The genetic model of Heijlen et al. (2008) further refined their model and concluded that halite dissolution was an important process for generating the saline mineralizing fluids that formed Kipushi, as indicated by Cl–Br–Na systematics of fluid inclusions. The mineralising fluid of the main ore-forming phase had a salinity of ≈ 30–43 eq. wt.% NaCl and likely originated from formation waters or metamorphic fluids that were expelled late in the orogenic evolution. After dissolving evaporites and perhaps evolving scapolites, the resulting saline fluids were capable of leaching metals from upper crustal country rocks during their rise to the surface, as indicated by lead isotopes. The relatively high metal content (Ba, Zn, Fe, Pb) of the NaCl–KCl–$CaCl_2$ fluid suggests that the source rocks included felsic basement. The absence of baryte, despite the high Ba concentration in the fluid, indicates that the mineralisation occurred in reducing conditions and sulphur was locally available as sulphide.

$\delta^{34}S$ signatures of the main orebody demonstrate that the sulphide was derived from seawater sulphate through thermochemical sulphate reduction (TSR), simultaneously oxidising organic material and generating H_2S. Part of the sulphide in the concordant orebody along the contact of the Kipushi Formation and the Série Récurrente, however, was most likely derived from bacterial sulphate reduction (BSR) during diagenesis. They may have been preserved in the form of pyrites up to the time of ore formation. Heijlen et al. (2008) suggest that mineralisation took place when highly saline and metal-bearing fluids encountered an H_2S-rich hydrocarbon reservoir during fault-controlled expulsion. The Sr and Nd isotopic composition of the gangue dolomite and the metal content of fluid inclusions, indicate that the mineralising fluid interacted with rocks of both mafic and felsic affinities in the basement and possibly in the Roan. These rocks provided the metals for the Kipushi mineralisation (Van Wilderode et al. 2013).

For the purposes of "on ground" targeting of an analogous deposit an exact distinction in terms of fluid timing may be largely academic when defining greenfield sites for a preliminary sampling program. What is obvious from the relationship of mineralisation to the halokinetic breccia at Kipushi is that the breccia margin in contact with organic-rich sediments was the precipitational focus for the mineralising solutions. This occurred either as the residual salt was still dissolving, or once it had dissolved and scapolite transformations were supplying the metal-entraining volatiles (Fig. 15.31). An exact determination of the time of the mineralisation is not the fundamental control on the location of the deposit. The salt structure induced focus to fluid flow and its associated redox front is what is important. This relationship in a mineralised halokinetic province, even when metamorphosed, is predictable and mappable.

Interestingly' across the various documented SSC deposits, it seems that halokinetic associations constitute the larger deposits, rather than the bedded association we shall discuss next. This is because the dissolving edge of a flowing salt mass can maintain its position in earth space as more salt will flow in and replace the salt that is lost by dissolution, until the contact with the mother salt layer is lost via salt welding or the mother salt bed is depleted. In contrast, the redox front at the edge of a bedded salt mass is more likely to be a retreating front, and only the underside of a thick bedded mass is stable over long enough time frames to form an economic sulphide accumulation. We shall return to this discussion later in the chapter, after we have considered non-halokinetic examples.

Sediment-Hosted Cu in Bedded Evaporite Context

In this type of deposit the associated evaporite is typically bedded and the size of the resource in individual is typically less than in the halokinetic association. We shall start this discussion with the Corocoro ore district of Bolivia as it offers an interesting quandary as to the relative importance halokinesis played in its genesis. The other deposits discussed in this section have bedded evaporite not halokinetic redox associations

Corocoro and Other Sandstone-Hosted Deposits of the Central Andes

Stratabound deposits of copper (+Ag) hosted by variably-dipping continental clastic sedimentary rocks occur in Central Andean intermontane basins and are known to postdate compressive deformation/uplift events in the region (Flint 1986, 1989). The deposits are relatively small and include; Negra Huanusha, central Peru (Permo-Triassic); Caleta Coloso, northern Chile (Lower Cretaceous); Corocoro, northwestern Bolivia (Oligo-Miocene); San Bartolo, northern Chile (Oligo-Miocene); and Yasyamayo, northwestern Argentina (Miocene-Pliocene). The Corocoro area has produced the largest amount of copper in the Andean examples, something like 7.8 million tonnes of copper at a grade of 7.1 % (Cox et al. 2007). The location of mineralisation is controlled by structurally-focused redox fronts in bedded sediment hosts, which abut a steeply-dipping translatent fault (Fig. 15.33). Deposits are irregular, usually elongate lenses of native metal, sulphides, and their oxidation products. Typically, deposits are hosted in alluvial fan and playa sandstones or conglomerate facies that also contain abundant gypsum and lesser halite. The undersides of some copper sheets at Corocoro even preserve mud-crack polygons and bed-parallel burrow traces (Savrda et al.

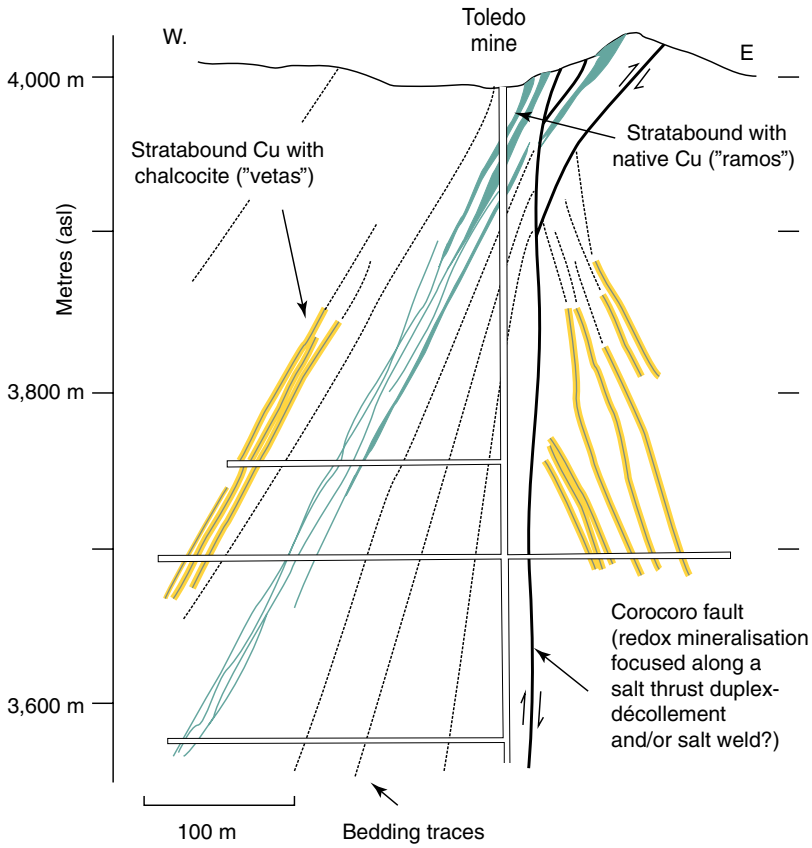

Fig. 15.33 Cross section of the Toledo mine in the Corocoro ore district (Adapted from Entwistle and Gouin 1955)

2006). Ore mimicry of mudcracks is not a feature controlled by on-for-one-replacement of organic material deposited in a sandstone, rather it is following preexisting permeability/redox contrasts.

The Corocoro deposits in Bolivia have been mined sporadically since they were first exploited by the local Indians, prior to the Spanish invasion in the sixteenth century and were largely exhausted in half a century of more intense mining operations beginning in 1873 (Fig. 15.33). Sandstone and conglomerate matrices show evidence of bleaching and leaching of the original redbed host with numerous red-greybed redox interfaces visible in the mined sequences. Ore minerals (dominantly native copper) are secondary fills within secondary intergranular pores created by the dissolution of earlier carbonate and sulphate masses and intergranular cements. Twelve grey sandstone beds, which were host to the long worked-out native copper ores, occur within a stratigraphic thickness of 60 m in a unit known as the Ramos Member which still hosts abundant $CaSO_4$ as gypsum.

Ores are stratabound, but not necessarily stratiform and the larger masses of native copper are typically present as vein fills. Sometimes the copper pseudomorphs large orthagonal-ended aragonite prisms that can be several centimetres across. There are two main styles of mineralization; (1) Ore minerals as a matrix to stratiform detrital silicates, typically low dipping and commonly highlighting primary sedimentary structures, such as cross stratification (2) Ores in stacked channelized bodies, that show steep dips in structurally complex and folded zones with local brecciation. Native copper commonly fills thin laterally extensive sheets in tectonic fractures in the limbs of such tight folds. Ljunggren and Meyer (1964) interpreted these folded diagenetic sheets of copper as a remobilization products precipitated during deformation of earlier matrix-pore filling copper.

Critical factors in Corocoro ore genesis include (Flint 1989): (1) Stratigraphic association of evaporites, organic-rich lacustrine mudstones, clastic reservoir rocks, and orogenic, igneous provenance areas for both basin-fill sediments and metals; and (2) Intrabasinal evolution of metal-mobilising saline brines derived from the buried and dissolving lacustrine evaporites that flush volcaniclastics, volcanics and feldspathic sediments. The same saline diagenetic fluids also caused the dissolution of early, framework supporting cement and large aragonite prisms, all now pseudomorphed by native copper.

The ore-hosting clastic horizons are consistently located in the highly gypsiferous Vetas Member of the Ramos Formation, which was deposited as redbeds in braidplains or fluviodeltaic playa margins centripetal to the edges of saline evaporitic lakes that were accumulating gypsum and halite (Fig. 15.34; Flint 1989). Abundant gypsum is still present in the Ramos Member as nodules and satinspar vein fills, both are secondary

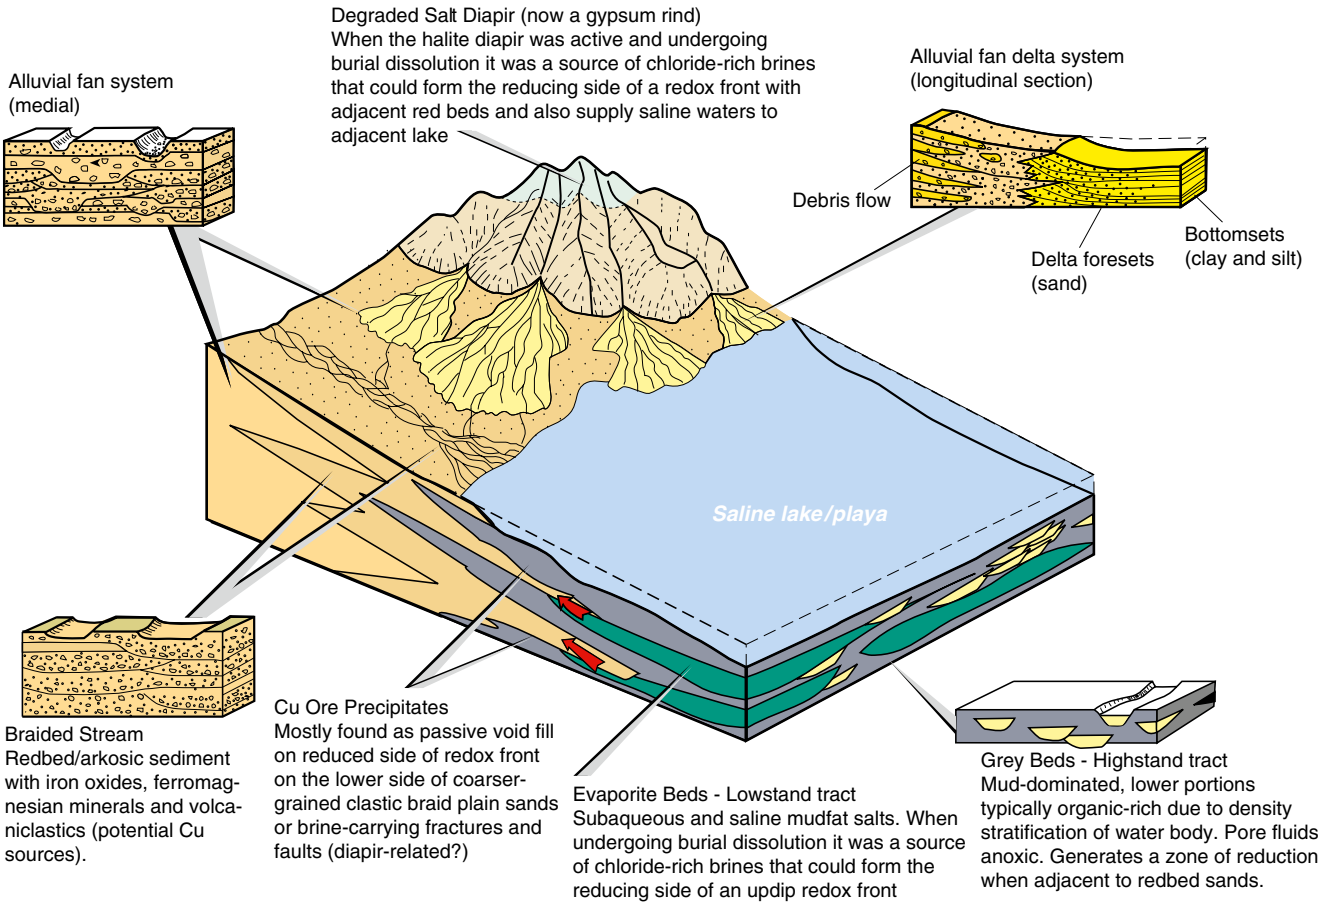

Fig. 15.34 Sedimentological model for precipitation of Corocoro ores showing source of metalliferous chloride brines by early burial dissolution of bedded evaporites or diapir or salt-décollement dissolution (or both) and the resultant setup of the Cu-precipitating redox front (In part after Flint 1989; Warren 2000b)

evaporite textures likely implying dissolution of previously more voluminous $CaSO_4$ and NaCl beds and masses. Gypsum along with celestite are the most common gangue minerals associated with native copper veins in all the Corocoro deposits (Singewald and Berry 1922). In the geological analysis of the first two decades of last century the copper-bearing beds of the westerly-dipping series were called "vetas" and those of the easterly-dipping beds "ramos" and, as a matter of convenience, the names became attached to the rocks themselves. The term "veta" is Spanish for vein and "ramo" the Spanish for branch (native copper). The 1922 paper by Singewald and Berry noted that the veta horizons were traceable continuously for over 5 km in outcrop, but there were no obvious primary trends related to ramos outcrops (Fig. 15.33).

Six mineralized layers of each kind were exploited in mining during the first two decades of last century, the thicknesses of which varied from a few centimetres to 7 m (Fig. 15.33). Sheets and masses of native copper, called charque, were up to 600 lb in weight, but larger volumes of copper were extracted from vetas sandstones where copper was found generally as diffuse minute grains, pellets, or granular masses of the native metal. Associated with the enriched copper zones were more oxidised minerals such as malachite, chrysocolla, azurite, domeykite, and chalcocite. Singewald and Berry (1922) noted gypsum and salt were the principal gangue minerals, while silver minerals were rare. The vetas sediment hosts tended to be coarser grained, often conglomeratic; whereas the ramos sediment hosts were finer-grained with copper present as smaller particles and masses.

The currently accepted interpretation of the Corocoro copper is that it formed during early diagenesis within a saline playa depositional environment, and in combination with dissolution of the adjacent bedded lacustrine evaporites (Fig. 15.34). This bedded combination is thought to have controlled the formation, transport and precipitation of the copper ore (Flint 1989). Playa sandstones, sealed between impervious evaporitic mudstones, created the plumbing for focused metalliferous fluid migration toward the basin margin. It is argued that the carbonaceous material at Corocoro was likely concentrated in the sandstones and conglomerates and not in the shalier members of the sedimentary sequence (Eugster 1989).

The organics were considered strata-entrained as primary plant matter (e.g. spores) preferentially in the sandstones, along with later possible catagenic/hydrothermally cracked products migrating as hydrocarbons out of the basin. This created locally reducing pore environments in the aquifers wherever these reduced fluids met with somewhat more oxidising updip pore waters. This updip migration of saline reducing waters, in combination with sulphur supplied as H_2S from the adjacent dissolving calcium sulphate beds and nodules, as well as from dissolving intergranular sulphate cements, precipitated copper in the newly created secondary porosity. The pore water chemistry and flow hydrology of this sandstone-hosted Cu system is thought to show many affinities with diagenetic uranium-redox precipitating systems, as defined by Shockey and Renfro (1974).

However there is, in my mind, a possible anomaly in this model, which assumes organics were deposited in fluvial sandstones at the time of deposition. It is highly unusual to have higher plant material accumulating in large volumes in a sandstone in a setting that is sufficiently arid and oxidising to precipitate ongoing interbeds of halite and gypsum. Such settings are typically too arid to allow abundant higher plant growth. Also, as we saw in Chaps. 2 and 9, groundwaters that are flowing basinward through bajada sandstones in Neogene sediments of the Andes are ephemeral or too oxidising to facilitate the longterm reducing conditions needed to preserve significant volumes of higher-plant remains in the sandstone aquifers.

What is also interesting in this sedimentological/diagenetic model of Tertiary age cupriferous redbeds deposits in the Andes, centred on Corocoro, but not considered in the published literature base, is the question…What controlled the folding, and the associated brecciation and perhaps even subsurface brine interfaces responsible for the Cu precipitation? All the stratabound Bolivian Cu deposits accumulated in sediment hosts that were deposited in fault-bound intermontane groundwater sumps. All are located in hydrologic lows in the crustal shortening tectonic scenario that typifies the Tertiary history of the Andes.

The variable ages of the host sediments and the predominance of evaporite indicators including gypsum in outcrop (often as diagenetic masses in fluvial hosts) and all intimately tied to the Corocoro ore forces the question...., "was the fluid focusing driving the Cu precipitation a response to compression-driven halokinesis in an evolving salt-lubricated thrust belt?" Did this on-ground scenario occur in a halokinetic hydrology, that was possibly related to a combination of thrust-driven telogenesis, redox setup, evaporite dissolution and aquifer focusing of brines with dissolution aiding local slumping? This, along with associated strike-slip prisms, could possibly better explain the stability of redox interfaces in sandstone aquifers across timeframes needed to accumulate significant native copper volumes. After all, most of the ore textures are passive precipitates, largely in pre-existing porosity. If so, perhaps these deposits are not a variation on a roll-front uranium theme, which is predicated on dispersed primary organic material in the host sandstones (Shockey and Renfro 1974).

Fig. 15.35 Corocoro district, Bolivia. Satellite image showing a gypsum-capped salt diapir that outcrops in a salt thrust décollement around a kilometer north of the main Corocoro deposits. Location is plotted using SaltWork version 1.6 mounted on the public version of the Bing® image base

When one plots the position of Corocoro using a GIS overlay of the region, the 1,000-lb gorilla that has been standing in the corner of the room for the past century becomes obvious. The Corocoro redbed copper is located on a fault system that is linked across less than a kilometre to an outcropping gypsum-capped remnant of a salt diapir that has intruded the anticlinal axis of a saline redbed/greybed Corocoro sequence (Fig. 15.35). The same diapir proximity is true of other nearby redbed copper deposits to the south-southeast, such as Veta Verde and Callapa. It is highly likely

that the saline fluid interfaces forming the redbed Cu deposits of Corocoro, Veta Verde and Callapa were halokinetically focused. A similar salt lubricated set of thrusts and strike-slip faults typifies halokinetic outcrops in Central Iran (Fig. 6.90). It is highly likely that much of the structuration that is controlling Corocoro ore positioning is a response to salt flow related uplift and fracture creation, probably in redox interfaces induced and controlled by regional salt-lubricated compressional tectonism and the associated salt-structure driven hydrology.

Work by Rutland (1966) did make an observation that the Corocoro ore deposits are related to an unconformity between the Ramos and Vetas Formations. Previously, the unconformity was interpreted as directly due to the outcrop of the Corocoro Fault. He noted that the fault and the unconformity were one and the same. In the 1960s there was no notion of a salt weld but it was nonetheless a highly astute observation by Roy Rutland. He went on to note a similar unconformity is tied to the growth of the Chuquichambi salt diapir, some 100 km southeast of Corocoro. Unfortunately, the halokinetic implications of Rutland's work were not considered 20 years later in Flint's key 1989 paper inferring a largely sedimentological origin for the Corocoro and other similar SSC deposits.

A possible halokinetic/weld association also leads to the question… Were the salt lakes, that are considered an integral part of the depositional and saline ore-precipitation systems at Corocoro by Flint, also a response to dissolution of the same nearby diapiric structures, when they were active in the mid to late Tertiary? This tie, between diapir/weld brines sourced in the drainage hinterland and bedded evaporite – lacustrine mud interbeds accumulating in the groundwater outflow sumps, is the case with groundwater inflow for the Salar de Atacama infill, as it is in other Quaternary salt lakes in the region. Figure 3.44 plots some of the many diapir remnants that typify the Andes region. It seems that the Corocoro style of Cu mineralisation is perhaps another example of suprasalt redox focusing in a halokinetic setting.

Whether the halokinetic scenario, or the currently accepted non-halokinetic bedded arid-lacustrine evaporite scenario, explains the Cu mineralisation Corocoro is yet to be tested. But in terms of future copper exploration for similar deposits, it probably requires an answer. A halokinetic association offers an exploration targeting mechanism, utilising satellite imagery and aerial/gravimetric data, prior to the acquisition of on-ground land positions and geochemical surveys.

Creta, Oklahoma

The Creta deposit occurs in the upper part of the Flowerpot Shale (Nippewala Group) within the Hollis-Hardeman Basin, Oklahoma. It is associated with the WNW-ESE trending Wichita basement high where the ore host strata overlie Cambrian bimodal igneous rocks. Similar cupriferous, but noneconomic, sediments occur in several other locations within Upper Permian strata in Oklahoma, Kansas, Texas and New Mexico. Regionally some 900–3,400 m of mixed clastic and chemical sediments of Ordovician to Permian age make up the Hollis-Hardeman basin fill, which, in turn, overlies a Precambrian to Cambrian basement made up of metasediments and metavolcanics. Locally, in the vicinity of the Creta deposit, sediment thickening is associated with movement on the Birch Fault, so that the sedimentary sequence is locally 3,200 m thick and dominated by fine-grained clastics that show a gradual upward increase in the proportion of evaporites in to the Upper Permian section.

Ore-grade material was mined, mostly as chalcocite, from the Creta copper-bearing shale in southwestern Oklahoma from October 1965 to February 1975, when a drop in the price of copper forced the mine to close. Production from Creta between 1965 and 1975 totalled around 1.8 Mt @ 2.3 % Cu, 5.5 g/t Ag. The nearby Magnum deposit is believed to have a sub-economic reserve of approximately 3.6 Mt @ 1 % Cu. This extracted volume makes Creta the second largest shale-hosted Cu deposit in the United States. Lead and zinc levels are negligible at Creta. At nearby Magnum, malachite [$CuCO_3Cu(OH)_2$] is the most abundant copper mineral, although chalcocite may be the dominant ore mineral in the subsurface.

According to Huyck and Chorey (1991), the mineralisation event at Creta was early diagenetic, as indicated by: (1) Copper sulphide replacing large spores and framboidal pyrite, (2) Lack of compaction of replaced spores relative to unreplaced spores, (3) Enclosure of uncompacted mud and copper sulphides by early "matrix gypsum", (4) Location of the ore bed within a thick sequence of fine-grained low permeability sediments.

Seven lithologic units occur in the upper 19 m of the Flowerpot Shale and include the Prewitt Shale member, which hosts the Creta deposit (Fig. 15.36). This interval is characterised by two common features: (a) Satinspar gypsum veins and (b) Variegated red-green layers. The veins both crosscut and parallel shale bedding and partings. They typically terminate within either nodular or massive gypsum beds or in gypsiferous green shale beds. In mineralised zones they usually encapsulate shale intraclasts and copper minerals. The variegated layers and lenses are composed of discontinuous silty (60–80 % silt) calcareous and gypsiferous red-brown layers. When the variegated layers are traced laterally they pass into adjacent gypsum, the layers obviously reflect dissolved gypsum or satinspar intervals.

The Prewitt Shale averages 2 % Cu in the mine area, with a matrix composed of illite and chlorite and as much as 20 % satinspar gypsum. It is made up of three layers: a lower blocky layer, a laminated layer and a discontinuous upper bed of impure gypsum (the "cap gypsum"). The lowest

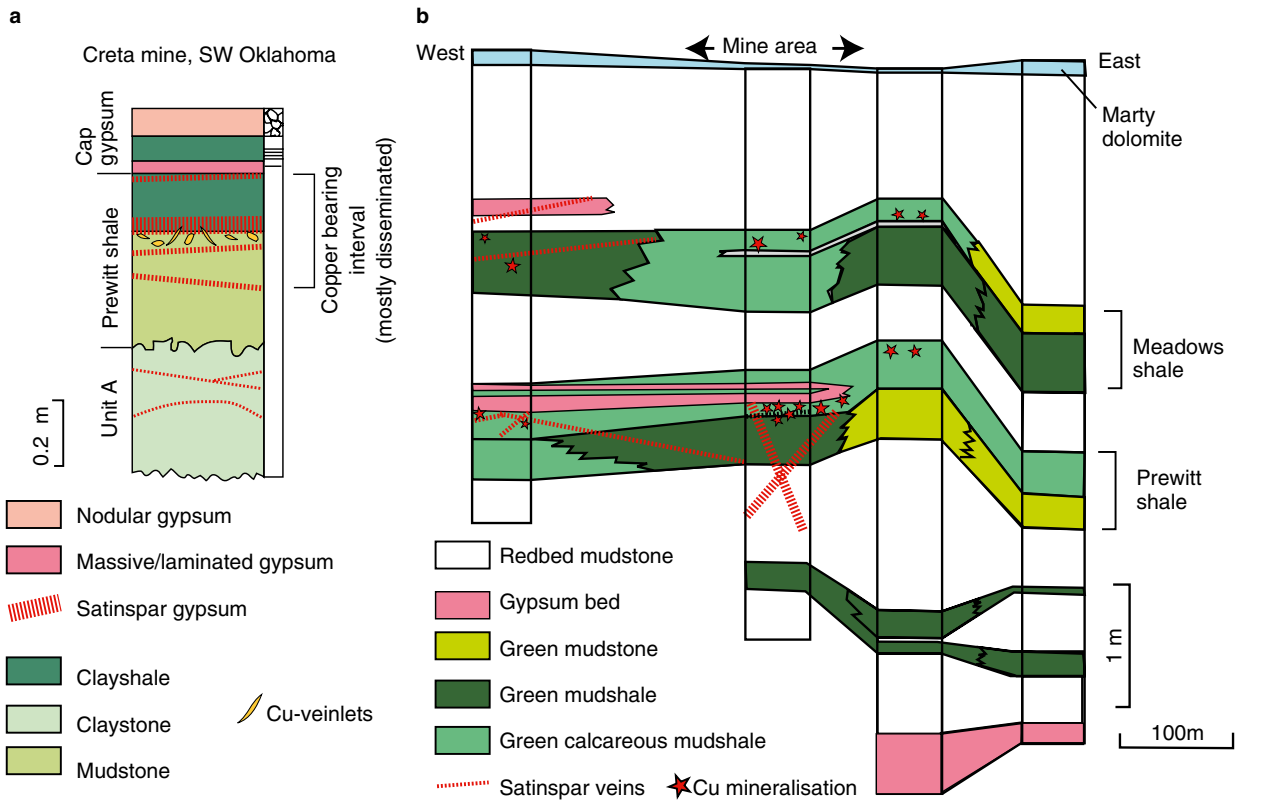

Fig. 15.36 Creta copper shale deposit, Oklahoma. (**a**) Mineralised stratigraphy in the Creta Mine. (**b**) Mine region stratigraphy showing intimate association between mineralisation and evaporite occurrence (After Huyck and Chorey 1991)

blocky layer is a claystone to mudstone; copper, when present, occurs only in the upper 10–13 cm and is concentrated in the mudstone (Fig. 15.36a). The overlying laminated shale, which contains as much as 4.5 % Cu, includes both gypsiferous and nongypsiferous clayshale. Copper is concentrated in the silty laminae both in outcrop (as malachite) and in thin section (as anilite). The cap gypsum bed directly overlies the laminated portion of the Prewitt Shale in the west, but pinches out in the east (Fig. 15.36b). Where fully developed the cap gypsum bed (10–25 cm thick) is made up of a lower gypsum, a thin green clayshale, and an upper gypsum.

Copper mineralisation only occurs in association with concentrations of pyrite and spores. The main ore mineral is anilite ($Cu_{1.75}S$) and is concentrated along silty or sulphide rich layers in the laminated unit. In gypsiferous shale the opaques are concentrated along the edge of the satinspar veins and within clay blebs in the matrix gypsum. Anilite is also weakly developed throughout the nongypsiferous portions of the Prewitt Shale. The association of Cu mineralisation with evaporite occurrence in the Prewitt Shale is obvious, and reflects a burial diagenetic mineralisation at a redox interface. In my opinion, it is associated with an anoxic reduction front (red-green transition) that was generated and maintained by the dissolving evaporites indicated by the satin-spar.

Most published work on this deposit documents satinspar gypsum as well as the cap gypsum, but none (including the most comprehensive work by Huyck and Chorey 1991) discuss its significance, nor do they mention the implications in terms of fluid focussing of a thick now variably-dissolved gypsum/anhydrite/halite units that dominate Blaine Formation and situated immediately above the mineralised portions of the Flowerpot Shale (Muir 1934; Askew 2013).

The presence of satinspar gypsum in the mineralised zone indicates a likely combination of halite solution-collapse and gypsum rehydration. As such, the current forms of $CaSO_4$ in the mine area are tertiary or telogenetic evaporites, a result of uplift and rehydration tied to salt dissolution (Chaps. 1 and 7). The current evaporites were not responsible for the precipitation of the sulphides as they postdate that event. They do, however, indicate the former presence of a more substantial, but now dissolved, evaporite unit composed either of anhydrite, or perhaps a combination of halite and anhydrite that focused mineralisation below it into the prepared ground in the Flowerpot shale. It was this former evaporite seal that was responsible for brine focusing and, through its dissolution (indicated by the cap and satinspar gypsum units), maintained a redox front that precipitated the copper sulphides. Creta is perhaps a smaller-scale subsalt example of a redox precipitation hydrology similar to the Kupferschiefer/Rudna Rote

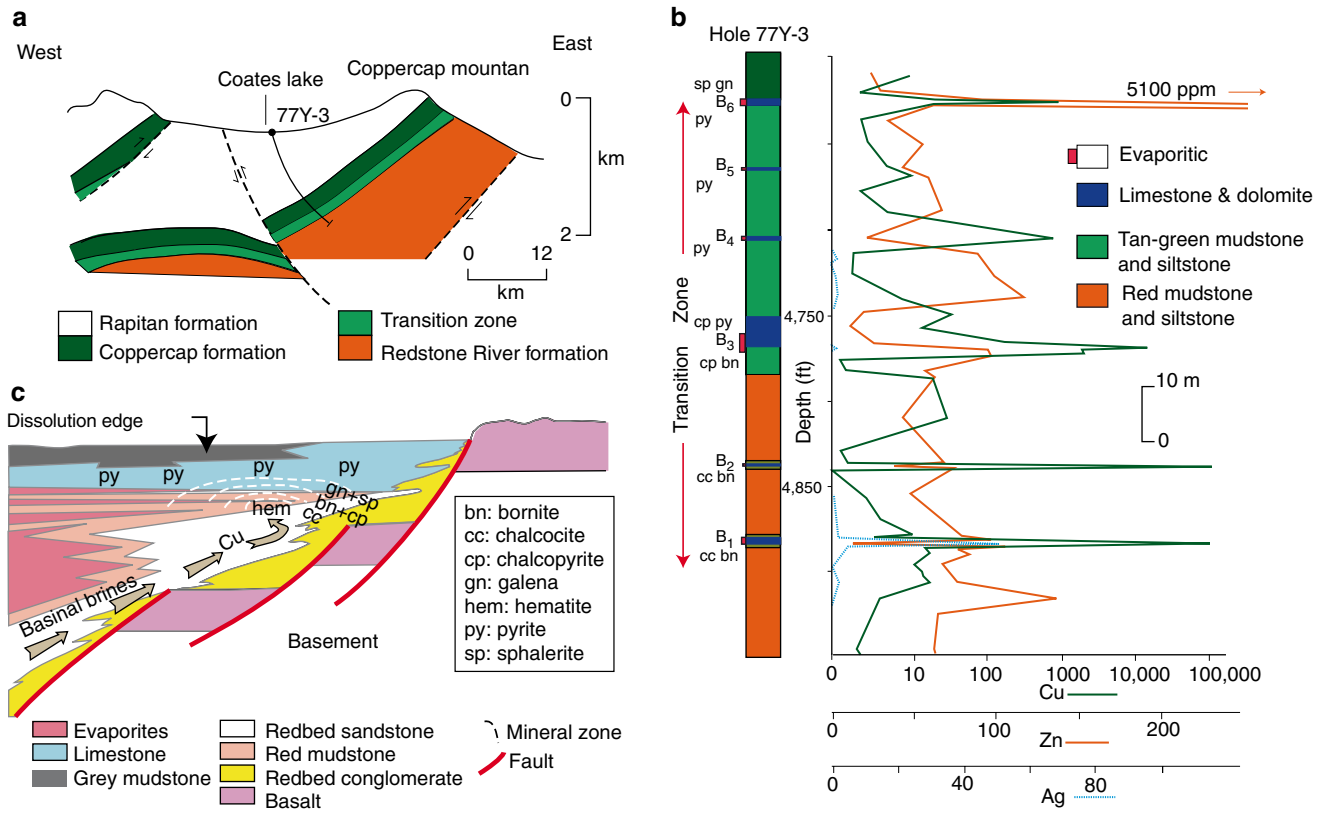

Fig. 15.37 Redstone Copper Belt, Canada. (**a**) E-W geological cross-section of Coates Lake region showing well 77Y-3. (**b**) Stratigraphy and metal content of well 77Y-3 (After Chartrand et al. 1989). (**c**) Diagrammatic section across a redbed-evaporite rift margin showing mineral zonation of precipitated sulphides. Modelled from Redstone Copper Belt, Northwest Territories, Canada (After Kirkham 1989)

Faule of Poland. Smaller perhaps, because the salt dissolution front was not maintained in a stable long-term position because of the lack of halokinetically driven salt resupply.

Redstone Copper Belt, Canada

Coates Lake is the largest stratiform redbed copper prospect in the Redstone Copper Belt, Northwest Territories, Canada. Associated with it are a number of smaller deposits (Hayhook, Keeles River), which all occur in a 250 km, northwest-trending, arcuate thrust belt made up of Neoproterozoic (Helikian) carbonates and redbeds. These sediments are part of the Mackenzie Mountain Supergroup (Fig. 15.37a and Table 15.10; Chartrand et al. 1989; Ruelle 1982; Brown 1997).

Coates Lake and the smaller various copper deposits occur at the contact (in the Transition Zone) between the continental alluvial redbeds of the Neoproterozoic (750 Ma) Redstone River Formation (0–1,220 m thick) and the shallow marine/ evaporitic rocks of the overlying Lower Coppercap Formation (≈250 m thick). The Transition Zone host strata are composed of several blanket-like variably-cupriferous units of dolomitic silty, evaporitic cryptalgal-laminated carbonates that were deposited atop the fault-bound Coates Lake, Hayhook Lake and Keele River embayments.

Sediments in the Transition Zone are made up of six shoaling peritidal cycles, deposited along arid shorelines with sabkha affinities (Chartrand et al. 1989). Higher levels of mineralisation are typically found within the evaporitic/ stromatolitic carbonate portion of each depositional cycle. At the base of a typical cycle, red siltstone and mudstone grade up over a few decimetres into tan and green-coloured siltstone, exhibiting the same sedimentary textures and structures as their underlying red counterparts (Fig. 15.37b). These terrigenous strata grade over a few centimetres into grey-green dolosiltite and dololutite overlain by microbial laminated carbonate, the principal host for the cupriferous sulphides. The dolosiltites and dololutites are capped by gypsum/ anhydrite-rich units that are decimetres thick. Evaporitic units are overlain by tan-green siltstone and mudstone and, finally, by red siltstone. Beds B4-B7 are dominated by tan-green colours with most of the entrained mudstone and siltstone intervals containing more calcite and/or dolomite than their counterparts in beds B1-B3 (Fig. 15.37b). The succession is crosscut by late-stage calcite and gypsum veins.

Beneath the Transition Zone sediments, in the Lower Redstone River Formation, Ruelle (1982) mentioned the presence of an unusual high Na-Mg Precambrian evaporite

Table 15.10 Stratigraphy of Redstone Copper belt

Unit		Description
Rapitan Formation (unconformable base)		Turbiditic, siliceous red siltstones, maroon and green debris flows and tillites, which lie with regional unconformity on the Coates Lake and Little Dal Groups.
Mackenzie Mountain Supergroup	Coppercap Formation (0–300 m)	Upper Unit (0–165 m) of well bedded, stromatolitic limestone and dolostone, Middle Unit (0–72 m) of argillaceous carbonate and calcareous shale, Lower Unit (0–63 m) of evaporitic limestone and dolostone, and laminated dolostone (Lower Middle and Upper Coppercap Formation carbonate sediments are all fetid and black).
	Transition Zone (40 to over 110 m)	Series of red, green, and tan coloured nearshore arid coastal deposits. Copper occurrences are hosted by up to eight fining-upwards, carbonate-evaporite beds, each composed of dolosiltite, dololutite, dolostone, gypsum, anhydrite and capped by a cryptalgal laminated carbonate bed.
	Redstone Formation (0–1,220 m)	A Lower "Evaporite" unit is composed of bedded and brecciated gypsum-anhydrite, which thins at basin margins and reaches thicknesses of over 215 m at basin centres. An Upper "Redbed" subunit is dominated by maroon mudstones with thin marginal fanglomerates.
	Thundercloud Formation (0–300 m)	Lower portion made up of basal volcaniclastics, alluvial fanglomerates, tidal arenites and paralic mudstones. These are overlain by rhythmically interbedded carbonate and dolostone locally containing evaporites, followed by cyclically interbedded sandstone and shale. Upper part of the formation is marked by evaporitic algal dolostones.
	Little Dal Formation contact	Contact with the underlying Little Dal Formation is marked by pillowed basaltic lava, or sandstone, dolomite, siltstone, and mudstone with local gypsum and conglomerate. Where basaltic lava is present the contact is conformable but the sedimentary units mark a distinct unconformity.

Based on Aitken (1981), Ruelle (1982), and Jefferson and Ruelle (1986)

assemblage now largely marked by collapse residues and breccias. Today, it is made up of 55 % glauberite [$Na_2Ca(SO_4)_2$], 20 % magnesite, 15 % talc and <10 % combined gypsum and anhydrite. Strauss (1993) consider these evaporites to be time-equivalent to the upper evaporite level, the Killian Formation, in the Amundsen Embayment At this time the significance of this sulphate-evaporite-rich residue assemblage in relation to the overlying sulphate evaporites and to focusing a redox front with any metal-transporting brines is neither well documented nor understood. At the time of mineralisation there may have been a much thicker, possibly halokinetic, halite mass. If so then the Transition Zone copper beds are suprasalt with affinities to the Lisbon Valley and possibly the Dzhezkazgan deposits. Without public domain detail beyond what was published in the 1980s, it is difficult to say. A map of the brecciation geometries in the Redstone Formation would be informative.

The largest and most economically promising Cu deposit in the Redstone Copper Belt is situated within the Coates Lake embayment and covers an area greater than 12 km^2. It occupies a bed 1 m thick and contains drill-indicated reserves of 37 million tonnes, averaging 3.92 % Cu and 0.33 oz. per tonne Ag (11.3 g/t). Mineralisation is best developed in the lower three carbonate units. For example, in drill hole 76Y-4, the richest Cu intersections are in bed 2a (0.15 m @ 5.5 % Cu) and bed 3 (1.16 m @ 1.18 % Cu), both occurrences are tied to preserved beds of nodular anhydrite (Ruelle 1982).

In well 77Y-3, the sulphide minerals are zoned vertically with bornite and chalcocite in the lower portion, passing up into a chalcopyrite-bornite interval, upwards into chalcopyrite-pyrite and finally into pyrite (Fig. 15.37b). Sphalerite and galena occur at the uppermost part of the Transition Zone in contact with the overlying carbonates of the Coppercap Fm (Chartrand et al. 1989). The relatively high silver content coincides with high copper contents in the base of the Transition Zone and, according to Ruelle (1982), indicates the silver is entrained within bornite.

Like the Kupferschiefer and Lisbon deposits, mineralisation in Redstone Copper Belt deposits show a pronounced mineral zonation, with the Cu:Fe ratio in the sulphides decreasing upsection through the Transition Zone and toward the embayment margins (Fig. 15.37c). The copper sulphides

occur as partial to complete diagenetic replacements of anhydrite nodules in the cryptalgal-laminated units and as disseminations of anhedral to euhedral grains in the intertidal mud flat facies. Bladelike anhydrite crystals are also partially to completely replaced by chalcopyrite. Preserved anhydrite nodules are ellipsoidal in cross section and up to several centimetres in diameter, although most are less than 1 cm. Mineralisation of these nodule layers creates a laminar fenestral fabric to the mineralisation. Further away from the Cu mineralisation front, pyrite with chert replaces the anhydrite nodules (Ruelle 1982).

Metals were leached and transported as metal-chloride complexes from volcaniclastic/redbeds that were derived from Cu-bearing mafic lavas in the Redstone River and Thundercloud formations (Fig. 15.37c). As slightly acidic and weakly oxidised basinal brines moved up and outward from the basin sediment pile, they were focused into the basin margins by the presence of overlying evaporite aquicludes. Near the margins, where the evaporite aquicludes were dissolved, had pinched out, or welded, the solutions seeped up section to encounter redox fronts associated with the organic-rich cryptalgalaminites of the Transition Zone. This interaction then fixed the metals on the reduced side of the redox front with a sulphide zonation identical to that found in the Kupferschiefer ore zones. In each of the cycles of the host stratigraphy the positions of oxidation reducing fronts are still preserved as the red to grey-green colour transition. Hematite is still visible in the red-coloured intervals and the proportion of Cu in the grey-green intervals is much higher (Rose et al. 1986).

Summary of SSC Deposits Tied to Evaporites

Clearly, stratabound copper accumulations in sediments can be related to redox fronts set up between saline, highly reducing pore waters and somewhat less saline, slightly acidic oxidising waters. The importance of the redox interface in diagenetic precipitation of copper was well known in the economic geology community since the 1970s (e.g. Rose 1976). and has been an integral part of the interpretive paradigm for redbed copper since that time. What is less appreciated is the role that evaporites both bedded and halokinetic can play in setting up and maintaining the position of the redox interface in earth space, so that substantial accumulations or copper can occur in a single buildups, such as in the Kupferschiefer-Lubin, or bed associated buildups as in the Dzhezkazgan district.

The redox interface is better maintained when the reducing side of the interface is supplied by dissolution of a halokinetic salt mass rather than an individual salt bed. This is because in a halokinetic system the salt is thick enough so that it will continue to flow into the site of dissolution until the conduit to the mother salt mass is lost either by salt welding or by the complete dissolution of the salt mass. Fractional dissolution of the halite also drives the enrichment of $CaSO_4$ at the site of dissolution. What is also obvious from the literature of SSC deposits is that salt residues are underappreciated or not even recognised. Yet they are indicators of former substantial salt masses which played significant roles as chloride brine sources and metal precipitation foci. We shall return to this notion of halokinesis supplying subsalt cupriferous brines and suprasalt/weld stability after we consider some of the larger Pb-Zn deposits in the same salty framework.

Stratiform Sediment Hosted Pb-Zn Deposits (Salt-Related)

Current economic geology literature typically considers SedEx (sedimentary exhalative) and MVT (Mississippi Valley Type) deposits as related responses to the flow of basinal fluids. SedEx deposits are typically a mineralised response to basinal fluid flow in deeper water mostly siliciclastic sediment hosts and MVT deposits the updip responses mostly hosted in carbonates (Fig. 15.38; Emsbo 2009; Leach et al. 2010).

Exact definitions of what constitutes a SedEx versus an MVT deposit vary, according to the syngenetic verses epigenetic inclination of the writer. For SedEx deposits, a good definition is that of Goodfellow and Lydon 2007. They define sedimentary exhalative (SedEx) deposits as typically tabular bodies, composed predominantly of Zn, Pb, and Ag, bound in sphalerite and galena, which occur interbedded with iron sulphides and basinal sedimentary rocks. Deposition was on the seafloor and associated with sub-seafloor vent complexes fed by hydrothermal fluids seeping into mostly reduced sedimentary basins in continental rifts. In the vicinity of the brine vent tract, SedEx deposits are typically zoned, with the proportion of Pb, baryte and Mn decreasing away from the feeder/vent zone, which is typically centred on one or more extensional faults (Fig. 15.74).

For MVT deposits a widely accepted definition is that of Leach and Sangster (1993). They define MVT deposits as a varied family of epigenetic ores, precipitated from dense basinal brines at temperatures ranging between 75° and 200 °C, typically in platform carbonate sequences and lacking genetic affinities to igneous activity. That is, in contrast to the basinal sediment host of SedEx deposits, MVT deposits tend to be hosted in dolomitised platform carbonates or more rarely in sandstone interbeds. Such mineralised systems are sometimes located at or near the high-energy fault-defined platform edge, as defined by the rock matrix character of the host (Fig. 15.38). And sometimes they are located adjacent to the dissolution edge of platform evaporites where the three features (fault, shelf edge, saltern edge) may coincide to focus ore precipitation,

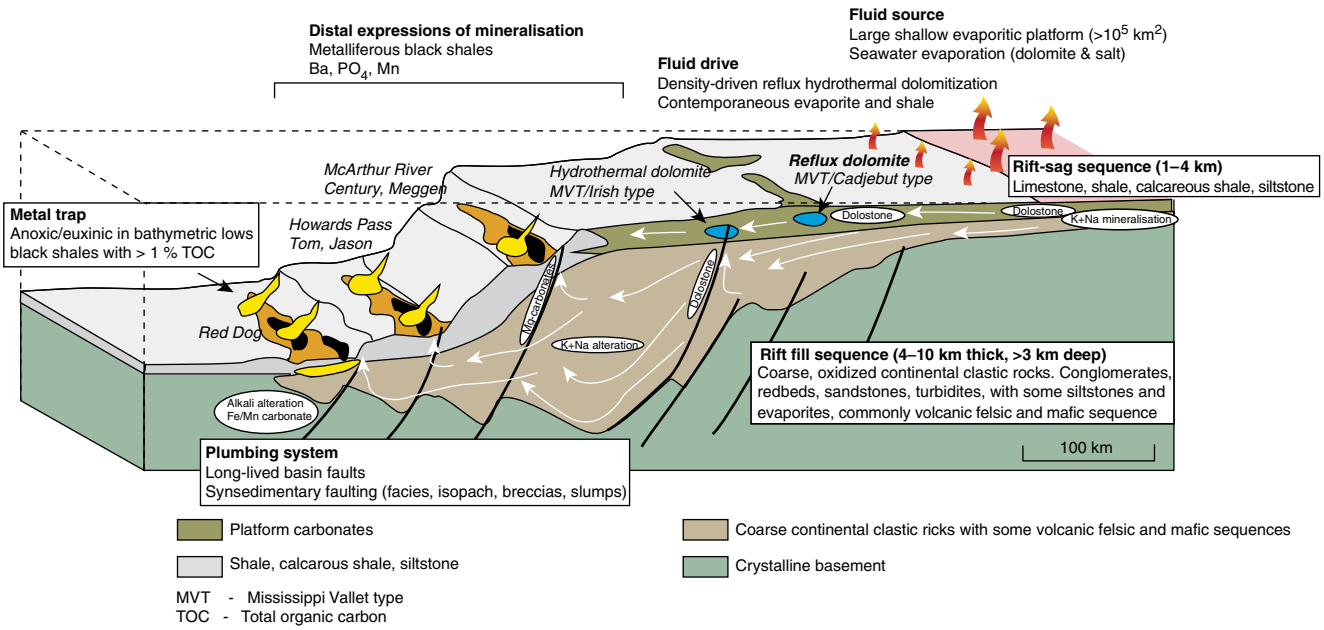

Fig. 15.38 Geologic setting and geologic assessment criteria for SedEx Zn-Pb-Ag deposits emphasising relationship between SedEx and MVT deposits as deduced by USGS worldwide synthesis (Emsbo 2009 and references therein). Likely locations of several important SedEx deposits relative to the shallow-water platform margin are indicated and may reflect the structural architecture of the basin or the maturity of the rift cycle (Figure based in part on Emsbo 2009)

as in the Cadjebut and San Vicente deposits. Other times they form in thrusted platform carbonates with a fluid flow system tied to evaporite-focused décollements, as in the Gays River/Ainslie deposit/prospects. MVT deposits often occur in fluid-defined clusters made up of a number of smaller deposits.

In contrast to the clustered nature within an ore district of MVT deposits, individual SedEx deposits tend to be larger stratiform deposits, spaced some distance apart. Russell et al. (1981) tied the larger separation of SedEx deposits to the size of convective fluid cells in thick sedimentary basin fills. As we shall see, whenever SedEx deposits can be tied syndepositionally to the presence of former evaporites they tend to be typified by orehosting sedimentary laminites deposited within deeper water anoxic seafloor lows filled with hypersaline brine (DHALs), with their seafloor positions controlled by a combination of halokinetic focusing of fluid flows and extensional feeder faults.

By the end of the chapter we will add an understanding of the importance of flowing and dissolving evaporites in a basin fills when SedEx and MVT deposits are forming. Once again, let me emphasise that evaporites do not form mineralised Pb-Zn deposits, rather as they dissolve and alter in the subsurface, evaporite masses focus and stabilise the position in earth-space of brine flow conduits and redox/thermal interfaces, within the diagenetic mineralising milieu of faults, vents and brine sumps that drives the creation of larger MVT districts and SedEx deposits.

Evaporite Associated MVT Deposits

Much like we have already seen in redbed Cu-evaporite associations, for MVT Pb-Zn deposits associated with evaporites, there are two fabric/structure styles: (1) Halokinetic edges, with the metalliferous brine interactions typically tied to fluid interfaces within the sulphate fringe (caprock or carapace), which defines the dissolutional periphery of a diapir crest or stem, a salt allochthon periphery, or below a salt-lubricated decollement plane, and; (2) Bedded sulphate interactions typically located where fault-controlled metalliferous fluids intersected with, and interacted with, one or more platform sulphate beds (salina or saltern). For SedEx deposits there is a third evaporite type, a suprasalt allochthon structuration that creates fault-fed, metal-prone, seafloor brine lakes. Thus we can target exploration in a predicative fashion for those MVT Pb-Zn deposits with an evaporite association: the targeting is based on identifying favourable intersections where fault structures (extensional faults or thrust planes) intersect units of dissolving bedded or halokinetic evaporites (now marked by residues and other "salt that was" textures, as detailed in Chap. 7).

Peridiapiric Diagenesis and Zn-Pb

For many years, the edges of diapirs or salt domes have been viewed as potential targets for petroleum, salt and sulphur accumulations. Lately, they have also come to be viewed as potential targets, or at least process analogs, for Pb and Zn

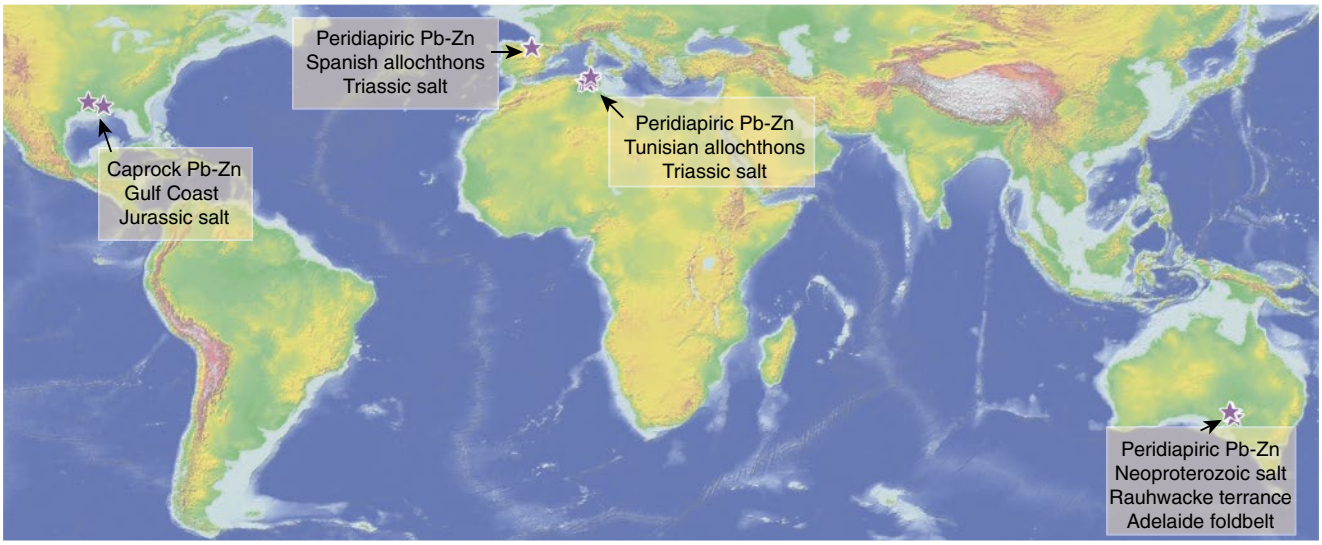

Fig. 15.39 Occurrences of documented MVT Pb-Zn occurrences related to diapirs or allochthons as discussed in text (Plot extracted from Saltwork GIS database version 1.6)

deposits (Wang et al. 1998a). Peridiapiric mineralised Pb-Zn systems can be divided into two types (Figs. 15.38 and 15.39): (1) Caprock/carapace hosted deposits, where the host rock consists of the anhydrite and bacteriogenic limestone carapace to the dissolving crest of a salt structure; (2) Diapir/allochthon proximal deposits, where the bulk of the mineralisation resides in laminar organic-rich sediment hosts, located adjacent to the diapir/allochthon or its residual carapace. Examples of both these deposit styles tend to be relatively small in volume and limited in extent.

Caprock-Hosted Pb-Zn, Gulf Coast & North Africa

Small deposits of Pb-Zn with a diapir association were recognised in northern Africa more than 100 years ago, but it was not until the geology of diapir-hosted subeconomic deposits in the Gulf of Mexico (Kyle 1991), and economic north African diapir- and peridiapir-hosted deposits, such as Bou Grine and Oued Jebs (Rouvier et al. 1985; Orgeval 1994; Bejaoui et al. 2013), were fully understood, that the significance of diapirism in controlling this style of small-scale Pb-Zn was fully appreciated (Fig. 15.39). Mineralogically, the diapir-associated mineral deposits are similar to many other carbonate and shale-hosted mineral deposits. They all contain pyrite, marcasite, sphalerite, galena and baryte; many deposits also contain high concentrations of pyrrhotite and celestite.

Caprock Pb-Zn Accumulations

Caprock sulphates and bacteriogenic limestones created during caprock formation are important ore hosts in this style of deposit. All that is required to form the anhydrite portion of a caprock is that the top of the diapiric salt stem or sheet be bathed in a solution that is undersaturated with respect to halite (see Chap. 6). To form the calcite portion from this anhydrite/gypsum precursor requires the presence of organics/hydrocarbons and sulphate-reducing bacteria in the region of the calcium sulphate cap (Fig. 15.40a). Such a situation exists subseafloor, as well as in zones of continental meteoric circulation. The anhydrite carapace that makes up the greater volume of a diapir caprock is not just a meteoric product, it is forming today on deep seafloor sites in zones of seawater driven fractional dissolution atop shallow salt diapirs and allochthonous salt sheets in the present day Gulf of Mexico (Kennicutt II et al. 1985; Roberts et al. 1990). These sites are coincident with petroleum seeps, so that the calcite cap, including that in entrained mollusc shells, has isotopic signatures indicating a crude petroleum source.

Pb-Zn sulphides begin forming as soon as an anhydrite cap rock carapace encrusts a developing salt structure. This can happen during the earliest phases of salt flow and continue, perhaps episodically, as long as the structure's crest is bathed in nearsurface halite-undersaturated waters and oil- or methane-bearing basinal fluids continue to circulate in the vicinity of the diapir. Some of the earliest minerals to form in the caprock are sulphides precipitated in equilibrium with anhydrite, where they often form laminar sulphide-anhydrite textures controlled by the morphology of the dissolution interface (Kyle and Posey 1991). Biogenic calcite forms as a byproduct of bacterial sulphate reduction as crude oil and thermogenic methane migrates up a diapir's margin to come into contact with anhydrite/gypsum in a low temperature environment (≈80 °C) (Fig. 15.40a). Sulphides, baryte and celestite can precipitate at the same time, or postdate, the calcite. Gypsum caprock continues to form after anhydrite and calcite caprock interfaces are well established, typically via the ongoing infiltration of undersaturated nearsurface

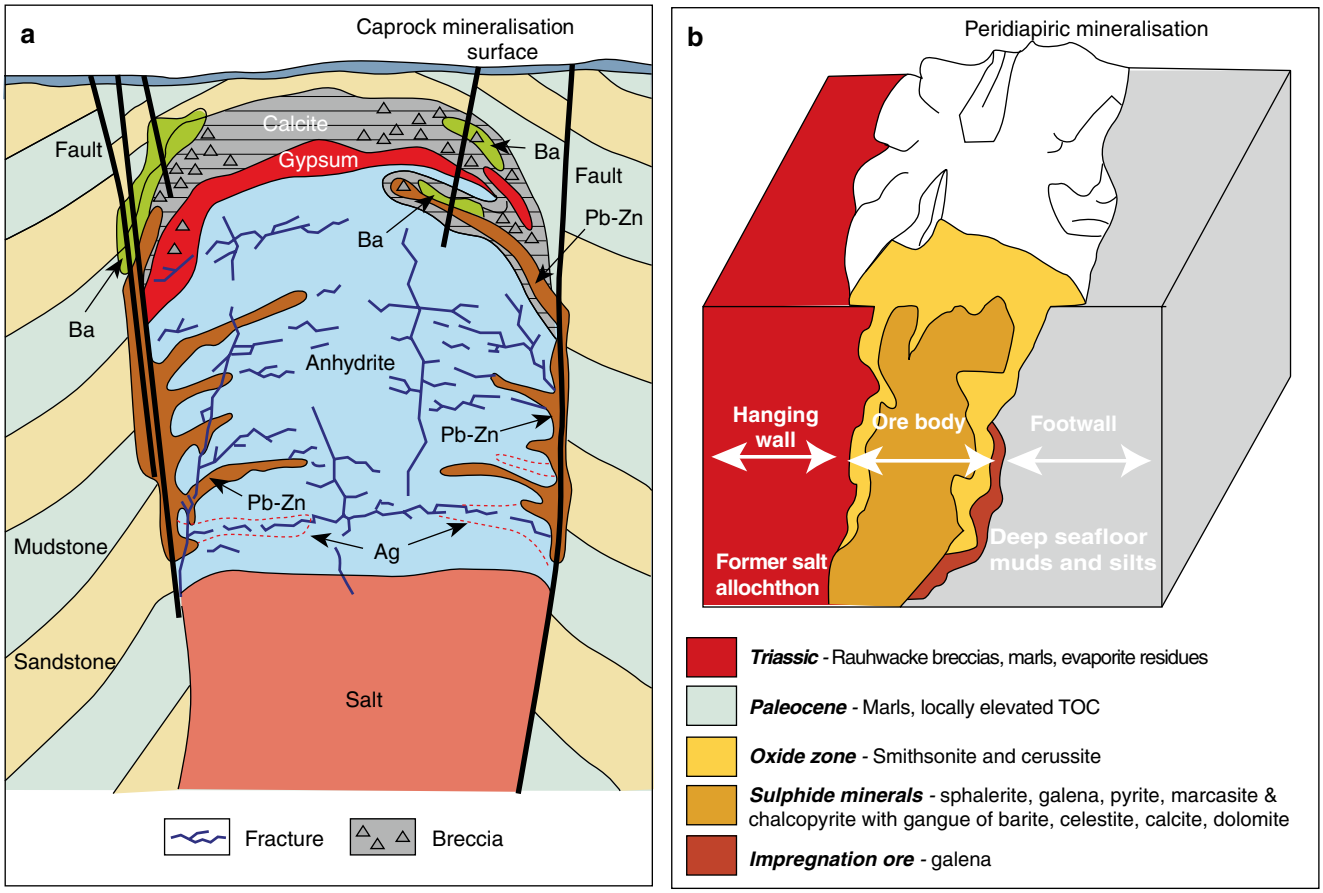

Fig. 15.40 Peridiapiric mineralisation. (**a**) Caprock rock -hosted model, based on the USA Gulf Coast as seen in the Winnfield, Hockley and Tatum salt diapir crests (After Kyle 1991). (**b**) Salt allochthon margin mineralisation, as seen in Ain Allega deposit, Tunisia (After Abidi et al. 2012)

waters that ultimately will rehydrate any remaining anhydrite (Werner et al. 1988).

Thus, iron sulphides typically form early at any particular site in a caprock/carapace deposit, even as the first laminar anhydrite residues accrue on the diapir periphery; galena and sphalerite form later; and baryte, celestite and sulphur are generally the last phases to precipitate. Banded or colloform textures, consisting of finely crystalline aggregates, are the most common textures exhibited by the iron sulphides and sphalerite. These base metal sulphides occur as; inter-anhydrite crystal cements, open-space fills in anhydrite, as carbonate/sulphate replacements, and as open-space (vug/cavity) fills. Most of the anhydrite-hosted mineralisation formed during anhydrite caprock accumulation, whereas most of the sulphides hosted in biogenic calcite formed prior to, or during, calcite precipitation, as seen in Hockley Dome caprock (Fig. 15.41; Kyle and Price 1986a, b).

In general, an anhydrite caprock accretes or thickens by growth along its underbelly by a process of underplating (Fig. 6.111). As diapiric salt dissolves from the uppermost portions of the underlying halite stem/sheet, it leaves behind the entrained anhydrite as a residue (Fig. 15.40a). Calcitic caprock also forms first at its bottom, but it does so via the progressive bacteriogenic replacement of the underlying calcium sulphate (Light and Posey 1992). Metal sulphides that precipitate syngenetically within either the anhydrite or the calcite cap rocks show isotopic compositions and major element compositions that vary with depth. This range in isotopic values may record chemical changes in upward migrating metal-bearing brines or changes in local chemical conditions relating to bacteriogenic overprints during sulphide precipitation (e.g. Fig. 9.72). The range in metal concentrations most likely reflects changes in brine composition due either to brine mixing or to evolution of brine composition.

A detailed record of episodic basin dewatering events is documented in mineralised anhydrite-rich cap rocks of two Gulf Coast salt domes: the Hockley Dome and the Winnfield Dome (Fig. 15.41; Kyle and Price 1986a, b; Hallager et al. 1990). There the majority of the highgrade mineralisation occurs as massive laminar sulphide lenses. The lenses are typically vuggy, fractured and brecciated. At Hockley, the highest sulphide concentrations occur in the periphery of the cap rock at depths ranging from 120 to 365 m (Fig. 15.41a). Elevated sulphide levels occur in both calcite and anhydrite

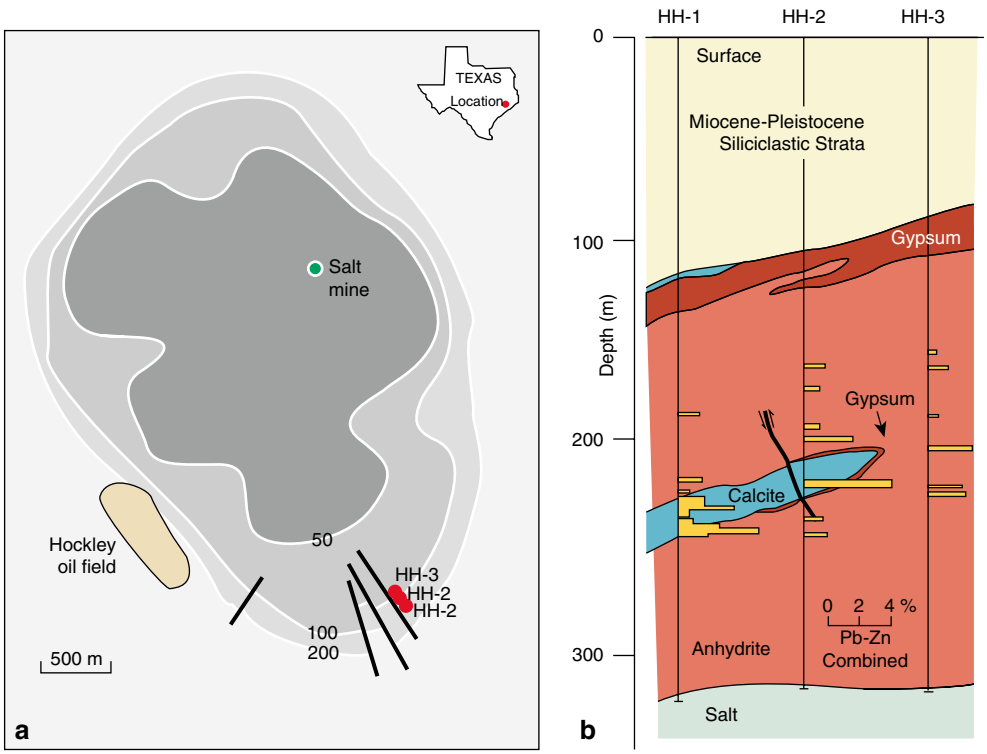

Fig. 15.41 Sulphides in caprock of Hockley Dome, Texas. (**a**) Structure contour map showing depth (metres) to top caprock. (**b**) Geologic cross-section in caprock based on wells HH-1 to HH-3. Intersections of Zn + Pb in wells are plotted on well trajectories (After Kyle and Price 1986a, Kyle 1991)

caprock hosts, are somewhat higher in the bacteriogenic calcite, with sulphide-rich zones between adjacent wells appearing laterally consistent in same-lithology units (Fig. 15.41b). Marcasite, pyrite, sphalerite, and galena range from trace components to local massive sulphide zones; significant Zn + Pb drill intercepts include 5.5 m of 7.1 % and 12 m of 4.2 %. Sphalerite is the dominant economic mineral, with an overall Zn/Pb ratio of about 3:1. Metal distribution studies suggest that there is a trend of increasing zinc/lead downward in the anhydrite cap rock (Kyle and Agee 1988).

The Winnfield Dome diapir is roughly circular in outline with a diameter of about 1.1 km at the −180 m structural elevation. The top of the salt is 76–80 m below sea level, is horizontal, and is directly overlain by anhydrite cap rock. The salt/anhydrite cap rock contact is marked by a brine cavity zone as much as a few meters thick. The anhydrite/calcite caprock interface at Winnfield is highly irregular and a gypsum zone as much as 12 m thick occurs locally. The calcite zone varies in areal extent and in thickness from about a meter to over 90 m. Sulphide layers in the caprock consist mostly of iron sulphides, with vugs and fractures lined with sphalerite, galena, baryte and calcite. The sulphide precipitates had their origins in deep metal-rich basinal brines that were intermittently expelled from geopressured zones deeper in the stratigraphic section. Brines were channelled upward along permeable escape structures bounding the diapir stems.

Sulphides at Winnfield mostly occur as laminar zones parallel to the tightly intergrown, layered anhydrite grains or as coarse euhedral crystals growing in open space within vugs in the anhydrite cap rock. Sulphide layers generally are less than one millimetre to several centimetres thick and can be traced laterally for tens of meters. The principal sulphide is monoclinic pyrrhotite, but sphalerite, galena, pyrite, and marcasite are abundant locally. A nearsurface overhanging caprock helped focus escaping metalliferous fluid into the zone of salt dissolution between the top of salt and the overlying residual anhydrite cap rock. Iron, lead, and zinc sulphides saturations were exceeded in this zone, possibly in response to H_2S generation related to periodic dissolution and biogenic reduction of the caprock sulphates.

In general, it seems that episodes when metalliferous brine entered accreting diapir caprocks are recorded as relatively thin bands of sulphide sandwiched between thicker bands of anhydrite. Continued dissolution of salt and underplating of residual anhydrite caused the sulphide bands to be displaced upward relative to the base of the cap, leading to an inverted stratigraphic record of basin dewatering events. Palaeomagnetic data from the Winnfield salt dome suggest that sulphide-producing basin dewatering events and anhydrite caprock accumulation occurred between 157 and 145 Ma, and that widespread sulphide precipitation in the cap is no longer active.

The paragenetic relationships among the metallic minerals and host caprocks at Hockley, Winnfield and other Gulf Coast salt domes are complex (Kyle 1991). Generally, iron sulphide minerals appear to have been the first sulphide precipitates, followed by sphalerite and galena, with the more oxidized sulphur species, such as elemental sulphur,

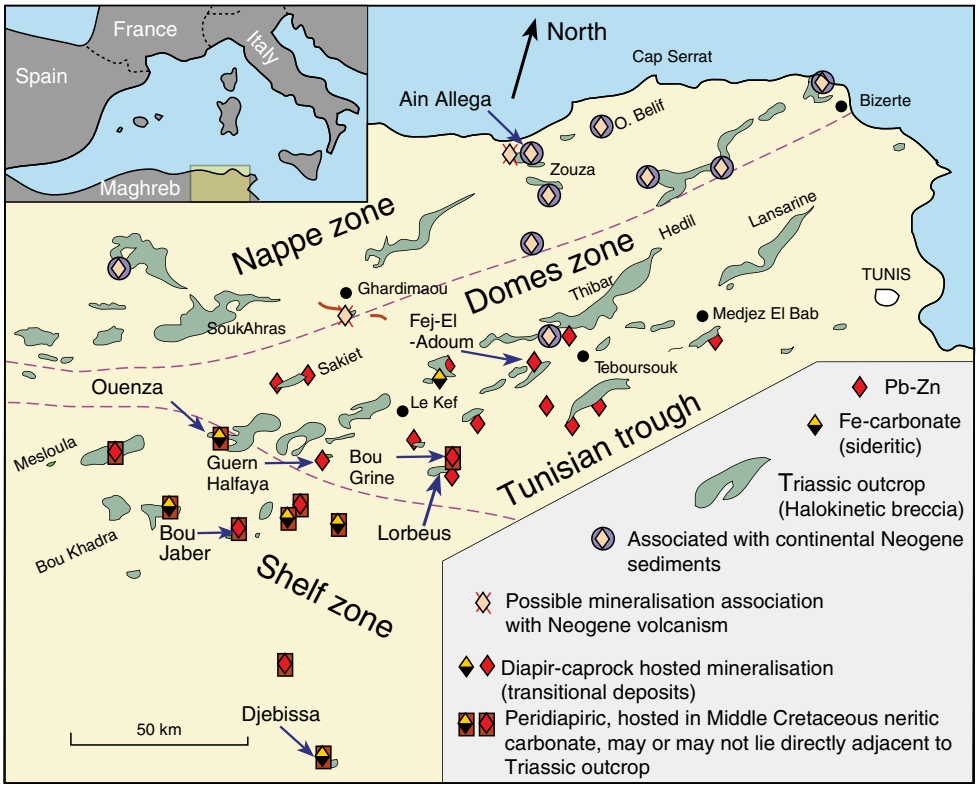

Fig. 15.42 Diapir-related mineralisation in the Triassic allochthon region known as Domes district in the Maghreb, Tunisia (After Rouvier et al. 1985)

manganese sulphides, and the sulphate minerals, forming later. This mineralisation sequence happened more than once in any dome cap.

Thus, stratiform laminar sulphide textures within the anhydrite cap rock are believed to represent mineralization at the salt/ cap rock interface (Ulrich et al. 1984) and are therefore syngenetic with regard to the enclosing host caprocks but epigenetic with respect to the encasing sediments. In addition, euhedral sulphide crystals can form simple open-space fillings of late fractures or vugs within the calcite cap rock; in other cases, earlier generations are brecciated and cemented by later sulphides or calcite (Kyle and Price 1986a). Calcite may also be intimately intergrown with sulphide minerals. Therefore, calcite precipitation, i.e. calcite cap rock formation, can pre-date, be contemporaneous with, or post-date local sulphide precipitation. The complex textural relationships among sulphide minerals and their host rocks is a function of an evolving geochemical system in which earlier mineral products are overprinted by pressurized fluids re-entering a zone of earlier sulphides with entry driven by later halokinetic and fluid events.

Allochthon-Edge Stratiform Pb-Zn (Sr-F)

As well as forming in the diapiric caprock, Pb-Zn deposits can be hosted in organic-rich pyritic and sideritic laminites located centripetal to salt sheets or halokinetic breccias, so making them stratiform peridiapiric ore deposits (Fig. 15.40b). The highly reduced, organic-rich, nature of laminated peridiapiric brine-pool sediments means that pyrite easily forms as a syndepositional precipitate in any adjacent DHAL laminite and its fault-fed surrounds (see Chap. 9). As this pyrite is buried deeper into the brine/ hydrothermal system it is bathed and altered by escaping metalliferous basinal brines. Examples of this brine pool or DHAL style of mineralisation are typically small to medium scale Pb-Zn accumulations, such as Bou Grine, Quern Halfaya and Ain Allegra in the Maghreb, North Africa and the Orduña and Murgía domes in Spain (Fig. 15.39; Bechtel et al. 1996; Jemmali et al. 2011, 2013; Grandia et al. 2003).

The eastern part of the Maghrebides fold–thrust belt in the southern Tunisian Atlas is perhaps the type area for outcrops of this style of deposit. The region is made up of the Nappe zone, which was formed by the stacking of Numidian flysch along south-verging Tellian thrust sheets and more importantly for this type of deposit, is the Domes region to the east and at the front of the Nappe zone (Fig. 15.42). This NE–SW trending, roughly 50-km-wide and 300-km-long zone comprises the Mejerda valley and is characterized by surface exposures of Triassic evaporitic lithologies related to the emergence of major thrusts and anticlines core with halokinetic salt and its associated breccias and residues (Perthuisot et al. 1999).

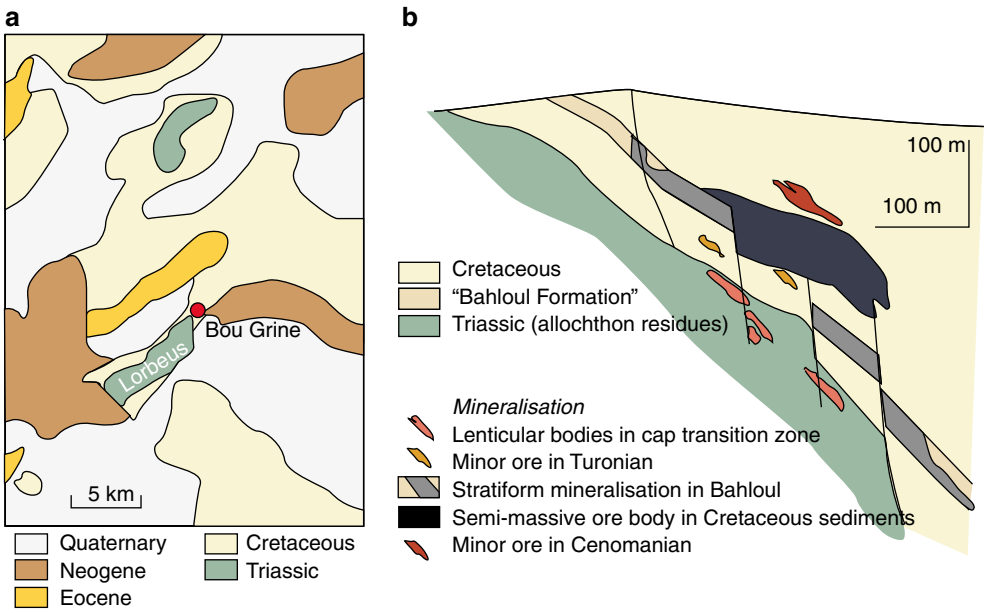

Fig. 15.43 Peridiapiric Bou Grine Pb-Zn deposit in plan (**a**) and section (**b**) views (After Bechtel et al. 1998)

The Domes region covers almost 8,000 km^2 with a large number of Triassic diapirs and allochthons piercing the Cretaceous cover rocks and aligned parallel to the regional folding. During the Early Cretaceous the area was a seafloor trough much like the modern slope and rise of the Gulf of Mexico and was then caught up in the subsequent Alpine Orogeny related to the collision of the African and Eurasian plates. Today remnants of the salt allochthon outcrops and subcrops are covered by pelagic Cretaceous sediments and in places are overlain by a variety of Tertiary sediments, including phosphates. All these postsalt sediments are variably pierced by diapirs and salt sheets, along with entrained sands, carbonate lenses and mottled clays with distributions controlled by highs and troughs related to salt flow. The Cretaceous cover includes a major discontinuity in the upper Albian strata that divides it into two megasequences: (1) an Early Cretaceous to Late Albian succession, and (2) a terminal Albian to Palaeocene sequence. There are strong facies and thickness variations in the Cretaceous sediments located close to the diapirs, indicating that halokinesis was active in the Aptian and continued into the Tertiary.

Pb-Zn (Ba, Sr, F) mineralisation in the Domes area occurs mainly in Cretaceous cover rocks near the edges of the Triassic diapirs in deposits such as Bou Grine, Oud Edeboua (Guern Halfaya), Jebel Hamra and Fej-el-Adoum. There are four main mineralisation types in these deposits: (1) Lenticular Pb-Zn-(Ba-Sr)-Fe bodies in the zone of transition from the Triassic to the Cretaceous host sediment (caprocks); (2) Stratiform Pb-Zn mineralisation in calcareous laminites, which are typically rich in organic matter (DHAL deposits in the Bahloul Formation); (3) Pb-Zn-Ba-F and Fe-Pb deposits, with vug-fill features similar to Mississippi Valley Type deposits, in the Aptian reef formations that formed atop seafloor highs created by diapir and salt allochthon emplacement; and (4) Vein-type deposits (Fig. 15.43).

The Bou Grine Zn-Pb deposit is situated at the edge of the Lorbeus diapir, in the Domes region of the Maghreb (Table 15.2 and Fig. 15.43a; Rouvier et al. 1985; Charef and Sheppard 1987, 1991; Orgeval 1991, 1994; Bechtel et al. 1996, 1998; Jemmali et al. 2013; Bejaoui et al. 2013; Masrouhi et al. 2014). Bou Grine mineralisation belongs mostly to the first and second groupings, that is, lenticular and stratiform (Fig. 15.43b). In this, the Bou Grine deposit differs from caprock sulphides in the Gulf of Mexico in that much of the Pb-Zn mineralisation resides not in diapir caprock but in the adjacent organic-rich limestone laminites of the DHAL successions in the Bahloul Fm adjacent to the diapir. As well, in Bou Grine a semi-massive ore body (hanging wall orebody) cuts the Cretaceous series in the second megasequence in the Cenomenian-Turonian Bahloul Formation. The geologic reserves, with a cutoff value of 4 % Pb+Zn, are estimated at 7.3 million tonnes of ore at 2.4 % Pb and 9.7 % Zn, equivalent to 880,000 tonnes of metal (Orgeval et al. 1989). Mining of Pb-Zn ore at Bou Grine ceased in September 2005.

The zinciferous laminites in the Bahloul Fm in the Bou Grine deposit are made up of mineralised bioclastic clayey-carbonaceous calcimicrites, whose major features are: (1) A regular, in places laminar, bedded structure implying low energy, subwavebase bottom conditions; (2) Numerous foraminifera and other bioclastic components showing open marine affinities; (3) Mineralisation that is in part affected by early diagenetic structures, especially ferroan and calcitic cements. Sphalerite is present as microcrystals disseminated along the bedding planes, or as coalescent flattened nodules; it also appears to have been remobilised as

concentrations along fissures and later fractures. Galena occurs in euhedral crystals along the bedding planes and as scattered crystals in later fractures associated with calcite and schalenblende[1]. Calcite is observed in fissures that were deformed during compaction, as well as in all the later fractures; it also pseudomorphs occasional sulphate crystals (baryte and anhydrite).

The early nature of mineralisation at Bou Grine is reflected in: (1) Convoluted mineralised laminar beds deformed by intraformational slip, with flow structures; (2) Compaction structures around rigid cores of pyrite nodules and galena crystals; (3) Deformed infilled fissures. Sphalerite developed as: (1) Early regularly disseminated microsphalerite crystals in a slightly compacted sediment; (2) As almost simultaneous concentrations along sedimentary structures, textures and discontinuities; (3) As later concentrations and deformations of the mineralisation due to compaction and subsequent fracturing; and (4) As diagenetic remobilised cements that were either passive infills or provoked by circulation of mineralising fluids.

Laminites of the Bou Grine region also show high total organic carbon contents (4–5 % TOC), low organic maturity (T_{max} = 423 °C) and a marine (Type II) phytoplankton origin (Bechtel et al. 1996). Hydrocarbon enrichment at particular levels suggests possible former hydrocarbon reservoirs in some of the sediments adjacent to the diapirs. Montacer et al. (1988) showed that sulphate reduction in the laminite facies was bacterially mediated, with evolution of the organic matter probably occurring by *in situ* maturation of the laminite source rock. Their isotope studies support the notion of a close relationship between the initial metal stock and the sedimentological/diagenetic setting. Sulphur isotopes also indicate development of mineralisation in a closed sulphur system. Along with Sr and Pb isotopes, they also show the deposit, and its aureole, formed under the influence of an organic-rich diagenetic paleocirculation, with Pb derived from a single source.

The Guern Halfaya deposit occurs comprises the perched Guern Halfaya syncline in the east and a tight anticline in the west (Figs. 15.42 and 15.44a, b; Jemmali et al. 2013). In the northwestern part, there are two longitudinal Triassic outcrops defining the Koudiat el Hamra–Jebel Oum Edeboua zone. The northern–northwestern parts are cut by NE–SW and N–S trending normal faults, which are at places invaded by Triassic evaporites. The lithologic succession at Guern Halfaya is composed of Mesozoic and Cenozoic sedimentary rocks.

The Triassic outcrop consist of chaotic gypsiferous clays, sandstones, black dolomitic-limestones, which are underlain in the subsurface by large amounts of anhydrite with a halite core (Hatira and Zouari 1997). Lower Cretaceous strata, which outcrop in the western part of the area, include Aptian–Lower Albian rocks, which encompass strongly iron-mineralized (oxidized siderite) micritic limestones and sandy clays overlain by thick *Orbitolina*-bearing limestones. Those limestones are covered by the Albian micrites and marls that can enclose lenses of coarse-grained platform limestones. The Upper Cretaceous is composed of Cenomanian marl–limestone alternations overlain by yellowish limestones. The Upper Cenomanian– Lower Turonian consists of laminated gray to black organic-rich limestones of the Bahloul Formation, with 3–7.5 % TOC. The while the overlying Turonian includes marls and banded limestones. The Upper Turonian–Eocene series are made up of the following formations, all of which outcrop in the SSW part of Jebel Oum Edeboua and form the vast syncline of Guern Halfaya. The Coniacian–Santonian Aleg Formation is primarily marly. The Upper Campanian–Lower Maastrichtian Abiod Formation consists of marl–limestones and limestones. The Paleocene–Lower Eocene El Haria Formation is a series of clays with marl, gypsum and rare limestone intercalations. The Ypresian Metlaoui Formation is a *nummulite-bearing* limestone forming the core of the Guern Halfaya syncline. The Miocene series starts with coarse conglomerates and carbonates and continues with micro-conglomerates, which are well represented at the northern foot of Koudiat el Hamra, and ends with sandstones and sandy clays. The Quaternary consists of alluvium and clayey sand aureoles on Miocene conglomerates.

The Guern Halfaya Pb-Zn deposit is composed of the Koudiat el Hamra Oum Edeboua orebodies, which are distributed around the periphery of NE–SW trending evaporite-bearing Triassic rocks and closely associated with the NE–SW and N–S trending normal faults (Fig. 15.44; Bejaoui et al. 2013). The deposits exhibit three styles of mineralization within the contact Triassic–Upper Cretaceous series, particularly in the Cenomanian marl–limestone alternations and in the Bahloul Formation and show strong affinites to mineralisation styles at Bou Grine, namely: (1) lenticular mineralization in the Cenomanian marl–limestone alternations consisting of abundant pyrite with marcasite, sphalerite, galena and celestite, hosted in halokinetically induced dolostone breccias as impregnations, substitutions and replacements of the clayey-dolostone matrix. (2) Stratiform mineralization in the Bahloul Formation consisting of framboidal and cubic pyrite, disseminated sphalerite and galena. (3) Veins, disseminations and stockworks in breccias of Cenomanian–Turonian limestones and of pyrite, galena and sphalerite.

Various workers in the Maghreb – Domes Pb-Zn deposits have found that sulphur isotope determinations in the host rocks and ores and gangues are consistently indicative of a

[1]Compact sphalerite and wurtzite masses of a pale brown colour, occurring in concentric layers with reniform surfaces, which also may contain pyrite and galena.

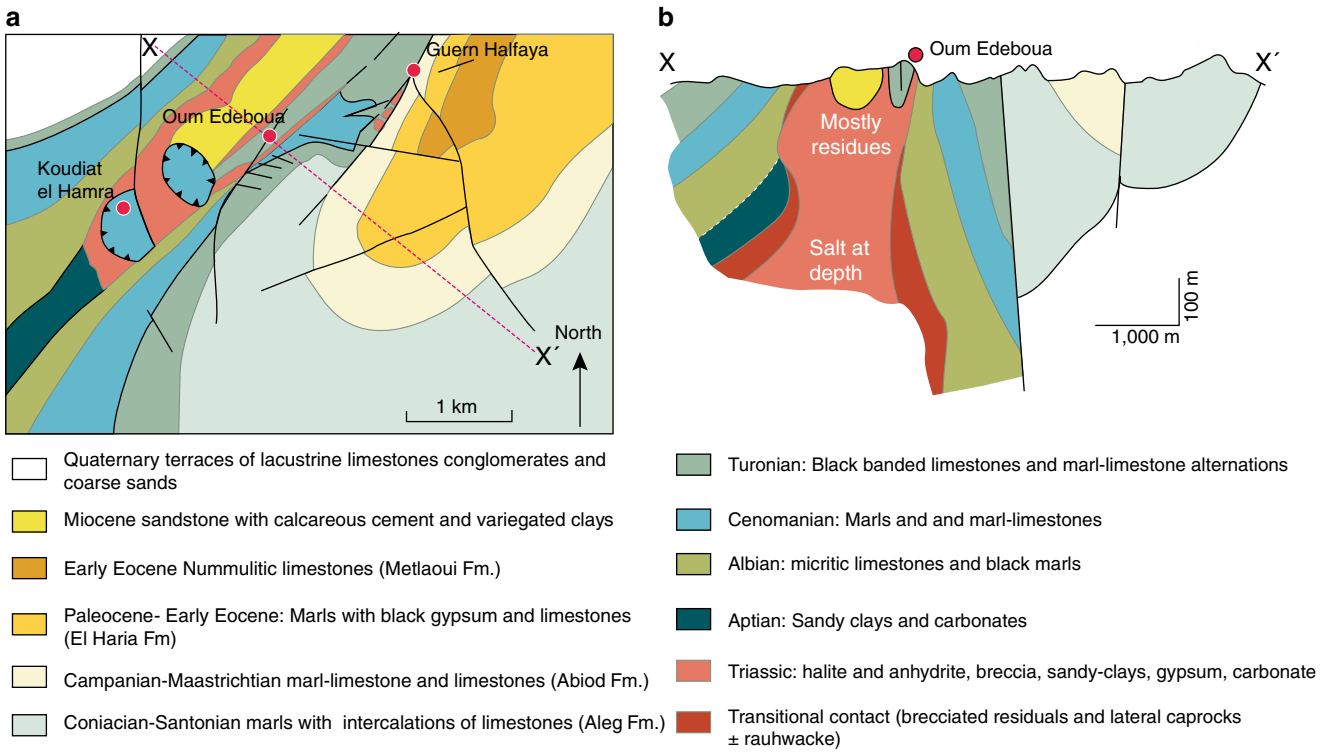

Fig. 15.44 Geological map (**a**) and schematic NW–SE cross-section (**b**) of the Guern Halfaya area where the Oum Edeboua mine and Jebel Guern Halfaya are located (After Jemmali et al. 2013)

bacterial sulphate reduction set of processes acting on sulphate evaporites, organics and hydrocarbons in the vicinity of the various Triassic salt structures (Jemmali et al. 2013; Bejaoui et al. 2013 and references therein) For example, gypsum, celestite and baryte in Triassic rocks at Oum Edeboua have $\delta^{34}S$ values ranging from 12.8 to 15.0‰, whereas anhydrite in Triassic evaporite (from drill core) at Tabbet Lahsan (Fej-el-Adoum district) yielded $\delta^{34}S$ values ranging from 14.2 to 15.6‰ (Fig. 15.45). These data are similar to typical $\delta^{34}S$ values of (a) about 16‰ obtained from anhydrite and celestite in Tunisian Triassic evaporite diapirs, (b) about 15‰ obtained from regional Tunisian sulphates and (c) 11–17‰ in Triassic marine sulphates (Fig. 15.45a). This consistency implies Triassic evaporites are likely sources of sulphur that can be associated with sulphate minerals in Triassic strata.

Galena in mineralized Triassic–Upper Cretaceous rocks at Oum Edeboua yielded $\delta^{34}S$ values of 3.3–9.5‰, whereas galena and sphalerite in mineralized Cenomanian–Turonian and Turonian rocks at Bou Grine yielded $\delta^{34}S$ values of 2.6–9.4‰. Such sulphur isotope compositions overlap sulphur isotope values of orebodies at Bou Grine (Fig. 15.45b). This implies the same or similar source of sulphur in the base-metal sulphide deposits in both the Oum Edeboua and Bou Grine with Triassic seawater brines and associated evaporites as likely ultimate sources of sulphur. In addition, diagenetic pyrite from the Bahloul Formation, with higher concentration in laminites, which were deposited in parts of the Bahloul deep seafloor that were Cretaceous DHALS.

More positive $\delta^{34}S$ values in base-metal sulphides from the Oum Edeboua and Bou Grine mines may suggest an additional sulphur input during abiotic thermally-driven sulphate reduction (TSR) of Triassic sulphates at depth. But, given the likelihood of lower temperatures at mineralisation, as documented in inclusion studies, it is less likely that TSR was a significant supplier of sulphur. TSR typically requires temperatures well in excess of 120–130 °C and produces sulphate–sulphide fractionations that typically range from ~0 to 10‰ (Chap. 9). Documented homogenization temperatures for mineralizations at Oum Edeboua and Bou Grine are 95–130 °C (Kassaa 1998) and 75–100 °C (Orgeval 1994). Bacterial sulphate reduction (BSR) typically occurs at temperatures lower than 110 °C and produce sulphate–sulphide fractionations that typically range from 15 to 60‰ with respect to seawater sulphur. Thus, both the sulphur isotope ranges and mineralisation temperatures favour BSR over TSR, with marine-derived sulphates and pyrite as the likely sulphur sources. The significance of BSR is further supported by the presence of bacterial relics in the Oum Edeboua mine (Kassaa 1998) and the Bou Grine mine (Orgeval 1994). In addition, pyrite associated with galena in the Oum Edeboua mine exhibits framboidal texture, which is

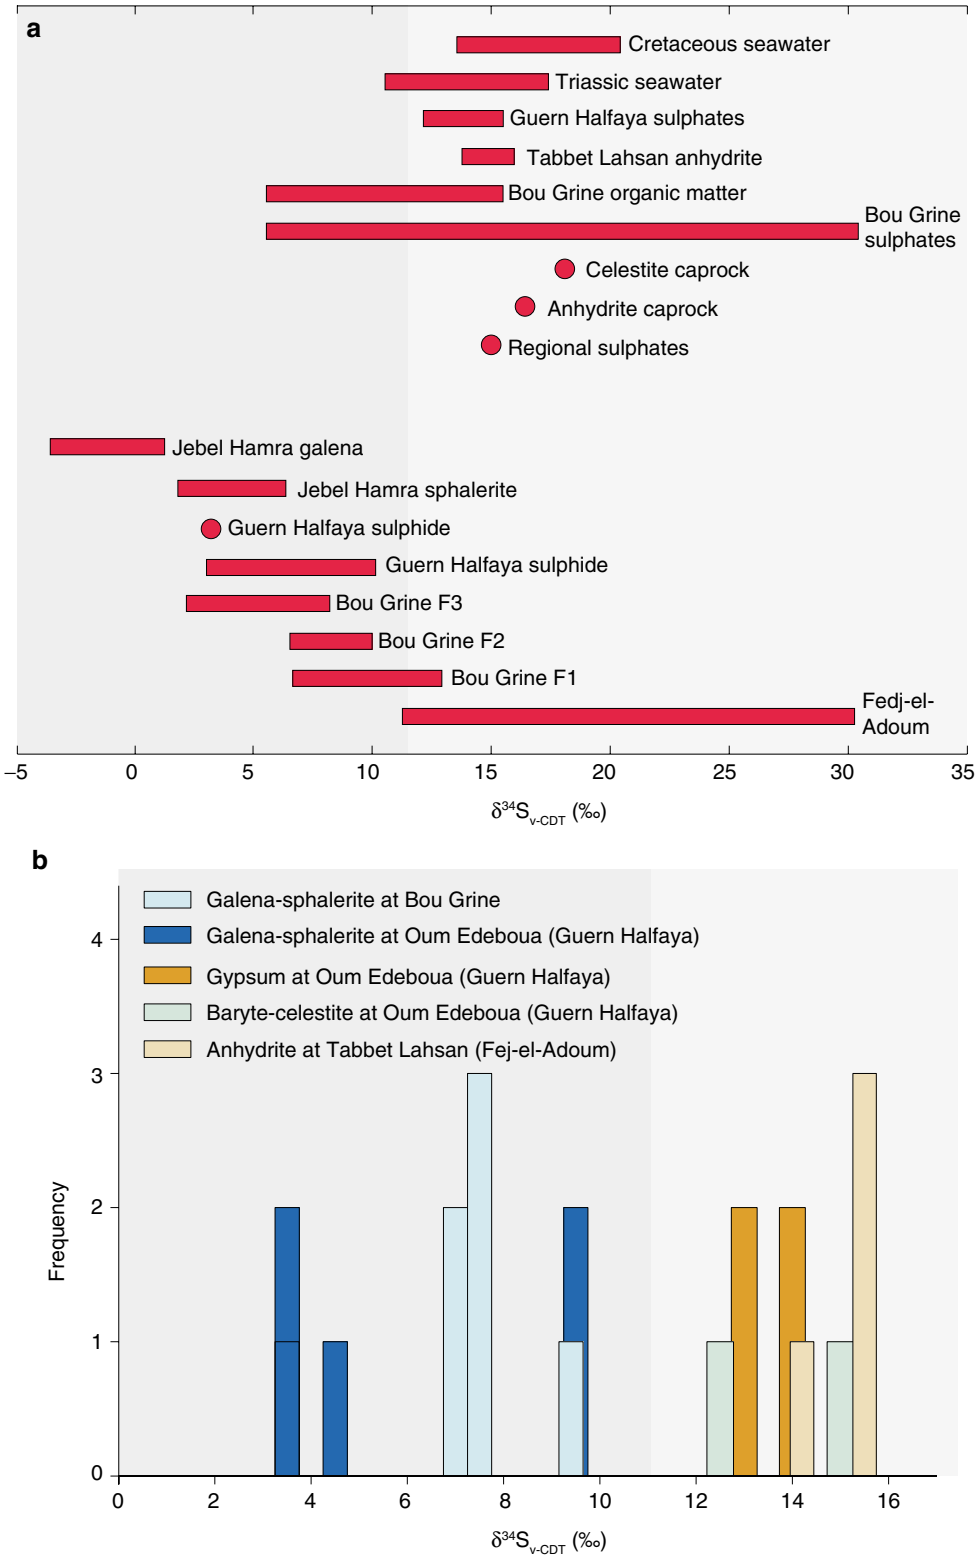

Fig. 15.45 Sulphur $\delta^{34}S$ isotope values in the Domes region of the Maghreb. (**a**) Spread of sample fields mostly collected from sites in Bou Brine, Guern Halfaya and Jebel Hamra regions. (**b**) Distribution (frequency) plot of site specific values of sulphides (galena + sphalerite) and sulphates (gypsum + baryte + celestite + anhydrite) from the Oum Edeboua, Bou Grine and Tabbet Lahsan deposits (After Jemmali et al. 2013 and Bejaoui et al. 2013)

characteristic of BSR-linked galena at several Pb–Zn deposits such as in Bleiberg, Austria and Navan, Ireland.

