In the vicinity of local freshwater entry points, an earlier nearsurface mixed-water environment locally affected sediments from the landsurface down to depths of several tens of metres thick. Freshwater entered the Smackover either through groundwater sinks (exposed palaeohighs or islands) or via the updip part of the regional groundwater flow system. Under these conditions, freshwater supply to coastal areas of the Northern Gulf, such as the Conecuh embayment, probably was limited to what was supplied by the updip drainage system between the Conecuh ridge and Pensacola arch. These waters leached aragonite allochems, leaving behind hollow grains preserved only by their micrite envelops. According to Prather (1992a) the $\delta^{18}O$ contents of these replacement dolomites are slightly depleted relative to seawater-seepage dolomites, slightly enriched relative to later rhombic dolomite cements, and closely associated with freshwater-phreatic calcite cements, suggesting a nearsurface mixed-water origin. Dolomite-replaced precursor marine cements, with only slightly depleted $\delta^{18}O$ compositions relative to seawater-seepage dolomites, have been encountered only in the Conecuh embayment. This is consistent with the notion that they are connected to isolated mixing zones. Their localized distribution probably reflects the limited extent of freshwater environments in such an arid climate.

Rhombic dolomite crystals of the shallow-burial mixed-water environment typically have cloudy cores and clear rims. These rhombic dolomite cements overgrow neomorphic fabrics, which formed after a period of leaching and sparry calcite precipitation. Paragenetic relationships show that vuggy and oomoldic pores within the Conecuh embayment and throughout the Northern Gulf region are virtually contemporaneous (Prather 1992a). Extensive leaching of this kind suggests considerable local artesian influxes of fresh to brackish water after evaporite deposition had ceased. The wide band of leached fabrics that parallels the updip limit of the Smackover suggests freshwater entry probably occurred along the Smackover outcrop in western Alabama and where Haynesville alluvial-fan sandstones interfinger with upper Smackover grainstones around the Conecuh Ridge and Conecuh embayment (Fig. 10.31a). Leaching trends similar to this are described by Moore and Druckman (1981) from the updip Smackover of Arkansas and Louisiana.

Their marginward position suggests that the downdip limit of leached fabrics is controlled by a change from less stable aragonite oolites updip to more stable calcite oolites downdip. In eastern Mississippi, Alabama, and Florida, however, the trend of leached fabrics is perpendicular to depositional strike. Therefore, the distribution of leached fabrics in the east is possibly more related to the downdip position of a zone of undersaturated groundwater (Fig. 10.31b). Sparry calcites that line the large vugs in the Smackover of the Conecuh embayment have somewhat depleted $\delta^{18}O$ signatures and low Fe^{++}/Mn^{++} ratios, which suggest precipitation in warm, slightly reduced, fresher subsurface waters. Abrupt changes of formation-water redox conditions or trace-element concentrations outlined by cathodoluminescent zonation patterns indicate these spars probably precipitated at sufficiently shallow burial depths to receive some recharge of oxidized fresher water from the surface after evaporite deposition had ceased.

These isotopically depleted dolostones of the deeply circulating regional fluid mixing stage constitute the signature of the most widespread reservoir rocks in the Smackover. They perhaps define areas where deeply circulating meteoric fluids (artesian waters) mixed with marine-phreatic or basinal brines and overprinted sediments from a few metres to hundreds of metres below the Buckner seal. They are confined to grain-supported and boundstone rock types below the Haynesville Formation, suggesting that the fresher water inflows, which mixed with formation brines, were confined to an aquifer lying below the evaporites and fine-grained siliciclastic rocks of the Haynesville Formation. By the time such brines were circulating, they were excluded from the now-tight carbonate mudstones and wackestones of the lower Smackover Formation. Recharge of the regional aquifer probably occurred as phreatic head rose along the Smackover/Haynesville subcrop during basinward tilting. Associated progradation of the overlying Cotton Valley strandline drove basinward migration of a thick continental freshwater lens atop the saltern evaporites.

In a tectonically stable area such as the Gulf Coast, large variations in recharge of regional confined aquifers, like the Smackover, are likely to occur only in response to substantial fluctuations of sea level (Harrison and Summa 1991). Maximum downdip limit of the regional mixed-water zone and associated dolostone reservoirs is likely, therefore, to have occurred during prominent sea level lowstands, such as those proposed for the Valanginian (Haq et al. 1987). The distribution of dolomite depleted in ^{18}O suggests that the interpreted regional mixedwater zone must have migrated downdip a minimum of 193 km from points of recharge along the Smackover subcrop and the Conecuh embayment (Prather 1992a).

Later precipitation of saddle dolomite in the deeper burial environment has been linked to chemical compaction of dolostones, thermochemical sulphate reduction, hydrocarbon migration, and epigenetic sulphide emplacement (Heydari 1997). Their depleted $\delta^{18}O$ values suggest formation temperatures higher than the other Smackover dolomites (Figs. 9.69a and 10.33a). Hydrocarbon inclusions suggest that the saddle dolomites are late burial cements that were at

least contemporaneous with hydrocarbon migration, which began in the middle Early Cretaceous. In the Smackover, as in the Arab D, evaporites played an early role in the formation of reflux dolomite and then a subsequent role as a focus (aquiclude) for regional flows of deeply circulating groundwaters and basinal waters.

Prather's analysis did not consider the possible influence of salt tectonism on isotopic evolution. In contrast, Heydari (2010) placed the isotopic signatures of Smackover dolomites in the Mississippi Salt Basin (situated east of the area in Alabama studied by Prather) in a halotectonic context and interpreted, what are isotope fields that overlap with Prather's C-O plotfields, in a somewhat different diagenetic context (Fig. 10.34). He defines two dolomite types with distinct geochemical compositions occurring near the inferred palaeoshoreline. One type of dolomite is fine crystalline (10–30 μm) and has positive $\delta^{18}O$ and positive $\delta^{13}C$ compositions (averaging +4.1‰ PDB and +5.0‰ PDB, respectively). It forms a relatively poor quality reservoir. The second Smackover Formation dolomite occurs on salt diapirs in the basin centre. This dolomite is coarsely crystalline (50–150 μm) and has negative $\delta^{18}O$ and positive $\delta^{13}C$ compositions, which is significantly lower than the palaeoshoreline (reflux) dolomite (averaging −2.2‰ PDB and +4.1‰ PDB, respectively). It forms excellent reservoir and is likely derived from more diagenetically evolved set of subsurface solutions tied to suprasalt convective flow.

Dolomite also occurs in the overlying Buckner Formation seal. This Buckner Formation dolomite occurs in nodular anhydrite layers, and formed by replacement of lime mudstone layers adjacent to anhydrite beds. The Buckner dolomite is finely crystalline (30–40 μm) and its $\delta^{18}O$ and $\delta^{13}C$ values are intermediate between the two Smackover Formation dolomites (−0.3‰ PDB and +4.4‰ PDB, respectively).

According to Heydari (2010), lithofacies association, geographical distribution, and isotopic compositions of dolomites of the Smackover and Buckner formations indicate three different processes of dolomitization (Fig. 10.34). The Buckner Formation dolomite formed as "primary" precipitates when saltern anhydrite was being deposited, and as a replacement of lime mudstones from a brine that had reached anhydrite saturation. Therefore, its isotopic composition is indicative of a Late Jurassic anhydrite-saturated seawater. The Smackover Formation dolomite that occurs along the presumed palaeoshoreline has $\delta^{18}O$ and $\delta^{13}C$ values, which are more positive than those of the Buckner Formation dolomite, suggesting it formed from more evaporated (possibly halite saturated) seawater, very likely within salt ponds. Dolomitization of the Smackover Formation on salt diapirs was accomplished by the seepage of evaporated, Mg-rich Buckner brine into Smackover grainstones through subaerial exposure surfaces on crests of salt diapirs. However, its $\delta^{18}O$ and $\delta^{13}C$ values are lower than those of the Buckner Formation dolomite suggesting that either the brine was diluted by meteoric water due to the exposed nature of the crestal structures or dolomite was recrystallised in meteoric water during burial.

Reservoirs Sealed by Bedded Basinwide Evaporites

As well as saltern evaporites sealing and driving alteration processes in intercalated platform carbonates, there a number

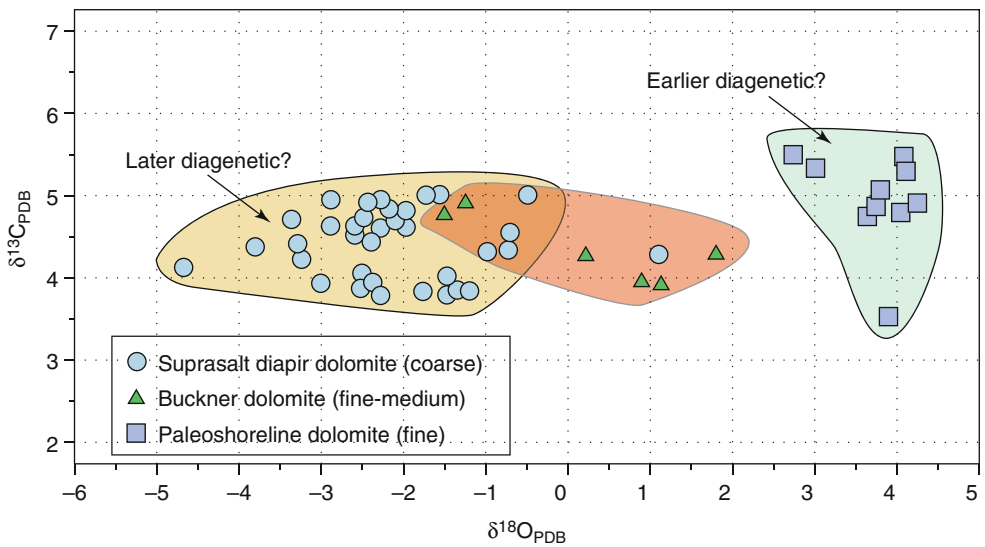

Fig. 10.34 Cross plot of $\delta^{18}O$ and $\delta^{13}C$ compositions of the three dolomites in Mississippi Salt Basin. The $\delta^{18}O$ and $\delta^{13}C$ values are the highest in the palaeoshoreline dolomite of the Smackover Formation, the lowest in the high-rise salt structure dolomite of the Smackover Formation, and intermediate in the dolomite of the Buckner Formation (Replotted from Heydari 2010). Note the values overlap with those of Prather 1992a – Fig. 10.33

of reservoirs sealed by thick caps of basinwide salts. Where the traps are stratigraphic, permeability tends to be developed in dolomitised carbonates beneath bedded seals. Such reservoirs tend to be patchy and of lesser quality compared to reservoirs hosted in the downdip areas of the saltern-sealed traps discussed in the previous section. But where the subsalt traps are structural, broadly-drained anticlinal culminations, as in the Miocene successions of the foreland foldbelt of the Zagros in Iraq and Iran, the fields are large and many are supergiants. This structural association reflects ability of evaporites to maintain seal integrity under deformation, while the underlying and intercalated dolomites and limestone fracture. This structural association is discussed in more detail later in the chapter, for now our discussion will focus on the effects of syndepositional reflux dolomitisation on reservoir quality below basinwide evaporites.

Eocene and Miocene Associations, Middle East

Carbonate platform and sandstone reservoirs beneath Tertiary-age basinwide seals in the Arabian Gulf and the Gulf of Suez have been overprinted to varying degrees by reflux dolomite. The evaporites define two main age-related saline associations:

Lower Eocene and Middle Miocene (Fig. 10.35). The Eocene evaporites are saltern evaporites precipitated in an intracratonic sag on the continental side of a foreland bulge in front of the rising Zagros chain. Across the Gulf they constitute widespread 10–20 m thick anhydrite/gypsum units within the Rus Formation and its equivalents. Salts in the Rus can perhaps also be considered the youngest example of widespread platform evaporites and accumulated immediately prior to the onset of icehouse eustasy (Chap. 5).

Miocene basinwide seals in the region are better known and perhaps more significant economically as they form caps to giant and supergiant fields in the Asmari limestone reservoirs of the Zagros fold belt. These salts accumulated in an isolated foreland deep in front of the Zagros suture and make up the Fars/Gachsaran formations in the Northern Arabian Gulf (Fig. 10.35 Alavi 2004; Gerdes et al. 2010). Today, the dissolution residues typify outcrops in the Dam Formation, the Fars equivalent in of Qatar and Saudi Arabia (Dill et al. 2005). Similar Middle Miocene basinwide evaporites are also highly effective seals to producing intervals in the rift-infilling Ras Maalab Group in the Gulf of Suez (Alsharhan 2003).

Eocene evaporites (bedded anhydrites) of the Rus Formation seal platform carbonate reservoirs in the northern Arabian Gulf (Iraq and Iran) and extend south over much of Saudi Arabia and the UAE (Steinhauff et al. 2007). Rus anhydrite is an important seismic reflector on the Arabian Plate where it is present above the Mesozoic and lower Cenozoic carbonate platforms. It provides reservoir top seal locally (e.g., Neutral Zone, Kuwait). In the subsurface the Rus typically comprises stacked meter-thick anhydrite parasequences interbedded with thinner limestone, dolomite, and marly beds with gross thickness in the shallowbasin centers of more than 200 m. Sub-meter scale, anhydrite bed sets can be traced on wireline logs for 100s of kilometers. Typically, the Rus has distinctive physical properties, including strong impedance contrasts with over- and-underlying strata. Less common are seismic zones lacking coherent reflectors and distinctive physical properties. Well penetrations show that many incoherent seismic reflectors at the level of the Rus typically include rubble and pass upsection into outcrop zones showing widespread evidence of evaporite dissolution.

Reservoir quality associated with the Rus seal in Iran, Iraq and Kuwait tends to be patchy and constitute the upper portions of thicker stacked Mesozoic pay horizons in giant and supergiant fields of the Northern Gulf. For example, in the 45 by 25 km anticline that is the Nahr Uhm supergiant field in Iraq the structural closure for the various pay zones varies with depth and ranges from 200 m for the Dammam (Eocene) down through the Rus Formation to about 800 m for the Lower Cretaceous Yamama reservoir. The Cretaceous is the main production focus for many of the huge fields of Iraq and Kuwait, but the Rus level can be host to significant volumes of heavy oil and bitumens. Such zones are typically overprinted by degradation products related to bacterial sulphate reduction, as in in the first Eocene reservoir level at the Giant Wafra Field, partitioned zone (PZ), Saudi Arabia and Kuwait (Fig. 9.67; Saller et al. 2014).

In the western and southern Gulf (Kuwait, Saudi Arabia, Qatar and the Emirates) the Rus anhydrite thins and is not present above many structural highs including much of the Qatar Arch, the Ghawar field, the Dammam Dome, and other large anticlines. Features attributed to karst are noted in many areas in this part of the Gulf. A lack of Rus anhydrite over these features can be explained by (1) non deposition because the structures were moving; (2) deposition followed by erosion, or (3) extensive subsurface dissolution of carbonate and sulphate-evaporite units under Middle Pleistocene wetter climatic conditions. Where the Rus and overlying Dammam outcrop or subcrop the succession is typically leached of its bedded and nodular evaporites (Dill et al. 2003; Holail et al. 2005). Once leached of its salts, the Rus section constitutes an important aquifer capable of producing potable groundwater. Only dissolution residues and collapse horizons remain in outcrop as indicators of the former presence of widespread bedded evaporites in the Rus Formation, along with associated slumps, digitate stromatolites, hollow cauliflower cherts and calcite nodules (pers. obs).

But the most productive Tertiary reservoirs in the northern Arabian Gulf are Miocene and are platform or deeper water carbonates (Asmari, Euphrates, Jeribe formations) that are sealed by Middle Miocene bedded salts of the Lower Fars/Gachsaran and equivalents (Fig. 10.36a). Core analysis of lower Miocene platform carbonates below these seals in

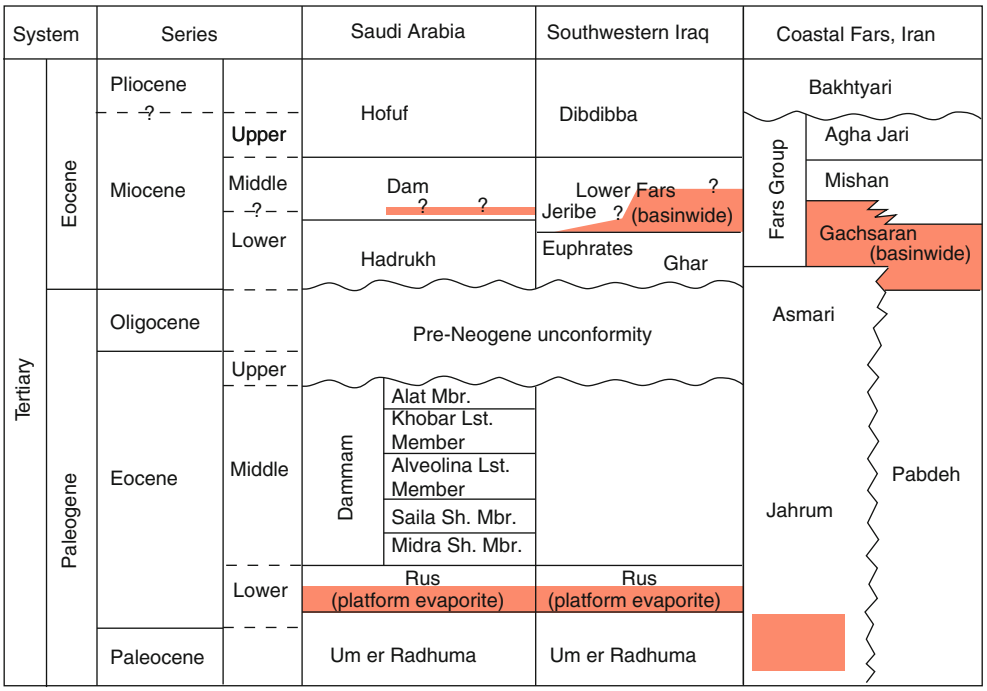

Fig. 10.35 Schematic Tertiary Stratigraphy of the Arabian Gulf, with evaporite-entraining successions shaded red (In part after Tleel 1973; Sharland et al. 2001; Alavi 2004)

Iraq show that openmarine subtidal carbonates have moderate to good porosity (10–35 %), but have highly variable permeabilities ranging from less than 1 md to several hundred millidarcies. Restricted tidal flat (evaporitic mudflat) carbonates intercalated in the same sections are tight (Figs. 10.36b and 10.37; Sun and Esteban 1994). In general, the best reservoir quality in the lower Miocene carbonates of the Middle East occurs in: (1) mud-lean skeletal packstones in which leached mouldic and vuggy porosity is well connected (e.g., Euphrates and Jeribe formations of Iraq and Syria), (2) oolitic packstones-grainstones with well-preserved primary intergranular porosity (e.g., local occurrence in the Jeribe Formation of Iraq), (3) coarsely crystalline dolomite (e.g., Euphrates and Jeribe formations of Iraq and Asmari Formation of southwestern Iran); and (4) highly fractured carbonates (e.g., Asmari Formation of southwestern Iran). Dolomitisation in many reservoirs substantially improves reservoir quality, especially in intervals hosting coarsely crystalline dolomites (Fig. 10.37). Asmari reservoirs and their seals are discussed later in this chapter.

In the Middle Miocene carbonates of the Gulf of Suez and the Red Sea, the spatial tie of the dolomites to basinwide rift evaporites, and their preferential distribution along the former platform margins, together with their relatively heavy oxygen isotopic values (averaging +4.65‰; Sun and Esteban 1994), all suggest that the bulk of the dolomite was formed by the lateral migration of evaporitic basinal brines into the shallow platform (a type of density-driven brine reflux). The formative hydrology was driven by the rise of brine levels associated with the evaporite filling the basin centre (Sun 1992; see also "spill and fill" discussion in Chap. 5 and later in this chapter). In contrast, downdip reflux of descending hypersaline brines, generated within platform salterns, were the main cause of extensive dolomitisation in the lower Miocene (Rus level) carbonate reservoirs of the Middle East. Differences in the two styles of hydrology can be recognised by mapping isotopic signatures of cements in cores from well to well and documenting the close stratigraphic relationship of reservoir quality to the transition zones between open marine platform carbonates (now dolomitised) and mapping (in seismic) the positions of restricted saltern evaporites or their residues.

Reservoir porosities in many of the evaporite-sealed Tertiary carbonate successions bear little relationship to depositional facies, rather they are strongly influenced by the distribution of anhydrite cements, burial corrosion, dolomite crystal size and fracture intensity. Undolomitised carbonates in the reservoir-hosting formations typically occur only in local areas: (1) encased units in marls, (2) platform interiors, and (3) areas with active freshwater drainage. This association of undolomitised intervals with basin margins or marine-cemented and exposed shoals is similar to that in the Smackover and San Andres formations.

Dolomite preferentially replaces magnesium-calcite skeletal grains (red algae, benthic foraminifera, and echinoderms) and micritised nonskeletal grains (ooids and peloids)

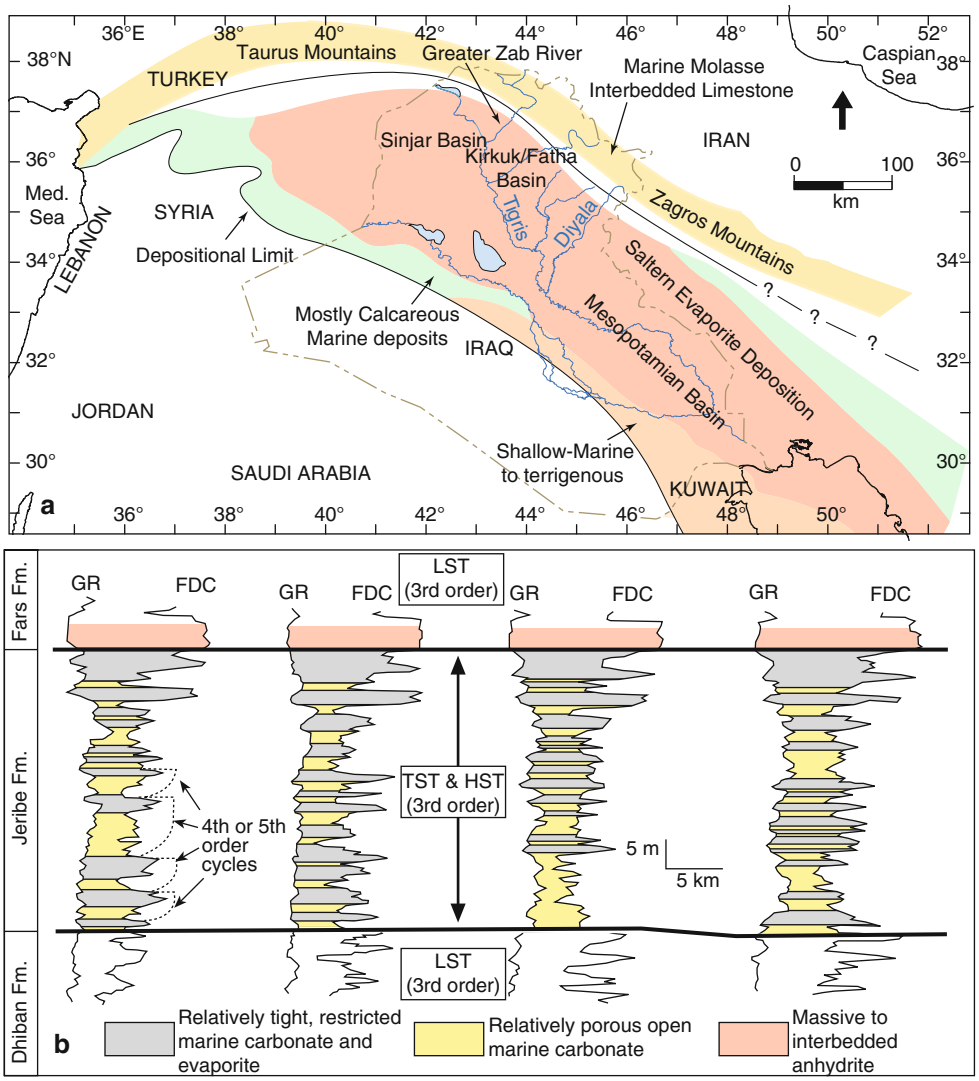

Fig. 10.36 Middle Miocene Fars evaporite seal in northern Gulf. (**a**) Distribution map showing the extent of Fars Evaporite and its equivalents in the Mesopotamian Basin and the locations of the Fatha/Kirkuk and Sinjar sub-basins (After Al-Juboury and McCann 2008). (**b**) Stratigraphic cross section of the Lower Miocene succession in the Middle East, centred on Iraq, showing higher order (4th or 5th) platform evaporite cyclicity within a 3rd order depositional sequence, which is made up of the lowstand Dhiban Formation, followed by transgressive and highstand platform carbonates of the Jeribe Formation, followed by lowstand evaporites of the Lower Fars (After Al-Murani 1986; Sun and Esteban 1994). Note the high porosity in the open marine carbonate intervals in the Jeribe Formationa and its equivalents, while the intercalated restricted marine carbonates and evaporites are tight (see Fig. 10.35a for Gulf nomenclature of the various Formations)

throughout most of the dolomitised Miocene carbonate section of the Arabian Gulf and the Gulf of Suez (Sun and Esteban 1994). Micrite matrix, internal muddy sediments, and micritised outer margins of aragonitic skeletons are also extensively replaced by dolomite. The replacement dolomites are subhedral to anhedral, finely crystalline (<10 μm) and show excellent preservation of original depositional fabric (mimetic dolomitisation), indicating that the dolomitisation was either syndepositional or relatively early in burial (Warren 2000a). Less common are coarsely crystalline dolomite cements lining secondary mouldic pores, often after dissolved evaporites. Sucrosic dolomites (40–80 μm, euhedral-subhedral) occur locally in some mixed carbonate-siliciclastic facies.

A particular diagenetic feature of evaporite-associated Miocene dolomite reservoirs of the Middle East is extensive leaching of skeletal aragonite without prominent karst surfaces or predolomite calcite cements (Fig. 10.37; Oswald 1992; Sun 1992). Mouldic and even vuggy porosity is well developed in carbonate hosts that contained abundant skeletal aragonite, whereas precursors dominated by high-Mg calcite bioclasts, such as red algae, echinoderms, and benthic foraminifera, are commonly mimetically replaced by reflux dolomite, with only minor moulds and other dissolution voids. As such, these nonvuggy units tend to show better-behaved poroperm relationships and more predictable wireline to core responses. Sun (1992) proposes that invading

hypersaline brines rather than fresh waters were the cause of large-scale leaching of skeletal aragonite.

With progressive burial and compressional folding, these evaporite-sealed Miocene dolomites have experienced repeated episodes of anhydrite cementation, fracturing, and late stage corrosion of pore walls (Sun and Esteban 1994). Anhydrite cementation is the most widespread porosity-occluding process. In many cases, both primary and mouldic porosities are almost entirely filled by anhydrite cements. Laterally, the distribution of anhydrite cements is highly variable in these Miocene reservoirs, but as a general rule, they are more abundant in relatively coarse, grain-supported carbonates, or those carbonates containing abundant skeletal aragonite, suggesting that original porosity and permeability played a major role in controlling access by later sulphate-bearing fluids. Brine-driven dolomitisation and skeletal aragonite dissolution during the early diagenetic stage produces excellent permeability networks. It enabled ongoing active circulation of anhydrite precipitating fluids and, if some permeability remains, even controlled the subsequent ingress of later burial fluids (including oil and gas).

Tectonically-induced fractures are common in the Lower Miocene carbonates of the Middle East, particularly along the Taurus-Zagros belt where these carbonates are intensively folded and fractured (Fig. 10.36a). There appear to have been several stages of fracturing. Most of the early-formed fractures were occluded by anhydrite cements, whereas relatively late-formed fractures, which postdate anhydrite cementation, remain open and effective. In places where the carbonate hosts have a relatively low matrix porosity and permeability, such as the Asmari Limestone in southwestern Iran, fracturing plays a vital role in enhancing the reservoir quality (McQuillan 1985). The mechanism of production in most Asmari reservoirs of southwestern Iranian oil fields is related mainly to open fractures beneath the Fars/Gachsaran seal (see later discussion), although variations in matrix porosity (e g., mouldic or intercrystalline) locally influence production.

