake Macleod. If there was no marine connection to the Coorong lagoon then the basal unit is a quartzose packstone to wackestone. These lowermost sediments can contain small percentages of diagenetic calcian dolomite (Rosen et al. 1989). Above the lowermost unit is a variably-developed massive to faintly laminated organic-rich unit. In lakes with an early marine connection the levels of total organic carbon (TOC) in this unit can be as high as 12 %, usually as an oil-prone proto-kerogen. Its formation indicates a seasonally stratified water column where fresh oxygenated water seasonally overlay stagnant marine water, during the transition from a surface connected marine estuary to a totally isolated groundwater-fed salina.

Above this is a mm-laminated unit of pelletal packstone to mudstone, deposited on the floors of perennial, but schizohaline, density-stratified brine lakes, which formed in the Salt Creek region once the estuarine connection to the open

Coorong Lagoon was cut off by beach-ridge accretion at the entrance to the chain of salinas around 6,400 years ago (Fig. 4.5a). The proportion of faecal pellets in the laminated unit is a direct reflection of energy level and organic binding on the subaqueous salina floor. In areas of higher wave energy/bottom currents and little or no algal binding, the sediment is a packstone. Such sediments are more common about the salina edge and in the shallower parts of the more central sediment fill. In areas of lower wave energy in relatively deeper water, or in areas of algal binding, the sediment is a wackestone or at times a mudstone. Muddier sediments are more common in the central parts of a salina. In a few coastal salinas with no early Holocene marine connection, such as Milne Lake, the laminated unit is dominated by magnesian dolomite in a unit up to 5 m thick (Fig. 4.5a). More typically the laminated unit in the Coorong ephemeral lake fill is composed of varying proportions of aragonite, hydromagnesite, magnesian calcite and low magnesian calcite. In one marine-seepage lake (Halite Lake), it is made up of laminated gypsum/aragonite couplets.

Capping the lake sediments is a "massive" unit of poorly layered packstone/mudstone. It is usually less than 60–80 cm thick and shows varying degrees of induration from brecciated crusts about the salina edges to domal leathery stromatolites in some of the more central water covered areas. Domal stromatolites seem to flourish in Coorong salinas filling with a mixture of hydromagnesite and aragonite (Fig. 4.6a). This, the uppermost part of the sediment fill, usually holds the bulk of the evaporative dolomite in the majority of the Coorong carbonate salinas containing dolomite, especially in the vicinity of Salt Creek. But the Massive Unit can also be composed of aragonite, hydromagnesite, magnesian calcite and magnesite. This uppermost unit in the Coorong lake fill stratigraphy contains numerous terrestrial burrows and root traces, as well as mud cracks, extrusion tepees and breccia fragments – all features indicative of at least occasional desiccation and thorough bioturbation (Figs. 4.6b).

Whatever the mineral assemblage, the dominant textural feature in the sediment column of a carbonate salina is lamination passing up section into a more massive unit with evidence of seasonal subaerial exposure of the sedimentation surfaces. Tepee-overprinted carbonate crusts are especially common in the desiccated strandzones of the lake margins (Fig. 4.6b), while domal stromatolites and cyanobacterial are common in areas of more permanent brine cover or saturation, especially in salinas precipitating hydromagnesite and aragonite. Brackish lakes, such as Lake Fellmongery, in the southeastern part of the Coorong coastal plain have well-developed algal tufa fringes, as described earlier, with some tufas first precipitated as monohydrocalcite and quickly altering to calcite. Surfaces of all the carbonate-filled salinas in the Coorong coastal zone are half a metre or more above sea level indicating the current nonmarine supply of waters (as groundwater cannot flow up hill). Some Coorong lakes had a marine seepage connection in their earlier stages of infill (e.g. Halite Lake, with a laminated unit composed of gypsum and aragonite; Fig. 4.5).

Organic content and biomarker stratigraphy in North Stromatolite Lake defines five discrete organic facies, each with a distinctive mineralogy (Fig. 4.7a; McKirdy et al. 2010). The organic-rich unit (6–12 % TOC) may be subdivided into facies 1 (Type I/II kerogen) and 2 (Type II kerogen), whereas the organically-leaner laminated and massive units are distinctly bimodal with respect to organic content, hosting both facies 3 (Type II/III kerogen) and 4 (Type III kerogen). The latter two facies together define an inverse relationship between hydrogen index and TOC content, which is a geochemical signature attributed to differences in the extent of pelletisation of carbonate muds by a diverse halotolerant fauna including brine shrimp, gastropods and ostracods during the shallowing perennial and ephemeral phases of the lake's history. One sample from the basal unit is representative of organic facies 5 (Type IV kerogen).

Aliphatic hydrocarbon distributions in these lacustrine sediments are dominated by C_{20} and C_{25} highly branched isoprenoids; and C_{12} – C_{33} n-alkanes displaying marked odd/even predominance above, and even/odd predominance below, C_{20}. This biomarker assemblage reflects the respective major contributions of bacillariophyceae (diatoms), chlorophyceae (green algae) and eubacteria (including cyanobacteria) to their preserved organic matter. Its passage through the guts of the aforementioned grazers and excretion as faecal pellets has dramatically enhanced the relative abundance of cholest-2-ene, thereby imparting to the pelletised upper sapropel, laminated and massive units a molecular signature indicative of mud ingestion and defecation.

Biomarker work across the sapropel underlines significant distinctions, not generally recognised in sedimentological studies, namely (McKirdy et al. 2010; Edwards et al. 2006): (1) Absence or presence of lamination in a fine-grained lacustrine succession does not necessarily mean that the sediment has or has not been ingested; however the absence or presence cholest-2-ene does. (2) If pellets are deposited as soft aggregations of micrite, then the pelleted texture will be quickly lost during the physical compaction associated with early burial and diagenesis, yet the organic signature of ingestion may remain. (3) In lacustrine associations, high levels of hydrogen-rich Type-1 protokerogen may have accumulated beneath relatively-shallow bottom waters (<5 m deep) that, although meromictic, were not necessarily perennially anoxic. We shall return to the discussion of organics in the Coorong lakes in Chap. 9.

Volumetrically, most salina carbonates in the various Coorong Lakes form by the evaporation of unconfined magnesium-rich continental groundwaters, driven to the

surface along the coastal zone as they float up over a more dense seawater wedge. That most dolomite forms where large volumes of resurging continental waters can evaporate, explains why the thickest Coorong dolomites form adjacent to the present coast. However, mineralogically similar dolomites are also precipitating 20–40 km further inland as thin capping units in fully continental ephemeral lakes. These areas are well away from the seawater wedge, but still in areas where the regional watertable intersects the land surface and continental groundwaters can pond and evaporate.

Dolomites in salinas in the Salt Creek region precipitate as two geochemically and isotopically distinct types (Type-A and -B), typically in association with other carbonate minerals. Type-A dolomite has a slightly heavier oxygen isotope signature than type-B, and is 3–6‰ heavier in ^{13}C (Fig. 4.7b). Type-A dolomite also has distinct unit cell dimensions

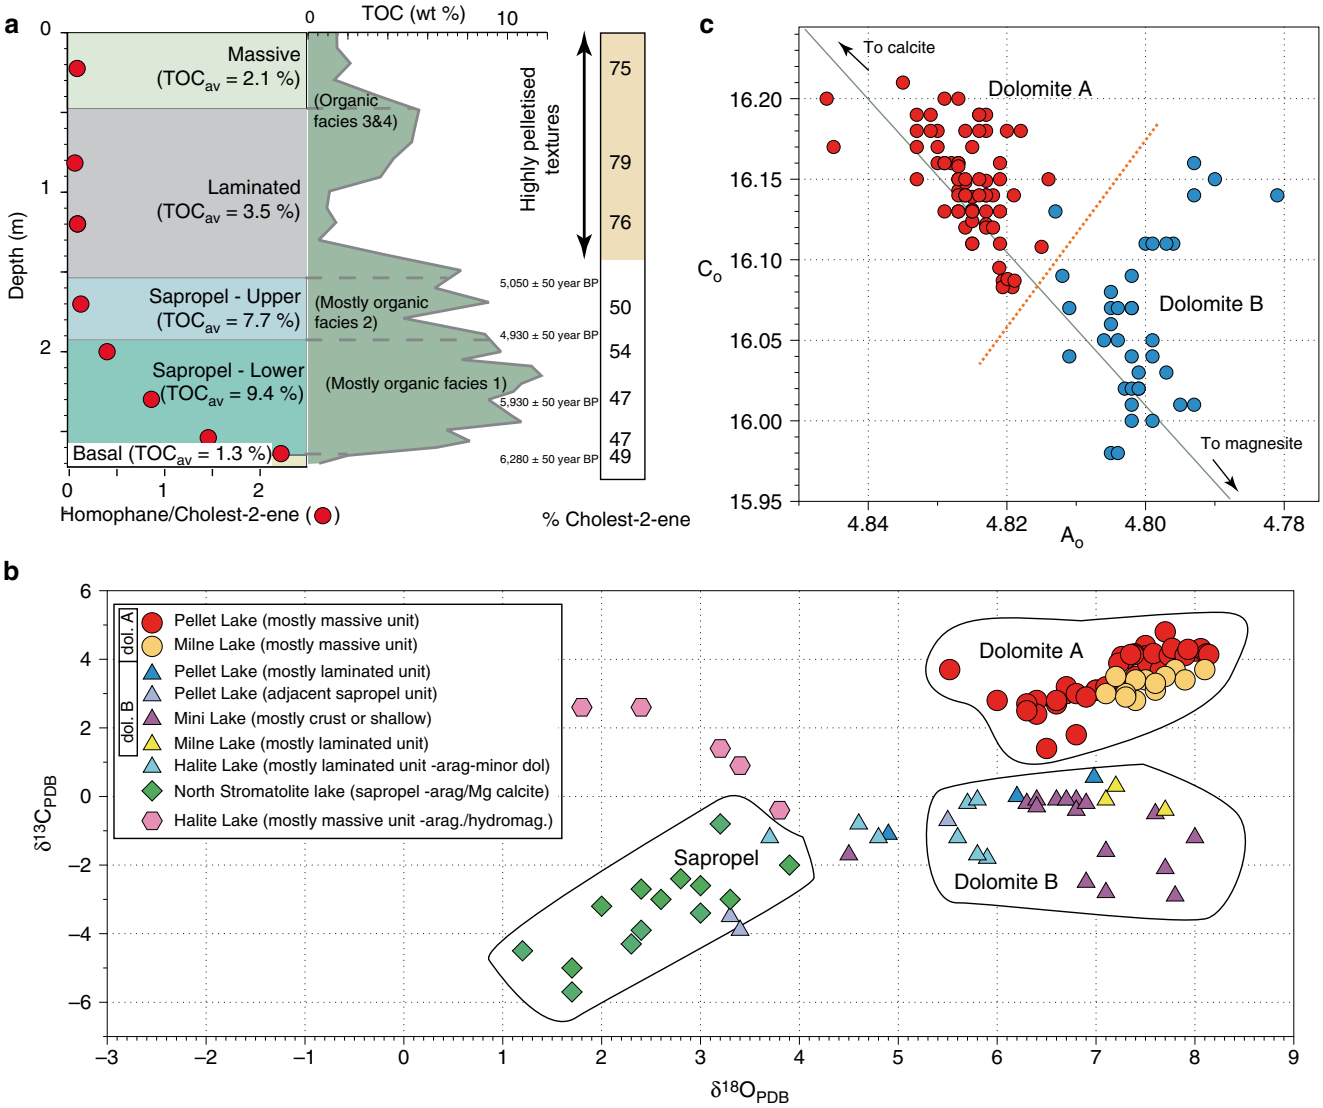

Fig. 4.7 Geochemistry of Coorong dolomites. (**a**) Plot of homohopane/cholest-2-ene ratio versus depth in a core from North Stromatolite Lake recording the up-section addition of faecal cholesterol to the mud by benthic microfauna that grazed on algae and cyanobacteria. The *right-hand panel* highlights a parallel increase in cholest-2-ene as a proportion of the total eukaryotic input of $C_{27}-C_{29}$ Δ^2-sterenes. (**b**) Isotopic signatures of Type A, Type B dolomite and sapropel carbonates across various Coorong Lakes. (**c**) Unit cell parameters of type A and Type B dolomite across various Coorong lakes (In part after McKirdy et al. 2010; Rosen et al. 1989; Warren 1990)

(Fig. 4.7c). It tends to be magnesium-rich with up to 3 mol% excess $MgCO_3$, while type-B is near stoichiometric or calcian-rich. Type-A dolomite typically occurs in association with magnesite and hydromagnesite, Type B with Mg-calcite. Transmission electron microscopy (TEM) shows that Type A dolomites have a heterogeneous microstructure due to closely spaced random defects, while type B dolomites exhibit a more homogeneous microstructure implying excess calcium ions are more evenly distributed throughout the lattice. TEM studies show that the two types of Coorong dolomite are distinct and are not intermixed with other mineral phases; they are primary precipitates, and not replacements and are not transitional (Miser et al. 1987).

Sapropel carbonates are typically mixtures of aragonite and Mg-Calcite, indicative of the somewhat lower ambient salinities when these sediments precipitated (McKirdy et al. 2010). As such sapropel carbonates tend to occupy a distinct isotope plot field compared to type A and B dolomite (Fig. 4.7b). Their somewhat more negative carbon isotope values may indicate a greater organic contribution to the carbonate precipitate in the sapropel. The separation of isotope fields for dolomite A from dolomite B is also largely due to differences in carbon values, with dolomite B tending to have more negative values. Rosen et al. (1989) attributed this to differences in water chemistry (more evaporitic versus more meteoric-influenced feeder brine).

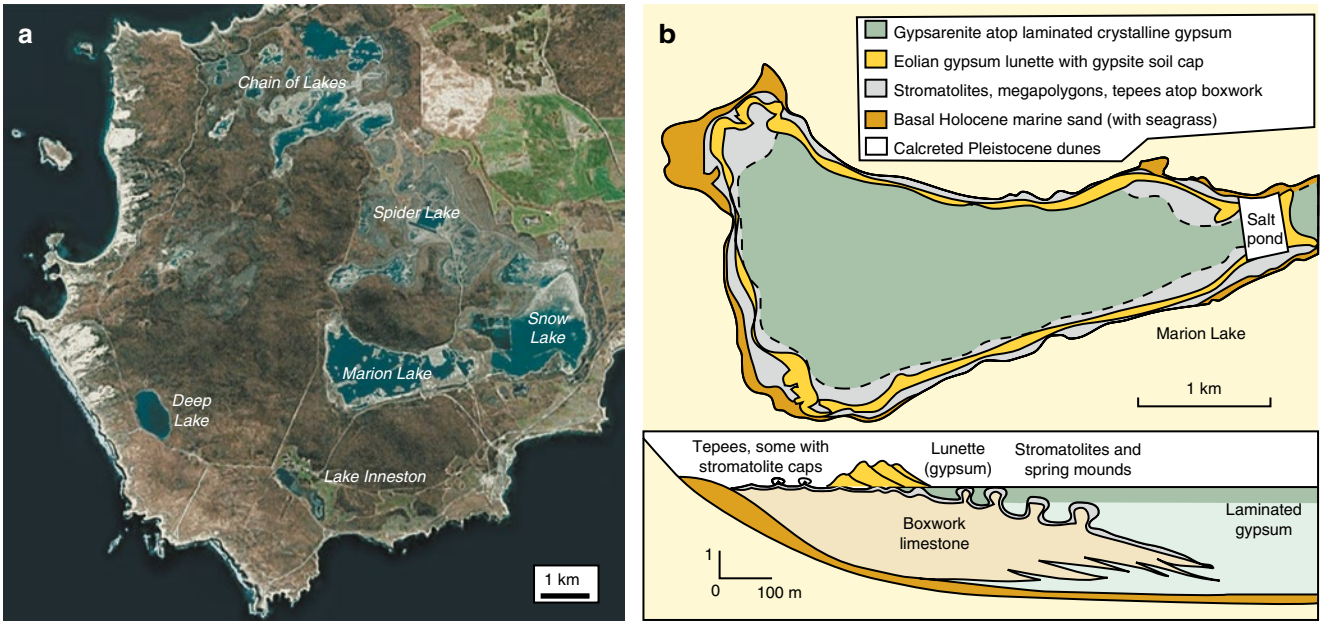

Fig. 4.8 Gypsum salinas. (**a**) Seepage fed coastal salinas of the Marion Lake complex at the southwest tip of Yorke Peninsula, South Australia. (**b**) Surface geology and cross section of Marion Lake are after Warren 1982a, b (Landsat image courtesy of NASA)

In later papers, Wright (1999), Wacey et al. (2007) argued dolomite formation in the Coorong salinas is bacterially mediated, based on a combination of SEM and sulphur isotope observations.

Bacteria can play a role in shaping all isotope signatures. However, neither type A and B dolomites show the negative carbon values typically associated with the bacterial sulphate reduction (BSR) and Coorong dolomite plotfields lie outside the documented sulphate reduction or methanogenic dolomite fields (Fig. 4.18). Wacey et al. (2007) argue this is because bacterially-mediated precipitates in the Coorong lakes incorporate carbon primarily from the inorganic, lakewater reservoir, partially diluted by an organic component. However, it is important that any proposed precipitation process does not oversimplify or overgeneralise a complex set of precipitation mechanisms across a range of evolving carbonate mineralogies. Figure 4.7b clearly shows dolomite mineral phases occupy separate isotope plot fields and so likely involve a range of feeder chemistries. The research on the relative importance of bacteria versus concentration on the formation of Coorong dolomite continues.

Dolomites in Coorong salinas are evaporitic carbonates, once thought to only form in areas free of preserved evaporites (von der Borch and Lock 1979). Yet, Milne Lake, a salina filled with 4 m of laminated dolomite-magnesite, lies less than a kilometre from Halite Lake, a depression filled with 2–3 m of laminated gypsum-aragonite (Fig. 4.5a; Warren 1990). Milne Lake was fed by seaward-flowing continental groundwaters throughout its infill history. Halite Lake, during the gypsum stage of its fill, was fed by landward-flowing marine groundwaters (evaporative drawdown stage). Today Halite Lake is filled to its hydrological equilibrium level; its present depositional surface lies above the level supplied by marine seepage and it no longer accumulates laminated gypsum-aragonite. Above its laminated gypsum-aragonite unit is a 10–50 cm thick capstone bed of pelleted aragonite-hydromagnesite, a mineral association that indicates the current surface hydrology is dominated by a non-marine groundwater feed, but with a distinct isotope plot field (Fig. 4.7b). Other Coorong Lakes in the same climatic zone, but located further inland, and more isolated from resurging marine groundwaters, are completely filled with this aragonite-hydromagnesite association (Fig. 4.5a; North Stromatolite Lake and South Stromatolite Lake).

Gypsum Salinas

Gypsum-filled coastal lakes in southern Australia are located mostly to the west of the Coorong coast (Fig. 4.2) and are best documented in the region of Marion Lake on the southwestern tip of Yorke Peninsula (Fig. 4.8a). Most of these gypsum salinas occur within a Mediterranean-style Csb Köppen climate regime; although the largest of the exploited gypsum salinas, Lake Macdonnell, lies in a BSk climate. Groundwater feeds to these salinas are dominated by seawater, so the current hydrological equilibrium surfaces (Stokes surface) in all the gypsum salinas are still up to 50 cm below sea level. In plan view, surface sediments in a gypsum salina define bull's-eyes, consisting of a carbonate seepage rim and a more central gypsum zone (Fig. 4.8b). Individual gypsum-filled salinas measure up to 20 × 12 km (Lake Macdonnell on

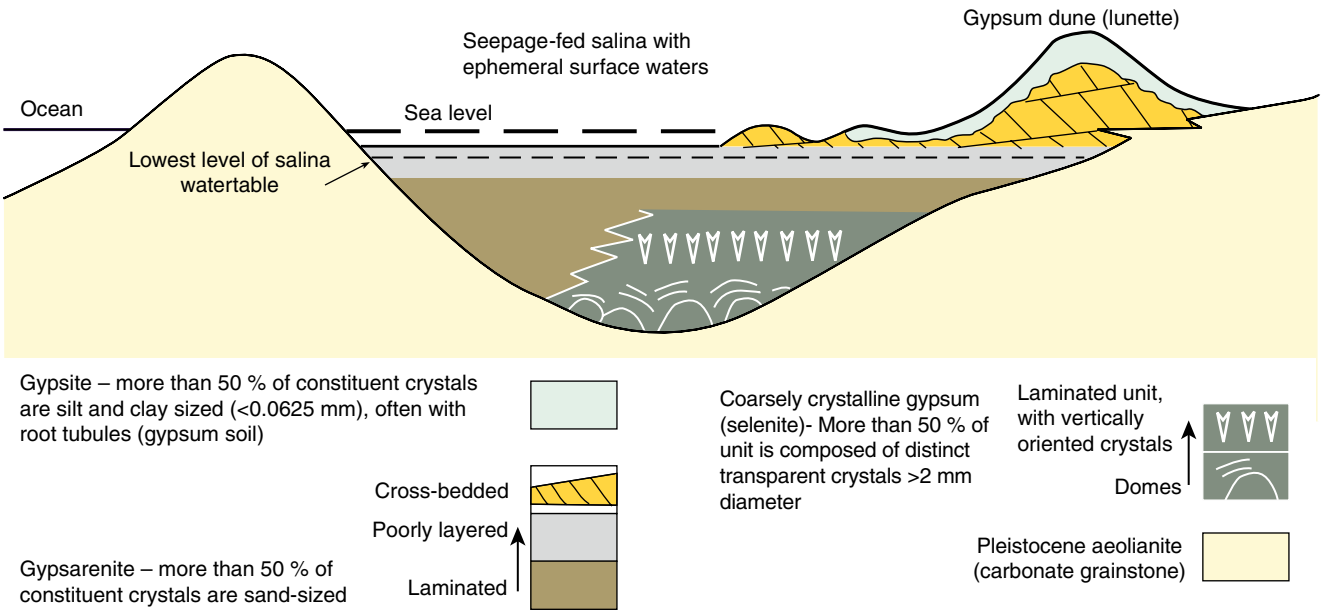

Fig. 4.9 Gypsum facies in South Australian salinas (After Warren 1982b), showing domes overlain by laminites and the eolian reworking of upper portions of the lake sediments into gypsite-capped lunettes. For simplicity, the carbonate rim is not shown (see Fig. 4.8b)

the coast of the Great Australian Bight), with centres filled by laminated gypsum units up to 10 m thick.

A carbonate unit forms a seepage rim about the salina edge and is composed of a boxwork limestone unit (up to 4–5 m thick) overlain by a fenestral limestone sheet or crust, which is typically less than 1 m thick (Fig. 4.8b; Warren 1982a). Boxwork limestone is a diagenetic unit created by the cannibalization of earlier marine-lacustrine carbonates and sulphates by inflowing "fresher," but still saline, marine-derived groundwaters. The "boxwork" contains relict algal structures, evaporite pseudomorphs and other highly altered bedded fabrics in proportions depending on pre-existing sediment types. Some areas of the limestone sheet above the boxwork limestone consist of tepee-overprinted crusts, others of mm-laminated subaqueous stromatolites and algal mats.

Taller stromatolites in Marion Lake grew as current-aligned mm-laminated elongate domes (up to 40 cm relief) in a brine-filled feeder channel, that focused the flow of marine seepage waters into the perennial gypsum lake of the salina centre (Fig. 4.8b). Other smaller domal and encrusting stromatolites define the water-saturated cyanobacterial terrace of the lake strandzone, where indurated biolaminites define areas of very shallow and sometimes ephemeral surface waters (von der Borch et al. 1977; Warren 1982b). Stromatolite domes cap tepee structures in some marine-fed seepage areas (Fig. 4.6c). Like stromatolites, tepee structures are confined to the capping carbonate unit and form an extensive fenestral limestone sheet or capstone, up to 60 cm thick. Tepees form readily in areas of resurging groundwater, where seasonal changes in the groundwater head encourage tepee growth (Warren 1982b). Most of the limestone sheets caught up in the tepee structures are capillary crusts composed of fenestral lime mudstones containing stromatactic-like voids, pisolites, laminar cements, and geopetal internal sediment partially filling pores and vugs. A similar lake-margin recharge hydrology controls the formation of stromatolite-capped tepees in Holocene Lake Walyungup in coastal Western Australia (Coshell et al. 1998; Coshell and Rosen 1994).

Salina gypsum in the central portions of Marion Lake is coarse-grained, porous, bottom nucleated and growth-aligned; it retains intercrystalline porosity of 15–25 %; pore infilling gypsum cement is rare (Figs. 4.6e, f and 4.9). South Australian salinas are one of a few Holocene occurrences where subaqueous gypsum is deposited as widespread units of coarsely crystalline bottom-aligned swallowtail and palmate crystals (Warren 1982a). Worldwide, gypsum in most modern salinas is a layered gypsarenite. The cm-scale gypsum crystals are usually more than 90 % pure and laid down as characteristic shallowing-upward growth-aligned crystal aggregates (Fig. 4.2). At the base of an idealized succession are massive, poorly layered domes of coarsely crystalline palmate and swallow tail crystals (aka selenite; Fig. 4.9). Modern growing examples of this style can be found regrowing on the floors of flooded mined-out salinas such as Lake Inneston (Fig. 4.6d). The elongate gypsum prisms in the early stages of dome growth show little or no preferred orientation, with carbonate pellets and flakes distributed randomly through the gypsum porosity. Active domes on the floor of Lake Inneston are coated by microbial slime and can be considered to be a type of coarsely-layered gypsum stromatolite.

Higher in the sedimentary section, the degree of lamination increases and dome amplitude decreases until domes pass into sub-horizontally layered and laminated units of aligned crystals (Fig. 4.6e). Higher still, individual laminae of pelletal and micritic aragonite appear to crosscut large upwardly-aligned gypsum crystals (Figs. 4.6f and 4.9). Such large crystals at first sight appear secondary and their Miocene equivalents in the Sicilian Basin were once interpreted as secondary gypsum after anhydrite (Ogniben 1957). Studies of identical Holocene gypsum in the South Australian salinas have shown that the crystals (30–50 cm long) are primary, not secondary. They grow with their long axes perpendicular to bedding, an effect of crystal impingement and growth alignment (Fig. 2.72; Warren 1982b).

Gypsum is not only deposited as coarse-grained gypsum (selenite) in South Australian coastal lakes. Some salinas are filled with laminated gypsarenites and are probably as common, if not more common, than those filled with the geologically more interesting coarsely-crystalline gypsum. Laminated gypsarenite fills large interdunal corridors near Streaky Bay and Point Fowler in South Australia and Hutt and Leeman Lagoons in Western Australia (Fig. 4.2).

In salinas with coarse-grained fills, the coarsely-crystalline laminated gypsum (selenite) unit, punctuated by carbonate laminae, is in turn overlain by a mm-laminated, sand-sized gypsarenite accumulation (Fig. 4.9). Parts of the horizontally laminated gypsarenite unit, especially near the salina strandzone, can be reworked into wave-oscillation ripples. Laminated and rippled gypsarenite is in turn overlain by a thin, massive, poorly-bedded gypsarenite unit deposited under seasonally vadose or subaerial conditions and represents accumulation in the salina capillary fringe.

Topping the whole succession is a unit of cross-stratified eolian gypsum and, in areas stabilized by vegetation, a pedogenic cap of gypsite (silt-sized). Throughout coastal and inland Australia, this gypsum soil is a degradational profile that is slowly cannibalising depositionally inactive regions of both lacustrine and eolian gypsum (Fig. 4.6g).

Carbonate laminae in the various gypsum units form by the precipitation and accumulation of aragonite pellets during the spring and early summer (Chap. 9). The pellets come from the faeces of ostracods and brine shrimp, mixed with the micritised remnants of algal tubules. At first the pellets mantle any underlying gypsum and often are captured by a cyanobacterial mat that covers the gypsum. During the ensuing summer and autumn, as the lake maintains its gypsum saturation, the pellets are encased by the upward poikilitic growth of large gypsum crystals (Figs. 2.72 and 4.6e, f).

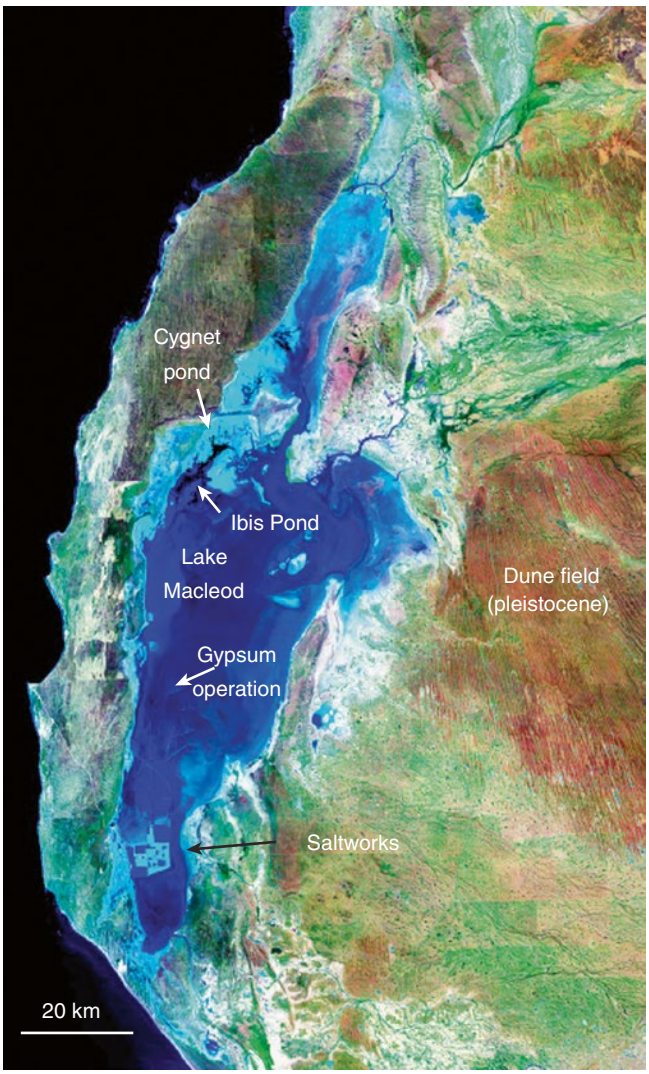

Fig. 4.10 Lake Macleod, Western Australia. It is the largest evaporite-filled coastal salina in the world. Marine-fed brine springs and sheets are visible in the central western and northwestern strandzone, while solar ponds are visible in the south. The interdunal depression only started to accumulate Holocene salts after its surface connection to the ocean at its southern end was cut off by longshore sand drift (Landsat image courtesy of NASA)

Halite Salinas

Lake Macleod is a halite-filled salina some 120 km long and 40 km wide, lying just to the north of Shark Bay (Fig. 4.10; Logan 1987; Handford et al. 1984). Climate is arid, with average rainfall around 230–260 mm and annual potential pan evaporation in excess of 2,600 mm (BWh Köppen Climate zone). The surface of much of Lake Macleod still lies well below sea level indicating evaporative drawdown and a groundwater feed from the nearby Indian Ocean. Some parts of the lake depression, especially near the marine seeps, are still covered with semipermanent water sheets. In its northern part, and across the current lake surface, the lake fill is a Holocene gypsarenite unit; it is as much as 5 m thick along the northern and western (seaward) sides of the lake (Fig. 4.11). To the south and beneath the laminated gypsum unit is a widespread halite bed up to 7 m thick. It is made up of stacked halite crusts, dominated by growth-aligned chevrons and cornets. Brines from this halite unit in the south

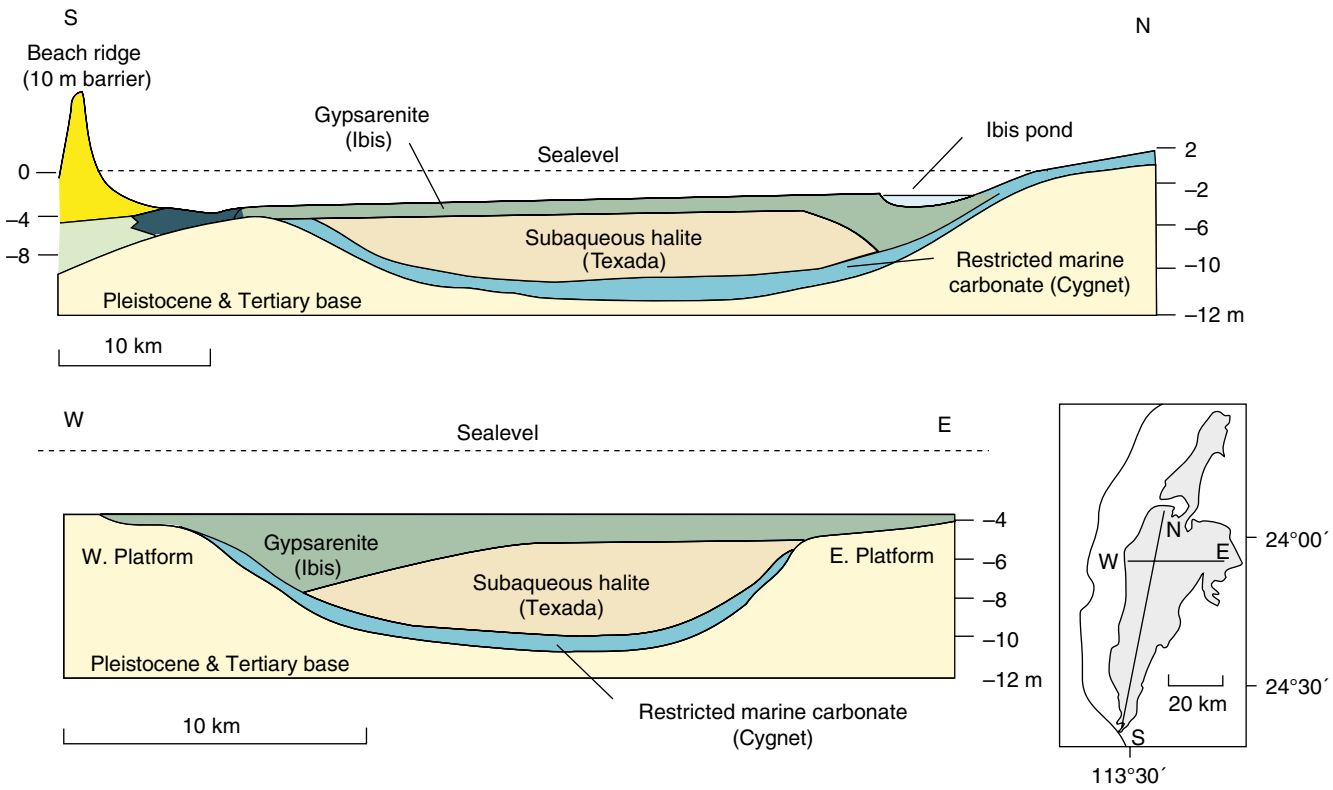

Fig. 4.11 Lake Macleod, Western Australia. Stratigraphic cross sections showing distribution of halite and gypsum as well as the effect of seepage decreasing the salinity so that the gypsum thickness increases toward areas of carbonate seepage defined by Ibis Pond and the western platform (After Logan and Brown 1976)

are pumped into saltwork ponds to produce halite for the chemical industries of southeast Asia. Gypsum was dredged in the central part of the lake and mostly used for wallboard manufacture. Both the gypsum and the halite units overlie a thin unit of Holocene lagoonal carbonate deposited prior to the depression's transition from marine embayment to coastal seepage lake.

Lake Macleod never possessed a surface (hydrographic) connection to the ocean at any time in its salt-accumulating Holocene history. Seawater seeps onto the subsealevel lake floor via a series of marginward carbonate-precipitating spring pavements and beds, fed from fractures and caves in the underlying and surrounding calcareous coastal dune aquifer. As the escaping water exits the dune aquifer it degasses and concentrates to salinities where it precipitates seepage or strandzone carbonates, including aragonite pisolites and tepees, especially about seeps along the eastern and northern edges of the Macleod salina (Handford et al. 1984).

Today, the northern part of the lake is a perennial seepage pond, called Ibis Pond, where the perennial inflow water gathers in ponds that are over a metre deep (Fig. 4.10). When the water first escapes into the pond it has normal to near normal marine salinities and supports a restricted population of halotolerant marine gastropods and small fish. A similar marine biota can be found in marine seepage ponds on the seaward side of gypsum-filled Lake Macdonnell of coastal South Australia. Spring-fed normal marine waters are thought to have supplied the Lake Macleod brine lake for the last 5,000 years, ever since the Australasian Sea rose to a level that was within a metre or two of its present level. At that time a series of laterally accreting beach ridges cut off the lake's southern surface connection to the Indian Ocean (5,100 years ago). Since then, evaporative drawdown has pulled seawater into the lake depression and bedded salts have accumulated.

From 5,300 to 3,800 years ago, seawater seepage flowing out over the lake depression concentrated to halite saturation and deposited some six billion tons known as the Texada Halite, with a remaining brine-filled porosity in the salt beds of around 30 %. As the salina filled with beds of stacked chevron halite, the depositional surface aggraded (fill and spill hydrology – see Chap. 2). Over time, this meant that the groundwater head drawing water into the lake was reduced. At the same time the once perennial brine lake, depositing the halite and the gypsum, began to dry out each year and evolved into a saline pan. Meteoric input became more important in this later stage in the depositional fill, much in the same way it did in the South Australian salinas (Warren 1982a). This meant the salinity of the surface brine sheet was reduced to where gypsum was the stable mineral phase

throughout the brine lake and the Ibis Gypsite[1] unit was deposited across the lake. Local springs fed the lake throughout its Holocene history, so that aragonitic carbonate was deposited adjacent to the springs, while gypsum and halite filled the salina in an asymmetrical fashion away from these water sources (Handford et al. 1984).

Coastal Salinas of the Middle East

In the coastal deserts of the Middle East there are a number of small-scale coastal depressions filling with subaqueous evaporites, mostly aragonite and gypsum. They are flooded by perennial brines and replenished by phreatic seawater drawn into the lakes by evaporative drawdown. Like the Australian salinas, these Holocene fills have low preservation potential and will be largely flushed and dissolved during the next glacial event and its associated sealevel low.

Solar Lake, Gulf of Elat

The Sinai coast of the Gulf of Elat is characterized by steep rifted-margin topography and a clearly defined fringing-reef (Aharon et al. 1977; Gavish 1980). In most areas along the northern part of the Gulf the mountainous granitic and metamorphic massif meets with gulf waters to produce a narrow steep shorezone composed of slump blocks, coarse beachrock plates and narrow reef flats. Locally wadis extend as fan deltas into the gulf to produce wider, flatter coastal plains. Small brine ponds or salinas can develop in sub-sealevel depressions in this narrow coastal plain. Probably the best known of these is Solar Lake, a salina located immediately north of a large fan delta (Wadi Murah), some 18 km south of Elat. It is located in the BWh Köppen Climate zone that typifies the Red Sea, Suez and Elat coasts (Figs. 3.22 and 4.12a).

Solar Lake is a meromictic brine pond, about 140 m long and 65 m wide, with a maximum depth of 5 m. It is separated from the open sea by a porous beach-barrier, some 60 m wide and up to 3 m high, composed of coarse sand and pebbles of igneous and metamorphic rocks, along with abundant molluscan shell debris (Fig. 4.12b). Water is drawn to the pond by evaporative drawdown especially during high tide when the piezometric head is at its maximum. Minor amounts of seawater may also enter the pond by splashing over the barrier during occasional winter storms. Evaporation exceeds inflow each summer, raising the total dissolved solids of the pond brine to 160–180‰ in an unstratified or mixed brine column (May-September). In winter, the combination of lessened evaporation, ongoing inflow of seawater and minor amounts of rainwater combine to create an upper water layer of lower salinity (70–100‰) atop an anaerobic hypersaline hypolimnion (≈180‰) and a corresponding seasonal thermocline separating the two brine masses and making the lake a meromictic system (Fig. 2.71).

The resulting heliothermal layered brines in Solar Lake are typical of many other density-stratified coastal brine lakes. Bottom water temperatures in Solar Lake reach 57 °C in winter and spring, while year-round surface water temperatures range from 20 to 28 °C (Fig. 2.71). During stratification, as the lower brine layer absorbs heat, convection between the two layers is inhibited, and the bottom layer becomes increasingly hot and anoxic, with elevated levels of H_2S. By summer, evaporation and concentration of the upper water body drives a weakening of the density stratification and finally overturn. At that time the water level in the pond is as much as 0.5 m below sea level. With overturn, the water body becomes homogeneous, aerobic, and cools by convective heat loss to a consistent 28 °C (Fig. 2.71).

Sediments accumulating in the pond reflect the style of water supply and the meromictic stratification of pond waters. Down to a bottom depth of 2 m the margins of the pond are covered by thick halotolerant cyanobacterial mats atop carbonate mud. Precipitation of carbonate in the mats is largely driven by the metabolic activities of sulphate-reducing bacteria (Lyons et al. 1984b). Slopes of the pond are composed of a white crust of interlayered bottom-nucleated gypsum crystals and aragonite mud, while the deep pond bottom is covered by black mud and a loose gypsum mush (Fig. 4.12b). There the halobiotial biomass changes to halophilic cyanobacteria with soft flocculent fabrics and an associated increase in the numbers of sulphur-dependent anoxy-photobacteria (Krumbein et al. 1977). Interestingly, the carbonate in these deep bottom mats is dominated by near-perfect hollow microspheres of monohydrocalcite, possibly precipitated in response to bacterial metabolic processes (Krumbein 1975).

A total of about 70 cm of biolaminated sediment has been deposited in 2,400 years about the lake margin. Seasonally exposed portions of the biolaminites are crosscut by well-developed polygonal cracks giving the cyanobacterial mat a "lily-pad" appearance identical to the "lily pad" mats of the Abu Dhabi sabkha and the Ras Muhammad pool. Cracks open to their maximum extent during the late summer and autumn when the lake water level is at its lowest and the mat surface is subaerially exposed. Carbonates in the mat laminae and in the gypsum are composed of aragonite, with lesser Mg-calcite, dolomite and calcite, with dolomite forming as a replacement of the aragonite (Friedman et al. 1973; Aharon et al. 1977). The bulk of the dolomite occurs in gypsiferous sediment and not in the algal mats. The dolomite indicates a throughflow of

[1]Use of the term gypsite by Logan and coworkers to describe a unit that is laminated and dominated by sand-sized gypsum prisms is unfortunate. Outside of the University of Western Australia, the use of the term gypsite follows general sedimentological usage to define a very fine grained silt or mud-sized sediment (pelite, micrite, etc.).

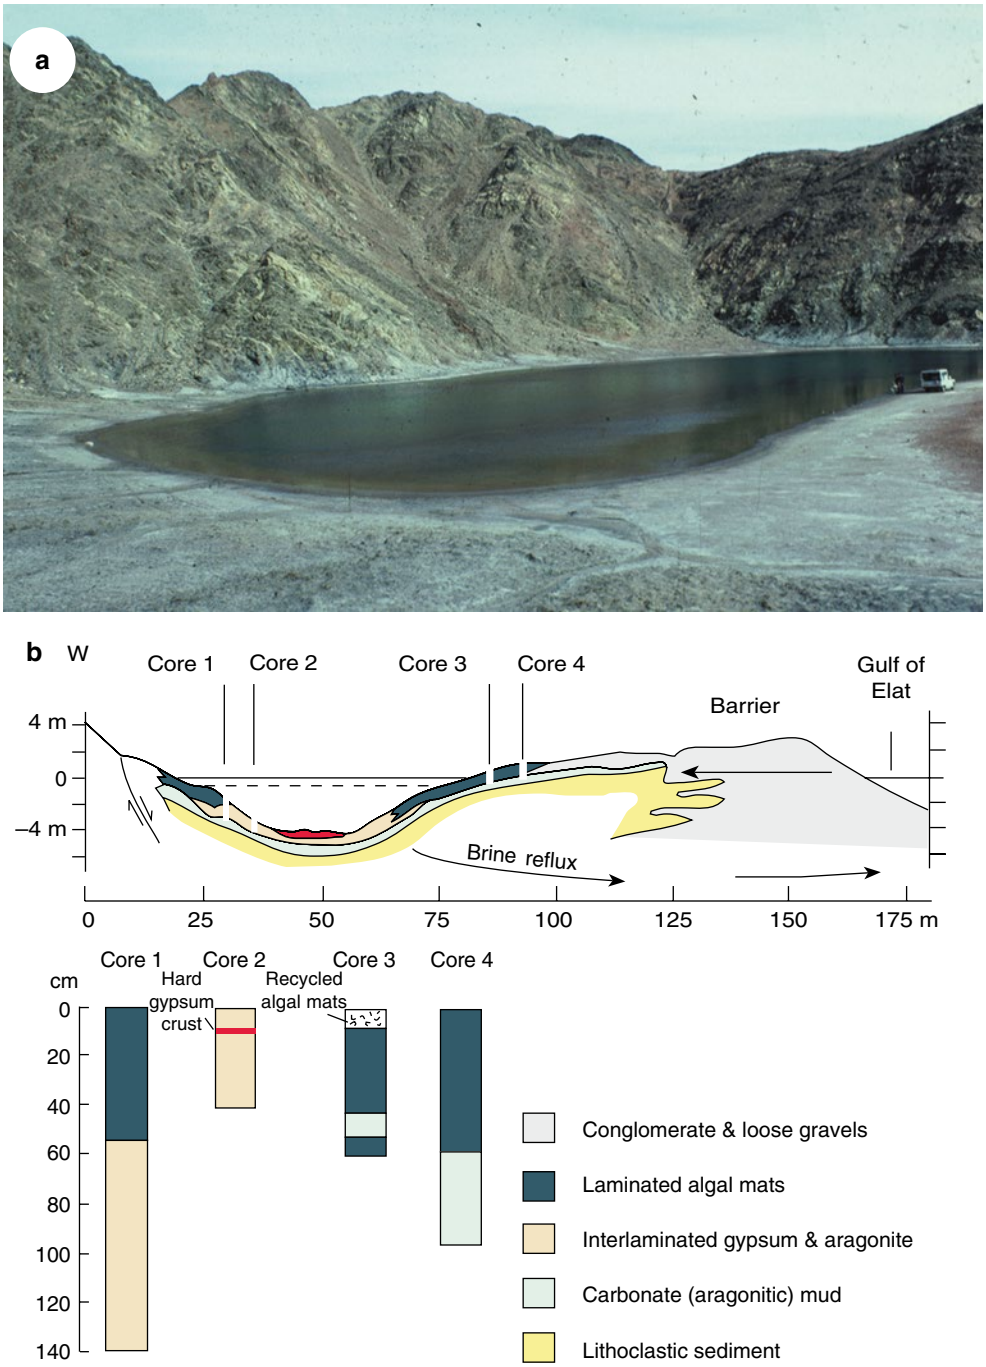

Fig. 4.12 Solar Lake, Gulf of Elat. (**a**) View shows cyanobacterial mats rimming the more central gypsum area. Note the steep-sided surrounds of the Precambrian Massif (Photo courtesy B. Lyons). Vehicle for scale. (**b**) E-W topographic and lithologic cross section based on cored sediments showing peripheral algal facies and a more central gypsum zone (After Aharon et al. 1977)

hot hypersaline brines, with a Mg/Ca ratio increased by the precipitation of gypsum, it is a local-scale brine reflux dolomite, possibly facilitated by bacterial sulphate reduction (Aharon et al. 1977). Beneath the cyanobacterial and gypsum layers of the pond is an earlier muddy aragonite unit with numerous *Cerithium* gastropod shells, indicating less saline deposition during the initial isolation of the pond.

Submersed sediments of Solar Lake are rich in organic carbon, a one metre deep core showed TOC values consistently in the range of 5–20 % (Schidlowski et al. 1985). Lyons et al. (1982) found significant levels of dissolved organic carbon, in the range 119–818 mg/l, in the pores of the same sediments. They concluded this material is not a "photosynthetic exudate," rather it is a build up from the early stages of the organic maturation, a response to early-onset catagenesis driven by high temperatures and high salinities attained in the sediment mass (see thermal maturation and early cracking in Chap. 9).

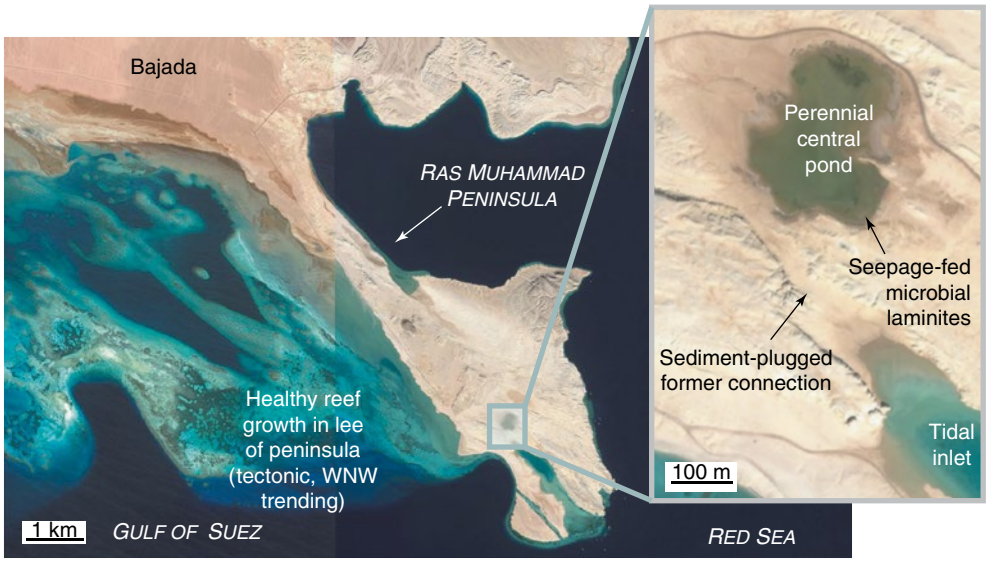

Fig. 4.13 Ras Muhammad pool, Southern Sinai Peninsula, view to the south, clearly shows seepage feed to the salt-encrusted perennial pool, tectonic alignment and its proximity to a seawater seepage source in the nearby tidal inlet (Bing® images scaled in MapInfo)

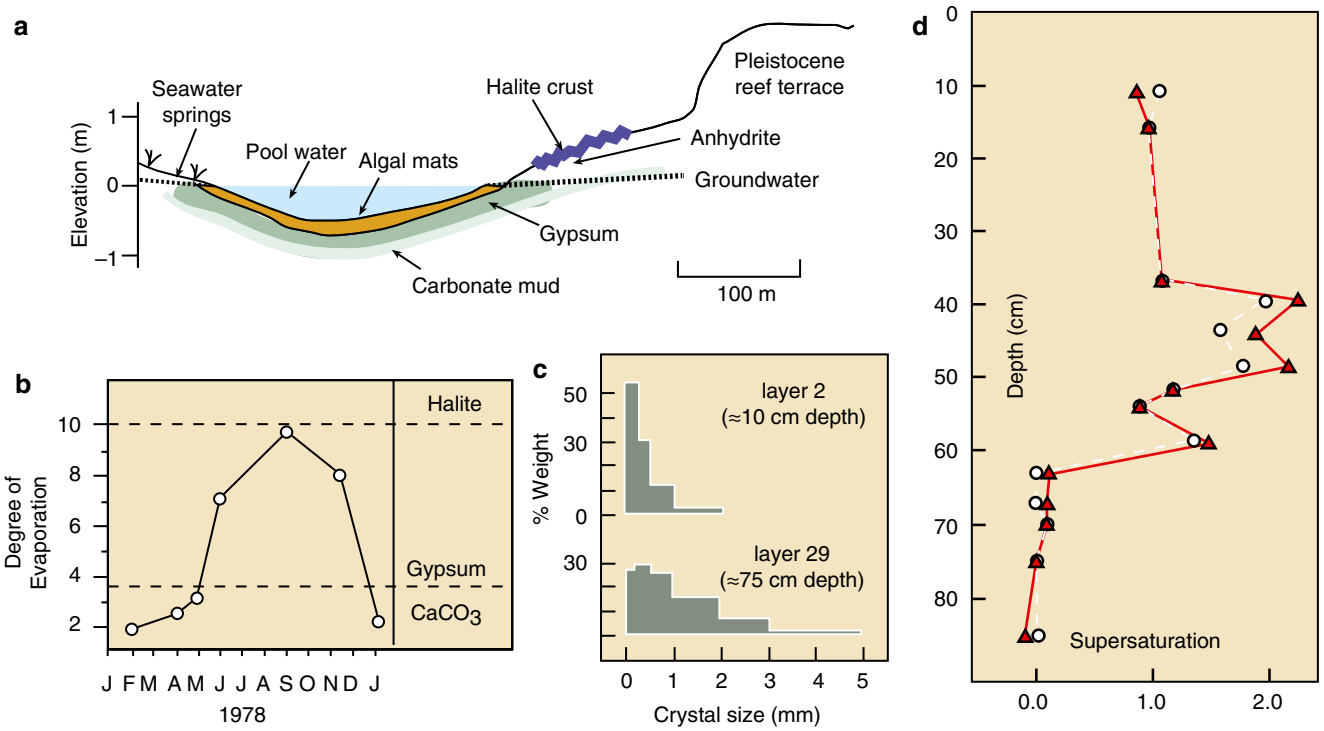

Fig. 4.14 Ras Muhammad pool, southern Sinai Peninsula. (**a**) Generalised cross section through the pool showing asymmetrical sediment distribution controlled by zones of seepage outflow. (**b**) Annual brine concentration cycle of surface waters for 1978 – Seawater is unity on the degree of concentration scale. (**c**) Gypsum crystal size distribution in a shallow and a deep sediment layer. (**d**) Gypsum saturation versus depth, using interstitial waters squeezed from gypsum layers (After Kushnir 1981)

Ras Muhammad Pool, Southern Sinai

At the southernmost tip of the Sinai there is a small peninsula, called Ras Muhammad, constructed by tectonically uplifted Pleistocene reefs (Figs. 3.22 and 4.13; Gavish 1980; Kushnir 1981). At the termination of this spit is a 1 km long tidal inlet with a small perennial brine pool at its end called Ras Muhammad Pool. The pool is an oval feature about 100–170 m in diameter and never more than 50 cm deep. It is separated from the inlet by a porous barrier, some 250 m wide, composed of reef material and carbonate sand (oolitic) that can be blown or washed into the pan. Most of the water in this subsealevel pool enters via a series of seawater springs around the pool's edge (Figs. 4.13 and 4.14a). The proximity of the groundwater source means the pool never dries up,

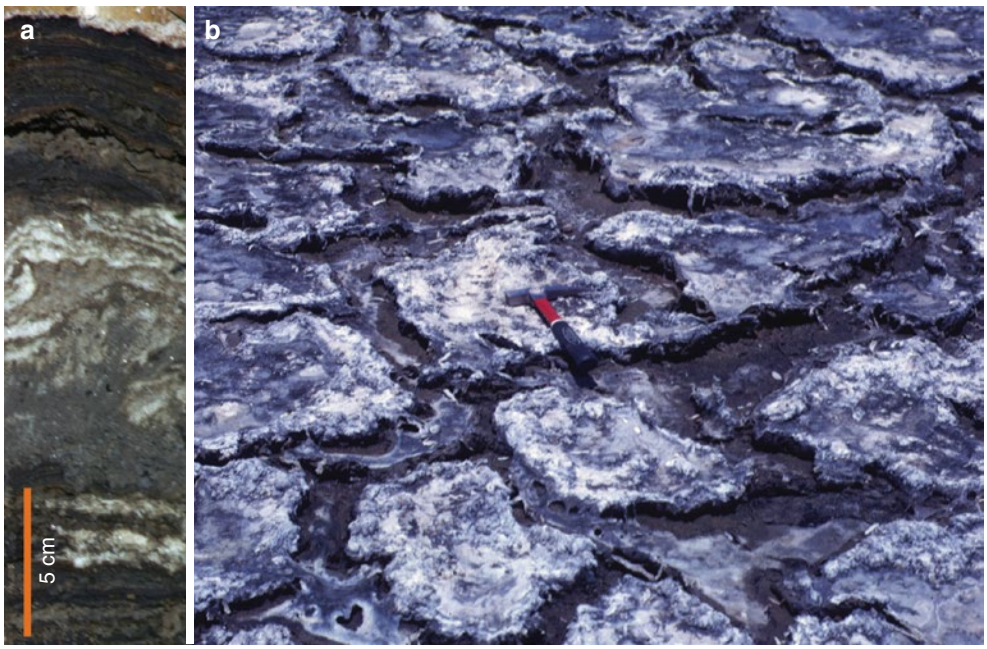

Fig. 4.15 Microbial mats of Ras Muhammad pool. (**a**) Core through irregularly layered mat from the strandzone. (**b**) Polygonal microbial mats ("lily pads"). Mats are seasonally desiccated and underlain by biolaminites and gypsum (geological hammer atop the mat in the *centre* of the image for scale) (Originals courtesy of G. M. Friedman)

although the extent and depth of surface water in the pool varies with the seasons. During summer and fall, the water volume in the pond is reduced by high evaporation levels (BWh; Köppen climate) and salinities in the pond can be more than 300‰. In winter and spring the pond expands and surface water salinities fall to 100‰ (Fig. 4.14b).

Sediments below the perennial pool are composed of alternating layers of gypsum mush and algal mats, there is no primary or diagenetic anhydrite (Fig. 4.15; Kushnir 1981). Thickness of gypsum layers ranges between 0.3 and 6 cm and averages 1.8 cm. Porosity in the gypsum layers ranges between 64 and 69 %. The gypsum in the layers is mainly prismatic (crystals up to 6 mm long) and associated with minor amounts of aragonite, calcite, quartz and feldspar. The gypsum in the upper younger layers (e.g. layer 2) consists mainly of small crystals whereas the deeper older layers (e.g. layer 29) have a broader, coarser size distribution (Fig. 4.14c). Mid-portions of cores taken through the cyanobacterial sediments can contain lenticular and prismatic gypsum crystals that have grown displacively within these biolaminites. The continued growth of gypsum eventually destroys the original lamination, as in the sabkha of Abu Dhabi. Likewise, much of the evidence of the original nearsurface organic binding (cyanobacterial filaments) is destroyed by the activities of heterotrophic decomposers that live below the surface of the mat. The final fabric as revealed in the lower-most layers of the cores taken by Kushnir (about 80 cm deep) is a laminated and disturbed gypsum mush with thin interlaminations of carbonate crusts and ooids with very little identifiable cyanobacterial material (Fig. 4.15a).

Strandzone sediments around the pool edge are cemented by an ephemeral halite crust, while beneath the crust and above the watertable are rare concentrations of anhydrite after gypsum, but salts in these strandzone sediments are dominated by gypsum. Pore fluids become increasing saline below the sediment surface and down to depths of 50–60 cm can be supersaturated with respect to gypsum by upward of a factor of 2 (Fig. 4.14d). High levels of gypsum supersaturation are relieved by the precipitation of gypsum and the growth of coarser prismatic crystals, as is seen in the coarser crystal sizes of layer 29 some 75 cm below the sediment surface (Fig. 4.14c). According to Kushnir (1981) high levels of organics in the supersaturated pore fluids inhibit precipitation of larger gypsum crystals in the uppermost capillary intervals. Alternatively, the coarser gypsum just above the watertable may indicate thermalitic precipitation. It is very likely that the precipitative mechanism for gypsum in the capillary fringe in Ras Muhammad is the same at the nearby Nabq sabkha/pan (Attia 2013) and in the Abu Dhabi upper intertidal section.

Late Pleistocene Salinas, Egyptian Red Sea Coast

Ongoing aridity along the tectonically stable area of the Egyptian coast of the Red Sea (BWh Köppen climate zone), has locally preserved Pleistocene remnants of embayment salinas (khors) that had filled with laminated subaqueous gypsum during the Last Interglacial (Eemian, 5e = 5.5 Marine Isotopic Substage; Plaziat et al. 1995; Orszag-Sperber et al. 2001). Heavily eroded remnants of the sediments in these small gypsum-filled khors, each up to a kilometre across, are scattered along a 400 km long narrow coastal strip, backing on to Precambrian basement, between Ras Shukheir on the Gulf of Elat and Ras Banas on the Red Sea coast (Fig. 3.22). Evaporitic sediment was initially

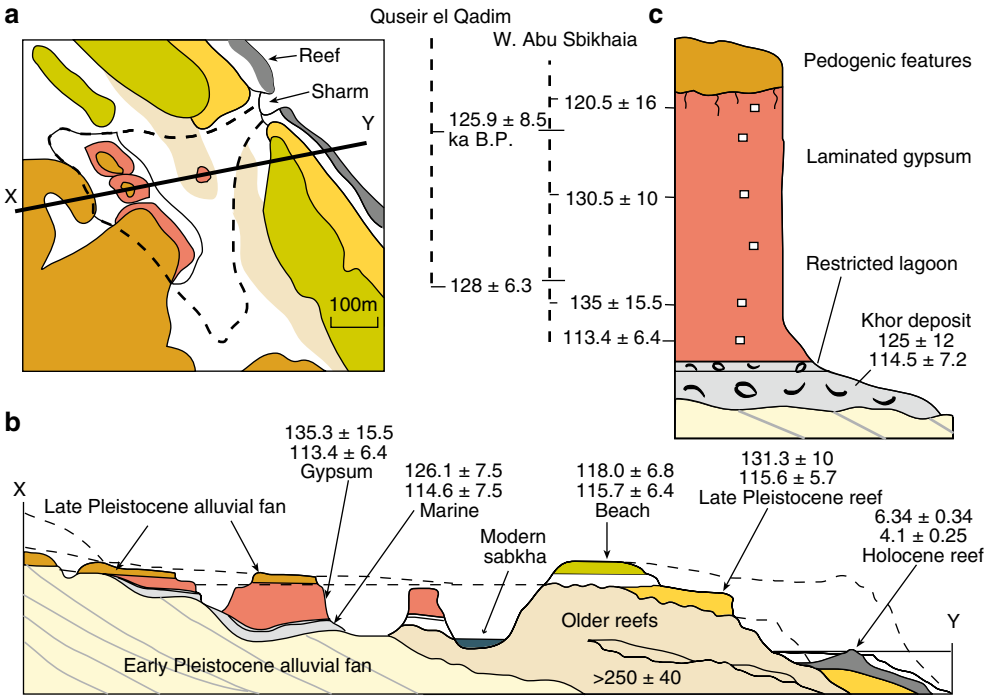

Fig. 4.16 Remnants of a Pleistocene salina, Red Sea coast, Egypt showing the geometry and age distribution of Late Pleistocene units and their Early Pleistocene alluvial fan substrate at Quseir el Qadim (**a** map; **b** cross section), (**c**) vertical section at wadi Abu Sbikhaia. The Late Pleistocene marine khor carbonates give U-Th dates similar to those of the overlying salina gypsum (After Orszag-Sperber et al. 2001)

deposited as shelly and subaqueous laminated gypsum in erosive depressions elongated parallel to the present shore and behind a subcontinuous Late Pleistocene fringing coral reef (Fig. 4.16a, b). The entrenched geometry and the marine to brackish evolution of the pre-evaporite faunas indicate deposition in a hydrographically-isolated depression behind a reef rim. Gypsum precipitation occurred during a brief relative sealevel drop that cut off the surface connection with the Red Sea. Both the reefal and gypsum units are Late Pleistocene, with a consistent set of U/Th dates around 123 ka bp. Ages from reef and gypsum are at times so close that there is no statistical difference between their respective ages in spite of the large number of dates collected by Orszag-Sperber et al. (2001).

This is not a matter of poor precision in dates, but indicates the very rapid rate of gypsum infill, once the khor lost its surface connection to the waters of the Red Sea. Narrow-mouthed embayments along the present coast quickly develop into kharms or khors that with further isolation and closure of the surface connection to the adjacent ocean of the Red Sea could became evaporitic drawdown basins filling with subaqueous gypsum units composed of coarse growth-aligned gypsum crystals up to 5–10 cm long (Plaziat et al. 1995). There is a possible Holocene counterpart to these systems on the Red Sea coast at Ras Shukeir (Aref et al. 1997) but laminar aragonite, rather than gypsum, dominates the fill in all modern kharms (Plaziat et al. 1995).

Textures indicating permanent Late Pleistocene salina waters atop the aggrading gypsum and the mm-laminae of carbonate that interrupted gypsum crystal growth suggest it was very similar in both its marine seepage hydrology and its depositional setting to the salinas of southern Australia and to Lake Asal (Fig. 4.16c). That is, it was an anchialine salina system (littoral saline lake) fed though the reef by permanent seawater seeps.

Tops of the laminated subaqueous gypsum outcrops locally grade up into polygonal gypsum pressure ridges near the top of the gypsum unit implying that the level of free-standing salina waters was about 3 m below the locally derived mean sea level as deduced from the shoreline of the former Late Pleistocene reefal unit (Orszag-Sperber et al. 2001). This reflects the evaporitic drawdown of the salina water level necessary to drive seawater seepage and gypsum precipitation.

Laminated salina gypsum in the Late Pleistocene Red Sea backreef is transitionally overlain by a massive pedogenic gypsum subunit (with root traces, burrows) interpreted by some as an emergent sabkha facies (Aref et al. 1997). It can grade laterally into older alluvial-fan substratum to become sloping gypsum crusts (gypcretes) cementing the gravels. These gypcretes and the sabkha facies clearly differ in process of formation and perhaps solute source from the laminated subaqueous gypsum. Likewise for the gypsum cements in coarse gravelly sand and sandy gravel about the khor edge, which were fed by a combination of marine aerosols and saline continental phreatic waters, seeping slowly seaward (Fig. 4.16b). Capillary rise of phreatic seawater is prevented by the elevation and coarseness of the host-material. Holocene gypcrete crusts throughout the Red Sea coast indicate a combination of marine aerosols and sulphate-rich

continental water leaching halokinetic Miocene gypsum, which outcrops near these Late Pleistocene salina remnants.

Slightly inland from the coast there are similarly textured laminated gypsarenite lenses in small depressions with heights ranging between 17.5 and 110 m above sea level. These are continental not marine fed salinas and are similar to continental salt lakes inland of El Alamein west of the Nile Delta (Fig. 3.24). There sediment fill lacks the basal marine fossiliferous sands that define the basal succession of many Late Pleistocene coastal salinas and watertable heights are so far above sea level that seawater seepage is impossible. Marine aerosol sources are a distinct but as yet untested possibility.

The highly dissected nature of all these 1-km scale examples of Late Pleistocene marine-fed evaporite khors along the Red Sea Coast attests to the low preservation potential of Quaternary coastal salina evaporites worldwide. The high frequency (100,000-year), high amplitude (100 m+) sealevel changes, that are diagnostic of icehouse climate, drive substantial dissolution of marine salts even in the very arid climate of the Red Sea (Chap. 5).

South American Salinas and Dolomite

One of the more interesting accumulations of modern evaporitic carbonate to be documented in the last two decades occur in a series of coastal depressions centred on Lagoa Vermelha, which is a small shallow isolated hypersaline coastal salina east of Rio de Janeiro, Brazil, situated in an Aw Köppen zone (Fig. 4.17a). Its Holocene fill provides the best evidence to date of the likely involvement of particular species of sulphate-reducing bacteria in producing primary dolomite (Vasconcelos and McKenzie 1997; van Lith et al. 2003; Vasconcelos et al. 2006; Delfino et al. 2012). Ca-dolomite is crystallizing within a black aragonitic sludge layer in Lagoa Vermelha muds at or near the sediment-brine interface under anoxic hypersaline conditions (Fig. 4.17b). Bacterial dolomite has also been identified, along with lenticular gypsum in nearby Brejo do Espinho (Delfino et al. 2012).

Although the near coastal setting is similar (compare Figs. 4.17a and 4.4), unlike the Coorong salinas, the source brines for these evaporitic carbonates on Vermelha are thought to be marine or connate groundwaters drawn into the salina by evaporative drawdown. Some marine-fed salinas in the Coorong occupy similar hydrographically-isolated subsealevel depressions (e.g. Halite Lake), but are in a more arid coastal setting and tend to precipitate greater proportions of laminated gypsum-aragonite, not dolomite in salinas with seawater feeds.

Both the initial precipitation and early diagenetic evolution of Lagoa Vermelha dolomites is strongly mediated by microbial activity. In fact, sulphate-reducing bacteria from Lagoa Vermelha samples, cultured in brines at low temperatures from artificial seawater, produced highly ordered dolomite in the laboratory at earth-surface temperatures (Vasconcelos and McKenzie 1997). *Desulphovibrio brasiliensis sp. nov*., a moderate halophilic sulphate-reducing bacterium from Lagoa Vermelha (Brazil) was identified as one of a number of BSR species that are mediating dolomite formation (Warthmann et al. 2005).

Evaporation lowers the lagoon water level in the dry season and drawdown then allows seawater to enter via seepage through the dune barrier. Elevated organic productivity in the lagoon leads to anoxia at the sediment-water interface and the formation of a black organic-rich carbonate sludge on the meromictic salina floor. The highly saline waters have elevated sulphate levels, which in the shallow subsurface provide a sulphur source for bacterial sulphate reduction, as well as elevated magnesium that is precipitated as Mg-calcite and calcian dolomite. Microbial activity in the sludge mediates the precipitation of these primary carbonates. Eventually microbial activity ceases, but the diagenetic precipitation of dolomite continues atop the microbially precipitated crystal substrate.

Vasconcelos et al. (1995) first suggested that sulphate-reducing bacteria in hypersaline waters promote the essential conditions needed for dolomite precipitation. Van Lith et al. (2002), after a detailed study of the hydrochemistry in the lagoons, concluded that elevated salinity and sulphate reduction are the main factors inducing dolomite precipitation in these lagoons (Fig. 4.17c, d). Their detailed measures of water and sediment conditions during an annual cycle (1996–1997) demonstrated that dolomite formed in May–June which was a time of high salinity. High $\delta^{34}S$ of pore water sulphate and high sulphide concentrations correlated with dolomitic horizons, demonstrating the association of bacterial sulphate reduction with dolomite formation.

Dolomite forms year round in another small nearby salina, Brejo do Espinho; perennial precipitation is a direct response to its higher year-long salinity compared to Lagoa Vermelha. High salinity apparently provides the ions and saturation state necessary for dolomite precipitation, while the observation that dolomite formed at times or in zones of decreased sulphate concentrations underlies the likely importance of bacterially-driven sulphate reduction in Brejo do Espinho. Bacterially-driven sulphide oxidation also drives dolomite precipitation in other as yet untested high salinity lakes in the same region (Moreira et al. 2004; Delfino et al. 2012). The precipitation of dolomite in the lab at earth surface conditions using various strains of halotolerant sulphate-reducing bacteria (Van Lith et al. 2003) underlines the fundamental role of microbial metabolism in these and likely many other saline anoxic environments (Chap. 9).

Sulphate ions in the muds form strong ion pairs with Mg^{2+} ions and so are held together in space like a single particle. When sulphate-reducing halotolerant bacteria metabolize

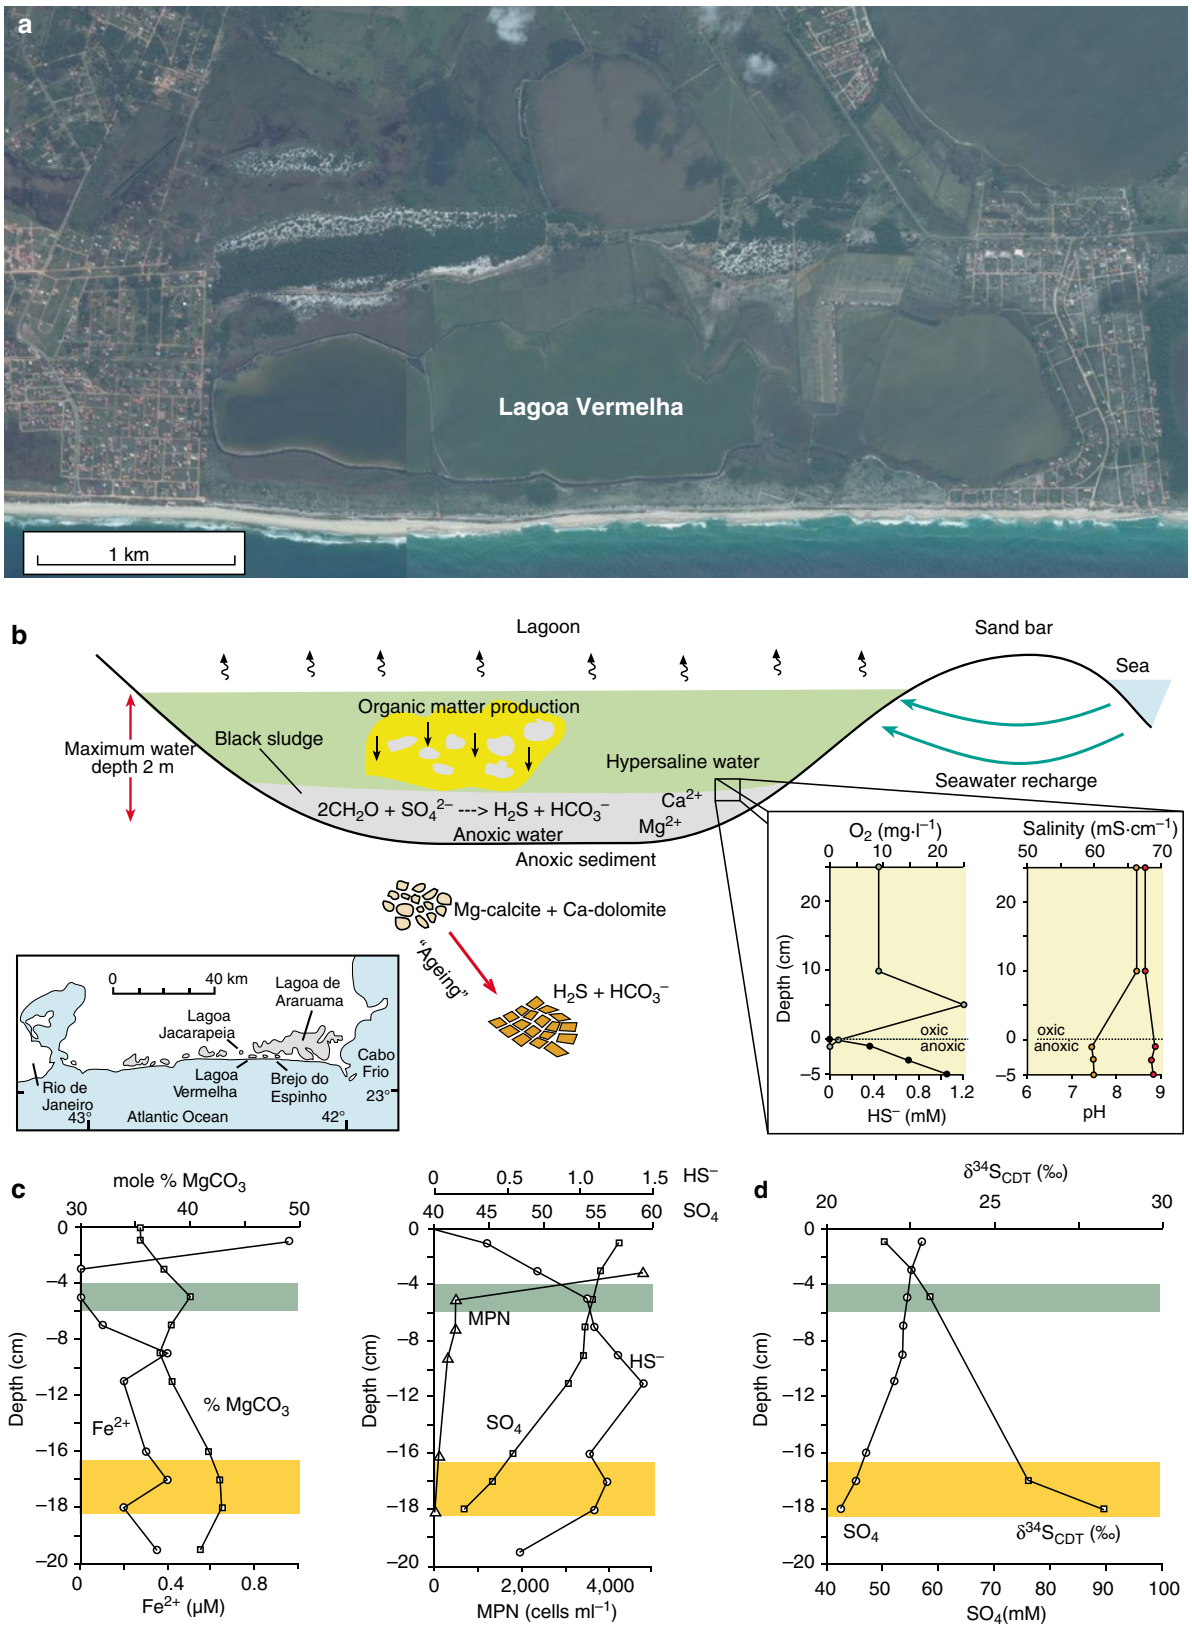

Fig. 4.17 Lagoa Vermelha, Brazil. (**a**) Aerial view of Lagoa Vermelha. (**b**) Schematic of microbial dolomite formation in Lagoa Vermelha and Brejo do Espinho, Brazil. Insets show the location of the salina on the Atlantic Coast and the pore water conditions immediately above and below the sediment brine interface. (**c**) Mol% $MgCO_3$ in carbonate, Fe^{2+}, HS^-, and SO_4^{2-} concentrations, and most probable numbers (*MPN*) of sulphate-reducing bacteria in Lagoa Vermelha sediment from 0 to 24 cm depth. (**d**) Dissolved sulphate concentration in pore waters of Lagoa Vermelha and its sulphur isotopic composition ($\delta^{34}S_{CDT}$). In April 1999 the core illustrated in **c** and **d** was taken and pore water extracted. The *coloured bars* indicate depths with well-developed Ca-dolomite horizons (After Vasconcelos and McKenzie 1997; van Lith et al. 2002)

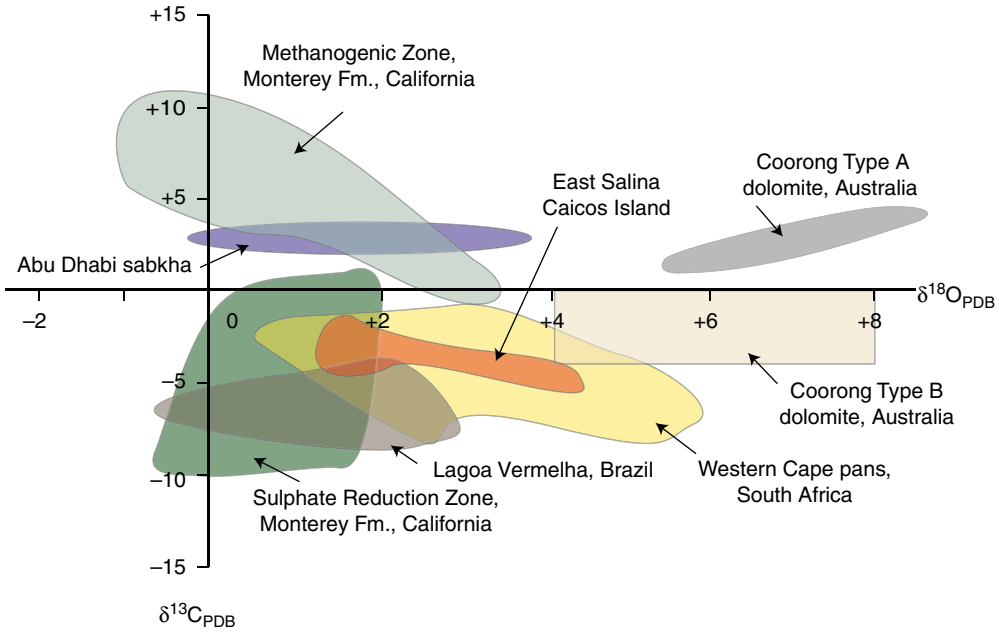

Fig. 4.18 Plot fields of $\delta^{18}O_{PDB}$ versus $\delta^{13}C_{PDB}$ values for Holocene dolomites and associated minerals in various documented sulphate reduction and methanogenesis zones (After Mauger and Compton 2011; Warren 2000a, and references therein)

SO_4 ions, they also metabolise the accompanying Mg^{2+} ions inside their cells. Magnesium is essential for many vital physiological functions in the bacterial cell, and makes up 0.5 % of the cell's dry weight in halotolerant strains. During bacterial metabolism, excess Mg is released together with other byproducts of sulphate reduction, such as bicarbonate ions and hydrogen sulphide (Chap. 9). Saturation with magnesium in microenvironments around the bacterial cell probably creates conditions favourable for preferential precipitation of dolomite, as is observed in lab-based bacterial culture experiments (Van Lith et al. 2003).

Using their understanding of the Lagoa Vermelha dolomite system as their starting point, Vasconcelos and McKenzie (1997) proposed a new actualistic model for dolomite formation that they call the microbial dolomite model (Fig. 4.17b). An anoxic turbid layer at the sediment surface creates a special magnesium-entraining environment where photosynthetically produced organic matter can be microbially recycled by sulphate-reducing bacteria on a submicron scale, with concomitant precipitation of high-Mg calcite and Ca-dolomite. In contrast, to the sulphate-reduction model of Kastner (1984), which required a lack of sulphate, this model requires a continuing supply of sulphate in order for halotolerant sulphate-reducing bacteria to metabolise and so precipitate dolomite (Fig. 4.17b). It seems that living sulphate-reducing bacteria are required to overcome the kinetic problems of penecontemporaneous dolomite formation.

Once dolomite bionucleation has occurred, the Ca-dolomite ages; as is indicated by depth-related trends of larger dolomite crystal size, more negative $\delta^{13}C$ values and increased stoichiometric ordering of the dolomite lattice. Bacteria apparently remain important in shallow burial, as seen by the continued presence of nanobacteria on the surfaces of the "aging" crystals. With time, and deeper in the sedimentary section (70–90 cm), the crystals grow by a layer-by-layer mechanism that creates smoother and euhedral crystals. Apparently, once the dolomite is nucleated, crystals can continue to grow by inorganic processes, but each new layer still appears to be composed of coalesced submicron-size bacterial balls (spheroids). The microbial dolomite model requires an ongoing supply of sulphate to maintain the microbial activity promoting dolomite precipitation. In contrast, it may be that the presence of sulphate in a sterile (bacteria-free) environment may act to inhibit dolomite precipitation as shown in the laboratory experiments of Baker and Kastner (1981) and Morrow and Ricketts (1988).

Wright (1999) and Wacey et al. (2007) present a similar set of microbial arguments and laboratory experiments to explain the ease of dolomite precipitation in some of the carbonate salinas of the Coorong. Likewise, Mauger and Compton (2011) document microbial (BSR) mediated formation of Holocene dolomite in the near-coastal hypersaline pans of western Cape (centred on Yzerfontein), South Africa (Köppen Csb). Isotopically, with the exception of the Coorong, these coastal lagoonal dolomites show similar carbon-oxygen plot fields indicative of bacterial sulphate reduction, while the Abu Dhabi dolomites show the more positive carbon signatures, perhaps associated with archaeal methanogenesis.

Coorong isotope data are perhaps more influenced by evaporative concentration and Raleigh distillation in increasingly saline brines (Fig. 4.18; Rosen et al. 1988, 1989; Warren 1990). When comparing stable isotope values (including sulphur values) from dolomite and non-dolomite lakes in the Salt Creek region of the Coorong, Wacey et al. (2007), found it difficult to interpret the dolomite as unequivocally bacterial based on isotopic analysis, although they

favoured this origin. The evaporative concentration trends noted in earlier work on dolomite type-A by Rosen et al. (1988, 1989) and the two isotopically and crystallographically separate dolomite cluster fields, in Coorong dolomites defined in this work support at least a partial contribution from inorganic concentrative processes, as illustrated in Figs. 4.7 and 4.18. The defining study for the unequivocal bacterial origin of Coorong dolomite is probably yet to be published.

Unfortunately, in the realm of bacterially-mediated dolomite studies, some authors have attempted to draw a dichotomy between bacterial mediation and evaporitic conditions favouring dolomite precipitation, but this is an extreme view. The Brazilian, South African and Coorong pore waters are all settings where sulphate-reducing or methanogenic bacteria flourish. The same settings are also hypersaline, and depending on climate and hydrology their waters capable of precipitating evaporite salts, including nearby gypsum, as in South Africa and the Coorong. This is where the dolomite-mediating microbial community thrives in schizohaline sulphate-entraining salinities that can be seasonally up to four to five times that of seawater. It is a halotolerant community that thrives at the expense of a less halotolerant biota. That is, it is the somewhat elevated salinities in surface and near surface waters that allow appropriate halotolerant sulphate-reducing bacteria to flourish in pore waters that can be marine, nonmarine or hybrid (see Chap. 9). High salinity and halotolerant bacterial mediation of natural primary dolomite are associated, not separated, features in many natural hypersaline waters.

Continental Subaqueous Basins

Examples of subaqueous evaporite deposits discussed so far occur in hydrographically-isolated subsealevel coastal depressions fed solutes via inflows of marine groundwaters. The resulting marine-fed evaporitic sediments accumulate at limited scales (1–20 km across) and limited thicknesses (<10 m). Such deposits have little or no longterm preservation potential within the rapidly migrating shorezone hydrologies that typify today's icehouse eustasy (Warren 1991). To find active examples of thick widespread subaqueous evaporite deposition in Quaternary sediment, we must move to continental lacustrine settings in lake depressions characterised by perennial saline water bodies. This setting corresponds to the third category of Hardie et al.'s (1978) classification of saline lacustrine settings described in Chap. 3; namely the perennial stream floodplain – perennial saline lake. In such a setting Quaternary evaporites have filled lake basins measuring up to a 100 km across with stacked saline beds that can be more than tens of metres thick.

Perennial Saline Lakes

Subaqueous lacustrine beds typically alternate with brine pan and sabkha salt beds in most active continental saline lakes. Changes from one depositional style to another relate to changes in inflow volume and chemistry and often indicate a change in climate, fluvial supply and/or tectonics. Saline perennial lakes and pans typify the topographically lowest part of a endorheic lake basin. Most subaqueous lake sediments are dominated by carbonates and siliciclastics, higher salinity salts are less common. This reflects the hydrology needed to form a permanent saline lake. That is, to maintain a perennial above-surface brine body requires continuous water inflow to the lake depression, either from river inflow or from spring seeps.

The definition of what surface salinity constitutes a modern saline lake varies between the Northern and Southern Hemispheres; Hardie et al. (1978) chose a minimum concentration of 5,000 ppm to define saline lake waters, based on Beadle's (1974) definition of the upper salinity tolerance of freshwater organisms. In contrast, most Australian limnologists use 3,000 ppm to separate freshwater and saline biotas (Geddes et al. 1981).

Regardless of its minimum salinity, a perennial brine lake and its biota is at the mercy of variations in the local climate and inflow intensity. Lake water levels and salinities are subject not only to seasonal changes but to longterm fluctuations in climate and tectonism. In the short term the volume of inflow water increases after a storm or winter snow melt; in the long term a change to a more humid climate increases the volume of water in the lake depression, while a change to more arid conditions decreases the volume of surface water and may convert a perennial saline lake into a saline pan or evaporitic mudflat. Tectonic uplift also affects lake deposition, it can convert what was formerly a hydrologically open basin into an endorheic basin, or vice versa, volcanism and lava flows can do the same. Tectonism can also change the position of the topographically lowest point in the lake and, via uplift in the drainage region-, can change the volumes of surface runoff, groundwater seepage and inflow chemistry.

The chemical make-up of continental lake brines is much more variable compared to the near isochemical seawater reservoir that supplies mostly gypsum and halite to modern coastal salinas (Table 4.2). Proportions of the various ions in perennial saline lake waters are controlled by chemistries of the dilute inflows, which are a combination of rainfall intensity and the lithologies in the drainage area surrounding the lake (Fig. 2.19).

Great Salt Lake, Utah

Great Salt Lake is a perennial water body and has been so for the last 30,000 years. It is the largest saline lake in the United States and one of the largest perennial saline lakes in the

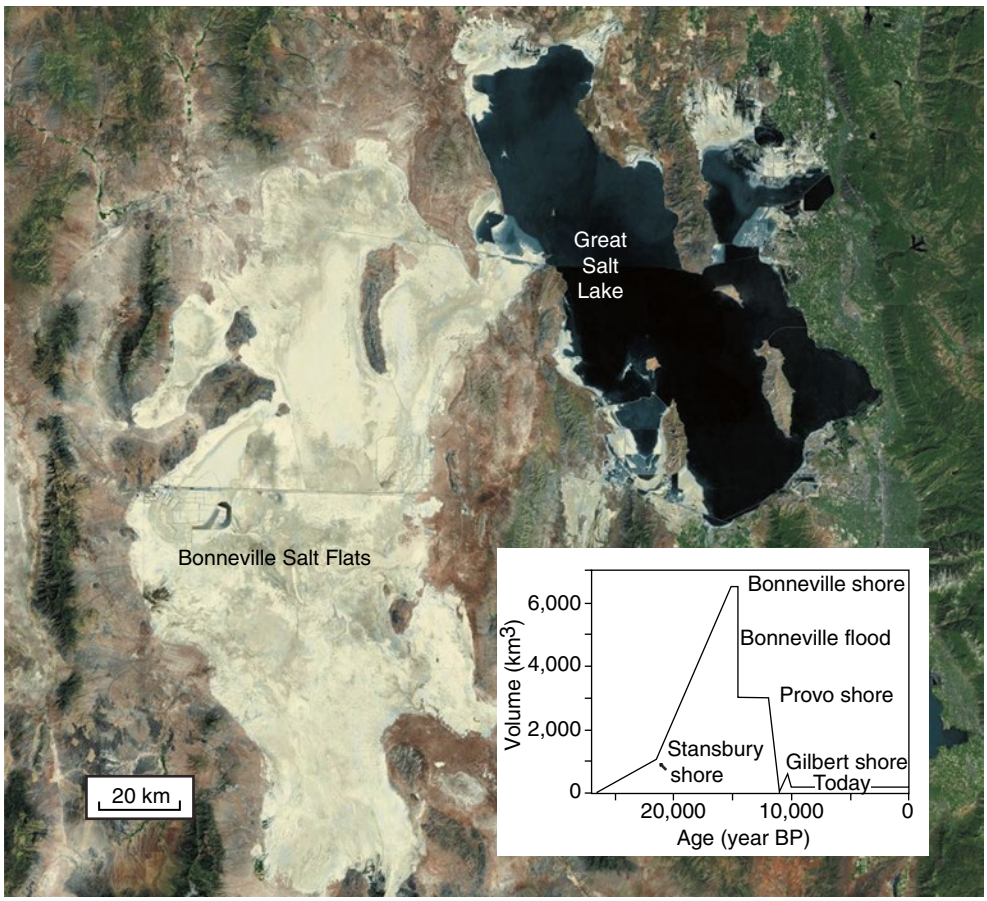

Fig. 4.19 Great Salt Lake and the Bonneville Salt Flat, Utah and the adjacent peaks of the Wasatch Mountains east of the lake depression. A railway causeway that transects the northern arm of the lake is visible, as are solar evaporation ponds. The Lake Bonneville salt flats (*lighter coloured*) lie to the west of the Great Salt Lake. *Inset* shows changes in lake water volumes over the past 25,000 years

world, measuring some 120 km (75 miles) long and 55 km (35 miles) wide, with a water surface elevation that oscillates around 1,280 m (4,200 ft) above sea level (Figs. 4.19 and 4.20). At this elevation the lake brines cover an area of 4,180 km^2 and have a maximum depth of 10 m. In a typical year the water surface fluctuates around 30–60 cm, reaching its highest level in May-July (after snow melt) and dropping to its lowest level in October-November. Since 1847 the water level of Great Salt Lake has varied from a low of 1,277.5 m in 1963 to a high of 1,283.75 m in 1986–87

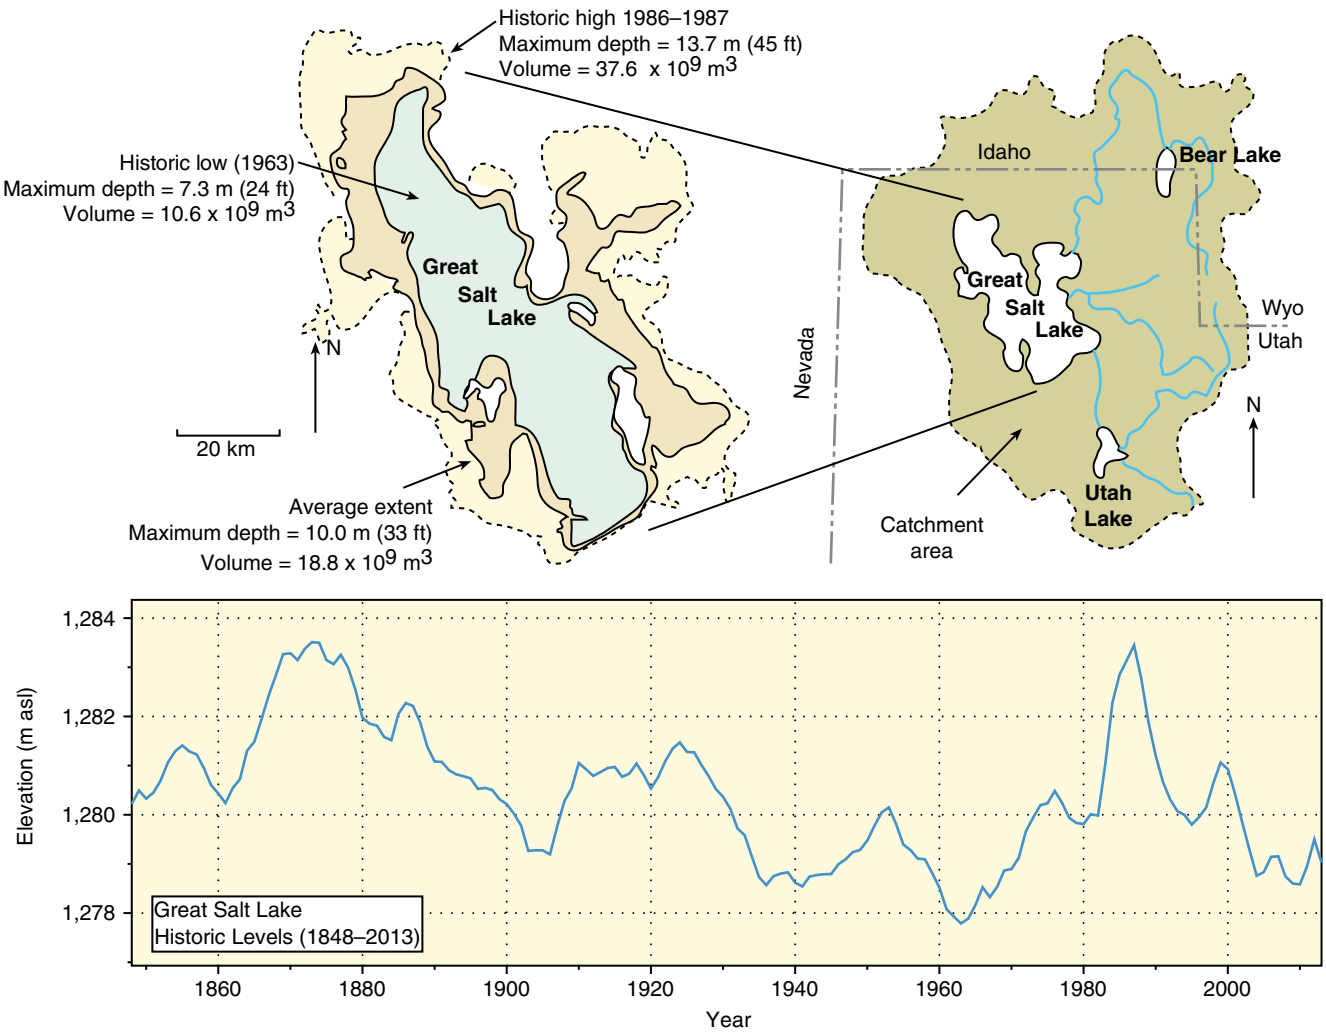

Fig. 4.20 Great Salt Lake, Utah. The lake is subject to large changes in the extent of its perennial water body. The *upper figure* shows the different extent of its highest and lowest levels in historical time. The chart plots yearly changes of lake water level since 1847

(Fig. 4.20). The 3.7-m rise in the level of the Great Salt Lake (Utah, USA) between 1982 and 1986, leading to the record historical high in lake water level, was at least partly related to the record rainfall and snowfall in its catchment during the 1982/3 El Niño (Arnow and Stephens 1990). Because the lake is so shallow and its floor so flat, small changes in water level correspond to large migrations of the strandline.

Great Salt Lake lies in an endorheic basin with no surface outlet. The main rivers entering the lake are the Bear River from the north, the Weber and Ogden Rivers from the east, and the Jordan River from the south (Jones et al. 2009). Together with small volumes of bajada runoff, the rivers supply around two thirds of the water currently entering the lake. Direct precipitation into the lake supplies some 31 %, while ground water supplies the remaining 3 %. The drainage basin of the lake today covers an area of about 57,000 km^2 (21,500 mile^2). Water is lost from the lake mostly through evaporation, with something like 3,500 km^3 of water evaporating annually (Fig. 4.20). When inflow equals evaporation, the level of the lake remains constant. If inflow is greater or less than evaporation, the level of the lake will rise or fall, respectively.

Being situated along the Wasatch Front at the eastern edge of the tectonically active Basin and Range Province, means the size, shape, and location of the Great Salt Lake depression has been a response to variable intensities of subsidence and faulting, overprinted by the intense climatic vagaries of the Late Pleistocene. It currently straddles BSk and Cfa Köppen climate zones. Present-day Great Salt Lake is a remnant of a much larger and fresher water body that was once linked into the Pleistocene Lake Bonneville system, as were Utah Lake, Sevier Lake, and the Bonneville Salt Flats (Fig. 4.21a). Areas of perennial fluvial inflow into Pleistocene Great Salt Lake are defined by classic "bird's-foot" or "Gilbert-style" hanging deltas (Fig. 4.21a). The downcutting of the current hydrology and the presence of Pleistocene shoreline terraces on higher levels of the delta prism suggest

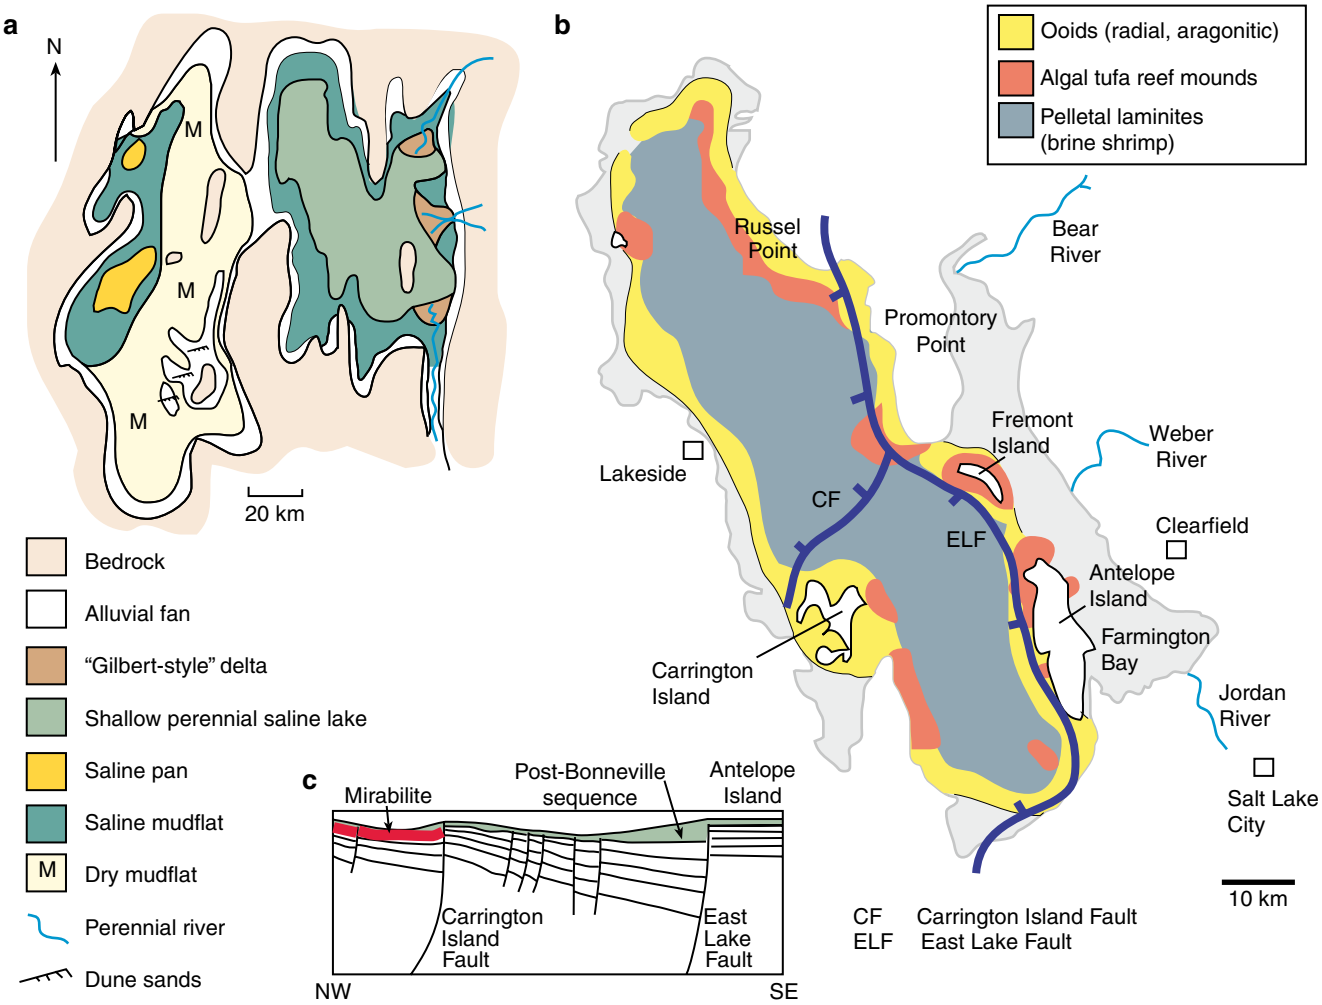

Fig. 4.21 Sediment distribution in Great Salt Lake and surrounds. (**a**) Distribution of depositional settings in the Bonneville/Great Salt Lake basin, Utah. The lake itself is a perennial water body fed by rivers with "bird's-foot" deltas at the older entry points into the lakes. The saline pan facies are halite-rich with lesser glauberite, while the dry and saline mudflats are subaerially exposed parts of the old subaqueous floor of Lake Bonneville. Carbonate mudstones, mostly aragonite pellets, dominate sediments currently accumulating on the subaqueous lake floor (After Smoot and Lowenstein 1991). (**b**) Distribution of algal tufa reefs and ooid sand shoals about the strandzone at the edge of the perennial water body in Great Salt Lake. Positions of the East Lake Fault (*ELF*) and the Carrington Island Fault (*CF*) are shown (After Eardley 1938; Colman et al. 2002). (**c**) Schematic cross section based on seismic lines between Antelope Island and Carrington Island showing the importance of syndepositional faulting in controlling thickness of post Bonneville (<13.5 ka) sedimentary packages (*grey*) and the distribution of the mirabilite bed in the lake (After Colman et al. 2002)

deltas were most active during Pleistocene lake full stages (Lake Bonneville time) when the lake was not accumulating evaporite salts (Spencer et al. 1985a, b; Balch et al. 2005; Jones et al. 2009).

Modern strandzone deposits are mostly shorezone spits and bars, which are dominated by aragonitic ooid and peloidal sands (mostly brine shrimp pellets). Carbonates also precipitate about the lake strandline in spring mounds, algal mounds, and in stromatolites (Fig. 4.21b; Eardley 1938; Halley 1977). Older algal reef mounds are located further out in the lake and are now buried by lake muds; they grew earlier in the Holocene when lake water levels were lower than today (Colman et al. 2002). Oolite shoals today form sand waves that define the lake strandzone (Fig. 4.21b). Individual ooids are aragonite with a radial crystal structure. When and how the individual ooids grew is not well understood, but halobacteria and organic matrices are thought to play a role (Sandberg 1975; Pedone and Folk 1996; Reitner et al. 1997).

Laminated mudstones, in large part composed of the faecal pellets of brine shrimp, are currently accumulating further out in the lake (Eardley 1938). The pellets are a mixture of aragonite and detrital matter, mostly quartz, clays and organics. The brine shrimp *Artemia gracilis* thrives in the lake, it is a filter feeder that flourishes in spring and summer. It supplies a seasonal rain of faecal pellets to the lake bottom and its droppings represent a sampling of the mineral matter

suspended in the water column. This implies aragonite is a seasonal precipitate within the upper part of the meromictic water column (see Chap. 9 for biology and feeding styles of brine shrimp and other halozoa).

Rippled sand lamina alternate with laminar mud in the deeper water deposits of Great Salt Lake, with many deeper beds disrupted by the growth of now-dissolved evaporites (Unit I; Spencer 1983). Remnants of bedded Holocene halite still remain on the deepest parts of the lake floor, preserved by longterm density stratification in the overlying waters. Spencer (1983) recovered euhedral gypsum in the upper 1–2 m of the now water-covered aragonitic sediments of the lake centre. This sediment also shows evidence of haloturbation and pinch-and-swell bedding. Below this is a 1 m-thick bed of finely laminated aragonitic clay and algal mat partings, which passes laterally into bedded mirabilite (Unit II; Spencer 1983). Shallow seismic shows this mirabilite unit is restricted to a fault-controlled depression north of the Carrington Island Fault (Fig. 4.21c). Laminated aragonite is underlain by laminated calcitic clays, interspersed with lamination-poor ostracod-rich horizons. Spencer (1983) interpreted this bed (his Unit III) as the deepest water unit recovered in his coring program. Only one core penetrated below this deeper water unit to recover clays and muds of what may be a subaerial mudflat (Unit IV).

Prior to 32 ka, the basin was an ephemeral pan – saline mudflat system (Unit IV). Since then, Great Salt Lake has mostly been a perennial water body, initially a shallow saline brine lake, then a brackish lake between 25 and 19.5 ka. Between 19.5 and 17.5 ka a fresher, but somewhat restricted, lake occupied the basin with a water surface near or above the Provo level (water was ≈ 195 m deep). Fresh water conditions with a standline near the Bonneville level existed around 17 ka (with waters around 310 m deep). Then 16,800 years ago a sharp drop in lake level occurred as Lake Bonneville was drained suddenly into the Snake River Basin through the Red Rock Pass region in Idaho. This catastrophic drop occurred after the rising waters of Lake Bonneville topped a natural dam formed by coalesced alluvial fans at Red Rock Pass. This flood set up an ongoing crossflow, which rapidly eroded and downcut into the fans, dropping the lake level by 105 m (see inset in Fig. 4.19; O'Connor 1993). The flood from this event was catastrophic, releasing some 4,168 km^3 of water in the first few weeks and lasting about a year. At peak discharge, flow was around one million m^3/s and the incision was some 100 m deep. The resulting scabland swath leading into in the Snake River Basin is some 5 km wide are still visible today. Before the catastrophic draining, Lake Bonneville had a surface area of 51,000 km^2 (on par with Lake Michigan or lake Huron) and was up to 300 m deep.

The lake shrank further around 14,000 years ago as glaciers retreated from North America and the climate became more arid. Between 14 and 8 ka the lake was at extremely low levels and at times was divided into two separate saline basins. For the past 8 ka the lake has fluctuated near its present level. Much of the salt now contained in the Great Salt Lake was originally dissolved solute in the waters of Lake Bonneville. An additional two million tons of dissolved salts now enter the lake each year via river and spring inflow, which carries leachate from the surrounding soils and rocks.

Recent study of a single long core that records the last four glacial/interglacial sequences in the Great Salt Lake Basin has shown that salt/freshwater marshes as documented by Spencer (op cit) were common during interglacials (Fig. 4.22; Balch et al. 2005). Deep freshwater conditions correspond with the maximum global ice volume in Oxygen Isotope Stage 2, and before a maximum in global ice during Oxygen Isotope Stage 6. Immediately following each deep lake period the lake level crashes via rapid desiccation that deposits thick evaporite units.

Fault-accommodated subsidence in the Great Basin has now filled the depression with more than 3,700 m of continental sediment, with most of the sediment carried in by the major rivers. Two currently-active faults underlie Great Salt Lake (Fig. 4.21b, c; Colman et al. 2002). The East Lake Fault passes along the west edge of Antelope and Fremont Islands and on northwards by the west side of Promontory Point. The Carrington Fault extends northeastward from Carrington Island to merge with the East Lake Fault of the southwest tip of Promontory Point.

Most of the current strandzone facies along the eastern side of the lake are tied to the topographic escarpment created by the East Lake fault, many now buried Holocene tufa-reef mounds also sit atop subsidiary faults in the lake. Similar broader-scale fault-controls to Late Pleistocene lacustrine geometries are seen in seismic facies throughout the lake basin. Colman et al. (2002) concluded that the Great Salt Lake basin has been, and continues to be, an area of active extensional tectonics and that tectonics has exerted a major effect on the distribution and type of sediments in the lake. Currently, the East Lake Fault is at least as active as any of those along the Wasatch Front, showing at least three episodes of significant faulting since lake water level fell around 13.5 ka from its Pleistocene high. The upthrown side of the Carrington Fault today forms a sill, with a seismically resolvable tip that is only about 5 m below present lake floor. Fluid flow into the lake along this and other fault planes may explain some of the indurated bioherm mounds and pavement sheets present on the lake floor.

The fall of the lake waters that marked the end of the high Bonneville phase led to the formation of a basin-wide seismic horizon associated with lowered lake levels (Colman et al. 2002). Mapping of this reflector shows that the southern basin comprises a distinct sediment wedge thickening toward the East Lake Fault, a geometry that contrasts, to

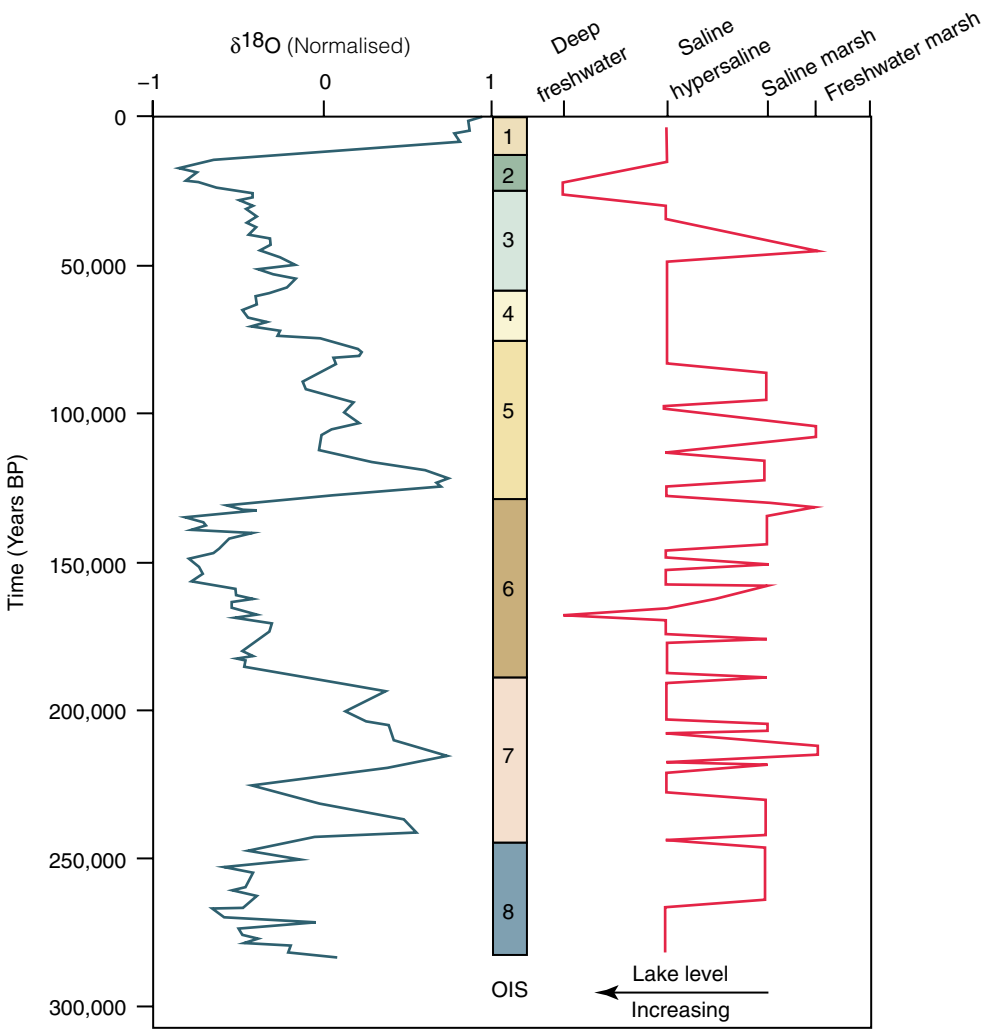

Fig. 4.22 Great Salt Lake, showing water elevation variations and corresponding environments over the last 300,000 years, plotted against Marine Oxygen Isotope stage (*OIS*) with corresponding $\delta^{18}O$ curve (After Balch et al. 2005)

some degree, with the smooth symmetry of the current lake floor (Fig. 4.21c). Seismic facies maps also show the lake level during the early Holocene was considerably lower than today; it was a time when the lake was an intermittently flooded playa and when up to 13 m of post-Provo halite accumulated near the East Lake Fault. At that time small remnant water bodies probably ponded in local lake-floor grabens along the downthrown sides of active fault scarps. Thus fault-controlled tectonics controlled the distribution of the various early Holocene pan evaporites, including the mirabilite/halite beds (Fig. 4.21c).

Within this tectonic framework, Late Quaternary climate change across the Great Basin altered solute proportions in the lake inflows and so influenced mineralogies in the evaporite suites accumulating in low water stages in Great Salt Lake. Spencer (1983) defined three major styles of inflow to the lake system; (1) concentrated Na-Cl dominant spring waters, (2) dilute Ca-HCO_3 river waters, and (3) dilute Ca-HCO_3 precipitation (rainfall and snow melt). During the fresh-water period of the Lake Bonneville and other pluvial times, the inherently higher levels of meteoric discharge to the lake meant inflow chemistries were dominated by calcium bicarbonate waters. Saline stages, as in most of the Holocene, are characterised by lowered meteoric inflow volumes and so fault-fed hydrothermal springs are an increasingly significant solute source. Between 15 and 8 ka the lake waters were cold and relatively depleted in Cl. Mirabilite accumulated in the lowermost parts of the cold, largely subaqueous meromictic lake floor, in a setting much like the subaqueous salts of the modern meromictic saline lakes of the Canadian interior (Fig. 12.19).

Since that time, conditions became drier and warmer, with higher proportions of Cl-rich waters entering the perennial lake. Halite was precipitated prior to mirabilite during hypersaline or droughty episodes in the lake and this mirabilite is still an ephemeral mineral in the pans of the North Arm. Before the lakewide drawdown that ended Lake Bonneville, the dominant lake carbonate was calcite. Since that time a more arid climate has dominated and aragonite is the dominant carbonate precipitate.

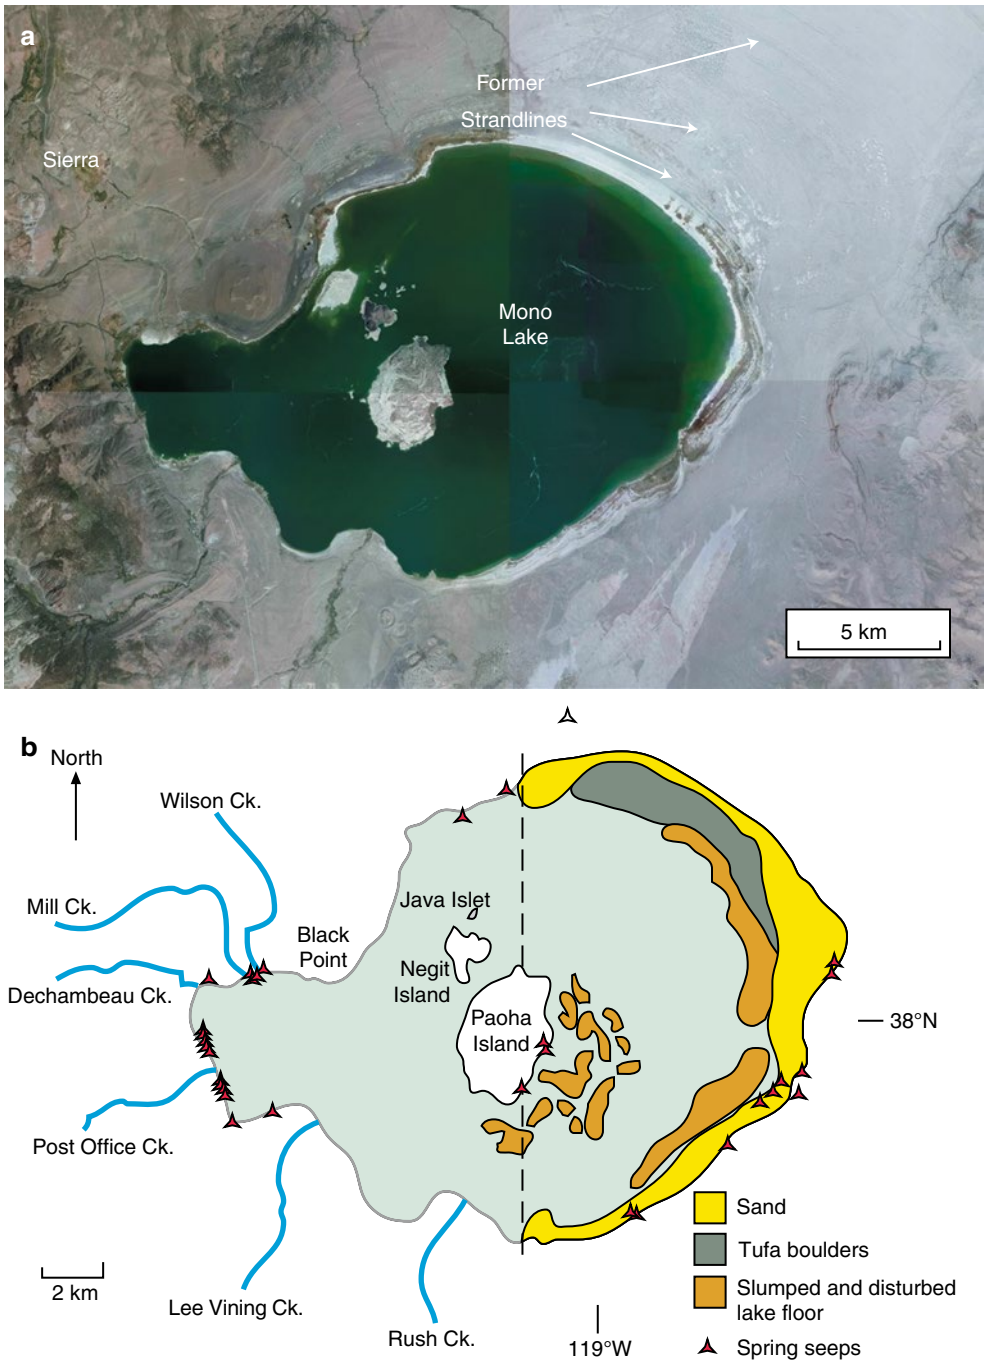

Fig. 4.23 (**a**) Mono Lake, California. Successive strandlines associated with lake shrinkage are visible in the Landsat image, as are the volcanic centres of Paoha Island and the adjacent lake plain to the northwest. High relief drainage source to the west in the Sierra Nevada is clearly seen in the high proportion of creeks entering the western side of the lake (Landsat image courtesy of NASA). (**b**) Geological interpretation of the type of sediment is only published for the eastern half of the lake – extent indicated by dashed line (In part after Benson et al. 2003)

Mono Lake, California

Mono Lake, an endorheic meromictic alkaline saline lake with an average depth of 17 m, in a volcanically active area at the edge of the Sierra Nevadas, California (Fig. 4.23a), which has been accumulating laminated lacustral sediments since 760 ka. Current free surface brine volume is ≈3.2 km^3, surface area is 184 km^2, annual total inflow is around 283.7×10^6 km^3 and current salinity is around 90,000 ppm. It lies in a Csb Köppen climate zone. Major anion content of lake brines is divided almost evenly between chloride, sulphate, and bicarbonate. The high pH (≈9.8) and alkalinity of lake waters leads to high concentrations of volcanic elements that ordinarily have short residence times in lakes (i.e. lanthanides and actinides, including naturally high levels of arsenic in bottom brines; Tomascak et al. 2003). Calcium carbonate (calcite and aragonite) precipitates spontaneously from the lake waters and makes up 3–10 % of the laminite sediment on deeper tufa-free bottoms, the remainder is detrital. Some of the lake bottom laminites are slumped, possibly initiated by ongoing volcanic disturbance

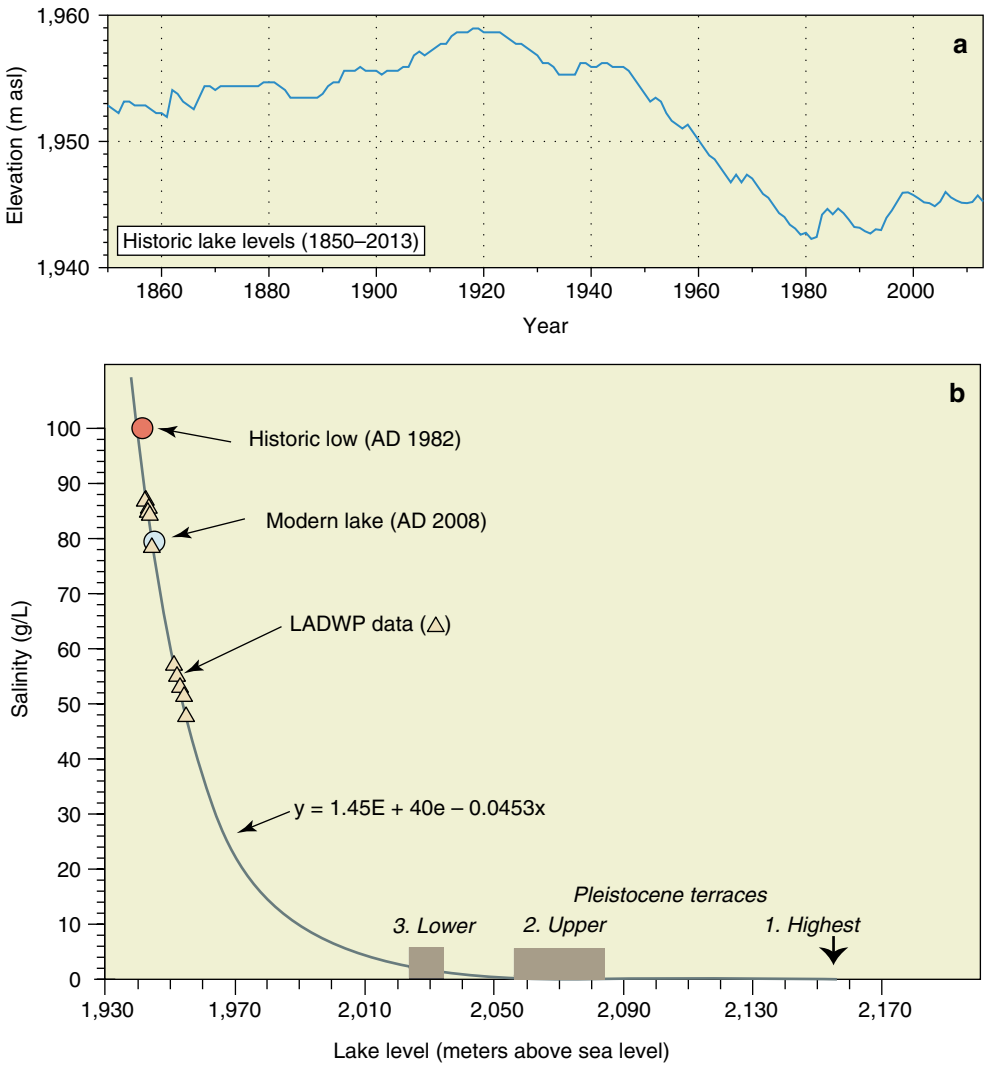

Fig. 4.24 Mono Lake levels (**a**) Historic levels from 1850 to 2010 (Replotted from online data of Mono Lake Preservation Society last accessed on June 3, 2013 at http://www.monolake.org/live/lakelevel/yearly.htm). (**b**) Exponential relationship between Mono lake level and salinity is extrapolated to show very low salinities in the ancient lake levels associated with the Pleistocene terraces that surround the current lake (After Zimmerman et al. 2011)

(Fig. 4.23b; Benson et al. 2003). Calcite accumulates, sometimes with an ikaite precursor, where resurging groundwaters degas on the lake floor and can form spectacular biogenically-bound towers of tufa.