But, was the ultimate source of the metals local or more distal? The present Pb isotope data are homogeneous with $^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$ ratios of 18.723–18.783, 15.667–15.685 and 38.806–38.889, respectively (Jemmali et al. 2013). This suggests a single source reservoir of Pb at some depth in the upper crust. The syn-diagenetic mineralization in the Bahloul Formation and the calculated age from the Pb isotopic data suggest an Upper Cretaceous age for the Pb-Zn

deposits in the Guern Halfaya and Bou Grine areas. During this period, NE-SW to ENE-WSW trending regional extensional tectonic structures likely favoured migration of mineralizing fluids and eventual deposition at Guern Halfaya and Bou Grine in metal-rich brine conduits in redox positions controlled by a combination of salt focusing and associated faulting.

Across the Domes region a Pb-Zn deposit's locality and host rock geometry was controlled by a feedback between salt flow and the creation of Cretaceous deep seafloor brine sumps in response to synkinematic movement of the seafloor. Thus halokinesis and the associated allochthons controlled: (1) Local deposition of conglomerates and breccias adjacent to the highs atop the growing salt allochthons, (2) Local deposition of organic-rich pyritic laminites in areas of brine ponding (DHAL) on locally deepened seafloor, (3) Tilting of panels of sediments by listric faults activated by the emplacement of allochthons and diapirs, (4) Overlapping of sedimentary bodies by shoal/shelf progradation or truncation. Halokinesis also led to marked thickness variations of the various facies across the regions via the repetitious pulsing of the active diapir and its ongoing dissolution.

In addition to Pb and Zn, recent work by Dill et al. (2014) has related significant accumulations of Sr and F to the peripheries of salt structures in the Domes Region and their associated brines. Shallow halokinetic units create a basin-and-swell topography in any landscape and so provided the local and regional unconformities to which many of the Sr and F mineral deposits are related. Syndiapiric salt dissolution and welding also created carrier brines and focused their upwelling. Dill et al. argue that there are five mineralizing processes or stages, each with characteristic sedimentary ore textures related to subsurface salt movement and ore emplacement: (1 + 2) Early- and late-stage replacement ("zebra rocks"), (3) hydraulic fracturing ("fitting breccia"), (4) remobilization ("spinifex structures"), and (5) open-space filling ("caves and vein-like deposits"). All can be related to the coming and going of evaporite beds and flows.

Basinal brines from Mesozoic aquifers delivered Pb, Zn, Cd, REE, Y, Hg, and Se, while Sr, Cs, Be, Li, Cu and Co were perhaps derived from Cenozoic salinas across the Neo-Tethyan basin (Dill et al. 2014). Mixing of Mesozoic and Cenozoic brines between 28 and 19 Ma drove emplacement of Sr–F minerals at temperatures below 200 °C, under strongly alkaline conditions. Epigenetic polyphase Sr–F deposits bearing base-metals which are closely related to salt domes (Tunisian-Type) can also be traced into epigenetic monophase Sr deposits within bioherms (Cyprus-Type) largely devoid of Pb, Zn and F. Moving eastward in the Domes region, syndiagenetic monophase Sr deposits in biostromes (Gulf of Mexico-Type) herald the beginning of Sr concentration in Miocene sabkhas of the Neo-Tethys. Dill et al. (2014) argue their work bridges the knowledge gap between epigenetic carbonate-hosted MVT and syndiagenetic evaporite deposits.

The Domes region, at its halokinetic Cretaceous beginnings, was a submarine slope at the edge of a structural high. At that time, other than near a few local diapirs and salt allochthons, this area never seemed to have shoaled sufficiently for a true shallow water carbonate platform to have developed. The organic-rich sediments probably accumulated in this region only in the deeper areas of rim synclines about the active diapirs and salt sheets, hence the localisation of the mineralisation to laminites in the peridiapiric areas. Throughout the metal evolution history the salt was halokinetic, first in an extensional and then in a compressional (squeezed-diapir salt thrust) tectonic association. Only later with the withdrawal of the seaway did arid Cenozoic sabkha and salina deposition come to dominate.

Evaporite-Cored Thrusts and MVT's in the Maritimes Basin, Canada

Beyond the very obvious evaporite-related and Cretaceous hosted peridiapiric Pb-Zn deposits of the Domes region and the Tertiary-hosted Gulf of Mexico caprocks, there are a number of other older carbonate platform-hosted MVT accumulations in compressional traps, which are tied to salt allochthons or salt-cored thrust décollements. One of most obvious of these occurs in the Maritimes thrust belt of Canada, tied to the strike-slip system centred on the Minas Geofracture and subsidiary thrusts (Fig. 15.46; Waldron et al. 2013). These various metal accumulations include the well known Gays River and Jubilee/Ainslie and Walton deposits (Fig. 15.46a) Gays River and Jubilee in most current ore deposit classifications are typically pigeonholed as type examples of MVT (Mississippi Valley Type deposits; e.g. Paradis et al. 2007; Taylor et al. 2009). Siderites and barytes of the Walton-Magnet baryte deposit are also part of this halokinetic Maritimes association, but were discussed earlier as an examples of baryte accumulation in fault-related halokinetic alteration haloes (Fig. 7.95a) and so will not be considered in detail in this metals chapter.

Because this tie of the Pb-Zn mineralisation to an evaporite allochthon décollement is so obvious in Gays River and Jubilee (Fig. 15.46b), I now discuss them the current section dealing with undeniable peridiapiric-salt allochthon Pb-Zn associations. But, under all current definitions of MVT deposits, they definitively belong also to the MVT pigeonhole. We shall come back to classifications of various low-temperature ore deposits at the end of this chapter.

Gays River, Nova Scotia

The Gays River Zn-Pb deposit of southern Nova Scotia, Canada has reserves ca. 2.4 million tonnes at 14.3 % Zn and 6.3 % Pb of either massive or disseminated ore. The deposit

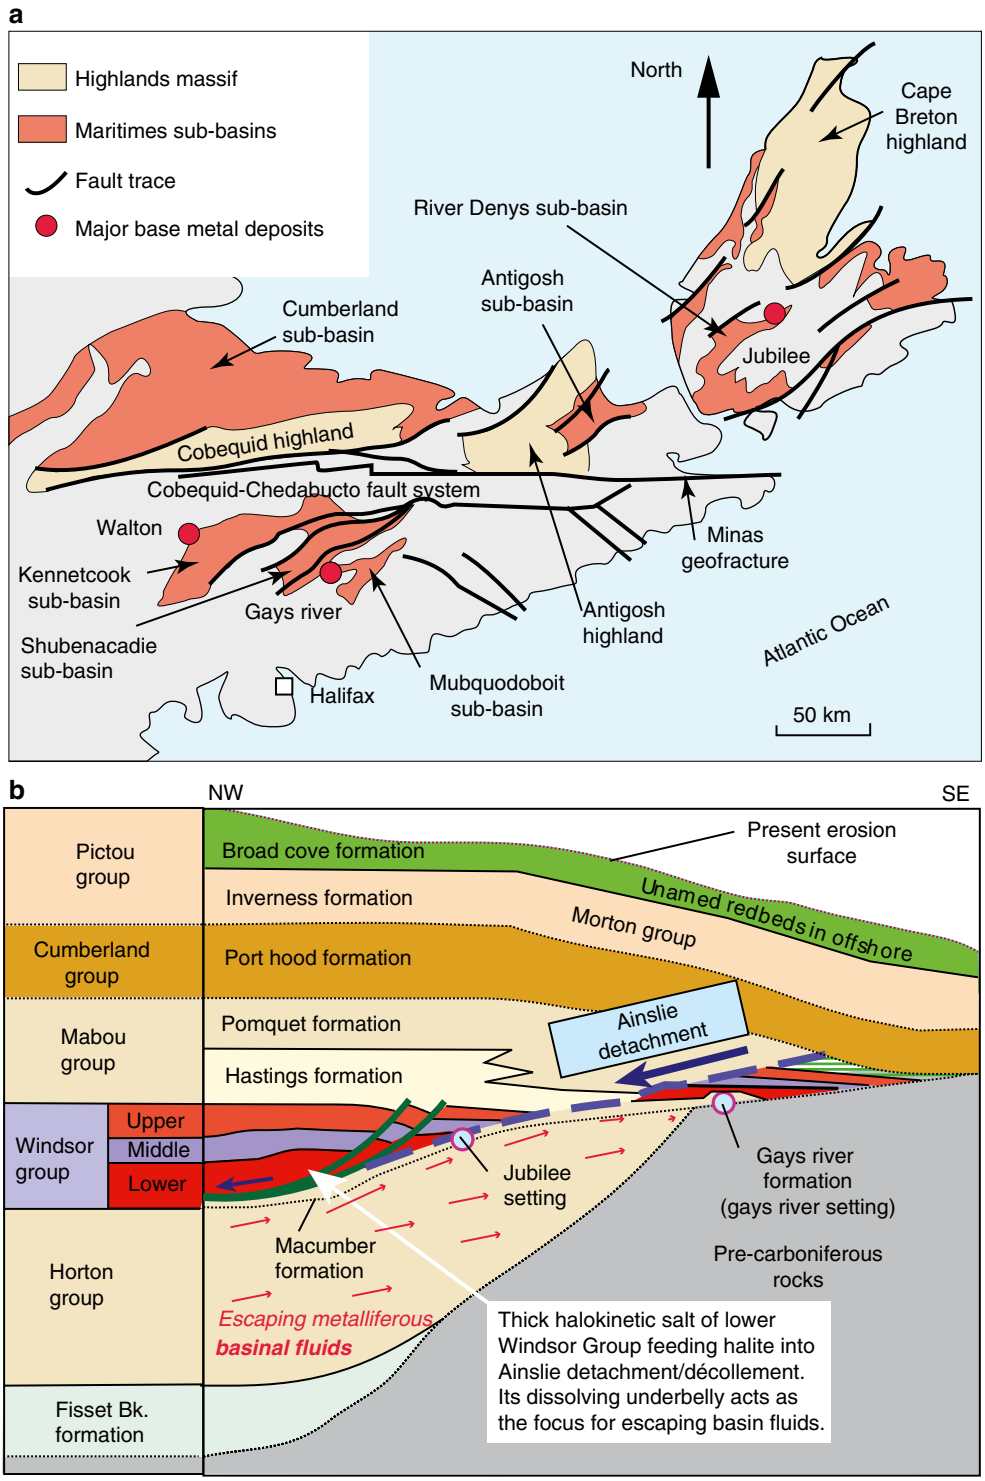

Fig. 15.46 Pb-Zn in the Maritimes Basin, Canada (**a**) Map of Nova Scotia showing Carboniferous sub-basins, major thrust fault traces and the Antigosh, Cape Breton and Cobequid highlands. (**b**) Schematic cross-section showing relationships between regional stratigraphy, mineralisation and the position of the Ainslie Detachment (After Lynch et al. 1998). Note that the timing of the detachment is indicated by a gap in the Windsor Group stratigraphy in the Gays River region created by the presence of a salt unit and salt flow. The thick salt, when it was formerly present at the level of the detachment, acted as a focus for the up-dip channelling of escaping basinal fluids

is located in the Meguma Terrane of southern Nova Scotia and is hosted by Windsor Group (Visean) carbonate/evaporites that were deposited in several sub-basins of the larger Maritimes Basin of eastern Canada (Fig. 15.46a; Kontak and Jackson 1995; Sangster et al. 1998a, b).

In terms of ore focusing, it was the adjacent dissolving and sealing evaporite units, along with associated entrapped hydrocarbons, and not the adjacent permeable dolomitised Carboniferous carbonate buildup, that controlled the locality and the process of mineralisation. The massive ore zone is directly adjacent to the sulphate evaporite bed and is made up of fine-grained, beige coloured sphalerite and medium to coarse-grained galena. The massive ore is only found along the carbonate-evaporite contact (Fig. 15.47a). Disseminated ore,

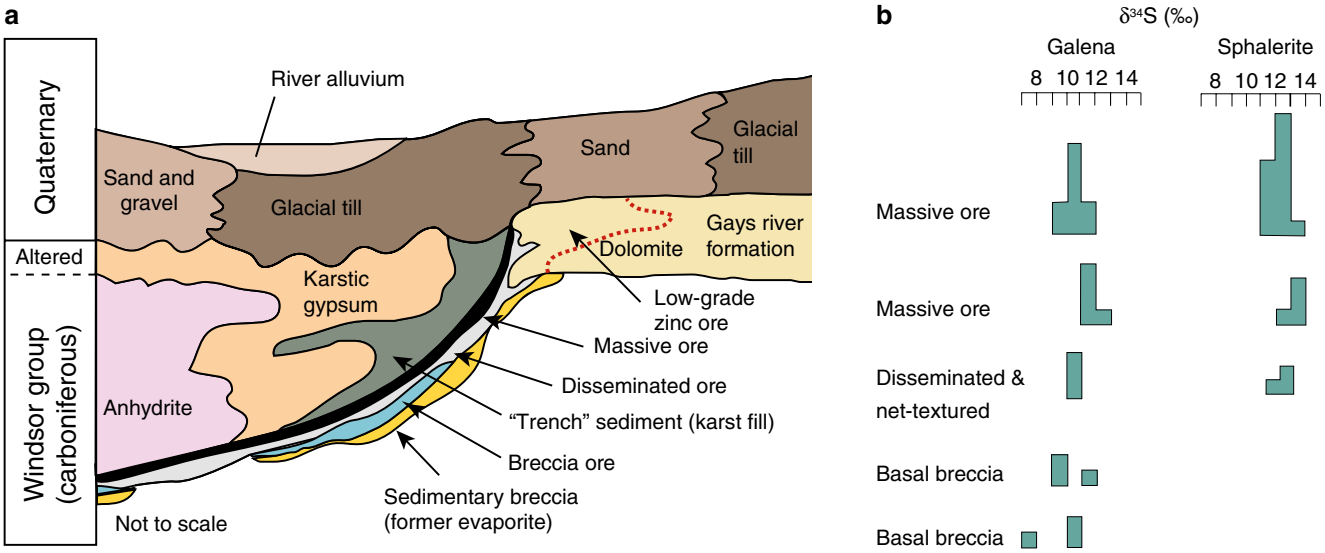

Fig. 15.47 Gays River Deposit, Nova Scotia (see Fig. 15.46a for location). (**a**) Schematic cross section showing intimate relationship between Pb-Zn mineralisation, ore textures, and the position of the gypsum-anhydrite residue as an indication of the position of former salt allochthon/décollement (in part after Kontak et al. 1994). (**b**) Sulphur isotopes classified using ore textures (After Sangster et al. 1998a, b)

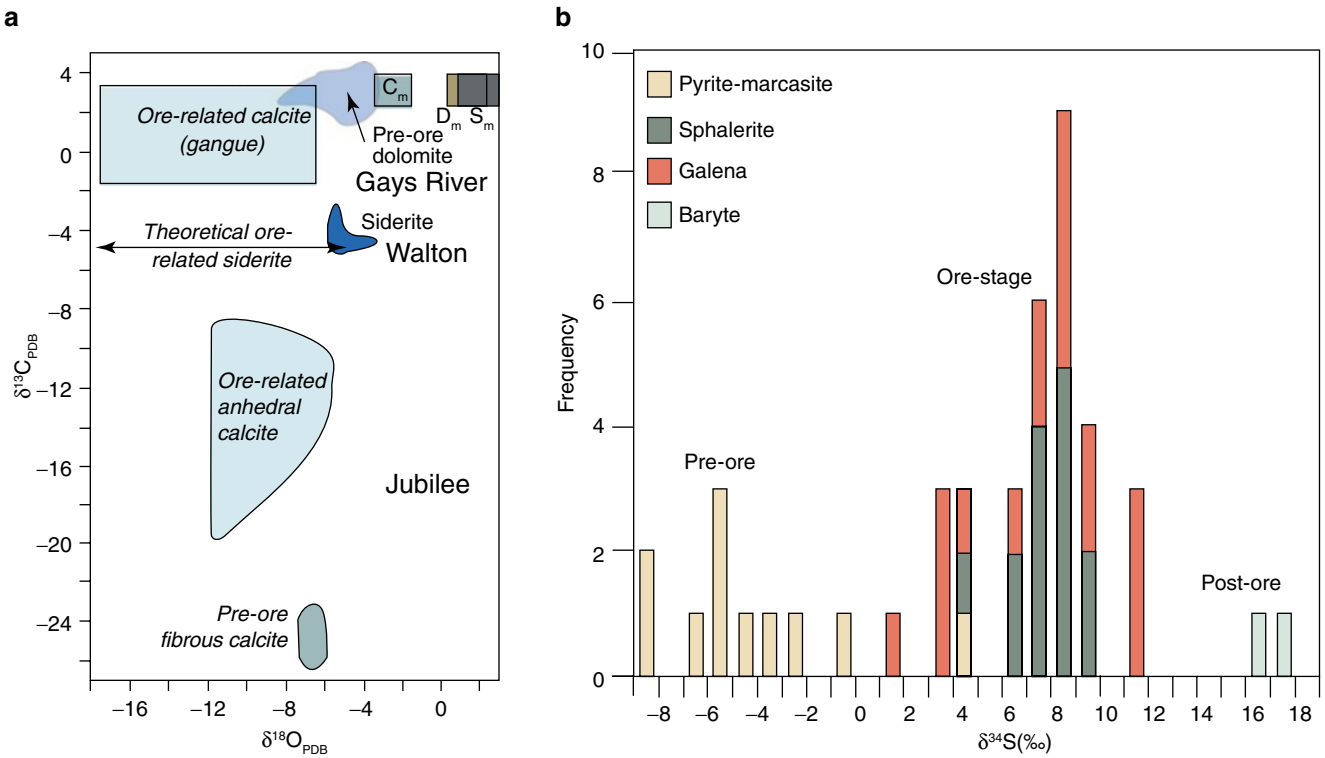

Fig. 15.48 Isotopes in selected Pb-Zn deposits of the Maritimes Basin (**a**) Carbon and oxygen plot-fields of pre-ore dolomite (*Dm*), calcite (*Cm*) and siderite (*Sm*) as well as ore-gangue calcites (more negative oxygen values indicate higher burial temperature). (**b**) Sulphur isotopes of pre-ore, ore and post-ore stage mineral precipitates in Gays River (After Sangster et al. 1998a, b)

adjacent to the massive ore and its evaporite seal, is hosted by Visean-age, dolomitised carbonate rocks that are part of a series of carbonate banks within the Gays River Formation. Both the galena and sphalerite show similar sulphur isotope values indicating they come from a similar, if not the same, sulphur source (Fig. 15.47b). When carbon oxygen values in the associated ore gangue calcite are plotted and compared with C-O plotfield of the earlier carbonate cements it is obvious that the fluids carrying the metals and gangue calcite are hotter and separate to the authigenic carbonate cements in the host dolomites (Fig. 15.48a).

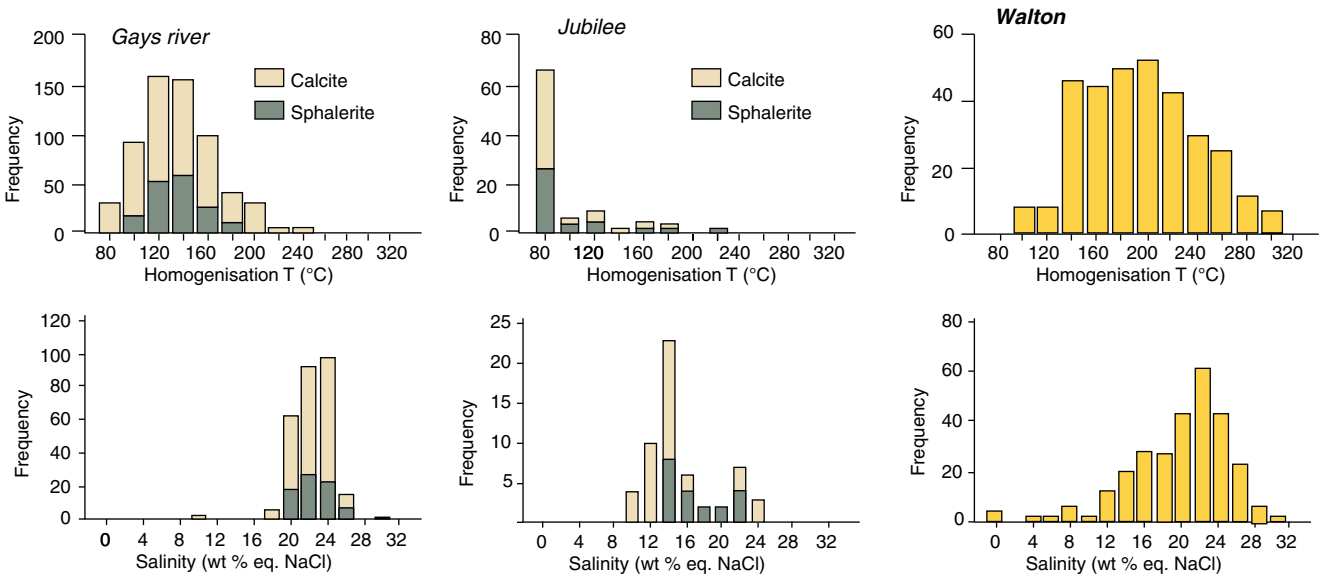

Fig. 15.49 Summary of fluid inclusion temperature and salinity in the three main deposits; Gays River, Jubilee and Walton (After Sangster et al. 1998a, b)

The Carboniferous sediments that host lower percentages of mineralisation than the evaporite contact initially grew on fault-controlled paleotopographic highs that were underlain by Lower Palaeozoic meta-turbidites of the Meguma Group, sometimes with local intervening breccia units (Horton Group). The breccias contain fragments (centimetre to metre scale) of Meguma Group lithologies within a dolostone matrix and are likely rauhwacke units (Figs. 15.46b and 15.47a). The disseminated, lower-grade mineralisation infilling porosity in the dolomitised carbonate banks consists of yellow to orange, millimetre-scale sphalerite and euhedral galena coating the walls of larger pores and cavities. Trace amounts of Fe and Cu sulphides as well as fluorite and baryte are also present.

To generate improved predictive exploration models based on a Gays River analog, requires that the evaporites at the mineralised contact are characterised in a basinal diagenetic context in as much, if not more, detail than the carbonates that host the lower ore grades in adjacent strata. Construction of surface plant and mill processing facilities commenced in 1978, and the mine was further developed to support an intended production rate of 1,350 t per day. Mill production commenced in October 1979, and by midsummer of 1981 a total of 554,000 t of ore and 272,000 t of waste had been mined. Throughout this period, efforts to achieve the full production rate, as well as efforts to mine areas of higher grade mineralization were continually thwarted by the combination of an extremely complex geological setting and severe hydrological problems. Throughout the life of the mine, water influx from karst piping tied to aquifers in the glacial overburden was an ongoing problem. Production operations at Gays River Mine were suspended indefinitely on August. 15, 1981, as a result of continuing problems with ore grade continuity and underground water. So today, the Gays River mine is now abandoned and flooded. The mine was only operational for 4 years from 1978 to 1981. This was more than three decades ago, in a time prior to our current understanding of diagenetic significance of various evaporite textures.

In the context of likely evaporite associations, the depositional setting of the carbonate banks hosting low-grade mineralisation and located adjacent to the main ore body is interesting. In the 1970s and 80s these banks were interpreted as shoalwater carbonate platform build-ups. But the abundance and perfection of preservation of filter-feeding brachiopods and bryozoans in many of the mounds was puzzling in a supposed shoal water photic community. The Gays River mounds were reinterpreted as vent-fed chemosynthetic mounds by von Bitter et al. (1992). Such an origin is more consistent with the distribution of the massive ore and with the obvious peridiapiric/allochthon distribution of the evaporite facies.

The main ore-hosting authigenic dolomite replaced its limestone precursor prior to the mineralisation event (pre-ore dolomite as seen in Fig. 15.48; Savard 1996). Dolomitization played a role in ground preparation, but was not directly tied to the Zn- and Pb-rich basinal fluids that mineralised the Gays River deposit. Stable isotopes show clearly that the main dolomite in carbonate buildups predates the mineralisation at Gays River (Fig. 15.48a). Fluid inclusion work on the coarse-grained sphalerites, and rare earth element profiles in late stage carbonate cements associated with the mineralisation, indicate that the mineralising fluids were warm (<120–140 °C), saline brines (>20–24 wt% NaCl)

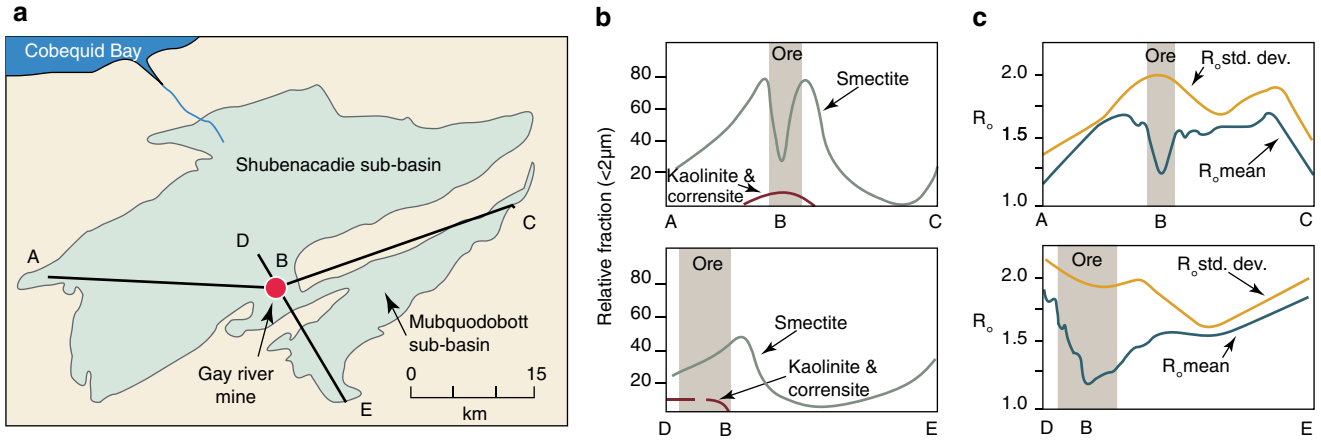

Fig. 15.50 Clay mineral and vitrinite reflectances as indicators of elevated temperatures associated with focused fluid flow in the Gays River Pb-Zn deposit. (**a**) Map showing position of sections *ABC* and *DBE*. (**b**) Relative abundance of authigenic kaolin±corrensite versus smectite in the vicinity of the orebody. (**c**) Variation in the mean reflectance and its standard deviation with respect to the orebody (After Heroux et al. 1996)

(Fig. 15.49; Akande and Zentilli 1984; Chi and Savard 1995; Kontak and Jackson 1995; Sangster et al. 1998a, b). $^{40}Ar/^{39}Ar$ dating places the mineralisation event at 300 Ma, while other isotopic data (Sr, C, O, Pb) indicate that the mineralising fluids were derived by fluid flushing of the underlying meta-turbidites of the Meguma Group or of the derived detritus that resides in the Devonian-Carboniferous Horton Group and carried to the sulphate-rich precipitation site by saline basinal brines (Kontak 1998; Kontak et al. 1994).

Heroux et al. (1994, 1996) found that the elevated temperatures and hydrocarbon contents of the mineralising brines also altered the clay mineralogy and organic maturity profiles of the adjacent carbonate/claystone matrix (Fig. 15.50a, b). The Gays River deposit is associated with smectite replacement of well crystallised detrital illite and chlorite. This forms a diagenetic halo around the main ore zone, while authigenic kaolinite and chlorite-corrensite typify the alteration halo in the immediate vicinity of the ore zone (Fig. 15.50b). Vitrinite reflectance (R_o) values and their absolute variability increase in the host rocks toward the ore zone (0.8–1.88 %) and show a relatively low R_o within the ore zone. That is, the R_o exhibits an anomalous suppressive effect with respect to depth of burial at the mine site, suggesting a chemical alteration of the organic matter in the mineralised zone.

Alternatively, as in other oil-generating basins in the world, vitrinite suppression can indicate overpressuring or the occurrence of H-enriched liptinites. The highest R_o values are associated with mosaic (recrystallised) textures in the host carbonates and outline a thermal anomaly in the region, probably related to the evaporite-focused escape of basinal brines. Heroux et al.'s work suggests that rock matrix relationships between clay mineralogies, organic anomalies and the mineralisation as defined at the Gay River Mine at the mine can be used as sedimentological guides in the exploration for base-metal sulphides in this area and elsewhere.

Inclusion studies in sphalerite and pre- and post-ore calcite also indicate that the mineralising fluids were hypersaline basinal brines with locally elevated temperatures (Fig. 15.49; Chi and Savard 1997, 1998). The $Na_{deficit}$- Ca_{excess} plot shows the mineralizing brines were not tied to meteoric waters, rather they were a product of mixing of halite-dissolution fluid and evaporated seawater (indicated by lines a and b in Fig. 15.51, respectively).

Rock matrix relationships, and the salt-décollement-adjacent position of the massive and disseminated ore zones in the Gays River deposit (Figs. 15.46b and 15.47) imply evaporite impermeability and the fractionated base-salt sulphate-dissolution residuum position controlled the precipitation position of the metal sulphides. That is, the presence of massive ore at the host-evaporite (anhydrite) contact is a response to the focusing effect of the impervious evaporites, and that the basal anhydrite along the underbelly of the thick evaporite package was probably the major source of sulphur. It is highly likely that halokinetic evaporites once covered the Gays River carbonate buildup and formed a regional focus and likely seal at the time of ore emplacement. The allochthonous salt mass stabilized the precipitation interface and allowed mineralising solutions to pond at the contact with the permeable dolomite host rocks beneath it (Fig. 15.47a).

Later the evaporite seal was breached by meteoric dissolution, perhaps in the Cretaceous, and the karst system is still active today (McKee and Hannon 1985). The effect of this breaching clearly has a surface expression in the present glacial landsurface in the presence of numerous collapse dolines in the tills and related lithofacies thicknesses and distribution above the deposit. These Pleistocene sediments infilled an evaporite karst landscape. Fluid temperatures in excess of 120 °C seen in the ore sphalerite and galena inclusions implies thermochemical sulphate reduction occurred much

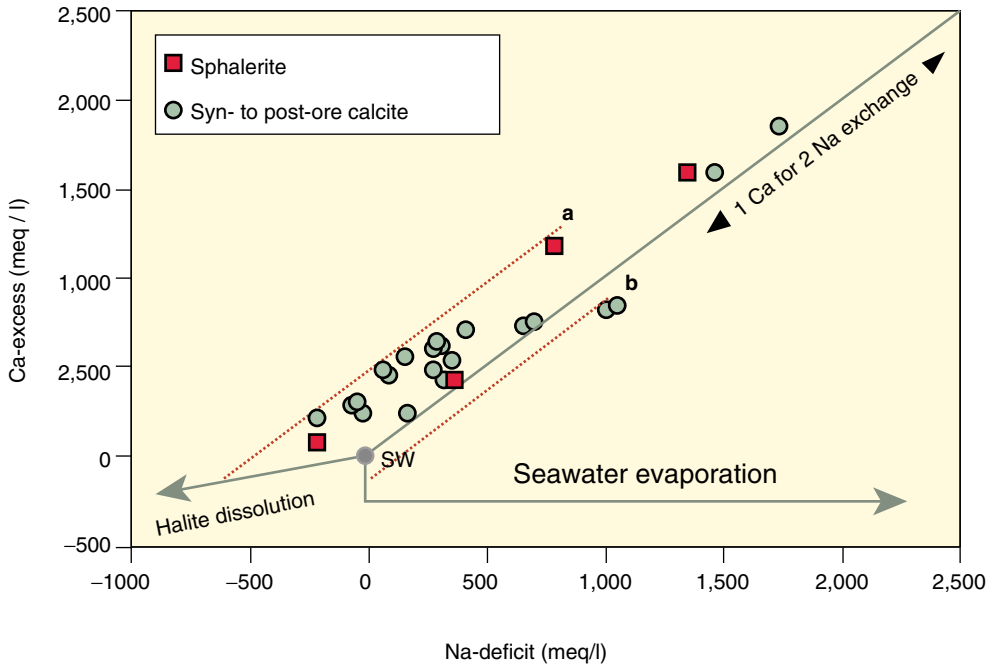

Fig. 15.51 $Na_{deficit}$ -Ca_{excess} plot of inclusion fluids from sphalerite and syn- to post-ore calcite in the Gays River MVT deposit (Data from Savard and Chi 1998; assumed salinity = 24 wt%). Lines *a* and *b* indicate the predicted position of a fluid with a [Cl] = 150 g/l originating from halite-dissolution and seawater evaporation, respectively

earlier than telogenesis, perhaps during or slightly later than the main thrust décollement and well prior to karst development. That is, all mineralisation and associated gangue calcite precipitation was mesogenetic and not telogenetic (Figs. 15.48a and 15.49). Ore was precipitated as a passive infill in whatever porosity was available at the time in the periodically overpressured subsurface TSR mixing zone (Chi et al. 1995; Heroux et al. 1996).

It was the evaporite-organic-sulphate TSR interface (not BSR) that focused the mineralising fluids. Pre-ore dolomitisation of the matrix was likely a response to the crossflow of the same evaporite-focused plumbing that later focused hotter mineralising hydrothermal brines. Dolomitisation is not a direct indicator of metal emplacement. The main economic role of dolomitised carbonate in the Gay's River deposit was that of passive host to the mixing of mineralising solutions, entrained hydrocarbons, and the thermochemically reduced sulphur derived from the dissolving evaporites. Prior dolomitisation events, likely related to less evolved escaping basinal brines, or even syndepositional brine reflux, may well have enhanced the aquifer properties of the ore host in the vicinity of the evaporite aquiclude.

Jubilee Zn-Pb Deposit, Nova Scotia

The Jubilee Zn-Pb prospect, Nova Scotia, is located 2 km southeast of Little Narrows village, near the quarry of the Little Narrows Gypsum Co. (Fallara et al. 1998). Like Gays River, it is one of many lead and zinc shows in Early Carboniferous limestones of the Maritime region, eastern Canada (Fig. 15.46a; Armstrong et al. 1993; Coron 1982). At Jubilee, a laminated limestone is overlain by transitional, interstratified limestone and anhydrite, with a massive anhydrite unit capping the sequence. The deposit extends over 2.75 km^2, and contains 0.9 million tonnes of 5.2 % Zn and 1.4 % Pb, and is hosted in the laminated limestones and breccias of Macumber Formation (basal Windsor Group). The Macumber Formation is the lateral equivalent to the Gays River Formation that hosts the Gays River deposit.

The Macumber Formation in the Jubilee deposit is made up of three main lithofacies: (1) A micritic lithofacies that locally contains ooids, oncolites and pellets, (2) A finely laminated lithofacies, and (3) A mineralised breccia facies (Fallara et al. 1998). The facies transition between the first two lithofacies is gradational and concordant, whereas the contact between the finely laminated lithofacies and the mineralised breccia is sharp. The breccia is conformable at the top of the Macumber Formation and never crosscuts it (Fig. 15.46b). The deposit is located near two faults interpreted as normal synsedimentary faults. Armstrong et al. (1993) suggested the mineralisation was a low temperature sulphide system related to the former presence of hydrocarbons.

Overlying the breccia at the base of the Carrols Corner Formation is a transitional zone of interbedded limestone and evaporite. Some of the limestone is replaced by anhydrite in the basal part of the transition zone. The overlying Carrols Corner Formation is a thick sequence of anhydrite and gypsum, up to 300 m thick. The breccia that hosts the ore has been variably interpreted as: (1) An evaporite solution collapse breccia, (2) A tectonic breccia that was the result of normal faulting and magmatic intrusions that created a horst structure, and (3) A collapse breccia produced by the

Table 15.11 Characteristics of the three breccia styles that constitute the various breccias that occur in the basal Windsor Formation, aka Pembroke Breccia sensu lato

	Early	Late	
	Early (synsedimentary)	Tectonic	Karstic
% clasts	60–95 %	40–75 %	40–90 %
Nature	Laminite	Laminite	Laminite, breccia, red mudstone, various siliciclastics (siderite in Walton)
Rounding	Some	None	Some for mudstone
Size	<1 mm–10 cm	>1 mm–5 cm	1 mm–50 cm
Matrix cement	Crushed fragments and lime mud	Crushed fragments and fibrous calcite cement	Carbonate fragments, red siliciclastics, lime mud, calcite cement
Sedimentary structures	Soft sediment deformation, concave upward shear failure planes, Cyclic pattern	Jig-saw puzzle like textures (crackle breccias)	Coarsening and fining upward, graded matrix
Diagenetic elements	Pre stylolite, prior to secondary dissolution	Post secondary dissolution	Dissolution surfaces on clasts. Oxidised rims and matrix. Post-stylolite (post siderite) and post sulphides
Timing of formation	Pre-burial and hydrocarbon migrations (Pre-Visean)	Syn-burial and hydrocarbon migration (locally) (Namurian Westphalian)	Post-burial and other breccias (Westphalian or younger?)
Unit	Macumber	Macumber	Pembroke *(sensu strictu)*

After Lavoie et al. (1995, 1998)

subsurface dissolution of evaporite during the circulation of the mineralising fluid.

Work on breccias in the lower part of the Windsor Group by Lavoie et al. (1995, 1998) and has shown that all three origins are correct. What previously was loosely called the Pembroke Breccia (*sensu lato*), and considered a single unit, does in part host the ore. The problem is that the Pembroke Breccia is a term that is used to describe all breccias in the region, when in reality it does not describe a single lithofacies or a formation specific unit. Rather, the term Pembroke Breccia has been applied to three temporally and genetically distinct breccia bodies (Table 15.11). There is a pre-ore syn-sedimentary carbonate slope breccia, a syn-ore tectonic breccia related to the Ainslie Detachment, and a modern karstic post-ore evaporite solution collapse breccia related to the modern groundwater system. The formation of the syn-ore breccia was aided by pressure buildup and hydrofracturing beneath the regional evaporite cap; processes which also facilitated the formation of the regional subsalt detachment (Ainslie Detachment) at the base of the Windsor Group (Fig. 15.46b).

The main ore host is this syntectonic hydraulic breccia; it is a mineralised-matrix breccia is that contains pyrite, marcasite, sphalerite, galena and baryte, in addition to burial calcite and siderite. Its clasts have been extensively recrystallised and commonly retain finely disseminated sulphides. Anhydrite is absent, as is true sedimentary interclast matrix. Instead, the recrystallised breccia fragments are cemented by equant sparry, or locally radiaxial fibrous calcite, together with sulphides. Liquid hydrocarbons and solid bitumens are abundant, particularly within sulphide-rich domains, and also occur as inclusions within sphalerite and baryte crystals. Stable isotope data clearly show the metals in the mineralised matrix breccia were derived from escaping basinal brines (Armstrong et al. 1993).

In contrast, the evaporite solution breccia that forms via surface related dissolution of the evaporites is a classic rock matrix collapse breccia; it contains clast-supported, chaotically distributed, centimetre-sized, subrounded to angular fragments of the Macumber Formation. Most of the clasts retain their original laminated texture and have not been extensively recrystallised. According to Hein et al. (1991), the clasts in the breccia fell into open spaces created by dissolving evaporite interbeds and interlaminae. The interclast matrix is made up of finely comminuted rock fragments of the overlying Macumber Formation. This rock matrix breccia can be present in cored intervals that also intersect mineralised intervals, hence the earlier confusion in separating the two styles of breccia.

The NNW-trending faults that cut the Jubilee deposit have been shown by Hein et al. (1991) to be synsedimentary and continued to be active solution conduits after they were overthrust by a thick evaporite seal. In the early stages, prior to the thrust emplacement of the evaporite, the faults supplied nutrient-rich waters that vented on to the sea floor. This allowed enhanced carbonate sedimentation on the deep sea

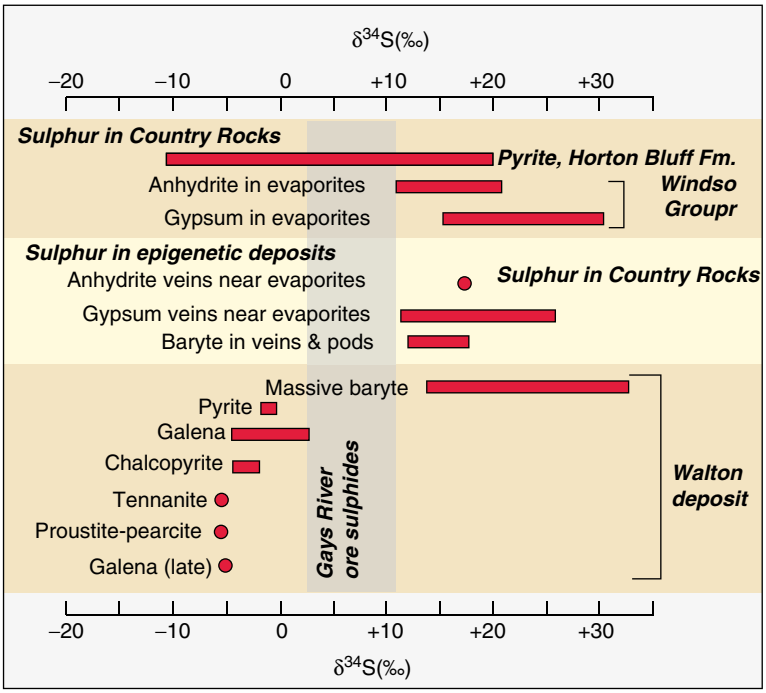

Fig. 15.52 Sulphur isotope ranges for various mineral phases in the Walton deposit and its evaporitic sulphate surrounds, shaded central panel shows sulphide range for the sphalerite and galena in the Gays River mine (After Sangster et al. 1998a, b)

floor in the vicinity of the vents, where chemosynthetic communities of fossil tubes, serpulid and spirorbid worms, conularids, brachiopods, bryozoa and ostracods flourished (von Bitter et al. 1990). Later, during burial diagenesis, and after thrust emplacement of the evaporite cap, the faults acted as conduits that carried metalliferous basinal fluids up into the base of the anhydrites where the sulphides then precipitated. This explains why, even though it is syn-ore tectonic breccia, the mineralised breccia unit is thickest and most heavily mineralised adjacent to the Jubilee Fault.

The Walton Ba-Cu-Pb-Zn-Ag deposit produced some 4.5 million metric tons (Mt) >90 % $BaSO_4$ and 412,850 t @ 0.52 % Cu, 4.28 % Pb, 1.29 % Zn, and 350 g/t Ag (Sangster et al. 1998a). It is hosted by Visean age carbonate rocks of the Macumber Formation and its associated breccia (Fig. 7.95a). The Macumber Formation in the Walton area is divided into two units, the lower Macumber, a laminated carbonate unit 9–12 m thick and the upper; Macumber, a synsedimentary carbonate breccia that forms two mounds up to 21 m thick.

Outside the immediate mine area the carbonate is either limestone or dolostone; the Macumber Formation surrounding the deposit has been altered to manganiferous siderite. Although three textural types of siderite are recognized, little variation in bulk chemical composition is evident among them. Minerals were deposited in the sequence: baryte, pyrite-marcasite, sphalerite, galena, tennantite, chalcopyrite, and (para)rammelsbergite. Each mineral replaces earlier minerals to varying degrees. Sulphur isotope data from the deposit are given in Fig. 15.52.

Based on baryte and metal content, two main ore types are defined (Sangster et al. 1998a). Type I, with a bulk composition of 0.3 % Cu, 2.5 % Pb, 0.2 % Zn, and 31.2 % $BaSO_4$, comprises baryte and variable sulfide contents. Type II, comprised of sulphides only, has a composition of 0.5 % Cu, 0.5 % Pb, 0.1 % Zn, 51 g/t Ag, and no baryte. Type I ore forms a roughly conformable sheet which straddles the upper Macumber-lower Macumber contact and contains lenses of Pb- and Cu-rich ore. Type II ore is most commonly associated with the upper Macumber mounds where it forms large pods which cut the type I ore zone. Type II ore also occurs within the underlying Horton Group sandstones but only where the upper Macumber mounds have developed. There is also a stratigraphic zonation in metal content in as much as all metals are higher, on average, in the lower Macumber relative to the upper Macumber.

The host stratigraphy is steeply dipping and faulted and both features are considered to be post-ore events. Karsting, which also postdates mineralization and probably folding, has removed portions of the stratigraphic upper parts of the deposit. The cavities produced by this process are now partially filled with sand and limestone breccia. This work by Sangster et al. considers the ore host breccias to be depositional carbonate slumps and did not consider the possibility that the prepared ground could have been a response to halokinesis and salt dissolution (Fig. 7.95a)

Gays River, Jubilee and Walton deposits are part of a larger regional scale Zn-Pb-baryte-evaporite association, with consistent sulphur isotope, carbon-oxygen isotope and fluid temperature ranges, related to evaporite focused outflow interfaces. These were active during dewatering and salt-lubricated thrusting as the various tectonic sub-basins of the Maritimes Basin of eastern Canada were created

(Lynch et al. 1998; Sangster et al. 1998a, b, Waldron et al. 2013). Throughout central Nova Scotia, Pb-Zn and baryte deposits are tied to faults and salt structures responding to compression of the once laterally continuous saline giant that defined the original salt distribution in the Maritimes Basin fill. Deposits are generally tied to features at the Touraisian-Visean (Mississippian) clastic carbonate-evaporite disconformity, and overlie Cambrian to Devonian metasedimentary and granitic rocks, which likely acted as sources for the metals.

In addition to Gays River and Jubilee, other significant deposits of this association include: the Southvale baryte occurrence, the Pembroke Pb deposit, the Smithfield Pb-Zn-Cu-Ba deposit, the middle Stewiacke baryte occurrence, the Brookfield baryte deposit, the Hilden baryte occurrence, the Walton-Magnet Cove Ba-Pb-Zn-Cu-Ag deposit and the Lake Fletcher baryte deposit. All these deposits occur on the southern margin of the >10 km thick Carboniferous Maritimes (Fundy-Magdalen) Basin. Regional isotope and inclusion studies show the deposits all formed from basinal brines, which were derived from >5 km depths in catabaric sediments that lay beneath the Visean evaporites (Figs. 15.47a, 15.48, and 15.52; Ravenhurst and Zentilli 1987). According to Sangster et al. 1998b, the isotopic evidence suggests that the Walton, Gays River and Jubilee deposits were derived from the same brine source, probably deeply circulating sulphate-rich brines, as noted by Boyle et al. (1976), these sulphur signatures in these brines are virtually identical to an evaporite source.

Regional salt-lubricated detachment surfaces such as the Ainslie Detachment, controlled and focused the escaping basinal fluids, were probably first created by lateral "into-the-basin" gravity sliding or displacements along the sole of the regional salt thick in a foreland basin setting not too dissimilar to the Maghreb. The remaining salt now resides in the lower Windsor Group and, away from the dissolution edges to the various tectonic sub-basins, is today made up of some 350 m+evaporites of the Carrols Corner Formation and its equivalents (Waldron et al. 2013). During regional compression, the impervious underside of the salt and its allochthons and detachments focused the flow and periodic trapping of escaping metalliferous brines. Prior to reaching the sulphates of the salt base, these same fluids had circulated through the Tournisian clastic rocks and the immediately adjacent tectonic breccias of the detachments. Rising metalliferous brines mixed with shallower basinal fluids across breach points in the evaporite aquiclude, which are now accessible for mining mostly about the basin margin (Fig. 15.46a). Thermochemical sulphate reduction was the main metal fixing reaction of the various deposits, with the sulphur/sulphate supplied by the adjacent evaporites and the organics from the migrating hydrocarbons (Savard et al. 1996; Sangster et al. 1998b; Lynch et al. 1998; Lynch and Keller 1998).

Mississippi Valley Type (MVT) Deposits and Bedded Platform Sulphates?

In addition to the relatively small evaporite focused Pb-Zn deposits discussed so far, many of the larger carbonate-hosted Pb-Zn deposits within the MVT group of deposits are associated with salt-sourced hypersaline ore fluids. The hypersaline affinity is based on fluid inclusion studies that indicate most MVT sulphides are precipitated from highly saline basinal fluids at temperatures within the normal range for diagenetic brines (80–150 °C; Anderson and MacQueen 1990). Many of the larger MVT examples listed are also tied to dissolving evaporites as a source of the chloride-rich basinal waters carrying the metals and many to sulphur sources that are either at or near the precipitation site as bedded platform sulphates or as H_2S in the pore waters derived by sulphate reduction (bacterial and thermogenic), typically from $CaSO_4$ sources. The setting is much like the deposits discussed so far but not a metal precipitation setting that is necessarily directly adjacent to thick current, or former, salt masses.

In what follows we shall focus on some of those MVT deposits located on the platform and tied to bedded calcium sulphate units (Fig. 15.53). In an accompanying plot of grade versus ore tonnage I have indicated some of the MVT deposits known to be associated with evaporites or derived brines (Fig. 15.54). This includes some very large deposits, such as Polaris and Admiral Bay, as well as the small Pb-Zn deposits discussed in the preceding sections. My approach in the remainder of section is not to attempt to define an all encompassing Pb-Zn/MVT model, this has been done in excellent papers by Leach et al. (2010) and Emsbo (2009). Rather, as in the preceding sections, I shall restrict my discussion to those Pb-Zn MVT deposits that have an intimate association with evaporite beds or their residues, so as to develop a specific understanding that can give predictive exploration paradigms for those MVT deposits created by their association with evaporites.

Cadjebut Region, Lennard Shelf, Australia

Bedded calcium sulphate evaporites, and their lateral dissolutional equivalents, have been cored in the area around the Cadjebut mine on the Lennard Shelf and they pass into mine sulphides in the mine and its immediate surrounds (Figs. 15.55 and 15.56). The details of Cadjebut Pb-Zn ore system and ore textures at the mine scale were discussed in detail in Chap. 7 as an example of hydrothermal karst development in a platform saltern and so are only mentioned here. Evaporite solution breccias (rock matrix breccias) are the lateral equivalents of the mineralised sequence in the Cadjebut mine The deposit undoubtedly represents one of the best documented examples of *in situ* burial replacement of a number of evaporite beds by Pb-Zn sulphides on a one

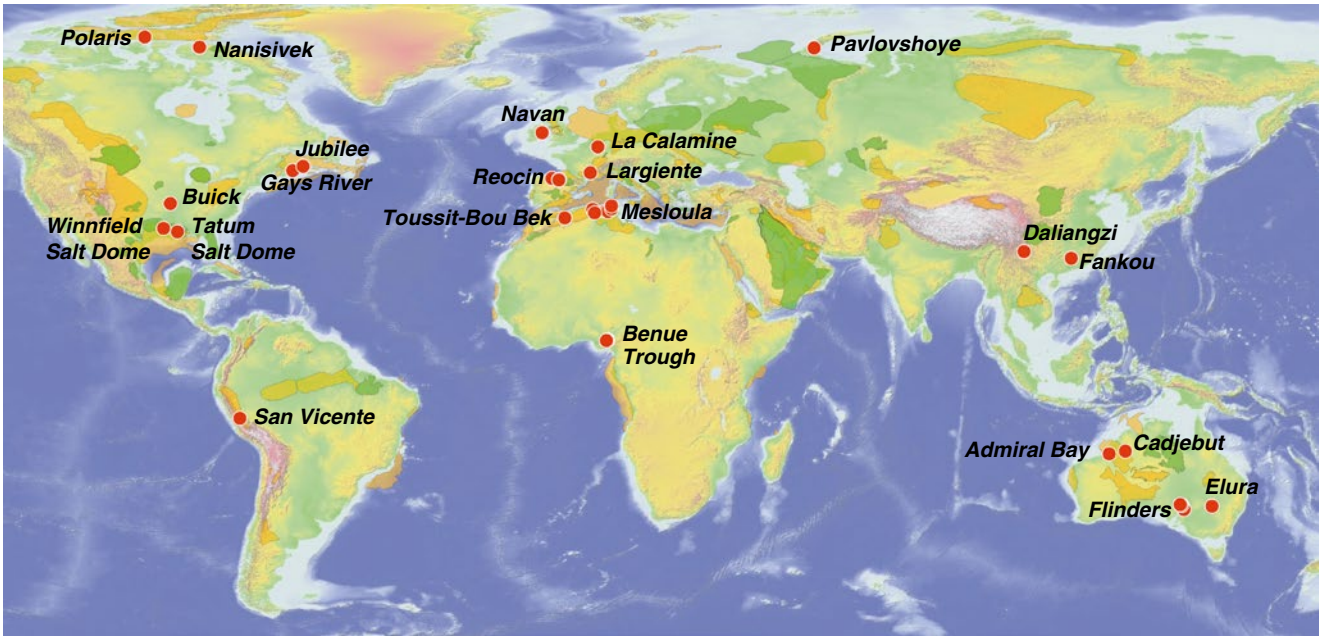

Fig. 15.53 Plot of some of the documented MVT deposits with known ties to evaporites, as detailed in the text

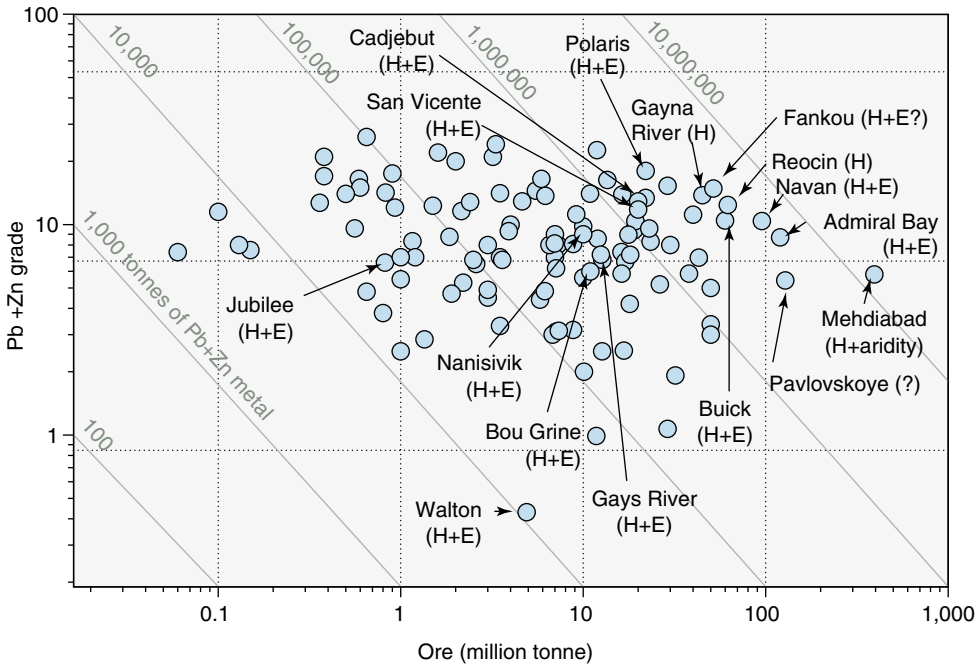

Fig. 15.54 Grade-tonnage plot of MVT deposits (Replotted from USGS data). *H* indicates hypersaline ore fluids, *E* indicates evaporites or indications of its former presence

for one basis (Tompkins et al. 1994a, b; Warren and Kempton 1997). That is, the pre-existing platform saltern beds are directly replaced by Pb-Zn sulphides and these saltern sulphates were the sulphur source. The sulphate to sulphide replacement process occurred across cm- to metre- sized cavities, and so the banded and breccia replacement textures are layered, sometimes forming "zebra" textures. This cavity infill replacement process means the ore textures are not necessarily a direct mimicry of the precursor laminar to nodular evaporite textures (Tompkins et al. 1994a, b versus Warren and Kempton 1997).

More broadly, the Cadjebut ore deposit is a Mississippi Valley Type (MVT) deposit hosted within the Givetian anhydrite entraining Lower Dolomite unit of the Cadjebut Fm. ramp. This sand-shoal-rimmed ramp was the depositional setting that immediately preceded the reef-rimmed Pillara Limestone platform, which defines the Lennard Shelf (Fig. 15.55). Regionally, the Givetian depositional setting

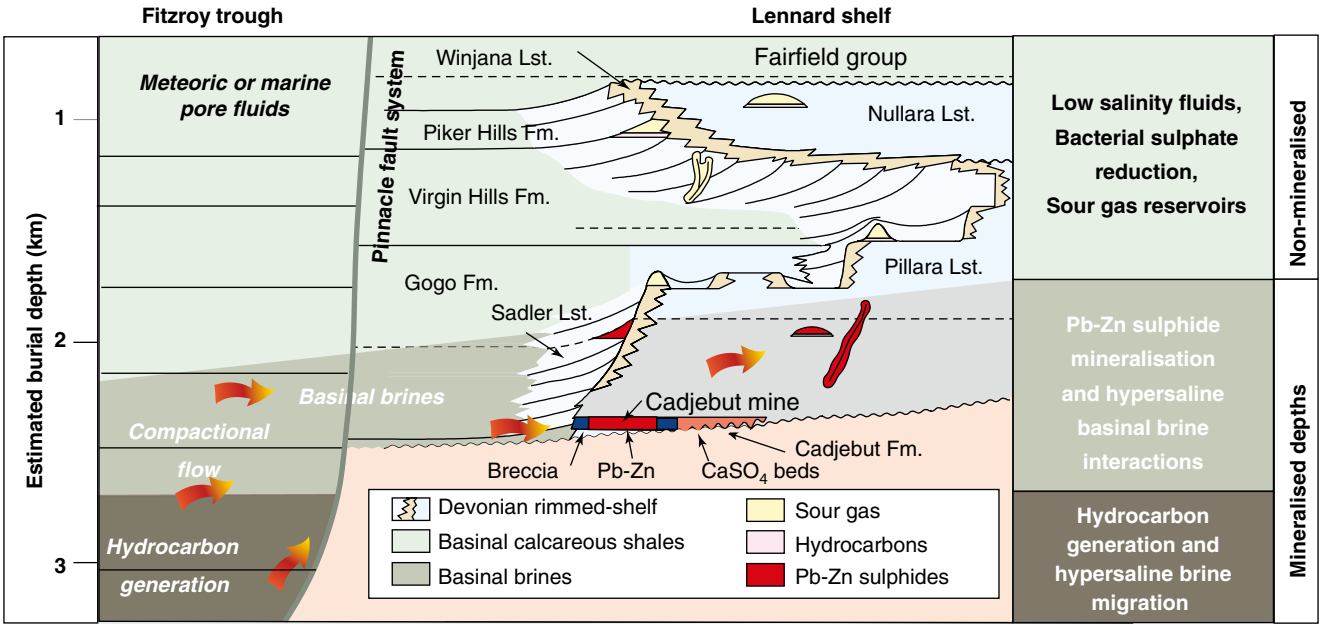

Fig. 15.55 Conceptual model for MVT sulphide precipitation on the eastern Lennard Shelf. At around 350 Ma, sediments of the Fitzroy Trough expelled metalliferous basinal brines and mature hydrocarbons by compactional flow. In shallow subsurface environments with low salinity and low temperature (60–70 °C) fluids, bacterial sulphate reduction occurred in and around saltern evaporite seals and hydrocarbon reservoirs within the Devonian platform. Sulphate reduction was largely fed by Givetian saltern $CaSO_4$ evaporites (Cadjebut Formation) and H_2S-rich reservoirs higher in the stratigraphy form in a variety of traps (faults, antiforms, and stratigraphic traps). Sulphides are precipitated when basinal brines interact directly with evaporites or invade intervals of trapped H_2S-rich (Modified from Playford and Wallace 2001; Wallace et al. 2002; Warren and Kempton 1997; Kerans and Harris 2008)

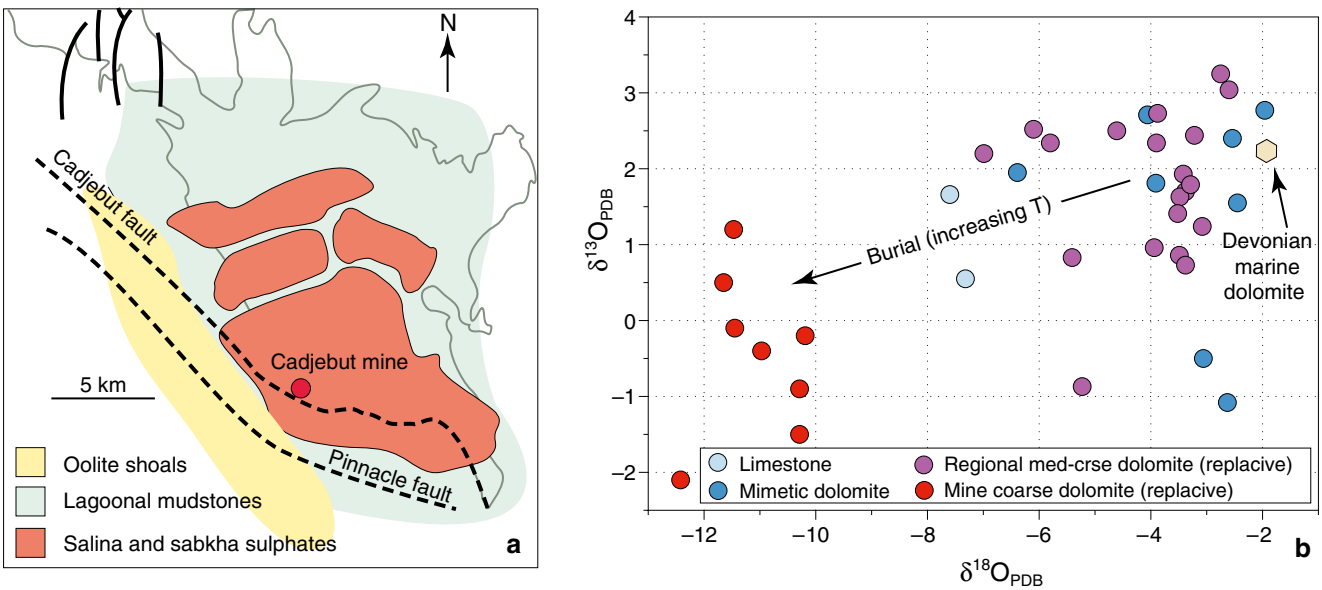

Fig. 15.56 Cadjebut Mine geological evolution. (**a**) Givetian paleogeographic reconstruction based on logged core intersections across the mine and its surrounds. *Grey line* defines the outline of the Emmanuel Ranges. Oolite shoals developed in vicinity of Cadjebut and Pinnacle faults, with dolomitised lagoonal wackestone and siltstone in back shoal area. A slight fall in relative sealevel created a sulphate mudflat complex in the vicinity of Cadjebut Mine. (**b**) Plot of $\delta^{18}O_{PDB}$ versus $\delta^{13}C_{PDB}$ for various dolomites in the Cadjebut mine and its surrounds (After Warren and Kempton 1997)

can be divided into two zones (Fig. 15.56a): (a) a higher energy shoal region in the vicinity of the mine and Cadjebut Fault and, (b) a landward more restricted, lower energy, at times evaporitic, lagoonal setting laid down in a series of shoaling carbonate cycles. The upper portion of each cycle is characterized by an evaporitic cap of laminar dolomitic

siltstone and mudstone with associated nodular anhydrite that formed a laterally extensive facies mosaic of sabkhas and salinas across an evaporitic mudflat. This originally shallow subaqueous or sabkha mudflat gypsum converted to nodular anhydrite during shallow burial and was subsequently replaced by Pb-Zn sulphides in the mine area.

Three petrographically distinct forms of dolomite occur in the lower dolomite unit across the Cadjebut region (Fig. 15.56b): (a) a regional finer-grained non ferroan mimetic form with $\delta^{18}O_{PDB}$ of −2 to −4‰ – this dolomite and (b) a ferroan medium to coarsely crystalline form with $\delta^{18}O_{PDB}$ -4 to −7‰ that is best developed about major growth faults. This dolomite overprints and replaces the finer grained stratabound mimetic dolomites as well as other carbonate facies. The finer grained ferroan dolomite formed by syndepositional brine reflux associated with the deposition of evaporites, while the coarser more ferroan dolomite formed during burial from escaping basinal fluids. These same fluids later carried metalliferous fluids from the Fitzroy Trough into sites of ore formation. Post-ore coarse replacement and saddle dolomites from the Cadjebut mine constitute the third dolomite type and are further depleted in $\delta^{18}O_{PDB}$ (−10 to −12‰) and likely indicate localized somewhat elevate thermal conditions related to sulphide mineralization.

Interaction of a metalliferous basinal brine with sulphate that was derived from the dissolving anhydrite beds precipitated the various ore lenses at Cadjebut mine. Sulphide-mineralised horizons in the Cadjebut mine can be correlated on a one to one basis with fine-rock matrix breccia horizons in the immediate area around the mine and with remnant bedded sulphate units well away from the mine. The precursor host lithology to the various ore horizons at Cadjebut are massive to bedded nodular anhydrite beds. The stratabound linear nature of the Cadjebut deposit reflects a time when metalliferous basinal fluids encountered bedded stratiform nodular anhydrites causing them to precipitate lead and zinc sulphides. This process locked in place a mineralization event at the stratigraphic position of each evaporite bed in the lower dolomite unit. Conduits for the metalliferous basinal fluids were the basin-margin-defining faults such as the Cadjebut and Pinnacle Faults (Fig. 7.71a). Fine-matrix breccias define subsurface evaporite dissolution both prior to and after the sulphide mineralization event. Today the remnant nodular anhydrite beds are rehydrating to satin-spar and poikilotopic gypsum as modern groundwaters seep into the units.

One of the problems with comparing nodular calcium sulphate and open-space filling zinc and lead sulphide textures in the Cadjebut region occurs when modern telogenetic effects go unrecognised. Much of the shallow anhydrite that was cored in the 1980's and 1990's is converting to porphyroblastic gypsum down to depths of hundreds of metres as it is flushed by modern meteoric waters (telogenetic alteration). Some workers (Tompkins et al. 1994a, b) did not realise that the current gypsum textures in relict anhydrite beds recovered in cores are replete with such telogenetic rehydration features (tertiary evaporites).

Such gypsum rose and cannonball textures should not be compared to possible primary depositional textures (erroneous assignment to a sabkha for massive sulphate units), nor to cavity fill and layered textures in the metal sulphides that formed in the mesogenetic realm. Ore evolution models that do not remove the effect of modern gypsum overprints, or any assumption that gypsum textures in recovered cored could be primary (has survived kilometres of burial and uplift) are erroneous. Respective precipitative processes for anhydrite rehydration and metal sulphide textures at Cadjebut are totally unrelated in terms of time and space (Warren and Kempton 1997).

The now depleted Cadjebut deposit is the largest and most concentrated of a number of MVT accumulations in the Lennard Shelf Pb-Zn province, mostly hosted in Devonian shelf carbonates, although the Cadjebut is deposited in ramp dolomites of the Givetian Cadjebut Fm, which immediately underlies the Frasnian-Famennian rimmed-margin dominated by the Willara and Pillara platforms (Fig. 15.55; Hocking et al. 1996). The rimmed-margin Frasnian-Famennian platform-hosted deposits include hydrothermal-karst dominated deposits (Goongewa and Bloodwood), and fault or fracture-hosted deposits (e.g. Pillara (aka Blendevale), Kapok, Fossil Downs). Fault and fracture hosted mineralization style dominates Frasnian and Famennian platform host across the Lennard Shelf (Wallace et al. 2002).

The Goongewa deposit is situated in the hanging wall of a normal fault (Cadjebut Fault). Stratigraphically, the mineralisation occurs around a Givetian platform margin and also occurs at the boundary between dolomitised and undolomitised carbonates. MVT sulphides there are largely present as cavity-filling cements within large hydrothermal karst caverns. The nearby Kutarta mineralisation (close to the old Price's Creek prospect) has a quite different style again, with much of the base-metal sulphide mineralisation being a replacement of dolomitised and brecciated back-reef carbonates (Pittari 1999).

The timing of MVT sulphide precipitation is well constrained by a number of techniques. Using carbonate cement stratigraphic relationships in host rock primary porosity, McManus and Wallace (1992) suggested that a single, widespread sulphide precipitation event (pyrite, sphalerite, galena, marcasite) occurred during early burial diagenesis during latest Devonian–earliest Carboniferous time (350 ± 15 Ma) within the reef complexes of the Lennard Shelf. This mineralisation age has since been confirmed by both Rb-Sr dating of sphalerite at Blendevale and U-Pb dating of ore-stage calcites from Goongewa (Wallace et al. 2002). Further south in the basin, the giant saltern

evaporite sealed Admiral Bay Pb-Zn deposit was discovered as part of an oil exploration program, but it is too deep to be exploited by conventional mining techniques McCracken et al. 1997).

Reinforcing the notion of ongoing fault focused fluid evolution controlling mineralisation in the Canning basin are the various stromatolite-baryte-sulphide mounds that constitute outcrops at a number of localities on the eastern Lennard Shelf. They are interpreted as fault-fed synsedimentary exhalative deposits on the Devonian deep basin-margin seafloor (Playford and Wallace 2001). For example, such stromatolite mounds occur near the Gogo Formation–base Virgin Hills Formation contact and are associated with extensive gossans in outcrop. In drill core, iron sulphides (marcasite and pyrite) are dominant, with base-metal sulphides only occurring as later stage cross-cutting veins.

The varying ore style geometries reflect the simple fact that no bedded evaporites were deposited in the Frasnian-Famennian backreef, only in the Givetian back-shoal region. And so, when the basinal fluid pulses of metalliferous fluids moved up along faults at the basin margin and through the various carbonate hosts, it precipitated well bedded ore units where metal-carrying fault conduits intersected anhydrites in the Cadjebut Formation and fault/ hydrothermal karst geometries where faults encountered mixtures of hydrocarbons and other reductants in the Frasnian-Famennian platform hosts. Once again, dissolving evaporites do not necessarily make ore deposits, when they do, they tend to focus the precipitative process and so make a more concentrated accumulation.

Polaris Zn-Pb Mine, Nanavut, Canada

The Mine, near the coast of Little Cornwallis Island, is hosted by the Ordovician Thumb Mountain Formation and located on the northeast flank of a large NW–SE oriented salt-cored antiform that formed in the Ellesmerian Foldbelt, during the Late Silurian to the Middle Devonian (Figs. 15.57 and 15.58; Thorsteinsson and Uyeno 1980 Dewing and Copper, 1991). Based on paleomagnetism Rb-Sr and Re-Os dates from ore sphalerites and bitumens, respectively, the mineralisation is known to have occurred at 366 ± 15 Ma and so is co-occurrent with tilting and compression that formed the Ellesmerian (Parry Island) foldbelt and the Boothia Uplift (Symons and Sangster 1992; Selby et al. 2005; Jober et al. 2007). The mine commenced operation in 1981 and closed in July 2002, When in operation, the mine had a reserve of over 20 Mt of sphalerite (ZnS) and galena (PbS) and was hosted in brecciated and dolomitised carbonate rocks of the Upper Ordovician Thumb Mountain Formation. The now-depleted Polaris Mine exploited one of the largest single Mississippi Valley-type ore deposits in the world (Reid et al. 2013).

Dimensions of the Polaris deposit are: 800 m strike length, 300 m at its widest point and a thickness ranging from 20 m in the west to 100 m in the central portion (Dewing et al. 2005). The deposit is blind, with the topmost ore lying 50 m below surface on the west and up to 160 m below surface on the east side. It forms a continuous sulphide body broken down based on grade, position and textures into a number of units; P_1 -P_2 and K_1 to K_3 (Table 15.12; Dewing et al. 2005). Of the five ore types recognized: two occur in the upper Thumb Mountain and three in the lower Thumb Mountain Formation (Fig. 15.59).

P_1 ore was the economically most important and formed a 10–30 m thick, high grade Zn-Fe-Pb, tabular unit hosted in

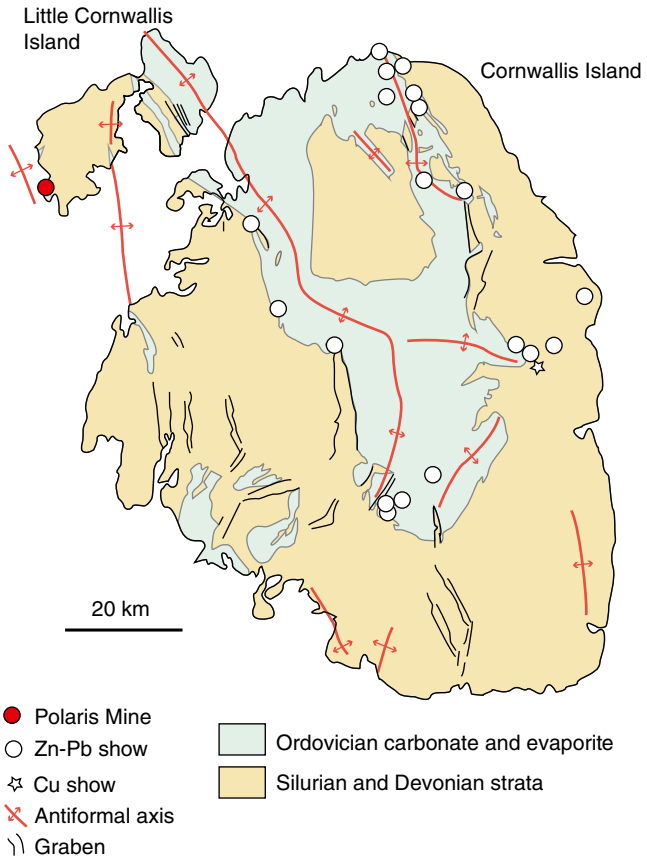

Fig. 15.57 Map of the Cornwallis Island region showing positions of salt-cored antiforms on the Boothia Uplift in the Ellesmerian foldbelt, the Polaris Mine on Little Cornwallis Island and a number of Zn-Pb and Cu shows (After Reid et al. 2013)

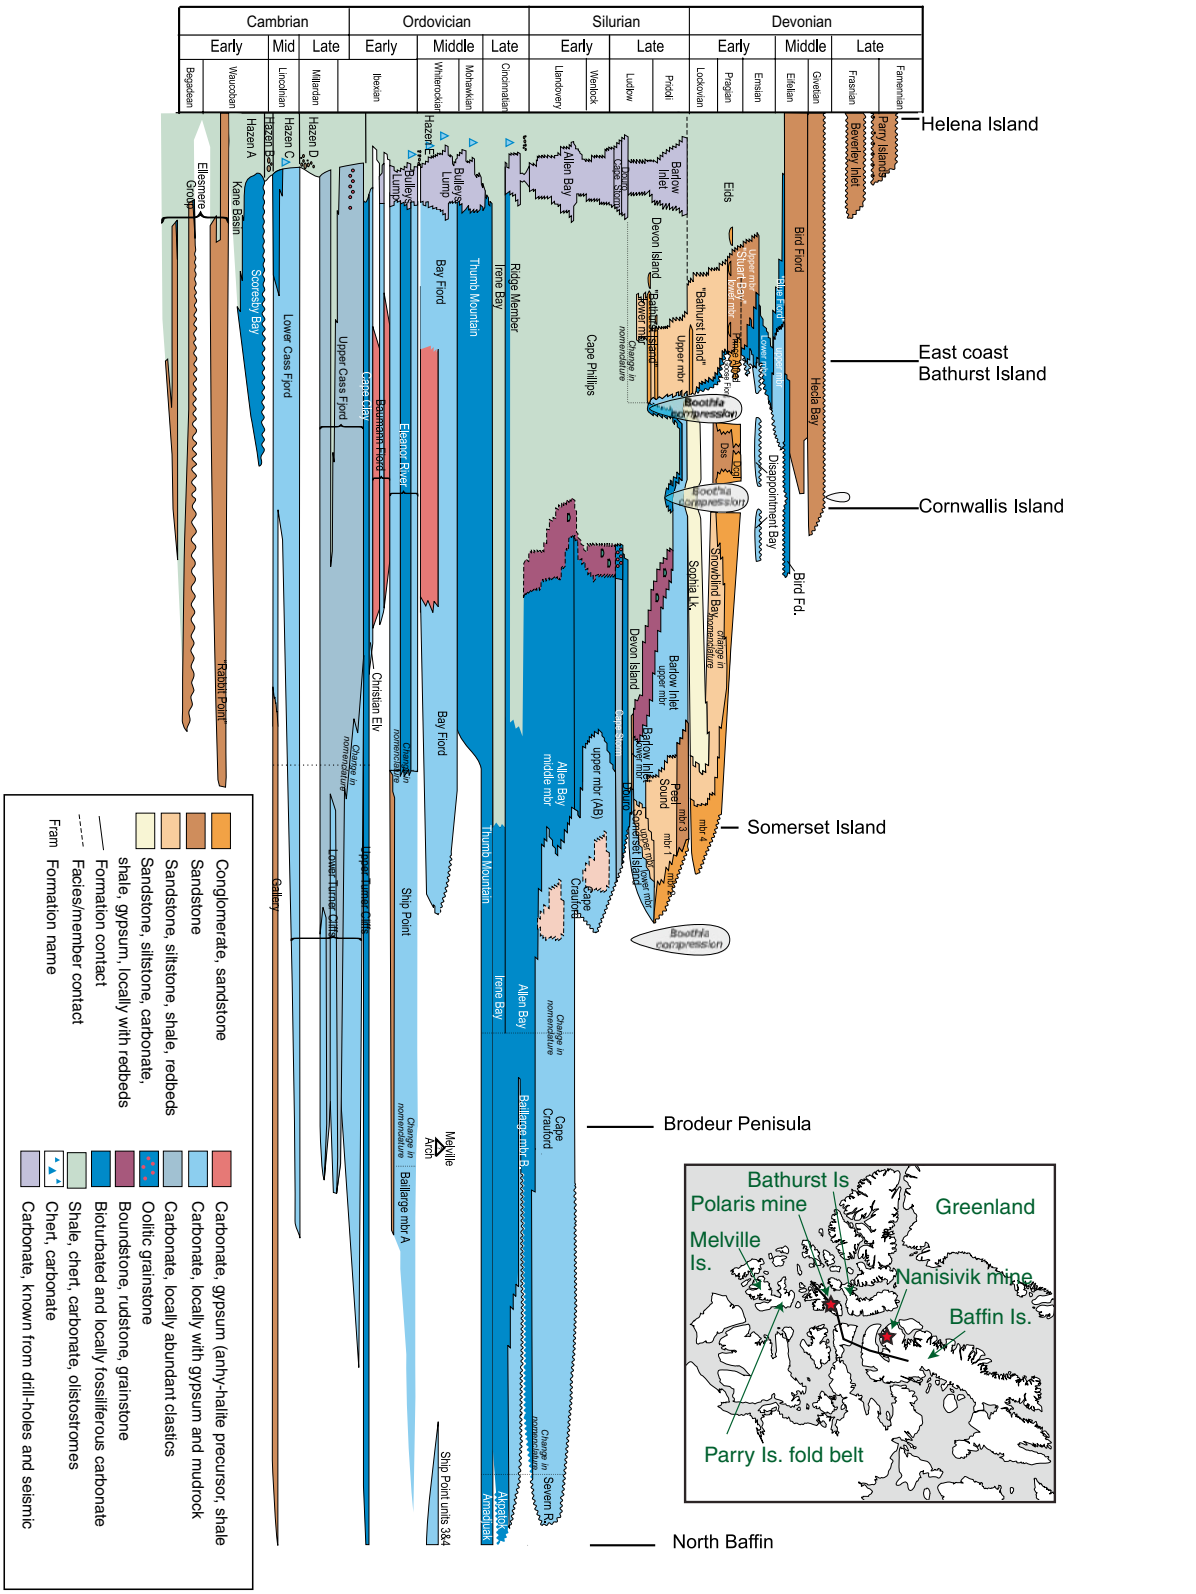

Fig. 15.58 Time-stratigraphic diagram showing a south to north transect from northwestern Baffin Island to northern Bathurst Island (see *inset*). The chart is after Dewing et al. 2005 and references therein. Importantly the cited chart is based on outcropping mineralogies and does not consider that textural evidence throughout the region indicates that much of the gypsum in outcrop is after halokinetically overprinted anhydrite and that this halite was once present in the region. It is still present in surface equivalents, for example, the *star* indicates gypsum/halite remnant breccias, in Bay Fiord Fm. as illustrated Fig. 15.59

the basal part of the upper Thumb Mountain Formation. P_1 ore consisted of massive, carbonate replacement, breccia-fill and vein sulphide averaging 4–5 % Fe with up to 30 % Fe (Table 15.12). Overlying the P_1 ore, above the major N-S structures defining the boundaries of the Keel graben, are blocks designated as P_2 ore. This ore is composed of numerous thin to 1 m thick veins of sphalerite, marcasite and galena oriented vertically, sub-perpendicular to bedding. Marcasite halos surround most P_2 veins. Directly underlying the P_1 tabular body is the high grade K_3 ore, composed of complex, cross-cutting veins along with massive to disseminated metal sulphides replacing *Tetradium* beds containing 3–5 % Fe (Fig. 15.59).

Differentiation between K_3 and P_1 ore was based mainly on lower iron contents of K_3 versus the P_1 ore. K_2 ore underlies the K_3 unit and is composed of fracture filling and vein sulphides with lesser replacement of carbonate, with local pods of mineralized brecciation carrying grades of 8–20 % Pb + Zn and 1–2 % Fe. The lowermost ore unit is K_1 ore composed of fracture-filling and vein sulphides, discontinuous and lower grade (10–15 % Pb + Zn, 1 % Fe). This ore unit follows either the N-S (mine grid) axis of mineralization or a NE-SW trend and is centred on lower stratigraphic horizons around a green marker bed in the lower Thumb Mountain Formation (Fig. 15.59). To the east and west of the orebody, sulphide mineralization dies out rapidly within 15 m of the ore boundaries. Sulphide feathers out into small, scattered lenses and sulphide vein systems to the north and south of the orebody and further out transitions into a breccia unit, called pseudobreccia, in the mine terminology

Diagenesis of the mine series is indicated by extensive hydrothermal alteration, including sequential dolomitisation, marcasite and baryte precipitation events (Figs. 15.60 and 15.61; Savard et al. 2000; Reid et al. 2013). There are three paragenetic stages: (1) Early replacement dolomites and marcasite; (2) Main stage sulphide and hydrothermal coarsely-crystalline (saddle) dolomite; and (3) Late calcite, marcasite and baryte. Ore mineral textures range from discrete crystals to massive crystal aggregates and formed as replacements of the dolomite host rock or as fracture- and open space-filling mineralization. Zinc concentration is highest in the core of the deposit where open-space fill and botryoidal aggregates predominate. Locally elevated T_h values $\approx$ 100 °C are associated with nearby organic-rich strata and bitumens, while the ore carries a geochemical signature that includes *in situ* sulphur fractionation. Detailed isotope

Table 15.12 Ore grade divisions in the Polaris Mine (Dewing et al. 2005)

Zone	Pb + Zn	Fe	Zn/Pb
P_2	16.5	4.6	3.1
P_1	22.4	4.5	3.5
K_3	19.1	3.1	5.6
K_2	17.3	1.7	4.3
K_1	15.5	0.8	8.1

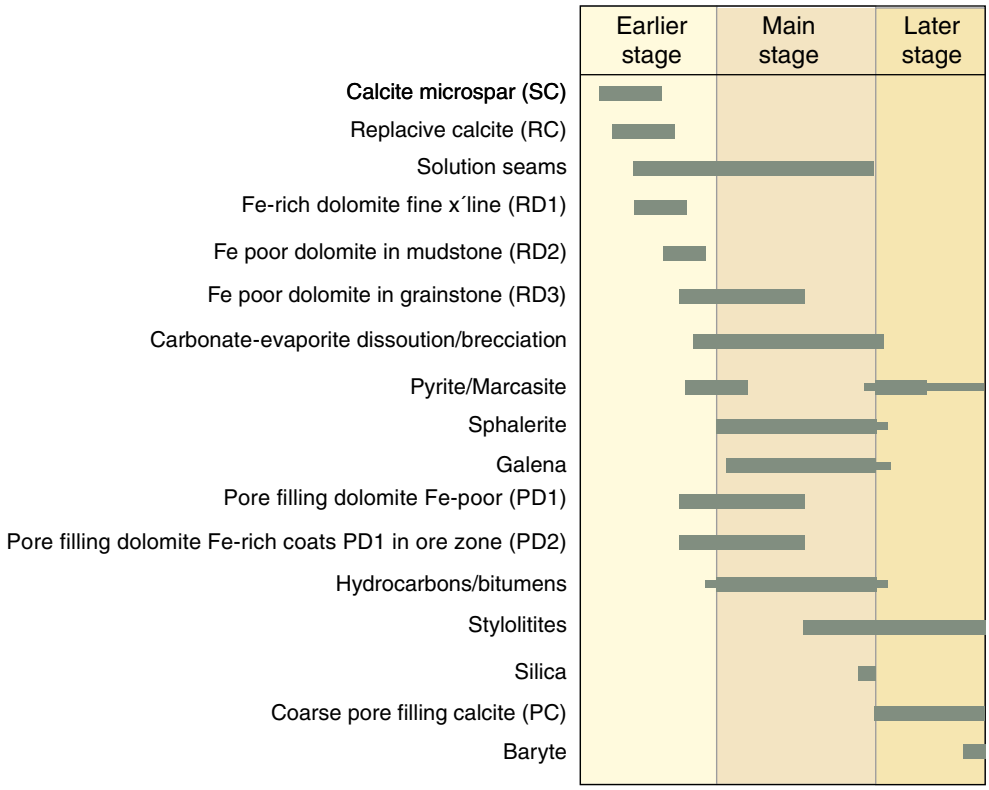

Fig. 15.60 Paragenetic-diagenetic sequence in the Polaris Mine (After Savard et al. 2000; Reid et al. 2013)

study tied to petrography clearly shows that replacive dolomite predates and is synchronous with ore emplacement. As in other MVT deposits so far, dolomitisation is associated with emplacement of sulphide minerals, but is not the controlling process for mineralisation.

Five types of dolomite were distinguished by Savard et al. (2000), including three replacement (RD) and two pore-filling dolomites (PD). The paragenetic order is RD1, RD2, RD3, PD1, and PD2. Pore-filling calcite (PC) postdates all other minerals. Baryte and silica are late-stage precipitates. In most cases, sulphides and dolomite did not co-precipitate, but sphalerite and galena largely overlap with RD3 and PD1. Various dolomites are dissolved or replaced by sulphide-precipitating fluids; sulphides in turn can be overgrown by dolomites. Colloform texture in sphalerite is widespread.

Early calcite, both microspar replacement (SC) and early replacive calcite spar (RC) have C-O stable isotope values closest to ambient seawater, as does early fine-grained dolomite (RD1). The isotopic values of RD2, RD3, PD1, and PD2 cluster tightly and form largely overlapping domains (Fig. 15.61a). With respect to the host limestone, they are depleted in ^{18}O, similar in $\delta^{13}C$, and slightly enriched in ^{87}Sr. Fluid inclusions were studied by Savard et al. (2000) in RD3, PD1, PD2, sphalerite, and PC. The overall ranges of homogenization temperatures (T_H) for non-stretched fluid inclusions in dolomites and sphalerites range from 67° to 110 °C, indicative of warm basinal brines with high salinities and elevated Ca/Na ratios (Fig. 15.61b). Gas chromatographic analysis of these same fluid inclusions indicates low concentrations of hydrocarbons (<0.06 mol%).

There are no regular spatial variations for fluid inclusion and isotope data during metal sulphide emplacement, indicating an overall geochemical homogeneity in the hydrothermal system at that time. Sulphur isotopes show slightly different groupings for galena and sphlarite, with sphalerite tending toward somewhat more negative $\delta^{34}S$ values (Fig. 15.61c). Some samples close to the fracture zones in the orebody show slightly elevated T_H and $^{87}Sr/^{86}Sr$ values and more depleted $\delta^{18}O$ values, suggesting that the fracture zone was the likely conduit for warm metalliferous brines.

Based on the geological and geochemical characteristics of the deposit, Savard et al. (2000) propose that sulphide precipitation at Polaris was caused by the mixing at the site of mineralization of a reduced, metal-rich, sulphur-poor fluid with a reduced, metal-poor, sulphur-rich fluid. The metal-carrying fluid ascended along fractures from below the deposit and was hotter than the host rocks, whereas the reduced sulphur-carrying fluid was delivered to the site of mineralization laterally from dissolving sulphate beds and was in thermal equilibrium with the host rocks (Savard et al. 2000). This model can explain the dissolution of dolomite/evaporite during sulphide precipitation and the abundance of colloform sphalerite, as well as the low concentrations of hydrocarbons in fluid inclusions.

An alternative model for the Polaris deposit is that sulphate was supplied by dissolution of anhydrites of the under-

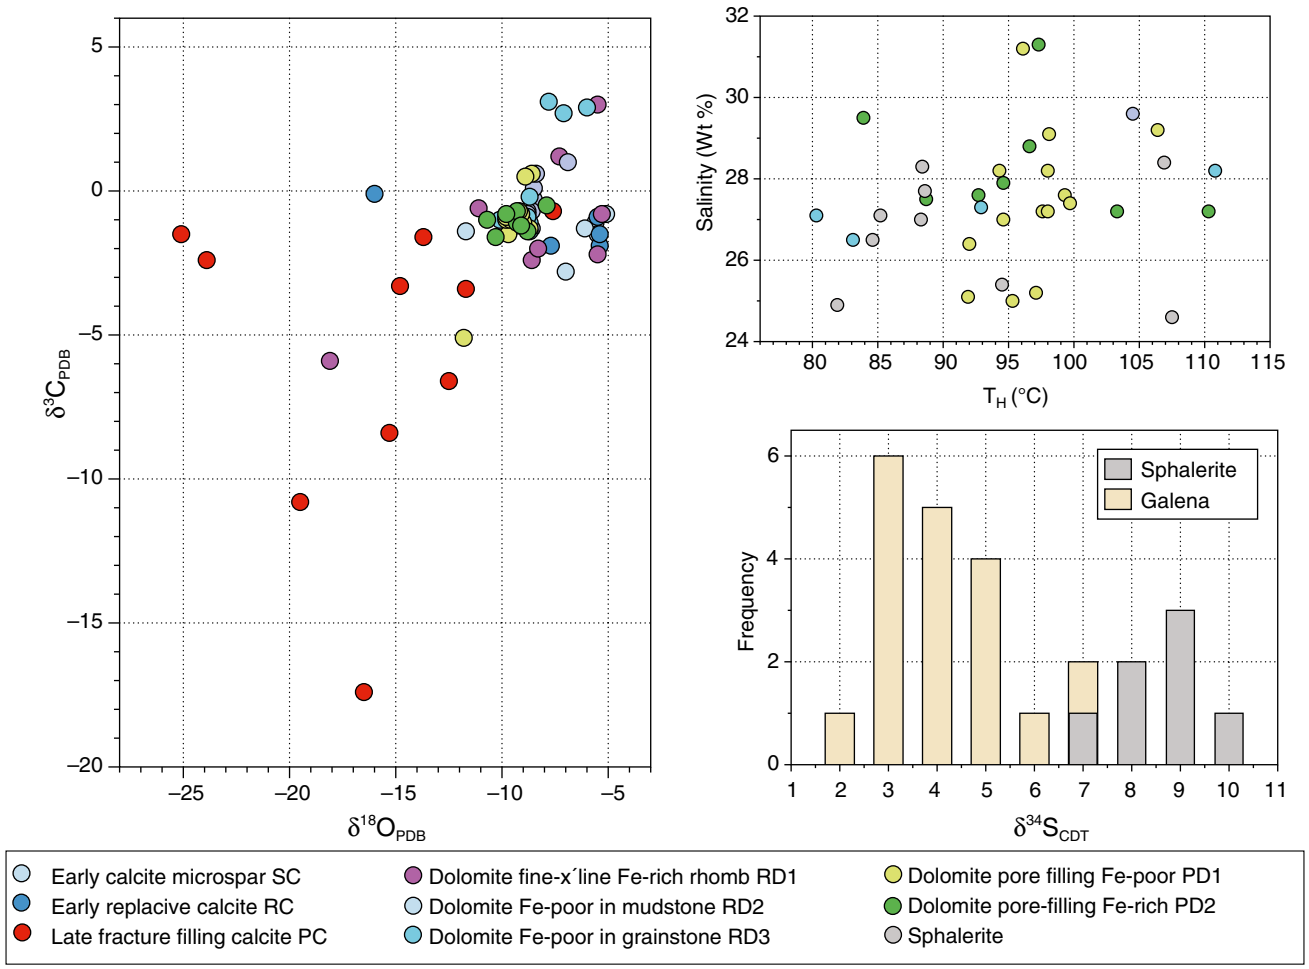

Fig. 15.61 Isotopes and temperatures in the Polaris Mine. (**a**) Carbon-oxygen isotope crossplot in various carbonate phases in the Polaris mine. (**b**) Salinities (wt%) and homogenisation temperatures (T_H) in inclusions of selected carbonate phases and sphalerite. (**c**) Sulphur isotope determinations in sphalerite and galena (From Savard et al. 2000; Reid et al. 2013)

lying Bay Fiord Formation, while the organic-rich shales of the Irene Bay formation acted as both seal and as a source of organics in the fault focused zone of sulphate reduction that drove the mineralisation (Fig. 15.62a; Reid et al. 2013; Dewing et al. 2005).