According to Sun and Esteban (1994) the last diagenetic event before hydrocarbon emplacement in subsalt Miocene carbonates of the Middle East was burial corrosion through which reservoir quality was typically improved, particularly in the hydrocarbon-producing reservoirs in tectonically active zones in the Gulf of Suez and Iraq/Iran. These late stage corrosive events can bear little or no relationship to depositional facies or stratigraphic position in the reservoir. Corrosion preferentially affects anhydrite cements, relatively fine-grained sediments, and matrix materials. Typically, the current reservoir quality of many Miocene carbonates in the Middle East reflects the intensity of such corrosive events. The combination of vugs and chalky microporosity, which dominates effective porosity in the matrix of most producing Miocene reservoirs, was largely produced by late stage corrosion. Other important porosity types, including moulds,

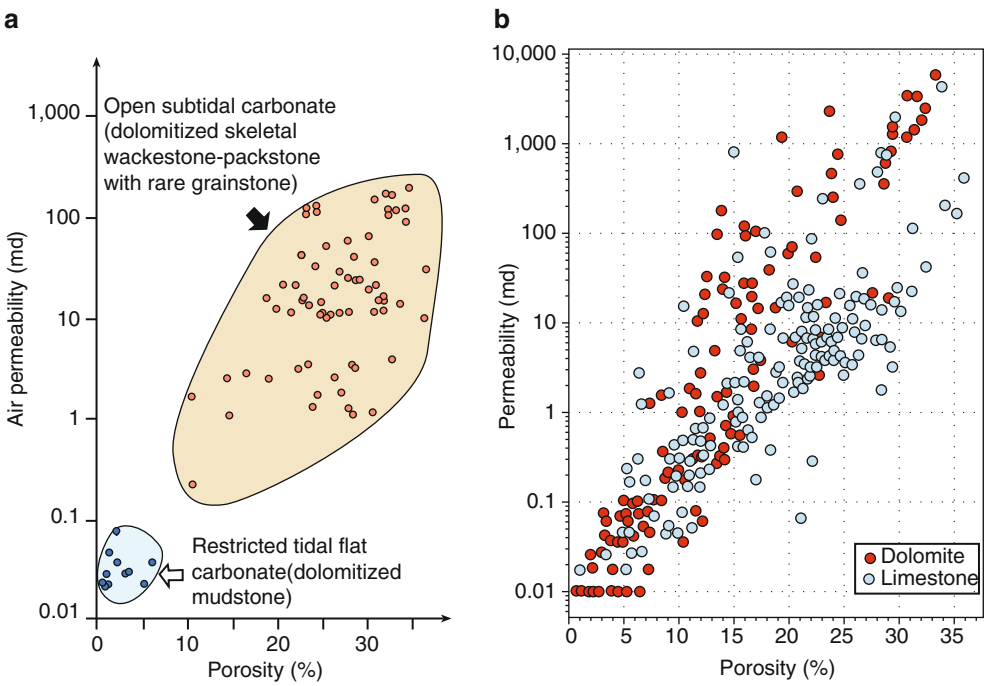

Fig. 10.37 Poroperm in the Tertiary of the Middle East. (**a**) Permeability versus porosity in Lower Miocene carbonates (Replotted from Sun and Esteban 1994). (**b**) Permeability versus porosity in Kirkuk Field, Iraq, showing the improvement in reservoir quality typical of dolomitised limestone successions (Cretaceous-Miocene)

intergranular pores, and fractures, were enlarged by corrosive processes. The distribution of such burial pore types is characterized by a lack of linear or branching permeability passages related genetically to identifiable recharge and discharge points, making these reservoirs difficult, but locally prolific producers.

Intensity of late stage corrosion is perhaps tied to levels of sulphuric acid created by the mixing of waters with different H_2S contents, or by oxidization of H_2S in an evaporite-rich hydrocarbon environment (Sun and Esteban op. cit.). In places, organic acids released through source rock maturation may have also contributed to the late stage corrosion and related to sulphate-reduction overprints. The development of the permeability network and the availability of migration pathways (faults and fractures) regionally connecting acidic subsurface fluids were two key factors controlling the degree to which fine-grained dolomites or anhydrite cements were corroded.

Silurian Pinnacle Reef Fields, Michigan Basin

Since the late 1960s, production from the numerous evaporite-encased Niagaran reefs of the Michigan Basin has been the main local source of oil and gas production for the state of Michigan (Figs. 10.38 and 10.39; Wylie and Wood 2005; Gill 1977, 1985, 1994; see Fig. 5.68 for detail on seal geology). Productive reef-substrate areas range from around 40 acres (0.16 km^2) to 840 acres (3.4 km^2). Recoverable reserves in individual pinnacles range from 30,000 to 22 MM BBL of oil equivalent (BOE). The ten largest fields in the Niagaran pinnacle play were found by drilling of the first 25 % of the exploration wells. The discovery per wildcat peaked at 1.55 MM BOE after 500 wildcats, and declined steadily thereafter to a level of 0.02 MM BOE per well after 1,900 wildcats, indicating that the play reached a state of maturity, as did the move to horizontal drilling to improve recovery efficiency. About 25 % of the discovered reserves were found in 5 % of the fields, indicating a more even reserve distribution pattern

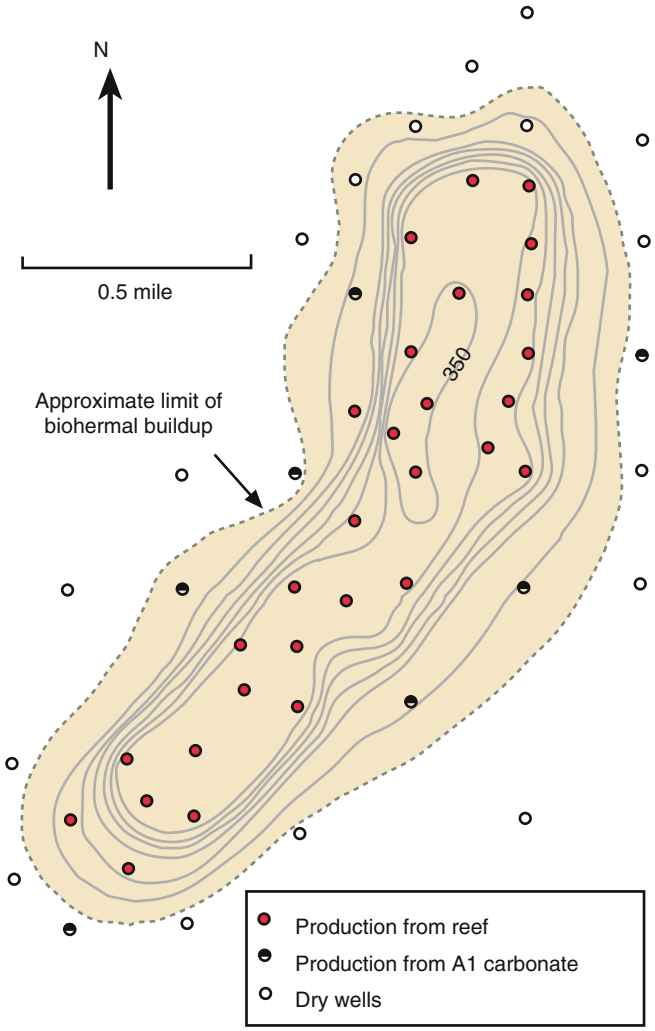

Fig. 10.38 Belle River Mills gasfield. Cumulative thickness or isopach of biohermal and organic reef stages, configuration at termination of organic reef stage (After Gill 1985)

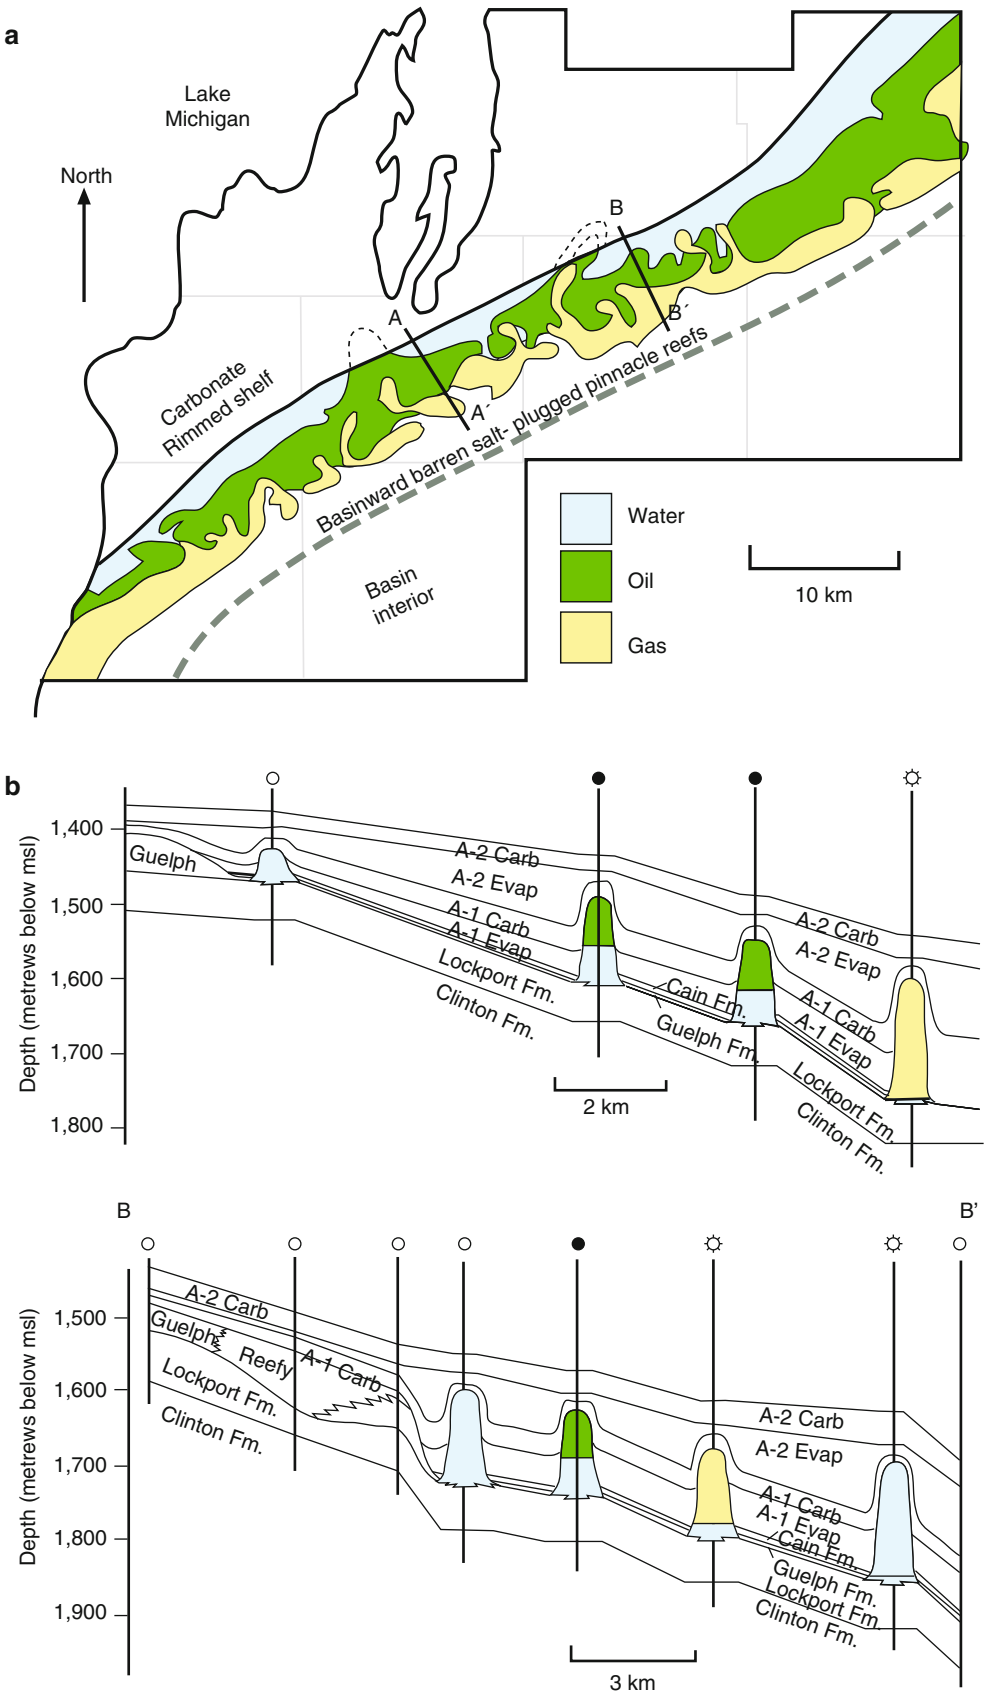

Fig. 10.39 Evaporite-sealed Silurian pinnacle reefs in the Northern Michigan Basin. (**a**) Distribution of salt plugged, gas-, oil- and water-bearing reefs. AA′ and BB′ show the positions of cross sections in Fig. 10.39b. (**b**) Cross sections through the pinnacle reef belt showing classical Gussow-migration controlled separation of oil and gas in the reefs. Pinnacles in positions more basinward than shown are not economic due to widespread salt plugging (After Gill 1985)

than in many other reefal plays, perhaps a reflection of the high efficiency of basinwide evaporites as seals to pinnacle reefs. Consequently, the relative rate of growth of discovered reserves was slower than in other reef plays.

Downdip pinnacle reefs in the Michigan Basin illustrate a major negative to any relatively un-fractured reef play that is sealed by thick basinwide evaporites. That is, the deposition of a thick sequence of salt atop and adjacent to the reef buildup typically leads to high volume flow of dense saturated brines through the underlying porous strata at the culmination of the reef (potential reservoirs). This tends to overdolomitise and extensively plug most of the uppermost porosity in downdip carbonates located in brine saturated lows. Such a poroperm distribution is clearly seen in the Niagaran trend (Fig. 10.39a), which shows a band of evaporite-plugged pinnacle reefs down-dip of the main pinnacle reef play. Within the pinnacle reef play the occurrence of oil updip of the gas accumulations is an indication of classic Gussow style migration and segregation (Fig. 10.33b).

Why updip reefs remain as reservoirs and the downdip reefs are salt plugged is an interesting quandary. In my opinion it reflects the likely recharge hydrology that influenced the basin when it was hydrographically isolated and the A1 and A2 halites were being deposited. As we saw in Chap. 5, the potentiometric surface created by hydrographic isolation created a marine-fed seepage margin to a drawndown saline giant (Fig. 5.69). Toward the basin edge, this head was sufficient to displace any dense reflux brines from the surrounding basinwide brine plume and so allow deeply circulated seawater to rise through the pinnacle reefs and from part of the marine-feed outflow zone. Crests of pinnacle reefs allowing groundwater egress have characteristic seepage carbonate caps (pisolite, tufa, stromatolite and anhydrite haloes) that differentiate them from the surrounding halite plain. Pinnacles further out in the basin did not have sufficient head to prevent the ingress of sulphate-saturated waters and so their porosity was plugged. Reef caps to these salt-plugged reefs lack or have attenuated indictors of seepage outflows. This palaeohydrology also explains why oilfields in pinnacle reefs that acted as marine seeps, such as the Bell River Mills gasfields, not only produce from the reef facies but also produce from the A1 carbonate fringe. Back in the Silurian these units were part of a single flow unit supplying pressurized phreatic seawater to the basin (Fig. 10.38). The hydrology that established the active seep reefs can be used as an exploration and development tool in such drawdown basins.

Once again, the presence of a thick sequence of bedded impermeable evaporites exerts a strong influence on reservoir distribution and quality from the time of first deposition well into burial. The Salina salts today acts as highly effective seals to oil and gas accumulations in the pinnacle reefs. During the early drawdown stage the formative hydrology perhaps allowed some pinnacle reefs to remain open, while others further out in the basin were plugged by evaporite cements from brine reflux. Then during later burial the salt bed focused the flow of upwelling basinal waters and the precipitation of later authigenic cements both along its underside and within the salt-sealed pinnacle reefs. Another interesting feature of the Niagaran pinnacle reef play is that many fractures and adjacent pinnacle matrices are overprinted by late stage saddle dolomite and calcite, with ponding of the precipitating fluids driven by circulation of late stage basinal fluids beneath the highly effective evaporite seal (Cercone and Lohmann 1986). The source of these basinal fluids is not well understood, but is thought to be from the leaching of underlying Ordovician shales by hypersaline brines.

This argument is supported by the occurrence of fault and fracture-controlled hydrothermal (thermobaric) dolomite reservoirs in Ordovician (sub-Niagaran) marine carbonates in a syncline that defines the oilfields of the nearby Scipio Albion trend (Fig. 10.40). Oil and gas have been produced in this region from what are interpreted to be fault-controlled hydrothermal dolomite reservoirs in the Ordovician Trenton and Black River carbonates since the late nineteenth century (Harding 1974; Hurley and Budros 1990; Smith 2006).

Whereas the play has been active for more than 130 years, new fields are still being discovered because of their unconventional structural style. At least 30 new gas fields were discovered in the Black River Group in New York over the last 15 years (Slater and Smith 2012). The fields are detectable on seismic profiles as elongate, faultbound structural lows or sags associated with transtensional wrench faulting (Smith 2006). Dolomite and porosity form around the faults but are absent away from the faults where the formations are composed primarily of impermeable limestone that forms a lateral seal (Smith 2006). Cores collected from these fields and others like them typically contain matrix dolomite as well as fractures, breccias, and vugs lined with white saddle dolomite (Davies and Smith 2006). Fluid inclusions and geochemical analyses suggest that the dolomites formed in a burial environment from high-temperature saline brines that passed through the basement or immature siliciclastics overlying the basement before precipitating the dolomite. These structures have been interpreted to form when oblique strike-slip faulting allows pressurized fluids to travel upward along fault planes to shallower units (Harding 1974). Metal sulphides, baryte and coarse sparry anhydrite are coprecipitates from the basinal fluids that formed this set of late-stage coarsely crystalline saddle dolomite. Yoo et al. (2000) argued for an evaporite source to these fluids. Later in this chapter we shall return to this association in a discussion of structurally-focused hydrothermal dolomite overprints and density-driven deep convective circulation cells below the dissolving undersides of highly effective evaporite seals.

Evaporite-Sealed Platform and Reefs, Devonian, Canada

The Keg River Formation forms the lower portion of the Upper Elk Point Subgroup in the western Canada Sedimentary Basin (Fig. 10.41a). Carbonate, evaporite and minor siliciclastic rocks of the subgroup were deposited in the widespread Elk Point Embayment which extended from northeastern British Columbia and the District of Mackenzie southeastward into the Williston Basin of southern Saskatchewan, Manitoba, North Dakota and Montana (Meijer Drees 1994). Early Devonian (pre-Keg River time) in the Alberta Basin of Canada was dominated by multiple-cycle platform evaporitic deposits ending with deposition of planar anhydrite sheets of the Chinchaga Formation and shales of the Ashern Formation (Tinker and Kirby 1991).

The lower Keg River/Winnipegosis was deposited as a marine carbonate ramp in shallow waters <75 m deep. Contemporaneous faulting and uplift during Middle Devonian time initiated development of a platform margin composed of stacked, porous (15–25 %) packstone and grainstone shoals (Fig. 10.41a).

Pinnacle and bank growth in on or near the platform edge was contemporaneous with epeiric shelf deposition. Keg River/Winnipegosis deposition ended with hydrographic isolation of the basin and subsequent deposition of the basinwide (intracratonic) evaporites of the Middle Devonian Muskeg/Prairie Formation. Figure 10.41b shows the geological nomenclature used in various parts of the Elk Point Basin (aka Western Canadian Sedimentary Basin)

Since the initial discoveries in the mid-1960s, the subsalt Keg River/Winnipegosis interval has produced hydrocarbons from a variety of dolomitic trap types, with the largest volumes coming from evaporite-sealed pinnacle reefs such as Leduc, Judy Creek and Swan Hills. In 1991, Tinker and Kirby listed the following produced volumes; Rainbow/Zama sub-basin (>650 MMBO cum.) and in equivalents in southern Saskatchewan (>2 MMBO cum.); shelf-margin carbonates at Temple Field (>3 MMBO cum.); middle shelf carbonates at Senex (>2 MMBO cum.); inner shelf carbonates in northeastern Montana, southern Saskatchewan, and southern Alberta (>10 MMBO cum.); and inner shelf siliciclastics at Utikima Lake (>75 MMBO cum.) (Fig. 10.41a).

Historically, regions of high production in Middle Devonian carbonates lay to the north and north-northwest of Calgary, where evaporites acted as the seal for most of the higher volume fields with Keg River/Winnipegosis production (Fig. 10.41a). Production in the Swan Hills an Rainbow-Zama sub-basin has been declining since the mid 1980s. More recent discoveries are smaller and lie along the basin edge, mostly in a region some hundreds of kilometres to the north of the areas of classic production and extending into British Columbia. There the evaporite seal is missing (whether from dissolution or lack of deposition is still contested) and much of the economic porosity is in patchy zones of late stage hydrothermal dolomites, now beneath shale seals.

Today, through enhanced recovery and directional drilling, the Middle Devonian Keg River/Rainbow pools in the mature production area of the Rainbow/Zama sub-basin have produced more than 1.1 billion-barrels of oil, mostly from evaporite-sealed pinnacle reefs and platform dolomites. Historically, the most productive reservoirs were pinnacle buildups encased by basinwide evaporites of the Muskeg/Prairie formations (Figs. 10.41b and 10.42; Schmidt et al. 1985; Majid 1987). Reservoirs in buildups in the upper member of the Keg River Formation consist of floatstone, rudstone and boundstone, with wackestone, packstone, and grainstone matrix. The principal faunal constituents are crinoids, brachiopods, stromatoporoids, corals, and *Stachyodes sp*. All are indicators of open marine sedimentation prior to the onset of evaporite precipitation. Reservoir porosity is a combination of primary intergranular and intragranular and secondary vuggy textures in partially dolomitised intervals. The primary role of the evaporite is as a seal to accumulations in the more permeable carbonates, but evaporite precipitation also drove earlier reflux dolomitisation and anhydrite plugging of the reef and platform strata during its precipitation as a saltern seal facies in the basinwide succession.

Prior to the basin's hydrographic isolation the buildups in the upper Keg River member in Alberta were patch reefs or banks, which grew in an open marine epeiric interior seaway fronted by Presqu'ile barrier to the westnorthwest (Fig. 10.41). Water depth was the main factor controlling the distribution of the more porous intervals of the bank and patch reef facies (Fig. 10.42). The back reef of the main platform became more restricted and anhydrite was precipitated as platform evaporites at times of hydrographic isolation on the shelf, prior to the main basinwide event. At times of open marine connection patch reefs were developed in areas of deeper water, whereas banks were formed in shallower areas of an open lagoon on the shelf. A direct relationship between the thickness of overlying anhydrite seal (Muskeg Formation) and hydrocarbon occurrences in the platform carbonates of the Keg River Formation was defined by Majid (1987). He concluded that trends beneath the evaporite seal can be reliably modelled using depositional fabric and seal thickness. Where the thickness of the anhydrite is more than 10 m atop areas of patch reefs, it constitutes an adequate seal. In contrast, buildups covered by less than 10 m of anhydrite constitute regions of higher risk (Fig. 10.42).

Areas of more recent exploration focus in the Keg River and its equivalents are located mostly in British Columbia to the north of the classic areas of Rainbow reef and platform production just described. There, late stage dolomitisation exerts a more significant control over reservoir quality and

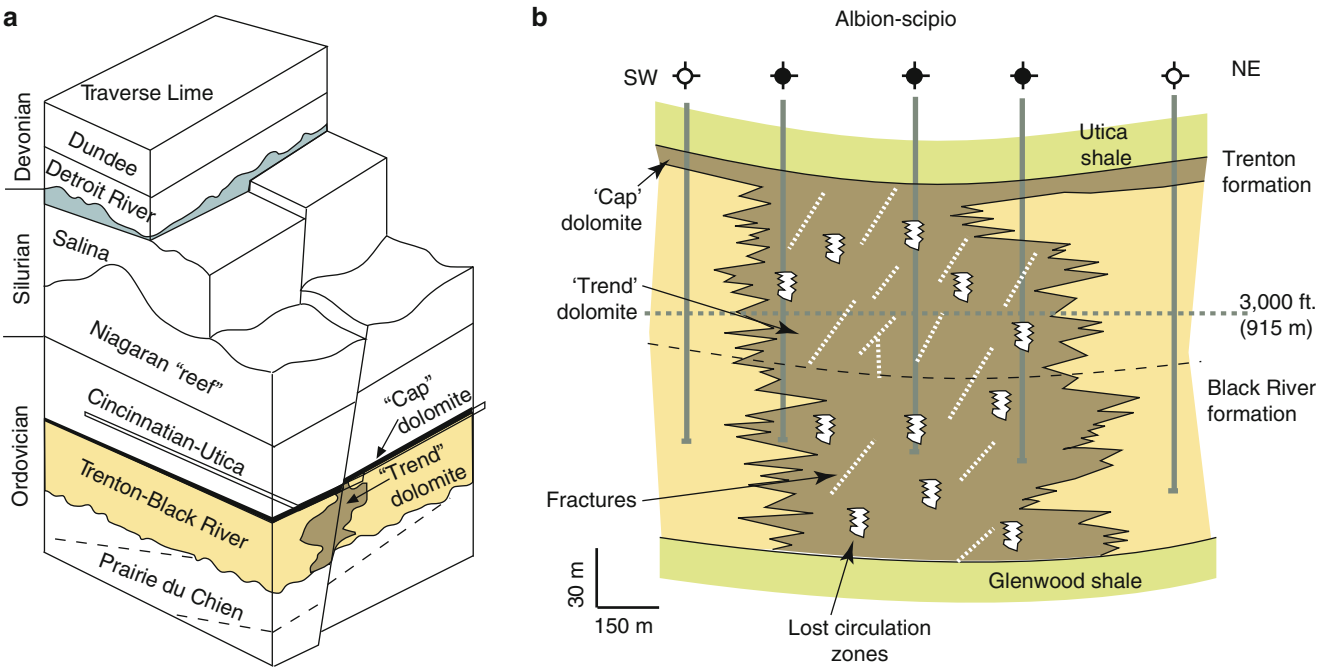

Fig. 10.40 Fault-focused late dolomitisation in the Scipio-Albion trend, Michigan (After Hurley and Budros 1990). (**a**) Structural stratigraphic interpretation of the Albion-Scipio trend. The fault/fracture set that controls dolomitisation is pre Devonian. (**b**) Structural cross section of the Scipio-Albion Field. Note that the field is located in a synclinal trend (not usual for a hydrocarbon trap) and there is a rapid lateral transition from a regional nonreservoir limestone into a permeable reservoir dolomite that also hosts late stage anhydrite and other authigenic burial salts. Lost circulation and fracture zones in such fields are common indicators of secondary dolomite-hosted porosity. Note that the seal is a shale not evaporite in this system, but the chloride-rich basinal brine responsible for the hydrothermal dolomite has a chemistry strongly influenced by evaporite dissolution deeper in the basin

porosity development does not always follow the depositional plumbing predicted by depositional facies. Much of the evaporite is missing and shale is the seal. But effective porosity development at the reservoir level still requires what Morrow et al. (2001) termed a "hydrostratigraphic template," first created by a combination of depositional fabric and early reflux dolomitisation. The high-salinity chloride-rich late stage brines driving this burial dolomitisation were largely sourced in regions of dissolving salts (Fig. 8.6).