Lake Levels and Conditions

From 1850 until the middle of last century the lake water level rose some 5 m, then the water needs of the City of Los Angeles caused a drastic water fall. In 1941 the State Resources Board diverted the distributaries that fed Mono Lake into the Los Angeles aqueduct. In the 50 years since the diversion, Mono Lake water level dropped more than 10 m, the lake water volume was cut in half, while the alkalinity and salinity of the lake waters doubled (Fig. 4.24). Water levels were as high as 1958 m above sealevel, before the diversion of Mono's tributary streams. Subsequent lower lake levels exposed numerous calcitic tufa mounds and pinnacles on the lake floor and enlarged the portion of the lake floor made up of subaerial saline mudflats.

To prevent further desiccation of the lake, some water from the former distributaries has been rediverted back into Mono Lake, which is now slowly refilling after reaching an all time low of 1,942.2 m asl in 1982 (Fig. 4.24a). The current lake level is 1,944.35 m asl (June, 2015). The projected stabilized lake elevation is 1,948.3 m, but reference to Fig. 4.24 argues this may not be attained in the next few years. Interestingly, the anthropogenic lowering of lake water level in the last half-century and the associated increase in lake salinity is still well within the range of natural fluctuations experienced by Mono Lake in the last 2,000 years (Fig. 4.25a, b). Historic salinity and lake levels measurements can be related, exponentially, Zimmerman et al. (2011) document this relationship (Fig. 4.24b). It clearly shows that as lake levels fall the lake salinity increases. It implies that lake waters were fresh in the Pleistocene at times the various high lake level terraces were formed.

In years with large fresh water inputs the lake may become meromictic. The more usual state of the lake is

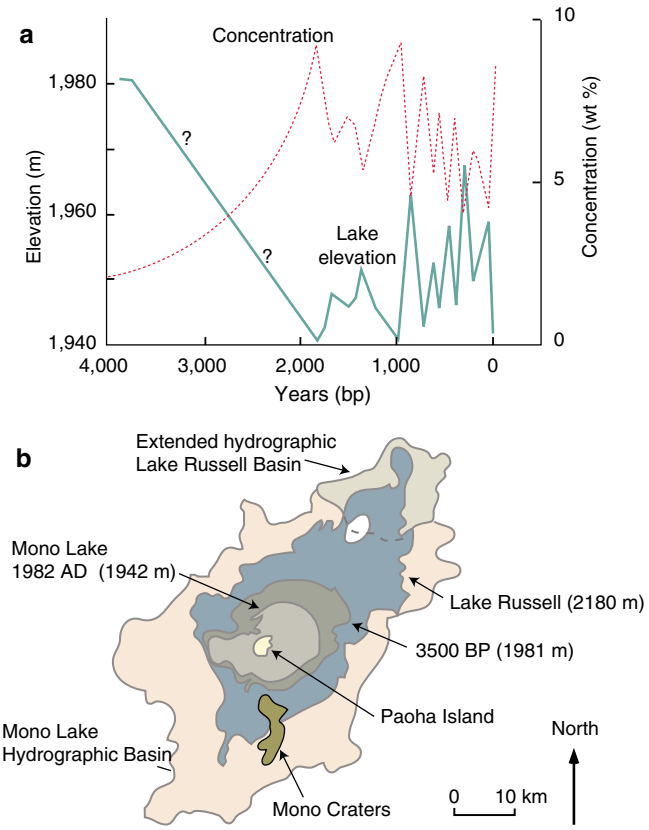

Fig. 4.25 Mono Lake, California. (**a**) Hydrological conditions for the last 4,000 years (After Stine 1990). (**b**) Map outlining different lake areas related to changing water elevations through time (After Rogers and Dreiss 1995a, b)

monomictic (annual mixing). In 1994, an unintentional consequence of lessening drainage water diversions from the Mono basin into the LA aqueduct was the onset of a period of anthropogenically induced "meromixis" (Jellison et al. 1998). Earlier, in 1982 and 1983, the lake had also become meromictic when exceptionally large volumes of freshwater runoff led to a rapid 2.6 m rise in surface elevation of the lake (Jellison and Melack 1993). In 1984 this chemical stratification accounted for a density difference of 1.2–1.5×10^{-2} g/cc between the 2 and 28 m water depths. At the same time the midsummer density difference between 2 and 28 m brine depths that was due to temperature was approximately 0.5×10^{-2} g/cc. Salinities ranged from 77 to 98 g/l across the interface and sodium, chloride, sulphate, and carbonate were the major ions in both the upper and lower water mass.

The lake's second transition from monomixis to meromixis began in 1994–1995 and had ended by 2004. A comparison of density differences between the 2 and 28 m water depths indicate thermal stratification predominated in 1993 and 1994 (monomictic years), while chemical stratification dominated the density differences in 1995, 1996 and 1997 (meromictic years) (Melack and Jellison 1998).

When monomictic, the lake has typically thermally stratified in March and mixed to the bottom by December. Since 2004, the lake has mixed annually with the loss of seasonal thermal stratification as it had in 1993 and early 1994, prior to 8 years of meromixis. During the meromictic conditions in the late 1990s, the absence of holomixis during winter created persistent anoxic conditions beneath the chemocline. This led to the accumulation of ammonium in the monimolimnion, its depletion in the mixolimnion, and low mixolimnetic chlorophyll concentrations in the spring and autumn (lessened photosynthetic activity).

Tufa Mound and Pinnacles

The most visually striking geological features of Mono Lake are its metres-tall tufa columns, which protrude from lake waters and line portions of the lake edge. These mounds and needle-like pinnacles of calcium carbonate frequently define linear trends that are the seepage expression of underlying faults and joints (Fig. 4.26). Soft bottom sediments surround columns and many columns are rooted in massive domal buildups of calcite. Dominant growth orientation is vertical and defines the rapid upward rise of less saline CO_2-rich waters. Branching of lithoid columns is rare and "pseudobranches" easily explained by the collapse of one or two adjacent columns imply much of the precipitation mechanism is via inorganic degassing of groundwater on reaching the lake floor. Microbial biofilms coat active tufa surfaces beneath the lake waters and create characteristic knobbly grumous microtextures in the reef mounds and pinnacles as they capture the precipitated carbonate (Fig. 4.26b).

In today's lake waters calcite and aragonite are the carbonate minerals with long-term stability and they dominate the nonsiliciclastic fraction accumulating in the lake (Benson et al. 2003). But during the colder Tioga glacial period of the Late Wisconsian (12–9 ka), and during the present day winter season, ikaite ($CaCO_3 \bullet 6H_2O$), was the dominant carbonate precipitate (Whiticar and Suess 1998). Ikaite is a metastable cryogenic carbonate and the low temperatures needed for ikaite stability are obvious in winter in Mono Lake. In the winter of 1985 ikaite crystals were visible as coatings on the subaqueous surfaces of active spring seep tufas about the shallow lake edge (*pers obs.*). If these small ikaite crystals were removed from the icy cold winter waters of the lake and held in an ungloved hand, the increase in ambient temperature caused the ikaite to deliquesce, so that in a few minutes it disappeared leaving behind a pool of milky water. Council and Bennett (1993) and Bischoff et al. (1993b) argued that during winter, calcite precipitation in Mono Lake is inhibited by low temperatures and high concentrations of phosphates and organic carbon. The same factors allow metastable ikaite to form. Ikaite decomposes into calcite during the spring warming, occasionally leaving pseudomorphs of the primary precipitate in the calcitic tufa.

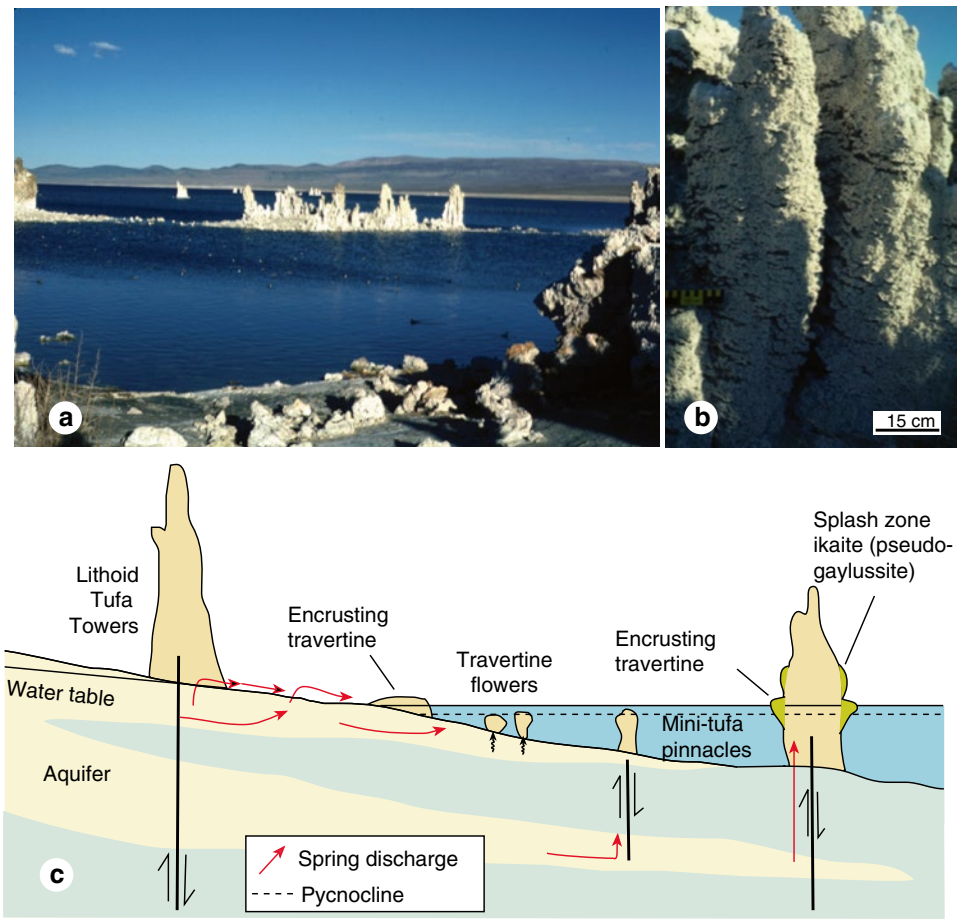

Fig. 4.26 Mono Lake, California. (**a**) Tufa pinnacles forming linear growths on the saline linear ridges in the lake floor in Nov. 1985. (**b**) Close up of algal-bound crenulated pinnacle surface and subhorizontal layering (scale bar is 15 cm long). (**c**) Schematic cross section showing aquifer control on the development of modern tufa mounds on the margin of Mono Lake California (After Council and Bennett 1993)

At a broader scale Council and Bennett (1993) demonstrated a strong hydrological control on the position of many of the larger lithoid tufa mounds. The unconfined aquifer that dominates the western side of the basin is composed of fluviodeltaic sediment and it controls the modern discharge at many points about the current lake shoreline (Fig. 4.26a, c). Currently active diffuse low-flow-rate seeps are dispersed across the strandzone, and extend from ≈200 m above the present lakeshore to around 1 m below the present lake water surface (Fig. 4.23). Diffuse outflows are geologically defined by flat beachrock-like zones of encrusting tufa and tufa flowers, and are most active about the present lake strandline.

Further offshore the aquifer is largely confined by lake muds, so CO_2-saturated groundwaters discharge onto the lake floor via fault and fracture focused conduits. The associated tufa (spring) mounds precipitate along linear trends, tied to positions where faults transect the confining clays. Other older, now exposed and mostly inactive, linear tufa mounds and encrustations define prior times of higher lake water levels and watertables. Modern springs mostly occur along the western side of Mono Lake with waters originating along the Sierra front. They discharge as Ca-HCO_3 waters, which are neutral to slightly acidic and their degassing drives present day tufa precipitation (Fig. 4.24b). In contrast, springs along the eastern shore typically discharge Na-HCO_3 waters, have lower hydraulic heads and are not generally associated with the formation of modern tufa sheets.

The identification of modern ikaite (pseudo-gaylussite) suggests that portions of many Pleistocene and Holocene tufas in the Mono Basin and other cold saline lakes in the Great Basin first precipitated as ikaite (Whiticar and Suess 1998; Shearman et al. 1989). These palaeo-ikaites have long since recrystallised to form their calcitic pseudomorphs (thinolites). Ikaite pseudomorphs are also found in recent and ancient sediments of Polar Regions where they are known as glendonites, or colloquially as "devil's horns". The environmental occurrence of ikaites and their pseudomorphs deem them as potential palaeoclimatic indicators of cold environments including saline lakes. Larger crystals are typically restricted to colder, deeper organic-rich marine sediments or groundwater outflow zones in cold moderately saline evaporitic basins (Buchardt et al. 2001).

Aside from Mono Lake and its spectacular tufa mounds, the other obvious geological feature in the immediate area of the lake is the Mono Craters (Fig. 4.25b). These are the remnants of 24 domes of explosive rhyolite, which erupted

over the last 40,000 years, with the last eruption occurring less than 700 years ago to form Panum Crater (actually a plug-dome volcano) located just above the south shore of Mono Lake. Black Point, Negit Island, and Paoha Island are all recent volcanic features of the lake geomorphology; Paoha Island emerged from the lake waters within the last 350 years. This recent volcanism drives hydrothermal circulation and is still active in the surface and subsurface hydrochemistry of the Mono Lake waters. It supplies elevated levels of sodium and bicarbonate ions compared to chlorine.

High concentrations of inorganic arsenic oxyanions (200 μM), rare earths and sulphate (130 mM) have also been reported (Tomascak et al. 2003; Oremland et al. 2000; Hoeft et al. 2004). Mono Lake water further contains very high levels of dissolved organic carbon (7 mM), although much of it is refractory to microbial mineralization and pulses of labile organic matter are released in spring and fall to the bottom from the breakdown of single- celled algae that inhabit the shallow lake water (Hoeft et al. 2004). Sulphate reduction accounts for 41 % of the mineralization of annual primary production in Mono Lake (Hoeft et al. 2004)

Hydrological and Hydrogeochemical Evolution

Up to 2 km of lacustral and volcanogenic sediments underlie Mono Lake, and saline groundwaters (>18,000 ppm) extend to the bottom of the basin's sediment fill (Rogers and Dreiss 1995a, b). The position of the saline-fresh groundwater interface within the lake basin reflects a balance between a dense saline brine plume or curtain beneath the lake and the force of inflowing fresh groundwaters fed from the Sierras and discharge near the lake's western shore. The rain shadow of the Sierra Nevada to the immediate west of the lake has had a dramatic effect on the asymmetry of surface and groundwater inflow to the lake depression. More than 114 cm of precipitation falls at the Sierra crest, which then supplies waters to the western side of the lake's drainage basin, mostly by surface drainage. Lee Vining Creek, Mill Creek, Rush Creek and Wilson Creek together supply $\approx 1.75 \times 10^{11}$ l/a to the lake (Fig. 4.23b; Tomascak et al. 2003). Less than 13 cm of precipitation falls on the eastern shore of Mono Lake. Altogether surface inflow supplies around 75 % of the lake's water and springs supply the remainder.

The much higher recharge rates for fresh surface and groundwater seepage along the western or Sierra Nevada side of the lake have pushed the saline-fresh water interface basinward of the shorezone beneath that side of the lake. This creates the artesian head that facilitates the formation of the more spectacular linear-trending tufa mounds. In contrast, the brine plume-freshwater interface lies near or directly below the shoreline around much of the rest of the lake. There the saline groundwater discharge zone is just below the playa surface and it contributes to development of saline mudflats and flat sandy beachrock/rubble atop recently exposed former lake beds in an area that lacks significant tufa pinnacles.

Simulations by Rogers and Dreiss (*op cit*) confirm that extensive faulting controls local permeability in the basin fill beneath the lake waters. Faulting increases vertical permeability and leads to focused or channelled regions of outflow and seepage in the lake floor. High permeability zones in the lake substrate on the western side means resurging less-saline groundwater can overcome the opposing force of the saline groundwater density plume and so can issue onto the lake floor where its degassing outflow is marked by linear belts of spectacular tufa precipitation, (Council and Bennett 1993).

In the longer time frame of the Mono Lake's Quaternary hydrology, the redistribution of the basin's solutes between the lake and underlying saline groundwater body is today still driven by late Quaternary lake level changes (Fig. 4.25b; Rogers and Dreiss 1995b). At times of low lake levels in the Late Pleistocene, the higher concentration and density of lake waters caused solute loss via free convection (brine reflux). This probably occurred more rapidly and penetrated deeper into the sediment column along open faults or fractures. At higher lake levels, the shoreline discharge zone moved closer to the basin edge (e.g. the Lake Russell strandline; Fig. 4.25b). The now-unrestrained saline groundwater mass subsided, drawing solutes from the lake waters into the basin sediments. Subsequent falling lake levels again constricted the saline groundwater zone beneath the lake, driving saline water and their solutes back into the lake waters and once again increasing solute content of surface waters. Sediment permeability below the lake is the major control on the solute transfer rate between the lake and its groundwater reservoir. Only the larger, longer-term lake level changes drive saline groundwater movement in the lake margin. Depending on permeability of the basin fill aquifer, the equilibration of the saline groundwater and lake solute content to lake water level requires hundreds to thousands of years. Rogers and Dreiss (1995a, b) suggest that current conditions, where a more saline Mono Lake brine pool (50,000–90,000 ppm) overlies less concentrated groundwater (≈18,000 ppm), reflects the still active impact of late Pleistocene lake high stands. In support of this they note that Mono Lake's historical salinity data have a large scatter, but suggest there was a 5 % decrease in the lake's solute content over the last 50 years of drawdown; they suggest this indicates a diffusive solute flux into lacustrine sediments for this period. Their conclusions are the opposite of the commonly accepted view of Mono Lake drawdown automatically increasing the salinity of the lake waters.

Saline Lakes of Turkey

Turkey, with its active compressional tectonics and semi-arid climate, is ideally situated to form a range of pans and lakes that include permanent ponded bodies of somewhat saline

water in mountainous endorheic depressions. It has some of the largest modern saline lacustrine systems in the Northern Hemisphere in subaqueous settings ranging from perennial water pools about the edges of ephemeral saline mudflat and pan systems like Tuz Golu and Aci Golu (Golu = lake), to large deep bodies of alkaline water, such as Lake Van which have extents comparable to Great Salt Lake and Lake Urmia (Fig. 4.27). As in the Andes, ongoing plate-to-plate compression and associated volcanism throughout the Neogene of Turkey has created rich deposits of exploitable saline minerals, especially borates and zeolites, in the many endorheic Tertiary lacustrine depressions of Turkey (Chap. 11).

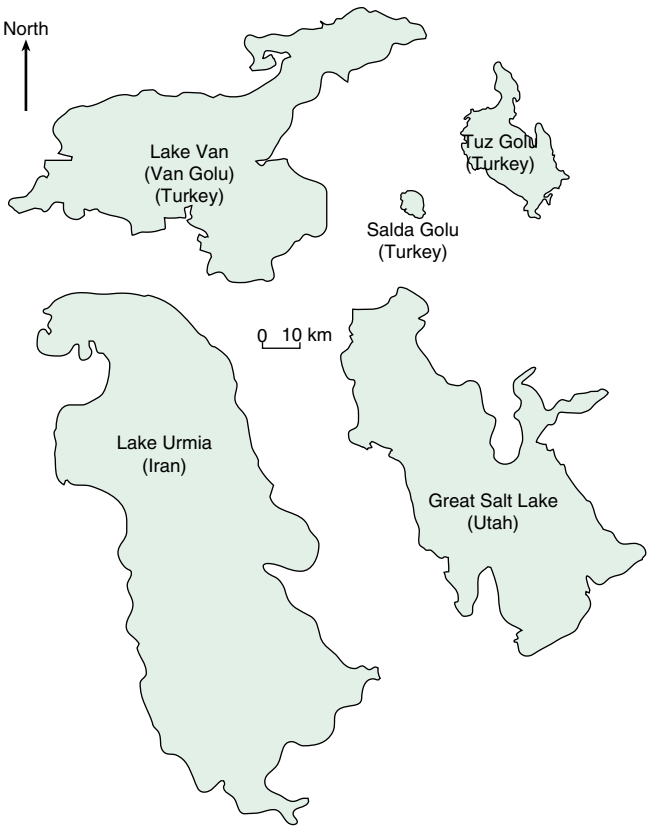

Fig. 4.27 Same scale outlines of the various Turkish Salt lakes compared to Lake Urmia (Iran) and Great Salt Lake (Utah)

Lake Van, Turkey

Van Gölü in eastern Turkey has an area of 3,574 km^2, a maximum water depth of 451 m, a volume of 576 km^3, a catchment of more than 15,000 km^2 and a cored sediment record that extends back for more than 600,000 years (Stockhecke et al. 2014). It is the world's largest soda lake and the fourth largest closed-basin perennial lake in the world (Reimer et al. 2009). It is the largest lake in Turkey and at its widest point it is some 119 km across (Figs. 4.28). The main water mass of the lake lies in its west, where waters are deeper than 400 m. The lake sits in the lower part of a steep-walled, fault-controlled basin, once drained by the Murat River (Fig. 4.28). During the mid Pleistocene, some 200 ka, a lava flow from the Nemrut volcano extended some 60 km across the southwestern end of the basin, blocking westward drainage from the lake via the Murat River and thereby transforming the depression into an endorheic basin.

Climate in the drainage basin is highly continental with hot dry summers and long cold winters (Köppen Climate Dsb). Annual precipitation across the drainage basin is variable and ranges between 400 and 700 mm. Most detrital influx into the lake is in April to June, carried by snowmelt and spring rains. In summer the present day lake waters are thermally stratified and temperatures within the uppermost water column reach as high as 19–20 °C (Fig. 4.29). Below 50 m depth, water temperatures are less than 3 °C and do not change much year round. In winter the shallower northern sections of the lake can freeze over, and the onset of lower

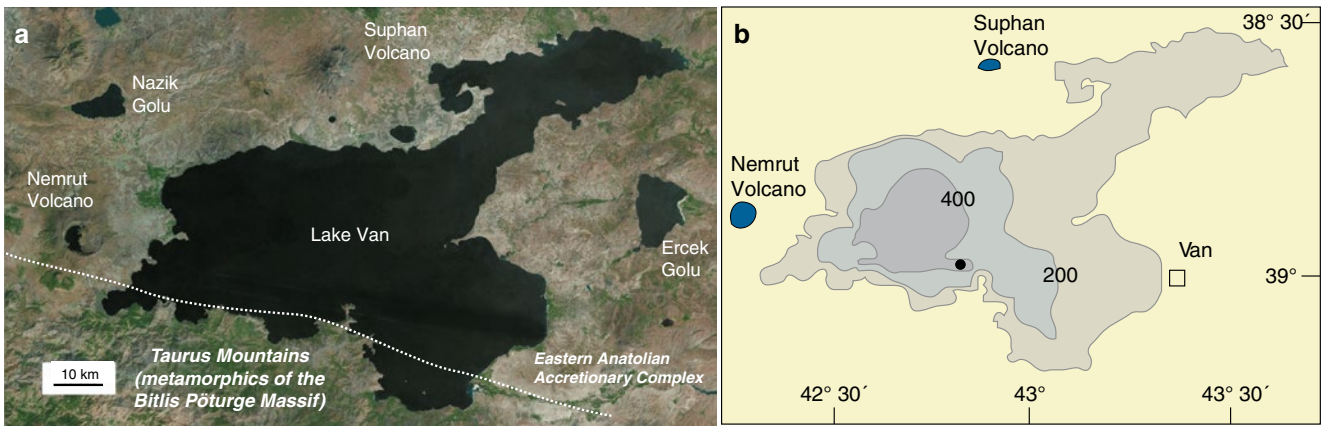

Fig. 4.28 (**a**) Lake Van, eastern Turkey, is the largest perennial saline lake in Turkey and is located at the southern edge of the East Anatolian accretionary complex (*dashed line*). Toward the *top* of the image are the Satak Mountains, Nemrut Lake, the crater lake of an active volcano, that last erupted in the year 1440 lies to the west. Ercek Lake can be seen to the east of Lake Van. To the north of Lake Van is the extinct Suphan Volcano, a circular volcanic maar with an elevation of 4,061 m (Bing® Image mounted in MapInfo®). (**b**) Bathymetry is in metres and the *black circle* indicates the position of piston core K10, with its geology and chronology illustrated in Fig. 4.31

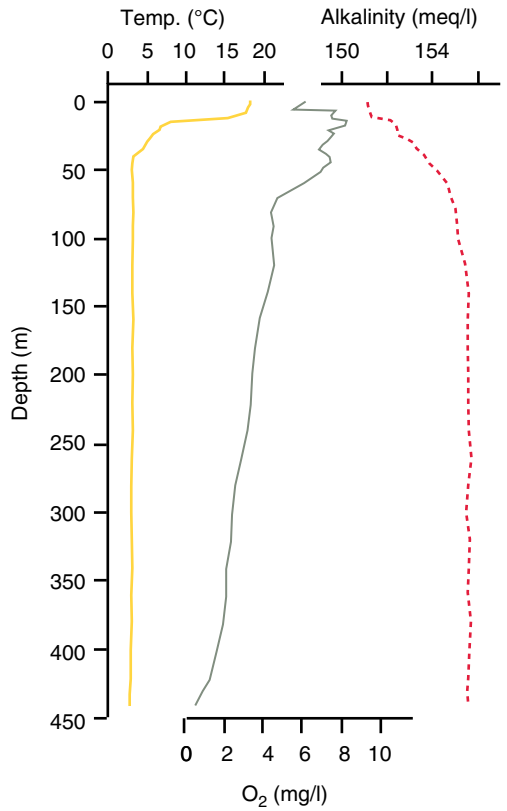

Fig. 4.29 Temperature, oxygen and alkalinity profiles in the Lake Van water column (After Thiel et al. 1997)

surface water temperatures in the autumn drives an annual overturn of the lake waters.

Salinity is 22‰, pH hovers around 9.5 and can be as high as 9.8, making the lake waters highly alkaline (≈153 meq/l; Fig. 4.29). Free oxygen is present throughout the water column, but drops to values <1 mg/l near the lake bottom. Calcium concentrations in the lake waters are low (≈4 mg/l; Thiel et al. 1997) The main cation in the lake waters, sodium, is not only balanced by chloride, but also to a near equivalent extent by high levels of carbonate and bicarbonate ions. As in Mono Lake, the high alkalinity reflects the preponderance of young volcanics in the drainage basin and ongoing hydrothermal circulation.

This high alkalinity in the lake's hydrogeochemistry explains the onset of trona deposition when the lake dried out some 15 ka. Relatively high salinity and very high alkalinity means modern lake waters host a low diversity, largely endemic phytoplankton population, dominated by diatoms and cyanobacteria (primary producers). Copepods and ciliates are the main contributors to the zooplankton.

Today, the lake water level is around 1,648 m asl and fluctuates around 50 cm annually, being lowest during the winter months and rising after the spring thaw to reach its highest level each July (Fig. 4.30a). Lake levels over the last few decades have been rising with some 2 m (2.1 m) of rise from 1944 to 2000 and levels continue to rise today, at an average rate of 3.7 cm/year (Fig. 4.30a; Deniz and Yildiz 2007). The swift rise, especially after 1987, drove a natural environmental disaster in the lake coasts, inundating approximately 5,200 ha of land. Tens of villages together with Van, Tatvan, Ercis, Adilcevaz and Ahlat cities were affected, and thousands of houses, tens of thousands of acres of agricultural lands, highways, the ferry harbour, historical sites, and wetlands in the mouths of streams, shelters of wild birds were damaged. In addition, drinking waters, canalization networks, urban infrastructure systems as well as some parts of Van Airport and many holiday camping areas have been detrimentally effected by the ongoing rise. Millennial lake level changes are also significant. Some 15 ka the lake had dried into a series of saline pans, precipitating sodium carbonate salts and the water level was more than 450 m below that of today (Fig. 4.30b; Landmann et al. 1996; Reimer et al. 2009). A few thousand years earlier, at the height of the last glacial, some 18 ka, the water level in Lake Van was 72 m above its present position (Degens et al. 1984). The rapidity of natural water level change is of the same magnitude as in the Dead Sea Basin (Fig. 4.45).

Lake Van deep bottom sediments were collected by a series of piston cores in 1990 and the results published in Landmann et al. (1996), Thiel et al. (1997) and Reimer et al. (2009). Their work, along with the results of an earlier piston core studies by Kempe and Degens (1978), are summarised in the next few paragraphs and illustrated in Fig. 4.30b. Sediments accumulating on the deeper parts of the Lake Van floor are mainly dark-coloured carbonaceous siliceous carbonate laminites/mudstones, with layering that indicates annual deposition cycles and so are true varves.

Varve counts in various K series cores recovered some 15,000 years of lake history (Fig. 4.30b). Lighter coloured laminae in each varve couplet are dominated by micritic carbonate and opaline silica. Darker laminae are characterised by higher amounts of organic material and high proportions of nonchemical detrital sediment matrix, which was carried into the lake by spring melt waters. Dolomite occurs in various lamina, but is detrital, not authigenic, and comes from eroded Cretaceous dolomites.

Snowmelt and rain peak from April to June and rising river discharge not only increases the lake level by about half a meter, but also delivers most of the clastics to the lake during this time of the year (Fig. 4.30b; Reimer et al. 2009). At the same time, the mass of the dissolved ions is delivered to the lake by the spring-time freshwater spreading over the underlying saltier lake water. While clastics and organodetritus settle directly to the lake bottom, dissolved ions concentrate during summer due to ongoing evaporation. Supersaturation necessary to cause $CaCO_3$-precipitation is surpassed in late summer and autumn when the surface layer starts to mix with the higher saline lake water below. Aragonite and calcite constitute about 35 wt% of the sediment (Landmann et al. 1996). Thus, laminated sediments are

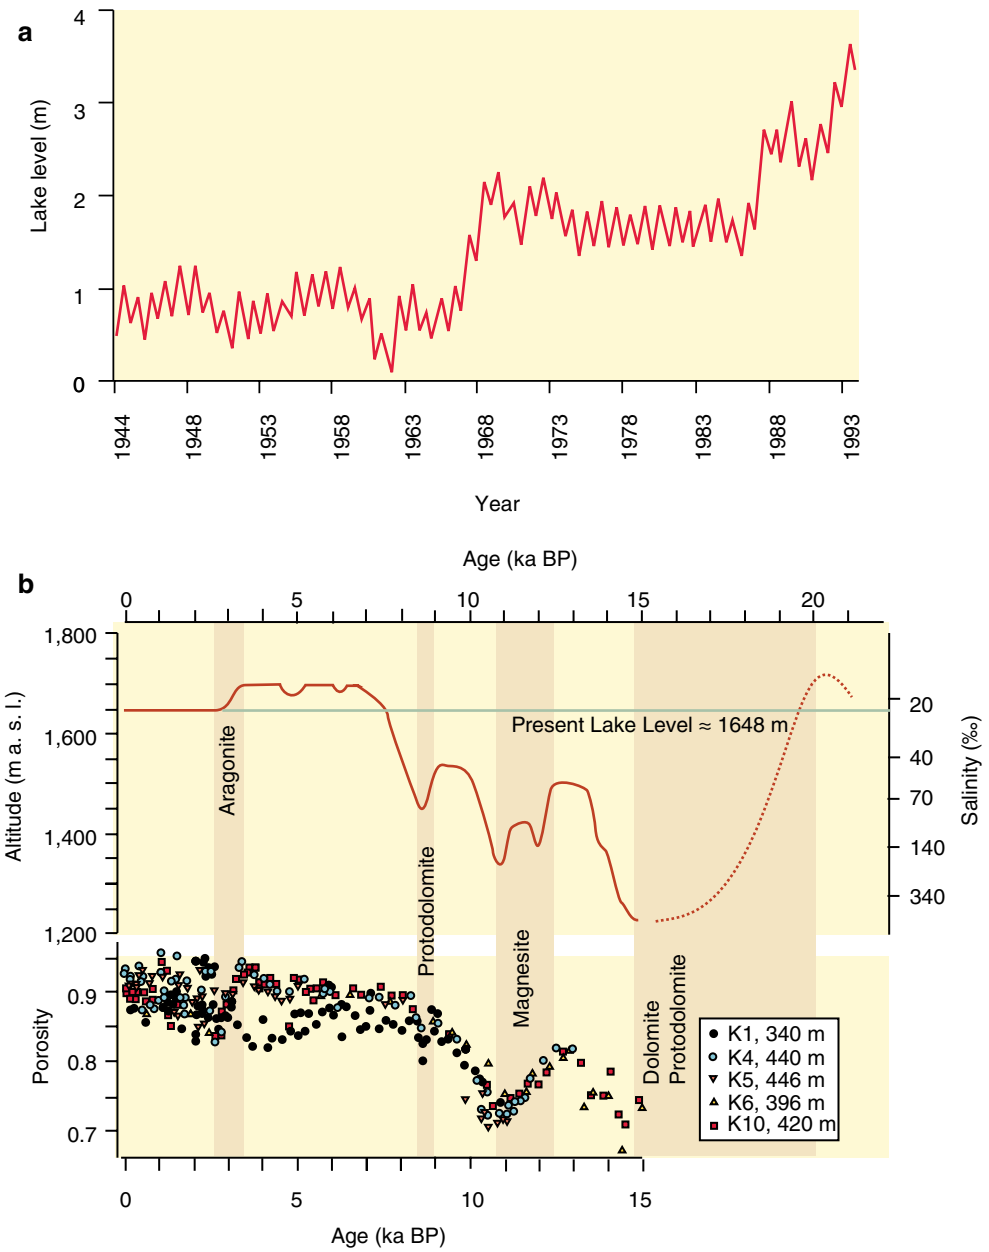

Fig. 4.30 Water levels and mineralogy across time in Lake Van (Vangolu), Turkey. (**a**) Water levels changes in the period 1944–1993 (After Kadioglu et al. 1997). (**b**) Lake level fluctuations of Lake Van in the past 20 ka, salinity and sediment porosity versus age. *Brown shaded* areas define periods in lake history with negative water balance and more evaporitic carbonates. Maximum depth of Lake Van today is 451 m, water depths of the various cores used to calculate porosity curves are given in the legend. Note that the scale of the salinity axis is not linear (After Reimer et al. 2009)

deposited as varves with darker laminae in winter and spring and lighter carbonate dominated bands in late summer and autumn (Kempe and Degens 1978).

Colours in the recovered core are mostly dark and range from dark brown to dark greyish green; they reflect largely anoxic deepwater conditions (Eh of 150 to −280 mV), which have prevailed on the subaqueous lake floor for the last 15 ka. Accordingly, organic contents in the bottom sediments are high, the organics are oil prone, and TOC ranges up to 5–6 % (Thiel et al. 1997). The base of the laminite unit is at around 8.5 m in core K10 and is defined by a sandy layer, thought to indicate the drawdown stage in the deeper parts of the lake, some 15 ka (Fig. 4.31). All piston cores for the lake are water saturated and show porosities that are typical of deepwater micrites, with porosity decreasing with age and depth (Fig. 4.30b).

Material caught in floating sediment traps in the central parts of the lake show that most of the micritic carbonate in the cored laminite was annual, probably precipitated in the evaporative surface layer each summer to fall (Landmann et al. 1996). Aragonite/calcite ratios, determined by X-ray diffraction analysis on core K10, scatter between 2 and 9 in sediments younger than 3,700 year B.P., and from 1 to 4 in older sediments (Fig. 4.30b). The other main chemical component in the sediment traps is opaline silica, largely derived from phytoplanktonic diatom tests.

Because present lake waters are supersaturated with respect to alkaline earth carbonates, carbonate precipitation is most obvious in the lake at positions of calcium input where fresher waters mix with more saline lake waters. This can be at the mouths of rivers, where whitings have been

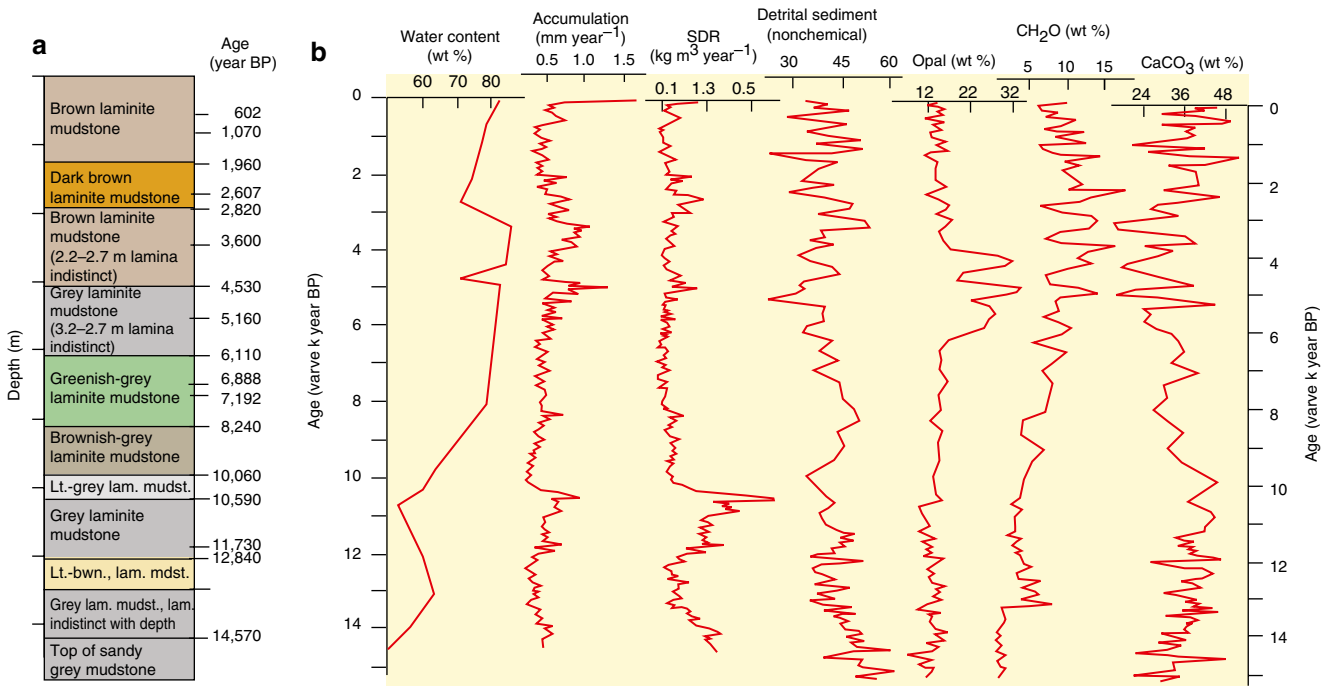

Fig. 4.31 Lake Van Core K10 (see Fig. 4.28 for location. (**a**) Laminite lithology plotted against depth and varve-determined ages. (**b**) Core properties plotted against varve determined time. SDR = rate of sediment deposition. Opal is dominantly from diatom tests and $CaCO_3$ is mostly from aragonite with lesser calcite (After Landmann et al. 1996)

documented, or it can occur on the shallow lake floor down to depths of 120 m, where the degassing of resurging calcium-rich groundwaters escaping into the lake waters creates tufa towers or pinnacles, up to 40 m high. These structures constitute some of the largest active microbial lacustrine buildups in the world today (Kempe et al. 1991). Lake Van does suffer from severe winters, but these aragonite/calcite tufa samples described by Kempe et al. (1991) were collected in the summer. The possibility of primary ikaite was not considered. So, it not known if some of the initial tufa in Lake Van was once ikaite, which then converted to $CaCO_3$. A textural comparison with similar structures in Mono Lake suggests this may be so, especially in older colder stages in the lake history.

The current condition of Vangolu is a useful analogue for the Pleistocene freshwater stages in many of the world's soda lakes that are currently in a hypersaline (trona) stage and for many pre-Quaternary alkaline lakes. It serves as a useful analogue for the laminites of High Magadi Beds of the Lake Magadi and Lake Natron and for the oil shales of the Eocene Green River Fm, USA. More arid episodes in the lake history, when water levels were lower and salinities are higher, are indicated by the presence magnesite and dolomite in the cores (Fig. 4.30b).

Salda Lake, Turkey

Saldagölu is another highly alkaline (pH >9) saline lake in southern Turkey, located in a collision belt at an elevation of 1,139 m asl. It is bowl-shaped and occupies the lowest part of a fluvial and seepage-fed endorheic depression at the foot of the Esler Mountains (Köppen Climate Csa). Lake waters are up to 184 m deep and cover an area of 43.7 km^2 (Fig. 4.32a, b). Lake levels rise about 50–70 cm each spring, but longterm levels are falling and have been doing so for decades exposing widespread beach-rock like terraces and stromatolites of hydromagnesite and aragonite. Inflow waters to Salda Golu are enriched in magnesium and carbonate and when compared to Lake Van are much fresher and are capable of supporting the local livestock (Shirokova et al. 2013).

The lake drainage is rimmed on three sides by serpentinites (ophiolites) and on the fourth by a downfaulted block of Upper Cretaceous limestone. Hazburgite is the dominant country rock, though in places it has been metamorphosed to lizardite ($Mg_3Si_2O_5(OH)_4$) and subsidiary dunite, all Mg-rich phases. All the rivers draining into the lake follow faults, flow across peridotites, and under the lowered water levels of today are losing streams. Waters typically seeping into fan deltas or into the lake surrounds before ever reaching the strandzone of Salda Golu (Russell et al. 1999).

Magnesium concentration averages 60 ppm in wells and cold springs in the lake surrounds, temperatures range up to 12–15 °C and pH lies in the range 8–10 (Braithwaite and Zedef 1996). Sodium levels in the groundwaters of the lake surrounds are low (≈5 ppm) as are most other ions, with the exception of HCO_3. In contrast, lake waters contain 300 ppm of Mg and 200 ppm of Na down to a depth of 80 m, with a pH around 9.1. Mg in the lake has increased by a factor of 6

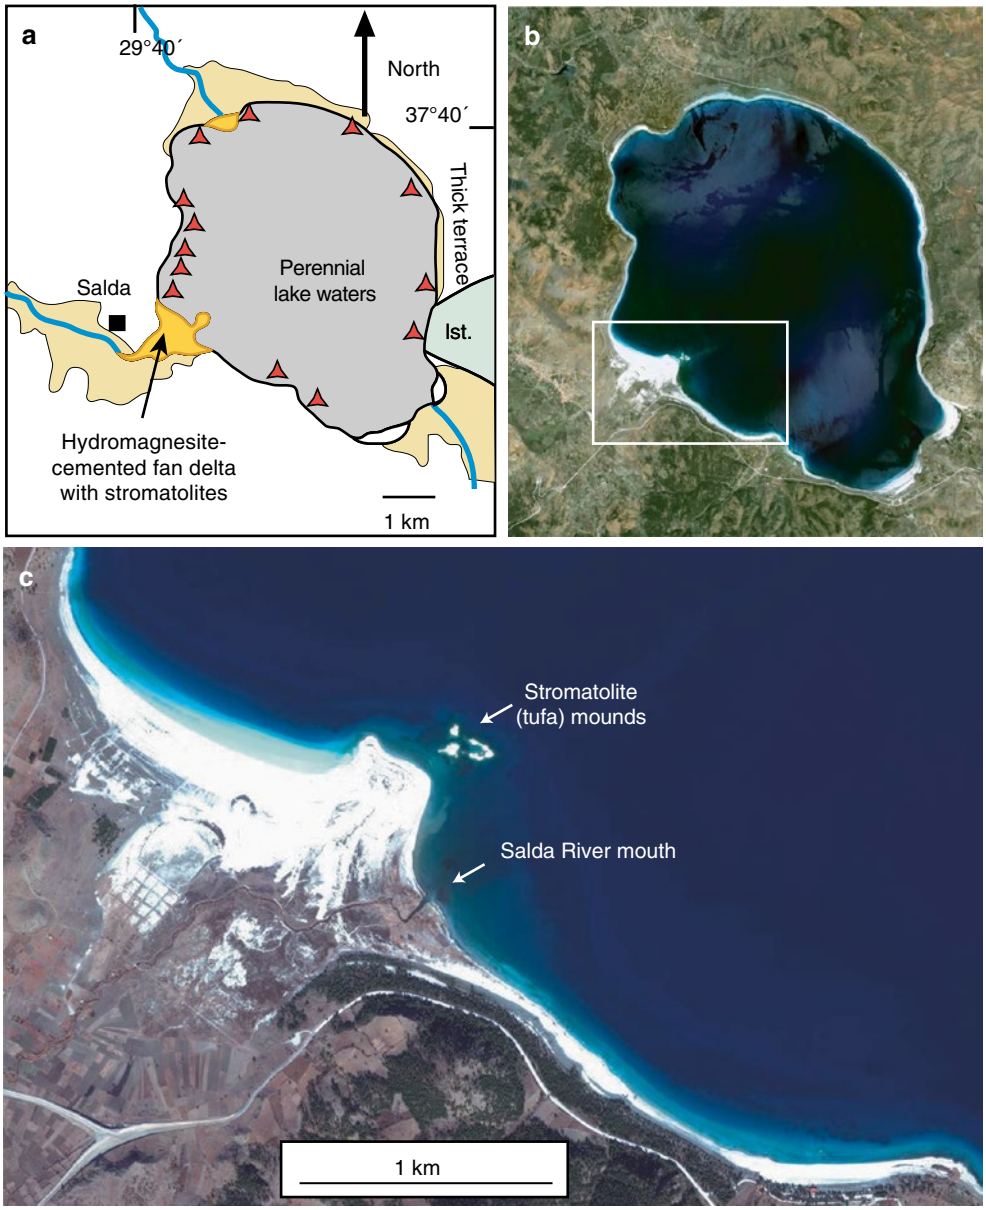

Fig. 4.32 Salda Lake, Turkey. (**a**) General geology of this perennial carbonate precipitating lake, currently accumulating hydromagnesite and aragonite. The lake is best known for the subaqueous stromatolites accumulating basinward of hydromagnesite strandline terraces, with most prolific occurrences indicated by *triangles* (For more detail on the stromatolites see Chap. 1 and Braithwaite and Zedef 1996). (**b**) General view. (**c**) Close up of Salda delta showing stromatolites and position of modern river mouth on the delta wedge

compared to waters in the surrounding aquifers, while Na in lake water is more than 40 times that in the lake surrounds. Obviously, the bulk of the groundwater seeping into the lake edge gathers Mg as it seeps lakeward through older river mouth fan deltas, which contain abundant cobble of metastable Mg-rich ultramafics such as lizardite (Russell et al. 1999). Lakeward seeping groundwater outside the deltas also picks magnesium, relative to Ca, as it cannibalizes the older hydromagnesite-cemented gravelly strandlines/terraces that circumscribe the present lake. Subsequent hydromagnesite precipitation in the lake is probably related to an increase in pH in the lake waters, tied to HCO_3 depletion (CO_2 depletion) as it enters the lake, perhaps indirectly brought about by the metabolic activities of microbialites.

Composite stromatolites, several metres high and composed largely of hydromagnesite, line significant portions of the current lake margin; they are best developed atop the now largely inactive fan deltas of the Salda River (Karakova Dere) in the SSW of the lake and the Yesilova delta in the ESE of the lake (Figs. 1.17 and 4.32c). On the Salda River delta they form three 20 to 100 m^2 partially subaerial mounds, situated ≈50 m offshore and rising ≈10 m from the lake bottom, reaching within 3–4 m of the lake surface (Shirokova et al. 2011). The deepest part of these mounds showed no evidence of stromatolites below 6–10 m water depth. There are other 1–1.5 m^2 stromatolites in other parts of the lake, within 10–20 m of the shoreline (Fig. 4.32b). In contrast to these lithified examples, most submerged pebbles in the littoral of the north side of the lake, are covered with actively forming, non-solidified stromatolites. The mineralised surface of the indurated stromatolites is covered by a layer of green algae, diatoms, and cyanobacteria with oxygen

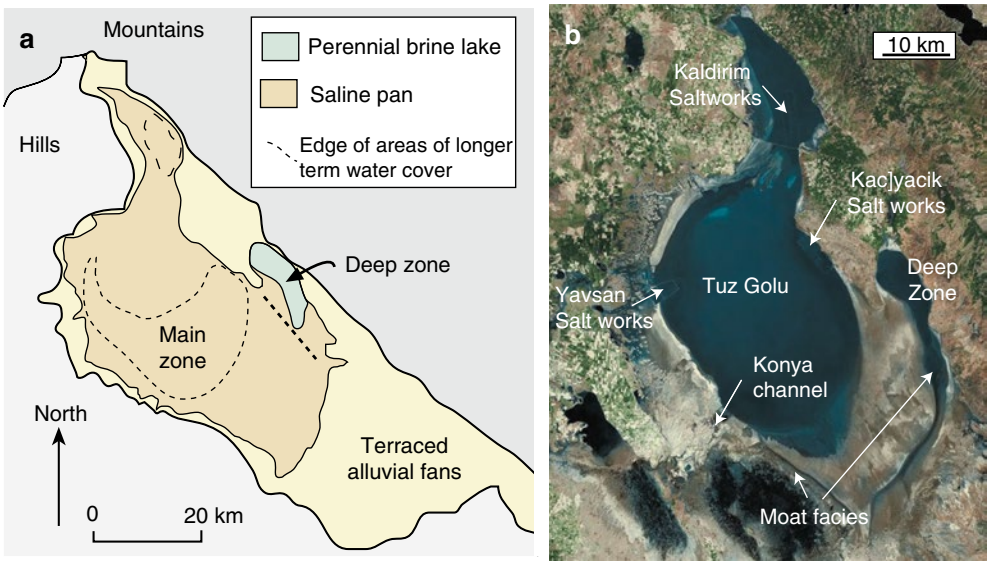

Fig. 4.33 Tuz Golu, Turkey. (**a**) Geological plan view ot the two hydrological zones (**b**) shows a partially desiccated stage in the lake when much of the saline pan is still water covered. The sill separating the main zone from the deep zone is clearly exposed. The man-made Konya drainage channel and its waste plume cutting into the southwestern part of main zone is also visible. The obvious linear separation between the mountains to the northeast and the terraced alluvial plain reflects the transtensional fault-controlled origin of the Acigolu depression (Bing® image mounted in MapInfo®)

bubbles adjacent to the surface of the microbial mats. The general depositional style of the stromatolitic tufa mounds is similar to the tufa mounds of Sleaford Mere.

Most of the detrital sediment currently accumulating along the strandzone between reef mounds is created by the mechanical (wave-driven) breakdown of former carbonate terraces and hydromagnesite microbialites; it is not derived from longshore transport of fluvial sediment (Braithwaite and Zedef 1994, 1996; Russell et al. 1999). Hydromagnesite precipitates, which are now exposed by falling water levels, give the present strandplain its bright white colour. Fine-grained hydromagnesite, reworked from tufa shorelines and from the terraces, is suspended in the water column during storms and is probably redeposited as micritic turbidites alternating with laminites in the deeper part of the lake.

Further landward from the present strandline, the earlier hydromagnesite terraces preserve no obvious stromatolites, but include boulders and blocks of reworked hydromagnesite up to 0.5 m across. Many of these circum-lake terraces appear to be inorganic precipitates that started to form when lake levels were higher. It seems that stromatolitic morphologies do not survive long-term exposure and lithification as they quickly degenerate into a porous, coarse-grained poorly lithified floatstone, with the positions of former microbialites sometimes still recognisable as mounded outlines in intervening muds (Russell et al. 1999). Like the hydromagnesite stromatolites of the Coorong region, stromatolites in Salda Golu have poor preservation potential.

Hydromagnesite precipitation and biofilm coating throughout the current lake is facilitated by the metabolic activities of the flourishing flora of diatoms and cyanobacteria (Shirokova et al. 2013). Biofilms cover the surface of the stromatolites and much of the littoral zone of the current lake. But precipitated crystals do not occur in direct contact with cell surface, implying CO_2 fluctuations may be driving precipitation rather than direct biomineralization. Interestingly, diatoms rather than cyanobacteria dominate the phytoplankton assemblage in the current surface waters of the lake and each year take up all the available silica (Russell et al. 1999). Silica averages 16 ppm in the wells and springs about the lake yet is below detection limit (1 ppm) in the lake surface waters. Opaline diatom tests rapidly dissolve out of the consolidating stromatolites and are rarely found as body fossils in any of the exposed hydromagnesite cliffs about the lake edge, once again a similar situation to that found in the hydromagnesite-aragonite lakes of the Coorong.

Lake Tuz, Turkey (Tuz Gölü)

Lake Tuz (*tuz* = salt; aka Lake Sereflikochisar) has an elevation of 905 m asl and a water full area of 2,600 km^2. After Lake Van, it is the second largest lake in Turkey (Fig. 4.27) and occupies the lowest part of a fault-defined (transtensional) endorheic depression in the arid Central Plateau (straddles Köppen climate zones BSk; Csb). Unlike Vangolu, much of the current lake floor is a salt-crusted saline pan for at least 6 months a year, with a small area of perennial brine along its eastern higher-relief edge.

To the east of the lake lies a mountainous highland of metamorphics dominated by granites and gneisses. Highlands to the north are composed of sandstones and shales, andesitic and basaltic volcanics lie to the northwest, ophiolite hills lie to the west, and rhyolitic tuffs and andesites constitute the lower relief hills to the south and southeast (Aydemir 2008). Flatter areas of the Konya drainage basin between these highlands are covered by gypsiferous lacustrine marls of various Neogene ages (Fig. 4.33).

At some 350 mm/year the area receives the lowest annual precipitation in Turkey, while potential monthly evaporation

After Helvaci et al. (2003)

ranges between 1,175 and 1,390 mm in a yearly cycle. Natural river inflow to the lake depression totals 88×10^6 m^3/year and comes from three main rivers (Peceneközü, Uluirmak and Insuyu). Each year a discharge from the artificial Konya drain releases around 75×10^6 m^3 of wastewater into the lake.

Maximum brine depth in the lake is 1.5 m, attained in the spring when meltwaters reach the lake from the adjacent highlands. Evaporative evolution of the natural inflow brines shows a continuous trend from Ca-HCO_3 rich spring waters to Na-SO_4-Cl rich brines with considerable variations in ionic proportions in inflow brines related to lithologic variations in the drainage area. There were times in the Late Pleistocene (20–17 and 13 ka) when lake levels were 15 m higher than today and the Tuzgolu depression was filled with permanent water up to 16 m deep (Kashima 2002). Older, but undated, Quaternary shoreline terraces occur some 100 m above the present lake level (Erol 1978). Tuzgolu waters show elevated lithium levels compared to other saline lakes in the region and so constitute a brine of potential economic interest (Table 4.3; Helvaci et al. 2003), although the associated elevated magnesium levels are problematic in terms of current extraction technologies.

Each year, by mid summer most of the lake floor has dried up and only a few small areas retain permanent surface water in spring-fed seep ponds or brackish marshes (aka moat facies). The largest area of pooled perennial brine lies south of the town of Sereflikochisar, in the eastern part of the lake. It has a permanent brine-covered area of 35 km^2 called the "deep zone" and it expands with each snowmelt in the nearby mountains. It is separated from the "main" salt pan, which constitutes much of the rest of the lake surface, by a low salt crusted ridge (Fig. 4.33).

Waters covering the "main" zone are ≈70 cm deep in spring, but dry out in summer to early autumn and leave behind a 1–30 cm thick halite crust over an area of 1,200 ha, which is mined by saltworks on the lake shore (≈750,000 t/year) to provide 55 % of Turkish salt needs. In contrast, waters in the deep zone are permanent, are not halite-saturated and can be as deep as 1.5 m in the spring.

Evaporite mineralogy in the seasonal salt crust in the "main zone", especially in the northern arm studied by Camur and Mutlu (1996), consists of mixtures of halite, gypsum, aragonite and calcite. Unconsolidated evaporitic sediment extends for 1–30 cm below the salt crust and consists of a gypsum-, huntite- and magnesite bearing level, which is up to 25 cm thick, with polyhalite occurring beneath the more central parts of the main zone. This is underlain by a layer up to 35 cm thick composed of gypsum, huntite, magnesite, illite and smectite-bearing sediment. Holocene dolomite was documented in shallow sediment cores collected from the central parts of the main zone (Irion and Mueller 1968) and minor anhydrite was noted along the northern edge of Tuzgolu by Camur and Mutlu (1996). Each summer halite cumulates cover the chevrons of the salt pan crust and coarsely-crystalline lenticular and prismatic gypsum crystals (0.3–4 cm diameter) are commonplace displacive growths (up to 50 % by volume) in the sediment immediately beneath the salt crust. They constitute a "desert rose" unit with a micritic matrix made up of varying proportions of magnesite, huntite and dolomite mixed with siliciclastic detritus.

The interaction of microbialites with the recycling salts in the "main" zone has produced interesting disc-like structures in dried halite known as salt biscuits (Mueller and Irion 1969). Biscuits are 2–7 mm thick crusts, with diameters between 3 and 8 cm. The upper surface tends to be smooth and covered with cumulates of small halite cubes (<2 mm diameter), the lower surface is made up of larger downward-aligned halite crystals up to a centimetre long. Irion and Mueller (1968) concluded that the biscuits are foundered halite rafts with ongoing underside growth fed by ongoing capillary rise after surface waters had receded. Tuzgolu is

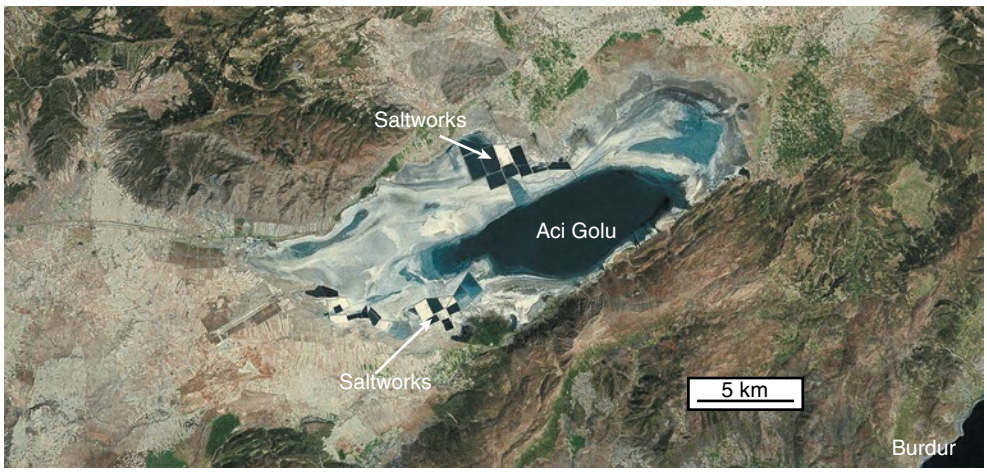

Fig. 4.34 Aci Golu, SW Turkey. Older strandlines are visible in the north of the lake, while an area of shallow perennial brine (aragonite + organics) occupies the more southerly portion of the lake depression. Part of the fresher water Lake Burdur is discernible toward the *bottom right* of the image. Numerous faults and lineaments are visible in the surrounding highlands and obviously control the linear orientation of the southwest lake edge

also a modern halite environment where halite oolites (halolites) are forming (Tekin et al. 2007).

A constant freshened, but unnatural, inflow today reaches Tuzgolu via the 150 km long Konya drainage channel (completed in 1974). It feeds a saline sump that drains agricultural wastewater from the Konya irrigation area to the south. In addition, all untreated sewage from Konya city and several hundred industries are periodically released into this drainage channel. This means that each year agricultural waste exuded from the channel into the lake includes the leached residues of more than 1,105 t of pesticides and 446 t of fertilisers applied to the Konya basin. Industrial waste includes outflows from dairy farms, aluminium and copper plants, leather processing units and a LPG bottling plant. Large amounts of nitrogen, oil, phosphorous, sulphur and organic wastes, as well as heavy metals, including borax, zinc, iron, lead, arsenic, cadmium and mercury today reach the lake depression through the Konya channel. Yet the lake brine is recovered annually for salt manufacture in a number of pans about the lake edge, which supply more than half of the domestic and industrial salt consumed in Turkey (Fig. 4.33). Pumping of industrial and agricultural wastes into salt sumps is an environmental quandary, typical of many developed agricultural and industrial areas in semi arid areas across the world. Only in the last decade have the some of the required hydrological and groundwater studies begun to assess wastewater and salinization effects in such drainage sumps in Australia, Egypt, Israel, Mexico, Turkey and the USA.

Lake Aci, Turkey

Acigolu lies at an altitude of 836 m in the next major intermontane valley to the northeast of Salda Lake (Fig. 4.34). It lies in an endorheic depression in a Csb climate zone, fed via run-off from the Yan and Maymun Mountains, more than 25 karstic springs – some with freshwater marshes, and the Kocacay stream, which enters the lake near Basmakci. Its surface water area varies greatly through the seasons, around 100 km^2 in spring and 35 km^2 in late summer, with a maximum depth around 2 m and salinities in excess of 100 g/l. It is a perennial brine lake surrounded by extensive saline pan and mudflat sediments, with saltworks focused on the production of sodium sulphate (Chap. 12).

Like Tuzgolu, the lake is fed by two distinct water sources, less saline Mg-HCO_3 groundwater from streams and local Na-SO_4 waters from springs mostly along a fault zone that defines the southern side of the lake. Final lake waters are Na-Cl-SO_4 brines with relatively lower lithium levels than Tuzgolu (Table 4.3; Mutlu et al. 1999; Garrett 2004). Differences in composition of the two inflow waters are attributed to different water cycles and different intensities of rock-water interactions. Like Saldagolu, it lies in a Csa climate zone. It is the second most saline lake in Turkey, only Tuz Golu is more saline.

Dry mudflats in Acigolu are composed of gypsum, calcite, dolomite and huntite, together with clastics. In contrast, wet or brine-soaked mudflats remain year round, typically near saline Na-SO_4 springs and are characterised by efflorescences of halite, bloedite; thenardite and/or mirabilite (Mutlu et al. 1999). Laminated to structureless gel-like sediments composed of aragonite and organic matter typify the bottom sediments of areas of perennial lake brines along the fault controlled southwestern margin and are also zones where halobacteria flourish year-round (Mutlu et al. 1999).

Lake Urmia, NW Iran

Lake Urmia, formerly Lake Rezaiyeh[2], is a shallow perennial saline lake in the lowest part of an endorheic depression in Azerbaijan Province of northwest Iran. Surface waters have a current elevation of slightly more than 1,280 m asl and

[2]In the early 1930s, Lake Urmia was called Lake Rezaiyeh after Reza Shah Pahlavi. In the late 1970s, after the Islamic revolution, the Government of Iran reverted to calling the lake by its previous name – Lake Urmia. Lake Urmia's ancient Persian name, however, was *Chichast* (meaning glittering), a reference to the glittering evaporitic salts suspended in the lake water and its shores. In the medieval times the lake came to be known as Lake Kabuda, meaning azure in Persian.

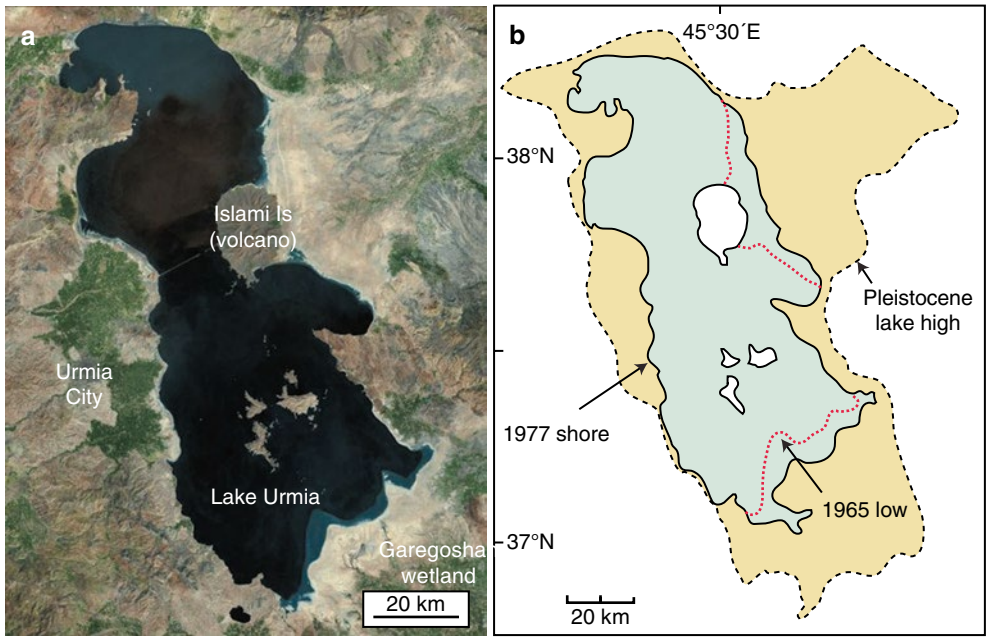

Fig. 4.35 Lake Urmia, Iran. (**a**) General distribution of lake sediments clearly showing the Talkerud alluvial braid plain and fan delta to the northwest of the lake and exposed strandline sediments along parts of the northwest and southeastern shores. (**b**) Varying extent of Lake Urmia, northwest Iran, shows outline of the lake as defined by its 1977 AD water level, as well as the 1965 AD shoreline and the much more extensive freshened lake that formed during the Pleistocene (In part after Kelts and Shahrabi 1986)

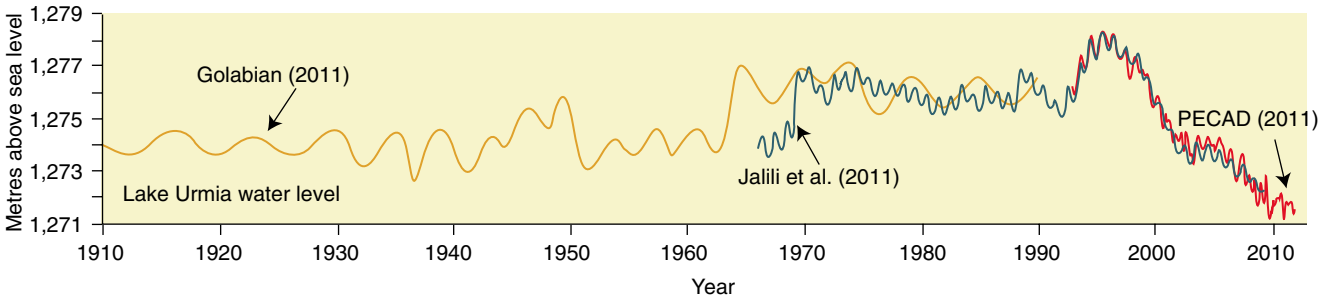

Fig. 4.36 Water levels changes in Lake Urmia, Iran, for the period 1910–2012 (Replotted from altimetry derived from TOPEX/POSEIDON and Jason-1 satellite passes last accessed on March. 4, 2014 at http://na.unep.net)

surface salinities range annually from 80 to 280‰. The lake is some 140 km long and 80 km wide, with an area of 4,700–6,000 km^2. It is the largest lake in Iran and, with a brine volume around 28 km^3, it is also one of the world's largest perennial hypersaline lakes (Figs. 4.27 and 4.35a). Average water depth is around 5 m, which deepens to 8 m in the south, where the maximum water depth is 15 m.

Lake Urmia lies at the bottom of an endorheic basin located further along the same alpine collision suture as the Turkish lakes. It was created as the Turkish and Eurasian plates were squeezed sideways along very active strike-slip fault systems. Palaeozoic metamorphics crop out in the Zagros Mountains to the west of Lake Urmia. Infracambrian sediments lie to the south, while the northern and northeastern lake margins are characterised by outcrops and subcrops of the evaporitic Middle Miocene Fars Formation and underlying marine limestones of the Lower Miocene. Several Miocene salt domes pierce the surface of the lake's drainage basin.

Climatically, the lake lies in a semi-arid, desert steppe environment (Köppen BSk), with precipitation averaging 30 cm per year. The climate is harsh with winter temperatures down to −20 °C and summers up to 40 °C. Surface inflow from the 52,000 km^2 drainage basin is strongly seasonal, driving an annual lake water level fluctuation of up to 1–2 m, especially during the spring melt when the Talkheh and Simineh Rivers discharge around 57 m^3/s into the lake (Fig. 4.35; UNEP 2012). By summer the inflow drops to 1.7–3.7 m^3/s and lake levels fall once more.

Topographically, the surrounding region is either plateau or mountain. Mountains west of the lake have peaks that exceed 3,350 m making that side of the lakeshore somewhat steeper. Salt flats and the fan deltas characterise lake sediments along the southern and western shores. Slight changes in water level can drive drastic migrations of the strandline across the evaporitic mudflats of the lake. In 1970 the lake had a water level of 1,277 m asl, while in 1965 the water level had hovered around 1,274 m; the lake level had risen by 3 m in a decade and the shoreline had migrated some 5–10 km (Fig. 4.35b). From 1996 until 2013, there was a 7 m fall in lake level (Fig. 4.36). This latest fall means the lake's water level has now reached

historical lows, while salinities have attained historical highs of 300–320 g/l (approaching halite saturation). The current scenario of ongoing falling water levels and elevated salinities is likely due to over-extraction from inflow water sources (13 rivers that supply the lake are now dammed and feed stored waters into various irrigation schemes; UNEP 2012). It defines an anthropomorphic hydrological/salinisation evolution that is detrimental to the diversity of the lake biota, much like the anthropogenic pressures that detrimentally effect biodiversity in other modern saline sumps such as the Dead Sea, the Aral Sea, Lake Texcoco and the Coorong Lakes (Gill 1996; Alcocer and Williams 1996). The pressure of a rapidly growing population, currently around of 6.5 million people within the Urmia watershed, will likely force continued diversions and damming of streamflow within the basin, before it reaches Lake Urmia sump.

Lake floor sediments are mostly aragonitic pelletal laminite/mudstones, near identical in appearance, depths of deposition and origin to those of Great Salt Lake, Utah. The Urmia pellets are composed of 80 % aragonite, along with small amounts of quartz and calcite, and rarely dolomite (Eimanifar and Mohebbi 2007). Laminites in both lakes result from seasonal biologically-mediated precipitation of aragonite (Kelts and Shahrabi 1986). When salinity and nutrient levels are suitable, Urmia's stratified surface waters support an abundant summer flora of the green alga *Enteromorpha intestinalis*, along with species of *Dunaliella* and *Tetraselmis*. Blooms can be so intense that in some years the water changes colour to a deep green and light penetration is measured in tens of centimetres. The algal bloom is followed quickly by a bloom of the endemic brine shrimp *Artemia urmiana* (up to 4,000 individuals per litre), which graze the alga. While feeding, the shrimp also ingest particulate aragonite that is precipitating in the lake waters. Thus aragonite in the Urmia laminites occurs both as 10 μm-long euhedral prisms in pelagic muds and as the major constituent in sand-sized brine shrimp faecal pellets. Both types of aragonite are interlaminated with organic-rich laminae in a matrix dominated by terrigenous sediment brought to the lake by spring melt. The aragonite is sometimes sufficiently cemented to form cm-thick crusts on and beneath the lake floor. The precipitation of aragonite, rather than calcite, in the lake reflects the high Mg/Ca ratio of the waters (molar ratio 28:1).

At the northern end of the lake the gypsum bed is now some 1.5 m below exposed laminites, with the latter tied to the same sedimentation style as the current subaqueous lake floor. The gypsum bed was interpreted as a sabkha unit by Kelts and Shahrabi (1986). That is, earlier in the Quaternary, the lake level was lower than today and portions of the lake floor became so saline that gypsum precipitated in a saline playa. Approximate U-Th dates based on aragonite-pellet lamina across a 100-m long piston core, studied by Stevens et al. (2012), places the playa episode at 15–55 ka. In other parts of the lake, partially exposed dolomitic mudflats were probably time equivalents to this now buried gypsum. Oolites shoals formed at the northeast end of the lake but they too are now buried beneath 30 cm of putrid, black organic-rich mud.

The biota and the general spectrum of carbonate sediments found in Lake Urmia are near identical to that of Great Salt Lake, Utah. Like Great Salt Lake, sediments accumulating in the deeper parts of the perennial saline lake are pelletal aragonite laminates. In shallower waters the sediments can construct aragonitic ooid strandzones (as near Gulman Khaneh on the western margin) or cemented crusts/beachrocks, as typifies much of the lake edge.

Lake Natron and Lake Magadi, East Africa

These two lakes are perhaps the most often cited saline alkaline (soda) lakes in the geological literature. Both are groundwater and hydrographic sumps, are small, and lie just south of the equator in the volcanically active eastern branch of the East African Rift (Fig. 4.37a). The rift extends for more than 3,000 km from the Afar Triangle in the north to Mozambique in the south. Lake Natron, the larger of the two lakes, is in northern Tanzania, at latitude 2° 20′ S, and longitude 36° 10′ E; it extends some 55 km N-S and 24 km E-W, with a total surface area of about 950 km^2 (Fig. 4.38). Its northern shore touches the territorial boundary with Kenya. Lake Magadi lies within Kenya slightly to the north of Lake Natron at the bottom of a steep-sided valley, which is the lowest point in the eastern or Gregory Rift Valley (Fig. 4.37a). It extends roughly 20 km N-S and is up to 6 km wide. Both lakes lie at an altitude of some 600 m above sea level and are surrounded by plateaus and active volcanoes reaching to more than 3,000 m asl (Fig. 4.37b). With an area of only 90 km^2, Lake Magadi is one of the most saline, but also one of the smallest, alkaline lake sumps in the Rift Valley.

The eastern Rift Valley stretches from Ethiopia to Tanzania and contains numerous endorheic soda lakes of varying salinity (Fig. 9.38a). Some lakes are fresh, like Lake Naivasha, others are quite saline Na-CO_3-HCO_3 solute systems like Natron and Magadi. Salinities range from 5 % in the more northerly lakes (Bogoria, Nakuru, Elementeria, Sonachi) to around 30 % and halite/trona saturation (Magadi, Little Magadi and Natron) in the south of the valley. The pH of surface waters in all is typically above 9, with values ranging up to 11.5 in the more saline alkaline depressions. Hydrographic closure is provided either by a lake's location in a volcanic crater or by formation of lake depressions in block-faulted lava and volcaniclastic terranes. The Rift Valley is volcanically active, with ongoing outpourings of sodic lavas and numerous hot springs (some boiling) about the edges of many of the modern lakes, indicating active hydrothermal circulation (e.g. Fig. 4.39). Spring outflows are

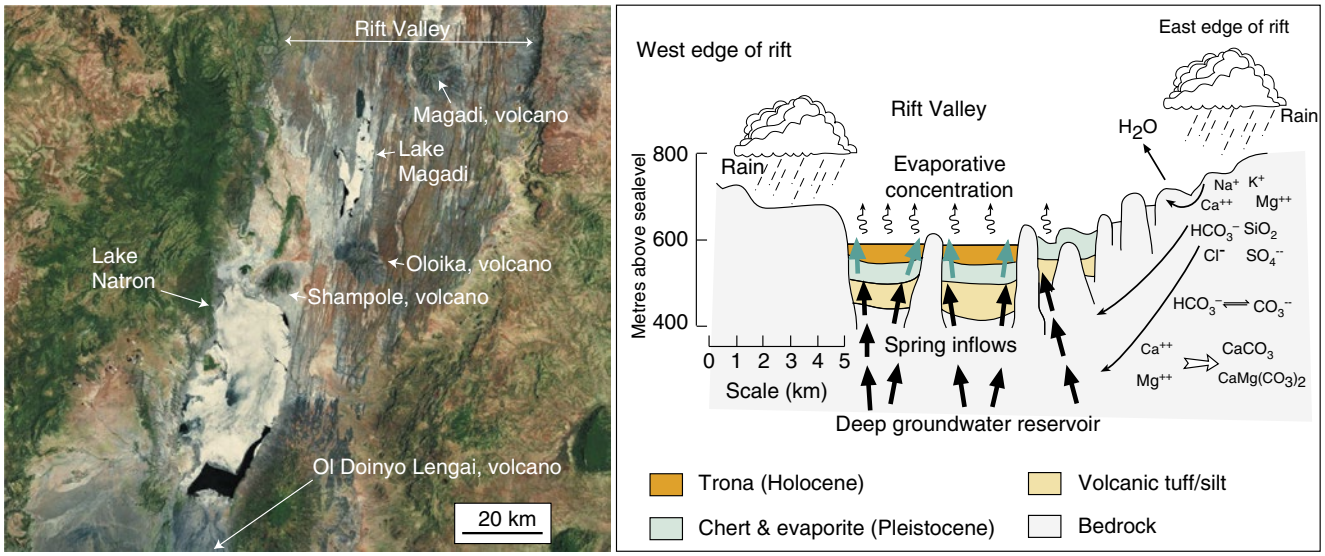

Fig. 4.37 Lake Natron and Lake Magadi, East African Rift. (**a**) Position in the East African (Gregory) rift showing adjacent and underlying volcanogenic basement (Landsat image courtesy of NASA). (**b**) Scaled schematic of the distribution of evaporitic lacustrine sediment in the rift valley based on an east-west transect of Lake Magadi (After Jones et al. 1977)

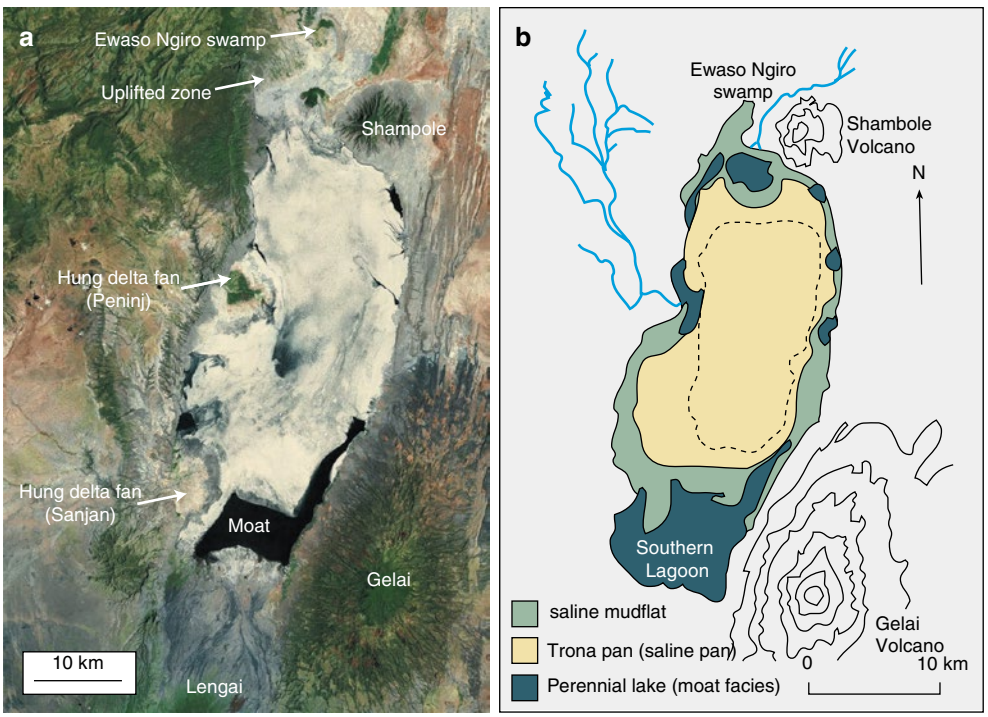

Fig. 4.38 Lake Natron, Kenya. (**a**) Plan view of Lake Natron showing moat facies about the lake edge and the white of the trona/halite pan-crust facies. Ol Doinyo Lengai (aka Mountain of God; 3,188 m asl). (**b**) Geological setting of Lake Natron

typically less saline than the lakes they feed and form biological refugia during times of widespread drought (Chap. 9).

Climate in the lowermost parts of the rift valley in the vicinity of lakes Natron and Magadi is arid, with high temperatures and an adiabatically reduced mean annual rainfall that is typically less than 500 mm in non El Nino years. Most precipitation falls in a single rainy season from March to May (Köppen Aw). Potential evaporation on the rift valley floor exceeds rainfall for most of the year so that the hydrological balance in the drainage region about both lakes is clearly negative. This facilitates the precipitation of aragonite in perennial brine pools (moats) about the lake edges and trona in the more central saline pan areas. Air temperatures around the lake can reach 40 °C in the dry season, while temperatures can be as high as 66–68 °C in dark-coloured mudflat sediment that make up the edge of

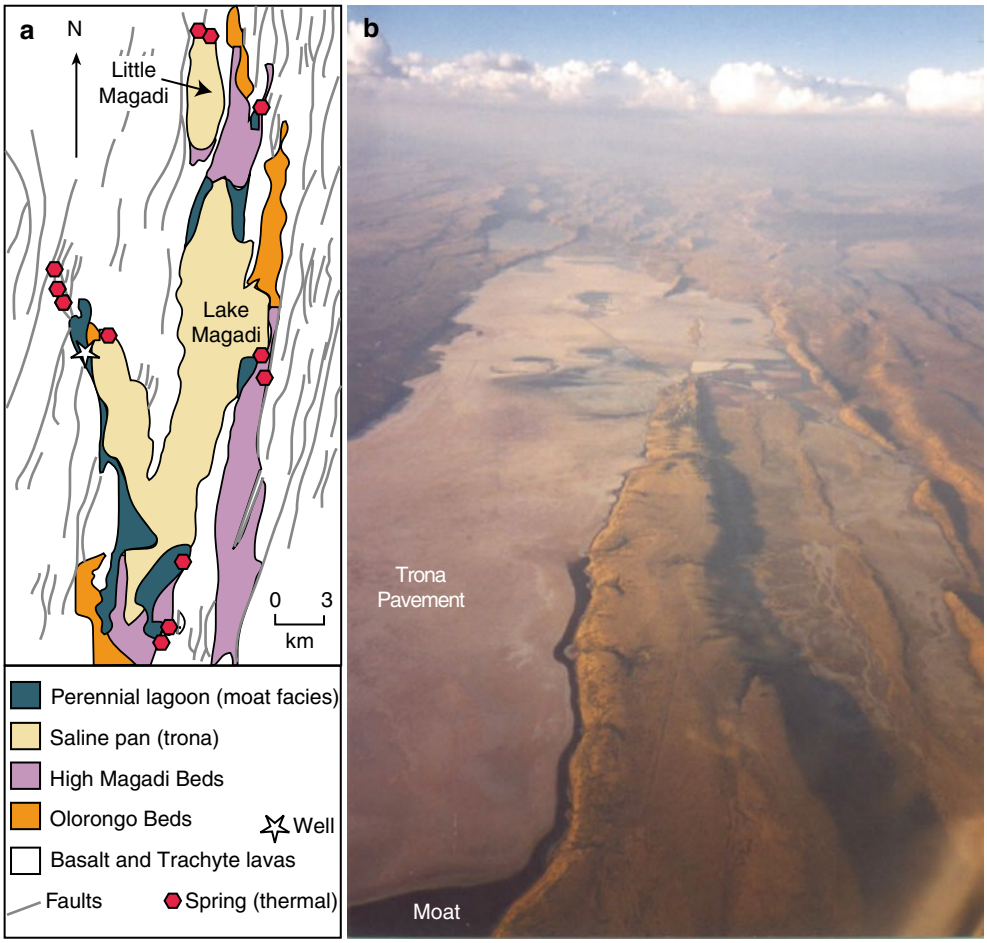

Fig. 4.39 Lake Magadi. (**a**) Geological setting of Lake Magadi. The well position locates the core in the High Magadi beds documented in Fig. 4.40. (**b**) Aerial view looks north and shows dark coloured moat facies of perennial lagoon defining lake edge

the moat facies and in the thin brine sheets in megapolygonal saucers in the trona areas. Pigments in periodic blooms of halobacteria or haloarchaea can turn more saline lake waters pink or red.

Both lakes are surrounded by metamorphosed Precambrian basement rocks. Volcanism began in earnest with the Neogene opening of the rift and continues today, with active volcanoes in the vicinity of both lakes. A general rule for volcanoes of the rift valley near Magadi and Natron is: the younger the volcanism the higher the alkalinity. Ol Doinyo Lengai, which is the youngest volcano in the vicinity of Lake Natron (≈20 km south of the lake), spews forth carbonatite lavas that are molten mixtures of sodium carbonate and calcium carbonate salts.[3] Hydrothermal circulation, associated with the numerous active volcanoes and their feeder faults, supplies hot alkaline brines to the many hot springs situated about the edges of both lakes (Table 4.4). More than 20 warm, saline springs, with temperatures between 32 and 52 °C, and release rates between 30 and 300 l/s, discharge into Lake Natron from scree slopes and hung fan deltas adjacent to the salt pan. There is no perennial stream flow into Lake Magadi, but it too has numerous warm surface springs feeding saline brines to the perennial lagoon portions of the Magadi depression (Figs. 4.37b and 4.39). Eugster (1970) argued that subterranean seepage from nearby Lake Naivasha contributes a solute load equivalent to that carried by all other saline groundwater springs in the Magadi depression.

Other than spring brines, the only other perennial water source to Lake Natron is the Ewaso Ngiro River, which drains into the north end of the lake. Yet today, no bedload sediment carried by the Ewaso Ngiro reaches Lake Natron. It is almost all deposited in an adjacent swamp created when the river was ponded and dammed behind a recently uplifted horst adjacent to the Shambole volcano. River blockage forced the river to dump its traction/suspended load into the waters of the burgeoning Ewaso Ngiro swamp. River water, minus any sediment load, now continually seeps out of the edge of the swamp into a perennial brine pool at the northern end of Lake Natron (Fig. 4.38). The effect of uplift on

[3] South of Lake Natron, within an ephemeral channel of the Engare Sero River, 120 ka hominid footprints are preserved in a tuff bed. It preserves the oldest modern human trackway in East Africa and one of the largest collections of hominid footprints in the world, giving an indication of the size of foraging parties of early modern humans (Richmond et al. 2011; Zimmer et al. 2012).

Table 4.4 Typical chemistry of waters and brines in saline East African rift valley lakes (ion contents in ppm, cited from various sources listed in text

	Ewaso Ngiro River	Hot spring (Natron)	Interstitial brine (Natron)	Surface water (Natron)	Hot spring (Magadi)	Salt pan brine (Magadi)	Moat brine (Magadi)	Surface water (Nakuru)

bedload in Lake Natron implies that mineralogical changes in ancient lacustrine units are not always a response to climatic changes; mineralogy in a lake depression can change due to tectonics.

Brine Chemistry

Interstitial groundwaters and hot spring waters come from parent waters with low levels of alkaline earths Mg and Ca, and high levels of Na, Cl and HCO_3 (Table 4.4). This chemistry is ideal for ongoing trona precipitation at higher salinities (Figs. 2.19 and 2.20). Rain falling in the drainage basin contains normal levels of Ca^{2+} and Mg^{2+} but on the way to the lake depression the same waters flow over and through highly alkaline and reactive volcanics. By the time these same waters flow out onto the lake as springs and seeps they have gathered a four-fold dominance in bicarbonate over the alkaline earths (Ca + Mg). They have already passed the calcium carbonate chemical divide and left behind their calcium and magnesium in various pedogenic and phreatic carbonates to become path I brines (Fig. 2.19).

Chloride in brines in both lakes behaves conservatively, and so its concentration can be used as a brine evolution marker (Eugster 1970). Chlorine levels show an 18,000 fold increase in concentration in the lake brine compared to river and spring inflow. Yet this is not sufficient to precipitate large volumes of halite within the Natron-Magadi depression, nor does the current warm climate favour the accumulation of natron over trona. Trona is the first Na-carbonate mineral to precipitate in equilibrium with concentrating lake brines. Natron could form as a coprecipitate if the surface brine temperature falls below 25 °C (Fig. 2.20). But, such low temperatures do not occur in either Lake Magadi or Lake Natron at the times trona precipitates.

As trona forms, there is a marked decrease in the bicarbonate proportion (relative to chloride) in the increasingly saline lake brine. As the brine continues to concentrate, lesser amounts of trona precipitate and ultimately halite should crystallise. But, the high humidities maintained over the lake brines in the deep valley bottoms of Lake Magadi and Lake Natron mean surface waters can only rarely attain concentrations where halite can precipitate in large volumes (no more than 5–10 % halite is preserved in the trona crusts in either lake). Higher temperatures at the time the various Na-carbonates precipitate from the lake brines means thermo-natrite (not natron) is the other sodium carbonate accumulating in both lakes (Fig. 2.20); only at rare to minor levels in Magadi, but it can locally constitute up to 30 % of the trona pavement in Lake Natron.

Interestingly, the concurrent fluoride increase between inflow and the trona stage of the lake brine is only 7,200 times (compared to 18,000 in chloride in the same waters), indicating its removal as a sodium salt. A lack of Ca in lake brines prevents direct fluorite precipitation in this fluorine-rich hydrothermal province. Accordingly, fluoride concentrations in the interstitial brines of the trona platform can be more than 1,400 ppm. This, and the elevated Na levels in the concentrated lake brines, leads to the precipitation of sodium fluoride salts[4] in the trona crust that include kogarkoite (Na_3SO_4F) and villiaumite (NaF) (Darragi et al. 1983; Eugster 1986). Prior to its documentation in a Lake Natron trona crust, kogarkoite had only been observed in hydrothermal deposits.

[4]Use of fluoride-rich trona (from the East African rift) as a food tenderiser has led to widespread fluorosis (mottled teeth and skeletal fluorosis) in the local population (Vuhahula et al. 2009; Rango et al. 2009).

Holocene Sediments

Spring and ephemeral stream-fed carbonate lagoons form permanent water-filled depressions that line the edges of the trona pan in both lakes. Unlike the more central trona-depositing saline pan, the lagoons never dry up and are sometimes described as a "moat" to the lakes (Figs. 4.38 and 4.39). In Lake Natron, which year-round contains more free-standing water than Magadi, the lagoon water depths during the wet season can be upwards of 10 m. The deeper parts of these perennial brine lakes are floored by black micritic laminites, which are mostly composed of aragonite and dolomite peloids, and can retain up to 16 % TOC. The lagoon floor laminites, nearby pisolites, and cemented crusts of the spring seeps, constitute a carbonate "moat" facies. Although located about the lake edge, the laminated carbonate unit is deposited in waters deeper than the ephemeral brine sheets forming the trona pavement lake centres. Less saline areas near spring seeps in the moat lagoons in both lakes can contain thriving populations of *Tilapia alcalica*, a small fish that survives at temperatures of 39 °C and pH up to 10.5. Away from the spring-freshened areas, the lagoon bottom waters and pore waters in pavements become too saline and too anoxic to support vertebrates and a well-adapted halophilic microbial biota flourishes, including endemic alkaphilic archaea (Chap. 9).

Trona accumulates in the central portions of both lakes as flat pavements composed of stacked saline pan crusts. Some 2,100 km^2 of the northeastern part of Lake Natron is covered by an impure trona bed averaging 1.5 m thick (Fig. 4.38). The Lake Magadi trona pan is some 74 km^2 in area and is 7–50 m thick, known locally as the "Evaporite Series" (Fig. 4.39). It is made up of cm-scale stacked trona-detrital couplets (Baker 1958). Light-coloured trona layers are composed of rosettes and splays of upward pointing, growth-aligned trona crystals. Thin bands of finer trona coloured by dark, mainly windblown dust separate the crust layers from each other. Even as it stacks and dissolves, each layer retains some porosity between interlocking growth-aligned crystal splays.

During the wet season the trona pans in both lakes are covered by shallow brine sheets (<1 m deep) and are subaerially exposed for the remainder of the year. When not covered by lake brines, the modern surface of both the Magadi and Natron trona pans are rock hard and occupy topographically higher positions compared to the water surface of the adjacent perennial lagoons. This "moat" geomorphology provides protection from predators for flocks of flamingoes that, once waters recede from the trona pan, nest in large numbers on the platform, especially in Lake Natron (see flamingo connection in Chap. 9).

Trona saturation is achieved when the shrinking brine sheets are 2–10 cm deep. At that stage the trona prisms grow upward from the pan surface as cm-scale aligned elongate blades and splays. Interlocking of the crystal splays give the accreting trona sheet an inherent strength that allows it to support expansion polygons or pressure ridges, with saucers up to several tens of metres wide and ridges up to a metre high. Ridging is the result of pavement overthrusting, driven by the sideways expansion of trona layers jostling for space in the various growing crystal pavements. The resultant cracking and thrusting of the layers cuts the trona pavement up into a series of overthrust-edged saucers, with small bright pink brine pools in the centre of each polygon; the colour is the result of a haloarchaeal bloom (see Chap. 9).

At the same time the ridges are forming, thin films or rafts float on the surface of the brine sheet. Trona rafts contribute only a minor amount to the total trona volume in the pavement unit, but are important in controlling mineralogy as they slow evaporation and raise the temperature of the underlying brine through a greenhouse effect. Temperatures of 60–65 °C can occur annually within thin brine sheets immediately below the trona rafts and so drive precipitation of thermonatrite (Fig. 2.20). As brine level continues to fall, the upward-growing bottom-nucleated trona splays break through the floating rafts. Prior to complete drying, high winds can break up and flounder the rafts or blow them into heaps about the local strandzones of small brine pools.

Finally, the brine level falls below the surface of the newly formed trona crystal crust and the annual primary depositional cycle is complete. Small volumes of trona continues to crystallise as minor interstitial cements, below the surface of the exposed pan. When the pan surface dries out, the brine level stays very close to the surface of the trona pavement. Even during exceptionally dry years it drops no more than 5 cm into the trona layer. It can be covered by a thin layer of windblown material whenever the surface of the layer is exposed during the dry season.

With the next rainy season the watertable rises as the pan is once again covered by water. Initially, these inflow waters are fresh and undersaturated with respect to the pore waters of the trona pavement. So they float above the top of the dense interstitial brines and any trona crystals poking up into these freshened waters start to dissolve. Last season's crystals are truncated by the influx of freshened waters. During this freshened stage, windblown clays and other detritus on the pavement surface can be retransported by waves. Then the wet-season rains cease and the trona precipitation cycle begins anew. Each season a trona layer 2–5 cm thick forms on the saline pan in both lakes but subsequent seasonal dissolution means the average Holocene accumulation rate for Lake Magadi trona is at most 0.4 cm/year. The much thinner layer of Holocene trona preserved in Lake Natron, implies dissolution levels are even higher compared to Lake Magadi. The annual trona crop in Lake Magadi is around 1.5 million tonnes/year, but the bulk of this crop (≈75 %) is recycled by pan dissolution each wet season. Lake Magadi has been

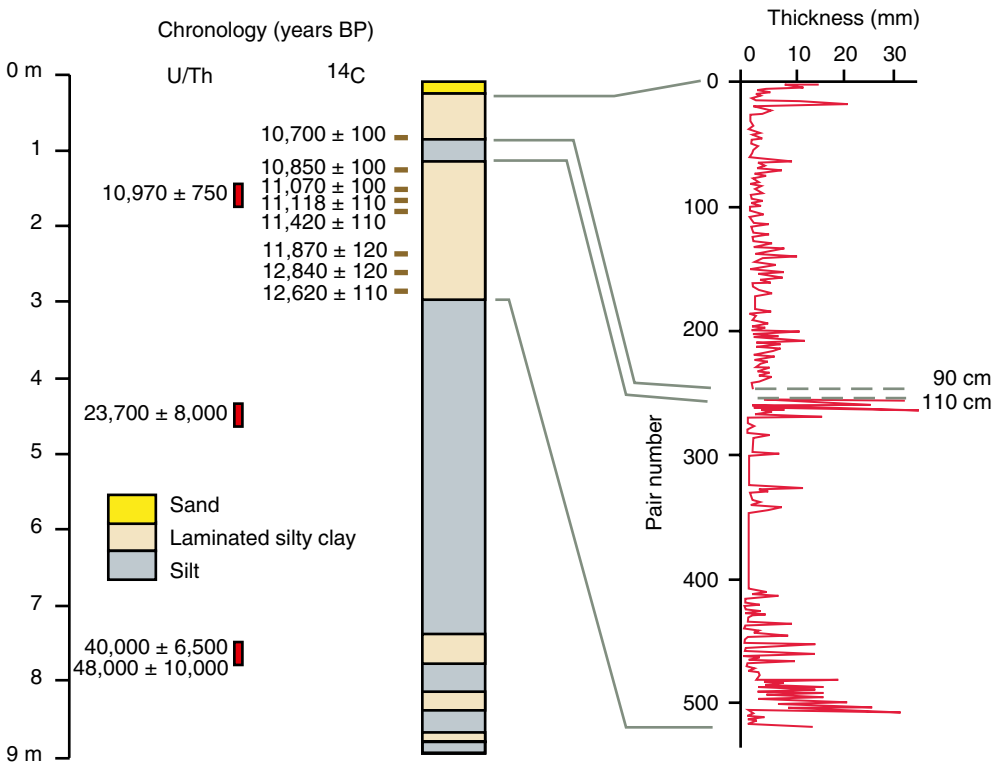

Fig. 4.40 Core in the High Magadi beds, Lake Magadi (See Fig. 4.39a for location; after Damnati and Taieb 1995)

described as an "ephemeral saline lake at the peak of its trona productivity" (Eugster 1980b). Trona in Lake Magadi has been extracted at various times from 1914 until today using dredging barges. Replenishment of trona in the lake is so rapid that at the rates the Magadi trona is mined (230,000 t/year) it is a renewable resource (Fig. 12.41).

Late Pleistocene Sediments

Aside from the Ewaso Ngiro River, two other significant rivers flow toward the shores of Lake Natron, the Peninj and Sanjan (Malambo) Rivers (Fig. 4.38a). Today, these rivers are ephemeral and any surface water sinks into the riverine sediment fans well before it ever reaches the current lake strandline. Some 9,000–10,000 years ago during the last high water stage, these rivers, and the Ewaso Ngiro, deposited fan deltas along the edge of a much fresher and higher Lake Natron. Today, these sediments form "hung" delta lobes on the surrounding landscape located well back from the lake shoreline, some 10–60 m above the present lake level. In earlier lake-full times the flood sands from these highstand deltas probably extended further out into the lake centre and so may now directly underlie the trona-hosting sediments of the lake centre and act as potential aquifers for fresher groundwaters that prevent the accumulation of thick trona units in Lake Natron.

At the time the fan deltas were active Lakes Magadi and Natron were both deeper, larger and fresher water bodies. At such times in the late Pleistocene the two lakes sometimes merged into a single pluvial lake (Hilaire-Marcel et al. 1987). Studies of stromatolites and tufa terraces from various high lake levels in the vicinity of both lakes show that the most recent high lake levels were part of a two-stepped climatic optimum that occurred some 12–11 ka (Williamson et al. 1993; Icole et al. 1990). The first humid period (between 12 and 11 ka) created a lacustrine highstand that topped the 635 m-elevation barrier (msl) separating the Magadi and Natron depressions. Between 11 and 10.7 ka the lake level dropped below the barrier, once again separating the two lakes. A second maximal high stand occurred around 10 ka, possibly once again joining the lakes. Since that time, and throughout the Holocene, the lake levels have been consistently near their present levels and some 60 m below their former highstands.

The High Magadi Beds were deposited as diatomaceous mudstones when lake waters were more than 13–14 m above the present level and relict shorelines from that time are still mappable (Fig. 4.39). Lake sediments of that time are mostly bedded volcanic muds and cherts, typically deposited as lakefloor laminates with abundant fish scales visible on partings. An 8.7 m core taken from this highstand facies in the Flamingo Nursery area on the northern edge of Lake Magadi recovered High Magadi beds that were deposited from 40 to 9 ka (Fig. 4.40; Damnati and Taieb 1995; Williamson et al. 1993). The lower (870–740 cm) and upper (295–6 cm) units in the core consist of laminated silts made up of alternating layers of magadiite (zeolite-rich) and organic-rich muds

(TOC >5 % dry weight). The middle unit (295–740 cm) contains homogenous inorganic clay silts that are unlaminated, suggesting the lake was not stratified at that time. The upper laminated unit was deposited 12–9 ka, the middle unit ≈23 ka, while the lower laminated unit contains sediments as old as 40 ka. Each unit is separated from the other by a thin sand, which is thought to mark a hiatus in chemical sedimentation and to be a flood sand from the feeder deltas and sheet floods.

The laminite episodes in the core indicate times when a relatively deep lake was chemically and thermally stratified. Light laminae in the couplets are in turn comprised of finer-scale micro-couplets. Each light layer is made up of a microlayer rich in detrital elements (quartz and feldspar) and broken diatom frustules that is overlain by a microlayer of magadiite (Damnati and Taieb 1995). The dark lamina in each couplet is composed of a microlayer made up mostly of well preserved diatom frustules, covered by a layer of microspheres (probably microbial) associated with autochthonous organics generated in the lake waters. White laminae indicate a more humid season climate and dark laminae indicate drier climatic conditions in the lake depression. Variations in lamina thickness can be tied to year-to-year variations in monsoonal intensity and to ENSO years. These Pleistocene laminites are very similar to those accumulating in Lake Van today, the general lake hydrologies and their humid settings are probably comparable, although one forms in a transtensional tectonic regime and the other is part of a rift valley fill.

Two hundred kilometres north of Magadi is Lake Bogaria, a shallow, perennial, saline (60–100 g/l total dissolved salts, alkaline, pH: ~10–10.5) lake with Na–HCO_3 –CO_3 waters. Today it is a permanent freshwater lake, that currently receiving more fluvial inflow than either Magadi or Natron. The northern margin of the lake basin is defined by the spill-over point into the drainage for Lake Baringo and is located almost on the equator (Aw). It occupies the lower part of what is locally an asymmetric rift valley with active fan deltas forming along the steeper gradient eastern side of the lake, Gilbert-style deltas and hydrothermal stromatolites typify Holocene deposits on the less steep western side and diatomaceous laminites are accumulating in the deep lake centre (McCall 2010; Scott et al. 2009). Its current sediment styles and hydrologies are likely Holocene counterparts for the Late Pleistocene situation when the High Magadi beds were deposited.

Holocene cores from Lake Bogoria have recovered crystals of trona and nahcolite from 5–10 cm thick beds at depths of a few metres below the current lake surface. In the lowermost unit cored by de Cort et al. (2013) there are four trona layers attributed to drier conditions during the second half of the first millennium AD and in the period equivalent to the Medieval Climate Anomaly, which lasted until the first half of the twelfth century AD. Lake Bogoria hydrology was probably polymictic at that time, its surface level standing significantly lower than today. The overlying sodium carbonate unit displays uniform deposition of nahcolite, interpreted as indicative of a strongly stratified lake where a layer of less saline surface water (near-) permanently covers a hypersaline water mass with high pCO_2. De Cort et al. (2013) propose that this depositional phase reflects a rising lake level related to the transition from dry to more humid climate conditions at the onset of the Little Ice Age. The third, uppermost sodium carbonate unit in Bogoria contains only sporadic magadiite of magadiite and various other sodium carbonate minerals. This, together with low magnetic susceptibility in the core, is interpreted to indicate humid Little Ice Age conditions, with highest lake level and reduced salinity occurring around the late-fifteenth to early-sixteenth century AD. From the late-eighteenth to early-nineteenth century and again in the 1870s, the region experienced two episodes of drought more severe than any other recorded in historical time. The result is interesting in terms of current discussions of anthropogenic climate change and illustrates significant hydrological excursions and climate-driven desiccation events over the past few thousand years that are unrelated to anthropogenic industrial activity.

An important general observation for saline systems, based on the African Rift valley lakes, is that perennial continental lakes in a single sump do not usually deposit bedded evaporites at the same time that they deposit thick fluviodeltaic successions. Nor do all lake sumps along the lower parts of a rift valley accumulate evaporites at the same time. Episodes of fluviodeltaic deposition and thick evaporite deposition are separate in time and space – a restriction inherent in the isolated lake hydrology needed to precipitate evaporites. That is, ancient lacustrine evaporite beds accumulating in separate but adjacent basins are not necessarily time equivalent. And, it is almost impossible to form evaporites when the lake waters are diluted by fresh water carrying siliciclastics into deltas. However, the time intervals resolvable in the siliciclastic-to-evaporite transition in the African Rift Lakes are less than a few thousand years. In pre-Quaternary lacustrine deposits, such as the Eocene Green River Formation, the two sedimentation styles may appear syndepositional and are easily mis-correlated.

Diagenesis – Magadiite and Evaporitic Chert

Pleistocene nodular and bedded chert outcropping in the lake margins in Lake Magadi, Kenya, are thought to form inorganically via early replacement of sodium silicate precursors – magadiite and/or kenyaite. These neoformed sodium silicates (especially magadiite) accumulate in alkaline carbonate-rich hydrogeochemical environments, especially in organic-rich diatomaceous laminites in the freshened stages of soda lakes. Such sodium silicates were first documented in the High Magadi beds (Eugster 1969, 1980b;

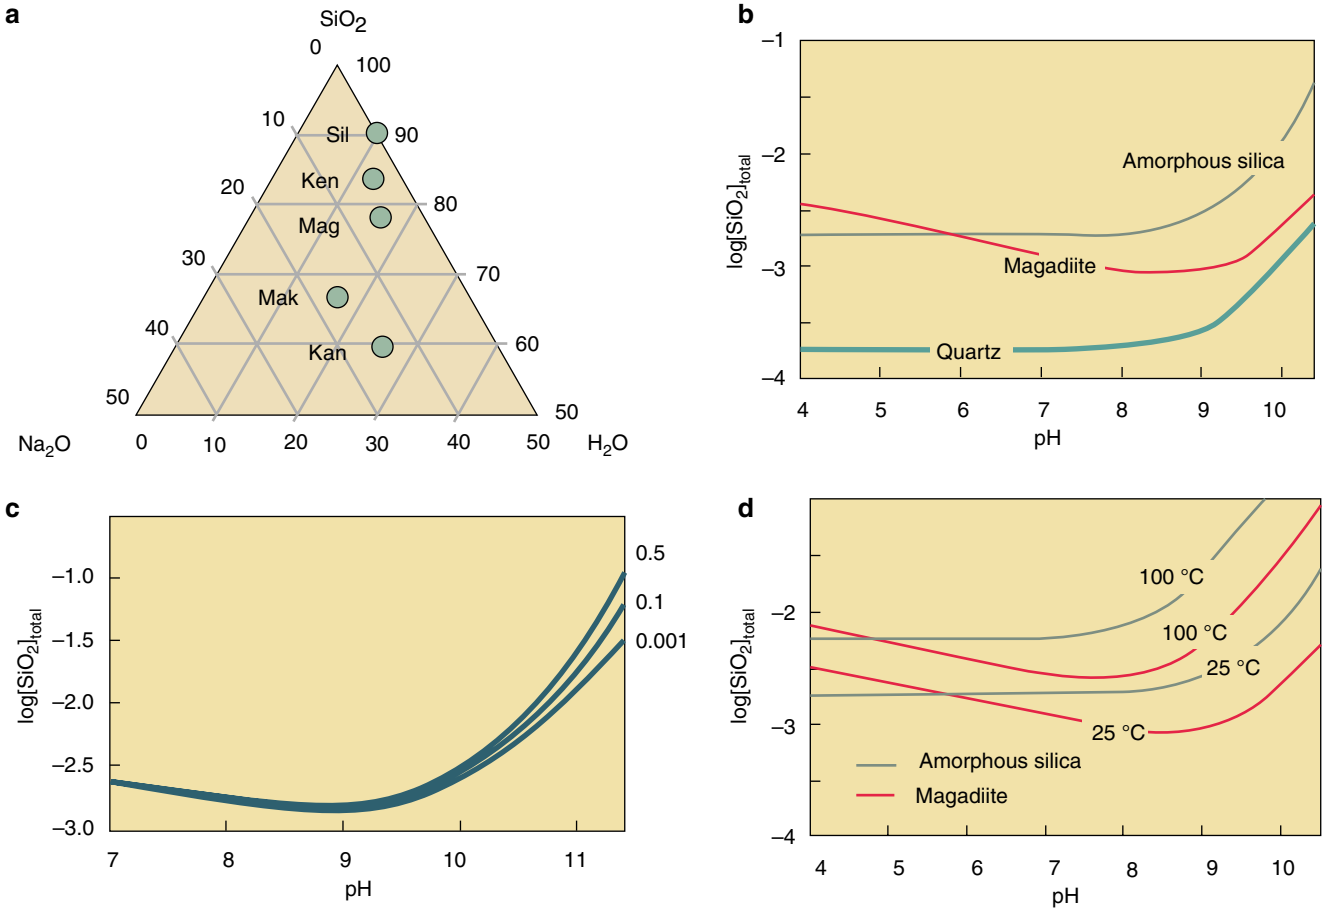

Fig. 4.41 Magadiite chemistry. (**a**) Sodium silicate minerals plotted in the *upper* part of the ternary diagram Na_2O±SiO_2±H_2O showing the position of various hydrous sodium silicates related to varying proportion of the constituent water silica and sodic contents (*Ken* kenyaite, *Kan* kanemite, *Mag* magadiite, *Mak* makatite, *Sil* silhydrite). (**b**) Concentration of $[SiO_2]_{total}$ at equilibrium with magadiite, amorphous (**c**) Concentration of $[SiO_2]_{total}$ at equilibrium with magadiite and amorphous silica at 25 and 100 °C (0.1 mol Na(OH,Cl) L1; I = 0.5). (**d**) Concentration of $[SiO_2]_{total}$ at equilibrium with magadiite as a function of pH at ionic strengths of 0.5, 0.1 and 0.001 at 0.001 mol Na^+ L^{-1}, 25 °C (After Dietzel and Letofsky-Papst 2002)

Baker 1958) and also occur in the High Natron beds. There are three sodium silicates in the High Magadi beds: magadiite – $NaSi_7O_{13}(OH)_3$ .H_2O, kenyaite – $NaSi_{11}$ O_2 $0.5(OH)_3$. H_2O, and makatite – $NaSi_2O_3(OH)_3.H_2O$ (Fig. 4.41a). Of these, only magadiite occurs in substantial quantities, typically as beds, mounds and nodules. Kenyaiite, never occurs as beds, but is not uncommon as nodules in the bedded magadiite laminites of Lake Magadi. Some magadiite nodules have kenyaite at their centres, perhaps implying kenyaite can be created by the weathering of magadiite.

When fresh, magadiite is white, soft, putty-like and easily deformable, but it dehydrates rapidly on exposure to air and hardens irreversibly to a fine-grained cherty aggregate. To date, magadiite has been found only in Quaternary alkaline lacustrine settings. In addition to Lake Magadi, Quaternary magadiite has been found in Lake Bogoria, Lake Kitagata, in Lake Chad in western central Africa, Alkali Valley playa in Wyoming, and Trinity County in California (Sebag et al. 2001; Ma et al. 2011). On a longer time scale, ancient Magadi-type (crocodile skin) chert has been found in many ancient lacustrine basins, in the Jurassic of Wyoming, the Proterozoic Callana Beds of the Adelaide geosyncline in South Australia, and in Precambrian banded iron formations in Western Australia (see also Table 7.13).

The solubility equilibrium curves for silica and amorphous silica are similar, with a marked increase in solubility occurring in more alkaline conditions (pH >9; Fig. 4.41b, c; Dietzel and Letofsky-Papst 2002). In contrast, SiO_2 contents at equilibrium with magadiite show a minimum value at a pH around 8.5 and follow a different dissolution pattern to silica. At low pH the concentration of silica in solution increases, as it does also in alkaline solutions at the other end of the pH spectrum. Thus, the concentration of silica in a solution saturated with respect to magadiite, at constant Na content, is lowest in neutral to slightly alkaline solutions. Below pH 5.9, which is the intersection point of the magadiite and

amorphous silica curves, magadiite exhibits a higher solubility than amorphous silica. Thus, at pH <5.9 magadiite will dissolve, while amorphous silica precipitates (Dietzel and Letofsky-Papst 2002).

Conditions associated with the precipitation of magadiite from lake brines in Lake Chad, and probably most other soda lake occurrences, including Lake Magadi, require fluctuations in alkalinity or mixing interfaces between alkaline and less alkaline groundwaters (Fig. 4.41b–d). Sebag et al. (2001) list the following conditions as typical of most modern magadiite occurrences; (1) Elevated alkalinity, typically in the lake dry season (pH >9) allow dissolution of silica, followed by lowering of alkalinity in the wet season driving precipitation of silica (Fig. 4.41b, c), (2) High concentrations of dissolved silica (up to 2,700 ppm), (3) Incorporation of sodium ions into the silica lattice that precipitates at the time of silica supersaturation (Fig. 4.41d). Depending on the concentration of Na and Si in the brine at the time of precipitation, the various sodium silicate minerals will precipitate (Fig. 4.41).

Bedded magadiite is widespread in High Magadi laminites, it precipitated in the Pleistocene when Lake Magadi was deeper, fresher and density stratified. Most of this magadiite is an authigenic phase precipitated during shallow diagenesis via the interaction of alkaline brines with reactive siliceous materials such as volcanic glass and zeolites (Jones et al. 1967). Even today, hydro–sodium–aluminosilicate gels precipitate about the edge of Lake Magadi where saline spring waters first emerge. With shallow burial the gels convert to analcime, erionite, and magadiite.

Two mechanisms are thought to drive the precipitation of the sodium silicates. One is intense evaporation, so the resulting sodium silicates are intimately associated with evaporite indicators, such as evaporite splays and dissolution breccias with evaporite pseudomorphs and moulds in the magadiite host. The other is the pH decrease that occurs when a brine comes into contact with more diluted or more acidic water as when two stratified water masses with differing chemistries mix (Fig. 4.41b–d). Likewise, although the pH change may be as little as 0.5, a decrease in pH from 10.3 to 9.8 lowers amorphous silica saturation more than 500 ppm (Fig. 7.79). In contrast to the modern occurrences, the pH and dilution changes needed to form the Pleistocene magadiite of the High Magadi laminites were probably related to the annual overturn of the stratified water mass.

Freshly precipitated, magadiite is a soft plastic white paste (Maglione 1980; Ma et al. 2010), and remains so while bathed in alkaline pore brines. However, when exposed to drying and dehydration it quickly loses its plasticity, cracks and shrinks as it irreversibly hardens into chert. Shrinkage (25 % volume change) of the hardening surface creates neoformed chert with a superficial crack network made up of small prisms separated by fissures (Icole and Perinet 1984).

Fig. 4.42 Magadiite chert from Lake Magadi showing cauliflower surface texture, also known as crocodile skin

It gives the surface of any resulting chert a characteristic "crocodile-skin" or cracked appearance (Fig. 4.42). This is a texture used to support an alkaline lacustrine interpretation in ancient counterparts, such as the crocodile cherts in the Eocene Green River Formation (Fig. 4.42). In Phanerozoic hosts, such nodules are readily distinguished from the much more commonplace and nondiagnostic smooth-walled chert nodule, which are widespread in both marine and nonmarine matrices.

Whenever a plastic magadiite horizon in the High Magadi beds is traced from depth (≈1 m) to the surface or from subcrop to outcrop, a conversion from magadiite to surface chert is always seen. In the perimeter sediments of Lake Magadi, Eugster (1969) described what he considered to be an impressive syndepositional result of this transformation, namely shrinkage megapolygons up to 50 m across in a bedded chert host with bounding upturned chert ridges up to 2 m high.

Subsequent work on the same structures by Behr and Röhricht (2000) concluded the megapolygons do not indicate a response to mineralogical transformation, rather they are part of a suite of prelithification structures in soft siliceous lake sediment. The chert megapolygons are a soft sediment response to strong deformation and local-scale diapirism, as are the associated pillow-chert mounds, chert extrusives along dykes and fault ramps, horizontal liquefaction slides with breccias, slumps, petees, flows and shear-structures in the magadiite beds (now all chert at outcrop). Collapse, liquefaction and extrusion of the pre-lithified siliceous matrix were caused by seismotectonic rift activity in the lake basin and it activated fault scarplets and large-scale dyke systems. Seismic activity led to liquefaction and other earthquake-induced intrasediment deformation, especially along fault ramps and on tilted blocks. The textures all

indicate the chert megapolygons are a form of seismite and do not indicate volume changes in the transition from magadiite to chert. After liquefaction and extrusion, the exposed magadiite material solidified via spontaneous crystallisation in an environment that was characterised by highly variable pH and salinity.

Since the work of Eugster in the 1960s, three sets of diagenetic processes are now thought to be responsible for driving the conversion of magadiite to chert in Lake Magadi and other soda lakes:

1. Leaching of sodium by dilute surface runoff during weathering of the High Magadi beds, as evidenced by tracing unweathered beds into outcrop and summarized in the chemical transformation (Eugster 1969);

$$NaSi_7O_{13}(OH)_3 \bullet H_2O + H^+ \rightarrow 7SiO_2 + Na^+ + 5H_2O$$

2. Spontaneous release of sodium driving the conversion of magadiite to chert, whatever the nature of throughflushing solutions and environments. In this process sodium is expelled even in the presence of brines; it does not require the fresh water needed for process 1, and perhaps better explains the occurrence of calcite-filled trona casts in cherts and the presence of chert nodules in unweathered magadiite horizons in Lake Magadi (Hay 1968, 1970).
3. To this inorganic perspective on the transformation to form chert, Behr and Röhricht (2000) added a biological one. Based on their field observations and microbiological studies of the cherts in Lake Magadi region, they argue that inorganic cherts are rare at the type locality of Magadi-style cherts. They go on to note that most of the cherts in the Magadi depression are older than the High Magadi Beds and developed from flat-topped calcareous bioherms of *Pleurocapsa*, *Gloecocapsa*, and other coccoid cyanobacteria, along with thinly bedded filamentous microbial mats, stromatolites, bacterial slimes, diatoms, *Dascladiacea* colonies and other organic matter accumulations. Silicification occurred from a silicasol[5] via opal-A to opal-C with final recrystallisation to a chert of quartzine composition. They conclude that metabolic processes of cyanobacteria controlled the pH of the brine and strongly influenced the dissolution-precipitation mechanism that created the chert (Fig. 7.74).

Dead Sea, Middle East

The Dead Sea water surface defines what is the deepest continental position (−415 m asl) on the earth's current terrestrial surface. It is our only modern example of bedded evaporitic sediments accumulating on the floor of a brine body, where water depths are measured in hundreds of metres. This salt-encrusted depression is 80 km long and 20 km wide, has an area of 810 km^2, is covered by a brine volume of 147 km^3 and occupies the lowest part of a drainage basin with a catchment area of 40,650 km^2 (Fig. 4.43). However, falling water levels in the past few decades mean the permanent water mass now only occupies the northern part of the lake, while saline anthropogenic pans occupy the southern basin so that the current perennial "Sea" is now only some 50 km long. Rainfall in the region is 45–90 mm, evaporation around 1,500 mm, and air temperatures between 11 and 21 °C in winter and 18–40 °C in summer, with a recorded maximum of 51 °C. The subsiding basin is surrounded by mountain ranges to the east and west, producing an orographic rain shadow that further emphasises the aridity of the adjacent desert (Fig. 4.43a).

So, until recently, the basin floor was physiographically divisible into two contiguous and permanent brine-covered water bodies, the Northern and Southern basins, largely separated by a diapir-cored shallow sill, the Lisan Ridge and joined at the Lisan Straits. Top of salt is 100–120 m below the surface in the Lisan Peninsula and a few metres below the surface at Mt. Sedom. The land surface of the Lisan Peninsula is slowly rising and being karstified, at a rise rate of a few mm per year, driven by salt flow (Closson et al. 2007). Widespread at-surface evidence of this rise is swamped by the changing of the depositional and hydrological system, driven by fluctuating lake water levels. Continuing falling water levels since the 1930s means that today the North Basin is the only permanent natural water mass, with waters some 320 m deep (Fig. 4.43b). The Southern Basin is today a saline pan/mudflat, which would be a subaerially exposed plain, except that brine-filled saltworks now cover much of the former Southern Basin lake. Perennial brine sheets are artificially maintained in these pans by continually pumping of brines from the Northern Basin (Fig. 11.25).

The basin floor beneath the waters of the Northern Basin is asymmetric, with the western slopes around 7° and the eastern slopes about 8°. The northern part of the Northern Basin is flatter and smoother than either its eastern or western slopes, and is covered by deltaic clays of the Jordan River outfall (Fig. 4.43a). Away from the northern slope the outflow zones of the various streams and wadis are defined by local clastic aprons or fan deltas, most of which are now "hung" in response to the lowered lake levels (Figs. 4.43b and 4.52a).

Geological Setting

The Dead Sea depression is a large strike–slip basin located within the Dead Sea transform; a plate boundary separating the Arabian plate from the African plate and connecting the divergent plate boundary of the Red Sea to the convergent

[5]Colloid grains in a silicasol are minute (10–20 nm) and so have relatively large specific surface areas, making them highly responsive to changing brine chemistries.