TSR is unlikely to have been the dominant precipitative mechanism in either model, since: (i) the temperatures are too low (>120 °C is needed), (ii) there is no blocky calcite with strongly negative $\delta^{13}C$ values that is typically produced during TSR, (iii) there is fractionation of the sulphur isotopes, a process that does not occur during TSR (Machel et al. 1995), and (iv) the $\delta^{34}S$ in individual sphalerite masses is inhomogeneous, typically showing a variation from 8‰ in the colloform centre of the sphalerite mass to 12‰ at the outer crystalline rim which is somewhat similar to the galena. Presumably this reflects pulses of fluid activity, with BSR producing a gas cap with strongly fractionated H_2S, followed by the introduction of metal-rich brine, rapid precipitation of amorphous colloform sphalerite, followed by slower precipitation of crystalline sphalerite as the gas cap is depleted and gas slowly produced by ongoing BSR.

Any model for the Polaris deposit (Fig. 15.61) must invoke a source of metal ions within the stratigraphic column, since strontium or lead isotopes show no indication of basement involvement. The likely metal source was units beneath the dissolving and deforming Bay Fiord salt seal where metals were convectively flushed by chloride-rich saline brines and were carried toward the basin edges through aquifers deep in the stratigraphic column. Driven by the Late Devonian Ellesmerian Orogeny, the fluids rose along faults until they encountered the organic-rich, permeable Thumb Mountain Formation limestone overlain by the impermeable Irene Bay Formation shale.

Bacterial sulphate reduction (BSR) likely reduced sulphate to H_2S utilising the abundant algal organic matter in the upper Thumb Mountain Formation as a reductant. The resulting H_2S explains a shift in $\delta^{34}S$ values of −15‰ (Fig. 15.62a). The H_2S reacts inorganically with zinc, lead,

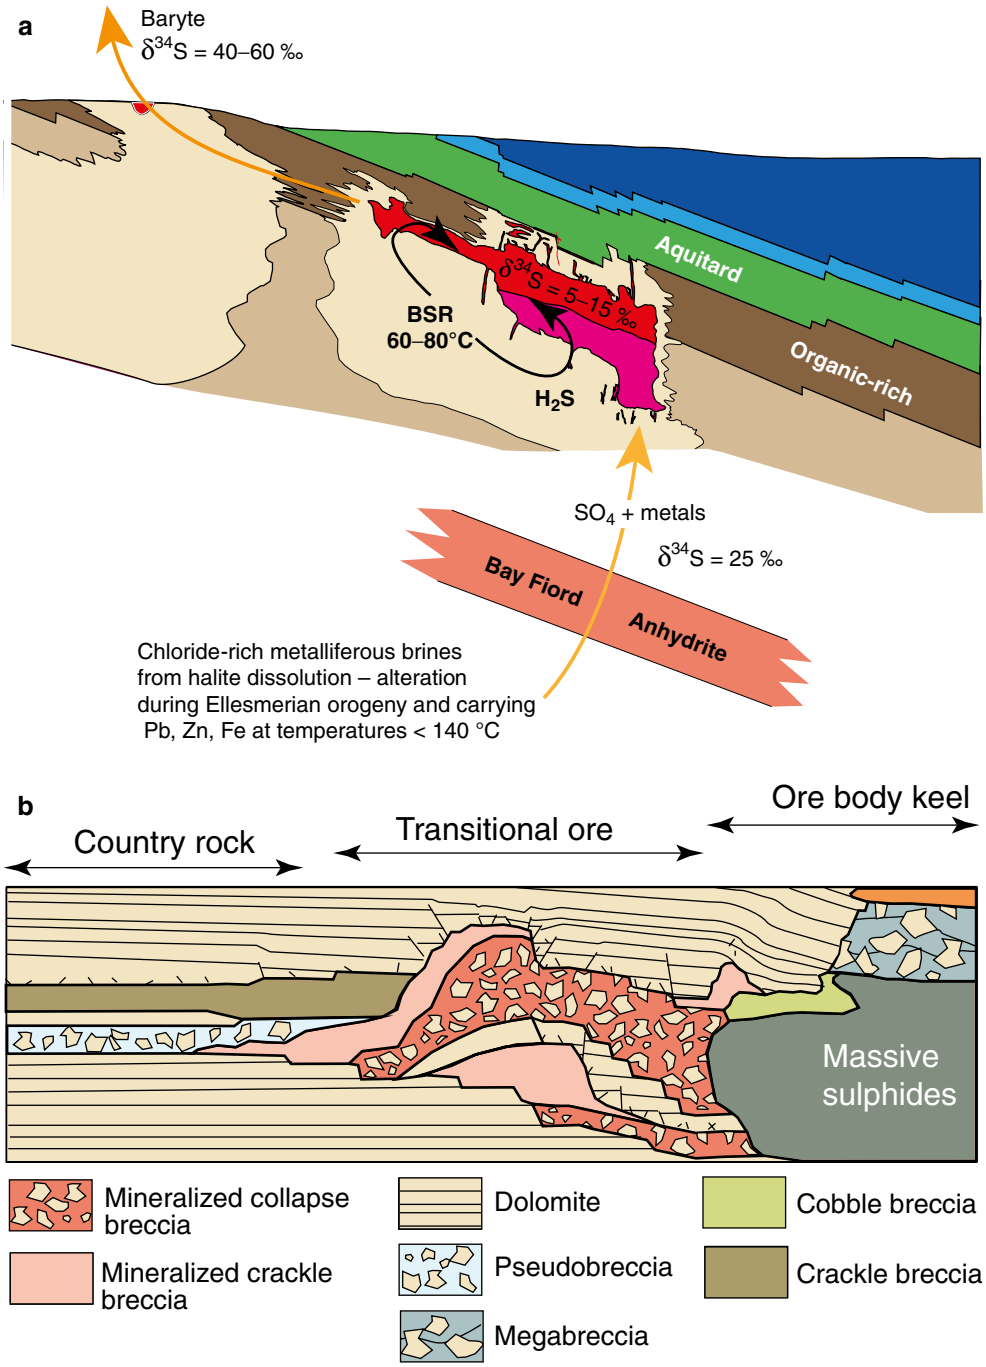

Fig. 15.62 Polaris Mine. (**a**) Mineralisation model showing the halite dissolution origin of metal and sulphate-rich fluids in the sedimentary pile. Transport was as a single saline fluid to site of ore precipitation, where reduction and fractionation was driven by bacterial sulphate reduction, in combination with isotopically light H_2S and metal ions to form ore and create acidic fluids that created hydrothermal karst cavities and associated open-space collapse textures. The expulsion of isotopically heavy sulphate produces a characteristic baryte halo. Refer to Fig. 15.59 for lithology legend (Adapted from Dewing et al. 2005). (**b**). Model of detailing the distribution of breccia types relative to massive sulphide mineralisation (After Reid et al. 2013)

and iron ions to produce sulphides with a $\delta^{34}S$ value of about 10‰. Released hydrogen ions dissolve carbonate resulting in dissolution breccias and other open-space dissolution fabrics. Excess sulphate was expelled from the system and produced a halo of baryte up to 10 km from the deposit, with $\delta^{34}S$ of +40 to +60‰ (Dewing et al. 2005). Evidence of a temporal link between baryte and ore is based on the following; (i) a sample from the 930–124 stope at Polaris that has sphalerite, which pre- and post-dates baryte, (ii) the proximity of baryte to Polaris (baryte is common on southern Little Cornwallis Island), (iii) the heavy sulphur isotope values, and iv) co-occurrence of baryte with late stage marcasite.

Temperatures measured from fluid inclusions in the sphalerite and inferred from the thermal maturity data from kerogens in the mine series indicate a range of 80–105 °C (Reid et al. 2013; Dewing et al. 2005). This is the appropriate range for bacterial sulphate reduction. Thermochemical sulphate reduction (TSR) is unlikely to have been active since; (1) The temperatures are too low (>140 °C is needed), (2) There is no blocky calcite with strongly negative $\delta^{13}C$ values that is

typically produced during TSR, (3) There is fractionation of the sulphur isotopes, a process that typically does not occur during TSR (Machel et al. 1995), and (4) the $\delta^{34}S$ in individual sphalerite masses is inhomogeneous, typically showing a variation from 8‰ in the colloform centre of the mass to 12‰ at the outer crystalline rim. Presumably this reflects pulses of fluid activity, with BSR producing a gas cap with strongly fractionated H_2S, followed by the introduction of metal-rich brine, rapid precipitation of amorphous colloform sphalerite, followed by slower precipitation of crystalline sphalerite as the gas cap is depleted and gas slowly produced by ongoing BSR.

Given this paragenesis, let us once again step away from the Polaris deposit look more broadly at its regional evaporite association. As Davies (1974) notes, there are two significant evaporite units that lie beneath the Thumb Mountain Formation, the Early Ordovician Baumann Fiord Formation and the Middle Ordovician Bay Fiord Formation (Figs. 15.58 and 15.62). The Baumann Fiord is exposed on eastern and southern Ellesmere Island, and extends southwestward to Cornwallis Island (Thorsteinsson and Kerr 1968), where it forms the exposed Ordovician core of a large central dome. The Baumann Fiord Formation is about 750 m thick in the type area on eastern Ellesmere Island; about 600 m of this current thickness is anhydrite with cyclically-interbedded carbonates, some stromatolitic (Mossop 1972, 1973). The anhydrite grades westward into shallow-water shelf carbonates, while to eastward it thins, becomes sandier, and may pass to an unconformity close to the shelf-craton margin. Mossop (1972) interprets the Baumann Fiord evaporite-carbonate units to be a succession of sabkha cycles. Halite in the Baumann Fiord is not exposed at the surface. I would interpret it as a series of stacked sulphate salterns in an intracratonic sag basin.

The next youngest and most extensive Ordovician evaporite unit is the Bay Fiord Formation (Kerr 1977) of Middle Ordovician age (Fig. 15.63). It lies immediately below the Thumb Mountain Formation and constitutes the basal formation of the Cornwallis Group. The Bay Fiord is exposed in eastern and southern Ellesmere Island, and can be traced southwestward to Cornwallis Island and Bathurst Island. In the type area on eastern Ellesmere Island (Kerr 1968), the Bay Fiord Formation contains gypsum and anhydrite in the lower part of a 500 m thick section of argillaceous and dolomitic limestone, siltstone and shale. The Bay Fiord are thought to lie within the carbonate-dominant shelf succession that extends southeastward of the Franklinian trough, approximately co-extensive with the older Baumann Fiord Formation. The thickness an purity of the sulphate units in the Bay Fiord once again indicates they are salterns within an intracratonic sag (Warren 2010). But more significantly away from their leached outcrop positions there are halite units in the Bay Fiord, and some are extensively thrusted and folded (Fig. 15.63; Chap. 6; Harrison 1995)

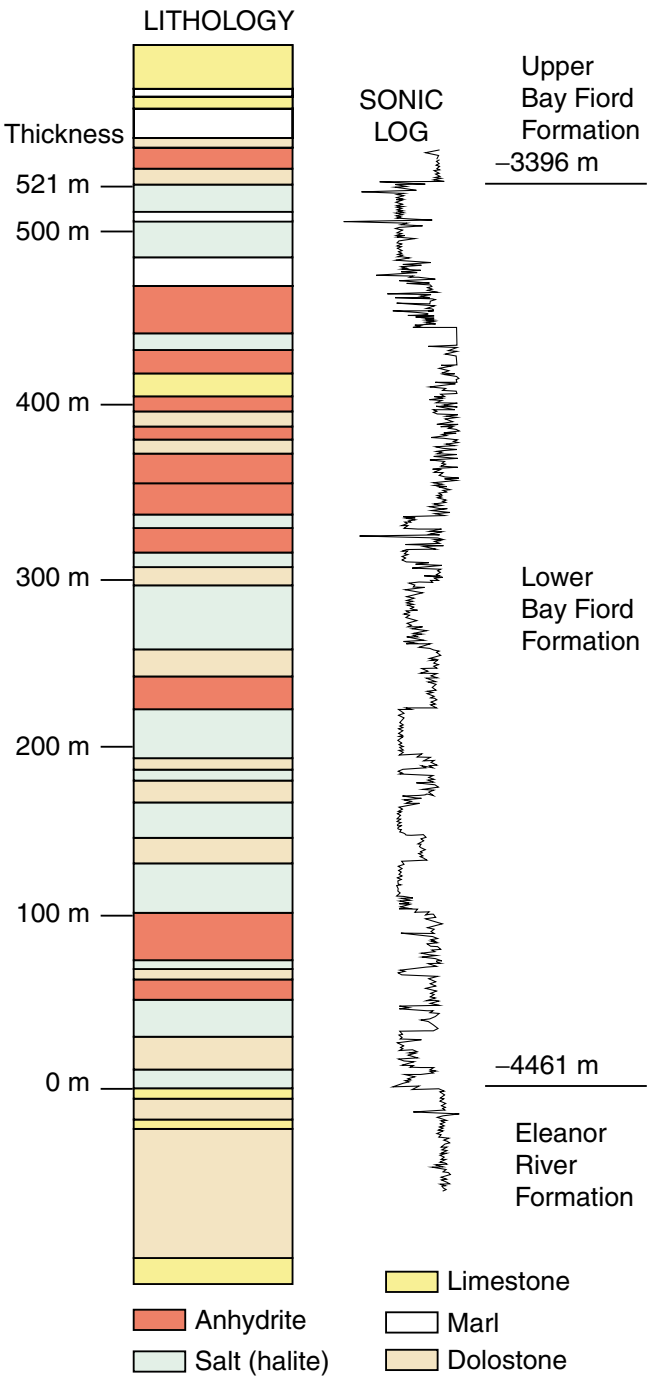

Fig. 15.63 Interpreted lithostratigraphy and sonic log trace showing the anhydrite – halite distribution in the Lower Bay Fiord Formation in Sabina Bay A-07 well on Melville Island (Harrison 1995) (See *inset* in Fig. 15.58 for location)

On Cornwallis Island, carbonate breccias in the Bay Fiord exposures are interpreted as solution-collapse breccias (Thorsteinsson and Kerr 1968) due to removal of halite. More than 1,000 m of halite apparently equivalent to the exposed Bay Fiord sulphate residues on Cornwallis Island occur in the subsurface of eastern Bathurst Island (Fig. 15.63;

Davies 1974; Harrison 1995); the km thickness on eastern Bathurst may be in part an expression of tectonic thickening and associated diapirism that occurred during the formation of the Ellesmerian foldbelt. The Bay Fiord is the key halokinetic stratum caught up in the Ellesmerian orogeny. Diapiric capstones to the Bay Fiord evaporites are exposed anhydrite carapaces on Bathurst Island. The Bay Fiord evaporites played an important role as a detachment zone and the creation of antiformal welts during mid-Palaeozoic Ellesmerian folding and the development of the Parry Island and Cornwallis Foldbelts structural junction (Harrison 1995).

The possibility of salt/thrust weld fluid focusing and a more localised anhydrite source is not considered in any of the current published models. In current Polaris models the Bay Fiord is typically offered as the sulphur source and that is the only evaporite association discussed (Fig. 15.62a). In the context I would like to note that there is anomalous clastic matrix dominant carbonate clast unit called the cobble conglomerate that is only found in the immediate mine area (Fig. 15.62b). "Cobbles" are 1 to 3 cm in size, usually of slightly elliptical shape, packed in a dark muddy terrigenous matrix that looks somewhat like a cobble-supported conglomerate (Randell and Anderson 1997). Earlier workers described this unit as "transported and re-deposited cobble conglomerate" as meteoric cave-fill and argued this jumble of cobble conglomerate clastics as completely incompatible with the environment of deposition of the Thumb Mountain Formation. It was attributed to the choking of meteoric karst by transgressive conglomerates advancing across the early Devonian unconformity.

But as noted by Randall and Anderson (1997) cobble conglomerate has gradational contacts with normal Upper Thumb Mountain Formation; occurs exclusively in Upper Thumb Mountain Formation; carries remnants of galena veinlets and dolomite veinlets exclusively in the cobbles, not in the "matrix"; is extensively riven by stylolites and, most tellingly, commonly exhibits whole fossils in place: many *Receptaculitids*, many *Cateniporids* and *Halysitids*, and the large solitary rugose coral *Bighornia.* Likewise, microfossils recovered from this rock match those of the usual Upper Thumb Mountain Formation. Cobble clasts preserved burrow structures, and the "matrix" an insoluble residue. "Cobble conglomerate" is not evidence for cave-fill, karsting or the exposure of Thumb Mountain cited by Kerr (1977). Randell and Anderson (1997) interpret the cobble conglomerate as a hydrothermal karst fill.

In my mind, I wonder if it and the other non-mineralised breccias could not be the remnants of a halokinetic salt tongue or salt lubricated thrusts with a now mineralized and replaced fault feeder sourced in the Bay Fiord (a remnant of a squeezed weld or diapir). In a key paper on salt-lubricated thrusting in the Parry Island foldbelt, located south of Polaris, Harrison and Bally (1988) noted that… "In the earliest phase of visible shortening (0–1 %), deformation is manifested by the buckling of the competent carbonate and black shale formations (upper Bay Fiord, Thumb Mountain, and Cape Phillips formations and age-equivalent strata). Evaporites in the lower Bay Fiord ductile zone, already weakened and buoyed up by the influence of high pore fluid pressures, simultaneously migrate into the axial region of each anticline. The shortening is redistributed through the upper ductile zone of the Cape de Bray Formation by thinning of shale over the crestal regions of the anticline." They go on to note that there are significant thrust detachment levels in the Thumb Mountain formation, as well as significant tectonic wedging of the upper Bay Fiord and Thumb Mountain formations (p. 318, Harrison and Bally 1988)

The various breccias at Polaris are still enigmatic mesogenetic units in their variably-thrusted platform carbonate host. The geological focus of most of the work at Polaris was on the ore and its paragenesis. A sedimentological study of "pseudo breccia" the "mega-breccia" and the "cobble conglomerate" (Fig. 15.62b) and an understanding of "the salt that was" would likely have improved our understanding of the deposit's diagenetic evolution. Whatever the origin of the various non-mineralised breccias, all workers agree that the sulphur source for Polaris was anhydrite, with BSR as the dominant precipitative mechanism (Reid et al. 2013). Halite/sulphate units of the Bay Fiord did not directly drive the formation of the Polaris MVT deposit. Rather, through their ongoing dissolution and deformation, they drove regional suprasalt structuration and hypersaline brine flows that supplied metalliferous brines and evaporite-derived sulphate to the structurally-focused trap configurations known as the Polaris deposit.

Nanisivik Baffin Island, Canada

The Zn-Pb-Ag ore at Nanisivek, near the north end of Baffin Island, consists of massive sulphides hosted in dolomite of the platform/ramp carbonates of Middle-Upper Proterozoic Society Cliffs Formation (Fig. 15.64a; Clayton and Thorpe 1982). The mine first opened on 15 October 1976 and permanently closed in September 2002. Textural and mineralogical variations divide the Main orebody into three vertical and four horizontal ore zones (Arne et al. 1991). The upper lens of the Main orebody can be further subdivided into six texturally distinct, laterally extensive mine units. Pyrite is the main sulphide mineral in the region, but in places sphalerite and galena are present in ore-grade proportions. Most of the known sulphides are in horizontal lenses about 10 m thick. The Main Ore Zone is 3,000 m long and, on average, about 100 m wide. This body is estimated to contain 11 million tonnes of sulphides, of which 6.5 million tonnes are ore-grade, averaging 12 % Zn, 1.5 % Pb and 50 g Ag/tonne (McNaughton and Smith 1986). There are also sulphides below the main lenses, either in horizontal lenses or in

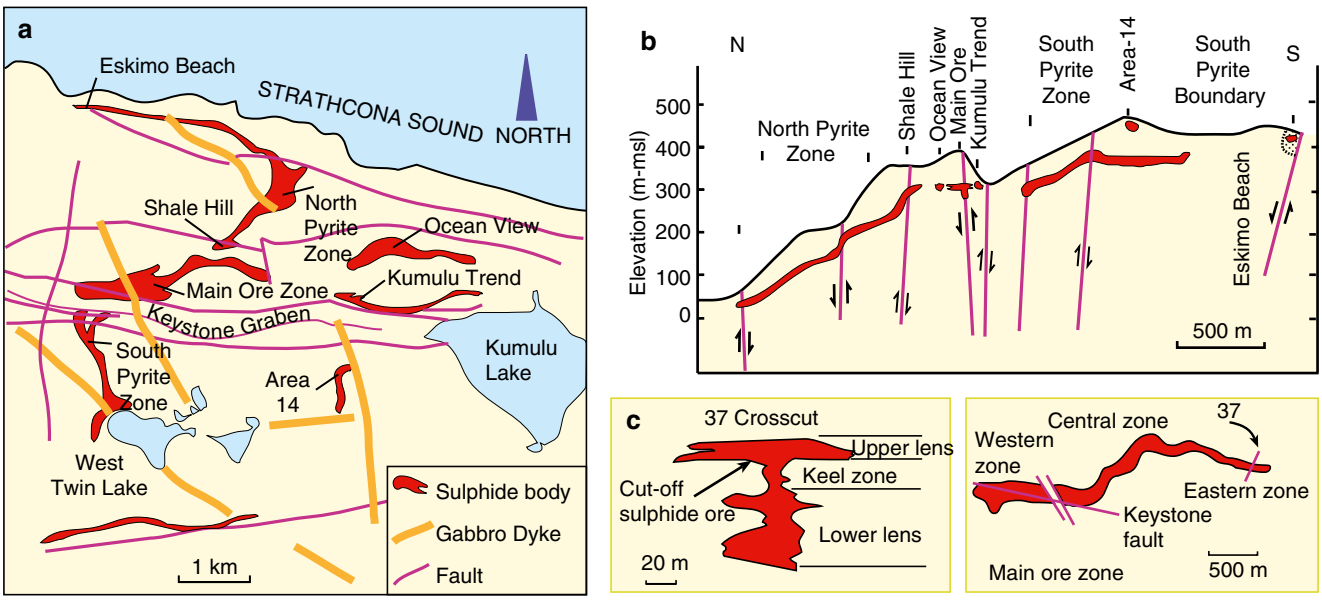

Fig. 15.64 Nanisivik region, Baffin Island. (**a**) Map of the major sulphide bodies and structural features in the Nanisivik Region. (**b**) Schematic N-S cross section howing major faults and sulphide bodies. (**c**) Cross section of Main Ore Zone showing upper and lower lenses connected by keel zone at crosscut 37 and the plan view of upper lens, Main ore zone (After Ghazban et al. 1990; Arne et al. 1991)

near-vertical vein-like structures. The host dolomite has been extensively block-faulted. Sulphide bodies pass laterally through some of these faults and appear to be confined to the upper half of the formation, which is mostly constructed of laminated algal dolomite that has been extensively brecciated and recrystallised. Crosscutting relationships shows the deposits are clearly diagenetic, not syngenetic.

The orebodies are characterised by well-banded ore textures, interpreted by Arne et al. (1991) as progressive replacement of the carbonate wall rock. In contrast, Ghazban (1988) noted the obvious knife-sharp contacts between the massive pyrite and the adjacent host dolostone, and the presence of unaltered relict "fins" of the host dolostone. Ghazban et al. (1992) use this relationship to argue for a more passive fill of hydrothermal karstic caves, with ore precipitating as the matrix was dissolving. There is a third possibility, namely the precipitation of ore in cavities adjacent to or within dissolving sulphate bodies, in a manner akin to that characterising the Cadjebut ores where similar "fins" and other equivalent ore textures are present (Warren and Kempton 1997). A study of the solution breccias in the Nanisivik deposit and listing of the presence or absence of evaporite indicators would help in resolving which of the three possible mechanisms is the most viable.

In this context, it is interesting to note that the sphalerite -galena body is dominantly stratabound and lies within the dolostones of the Society Cliffs Formation, which dips 10–20° to the north (Fig. 15.64b, c). Gypsum outcrops in the Society Cliffs Formation near Arctic Bay (25 km west of Nanisivik) and in the southeastern Borden Basin (Fig. 15.65;

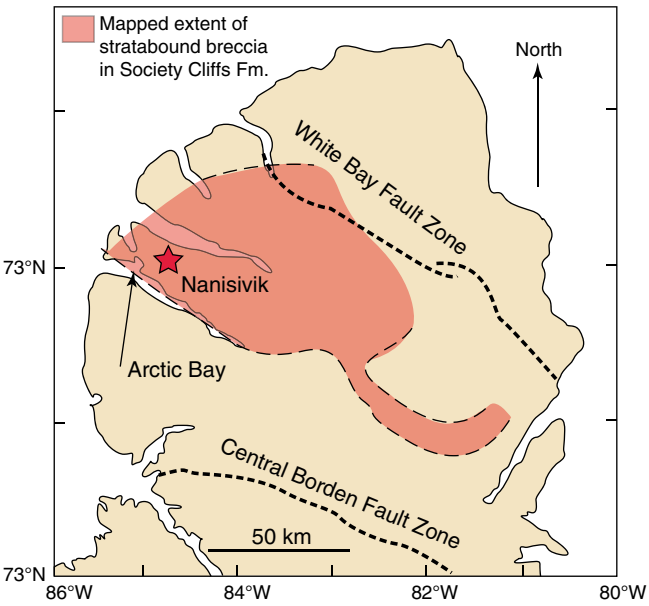

Fig. 15.65 Extent of brecciation mainly within the upper part of the Society Cliff Formation in the western Borden Peninsula (After Jackson et al. 1978)

Ghazban et al. 1990, 1992) Kah et al. (2001) noted that the 1.2 Ga Society Cliffs Formation (Bylot Supergroup, northern Baffin Island) today consists of some 720 m of peritidal carbonates, evaporites, and minor siliciclastic rocks. Evaporites occur predominantly in the lowermost 300 m of the Society Cliffs Formation, where gypsum beds (1–250 cm thick) constitute up to 15 % of the exposed strata. Stratigraphic and

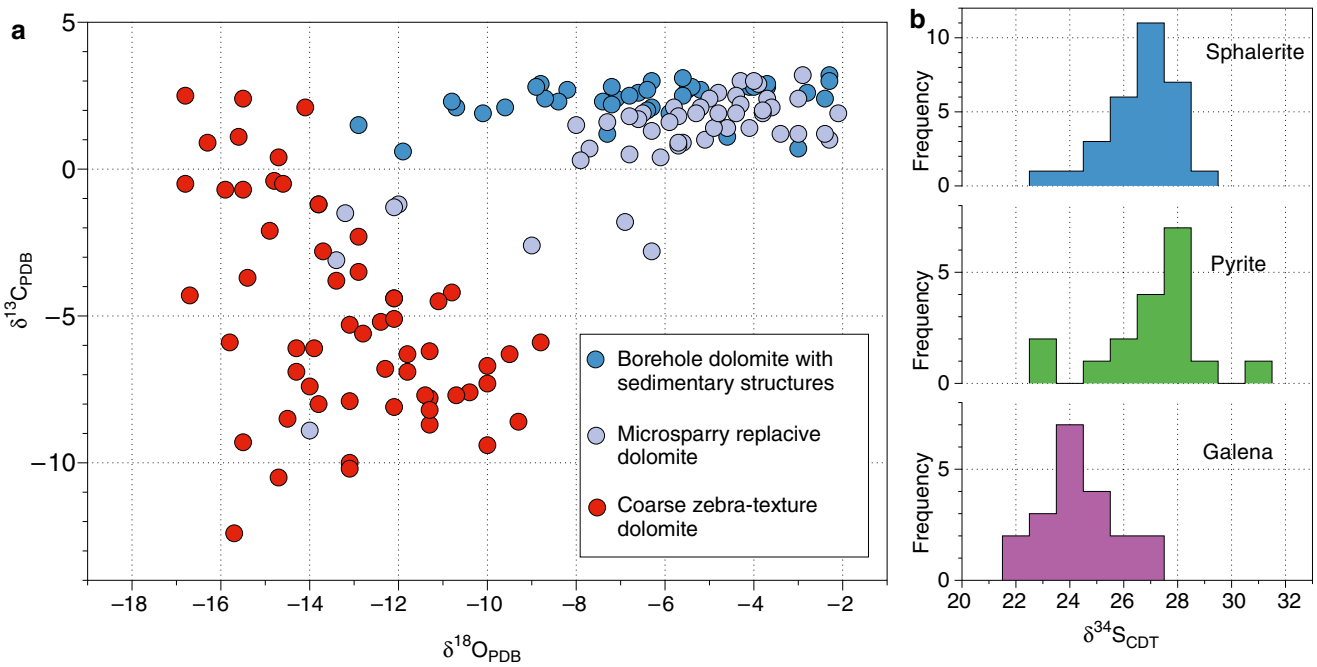

Fig. 15.66 Isotopes in the Nanisivik ore deposit. (**a**) Carbon-oxygen isotope crossplot of the various dolomites associated with the Nanisivik deposit. (**b**) Sulphur isotope values of metal sulphides in the Nanisivik deposit (Replotted from data tables in Ghazban 1988)

sedimentologic constraints, as well as isotopic (C, O, Sr) and elemental (Ca, Sr, Na, K, Ba) compositions of evaporites and associated carbonates, indicate a initial marine origin for Society Cliffs gypsum. However it must have experienced a significant degree of mineralogical alteration during its passage through the mesogenetic and telogenetic environments to where no more than relicts of the original beds outcrop today.

There are also red beds with halite casts and associated with gypsum-bearing mudflat sequences within the lower Society Cliffs Formation on Bylot Island, some 150 km east of Nanisivek (Jackson and Cumming 1981). Outcrops patterns on Bylot Island show high levels of deformation and evaporite-related folding in the Society Cliffs Formation (Jackson and Cumming 1981). The documented extent of such salty features in the Society Cliffs formation for may kilometres east and west of Nanisivik suggests that at least portions of the Society Cliff succession once contained a much greater volume of halite and that the unit, at least in some regions was halokinetic.

Closer to the Nanisivik deposit, a thin bed of relict gypsum (5–10 cm thick) was encountered at the same stratigraphic level as the ore zone in two boreholes immediately west of the main ore zone. In addition, gypsum (satin spar) commonly fills fractures in the dolostones surrounding the ore zones in the mine area. Much of the Society Cliffs Formation outcrop is extensively brecciated, particularly in the western Borden Peninsula, with interfragment spaces filled with sparry dolomite and less frequently with sulphide minerals (Fig. 15.65). The breccia zones are stratabound appear to be stratigraphically controlled, they bear no close or obvious relationships to faults and folds within the formation (Olson 1984). The association of secondary $CaSO_4$ and stratiform brecciation implies the karstic brecciation is associated with, and perhaps controlled by, evaporite solution collapse (Jackson et al. 1978).

Three distinct stages of dolomitisation can be distinguished by their petrographic, cathodoluminescence, and isotopic characteristics (Fig. 15.66): (1) Massive fine-medium crystalline dolomitisation of precursor carbonates preserving sedimentary features, and (2) Microsparry replacive dolomite, (3) Coarse latestage dolomite cementation forming "zebra" dolomites (Fig. 15.66a; Ghazban et al. 1992). The massive dolomites in the sulphate-bearing facies of the lower member of the Society Cliffs Formation and laminated algal stromatolitic to massive dolostones of the upper member are isotopically similar. Covariant C-O isotope signatures imply later dolomite cements was precipitated from warmer pore fluids, along with ongoing replacement and isotopic re-equilibration of some of the earlier dolomite precipitates. Such rock-fluid interactions with increasing fluid temperatures typify mesogenetic textures in fold and thrust belts worldwide (Warren et al. 2014). Dolomitising fluids responsible for later fracture and vug filling zebra dolomite cements may have been released by compaction of the underlying Arctic Bay Shale, which also appear to have been the source of the base metals (Ghazban et al. 1992).

Heavy $\delta^{34}S$ values of sulphides, ranging from 21.5 to 31.2‰, suggest complete reduction of marine evaporitic sulphate, with no isotopic difference between sulphate and sulphides. Isotopic temperatures from intersulphide fractionations range from 90 to 270 °C. Plots of fractionation versus $\delta^{34}S$ show that the sulphur source was heavy throughout sulphide precipitation, and was also consistent with total *in situ* thermochemical sulphate reduction (Fig. 15.66b; Ghazban et al. 1990). The likely reductant was organic matter, traces of which remain as pyrobitumen, although methane and volatile hydrocarbons may also have been involved. Striking evidence for the role of organic derivatives is found in $\delta^{13}C$ values of the white sparry ore dolomite, which varies between +6 and −12‰ (Fig. 15.66a; Ghazban et al. 1992).

Whatever the fine-scale paragenetic detail, overall ore formation at Nanisivik reflects processes involving *in situ* reduction of calcium sulphate in the presence of hydrocarbons and derived H_2S at the site of ore deposition. The location and configuration of the orebodies was probably controlled by the former position of near horizontal fluid redox interfaces. The question to be resolved by future matrix characterisation is: was that interface there because of a now-dissolved evaporite seals?

San Vicente, Peru

The San Vicente Zn-Pb deposit is the largest of a number of similar Pb-Zn-Ag accumulations hosted in the Upper Triassic Lower Jurassic Pucará Group in central Peru (Fig. 15.67) and situated 300 km east of Lima, in central Peru. It is part of an outcrop belt that defines the eastern part of the NNW-trending Pucará Basin at the margin of the Brazilian Shield. In the San Vicente district, evaporitic platform carbonates of the Pucará Group constitute a thrust prism that overlies magmatic and continental siliciclastic rocks of the Upper Permian – Lower Triassic Mitu Group. Phyllites of the Lower to Middle Palaeozoic Excelsior Group occur regionbelow the Mitu Group (Fig. 15.68; Badoux et al. 2001). During Late Permian – Early Triassic time, various intrusions were emplaced, such as the San Ramon granite and the Tarma granodiorite. In the San Vicente area, the Tarma granodiorite and Precambrian metamorphic basement rocks have been thrust over the Pucará carbonate rocks from west

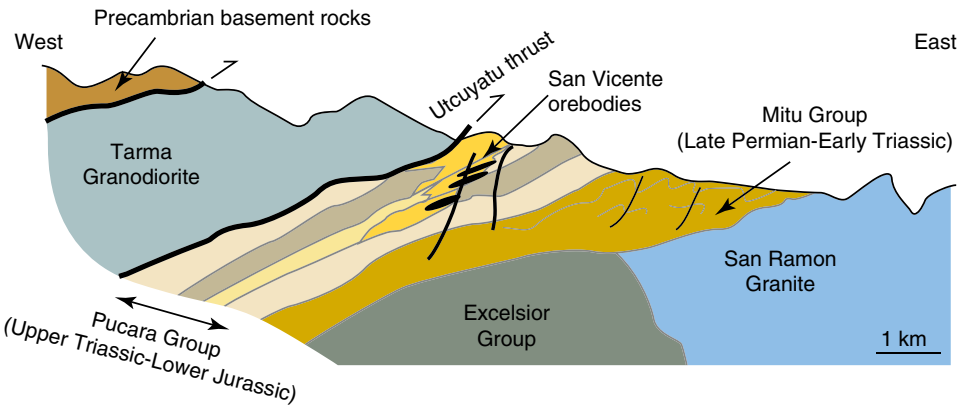

Fig. 15.68 Schematic cross-section of the San Vicente district, Bolivia. The Pucará Group has been overthrust by the Tarma Granodiorite along the Utcuyatu fault. The Pucará Group is a variably dolomitic and evaporitic sequence undergoing shearing along a westerly plane dipping ~25–30° (After Badoux et al. 2001)

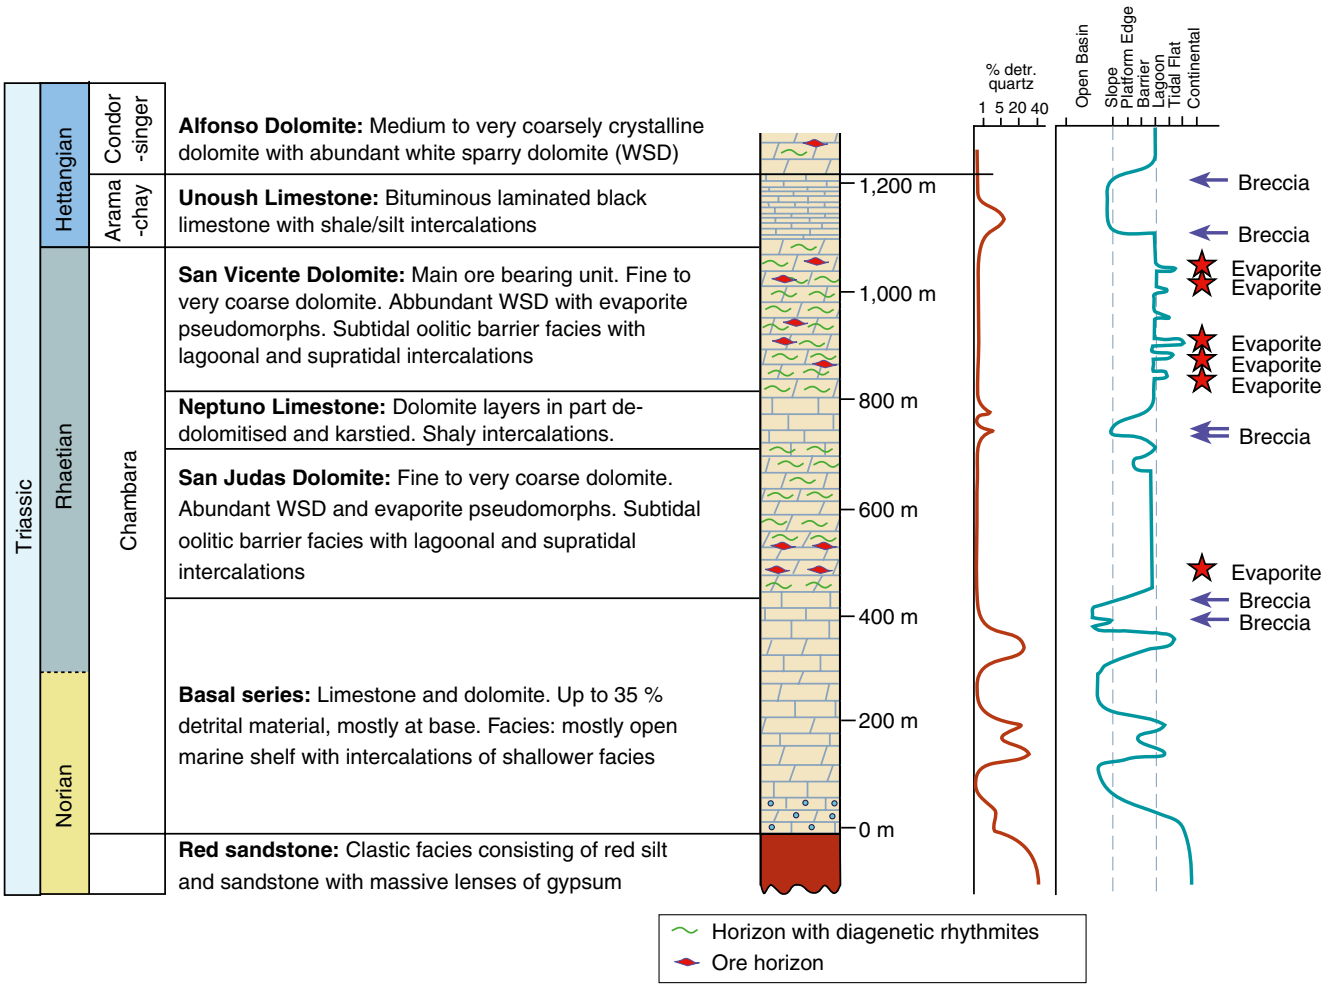

Fig. 15.69 Stratigraphy of part of the Pucará Group in the San Vicente Mine area (In part after Fontboté and Gorzawski 1990)

to east along the Utcuyacu thrust. Minor thrust zones also occur in the Pucará Group. The thrusts are located along a major Andean thrust zone, which is probably Miocene in age (Badoux et al. 2001).

The first written records of mining activity in the San Vicente region are from 1820, when the area was named the Guernica Mine. Various operations continued, at times sporadically, since then and operations continue today. Production during the past 20 years, plus present reserves, exceeds 12 million tonnes of ore assaying about 12 % Zn and 1%Pb. Sphalerite and galena, the only ore minerals, occur as lens-shaped bodies generally parallel to the bedding. There are three ore-bearing dolomites that lie within the 1,400 m thick Pucará sequence (Figs. 15.68 and 15.69). The San Vicente dolomite is the main ore-bearing unit and hosts the exploited part of the San Vicente mine. Other ore occurrences are located in the San Judas Dolomite and the Alfonso Dolomite. Individual ore lenses are hosted in dolomitised tidal flat and lagoon facies characterised by cryptalgal laminae and evaporite moulds after former sulphate evaporites (including gypsum).

Sphalerite and galena are the main ore minerals, with accessory pyrite and traces of marcasite, chalcopyrite and sulphosalts. The gangue consists predominantly of dolomite with accessory calcite. Different generations of hydrothermal carbonates can be distinguished: (1) early, dark replacement dolomite; (2) open-space filling, white sparry dolomite; (3) late stage void-filling dolomite and calcite; and (4) dolomite and calcite replacing sulphates in evaporitic units. Most of the sphalerite occurs in the same paragenetic position as the hydrothermal dolomite. Fine-grained, dark brown sphalerite accompanies early, dark replacement dolomite, and coarse-grained brown to yellow sphalerite is associated with white sparry dolomite. Galena precipitated mainly with late stage void-filling dolomite (Fontboté and Gorzawski 1990).

Three major types of gangue structures can be at the San Vicente mine (Fig. 15.69): (1) rhythmic, inter-layering of dark replacement and white sparry dolomite, defining typical zebra structures; (2) breccia with clasts of dark replacement dolomite in a matrix of white sparry dolomite; and (3) veins

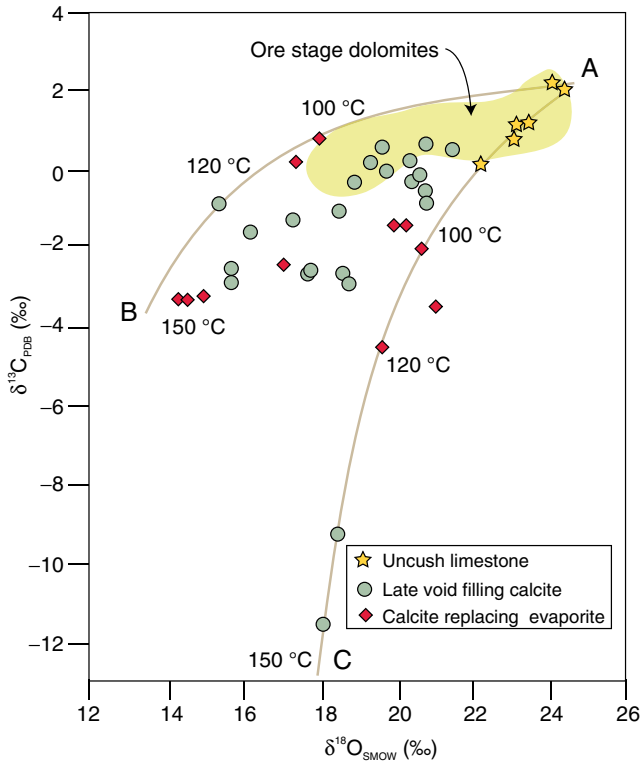

Fig. 15.70 $\delta^{13}C$ vs. $\delta^{18}O$ for various calcites from the San Vicente mine. Also plotted are theoretical temperature curves for calcites indicated by mixing of fluids (A, B, C). *Shaded field* indicates plot field occupied by ore-stage dolomites (Based on analyses listed and interpretation by Fontboté and Gorzawski 1990)

filled with white sparry dolomite. These structures are recognised in both economic and barren areas of the mine. In ore-bearing areas, brown to yellow sphalerite generally occurs between dark dolomite and white, sparry dolomite, whether it is zebra, breccia or vein-type ore (Fontboté and Gorzawski 1990). Ore lenses tend to occur as stratabound units adjacent to oolitic grainstones of former barrier-shoal facies. All three ore-hosting dolomite units were deposited in a peritidal carbonate platform that comprised: (1) the inner margin of the lagoon (tidal flat), (2) the lagoon sensu stricto and (3) the outer margin of the lagoon (barrier subenvironment).

Strontium, carbon, oxygen, and sulphur isotope geochemistry was carried out on consecutive crystallisation generations in the San Vicente region (Spangenberg et al. 1996; Moritz et al. 1996). The results obtained display systematic trends that all show San Vicente lead-zinc deposit formed during burial diagenesis via the mixing of incoming hot saline, slightly acidic, radiogenic (Pb, Sr) basinal fluids and local sulphate-rich formation waters derived from calcium sulphate beds. The temperatures indicated by sulphur isotope geothermometry and carbon and oxygen ore stage dolomites are consistent with temperatures of 75–92 °C (Fig. 15.70).

According to Fontboté and Gorzawski (1990), such burial temperatures would have been attained when sediments reached at a burial depth of ≈2–3 km and indicative of burial depths reached by the end of the Jurassic. However, the timing of the ore emplacement is controversial. Fontboté and Gorzawski (1990) suggested that brine circulation was related to uplift of the Marañon geoanticline at the end of the Jurassic, and Moritz et al. (1996) proposed that the San Vicente deposit was contemporaneous with the Incaic phase of the Andean orogeny at ~40 Ma. Underground mine extensions in recent years have revealed abundant ore-bearing structures suggestive of a syntectonic origin for the San Vicente deposit (Badoux et al. 2001). Thus, the deposit might be as young as the host thrust zone, which is probably Miocene in age.

Whatever the emplacement age, ores were emplaced by the thermochemical reduction of evaporite-derived sulphates at or near the ore site and the introduction of a zinc- and lead-bearing basinal brine (Fontboté and Gorzawski 1990). After the low temperature sulphide ore emplacement stage, the replacement of the evaporites continued with the precipitation of calcite replacing evaporites with isotope characteristics indicating fluid temperatures in excess of 150 °C (Fig. 15.70).

Interestingly, San Vicente ore zones are associated not just with sulphate evaporites, but with well developed stratabound breccia layers. Historically, these breccias were interpreted as depositional slope deposits by Fontboté and Gorzawski (1990). Their interpretation was done 25 years ago, before there was a widespread understanding of evaporite solution breccia textures. More broadly, the Pucará group was deposited in an extensive system of Traissic rift-to-drift grabens that constitute the Oriente-Ucayali-Ene Basin. In northeast Peru the Pucará Group depositional system contains thick halites at the level of the Mitu Group. This same salt level is now the mother salt horizon for a number of diapiric structures, such as the Huallaga diapirs, which have seen seismically imaged and drilled by the petroleum industry (Alemán an Marksteiner 1995, 1997). The same salt is also caught up in thrusts and other Andean deformation features. If the same halite level once extended as far south as the San Vicente area is not known, but the evaporitic conditions certainly did, as evidenced by the gypsum beds in the Alfonso dolomite, the San Vicente dolomite and the San Judas Dolomite.

Largentière, Ardèche, France

The Largentière Pb–Zn deposit is located at the boundary between the sedimentary cover and the Massif Central block and belongs to the Cévennes Pb–Zn MVT province (Fig. 15.71a; Aquilina et al. 2011; Leach et al. 2006; much of the following is based on these references). Since it is not in limestone, the sandstone-hosted Largentière deposit lies

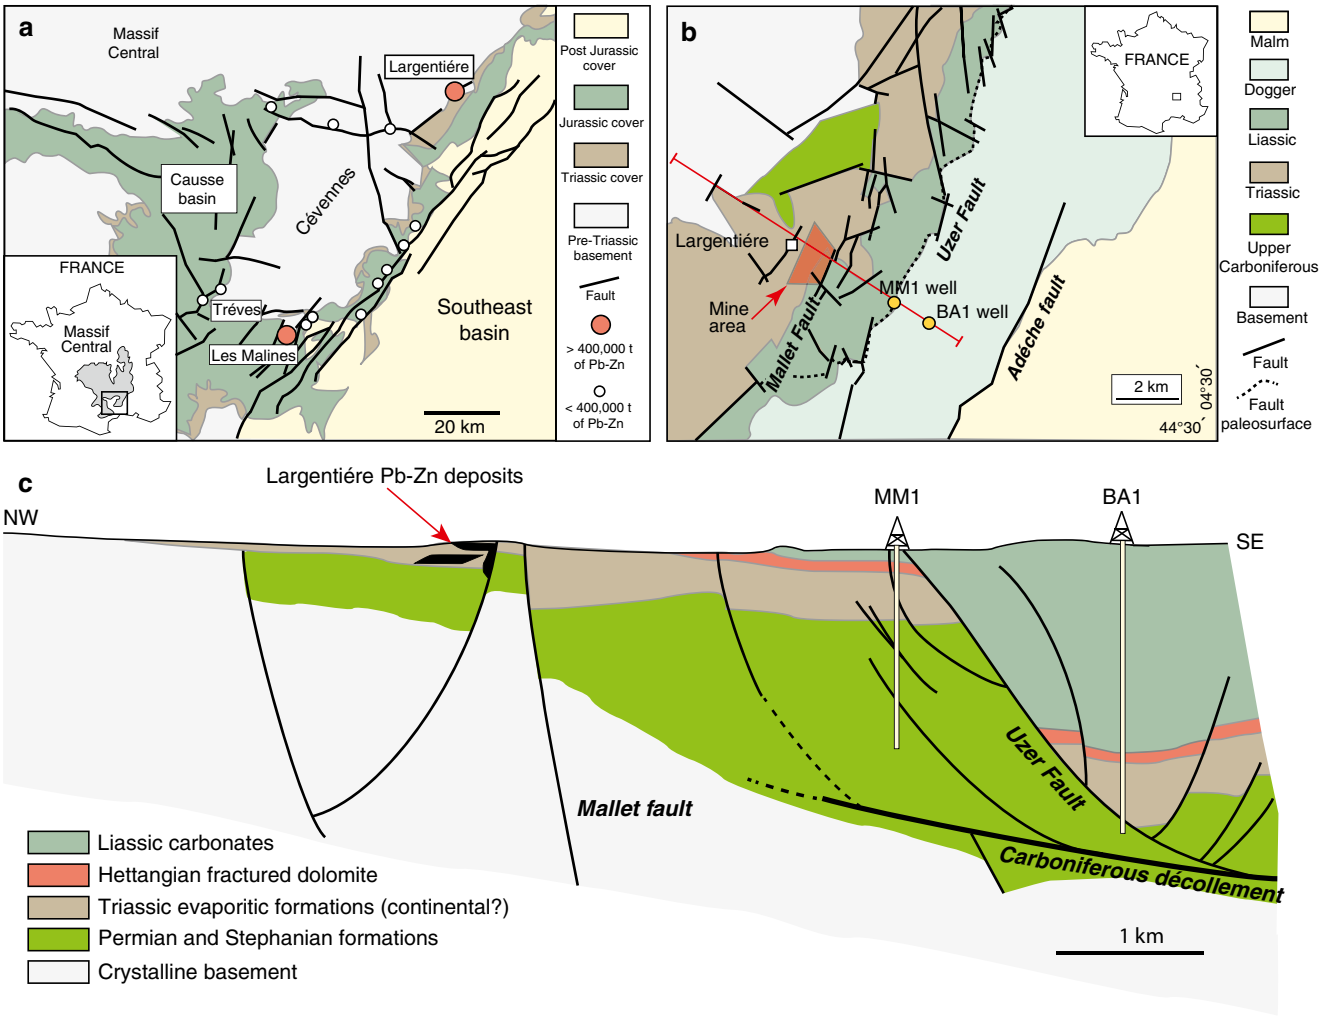

Fig. 15.71 Largentiére Pb-Zn, SW France. (**a**) Regional geological map showing Pb-Zn occurrences in the Cevenne District. (**b**) Local geology of the Largentiére region. (**c**) Cross section of the Largentiére region, position of section indicated on Fig. 15.71b (After Aquilina et al. 2011)

outside the typical carbonate platform host assumed for MVT Zn-Pb mineralisation deposit (Sverjensky 1986). Largentière is considered to be part of a broader sandstone-hosted Pb-Zn association, mostly related to saline basinal-brine metal carriers (Schrijver 1992). In addition, there are many Zn-Pb deposits along the same Cévennes margin, hosted in platform carbonates. Hence, the area is also considered an MVT district, made up of numerous small deposits, including those with sandstone ore hosts.

Independent of host lithology there is clearly a common genetic origin to the Pb-Zn deposits of the Cévennes district that ties them to a combination of chloride-rich fluids, structure and calcium sulphate. The Cévennes district is structurally related to the Mesozoic Southeast Basin to the east as well as the Triassic and Jurassic cover of the Causse basin to the west (Fig. 15.71a). The fact that the host is a sandstone is why I will describe these deposits in a fair degree of detail. I use Largentière to illustrate that Pb-Zn precipitation association is a fluid-driven set of processes tied to a chemistry and hydrology driven by dissolving evaporites; it is an precipitative interaction between evaporitic sulphate, chloride brines and hydrocarbons/ organic matter. "MVT" style precipitation can be independent of the ore matrix, although sulphate evaporites are more typically found in platform carbonates. In Largentiére, sulphates reside in redbed sandstones, not salterns or carbonate hosted evaporitic mudflats. Locally, the precipitation process (in this case TSR) can be independent of the matrix lithology (sandstone or carbonate). The commonality between the two matrices (carbonate versus siliciclastic) is in the presence of calcium sulphate on the reducing (greenbed) side of the redbed/greenbed diagenetic front.

Ores in the Cévennes MVT district occur in various geological contexts: Cambrian and Jurassic carbonates, fault-related or massive deposits, vug fillings in carbonates, etc. as well as in various types of mineralogical sequences (Aquilina et al. 2011). Most of the economic precipitates are

hosted in platform carbonate rocks and consist of sphalerite, galena, pyrite and baryte (and fluorite). On a larger scale, they can be related to the MVT deposits of Mesozoic sedimentary basins in western Europe associated with the break-up of Pangea (Heijlen et al. 2001; Muchez et al. 2005). There are numerous mining sites along the Cévennes chain (Fig. 15.71a). The deposits of Les Malines include massive sulphide bodies in Bathonian karst cavities (40 % of the total tonnage) and ore bodies within Triassic karstic infills of cavities developed in Cambrian dolomites (35 % of the total tonnage).

The Cévennes is one of the most important Pb–Zn districts in Europe, with a total metal content of 2 Mt of Pb and Zn (Aquilina et al. 2011). Largentière, the northernmost deposit, was estimated as hosting 350,000 t of Pb and 70,000 t of Zn (9.6 Mt of ore mined) and 710 t of Ag. The most recent mine at Largentiére operated as France's largest Pb mine from 1953 to 1984, but silver was mined in the region as early as the 14th and 15th centuries. The mine site at Largentiére is on the western edge of the Cévennes is Trèves, with an estimated 80,000 t of Zn and 20,000 t of Pb (3,600 t Zn and 817 t Pb produced, respectively) (Fig. 15.71b).

Largentière Pb-Zn mineralization covers an area some 1.5–3 km across, where precipitates include galena, sphalerite, pyrite and baryte (Fig. 15.71b). Mineralisation occurs mostly within Lower Triassic sandstones and arkoses (30–50 m thick), less frequently in about 20 m of overlying Middle Triassic dolomite, and rarely in Upper Triassic argillaceous sandstones (Bouladon 1984). Ore at Largentière occurs either as fracture fillings, as disseminated sulphides, or as fracture controlled massive sulphide ore. Whilst pyrite appears in the mineralized area associated with quartz, anhydrite is observed in the western part of the district. At the scale of the Southeast basin, the ore deposits always appear at the contact between the sandstone and the sedimentary anhydrite facies (Fig. 15.71b, c; Debrand-Passard 1984).

For example, Bed 5 ore at Largentiére formed as a cement within coarse-grained sandstones at the base of the Triassic section and is located less than 15 m above the Permian contact. There is not always a single mineralised horizon, but stratiform character is the rule at Largentiére. Local ore enrichments are related to shear zones, the general connection between mineralisation and faults in bed 5 ore is not always clear, but the tie to the redbed-green bed ($CaSO_4$) contact is. About 10 m above bed 5, the redbed sandstones change to dolomite-cemented greenbeds and green argillaceous, gypsum-bearing lagoonal siltstones appear (the reduced facies). The Pb-Zn mineralisation in beds 1, 2 and 3 (termed the "upper mineralised horizon") is consistently tied to the presence of gypsum within the mineralised intervals (Bouladon 1984). In this upper interval, mineralisation is associated with faults, and "fissure ore" dominates in dolomitic sandstones and marls. Gypsum has been reprecipitated in the Volpilliare region, along with galena in fibrous veins (satin-spar) crosscutting the marls. The possible significance of satinspar texture as a likely indicator of former more widespread halite is not considered in the existing literature.

The coincidence between sedimentary facies, faulting and the location of mineralization implies a lithologic/structural control to the ore deposit. Regionally Pb-Zn mineralization appears along the Hercynian faults of the Mallet horst but is also controlled by synsedimentary faults in some Triassic beds (Fig. 15.71c). Mixing of hot basinal chloride brines (high metal content) derived in part from dissolving downdip Permian evaporite masses and cooler meteoric fluids leaching of Triassic sulphates (high sulphur content) is proposed for the Trèves deposit located close to Largentière (Fig. 15.71a; Leach et al. 2006).

The key to the interpretation of the mineralisation paragenesis at Largentiére comes from placing the isotopic and petrographic signatures of this and other nearby Pb-Zn deposits in into a more regional diagenetic and structural context, as was done by Aquilina et al. 2011 (Fig. 15.72). Their synthesis shows that a major fluid circulation event occurred across the Alpine margin of Tethys during the Early Jurassic (Hettangian–Bathonian). It produced a general cementation of the rock porosity, through precipitation of dolomite, burial anhydrite and baryte. Fracture fillings yield isotopic signatures distinct from the matrix cements (Fig. 15.72; sedimentary sulphate versus fluid-related sulphate plot field). Matrix cements have particular characteristics, i.e. $\delta^{34}S$ and $\delta^{13}C$ values that indicate a marine-brine hypersaline source. The $\delta^{34}S$ values of Permo-Carboniferous to Triassic sulphides from fracture cements likely indicate thermo-chemical reduction of sulphates. Fracture sulphates in the same geological formations yield $\delta^{34}S$ values that define a relatively homogeneous end-member, with compositions similar to fluid-related calcium sulphates in the Largentière Pb–Zn ore deposit. The source of S and the metalliferous chloride-rich brines is attributed to dissolving evaporite masses in the Permo-Carboniferous succession. The extensional geometries so obvious in Fig. 15.71c show structural similarities it the updip salt-withdrawal basin-edge grabens in the Gulf of Mexico, onshore Texas.

The borehole fracture fillings are attributed to a major fluid circulation stage compatible with the Early Jurassic stage. The formation of the Largentière deposit is considered as resulting from the mixing of Early Jurassic fluids with hydrothermal fluids circulating in a basement horst, along the basement high that constitutes the up-dip margin of the sedimentary basin (Fig. 15.71c). Other nearby Pb–Zn deposits are also related to fluid migration along the basement/sedimentary cover interface in the eastern and western parts of the Massif Central. According to Aquilina et al. (2011), this regional fluid circulation event is a likely geodynamic marker of the Jurassic extensional phase.

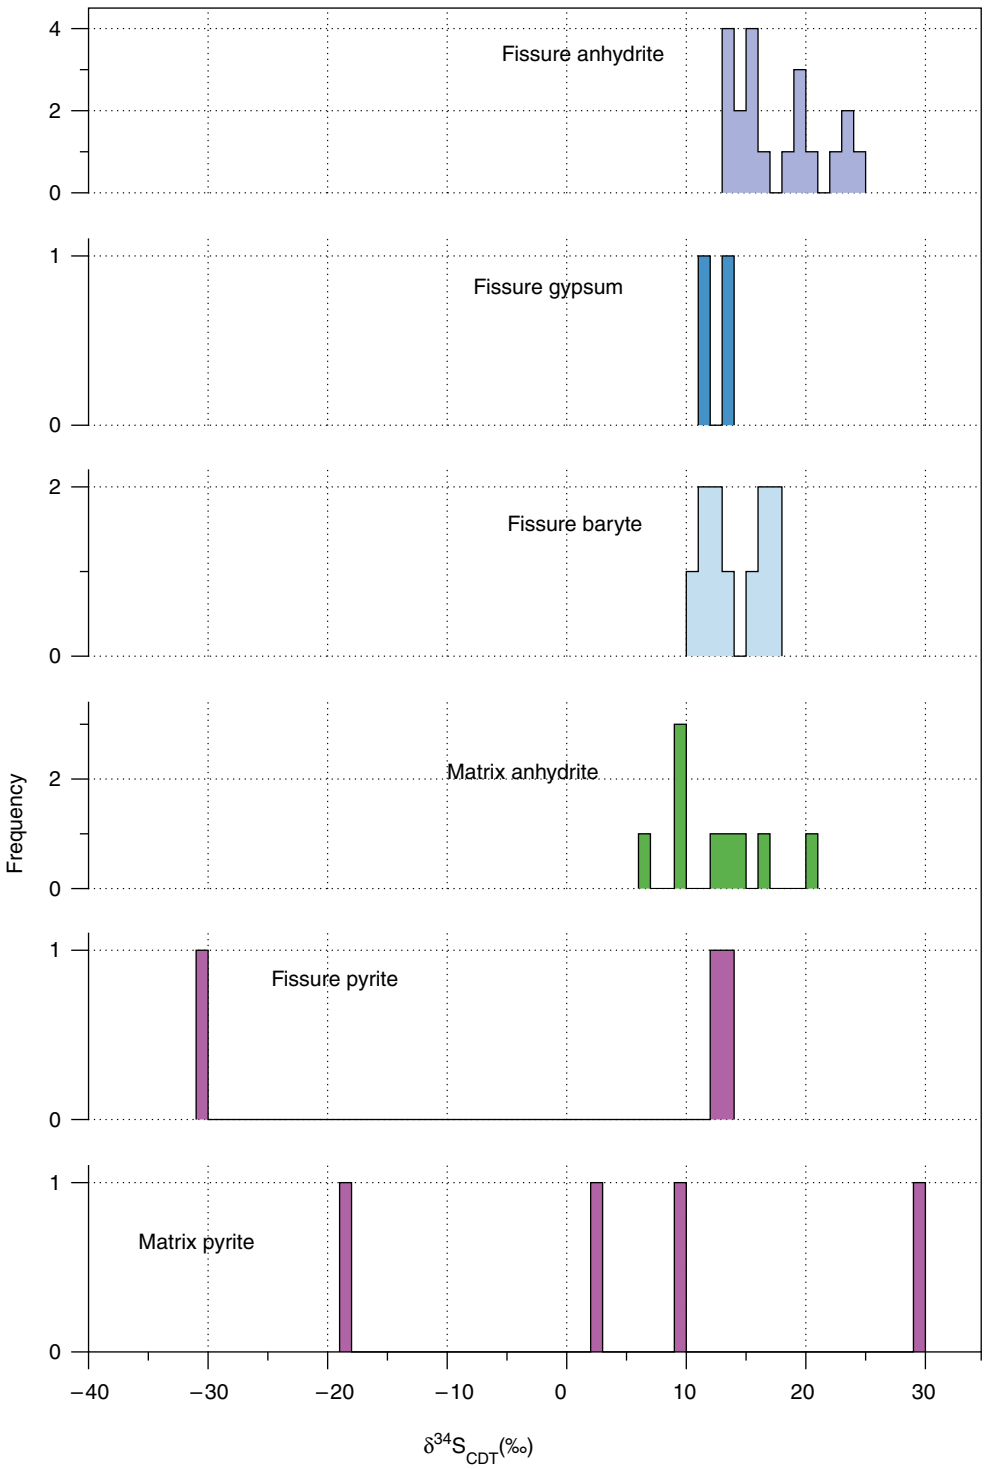

Fig. 15.72 Sulphur isotope frequency histograms from samples collected in the MM1 and BA boreholes. Largentiére region (Replotted for data tables in Aquilina et al. 2011)

In the Palaeozoic formations in the Largentiére region, sulphur from sulphates and sulphides shows a relatively narrow range of isotopic variation (−10‰ to +5‰, except for two pyrite values), similar to the Largentière Pb–Zn deposits (−10‰ to +6‰). Such values are different from the marine sedimentary signature (Fig. 15.72). They likely indicate the thermal sulphate reduction of calcium sulphates to sulphur or biological reduction of sulphate followed in both cases by precipitation of pyrite and other metal sulphide via interaction with H_2S. Both the TSR and BSR mechanisms lead to stable isotope fractionation plot fields of pyrite sulphur that can overlap (−20‰ to −10‰ at 200–100 °C and −15‰ to −30‰ at ambient temperature). Biological reduction is unlikely at Largentiére because (1) Excessively high

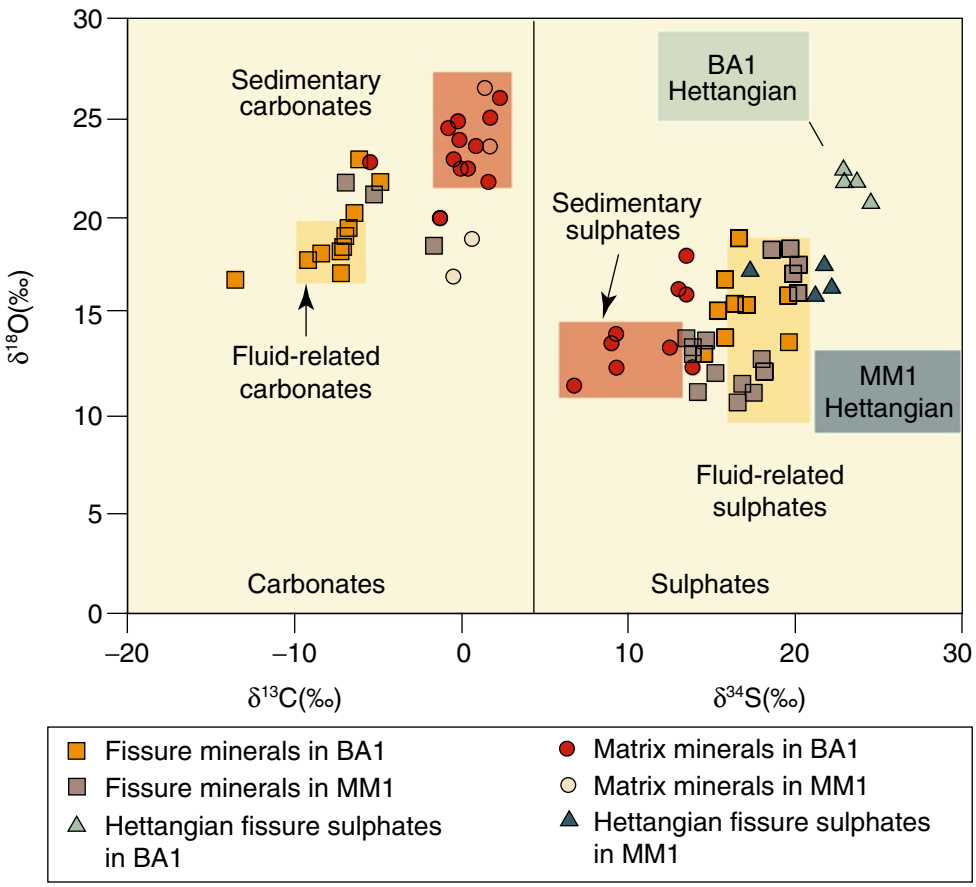

Fig. 15.73 Carbonate and Sulphate stable isotope plot fields indicating the diagenetic nature of the calcium sulphate in the BA 1 and MM wells in the Largentiére region. See Fig. 15.71b for location (After Aquilina et al. 2011)

temperatures are indicated in fissure cements in the Palaeozoic (about 100–200 °C), (2) $\delta^{34}S$ are higher (more positive) than the values found in matrix sulphides related to biological sulphate reduction and (3) lower fractionation differences at the relatively high temperatures produced by thermo-reduction, compared with biological reduction, fits better with the data (e.g., note the strong overlap between fluid-related sulphates and the sulphide pyrite values in Fig. 15.72).

The $\delta^{34}S$ values in the fissure sulphates from Palaeozoic and Triassic formations vary from +13‰ to +22‰ (Fig. 15.72). This is interpreted by Aquiliana et al. (2011) as the result of mixing between the sedimentary sulphate pool of the Triassic middle sulphate unit and sulphate with a higher $\delta^{34}S$ signature. The Triassic sulphate signature is particularly marked at the base of the middle calcium sulphate unit in the well MM1 and immediately below the equivalent unit in the BA1 well. The high $\delta^{34}S$ population observed in the calcium sulphates of the Triassic, and even more clearly in the Palaeozoic formations, is in the range +17‰ to +20‰. This range is similar to that observed in the Largentière Pb–Zn deposits (+17‰ to +22‰). This very narrow range of $\delta^{34}S$ for the sulphate deposits across the region in a sedimentary pile about 800 m thick, as seen in the two boreholes, requires a large-sized and homogeneous sulphate pool.

Three potential sulphur sources are considered by Aquilina et al. (2011): (1) Triassic evaporitic units: but, as already mentioned, the S isotope signature of the sedimentary anhydrites is too low to be a diagenetically unmodified calcium sulphate source. (2) Hypersaline brine migration from the eastern part of the basin: fluid migration related to Triassic diapirs has been identified from fluid inclusion studies in the deeper eastern part of the southeast basin, but similar fluid inclusions (NaCl type) were not identified in cements in the BA1 and MM1 boreholes. Furthermore, the isotopic signature of the calcium sulphates of these fluids should be similar to those of the Triassic evaporites in BA1 and MM1, since the evaporitic formations in the Southeast basin are contemporaneous. (3) Palaeozoic calcium sulphates: Permian and Carboniferous evaporitic formations attain a great thickness over the whole margin (about 1,000 m), representing a large source of S with a marine isotopic signature. Burial of these Permian formations to a depth close to 1,000 m at the end of the Triassic, and reaching 2,500–4,000 m during the Jurassic, along with ongoing dissolution of the Permian halites created early conditions for fluid expulsion.

The link of the Uzer fault with intra-Carboniferous décollement led to Permo-Carboniferous derived fluid moving up along the Uzer and other related extensional faults (Fig. 15.71c). As observed for the sulphate $\delta^{34}S$ values in the anhydrite cements, the $\delta^{13}C$ of the fissure carbonates is relatively homogeneous across the Palaeozoic and Triassic, with a narrow range of −5‰ to −10‰ (Fig. 15.73). Such values

do not represent marine sedimentary carbonates and cannot be attributed to simple C-isotope fractionation between calcite and CO_2 or HCO_3. This is because, at 100 °C, calcite is enriched in ^{13}C by about 1.5‰ compared with these fluid species. These low carbon isotope signatures imply the contribution of low-$\delta^{13}C$ organic carbon, a common feature that has already been observed under similar burial conditions in other Pb-Zn deposits (Aquilina et al. 2011). Indeed, organic matter is present in this context, as well as CO_2 accumulations with negative $\delta^{13}C$ (−2.7‰ to −3.2‰). Furthermore, this carbon signature represents a relatively homogeneous 'crustal' carbon, even though it originates from both a marine and an organic source. As such, it provides another indication of fluid transfer at the margin scale, including density and thermal-driven convective circulation within the margin basement (See Chap. 8).

The fissure sulphates in the Hettangian interval can have high $\delta^{34}S$ and high Sr isotope ratios in both the boreholes, which could indicate a different fluid circulation stage and/or slightly different source or conditions of evolution for higher value cements. However, as observed in Fig. 15.73, this mainly applies to cements the Hettangian in BA1, but is less clear for MM1, which yields $\delta^{34}S$ overlapping values than the Triassic fluid carried sulphates. Although affected by the same generalized fluid circulation event at a geological scale, the Hettangian hosted cements in well BA1 may represent a different regime with higher temperatures lower fluid/rock ratios and slightly different fluids. Such a difference between the two geological formations may be linked to the Uzer fault. The very high initial porosity of the Triassic upper sandstone unit (and, to a lesser extent, the lower sandstone unit) may have channelled the fluid circulation, whilst more limited fluid flow could have occurred in the Hettangian.

Largentiére and all the other Pb-Zn deposits discussed in this section illustrate what happens when metalliferous chloride-rich saline fluid climbs into basin margin sediments, where they precipitate Pb-Zn sulphides at a chemical interface, which is typically a redox front tied to either bacterial or thermogenic sulphate reduction. The sulphur that ends up in the metal sulphide is typically evaporite-derived; it may be locally sourced in saltern beds or nodule sulphate in evaporitic mudflats, it may be a burial anhydrite cement in a sandstone, or it may be a residual carapace or caprock to a salt structure. Alternatively sulphur may be carried to the final site of precipitation (trap) in solution as sulphate or as H_2S, depending on the chemical state of the carrier fluid. Much of the time the carrier bed geometries are tied to combinations of dissolving salt masses, permeable beds and fault foci. Much of the faulting, either suprasalt or updip is related to structural accommodation driven by flowing and dissolving downdip salt masses. Such fault and salt mass focused fluid flow and mixing can occur in either extensional or compressional tectonic settings.

We shall come back to this notion of regional salt-related controls to low temperature diagenetic ore deposits in a variety of tectonic settings, after we consider what happens to saline fluids from the haloes of halokinetic salt masses that pass vertically to seafloor rather than migrating to the basin margin. We touched on this type of ore deposit in the discussion of the Atlantis II Deep sulphides and brine pools at the edge of dissolving salt allochthons in a salt-covered rift-induced basinal brine sump, and so we come to a discussion of evaporite-associated SedEx deposits

Evaporite-Associated SedEx Deposits

Associated with a hydrothermal vent-related origin for various sediment-hosted exhalative (SedEx) deposits, most authors currently accept there are two laminite endmember models, namely, SedEx deposits that are; (1) Vent-proximal laminites formed by rain-out of a metalliferous plume spreading in the water column, considered by some to tied to VMS black-smoker or Cyprus-style vent deposits (see Chap. 16) versus, (2) Vent-distal laminites formed in a bottom-hugging saline pond in a sea-bottom brine sump or lake, much like the Atlantis II deep discussed earlier (Fig. 15.74). The matrix within many Pb-Zn laminite deposits typically contains little or no carbonate. Within this classification framework, additional subtypes, typically listed by economic geologists as SedEx in the broader sense can include; Broken Hill type (BHT) deposits and those Pb-Zn deposits that formed below, but near, a seafloor vent system (e.g., Irish-type Navan deposits; Goodfellow and Lydon 2007). The Irish type of SedEx deposit is hosted predominantly in carbonate rocks and these deposits, either individually or collectively (district-wide), may show characteristics of saline brines involved in both seafloor deposition (seep-related chemosynthetic communities) and in epigenetic/hydrothermal karst settings, which many geologists consider more typical of Mississippi Valley-type deposits.

Irish-type deposits are considered to have formed by ore-forming processes similar to those of seafloor SedEx deposits. But, because carbonate platforms are highly soluble in mildly acidic ore fluids, the ores were typically deposited subsurface rather than at-surface, as passive precipitates in open porosity in a carbonate host that commonly formed by hydrothermal karsting (e.g., mineralisation in hypogene dissolution voids, collapse breccias; stylolite replacements; Reed and Wallace 2004). Broken Hill Type deposits are characterized by higher metamorphic grade, elevated base metal to sulphur ratios, a spatial and temporal association with Fe-Si-Mn oxide exhalites, and bimodal felsic-mafic volcanic/intrusive and fine- to coarse-grained, mostly clastic sedimentary host rocks (Figs. 14.64 and 15.38; Conor and Preiss 2008).

A plethora of overlapping characteristics and poorly defined associations to particular analogs typifies the current state of classification of low temperature Pb-Zn SedEx

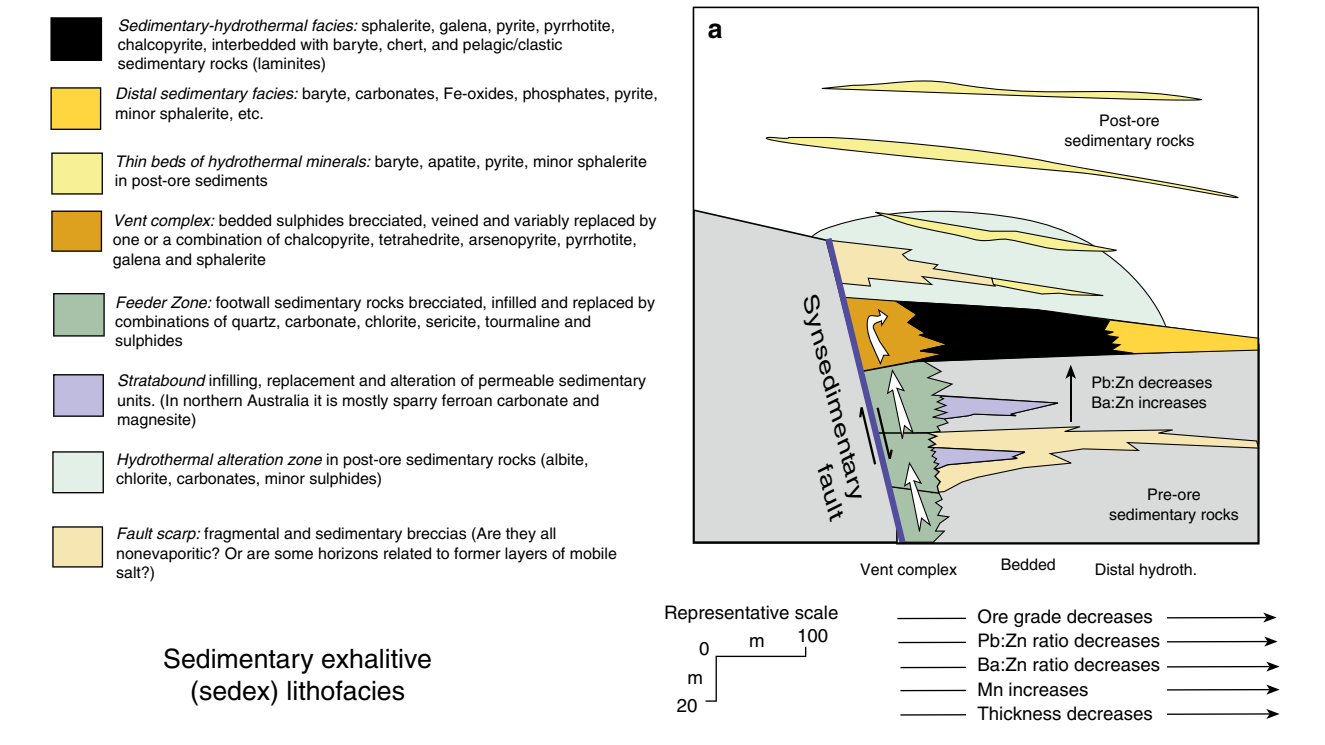

Fig. 15.74 Sedimentary exhalative (SedEx) deposit model. (**a**) Schematic cross section of SedEx mineralisation showing zonation and accompanying lithofacies. (**b**) SedEx in proximal position with brine plume dispersal. (**c**) Brine lake style with brines venting some distance from the brine lake. Venting brines are dense and hug the seafloor as they flow toward the deep-seafloor brine sump (After Goodfellow et al., 1993; Goodfellow and Lydon 2007; Warren 1999, 2000b)

deposits (as noted by Groves et al. 2005, 2010). In the economic geology literature it is generally argued, especially at the deposit scale, that, no matter what criteria are used to define a SedEx deposit, there is a continuum of characteristics between SedEx and VMS (volcanogenic massive sulphide) deposits on the one hand, and SedEx and MVT deposits on the other hand.

I disagree, the following sedimentologic/diagenetic/meta-evaporite criteria clearly separate the three deposit styles, namely; (1) the nature of the associated $CaSO_4$ (depositional beds versus burial diagenetic verses hydrothermal in an igneous-rich matrix), (2) tectonic settings that facilitate thick bedded halite deposits, thick halite cannot precipitate at open ocean basalt ridges. At continent -continent promixal young-oceanic ridges, the halite must be halokinetic – as in the thermal Atlantis II deep, (3) solution chemistry and characteristics of sulphide and non-sulphide cements in the associated breccias in the immediate vicinity of ore lenses [either warm as in diagenetic (<200–250 °C; versus hot >250–300 °C] in igneous VMS associations. The differences in these three factors are indicators of the specific ore system; as is the nature of the surrounding non-ore matrices, as well as the type and geometry of the alteration residues. In addition, differences in ionic proportions seen in the hydrochemical details, captured in fluid inclusions, are pointers to the ultimate brine source. In combination, all these factors can be used to separate the three deposit styles.

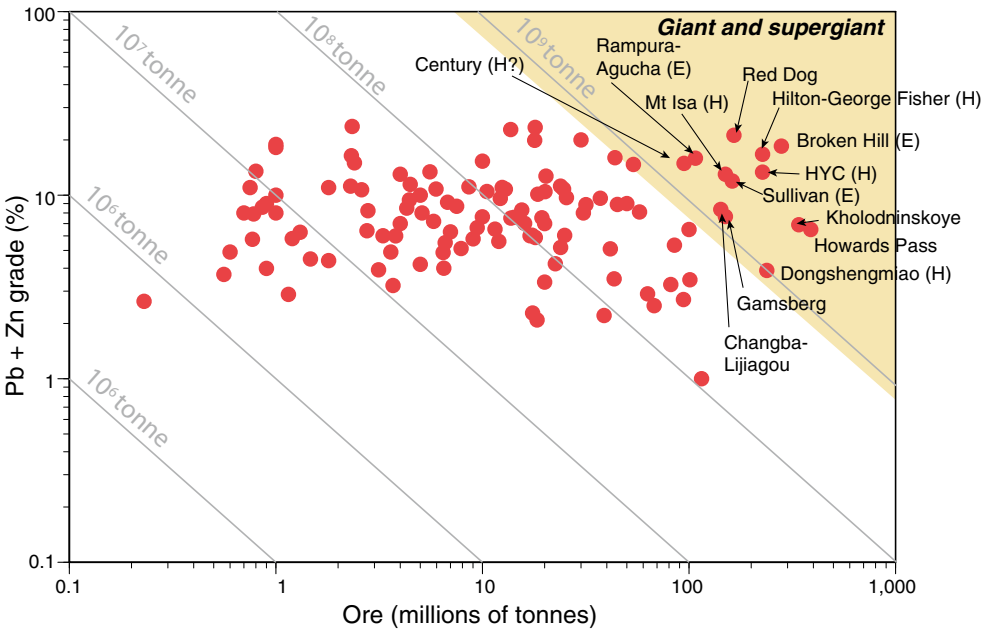

Fig. 15.75 Resource plot for sedimentary exhalative deposits. Halokinetic association indicated by *H*, bedded evaporite association by *B* and metamorphic evaporite association by *M* (Plotted data values were extracted from, integrated with the SedEx evaporite association GIS base and classification extracted from the SaltWork database version 1.6)

SedEx and MVT deposits tend to occur within slope deposits of thick sedimentary basin fills or in platform carbonates, respectively. Both are the result of the upward and lateral migration of slightly acidic basinal chloride-rich metalliferous somewhat lower-temperature saline fluids. Updip fluid movements often enhanced or focused by fault and fracture-related conduits, which are related to halite flow (diapirism and gravity gliding) and salt dissolution. And, as we shall see, the strength of the ore-depositing SedEx system can be enhanced by the dissolution of basinal or platform evaporites.

In contrast, VHMS deposits occur in submarine volcanic-sedimentary host sequences (associated with Kuroko-style anhydrites), which host hot convective hydrothermal flows of seawater and/or magmatic fluids, mostly through igneous basement, driven by the heatflow from a subvolcanic magma body. Typically, no sedimentary evaporites are involved in the metal transport or precipitative portions of a Volcanic Hosted Massive Sulphide (VHMS) deposit, although remnant textures from hydrothermal-seawater anhydrites can be a common gangue phase. VHMS deposits are discussed in the next chapter.

Using Goodfellow and Lydon's (2007) definition, SedEx deposits encompass a broad range of tonnages and grades (Fig. 15.75). They account for more than 50 % of the world's zinc and lead reserves and furnish more than 25 % of the world's production of these two metals (Emsbo 2009). More than 130 deposits of this type have been recognized in sedimentary basins around the world (Leach and others 2005; Goodfellow and Lydon 2007). A compilation based on Sangster and Hillary (2000) shows that the largest 65 deposits occur in 25 sedimentary basins, six of which contain more than 10 metric tons (Mt) combined Pb + Zn. In order of decreasing endowment these six are; Mt. Isa–McArthur basins (7 deposits totalling 112 Mt of Zn + Pb metal), Selwyn basin (17 deposits totalling 55 Mt), Brooks Range (3 deposits totalling 40 Mt), Rajasthan (5 deposits totalling 20 Mt), Belt-Purcell (1 deposit totalling 19 Mt), and the Rhenish Basin (2 deposits totalling 11 Mt) (Figs. 15.75 and 15.76).

Distribution of SedEx deposits is not equally spread across geological time (Fig. 15.77; Lyons et al. 2006). SedEx Zn-Pb-sulphide mineralization first occurred on a large scale during the late Paleoproterozoic with only a few small dubious set of examples in the Archaean, most of which are better pigeonholed in a VMS setting. Because free oceanic sulphate ions and resulting sulphate evaporites are produced mostly through weathering of the continents in the presence of oxygen, a lack of calcium sulphate beds in the Archaean and the beginnings of sulphate bedded deposits in the early Proterozoic implies a transition into more oxygeneated ocean surface waters. Sulphate (not H_2S) typified ocean waters at that time and since. This event was biogenically driven and is called the first "Great Oxidation Event." Colloquially, it is known as the time when the oceans rusted and widespread oceanic banded iron formation (BIF) precipitation largely ceased (Chap. 2). The subsequent period (≈1,800–800 Ma) was typified by relatively low oxygen concentrations, when atmospheric levels lay between the abundances of the Phanerozoic and the deficiencies of the Archaean, as indicated by the Precambrian sulphur isotope record (Chap. 2).

Given the limited availability of atmospheric oxygen, deepwater anoxia may have persisted well into the Proterozoic in the presence of a growing sulphate reservoir,

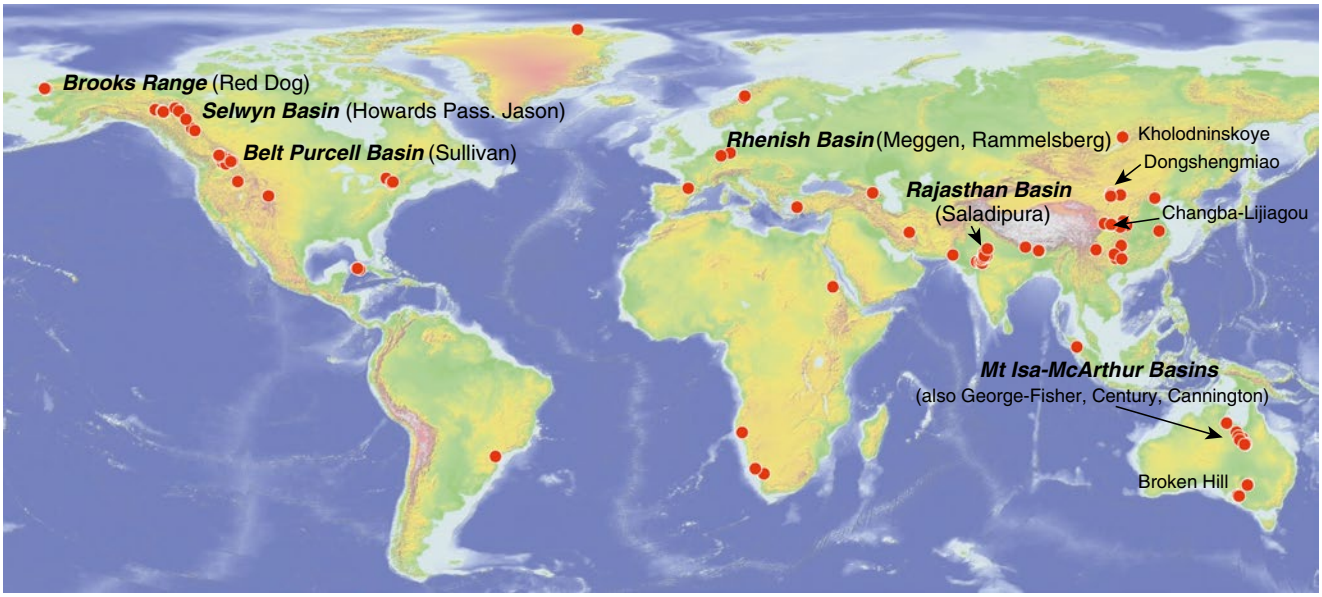

Fig. 15.76 Location of the world's larger SedEx deposits and the sedimentary basins in which they occur (Replotted from Pb-Zn module in SaltWork database, version 1.6)

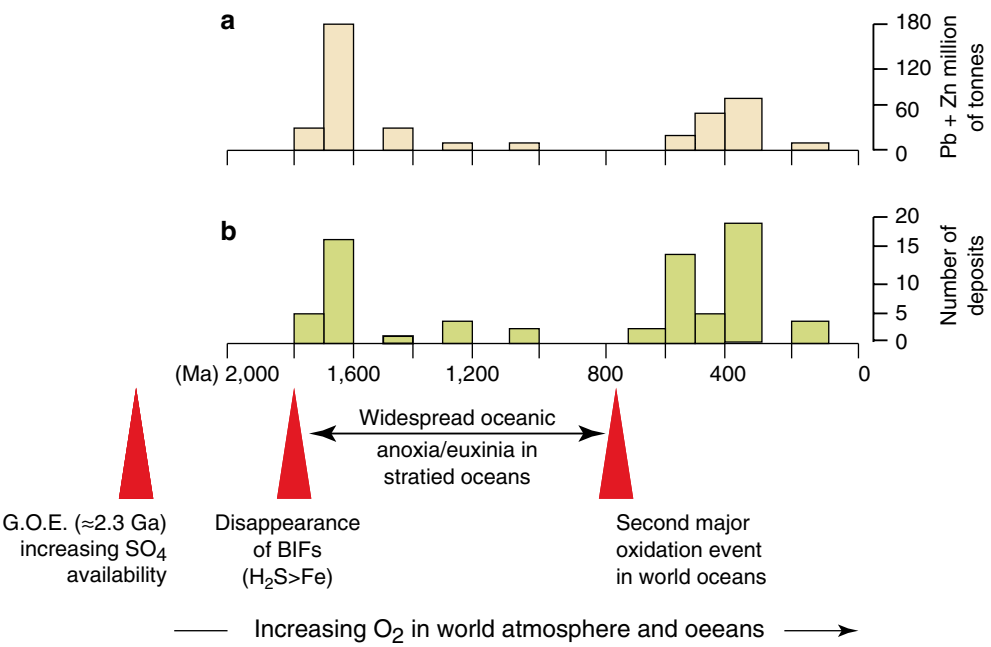

Fig. 15.77 Age distribution of SedEx mineralization as (**a**) tons of Zn and Pb per 100 m.y. interval and, (**b**) number of deposits per 100 m.y. interval (After Lyons et al. 2006)

which promoted prevalent euxinia. Collectively, these observations suggest that the mid-Proterozoic maximum in SedEx mineralization and the absence of Archaean deposits indicate a critical threshold in the accumulation of oceanic sulphate and thus sulphide within anoxic bottom waters and pore fluids—conditions that favoured both the production and preservation of sulphide mineralization at or just below the seafloor. Consistent with these evolving global conditions, the appearance of voluminous SedEx mineralization around 1,800 Ma coincides generally with the disappearance of banded iron formations—marking the transition from an early iron-dominated ocean to one more strongly influenced by sulphide availability. By contrast, the generally more oxygenated Phanerozoic ocean may have only locally and intermittently favoured the formation and preservation of exhalative mineralization in brine-floored sumps, and most Phanerozoic deposits formed from reduced fluids that carried some sulphide to the site of ore precipitation.

Within this worldscale breakdown it is also worthwhile noting the number of large SedEx deposits in the Proterozoic

and Phanerozoic that are located above, or lateral to, a present or former halite mass in the same sedimentary basin (indicated by E in Fig. 15.75). In my mind this regional association with a thick dissolving salt bed in the basin stratigraphy is more than fortuitous and once again illustrates the principle that evaporites do not form sulphide accumulations. Rather, ongoing salt flow and dissolution tends to stabilise the metal precipitation interface in a particular position in earthspace, so sediment-hosted deposits associated with disappearing evaporites tend to be larger and richer.

To illustrate the significance of this evaporite association I will focus on Proterozoic examples in Australia that I have worked during consultancy projects over the past 30 years. These and all the other examples I will discuss in this section are SedEx deposits tied to present or former dissolving halokinetic salt masses. They are chosen to illustrate how salt dissolution, and associated brine flow, can aid in the formation of sulphide precipitates in seafloor brine lakes (Fig. 15.74c). Broader SedEx compilations are published in excellent papers by Leach et al. (2010), Goodfellow and Lydon (2007) and Lyons et al. (2006).

We have already looked at the best documented active SedEx brine system in a metalliferous halokinetic association, namely the modern Atlantis II Deep. There metal sulphides are accumulating in a deep seafloor saline brine lake, mostly sourced from an adjacent basalt-volcaniclastic aquifer, with outflow focused about the thinned and faulted edges of a thick halokinetic salt mass. In the remainder of this chapter, we shall look at some older examples of a similar set of salt-dissolution brine focusing processes, but where the dissolution brines are partially suprasalt and have passed along leaky fault conduits through a substantial thickness of passive margin sediments. Unlike the Atlantis II deep, they do no sit atop or adjacent to seafloor basalts. Differences in source-feeder mineralogies explain why the Atlantis II Deep is a Cu-Pb association (leaching Cu from the subsalt basalt-redbed understory), while most SedEx deposit are Pb-Zn, largely leaching their metals from the suprasalt sediment pile (Sverjensky 1989).

To understand how the system operates we will also need to look through a veil of textural confusion in the economic geology community, especially what constitutes a replaced or altered evaporite association in Precambrian successions where the evaporites are typically long gone or represented by recrystallised anhydrites. There is also a widespread problem where some Proterozoic carbonate successions dominated by early marine cementstone textures on the floor of a CO_2 -saturated shallow ocean floor have been misinterpreted as evaporitic. I will do this in detail for the McArthur Basin where I have some experience of the geology, both in the field as well as in core study. A study of the literature base in other SedEx basins makes it clear that similar analysis and refinement of possible evaporite indicators is needed in many Precambrian basins worldwide.