Such a hydrostratigraphic template defines hydrocarbon occurrences in the July Lake gas pool of the Keg River Platform and the Helmet and Peggo gas fields in the Slave Point Formation, all located along the shelf-to-basin transition of the Cordova Embayment in northeast British Columbia (Wendte et al. 2009; Qing and Mountjoy 1994). There, burial-stage, coarsely crystalline replacement dolomites and associated saddle dolomite cements and zebra dolomites form a widespread diagenetic facies in the Middle Devonian Presqu'ile barrier that extends southwestward from outcrop near Pine Point to the subsurface of the Foothills in northeastern British Columbia. Dissolution and subsequent precipitation of coarsely crystalline burial and saddle dolomites creates hydrocarbon reservoirs with intercrystalline porosity in otherwise tight limestone hosts. The same system hosts sub-salt breccia Mississippi Valley–type Pb-Zn deposits at nearby Pine Point (Chap. 15). Porous burial dolomites replacing blocky sparry calcite cements, occur continuously across the sub–Watt Mountain unconformity. They postdate stylolites and earlier replacement dolomites, overlap sulphide mineralization and show regional oxygen isotope signatures that are indicative of deep hot saline basinal fluids escaping via fault and fracture feeds into the adjacent carbonate platform sediments (Fig. 10.43).

Recognition of late stage dolomite as a reservoir-former led to a re-examination of core from some of the producing intervals in platform-interior dolomites in the more mature Rainbow subbasin to the south. Previously, platform carbonate production away from the main pinnacle reef plays had been related to what were considered in the 1970s to be thin pinnacle reefs, biostromes and low relief shoals, all with a depositional control to the reservoir plumbing. But the mechanism and chemistry of porosity retention was never well documented by the explorationists. Subsequent core and thin section studies in the same dolomitised platform intervals established that production was actually tied to later secondary porosity, not relict primary porosity. It was mostly associated with dolomitised subtidal facies at the bases of stacked metre-scale evaporitic depositional cycles (Muir and Dravis 1995). For example, the Keg River and Muskeg pools on Comet Platform are combination

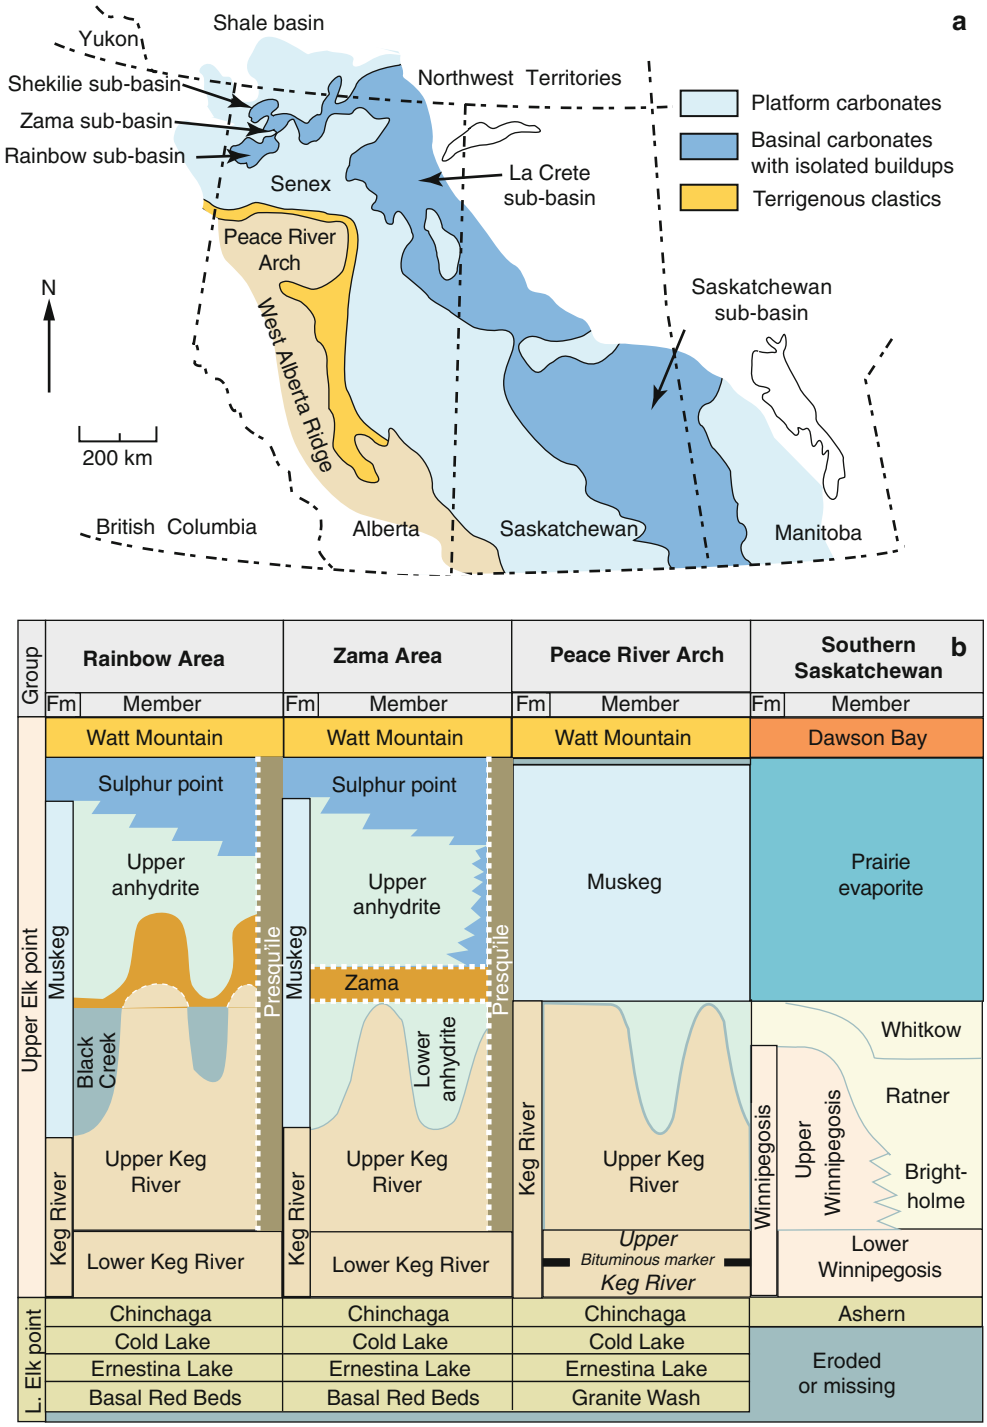

Fig. 10.41 Keg River Formation and its seal. (**a**) Paleogeographic map showing the major palaeoenvironmental facies of the Middle Devonian Keg River Formation deposited in the Elk Point Basin, Western Canada. (**b**) Stratigraphic nomenclature of the Elk Point Group in the Rainbow and Zama areas, Peace River Arch and northeastern Alberta, and southern Saskatchewan (After Wiebe et al. 2013)

structural-stratigraphic-diagenetic traps with reservoir quality strongly influenced by fracture intensity. Reservoir facies are confined principally to fractured platform-interior beds of restricted subtidal *Amphipora*-peloidal dolopackstones and dolowackestones. They constitute the base of anhydritic 7–12 m thick depositional cycles, which are correlatable across the Comet Platform. It is likely that the underside ot these dolomites focused the flow of the burial-stage porosity-creating and dolomitising fluids.

Better quality reservoirs in the platform interior occur at or near the base of each major cycle and result from dissolution of the platform carbonate, tied to the precipitation of burial dolomite cements. For example, the Keg River pool on the western edge of the Rainbow-Zama sub-basin is locally

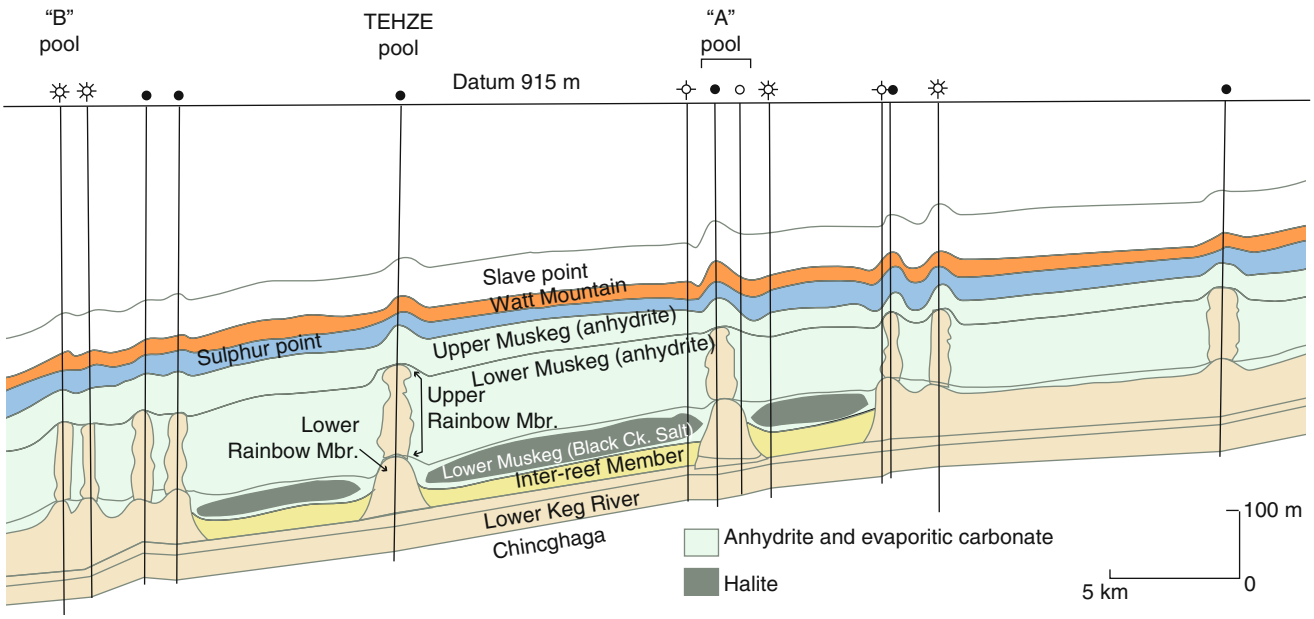

Fig. 10.42 Rainbow Basin, Alberta. NE-SW cross section through the mature Rainbow area showing development of carbonate platform in the Upper Keg River and the platform evaporite seal created by the basinwide anhydrite salts of the Muskeg Formation (After Schmidt et al. 1985)

dominated by spectacular zebra dolomites with vuggy porosity tied to anhydrite dissolution, while Muskeg pool dolomites all exhibit mouldic and vuggy porosities (Muir and Dravis 1992; Morrow 2014). Termination of stylolites and fractures into these secondary pore types confirm their burial origin.

Regional tectonic influences on oil pool development in the Comet Platform are indicated by horizontal fractures, vertically-oriented stylolites, and spectacular burial-stage evaporite solution-collapse breccias. Pools are localized over regional fault and fracture trends that affected the carbonates, but did not fracture the evaporite seal, and are related to reactivation of the Great Slave Lake shear zone. Faults and fractures aided burial diagenesis and the creation of late secondary porosity development by focusing the ascent of hot, dolomite-dissolving basement-derived and calcium-rich basinal fluids. Seismic data indicate these faults were largely collapse structures generated by salt loss and subsalt breaching in the underlying Cold Lake Salt Formation. Further, some of these faults localized precipitation of massive diagenetic anhydrites (retrograde precipitates) that now provide updip side closure to some pools. This current understanding of reservoir control is a long way from the simple early notions in the 1970s of relict primary porosity in a carbonate biostrome.

Much of the hydrocarbon-hosting porosity is enhanced or sometimes induced by the cross flow of calcite undersaturated dolomite-precipitating evaporite derived hot brines (Morrow 2014). The passage of these aggressive waters is indicated by ubiquitous zebra and boxwork fabrics in cross-stratal Manetoe and Presqu'ile hydrothermal dolomites in Devonian strata in Northern Canada (Fig. 10.43). Early indications of the presence of this characteristic texture is indicated by sets of weakly imbricated, decimetre-sized curvilinear lenticles of white dolospar, developed within sub-metre sized tongues of greyish-white dolomitised crinoidal packstone and grainstone. This nascent zebra fabric has developed along wavy to nodular intra-bed sedimentary partings. Primary bedding can be traced through dolomitised masses containing these fabrics, into the surrounding undolomitised limestone. Similar textures occur in the Pb-Zn ore peripheries hosted in the Devonian Cadjebut Fm of the Canning Basin, Australia (Wallace et al. 1994; Warren and Kempton 1997 – see Chap. 15 for further discussion of the MVT- Zebra texture association).

All zebra and boxwork fabrics are confined within single beds in the Elk Point Basin, consistent with an early burial time of origin. No change in bed thickness occurs across zebra or boxwork fabrics within beds; this indicates a dissolutional, rather than a dilational, origin for the creation of pore space partly cemented with white dolospar. The dolomitised groundmass displays an abruptly gradational or sharp transition to centripetal saddle dolomite cement, which partially to nearly completely, occludes vugs. Circulation of geothermally heated hypersaline Devonian Elk Point basinal seawater-influenced brines led to dissolution and replacive dolomitization of limestone adjacent to vugs, and near-contemporaneous precipitation of white dolospar within dissolutional vugs, consistent with geochemical simulations (Fig. 10.43b). The presence of downward-extending galleries of white dolospar-cemented solution-collapse breccia provides further support for an interpretation of regional thermally driven convection of hydrothermal evaporative seawater-influenced brines across a broad area of northern Canada.

The absence of gases under pressure in vacuoles within fluid inclusions from Manetoe and Presqu'ile dolospars is also more consistent with a dissolutional and contemporaneous dolomitization origin for these fabrics, rather than an origin involving dilational fracturing for space creation and dolospar precipitation. The ubiquitous presence of zebra and boxwork fabrics in hydrothermal dolomite reservoirs indicates that they are not confined to fault zones and instead occur wherever precursor limestones had relatively greater porosity and permeability prior to dolomitization. Dissolution by hot, basement-derived fluids throughout most of the region is supported by the presence of diagenetic fluorites, megaquartz and polysulphide minerals, helium gas, fluid inclusions, and high carbon dioxide and hydrogen sulphide gases in these hydrocarbon pools (Davies and Smith 2006).

Thus, these platform-interior pools in the Devonian carbonates of the Elk Point Basin are combination structural-stratigraphic-diagenetic traps with reservoir quality tied to reactivated basement faults and are not directly to depositional porosity in pinnacle reef occurrences. Once reservoir quality in platform cycles was tied to salt solution-brine induced fractures, rather than to inferred low relief pinnacles, it permitted correlation of larger 7–12 m-thick composite cycles over distances of several kilometres. This meant reservoirs could be more effectively zoned (Muir and Dravis 1995). By 1989, daily cumulative oil production rates in platform dolomites were increased from 500 m^3/day (1988) to 1,400 m^3/day as a direct result of this revised understanding of reservoir layering. It also led to improved conformance, sweep, and minimization of oil sandwich loss in these miscibly- and gas-flooded pools and to more effective horizontal well design.

Clearly, reservoir quality in the Rainbow-Zama sub-basin, and equivalents to the north, is in large part tied to the ongoing diagenetic evolution of the dolomitised host and its strong interaction with evaporite aquicludes that controlled subsequent brine passageways. As well, later salt-dissolution brines were derived by early brine reflux and later tectonically driven induced fracturing, basinal fluid flow and brine escape to form a characterised suite of dolospar and coarse burial anhydrite cements tied to this dolospar. As Warren (2000a) observed, ancient dolomite is never a single-phase mineral. In all areas of Keg River associated production there are at least two styles of dolomite present, an earlier brine reflux dolomite, created when the overlying evaporite was porous and a supplier of dense Mg-rich brines and a later dolomite formed when the evaporite bed was a seal that focused and facilitated convective circulation in sediments beneath and adjacent to the slowly dissolving salt mass.

Reservoir Quality Tied to Bedded Evaporite Seal Type

Depositional facies preserved in a sealing salt bed atop an oil or gas field can be useful indicators of palaeotopography, energy levels and volumes of syndepositional authigenic cements in the underlying reservoir. Lowermost facies in a bedded evaporite seal can typically be related to the topography of the reservoir's upper contact at the time the seal was precipitated. This means wireline signatures of the seal can be used to differentiate stratigraphic traps from simple drape traps. Drape traps are created by compactional or structural draping sometime after the reservoir and seal were deposited. Other than possible erosional thinning, wireline signatures through seal facies in this scenario typically show no depositionally-controlled thickness changes or internal depositional differentiation between top seal and lateral seal.

In contrast, repeated evaporitic transgressions over an underfilled carbonate or siliciclastic platform can deposit alternating cyclic carbonates/siliciclastics and evaporites in broad, shallow to ephemeral brine environments. Depositional textures in the sealing evaporites are then controlled by zones of marine-fed brine springs and the permanence and depth of the saltern and evaporitic mudflat brines. Top seals to pre-existing highs such as shelf margin reefs or shoals, dune crests or slope carbonate buildups show internal fabrics related to palaeorelief. Such topography-related facies mosaics typify the wireline and core textures in the lower levels of the basinwide evaporites sealing the Silurian pinnacles of the Michigan Basin. Nodular mosaic anhydrites of supratidal sabkhas dominate evaporitic mudflat seal facies atop and adjacent to the crests of underlying pinnacle reefs, while subaqueous saltern facies, made up of bedded massive/mosaic anhydrite and allochthonous dolomite-anhydrite breccias, typify the lateral seals (Figs. 5.67 and 5.69). Pisolitic textures and sometimes tepees tend to form in regions of brine-spring outflow on a now exposed drawndown basin floor.

Mapping of Permian anhydrites textures (salinas versus sabkhas) in the Khuff C in the Hawiyah area in Ghawar field, Saudi Arabia, showed the sabkha successions on the highs sourced much of the anhydrite-plugging cements in the underlying Khuff carbonate reservoir (Al Eid and Al Tawil 2009). Similar textural transitions occur between sabkha and salina seals that make up the top seal to karstified shelf margin reservoirs of the Permian San Andres reservoir of Yates Field, West Texas, as well as other Guadalupian sequences in the Permian Basin of West Texas. Around two thirds of the reservoirs in Permian rocks of West Texas and New Mexico are sealed by bedded platform evaporites (Fig. 10.44; Table 10.6), most show an intimate relationship between evaporite facies in the seal and reservoir quality beneath (Ward et al. 1986; Warren 1991; Sarg 2001).

Yates Field, West Texas

Yates Field, discovered in 1926, is located in the southernmost Central Basin Platform of West Texas and is one of the most prolific reservoirs ever discovered in the United States (4 billion barrels original oil in place). It is shallow

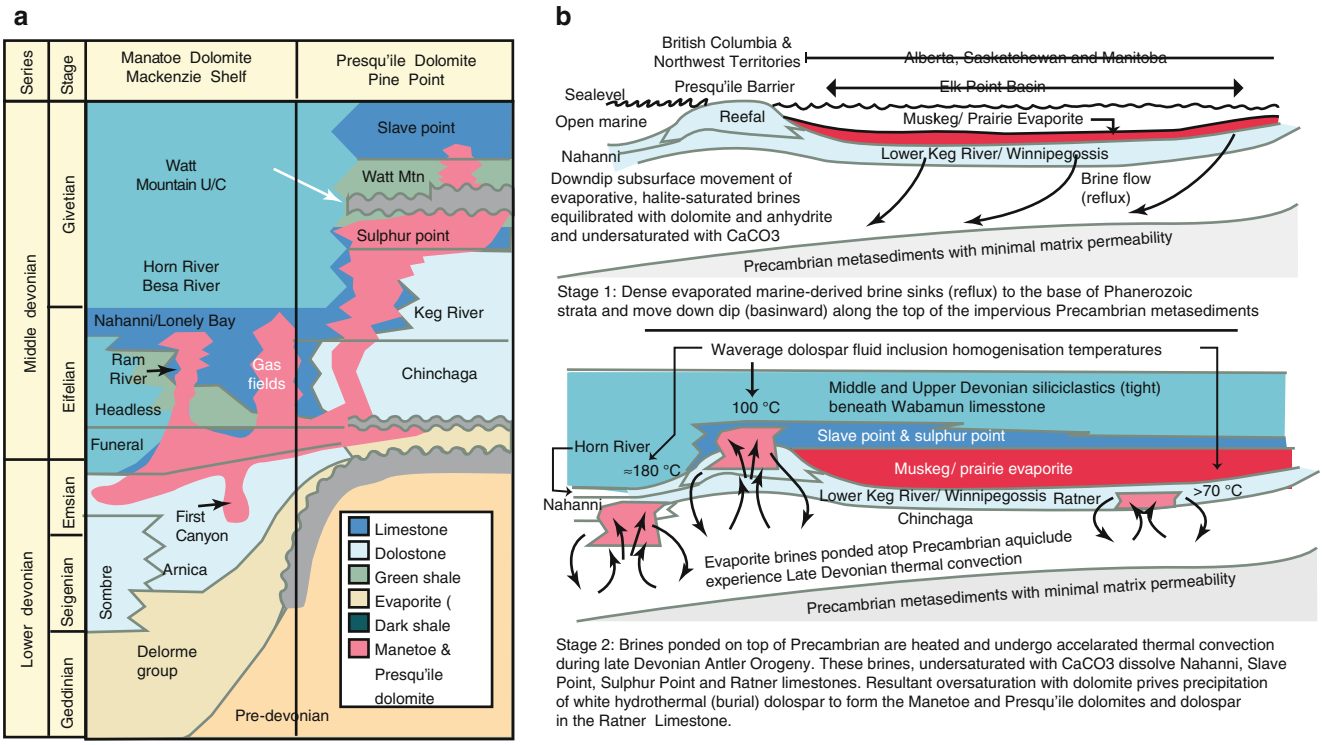

Fig. 10.43 Late porosity evolution in Devonian Elk Point Basin, Canada. (**a**) schematic chart of Devonian stratigraphic relations across the southern Northwest Territories of Canada. The Manetoe Dolomite has partly replaced Lower and Middle Devonian limestone and shaly limestone units (Landry, Headless and Nahanni formations) in and around Ram River. The Presqu'ile Dolomite analogously has replaced Middle and Upper Devonian limestone and shaly limestone units (Sulphur Point, Watt Mountain and Slave Point formations) in the Pine Point area. (**b**) Schematic representation of the origin of Elk Point evaporative hypersaline seawater brines and their role as hydrothermal fluids during Late Devonian geothermally driven diagenesis. Buoyant circulation of geothermally heated, dolomite-saturated, but calcite undersaturated, subsurface Elk Point brines is hypothesized to have caused some dissolution of Middle and Upper Devonian limestones (Landry, Nahanni and Sulphur Point) in the shallow subsurface in Late Devonian time. This dissolution resulted in equilibration with respect to calcite, but oversaturation with respect to dolomite so that these limestones were partially dolomitized to form the Manetoe and Presqu'ile dolomites, as well as dolomitization within the Ratner Limestone of Saskatchewan (After Morrow 2014)

(305–460 m; 1,000–1,500 ft) and produces mostly from the Upper Permian San Andres Formation, with additional secondary production from stringers in the overlying Grayburg, Queen and Seven Rivers Formations. The field covers approximately 100 km^2 with more than 1,600 wells in the field. The field is now largely depleted of easily recoverable hydrocarbons, but continues to produce utilising enhanced recovery techniques. Estimated recovery after 84 years of production since 1927 is about 35 % after primary depletion, water and gas injections (Cheng and Kwan 2012).

At the level of the Permian section, it sits on the structurally highest point of the Central Basin platform (Fig. 10.44a). Structural closure is dominated by a broad asymmetric domal or anticlinal feature, which appears to be formed by the intersection of two separate tectonic structures that combine to create the horseshoe-shaped high that defines the outline of the field. Yates Field was discovered in 1926, high pressures, supplied by the combined gravity segregation, bottom water and gas cap drives, resulted in unusually high initial production rates and it produced by depletion drive until 1976. As pressure depleted throughout that half century, free gas evolved and migrated rapidly through the natural fracture system to the structural top of the field to form a slowly expanding gas cap drive beneath its evaporite seal. The efficiency of the evaporite seal atop the fractured reservoir system can be seen in an official proration test on the Mid-Kansas Oil and Gas Co. and Transcontinental Oil Co. #30 I. G. Yates "A" well, which in 1929 lists a daily potential production of 204,681 barrels (Hennen and Metcalf 1929) in a system that is less than 500 m below the land surface.

Yates Field is one of a number of fractured dolomitic reservoirs in San Andres Formation of West Texas with an evaporite topseal centred on the Seven Rivers Formation (Guadalupian; Fig. 10.44b). Systems tracts in the seal facies are characterized by stacked successions of metre-scale, brining upward parasequences deposited across an epeiric platform interior. Depositional facies in the seal in all these fields can be used to infer palaeotopography in the underlying San Andres reservoir and to separate the relative importance of deposition, drape and tilt in controlling the hydrocarbon distribution in carbonates below the seal.

Evaporite deposition during Seven Rivers time in Yates Field occurred in two major settings, sabkha (subaerial mudflat) and salina (subaqueous) in an evaporitic mudflat seal, with their areal separation controlled by the positions of underlying carbonate shoals. Wireline character through areas of subaqueous anhydrite is blocky, indicating 10–30 m thick sequences of relatively pure subaqueous evaporite (Fig. 10.45a). Wireline signatures in areas of sabkha in the seal facies are richer in dolomite matrix and individual cycles are thinner (≈1 m) giving a stacked spikier wireline signature to both the gamma and the neutron-density logs (Fig. 10.45b; Warren 1991). Subaqueous signatures dominate in what were the topographic lows, while subaerial evaporites are more common above what were the topographically higher parts of the seaway floor. When seal facies are defined in this way, mapped and related to production statistics across the field, it shows that for cumulative production in the Yates Field unit, as of October 1986, only 85 million barrels of oil had been produced from under the thick

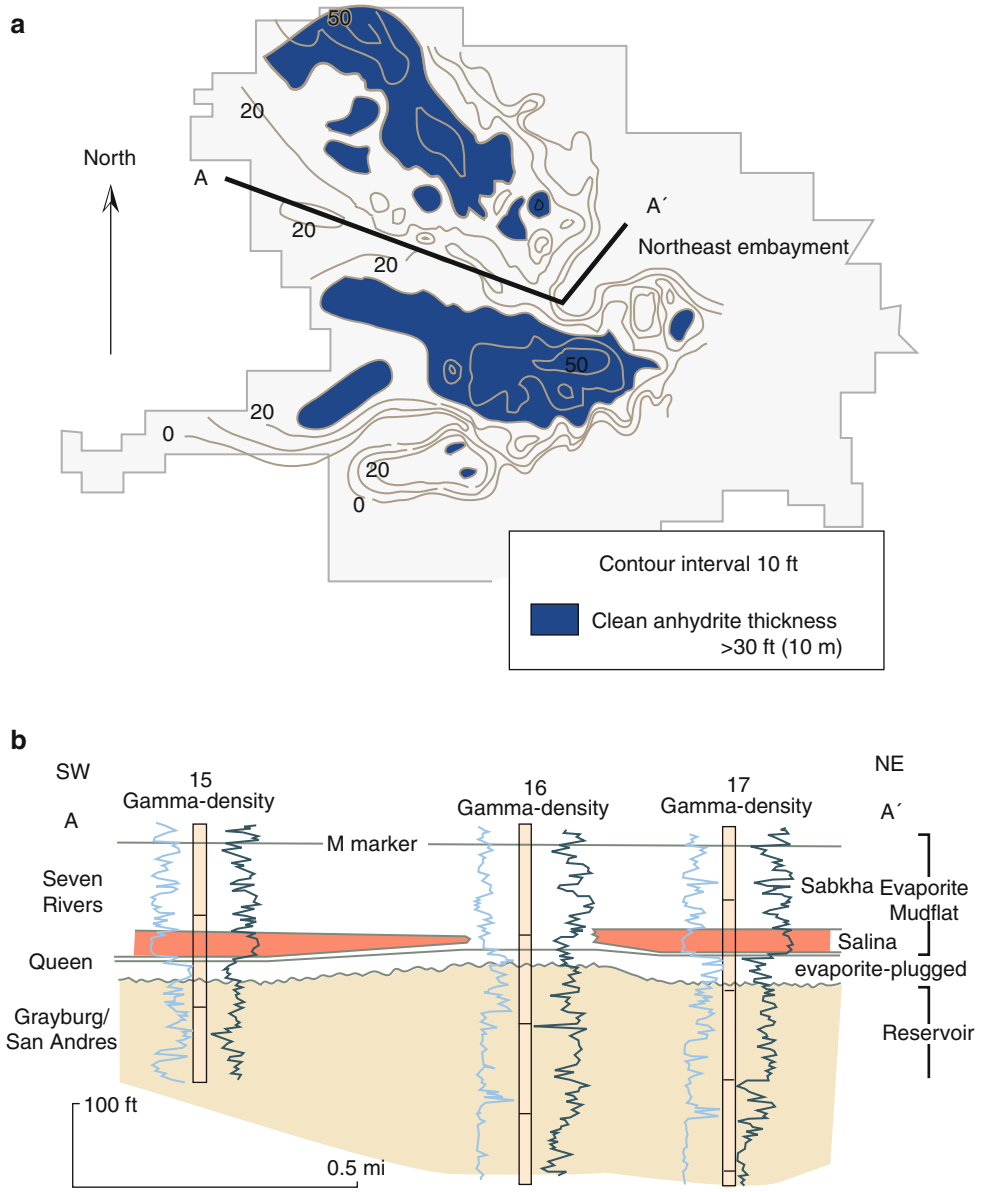

Fig. 10.45 Yates Field, West Texas. (**a**) Isopach of the massive anhydrite that typifies much of the base of the Seven Rivers seal to the field, thicknesses were mapped based on core and log signature. Clearly shows the subaqueous evaporites formed in lows that define the palaeotopography and hence quality of the underlying reservoir (see text). (**b**) Section using wireline lsignature to define depositional setting of the seal facies in the Seven River Fm. atop the San Andres Reservoir. Shows how the position of the salinas in the evaporitic mudflat defines the off structure positions (After Warren 1991)

salina accumulations, whereas almost 985 million barrels had been produced from the area under the sabkhas. Yet the two styles of anhydrite deposition cover roughly equivalent areas of seal over the field (Fig. 10.45a; Warren 1991).