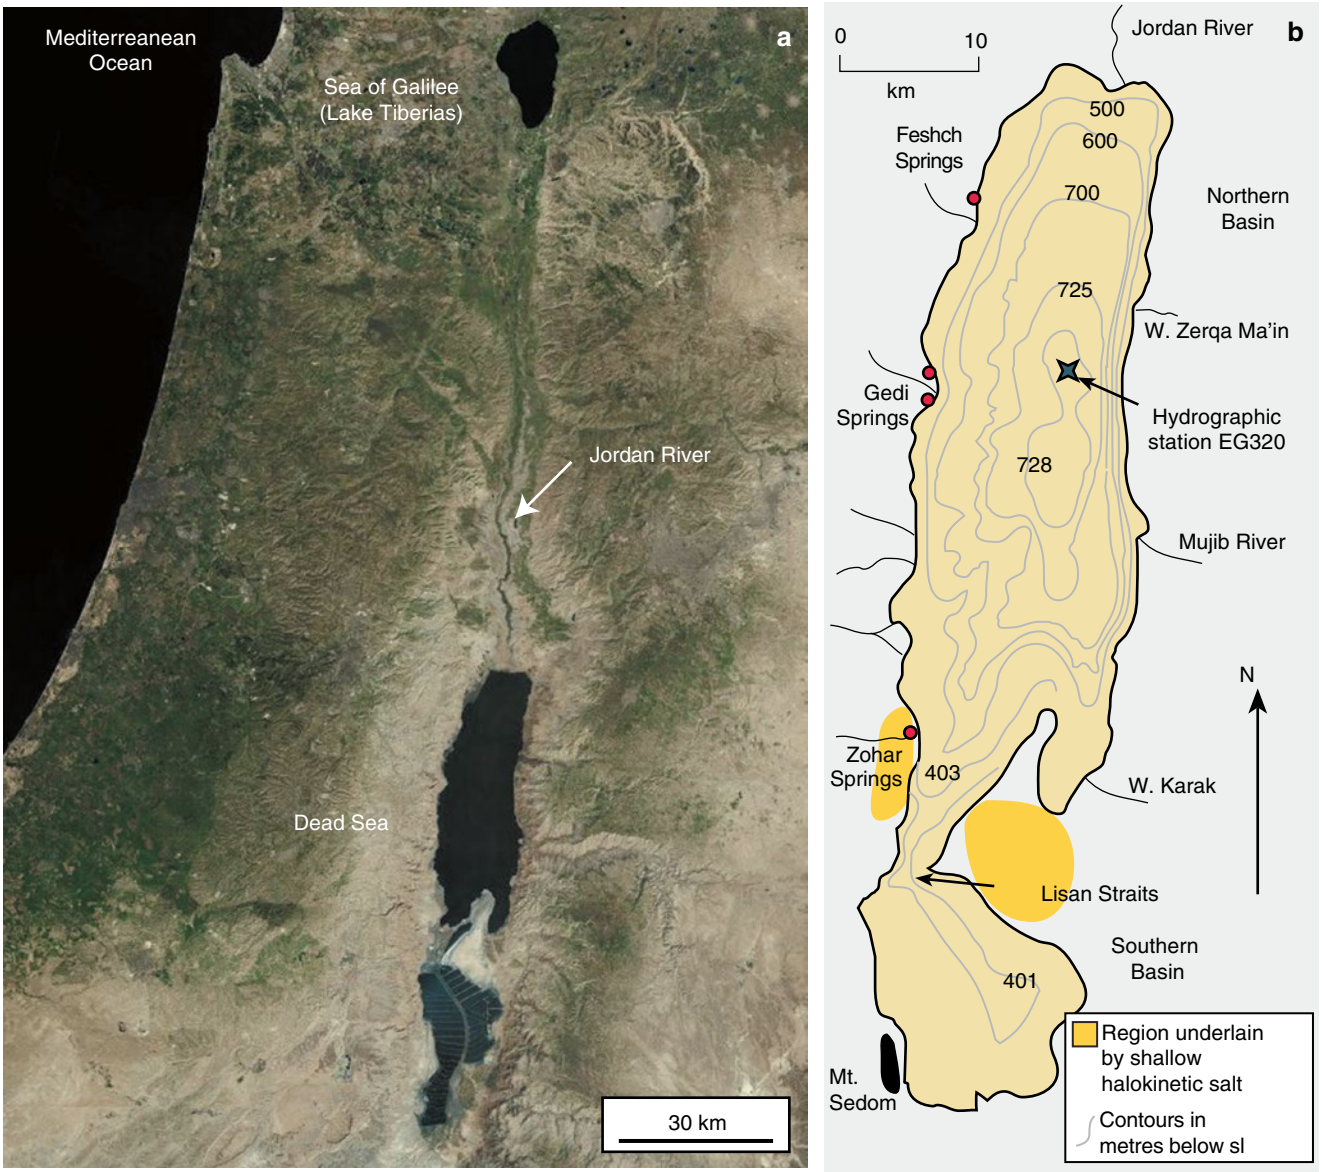

Fig. 4.43 Dead Sea depression, Middle East. (**a**) Dead Sea Valley. Image of the depression in the early 1990s, showing the Dead Sea separated into a deep Northern Basin separated by the Lisan Straits from the Southern Basin with its solar ponds. The Jordan River enters the Dead Sea at its northern end. Sea of Galilee is visible in the northern end of image. (**b**) Bathymetry of lake floor in metres below sea level, the basin shows E-W basin asymmetry with a somewhat steeper eastern margin

plate boundary of the Taurus Mountains in southern Turkey. Since it formed, 105 km of left-lateral horizontal movement has occurred along the transform. In places along the transform where crust is stretched or attenuated, plate stress is accommodated via several rapidly subsiding en-echelon rhomb-shaped grabens separated across west-stepping fault segments. The Dead Sea basin and the Gulf of Elat to its south are the largest of these graben depressions and are separated by the Yotvata Playa basin (Fig. 3.34). The Dead Sea basin fill is 110 km long, 16 km wide and 6–12 km deep and located in the offset between two longitudinal faults, the Arava Fault and the Western Boundary (Jericho) Fault (Fig. 4.44a; Garfunkel et al. 1981; Garfunkel and Ben-Avraham 1996).

Movement began 15 Ma in the Miocene with the opening of the Red Sea and is continuing today at a rate of 5–10 mm/year. The Dead Sea basin floor is more strongly coupled to the western margin (Levantine plate) and is being left behind by the northward moving Arabian plate. Since the Miocene, depocentres in the Dead Sea region have moved 50 km northward along the shear zone (Zak and Freund 1981) to create the offlapping style of sedimentation in the Dead Sea–Arava Valley, with a basin geometry reminiscent of the Ridge Basin in California. Continued extensional movement has

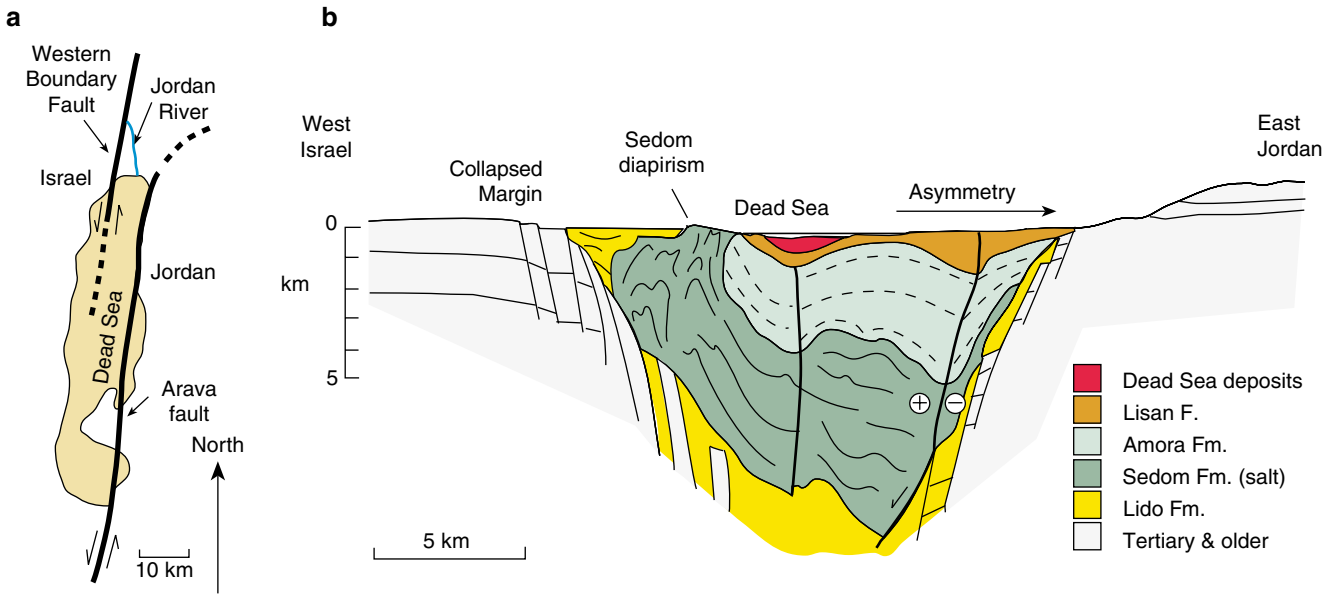

Fig. 4.44 Dead Sea, Middle East. (**a**) Plan view show the location of the Dead Sea depression in relation major transtensional faulting. (**b**) Schematic cross section of lake geology showing the importance of subsidence, in relation to salt tectonics and strike-slip faults as controls on sediment distribution in the depression (In part after Zak and Freund 1980, 1981)

triggered halokinesis in the underlying Miocene evaporites so that diapirs subcrop along the Western Boundary Fault and its offshoots (Figs. 4.43b and 4.44b; Neev and Hall 1979). Salt in these structures is equivalent to the salt in the outcropping Mount Sedom diapir. The Holocene to Miocene fill is 8–10 km thick beneath the Dead Sea, with at least 90 m of Holocene fill beneath the Southern Basin. There have been three stages of deposition since the Miocene inception of the Dead Sea valley (Fig. 4.44b; Garfunkel and Ben-Avraham 1996). The bottom 2–3 km of fill is made up of continental conglomerates of the Hazeva (Lido) Formation. This represents the first stage of basin fill, during which deposition kept pace with subsidence of the rift. It ended in the late Miocene (8–10 Ma) when differential uplift along the transform edges and rapid subsidence of the basin led to a deep topographic trough. During this second stage (4–6 Ma) the trough was invaded by Mediterranean seawater through the Yizre'el Valley to create a highly restricted arm that was periodically cut off from the ocean and deposited the 2–3 km thick halite-rich evaporites of the Sedom Formation (also known as the Usdum Fm.). This 2–3 km-thick section is now halokinetic in the Dead Sea region. In its third stage, the basin was cut off from the Mediterranean seepage to become a closed continental basin. A series of large lakes formed during this time and 3–4 km of fluviatile and lacustrine sediments of the Plio-Pleistocene Amora and Samra-Lisan formations were deposited (Fig. 4.44b). The Pleistocene Amora Fm. in the region of the Dead Sea is a fluvio-lacustrine chalky marl with entrained gypsum, anhydrite, sands, conglomerates and thin halite layers. The overlying Lisan-Samra Fm. was deposited in the last large lake that filled the majority of the Dead Sea-Jordan Rift Valley during the late Pleistocene. It consists mostly of finely layered marls, laminites and chalks with gypsum and aragonite couplets in its more evaporitic portions.

Unlike the marine isotopic signatures of the salts in the Sedom Formation, isotopes in the evaporites of the various Pleistocene sequences indicate their precipitation from lacustral CaCl-rich connate brines. Groundwater inflow chemistries were created by rock-water interactions with an original connate seawater brines, first trapped in sediments of the rift walls in "Sedom time" (Raab et al. 2000). After the final Pliocene disconnection from the sea and a lowering of the lake levels, these residual brines gradually seeped and leached back in to the Sedom basin (García-Veigas et al. 2009). There was never a hydrographic connection of the Dead Sea to the Gulf of Aqaba in the south and all of the Pleistocene salts in the depression come from the evaporation of continental groundwaters, not from ongoing marine-fed seepage. Neogene parts of the intervening rift valley were always above sea level and even today the Arava Valley is characterised by ridges up to 200 m above sea level in the Gulf of Aqaba.

The rapid accumulation of Amora and Samra sediments within a subsiding and extending valley, atop thick bedded evaporites of the Sedom Fm. initiated several salt diapirs along the valley floor, the best known being Mt. Sedom (Fig. 4.44b; Larsen et al. 2002). The Mount Sedom diapir has pierced the surface atop a 200 m-high salt wall. Throughout the Holocene, salt has been rising in Mt. Sedom at a rate of 6–7 mm a^{-1} (Frumkin 1994a).

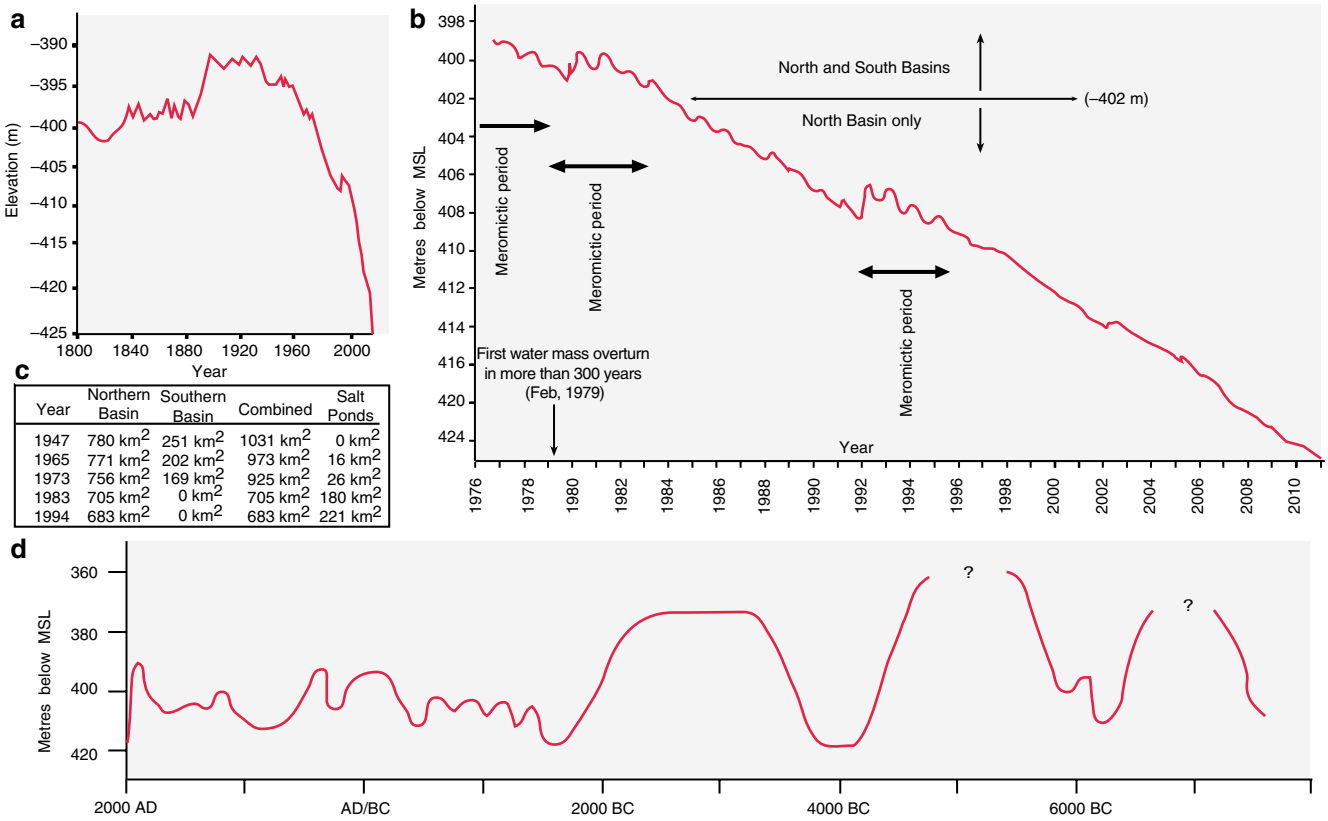

Fig. 4.45 Changes in the Dead Sea water level at various time scales. (**a**) Historical changes in the water level of the Dead Sea brine level since 1800, showing obvious acceleration in rate of fall since the 1960s and the "droughty" or falling trend since 1918. (**b**) Detailed curve for the last four decades showing how rapid rises are tied to "wet" years and the consequent meromictic lake hydrology. (**c**) Variations in the areas of the Northern and Southern Basins and the growing area of anthropogenic salt pans as it relates to changing brine levels. (**d**) Changes in the Dead Sea level for the past 8,000 years (**a**, **c**: Replotted in part from Enzel et al. 2003, **b:** Replotted from Gertman and Hecht 2002, data from http://isramar.ocean.org.il and more recent measures)

Water Level Changes

The highest recorded level of the Dead Sea (–392 m asl) was reached in the 1920s (Fig. 4.45a), since then the lake level has been decreasing and today (2014) is around –427 m asl and still falling. At the beginning of 1978 the falling waters reached a level of –399.6 m asl, which dried out the Lisan Straits and divided the water covered area of the Dead Sea into separate Northern and Southern basins (Fig. 4.45a). Since 1977, the surface level of the Dead Sea has been falling at a rate ≈60 cm/year. The lake water surface reached –410 m (msl) in 1997 and from 1998 to 2002 the lowering rate reached 100 cm/year. Since the 1930s, the trend of water levels in the Dead Sea lake has been falling or "droughty" (Fig. 4.45a). In a "droughty" year the total level rise in winter is smaller than the yearly drop, and in a "rainy" year-larger. For example, in the droughty period 1981–1988, the net level drop in water level in every single year is in the range 70–90 cm year^{-1} (Fig. 4.45b; Anati 1998; Yechieli et al. 1998; Gertman and Hecht 2002). An exactly balanced year, which is the common situation in most of the world's perennial lakes in temperate climates, has never been recorded in the Dead Sea. Dead Sea water level changes underline the general observation that differences in the hydrological balance in a lacustrine setting are the dominant control on the various styles of lake fill and that evaporites only accumulate in underbalanced lacustrine settings (Fig. 5.10).

It seems the rate of fall has been accelerating since the 1960s. This more rapid rate of fall is largely a response to the diversion of river water from the Jordan and Yarmuch Rivers into irrigation projects in Syria, Israel and Jordan. As a result, the inflow of fresh water into the Dead Sea has diminished significantly in the past half century. In the 1950s, the yearly Jordan River input to the Dead Sea was estimated to have been 1,370 million m^3, while present annual inflow is between 250 and 300 million m^3. Moreover, Israel and Jordan are pumping Dead Sea waters from the northern basin into saltworks in the southern Basin, further contributing to the falling water levels. Streams other than the Jordan River supply surface runoff to the Dead Sea and include; Wadi Mujib, which discharges around 83×10^6 m^3, Wadi Karak, which discharges around 18×10^6 m^3; Wadi Hasra, which discharges about 34×10^6 m^3; and the Zerqa Ma'in Springs

Table 4.5 Major inputs to the Dead Sea and their solute compositions

		Flow	Na	K	Mg	Ca	Cl	SO_4	HCO_3	Br

Flow is in 10^6 m^3/year and concentrations in mg/l

which discharge about 23×10^6 m^3. Small intervalley catchments provide an additional 30×10^6 m^3 (Table 4.5, Fig. 4.43b; Abu-Jaber 1998; Salameh and Bannayan 1993).

Until the 1960s, the Jordan River, flowing south from the Sea of Galilee, provided 80 % of the water received by the Dead Sea (Eugster and Hardie 1978). The Sea of Galilee is the largest freshwater lake in Israel. Storm runoff centripetal to the Dead Sea provided around 8 % and spring inflow the remainder. Historically, the bulk of the water and detrital sediment entering the Dead Sea Basin was carried by the Jordan River into the northern end of the lake. However, even before the current drastic lowering of the Jordan's flow to a quarter of previous levels, the bulk of the solutes forming chemical precipitates in the Dead Sea came from saline springs fed by dissolving Miocene salt and not from the Jordan inflow. Annual spring inflow is thought to be around 80 million cubic metres and up to 300 times more saline than the waters of the Jordan River. As in many other evaporite basins, hydrography and solute cycling in the Dead Sea are largely decoupled (Chap. 2).

Given the marked fall in brine level over the last 50 years, Yechieli et al. (1998) addressed the interesting quandary, "Will the Dead Sea ever dry up?" They argue it will not dry up completely as the rate of evaporation will continue to decrease as the salinity of the brine increases. The evaporation rate of fresh water under Dead Sea conditions is about 3.5 m/year, while the evaporation rate of Dead Sea surface waters is about three times lower (Fig. 2.9a). In 1944, when the surface salinity of the Dead Sea was about 280 g/l, the rate of evaporation was 1.7 m/year. By 1960, it decreased to 1.5–1.6 m/year at a salinity of 300 g/l, and in 1979–1980, the evaporation rate was 1.3–1.4 m/year at a salinity of 330 g/l. An extremely low evaporation rate (1.05 m/year) characterised the period 1983–1987. The present rate of evaporation is believed to be ~1.25 m/year (range 1.1–1.4 m/year).

Assuming water inflow remains at present levels, a new equilibrium between evaporation and water input will be reached in about 400 years (Yechieli et al. 1998). The brine surface will then be at –500 m, more than 80 m below the present value. The surface area of the lake will be 526 km^2, and the water volume will have decreased by about one-third from its present level. The remaining brine, in equilibrium with the air of 50 % humidity, will contain about 380 g/l dissolved salts, and have a density of 1.27 kg/l (Krumgalz et al. 2000). Over longer time frames encompassing the Holocene, the current levels of the lake are not unusual, although the rate at which levels are changing may well be (Fig. 4.45c). Similar lake level lows ≈−500 m asl characterised the Dead Sea some 2.5 and 4 ka (Enzel et al. 2003). However, in December 2013, Israel, Jordan and the Palestinian Authority signed an agreement for laying a water pipeline to link the Red Sea with the Dead Sea. The pipeline will be 110 miles long and is estimated to take up to 5 years to complete. It is designed to prevent the ongoing fall of the Dead Sea level and stabilise brine intakes for the salt processing works.

Density Stratification: Holomixis Versus Meromixis

Until 1979 lake waters were meromictic or "permanently stratified" and had been so for 300 years (Stiller and Chung 1984). In the 1950s there was a well-developed permanent pycnocline and thermocline at a depth of 50 m (Fig. 4.46; Neev and Emery 1967). The average temperature of the upper 50 m of the water body was between 16 and 36 °C and density around 1.205 g/cc, while at brine depths greater than 50 m, the temperature was a constant 21.5 °C and the water density was 1.232 g/cc. But in the 1960s and 70s the lessening inflow from the Jordan meant the surface water mass became increasingly saline and the permanent pycnocline deepened. In 1975 the pycnocline was some 100 m below the lake surface and the upper water mass had a density of 1.229 g/cc. In February 1979 the densities of the upper and lower water masses equalised and the lake overturned, whereby the lower water mass mixed with the upper water mass and the lake had become holomictic (Steinhorn 1983).

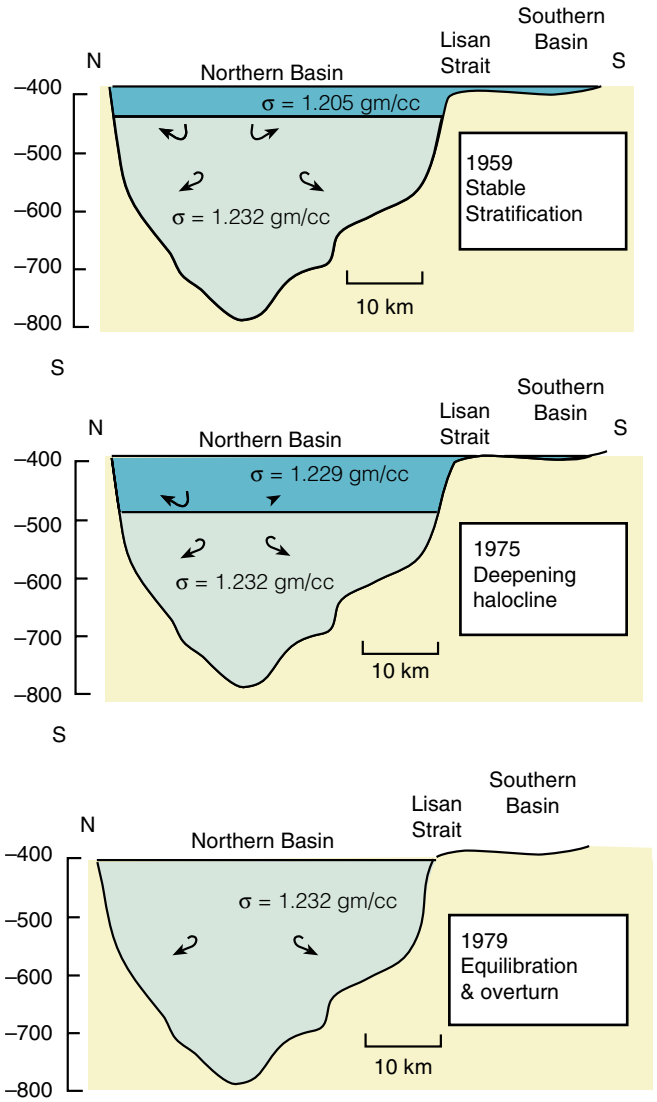

Fig. 4.46 Evolution of Dead Sea stratification in the period 1959–1979 showing the loss of brine stratification via lessening of freshened inflow from Jordan River and entry of brine waste from south. This resulted in increased salinity of surface waters, a deepening of the halocline and final equalisation of densities of the two masses and their overturn in 1979

It was marked by a strong and persistent H_2S smell as bottom waters came into contact with the atmosphere for the first time in centuries. Prior to the 1979 overturn, the lake had been continually stratified (meromictic) since its last holomictic period some 300 years earlier. Overturn has occurred naturally a number of times in the lake's Holocene history and these episodes are marked by beds of massive coarsely-crystalline deepwater halite.

After 1979 the lake entered a new phase in which its hydrological regime see-sawed between holomictic and meromictic regimes, depending on the size of the storm runoff into the lake (Gertman and Hecht 2002; Anati 1998). The Dead Sea level occasionally rises, typically in winter, in an relatively unpredictable fashion driven by short events of varying intensity (storm runoff and sudden floods), and drops via evaporation at a fairly constant rate for the rest of the year (Fig. 4.45b). The first holomictic period, 1979–1980, lasted for 2 months only. It was succeeded by a 4-year meromictic period (1980–1983). The second holomictic period lasted for 9 years (1983–1991; Fig. 4.45b). Then, during an unusually wet winter in 1991–1992, some 1.5×10^9 m^3 of meteoric water entered the lake. This caused the lake level to rise by 2 m and formed a freshened relatively stable upper water mass, which persisted until November, 1995 when stratification collapsed and the lake overturned once more and a new holomictic period began (Anati et al. 1995). Since then, there has not been another well developed meromictic period in the Dead Sea hydrology.

During each meromictic period, the hydrological regime of the Dead Sea is characterized by following long-term trends ultimately leading to holomixis (Gertman and Hecht 2002): the mixolimnion thickens as the depth of the summer thermocline increases from 12–15 to 25–30 m; the quasi-salinity of the upper layer[6], initially around 164 kg/m^3, increases rapidly at a rate of about 16–18 kg/m^3/year; the quasi-salinity of the deep water, initially of about 235 kg/m^3, decreases slowly at a rate of about 0.08–0.10 kg/m^3/year; and the winter minimal temperature of the upper layer, initially of about 16 °C, increases rapidly at a rate of about 2 °C/year. In November 1995, the latest meromictic period of the Dead Sea came to an end.

In other words, even though the meromictic upper water mass persists for years, its physical properties not only change annually, driven by seasonal changes in temperature and evaporation intensity, it also evolves from year to year as it becomes increasingly warmer, more saline and denser until its physical properties equal those of the underlying deep water mass and the lake waters overturn. This evolution can be clearly seen in maps of the time-based evolution of temperature-salinity space (Fig. 4.47a; Anati 1998).

During holomictic periods, as exemplified by the period 1983–1991 and 1996–2013, the hydrological regime of the Dead Sea *in toto* is also characterized by long-term trends (Figs. 4.47b, c and 4.48; Gertman and Hecht 2002; Anati 1998): in 1983–1991 the quasi-salinity of the entire Dead

[6]Solute proportions of the waters of the Dead Sea are relatively rich in calcium, magnesium, potassium and bromine, and relatively poor in sodium, sulphate and carbonate, thus are significantly different from those of modern seawater (Table 4.4). Strictly speaking, in view of the peculiar chemical composition of its waters, the accepted definition of "salinity" based on seawater ionic proportions does not apply to the waters of the Dead Sea and it has been replaced by an "equivalent salinity" based on pycnometry (Anati 1999; Gertman and Hecht 2002) and referred to as "quasi-salinity." Thus, quasi-salinity is defined as the Dead Sea water density anomaly from 1,000 kg/m^3 at an arbitrary reference temperature of 25 °C. For the sake of comparison, a quasi-salinity of 235 kg/m^3 is the equivalent of 280‰.

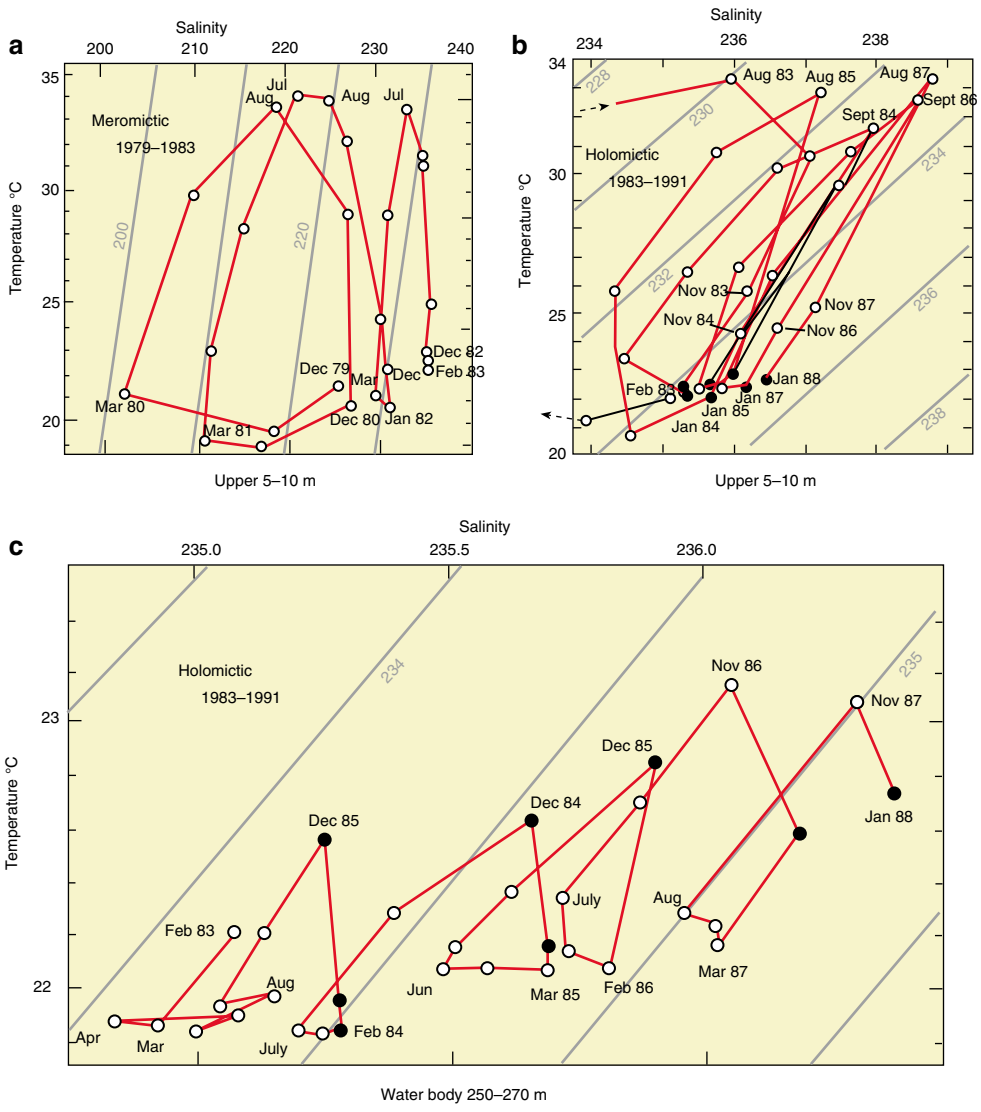

Fig. 4.47 Dead Sea hydrological evolution in temperature-salinity space (T-S diagrams after Anati 1998) (**a**) Upper 5–10 m water trends in the meromictic period 1979–1983. (**b**) Upper 5–10 m water trends in the holomictic period 1983–1991. (**c**) Water trends in lower water mass at 250–270 m depth for much of the holomictic period 1983–1991

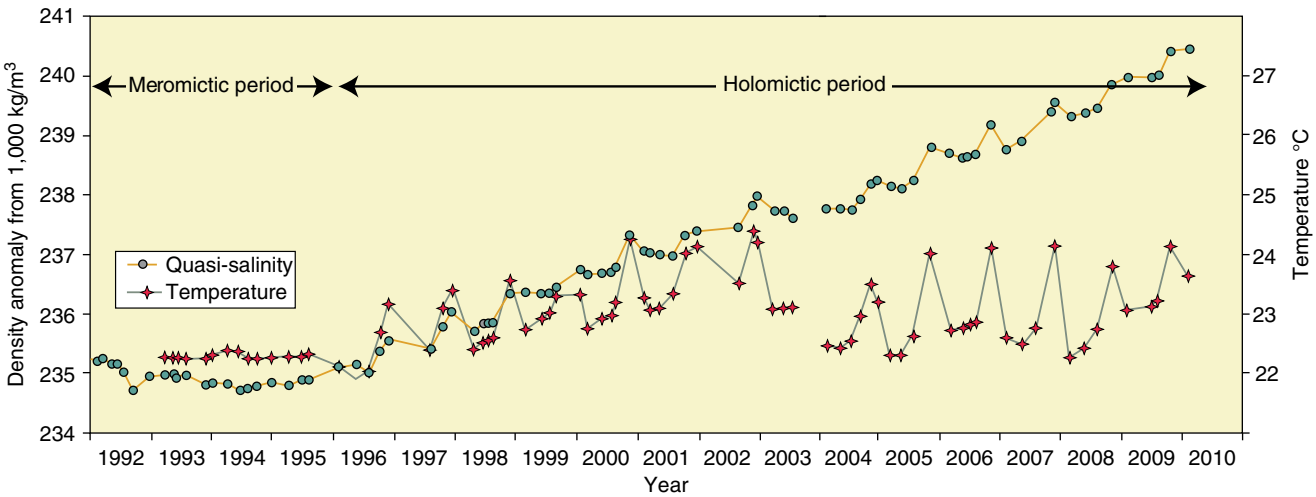

Fig. 4.48 Long-term changes in quasi-salinity and temperature in the deep water body (below 100 m) of the Dead Sea in a meromictic to holomictic period (In part after Gertman and Hecht 2002 and replotted data from http://isramar.ocean.org.il. Last accessed Jan 7, 2013)

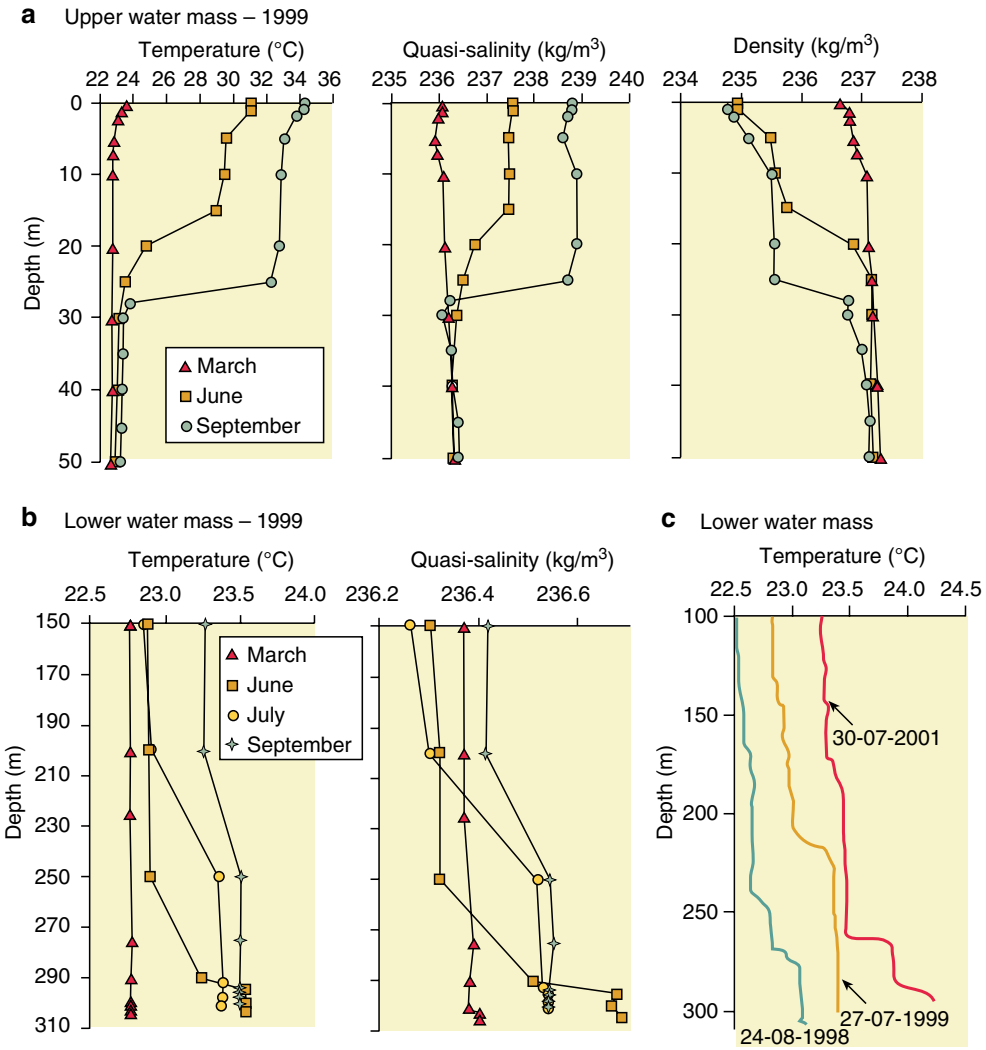

Fig. 4.49 Stratification of the Dead Sea during holomictic years as illustrated by temperature, quasi-salinity and density profiles (After Gertman and Hecht 2002). (**a**) Stratification builds in the upper water mass at a depth of 20–30 m in the summer (June-September) and is destroyed by overturn in the autumn (March). Note the smaller daily increase in temperature and salinity/density in the uppermost 5 m of the water mass due to intense daily evaporation. (**b**) Temperature and salinity anomalies in the lower water column in September 1999. (**c**) Temperature anomalies in the lowermost part of the lower water column. All profiles were measured at site EG320, its location is shown in Fig. 4.43b

Sea increased at a rate of about 0.5 kg/m^3/year, with practically no decrease during the winters; the temperature of the deep water mass increased with a rate of about 0.25 °C/year; and the period of vertical convection of the entire water column, initially about 3 months, increased at a rate of about 1 week/year (Figs. 4.47c and 4.48). Moreover, the temperature and salinity of the bottom layer in the deepest part of the Dead Sea rose by about 0.5–0.6 °C and 0.15–0.25 kg/m^3 during each holomictic summer.

During holomictic years, a stratification builds during the summer months with a thermocline generally located between 15 and 30 m depth (Fig. 4.49a). The density contrast at the base of the upper water mass is large enough to balance an ephemeral destabilising halocline formed daily in the uppermost few metres as a result of intense evaporation. At night the same uppermost waters cool and mix with underlying waters above the major thermocline. This stable thermocline persists throughout the summer and into autumn when the overlying air mass cools, so driving a cooling of the whole upper water mass until temperature and densities equalise and overturn occurs, usually in November. A temporary dilution of the upper water layers may occur due to winter rain floods, but in a holomictic year it is destroyed by summer evaporation, so preventing the year round stratification that characterises the lake in its meromictic stage.

Detailed work on the lower Dead Sea water mass by Gertman and Hecht (2002) shows an additional interesting stratification in the lowermost parts of the lower water mass (Fig. 4.49b, c). Temperature profiles of the bottom layer exhibit a step-like feature indicating advection of saltier, warmer and denser water into the lowermost parts of the Dead Sea. The differences in the size of the steps indicate the changes in the intensity of the advection in this part of the column. There are three possible sources for such waters; (1) End-brines pumped back into the Northern Basin from the Dead Sea Works at the southern end of the Dead Sea, (2) Subsurface hot springs similar to those documented by Niemi et al. (1997), (3) Slope convection of warm saline dense brines from the shallow

edges of the Dead Sea. At this time there has been insufficient monitoring to determine which of the possibilities is the most likely, or if all can contribute to the bottom anomaly.

Deepwater Halite

The transformation of the brine column since 1979 has allowed substantial halite to accumulate on the deepwater floor of the basin for the first time in 300 years. Halite first crystallised in at-surface lake brines in 1979, while massive halite began to crystallise from the entire brine column toward the end of 1982, when ropes suspended in the water would quickly accumulate cm-thick rinds of centripetal halite (Steinhorn and Gat 1983; Stiller and Sigg 1990; Stiller et al. 1998). The mass of halite that precipitated between 1976 and 1992 is estimated to be about $2{,}550 \times 10^6$ tonnes (Gavrieli 1997).

The result of holomictic saturation in the Dead Sea is a layer of coarse crystalline halite accumulating rapidly on the deep lake bottom that today (30 years after it began) is already several tens of centimetres thick. For the period 1983–1989 the estimated annual accumulation rate for halite on the Dead Sea floor was 3–6 cm/year. This new bed of halite defines the end of several hundred years of longterm brine stratification (meromixis) when halite did not precipitate in the hydrologically isolated lower brine mass. Instead a pelagic/detrital carbonate laminite had accumulated (see next section). Previous episodes of nonstratification in the deep brine column (holomixis) are indicated by similar but now buried beds of widespread metre-thick massive halite beneath the lake floor (Levy 1984).

Several crystal morphologies define the halites currently accumulating above and on the deep bottom of the Dead Sea (Gavrieli 1997; Herut et al. 1998); (a) Clear aggregates of sedimentary halite crystals forming interlocked aggregates and massive dm-thick bed on the lake floor that are made up of white to clear crystals up to 1 cm in diameter and typically interbedded with layers composed of fine grained (<1 mm diameter) halite crystals and brown mud, (b) Individual clear idiomorphic cubes up to a cm across floating within brown mud layers and, (c) Large interlocked clear centripetal halite crystals (0.5–2.0 cm long) growing on ropes suspended in the brine column. Much of the halite on the Dead Sea floor consists of intercalations of types a and b, with each constituting around 50 % of the newly formed halite layer. Mud layers entraining halite are thought to indicate wet years in the lake hydrology, such as the period 1992–1993 (Gavrieli 1997).

Finer-grained halite and gypsum layers in shallower waters (<50 m) about the lake edge, particularly in the western and southern parts of the Northern Basin where they cover much of the lake floor and may well indicate the sedimentary response the effects of brine outfall. Prior to 1979 this occurred naturally where dense brine plumes, created in the areas of more intense evaporation about the lake edge sank into the deeper part of the basin (Fig. 4.47c). Anthropogenic outsalting, via mixing between Dead Sea waters and the industrially concentrated end brines pumped into the Northern Basin from the solar operations of the Southern Basin is most obvious in the southern part of the Northern Basin (Fig. 4.50; Epstein et al. 1975; Gavrieli 1997). At 480 g/l these bottom hugging waste brines from potash manufacture are more concentrated than waters of the Northern Basin and have different relative proportions of the major ions. They are depleted in potassium and sodium and are enriched in magnesium and chloride relative to the Dead Sea waters, creating a situation ideal for saltout at the mixing zone between the two waters (Gavrieli 1997; Yechieli et al. 1998). Saltout has probably occurred in the southern part of the Northern Basin for decades, even prior to 1979, and is defined by bottom sediment areas where finer-grained halite occurs as 1–20 cm thick layers interbedded with gypsiferous brown mud. Descending brine plumes probably allowed halite and coarse-grained gypsum to accumulate beneath zones of mixing, even prior to the 1979 turnover, as can be clearly seen in preholomixis maps of bottom sediments (Fig. 4.50).

But mixing-induced saltout does cannot explain all of the halite currently accumulating across the floor of the Northern Basin. Another possible mechanism is the annual cooling of the uppermost brine layer in holomictic years (Gavrieli 1997). Temperatures in summer in the upper water 30 m in holomictic years are ≈34–36 °C, while in winter they are ≈22–24 °C (Fig. 4.49a). Although annual precipitation due to cooling of surface waters creates supersaturated chemistries, no unequivocal halite crystallisation driven by seasonal cooling has been observed in the Dead Sea. Yet, when saturated brines are collected and allowed to cool in the lab, halite precipitation as mm-scale crystals does occur spontaneously (Gavrieli 1997).

Brine mixing and seasonal cooling explain the formation of finer-grained cumulate halites, but do not explain the formation of cm-scale crystal aggregates and layers. Yet such crystals can and do form in the current waters of the Dead Sea, as evidenced by coarse clusters in the current seafloor bed and large crystals hanging off anchor ropes. Gavrieli (1997) argues that these larger crystals in the bottom layers are authigenic and indicate slower ongoing authigenic growth in halite-saturated pore waters and brine columns situated at or just beneath the present day lake floor. Such saturated growth can only be maintained when the lake waters are holomictic. It seems that authigenic growth and recrystallisation is an ongoing process, as is seen in the pervasive recrystallisation and coarse crystalline overprint preserved in the 500 year old Dead Sea halite layer cored by Levy (1984).

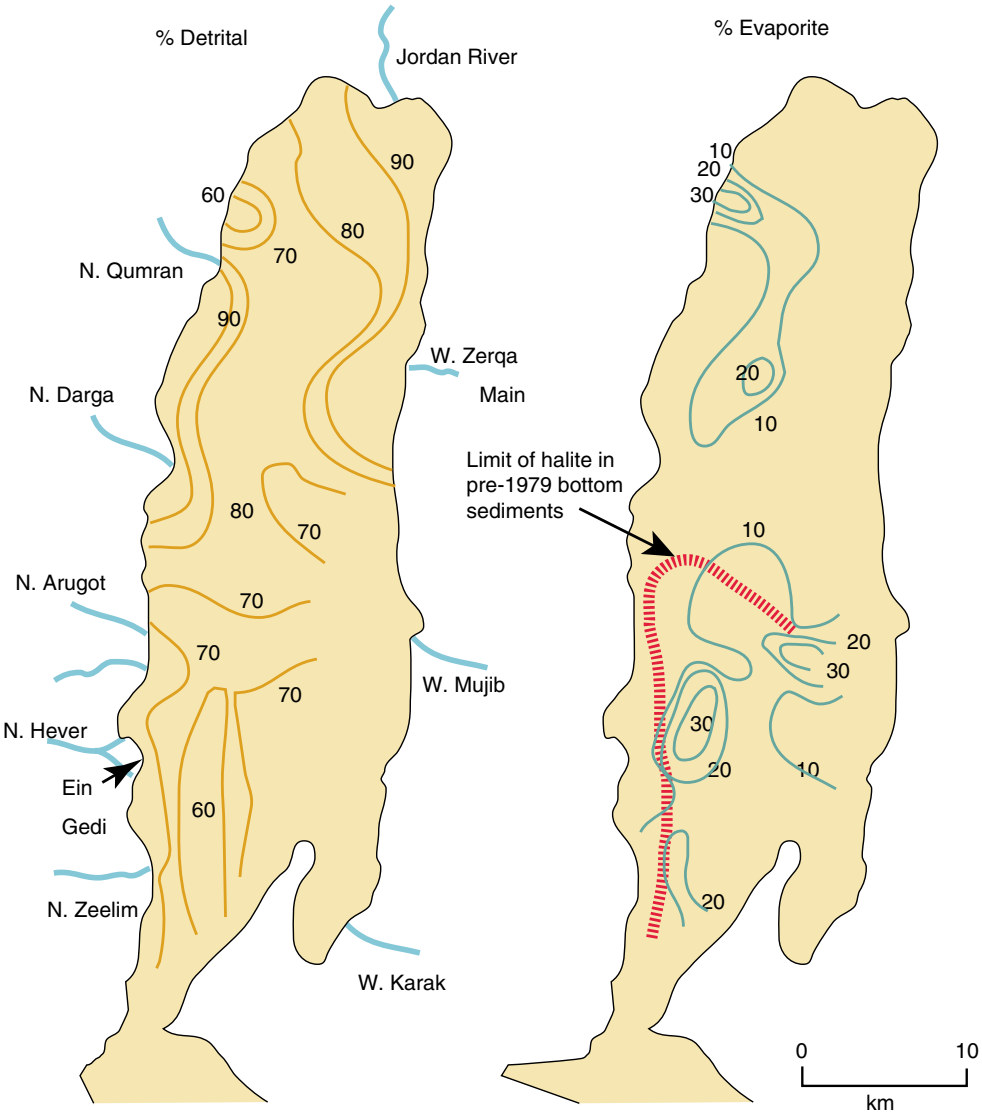

Fig. 4.50 Bottom sediment distribution map of sediment mostly created prior to monomictic halite precipitation in 1979. The eastern or Jordanian parts of the Lake floor was not sampled (In part after Garber et al. 1987)

Interestingly, cores taken 20 years earlier in the 1960s, below water depths of 40 m at the southern end of the Northern Basin, bottomed on a hard halite bed after passing through 10–80 cm of soft carbonate laminite (Neev and Emery 1967). This halite was likely deposited some 300–500 or so years ago during a previous holomictic event. Similarly, four shallow seismic reflectors, obvious in sediments of the deeper part of the Northern Basin, probably mark contacts between carbonate marls and beds of massive rock salt (Ben-Avraham et al. 1993). If the massive cm-scale inclusion-poor randomly-oriented crystals of the halite bed intercalated with finer-grained halite layers that are currently accumulating on the floor of the Dead are similar to textures in this buried deep water halite, then the notion that deepwater halite is solely a silt-sized "rain from heaven" or "salt and pepper" laminite is problematic. But, then again, the uniqueness, the small scale, and the continental transform setting of the Dead Sea, with its steep walls and lack of an extensive evaporite platform means its utility as an direct analogue for ancient marine-fed basinwide evaporites is also somewhat problematic (Chap. 5).

Deep Water Laminites

Prior to overturn in 1979, away from the Jordan River delta, away from wadi aprons and away from the influence of end brine mixing, the deep bottom sediments were mostly carbonate laminites accumulating in water depths ranging from more than a few metres down to the deepest parts of the basin. These laminites are today being covered by coarsely-crystalline halite, but prior to the onset of holomixis in 1979 carbonate laminites were the main sediment accumulating on the deep lake floor. Lamina in the mm-scale light-dark couplets are dominated by two time-separate pelagic components, namely terrigenous detritals and chemical precipitates (Garber 1980; Garber et al. 1987). Light coloured lamina are dominated by chemical precipitates, mostly made up of stellate aragonite clusters precipitated in the upper water mass (Fig. 4.51). Dark-coloured detrital layers in laminites

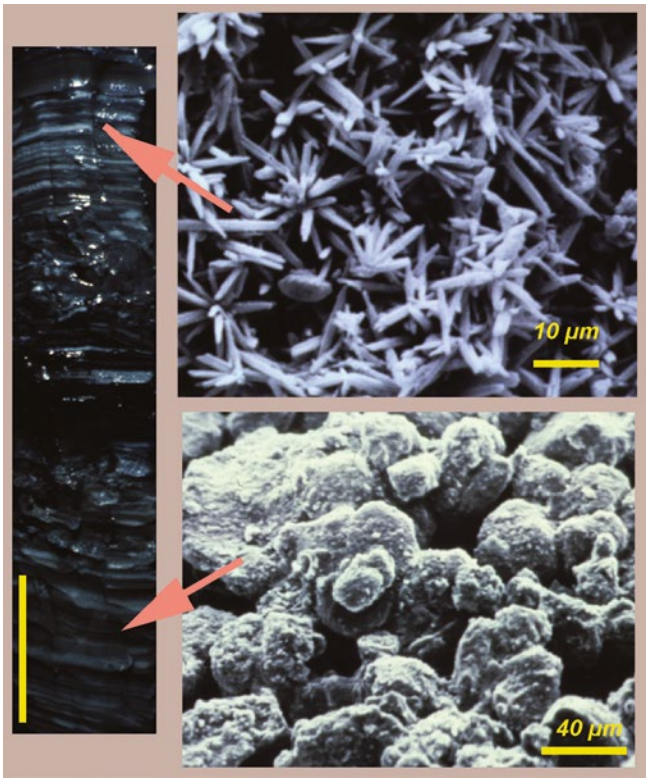

Fig. 4.51 Dead Sea deep water laminites in bottom core collected in Northern Basin in water depths of more than 200 m. It was collected in late 1970s when water mass was still stratified. *Light coloured* laminae are composed of stellate aragonite prisms precipitated as "whitenings", while *dark-coloured* laminae are dominated by detrital calcite. Scale bar on core is 5 cm (Images courtesy of Ray Garber)

contain limestone (calcite) grains, quartz, and silicate clays, along with minor feldspar and dolomite, all allochthonous components carried into the basin as bottom load, suspended load and air-borne detritus. The proportion of terrigenous material in the laminites increases toward the lake shoreline, especially toward river and stream mouths (Fig. 4.50). Illite averages about 40 % of the carbonate-free clay fraction of the laminites, smectite about 32 %, and kaolinite about 28 %. Locally, there are lesser and varying proportions of pelagic gypsum and coarser "in situ" gypsum roses within the carbonate/detrital laminites (Fig. 4.52b).

Whitening events precipitating the aragonite occurred in the surface waters of the Dead Sea every few years prior to 1979. For example, Neev and Emery (1967) sampled two summer "whitenings" of surface waters that occurred in 1959 and determined a gypsum-to-aragonite weight ratio of 3.14. Yet the aragonite in light lamina in the laminites from shallow bottom cores, collected from the seafloor hundreds of metres below the air-brine interface, were almost 100 % $CaCO_3$. They had identified a chemical discrepancy that needed an explanation and attributed the alternation of aragonite in the lighter lamina and calcite in the darker lamina to the activities of sulphate-reducing bacteria acting on pelagic gypsum settling through the anoxic density stratified water column and converting it to bacterial calcite. Elsewhere, sulphate-reducing bacteria are known to destroy organic matter and gypsum, converting them to sulphides, energy, and H_2S with calcite as a byproduct (Fig. 9.65a).

Subsequent isotopic work on the calcite lamina by Garber (1980) showed the calcite was detrital, not bacteriogenic. He also found that the laminites were not annual or "true" varves, only 15–20 lamina couplets had been deposited on the Dead Sea floor in the first 75 years of the last century. More recent work on CO_2 flux in the Dead Sea water during the meromictic period from February 1993 to December 1994 showed that summer whitenings are probably not the major source of aragonite in the laminites (Barkan et al. 2001). Rather aragonite precipitation occurs via mixing (salting out) in the upper water mass after a massive bicarbonate input from winter floods. This notion of precipitation resulting from winter flooding and brine mixing is contrary to the accepted notion of summer precipitation of aragonite in the uppermost surface waters of the historic Lake Lisan, the predecessor of the Dead Sea (see next section). But it better explains the lack of annual varving noted by Garber and means that either the origin of the aragonite laminites in the Lisan Fm should be re-evaluated, or the present Dead Sea should not be considered a direct hydrologic analogue for the somewhat fresher and deeper waters of Lake Lisan.

The dark coloured detrital-dominated mm-scale layers of the Dead Sea laminites lack a pervasive microfossil/diatom component, unlike laminites forming in less saline perennial lakes such as Lake Van. Diatom frustules do accumulate on the lake floor where diatoms flourish in areas of longterm freshened water. Their remains are common only in the detrital-rich prodelta laminites of the northern region of the Dead Sea. There, the Jordan River delta is building out into the lake and carries the remains of diatoms, along with abundant clays and silts. Surface waters over the rest of the Dead Sea are too saline to allow diatoms to live.

Prior to the onset of holomixis, intrasediment gypsum made up of individual crystal disks, constituted around 6 % of the sediment volume in deep basinal laminites. Garber (1980) found gypsum in all cores recovered in the mid 1970s from laminites in lake bottom settings ranging from shallow sea-marginal, through slope to deep basinal settings. Gypsum rarely formed in discrete laminae, small lenticular crystals were mostly disseminated through the terrigenous (dark) layers but larger crystals cut though both light and dark lamina. Garber (op cit.) concluded that gypsum in the deepwater laminites was present even during the studies of Neev and Emery. He argued that finely crystalline sand-sized gypsum was probably the settled-out remnants of gypsum precipitated in the surface waters, either as documented in the whitings by Neev and Emery (1967) or by brine mixing near the contact of the upper and lower water masses. Further gyp-

(**b**) Intrasediment gypsum rose growing in bottom sediment in brine depths of more than 200 m. Brines may be supplied from brine plumes from dissolving salt diapir crests. (**c**) Exposed unconsolidated laminite muds on the eastern margin of the Dead Sea. (**d**) Trench in muds shown in (**c**); Note the soft sediment deformation in some layers (All photos courtesy of Ray Garber)

sum crystal growth into desert-rose like displacive aggregates in the sediment (Fig. 4.52b) was interpreted to indicate upward brine diffusion through the bottom sediments. Such upwelling brines were perhaps derived by the dissolution of nearby subcropping salt structures.

More recently, Reznik et al. (2009) have addressed the relative paucity of gypsum compared to halite in Dead Sea precipitates. They note that their laboratory experiments and evaluation of historical data show gypsum nucleation and crystal growth kinetics from Dead Sea brine are both slower in comparison with similar brine solutions at a similar degree of supersaturation. Slow kinetics of gypsum precipitation in the Dead Sea brine is mainly attributed to the low solubility of gypsum which is due to the high Ca^{2+}/SO_4^{2-} molar ratio (115), high salinity (≈280 g/kg) and to Na^+ inhibition in the Dad Sea waters (Table 4.5). Their experiments with various clay minerals (montmorillonite, kaolinite) indicate that these minerals do not serve as crystallization seeds. In contrast, calcite and aragonite, which contain traces of gypsum impurities, do prompt precipitation of gypsum but at a considerable slower rate than with pure gypsum.

This implies that transportation inflow of clay minerals, calcite and local crystallization of minerals in the Dead Sea, in times of meromixis and holomixis does not prompt significant heterogeneous precipitation of gypsum. Based on their historical analyses of the Dead Sea, it is clear that over the last decades dominated by holomixis, as inflows to the lake decreased and its salinity increased, gypsum still continuously precipitated from the brine. The increasing salinity and Ca^{2+}/SO_4^{2-} ratio, which results from the precipitation of gypsum, led to even slower kinetics of nucleation and crystal growth, which resulted in an increasing degree of supersaturation with respect to gypsum. Today the amount of gypsum in the bottom sediment is swamped by the high volume of halite. Herut et al. (1998) predict that as the salinity of the Dead Sea brine continues to increase (accompanied by Dead Sea water level decline), the degree of halite supersaturation will increase, but gypsum will also continuously precipitate

at these higher saturations due to progressively slower kinetics.

The relative paucity of bedded evaporitic salts, other than aragonite, during meromixis was the most surprising aspect of the deepwater sediments accumulated in the Dead Sea in the 300 years prior to 1979. Why were more saline salts absent on the bottom when the upper water mass was at gypsum saturation a number of times each summer and the lower water mass was at or near halite supersaturation year round? The answer lay in the permanence of the upper water mass, it prevented chemical change in the lower mass and hence, although the lower waters were supersaturated there was no concentration mechanism to allow it to accumulate salts. Only pelagics made it to the bottom until the brine column mixed and the Dead Sea became a holomictic system in direct contact with the atmosphere. Then large volumes of evaporitic halite could accumulate on the deep basin floor in areas covered by waters hundreds of metres deep. The Dead Sea clearly shows that halite and other salts can accumulate at the base of a brine column several hundred metres deep. But, they do so mostly as coarsely crystalline aggregates, not fine-grained laminites, and can only do so when the whole brine column is a well mixed (holomictic) water mass. When a brine column is permanently stratified, no "in situ" bottom growth occurs. The dominant depositional style is a "rain-from-heaven" made up of less saline precipitates and siliciclastic fines, with chemical precipitates forming either at the mixing zone between the two water masses, or at the air-brine interface.

Basin Margin Sediments

Layers of siliciclastic and calcitic detritus in the deepwater bottom sediments are generally tied to floods and wind borne dust sourced in the highlands about the basin margins. Fan delta lobes about the basin margin indicate positions where streams and wadis drain into a water- filled depression. In the Dead Sea they show two main styles; (1) Currently active deltas that reach down to the present lake shoreline (Fig. 4.53) and, (2) Late Pleistocene fan deltas that are typically smaller in extent than their Holocene counterparts and form "hanging" deltas such as Ein Gedi (Fig. 4.52a; Sneh 1979; Bookman et al. 2004). The more obvious hanging deltas were actively accumulating sediment in Lake Lisan time when lake waters were fresher and lake levels were up to 200 m higher. Sizes of the fan deltas vary, with the Nahal Zeelim delta being the largest of the active deltas located along the western margin of the depression (Sneh 1979). In terms of the morphometry of fan deltas worldwide, Nahal Zeelim is relatively small (≈6 km^2), its slope is steep (2.5°), and its catchment (235 km^2) is quite large for the size of the sediment lobe. Its morphometry reflects its arid setting whereby water supply volume is low and pulsed, with resupply during times of short intense storm floods.

Each delta lobe is made up of several successive fan sequences, with facies changing from dominantly conglomerates at the head of the fan to sands and muds at the foot (Fig. 4.53). In the proximal parts of a Dead Sea fan delta lobe, units of crudely stratified conglomerate alternate with coarse to medium sands that show cut and fill textures, along with abundant trough and planar cross beds. In the sand-dominated medial parts, structures range from unstratified or poorly layered sandy beds, through granule and mud-ball layers, into trough and planar crossbedded sands. Many of the finer sands in this zone preserve ripple cross laminae. Further into the basin, the more distal parts of the fan lobes are composed of interlayered sand/mud facies intercalated with carbonate laminites. Alternations of coarse to medium sand with layers of very fine sand characterise distal fan sediments, as do thin 2–3 cm thick layers of mm-layered aragonitic laminite. Rapid deposition of fan sediments atop water-saturated laminites creates numerous examples of convolute bedding that formed as rapidly deposited sands loaded brine-soaked muds.

In strandzones away from the direct influence of active fan deltas, the grain size of sediments tend to indicate distance of the strandline from the base of the cliffed escarpment, which defines the edge of the present Dead Sea basin. Where the present shoreline of the Dead Sea is a long distance from the fan-lined border escarpment, sediments tend to be muddy laminites, deposited during times of relatively higher water (meromictic) during the last few centuries and including blocks derived by reworking of Lisan marls (Fig. 4.52c, d). In strandlines closer to the escarpment the shores are moderately steep with beaches and bars of sand and gravel reworked from the base of the escarpment, especially where waves are eroding older bajada sediments. Where the shoreline is a cliff at the base of a border escarpment, the sediments tend to be reworked blocks and muddy slumps of Pleistocene Lisan Formation (Neev and Emery 1967). Fluctuations in water levels throughout the Quaternary have created numerous terraces; more than 30 near-horizontal sandy shore terraces and gravel bars have been recognised behind the current lake strandline (Bookman et al. 2004).

The shorezone of the Dead Sea is also of interest in that there may be local accumulations in the shorezone sediments of blocks of asphalt. Similar blocks of floating asphalt have been collected in the Dead Sea waters. The ultimate source of this material is possible seeps from Cretaceous organic-rich shales. Asphalt has been collected from the Dead Sea depression since the time of the ancient Egyptians[7].

[7]The Ancient Egyptians used Dead Sea asphalt in the mummification process. The word "mummy" comes from the Arabic word "*mummiyah*," which means asphalt. Mummiyah also has what are considered by some to be medicinal properties (Nissenbaum et al. 2002).

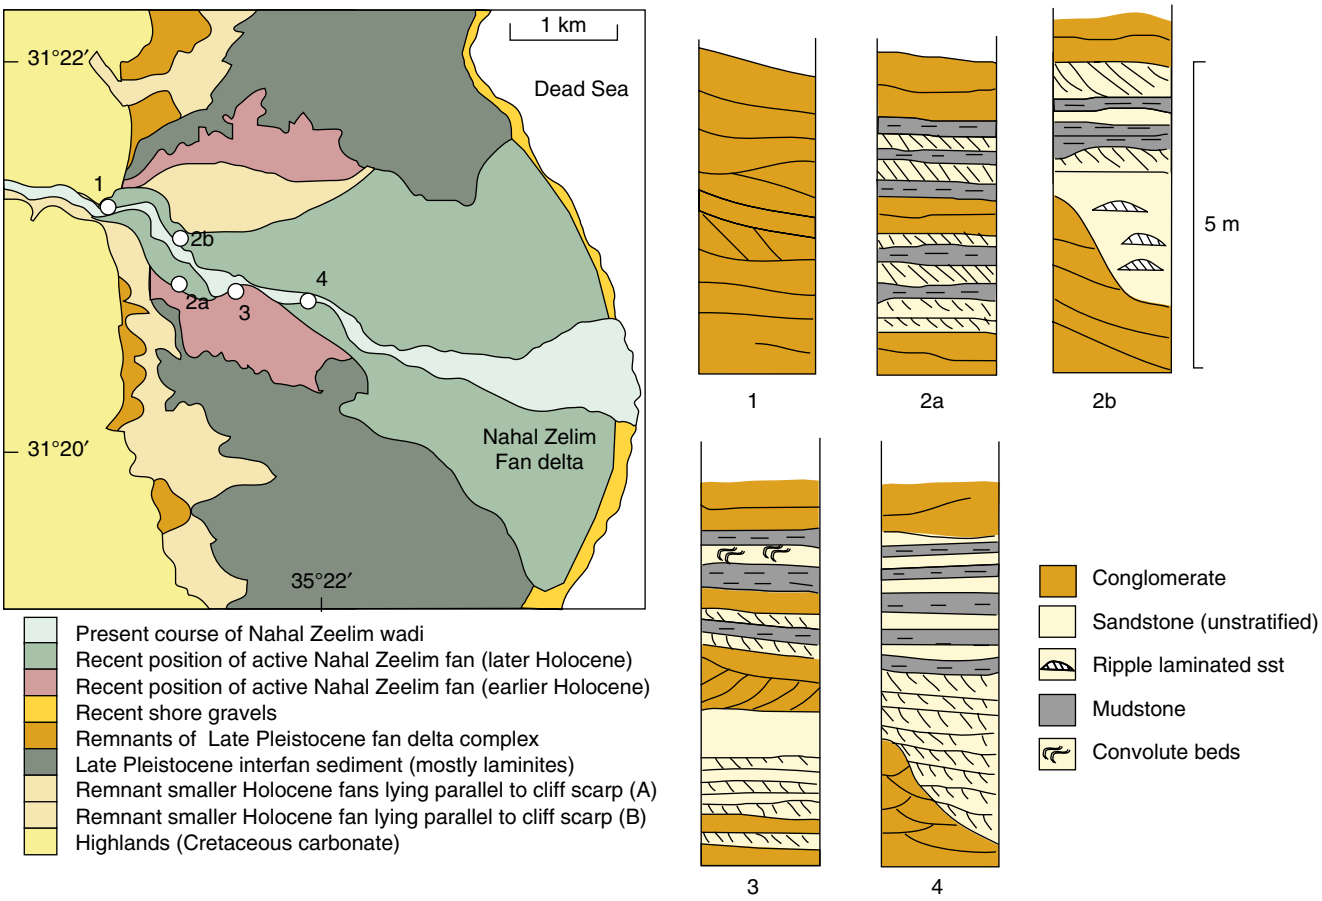

Fig. 4.53 Nahal Zeelim (Tze'elim) fan delta, Dead Sea margin. Map shows multiple overprinted fan delta lobes from avulsion. Lobes of the Holocene delta lie below "hanging" late Pleistocene fan delta sediments deposited when the lake water level was 180 m above its present level. Vertical successions of five measured fan delta sections (*1–4*; localities shown on map) show a fining into the basin trend in average grain size (After Sneh 1979)

The asymmetry of the tectonic setting of the Dead Sea depression is reflected in the granulometry of the fans. The eastern side of the Dead Sea is the more active transform escarpment, so slopes are somewhat steeper and fans are dominated by poorly-sorted debris flows, which often reach all the way to the modern strandline. On the western side of the depression the slopes are not as steep (Fig. 4.43b). Based on comparisons with the rift lakes of Africa, there should be sand aprons created by widespread longshore reworking of fan delta sediments along this western side. But this is not happening in the Dead Sea, any clean sands created by wave action on the western side of the depression are swamped with sheets of muds derived by erosive reworking of Lisan Fm. laminites which blanket the depression. In terms of the Dead Sea's ability to act as a Holocene lacustrine analogue for modelling reservoir sand distributions in ancient evaporite-sealed lacustrine counterparts, it suffers from the same problems as that other deep hole in the ground with evaporites – Death Valley, California. Both depressions are too deep, with sides simply too steep, to allow well-sorted sand bodies to accumulate in substantial volumes about the lake edge.

Much of the exposed margin of the Dead Sea between active fan delta lobes is made up of soft laminites and intercalated indurated beach-rock-like aragonitic crusts. These exposed recent laminites were deposited from meromictic lake waters and were deposited prior to 1979 (Fig. 4.52c, d). Intercalated with the sea margin laminites are gravels and sands reworked from fan sediments and perhaps acting as aquifers or at least zones of high crossflows of waters into the lake margins. Exposed gravels and sands are sometimes cemented into beach rock sheets and have been coated with mm-scale laminated aragonite encrustations and stained with manganese (Garber et al. 1981; Garber and Friedman 1983). Some of these aragonite precipitates are botryoidal, others are encrusting, yet others are oolitic/pisolitic, all are interpreted by Garber as largely inorganic precipitates. They are reminiscent of the microbial, stromatolitic and pisolitic crusts of the South Australian salinas and like them indicate strandzones and seeps in ancient counterparts.

In summary, surface sediment distribution in the Dead Sea region is a combination of Holocene accumulations and palimpsest Lisan Fm. derivatives (Fig. 4.54). Today the lake

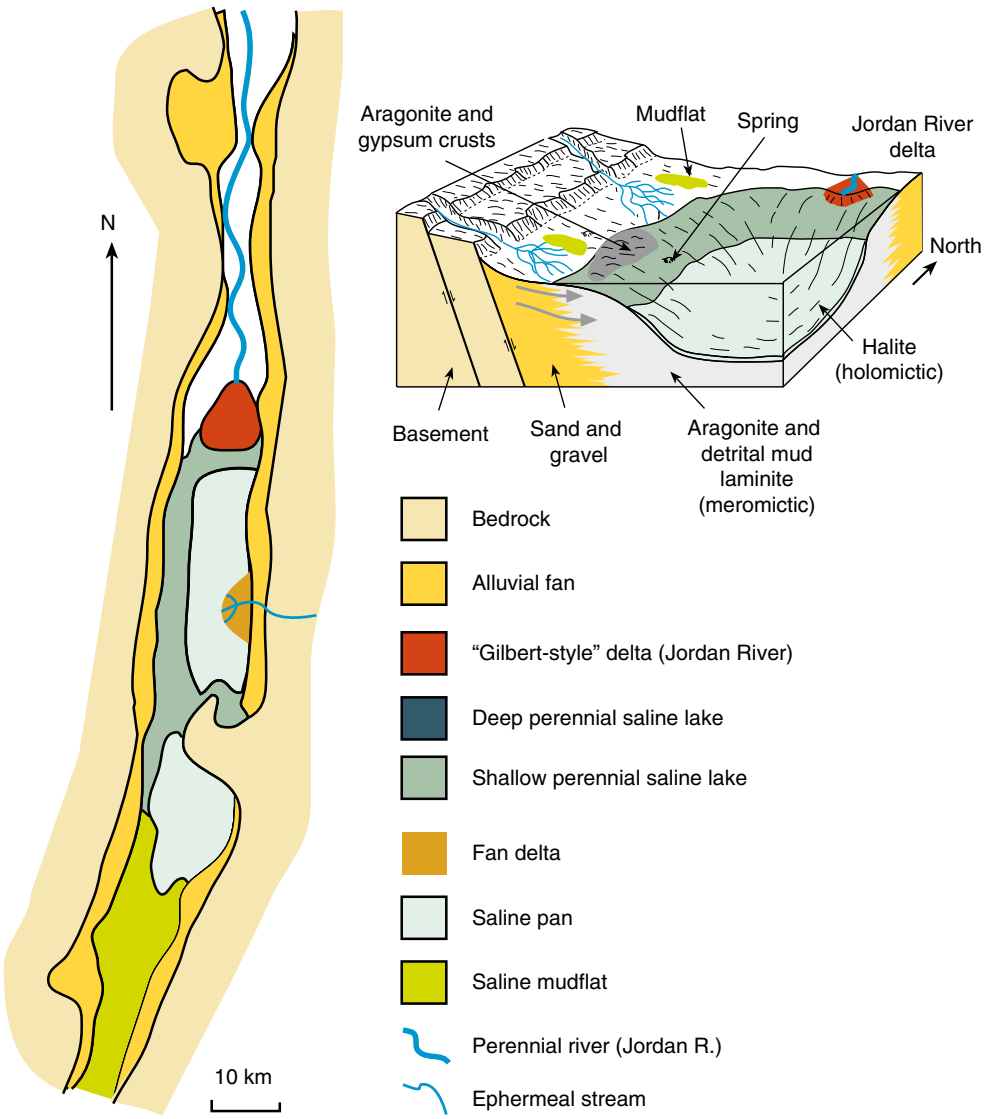

Fig. 4.54 Geology of the Dead Sea basin showing the distribution of the various depositional settings in plan view and as a block diagram of the Northern Dead Sea basin. The River Jordan forms a fluviodeltaic wedge in the northern part of the basin. Active transtension faulting and block rotation has exposed older lake deposits of the Lisan Formation at higher elevations as well as an apron of alluvial fan sediments with a number of "hung" fan deltas tied to older higher water levels in the lake. The saline pan in the southern basin is dominated by halite, artificial pans fed with deep brines have been constructed in this area to produce sylvite and other potash products (see Chap. 11)

is holomictic and a bed of coarsely-crystalline, inclusion-free halite is accumulating on the deep water floor of the lake. At the same time detrital accumulations fed from stream inputs, especially the Jordan River, dominate the northern parts of the lake. In the recent past (pre 1979) the lake was permanently stratified and deposition of carbonate laminite was the dominant depositional style on the deep lake floor. Fluvial input to the fresher surface waters of the lake supplied both the detritals (calcite, aluminosilicate clays and siliciclastics) and drove the mixed water chemistry that created the aragonite rich portions of the laminite couplets. Dust storms also supply detritus to the deep lake bottom.

Lake Lisan, Jordan Valley

Beneath and surrounding the Holocene sediments of the Dead Sea are the sediments of the Quaternary Lisan[8] (70–17 ka) and Damya (17–12 ka) formations (Bartov et al. 2002; Haliva-Cohen et al. 2012). The Lisan Formation forms a blanketing cover throughout the Jordan Valley (Fig. 4.57a). Pleistocene Lake Lisan waters left behind dissected terraces of lacustrine sediment, consisting of laminated marls up to 40 m thick, that extend from Lake Tiberias (Sea of Galilee) in the north to a boundary ridge some 35 km south of the Dead Sea (Fig. 4.55). The highest outcrops of Lisan laminites are found at −180 m asl, but there is morphological evidence for lake waters as high as −150 m or even −130 m asl during Lisan time (Fig. 4.56). During its highstand, Lake Lisan covered several subbasins in the Jordan Valley, it had a maximum area of some 2,000 km^2 and a drainage basin of 40,000 km^2. Pre-Holocene, but post-Lisan, sediments occur in fan delta regions near the current Dead Sea shore and in the vicinity of the city of Damya in Jordan, which is the type area for the Damya Formation.

Mineralogical variations in the Lisan Formation along the Jordan Valley show lake waters varied both in aerial extent and salinity. The lake was permanently stratified for much of

[8] *Lisan* is Arabic for tongue and describes the shape of the Lisan Peninsula where the type section was measured.

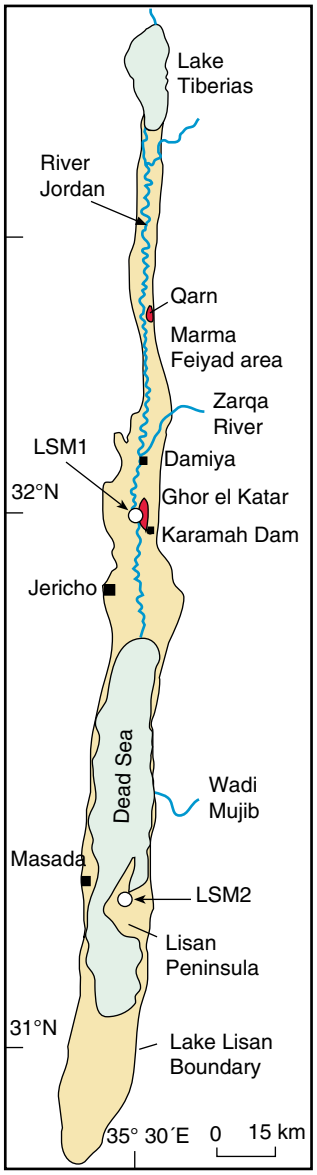

Fig. 4.55 Extent of Pleistocene Lake Lisan in the Dead Sea transform. Positions of sites LSM1 and LSM2 are indicated (see Fig. 4.58 for detail)

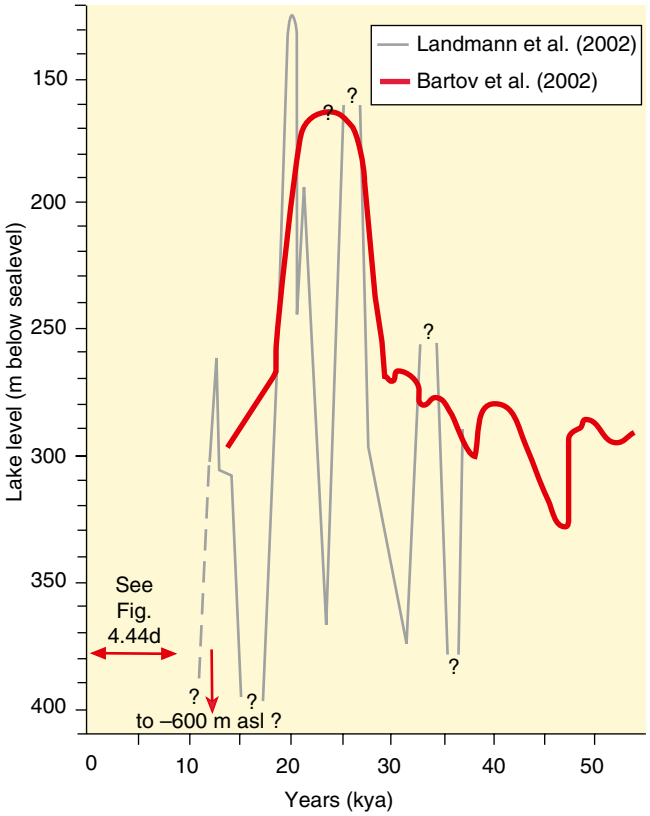

Fig. 4.56 Lake Lisan levels between 15,000 and 50,000 years ago

its history. In its southern part, the sedimentary sequence consists mainly of laminated evaporites, and salinity is thought to have ranged between 100 and 300 g/l and lake water levels were probably lower. At the higher elevations that characterise Lisan outcrops in the north in the Kinarot basin, sediments of the Lisan Formation are very different, and the sequence is mainly diatomite. The change from south to north probably indicates inflow from the north and a freshening of surface waters during the highest stands of the lake. Salinities throughout Lisan time were hypersaline but probably less than those of the present Dead Sea (Fig. 4.56) (Abed and Yaghan 2000).

Landmann et al. (2002) document two styles of couplet in the Lisan laminites; (1) detritus–aragonite (most common), and (2) detritus–aragonite–gypsum. Begin et al. (1974) documented the lithology and biota of the Lisan Formation along the Jordan Valley west of the Jordan River. They subdivided it into a lower Laminated Member and an upper gypsiferous White Cliff Member (Fig. 4.57). Along the Jordan Valley they described three laminite facies; a gypsum facies in the Dead Sea region, and an aragonite facies north of the Dead Sea up to Marma Feiyad and a diatomite facies further north. Later work by Abed and Yaghan (2000) in the vicinity of Ghor el Katar and the nearby Karameh Dam reclassified the Lisan into three members; Lower Laminite, Middle Clay and Upper Laminite with the White Cliffs making up the upper part of the Upper Laminite. The contrast in gypsum content in laminites of the Lisan formation from the Ghor el Katar region (LSM1) compared with those of the Dead Sea region (LSM2) is clearly documented in the detailed mineralogy of two outcrop sections published by Landmann et al. (2002; Figs. 4.55 and 4.58).

The Lower Laminite is made up of thinly interlaminated calcareous silt and aragonite with subordinate sand layers. In the Ghor el Katar area (LSM1) the Lower Laminite is 15 m thick and the aragonite proportion is less than 30 %. The Middle Clay is composed of massive black clays, and is around 9 m thick. The clay matrix is mostly mixed layer illite/smectite with minor kaolinite. No gypsum or other evaporites occur in the Middle Clay and its organic content can be as high as 6 %. The Upper Laminite is once again mostly interlayered aragonite and detrital silt (Fig. 4.58).

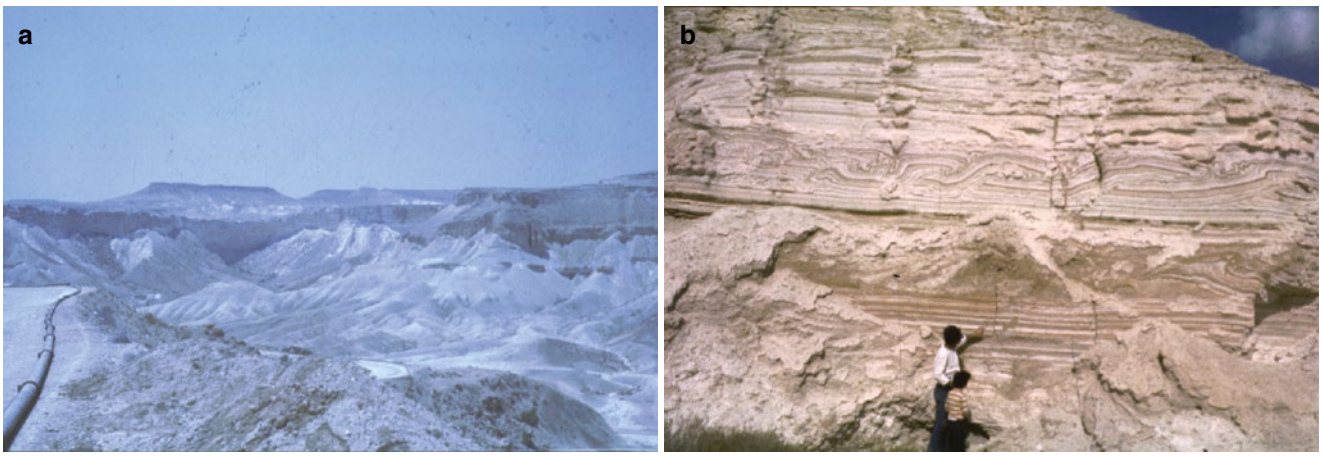

Fig. 4.57 Lisan Formation. (**a**) View of Lisan Formation outcropping along the escarpment of the Dead Sea, (**b**) Syndepositional slump in the Lisan Formation (Images courtesy of Ray Garber)

Thin sand and clay layers are not uncommon in this unit. Its uppermost 5–7 m crops out as a conspicuous white cliff that entrains layers with abundant gypsum. This upper portion in section LSM1 is equivalent to the White Cliff Member of Begin et al. (1974) as documented in section LSM2 (Fig. 4.58). To the south of Ghor el Katar area, the White Cliff unit thickens until it is more than 25 m thick on the Lisan Peninsula (LSM2; Fig. 4.58).

The Lower and Upper Laminated members are composed of very fine, varve-like white and dark laminae. White laminae are usually monomineralic and composed mainly of aragonite needles with diatom frustules. In the White Cliff unit the light-coloured laminae are composed almost entirely of gypsum or mixtures of aragonite and gypsum. Gypsum laminae are dominated by fine lenticular gypsum crystals (0.25–0.50 mm) with their long axes arranged parallel to the bedding. Dark laminae are predominantly detrital mud-sized calcite, the reworked remnants of microfossils, nannofossils and rock fragments. Quartz, dolomite, clay minerals (kaolinite, smectite, illite, and palygorskite), halite, and gypsum also occur in these detrital calcitic layers, much like in the laminites of the present Dead Sea floor.

In the vicinity of the modern Dead Sea the laminae in the Lisan Formation are sometimes crenulated and may contain sulphur concretions. Some layers display sediment slumps and overfolds, water escape structures, growth faults, and other evidence of soft sediment deformation (Fig. 4.57b). Many slumps and other fluidisation features are likely seismites, triggered by the ongoing seismic activity in the basin. That is, within the Dead Sea basin, earthquakes have kicked off multiple episodes of sediment movement, both syndepositionally and in the shallow subsurface (Weidlich and Bernecker 2004). Similar seismic response textures have been documented in the epeiric carbonates and evaporites of the Ordovician Red River Fm., Canada (El Taki and Pratt 2010)

Historically, seismic events preserved in Holocene (post-Lisan Fm) laminites have been given religious significance in the Christian Bible[9], although the actual timing of events has been altered for a more dramatic effect and tied to the crucifixion (Williams et al. 2011)

Some of the non-gypsiferous aragonitic couplets in the Lisan Fm are interpreted as accumulating in lake-waters some 400–600 m deep. But gypsum in some of the Lisan laminites in the White Cliff Member show evidence of much shallower deposition in the form of large vertically aligned gypsum crystals. These giant crystals fit better an earlier model of Lisan Formation deposition by Picard (1943) who described the coarsely crystalline gypsiferous parts of the Lisan Formation as being deposited in a combination of settings, a shallow lake, a large playa, and/or a giant sabkha. The presence or absence

[9]There is the report in the 27th chapter of the Gospel of Matthew in the New Testament that an earthquake was felt in Jerusalem on the day of the crucifixion of Jesus of Nazareth. Williams et al. (2011) tabulated a varved chronology from a late Holocene core from Ein Gedi on the western shore of the Dead Sea between deformed sediments due to a widespread earthquake in 31 BC and deformed sediments due to an early first-century earthquake. Twenty-eight historically documented earthquakes were identified in the 1598-year interval between 140 BC and 1458 AD preserved in the Ein Gedi core. The early first-century seismic event is tentatively assigned a date of 31 AD with an accuracy of ±5 years. Plausible candidates for this event include the earthquake reported in the Gospel of Matthew. That is, there is an earthquake event preserved in the sediments that occurred sometime before or after the crucifixion and it was of sufficient magnitude to be impressed in the popular mind. So, earthquakes were ongoing in the region and one was in effect "borrowed" or time shifted by the author of the Gospel of Matthew. It is highly likely a local earthquake occurred during the time of writing of the Gospel of Matthew and it was "called upon" so as to match the date of the crucifixion. The aforementioned event occurred sometime between 26 and 36 AD and was sufficiently energetic to deform the sediments at Ein Gedi, but not energetic enough to produce a still extant widespread and extra-biblical historical record (unlike the higher magnitude earthquake of 31 BC with its widespread historical documentation).

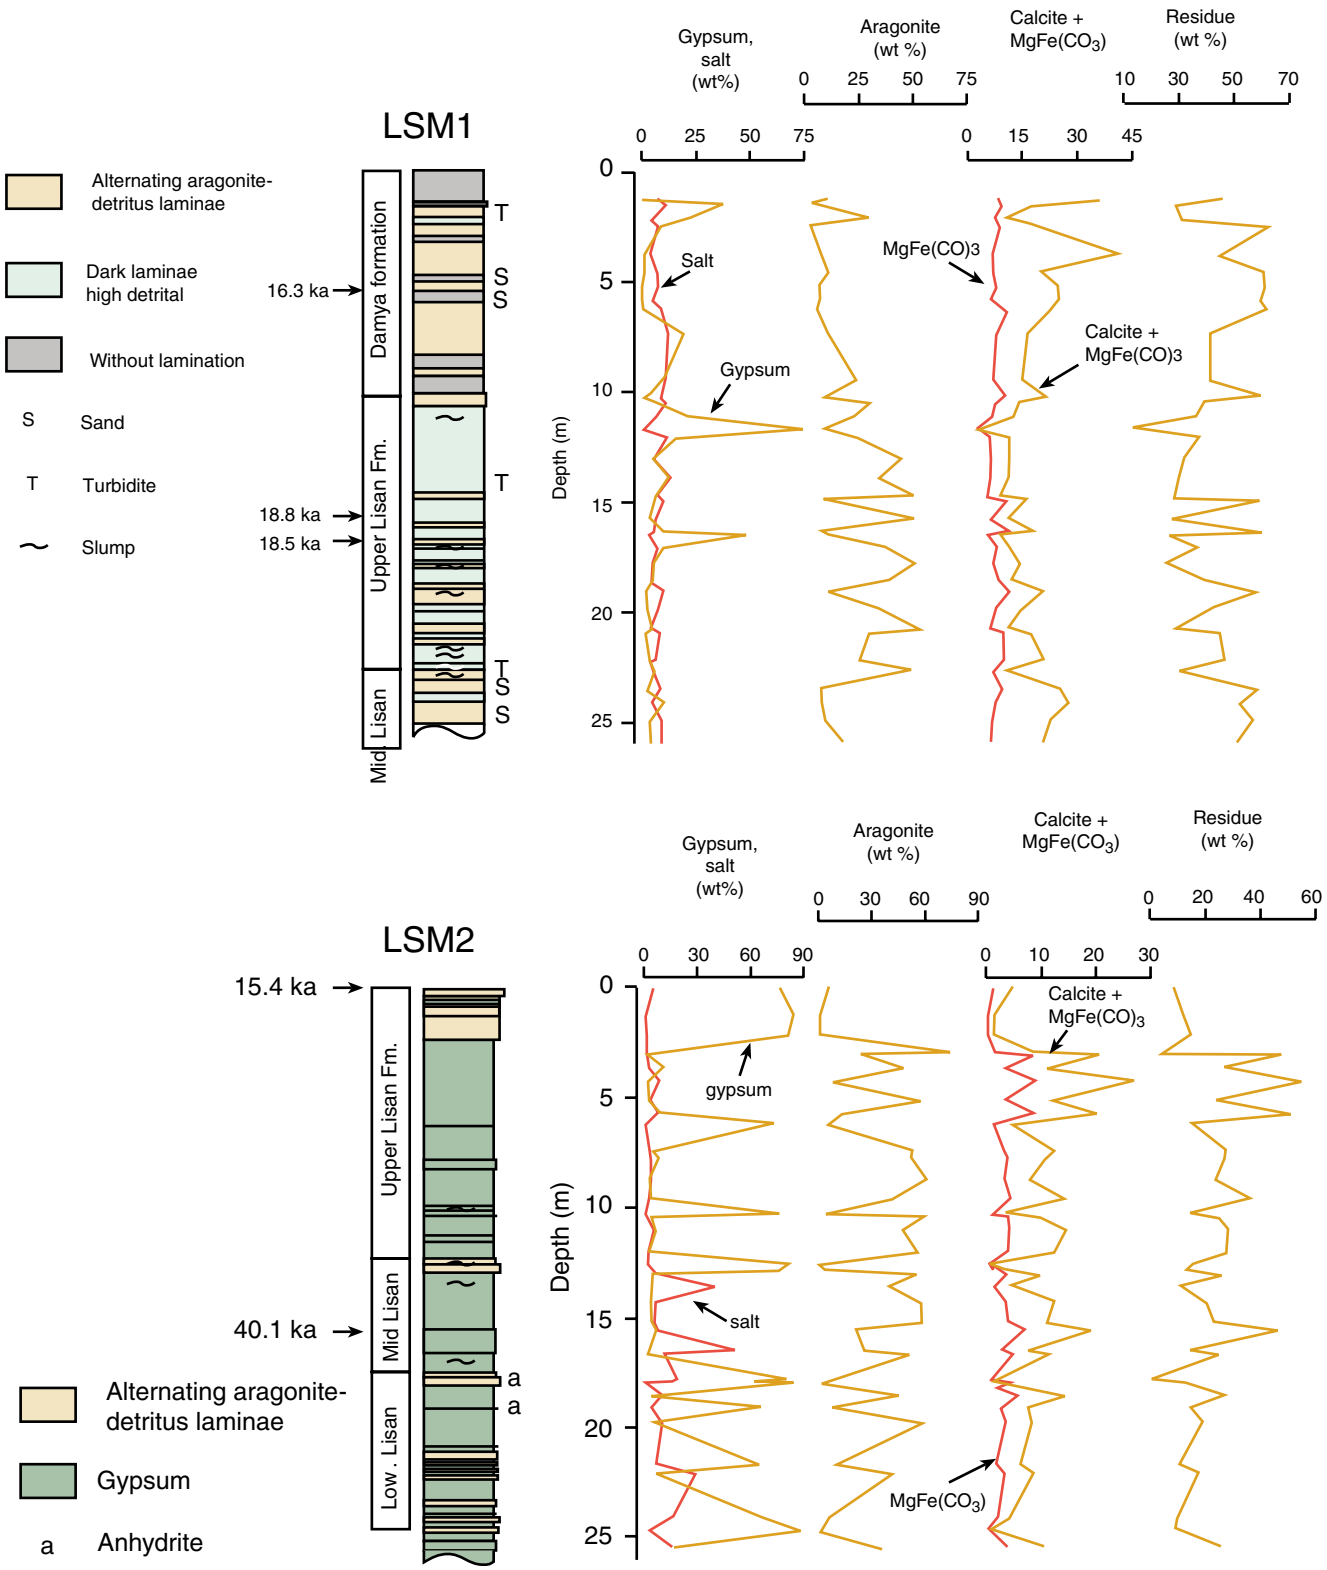

Fig. 4.58 Stratigraphy and mineralogy of the Lisan and Damya formations in the Jordan Valley. Positions of the sections are shown in Fig. 4.55 (After Landmann et al. 2002)

of gypsum perhaps indicates changing water levels in the Lisan Lake so that when bedded and growth-aligned gypsum is commonplace the Lisan water levels were lower.

Overlying the Lisan Formation is up to 14 m of clastics of the Damya Formation (equivalent to the "unnamed unit" of Begin et al. 1974). Damya sediments are mostly clays, silts and sands, some gravels, and no evaporites (Abed and Yaghan 2000). It was deposited in a freshwater to brackish lake stage with a water level of −160 m at the onset of Lake Damya some 15–16 ka. According to Begin et al. (1985), the Lake Damya ended some 10–11 ka with a drop to −700 m asl, a fall in lake level of more than 800 m in a few thousand years (Fig. 4.56). If real, it means the driest period in Lake Lisan's history was immediately preceded by the wettest time in Damya climate. Clearly, waters levels in perennial saline lakes are subject to high frequency, high amplitude changes in water level with rates of change that can be four to eight times greater that marine eustatic changes in an icehouse climatic mode (Chap. 5).

Throughout its Pleistocene history the Dead Sea/Lisan succession preserves evidence of its hydrological state in the dominant mineralogy of the chemical precipitates preserved in the laminites. Aragonite dominance in the lacustrine laminites (Lisan) indicates least saline waters and highest lake water levels. At the other end of the climatic spectrum, halite beds indicate lowest lake levels and highest salinities, while gypsiferous laminites indicate intermediate water levels and salinities in the basin. The other component in the laminites is non-chemical detrital sediment. Interestingly, this detrital input to the laminites and halites is present in all three evaporite styles from evaporitic carbonates to halites, although the rapid aggradation rates in the halite beds make it less obvious as separate laminae. Earlier work assigned much of this non-chemical detritus to a fluvial source (Jordan River and various wadis). However it is becoming increasingly apparent that much of the non-chemical detritus, especially the fines, is windblown and ultimately derived from adjacent deserts, including the Sahara with the greatest influx at times in the past when wind intensities were greatest. It is also obvious that during lake level lows there are sediments accumulating about the lake margins in the various subaerial zones above the water level that are non-aragonitic (as in lower portion of the Holocene Zeelim formation, Fig. 4.59).

Laminites outcropping in the modern margins of the Dead Sea Basin encompass the Samra, Lisan and Zeelim formations (Fig. 4.59; Haliva-Cohen et al. 2012). Mineralogically they can be broken down into two sedimentary facies, based on the presence or absence of aragonite: (1) The *aad* facies, which consists of alternating laminae of primary aragonite and silty detritus material; (2) The *ld* facies, which consists mainly of laminated detritus particles and typically lacks aragonite. The *aad* facies characterizes glacial intervals (e.g. MIS; stages 2 and 4) when lake levels in the basin were high, while the *ld* facies characterizes interglacials (e.g. MIS; stages 1, 5) and warmer glacial intervals (e.g. MIS; stage 3), when lake levels were low and evaporites were probably accumulating at times of holomixis in the adjacent drawndown lake (Fig. 4.59).

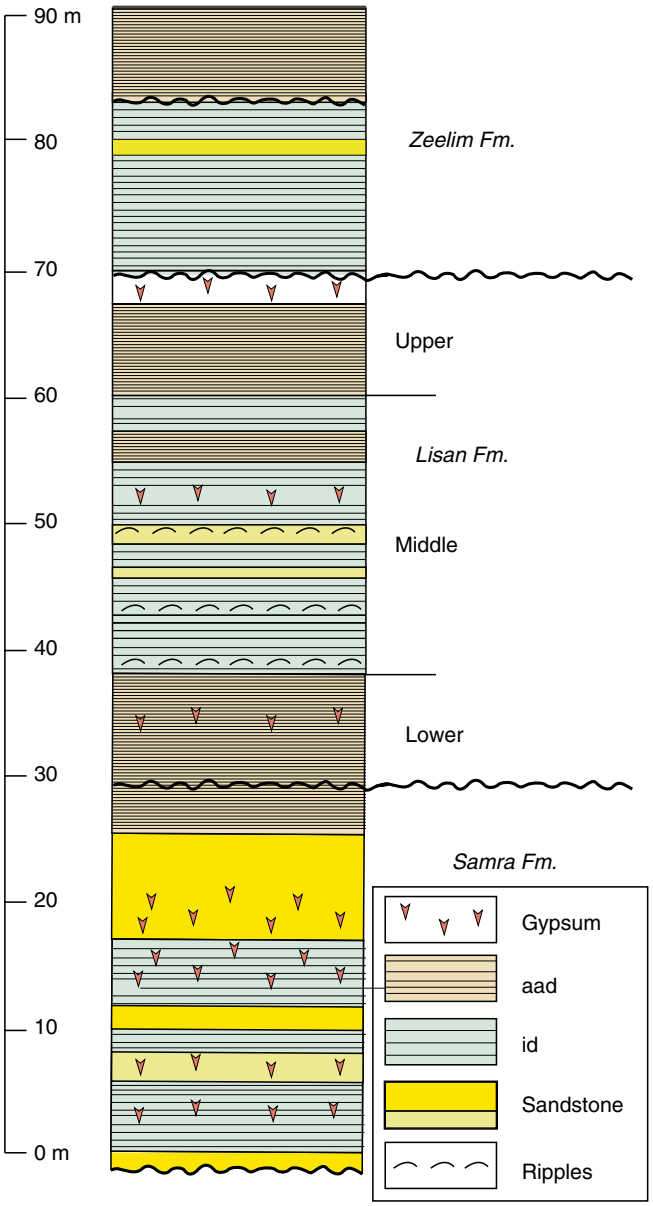

Fig. 4.59 Composite stratigraphic section of upper Samra Fm. (Last Interglacial: late MIS5), Lisan Fm (last glacial, MIS4, 3 and 2) and Zeelim Fm. (Holocene, MIS1). The Samra Fm. comprises mainly sequences of laminated calcitic detritus (the ld facies). The Lisan Fm. is divided to three Members: The Lower and Upper Members are mainly composed of sequences of laminated primary aragonite and silty-detritus (the *aad* facies, Figs. 3 and 5). The Middle Member consists of sequences of both the *aad* and *ld* facies. The lower and middle parts of the Holocene Zeelim Fm. consist mainly of the *ld* facies with more of the *aad* facies in the upper part (past 3,000 years) (After Haliva-Cohen et al. 2012)

The detritus in both *aad* and *ld* facies show similar mineralogies: mainly quartz ± calcite grains, with minor feldspars and clays, but with distinct grain-sizes (8–10 μm and

50–60 μm, respectively). They also show distinct $^{87}Sr/^{86}Sr$ and ƐNd (0.711–0.712 and ≈−7 to −8, versus 0.709–0.710 and ≈−5, respectively). Detrital fines in the *aad* and l*d* comprise desert dust of mixed granitic – basaltic composition that was blown from the Sahara desert and from the Nile delta to the northern Negev desert (loess deposits) and the Judean Mountains bordering the Dead Sea basin, mainly during glacial intervals along with enhanced Mediterranean rain fronts. The *aad* fines imply an enhanced transport of Saharan granitic dust to the vicinity of the lake mainly during glacials. The *ld* fines were recycled from the loess surface cover of the Negev desert mainly during interglacials and warm glacial intervals when lake levels tended to be lower.

Lake Asal, Republic of Djibouti

Lake Asal, with a water surface some 155 m below sea level, is the lowest place in Africa and defines the lowest part of the Afar rift (Fig. 4.60). Asal lake is small (area 52 km^2), endoheic and shallow, with a maximum water depth of 30 m and an average depth of 7.4 m. The Afar depression contains a series of lakes and salt pans at various depths below sea level: Lake Badda (−50 m), Lake Assale (−118 m), Lake Bakili (−120 m), Lake Afrera (−111 m), Lake Acori (−94 m) and the lowest Lake Asal (−155 m). Regionally, the area is extremely arid with average rainfall below 100 mm/year and evaporation of about 5 m/year (Köppen climate – BWh). Locally, in the Asal area, mean annual rainfall in the area is 175–200 mm/year and evaporation exceeds 3.5 m/year. The lake depression lies in the NW-SE oriented Asal – Ghoubbat al Kharab (Ardoukôba) rift extending northeast into the Gulf of Aden.

In the vicinity of Asal, the rift is subaerially exposed over a 12 km distance between Lake Asal and the Red Sea and is part of a tectonic system considered to be one of two examples where an oceanic ridge outcrops; the other being on the island of Iceland. This part of the rift extends southwest into the East African rift and is at the marine-fed end of what is our type example (Afar triangle) of a spreading centre (triple junction) in an arid part of world's rift systems.

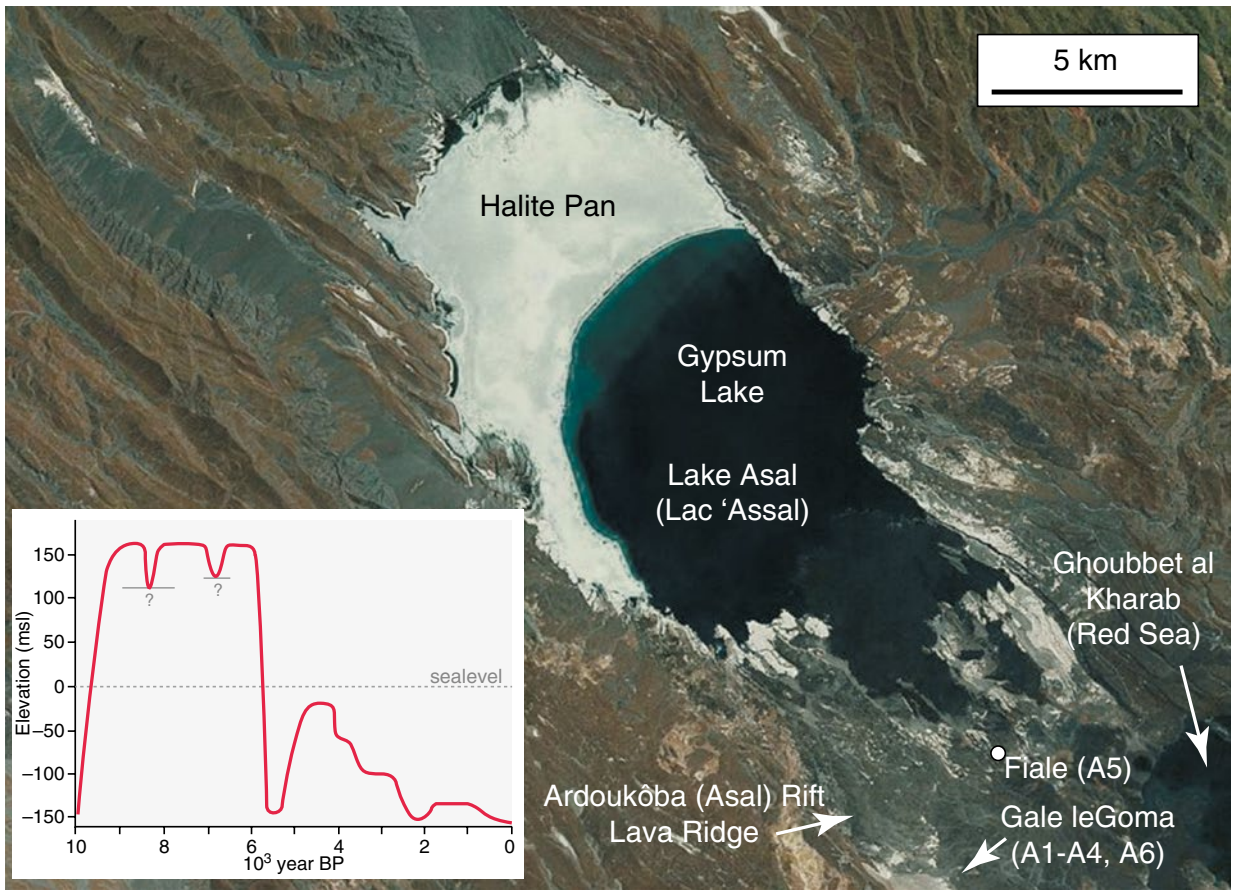
Locally, the ridge shows a spreading rate of 30–60 mm/year. Magma-water interaction has produced tuff cones, some of which form islands or are breached by the Red Sea. The most recent lava flows on the ridge are younger than lake sediments deposited 5,300 years ago and thought to have been erupted during the past 3,000 years. The Ardoukôba fissure last erupted in 1978, producing numerous fissure and vent lavas, as well as scattered hornitos and a large spatter ring that marked the climax of the eruption.

Although small, Lake Asal is one of the few modern examples of a marine-fed rift basin that is actively accumulating bedded evaporites. As such, it is the only Quaternary analogue for ancient marine-fed rifts including the numerous Mesozoic evaporitic lacustrine basins that underlie passive margins on either side of the Atlantic (Chap. 5). The lake surround today is completely continental with no surface connection to the ocean. Yet the fact its −155 m asl level has changed little in the last few centuries argues it is fed a steady flow of seawater through the highly fractured 10 km wide volcanic ridge that separates oceanic water at Ghoubbat al Kharab from the hypersaline waters of Lake Asal. It constitutes an excellent example of a drawndown marine seepage basin fed through a volcanic ridge (Fig. 4.60).

Over the longer time frame of the past 10,000 years, lake levels have changed drastically (Fig. 4.60; inset from Gasse and Fontes 1989). Some 10,000 year ago Lake Asal was almost dry in the late Pleistocene. A highstand lake level at 160 m asl existed in the early Holocene, between 8.6 and 6 ka, and the lake at that time drained to the Ghubbet el Kharab, across a shallow sill at an elevation of some 4 m bsl, to the Gulf of Aden, both as surface and subsurface flows (Fig. 4.60). Subsequent to this time span, the lake level dropped considerably to 150 m below sealevel enabling at the first time subsurface seawater infiltration from the sea to the lake across the fractured divide. Since then, the lake water salinity is controlled, mainly, by seawater input and high evaporation, responsible also for Ca-sulfate and halite deposition.

Today, any actively flowing springs, locally called manda, are dotted along the southeastern strandzone of the lake. Their geochemical makeup is very close to seawater proportions (Sanjuan et al. 1990). Outflow zones of some perennial thermal ponds support populations of small halotolerant fish of Family *Cyprinodontidae* (minnows and killifishes). Total marine inflow to the lake is estimated to be of the order of 60–80 m^3 per second, with transit times for waters seeping from the ocean to the lake floor measured in less than tens of years, or at most two centuries (Demange et al. 1971; Fontes et al. 1980). Outflow is focused along shallow narrow fracture networks that cut the volcanic ridge (Mlynarski and Zlotnicki 2001). There are also several hydrothermal springs and many fumaroles still active in the area and it is clear that the subsurface temperatures are still very high below the fracture meshworks carrying cooler seawater inflows to the lake depression making the region a possible candidate or geothermal energy.

Three independent geothermal systems have been identified, so far, namely. Gale le Goma, Fiale and South of Lake (Houssein and Axelsson 2010). Six deep wells have been drilled in the region, the first two in 1975 and the others in 1987–1988. Well A2 was damaged and wells A4 and A5 encountered impermeable yet very hot (340–365 °C) rocks. Wells A1, A2, A3 and A6 produce highly saline (120 g/L TDS) fluids leading to significant mineral scaling. The first two deep wells, Asal-1 had a final depth of 1,154 m and Asal-2, a final depth of 1,554 m. These thermal test holes were drilled at the southwest edge of the geothermal area in a region where there is no direct inflow from the sea. Asal-1 produced 22 kg/s of high salinity water with a measured tem-



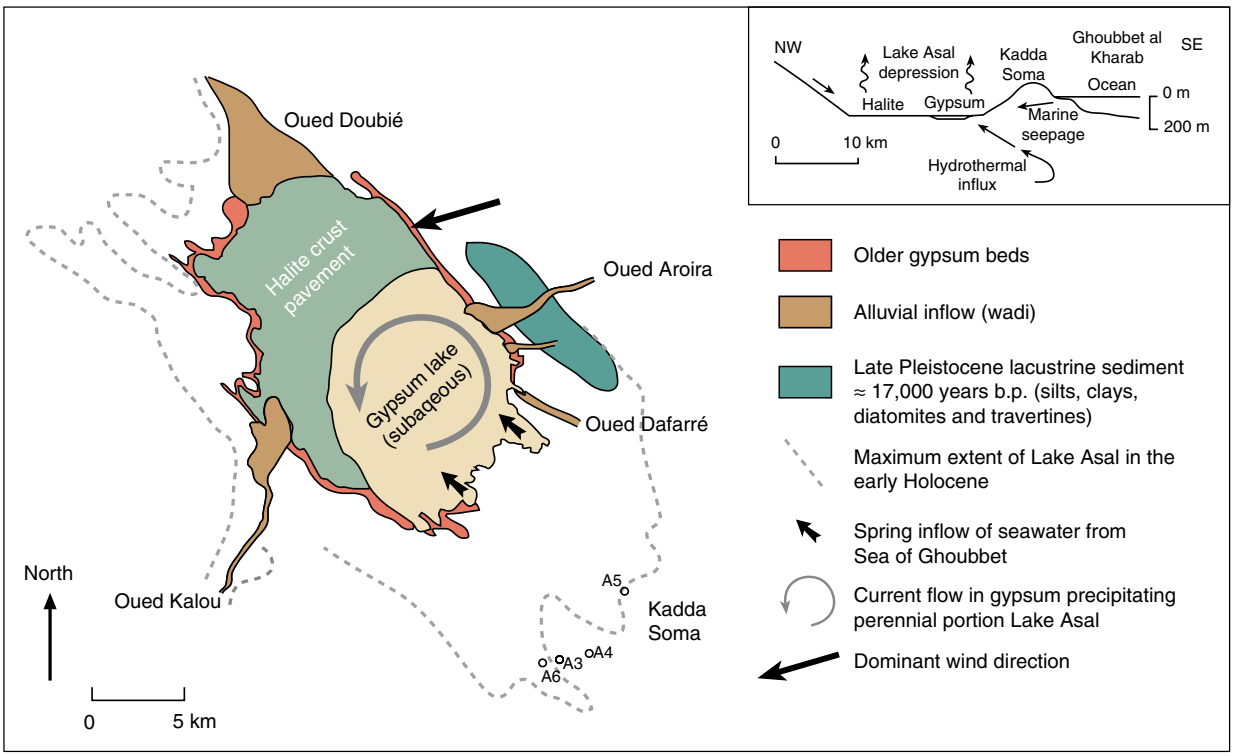


Fig. 4.60 Holocene sediment distribution in Lake Asal, Republic of Djibouti (surface geology after Stieljes 1973). Marine inflow is via fractured basalts of the Kodda Soma. A_{3-6} indicate positions of geothermal test wells – A_1 and A_2 lie further to the southwest. Insets show water levels in past 10,000 years (After Gasse and Fontes 1989) and an idealised cross section from the ocean to the lake depression (Landsat image courtesy of NASA)

perature at 1,040 m of 255 °C prior to flow testing, and 260 °C during a flow test in 1981 (Fig. 4.61). Water produced by Asal-1 had a very high solids concentration (128 g/l) and during the 1981 flow test, rapid incrustation in the casing had plugged the well in less than 3 months. The other well, Asal-2, was plugged inside the casing, possibly by drilling mud, and is no longer producing steam. Well test data from all six wells indicate that the reservoir might be producing from layered fractured and porous zones (Fig. 4.61). The estimated permeability-thickness of the deep Gale le Goma reservoir is in the 3–9 darcy-meter range.

Free-standing lake brines reach salinities of 350‰ and, like their marine spring feeds have seawater like proportions, dominated by Cl, Na, K, SO_4 and Mg. Salts in the perennial standing body of lake brine (up to 40 m deep, mostly 5–7 m deep) are mostly gypsum, which is accumulating with mounded and bottom-nucleated aligned-layer textures identical to those that characterise the South Australian salinas. Gypsum precipitation dominates in this the southeastern part of the lake depression, located next to the seeps that bring seawater to the surface. Fractures also intersect the subaqueous lake floor and seawater can be seen to rise up along fractures cutting the lake bottom. Older layered and mounded gypsum beds crop out around the lake edge to as high as 55 m above the present lake level (Stieljes 1973).

Stacked halite crusts characterise the saline pan facies that covers much of the northeastern part of the lake where it forms a wide (≈60 km^2) and thick (20–80 m) accumulation of pan halite. Prior to 1978 the top of this halite plain lay some 30–80 cm above the typical water surface of the perennial gypsum lake. Then in 1978 renewed volcano-tectonic activity in the region reopened fractures and faults leading to an increased influx of waters from the Ghoubbat al Kharab and a rise of lake waters which partially submerged the top of the salt pan (Ruegg et al. 1979). Once again, as in most other basins accumulating bedded evaporites, the changes in hydrological base level in this depressed pan are in large part driven by tectonics, not marine eustasy (see Chap. 5). The separation between areas of subaqueous gypsum and pan halite clearly shows how two mineral phases cannot accumulate simultaneously in a single holomictic brine lake, but can be adjacent facies controlled by separate hydrologies (salina versus mudflat).

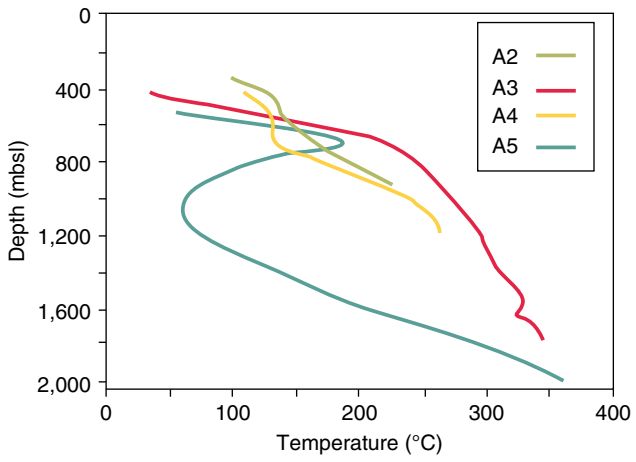

Fig. 4.61 Temperature profiles of Asal wells A2–A5 (After Houssein and Axelsson 2010). Layering indicated by variable geothermal gradients in each well (Locations in Fig. 4.60)

Are Modern Saline Lakes all Shallow?

Table 4.6 shows the relative importance of saline lakes in the total volume of the world's surface waters. There is as much water caught up in the world's saline lakes as there is in stored in freshwater lake systems. Figure 4.62 plots the salt mass held in various saline water bodies, including the Caspian Sea which exceeds all other saline lake examples by an order of magnitude, holding some 70 % of the stored total salt mass listed in Table 4.6. The Caspian Sea has a surface area of 371,000 km^2, not including Karabogazgol, and a volume of 78,200 km^3. However, the relatively low salinity of the Caspian (12‰, some 1/3 of seawater) may preclude it from this compilation of salt masses in non-seawater saline water masses, especially if an additional defining criteria was that the basin must be precipitating salt, making the Dead Sea the largest mass of salt stored in a freestanding non-oceanic brine. Ultimately the Caspian Sea does precipitate a substantial salt mass, via the Karabogazgol depression.

Table 4.7 summarizes the physiographic variety of some of the larger Quaternary perennial brine lakes. The Caspian

Table 4.6 Water volumes in the global water compartments

Hydrological compartment	Volume of water held (1,000 km^3)	Percent
Oceans	1,370,000	97.61
Glaciers, ice, snow	29,000	2.08
Subsurface	4,067	0.295
Freshwater lakes, rivers	126	0.009
Saline lakes	104	0.008
Atmosphere	14	0.001

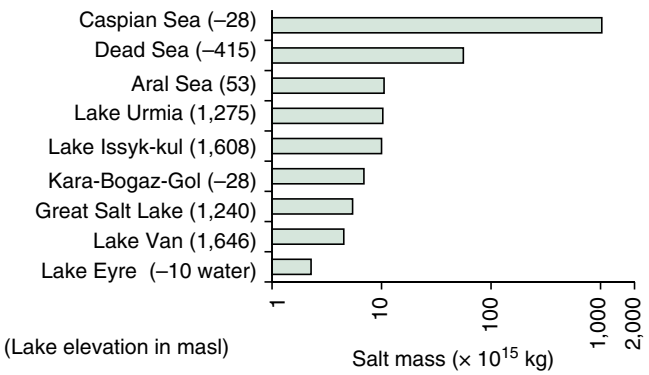

Fig. 4.62 Mass of salt held in selected freestanding lake waters. Note logarithmic scale

Table 4.7 Representative listing of variations in Quaternary evaporite deposits

	Area km^2	Brine surface	Hydrological setting (Brine source)	Tectonic setting	Characteristics
Lake Macleod, Australia (Köppen BWh) (Logan 1987)	2,500	≈1 m below sealevel	Evolved from stratified perennial to ephemeral during sediment infill (marine)	Passive margin	Holocene marine-fed coastal salina with 10 m thick bottom-nucleated salt beds. Stable brine curtain maintains salt beds and marine-fed seepage margin. Salts have filled an interdunal depression to within a metre of ambien t sealevel via seepage of mostly marine-fed groundwater.
Abu Dhabi mudflats (Köppen BWh) (Evans et al. 1969)	≈300	≈1 m above sealevel (asl)	Ephemeral with water cover during marine flood stage (marine)	Ramp in foreland basin	Holocene marine-fed coastal mudflat with 1–2 m thick displacive salts growing in detrital matrix of supratidal and intertidal units. Stable brine curtain is maintained by capillary evaporation and marine seepage.
Dead Sea, Middle East (Köppen BSh) (Ben-Avraham et al. 1999)	1,000	−415 m asl	310 m deep lake hypersaline lake with alternating longterm meromictic and holomictic brine columns (nonmarine)	Continental transform basin	Quaternary fluvial/seepage-fed deep perennial lake. Thick stable brine curtain bathes multiple stacked subaqueous beds. Beds in Northern Basin deposited in deep water, Southern Basin in saline pan/salina settings. Much of the solute is fed to the lake from springs carrying dissolved Miocene (4–6 Ma) evaporites (diapirs also outcrop on lake floor).
Kara-Bogaz-Gol, Turkmenistan (Köppen BSk)	13,000	28 m below sealevel	Endorheic basin joined by a narrow inlet to Caspian Sea (nonmarine)	Intramontane basin in a continent-continent collision belt	In the last 0.5 million years three separate Mg-Na-SO_4-rich salt layers have formed across the gulf, perhaps forming best in glacial episodes when the connection to the Caspian was reduced compared to today, and year round temperatures were much lower. Such glacial conditions favoured a perennial lake to pan mode of cryogenic mirabilite precipitation (Fig. 12.21)
Lake Eyre, Australia (Köppen BWh) (Magee et al. 1995)	9,300	−15 m asl	Ephemeral lake mudflats with up to 6 m of freshwater cover emplaced during occasional storm flood (nonmarine)	Intracratonic sag atop Precambrian rift	Quaternary fluvial-seepage fed, has changed from fresh (100 ka) to the ephemeral salt lake of today, showing the decreasing effect of the monsoonal feed. Upwelling and through flushing of freshened artesian waters beneath the lake destroys the brine curtain and so prevents more than 2–3 m of halite accumulating beneath the lowermost parts of the lake floor
Salar Uyuni, Bolivia (Köppen BWk) (Risacher and Fritz 2000)	10,600	+3,653 m asl	Saline pan with peripheral mudflat (continental/ hydrothermal)	Intramontane basin in a forearc collision belt	Largest salt pan in the world today. A 121 m deep well intersected 12 saline-pan beds separated by 11 lacustrine mud beds, all bathed in a stable brine curtain. Mud layers thicken upwards, while the thickness of the salt beds decreases markedly from the base upward.

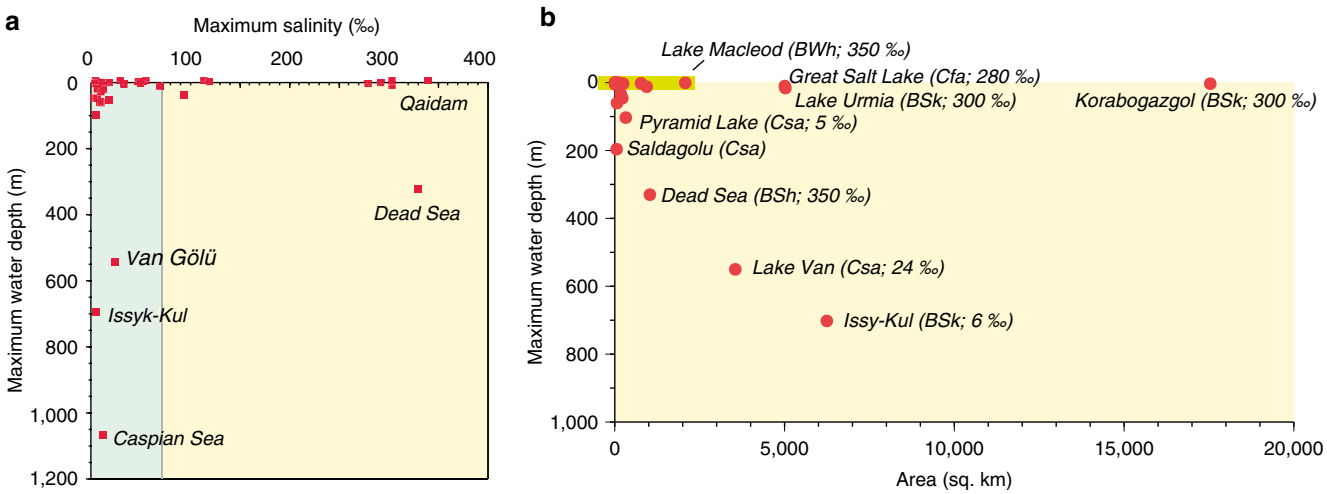

Fig. 4.63 Physiography of saline lakes of the world. (**a**) Plot of maximum salinity of freestanding saline lake waters versus maximum water depth. Note logarithmic scale (see also Table 4.1) (**b**) Plot of maximum brine depth versus brine area (also shown is Köppen climate and maximum salinity reached by most saline brines). Larger saline lakes tend to be less saline and in cooler arid climates. *Green rectangle* encompasses plot field of all Holocene coastal salinas, including the largest – Lake Macleod

and the other perennial saline lakes of western Asia (Karabogazgol, Lake Urmia, Lake Issyk-Kul and Lake Van) are all located in foreland basins created by Neogene collision tectonics and together contribute a high proportion to the world's total volume of saline lake waters. Then again, over 40 % of the listed freshwater volume in Table 4.6 comes from the combined volumes of Lake Baikal and the Great Lakes of the North Americas. Also, most saline water bodies are shallow, so the area of the world's surface covered by saline lakes is probably greater than that covered by freshwater lakes.

In terms of saline lake sediments associated with saline water bodies, the largest contiguous area of Quaternary bedded salt accumulating today is in Salar Uyuni, a continental lake (saline pan/mudflat) with a water level some thousands of metres above sea level. The Dead Sea, with a water surface more than 415 m below sealevel, is our one Holocene example of a substantial deepwater evaporite basin currently accumulating halite. Its inflow is a combination of river and saline spring inflow, with most of the solute content coming from groundwaters flushing nearby Miocene salts. One of our best examples of an active marine-fed perennial saline lake, which is still accumulating bedded shoalwater gypsum and pan halite, is Lake Asal, a rift depression lake with a water surface some 155 m below sea level. In area, it is exceeded by many of the marine seepage-fed Holocene coastal salinas of southern and western Australia. Unlike Lake Asal, the Australian coastal salinas have equilibrated within a metre of the height of their sea level source and are no longer actively accumulating subaqueous bedded salts. Active subsidence in a rift seems to allow a continental lake to maintain permanently subaqueous brines, as is the case in the Dead Sea. After Lake Asal, Death Valley at −86 m asl, is the next deepest hole on the world's surface that is occupied by a saline lacustrine system. In its current form it is a saline pan rather than a perennial halite accumulating lake, but in the Late Pleistocene it was a deep perennial system (Chap. 3). Although well studied, the volume of salts accumulating in Death Valley is relatively minor in terms of the total volume of salt in saline lacustrine settings of the world.

A plot of salinity versus brine depth in the world's perennial saline lakes shows that perennial lakes accumulating salts more saline than calcite/aragonite/dolomite couplets (salinities >70‰) tend to be shallow, river fed and with brines typically less than 10 m deep (Fig. 4.63a). In terms of total salts held in the lake waters, the less saline lakes dominate – Caspian, Aral Sea, Lake Urmia (Fig. 4.63).