McArthur River Basin and the HYC Deposit, Northern Territory

The McArthur River (aka HYC) zinc-lead deposit is one of the largest in the world and is one of a number of Proterozoic Pb-Zn deposits in northeastern Australia, south of the Gulf of Carpentaria (Figs. 15.78 and 15.79). Current mineral resources at the HYC McArthur River deposit are estimated at 157 Mt @ 11.3 % Zn, 4.9 % Pb and 49 g/t Ag. The ore is made up of laminites dominated by fine-grained galena and sphalerite, with pyrite and pyrrhotite. There is either a iron-manganese or a silicate alteration halo to the ore zones, which show combinations of synsedimentary and replacement ore textures. The McArthur River (HYC) deposit comprises 50 % of the world's current zinc and lead reserves and some 20–25 % of world zinc and lead production. The HYC ("Here's Your Chance") deposit occurs at or near the base of the HYC Pyritic Shale Member and the deposits proximity to feeder faults (e.g. Western and Emu faults) is regarded as being an important factor in understanding the genesis of HYC and nearby Ridge Cooley deposits (Fig. 15.80; Ireland et al. 2004; Large et al. 2005).

Current consensus is that the HYC deposit is a SedEx deposit, which accumulated in an anoxic seafloor brine basin, adjacent to a set of feeder faults that supplied brine and metals to the deep seafloor sump. Likely formative mechanisms are detailed in an excellent paper by Large et al. (2005) and associated papers by Davidson (1999), Bull (1998), Walker et al. (1977a, b). I will not repeat the details here other than to note the proximity of the deposit to the Western Fault, its alteration halo and the association of the Cooley Dolomite breccia unit to the deposit and the overlying HYC Pyritic Shale (Fig. 15.80a). The Western Fault and the adjacent Emu Fault acted as a source of the debris and hydrothermal fluids, as noted by Ireland et al. 2004 (Figs. 15.79 and 15.80b, c). The source of hypersaline fluids seeping into the basin sump appears to change from a more northerly source during the deposition of ore lenses 1–4, to a more easterly source for the upper ore lenses 5–8 (Fig. 15.80b). Throughout the time metalliferous laminites accumulated in the lower part of the HYC pyritic shale, the depositional setting was a deep seafloor sump where noncarbonate laminites accumulated, surrounded by shoal-water carbonate platform sediments and separated across a deep-basin bounding fault (Fig. 15.80c).

Beyond this consensus, which is also consistent with the brine pool model of Goodfellow and Lydon (Fig. 15.74c), there is the question of the deposit's regional significance with respect to future exploration and exploitation for similar SedEx laminites, both within the basin and elsewhere. That is, what drove and maintained the intraplatform sumps or lows where the metalliferous sediments accumulated? At the broad scale, the deposit sits in an intracontinental sag known as the Batten Fault zone (Fig. 15.78). But, more locally, what

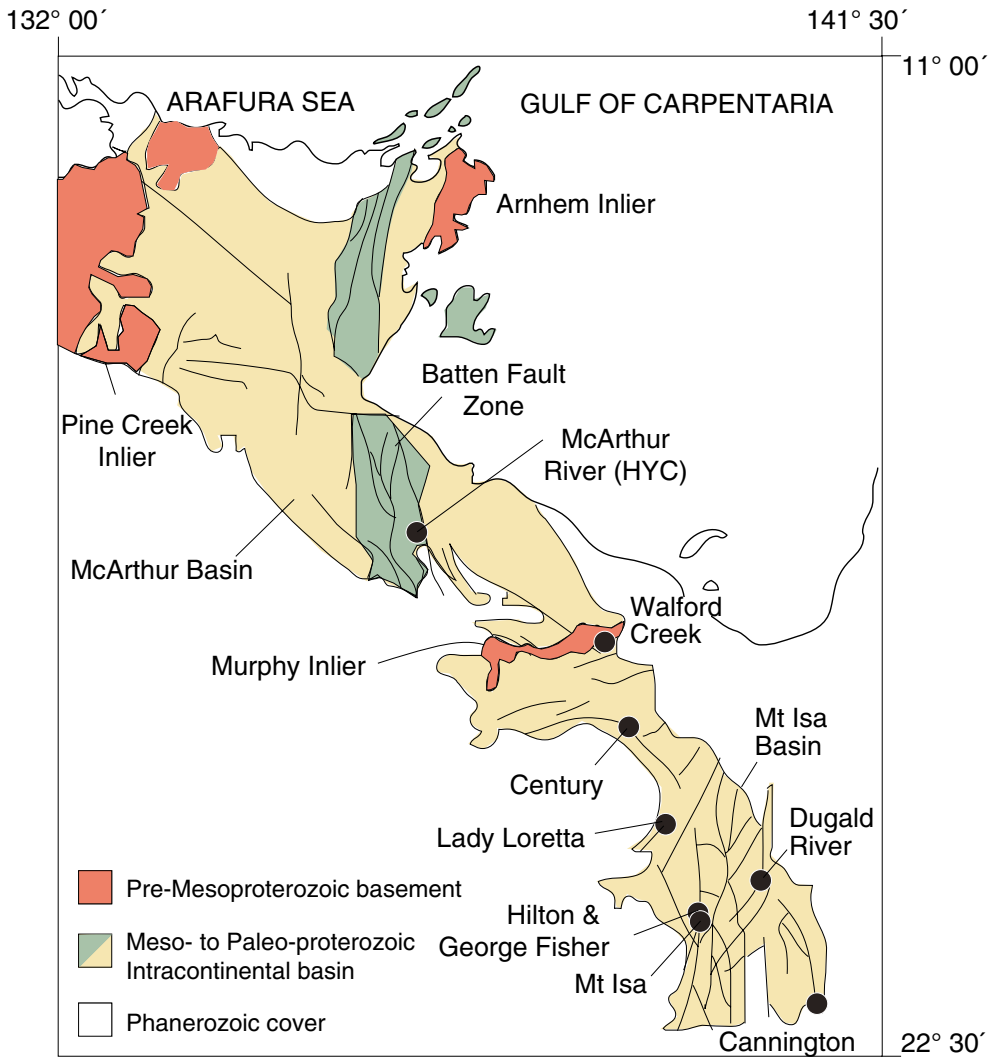

Fig. 15.78 Proterozoic Pb-Zn SedEx deposits in northeastern Australia

drove and maintained the anoxic brine ponds where the metalliferous sediment has accumulated? The lack of a pervasive metamorphic overprint makes the McArthur Basin a suitable place to study mineralising characteristics in syndepositional and early burial settings. These determinations can then be used to better understand other similar but more heavily metamorphosed SedEx successions, such as the Mt Isa, Dugald River, Hilton and Century deposits.

With this question of regional controls to mineralisation in mind, what I want to explore is the broader depositional association of the McArthur River (HYC) deposit, with ties to possible salt flow, withdrawal and related diagenesis, in a framework of evaporite indicator distribution in the basin stratigraphy. This has not been done before in the public realm, and to do so in a reliable way requires a relook at the nature and distribution of evaporites and their indicators in the McArthur Basin sediments. Table 15.13 and Fig. 15.81 list the distribution of evaporite indicators in the basin stratigraphy in the units that overlie and underlie the McArthur River (HYC) Zn-Pb deposit, which is hosted in the Barney Creek Formation. Table 15.14 lists the characteristics of evaporite occurrence in some other major "SedEx" deposits hosted in the Proterozoic sediments of northeastern Australia.

In studies conducted in the McArthur Basin across the 1960s through the 1980s, evaporites were interpreted as occurring throughout much of the Proterozoic stratigraphy in the McArthur Basin (see Walker et al. 1977a, b); Wells 1980 and Jackson et al. 1987b for a good summaries of this literature). The ubiquitous and pervasive nature of inferred evaporite indicators across large portions of the stratigraphic column, immediately arouses suspicions as to its validity. In all basins with significant evaporites, thick sequences of evaporite salts, especially halite, are typically confined to particular tectonically-controlled positions in the stratigraphy (see Chap. 5 and Warren 2010).

My field work, as part of a number of consultancy contracts, including walking out and mapping of contacts of key units in the McArthur Basin, shows that the "siderite marbles" of Jackson et al. (1987), one of the most ubiquitous indicators of former evaporites across the stratigraphy, were

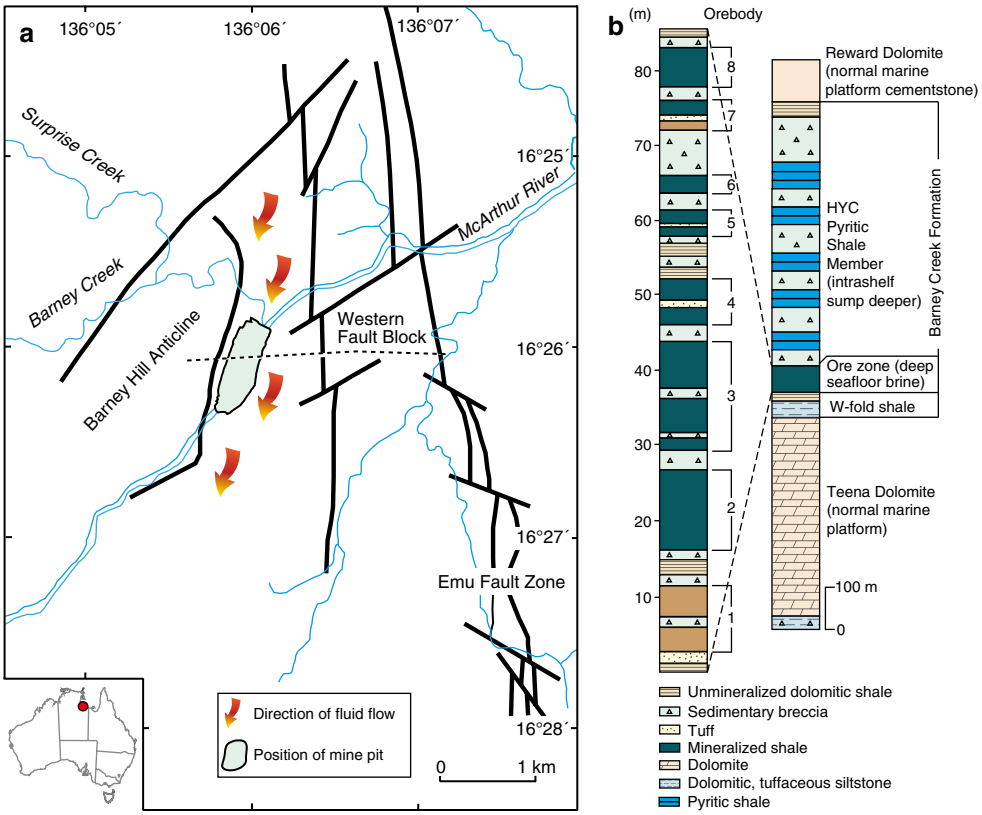

Fig. 15.79 McArthur River Mine (HYC Pb-Zn-Ag deposit), Northern Territory, Australia. (**a**) Deposit location within the Barney Creek graben and the position of metalliferous fluid flow in the graben. Dashed line indicates approximate position of schematic section in Fig. 15.80a. (**b**) McArthur Basin stratigraphy in the ore interval with an expanded view of the HYC deposit showing the eight ore bodies (Based on Williford et al. 2011). *Dashed line* indicates approximate position of schematic section in Fig. 15.80a

incorrectly interpreted as gypsum pseudomorphs (Fig. 15.82). Rather, "siderite marbles" are fault-controlled diagenetic brine haloes made up of sparry hydrothermal ferroan replacements in marine platform sediments (Warren 1999). "Siderite marbles" occur along and adjacent to faults, fractures, salt welds and joints that were fed by subsurface $FeCl_2$-rich basinal brines. Away from their transtratal feeder faults, the "siderite marbles" show a tendency to become bedding parallel and then pass laterally into non-replaced sediments. This reflects preferential fluid entry along beds that were more permeable at the time the Fe-Cl rich basinal brines were ascending the feeder faults. Thus, at the time of fluid crossflow, such coarser grained beds (grainstones and floatstones), along with joint planes, show a propensity to be replaced first and most effectively by ferroan carbonate. Less permeable micritic intervals tend not to be fully replaced and so retain less pervasive overprints of ferroan carbonate precipitates, such as cm-sized isolated lozenges of ferroan carbonate with pinolitic[2] textures (Fig. 15.82).

These sparry lozenge-shaped crystals originally formed as diagenetic replacements in dolomitic, open marine, intraclastic and peloidal wackestones, grainstones and rudstones. They do not, as reported in earlier work, define former beds composed of lenticular gypsum. A nonstratiform facies expression of the "siderite marbles" can be clearly seen when the edges, and not the permeability-parallel tops, of these stratiform ferroan bodies are walked out and mapped. The margins of the replaced regions are typically pinolitic and facies transgressive. The edges of a "sideritic marble" unit do not parallel bedding but, at the broad scale, follow faults or pass laterally into unaltered carbonate. These textures clearly do not indicate a replaced $CaSO_4$ bed.

At the mesoscale, replaced ferroan intervals can sometimes be seen to nucleate off joint planes (e.g. Figs. 74, 75 in Jackson et al. 1987 and Plate 1 in Pietsch et al. 1991). Similarly, bedding planes and chert nodule horizons in adjacent unaltered carbonates can be traced into the sparry ferroan carbonate replacement zones without any loss in vertical spacing of the bedding indicators. This clearly shows that the sparry replacement did not form as a replacement of a bedded evaporite unit, nor of its solution breccia. Likewise, the chert nodules that are encased in the "siderite marble" zones are smooth-walled nodules with normal marine affinities. There are no knobbly-surfaced cauliflower cherts after anhydrite, gypsum or trona in any of the "siderite marble" units in the McArthur Basin. Historically some these smooth-walled cherts, which internally retain uncompacted marine peloids and no evaporite pseudomorphs, have

[2]Pinolitic describes crystal splay textures made up of elongate lenticular crystals of ferroan to magnesian carbonate (siderite, ankerite, brunnerite, magnesite) with outlines in two dimensions that resemble the patterning along the outside of a closed or partially closed pine-cone (*Pinus pinea*).

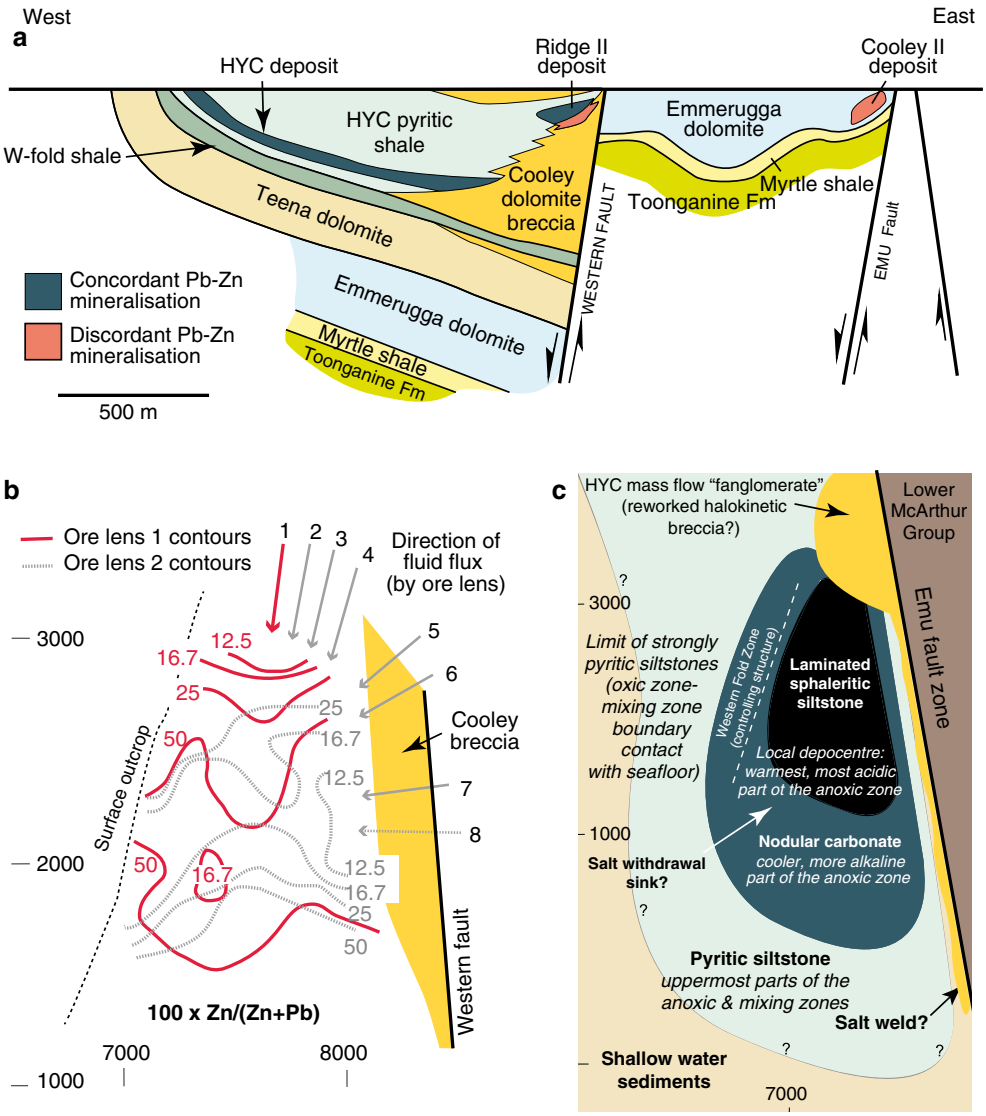

Fig. 15.80 HYC Geology. (**a**) Schematic E-W cross section see Fig. 15.79a for approximate position. (**b**) Combined plot showing up-section change in the orientation of metal zonation within the deposit, and the contours of the ratio 100×Zn/(Zn+Pb) for the lowermost and uppermost ore lenses. *Arrows* depict the interpreted direction of fluid flux through the mineralising system during formation of each ore lens (**c**) Schematic plan view showing likely synsedimentary spatial relationship between pyritic siltstones, nodular carbonates, and base metal-mineralized siltstones in the HYC subbasin. Fault control of the eastern basin margin and impingement of a fanglomerate wedge in the north (Adapted from Walker et al. 1977b; Ireland et al. 2004)

been misinterpreted as replacements of anhydrite nodules in gypsum beds.

XRD analysis shows "siderite marbles" of the McArthur Basin are not composed solely of siderite but of a range of ferroan carbonates dominated by sparry ferroan magnesites. In many sampled outcrops siderite was not present in the coarse spar facies. The mineralogy of the replacing sparry carbonates is in large part dependent on what lithology was replaced. Ferroan magnesites tend to dominate where platform dolomite was replaced. Siderite tends to occur where a calcitic precursor mineralogy dominated, or in more localised limestone regions that were flushed by large volumes of bathyphreatic $FeCl_2$ brine. In outcrop, ferroan carbonate phases ultimately weather to fine powdery to massive goethite/hematite, and so reliable analysis of the ferroan carbonate parent is best conducted on samples from core or in mine workings.

Thin sections of the "siderite marbles" retain poikilotopically enclosed ghost textures of peloidal carbonate grain fabrics, which were the dominant textures in the precursor open-marine platform carbonates and are not evaporite indicators. Likewise, the lenticular outlines of individual ferroan crystals (e.g. Fig. 74 in Jackson et al. 1987) do not mimic lenticular bird-beak gypsum or axe-head anhydrite (Chap. 1). Rather, the crystals show the characteristic blunt-ended or stubby lozenge-shaped outlines of pinolitic ferroan carbonates (especially, sparry ferroan magnesite and siderite; Fig. 15.82).

The notion of a "sideritic marble" being a replacement of a syndepositional gypsum mush bed, means the presence of siderite lozenges were used incorrectly by some authors to assign and evaporite depositional setting to outcrops of a number of formations in the McArthur Group cross cut by feeder faults, such as the Amelia Dolomite, Reward Dolomite, Teena Dolomite, Emmerugga Dolomite that were actually normal-salinity epeiric marine carbonates (Table 15.13). Elsewhere, in other Proterozoic basins of the Northern

Table 15.13 Re-interpreted evaporite occurrence chart in the McArthur Basin stratigraphy, emphasising the overinterpretation of evaporites in the stratigraphy by some earlier studies (e.g., Jackson et al. 1987 and references therein)

Formation	Member	Dominant lithologies	Thickness (m)	Evaporite indicators	Significance
Looking Glass Formation (Amos Fm)		Chert; chert breccia; minor dolomite	25–230	None noted	Coarse dolospar in the Caranbirini Member is a possible late stage dolomitisation overprint
Stretton Sandstone		Flaggy quartz sandstone	30–245	None noted	
Yalco Formation		Chert; chert breccia; minor dolomite	130	C, LD, DBH	Non-evaporitic shallow carbonate platform
Lynott Formation	Donnegan Member Hot Spring Member Caranbirini Member	Dolomitic siltstone; chert; chert breccia; minor dolomite	50–300	N, Co, DBH?	Non-evaporitic shallow carbonate platform
Reward Dolomite		Dolomite with chert pellets; minor dolomite	210–760	LD, C, DBH?	Non-evaporitic shallow carbonate platform
Barney Creek Formation	HYC Pyritic Shale Mbr (basinal) W-fold Shale Mbr. (basinal) Cooley Dolostone member (platform).	Pyritic carbonaceous dolomitic shale; dolomite, dolomitic breccia; HYC deposit	0–490	Non-noted; breccias are commonplace; possible DBH	Infill of deeper intraplatform depressions on a shallow carbonate platform. Tectonism possibly associated with halokinesis.
Teena Dolomite	Coxco Dolomite Member	Massive and laminated stromatolitic dolomite	57	H, N, Co, DBH, SM	Non-evaporitic shallow carbonate platform
Emmerugga Dolomite Massive and laminated	Mitchell Yard Dolomite Mara Dolomite Member	Massive and laminated stromatolitic dolomite	500	H, LD, N, Co, DBH, SM	Non-evaporitic shallow carbonate platform
Significant interstratal and transtratal evaporite dissolution breccia layer mostly at or near Mara/Myrtle contact; likely indicative of former allochthonolayer.					
Myrtle Shale		Thin evaporitic red bed unit	30–100	H, DBH	Transitional restricted terrigenous evaporitic platform (?lacustrine in part)
Leilia Sandstone		Coarse-grained and crossbedded dolomitic sandstone	20–30	None noted	
Tooganinie Formation		Stromatolitic dolomite; dolomitic shale; quartzarenite; dolomitic siltstone	800	H, LD, SM	Non-evaporitic marine dolomites and cherts overprinted by coarsely crystalline diagenetic magnesite (not primary evaporite).
Tatoola Sandstone		Quartz arenite; dolomitic siltstone	140	LD	
Amelia Dolomite		Laminated and stromatolitic dolomite, (passive gypsum pseudomorphs in beds)	90–240	H, LD, C, DBH, false SM	Ferro-magnesite haloes near fault zones that were incorrectly interpreted using SM. These are fault -fed diagenetic ferroan carbonate haloes that crosscut primary bed contacts

(continued)

Table 15.13 (continued)

Formation	Member	Dominant lithologies	Thickness (m)	Evaporite indicators	Significance
Mallapunyah Formation		Purple dolomitic siltstone; minor dolomite; quartz arenite	30–750	H, LD, C, DBH, SM	Diagenetic anhydrite nodules perhaps formed by post-depositional brine reflux (evaporites are possibly arid lacustrine, but not sabkha)
Masterson Sandstone		Coarse braided sandstone, ferruginous and siliceous cement sandstone	30–350	H, LD, in uppermost beds	Post-depositional halite growth in an alluvial fan/fluvial uppermost beds. Indicates reflux rather than evaporitic at deposition

KEY *H* Halite casts, *LD* Euhedral and discoidal gypsum and/or anhydrite pseudomorphs, not all are syndepositional, *N* Acicular gypsum pseudomorphs, *C* Cauliflower chert nodules, *SM* Sideritic "marble" (incorrectly interpreted as after bedded gypsum?), *DBH* Dissolution breccia horizon "Coxco" (cock's-comb) structures incorrectly interpreted as gypsum pseudomorphs, actually marine aragonite cement splays in cementstone units SM is not siderite but ferro-magnesite under XRD (brunnerite) and is a diagenetic hydrothermal precipitate. It is not a replacement of a primary gypsum bed (incorrect earlier interpretation). LD is mostly displacive and replacive late stage ferroan carbonate associated with "SM" haloes. N is a Proterozoic seafloor carbonate cement, no association with a gypsum precursor. Some DBH units are halokinetic residue layers

Territory, the same lenticular texture in sparry ferroan carbonates was applied inappropriately as an indicator of evaporite pseudomorphs. For example. Muir (1987) makes an early diagenetic lenticular gypsum interpretation of what are hydrothermal pinolitic structures in fault-fed metasomatic magnesites in the Pine Creek Inlier. Work by Bone (1983), and later by Aharon (1988), on the same Pine Creek magnesites correctly interprets them as indicators of epigenetic replacement of a dolomite precursor by throughflushing of hot basinal brines. Interestingly, Muir (p.8 *opp. cit.*) quotes the misinterpreted "sideritic marbles" of the Amelia Dolomite in the McArthur Basin as her main argument that the Pine Creek magnesites are low temperature replacements of an earlier evaporite bed and so erroneously concludes the marbles cannot be hydrothermal replacements.

Sideritic marbles in the McArthur Basin, and other similar fabrics worldwide, are not formation or precursor specific but process specific; they indicate diagenetic replacement of platform carbonates by ferruginous chloride-rich basinal waters, supplied via hydrothermal feeder zones, located near active faults or salt welds. The ultimate source of these chloride-rich waters was from convecting basinal brines, with their high levels of chloride supplied by thick dissolving halite units buried deeper in the basin. The dissolving and flowing salt mass focused leaching of iron as the brines circulated through subsalt sediments during passage to the salt edge and/or the basin margin.

The other major misinterpretation of an evaporite indicator, leading to inappropriate evaporite distribution maps in the McArthur Basin stratigraphy, was that of dolomite-replaced splays of aragonite cement as being indicators for replaced gypsum (Table 15.13). Terminations of many of the crystal outlines suggest the precursor was dominated by grasslike cementstone layers and botryoids of aragonite or Mg-calcite, which were subsequently dolomitised. The crystal splays, locally know as Coxcos[3], because of their resemblance in two-dimensions to a "cock's-comb," were used, like occurrences of siderite marbles, in studies in the 1960s through 90s, to indicate former evaporites. A predominance of replaced splays in one particular unit gave that formation its name, the Coxco Dolomite. But as with siderite marbles, "Coxcos" are a process indicator and so are not formation specific. Rather they indicate the predominance of aragonite cements in the carbonate-saturated tropical normal-marine seaways of the Proterozoic when CO_2 levels in the atmosphere and oceans was much higher than today (Grotzinger 1995). They define widespread cementstone layers and typify shallow marine hardgrounds in a number of formations in the basin, and are found numerous cores from wells in the basin, including the shoal water platforms that surround and underlie the mineralised zones of the Barney Creek formation (Table 15.13)

When occurrences of "siderite marbles" are plotted in the McArthur Group stratigraphy, the "siderite marbles" are not found deeper in the stratigraphy than the Wollogorang Formation, implying the ultimate source of the ascending chloride-rich brines was at this level in the stratigraphy. In the McArthur Basin the primary salt weld was probably at the level of the Wollogorang Formation (Fig. 15.81).

Multiple layers of evaporite dissolution breccias, as in the well DD91RC18 (Fig. 15.83), indicate the former presence of a number of thick intervals of now dissolved bedded halite within the Mesoproterozoic Wollogorang Formation. This

[3]The coxco features were correctly interpreted as marine aragonite splay pseudomorphs Brown et al. (1978), then misidentified as pseudomorphs after radiating gypsum splay in subsequent studies; e.g. Walker et al. 1977; Jackson et al. 1987)

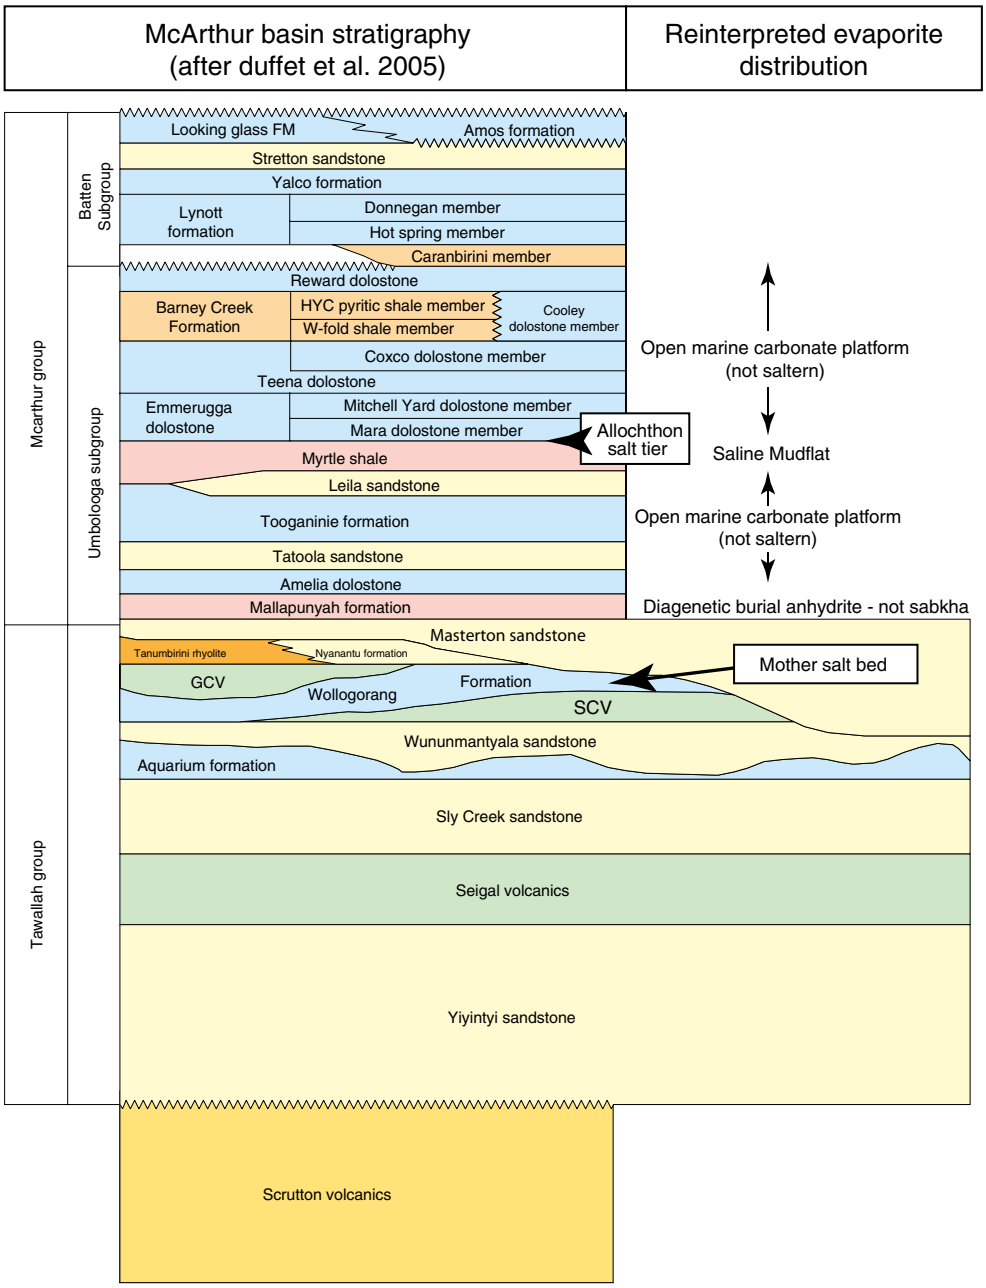

Fig. 15.81 Stratigraphy of the McArthur Basin in the vicinity of the McArthur (HYC) mine, Batten Trough, Northern Territory, Australia (After Duffett et al. 2005) and the interpreted evaporite distribution, based on discussion in this chapter

core, and many Wollogorang breccia outcrops, show characteristic salt dissolution features, such as smooth breccia bases that are overlain by thin beds of insoluble residues, along with commonplace radial quartz micronodules and length-slow quartz euhedra preserved within the breccia matrix. The breccia beds at each former halite level pass up through rubble breccia into mosaic to crackle-brecciated bed tops (see Chap. 4).

When public-domain base-metal data are replotted against same scale sedimentological log, the utility of an applied sedimentological approach in the economic geology of the region is obvious (Fig. 15.83). The plot clearly shows that the Pb and Zn anomalies are suprasalt and centred on dark organic-rich laminites (locally known as the "ovoid beds"), while the Cu peaks occur mostly in dissolution-effected breccia intervals. Cu migration through this sequence is clearly later diagenetic and postdates salt solution. In contrast, the Zn and Pb anomalies show an early diagenetic (possibly syngenetic) control.

Work by Williford et al. (2011) on organic signatures in extractable hydrocarbons from the mineralized shales of the HYC deposit further reinforces the importance of the evaporitic brines sourced at the Wollogorang level in the stratigraphy. δD of n-alkanes, branched alkanes and bulk aromatic fractions were measured, and $\delta^{13}C$ of n-alkanes, polynuclear aromatic hydrocarbons (PAHs) and bulk kerogen were measured to

Table 15.14 Characteristics of relatively low temperature (subgreenschist to greenschist grade) Proterozoic SedEx deposits, Australia

Deposit	Age (Ma)	Characteristics	Host, its age and depositional setting	Tonnes (Mt)	Grade	Ore	Metamorphic grade	Model	References
Mount Isa	1,653	30 stacked lenses, most of which occur in the upper 650 m of the Urquhart Shale; deposit is located to the east of the Mount Isa fault zone and in the hanging wall of the syn-extensional Paroo fault; intense overprinting during the Isan orogeny	Urquhart Shale (1,652 Ma): carbonaceous, pyritic, and dolomitic siltstones; tuffaceous horizons. Neudert and Russell (1981) and Neudert (1986) favour deposition in a sabhka setting, whereas Domagala et al. (2000) interpret the Urquhart Shale to be turbidite and/or tempestite sediments related to a submarine fan. A halokinetic association favors a deepwater interpretation.	150	7 %Zn 6 %Pb 150 g/t Ag (248Mt @ 3.3 % Cu)	Bedding-parallel bands of galena and sphalerite; fine grained pyrite, pyrrhotite, and minor chalcopyrite, arsenopyrite, and marcasite. At Mt Isa the orebodies are on one limb of a plunging anticline and are extensively faulted. Also in the Mt Isa mine is a Cu ore zone, hosted in the epigenetic silica-dolomite halokinetic unit (preserves a massive anhydrite unit)	Greenschist	Both sedimentary exhalative and diagenetic models; overprint during the Isan orogeny has resulted in remobilization of the Pb-Zn mineralization; remobilized ore has been used to argue for synorogenic epigenetic mineralization (Perkins and Bell 1998). Sulphur isotopes indicate sulphur source was local sulphate evaporites, pseudomorphs of which are present throughout the Urquhart Shale (i.e., gypsum, anhydrite, and baryte). Deep-burial diagenetic replacement of these evaporites resulted in sulphate-bearing basin waters which migrated parallel to bedding. Were the sulphates primary, or halokinetic dissolution residue layers sourced above or below the mineralisation level?	Neudert and Russell et al. (1981), McGoldrick and Keays (1990), Forrestal (1990), Painter et al. (1999), Wilde (2011)
Hilton	1,653	7 stacked ore lenses in the upper Urquhart Shale, complicated by intense shortening associated with the Isan orogeny		120	10.2 % Zn 5.5 % Zn 100 g/t Ag		Greenschist		Forrestal (1990), Valenta (1994)
George Fisher	1,653	11 stacked ore lenses in the upper Urquhart Shale		108	11.1 % Zn 5.4 % Pb 93 g/tAg		Sub- to lower greenschist		Chapman (2004)
Lady Loretta	1,650	Approximately 50-m-thick single ore horizon; the ore horizon is preserved within a regional syncline and is bounded to the north and west by inverted extensional faults	Lady Loretta Formation (1,647+ 4 Ma): carbonaceous pyritic, dolomitic, and sideritic, siltstone and shale. Deep water laminite	8.3	18.4 % Zn 8.5 % Pb 125 g/t Ag	Sphalerite, galena, and pyrite, baryte-chert-sulphide, minor chalcopyrite, quartz, siderite, tetrahedrite, and freibergite	Sub-greenschist	Interpreted as a combination of sedimentary exhalative and diagenetic processes in which hydrothermal brines were transported along extensional faults during the deposition of the Lady Loretta Formation	Hancock and Purvis (1990), McGoldrick et al. (1996), Domagala et al. (2000)

Century	1,575	Mineralized 40-m interval with 2 ore horizons; preserved in an open fault-bounded syncline; stylolitic layering in ore succession focused mineralization, mineralization transgresses bedding at deposit scale; deposit is proximal to intersection of the Termite Range fault and a buried normal fault. Mineralisation ≈ 1,558 ± 4 Ma	Lawn Hill Formation (1,595 + 6 Ma): siliciclastic, carbonaceous (TOC 1–5 %), sideritic, shale and siltstone, with tuffaceous horizons. Deposited in a deep water laminate setting (sea-bottom brine lake).	118	10.2 % Zn 1.5 % Pb 36 g/t Ag	Sphalerite dominated; bedding-parallel, finegrained sphalerite, galena, and pyrite; siderite is the main Fe gangue phase and is developed in siderite siltstone and siderite carbonaceous mudstone layers that separate the mineralized horizons	Sub-greenschist	Epigenetic mineralization in which hot basinal brines (120–180 °C) caused maturation of organic material (pyrobitumen) leading to sulphate reduction and base metal precipitation; deposit is interpreted to have formed at a depth between 800 and 3,000 m; fluid flow is interpreted to have been tectonically driven, occurring during basin inversion, and it has been compared with Mississippi Valley-type ore-forming environments	Broadbent et al. (1998), Large et al. (2005), Polito et al. (2006), Kawasaki et al. (2010)
HYC	1,640	8 ore lenses in 70-m interval; deposit located in unmetamorphosed successions and preserved in the hanging wall of inverted (strikeslip?) Emu fault near its intersection with a normal fault	Barney Creek Formation (1,640 + 3 Ma): dolomitic siltstone, coarse sedimentary breccias, tuffaceous horizons, pyritic shale; pyritic shale is organic rich (7 % TOC). Deposited in a deep water laminate setting (sea-bottom brine lake).	240	9.2 % Zn 4.1 % Pb ~41 g/tAg	Pyrite, galena, and sphalerite, finely disseminated throughout the siltstone interlayered with poorly mineralized siltstone, fine sandstone, breccia, and mudstone horizons	Sub-greenschist	Sedimentary exhalative (e.g., Large et al. 1998) vs. early diagenetic (e.g., Rye and Williams 1981; Eldridge et al. 1993; Hinman 1995; Logan et al. 2001) models proposed; in synsedimentary exhalative model the formation of numerous ore lenses when metalliferous brines were exhaled during several pulses of mineralization, related to episodic fault movements; in diagenetic model fewer pulses of mineralization are envisaged, with epigenetic mineralization occurring through lateral flow of metalliferous fluids via the Emu fault zone	Williams (1978), Eldridge et al. (1991, 1993), Hinman (1995, 1997), Bull (1998), Large et al. (1998, 2000), Logan et al. (2001)

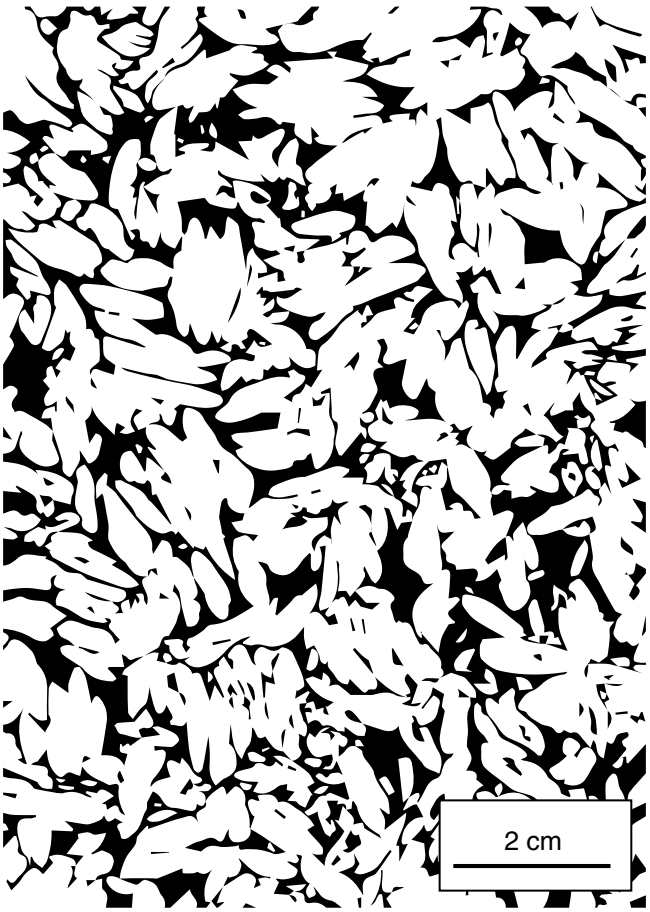

Fig. 15.82 Pinolitic texture from a scanned black and white field photograph of a siderite marble (brunnerite) halo. This texture was incorrectly interpreted in the 1960s and 70s as replaced gypsum beds, as were some baryte rosettes. A few hours of walking out contacts of this diagenetic units clearly shows that although it is locally stratiform, on the broader scale it is mostly transtratal and ties back to feeder-fault haloes

assess the isotopic effects of a varying degree of hydrothermal alteration on different components of HYC organic matter (Fig. 15.84a–c respectively). Relative to n-alkanes in Barney Creek Formation sediments that did not undergo mineralization, HYC n-alkanes are enriched in deuterium (D) by 50–60 ‰. This is likely to be a result of equilibrium hydrogen exchange during ore genesis with a highly D-enriched fluid that originated in an underlying evaporitic unit.

Trends with distance along the sample transect are ambiguous, but from the northernmost to southernmost point, n-alkanes are less D-enriched, and PAHs are less abundant and less ^{13}C-enriched (Fig. 15.84). This could be due to decreasing hydrothermal alteration effects, decreasing delivery of highly altered OM by the mineralizing fluid, or both, hence the fluid flow path illustrated in Fig. 15.79. The carbon isotopic composition of HYC PAHs is inconsistent with a Barney Creek Fm source, but consistent with an origin in the underlying Wollogorang Formation. PAHs are ^{13}C-depleted relative to n-alkanes, reflecting a kerogen source that was ^{13}C depleted compared to n-alkanes, typical for Precambrian sediments (Fig. 15.84b, c). PAHs are more ^{13}C-depleted with increasing molecular weight and aromaticity, strengthening the case for a negative isotopic effect associated with aromatization in ancient sediments. According to Williford et al. (2011) these data are consistent with an ore deposition model in which fluids originated in an evaporitic deposit lower in the basin and interacted with metals and organic matter in the Tawallah Group at temperatures above 250 °C and a depth of ~ 6 km, before ascending conduits associated with the Emu Fault and cooling to 200 ± 20 °C before reaching Barney Creek sediments.

In summary, if ancient fine-grained or sparry ferroan replacements in sedimentary hosts in the McArthur Basin are interpreted as possible palaeoplumbing indicators, rather than as ubiquitous pseudomorphed primary evaporite beds, they become useful indicators of fluid conduits, which typically can be traced back to extensional feeder faults. This reinterpretation of evaporite textures defines an evolving diagenetic hydrology where metalliferous $FeCl_2$ -rich basinal brines have ascended from depth. The lowest occurrence of the "siderite marbles" in the stratigraphy, at the Wollogorang Fm. level, likely defines the level of the former thick mother salt bed that, as it flowed and dissolved, supplied the high chloride content and metal carrying capacity to the basinal brine. Before the mother salt level and its allochthon tiers were halokinetically breached and evolved into welds, it also acted as an overpressured seal, facilitating hydrothermal convection and metal enrichment in density-fed brines flushing the underlying marine shales. The flow and breaching of the same mother salt also facilitated the formation of various structures that acted as conduits for the escape of the Fe-rich basinal brine. During their subsequent ascent along focused conduits (faults, fractures, joints and salt welds), the brines leaked into adjacent permeable sediments to form characteristic pinolitic and massive ferroan replacement fabrics.

When evaporite textures are correctly interpreted, then a depositional model for the McArthur River (HYC) deposit HYC becomes a fault-bound hydrographically closed intrashelf anoxic deep atop salt withdrawal seafloor sumps within a typical Proterozoic normal marine platform carbonate succession. Relogging of a number of relevant cores and mapping of the stratigraphy below the Pb-Zn laminites of the HYC mine region, from an evaporite-aware perspective, shows that feeder faults intersect underlying breccias that entrain indicators of former evaporite beds and allochthons. These feeder faults have hydrothermal haloes of diagenetic ferroan carbonate cements that replace adjacent platform carbonate.

The stratigraphy of most wells in the McArthur Basin that pass through the equivalents of the Barney Creek Formation, host to HYC deposit, clearly show a deepening (gradational) profile upward from the platform cementstones of the Teena and Coxco dolomites, and equivalents, into the deepened waters of the Barney Creek mass flows and laminites

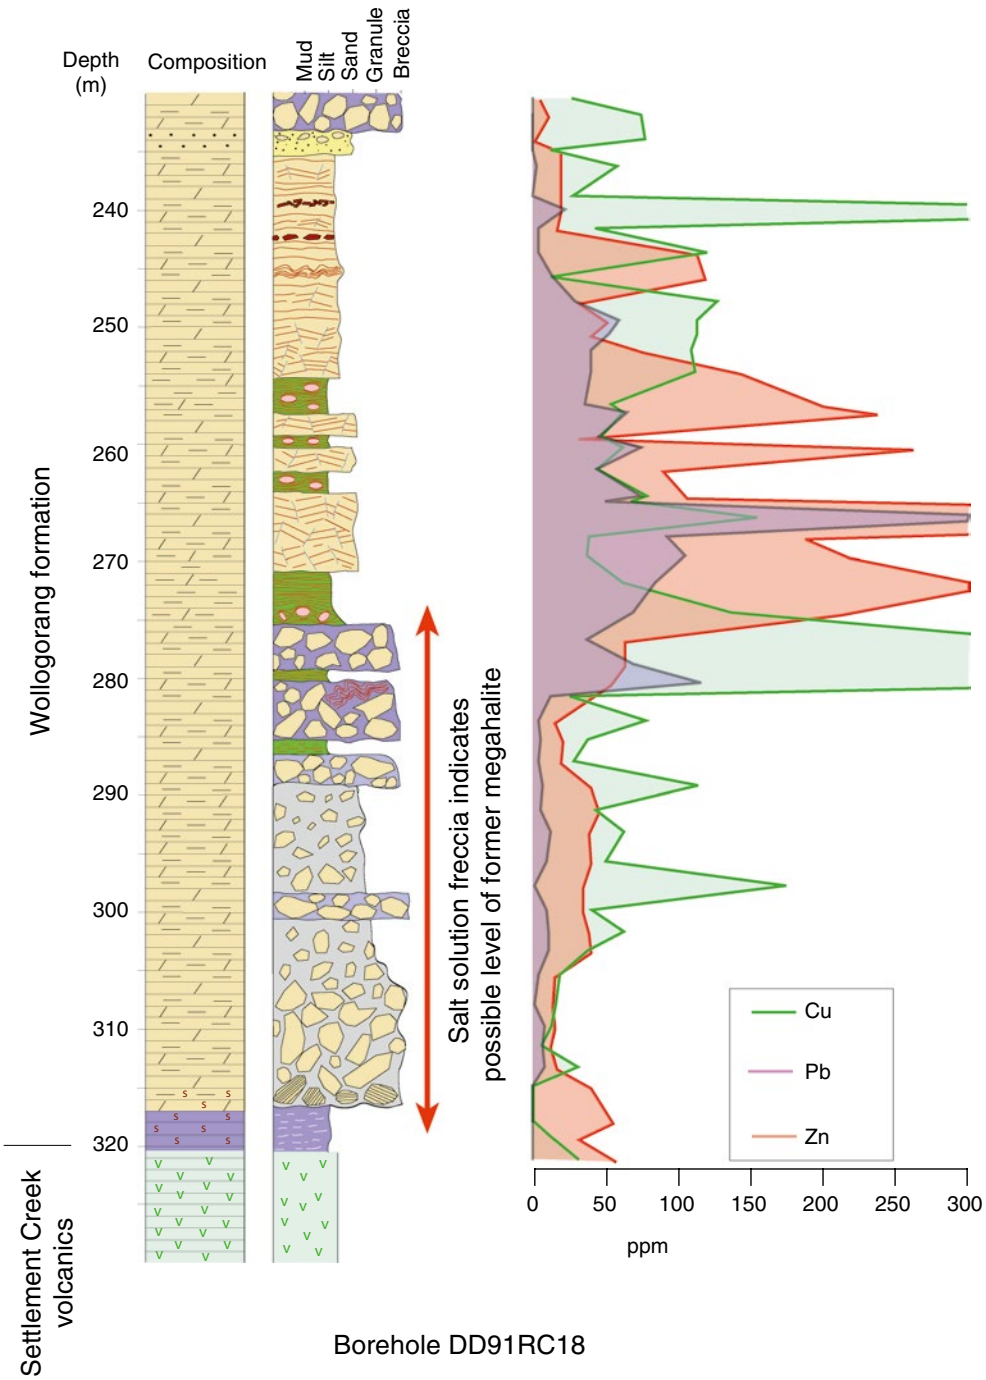

Fig. 15.83 Log of the mother salt level in the Wollogorang Formation in the DD91RC 18 borehole in the McArthur Basin. See text for detail

(Fig. 15.85). Units in almost all wells through the Barney Creek Formation and its equivalents can be broken down into three facies belts (A, B, C; Figs. 15.85 and 15.86).

Facies A is now dolomitised; it was originally deposited on the floor of a shallow normal-marine tropical ocean as cementstones interlayered with micritic intraclast packstones and rudstones. Terminations of many of the crystal outlines suggest it was dominated by grasslike cement layers and botryoids of aragonite and perhaps Mg-calcite that were subsequently dolomitised. This facies, with its abundant normal marine cements, is identical to other tropical carbonate platform sediments of the same age and is indicative of a CO_2-enriched Proterozoic atmosphere (e.g. Grotzinger 1995; Grotzinger and Knoll 1995).

Facies B is a layered to laminated dolomitised siltstone with interbedded packstones. It is usually slumped or cross-laminated and was deposited as some form of intrabasin slope deposit. Its lack of cementstone layers implies it was deposited in deeper, but still oxygenated, shelf waters. It too is now extensively dolomitised, although the occasional siliceous interval is still cemented by calcite not dolomite. The dolomitising mechanism for the region was relatively

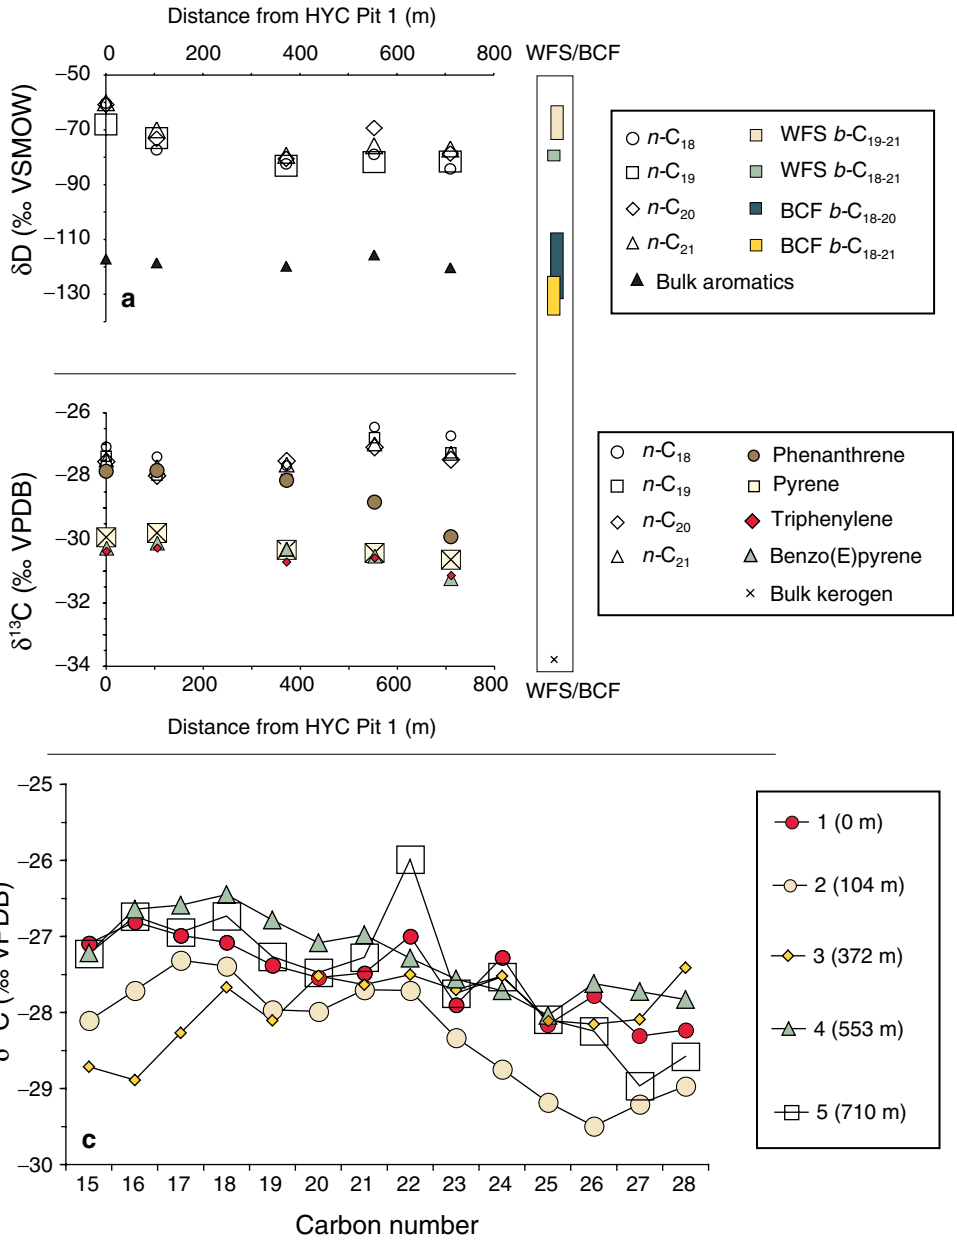

Fig. 15.84 Organic characteristics in the HYC deposit (After Williford et al. 2011). (**a**) δD of four n-alkanes and bulk aromatic fractions with distance from Pit 1 (S 16° 25′ 53.3742″ E 136° 6′ 1.0368″) along a northeast–southwest transect in the HYC deposit. Also plotted are n-alkane and branched (b-) alkane values for the W-Fold Shale (WFS) below the HYC deposit and previously reported n-alkane values for bitumen recovered from the Barney Creek Formation (BCF) (Sessions et al. 2004). (**b**) $\delta^{13}C_{PDB}$ for four n-alkanes and four PAHs with distance south from Pit 1. (**c**) $\delta^{13}C_{PDB}$ of n-alkanes recovered from five samples in the HYC deposit. Note; Size of data points in (**a**) and (**b**) and (**c**) indicates analytical uncertainty (±1σ) for replicate measurements of indicated compounds averaged across all samples

early and driven by hydrological processes that were most active in platform sediments (e. g. epeiric brine reflux).

Facies C is a finely laminated organic-rich siltstone. Its inherently higher levels of organics and framboidal pyrite imply it accumulated under anoxic bottom conditions. Of the three platform facies it was deposited in the deepest waters in intrashelf basins that were too anoxic and acidic on the bottom to accumulate significant carbonate, even hemipelagic carbonate mud did not survive on this H_2S-enriched deeper seafloor. This is the facies style that hosts the HYC ore.

The presence of an evaporite solution breccia (possible former allochthon tier) at the Myrtle-Mara contact immediately below the level of the Barney Creek Formation (Table 15.13), and evidence of a major thick regional mother salt bed at the level of the Wollogorang Formation (Fig. 15.81), suggests an alternative salt-floored halokinetic model of formation for SedEx deposits in the McArthur Basin and other SedEx entraining basins in Northern Australia. This model can only be applied to sedimentary basins with evidence of former thick salt units below the ore level, located regionally in an extensional passive margin tectonic setting at the time of mineralisation.

Analysis of underlying evaporite solution breccias and vertical changes in sedimentation style in the vicinity of the McArthur Deposit, and its equivalents in other nearby sediment thicks such as the Glyde sub-basin, suggests the various intraplatform deepwater pyritic thicks in the Barney Creek Formation where metalliferous basinal brines seeped

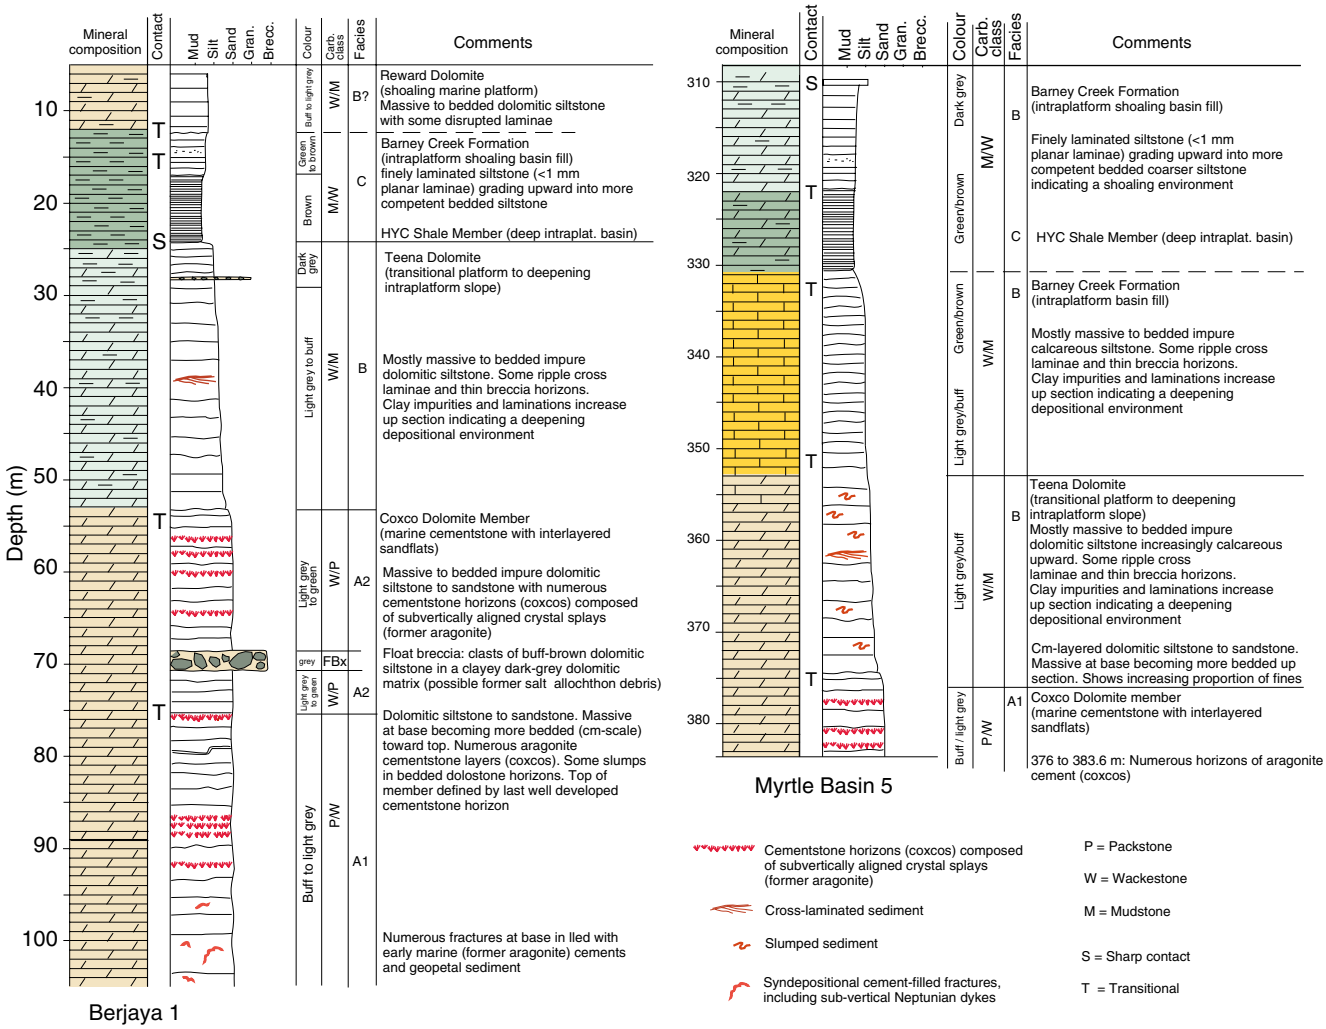

Fig. 15.85 Facies and depositional setting in the Berjaya 1 and Myrtle Basin 5 wells, McArthur Basin, Northern Territory, Australia. Facies belts are illustrated in Fig. 15.86

into local brine-filled anoxic deeps. The subsurface passage of the halite-dissolution-derived Fe-chloride rich brines that fed these pools is indicated by Fecarbonate haloes along faults and glide shears, such as portions of the Emu fault zone in the vicinity of the HYC deposit.

However, as in the peridiapiric North African deposits discussed earlier (Fig. 15.42), these ferroan carbonate haloes are not deposit or formation specific, and can be found over much wider areas than the immediate region of metalliferous laminites of the McArthur deposit. The accumulation of substantial sulphides, especially pyrite framboids formed in the early stages of sulphide accumulation, requires the presence of stable anoxic bottom brines in the deeper portions (brine sumps) of isolated depressions on the shelf floor.

Sedimentological analysis of public domain cores and well exposed outcrops in the vicinity of the HYC deposit suggests allochthonous salt sheets, such as those that define the Myrtle Mara contact (disconformity), played a role in controlling seafloor positions of ore-hosting pyritic shales. The halokinetic scenario outlined in Fig. 15.87 is one possible halokinetic scenario that can explain the regional setting of the HYC deposit. It uses a five stage model of a deforming salt allochthon in a salt entraining basin that is undergoing extensional deformation and is based upon a typical extensional margin undergoing raft tectonics (see Chaps. 6 and 9 for a full discussion of the relevant halokinetic and raft tectonics mechanisms that can form local organic-rich deeps and depopods). Salt flow settings, other than the salt-hinged platform-edge raft tectonic model given in Fig. 15.87, are also possible. Which of the various halokinetic deformation styles was the most likely requires a detailed sedimentological analysis of breccias, both beneath and within the ore deposit, to be tied to a back-stripped regional structural analysis. This requires access to proprietary company-held core and the permission to publish the results.

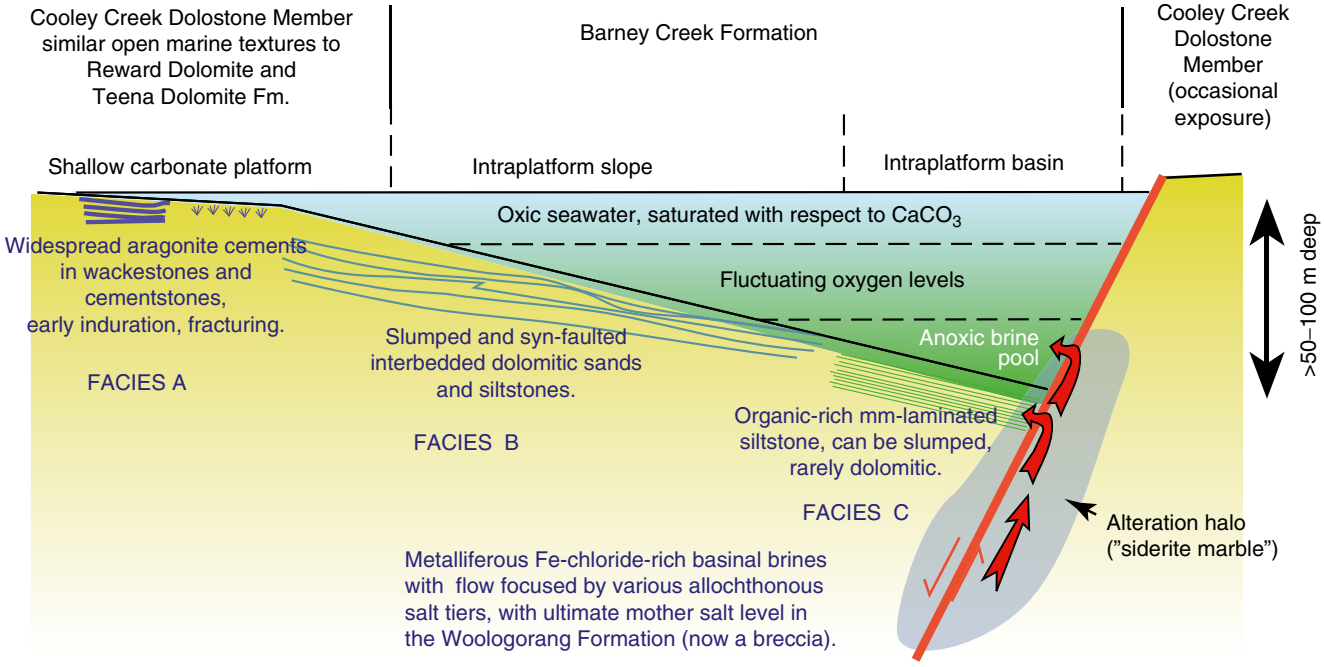

Fig. 15.86 Interpreted intra-platform deep setting for mineralised portions of the lower Barney Creek Formation. Seafloor low formed atop salt withdrawal sinks adjacent to active basin -edge fault (Based on author's work in the basin in the 1990s)

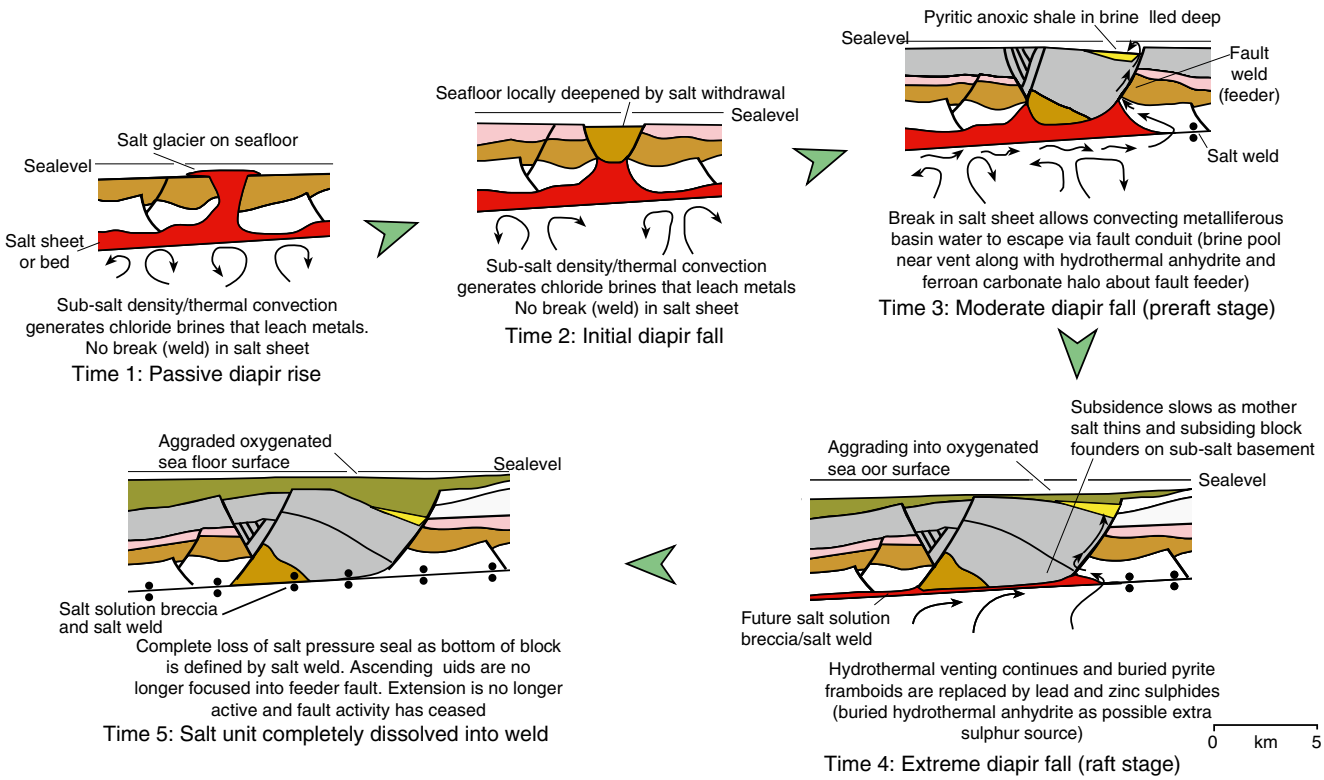

Fig. 15.87 Salt-floored extensional basin model explaining the formation of localised intraplatform brine-pool laminites in the HYC (McArthur River) deposit

For the purposes of this discussion, I will only use the salt tectonic style shown in Fig. 15.87, for the HYC deposit, it does explain:

- Underlying and syndeformational halokinetic solution breccias;
- Ongoing soft sediment extensional faulting, which breaks up the continuity of individual ore layers in the HYC deposit;
- Pyritic and organic-rich nature of the ore host;
- Localised syndepositional thickening of the Barney Creek Formation within an otherwise shallower water setting (compare Time 3 scenario with depositional setting based on sedimentological analysis shown in Fig. 15.86);
- Ferroan carbonate halo distribution about faults, especially along the intrashelf basin edge; and
- Syndepositional extensional graben structuring seen in the regional structure of HYC the deposit.

Time 1 encapsulates a typical passive diapir scenario, where the upper portion of the diapir is near, or at, the seafloor. The underlying source salt bed or allochthon is intact and acting as a pressure seal to deep basinal brines. Ongoing dissolution along its underbelly is continually supplying dense chloride-rich basinal brines into active hydrothermal convection cells. These convecting brines are leaching metals from sediments and volcanics below the salt sheet. At the surface, periodic dissolution and slumping of the allochthon carapace is creating monomict and occasional polymict sedimentary breccias atop the surrounding seafloor (facies A).

Time 2 is the falling diapir stage, where ongoing extension causes the diapir crest to fall, with the formation of a local deep atop the falling diapir crest (the bicuspidate diapir stage). The deepening of the seafloor is indicated in core by the transition from the shoal water platform carbonates of facies A to the deeper water carbonate slope deposits of facies B. Hydrothermal circulation continues unabated beneath the source salt unit (Fig. 15.86).

By time 3, ongoing basin extension has created a breach in the mother salt unit (a salt weld), which allows pressured hot Fe-rich basinal waters to escape across the weld. Their subsequent upward passage is focused into the still active zone of extension associated with the growth fault. The subsurface passage of these rising and cooling Fe-rich hydrothermal waters along the feeder fault creates replacement haloes of ferroan carbonate cement in the adjacent sediments. Cooling of these ascending waters means copper is not carried far above the level of the sealing salt bed and so does not make it to the seafloor at this early diagenetic stage of burial (see copper transport discussion in next chapter). Where these brines vent and pond as a seafloor brine pool it facilitates the formation of pyritic shales in anoxic closed deeps (facies C). The anoxic acidic bottom conditions mean that little or no carbonate matrix survives in the pelagic shale intervals.

By the end of time 3, the subsidence of the down-hinged structural block is slowing as the mother salt bed is thinning to where the bottom of the block begins to founder on the sub salt basement. Throughout time 3 and time 4, the dissolution feather-edge of the mother salt continues to focus the ascending hydrothermal brines into the main set of basin defining faults. The burial of the pyritic ore-host laminites means hotter ascending brines now have access to the pyritic laminites. The early diagenetic replacement of the pyrite and other early sulphides by coarser hotter Zn and Pb sulphides begins.

As long as the withdrawal edge of the mother salt bed continues to focus ascending hydrothermal brines, the feeder fault continues to act a focus for the ongoing subsurface influx of metalliferous basinal brine into the now shallow-buried pyritic laminites. The elevated burial temperatures associated with ongoing brine flushing facilitate the nearsurface replacement of earlier formed pyrite by Pb and Zn sulphides, driven by BSR at lower pore temperatures and TSR at higher temperatures. Any hydrothermal anhydrite initially formed near the brine vent will now redissolve and may act as an extra source of sulphur for newly forming metal sulphides. Once the mother salt mass is completely dissolved or drained from the system, then its focusing effect on fluid flow is lost and the mineralisation process becomes inactive (time 5).

At the surface, this cessation of salt-induced subsidence, or a lessening in the rate of supply of brine, means the brine pool sediment surface can now aggrade back into oxic settings (facies C to B in Figs. 15.85 and 15.86). Ultimately, pyrite accumulation on the seafloor ceases as shallower, oxygenated seafloor sediments cover pyrite-rich laminites for the last time (Time 5 in Fig. 15.87).

SedEx Deposits Within Fe-carbonate Haloes/ Hosts in the Mt Isa Inlier, Australia

In terms of zinc, lead, and silver metal endowment, the Proterozoic sedimentary basins of northern Australia, especially those in the Mt Isa Inlier, rank number one in the world (Fig. 15.75; Large et al. 2005; Murphy et al. 2011). In total the Mt. Isa-McArthur basin system hosts five supergiant, stratiform, sedimentary rock-hosted Zn-Pb-Ag deposits (McArthur River, Century, Mt. Isa, Hilton, and George Fisher) at or below greenschist grade and one supergiant strata-bound Ag-Pb-Zn deposit (Cannington) at amphibolite grade (Table 15.14). As well as some of the largest Pb–Zn stratiform deposits in the world (e.g., Mount Isa, HYC, Century), the Mount Isa Inlier hosts and also several IOCG (Iron Oxide Copper Gold) deposits (e.g., Ernest Henry, Eloise, Starra) that are discussed in the next chapter.

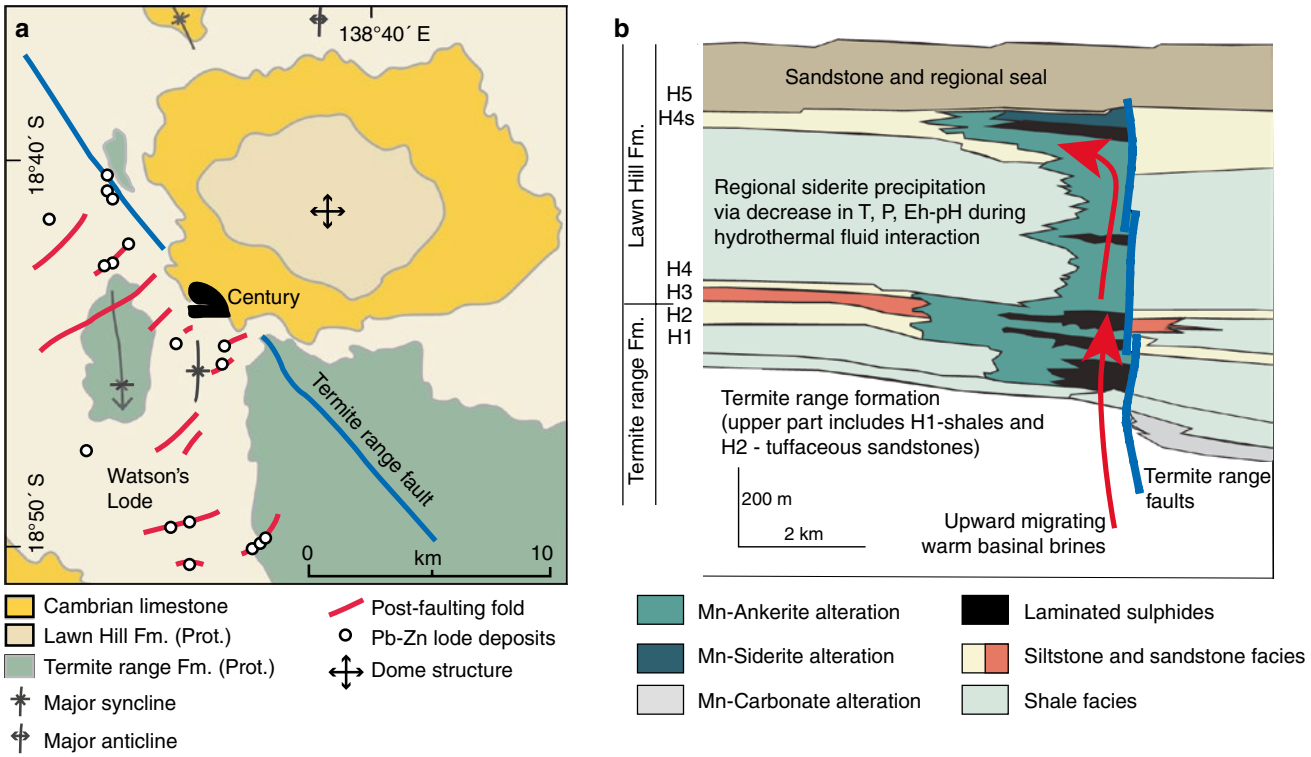

Fig. 15.88 Century deposit, Queensland. (**a**) Map view showing proximity to domal structure (interpreted as astrobleme or diapiric sag). (**b**) Model of mineralisation emphasizing fault focus to metalliferous fluid supply (After Kawasaki et al. 2010; Large et al. 2005; Pirajno 2009)

Common to almost all these economic deposits are: (1) ties to highly saline evaporitic brines, (2) the proximity of deposits and prospects to faults that were active during basin evolution (Neudert and McGeough 1996; Betts and Lister 2002) and, (3) a thick, now dissolved and altered halite unit that deformed halokinetically and gave a strong structural focus to the various mineralising events, both synsedimentary and syntectonic (see also Chap. 16 and Betts et al. 2004).

The Century deposit, Queensland, with its mineralisation hosted in deepwater sideritic siltstones, like the HYC deposit is a structurally and hydrothermally focused metal trap and like the HYC shows textures that have not been obliterated by subsequent metamorphism (Table 15.14; Waltho and Andrews 1993; Broadbent et al. 1998). It is located close to the Termite Range Fault, which was probably the major conduit for ore fluids.

Century Zn-Pb deposit is located on the west side of an interesting 20-km-diameter circular structure (Fig. 15.88a). This structure has been interpreted as a possible meteorite impact feature (Shoemaker and Shoemaker 1996; Salisbury et al. 2008) and is outlined by a brecciated Cambrian Thortonia Limestone fill. The notion of an impact crater has not been accepted by most geologists in the companies working the deposit (Salisbury et al. 2008). In my mind this circular feature, if it is an astrobleme, is unlikely to be associated with the mineralisation event as the Termite Range Fault and the mineralisation that is Century continues unabated across the edge of the circular structure. Likewise the widespread breccia textures are as easily interpreted as evaporite dissolution features as due to an astrobleme. If so, it is an indicator of the former presence of a salt-cored anticlinal dome, with the salt now dissolved. The co-occurrence of a domal feature and a fault intersection better explains the association with the mineralisation and the subsequent weathering also explains the Cambrian sag fill. Stewart (1999) discusses criteria that can be used to interpret various circular structures preserved in the rock record. A new look at how hydrothermally altered breccias formed in Century, starting with the capping breccia in the mine pit, perhaps as possible salt allochthon and rauhwacke residues, would help refine the deposit's genesis.

Century has a higher Zn:Pb ratio (6.8) than other major Australian SedEx deposits (1.2–2.9), with a geologic resource of 167.5 Mt (8.2 wt % Zn, 1.2 % Pb. and 33 g/t Ag), including a higher grade mining resource of 105 Mt (12.1 wt % Zn, 1.75 % Pb, and 46 g/t Ag; Large et al. 2005). Although the Century Deposit's hosting laminite has many depositional similarities to the synsedimentary McArthur River deposit, it's Zn-Pb mineralisation likely has a different, deeper diagenetic replacement origin, synchronous with fault-focused metalliferous fluid crossflows, perhaps driven by an episode of compression and basin inversion (Broadbent et al. 1998, 2002).

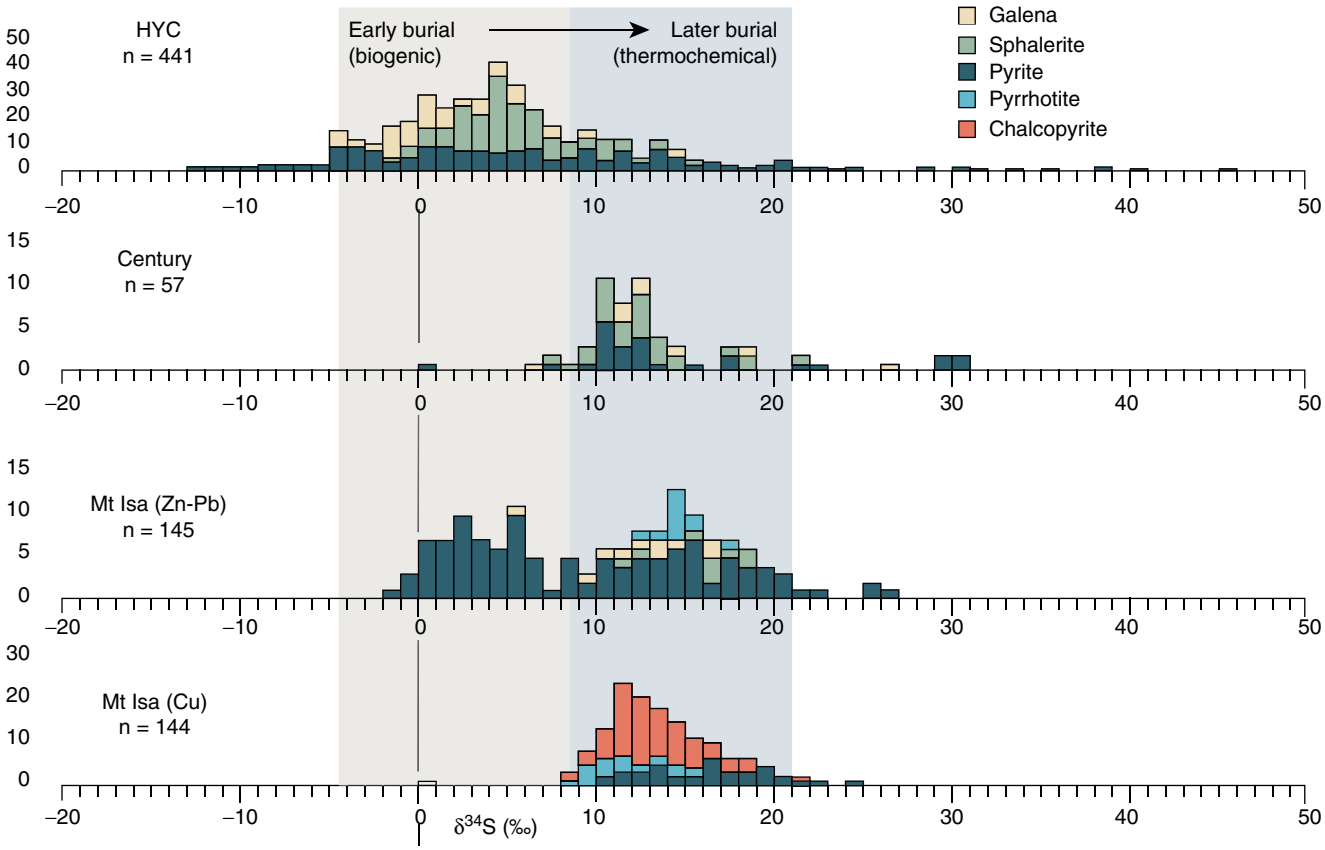

Fig. 15.89 $\delta^{34}S$ values for sulphide minerals from McArthur HYC, Century and Mount Isa Zn-Pb and Mt Isa Cu ores after Pirajno (2009) and references therein

Ore-hosting siderites were likely emplaced earlier via predominantly subsurface seepage during extension, followed by compression driven, fault-focused metalliferous basinal brine crossflows that were focused into anticline traps in their ferroan carbonate-rich deepwater sediment hosts (Fig. 15.88b; Broadbent et al. 1998; Large et al. 2005). That is, the Zn-Pb mineralisation at Century transgresses the stratigraphy, in that the higher grade zones are associated with thicker black shale host rocks (Fig. 15.88b). The deposit is spatially associated with regional-scale lode mineralisation, mainly veins and breccias within fault zones. The main ore mineral is sphalerite, of which two varieties are present: one porous and associated with abundant pyrobitumen, the other is non-porous and with a low pyrobitumen content. The intergrowth of the sphalerite with hydrocarbons, suggests that thermochemical sulphate reduction (reaction of deeper sulphate and metal-bearing fluids with liquid and gaseous hydrocarbons), took place in a burial setting and perhaps not syndepositionally (Fig. 15.88b; Pirajno 2009).

Broadbent et al. (1998) argues that the sulphate-bearing hydrothermal solutions originated from the deeper more saline parts of the basin stratigraphy and were channelled up along faults (Termite Range Fault system). The movement of fluids was driven by phases of basin inversion and regional compression. Hot fluids reacted with organic-rich sideritic shales, producing gas and liquid hydrocarbons. This led to the thermochemical reactions, which resulted in the precipitation of sulphides. Sulphur isotope systematics revealed progressively higher $\delta^{34}S$ values, from 5–10 % to 20–25 %, reflecting a closed-system hydrothermal reservoir with enrichment in heavy sulphur over the life of the mineralisation event reflecting the passage from biogenic to thermochemical sulphate reduction with increasing burial (Fig. 15.89). Illite and chlorite crystallinity variation across the Lawn Hill Platform suggest the southern part of the platform experienced higher temperatures (up to 300 °C) than similar stratigraphic horizons in the north. Much of the more intense thermal alteration is focused by fault conduits, which were active a number of times in their tectonic history (Golding et al. 2006).

There is also the obvious burial-related bimodal isotope signature of the Mt Isa Zn-Pb sulphides and the clear later burial origin of the copper sulphides there (Fig. 15.89). The sulphate bearing fluids in Century were likely derived from evaporitic rocks in the deeper parts of the basin (Broadbent et al. 1998, 2002; Pirajno 2009). What is not considered in

the existing literature in the origin of the various Proterozoic SedEx deposits of Australia is the strong likelihood of halokinetic focusing to the fluid flow from early to later burial and the importance of now dissolved salt in the extensional welds and décollements, similar to the various halokinetic examples discussed earlier in this chapter and also explains the ore distributions in SedEx deposits with host matrices now in the metamorphic realm (see Chap. 14 for a discussion of Mt Isa and the eastern foldbelt – Mary Kathleen meta-evaporite deposits).

Arid-Zone Diagenetic Uranium and Copper Associations

As well as the low temperature base metal evaporite associations that benefit from the presence of dissolving and flowing evaporites in their burial evolution there are other economic accumulations that benefit from the brine concentrating effects in near surface waters in arid evaporitic climates. They include low temperature secondary enrichment phases in uranium and porphyry copper deposits.

Duricrusts: Yilgarn Australia and Namibe, Africa

In the arid desert zone that is the northern Yilgarn of West Australia, U deposits occur in playa and paleochannel calcretes, with an intermediary third type occurring geomorphologically between the two settings, typically designated as platform or delta calcretes, often located where channel drainages enter playas (Table 15.15 and Fig. 15.90a; Noble et al. 2011). All deposits are at or near the land surface and have a similar capillary-driven genesis and ore mineralogy. They are responses to concentrative changes in shallow groundwater redox interfaces, with circulations driven by evaporation, and U-precipitates typically dominated by carnotite ($K_2(UO_2)_2(VO_4)_2 \cdot 3H_2O$). Uranium-rich secondary silica is also important locally in the mineralised zones (Fig. 15.90b). Carnotite deposits occur along the drainage systems throughout the Yilgarn region and include the world class Yeelirrie deposit (Fig. 15.91a). Other potential U-resources on the Yilgarn craton are the Lake Maitland, Centipede and Lake Way prospects (Table 15.15; Carlisle et al. 1978; Noble et al. 2011).

Uranium in the Yilgarn groundwater is sourced from granite weathering, and vanadium from greenstones and alluvial sediments (Mann and Deutscher 1978; Morgan 1993; Noble et al. 2011). Groundwater moves down gradient into the channels (Figs. 15.90 and 15.91a), where capillary evaporation occurs (both in channels and playas) and, as a result, carbonate and apatite (if PO_4 is present) precipitates. This is important for two reasons (Noble et al. 2011): (i) carbonate-rich zones will have a high-pH groundwater; and (ii) the formation of carbonate and apatite will result in the loss of P and HCO_3 from the groundwater. Both of these conditions force the reaction of the aqueous species of U, V and K and so form carnotite.

Although apatite precipitation could drive this reaction, it is a minor contributor to the carbonate formation in the Yilgarn. The role of PO_4 in the solubilisation of U is hypothesised by Noble et al. (2011) to be most important where groundwater pH is more acidic, such as the active weathering uplands (closer to the breakaway crests). Apatite precipitation is more likely near these zones and away from the carnotite mineralisation. This process will shift the pH to more alkaline and change the dominant U-bearing aqueous species from UO_2HPO_4 to $UO_2(CO_3)_2$. The arid association of the uraniferous calcretes in Australia means gypsum is often present as a gangue mineral and this can create processing problems (Pownceby and Johnson 2014). The presence of gypsum is a processing hindrance when an alkaline leach solution is used as it reacts to precipitate calcium carbonate and forms sodium sulphate in solution. A gypsum content of more than 4 % in a surficial calcrete uranium ore leads to excessive reagent consumption and sufficiently

(**b**) General model of water–rock interaction, processes and hydrogeochemistry in regions of uraniferous calcrete (After Morgan 1993)

affects processing costs to rule out the use of relatively cheap sodium carbonate-based leach solutions.

As well as the Australian calcrete examples listed in Table 15.15, significant uraniferous calcrete accumulations have been identified at the northern margin of the Namibe Erg, south-west Africa and include Langer Heinrich, Tubas Grant, and Klein Spitkoppe (Carlisle et al. 1978). The Langer Heinrich deposit became an operational uranium mine in 2007 (Fig. 15.91b). Mineralisation at Langer Heinrich consists of sub-horizontal carnotite that has been precipitated within clastic valley-fill rock units, which vary from conglomerates through grits and sands to micaceous claystone. In a general way, ore becomes finer grained with depth and hence ore from beneath the watertable is mainly micaceous claystone (Princep and Hutson 2010). The mineralisation occurs as an undulating 1–30 m thick layer, which is shaped like a subterranean meandering river. At intervals down the valley, thick "pond-like" pods of higher-grade uranium have formed. These are generally located immediately upstream of a narrowing of the valley edges. Carnotite occurs preferentially in less cemented sections of the ore but shows no relationship to any rock type in the alluvial matrix. Nor does it occur within any of the detrital clasts, whether boulder, sand, or silt size.

The uraniferous calcrete and gypcrete-hosted deposits in Namibia differ from the Australian calcrete deposits in the following ways: (1) A likely Late Tertiary age with uplift-related erosion of the upper parts of some deposits, (2) An

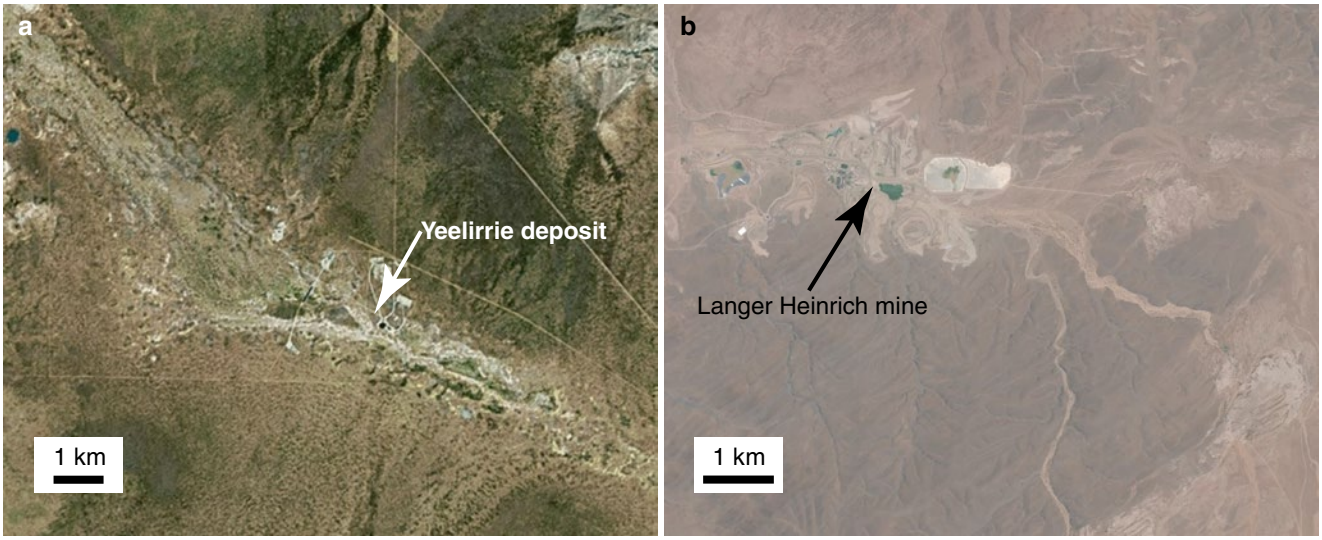

Fig. 15.91 Arid zone uraniferous calcretes. (**a**) Yeelirrie deposit, West Australia. (**b**) Langer Heinrich Mine, Namibia

abundance of coarse detrital fragments in a braidplain host, which constitute the skeletal framework of the uraniferous calcrete. Radiogenic carbonate cement typically making up around 15 % of the rock volume, (3) This carbonate cement is predominantly sparry calcite, with neither dolomite nor opaline silica as co-precipitates, (4) The presence of abundant gypsum in the upper parts of profile in occurrences within 60 km of the Atlantic and the gypsum is probably marine saltspray derived (Chap. 2), and (5) A vertical gradation upward into pedogenic sheet calcrete and gypcrete (perhaps indicative of the greater age compared to the Yilgarn deposits).

Reasons for the coarse detritus host in Namibe are: (1) the very appreciable relief between the Great Western Escarpment, with hinterland elevations in excess of 2,000 m in the Khomas Hochland, and the broad coastal platform (lowland) of the central Namib Desert and, (2) the relatively modest degree of chemical weathering in the basement compared to the deep sapropelic weathering in Australia. Namibian calcretes do not typically develop abundant dehydration or shrinkage cracks, and unlike the Australian calcrete hosts, the lack of current microporosity means they today are not as permeable aquifers, though locally there can be appreciable permeability. In several places, irregular open solution tubules and replacement bodies about the size of a finger, but sometimes much larger, have developed in the calcrete. Commonly, the tubules have a shell of impure calcite and a sandy porous filling, which, under some conditions, is richly mineralized with carnotite. Owing to the higher gradient setting of the local and regional hydrology draining toward the coast, Namibian uraniferous-calcretes do not seem to occur preferentially in playa or saline delta settings.