Assuming that the M datum in the Seven Rivers approximates a level depositional surface, then the thick anhydrite in the lower Seven Rivers indicate palaeo-lows, while thin areas define ancient highs (Figs. 10.45b and 10.46). Massive anhydrite is found only over the central and western parts of the field. The anhydrite thins to zero roughly parallel to the platform margin, and shelfward of the San Andres shelf edge. The isopach map of the massive clean anhydrite (Fig. 10.45a) shows closed contours surrounding pod-shaped areas of salina anhydrite (originally gypsum) up to 15 m (50 ft) thick. Two salina areas were generally present in Yates Field during early Seven Rivers time, one on the northern and the other on the southern side of the field. The north and south salina ponds are flanked by smaller pod-shaped thicks and are separated by a line of zero evaporite trending north-northwest through the central part of the field. This linear feature is referred to as the northwest trend. Massive anhydrite is also absent in cores and logs in the northeast

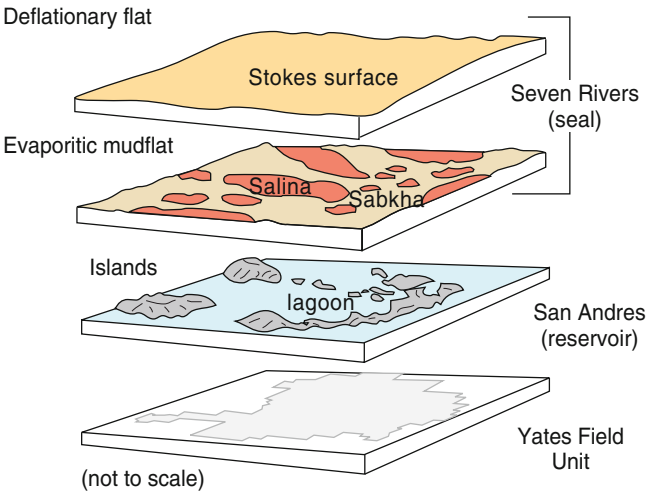

Fig. 10.46 Geological evolution of Yates Field region. During San Andres time the reservoir (fusulinid grainstone) was a set of karstified carbonate islands. By Seven Rivers time the reservoir was buried but the underlying palaeotopography (and the associated differential compaction) was still sufficiently developed to control the position of the depositional lows (salinas) and highs (sabkhas) (After Warren 1991)

corner of the field and forms what appears to be an embayment largely devoid of evaporite at the basal level of the Seven River and so defines the area of production called the "northeast embayment."

Evaporite facies distribution in the basal part of the Seven Rivers Formation was controlled by palaeotopography, which was in turn controlled by the depositional facies relationships in the underlying San Andres Formation (Fig. 10.46). The San Andres lagoon was an area that was depositionally low and one that remained low throughout Queen and Seven Rivers deposition, because of dewatering and mudstone compaction. When sufficiently karstified and fractured the lagoon muds hold producible fluids, are poorer quality reservoirs compared to adjacent karstified fusulinid shoals (Craig 1988). The lagoonal low was covered by a thick section of massive salina anhydrite that today provides a lateral seal to the adjacent sabkha-capped reservoirs. Sabkha-crested topographic highs sit atop the more permeable reservoir intervals, which are made up of karstified and fractured San Andres mounds and shoals (Craig 1988). The platform-edge fusulinid grainstones to packstones that are the main reservoir in Yates Field were cemented, fractured and karstified early. The lack of early burial compaction, compared to adjacent lagoonal mudstones, meant areas atop mounds and shoals remained as highs during early burial and into the time when the sealing evaporites were deposited.

That is, during lower Seven Rivers time, the then-buried San Andres depositional segregation still controlled the facies mosaic in the evaporite seal. Once this marine-fed evaporite system filled the available accommodation space, subsequent depositional style was controlled by a series of aggrading Stokes surfaces within an aggrading eolian sandflat/mudflat. At times of higher eolian sand flux the mudflat became a deflationary sand flat (Fig. 10.47b). Such deflationary sandflats can constitute reservoirs in other parts of the Central Basin Platform, as in North Ward-Estes Field.

North Ward-Estes Field, Texas

North Ward-Estes Field, Ward County Texas, is the largest and most prolific of a chain of producing fields in the Guadalupian Yates Formation, which extends along the western margin of the Central Basin platform for approximately 150 km, with a width of 1.5–6.5 km (Fig. 10.47a; Andreason 1992). Cumulative oil production within the North Ward-Estes Field from 1929 through 1989 was more than 365 million BBL, with oil-in-place estimated at more than 1 billion BBL. Siliciclastic reservoirs in the middle shelf provide most of the hydrocarbon production within the trend, whereas associated interbedded dolomites contributed patchy minor amounts of economic porosity to this play. Porosity distribution in the various Ward-Estes reservoir layers is best modelled using a depositional model based on a continent-coupled eolian to evaporitic mudflat to shelf setting, with superimposed early evaporite dissolution along the strandzone. Hydrocarbon traps form on gentle structural culminations sealed by updip evaporites. Hydrocarbon maturation and migration from the Delaware basin to the shelf reservoirs occurred during the Cretaceous and early Tertiary (Hills 1984).

In his comprehensive analysis of the late Guadalupian (Permian) Yates Formation reservoir sands, Andreason (1992) showed that the siliciclastic facies were part of a broad, evaporative mudflat that extended across a wide area of platform behind the Capitan reef. Cyclic sea level fluctuations produced a succession of dolomites, evaporites, and siliciclastics as the evaporative coastal plain oscillated across the Yates shelf. Moving landward, the environments were; (1) lagoon, (2) intertidal algal flat, (3) beach ridge, (4) siliciclastic sabkha, and (5) sand sheet/playa mud flat/salina/saltern (Fig. 10.47a). Evaporitic cycles, which formed on the inner shelf and landward, grade upward from massive subaqueous-dominant anhydrites into nodular mudflat anhydrites with increasing volumes of siliciclastic mudstone interbeds (playa mudflats). Carbonate-based depositional cycles consist of basal lagoonal peloid and skeletal dolostones, which grade upward into tidal-flat dolostones, beach-ridge sandstones, and finally into siliciclastic sabkhat.

The characteristic disrupted (haloturbated) textures of the Yates siliciclastics were created by surficial and interstratal halite growth during seasonal flooding and subsequent desiccation in a sabkha environment (Andreason 1992). A siliciclastic accretionary complex, composed of stacked beach ridges and detrital sabkhas, formed behind a pisolitic strandzone. Local siliciclastic accumulations also occurred over

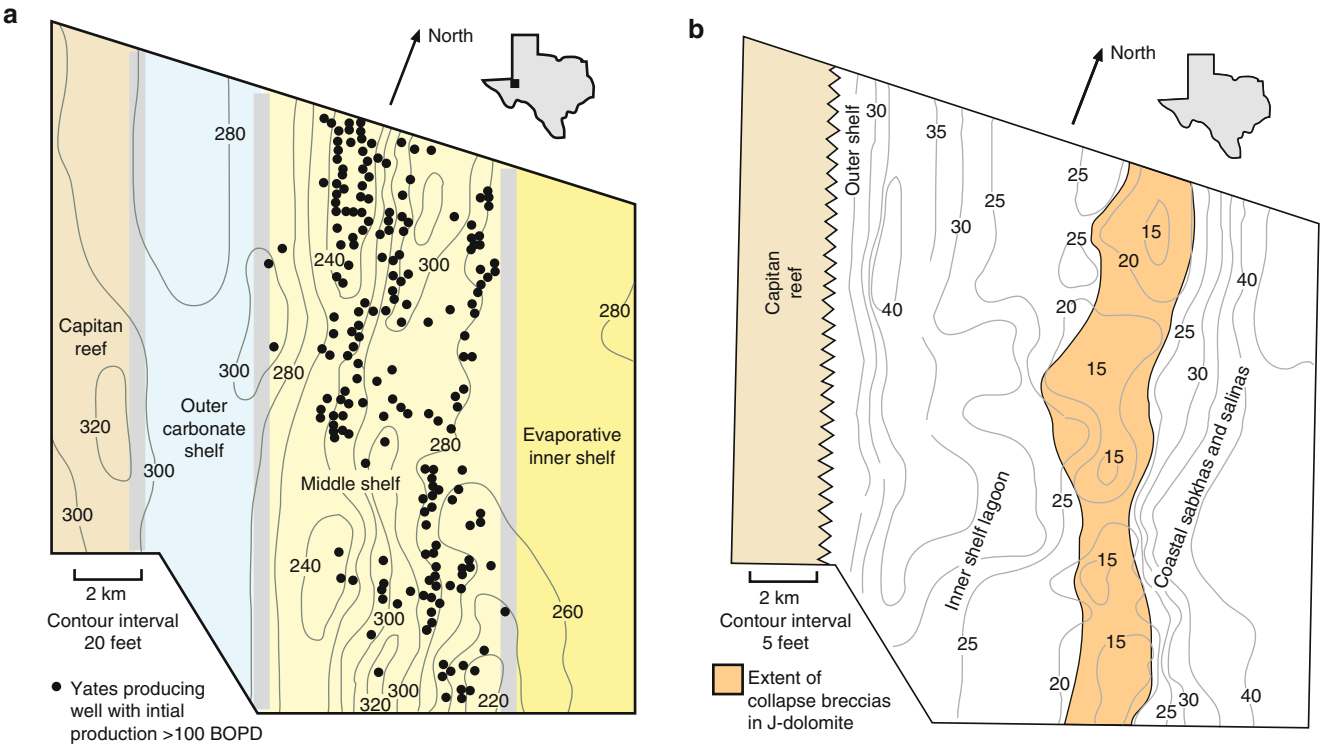

Fig. 10.47 Characterisation of Yates Fm., Ward-Estes Field (After Andreason 1992). (**a**) Total Yates interval isopach showing Yates shelf is divisible into; (1) an outer shelf that includes the Capitan Reef, the backreef flats and the pisolite shelf crest, (2) a middle shelf composed of stacked beach ridges and siliciclastic sabkhas, and (3) evaporitic mudflats made up of extensive flats, salinas and stabilised sand sheets. Hydrocarbons are concentrated in the middle shelf. (**b**) Isopach of the intra-Yates J-Dolomite unit. Shaded unit defines the extent of the evaporite collapse breccias that separates inner shelf lagoon from evaporitic mudflat. Depression defined by collapse was filled with greater thicknesses of overlying siliciclastic sand. See Fig. 10.44a for location

sinks or depressions produced by the dissolution of underlying bedded sulphates. Such dissolution breccias are defined by stacked horizons, made up of sharp clast-to-clast angular rudstones to floatstones with sharp basal contacts with the underlying cryptalgalaminated dolostones and sharp to gradational crackle upper contacts with the overlying subtidal carbonates (peloidal and fossiliferous dolostones). Because of pervasive soft-sediment deformation atop the dissolving mudflat evaporites, these intervals are easily misidentified in core as storm beds or erosive marine transgressive surfaces. Breccia beds correlate with anhydrite beds (mostly subaqueous) in the inner shelf and with dolomitic mudstones to the west (middle to outer shelf). That dissolution was early is indicated by the excellent correlations between the zone of collapse and a region of differential thickening within the overlying siliciclastics (Fig. 10.47b). What is unclear is whether dissolution was driven by a relative sea level rise or fall.

As we saw in Chap. 2, preservation of evaporites into the early burial realm depends on the maintenance of a narrow range of saline conditions. Dissolution occurs if undersaturated fluids contact the bed at any time during the evaporite's deposition or shallow burial, either from an influx of fresh, meteoric water or from "freshened" seawater. Solution breccias of the lower Yates occur only in the middle shelf and develop preferentially along the seaward extent of the region of massive epeiric saltern sulphates, suggesting dissolution was driven by influxes of normal marine water during relative sealevel rises (Andreason 1992).

The boundary between the collapse breccias and the massive sulphates marks the position of a concentration boundary on the submerged shelf where evaporative outflow exceeds marine free inflow and gypsum saturation was reached. Andreason argues this concentration boundary was shifted laterally relative to the magnitude of the sea level rise. When located seaward of this concentration boundary, and given sufficient time, evaporites originally present within the now-disturbed siliciclastic facies and the massive sulphate deposits underwent dissolution. Although the shelf position of the collapse breccias strongly suggests dissolution during a relative sea level rise, the possibly of dissolution by meteoric waters during periods of subaerial exposure and sealevel falls cannot be totally excluded.

The Yates Formation is part of the Seven Rivers, Yates, and Tansill trilogy, which in ascending order comprise the shelf-equivalent formations of the upper Guadalupian Capitan reef and represent a complex of lagoonal, coastal and evaporitic platform environments (Figs. 10.44b and 10.48). The Yates

Formation is unique among upper Guadalupian shelf formations in the Permian Basin in that it marks a period of major siliciclastic shelf deposition, as compared with predominantly carbonate and evaporite deposition of the Seven Rivers and Tansill formations (Fig. 10.48; Andreason 1992). The increased siliciclastic influx onto the shelf, particularly along the western margin of the Central Basin Platform and the northern margin of the Delaware Basin, probably indicates filling of the Midland Basin, which was located to the east (Fig. 10.44a). Eolian and wadi-driven siliciclastics, having filled the available accommodation space, now moved westward, fed from the distant hinterlands to the east and northeast and previously trapped by the shallow Midland pontic sea. The erg migrated across the vast deflationary region of the filled Midland Basin and Central Basin Platform to prograde into the Delaware Basin. Siliciclastics and evaporites had reached the southern portions of the Central Basin platform from the northeast (Midland Basin) by the beginning of the late Guadalupian, as evidenced by the prevalence of these deposits within the upper Queen Formation (Tucker and Chalcraft 1991).

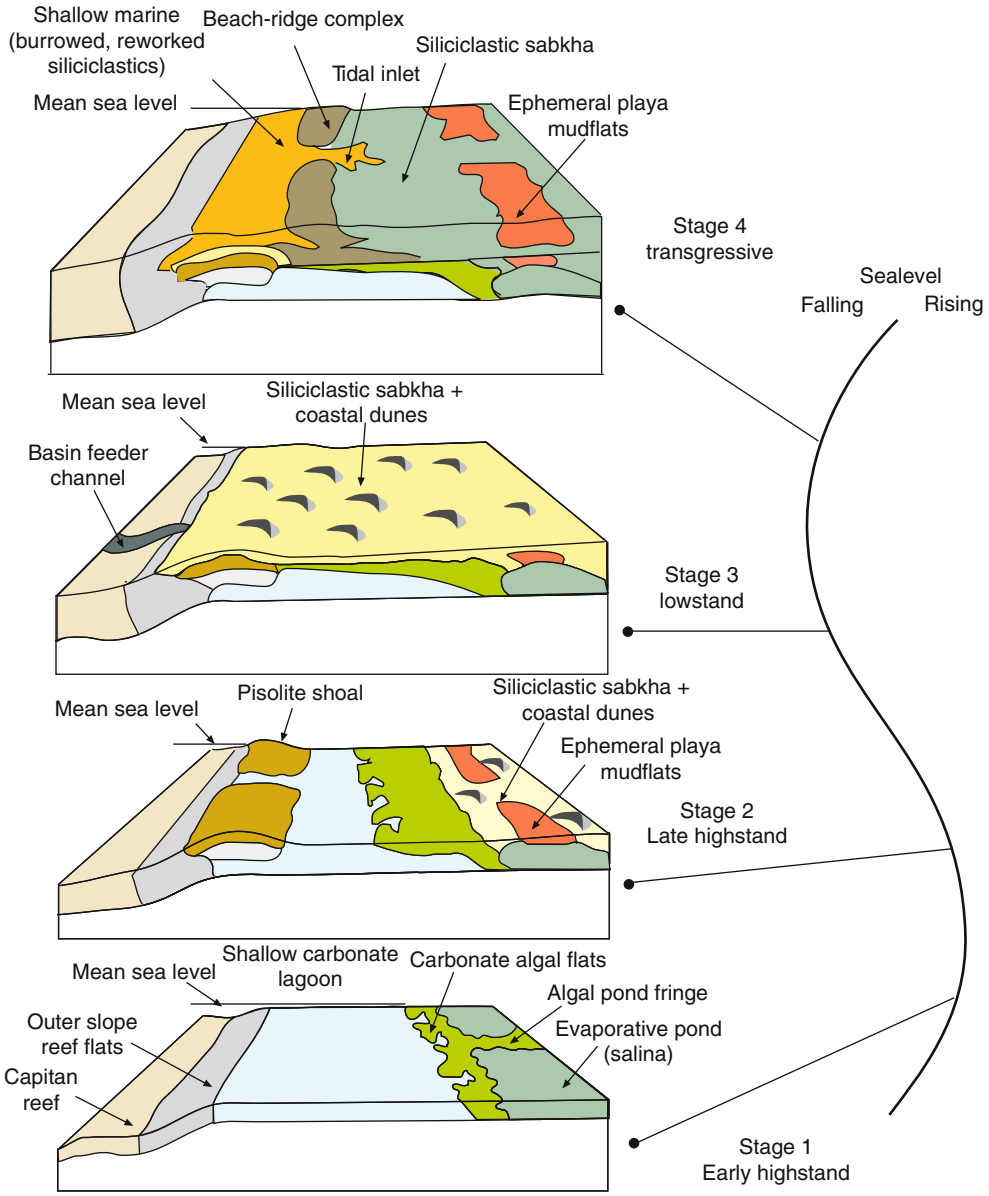

Fig. 10.48 Evolution of Yates Shelf (After Andreason 1992). Early highstand (Stage 1) is characterised by shelf submergence, lagoonal carbonate deposition across the middle shelf and massive evaporites precipitating in embayments and isolated ponds on the inner shelf. As the shelf becomes more emergent during late highstand (stage 2), broad tidal flats extend across the middle shelf and the pisolitic shelf crest becomes re-established. Eolian driven siliciclastics bypass the shelf during lowstand (Stage 3) and deposit within the Delaware Basin, As sealevel rises during the transgressive phase (Stage 4), beach-ridge complexes and siliciclastic sabkhas accrete and prograde in response to a rising watertable. This is the phase when most of the siliciclastic Yates reservoirs were deposited

It was a depositional setting much like the modern coastal zone for southeast Qatar and eastern Saudi Arabia (Figs. 2.59 and 3.64), but in a coastal strandzone under greenhouse, not icehouse, eustatic control. Throughout the late Guadalupian, the Midland Basin was a site of siliciclastic, anhydrite, and halite deposition within eolian, evaporative mudflat, and playa environments (Ward et al. 1986). In addition, the advancement of a siliciclastic wedge within the upper Seven Rivers Formation from the northeast onto the Central Basin Platform supports the possibility of siliciclastics migrating across the Midland Basin by the close of Seven Rivers deposition. Palaeogeographic reconstructions by Handford (1981b) place prevailing winds from the northeast, off the Central Basin Platform. These eolian systems prograded across the Yates Shelf during periods of relative sea level fall and subaerial exposure of the shelf (Fig. 10.48).

What is most important in terms of exploration and development models based on this evaporite-sealed siliciclastic setting is that the thickening and stacking of the better quality reservoir sandstones was controlled by an aggrading marine fed saline watertable at the edge of an aggrading pisolitic shoal. Accommodation space for the sands was created by the syndepositional dissolution of a saltern edge along the seaward side of what is now a zone of stacked thick anhydrite beds. The generation of accommodation space for thicker better quality quartzose sands was diagenetically not depositionally controlled. The resulting thickened intervals of higher quality quartzose reservoir sands were then sealed by bedded saltern anhydrites of the Tansill Formation.

Rotliegende Sands of Northern Netherlands and North Sea

Rotliegende Formation sandstones in the southern North Sea are important Lower Permian gas reservoirs, with recoverable reserves of 4.25×10^{12} m^3 (150 tcf; Fig. 10.49a; Glennie 1990; Sweet 1999), they also host much of the onshore gas of the Netherlands and NE Germany including the giant Groningen gas field in the Netherlands. Rotliegende reservoirs in the Netherlands are mostly sandstones and conglomerates deposited in an arid alluvial to marginal desert sand/mudflat and fluvial environments. They are intercalated with shales and evaporites deposited in saline lake/playa settings (Legler et al. 2011; Figs. 10.49b and 10.50a). The northward transport of metamorphic, volcanic, and sedimentary rocks shed from Variscan highlands supplied most of the siliciclastics. In the Netherlands, reservoir quality was significantly affected by early diagenetic processes in a marginal desert/playa lake environment (Figs. 10.49b and 10.50a, b; Amthor and Okkerman 1998).

Further offshore in the southern Zechstein Basin, burial-related products and processes are perhaps more significant and have received more attention than early diagenetic processes as controls on reservoir quality (Figs. 7.99 and 7.100). According to Amthor and Okkerman (op. cit.) previous studies of burial anhydrite cements have largely neglected the effects that early diagenesis can have on reservoir quality and well productivity of Rotliegende sandstones. They argue that much of the precipitation of the main porosity-occluding cements (dolomite, anhydrite, and quartz) occurred early, not late, in the diagenetic history of the Rotliegende reservoirs of the Northern Netherlands and was tied to variations in the syndepositional hydrology. Oxygen isotope values of dolomite cements ($\delta^{18}O_{SMOW} = 18.4–23.4‰$) suggest that meteoric water played a major role throughout the diagenetic history (Fig. 10.50c), and that precipitation of the cements occurred at low temperatures (<80 °C) characteristic of a desert and shallow burial. The strontium isotopes of dolomite cements ($^{87}Sr/^{86}Sr = 0.70935–0.71387$) and the sulphur isotopes of anhydrite cements ($\delta^{34}S_{CDT} = 6.7–9.7‰$) are consistent with formation from continental water within a

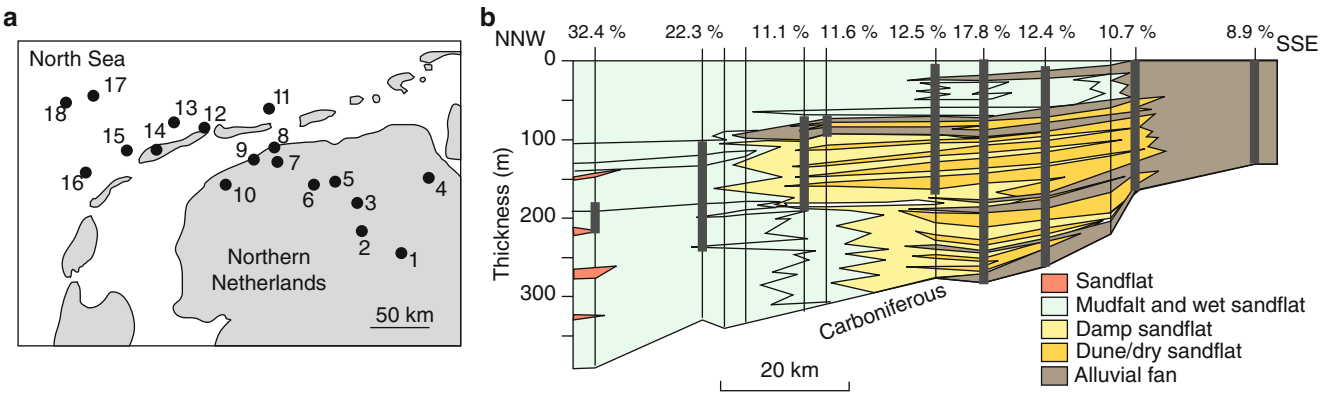

Fig. 10.49 Characterisation of Rotliegende Sand reservoirs (After Amthor and Okkerman 1998). (**a**) Well locations in Northern Nederlands and North Sea. (**b**) Cross section (perpendicular to depositional strike) of the Rotliegende Sand (Slochteren Sandstone) showing the major depositional environments. The average abundance of dolomite and anhydrite (total indicated in percent) increases in a NNE direction from the proximal alluvial fan and dunes/dry sand flat to the distal desert lake (saline pan and mudflat) environments