The current condition of the Dead Sea is an obvious exception to the general observation that gypsum/halite-accumulating lakes are characterised by shallow to ephemeral surface waters (Fig. 4.63a). The Dead Sea's physiography as a narrow rapidly subsiding basin in the deepest continental position on the world's surface makes it unique amongst the world's modern saline lakes. But the Dead Sea can accumulate halite in its deepest waters only when its longterm density stratification is destroyed (holomixis). The destruction of the halocline is not an annual event, as it is in some of the less saline lakes (e.g. Lake Van), but seems to occur every few hundred years. A plot of lake water area versus depth shows that larger nonmarine-fed saline lakes tend to be located in cooler deserts (Fig. 4.63b; see also the more detailed discussion on climate controls in Chap. 2).

All of the largest active perennial saline water bodies, which are depositing substantial volumes and areas of

Quaternary subaqueous salts over time frames measures longer than 10,000 years, are continental not marine depressions. All the largest perennial saline lakes occur in semi-arid rather than arid to hyperarid climates and all are located in tectonically active and subsiding (underfilled) basins such as in the Andes, the tectonic collision zones of Turkey and Iran, and the Basin and Range of USA (Table 2.3). Tectonism facilitates steep topographic gradients, endorheic closure and subsidence within large intermontane depressions, all three factors seem to be needed in order to form a permanent brine body in Quaternary systems. Milder levels of aridity allow waters to persist above the land surface and do not drive the conversion of the hydrology to sabkhas and evaporitic mudflats that characterise the more arid settings.

Climate and Scale of Quaternary Saline Systems

The other significant factor common to the formation of large perennial saline lakes is longterm climate change. Ephemeral flood-pan lacustrine systems, such as Lake Eyre and Lake Frome in Australia, which today are combinations of saline pans and evaporitic mudflats, were large perennial brackish to freshwater lakes in milder climatic episodes in the Late Pleistocene. These southern hemisphere "mega-lake" phases are tied to a more southerly influence of the monsoonal belt during these times. Even historical flooding events in the central Australian playas are frequently tied to La Nina phases in the El Nino-Southern Oscillations (ENSO). Laminated Pleistocene (10–12 ka) lacustrine sediments from Lake Magadi also preserve evidence of ENSO changes in the variations of laminae thickness (Damnati and Taieb 1995). Changes in Pleistocene climate also explain why many modern playas and pans in the Basin and Range were once perennial lakes; during pluvial episodes of the Late Pleistocene some were even freshwater lakes with waters more than 100 m deep (Smoot and Lowenstein 1991).

Many such Late Pleistocene lakes during their humid or wetstage were huge, are termed megalakes as they had water covered extents that extended far beyond the borders of their current saline residuals. Some 48,000 year ago lakes Mega-Frome and Mega-Eyre were joined to create one of the largest Pleistocene systems of perennial palaeolakes on the Australian continent. When joined the combined lakes had a water covered area of 25,000 km^2 and a volume of 285 km^3 with a water level of +5 m AHD (Cohen et al. 2012). Even larger in the Australian context was the gypsiferous Bungunnia megalake, which occurred in southern Australia in the late Neogene, when it covered an area of more than 50,000 km^2 in the Murray Basin in its brackish phase and a lesser area in its underfilled more evaporitic phase (McLaren and Wallace 2010; McLaren et al. 2012). Another impressive megalake was Lake Chad some 8,000–10,000 years ago when its freshwater-covered area of more than 50,000 km^2 was equivalent to that of the present Caspian Sea. Yet another, even larger, lacustrine system was the Late Pleistocene Kalahari mega-lake, which had an area of more than 66,000 km^2, extending across the current Makgadikgadi (Sua Pan) and adjacent depressions of Africa (Burrough et al. 2009). All these mega lakes occupy what are today desert-margin areas (see Chap. 2) Interestingly, some modern perennial saline lakes, currently in their fresher saline stages (Lake Van and Lake Urmia), experienced times of shrinkage and desiccation in the Late Pleistocene.

To state everything we have discussed so far in its simplest terms: To accumulate bedded salts, you need a large, deep centrally-draining somewhat leaky hole in the ground (a groundwater sump). And, like Goldilocks, such saline systems perform best in a climate that is not "too hot" and not "too cold" and not "too wet" and not "too dry." Variation in climate and tectonics causes these lacustrine systems to expand and contract, they oscillate between less saline water-full and highly saline drawndown stages.

If we use Quaternary examples of evaporite deposition as strict uniformitarian analogs for ancient evaporite deposits then we must conclude that the largest and thickest, laterally extensive salt beds are always continental lacustrine deposits, accumulating in tectonically-induced, rapidly-subsiding intermontane basins and sags. The most voluminous accumulations of pure halite are not in intracratonic sags like megalakes Chad and Eyre, which retain only thin impure evaporite beds, but in more hydrologically focused Quaternary intermontane salar depressions in the Andean Altiplano. There, Uyuni and Atacama are saline pans today, but were perennial aerially-larger saline lakes in the Late Pleistocene. In the largest Andean salar deposits the salt depositional surface is more than 2,000 m above sea level. This is a setting with limited lateral continuity, some tens of kilometres across and, as will shall see in Chap. 5, not relevant to the scale or setting of ancient marine fed sumps, such as those that deposited the Messinian of the Zechstein, salts.

Likewise, note that there are scale, continuity and preservation limitations if we consider as analogs the geological setting and extent of the well documented various Quaternary saline pans and sabkhas that occupy various intermontane depressions, such as in the Southwest USA. Figure 4.64 illustrates the extent of the region to the west of the Bonneville salt flats and Great Salt Lake, which are visible in the upper right side of the figure. Note the 100 km scale bar in this figure, it emphasises the limited extent and thickness of the various thin, laterally-discontinuous 1–10 m thick salt beds that form as veneers in the lower portions the intermontane valley sumps. These salt beds form as the result of evaporation of ponded continental and magmatic brines. It is not an hydrological environment where salt masses hundreds to thousands of meters across and hundreds

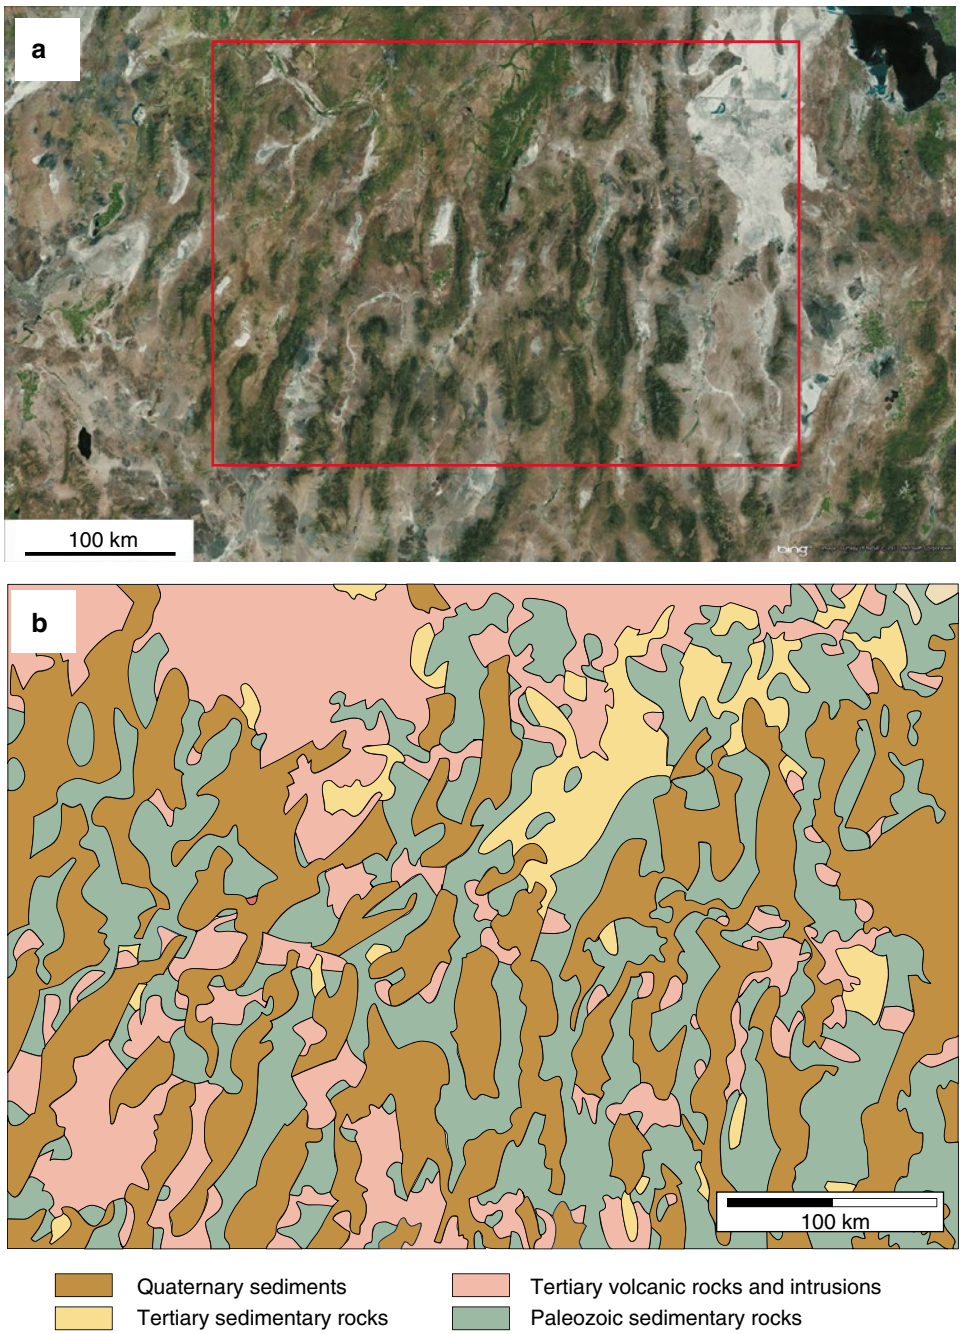

Fig. 4.64 Basin and Range: scale of depositional setting. (**a**) Landsat image (**b**) General geology showing a strong structural grain to the distribution of the various laterally discontinuous Quaternary sediments including thin veneers of saline minerals. *Red rectangle* indicates area of geological map.

of meters thick can form. Such megasalt geobodies require a marine-feed and a subsealevel sump setting to facilitate the ongoing hydrology that facilitates the accumulation of such salt volumes (Chap. 5).

Such marine-seepage fed platform and basinwide evaporite settings do not exist today. But, the next chapter will show that most of the larger examples of ancient evaporites are actually marine-fed precipitates, deposited under eustatic and tectonic conditions for which there are no Quaternary counterparts.

Comparing Quaternary Sabkhas, Pans and Lakes

So, in this and the preceding chapter we looked at some the better documented, hydrologically active, examples of the world's modern evaporite systems. We can now begin to construct an understanding framework needed to test and answer that perennial geological question: Is the present the key to the past? When documented Quaternary saline lakes are climate-sorted and plotted using a similar climate-sorted approach, as was done with saline pans and sabkhas at the end of Chap. 3, a number of similarities and significant dif-

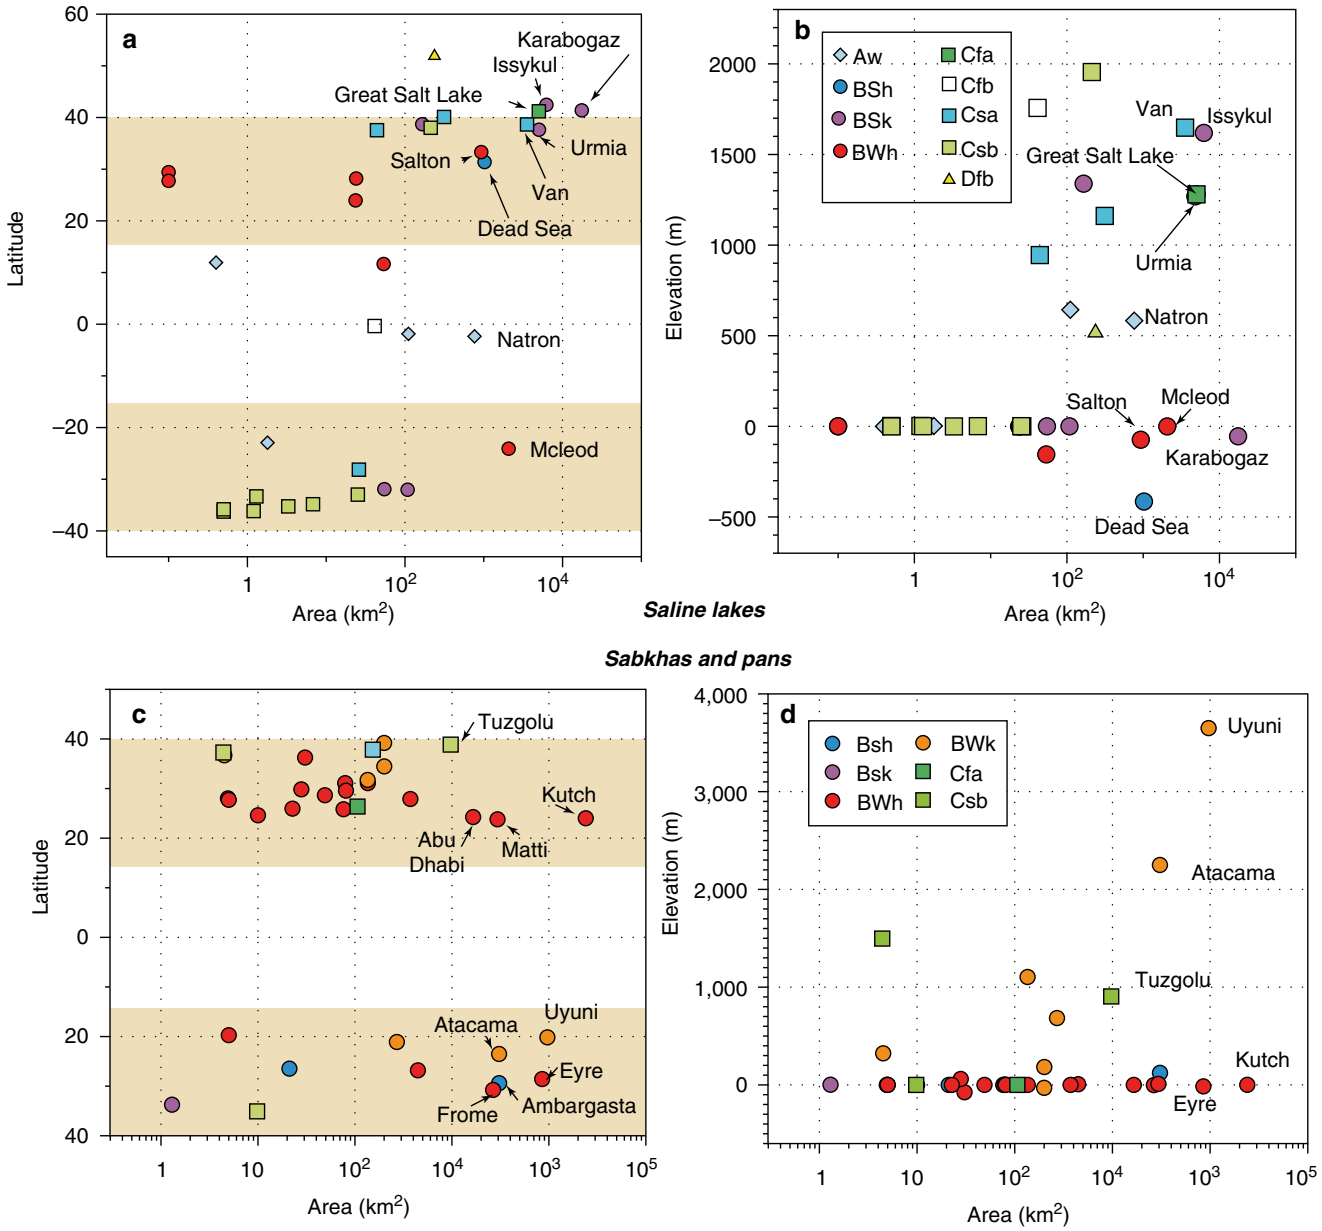

Fig. 4.65 Köppen climate sort plots of area (km^2) versus latitude and elevation (with respect to sealevel = 0 m). (**a**) and (**b**) plot saline perennial lakes, based on Table 4.1. (**c**, **d**) Plot sabkha and saline pan occurrences, based on Table 3.1. *Colour bands* indicate approximate latitudinal positions of descending arms of Hadley Cells (15–40° north and south of equator)

ferences are seen between perennial saline lakes versus sabkha/pans (Fig. 4.65).

1. Many significant perennial saline lakes occur outside the trade wind belts (beyond the influence of Hadley cells). For example, Lake Magadi and Natron occur in adiabatic dry zones within an Aw climate zones, located within a few degrees of the equator. Issykul and some of the Himalayan/Chinese perennial lakes occur as far as 55° north of the equator in cold arid deserts. The distribution of perennial saline lakes is more latitudinally dispersed than sabkhas and pans.
2. Steep intermontane (rain shadow-or adiabatic) arid continental settings encourage the formation of suitable at-surface saline hydrologies need to maintain large perennial saline lakes and pans. The five largest modern saline lakes (Karabogaz, Issykul, Urmia, Great Salt Lake and Van) and the two largest saline pans (Uyuni and Atacama) occur in cool, rather than hot, arid settings.
3. Although transitions from fresher to more saline perennial or pan systems is often a response to climate change, the transitions can also be tectonic or sedimentologic. This was the case with the rapid fall and transition into a saline system that marked the end of Lake Bonneville,

Utah. It seems that megafloods are more typical of saline lakes located in semi-arid regions, where in the Quaternary icehouse earth water levels tend to oscillate between higher and fresher, to lower and more saline (O'Connor and Costa 2004). The associated rapid changes in water head in an intermontane setting are more likely to set up mechanical instabilities in the encasing unconsolidated sediments (overtopping and groundwater sapping).

4. Megafloods can also occur when a rapidly rising sea breaches a previously continental lacustrine depression. A Holocene example of this style of marine megaflood occurred in the Black Sea Basin (as opposed to the much gentler marine seepage-flooding that typifies many Holocene coastal salinas). Some 7,500 years ago the Black Sea was catastrophically flooded by seawater from the rising Mediterranean Sea as it overtopped and eroded a former divide at the present-day Bosporus Strait. Ryan and Pitman (1999) speculate that this event was the folk memory that is the basis for the biblical myth of the worldwide Noah's Flood.
5. The largest saline lake sump known today is Karabogazgol, which formed as a natural concentrative sump to the already somewhat saline waters of the hydrographically-isolated fluvial-fed Caspian Sea. Karabogazgol is accumulating cryogenic salts, not salts formed by solar evaporation in a hot arid desert. Also the greater volumes of preserved and buried salts in Karabogazgol accumulated in cooler glacial periods, not in the warmer interglacials, such as that of today.
6. Because of the importance of relief and lower temperatures in facilitating the ponding of surface water in arid conditions with reduced evaporation rates, the five largest extant saline lakes (Karabogaz, Issykul, Van, Great Salt Lake and Urmia) are not found in BWh climates. Rather hot arid climates favour the formation of sabkhas especially adjacent to a large standing brine mass or ocean. The largest extant saline lake in a BWh setting is Lake Macleod, which is supplied large volumes of seawater via evaporitic drawdown and seepage.
7. Unlike sabkhas, where the majority of the documented BWh deposits occupied at-sealevel positions (Chap. 3), many of the documented at-sealevel Quaternary saline lake coastal deposits occur in milder Mediterranean (C) or arid steppe (BS) climatic settings, with many of the larger perennial saline lakes being continental, not marine-fed, in intermontane settings at elevations well above sealevel.

So, when comparing saline deposit styles in Quaternary sabkha versus subaqueous climatic settings, it seems larger bedded saline lake deposits require somewhat less extreme desert or steppe conditions to form (BWk or BSk). Perennial Quaternary brine lakes seem to form best in cooler arid settings where there is a steep sided topography to the lake sump (the "Goldilocks syndrome"). In contrast, hot arid desert and steppe climates (BWh and BWk) favour the accumulation of sabkhas and pans, especially in sump areas with low relief in the surrounding topography and a relatively shallow watertable. Often in these ephemeral water hydrologies the bulk of the sabkha salts are subject to deflation and thick stacked salt accumulations are rare.

In summary, because modern continental settings lack a hydrology suitable for supplying huge volumes of brine, sufficient to form a megasalt deposit, neither modern sabkhas or salinas are directly relevant to the formation of the hydrologies and eustasies needed to deposit the huge masses of ancient marine-fed subaqueous salts detailed in Chap. 5.

Ancient Basins and Stratigraphic Evolution

5

Introduction

Is the present the key to the past in evaporite studies? It's part of a broader question that has plagued geologists working with salts since the seventeenth century, when Werner's Neptunist postulates explained world geology (including igneous strata) as layered precipitates from cooling oceanic waters. And, like Werner's Scottish antagonists, we are still discussing the merits of strict uniformitarianism. In this chapter I am not questioning the fundamental principle of using present-day process studies to interpret the past. Nor am I questioning the utility of detailed studies of process analogs and the use of physical constants to reliably interpret the past. Let me put it plainly for the creationist community and proponents of "intelligent design," all the geological evidence clearly shows the earth is not 8,000, but more than 4 billion years old. Biological evolution is fact, it interacts with and responds to the physical environment and has been in operation on the earth's surface for at least the past 3.45 billion years. There is no need to invoke the supernatural and sky faeries to explain biological evolution and other earth processes, and there is no geological evidence for a worldwide biblical flood of epic proportions drowning mankind and covering all the land.

What I am questioning is strict actualistic approaches to sedimentological interpretation of evaporites, whether the depositional diversity we see in our current icehouse climate mode and eustasy is sufficiently broad to explain the diversity of ancient evaporites (Table 5.1). If our present climate is the key in terms of all scales of deposition and climate, then why are no marine platform evaporites forming today and why are there no evaporitic seaways? Chapters 3 and 4 show that the largest and thickest Quaternary evaporites are continental lacustrine deposits, not marine-fed systems. We shall shortly see that such lacustrine systems are directly and completely comparable with their ancient lacustrine counterparts in terms of facies, salt thicknesses and lateral extents. But the scale of lacustrine evaporite development, past and present, pales in comparison to some ancient marine-fed saline systems. There are no modern counterparts to such ancient marine-associated systems. Our inability to compare all aspects of evaporite deposition, past and present, reflects a present-day lack of both longterm shallow epeiric seas and of large drawdown basins fed by seawater seeps.

The Hith Anhydrite of the Middle East, the Zechstein salts of Europe and the Messinian evaporites of the Mediterranean have no modern same-scale counterparts. An understanding of the shortcomings inherent in applying strict uniformitarian models is tied to current styles of continent-scale tectonics and icehouse eustasy. Put simply, the rates and amplitudes of seafloor spreading, orogeny and eustasy are not constant across deep time, nor is the climatic system they drive. Widespread marine evaporites require particular tectonic and/or eustatic conditions to accumulate, conditions that are not present on the world's modern surface (Table 5.1). They will be in the future, and they have been many times in the past.

This chapter demonstrates the importance of differences between icehouse and greenhouse climate/eustasy as controls on evaporite style in marine platforms. It shows how particular tectonic and climatic settings are needed to form saline giants in isolated subsealevel drawdown depressions. It also shows how interpretations using sequence stratigraphic marine eustatic frameworks do not work as well in ancient basinwide saline giants as they do in interpreting evaporites laid down on ancient marine platforms. Even on an ancient continental shelf, we need to separate icehouse from greenhouse platforms in order to understand variations in evaporite distribution.

By the end of this chapter, I hope it will be obvious that when trying to predict and model ancient evaporites it is much more useful to consider tectonics and hydrologies of large evaporite basins as the fundamental controls of basin-scale evaporite geometries, mineralogies and bounding surfaces. One should not force marine-seepage-fed drawdown systems into a marine-eustatic icehouse model. Nor should our interpretations be driven by the hydrologically dubious notions of ongoing surface (hydrographic) connections between ocean waters and restricted basins at the time thick salts accumulate (Chap. 2); and yet these assumptions still dominate many interpretations of ancient evaporite basins.

Table 5.1 Climatic and depositional contrasts between icehouse and greenhouse earth

	Icehouse	Greenhouse
Age	Icehouse Late Cenozoic, Late Carboniferous to Early Permian, Late Neoproterozoic	Greenhouse Cambrian to Middle Carboniferous, Middle Permian to Early Cenozoic
Tectonic style	Collision, telescoping	Stretching, rifting
Seafloor spreading	Slow	Rapid
Subduction/volcanism	Low	High
Marine margin basins	Narrow shelves, limited short-lived interior seaways with small aerial extent, evaporites mostly in lower latitudes	Wide shallow shelves and large long-lived interior seaways (epeiric seas). Evaporites with broader latitudinal spread
Marine eustasy	High amplitude (≈100 m) change on 100,000 year times scale (4th order). World sealevel is low (caught up in longterm polar ice sheets)	Low amplitude (>5–10 m) change on 100,000 year times scale (4th order). World sealevel is high (no polar ice sheets)
Ocean Basins	Cold, oxygenated, low sealevel, aragonitic ocean, (high Mg/Ca), low $MgSO_4$	Warm, often anoxic, high sealevel, Mg calcite ocean (low Mg/Ca), high $MgSO_4$
High latitude climates	Glaciers, taiga and tundra	Deciduous forest
Mid latitude climate	Deciduous forest, glacial advances and steppe	Tropical wet and stressed forest
Low latitude climate	Rainforest, savanna and desert	Desert
Erosion/weathering	Fast, mechanical	Slow, chemical
Depositional styles of large evaporite basins	Tectonically induced endorheic continental depressions (terrestrial lacustrine; no significant marine-seep platform and basinwide evaporites accumulating at present time; but basinwides can form in suitably isolated icehouse conditions, and did so most recently in the Middle and Late Miocene)	Tectonically and eustatically induced endorheic continental and marine margin depressions (terrestrial lacustrine, marine platform and marine-fed basinwide styles can be widespread whenever suitable combinations of tectonics and eustasy occur)

Linking Present to Past Aridity

In order to understand possible linkages between present and past evaporites, we must first understand geological indications of past and present climate. After all, the preceding chapters clearly show it is ambient climate that drives the accumulation of salts in the deserts, lakes and sea margin systems of today and the same was true in regions of saline giants of the past. Only with a sturdy palaeoclimate understanding can we reliably compare Quaternary to older saline depositional settings. Quaternary and late Neogene climatic systems, characterised by waxing and waning polar ice sheets, define the current "icehouse" climate mode. Today, some 10 % of the world's surface is covered by ice, representing about 80 % of surface freshwater, and a further 20 % is affected by permafrost. Of these ice-covered lands, Antarctica has 86 % by area and Greenland 11 %. In the last glacial maximum (18–20 ka) a staggering 30 % of the earth's surface was covered by ice.

The current icehouse mode evolved during the latter part of the Tertiary period and is characterised by glacially -driven oscillations in sealevel, with amplitudes around 100 m, with repeat frequencies of 100,000 years for the past 780,000 years. Ice sheet oscillations in this very short portion of the earth's history is paced primarily by the ~100,000 year eccentricity cycle of the earth's orbit (Fig. 5.1). Smaller amplitude changes (typically <60 m) dominated prior to this time when these earlier ice sheet fluctuations were paced primarily by the 41,000-year tilt cycle of the earth's axis. Growth and decay of a continental-scale ice sheet in Antarctica caused 50–60-m variations on the 10^6-year scale beginning ~33.5 million years ago. Prior to this time, Earth had been a warm, high-CO_2 "greenhouse" world that was largely ice-free back to 260 million years ago (Figs. 5.2 and 5.3; Miller et al. 2011) Modern marine-fed evaporite distributions, associated with icehouse earth and its older counterparts at the end of the Palaeozoic and the Neoproterozoic, are not the same as that of the "greenhouse" climate mode, which has dominated much of the earth's history (Table 5.1).

Quaternary climate (icehouse), especially in semi-arid to temperate latitudes over the past 500,000 years, is characterised by repeated rapid temperature swings from levels much like those of today (interglacial) to levels many degrees colder. Colder (glacial) times are associated with growth of huge km-thick circumpolar and high latitude/high elevation ice sheets and lowered sealevels. Ocean surface temperatures were up to a few degrees cooler at such times, while sealevels fell more than a hundred metres compared with interglacial highstands. On the land, mountain tree lines shifted to lower positions during glacial periods, grasslands replaced forests, continental ice-and periglacial-driven processes were more widespread and large volumes of dust and sand were blown about by cold, intense winds. There were rapid pulses of sealevel fall during passage into the cooler climatic phases (glacials) of icehouse mode climate, while in the passage to warmer (interglacial) periods the rates of sealevel rise were even more intense over periods measured in hundreds to thousands of years (Fig. 5.1a). There have been more than 15 glacial periods in the last 1.7 million years. It was in the latter part of this icehouse regime of rapid change and climatic stress that *Homo sapiens* first came to be, some 150 ka.

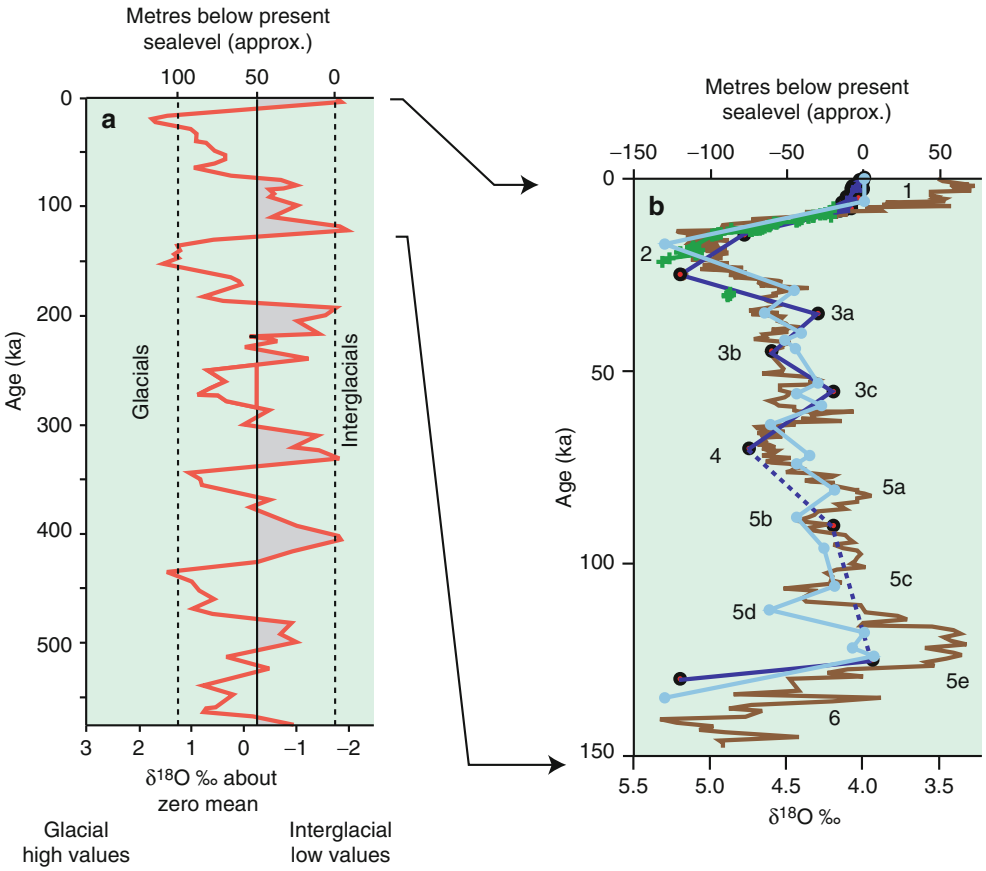

Fig. 5.1 Sea level change through the Late Quaternary. (**a**) Oxygen isotope curve for high latitude seawater for the past 400,000 years based on benthic forams in deep marine sediment cores in the Southern Ocean. Isotope scale is corrected to a zero mean (after Williams et al. 1993). Scale to mean sea level. (**b**) Late Pleistocene sea level (last 150,000 years, from continental margins and $\delta^{18}O$ (eastern Pacific piston core V19-30; Shackleton et al. 1983) record. The mid-Atlantic US margin, *solid blue-edged circles*; Huon Peninsula, Papua New Guinea, *light blue curves and circles*; Barbados, *green*), all show excellent agreement except for the Holocene Chron 1 and Marine Isotope Chron 5e where the prediction of sea level from scaling $\delta^{18}O$ is too high. *ka* thousands of years ago (After Miller et al. 2011; Isotope curve is relative to SMOW)

The 2.5 Ma climatic period known as the Quaternary[1] is the culmination of a slow and uneven climatic progression toward cooler conditions that typified much of the latter part of the Tertiary and a transition from the Cretaceous greenhouse to icehouse earth of today. At the start of the Tertiary, Antarctica was ice-free. Oxygen isotope palaeotemperatures suggest that the nearby southern oceans were quite warm, perhaps 18 °C at the surface, atmospheric CO_2 levels were well above those of today and forests were flourishing even at very high latitudes (Fig. 5.2; Frakes et al. 1992; Williams et al. 1993, p. 21; Zachos et al. 2001; Miller et al. 2011).

The penultimate cooling of the world's oceans, as interpreted from $\delta^{18}O$ data, started during the early Eocene climatic optimum (≈50–52 Ma) when the measured $\delta^{18}O$ reached a minimum for the Cenozoic with equivalent deep ocean temperatures of +12 °C. The Early Eocene (around 55–50 million years ago) is thought to be the warmest climate phase of the last 100 million years and this warmth is usually thought to be caused by unusually high atmospheric CO_2 conditions, possibly four times current levels and a time when nahcolite was a commonplace sodium carbonate evaporite (Huddart and Stott 2010). Melting of seafloor methane hydrates may also played a role in the development of the Eocene climatic maxima.

From ≈50 Ma until the early Oligocene the world's ocean seems to have steadily cooled. The reasons for this cooling and the onset of the current icehouse mode are a topic of ongoing debate. All agree the underlying cause is plate tectonics. Interpretations as to mechanism are split between proponents supporting changing oceanic circulation, driven by a widening Southern Ocean and a closing Tethys as the main driving mechanism, versus those arguing that falling CO_2 levels was the major driver driven[2] by the rising

[1]Prior to 2009 the proposed base of the Pleistocene (Quaternary was at 1.805 Mya, long after the start of the major glaciations of the northern hemisphere. The ICS (International Commission on Stratigraphy) then proposed to abolish use of the name Quaternary altogether, which appeared unacceptable to the International Union for Quaternary Research (INQUA). In 2009, it was decided to make the Quaternary the youngest period of the Cenozoic Era with its base at 2.588 Mya and including the Gelasian stage, which was formerly considered part of the Neogene Period and Pliocene Epoch.

[2]Major climatic cycles are possibly related to plate tectonics; every time the continents are pulled apart huge quantities of volcanic water, carbon dioxide and methane are released into the atmosphere and greenhouse climates prevail on Earth. On the other hand, when continents come together and mountain ranges are created, the mountains are eroded, new soils form and remove CO_2 from the atmosphere, these soils are also eroded and the CO_2 becomes locked in ocean floor sediments. So when atmospheric CO_2 is low, glaciation occurs (as in the Late Ordovician about 440 mya and in the Permo-Carboniferous at about 310–270 mya.)

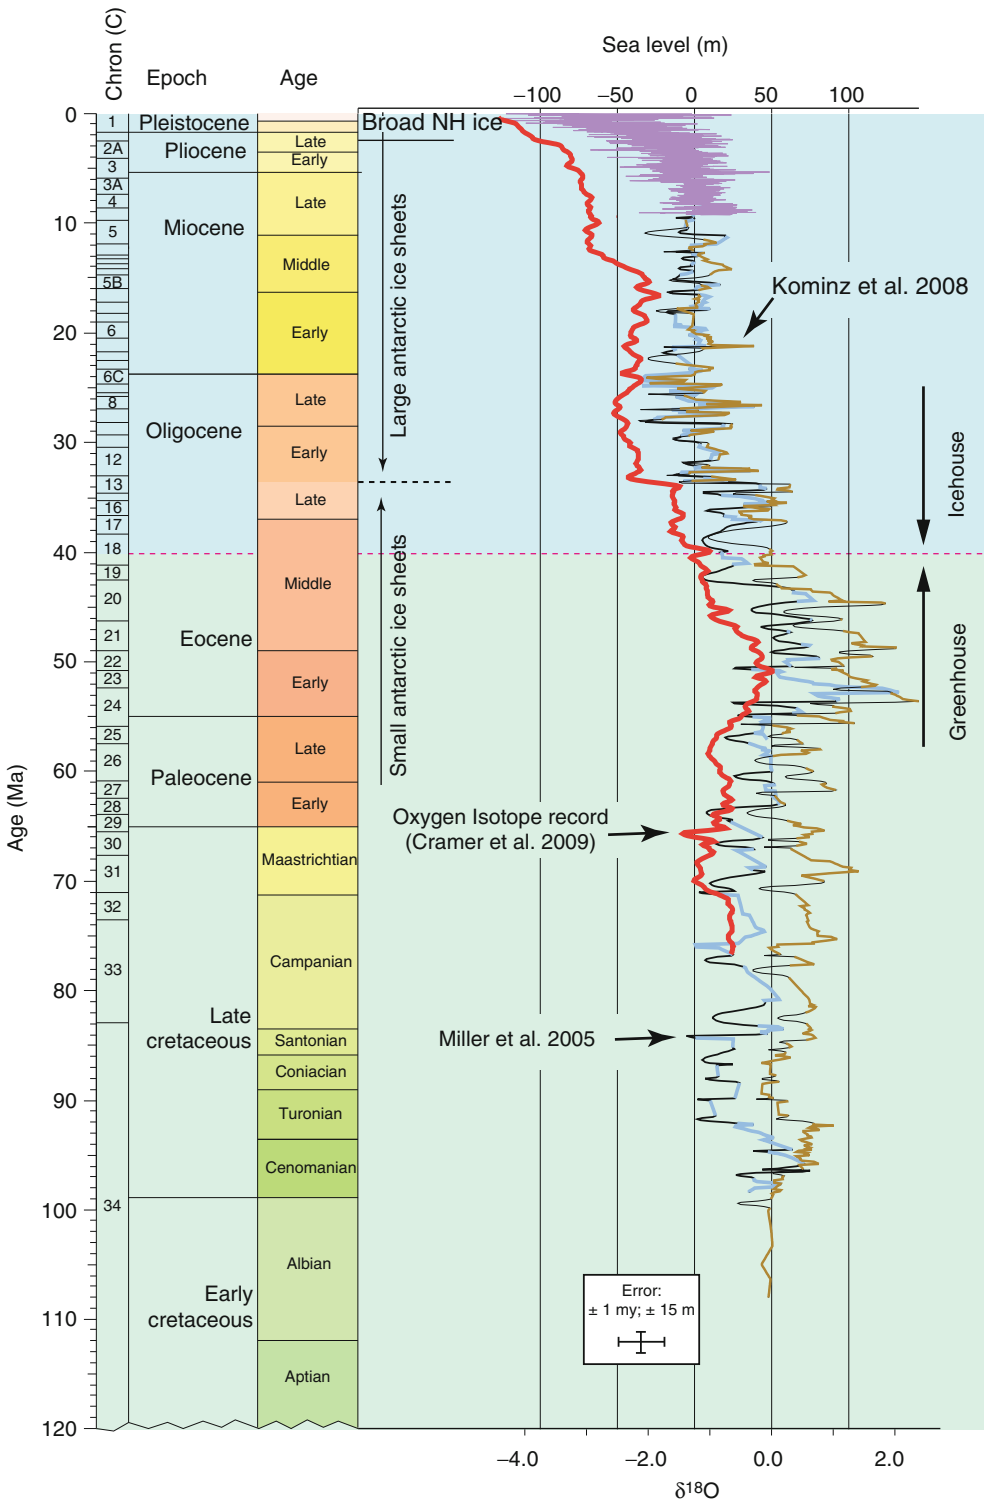

Fig. 5.2 Sea level estimates derived from New Jersey that provide a record of global sea level for the past 100 million years (After Miller et al. 2011; Kominz et al. 2008). The figure also shows the oxygen isotopic world synthesis of Cramer et al. (2009). *NH ice* Northern Hemisphere ice sheets, *Ma* millions of years ago

Himalayas and burial of significant quantities of terrestrial biomass. The post-Cretaceous lessening of oceanic ridge activity may be another contributing factor to gradual Cenozoic cooling.

Around 50 Ma Australia began to drift north, opening the Southern Ocean Seaway and so establishing the beginnings of the Antarctic Circumpolar Current (ACC). From that time the ACC completely encircled the Antarctic continent. It acted as a barrier that prevented warm currents of the lower latitudes ever reaching the Antarctic coast and reduced the transport of "sensible" heat to the higher latitudes, so contributing to the growing polar cold. The tropics were little

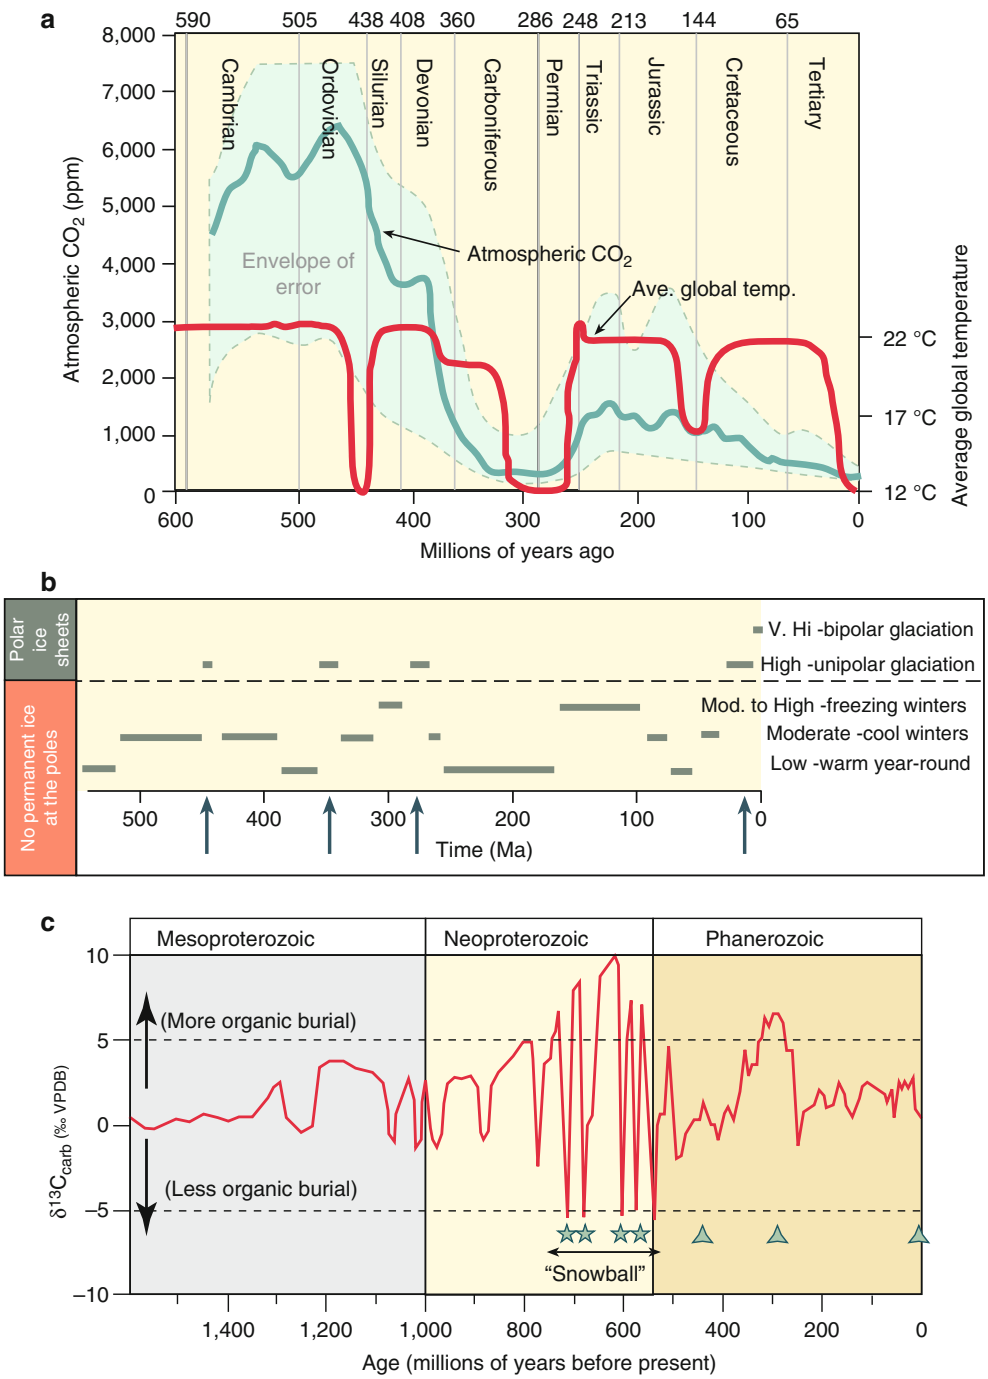

Fig. 5.3 Climate change across geological time. (**a**) Global temperature and atmospheric CO_2 change over time (After Berner 1999). (**b**) Pole to Equator climatic gradient through time, arrows indicate episodes of polar ice (Replotted from data in Boucot and Gray 2001) (**c**) Secular variation in Carbon-13 content of shallow marine carbonates over the last 1,600 million years – see also Fig. 2.33 (After Kah et al. 2001)

effected and so the equator-pole temperature gradient began to increase, invigorating the intensity of worldscale atmospheric circulation.

Throughout the Paleocene and the Eocene it was still possible for the major equatorial ocean currents to encircle the globe, passages were still open between the Americas, between India and Europe, and between Australia and Indo-China. Worldwide climate was still generally warm. A powerful western equatorial drift passed through the open remnants of the Tethyan Ocean and allowed ongoing transfer of tropical heat to the polar regions. Closure of the Tethys, as India approached the Eurasian continent, ended circum-equatorial circulation and forced circulation south of Africa into the temperate zone. This early Eocene event is the first of four major steps that punctuate the longterm history of Cenozoic cooling (McGowran et al. 1992).

But even when the Tethyan connection closed, the initial effect on Antarctica's cool, but not frigid, climate was

relatively minor. As the Eocene progressed, the Southern Ocean continued to widen but the ACC circulation did not develop to its present intensity because of shallow barriers or seafloor baffles between Australia and Antarctica (East Tasman Rise) and in the region of the Drake Passage between South America and Antarctica. Even so, high latitude cooling continued to increase, driven forward by the ongoing widening of the Southern Ocean.

At the end of the Eocene, around 33–34 Ma, there was a major cooling episode (Fig. 5.2; Lawver and Gahagan 2003). High latitude deep water temperatures in the Southern Ocean dropped 4–5 °C, probably indicating the development of freezing conditions at sealevel around Antarctica and the first formation of significant Southern Hemisphere sea ice. Land temperatures over high latitudes in both hemispheres probably dropped by 10 °C. With the opening of the Drake Passage around 32 Ma to water depths greater than 2,000 m, South America completely parted from Antarctica. This enhanced the intensity of the ACC, so producing further cooling and formation of greater volumes of ice on the Antarctic land mass (Lawver and Gahagan 2003). The very rapid cooling of ocean temperatures at the end of the Eocene probably reflects a positive feedback between growing Antarctic ice and an increase in the world's albedo (increased reflection of sunlight).

The continuing widening of the Southern Ocean and the complete floundering of Drake Passage around 25 Ma allowed the ACC to begin to develop to its full intensity, including the set up of cold bottom water circulation, which effectively cut off Antarctica from any warming equatorial influences. By the Miocene, the ACC had attained levels of flow volume comparable to those of the Quaternary (Rack 1993).

Widespread thick ice sheets covered Antarctica by the Middle Miocene and ice sheets moved out onto the continental shelf by the Late Miocene, as indicated by ice-rafted continental debris in deep oceanic sediments around much of Antarctica at that time (Lawver and Gahagan 2003). It heralded the arrival of permanent thick glacial ice at sealevel, a circum-Antarctic condition that persists today. Significant cooling is seen in the oceanic paleotemperature curve at this time. It is still not well understood why it took until the Mid-Miocene for the Antarctic ice to reach extents similar to those of today, long after the development of the ACC in the early Miocene. But the associated effects on equatorial-pole temperature gradients are clear. The resulting strengthened winds intensified Mid-Miocene ocean water circulation, which in turn was associated with increased upwelling and biological activity in many of the world's oceans.

A further global cooling took place in the Late Miocene when world sealevel dropped a further 40–50 m (Kennet 1982). This regression, in association with local tectonic activity, contributed to the isolation of the Mediterranean from the rest of the world's oceans. It perhaps helped deposit huge thicknesses of salt in giant shallow lakes across the lower parts of the former Mediterranean seafloor in the MSC. But this widely accepted correlation of an icesheet-induced major sealevel fall and widespread evaporite deposition in the Mediterranean was questioned by Hodell et al. (2001) who defined a Miocene glacial period that lasted from ≈6.26 to 5.50 Ma. It consisted of 18 glacial-to – interglacial oscillations that were controlled by the 41-kyr cycle of obliquity. Although the intensification of polar glaciation at 6.26 Ma may have contributed to the restriction of the Mediterranean, it preceded the depositional onset of the lower Messinian evaporite unit at 5.96 Ma by some 300 kyr. It seems that the initiation of evaporite accumulation in the Mediterranean evaporite basin, the world's last "saline giant," was largely tectonic and not glacio-eustatic.

However, Pérez-Asensio et al. (2013) argue that although ongoing tectonic uplift had reduced the depth of the Rifian Corridors considerably in the Late Miocene it was not sufficient to account for the complete hydrographic of the corridors. They note that at 5.97 Ma, a global cooling event occurred with an associated glacioeustatic sea-level drop, which they estimated to be ≈60 m (Fig. 5.48). This they infer was sufficient to restrict the uplifting Rifian Corridors and to trigger the onset of hydrographic isolation that created the Messinian.

Whatever the ultimate cause of the Messinian isolation, the volume of oceanic salt deposited in the Mediterranean during the salinity crisis is 40 times that which would be deposited if the present Mediterranean evaporated to complete dryness, illustrating that there was a phreatic inflow of subsurface seawater brines into the drawndown Mediterranean depression. Removal of this volume of salt from the world's oceans lowered the salinity of the open ocean water by 6 %. As less saline seawater freezes at a higher temperature, this in turn fed back into global climate by allowing yet more sea ice to develop in higher latitudes, so further reinforcing high latitude cooling.

After a slight warming in the early Pliocene, conditions cooled still further. As North and South America united across the Panama Isthmus, late Pliocene (around 3 Ma) climatic conditions in the Northern Hemisphere had cooled to where ice-rafted debris was being deposited in deep water sediments of the Northern Atlantic. By 2.4 Ma, soon after the beginning of the Quaternary, permanent moderate-sized ice sheets characterised the high latitude lands of the Northern Hemisphere. This marked the beginning of a climatic phase characterised by the repeated waxing and waning of polar ice sheets in the high latitudes of both the Southern and Northern Hemispheres, further enhancing high amplitude and high frequency changes in sealevel and further intensifying the alternation of warmer (interglacial) and cooler (glacial) climatic episodes.

By the Matuyama magnetic chron (0.78–1.77 Ma) the warm to cool climatic alternations followed a periodicity of 41 ka (Williams et al. 1993). This is equivalent to the repeating cyclicity in the obliquity of the earth's axis in terms of the plane of its ecliptic (21.8–24.4°). From 0.8 Ma the amplitude of climatic fluctuations recorded in marine sediments seems to increase, reflected in the increased sizes of the cold phase ice sheets. The periodicity of climatic fluctuations in this time also appears to increase to a cycling time of 100 ka. This correlates to the eccentricity of the earth's orbit around the sun as it varies from nearly circular to somewhat elliptical. This 100 ka periodicity, with sealevel amplitudes of more than 100 m, is especially dominant in the last 400 ka of world history, but superimposed on this are the 41 ka cycles and 23 ka precession cycles of the earth's equinoxes (Fig. 5.1; Miller et al. 2011).

Rapid climatic change and high amplitude high-frequency glacio-eustatically-driven changes in sealevel are the hallmarks of the Quaternary, and probably most of late Neogene. Relative to the previous 200 million years of climatic history, the climatic/eustatic fluctuations of the Quaternary and the Neogene were unprecedented in terms of their speed and amplitude. For example, the mean annual temperature difference between the last glacial maximum (18 ± 3 ka) and the early Holocene climatic optimum (9 ± 3 ka) is around 10 °C in many temperate land areas of the world (Williams et al. 1993; p. 223). This is roughly equivalent to the inferred longterm drop in temperatures between the early Eocene and early Pliocene in these same regions. The surface of the Southern Ocean cooled by 10–15 °C over this 40 million year period. Temperature drops of a similar magnitude occurred in eastern Australia over the 100,000 year time span that separates the last interglacial from the last glacial maximum in this region. Similar high frequency changes typify the Quaternary in many other parts of the world.

Prior to our present "icehouse" climate mode of the last 30 million years, the last time when there were widespread polar ice sheets, high amplitude-high frequency sealevel fluctuations, and a similar "ice house" climate was the Permo-Carboniferous some 270–315 Ma (Fig. 5.3a, b). Prior to this we must go as far back as the Late Ordovician and then to the Neoproterozoic to see evidence of other worldwide "icehouse" conditions (Fig. 5.3). The late Ordovician glaciation (≈440 Ma) was unusual compared to the icehouse episodes that preceded and postdated it. Major glaciation was apparently confined to South America and Northwest Africa and nowhere else. Timewise, it is also the most contentious of the Phanerozoic icehouses. Brenchley et al. (1994) argue it was restricted to the Hirnantian and was some 0.5–1 m.y. long, rather than the 35 m.y. of earlier estimates. In terms of paleogeography, it probably defines the southern polar position of a uniting Gondwana. It was an Ordovician Antarctica equivalent, not associated with the breakdown of worldscale ocean circulation and it probably had no more than local climatic influence in a overall warming greenhouse world (Drury 1999).

In fact, in the last 600 million years the late Carboniferous to the early Permian (315–270 Ma) was the only time when atmospheric CO_2 and average global temperature were both as low as they are today. Even so, today's bipolar glaciation appears to be a unique icehouse scenario compared to the rest of the Phanerozoic (Fig. 5.3b). The obvious conclusion is that the last 20–30 Ma, and certainly the last 2.5 Ma of the Quaternary experienced climate and eustatic styles that are simply not representative of non-icehouse conditions covering the majority of Phanerozoic time.

Prior to the Phanerozoic, preceding Proterozoic icehouse regimes consist of at least three and maybe up to five glacial pulses between 900 and 550 Ma (Fig. 5.3c), the latter part of this interlude encompasses the notion of a completely ice-covered "snowball earth" (Fig. 2.50; Hoffman 2011; Hoffman et al. 1998; Eriksson et al. 2013). If real, this was a cryogenic system far more intense than the bipolar system of today, with its own unique climatic and sedimentologic implications. Prior to this Neoproterozoic icehouse, there is evidence of earlier worldwide glacial (icehouse) conditions at 2,200 Ma and possibly at 2,500 Ma. If snowball conditions did encompass the Neoproterozoic earth with an ice envelope, and ultimately lead to the Phanerozoic explosion of life, then the only possible "evaporite" salts that could have accumulated in snowball episodes would have been hydrothermal anhydrite in the vicinity of volcanic vents and spreading ridges, or cryogenic hydrohalite precipitates and volumetrically minor slushes of mirabilite and hydrohalite created during the formation of widespread sea ice. Hydrohalite ($NaCl{\cdot}2H_2O$) is the stable form of halite below temperatures of 0.1 °C, it is anhydrous at higher temperatures; hydrohalite has four times the volume of mirabilite in modern sea ice (Richardson 1976). The possibility of preservation of either mineral, other than as isolated pseudomorphs, along with ikaite in glacial meltwater deposits is zero.

The rapid melting of the global icesheets of Snowball Earth and the transition to widespread temperatures as hot as 50 °C during the formation of successive cap dolomites, along with the likely encroachment of shallow epeiric seaways via the return of continental glacial waters to the sea, would have encouraged the formation of widespread platform evaporites in association with the cap carbonates. Widespread megapolygonal tepees and/or salt karst does outcrop in the appropriate stratigraphic position in the Neoproterozoic dolomite capstones in Oman (pers. obs.) and atop the Elatina Shale in the Flinders Ranges of Australia. Defining the worldwide timing of such Neoproterozoic

evaporites and their dissolution residues may be an interesting test of the validity the "freeze and fry" climate conjectured for snowball earth.

Some megapolygons beneath cementstone layers have been interpreted in a very non-uniformitarian fashion by Snowball Earth proponents. The structures are tepee-like, but with unbroken crests and not thought to be true tepees (definition of Kendall and Warren 1987). One hypothesis is that they are mechanically-formed chevron-like wave structures indicative of wave periods of 21–30 s and formed by consistent flow velocities of up to 20 m/s in megawinds blowing across oceans with unlimited fetch (Allen and Hoffman 2005). An alternative hypothesis, by Lamb et al. 2012, agrees that the megapolygons are giant wave ripples but not indicative of mega-winds. Rather they are restricted to episodes of cap carbonate and are a consequence of the unusual mode of carbonate precipitation tied to a global carbon cycle and climate perturbation unprecedented in Earth history (Fig. 2.49).

Clearly, our present icehouse climatic regime does not encompass all climatic and sealevel regimes that have occurred across geological time. The present style of icehouse climate dominates the amplitude and frequency of sealevel changes for the past 20–30 million years. Greenhouse climate and its associated eustasy, which typifies much of earth history, is not tied to icesheet hydrologies and volume changes. Thus we must not assume constancy in glacioeustasy as the dominant control on Phanerozoic or Precambrian sedimentation, especially in biochemical and evaporite sediments. As Charles Dickens once wrote on contemporary time, "It was the best of times, it was the worst of times." In terms of marine evaporite deposition, a lack of "strict uniformitarianism" leads to a paucity of Quaternary analogs for most large marine-fed evaporite deposits.

Varying Extent of Ancient Evaporites

Nowhere in Quaternary depositional systems is there Holocene proof of a desiccated ocean basin, yet in the Late Miocene (Messinian) salinity crisis a series of subsealevel saline depressions on the Mediterranean floor filled the lowest parts of the Mediterranean with 2-km-thick sequences of halite and gypsum in less than 300,000 years (e.g. Balearic Basin; Fig. 5.4). The various Messinian evaporite pods were laid down on the floors of a chain of shallow saline seas that were more than a 1,000 km long, more than 2,000 km across, with brine surfaces more than 2,000 m below ambient sealevel. They formed in the lowermost parts of a hyperarid to semiarid seafloor desert that extended over much of the current extent of the Mediterranean, stretching from Spain to Israel and from northern Italy to Libya (Rouchy and Caruso 2006; Cita 1983; Hsu et al. 1973).

Similarly, there is no Holocene proof of evaporitic brine-reflux dolomitisation and the associated salt seals, simply because there is no Holocene example of a whole carbonate platform being covered by an evaporite deposit. Yet in most ancient evaporite basins, reflux dolomitisation was a widespread and pervasive mechanism that yielded substantial intercrystalline porosity in platform carbonates beneath laterally continuous beds of platform evaporite salts (Chap. 10).

Many thick ancient salt accumulations are underlain or overlain, and sometimes intercalated, with thick widespread marine carbonate beds. A major dilemma facing geologists interpreting such strata is the lack of Quaternary marine counterparts with comparable depositional scale and unit thickness (Figs. 5.4 and 5.5). All thick Quaternary salt deposits are medium-scale accumulations of continental lacustrine evaporites in tectonically active settings (Table 5.2;

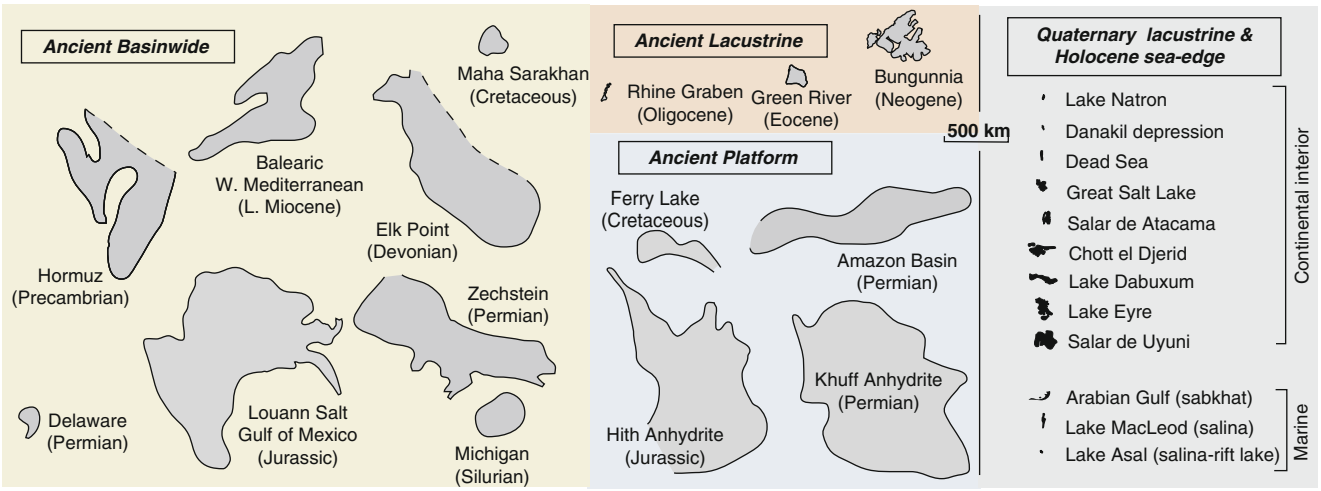

Fig. 5.4 Area contrasts of Quaternary and ancient evaporites

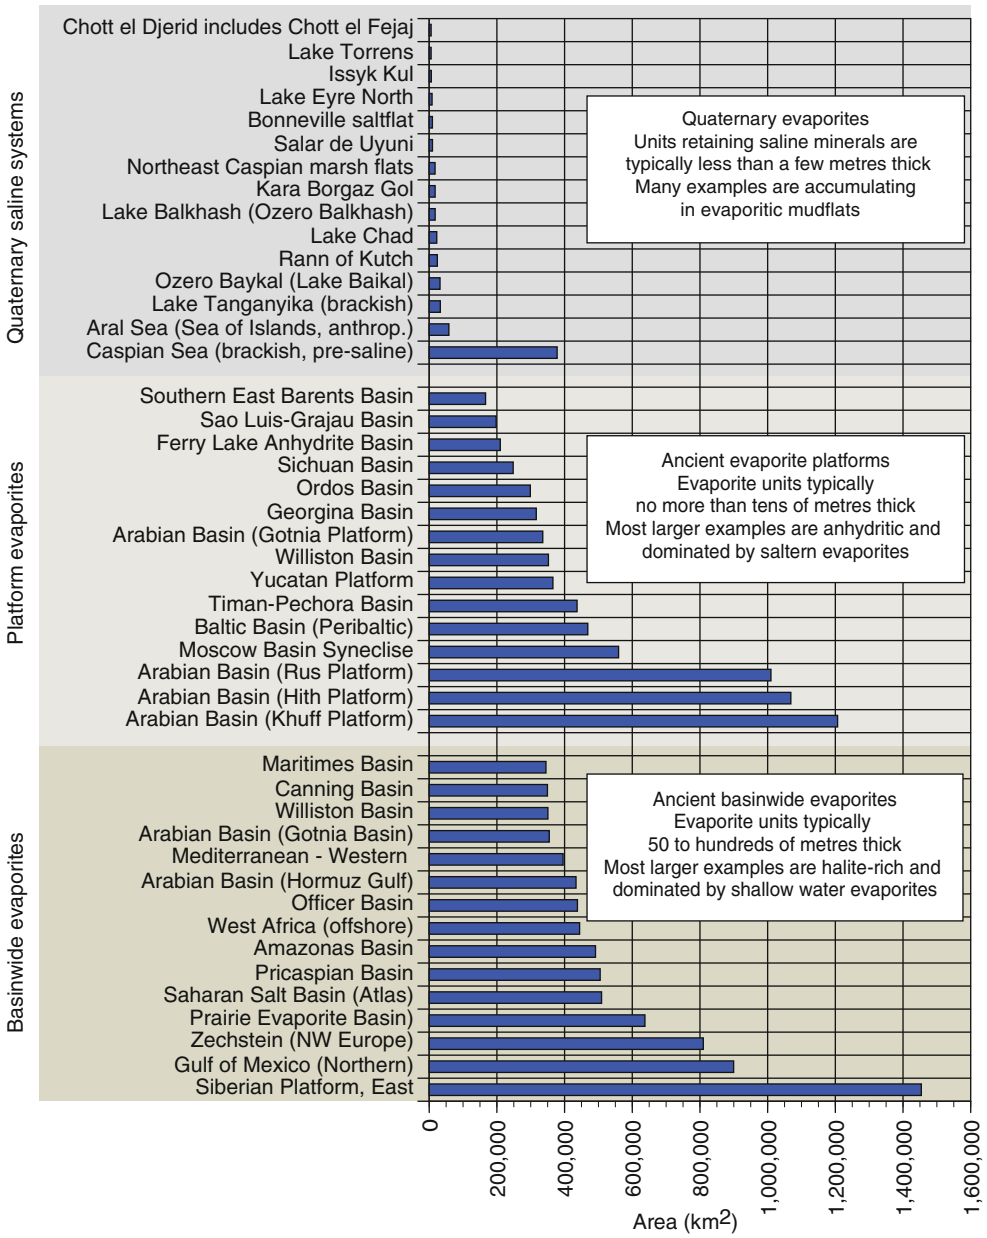

Fig. 5.5 Plots of the areas of each of the 15 largest examples of Quaternary lacustrine, Platform evaporites and basinwide evaporites (Extracted from centroid areas listed in SaltWork version 1.6)

Chaps. 3 and 4). The ancient evaporite record entrains much larger volumes of salts precipitated in platform or basinwide settings tied to a seawater feed (marine-fed evaporites), as well as ancient continental lacustrine deposits (continental evaporites) with similar thicknesses and extents to the Quaternary examples discussed in Chaps. 3 and 4 (Fig. 5.3). Larger examples of modern evaporites are dominantly supra-sealevel nonmarine lacustrine deposits, while ancient evaporites are subsealevel marine-fed systems. Yet, the first-order latitudinal distribution of modern and ancient evaporite basins is similar. That is, the dominant world-scale control on evaporite distribution is climatic and largely the result of the presence of Hadley cells (Figs. 2.1 and 5.6; Edwards et al. 2006).

As we saw in Chap. 2, Hadley cells are a planet-scale atmospheric circulatory response to the varying intensity of solar irradiation from the equator to the poles. Unfortunately, the climate of the Holocene and the Pleistocene (Quaternary) is not well suited to act a baseline for the extent and distribution of arid Phanerozoic climates. The last 8,000–10,000 years is an interglacial and, based on world $\delta^{18}O$ curves in deepsea sediments, is a state typical of some 10 % of the icehouse climate of the past few million years (Fig. 5.1; Hay et al. 1997). The current interglacial, and older counterparts over the past 780 ka, are highstands and times of relative sea-level stability, some tens thousand years long, occurring after rapid 100 m-scale rises from the lowstand of the preceding glacial maximum. The last glacial maxima

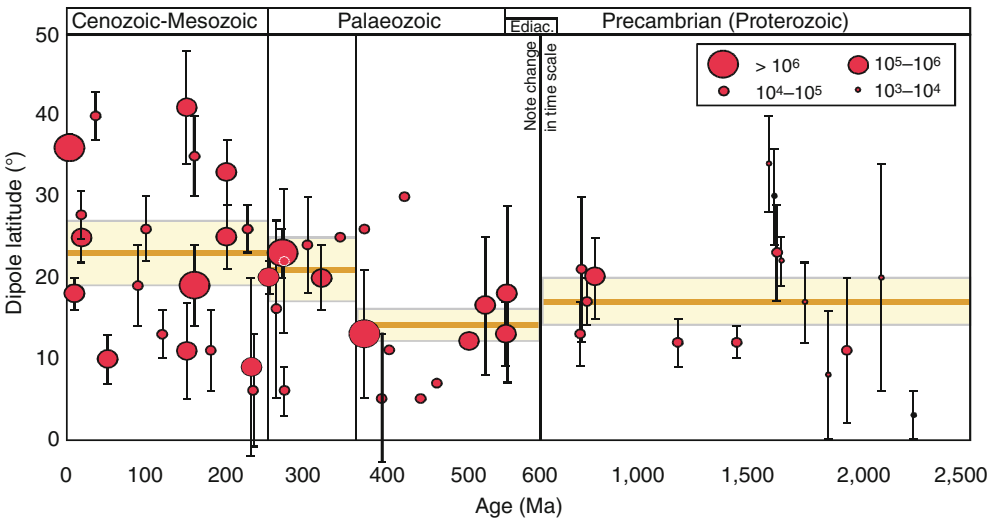

Fig. 5.6 Evaporite palaeomagnetic latitudes through time, individual basin plots are schematically scaled to evaporite volume (*circle sizes* are scaled in km³ as in the *inset*) and shown with 95 % uncertainty limits in palaeolatitude. Volume-weighted means (*solid brown bars*) and 95 % error envelopes (*shaded light yellow*) are broken down into four age intervals. Note the change in time scale at 600 Ma (After Evans 2006)

occurred some 18,000 years ago. The last few million years of intense icehouse-mode climate, is a period of glacial-interglacial alternations when physical geologic processes operate at unusual rates compared to the bulk of the Phanerozoic and when much of the earth's geochemical system is not in a steady state.

Times of expanded ice sheets, with their more intense ice sheet-induced atmospheric circulation cells, are probably the least representative states for the world's Phanerozoic climate. Interglacial periods within icehouse mode, like the Holocene, are perhaps a little closer to the "average" Phanerozoic climate. But today's climate is still a long way

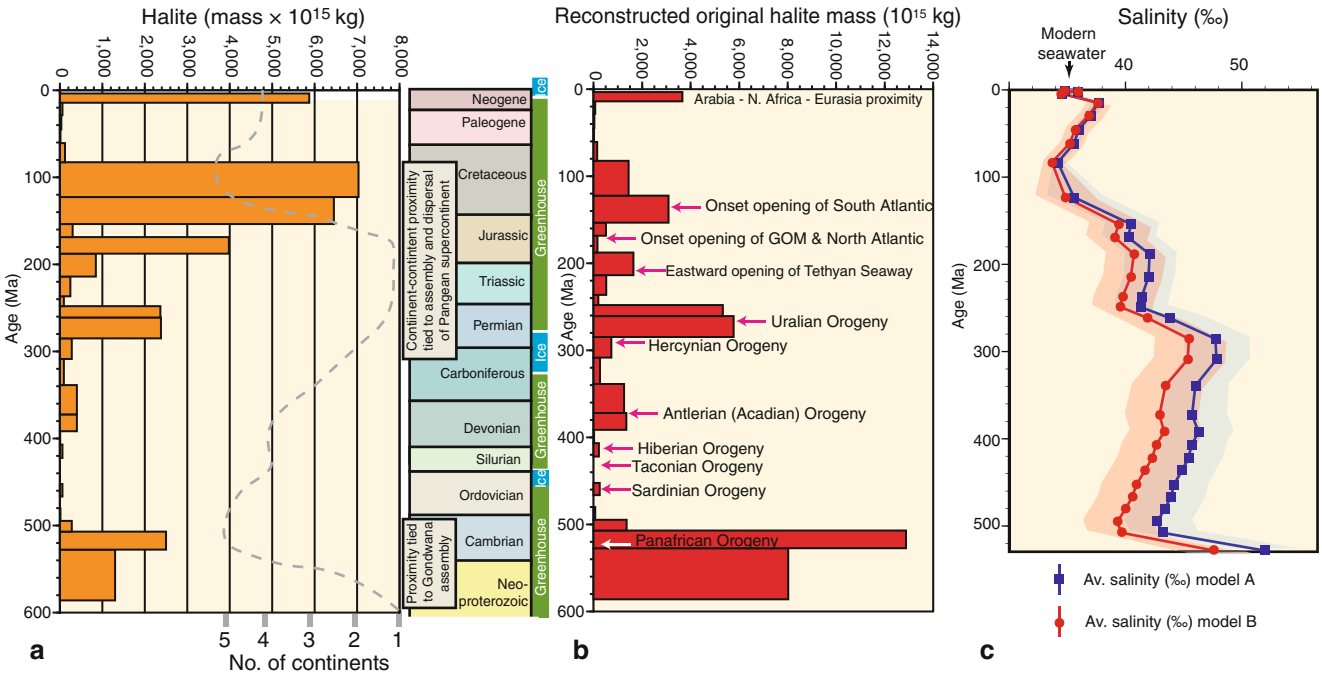

Fig. 5.7 Phanerozoic evaporites in Deep Time (After Warren 2010). (**a**) Mass of Phanerozoic halite currently residing in basin (After Hay et al. 2006; Number of continents curve from Condie 2004). (**b**) Reconstructed mass of recycled Phanerozoic halite lost by combination of erosion and dissolution (After Hay et al. 2006). Time of halite precipitation as influenced by accretion and disintegration (dispersal) of Pangean supercontinent as well as other orogenic and tectonic events is also shown (greenhouse after Fischer 1981; tectonics after Haq and Van Eysinga 1998; Haq and Al-Qahtani 2005). (**c**) Oceanic salinity changes for the last 500 my (After Hay et al. 2006)

from a climate more representative of the bulk of Phanerozoic time, when the polar regions were free of permanent ice and world climate and the eustatic frequencies and amplitudes were in "greenhouse" not "icehouse" mode (Fig. 5.7).

In greenhouse times there are no widespread continental or polar ice sheets and the planet's meridional temperature gradient is much less steep than it is at present (Table 5.1). For the past few million years, since the initiation of permanently grounded Antarctic ice sheets in the Miocene (≈12 Ma) and possibly as long ago as the Eocene (≈33 Ma), the distribution and effects of broad-scale atmospheric circulatory belts (including the Hadley cells) have been modified by the waxing and waning of polar ice. During glacial periods the expanded circum-polar ice sheets act as frigid plateaus, forcing a stronger meridional temperature gradient, so altering significant portions of the world's atmospheric circulation, as well as creating their own ice-cap associated pressure systems.

Whenever ice-caps expand, the Hadley-related circulation belts are pushed and compressed toward the equator; this occurred numerous times during glacial maxima of the current icehouse climate mode. These ice-sheet forced climatic oscillations have a marked effect on sediment styles in Quaternary deserts. Many halite-entraining continental playas and pans have sedimentary records extending back a few hundred thousand years and entrain alternating water-full versus drier stages (e.g. Baker et al. 2001a; Hesse et al. 2004; Yan et al. 1998). In contrast, the world's marine-fed subaqueous[3] deposits are Holocene, with little or no preservation of Pleistocene salts. There is a similar lack of Pleistocene salts preserved in the type area for modern marine-fed evaporitic mudflats, or sabkhas, in the Arabian Gulf (Warren and Kendall 1985; Warren 1991). The largest such Holocene marine deposits fill coastal salinas with halite or gypsum beds up to 10 m thick along the semi-arid western and southern coasts of Australia. These are marine-seepage sumps that can be up to tens of kilometres wide (areas up to 2,500 km^2) with extents and thicknesses much less than contemporary continental evaporite deposits (Fig. 5.4). Even the largest Holocene marine coastal deposits pale in size and volume when compared to ancient marine-fed accumulations (Fig. 5.5), although they are excellent natural environments to study the sedimentary textures of precipitation in relation to brine stability and permanence, and to document early alteration mechanisms.

[3]The term "marine-fed" refers to the dominant source of the inflowing groundwaters at the time the evaporites are deposited, not to the presence of a hydrographic connection to the ocean, which these deposits typically lack.

The largest accumulations of Phanerozoic marine-fed salts are basinwide deposits, which were laid down in hydrographically-isolated subsealevel depressions, created by divergent, convergent and intracratonic (intraplate) tectonics. Their sediment volumes are not evenly distributed across the Phanerozoic and times of widespread salt deposition correspond to falls of salinity in the world's oceans (Fig. 5.7; Hay et al. 2006). That is, the greatest falls in oceanic salinity are related to major extractions of NaCl into young oceans (extensional continent-continent proximity) or foreland ocean basins (compressional continent-continent proximity; Warren 2010).

Phanerozoic seas were at their freshest in the Late Cretaceous some 80 Ma, not today. This is because a substantial part of the Mesozoic salt mass, which was deposited in the megahalites of the circum-Atlantic and circum – Tethyan basins, has since been recycled back into today's ocean via a combination of dissolution and halokinesis. Periods characterised by marked decreases in salinity (Fig. 5.7b) are defined by times of mega-evaporite precipitation, while periods of somewhat more gradual increases in salinity define times when portions of this salt were recycled back into the oceans (compare Fig. 5.7b, c).

The last major extractions of salt from the ocean occurred during the late Miocene in the various Mediterranean Messinian basins created by the collision of Eurasia with North Africa. This occurred shortly after the large-scale extraction of water from the ocean to form the ice cap of Antarctica and the deposition of the Middle Miocene Red Sea rift evaporites. Accordingly, salinities the early Miocene were between 37 and 39‰ compared to the 35‰ of today (Fig. 5.7c). The preceding Mesozoic period was a time of generally declining salinity associated with the salt extractions in the opening North Atlantic and Gulf of Mexico (Middle to Late Jurassic) and South Atlantic (Early Cretaceous).

Across the Phanerozoic, after deposition of the Hormuz/Ara salt successions at the Cambrian-Precambrian boundary, the next major salt extractions occurred during the Carboniferous – Permian and were related to the final accretion of the Pangaea supercontinent[4] (Fig. 5.7). During the intervening Palaeozoic periods there were only a few large extractions of halite from seawater, mostly in intracratonic sag settings. The Hay et al. (2006) model suggests that the Palaeozoic was a time of relatively stable, but slowly increasing, salinity ranging through the upper 40s into the lower 50s (in parts per thousand).

The somewhat elevated Palaeozoic ocean salinities, (c.f. 35‰ today) implies that arid-zone marine-fed evaporites and evaporitic mudflat carbonates perhaps formed more readily from concentrating seawater brines in the early Phanerozoic epeiric seas. That is, for much of the Palaeozoic and part of the Mesozoic, marine-fed evaporation started from a higher base, compared to the less saline oceans and narrower steeper icehouse continental shelves of today (less freeboard). This implies that halite saturation was more easily attained from Palaeozoic ocean waters, and yet the volumes of extracted marine halite were low for most of the Phanerozoic (300–500 mya) (Fig. 5.7). Perhaps conditions were less suitable for world-scale salt extractions at that time due to the more dispersed nature of the major continental plates and the associated paucity of locales of plate-scale continent-continent proximity. Most Palaeozoic megahalites accumulated in epeiric intracratonic sags (distal effects of orogeny) rather than as deposits along a cratonic periphery (see later basinwide and platform evaporite discussion).

When estimates of the volume of salt being recycled back into the oceans are added to volumes of actual salt in the various megahalite beds of the world an interesting picture emerges of actual precipitated salt volumes at various times of enhanced evaporite deposition (Fig. 5.7b; Hay et al. 2006). The greatest volumes of halite still remnant in sedimentary basins are defined by Jurassic and Cretaceous successions. Deposition was largely within the circum-Atlantic salt basins and tied to the early rift to drift transition during the opening of the Neo – Tethys and the northern and the Southern Atlantic. Yet when recycled halite estimates are added, these Mesozoic deposits are lesser volumes compared to the Permian and Neoproterozoic/Cambrian successions, with the greatest volume of salt deposited across the past 600 million years occurring in the various Neoproterozoic-early Cambrian Hormuz and Ara halite deposits of the Middle East (Fig. 5.7). In the Phanerozoic, the period from the Permian through Jurassic generated the greatest volumes of both halite and total evaporites (Fig. 5.7). This corresponds to the time of the assembly and disassembly of the Pangaean supercontinent. A supercontinent is the culmination of a mega-longterm (300–600 million year duration) tectonic pattern of continental accretion and fragmentation, whereby a supercontinent gradually assembles then rifts and drifts apart prior to reassembling (e.g. Veevers 2004). Substantial accumulations of basinwide evaporites are most likely to accumulate on the floors of isolated subsealevel depressions at times of close proximity of drifting landmasses. This occurs both during the building of the supercontinent and then during times of its early disassembly. Ongoing marine drawdown incursions into marine-fed arid-zone subsealevel basins takes place both as a supercontinent assembles (collision and foreland basins) and then as it unzips (rifts and sag basins). Intracratonic evaporite basins, the third setting of substantial ancient salts typically form in the continental interior in zones of distal crustal flexure in response to tectonic interactions at the continent margins (see later).

[4] A widely accepted definition of the term "supercontinent" is that it describes an assembly into a single landmass of all, or nearly all, the Earth's continental blocks (Bradley 2011).

Marine platform evaporites are the other major type of ancient marine-fed salt accumulation. They formed on continental margins throughout much more of Phanerozoic time than basinwide evaporites. They are characterised by bedded units of calcium sulphates (with lesser halite), typically 10–50 m thick and interbedded with marine carbonates. Stacked platform sections with this style of accumulation encompass depositional time frames of ≈1–10 my. Basinwide evaporite fills tend be thicker (>100 m), more halite prone and purer than platform evaporites and to accumulate rapidly across time frames of less than a million years. Platform evaporite occurrences are largely tied to times in earth history when climate was in greenhouse mode. Hence, the wider extents, greater depositional and diagenetic diversity and greater thicknesses of Phanerozoic marine-fed evaporites (Pre-Quaternary) reflects two sets conditions not actively influencing modern marine evaporites:

- *Warmer climates of greenhouse earth* creating wider latitudinal distributions of reefs, shoal-rimmed platforms and epeiric seaways under styles of eustatic fluctuation that were more suited to extensive evaporite deposition in the isolated backreef and lagoon.
- *Set up of the correct tectonic and climatic conditions* for the hydrographic isolation of large subsealevel tracts in a tectonic depression where marine groundwater feed was the dominant source of solutes onto the arid basin floor.

Study of ancient marine evaporite deposits underscores limitations inherent in the strict actualistic application of the Law of Uniformitarianism. Processes and textures of deposition and early diagenesis can be studied in modern settings (as detailed in Chaps. 1, 2, 3 and 4), but current climatic eustatic and tectonic interactions do not encompass all the levels of climatic and tectonic variation that have occurred across deep time.

Building Blocks of Ancient Salt Beds

Whatever an ancient evaporite basin's regional or tectonic setting, the depositional signature can be broken down into three main building blocks: (1) Mudflats (with sabkhas, salinas and saline pans), (2) Salterns and, (3) Deeper water slope/basin deposits (Table 5.3; Fig. 5.8).

Evaporitic mudflats form laterally extensive strata composed of stacked, shoaling-upward, matrix-dominated units (1–5 m thick). The mudflat package is typically widespread and readily correlatable across scales of up to hundreds of kilometres, but individual evaporite beds or layers within the package are not easily traced across the same lateral extent. Salts accumulate as a mosaic of dry and saline mudflats (sabkhas) separated by local brine-filled depressions (salinas/salt pans) in both marine-fed and continental settings. Much of

Table 5.3 Characteristics of depositional systems that define ancient evaporite deposits

	Evaporitic mudflat	Saltern	Slope and basin
Brine depth and stability	Ephemeral shallow brine sheet to subaerial	Longterm brine sheet to permanent shallow seaway	Permanent brine lake or sea deeper than 2–10 m up to hundreds of metres
Dominant evaporative/precipitation mechanism	Capillary evaporation, wind-blown thin brine sheets	Solar concentration of permanent surface brine mass, typically density stratified for at least part of its annual depositional cycle	Solar concentration with laminites in density stratified bodies, massive coarsely crystalline in unstratified brines
Textures	Displacive and replacive capillary salts, chicken wire and nodular textures, skeletal and pagoda halite, chaotic halite, haloturbation, Stokes surfaces, syndepositional micro-karst cements, eolian silt and sand ripples in evaporitic beds	Bottom nucleation, growth-aligned laminar to chevron textures crosscut by dissolution. Mechanically reworked beds with ripples, cross beds, gypsolites/halolites. Syndepositional exposure with water-table drawdown is not common, but does occur	Pelagic settling of cumulates and rafts, dense brine underflows, turbidity cur-rents in density stratified brines. Massive beds of inclusion-free coarsely crystalline bottom growths at the base of unstratified saturated brine bodies
Holocene depositional analogs	Sabkhat, salt pan, salina	Salt pan, salina	Some aspects of deepwater brine lakes (esp. Dead Sea)
Lateral extent and wireline correlation	Whole unit is laterally continuous, but it exhibits strong lateral variability in proportions and distributions of internal salt masses. Tendency to be matrix-rich and show a "spiky" signature in conventional wireline logs. Conventional wireline not calibrated to core can be confused with reflux-generated evaporite cements	Good lateral continuity of whole bed. In a marine shelf this can extend over the whole extent of underlying platform. Good lateral continuity of various internal salt horizons within a saltern unit. Tendency to be evaporite-rich with little matrix and show "blocky" signatures in conventional wireline logs, which can be similar to slope and basin	Good lateral continuity of bed. Internal salt units tend to be laterally continuous in deeper parts of basin and individual layers in laminites can extend for 50–100 km. Slope units tend to show less lateral continuity. Tendency to be matrix-poor. Conventional wireline signature similar to saltern. FMI can be distinctive

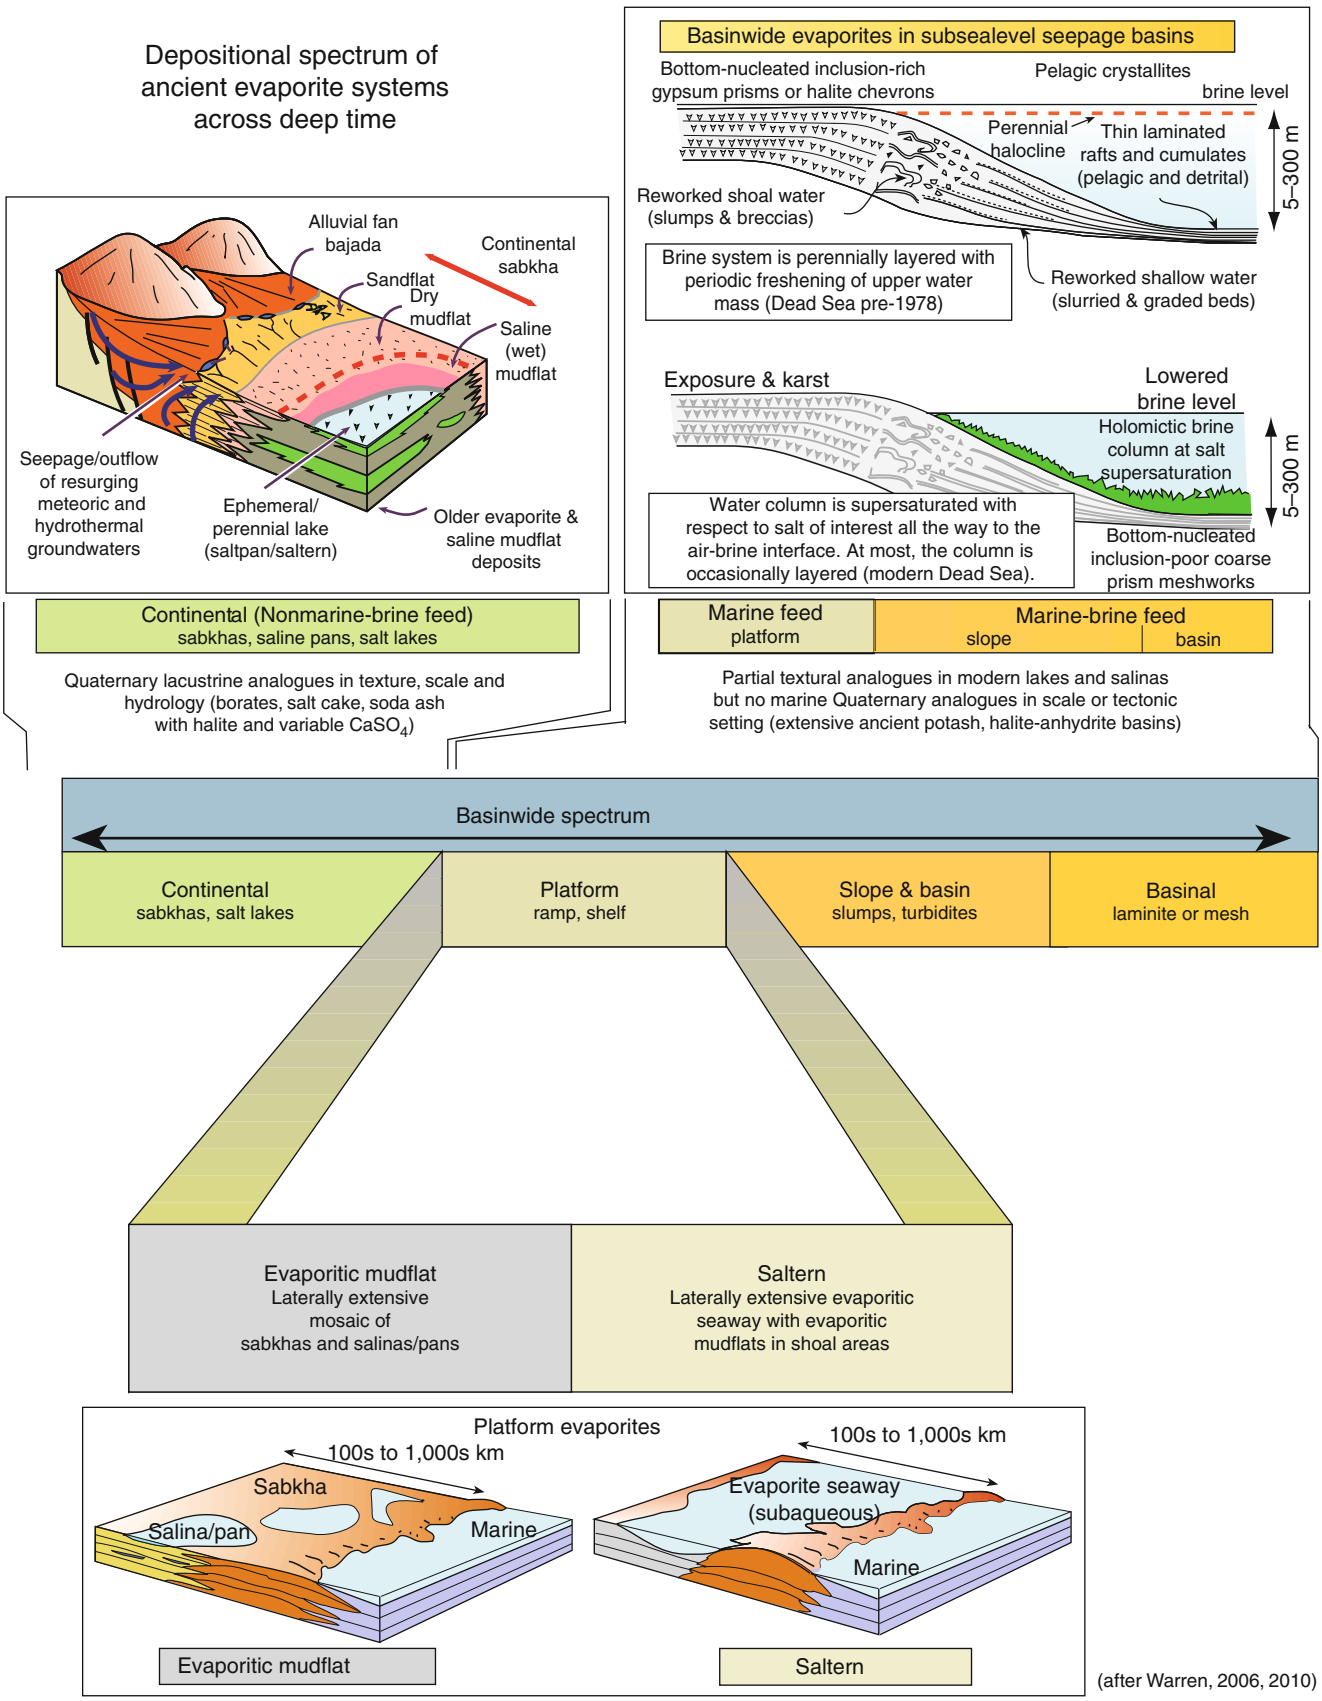

Fig. 5.8 Evaporite depositional settings in the context of time and process (After Warren 2010). Only continental lacustrine settings have same-scale ancient and Quaternary age counterparts

the matrix is deposited by storm-induced sheet floods, feeding sediments and surface waters onto the mudflat, both from the land and from the lake or seaway. Matrix on the "seaward" side tends to be carbonate mud, but typically lacks stenohaline marine fossils. On its "landward" side, beds are often interlayered with eolian or fluvial braidplain/sheetwash sediments (Fig. 5.8).

As stormwaters dry up on an evaporitic mudflat, windblown cm-thick evaporating brine sheets ooze and trickle back and forth atop the very flat mudflat surface. The vast extent of the ancient mudflat, and resulting high humidity in the overlying air, greatly slowed the rate of evaporation so that halite and gypsum were the dominant precipitates. Large parts of these ancient mudflats were sabkhat accumulating displacive and replacive capillary salts. Hence, much of an ancient evaporitic mudflat mosaic is characterised by nodular and enterolithic $CaSO_4$, pseudomorphs after discoidal gypsum, skeletal and chaotic halite.

Thin sheets of brine covered extensive tracts for weeks or months after a storm or flood, depositing thin layers and stringers of pan gypsum or halite a few centimetres thick atop the freshly deposited silts and sands. Later, once the brine sheet had dried up or was blown to another locality on the mudflat, it left be-hind a freshly deposited salt crust exposed to the vagaries of air, sun, wind, haloturbation and diagenesis. Ongoing exposure and deflation of the mudflat surface created Stokes surfaces, drove additional precipitation of intrasediment salts, exposed earlier carbonate crusts, altered gypsum to anhydrite, and meant the partial or complete dissolution of early brine sheet crusts. Throughout, the aggrading mudflat periodically captured influxes of eolian silt blown in from adjacent dry mudflats.

Somewhat longer-term ponding of brine sheets (months to years) occurred within local sumps where small shallow brine lakes (salinas and pans) formed atop the more regionally extensive mudflat. Water bodies were a few to tens of kilometres across and a few dm to metres deep (Fig. 5.8). Resulting salt crusts and subaqueous beds were purer and somewhat thicker (>1–2 m) than time-equivalent intervals of capillary salts accumulating in the subaerial mudflat surrounds. Such purer units are resolvable in the vertical perspective of a conventional wireline log, especially in an image log, but are not readily correlated from well to well due to limited lateral extents of individual pans or groundwater sumps. Overall the matrix-rich evaporite mudflat log is a distinguishable wireline signature. But, if it is not calibrated to core or to an image log, it is readily confused with units of open marine carbonate plugged by evaporite cements precipitated during brine reflux.

The term tidal-flat or peritidal evaporite is inappropriate in describing these gigantic epeiric/continental mudflats as large parts of the mudflat were not ever covered by tidal waters (only storm surges and sheet floods). Yet, Holocene marine-edge terminology is widely used by some sedimentologists in describing ancient evaporitic mudflats. They base its application on textural comparisons with the coastal sabkhas of Abu Dhabi. But as we saw in Chap. 3, nodular and displacive sabkha salts form in capillary settings ranging from continental lacustrine to coastal. Capillary salts, even in the classic sabkha, come mostly from resurging deeply-circulated groundwaters, a transport and emplacement mechanism that is independent of any possible tidal association. Plus, the huge lateral extent of ancient mudflats, typically constituting the edges of huge interior seaways or shallow brine lakes, meant there was little or no tidal exchange with open ocean waters (Hallam 1981; Warren 1991). Strandplain or strandzone evaporite is apropos when describing the vast expanses of ephemeral water edge in ancient evaporitic mudflats.

Examples of evaporitic mudflat-dominated deposits include; the La Manga Formation (Oxfordian), Neuquén Basin, Men-doza, Argentina (Palma et al. 2013); Sequence 4 in the Upper Triassic Argilo-Greseux Inferieur of the Berkine Basin, Algeria (Turner et al. 2001); Jurassic Arab Cycle seals of the Middle East (Lindsay et al. 2006); Permian Minnelusa Formation in Wyoming (Achauer 1982); seal facies in the Permian Basal Seven Rivers Formation in Yates field, West Texas (Warren 1991); northern regions of the Palo Duro Basin during deposition of the Permian Upper San Andres Formation, Texas Panhandle (Hovorka 1987); more landward parts of the Lower Clear Fork Formation of Texas (Handford 1981b); Cambrian Red Heart Dolomite of the Georgina Basin, Australia (Nicolaides 1995); Neoproterozoic of South Gabon (Schisto-Calcaire Subgroup, Nyanga Basin, (Préat et al. 2010); Archaean Wittenoom Dolomite of the Hamersley Group, Western Australia (Kargel et al. 1996).

Saltern describes extensive shallow-subaqueous evaporite beds (5–50 m thick) deposited across hundreds of kilometres in the hypersaline portions of an ancient evaporite lake or seaway (Warren 1991). Deposition took place in both marine-fed and continental settings (Fig. 5.8; Table 5.3). Unlike evaporite mudflats, units tend to lack matrix within the stacks of salt layers that constitute the unit. Internal textures range from aligned crystals layers, or their ghosts, which preserve little evidence of syndepositional exposure through to stacks of salt pan crusts separated by abundant dissolution surfaces.

There are no modern counterparts for salterns in terms of scale or location, unlike the sabkha, pan and salina components of an evaporitic mudflat. Salterns formed in extensive salt-depositing seaways that covered former open marine platform carbonates or accumulated on 100 km+ wide evaporite shelves about the edges of giant deep brine seas (Fig. 5.8). Even so, most saltern texture can be interpreted using analogous textures documented in subaqueous salt beds in Quaternary lakes (Chaps. 1 and 4).

Individual saltern beds were precipitated from perennial brine sheets that were a few tens of centimetres or more deep and were originally accumulations of growth-aligned crystals, rafts, clusters and crusts. Horizontal laminae in calcium sulphate beds were often crosscut or interrupted by aragonite or dolomite layers. Primary sulphate textures were altered and recrystallised syndepositionally or during burial into nodular and coarsely crystalline textures. Primary halite chevron textures tend to be retained as remnants in a variably recrystallised matrix of halite spar. The end result of saltern deposition is a number of superimposed shoaling-upward beds (parasequences) composed of one or two dominant minerals, usually halite or gypsum (now nodular anhydrite).

Smaller crystals were reworked by storms into subaqueous traction deposits characterized by graded and reverse-graded beds, rippled and crossbedded layers, and algal rip-up structures. The graded beds and the rippled layers probably recorded waning storm-flood conditions (Hardie and Eugster 1971). Reverse-graded mechanical beds recorded either episodes of storm surging (increasing energy levels) across the saltern, or episodes of brine dilution that had slowed precipitation, so that coarser crystal overgrowths came to dominate the upper part of the lamina or layer.

Longer term freshening of saltern waters to where salinities were undersaturated with respect to halite or gypsum created cm-dm mudstone to wackestone layers that entrained intraclast breccias, tepees, pisolites, cross beds, cryptalgalaminites, micritic domal stromatolites, often with numerous pellets coming from brine shrimp and ostracodes or other opportunistic halotolerant species. Mud interbeds can also preserve rare vertebrate tracks.

Using the high-resolution outputs from a conventional wireline logs suite (e.g. Neutron, PEF or MSFL), a saltern is typically resolvable into internal beds of relatively pure cyclic salt sets (parasequences). Core and image logs show cycles are typically shoaling (e.g., domes passing up into laminites) with decimetre to metre scale layering that can be traced over significant well-to-well distances (> tens of kilometres). When using conventional wireline profiles for subsurface correlation, the relative purity (>95 % salts), greater thickness of bed cycles and improved lateral continuity gives saltern beds a blocky wireline signature that frequently allows their distinction from the more spiky signal in evaporitic mudflats (Table 5.3). Mapping this distinction can be an important reservoir quality predictor in underlying strata (Fig. 10.45).

Ancient examples of saltern deposits include; D-member of the Miocene Qom Formation, Central Iran (Khalili et al. 2007); Cretaceous Ferry Lake Anhydrite in the northern Gulf of Mexico (Pittman 1985); ramp interior evaporite cycles of the Early Cretaceous of the Caohuila platform (Lehmann et al. 1998); P_1 and P_2 evaporites of the San Andres Formation on the northwest shelf of the Permian Basin; the Lower San Andres Formation of the Texas Panhandle (Elliott and Warren 1989); upper Visean anhydrites of southern Belgium (De Putter et al. 1994); Upper Ordovician halites of the Canning Basin (Kovalevych et al. 2006b); Jurassic Hith Anhydrite of the Middle East (Azer and Peebles 1998); and the Herald Formation in the Ordovician red River Group, Saskatchewan (El Taki and Pratt 2010).

Deepwater evaporites accumulated beneath deeper brines of lacustrine and basinwide evaporite successions and encompass the slope, rise and basin deposits (Fig. 5.8). Fine-grained halite or gypsum laminites accumulated in the central deeper parts of a density-stratified basin, typically intercalated with less saline salt beds, as well as with carbonate or organic laminites. The fine layering reflects change in the saturation states of the surface brines or variations in the rate of sediment supply and grain size from the more marginward slope deposit feeds (Fig. 5.8). These "deepwater" laminites accumulated in two main ways: (1) As "rain from heaven" with crystallites first forming in the upper supersaturated metre or two of the brine column and then settling to the deep brine seafloor, (2) As the distal ends of evaporite turbidites and debris flows that typify the slope and rise in basinwide deepwater settings. Slope deposits accumulate up-dip from the laminites of the basin floor and are mechanically reworked from saltern or mudflat parent. They are characterised by textural associations typical of deeper water in all sedimentary basins and include; turbidite fans, Bouma cycles, slumps and debris flows, sole marks, tool marks, scour and fill, ball and pillow structures. All are relatively high-energy features, intercalated with laminites deposited during times of quiet bottom settle-out.

Studies of basin-centre and slope evaporites in the Permian of the Delaware and Zechstein basins, the Visean evaporites of the Canadian Atlantic, and the Miocene of Red Sea rift in the Yemen Republic, the Messinian of circum-Mediterranean, indicate these ancient deepwater sequences can be interpreted in much the same way that deepwater deposits are interpreted in carbonate and siliciclastic depositional systems (Anderson et al. 1972; Clark 1980a, b; Richter-Bernburg 1986; Schlager and Bolz 1977; Schenk et al. 1994; El Anbaawy et al. 1992; Rouchy et al. 1995a, b; Peryt 2000; Orti et al. 2003; Roveri et al. 2006). The main difference when compared to other deepwater clastics relates to water depth and the relative importance of "rain from heaven" versus resedimented shelf deposits in depositing the fine laminites of the basin centre.

Interpreting actual water depths above the basin floor is more difficult than separating subaqueous and subaerial depositional styles (Warren and Kendall 1985; Warren 1985). A lack of a benthonic microfauna, similar conventional wireline signatures and varying degrees of drawdown during ongoing deposition of thick interlayered coarsely crystalline and laminated evaporite sequences, means water depth deter-

minations are difficult in ancient slope and basin evaporites. Varying intensities of draw-down as evaporites accumulate in a basin centre plays havoc with the assumptions of rates of water-level change that are inherent in estimating water depths in open marine deposits. Unlike marine basins where sealevel tends to fluctuate tens of metres above and below the shelf break, brine surfaces in basins accumulating evaporites in drawndown basin centres can be 2 km or more below sea-level and basinal of the position of what was the shelf break prior to basin isolation. Drawdown of hydrologic baselevel can happen in the space of a few tens of thousands of years, as can the return to a marine baselevel once the basin in fully reconnected to the waters of the open ocean.

The effects on basin sediment of such substantial drawdown over relatively short times are likely substantial. Based on three-dimensional seismic mapping, Bertoni et al. (2013) document a field of pockmarks in the Levant Basin (south-eastern Mediterranean) buried at present depths of ≈4 km. The pockmarks cover an area of ≈1,000 km^2, have diameters as great as 2 km, and erode as much as 200 m into their substrate of deep-water clastic sediments, which immediately predate sediments of the Messinian Salinity Crisis (MSC; 6.2–5.5 Ma). These craters are filled by the basal units of the Messinian evaporites, implying they formed at or close to the time of the earliest major drawdown of Mediterranean sea level. All the pockmarks are developed at a single, regionally correlatable surface, Horizon N, which is observed throughout the Mediterranean to coincide with the onset of the MSC. In the Levant region, this surface formed during erosion and drawdown with a magnitude of 900–1,000 m. Rapid basinal drawdown, and the removal of hydrostatic pres-sure exerted by a kilometre of water, led to a dramatic increase of the shallow subsurface pore-fluid overpressure regime in the mostly fine-grained pre-Messinian sediments. Subsequent pres-sure release then resulted in high flux fluid venting, sediment remobilization, pockmark formation and general near-surface sediment instability. The spatial association of the craters with an underlying canyon suggests that their formation is linked to biogenic methane generation. Their model of drawdown-induced overpressuring and remobilization is likely applicable to many other evaporitic basinwide setting. It offers a novel mechanism for inducing large-scale sediment remobilization of shallow buried depositional systems during the earliest stages of salt basin development.

Using a deep "water full" basin model, Richter-Bernburg (1957) estimates water depths of more than 1,000 m for anhydrite laminites in the centre of the Permian Zechstein basin. Subsequent work by Schreiber (1988) postulates a minimum relief of 100–200 m for the shelf to base-of-slope transition during anhydrite deposition. Warren (1989, 1991) argues that determinations of deep versus shallow in a drawndown basin are difficult, but favours typical water depths of no more than 100–200 m. Kendall (1992) argues deepwater evaporites typically form in water depths greater than 20–40 m; but, like Warren (1985), notes that "deepwater" sulphate laminates can form in brines less than a few metres deep. The mechanism driving resedimentation in "deepwater" salts is also contentious; Schlager and Bolz (1977) favour turbidity currents, while Clark (1980a) favours a control by storm surge instability (Fig. 5.8). Reworked deepwater clastic gypsum textures (uncomplicated by a conversion to burial anhydrite) have been documented in the Messinian gypsum in Apennines of Italy and in cores recovered from canyon fill in the lower Messinian evaporites of offshore Israel (Lugli et al. 2012).

Unlike deepwater $CaSO_4$ laminites and slumps, resedimented ancient halites are not widely recognised and their interpretation in ancient salt beds typically stems from their entrained nonevaporite clasts, rather than from textures in any finely layered halites (Czapowski 1987). One of the better-documented examples of platform halite being redeposited into deeper water is the halite breccias and olistoliths in Middle Miocene evaporite in the Wieliczka and Stebnyk salt mines of Poland (Peryt and Kovalevich 1997). There, the salt breccia is interpreted as a series of subaqueous fans, with redeposition of the originally shallow water halite into deep water, driven by vertical tectonic movements and the northward advance of the Carpathian Nappes, some 13.81 Ma (De Leeuw et al. 2010). Water depths at the time of halite deposition are interpreted to have been between ten and tens of metres deep. Others have interpreted the same mine sequence textures to be halokinetic.

In understanding ancient deepwater evaporites and reliably tying down water depths, a significant problem is that there are only two Holocene settings, both continental lakes, where "deep water salts" are accumulating in waters deeper than 30 m (Dead Sea halite and Canadian mirabilite lakes; Chaps. 4 and 10, respectively). Deepwater sediments in almost all other modern saline lakes are carbonate laminites (pelagites). Modern deepwater analogs accumulate in small steep sided continental depressions, while deepwater ancient evaporites accumulated across the flat deep-brine-covered floors of broad drawndown marine basins, with no modern counterpart. If we take the two Holocene examples as direct analogs they show the following: (1) Massive beds made up of coarsely crystalline meshworks of sodium sulphate salts are accumulating beneath 30 m deep brine columns in small salt lakes in the interior of Canada. (2) Finely-laminated bottom carbonates, alternating with massive crystalline halite beds, are accumulating on the floor of the Northern basin of the Dead Sea (≈300 m deep brine).

Using the current lacustrine textures in the salts of the Dead Sea and Canada as a process analogue we should add another style of deepwater evaporite; namely, beds made up of rapidly deposited, coarsely crystalline, inclusion-free, meshworks of prisms. The prisms accumulate on stable

bottoms and so show little upward crystal orientation with a characteristic lack of inclusion-rich layering in individual prisms. These beds indicate times when the deep brine column was holomictic, stable, and saturated with respect to the salt of interest (Fig. 5.8). From strandzone to deep basin floor, this coarsely crystalline halite is a lakewide time-synchronous holomictic unit.

In contrast, laminites probably indicate periods when deep bottom brines in the centres of many ancient evaporite basins were density-stratified, sediment starved and anoxic, or at best dysaerobic for long periods (Kirkland and Evans 1981; Hite and Anders 1991). The resulting cumulates ("rain from heaven" textures) entrain significant volumes of pelagic organic matter and, with suitable burial, have yielded hydrocarbons or ultimately were converted to graphitic schists. For example, the bottom sediments in the deepwater gypsum of the Gibellina Basin contain up to 7 % TOC, similar elevated levels occur in the mesohaline laminite of the Paradox basin (Chap. 9). At present the organics entrained in the evaporitic carbonates of the Sicilian basins are still thermally immature, while those in the Paradox are mature but mostly locked in placed by pervasive diagenetic salt cements. The evaporite association of many of these deepwater meromictic pelagics means their potential to act as source rocks is limited to a few particular hydrologic settings (Fig. 9.4).

Evaporites: Broad-Scale Depositional Models

Saltern and mudflat beds, along with varying development of slope and basin deposits, occur in three interrelated regional depositional settings (Figs. 5.8 and 5.9):

Platform evaporites: Stratiform beds typically <50 m thick and composed of stacked <1 to 5 m thick parasequences or cycles with a variably present restricted marine carbonate base. Salts were deposited as mixed evaporitic mudflat and saltern evaporites, sometimes with local accumulations of bitterns. Typically they were deposited in hydrographically-isolated subsealevel marine-seepage lagoons (salterns) or evaporitic mudflats. These regions have no same-scale modern counterparts and extended as widespread depositional sheets across large portions of marine platform areas that in passed seaward across some sort of subaerial barrier into open marine sediments (Fig. 5.9a). In marine-margin epeiric settings, such as the Jurassic Arab/Hith and Permian Khuff cycles of the Middle East, these platform evaporites are intercalated with shoalwater marine-influenced carbonate shelf/ramp sediments, which in turn pass basinward across a subaerial sill into open marine carbonates. Landward they pass into arid zone continental siliciclastics or carbonate mudflats. Deposition occurred in pericontinental or intracratonic settings

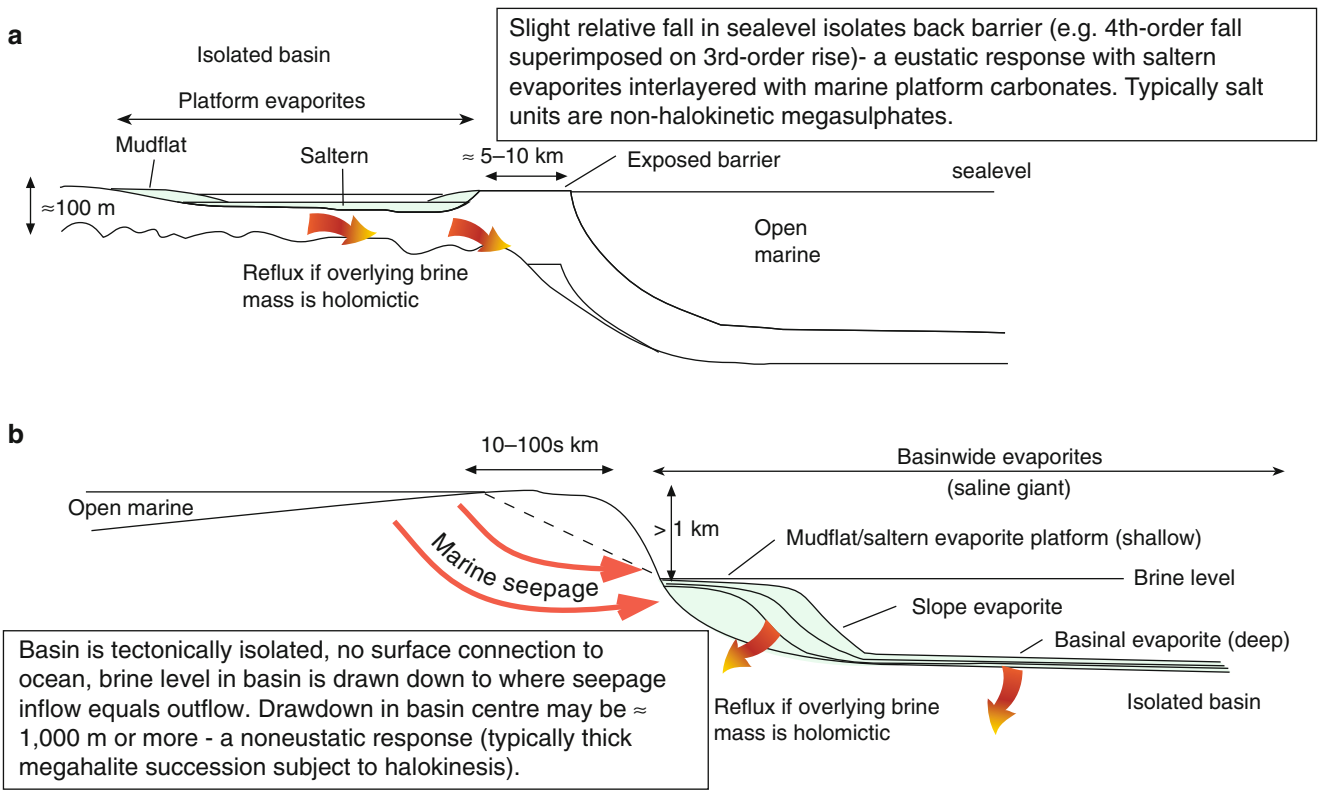

Fig. 5.9 Schematic cross sections of ancient evaporite settings that have no modern analogs. (**a**) Platform evaporites. (**b**) Basinwide evaporites (See text for explanation)

Platform evaporite successions may contain halite beds, especially in intracratonic basinwide settings, but in periplatform settings are typically dominated by 5–40 m thick Ca-sulphate beds intercalated with normal marine platform carbonates (Fig. 5.9a; Table 5.5). The lateral extent of these epeiric platform salts, like the Khuff Anhydrite with its area of 1,206,668 km^2, constitute some of the most aerially extensive evaporite beds ever deposited (Fig. 5.4).

Platform-wide megasulphate beds of Eocene age in the Middle East, centred on Iraq, Kuwait and Saudi Arabia (Rus Fm. and equivalents) are our most recent example of a time when an epeiric carbonate platform succession was covered and interlayered with a widespread combination of saltern and evaporitic mudflat gypsum and anhydrite (Table 5.8). A similar set of bedded platform-carbonate saltern-sulphate interlayers characterises the depositional cycles of Jurassic Arab Fm sediments (especially the Hith Anhydrite) of the Middle East, the Middle Anhydrite Marker (and equivalents) in the Permian Khuff Fm of Saudi Arabia, Qatar and the Emirates. There are numerous other large-scale Ca-sulphate saltern/mudflat examples including the anhydrite portion of depositional cycles in the Cretaceous limestone platforms and atolls of the circum Gulf of Mexico (e.g. Ferry Lake Anhydrite), the Permian back-shoal lagoons of West Texas and New Mexico (e.g. San Andres Fm. and equivalents) and the Cambrian carbonates of the Georgina Basin in Australia (e.g. Red Heart Dolomite and equivalents).

In many cases, especially in older examples, such as the such as the Red Heart Dolomite and Cambrian Cool Creek Fm of Oklahoma, the anhydrite unit has dissolved and all that remains as evidence of a former widespread $CaSO_4$ bed is a dissolution breccia, or dispersed and altered nodules and associated burial salt cements. In some cases these dissolution breccias are now mineralised MVT deposits, as with the San Vicente Mine, Peru and the ore zones in the Cadjebut mine region of the Canning Basin Platform, Australia. In the latter case the ore zones pass laterally into saltern anhydrite beds (Warren and Kempton 1997).

Basinwide evaporites Thick, basinwide units >50–100 m thick of deepwater/shallow water evaporites retain textural evidence of different but synchronous depositional settings, including mudflat, saltern, slope and basin (Figs. 5.8 and 5.9b). When evaporite deposition took place, the whole basin was evaporitic typically saturated with the same mineral phase across large areas of the basin (as when halite today forms decimetre-thick chevron-dominated beds on the saline-pan floors and coarse inclusion-poor crystal meshworks on the deep basin floors of the Dead Sea).

Basinwide successions are typically dominated by thick massive salt beds (more than 100 m thick), which typically are made up of stacked thick halite beds, but can also contain substantial volumes of thick-bedded Ca-sulphate and evaporitic carbonate, as in the intracratonic Delaware and Otto Fiord Basins. Some basinwide systems (mostly marine-fed intracratonic) also entrain the larger accumulations of the world's potash salts, even though our only Quaternary examples of economic potash are continental systems (Chap. 11). Many halite-dominant basinwide beds are also remobilised into various halokinetic geometries owing to the purity and thickness of the deposited halite (Chap. 6).

Basinwide evaporite deposits are the result of a combination of tectonic and hydrological circumstances that are not currently active on the world's surface. They were last active in the Miocene in association with soft-suture collision basins tied to the Alpine-Himalaya orogenic belt and to rift basins developed in the early stages of the Red Sea. They will be active again in the future at sites and times of appropriate plate-plate interaction, when two continental plates are in close proximity and the intervening floor at or near a plate-edge rift or suture is both subsealevel and hydrographically isolated.

Continental playa/lacustrine deposits These are constructed of stratiform salt units, typically with the greater volume of sediment made up of nodular gypsum and displacive halite deposited in widespread evaporitic mudflats and saltpans, rather than in perennial brine lakes (Chap. 4). Total thickness ranges from metres to hundreds of metres, with lateral extents measured in tens to hundreds of kilometres (Fig. 5.4). Such salt beds are separated and often surrounded by deposits of lacustrine muds, alluvial fans, ephemeral streams, sheet floods, eolian sands and redbeds. Typically the salts accumulated in endorheic or highly restricted discharge basins. Basins typically have a shallow watertable in the saline mudflat area and a lowermost depression or sump typified by ephemeral ponded brine pan deposits. Perennial saline lakes formed during more humid periods in the same continental depression or in parts of the saline lake floor located below the regional watertable (moat facies).

Evaporite mineralogies depend on compositions of inflowing waters (Fig. 2.19); suitable settings accumulated thick sequences of trona, glauberite and the nardite as well as more typical sequences of halite and anhydrite. Highwater stage perennial sediments tend to be carbonate-rich or silica-rich (diatomaceous) laminites. Ancient examples include the Eocene Green River Formation of Wyoming and the Permian Pingdiquan Formation of the Junggar Basin, China. Evaporites deposited in suprasealevel lacustrine basin (especially Neogene deposits) have numerous same-scale Quaternary analogs and so are discussed first.

Lacustrine Evaporites

According to the degree of accommodation space, all ancient lacustrine deposits can be subdivided into three types: underfilled, balanced and overfilled (Fig. 5.10; Bohacs et al. 2000, 2003). Accommodation is the space available for sediment

Lake type & lacustrine facies association	Stratigraphy	Lithologies	Sedimentology	Organic matter	Kerogen-hydrocarbon characteristics
Overfilled Fluvial-lacustrine facies association	Maximum progradation: • parasequences related to lateral progradation (relatively stable) • maximum fluvial input	Terrigenous sediment dominant • mudstone, marls • sandstone • coal, coaly shale • coquina (isolated highs in basin)	Physical sedimentation dominant: • ripples, dunes, flat bed • root casts • burrows (infaunal and epifaunal)	• freshwater biota charophytic and aquatic alga OM • low to moderateTOC • terrigenous and algal biomarkers	• mixed type I-III kerogen • both oil and gas generative • very waxy, low sulphur oils
Balanced fill  Fluctuating-profundal facies association	Mixed progradation & aggradation  • distinct shoaling cycles common • fluvial input variable	Mixed chemical and terrigenous sediment: • marl, mudstone • siltstone, sandstone • carbonate, grainstone, wackestone, micrite • kerogenite	Physical & biogenic sedimentation: • flat beds, • current,wave and wind ripples • stromatolites, pisolites and oncolites • mudcracks • burrows (epifaunal)	• saline tolerant biota aquatic algal OM minimal land plant • moderate to highTOC • algal biomarkers	• predominantly type I kerogen, type I-III mixtures near flooding surfaces • mostly oil generative • paraffinic but relatively nonwaxy oils, low sulphur
Underfilled Evaporitic facies association	Maximum aggradation minimum progradation  • high-frequency wet-dry cycles • minimum fluvial input • maximum evaporite input	Chemical sediments dominant: • mudstone, kerogenite • evaporite • siltstone, sandstone • grainstone, boundstone wackestone, micrite • flat-pebble conglomerate	Chemical, biogenic & physical sedimentation: • cumulative textures • displacive fabrics • stromatolites, pisolites and oncolites • climbing ripples • flat beds • eolian cross beds	• low diversity halotolerant to halophilic biota • algal-bacterial OM • low TOC in oxidised margins • high to very high TOC oil shale in basin centre • "hypersaline" biomarkers	• type I kerogen • mostly oil generative • paraffinic oils, moderate to high sulphur

Fig. 5.10 Attributes of the three major styles of lacustrine basins (After Bohacs et al. 2000)

accumulation below the basins outlet or spill-point. The type of lake is defined by how much of that space is filled by some combination of sediment + plus water over a particular time span. Hence climate (≈ sediment supply + water depth and permanence) and tectonics/inherited topography (≈ potential accommodation) exert coequal controls on the nature and distribution of the various lacustrine deposits. Changes in climate or tectonic subsidence means ancient lacustrine basin fill can evolve from one lake type to another a number of times in the infill history of the basin (Lambiase 1990).

The fluvial-lacustrine facies association in overfilled (humid) lakes is composed of marlstone, argillaceous coquina and bioclastic grainstone, along with widespread sandstones, carbonaceous mudstones and coals with a freshwater fauna. Beds retain mixtures of aquatic and terrigenous organic matter and most sedimentary textures indicate physical, not biogenic, processes (Fig. 5.10; Bohacs et al. 2000, 2003). A fluctuating-profundal lacustrine facies association is common in balanced lakes and is made up of a complex of interbeds of heterogenous lithologies including; carbonates, siliciclastics, argillaceous and organic rich mudstones, with a fresh to saline water biota, Dominantly aquatic organic matter is found in beds and bedsets, while sedimentary structures are typified by a combination of physical and lesser biogenic features.

Evaporitic lacustrine facies typically accumulate in underfilled basins, with lithologies ranging across clastic sandstone and carbonate grainstones, kerogenites (oil shales) and evaporites. Widespread shoalwater evaporites typically fill the lowermost parts of the basin during the most arid or underfilled times in the lake history. Halophilic organic matter can accumulate in moat facies at that time, or halotolerant organic remains can accumulate across larger parts of the lake floor when water levels are somewhat higher and fresher (Chaps. 4 and 9). Sedimentary structures include both physical and biogenic structures, as well as textures indicating periodic desiccation (mudcracks) and crystallization in fluctuating brine conditions (inclusion-rich cumulate, growth-aligned and displacive textures).

Studies of sizes of modern lakes of all three types, water depths and the character and thickness of ancient counterparts typically do not correlate with measured or inferred climatic humidity (Bohacs et al. 2003). Interestingly, the drainage basins of the world's largest rivers contain no large lakes, only a few relatively small ones (e.g., Amazon, Congo, Orinoco and Mississippi River basins). Ancient lake systems show a similar lack of correlation between lake size, climate and fluvial volumes (Carroll and Bohacs 1999; Bohacs et al. 2003). Of the three types of ancient lakes, the focus for the remainder of this section is on the underfilled or evaporitic lakes. For further discussion of the sedimentology of other two lacustrine associations, the interested reader is referred to the excellent review papers by Bohacs et al. (2000, 2003) and the references therein.