When comparing deposits between the two regions, the marked process similarities are obvious (Fig. 15.90). Interestingly, the Langer Heinrich mine, the richest of the various known Namib examples, is located in a definite valley constriction. First and foremost is the required combination of groundwater and aridity to drive capillary concentration of the uraniferous salts, and the co-precipitation of evaporitic capillary salts. Lateral transport of uranium in brackish to increasingly saline groundwater in the outflow sump is essential to ore deposition in both regions, as is the presence of bedrock barriers or constrictions in order to narrow the channel of subsurface flow, and act as sills. This forces the groundwater to pond and so move closer to the land surface, where it is subject to evaporation and loss of dissolved CO_2. In both regions the larger part of all valley calcretes and gypcretes are unmineralized. Ore-grade mineralization is roughly horizontal in attitude and related to capillary concentration of shallow past or present groundwater tables. Source rocks in both regions are weathered Proterozoic to Archaean migmatites, pegmatites, alaskites, and granites; many are "hot" sources, that is, they are already appreciably enriched in uranium. Lastly and most significantly, deposits in both areas could not form without evaporitic ground conditions. The uranium salts in both regions are true evaporite salts in the same way that capillary anhydrite and capillary halite are true evaporite salts.

Porphyry Copper, Supergene Enrichment and Aridity

Porphyry copper deposits are well developed in the in the Atacama Desert of northern Chile, where supergene enrichment is considered to be the principal factor in making this region the greatest producer of Cu in the world. Classic

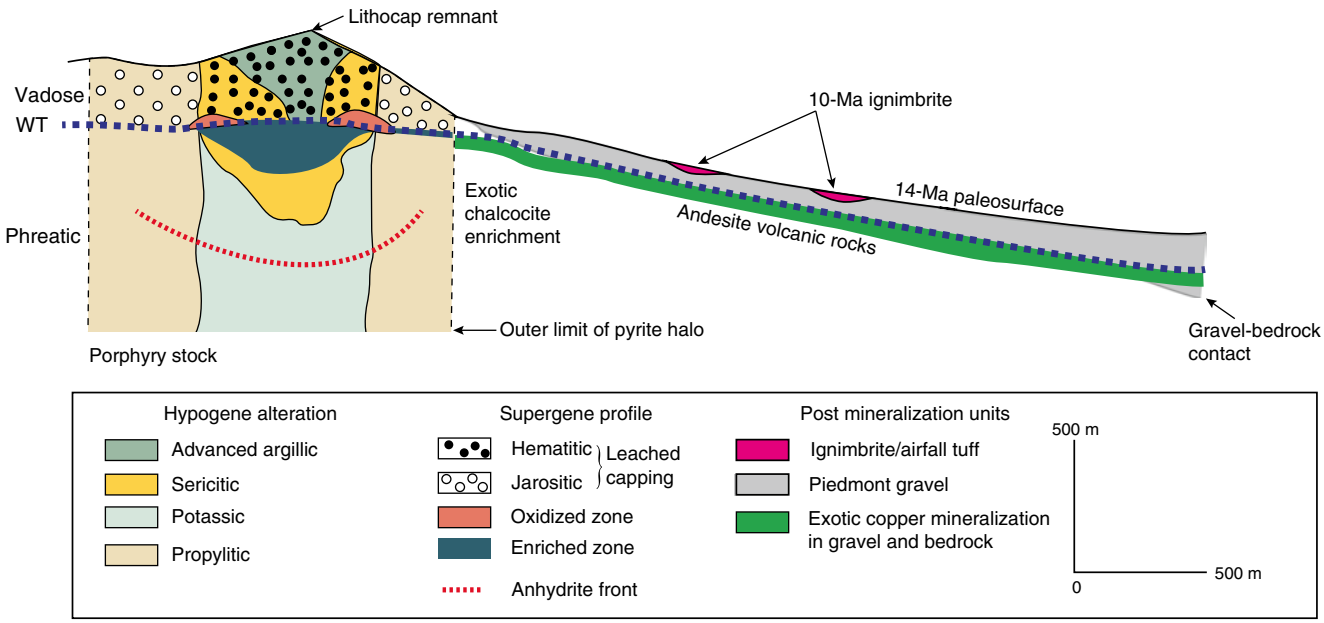

Fig. 15.92 Mature supergene profile based on porphyry copper deposits in northern Chile (After Sillitoe 2005). Position and configuration of leached capping (patterned) and the enriched sulphide ore zone (*dark green*) are controlled by relatively unreactive advanced argillic and sericitic alteration. Copper oxide ore is stabilized by higher pH fluid in outer potassic and inner propylitic alteration zones. Position and configuration of exotic chalcocite enrichment and exotic copper oxide mineralization in gravel and bedrock are controlled by the pyrite halo and paleo-watertable. Anhydrite front defines depth above which anhydrite has been leached

models argue that supergene enrichment was driven by the exposure of Cu sulphides to the effects of oxidative weathering during times of moderate precipitation (Fig. 15.92; Sillitoe 2005; Sillitoe and McKee 1996). Thus, the development of porphyry copper "giants" in the Atacama Desert is strongly coupled to climatic evolution. Isotopic dating of supergene minerals, principally alunite group minerals, has shown that supergene enrichment in the Atacama occurred over a long period from ~45 to 9–5 Ma, possibly reaching a maximum at 14–21 Ma (Reich et al. 2009).

Supergene enrichment is traditionally believed to have ceased when semi-arid conditions in the Atacama, with significant pluvial precipitation periods, changed to hyperarid. However, there is no consensus about the onset of hyperaridity, which may have commenced as early as 25 Ma and even extend back to the Triassic (Clarke 2006). If this is so, then Cu enrichment may not be driven solely by periods with relatively abundant fresh meteoric waters. There may be as aspect of Cu concentration in the Atacama that is associated with more saline groundwaters.

Recent geochemical and isotopic studies reveal that atacamite ($Cu_2Cl(OH)_3$), a major constituent of supergene Cu-oxide zones in Chilean deposits and co-associated with capillary gypsum, formed within the last few million years (Palacios et al. 2011; Reich et al. 2009). Atacamite is a product of the upward flow of saline basement waters through the pre-existing oxide zones, focused along active faults and has been preserved in the hyperarid climate prevailing since that time. If this is so then, as suggested by Clarke (2006), supergene enrichment is tied to periods of landscape uplift and dissection, not to landscape stability. Such periods of uplift in the Andes would drive a relative fall in the watertable and vadose (supergene) mineral cycling independent of the transition to hyperaridity.

It seems that in the hyperarid sediments of the Atacama desert the distribution of copper minerals is controlled by a combination of evaporatively driven "*per ascendum* and *per descendum*" hydrologies. The first stage of supergene oxidation peaked between 21 and 15 Ma as the result of percolating oxygenated meteoric waters in a semi-arid setting. This was followed by a second stage of supergene oxidation where atacamite formed from uprising basinal brines and subsequently preserved under hyper-arid conditions for at least the last 2 Ma.

Evaporitic high-altitude low-temperature conditions are not directly involved in the formation of porphyry copper accumulations, which are formed by a combination of igneous emplacement and hydrothermal circulation (John et al. 2010). But the transition from semi-arid to hyperarid climates in Chile were responsible, first for supergene enrichment and then for preservation of the resulting deposits, along with ongoing deposit enrichment. Understanding the history of Neogene aridity, responding to uplift/adiabatic climate is a significant component in understanding ore distribution in high-altitude arid-zone porphyry copper deposits (Fig. 15.92).

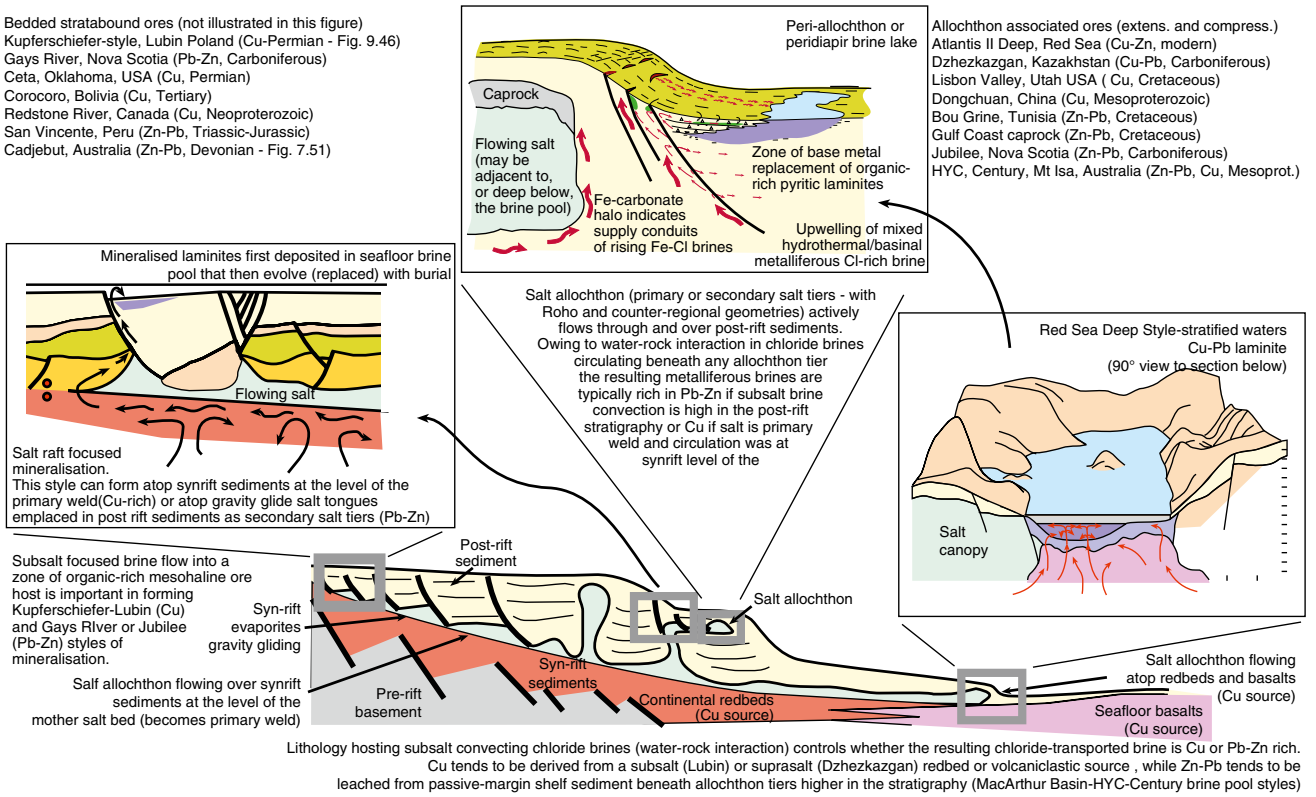

Fig. 15.93 Base metal associations in the context of a salt allochthon terrane (After Warren 2000b)

Base Metals, Evaporites and Diagenetic Accumulations: A Summary

Many low-temperature base metal deposits in evaporite entraining sedimentary basins can be related to the presence of preserved evaporites or indicators of the former presence of evaporites, such as bedded and halokinetic breccias, chert nodules and other indicators of "the evaporite that was" (Fig. 15.93). The link is either direct, with metal accumulation at the site of the present or former evaporites, especially calcium sulphate beds; or indirect, from ascending hypersaline fluids supplied from a dissolving mother salt bed via a single or a series of feeder faults. Thus mineralisation can be subsalt, intrasalt, or suprasalt and the salt, or its breccia, can be bedded or halokinetic. In many cases the H_2S that causes the ore to precipitate at the redox interface is derived from bacteriogenic or thermochemical reduction of nearby evaporitic sulphate in combination with organics supplied by hydrocarbons ponded beneath an evaporite seal (Table 15.2).

The diagenetic evaporite-base metal association includes world class Cu deposits, such as the Kupferschiefer-style Lubin deposits of Poland and the large accumulations in the Dzhezkazgan region of Kazakhstan. The Lubin deposits are subsalt and occur where longterm dissolution of salt in conjunction with upwelling metalliferous basin brines created a stable redox front, now indicated by the facies of the Rote Faule. The Dzhezkazgan deposits (as well as smaller scale Lisbon-Valley style deposits) are suprasalt and formed where a dissolving halite-dominated salt structure maintained a structural focus to a regional redox interface. It also drove the circulation system whereby metalliferous saline brines leached adjacent redbeds. In both scenarios the resulting sulphides are zoned and arranged in the order Cu, Pb, Zn as one moves away from the zone of salt-solution supplied brines. This redox zonation can be used as a regional pointer to both mineralisation and, more academically, to the position of a former salt bed. In the fault-fed suprasalt accumulations the feeder faults were typically created and maintained by the jiggling of brittle overburden blocks atop a moving and dissolving salt unit. A similar mechanism localises many of the caprock replacement haloes seen in the diapiric provinces of the Gulf of Mexico and Northern Africa.

Evaporite-associated Pb-Zn deposits, like Cu deposits, can be associated with both bedded and halokinetic salt units or their residues. Stratiform deposits such as Gays River, Cadjebut and Nanisivek, have formed immediately adjacent to or within the bedded salt body, with the bedded sulphate acting as a sulphur source. In diapiric deposits the Pb-Zn mineralisation can occur both within a caprock or adjacent to the salt structure as replacements of peridiapiric organic-rich

pyritic sediments. In the latter case the conditions of bottom anoxia that allowed the preservation of pyrite were created by the presence of brine springs and seeps fed from the dissolution of nearby salt sheets and diapirs. The deposits in the peridiapiric group tend to be widespread; but, in Phanerozoic strata, the individual deposits are relatively small and mostly subeconomic. However, the fluid flow and brine pool mechanisms, as well as models of replacement haloes in bottom brine sediments, can be used to model larger counterparts within Proterozoic settings for which there are no modern analogs. This notion is developed further in the next chapter.

In all the deposits discussed in this chapter there are four common factors that can be used to recognise suitably prepared ground and so improve exploration models:

- A dissolving evaporite bed acts either as a supplier of chloride-rich basinal brines capable of leaching metals, or as a supplier of sulphur and organics that can fix metals.
- Where the dissolving bed is acting as a supplier of chlochloride-rich brines, there is a suitable nearby source of metals that can be leached by these basinal brines.
- There is a redox interface where these metalliferous chloride rich waters mix with anoxic waters within a pore fluid environment that is rich in organics and sulphate/sulphide/H_2S.
- There is a salt-induced focusing mechanism that allows for a stable, longterm maintenance of the redox front, e.g. the underbelly of the salt bed (subsalt deposits), a dissolution or halokinetically maintained fault activity, the overburden (suprasalt deposits), a stratiform intrabed evaporite dissolution front (intrasalt deposits).

Most important is the notion that the sulphide orebodies that form at the redox interfaces can remain long after the actual salt units have dissolved or evolved into metaevaporites. To an explorationist trained in the recognition of former salts, the indicators remain visible and act as pointers to zones of structural or diagenetic foci for the mineral-depositing redox system. When such zones are recognised, and placed within the regional framework or basin architecture, then particular zones or lithologies of interest are quickly defined and suitable for more intense exploration.

Magma-Evaporite-Hydrothermal Metal Associations

16

Introduction

Metalliferous fluid indicators and ore deposits due to direct and indirect interactions between magma and evaporites at a regional scale are neither well documented, nor well understood. Mostly, this is because little or no actual salt remains once these high temperature interactions have run their course. On top of that, some hard-rock geologists with a career working in igneous and metamorphic terranes may not be well versed in sedimentary evaporites or their meta-evaporitic siblings. The term pyrometasomatic encompasses some, but not all, of the types of salt-magma interaction that are the focus of this chapter.

For the purpose of our discussion, styles of evaporites interacting with magma to form various economic metal accumulations are divided into two; (1) orthomagmatic (salt-assimilative and internal to the magma), and (2) paramagmatic (salt-interactive and external to the magma). Both outcomes, which include a variety of substantial ore deposits, are typically inferred not from the presence of evaporite salts, but from chemistry and mineralogy of the reaction products. Only where igneous sills and dykes have intruded salt masses, with contacts preserved, can direct effects of magma-salt interaction be documented.

Orthomagmatic and paramagmatic associations are distinct from occurrences of primary igneous/magmatic anhydrites, which precipitate from sulphate-saturated melts, as in the anhydrite crystals crystallised in trachyandesitic pumices erupted from El Chichón Volcano in 1982, dacitic pumices erupted from Mount Pinatubo in 1991 and acidic lavas in the Yanacocha district of northern Peru (Luhr 2008; Chambefort et al. 2008). They are also distinct from fumarolic anhydrite, which precipitates where groundwaters and sulphur-bearing magmatic fluids interact, as on Usu Volcano, Hokkaido, many central American and Andean volcanoes, including El Laco (Zimbelman et al. 2005). Likewise, they are distinct from the anhydrite precipitates (white smokers) in and below submarine vents across numerous mid-oceanic ridges (Humphris et al. 1995).

Fumarolic and vent (white-smoker) anhydrites can form significant anhydrite masses that in the subsurface can be confused with metasedimentary anhydrite, and so are discussed in some detail later in this chapter. Primary magmatic anhydrites are interesting in terms of defining particular magma chemistries, but do not form anhydrite in significant volumes and so are not discussed in detail. The maximum amount of sulphur (S) that can be dissolved in silicate melt is controlled by saturation of the melt with an S-bearing phase (Fig. 16.1a). At relatively low oxygen fugacities, this phase is either an immiscible iron-rich sulfide liquid (with as much as 10 % oxygen), which occurs in high-temperature basaltic melts, or crystalline pyrrhotite ($Fe_{1x}S$) in intermediate (andesitic) and silicic (rhyolitic) melts. A Cu-Fe sulfide mineral known as "intermediate solid solution," may also crystallize from andesitic to rhyolitic melts. At higher oxygen fugacities, anhydrite crystallizes from a wide range of melt compositions. Silicate melts at intermediate oxygen fugacities can crystallize both pyrrhotite and anhydrite, an assemblage that occurs in the trachyandesite tephra from the 1982 eruption of El Chicho'n in Mexico. The interested reader is referred to Luhr 2008 for a comprehensive discussion of primary igneous anhydrites and their chemistries.

Orthomagmatic ore deposits, tethered to the assimilation of evaporite masses into a magma, form prior to complete solidification of the igneous melt. That is, potential ore-forming liquid magmas assimilate salts and then fractionate/metasomatise *in situ* into ore segregations, before solidus. In contrast, paramagmatic-hydrothermal ore deposits form external to the melt. They are produced by country-rock/basinal brine interactions with magmatically-derived or thermally-driven super- or sub-critical fluid circulation under a general grouping sometimes called hydrothermal alteration.

Base metal sulphides (Ni, Cu) oxides (magnetite, ilmenite, chromite) and many ores of the precious metals (Au, Pt, Pd) are typical orthomagmatic ores in ultramafic and mafic igneous rocks (Pohl 2011). Less often, various magnetite-hosted ores occur in intermediate and silicate melts.

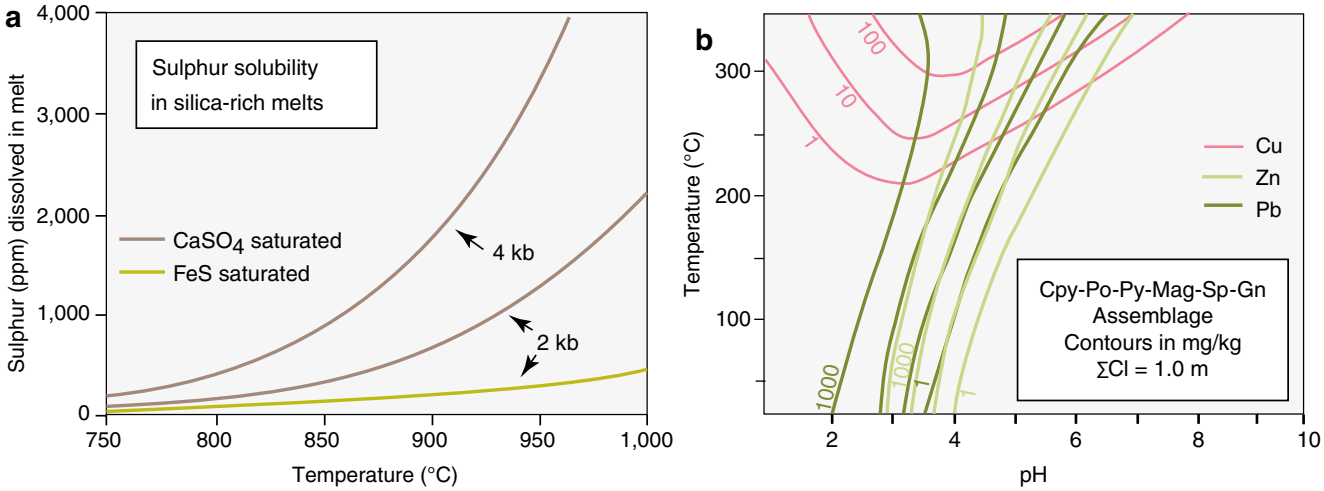

Fig. 16.1 Sulphur carrying capacity. (**a**) Experimental determinations of sulfur solubility versus temperature for hydrous silica-rich melts at different pressures and oxygen fugacities. (**b**) Sulphide solubility patterns due to chloride complexing. Calculated total metal concentrations (in $mg \cdot kg^{-1}$) in a 1 m solution in equilibrium with a chalcopyrite-pyrite-pyrrhotite-magnetite-sphalerite-galena assemblage. Note that the sulphur content of the solution ranges from <<1 $mg \cdot kg^{-1}$ at low pH and low temperature to >10,000 $mg \cdot kg^{-1}$ at high pH and high temperature. The isothermal decrease in chalcopyrite solubility with decreasing pH at low pH is due to the decrease in activity of Cl- as the relative proportion of chloride complexed with metals increases (After Lydon 1984)

Orthomagmatic deposits show ore textures that indicate precipitation at magmatic temperatures, while the adjacent melt was essentially liquid. These ores form as various types of fractionation segregates and cumulates, with fluctuating levels of "filter pressing" in the magma chamber. As such, many orthomagmatic ores are located within intrusive masses, but there are notable extrusive examples, like the Ni-Cu-Fe-sulphides of the Archaean Greenstone belts of the Yilgarn craton in SW Australia and the magnetite-haematite lavas and tuffs in andesitic-rhyolitic volcanoes in Chile, Mexico and Pakistan.

Paramagmatic deposits are related to solutions and gases segregated and generated by magmas containing more dissolved volatiles (H_2O, CO_2, S, B, F, Li, Cl etc.) than the proportion that can be accommodated by silicates during their crystallisation. These volatile-rich fluids tend to convectively circulate in the adjacent country-rock strata and can drive alteration haloes, as well as produce further heat-generated volatiles and mineral phases via heating and interacting with labile phases in the country rock. Mineralogies in the country rock are indicative of the chemistry of the interacting lithologies and the parent (including juvenile) fluids. Compared to ores tied to orthomagmatic deposits, this style of deposit is more subject to controversy in terms of genesis and the relative contributions of magmatic versus country-rock volatiles and/or basinal brines.

Worldwide, the majority of paramagmatic and orthomagmatic ore deposits are likely not tied to evaporite interactions; but once again, as in previous chapters, in this chapter we will focus on those that are (Table 16.1). The single most important point that comes out the various deposit analyses in this chapter, is that the presence of evaporites once again enhances ore volumes, not creates them. It does so by increasing metal transport efficiency and/or precipitative focusing, rather than directly spawning a metalliferous ore deposit. As in the previous chapter, the role of evaporites is to create and enhance the metal carrier system and to locally contribute reductants that can fix various metal sulphides and oxides. For example, such sulphate evaporite enhancement explains the large ore volumes in the orthomagmatic supergiant Noril'sk Ni-Cu deposit in Siberia and the paramagmatic supergiant Muruntau gold deposit of Uzbekistan (Li et al. 2009; Wilde et al. 2001)

In elucidating the igneous-ore-evaporite association, we shall use a framework of direct and indirect magma interactions with basinal fluids and sediments, with an emphasis on outcomes in systems where bedded or halokinetic evaporites were present. Purely orthomagmatic interactions (assimilations) of evaporites are discussed separately from paramagmatic interactions, but in the real world the two styles can be co-occurrent. From this, and observations of pervasive diagenetic iron mobility within halokinetic systems, as documented in the previous chapter, we shall attempt to define criteria indicative of former evaporite interactions in various evolving igneous-driven mineralised systems.

We already know from our discussions of meta-evaporites and low temperature stratabound mineralisation that, by the time a rock attains the elevated temperatures and pressures that define the igneous-emplacement realms, most sedimentary salts have been pervasively altered and transferred into basinal fluids or chloride-sulphate meta-evaporites. Before we consider the various economic deposits created by the

Table 16.1 Selected orthomagmatic examples that illustrate some of the many possible styles of evaporite-igneous interactions

Unit, location and age	Character	Reference
Crustal silicocarbonatites (515–504 Ma) in southern Madagascar	Pegmatites and associated syenites crystallised from immiscible silicocarbonatitic and peralkaline syenitic melts in the final extensional phase of the Panafrican continental collision and connected metamorphic/metasomatic events. The studied pegmatites and genetically associated syenitic rocks are very rare examples for crustal silicocarbonatitic melts generated in a Panafrican collisional setting. Model T-Nd ages suggest that the melts were produced by partial melting of 3.5 Ga partially evaporitic continental crust	Morteani et al. (2013)
Salts in southern Yakutian kimberlites, Siberia (≈360 Ma)	Alkali carbonates, sodalite, gypsum, anhydrite, halite and sylvite are present in the groundmass and matrix of many kimberlites in the southern part of the Yakutian kimberlite province. In the global context, southern Yakutian kimberlites are unprecedented in the amount of the crustal carbonate and evaporite material included in the pipes, as evidenced by the bulk major element chemistry and isotopic compositions of Sr, C, O, Cl and S. The kimberlites were emplaced through 2 km-thick section of evaporite-bearing carbonate sediments, saturated with hypersaline brines	Kopylova et al. (2013)
Cihai diabase in the Beishan region, NW China (128.5 Ma)	Diabase dykes in Cihai, Beishan region, NW China are spatially and temporally associated with Cornwall-type iron deposits. The iron-rich fluids were derived from deep sources, and the iron ores were concentrated through a convection cell driven by temperature gradients established by the intrusion of the diabase sills. The deposits are the result of the combined processes of subduction-related enrichment in the source, shallow depth of emplacement, and the involvement of large-scale circulation cells of basinal brines from an evaporitic source	Hou et al. (2013)
Gabbros of the Pasveh pluton, NW Iran (≈40 Ma)	Pasveh gabbros can be divided into two groups: free scapolite and scapolite-bearing gabbros. Two stages of metasomatism affected the primary composition of mafic rocks. Firstly, high temperature reactions inverted primary high-Ti clinopyroxene to low-Ti clinopyroxene + high-Ti amphibole. This reaction was extensive and included all gabbroic samples. Hydrothermal fluids involved in this process were derived by dehydration reactions of country rocks or from other magmas incorporated in the formation of Pasveh complex pluton. The second metasomatic stage relates to scapolitization of limited parts of gabbroic rocks. An external saline fluid, which is composed dominantly of NaCl and minor KCl and P2O5 components, impacted locally on Pasveh gabbros and formed the second metasomatic stage. Likely sources of Na and Cl were primary evaporites or hypersaline basinal brines, which were present in the host sediments of the gabbros. The carbonate-free nature of these hydrothermal fluids suggests that hydrothermal fluids responsible for the formation of scapolite in Pasveh gabbros are derived mostly from a marine evaporite parentage	Mazhari et al. (2011)

interactions of salts with magmas and related fluids, we need to define the basics of metal transport in higher temperature fluids associated with igneous emplacement, namely; hypothermal (300–700 °C), mesothermal (200–300 °C) and epithermal (50–200 °C).

Metal Transport in the High Temperature Saline Realm

In Chap. 15 we discussed the transport and precipitation of Pb, Zn and Cu in relatively low-temperature diagenetic hydrothermal settings, with a stratabound sediment host to the mineralisation at temperatures < 200–250 °C, encompassing the mesothermal and epithermal and the lower temperature portion of the hydrothermal range. A hydrothermal mineral deposit tends to form via precipitation of ore and gangue minerals in fractures, faults, breccia openings, or other permeable spaces. It is typified by replacement textures or open space fillings, fed by aqueous fluids ranging in temperature from 50 to 700 °C, but generally below 400 °C, under pressures in the range 1–3 kilobars. Parent fluids are of diverse origins and varying degrees of alteration in the host rock are common.

Once the metamorphic and igneous realms are entered, temperatures of subsurface/hydrothermal waters interacting with an evaporite mass can be well above 300 °C and cool into the mesothermal and epithermal range, either with distance from the molten mass, or with time. At these high temperatures and pressures, hypothermal fluids can be chloride-rich independent of the involvement of dissolving evaporites. But hydrothermal fluids are especially chloride-rich if the interacting country rock was originally halite-rich (Henley 1973; Yardley and Graham 2002). The resulting hot chloride brines are capable of transporting Fe, Cu, Au, Pb and Zn over considerable distances (Figs. 16.1b and 16.2)

Like Cu, Pb and Zn, the solubility of gold increases with temperature in both chloride and bisulphide complexes

(Fig. 16.2a; Williams-Jones et al. 2009). The relative importance of temperature change in gold transport and precipitation is poorly understood, as temperature interacts with other known transport parameters, such as pH and fO_2, either of which may exert a greater influence on precipitation than temperature or salinity fluctuations, especially in mesothermal and epithermal temperature ranges (Fig. 16.2b; Williams-Jones et al. 2009).

The relevant transport reaction equation for chloride complexes carrying gold at higher temperatures (>350 °C), and influenced by the presence of dissolved or altered halite is (Fig. 16.2a; Williams-Jones et al. 2009);

$$4AuCl^-_2 + 2H_2O = 4Au^{(0)}_{(s)} + 8Cl^- + 4H^+_{(aq)} + O_2$$

This reaction indicates gold precipitation within this part of the hydrothermal temperature range is from a chloride carrier. Precipitation is driven by a lowering of temperature, a decrease in salinity (lowering of aCl^-) or a decrease oxygen fugacity (fO_2); all of which can be tied to zones of fluid mixing (between less saline and more saline hydrothermal or basinal brines; Simon et al. 2005). At lower temperatures (mesothermal, epithermal), where bisulphide transport is more typical, gold is thought to precipitate via an increase in pH, which is often tied to boiling and the loss of volatiles (Fig. 16.2b).

When chloride-dominant hot basinal brines are part of the gold transport system, then changes in pH can also be related to changes in hydrocarbon levels in the pore fluids, as well as to more classic consideration of changes related to redox/pH interfaces. This the case in the fine-gold deposits in the shale-hosted Carlin-type gold deposits, such as those of the Alligator Ridge District, Nevada and other sediment-hosted orogenic gold deposits (Large et al. 2011). Precipitated gold at Alligator Ridge retains penecontemporaneous inclusions of hydrocarbons within a hydrothermally altered host rock, made up of the strongly decalcified, silicified, and collapse-brecciated Mississippian to Devonian Pilot Shale (Hulen and Collister 1999).

High temperature chloride transport has created a large group of Proterozoic Cu-Au deposits emplaced in igneous masses surrounded by meta-sediments in Australia, Scandinavia and elsewhere and sometimes classified under the broad umbrella of iron-oxide copper gold (IOCG) deposits. Many of the metasediments in these systems show evidence of the former presence of evaporites. All show inclusion and isotopic characteristics that indicate hydrothermal transport of Cu and Au via hot chloride-rich brines and, by association, their relative lack of pyrite. As such, this group of deposits can be distinguished from the more typical lower temperature sediment-hosted orogenic gold deposits and the pyritic epithermal and VHMS deposits of the Phanerozoic and Archaean.

Lower salinity mesothermal hydrothermal waters are capable of entraining abundant sulphur, and so typically transport and deposit gold in equilibrium with pyrite or pyrrhotite and arsenopyrite (Fig. 16.3). If nearby sedimentary or

(**a**) Gold solubility (in terms of molality, m, and parts per billion) and speciation at 1 kbar as a function of temperature for an aqueous solution containing 1.5 molal (m) NaCl and 0.5 m KCl, with pH buffered by the assemblage K-feldspar–muscovite–quartz. ∑S (total S) = 0.01 m and fO_2 (oxygen fugacity) is buffered by the assemblage hematite–magnetite. (**b**) ∑S and fO_2 are buffered by the assemblage pyrite–pyrrhotite–magnetite; the maximum value of ∑S is 0.1 m. The black line (∑Au) indicates the total solubility of gold. C) Gold solubility (in parts per billion; solid grey lines) and speciation at 500 bar and 250 °C as a function of log fO_2 and pH in a solution containing 1 m NaCl with ∑S = 0.01 m. The solid black lines separate regions of predominance of H_2S, HS^-, SO_4^{2-} and HSO_4^-. Regions of high solubility are highlighted in *yellow* and *red* (After Williams-Jones et al. 2009)

metasedimentary sulphate evaporites are bathed by these waters, then the dissolving evaporite can contribute sulphur to the transport complex. Gold in VHMS (volcanic-hosted massive sulphide) deposits typifies this sulphur system and Au is transported as lower temperature sulphidic ligand complexes (Davidson and Large 1994). Thermal waters supplying such pyritic mesothermal deposit styles typically have temperatures of 200–300 °C, are reduced H_2O-CO_2-CH_4 waters, with relatively low salinities and typically not associated with basinal brines. Rather, they are associated with prograde precipitation of somewhat ephemeral but massive hydrothermal anhydrite haloes (see later).

Iron Oxide Cu-Au (IOCG) systems are typified by initial temperatures at the upper end of the hydrothermal spectrum where chloride transport dominates (Fig. 16.3). They typically show a marked lack of iron sulphides; rather, they are associated with iron oxides and significant quantities of Cu, along with other chalcophile elements such as U, REE, Bi, Co and Mo, all metals that can be carried in high-salinity chloride brines (Davidson and Large 1994; Williams-Jones et al. 2005). Inclusion studies show these deposits generally precipitate from high salinity (15–35 wt. % NaCl equiv.), low total sulphur (a_{SS} = 10^{-3} to 10^{-2}), high fO_2 hydrothermal fluids (Fig. 16.3). But, as mentioned earlier, high salinity fluids in the igneous realm do not necessarily mean an evaporitic parent; we shall discuss this in more detail when we look at IOCG systems later in this chapter.

Regional Orthomagmatic- Evaporite Interactions

Fe-rich examples related to the assimilation of evaporites into a magma are numerous and well documented in the Phanerozoic, others, associated with Cu-Ni deposits, are more contentious. When substantial halite-rich masses are absorbed into a magma body, the response is a more sodic chemistry and the precipitation of a number of chloride daughter products. Likewise, a more sulphidic magma results, when substantial volumes of anhydrite are assimilated. For example, the

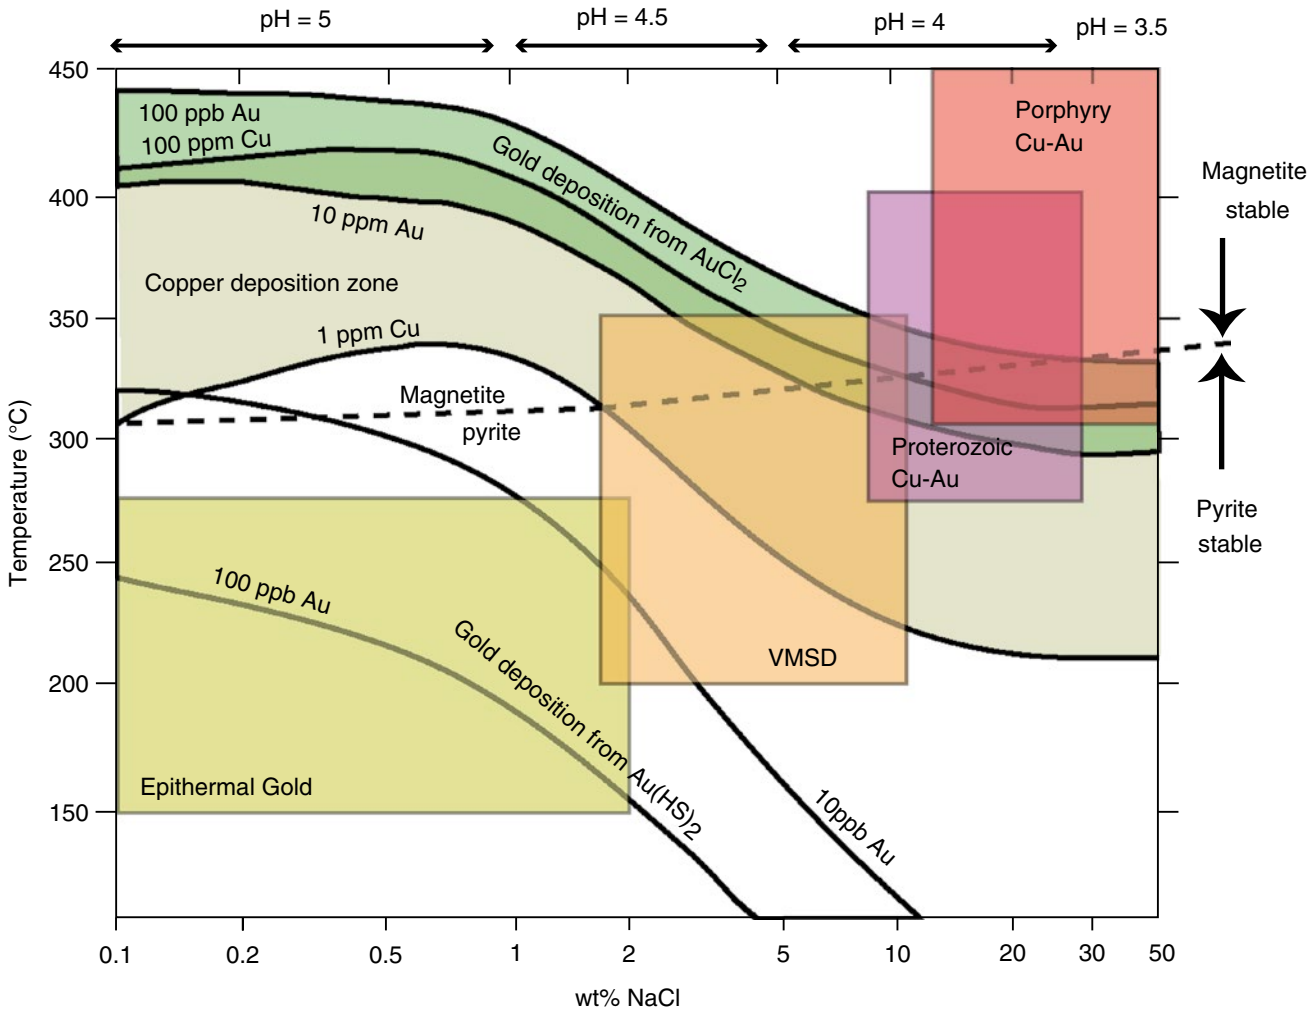

Fig. 16.3 Copper and gold controlled by temperature and NaCl content (After Davidson and Large 1994)

15 m thick alteration aureole off the main Kharaelakh shoot in the Noril'sk deposit contains; high-Ti (up to 10–11 wt.% TiO_2) biotite and phlogopite with significant contents of F and Cl, apatite (from F-containing to Cl-rich (5–7 wt.% Cl)), brown green hornblende (pargasite; an amphibole group mineral with formula $NaCa_2(Mg,Fe_2^+)_4Al(Si_6Al_2)O_{22}(OH)_2$), anhydrite, and Cl-containing alkaline sulphides such as djerfisherite $\{K_6Na(Fe^{2+},Cu,Ni)_{25}S_{26}C\}$ and bartonite $\{(K,Na)_{5.68}(Fe,Cu,Ni)_{20.27}S_{26}(S,Cl)_{0.93}\}$ (Spiridonov 2010)

But in terms of recognising a mineralogic outcome indicative of evaporite assimilation, it can difficult to unequivocally define the precursor to a final rock product alteration halo for high levels of sodium and sulphur and chloride can characterise many magmas, especially in the later stages of solidification (solidus) without any evaporite input to the magma chemistry. Published examples where evaporites have been recognised as playing a role in the final product include (Table 16.1): (1) the assimilation of salts or brines from Triassic evaporites in the polymetallic Sb-As-Au-W deposits hosted in granodiorites at Dubrava, in the Western Carpathians (Chovan et al. 1995); (2) Evaporite-derived solutions that played a significant role in forming the Saint-Salvy vein-hosted Zn (+Ge) deposit on the southern margin of the late Variscan Sidobre Granite (Munoz et al. 1994). (3) Creation of scapolite-bearing gabbros in the Pasveh gabbros of the northwest Sanandaj-Sirjab zone of Iran (Mazhari et al. 2011).

Wherever an intrusive magma body comes into contact with calcium sulphate-entraining sediments, the interaction can facilitate the precipitation of sulphide-associated metals, which may already be in solution within the pores of the adjacent sedimentary system. For example, when igneous trap intrusives interact with sediments containing hydrocarbon-water-sulphate-carbonate at temperatures of 100–700 °C, the sulphates and carbonates in a skarn typically decompose to form large volumes of hydrogen sulphide and carbon dioxide, respectively. At the same time mercaptans appear among the hydrocarbons (Kontorovich et al. 1996). A mercaptan is an organic compound containing the sulphydryl group (—SH), they are the sulphur analogs of the alcohols in that the oxygen in the alcohol group (—OH) is replaced by sulphur. The H_2S and mercaptans can then act as reductants to fix any metals that may be in solution within the adjacent hydrothermal system. Alteration aureoles, with mercaptans, about dolerite intrusives extend 1–10 m into the salt in the Werra Potash zone of Germany, in the Yesso Hills in New Mexico, in Castle Valley in Utah and in Permo-Carboniferous massive bedded salt sequences of the Amazon Basin (Sidle et al. 1985; Pavlov 1970; Szatmari et al. 1979).

Regionally, Permian igneous activity throughout much of the Siberian evaporite platform has driven the alteration and melting of masses of nearby salt and been responsible for two styles of ore mineralisation – (1) Noril'sk Ni-Cu deposits (deeper assimilative interactions with Permian sulphate evaporite and coals) versus (2) Korshunovskoye iron ores (shallower hydrothermals encompassing volatile interactions with bedded Cambrian halite and organic-rich muds). Likewise the kimberlite pipes in the Yakutian Kimberlite province of the Siberian Platform have assimilated Cambrian evaporite phases, so that they now contain elevated amounts of alkali carbonates, sodalite, gypsum, anhydrite, halite and sylvite (Kopylova et al. 2013). And yet ambiguity rather than certainty is the rule with many possibly evaporite-associated halo minerals. For example, precipitates of the late-stage chloride salts, hibbingite (γ-$Fe_2(OH)_3Cl$) and kempite ($Mn_2(OH)_3Cl$), which probably constitute a solution series, occur in a number of Ni-Cu and magnetite ore deposits (Fig. 16.4; Saini-Eidukat et al. 1998). Some metalliferous orthomagmatic occurrences, such as Noril'sk and Korshunovskoye, are likely associated with the assimilation of evaporites into the magma prior to solidus, others, like Sudbury and Duluth, are not. As we shall see in the following sections, isotopes, rather than mineralogies, are key in determining likely evaporite associations.

Orthomagmatic Ni-Cu Associations with Evaporites as a Sulphur Source

Assimilation of evaporites in a ferroan skarn typically forms smaller-scale magnetite and sulphide deposits in the immediate vicinity of the emplaced magma. This is the case in the stratiform Mesozoic Longqiao iron (magnetite and minor pyrite) ore deposit in its carbonate host in the Lu-Zong volcano-sedimentary rift basin, Middle-Lower Yangtze (Changjiang) River Valley, Eastern China. There the magnetite ore skarn passes laterally into evaporite-bearing sideritic carbonate beds of the Triassic Dongma'anshan Formation (Taofa et al. 2011).

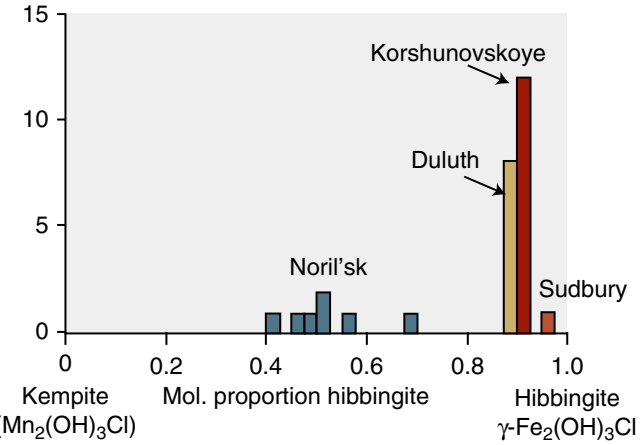

Fig. 16.4 Histogram showing compositional range of the chloride minerals hibbingite and kempite in major Ni-Cu deposits (Saini-Eidukat et al. 1998)

Some of the larger orthomagmatic metal accumulations, such as Noril'sk, have formed where substantial volumes of assimilated sulphate evaporites contributed significant volumes of sulphur into a sulphur-depleted magma and so gave rise to magmas rich in metal sulphide precipitates. Magma chemistry driving assimilation of the sedimentary sulphur to form magmatic sulphides tends to be picritic or komatiitic (sulphur-undersaturated). This is a different ore-forming mechanism to that created by halite salts contributing large volumes of chloride to the chemistry of the circulating hydrothermal basinal and metamorphic fluids, (and so forming a number of IOCG deposits).

The importance of komatiitic and picritic magmas in ore forming processes arises from the fact that they are among the few mafic/ultramafic magma types that are sulphur-undersaturated at the time of magma formation (Keays 1995). As a general rule, and independent of whether sulphate evaporites were involved, the magmatic ore forming process is controlled by the availability of S, not Ni or Cu. Sulphur-saturation of a magma as it forms leads to marked depletion in the chalcophile metals. Komatiitic and picritic magmas are S-undersaturated because they are high temperature magmas, produced by large degrees of partial melting in upper mantle source regions, which were already depleted in sulphur through earlier partial melting events.

Most mafic magmas, produced by less than 25 % partial melting, are S-saturated and hence depleted in the ore-forming chalcophile elements. In contrast, komatiitic and picritic magmas have their full complement of chalcophile metals. When they do become S-saturated, they form sulphide precipitates, which are strongly enriched in Ni, Cu, Au and PGEs (platinum group elements). The metals may accumulate to form ore deposits directly (e.g., magmatic Ni-Cu-PGE sulphides via "squeeze-filtering") or be dispersed in komatiitic/picritic rocks and their fractionation products, so making igneous source rocks for hydrothermal Au or VMS (volcanic massive sulphide) deposits.

Sudbury, Noril'sk and Jinchaun are three of the largest currently mined magmatic Ni-Cu deposits (Fig. 16.5; Naldrett 1999). Although of less tonnage, the higher grade of the Noril'sk ore (900 million tonnes of 2.7 wt.% Ni gives a reserve of 23.1 million tonnes) means that its Ni reserve is

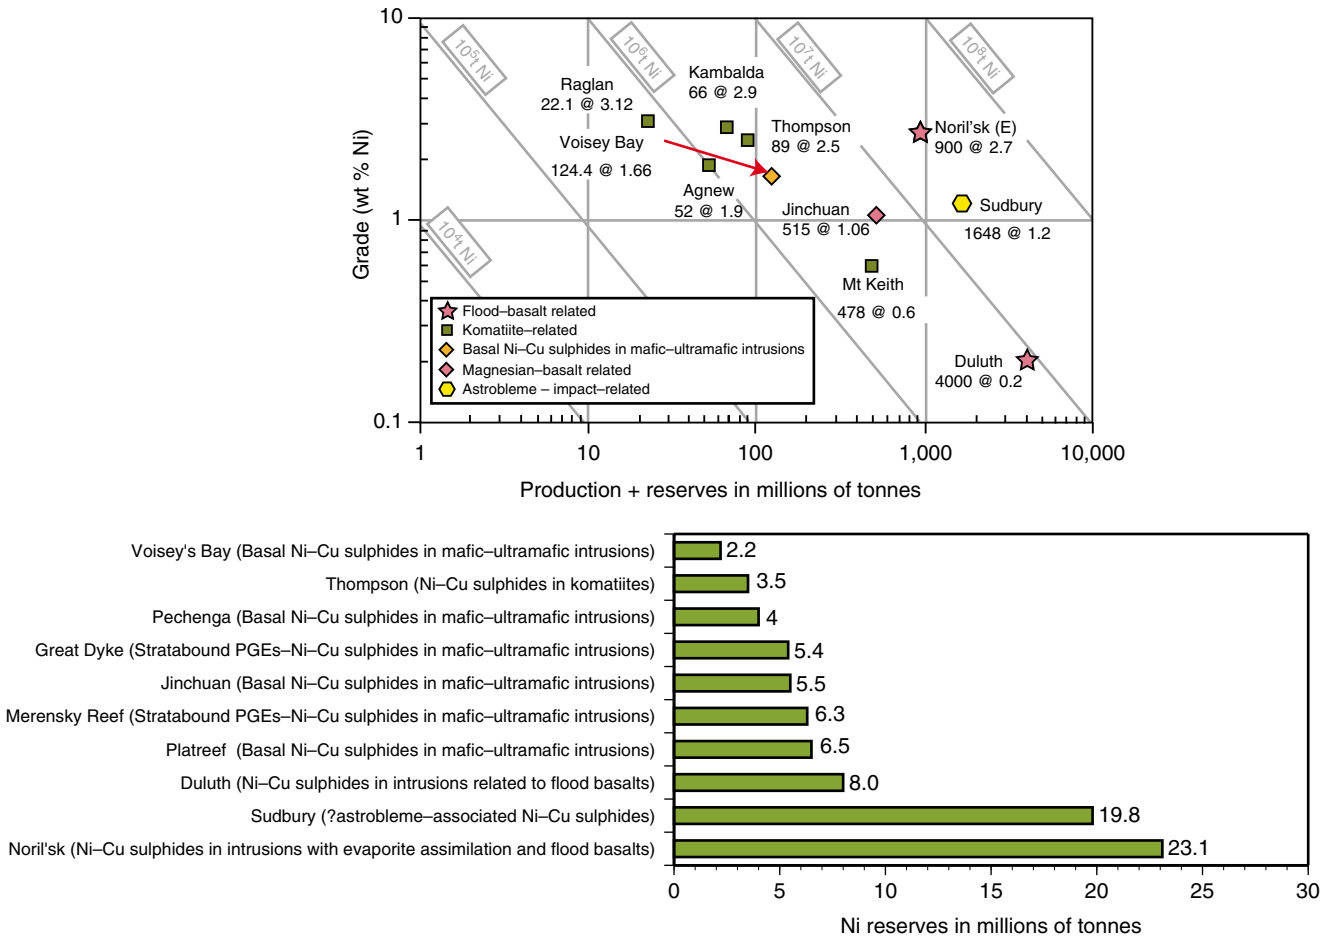

Fig. 16.5 Ore grade in wt.% Ni versus production and reserves in millions of tonnes for major Ni sulphide deposits of the world (Modified after Naldrett 1999). Lower figure ranks the deposits by their reserves

larger than Sudbury, which is considered the largest known Ni deposit in the world by nickel-hosting rock volume (1,648 million tons at 1.2 wt.% gives a Ni reserve of 19.8 million tonnes). The Noril'sk ore also contains 2 times as much Cu and 15 times as much platinum group elements as at Sudbury (Naldrett 1993). Jinchuan in China is the world's third largest Ni deposit with 515 Mt. at 1.06 wt.% of Ni (production + reserves) and forms the keel of a much larger body of magnesian basalt. The Noril'sk ore field contains ~75 % of the world's known Pd and 15 % of the world Pt resources, as well as a significant portion of the Russian Ag and Au resources (Spiridonov 2010).

Unlike Noril'sk, most worldclass Ni deposits are Precambrian, including the komatiitic lava-hosted deposits of the Archaean, and typically show no association with evaporites. Some Proterozoic Ni deposits (like Duluth) are associated with the assimilation of S-rich meta-sediments. Sudbury Ontario is unusual in the spectrum of Cu-Ni deposits, as it considered, at least in part, to be the result of a bolide impact, some 1.7 Ga (Reimold 1993). Most Australian Ni deposits in the Archaean Agnew-Wiluna greenstone belt of Western Australia formed as hot (1,600 °C+) thermally-erosive Archaean ultramafic lava rivers (komatiite), which when contaminated with sedimentary sulphide created the rich nickel ores of the district (Hill et al. 1989; Evans et al. 1989). Such mineralising systems are tied to the more active tectonics, thinner crust and strongly reducing atmosphere in the Archaean and not to evaporites.

Noril'sk Region Siberia

Noril'sk-Talnakh, like Sudbury, is an unusual Cu-Ni deposit. It did not form in the Archaean, and so is much younger than most Ni deposits. It formed at the end of the Palaeozoic, straddles the Permo-Triassic boundary, and crystallised outside the influence of a reducing planetary atmosphere that typifies Archaean Ni deposits. The high temperatures and near complete assimilation of sulphate evaporites within the Noril'sk magma mean that this is one of the more enigmatic ("salt is elsewhere") styles of evaporite-related ore deposit discussed in this chapter.

Notions of evaporite assimilation for these sorts of deposits are usually only one of multiple possible explanations, but in my opinion for Noril'sk this is the most likely. For the purposes of this chapter, I have chosen to emphasise the evaporite connection for the Noril'sk deposit in Siberia (Fig. 16.6a). Alternate nonevaporitic orthomagmatic explanations for the same deposit can be found in papers such as Wooden et al. (1992) and Lightfoot and Hawkesworth (1997).

In the vicinity of the Noril'sk Talnakh nickel deposits, lower Palaeozoic marine argillaceous sediments are overlain by thick extensive Devonian evaporite deposits, along with lower Carboniferous lagoonal and continental sediments, the Tungusskaya Series, that include a number of coal measures (Fig. 16.6b, c). An extremely large volume (approximately one million cubic kilometres) of Permo-Triassic flood basalts, known as the Siberian Traps, now covers this sedimentary sequence (Figs. 16.6a and 16.7a). Sill-like tholeiitic intrusions, varying in composition from subalkaline dolerite to gabbro-dolerite were emplaced into the sediment pile at the same time as the overlying flood basalts, and were part of the feeder system to the flood basalts. The ore-bearing gabbroic-dolerites can be differentiated, whereby picrite and picritic dolerite are overlain by more felsic differentiates. Individual sills may attain lengths of 12 km, widths of 2 km and thicknesses of 30–350 m. The Cu-Ni-platinoid mineralisation forms relatively persistent horizons of massive sulphides, which in the lower portions of the intrusions are made up of segregations and accumulations of pyrrhotite, pentlandite and chalcopyrite.

The regional structure of the Noril'sk district is dominated by NNE-NE Permo-Triassic block faulting, which was coeval with the magmatic activity. Individual faults may be over 500 km in length with throws of up to a kilometre (Naldrett 1997). Mineralised intrusions radiated outward and upward from intrusive centres as they penetrated the sedimentary sequence. Many of the intrusive centres are associated with prominent block faulting. The main Noril'sk-Kharaelakh fault occurs within the Siberian Platform, but is parallel to the main fault system that defines the boundary between the platform and the nearby Yenisei Trough. The Kharaelakh-Noril'sk fault guided the main upwelling magma body Fig. 16.6c).

The anomalous Phanerozoic age of the Noril'sk ore deposits, compared with the Precambrian ages of other magmatic Ni-Cu deposits, and its relative enrichment in Ni, Cu, Pt and Pd compared with Sudbury and Jinchuan, is thought to reflect the anomalously high volumes of sulphur contributed to the evolving magma chamber via assimilation of a thick bedded sulphate evaporite succession (Fig. 16.7a; Naldrett 1981, 1993, 1997; Pang et al. 2013). Its rich sulphur supply from assimilation of bedded sulphates contrasts with that of the Archaean Cu-Ni deposits, where the sedimentary sulphur supply came from more ubiquitous, less-focused sulphur sources entrained in widespread sedimentary pyrite. Such pyrite characterised a significant portion of the fine-grained Archaean sediments accumulating under an anoxic reducing atmosphere.

Abundant crystals of magmatic anhydrite today typify the olivine-bearing (picritic) gabbros in the Kharaelakh intrusion (Li et al. 2009; Spiridonov 2010). Along with disseminated sulphides, the anhydrite crystals are characterized by planar boundaries with co-associated olivine and augite. Dihedral angles of ~120°, characteristic of simultaneous crystallization, are common throughout the anhydrite-augite

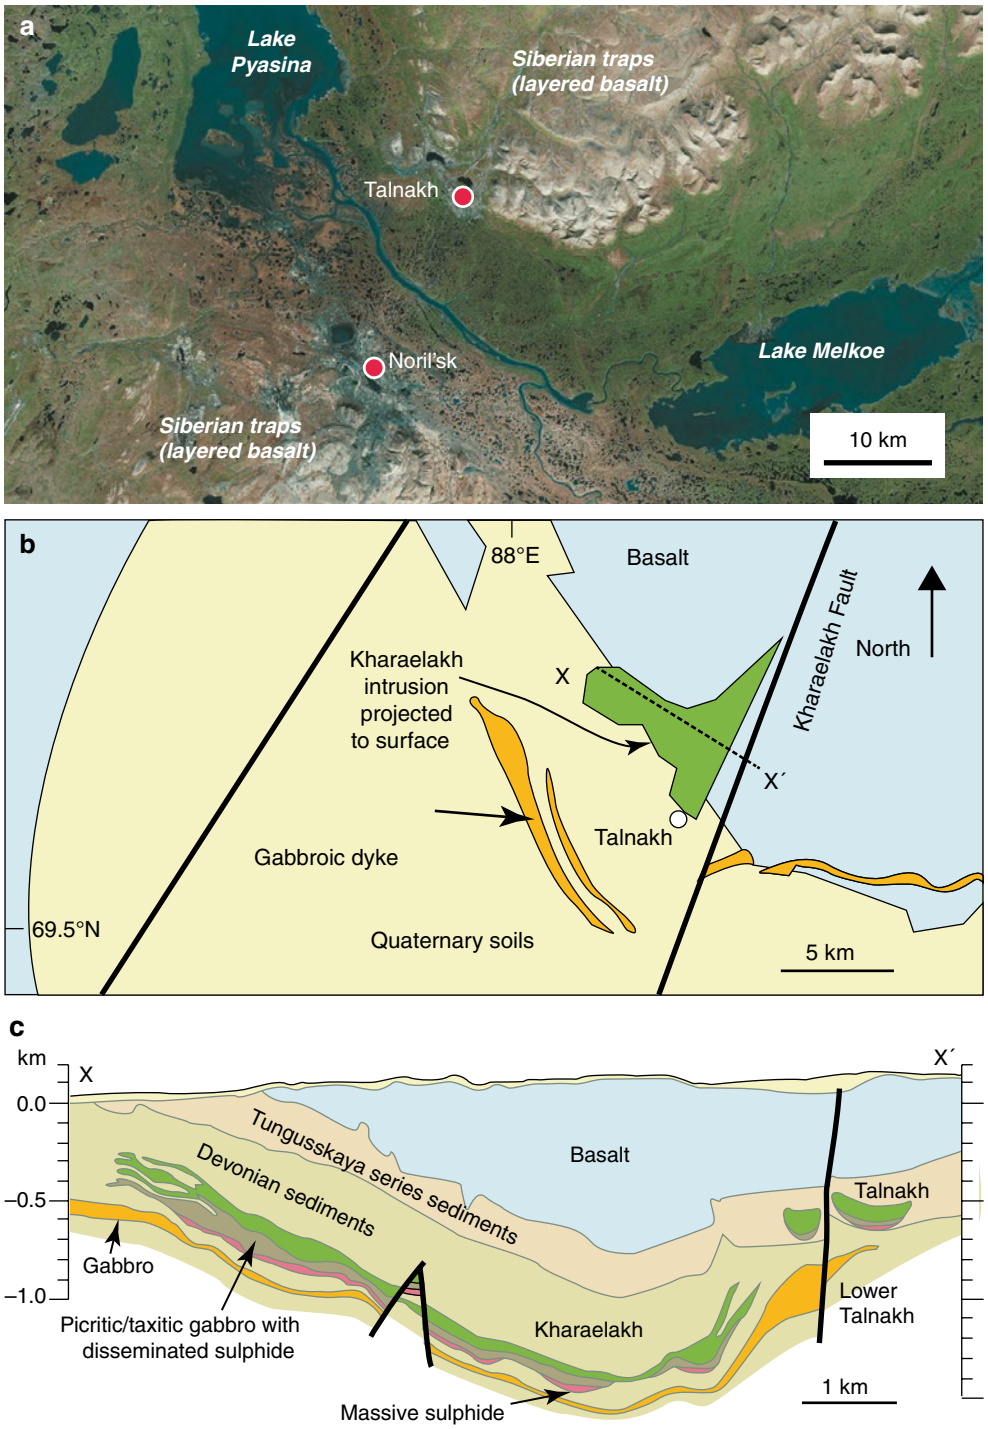

Fig. 16.6 Geology of the Talnakh-Noril'sk area. (**a**) Scaled satellite image showing relative positions of the Talnakh and Noril'sk mines. (**c**) Cross section X-X' showing depth and relative positions of the Kharaelakh and Talnakh intrusions (After Ripley et al. 2010)

assemblages. Inclusions of anhydrite in augite and vice-versa are also typical. Rounded and subrounded sulphide inclusions composed of pyrrhotite, pentlandite, and chalcopyrite, that crystallized from immiscible sulphide liquid droplets in the magma, are commonplace within the magmatic anhydrite crystals. Visual estimates by Li et al. (2009), based on 5 polished thin sections indicate that the ratio of anhydrite to sulphide in the samples varies from 0.05 to 0.1.

Isotopic analysis of $\delta^{34}S$ in the magmatic anhydrites and associated metal sulphides in the Kharaelakh intrusives require the assimilation of externally-derived high-$\delta^{34}S$ sulphur from the adjacent country rock (Ripley and Li 2007, 2010).

Where complete sulphate reduction occurred, the $\delta^{34}S$ values require mixtures of some 60 % anhydrite-derived evaporitic marine sulphur ($\delta^{34}S$ values near 20‰), with 40 % mantle-derived sulphide ($\delta^{34}S$ of 0‰) to produce the required measured magmatic sulphide values ≈ 12‰ (Fig. 16.7b).

Intense intracontinental rifting in the Noril'sk region brought mafic magmas into contact with supracrustal sulphur from evaporitic sulphates. Noril'sk lies at the extreme northwestern margin of the Siberian Platform, an area that has been a stable cratonic block since the end of the Palaeozoic. To the north, the Khatanga Trough separates the Siberian Platform from a second stable platform (the Taymyr Peninsula). To the east, the Yenisei Trough separates the Siberian Platform from the East European-Urals cratonic block. Thus, the area is a classic rift aulacogen.

Naldrett and Macdonald (1980) noted that plate-scale triple junctions, in particular the aulacogens that may result, are areas where substantial thicknesses of evaporite and mafic magmatism are natural consequences of the tectonic development (Chap. 5). Thus, in arid latitudes in the Phanerozoic, such settings are likely regions for magmatic Ni-Cu sulphide ore formation, with the prerequisite sulphur supplied by the assimilation of bedded sulphate evaporites.

Sulphur isotope data show the mineralised intervals at Noril'sk are anomalously heavy in $\delta^{34}S$, as at Kharaelakh (Fig. 16.7b). These data are inconsistent with sulphur derived from the mantle ($\delta^{34}S$ values near zero), and are consistent with assimilation of an evaporitic sulphate source (Godlevski and Grinenko 1963; Grinenko 1985; Li et al. 2009; Pang et al. 2013). As the magma rose through the sedimentary

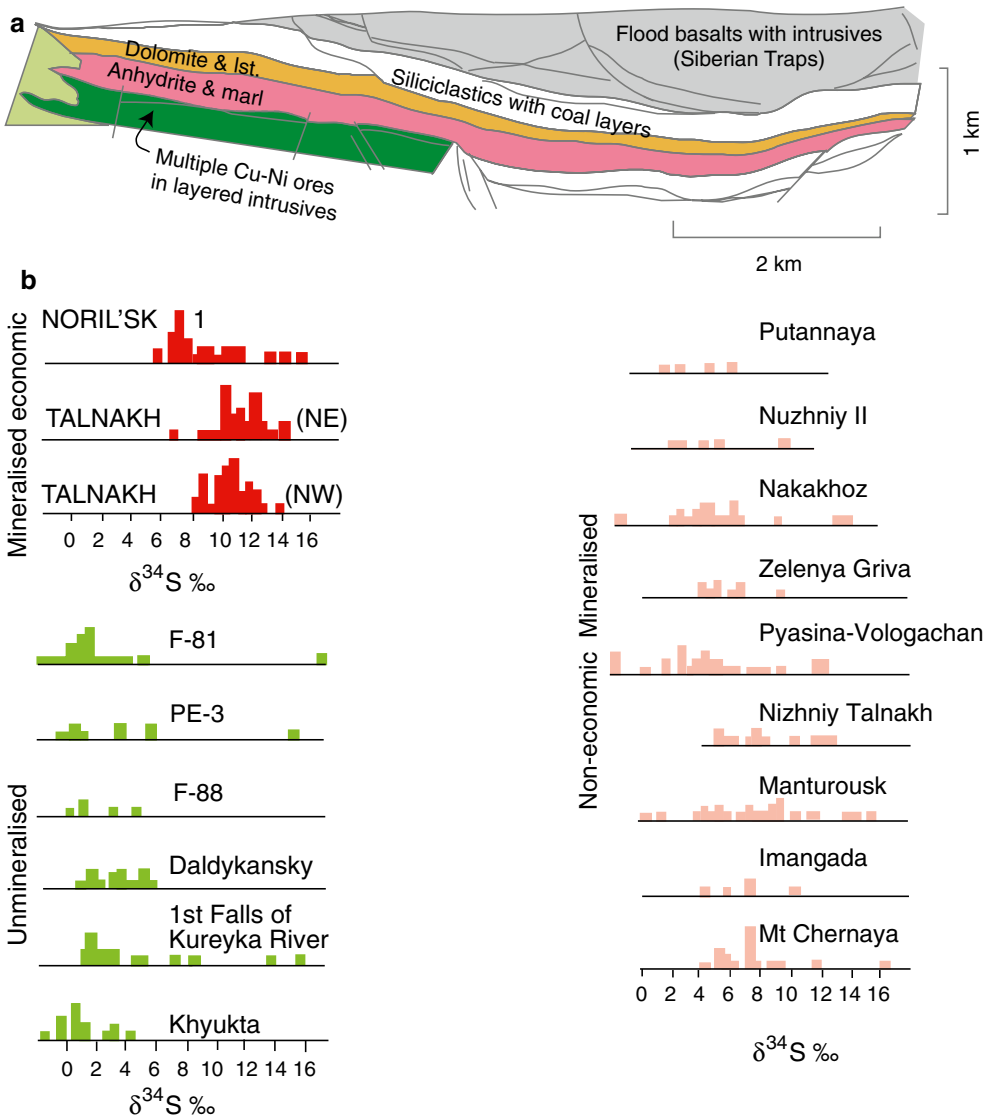

Fig. 16.7 Isotopic responses tied to intrusions Noril'sk-Talnakh region, Siberia. (**a**) Geological section through the northwestern part of the Talnakh ore field (Simplified from Naldrett 1993). (**b**) Isotopic composition of sulphur in unmineralised, mineralised economic and mineralised subeconomic intrusions of the Noril'sk – Talnakh region (After Grinenko 1985; Naldrett 1993, 1997)

cover, it penetrated and assimilated sulphur from extensive thick sedimentary evaporites (Fig. 16.7a). Sulphur in calcium sulphate was reduced to sulphide, CaO entered the magma, and iron from the magma reacted with reduced sulphur so that the end result was droplets of immiscible iron sulphide dispersed through the melt (Naldrett and Macdonald 1980). These droplets acted as collectors for Ni, Cu and the platinum group elements, which are now so enriched in the Noril'sk ores.

Naldrett (1993, 1997) suggested that prehnite + biotite + anhydrite + carbonate + zeolite + chlorite ± sulphide globules, which typify chromite agglomerations in the picrite of the Noril'sk intrusions, could represent remnants of partially assimilated sulphate-rich country rock. Assimilation of anhydrite-rich rocks, coupled with the reduction of sulphate to sulphide, would have introduced considerable oxygen into the silicate melt, which then drove precipitation of chrome-spinel minerals (chromite – $FeCr_2O_4$; mangnesiochromite – $MgCr_2O_4$). Inclusions of anhydrite-rich material, floating in the magma, would have served as loci for chromite crystallisation, thus giving rise to the association between the agglomerations and the globules. Tarasov (1970) pointed out that Middle Carboniferous coal measures were also assimilated and may have supplied organics that assisted in the reduction of calcium sulphate.

That is, during the magma chamber-driven assimilation and contact metamorphism with the anhydrite and the coals, huge amounts of high-temperature reduced gases were produced (methane, hydrogen, CO, etc.), which actively interacted with anhydrite in the Palaeozoic strata (Fig. 16.8; Spiridonov 2010). Thermochemical sulphate reduction in the country rocks resulted in sulphurous gases, sulphur, hydrogen sulphide, sulphur dioxide, carbon disulphide, etc. Ore sulphur has an anhydrite-parent-dominated isotopic composition and so is richer in the heavier isotope compared with mantle sulphur (Fig. 16.7b). These sediment-derived gaseous products penetrated into cooling and shrinking intrusions and so intensely interacted with Fe-containing minerals to produce fine sulphide disseminations in rocks and secondary sulphide melts.

Assimilation of sulphate via partial melting of a basaltic magma is difficult, owing to the high melting points of calcium sulphate minerals (typically ranging between 1,360 and 1,450 °C). Therefore, either a fluxing mechanism is envisioned, or hydrothermal leaching of sulphate followed by partial reduction, or a process involving the dissolution, rather than melting, of sulphate in mafic magma, hence the TSR mechanism outlined in the preceding paragraph (Ripley and Li 2007). The observation of abundant wollastonite in contact aureole rocks suggests that reactions such as $CaSO_4 + SiO_2 + H_2O = CaSiO_3 + H_2S + 2O_2$ occurred, and that sulphate was likely reduced to sulphide prior to incorporation into the magma.

Such igneous – sulphate sediment interaction explains, at least in part: (1) the huge amount of sulphide melt in the Noril'sk ore field; (2) the heavy quasi-anhydrite isotopic composition of

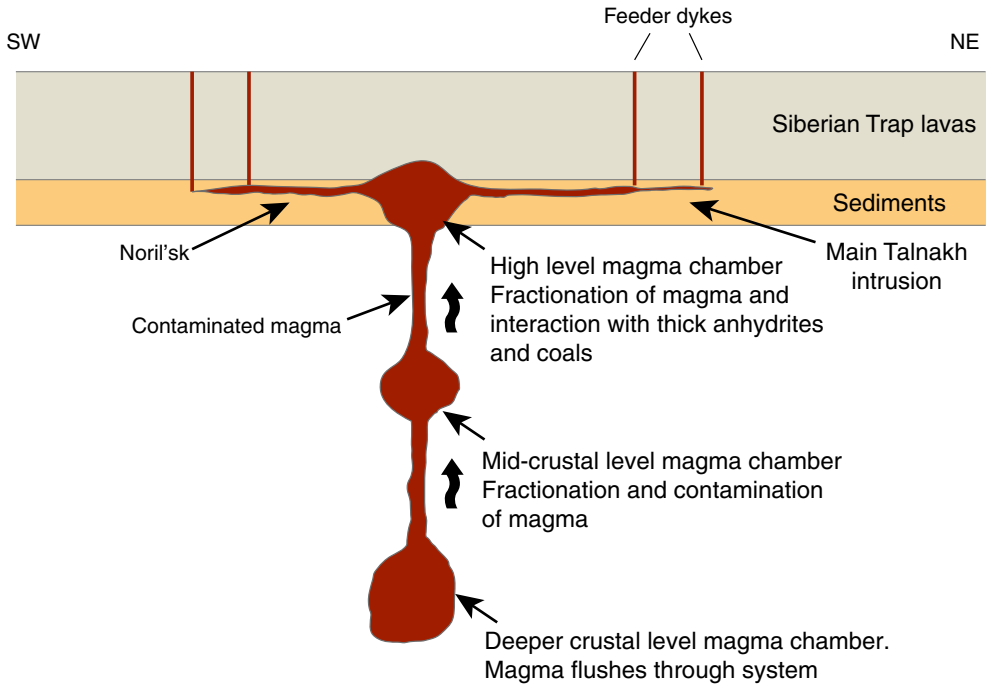

Fig. 16.8 Schematic of likely contamination and sulphur addition sites in the ascending magma pathway supplying the Ni-Cu Noril'sk and Talnalkh intrusions, Siberia (After Pirajno 2007; Naldrett 1997)

sulphur in sideronitic and massive ores; (3) the reduced contents of noble metals in these ores (compared with the drop sulphides that occur toward base of the intrusions and have a likely mantle sulphide source); and (4) the high contents of radiogenic (crustal) osmium in sideronitic and massive ores (Spiridonov 2010; Walker et al. 1994). In summary, this world class Ni-PGE deposit at Noril'sk, with its anomalous Mesozoic age, likely reflects a fortuitous occurrence of thick sulphate evaporites (ultimate sulphide source) atop an active later set of deep mantle-tapping rift grabens.

Evidence of the assimilation of large volumes of anhydrite and coaly organics into the magma mass has implications beyond the formation of the Noril'sk ore deposit. Li et al. (2009) identified magmatic anhydrite-sulphide assemblages in a subvolcanic intrusion associated with the Siberian Traps. The $\delta^{34}S$ values of anhydrite and coexisting sulphide crystals analysed by ion probing are 18‰–22‰ and 9‰–11‰, respectively, much higher than the anhydrite-contaminated ore values shown in Fig. 16.7b. To obtain this level of fractionation means more than 50 % of the total sulphur in the intrusion was derived from marine evaporites in the footwall strata. The contaminated magma was highly oxidized and able to dissolve up to one order of magnitude more sulphur than pure mantle-derived basaltic magma. Such sulphur-contaminated magma, if erupted, would have released far more SO_2 into the atmosphere than is generally appreciated (Black 2012). That is, the eruption of the evaporite-contaminated magma that is the Siberian Traps may help explain the intensity of the end-Permian extinction.

Paramagmatic Interactions

By definition, paramagmatic associations are external to the magma body, but with hydrologies and alteration haloes driven, or at least influenced, by the heating created by the emplacement of the magma. This influence can be as simple as the local heating effects of a sill or dyke extending out a few metres into the adjacent salt. Or, it can create unique salt/magmatic skarns such as the borosilicate skarns (datolite and danburite) near Dal'negor'sk in far-eastern Russia, which are cogenetic with Pb-Zn-Ag skarns and replacements in the same ore field (Chap. 13; Dubinina et al. 2011; Baskina 2008). Or, it can drive regional phreatomagmatic explosions, via heating of the high levels of volatiles trapped and stored as hydrocarbons in the lower parts of a thick evaporite succession.

Cooking the Salt: Dykes and Sills in Salt

At a local scale (measured in metres) with respect to an intrasalt-igneous interaction, there are a number of documented thermally-driven alteration styles, typically created by the intrusion of dolerite dykes and sills into cooler salt, or the outflow of extrusive igneous flows over cooler salt beds (Knipping and Herrmann 1985; Knipping 1989; Grishina et al. 1992, 1998; Gutsche 1988; Steinmann et al. 1999; Wall et al. 2010). Hot igneous material interacts with somewhat cooler anhydrous salt masses to create narrow but distinct heat and mobile fluid-release envelopes, also reflected in the resulting salt textures. At times, relatively rapid magma emplacement can lead to linear breakout trends outlined by phreatomagmatic explosion craters, as imaged in portions of the North Sea (Wall et al. 2010).

Based on studies of inclusion chemistry and homogenization temperatures in fluid inclusions in bedded halite near intrusives, it seems that the extent of the influence of a dolerite sill or dyke in bedded salt is marked by fluid-inclusion migration, evidenced by the disappearance of chevron structures and consequent formation of clear halite with a different set of higher-temperature inclusions. Such a migration envelope is well documented in bedded Cambrian halites intruded by end-Permian dolerite dykes in the Tengushka region of Siberia (Grishina et al. 1992). Defining h as the thickness of the dolerite intrusion in these salt beds, and d as the distance of the halite from the edge of the intrusion, then the disappearance of chevrons occurs at greater distances above than below the intrusive sill. For $d/h < 0.9$ below the intrusion, $CaCl_2$, $CaCl_2$, KCl and $n CaCl_2$, $m MgCl_2$ solids occur in association with water-free and liquid-CO_2 inclusions, with H_2S, SCO and orthorhombic or glassy S_8. For a d/h of 0.2–2 above the intrusion, H_2S-bearing liquid-CO_2 inclusions are typical, with various amounts of water. Thus, as a rule of thumb, an alteration halo extends up to twice the thickness of the dolerite sill above the sill and almost the thickness of the sill below (Fig. 16.9).

A similar situation occurs in the dyke-intruded halite levels exposed in the mines of the Werra-Fulda district of Germany (Steinmann et al. 1999). There, the Permian Zechstein salt series contains two important potash salt horizons (2–10 m thick), which are mined at a depths ≈ 800 m from within a 400 m thick halite host (Fig. 16.10a). In the late Tertiary, basaltic melts intruded these Zechstein evaporites, but only a few dykes reached the Miocene land surface. Basaltic melt production was related to regional volcanic activity some 10–25 Ma. Basalts exposed in the mine walls are typically subvertical dykes, rather than sills. These basaltic intervals can crosscut the salt over zones up to several kilometres wide (Fig. 16.10b). However, correlations of individual dyke swarms, between different mines, or between surface and subsurface outcrops is difficult.

The basalts are phonolitic tephrites, limburgites, basanites and olivine nephelinites. The dyke margins are usually vitrified, forming a microlitic limburgite glass along dyke edges in contact with salt (Knipping 1989). At the contact on the evaporite side of the glassy rim there is a cm-wide carapace of

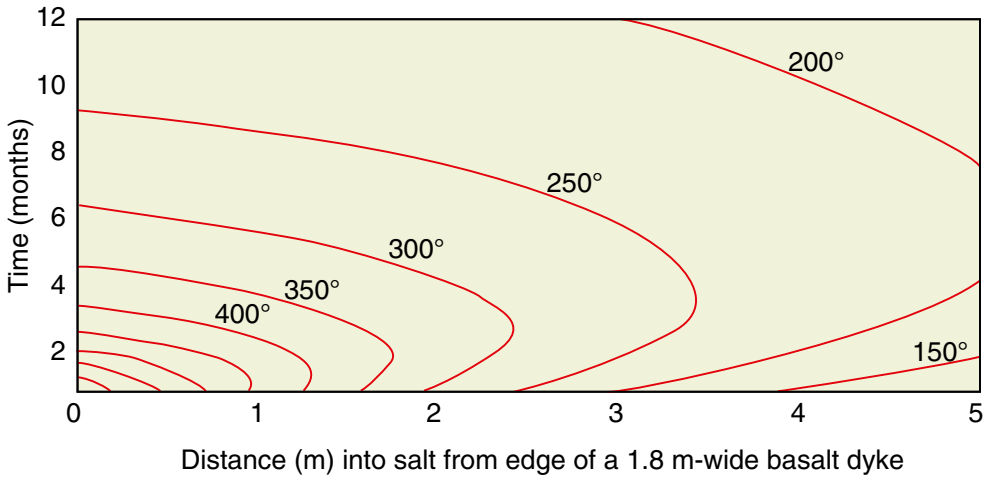

Fig. 16.9 Temperature effects in salt across time (1 year) and distance (m) from the edge of a 1.8 m-wide basalt intrusion into halite (After Knipping 1989)

high temperature salts (mostly anhydrite and ferroan carbonates). Further out, the effect of the high temperature envelope is denoted by transitions to clear halite, with higher temperature fluid inclusions (Knipping 1989). All of this metre-scale alteration is an anhydrous alteration halo, the salt did not melt (melting temperature of 804 °C), rather than migrating, the fluid driving recrystallisation was largely from entrained brine inclusions. The dolerite/basalt interior of the basaltic dyke is likewise altered and salt soaked, with clear, largely inclusion-free halite typically filling vesicles in the basalt.

Worldwide, dykes intersecting salt beds tend to widen to become sills in two zones: (1) along evaporite units within the halite mass that contain hydrated salts, such as carnallite or gypsum (Fig. 16.10d, e) and, (2) where rising magma has ponded and so created laccoliths at the upper or lower halite contact with the adjacent nonsalt strata or against a salt wall (Figs. 16.10 vs. 16.11). The first is a response to a pulse of released water as dyke-driven heating forces the dehydration of hydrated salt layers. The second is a response to the mechanical strength contrast at the salt-nonsalt contact.

Heating of hydrated salt layers, adjacent to a dyke or sill, tends to drive off the water of crystallisation (chemical or hydration thixotropy) at much lower temperatures than that at which anhydrous salts, such as halite or anhydrite, thermally melt (Table 16.2). For example, in the Fulda region the thermally-driven release of water of crystallisation within particular salt beds creates thixotropic or subsurface "peperite" textures in carnallitite ore layers, where heated water of crystallisation escaped from the hydrated-salt lattice. Dehydration-driven loss of mechanical strength focuses zones of magma entry into to particular horizons in the salt mass, wherever hydrated salt layers were present (Fig. 16.10c verses d). In contrast, dyke and sill margins are much sharper and narrower in zones of contact with anhydrous salt intervals (Fig. 16.10b; Schofield et al. 2014).

Accordingly, away from immediate vicinity of the direct thermal aureole, heated and overpressured dehydration waters can enter a former carnallite halite bed, and drive the creation of extensive soft sediment deformation and peperite[1] textures in the former hydrated layer (Fig. 16.10d, e). Mineralogically, sylvite and coarse recrystallised halite dominate the salt fraction in the peperite intervals. Sylvite in these altered zone is a form of dehydrated carnallite, not a primary-textured salt. In the Fulda region, such altered zones and deformed units can extend along former carnallite layer to tens or even a hundred or more metres from the dyke feeder. Ultimately, the deformed potash bed passes back out into the unaltered bed, which retains abundant inclusion-rich halite and carnallite (Fig. 16.10d versus e). That is, nearer the basalt dyke, the carnallite is largely transformed into inclusion-poor halite and sylvite, the result of incongruent flushing of warm saline fluids mobilized from the hydrated carnallite crystal lattice as it was heated by dyke emplacement. During Miocene salt alteration/thermal metamorphism in the Fulda region, NaCl-fluids were mixed with fluids originating from thermally-mobilised crystallisation water in the carnallite, as it converted to sylvite. This brine mixture altered the basalts during post-intrusive cooling, an event which numerical models suggest was quite rapid (Knipping 1989): a dyke of less than 0.5 m thickness probably cooled to temperatures less than 200 °C within 14 days of dyke emplacement.

The contrast in alteration extent between Fig. 16.10b, d shows alteration effects are minimal wherever the emplacement temperature of the magma is below that of the anhydrous salt body it is moving through. This is the case in the La Sal Mountain laccoliths of the Paradox basin, Utah (Ross

[1]Peperite is a sedimentary rock that contains fragments of igneous material and is formed when magma comes into contact with wet sediments.

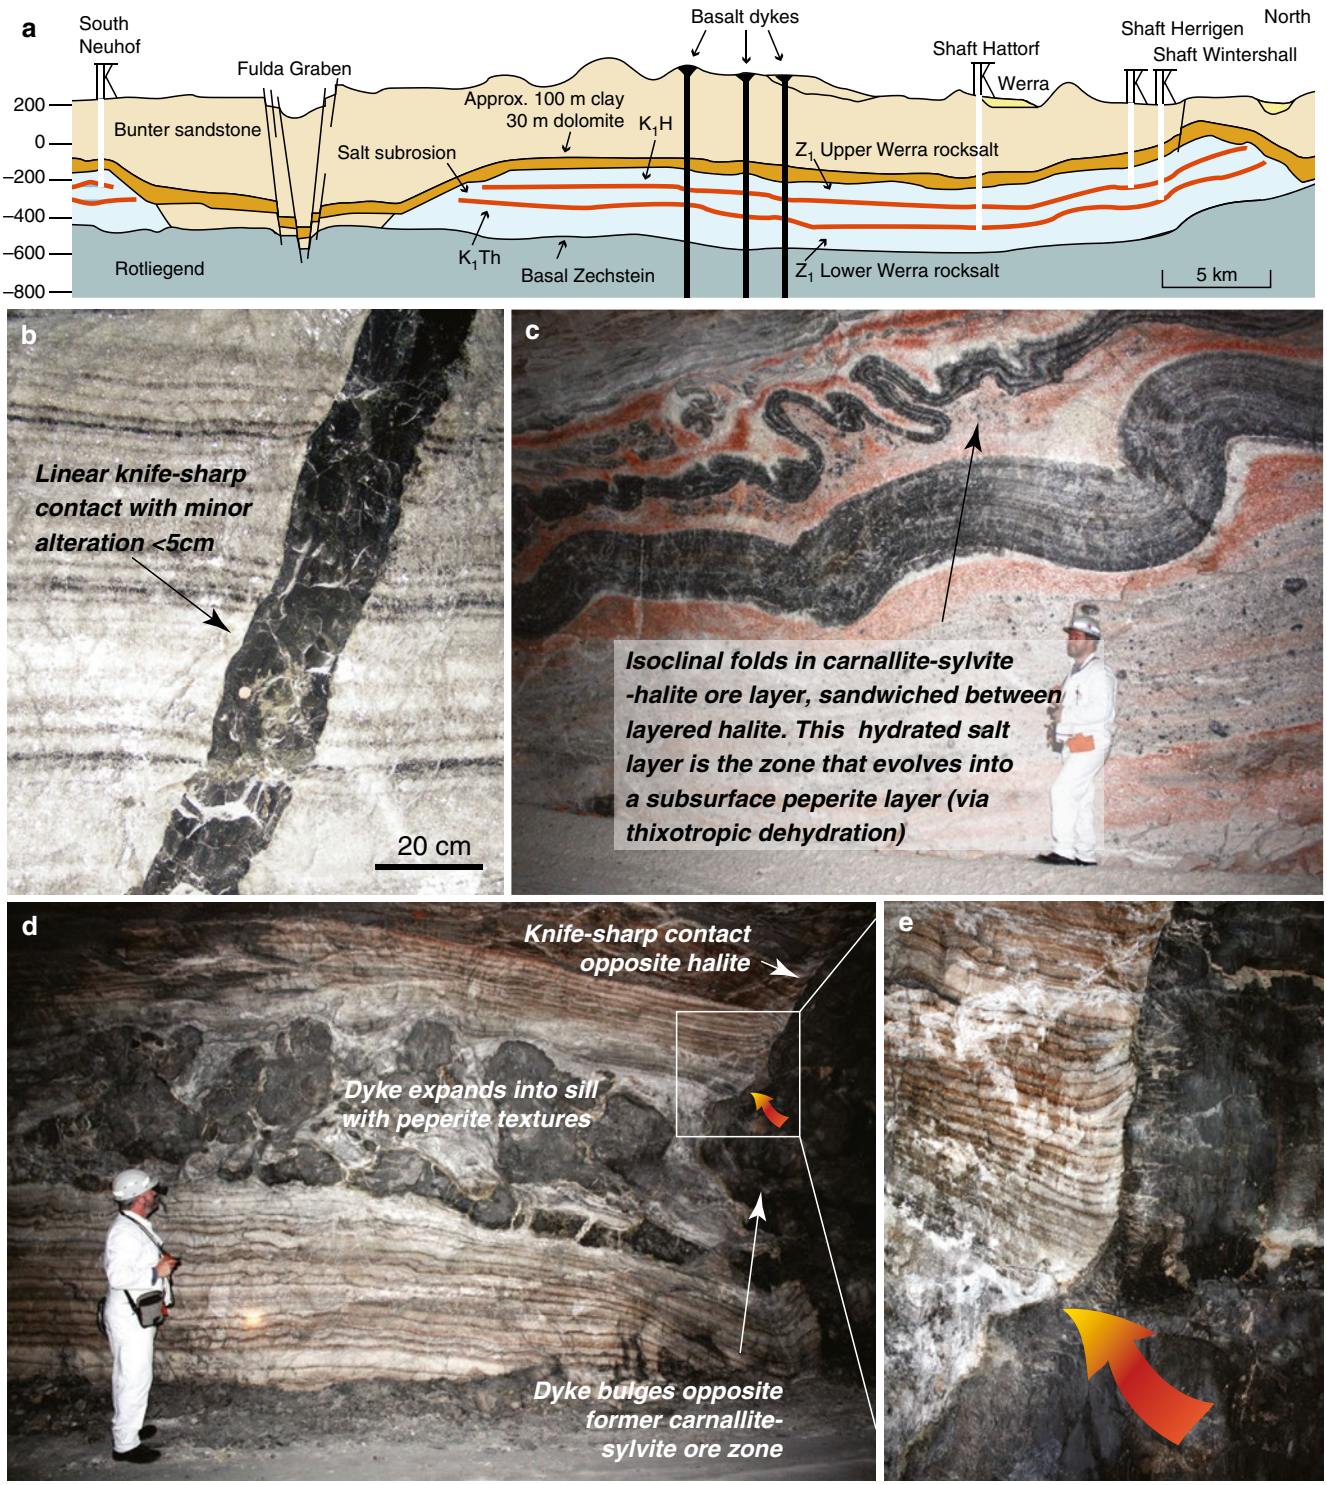

Fig. 16.10 Tertiary basalt dyke intrusions in Zechstein halite in the Fulda region, Germany. (**a**) Geological cross section. (**b**) Steeply inclined dyke in laminated halite showing knife-sharp contacts. (**c**) Carnallite-sylvite ore zone showing typical isoclinal folds sandwiched between layered halite units. 1998; Doelling 2001). There, the northern and southern intrusive centres, dominated by diorite porphyry, were emplaced some 25.1–27.9 Ma into pre-existing elongate salt anticlines (salt walls) composed of Permian Paradox salt that had largely stopped flowing in the Jurassic (Fig. 6.83; Ross 1998). The trachyte-dominated intrusions now form several laccoliths, plugs, and sills in a circular cluster arrangement (Fig. 16.11). Other than the elongation that parallels the salt

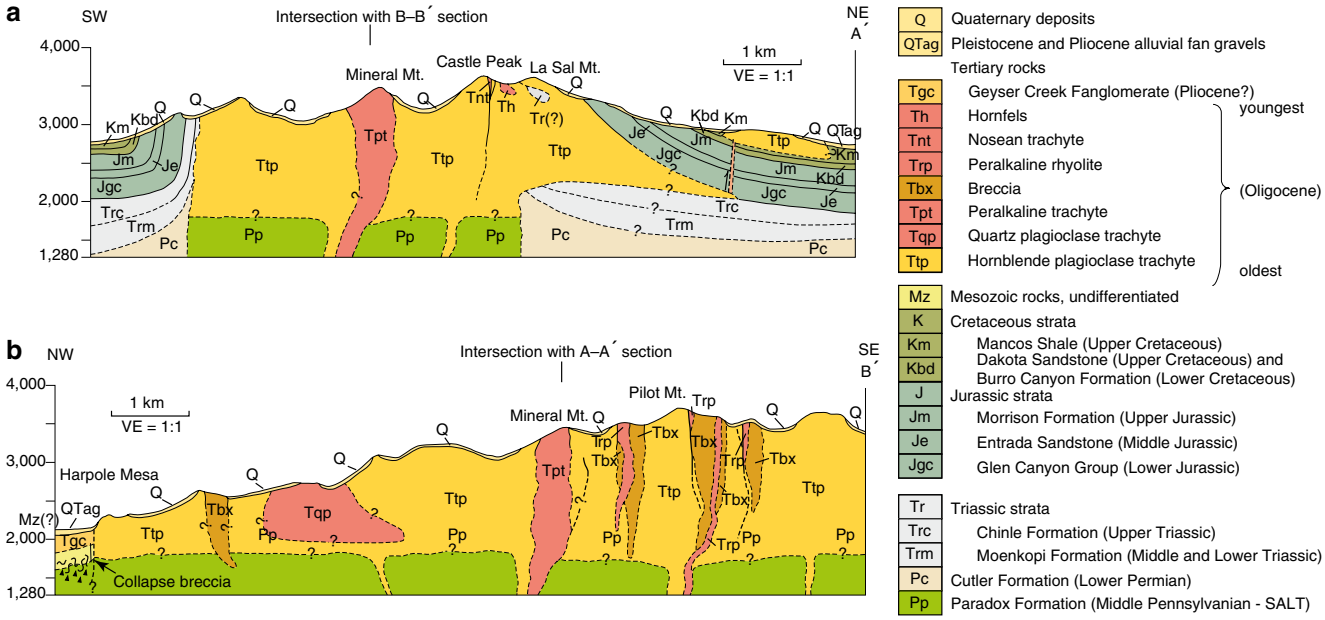

Fig. 16.11 La Sal Mountains, Utah. Interpretive cross sections through the Warner Lake and Mount Waas quadrangles showing laccolith position is focused by the pre-existing salt wall (See Fig. 6.83). Note the intensity of solution collapse in the section covered by sediment rather than laccolithic material (After Ross 1998)

Table 16.2 Decomposition and melting points of selected salts and typical ranges of magma temperatures

Salt	Formula	Decomposition/melt point (°C)
Halite	NaCl	804 anhydrous melt
Gypsum	$CaSO_4{\cdot}2H_2O$	100–150 loss of water
Anhydrite	$CaSO_4$	1,460 anhydrous melt
Carnallite	$KMgCl_3{\cdot}6H_2O$	110–120 loss of water
Sylvite	KCl	750–790 anhydrous melt
Bischofite	$MgCl_2{\cdot}6H_2O$	>118 loss of water
		712 anhydrous melt
Epsomite	$MgSO_4{\cdot}7H_2O$	>70–80 loss of water
Kieserite	$MgSO_4{\cdot}H_2O$	150–200 loss of water
		1,120–1,150 anhydrous melt
Trona	$Na_3H(CO_3)_2{\cdot}2H_2O$	>70 loss of water
Nahcolite	$NaHCO_3$	270 anhydrous melt
Typical magma/eruption temperatures		
Picritic		1,400–1,500
Basaltic		1,100–1,200
Rhyolitic		800–900
Natrocarbonatite		500–600

trend wall, the exact shape and size at depth of the hornblende plagioclase trachyte intrusions making up the main pluton (within the preexisting salt-cored anticline) are poorly understood.