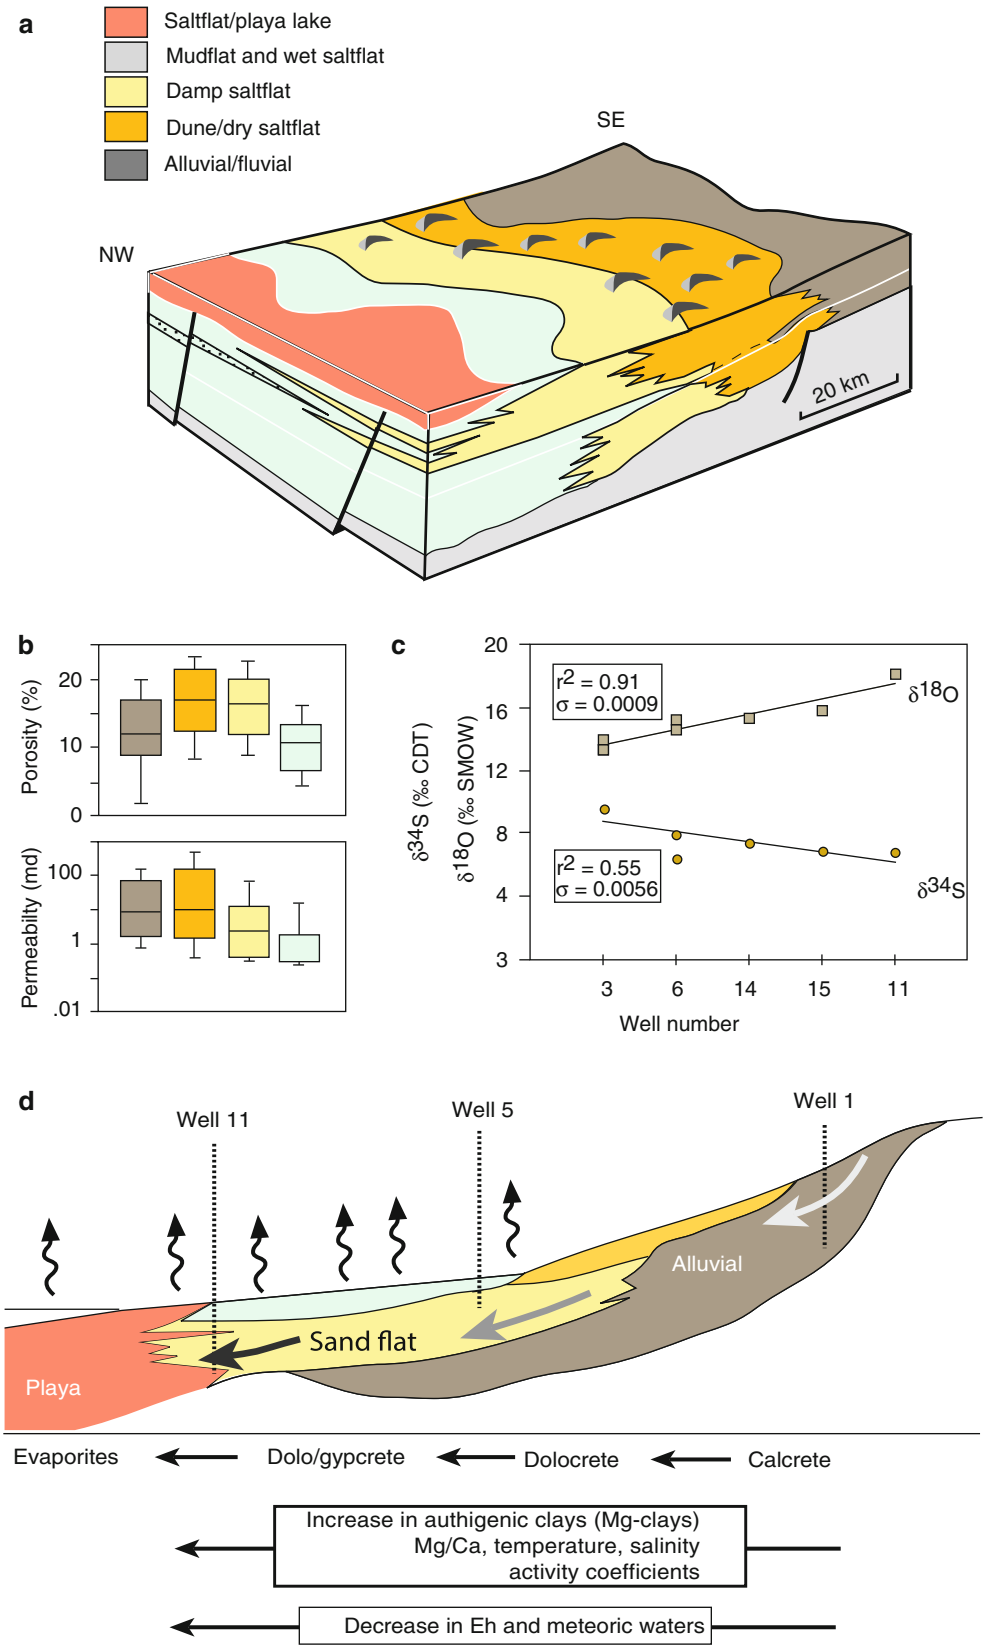

Fig. 10.50 Rotliegende of Northern Netherlands (After Amthor and Okkerman 1998). (**a**) Depositional setting. (**b**) Distribution of porosity and permeability, indicating a relationship between depositional environment, early diagenesis, and reservoir quality. (**c**) $\delta^{34}S$ and $\delta^{18}O$ of anhydrite cements relative to geographic well position; oxygen isotopic compositions increase progressively from proximal to distal wells, whereas the sulphur isotopic compositions decrease. Such depletion in $\delta^{34}S$ and concomitant enrichment in $\delta^{18}O$ is the result of progressive evaporation in an arid alluvial to marginal desert-sabkha Rotliegende depositional setting. (**d**) Conceptual model of groundwater evolution and its precipitates across an alluvial to sand flat/playa profile with the likely positions of three Rotliegende wells from Fig. 10.49a indicated

restricted basin and rule out Permian or younger seawater seeps as a source for these cements.

The early diagenetic origin of the cements is also suggested by the fact that the majority of sandstone samples have lost more porosity via cementation than through compaction. Most samples with high amounts of porosity loss via cementation (20 %) were affected by early dolomite and anhydrite cements (Fig. 10.49b). The relative abundance of dolomite and anhydrite cements can be correlated with depositional environment. Wet depositional environments with watertables close to the surface (interdune and fluvial sandstones) show the highest amount of dolomite and anhydrite cements, whereas dry environments with relatively deep watertables (e.g., dune sandstones) are characterized by low amounts of cements (Fig. 10.50d). The precipitation of early diagenetic cements has strongly influenced the present day porosity patterns in the reservoir, with depositional environments interpreted as depositionally "drier" showing less cements. Early capillary and vadose precipitation of cements significantly altered the porosity patterns in the sandstones and playa mudstones. In effect, the intensity of subsequent cementation in this system largely tracks the palaeohydrology of the depositional setting.

A similar set of syndepositional palaeohydrological factors controls subsequent reservoir quality in the Carboniferous eolian sabkha reservoir sands in the anhydritic Juruá Formation in the Solimões Basin (Elias et al. 2004). This is the largest gas sand reservoir in Brazil.

Exploration Paradigms in the Bedded Evaporite Hydrocarbon Association

Bedded evaporite seals encompass both platform and basinwide settings (Fig. 10.51). Within both subsalt setting dolomitisation and other diagenetic alteration features are important controls on reservoir creation and retention in most scenarios, even in the largest accumulations such as the Arab cycles in Ghawar, Saudi Arabia. Understanding the timing and relative importance of seal focused brine reflux and later hydrothermal circulation or recirculation is important. In subsalt and salt-adjacent settings, the resulting intercrystalline poroperm geometries are superimposed on pre-existing depositional facies. Tying the dolomite distribution back to the salt/brine source means the poroperm distribution is understandable at both the exploration and reservoir scale (Fig. 10.51). The effects of evaporite brine derived fluids can be early, as in brine reflux settings, or much later, as in hydrothermal- burial dolomite settings, as in the various Devonian carbonate hosted gas field of British Columbia. Reflux dolomitisation can convert low permeability mudstones into reservoir quality intervals, as in the Levelland Slaughter trend, or alter reservoir properties in the original depositional system to enhance, alter or destroy reservoir poroperm. Multiple dolomite-related poroperm changes can occur even in a single field, related to superposition of different episodes and styles of dolomitisation (Warren 2000a), as in Ghawar, Saudi Arabia.

Another typical result of intense reflux is salt plugging (usually anhydrite cements) immediately below or adjacent to the brine source. In this case the poroperm is enhanced not in the immediate vicinity of the salt bed but at some distance further out along the brineflow pathway (Levelland-Slaughter and Feixianguan fields). In other cases, formerly porous reef fringe sediments can have porosity completely plugged by the entry of salt saturated brines. This is the case with downdip pinnacles in the Michigan basin. There, a reservoir fairway was created in up dip pinnacles by ongoing marine-seep flushing. In such a scenario, the presence of seepage indicators in a pinnacle fringe facies can be a useful indication of which pinnacles remain open hydrological conduits during evaporative drawdown episodes (Fig. 10.51).

Regionally, preservation and prediction of both primary and secondary porosity in bedded evaporite-sealed reservoirs is controlled in large part by varying combinations of the following factors. (1) A relatively arid climate, which means a relatively limited recharge of fresh groundwater during the evaporite drawdown stage, thus minimizing meteoric leaching and calcite cementation. (2) The presence of an extensive cap or lateral facies made up of impermeable saltern and mudflat dolomite and anhydrite. This bedded evaporite and associated cement plugging effectively seals off large parts of the underlying permeable carbonate from ongoing early phreatic cementation as it slows or stops surface-groundwater driven flushing by large volumes of meteoric or sulphate-bearing fluids. (3) Early marine cementation and hypersaline reflux dolomitisation, which strengthens the reservoir rock framework below the evaporite seal, thus retarding physical compaction and making it more likely to fracture. (4) The presence of thick evaporites atop carbonates tends to form pressurised buffer zones below the salt seal. Hence, a thick evaporite retards mechanical compaction in sediments beneath it via the early onset of overpressure, it also prevents an influx of surface-derived cementing waters into the carbonate reservoir.

This generalised listing of controls has been in the literature for two decades (e.g. Sun and Esteban 1994; Warren 1989) and helps explain the evaporite-hydrocarbon association mentioned at the start of this chapter. Yet, the bedded evaporite-hydrocarbon association has been poorly understood by exploration and development teams designing exploration or development programs in bedded evaporite-sealed systems, and has led to some expensive errors and remediation programs. To create a predictive understanding of reservoir quality beneath bedded evaporite seals is more difficult as it requires knowledge of evaporite texture, likely fluid migration pathways, and the ability to understand and construct models of seal-related diagenesis in the potential

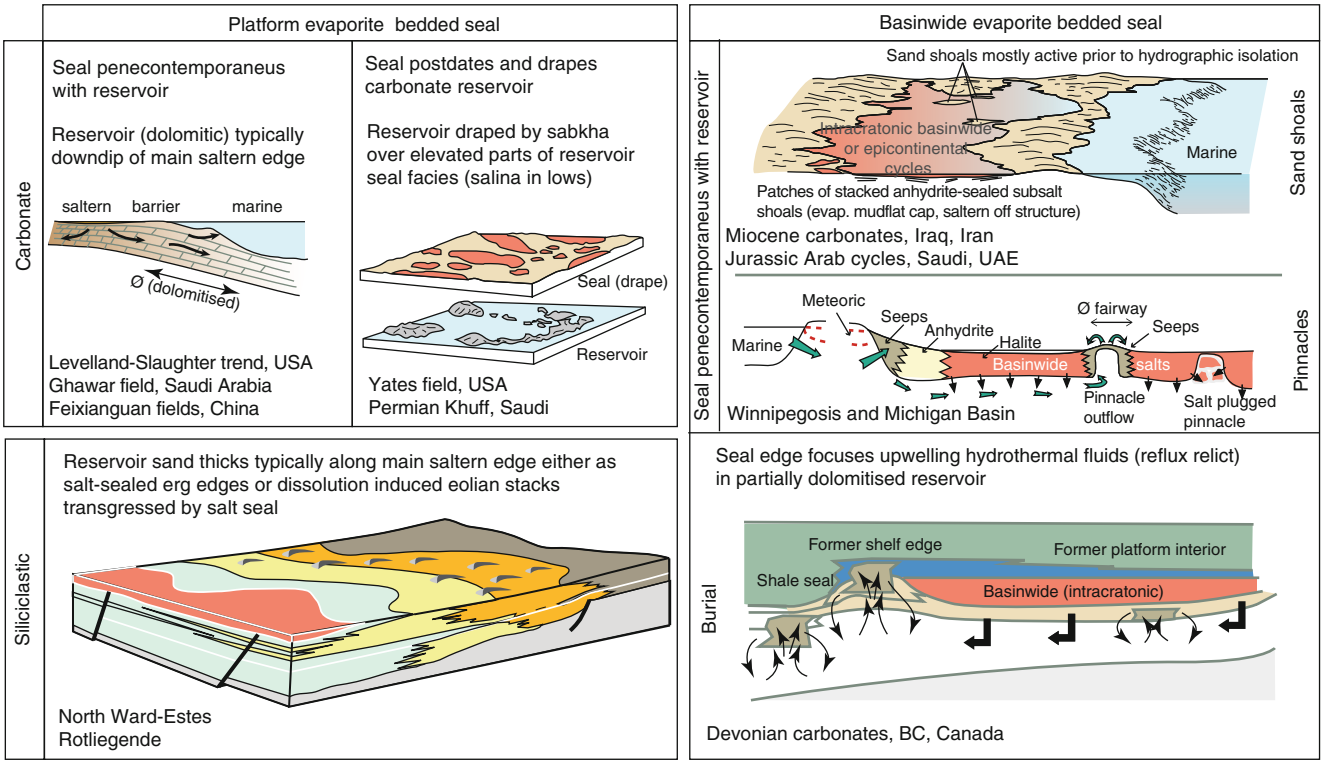

Fig. 10.51 Summary of the various ancient platform and basinwide bedded evaporite settings where a combination of evaporite sealing, dolomitisation (both early and lake) and focused evaporite related fluid flow create a variety of hydrocarbon traps. See also Table 10.7

reservoir carbonates below the bedded evaporite seal. What follows is a listing of some of the pertinent observations I use to understand poroperm distribution in subsalt and salt-adjacent bedded evaporite association (Table 10.7).

Importance of Recognising Depositional Differences

Our discussion so far has demonstrated how bedded evaporites constitute the seal to many of the world's largest oil and gas accumulations (Fig. 10.1). Without exception, the largest of the various oil and gas fields sealed by bedded evaporites are subsalt and mostly hosted in partially dolomitised marine platform carbonates. In most giant and supergiant fields the evaporites not only hold back the hydrocarbon column, but also help create and maintain reservoir quality. The most impressive examples are the various Arab D reservoirs in the Middle East, with slightly smaller but still very significant accumulations in oil pools in San Andres Formation of West Texas and reservoirs in the Sichuan Basin of China. In all these examples the depositional porosity of the reservoir has been altered and variably enhanced by brine-related allochem leaching and early reflux-driven dolomitisation. The degree of meteoric overprint at this early burial stage of diagenesis is minor to nonexistent. Syndepositional edge-of-evaporite dissolution from seawater freshening can occur and it leads to substantial thickening of high quality groundwater-controlled eolian depopods, as in the billion barrel North Ward-Estes Field (Table 10.7). Deeply circulating regional meteoric influx driven by a lateral groundwater head, mixing with brines of the reflux plume, can also occur create or alter poroperm distributions below evaporite seals and so influence reservoir quality, as in the Smackover Formation reservoirs of the Gulf of Mexico.

In my experience, most variation in subevaporite reservoir quality is the end product of a combination of depositional facies and varying intensities of evaporite plugging, dissolution, reflux dolomitisation and burial stage cementation. Lateral and vertical variations in all but the latter are typically indicated by facies variations in the seal itself. Yet, for much of the oil industry, evaporite plugging and reflux dolomitisation are associations that geological and geophysical staff do not quantitatively integrate into a reservoir model (other than via loosely controlled geostatistical formulations). The relevance of a bedded evaporite at any scale, beyond the consideration of its seal integrity in exploration or field development, is not part of most reservoir evaluation studies (The typical question to be asked and answered of the evaporite seal in a petroleum system is; Is it thick enough? Typical magic numbers worldwide for answering yes are; greater that 10 m thick for a clean anhydrite seal, and greater than 5–10 m thick for halite). Once the integrity of an evaporite seal or cap to a potential reservoir is considered established, further study of the seal properties or intra-seal textures is not considered relevant, other than hoping

Table 10.7 Identification and prediction of features associated with bedded evaporites that are useful in helping define distribution of subsalt or salt adjacent reservoirs Refer also to Fig. 10.51

	Feature	Outcome	Recognising in the subsurface
Platform evaporite	Anhydrite is the dominant seal mineralogy	Immediate subsalt region is typically evaporite plugged Depositional facies variations in subseal facies may be indicated by textures in the seal itself	Require understanding of variations of intrasalt wireline signatures (gamma-neutron-density FMI or acoustic image logs) sabkha versus salina in seal?
	Reflux dolomitisation in subsalt and salt-adjacent positions	Best reservoir is typically located downdip and basinward of thickest saltern interval Hydrodynamics define stepout distance from saltern edge to likely economic reservoir poroperm	Resolve whether the current salt edge indicates the primary position, or is the result of salt dissolution. Reliably recognise signatures of marine flooding, subaerial exposure and salt dissolution horizons (core tied to gamma-neutron-density, FMI and acoustic image logs)
Basinwide evaporite	Halite is the dominant seal mineralogy	Anhydrite proportions typically higher in intracratonic settings and/or atop former subsalt highs	Require understanding of variations of intrasalt wireline signatures (gamma-neutron-density FMI or acoustic image logs)
	Diagenetic overprints can control poroperm distribution (stable isotope and trace element values are useful discriminants of fluid source)	Non-intracratonic salt systems tend toward halokinesis	Halokinetic reservoir associations are discussed later in chapter
		Shelf edge with buildups: Shelf edge is typically exposed during episodes of evaporative drawdown, and may be karstified	Definable patterns of drawdown-induced seepage fringe outflow and associated alteration in basinal sediments
		Downdip pinnacle reefs: Crests acting as seep outflows during drawdown	Indicated by reef fringe cap facies made up of seep indicators, such as pisolites and tepees
		Problems related to salt plugging of reef further out in basin	Circum-basin poroperm fairway can be defined by combination of wireline and seismic mapping of basin architecture
Common features of note in both platform and basinwide settings			
Intrabasin deposition	Thick evaporite beds require stable long term aridity	Typically meteoric effects are minor in most parts of drawndown part of basin during time the evaporite seal is precipitated	Meteoric waters can be derived updip via deep meteoric circulation and outflow occurs in particular circum salt or salt-adjacent positions (stable isotope and trace element values are useful discriminants)
Dissolution is ongoing	Exposure surfaces	Penecontemporaneous local intrabed dissolution can occur during short term freshening via increased marine or meteoric seepage (recognition of intra salt leachate styles)	Stable isotope and trace element values are useful discriminants using core or cuttings. If regional, can be inferred by anomalies in wireline or seismic
	Early burial	Brine reflux	Identified by subsalt dolomite intensity map – wireline derived tied to basin architecture
	Later burial	Hydrothermal brine crossflow alters poroperm distribution	Occurs in particular positions in basin architecture (fault, fracture and folding controls), typically salt adjacent, but can be subsalt
	Edge effects (Mesogenetic focus)	Presalt can create karst overprint in subsalt reservoir facies	Defined by combination of core study, wireline and seismic mapping of basin architecture
		Synsalt, can created zones of non salt sediment thicks (e.g. increased thickness in fluvial sediments or eolian sandflats)	
		Post salt, act as escape conduits for subsalt basinal fluids can be carrying hydrocarbons and/or metals	
	Uplift (Telogenetic focus)	Dissolution reservoir associations are discussed later in chapter	
Confusion between dissolution residue layers and marine flooding surfaces (different diagenetic associations)		Ambiguity can lead to errors in basin history, diagenetic history, maturation timing, etc	Distinction requires core, or wireline tied to seismic, or core-calibrated FMI interpretation.

for, or establishing, its lateral persistence. Rather, subsequent study and measurement focuses on the properties of the reservoir itself, the seal is rarely cored and, if it is, this is usually the result of an error in picking depth to top reservoir.

Attempting to better understand diagenetic intensity in the reservoir using signatures from wireline tool measurements taken across the seal intersection is typically considered too difficult, or the possibility is not even understood. Yet, as any carbonate geologist will testify, diagenesis is what distinguishes properties in any carbonate reservoir from those in a sandstone (Ahr 2008). Pervasive, but variable, diagenetic intensity is what controls carbonate reservoir quality in every bedded evaporite-sealed petroleum system worldwide. Almost all of the matrix quality in the world's giant and supergiant bedded evaporite-sealed carbonate fields was established during deposition and early burial. This is when surface topography controls intensity of circulation in the diagenetic hydrology (Table 10.7). Resultant poroperm plumbing can be locally enhanced by later fracture development and perhaps the formation of coarsely crystalline saddle dolomites (typically fed by fractures and faults). In petroleum systems exemplified by the examples of Yates and North Ward-Estes fields, reservoir quality is predictably tied to the style and position of the early evaporite hydrology and is indicated by evaporite textures in the seal. The same approach is also useful in other reflux-dominated carbonate reservoirs, as in the Arab and Khuff formations in the Middle East.

Much more reliable seal prediction and modelling (both seismic and reservoir scale study) is done by the oil industry in sandstone-shale associations than in carbonate-evaporite systems. Our understanding of reservoir problems in a carbonate reservoir is more often post-mortem than predictive. More reliable maps of anhydrite plugging at the reservoir level and flow unit correlations for waterfloods in carbonates are sorely needed. In bedded evaporite-sealed systems this requires the integration of field-scale maps of seal facies with maps of reservoir properties in intervals below the seal. This is not currently done by most oil companies. Worldwide the focus of the map of lateral and vertical rock property variation is in the reservoir itself and it is almost never related to variation in seal facies. Yet wireline property variation in the evaporite seal is easily done. There is no complication of the wireline signature by porosity or fluid variation. That is, evaporite seals are tight, they lack porosity and fluid content, so what is seen in a wireline signature in an evaporite seal intersection is directly related to style and purity of the evaporite and these properties are directly relatable to deposition style (Chap. 5).

The first step is the construction of a map of the facies mosaic preserved in the seal, using wireline-based core-calibrated image and conventional logs. At the local scale such a map uses separation of sabkha from salina signatures, at the broader scale it uses wireline-based separations of evaporitic mudflat from saltern. Next a field-wide map of reservoir quality is constructed or existing maps of quality can be checked by recalibration to existing core and wireline/image data (in a producing field this data is available at varying degrees of reliability). The fieldwide facies mosaic map derived from the seal is then overlain on the fieldwide map of reservoir quality and production data. A match or mismatch of the two outputs tests whether the early burial hydrology and associated palaeotopography has controlled much of the reservoir leaching/dolomitisation and anhydrite plugging.

These maps can then be used to better define untested reservoir zones. With a depositional seal, rather than a drape seal, the better quality reservoir sweetspots are typically below mudflat seals (Fig. 10.51). If the evaporite seals across stacked platform cycles are sufficiently thick and possess sufficient impedance contrast, then a seismic facies map can be constructed over the area of interest and be used to better identify potential sweetspots and other directional drilling targets in the field. This approach of integrating evaporite signatures into maps of reservoir properties is especially useful in carbonates beneath epeiric platform anhydrite beds in systems that have not been substantially overprinted by later stage burial alteration or halokinesis.

But, porosity/permeability in any evaporite-sealed system continues to evolve to varying degrees, long after the reservoir has subsided into the mesogenetic realm and early evaporite plugging (via brine reflux) of the subsalt interval has ceased. In some fields the burial overprints are significant and can control reservoir quality, in others they do not. Porosity evolution in the mesogenetic realm is typically driven by focused vertical and lateral flow of ascending basinal brines. Close to their feeders, these waters pervade permeable intervals below the evaporite seal and so overprint the platform carbonate/dolomite to varying degrees, especially atop zones where active faults and fractures cut the reservoir but do not penetrate the evaporite seal. In more diagenetically mature fields, such as the Keg River pools in the western Rainbow-Zama sub-basin, much of the lateral variation in reservoir quality is tied to burial stage leaching of anhydrite cements, the precipitation of saddle and zebra dolomite, and the formation of coarse, patchy but connected, intercrystalline burial-stage porosity (Fig. 10.51; Table 10.7). Now the reservoir-altering fluids are fed by ascending brines rising along faults and fractures, these structures are sometimes visible in seismic and this association can be used as an exploration tool. Zones of most intense alteration tend to occur in haloes around the fault or in zones immediately below the evaporite seal and sometimes the drilling target is a narrow zone at the base of a synclinal trough (as in Scipio Albion trend, Michigan Basin). Convincing management to drill a syncline is not an easy task!

In more diagenetically mature portions of a basin, these fault-focused ascending basinal waters can carry high levels of metals and can form MVT deposits via thermochemical sulphate reduction (as in the growth fault-fed accumulations of lead and zinc in the Devonian Platform of the northern edge of the Canning Basin, Australia). In such stratiform MVT deposits the evaporites are typically long gone and all that indicates their former presence are laminar beds of metal sulphides with their coarsely crystalline dolomite gangue (Chap. 15). Even in less diagenetically mature supergiant oil and gas fields, where relict depositional porosity is the dominant control over reservoir quality and reservoir topography can be defined in the wireline signature of the seal, the early stages of overprint from ascending basin fluids will have locally altered reservoir quality, especially in the vicinity of active faults and fractures (as in the Arab D reservoir in the 150 billion barrel-plus Ghawar Field of Saudi Arabia).

Importance of Recognising Bed Dissolution

Listings of controls of permeability in evaporite-sealed systems, such as that by Sun and Esteban (1994), also underline another problem with many current field-scale geological studies of reservoir quality controls in evaporitic successions. Such studies, even where core is available, have typically not considered the likely presence in many evaporitic platform reservoirs of thin horizons that once were much thicker sequences of bedded evaporite. Yet bedded evaporites are highly soluble both at the surface and in the subsurface (Chaps. 1 and 7), their residues are widespread and they can create regional markers easily misidentified in wireline as a correlatable well-to-well flooding surface (Table 10.7).

Carbonate reservoirs worldwide are made up of stacks of platform cycles or parasequences, some with and some without evaporitic capstones. When they were deposited, evaporite capstones in both ramp and shelf settings typically mark the tops of zones of shoaling and perhaps cleaning-upward carbonate parasequences situated in a zone of hydrographic isolation behind some sort of grain shoal. Associated reflux brines were often responsible for formation of stratiform reflux dolomites in the carbonates below, along with variable levels of intergranular anhydrite cement that plug the upper portions of the carbonate cycle. Sometimes the evaporite capstones are absent because they were never deposited, other times the evaporitic capstones to these parasequences have been leached, along with the evaporite plugging cements in the underlying reservoir intervals.

Post-dissolution, all that may be left of a former bedded saltern evaporite is 5–50 cm thick stratiform layer of fines, made up of insoluble residues that once were dispersed in the evaporite bed (eolian silts, clays and dolomite rhombs). The overlying succession often shows a characteristic vertical transition of mosaic to crackle breccia or into a zone of syn-depositional solution collapse. Leaching of former anhydrite cements from intergranular positions in the carbonates below the residuum layer can create a high permeability interval below the residuum layer, while suprasalt fractures can poroperm in this zone (see later in this chapter). Sometimes beds on either side of the dissolution residue layer may retain nodules of chert, baryte with minor relict anhydrite. The nodules, when present tend to be dispersed as a band on either side of the residuum layer. Using cores and FMI imagery, the associated breccias, sharp bases, crackled and fractured tops, along with slumps into karstic accommodation space created by salt dissolution can be used to define the former positions of these now dissolved parasequence tops.

Unfortunately, many practising geologists in the oil industry are well versed in sequence stratigraphic principles, but not accustomed to thinking and interpreting stratiform surfaces from well to well, other than as a depositional interface or perhaps as a marine or subaerial exposure surface. When they see residual horizons in core and an associated clast-to clast breccia they tend to interpret it as either a storm bed or as zones of seafloor disturbance and starved sedimentation "formed at a time immediately prior to the creation of a maximum flooding surface." These layers of dissolution residuals are often clay rich and radiogenic and so show up as spikes on the gamma log through the carbonate platform. If the now dissolved bed was previously associated with an underlying zone of anhydrite cement, then dissolution of this anhydrite can create a zone of high permeability in the interval below the gamma kick (Table 10.7).

Without core or core calibrated image-log control, intervals with such high gamma signatures can be easily misidentified as thin shales or mudstones that define flooding surfaces along the muddy base of the next parasequence cycle. Widespread gamma kicks in a carbonate reservoir can then be miscorrelated well-to-well as depositional surfaces beneath low permeability muddy carbonates at the base of the next shoaling cycle. They are then tied from well to well and used to define regional flooding surfaces. These are in turn used as intra-reservoir well-to-well markers to zone up the reservoir into flow units across a field. This misidentification is especially common in correlation studies done in thick carbonate sequences, largely lacking any other markers, and where the team conducting a reservoir zoning study uses a sequence stratigraphic framework for correlation and quality prediction between wells. This leads to poorly understood zones of fluid leakage or influx across flooding surfaces within in the reservoir model. Diagenetic alteration features tied to former salt levels are not mapped by a evaporite residuum unaware reservoir model. As discussed in Chap. 5 most sequence stratigraphic and seismic studies currently conducted in carbonate terrains do not deal well with the "comings and goings" of subsurface evaporite beds.