Ancient saline lacustrine deposits range in age from Neogene to Precambrian (Table 5.4). Facies patterns and distributions in saline lakes are different to marine carbonate or siliciclastic-filled basins as; (1) the depositional base level

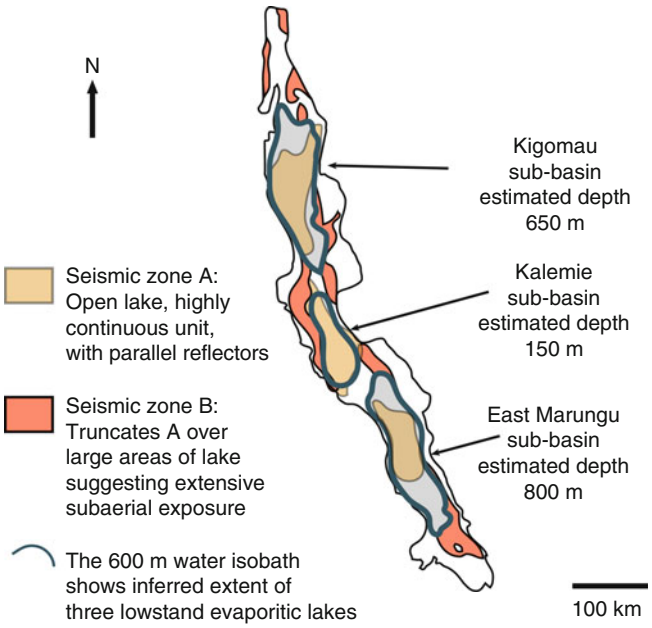

Fig. 5.11 Subdivision of Lake Tanganyika into three separate sub-basins during a mid- to late-Pleistocene lowstand (After Tiercelin and Mondeguer 1991)

changes much more rapidly and frequently in lakes and with much higher amplitudes, (2) salinity is not constant. Water/brine depth and lake salinity can change hundred of metres in less than a few 1,000 years, from a highstand deep perennial fresher lake accumulating deepwater chemical laminites, along with lake-plain and highstand deltas, to a shallow or ephemeral lake made up of small saline pans on broad salt flats and mudflats. In Lake Van, Turkey, there was a change of 600 m in 2,000–3,000 years, Lake Malawi in the East African rift dropped as much as 140 m in just 340 years (Owen et al. 1990) and the lake level in the Dead Sea is currently falling at similar rates. Changes are related to local climate and uplift and, unlike the base level changes in marine eustasy, do not show time synchronous change tied to worldwide climate mode (icehouse versus greenhouse). Facies analyses tied to dated cores in Lake Tanganyika, Africa, show the current lake was made up of three separate saline lakes when water levels were lower in the mid to late Pleistocene (Fig. 5.11). Compared to Lake Tanganyika, Lake Magadi and Salar Uyuni show the opposite effects in terms of timing of late Quaternary high water in that their current salt pan surfaces are some tens of metres below what were the much higher lake water surfaces in the late Pleistocene.

Vertical changes in facies and lithologies are abrupt in many ancient saline lake systems, a reflection of these rapid high amplitude changes in water levels. Large falls in lake water level lead to "hanging" deltas and terraces along with deep incisions through highstand Pleistocene deposits. In arid lowstand lakes, newly exposed lake floor sediments can be overprinted by subaerial weathering and the processes of soil formation. Exposed lake floor laminites can be sabkharized, as is happening today in Salt Flat Playa, West Texas (Hussain and Warren 1989).

Intuitively, many sedimentologists assume that climate is the major control on water depth and salinity in a saline lake basin. That is, larger deeper lakes, with thicker lake sediment packages, should accumulate in wet or humid climatic periods, while drier saline periods should be characterised by saline deposits with lesser aerial extents. But the hydrology of all lake basins, including endorheic basins, is never truly closed and varying degrees of reflux and leakage play significant roles in the final salt distribution (Chap. 2). Concurrent saline lakes in Turkey or the African Rift Valley can range from hypersaline to brackish in intermontane valleys located only a few tens of kilometres apart. Assuming all ancient lakes in an area are arid or humid at the same time is not a valid approach to correlation of salt beds in adjacent saline lake basins (e.g., Bohacs et al. 2003).

Eocene Lake Gosuite, USA

Lacustrine sediments deposited in Eocene Lake Gosiute are preserved in the Green River Formation, which has several members corresponding to major lake high- and low-stands, each of which probably lasted several hundred thousand years or more. Saline lacustrine phases of the Green River Formation, such as the Wilkins Peak Member, have two main modes: (1) Lake high-stands are marked by oil shales (laminated dolomitic kerogenites). (2) Lowstands, when water covered areas of the lake contracted and salinity increased, are indicated by salt beds of saltern/pan trona or halite deposited atop the oil shale layers and stromatolite dominated sediments in the more marginward mudflats (Aswasereelert et al. 2013; Seard et al. 2013; Smith et al. 2008).

Dolomitic mudstones were deposited during lowstands as subaerial evaporitic mudflats across over the dried and exposed lake floor. These strandzone to shoalwater carbonates are made up of structureless to laminated muds, algal dolomudstones algal boundstones, oolitic pisolitic grainstones and ostracode grain-stones, which a comparison to the massive unit in the Holocene Coorong lakes show are mostly ephemeral to strandzone indicators. The various Eocene shallow water microbialite-insect buildups in the Laney Member are considered excellent analogs for the subsalt lacustrine Albian reservoir carbonates in Tupi and other subsalt targets of offshore Brazil and western Africa (Seard et al. 2013).

Sandstone and siltstone line the basin edge and may be present as thin interbeds in the basin-centre kerogenites. Roehler (1993) identified 77 depositional cycles of mudflat/kerogenite in cores from the Wilkins Peak Member. Based on an estimated duration of 1.6 My for the member, he calculated an average period of 21 kyr for the cycles and

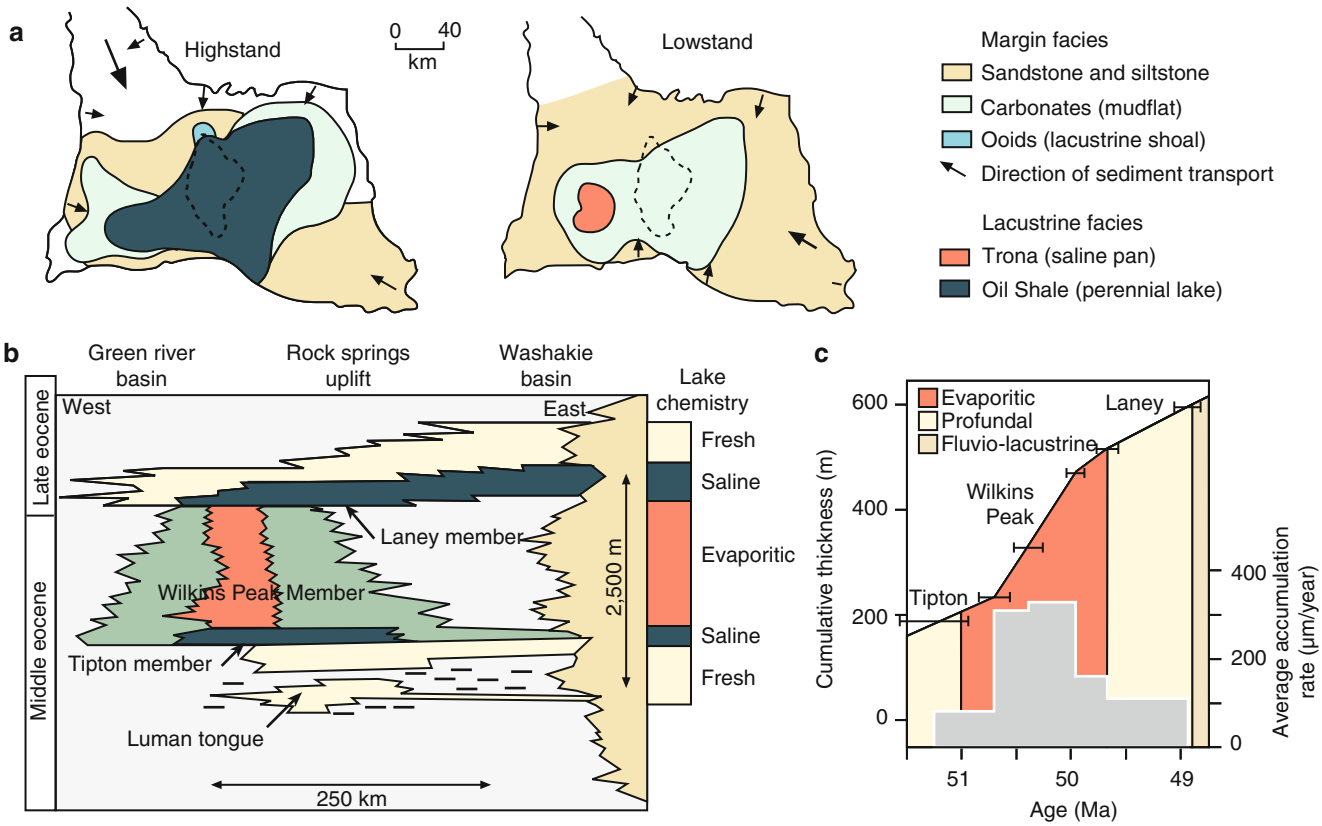

Fig. 5.12 Lithofacies distribution of Eocene Lake Gosuite as preserved in the Green River Formation, Wyoming. (**a**) Wilkins Peak time showing highstand conditions with extensive accumulations of oil shale beneath the salinity-stratified waters of a perennial lake versus lowstand conditions when carbonate mudflats dominated and trona was precipitated beneath very shallow to ephemeral waters of a hypersaline brine lake (After Surdam and Wolfbauer 1975). *Dashed line* outlines the approximate position of the Rock Springs Uplift. (**b**) Schematic E-W cross section showing lateral extents and thicknesses of various lacustrine units (After Bohacs et al. 2000). (**c**) Average sediment-accumulation rates for the Green River Formation based on a reference section in the southern Greater Green River Basin (After Smith et al. 2003, 2008, 2014)

suggested they were probably caused by the earth's precession, which has periodicities of 19 and 23 kyr. Pietras and Carroll (2006) found that tectonism was the primary control on basin fill and that differential accommodation was most pronounced during deposition of the lower Wilkins Peak Member and became progressively less so after that time. Based on their detailed structural and stratigraphic observations, they concluded a period of increased tectonic uplift commenced concurrent with deposition of the evaporitic lower Wilkins Peak Member (underfilled stage).

The oil shales (kerogenites) in the Green River Fm. are composed of mm-scale alternations of amorphous-algal organic matter (kerogen) and slightly thicker laminae of carbonate (mostly dolomite) and clay. TOC content can exceed 25 %. Comparisons to laminites accumulating in the various Quaternary saline lakes detailed in Chap. 4 means most authors now agree the Eocene kerogenites of the Green River Basin indicate highstand conditions (Fig. 5.12). But the definition of "deep" for the water depths accumulating kerogenite varies from author to author. The thickest beds of oil shale tend to occur toward the basin centre and some oil shale intervals are laterally extensive, perhaps indicating deposition at the bottom of a substantial body of perennial lake waters. Toward the basin margin the oil shales change to marlstones, kerogen-rich marlstones and lean oil shales (Hite and Anders 1991). Basin-centre oil shale accumulations can also contain diagenetic dawsonite, halite and nahcolite (Dyni 1981). They may also entrain mud-cracked horizons and solution breccia beds. To interpret the shales, some authors focus on the large lateral extent of the finely-laminated kerogenites and infer deposition at the bottom of a deep stratified water mass with density-stratified permanent waters more than tens of metres deep (Bradley and Eugster 1969; Desborough 1978; Dyni 1981). Others focus on the intercalation of the oil shales with evaporites and subaerial indicators such as mud-cracks, along with the dolomitic nature of the matrix and propose a shallow lake/saline pan depositional model for the widespread kerogenites (Eugster and Surdam 1973; Smoot 1983).

Changes in Lake Gosuite water levels mean the highstand sediments of kerogenite have a somewhat greater areal extent than the salts (Fig. 5.12a), but their deposition on the floor of

a perennial body of water does not mean they also show greater thicknesses. The freshest "lake-full" organic-enriched sediments of the Green River Formation in Wyoming are actually the thinnest and least aerially extensive of the various organic-rich units of the Green River Formation (e.g. Luman Tongue). In contrast, the Tipton and Laney members, which accumulated as varved oil shales beneath more saline meromictic lake waters have greater extents and thicknesses (Fig. 5.12b; Hite and Anders 1991).

Within the saline lake phase, those sediments deposited when the lake was at its driest (the Wilkins Peak Member), were deposited much more rapidly than the perennial saline lake laminites either of the Tipton or Laney members. $^{40}Ar/^{39}Ar$ based accumulation rates of Smith et al. (2003, 2008) are direct measurements of accumulation rates and do not rely on lamina counts being annual varves (Fig. 5.12c). For a reference section near the southern Green River Basin depocentre, they calculated accumulation rates of 88 ± 34 and 104 ± 18 μm/yr for the Tipton and Laney members; both values are consistent with an annual origin for the laminae. A much faster accumulation rate emerges from the Wilkins Peak Member. In the same reference section they calculated a net average rate of 327 ± 85 μm/yr, which is three times as fast as the Tipton or Laney Members.

Their observation of faster accumulation rates for saline phases is in accord with U-series disequilibrium-based results from Quaternary playa-lake evaporites. Ku et al. (1998) found that accumulation rates in a core from Death Valley were much higher for the salt-pan evaporite facies than for perennial lake muds, and Bobst et al. (2001) noted that accumulation rates during dry phases of the Salar de Atacama were up to three times as high as during wet periods (see Chap. 3). Net accumulation rates in these cases range between 0.5 and 1.8 mm/yr, which are up to five to six times faster than deposition of the Wilkins Peak Member. However, higher rates of Wilkins Peak Member evaporite accumulation may have occurred in the basin's subsurface depocentre, which lies to the west of the reference section (Smith et al. 2003).

Evaporitic sediments of Wilkins Peak Member, which accumulated at a time when the lake's waters were at their shallowest (perennial saline lake) and saltiest (pan/mudflat), are stratigraphically the thickest member of the Green River Formation (Smoot 1983; LaClair and Lowenstein 2009). This more saline lacustrine phase separating the kerogenites is enriched in sodium bicarbonate minerals such as trona and nahcolite in layers and is discussed in more detail in Chap. 11.

The alternation of playa and perennial lake modes explains accumulations of hydrogen-prone organics as oil shales in many saline lacustrine systems (Table 9.2). Boyer (1982) argues that hydrogen-rich oil shales in the Green River Basin accumulated beneath an anoxic lower brine layer in a density-stratified meromictic and relatively shallow saline lake. Stratification was created and maintained by ongoing dissolution of under-lying pan evaporites, especially trona/halite. He named this evaporite-induced stratification, ectogenic meromixis. If true, then accumulations of very thick oil shales in the Laney Member of the Bridger-Washakie basins and the Mahogany Bed of the Uinta-Piceance Creek basins are also a likely response to shallow subsurface dissolution of lake evaporites. The lack of similar underlying soluble beds in fresher water lacustrine oil shale basins (as in Honyanchi Fm. of China and the Rundle oil shale of Australia) may help explain why the trona-associated oil shales of the Green River Fm. are unique in their very high oil content. It also explains why virtually the entire Green River fish fauna, world famous for its high quality of tissue preservation, is made up of pelagic freshwater taxa, which flourished in the freshened upper water mass (Grande 1980). The permanent saline anoxic bottom layer was too nasty to support most life, other than well-adapted microbes (see Chap. 9).

Oligo-Miocene Lake, Calatayud Basin, Spain

The Oligocene-Miocene Calatayud basin of Spain is a foreland basin formed by the uplift of the Pyrenean chain to the north and is bounded to the southeast by the Catalonian Coastal Range and the Iberian range to the southwest (Fig. 5.13a). Thick beds of lacustrine salts accumulated in the endorheic lower parts of the basin. These deposits entrain a combination of carbonate and sulphate lacustrine environments, fed by a combination of Pyrenean waters via resurging groundwaters and alluvial systems. Deposits show strong similarities in distribution patterns and textures with the lacustrine evaporites and clastic aprons of the adjacent Ebro Basin (Fig. 8.17; Salvany et al. 2007; Arenas and Pardo 1999).

Miocene climate fluctuated from arid to more humid but, more importantly, the mountains to the North of the lake depression were composed of Triassic evaporites and Mesozoic marine carbonates. As they weathered they supplied ions for the salts accumulating in residual brines within the topographically lowest parts of the lake floor. The nearby Ebro Basin is well known for its economic accumulations of lacustrine glauberite that, as in the Calatayud Basin, largely occur in the central part of the basin (Fig. 12.26). Two distinct lake styles alternated through time: (a) High lake levels associated with a single body of dilute carbonate water, where massive biogenic carbonate facies proliferated. These lakes had wide palustrine vegetated margins, where bioturbated facies dominated the depositional signature. (b) Low lake levels of a playa-lake with extensive development of saline pans and mudflats surrounding a more permanent gypsum-saturated brine body in the lowermost parts of the lake depression.

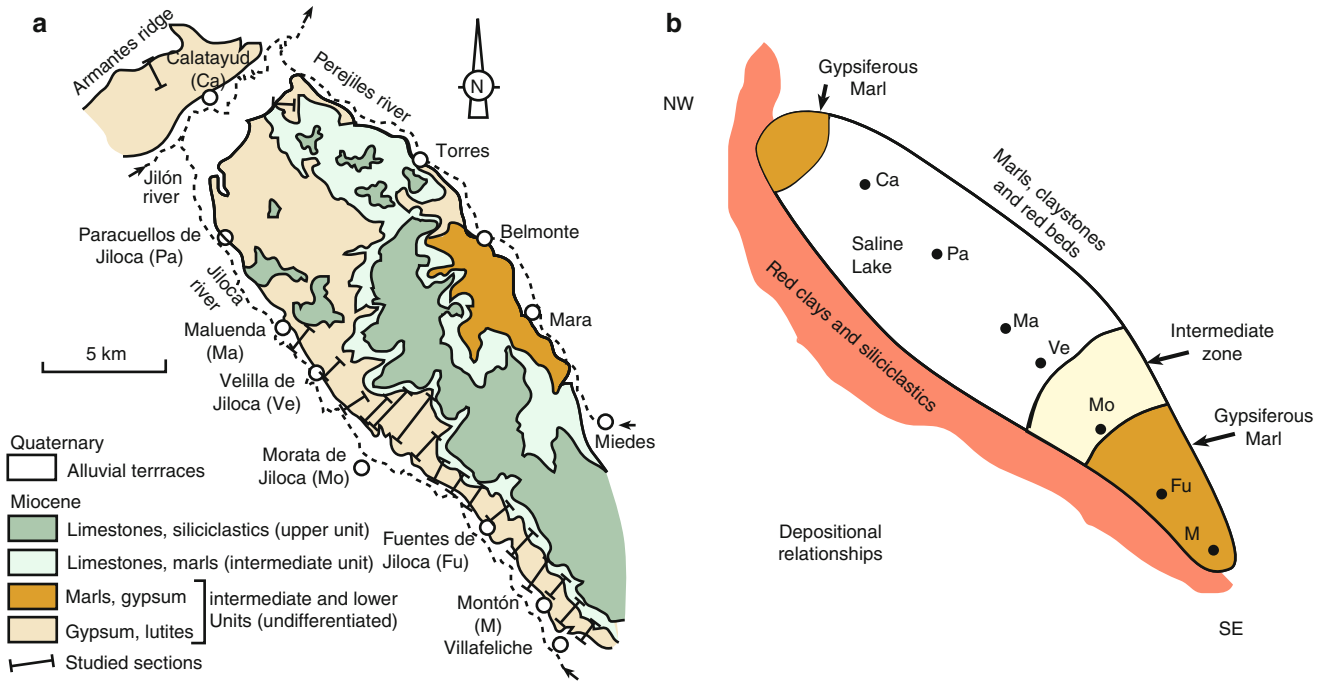

Fig. 5.13 Lacustrine sediment distribution in Cataluyud Basin, Spain. (**a**) Lithologic map showing distribution of Miocene lacustrine sediments in the area between the Armantes Ridge in the northwest, the village of Villafeliche in the SE and the area between the Jiloca and Perejiles rivers. (**b**) Schematic of the same area, showing areal distribution of the main lacustrine subenvironments in the lower evaporite unit (After Orti and Rosell 2000)

In the drawdown or playa stage a subaerial basin floor sloped gently down from a northern marginal mudflat zone to a central saline complex. Gypsum accumulated across the lake depression as both primary beds of mechanically reworked and 'in situ' gypsarenite, as well as early diagenetic precipitates of lenticular anhydrite (Fig. 5.13a). Surface runoff from nearby highlands constructed a bajada along the southern margin of the lake depression. But, transport of the greater volume of solutes into the basin was from the north and largely subsurface, via groundwater flow through an extensive karst systems in the evaporitic Mesozoic limestones that made up the hinterlands. Shallow groundwaters seeping south down the hydrologic gradient supplied increasingly fractionated and saline brines to lakes and pans all the way from the basin margin to the basin centre (Fig. 5.13b; Salvany and Orti 1994; Salvany et al. 1994; Orti and Rosell 2000).

Calcium carbonate and gypsum precipitated in the fan edges and in marginal palustrine marshes and ponds, while substantial beds of dolomite and charophyte residues accumulated over large parts of the lake floor during more humid climatic episodes (Fig. 5.11a). Many of the laminated gypsarenite beds are bioturbated, indicating periodic episodes of freshening and exposure, even as the gypsum was accumulating (Fig. 5.14a; Rodríguez-Aranda and Calvo 1998). Margin mudflats, marshes and ponds acted as preconcentrators for shallow groundwaters seeping slowly toward a central sump. By the time these fractionating brines reached the central drainage low, they were highly concentrated and capable of precipitating thick beds of gypsum, halite and glauberite. Much of the glauberite and polyhalite, along with some of the gypsum, was an early diagenetic interstitial precipitate, created by capillary evaporation of cross-seeping brines. The halite beds were predominantly primary saline pan units, composed of hoppers and chevrons, interbedded with laminated primary gypsum (Fig. 5.14a). The whole Oligocene Miocene lacustrine succession in the Cataluyud Basin is made up of six 100–200 m thick cycles. The lower part of each cycle commences with beds of saline lake salts (including glauberite) that show typical playa mudflat/pan textures and have the greatest lateral extent (Fig. 5.14b; Orti and Rosell 2000; Salvany and Orti 1994; Arenas and Pardo 1999). Saline facies then shrink toward the basin centre as the lakes evolve into a freshened palustrine carbonate-dominant stage. The top of each cycle is dominated fine-grained siliciclastics and alluvial fan sediments, indicating progressive progradation of alluvial fans toward the lake centre. Tops of some cycles are composed entirely of clays and fine-grained clastics. Over time, depocentres of successive cycles shift toward the north, suggesting the ultimate control on the cyclicity and accommodation space creation was tectonic, not climatic.

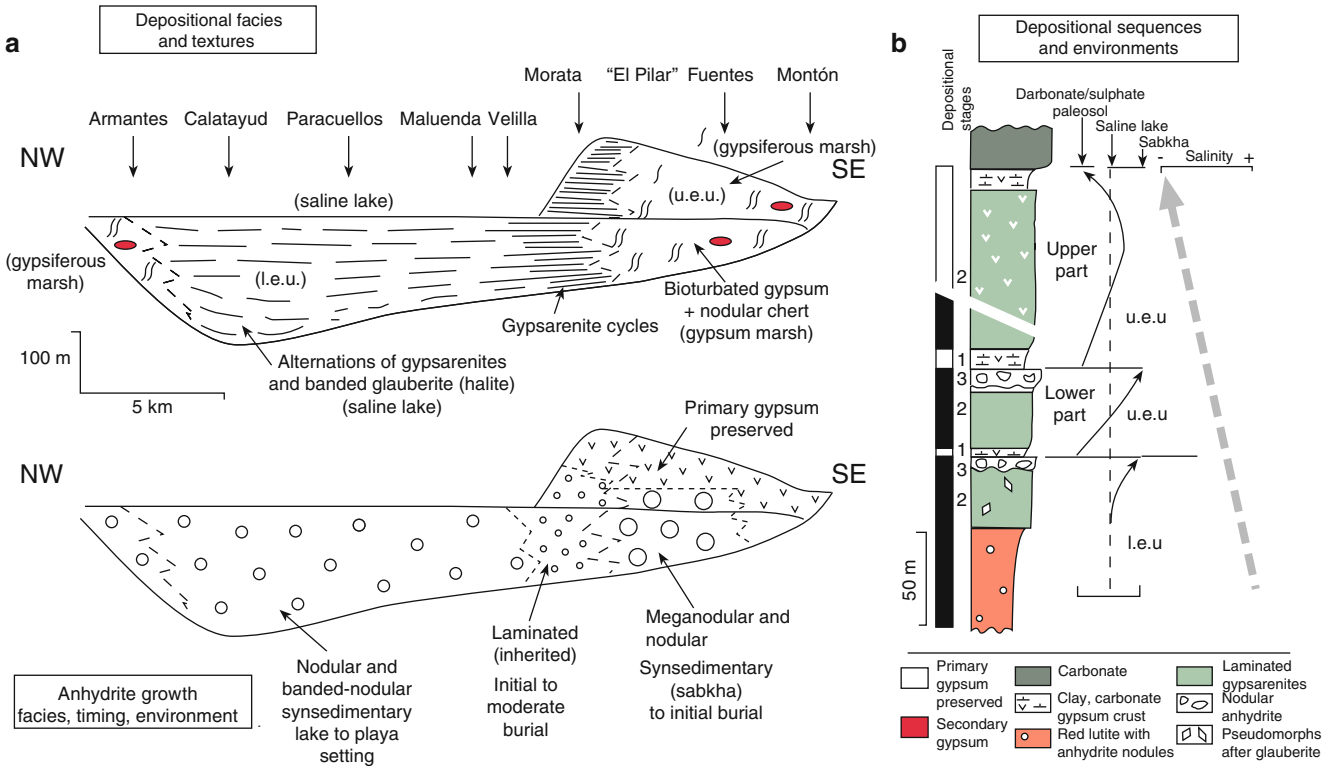

Fig. 5.14 Lacustrine evaporites in the Calatayud Basin, Spain. (**a**) Depositional facies distribution and their differential conversion to anhydrite: *l.e.u.* lower evaporite unit, *u.e.u.* upper evaporite unit (See Fig. 5.13 for location of sections and Fig. 12.26b for depositional style). (**b**) Depositional sequences and evaporite units in the area of the village of Morata. Salinity arrow indicates a decrease in the ionic concentration of the parent brines with time. The lower part of the upper evaporite unit shows a complete depositional cycle with associated salinity increase. Depositional stages: (*1*) dilution stage: gypsiferous-calcareous horizon (carbonate-sulphate palaeosol); (*2*) concentration stage: laminated gypsarenite (saline lake); (*3*) subaerial, hypersaline stage: nodular anhydrite (sabkha) (After Orti and Rosell 2000)

Much of the Miocene evaporitic sediment in the Calatayud Basin today outcrops or subcrops along the southwestern part of the basin, where it is liable to karstification and collapse. Ongoing groundwater crossflow, throughout the late Tertiary period, means primary evaporite textures have been diagenetically overprinted at various times in the burial and uplift history (Orti and Rosell 2000). In the gypsiferous marsh facies, the dominant, massive, bioturbated gypsum was partly replaced very early in the sediment history by synsedimentary chert nodules and siliceous crusts (Fig. 5.14a). In the saline lake facies, replacement of portions of the laminated glauberite by anhydrite also occurred soon after deposition. Multiple episodes of subaerial exposure and pedogenic/capillary alteration are indicated by: (1) pedogenic carbonates (with nodular magnesite) and gypsiferous crusts composed of poikilitic crystals; and (2) nodular anhydrite, which began forming in the capillary zone of a lacustrine sabkha or mudflat and continued to form during ongoing shallow burial. Additionally, a somewhat later pervasive meganodular secondary anhydrite texture overprints much of the laminated lake gypsum, presumably driven by heating of ascending, highly saline groundwaters. Thus anhydritization was controlled by the salinity of the pore solutions, and was ongoing from the onset of deposition to moderate burial to uplift (Orti and Rosell 2000). Anhydite meganodules, the most visually impressive type of anhydrite in these lacustrine sulphate salts, were telogenetically generated via the rise of deeply circulated meteoric waters, as discussed in Chap. 1 (Fig. 1.56; Ortí et al. 2012). The basin's diagenetic history indicates the typical complexity of evaporite textural evolution, even in strata that are undeformed and have undergone no more than shallow burial prior to exhumation.

Permian Lacustrine Redbeds, Kansas

The Permian (uppermost Leonardian-Kungurian) Nippewalla Group of Kansas and the Opeche Shale of North Dakota are part of an extensive redbed succession deposited in an arid continental interior sag basin on the Pangaean megacontinent (Fig. 5.15a; Benison and Goldstein 2000, 2001; Zambito and Benison 2013). Characteristic lithologies comprise bedded pan evaporites, red-bed siliciclastics and grey siliciclastics, all laid down in a series of continental playa depressions (Fig. 5.15b, c). Most evaporite deposition took place in a series of halite-dominated ephemeral saline lakes surrounded by saline and dry mudflats, sandflats and sand dunes. It was an evaporitic environment characterised by acid groundwaters with hydrologies not unlike those of

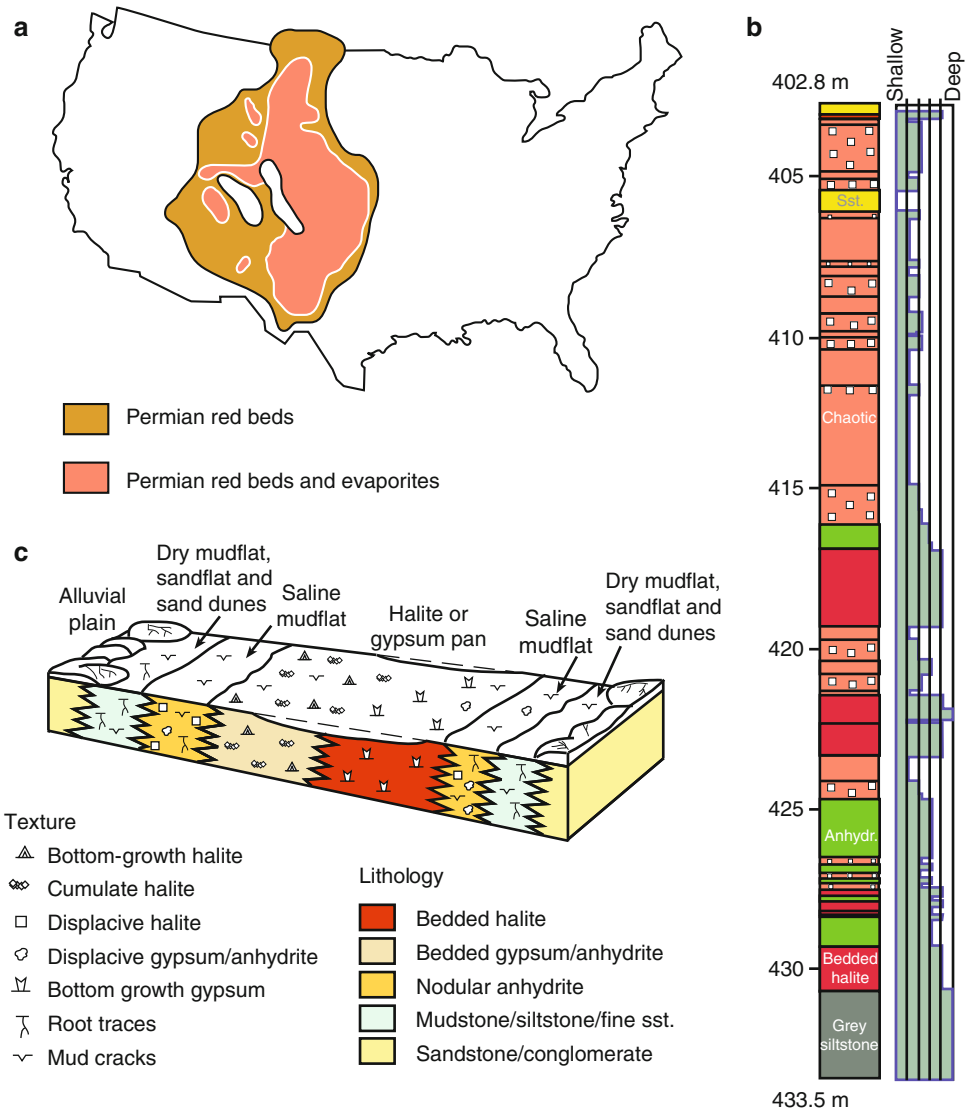

Fig. 5.15 Permian redbeds of interior USA. (**a**) Distribution of Permian red beds and evaporites in the USA. (**b**) Lithological description and relative depths of depositional environments of the Nippewalla Group from the subsurface of western Kansas; Anadarko-Davis No. 1 core, Seward County, Kansas. Deeper probably indicates a wetter climate and so this core seems to represent a transition from a wetter to a drier climate. (**c**) Inland playa associations that controlled sediment patterns in red beds of both the Opeche Shale and Nippewalla Group (After Benison and Goldstein 2000, 2001)

southeastern interior Australia and exemplified by the redbed lacustrine associations forming today in and around Lake Tyrell, Victoria and the salt lake landscape of southwest Western Australia (Bowen and Benison 2009; Benison and Goldstein 2002; Fig. 2.32).

Permian climate alternated between arid, when red siltstones and bedded evaporites dominated the various saline lake centres, and more humid, when grey siltstones and palustral carbonates were widespread. Much of the fine matrix in the ubiquitous Permian redbeds deposited at this time (e.g. Blaine Formation and Flowerpot Shale) is likely eolian dust and silt, rather that waterlain sediment (Sweet et al. 2013). An eolian origin to much of the redbed matrix is indicated by the fine and remarkably uniform grain size, internally massive structure, blanket-like geometry, and common palaeosols.

Bedded evaporites were deposited as saltpan and chaotic halites, or as less widespread bedded units containing calcium sulphate salts. Like the acid drainage basins of Australia, the system lacked widespread carbonates. These evaporite-depositing depressions were surrounded by extensive redbed mudflats and sandflats. Lithologies and sedimentary features indicate lacustrine and eolian deposition, subaerial exposure and palaeosol formation. Grey siliciclastic mudstones represent a freshwater-brackish perennial lake facies and are characterized by planar and convolute laminations, ostracods, peloids and plant material. Water levels were higher and the climate more humid when the grey siltstones were deposited. Bedded anhydrites containing gypsum-crystal pseudomorphs, clastic anhydrite grains, along with grey mud drapes and partings, all suggest deposition in saline lake depressions. Bedded halites consist of chevron and cumulate crystals, dissolution surfaces and pipes, and mudcracked microcrystalline salt crusts. They were deposited in saline pans subject to flooding, evaporative concentration and desiccation. Chaotic halite, composed of

red-bed mudstone and siltstone with displacive halite crystals, formed in saline mudflats surrounding the salt pans. Red-bed mudstone and siltstone with little or no displacive halite, but with abundant ped-cracking, root and plant features were deposited in dry mudflats in areas where water throughputs were less saline and waters were sufficiently fresh to allow halophytes to grow. Red-bed sandstone, composed of well-sorted, well-rounded quartz grains cemented with halite, preserve textures that indicate eolian and rare shallow-water deposition.

Evaporation, desiccation, flooding and wind reworking played significant roles in this environment (Benison and Goldstein, op. cit.). The Nippewalla Group/Opeche Shale siliciclastics and evaporites represent an evolution from a muddy perennial lacustrine system to a nonmarine, acidic saline pan system in the mid-continent of North America. Inclusion data from primary chevrons in the pan halite preserve temperature fluctuations at the seasonal scale and act as first-rate proxies for Permian climate in an arid megadesert created by the formation of Pangaea (Fig. 2.42). To the south, time equivalent evaporitic sediment in the San Andres and Clear Fork formations of the Palo Duro Basin, show an increasing marine influence in the form of intercalated carbonates. There widespread pan halites and bedded gypsums are intercalated with oolitic, restricted-marine platform carbonates, cryptalgalaminites become significant contributors to the sediment volume, and bioturbation from marine burrowers are locally important in some of the carbonate units (Handford 1981b; Hovorka 1987). Halite pseudomorphs after bedded coarse-grained gypsum is an important early diagenetic fabric in some of these sediments.

This passage to more marine-influenced saline pan and saltern salts in the south illustrates a correlation problem common to many ancient evaporites deposited atop cratonic landmasses. Namely, what defines an evaporite bed as marine or marine seepage-fed versus continental lacustrine in what where highly restricted settings where even marine-fed depressions had no surface connection to the ocean. This paradox is discussed in more detail later in this chapter.

Later work on this Nippewalla Group, using a halite core recovered from the Amoco Rebecca K. Bounds well, has further re-fined the climate-temperature significance of brine inclusions in aligned chevrons in bedded halite deposited in what was a continent interior playa system. Extremely high temperatures, to 73 °C, and large diurnal temperature ranges are evidenced in the lower Nippewalla Group, suggesting conditions more extreme than anywhere on Earth today (Fig. 5.16; Zambito and Benison 2013). In contrast, the upper Nippewalla Group was cooler; maximum temperature was 43 °C and diurnal temperature ranges were smaller, though even these conditions are similar to modern extremely hot environments, such as Death Valley, California. Comparison to prior studies suggests that these temperature results may be indicative of regional patterns. In may well be that the huge supercontinent interior deserts of Pangaea at times experienced more extreme temperatures than today, due to the high degree of continentality in such deserts and the fact that the Neogene Earth climate is in icehouse mode.

Other Lacustrine Red Bed Associations

In a number of underfilled lacustrine basins the supply of water may be insufficient to maintain a shallow watertable or a perennial lake in the drainage basin sump. In this situation the basin dries to where much of the sediment is reworked by wind action and little evidence of bedded lacustrine evaporites remains. Much of the basin fill is wind-reworked silt and loess. This is the situation in the present day Lake Eyre drainage basin of Central Australia and was also the case in the Middle to late Triassic across much of northwest Europe (Fig. 5.17; Talbot et al. 1994; Reinhardt and Ricken 2000; Porter and Gallois 2008; Brookfield 2003, 2008). This was when the Mercia Mudstone Group was deposited in Great Britain and the various Kueper lithofacies in Germany. Deposition was dominated by a characteristic assemblage of fine-grained sediment, the most widespread of which is a variably dolomitic red mudstone. It is typically massive and unfossiliferous except for occasional vague horizontal laminae and irregularly distributed wispy sand patches (e.g. Brookfield 2008). Desiccation features are common, as are blocky ped-like weathering patterns. Ainsworth et al. (2012) identified mud drape and other textural features in portions of this formation that indicate sedimentation similar to that seen in the terminal splay complexes, which periodically feed flood-stage sediment into modern Lake Eyre.

Nodular beds of gypsum/anhydrite and celestine are associated with the Mercia mudstone, along with gypsum-filled desiccation cracks and pseudomorphs after displacive halite and suggestions of haloturbation. Locally there are also 10–30 cm thick beds of dolomite and limestone. These thin beds range from micritic mudstones to ooid grainstones and packstones with freshwater algal remains (charophytes and *Botryococcus*). The local freshwater intervals are interpreted as areas of ponded floodwaters brought to the basin by exceptional rains (Talbot et al. 1994). As for the rest of the Mercia lithotypes, they too have their counterparts in times of freshened lacustrine sedimentation tied to flooding of the Quaternary Lake Eyre Basin, Australia and the Lake Chad Basin, Africa (Chap. 3).

Details of other ancient, mostly Neogene, saltpan and perennial lacustrine deposits, where the bedded salts are an exploited resource or a intimately associated with an exploited resource, are discussed in Chap. 11 (borates, lithium, magnesites, nitrates, potash, sodium carbonate, sodium sulphate, zeolites).

Platform Evaporites on Epeiric Shelves

Platform evaporites accumulated in epicontinental (epeiric) or pericontinental settings and constitute the salt layers in many stacked shoaling marine platform cycles, where

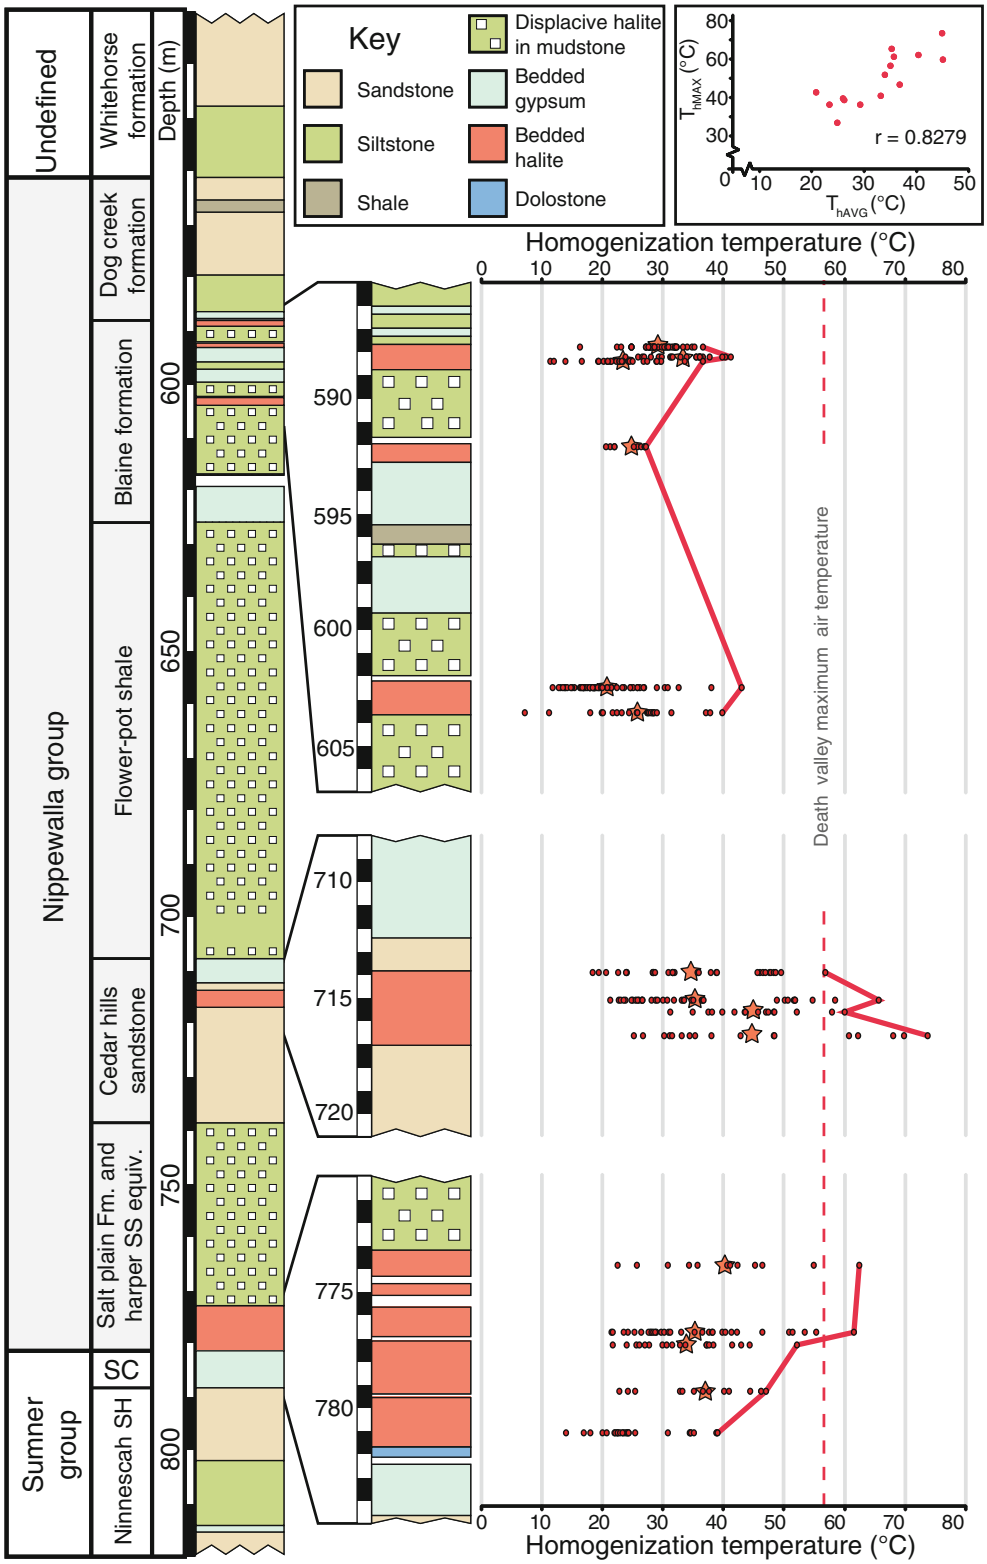

Fig. 5.16 Homogenization temperatures (T_h; *MAX* maximum, *AVG* average) for fluid inclusions within Nippewalla Group halite in the Amoco Rebecca K. Bounds core, Individual values represented by *black-edged red circles. Stars* represent T_{hAVG} for each sampled bed; T_{hMAX} is traced within subgroup units by *solid red line. Thin red dashed line* marks 56.7 °C, the hottest known air temperature measured on Earth (Death Valley, California). *Inset plots* T_{hmax} versus T_{hAVG} for all beds sampled (After Zambito and Benison 2013)

5–10 m thick evaporite units (typically anhydrite with lesser halite) are repeatedly interbedded with open-marine shoal-water carbonates or continental siliciclastics. Epeiric seaways were huge very shallow shelf and interior seas, up to thousands of kilometres across, that typically held waters no more than tens of metres deep and were usually much shallower during the hydrographically-isolated bedded salt phases (Fig. 5.18; Table 5.5). Epeiric seaways occupied large areas of continental interior (intracratonic seaway), while pericontinental (pericontinental seaway) describes situations

where large portions of the continental margin freeboard are covered by seawater. Both styles tend to be commonplace at times when world sealevels were high, as exemplified by greenhouse climate modes. In the world's current icehouse mode, sealevels are low as much of this water is caught up in polar icesheets and continental freeboard is limited. Consequently, there are few Quaternary examples of epeiric seaways and, because the icecap driven eustatic signal is one of high amplitude (120 m) and high frequency (100,000 years). They are all open marine systems: e.g. Gulf of Carpentaria, northern Australia, with its patchy but widespread *Halimeda* mounds, and the Yucatan Shelf of Mexico with its well developed strandline of calcareous eolianite.

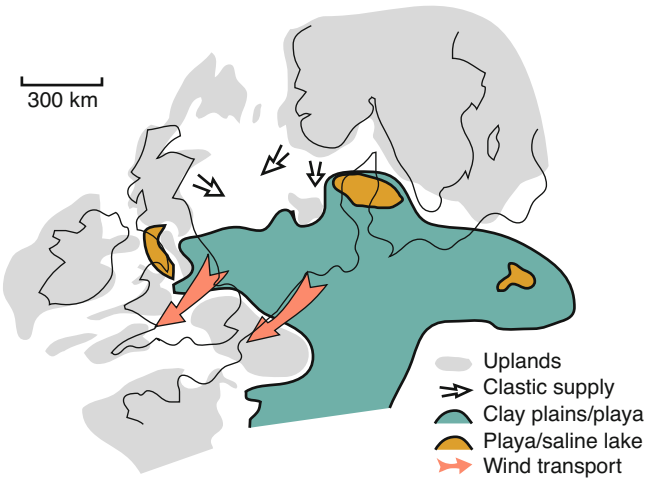

Fig. 5.17 Late Triassic palaeogeography of northwest Europe showing how deposition was predominantly in an endorheic basin and wind was blowing dust from mudflats about large discharge playas (After Talbot et al. 1994)

When an epeiric basin is cut off from a surface connection to the open ocean (hydrographically-isolated), saline deposition occurs either in: (1) Widespread evaporitic mudflats surrounded by desert dunes and wadi plains or, (2) Beneath sluggish, slowly circulating perennial sheets of marine-fed brine (saltern seaways) that cover the lower parts of the basin. These saltern water sheets can become holomictic and attain sufficient salinity to precipitate and stack widespread salts beds into units as much as 5–10 m thick. A region of subaerial evaporitic carbonate mudflats and sandplains, or an older now exposed platform edge shoal, typically separated the brine sheets from the open ocean.

At other times, when the same areas on the epeiric platform had a surface connection to the adjacent ocean (hydrographic connection and sealevel high), they were covered by shallow

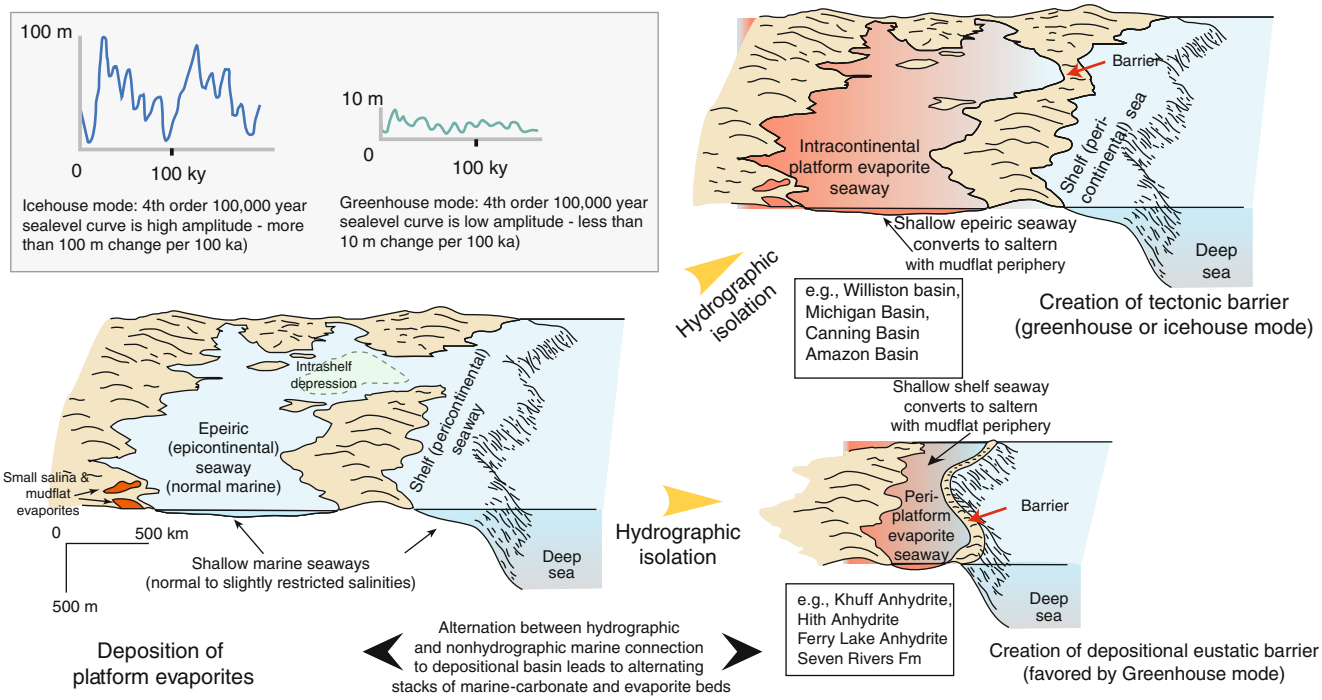

Fig. 5.18 Epeiric (epicontinental) seaways that covered large areas of the continental interior with shallow marine waters are known as intracratonic basins, while epeiric seaways that formed as very wide shelf edges along the continental margin as known as pericontinental seaways. Waters were very shallow over areas that were hundreds to thousands of kilometres across. Neither setting has a modern counterparts; pericontinental seaways that evolve into salterns and or evaporitic mudflats are more typical of marine-margin eustatic styles on the earth in greenhouse climate mode, when the lack of permanent polar icecaps, especially coupled with higher rates of seafloor spreading, meant the continental freeboard was much larger than it is today. Greenhouse meant relatively stable low-amplitude 4th-order sealevel and that there was time to build up a near continuous platform edge shoal. Intracratonic basins tended to go evaporitic with tectonically driven hydrographic isolation, in both greenhouse and icehouse mode. With hydrographic isolation both these restricted marine seaways quickly became salterns or evaporitic mudflat systems (After Warren 2010)

Table 5.5 Selected platform evaporites (dominantly megasulphate systems)

Periplatform evaporite successions	Age	Comments/key references
Ferry Lake Anhydrite, NE Gulf coast, USA	Cretac., Lower	Divided in 9 individual saltern anhydrites that are traceable from southern Mississippi to southern Florida and intercalated with normal marine bioclastic limestones (Pittman 1985; Petty 1995)
Rus Fm., Arabian Basin, Qatar, Saudi Arabia	Eocene, Lower	Has a total thickness of about 100 m, composed of limestones and dolomitic limestones (often argillaceous) passing upward into massive 10 m thick saltern anhydrite (Whittle and Alsharhan 1994; Ziegler 2001; Al-Saad 2003; Steinhauff et al. 2008)
Smackover/ Buckner Fm., N Gulf Coast, USA	Cretac., Lower	Buckner Anhydrite made up of intercalated 2–6 m thick saltern anhydrites and marine limestones. It extends from Florida Panhandle to South Texas (Mann 1988)
Hith Anhydrite, Arabian Basin, Middle East	Jurassic, Upper	Hith anhydrite is a regional seal that extends across much of the Arabian Peninsula and locally reaches 170 m in thickness. It is composed of bluish-gray to alternating bands of blue and white anhydrite with two internal carbonates and separates marine carbonates of underlying Arab Fm from overlying Yamama (unconformable base) (Alsharhan and Kendall 1994; Ziegler 2001)
Middle Anhydrite Marker, Khuff Fm., Middle East	Permian, Upper	Middle Anhydrite can be traced from eastern Saudi Arabia to offshore UAE, and reaches the onshore Fars Province of Iran. This anhydrite is some 12–17 m (20–39 ft) thick and consists of massive saltern anhydrite with minor thin interbeds of dolomite (Alsharhan 2006)
San Andres Fm., Northern Delaware Basin margin, USA	Permian, Upper	Anhydrite occurs as widespread saltern units composed of massive nodular mosaic anhydrite beds up to 5 m thick capping cyclic shoaling variably-dolomitised platform carbonates. Individual anhydrite beds (P1-P5) that can be traced from Palo Duro basin into shelf edge of the Slaughter-Levelland trend (Elliott and Warren 1989)
Cadjebut Fm., Canning Basin margin, Australia	Devonian Middle	Saltern anhydrites up to 5 m thick extend across a Devonian platform embayment pass and pass laterally into the sulphide mineralised ore horizons of the Cadjebut Mine region. Saltern sulphates capped shoaling oncolitic and bioclastic muds that overlie normal marine grainstones and wackestones (Cathro et al. 1992)
Cool Creek Fm., Arbuckle platform, USA	Ordovic., Lower	At least three 1–2 m thick breccias, interpreted to be of solution collapse origin, are present in the Cool Creek and define the presence of former widespread saltern anhydrite units that capped restricted marine stromatolitic carbonate platform sediments (St John and Eby 1978)
Red Heart Dolomite, Georgina Basin, Australia	Cambrian, Lower- Middle	Red Heart Dolomite which extends across much of Central Australia is a completely dolomitised 100 m thick platform carbonate deposited in an evaporitic shallow-water epeiric seaway It is characterized by at least four shallowing-upwards saltern anhydrite-capped cycles. Many of the surface and near-surface anhydrites caps are now leached and represented by collapse breccias (Nicolaides 1995)
Intracratonic Platform evaporite successions	Neoproterozoic to Eocene	North Sahara Basin, Africa; Canning Basin, Australia; Muschelkalk and Paris Basins, SW Germany and Spain; Amazonas Basin, South America; West Siberian Basin, Russia; Michigan Basin and Williston Basin, USA (see also Tables 5.6 and 5.8)

The shallow water textures and intercalated marine carbonates mean many basinwide intracratonic evaporites are also classified as platform evaporites

seawater (e.g. Feng et al., 1998; Fuersich et al., 1995). These waters could concentrate into the mesohaline range, especially in more restricted parts away from areas of marine resupply, but could not reach sufficient concentration to produce bedded salts (Chap. 2). The greater volume of the platform sediments at times of hydrographic connection were muddy marine carbonates, mostly peloid wackestones and mud-stones. Skeletal and peloidal (oolitic) grainstone shoals built up in areas where current energies from waves, or possibly tides along the marine edge, were sufficient to winnow lime mud but not grains. This created sandflat islands or shoals with long axes subparallel to the direction of dominant current transport, and subsequently encased in peloids or muds. These sandy beds constitute the reservoir sands in many mudflat and saltern-sealed epeiric sequences, such as the Arab D and Khuff carbonates in the Middle East (Chap. 10). Repetitive and characteristic shoaling-upward stacks or parasequences accumulated on the platform as the various types of marine sediments aggraded and prograded in this dominantly carbonate milieu. Extensive flat arid areas circumscribing the seawater-covered areas of the open seaway were typically huge evaporitic mudflats. Salinities along the low-relief strandzones of these huge shallow seaways were sufficiently elevated that the only fossil evidence of life was the occasional stromatolite or thrombolite and a mass of flat-laminated microbially-influenced mudstones (cryptalgal laminites).

Marine-fed mudflats and holomictic salterns generated dense seaward-flowing seeps of residual reflux liquor, via a reverse flow hydrology situated below the less dense marine-inflow seep groundwaters. Such dense groundwater brines cycled through and across the underlying platform sediment to create reflux dolomites (Fig. 2.73). The return fluxes were sometimes sufficiently voluminous to supply longterm chemosynthetic seeps in the outflow zones on the open sea floor of the adjacent open marine platform. At times of hydrographic connection, brines escaping from an adjacent mud-

flat into the seaway would become bottom-hugging waters, which trickled and seeped into local brine sumps on the marine platform floor. Ultimately, these denser, bottom waters formed areas characterised by longterm dense anoxic bottom water beneath a column of normal platform seawater. These areas were intraplatform or intrashelf basins that were local, slightly deeper, warmer (heliothermic) depressions on the seaway floor (Chap. 9).

The intrashelf subaqueous sumps could be up to hundreds of kilometres across, but water columns were no more than 10–30 m deep. By the time the mudflat-derived bottom brines finally ponded in the deeper parts of such intraplatform lows, salinities may have been diluted, via diffusive mixing, to where they were no more than a few ‰ higher than normal seawater. This was sufficient to maintain a density/thermal stratification, so that the bottom waters were dysaerobic to anoxic. A number of organic-rich oil-prone carbonate laminites and marls (source rocks) accumulated in these lows, such as the Jurassic Hanifa Formation a significant source rock of the Arabian Platform (Figs. 9.4 and 9.5). At times of hydrographic connection between the epeiric platform and the world's oceans, the platform areas surrounding these intraplatform depressions were shallow and more oxygenated than the depression floor, with largely normal marine salinities and water depths typically less than 10 m. This encouraged the local accumulation of reef mounds and sandy shoals on the highs.

Hydrographic connection between the open ocean and the epeiric seaway could be lost for a number of reasons; a sand shoal buildup at the platform rim, a slight fall in sealevel, or tectonic tilting. Once portions of epeiric or pericontinental seaways lost their hydrographic connection to the open ocean, bedded marine-fed saltern and mudflat evaporites were laid down. This occurred within one of two carbonate platform chassis; either on a *carbonate ramp* or on a *carbonate shelf* (Fig. 5.19). Carbonate ramps have slopes of less than 1°, the wave agitated zone is typically close to the seashore, and there is no high relief shelf break located some distance seaward from shoreline (Ahr 1973, 2008). Slopes in ancient epeiric ramps in greenhouse times and in intracratonic seas were as low as 1 in 50,000, compared to modern ramp gradients of between 1 in 500 and 1 in 2,500 (Fig. 5.19a; Burchette and Wright 1992; Warren 1991). In contrast, carbonate shelves are shallow water, land-coupled platforms with a pronounced break in slope into deeper water (Fig. 5.19b). The break in slope is typically a wave agitated to high-energy feature, it may be composed of a reef rim or a series of mechanically-reworked sand shoals and islands. The slope, seaward of the platform edge, is typically measured in degrees of inclination. In modern reef-rimmed platforms the seaward slope ranges from 30° to vertical.

Rather than the icehouse climate mode of today, periplatform evaporite systems require greenhouse eustasy in order to establish the required seepage hydrology (Warren 2010). Times of greenhouse climate were times when 4th order (100,000 year) sealevel changes were an order of magnitude less than the 100 m sealevel cycles that typify 4th order eustatic cycles in the icehouse-driven world of the last 10–12 million years (inset in Fig. 5.18). There was another Phanerozoic episode of icehouse-dominated eustasy some 300 Ma in the Permo – Carboniferous and another somewhat shorter possible episode some 440 Ma in the Ordovician (Fisher 1981).

During icehouse times the oceanic eustatic response to rapidly waxing and waning polar icesheets is in terms of amplitude excessively high, and time-wise too short, to allow sufficient time for periplatform-margin biogenic buildups to grow into continuous platform-edge barriers. It is the long-term elevated sealevels of greenhouse times, along with their lower fourth order amplitudes (less than 5–10 m of sealevel change every 100,000 years), that allow persistent platform-edge reefs and shoals to form (see inset in Fig. 5.18). With a subsequent slight fall in sealevel, these contiguous platform-edge barriers became subaerial barriers to any hydrographic connection of the back-barrier lagoon to the open ocean. This initiates marine-seepage fed lagoons (salterns) in their hinterland.

Periplatform evaporites tend to megasulphate rather than mega-halite affinities and today act as regional seals to many of the world's oil and gas fields (e.g. Hith Anhydrite, Middle Anhydrite marker of the Khuff Fm and the Ferry Lake Anhydrite; see Chap. 10 for details on various evaporite-sealed oil and gas fields). But in addition to the periplatform settings, there are shallow-water platform evaporite systems in continent-interior (intracratonic) settings. There, laterally extensive sulphate and halite beds are interlayered with units of normal to restricted marine platform carbonates, defining cycles more than 30–60 m thick. Well preserved nonhalokinetic bedded halite in these cycles tends to be part of the depositional succession in this type of platform evaporite. These platform evaporite successions tend to occur in intracratonic sags (typically tied to aulocogens in extensional or distal flexures in compressional settings), as in the Amazonas and Michigan basins (Table 5.5). At the basin scale, such intracratonic halite beds can become halokinetic, but only when later caught in tectonic events such as a zone of continent-to-continent collision.

Unlike periplatform evaporites, where the hydrographic isolation is a eustactically-driven, typically greenhouse, response; the hydrographic isolation needed to create an intracratonic evaporite phase tends to be tectonically induced. Compared to saline giants (megahalites) deposited in rift and collision basins along the continental edge, intracratonic evaporites can be considered a transitional tectonic subset of basinwide evaporite successions. Deposition is related to gentler topographic expression in a intracratonic sag with slow relative subsidence an occasional marine ingress. This encourages stacking of a number of shoalwater saline episodes (up to 5 or more third-order evaporite-carbonate cycles, sometimes spread over tens of millions of years in an intracratonic system). In contrast, typical basinwide evaporite (megahalite and megasulphate) are deposited as thicker salt masses (>100–200 m thick) over shorter active saline

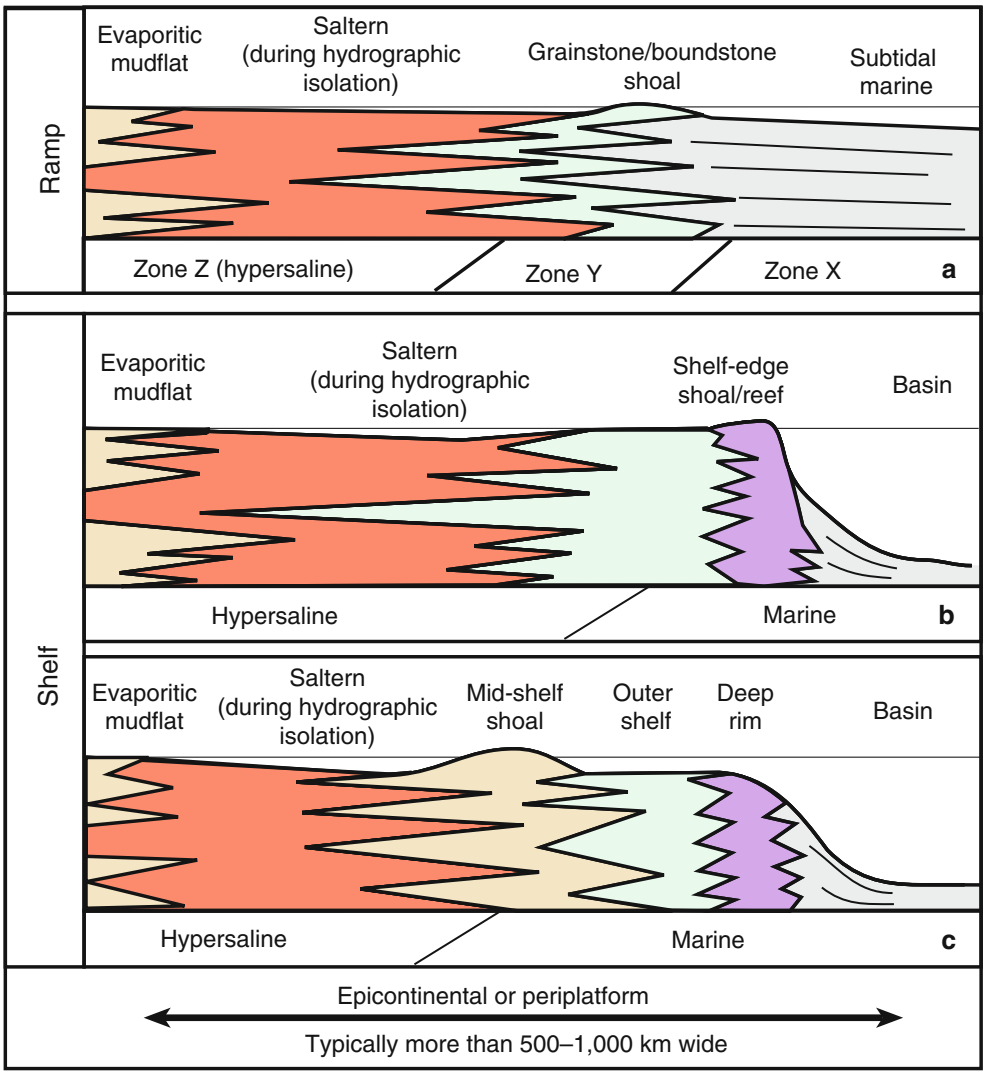

Fig. 5.19 Evaporite depositional styles – ramp and shelf. (**a**) Gently deepening ramp with restriction created by exposed zone Y shoal. (**b**) Rimmed shelf with restriction supplied by exposed reef/shoal that defines the platform margin. (**c**) Rimmed shelf with deep rim and restriction supplied by exposed mid-shelf shoal

basin time frames (forth-order cycles stacking into a thick evaporite sequence over ≈1 million years). These evaporites tend to have higher average sedimentation rates than the underlying or overlying nonevaporite sediments within the incipient marine rift and continent-continent collision basins where they form. The greater thickness of salt and its relatively purity makes these salt masses more susceptible to halokinesis than the intracratonic evaporite units (Chap. 6).

Evaporitic Epeiric Ramps

Ahr's 1973 ramp model envisaged a uniform slope from the shoreline into the basin, later termed a homoclinal ramp by Read (1985). However all modern ramps, and some ancient ramps appear to have a subaqueous slope break in deeper water and are termed distally-steepened ramps. The overall inclination of the slope is still flat (<1–2°) and never approaches that of a carbonate shelf. Modern ramps characterise the tropical arid carbonate coasts of the southern Arabian Gulf, the Gulf of Carpentaria and the more humid Yucatan shelf. All these modern ramps face directly into the open ocean and have never shallowed sufficiently to isolate large portions of their lagoons and so lack widespread salt beds. Minor marine-fed evaporites do accumulate in small volumes as laminites and displacive aggregates in the transitional marine portions of the Arabian and Carpentarian gulfs.

The best-documented example of a modern carbonate ramp, with some evaporite deposition, is the Trucial Coast of the southern Arabian (Persian) Gulf (Purser and Evans 1973). But, it is a poor analogue for any epeiric or pericontinental counterpart as it is not supplied solute from a seawater source, its evaporite belt is supratidal, less than 10–15 km wide, matrix-rich and less than a metre thick (Chap. 3). In the Gulf of Carpentaria, evaporitic conditions some 70 ka produced a decimetre-scale unit made up of repetitive alternations of μm to mm-thick gypsiferous and micritic laminae, with a varve-like appearance. These precipitates are interpreted as primary features, deposited in a shallow lake that retained limited water in its centre (core MD-32; Playa et al. 2007). Elemental and isotope geochemistry of the laminae show a complex evaporitic environment where initially marine waters evaporated with the input of continental waters compensating for evaporative losses.

Unlike most modern arid-zone carbonate ramps, which are tens to a few hundred kilometres wide, ancient hypersaline epeiric ramps were hundreds to thousands of kilometres across and formed huge evaporitic seaways at the edges of continents (pericontinental seaways; Fig. 5.18) or extended as near-land-locked interior seaways that spread out across large areas of various continental cratons (epicontinental seaways and intracratonic basins). The Permian red beds discussed earlier in the lacustrine section are the landward end of one such interior evaporitic lake or seaway (saltern). The world's last development of such a huge interior seaway was in the Eocene in evaporitic platform carbonates of the Middle East (Table 5.5). But these platform evaporites (Radhuma, Rus and Dammam formations) are perhaps better considered as basinwide back-bulge or intracratonic sag salts, deposited in a response to flexural sag and basin isolation behind the migrating forebulge of the Zagros Orogeny (Alavi 2004; Steinhauff et al. 2008). If so, this makes the world's most recent episode of marine periplatform evaporite as old as the Paleocene or the Cretaceous (Table 5.5; Fig. 10.36).

The transition into an icehouse climatic mode in the Eocene, the capture of large volumes of ocean water in oscillating ice caps, and a slowing in the rate of seafloor spreading, meant large evaporite seaways, so conspicuous on the Late Permian and Mesozoic platforms, had disappeared from the face of the earth by the mid Tertiary. A lack of modern analogs means we cannot directly observe the influence that epeiric seaways had on the depositional styles of ramp evaporites. We are forced to scale up sediment patterns in Quaternary coastal evaporites in the knowledge that the high amplitude, high frequency, eustasy of today is not the hydrological or eustatic equivalent of the sea-margin periplatform ramps of greenhouse earth.

Epeiric ramps were first modelled by Shaw (1964) and Irwin (1965), they both concluded that the huge areas of restricted stagnant circulation on the hind parts of these seaways were capable of periodically accumulating extensive beds of evaporites. Irwin's epicontinental-sea model proposed there were three zones of varying hydraulic energy on ancient platform ramps (Fig. 5.19a):

- *Zone X* was a wide low-energy region situated below wavebase on the open-marine side of the platform, so that sediments were mainly bioturbated marine mudstones and wackestones. It was often hundreds of kilometres wide and locally characterized by limited water circulation, with occasional stagnation. Now and then, this led to the deposition of organic-rich laminated sediments.
- *Zone Y* was a narrow, intermediate to high-energy belt beginning where waves first bottomed on the seafloor and extending landward to the limit of any tidal action. Sediments in this zone included sand and grainstone shoals, mud banks, reef mounds and patch reefs. These sediments could build elongate shoals that restricted and at times prevented the surface entry of seawater into the adjacent zone Z.
- *Zone Z* was an extremely shallow, restricted low-energy region on the landward side of zone Y. In arid settings, wherever zone Z was hydrographically isolated from zone X, extensive saltern and mudflat evaporites were deposited. At times when zone Z and zone X had a surface connection through zone Y, the seaward portion of zone Z was covered by restricted-marine mostly muddy sediments with local sandier carbonates. The more distal portions on its continental side were evaporitic mudflats.

Marine wave energy was dissipated some distance basinward from zone Z as it spent itself against the seaward side of the shoals, bars, and reefs of zone Y. Shallow wave-agitated facies of zone Y passed down the slope into deeper-water subtidal open-marine facies of zone X without a rapid change in slope angle. Behind the zone Y shoal, bottom slopes in zone Z were even less than on the open marine ramp and had maximum bottom angles of only a few seconds of arc (≈1:50,000). Thus, huge areas of zone Z were covered by extremely shallow water sheets, much of it only tens of centimetres deep. This is a setting replicated at a much smaller scale in the modern khors of the United Arab Emirates (e.g. Khor al B'azm). During times of widespread evaporite deposition across zone Z there was no hydrographic connection to the ocean and so tidal effects were negligible. Depositional textures were largely akin to those formed in modern saline pans and sabkhas although perennial seaways depositing salterns were a distinct possibility in zones with more relief behind Zone Y.

Zone Z water levels fluctuated most rapidly during intense storms or hurricanes, as sheets of sediment-laden seawater could be washed landward over zone Y into zone Z, or during exceptional episodes of flash-flooding generated by torrential rainstorms in the continental hinterland. Both marine and meteoric influx freshened the surface and nearsurface brines of Zone Z as sheets of water migrated tens of kilometres across the strandplain. At the same time a new pulse of marine or continental clastic sediment matrix was delivered. Evaporite-forming areas in zone Z were up to hundreds of kilometres wide, far wider than any evaporitic area on the modern land surface.

On any evaporitic ramp there was some degree of topographic relief about zone Y, and restriction of water flow across it. When salts were accumulating in Zone Z there were no perennial surface channels connecting it to the waters of Zone X (no longterm hydrographic connection Fig. 5.19). Vertical sequences of evaporites deposited in zone Z were very much dependent on the relative physiography of zone Y. If zone Y was a well developed low-relief shoreline with extensive washover flats behind, then much of zone Z was an evaporitic mudflat; a mosaic of sabkhas and salinas. Or, if zone Y was a higher-relief shoal, it would be backed by a marine seepage-fed evaporite lagoon, and zone Z would consist of saltern evaporites with an increasing proportion of subaerial mudflat indicators (desiccation cracks, karst, erosion features, displacement textures) toward the top of the unit and toward the landward and seaward strandplains.

Units P_1 and P_2 of the San Andres Formation in the northwestern platform of the Permian Basin and the Palo Duro Basin illustrate the saltern-ramp end member (Fig. 10.22; Elliott and Warren 1989). Similar saltern signatures dominated the San Andres and Clear Fork formations in the Palo Duro Basin (Fig. 5.27). Correlatable units of saltern anhydrite or halite in the Palo Duro Basin have areas of more than 26,000 km^2. At times of widespread evaporite deposition on the Palo Duro Basin and the northwestern shelf of West Texas, one could have travelled 50–150 km south and seaward from the strandplain of the brine sheet and never crossed through water that was much more than a few metres deep, nor less saline than gypsum-saturated.

The northern portions of the Lower Clear Fork Formation of the Palo Duro Basin illustrate the evaporitic mudflat-ramp end member where extensive "dirty" halite beds are intercalated with fine-grained siliciclastics (Fig. 5.20a; Handford 1981b, 1991). Deposition took place in an evaporitic mudflat and pan complex that passed further northward into the large continental desert made up of salt pans, wadis and dunes documented by Benison and Goldstein (2001). Southward, the Clear Fork ramp passed from highly continental mudflats into marine-fed saltern deposits and then across the restriction of the Zone Y phylloid buildups into open-marine carbonates of zone X (Fig. 5.20b; Ramage 1987). Deciding where to place a line separating marine from nonmarine brines is near impossible; although it is generally true in this and in most other arid successions passing from the marine into huge interior redbed deserts that the thicker bedded salt accumulations are more likely on the marine side of the system.

Thick evaporitic carbonates and intercalated anhydrites of the Khuff Formation define a huge evaporitic platform (≈255 Ma) in the Arabian Gulf, with an upper section that straddles the Permo-Triassic boundary (Fig. 5.21a; Al-Jallal, 1991, 1995; Dasgupta et al. 2002). In eastern Saudi Arabia, the Khuff Formation is divided into five units or members designated as Khuff A through E. However, throughout the Gulf region the Khuff may comprise as many as eight designated mappable subsurface units or members (KS1-7; Alsharhan 2006; Al-Jallal 1995; Strohmenger et al. 2002). Most of the Khuff Formation is composed of carbonates and evaporites; major siliciclastic facies increase towards the west and toward the base of the sequence, especially in Saudi Arabia (Ehrenberg et al. 2007). As many as six or seven grainy units are capable of acting as hydrocarbon reservoirs and correspond to depositional carbonate-anhydrite cycles where transgressive marine carbonates are capped by regressive anhydrites.

The Khuff Formation thickens from about 260 m in southwestern Saudi Arabia to more than 915 m in the central Rub 'al Khali Basin, 1,220 m in Oman, and 1,520 m in Iran. Typical thickness for the Khuff ranges between 370 and 490 m over most of central and eastern Arabia (Al-Jallal 1995; Strohmenger, et al. 2002; Alsharhan 2006). The basal Khuff section consists mostly of siliciclastics throughout southern Arabia. The "basal Khuff clastics" in Saudi Arabia are made up of shale, carbonaceous shale, limestone streaks, and incised channel-fill sandstones. Individual channel-fill sandstone units of the basal Khuff clastics are as much as 18 m in thickness and can cut deeply into the underlying Unayzah Formation. In the Hazmiyah field of central Saudi Arabia, the reservoir occurs entirely within these channel sandstones in the basal Khuff (Fig. 5.21b; Senalp and Al-Duaiji 1995). The Unayzah and basal Khuff sandstones form the principal reservoirs in central Saudi Arabia and extend north in Kuwait; however, widespread reservoir quality variations occur in

these sandstone reservoirs owing to heterogeneous sedimentary facies and variable diagenetic intensity (Aktas and Cocker 1995; Polkowski 1997; Tanoli et al. 2008).

Over most of the rest of Saudi Arabia and west into Oman and the UAE the Khuff is more than a 1 km thick and composed of numerous 2–10 m thick shoaling stacked dolomitised carbonate cycles or parasequences. These Late Permian dolomites are major gas reservoirs along the offshore in the Arabian Gulf north and west of Qatar. In contrast, the regionally extensive anhydrite, shale, and tight (low-permeability) carbonates of the Khuff Formation form the major regional seal for Pre-Khuff hydrocarbon accumulations in central and eastern Saudi Arabia (Al-Jallal 1995; Wender and others 1998; Alsharhan 1993, 2006).

Deposition of this thick carbonate succession was initiated as a ramp in the late Khazanian or early Tatarian and had evolved into a reef-rimmed evaporitic platform by the later Permian to early Triassic (Fig. 5.22). Most of the cycles in the upper part of the Khuff are capable of producing gas and are variably dolomitised oolite-peloid successions that typically grade upward into fine-grained laminites and nodular mudflat/pan anhydrite. Carbonate cycles atop siliciclastics in the lower part of the Khuff tend to be more dominated by coarsening-upward shoreface/shoal cycles with lesser mudflat laminites.

All the Khuff beds and anhydrite saltern marker pass westward via a belt of mixed detrital carbonate and siliciclastics onto the palaeohigh of the Arabian Shield (Fig. 5.21b; Alsharhan 2006). Correlations and definitions of time-equivalence in adjacent wells or outcrops in this belt is problematic due to a lack of appropriate fossils and similarity in wadi/dune depositional styles throughout large passages of Palaeozoic and Mesozoic time in the circum-Arabian Shield area.

The Khuff succession is punctuated by numerous intervals of subaqueous and pan anhydrite (after gypsum) with local development of evaporitic mudflat facies atop shoals (pers. obs.). In the middle of the Khuff succession is a thick saltern sulphate bed called the Middle Anhydrite. It is a regional marker bed originally deposited as a thick sequence of bottom-nucleated subaqueous gypsum. This marker defines a time when the whole of the Khuff platform was converted to a saltern rather than the more typical combinations of evaporitic mudflats and pans (see also Chap. 10).

The Jurassic section atop the Khuff in Saudi Arabia and the Emirates is another evaporitic platform succession. It constitutes the most significant source-reservoir-seal association for hydrocarbons anywhere in the world (see detailed discussion of Hanifa, Arab D and Hith Anhydrite in Chaps. 9 and 10). Both the Arab and the Khuff formations accumulated at different times along the southern shore of the Neo-Tethyean Ocean when sediment accretion atop an original Hercynian horst and block terrain periodically isolated large parts of the platform interior. This led to the

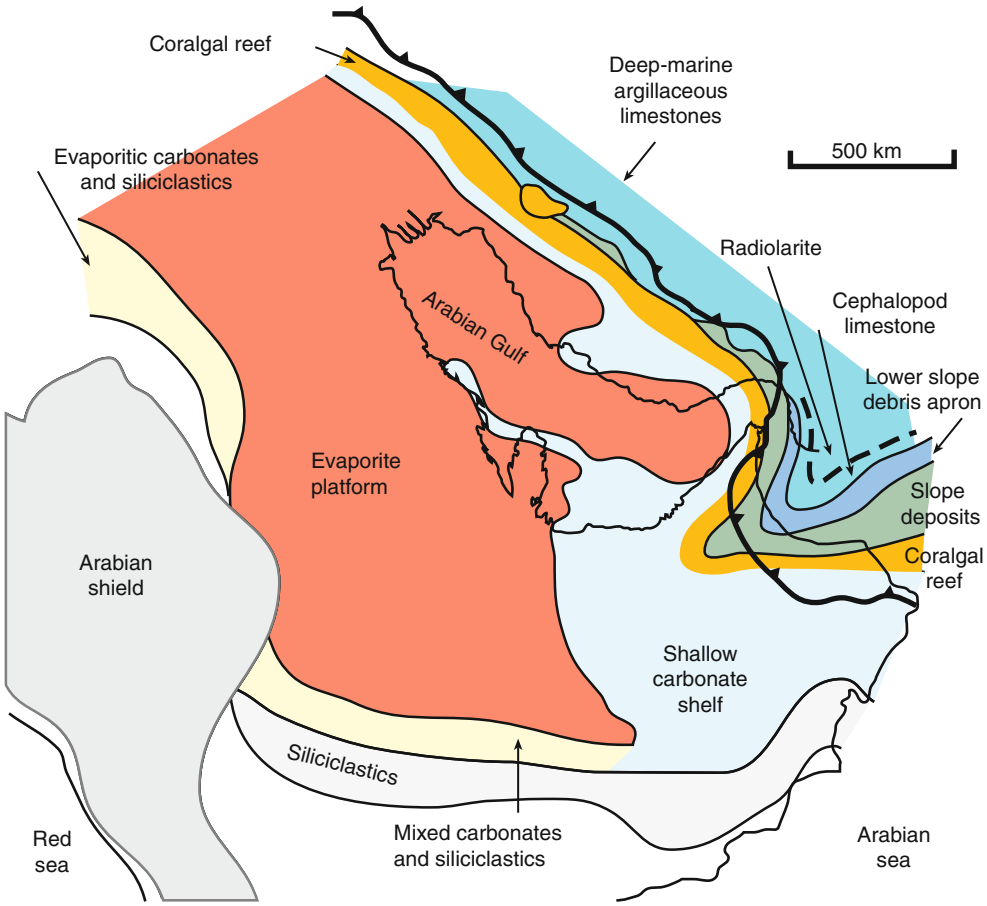

Fig. 5.22 Major facies belts and their interrelationships in the Permian Khuff Formation of the Middle East (After Al-Jallal 1995)

punctuation of the carbonate platform record with evaporite beds throughout much of the Mesozoic.

Regionally, the Mesozoic in the Middle East was a period of tectonic activity centred on the opening and closing of the Tethys. The Late Permian ocean backed onto the huge landmasses of Pangaea and in both opening and closing stages of the supercontinent the ocean created large subsealevel marine margin areas where epeiric carbonate seas formed that were periodically isolated as intracratonic sags and then filled to hydrologic base level with bedded salts. Similar evaporite entraining epeiric carbonate ramps also characterised the Infracambrian of the Middle East, the lower Palaeozoic of North America and Australia, the late Palaeozoic of America and Russia, and the Triassic and Jurassic of Europe (Table 5.5).

Evaporites Atop Rimmed Epeiric Shelves

Ancient rimmed-shelves were shallow-water carbonate platforms with an outer wave-agitated edge marked by biogenically induced buildups or highs and a pronounced increase in slope that was typically a few degrees, less often more than 60°, into deep water (Read 1985). Platform evaporites can be found behind such rims throughout the Phanerozoic (Fig. 5.9a). Subsurface examples of this style of carbonate deposition, as opposed to ramps, are readily identified seismically using obvious clinoforms and reflection discontinuities that define the shelf edge or shelf break. Many modern reef-rimmed shelves are constructed by combinations of coral and coralline algae, but different organisms have occupied the framebuilder niche in the past; stromatolites in the Proterozoic, stromatoporoids in the Devonian and rudistids in the Cretaceous. When Phanerozoic reef occurrences are plotted in time against evaporite volumes there is little or no correlation implying reef-rimmed platforms are not the dominant mechanism driving times of widespread evaporites. It implies tectonic isolation during times of continental make-up or break-up, and not eustasy, created the depressions and the drawdown hydrologies that precipitated the greater volumes of world's ancient evaporites as basinwide not eustatic reef-rimmed platform evaporites (Fig. 5.23).

The platform rim in greenhouse times was continuous to semicontinuous during times of open marine carbonate growth, characterized by high-energy reefs and reef mounds with intervening grainstone shoals and flats. Areas behind platform rims in arid settings are typically made up of seepage-fed evaporitic carbonate flats alternate with salterns and mudflat evaporites or arid zone siliciclastics. Rimmed shelves require biogenic binding and cementation to maintain an elevated biogenic rim, they do not form on siliciclastic platforms, nor can reef flourish if they are connected at the surface to hinterland areas where extensive evaporites are accumulating. Both these scenarios set up inimical seaward-flushing waters; in the former the reef-biota is killed off by detrital plugging, in the latter by elevated salinities.

The degree of restriction in the evaporite-depositing lagoon area behind the platform edge is controlled by the continuity of the rimming shoal. To form a saltern or an evaporitic mudflat in an ancient lagoonal depression requires the rim crest to be at or above sealevel, with any channels cutting across the rim and its sandflat to be choked with sediment (Lucia 1972). This prevents freshening via the free exchange of marine and

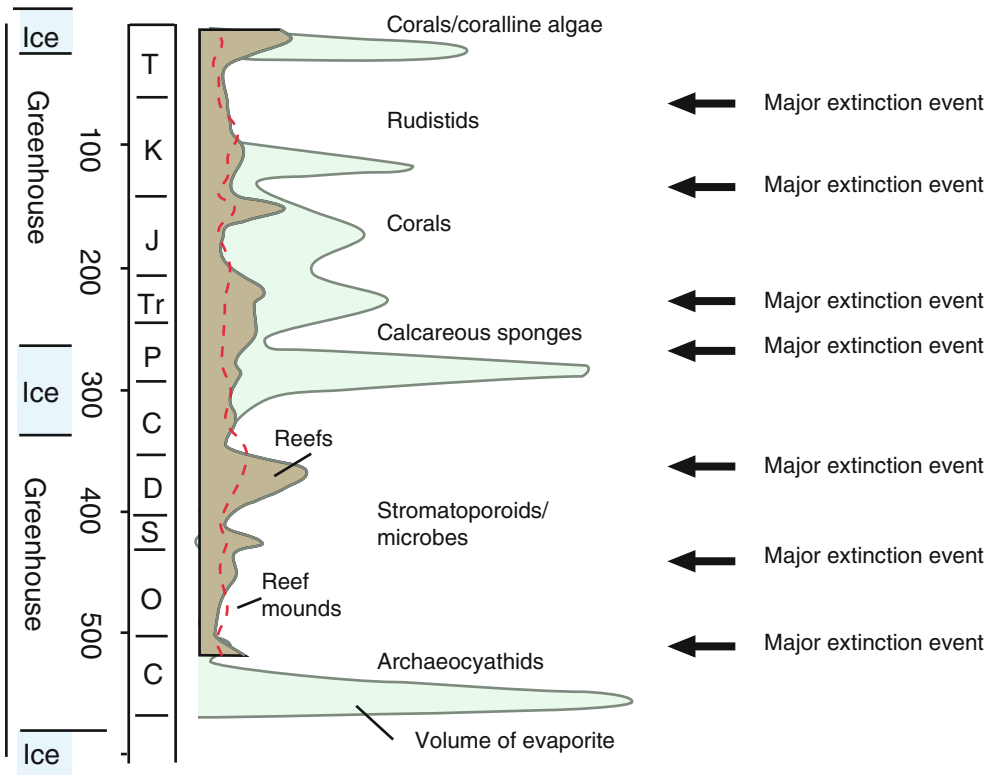

Fig. 5.23 Phanerozoic distribution of reefs (*brown shading*), reef mounds (*dashed line*), major extinctions and the dominant reef formers through time (After Kiessling et al. 1999) versus the worldwide volume of evaporites (After Hite and Anders 1991)

backrim waters. Otherwise, like the carbonate platforms of today, conditions behind the shelf rim or shoal can never become saline enough to deposit widespread evaporites and, at best, restricted marine carbonates are deposited.

Evolution of major reef biota through time does create some interesting variations in the ability of the living reef formers to live proximal to evaporite accumulating areas. Precambrian stromatolitic platform-edge reefs could grow in close to an evaporitic mudflat; some stromatolitic horizons are repeatedly intercalated and even penetrate saltern beds in the Neoproterozoic Ara salt of Oman. Cambrian archeocyathids were much more fragile. For example, in the well-exposed reef outcrops of the Flinders Ranges in South Australia the archeocyathids never occur in close proximity to evaporitic mudflats. There are always debris aprons and unconformities separating bioherms from overlying evaporite dissolution breccias. Stromatoporoids in lagoonal bioherms in the Alberta Basin appear to have better tolerated exposure to mesohaline waters, at least for short periods. But with no modern analogue it is difficult to define why this is so (e.g. were stromatoporoids related more to calcareous sponges or to cyanobacterial plexi?). Phanerozoic corals (rugose, tabulate and scleractinian) consistently show a poor tolerance to salinity change (stenohaline fauna) and living communities were never able to tolerate salinity changes for more than a few hours. Rudists appear to have been more robust in their salinity and temperature tolerances. In core recovered from the subsurface of Texas I have seen small *in situ* buildups forming units adjacent to both oyster bioherms (estuarine) and the less saline portions (mild sabkhas) of ancient evaporitic mudflats. This ability of rudists to survive changed salinity and temperature is probably related to their molluscan pedigree. When conditions became too saline, too hot or too fresh they could retract their filtering apparatus, pull down their opercular caps and wait out the adverse conditions, at least for a day or two. Even today, chemosynthetic molluscs survive in close proximity to deep seafloor brine lakes (Fig. 9.50).

The Cretaceous Ferry Lake Anhydrite formed behind a rimmed rudist platform as a 90 m-thick unit extending from east Texas to Alabama (Fig. 5.24). It is made up of metres-thick alternating units of carbonate and anhydrite deposited in the lagoonal area of a broad, shallow reef/shoal-rimmed carbonate platform. Using wireline signatures, individual sulphate beds can be traced over distances of more than 160 km (Fig. 5.24a; Pittman 1985). Where it subcrops toward its present landward extent the anhydrites have been dissolved by meteoric waters. At the time of deposition they passed further landward into alluvial plain conglomerates and redbeds. Detailed core study in the J. B. Kitchens No. 1 well (Henderson Co, Texas) showed the anhydrite beds are mostly composed of vertical- to near vertical-aligned nodules separated by fine mm-laminated anhydrite (Loucks and Longman 1982). These structures are diagenetic "ghosts" after original bottom-nucleated gypsum. Throughout much of its subsurface extent the wirelines signature of the correlated anhydrites show a clean blocky appearance with neutron-density crossplots indicating high levels of sulphate purity, making it a saltern deposit (Warren 1991). Sabkha mudflat signatures in the anhydrites are rare. The saltern/lagoon was up to 260 km (160 miles) wide and was separated from open marine waters by shelf-margin bank or shoals dominated by rudistid debris of the Glen Rose Formation (Fig. 5.24b). The position of the shoal was possibly controlled by down-to-the-basin faulting. This in turn was controlled by into-the-basin salt flow and associated growth faulting, driven by halokinetic movement of the underlying Jurassic Louann Salt (Chap. 6).

The anhydrite beds are up to 7 m thick and contain thin mudstone layers with entrained anhydrite rip-up clasts. The thicker carbonate beds, which separate the anhydrites, are near-normal marine lagoonal bioclastic/oolitic wackestones indicating times of hydrographic connection through the rim facies to the open ocean. The entrained fauna includes ostracodes and molluscs, several units contain *Orbitulina* and echinoid fragments, indicating that normal marine waters were present either during highstands or in times of storm-induced marine floods. Loucks and Longman's original 1982 interpretation was that the marine carbonate beds were deposited during periodic storm flooding of a restricted carbonate lagoon by marine waters. They also postulated that a single perennial evaporite lagoon was capable of depositing gypsum on its seaward side and halite on its landward side. Given a lack of widespread halite and what we now know about saltern hydrology this surface-connected scenario of marine on one side of a lagoon and halite on the other is somewhat unlikely. To deposit a widespread subaqueous evaporite unit requires total or near total isolation from a surface connection to the ocean in a system where a single perennial brine is at saturation with a single mineral phase (see later hydrological discussion in this chapter). A more likely scenario is that the Ferry Lake Anhydrites were precipitated simultaneously across a gypsum-saturated seaway during times of complete surface isolation from the ocean, and halite was perhaps forming stacked crusts in isolated pan depressions within subaerial mudflats in the most landward parts of the basin (as in Lake Asal today). On the seaward side of the saltern the crests of the rudistid shoals and reefs were subaerially exposed, while the underlying shoal sediment was an unconfined aquifer facilitating the phreatic supply of marine water into the drawdown saltern filled with gypsum-saturated brine sheets up to a few metres deep. Interestingly, the Ferry Lake Anhydrite retains remnants of the actual primary gypsum as gypsum cores encased in secondary anhydrite nodules at depths as great as 3,993 m (13,100 ft; Amadi et al. 2012).

An even more thoroughly documented example of a rimmed evaporitic platform is the Permian margin of the Delaware Basin in West Texas and New Mexico, USA (Fig. 5.25a). The margin is exposed in the Guadalupe Mountains, while its dolomitised, evaporite-sealed, subsurface lagoonal counterparts form the most productive reservoir intervals from the NW shelf into the Central Basin

Fig. 5.25 Permian reef complex of the Guadalupe Mountains, West Texas. (**a**) Schematic cross section of the Permian carbonate platform based on outcrops in the Guadalupe Mountains of Texas and New Mexico. Note the initial strongly progradational ramp-like profile in the San Andres Formation and its evolution to a reef-rimmed shelf with a well defined slope break, along with a steep shelf margin that was several hundred metres high. The platform interior is dominated by saltern evaporites (*white*) that pass seaward through pisolitic island shoal/strandzone facies into the deep-rim reef of the Capitan Formation (After Kerans et al. 1993; Kerans and Fitchen 1996). The basinward slope of the evaporite sequence is based on the current configuration of the basin margin and probably does not reflect the original slope. It is created by post depositional regional tilting. Map *inset* shows major physiographic provinces of the Permian Basin in West Texas and New Mexico. (**b**) Detailed facies and dolomitisation relationships based on measured sections in the Yates/Tansill Formation showing the position of the shelf crest landward of the reefs of the Capitan limestone (After Mutti and Simo 1993). (**c**) Dolomitisation of the Capitan shelf strata and reef by dense mesohaline fluids that originated in the near back reef evaporitic shelf-lagoon (Hunt et al. 2002). Basinward flow of the dolomitising fluids was along aquifer units within the shelf—the sandstones resting on sequence boundaries. The basinward tilting of the back reef strata between the shelf crest and the Capitan may have helped promote a basinward flow of the dolomitising fluids, but the main hydrological gradient came from natural brine reflux. In areas updip of the faults (*zone 1*, the basinward flow of the dolomitising fluids would have primarily been along aquifers and downward through the reef and forereef (both areas here are extensively dolomitised). The flow of fluids through the forereef followed bedding, and dolomitisation decreases downward through these strata (Melim and Scholle 2002). Further downdip in the cross-section (*zone 2*), much of the basinward flow of the dolomitising fluids would have been captured by the syndepositional faults and related fracture systems that reach high into the platform stratigraphy. Here, the sandstone-dominated fill of the faults and fractures provided vertical conduits for the dense dolomitising fluids through the platform. Capture of the flow of the dolomitising fluids by the fault zones in updip locations (*zone 2*) may have acted to inhibit the extensive dolomitisation of the middle and upper Capitan reef further downdip (*zone 3*). Here, dolomitisation is mostly limited to tepee–pisolite facies. Hunt et al.'s model is a logical extension of that developed by Melim (1991) and they argue dolomitisation was likely a discontinuous process typical of TST and HST times, while fracture-controlled dissolution prevailed during lowstands

Platform. The Permian Basin of West Texas covers an area of more than 100,000 km^2 and is almost completely encircled by the reef-rim sediments of the Goat Seep and Capitan formations. Some distance landward of the reef is a 13 km wide belt of highly cyclic platform carbonates made up of widely correlatable stacks of dolomite mudstone and wackestone, capped by anhydritic laminites, which Sarg (1981, 2001) interprets as subaqueous. Even further landward are thick belts of saltern evaporites, which have been largely dissolved from their outcrop expressions in the Guadalupe Mountains.

Seaward of the cyclic platform dolomites, in a position somewhat closer to the reef mass proper, is an 0.8–3 km wide belt of carbonate sands and pisolitic rudstones. These were deposited as mostly coarsening-upward, cyclic stacks, which culminate in tepee-overprinted pisolite beds with subaerial exposure or truncation surfaces. These evaporitic carbonates constitute the tepee-overprinted pisolitic strandzone and barrier island shoal facies of the Guadalupe platform (Esteban and Pray 1983) and were described in some detail in Chap. 1. Evaporite-sealed counterparts to the dolomitised pisolitic cycles also constitute high quality subsurface reservoirs (Chap. 10).

During deposition the pisolite facies constituted a series of shoals that are considered by many to have been the topographically highest part of the platform (Esteban and Pray 1983; Mutti and Simo 1993; Rush and Kerans 2010). Located landward of the reef, the island shoal facies distinguishes this style of platform from the more usual reef-rimmed reconstruction, where the reef mass and its sand flat occupy the topographically highest position on the platform profile (Figs. 5.25b and 5.26b). The pisolitic high of the Guadalupe region is the type area for what is called a distally-steepened reef rim or deep reef-rimmed shelf. This platform profile occurs in other shelf margins characterised by platform salterns (Fig. 5.25c). A little further basinward of the pisolites and tepees are the reef masses of the Goat seep and Capitan formations. Separating the pisolitic shoal zone from the reef rim proper was a narrow belt of carbonate wackestones, typified by a low diversity marine fauna.

The basal part of the reef mass is pervasively cemented by cm scale aragonite botryoids (now calcite), which can constitute up to 90 % of the reef matrix. This zone of intense cementation passes upward into prolific biogenic masses of sponges, bryozoa, brachiopods and *Tubiphytes*, all bound by calcareous algae and marine cements. Some of the calcareous algae are coelobites, which flourished in dark aragonite-cemented fractures in the growing reef. The reef mass is largely undolomitised and internally shows no evidence of subaerial exposure, implying aragonite cementation was early and that the reef was never capable of growing to sealevel.

It may well be that the stenohaline biota of the reef rim could never grow to sealevel, nor form closer to the pisolitic shoreline, because of the debilitating effect of increased salinities. Dense brines, created by evaporative drawdown on the landward side of the island shoal, refluxed seaward via sandstone aquifers and growth faults beneath the unconfined marine phreatic lens to seep back to the seafloor just seaward of the basin shoreline to create a facies belt characterised by a low diversity, halotolerant biota. Brines mixed freely with seawater in this near coastal seafloor zone and so were dissipated into the huge reservoir of open ocean water that occupied the Delaware Basin (Fig. 5.26a). If the deep reef rim grew up toward the sea surface it would create greater

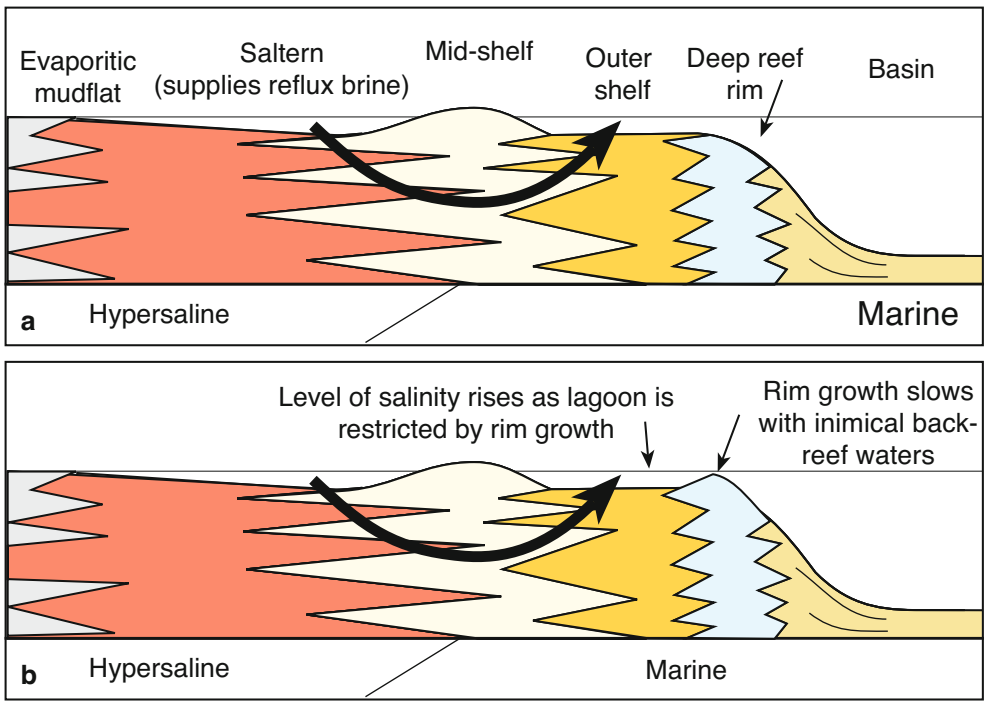

Fig. 5.26 Effect of a deep reef-rim growth in a saltern-backed platform. (**a**) Rim below sealevel (**b**) rim near or at sealevel

restriction immediately behind the reef rim allowing the escaping reflux brines to gather and increase the salinity of the back reef waters. As these more saline waters spilt and washed over the still subaqueous reef rim it would slow the growth of the reef until subsidence allowed freshening of the lagoon once again (Fig. 5.26b). Hence the reef could never grow to approach the sea surface in front of a huge area of widespread evaporites and refluxing dolomitising brines. Whenever it did so, it shot itself in the back before it ever reached the sea surface.

Seaward of the reef rim is a 2 km wide belt of carbonate slope and rise sediments, which also defines the shelf break. It is made up of massive to thinly bedded limestones with intercalated slumps of shelf material, breccias and debris flows (Melim and Scholle 2002). Small downslope buildups are found on the shallower parts of some slopes. Portions of the deepwater carbonate sands and the deeper parts of the shelf margins of the Delaware Basin are dolomitised to lesser degrees than the platform. Even so, the distribution of dolomite in these sediments reflect the influence of widespread evaporite deposition and brine reflux in the hinterland and the more seaward focusing action of syndepositional growth faults (Fig. 5.25c; Hunt et al. 2002).

Further out still, widespread siliciclastic sand sheets dominate the basin floor. These form a channelized deepwater belt at the foot of the carbonate slope in a zone some 6 km wide and up to 35 m thick. The sand sheets were fed from the continental hinterland by reworked desert dune sands, which largely bypassed the shelf margin, via canyons transecting the reef. Some of these basinal channelized sands are unusual, compared to typical deepwater marine sand channels, in that they contain drape muds on the channel floor and a rather homogenous set of sedimentary structures. They are interpreted either as density flows created by bottom-hugging saline brine flows, which originated in the platform salterns (Williamson 1978) or as settle-out muds and silts carried out over the seaway by intense winds from an adjacent sand sea (erg), much in the same way that silt and mud is carried out into the Atlantic off the Saharan coast of north Africa today (Fischer and Sarnthein 1988).

Evaporitic platform sequences have been recognised as far back as the Archaean (Fig. 5.27). For example, a number of impure dolomitic limestone beds in the latest Archaean (≈2.5 Ga) Wittenoom and Carawine dolomites of the Hamersley Group in Western Australia contain features such as mud cracks and evaporite pseudomorphs that indicate shallow water with local evaporitic mudflats (Kargel et al. 1996; Awramik and Buchheim 2009). The depositional system extended across what was possibly the original extent of the Hamesley Basin as defined by Trendall (1983) in his evaporite-basin model for initial banded iron precipitation. Likewise, in the barred platform model for initial iron precipitation, published by Morris (1993), deposition took place in what was interpreted to be a broad carbonate platform passing into deeper marine waters to the south. In either case, during the accumulation of the Wittenoom and Carawine dolomites the depositional setting was a carbonate platform that at times was evaporitic.

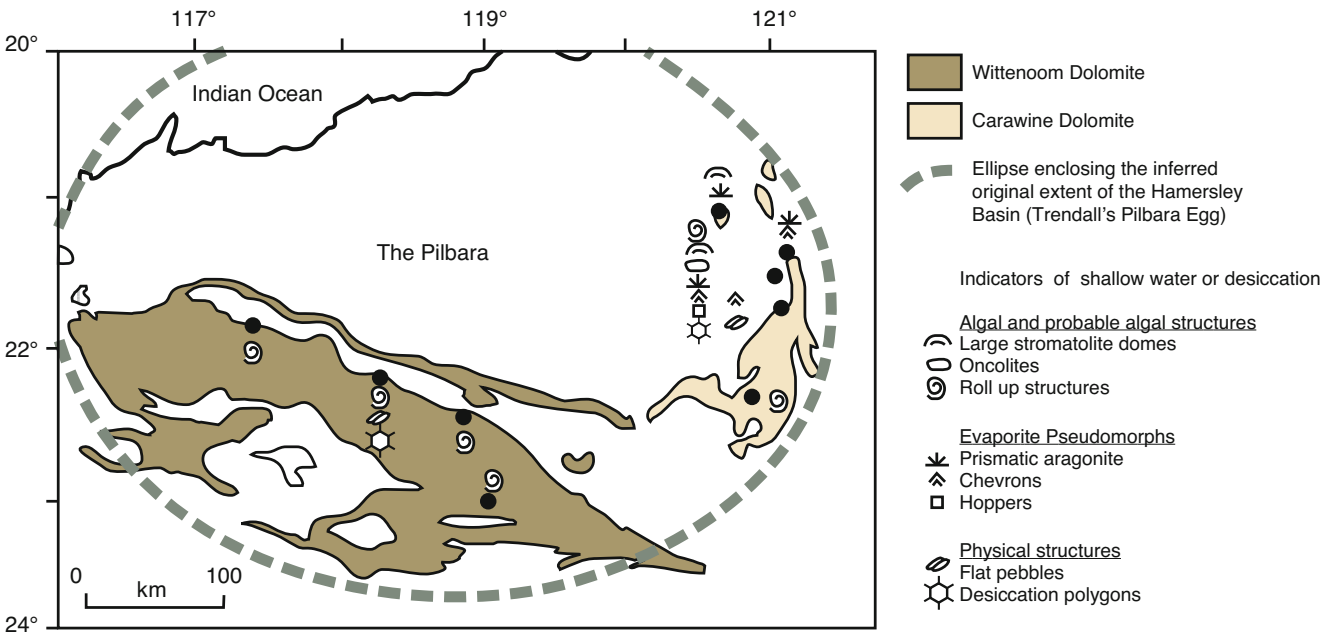

Fig. 5.27 Sketch map showing the distribution of sedimentological features that indicate shallow water and evaporitic conditions in the Archaean Wittenoom and Carawine dolomites in the Pilbara of Western Australia (After Kargel et al. 1996) and used as evidence to indicate that the widespread banded iron ores in this region first precipitated as saline precipitates in a barred marine platform basin

These evaporitic dolomites underlie the world-scale banded iron ores (BIFs) of the Hamersley Basin, deposits that contain 10 % of the world's known iron ore reserves. As in all models of ore deposits of this age, explanations for the formation of the banded iron ores are contentious. Trendall (1983) favours an evaporitic basin to explain the precipitation of the ore, Morris (1985) favours supergene enrichment beneath a Paleoproterozoic weathering surface, Li et al. (1993) favour a hypogene origin, while Powell et al. (1999) argue for synorogenic Paleoproterozoic hydrothermal fluids squeezed northward away from the Ophthalmian foldbelt. Awramik and Buchheim (2009) argue the carbonate-rich layers in the intracratonic BIFs are part of the world's oldest known carbonate-rich lacustrine system, which they call the Meentheena lake system.

Marine Versus Nonmarine Stages in Epeiric Seaways

Correlations across the Clear Fork ramp passing into the siliciclastics of the Opeche Shale or the Khuff Formation anhydrites passing laterally into basin rim continental siliciclastics derived from the Arabian Shield, or Guadalupe salterns passing landward into wadi and dune deposits are all problematic. They underline the everyday problem of reliably tying facies to time horizons in many ancient mixed siliciclastic/evaporite/carbonate platforms. Fossil-lean but extensive areas of saltern evaporites typically backed onto, and were surrounded by, evaporitic mudflats and fossil-lean sand-sheets with numerous internal disconformities that are Stokes surfaces. Reliable correlation of beds across ancient ramps are more difficult; bed layers lack well developed clinoforms, which can be used seismically to define the seaward side of a subsurface carbonate platform. Something as simple as determining whether the platform had a marine or nonmarine brine feed can be problematic in many subsurface salterns. Little if any open-marine carbonate matrix was ever transported into the highly isolated parts of the hinterland, even during intense hurricane events. For much of the time the water conditions in the saltern/lagoon were too saline for most marine or carbonate-secreting organisms with the possible exception of cyanobacteria and halophilic mats. When the base of a saltern evaporite cycle is made up of carbonates, they usually retain some evidence of a marine biota so that it is likely that the overlying salt beds were fed by marine seepage. But, if the intrasalt beds are dominantly mud, with no fossils, what was the precursor depositional setting?

This problem beleaguers depositional interpretations of the Permian (Leonardian) Nippewalla Group of Kansas, a lateral time equivalent succession to the Clear Fork Formation of the Palo Duro Basin. As mentioned earlier, Benison and Goldstein (2001) argue the Nippewalla Group siliciclastics and evaporites represent an evolution from a lacustrine system to a nonmarine, acidic saline pan system in the midcontinent of North America. Most evaporite deposition took place in halite-dominated ephemeral saline lakes surrounded by saline and dry mudflats, sandflats and sand dunes. The key to their continental interpretation comes, not from the textures in the nodular anhydrite or the halite and chaotic halite beds, which are equivocal, but from a volumetrically unimportant grey mudstone facies. This they interpret as a perennial lake deposit akin to the acid redbed lakes in parts of modern Australia. It is a grey siliciclastic mudstone characterized by planar and convolute laminations, ostracodes, peloids and plant material laid down in a freshwater-brackish perennial lake.

More reliable interpretations of a salt bed as marine or nonmarine are usually best done by studying the less saline intrasalt beds. In fact, it is the first feature on the list of four criteria noted by Hardie (1984) as most useful in separating marine and nonmarine evaporites. He listed; (1) sedimentology of the associated nonsaline facies, (2) kinds of fossils, (3) kinds and associations of primary evaporite minerals and, (4) geochemical characteristics of evaporite minerals. Then there is the problem of the volume of brine supply needed to accumulate thick widespread evaporites. As we saw in the hydrological discussions of Chap. 2, continental supra-sealevel meteoric-dominant intramontane hydrologies cannot supply sufficient water volumes or solutes required to form the volumes of salts that typify ancient saline giants or basinwide evaporites.

Basinwide Evaporites

Basinwide evaporites are thick basin-filling evaporite units, often described as "saline giants" or "mega-evaporites." Salt sequences typically extend across large areas of the central parts of a sedimentary basin and contain textural evidence of a variety of depositional settings ranging from deepwater to saltern to mudflat (Figs. 5.9b and 5.28; Table 5.6). Basinwide

In some the former evaporite beds are now represented by laterally extensive solution breccia horizons. This listing is representative, not complete, compare with Fig. 5.30. Also, it does not consider the many examples of meta-evaporites including numerous examples older than Neoproterozoic (see Chap. 14)

evaporites are not accumulating anywhere on the surface of the world today as the necessary interactions between tectonics, hydrology and climate do not exist. Basin-central evaporite is another term to describe this grouping of ancient deposits (Kendall 1992). I prefer the term basinwide as the evaporite sequence can fill the basin centre and then climb out over the old basin margin (e.g. the transition from Castile to Salado formations in the Delaware Basin).

Basinwide evaporites can constitute large proportions of the sediment fill in many ancient evaporitic basins, such as the Delaware Basin of West Texas, the Zechstein Basin of Europe, the Louann Salt Basins in the Gulf of Mexico, the Hormuz Salt Basins in the Arabian Gulf and the Late Miocene Messinian sub-basins in the Mediterranean (Figs. 5.29 and 5.30). The total evaporite fill in such basins is often hundreds to thousands of metres thick and composed of numerous stacked "brining upward" evaporite cycles tens to hundreds of metres thick (e.g. the Z1–Z4 of the Permian Zechstein of northwest Europe). Rather than the anhydrite that dominates the mineralogy of many marine platform evaporites, basinwides typically contain thick halite beds that can source halokinetic structures.

Saltern textures (salt pan and salina) dominate basinwide deposits, although basin and slope deposits can also occur, especially in the early stages of each depositional cycle. Sometimes, especially in the gypsum/anhydrite stages of an evaporite fill the saltern constructs a "platform" area in the basin with deeper water sulphate laminites accumulating in the central part of the basin (Figs. 5.8 and 5.29a). At other times the basin centre had filled and shallowed to where a saltern extended across the entire depositional area of the basin (Fig. 5.29b, c). Stacking of a number of saltern cycles into a thick basinwide sequence indicates the basin did not fill in a single depositional episode, but as a number of

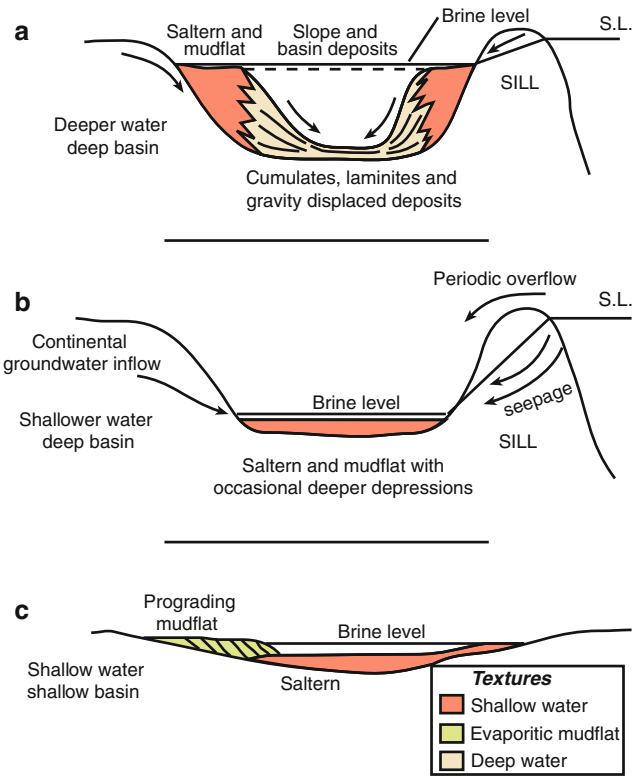

Fig. 5.29 Basinwide evaporite settings as three endmember associations (Modified from Warren 1989; Kendall 1992)

brining-upward and/or shoaling-upward depositional cycles typically composed of even finer scale parasequences. Compared with saltern deposits in marine-margin platform evaporites, the salterns in many basinwide evaporite basins tend to accumulate as much thicker units (>100 m), and bedded salts are not restricted to the shoalwater/lagoonal portions of any underlying carbonate platform. Rather, they tend to cover and encase underlying carbonate reef rims and pinnacles.

Depositional Styles

Basinwide evaporites can be classified into three settings (Fig. 5.29):

- Deeper water–deep basin
- Shallower water–deep basin
- Shallow water–shallow basin

Deeper water–deep basin evaporites have basin centres dominated by "deepwater" evaporites composed mostly of finely laminated salts (mostly sulphates) or coarsely crystalline inclusion-free halite meshworks. Individual laminar groupings in the basin-centre laminites can be correlated over wide areas (Fig. 5.29a). This style of deposition dominates a hydrographically isolated marine-fed basin that reaches hydrologic equilibrium (water inflow = loss) at a time when a relatively-deep water mass still covers the basin centre. The contentious part of this model lies in what water depth defines a deepwater brine in the basin centre, is it 30, 100 or >1,000 m? At times when the basin water column is meromictic, basin slopes are dominated by reworked saltern evaporites deposited as slumps and turbidites, while pelagic laminites dominate the basin centre during times of a stratified brine column (Fig. 5.8). At times when water levels are somewhat lower and the water mass is holomictic then coarsely crystalline evaporites (either gypsum or halite) are deposited across the basin floor (Fig. 5.8).

Seawater flows into the drawdown basin as a perennial seepage; if the basin remains hydrographically isolated, evaporites can fill the basin to a water level just below that of the supplying ocean (Fig. 5.29a). Consequently, the evaporite unit "in toto" is a shallowing upward succession, often composed of smaller shallowing-upward cycles (parasequences). The basin fill starts off dominated by deeper water laminated and resedimented salts that pass up section into shallowwater salterns, pans, mudflats, or continental playas. But it can also preserve coarser crystalline units indicating holomictic but still "deep" episodes in the basin fill.

The Permian Castile Formation and the transition into the overlying Salado Formation in the Delaware Basin in West Texas is a good example of this passage from predominantly deep to predominantly shallow. The basin-centre started off relatively deep with the deposition of the varved sediments of the Castile Formation, and with time filled and shallowed into the shoalwater/playa deposits of the Salado Formation. Any sediments that immediately postdate the evaporites of this overall shallowing sequence will also be shoal water or saline mudflat deposits. This is the case with the shoalwater/mudflat deposits of Rustler Dolomite where it overlies the Salado Formation in the Permian Basin, West Texas. Other examples of deeper water deposition occur in the basin-centre deposits of the north and south Zechstein basins of NW Europe and the deeper parts of the marginal basins in the Messinian of the Italian Apennines.

The *shallower water–deep basin* sequence is dominated by shallow water evaporites deposited as stacked saltern to mudflat cycles in a basin with a hydrological base level hundreds to thousands of metres below sealevel. This type of basin is supplied by evaporative drawdown, pulling seawater into the basin as a series of marginward seeps perhaps interrupted by the occasional refill tied to a marine-fed cataract (Fig. 5.29b). It characterises the more drawndown stages of evaporite deposition in both soft suture collision belts and some intracontinental rift to drift tectonic settings. This style of evaporite fill is often intimately related to the deeper water-deep basin style of deposits and indicates a more arid period in the same depositional basin. That is, its hydrological equilibrium is reached when much shallower waters cover the basin centre and there are many topographically

deep evaporite basins where deeper fills alternate with shallower fills.

In the collision setting the underlying basin-centre succession is typically a deep marine sediment, often a pelagic carbonate that passes upward across a disconformity or unconformity into alternating stacked saltern and deeper water evaporites. Normal marine pelagics were deposited before the basin depression was hydrographically isolated from the ocean and can return to dominate the basin fill if a hydrographic connection is re-established. The transition from a deeper marine basin to an evaporitic sump can be marked by organic-rich restricted marine-influenced deposits (Chap. 9). Basin margin regions can contain reefal deposits from the preceding marine phase and their higher position in the basins means they are colloquially described as the "bathtub scum rim."

Shallower water-deep basin fills dominate the evaporite fill in many marine-fed rift successions, such as the Aptian South Atlantic Salt Basin. Thick salts precipitated atop an endorheic rift valley floor that was hundreds of metres below sealevel (Szatmari 2000). Unlike the relatively small volumes of marine-fed salts being deposited in today's best example of a shallow water-deep basin marine-fed rift (Lake Asal depression; Fig. 4.60), the volumes of salt deposited in ancient rift sags could be huge. Consider the wedge-shaped body of Upper Aptian salt, it was deposited in the South Atlantic Salt Basin as Africa separated from South America about a rotational pole in NE Brazil (Szatmari 2000; Torsvik et al. 2009). The salt basin was more than 2,000 km long, some 400 km wide at its southern end in the Santos Basin and tapered northward to less than 100 km wide in the Sergipe-Alagoas Basin. Prior to halokinesis, the original salt thickness in the various sub-basins was around 2 km. Most of the salt was deposited as halite in a series of saline lakes/salterns within a pre-existing continental rift depression, with a floor some 2 km below sealevel. Marine flooding ended the depression's isolation from the sea in the late Aptian. It required nearly one million cubic kilometres of water to fill the depression to sealevel, an event that would have caused a geologically instantaneous drop of 3 m in global sealevel (Szatmari 2000).

The *shallower water–shallow basin* association forms under conditions of ongoing subsidence where the rate of evaporite aggradation keeps pace with tectonic subsidence (Fig. 5.29c). The basin depositional setting starts off shallow and remains shallow throughout the deposition of the evaporite sequence. Sedimentary signatures are dominated by interfingering saltern, saline pan and mudflat successions often crosscut by karstic erosional surfaces. There is little or no evidence of deeper water evaporites. Shallow water–shallow basin evaporites are typical of intracratonic sag fills, such as in the Williston Basin in the USA and the Silurian-Ordovician Canning Basin in Australia. Salt beds in intracratonic fills are typically intercalated with shallow-water open-marine carbonates and siliciclastics and tend to form stacked cyclic units with thicknesses between 10 and 100 m, unlike the thick rift and collision successions (>100–1,000 m thick). Using data from one or two wells it can be very difficult to distinguish intracratonic basinwide evaporites from marine-margin platform evaporites. The distinction requires a thorough knowledge of the basin's architecture and tectonic history and is often best resolved using regional seismic and well data. This style of deposition also dominates the later stages of basin infill in what were previously deep hydrographically-isolated evaporite basins, as described in the other two members of this classification (Figs. 5.29 and 5.30).

In reality, codifying basin-filling evaporite successions is never as simple, nor as predictable, as a three-end-member classification suggests. Changes in brine level, subsidence rates or climate, play havoc with a simple tripartite breakdown of evaporite basins. Water depths in an evaporite basin are never constant, they rise and fall in response to intensity of tectonism, climate, sealevel change, playa capture and associated changes in the degree of seepage, evaporation intensity and surface runoff in the inflow zones. Basinwide provinces such as the Mediterranean Basin during the Late Miocene, or the Permian Basins of Texas and northern Europe in the Late Permian, are actually composed of a series of large sub-basins. Each subbasin in an evaporitic province responds in its own fashion, depending on the local topography, tectonics, and climate and the total fill can contain examples of all three end members. Understanding and predicting facies evolution in a basinwide evaporite setting is simplified if the various deposits are placed in their plate tectonic setting using the Wilson Cycle as the first order control on the possibility of hydrographic isolation. Such an evolution must a first be broken down into mega-evaporites formed at a tectonically active continental margin edge and the more tectonically quiescent continental interior (intracratonic).

Tectonic Styles of Basinwide Evaporites Across Time

Throughout earth history, basinwides tend to accumulate in three tectonic settings: (1) Areas of rifting continental plates; (2) Areas of converging continental plates (collision belts); (3) Areas of intracontinental or intraplate sags, which are often the result of farfield plate stress induced by continental orogeny acting on zones of pre-existing crustal weakness such as an old rift belt (aulocogen) or foreland depression (Table 5.6; Warren 2010). Evaporating brines in most basinwide lows tend to be maintained by a continuous inflow of marine groundwaters into tectonic depressions (marine-fed hydrological systems). This hydrology is created in an arid setting wherever tectonically driven subsidence moves the basin floor to sub-sealevel elevations without allowing a surface connection to the open ocean.