According to Ross (1998) there appears to have been little interaction or contamination of the magma as it passed through the halite mass. However, little is published on the nature of the igneous material where it is in contact with the salt as this contact is covered bya dissolution debris-collapse apron about the edge of the deposit. Low levels of intrasalt alteration implies the temperature of magma emplacement was below that of the melting point of halite. Also, there is a lack of salt dissolution induced collapse features across the area covered by the emplaced magmas, implying a lack of dissolution beneath a relatively impervious magma mass. This is in stark contrast to the situation in adjacent areas, where salt lies beneath the sedimentary cover. One of the reasons for the contrast in salt karst intensity is that the emplacement of a laccolith dome would have elevated the Oligocene landscape in the vicinity of the emplacement by more than 1,500 m. This would ensure that the margins of the laccolith focused groundwater and surface runoff from

the newly formed supra-laccolith mountains into the area about the laccolith periphery wherever it was in contact with the adjacent permeable sediments.

A corollary to these contrasting examples of igneous emplacement in salt is that they offer accessible evidence of heated-halite containment over narrow zones across very large spatial domains and long time periods. As such, they offer real-world analogs for qualitative performance assessment arguments supporting complete containment of nuclear waste stored in halite cavities, even if heated (Chap. 13). But also in this context, a thorough knowledge of the possible distribution of hydrated salts in the halite mass is extremely important. An obvious rule of thumb is; keep the locale of any purpose-built nuclear waste cavity away from zones and layers of hydrated salts.

Molten Salts: Natrocarbonatite and Brine

In terms of its formative conditions, the carbonatite[2] group perhaps lies astride the orthomagmatic and paramagmatic association. Natrocarbonatites are highly alkaline igneous rocks, with the more sodic members exemplified by modern sodium carbonate lavas, which are extruded at Oldoinyo Lengai in Tanzania in the African Rift. Across the latter half of the twentieth century, carbonatite eruptions had filled the northern summit crater of Oldoinyo Lengai to the brim with mottled brown, white, gray and black lava flows, studded with spike-like spatter cones. However, the explosive summit eruption of 2007–2008, destroyed this fantastic landscape, leaving a gaping collapse pit in its place.

Oldoinyo Lengai lavas are unique in terms of their magmatic petrology (Keller and Zaitsev 2012). With eruption temperatures between 500 and 600 °C, about half that of an erupting basalt, they exhibit what are the lowest known magmatic eruption temperatures for modern lavas. When erupting, temperatures of carbonatite lavas are so low that they lack the red shimmering glow, which in daylight characterises most of the world's active lava bodies. In daylight, flowing lavas more resemble a runny black mud and move much more rapidly than silicate lavas, more like motor oil flowing over the ground and typically construct a fresh lava layer only a few centimetres thick. Fresh lava and spatter changes colour from black to white within a few hours of extrusion, due to alteration and hydration of highly labile anhydrous igneous minerals, dominated by nyerereite $(Na,K)_2Ca(CO_3)_2$ and gregoryite $(Na,K,Ca_x)_{2x}(CO_3)$.

[2]Carbonatites are igneous rocks made up of at least 50 % carbonate minerals. Although most carbonatites occur as plutonic rocks, there are well over forty localities with extrusive carbonatites, at nine of which there are lavas, mostly in the East African rift. Carbonatite masses can also take the form of hydrothermal and replacement bodies.

Carbonatite lavas are also highly fluid when moving over the landscape. They have viscosities around 0.5 pascal seconds (Pa.s), which is around 500 times the viscosity of water). This end of the viscosity range also encompasses most fluid endmembers of one of the most common magma types, namely the basalts. At the other end of the lava viscosity range are the silica-rich rhyolites; dry high-silica rhyolites can have viscosities that exceed 10^{12} Pa s. Because of their typically low viscosities, carbonatite flows tend to flow across the landscape in a way that is more akin to a spreading water sheet and, if extruded down slope, quickly move to the lowest part of the landscape to form laterally confined lava flows or "canali."

Natrocarbonatites at Oldoinyo Lengai are extremely alkali-rich, with Na_2O+K_2O generally about 40 wt.%, with high CaO contents of 14–18 wt.%. This initial alkaline composition is due the presence of phenocrysts of nyerereite and gregoryite dominating the highly porphyritic natrocarbonatite lavas, with sylvite and fluorite as main groundmass minerals. Mineralogy of the extruding Oldoinyo Lengai lava has fluctuated over two decades of sampling and study (Keller and Zaitsev 2012): (1) Silicate-bearing natrocarbonatites, characterized by the occurrence of nephelinite spheroids, typify the 1993 and 2006 lavas; (2) Residual melt compositions, as described from the 1988 eruptive period, are indicated by an aphyric filter-pressed interstitial melt of solidifying porphyritic lavas; (3) A separate interlude during the year 2000 when natrocarbonatites with sylvite and fluorite microcrysts were emitted. After 25 years of mostly mild activity, characterized by effusion and spattering of fluid natrocarbonatite lava, there was a paroxysmal ash eruption on September 4, 2007, which changed dramatically the crater morphology, eruptive dynamics and magma composition of Oldoinyo Lengai. This renewed burst of activity means fresh natrocarbonatites, if present at the bottom of the new deep crater pit that formed during the 2007–2008 explosive activity, will possibly remain inaccessible for decades.

Once emplaced the magmatic minerals of Oldoinyo Lengai natrocarbonatite lavas are unstable under atmospheric conditions (Zaitsev and Keller 2006; Keller and Zaitsev 2012). The subsolidus minerals in natrocarbonatites, as listed in Table 16.3, form; (i) Along cracks on the lava surface from hot gases escaping during cooling, (ii) As atmospheric alteration products via solution of water-soluble igneous salt minerals, in particular halides and gregoryite, and by hydration of nyerereite under the influence of meteoric water and, (iii) By reaction with fumarole gases. After solidification, the lavas are cut by a network of thin shrinkage cracks, the edges of which are covered by polymineralic encrustations.

Lava samples from Oldoinyo Lengai, collected 2–24 h after eruption, contain nahcolite, trona, sylvite, and halite with accessory kalicinite and villiaumite (Table 16.3). Atmospheric humidity results immediately (>2 h after

Table 16.3 Subsolidus minerals in Oldoinyo Lengai natrocarbonatites

Minerals	Minerals formed due to		
	Lava degassing during cooling	Atmospheric alteration and hydration by meteoric waters	Reaction with fumarole gases
Nahcolite, $NaHCO_3$	Major	Major

After Zaitsev and Keller (2006)

eruption) in hydroscopic alteration of black lavas, which is marked by the appearance of white powdery thermonatrite, along with nahcolite, on the lava surface. Subsequent reaction (weeks, months, years) of natrocarbonatite with meteoric water and the atmosphere results in the formation of hydrated sodic salts dominated by pirssonite, as well as gaylussite, shortite, trona, thermonatrite, nahcolite as well as calcite (Table 16.3). Generally, the first important step is the formation of pirssonite, along with other end-members including calcite carbonate rocks and loose nepheline-entraining volcanic aggregates and agglomerates. The carbonatite flows in nearby, now inactive, Kerimasi have somewhat higher carbonate contents than Oldoinyo Lengai; silicates are more undersaturated, with less feldspar and more nepheline ($Na_3KAl_4Si_4O_{16}$) and melilite $(Ca,Na)_2$ (Al,Mg,Fe^{2+}) $[(Al,Si)SiO_7]$. There is also strong evidence that calcite was a primary magmatic phase in some carbonatite flows at Kerimasi (Mariano and Roeder 1983).

Rapid post-extrusion changes in mineralogy of the natrocarbonatite drive substantial geochemical transformations in the lava mineral suites and the surrounds. Most obvious is the loss of Na, K, Cl and S to the groundwater system, combined with an increase in H_2O, Ca, Sr, Ba, F and Mn in the lava mineralogy. This is seen in the nearby but slightly older, now inactive, Kerimasi and Mount Homa volcanics, where the natrocarbonatite tephra is converted to supergene Ca-carbonatite that co-mingles with calcrete (Mariano and Roeder 1983).

The oxygen and carbon isotopic composition of altered natrocarbonatites shows a significant shift from the primary "Lengai Box" to high values of $\delta^{18}O$ and $\delta^{13}C$. Calcite exhibits $\delta^{13}C_{PDB}$ values between −2 and −4 ‰ and $\delta^{18}O_{SMOW}$ values of +23‰ to +26‰ (Fig. 16.12). The observed assemblages of secondary minerals formed by reaction with atmosphere and meteoric water, the changes in chemical composition of the natrocarbonatite and field observations suggest that alteration of natrocarbonatite is an open-system low-temperature process. It takes place at temperatures between 8° and 43 °C with the addition of H_2O to the system and the removal of Na, K, Cl and S from the carbonatites.

At Oldoinyo Lengai, Na_2O makes up 32 % of the lava chemistry and the Na_2O/K_2O ratios hover around 4. This, and proximity to the nearby trona deposits of Lake Natron and Lake Magadi, has led some authors to postulate that their unique sodic-rich igneous chemistry indicates an interaction/cycling between a silicate melt and either soda-rich subsurface trona beds (Milton 1968, 1989) or associated saline basinal brines (Eugster 1970, 1986). In this context, they can be considered at least partial paramagmatic deposits.

But any sedimentary influence in the magma chemistry is strongly contested by many in the igneous community, who interpret natrocarbonatites as the end result of a highly saline magmatic separation. For example, Bell and Dawson (1995)

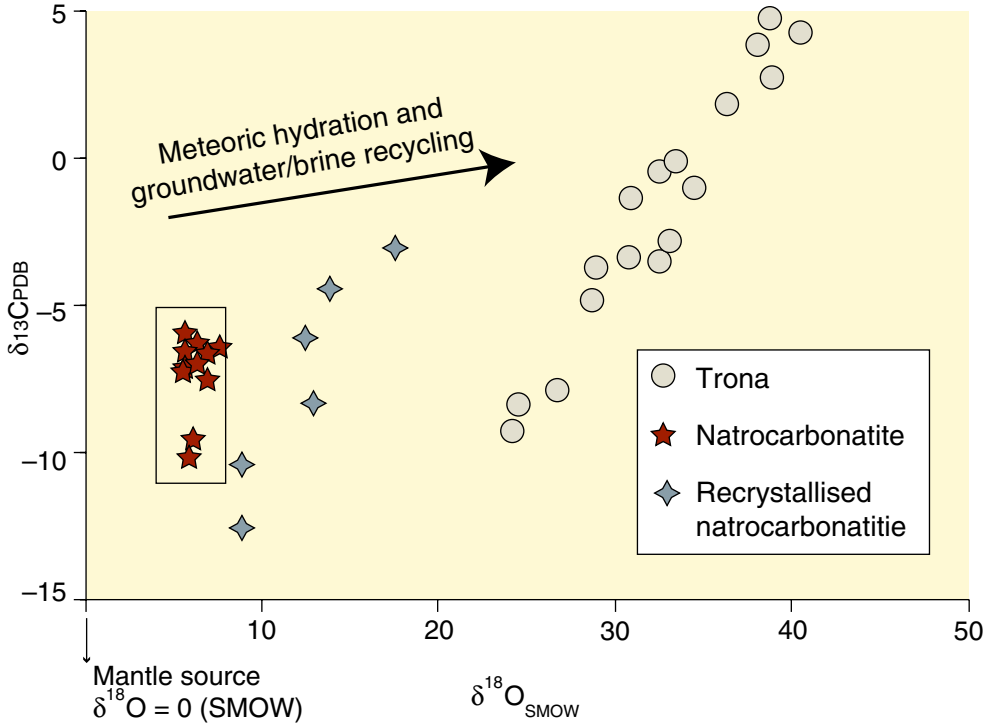

Fig. 16.12 Carbon-oxygen crossplot of natrocarbonatites from Oldoinyo Lengai and trona from Lake Magadi. Recrystallised natrocarbonatites are either altered or recrystallised in the presence of meteoric water (Plot compiled from Bell and Dawson (1995) and data sources therein)

conclude the stable and radiogenic isotopic signatures of natrocarbonatites of Oldoinyo Lengai are different to those of sedimentary trona and similar to other magmatic rocks, including young carbonatites, from elsewhere in east Africa (Fig. 16.12). Therein lies the problem; Bell and Dawson's isotopic data for trona comes from unaltered sedimentary trona, they ignore the highly reactive nature of buried evaporites within active hydrothermal hydrologies, which characterise rift systems (Chap. 2). Nor does their argument consider temperature related fractionation effects that typify evolving stable isotope signatures of oxygen-entraining minerals undergoing burial diagenesis. How much is the oxygen isotope signature of trona lightened as it is buried in settings where it undergoes dissolution/reprecipitation interactions with increasingly hotter throughflowing hydrothermal brines?

The fact that these sodium carbonate lavas at Oldoinyo Lengai, with their highly elevated sodium contents, are: (1) Unique amongst all the world's carbonatites; (2) erupting today; and, (3) Occur in proximity to one of the largest examples of modern endoheic trona accumulation (see Lake Magadi in Chap. 11); must at least argue for some subsurface interaction with trona-derived brines. This is the model proposed by Eugster (1970, 1986) who envisaged a deep actively-circulating saline groundwater reservoir in the Magadi Basin. He interprets the sodium carbonate lavas of Oldoinyo Lengai, not so much as remobilised sedimentary trona, but as the product of the interaction of an evaporite-influenced basinal brine with alkaline silicate magmas.

There can be no doubt that the sodium and bicarbonate ions now held in trona salt beds of the Magadi and Natron basins were derived, at least in large part, by surface weathering and groundwater leaching of the surrounding volcanic ashes and flows, including the natrocarbonatite lavas of Oldoinyo Lengai (Chaps. 2 and 13). Even today, this leachate is carried into perennial trona lakes that occupy the lowermost parts of the two basins. There it is concentrated by solar evaporation to deposit beds of sedimentary trona. Ongoing extension and subsidence within the rift then caries this evaporite into the subsurface, where it is leached by an active hydrothermal hydrology.

But, the carbonatites of this part of the African rift are unusual in the intimate relationship between these sodic-carbonate lava flows and the formation of nearby trona-natron bedded salts and relates to the adiabatic shadow and arid conditions that define this part of the rift. More generally, bedded trona deposits are not part of the association, then again most other carbonatites do not show such high levels of what are evaporite-like sodic mineralogies, rather the bulk of the world's carbonotites deposits are typified by combinations of; calcite, dolomite, phlogopite, biotite, quartz, aegerine, ankerite and K-spar, along with ore minerals such as apatite, pyrochlore, baryte, magnetite, pyrite, monzonite and fluorite. Carbonatites are also the world's main source of rare earth elements and so are of considerable economic import (Berger et al. 2009).

In a GIS-based compilation of known carbonatites, ranging in age from Archaean the modern, Woolley and Kjarsgaard (2008) concluded that the majority of carbonatite deposits are localized within stable continental tectonic units, such as shields, cratons, and crystalline blocks, with well-developed old Earth crust. Inside these large regional structures, carbonatites are confined to alkaline magmatic provinces controlled by intracontinental rift and fault systems. In the correct climatic and hydrologic setting, such sites also likely regions of evaporite accumulations. Carbonatites (but not natrocarbonatites) define an igneous lithological grouping across geologically broader ranges than Oldoinyo Lengai and the Gregory Rift (Morteani et al. 2013; Zaitsev et al. 2013). Some examples, such as the 500 Ma carbonatites of Madagascar, likely assimilated crustal evaporites to help attain their characteristic alkaline earth-rich magma chemistry

Phreatomagmatic Iron-Rich Associations

If the amount of produced volatiles is large when a magma body interacts with country rock sediments, then the result can be a mobile mixture of igneous and sedimentary material that moves rapidly and explosively to the surface in phreatomagmatic breccia pipes, typically with cratered tops (Mazurov et al. 2007; Svensen et al. 2009). When such phreatomagmatic breccia pipes transect salt layers, especially if there are beds of hydrated salts, then the breccias are typically halite-cemented and with a highly altered glassy matrix and numerous large angular volcanic clasts (Korshunovsky-style breccia pipes).

Anhydrite's melting point is much greater than halite, carnallite or sylvite, so rather than melt it tends to dissolve in the hydrothermal milieu generated by most magmas, except picritic, which have emplacement temperatures sufficient to melt anhydrite (Table 16.2). In the 10 m-wide alteration zone formed in lower Cambrian halite at Irkutsk/Nepa, the clear halite crystals adjacent to the dolerite sills are 4–6 cm across (Fig. 16.14). The anhydrite has been altered to rounded grains with characteristic fused edges, which indicate partial exsolution as the molten halite cooled (Pavlov 1970). Sylvite also appears as separate crystal segregations in the clear recrystallised salt, whereas prior to melting it was finely dispersed in brine inclusions throughout the chevron halite.

Korshunovsky (Korshunovskoye) Iron Ore Deposits, Siberia

This region, in the Irkutsk district, is the eighth largest iron ore producer in Russia, with an annual output of 5 Mt of iron ore concentrate. Ore is extracted from magmatic intrusions that completely penetrated a highly evaporitic Phanerozoic succession (Fig. 16.13; Mazurov et al. 2007). Early work on this intrusive magnetite style, which surrounds brecciated diatreme-like pipes, classified it as a skarn association forming a halo around a set of explosive pipes, accompanying regional trap magmatism (Ivashchenko and Korabel'nikova 1960). Some of the more texturally interesting examples of this dolerite/evaporite interaction are in contact-reaction magnesian skarns surrounding Angara-Ilim volcanics in the intracontinental paleorift zones of the Siberian Platform (Mazurov and Titov 1999). There characteristic spinel-forsterite magnesian skarns are confined to the overdome parts of large doleritic bodies and are the result of interactions of massive evaporitic and petroliferous dolomites with fluids released from liquid magma.

Magnesian skarns of the postmagmatic stage are localized in the marginal parts and on the front (outwedged portions) of doleritic sills, apophyses, and the branches of intrusive bodies hosted in Cambrian carbonate-evaporite successions (Fig. 16.13). The skarns have a banded or layered structure and resemble gravel conglomerates, with carbonate cements. The round fragments (pseudo-conglomerates) are composed of globules of disintegrated doleritic porphyrite, completely or partially substituted by zonal magnesian skarns. Their mesostasis is cryptocrystalline and early phenocrysts of olivine, plagioclase, and pyroxene have undergone dispersion and substitution. Unaltered cores of 'conglomerate' are in contact with a fassaite zone, which passes outward into a spinel-fassaite zone and then into a forsterite-magnetite and calciphyre zone (Fig. 16.13).

In typical nonevaporitic palaeo-island-arc and continental-margin regions elsewhere in the world, these skarns have no analogs, in either texture-structural peculiarities or formation mechanisms. They are the texture-specific result of intrusion and solidification of basic magma in a chemically active carbonate-evaporite country rock. Some of the conglomeratic appearance may be indicative of ongoing subsurface dissolution of evaporite salts that were originally part of the rock matrix. In my mind, a partial emplacement analog is seen in the interaction of basalts with hydrated salts in the Fulda region (Fig. 16.10d).

Magnetite pipes and the associated Siberian traps likely played a significant role in the end-Permian extinction event (Fig. 16.15; Svensen et al. 2009; Li et al. 2009). Emplacement of the Siberian Traps set up a life-threatening phreatomagmatic events tied to (1) magma interacting with high levels of hydrocarbon volatiles trapped in and below halites in the Tunguska Basin, and (2) SO_2 release, which was tied to massive Devonian anhydrite assimilation in the nearby Noril'sk region. Together these two styles of magma-evaporite-hydrocarbon interactions released huge volumes of toxic gases into the atmosphere.

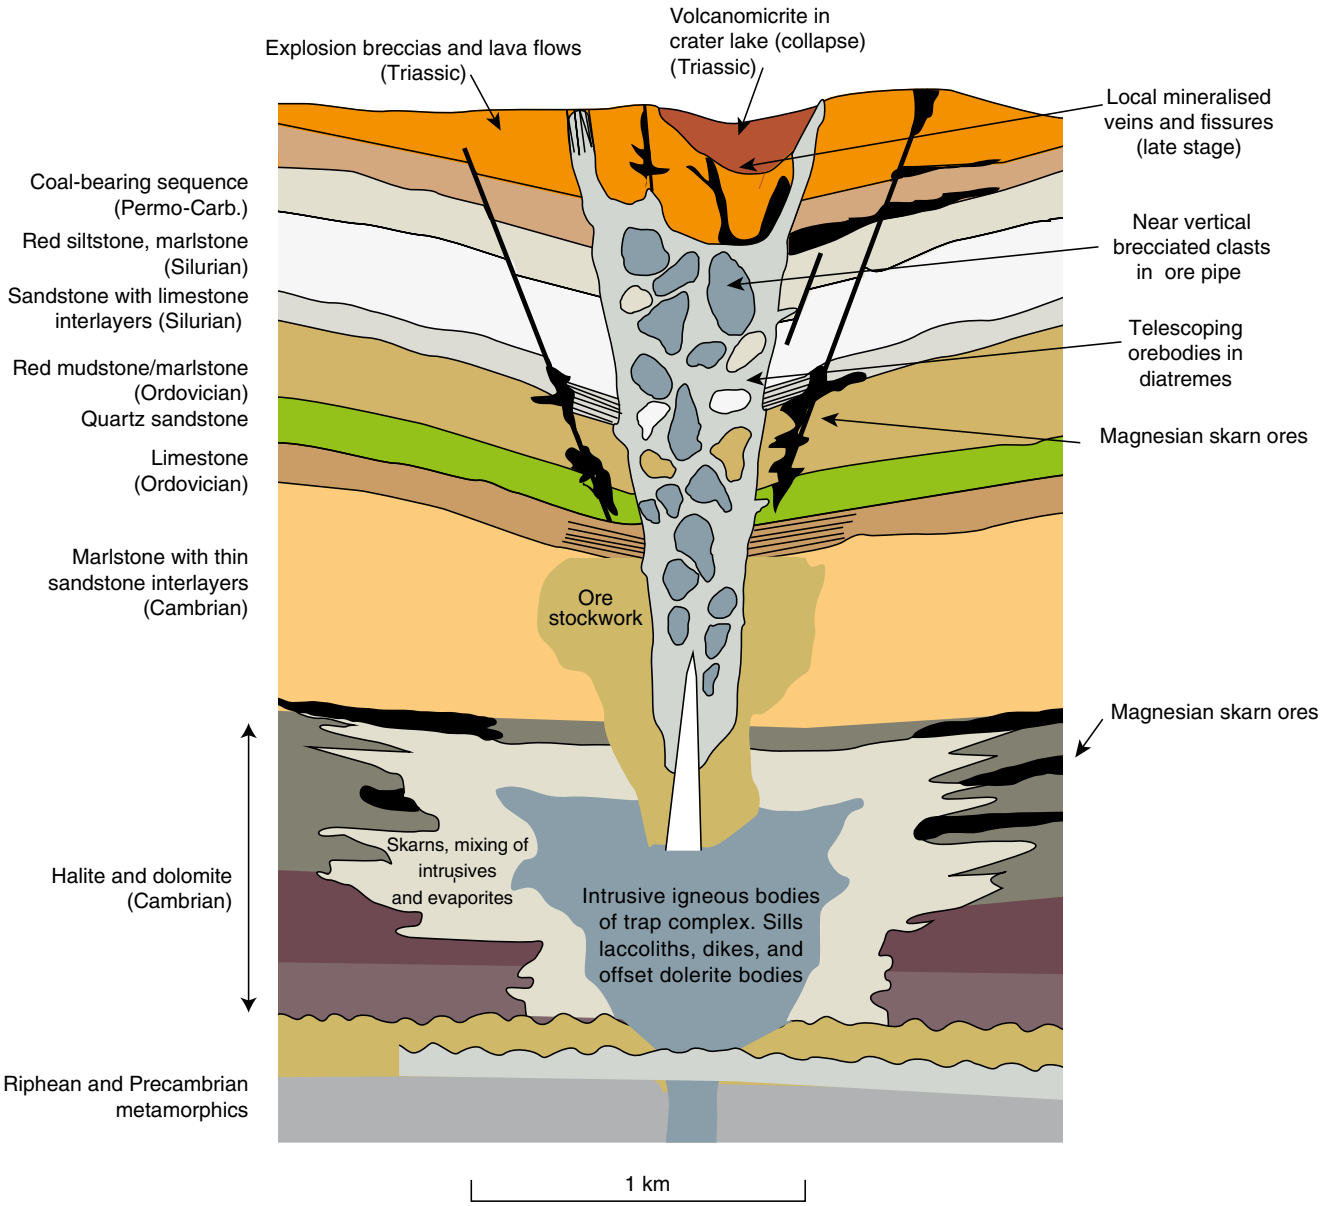

Fig. 16.13 Schematic cross section of an ore-magmatic system of the Angara–Ilim type (After Mazurov et al. 2007), see Fig. 16.14 for stratigraphic detail

As noted by Svensen et al. (2009), across earth history there are a number of large igneous provinces that are associated with significant extinction events and then there are others with similar emplacement volumes that are not. The key question becomes why some large igneous provinces are associated with extinctions, whereas others had apparently minor effects on the biosphere. Sediment composition around sill intrusions of large igneous provinces is perhaps the most important parameter in causing broader environmental change. Significant extinctions tend to occur when sedimentary basins with major evaporite and organic matter deposits are intruded by thick sills, typical of large igneous provinces (megaplume emplacement) or are caught up in a bolide impact (end-Cretaceous). That is, emplacement of widespread intrusions, which typify the Siberian Traps, led to huge outputs of toxins and likely led a mass extinction, whereas the formation of many other large igneous provinces did not: a few kilometre-thick interval of intruded evaporites, trapped hydrocarbons and coals, likely made the difference.

Paramagmatic Saline Haloes

So far, we have focused on orthmagmatic-evaporite interactions, where the magma body is in direct contact with, and is assimilating, evaporite salts or interacting with associated entrapped volatiles. But, there is a much larger spectrum of

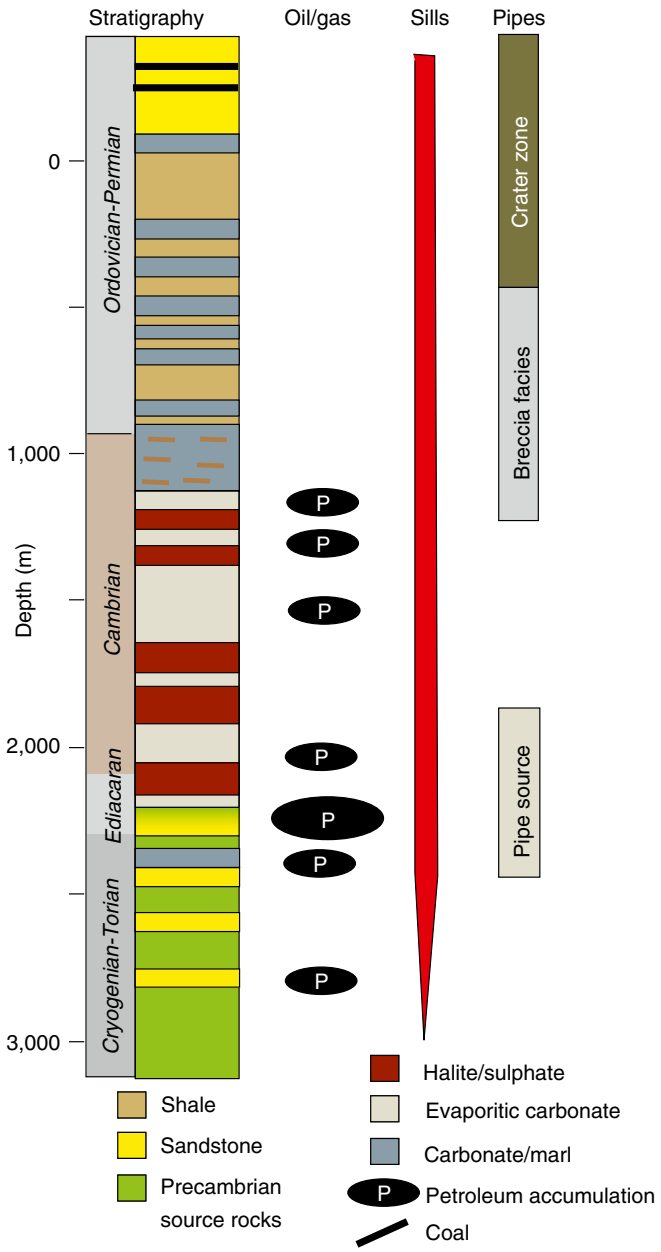

Fig. 16.14 Nepa district stratigraphy in the Tunguska Basin showing levels with petroleum occurrences (After Svensen et al. 2009). The stratigraphy is representative for the basin segment with outcropping or subcropping pipes. Thicknesses of the Precambrian strata vary considerably (1–10 km) but has not been drilled in the central parts of the basin. Sill intrusions are present throughout the basin stratigraphy. The pipes are rooted in the Cambrian evaporite or possibly deeper, but have only been drilled to Upper Cambrian levels, as at Nepa. The inferred source region of the pipes, where intense magma-sediment interactions took place, is likely within the lower Cambrian strata. Craters are filled with up to 750 m of crater-lake sediments

metal deposits where the ore body is largely the result of the mixing/cooling of hydrothermal fluids. In some cases the fluids are derived largely from the cooling magma (juvenile waters), while at the other end of the hydrothermal spectrum the magma acts as little more than a heat source driving the circulation and mixing of highly saline basinal brines. In yet other cases, the circulating brines are part of the burial/metamorphic milieu and may not require a magmatic heat source (Fig. 16.16). The resulting deposit styles range from successions best interpreted as skarns, to others best interpreted in the context of mineral haloes related to regional metamorphism (Chap. 13).

One of the keynote papers to summarise notions of ore deposits from evaporite-related paramagmatic hydrothermal haloes was that of Barton and Johnson (1996), followed by Barton and Johnson (2004). They explored the notion that hybrid evaporite/magmatic chloride-rich hydrothermal fluids play a significant role in the formation of some igneous ore

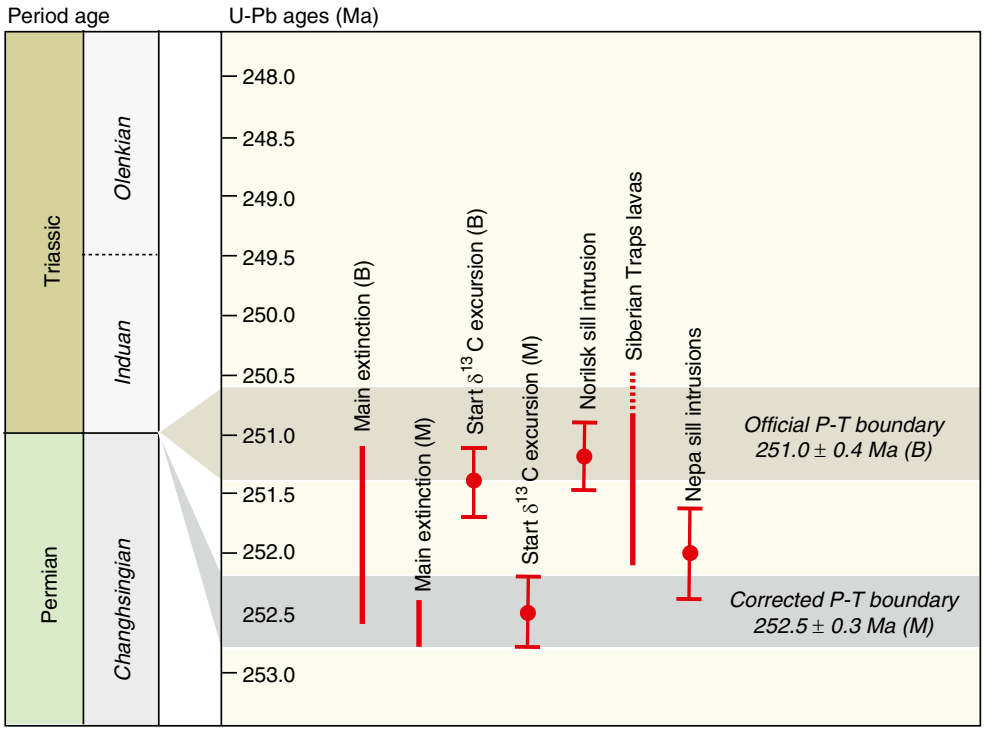

Fig. 16.15 Compilation of zircon U–Pb ages of key end-Permian events (After Svensen et al. 2009). The ages of the P–T boundary are from Gradstein et al. (2004) deduced from Bowring et al. (1998) (labelled "B"), and from a revised age by Mundil et al. (2001), (labelled "M"). The age of the sill emplacement at Nepa is synchronous with pipe formation and release of carbon gases and halocarbons to the atmosphere. The main phase of the extinction is dated to have occurred between 252.3 ± 0.3 and 251.4 ± 0.3 Ma by Bowring et al. (1998) (labelled "B") and 252.6 ± 0.2 Ma by Mundil et al. (2004) (labelled "M")

deposits, including many of major Fe-oxide-Au deposits or IOCG deposits (Table 16.4). Their conclusions encompassed evaporite/saline brine/aridity associations ranging from Proterozoic Cu-Au deposits, back to the Archaean and into the Neogene, in tectonic settings ranging form rifts to collision belts. In both papers, they concluded that variation in primary magmatic composition is a secondary control when compared to variations in the hydrothermal chemistries contributed by dissolving chloride-rich evaporite sediments and metasediments (Fig. 16.16). In other words defining the evaporitic origin and flow pathway indicators of chloride brines are key to understanding this type of ore distribution.

According to Barton and Johnson (2004), evaporite-associated hydrothermal deposits have abundant Fe oxides, as well as a characteristic suite of accessory elements, at least some sodic hydrothermal alteration, along with evidence for vigorous emplacement processes, and a genetic link to magmatic interactions in evaporitic terrains (Table 16.5; Fig. 16.16). The circulation systems are typified by large volumes of Ti-poor Fe oxides (commonly >10^6 tonnes magnetite or haematite) with lesser amounts of phosphates (apatite, REE phosphates), Cu-Fe sulphides and sporadic Au, U, Ag and Co minerals. Proximal and deeper mineralisation consists of early magnetite ± apatite rocks, commonly with abundant sodic (albite ± scapolite ± hornblende) wallrock alteration. Superimposed or distal mineralisation consists of haematite ± Cu-Fe sulphides ± REE minerals with ± potassic alteration. Variants include deposits with substantial sodic alteration and Cu or U mineralisation, but subordinate Fe-oxide. Sodic alteration occurs in nearly all districts, is typically voluminous, and a number of examples have local peralkaline assemblages containing Na-Fe^{3+} bearing amphibolites or pyroxenes. Calcareous host rocks contain calcic or magnesian skarn assemblages with hydrous distal assemblages (actinolite-chlorite-carbonate) that are superimposed on anhydrous assemblages (pyroxene + garnet). In shape, these deposits may consist of stratabound massive Fe-oxides hosted in volcanic and sedimentary rocks, although most commonly they are discordant, variably brecciated, tabular to irregular masses. The former have previously been interpreted by others as syngenetic replacement bodies, while the latter have been interpreted as veins, dykes and breccia fills associated with magmatism.

Igneous rocks can be closely linked to these deposits, but there appears to be little correlation of mineralisation to igneous composition or intrusive phases (Barton and Johnson 1996, 2004). The ions in the circulating hydrothermal fluids are, at least in part, derived by reflux/dissolution of coeval or older evaporitic sources. Circulation is usually driven by the thermal effects of the magmatism. Igneous rocks typically also serve as the source and host for mineralisation, making the total system a form of large-scale

Table 16.4 Characteristics of a selection of aridity/salinity associated Fe-Oxide(−REE-Cu-Au-U) bearing regions

Region and district	Age and setting	Size* and metals, sodic alteration	Comments	References
Red Sea region (Afar, Atlantis II)	Holocene - rift basaltic volcanism, abundant evaporites	>100? (>15?) FeOx + MnOx ± Zn-Cu-Pb sulphides seds; localised peralkaline alteration	Modern geothermal circulation through evaporitic beds	Zierenberg and Shanks (1983), Bonatti et al. (1972)
Chilean Andes (El Laco, Magnetita Pedernates)	Neogene – interm. Volcanic centres in closed basins	>1,000? (>500) FeOx in 2 districts; minor sodic ± peralk alt	Arid; volcanos adjacent to salars containing halite	Vivallo et al. (1994)
Mexican Altiplano (Cerro de Mercado, La Peria)	Mid-Tertiary - continental arc felsic volcanic centres	>300 (>100) FeOx ± REE, Cu in >20 locs; modest sodic ± peralk alt	Arid palaeoclimate, sulphates in volcanic basins, Jurassic salt	Lyons (1988)
Basin & Range, USA (Cortez Mtns., Humboldt complex)	Jurassic – back-arc mafic and felsic volcanic complexes	>1,000 (>75) FeOx ± REE, Cu; >40 locs; ext sodic ± peralk alt	Arid palaeoclimate, evaps in region; heavy S, saline fluids	Battles and Barton (1995), Barton et al. (1991)
Andean coastal belt, Peru & Chile (El Romeral, Raul, Candelaria, Monterrosas)	Jurassic-Cretaceous – extensional arc interm-mafic volcano-plutonic centres	>3,000 (350) FeOx ± major Cu(Au), minor Co, REE; >150 locs; ext sodic ± peralk(?) alt	Arid palaeoclimate, Jurassic evaps; variable S, saline fluids, VMS in same arc	Vidal et al. (1990)
Mid-Atlantic, USA (Cornwall, Grace)	Triassic-Jurassic – mafic sills in rift basins	>350 (>100) FeOx ± Cu, Co (± U); >50 locs; skarn & sodic alt	Redbeds ± evaps; geochem evidence for evap source	Rose et al. (1985)
Siberian Platform, Russia (Korshunovsk, Tagar)	Permo-Triassic - mafic intrusions with flood basalts	>3,000 (>650) FeOx + minor Cu, Co in >150 locs; skarn and sodic alt	Basalts interact with Cambrian salt, saline fluids, heavy S	Smirnov (1977), Vakhrushev et al. (1981), Zharkov (1984)
Turgai, Kazakhstan (Sarbat, Kachar)	Carboniferous – intermmafic arc volcanic centres	>4,000 (>1,500) FeOx + minor Cu, Co; ext sodic alt & skarn	Arid palaeoclimate, possible evaps	Smirnov (1977), Zharkov (1984)
Central Iran (Bafq, Gole Gohar, Hamadan)	Cambrian & younger -anorogenic felsic volcanic centres	>2,500 (>1,000) FeOx ± Cu, REE; >25 locs; sodic ± peralk alt	Extensive Cambrian & younger evaps; distal MnOx & Pb + Zn	Forster and Jafarzadeh (1994)
NW Canada (Great Bear, Wernecke Mtns.)	Proterozoic – interm arc volcano-plutonic centres	>50? (>10?) FeOx ± Cu, U, Ag, Co; >25 locs; regional sodic alt	No evaps reported; zoned from FeOx to distal Ag-Co-U	Hildebrand (1986), Hitzman et al. (1992)
South Australia (Acropolis, Olympic Dam, Emmie Bluff)	Mid-Proterozoic – anorogenic felsic-mafic(?) suite	>3,000 (>2,000) FeOx + major Cu, REE, U, Au; >5 deposits	High salinities, but no described Proterozoic evaps	Haynes et al. (1995), Gow et al. (1994)
Northern Sweden (Kiruna, Gallivare, Ekstromberg)	Mid-Proterozoic – maficfelsic volcanic suite, extensional(?)	>5,000 (>2,000) FeOx ± Cu, REE, Au, U; >20 locs; ext sodic ± peralk alt	Evidence for rifting with coeval evap source	Hitzman et al. (1992), Hauck (1990)
Northeastern USA (Benson mines, Mineville, Dover)	Mid-Proterozoic(?) – felsicinterm anorogenic suite	>1,000 (200) FeOx + REE ± Cu, U; >30 locs; ext sodic ± peralk & skarn	Evaps present; some interpret FeOx to be related to Grenville	Foose and McClelland (1995)

After Barton and Johnson (1996)

contact metamorphism. The dissolving evaporite or meta-evaporite provides much of the chloride necessary for metal transport, as well as the Na observed in the widespread sodic haloes that typify the dominant alteration in many of these deposits.

During extensional events, the downward penetration of surface/basinal pore fluids into basement rocks can occur along fault zones penetrating the basement (e.g., Fig. 14.57; Oliver et al. 2006). These fluids can leach metals from the basement and transport them, leading later to the formation of hydrothermal ore deposits in the basement and/or the overlying cover sequences. Indeed, many hydrothermal ore deposits in sedimentary basins have isotopic and geochemical signatures pointing to the involvement of basement rocks, particularly as a source of metals (e.g., Shelton et al. 1995; Piqué et al. 2008).

Products from the dissolution of thick halite beds generally are caught up in circulating basinal fluids. Owing to the chloride-rich nature of dissolving halite beds, sulphur levels tend to be relatively low in the brine. Reaction of these

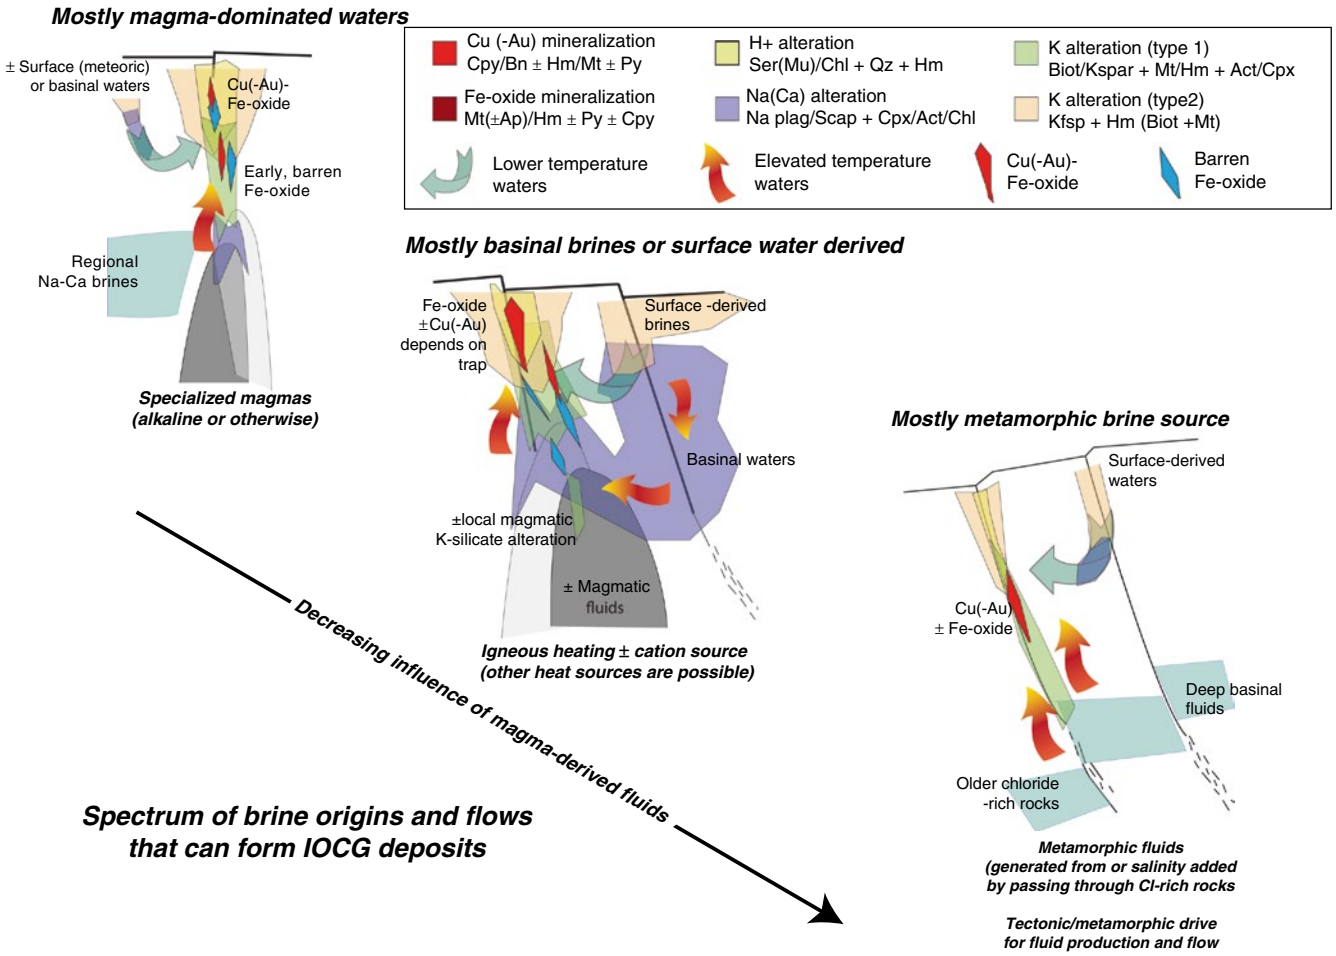

Fig. 16.16 Spectrum of brine origins and contributions of various hydrothermal brines and waters in IOCG deposits across the range of models from magma-dominated to basin-brine-dominated to deposits created by chloride-rich metamorphic fluids (Modified from Barton and Johnson 2004). See also Table 16.4

fluids along hydrothermally-driven circulation pathways produces predictable patterns of alteration and mineralisation (Fig. 16.16; Barton and Johnson 2004). Patterns can be similar to those created by nonevaporitic igneous-related hydrothermal circulation cells (e.g., metamorphosed porphyry deposits). However, there are diagnostic differences in the proportions of indicator minerals in the alteration haloes and nearby metaevaporites, such as scapolite and sodic amphiboles, along with characteristic solution breccia textures that distinguish these deposits. Voluminous sodic alteration typically dominates, independent of other factors of the magmatic history, and in far greater volumes than any potassic alteration that develops later in the circulation history.

On the downwelling limb, sodic alteration reflects the high Na contents in relatively low temperature fluids (Fig. 16.16). Alteration volumes are limited only by the amount of fluid that can circulate (heat balance), rather than by the S and Cl contents of causative intrusions, and so contrast with the typical situation in many porphyry-type systems. Coincident with sodic alteration, downwelling fluids can leach components in which it is undersaturated (Fe, K, Ca, reduced S, REEs, SiO_2; Barton et al. 1991; Dilles and Proffett 1995).

If temperatures are relatively high, marialitic scapolite (scp) + hornblende (hbl) dominate the alteration halo. However, the presence of scapolite and hornblende is, by itself, not diagnostic of an evaporitic source as both minerals can also form in nonevaporitic intermediate and mafic systems. It is the total association, its geometry and the recognition of a range of former evaporite/meta-evaporite textures and/or salt mass/halokinetic geometries in the country rock that are key to an interpretation of the relative importance of evaporite/basinal brine versus magmatic fluid inputs to the mineralizing system. However, many economic geologists, well versed in their understanding of rocks and processes formed or overprinted by high temperature fluids, do not promptly recognise indicators of the involvement of precursor saline mineral masses or beds (see Chaps. 7 and 13).

Table 16.5 Synopsis of likely evaporite indicators tied to IOCG styles and paramagmatic brine/hydrothermal associations, as defined by Barton and Johnson (2004)

Fluid source	Mostly magmatic waters	Mostly non-magmatic waters	
		Basinal and/or surface-derived	Metamorphic waters
Fundamental processes	Release of S-poor metal bearing brine from magma; fluids rise by buoyancy	Thermal/density convection of nonmagmatic brines; wall rock reaction provides metals	Metamorphic release of brine components by devolatilization or reaction with other aqueous fluids; rise by buoyancy
	Cooling, wall-rock reaction ± fluid mixing provide trap	Cooling, wall-rock reaction or fluid mixing provide trap; second fluid may provide metals	Cooling, wall-rock reaction ± fluid mixing provide trap
Igneous associations	High-K, oxidized suites ranging in composition from diorites to granites	Igneous rocks diverse (gabbro to granite); nonmagmatic examples known	No necessary connection, though commonly present
	Carbonatite and strongly alkaline connections proposed by some workers	Key heat source in most	Could be heat source in some settings
		Material source, diversity reflected in geochemistry	Can be material source
Hydrothermal alteration in feldspathic hosts	Na(Ca) and other types (K, H+) link to magmas	K (type I), $H^+ \pm$ Na(Ca) in upwelling zones	Primarily K and H^+ alteration associated with deposits
	Regional Na(Ca) coincident but not directly related to Cu(−Au)	Na(Ca) ± K (type II) in recharge zones	Regional Na(Ca) association reflects sources
Relationship of Fe-oxides to Cu(−Au)	Some Fe-oxides with Cu(− Au), may be deeper or higher-T equivalents	Mt-rich are deeper, earlier, higher temperature parts of ore-forming; Mt or Hm also typical with Cu	Fe-oxides present, but relatively minor (Bi or Chl common); Fe oxides commonly generated by breakdown of mafic minerals rather than Fe introduction
	Barren Fe oxides may form from distinct fluids and commonly in older hydrothermal systems in same area	Barren Fe oxides represent lack of S trap for Cu or lack of second Cu-bearing fluid	
Local setting: depth/structure	Shallow to mid crustal levels; commonly along regional structures but near causative intrusions	In (mainly) brittle upper crust; plumbing provided by regional or volcanotectonic structures	Mid- to shallow crustal levels near or on major structures; surface fluids require shallow levels
Global setting	Arcs or extensional environments that produce characteristic magmas (oxidized high-K or alkaline)	Regions with appropriate brine sources (arid settings or buried Cl-rich evaporitic materials), faultfocused plumbing systems, and thermal/density drives	Regions with Cl-rich low to intermediate-grade source rocks (typically meta-evaporites); compressional setting (e.g., basin-collapse) or prograde metamorphism
Possible evaporite indicators	Not typically noted, may be present if any interactions with nearsurface evaporites, saline waters and/or hypersaline brines have occurred	Salt beds, dissolution breccias, halokinetic geometries, alteration haloes can outline fault/salt welds, meta-evaporite indicators in more deeply-buried Cl sources	Meta-evaporite indicators, dissolution breccias, halokinetic geometries, alteration haloes can outline fault/salt welds

Albite (alb) + actinolite (act) + chlorite (chl) tend to form as co-precipitates in more mafic systems (Fig. 16.16). Such peralkalic assemblages are typically present in many evaporite-associated Fe-oxide occurrences. They are hard to rationalise by ordinary igneous or magmatic hydrothermal mechanisms (Barton and Johnson 2004). In contrast, the extremely high Na^+/H^+ levels of a dissolving evaporitic source can drive reactions such as:

$$2NaCl_{aq} + Fe_2O_3 + SiO_2 + H_2O \text{—} > 2NaFeSi_2O_6 + 2HCl$$

On the upwelling limb, cooling wallrock reaction and mixing of hot fluids with other basinal fluids creates distinctive mineral products, dependent on rock type and flow path. Sodic alteration persists where fluid-to-rock ratios are high. Hydrolytic alteration haloes [producing K-mica (sericite) + quartz in felsic rocks, chlorite in mafic rocks] form in response to cooling, along with precipitation of metals from chloride complexes. In rocks with moderate K_2O contents, potassic alteration (secondary biotite + K-feldspar) can form by alkali exchange (Hitzman et al. 1992).

Evaporitic brines sourced from dissolving thick halites have exceptionally high Cl/S ratios; thus metal content greatly exceeds the amount of sulphur available to precipitate them (Barton and Johnson 1996, 2004). Partial reduction and incorporation of sulphides may modify any original sulphate-bearing fluids, but they generally have too little sulphur to precipitate sulphide minerals at higher temperatures associated with circulation close to the intrusive. Consequently, only the least soluble chalcophile elements (e.g., Cu) form sulphides, along with the other elements that precipitate oxides or oxysalts (Fe, REEs, U) or the native elements (e.g., Au). Because adequate S is lacking, Pb and Zn will be removed from the system, and Fe-sulphides will be sparse. In some circumstances, reduction of these fluids

might precipitate distal Co-As-U. Early precipitation of magnetite/apatite is superseded by haematite ± copper-iron sulphides (Cp-Py) ± other REE minerals, as H-O(−Cl-S) fluids become more oxidising and sulphidising with decreasing temperatures (Barton et al. 1991). Barton and Johnson's (1996, 2004) broad grouping of igneous-evaporite/aridity related deposits includes the evaporite-associated IOCG deposits discussed next, but does not encompass the complete broad spectrum of styles and mechanisms inherent to the formation of all IOCG deposits.

Iron-Oxide Copper Gold (IOCG) Deposits

The discovery by Western Mining in the 1970s of the giant (2,320 Mt) Olympic Dam deposit near the edge of the Gawler Craton, South Australia, and the ensuing increase in exploration and research aimed at the discovery of similar low sulphidation ore deposits, led to the recognition of a new and what was first, and is still to many workers, a very broad deposit class, called iron oxide Cu-U-Au-rare earth elements (REE) deposits (e.g., Einaudi and Oreskes 1990; Gandhi and Bell 1990) and abbreviated to IOCG deposits (iron-oxide copper gold). The poorly defined class of ore deposits known as IOCG deposits, although better defined in recent years, still encompasses a diversity of formative settings that in earlier classifications of IOCG deposits grouped occurrences that ranged across orthomagmatic (intrusive and extrusive) to magmatic-hydrothermal deposits (Fig. 16.17). In the early days of IOCG studies, little space was given to defining the relative importance of magmatic versus basinal contributions to the ore forming hydrology. Many would say, including I, that the IOCG deposit class is still so broad, and still not tied to indicator chemistries and textures, that it is of little use as an on-ground exploration tool.

IOCG classification has been problematical at least since the definition of the Fe oxide–Cu–Au (IOCG) class of deposits by Hitzman et al. (1992). Subsequent research has refined the definition of this depositi style (Hitzman 2000; Williams et al. 2005; Groves et al. 2010), and suggested the Fe oxide-apatite (Kiruna-type) deposits likely are a separate, but related, type of ore deposit. A range of genetic models have also been proposed for IOCG deposits, many include the involvement of basinal brines, or fluids that have interacted with meta-evaporites, or surface-derived brines (e.g., Barton and Johnson 1996, 2002) and subsequent interactions with magmatic fluids.

Olympic Dam was, and is, considered to be the "type" IOCG deposit, and it is still the only supergiant ore deposit in this class. A comprehensive description of general characteristics across a range of IOCG deposits, published by Hitzman et al. (1992), was based largely on studies of iron-rich sulphide-poor deposits centred on Olympic Dam and prospects in the Stuart Shelf (Australia), along with deposits in the Cloncurry District of Queensland, the Kiruna district (Sweden), the southeast Missouri (Pea Ridge) iron district (USA), and the Wernecke Breccias (Canada). Within this IOCG classification, Hitzman (2000) identified 3 broad

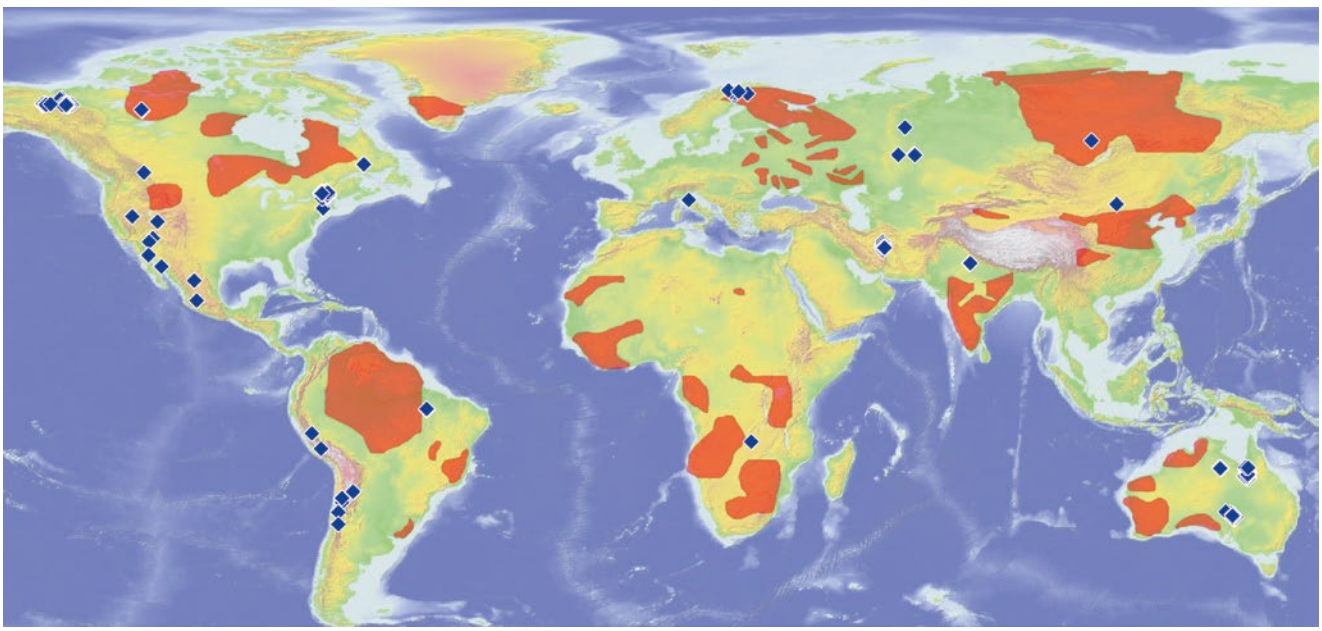

Fig. 16.17 IOCG deposits (*sensu lato*) with ties to basinal brine/evaporite fluids shown as *blue diamonds* on a world topographic base, also plotted are the larger Archaean craton blocks (*red areas*) (Plot compiled as GIS, using MapInfo® and SaltWorks IOCG version 1.6 data module as data source)

tectonic associations: (1) Intracontinental orogenic collapse (e.g., Cloncurry district), (2) Intracontinental anorogenic magmatism (e.g., Olympic Dam and Pea Ridge districts) and, (3) Extensional environments along a subduction-related continental margin (e.g., Chilean Iron Belt).

Some deposits previously classified as IOCG deposits and, often as not, associated with nearby evaporites, basinal brines and meta-evaporites, did not sit comfortably within the notion that IOCG deposits were the result of hydrothermal processes driving Cu-Au precipitation. Such *sensu lato* examples of IOCG deposits encompass the Proterozoic Kiruna iron ores of Scandinavia and the Pliocene magnetitic and extrusive iron ore bodies at El Laco, Chile. And so, as such *sensu lato* examples lacked elevated levels of Cu and Au, the definition of IOCG deposit was further refined by Hitzman (2000) in a reclassification that excluded Kiruna-type magnetite-apatite deposits. Instead, the magnetite-apatite deposits of Kiruna and iron extrusives such as El Laco were listed as likely endmembers in a spectrum of iron-rich deposits. Since then, most more recent classifications and listings, follow with this tenet, and tend to exclude the Kiruna and El Laco styles of deposits from the IOCG group (Groves et al. 2010).

The debate continues, but the consensus is that IOCG deposits are hydrothermally influenced and external to a magma body. There is a strongly-hydrothermal saline association in the country rock with variable levels of magmatic volatiles, rather than a purely orthomagmatic derivation. This is now the widely accepted mechanism for the larger economic examples of the IOCG group of deposits, including the "type" IOCG deposit at Olympic Dam in the Gawler Craton, South Australia (Gillen 2010; McPhie et al. 2011). For a comprehensive discussion of the geology of the broad range of Iron-Oxide Cu-Au deposits, the reader is referred to excellent reviews by Davidson and Large (1994) of the Australian deposits, while Frietsch et al. (1997) provide an excellent summary of the Scandinavian deposits. Williams et al. 2005, Pirajno et al. 2008, Groves et al. 2010 and Gillen (2010) provide comprehensive world overviews of the IOCG deposit class.

According to all these authors, the IOCG end of the hydrothermal iron-deposit spectrum is still very loosely defined. It encompasses copper ± gold (± uranium) deposits of Archaean to Tertiary age, which are linked primarily by the presence of abundant Ti-poor (<2 wt.% TiO_2) magnetite and/or haematite, and extensive alteration, particularly Fe-, Na-, and K-metasomatism (Hitzman et al. 1992; Hitzman 2002; Sillitoe 2003; Williams et al. 2005; Hunt et al. 2007; Gillen 2010). But, as recently noted by Groves et al. 2010, this still somewhat broad grouping encompasses numerous small iron-rich deposits that make the definition of an exploration-relevant tectonically-focused exploration model an impossible task.

Groves et al. (2010) suggests breaking out of this broad IOCG grouping, a tighter definition focused on characteristics of known economic associations. The resulting IOCG *sensu stricto* deposits are all: (1) magmatic-hydrothermal deposits that contain economic Cu and Au grades; (2) are structurally controlled, typically contain significant volumes of breccia; (3) are commonly associated with presulphide sodic or sodic-calcic alteration; (4) have alteration and/or brecciation zones at a broad, typically regional, scale relative to economic mineralization; (5) have abundant low Ti iron oxides and/or iron silicates intimately associated with, but generally paragenetically older than Au-Cu sulphides, with REE enrichment and low S sulphides (lack of abundant pyrite) and; (6) lack widespread quartz veins or silicification. Many of the IOCG deposits in this more narrowly defined group of IOCG deposits show a temporal, but not a close spatial, relationship to major magmatic intrusions and most encompass a range of evaporite associations (Table 16.6, Fig. 16.18).

This tighter definition excludes most porphyry and skarn deposits from the *sensu stricto* IOCG grouping. Intrusions, where identified, are typically alkaline to subalkaline, mixed mafic (even ultramafic) to felsic in composition, with evidence for mantle derivation of at least the mafic end members of the suite. According to Groves et al. (2010), the giant-size of many of the *sensu stricto* IOCG deposits and surrounding alteration zones, the highly saline ore fluids, and the available stable and radiogenic isotope data indicate likely release of deep, volatile-rich magmatic fluids through devolatization of causative, mantle-derived magmas and variable degrees of mixing of these magmatic fluids with other crustal fluids, especially basin brines, along regional-scale fluid flow paths.

Within such a *sensu strictu* classification, Precambrian IOCG deposits are the dominant members of the IOCG group in terms of both copper and gold resources. Within this *sensu stricto* grouping there are twelve IOCG deposits with >100 tonne resources that are located in intracratonic settings within some 100 km of the margins of Archaean or Paleoproterozoic cratons or other lithospheric boundaries. They tend to have formed 100–200 m.y. after supercontinent assembly (Fig. 16.18). Their tectonic setting at formation was mostly anorogenic[3], with magmatism and associated hydrothermal activity likely driven by mantle underplating and/or plume hot spots. According to Groves et al. (2010), limited amounts of partial melting of volatile-rich and possibly metal-enriched metasomatized early Precambrian sub-

[3] Anorogenic means not orogenic, and so such plutons were emplaced in periods lacking in, or unrelated to orogenic disturbance. A-type granitoids are emplaced in such periods in settings that typically encompass apparently stable cratons and intraplate (within-plate) extensional continental rifts, but can also include oceanic islands, generally near spreading ridges (Réunion, Ascension, Azores, Canary).

Table 16.6 Typical examples within the spectrum of Iron-Oxide-Copper-Gold (IOCG) deposits

Deposit	Tonnes ($\times 10^6$)	Commodity grade	Associated metals	Mineralization styles	Evaporite/fluids association
Non-Magmatic End-Member IOCG					
Wernecke Breccia, Yukon, Canada (ca 1,710 Ma) Hunt et al. (2005), Gillen (2010)	Slab: 20	Cu(%)0.35	U, Co, Mo	Disseminations, veins, breccia infill	Wernecke breccia is likely halokinetic. Mother salt was in Fairchild Lake Group, indicated by widespread evaporate solution breccias, deposits associated with abundant Naand Cl-rich (marialitic) scapolite and Mg-rich biotite.
Tennant Creek, Northern Territory, Australia ca. 1,860 Ma Williams and Pollard (2003)	W. Peko: 3.2 Eldorado: 0.0292	Cu (%) Au (g/t)4 20.8	Bi	Massive and vein mineralization overprinting ironstone	Small high-grade Cu-Au ironstone deposits hosted in fault-focused zones in deformed greenschist metasediments. Ironstones formed from hypersaline basinal brine with possible magmatic contribution
Redbank area, Queensland, Australia (<1,780–1,720 Ma) Knutson et al. (1979)	Bluff: 2 Sandy Flat: 1.5	Cu (%)1.6 Cu (5)6 2	Pb, Zn, REE	Breccia infill, veins, disseminations	50 breccia pipes located along a series of basement faults and source in halokinetic interval in Tallawallah Grp (pers. obs). Abundant K feldspar, hematite, and chlorite in breccias and host strata. Mostly from heated connate brines and/or marine waters rather than magmatic-hydrothermal fluids
Hybrid Magmatic-Non-Magmatic IOCG					
Olympic Dam, Gawler Craton, South Australia (ca. 1,590 Ma) McPhie et al. (2011)	2320	Cu (%)1.3 Au (g/t)0.5 Ag (g/t)2.9 U308 (kg/t) 0.4	Co, REE (dominantly La and Ce), Ni, As	Disseminations, veinlets, and fragments within breccias zones, primarily within breccia matrix with sedimentary clasts in breccia. Historically interpreted as diatreme.	Red-beds (possibly evaporitic) of the Pandurra Formation etc. lie beneath the younger cover sequence and pinch out against a crystalline basement high of predominantly foliated Donnington Suite granite. Strong intraclast breccias evidence for involvement of overlying (now eroded) sedimentary system in mineralisation.
Aitik. Northern Fennoscandia (ca 1870 Ma) Wanhainen et al. (2003), Frietsch et al. (1997)	800	Cu (%)0.3 Au (g/t)0.2 2	Mo	Disseminations and veins	Main ore was deposited from an aqueous, highly saline (31–37 eq. wt% NaCl + CaCl2) fluid. There was a contribution from dissolving evaporitic rocks to the salinity of mainly magmatic-hydrothermal fluids.
Candelaria, Chilean Coastal Belt (Early Cretaceous) Chiaradia et al. (2006)	470	Cu (%).95 Au (g/t).22 Ag (g/t)3.1	Zn, Mo, As, LREE	Vein, breccia- hosted, mantos, overprints magnetite replacement bodies	Inclusion studies indicate mixing of a high ^{37}Cl magmatic fluid with near zero values from ^{37}Cl basinal brines. That is early fluids were magmatic followed by mixing with likely evaporite-dissolution sourced basinal brine
Salobo, Carajas district, Brazil (2,580 Ma) Xavier et al. (2008)	450	Cu (%)1.15 Au (g/t)0.5	Ag, U, Co, Mo, F, LREE	Lenses, veins, pipelike or ringlike bodies of mineralisation	$\delta^{11}B$ values from 14 to 26.5‰ in the associated tourmalinites confirm marine evaporite-derived brines were present in the ore fluids
Ernest Henry, Cloncurry IOCG district, Australia (ca 1780–1720 Ma) Marshall and Oliver (2008); Foster et al. (2007)	166	Cu (%)1.1 Au (g/t)0.54	Co, Mo, U, REE, F, Mn, As, Ba	In isolated breccias pipes	Mixing of hypersaline basinal brines (mostly from evaporite-dissolution, e.g., meta-evaporite remnants of halokinetic scapolitic Corella Fm.) mixed with evolved magmatic-derived fluids
Magmatic End-Member IOCG					
Lightning Creek, Cloncurry IOCG district, Australia (≈1,540 to 1,500 Ma) Perring et al. (2000)	–	Cu (%) minor Au (g/t) minor	–	Qz-Mt ± Py ± chalcopyrite veins	Hosted by intrusives, largely made up of sodic-calcicaltered quartz monzodiorite. Sills are interpreted to be late-stage differentiates that crystallized under hydrous conditions with the episodic release of a fluid phase that underwent phase separation resulting in CO_2–rich vapour and a hypersaline (33–55 wt.% NaCl eq.) aqueous phase

Table 16.6 (continued)

Deposit	Tonnes (× 10^6)	Commodity grade	Associated metals	Mineralization styles	Evaporite/fluids association
Eloise, Cloncurry IOCG district, Australia (≈1,540 to 1,500 Ma) Baker et al. (2001b)	3.2	Cu (%)5.8 Au (g/t)1.5 Ag (g/t)19	Co, Ni, Zn, As, Bi	Veins, stockwork veins, massive sulphide	Fluids of pervasive pre-mineralization albite and hornblende-biotite assemblages were high-temperature (400–600 °C), highly saline (≥26–68 wt.% total salts) brines. Copper-gold-bearing assemblages were precipitated from lower temperature (200°–450 °C), lower salinity (30–47 wt.% total salts) fluids. Source of fluids is interpreted to be magmatic based on the high salinity of the fluids and the magmatic signature of the isotope data

After Hunt et al. (2007) and Saltwork IOCG GIS database, Version 1.6

Compare this table with the models illustrated in Fig. 16.15

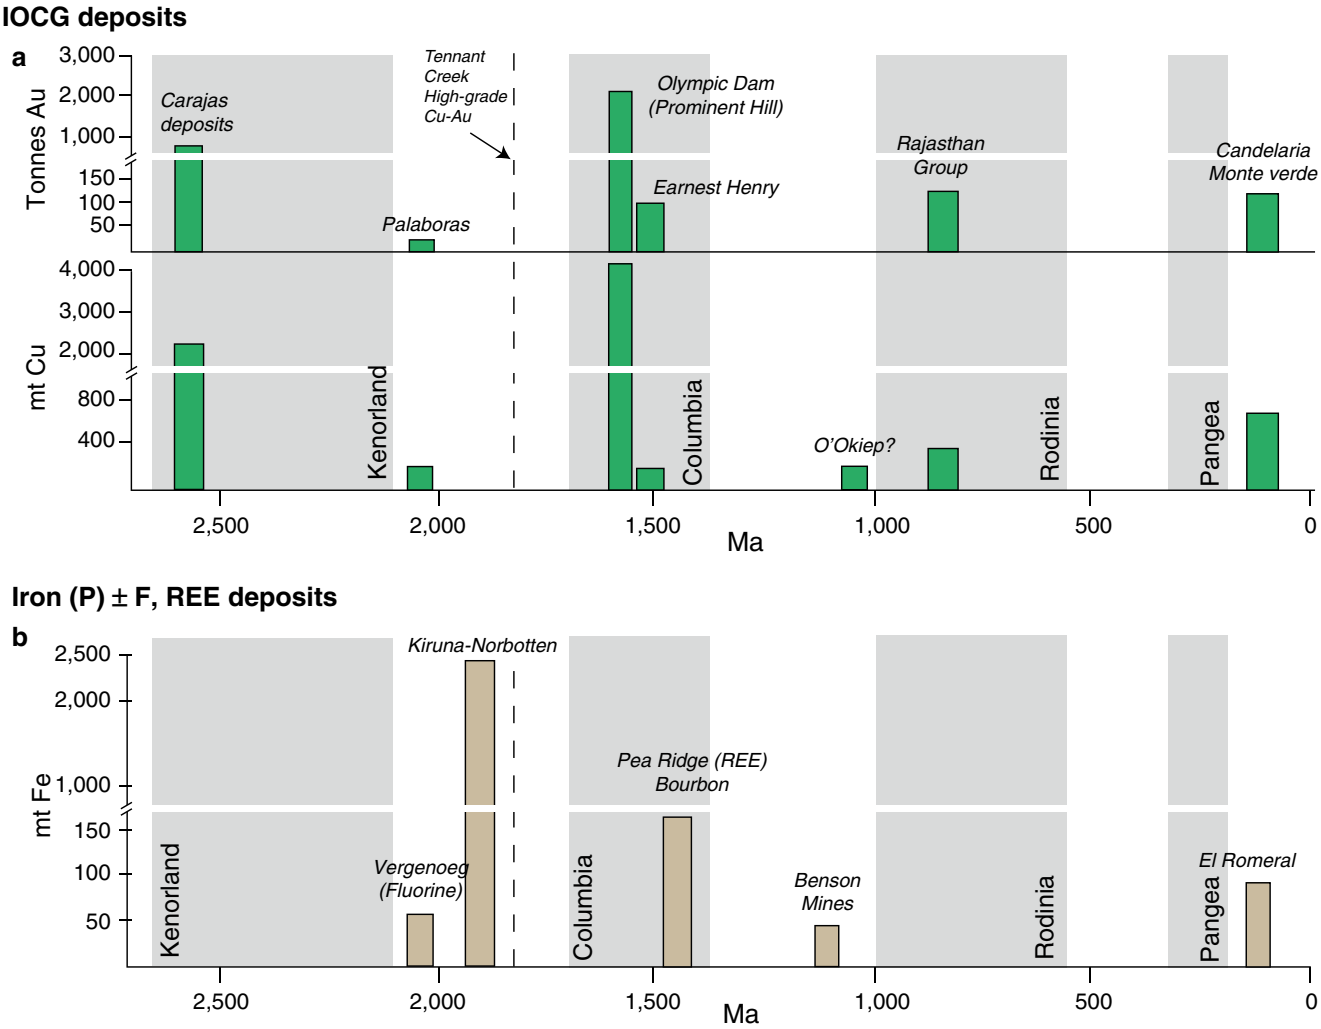

Fig. 16.18 IOCG deposits, tonnages and occurrences across geological time. (**a**) *Sensu strictu* IOCG deposits. (**b**) Fe (Ap) – Kiruna style (After Groves et al. 2010)

continental lithospheric mantle (SCLM), fertilized during earlier subduction, likely produced basic to ultrabasic magmas, which melted overlying continental crust. This mixed with felsic melts, along with devolatilization and some pene-contemporaneous incorporation of other lower to middle crustal fluids, combined to produce the larger IOCG deposits. Others of a more hydrothermal bent, would argue the metal source was largely in basinal waters flushing sediments

deposited under a less oxic Precambrian atmosphere. Preservation of near-surface deposits, such as Olympic Dam, is possibly due to their formation above buoyant and refractory SCLM, which resisted delamination and associated uplift from the time of formation until now (see Chap. 13).

Most other Precambrian iron oxide (P-rich) or magnetite-apatite (Kiruna-type) deposits (IOCG *sensu lato*) have a different temporal distribution, apparently forming in convergent margin settings prior to or following supercontinent assembly. It is only in the Phanerozoic that IOCG (*sensu lato*) and magnetite-apatite deposits are roughly penecontemporaneous within convergent margin settings (Fig. 16.18; Groves et al. 2010). Economically significant Phanerozoic IOCG deposits, such as Candelaria in Chile, occur in anomalous extensional to transtensional zones in the Coastal Cordillera, which are also the sites of mantle-derived mafic to felsic intrusions that are anomalous in a regional Andean context. This implies that special conditions, possibly detached slabs of metasomatized SCLM, may be required in convergent margin settings to generate worldclass IOCG deposits. It is highly likely that formation of giant IOCG deposits was mainly a Precambrian phenomenon related to the extensive mantle underplating that impacted on buoyant metasomatized SCLM (see Chap. 13). Generally, smaller and rarer Phanerozoic IOCG deposits formed in tectonic settings where conditions similar to those in the Precambrian were locally replicated.

Within the *sensu lato* set of IOCG deposits there is a general consensus that the formation of an IOCG deposit requires hypersaline CO_2- and $CaCl_2$-rich and S-poor fluids, active at shallow to mid-crustal levels, typically within cratonic or crustal-margin settings. Although IOCG deposits are often hosted by magmatic rocks, the fluids are not always clearly related to igneous activity. As noted by Hunt et al. (2007) and Chiaradia et al. (2006), there are noteworthy differences, both between deposits within an IOCG district and between districts, leading to a number of contrasting genetic models for IOCG deposits.

Some authors propose IOCG deposits developed from dominantly magmatic fluids – that is, dominantly orthomagmatic deposits (e.g., Hitzman et al. 1992; Pollard et al. 1998; Wyborn 1998; Skirrow 1999; Perring et al. 2000; Pollard 2001, 2002). Others propose a strongly magmatic fluid was the main source of metals (and sulphur), but invoke mixing with different fluids, usually cooler, less saline and more oxidizing, as the mechanism responsible for metal precipitation-i.e., paramagmatic deposits (e.g., Reeve et al. 1990; Baker 1998; Marschik and Fontbote 2001). Yet others propose that hydrothermal circulation of basinal fluid is a necessary requirement to form the larger IOCG deposits (Barton and Johnson 2004). The relative contribution made to the metal budget by these additional fluids is not clear, although there is a growing body of evidence that saline nonmagmatic waters are involved in most IOCG deposits, even in the formation of Olympic Dam (McPhie et al. 2011). Several authors suggest large volumes of saline non-magmatic fluids, that are perhaps evaporite-derived, are necessary for the formation of significant volumes of IOCG mineralization (e.g., Haynes et al. 1995; Barton and Johnson 1996, 2002; Haynes 2002; Hitzman 2002, McPhie et al. 2011). The corollary is that magmatism is important primarily as a source of heat to drive hydrothermal convection, but not necessarily as a source of the actual metals (Barton and Johnson 1996, 2002; Rhodes and Oreskes 1999). Figure 16.19 illustrates an example of the isotopic evidence that can be useful as indicators of fluid mixing during the formation of typical Phanerozoic IOCG deposits (*sensu lato*), as well as in interpreting batholith-driven hydrothermal fluid mixing with evaporite-influenced basinal brines

Much of the following geological detail on IOCG deposits is drawn from the preceding references but, as in previous sections on the metal-evaporite association, I divide my discussion of IOCG into a simple two-part classification, based on whether or not salts or their indicators are present or can be inferred from textural and mineralogic evidence in the ore forming system. I focus on the evaporite-associated class of IOCG deposits and deal more generally with those deposits that are not (Table 16.6). If I didn't, then the length of this chapter would have doubled. However, even in the following examples I give of the evaporite-IOCG association, the intrinsically high degree of sodic alteration and pervasive hydrothermal flushing that forms these deposits, means that undeniable evidence for a former salt masses supplying chloride to the transport system and/or focusing the precipitating system can at times be somewhat equivocal or enigmatic. So, the reader should be familiar with the material in Chaps. 7 and 13 in order to make best use of the following discussion.

Interestingly, when 12 of the larger IOCG deposits (*sensu strictu* of Groves et al. 2010) are placed in this evaporite spectrum, all show an affinity with hypersaline basinal fluids, evaporites or both (Table 16.5; Fig. 16.17). In general, deposits associated with either former evaporites or saline basinal brines show a broad tonnage range from high grade-low tonnage such as Juno and Peko in the Tennant Creek region to low grade-high tonnage such as Olympic Dam, Carapateena and Salabo (Fig. 16.20). Other than the supergiant Olympic Dam deposit, most of the known IOCG deposits are higher grade and lower tonnage than porphyry Cu deposits and related skarns, although the overall metal content of the two deposit styles is similar, falling in the range 10–100 tonnes Au-equivalent (Davidson and Large 1998).

IOCG in an Evaporite/Basinal Brine Milieu

Because evaporites are best preserved in Phanerozoic successions, we shall start our evaporite-IOCG deposit discussion there; first, with a discussion on iron oxide deposits

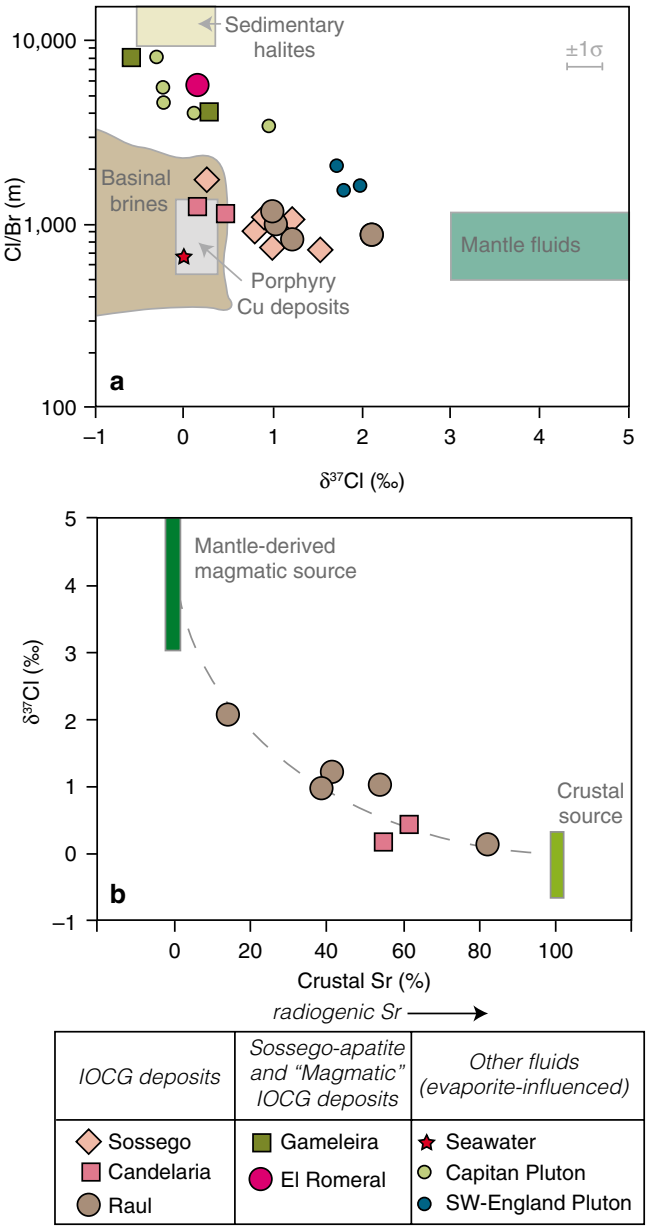

Fig. 16.19 Fluid chemistry from various South American IOCG deposits (After Chiaradia et al. 2006). (**a**) Cl/Br (molar) vs $\delta^{37}Cl$ diagram of fluids and relevant summary brine fields from various settings. (**b**) $\delta^{37}Cl$ vs crustal Sr(%) diagram for the fluids of the Candelaria, Raúl–Condestable, and El Romeral deposits. The crustal Sr (%) contribution was calculated using the mixing equations; $X_{magmatic} \times R_{magmatic} + X_{crustal} \times R_{crustal} = R_{measured}$ and $X_{magmatic} + X_{crustal} = 1.0$. X represents the percentage of contribution from the mantle-derived magmatic or crustal source, $R_{magmatic}$ is the $^{87}Sr/^{86}Sr$ values reported from the magmatic rocks associated with the various deposits, and $R_{crustal}$ is $^{87}Sr/^{86}Sr = 0.7073$ taken as the average value of an evaporitic source during the Cretaceous–Jurassic

formed where a magma mass may be the dominant driver for the hydrothermal fluid system. The most striking examples are magnetite bodies in the El Laco volcanic district of Chile that include magnetite lavas, as well as magnetite intrusives. Many of the Phanerozoic magma-fluid dominant Fe-oxide deposits are classified as IOCG deposits only under a *sensu lato* definition. They are excluded in deposit classifications using stricter definitions of IOCG deposits requiring the presence of economic levels of Cu-Au.

Phanerozoic Fe-Oxide Deposits

Phanerozoic magmatic IOCG (*sensu lato*) deposits are exemplified by Late Tertiary magnetite intrusive/extrusive volcanic complexes centred on El Laco, Chile and the Late Mesozoic (110 Ma) manto and Kiruna-style deposits of the Chilean Iron Belt. This latter grouping includes the large Fe-oxide accumulations at Marcona, El Romeral and El Soldado in the Andean subduction belt. In some ways these dominantly magmatic Fe-oxide deposits overlap nearby Cu-porphyry styles (Tornos et al. 2010). Like Cu-porphyry deposits, many of the exploited magnetite examples are tied to subduction, while those with noticeable Cu-Au mineralization show evidence of an early magmatic-fluid episode, which was dominantly characterised by hotter barren Fe-oxide (magnetite) styles, and later economic (Cu-Au precipitative) interactions with cooler nearsurface and saline basinal brines.

Interestingly, Carrillo-Rosúa et al. (2014) document extremely negative and inhomogeneous sulphur isotope signatures in Cretaceous Chilean manto-typeCu-(Ag) deposits in the Coastal Range of central Chile. For example, values in the MelipellaNaltahua deposit are as negative as $\delta^{34}S$ −50.4‰, which are among the lowest values found in any magma-associated ore deposit, worldwide. The ore precipitates are thought to be tied to bacterial sulphate reduction of basinal brines, relayed to the precipitation site by saline subsurface waters carrying hydrocarbons and sulphates from dissolved continental evaporites.

The El Laco volcano in the Andean Cordillera of northern Chile, contains the youngest, least altered, and best preserved magnetite-apatite ores known (Fig. 16.21). It was first described by Park (1961), who reported iron oxide ore bodies that resembled lava flows, and he suggested that the deposit was a result of a volatile-rich, iron-rich magma, which intruded the local volcanic sequence at shallow depth and in places erupted. This extrusive interpretation was assumed by many subsequent investigators focusing on the geochemical specifics of the deposit (Naslund, et al. 1997, 1998, 2002, 2003; Henriquez et al. 2003). However, others have suggested that the El Laco iron-oxide deposit has a hydrothermal origin (Hitzman 2000; Sillitoe and Burrows 2002).

The El Laco iron deposits are exposed at elevations between 4,700 to 5,300 m on the flanks of El Laco, a calc-alkaline volcanic complex in the Central Andes of northern Chile (23°48'S, 67°30'W). Within an area of 30 km^2 there are seven Fe-oxide deposits, with total resources on the order of 500 million tons of high-grade iron ore (Nystrom and Henriquez 1994). The ore bodies are not just rich in

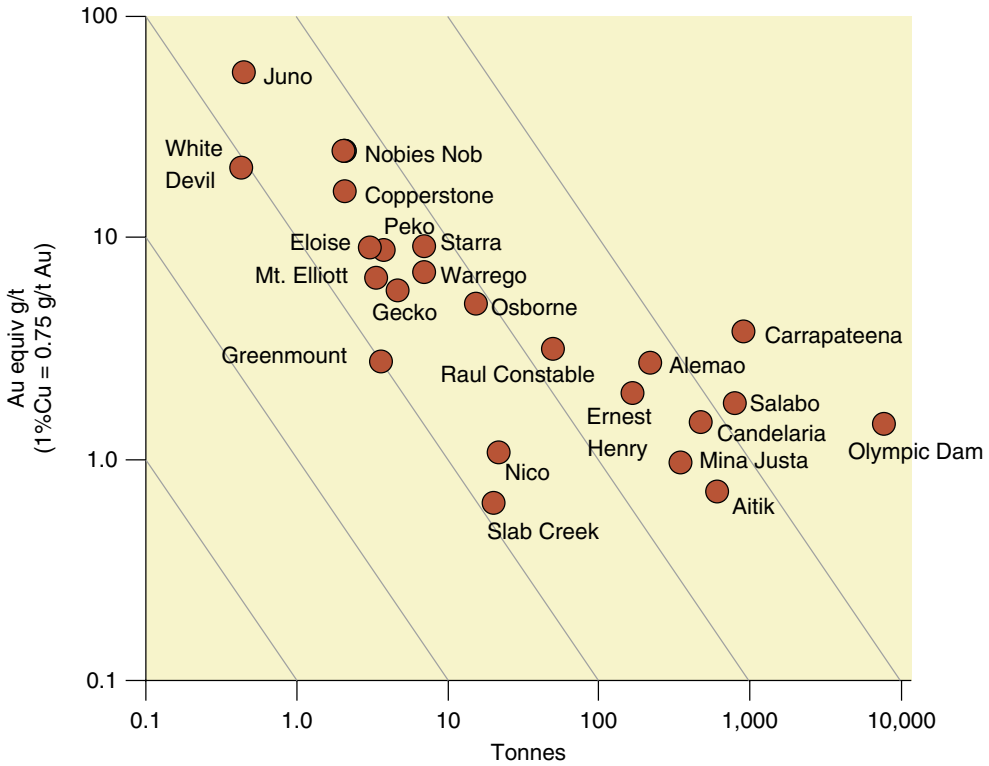

Fig. 16.20 Tonnage grade plot of selected IOCG deposits (sensu stricto due to elevated Cu ± Au levels) See Table 16.5 and text for details

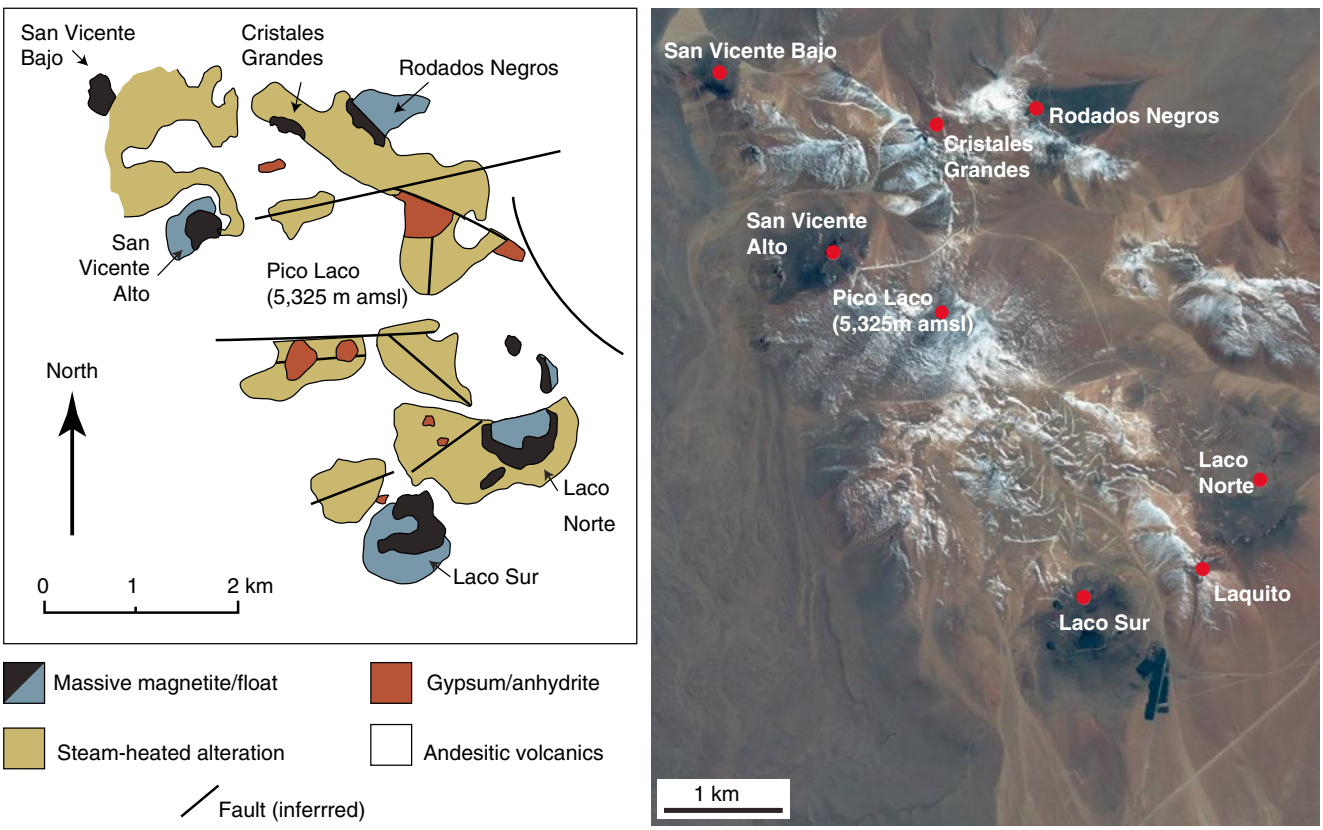

Fig. 16.21 Map of the El Laco magnetite deposits (After Vivallo et al. 1991. Laco Sur is the only one that has been extensively mined)

iron oxide, they are extremely rich in iron oxide, with many samples > 98 % iron-oxide; such rocks could be called "magnetitites."

Magnetite units at El Laco are porous, with high internal surface areas. Although composed primarily of magnetite and haematite, some samples have densities less than 2.0 and densities less than 3.0 are quite common. Open, unfilled void spaces in these samples can be described as pore-spaces and interpreted by some as the product of degassing during the eruption and crystallization of volatile-rich, Fe-rich magmas. Other investigators have suggested that some pore spaces are formed by the replacement of original vesicular silicate material by magnetite derived from Fe-rich hydrothermal fluids, and that other pore spaces were formed during the replacement process and represent open spaces leached out of the original protoliths by the removal of pre-existing material.

With the exception of the magnetite ore bodies, the El Laco district is similar to other volcanic complexes in the area in terms of silicate lava compositions, phenocryst assemblages, general eruptive history, and degree and distribution of alteration (Fig. 16.21). The ore deposits are dated by apatite fission track analysis at 2.1 ± 0.1 Ma and the overlying silicate lavas have been dated at 2.0 ± 0.3 by K/Ar. Andesitic to dacitic lavas predate and postdate ore deposition. Fumarolic activity continues at El Laco to the present day and is responsible for a number of sulphate (gypsum/anhydrite) accumulations in the region, as well as saline groundwater runoff into the intervolcanic salinas and salars (Chaps. 2 and 4).

El Laco is located slightly behind an active volcanic arc, as defined by the volcanoes Láscar, Licancabur, and Putana to the north, and Socompa, Lastarria, and Antofalla to the south. Crustal thickness beneath El Laco is ≈ 60 km, and the depth to the well-defined Benioff zone beneath the volcano is approximately 125 km (Frutos 1990). Tectonic reconstructions suggest that the crustal section below El Laco contains a Lower Palaeozoic basement of marine sedimentary rocks, unconformably overlain by Mesozoic and Lower Tertiary continental sediments and Upper Tertiary volcanic rocks (Frutos 1990).

A recent core-based study of the effects of magmatic metasomatism showed that even in these young volcanics (≈2 Ma) the effects of extensive subvolcanic contact-metasomatism is significant (Naranjo et al. 2010). This reflects the shallow-level emplacement of a volatile-rich iron-oxide magma, with associated fluid discharge and fracturing of overlying volcanic rocks. The brecciated rocks were altered by hot magmatic fluids emitted from the cooling intrusion (mainly extensive scapolitization and formation of pyroxene), and were accompanied by magnetite deposition. With time and decreasing temperature, the metasomatic fluids evolved to hydrothermal fluids, with a final recent geothermal pulse that deposited superficial gypsum over a large part of the El Laco Volcanic Complex (Fig. 16.21).

The extensive preservation of high-level extrusives in the El Laco deposit is unusual. More typical of the IOCG deposits within the *sensu strictu* members of the IOCG class are a number of intrusive members in the Mesozoic Chilean Iron belt; they include La Candelaria-Punta del Cobre, Mantoverde, Raul-Condestable, and Mina Justa. There are other members, also Mesozoic intrusives, in the same iron belt that contain lower levels of Cu-Au and only belong to the *sensu lato* IOCG grouping. A recent study of Marcona, one of the larger IOCG *sensu lato* deposits, by Chen et al. (2010) focused on the nature of the Fe oxide and Cu (−Zn-Pb) distributions across this deposit. Marcona, is a pre-eminent Mesozoic Andean magnetite deposit (1.9 Gt @ 55.4 % Fe and 0.12 % Cu) located in the IOCG subprovince of littoral south-central Peru. Chen et al. found that mineralization was controlled by northeast-striking faults transecting a Middle Jurassic (Aalenian-to-Oxfordian) andesitic, shallow-marine arc.