Such inappropriate interpretations are not too much of a problem when the reservoir is in the early stages of primary

production, or if the field is a single-phase gas field. But they become problematic when the same layer-cake reservoir model is utilised in developing notions of linked flow units via what are considered viable well to well correlations. In the more mature stages of planning of field development it is very important to reconsider any laterally continuous zone in the field, especially if defined by a gamma kick atop or within what is often a dolomitised or high porosity level. It should be redefined for what it is based on its signature in core or a core-calibrated image log and not assumed that it is always indicative of some sort of correlative well-to-well maximum flooding surface.

Gamma kicks in wirelines taken through anhydritic evaporite platform carbonates do not necessarily indicate depositional shale/micrite. Rather, if it is indicating a solution residuum layer, then depending on how and when it formed and how the overlying section was let down during dissolution, some of these stratiform residuum horizons may indicate a set of formative processes that have created widespread crosscutting extensional fractures and microfractures in the overburden. In other words, the question should be asked; did undersaturated water access the dissolving evaporite from the side, top or base of the former evaporite bed? – as discussed in Chap. 7. Thus gamma kicks associated with an evaporite residuum can be associated with laterally extensive zones of higher fracture permeability above or below the marker. If the creation of the residuum layer was tied to the dissolution of former anhydrite cements in the underlying carbonates then high permeability occurs below the marker. If the formation of the residuum was created by lateral solution loss, then solution induced fracturing can occur across a retreating front in the layer above. In either case there is the distinct possibility that adjacent high flow units are joined by dissolution induced vertical fractures.

Such a misidentified system becomes more problematic once production induces an oil–water interface rise. Water then penetrates unexpectedly into what were projected to be longterm productive intervals separated by "shales" based on depositional assumptions of well-to-well marker or flooding surface correlations. Unrecognised high-permeability vertically-linked zones will drastically reduce sweep efficiencies when production planning of a waterflood continues to evolve based on inappropriate correlations of intra-reservoir permeability. There will be early and unexpected water breakthroughs during the waterflood. Depositional marker-based models do not account for likely vertical fluid transfer via cross fractures that developed at the time of evaporite dissolution. Nor does a sequence-stratigraphic-focused team tend to consider the possibility that likely zones of highly interconnected permeability can be formed by the leaching of former anhydrite or even halite cements in the grainy interval below the now dissolved evaporite unit (e.g. some very high permeability intervals that cut across depositional facies in the carbonate host).

But the reality is that most reservoir models for waterfloods and longterm production must be constructed over large areas of a producing field where closely spaced core to wireline calibrations are not available. The two end-member modes of marker occurrence (dissolution residue versus marine shale) can sometimes be separated using a high-resolution conventional wireline tool, such as the MFSL, or better yet an image log. Many residue horizons are systematically associated with a halo of anhydrite or chert nodules on either side of the gamma kick, flooding surfaces typically are not, and marine chert nodules, if present, tend to occur within the marker and not above. Clearly, any wireline-based definition of a dissolution surface can be complicated by the development of patchy high density, high resistivity carbonate cements. In this situation wireline separation of the two styles of picks is best done by an interpreter with an detailed understanding of the significance of evaporite cements in the reservoir and who is using a core-calibrated set of wireline and image log signatures, rather than just conventional log shapes for correlation (Table 10.7).

Changing Directions of Brine Flux in an Evaporite Sealed System

At the regional scale, brine reflux flushing is most active in the early stages of evaporite deposition, when the evaporite beds retain porosity and permeability and concentrated Mg-rich brines sink from the overlying free brine pool, through the still permeable bedded evaporite (usually gypsum), and into the underlying sedimentary succession. Elliott and Warren (1989), Saller and Henderson (1998) and Lucia (1999) all point out that the downward cyclic transition from a relatively impervious overdolomitised and salt-plugged platform dolomite (typically with thick intercalated saltern and mudflat seals) into partially dolomitised subtidal platform carbonate reservoirs (with thinner seals) corresponds to a downward decrease in the flux of saturated reflux brines and an increase in dolomite crystal size. This corresponds to a downward decrease in dolomite saturation as the refluxing brines sink deeper and further from the brine source. Thus, better-quality reflux-enhanced platform reservoirs occur in structures not directly beneath the thicker accumulations of saltern salts, where salt plugging, overdolomitisation and mimetic dolomites tend to dominate. Better potential reservoirs tend to occur more toward the seaward margin of the thickest saltern accumulation where coarser dolomite, partial dolomitisation and thinner evaporites are found.

Long term salt plugging, tied to large crossflow volumes of saturated brine reflux waters, means that many hydrocarbon accumulations in reef pinnacles sealed by basinwide evaporites are typically smaller and less productive fields compared to their platform counterparts (e.g. the relatively

small volumes of hydrocarbons in salt-encased Silurian pinnacles of the Michigan Basin and the pinnacles of platform edge of the Rainbow-Zama sub-basin). A lack of widespread potential reservoir in the muddy deepwater setting that immediately predates most basinwide evaporite beds adds to the likelihood of smaller accumulations beneath basinwide salt seals, compared to platform settings. Even so, thick massive basinwide evaporites trap and preserve some of the geologically oldest oil and gas fields in the world (e.g. fields producing from platform carbonate slivers suspended in the Neoproterozoic Ara Salt of Oman). The situation is different when draping of epeirogenic regional highs are fed hydrocarbons beneath a salt seal. This is the case with some giant Miocene- Cretaceous hosted fields in Iraq and western Iran. There the continuity of intracratonic bedded salt seals constitute zones of lateral seal integrity and subsalt drainage feeds into what are low-quality reservoirs but capable of holding significant volumes of extractable oil and gas.

This is why Sun (1995) found porosity distribution in such variably dolomitised reservoirs associated with basinwide evaporites typically show no direct relationship to stratigraphic position or depositional trend. His conclusions emphasise the problems of reliable porosity prediction in a syndepositional hydrological system characterized by large autocyclic fluctuations in hydrologic base level (≈1 km) over time frames of thousands of years (Chap. 5). It also indicates the lack of differentiation of strandzone versus basin-centre reflux dolomites by most workers, yet both dolomite styles typify basinwide evaporite settings (Warren 2000b). Unlike the dolomites associated with platform evaporites, this group of basinwide reservoir seals cuts across both icehouse and greenhouse periods as basinwide evaporites require tectonics that are independent of sealevel character (Chap. 5).

An evaporite bed can only act as a seal once it has lost its intrinsic permeability. For a gypsum bed converting to anhydrite this happens somewhere in the first 500–1,000 m of burial, while for halite it can happen as shallow as a hundred metres below the landsurface. Until then, the permeable evaporite bed facilitates brine reflux, but once tight it only supplies brines to its surrounds via dissolution of its edges and focuses fluid flow along its underside. This transition in rock properties has an interesting effect on diagenesis and explains much of the later stage dolomitisation overprint on early reflux dolomites that are seen in many evaporite-sealed reservoirs (e.g. Canadian pinnacle reef traps and the dolomites of the Arab cycles in Saudi Arabia). As the evaporites were accumulating they flushed the underlying carbonates with dense sinking Mg-rich brines. Once buried and tight, the evaporite seal then prevents the free vertical escape of hot rising brines, which ponded in carbonates immediately below the slowly dissolving underside of the evaporite seal. The resulting chemical interface drives salting out of hydrocarbons, creates predictable zones of burial porosity, and drives the precipitation of authigenic or burial cements, including coarse sparry dolomite. It means most dolomitic reservoirs below an evaporite seal retain evidence of diagenesis first driven by descending reflux brines, which were created as the evaporite seal precipitated. Then later the same subsalt carbonate gathers a new diagenetic signature (of varying intensity) via the seal-focused flushing of hot ascending basinal brines moving along active subseal fractures.

Halokinetic Salt Traps

In many parts of the world, such as offshore Brazil, offshore west Africa, the North Sea and the Gulf of Mexico, a significant part of the association of evaporites with hydrocarbons can be tied to salt's ability to flow, and by its flow generate large and numerous structural and stratigraphic traps. As in bedded evaporites, emplacement of broad sheets of salt against more porous sediment greatly improves the efficiency of hydrocarbon drainage, both in terms of area drained and in tightness of the reservoir seal (Demaison and Huizinga 1991; Hindle 1997).

We saw in Chap. 6 how advances in 3D depth migration and computing power, still occurring today, have revolutionized subsalt and suprasalt hydrocarbon exploration. Only a decade or so ago, most seismic reflection information in halokinetic provinces was acquired as 2D data; today, most seismic data is acquired as 3D data volumes. A 3D cube provides a dense grid of subsurface information, which can be used to more accurately map salt body contacts and shapes. Older vintage seismic used mathematical models for conventional migration and processing, which assumed that the acoustic properties of subsurface sediments did not make abrupt lateral variations. This assumption obviously breaks down near salt flows; a solution required cheap computing power, more sophisticated depth migration techniques and denser data grids. Positioning of contacts in older vintage data can sometimes be improved using more recent processing algorithms and greater computing power, offering a cheaper but less accurate alternative to reshooting a grid.

By the late 1980s, the notion that salt flow could be a horizontal as well as a vertical emplacement process was increasingly accepted by the geological community. This new paradigm, along with increased computer processing speed, power and storage, opened up a whole new set of subsalt or more correctly suballochthon or salt tiered plays in the deep waters of the slope and rise in the circum-Atlantic salt basins and similar terranes elsewhere in the world. At the same time drilling technology was improving rapidly, along with geosteering capabilities and broader MWD logging tool suites. Each year wells are being spudded in progressively deeper water. For example, ultradeepwater exploration in Gulf of Mexico, in the decade through to the early millennium, has

found more than 3–4 billion BOE in nine major discoveries, in a hydrocarbon exploration province previously considered mature (Table 10.7; Enger and Logan 2001). But, before we discuss these increasingly exploited sub-allochthon traps we will look at the suprasalt trap, which was the classic exploration association in halokinetic regions prior to the 1980s.

Historic limitations in seismic resolution meant that, until the 1980s, exploration for suprasalt-related oil and gas traps was undertaken using salt models dominated by notions of subvertical thumb-like intrusives, fed salt by a direct connection to a mother salt bed below. Interpretations of the many producing salt structure peripheries in the onshore and shelf waters were biased toward this older notion of strongly vertical salt flows with salt pillows as the precursor to subvertical diapir stems. We now know that many nonpiercing pillow structures can be compressional features created during inversion or foot of slope gravity gliding (Fig. 6.67). Other pillows do form in response to depositional loading as a flow stage preceding the diapiric stage (Fig. 6.1). This is the classic model of Trusheim (1960) and based on his extensive work in the Zechstein salt structures of northern Germany. More recent work, even in this classic area, shows thumb-like geometries and associated assumptions of a connection to a more deeply buried mother salt bed are not necessarily correct (Mohr et al. 2004). Isolated rising blebs cut off from the source layer are more likely in the mature portions of many salt basins undergoing compression and inversion. This offers possibilities for future sub-salt flange sealing plays even in very mature regions of onshore and shelf exploration in the Gulf of Mexico and onshore Europe. But, such traps are likely to be small and discontinuous. Currently the possibility of drilling giant structures in the deep waters of the Gulf of Mexico and other circum-Atlantic salt basins are more appealing to exploration economics within large and mid-sized oil companies.

Supradiapiric Traps

Oil and gas reservoirs atop salt structures are as varied as the shapes and timings of the salt structures that caused them. Salt buoyancy means areas above shallow actively flowing salt structures are topographic highs, while the areas between are topographic lows Fluvio-deltaic, coastal, and submarine slope deposits are usually sand poor over the salt crest (Fig. 6.96). Most of the coarser-grained sediments in either setting is deposited in troughs as various types of channel fill and shoreface deposit, especially in landscape depressions atop zones of active salt withdrawal. In continental settings the pinchout of the high-porosity sand occurs along the flanks of a salt structure, usually well down-dip from the crest. Occasionally, reservoirs can form in the muddy crestal sediments in a continental setting due to diagenesis associated with subaerial exposure and/or unconformities. In arid coastal areas the crest could have been covered by evaporitic mudflats as environments tied to the development of early dolomite in pelleted mudstones with the associated formation of good intercrystalline porosity.

High-porosity sediments tend to form atop or immediately adjacent to a suprasalt crestal shoal in nonpiercement structures in shelf settings (Fig. 6.96). Boundstones, skeletal and oolitic grainstones, and well-winnowed siliciclastics are found on such highs. For example, studies by Mancini and Benson (1980) and Ahr and Palko (1981) of the Jurassic Smackover Formation reservoirs in southwest Alabama and Louisiana show that reservoirs often occur in oolitic-pisolitic grainstones located over salt pillow crests, while Montgomery et al. (1999a, b) describe hydrocarbon accumulations in numerous inboard Jurassic (Cotton Valley – Bossier) reefs atop salt pillows and diapirs in the East Texas Basin (Fig. 10.52). Similar Jurassic stromatolite and coral stromatoporoid reefs are found in the Smackover atop other salt pillows, such as the Walker Creek Field, Arkansas, in the Hico Knowles Field, Louisiana (Baria et al. 1982), and Hatters Pond in southwest Alabama. There the Smackover buildups are typically 3–40 m (10–130 ft) thick, commonly elongate, and several square kilometres in plan.

Reef rubble zones throughout the Smackover trend tend to have reservoir-quality porosity, but reef boundstones are economic only when extensively leached, dolomitised, and fractured. Such alteration can create commercial production from reef crests with mean porosities of 15 % and permeabilities of 20 md. Hatters Pond Field is typical of a field where the reef crest is tight and depositional facies crosscut the reservoir trend. The distribution of the reef was controlled by the position of the Jurassic high above a growing autochthonous salt pillow, while the trap was created during Cretaceous faulting associated with the structure's diapiric stage (Worrall and Warren 1986). The level of the reservoir dolomite lies well below the reef crest and above a dolomite unit characterised by post-hydrocarbon saddle dolomite. As in bedded evaporites, the initial porosity controls in carbonate reservoirs atop salt pillows and diapirs are often depositional, but are usually complicated by closures and diagenetic alteration haloes related to fault welds and subsequent fluid flow.

Siliciclastic examples of closure forming high capacity suprasalt reservoirs by sand-shale juxtaposition across clay-smeared extensional faults can be seen atop salt structure crests in the West Bay Field in Louisiana and the Heidelberg Field in Mississippi (Halbouty 1979). Bay Marchand – Caillou Island Field is a classic example of this style of fault-controlled suprasalt sand reservoir above the crest of salt structure (Figs. 8.35 and 10.53). The three diapirs that constitute the field structure are passive diapirs atop a salt wall feed. Under the new paradigms of flow that have been

developed since this structure was documented by Frey and Grimes (1970), it can now be seen to be the remnant of what was an active salt feeder system, with the current fault weld once acting as a salt wall feeding diapiric allochthons higher in the section. Most of the extension driving the faulting was a response to gravity gliding and salt deflation and not the active intrusion visualised in the original interpretation. The faults show radial, peripheral, or tangential patterns relative to the salt stock. Elsewhere in the Gulf of Mexico similar faults have downfaulted, uplifted, or overthrusted sands against impervious shales and multiple stacked reservoirs are stacked up against the fault (e.g. Bryan Salt Mound, Brazoria County, Texas).

Many of the numerous radial faults drawn in older interpretations of suprasalt traps (pre-1990), were published prior to the industry's recognition of salt's intrinsic lack of strength under tension. These interpretations tended to visualise faulting (mostly inferred rather than intersected) as a response to buoyancy and active salt intrusion. This is understandable as in most cases much of the salt that fed into an allochthon has long since dissolved or moved on to higher levels in the stratigraphy, via what are now deflated salt welds. In more recent interpretations of the same structures the faults are seen to be a response to salt withdrawal and to downbuilding in the adjacent sediments. High resolution seismic has shown that many of the inferred radial faults of older interpretations do

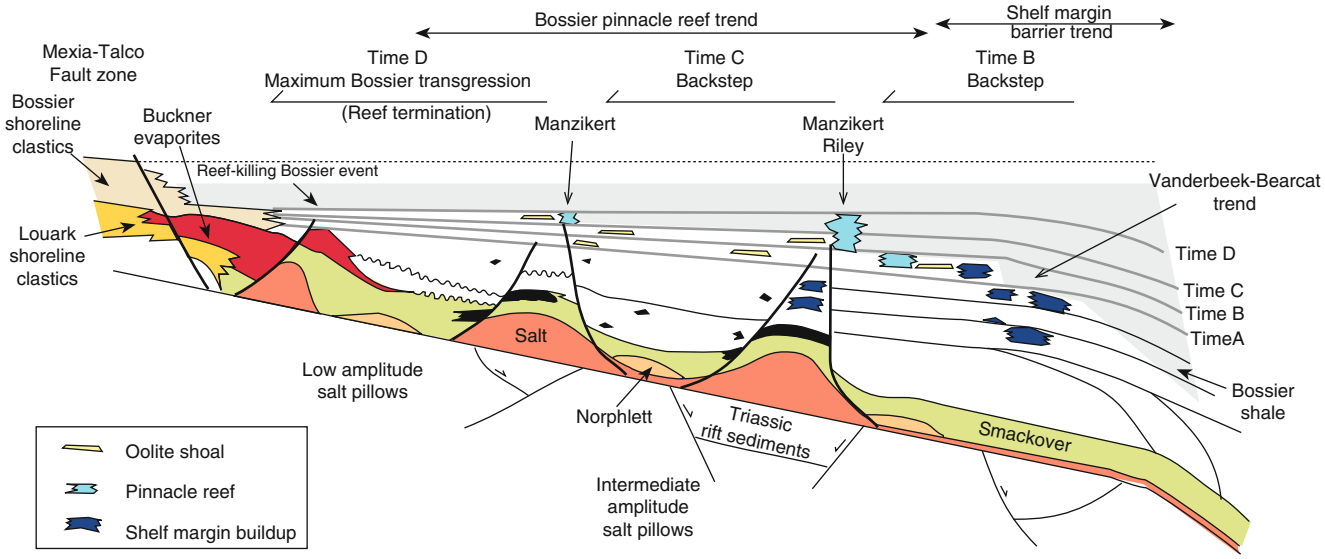

Fig. 10.52 Regional model of the development of outboard shelf/ramp margin buildups (structural control to shelf margin) and the "inboard" pinnacle reefs growing in seafloor shoals created by salt pillows in the Marquez Platform, East Texas Basin in Upper Cotton Valley to Lower Bossier time (After Montgomery et al. 1999a)

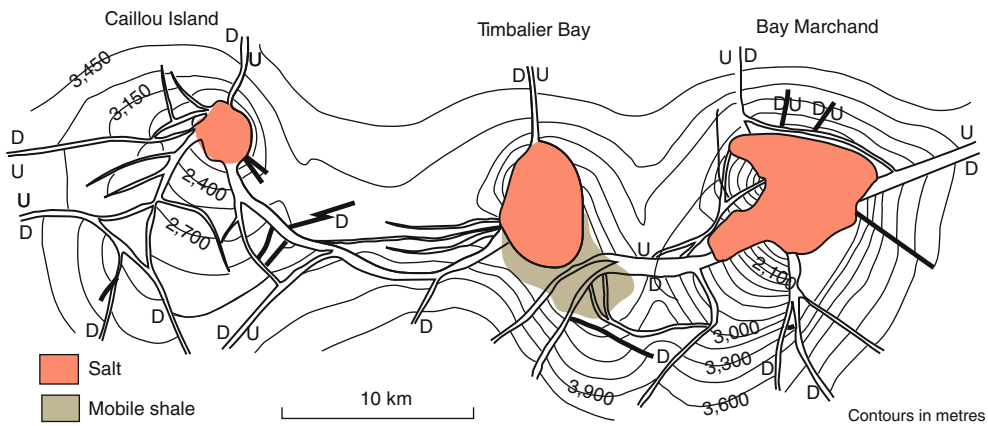

Fig. 10.53 Structure contours (in metres) on the productive Upper Miocene sand in the vicinity of the Bay Marchand – Timbalier Bay – Caillou Island diapirs, coastal Louisiana. Diapirs merge at depth into a salt wall and occur along a main extensional fault linking all three domes, each with its own association of radial faults (After Frey and Grimes 1970)

not exist. Such faults were inferred in order to explain discontinuities between sands in adjacent areas. In reality, many of these discontinuities, are more often a response to unconformities and depositional pinchouts rather than fault-outs, especially in flank traps.

For example, a reinterpretation of the Cote Blanche Field in Louisiana in the mid 1990s, based on newly acquired 3D seismic reduced the number of radial faults in the crest of the field to nine, compared to more than thirty in mid 1970s vintage 2D interpretations. However, radial faults do occur about salt structures and are largely a response to salt deflation during the passive stage of diapirism or are a response to later basin inversion and diapir squeezing. In halokinetic extensional terranes that have been subject to later compression, such as in parts of the North Sea, offshore UK and Norway, there many of the earlier radial faults are reactivated and have evolved into inversion structures (Fig. 6.81).

Syndepositional suprasalt traps occur in the sand-rich edges to withdrawal synclines, along with associated pinchouts onto the diapir crest (Fig. 10.54a). An example of this type of reservoir is the West Saratoga Field, Hardin County, Texas. There, multiple Yegua sand reservoirs shale out as they pass into the Saratoga Salt Dome (Galloway et al. 1983). The secondary peripheral sink continued to subside as the diapir grew (downbuilding), resulting in steep dips in the sand units as they shale out into the diapir stem (Fig. 10.54a) Subsequent loss of salt supply and cap rock formation may cause loss of salt volume and local collapse around the salt stem (Fig. 10.54b). Steeply dipping suprasalt reservoirs are characterized by stacked thick oil columns, which may approach 300 m (1,000 ft) where they pile one atop the other alongside the salt or a clay-smeared fault weld. Efficient gravity segregation aided by water influx results in high recovery efficiencies.

Grainstone shoals and reefs may rim the diapir or allochthon crest in carbonate shelf settings. With ongoing subsidence, these units tend to aggrade into a porous rim around the salt stem. A good example of this style of grainstone trap is the West Purt Field in the East Texas Basin, where the reservoir (Rodessa Limestone, Lower Cretaceous), is a fractured mollusc peloid grainstone and rudstone unit abutting the northwest side of the Brushy Creek Diapir (Lomando et al. 1984). The same style of carbonate facies, growing around diapirs and salt welds, now outcrops as the various carbonate lentils associated with the La Popa weld in Mexico (Fig. 6.105).

Pulsing salt emplacement, with numerous switches from active to passive, means that any sediment deposited above a passive allochthon or diapir crest is temporary. Whatever the depositional setting atop the crest, it is shed periodically into the structure's flanks. The resulting salt ablation unconformities can cut into flanking coarser grained deposits, which may then be sealed by subsequent finer-grained deposition or by the encroachment of allochthonous salt (Figs. 6.106 and 6.108). The resulting unconformities and truncational traps can be located some distance from the diapir stem. The dip of such unconformity traps is as steep as the dip of the adjacent shaled-out sands. Unconformity traps have thick oil columns and can stack, but show a limited lateral extent away from the

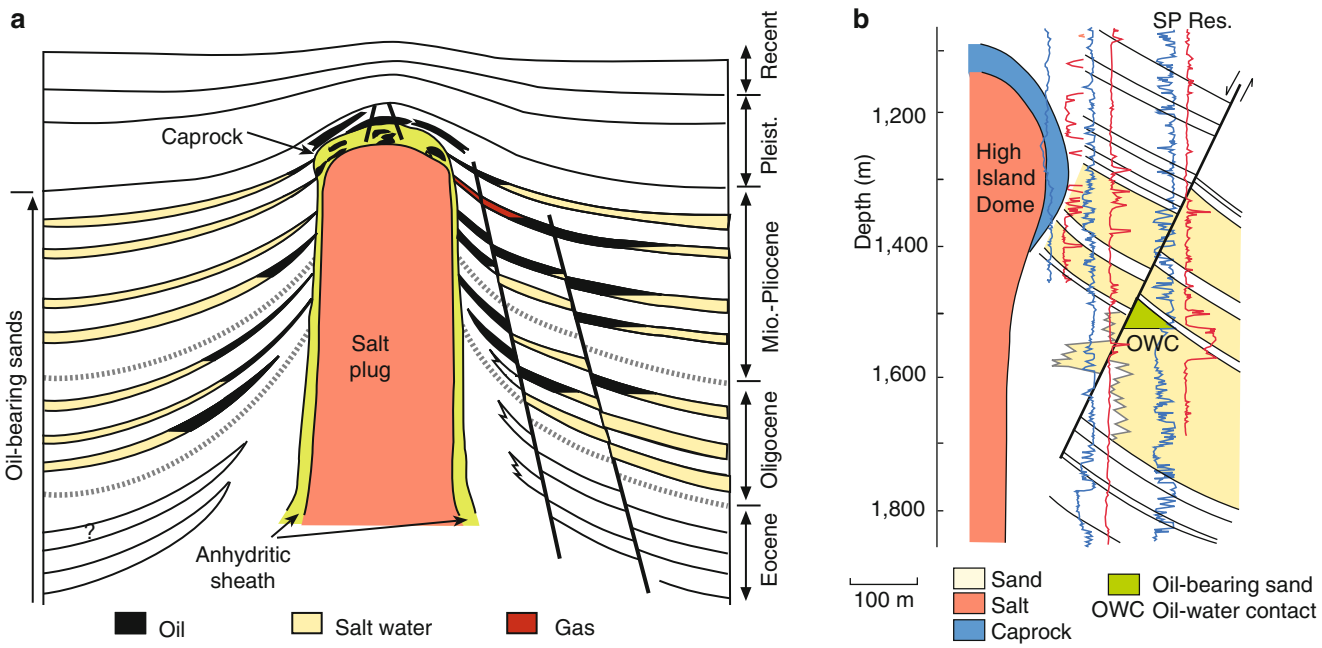

Fig. 10.54 Reservoir sands in the Gulf of Mexico (**a**) Stacking of Tertiary-age peripheral reservoir sands creates some of the most productive acreage in the world (After Halbouty 1979). (**b**) Cross section of the south flank of the High Island Dome, Chambers County, Texas, where the trap is interpreted as due to peripheral faulting juxtaposing a reservoir sand to a shale seal across the fault (After Galloway et al. 1983)

salt stem. A good example occurs along the north side of Nash Dome in Texas, where steeply dipping Frio sands (Oligocene) are truncated by multiple dome-flank unconformities.

Stacked flank traps dominate below the crestal level of many producing salt structures in the onshore Gulf of Mexico, reflecting sedimentation about a salt system during the passive stage of its growth. The crest of the structure maintained its position in earth space while the flanks subsided so that most flank traps are of two interrelated types (Fig. 10.54a; Halbouty 1979): (a) Traps created by sedimentation and erosion contemporaneous with salt movement; (b) Traps created by the relative upward movement of the salt (downbuilding). Stacked flank and unconformity traps have yielded greater volumes of hydrocarbons per acre than any other type of trap in the Gulf of Mexico (Halbouty 1979).

The diapir stage is also the time when turtle structure anticlines form in the salt-withdrawal basins between diapirs. The region above a turtle is often a topographic high where high-energy shelf sands and reefs accumulate atop an anticlinal drape, creating an excellent trap for the subsequent accumulation of hydrocarbons. A good example is the giant Fairway Field in Lower Cretaceous James Reef Limestones in Henderson and Anderson counties, east Texas (Terriere 1976; Achauer 1985). The reservoir is a rudist-reef complex above a shoaling turtle structure and is situated on a saddle between the salt-withdrawal areas of Boggy Creek, Brushy Creek, and La Rue Domes (Fig. 10.55).