Basinwide evaporite styles at continental margins change as continents accrete and suture. For example, the various salt-filled basins, that together make up the Pangaean peak in the salt volume curve, were created mostly by plate tectonic mechanisms within what were tectonically-induced arid to hyperarid climatic zones of the latest Palaeozoic to Mesozoic earth (Fig. 5.7). Volumes of salts caught up in this association dwarf all Quaternary salt volumes. Zharkov (1981) recognized 95 Permian evaporite basins with a total volume of 1.5×10^6 km^3 (37 were halite-dominated and 48 sulphate-dominated). The basinwides that make up the Pangaean peak came into being as the continents collided to construct the Pangaean supercontinent and then as it rifted and sagged during its breakup into a number of smaller continental landmasses.

That is, continent-continent proximity and associated tectonic flexures and downwarps during the accretion of the Pangea supercontinent facilitated the deposition of widespread collision-and intracratonic evaporites. Carboniferous basinwide evaporites were precipitated in the Williston Basin and northern Ellesmere region in North America, in northern Brazil, North Africa, the East-European Platform, and Kazakhstan (Trappe 2000). Early Permian evaporite basins form a broad saline sediment belt along the western Pangaean margin and also in northeastern North America and eastern Greenland, as well as in northern South America (including western Brazil). Large collision-induced salt deposits of the same age are found in central Europe including portions of the East-European Platform and the Urals. The largest Early Permian deposit fills the East European Basin from the Caspian to the Black Sea with some 500×10^3 km^3 of halite and 100×10^3 km^3 of anhydrite (Magaritz 1987). Late Permian Pangean evaporites also include major deposits in the Zechstein Basin of northwestern Europe and the evaporites of West Texas. Together these basins define a broad band of equatorial aridity extending from about 50°N to about 30°S palaeolatitude, with basinwide salt deposition ranging in time and world climate across Carboniferous icehouse to Permian greenhouse.

Permian halite volumes are in their turn dwarfed by those of the Triassic Pangean-breakup, which account for 22 % of all Phanerozoic halite, while Permian and Triassic halite together make up 35 % of the world's halite (Fig. 5.7). During the Early Triassic, evaporite formation intensified as huge sea-edge drawdown rift-to drift basins and continent interior evaporite pans, associated with redbeds, developed in southeastern and western USA, western Canada, northwestern Africa, western and southeastern Europe, central South America, south–central Africa and eastern Greenland (Tables 5.6 and 5.8). Huge evaporite platforms were established in the same time period in northern Arabia, Iraq, Kazakhstan, and northern China. The increased salt volume reflects intensified rift activity in low latitude regions during the Triassic breakup of Pangaea. Extension, followed by cooling and sagging, established a number of large isolated subsealevel rifts and intracratonic sags, which acted as the pre-eminent salt accumulators.

Thus, the profusion of Pangaean basinwide evaporites is allied with three time-plate tectonic associations (Table 5.7; Fig. 5.7): (1) Pennsylvanian to Permian accretion of the Pangaean supercontinent, as mostly marine-fed collision basin evaporites were deposited along the soft collision belt of the irregularly embayed margins of Gondwana, Laurussia and Siberia; (2) Intraplate extensional depressions created during the subsequent Mesozoic breakup of Pangaea into Gondwana/Laurasia; salt beds deposited in these widening marine-fed rift basins, including the continental salts of the Newark Basin (Triassic), the marine salts of the Gulf of Mexico (Jurassic), the Campos Basin (Cretaceous) and the various mostly marine-fed salt basins of offshore west Africa (Evans 1978); and (3) Associated intracratonic sag salt accumulations in basins that typically sit atop the failed arms of earlier more sharply-defined fault-bound rift successions (Youssef 1998) or in the hinterland or foreland of orogenic belts created by farfield stresses driven by interplate collision (Pysklywec and Mitrovica 2000). The intracratonic-sag basins in the Pangaean association are especially obvious in the various Triassic and Jurassic salt basins of Northern Africa, which formed isolated subsealevel marine-fed depressions as Pangaea unzipped along its Tethyan and Atlantic axes.

Large intracratonic sags also typify many other subsea-level isolated marine-seep fed saline giants, precipitated

Table 5.7 Timing of the assembly and disassembly of the Pangean supercontinent

Late Palaeozoic accretion of Pangean supercontinent	Pennsylvanian collision of Laurussia, Kazakhstania and Siberia to form Laurasia (≈280 ma), followed by Permian collision of Laurasia and Gondwana Associated orogenic events Appalachian/Alleghenian orogeny of eastern North America Mauritanide/ Moroccan foldbelt of northwest Africa Hercynian orogeny of southern Europe Marathon/Ouachita orogeny of southern North America Uralian orogeny of Europe-Siberia
Mesozoic breakup of Pangean supercontinent	Breakup of Pangea (into Laurasia and Gondwana): 220–190 Ma: Newark and other rift basins in northeast North America and northwest Africa 175 Ma: Opening of Neo-Tethys 135 Ma: Separation of South America from Africa (opening of south Atlantic)
	Breakup of Gondwana (as it unzips around Antarctica): 165 Ma: Rifting of Africa from Antarctica 125 Ma: Separation of India from Antarctica 100 Ma: Separation of Australia from Antarctica 85 Ma: Separation of New Zealand from Antarctica
	Breakup of Laurasia: 90–50 Ma: Opening of the north Atlantic between North America and Eurasia/Greenland

Table 5.8 Listing of tectonic setting of various halite-entraining basins at the time that thick halite was precipitated

Divergent	Abenaki (N. Scotian), Adelaide foldbelt, Adriatic -Albanian foredeep, Apennine, Aquitaine, Arabian Basin (Gotnia Salt Basin), Arabian Basin (Hith Salt Basin), Atlas (Algerian-Tunisian), Atlas (Moroccan), Baltimore Canyon, Berrechid, Betic-Guadalquivir Basin, Brazilian Aptian Basin (Camamu), *Brazilian Aptian Basin (Campos-Santos), Brazilian Aptian Basin (Ceara), Brazilian Aptian Basin (Cumuruxatiba), *Brazilian Aptian Basin (Sergipe-Alagoas), Cantabrian-West Pyrenees, Carson Basin (Grand Banks), Chu-Sarysu (Devonian), Cuban, Danakil, Dniepr-Donets, Eastern Alps, Flemish Pass Basin (Grand Banks), Georges Bank, Gulf of Mexico (Northern; Gulf coast), *Gulf of Mexico (Southern; Salina-Sigsbee), Haltenbanken, Horseshoe Basin (Grand Banks), Ionian, Jeanne d'Arc Basin (Grand Banks), Jura/Rhodanian, Katangan, La Popa (Monterrey) Basin, Lusitanian, Maestrat, Majunga Basin, Mandawa Basin, Ma'Rib-Al Jawf/Shabwah (Hadramaut), Moesian, Nordkapp Basin, Olduvai depression, Orpheus Graben, Palmyra, Red Sea (North), Red Sea (South), Rot Salt Basin, Ruvuma Basin, Sabinas Basin, Salar Basin (Grand Banks), Scotian Basin, Somalia-Kenya, South Whale Basin (Grand Banks), Tadjik Basin, Takutu Salt Basin, Tromso Basin, *West Africa (Angola-Gabon), West Africa (Gambia-Guine Bissau), West Africa (Mauritania-Senegal), West Africa (Morocco-S. Spain), Whale Basin (Grand Banks), Zechstein (NW Europe), Zechstein (onshore UK)
Convergent	Adavale, Amadeus Basin (Chandler), Andean, Arabian Basin (Hormuz central Saudi), Arabian Basin (Hormuz Gulf region), Arabian Basin (Hormuz-Kerman region) Bohai Basin, Cankiri-Corum, Carpathian foredeep, Chu-Sarysu (Permian), Cicilia-Latakia, Ebro Basin, Green River Basin, Haymana-Polatli, Holbrook Basin, Jianghan Basin, Khorat Basin, Kuqa Foreland (Tarim Basin), Mediterranean-Western, Mediterranean-Adriatic, Mediterranean-Andros Basin, Mediterranean-Cretean Basin, Mediterranean-Samothraki Basin, Mediterranean- Tyrrhenian, Mediterranean-Central, Mediterranean-Eastern, Mediterranean-Sicilian, Neuquen Basin, Oman (Fahud Salt Basin), Oman (Ghaba Salt Basin), Oman (Ghudun Salt Basin), Oman (South Oman Salt Basin), Paradox Basin, Pricaspian Basin, Qaidam Basin, Qom-Kalut, Sachun Basin, Salt Range (Hormuz – Punjab region), Salt Range (Kohat Plateau), Sirjan Trough, Sverdrup Basin (Ellef Ringnes – NW Ellesmere), Sverdrup Basin (Melville Is), Tabriz Salt Basin, Transylvanian, Western Canada (Alberta Basin), Zagros (Mesopotamian Basin), Zipaquira Basin
Intracratonic	Amadeus Basin, Amazonas, Appalachian, Bonaparte (Petrel), Canning Basin, Carnarvon Basin (Yaringa), Hudson Bay, Mackenzie Basin, Maritimes Basin, Michigan Basin, Moose River Basin, Officer Basin, Oriente-Ucayali (Pucara) Basin, Parry Islands Foldbelt, Pripyat Basin, Saltville (Appalachian), Siberia-East, Solimoes, USA Midcontinent, Williston Basin
Transform	Dead Sea

It is based on an interpretation of the synprecipitational setting, so in basins with an ongoing polyphase tectonic history (like the various Zechstein sub-basins of Europe) it is not the same as the salt's current tectonic situation. See Fig. 5.30 for basin age and location, asterisk indicates postrift megahalite deposition

outside of the time of the Pangaean supercontinent (e.g. the Devonian Elk Point Basin, the Palaeozoic Williston Basin, the Silurian Michigan Basin and Ordovician Canning Basin), as do other rift (e.g. Frasnian of Dniepr-Donets of eastern Europe) and collision (Miocene of the alpine Mediterranean and the Zagros foreland) associations (Table 5.8).

Creation and destruction of the Rodinia/Gondwana[5] supercontinent(s) in the Neoproterozoic-Early Cambrian (≈550 Ma) defines earlier, but not as well documented, peaks in the evaporite distribution curve, as shown in Fig. 5.7. Thick layers of preserved rock salt (halite) are widespread in the latest Ediacarian to the Early Cambrian in the Middle East, Pakistan, Siberia and Australia. Indeed, these strata contain some of the world's thickest successions of rock salt (Table 5.6). They include the Hormuz Salt of Iran and the Arabian Gulf, the Ara Salt of Oman (both thought to be latest Ediacarian), the Salt Range salt of Pakistan (Atdabanian-Botoman), and the Usolka and equivalent salts of Siberia (Tommotian-Atdabanian). The assembly of Gondwana took place during the Ediacarian to Early Cambrian. It involved the amalgamation of the separate crustal blocks of Avalonia, Europa, Arabia, Africa, Madagascar, South America, and Antarctica (together forming West Gondwana) and resulted in the compressional Pan-African orogeny, which culminated between 560 and 530 Ma. East Gondwana (India, South China, North China and Australia) collided with West Gondwana along the Mozambique suture between ca. 600 and 550 Ma. The development of thick salts in the Ara Formation, once thought to be rift deposits of Tommotian age, now appear to be foreland basin deposits of late Ediacarian age, tied to the Pan-African orogeny and Gondwana assembly

Even older thick halite beds (early Neoproterozoic) such as the Bitter Springs Fm. in the Amadeus and the halites of the Browne and Madley Fms. in the Officer Basin of Central

[5]Rodinia, is generally regarded as having been assembled near the end of the Mesoproterozoic and disassembled in stages during the Neoproterozoic. Reconstructions of Rodinia are notable for their lack of agreement (Bradley 2011), but published assessments of Rodinia's dates are in general agreement. It was assembled between 1,300 and 950 Ma, lasted from 950 to 850 Ma, and was disassembled from 850 to 600 Ma.

Whether or not the next youngest continental assemblage in deep time–Gondwana– qualifies as a supercontinent depends on the definition of a supercontinent (what does "nearly all" mean as used in the definition of a supercontinent – see footnote 5.4). Gondwana consisted of all the cratons now in South America, Antarctica, Africa, Arabia, India, and Australia, as well as microcontinents in the Appalachian and Paleotethyan realms. Its fit is well constrained because the now-dispersed pieces can be brought together by closing the modern South Atlantic, Indian, and Southern Oceans; this is essentially the southern half of the Pangaea fit. The collisional assembly of Gondwana spans the interval 690 to 530 Ma, and it remained intact as the southern portion of Pangaea until it began to break up around 300 Ma when it was re-established as Gondwana, a separate large landmass south of Laurasia (Table 5.7).

Australia, as well as the widespread dissolution breccia after Callana Fm. halites in the Flinders Ranges and the Duruchaus Fm. in Namibia and its equivalents in the Katangan copper Belt are perhaps related to the breakup some 800–850 Ma of the Mesoproterozoic supercontinent known as Rodinia (or Kanatia). The Centralian and Namibian evaporites are the oldest preserved masses of actual salts, beyond that age only meta-evaporites are preserved, such as those of associated with the Grenvillian Orogeny, which occurred during the accretionary phase of the Rodinian supercontinent (Chap. 13).

Volumes of salt deposited in saline giants can be huge, with individual deposits accumulating over geologically short time frames of no more than a few million years. For example, the deposition of the Jurassic Louann Salt in the Gulf of Mexico some 175 Ma, sequestered approximately 8 % of world-ocean NaCl (Land et al. 1988), while the Messinian evaporites of the Mediterranean were deposited in less than 300,000 years, yet lowered oceanic salinities by 6‰. Unlike platform evaporites, which can be tied to climate and eustasy on greenhouse epeiric platforms, the formation of basinwide deposits is not related to icehouse or greenhouse episodes in earth history. Placing basinwide evaporite occurrences into a plate tectonic framework simplifies the discussion of where suitable worldscale subsea-level marine seepage evaporite depressions can occur. At the plate tectonic scale the world's lithosphere is divisible into a number of major and minor plates, which because their interiors are relatively cool and rigid are mostly tectonically stable. Plate edges, also known as plate margins, are zones where moving plates interact one with another and tend to be tectonically unstable, these are the zones where the largest and thickest basinwide evaporites tend to form.

Plates are composed of variable amounts of continental and attached oceanic lithosphere. They float atop the athenosphere and are carried about on the upper part of its convective cells. In places where the lithosphere in a plate is largely composed of continental siliceous material (sial) it is less dense and tends to float above the geoid (and above sealevel) so constituting the suprasealevel portions of the larger continents. Where the plates are dominated by less dense basaltic material (sima), the surface of the plate tends to lie below the geoid and sealevel, constituting much of plates beneath the deep ocean floor (Fig. 5.31a).

Most of the larger continental blocks have elevations within a few hundred metres of sealevel, while most of the ocean floor lies some 5 km below the seasurface (Fig. 5.31a). The difference in elevation between the continental surfaces and the ocean floors is the result of a number of factors that include; thickness and density contrasts between continental and oceanic crusts, tectonic activity, erosion, sealevel and the ultimate strength of continental rocks, which determines their ability to maintain an unsupported slope above oceanic crust.

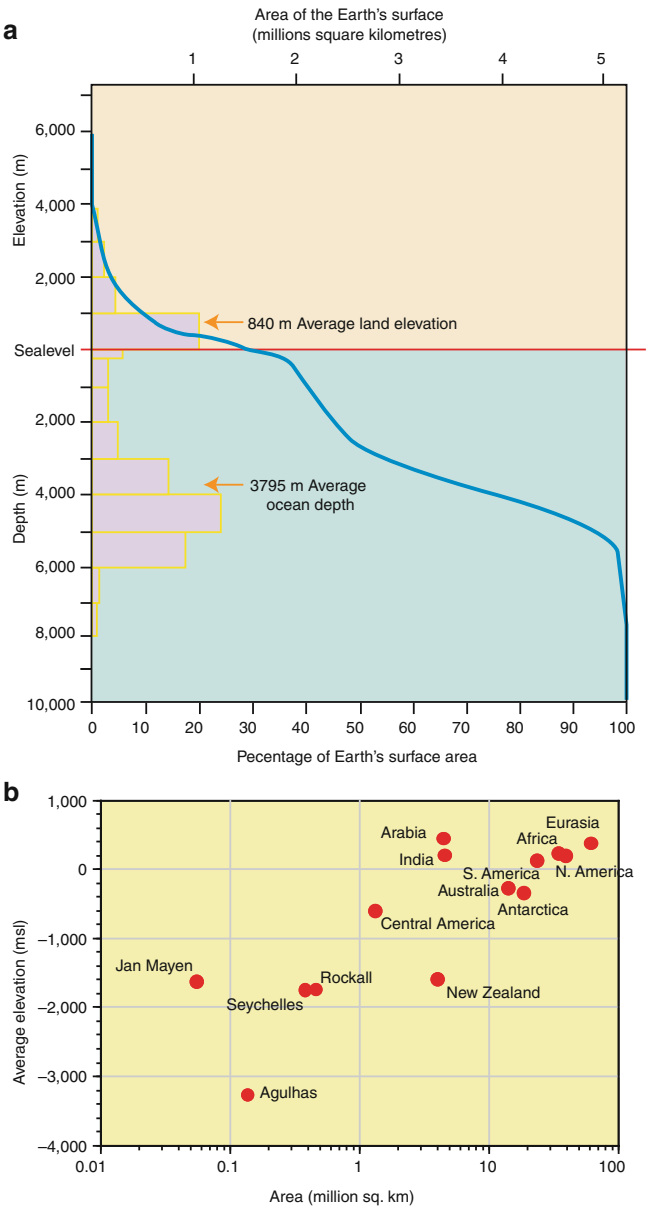

Fig. 5.31 Isostasy. (**a**) Distribution of earth surface elevations. Histogram shows percentage/area of the earth's surface within elevation intervals of 1 km. Cumulative curve (*blue*) shows the percentage of the earth's surface that is above a particular elevation. (**b**) Mean continental heights as a function of areas of continental lithosphere in selected continental and micro-continental blocks (Replotted from data in Cogley 1984)

There is an overall positive correlation between areas of continents and microcontinents and their average elevation relative to sea level (Fig. 5.31b; Cogley 1984; Condie 2004). Small continental fragments, such as Agulhas and Seychelles, lie 2 km or more below sea level. Arabia and India are higher than predicted by the area-height relationship, a feature probably related to their collisional tectonic histories. The height of a continental block relative to sea level depends on the uplift rate and the rates of erosion and subsidence.

Collision between continents resulting in lithosphere thickening is probably the leading cause of continental uplift in response to isostasy. The anomalous heights of India and Arabia undoubtedly reflect the Neogene collision of these microcontinents (Fig. 5.31b).

The six large continental blocks have undergone numerous collisions in the last 2 Ga, each thickening of the lithosphere in collisional zones leads to a greater average continent elevation both in the lead up to and after the collision. Hotspot activity can also elevate continental interiors and portions of the seafloor, it explains the relatively high elevation of the basaltic Jan Mayen Island mass. In both uplift situations any supracrustal depositional system has the potential to pass from submarine to continental. Likewise, in a newly formed continental rift atop an upwelling mantle plume, the depositional system will pass from continental to submarine as the rift widens and underlying crust thins and cools.

It goes beyond the needs of this chapter to delve more deeply into the causes and outcomes of hypsometric analysis, other than to note one self-evident truism and then make a set of simple deductions that must characterise basinwide and platform evaporites. First the truism: Sediments deposited within a continent tend to accumulate above sealevel. This may seem to be a trite statement, but it has substantial implications in terms of hydrological controls on ancient evaporites. We have seen in Chap. 2 how the volumes of solute needed to explain the huge volumes of halite in ancient evaporites must come from seawater (or dissolution-related reworking of older marine evaporites into the landscape drainage). We know that water cannot flow uphill and so such marine-derived evaporite systems must by definition be accumulating in subsealevel depressions. Yet, we also know that evaporites cannot form when a restricted basin has a surface connection to the ocean. Evaporite basins require hydrographic isolation and a surrounding barrier that facilitates marine seepage. Thus, substantial volumes of evaporites can never accumulate in open marine situations (characterised by large distances between continental masses), nor in highly elevated continental situations where there is no huge isochemical solute reservoir to draw upon (seawater cannot flow uphill). We saw earlier how endorheic drainages at suprasealevel elevations in continental settings so allow relative small evaporite deposits to form. These are the borates, salt-cake and soda-ash salts discussed earlier, which have precipitated from the requisite nonmarine mother brines (Chap. 12).

The need for a large volume of seawater, in order to accumulate huge volumes of halite or calcium sulphate in a sedimentary basin, means it can only happen in an arid, subsealevel, hydrographically isolated marine-fed seepage depression. That is, the evaporite basin is isolated from a hydrographic connection to the ocean, yet still remains in a subsealevel position so as to allow seawater seepage. The basin is desiccated and its hypsometric position is passing either from the continental into the marine realm or immediately prior to the passage from the marine to the continental realm. This happens in a continental margin position when two or more continental plates are in close proximity, either as; (1) an opening continental rift causes the floor of a rift valley to pass below sealevel or, (2) in a situation of continent-continent closure as the rising floor of the closing basin is still subsealevel as the hydrographic connection is lost (Fig. 5.32; Table 5.8). The former situation characterised the formation of Miocene halite in the Red Sea, the latter characterised the precipitation of Messinian halite across the floor of the Mediterranean.

Timing and styles of plate-plate interaction are summarised by the Wilson Cycle, which breaks down a plate tectonic cycle into a time of divergence passing to convergence via stages A through H (as shown in inset in Fig. 5.32). Named in honour of J. Tuzo Wilson, the Wilson Cycle encapsulates the notion that as new ocean basins open, via the formation of new seafloor, others must close, driven by the process of subduction and ultimately by continent-continent collision (Wilson 1966).

Compilations of the time-related distribution of ancient marine evaporites shows there are four plate tectonic situations where thick evaporite beds have accumulated at particular times in the past (Fig. 5.9). As illustrated in Fig. 5.32, they are: (1) Areas of rifting where continental plates are beginning to move apart (divergent plates in "rift to drift" transition in Wilson Cycle stages B to early C); (2) Areas where continental plates are coming close to one another (convergent or colliding plates in Wilson Cycle stage F); (3) Areas of intracontinental or intraplate sagging (intracratonic basins), which are often the result of farfield plate stress induced by continental orogeny acting on zones of pre-existing crustal weakness such as an old rift belt (aulocogen) or farfield sags tied to the formation of foreland depressions (intracratonic basins in Wilson Cycle stage A). (4) Thick (km-scale) halite sequences in local regions of rapidly subsiding continental crust in transform or strike-slip settings where the plates are sliding horizontally past one-another (conservative or neutral plate margin).

Only in Wilson stages F (continent-continent collision) through the onset of Stage C (intracratonic through rift through incipient ocean) can continental plate edges be in sufficient proximity to create the hydrographic isolation needed to facilitate marine seepage to a desiccated subsealevel basin floor and so precipitate marine-fed saline giants. The same plate edge interactions likely also drive the gentle continent interior flexures that create intracratonic sags.

Isostatic responses to plate edge and plate interior flexure explains why many regions of basinwide evaporites are underlain by thinned or transitional continental lithosphere,

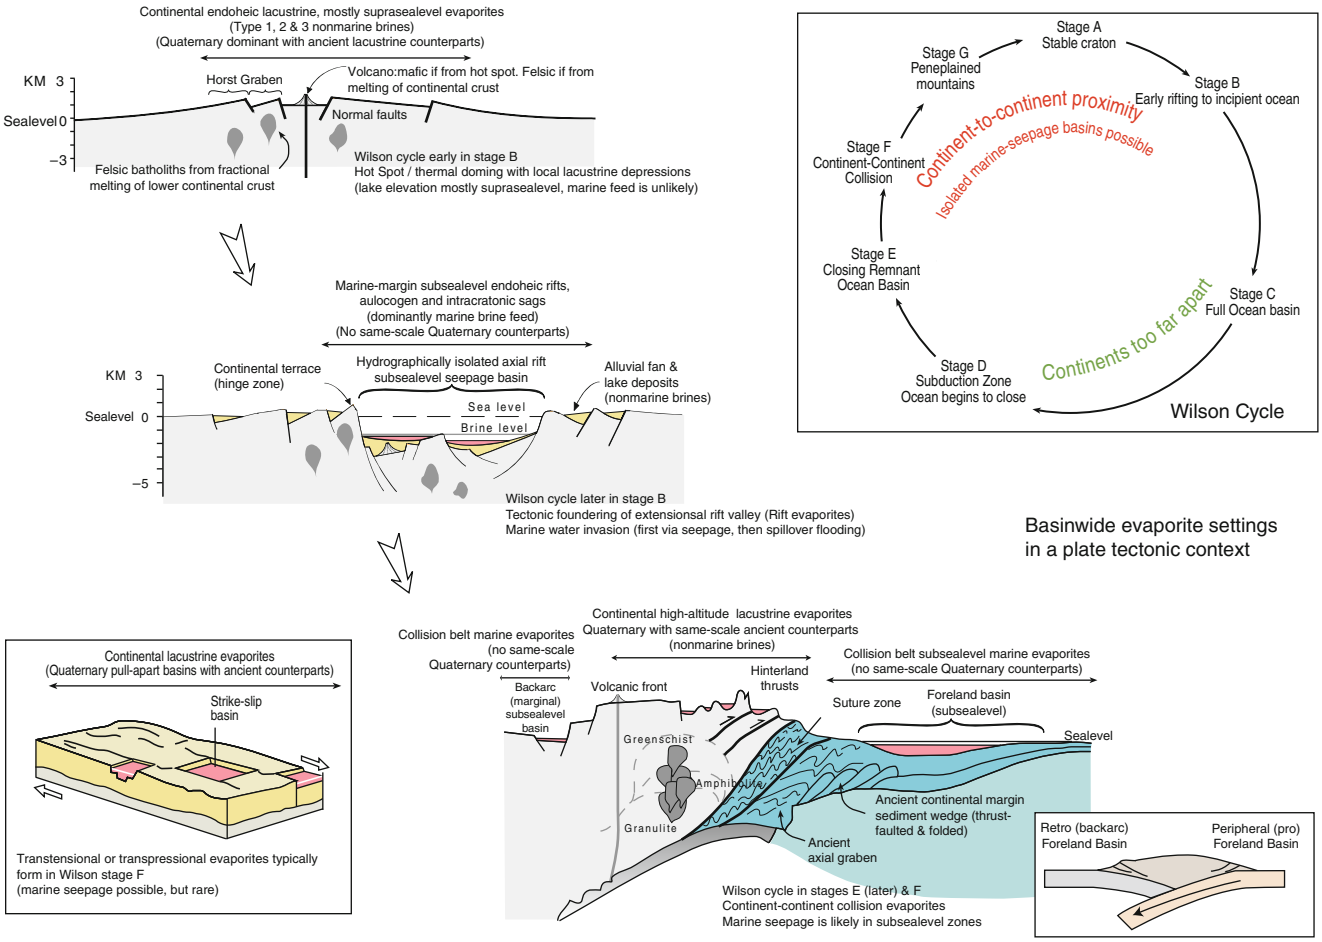

Fig. 5.32 Tectonic and hydrographically isolated (marine endorheic) continent-margin situations where basinwide evaporites tend to accumulate (evaporite beds are shaded *pink*). Positions are largely tied to world-scale times of continent-continent proximity and so can be tied to the various stages of the Wilson Cycle (After Warren 2010)

although in some cases hydrographically isolated parts of the basin floor can be underlain by oceanic crust (e.g. some South Atlantic Aptian salt basins; e.g. Jackson et al. 2000). Stages C, D and E of the Wilson Cycle encapsulate open marine settings where any deposited sediments are situated atop and surrounded by dense ocean lithosphere with a hypsometry that favours ongoing hydrographic connection to the waters of the open ocean, so precluding subsealevel hydrographic isolation, unless the plate was elevated by the effects of local tectonism or migration over a mantle plume (hot spot).

An extensional basinwide evaporite succession typically passes up into marine carbonates as it is deposited in an extensional setting where a widening subsealevel rift opens into a hydrographically-isolated incipient ocean (Fig. 5.32). Evaporite deposition then ceases as the marine basin opens further into a passive margin with its continuous surface connection to waters of the open ocean. The transition from continental interior rift with continental lacustrine brine-fed evaporite mineral and carbonates, to marine-fed rift successions with marine evaporite mineralogies, to open marine passive-margin carbonates is seen in most rift evaporite fills, worldwide (Fig. 5.33).

A compressional basinwide evaporite sequence typically overlies marine sediments and is in its turn overlain by continental sediments. Like epeiric periplatform evaporites, both these ancient tectonically induced marine-fed deposits have no modern same-scale Quaternary analogs. They are the result of a combination of tectonic and climatic processes that are not present on the world's surface today. They have been in the past and they will be again in the future.

Brine inflow to these ancient tectonically-induced evaporitic lows tends to be maintained by continuous seepage of marine groundwaters into the depression (i.e. they are subsealevel marine-fed hydrologies), along with the occasional marine flood of the barrier. This ancient evaporite hydrology is tied to arid climates as these are the zones of the world's ocean surface where there is always the potential to lose more water from the basin than can actually enter via a combination of groundwater seepage and surface floods.

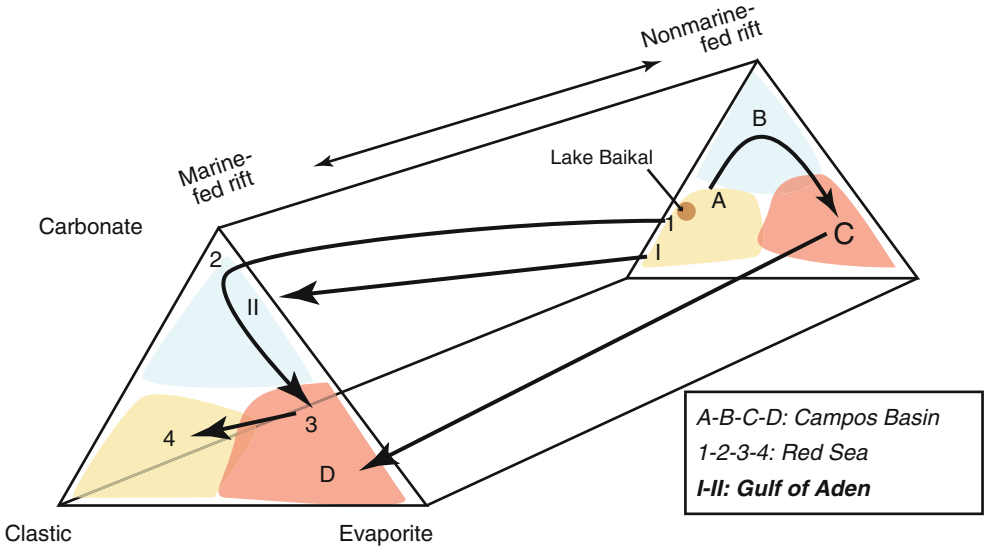

Fig. 5.33 Selected sediment response pathways to an evolving brine feeder hydrology in a opening rift that is passing from nonmarine to marine, a typical evolution in the Wilson Cycle (In part after Bosence 2012)

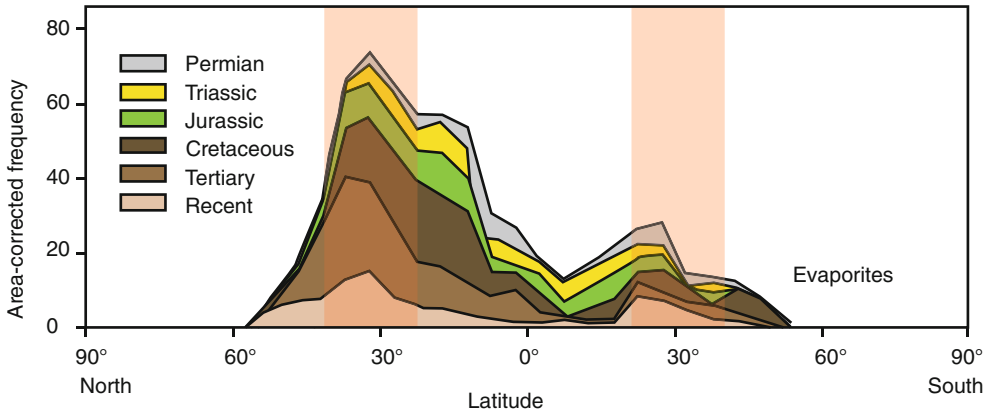

Fig. 5.34 Latitudinal distribution of evaporites from Permian to present (After Ziegler et al. 2003). *Shaded belts* indicate *horse latitudes*. Note, this plot is a count of an evaporite occurrence in each one degree latitude-longitude region; unlike Fig. 5.7, it plots latitude occurrence and is not a plot of evaporite volume. The dominance of northern hemisphere occurrences reflects the dominance of landmasses in the northern hemisphere across the Permian to Recent

Throughout deep time, evaporite sediment occurrence occupied the same two latitudinal belts, known as the Horse Latitudes, which also typifies the majority of occurrences of Holocene evaporites (Fig. 5.34). However, the same plot shows that marine evaporite occurrences in greenhouse earth (Pre-Eocene-Permian) were more latitudinally diverse and more equally distributed over broader latitude ranges

What is more variable is the volume of evaporite sediment deposited in arid latitudes (Fig. 5.7a, b). This is why there are no Quaternary examples of megahalites. Our largest and thickest bedded modern halites are forming in suprasealevel Quaternary collision belts as lacustrine "piggy-back" basins in the salars of South America (Bobst et al. 2001; Jordan et al. 2007). The only Quaternary examples of marine-fed subsealevel rifts are small-scale and include Lake Asal, Djibouti and the late Pleistocene marine-fed halites (with $MgSO_4$ bitterns) in the Danakil depression. Modern inflow waters in the Danakil are continental/hydrothermal and not marine, so the modern bittern precipitates lack $MgSO_4$. Earlier in the Pleistocene, the inflow to the same region was marine/hydrothermal seepage into the widening subsealevel rift, and kainite precipitated.

In the relatively recent geological past the best example of a full-scale rift-associated marine-seepage evaporite is probably the thick Middle Miocene salt layer beneath much of the Red Sea (Bosworth et al. 2005). Other well-studied older examples of rift-associated evaporites include the Mesozoic circum-Atlantic salt basins (Manspeizer 1982; Mohriak et al. 2008).

Evaporites deposited in ancient continental rifts that passed into incipient ocean basins have a sediment fill that can be further subdivided in prerift, synrift and post-rift

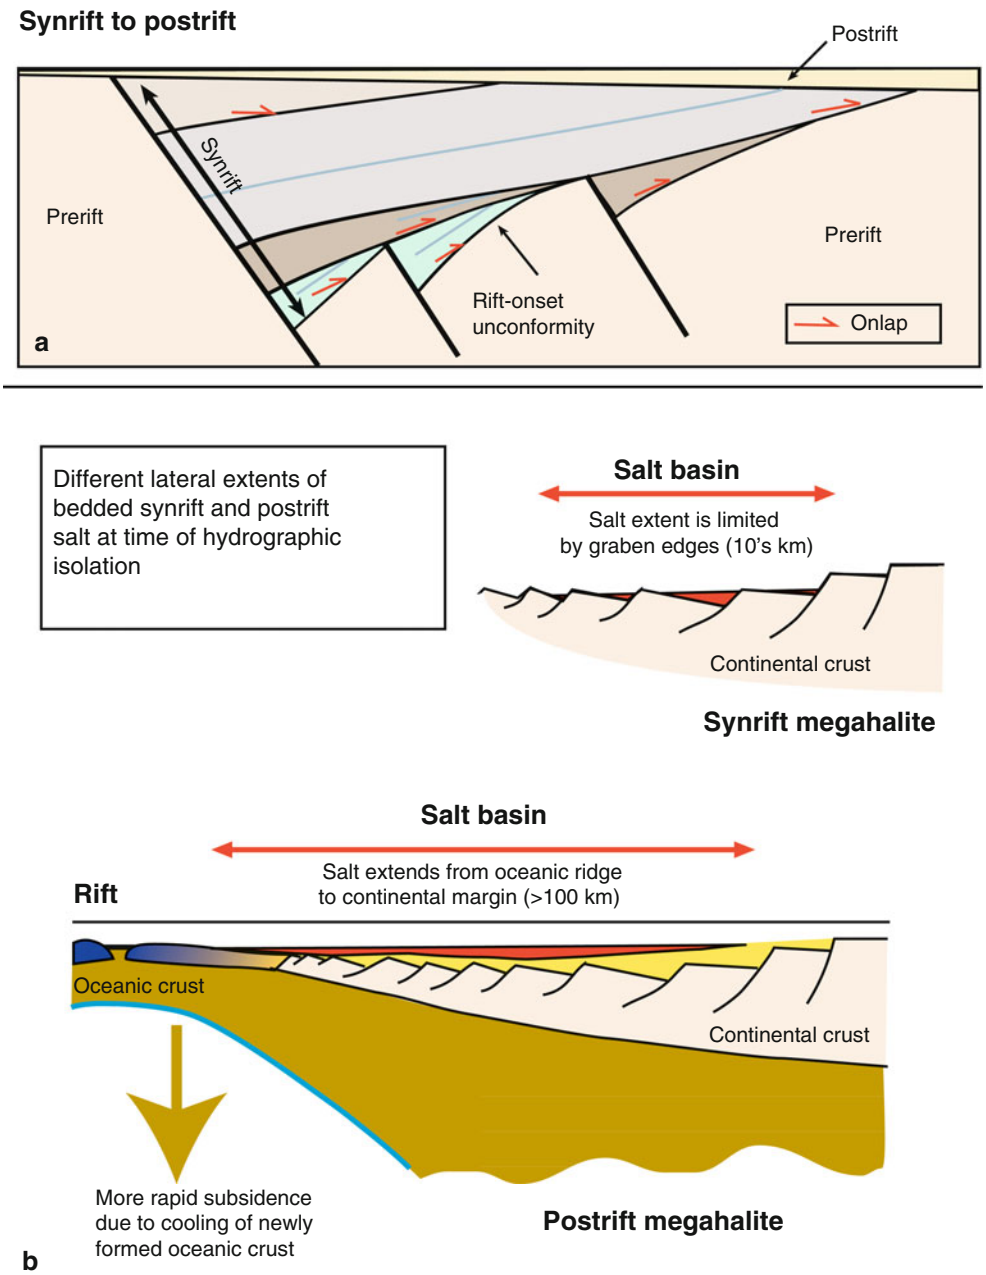

Fig. 5.35 Synrift to postrift associations. (**a**) Stages in rift related sedimentation showing typical characteristics of prerift, synrift and postrift sediment packages. (**b**) Lateral extents of megahalite basins in synrift and post rift settings See also Figs. 6.59 and 6.70

(Fig. 5.35a). Prerift accumulations are lithologies that predate the onset of the extensional faulting that defines the rift. Synrift sediments are deposited in a subsiding zone that thickens toward active normal fault(s) along the rift margin. There is typically a well-defined rift onset unconformity at the lower contact of the synrift with the prerift sediments. The synrift sediment package typically expands over an ever-larger area with time, driven by subsidence related to ongoing normal fault activity. Expansion in the area of synrift sediments is associated with onlap of sedimentation surfaces and is a characteristic feature that is usually recognizable in associated seismic reflectors. Post-rift sediments are deposited when the rift-bounding normal faults are no longer active. These sediments tend to be deposited atop and over the rift graben edges (Fig. 5.35b).

When this classification of pre-rift, synrift and postrift sediment packages is applied to thick salt fills accumulated at divergent plate margins, it seems most megahalites in divergent settings were deposited as synrift packages within well-defined graben profiles, as exemplified by the various Triassic salt basins of the northern Atlantic rim. Permian and Triassic salt basins of Europe and the North Sea are also synrift deposits (Fig. 5.36; Table 5.8).

And yet, a plot of world salt basins at divergent margins shows the largest and thickest halite accumulations (remaining salt) are postrift, not synrift packages (Fig. 5.35b;

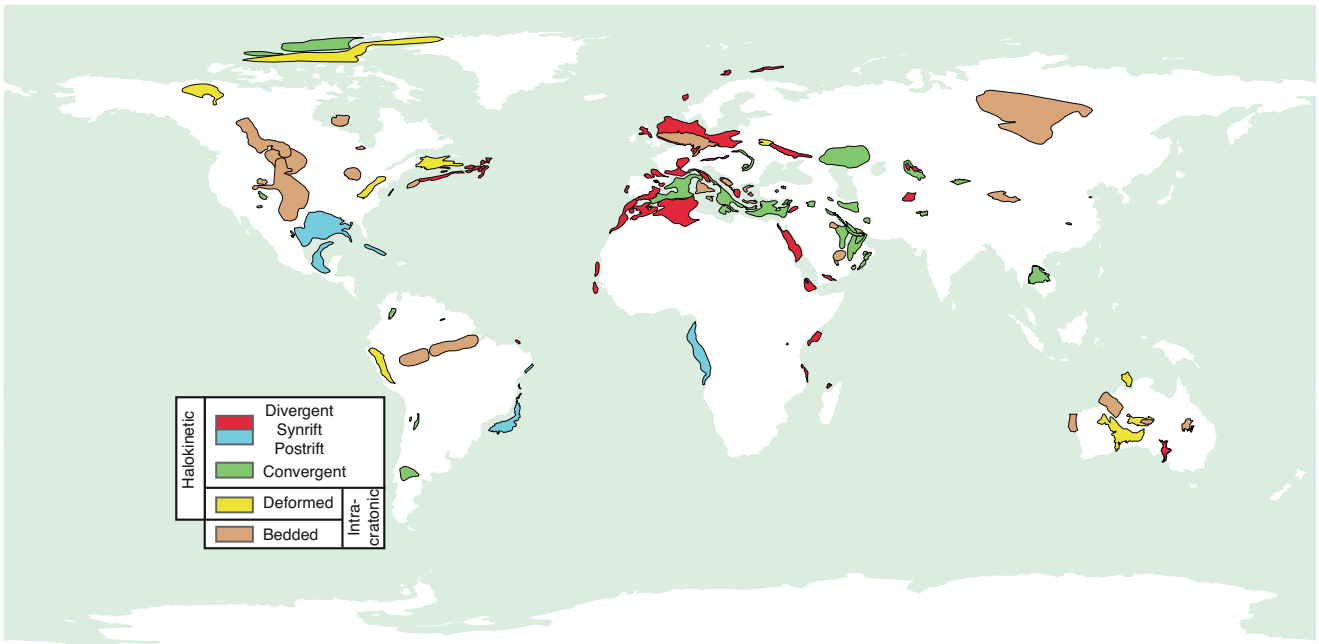

Fig. 5.36 Classification of selected NaCl-dominant basinwide evaporite deposits in terms of tectonic situation, including lacustrine associations (Refer to listed basin key in Fig. 5.30 for basin names)

Table 5.8). They formed in palaeo-Gulf of Mexico and in the South Atlantic Aptian salt basins of Brazil and West Africa. The lateral extent of the salt beds into the synprecipitational basin were not defined by a graben edge atop transitional crust, but in places thick postrift halites were in direct contact with seafloor basalts of the oceanic crust (Salvador 1987; Jackson et al. 2000). It is very likely that the hydrographic barrier that facilitated the hydrology of these subsealevel megahalite basins was also an offset volcanic ridge. It also implies that the northern and southern Jurassic salt masses of the Proto-Gulf of Mexico, and the Brazilian and Angolan Aptian salt masses were never in direct depositional contact, rather, they were separated by a basaltic midoceanic ridge, even as they precipitated. Recently, Huismans and Beaumont (2008) proposed that, compared with earlier one-dimensional depth-dependent models, the post-rift Mesozoic salt basins of the Atlantic are better explained by a model that includes notions of decoupling between upper and lower parts of the lithosphere during stretching, with contrasting wide and narrow extensional styles above and below the decoupling level and progressive focusing of crustal extension toward the rift axis.

Halokinesis in postrift evaporite-floored basins is characterised by well-developed allochthonous salt tiers, strong components of subhorizontal salt translation and secondary minibasin-capped canopy levels (Aptian salt basins of the South Atlantic and the Gulf of Mexico; Davison 2007; Tari et al. 2003; Hudec and Jackson 2007). Stronger vertical aspects of salt flow (c.f. lateral flow), both in extension and compression, characterise synrift basins such as the Permian Zechstein Basins of Europe and the Triassic salt basins of the circum North Atlantic (Warren 2008).

A classification of ancient salt basins, as illustrated as the inset in Fig. 5.36, shows that halite sequences in intracratonic sag basins tend be less subject to halokinesis than halites in rift and collision basins. The NaCl remains as a bedded deposit unless an intracratonic basin is caught up in a subsequent deformation belt, as has affected Neoproterozoic halite in the Amadeus and Officer basins, the Cambrian salts in the Mackenzie Basin and the Silurian salts in the Appalachian basins. The lack of halokinesis prior to later superimposed deformation in intracratonic sag basins is in large part a reflection of their depositional style. As mentioned earlier, halite beds in these basins tend be intercalated with anhydrites and marine platform carbonates. As such, the beds rarely attain the 80–100 m thicknesses of pure salt typically needed for syndepositional salt flow (Chap. 6).

Problems in Correlation *Sans* Hydrology

The need for hydrographic isolation means thick salts are not simultaneous with marine carbonates. Likewise, there are fundamental hydrological problems with the notion that evaporite beds pass laterally below the same sheet of water into contiguous synchronous carbonates and clastic beds. This requires longterm maintenance of subvertical density interfaces in a fluid, which is a physical impossibility. Put

simply, if you ignore the unique hydrology needed to deposit a thick evaporite bed, the correlation will fail. Thick evaporites must correlate to unconformities in their surrounds and subaqueous evaporite deposition in a single brine-filled water body (basin) must be a simultaneous holomictic event.

Shaw (1977) in a landmark paper was one of the first geologists to recognise that the classic silled-basin model, with evaporites accumulating in the basin centre and a restricted surface connection to the ocean defined by growing reefs, is hydrostatically unsound. He went on to demonstrate that in such a scenario deepwater evaporites cannot accumulate. Kendall (1988) further develops this argument by integrating his conclusions with the work of Lucia (1972) to illustrate that when an evaporite basin is depositing widespread salts it must be totally isolated from a surface supply of seawater. Deepwater evaporites are possible in such isolated nonstratified basins (see discussion of the Dead Sea halite in Chap. 4).

Deepwater halite accumulating simultaneously with platform gypsum and basin entry carbonate in a single water mass is not possible, yet it is commonly invoked in models of many ancient evaporite basins. In order to deposit gypsum in a shallow area of a brine body and halite in a deeper area of the same brine body requires an inclined halocline. The required fluid system cannot exist over the longterm in a single brine body. Any body made up of liquids of two different densities cannot support shear. The inclined halocline required by this model will spontaneously collapse in order to regain its gravitational equilibrium. Once it has restratified to a horizontal interface the precipitation of salts in the deeper brine body ceases until the salinities of the upper and lower brine bodies are equalised by the concentration of the upper less saline water body (Chaps. 2 and 4). There never has been and there never will be a brine lake or seaway with a permanently non-horizontal halocline.

In terms of stratigraphy, this means a thick subaqueous bedded halite intersection in one well is an unlikely time correlative of a thick subaqueous anhydrite/gypsum bed in an adjacent well a few kilometres away. The only exception is if they were deposited in nonconnected water bodies in two separate sub-basins or if one or both units were capillary salts not bottom growths. Monomineralogic subaqueous evaporite beds are perhaps one of the few examples of true "layer cake" stratigraphy. Many of the supposed correlations and basin reconstructions in the literature, which propose that a deep subaqueous halite in the basin-centre is time-equivalent to a shallower subaqueous basin marginward anhydrite and to a biologically restricted, but growing, reef carbonate in the seawater inflow area are wrong as they ignore fundamental principles of physics and hydrology. By implication, the geological interpretations and correlations in the same regions will be marked by the nonrecognition of the significance of erosion surfaces, hiatii or dissolution horizons in adjacent wells or in the carbonates or other marine strata that occupy the basin margin. A time of evaporite deposition corresponds to a time of exposure and the creation of a subaerial unconformity in adjacent carbonate sills.

Table 5.9 Typical evaporitic sediment accumulation rates

Mineralogy	Accumulation (cm/ka)
Carbonate bed	50–100
Gypsum/anhydrite bed	1,000
Halite bed	5,000

Kendall (1988) lists five factors that should be addressed when correlating evaporite units or applying the principles of sequence stratigraphy to evaporite basins:

1. *A lack of stratigraphic control;* evaporite depositing areas tend to be populated by halotolerant organisms that have low biostratigraphic potential. This means that biostratigraphic faunal analysis can be used to bracket the evaporite group (using fossils in nonevaporite strata above and below the unit of interest); but intra-evaporite biostratigraphic subdivision is near impossible.
2. *The rapidity of evaporite deposition;* evaporites can accumulate at some of the most rapid sedimentation rates known (Table 5.9; Einsele 2000; Warren 1989). Even if fossils are present in intrasalt units that separate a number of evaporite beds, the very short time required to deposit thick evaporite sequences means the biota are incapable of evolving fast enough to be used for biostratigraphic control of the evaporites.
3. *Complexity of stratigraphic relationships;* stratigraphic relationships between the surrounding nonevaporite lithologies and the evaporites are typically dynamic and problematic. Their hydrology and rapid rate of deposition mean evaporites accumulate so rapidly that lateral correlatives to the evaporite deposit are at best thin, or more typically, are surfaces of erosion or nondeposition.
4. *Early dissolution about basin edge;* A high likelihood of partial to complete subsurface dissolution exists, especially of the more soluble salts, almost from the time the salts accumulate (Fig. 5.37). This means most ancient evaporite deposits show clear evidence of thinning, especially about the edges of a thick evaporite succession where flushing by meteoric and basinal waters is most likely to occur. As we shall see in Chap. 7, a salt bed or halokinetic salt mass shrinks like a block or ice, inwards from its edges. If the evaporite dissolves completely, remnants may be missed (such as layers of insolubles or thin dissolution breccias), and a whole episode of basin history and structural evolution ignored. Even when evaporites remain in the basin, a greater degree of dissolution in zones of freshening about the basin edge means the current distribution of mineralogies may bear no relation to

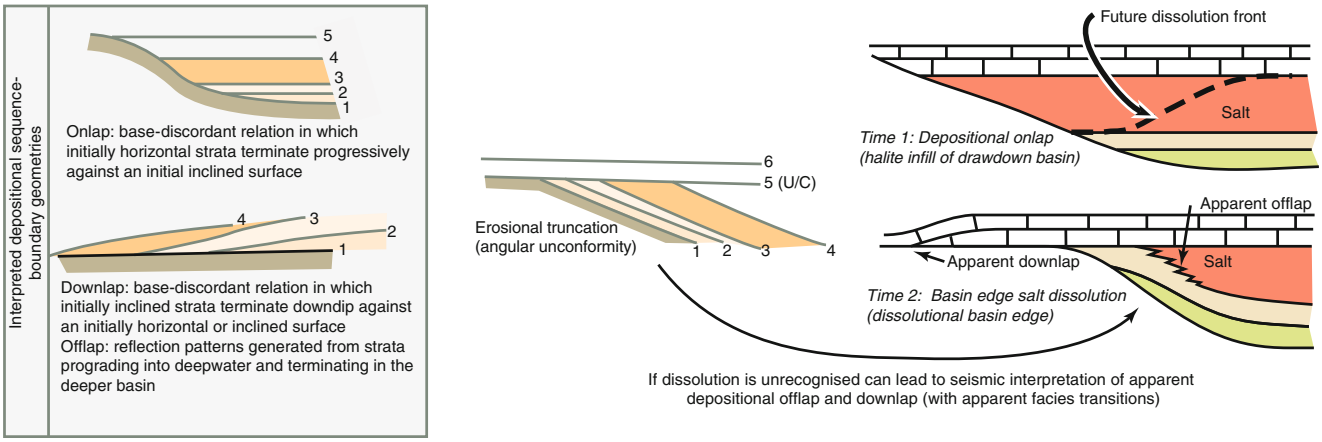

Fig. 5.37 Dissolution of evaporites about the margin of a basin can create an apparent downdip offlapping and updip downlapping stratigraphy from an original depositional onlap situation (In part after Kendall 1988). See also Fig. 5.38

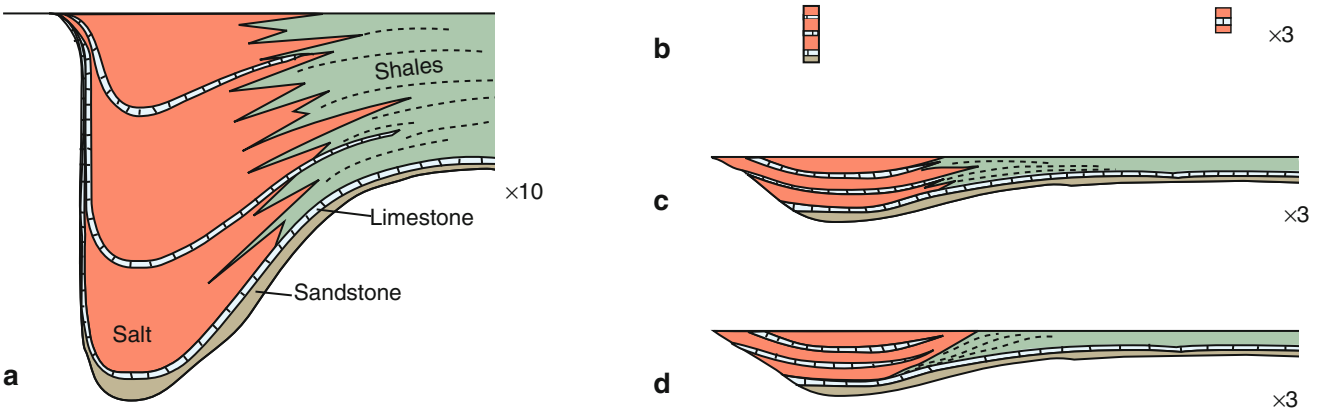

Fig. 5.38 Effect of vertical exaggeration on correlation between thick evaporite sequences and marginal clastics or carbonates (After Busson 1980; Kendall 1988). (**a**) Conventional correlation with significant vertical exaggeration showing lateral equivalency of evaporites and marginward clastics or carbonates. (**b**) Original data drawn with less vertical exaggeration. (**c**) Conventional correlation with less vertical exaggeration (hydrologically unlikely in an evaporite basin accumulating thick salt beds). (**d**) Alternative correlation, which assumes drawdown is require and so there is no equivalency between salt beds and marginward clastics or carbonates (hydrologically likely in drawdown basin). Alternative (**d**) is reasonable to most geologists when not suffering from a psychological need to draw near-horizontal correlation lines. It implies times of thick salt accumulation were distinct from times of carbonate deposition

their original distribution in a basin (Fig. 5.30). Removal of the marginal portion of a halite layer that had overstepped an earlier anhydrite unit will convert an onlapping situation to an apparent offlapping situation in a seismic section in an area without well control. Likewise many apparent "bull's-eye" basins may be the result of marginward dissolution of the more soluble evaporite layers.

5. *Inappropriate scaling*; We tend as a profession to use vertically exaggerated cross sections to make relationships more obvious in what are natural systems with thin beds with low bed thickness relative to width ratios (Fig. 5.38a). Our training in mapping skills makes most geologists reluctant to draw steeply inclined bed-to-bed correlations when more horizontal possibilities are available (Kendall 1988; Busson 1980). A propensity for large vertical exaggeration in basin cross-sections leads to a tendency to draw correlation lines that show transitional facies between the evaporite beds and the surrounding nonevaporites, and to impose age equivalence of evaporites and nonevaporites (Fig. 5.38b, c). But the inherent hydrological constraints required to form a platform or basinwide evaporite fill means salt beds tend to accumulate rapidly in isolated depressions on the land's surface. Times of evaporite deposition correlate to times of isolation and so to times of nondeposition or gaps (unconformities) in adjacent nonevaporite strata. In such situations we should be quite happy to draw inclined correlation lines showing that at the time of evaporite deposition there was little or no deposition taking place in the adjacent nonevaporite strata (Fig. 5.38b, d).

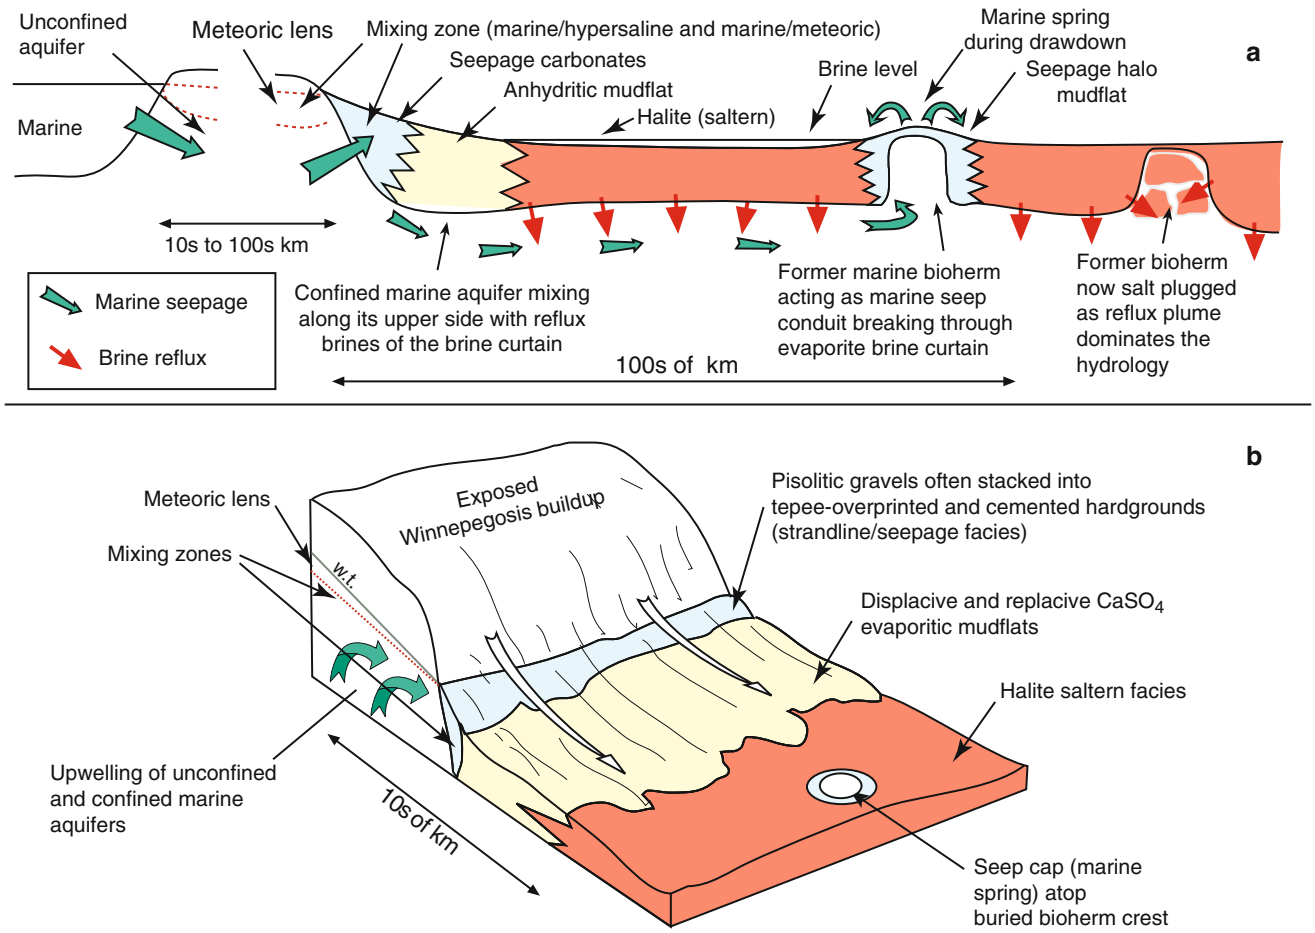

Fig. 5.39 Evaporative drawdown dolomitisation. (**a**) Hydrology of basin showing seepage facies and halite in basin centre. Note the potential for the mixing of seawater seepage with refluxing brines both about the margin of the drawdown basin and beneath the reflux curtain across much of the basin floor. Diagram is not drawn to any consistent lateral scale. (**b**) Close-up of facies pattern associated with seepage outflow zones and the potential positions of marine/meteoric and marine/hypersaline mixing zones (In part after Warren 2000a; Kendall 1989)

Dolomite Aprons in a Drawdown Basin

There is good evidence that much of the finer-grained mimetic dolomite, which is intercalated and dispersed within the main evaporite mass of a basinwide evaporite, has, at least in part, a microbial genesis (Dela Pierre et al. 2012; de Lange and Krijgsman 2010). Such primary dolomite is not discussed further in this section, rather, it focuses on the replacive mesogenetic dolomite in the apron carbonates, beneath and adjacent to the main evaporite body. These dolomites can enhance poroperm levels in these evaporite-sealed carbonates. Requirements of hydrographic isolation for basinwide evaporites have consequences for reflux dolomites. In contrast to well documented reflux dolomite geometries and distribution s in platform evaporite associations, outputs from dolomitising hydrologies in saline giants are a shade more complicated and as well as classic per descendum reflux hydrologies can include aspects of meteoric or brackish waters mixing with dense seawater derived brines (Fig. 5.39; Lu et al. 2002; Li et al. 2013).

Brine plume and seawater seepage inflow phreatic volumes in drawndown basinwide-accumulating depressions are driven by the piezometric head between sealevel and the brine -air interface, which can be hundreds or more metres below sealevel (Fig. 5.7b). With no modern counterpart, one can only infer, not observe, the hydrological and diagenetic character of such basinwide systems by studying the more accessible outcrop examples of platform and basinwide evaporites, as in the Messinian evaporite/dolomite associations of the circum-Mediterranean (Sun 1995; Sun and Esteban 1994; Lu and Meyers 1998), the Permian Zechsteinkalk dolomites associated with basinwide evaporites of NW Europe (Clark 1980a; Peryt and Scholle 1996) and the Devonian basinwide evaporites and associated dolomites of the Keg River- Pine Point Presqu'ile of Canada (Maiklem 1971; Kendall 1989).

Maiklem (1971), Cercone (1988) and Kendall (1989) pointed out the potential for widespread dolomitisation via seawater seepage beneath subaerially exposed carbonate slopes about a drawndown basin mmaiklargin is largely independent of marine eustasy (Fig. 5.39). Drawdown basins have the potential to flush huge volumes of phreatic seawater through the basin edge. As the groundwater heads in such systems are measured not in metres but hundreds of metres, and if one accepts that seawater flushing has the potential to dolomitise marine limestone, then the potential for dolomitisation is huge within carbonate aquifers about the margin of an evaporite drawdown basin. "Mixing" zone dolomites are also likely, but not in a classic seawater-freshwater Ghyben Herzberg interface on the marine side. Rather dolomite will form in rapidly fluctuating and flushed interfaces and outflows in and about the now isolated and exposed carbonate slope and rise shown in Fig. 5.39. The schematic is drawn assuming an unconfined aquifer in the interval separating the marine from the seepage zone. The reality is much more likely to be a combination of confined and unconfined aquifers feeding predominantly seawater into the basin margin. This zone of mixing and seawater spring outflows will move to and fro over the exposed basin edge as the brine level in the basin responds to changes in tectonics and climate.

Outflow points of these predominantly seawater brines develop a characteristic set of pisolitic/tepee cementstone lithologies the strandline/seepage facies described in Chap. 1. Kendall (1992) showed how such a carbonate seepage facies can be used to define hydrologies in the Devonian Keg River Basin where these spring-aprons were mostly located about exposed former shelf slopes and pinnacle reefs (Fig. 5.39b). When part of an inactive pinnacle reef or other aerially exposed bioherm, these permeable carbonates can act as confined aquifer outflow zones capable of breaching the active reflux curtain on the basin floor, much like the modern spring mounds of Lake Eyre and Lake Frome (Fig. 5.39a). Slightly down dip of the seepage facies were evaporitic mudflats dominated by anhydrite and in the lowermost sections of the basin floor were widespread areas of perennial surface brine (the halite seaways of the Keg River Basin). Away from seawater and meteoric discharge seeps, the downward reflux associated with the brine curtain moved Mg-rich waters into underlying sediments driving reflux dolomitisation and evaporite plugging. This water ultimately mixed with deeply circulating seawater seepage fluids and other subsurface waters (Fig. 5.39a).

Such a basinwide hydrology creates both reflux and mixing zone chemistries, which have the potential to dolomitise any limestone host in contact with the outer parts of the brine curtain. Detail of such drawdown mechanisms can be inferred in dolomite distribution within Neogene evaporitic sub-basins of the Mediterranean. For example, Meyers et al. (1997) and Lu and Meyers (1998) have documented pervasive dolomites that cut across intra-Miocene sequence boundaries in the Nijar Platform and also occur in the youngest Messinian reef/oolitic units (Fig. 5.40a). The dolomites do not transect the Miocene-Pliocene unconformity, although they do occur as clasts in overlying basal Pliocene lime grainstones. This constrains the dolomitisation as being latest Miocene and pre-Pliocene, suggesting this widespread dolomitisation occurred within 600,000 years and possibly in less than 200,000 years. It is a excellent indication of the large volumes of phreatic seawater that can be cycled through the rock pores in short times in drawdown hydrologies.

Carbon and oxygen isotopes of Nijar dolomites show marked positive covariation, with most values ranging from +5.4 to −1.2‰ $\delta^{18}O_{PDB}$ and +2.5 to −4.3‰ $\delta^{13}C_{PDB}$ (Fig. 5.40b; Meyers et al. 1997). The highest $\delta^{18}O$ values are heavier than reasonable estimates of Messinian normal-salinity seawater dolomites, suggesting the involvement of evaporative brines in the dolomitisation process. Calculations of covariations of O and C isotopes during water-rock interaction and fluid-fluid mixing argue against recrystallisation of Nijar dolomites, an interpretation also supported by their Ca richness (49–57 mol %). Mixing calculations show that four-fifths of Nijar data are consistent with dolomitisation via mixtures of freshwater and a few tens of per cent of marine-derived evaporative brine, while one-fifth are consistent with mixtures of freshwater and normal-salinity seawater (e.g. covariant isotope curve in Fig. 5.40b) Likewise, modelling of covariations of $^{87}Sr/^{86}Sr$ and Sr/Ca ratios that developed during mixing, further supports involvement of evaporative brine, and suggests that any freshwaters involved in the dolomitisation had low Sr/Ca ratios and relatively high Sr and Ca concentrations. Na, Cl, and SO_4 concentrations in Nijar dolomites (200–1,700 ppm, 300–600 ppm, and 600–6,500 ppm, respectively) also argue for involvement of evaporative brines, and for mixtures of brine with freshwater and/or seawater (Fig. 5.40c).

Meyers et al. (1997) and Lu and Meyers (1998) proposed that most dolomitisation occurred after Messinian reef formation during multiple relative sealevel/brine level changes associated with evaporative drawdown. Marine carbonate deposition of the Nijar shelf occurred during high sealevels, and evaporite deposition during lowered basin water levels associated with evaporative drawdown. During drawdown, basin brines with five to sixfold seawater concentrations (gypsum precipitating) developed on the floor of the Nijar Basin. Brines mixed with freshwater and seawater mainly in a groundwater setting about the basin margin as fluctuating base levels of the brine curtain drove before it a zone of freshened/meteoric water seepages (Fig. 5.40d).

Similar drawdown dolomites can be found in the Zechstein of NW Europe where dolomitised algal-bryozoal reefs, oolites and intertidal to shallow subtidal skeletal grainstones to mudstones occur adjacent to the margin of

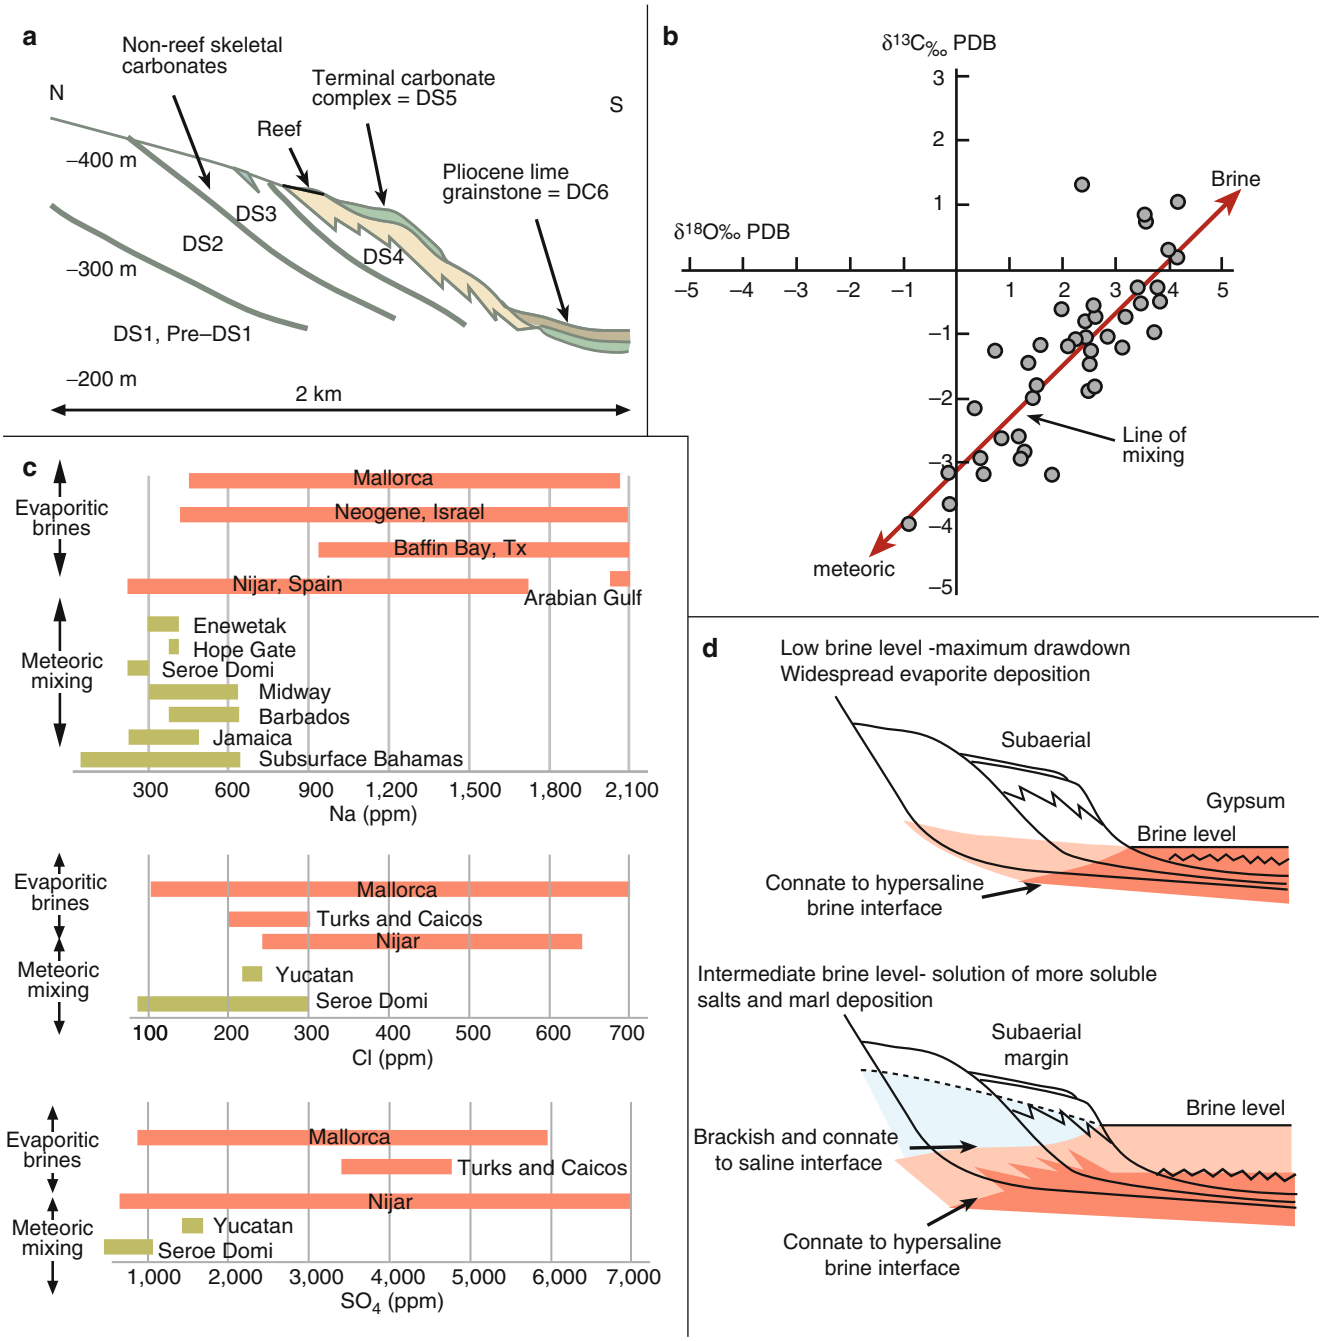

Fig. 5.40 Nijar dolomites in the Messinian of Spain. (**a**) Composite stratigraphic cross section of the Tortonian-Messinian carbonate platform at Nijar. *DS* depositional sequence. (**b**) Oxygen and carbon isotopes of the Nijar dolomites (**c**) Na, Cl and SO_4 contents of Nijar dolomites compared to other Tertiary and modern dolomites formed in mixing zone, seawater and evaporative brines. (**d**) Model of migration of mixing interfaces between hypersaline brine, connate seawater and meteoric brackish waters. Their position within the carbonate margin is controlled by fluctuation in brine level in the basin (After Meyers et al. 1997; Lu and Meyers 1998; Lu et al. 2002)

the Zechstein salts. They are interlayered with the platform portion of basinwide evaporite beds composed of anhydrite and halite (see later in this chapter). Evaporite salts were deposited during the complete isolation and drawdown of the Zechstein Basin. It was at this time of drawdown that reflux dolomites replaced the adjacent and underlying Zechstein limestones (Clark 1980a). At the same time the regression of facies associated with the drawdown of the brine base level caused the encroachment and displacement of formerly marine to hypersaline porewaters by meteoric waters in the dolomites of the Magnesian Limestone (Kaldi and Gidman 1982).

Sequence Stratigraphy in Evaporite Basins?

Sequence stratigraphy is the study of ancient rock relationships within a chronostratigraphic framework of repetitive, genetically related strata, bound by surfaces of erosion or nondeposition or their correlative conformities (Posamentier and James 1993). Stratigraphic sequences are deposited during a single cycle of relative sealevel change and the rise and subsequent fall of sealevel within the shallow marine setting generates a characteristic sedimentary wedge with a specific geometry and vertical stacking pattern. Sequences are conformable successions constructed by genetically related strata, bound at the top and bottom by unconformities and their correlative conformities (Fig. 5.41; Van Wagoner et al. 1988, 1990; Tucker 1993). Unconformities bounding sedimentary wedges may represent a significant time gap and may die out in more basinward positions where sealevel oscillations do not expose the sedimentation surface.

In classic sequence stratigraphic interpretations of marine sequences, the major control on depositional extent and geometry is assumed to be relative sealevel change, determined by rates of eustatic sealevel[6] variation and tectonic subsidence. Depositional sequences are generated by a single cycle of relative sea-level change, and a complete depositional sequence, bounded by unconformities, consists of, from oldest to youngest, lowstand, transgressive, and highstand components (= systems tracts). This evolution creates the characteristic transgressive-regressive pattern of sedimentary facies within a depositional sequence with the outline of a sigmoidal wedge or prism (Fig. 5.41b); lowstand systems tract (LST), transgressive systems tract (TST) and highstand systems tract (HST). A seismically resolvable depositional sigmoid typically has a thickness of 10–100 m, extends laterally for 10–100's km, and represents a depositional episode of 1–5 million years in duration. According to Haq et al. (1987), it is a response to 3rd order sealevel changes (Table 5.10; Fig. 5.42). Internally, depositional sequences are constructed of sub-seismic-resolution parasequences (metre- to decametre-scale 4th and 5th order depositional cycles). Parasequences are typically bound by local scale unconformities and disconformities are visible in most outcrops and cores.

Chronostratigraphic correlation is an important application of marine sequence stratigraphy. It is tied to the notion that sediment wedges form in response to worldwide sealevel cycles of rise and fall. If so, then seismic geometries can be used to extract a global sealevel cycle chart (aka Vail or Exxon sealevel curves). This then leads to the construction of age models for given stratigraphic successions that

[6]Eustatic change (as opposed to local change) results in a worldwide alteration to the global sea levels due to changes in either the volume of water in the world oceans or net changes in the volume of the ocean basins.

Table 5.10 Orders of sealevel change and likely driving mechanisms (In part after Tucker 1993)

Order	Years	Tectonoeustatic	Rifting and thermal subsidence	Global eustatic	In-plane stress	Glacioeustatic, tectonic, sedimentary	Basinwide evaporites time to deposit 1–2 km of fill
1st	10^8						
2nd	10^7						
3rd	10^6	Seismic sigmoids					
4th	10^5						
5th	10^4	Typical limit of seimic resolution in siliciclastics and carbonates					
6th	10^3	Parasequences					

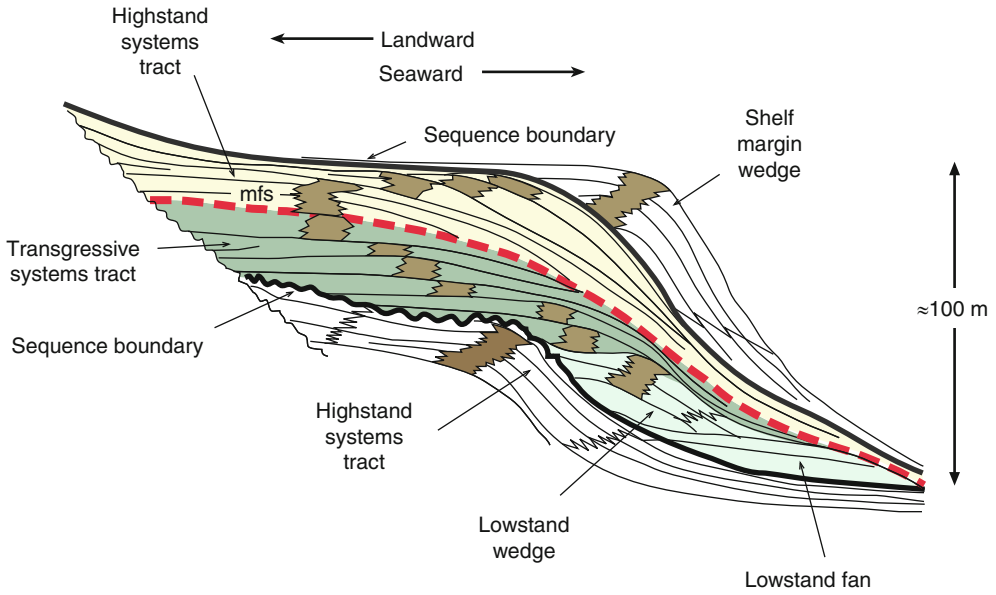

Fig. 5.42 The familiar sigmoidal or "slug" model of a marine carbonate depositional sequence used by sequence stratigraphers with the brown shaded areas representing carbonate shoal/reef sediments. A single depositional sequence consists of lowstand, transgressive and highstand systems tracts (After Van Wagoner et al. 1988 and other sources). A maximum flooding surface (*MFS*) separates a transgressive (retrogradational) from a highstand (progradational) system tract. In terms of associated evaporite deposition each sequence boundary (unconformity) may be time equivalent to a thick sequence of basin-wide evaporite fill, which accumulated further out in the basin (low-stand? but there is no hydrographic connection to ocean). Saltern evaporites tend to accumulate on the platform landward of the reefs within transgressive system tract sediment packages when higher order sea sealevel falls expose reef crests and isolate lagoons from a surface connection to the ocean

are based on the correlation of a local stratigraphic sigmoid to this global sealevel curve (Posamentier and James 1993). Different orders of sealevel change are recognised based on the time interval encapsulated in the sealevel cycle (Table 5.10). The use of sequence stratigraphic principles to construct age-eustatic (chronostratigraphic) models is based on the assumption that stratigraphic successions are a function primarily of eustatic rather than local tectonic fluctuations or that the effect of tectonics can be reliably removed so as to allow sealevel curve fitting.

First and second order changes in world sealevel are a response to changes in the volume of the ocean basins caused by continental dispersal and collision (Figs. 5.43 and 5.44). High rates of seafloor spreading during continental dispersal reduce ocean basin volume, leading to high sealevel. Third order changes have durations of 1–10 m.y. and are typically about 2.5 m.y. in length. The cause of third order cycles is controversial as they are too short to attribute to most world scale tectonic events affecting the volume of the ocean basins, but too long to attribute to glacio-eustatic responses. Other more local tectonic events, such as changes in plate stress and regional tectonism, are of the correct duration, but do not appear to be capable of generating sufficient change in water depth to account for the magnitude of world scale third order cycles. Fourth order (500–200 ky) and fifth order (200–10 ky) cycles are widely documented in marine sediments (outcrop and core based parasequences) in many periods of the Phanerozoic in both shallow marine and pelagic

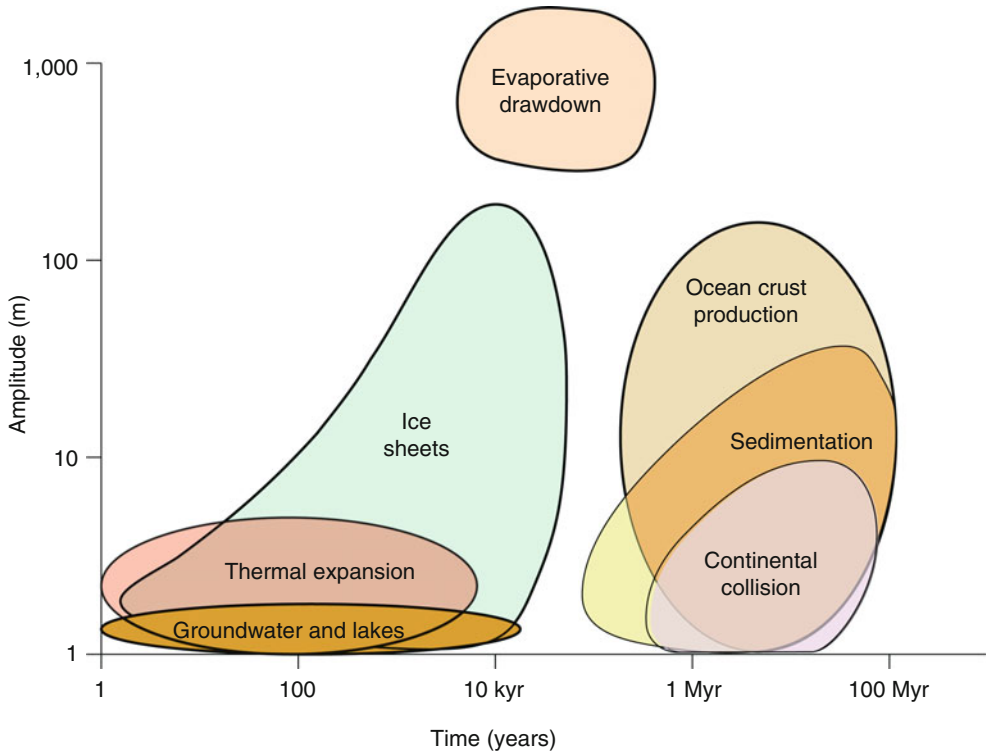

Fig. 5.43 The various geological processes that drive different amplitudes of sealevel change across different time periods (In part after Miller et al. 2011; see also Table 5.10)

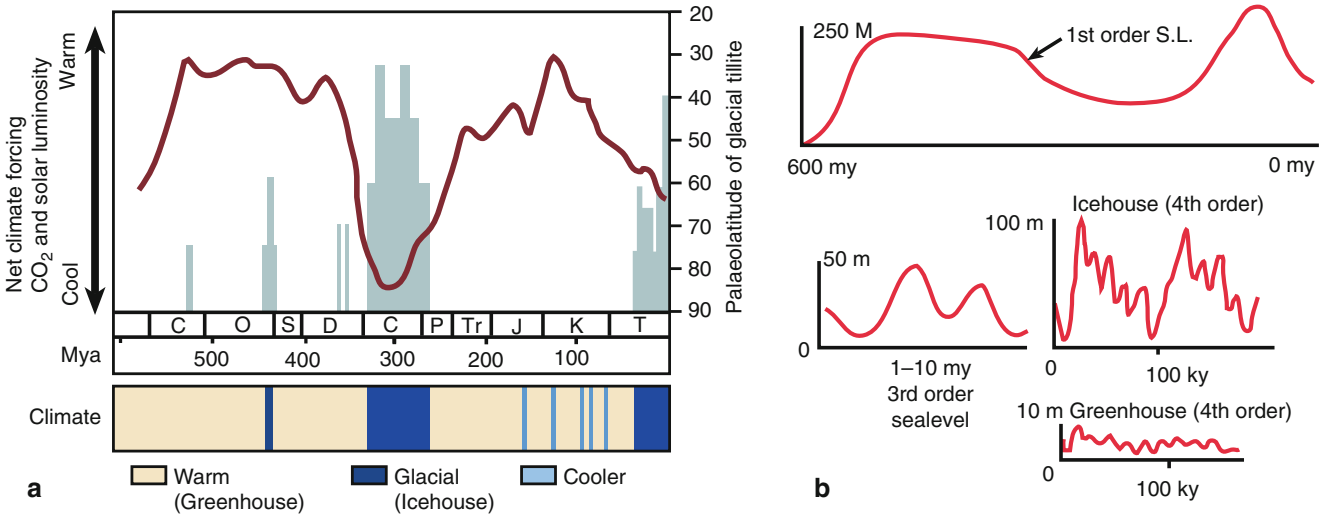

Fig. 5.44 Relationship between icehouse and greenhouse conditions, eustasy and global CO_2. (**a**) Palaeolatitudinal extent of glacial tillite in relation to net forcing of climate due to variations in CO_2 and solar luminosity. Inferred times of general greenhouse, icehouse and short cooler climate periods in Mesozoic (After Royer et al. 2004). (**b**) Eustatic sealevel curves, showing first order Vail sealevel curve in the upper part. Rest of diagram plots typical amplitudes and periodicities of higher order sealevel curves. Third order curves have a 1–10 my periodicity. Schematic 4th order with superimposed 5th order sealevel curves are drawn for icehouse and greenhouse conditions (See text for explanation)

strata. These cycles are possibly the result of changes in global climate driven by cycles in the Earth's orbital parameters and tilt, collectively referred to as Milankovitch Cycles.

There is still much debate in the literature as to controls on the magnitude and frequency of the various sealevel changes that could facilitate a correlation of sedimentation packages worldwide; especially at the third order world scale cycles where seismic and rock based interpretations overlap. At that scale, some authors well versed in outcrop and core study go further and question the reality and the scientific basis for the construction of world scale age correlations based on seismic-based third-order eustatic age curves in almost all sedimentary basins (e.g. Miall 2010).

For evaporites, there is also the additional problem of different depositional rates of water level change inside and outside a hydrographically isolated groundwater sump

(Fig. 5.40). Rates of evaporite deposition, especially in basinwide settings, are an order of magnitude higher than that of marine shelf carbonates or siliciclastics (1–2 km in 300,000–500,000 years are typical). Seismic geometries resolvable in evaporite fills are typically 4th and 5th order, with parasequence sets resolving time frames of the order of a 1,000 years (6th order). Comparing seismic stratigraphies inside and outside a basinwide evaporite basin and attempting, based on the evaporites, to relate the eustatic interpretation to the global curve is difficult if not impossible. We are not resolving depositional evolution at the same time scale (Table 5.10).

More generally accepted than worldwide chronostratigraphic correlation is the application of seismic sequence stratigraphy to lithology prediction based on interpretation of depositional geometries and basin architecture using a combination of seismic, wireline, core and outcrop data (Miall 2010). For example, the favoured sites for major porosity development in carbonate-dominated depositional sequences include large, isolated buildups within the transgressive phase, massive grainstone aprons located immediately landward of the shelf-margin facies within the regressive phase, and karst-affected platform interior facies immediately beneath the sequence-bounding inter-regional unconformities (Fig. 5.39).

There are numerous volumes and papers now published that deal with high resolution sequence stratigraphy of arid zone carbonate shelves and ramps and how they differ from siliciclastic sequences in their response to sealevel changes (Fig. 5.39; Miall 2010; Read et al. 1995; Budd et al. 1995; Loucks and Sarg 1993; Tucker 1993; Posamentier and James 1993; James and Kendall 1992). The details will not be repeated here and the interested reader should refer to these volumes. There are only a few published papers that deal specifically with the sequence stratigraphy of evaporite systems; key papers include, Tucker 1991; Goodall et al. 1992; Strohmenger et al. 1996a, b; Sarg 2001. The results are contentious and most concentrate on the carbonate (marine-connected?) stage of the evaporite basin. This is understandable as it is in these carbonate units that potential hydrocarbon reservoir facies are to be found, often beneath or adjacent to the evaporite seal.

Does Sealevel Control Salt Sequence Boundaries?

When attempting to interpret eustatic effects (global sealevel) in evaporite basins, a requirement of no effective hydrographic connection to the open ocean during times of extensive evaporite accumulation plays havoc with the fundamental marine eustatic paradigms of sequence stratigraphy. Documented brine level changes in lacustrine and marine basinwide settings are ≈1 km in a few thousand years and there is no simple relationship between sealevel changes going on outside the basin and the geometry of the evaporite body in the isolated evaporite-accumulating basin (Fig. 5.43).

All evaporite basins with a marine-seepage feed have a brine level that is below sealevel. It is, after all, drawdown that drives brine influx in ancient marine-fed basins. The relative difference in water level across the isolating barrier may be no more than a few metres, as it was in the platform evaporites of Guadalupian backshoal strata in West Texas, or it may be thousands of metres as it was in the late Miocene salinity crisis in the Mediterranean, the Cretaceous evaporites of the southern Atlantic and the early stages of the Permian salinity crisis in the Zechstein Basin of NW Europe. Brine salinities and the rate of salinity change in a brine-filled depression, as well as the absolute brine level in an isolated basin, are controlled by the local climate, the rate of brine leakage through the underlying brine curtain and the rate of seepage replenishment of the inflow waters and brines about the depression's margin. With most ancient saline giants the creation of a depression capable of accumulating and preserving thick lacustrine and basinwide evaporite fill is a response to tectonics, not eustasy.

Marine-fed platform evaporites must be distinguished from basinwide evaporites if one wishes to apply the marine eustatic concepts. At our present level of understanding we can probably fit marine-margin platform evaporites and some intracratonic saltern fills (epeiric seaways) into a global eustatic context. In the absence of tectonic tilting in these two settings, the precipitation of large volumes of platform salts is largely dependent on marine phreatic seepage through a carbonate barrier. It requires platform isolation brought about by a slight fall in sealevel, perhaps a 4th order fall on a 3rd order rise in greenhouse mode (Fig. 5.7a). The evaporites can fill the depression behind the barrier; but cannot, as they are seepage fed, rise any higher than sealevel and still be active. The isolating barriers in turn have geometries and distributions across the platform that are controlled by sealevel changes (Miall 2010; Read et al. 1995; Loucks and Sarg 1993).

In contrast, tectonically-formed subsealevel basinwide evaporite units, with their much lower hydrological base level, are more problematic in terms of using the effects of sealevel fluctuations to understand and predict evaporite geometries and mineralogies. The problem will remain until the hydrologies of large-scale drawdown systems are better understood. Formation of basinwide evaporite sequences are largely tied to a suitable juxtaposition of tectonics and climate. In such a scenario the decametre sealevel fluctuations on the marine side of the isolating barrier are largely irrelevant to evaporite depositional styles within the lowermost

portions of an isolated basin experiencing a drawdown that is up to 1,500–2,000 m below sealevel. Likewise continental lacustrine evaporites are not directly tied to the world sealevel curve. In both basinwide and continental lacustrine scenarios the application of sequence stratigraphic modelling is most useful in a genetic rather than an age (world sealevel/eustatic) context.

Icehouse and Greenhouse Eustasy

Sequences in seismic stratigraphy are unconformity-bound packages generated by high amplitude sealevel changes, with bounding surfaces typically produced during relative sealevel falls (Tucker 1993). High amplitude sealevel changes producing regional sequence boundaries can occur on several time scales depending on the presence or absence of polar ice caps and glacial tillites (Fig. 5.44a). At times of no polar ice cap (greenhouse earth) the high amplitude changes that produce sealevel oscillations of several tens of metres are a response to second and third order processes, while fourth/fifth order processes produce only metre-scale relative sealevel changes and associated parasequences (Fig. 5.44a). In contrast, when there are polar ice caps (icehouse earth) the high amplitude sealevel changes (typically greater than 100 m) are brought about by fourth/fifth order processes.

The driving force for these high amplitude/high frequency oscillations is change in polar ice volume driven by Milankovitch rhythms (Figs. 5.1 and 5.2). During icehouse times the same longer term second-/third-order fluctuations in sealevel that dominate the greenhouse style still occur, but they now have a lower amplitude and longer period than the glacially driven changes. Thus the glacially-driven eustatic cycles swamp these longer term effects, so that in icehouse times fourth-order sequences are produced and are arranged into sequence sets (Tucker 1993). Greenhouse periods produce third order sequences constructed by fourth-/fifth order parasequences and show a much more prevalent cyclicity in lagoonal parasequences (Fig. 5.44b).

The Neogene sedimentary marine record is an icehouse record, where fourth-order sequences dominate the continental margin as unconformity-bound, relatively thin (5–30 m thick), stratal packages. Other older icehouse intervals include the late Precambrian and the Permo-Carboniferous (Figs. 5.2 and 5.44a). In contrast in greenhouse times (Late Cambrian to Middle Ordovician, Silurian to Early Devonian, Late Permian to Oligocene), marine stratal packages consist of much thicker unconformity-bound sequences (50 m to hundreds of metres thick) deposited as third order cycles made up of fourth-fifth order parasequences that are 1–10 m thick.

Marine-Margin Platform Evaporites

Marine carbonate platform systems show a different set of depositional responses to sealevel change compared with siliciclastics, the differences were not recognised in the early Vail/Exxon models (Fig. 5.45; Miall 2010). The difference is there because almost all marine carbonate is ultimately biogenic. Unlike siliciclastic shelves (Fig. 5.45a–c), carbonate shelves most actively aggrade and then prograde both seaward and landward during times when the continental margin and interior is covered by shallow seas. That is, those most rapidly growing parts of any epicontinental carbonate platform, usually the reef crest and associated grainstone belts, aggrade most rapidly when part of a transgressive systems tract (Fig. 5.45e). In contrast, the marine carbonate platform progrades most rapidly when part of a highstand systems tract and the accommodation space in the platform lagoon is filled (Fig. 5.45f). When part of a lowstand systems tract, the much more restricted area of the "carbonate factory" means little or no growth can take place in either deep or shallow water, karstification of exposed platform sediments dominates at the sequence boundary on the platform (Fig. 5.45d). The lowstand response is very different in carbonate and siliciclastics.

Carbonate sedimentation rates cannot be assumed to be near-constant across a water-covered platform. The variation in unit thickness reflects the strong environmental controls imposed on biogenic sedimentation rates. Thus, changes in geometric stacking patterns in carbonates do not necessarily directly reflect changes in the rates of relative sealevel rise as environmental changes are not always directly linked to changes in sealevel, but may reflect differing rates of deposition due to differing biotal growth rates across the platform (James and Kendall 1992; Hunt and Tucker 1992).

In a marine carbonate system the TST is the time when the maximum growth potential of the carbonate platform is realised and the parts of the open marine platform with the greatest growth potential typically aggrade to sealevel and then begin to prograde both seaward and into the lagoon (Fig. 5.45e). In contrast, evaporite deposition occurs on a marine platform when a back-reef or lagoonal depression is isolated from a surface connection with the sea (Fig. 5.45h). On a ramp, the barrier is usually a buildup of some sort of continuous zone Y shoal, on a rimmed shelf it is typically the reef belt or the associated grainstone/pisolite flat that have built up to sealevel.

Hydrographic isolation across the barrier crest and the onset of thick platform evaporites are usually initiated by a slight fall in sealevel, following a time of vertical aggradation (catch up) in the more rapidly growing parts of the carbonate platform; e.g. a fourth order fall superimposed on a third order rise in greenhouse mode. Thick platform evaporites are most likely to form as part of a transgressive systems

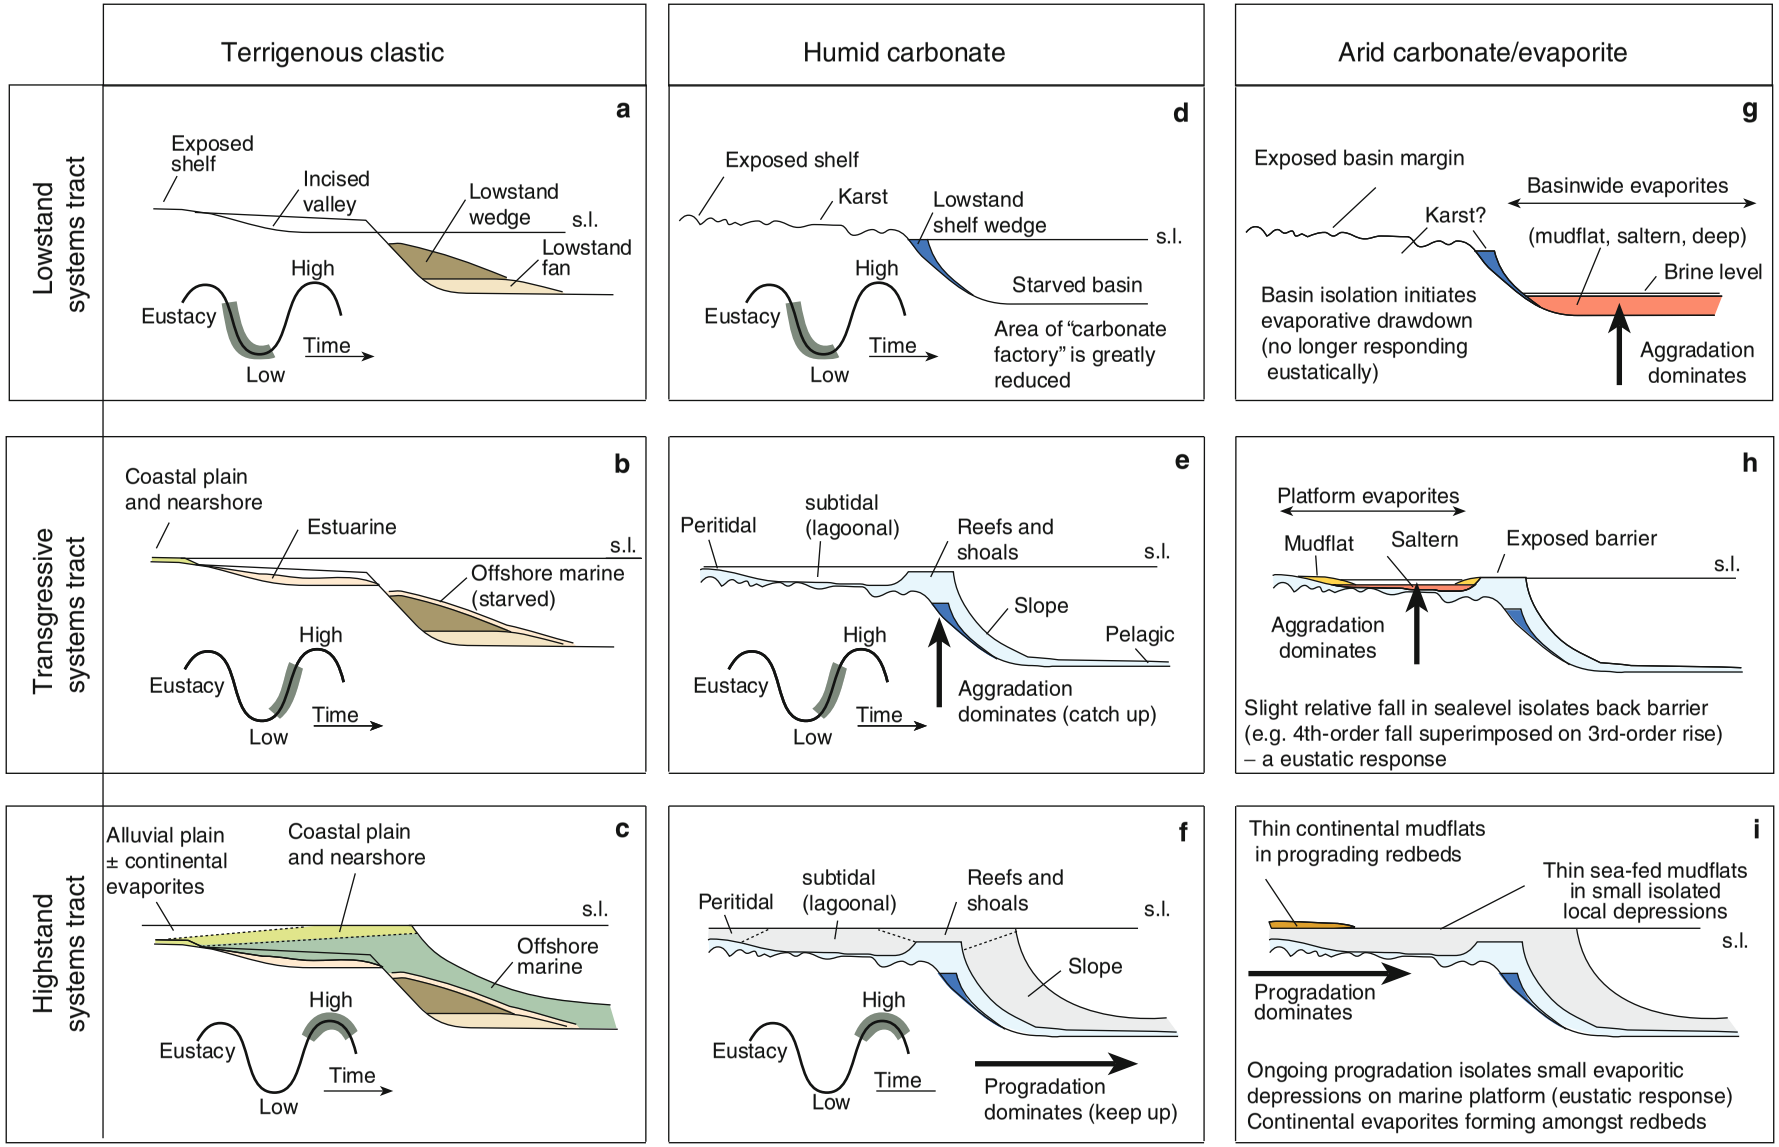

Fig. 5.45 Sequence stratigraphy of siliciclastics, carbonate and evaporite platform sequences (see text for explanation)

tract (third order) in a greenhouse earth. Any slight fall in sealevel will be marked by an unconformity across the topographic high (rim/shoal), which isolates the marine from the evaporite-depositing areas (Fig. 5.45h). Thinner evaporative mudflat (sabkha/salina) units may form as part of a highstand systems tract where ongoing progradation of the shelf (keep up) isolates small depressions further landward (Fig. 5.45i).

When platform evaporites were deposited, the subaerial isolation either of the rim/grainstone buildups on a rimmed shelf or of the zone Y shoal facies on a ramp were responsible for the restriction of the lagoon to the point where evaporites could accumulate (Fig. 2.80; Lucia 1972). Otherwise, like the carbonate shoals and reefs on platforms of today, subaqueous conditions behind the shelf rim or shoal would have never become saline enough to deposit subaqueous evaporites and only thin capillary zone sabkha caps (<1 m thick) could prograde across the landward feather edge of marine lagoon sediments. Prior to hydrographic isolation, normal marine to restricted marine sediments had been accumulating in the lagoon, so that in a vertical profile normal marine bioturbated shelf wackestones and mudstones typically underlie bedded platform evaporites. In sequence stratigraphic terms, episodes when platform evaporites accumulate correlate to karstic exposure surfaces or bounding surfaces on the platform crest. But, as it occurs in greenhouse eustasy, 4th-order sealevel did not fall more than a few metres, so it is a type 2 sequence boundary. In contrast all basinwide deposits are defined by type 1 sequence boundaries (in truth, applying marine seashore terminology to a hydrographically isolated and drawdown basin is probably wrong usage, or at least inappropriate).

Once an evaporite lagoon on the platform is hydrographically isolated from the open ocean, two end members can be deposited behind the rim; either saltern sequences or mudflat-dominated successions (Fig. 5.7). The dominance of one or the other reflects the response of evaporite drawdown hydrology to changes in relative sealevel on the platform. An evaporitic mudflat mosaic forms when there is intense evaporation and relatively slow rates of marine seepage recharge and longterm surface brine cover is relatively rare. Mudflat fills dominate if there is little difference in elevation between the sealevel on the other side of the exposed barrier crest and the floor of evaporitic depression. Sediments of the rim/shoal (oolite/grainstone/pisolite/boundstone) pass directly upward into thin intercalated sabkha/salina units or stacked sabkha cycles and back to shoal facies that make up the base of the next cycle, with no intervening saltern sequences.

Saltern fills tend to dominate evaporites of the lagoon fill when evaporation is less intense and/or there is a greater rate of seepage replenishment through the isolating barrier. Salterns are more common if there is a greater potentiometric head across the barrier between ambient sealevel and the water surface in the lagoon. This tends to occur when the platform lagoon was deeper at the time of its isolation. This happens during a transgression in settings where the rim/shoal aggrades relatively rapidly, while the backshoal platform does not keep pace with the same rise in sealevel. Early shoalwater carbonates deposited on the lagoonal side of the rim are not all that different from those on the seaward side of the rim. This is especially true where the rim is incipiently drowned at the onset of the transgression. While the rim was growing and catching up to a new, higher sealevel the waters in the lagoon could freely exchange with the open ocean and so a diverse open-marine biota flourished within the lagoon.

When a rim reef or shoal catches up to the new higher sealevel and coalesces into an isolating barrier, conditions in the carbonate-accumulating epeiric lagoon become more restricted. As the exchange with open ocean waters is reduced; sediments are now deposited as restricted-marine carbonates. With complete restriction across the rim or shoal, the lagoonal waters become sufficiently saline to deposit evaporites and fill the drawdown lagoon with a shoaling-upward saltern cycle, perhaps capped by a mudflat sequence. The saltern evaporite unit is as thick as the lagoon was deep at the inception of evaporite deposition (Figs. 5.7a and 5.45h).

Such subaqueous saltern beds tend to be widespread across the evaporite lagoon and so are easily correlated from well to well as metre- to decametre-thick clean evaporites. The ten or so subaqueous cycles of the Cretaceous Ferry Lake Anhydrite in the northern Gulf of Mexico region (Fig. 5.24a; Pittman 1985) and the Permian San Andres cycles on the northern margin of the Delaware Basin (Elliott and Warren 1989) are examples of stacked saltern beds, while the base of the Late Permian Seven Rivers Formation atop Yates Field on the Central Basin Platform in West Texas is an example of the stacked mudflat mosaic (Fig. 10.44). The geology and reservoir/seal properties of these platform evaporite units is detailed in Chap. 10.

Unlike bedded carbonates and siliciclastics, the effects of syndepositional and later evaporite dissolution can greatly complicate any attempt at high-resolution stratigraphic interpretation in an evaporitic platform. Dissolution typically occurs as the subsiding platform evaporite passes from an active phreatic hypersaline hydrology into a compactional or thermobaric regime. This creates thin dissolution breccias and residue layers that extend over large portions of the platform (Chap. 7). Such breccias can be confused with subaerial exposure surfaces and humid/temperate phreatic karst. Unless the significance of evaporite dissolution breccias and the timing of dissolution in relation to burial is recognised, whole episodes of platform isolation may be miscorrelated. Many published outcrop-based studies of high-resolution stratigraphy in carbonate-evaporite platforms are problematic because dissolution breccias, which tend to be thin and recessive, are largely unrecognised or, if recognised, misin-

terpreted as marine flooding surfaces. And yet, a 1-m thick breccia may mark the position of a former 100 m thick salt bed. This is especially true in Precambrian platforms where biostratigraphic checks on correlation are not possible.

Clearly, there are significant differences in response geometry and basin position across the three lithologies (siliciclastic/carbonate/evaporite). In a lowstand systems tract there are substantial volumes of terrigenous sediment deposited at the foot-of-slope, but relatively minor carbonate deposition if sealevel is below the shelf break (lowstand shelf wedge). In a hydrographically isolated basinwide setting large volumes of evaporites can accumulate as a lowstand systems tract, but as widespread sheets across the hydrographically-isolated basin floor. In a transgressive systems tract, carbonate sedimentation in a humid setting reaches its highest growth potential. If a transgressive systems tract is also subject to a higher order fall that isolates a seepage depression on the shelf, then thick sequences of platform evaporites can form. In a highstand systems tract only thin mudflat evaporite units can form, while thick sequences of platform clastics and carbonates can accumulate.

Platform Evaporites in a Greenhouse Earth?

The high amplitude rapid to-and-fro of the icehouse seas across Neogene platforms has discouraged the deposition of extensive shallow-water platform evaporites. The most recent time of extensive platform evaporites is perhaps the Eocene in the Middle East, centred on Iraq and Iran or the Paleocene of North Africa (Table 5.5; Rus Fm.). Platform evaporites tend to form under greenhouse earth conditions characterised by lower amplitude sealevel fluctuations and higher world sealevel with marine waters over large parts of the continental masses (epeiric seaways). The high-amplitude high-frequency sealevel changes of icehouse earth encourage local high-relief "catch-up" reefs and banks due to ongoing rapid flooding and exposure of the platform, along with substantial unconformities and pervasive meteoric diagenesis deep in the reefs. Hence icehouse carbonate facies show considerable lateral thickness variations (Read and Horbury 1993). Throughout the Quaternary and the Neogene there has never been sufficient time for shelf-edge periplatform reefs and sand belts to grow and accrete into a single continuous shelf margin facies belt, unlike the periplatform buildups that characterise greenhouse time. Before a continuous periplatform rim can happen, icehouse sealevel falls off the shelf edge every 100,000 years or so (Fig. 5.44).

Thus, platform-edge reefs and shoals typically do not develop into laterally continuous strike-parallel belts under an icehouse scenario. Converting large areas of periplatform lagoons into isolated depressions with marine-seepage hydrologies suitable for precipitating evaporites simply does not happen. The only place where marine-fed isolated seepage depressions can occur in today's icehouse scenario is in narrow sea-marginal highstand bands, as evidenced by numerous small scale sabkhas and salinas along the marine coasts of many arid areas (Chaps. 3 and 4). Shoreline/sealevel repeatedly falls off the platform in icehouse earth mode (>100 m fall; type 1 boundaries) and so any local areas of sea-marginal peritidal or seepage evaporites that may have formed in a highstand are subject to widespread dissolution via vadose flushing, as is seen in the worldwide lack of well preserved Pleistocene marine sabkhat and salinas (Warren 1991). Even in the hyperarid coastal zone of the Red Sea, only small isolated remnants of marine-fed evaporites from the last 100 ka sealevel high remain and none remain from the previous 200 ka high. Thus, modern highstand marine-edge evaporites are small in scale and have little or no long-term preservation potential.

In contrast, the low amplitude low frequency 4th-order sealevel oscillations that characterise epeiric seaways and shelves in greenhouse earth intervals favour the formation of stable, large, highly restricted, at times evaporitic, depressions on the inner shelf portions of many marine platforms (Fig. 5.44b). A lack of permanent polar ice meant sea levels were high and covered more of the craton. Likewise, carbonate-amenable temperatures had wider latitudinal distributions. Carbonate platform rims had growth potentials that could more than keep pace with the low amplitude fourth order sealevel fluctuations. Wide, flat carbonate platforms with huge back-platform lagoons were commonplace (epeiric seas). A slight fall in sealevel meant seepage waters easily ponded in isolated large shallow shelf depressions behind continuous, now subaerially exposed reef or shoal rims. In areas where epeiric seaways covered large inland portions of the continental interior, the formation of a tectonic or shelf rim barrier followed by a fall in sealevel meant that the entire platform interiors and intracratonic sag basins could become evaporitic.

Thus, episodes of stacked platform evaporites tend to favour epeiric and pericontinental seas in greenhouse times as rapidly deposited, but extensive, saltern and mudflat beds precipitated atop marine lagoon sediments (Fig. 5.18). They were part of an overall TST, but only precipitated during short intervals characterised by higher-order low amplitude falls in sealevel. At such times the platform crest was subaerial and much of the platform was brine saturated. Today there are no substantial epeiric seaways and the isolating effects of slight sealevel falls, as well as any possibility of accreting an ongoing laterally continuous carbonate platform rim, are swamped by the overriding influence of rapid, high-amplitude, icesheet-induced 4th order sealevel changes moving across relatively narrow and steeper continental shelves. Conditions suitable for the formation of platform evaporites simply do not exist under today's icehouse eustatic regime.

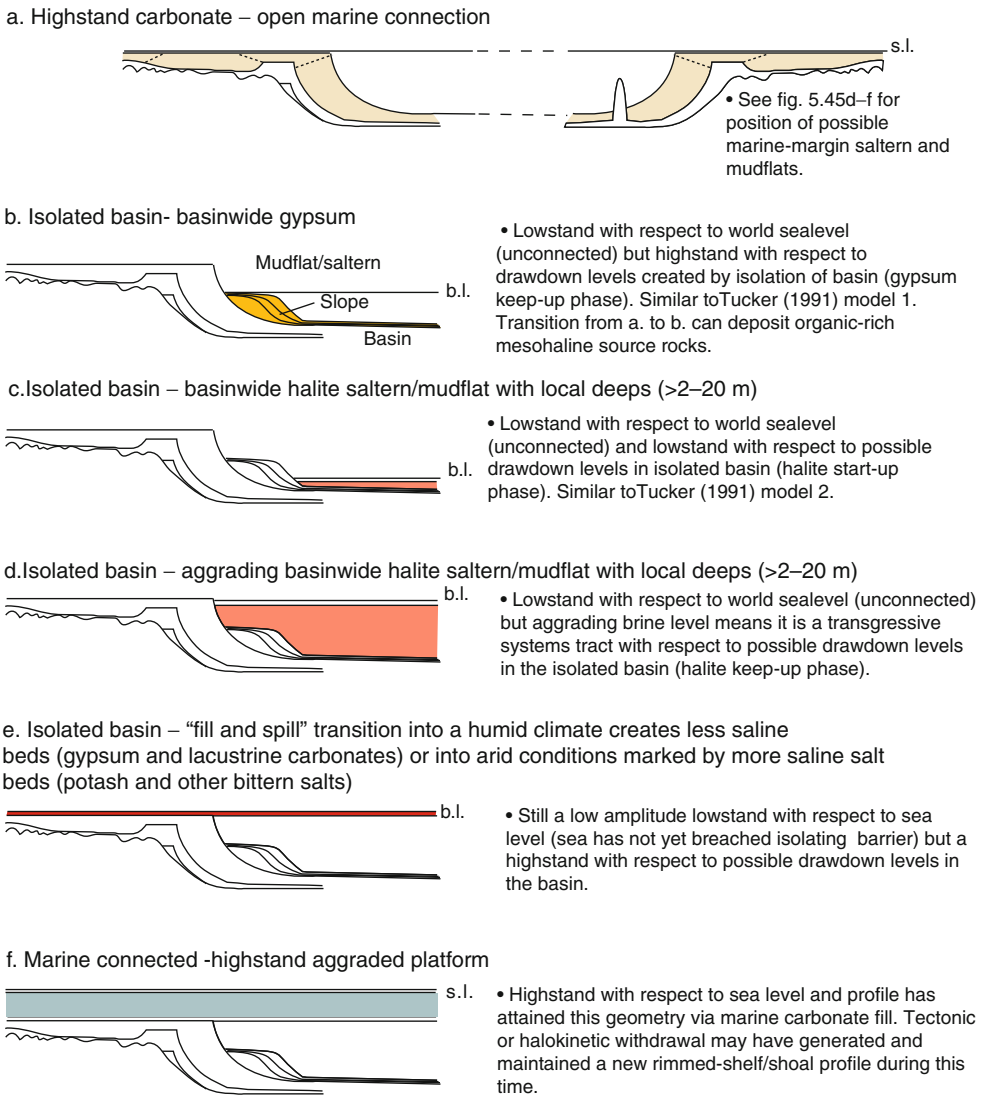

Fig. 5.46 Sequence stratigraphic model for basinwide evaporite deposition in a basin undergoing complete isolation from a surface connection to the world's oceans and subsequent drawdown. See text for detailed discussion of stages **a–f**

Basinwide Evaporites

Thick basin-filling evaporites (more than 500–1,000 m thick and hundreds of kilometres across) accumulated in both greenhouse and icehouse periods. They did so, not because of fluctuations in sealevel, but as a result of tectonic isolation of large parts of the earth's surface from the direct surface influx of the world's ocean waters (hydrographic isolation). Evaporite fills tend to be autocyclic and tectonically induced, although subsequent fluctuations in sealevel may have aided erosional breaching and refilling of the depression by seawater episodes (Table 5.6; Fig. 5.46). Once isolated, changes in sealevel outside the basin rim may change potentiometric head with respect to the free brine surface in the basin and so drive changes in the rate of supply of brine. A relatively high sealevel outside of the basin will create a steeper potentiometric gradient and hence encourage more rapid replenishment of brine and a greater volume of brine seeping through the permeable barriers that separate the brine depression from the open ocean (e.g. Kendall 1992). When relative sealevel is lower, this decreases the potentiometric gradient and slows the rate of brine flow. A fall in sealevel also causes the sea coast to retreat from the isolated depression, which further decreases seawater supply.

But autocyclic mechanisms, including the vagaries of climate, tectonics and adiabatic effects, along with the rate of formation and efficiency of intrabasin brine curtains or hydroseals, all interact to swamp the influence of sealevel changes to the hydrology of the evaporite basin (Chap. 2). For example, the aggradational infill of a tectonic depression by salt beds that create their own underlying aquitard or brine curtain has the same effect as the change in sealevel on potentiometric gradient of the inflow. As the sequence aggrades it decreases the potentiometric gradient and so slows the rate of marine recharge independent of changes in absolute sealevel.

The effect was noted by Warren (1982b) and used to explain the changes in the infill cycle textures in Holocene gypsum-filled salinas in coastal southern Australia. Logan (1987) discusses similar hydrological transitions in controlling vertical sequences and the transition from halite to gypsum with aggradation in Holocene Lake Macleod, Western Australia. Kendall (1989) used such Holocene analogs to interpret the upward transition from anhydrites to carbonates in the Middle Devonian of northern Alberta (Muskeg and Sulphur Point Formations). Previously the transition was interpreted as reflecting a sealevel rise, but Kendall argued it would more likely reflect a transition related to sealevel fall outside of the basin and a decreasing volume of marine inflow into a marine-fed basin with no surface connection to the ocean. His model better explains the terminal nonmarine bed that makes up the overlying Watt Mountain unit.

In summary, unless a rise in sealevel breaches the tectonic sill and converts the basin once more to a restricted mesohaline seaway, decametre-scale sealevel fluctuations outside the isolated evaporite basin exert a relatively minor influence on basinwide hydrology and hence on the detailed stratigraphy of a basinwide evaporite unit. While the basin is isolated much of the fill is autocyclic, it reflects changes in the hydrological base level that have more to do with fluctuations in tectonics and climate as they effect inflow/seepage hydrology. In the larger saline giants, such as the Messinian sequences of the Mediterranean, the Zechstein of NW Europe, and the Late Precambrian-Cambrian Ara Salt in the South Oman Basin, any changes in relative sealevel that occurred outside the drawndown evaporite basin and probably across a barrier that was hundreds of kilometres from the drawndown strandline were largely irrelevant to the style and geometries of evaporite deposition in the basin.

Basinwide Sequence Stratigraphy?

Given our rudimentary understanding of hydrology and isolation in basinwide settings, let us now look at some of the implications in terms of high-resolution stratigraphic analysis in basinwide evaporite deposits. Documented examples are few and far between, and tend to concentrate on patterns in the mesohaline to marine carbonate facies. High-resolution interpretation of any intercalated thick salt beds is more challenging because:

- Outcrop studies of geometries of evaporite units are near useless as most of the evaporite is dissolved well before it approaches the land surface – differential collapse and flow during dissolution means detailed internal relationships and depositional geometries are lost not just at outcrop but also in the shallow subsurface,
- Seismic analysis tied to well data in bedded saline giants is rarely undertaken because very few oil companies wish to characterise the internal stratigraphy of what is an undeniable seal facies,
- Deeply buried thick basinwide salt sequences are routinely subject to flow into diapiric and other structures – this largely destroys the stratigraphic integrity of internal reflectors in halokinetic portions of the basin fill and the onset of this flow can be very early, even synprecipitational (see Chap. 6).

All authors working on basinwide systems (aka basin-centre and saline giants) agree that they are lowstand deposits (Kendall 1988; Strohmenger et al. 1996a, b; Tucker 1991; Warren 1999; Sarg 2001). Kendall (1988) and Warren (1999) attempt to address the principles of sequence stratigraphy in terms of the isolated hydrological framework and the need to precipitate widespread and thick salt sequences. Others consider that basinwides require a reduced connection to the world's oceans, yet others allow intrabasinal marine carbonates to be possible syndepositional sediments with basinwide evaporites. The latter modelling expresses a blissful ignorance of the fundamentals of hydrology and hydrography seen in sediment textures and distributions in all modern evaporite basins.

Tucker (1991) derives two end member models to interpret the evaporite carbonate relationships in saline giants: Model 1, incomplete drawdown with marginal gypsum wedges and basinal laminated gypsum; and Model 2, complete drawdown with halite basin-fills. However, his hydrological constraints are not clearly stated and his hydrological assumption that marginal gypsum wedges typically form in relation to a lowered sealevel without isolation (his Fig. 2) is probably not correct (see Goodall et al. 1992).

Figure 5.46 assimilates some of the concepts of Tucker (1991) as well as the work of Kendall (1988) and my own work. It is a preliminary attempt to place basinwide evaporite geometries and overall basin fills into a sequence stratigraphic context. Unlike Tucker (1991) it is based on the notion that in an isolated basin the drawdown hydrology is largely independent of decametre scale sealevel fluctuations that are going on outside the basin. In my opinion, most of the internal decametre-scale evaporite geometries in a saline giant are autocyclic, while larger scale geometries reflect ongoing interactions between tectonics and climate. Only if and when the basin is connected at the surface to the world's oceans do the geometries of the carbonate units reflect a marine eustatic control and by then basinwide evaporites are not accumulating.

In the time prior to the onset of hydrographic isolation the basin has a surface connection to the world's ocean (Fig. 5.46a). The depositional response at this time is a classic marine carbonate response and the only widespread evaporites that precipitate are typical marine-margin saltern/mudflat evaporites that are intercalated with normal marine platform sediments (see Figs. 5.7a and 5.45 for interpretations of this style). Pinnacle reefs and mud mounds may grow on the shelf foreslope during the marine TST (e.g. right-hand part of Fig. 5.46a). In the basin centre, thin (condensed) pelagic deepwater carbonates and hemipelagic mudrocks will

be deposited, mostly as thin finely-laminated units that pass laterally into slope deposits about the basin edge.

Once sealevel starts to fall below the sill height —either through a eustatic change in sealevel or, more likely, through regional tectonic movement that cuts off the basin from a surface connection with the world's oceans— evaporative drawdown will quickly lower the brine level in the evaporite basin to where it is well below the old carbonate shelf break (Fig. 5.46b). Under an arid climate, water within the now isolated basin will rapidly become hypersaline. Seawater, along with formation, continental, and hydrothermal waters, now seeps into the depression. It enters through permeable, now subaerially exposed, formerly deepwater carbonate slopes and former pinnacle reefs (Fig. 5.46). These outflow zones generate spring and tufa deposits with characteristic textures such as pisolites, tepees, tufas and stromatolites. In the relatively-deep subaqueous basin centre, organic-rich mesohaline carbonate laminites typically mark the onset of basin isolation and continue to form until the basin is hydrographically isolated and equilibrium is reached.