The mineralisation penetrates a succession of contiguous, plate-boundary-parallel, Late Jurassic to mid-Cretaceous volcanosedimentary basins. At Marcona, hydrothermal activity was initiated in the earliest Middle Jurassic (161–177 Ma) by high-temperature Mg-Fe metasomatism represented by cummingtonite and phlogopite-magnetite assemblages. Subsequently, during the terminal eruptions (156–162 Ma) of the arc, widespread albite-marialite alteration (Na-Cl metasomatism) was followed by the emplacement of an en echelon swarm of massive magnetite ore-bodies with subordinate, overprinted magnetite-sulphide assemblages, hosted largely by Palaeozoic meta-siliciclastics. As such, the hydrothermal evolution of this Cretaceous iron belt is not dissimilar to the smaller scale hydrothermal Fe-system driven by intrusive processes and sequences at El Laco.

The various magnetite orebodies exhibit abrupt, smoothly curving contacts, dyke-like to tubular apophyses, and intricate, amoeboid interfingering with dacite porphyry intrusions. There is no convincing megascopic or microscopic evidence for large-scale Fe-metasomatism associated with the main, sulphide-poor mineralization. The largest example in the district, the 400 Mt Minas 2-3-4 orebody, is interpreted as a bimodal magnetite-dacite intrusion, comprising commingled immiscible melts generated through the dissolution of metasedimentary quartz in parental andesitic magma. Oxygen and sulphur stable-isotope geothermometry indicates that, at ≈ 159 Ma, the evolution from magnetite-biotite-calcic amphibole ± phlogopite ± fluorapatite to magnetite-phlogopite-calcic amphibole-pyrrhotite-pyrite assemblages, coincided with quenching from above 800 °C to below 450 °C and the concomitant exsolution of dilute aqueous magmatic brines.

Subsequently, chalcopyrite-pyrite-calcite ± pyrrhotite ± sphalerite ± galena assemblages, in part metasomatic, were

deposited from lower temperature (≈360 °C) brines. The Cu-poor Marcona (Kiruna-type, Cu-Au barren magnetite phase) and the Cu-rich IOCG deposits in the same region, therefore, although spatially contiguous, represent contrasting ore deposit types. The former are mostly barren in terms of economic metals, other than iron, and are interpreted as the product of Fe-oxide melt coexisting with dacite magma, within an andesitic arc that failed (collapsed) during the closure of a back-arc basin. The weak associated magmatic-hydrothermal Cu-sulphide mineralization at Marcona was generated through melt vesiculation and was a localised product.

This stands in stark contrast with later considerably higher grade Cu- and Ag-rich orebodies of the major Cu-rich IOCG deposits in the Central Andes, e.g., La Candelaria-Punta del Cobre, Mantoverde, Raul-Condestable, and Mina Justa, which were the products of cooler, oxidized, hydrothermal and saline fluids, likely expelled from the adjacent evaporite-entraining basins during tectonic inversion (Fig. 16.19; Chiaradia et al. 2006; Chen et al. 2010). If we look at the Cu-Au grouping in the Phanerozoic deposits centred on the Andes, then hydrothermal processes and saline basinal waters (often evaporite-dissolution associated) are a significant component in the formation of the majority of larger *sensu-strictu* IOCG deposits.

Next, we consider whether the same external process set, i.e., hydrothermal and basinal brines, rather than purely orthomagmatic waters, also influences Proterozoic IOCG deposits. This next section focuses on Australia, where most of the larger known economic IOCG deposits (*sensu strictu*) occur, including the supergiant Olympic Dam deposit.

Proterozoic Iron-Oxide Deposits in Australia

Davidson and Large (1994) noted there are four styles of Proterozoic, iron-oxide, gold-producing deposits in Australia and all accumulated some 1.55–2.00 Ga (Fig. 16.18). The Australian IOCG groupings are (Fig. 16.22):

- *Type 1:* Stratabound Au +/− Cu-bearing iron formations (152.4 t Au) – exemplified by the Starra deposit.
- *Type 2:* Unconformity-style U +/− Cu/PGM/Au deposits (53 t Au) – exemplified by the Jabiluka and Coronation Hill deposits.
- *Type 3:* Iron oxide-dominated Au+Cu mineralisation hosted within elements of ductile deformation (146.7 t Au) – exempli-fied by the Tennant Creek deposits.
- *Type 4:* Iron oxide-dominated, breccia-hosted, Cu-U +/− Au hydrothermal replacement deposits spatially associated with felsic intrusions (273 t Au) – exemplified by the Olympic Dam deposit.

A key point is that in all examples discussed, with the possible exception of Olympic Dam, the mineralisation is hosted in sedimentary or metasedimentary hosts, not in a granite; so hydrothermal circulation must be a significant part of the emplacement process. Davidson and Large (op. cit.) go on to postulate that the most effective method of metal fixing in all four types is via subsurface fluid mixing. This hydrothermal process set achieves a synchronous decrease in fO_2 and temperature. In some IOCG deposits outside Australia, especially those in Scandinavia, the redox barrier that regulated the deposition of copper and gold is tied to the presence of graphite, typically in graphitic schists.

In Australia, Type 1 through 3 deposits usually occur in association with well developed, stratabound, ironstone units, suggesting the same reducing environment that formed the ironstones was also capable of fixing the Cu and Au. Davidson et al. (1989) interpret the ironstones of the Starra deposit as syngenetic exhalites (their 'magnetite-rich VHMS deposits').

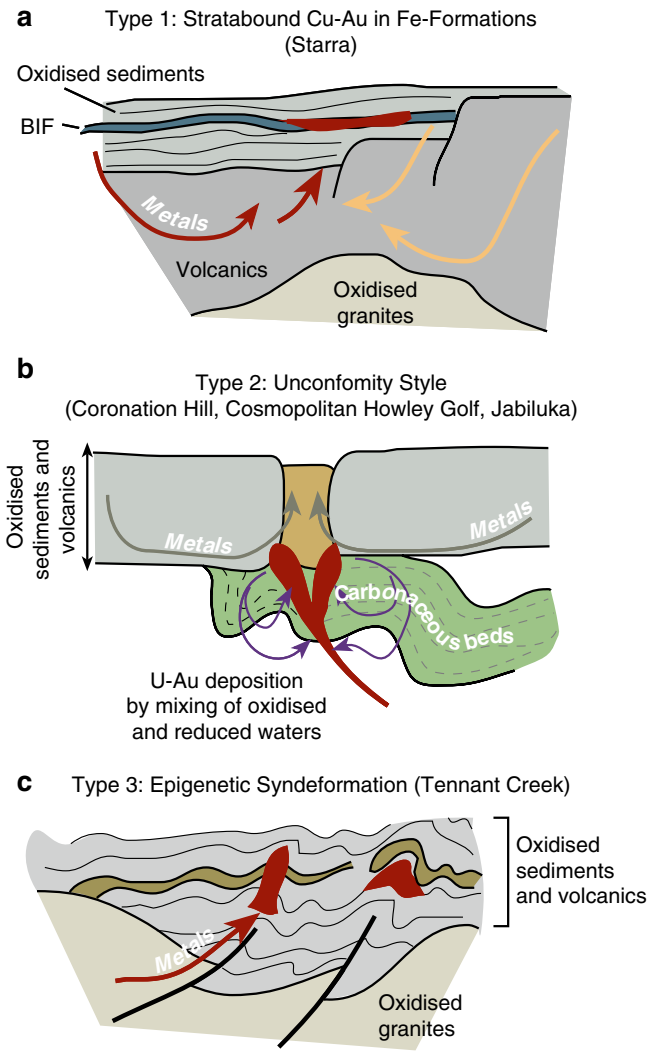

Fig. 16.22 Models of Proterozoic gold (±Cu) deposition (Types 1–3 indicated by **a**–**c** and discussed in detail in text). All involve chloride brines, high temperatures and evaporites (Modified from Davidson and Large 1994). One of the key points to be noted is that the mineralisation is in a sedimentary or metasedimentary host not in a granite or granite carapace, unlike Olympic Dam (Type 4; see Fig. 16.23)

Williams (1994) argues that different modes of occurrence of various ironstones indicate an epigenetic origin, whereby late hypersaline fluids generate magnetite replacement bodies. In my opinion, both styles of formation can be encapsulated in the notion of FeCl-rich brines supplied by sequences flushed by brines that are fed by dissolving and altering halite-dominated halokinetic evaporites (Fig. 15.80).

Type 1, stratabound Au +/− Cu-bearing iron formation deposits, are exemplified by the Starra deposit, Queensland (Fig. 16.22a; Davidson 1994). The Starra ore bodies are hosted by the meta-evaporitic Staveley Formation (1,720 Ma) of the Mary Kathleen Group, Mt Isa Eastern Succession (Chap. 14). Starra is the major mine of the Selwyn Cu-Au Project, consisting of 4 geographically separate outcropping ironstone hosted lodes, totalling 5.3 million tonnes at 5.0 g/t Au and 1.98 % Cu. Stratabound Cu-Au mineralisation occurs in a series of massive ironstone ridges, known as the Western Hematites, with a strike length of 6.5 km near the base of the Staveley Formation (Fig. 14.60). The ironstones strike north-south and occur as discontinuous lenses, that in places cross-cut the host rock. Unmineralised varieties of ironstones crop out over a much larger area.

Within the ironstones, the Cu-Au mineralisation occurs at the lithological contact of a metamorphosed sandstone/siltstone sequence with a succession of foliated chlorite-biotite-magnetite schists (Fig. 16.22a; Rotherham 1997; Davidson 1994). Ore lenses are immediately underlain by variably sheared albite-magnetite-haematite-pyrite-bearing rocks, and overlain by mainly unaltered, less-sheared, metasediments. Evidence indicating that albite was abundant prior to deformation, and also prior to the main hydrothermal addition of Fe, S, Cu and Au, includes; (1) regional albite development at this stratigraphic level; (2) alteration of albite by ore-related sericite; and (3) inclusion of unfoliated inclusions of albite and haematite in ore-related pyrite. Nevertheless, albite also developed around dolerites and within hanging wall shears during ongoing metamorphism and deformation.

Magnetite ironstone textures are generally massive in appearance, but relict deformed breccia and foliation textures are locally preserved. Sulphide ore textures are more brittle and consist mostly of fine, pervasive breccias in the ironstones and host rocks. Isotopically the vein gangue-calcites in the mineralised ironstones indicate a more reducing setting at the time of mineralisation, compared to other non-ironstone hosted IOCG deposits in the region, which show the effects of meteoric mixing and mantle sources (Fig. 16.23b; Marshall et al. 2006).

Davidson (1994) interprets the sodic metasomatism that formed the albite as a metasomatic halo fed by the metamorphic evolution of pre-existing halite-dominated evaporites. Regionally, the sodic rocks in the Proterozoic Mt Isa Eastern Succession are increasingly being recognised as the legacy of volatile-derived fluids fed, at least in part, by evolving meta-evaporites. There were several episodes of sodium introduction prior to, during, and following the major deformation. They were in part driven by hydrothermal fluid flow associated with granite intrusions and by halite/scapolite metamorphic evolution (Oliver and Wall 1987; Oliver et al. 1992; Williams et al. 1993; Williams 1994; Marshall et al. 2006).

Rotherham's et al. (1998) petrological and textural observations support a hydrothermal origin for both ironstone and mineralisation in the Eastern Succession. He recognised three dominant post-peak metamorphic paragenetic stages of alteration and mineralisation: (1) Early widespread Na-Ca metasomatism consisting of albite-quartz-actinolite-scapolite, (2) Localised K-Fe metasomatism consisting of biotite-magnetite-hematite-quartzpyrite and, (3) The mineralising stage, consisting of anhydrite-calcite-haematisation of magnetite-pyrite-chalcopyrite-gold and extreme chloritisation of biotite. The Na-dominant alteration occurs throughout the Eastern Foldbelt and for at least 50 km to the east and 150 km to the north of Starra (Fig. 16.23a). The ironstones that host the ore are interpreted as products of localised Fe-metasomatism associated with shearing and brecciation of previously Na-metasomatised host rocks. Gold and copper mineralisation resulted from the interaction of magnetite, a late oxidising fluid, and an increase in pH. This produced variable haematisation of magnetite and caused the solubility of chloride-complexed gold to decrease dramatically.

Albite was abundant prior to deformation in the Starra deposit, and also prior to the main hydrothermal addition of Fe, S, Cu and Au (Davidson 1994; Davidson and Large 1994; Rotherham et al. 1998). Davidson (1994) goes on to conclude that the fluids responsible for the sodic alteration at Starra, and for ore deposition, were saline, acidic (pH = 3.9–6.0) and high temperature, with relatively low levels of sulphur, with the gold carried as chloride complexes (Fig. 16.3). This, and the association with abundant meta-evaporite indicators in the region (mostly a NaCl, not $CaSO_4$, protolith), suggests that dissolving halite at high temperatures (or chloride released during the pressure-induced lattice collapse of marialitic-scapolitic daughter products – see Chap. 14) were responsible for the chloride transport and perhaps focusing of the gold precipitates into the deposit shear zones.

Albite in the Starra region also shows protolith and structural controls. As well as being preserved as bedding parallel units, it is often developed around dolerites and within hangingwall shears. Davidson saw this as a possible problem in interpreting the sodic metasomatism as being related solely to an evaporite precursor. In my opinion, the nonstratiform fault- and dolerite-related geometries of some of the sodic metasomatism is not a problem when invoking a metaevaporite fluid genesis. All it is reflecting is the typical reality that deforming salt is non stratiform. Once a salt body flows, it

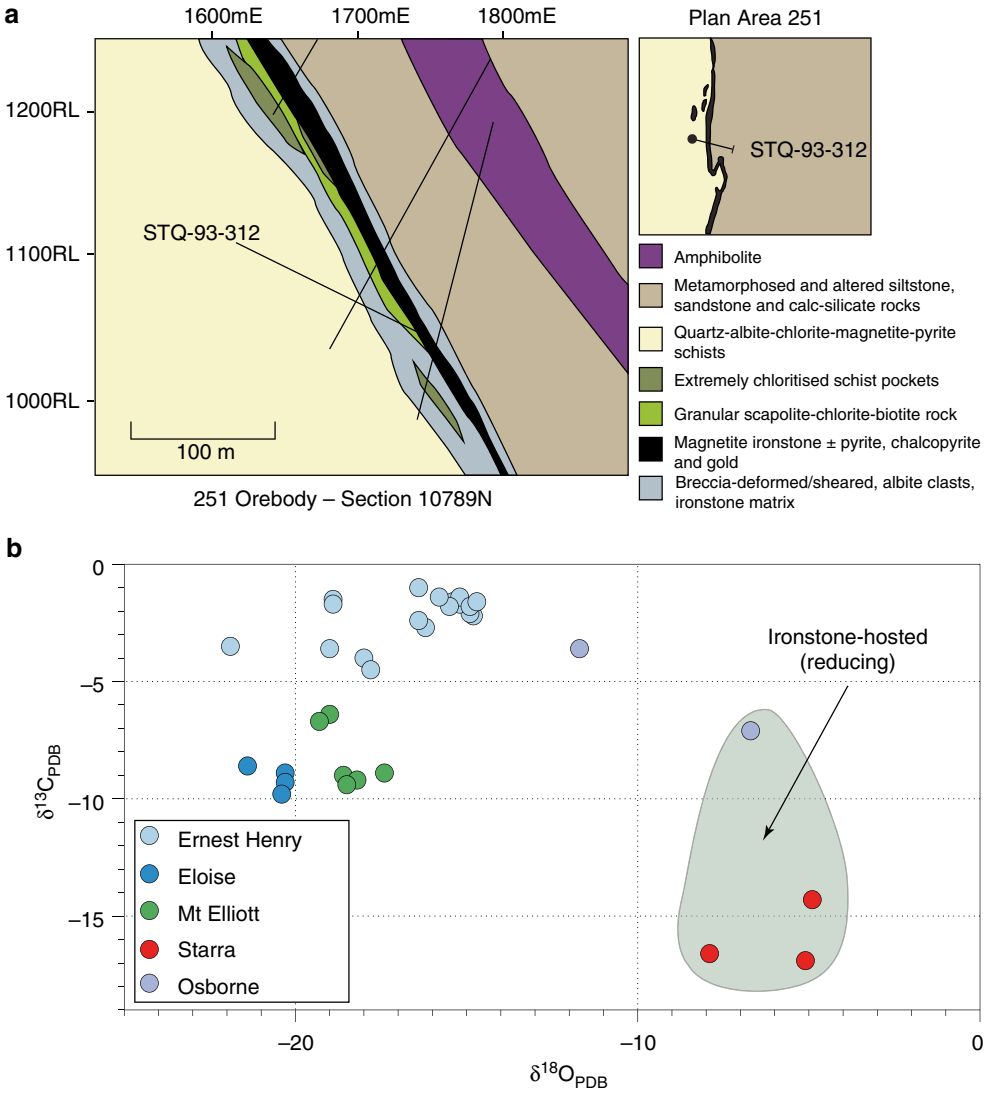

Fig. 16.23 Starra deposits. (**a**) Local geology (cross-section and plan the 251 ore body (After Rotherham et al. 1998). (**b**) Isotopic signature of ore-associated vein calcites in the ironstones of Starra and Osborne deposits define a separate plot field indicative of reducing conditions compared to warmer, more burial related signatures in the gangue vein calcites of the Ernest Henry, Eloise and Mt Elliott deposits (After Marshall et al. 2006)

and its brine products will have climbed the stratigraphy as a number of salt slugs and tiers that generate both salt and fault welds. These features can evolve from salt welds to fault welds and continues to act as ongoing planes of weakness (shears) and as fluid conduits in the metamorphic realm. They can be reactivated whenever the succession undergoes renewed extension, compression or even igneous intrusion. With ongoing metasomatism the fault/shears will gain sodic haloes, supplied by the evolving salt or metamorphic fluids from its daughter products. Even in the metamorphic realm, sodic alteration, which is commonly associated with meta-evaporites, will show nonstratabound trends that can be related to the deformation of a flowing salt body as it is squeezed through the subsurface (e.g., Wang et al. 1998a).

Type 2: Unconformity-style, U ± Cu/PGM/Au deposits are exemplified by two provinces in Northern Australia; the South Alligator Valley minerals field in the Pine Creek Inlier and the Alligator Rivers mineral field, both within the Pine Creek Orogen (Figs. 16.22b and 16.24; Davidson and Large 1994; Ahmad et al. 2009). Mineralisation in both provinces is localised at an unconformity between overlying relatively undeformed oxidised siliciclastic sediments and strongly deformed carbonaceous graphitic units. Coronation Hill is a viable, South Alligator Valley deposit, but legally unmineable due to its proximity to Jabiluka (Mernagh et al. 1994; Needham and De Ross 1990), while exploited uranium deposits like Jabiluka are well documented in the Alligator River minerals field (Fig. 16.24). Similar evaporite-related

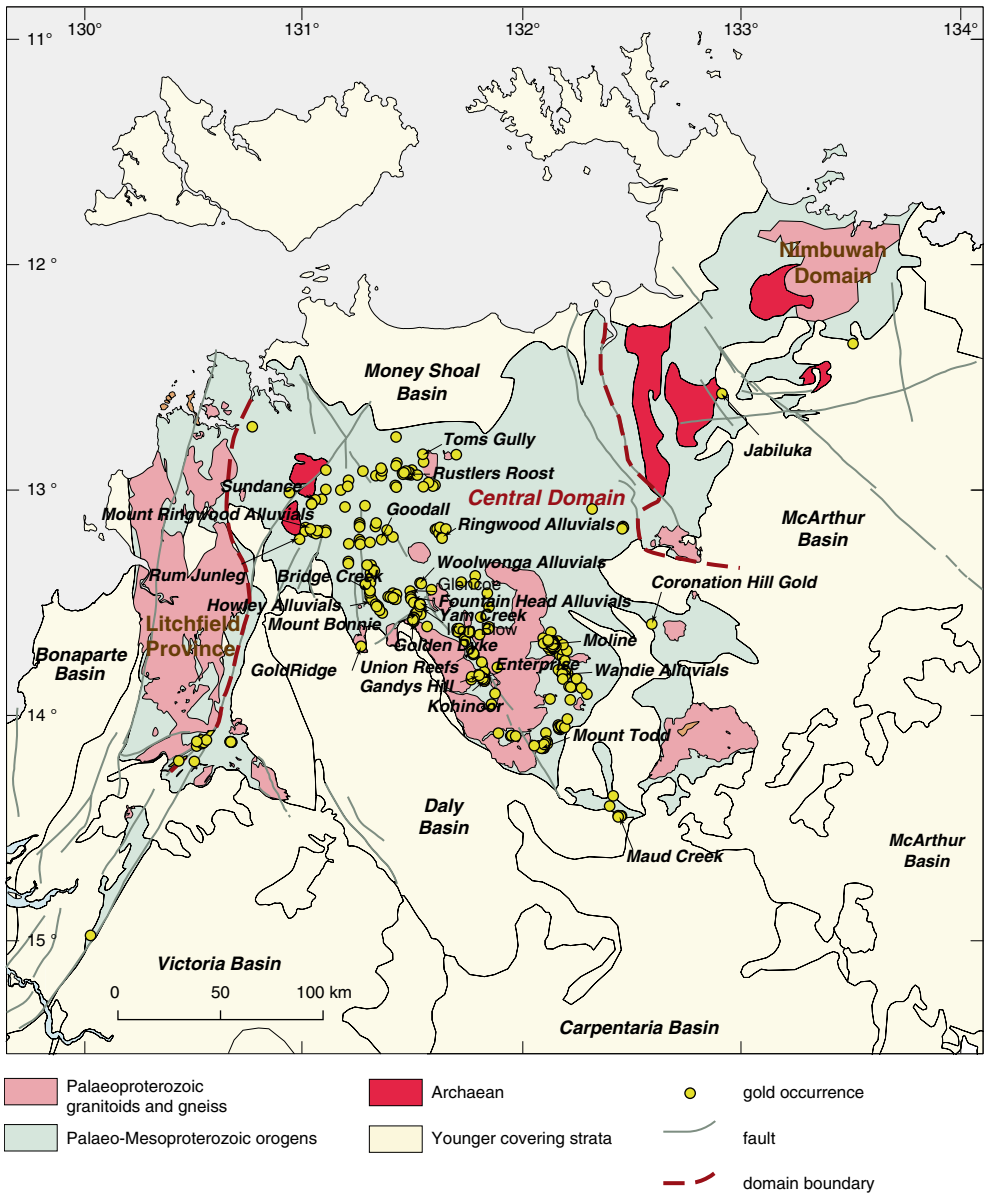

Fig. 16.24 Regional geology also showing gold occurrences in the Pine Creek Orogen (After Ahmad et al. 2009)

uranium distributions, tied to high-grade metamorphism of evaporites, occur in the Western Zambian Copperbelt of Africa (Eglinger et al. 2014)

From west to east, the Pine Creek Orogen is divided into three domains (Fig. 16.24: the Litchfield Province, Central Domain, and Nimbuwah Domain (Ahmad et al. 2009 and references therein). The Litchfield Province encompasses an area of high-temperature, low-pressure greenschist to granulite facies, meta-sedimentary and meta-igneous rocks. The Central Domain contains greenschist facies metasedimentary rocks and simple structures dominated by upright northwest- and north-trending folds. The Nimbuwah Domain is characterised by amphibolite facies Palaeoproterozoic metasedimentary rocks and granite, with widespread gneissic Archaean basement and upright to recumbent folds. The Pine Creek Orogen succession unconformably overlies Neoarchaean (≈2,670–2,500 Ma) granitic basement, which is exposed in the Rum Jungle Complex of the Central Domain, and the Nanambu Complex and Kukalak gneiss in the Nimbuwah Domain. Pine Creek Orogen is made up of an alternating succession of sandstone and shale, with minor carbonate and volcanic rocks. Dolerite sills (Zamu Dolerite and equivalents) intruded the succession prior to deformation and metamorphism.

The timing of deposition of the Pine Creek Orogen succession is constrained between 2,470 and 1,860 Ma and the succession is divided into two supergroups. The older Woodcutters Supergroup includes the Manton and Mount

Partridge groups and equivalent strata. This supergroup unconformably overlies the Archaean basement and consists of current-bedded and ripple-marked fluvial to shallow-marine sandstone, intertidal stromatolitic-evaporitic carbonates and shale, including carbonaceous and pyritic shale. Tuffaceous sediments from the Mount Partridge Group give ages of ≈2,020 Ma. The younger Cosmo Supergroup is made up of the South Alligator and Finniss River groups and equivalent strata. This succession is more widespread than the unconformably underlying Woodcutters Supergroup and comprises BIF, mudstone and tuff, succeeded by a monotonous flysch succession.

Tuffaceous sedimentary rocks in the Gerowie Tuff of the South Alligator Group give zircon ages of 1,861 ± 3 Ma and 1,863 ± 3 Ma (Worden et al. 2008), while zircon from the Warrs Volcanics in the Finniss River Group yield an age of 1,862 Ma ± 3 Ma. There thus appears to be a major depositional break between the Woodcutters and Cosmo supergroups, extending over a period of about 150 My. Recent detrital zircon geochronology across the Pine Creek Orogen suggests that the metamorphosed successions in the Litchfield Province represent stratigraphic equivalents of the Woodcutters and Cosmo Supergroups. In comparison, the Palaeoproterozoic succession in the Nimbuwah Domain (Nourlangie Schist and Cahill Formation) has a different provenance to sedimentary rocks in the central Pine Creek Orogen, and was deposited earlier, in the interval 1,900–1,870 Ma.

Regional deformation and metamorphism occurred across the Pine Creek Orogen in the interval 1,865–1,850 Ma. In the Nimbuwah Domain in the east, high-pressure mid- to upper amphibolite-facies metamorphism occurred at 1,865–1,860 Ma, accompanying intrusion of granites of the Nimbuwah Complex and regional west-directed compressional deformation. In the Litchfield Province in the west, high-temperature low-pressure metamorphism occurred at ≈1,853 Ma, probably in an extensional environment. The timing of upright deformation and low-grade metamorphism of the Central Domain is less well constrained, but must postdate the deposition of the Finniss River Group at ≈1,860 Ma.

In the Central Domain, the earliest deformation, D_1, caused north-trending monoclinal warping, recumbent north-trending isoclinal folding and shear zones. D_2 deformation is represented by thrusting and recumbent folding. The D_3 deformation event was more widespread and is indicated by north- to northwest-trending non-cylindrical, closed to tight folds. These folds are an important structural control for vein-type mineralisation in the Central Region. D_4 deformation was associated with granitic intrusions and produced open, small-amplitude regional folds, which are responsible for the formation of elongated basins and domes. D_5 deformation produced steeply plunging polyclinal kinks and drag folds associated with dextral movements along major faults.

A major period of igneous activity, minor deformation and rift-related sedimentation occurred in the Central Domain at 1,835–1,800 Ma and this is termed the Cullen Event (Ahmad et al. 2009). Albite-epidote hornfels is present in all contact aureoles, commonly with a narrow, inner continuous zone of hornblende-hornfels. Effects of contact metamorphism are seen up to 10 km away from granite contacts. The Central Domain, where I-type[4] granites dominate, contains the majority of the gold, base metal and tin deposits, as well as stratabound gold and polymetallic deposits. The Litchfield Province S-type granites are related to Sn-Ta bearing pegmatites (Ahmad et al. 2009).

Coronation Hill in the Central Domain, is a typical unconformity-style deposit (Fig. 16.24; Mernagh et al. 1994; Ahmad et al. 2009). Pd–Pt–Au mineralization at Coronation Hill occurs in structurally-controlled lenses in Proterozoic metasediments and in altered volcanics near the unconformity with overlying sediments (5.4 Mt grading 4.31 g/t Au, 0.65 g/t Pd and 0.19 g/t Pt (Fig. 16.25; Carville et al. 1990). Although economic, it will not be mined due to the deposit's proximity to Kakadu National Park. The sub-unconformity mineralisation separates a deformed and metamorphosed basement (composed of igneous intrusions, volcaniclastic rocks, and calcareous and carbonaceous meta-sedimentary units, including sparry magnesites and tourmalinites) from a cover sequence (Kombolgie Group) of little-deformed haematitic quartz sandstones, organic shales and sedimentary breccias. Uranium ore is located in semi-brittle shears and breccias that are subparallel to the units in the Nanambu Complex and typically developed at the hinge zones of fault-related folds. Uraninite veins are intimately associated with chlorite, sericite, haematite, quartz, and illite veins, which extend in to the basal 2 m of the Kombolgie Formation

Geologic, fluid inclusion, stable isotope, and thermodynamic data indicate mineralization at Coronation Hill was driven by reaction of oxidised and acid hypersaline basin brines (originating from the supra-unconformity Palaeoproterozoic cover sequence and its hydrosphere), with feldspathic and reducing rocks and fluids supplied by sub-unconformity crystalline Archaean basement (Mernagh

[4]I-type granite is metaluminous to weakly peraluminous, relatively sodic, and has a wide range of silica content (56–77 wt% SiO_2). It was inferred to have formed from a mafic, meta-igneous source. The other dominant granite type is strongly peraluminous, relatively potassic and restricted to higher silica compositions (64–77 wt % SiO_2). Chappell & White in a widely distributed 1974 abstract called these S-type granitoids because these they are inferred to have formed from melting of metasedimentary rocks. This scheme received instant popularity and has been applied worldwide (Chappell and White 2001). It is based upon the assumption that one can easily distinguish the origin of the granitoid precursor utilising whole rock geochemistry. However, similar granitic compositions can be produced by partial melting and/or assimilation of a variety of sources including highly sodic evaporites and meta-evaporites.

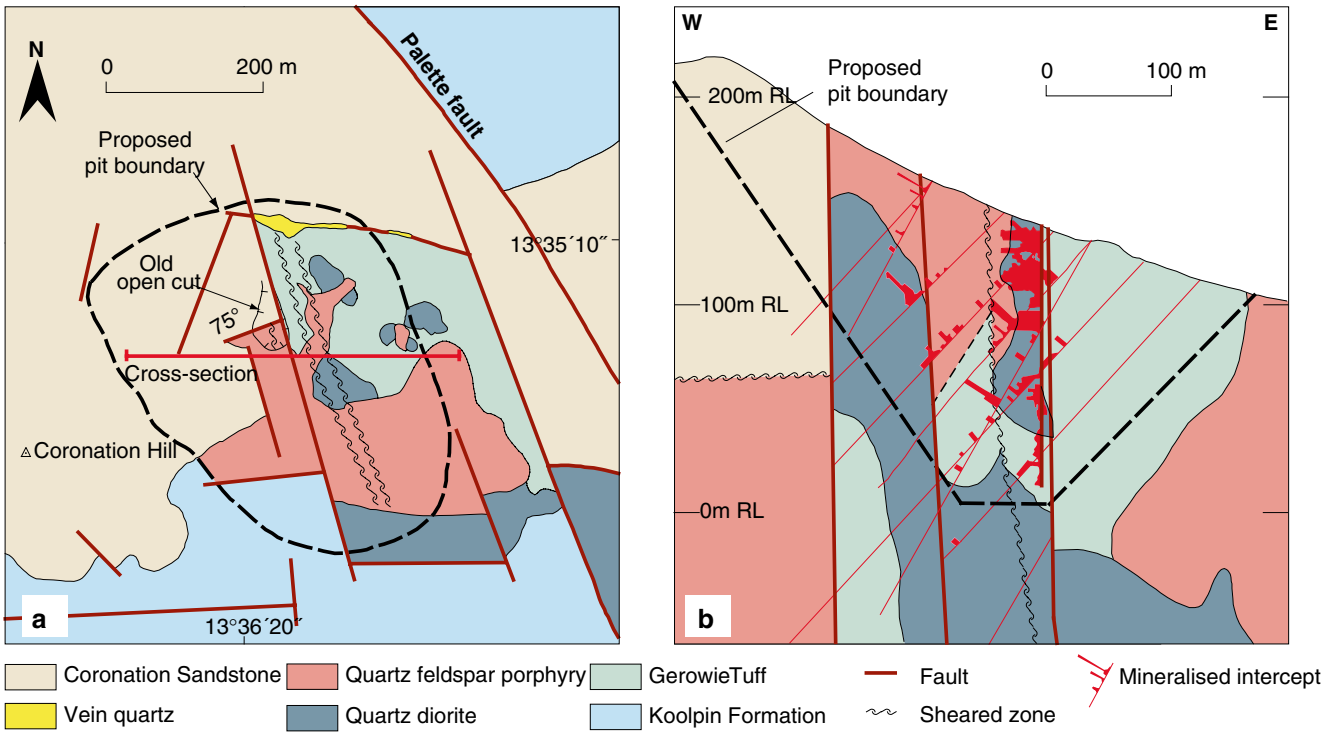

Fig. 16.25 Coronation Hill, Northern Territory, Australia (After Carville et al. 1990). (**a**) Plan view. (**b**) Cross section. Note higher mineralised section is associated with quartz feldspar porphyry quartz diorite intersection, adjacent to unconformity

et al. 1994). Inclusion analysis shows the ore fluids were hypersaline and calcium-chloride dominated (≈26 wt% $CaCl_2$ equiv.) and that mineralization occurred at around 140 °C. These are the characteristics of hydrothermal basinal brines in evaporite-entraining basins (Chaps. 2 and 8) and similar marine evaporite-derived brines played a similar role in the formation of the 1.8 Ga unconformity-related U deposits of the Athabasca Basin, Canada (Richard et al. 2011; Mercadier et al. 2012).

The lowest member of the Palaeoproterozoic cover sequence at Coronation Hill is the Koolpin Formation. It was deposited in a terrigenous-dominated arid peritidal setting in an opening rift depression (Matthai and Henley 1996). Further south, the unit hosts the Cosmo Howley Au deposit. The Cosmo Howley deposit straddles the axis of the Howley Anticline, a regionally continuous 30 km long structure. In the mine area the fold axis plunges at 50° towards 325°, with a well-developed consistent slaty cleavage (Fig. 16.26). The global resource, including underground ores centred on the mine, was stated in 1995 at 10 Mt @ 2.75 g/t Au (Matthai et al. 1995). Intense faulting, sometimes with associated brecciation, parallels the cleavage through the axial zone and east limb in zones from 1 to 10 m wide.

The Koolpin Formation, the main host to the Au ore is divided into three members: (1) 250 m thick Lower Member of carbonaceous and micaceous mudstone and siltstone. (2) Middle Member, which is up to 100 m thick and mainly composed of interbedded iron formation (10–15 % Fe as oxide and sulphide), carbonaceous mudstone and mudstone, and (3) 50–150 m thick Upper Member of carbonaceous mudstone. Significant gold ore is developed at a number of levels within the Middle Member, although substantial economic mineralisation is also found in ironstones and mudstones in both the Upper and Lower Members. Some 40 % of the reserves are in the Lower Member.

The dominant ore host in the Cosmo Howley Au deposit consists of quartz veins along steeply dipping limbs and across the hinge of the Howley Anticline, perhaps located regionally in what was the high-temperature aureole of the Cullen Batholith. Veins are hosted by upper greenschist to lower amphibolite facies comprised of carbonaceous pelites, metasiltstones, and ironstones of the Koolpin Fm., which also contains recrystallised chert nodules and bands, metadolerite sills, along with scapolite (Fig. 16.26; Ahmad et al. 2009). Gold is concentrated in structurally controlled sites developed at or near the contact between ironstone and carbonaceous units and it forms inclusions in arsenopyrite and pyrite, hosted by both concordant and discordant quartz veins. Associated ore minerals include chalcopyrite, pyrrhotite, galena, and sphalerite (Ahmad et al. 2009). Matthai et al. (1995) suggested that reduction of late magmatic brine by mixing with saline metamorphic fluids near the carbonaceous pelite was responsible for localization of gold. Heat from the prolonged intrusive and cooling history of

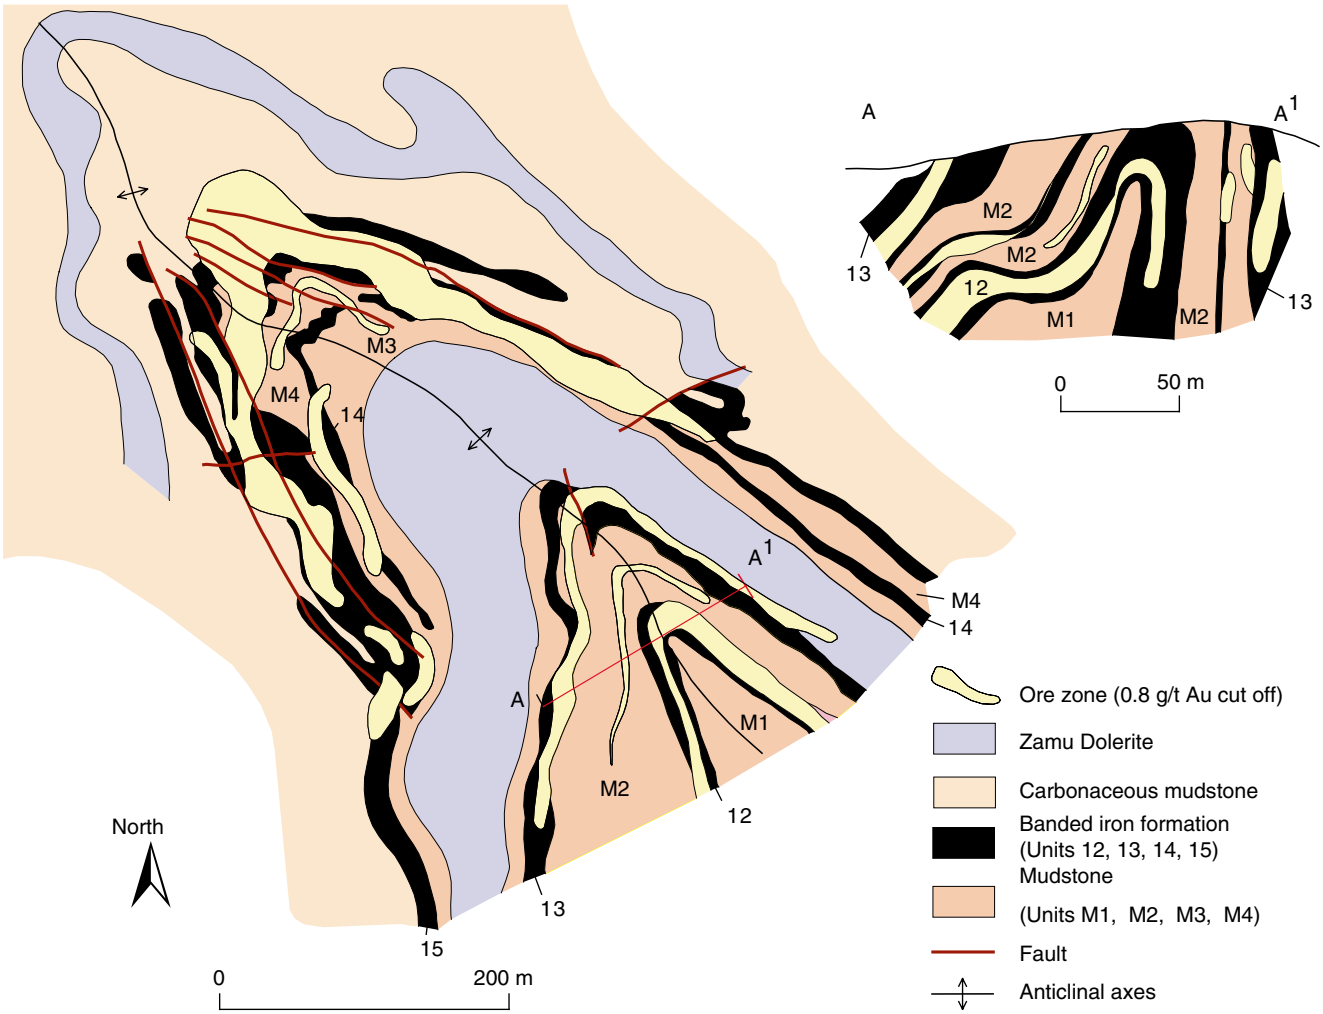

Fig. 16.26 Cosmo Howley Mine, Northern Territory, Australia, showing plan view and cross section A–A' (After Ahmad et al. 2009)

younger ≈ 1,800 Ma granites in the Cullen Batholith, coupled with pre-existing faults and shears, allowed long-lived hydro-thermal systems to channel fluids from granite and metamorphic sources (Kominsky et al. 1996).

Some outcrops of the Koolpin Formation contains textures indicating the former presence of evaporites, as does sodic scapolite, suggesting metal transport as chloride complexes (J. Stewart, pers. comm.). It would be an interesting exercise to test, via matrix characterisation, if some of the "sedimentary breccias and chert breccias" along the unconformity are possible evaporite solution breccias, including those in portions of the Kombolgie Unconformity that regionally host the gold and U ores. That is, did a now-dissolved, once clean thick salt unit reside atop this unconformity, and prior to and during its dissolution act as a focus for mineralising fluids? Under this scenario, any improved exploration targeting requires better definition of mineralised relationships to alteration haloes with respect to faults, which would also intersect or sole out into synkinematic breccias. Sparry carbonate replacement haloes, which occur around some feeder faults to the mineralisation in the region, should be redefined and mapped with a possible halokinetic perspective. This would test any regional mineralisation/lithological/salt solution relationships.

Regionally, in the Alligator Rivers mineral field, a structural control to the mineralisation is less obvious than at Coronation Hill, although mineralised reverse (thrust) faults are present and several deposits are fault displaced. Regionally, the massive haematitic Kombolgie Sandstone (1,648 ± 219 Ma) and mafic Nungbalgarri Volcanics unconformably overlie polydeformed semipelitic to graphitic schists and amphibolites of the Lower Proterozoic Cahill Formation and the Myra Falls Metamorphics (Davidson and Large 1994). A thick (up to 1,800 m presently preserved) unmetamorphosed detrital sequence, composed of fluvial and aeolian sandstones (the 'Kombolgie Sub-Group'), unconformably overlies the crystalline and metamorphic basement and is dated at 1,822 and 1,720 Ma (Boiron et al.

2010). The youngest members of the Kombolgie Sub-group were deposited in marine conditions, as suggested by the occurrence of glauconite and halite crystal casts (Kyser et al. 2000) and by stromatolitic and evaporitic dolostones-sandstones in the McKay formation (Rawlings 1999). The deepest mineralisation (mostly U) occurs as much as 500 m below the unconformity. Primary ore at Jabiluka occurs as uraninite-filled veins, cements and disseminations in which gold and tellurides are present as inclusions and veins, along with magnesian chlorite and anhydrite (Binns et al. 1980).

Sparry ferroan magnesite occurs in the Coomalie and Celia dolomites in the nearby Rum Jungle area. Disparate interpretations of halite and gypsum pseudomorphs (Crick and Muir 1980), versus high temperature recrystallised magnesite (Bone 1983), versus hydrothermal replacement of precursor dolomite (Aharon 1988) were discussed in Chap. 14. These, at first, disparate explanations, can be drawn into a much more coherent escaping-basinal-water model, centred on fluids derived as host strata pass from the diagenetic into the metamorphic realm. All it requires is that protolith analogies are drawn with fault-fed hydrothermal sparry replacements, which occur atop halokinetic provinces in northern Africa and the McArthur Basin. Such intervals show fluids capable of carrying metals have been focused along faults carrying hypersaline brines outlined by sparry ferroan replacement haloes.

Type 3 deposits are exemplified by Tennant Creek style deposits, where iron-oxide -bearing Cu-Au pipes are the main ore bodies (Fig. 16.22c; Davidson and Large 1994; Rattenbury 1994). Since 1932, the Tennant Creek mineral field has produced 130.2 t Au, 345 000 t Cu, 14 000 t Bi, 220 t Se and 56 t Ag from over a hundred small- to medium-sized mines (Fig. 16.27). To the south, in the Davenport Province, there are several minor gold occurrences in quartz veins and stringers that have contributed 75 kg Au. The bulk of historical gold production was in the period 1960–1980, during which the Tennant Creek mines produced about 64 t Au. Most production was derived from 12 main deposits, with Warrego, Nobles Nob and Juno providing over 96 t Au (Fig. 16.28)

The Tennant Creek goldfield is characterised by large massive haematite/magnetite + quartz + chlorite "ironstones", which host gold, copper and bismuth ores in metasediments of the rift-fill Warramunga Group (Figs. 16.27 and 16.28). Once again, the dominance of gold occurrence in metasediment, not igneous apophyses, implies that the igneous suite did not directly control the precipitative positions of the gold mineralisation (Fig. 16.27). Rather, the juxtaposition of ironstone and faults/shears is the dominant control. The ironstone bodies are irregular, flattened, ellipsoidal and pipe shaped, and range in mass from a few tonnes to over 15 Mt. Over 700 ironstone bodies have been recorded throughout the Tennant Creek ore field, but fewer than 200 are known to contain significant mineralisation, and only 25 have produced more than 100 kg Au (Ahmad et al. 2009)

The ironstones formed during east-west folding, initially from crossflows of high salinity basinal brines, which later mixed with magmatic brines to form the Cu-Au-Bi mineralisation stage. Rattenbury (1994) interprets the folding as derived from a relatively thin skinned thrust system that deformed the Warramunga Group, thrusting mostly metasedimentary rocks up and over from the south toward the north resulting in a series of steep listric reverse fault splays and folds. The hypersaline ironstone-forming fluids used the thrust faults as major conduits as well as the developing cleavage planes in the turbidites and other deepwater sediments of the Warramunga Group. Ironstones then formed mineralised zones where the cleavage-parallel conduits intersected iron-rich parts of the stratigraphy, and in numerous instances show a close spatial association with stratiform quartz-feldspar porphyries. The latter has been interpreted as being emplaced into the sediments of the Warramunga group while they were still unconsolidated and water-saturated (McPhie 1993). Thus the ironstones formed early in the burial history of the basin sediment pile. It is tempting to argue such a mechanism may well be tied to ascending FeCl-rich evaporite-associated basinal waters.

Based on fluid inclusion work, Zaw et al. (1994) favour a mostly basinal brine genesis for the chloride-rich solutions that first created the ironstones and then mineralised them. They also acknowledge that some magmatic contribution cannot be ruled out. Fluid inclusions in the ironstones have a salinity range of 10–30 NaCl equiv. wt % and homogenization temperatures of 100–350 °C, with a mode at 200–250 °C. Salinity measurements on fluid inclusions in the mineralised ironstones gives a range of 10–50 NaCl equiv. wt %, with a mode of 35 NaCl equiv. wt%; while homogenization temperatures range from 250 to 600 °C, with a mode of 350 °C. Similar elevated salinities in basinal brines are typically found in modern basins where evaporite beds are dissolving (Chap. 8).

No evaporite solution breccias have yet been recognised associated with the sediments of the mineralised Tennant succession. If they are present, there are two likely positions in the stratigraphy for the primary weld. One likely position is near the base of that portion of the Warramunga sediments that indicates the first incursion of marine waters into the opening rift. Given the deepwater setting of the ore-host sequence, this tectonic setting means the dissolution breccia would likely lie below the mineralised part of the stratigraphy. The other setting likely to deposit widespread evaporites, which could have supplied ions and high salinity to the basinal brines, would be at or near the time of the collision event that created the thrust faulting. These beds would tend to lie stratigraphically above the mineralised intervals.

Type 4 deposits are exemplified by the Olympic Dam Breccia Complex, in the northeast part of the Gawler Craton,

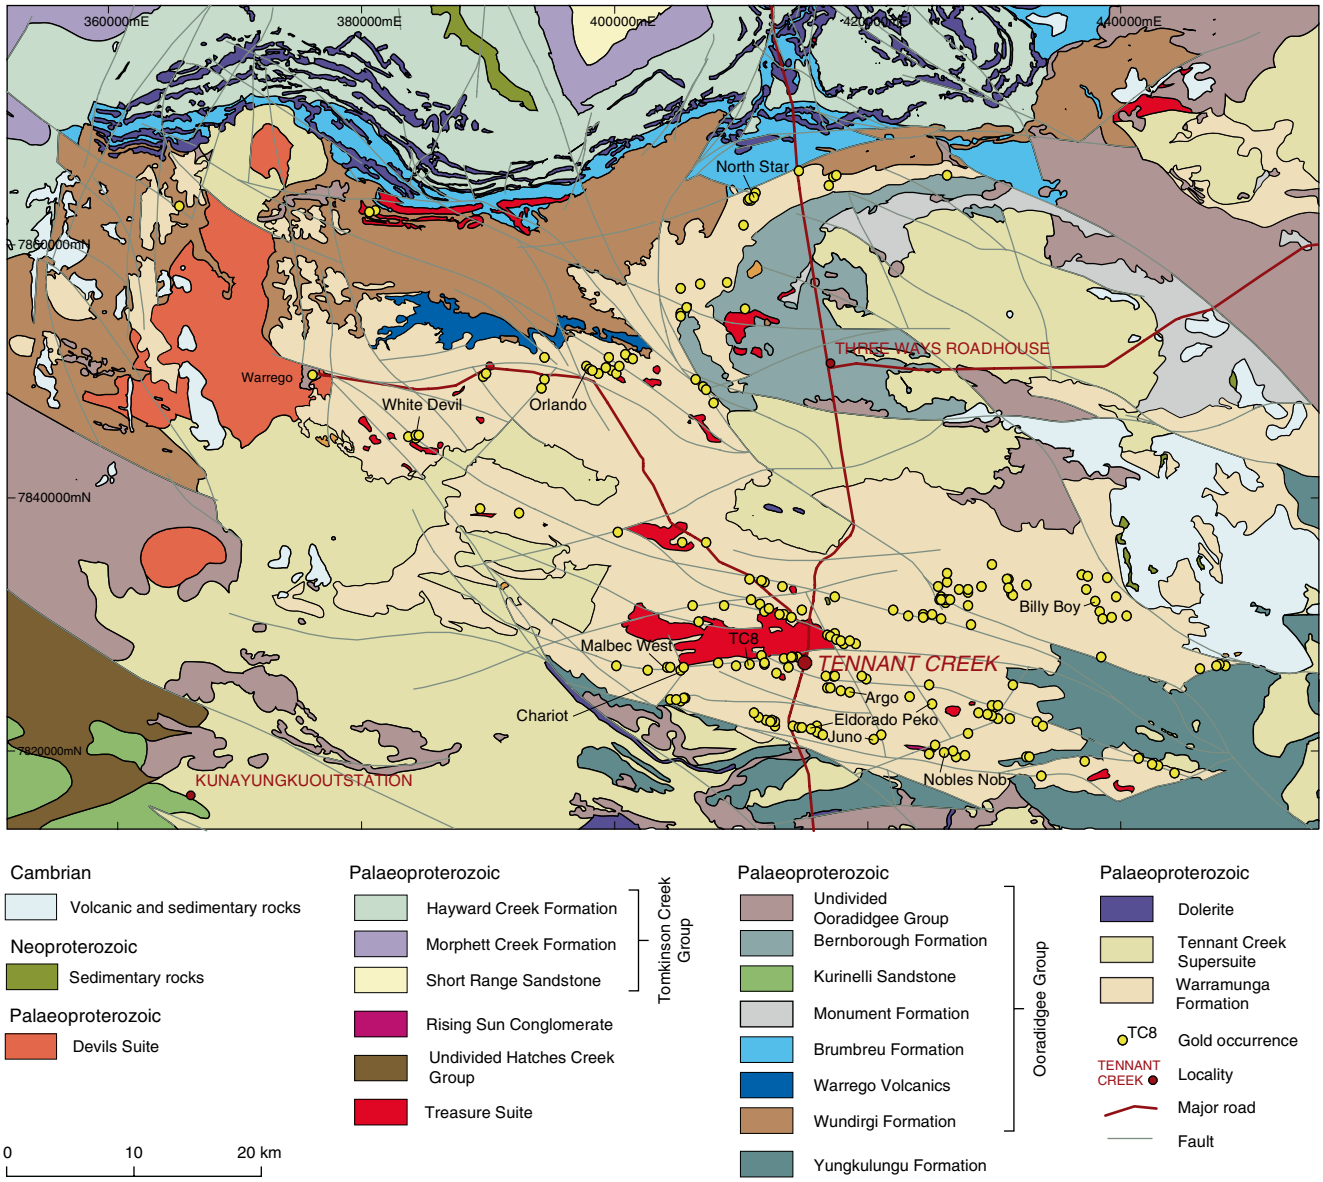

Fig. 16.27 Regional geology and gold deposits of Warramunga Province, Tennant Creek Region (After Donnellan et al. 1999; Ahmad et al. 2009)

South Australia (Haynes et al. 1995). The geologic setting of this world-class ore body is poorly defined as the breccia complex is buried beneath approximately 300 m of Stuart Shelf cover rocks, and the nearest exposed rocks of the Gawler Craton are more than 100 km distant (Fig. 16.29). The upper parts of the deposit and the surrounding rocks have long since been removed by Precambrian erosion. Any local geologic setting at the time of mineralisation must be inferred from the remnants of the upper parts of the complex, now preserved within the breccia complex, and from coeval rocks preserved elsewhere in the northeast part of the Gawler Craton. The geological setting that drove the mineralising system at Olympic Dam is even more enigmatic than the other three types, with divergent opinions as to its ultimate origin. Interpretation is further complicated by multiple brecciation and alteration events within the breccia body. Of prime importance to the genesis of this deposit is the relative significance of direct magmatic versus hypogene hydrothermal processes, and the relative levels of fluid mixing with nearsurface and basinal brines, generated via dissolving evaporite units.

A two-fluid mixing hypothesis for ore formation at Olympic Dam was first proposed by D. W. Haynes (in Roberts and Hudson 1983) and was based on the sulphide-pitchblende-haematite association of the ore body, as well as the ore textures and the overall sulphide zonation pattern. Reed and Haynes (in Haynes et al. 1995) numerically modelled a hypothetical Olympic Dam system where an oxidised 150 °C water, derived from a synthetic arkose, interacted with a proto-ore assemblage consisting of siderite,

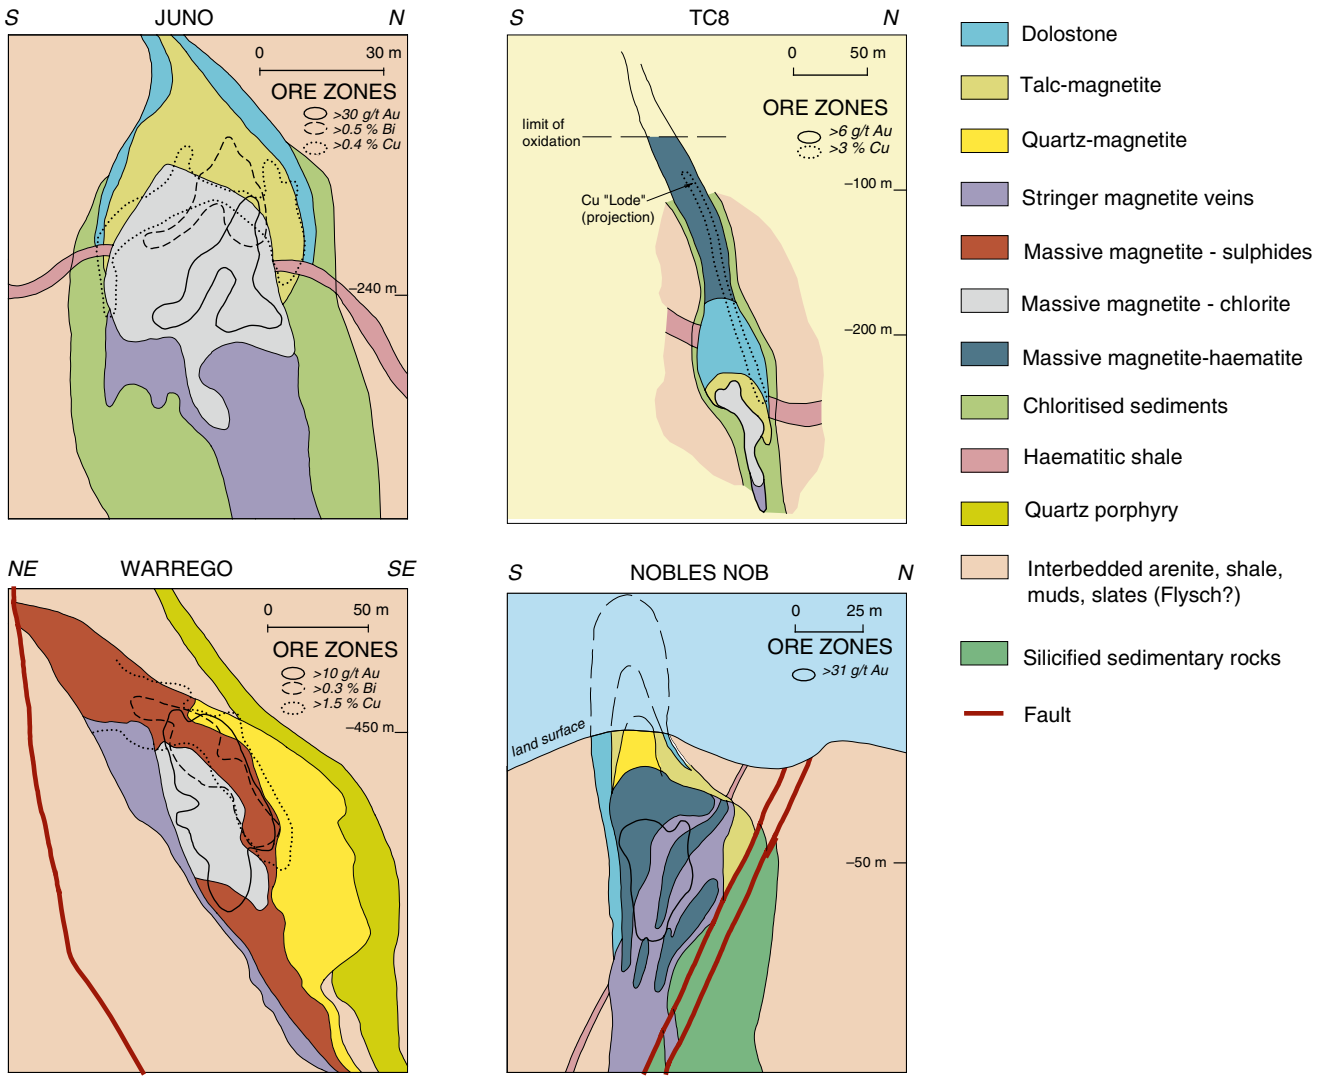

Fig. 16.28 Tennant Creek gold district Northern Territory, Australia. Show relationships between ironstone zones and ore grades (After Ahmad et al. 2009). See Fig. 16.27 for locations

pyrite, magnetite and chlorite. Wall and Valenta (1990) speculated that an analogous, but two-stage, mechanism was responsible for the genesis of both the Olympic Dam and the Tennant Creek orebodies. The modelling of Reed and Haynes implied that such a two stage mechanism was unlikely to result in ore formation at Olympic Dam, and was not consistent with textural and mineralogical characterisation of the orebody (Reeve et al. 1990) nor with its Sm/Nd and U/Pb isotopic signatures (Johnson and Cross 1991).

Einaudi and Oreskes (1990) and Oreskes and Einaudi (1990) also presented a multistage mechanism for the development of the deposit. They proposed a primary hypogene origin for the iron and some of the copper and uranium in the deposit, but suggested that much of the ore-grade mineralisation was produced by a discrete (up to 200 My younger) second stage Cu-U overprint. They argued that the orebody had undergone a low temperature secondary enrichment as a result of uplift, unroofing and weathering at the Proterozoic landsurface. Reeve et al. (1990) described a model involving nearsurface cyclic interaction of hot ascending saline magmatic waters and cooler, more oxidised saline waters. They argued against the notion that the orebody had been extensively upgraded by any distinct low temperature weathering event, and supported a two fluid mixing model first presented in Roberts and Hudson (1983).

Oreskes and Einaudi (1992), with reference to fluid inclusion and isotopic data, refined their earlier hypothesis noting that two fluids were likely involved in ore genesis. They concluded that a deep-seated or magmatic fluid was responsible for the genesis of the magnetite-rich proto-ore. Water of surficial origin was then involved in the later stages of hydrothermal activity, which in turn formed the haematite breccias, and that sulphide deposition mainly occurred late relative to brecciation and deposition of haematite. They speculated

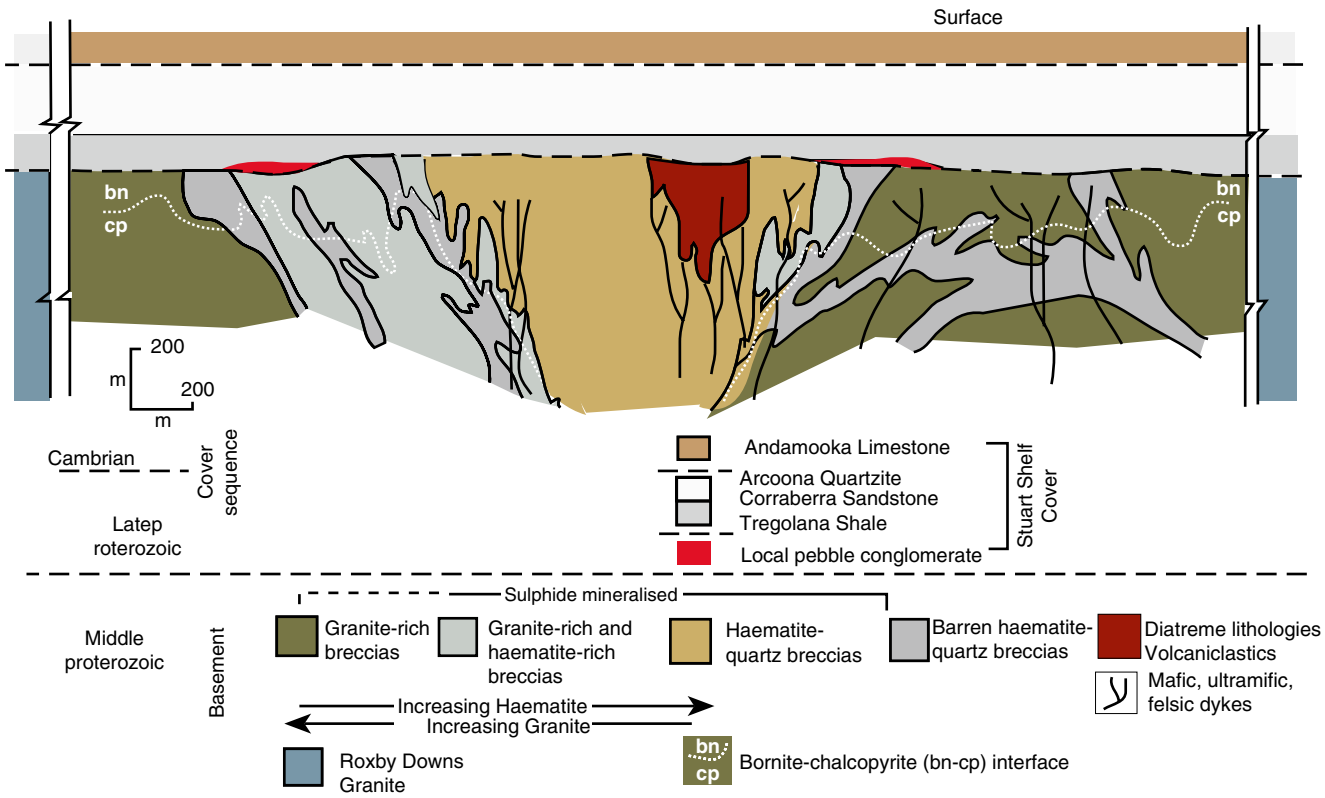

Fig. 16.29 Simplified geological section of the Olympic Dam Breccia Complex (After Haynes et al. 1995)

that the magnetite deposition may have preceded haematite deposition by some 150 My. In contrast, Haynes et al. (1995) concluded that their two-fluid fluid mixing model best explains the precipitation of the sulphides, magnetite and haematite and many associated minerals. They do not think the data support a discrete episode of sulphide enrichment related to later hypogene hydrothermal events, or to later weathering of the upper part of the orebody. The debate continues.

If both Haynes et al. and Reeve et al. are correct in their assertion of the presence of a saline water body in the caldera, which mixed with deeper magmatic water to form the deposit, then there may well be indications of former saline minerals and burial salts still preserved in the locally preserved pods of slumped and deformed caldera sediment fill. To my knowledge these textures have yet to be documented in any published literature base.

However, in support of the significance of a nonmagmatic pore fluids in the generation of this supergiant, McPhie et al. 2011, note the presence of sedimentary fragments in the main breccia, now enclosed by granites (Fig. 16.30). The breccia is composed mainly of granite clasts and minor amounts of Mesoproterozoic volcanic clasts. Very thick (>350 m) sections of bedded sedimentary facies that occur in the breccia complex include laminated to very thin planar mudstone beds, thin to medium internally-graded sandstone beds, and thick conglomerate beds. The bedded sedimentary facies extend continuously across a 1.5 km by 0.9 km area and are not limited to small separate maar craters, as previously thought. Detrital chromite and volcanic quartz in the bedded sedimentary facies cannot be matched with local sources, and imply that the provenance extended beyond the area of Olympic Dam. The lateral continuity, provenance characteristics, great thickness, below-wave-base lithofacies, and intracontinental setting suggest that the bedded sedimentary facies are remnants of a sedimentary basin that was present at Olympic Dam prior to formation of the breccia complex. McPhie et al. (2011) conclude that the Olympic Dam hydrothermal system operated beneath and partly within an active sedimentary basin, was not confined to maar craters, and did not vent. This new view of the setting raises the possibility that sedimentary processes, as well as actively circulating basinal fluids, were involved in ore genesis (Fig. 16.30).

Candaleria As a Younger Analog?

The Lower Cretaceous Candelaria Cu-Au skarn deposit (IOCG) of Mexico is a more recent example of ferroan/evaporite hydrothermal circulation, with many of its early fluid system features comparable to Olympic Dam style circulation (Fig. 16.31; Ullrich et al. 2001). Its andesite-hosted mineralization (470 Mt @ 0.95 % Cu, 0.22 g/t Au) was largely

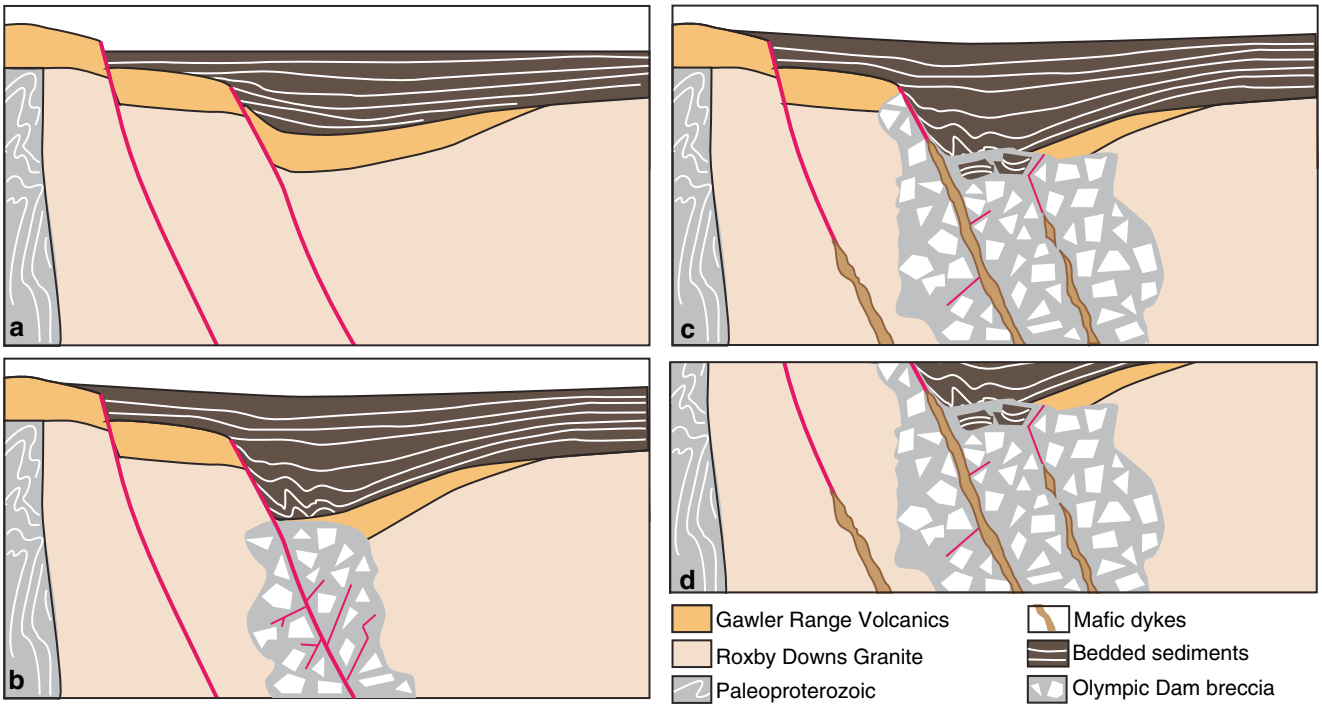

Fig. 16.30 Evolution of Olympic Dam facies. (**a**) Bedded sedimentary facies accumulated in fault-bound basin above Meso-proterozoic granite and lavas. (**b**) Fault-controlled subsurface fragmentation of Roxby Downs Granite, Gawler Range Volcanics lavas, and bedded sedimentary facies to form the Olympic Dam breccia complex. (**c**) Mafic dykes intruded granite and breccia complex along faults. (**d**) Erosion unroofed the breccia complex, removing almost all traces of bedded sedimentary facies (After McPhie et al. 2011)

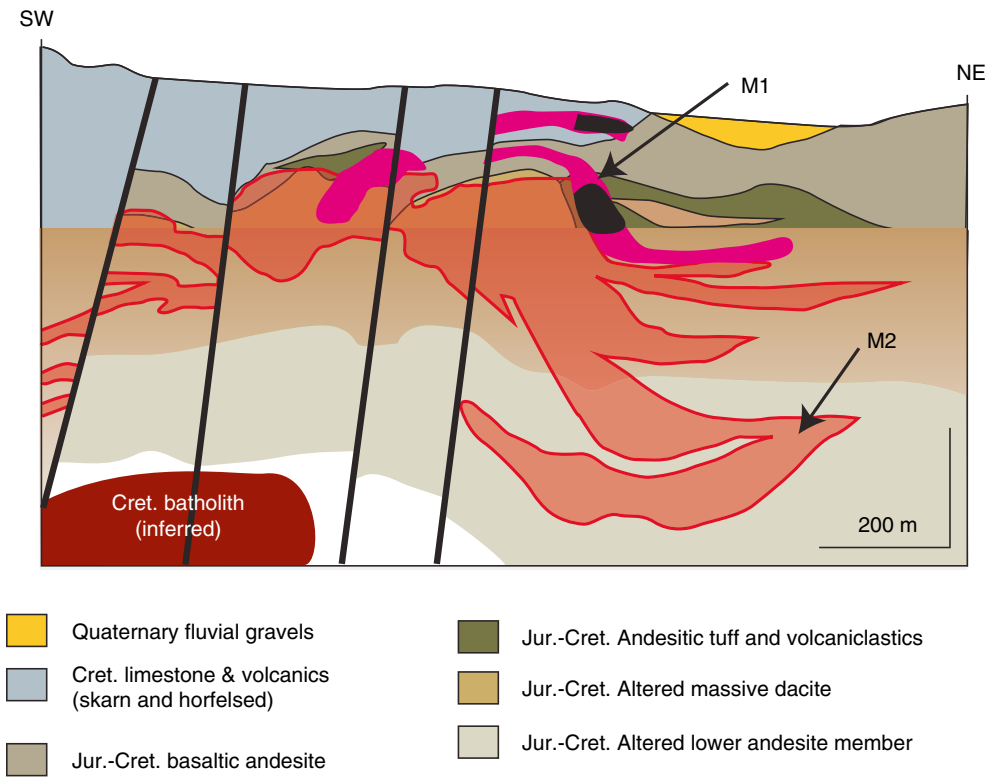

Fig. 16.31 Cross section of Candelaria Cu-Au deposit, Tierra Amarilla, Chile. M1 Marginal Cu ore replacing metasediments (*solid black* indicates massive pyrrhotite). M2 Main orebodies, Chalcopyrite with magnetite "mantos" in early K-silicate (mainly biotite) altered andesite, overprinted by Ca-Na alteration synchronous with Cu emplacement

associated with Ca-amphibole (^{40}Ar-^{39}Ar plateau at 111.7 ± 0.8 Ma), albite, microcline, magnetite and green biotite emplacement (112.8 ± 0.7 Ma), followed by subordinate chalcopyrite-epidote-chlorite and, finally, chalcopyrite-haematite-calcite-chlorite stages.

The hydrothermal system, which was hypersaline and CO_2-rich throughout, cooled from over 400 °C to below 275 °C. Ore deposition and Ca-metasomatism, simultaneously generated Cu-poor andradite-diopside-scapolite "skarns" in the andesitic hangingwall of the orebody. They were preceded at 114.1 ± 0.7 Ma by a large-scale and locally intense Fe- and K-metasomatism event, which generated magnetite and brown biotite, respectively. This process was contemporaneous with ductile deformation along major faults in the deposit. It was a barren precursor alteration stage to ore deposition and was superimposed on a wider zone of quasi-pervasive albitization of the andesites and, locally, of adjacent granitoids.

O and S isotopic compositions of ore and alteration minerals predicate progressive changes in fluid chemistry during hydrothermal activity (Ullrich et al. 2001). Thus, $\delta^{18}O_{fluid}$ evolved from around +7.0‰ for pre-ore K-metasomatism, similar to values for contiguous granitoids (+5.4 to +9.6‰), to ≈ −0.2‰ in the late "Olympic Dam-like" stage. $\delta^{34}S$ fluid simultaneously increased from "magmatic" values of +5.7‰ in the earliest Cu (−Mo, Zn, Au, Ag) ore sub-stage to +12.0 < × < +20.2‰ during precipitation of late-stage chalcopyrite-haematite and terminal-stage anhydrite. Hydrothermal activity was focused at the western margin of a defunct Valanginian-to-Barremian (ca. 138–119 Ma) back-arc, shallow-marine basin, which incorporated significant evaporites. The isotopic data record a progressive mixing of magmatic-hydrothermal waters with non-magmatic, plausibly evaporite-sourced waters. Mineralization overlapped temporally with the intrusion of the medium-K calc-alkaline Ojancos Plutonic Complex from 117.2 ± 1.0 to 110.5 ± 1.7 Ma, a probable source of ore-metals and juvenile fluids, and also with the uplift and recycling in basinal waters of the nearby evaporites.

Other Proterozoic Cu-Au Fe-Oxide/Evaporite Associations

As well as Australian examples, there are numerous other Proterozoic IOCG (*sensu lato*) deposits that show strong affinities with hypersaline basinal waters and possibly with chloride-rich brines, derived from dissolving evaporites (Table 16.5). Some of the best documented Proterozoic Cu-Au meta-evaporite/volcanic associations (IOCG *sensu lato*) are to be found in the Cu or Cu-Au deposits of Scandinavia. In the Kiruna-Tjåmotis-Arjeplog district of Northern Sweden, the iron oxide deposits and associated greenstone lithologies are extensively scapolitised (Parák 1991). These Kiruna greenstones were formed close to 1.9 Ga. Magma eruption and emplacement, along with associated evaporitic rift sedimentation, was closely followed by metamorphism and hydrothermal circulation driven by the volcanism.

Scapolitisation can often be seen around lava pillows as well as in syenite, gabbro and diabase. Scapolite is commonplace in the copper mineralised areas at Svappavaara and Nautanen where it is accompanied by apatite, tourmaline, magnetite and skarn. At Ultevis it occurs as well developed crystals up to several centimetres in size in coarse-grained skarn and as pegmatite in a rusty, graphite-bearing rock. The most impressive scapolite occurrences occur in the metasedimentary pile, where it forms almost pure bands or layers in skarn, biotite-bearing limestone, biotite-bearing schist, and graphite bearing schist. In some cases, scapolite in the metasediments makes up more than 50 % of the rock volume. The strongly stratiform distribution of scapolites in the Kiruna district implies a sedimentary sodic precursor (Parák 1991).

The nearby (now depleted) Viscaria copper deposit reflects a strongly evaporitic protolith with mineralisation occurring in Proterozoic playa metasediments in a mafic volcanic terrane (Godin and Lager 1986). Within a 700-m section of predominantly tholeiitic basalts there are four mineralised horizons. The highest concentration of sulphide minerals occurs within graphitic schists and calcsilicates lenses and layers within the meta-basalts. The graphitic units are interpreted as original organic-rich sediments deposited in the deeper parts of a fault-bounded anoxic lake and were the units that likely acted as reductants to the Cu carrying chloride brines (see Chap. 15 for a discussion of organic-associted redox mechanisms in the diagenetic realm). The calcsilicates were originally limestones deposited as shallower nearshore deposits. The original shallow water setting is also reflected in locally preserved sedimentary structures: mud cracks, ripple marks, shallow-water crossbeds, erosion surfaces, and breccia beds.

Evaporite mineral pseudomorphs suggest the chert-albite units were formed in a saline lake as magadiite chert replacements of sodium silicate precursors (Godin and Lager 1986). Some of the aligned growth fabrics, still preserved in the albite-chert layers, are reminiscent of bottom-nucleated and splayed trona precursors (pers. obs, 1986). Areas of more intense scapolite and albite alteration may represent metamorphosed endproducts of authigenic reaction haloes in the volcaniclastics that surrounded the lake. Sulphide minerals appear to have begun to replace the organics relatively early in the diagenetic history of the lacustrine sediments. Parák (1991) suggests that the hydrothermal system of this greenstone belt, which was driving alteration in the subsurface, may also have supplied the ionic components to the depositing primary evaporites at much shallower burial depths.

The likelihood of an evaporite protolith for the Swedish Cu deposits is further reinforced by the presence of anhydrite

lenses in the Kiirunavaara deposit, where re-examination of drill core from the deposit showed anhydrite in 26 holes, partly as lenses and partly as secondary fissure-filling (Parák 1991). Tuisku (1985) discussed the origin of scapolites in the schists of nearby central Finland; as in Kiruna, he concluded the chlorine for the scapolitisation was provided by dissolving precursor evaporites. "…The chlorine of the basic igneous rocks was either introduced directly into the magma from evaporites or brines or into the cooling igneous rocks from later circulating brines" (p.169).

Evaporite-associated Au-Cu deposits also occur at Pahtohavare and Bidjovagge in the greenstone terranes of Norway (Lindblom et al. 1996; Ettner et al. 1994). The Pahtohavare deposit is located some 10 km south of the Viscaria Cu deposit, while Bidjovagge is located in greenstones some 200 km to the northeast. At Pahtohavare the gold mineralisation occurs as impregnations, epigenetic quartz-rich breccias and fracture fillings, along with pyrite, chalcopyrite and pyrrhotite. It is hosted in zones of fine-grained albitised rocks within tuffite, black graphitic schists and mafic sills (Fig. 16.32). The graphite horizons in the albite-altered blackschist have been replaced completely by albite in the most mineralised sections. Albite-altered zones are surrounded symmetrically with barren biotite-scapolite-altered rocks. The scapolite is marialitic and occurs as porphyroblasts and irregular veinlets or networks. Coarse-grained carbonate veins are common both in the ores and surrounding altered rocks. Syngenetic magnetite occurs at several stratigraphic levels within the tuffite (Lindblom et al. 1996).

At Bidjovagge the deposit is hosted in the metavolcanic and metasedimentary Cas'kejas Formation, which is composed of amphibolites and mafic metavolcanics, interbedded with minor thin beds of carbonate, graphitic schist, albitic felsite and metatuffite (Ettner et al. 1994). Originally, the host sequence is thought to have been a sequence of lava flows, ash deposits, black shales, limestones and evaporitic shales deposited in a shallow early rift basin. A series of thick diabase sills intrude the Cas'kejas Formation and a zone of albitic felsite has developed between the contact of the diabase sills and graphitic schists. Mineralisation is of two types (Au-rich and Cu-rich), hosted in a series of mineralised lenses along a shear zone some 2.5 km long. This mineralised shear zone lies in an albitic felsite made up very fine-grained albite with impurities of rutile and carbonate. It is a product of sodic metasomatism of black shales, driven by the intrusion of the diabase sills and associated circulation of hot saline brines. The gold-rich ore is hosted within ductile to brittle structures in the shear, while the copper-rich ores occur within brittle structures in shears that crosscut the ductile fabric. A series of syenodioritic intrusions crosscut the shear texture in the albitic felsite and are cross cut by quartz-carbonate chalcopyrite veins. Based on crosscutting relationships these dykes probably intruded during the period between the gold-rich and copper-rich mineralisations.

Inclusion studies in both Pahtohavare and Bidjovagge show gold transport can be tied to highly saline NaCl fluids (30–45 wt%) that carried CO_2 and CH_4 at temperatures near 350 °C. This is consistent with the broader highly saline character of fluid inclusions in quartz across the range of

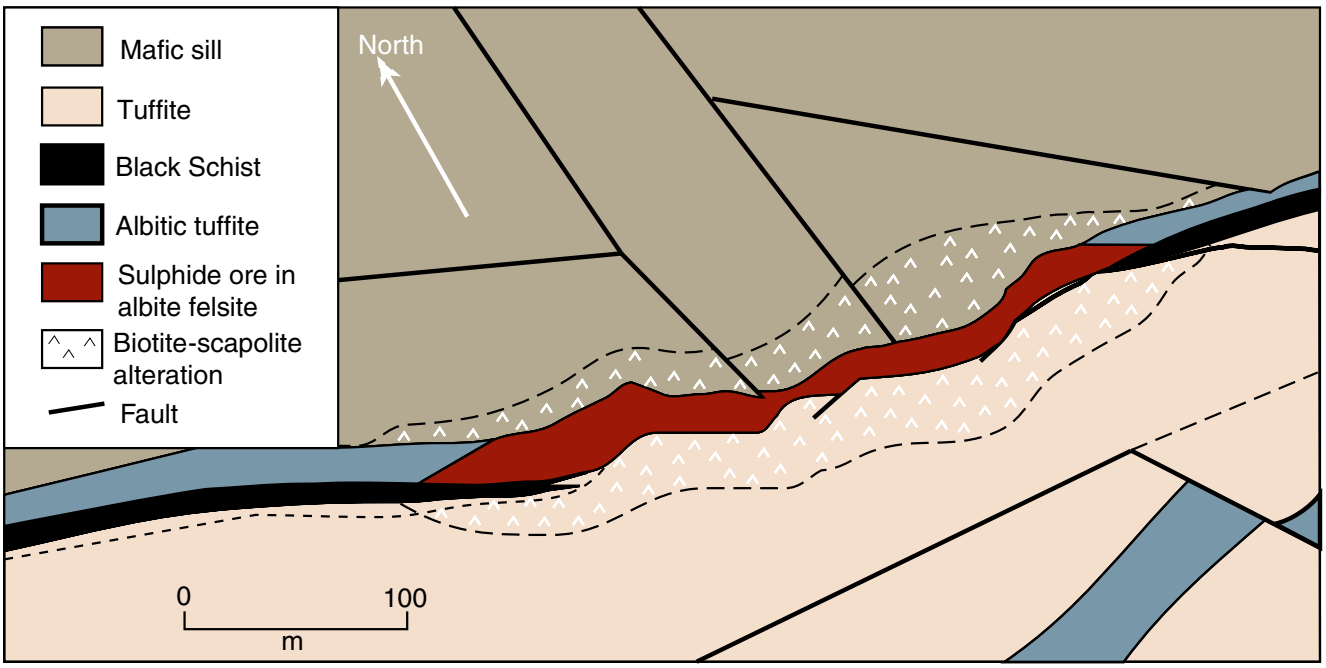

Fig. 16.32 Geology of the Pahtohavare copper deposit, Norway (After Ettner et al. 1994)

IOCG deposits in the Kiruna district of Sweden (Fig. 16.33; Smith et al. 2013). Fluid inclusions in quartz veins cutting Fe oxide-apatite of these deposits range in salinity from 33 to 37 wt.% NaCl eq., and those in IOCG-type deposits from 41 to 54 wt.% NaCl eq. (Fig. 16.33a). According to Smith et al. 2013 the minimum trapping conditions for these inclusions are ≈200–300 MPa and 200–300 °C in the Fe oxide-apatite bodies, and 250–300 MPa and 300–500 °C in the IOCG deposits. Deformed Cu-Au deposits have similar early fluid characteristics, but contain complex secondary fluid inclusion assemblages including halite-saturated (20–30 wt.% NaCl eq.), aqueous-carbonic (3–13 wt.% NaCl eq.; $X(CO_2) \approx 0.17–0.29$) and CO_2-rich fluids. The aqueous-carbonic and carbonic inclusions are consistent with aqueous-carbonic fluid immiscibility at ≈150 MPa. A secondary inclusion population, with a high Ca-content occurs in all deposit types.

Halogen contents in the Kiruna district indicate a range of salinity sources with possible inputs from both magmatic and halite-dissolution brines (Smith et al. 2013). Although some samples have Cl/Br ratios consistent with a magmatic source for the halogens, the Cl-enrichment apparent in the total dataset is a strong indicator of interaction of fluids with (meta-) evaporites and consequent halite dissolution (Fig. 16.33a, b), followed by extensive water–rock interaction. No single group of inclusions or sample type shows a range of ratios consistent with a single fluid source, nor do all higher Cl/Br ratios correlate with the highest salinity fluids (Fig. 16.33a), implying that halite dissolution was not the only mechanism that generated highly saline brines. Typical magmatic-hydrothermal fluids are expected to have low salinities and salinities of 6 wt.% NaCl eq. were used by Barton and Johnson (2002) for mass balance models of IOCG deposit formation. In this situation, however, highly saline magmatic brines could be produced by aqueous–carbonic fluid exsolution from magmas at relatively high pressure. In general the geological distributions and inclusion chemistry favours the involvement of evaporite-derived brines and daughter products such as scapolite, but it does not exclude magmatic influences.

Element ratios suggest the alkali content of the fluid exceeded the buffer capacity of the host rocks. Iron and other transition metal contents correlate strongly with Cl concentrations, with secondary controls on solubility from pH, redox and temperature. Copper and Ag contents are higher in lower salinity aqueous-carbonic brines (up to 5,000 ppm Cu, 900 ppm Ag) than in the most saline brines (up to 2,297 ppm Cu, 837 ppm Ag). This may reflect differences in metal source between deposit types, but is also consistent with the complexation of Cu by bisulphide in the lower salinity fluids. Late stage aqueous-carbonic fluid flux through the deformed deposits either introduced additional

copper to the deposits, remobilised pre-existing copper or both (Smith et al. 2013)

These fluid characteristics are very similar to those associated with the emplacement of the higher temperature Australian Cu-Au deposits. Ettner et al. (1994) relate gold precipitation at Bidjovagge to redox reactions between the fluid and the graphitic schists. Lindblom et al. (1996) suggest gold precipitation at Pahtohavare was the result of cooling of a chloride brine as it mixed with a lower salinity fluid during tectonic fracturing along with associated pressure fluctuations and CO_2 mixing. They go on to suggest, by comparison with Olympic Dam (as per Oreskes and Einaudi 1992), that the saline ore fluids were magmatically derived. Subsequent work of Haynes et al. (1995) showed that magmatic fluids at Olympic Dam may have mixed with saline evaporite-derived subsurface waters. They also ignore the possibility that the source of the chlorine and sodium in the inclusions, and the marialitic scapolites, and the albitites, could reflect a meta-evaporite association. This in a deposit located less than 10 km from the Viscaria Copper deposit and along the same greenstone trend as the classic meta-evaporite Viscaria locality of Godin and Lager (1986). Ettner et al. (1994) are a little more circumspect in their interpretation of the origin of the Na-Cl brine, and suggest these highly saline chloride brines may have had either an igneous or a metasedimentary source, as does subsequent work by Smith et al. (2013).

Non-IOCG Gold- Evaporite Associations

The Santa Rita gold deposit in the Middle to Upper Proterozoic Paranoá Group in Goiás, Brazil, is another example of a possible evaporite/brine formed gold deposit. But, in this case, the solutions were at times also capable of precipitating pyrite within the quartz-carbonate veins that host the ore (Giuliani et al. 1993). Fluid inclusion studies of quartz from these veins identifies two fluids: (1) a highly saline CO_2-N_2-rich aqueous fluid with halite ± sylvite daughter minerals, and (2) a CO_2-N_2-rich aqueous fluid with moderate salinity. The two fluid types can occur in the same quartz domain and display great variation in the degree of filling, as well as notable dispersion of the microthermometric data. On heating, all the inclusions decrepitate between 200 and 300 °C. The simultaneous entrapment of compositionally variable fluids in the system H_2O-CO_2-N_2-NaCl-KCl is interpreted as heterogeneous trapping resulting from the mixing of high-salinity fluids (H_2O-NaCl-KCl system) with carbonic fluids (H_2O-CO_2 system). The latter moderate-salinity fluids were produced by devolatilisation of carbonate and phyllitic host rocks. The former, the high salinity brines, were derived by leaching of the evaporites that characterised the lower part of the Paranoá Group (Giuliani et al. 1993).

Gold was initially transported as an $AuCl_2$-complex ($T > 300$ °C, low pH, moderate *fO2*) much like the Proterozoic Cu-Au deposits of Australia. When temperatures fell below 290 °C, the "switch-over" process (Large et al. 1989 – see Fig. 16.3) lead to a predominance of $Au(HS)_2$ in the carrier fluid, so that pyrite was a coprecipitate at these lower temperatures. The oscillatory zoning in the As-Co-Ni-bearing pyrites also indicates episodic fluctuation of the fluid composition. Such changes in fluid character typify fluid-mixing systems subject to fluctuating levels of feed waters within an active hydrothermal system. The model proposed by Giuliani et al. encompasses a Proterozoic geothermal system that was characterised by a heated fluid flow regime along fault feeder structures that also crosscut the dissolving Paranoá evaporites. Today, the preserved equivalents of such brine-fed systems are likely to be represented by dissolution breccias and salt welds intersecting the faults rather than actual salt beds that have long since dissolved.

A similar fluid mixing system, involving highly saline evaporite-derived basinal brines and magmatic waters, is also suggested as the mechanism for mesothermal gold mineralisation in the Transvaal Sequence in South Africa (Anderson et al. 1992). In this case, mixing occurred between a deep-seated homogenous CO_2-rich fluid of magmatic/metamorphic origin and a saline (subsurface/intraformational) basinal brine derived by the dissolution of evaporites in the sediments of the Chuniespoort and Pretoria groups of the Transvaal sequence, where Tyler (1986) documented widespread salt casts.

Another evaporite-associated gold setting is the Cu-Co-Au deposits of the Idaho Cobalt Belt, USA (Nash and Connor 1993). These deposits are stratabound and, in the Blackbird Mine, the mineralisation is locally stratiform. The ore host is the Mesoproterozoic Yellowjacket Formation, composed of dark-coloured, thin-bedded to laminated argillites and siltites, quartzites and minor marbles. These units have equivalents in the Belt Supergroup that are known to be meta-evaporitic. The mineralised Blackbird Member shows anomalously high levels of Cl, K and Fe in the biotites, as well as the presence of stratiform scapolite and tourmalinites (Trumbull et al. 2011). Locally, Fe-enriched sediments become ironstones. The Blackbird Member is also characterised by crosscutting growth faults, soft sediment disruption zones and likely hydrothermal seafloor vents. Nash and Connor (op. cit.) underline similarities in the mineralising system with the evaporite-associated Red Sea deeps and the Salton Sea hydrothermal sulphides, while Trumbull et al. (2011) utilise boron isotopes to argue for a marine meta-evaporitic origin for some of the tourmalines.

The most impressive evaporite-associated gold system is probably Muruntau in Uzbekistan, which is one of the biggest gold deposits in the world, with 5,200 t of contained Au (Fig. 16.34a, b; Wilde et al. 2001; Bierlein and Wilde 2010). The origin and genesis of gold mineralisation at Muruntau

remain highly contentious. Based on strong structural control and its overall tectonic setting, it has been interpreted as a typical shear zone-related, Au-bearing quartz-vein association, perhaps in a metamorphic belt-hosted orogenic-gold system. Others propose a thermal-aureole gold origin for the deposit, with the ore fluid inferred to have been largely derived from the Murunski Granite, which has been intersected in diamond drillcore at 4 km depth beneath the deposit. Opposing schools argue over the relative import of magmatism versus basinal waters in its genesis. Magmatists emphasise the close spatial association of gold with post-tectonic Permian felsic intrusions and superimposition of hydrothermal alteration upon a contact metamorphic aureole as indicating a magmatic origin for metals, heat, and ore-forming fluids.

The $^{40}Ar/^{39}Ar$ ages of hydrothermal sericite suggest that ore formation occurred in at least two pulses at about 245 and 220 Ma (during the Triassic period), some 30 m.y. after intrusion. However, the intrusion age is poorly constrained. Orebody genesis via regional metamorphic devolatilization is implausible, because basement rocks would have been substantially devolatilized during the Caledonian deformation about 200 m.y. prior to intrusion. Detectable H_2S in fluid inclusions raises a distinct likelihood that gold was transported into the deposit as a bisulphide complex and offers a somewhat distinct set of precipitative processes for this supergiant gold deposit (Wilde et al. 2001).

If bisulphide transport was the case, then a likely explanation of the huge gold endowment is that an unusually large reservoir of reduced sulphur was available to the ore-forming fluids. Furthermore, if fluids were able to scavenge gold from a particularly large source area, then the probability of generating a giant deposit would have been increased. Wilde et al. (2001) suggest, therefore, that a possible source of fluid and metal for the Muruntau deposit was the anhydrite-rich evaporitic sediments in cover sequences 1 and 2.

This setting would have provided large volumes of H_2S, via thermochemical sulphate reduction. Anhydrite begins to break down in the presence of methane at temperatures of about 140 °C to yield calcite and H_2S, via a reaction such as; $CaSO_4 + CH_4 = CaCO_3 + H_2S + H_2O$ (thermochemical sulphate reduction; Worden et al. 1995). High H_2 S gas activity would favour gold transport by increasing the dissolved reduced sulphur activity of a coexisting aqueous fluid phase.

The $^{40}Ar/^{39}Ar$ and Rb-Sr ages suggest that deposition of auriferous quartz veins and associated sericitic alteration occurred in the same frame time as deposition of cover sequence 2 sediments and volcanic rocks in the adjacent rift. Petroleum studies show that this cover succession loaded and buried the basal Devonian sedimentary rocks (with their significant entrained volumes of $CaSO_4$) to depths of more than 7 km (this is the maximum known thickness of cover sequences 1 and 2). At such depths large volumes of $CaSO_4$ experienced temperatures of 140 °C and so TSR volatilisation was highly likely. Cover sediments were then uplifted during a number of superimposed compressional events (Fig. 16.34b, c)

Fluid inclusion data suggest that hydrothermal fluids at Muruntau evolved from a relatively reduced (CH_4-rich) to a more oxidized (CO_2-rich) content during gold deposition (Fig. 16.34c; Wilde et al. 2001). Thus, oxidation of evaporite-derived gold bisulphide complexes is a possible precipitative mechanism. The origin of oxidized fluid is uncertain. Source options include meteoric, magmatic water or a more oxidized saline connate water from the adjacent evaporite-entraining rift sequence. At this time, the ultimate fluid source is still contentious.