The growth of a turtle structure between the La Rue, Brooks and Boggy Creek diapirs converted what was a muddy area of open shelf limestones into a shoal area of rudist reefs and grainstone shoals. Postdepositional faulting truncated the northwestern and northeastern margins of the trap, which is now a southeast-plunging nose (Fig. 10.55a). Reservoir porosity is largely secondary and is better quality in the meteorically leached portions of mechanically deposited suprasalt rudist grainstone belts rather than in the reef proper (Fig. 10.55b). Secondary porosity development tied to halokinetic activity after the reef growth stopped is also the case in many other rudist grainstone buildups atop or adjacent to salt structures in the Gulf of Mexico and the Middle East (e.g. Mishrif Formation in Umm al Dalk Field, UAE). The main control on reservoir quality in these

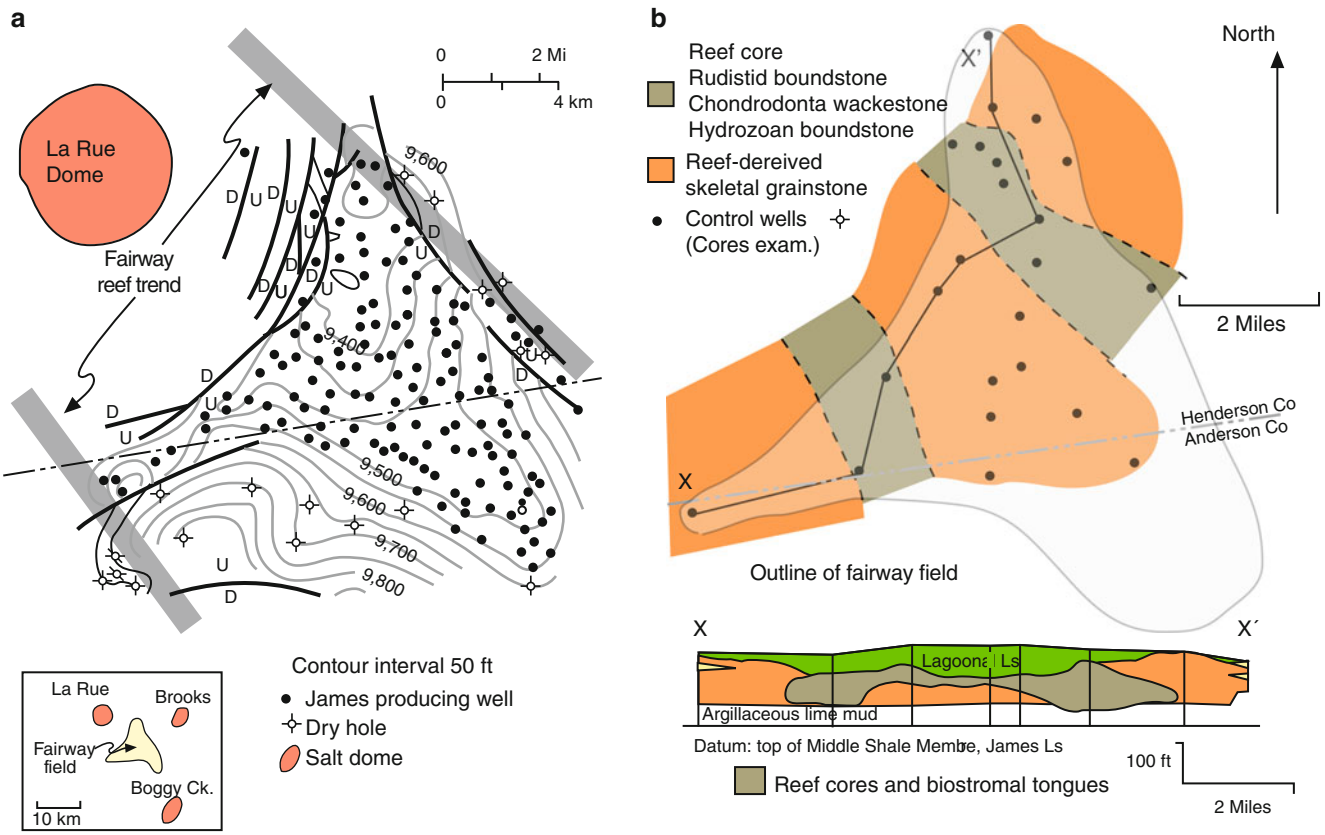

Fig. 10.55 Fairway Field, East Texas Basin (After Achauer 1985). (**a**) Structure map on top of Cretaceous James Limestone Fairway Field, Henderson and Anderson Counties, Texas. The trap is a fault bounded southeast-plunging nose crossed by the northwest trending James Reef Complex. Inset shows Fairway Field formed atop a turtle structure between three salt domes. (**b**) Facies map and interpreted depositional setting of the James Limestone. The main reef core lies in the northwestern part of the field, while satellite reefs to the southeast and southwest are composed of corals, stromatoporoids, algae, and rudists. Carbonates sands and gravels were deposited in the southern part of the field; while elsewhere, muddy lagoonal sands are the dominant lithology

Cretaceous oil and gas fields is karstification and exposure, driven by periodic seafloor shoaling near or atop the underlying salt structure. Pervasively dolomitised Albian oolite pisolite sands also form extensive reservoirs atop turtle structures in the offshore of Angola (Eichenseer et al. 1999).

Chalk reservoirs above salt structures, such as Danian chalks in Ekofisk, Machar and Medan fields in the North Sea, often had the crestal reservoir properties enhanced by the movement of subadjacent salt during basin inversion (Fig. 10.56). Tension was created in the chalk unit above the growing salt structure and this lead to gravitationally-induced microfracturing (D'Heur 1990a). Oil migrated up these fractures in the chalk and, when the oil column in the fracture system was 50–100 m tall, the buoyancy force was sufficient to overcome the high entry pressures inherent in narrow pore throats. Oil was then stored in the matrix as well as in the various fractures. Hardman and Kennedy (1980) postulated that this process explains why high-relief features in the North Sea chalk/salt structures have better oil saturations and why low-relief traps can have waterwet matrix porosity. Early entry of oil into matrix pores and the associated overpressures then retarded the normal sequence of chalk lithification with burial by inhibiting chemical diagenesis and reducing overburden pressure on the matrix grains (D'Heur 1990a, b). These processes were most effective in reservoirs above the centre of the salt structure and with time migrated out into the flank reservoir; hence the reduction of porosity and increase in water saturation radially and the concave-upward oil water contact at West Ekofisk.

In a study of fracture distribution in chalks reservoirs from a number of rejuvenated diapir fields in the North Sea, including Machar, Davison et al. 2000b found that almost all (>99 %) faults and fractures observed are extensional, and form at high angles (>70°) to bedding. Fracturing in the chalks is a response to the rejuvenation of salt flow as the North Basin underwent mild inversion in response to the Alpine

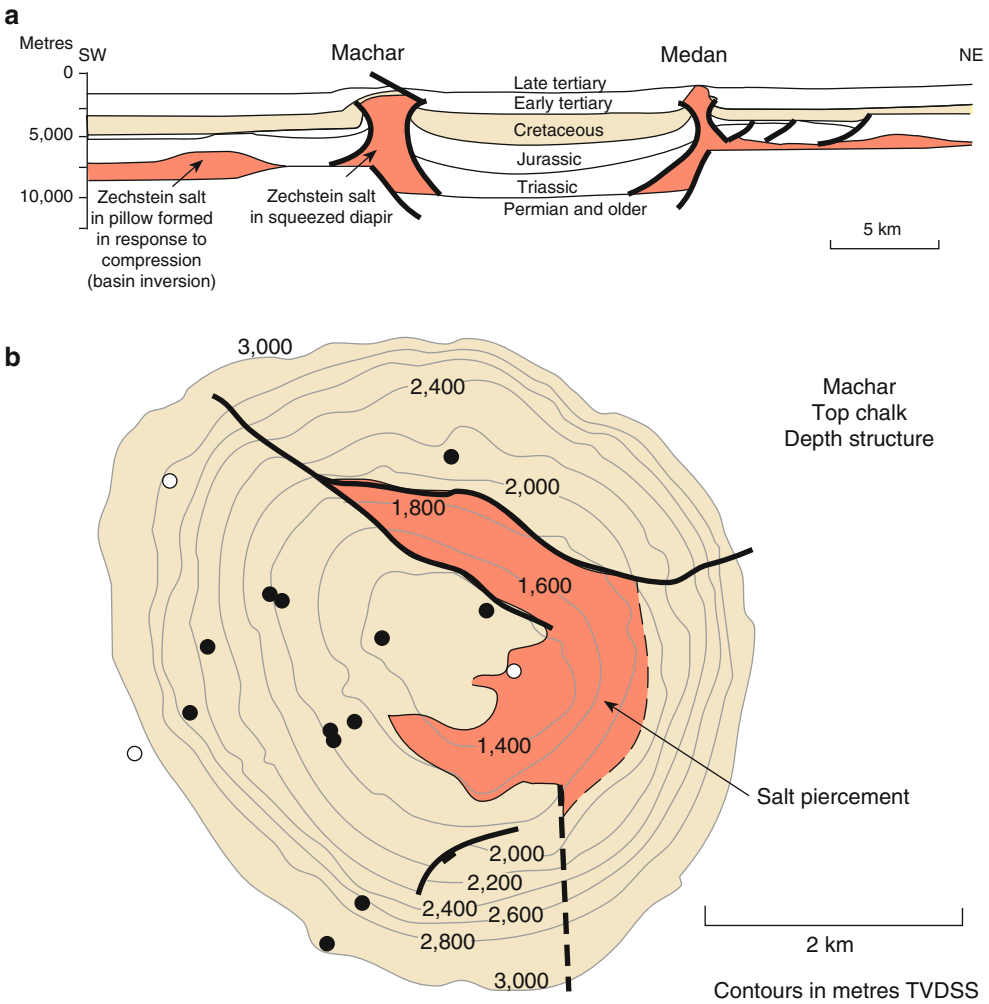

Fig. 10.56 Machar Field, UK sector North Sea. (**a**) Interpretive cross section showing position of field and a geometry that is a response to compression of a formerly extensional salt structure. (**b**) Contoured top of chalk in metres TVDSS showing zone of piercement of Zechstein salt (After Foster and Rattey 1993)

Orogeny. The greatest amount of interconnected fracturing and brecciation (natural rubble zones) in the chalk unit is in wells at or near the crests of this and other North Sea suprasalt chalks such as Ekofisk (Casabianca et al. 2007). The fractures are commonly open, indicating that deformation has continued until the present day, and/or cementation has been inhibited owing to the presence of hydrocarbons, which began to accumulate in the fractures after chalk deposition. Close to the diapir contact (<50 m), the fractures in the chalk are cemented with calcite or anhydrite, which is interpreted to be due to increased fluid flow concentrated along the diapir contact.

This plume of rising saline fluids rising along the dissolving diapir has created a celestite halo in the cap of Machar Field. The fracture intensity within the chalk does not vary consistently from base to top at any one position on the diapir. Reservoir productivity in the chalk is significantly enhanced by fracture permeability over the crest of the diapir structure, where intrinsic permeability in the chalk is insufficient to sustain economic flow rates. However, the chalk is absent on parts of the crest due to non-deposition or downslope sliding (Fig. 6.81b; Davison et al. 2000a; Casabianca et al. 2007). These are areas where salt sometimes made it to the Cretaceous seafloor as small allochthon wings off the main salt trend stem. Stylolite and dissolution residue seams, which are parallel to bedding, can slow vertical flow rates in the chalk (Davison et al. 2000b). They are made of clays and other insolubles and show very low permeabilities on the order of nannodarcies.

The main controls on intrinsic chalk poroperm in the Cretaceous Tor and Palaeogene Ekofisk chalk reservoir units are; (1) Sorting as expressed by Dunham texture, so that mudstones tend to have highest porosity and packstones the lowest; (2) Sorting of the carbonate mud, where a mixture of clay-size chalk particles and silicates tend to reduce porosity; and (3) Intensity of porefilling cementation. The presence of chalk clasts as an indicator of re-deposited chalk seems to have no relationship to porosity (Fig. 10.57; Fabricius et al. 2007). The relative significance of these parameters varies from field to field, while the most significant production qualities are related also to fracture intensity, which varies with proximity to faults and crestal position. What is also interesting is that chalk porosity varies by more than 20 % within a reservoir in a single field but appears to be depth insensitive across the fields, perhaps related to compression induced fracturing and associated early emplacement of hydrocarbons in the reservoir matrix.

Understanding the fault and fracture network in Machar chalk as a response to diapir squeezing and the rise of the diapir crest created a new fracture and fault model for the field. Using this knowledge in the field development plan, along with greatly improved seismic imaging, controlled acidising of the chalk, and steered MWD drilling technology, converted Machar from a field that appeared subeconomic in the early appraisals of the late 1980s with test wells returning at best 8,000 bopd to the current producing field with acidised intervals in fractured zones capable of reliably producing at rates of up to 30,000 bopd.

Even as a diapir crest becomes buried and caprock formation comes to dominate, potential reservoirs can still be created. Caprocks host hydrocarbons in many Gulf of Mexico domes show porosities as high as 40 %, with porosity types ranging from pinpoint to vuggy to cavernous. Caprock reservoirs in the Gulf of Mexico onshore are shallow and so were attractive targets in the early heyday of drilling in Texas. Many of the famous early Texas reservoirs were in caprocks; examples include Spindletop (the most famous), Sour Lake, and Humble. Caprock reservoirs tend to be made up of relatively small, but numerous, pools. Today, most onshore diapir crests have been drilled and offshore the small size of possible caprock pools means they are not primary targets in most exploration programmes.

Traps can occur below a salt wing (remnant allochthon) or an overhang in a squeezed salt structure with a shape like an inverted teardrop. Prolific production comes from beneath the overhang of Barber Hill Dome in Chambers County, Texas; High Island Dome in Galveston County, Texas; Batson Dome in Hardin County, Texas; and the Weinhausen-Eicklingen and other salt domes in the Zechstein Basin of northwest Germany (Figs. 10.58 and 10.59). Sands below the Barber Hill overhang in east Texas have produced more than 100 million barrels of oil (Halbouty 1979). All these traps are onshore and were interpreted under the classic styles of Trusheim's pillow to diapir model using the notion that salt was capable of sill-like intrusion at depth. Today they would be interpreted as remnant allochthons created by passive diapirism or allochthons created by reactivated flow due to salt squeezing.

Tiered Allochthon Plays in the Deepwater Realm

Across the last three decades, offshore exploration in the offshore Atalintic has expanded into a deepwater realm where much of the trap structuration in the continental slope and rise is a response to salt flow, often creating multiple salt tiers in the stratigraphy. In this region the deeper water offshore province of Gulf of Mexico and more recently offshore Brazil, have been a focus for the development of improved deepwater drilling and seismic technology (Fig. 10.60a). Much of the currently published exploration paradigm for deepwater tiered-salt allochthon plays comes from the Gulf of Mexico. However, similar paradigms for allochthon development are being used to drive exploration in other circum Atlantic basins located in offshore Brazil and west Africa.

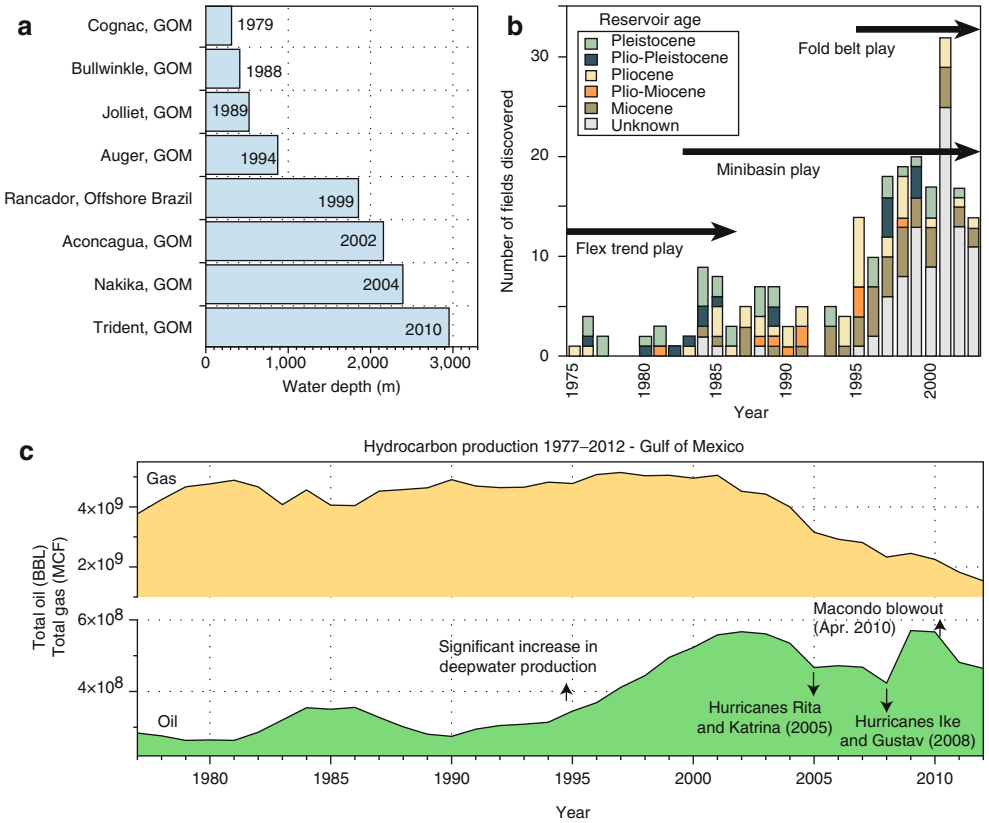

Fig. 10.60 Deep water exploration. (**a**) Water depth to seafloor for deepwater developed fields across the period 1979–2010, with much of the technology expansion driven by Gulf of Mexico (*GOM*) developments. This figure shows a technology-driven expansion of offshore drilling by the oil industry into ever greater water depths in salt allochthon provinces -see also Table 10.8. (**b**) The number of GOM discoveries for the years 1975–2003, showing reservoir age and dominant play type. It also shows the large increase in discoveries from 1995 onward after the passing of the Royalty Relief Act removed some government tax restrictions to deepwater exploration. There were no discoveries in 1978, 1979 or 1992 (After Richardson et al. 2004; Cossey 2004). (**c**) Hydrocarbon production from Gulf of Mexico replotted from BOEM data (<http://www.data.boem.gov> last accessed Dec. 20, 2013)

As yet this work is not as extensively documented as the Gulf of Mexico, but it constitutes a rapidly expanding dataset (Beglinger et al. 2012).

Since 1975 more than 23 billion barrels of oil equivalent have been discovered in the deepwater Gulf of Mexico, while some 9.2 tcf of gas and 2,200 mmbl were produced between 1979 and the end of 2002. Deepening water depths of the various discoveries reflect this time-related technological development (Fig. 10.60a; Table 10.8). There were 232 commercial fields discovered in the Gulf of Mexico during the period from 1975 to the end of 2003 (Cossey 2004). The mean size of these discoveries is 94.3 mmbl oil equivalent. The two largest deepwater fields found to date in the Gulf of Mexico (GOM) are Mars (750 mmbl oil equivalent) and Thunder Horse (1,000 mmbl oil equivalent and possibly as high as 2,000–3,000 mmbl). Thunder Horse was not discovered until 1999, a quarter century after the 1975 discovery of Cognac, the first deepwater field (Table 10.8). Initial well flow rates in wells in the GOM deepwater province did not exceed 10,000 bbl/day until 1995, some 20 years after the discovery of Cognac. Three years later, individual well rates at Ram-Powell and Troika had exceeded 20,000 bbl/day.

Likewise, the salt-cored fold and toe-thrust play has been a successful one in the Gulf of Mexico (Fig. 10.60b, c; Table 10.8). Major discoveries in the Mississippi Fan (Atwater-Valley) Fold Belt include Neptune (discovered 1995), Mad Dog (1999), Tahiti (2002), Knotty Head (2005), Genghis Khan (2005) and Big Foot (2005). Thunder Horse (1999) is the largest of the known fields, with an estimated mean size of 1 billion barrels of oil equivalent (Cossey 2004). "First oil" from Thunder Horse came on line on June 14, 2008. Since then, Thunder Horse has steadily ramped up its production by bringing on new wells. In March 2009, Thunder Horse produced close to 250,000 barrels per day (40,000 m^3/day) oil equivalent in oil and natural gas from seven wells. Plans were in place to add two additional wells in 2009 to further develop the north end of the field. By January 2010 total daily production during 2009 had declined from near 250,000–175,000 barrels per day (40,000–27,800 m^3/day). A similar lower than expected rate

Project/field name	Area/blok	Water depth (m)	Total depth (m)	Discovered/ drilled	First production	Est. equiv. reserves MMbbl	Comments
Atlantis	GC 699	2,133	5,951	1998	2007	575	Deepest moored floating oil and gas production facility in the world and also one of the largest oil fields in the Gulf of Mexico. Structure is an elongated faulted anticline with overall 4-way dip closure from the top of the Miocene down to the top of the autochthonous salt. Approximately 60 % of the geological structure lies beneath salt and the Sigsbee Escarpment
Auger	GB 426	872	5,000	1989	1994	220	Salt withdrawal minibasin -turbidite play. Initial development costs exceeded US$ 1 billion. Auger's tension leg platform (TLP) has 17 wells connected to system and is also processing hub for nearby fields (Now, Cardamom, Habanero, Serrano, Llano, Oregano and Macaroni). Oil from Auger is sour. Initial wells flow at more than 10,000 bbl/day. Prodigous production rates made sub sea completions economic in the Gulf of Mexico.
Baha	AC 600	2,323	–	1996	–		First ultradeepwater well in Gulf of Mexico, well did not reach target but proved sands were present in ultradeep plays. This discovery initiated the Perdido Foldbelt play in water depths greater than t 8,000 ft (2,400 m).
Bullwinkle	GC 65	412	4,800	1983	1989	190	Pinchout trap in Upper Pliocene, lower Pleistocene sands in salt withdrawal basin (first minibasin play). Has produced more than 120 million barrels of oil and 185 billion cubic feet of natural gas. Deepest fixed-leg platform in the Gulf. Field is now in decline, initial high production rates
Champlain	AT 63	1,359	7,300	2000	–	50	Draped deepwater sands over salt-cored detachment fold. The trap style is a crestal four-way with a larger three-way dip closure with updip salt truncation
Chimichanga	GB 127	192	4,490	1995	–	400 Gcf	Second commercial subsalt discovery, drilled 396 m of salt, tested 2,100 bbl of oil/day, and 20 MMcf of gas/day. Hydrocarbons in Pliocene age, upper slope channelized turbidite sands are located adjacent to and below a major tabular salt mass. (Flex trend)
Cognac	MC 195	312	2,805	1975	1979	150	Historically, deepwater oil production began in 1979 with Shell's Cognac Field First proof of Flex trend and first GOM drilling success in 1,000 ft (300 m) of water. It won the American Society of Civil Engineers 1980 award for "Outstanding Civil Engineering Achievement"
Diana	EB 945	1,372	3,350	1990	2000	100	Deepwater discovery in turbidite sands located on east flank of a north-south–trending salt-cored ridge in the western GOM
Enchilada	GB 128	215	5,625	1994	–		Salt weld discovery. Hydrocarbons in Pliocene age, upper slope channelized turbidite sands are located adjacent to and below a major tabular salt mass (Flex trend)
Europa	MC 935	1,180	5,700	1994	2000	160	Multiple Miocene sands
Gemini	MC 292	1,038	5,479	1995	1999		Third commercial discovery in subsalt play (Pliocene-Miocene sands) Gemini salt body currently overhangs the apparent sediment entry point of deepwater reservoir sands into the Gemini basin. Projected recoverable reserves for the project are estimated at 250–300 billion cubic feet of gas and 3–4 million barrels of condensate
Genesis	GC 205	792	3,700	1988	1999	98	Turbidite sands located on the eastern flank of a buried salt ridge. SPAR platform

Table 10.8 (continued)

Project/field name	Area/blok	Water depth (m)	Total depth (m)	Discovered/ drilled	First production	Est. equiv. reserves MMbbl	Comments
Hickory	GI 116	98	6,584	1998	–		Penetrated 2,438 m (8,000 ft) of salt. atop local minibasin play with subsalt basin open to the northeast, toward potential sand sources.
Jack 2	WR 759	2,088	8,598	2006	–		Willcox test, deepest extended drillstem test in deepwater Gulf of Mexico history proved the viability of the Lower Tertiary deepwater play (Wilcox-equivalent Eocene/Paleocene). Drilled in 7,000 ft (2,130 m) of water and penetrated 20,000 ft (6,100 m) beloe the seafloor.
Kaskida	KC 292	1,786	9,906	2006	–	3,000?	First Willcox subsalt test situated significantly inboard of Sigsbee escarpment, northern frontier of Willcox prospect, intersected 2,444 m (800 ft) of net pay. Edge of a primary basin is juxtaposed against a secondary minibasin across a high-angle weld. One of the largest Paleogene discoveries.
K2	GC 562	1,221	3,979	1999	2005	100	Drilled through 3,050 m (10,000 ft) of salt canopy in Miocene fold belt trend.
Lena	MC 280	305		1976	1984		Lena, the third field in Gulf of Mexico, started production in 1984. The field is situated in lowstand fan on the western flank of a salt diapir within a faultbounded intraslope basin
Mad Dog	GC 782	1,372	6,957	1998	2005	450	91 m (300 ft) of net subsalt pay discovered in Mississippi Fan fold belt. Field extends across the Sigsbee Escarpment. Truss spar platform. Infrastructure (spar platform) damaged by Hurricane Ike in 2008
Mahogeny	SS 349	113	5,048	1993		100	Put on line before Mica, became the first commercial development in the Gulf of Mexico subsalt play. Wells did not produce at projected rates.
Magnolia	GB 783	1,432	5,141	1999	2006	150	Tension leg platform (TLP) installed in record water depth for TLP. Located on southern edge of Titan mini-basin where multiple deep water reservoir sands are positioned across a series of down-to-the-basin and antithetic faults adjacent to salt bodies
Mars	MC 807	896		1989	1996	400–500	TLP located due south of Mississippi mouth in some 3,000 ft of water. Stacked Miocene sand reservoir interval several hundred meters thick, confirmed the Mini-Basin trend in the Gulf as a bona fide play. First well came in at 15,000 barrels per day. Initial flow rates some early wells were as high as 50,000 bbl/day Platform was damaged during installation Hurricane Katrina.
Mensa	MC 731	1,621	4,815	1986	1997		Upper Miocene; proximal lobate turbidite sheet sand associated with a faulted four-way closure
Mica	MC 211	1,328	3,890	1980			First significant intersection of hydrocarbons in 5 thin pays below salt
Neptune	At 573	588		1996	2008	150	First discovery in the Western Atwater Foldbelt. oil in Lower to Middle Miocene turbidite sands. Developed by a standalone Tension Leg Platform (TLP). First spar production facility in GOM
Pompano	VK 990	393		1981	1994	75	Upper Miocene reservoir in a turbidite channel system draped over a salt cored plunging anticline
Popeye	GC 116	610	3,505	1985	1996		Turbidite in minibasin between a salt-stock system to the west and an extensional salt tongue to the east
Ram-Powell	VK 956	980		1985	1997		Miocene sand reservoir. Field went onstream in 3,200 ft of water. TLP was considered a “Mars” clone.