If hydrological equilibrium is reached at gypsum saturation then gypsum has the potential to accumulate across the whole basin. When the water column is meromictic coarsely crystalline zigzag or laminated gypsum dominates the "chemical factory" of the shallow basin edge, while detrital and pelagic laminites accumulate in the basin centre, and possibly inclusion-free crystal clusters as well (Fig. 5.46b). If the basin does not subside greatly as it becomes isolated, the level of this new gypsum wedge (platform) will first form atop old slope carbonates and below the old carbonate shelf break. With respect to sealevel outside the isolated basin this is a lowstand deposit associated with the creation of a karstic type 1 sequence boundary on the old carbonate shelf prism in areas about the basin edge not covered by brine. But, with respect to the subsequent drawdown hydrology of the basin, it is a highstand system tract.

Resedimentation of the saltern/mudflat sediments of the gypsum wedge into deeper density-stratified waters by storms, slope failures, debris flows and turbidity currents will deposit graded beds, slumps and breccias as gypsum slope deposits and fine-grained "rain-from-heaven" gypsum laminites in the basin centre. At times when the brine column is holomictic, coarse-crystalline inclusion-free gypsum can perhaps accumulate across the deeper basin floor (there are no Holocene analogs for deepwater gypsum, but there are for halite and mirabilite).

If this situation of gypsum saturation is hydrologically stable, that is hydrological inflow balances outflow at gypsum-precipitating salinities, and the situation is maintained for time frames $\approx 10^5$ years or more, the whole basin evaporite fill may be composed of gypsum. Such was the case during precipitation of large portions of the Permian Castile Formation of Texas (Chap. 1). Metre-scale sedimentary cycles (parasequences) will be developed within the prograding gypsum wedge reflecting higher-frequency low-amplitude autocyclic brine-level changes within the basin (5th/6th-order $-10^4/10^3$ year cycles).

If hydrological equilibrium is still not maintained in the basin, and brine losses continue to exceed inflows, the brine level will continue to be drawn down and the salinity of the residual brine will increase. Saltern gypsum will begin to precipitate in the basin centre if the brine depth drops below 10–30 m. If a hydrological balance is still not reached and the brine level continues to fall, the brine body next reaches halite saturation (Fig. 5.46c). Based on most Holocene analogs (except the current Dead Sea) water depths at the onset of halite deposition are less than a few tens-of-metres to metres and saltern or pan halite will be deposited across the whole basin floor. If the waters are density stratified then locally there may be deeper-water depressions on the basin floor that fill with fine-grained laminated "salt-and-pepper-textured" deepwater halite cumulates lacking any evidence of subaerial exposure (if Lake Macleod and the artificial halite pans of the southern Dead Sea Basin are used as textural analogs, this requires brine depths of 2 m or more; Warren 1991). If the brine column is holomictic, then beds of coarsely-crystalline randomly-oriented inclusion-free halite meshworks will accumulate, rather than fine-grained halite or gypsum cumulates. This stage of the sedimentation is still a lowstand with respect to sealevel outside the basin, and is now a lowstand systems tract with respect to the basin hydrology and earlier evaporite platform wedges.

Once thick pan halite units begin to accumulate across the basin floor, the degree of permeability loss in salts below the precipitation surface increases drastically, reflecting a near complete loss of porosity in metre-decametre thick halite beds. The brine curtain and its cement aquitard can now support a permanent halite-saturated brine body. This can maintain a near permanent position atop the primary crystallisation surface with only occasional episodes of complete desiccation or flood-induced surface freshening. Thus the halite body begins to aggrade as a series of subaqueous metre-thick autocyclic parasequences, with each metres-thick cycle deposited in time frames of 10^2–10^3 years. The maintenance of this aggrading hydrology allows the basin to fill with predominantly saltern halite (Fig. 5.46d).

With respect to sealevel outside the isolated basin it is still a lowstand system, but in terms of the intrabasin geometries it is a transgressive systems tract. But it is a transgressive systems tract that has no parallel in the marine realm. It is an autocyclic transgression that aggrades as it maintains and grows its own near impervious base soaked in a saturated brine curtain that is maintained by slowly refluxing brines. There is no suitable eustatic term in the classic sequence stratigraphic literature to describe this, as there is no concept of autocyclic transgression where the sedimentation surface creates the stabilising hydrology that in turn facilitates the rise of the sedimentation surface. Tucker (1991) terms this

unit the lowstand basin-fill-halite; I am more comfortable calling it an intrabasinal transgressive systems tract halite.

As the halite fill continues to aggrade it climbs over the old gypsum wedge and, if the basin is subsiding but still isolated, it can also climb over the old gypsum and then the carbonate shelf margin (Fig. 5.46e). As the fill tops an older platform margin it reaches a vast flat karst-etched plain. Before being retained the permanent basin waters must now spread over a much wider area of an older platform top. I call this the "fill and spill" stage of the basin's sedimentation and hydrology. It is still a lowstand systems tract with respect to external sealevel and the marine groundwater feed, but a transgressive systems tract with respect to intrabasin geometries. It is typically a mudflat system, although salterns may still occur. The fill and spill point horizon is often marked by a change in mineralogy, which indicates a change in depositional hydrology.

In a semi-arid system this spill point is often defined by beds of less saline evaporite minerals such as gypsum or lacustrine carbonates. Rainfall and meteoric influx are an increasingly important part of the ponded surface water volume as they spread outside the former less aerially extensive depression. In contrast, if fill and spill occurs in a very arid setting, the effect of meteoric freshening is minimal and as the piezometric head is less than at the onset of evaporite deposition in the drawndown basin. Surface brines are less diluted and the hydrology may pass into bittern saturation so that syndepositional bittern or potash salts are possible precipitates. A hydrological transition to "fill and spill" under a hyperarid scenario explains why the potash cycles in the Salado Formation of the Delaware Basin are largely confined to regions in the vicinity of the old carbonate platform margin (Chap. 11).

Once again the transition is autocyclic and dependent on climate/hydrology within the basin. The system is still a lowstand with respect to sealevel outside the basin. In terms of the intrabasin geometry it is a transgressive systems tract either atop the older HST gypsum wedge or atop the former HST of the older carbonate margin. Tucker (1991) also recognises this TST (his early TST gypsum or TST retrogradational sabkha evaporite lagoons), but he only allows for a $CaSO_4$ mineralogy and he relates it to a surface reconnection with the world's oceans. Unlike Tucker (1991), I feel that this widespread thin unit is deposited subsealevel in a still isolated basin where surface reconnection to the ocean has yet to occur. I also emphasise that this TST is not always gypsum/anhydrite, it can be composed of a multiplicity of mineralogies depending on the degree of climatic restriction in the basin. Kendall (1992; his Fig. 40) also recognises this stage, but he relates the mineralogical transition to less saline minerals to a transgression beyond a hydroseal or basal aquitard, that allows greater volumes of brine to be lost from the system, and so average salinities in the surface brines are lowered. This is a valid concept, but it is not complete as it does not explain why some basins are actually precipitating more hypersaline minerals and bittern salts in the upper parts of the halite basin fill.

Once the basin is reconnected to the open ocean, the formerly exposed carbonate platforms are reflooded and a carbonate TST re-established. In this scenario any subsequent platform evaporite deposits can be considered equivalent to the marine marginal platform evaporites discussed in the preceding section and their internal geometries behind the isolating platform rim or shoal may well once again reflect eustatic controls (Fig. 5.46f). Because the aggraded evaporite surface is a flat plain at the time of marine reflooding, the onset of marine carbonate deposition is typically characterised by ramp deposits. If the carbonate biota also contains appropriate binders and reef formers the profile quickly evolves into a rimmed carbonate shelf. The transition to a rimmed shelf in many ancient basins undergoing regional extension is typically focused by halokinetically induced shallowing of the seafloor driven by flow of the thick underlying halite (Chap. 6).

Basinwide Examples

Four of the better documented areas where high resolution sequence analysis has been attempted on bedded basinwide evaporites are; (1) Gypsum-halite evaporites of Messinian age in the marginal and central basins of the Mediterranean, (2) the basinwide anhydrite-halite evaporites of Permian Zechstein Series in NW Europe, (3) the halite-dominated salt beds of the Silurian Salina Group salt of the Michigan Basin, and (4) the highly halokinetic terrain of the Jurassic Louann Salt in the Gulf of Mexico. We shall start the discussion with the Mediterranean salts as it is a saline giant where much of the $CaSO_4$ is still present as gypsum that retains depositional textures and much of the basin centre halite away from tectonic suture zones is still largely flat bedded. Then we shall discuss Permian and Silurian examples, where the gypsum has altered to anhydrite and in the Zechstein a substantial portion of the halite is halokinetic. In the fourth case example, the Jurassic Louann Salt in the Gulf of Mexico, almost all of the salt has flowed into salt structures with varying internal complexity. We shall look at these structures in the Gulf of Mexico in much more detail in Chaps. 6 and 10. In the current chapter we shall discuss the depositional setting for the Louann Salt in the context of its rift setting and likely stratigraphy. In all cases the interpretations of depositional setting in terms of water depths, and associated correlations between halite, $CaSO_4$ and carbonate beds, are still actively debated.

Messinian Evaporites of the Mediterranean

There are two styles of marine-fed evaporite occurrence in the icehouse world of Messinian evaporite deposition in the Mediterranean. One is characterised by high level, margin-

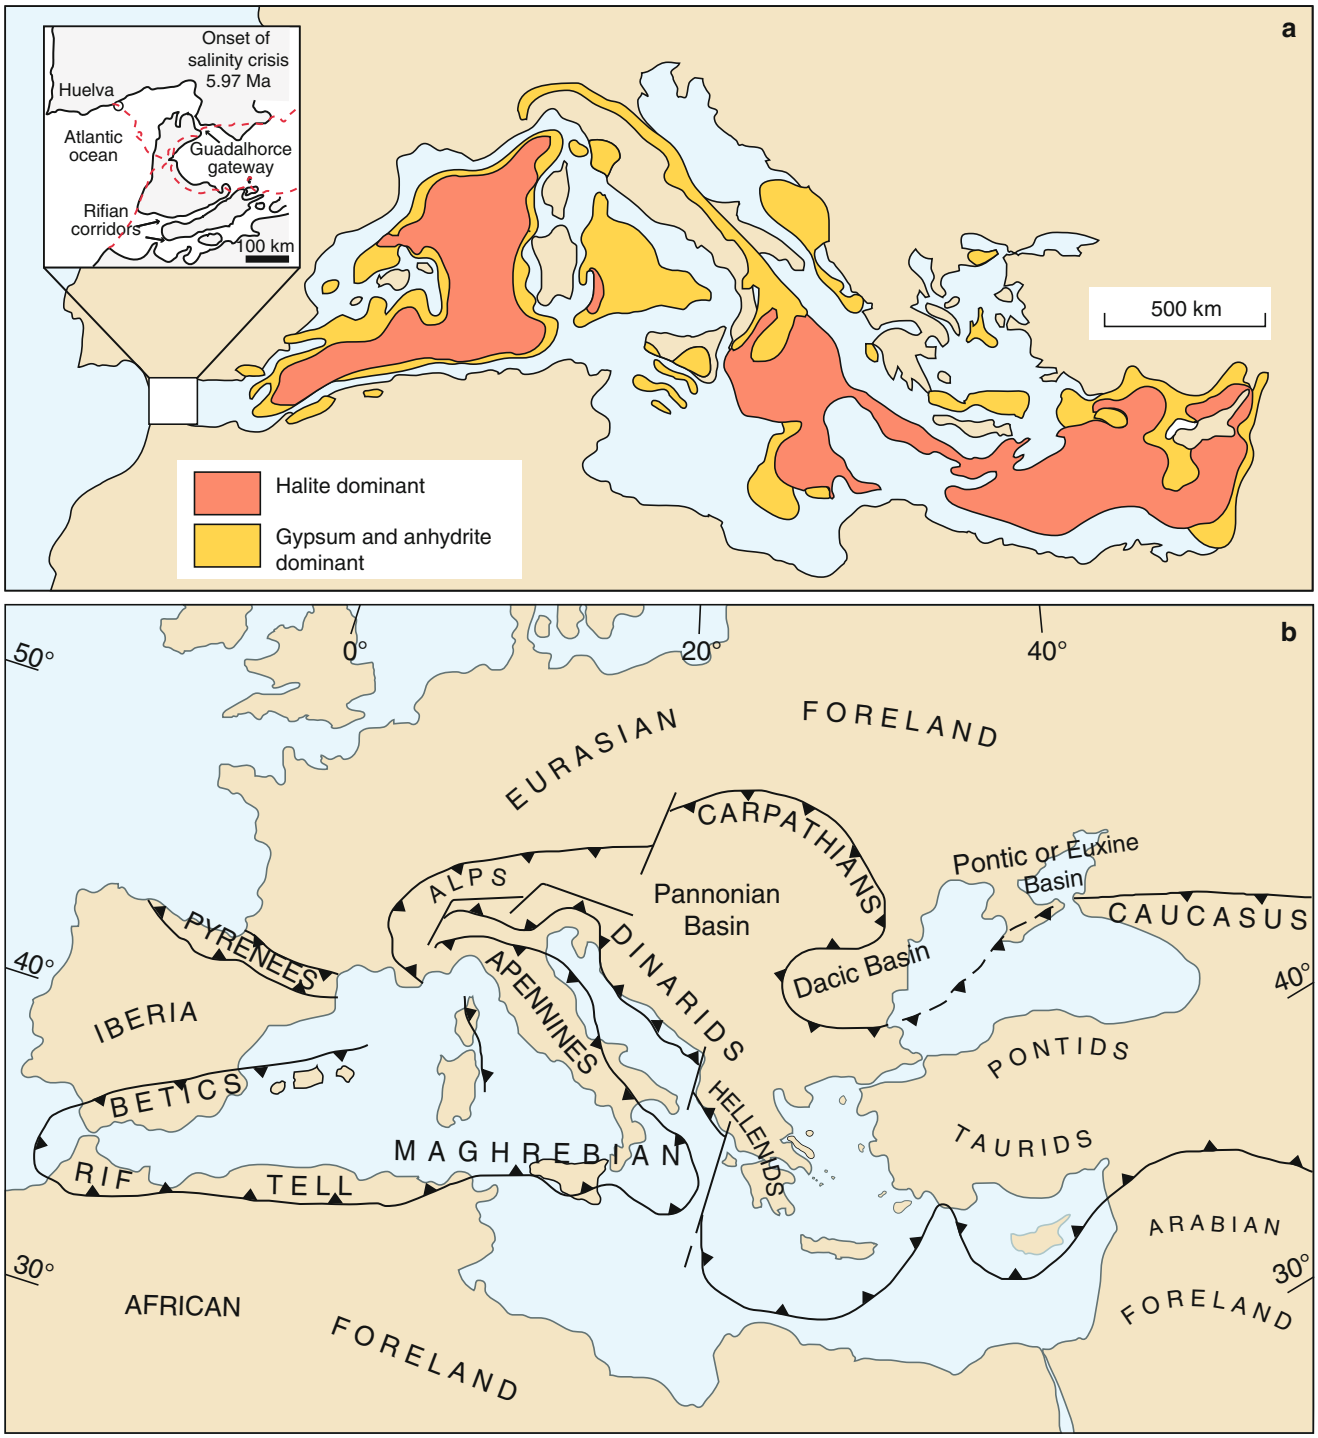

Fig. 5.47 Messinian evaporites and tectonic setting. (**a**) Distribution of basinwide Messinian evaporites, both onshore and offshore. *Inset* shows region of the Gibraltar Straits at the onset of the Messinian salinity crisis from Pérez-Asensio et al. 2013 (*red dashed line* shows approximate position of present-day coastline. (**b**) Tectonic (Alpine) – foreland basin associations in the Mediterranean region

ward circum-Mediterranean deposits, the other by a number of much larger, thicker, basin-centre deposits, which now lie below more than 2,000 m of water and hundreds of metres of Plio-Pleistocene overburden in the deeper parts of the Mediterranean Sea (Hsu et al. 1973). There are excellent onshore exposures in the marginal Messinian basins in Sicily, Spain and Cyprus (Fig. 5.47a). In contrast, in the various sub-basins in the deeper parts of the Mediterranean Sea, where seismic lines show thick sequences of salts were deposited during times of maximum drawdown, there has been little core sampling and so there is little reliable facies interpretation based on rock samples. There is an

increasing amount of high quality offshore seismic now coming into the public realm, especially in the eastern Mediterranean, driven by gas discoveries in the region off the Israeli coast and southwest of Cyprus. What is clear in the distribution of Messinian evaporites across the Mediterranean is the significance of the various suture and thrust belts, both during deposition and in subsequent reworking (compare Fig. 5.47a, b).

DSDP (Deep Sea Drilling Project) wells in the Mediterranean that did manage to recover core in evaporites sampled a possible combination of salt pan halite and sabkha anhydrite, implying the salts accumulated on a basin bottom that was covered with brine lakes, which at times dried up sufficiently to accumulate pan halite (Hsu et al. 1973). For 30 years the notion of pan and sabkha deposition dominated interpretations of basin centre evaporites. While not questioning the hydrographic isolation of the Mediterranean during the Messinian salinity Crisis (MSC), Hardie and Lowenstein (2004) have questioned the notion of basin desiccation and saline pan deposition. Rather, they argue for a sub-wavebase subaqueous origin to much of the evaporite recovered in the DSDP cores. That is, the Mediterranean Basin salt fill contains an as yet unknown, but perhaps substantial, proportion of deeper water halite. Likewise, Krijgsman and Meijer (2008) argue for a deep water setting for the basin centre deposits. They also infer an ongoing surface connection to the world's oceans as these evaporites were deposited.

In the last decade, the interpretation that has come to dominate is that gypsum deposited during initial basin drawdown, prior to the salinity maximum that deposited widespread halite, was laid down in deeper water (Briand 2008). In some regions these gypsum deposits moved downslope via active slumping and gravitational reworking. Undeniable evidence for Mediterranean isolation and widespread water-level drawdown of at least a kilometre comes from seismic and the presence of the "M" reflector. It indicates subaerial exposure about much of the Mediterranean margin and slope during the peak of the Messinian Salinity (Ryan et al. 1970; Montadert et al. 1970).

Basinwide drawdown also deepened the thalwegs of many major rivers draining into the various Late Miocene Mediterranean sumps. Wells in the Nile Delta at the eastern end of the Mediterranean, which are more than 300 m (1,000 ft) deep and enter Messinian strata, do not reach the bottom of Nile canyon (Aal et al. 2000). Said (1993) shows the Messinian incision of the Nile thalweg reached a depth of 170 m at Aswan, 800 m at Assuit and more than 2,500 m immediately north of Cairo. Similar deep Late Miocene channels occur at the western end of the Mediterranean in Libya and Algeria, and the eastern end in offshore Israel and Syria (Griffin 2002). Likewise, the thalweg of the northern end of the Rhone River gorge was cut deeply into its granite basement in the Late Miocene and is now filled with marine sediments.

For the same reason, some of the deepest karst in the world formed in Yugoslavian (Montenegran) and Ukrainian carbonate hosts during this time of maximum drawdown, with a number of caves now more than 900 m deep. The deepest of these Messinian-drawdown induced caves is the Krubera-Vornja cave in the Ukraine, which is now documented to descend for more than 2,191 m below the current landsurface, and well below the current hydrographic level of the Black Sea (Macnamara and Furnell 2009). This is also the deepest cave currently known in the world. Its depth and steeply descending cavern pattern are clearly responses to the drastic hydrological drawdown induced by the MSC (Klimchouk et al. 2008).

Assuming a surface marine connection to the Atlantic immediately prior to the time of evaporite precipitation, Krijgsman et al. (1999, 2002) and De Lange and Krijgsman (2010) argue that the onset of drawdown marking the beginning of the MSC was synchronous over the entire Mediterranean basin, at 5.96 ± 0.02 Ma (Fig. 5.48a). Basin centre drawdown was established between 5.59 and 5.33 Ma, associated with a large fall in Mediterranean water level, followed by circum-Mediterranean erosion (M-marker) and basinwide evaporite deposition 5.59–5.50 Ma. This was followed by deposition (5.50–5.33 Ma) of nonmarine sediments in a large 'Lago-Mare' (Lake Sea) basin immediately prior to surface reconnection with the world's ocean with a complete reconnection in the early Pliocene (Bache et al. 2012; Salé et al. 2012).

Once hydrographically isolated, the cyclic evaporite deposition in the various Messinian marginal basins can be almost entirely related to circum-Mediterranean climate changes driven by obliquity-induced glacio-eustatic sealevel changes. Govers et al. (2009) argue in favour of a dominantly tectonic/isostatic origin and evolution the MSC, although its exact timing of some of its parasequence boundaries may well have been controlled by the ≈40-kyr component of the Earth's eccentricity.

It is now clear that the stratigraphy in marginal basins of the Mediterranean Ridges, Sicily, and other Messinian basins, such as Crete and Cyprus, are defined by mineralogies that evolved separately in a series of rising "piggy-back" highs and foreland basins, created during thrusting-related uplift, which were active in the Messinian and continues today in some areas (Figs. 5.47b and 5.49; Westbrook and Reston 2002; Calon et al. 2005; Roveri et al. 2008). In some marginal basins, as in Spain, changes in the level of drawdown were related to syndepositional transcurrent faulting and rifting altering the degree of connection to the adjacent seaway. It is this association of marginal basins on the highs and basin centre deposits in the lows that typify evaporite distribution in the Mediterranean (Fig. 5.49).

Much of the tectonic drive creating the evaporite fill in the various marginal basins, prior to the main drawdown, was a result of the collision of Africa with Eurasia, which ultimately drove the closure of the surface connection to the

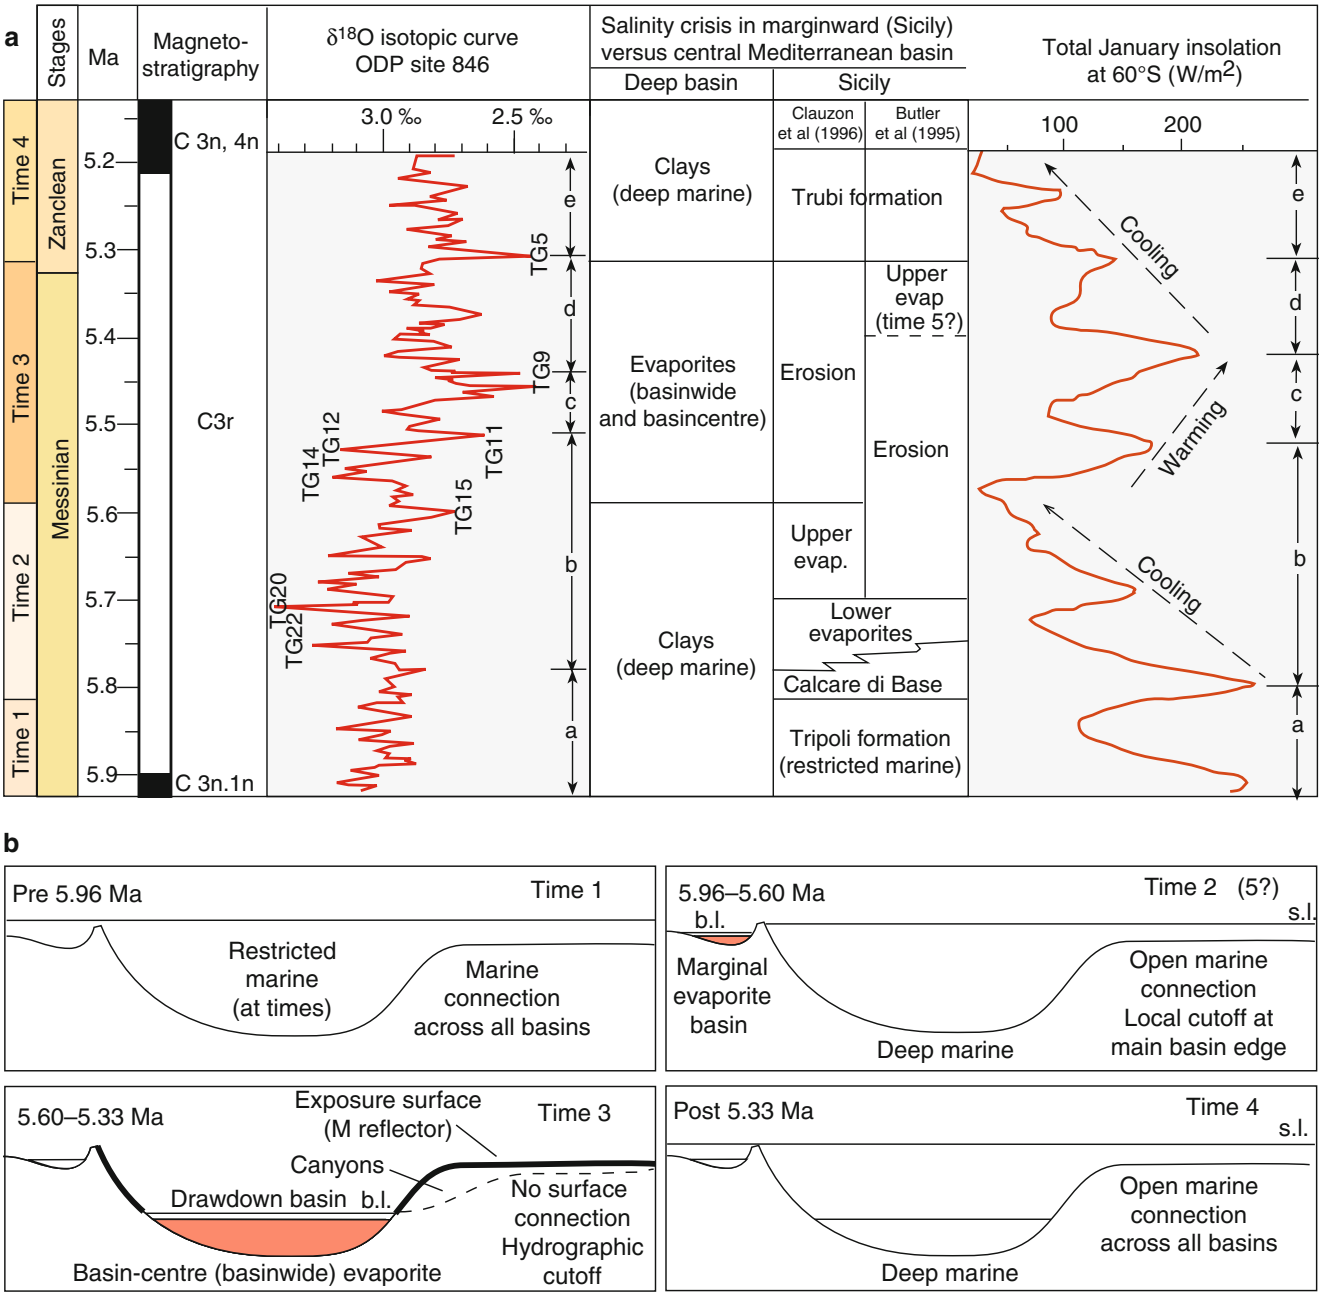

Fig. 5.48 Messinian salinity crisis in the Mediterranean. (**a**) Plot of $\delta^{18}O$ of equatorial Pacific tied to magnetostratigraphy, Messinian stratigraphy and modeled January insolation for that time frame (Modified after Clauzon et al. (1996) and Butler et al. (1995)). Note the difference in interpretation of the upper evaporite in Sicily compared with Fig. 5.60; Briand 2008. (**b**) Schematic times sequence showing mode of formation of marginal and basinwide evaporites in the Mediterranean. Note that the interpretation of Butler et al. (1995) requires a time 5 when the upper evaporites were deposit after the main drawdown

Atlantic and ultimately caused the whole Late Miocene Mediterranean deep basin floor to become a series of isolated and evaporitic marine-fed salterns (Fig. 5.47b; Govers et al. 2009). According to Clauzon et al. (1996) the first major evaporite-depositing episode (5.75–5.60 Ma) took place during a cooling period associated with a weak global sealevel fall that isolated numerous tectonically induced circum-Mediterranean marginal basins in Spain, Libya, Morocco, the Apennines, Sicily, and Cyprus. Isolation of these marginal basins occurred while the adjacent Mediterranean Sea still, at least at times, retained a direct surface connection with the Atlantic (Time 2; Fig. 5.48b). Even so, the evaporite and underlying stratigraphy of Cyprus suggest restriction and isolation of the Mediterranean Sea prior to the MSC was not a single event (Orszag-Sperber et al. 2009). Stratigraphic sections on Cyprus below the Messinian gypsum show a

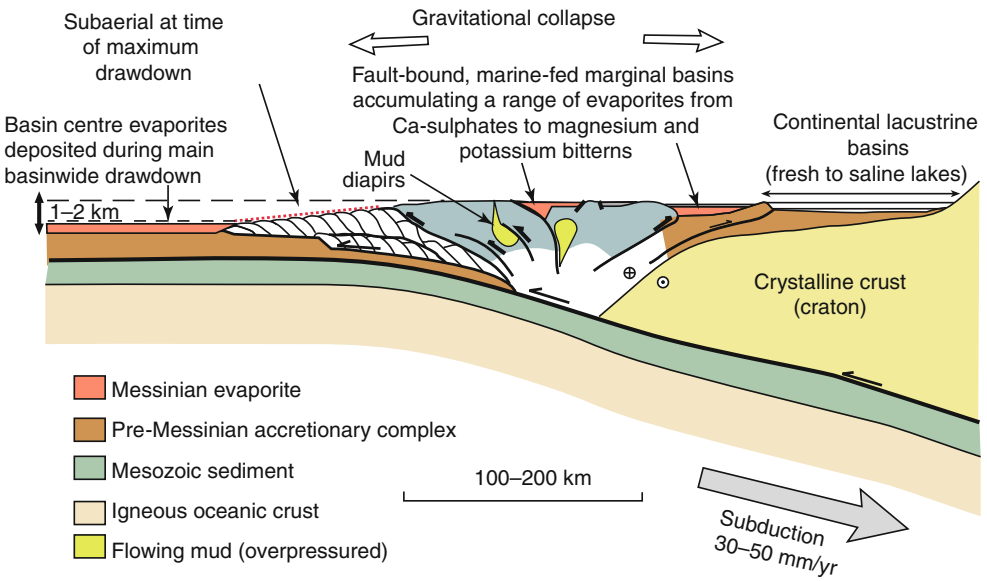

Fig. 5.49 Schematic shows tectonism related distribution of continental, marine margin and basin centre lacustrine evaporites around the time of closure of the Mediterranean basin and the Late Miocene salinity crisis. Schematic is constructed based on geology of the Mediterranean Ridges, Sicily and the Italian Peninsula (In part after Westbrook and Reston 2002)

general evolution of the depositional environment from marine to restricted conditions was emphasized by dates at 7.16, 6.7, and 6.1 Ma. If so, isolation was preceded by a progression of associated events spread over 1 million years.

The notion that restriction and perhaps even the formation of a land bridge between Spain and North Africa occurred sometime prior to the MSC is supported by Late Miocene mammalian biogeography (Gibert et al. 2013). African mammals migrated to Iberia and European mammals migrated to North Africa at the same time and before isolation of the Mediterranean Sea during the Messinian. This two-way African-Iberian mammal dispersal occurred just before 6.2 Ma showing that an ephemeral land corridor existed between the two continents some 250 k.y. before the onset of the MSC at 5.9 Ma, reflecting a tentative initial hydrographic isolation of the Mediterranean Sea from the Atlantic. This land corridor developed after tectonics closed the Betic Seaway at 6.3 Ma and perhaps during the intensification of the latest Miocene glaciation at 6.26 Ma, when water circulation in the Mediterranean became very restricted (Gibert et al. 2013).

When continent-continent collision hydrographically isolated the whole Mediterranean, basinwide or basin-centre evaporites were deposited in a series of giant evaporite subbasins (hundreds to thousands of kilometres across) in regions now located beneath the present deep Mediterranean floor (Time 3; Fig. 5.48b; 5.60–5.33 Ma?). Away from marginal basins and tectonic ridge-associated halokinesis, none of these sump areas outcrop on the Mediterranean seafloor, and only their uppermost portions were sampled by the wells in the DSDP programme (Hsü et al. 1970). At the time halite accumulated in the central sumps there was a huge drop of some 1,500–2,000 m in Mediterranean water level. The various basin-centre sumps were completely isolated from any surface connection with adjacent Atlantic or Tethyan remnants. At the time of the complete isolation of the Mediterranean Basin there was a worldwide warming trend and a likely global sealevel high, but tectonic isolation negated the effects of eustasy within the Mediterranean.

The evaporite phase of many marginal basins in Spain and Italy was typically preceded by cyclic Late Miocene carbonate ramp or reef cycles; which are readily interpreted using the principles of high-resolution carbonate sequence stratigraphy (e.g. in Spain and Italy- Martin et al. 1996; Esteban 1996: in Morocco- Benson et al. 1997; Cunningham et al. 1997). Postreef growth, the typical response of the marginward basins to isolation and the onset of basin drawdown was the accumulation of an evaporitic carbonate rim (aragonite/dolomite) about a drawndown bedded-gypsum saltern, with marine-fed bitterns accumulating in the most isolated portions of these subsealevel depressions. Such a situation outcrops today as the Calcare di Base rim facies circumscribing the bedded salts of the dominantly gypsum saltern fill in the Sicilian Basin. There Calcare Di Base sections more than 50–60 m thick typify the pre-gypsum fill (Fig. 5.50a).

Sorbas and Fortuna basins, Spain: There is still a degree of chrono-stratigraphic confusion in relating the evaporite fills of many of the marginward basins of Spain to the main Mediterranean drawdown event. There is also the problem that some of the Spanish evaporite basins evolved from a continental to a marine feed to their saline hydrologies The Sorbas Basin, Spain, is a good illustration of the chronostratigraphic problem while the Fortuna Basin illustrates an evolution in its saline hydrology from nonmarine to marine.

Depending on the author, the main saltern unit (Yesares gypsum) is considered to be time equivalent to the Lower Evaporite unit of the main Mediterranean drawdown event, or it postdates it or predates it (Fig. 5.50a). The key to where it is positioned in the stratigraphy relates to where the equivalent to the main erosion surface (M-equivalent) is placed. Riding et al. (1999), place a regional erosion surface and

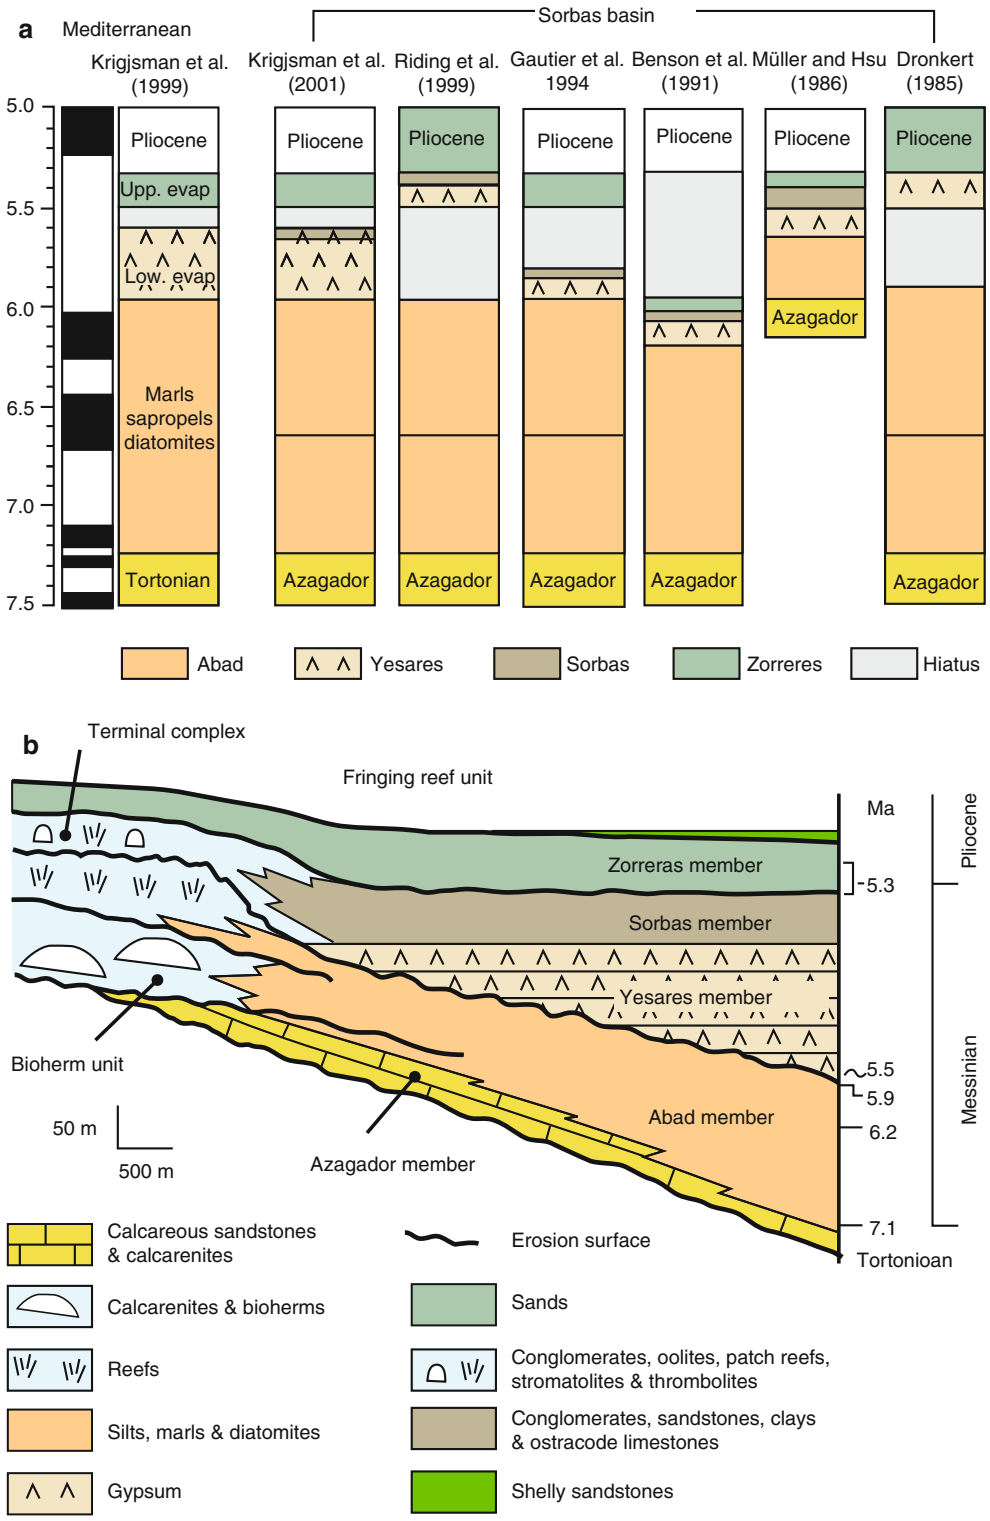

Fig. 5.50 Messinian lithofacies, Sorbas Basin, Spain. (**a**) Overview of different chronostratigraphic models for the marginal Sorbas basin showing the large controversies in timing and duration of the various stratigraphic members in relation to the recently established Messinian Mediterranean astrochronology (Krijgsman et al. 2001). The models of Dronkert (1985) and Riding et al. (1998) are based on a correlation of the Yesares Member to the 'Upper Evaporites' of the Mediterranean. The models of Müller and Hsü (1987) and Gautier et al. (1994) are plotted along with the timing by various cited authors of Yesares Member to the 'Lower Evaporites' and the Zorreras to the 'Upper Evaporites'. (**b**) The Messinian–Pliocene succession in the Sorbas Basin. According to Riding et al. (1998) the "Salinity Crisis" sealevel fall occurred within the interval 5.9–5.5 Ma, and the resulting drawdown-driven erosion surface is below the Yesares Gypsum Member, and atop the Fringing Reef Unit. Note the marginal onlap of the Sorbas–Terminal Complex

unconformity (300,000 years exposure) at the base of the Yesares Formation, making the Yesares equivalent to the Upper Evaporite, while Krijgsman et al. (2001), argue any discontinuities at the base of this unit are not regional but reflect no more than local slumping. The debate continues and is yet to be resolved. Resolution will require application of evaporite textures as indicators of watertable, brine depth and brine stability indicators, as has been done for the Italian basins (Roveri et al. 2003; Dela Pierre et al. 2011).

The Sorbas Basin is one of a number of marginward basins formed in a complex system of transcurrent faults, with both transpressive and transtensional characteristics. Tectonics controlled depositional geometries in the evaporite fill of the marginal basins of the Betic Cordillera of SE Spain, not sea-

level changes outside the hydrographically isolated depression (Fig. 5.53a; Playa et al. 2000; Michalzik 1996). The Spanish Messinian basins are seepage basins and there is no evidence for any cataract-like connection of any of these basins before, during or after the formation of Messinian evaporites.

The most frequently occurring gypsum lithofacies in all the Spanish basins indicate shallow-water depositional environments and textures include: crystalline selenitic gypsum ('grasslike gypsum'), laminated gypsum and crossbedded gypsarenite. Sabkha-type chickenwire alabastrine gypsum is rare in the Spanish sea marginal basins (Michalzik 1996). Evenly-laminated gypsum units interbedded with graded gypsarenites (turbidites), gypsrudites (debrites) and slumps also occur in basins or parts of basins with considerable palaeoslopes. Evidence for early diagenetic overprinting includes the formation of giant gypsum twin crystals, 'super cones' and alabastrine nodular gypsum. The accumulation of Messinian evaporites in SE Spain was likely instigated by a third-order sealevel lowstand that isolated these marginal tectonic basins from the Mediterranean Sea. But all the smaller-scale evaporite units (parasequences) in the various marginal basins, at the scale of shoaling decametre-cycles, are fourth- to sixth-order cyclic and rhythmic responses. They are clearly related to basin dynamics or to autogenetic processes of the local facies (facies dynamics). None are related to high-frequency marine eustasy (Michalzik 1996).

Inland from the marine fed sea-marginal Messinian basins of Spain are large saline lacustrine basins fed both by seawater seeps and continental waters from the Pyrenees with a substantial solute component coming from the dissolution of Triassic sulphate salts. The saline fills of these largely continental depressions started earlier in the Miocene than the sea-marginal marine-fed depressions (Tortonian versus Messinian) with both their surface and groundwater feeds showing a more continental provenance (Fig. 5.51a). For example, Playa et al. (2000) differentiated a number of continental-influenced evaporite units in the inner basins of the Murcia-Alicante region. The more continental saltern gypsum lithofacies have the following characteristics (Fig. 5.51b): (1) Variable strontium contents, with mean values (primary gypsum) between 1,121 and 2,380 ppm; (2) Isotopic compositions of sulphur ($\delta^{34}S$) ranging from those characteristic of the Tertiary marine water (+20.3 to +25.5‰) to those characteristic of the Triassic sulphates (+8.0 to +16.0‰), the latter suggesting recycling of the sulphate anion in meteoric waters; intermediate values (+17.4 to +19.6‰) are attributed to mixed mother brines; and, (3) Strontium ratios ($^{87}Sr/^{86}Sr$) between 0.70804 and 0.70888; these values range from those of the Tertiary marine water to those exceeding the Triassic sulphates, suggesting additional continental contributions (from both dissolving country rocks and hydrothermal solutions). The comparison between the sulphur and strontium isotopic compositions of the sulphates, together with the study of the biota present in the marls associated with the gypsum, distinguishes marine, continental, and mixed units (Playa et al. 2000).

In the marine-fed sea marginal basins of the Eastern Betics, where single evaporite units characterized by selenitic gypsum prevail: (1) the strontium contents are more homogeneous, with mean values (primary gypsum) between 493 and 625 ppm; (2) the isotopic compositions of oxygen ($\delta^{18}O$) and sulphur ($\delta^{34}S$) between +12.2 and +14.8‰, and between +22.0 and +23.5‰, respectively; and (3) the strontium ratios ($^{87}Sr/^{86}Sr$) varying from 0.70890 to 0.70895. The clear separation between properties of the two gypsum-entraining foreland depressions (Fortuna Basin versus San Miguel de salinas Basin) illustrate that, although gypsum deposition occurred in two side-by-side basins, some units on the continental side started to accumulate bedded gypsum earlier than the Messinian and with isotope signatures that reflect a mixed continental-marine parentage (Fig. 5.51c).

The Apennines: Complicating the resolution of any marine eustatic history for evaporite cycles in MSC sediments is ongoing penecontemporaneous tectonism and gravity in moving large blocks and detrital volumes of shallow water evaporites into deeper water settings. Such olistoliths and turbidites characterise many continent-to-continent collision belts and such a gravity slump system controlled the distribution of Messinian sediments about the Riolo anticline in the Italian Apennines and the Lower Evaporites of Sicily (Roveri et al. 2003; Manzi et al. 2005, 2011).

Lateral and vertical facies changes within the underlying deepmarine turbidites of the Marnoso-Arenacea Formation show Messinian evaporite precipitation occurred in a thrust-top basin (Vena del Gesso basin), bound to the north and to the east by the thrust-related Riolo anticline, which had been actively growing since the late Tortonian (Fig. 5.52a). Both gypsum deposition and its subsequent deformation were strongly controlled by evolving palaeobathymetry driven by gravity/thrust tectonics.

Primary growth-aligned gypsum, which outcrops in the Apennines, originally accumulated in a shallow, silled marginal basin (Vena del Gesso basin) that lay to the east of the growing Riolo anticline, while organic-rich shales were deposited in the adjacent deeper and larger foredeep basin to the west (Fig. 5.52b, c). These gypsum deposits underwent severe postdepositional deformation related to large-scale gravitational collapse, tied to regional uplift events. Deformation was also coincident with the end of the evaporitic phase in the marginal thrust-top basin. Along the inner, shallower-dipping limb of the anticline bounding the basin, large-scale, weakly deformed gypsum slabs slid downslope along a detachment surface developed at the contact with the underlying euxinic shales, forming both extensional and compressional features and showing an overall southwestern vergence (Fig. 5.52d).

The identification of a south-southwest–dipping palaeoslope by Roveri et al. (2003) suggested that the initial deformational features affecting the gypsum unit were likely driven by gravity perhaps tied to highs atop active thrust planes (Fig. 5.52). The steeper frontal limb of the anticline

Marine-fed gypsum in the sea-marginal basins shows a much tighter clustering of values reflecting its near isochemical seawater parent. Plot on the *right* shows primary gypsum samples. *Group I*: selenites (aligned coarsely crystalline gypsum of the sea-marginal basins. *Groups II and III*: gypsum lithofacies of the inner more continental basins. The areal distribution of the Messinian marine sulphates from the Mediterranean region is shown shaded in grey. (**c**) Schematic showing the distribution of Neogene evaporite sediments from more continental basins in the west (inner basins such as the Fortuna basin) to the east (sea-marginal basins such as the San Miguel de Salinas basin) in the easternmost part of the Betics (Murcia–Alicante region)

promoted the transformation of gypsum slides into debris flows and turbidite currents that deposited their load in the adjacent deeper basin to the west. This gravitational deformation was sealed by postevaporitic upper Messinian Lago-Mare deposits.

The sedimentary history of the Vena del Gesso basin, as documented by Roveri et al. (2003) and Manzi et al. (2005), suggests that the MSC in the Apennine foredeep was tightly linked to a combination of intra and extrabasinal tectonic processes, not worldwide eustasy. This is now thought to be also true in the Balearic, Tyrrhenian, Sicilian, and Eastern Mediterranean Basins.

By using the Moncucco gypsum quarry in the Torino Hill – Monferrato outcrops of the Tertiary Piedmont Basin, some 50 km to the west of the Apennines, Dela Pierre et al. 2007 further defined Messinian depositional detail. They document the inherent tectonically-driven complexity which overprinted the Messinian stratigraphy prior to Lago Mare deposition (Fig. 5.53). The geology includes episodes of mud diapirism (overpressure) that in part overprints the fragmented Messinian evaporitic section. This section was deformed prior to the deposition of the Lago Mare sediments. Three chaotic units are exposed in the quarry: together, they make up a composite chaotic unit that is

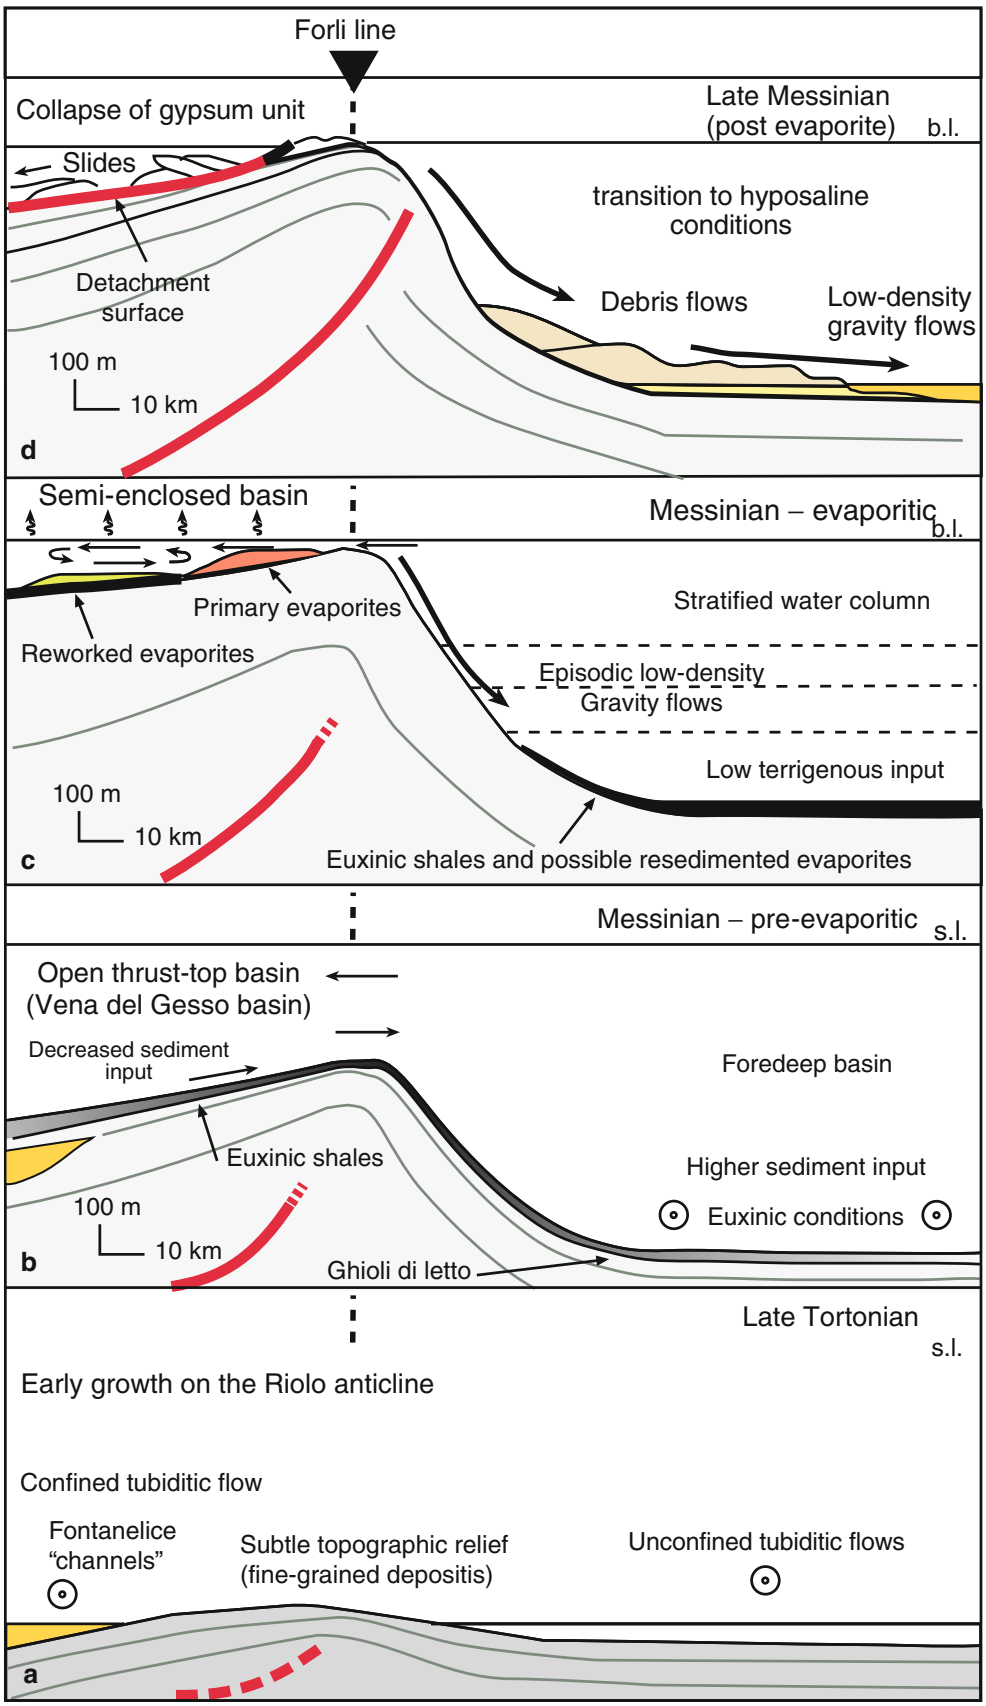

Fig. 5.52 Evolution of the Vena del Gesso basin, Italian Apennines, from the Tortonian to the late Miocene with respect to facies and the evolving thrust basin topography indicated by the Forli Line (After Roveri et al. 2003)

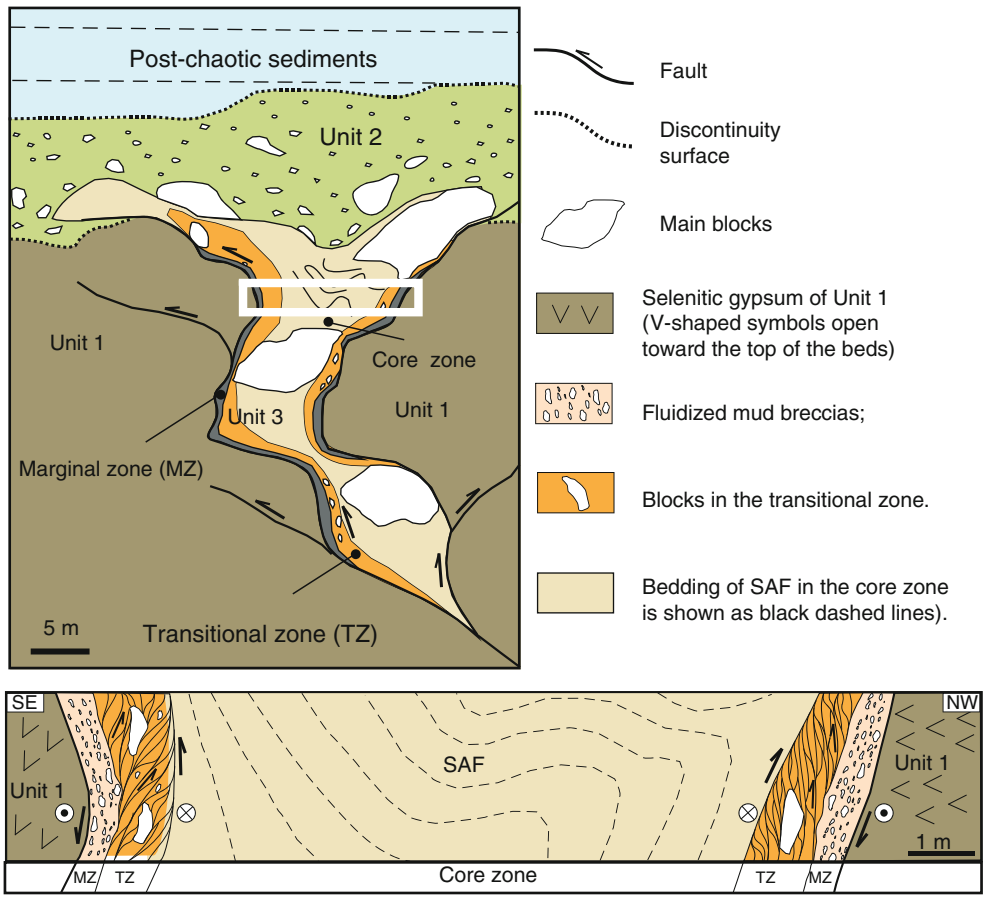

Fig. 5.54 Deformation styles associated with mud diapir emplacement in the faulted and brecciated gypsum of the Lower Evaporite. The intensity of mud deformation (argillokinesis) increases from the muddy folded core of the Sant'Agata Fossili marls (*SAF*) outwards toward the tectonised margins. Opposing senses of shear on the opposite margins of the structure are clearly indicated by the orientation of S-C fabrics in the transitional zones (After Dela Pirre et al. 2007)

unconformably overlain by post-chaotic sediments, including Lago Mare beds (Fig. 5.53). Unit 1 is composed of blocks of primary evaporites that are juxtaposed to marine marls by subvertical transpressive faults and are parallel to the fault surfaces. Unit 2 unconformably overlies Unit 1, and consists of a lenticular sedimentary body containing both angular and rounded blocks, randomly distributed in a fine-grained matrix.

Unit 3 consists of a 10-m-wide body bounded by transpressive faults, and it pierces both Units 1 and 2. It is composed of strongly deformed muddy deposits (argillokinetic textures) that envelop blocks of gypsum and carbonate rocks. Between the core and the margins of unit 3, three zones are defined based on the increasing amount of deformation toward the margins (Fig. 5.54). The distribution, size, and shape of the cemented blocks floating in the matrix are related to differences of velocity gradient of the poorly consolidated Sant'Agata Fossili marls, acting as a viscous fluid as it migrated through a rigid but faulted rock mass. The alignment of long-axis blocks to the scaly cleavage, and their increased clustering toward the external zones are consistent with an increase in velocity gradient toward the marginal contacts (Fig. 5.54).

Bedded post-chaotic sediments unconformably overlie both Units 1 and 2, sealing the main fault systems an indicting the cessation of diapirism. Thus the composite chaotic unit is related to thrust propagation during a regional phase of deformation that occurred pre-Lago Mare deposition.

The current distribution of various beds preserves the result of different evolutionary stages, in each of which a single genetic mechanism prevailed (Fig. 5.53). Tectonic faulting prevailed during stage 1 and was responsible for the formation of a tectonically disrupted assemblage (Unit 1). During stage 2, gravity-driven sedimentary phenomena, related to slope oversteepening triggered by ongoing thrust propagation, resulted in the deposition of Unit 2. Gravity sliding was favoured by the mechanical weakening of sediments caused by tectonic faulting. Over-pressured conditions resulting from the rapid deposition of Unit 2 triggered mud diapirism (Unit 3) so that the Sant'Agata Fossili marls pierced Units 1 and 2. The involvement of methane-rich fluids in the formation of the mud diapir is suggested by the occurrence of blocks of methane-derived carbonates, found not in the quarry, but just outside it (Dela Pierre et al. 2012). Most significantly, the Moncucco study illustrate clearly that thrusting mobilised Messinian evaporites prior to deposition

of the Lago Mare succession, a unit that indicates the end of the MSC and the transition back into marine sedimentation.

Sicily: Historically, much of the stratigraphy used to interpret the history of Messinian sedimentation is based on work done in Sicily, mostly in the Caltanisetta Basin, which is the largest depozone of the Sicilian-Maghrebian foreland basin (Fig. 5.47b; Decima and Wezel 1971). Depocentres that make up Messinian-entrained marginal basins in Sicily, including the Caltanisetta Basin, contain gypsum ± halite, and are located in synclines tied to foreland depressions and underlying thrust structures in the frontal part of the Maghreian chain (Fig. 5.47b). Prior to hydrographic isolation from the Mediterranean seawater, these basins are interpreted as being hydrodynamically linked through the thrust foredeeps to water levels in the adjacent Mediterranean (Fig. 5.55a; Butler et al. 1995). Accordingly, early isolation and drawdown of the Mediterranean base level is marked across the thrust belt by first cycle evaporitic carbonates (Calcare di Base) on the structural highs and evaporites in lows, respectively.

Hence, significant accumulations of halite and potassium salts (up to 1,200 m thick) are restricted to growing thrust synclines in the Sicilian basin. Salts were deposited once the subsealevel depressions were hydrographically isolated from the adjacent Mediterranean. At that time different evaporite signatures were related to different water conditions, reflecting various continental and marine seepage plumes and circulations across various sub-basins (Fig. 5.55a, b; Butler et al. 1995). Thrusting provided accommodation space for evaporite sumps and also controlled the groundwater pathways into the desiccating basins. In similar fashion to Messinian sediments of the northern Apennines, the Sicilian salts form part of a syn-orogenic foreland basin succession that underwent shortening by thrust-related folding soon after deposition (Mazzoli 1994).

Clauzon et al. (1996) group the deposition of the Upper and Lower Evaporites of Sicily into a single period from 5.75 to 5.60 Ma. The initial eustatically-induced marginward isolation was then followed by complete isolation and drawdown of the whole Mediterranean (Fig. 5.51a). In contrast, and although they use only relative time, Butler et al. (1995) recognised a major sequence boundary between the Upper and Lower Evaporites of the Sicilian Basin, also called the First and Second cycles (Fig. 5.55). They interpreted this sequence boundary as corresponding to the major drawdown of the whole Mediterranean and the formation of a major regional unconformity, which now surrounds all these basin-wide deposits (M reflector; see Lofi et al. 2005). They went on to interpret the Upper Evaporite (Second Cycle – mostly saltern gypsum, not halite or bitterns) as being deposited in the isolated marginal seepage basins of Sicily once the Mediterranean was again flooded by seawater entering via a newly re-established surface connection (Fig. 5.51b). The contact with the upper evaporites and the overlying deepwater marine Trubi Formation is a maximum flooding surface in both scenarios.

The tectonic scenario has now been further improved by the recognition of that the major unconformity separating the Upper and Lower evaporites in Sicily actually separates a system that was thrust into its present position from a deeper water setting. It was the work in the Apennines that drew the conflicts in the Sicilian stratigraphy and hydrogeology into focus and ultimately led to a revised stratigraphy incorporating aspects of both regions. The following lists some of the problems in the Messinian sequences of Italy that required solving in the middle of the first decade of the current millennium (Lugli et al. 2008).

1. Deposits traditionally included in the Lower Evaporites are actually clastic sediments that derive from the dismantlement of autochthonous Lower Evaporites.
2. Many of the Lower Evaporites outcrops in Italy are actually large-scale blocks emplaced by extensive mass-waste movements; some of these chaotic complexes were previously interpreted as collapse deposits due to halite dissolution.
3. Some Lower Evaporites outcrops were commonly considered Upper Evaporites and vice-versa.
4. Laminated clastic sulphate sediments were commonly mistaken for primary cumulate deposits and vice-versa.
5. The significance of halite deposition, which actually bears the only unequivocal sign of exposure found within the Messinian evaporites in the Sicilian Basins, has been overlooked, as has its likely tie to the main evaporite drawdown stage in the Mediterranean.
6. The Calcare di Base carbonates commonly show evidence of resedimentation.
7. The Calcare di Base is never found at the base of the Lower Evaporites primary “in situ” selenites.
8. Lateral transitions between carbonate, gypsum or halite primary evaporites cannot be directly observed and must be considered speculation.

These problems led to further study and a revision in the way the various outcrops of Sicily are interpreted. A key question in resolving the stratigraphic conflicts in the Sicilian basins is how does the unit known as the Calcare bi Base, which tends to occupy highs and basin margins, relate to evaporites that tend to occupy the basin (syncline) lows. Historically, the Calcare di Base (CdB) in the Sicilian basins has been interpreted as indicating initial drawdown. It has an isotopic signature that becomes increasingly heavy toward the sites of gypsum and halite precipitation (Fig. 5.56a; Decima et al. 1988). Its “in situ” outcrops have historically been interpreted as dolomitic seepage units with a distribution mostly restricted to highs (edges) of the Sicilian Basin

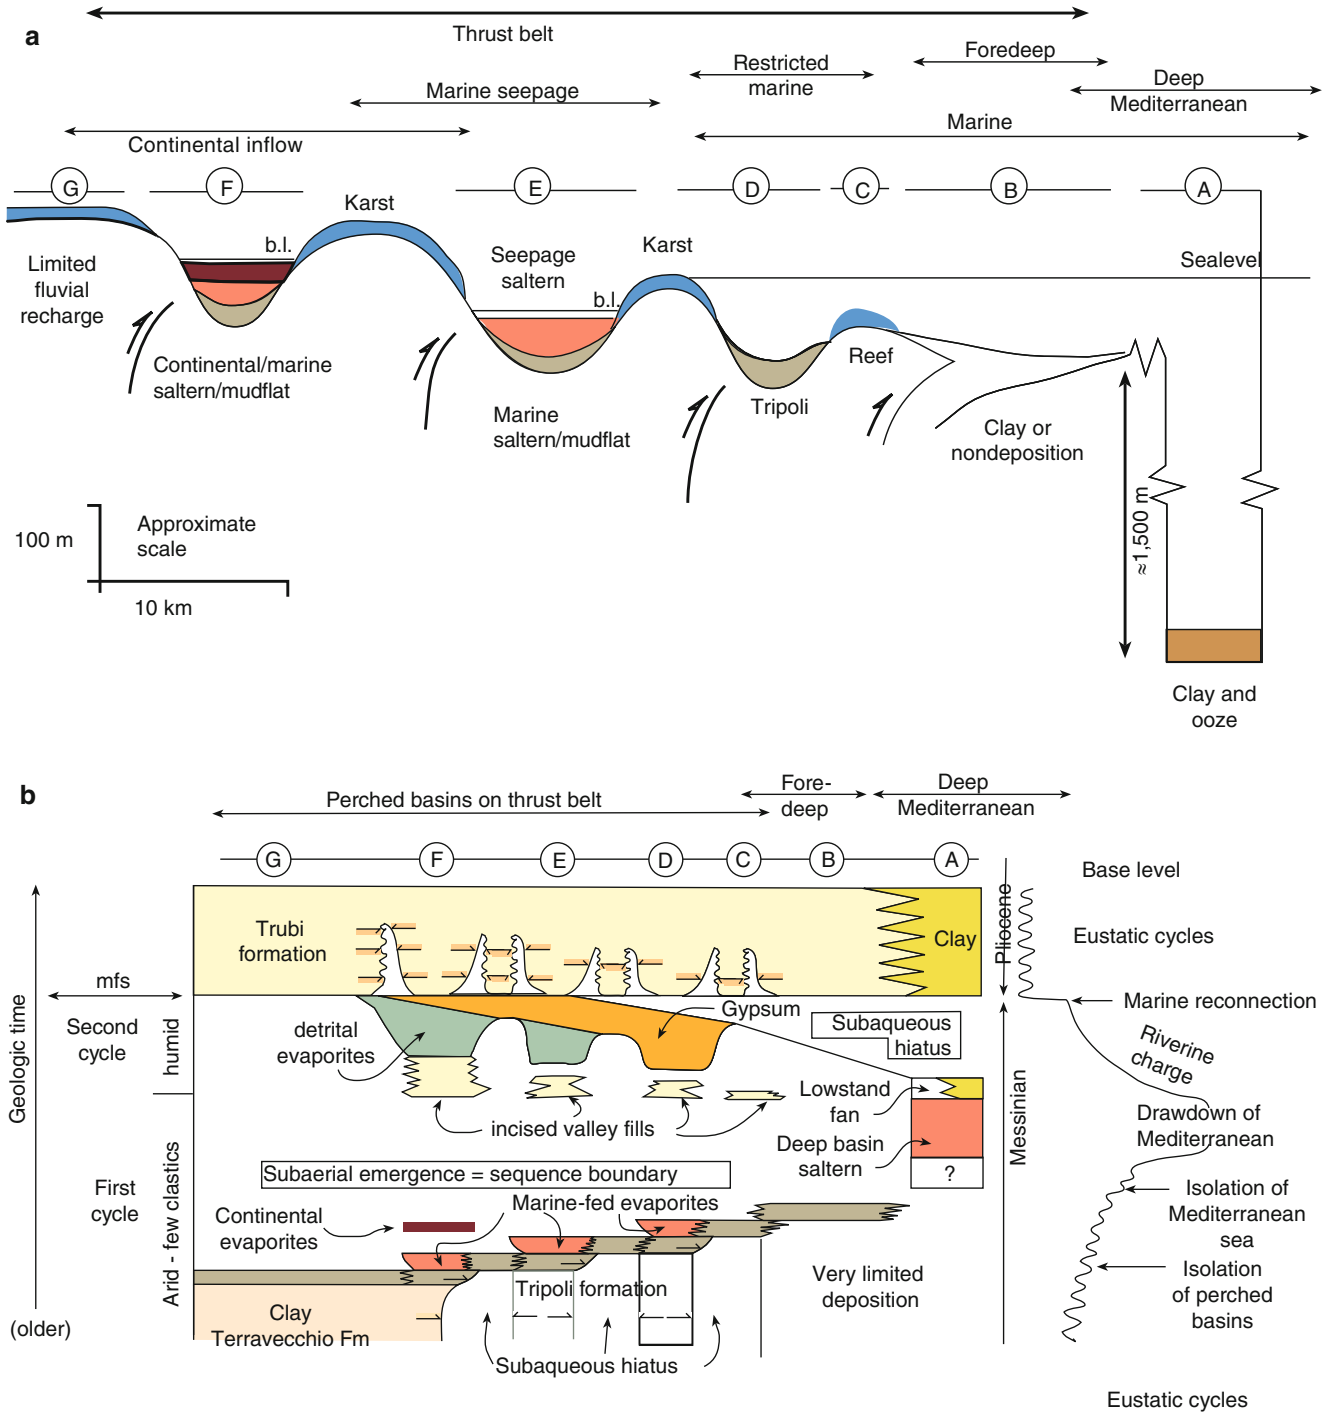

Fig. 5.55 Marginal thrust top evaporites in Sicily (Modified after Butler et al. 1995). (**a**) Sequential model for stratigraphy across different thrust top basins during deposition of the Lower Evaporites. Note the evaporite forming basins are isolated from a surface connection with the Mediterranean, but have a seepage connection. Restricted surface marine circulation facilitates deposition of the Tripoli Formation. Progressive thrusting leads to progressive reduction of import of marine inflow and finally to deposition of potash evaporites under conditions of hyperaridity and predominantly continental recharge. (**b**) A relative chronostratigraphic model for Messinian and Lower Pliocene deposits of Sicily and their correlation with basinwide deposits of the central Mediterranean sub-basins. Note that deposition of basinwide evaporites on the floor of the Mediterranean corresponds to an unconformity (sequence boundary) that separates the Lower and Upper Evaporites

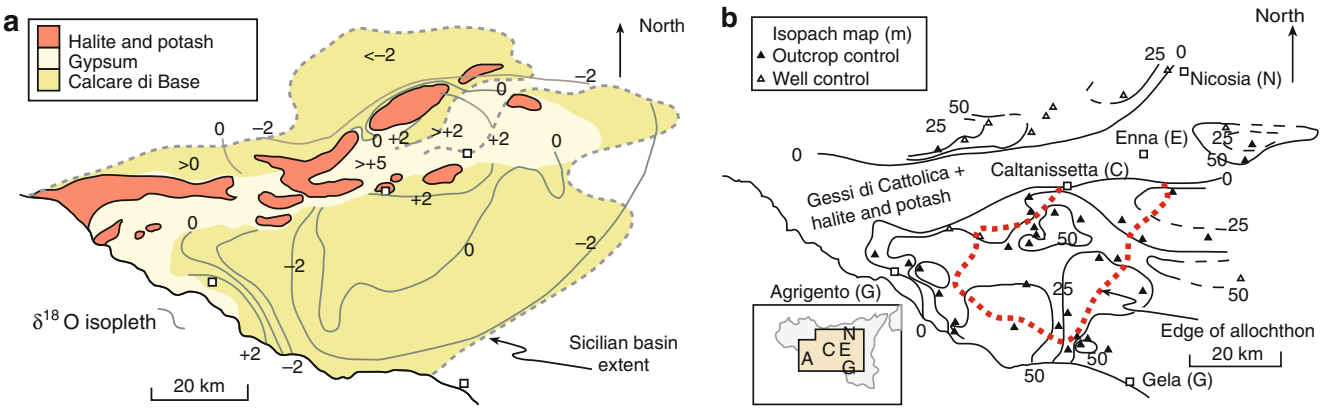

Fig. 5.56 Calcare di Base and equivalents, Caltanisetta Basin. (**a**) Distribution of main mineralogies overlain by oxygen isotope distribution ($\delta^{18}O_{PDB}$ ‰) in the in situ unit showing depletion in parts of Calcare di Base deposited further from areas of contemporaneous salt deposition (gypsum, halite and potash) (**b**) Isopach (in metres) of Calcare di Base and breakdown into an "in situ" unit and an allochthon block that was thrust over the evaporite salts (After Decima et al. 1988)

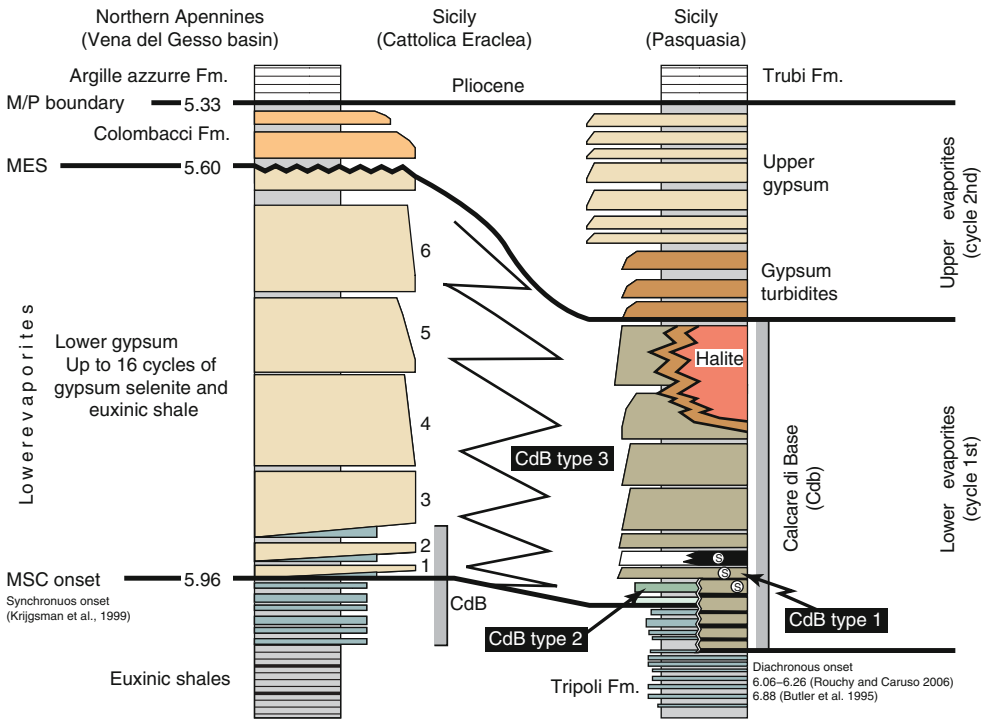

Fig. 5.57 Comparison of the Messinian successions of the Northern Apennines and of Sicily, showing the stratigraphic distribution of "Calcare di Base" (*CdB*). Note the inferred lateral transitions and timings between Lower Gypsum, Calcare di Base, and halite. (Fig. 5.56b). More recently these dolomites, or at least that part of the CdB that is stromatolitic, is interpreted as having a microbial genesis (bacterial sulphate reduction; Oliveri et al. 2010). Three different types of carbonate deposits are now known to be included in the unit described as the "Calcare di Base," which is commonly envisaged to record the MSC onset (Fig. 5.57; Manzi et al. 2011): They are: Type 1, which consists of sulphur-bearing limestones, representing the biogenic product of bacterial sulphate reduction after original gypsum; Type 2, which comprises dm-thick, laminated dolomitic limestones interbedded with diatomites, sapropels, and marls found at the top the Tripoli Formation; and Type 3, the most common variety, consists of m-thick, brecciated limestones interbedded with shales and clastic gypsum. Type 3 shows sedimentary features suggesting a clastic origin and deposition from high- to low-density gravity flows; thus, these deposits can be regarded as an end-member of a large variety of evaporite-bearing, gravity-flow deposits, with a dominant carbonate component. They are likely equivalent to the gypsum clastic cycles in the Lower Evaporite in the Apennines.

The new genetic and stratigraphic characterization of the CdB carbonates has strong implications for a better comprehension of Messinian events; the three types of Calcare di

Base (CdB) seem to have formed during different stages of the MSC (Fig. 5.57). Type 2 formed in the first stage (5.96–5.60 Ma), and is the only type that can be regarded as the Lower Gypsum time-equivalent. Type 3 was deposited in the second stage (5.60–5.55 Ma), and its base is associated with a regional-scale hiatus and erosion (Messinian erosional surface). Type 1 formed even later, likely in post-Messinian time, through diagenetic processes affecting resedimented gypsum deposited during the second stage of the MSC. It follows that not all the CdB deposits record the onset of the MSC, as commonly thought. We shall discuss this further after we have looked at Messinian evaporites in the eastern Mediterranean and use this to develop an understanding of the saline hydrology tie to the basins hypsometric evolution.

Cyprus and the Levantine basin: The Latika, Tartus and Levantine basins of the Eastern Mediterranean were covered by widespread Messinian evaporites during the main Messinian Mediterranean drawdown (Fig. 5.58a; Calon et al. 2005; Roberts and Peace 2007; Hübscher et al. 2009). In these eastern Mediterranean deep basins, three distinct seismic units (the Messinian "trilogy") have been identified. This trilogy is observed beneath modern abyssal plains across the Mediterranean from the Gulf of Lions to the Levantine and laterally onlaps the margins (Montadert et al. 1970; Lofi et al. 2005). This onlap geometry is interpreted as a progressive infill of the abyssal plains when subsidence apparently did not compensate the high sedimentation rates (partial fill and spill).

For a long time, the three members of the offshore trilogy were called, respectively; Lower Evaporites, Salt, and Upper Evaporites and considered equivalent to the outcrop stratigraphy. However it is likely that the offshore unit referred to as the Lower Evaporites is mostly non-evaporitic, made up of varying combinations of marine turbidites, slumps and pelagics, typically with evidence of periodic restriction prior to the MSC. Onshore, the unit referred to the Lower Evaporites is just that — evaporitic. To avoid confusing these offshore terms with the stratigraphy of the onshore outcropping Messinian units, Lofi et al. 2005 proposes that we refer to the offshore trilogy as the Lower Unit at the base of the seismic trilogy (LU, which is at least partly turbidite), the Mobile Unit in place of the term Salt (MU, which in seismic typically shows the variably transparent characteristics of halite and in places has experienced plastic deformation), and the Upper Unit at the top of the trilogy (UU, made up of marls and evaporites, and interpreted as being deposited under increasing less saline conditions ≈ Lago Mare).

The basins are located east and southeast of Cyprus and are associated with the collision front between the African and Anatolian plate (Figs. 5.47b and 5.58a). The Pliocene-Quaternary sediment succession is underlain by up to 1-km thick Messinian evaporites. Both thick-skinned plate tectonic and thin-skinned salt tectonics control fluid dynamics and associated mud volcanism in the Latakia and Cyprus Basin as well as along the Troodos Latacia Culmination, which separates both basins.

An end-member model to explain the current distribution of basin-centre Messinian salts was proposed by Hübscher et al. (2009) that also explains the presence of elongated topographic highs and trenches along the Troodos Larnaca Culmination, and south of it. It calls upon gravity gliding of the Messinian evaporites and associated fluid migration (Fig. 5.58b). Thin-skinned extension in the Troodos Larnaca Culmination and boudinage, respectively, facilitate fluid flow through and out of the deforming evaporites. Fluid or mud crossflows dissolve the salt layer and create elongated dissolution and salt withdrawal trenches. Pressurised subsalt mud then intrudes Pliocene-Quaternary sediments atop and between the trenches. Consequently, the overburden is thickened and forms morphological ridges. The small-scale outcrop analogy for this style of argillokinetic deformation may be the Moncucco gypsum quarry (Fig. 5.53).

South of the Troodos Larnaca Culmination in the Tartus Basin, the evaporites and overburden are folded due to thin-skinned shortening of the evaporites. Fluid extrusion out of the evaporites can inferred from discontinuities in the seismic. The outflow caused a volume reduction and collapse of the evaporites. Mud volcanoes and fold anticlines align above deep-rooted transpressional fault systems which are associated with the African-Anatolian collision zone, where the faults acted as conduits for rising fluids. Mud volcanoes emerge in the western part of the same region, where the Cyprus Arc (thrust) strikes almost West–east and the plate collision occurs more frontally, so stress is highest. Fold anticlines evolved further to the east, north of the Aleppo High where the Cyprus Arc runs SW-NE and sinistral strike-slip has been proposed. Particular mud volcanoes and folds had emerged prior to the deposition of the Messinian evaporites. The undisturbed upper Pleistocene sequences, as well as the absence evidence of significant mud outflow on the seafloor, strongly suggest that the main fluid dynamic ceased prior to Quaternary sedimentation.

Further south is the Levantine basin and then the Nile Delta cone, both areas of active hydrocarbon exploration (Fig. 5.59; Cartwright and Jackson 2008). In both regions the current edge to the Messinian salt is not the depositional edge of the salt, rather, as in many basinwide salt masses on passive margins the current salt edge is controlled by gravity sliding and salt withdrawal associated with sediment loading (Chap. 6).

Regional 2D and 3D seismic data from the Levant Basin reveal the updip extensional component of thin-skinned gravity tectonics on this continental margin (Fig. 5.59; Cartwright and Jackson 2008). Because of its youth (5–7 Ma), the earliest stages of deformation of this salt basin are preserved without the severe structural overprinting, typ-

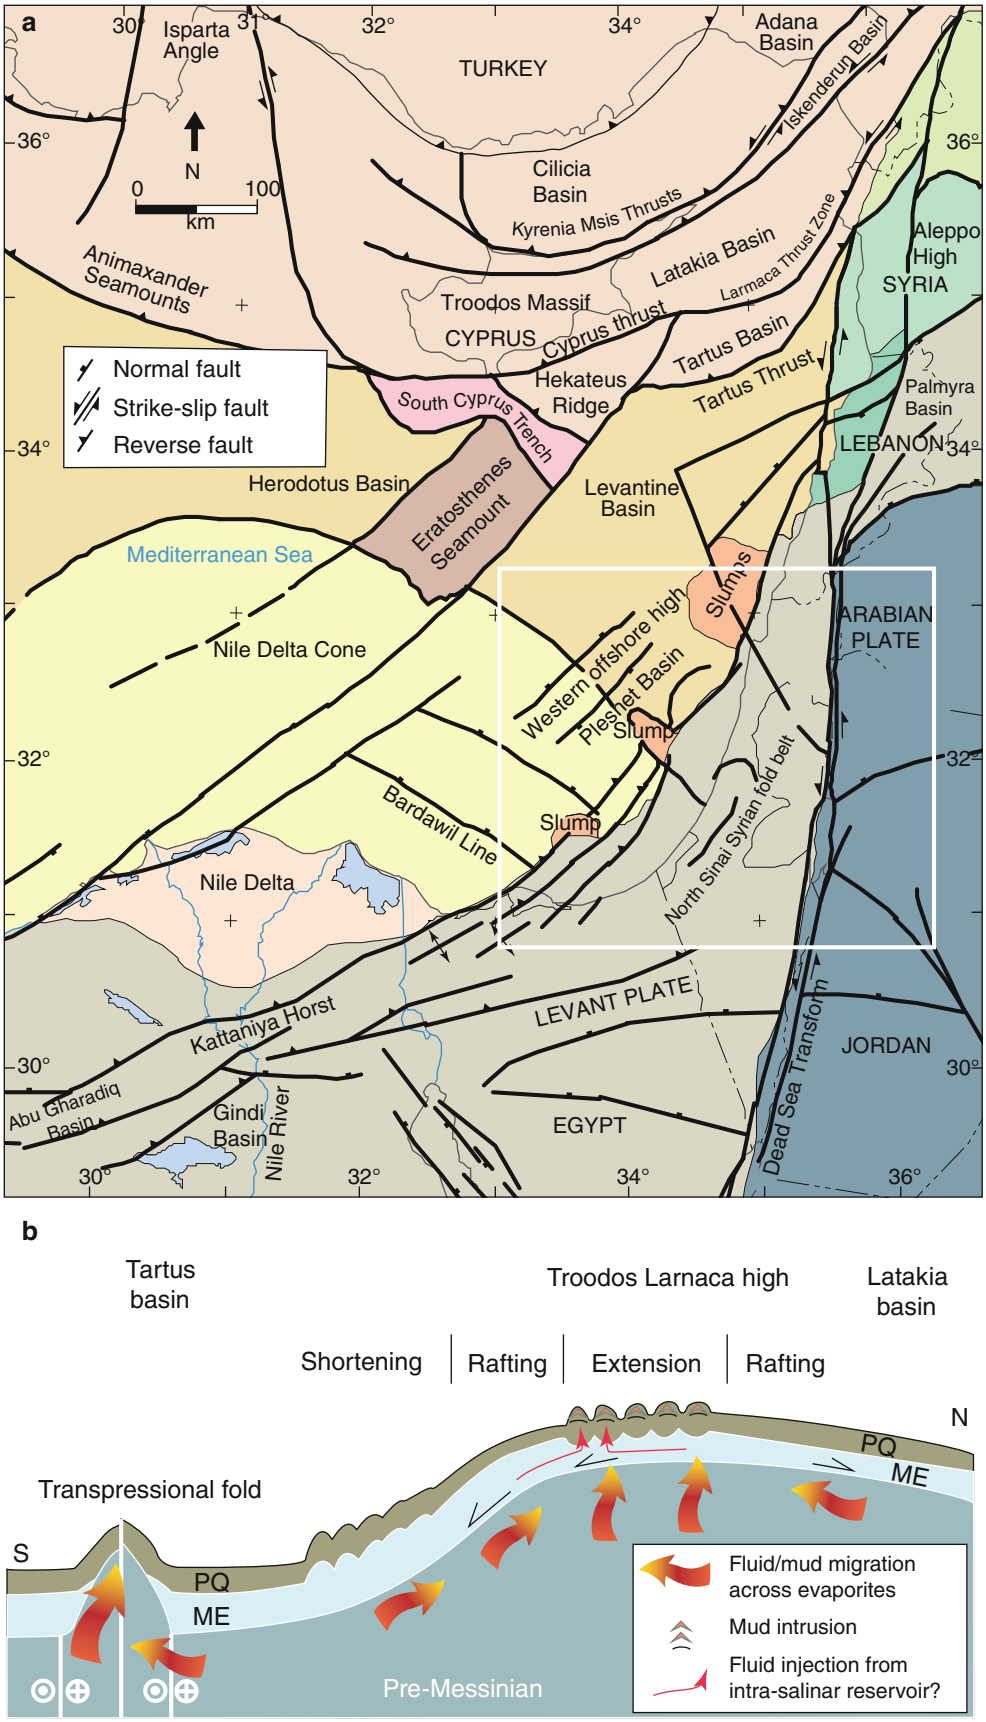

Fig. 5.58 Eastern Mediterranean. (**a**) Tectonic elements in the East Mediterranean Basin. The main elements defining the Levantine Basin include the Nile Delta Cone, Eratosthenes Seamount, the Cyprus/Larnaca Thrust Zone and the coastal margin faults along the Eastern margin of the Basin (After Roberts and Peace 2007). (**b**) Morphostructure along the Troodos Larnaca Culmination driven by salt tectonics. Downslope creeping salt leads to extension or salt boudinage at the culmination itself. Here, fluids flow through or out of the salt and dissolute elongated trenches. Mud intrusions thicken the overburden. Downslope creeping results in compressional folds in the salt and overburden. The thin-skinned tectonics as outlined here superimposes active plate tectonics. In the Cyprus Basin fold anticlines emerged above fault traces of deep-rooted strike-slip fault systems. *ME* Messinian evaporites, *PQ* Pliocene–Quaternary (After Hübscher et al. 2009). The *white rectangular outline* shows the approximate position of Fig. 5.59)

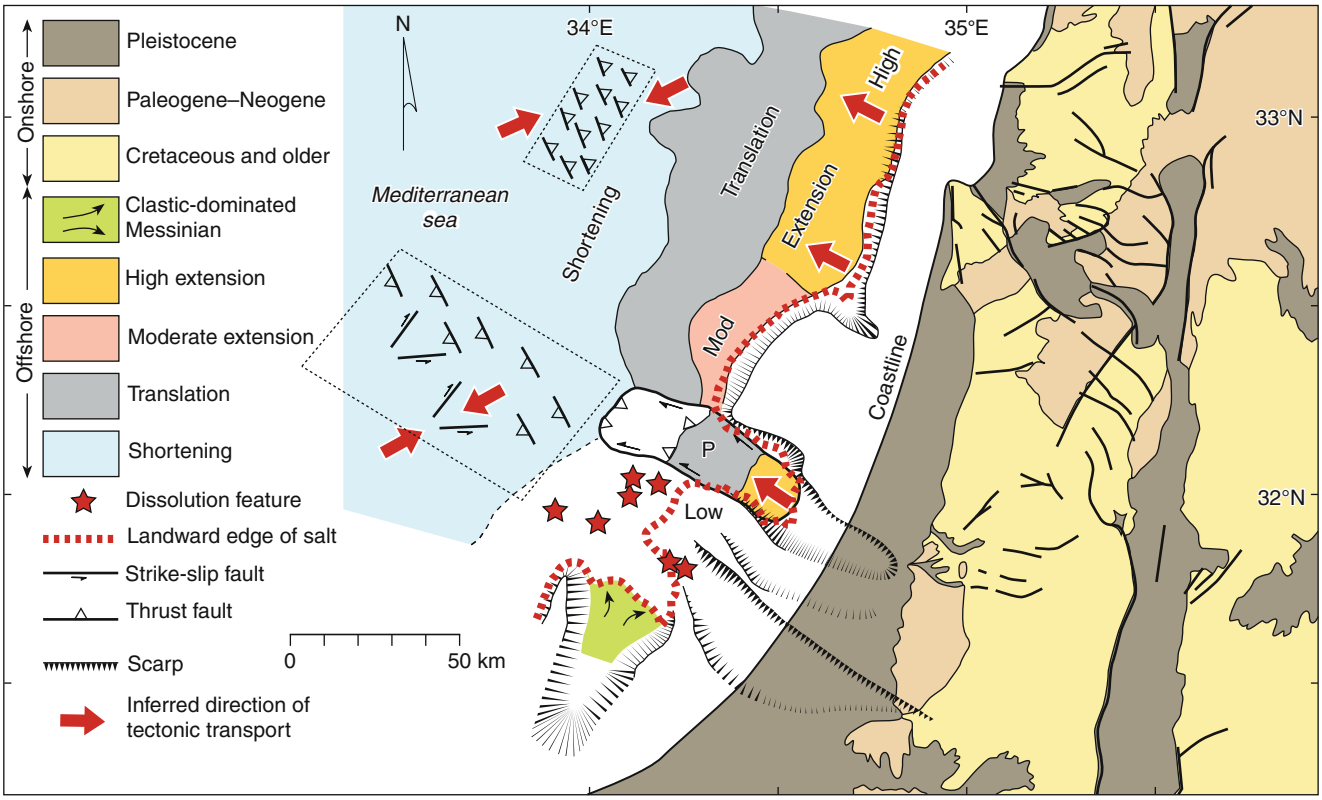

Fig. 5.59 Structural domains and features along the Levant margin. The updip edge of Messinian salt (*red dashes*) correlates closely with the updip limit of extension. The frontal scarp (hachured) also tracks these features in the north but deviates in the south, where it deflects into and merges with major pre-Messinian canyons. P marks the Palmahim submarine landslide. The degree of onshore exhumation is shown by the three geologic units, the ages for which correlate with increasing elevation (After Cartwright and Jackson 2008)

ical in more mature, giant salt-tectonic systems. Extension detaches onto and within Messinian evaporites up to 1,800 m thick. Structural restoration suggests that the Mediterranean drawdown during the Messinian Salinity Crisis was ≈800 m. The 10- to 15-km wide extensional domain tracks the landward pinch-out of the mobile Messinian evaporites against an older Late Miocene scarp. Diachronous extension began in the centre of the margin in the mid-Pliocene, then spread northward in the late Pliocene, then finally southward in the early Pleistocene. Extension continues today on many of the most landward faults. Extensional strain varies greatly along strike from <1 km to as much as 12–15 km. Extension and seaward salt flow thinned the evaporite margin and its overburden. Both processes were triggered by a combination of uplift of the continental shoulder of the Dead Sea Rift and subsidence in the Mediterranean Basin. At least three factors controlled variations in extension: (1) degree of tilting of the salt wedge, related to the interplay of coastal uplift and basin subsidence; (2) presence of pre-Messinian canyons overlain by landward salients of salt; and (3) variations in evaporite facies and the proportion of siliciclastic admixture.

In general, work in the offshore of the eastern Mediterranean has established the following (Briand 2008)

1. There is no evaporite underlying the Anaximander area and at Erathostenes seamount, implying these structures predated the MSC.
2. Layered halite (MU) is the predominant phase found in most of the eastern Mediterranean basin-centre sumps.
3. Gypsum/anhydrite (typical of the Upper Evaporite in marginal basins) is a minor contribution, with only one site where the gypsum contribution seems more important than halite to the Messinian succession (located on the Nile fan with an approximately 1,200 m present-day waterdepth).
4. Mg-Cl salts are a minor but rather variable contribution to deep brine sites on the current seafloor of the Mediterranean. In particular, the Discovery Brine basin in the mid-Ionian Sea, consisting of waters associated with almost pure bischofite, is an extreme case.

When seismic character of halite in the Eastern Mediterranean is compared to that in the western Mediterranean there are some obvious, as yet unexplained, differences (Lofi et al. 2011; Topper and Meijer 2013). In the Western Mediterranean there is a single transparent layer of halite, suggesting negligible amounts of intermixed clastics,

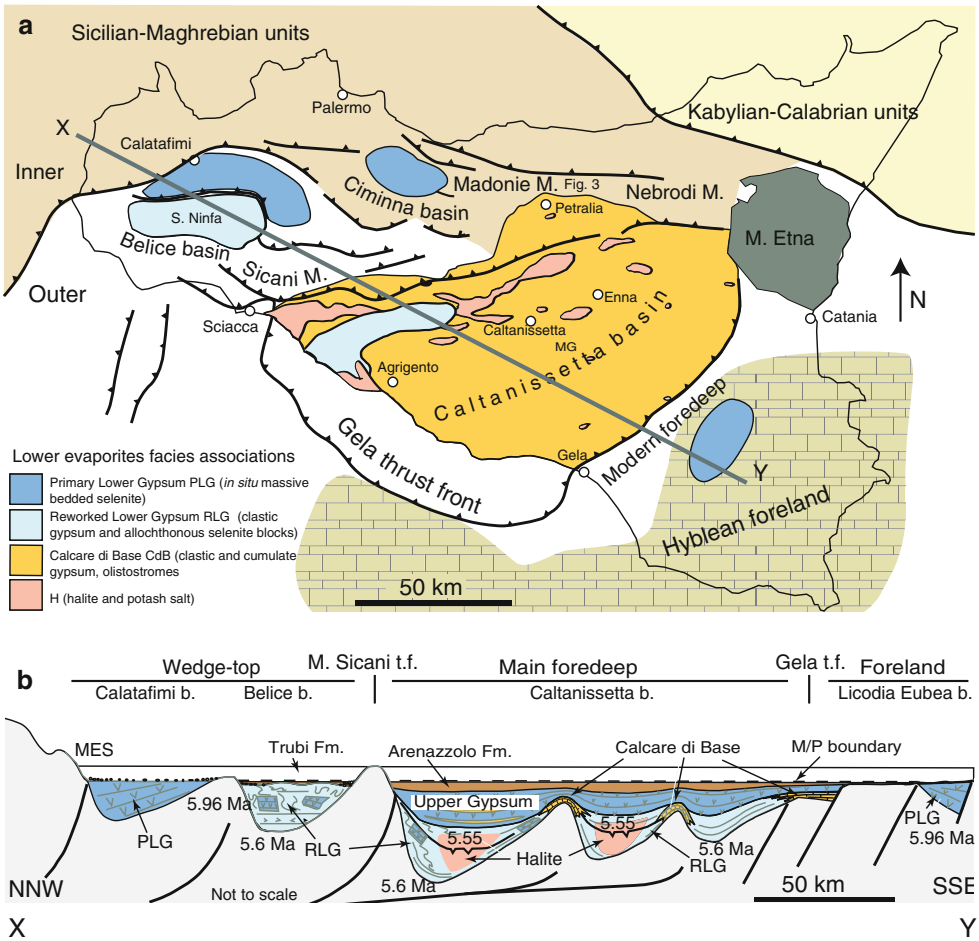

Fig. 5.60 Geology of Sicily with the distribution of the Lower Evaporites (Modified after Roveri et al. 2008; Manzi et al. 2011) (**a**) Distribution of the major geologic units (**b**) Schematic geologic cross section across the Sicilian Basin flattened at the base of the Pliocene showing the upper Messinian deposits (above the Tripoli Formation). *MES* Messinian erosional surface. Also shown are ages of main surfaces in million years

with a maximum thickness of 1,200 m in the Provencal basin. In the Eastern Mediterranean, up to six layers with alternating seismic facies, transparent–nontransparent, add up to a thickness of 2,100 m in the central deep basins. Three packages with alternating transparent– nontransparent halite have been drilled in the Nile delta (Ottes et al. 2008), The oldest (deepest) halite of the three has a more chaotic seismic character and possibly consists of redeposited evaporites, mixed with some clastics. It is assigned a Tortonian age (with an uncertainty of a few Ma). The middle halite unit is the cleanest (most transparent) and has undergone no more than minor deformation. These three halites are considered by Ottes et al. (2008) to be likely time equivalents to condensed anhydrite-rich sections in the up-dip shelfal areas.

A More Realistic Messinian Stratigraphy

A comprehensive integration of as yet undrilled basin-centre evaporites, as studied in seismic across the Mediterranean, and the various basin margin outcrops with their well-preserved stratigraphic detail, is needed if sequence stratigraphic principles are to be tested across this our youngest example of a saline giant.

Since the 1990s, textural studies have shown significant volumes of deeper water evaporites are present in the Apennine, Sicilian and Cypriot outcrops (Roveri et al. 2008). The large-scale, postdepositional gravity collapse of primary evaporitic (mostly gypsum) deposits into the deeper parts of adjacent foreland basins is a widespread feature in the Mediterranean peripheral basins of Italy and Cyprus. Similar but larger scale evidence is seen in seismic across basin edges in the Eastern Mediterranean. Such slumping and collapse has altered original stratigraphic relationships in some places and means the amplitude of any waterlevel fall cannot be easily determined in some marginal basins where beds can be allochthonous. It means the simple bipartite stratigraphic separation, based on Butler et al. (1995), is somewhat more complicated by ongoing "piggy-back" tectonics (Figs. 5.60 and 5.61). Many authors (see Briand 2008) now accept that the Sicilian, and possibly the Cypriot, basins differ from the Spanish marginal basins in that they preserve evidence of the halite unit that was deposited at the time of maximum drawdown of the Mediterranean basins (Time 3 scenario in Fig. 5.48). The halite (and associated potash salts) that subcrop in Sicily is autochthonous. It was thrust

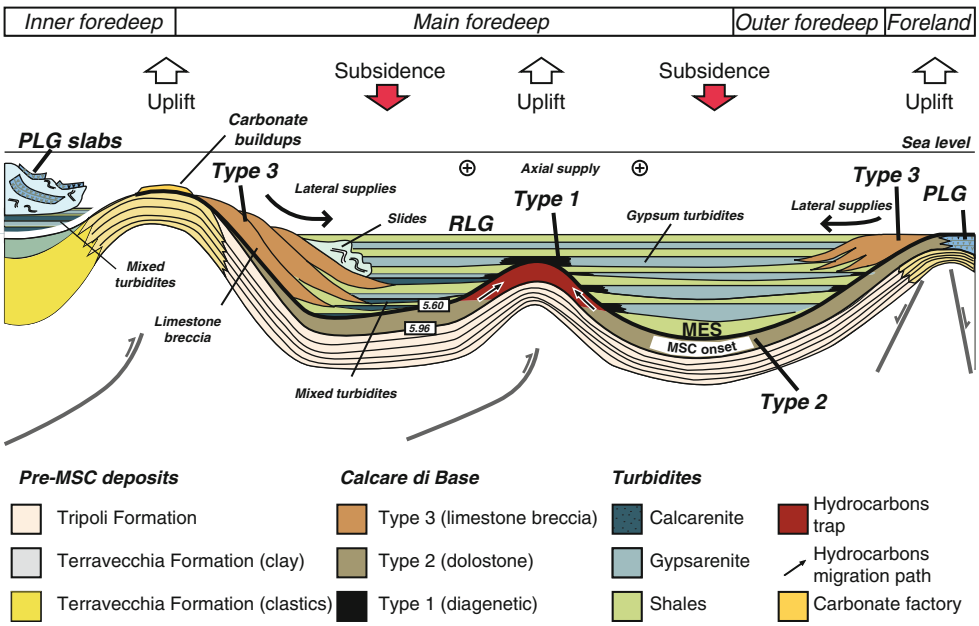

Fig. 5.61 Schematic reconstruction of the Sicilian foredeep during the Messinian salinity crisis (*MSC*) in the Sicilian Basin showing also the distribution of the three Calcare di Base types and their relationship to underlying open marine (*pre MSC*) and overlying retransported units of the lower Gypsum unit (Lower Evaporite; see Fig. 5.57, after Manzi et al. 2011)

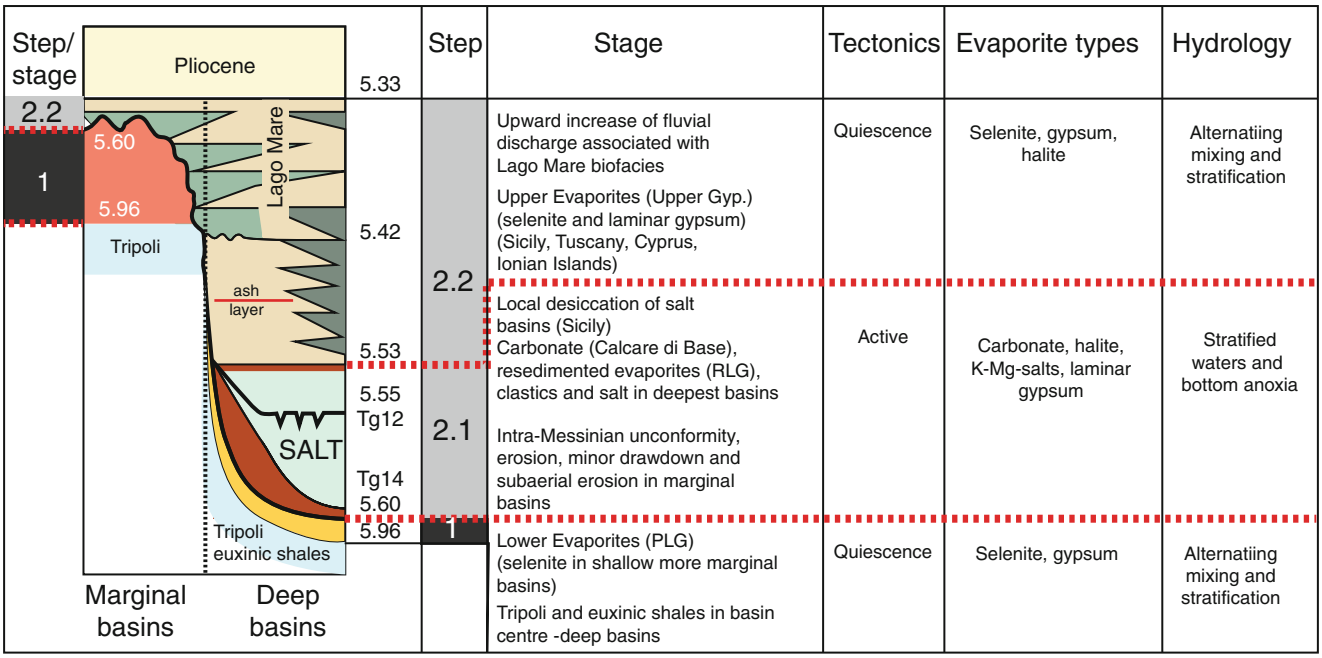

Fig. 5.62 A tentative integrated stratigraphy for the Messinian evaporites of the Mediterranean region (Briand 2008)

into its current elevated position on the isle of Sicily, while gypsum of the marginal basin was gravitationally reworked into deeper water (Figs. 5.60 and 5.61). This autochthonous section is overlain by bedded gypsum of the Upper Evaporite and the Lago Mare.

Accordingly, Roveri et al. (2008) and Manzi et al. (2011) postulate a three stage depositional association in the Sicilian Basins (Fig. 5.60b). The Lower Gypsum of Sicily comprises primary and resedimented evaporites, separated in space and time by the intra-Messinian unconformity. At that time a composite unit including halite, potash (kainite), resedimented gypsum and Calcare di Base equivalents accumulated between 5.6 and 5.55 Ma in the main deep basin shallow-water depocentres. Simultaneously, gypsum in more marginal basin settings was reworked and brecciated; it records the acme of the Messinian Salinity Crisis during a tectonic phase coupled with sea-level falls at glacials TG14-TG12 (Figs. 5.61 and 5.62). These basin-centre deposits post-date *in-situ* primary selenite gypsum, which had precipitated in shallow-water wedge-top and foreland ramp

basins between 5.96 and 5.6 Ma. The revised stratigraphic framework defines a three-stage Messinian Salinity Crisis (MSC) scenario characterized by different primary evaporite associations: selenite in the first and third stages, carbonate, halite and potash salt in the second one that was also associated with hybrid resedimented evaporites. Such a stratigraphy better ties to the offshore record.

Further east in the Mediterranean, in Cyprus, where now outcropping Messinian gypsum units accumulated in a series of semi-isolated tectonically-induced small marginward piggyback basins, the stratigraphic evolution is not dissimilar to the Italian basins. Dominantly, the gypsum deposits formed from landlocked marine-fed brine sheets (gypsum salterns of the Upper Evaporite unit) located not far below ambient sea-level (Robertson et al. 1995). Evaporites in south Cyprus (Maroni Basin) formed in elongate marginal basins between compressional lineaments instigated by Early Miocene thrusting in a tectonic situation similar to that described for Sicily. In the sub-basins of west, southwest and south Cyprus, large scale slumping of saltern gypsum into deeper water formed megarudite debris flows, which are thought to have been triggered by one or several phases of extensional faulting tied to regional thrust tectonics.

The improved, but still tentative, understanding of the tectonic evolution of the tripartite Sicilian section and thrust-related Cypriot counterparts underlines the considerable limitations that still exist in our current understanding of any Mediterranean-wide evaporite stratigraphy. That is, through ongoing studies of circum-Mediterranean Messinian outcrops, we now have a thorough understanding of the sequences and the relative importance of drawdown versus tectonic position in their formation. But, still we can only tentatively relate our detailed outcrop-based understanding to the much thicker, uncored, largely undisturbed, flat-bedded successions of the main drawdown stage, which seismic shows occupy huge areas across the deep Mediterranean seafloor.

What is clear from the basin hydrology required to form gypsum in the marginal basins it that it cannot be time-equivalent to the halites that dominate the drawdown deposits of the basin-centre sumps (Fig. 5.61). While gypsum was accumulating in the marginal basins, euxinic carbonates and clastics, including equivalents to the Tripoli Fm, were accumulating beneath kilometres of water cover atop the deepwater sumps on the Mediterranean floor.

How Did the MSC End?

Lago-Mare (literally "lake-sea") deposits in the Mediterranean typify the transition from the evaporites of the Messinian salinity maxima back into the open marine waters of the Pliocene. According to Orszag-Sperber (2006) the term "Lago-Mare" is now employed unanimously by geologists across the Mediterranean to designate dominately transitional sediments deposited in what were mostly oligo-mesohaline lacustrine settings that ended Messinian time, immediately prior to the Pliocene marine re-flooding.

The Pissouri and Polemi basins of south Cyprus preserve excellent outcrops of late Messinian-Early Pliocene "Lago-Mare" sediments, as do approximately equivalent sediments in the Mediterranean on the edge of the Erathostenes Seamount (Fig. 5.61; Orszag-Sperber et al. 2009). In fact, all the Messinian-Pliocene transitions that define the end of the salinity crisis in the Eastern Mediterranean are marked by a very rapid environmental change, as indicated by sharp variations in lithology, sedimentology, microfaunal assemblages and stable isotope composition (Rouchy et al. 2001).

The most striking feature in the Pissouri Basin is the intercalation between the uppermost gypsum bed and the base of the Zanclean (Early Pliocene) deposits of four main horizons of palaeosols interbedded with carbonates and conglomerates. Palaeosols indicate periods of subaerial exposure in the marginward basins of Cyprus that were long enough to permit pedogenesis during the transition to less evaporitic conditions. The Lago-Mare succession is not indicative of a geologically instantaneous event. Intercalated conglomerates indicate intense erosion of the Troodos Massif and its sedimentary cover. In contrast, shallow oligohaline conditions persisted in the deeper parts of the Mediterranean basin, as indicated at ODP Site 968. Both in the Pissouri Basin of Cyprus and on the flank of the Erathostenes Seamount in the Mediterranean the late Messinian sediments are directly overlain by the lowermost Pliocene sediments deposited in well-oxygenated deep marine conditions (Orszag-Sperber et al. 2009). The drastic change of water depth that typifies the basinwide end to the salinity crisis shows that as in the earlier evaporite stages, water levels of the latest Messinian "Lago-Mare" were still far below that of the world ocean, by at least more than several hundred metres.

Moreover, the study of the Polemi sections shows that oligohaline conditions had already started during the deposition of the Upper Gypsum sub-unit (Fig. 5.61). Typical brackish and fresh water assemblages are present in the last two gypsum layers and inter-gypsum beds on Cyprus (Rouchy et al. 2001). This indicates that freshwater dilution, i.e. passage into the Lago-Mare conditions, resulted from a progressive change of the hydrological budget. It started during deposition of the Upper Evaporites and climaxed after the deposition of the uppermost gypsum layer (passage into the classic Lago-Mare facies). This basinwide evolution is interpreted as being due both to the severance from the marine brine-seep feed and to the increasing contribution of the runoff-precipitation versus marine inputs in the hydrological budget of the Mediterranean. This occurred toward the end of the salinity crisis, immediately prior to the re-establishment of open marine conditions. (In my opinion it reflects a transition into a fill and spill mode of deposition in a relatively humid setting).

The marine refilling at the beginning of the Zanclean and associated with the end of the Mediterranean Lago-Mare is considered to have been very rapid (Orszag-Sperber 2006). For Hsu et al. (1973), the event length of the re-flooding event was evaluated at "probably less than 10,000 years". It was considered as a "catastrophic deluge" by Cita et al. (1978a), with associated instantaneous marine flooding through the Mediterranean basin (Hilgen and Langereis 1988). This has led some envisaging a series of cataracts (mega-Niagara waterfalls) in the vicinity of the Rifian corridors at the western end of the Mediterranean (inset in Fig. 5.47). Blanc-Valleron (2002), who takes into account both the present exchanges of water between the Atlantic Ocean and the Mediterranean Sea and the morphology of the Gibraltar Strait area, estimated that only 36 years were needed "to fill an empty Mediterranean, even when taking into account the evaporation." The velocity of the flow refilling the Mediterranean from the Atlantic through the Gibraltar Strait is evaluated at several tens to more than 100 m s^{-1}, and termed "cataclysmic". But the sedimentological evidence for this spectacular scenario is enigmatic.

Evaporites indicative of the Messinian Salinity Crisis must have resulted from a significant drop of the Mediterranean sea level and associated hydrographic isolation. As outlined above the subsequent reflooding is generally thought to have been very sudden. Offshore seismic evidence from the Gulf of Lions and re-visited onshore data from Italy and Turkey, as interpreted by Bache et al. (2012), offer a new concept of a two-step reflooding of the Mediterranean Basin after the Messinian Salinity Crisis. The refilling rate was first moderate and relatively slow, accompanied by transgressive ravinement, and later on was very rapid, preserving the subaerial Messinian Erosional Surface (M-reflector). The amplitude of the two successive rises of sea level is estimated at ≤500 m for the first rise and 600–900 m for the second rise. Upper Evaporites from the central Mediterranean basins appear to have been deposited principally at the beginning of the first step of reflooding. After the second step, which preceded the Zanclean Global Stratotype Section and Point, successive connections with the Paratethyan Dacic Basin, then the Adriatic foredeep, and finally the Euxinian Basin occurred, as a consequence of the continued global rise in sea level. Marine flooding (transgression) across a complex basin-floor morphology, with sills and sub-basins, led to somewhat diachronous events encompassed in the term "Lago-Mare" succession.

Implications for Eustatic Correlations

If we summarise our current understanding of Late Miocene evaporites in the Mediterranean (Fig. 5.62; Topper and Meijer 2013) then; (1) During the Messinian Salinity Crisis (5.96–5.33 Ma) deposition took place in two distinct settings in the Mediterranean: marginal and deep basins. In (former) marginal basins all around the Mediterranean, Messinian sequences start with up to 16 distinct cycles of gypsum intercalated with marl/carbonates. A duration of ≈360 ka has been calculated for their formation by linking the cycles to precession-driven climate changes. This first phase of the MSC, the so-called Primary Lower Gypsum phase (PLG, 5.96–5.61 Ma), is followed by the second phase of the MSC, the halite phase (5.61–5.55 Ma), which is characterized by widespread erosion of the PLG deposits, redeposition of the eroded gypsum, and formation of a halite unit in deep marginal basins in Sicily, Calabria, and Cyprus and likely across the deep basins of the Mediterranean (Roveri et al. 2008). The third and last phase recognized in marginal basins is the Upper Evaporite phase (5.55–5.33 Ma), which generally consists of non-evaporitic shallow-marine deposits and the mesohaline to brackish water Lago Mare sediments that defines the end of the MSC.

Depending on the author, different Late Miocene-Pliocene intervals are defined in the Mediterranean as indicative of the MSC, with the main differences mainly relating to the way the Messinian event is studied (onshore through fieldwork or offshore using seismic data). The water-level fall in the basin driving evaporite deposition in the more central Mediterranean sumps is estimated to have been at least 1,000–2,000 m. It drove the loss of any surface connection to the world's oceans and the massive erosion of the surrounding continental margins. It created marine seeps and deep karst, as well as large quantities of clastic detrital deposits (including reworked evaporites) before, during, and after widespread marine-fed salt deposition in the deep basin centres (Loncke et al. 2006). Offshore, the top and base of the evaporites can generally be identified on seismic profiles. However, because the deep-basin evaporites themselves have never been sampled by wells, establishing a reliable seismic stratigraphy tie to the onshore is difficult.

What marine geologists tend to call the 'Lower Evaporites' in much of the Mediterranean corresponds to a highly reflective series of probably detrital sediments deposited by slumping processes during the first stage of drawdown (Loncke et al. 2006). In the deep basin, above these layers, acoustically transparent layers characterize locally-mobile evaporites, made essentially of halite. The Upper Evaporites, appearing as layered and reflective packages above these transparent layers, most likely correspond to cyclic alternations of marls and gypsum, as defined by Rouchy and Saint Martin (1992). These beds were possibly deposited in the first stage of transgression marking the end of the MSC. The problem in typing evaporites in the marginal basin to those in the deep basins is that during the maximum intensity of the salinity crisis, erosion was active on the exposed margin and this level shifted in time with the changing water level, leading to various detrital deposits interfingered between salt and the upper evaporites.

The preceding discussion of the inherent, and still not fully resolved, largely tectonically controlled climatic and hydrologic complexities in the Messinian of the Mediterranean is based on more than five decades of detailed scientific work, mostly in exposed marginal basin stratigraphies, where the evaporites are still largely preserved as primary gypsum. With the possible exception of an initial third-order fall in worldwide sealevel cutting off the basin, all these deposits were isolated via active tectonism. Their finer stratigraphic geometries are not reflective of world eustasy but of more local tectonically-induced drawdown, climate variation and autocyclicity.

The crux of the problem in applying the results of detailed Mediterranean Messinian studies to better interpret the internal stratigraphy of other older basinwide evaporites is that the larger more representative volumes of basinwide Mediterranean evaporites are as yet unstudied. They are preserved beneath the present deepwater centres of the various Mediterranean basins. These bedded sections currently lie beneath hundreds of metres of Pliocene and Pleistocene sediment; only halokinetic intervals or dissolved salt edges lie within a few tens of metres of the modern deep seafloor. With the exception of a few DSDP holes that intersected the uppermost few metres of these salts, the internal stratigraphies of these saline giants are largely unsampled and uninterpreted. And yet, we know deposition of a km-thick basinwide salts took place in less than 300,000–400,000 years. By definition, the total package of the Messinian sequence must be a fourth-order sequence (Table 5.8). It implies that internal reflectors layers and cycles seen in seismic sections through thick evaporites, must reflect fifth and sixth order time frames.

Any eustatic curves, based on seismic that encapsulates the very high accumulation rates of basinwide evaporites in large basin-centre positions in the Mediterranean, will outline very high frequency responses. Work on Messinian evaporites implies that ancient basinwide evaporites are also depositional systems with internal responses not related to world sealevel changes. If so, then a comparison of eustatic curves derived from internal geometries of basinwide evaporites with lower order eustatic curves, derived from the worldwide study of various marine carbonate or siliciclastic sequences, is simply not possible. The internal reflectors and responses that we can resolve seismically within a basinwide evaporite unit are responding to water level changes that are far too short-term to be compared with the eustatic information captured in classic Vail or Exxon-style sealevel curves.

We cannot correlate the various eustatic peaks and troughs outlined by the depositional tracts in either open marine carbonates or siliciclastic system to layers in thick evaporite beds, they are responding to different time-based waterlevel amplitudes and climatic frequencies. The highest seismically resolvable frequencies in an open marine sequence are third, and perhaps the occasional fourth, order responses. In basinwide evaporite cycles we are looking at seismically resolvable bounding surfaces that are responses to fifth or sixth order environmental changes.

Outside of the Mediterranean we can see other complications to a notion of world-scale Miocene eustasy controlling basinwide evaporite deposition. Work in the Neogene sediments in the Red Sea and the Gulf of Suez has shown that the concept of maximum regional aridity corresponding to times of maximum evaporite accumulation and minimal clastic accumulation is not that simple (Griffin 1999). Studies of the Miocene/Plio-Pleistocene succession in the Gulf of Suez and the Red Sea have shown that the Messinian sediments (Zeit Formation and equivalents) were deposited at rates greater than other units of the Miocene/Plio-Pleistocene. The Zeit Formation contains a significantly higher clastic content than the underlying evaporitic South Gharib Formation indicating that the Messinian interval in this region, adjacent to the main Mediterranean basin, was a time of high rainfall and high sediment yield rates. This period, named the Zeit Wet Phase, stands in marked contrast to the arid conditions of the preceding Tortonian Stage when halite-bearing South Gharib Formation and its equivalents were precipitated in the Gulf of Suez and Red Sea (Griffin 1999). It suggests that the Zeit Wet Phase was marked by high monsoonal activity and that this wet phase peaked in the late Messinian. This was the time of the lowstand maximum in the Mediterranean. So, using the most recent example we have of a saline giant, the deposition of the 1-km-plus evaporite units in the various Mediterranean basin centre sumps corresponds to a two dimensional bounding surface or centripetal unconformity (M-marker) on the basin margins immediately outside of the evaporite depositing areas. This should be the starting point for any seismic-based correlation of the evaporites (or their subsequent dissolution breccias) with adjacent normal marine sediments. This erosion surface (a major sequence boundary) is millions of years younger than the erosion surface formed when Middle Miocene salts formed in the adjacent Red Sea basin. It underlines that scientific principle well known to Ancient Greek philosophers, namely, “similarity is not equivalence”.

The corollary, when interpreting intrasalt seismic reflectors in any ancient evaporite, is a question; Is it possible to attempt a sequence stratigraphic age comparison between marine sediments and layered non evaporite deposits sandwiched between the various salt beds of a marine-fed saline giant? Unless we clearly define all sequence boundaries and realise that thick beds of evaporites equate with regional unconformities in surrounding sediments, we may be comparing chalk and cheese. Yet some authors have been courageous enough to attempt internal sequence stratigraphy of ancient saline giants based on various eustatic scales. We shall now look at such a set of studies in the Zechstein evaporites.

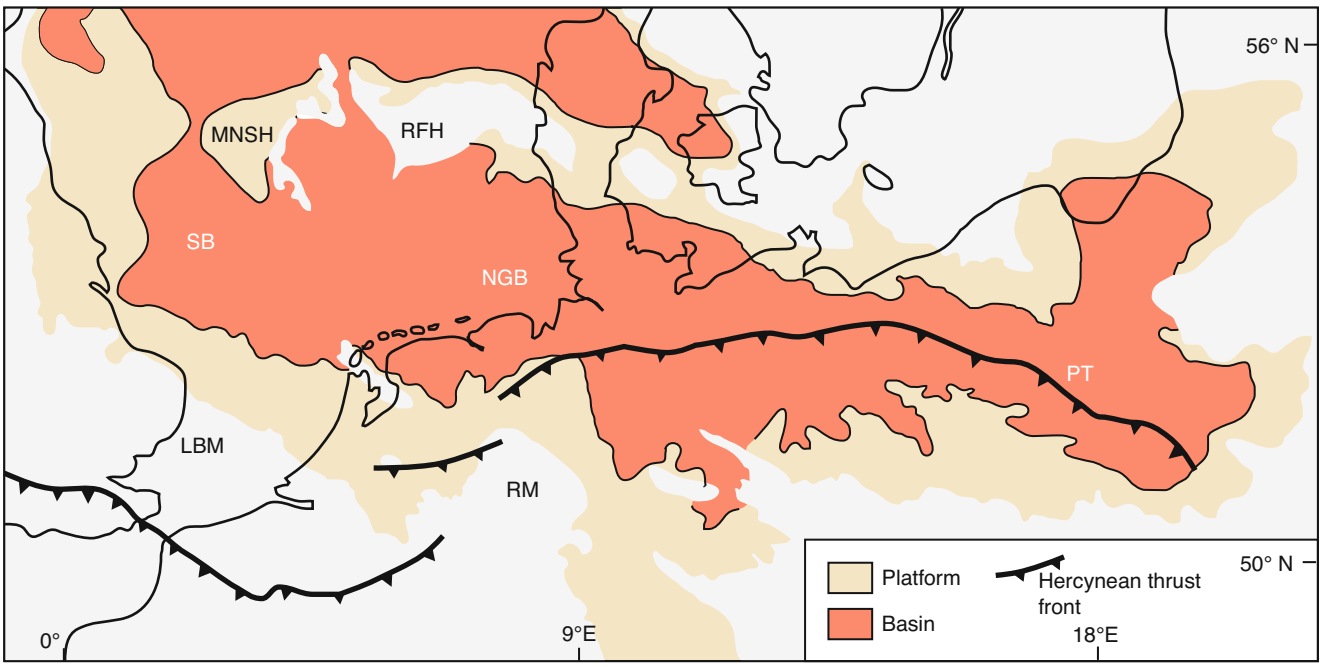

Fig. 5.63 Facies distribution in the southern Zechstein Basin (After Geluk 2000). The basin is bordered to the north by the Mid North Sea High and Ringkøbing-Fyn High and the London-Brabant Massif and Rhenish Massif in the south. Stratigraphic Evolution in the Zechstein

In the Late Permian greenhouse world an area of approximately 600,000 km^2 in northern Europe was covered by the waters of the epicontinental Zechstein Sea (Fig. 5.63). The sea was relatively shallow; its maximum basin-centre depth is estimated to have been ≈300 m in the early mesohaline stage prior to complete isolation and drawdown (Brongersma-Sanders 1971).

The basin was subdivided into two main east–west oriented basins, called the Northern and Southern Permian Basins, which were separated by a sequence of palaeo–highs, the Mid-North Sea and Ringkøbing-Fyn Highs. Lithostratigraphic similarities between the evaporitic fill of the two basins suggest that the highs did not prevent the free surface exchange of brine between the north and south regions of the Zechstein depression.