So What Is a IOCG Deposit and Is Mineralisation Evaporite/Brine Related?

Interestingly, Chen (2013) argues that the sulphur source for many Cu-rich IOCG deposits worldwide is external and the result of mixing of multiple fluids and can be used to classify (Fig. 16.35; Table 16.7). Some deposits are derived from mixing of magmatic and saline basinal brines or refluxing seawater-derived brines (e.g., Central Andean and Carajás deposits), or from formation water and metamorphic fluids (e.g., the Cloncurry deposits), or introduced by magmatic assimilation of metasedimentary units (e.g., Phalaborwa),. However, only the evaporite-sourced fluids yield diagnostically high $\delta^{34}S$ values (i.e., >10‰), while sedimentary formation waters or metamorphic fluids commonly have lower values and are less clearly distinguishable from magmatic fluids, as in the Cloncurry deposits. There the involvement of external fluids is revealed by other evidence, such as noble gas isotopes,

A common theme in the various Proterozoic Cu-Au deposits is transport of copper and/or gold at relatively high temperatures within saline chloride complexes, often derived from the dissolution of deeply buried salt units or their metamorphosed successors. Precipitation was typically either at some sort of redox front associated with graphitic schists, to give a stratabound style of precipitation, or at some form of subsurface groundwater/fluid mixing zone, often with a more structurally focused mode of precipitation associated with ironstone precipitation or replacement. Those cases showing a strong structural control to the mixing zone, imply precipitation was coincident with, or later than, a major deformation event that had facilitated the formation of a more permeable pathway. Precipitation was often associated with some form of tectonic pressure shadow. In most cases a strong argument can be made that the high-temperature metal-carrying brine was derived by dissolving chloride-rich evaporites or pressure-driven escape of chloride-rich volatiles from subsequent meta-evaporites. In some cases, a strong argument can be made for an evaporitic association in

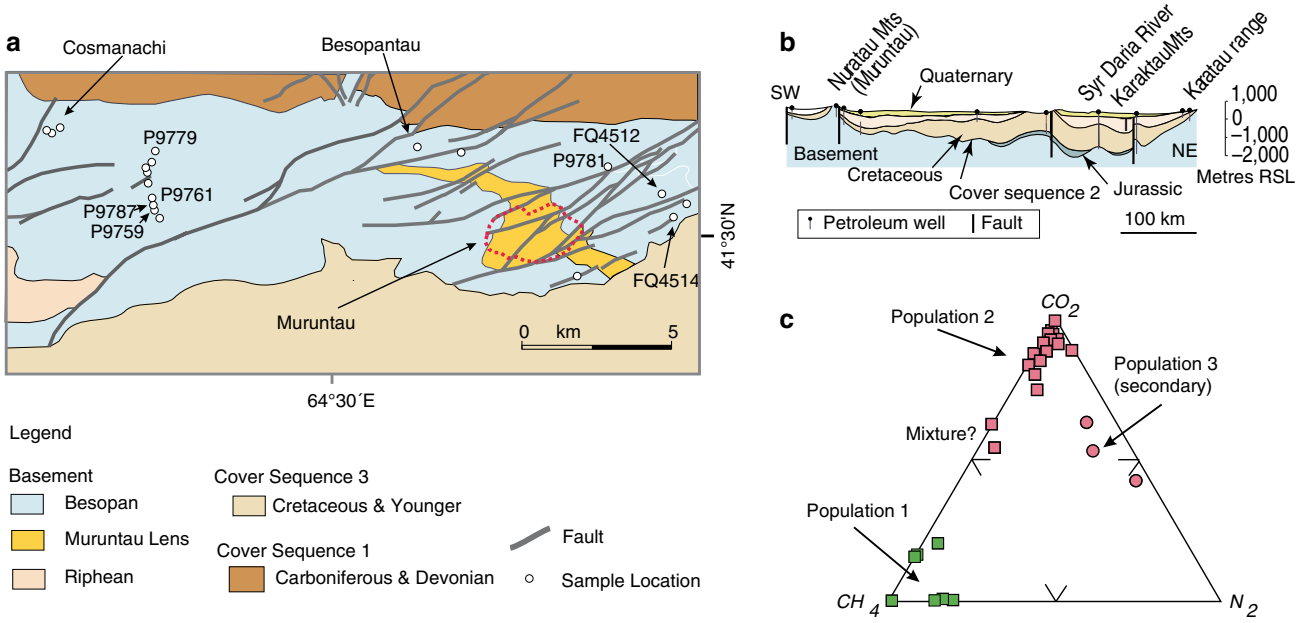

Fig. 16.34 Supergiant Muruntau gold deposit, Uzbekistan, (**a**) Geology of the Muruntau mine areas howing the contact between the deformed basement and overlying Devonian and Carboniferous rocks is a low-angle fault, which dips to the north. (**b**) Idealised SW NE section in the Muruntau area based on Soviet-era petroleum wells. (**c**) Ternary diagram illustrating the measured gas content of primary fluid inclusions. The data have been interpreted to indicate two discrete fluids (After Wilde et al. 2001)

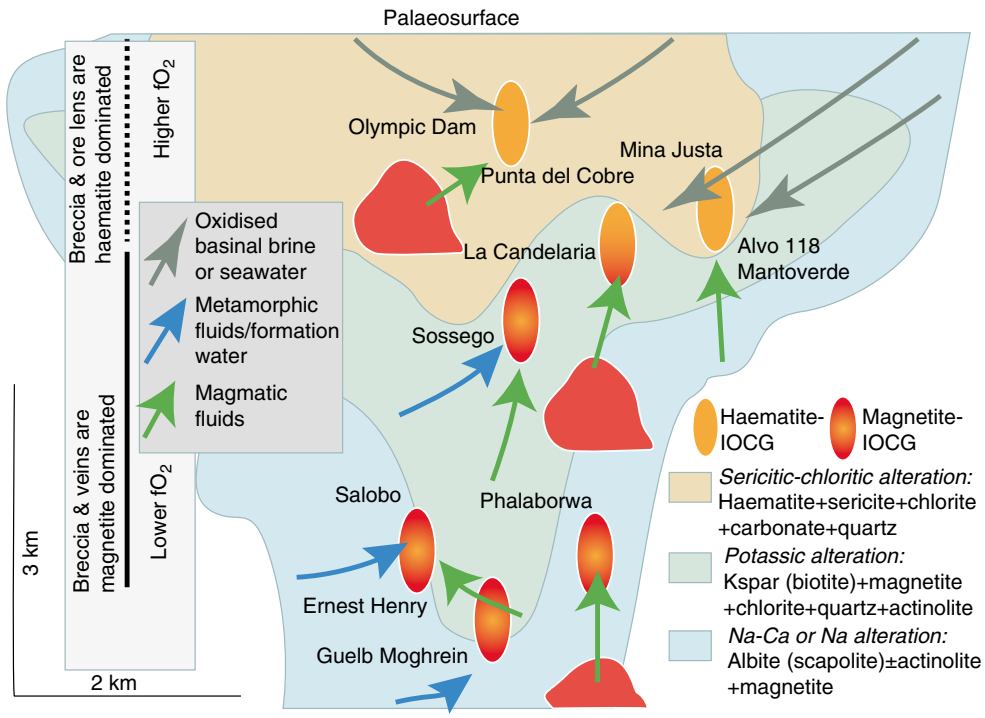

Fig. 16.35 Fluid-related settings of various IOCG deposits (After Chen 2013). Regional Na\Ca or Na alteration commonly precedes mineralization, while potassic alteration and hydrolytic (sericite–chlorite) alteration are usually mineralization-related. (1) Ca-metasomatism dominates the La Candelaria-Punta del Cobre district. (2) Na\Ca alteration widespread in the Cloncurry district, whereas Na-alteration dominates the Central Andean IOCG centres. Under conditions of high thermal gradient/heat-flow, the Y-axis will be compressed. Basinal brines or seawater are probably more oxidized than magmatic and metamorphic fluids. With the exception of Phalaborwa, the other IOCG deposits are the result of more than one fluid source

Table 16.7 Classification of IOCG deposit as proposed by Chen (2013)

Deposit types	Iron oxide (IO)[a]	IOCG	
Subtype	Magnetite	Magnetite subclan	Hematite subclan
Ore-forming fluids	Magmatic[b]	Magmatic[c] and hybrid magmatic — nonmagmatic	Hybrid magmatic — non-magmatic and non-magmatic
Examples	Lightning Creek, Acropolis (Australia); Acari, Morritos, part of CIB[d] (Central Andes); Benson, Cornwall (USA); Esfordi (Iran); and "ironstone" in IOCG	Sossego, Salobo (Carajas); Ernest Henry, Eloise (Cloncurry); West Peko (Tennant Creek); La Candelaria-Punta del Cobre, Raul-Condestable (Central Andes); Tjarrojakka, Aitik[e] (Norbotten); Khetri (NW India); Boss-Bixby (SW Missouri); Wernecke, Nico (Canada); Guelb Moghrein (Akjoujt); Ossa Morena (Spain); Phalaborwa (South Africa)	Olympic Dam, Prominent Hill, Redbank (South Australia); Mantoverde, Mina Justa, Mantos Blancos (Central Andes); Alvo 118 (Carajas); Mont-de-1'Aigle, Sue-Dianne (Canada); Salton Sea (USA); Malundae (Lufilian arc); Boleo (Mexico)
Economic elements	Fe (±P)	Cu-Au (±Co ± Bi ± U ± REE ± Ni)(P-Mg: Phalaborwa)	Cu ± Ag ± Au ± Co ± Zn (U-REE: Olympic Dam)
Ore assemblages	mt-act-apt-qtz±ab±cpx±bt±K-feldspar ± py ± cpy	Commonly: mt-cpy-py ± po ± hem Locally: mt-cpy-bn-cc (Salobo, Phalaborwa)	hem-cpy-bn-cc and hem-cpy-py
Hydro thermal alteration	Regional: Na-Ca ± Cl ± B Mineralization-related: Fe-K-Ca	Regional: Na ± Ca Mineralization-related: K ± Fe ± Ca ± CI ± Na	Regional: weak Na ± CI ± Ca Mineralization-related: K-Cl ± Na ± Ca
Ore morphology	Veins, stockwork; local breccias	Veins and breccias; local lenses (Salobo)	Breccias, lenses (manto) and veins
Ore precipitation mechanism	Cooling	Fluid mixing and cooling	Fluid mixing and fluid reduction
Non-magmatic fluids	No	Basinal brine/seawater (Candelaria); $\delta^{34}S_{fluids} > 10‰$; Metamorphic fluids/formation water (Ernest Henry; Guelb Moghrein): $\delta^{34}S_{fluids} < 10‰$	Basinal brine/seawater: $S^{34}S_{fluids}$ commonly >10‰
Characteristics of oreforming fluids	High T (>450 °C) and salinity (>25 wt.% NaCl eq.); CO_2-rich or CO_2-bearing[f]	High-T (Ernest Henry: >350 °C) or wide range of T (Salobo: 100–500 °C); moderate-high salinity (15–50 wt% NaCl eq.); Na-Ca dominant and Na > Ca; CO_2-rich or CO_2-bearing	Moderate-low T (<300 °C), and moderate-high salinity (>15 wt% NaCl eq.); Ca-Na dominant and Ca > Na; CO_2-bearing or CO_2-poor
Mineralization level	Deep (>3 km) to shallow	Deep (>6 km, Ernest Henry) to shallow (<3 km, Candelaria)	Shallow (generally <3 km)
Ore-controlling structure	Shear zone, local rift	Shear zone	Normal fault-detachement-dilational zone/Shear zone
Subtype	Magnetite	Magnetite subclan IOCG	Hematite subclan IOCG
Host rocks	Sedimentary and volcanic rocks and intrusions	Sedimentary and volcanic rocks and intrusions	Sedimentary and volcanic rocks and intrusions
Distance to syn-mineralization magmatism	Close (<3 km)	Close (<3 km) — Sossego, Eloise, La Candelaria; Far (>3 km) — Ernest Henry, Wernecke	Close (<3 km) — Olympic Dam; Mantos Blancos Far (>3 km) — Mina Justa, Mantoverde[g]
Mineralization age	Mesoproterozoic to tertiary	Archean to tertiary	Mesoproterozoic to pleistocene
Tectonomagmatic setting	(A) (Acropolis) (B) (Central Andean deposits) (C) (Lightning Creek)	(A) Precambrian intracratonic basins, anorogenic; A-type magmatism (Carajas, Norbotten, SW Missouri, Phalaborwa) (B) Inversion of basins in extensional arc on subduction-related continental margin; calc-alkaline arc magmatism (Central Andes) (C) Inversion of post-collisional orogenic basins; calc-alkaline magmatism postdating metamorphic peak (Cloncurry) (D) extension following retrograde metamorphism (Guelb Moghrein, Wernecke)	(A) (Olympic Dam, Prominent Hill) (B) (Central Andean deposits) (C) (Mont-de-1'Aigle)

[a]Melt-origin "Kiruna-type" magnetite-apatite deposits not included
[b]Magmatic fluids without external sulphur
[c]Magmatic fluids with external sulphur, e.g., Phalaborwa
[d]CIB-Chilean Iron Belt
[e]Late IOCG-like magnetite-bornite-chalcopyrite stage
[f]Defined in this table: CO_2-rich — fluid inclusions containing $CO_2 > 20$ %; CO_2-bearing: a few fluid inclusions (<20 %) contain CO_2; CO_2-poor: no CO_2 identified in fluid inclusions
[g]Intra-mineralization dykes locally developed

the organic-rich-shale precursor of the graphitic schists, which later set up a metal-precipitating redox interface.

Most published papers to date have not considered an evaporite associated protolith to any of the ore-hosting ironstones. And yet, as was documented in Chap. 15, refluxing brines associated with dissolving evaporites can build up high metal contents and then release ferroan chloride-rich basinal brines along structurally focused paths (salt welds and fault welds). As the ferroan chloride brines seep upward or laterally they precipitate ferroan carbonate haloes along the fault or thrust conduits, or in structurally focused traps or as parts of widespread stratiform iron-hydroxide and iron-sulphide rich sediments about the brine outflow zones. Could these diagenetic ferroan replacements and structurally controlled ferroan haloes along regional basinal faults be the precursors ("prepared ground") to some of the stratiform and structurally aligned ironstones in strongly sodic metasedimentary terranes? Only when the rock matrix is characterised by geologists who understand possible evaporite and metal precursors, as well as high temperature magmatic systems, can exploration paradigms based on hybrid fluids from magmatic and meta-evaporite sources be considered.

In summary, evidence of former evaporite influence and associated basinal brines and hypersaline hydrothermal waters in IOCG deposits is subtle and unless one seeks it out, will be largely lost in a broader milieu of hydrothermal alteration. Criteria for upgrading the possibility of an evaporite association in an Fe-oxide Cu-Au deposit include: (1) abundant sodic alteration, often combined with widespread elevated Cl content in some minerals (e.g., abundant marialitic scapolite, and increased Cl content in amphiboles and biotites); (2) laterally equivalent metasediments or sedimentary remnants that retain evaporite pseudomorphs or dissolution breccias; (3) sediment systems that were deposited under arid/redbed conditions; (4) an abundance of transported iron with little evidence of sulphur in the transport system. As mentioned earlier, IOCG deposit comparisons across the Precambrian to Phanerozoic time scale shows the larger *sensu strictu* IOCG examples are Paleoproterozoic (Fig. 16.18). This time period may be related a unique set of world-scale underplating conditions related to the long term cooling and slowing of the asthenosphere (Groves et al. 2010).

Hydrothermal (Non-evaporitic) Salts and Metalliferous VHMS Deposits

Volcanogenic-hosted massive sulphide (VHMS) deposits are distinctive in that they formed in close temporal association with submarine volcanism and associated hydrothermal circulation and exhalation of sulphides, which are largely independent of sedimentary processes. This sets VHMS deposits apart from sedimentary exhalative (SedEx) and most IOCG deposits. However, anhydrite is a widespread mineral precipitate in VHMS deposits formed at or just below the seafloor. This anhydrite is hydrothermal not sedimentary.

Anhydrite's retrograde solubility means the solubility of anhydrite decreases rapidly with increasing temperature (Fig. 16.36a; Blount and Dickson 1969, 1973). Hydrothermal anhydrite precipitates within submarine volcanics and volcaniclastics during the heating of seawater caught up in submarine hydrothermal circulation cells (Fig. 16.36b). Retrograde solubility also ex- explains why anhydrite is most obvious in the upper portions of vent mounds and in black and white "smokers". Its heating behaviour is the opposite of baryte, another common hydrothermal sulphate precipitate. Simple heating of seawater adjacent to seafloor vents, even without fluid mixing, will precipitate anhydrite, while simple cooling of hydrothermal waters will precipitate baryte. Once buried, hydrothermal calcium sulphate, in the presence of organic matter or hydrocarbons and circulating hydrothermal brines, acts as a sulphur source to create H_2S, which then interacts with metal-carrying pore waters to precipitate metal sulphides. Although hydrothermal forms of $CaSO_4$ are not "true" evaporites, it needs to be discussed in the metals context of this chapter. Hydrothermal anhydrite, or indicators of its former presence, are commonplace within volca-plains why anhydrite is most obvious in the upper portions of ventnogenic hosted massive sulphide (VHMS) deposits. VHMS deposits typically form in submarine depressions as circulating seawater becomes an ore-forming hydrothermal fluid through interaction with the heated upper crustal rocks. Submarine depressions, especially those created by submarine calderas and/or by large-scale tectonic activity (median rift valleys), are favourable sites.

Fundamental processes leading to the formation of VHMS deposits include Ohmoto (1996):

- Intrusion of a heat source (typically $\approx 10^3$ km size pluton) into an oceanic crust or a submarine continental crust, which causes deep convective circulation of seawater around the pluton (Fig. 16.42). The radius of a circulation cell is ≈ 5 km. The temperatures of fluids that discharge on the seafloor increase with time from the ambient seafloor temperature to a typical maximum of ≈ 350 ° C, and then decrease gradually once more to ambient temperatures on a time scale of $\approx$ 100–10,000 years. The majority of subsurface sulphide and sulphate mineralization occurs during the waxing stage of hydrothermal activity,
- Reactions between warm country rocks and downward percolating seawater cause seawater SO_4^{2-} to precipitate as disseminated and fracture-fill hydrothermal anhydrite in the country rock in areas where internal temperatures are greater than 150 °C.
- Reactions of "modified" seawater with higher-temperature rocks during the waning stages of hydrothermal circulation transform this sulphate-depleted "seawater" into

metal-rich or H_2S-rich ore-forming fluids. Metals are leached from the country rocks, while previously formed hydrothermal $CaSO_4$ is reduced by Fe^{2+}-bearing minerals and organic matter to provide H_2S. The combined mass of high temperature rocks that provide the metals and reduced sulphur in each VHMS marine deposit is typically $\approx 10^{11}$ tonnes ($\approx$40 km^3 in volume). Except for SO_2, which produces acid-type alteration in some systems, the roles of magmatic fluids or gases are minor in most massive sulphide systems.

- Reactions between the ore-forming fluids and cooler rocks in the discharge zone cause alteration of the rocks and precipitation of ore minerals in the stockwork ores.
- Mixing of the ore-forming fluids with local seawater within unconsolidated sediments and/or on the seafloor can cause precipitation of "primitive ores" with the black ore mineralogy (sphalerite + galena + pyrite + baryte + anhydrite).
- Reactions between the "primitive ores" with later and hotter hydrothermal fluids beneath a sulphate-rich thermal blanket causes transformation of "primitive ores" to "matured ores" that are enriched in chalcopyrite and pyrite.

Hydrothermal anhydrite distribution in VHMS deposits is reflected by REE distributions in mid-oceanic ridges. For example, anhydrite is co-associated in hydrothermal/marine solutions, hotter than 400 °C, emanating from various white smokers in two submarine hydrothermal vent fields at 5°S on

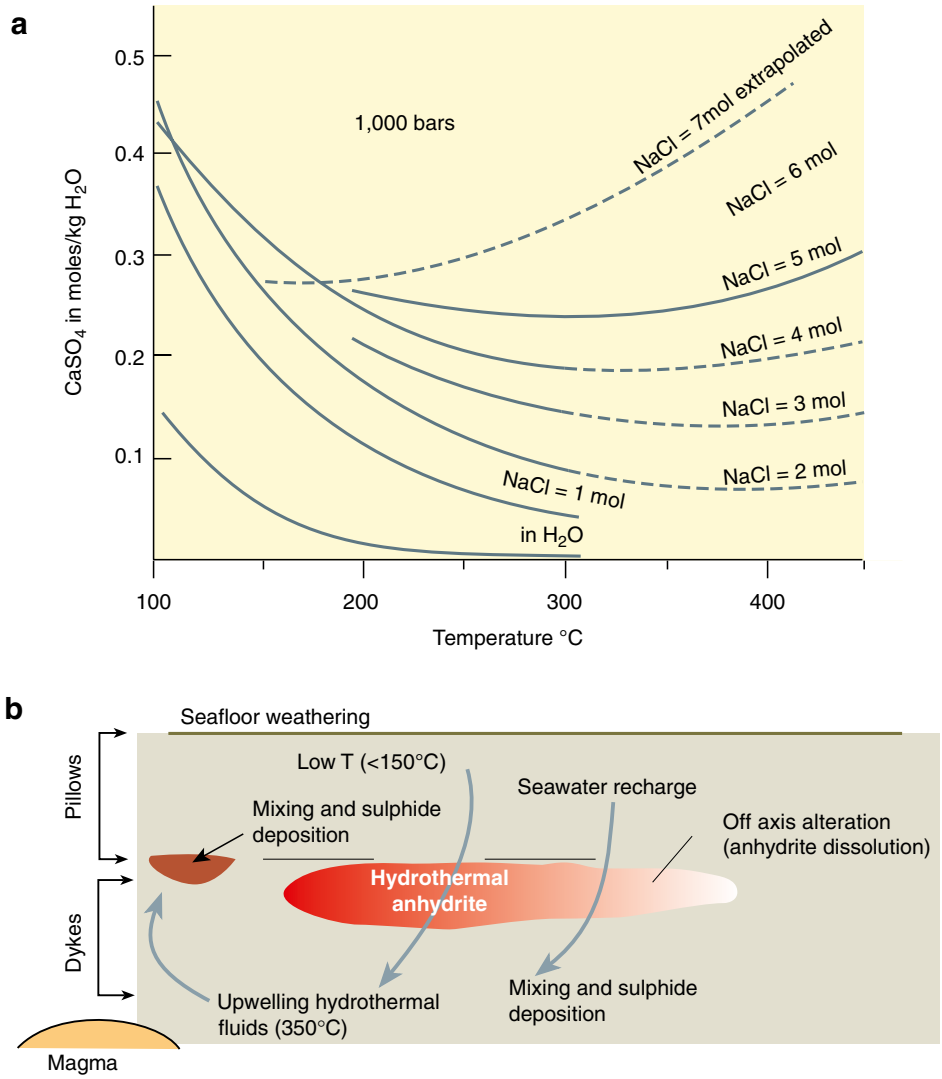

Fig. 16.36 Hydrothermal anhydrite. (**a**) Anhydrite solubility as a function of temperature at 1,000 bars in H_2O and NaCl-H_2O solutions of various concentrations. *Dashed lines* indicate extrapolated values (After Blount and Dickson 1969, 1973). (**b**) Formation of hydrothermal anhydrite from heated seawater in oceanic crust

the Mid-Atlantic Ridge (MAR) – Turtle Pits and Comfortless Cove. There, the distribution of anhydrite controls the distribution of the rare earth elements (REE) and yttrium (Fig. 16.37; Schmidt et al. 2010). The emanating brines define vapour-phase fluids at conditions close to the critical point of seawater (407 °C, 298 bars). According to the authors, the positive correlation of total REE, Ca, and Sr concentrations in Turtle Pits and Comfortless Cove fluids, indicates that precipitation/dissolution of hydrothermal anhydrite controls the variability in REE concentrations and distributions in these fluids and the transformation of one fluid type to the other. They note that the variable distribution of REE can be explained by the accumulation of particulate anhydrite (with concave-downward REE distribution and negative Eu anomaly) into a fluid with a more common REE distribution (type I), followed by the modification of the REE fluid signature due to subsequent dissolution of the incorporated anhydrite.

In order to form VHMS deposits on the seafloor, through-flushing hydrothermal fluids must transport sufficient amounts of metals and reduced sulphur, each at concentration levels > 1 ppm Ohmoto (1996). For a hydrothermal fluid with the salinity of normal seawater (≈0.7 m $\sum$Cl) to be capable of transporting this amount of Cu and other base metals, it must be heated to temperatures > 300 °C. Fluids with temperatures in excess of 300 °C will boil at pressures >200 bars. Under such conditions the resulting vapour cannot carry sufficient quantities of metals to form a VHMS deposit. Boiling of a metalliferous hydrothermal brine outflow is prevented when the fluid vents into water that is deep enough to generate a sufficient confining pressure. At 350 °C, a minimum seawater depth of 1,550 m is necessary to prevent boiling. If the fluid passes through a sedimentary package where it loses temperature and metals (Cu, Ba) before emanating, the water depth beneath which boiling is prevented is less (≈1,375 m). Once vented, the turbulent mixing of hot hydrothermal waters with cooler seawater causes rapid precipitation of sulphides and calcium and barium sulphate, which produces the familiar black and white smokers (Blum and Puchelt 1991).

VHMS deposit styles of mineralisation are always related to submarine volcanism and hydrothermally-driven circulation within adjacent deepwater sediments, but typify a variety of tectonic settings and sediment types:

- VHMS deposits formed in subduction-related island-arc settings (Kuroko-type deposits);
- VHMS deposits formed at mid-oceanic or back-arc spreading centres (Cyprus or TAG mound type deposits);
- VHMS deposits formed at spreading centres, but, due to the proximity of one or more landmasses, the deposit is

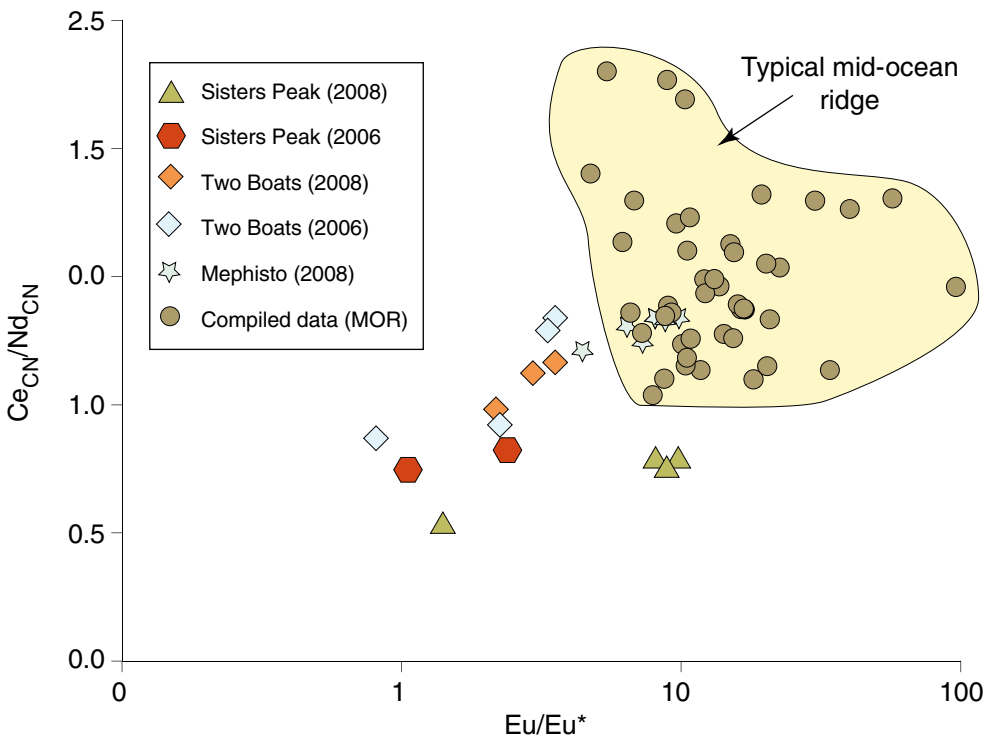

Fig. 16.37 Plot field of Eu anomaly (Eu/Eu*) as function of LREE fractionation (Ce_{CN}/Nd_{CN}) comparing typical values of mid-ocean ridge hydrothermal fluid compared to anhydrite emanations (>400 °C). Plots from various sites and times define the distinct REE signature associated with hydrothermal anhydrite as seen at Two Boats and Sisters Peak. Note the positive correlation of both parameters for each sampling campaign, although the determinations are 2 years apart (After Schmidt et al. 2010)

sediment-hosted (Besshi-type deposits). This style of deposit shows some affinities with SedEx deposits, but unlike a SedEx deposit the hydrological drive is always tied to igneous intrusion

For brevity and relevance, the emphasis in the following discussion of VHMS deposits is on the location and significance of the hydrothermal salts in the VHMS deposit, especially anhydrite and gypsum, rather than on a general discussion of mineralisation style. For excellent summaries of the relevant economic mineralisation literature, the interested reader is referred to Pirajno (1992), Ohmoto (1996), Shikazono et al. (2012).

VHMS Deposits in Subduction-Related Island-Arc Settings: Kuroko-Style Deposits

Kuroko-style deposits are composed of copper-and zinc-bearing massive sulphide deposits and typically hosted in felsic to intermediate volcanics (Fig. 16.38; Ohmoto and Skinner 1983; Ogawa et al. 2007). Deposits tend to occur near felsic domes and toward the stratigraphic top of the volcanic or volcano-sedimentary sequences. Host strata can be marine rhyolites, dacites, subordinate basal and organic-rich mudstones and shale. Often the host strata are brecciated or made up of volcanic flows, tuffs, or, in some cases, are actually part of a preserved felsic dome. Pyritic siliceous rock (exhalite) may mark the horizon at which the deposit occurs, and proximity to a deposit is often indicated by sulphide clasts in a volcanic breccia. Some deposits appear to be gravity transported. Ancient examples range in age from Archaean to Cenozoic and the type example of this Kuroko-style of mineralisation is located in Miocene volcanics of northern Japan.

There, hydrothermal $CaSO_4$ is widespread in the type region in the Miocene Hokuroko Basin, where it forms an integral part of the Kuroko-type ore association (Figs. 16.38 and 16.39; Ogawa et al. 2007). Kuroko polymetallic massive sulphide deposits form at discharge sites of submarine hydrothermal systems, associated with caldera structures (Ohmoto 1996). Calderas create depressions, such as the Hokuroko Basin, which become loci for discharging and ponding hydrothermal metalliferous solutions. Faulting associated with caldera formation provides permeable channel-ways for the circulating hydrothermal fluids. Type localities are in the Miocene Green Tuff Belt on Honshu and Hokkaido Islands (Fig. 16.39a). There the metal production is dominated by ore clusters centred around caldera structures, such as the Hokuroko Basin (Fig. 16.39b). Similar base metal deposits, in terranes characterised by submarine felsic volcanics and secondary ores containing varying amounts of hydrothermal anhydrite, have now been identified around the entire Pacific Rim (Sawkins 1990; Shikazono et al. 1983; Kusakabe and Chiba 1983; Chen 2013). The isotopic signature of anhydrite and baryte in most Kuroko-style deposits is intermediate between that of Miocene seawater and sulphate in hydrothermal fluids, suggesting that both types of sulphate precipitated from mixtures of hydrothermal fluids and local unaltered seawater (Ohmoto 1996).

The Japanese Kuroko deposits are, in general, characterised by a common stratigraphic mineral zonation (Figs. 16.39 and 16.40; Table 16.8) from the lowermost siliceous ore zone (keiko), through the overlying yellow ore zone (oko), to the upper black ore zone (kuroko). Baryte occurs mainly in the black ore zone and the overlying bedded baryte zone (Figs. 16.40 and 16.41). Keiko (siliceous) ores indicate the highest fluid temperatures (>300 °C) and were the feeder zone to the yellow and black ore systems. Most ores are compact, and massive but bedded, brecciated, or colloform textures dominate locally and graded sedimentary bedding and other sedimentary features, such as slumps, can be seen in the black ore.

Each of the major mines is centred on a cluster of ore lenses that range in size from less than 0.1 million tonnes to ≈ 10 million tonnes (Fig. 16.39b and 16.40). The stratabound lenses are typically elongate, with sharp upper boundaries and more diffuse lower boundaries that grade downward through lower grade stockworks into unmineralised footwall volcanics and tuffs. In many cases, hydrothermal anhydrite, with gypsum, occurs at the periphery of the black ore zone, either as near-monomineralogic aggregates or as units containing sulphide minerals (sekko ore). Anhydrite is rare in the central part of the sericite-chlorite alteration zone where temperatures were >300 °C, but is increasingly common in the more peripheral montmorillonite and zeolite alteration zones (T < 300 °C). Calcium sulphate underlies black ore in almost all mines in the Kuroko region and forms a mineable horizon of sekko ore; between 10^5 and 10^6 tonnes of sekko ore have been removed from individual deposits. Sekko ore can be further subdivided into sekko-kuroko and sekko-oko ores (Table 16.8).

There are four types of hydrothermal anhydrite in sekko ores: (1) nodular anhydrite, (2) anhydrite associated with sulphide minerals, (3) anhydrite in sulphide ore, and (4) vein anhydrite (Fig. 16.40). Type 1, or nodular anhydrite, is the most abundant and typically constitutes more than 90 % of the anhydrite in individual deposits. It occurs within dacitic tuff breccias and in tuff hosts, and changes up section into type 2 massive nodular anhydrite at the uppermost part of the sekko ore horizon. The diameters of the anhydrite nodules in sekko ore increase upward from a few mm to several metres. The thickness of the sekko ore varies within and between different deposits. The maximum thickness of sekko in the

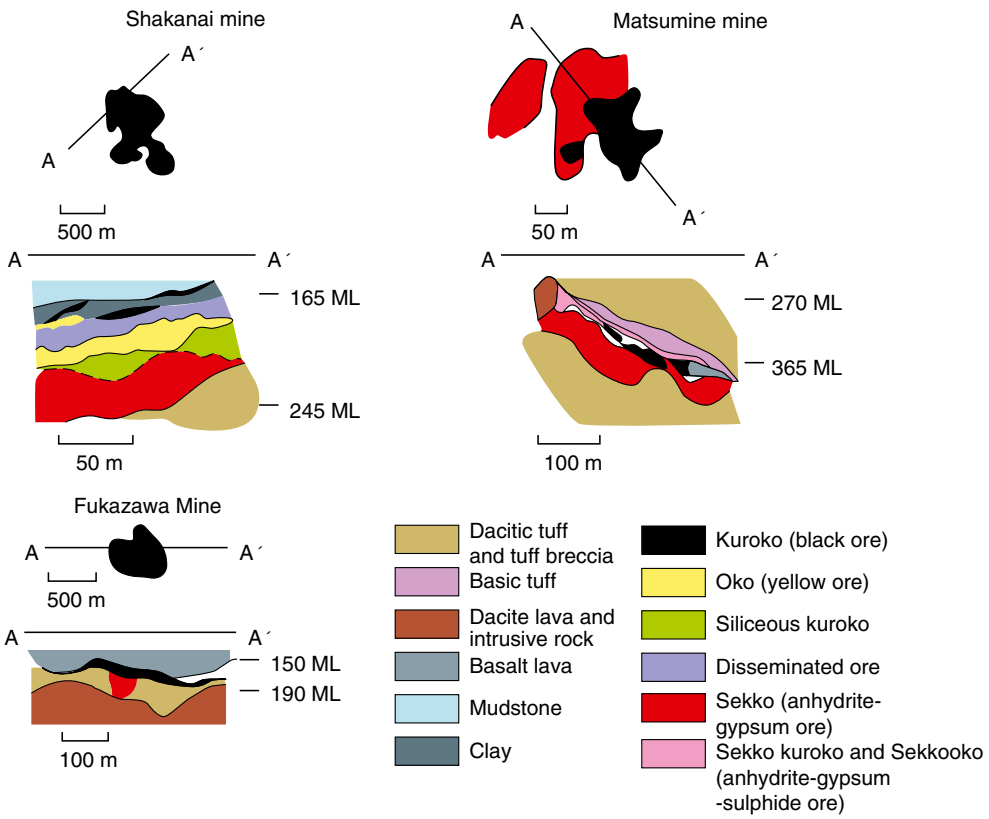

Fig. 16.39 Geology of selected mines in the Kuroko region, Japan (see Fig. 16.38 for locations). Note the common association of ore zones with hydrothermal calcium sulphate (After Shikazono et al. 1983)

Matsumine and Shakanai mines is more than 100 m, but is less than 50 m in the Fukazawa Mine (Fig. 16.39). Thicknesses of sekko-kuroko or sekko-oko are generally less than 10 m.

That is, anhydrite typically occurs in sekko ore together with local near-surface gypsum, which is a secondary mineral. Much of the gypsum that outcrops or subcrops in the region (Fig. 16.39) is a secondary rehydration product from original hydrothermal anhydrite (Kuroda 1983; Shikazono et al. 1983). The proportion of gypsum to anhydrite in the sekko ores probably reflects the rate of penetration of the modern meteoric groundwater system into the massive stratiform anhydrite units.

For example, gypsum/anhydrite and small amounts of sulphides (e.g., chalcopyrite, sphalerite, fukuchiite) and baryte are found at the marginal zone (upper horizon) of the anhydrite zone in the centre of the sekko ore in the Motoyama deposits of the Hanawa mine. The minerals associated with anhydrite are Mg-bearing minerals (Mg-chlorite, talc, Mg-chlorite/saponite mixed layer clay mineral, dolomite). Based on observations from the Shakanai and Matsumine Kuroko deposits, sekko ore consisting of anhydrite, gypsum, Mg-chlorite, sericite/montmorillonite mixed-layer clay minerals, changes gradually in ascending order to sekko-rich yellow ore, to sekko-rich black ore to yellow ore and rich black ore, (Fig. 16.40). In the sekko-rich black ore and sekko-rich yellow ore, sulphide minerals such as pyrite, chalcopyrite, sphalerite, and galena and baryte occur and are associated with nodular anhydrite.

Shikazono et al. (1983, 2012) concluded the anhydrite in the Kuroko ores formed by the mixing of a connate hydrothermal solution (containing high concentrations of Ca^{2+} and very little Sr^{2+} or SO_4^{2-}), with seawater. This took place at shallow depths, just slightly below the seafloor and was accompanied by hydrothermal/zeolite interactions with labile volcanic rocks (dacitic tuff breccia) under seawater-

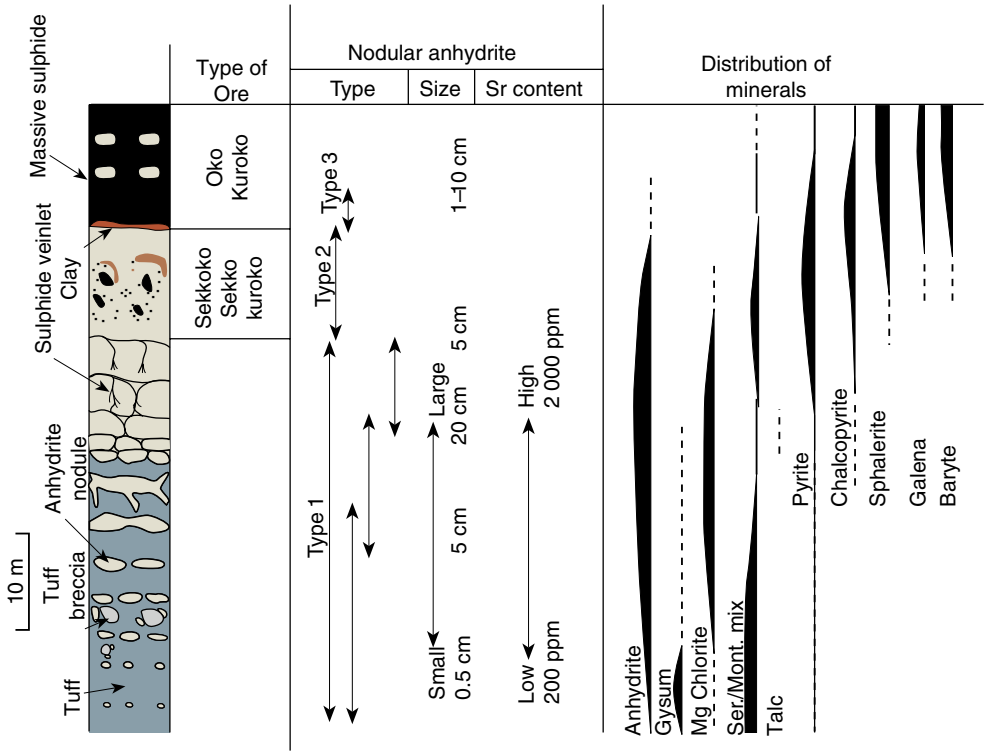

Fig. 16.40 Vertical zonation of anhydrite in Kuroko ore, see text for discussion of the anhydrite types (After Shikazono et al. 1983)

Table 16.8 Mineralogy of mineralised zones in classic Kuroko deposits

Name	Mineral phase
Kuroko Ore	Sphalerite + galena + baryte
Oko ore	Chalcopyrite + pyrite
Sekko	Anhydrite + gypsum
	Anhydrite + gypsum + sphalerite + galena + baryte
	Anhydrite + gypsum + chalcopyrite + baryte
Keiko Ore	Quartz + pyrite + chalcopyrite

dominated conditions. Thus, most of the anhydrite formed during the early stages of Kuroko mineralization, accompanied by precipitation of authigenic/hydrothermal Mg-bearing minerals (Mg-chlorite etc.) from a seawater-dominated Mg- and SO_4 -rich fluid. Reactions between warmer country rocks (T > 150 ° C) and percolating seawater precipitated seawater sulphate as disseminated hydrothermal anhydrite. Kuroda (1983) in an inclusion-based study of the Furutobe and Matsuki deposits showed how convecting seawater was heated as it approached the high temperature zone nearer the ore deposit core and so precipitated anhydrite along the way, mostly in the interstices of dacitic pyroclastic rocks and fine grained tuffs and in occas-sional fractures and fissures. This is the texture that is illustrated in the lower two-thirds of the type 1 texture in Fig. 16.40.

The Kuroko ore funnel from the Hanaoka mine is divided into four zones (Shimazaki and Horikoshi 1990), and baryte is abundant in all four, including the outermost zone. In contrast, quartz precipitates only in the interior zone. This indicates that baryte formed at lower temperatures in the precipitation series than quartz. Figure 16.41 shows the relationship between the content of baryte and quartz in the Kuroko ore samples studied; no positive or negative correlation was found to exist. From the figure, it is seen that the Kuroko ore can also be divided into either baryte-rich or quartz-rich ores. The black ore (kuroko) samples are baryte-rich whereas the siliceous (keiko) ore samples are quartz-rich. Most of the yellow ores contain quartz but not baryte, although some are locally baryte-rich.

In many Kuroko deposits, the nature of the up section increase in anhydrite nodule size and purity, along with an associated upsection increase in Sr content, is still not completely understood (Shikazono and Holland 1983; Ogawa et al. 2007). Given the hot hydrothermal nature of the precipitating setting and the deep seafloor setting of adjacent sediments, the zones of coalesced anhydrite nodules (upper part of type 1 and type 2) cannot reflect ghosting of a gypsum precursor. Changes in nodule size and purity are more likely to reflect rates of hydrothermal anhydrite crystallisation/replacement or the stability of the anhydrite-precipitating environment (larger nodules probably indicate slower, more stable, growth settings). At the time of anhydrite precipitation the host sediment was at times a thixotropic slurry, which passed laterally, away from the ore sites, into normal deepwater bottom sediment (diatomaceous fine-grained volcaniclastics and ash)

The ongoing preservation of widespread anhydrite, adjacent to, and beneath the massive sulphide bodies in the Hokuroko district requires more than the accumulation of anhydrite derived from chimney vent (smoker) remains (Ogawa et al. 2007). It supports the notion of a characteristic zone of widespread subsurface anhydrite precipitation in this type of deposit and, as well shall see in the next section, this is also true in many other hydrothermal seafloor deposits (Fig. 16.42; Shikazono et al. 2012). But anhydrite quickly dissolves beneath the shallow seafloor once heated pore brines are replaced by cooler waters with temperatures below 150 °C. That is, once active hot hydrothermal circulation ceases, hy-drothermal anhydrite is susceptible to flushing and leaching by cooler seawater. On uplift, it also converts to gypsum when anhydrite's widespread occurrence and preservation in the Kuroko ores implies hydrologic isolation of Kuroko anhydrite from cold seawater, perhaps because it tended to form a cemented zone in volcanic breccias rather than as piles of more porous vent precipitates. Its partial conversion to gypsum during post-Miocene

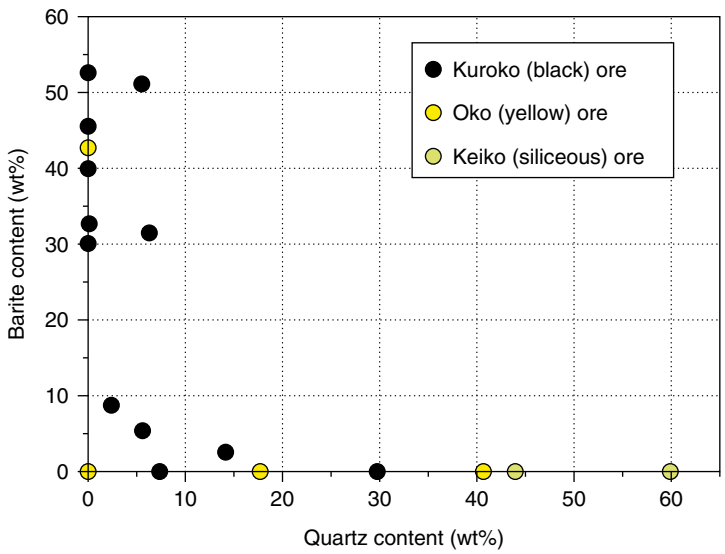

Fig. 16.41 Baryte and quartz contents of the Kuroko ore (Replotted from Shikazono et al. 2012)

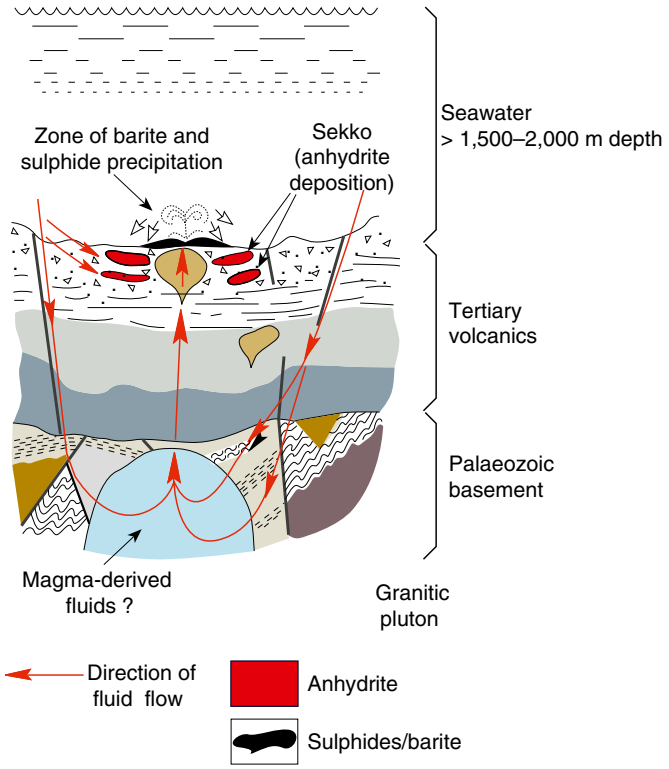

Fig. 16.42 Hydrothermal circulation that characterises Kuroko deposits (After Shikazono et al. 1983)

uplift indicates subsequent meteoric flushing. Anhydrite's solubility in cool seawater pore brines (<150 °C) also explains the lack of abundant $CaSO_4$ in massive sulphide bodies from older Kuroko-style deposits outside of Japan. There are, however, some intriguing breccias in these older Kurokostyle VHMS deposits. Table 16.9 compares the character of hydrothermal anhydrites in active Kuroko-style deposits and deep seafloor spreading centres, which are discussed next.

VHMS Deposits with Thermal Anhydrites at mid Ocean and Back-Arc Spreading Centres

Hydrothermal anhydrite is common also in extensional active back-arc basin and mid-oceanic ridge hydrothermal systems (Shikazono et al. 2012). The rare earth element (REE) content, strontium content, and the isotopic composition of strontium, oxygen, and sulphur indicates that most of this anhydrite also precipitated due to the mixing of ascending hydrothermal solutions an heating of ambient cold seawater, as in the Kuroko ores just discussed (Table 16.9). However, unlike the onshore Kuroko deposits just discussed, the formation mechanism of anhydrite below the seafloor in these extensional mid-ocean ridge settings has not been well studied, and is to date only well documented in the TAG mound region (Humphris et al. 1995).

TAG mound is an active hydrothermal mound, located 2.4 km east of the neovolcanic zone at 26° N, Mid-Atlantic Ridge. It is 200 m in diameter, exhibits 50 m of relief, and is covered entirely by hydrothermal precipitates. It made up of two superposed platforms representing different phases of active growth (Fig. 16.43: Humphris et al. 1995; Robert 2009) The larger lower platform shows evidence of mass wasting and supports a complex of white smokers venting fluids at temperatures of 260–300 °C. The narrower upper platform is characterised by black smoker complex of high temperature fluid discharge. The white smoker fluids (which principally precipitate anhydrite and low-Fe sphalerite, with minor marcasite and amorphous silica) are believed to be derived from the black smoker fluid (which principally precipitate pyrite, chalcopyrite and lesser anhydrite).

Smokers are the result of fluid cooling, mixing with seawater and precipitation of sulphides within the mound. Flanks of the mound are relatively steep and in part covered by aprons of sulphide debris, as well as fine-grained oxides eroded from the weathered slopes, which grade outward into biogenic oozes. The surrounding seafloor sediments are locally silicified (red chert). It is thought that the growth and collapse of sulphide chimneys in TAG Mound progressively built accumulations of brecciated sulphide deposits during the Late Pleistocene and the Holocene.

Surface samples were recovered from TAG mound by the submersibles "Alvin" and "Mir" in 1986, 1990, and 1991. In

Table 16.9 Characteristic features of anhydrite and hydrothermal solutions responsible for the hydrothermal anhydrite in East Pacific Rise N21°N and Kuroko deposits

	Kuroko-type deposits	East Pacific Rise N21° sulphide deposits
Occurrence	Nodular, massive in tuff under the sulphides with silicates 0.0n mm-n cm in diameter Rectangular crystals	White smoker, white chimney, white snow balls, black smoker with sulphides and silicates 0.00n-n mm in diameter Acicular and rectangular

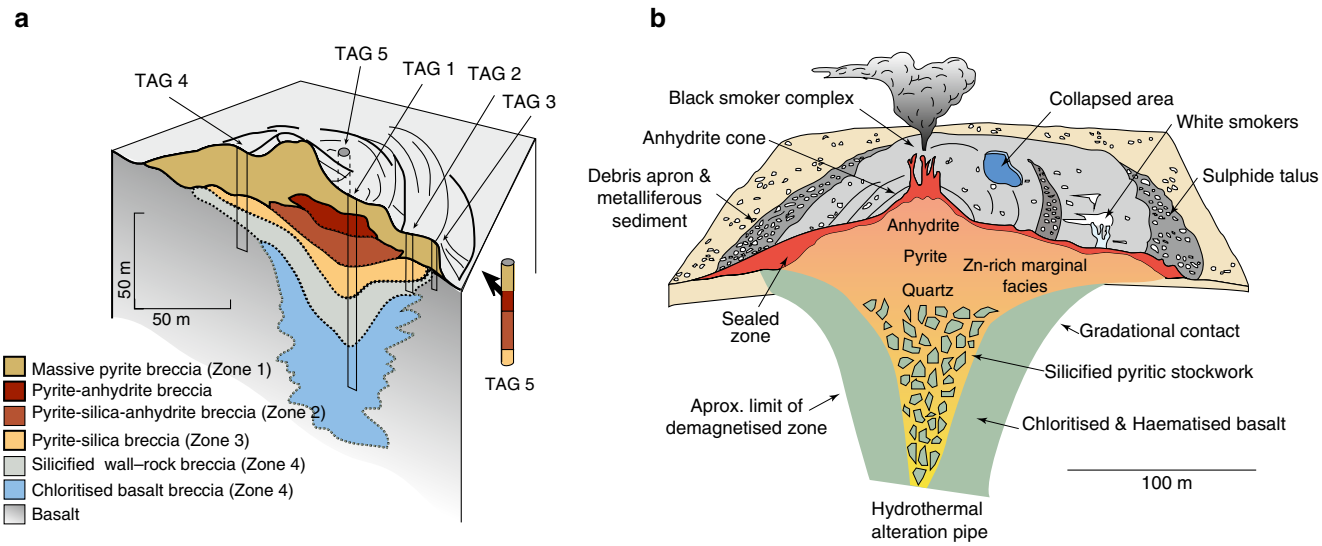

Fig. 16.43 Volcanic Hosted Massive Sulphides. (**a**) Hydrothermal anhydrite distribution within the internal mineral zonation of Tag mound. Note the importance of hydrothermal anhydrite in the internal structure of the mound. Well Tag 5 is out of the plane of section (After Humphris et al. 1995). (**b**) Cross section of a typical VHMS deposit showing accumulations of massive sulphides on the seafloor are related to and underlying zoned succession of anhydritic zone of stockwork mineralisation (After Hannington et al. 1998)

September-November 1994, the Ocean Drilling Program Leg 158 drilled a series of holes into the active mound to reveal unexpected high volumes of hydrothermal anhydrite within the sulphide mound. In fact, anhydrite occurs in breccias and as late-stage veins throughout most of the mound and its stockwork, down to at least 125 m below sea floor. As stated by Humphris et al. (1995): "These observations demonstrate the role of anhydrite in the growth of massive sulphide deposits, despite its absence in those preserved on land". Similar significant volumes of hydrothermal anhydrite have since been confirmed in other mounds, such as Manus mound, in a back-arc basin, offshore Papua New Guinea (Craddock and Bach 2010).

Modern hydrothermal activity on the TAG mound surface includes highly focused outflow of a 363 °C fluid from a chimney cluster on the top of the mound and deposition of a high S_2-O_2 mineral assemblage, reflected in low concentrations of H_2S in the black smoker fluid (Tivey et al. 1995). Blocks of sulphide and white smoker chimneys (enriched in Zn, Au, Ag, Sb, Cd, and Pb) are accumulating atop the mound as settleout and precipitates from venting black smoker fluids. The outflow fluid chemistries are modified by mixing with entrained seawater, so precipitating metal sulphides and anhydrite. The amount of anhydrite precipitating from the venting fluids of TAG mound is estimated at $5–15 \times 10^7$ kg/yr (James and Elderfield 1996). This is an order of magnitude greater than that of the Cu and Zn sulphides (10^6–10^7 kg/yr), clearly illustrating that much of the anhydrite forming on the mound surface is rapidly redissolved into the ambient seawater, leaving behind the sulphides.

Away from the active smoker vents, the bathing of the mound surface in normal seawater dissolves the anhydrite and oxidizes the sulphides to leave behind a carapace of ochreous and iron oxide-rich material. Such outer red-oxide layers, which formed during previous hydrothermal episodes, are now exposed on the steep outer walls of the lower part of mound. These flank deposits include a novel form of moss agate dominated by ferric iron oxyhydroxides (Hopkinson et al. 1998). The agate has an isopachous concentric laminar texture that formed during a series of rapid irreversible fluid changes as cooling fluid passed across a redox and pH front that separated oxidizing highly viscous siliceous gels from a mixed pyrite-iron oxide sediment. The laminar texture is a totally inorganic construct, and yet, based on its laminar accretionary texture, the agate could easily be confused with a biogenic structure. If such features are also present in ancient vent mounds they may easily be confused with stromatolitic features (e.g., see discussion of North Pole, Pilbara, in Chap. 2).

Beneath the mound surface lies a complex assemblage of sulphide-anhydrite-silica breccias (Fig. 16.32a; Humphris et al. 1995). Drilling has shown that sulphide seafloor mounds grow largely as an *in situ* accretionary breccia pile, driven by ongoing episodes of hydrothermal activity, with thermallydriven seafloor hydrologies, not too dissimilar from Kuroko-style deposits. Ridge mounds do not grow simply by the accumulation of sulphide fallout onto the sea floor. During times of active hydrothermal circulation the internal mixing of black smoker fluids and heated seawater precipitates widespread sulphides and anhydrites. Inactive periods are marked by dissolution of anhydrite and collapse and brecciation of the mound interior. Subsequent episodes of hydrothermal activity form new hydrothermal precipitates, as well as cementing earlier breccias.

Breccia in the mound can be broken down into 4 zones (Fig. 16.43a; Humphris et al. 1995). Zone 1 is dominated by clastsupported massive pyrite breccias that dominate in the upper 10–20 m of the mound. These are underlain by the anhydritic zone 2 in the central part of the mound. Pyrite-anhydrite breccias are present down to 30 m below sea floor and are underlain by pyrite-silica-anhydrite breccias that extend to the bottom of the anhydrite-rich zone 2 at about 45 m below the seafloor. Anhydrite veining is extremely well developed throughout zone 2, where composite anhydrite veins up to 45 cm thick are present. They comprise multistage fracture fillings and linings some of which include disseminated, fine-grained pyrite and chalcopyrite, as well as trace amounts of haematite. Zone 3 consists of intensely silicified and brecciated wall rock, which comprises the upper part of the upflow zone beneath the mound. Pyrite-silica breccias occur in the upper part of this zone and are underlain by silicified wallrock breccias. Below about 100 m below the seafloor the silicified wall rock breccia grades into a chloritised basalt breccia (zone 4), where chloritised and weakly mineralised basalt fragments (1–5 cm diam) are cemented and veined by quartz ± pyrite.

Dating of the sulphides and anhydrites within the mound breccias clearly shows that sulphide accumulation and mound growth is not a continuous process (You and Bickle 1998). The oldest material (11,000 to 37,000 years old) forms a layer across the centre of the mound stratigraphy, with younger material (2,300 to 7,800 years old) both above and below. This age distribution implies that TAG mound accreted via episodic activity of the hydrothermal system, with growth recurring at intervals of up to 2,000 years.

Extensive precipitation of anhydrite within the TAG mound indicates extensive entrainment and heating of seawater. Teagle et al. (1998) found that the $^{87}Sr/^{86}Sr$ ratios indicate that most of the anhydrite formed from ≈2:1 mixture of seawater and black smoker fluids (65 % ± 15 % seawater). The oxygen-isotopic compositions imply that anhydrite precipitated at temperatures between 147 and 270 °C (Table 16.9). This means the circulating seawater must have been conductively heated to between 100 and 180 °C, before mixing and precipitation occurred. Precipitation of anhydrite within the TAG mound is also the major mechanism for removal of REE during mound circulation. Something like 0.15–0.35 g of anhydrite is inferred to precipitate from every kg of fluid venting from the white smoker chimneys (Mills and Elderfield 1995).

Collapse and mass wasting of the porous sulphide in TAG mound during burial was followed by recrystallisation of most sulphide minerals into pyrite. There is textural evidence that the anhydrite matrix in the pyrite-anhydrite breccias did not replace a pre-existing matrix and did not fill pre-existing cavities. It is probable that in situ precipitation of anhydrite was made possible because of high fluid pressure compensating for burial and fluid percolation through displaced sulphide clasts. This process probably led to significant internal expan-

sion and fracturing of the TAG mound (Robert 2009). Variations of hydrothermal activity during the Late Pleistocene and the Holocene likely resulted in a succession of internal collapses (anhydrite dissolution) and reactivations (anhydrite precipitation) leading to disruption of the breccias and uplift of older fragments of breccia and altered basalt. However, anhydrite veins seem to have formed through filling of fissures and fractures which developed within the mound and acted as pathways for hydrothermal fluids. The pyrite-silica breccia evolved from pre-existing pyrite-anhydrite breccia through progressive replacement of the anhydrite matrix by quartz aggregates. It is probable that initial deposition of amorphous silica and/or cryptocrystalline quartz was followed by hydrothermal recrystallization and a related minor decrease in volume. The relationships between pyrite and quartz are confused by mutual intergrowth and replacement.

The upper pyrite-silica breccia corresponds to the inferred depth of the oceanic crust, and the presence of altered basaltic clasts increasing with depth suggests that for a large part this unit was initially oceanic basalt. This is reflected in the general model of zonation in a VHMS deposit (Fig. 16.43b; Hannington et al. 1998). The hydrothermal alteration of the oceanic crust started with the chloritization of the basalts through interaction with Mg-bearing hydrothermal solutions. Chloritization was especially intense below the currently active hydrothermal mound, decreasing in importance at the periphery. As alteration progressed, most of the previously altered and relict minerals were replaced by paragonite, quartz and pyrite. The presence of pyrite crystals with quartz corona and zoned quartz with pyrite veins suggest that recurrent intervals of silicification and pyritization deeply altered the basaltic stockwork. Anhydrite locally precipitated as veins in open spaces, as in the upper parts and surrounds of the mound, as a consequence of significant infiltration of seawater into the active hydrothermal system.

Another seafloor ridge region with significant documented volumes of anhydrite is in the sediment-hosted Grimsey hydrothermal field in the Tjörnes fracture zone on the seafloor, north of Iceland (Fig. 16.44a: Kuhn et al. 2003). There the fracture zone is located at a ridge jump of 75 km, which caused widespread extension of the oceanic crust in this area. Hydrothermal activity occurs in Grimsey field over a 300 m by 1,000 m area, at a water depth of 400 m. Active and inactive anhydrite chimneys up to 3 m high and hydrothermal anhydrite mounds are typical of the seafloor in this are. Clear, metal-depleted, up to 250 °C hydrothermal fluids are venting from active chimneys and fluid inclusion in the precipitated anhydrites show the same homogenisation temperature range (Fig. 16.44b).

Anhydrite samples collected from Grimsey field average 21.6 wt.% Ca, 1,475 ppm Sr and 3.47 wt.% Mg. The average molar Sr/Ca ratio is 3.3×10^{-3}. Sulphur isotopes from anhydrites have typical $\delta^{34}S$ seawater values of $22 \pm 0.7‰$,

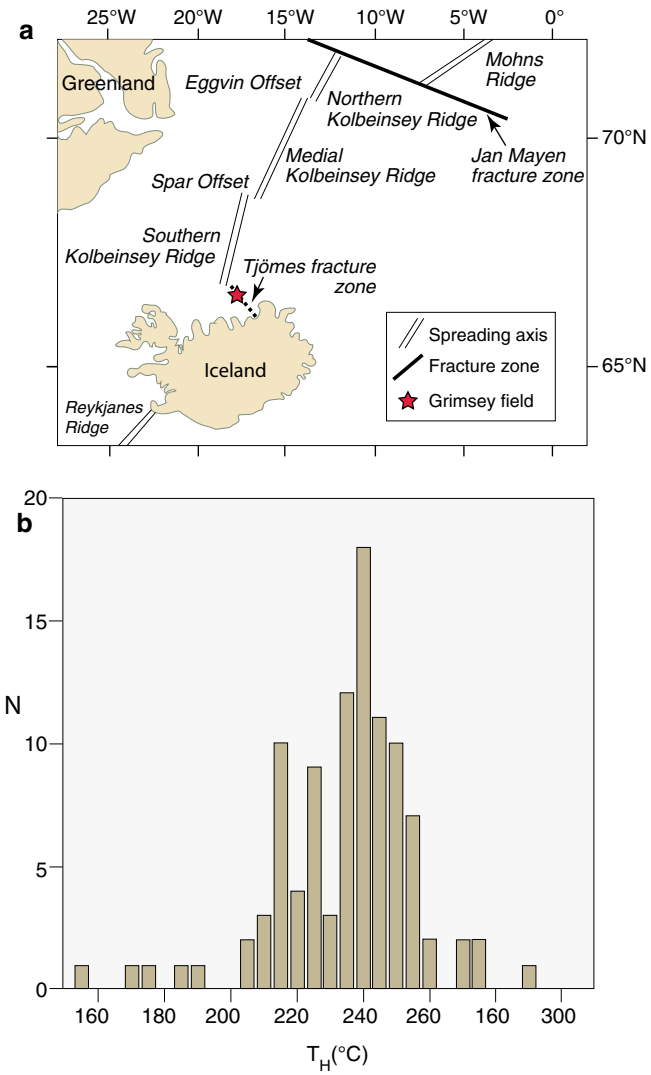

Fig. 16.44 Grimsey hydrothermal field, offshore Iceland. (**a**) Location map. (**b**) homogenization temperatures of fluid inclusions in anhydrite. Most of the temperatures range between 200 and 280 °C and therefore, are consistent with the *in situ* temperature of the venting fluids of 248–250 °C (After Kuhn et al. 2003)

indicating a seawater source for SO_4^{2-}. Strontium isotopic ratios average 0.70662 ± 0.00033, suggesting precipitation of anhydrite from a hydrothermal-seawater mixture. The endmember of the venting hydrothermal fluids, calculated on a Mg-zero basis, contains 59.8 µmol/kg Sr, 13.2 mmol/kg Ca and a $^{87}Sr/^{86}Sr$ ratio of 0.70634. The average Sr/Ca partition coefficient between the hydrothermal fluids and anhydrite is about 0.67, implying precipitation from a non-evolved fluid. In combination, this suggests anhydrite forms in a zone of mixing between upwelling hydrothermal fluids and shallowly circulating seawater. Before and during mixing, seawater is heated to 200–250 °C, which drives anhydrite precipitation and the likely formation of an extensive anhydrite-rich zone beneath the seafloor, as in Tag Mound and the Hokuroko Basin.

Once hydrothermal circulation slows or stops on a ridge or mound, and the "in-mound" temperature falls below 150 °C, anhydrite in that region is likely to dissolve. During such inactive periods, the collapse of sulphide chimneys, the internal dissolution of mound anhydrite, and ongoing disruption by faulting will all cause an internal brecciation of the deposit. Through dissolution, former zones of hydrothermal anhydrite create intervals of enhanced porosity and cavities in the mound. Such intervals initiate fracture and collapse in the adjacent lithologies, which become permeable pathways during later renewed fluid circulation episodes. The alternating "coming and going" role of hydrothermal anhydrite creating preciptation space within the mound hydrology is similar to that of sedimentary evaporites in the sedimentary mineralising systems.

TAG mound, along with other active seafloor mounds (smokers), are considered to be modern analogs for Cyprus-style ore deposits. Prior to the drilling of the TAG mound, the importance of widespread hydrothermal anhydrite in modern and ancient seafloor ridge mounds, both as a sulphur source and as an integral mechanism for internal brecciation and pore space creation, was not well understood. Take away the anhydrite, and the internal structure of the TAG mound bears a striking resemblance to ancient volcanic-hosted massive sulphide exposed in ophiolite terranes (Cyprus-type deposits). Or, if we mentally replace the sea floor basalt with dacite, the zonation and distribution of the anhydrite and mineralisation is near identical to that in a Kuroko-style deposit. This underlies the significance of seawater-fed hydrothermal circulation cells, rather than the mineralogy of the host matrix, in controlling both sulphide mineralisation and the precipitation of anhydrite.

Although hydrothermal anhydrite ultimately dissolves it can, while the mound is active, act as a concentrated subsurface sulphur source, which plays an fundamental role in the growth and maturation of sulphide mineralisation in the mound (Ohmoto 1996). The question that have yet to be addressed in this and other styles of VHMS deposits are: "What are the indicators of the hydrothermal salt that was?" Are they similar to those of dissolved low temperature evaporites (Chap. 7) or is there a whole new and distinctive suite of indicators and breccias that, once fully documented, will be used to refine predictive models of hydrothermal deposits?

VHMS Deposits with Hydrothermal Anhydrite at Sediment-Covered Spreading Centres: Besshi-Style and the Guaymas Basin

The type Besshi deposit is in Japan, it is metamorphosed, with a Precambrian age. This and other ancient Besshi-style deposits typically form stratiform lenses and sheetlike accumulations of semi-massive to massive sulphides, which lack any preserved calcium sulphate but show evidence of being dominated by seafloor sediments at the time of ore formation. Given the Precambrian age of most examples of this deposit style and its seafloor genesis, a lack of preserved hydrothermal anhydrite is not surprising, even if precipitation of prograde thermal anhydrite was a fundamental part of its formation. Besshi ore minerals are dominantly pyrite and/or pyrrhotite with variable amounts of chalcopyrite and sphalerite and minor to trace galena, arsenopyrite, and gold or electrum; baryte is generally absent (Slack 1993). Many deposits have significant cobalt and high cobalt/nickel ratios. Typically associated with the deposits are a variety of wall rocks, including metachert, magnetite iron formation, sericite- and chlorite-rich schist, tourmalinite and albitite. According to Slack (1993), these wallrock lithologic units formed by pre-metamorphic hydrothermal alteration and/or by chemical sedimentation coeval with massive sulphide deposition.

Besshi-type deposits typically form where a hydrothermal ridge or axis is proximal to a source of terrigenous sediment, so that the axial ridge is covered by beds of finer-grained deep sea sediment (Fox 1984). In this situation the ascending magmas do not make it to the seafloor, but form sills and dykes in sedimentary hosts. These features then act as a heat source driving hydrothermal circulation cells within the sediments. The presence of ubiquitous host sediment between ore layers distinguishes this type of deposit from the more open-marine sediment-free Cyprus-style of marine rift deposit exemplified by the modern TAG mound and from the sediment-starved style of rift deposit exemplified by the metalliferous deeps of the Red Sea.

A modern day counterpart to Besshi-style ores is located in the Guaymas Basin of the Gulf of California (Fig. 16.45a). There muddy biogenic and turbiditic sediments, up to 500 m thick, cover a series of spreading ridges and transform faults. In Chap. 9 this region was discussed in terms of hydrothermal cracking creating hydrocarbons from the rapid heating of organic-rich diatomaceous ooze (Fig. 9.73). The shallower intrusions lie some 400 m below the sediment surface beneath waters more than 1,800 m. There a section extending over a little more than 120 km long, encompassed more than 120 hydrothermal vent sites, all with mineral deposits. The same side scan sonar deep-tow vehicle passed through 20 thermal plumes along the same trackway (Lonsdale and Becker 1985; Peter and Scott 1991a, b). Temperatures as high as 315 °C were measured at some vent exits. A dredge sample from one of these sites – the Seacliff hydrothermal site – contained sulphates (anhydrite and baryte), as well as talc, calcite, pyrrhotite, sphalerite, wurtzite, marcasite, chalcopyrite and galena, all soaked in hydrothermal petroleum condensates.

The isotope signatures of the anhydrite, as well as the hydrothermal baryte and metal sulphide phases show sulphur signatures reflecting their genesis from hydrothermally

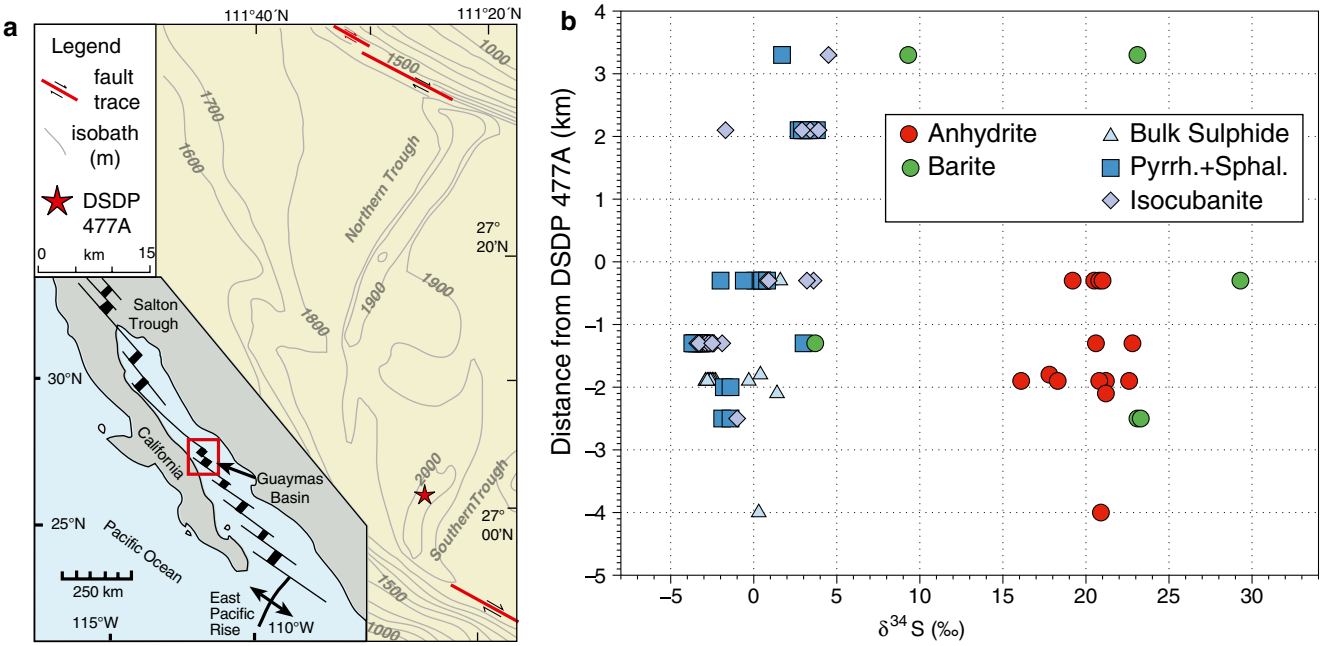

Fig. 16.45 Guaymas Basin. (**a**) Location of DSDP drill hole 477A. (**b**) Sulphur isotopes from hydrothermal anhydrite and baryte and various sulphide phases in seafloor samples from the Southern Trough in the vicinity of DSDP 477A (Replotted from isotope data in Peter and Shanks 1992)

heated seawater. Notably, the sulphur isotope field of this hydrothermal anhydrite is the same as that of evaporitic anhydrite and gypsum. Also of some interest, but not as yet considered a feature incorporated in fluid evolution models for this type of hydrocarbon genesis, is the recently-documented presence of a 2-km thick, 50×100 km long evaporite body, which defines the eastern margin of the Guaymas Basin (Miller and Lizarralde 2013). This halokinetic body of salt lies to the immediate west of the portion of the Guaymas Trough where the documented hydrothermal hydrocarbons occur and likely exerted some influence on the basin's brine chemistry.

Cooling hydrothermal outflow waters construct anhydritic chimneys, mounds and spires, with local clogging by worm tubes. The mineral chimneys and other constructs can rise up to 5 m on mounds that in turn rise 5–25 m above the surrounding seafloor. Chimneys are dominated by mixtures of anhydrite and pyrrhotite with lesser amounts of the other metal sulphides. The mounds can grow upwards, sideways and downward depending on how the mineral precipitates clog the outflow vents. The resulting vent shapes range from simple conical chimneys to multi-tiered pagoda-like spires with multiple horizontal eaves. Ultimately, the chimneys become unstable and collapse, causing the broken vent base to reopen and chimney growth to begin anew.

Web-like mats of the filamentous sulphide-oxidising eubacterium *Beggiatoa sp.* occur among the chimneys and worm tubes and on the surface of zones of nearby anoxic bottom sediment (Jannasch et al. 1989; Gundersen et al. 1992). This monospecific bacterial buildup constructs mats up to 30 cm thick in areas between the wormtubes, while thicknesses of up to 3 cm are common as bright yellow and orange mats on the seafloor adjacent to hydrothermal vents. Individual bacteria are gigantic, made up of cell filaments up to 120 µm in diameter. They are so large that individual filaments can be seen with the unaided human eye and resemble glass fibres in the lights of a submersible.

Because hydrothermal anhydrite dissolves under open seafloor conditions, it is usually absent in the material that covers inactive vents in the Guaymas Basin. It does, however, convert to gypsum which can be found in sediment cores from areas where the vents are no longer active (Sturz et al. 1996) $\delta^{34}S$ values for the sulphate minerals in the mounds range from 16.1‰ to 23.1‰ for the anhydrite, and from 23.1‰ to 215.3‰ for the baryte (Fig. 16.45b; Peter and Shanks 1992). Sulphur-isotopic composition indicates an unfractionated seawater sulphate source, although some samples from within the chimneys have more negative values, which suggest local sulphate reduction and sulphide oxidation related to bacterial processes. Differences in $\delta^{34}S$ between coexisting sulphide minerals from the mounds are generally small, suggesting sequential deposition of copper, zinc and iron sulphide minerals from a hydrothermal fluid of nearly constant $\delta^{34}S_{H2S}$ composition. During mineral replacement processes, which are common in the chimneys, secondary sulphides undoubtedly inherit some of their sulphur from precursor sulphide minerals (Peter and Scott 1991a, b).

Overall, the hydrothermal circulation processes involving anhydrite precipitating in Guaymas vent regions are similar to those acting in Kuroko and TAG mound settings. That is the precipitation of hydrothermal anhydrite is a response ot the heating of circulation seawater pore brines and is largely independent of host lithology. The host tends to be an acidic volcanic in a Kuroko (arc) setting, a mafic or ultramafic/basaltic host in an mid oceanic and ridge setting, and fine-grained diatomaceous/siliciclastic sediments in a Besshi/Guaymas setting. The relative volumes and significance of high-temperature anhydrite preserved within and below the mineralised mound features across all three styles cannot be quantified without more detailed drilling of all three styles. Suffice it to say that anhydrite is a supplier of sulphur to the mineralisation in all settings (Fig. 16.46). It would not be surprising if subsurface hydrothermal anhydrite made up a large proportion of the hydrothermal precipitates in zones of actively circulating hydrothermal seawater, in all as more detailed drilling and mining has shown in TAG mound and the Kuroko-style deposits. One possible difference between vent deposits of the Guaymas Basin compared with other VHMS deposits may well be the volume of entrained organics in sediment-covered hydrothermal cells. These organics are hydrothermally cracked and so have distinctive organic signatures (Fig. 9.73).

Evaporites and Metalliferous Deposits

What our discussions in this and the previous few chapters clearly show is that evaporites do not directly create base and precious metal accumulations, nor are they direct indicators of gemstone occurrence. Rather, what evaporites tend to do in the diagenetic or metamorphic/igneous realm is to enhance conditions likely to lead to an economic accumulation of base and precious metals.

They can act as a source of chloride-rich brines, which are capable base metal carriers, even of gold at higher temperatures. They do this via dissolution and metamorphic evolution. In the lower temperatures of the diagenetic realm they do this via dissolution of chloride salts, mostly halite, which is an ongoing process deep into the subsurface. In the high temperature metamorphic realms they do this as suppliers of ionic components to metamorphic and hydrothermal waters, or via daughter products, such as scapolite, which continue to release chloride as the scapolite lattice cage is compressed in response to increasing temperature and pressure. In basins with thick buried halites passing into the metamorphic realm, there is a pulse of chloride-rich brine released at the onset of greenschist conditions. It is the result of the change in the polyhedral lattice structure of salt, which turns a halite aquitard/aquiclude into a warm halite aquifer undergoing self cannibalisation.

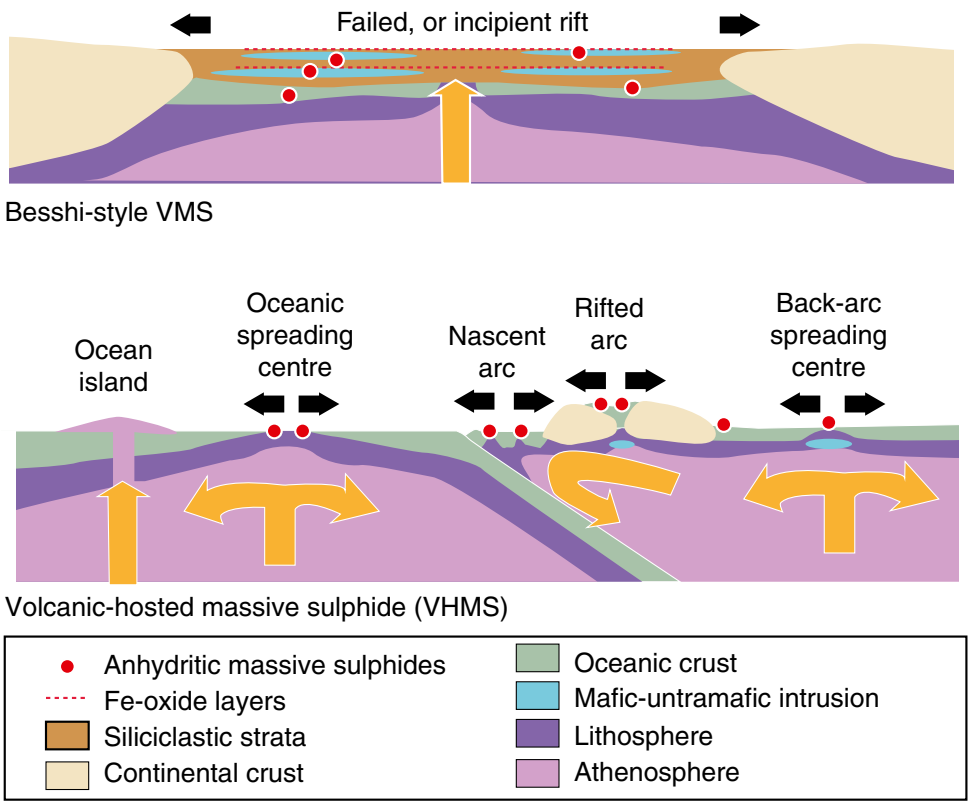

Fig. 16.46 Typical plate tectonic settings where hydrothermal anhydrite precipitates in VHMS and Beshi-style deposits

Sulphate evaporites, as they dissolve, can also act as sulphur sources and hence can help fix metals via biochemical sulphate reduction in lower temperatures (<110 °C) of the diagenetic realm or by thermochemical reduction at the upper end of the diagenetic realm and into the metamorphic realm. Thick calcium sulphate beds can also be assimilated into magma and so introduce addition sulphur to the igneous system, as they did in helping form the Phanerozoic nickel and iron deposits of Siberia and the supergiant Muruntau gold deposit in Uzbekistan.

Thick salt beds not only dissolve but also tend to flow. Halokinesis can thus stabilise a redox front and so lead to significant increases in size and purity of metal deposits both at precipitative sites. This is true in the subsurface, as was the case in the Permian-hosted sub-salt stratiform copper deposits in the Lubin region Poland and the late Palaeozoic supra-salt copper deposits of the Dzhezkazgan region in Kazakhstan. Brine outflow, associated with shallow halokinesis, can also focus and stabilise brines venting onto the deep seafloor and so stabilise brine lakes in deep sea floor settings where the sumps accumulating the brines are often a result of halokinetic structuration of the seafloor. This creates longterm anoxic interfaces and reducing settings where significant volumes of base metal laminites can accumulate. This was the case in the McArthur River, Mt Isa, Cloncurry deposits of Australia and the Atlantis II deep in the Red Sea.

What is common to all economic examples is that the role of evaporites and hydrothermal salts becomes significant in mineralisation only when the salts and their daughter products convert to brines. This is why the role of evaporites in forming metal accumulations is not well understood. The evaporite beds and masses must go, in order to form metal accumulations. If you have a metal accumulation where evaporites played a role in focusing and concentrating precipitation, the actual evaporite salts are typically long gone and all that remains are subtle indicators of "the salt that was."

The influence of "the evaporite that was", is also seen in the many igneous economic accumulations associated with the disappearance of evaporite salts as discussed in this chapter. The fact that the evaporites dissolve in circulating waters or are assimilated in magmas makes recognition of the associations in this chapter even more enigmatic and difficult. Identifying the presence of hydrothermal salts such as some forms of anhydrite, which are commonplace precipitates in volcanogenic massive sulphide deposits is very difficult once the salts dissolve from their igneous matrix. Yet, both metasedimentary and hydrothermal $CaSO_4$ play important roles in the formation of many high temperature metal accumulations. Hydrothermal anhydrite in a VHMS deposit is retrograde salt, which like most calcium sulphate in evaporite beds is sourced in seawater, but as was first pointed out in Chap. 1, it is not a "true" evaporite salt formed by solar evaporation of a brine. In contrast, the greenschist calcium sulphate that dissolved to create the bisulphide carrier for Au in the supergiant Muruntau gold deposit has a sedimentary source. Defining and separating origins of the major ions in metalliferous fluids, which precipitate high temperature precious and base metal accumulations, is one of the most difficult aspects of the broader field of evaporite studies.

Syn-rift basins, 551
Szechuan region, China, solution mining, 1311

T

Tachyhydrite
carnallite and, 1274
description, 1276–1278
occurrences, 1274–1275
TAG mound type deposits, 1660–1664
Talc
meta-evaporitic mineralisation, 1424
sodian phyllosilicates and, 1421–1424
and tourmalines, 1423
Tank-track advance/frontal rolling, 524
Tanzanite, tsavorite and, 1433–1435
Tarim Basin, China, 1079
Tartus Basin, Troodos Larnaca Culmination, 469

Tata Chemicals Magadi Ltd, 1250
Tectonic stresses, 795
Tectonic stresses, by overpressure, 795
Tennant Creek style deposits, 1641, 1643
Tepees
  Permian Basin, West Texas, 35
  ridges, 36, 37
  saline-tepees, 36
  stacked sequence, 35
  Tansill formation, 35
Tersanne, France, salt creep effect in, 1373
Tertiary evaporite
  depositional textures, 10, 12
  fibrous gypsum and halite, 76–80
Tertiary foreland basin, 564–565
Tertiary Piedmont Basin, 462
Tertiary salt welds, 540
Textures
  borate salts, 1207
  dynamic metamorphism, 1382
  sulphur, 1295–1297
Thenardite, 1216
Thermal effects, salt flow, 505
Thermal maturation, 837
Thermobaric-thermohaline fluids
  fluid movement, 773–774
  natural hydrofracturing, 774
  thermal properties, 777
Thermochemical sulphate reduction (TSR), 1512, 1525
  BT *vs.* DBT values, 952, 953
  efficiency of, 949
  Jialingjiang Formation, 953, 954
  Khuff Formation, 950
  low salinity subsurface water, 950–951
  post-diagenesis, 953
  pre-diagenesis, 952–953
  reactants and sulphur generation product, 953
  Smackover Formation, 951, 952
Thermohaline suprasalt convection, 791
Thin-skinned fold, 560–565
Thrombolites
  biolithification of, 24
  Evolution and distribution of, 29
Thrust advance, 530
Thrust belts, 560–565
  décollement, 562
  dynamic/regional metamorphism, 1394–1401
  Lufilian foldbelt, Central Africa, 560
  taper angle, 560
Thumb Mountain Formation, 1555, 1557, 1562
Thylacoleo carnifex, 287
Thyroid-stimulating hormone (TSH), 1282
Tiered allochthon plays, deepwater realm, 1043–1048
Timor Sea, 779–781
Tincal. *See also* Borate salts
  definition, 1195–1196
  description, 1196
Tincalayu, Argentina, borate deposits, 1198, 1207
Tonalite, trondhjemite, and granodiorite (TTG) production, 1390
Topographic relief, 572, 589, 590
Torrens Lake, Australia, 881
Total dissolved solid (TDS) boundary, 1485–1486
Total Organic Carbon (TOC)
  and carbonate proportion, 918, 919
  modern saline settings, 857, 858
Tourmalines
  aluminium borosilicates, 1412
  boron isotopic composition, 1416, 1417, 1424, 1432
  characteristics, 1413
  composition, 1413
  dravite-uvite series, 1413
  lattice structure of, 1412
  with marine evaporites, 1414
  meta-evaporitic settings, 1413–1414
  mineralization characteristics, 1418
  Rum Jungle geochemistry, 1467–1468
  in Sullivan deposit, 1416, 1417
  talc and, 1423
  and tourmalinisation, 1412–1420
Tourmalinite, 1412
  mineral, 1412
  worldwide examples of, 1420
Transvaal Sequence, South Africa, 1649
Trap styles, 1079
Triassic Chinle Formation, 1518
Triassic evaporites, 781, 820–821, 833–834
Triassic extensional faults, 566–567
Triaxial deformation experiments
  carnallite, sylvite and rock salt, 499–500
Trona, 1238. *See also* Sodium carbonate
  in African Rift, 1249–1251
  deposits, 114–116
  evaporites in Lake Magadi, 115
  in North America, 1243–1247
  solution mining, 1322–1324
Trump method wells, solution mining, 1315
Truncations (unconformities), 587
Tsavorite
  genetic model, 1433
  nodules of, 1433–1434
  structure, 1434
  and tanzanite, 1433–1435
TSH. *See* Thyroid-stimulating hormone (TSH)
Tubeworm carbonates, 941
Tufa
  annual growth rates, 26
  Big Soda Lake, Nevada, 26
  mound and pinnacles, 332–334
  reef mounds, 307
Tully method wells, solution mining, 1315
Tumuli, 627
Turkey
  borate salts in, 1192, 1197, 1202–1207
  colemanite in, 1197, 1198
  mirabilite in, 1234, 1236
  sodium sulphate in, 1233–1236
Turtles, 520–521
Turtle-structure anticlines, 520
Tusanj site in Tuzla
  solution mining, 1342
Tuz Golu, Turkey, 340–342
Tuz Lake, Turkey (Tuz Gölü), perennial saline lakes, 340–342
Two Way Time (TWT) structure map, 583, 585
Tyrell Lake in Victoria, acid groundwater in saline, 128–129

U
Ukrainian Dniepr-Donets Basin (DDB), 572, 573
Ulexite, 1202
  nodules, 1204
  in Turkey, 1197, 1198
Umm Ash Shurabyat, Saudi Arabia, Sabkhat, 298
Umm as Samim sabkha, in Oman, 295
Underpressure, 794
Untersee Lake, East Antarctica, conical stromatolites in, 27
Upper Convective Layer (UCL) of Atlantis II Deep, 1505

Upper Kama Potash Region, Cis-Urals Russia, ancient potash evaporites, 1161–1165
Upper Mexican Ridges (UMR) unit, 556
Upper Red Formation, 578, 580
Upper Rhine Graben, France, ancient potash evaporites, 1141–1144
Uraniferous calcretes, 1593–1595
Uranium ore, 1638
Urmia Lake, NW Iran, perennial saline lakes, 342–344

V
Vadose caves
  Miocene epikarst, Madrid Basin, Spain, 682–684
  Modern Gypsum Karst, Saudi Arabia, 686–687
  modern karst in Cretaceous Gypsum, Texas, 684–686
Van Lake, Turkey, perennial saline lakes, 335–338
Van't Hoff plots, 106
Variable point injection, solution mining, 1316
Vein textures and inclusion studies, 779
Vena del Gesso basin, 462–463
Vent anhydrites, 1601
Vesicoya cordata, 936
VHMS deposits. *See* Volcanogenic-hosted massive sulphide (VHMS) deposits
Viscaria copper deposit, 1646, 1649
Visean Belle Roche breccia, 646
Vitrinite, 839
Vitrinite reflectance, 1547
Volcanogenic-hosted massive sulphide (VHMS) deposits, 1574
  formation, 1653–1654
  gold in, 1605
  hydrothermal anhydrite
    chimneys, 1665
    chloritization, 1663
    distribution, 1654–1655
    at mid ocean and back-arc spreading centres, 1660–1664
    plate tectonic settings, 1666
    at sediment-covered spreading centres, 1664–1666
    sulphur isotopes, 1663
    TAG mound, 1660–1664
  mineralisation, 1655–1656
  in subduction-related island-arc settings, 1656–1660
Vuggy carbonates, 940–941

W
Walton Ba-Cu-Pb-Zn-Ag deposit, 1550
Walton-Magnet baryte deposit, 1543
Warramunga Group sediments, Australia, 1641, 1642
Waste disposal, salt caverns, 1329
  nonradioactive, 1330
  radioactive, 1330–1331
Water-based drilling fluids, 807–808
Water level changes
  Dead Sea, 336, 356–357
  Great Salt Lake, USA, 325
  in Lake Urmia, Iran, 343
  Lake Van, Turkey, 336
  Mono Lake, USA, 331

Watt Mountain shale, 776
WCSB
  fluids, 1173
  potash geology, 1169–1173
Weeks Island, Louisiana, salt caverns, 1363–1365
Welded basins, 541, 542
Welded-listric basins, 542
Welded listric (Roho) basins, 541
West Canadian Potash (Devonian), ancient potash evaporites, 1168–1169
Western Hematites, 1635
Western Mining, 1626
Western Nile Delta Coast, Mediterranean, Egypt, 242–244
West Hackberry explosion, salt caverns, 1365
Westhazel General Petroleums Pool of west-central Saskatchewan, Canada, 1080
Wet salt
  creep and frictional strengths, 501
  specifics deformation of, 500
  weakness of, 502
Whiteschist, 1421–1423
Wieliczka site, Poland, solution mining, 1337–1341
Williston Basin, 783
Willyama Supergroup, meta-evaporites, 1461
  Broken Hill Block, 1464–1466
  Olary Block, 1462–1464
Windsor brinefield, Ontario, solution mining, 1347
Windsor Formation, 1549
Wink Sink, USA, solution mining, 1349–1355
Winsford Mine, Cheshire, salt caverns, 1324
Wolf Springs fields, 1081
Wollogorang Formation, 1581–1582
Wormy carbonate cement, 937
Wucheng, China, trona, 1247

Y
Yaninee Lake in South Australia, acid groundwater in saline, 128
Yas Island diapirs, 593, 594
Yates Field, West Texas, 1021–1025
Yilgarn Craton, West Australia, acid saline lake system, 130, 131
Yilgarn deposit, Australia, 1593–1595
Yinmin Formation, 1518–1520
Yorkshire deposit, halite in, 1423
Yudomski event, 159, 160

Z
Zabuye Lake, China
  lithium, 1271–1273
Zagros deformation front (ZDF), 582
Zagros Foldbelt, Iran, 1068–1073
Zagros front, 574–576
Zagros/Hormuz region, Arabian Gulf, 640–642
Z3 - Boulby Potash, UK, 1155–1159
ZDF. *See* Zagros deformation front (ZDF)
Zechstein evaporites, England
  potash from, 1154
  stratigraphic evolution in, 477–483
  transition depth, 74
Zechstein salt
  in Germany, 1319–1320
  potash salt horizons in, 1612
  structures, 496, 504
Zeolites, 1297
  in agriculture, 1299
  facies of, 1386
  geological occurrence, 1300
  Lake Lewis, Central Australia, 1304–1305
  properties, 1298
  in saline settings, 1299–1304
  usage and production, 1298–1299