During the Late Permian, this part of northern Europe lay at a palaeolatitude of ≈25°N and within the Pangaean supercontinent. This, coupled with the restricted and at times marine-fed seepage supply of seawater from the Boreal Ocean to the North and the Tethys Ocean to the Southeast, resulted in deposition of thick sequences of bedded sulphate and halite evaporites, along with minor volumes of bittern salts. Prior to the onset of marine-fed seepage that typifies the Zechstein Series, the basin accumulated terrigenous desert sediments of the Rotliegende/Wiessliegend Formation, in an arid continental playa/eolian/wadi setting. It was a sub-sealevel depression created by the final stages of the Variscan Orogeny (Carboniferous-Early Permian). During times of increases runoff, a saline ephemeral Rotliegend lake periodically covered wide expanses of the southern Permian basin (Legler et al. 2011). As it dried, waters reached $CaSO_4$ saturation but widespread deposition of halite beds did not occur. The region at that time was characterised by the development of pull-apart rift basins that evolved into passive margins by the Middle Permian-Triassic period.

This time frame encompasses the main stage of basin subsidence and is characterised by aridity and periodic widespread evaporite deposition including Zechstein evaporites in the Late Permian, followed by Muschelkalk salts in the Middle Triassic and Keuper salts in the Late Triassic (Fig. 5.64a). The Mesozoic of NW Europe was also characterised by ongoing metasomatic and hydrothermal activity, as evident from multiphase, cross-cutting, intraformational veinlets. The following Rhaetian through Lower Cretaceous period was marked by intensive faulting, rifting, and the initiation through much of the basin of large-scale halokinesis, sourced in the Zechstein halites.

The Zechstein encompasses the last 5–7 million years of the Permian (Fig. 5.64a; Menning 1995). Most drill intersections and most sequence stratigraphic interpretations have been completed in the southern basin. This is the region associated with onshore hydrocarbons in the Zechstein of the Nederlands and northern Germany and is also a region where

halite and potash salts have been mined for centuries (Chaps. 6 and 11). Late Permian fill in the southern Zechstein Basin constitutes a classic basinwide deposit, with circumbasinal transitions from an evaporite platform about the basin edge into a deeper-water centre dominated by laminites (Figs. 5.65 and 5.66b).

Traditionally, the Zechstein Group is divided by its mineralogy into evaporitic cycles that reflect progressive evaporation from less saline to more saline salts. This method defined four main evaporite cycles (Z1–Z4) and rudimentary fifth and sixth cycles (Z1–Z6; Fig. 5.65a). An ideal Zechstein cycle starts with a transgressive nonevaporitic "shale," followed by carbonates and culminates in thick evaporites (mostly halite/anhydrite). Since most of the classic formation boundaries are picked at what are now considered by sequence stratigraphers to be maximum flooding surfaces (at base Z1: Coppershale or Kupferschiefer Member; base Z3: Grey Salt Clay Member; base Z4: Red Salt Clay Member), the lithostratigraphy of the Zechstein Group closely approaches that of units broken out using the concepts of genetic sequence stratigraphy (Fig. 5.64b; Geluk 2000). It means these basal transgressive units (mfs) provide a base for correlation of the main lithostratigraphic units. The lower three Zechstein evaporite cycles (Z1–Z3)

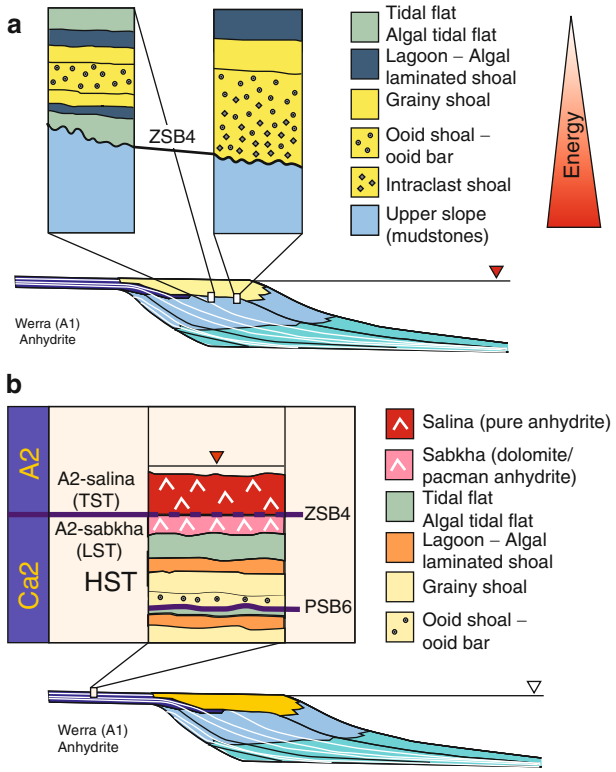

Fig. 5.66 Facies associations in Ca2 carbonate platform, Zechstein Basin, northwest Germany (After Leyrer et al. 2001). (**a**) Slope position (HST of ZS3 to TST of ZS4). (**b**) Platform position (HST of ZS3 to TST of ZS4)

are marine-fed basinwides. They contain evaporitic carbonates in their basal parts that indicate initial precipitation from brines with near normal marine salinities (Taylor 1990; Leyrer et al. 2001). The overlying anhydrites and salts in these cycles reflect the progressive evaporation of marine-fed salterns and deeper water brine lakes. The question is how do these mineralogies relate to changes in relative water depth in the Basin?

Classic transgressive/regressive cycles interpreted in the Z1 and z cycles have been related to glacio-eustatic sealevel fluctuations by Strohmenger et al. (1996a, b) and Leyrer et al. (2001). Earlier, Tucker (1991) published an alternative to the classic Zechstein stratigraphy based on what he interpreted as third order sequences (ZS1–ZS7). In it he correlates evaporites with sealevel lowstands (LSTs) and carbonates with sealevel highstands (TSTs and HSTs). Tucker's approach, in tying evaporites to lowstands, is opposite to that of the classic stratigraphic approach in the basin (pre-sequence stratigraphy) that tied evaporite deposits to highstands, but his approach is more realistic in terms of evaporite hydrology. His classification was criticised firstly by Goodall et al. (1992) on the basis he assumed external sealevel exerted a one-for-one control on evaporite mineralogy and position, and then by Strohmenger et al. (1996a) as his classification did not respect exposure surfaces and stratal geometries.

Strohmenger et al. (1996a, b) and Leyrer et al. (2001) went on to refine a sequence stratigraphic approach for the basal Zechstein (Z1 and Z2) using facies analysis, geometric relationships, stacking patterns and forward modelling based on core and seismic from the subsurface of northern Germany (Fig. 5.66). However, Strohmenger et al. (op. cits.) found that due to the poor quality of internal reflectors in the Zechstein sequence they could not use the usual approach of interpreting the major depositional units from seismic, then establishing a seismic stratigraphic model and then tying well data to seismic. Rather they had to first establish a geological model based on detailed stratigraphic analysis of core and outcrop. Then they developed a sequence stratigraphic framework and then interpreted and forward modelled the intra-Zechstein reflectors. Their analysis (Fig. 5.66) shows that reworked sandstones of the Weissliegend and/or the Zechstein conglomerate (Z1C) record the initial transgression of the Zechstein sea and overlie the Zechstein sequence boundary (ZSB1). Transgressive systems tract (TST) deposits of the first Zechstein sequence (ZS1) are also represented by deeper marine carbonates of the Mutterflöz (T1Ca). The overlying Kupferschiefer is interpreted as a condensed section (CS) indicating maximum flooding (mfs) of the first Zechstein sequence. The bulk of the shallow water Zechstein limestone (Ca1) is interpreted as a highstand systems tract (HST). It is separated from the thin uppermost part of the Zechstein Limestone by a karst horizon corresponding to an erosive sequence boundary (ZSB2).

Correlatable shallow water carbonates (oncolites and stromatolites) indicate lowstand systems tracts (LST) of the second Zechstein sequence (ZS2; Fig. 5.66). The uppermost part of the Zechstein Limestone represents the transgressive systems tract of the second Zechstein sequence (ZS2). According to Strohmenger et al. (1996a, b) there is no indication of a sequence boundary at the top of the Ca-1 platform carbonates (contrasts with Tucker 1991). They argue Ca1 carbonates, in a basinal position, show a deepening upward tendency toward the superimposed deposits of the A1 sulphates. They place the maximum flooding surface (mfs) of the second Zechstein sequence at the top of the Ca1 platform carbonates. The overlying anhydrites of the A-1 sulphate platform (Werra Anhydrite) are interpreted as predominantly highstand systems tract deposits displaying an erosive sequence boundary (ZSB3) at its top. This is in direct contradiction with Tucker (1991) and according to Strohmenger et al. (1996a, b) it is only in the slope and basinal environments that the A1 also represents lowstand wedge deposits of the third Zechstein sequence (ZS3).

In reality, each of the evaporite cycles is made up of a highly complicated stack of parasequences that sequence stratigraphers argue represent higher order sea-level fluctuations. In my opinion, climate-related intrabasinal autocyclicity is a more likely driving mechanism at the scale of the

parasequences. The contradiction underlies the difficulties in sequence stratigraphic analysis of evaporite deposits using models derived from geometries and 3rd order eustatic responses of marine systems. The terms highstand systems tract and lowstand systems tract are largely defined by whether the shelf of the basin that is under consideration is covered by water. There is no concept as yet in the sequence stratigraphic literature that an aggrading evaporite bed causes its overlying brine level to rise (autocyclic hydrologic feedback – the concept of evaporites "fill and spill").

Most Zechstein sequence stratigraphic interpretations of the Zechstein prior to 2000 assume a surface connection to the ocean at all times and that there were direct marine eustatic responses in brine base level. Using the late Miocene sediments of the Mediterranean as a template, we have already discussed the likely errors inherent in this assumption of hydrographic connection to the open ocean. In the marine realm we are talking about eustatic sealevel amplitudes of no more than a 100 or so metres in icehouse periods and less than decametres in greenhouse periods. There is an inherent assumption in classic sequence stratigraphy that in greenhouse and icehouse times the prime locus of sedimentation is near a marine shoreline, either on the shelf or just basinward of the shelf break (Type 2 and Type 1 boundaries). In an evaporite basin that is undergoing drawdown we are discussing an initial hydrographic isolation (mesohaline carbonates are considered to indicate the mfs by most sequence stratigraphers) quickly followed by a water level fall of more than 500–1,000 m and the onset of widespread evaporite precipitation. Any strandline in the system will likely have migrated hundreds of kilometres and be situated well out on the old continental slope at the onset of evaporite accumulation. These drawdown unconformities are likely correlate to salt deposition in basin sumps. Clearly, marine eustatic models do not apply. At hydrologic equilibrium (inflow = loss) the whole marine highstand shelf and slope, as well as part of the basin floor, is exposed. Water levels even in the deepest parts of the basin are mostly less than a few tens of metres and no more than 100 or 200 m. In this scenario the locus of maximum deposition is not tied to sediment supply from outside the basin (siliciclastics) or to any need for shallow waters atop a carbonate platform. The maximum locus of evaporite deposition is in the lowest part of the isolated depression in many drawdown basins with no surface connection to the ocean. This area is assumed to be deep water by sequence stratigraphers, but textures from the salts accumulating there are typically saltern or salt pan with local deeper water cumulates.

Defining the stratigraphic significance of sequence boundaries, such as the ZSB2, are more problematic in such hydrographically isolated drawdown scenario (Fig. 5.65). Strohmenger argues that the Ca1 carbonates, in basinal position, show a deepening upward tendency toward the superimposed deposits of the A1 sulphates. What he is observing is a gradational transition. The term deepening is probably too categorical in this scenario. If the basin is isolated so that thick gypsum/anhydrite can accumulate, then the brine level in the basin must be lowered with respect to the old shelf. The A1 profile above the ZSB2 sequence boundary is most likely subaqueous throughout, and is a "brining upward" profile. The sequence does not deepen upward, it is continuously subaqueous but brines upward as the regional water level is lowered. That is, the average annual salinity of the brine body is increasing up section and ongoing lowering of the brine level does not stop until an effective brine curtain/inflow equilibrium is established. The brine level is not reflecting marine eustasy but a hydrological/climatic balance.

Stacking patterns laid down in such scenarios are not well understood, but should not be forced to fit the classic paradigms of marine sequence stratigraphy. We are looking at an evaporite system that probably was at any time deeper or shallower depending on the vagaries of climate and tectonics and largely independent of eustasy. For example all we can say in terms of the A1-sulphates is that at no time during the deposition of the sulphate phase was the water deeper than a few hundred metres and probably was mostly less than tens of metres deep (Warren 1989; Kendall 1992). During the preceding carbonate platform phase the water body was obviously less saline and probably deeper on average than during sulphate deposition and tended toward meromictic rather then holomictic conditions.

Even in the carbonate horizons separating the main evaporite phases, thought by many to be marine, the drastic changes in intrabasinal base level create problems in creating a reliable sequence stratigraphic interpretation if interpreters have assumed a hydrographically connected sealevel in the basin. The Zechstein 2 Carbonate (Ca2) overlies the A1-Sulphate (Werra Anhydrite) and according to Strohmenger et al. (1996a, b) and Leyrer et al. (2001) encompasses transgressive systems tract as well as highstand systems tract deposits of Zechstein sequence ZS3. The maximum flooding of the Ca2 is correlated with the flooding of the A1-sulphate platform. Therefore, Ca2-platform carbonates (Main Dolomite) are dominated by shallow-water highstand deposits of the third Zechstein sequence (ZS3). Deposits of the Ca2 transgressive systems tract are coated-grain and composite-grain packstones/grainstones that contain reworked anhydrite clasts of the underlying Al. Leyrer et al. (2001) clearly demonstrate that the depositional facies, and hence the porosity distribution of the gas-bearing Ca-2 carbonates in the subsurface of northern Germany, are in large part controlled by high energy positions that reflect a shallow "sea" superimposed on the underlying evaporite topography. This topography was created prior to evaporitic carbonate

deposition by saltern to basin transitions in the underlying Werra (A1) Anhydrite.

An upper contact of the Ca2 carbonate is defined by the transition of shallow-water Ca2 carbonates into the overlying anhydrites of the A2 (Strohmenger et al. 1996a, b; Leyrer et al. 2001). The stratigraphic limit between the Ca2 and A2 is highly arbitrary and conventionally drawn in wells by the last up-section occurrence of bedded dolomite, but is gradational. Carbonates near the contact show typical Ca2 facies (e.g. algal-laminated coated-grain and composite-grain wackestones/packstones and algal bindstones) and are often intercalated with bedded anhydrites of the A2 (Fig. 5.66). Furthermore, according to Strohmenger et al. (op. cit.), the platform anhydrites of the A2 at this contact can display ghost structures of Ca2 facies. Leyrer (pers comm.) appropriately describes this as "Pacman" anhydrite, although it is perhaps more widely known as anhydritization. It indicates that the lower part of the A2 can be interpreted as sabkha/pan deposits (A2-sabkha) cannibalising the Ca2 carbonate and indicating the emergence of the Ca2 platform at the end of Ca2 time (Fig. 5.66b). Alternately, the widespread evaporites within and replacing A2 carbonates could be a form of reflux-driven cementation/replacement created during deposition of the overlying saltern anhydrite. In my opinion this contact is perhaps tied to the time when the ooid/grainstone shoal along the basin edge became sufficiently well developed to isolate the platform lagoon and so it converted to an evaporitic mudflat or saltern.

According to Strohmenger et al. (1996a, b) the fourth sequence boundary of the Basal Zechstein (ZSB4) occurs not on top of the Ca2 shallow-water carbonates, but somewhere within the A2-platform deposits, once again in contrast to the model of Tucker 1991. The lower part of the A2 (anhydritised or Pacman-style Ca2 facies) is interpreted as the time equivalent of shallow-water Ca2 carbonates that overlie deeper-marine upper slope carbonates in a basinward position, corresponding to the lowstand systems tract (lowstand wedge) of the fourth Zechstein sequence (ZS4; Fig. 5.66a). The uppermost part of the A2 (pure salina-type anhydrites on top of pacman anhydrites showing ghost structures of Ca2-platform facies) is thought to represent the transgressive systems tract of the fourth Zechstein sequence (ZS4; Fig. 5.66b). The relatively thick anhydrite accumulations of the A2 (approx. 100 m), which occur basinward of the Ca2 slope, are thought to represent both lowstand systems tract as well as transgressive systems tract deposits of the fourth Zechstein sequence (ZS4).

According to Strohmenger et al. (1996a, b) the basinward progradation of the third-order Basal Zechstein depositional sequences is forced by the tectono-eustatic, first- and second-order sealevel lowstand of the latest Permian. The cyclicity observed within the different systems tracts are thought to be caused by higher order sealevel fluctuations with durations of 0.08–0.5 Ma (fourth-order cycles), 0.03–0.08 Ma (fifth-order cycles) or 0.01–0.03 Ma (sixth-order cycles) and related to orbitally controlled Milankovitch cycles (Leyrer et al. 2001). Strohmenger et al. (1996a, b) go on to argue that the 0.1 and/or 0.4 Ma Milankovitch cycles indicate to high-amplitude sealevel fluctuations throughout the Late Permian. They draw analogies to small-scale sequences as described from the Yates Formation (United States, Permian Basin) by Borer and Harris (1991) and from the Wegener Halvø Formation (Jameson Land Basin, East Greenland) by Scholle et al. (1993).

In my opinion, there is a problem in comparing eustatic sealevel models, derived from platform evaporites of the Permian of Greenland and West Texas, to the basinwide drawndown platform evaporites of the Zechstein. Work by Strohmenger et al. (1996a, b), and Steinhoff and Strohmenger (1999) provide excellent core-based facies breakdowns of the evaporite stratigraphy and mapping of water level changes and hence predictors of porosity in units such as the Ca-2 carbonates, which are the major onshore gas reservoir in northern Germany (Leyrer et al. 2001). Where I have a problem is accepting the leap of faith in applying marine-derived Vail-curve age models (timing of cycle orders) to the brine level fluctuations that controlled the shelf to basin geometries of the Basal Zechstein. This approach ignores the need for complete lack of a surface connection with the ocean to deposit thick evaporite sequences. Furthermore, if we look to analogies in the marine-fed saline giants subbasins of the Messinian, then sedimentation rates used by Strohmenger et al. for sealevel ties to evaporite packages, such as the A1 sulphates, are much too slow. Thick basin-centre evaporites require particular conditions of tectonic isolation to form, when this does occur the evaporites are laid down very rapidly (5th and 6th order cycles), as they were in the Mediterranean. Since 2005, studies of Zechstein sequence stratigraphy have come to the conclusion that the layering/geometries in the Zechstein Series largely reflects variation basin bottom topography and autocyclic/climatic changes. Accordingly, when building sequence stratigraphic interpretations, authors\tend to focus on the rock textures and assume basin isolation from any eustatic marine connection (Becker and Bechstadt 2006; Slowakiewicz and Mikolajewski 2009). Outcomes tend to underline the difficulty in applying a single interpretive model at the scale of the Zechstein Basin. To quote Becker and Bechstadt (2006, p. 1116)

"Sequence stratigraphic interpretation of isolated evaporite basins is challenging, given that physico-chemical conditions influence sedimentation rates and evaporite deposits geometries. Brine fluctuations, often independent from sealevel changes, create and destroy accommodation space. Sequence stratigraphic correlation with the Southern Zechstein Basin based on shallowing-upward parasequences reflects related water/brine level fluctuations in the two

regions. Correlation with the Southern Zechstein Basin results in a reinterpretation and redefinition of the cyclicity of this basin: in contrast to other cyclostratigraphic models assuming deepening-upward, the cycles in the Southern Zechstein and the Hessian Basins are both interpreted here as shallowing-upward successions."

Sequence Stratigraphy in the Silurian Salina Group of the Michigan Basin

The Michigan basin in the Late Silurian (greenhouse climate mode) was a roughly circular intracratonic sag basin, approximately 400 km in diameter and fringed by reef pinnacles passing updip into an extensive rimmed platform (Fig. 5.67a; Brennan and Lowenstein 2002). The reefs are encased in salts of the Salina Group. When Salina Group evaporite deposition commenced some 423 Ma the palaeolatitude was approximately 26°S, and approximately 20°S by 417 Ma, when Salina Group deposition ended (Brennan and Lowenstein 2002). Prior to its hydrographic isolation, marine waters entered from the southern Kokomo Sea, via the Clinton Inlet, and from the northern Moose River Basin via the Georgian Inlet (Briggs et al. 1980). A relative sea-level drop in the late Wenlockian produced restriction and isolated the Michigan Basin from the Silurian ocean;

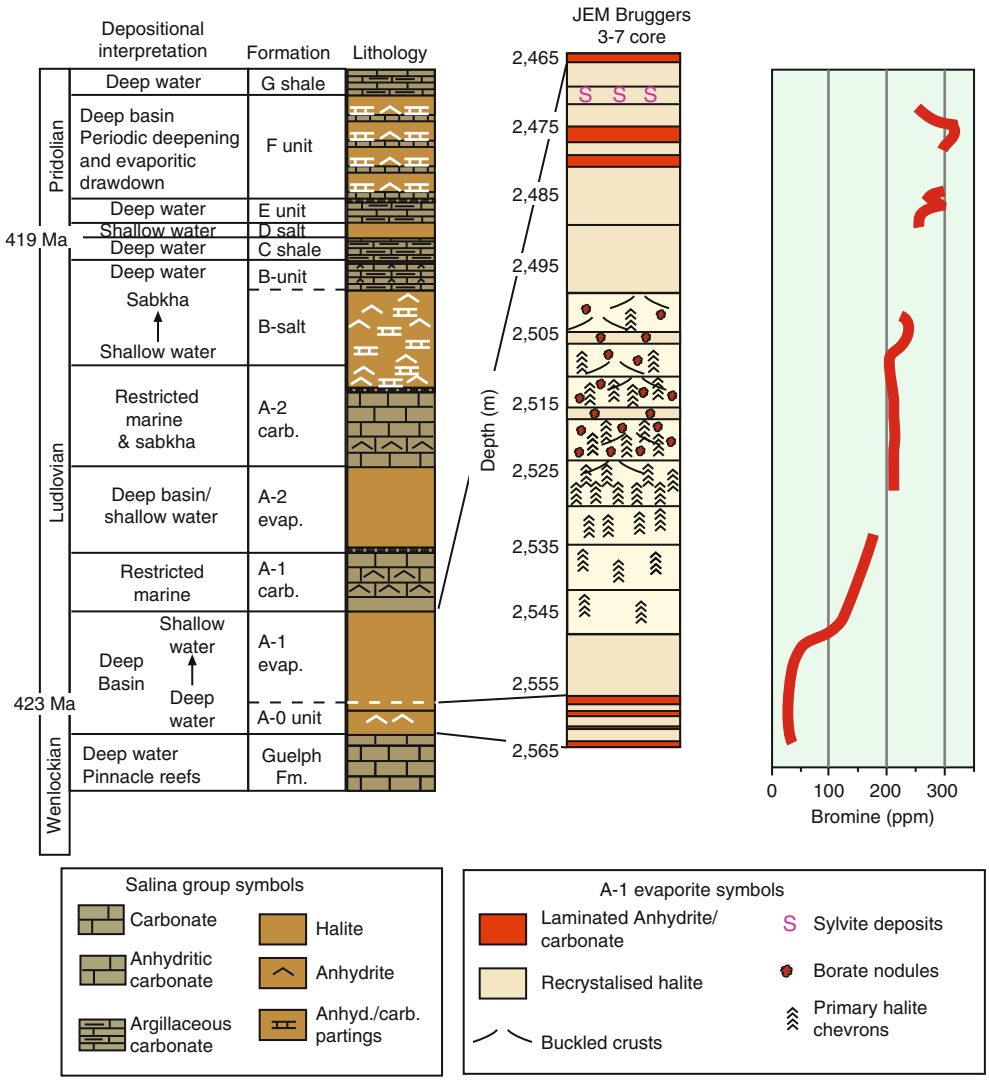

Fig. 5.68 Stratigraphy of the Salina Group (*left column*) and detailed facies of A-0 and A-1 Evaporites in Bruggers 3–7 core (*right column*), Michigan Basin (Upper Silurian). The thicknesses of the Salina Group Formations are not to scale. The depositional interpretations of the Salina Group are primarily from Leibold (1992) (After Brennan and Lowenstein 2002)

throughout, the earth was in greenhouse climate mode (Dellwig 1955; Dellwig and Evans 1969). The deep-water A-0 unit (calcite–anhydrite–halite), the first deposit associated with this sealevel drop, is conformably overlain by the A-1 Evaporite and defines the transition into mesohaline conditions as the surface connection to the open ocean was lost (Fig. 5.68; Dellwig 1955; Nurmi and Friedman 1977; Gill 1977; Briggs et al. 1980; Cercone 1988; Leibold and Howell 1991).

Middle Silurian pinnacle reef reservoirs in the Michigan Basin are isolated stromatoporoid/coral-crinoid buildups, which are encased and sealed by a combination of Upper Silurian halite, anhydrite and fine-grained carbonate (Figs. 5.66 and 5.67). Reef pinnacles form two hydrocarbon belts some 16–24 km (10–15 miles) wide that extend basinward from the steep inner face of an extensive, but nonproductive, barrier reef (Chap. 10). The basinal equivalent of the reefs is a thin carbonate some 18–24 m (60–80 ft) thick. The reef/bank rimmed platform is dolomitised, as are most of the pinnacles, although a few of the more basinal pinnacles are still limestone (Sears and Lucia 1979, 1980). Pinnacles are capped by an erosional unconformity and reef growth had ceased well before the basinwide drawdown events that deposited the encasing evaporite cycles (Fig. 5.67a; Gill 1985). Drawdown created the karst horizon that caps the marine reef sediments of the Guelph Formation and immediately underlies the stromatolitic capstones formed during deposition of the A-1 evaporitic carbonates (Mesolella et al. 1974). During drawdown the pinnacles formed topographic highs and were sites of marine groundwater escape (pisolitic/stromatolitic seepage facies) until they were enveloped in aggrading salts of the A-2 cycle.

The sealing evaporites of the Lower Salina Group were some of the first thick sequences of salt to be interpreted as containing textures of more than one depositional setting. The earliest depositional interpretations of these salts were as deepwater deposits (Dellwig 1955; Dellwig and Evans 1969). Nurmi and Friedman (1977) challenged many of Dellwig's conclusions. They interpreted much of the halite as having formed as stacked halite crusts precipitated beneath shallow brine sheets subject to periodic drying. The arguments of Nurmi and Friedman were rooted strongly in processes observed in Holocene salt crusts. A shallow to ephemeral water model came to dominate subsequent interpretations and have been reinforced by subsequent detailed geochemical studies (Fig. 5.52; Brennan and Lowenstein 2002).

Thus, the evaporites imply episodes of evaporative drawdown and that there was subaerial exposure of the reef crests prior to their encasement in salt, via a process of "fill and spill." The complex rapid rise and fall of the brine level over vertical distance of several tens of metres during the accumulation of the Salina Group drove ongoing alteration, dolomitisation and evaporite plugging, not just of the Salina Group but also in the Niagaran, especially in those pinnacles sitting below zones where thick sequences of evaporites were accumulating.

Detailed stratigraphic analysis of the evaporites and evaporitic carbonates in the vicinity of producing pinnacles clearly define the complexity of sequences accumulating under a system of basinwide evaporitic drawdown. Using more than 350 wells and numerous cores, Leibold (1992) and Howell and Leibold III (1992), defined four composite sequences: Niagaran, A-1 Unit, A-2 Unit, and the B Unit (Fig. 5.67). The Niagara Group carbonates comprise a dominantly intrabasinal highstand composite sequence that was deposited on a pre-existing carbonate ramp and was interrupted by at least one major drawdown event. Numerous Type 1 unconformities on the carbonate platform margin were recognised by Leibold (op. cit.) and related to evaporative drawdown events. Thus, the Niagaran is a composite sequence made up of two sequences separated by an unconformity. The lower sequence consists of three parasequence sets: aggradational ("White Niagaran" ramp), transgressive ("Gray Niagaran"), and progradational ("Brown Niagaran"). The Brown Niagaran includes a distinct stromatoporoid shelf-bank margin and a zone of pinnacle reef growth. Biostratigraphic, lithostratigraphic and isotopic evidence indicates Upper Niagaran water depths in the basin exceeded 250 m prior to drawdown. The Brown Niagaran parasequence set is interrupted by a drawdown unconformity, represented by the subaerial exposure surface mentioned earlier. It extends below the shelf margin into the inter-pinnacle reef areas and defines a type 1 boundary (Fig. 5.67).

A second drawdown event ended Niagaran deposition and initiated the A-1 Unit as a thick (140 m) lowstand evaporite wedge in the basin (Figs. 5.67 and 5.68). Deposition of the halitedominated A-1 Evaporite occurred in an initially somewhat deeper brine that progressively shallowed. The JEM Bruggers 3–7 core, Missaukee County, Michigan completely cored the A-1 evaporite (Fig. 5.68; Leibold 1992). The basal 10 m of the A-1 Evaporite is composed of alternating layers of coarse, clear halite (50–150 mm thick) and anhydrite (30–100 mm thick). It was interpreted as a possibly deeper water unit showing widespread halite recrystallisation, but models of meshwork halite (Dead Sea holomictic/meromictic analogue) were not available in the early 1990s. This unit is overlain by 25 m of chevron-rich halite, the upper 5 m contains bedding planes dipping up to 40°, which have been interpreted by Leibold (op cit.) as buckled pressure-ridged pan halite crusts, formed during subaerial exposure (Leibold 1992). This is overlain by the "mid-basin potash facies", which is up to 60 m thick and composed of halite and sylvite elsewhere in the Michigan Basin (Leibold 1992). The potash facies in the JEM Bruggers core does not contain bedded sylvite; however, primary fluid inclusions in the halite do contain daughter crystals of sylvite, carnallite, and tachyhydrite (Leibold 1992). These potash facies also contain borate nodules and buckled salt crust polygons indicating salinepan deposition with periodic basin desiccation. The mid-basin potash facies is overlain by halite that has been pervasively recrystallised (Leibold 1992) (Fig. 5.69).

Leibold (1992) and Raup and Hite (1993) analysed bromide from bulk halite samples in the JEM Bruggers 3–7 core and showed that coarse halite and chevron-rich facies at the bottom of the A-1 Evaporite display a systematic upsection increase in Br concentration, ranging from 25 to 200 ppm. This type of bromine profile, along with the upward increase in the density of chevrons, and buckled crust polygons towards the top of the chevron-rich facies indicate that this lowermost section of the A-1 halite formed by the progressive evaporation of a large shallow body of brine, which dried out at the top of the unit. In contrast, halite from the mid-basin potash facies does not exhibit any systematic increase in the Br concentrations. Instead, the Br is relatively high (210 ppm) throughout, which suggests these halites did not form strictly by the progressive evaporation of a large body of Silurian seawater (Fig. 5.68). The A-1 Evaporite is overlain by the A-1 Carbonate, which signifies a higher volume of marine brine in the Michigan Basin, this could indicate a more humid climate or a possible renewed surface connection to the Silurian ocean. The A-1 Carbonate is overlain by the A-2 Evaporite, which indicates a second period of increased aridity or the

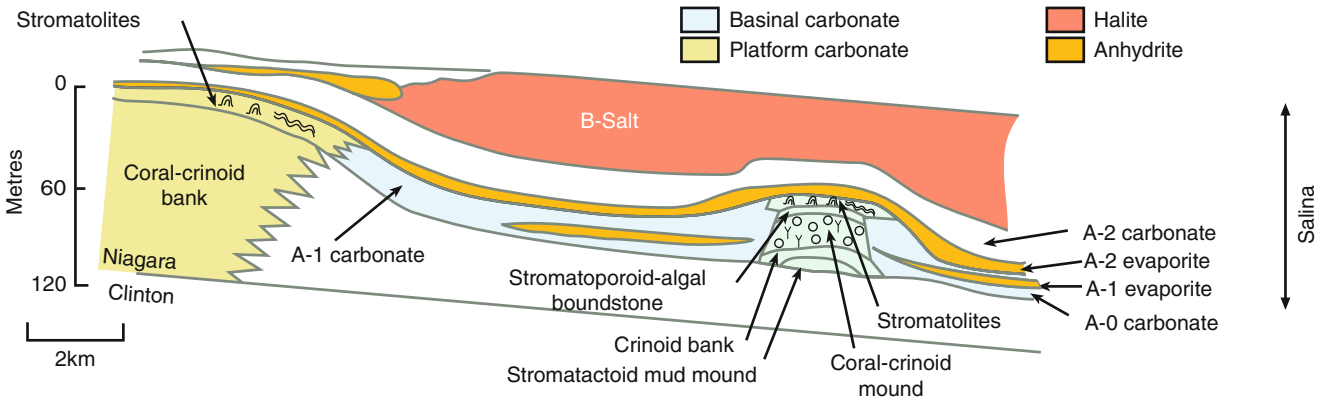

Fig. 5.69 Schematic showing facies relationships of a shelf to basin profile in the Silurian of the southern Michigan Basin (In part after Sarg 2001)

return to isolation of the Michigan Basin from the Silurian ocean. The A-2 carbonate, a gray, nonfossiliferous mudstone, conformably overlies the A-2 Evaporite. The B Evaporite conformably overlies the A-2 Carbonate and is composed of two units, the B-Salt and the overlying B Unit. The B-Salt deposits consist of halite interbedded with anhydrite and dolomite partings (Leibold 1992), which likely formed within a shallow isolated central basin. The B-Unit is interpreted by Leibold (op, cit.) as a deepwater, anhydrite-rich, argillaceous carbonate, which marks the beginning of a regional transgression. The C Shale, D-Salt, and the E-Unit possibly indicate alternating incursions of seawater and isolation and concentration of the basin waters (Droste and Shaver 1985) or more likely they are responses to climatically induced transitions from meromictic to holomictic basin waters.

The mid-Pridolian F-Unit is the uppermost evaporite formation of the Salina Group and comprises six separate halite units, F-1 to F-6, that are separated by shales, dolomites, and anhydrites (Sonnenfeld and Al-Asam 1991). The lowermost F-1-Salt is composed of continuous beds of chevron-rich halite separated by anhydrite partings (Dellwig and Evans 1969) and resembles similar facies in the A-1 Evaporite. Bromide concentrations increase systematically upsection in the halites of the F-1-Salt (Das et al. 1990), consistent with the profile expected for evaporation of a large body of seawater-fed brine. Sulphur and strontium isotopic analyses of the anhydrite in the F-1 salt are also consistent with Silurian seawater values (Das et al. 1990).

The thickness, orientation and mineralogical zonation of marginal evaporite wedges in the basal A-1 Evaporite overlying the Niagaran sequence required initial minimum brine depths of 20 m and so imply wind and water currents influenced evaporite deposition (Sarg 2001). Overlying lower A-1 Evaporite salts were deposited in shallower brines, less that a metre or two deep, as indicated by chevron-rich growth-aligned halite pan textures. Middle and upper A-1 evaporite lithofacies contain evidence of alternating very shallow brine and subaerial depositional conditions (Leibold 1992). The Middle A-1 lithofacies are sylvite- and borate-rich, with sylvite beds present only in the central Michigan Basin (Fig. 5.67a). Upper A-1 evaporite lithofacies, which Sarg (2001) calls transgressive (I prefer fill and spill), are dominated by stacked, saltpan morphologies. The brine level at this time was well below sealevel and the basin had no surface connection to the open ocean.

Periodic seawater flooding or climatically-induced freshening then renewed carbonate deposition as the A-1 carbonate was deposited across the basin and platform region (Leibold, op. cit.). The A-1 composite sequence was terminated by further drawdown, resulting in a second thick lowstand evaporite wedge (A-2 halite). Reflooding and/or climatically induced freshening initiated multiple stacked A-2 carbonate aggradational sequences, separated by several drawdown unconformities. The B Unit is a composite of carbonate/evaporite sequences, each consisting of an aggradational carbonate parasequence and a lowstand evaporite wedge. These sequences mark the final filling of the basinal depression created during Niagaran carbonate deposition. Thus the A-1 and A-2 units of the Salina Group each comprise a lowstand relative to external sealevel, with each evaporite sequence set overlain by a relative highstand carbonate sequence set. Both composite sequences are punctuated by several, widely-correlatable drawdown events. The B-Evaporite is dominantly a "lowstand" composite sequence consisting of stacked, shallowing-upward evaporite cycles.

Sequence stratigraphic interpretation in the Michigan Basin sequence underscores the difficulties in interpreting an isolated intracratonic basin using unconformity/bounding-surface terminology tied to a set of marine sealevel implications. It is very hard to do this reliably in a basin that lacked a marine connection for most of its evaporite history and in a hydrological situation where intrabasinal water level fluctua-

tions were not necessarily related to extrabasinal eustatic changes. Recognising regional unconformities in core and seismic is the key to any reliable sequence stratigraphic interpretations in this situation. Unfortunately unconformities are numerous in drawdown sequences and correlations of supposed regional unconformities from basin edge to basin centre are difficult. Often it is done based on marine eustatic assumptions and this of course leads to circular arguments in interpretations of eustasy based on a sequence stratigraphic interpretation.

Sarg (2001; his Table 1) lists the Michigan Basin as a type example of a third-order basin centre fill (10–100 m thick) with an onlap basin margin and he places it in the same classification category as the Z1–Z4 units in the Zechstein Basin. A fact to remember when attempting unconformity-based correlation and sequence stratigraphic interpretation is that evaporite aggradation rates are so rapid in a basinwide systems that the basin fill quickly aggrades to the intrabasin hydrological equilibrium (time frames of up to 1–2 km of fill in a few hundred thousand years). It means that in the 1–7 million year long history of any evaporite-filled basin there were long periods, post the attainment of hydrological equilibrium, when not much was happening depositionally. That is, based on the hydrologies detailed in Chaps. 2, 3 and 4 and the chronology of the Messinian in the Mediterranean, we know that evaporite basins fill rapidly with stacks of 5th and 6th order cycles. Using salt thickness to divide evaporite successions into second order (100–1,000 m) versus third order (10–100 m) cycles is an irrelevancy that comes from applying assumptions inherent in a marine eustatic terminology.

Thick-bedded marine-fed evaporites are intrabasinal responses to hydrological evolution and should not be tied to any marine eustatic implication. Marine-fed and the associated concept of hydrological equilibrium (drawdown) are not the same as assuming marine salts fill the basin to sealevel. When 1–2 km thick halite beds were accumulating in the Messinian in Mediterranean basin, the saltpan surface never came within a kilometre of sealevel in the adjacent Atlantic.

Sarg (2001) also argues that the coral-crinoid growth occurred in Michigan Basin pinnacles in a marine reconnection episode, following the A1 evaporite drawdown stage. He equates subsequent coral-crinoid growth to ongoing growth in the Niagaran Platform via a set of regional unconformities. Others have difficulty with this correlation and see stenohaline crinoidcoral deposition ceasing throughout the basin at the end of the Niagaran with subsequent mud mound growth occurring in mesohaline marine-seepage fed conditions. This group of workers choose a different set of unconformity correlations. They see the euryhaline stromatolite/stromatoporoid biomes as the major contributors to mound growth once the Michigan Basin lost its surface connection to the ocean.

This debate of a possible marine surface connection post-A1 carbonate and a definition of the A-0 carbonate, first detailed by Mesolella et al. (1974) in three models of pinnacle-evaporite inter-relationships, continues today. What we have learnt since the early 1970s is that all of the salts in the Michigan basin were deposited in shallow drawndown waters. At the time of evaporite deposition the basin's shelf margin and the crests of the pinnacle reefs were subaerially exposed, the tops of the inactive pinnacles acted as spring mound feeds to the surrounding lows characterised by a halo of anhydritic mudflats passing further out in to halite pans. Anhydrite is present both as a sabkha nodules and as widespread diagenetic cements within marine carbonate hosts. The possibility of widespread early burial anhydrite in Niagaran carbonate is something largely ignored by sequence stratigraphers working in pinnacles in the Michigan Basin, who tend to see anhydrite as a mostly marine mudflat facies not a seepage facies. With the possible exception of the pinnacle crests, no widespread open marine sediments accumulated in the Central Michigan Basin, even at times of freshened (but still evaporitic) carbonate accumulation, such as the A1 and A2 carbonates.

Jurassic Louann Salt, Gulf of Mexico'

Unlike the previous three examples, the Louann Salt has not been sampled or studied as a bedded unit. It has been mined, but only in the crest of diapirs in various onshore localities in the northern Gulf of Mexico. It has been extensively imaged seismically by the oil industry, and the intensity and density of this imaging is what makes the Louann unique in that it is the best documented examples for the study of the evolution of flowing salt features on a passive margin (Chaps. 6 and 10). In this section we shall look at the Louann as an example of the inherent complexity of a basinwide salt bed deposited in a subsealevel rift and consequently subject to the twin deformation mechanisms of gravity gliding and differential loading.

Because of pervasive halokinesis throughout its known extent, little is known of its original depositional layering and so its stratigraphy is typically given as a massive salt unit called the Louann Salt and further subdivisions are not attempted (Fig. 5.70). Anhydrite is present dispersed in the salt mass as are, locally, various potash and borate minerals. The distribution of these bitterns and whether they define particular isolated subbasins with the Louann Salt Province is not known. Seismic shows the current distribution of the Louann Salt is broken up into a series of basins and sub-basins separated by highs where salt is no longer present (Fig. 5.71).

Hudec et al. (2013a, b) use "Gulf of Mexico salt basin" to refer collectively to all Callovian salt basins and sub basins in the Gulf of Mexico (Fig. 5.71). As in many passive-margin salt basins, the main salt mass in the Gulf of Mexico currently lies in two pieces on the opposite sides of an ocean basin. The northern Gulf of Mexico salt basin is typically called the "Louann salt basin." The southern Gulf of Mexico salt basin has many different names, Hudec et al. (2013a) prefer "Isthmian salt basin" (*Cuenca Salina del Istmo*). The Louann salt basin consists of the central Louann salt basin

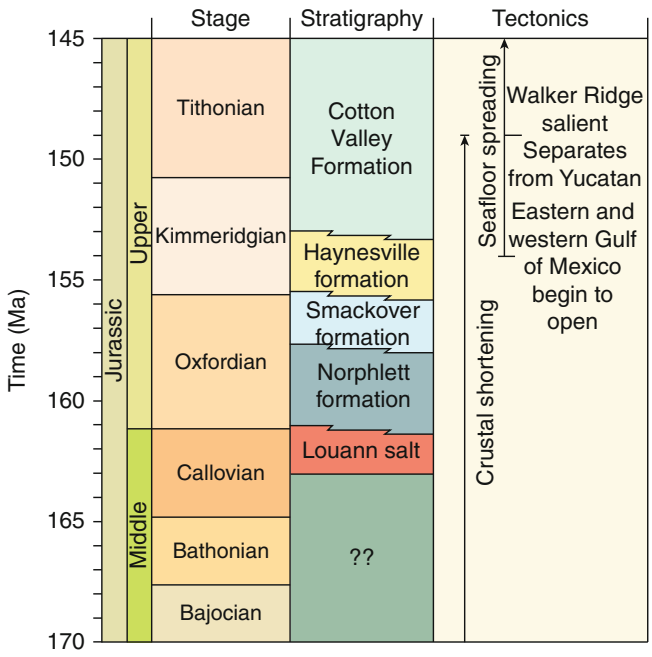

Fig. 5.70 Jurassic stratigraphy in the Gulf of Mexico

and two sets of interior basins around its periphery (Fig. 5.71). On the north, the Toledo Bend flexure separates the central Louann salt basin from the Mississippi, North Louisiana, and East Texas interior salt basins.

The paucity of salt domes and growth faults above the Toledo Bend flexure suggests that salt is thin or absent there, which, in turn, indicates a likely structural high during salt deposition. Anderson (1979) inferred that the flexure localized the Louisiana shelf edge throughout most of the Cretaceous. To the west, the Sabinas and La Popa interior salt basins and the Monterrey salt basin (part of the Monterrey trough) are separated from the central Louann salt basin by the Burro-Salado and Tamaulipas arches. The northwestern end of the Sabinas salt basin connects to the border rift system of Dickinson and Lawton (2001), but most of this rift does not contain significant Callovian salt.

Hudec et al. (2013a) divide the Isthmian salt basin into two subbasins, with thinner salt separating them across a basement ridge extending to the northwest from the northwestern corner of the Yucatan platform (Fig. 5.71). The Campeche salt basin lies southwest of this ridge, in the Bay of Campeche and adjacent onshore areas. The Yucatan salt basin is northeast of the ridge, in the offshore of Yucatan state.

The Proto Gulf of Mexico Basin began forming in Triassic rifting between the Yucatan microplate and the North American plate (Figs. 5.70 and 5.71). It was part of the disassembly of the Pangaean supercontinent. The advent of plate tectonic theory led to the theory, still popular today, that the main salt mass was deposited as a single thick body and was then split into two main bodies via the emplacement of oceanic crust. Until now, how these two main masses beneath the deep waters of the Gulf of Mexico relate to salt in the various peripheral basins was not well defined. Based on a new integration of seismic across the Gulf of Mexico Hudec et al. argue the system was akin to that of the Mediterranean and characterised by a main drawdown stage when the bulk of the Louann salt was deposited in a more central hydrographically isolated sump. In contrast, the timing of halite precipitation in the various marginal basins occurred in peripheral or marginal basins when water level in the central basin was higher. Also still somewhat contentious is the timing of salt deposition relative to the emplacement of ocean crust (sea floor spreading).

Utilising a synthesis of existing seismic across the Gulf of Mexico Hudec et al. (2013a, b), construct the following scenario for the Jurassic plate-tectonic evolution of the Gulf of Mexico basin and discuss how this evolution influenced Jurassic salt tectonics. Four interpretations, some based on new data, constrain their hypothesis. First, the limit of normal oceanic crust (LOC) coincides with a landward-dipping basement ramp near the seaward end of the salt basin, which has been mapped on seismic data. Second, the deep salt in the deep-water Gulf of Mexico can be separated into various salt provinces on the basis of position with respect to this ramp. Third, paleodepths in the postsalt sequence indicate that salt filled the Gulf of Mexico salt basin to near sea level. Fourth, seismic data show that postsalt sediments in the central Louann and the Yucatan salt basins exhibit large magnitudes of Late Jurassic salt-detached extension, which is not balanced by equivalent salt-detached shortening.

In their hypothesis, Callovian salt was deposited in preexisting crustal depressions on hyperextended continental and transitional crust. After salt deposition ended, rifting continued for another 7–12 m.y. before sea-floor spreading began (Fig. 5.72a–d). During this phase of postsalt crustal stretching, the salt and its overburden were extended by 100–250 km, depending on location. Sea-floor spreading divided the northern Gulf of Mexico into two segments, separated by the northwest-trending Brazos transform. The eastern segment opened from east to west, leaving the Walker Ridge salient in the centre of the basin as the final area to break apart. In some areas, salt flowed seaward onto new oceanic crust, first concordantly over the basement as a parautochthonous province, then climbing up over stratigraphically younger strata as an allochthonous province (Fig. 5.72e, f).

This scenario meshes well with the model of post rift basinwide deposition summarised in Figs. 5.72 and 5.73. The postrift subsealevel drawdown setting, where the salt mass is flowing basinward and is not broken up by rift-related faults in a set of fault-bound grabens facilitates a strong lateral or allochthonous component to the basin halokinesis (Warren 2010). As well as geometries in the Gulf of Mexico it also explains the allochthonous deep salt geometries of other larger circum-Atlantic Aptian salt basins such as the Santos and Angolan salt basins.

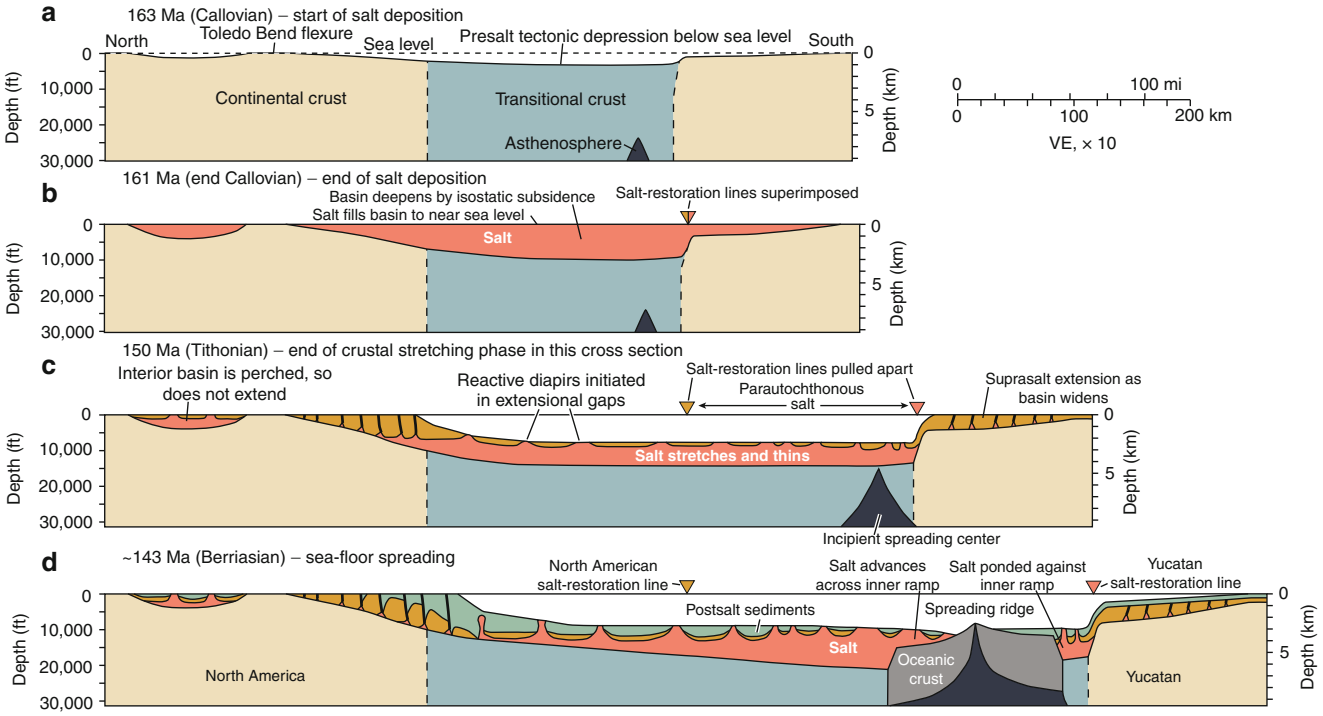

Fig. 5.73 Schematic section restoration of basin evolution, emphasizing salt and its overburden. Internal structures in the crust are not shown. Line of section passes through the Walker Ridge salient, where sea-floor spreading began relatively late (After Hudec et al. 2013b)

Summary

Modern and ancient evaporite basins can deposit kilometre-thick sequences in less than 300,000 years. Such infills only occur at times of complete basin isolation when there is no surface connection to the world's oceans. Once we realize that thick evaporite accumulations require subsealevel depressions to have a stable longterm brine curtain ($\approx 10^5$–10^6 years) in order to accumulate to substantial thicknesses and lateral extents, we reach an understanding of why the present is not a good time to study the scale and diversity of possible evaporite settings. High amplitude, high frequency 4th-order sealevel oscillations of our current "icehouse" climate do not allow the set up of stable brine curtains in present-day continental platforms. Nor are there suitable subsealevel marine-seepage rift or collision belts where conditions are suitable for the creation of marine-fed basinwide drawdown deposits. The last such basinwide event occurred in the Mediterranean some 5.5 Ma. Thick stable brine curtains are today only found in continental settings.

Sequence stratigraphic analysis must be tied to a subdivision of ancient evaporites into three depositional styles, continental lacustrine, marine platform and marine basinwide. All three are suitable for high-frequency seismic interpretation and the unique nature of salt mean it is easily recognised and traced in a seismic section. The hydrology needed to form a salt bed also makes it a close approximation to a time line in the basin architecture. But, of the three styles, a marine eustatic interpretation tied to sealevel is only possible in a marine platform evaporite succession. Once halokinesis occurs, the internal reflectors indicative of depositional layers and hence sequence boundaries are lost.

So, to return to the notion of strict uniformitarianism in the study of evaporites, with which we started this chapter, as Confucius once said: "Study the past, if you would define the future."

Flowing Salt: Halokinesis

6

Introduction

Many of the world's larger oil and gas fields occur in halokinetically-influenced structures across many of the world's salt basins (e.g. Campos Basin, Gulf of Mexico, North Sea, Lower Congo Basin, Santos Basin and Zagros). An understanding of the physics of salt and how salt flow influences tectonics and sedimentation is therefore critical to effective and efficient petroleum exploration (Chap. 10). And, I would argue, is also critical to a significant portion of the world's base and precious metal occurrences (see Chaps. 15 and 16). Halokinetic salt is also a resource[1] in salt, potash, gypsum and nitrate extraction (Chaps. 11 and 12). Salt dome salt has the potential to be employed as a repository for radioactive and other wastes, and can act as a highly efficient seal to sequestered CO_2 (Chap. 13).

Outcrops of flowing salt are rare because of halite's high solubility, but do occur in a number of arid settings and some are spectacular. In Iran, flowing glaciers of salt (namakiers are salt glaciers; *namak* is Farsi for salt) rise up to 400 m above the surrounding Zagros landscape. Diapiric salt also outcrops in the Andes, the Canadian Arctic, in Cardona in Spain, and subcrops near Hallestat/Dachstein in Austria and along the banks of the Nam Theun River in Laos. Flowing salt produces some of the most complex and visually impressive low-temperature geological deformation to be seen on the earth's surface. Work in numerous salt provinces over the past 50 years has now developed a series of saltflow models that are predictive and quantitative (Fig. 6.1a, b).

Salt tectonics (syn. halotectonics and halokinesis) is a general term that encompasses notions of lateral and vertical salt flow, trans-stratal salt movement, salt pillowing and diapirism. It refers to tectonic deformation involving halite or other evaporites as a substratum or source layer. Concepts of salt tectonics have undergone a major revision in the last 30 years to now encompass notions of strong lateral intra-stratal flow, as well as the long accepted vertical flow. This over-arching revision in our understanding is based mainly on advances in 3D seismic acquisition and processing, especially 3D prestack depth imaging, and the realisation that salt tectonics is best modelled by considering a salt bed as a pressurized fluid layer overlain by brittle sediment (Fig. 6.2; Hodgkins and O'Brien 1994; Ratcliff and Weber 1997).

Salt tectonics can be summarised in two simple geological principles. First, differential loading drives salt tectonics; this make halokinesis a much more passive process than had been believed. Second, salt is a very weak and incompetent layer in the subsurface; its lateral flow and sliding carries along its overburden in extension and acts as a décollement in compression. Salt sheets, tongues, and allochthonous nappes are major subhorizontal components of the salt tectonic realm (Fig. 6.1). Like any less competent layer in extension salt undergoes boudinage and drives fracturing in its more brittle overburden.

The word diapir originally comes from the Greek *diaperainen*, meaning "to pierce-through" and was coined by L. Mrazek in 1907 to describe salt features of the Romanian Alps. It was defined at a time when salt diapir emplacement was considered to be a forceful intrusive process, akin to igneous diapirism, and capable of pushing aside kilometres of overburden. Today, salt diapirs are defined as salt flow features showing discordant interactive contacts with the encasing sedimentary strata, with shapes and geometries that are a response to salt's inherent mechanical weakness. Salt

[1]That rising salt can maintain units of highly soluble nearpure halite near the earth's surface is why the richer sites of Neolithic salt exploitation in Europe were inland and centred on mines at Cardona and Hallestat, and in the fourth Century BC at Zanjan in Iran, as opposed to sites of seasonal evaporation along the coastal plain. Some diapiric salt masses have superstitious significance (Genesis 19:26); Lot's wife was noted in the journals of Fulcher of Chartres (Chaplain to King Baldwin) who accompanied the crusader Baldwin I across the Dead Sea valley in December 1100 AD. In reality, the apophenic feature described as Lot's wife is a 12 m-high column of salt lying at the foot of the much larger Mt Sedom (Usdum) on the edge of the Dead Sea. It is one of a number of dissolutional remnants along the gypsum-capped cavernous edge of an outcropping diapir composed of Miocene salt, which also makes up Mount Sedom (Frumkin 2009). But Sedom's description as a mountain is somewhat of a misnomer, it is certainly 8 km across, but only rises a 100 m or so above the floor of the Dead Sea Valley.

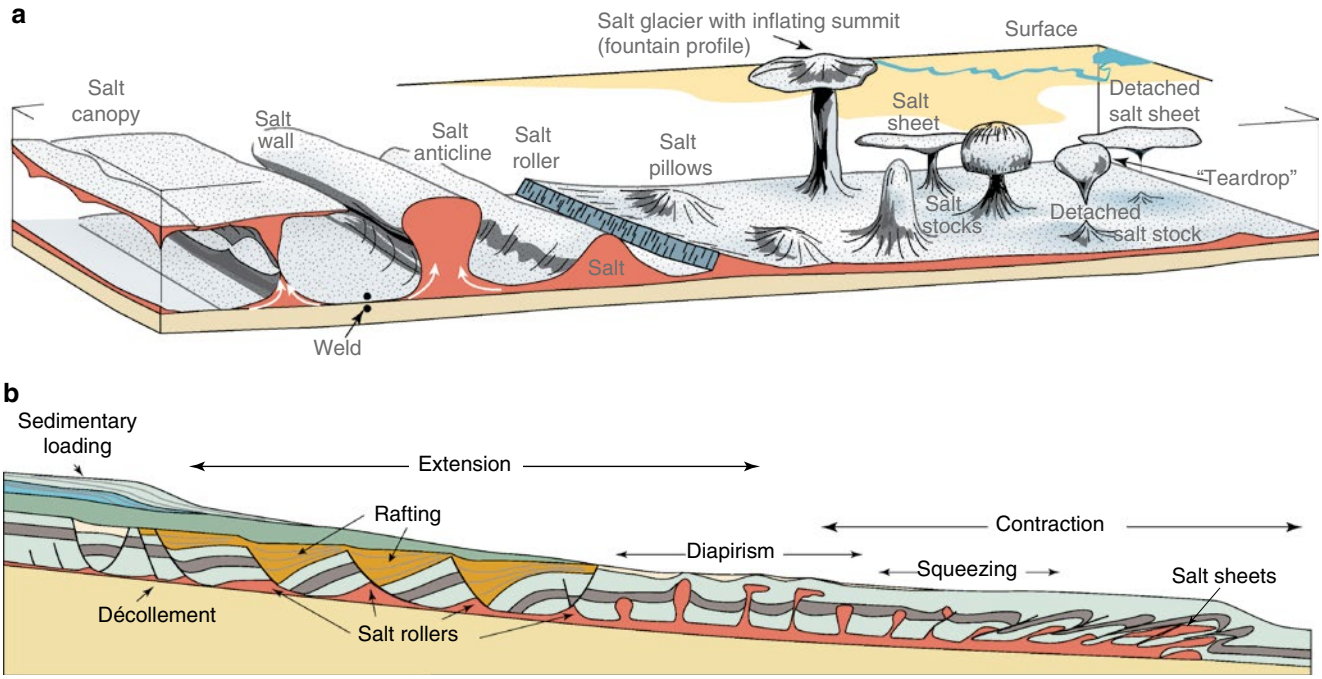

Fig. 6.1 Salt Structures. (**a**) Morphological classification of the different external shapes and deformation styles that define salt distribution in halokinetic basins. Structural maturity of the features increases left and right from the central part of the diagram, with linear structures on the left and vertical (plug) structures on the right. (**b**) Salt morphologies placed in the typical evolutionary framework of salt structures in a deforming passive-margin salt-floored succession, typified by up-dip extension and down-dip compression (After Jackson and Talbot 1986; Fossen 2010)

can push aside a thinned zone of weak overburden, but all current definitions of salt diapirism do not uncritically encompass notions of active piercement and the shouldering aside of kilometres-thick overburden successions. Where feasible, salt constituting a diapir should be further classified as either allochthonous or autochthonous.

Allochthonous salt structurally overlies parts of its (stratigraphically younger) overburden and is often no longer connected to the primary salt bed (mother-salt level). For example, spectacular allochthonous salt sheets in the northern Gulf of Mexico form a line of five or so huge asymmetric tongues of Jurassic salt that now overlie and seal Pliocene to Pleistocene sediments. They coalesce behind the Sigsbee Scarp to form a minibasin-covered salt tongue canopy, which can be considered analogous to gravitational nappes in salt-cored orogenic belts (Fig. 6.2a, b; Worrall and Snelson 1989; Wu 1993; Hudec and Jackson 2006). Allochthonous salt bodies climb the stratigraphy of the Gulf of Mexico via a series of tiers or canopies, leaving evidence of their passage as thin salt pods, dissolution residues and alteration aprons along salt welds or overburden touchdowns, much like a garden slug leaves behind a slime trail (Fig. 6.46). Autochthonous salt structures are those still firmly rooted in the stratigraphic level of the primary salt bed. Prior to the application of current seismic imaging and processing techniques most diapiric structures were interpreted as autochthonous thumb-like appendages connected at the level of the primary salt layer or its former position now marked by a salt weld. Sometimes the term parautochthonous is used to describe a salt geometry that is intermediate between allochthonous and autochthonous.

A whole new realm of salt/sediment configurations and oil exploration plays have opened up in the last few decades with the realization that; (a) salt sheets can be allochthonous and subhorizontal over large areas in a sedimentary basin, and (b) structures in the salt allochthon overburden are tied either to the trailing edge of the allochthon where salt is evacuating/ withdrawing, or the leading edge where salt is flowing at or near the surface. A range of potential subsalt hydrocarbon traps have now been successfully drilled in the Americas (Brazil, eastern Canada, Gulf of Mexico), where the move into deeper water revitalised what were considered mature exploration provinces (Montgomery and Moore 1997; Meisling et al. 2001; Mohriak et al. 2012).

This chapter will concentrate on salt structures, their geometries and the mechanisms that create them; the halokinetic breccias remaining once flowing salt has dissolved are discussed in Chap. 7. Diapirs do not just form in salt, they can occur in any geological material with markedly different pressure and strength compared to its overburden. Contrary to earlier notions of forceful diapirism, some of the principles and concepts developed in interpreting salt diapirism as Newtonian fluid responses can be successfully applied to overpressured shales, serpentinites and even molten granites

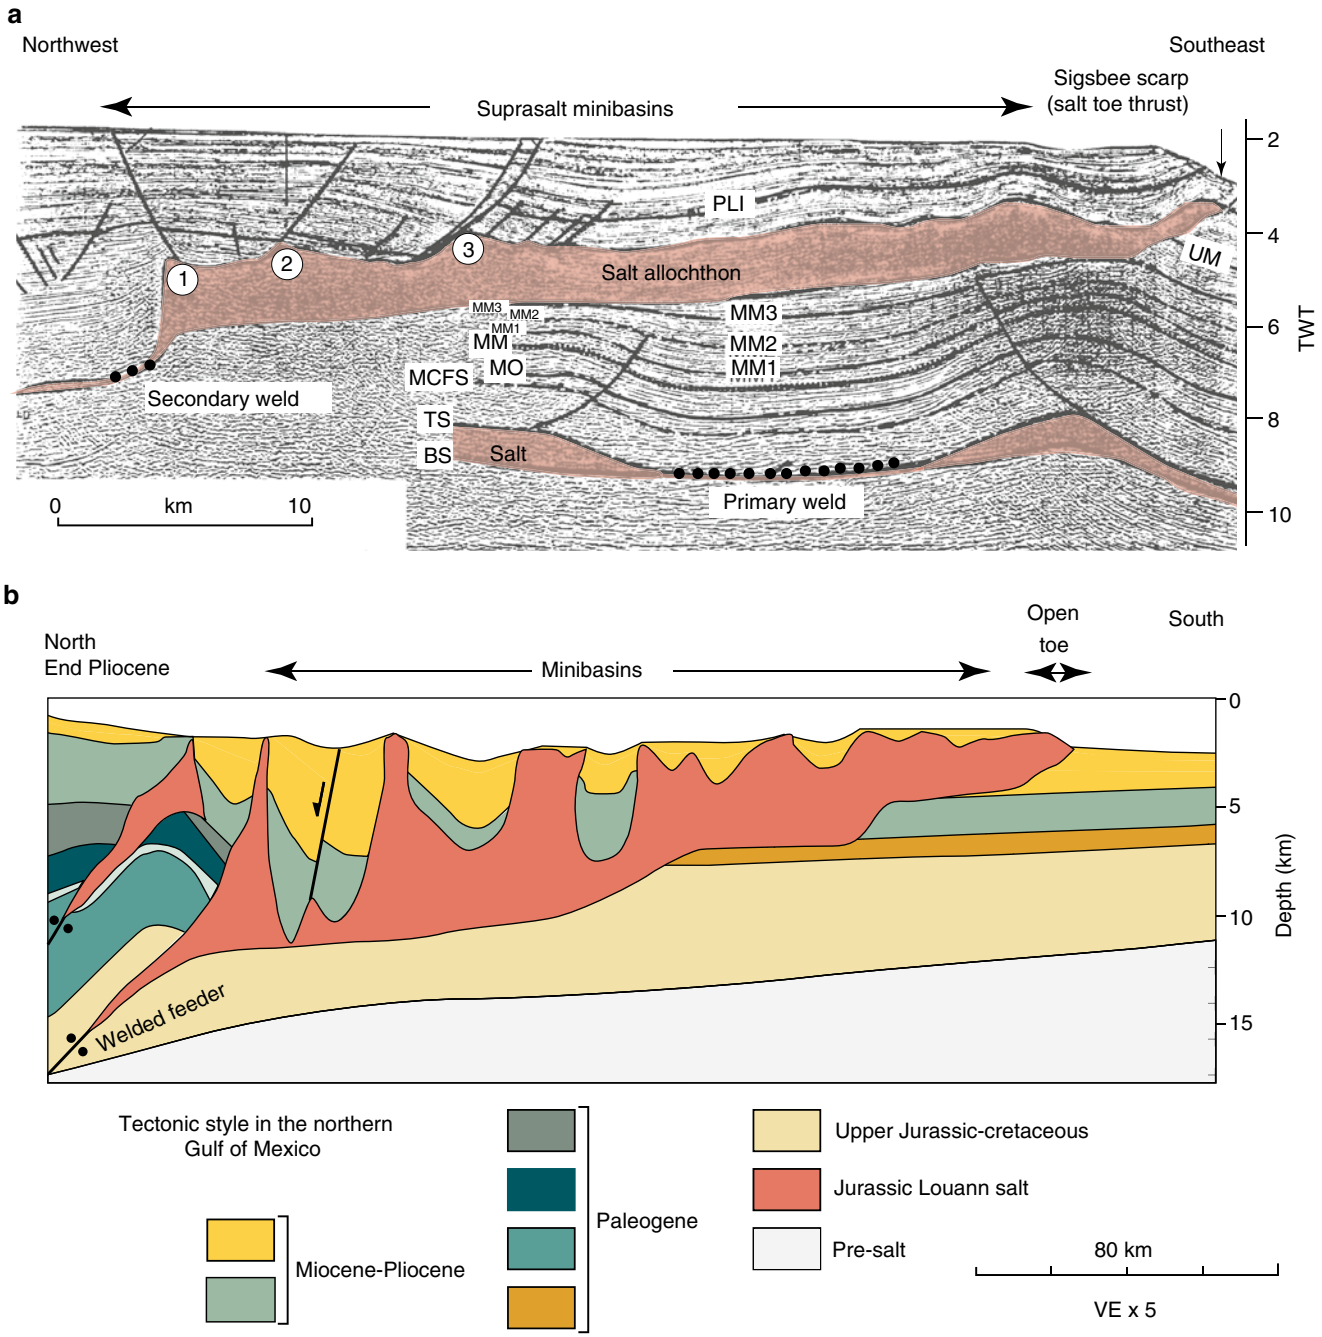

Fig. 6.2 Salt tectonic style in the Northern Gulf of Mexico. (**a**) Interpreted seismic profile through allochthonous salt sheets that build the Sigsbee Escarpment (to southeast), base of continental slope off Louisiana, Gulf of Mexico (After Wu 1993; Jackson and Vendeville 1994). Note how supra-allochthonous faults have initiated diapiric upwelling at 1, 2 and 3. The allochthon is underlain by shortened strata of the Mississippi Fan Foldbelt. *BS* base of Jurassic Louann Salt, *TS* Top of salt, *MCFS* Middle Cretaceous flooding surface equivalent, *MO* Middle Oligocene, *LM* Lower Miocene, *MM1* Lower Middle Miocene, *MM2* Middle Miocene, *MM3* Upper Middle Miocene, *UM* Upper Miocene, *PLI* Pliocene. Note how Jurassic salt has climbed the stratigraphy and now overlies and seals Neogene deepwater sediment. (**b**) Restoration of a salt-canopy geometry at the end of the Pliocene, East Cameron South, Garden Banks, and Keathley Canyon areas, northern Gulf of Mexico, based on seismic as shown in Fig. 6.2a where 10-km-wide open toe of emergent Louann Salt has been inferred at the Sigsbee paleoescarpment. Exposed salt massifs separate synclinal minibasins (After Peel et al. 1995; Hudec and Jackson 2006). Note the differences in horizontal and vertical scales between **a** and **b**

rising through the mantle (Talbot 1992a). Any rock will flow if it gets hot enough and deep enough, around 300 °C for a quartz-rich rock, closer to 550 °C for a feldspathic rock, and even more for olivine-rich rocks. What makes salt so interesting is that it is capable of flowing at surface and nearsurface temperatures and pressures.

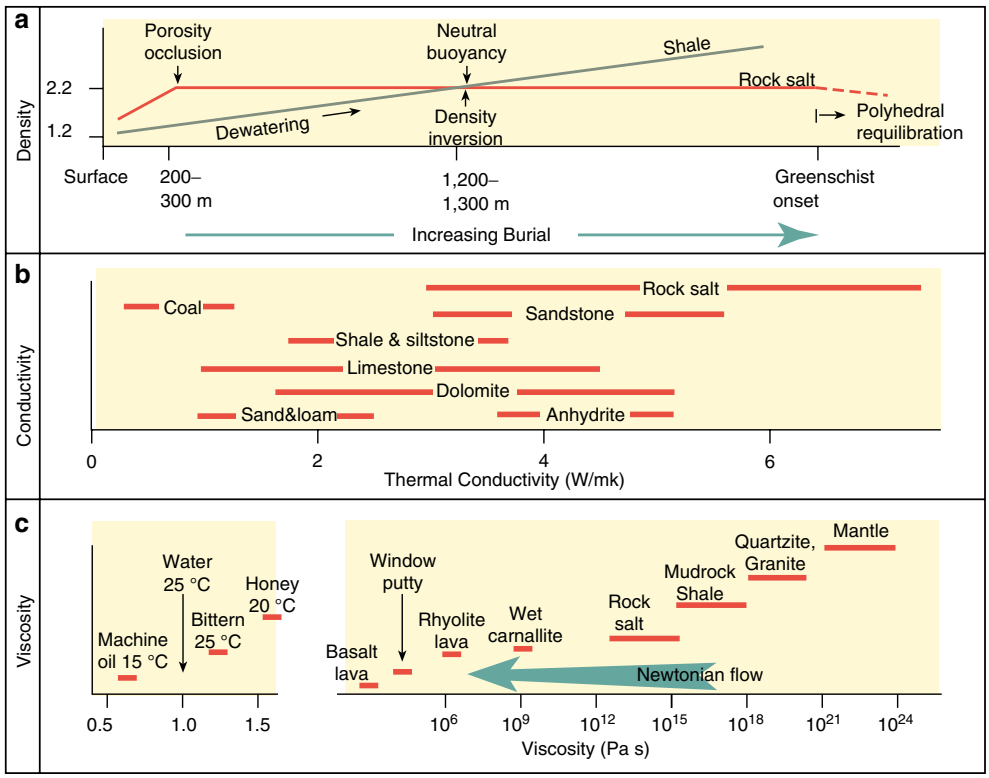

Fig. 6.3 Physical properties of rock salt compared to other lithologies. (**a**) Density changes with burial. (**b**) Thermal conductivity (see also Fig. 8.31a). (**c**) Viscosity

Physics of Salt Systems

Even with our greatly improved ability to seismically outline salt features, the comments made by Richter-Bernburg, more than two decades ago, still hold true today. In a 1980 review he noted that our geological understanding of the world's various salt structures is still very much like that of a sculptor to the human body; the whole figure can be perfectly described, especially using 3D seismic and forward modelling, but the anatomy, the inner organs and the complicated inner structures remain largely irresolvable, unless seen in a mine wall or a dissolving namakier (Strozyk et al. 2012). In a benchmark paper on the internal complexity of Zechstein salt structures in Europe Richter-Bernburg (1980) made a number of interesting observations:

- Salt deposits are not, or have not always been, in mechanical equilibrium with their ambient environment and deformations caused by salt flow have to be expected in all subsurface situations
- Isoclinal and overturned folds can occur in simple salt ridges so that stratigraphically older members of a formation can dip into the local area from above a particular horizon.
- By the diapir stage, possibilities are open for building folds of all imaginable – or even unimaginable – features and shapes (including migmatitic and boudinage styles). Axes of curtain folds in a diapir are not simply vertical, they may be inclined in all – mathematically! – possible directions.

He concludes that any prognosis about the interior structure of a halokinetic salt mass -even if it is scarcely diapiric- is not possible without seeing it from the inside. So before we look at the various external geometries sculpted by salt, which is the main concern for most of this chapter, let us look at the physical properties of salt that drive salt flow and at the internal textures indicative of this flow.

Density, Viscosity, Strength & Buoyancy

After it loses effective porosity, typically by 100–200 m burial, halite's density of 2.2 g/cc remains near constant throughout the diagenetic realm and it is near incompressible to depths of 6–8 km (Fig. 6.3a). With entry into greenschist depths, deeply buried halite can experience massive recrystallisation and dissolution, along with a slight decrease in density due to thermal expansion (Figs. 6.3a and 14.10; Lewis and Holness 1996). In contrast, burial compaction in shales and most other sediments is defined by a progressive loss of porosity, with an associated increase in density and strength until it exceeds that of the salt below. This means that salt has positive buoyancy when buried beneath nonevaporitic overburden to depths in excess of a kilometre. With a muddy overburden, the depth of density crossover, sometimes called the level of neutral buoyancy, is typically shallower than 1,300–1,500 m. It can be much shallower beneath reefs and other cemented carbonates, which can have densities equal to, or greater than,

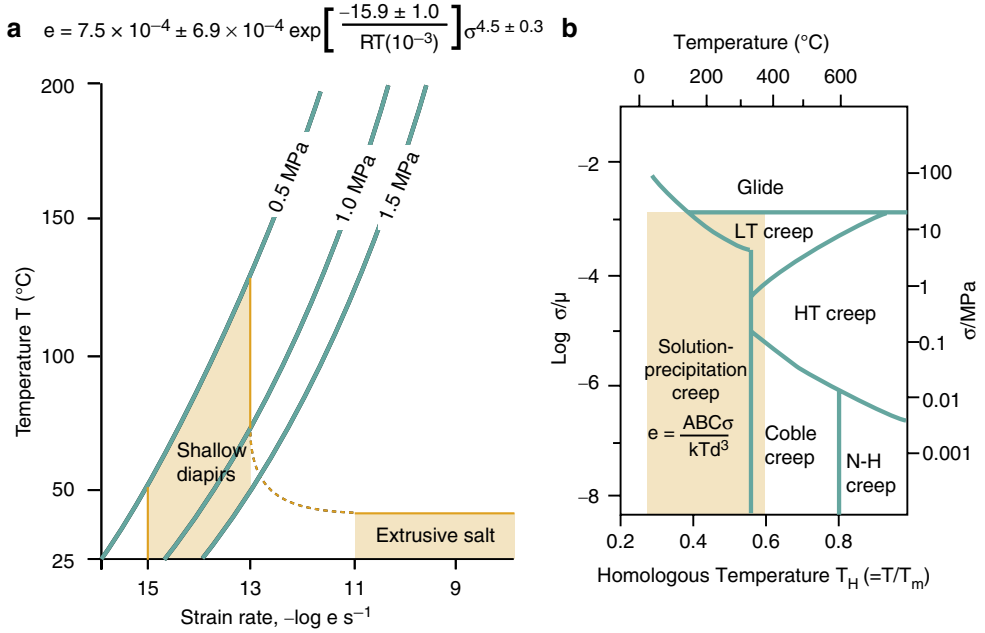

Fig. 6.4 Strain map showing conditions of temperature and strain where salt tends to flow rather than fracture (After Talbot and Jackson 1987a; Carter and Hansen 1983). (**a**) Power law behaviour of dry rock salt where the relation between steady-state strain rate (e) and differential stress (σ in MPa) is highly nonlinear (stress exponent, n = 4.5). This power law does explain deformation in salt diapirs but not the much higher strain rates of extruded salt/salt glaciers. There much of the flow is periodic and facilitated by the presence of water. R is universal gas constant and T the absolute temperature. (**b**) Diffusion mechanism map for damp rock salt showing dominant deformation mechanisms for different homologous temperatures and stresses. Shaded area shows the dominant field for most natural salt flow, which lies mainly in the solution-transfer field (solutant diffusivity terms; *C* grain boundary structure parameter, *k* Boltzmann constant, *d* grain size. *T m* melting point of halite, *LT* and *HT* is low and high temperature, *N-H* is Nabarro Herring (After Urai et al. 1986))

salt almost from the time of deposition. This can lead to rapid foundering and brecciation of reef materials, especially in areas of overburden extension and allochthon spreading.

Few other rocks are as thermally conductive or as close to truly viscous (Newtonian) as natural rock salt (Fig. 6.3b, c). Viscosity is a measure of a fluid's resistance to flow or its internal friction and is measured by the ratio of shear stress to the rate of shear strain. Laboratory measurements show wet carnallite can have a viscosity as low as 10^8 Pa.s, while dry halite has a viscosity around 10^{18} Pa.s (for comparison, honey at 14 °C has a viscosity ≈ 60 Pa.s; window putty ≈ 10^5 Pa.s; and road tar ≈ 10^7 Pa.s; 1 Pa.s = 10 poise). The viscosity of salt in the Gulf of Mexico is 10^{13}–10^{17} Pa.s, depending on moisture content, crystal size and temperature. An adjacent overburden of clay or sands is less viscous by four to five orders of magnitude. Davison et al. (1996a) estimates the ratio, sedimentary rock: evaporite rock viscosity, ranges from 50 to 10^4. As different parts of a diapir deform at different rates and by different mechanisms, the effective subsurface viscosity values for diapiric salt vary with position in the diapir, the water content of the salt and time. Due to its much higher moisture content (from meteoric water infiltration), diapiric salt is much less viscous when it reaches the surface as a tongue of extruded salt than at depth (Fig. 6.4a).

Across geological time frames, finer-grained wet salt approaches Newtonian[2] viscous behaviour, unless it is atypically coarse grained. And, like any fluid, it cannot support shear stress so a mound of wet salt emplaced on the earth's surface will spread under its own weight (gravity spreading). Using a viscous fluid model, salt diapirism and its relationship to its overburden can be likened to Rayleigh-Taylor instability with a viscous substratum (salt) and an overlying denser viscous fluid (overburden; e.g. discussions in Koyi 1991; Talbot 1992a, b). Under such a fluid-fluid model, diapirism is spontaneously initiated by small irregularities in the fluid-fluid interface that then amplify with time and buoyancy contrast. Diapirs rise continuously and inevitably until the less dense salt overlies its overburden. The only requirement for Rayleigh-Taylor instability in a fluid-fluid system is density inversion; diapirism modelled in such as way does not require any external trigger such as regional extension or differential loading. Under this fluid-fluid scenario, any regional extension thins the fluid overburden and the source layer, so reducing the overall thickness. The resulting diapirs are

[2]Newtonian (or viscous) flow occurs when the rate of shear stress is directly proportional to the shear strain (linear relation between stress and strain rate). Non-Newtonian flow is typified by a power law relationship between stress and strain.

Table 6.1 Representative strain and flow rates

Type of flow	Strain rate (s^{-1})	Speed (mm a^{-1})	Speed
Lava flow (faster when hotter)	10^{-5} to 10^{-4}	5×10^{11} to 3×10^{13}	1 to 60 km h^{-1}
Ice glacier (surges with increased temperature)	10^{-10} to 5×10^{-8}	3×10^{5} to 2×10^{7}	1 to 60 m day^{-1}
Salt glacier (surges when wet, after a rainstorm)	10^{-11} to 2×10^{-9}	2×10^{3} to 2×10^{6}	10 to 100 km Ma^{-1}
Mantle currents (temperature and pressure controlled)	10^{-15} to 10^{-14}	10 to 10^{3}	2 m a^{-1} to 5 m day^{-1}
Spreading salt tongue (<30 km wide extrusion)	8×10^{-15} to 10^{-11}	2 to 20	2 to 20 km Ma^{-1}
Spreading salt tongue (>30 km wide extrusion)	3×10^{-16} to 10^{-15}	0.5 to 3	0.5 to 3 km Ma^{-1}
Rising diapir in stem (increases with water content)	2×10^{-16} to 8×10^{-11}	1×10^{-2} to 2	10 m to 2 km Ma^{-1}

After Jackson and Vendeville (1994)

smaller, more closely spaced, and more slowly rising than those in unthinned counterparts (Koyi 1991).

Rather than model the salt's overburden as a viscous fluid, proponents of the "brittle school" tend to model salt as a pressurized pseudo-fluid at subsurface flow rates, and consider its sedimentary overburden liable to show brittle responses to stress (e.g. Jackson and Vendeville 1994). In most subsurface situations it means that relative density as a trigger and a subsequent control to halokinesis, is a less important consideration than relative strength of salt and its overburden. This style of modelling is better supported by the geological observations that; (1) diapirs rise episodically rather than continuously, (2) that salt flows when loaded (much like toothpaste is squeezed out it its tube) and (3) that faulting, rather than folding, characterises much of the early deformation in the overburden. In reality, the strength response of a buried salt bed and its overburden will depend on the strain rate and the rate of deformation in the overburden. Salt can fracture and fault at high strain rates (brittle response), but the required strain rate is much higher than experienced in many typical subsurface situations (Jackson and Talbot 1994; Davison 2009).

Subsurface nonevaporitic sediments, including indurated shales, show time-independent, pressure-dependent brittle behaviour under stress and deform most readily by frictional slip along faults. In contrast, bedded salt under stress typically flows and deforms via folding and recrystallisation rather than fracturing. Most adherents of the brittle school contend that varying combinations of regional extension, differential loading and gravity sliding, will localise, initiate and promote diapirism of salt and shale. The conclusions of the "brittle" school are supported by studies showing virtually all sediments at shallow crustal depths (<8–10 km) deform as faulted brittle masses, rather than by the creep and folding that typifies deforming evaporite salts. This depth range encompasses much of the realm of salt tectonics in sedimentary basins.

Evaporite salts are unique in their tendency to flow in the diagenetic realm. Representative strain rates and speeds of salt deformation are listed in Table 6.1. A strain value of $10^{-15}\,s^{-1}$ indicates that a rock stretches at a rate of 10^{-15} of its length per second and is representative of the slow strain rates encountered in rock deformation rates in active orogenic belts. A value of 10^{-9} is 1 million times faster and represents strain rates in active (wet) salt glaciers in Iran (1.6×10^{-13} to 1.8×10^{-8} per second; Wenkert 1979), which equates to an annual rate of rise of ≈2 m/year in the salt stem. But the rate of salt supply and surface flow is not constant. Salt glaciers (namakiers) in Iran always flow faster after a rain; the Dashti glacier at Kuh-e-Namak (28.26°N, 51.71°E) flows at up to 0.5 m/day during the few weeks of the annual wet season, but flows little if any during the dry season when the glacier expands and contracts diurnally in response to changes in surface temperature. The Kuh-e-Jahani salt glacier in Iran (28.60°N, 52.46°E) rises out of its orifice at 2–3 m/year, (Talbot et al. 2000), which is equivalent to a vertical strain rate of $1\times10^{-11}\,s^{-1}$. According to Davison (2009) this is close to the critical strain rate required for salt to fault.

But what do these observed rates of deformation mean in terms of driving mechanism and how does flow occur at the crystalline scale? First and foremost it means wet salt has little or no strength in most geological settings and so deforms by diffusion[3] creep in a fluid-like fashion. In contrast, cataclastic[4] or brittle responses to deformation, involving microfracturing and sliding of grains and grain fragments (grain crushing), are important deformation mechanisms in non-evaporite indurated sediments at low temperatures and confining pressures[5] (Talbot and Jackson 1987a, b; Kukla et al. 2011a).

[3]Diffusion creep changes the shape and size of crystals through the movement of vacancies and atoms within crystals and along grain boundaries. Indicative textures can include equant grain shapes, indented grains, overgrowths and a lack of crystallographic preferred orientation (although preferred crystallographic orientations can also form during diffusion creep)

[4]Brittle response encapsulate microfracturing, cataclasis, and frictional sliding involve the formation, lengthening, and interconnecting of microcracks; frictional sliding along microcracks and grain boundaries; and the formation and flow of pervasively fractured, brecciated, and pulverized rock and crystal fragments (micropemeability).

[5]Confining pressure describes an equal, all-sided pressure, such as lithostatic pressure produced by the weight of overlying rocks in the crust of the earth. It is considered equivalent to overburden pressure or geostatic pressure and is sometimes called vertical stress. It contrasts with the term formation pressure, which includes a pore pressure component.

Kinking of crystal lattices by various combinations of slip, glide or dislocations of grains in the halite lattice itself is known collectively as dislocation creep. Based on naturally and artificially deformed salt samples, Carter et al. (1993) concluded dislocation creep occurs at temperatures and pressures relevant to subsurface salt deformation. They found that short-term, high-stress flow properties of dry salt can be reasonably encapsulated in an empirical power-law equation (Fig. 6.4a). This power law explains the rates of creep and differential[6] stress fields interpreted in shallow (dry) diapiric salt. It does not explain the much higher strain rates of 10^{-8}–10^{-11} measured in salt allochthons and salt glaciers (extruded wet salt) at stress differentials estimated to be around 0.5 MPa and at ambient surface temperatures (Talbot and Jackson 1987a). Nor do their stress/strain triaxial experiments duplicate the elongate recrystallised textures of naturally deformed salt; such textures imply diffusional flow mechanisms (Urai et al. 1986).

Ductile flow occurs through three main mechanisms. (1) change of grain shape by crystal plasticity, which is referred to as dislocation creep; (2) change of grain shape by diffusion through or around grains, called diffusion creep; and (3) relative movement of grains, referred to as granular flow or grain-boundary sliding (Fig. 6.5a). Strain by diffusion of ions along grain boundaries is also known as Coble creep, while stain uptake through crystals via crystal lattice adjustment to imposed stress is known as Nabarro-Herring creep and is typical of most rocks at high temperatures (Fig. 6.4b). Diffusion creep textures may grade into ductile grain-boundary sliding and frictional grain-boundary sliding textures.

The high solubility of chloride salts means solution transfer creep (aka solution precipitation creep and pressure solution creep and stress-induced solution transfer) is the prevalent deformation mechanism in wet salt flowing in the diagenetic temperature realm (Figs. 6.4b and 6.5a; Urai et al. 1986, 2008). That is, diffusion mechanisms can operate at much lower temperatures and differential stresses in wet salt than in non-salt rock types, where temperatures measured in hundreds of degrees are more typical of diffusion. Hence, the use of the homologous[7] temperature scale (T_H) when discussing creep mechanisms. Triaxial deformation experiments by Urai et al. (1986) using carnallite, sylvite and rock salt showed that flow laws based on short-term high-stress experiments conducted on dry salt should not be extrapolated to salt deforming under lower strain rates and nondilatant conditions. They found that both dry salt (≈0.05 wt% inherent water) and wet (brine-saturated) salt both deformed by power law creep with $n > 5$ at strain rates faster than 10^{-7} s^{-1}, as found by Carter and Hansen (1983). However, the same rocks deformed by power law creep with $n \approx 2$ (dry) or $n \approx 1$ (wet) when samples were stained more slowly by suppressing the rate of dilatancy (either by increasing confining

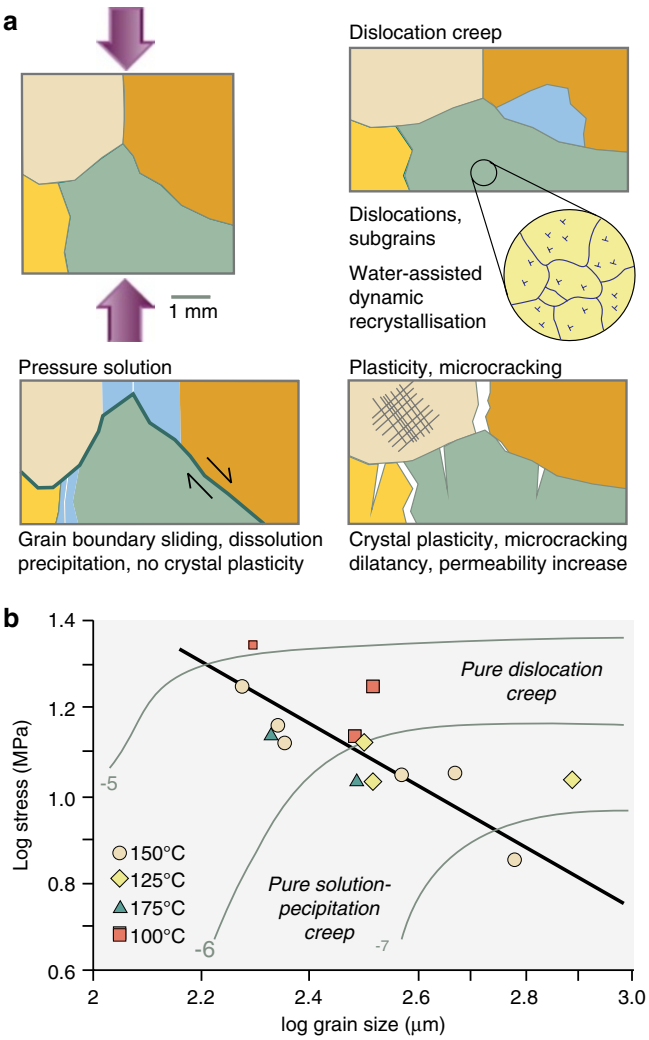

Fig. 6.5 Crystal-scale deformation. (**a**) Schematic showing the microstructural processes that can operated during the deformation of rock salt at temperatures in the range 20–200 °C. Different shades represent crystals with different orientation. The circular expanded inset illustrates subgrains (with same orientation) See text for further explanation. (**b**) Dynamically recrystallised grain size versus stress data for synthetic rock salt samples, superimposed on a deformation mechanism map, showing that halite deformed in the transition region between dislocation creep and solution- precipitation creep, both played a role in the deformation (After Ter Heege et al. 2005; Urai et al. 2008)

[6]Differential stress (sometimes called deviatoric stress) is any stress system where the forces acting on a unit cube are not the same in all directions, it is typically measured as σ_1–σ_3.

[7]Homologous temperature scales (T_H) make it possible to compare creep response for solids with different melting points. T_H is defined as T/T_m, which is the ratio of the material's temperature to its melting point (T_m). For water, with a T_m of 273 K, the homologous temperature at 0 K is 0/273 = 0, while at 0 °C the T_H = 1 (273/273), and 0.5 at −100 °C (137/273). Homologous temperatures involved in creep processes are typically greater than 0.5, with creep processes becoming more active as T_H approaches 1. This is why ice glaciers can flow like salt glaciers: that is, ice deforms by creep at the high homologous temperatures of natural glaciers, as does salt, as illustrated in Fig. 6.4b.

pressure to between 5 and 10 MPa, or adding brine under dilatant conditions).

Urai et al. (op cit.) also found that samples deformed under these more geologically realistic conditions had completely recrystallised into flattened fabrics very similar to those of naturally deformed salt, which is typically dominated by biaxially flattened geometries (Fig. 6.16a). The process of solution transfer creep in deforming salt produces new gneiss-like crystal textures made up of amoeboid-like strain-free flattened salt grains, showing flow parallel fabrics. Solution-transfer creep or pressure solution creep occurs in regimes of differential stress where halite grains dissolve in regions of high stress and reprecipitate in regions of low stress (Fig. 6.5a; aka strain shadows). The basic processes involved are the migration of existing grain boundaries and the formation of new high angle grain boundaries (Drury and Urai 1990). New crystals are less sub-structured and replace older more substructured grains as migrating crystal grain boundaries consume and sweep through the older milky inclusion-rich portions of the salt (Schenk and Urai 2004). Crystals in an area swept by grain boundary migration tend to be inclusion-free, with fluid inclusions now focused along the grain boundaries and so providing conditions suitable for pressure-solution induced creep of the salt mass (Urai et al. 1986; Spiers et al. 1990; Schenk and Urai 2004). Hence, much of this new salt is clear and sparry, rather than milky from intracrystalline inclusions.

Grain boundary migration in deforming wet salt typically leads to grain growth during recrystallization, but can also lead to grain size reduction if new grain boundaries are formed at grain boundary bulges or as a result of grain dissection by migrating boundaries (Fig. 6.5b; Ter Heege et al. 2005). New grain boundaries may also form from subgrain boundaries by progressive misorientation of subgrains or by migration of a sub-boundary through an area of cumulative lattice rotation. This is called rotation recrystallization. The relative importance of migration and rotation recrystallization is dependent on the deformation conditions (i.e. temperature, strain rate and stress). The mean grain size D of dynamically recrystallised materials has been found to be related to the steady state flow stress (σ) by a general theoretical relation of the type $D = K\sigma^{-p}$, a power law, where K and p are material and mechanism specific constants (see also Fig. 6.18 and discussion). Ter Heege et al. (2005) experimentally modelled the specifics deformation of wet salt and concluded that the equation is of the form:

$$\left(D/\beta\right) = 10^{-1.55\pm0.24}\left(\sigma/\mu\right)^{-1.85\pm0.23}\exp\left(14.2\pm2.8/RT\right)$$

with D denoting mean recrystallised grain size, Burgers vector $\beta = 3.99\times10^{-4}$ μm and the shear modulus $\mu = 1.5\times10^{4}$ MPa. Their experiment illustrates that there is a clear relationship between grain size, stress and deformation mechanism (Fig. 6.5b) with salt in a range of temperatures from 100 to 175 °C deforming by a combination dislocation creep and solution precipitation creep.

Figure 6.5 summarises the various microstructural processes that allow halite in the temperature range of 20–200 °C to adjust to imposed deviatoric stresses and so facilitate salt flow (Urai et al. 2008). At very low effective confining pressures (less than a few MPa) and high deviatoric stresses (>15–20 MPa), inter- and intragranular microcracking, grain rotation and intergranular slip are important strain accumulating processes, alongside crystal plasticity. Mechanical properties and dilatational behaviour within this scenario are dependent on the[8] effective mean stress or effective confining pressure. At sufficiently high deviatoric stress, the material fails in a (semi)brittle manner, with failure described by a pressure (or effective mean stress) dependent failure envelope. With increasing effective mean stress, microcracking and dilatancy are suppressed and plastic responses come to dominate.

Of the various plastic responses in the temperature range 100–200 °C, dislocation creep is important and, even at confining pressures as low as 10 MPa, polycrystalline halite can deform to large strains by this mechanism (Figs. 6.4 and 6.5b). During this process, subgrains are formed in the halite grains with the diameter of the subgrains showing a near-linear, inverse correlation with deviatoric stress. If the polycrystal precursor contains small but significant amounts of water in the form of saturated brine inclusions or grain boundary films, as is generally the case for both natural and synthetic samples, fluid assisted grain boundary migration typically operates. This is an efficient process for reducing dislocation density and hence removing the stored energy of dislocations, even at room temperature (Schenk and Urai 2004).

While dislocation creep processes take place in the crystal lattice of halite grains, fluid-assisted grain boundary migration involves solution-precipitation transfer across grain boundaries. Such solution-precipitation creep, or "pressure solution" plastic responses, involve mass transfer centred around grain boundaries (Fig. 6.5a). There, in the presence of a small amount of saturated grain boundary brine, grains dissolve at highly stressed boundaries and after diffusion of the material through the grain boundary fluid, the material crystallises at interfaces and strain shadow areas subject to low normal stress. This process is typically accompanied by intergranular sliding and rotation (grain rearrangement), and can lead to compaction of porous salt or to deviatoric strain (biaxial flattening of non-porous aggregates (Fig. 6.16a). Solution-reprecipitation creep is an important deformation mechanism in most wet rock systems in the Earth's crust, but is especially rapid in low-temperature extruded rock salt,

[8]Effective stress is equal to the total stress minus the pore pressure.

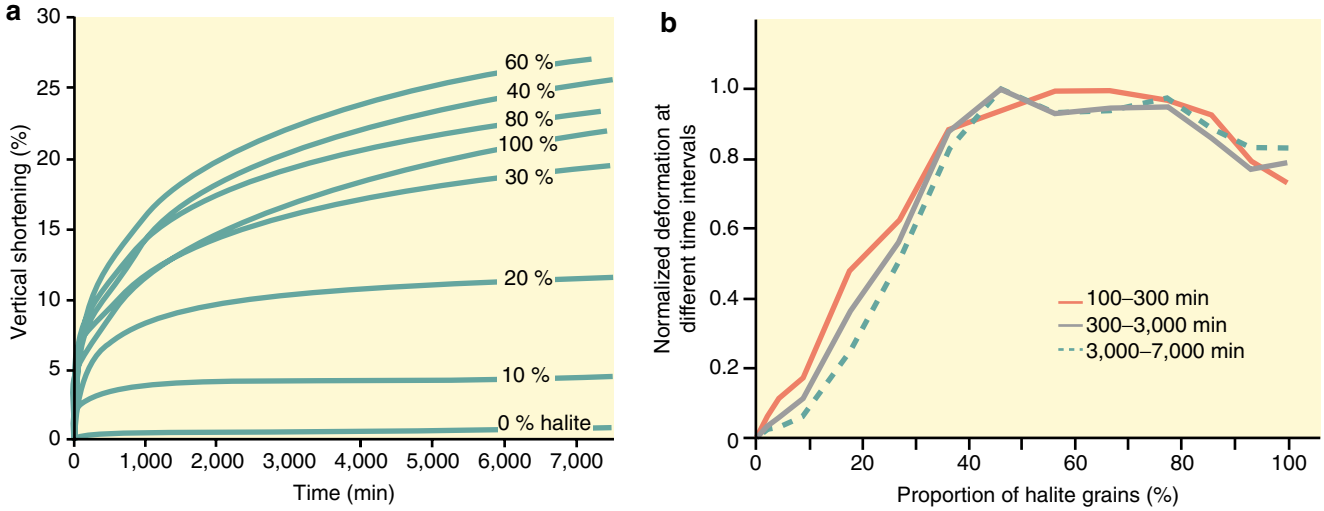

Fig. 6.6 Effect of impurities on salt compression, cementation and pressure solution. (**a**) Result of drained compaction experiments. Compaction curves $E(t) = (x_0\ x(t)/x_0)$ for different samples show that the total amount of compaction after 7,000 min (roughly 5 days) depends on the relative proportion of halite and calcite grains. The highest finite compaction (vertical shortening) does not occur in a sample composed of 100 % halite grains. (**b**) Effect of the mineralogical composition on the amount of vertical shortening on a halite-calcite aggregate. The three curves are normalized to the average maximum deformation of the tested samples at the given elapsed time and they show the same trend, within experimental errors. The mixtures with halite contents between 0 to about 40 % do not exhibit this behavior. The rate of deformation goes down during progressive deformation for halite proportions ranging between 10 and 40 % (After Zubtsov et al. 2004)

where it is the dominant low temperature stress-adjustment mechanism (Fig. 6.3).

The intensity of salt flow and recrystallisation (re-annealment) can in part depend on levels of impurities in deforming and compressing salt. Various lab-created mixtures of crushed halite aggregate and calcite crystals show an interesting set of responses under triaxial compression with free drainage of fluid products (Zubtsov et al. 2004). A 100 % halite sample, or an 80:20 halite-calcite mixture, are both less susceptible to compressional shortening than halite-calcite mixtures of between 40 and 60 % halite (Fig. 6.6a). This is true at all time ranges in the experiment, which ran for periods of up to 5 days (Fig. 6.6b). Mixtures with <30 % halite show less shortening than all samples with higher proportions of halite in the mix.

These responses indicates two mechanisms competing at the grain-to-grain scale: (1) intergranular pressure solution at grain contacts, which facilitates compression, especially across boundaries with different chemical potential, as typically occurs at contacts between grains with different mineralogies, and, (2) grain boundary healing (re-annealment), as occurs between halite-halite grains and studied in pure halites by Urai et al. (1986). This drives the ongoing annealment that then hinders further compaction. As the halite content in the mixture increases, more and more halite-halite grain contacts can heal and so act to resist compression. Volume loss by draining of pressure solution fluids becomes less efficient in such healed or partially healed contacts (Zubtsov et al. 2004). This is another illustration of pure salt's ability to act as an effective seal, it shows that even when faulted, salt will quickly anneal itself unless impurities can enter the fault plane.

When the creep and frictional strengths of wet and dry salt are compared with equivalent strengths of other sedimentary rocks, using a representative strain rate of 10^{-14} s^{-1}, it can be seen that even dry salt is much weaker than any overburden sediment, except perhaps for extremely shallowly-buried water-saturated muds, less than a few hundred metres deep, where water contents can be in excess 50 % (Fig. 6.7). Damp salt, which deforms by solution-transfer creep is hundreds of times weaker than dry salt, which deforms by dislocation creep, where stain uptake is dominated by slippage along lattice defects (Urai et al. 1986).

Because deforming salt has almost no shear strength at most geological time scales of applied stress, it is considered a pseudofluid (Fig. 6.7a; Weijermars et al. 1993). Damp salt does not even require external water to act as a Newtonian fluid (Urai et al. 1986). Rather, the minute quantities of brine caught up as inclusions and the intergranular films in confined natural salt are sufficient to effect salt strength. Water content in a deforming salt unit may be enhanced from an external source, as it does in Iranian namakiers, which tend to flow after rain. However, brine-filled inclusions, naturally present in the halite at the time of deposition can contain sufficient water (up to 4–5 % by volume) to allow salt to flow naturally at the earth surface conditions. In other words, wet salt can flow spontaneously by solution transfer creep, once

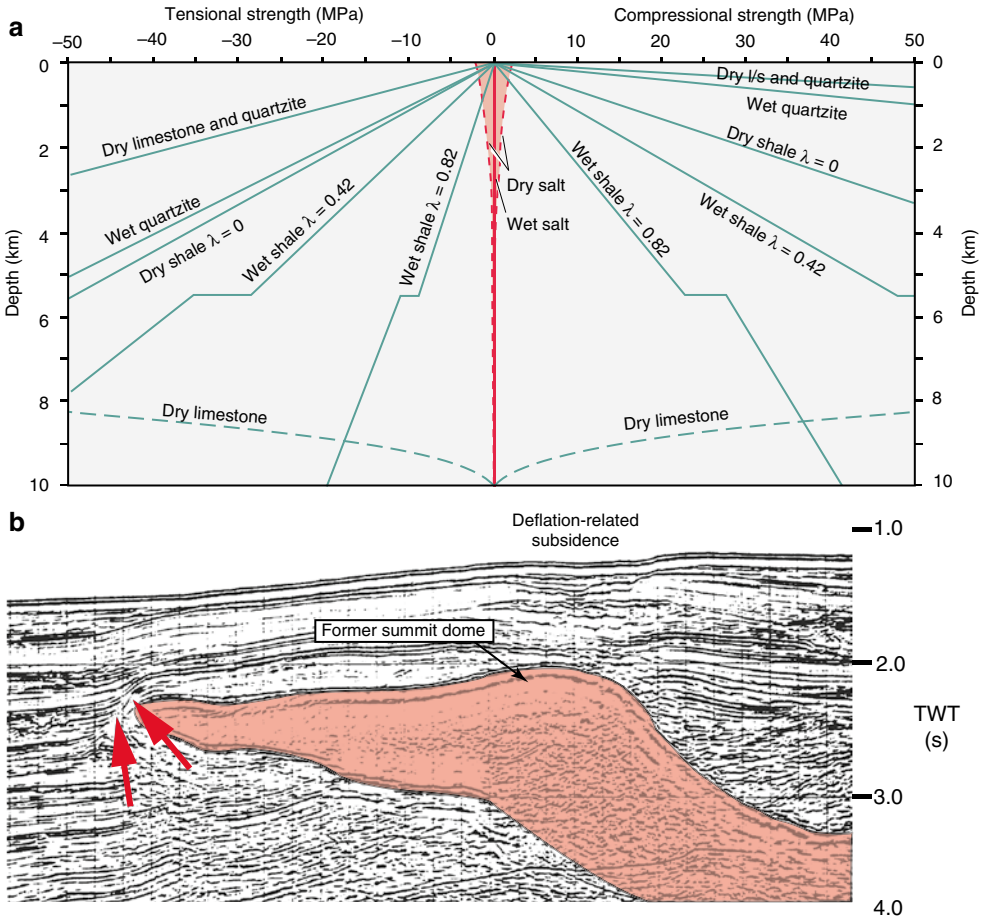

Fig. 6.7 Salt strength. (**a**) Comparison of creep and frictional strength of dry salt with equivalent strengths of dry and wet sedimentary rocks and sediments (After Jackson et al. 1994a, b). Creep strength is the deviatoric stress required to drive salt flow at a representative strain rate of 10^{-14} s^{-1}. Pore pressure coefficient (λ) is the ratio of pore pressure to lithostatic pressure: λ = 0 for dry rocks, λ = 0.46 for hydrostatically pressured rocks and λ = 0.86 for overpressured rocks. Note the extreme lack of strength of wet salt (*red line*) and the almost as weak field outline by dry salt (*shaded light red*). Wet salt is so weak (strength of 0.01 MPa at this strain rate) that its creep curves plot virtually on the central axis (hence modelled as Newtonian response). (**b**) Salt allochthon, northern Gulf of Mexico (After Nelson 1991). Onlap of frontal reflectors above a thin roof, averaging only 100 m thick (*red arrows* on left hand edge of salt tongue), indicates shallow emplacement of the allochthonous salt tongue

extruded at the surface it will collapse or spread under its own weight (gravity collapse or gravity spreading).

The extreme weakness of natural wet salt at the surface is seen in seismic onlap patterns of allochthonous salt sheets deforming by gravity gliding in the Gulf of Mexico. Salt sills are emplaced into low-density water-saturated shales at depths of less than 250–300 m beneath the sediment-water interface, with a mean depth of 150 m (Fig. 6.7b; Nelson and Fairchild 1989; Nelson 1991). Shales deeper than 300 m or so are too strong to be laterally intruded by a salt sheet. Were density contrast, rather than relative strength, the controlling factor then salt sheets would have spread out at depths ≈ 1,400 m, which is the level of neutral buoyancy beneath this part of the Gulf of Mexico (Nelson 1991). Salt weakness, or lack of strength, is thus more significant than buoyancy contrast in controlling the position of these allochthonous salt sheets.

In essence, the extremely weak nature of salt means that there can be essentially no shear stress acting on an interface between the salt and the adjacent formations. This means that there will be a tendency for principal stresses to re-orient themselves to be parallel and perpendicular to these weak planes. Ignoring how stress orientation and magnitude are affected by the presence of salt bodies can lead to costly well failures. In the Gulf of Mexico salt allochthons, Fredrich et al. (2003) found that stresses within the salt body may not be uniformly equal to lithostatic (as commonly assumed). Some of the drilling problems encountered when drilling through the bottom of a salt structure, that are usually attributed to very weak rock in a hypothesized rubble-zone (gumbo), may actually be associated with concentrated stresses at the bottom of the salt body.

The weakness of salt at geologic strain rates means the viscous forces in flowing salt cannot easily drag or stretch the overburden. Rather, thick flow-susceptible salt sheets act as a pressurized layer of lubricant that effectively decouples the overburden from the basement. A thick salt bed tends to act as a ductile "crack stopper" whereby it hinders faults and dykes propagating into higher or lower levels of the stratigraphy. A thick salt layer segments the basin sediments into suprasalt and infrasalt layers, which can deform independently or even by different processes. The impervious but fluid nature of salt focuses and entraps petroleum and mineralising fluids against a salt seal at the tops of subsalt faults, even if the faulting postdates deposition of the subsalt and suprasalt layers (Chap. 10). About the salt basin edge the degree of structural inheritance across a halokinetic salt layer depends on the distribution the mother salt in

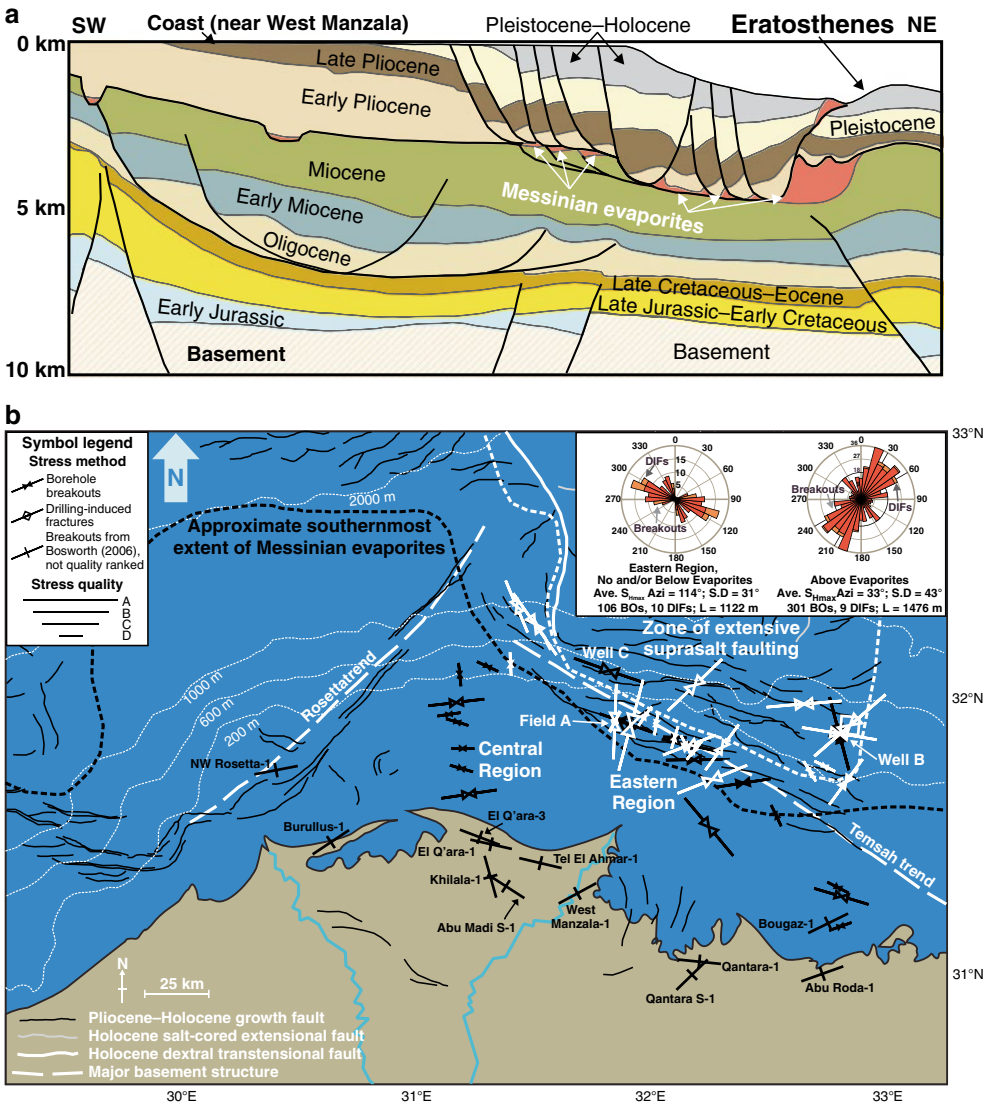

Fig. 6.8 Stress field in Nile Delta (**a**) Schematic cross section of the eastern Nile Delta illustrating major structural styles, in particular the suprasalt extensional faults that sole out on the withdrawal weld that is the Messinian evaporite level. (**b**) Present-day S_{Hmax} orientations interpreted from borehole breakouts and drilling-induced fractures (DIFs) in the Nile Delta. Stress orientations below or south of the Messinian evaporites (*black symbols*) indicate an approximately E-W S_{Hmax} orientation in the central region and an approximately ESE-WNW S_{Hmax} orientation in the eastern region of the Nile Delta. These orientations are broadly consistent with those observed in Bosworth (2006; black crosses). However, S_{Hmax} orientations are fairly scattered in sequences overlying Messinian evaporites (*white symbols*), although they show a predominately NE-SW S_{Hmax} orientation. Hence, the average S_{Hmax} orientation in sequences above the evaporites is approximately perpendicular to that observed below the evaporites (see inset rose diagrams), indicating that the subsalt and suprasalt sequences are mechanically detached. Furthermore, it is interesting to note that the S_{Hmax} orientations observed in suprasalt sequences are inconsistent with the predominately extensional faulting observed in this region. *Ave*. Average, *Azi* Azimuth, *BOs* Breakouts, *L* Total Breakout Length, *S.D* standard deviation (Adapted from Tingay et al. 2011)

relation to basin defining faults, prior to salt flow (Lewis et al. 2013).

Although widely assumed, actual quantified examples of differing stress tensors above and below a regional salt unit are rare. Recently, Tingay et al. (2011) examined present-day stress orientations, inferred from borehole breakout and drilling-induced fractures, in 44 boreholes in the offshore Nile Delta. There the presence of Messinian salt has influence stress fields. The salt extends part way beneath the Nile Delta and shows geometries indicative of loading and squeezing (Fig. 6.8a). A total of 446 breakouts and 19 drilling-induced fractures from 37 wells reveal sharply contrasting present-day maximum horizontal stress (S_{Hmax}) orientations in sequences above and below the extensive Messinian evaporites of the eastern Nile Delta (Fig. 6.8b). A typical deltaic margin-parallel S_{Hmax} (E-W in the central and ESE-WNW in

the eastern Nile Delta) occurs in parts of the Nile Delta that are below, or do not contain, evaporites. However, a scattered but largely margin-normal (NNE-SSW) S_{Hmax} is observed in sequences underlain by evaporites (inset in Fig. 6.8b). The ≈90° variation in present-day S_{Hmax} orientation above and below the Messinian salts provides convincing *in situ* quantified evidence that evaporite sequences act as major mechanical detachment horizons. In addition, the margin-normal S_{Hmax} orientation is subperpendicular to the strike of nearby active extensional faults, indicating the existence of non-Andersonian faulting in the suprasalt region. Furthermore, this evidence that the Messinian evaporites act as an effective mechanical detachment suggests that suprasalt faulting in the eastern Nile Delta is not the result of basement-related deformation and so raises doubts about the often-postulated extension of the Suez fault zone into the eastern Mediterranean.

Salt structure also alters the alignment of regional stress fields in compressional halokinetic regions in Germany (Brandes et al. 2013). The simple layer-cake geometry of the basin-fill in the Subhercynian Basin of northern Germany is dominated by several piercing and non-piercing salt structures sourced in Zechstein salt. Most Zechstein salt structures first formed in extension but underwent later compression (e.g. Fig. 6.77) On a regional scale, the Sub-Hercynian foreland basin-fill is characterized by a horizontal compressional paleostress vector that is mainly NNE-SSW-oriented, which reflects the Late Cretaceous inversion phase in Central Europe. However, the local paleostress field is distinctly perturbated due to the Zechstein salt structures. Along the edge of various salt pillows, the maximum horizontal paleostress vector is deflected by up to 90° from the regional trend. In the case of the Elm salt pillow, it forms a radial pattern. Brandes et al. (2013) derive four main controlling factors for the Subhercynian Basin and argue similar effects should typify salt-dominated contractional basins in a foreland setting. They are: (1) the wedge-shape basin-fill is the product of the dynamic load at the southern margin of the basin, (2) a basal salt layer fed the diapirs and acted as a detachment horizon during the later shortening, (3) detachment folding was the dominating deformation mechanism during contraction, and (4) the pre-existing diapirs controlled the position of the detachment folds.

Salt layers typically act as a lubricant in deforming sediment masses and in the extensional and compression examples just discussed. That is, the lubricious effects of salt layers are seen in the widths, taper angles, and internal structures of dynamic wedges at both converging and diverging plate boundaries. By lubricating regional décollements, even thin layers of salt influence how huge areas shorten or extend during gravity gliding. It leads to the complexities of raft tectonics, where rapidly opening ocean basins generate

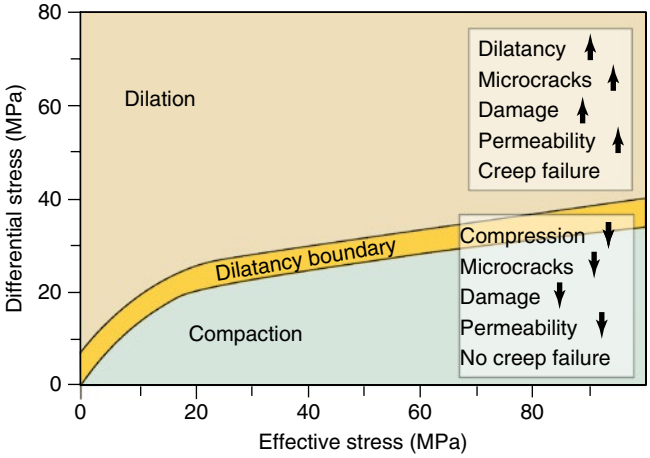

Fig. 6.9 Effective stress versus differential stress diagram for rock salt (After Schoenherr et al. 2007b). The dilatancy boundary separates domains where microcracking is suppressed (compaction domain) from those where rock salt dilates

floundering blocks of brittle sediments (tens of kilometres across and kilometres thick) that glide down into the widening basin atop a layer of lubricating salt. For the same reason fold thrust belts in converging plate margins that are deforming over salt layers are much wider, with critical taper angles <1–2°; while those deforming over more competent décollement layers are narrower, with taper angles nearing 8° (Davis and Engelder 1987).

Salt's fluidity and ability to reanneal make it a highly effective low permeability barrier to fluids escaping from the underlying sediments. As sediment is deposited atop an impervious but fluid salt layer, pressure beneath it builds as it acts as a pressure blanket. A layer of salt in a subsiding basin exaggerates overpressure in the section beneath the salt and mitigates transfer of overpressure to the section overlying the salt. If there are no breaches in the salt layer this can result in a tremendous increase of overpressure across the lower salt boundary (Fig. 8.22). Even thin salt sills can be highly efficient fluid seals. As a result, extremely overpressured sediments can be intersected immediately under a salt sill, creating a drilling hazard. When or where a salt sheet is breached by salt dissolution or salt evacuation, a highly pressured pulse of subsalt fluids may move up through the breach. In many situations the sole of a growth fault marks the breach and the extending fault becomes a conduit for the escape of hot basinal fluids, along with their elevated metal contents (Chap. 15).

In reality, a simple division into brittle versus viscous fluid response models is an oversimplification as salt and the adjacent sediments can, depending on the circumstances, exhibit either brittle or viscous responses to stress (Fig. 6.9; Davison et al. 1996a; Poliakov et al. 1996; Schoenherr et al. 2007b, c). Salt at the surface is brittle

enough to fault or shear, and such displacements are not uncommon in salt mines or in faults cutting across the surfaces of some dry salars of South America (Fig. 3.51). Likewise the overburden can show evidence of viscous behaviour. Sediments atop allochthonous salt sheets in the Mexican fold ridges in the Gulf of Mexico are mostly folded not faulted. Seismic also shows many diapirs have sedimentary margins with smooth drag profiles known as shale sheaths, rather than brittle faulted margins adjacent to fluid salt.

In some overpressured subsurface situations, halokinetic salt can become sufficiently dilatant as to allow entry or crossflow of pressurised fluids (Fig. 6.9). For example, salt cores recovered from the Cambrian Ara Salt in the South Oman Salt Basin are occasionally stained black with oil (Fig. 8.26; Schoenherr et al. 2007a, b; Kukla et al. 2011a, b). In some cases, up to 10 m of vertical section above the stringer contained mm-scale hydrocarbons lining polyhedral halite boundaries (Schoenherr et al. 2007a). In these stained zones cm-scale bands of millimetre-sized fluid inclusion-rich alternate with thinner fluid inclusion-free bands. In the same stained zones hydrocarbon-impregnated microcracks are frequently filled with solid bitumen, along with fluid inclusion trails with oil inclusions and gas bubbles. Subgrain-size piezometry on the Ara Salt indicates a maximum differential paleostress of <2 MPa (Schoenherr et al. 2007a) in rock salt adjacent to carbonate stringers. At a differential stress of <2 MPa, rock salt can dilate only at near-zero effective stresses (Fig. 6.7a). This is only possible at great depth when fluid pressure in the rock salt is very close to the minimum principal stress σ_3 (Fig. 8.25).

Thermal Effects

In addition to pressure/strength interactions, variations in burial temperature gradients can influence salt flow intensity. In terms of its thermal properties halite is an unusual mineral. It is one of the most thermally conductive sediments, at 43 °C the thermal conductivity of halite is 5.13 W/m-K, while a typical shale at the same temperature is 1.76 W/m-K (Figs. 6.10 and 8.25). Halite's volumetrics also respond differentially to heating. At a depth of 5 km, under a geothermal gradient of 30 °C/km, halite expands 2 % due to heat and contracts 0.5 % due to pressure (Jackson and Talbot 1994). Under such a scenario (assuming zero porosity at either depth) the base of a thick salt unit becomes slightly less dense with the increased temperatures associated with burial and so creates a temperature-induced density inversion. Thermally induced convective flow is theoretically possible in a salt layer thicker than 2.9 km under a geothermal gradient of 30 °C per km (assuming a viscosity of $<10^{16}$ Pa.s).

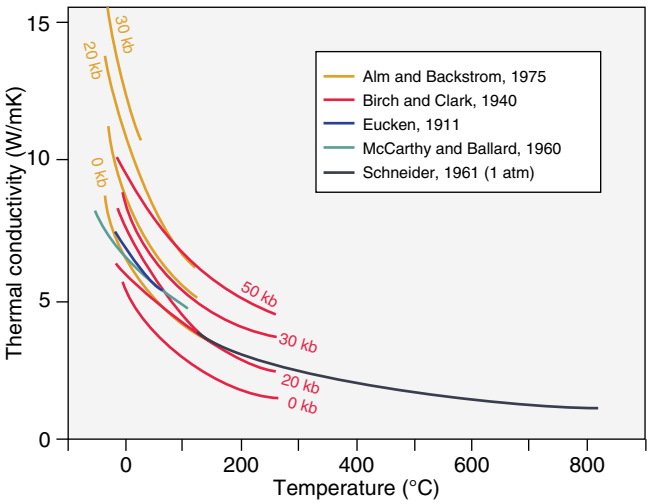

Fig. 6.10 Temperature and pressure effects on the measured thermal conductivity of halite (After Robertson 1988), see also Fig. 8.22

This mechanism may trigger diapirism in salt-filled rifts characterised by elevated nearsurface temperatures and high geothermal gradients (Talbot 1978). The volcano-shaped mounds associated with hot springs in Ethiopia's Danakil Depression, such as Da nakil Mound and its hornitos, may be located above the tops of thermally convecting plumes of salt (Fig. 11.16), as may the diapiric features on Europa, a moon of Jupiter (Pappalardo and Barr 2004) and the layered ice diapirs on Triton a moon of Neptune (Schenk and Jackson 1993; Talbot 2008).

Gussow (1968) argued that outcropping Iranian salt glaciers were catastrophic extrusives emplaced hot, in a similar way to a lava flow. He thought that heated salt was intrusive and that the salt glaciers have now cooled and so are no longer flowing. He was strongly influenced by early experimental work on dislocation creep using coarse-grained dry salt that had indicated salt could only flow at temperatures above 200 °C. We now know that most confined salt in the sedimentary realm is wet, extremely weak and capable of flow at earth surface temperatures. Later work in Iran by Kent (1979, 1987) and Talbot (1979) indicated that the salt in many namakiers is still flowing today. Temperature triggers, as first noted by Gussow (1968), do become an important consideration that can create intrusive sills and dykes once bedded salt enters greenschist facies conditions, as is perhaps seen in intrusive Neoproterozoic salt remnants in the thrust belt of the Damara Orogen in Namibia and in the Ugandan copper belt (Chap. 13 for discussion). Hot molten salt intrusion is not a major mechanism of salt emplacement in the diagenetic realm in this or in other sedimentary basins. Sodic carbonatites are another matter altogether and are discussed in Chap. 16, along with dolerite dykes cutting through salt masses,