Table 10.8 (continued)

Project/field name	Area/blok	Water depth (m)	Total depth (m)	Discovered/ drilled	First production	Est. equiv. reserves MMbbl	Comments
Redhawk	GB 877	1,615	7,163	2001	–		Produced from the world's first truss spar facility
St. Malo	WR 678	2,145	8,859	2003	–		First subsalt well of Wilcox Trend, drilled through 3,048 m (10,000 ft) of Sigsbee salt canopy, intersected 137 m (450 ft) net pay. Wilcox-equivalent Eocene/Paleocene deepwater play
Tahiti	GC 640	1,224	8,170	2002			Middle Miocene trap beneath 3,353 m (11,000 ft) of salt canopy
Tanzanite	EI 346	96	3,607	1998			First well tested 1,917 bbl/day of oil and 29.7 MMcf/day of gas, one of the highest in the shallow Gulf of Mexico
Thunder Horse	MC 778	1,844		1999	2007	640	Largest field in the Gulf of Mexico, but wells not producing at projected rates (initial estimates of 1 billion bbl of oil equivalent). Thunder Horse sands were unusually high pressure/high temperature reservoirs. Reserves were estimated at 757 Mb in 2002, 653 Mb in 2004 and 643 Mb in 2006. Thunder Horse complex was brought on production with the largest semi-submersible platform ever built (130,000 t) at a cost in excess of US$ 6 billion. Drilled in 6,000 ft of water. Platform required repair and re-righting after Hurricane Dennis in 2005. By March 2009, production had ramped up to 250,000 barrels per day, 4.5 % of total U.S. daily production.
Troika	GC 244	829		1994	1997	200	S10 turbidite reservoir has outperformed the original reservoir model. Initial flow rates were as high as 31,000 bbl/day
Ursa	MC 809	1,225		1989	1999	400	Deepwater sands located within an intraslope, salt-bounded minibasin. Ursa TLP was designed to accommodate initial well-production rates of 30,000 barrels per day; in September 1999, a well at Ursa broke all records with a production rate of nearly 50,000 barrels of oil equivalent per day
West Toga	GC 726	1,433	7,827	2007			Discovered 107 m (350 ft) of net oil in 3 Miocene sands
Zinc	MC 354	451		1977″	1993		Flex trend discovery.

Compiled in part from Graham et al. (2011), Richardson et al. (2004), Dribus et al. (2008)

of production is also seen in wells in Mad Dog field. Reasons for this decline are still being investigated.

Several early subsalt wells were accidental subsalt penetrations where operators were drilling to test anomalous seismic reflectors and found salt where they expected hydrocarbons. The first subsalt well drilled in the Gulf of Mexico Outer Continental Shelf was Placid Oil Company's Ship Shoal 366 well in 1983. This well encountered three separate salt intervals, but only 90 m of subsalt sediment were penetrated. Over the next several years, sporadic subsalt drilling continued. One of the more interesting early subsalt wells was Diamond Shamrock's 1986 well, South Marsh Island 200, which encountered a reservoir-quality sand with a massive 245 m net thickness. The potential for worldclass reservoir sands beneath salt allochthons became apparent with this well, but the absence of reliable subsalt targeting from existing seismic technology limited drilling activity (Farmer et al. 1996).

Porosity and permeability in what are producing deepwater sands in these subsalt fields can be impressive, even though deposition has occurred on deepwater bottoms, situated well out on the continental slope and rise, sometimes in regions that were more than 100 km from their contemporary shorelines. Sands in the Auger Field (Garden Banks 426) retain porosities of 26 % and permeabilities up to 350 md. Pliocene and Pleistocene turbidite sands in Green Canyon 205 Field have reported porosities ranging from 28 to 32 % with permeabilities between 400 md and 3 darcies. Connectivity in these deepwater sheet sands and amalgamated sheet and channel sands is high for deepwater turbidite reservoirs worldwide and recovery efficiencies are in the 40–60 % range (Table 10.8; Cossey 2004).

High production potential of ultra-deepwater reservoirs in the Gulf of Mexico deepwater was documented in Troika and Mars discovery wells, where initial flow rates from turbidite sands were as high as 31,000 and 50,000 barrels of oil per day per well, respectively, far surpassing the previous Gulf of Mexico single well record of 12,000 barrels of oil per day at Auger. This compared nicely to 500–1,000 b/d from a good well on the shelf in the Gulf of Mexico. Although these GOM fields do not compare in size (storage) to the Middle East, they can generate Middle Eastern rates of production, at least in the early stages. The surprising discovery in 1994 of how productive these reservoirs were in tests at Shell Oil's Auger platform entirely changed the company's cost structure for this deepwater play. However, as mentioned earlier, a number of later deepwater projects (including Thunder Horse and Mad Dog in the Gulf of Mexico) have not produced at the peak rates anticipated, and production has declined much more rapidly than predicted, both as a consequence of the reservoir complexity, strength of the water drive, and technology problems arising from remote, high pressure, high temperature subsurface conditions (Cohen 2007; http://www.theoildrum.com/node/6415). Accordingly estimates of ultimate recoverables have been reduced across these fields (Table 10.8).

Regionally-Tiered Salt Plays in the Gulf of Mexico

Regionally, there are three subsalt-associated allochthon trends in the deepwater Gulf of Mexico (Figs. 10.60b and 10.61a): (i) Flex trend, (ii) Minibasin, and (iii) Foldbelt (Cossey 2004). The term subsalt is used by GOM explorers to describe plays obscured by a salt canopy. The flex trend describes the shallowest region of the three plays (in terms of water depth) and it covers a geographic area encompassing the outermost shelf and uppermost slope. Geologically it constitutes the halokinetic zone in front of the Plio-Pleistocene Roho, and is an area where there is no widespread salt canopy. It can be further divided into a "toe thrust" or flex belt and a "primary basin" belt (Fig. 10.62a). Large volumes of salt have been lost in this region via allochthon evacuation, dissolution and weld creation. In terms of salt allochthon evolution much of the Flex trend and the Primary Basin region has evolved well past the canopy stage and the area is now a relict thrust foldbelt (Fig. 10.62b; toe thrust zone). The minibasin play, as the name implies, encompasses sand deposition associated with the development suprasalt depopods and minibasins (Fig. 6.47). It is typically located in somewhat deeper water in the Gulf of Mexico than the toe thrust belt, and its exploration began in 1983 with the discovery of Bullwinkle. The foldbelt trend is located beneath and downdip of the canopy belt and encompasses reservoirs developed by compressional folding at the downslope end of a developing allochthon belt. It constitutes the deepest water region of current areas of exploration activity in the Gulf of Mexico (Figs. 10.62b and 10.63).

Flex trend exploration began in the early 1970s with the discovery of Cognac Field located just beyond the present-day shelf edge where there is a "flex" in the sea floor profile (Cossey 2004). Some of the larger flex discoveries were Lena, Zinc, Pompano and Green Canyon 18 (Table 10.8). Most discoveries in the Flex Trend are fields with small reserves, characterised by discontinuous sands with producing wells showing relatively low flow rates. Exploration wells in this trend generally targeted "bright spots" on 2-D seismic. Gemini, for example, showed up as a very strong event on the seismic. Texaco was so confident of its Gemini prospect that based on a very strong event on the seismic they stopped drilling and set casing just before entering the pay zones. In fact, this hydrocarbon-indicating anomaly could be seen on non-reprocessed, mid-1980s vintage 2D seismic.

Exploration for minibasin plays typically targets the flanks of intraslope basins where reservoir sands pinch out and form combination structural/stratigraphic traps, or it targets zones of drape over turtle structures. Many minibasins plays are sealed and obscured by allochthonous salt sheets, which can fuse into a salt canopy (Chap. 6). Some of the larger mini-basin fields discovered to date are Auger, Mars, Diana, Genesis, Troika and Europa. Ram-Powell field was discovered in 1985 and is a very large, stratigraphic trap, developed in a more unrestricted mini-basin. Larger minibasins typically have turtle structures developed in their centres. The first mini-basin fields brought on-line (Bullwinkle in 1989, Auger in 1994) produced at much higher than expected rates, had better than expected aquifer support and needed fewer wells to develop them. Much of the early production from these minibasin fields ended up facility constrained.

Suballochthon exploration for minibasin traps in the deepwater offshore Gulf of Mexico was first successful south of New Orleans in the region known as the "Isolated Salt Tablets" province or Florida slope. It is located in the easternmost Mississippi Canyon area in waters 1,000–2,000 m deep (Fig. 10.62a; Shirley 2000; Hall 2002). Productive reservoirs there are Pliocene to Miocene unconfined turbidites occurring some 3,000–4,500 m subseafloor. These are usually sealed beneath allochthonous salt and are considered combination structural/stratigraphic traps. Exxon made the first deepwater subsalt discovery of oil and gas in this region with its Mississippi Canyon 211 well. This prospect, nicknamed "Mickey" because of the resemblance of three allochthon sheets in plan view to the head and ears of "Mickey Mouse" has hydrocarbons below salt canopy and lies beneath 1,310 m (4,300 ft) of water. Reserve estimates for "Mickey" range between 50 and 150 million barrels of oil equivalent, but the discovery was deemed subeconomic and has yet to be put on production. The "Mickey" discovery indicated the prospectivity of subsalt plays in this region and focused

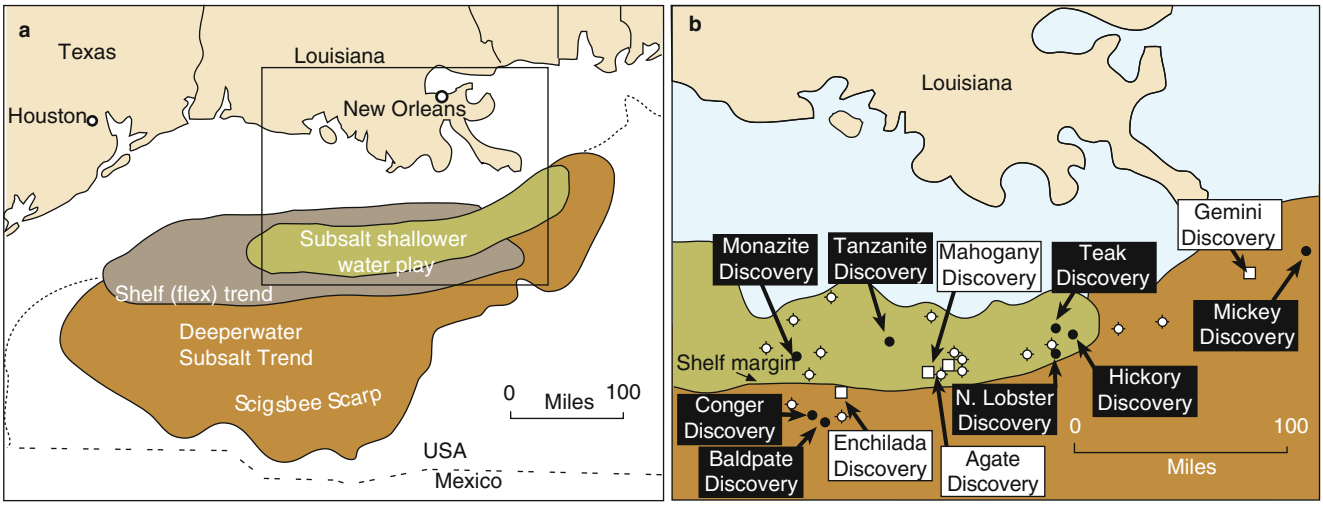

Fig. 10.61 Allochthon-related discoveries in the Gulf of Mexico. (**a**) Distribution of shelf and deep water salt plays in the Northern Gulf of Mexico. *Rectangle* indicates position of Fig. 10.61b (In part after Cossey 2004). (**b**) Selected early discoveries, until the mid 1990s, in the updip slope and rise minibasin province in the eastern Gulf of Mexico (drilling in relatively shallow water, near shelf break – see Table 10.8)

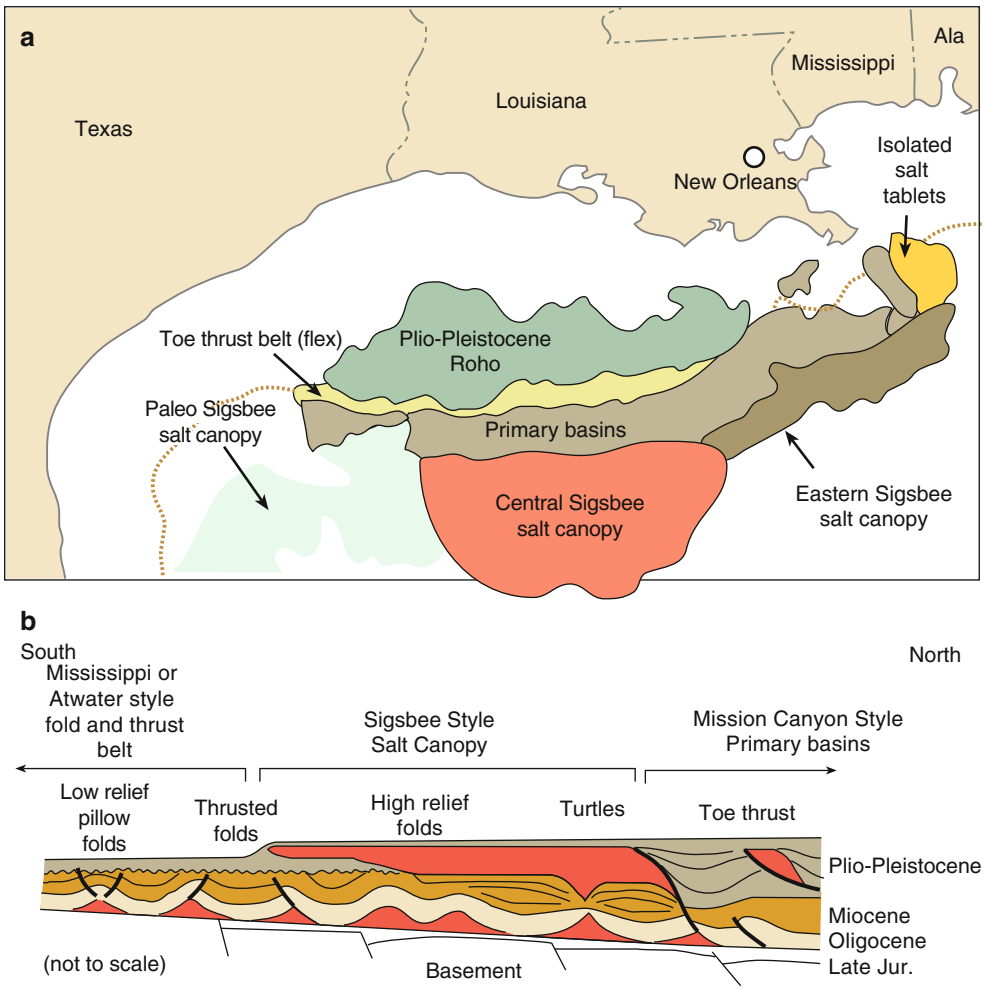

Fig. 10.62 Distribution of the various salt fairways in the Northern Gulf of Mexico. Also shows an idealised south to north cross section illustrating typical subsalt and suprasalt structures where the position of the salt defines major play types. Note that the low relief pillow folds in the south are autochthonous and probably define the original southern extent of thick Jurassic salt in the basin

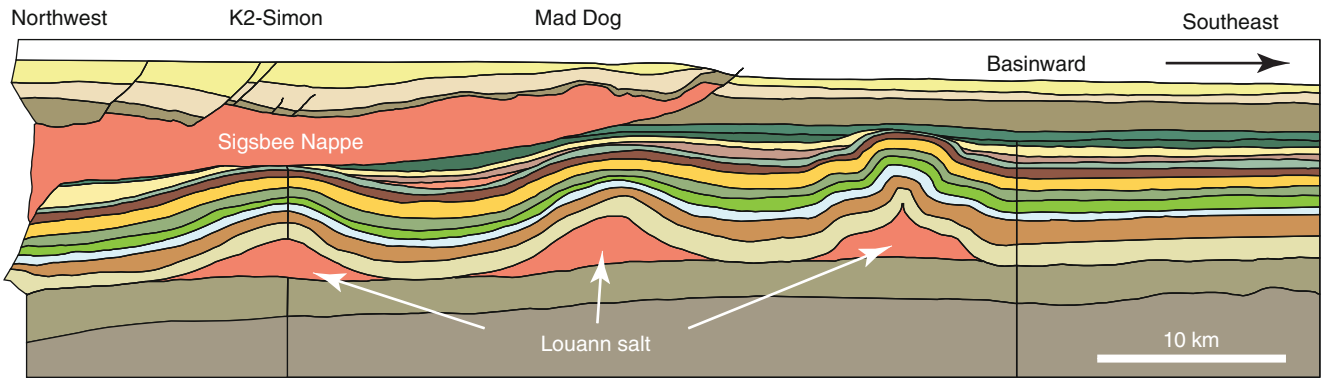

Fig. 10.63 Depth section through the western part of the Mississippi Fan Foldbelt showing a series of symmetrical, salt-cored detachment folds between welded synclines and the resulting closure that formed the Mad Dog and K2-Timon fields (After Rowan et al. 2004). See Fig. 6.61 for location

exploration efforts into sub-allochthons, both on the shelf and in deeper water.

As drilling technology and subsalt imaging improved throughout the later 80s and into the 90s, subsalt exploration moved into progressively deeper water. Drilling now reliably reaches larger potential suballochthon minibasin structures, including turtles located further out in the Gulf and targets requiring the drilling of more than 3,000 m of salt (Table 10.8; Richardson et al. 2004). Minibasin fields currently contain the largest economic resource base in the deepwater Gulf. The subsalt "Mahogany" Field, operated by Phillips Petroleum, is a minibasin play that was discovered in 1993 by the Ship Shoal 349 well in the Mission Canyon region. This field, which began production in December 1996, was the first commercial subsalt oil development in the Gulf of Mexico. In 1994, Shell Offshore, Pennzoil, and Amerada Hess announced another significant minibasin discovery in Garden Banks 128 well, nicknamed "Enchilada" (as in the idiomatic "it's the big enchilada"). Enchilada has combined reserves estimated at 400 bcf of gas and 25 million bbl of oil/condensate (DeLuca 1999), and was brought online in July of 1998. In 1996, nine subsalt wells were drilled and three were discoveries. The largest discovery (Anadarko and Chevron) was "Gemini" in Mississippi Canyon Block 292 with estimated reserves of 250–300 Bcf of gas and 3–4 million bbl of condensate (DeLuca 1999). It currently produces from a single reservoir using a subsea system. Gemini was the first deepwater subsalt production in the Gulf of Mexico – and showed explorers the potential for prolific production from the deeper water portion of the subsalt play.

In June 1999 one of the Gemini wells tested around 76 million cubic feet of gas and 1,370 barrels of condensate a day. Agate Field in Ship Shoal 361 was discovered in 1996 by Anadarko and Phillips and is produced through a tieback into the neighbouring Mahogany platform. Anadarko, along with partner BHP, also announced a second subsalt discovery in 1996 in Vermilion 375, called Monazite. The discovery well revealed multiple pay zones, but because of problems during testing, the hole was plugged and abandoned. Amerada Hess and Oryx made a major discovery in late 1997 in their Penn State prospect in Garden Banks 216, the field came on stream in 1999 through a tieback to the Baldpate production facilities. In July of 1998, Anadarko announced a subsalt discovery at the Tanzanite prospect in 95 m (314 ft) of water in Eugene Island 346 with reserves estimated at 140 million BOE. Later in 1998, Anadarko also announced the discovery of their Hickory prospect in Grand Isle 116 in 97 m (320 ft) of water. The discovery well, drilled to a total depth of 6,580 m (21,600 ft), penetrated approximately 2,400 m (8,000 ft) of salt before passing into the reservoir. Reserves are estimated at 40 million BOE (DeLuca 1999).

Thunder Horse Field (formerly known as Crazy Horse Field) in Mississippi Canyon Blocks 776, 777 and 778 is a substantial minibasin field with a turtle style of reservoir development. It is located in the Boarshead Basin, 200 km south-east of New Orleans and is the largest deep water discovery made to date in the Gulf of Mexico (Enger and Logan 2001). It had initial estimated reserves of greater than a billion barrels of oil equivalent in early and middle Miocene sands at about 7,000–8,500 m (23,000–28,000 ft) depth. BP-Amoco has said reservoir characteristics are excellent and compared Thunder Horse favourably to Magnus Field in the UK North Sea, where wells flowed at rates exceeding 20,000 bbl/day at peak. Thunder Horse showed that deepwater subsalt sands can be productive, even at depths well below 7,500 m. It is one-and-one-half to twice the size of the next biggest structures in the region (Enger and Logan 2001) and is one of three large discoveries on a turtle structures worldwide. Other turtle-associated discoveries are Pluto (aka BS and T; Mississippi Canyon 718) and Mensa (Mississippi Canyon 731). Both the Thunder Horse field and Pluto discoveries are partially covered by shallow salt canopies.

Methods of most effectively exploring for minibasin plays are still emerging, especially if a turtle is obscured by a salt

canopy (Shirley 2000). Deeper turtle structures are still difficult to reliably image on 3D seismic data, especially beneath thick salt canopies and there are no diagnostic hydrocarbon-indicating amplitudes (bright spots) related to this play, so structures rather than accumulations are targeted. Geologically, turtle structures can be complicated as these structures were synclines at the time they were receiving sediments (Fig. 6.29). Then the structure inverted due to ongoing salt withdrawal. That in itself implies there is a complex relationship between timing of trap formation, hydrocarbon charge and migration. The key uncertainty with turtle structures in this style of play is whether a trap was in place during the hydrocarbon migration phase. Also, there can be crestal faulting on these structures that can degrade the top seal of the traps, but the size of the potential discoveries makes the risk worthwhile.

Petroleum systems in the foldbelt give prominence to underlying high-relief salt-cored folds (mostly to the west) and thrusted folds to the east in what is called the Atwater Valley style structural province (Hall 2002). Lower and middle Miocene turbidite reservoirs extend across the crests of folds, which typically formed during foot of slope compression in the mid-Miocene to Early Pliocene. Three major foldbelt trends are considered prospective: the Mississippi Fan, the Perdido and the Port Isabel foldbelt, all are located in deeper water downdip of the salt canopy/minibasin trend (Figs. 6.65 and 6.66) The Foldbelt play began to be exploited in 1995 with BP-Amoco's discovery of Neptune in Atwater Valley 575 in the Mississippi Fan foldbelt. Soon thereafter BP discovered Atlantis and Mad Dog (Fig. 10.63; Hall 2002). K2/Timon was found just north of the earlier discoveries, and more recently Texaco discovered the Champlain Field in the middle of Atwater Valley, extending the play further east (Table 10.8; Rowan et al. 2004).

To date, in the Mississippi Fan belt, a significant portion of the discoveries are centred in the foldbelt of the western part in a small area of the southeast Green Canyon area. All are near the edge of the Sigsbee Escarpment and within 50 km of each other in water depths ranging from 1,200 to 3,000 m (4,000–6,500 ft). Target reservoirs are found in the 5,000–8,000 m (17,000–26,000 ft) depth range, and the structures can be prolific with greater than 300 million barrels of oil equivalent. Mad Dog is currently one of the more prolific of the foldbelt discoveries, with reserve estimates ranging from 400 to 800 million barrels of oil equivalent from about 100 m of net hydrocarbon pay in a large, high relief fold under the edge of the Sigsbee Escarpment (Fig. 10.63). Atlantis, vies with Mad Dog in terms of field size. Current seismic quality in this part of the fold-belt province is good to fair, but companies are exploring very high relief features, which are difficult to miss. For example, Mad Dog is a 3,000 m relief feature below the Sigsbee Nappe. Even though imaging is not the best quality, it's hard to overlook a 3,000-m-tall closed structure. Plays in the area known as the Eastern Sigsbee Escarpment do not involve the search for the subtle trap! The province's western portion is relatively well drilled now, so the play's future lies in taking the charge risk and moving east to determine how far the play will extend. In contrast, the Perdido Foldbelt Play is under explored. The play is similar to the Mississippi Fan Foldbelt Play in that it consists of very large compressional foldbelt structures. Like the Mississippi Fan Foldbelt Play, the compressional folds extend a considerable distance landward beneath the Sigsbee Salt Canopy. However, the plays differ in the age of the structures and the targeted reservoir.

Early exploration drilling in the deepwater Gulf of Mexico in the early 2000s found over 2 billion BOE (Richardson et al. 2004). Today the traditional deepwater mini-basin plays are still providing many successful exploration opportunities (e.g. the Thunder Horse and North Thunder Horse discoveries in southern Mississippi Canyon), but recent discoveries in new foldbelt deepwater plays continue to expand the exploration potential of the deepwater Gulf of Mexico (e.g. Perdido). Currently, some 99 % of total production in the deepwater Gulf of Mexico is from Neogene reservoirs (Pleistocene, Pliocene, and Miocene; Fig. 10.60).

Several recently announced deepwater discoveries encountered large potential reservoirs in sands of Paleogene age (Oligocene, Eocene, and Paleocene); for example, the Tiber discovery in 2009 and the Coronado Discovery in March 2013. Transocean's Deepwater Horizon semisubmersible made the historic discovery for BP at the company's Tiber[8] prospect in the Keathley Canyon in September 2009. Drilling in 1,220 m of water and to a world-record total depth of 10,685 m, Deepwater Horizon tapped in a pool of crude estimated to contain 4–6 billion barrels of oil equivalent, one of the largest U.S. discoveries. Six months later, in March 2010, Shell (with partners Chevron and BP) started production at its Perdido spar in 2,438 m of water in the Alaminos Canyon. A hub for the development of three fields, Perdido was the world's deepest offshore platform, and the first project to pump oil and gas from the Lower Tertiary in the Gulf of Mexico. In 2010, Petrobras began to develop the Gulf's first floating production, offloading, and storage facility to produce from Lower Tertiary reservoirs at its Cascade and Chinook prospects. By end 2010, the industry had announced 19 discoveries in the Lower Tertiary trend, 14 of them containing more 100 million barrels of oil equivalent. However the aftermath of the BP Horizon spill in April 2010 was a decline in exploration, from which the Gulf is still recovering (Fig. 10.60c).

[8]The Tiber oilfield was drilled in 2009 by the semi-submersible oil rig Deepwater Horizon. The same rig was destroyed as the result of an explosion 7 months after the discovery at Tiber, while drilling its next well at Macondo in April 2010.

Minibasin Plays

Salt-withdrawal minibasins are characterized by Karlo and Shoup (2000) as either; (1) shelf-loaded, or (2) slope-loaded (Figs. 10.64 and 10.65). Salt withdrawal minibasins on the shelf, which mostly host fluvio-deltaic reservoirs of the shelf trend in northern Gulf of Mexico, are rooted in autochthonous salt at depths of 12,000–14,000 m (40–45,000 ft). They typically show continuous subsidence in a seaward-migrating belt of sediment loading from the Cretaceous onward, with some basins beginning to fill with sediment even earlier in the Jurassic. The basins are aligned in sub parallel linear trends with salt domes intermittently dispersed along the bounding faults. Updip they tend to be simple minibasins while their downdip extent is defined by stepped counter-regional fault basins, often with a secondary turtle structure on the 'step,' along with some local Roho development (Fig. 10.66; Karlo and Shoup 2000). Associated salt masses grade from simple diapirs updip into larger volume, overhung salt domes and successively into salt wings and allochthons downdip. Block 330 is one such system (Figs. 6.104 and 8.28).

Plio-Pleistocene Roho systems are shelf-loaded features (Fig. 10.65) with updip zones of extension marked by a series of nested highly listric faults, which display a characteristic horseshoe geometry in map view (Fig. 10.65b; Karlo and Shoup 2000). Deltaic sands and shales tend to be stacked in lower parts of the seafloor in a feedback between depositional loading of the rotated wedges associated with these growth faults. The central portion of the same depositional system is typically manifest as a complicated zone of remnant salt, perched diapirs, salt-floored faults, and strike-slip faults. Basinward of this region is the compressional toe, which consists of a melange of salt and deformed sediment. All faults sole into the evacuated remnant of the original salt tablet, which typically overlies a salt-withdrawal minibasin. In map view, the overall geometry of the salt-based detachment system is constrained by the geometry of the salt tablet upon which it is forming.

Slope-loaded minibasins (turbidite reservoirs) are similar to shelf minibasins in terms of sand distributions, but involve much more salt than the shelf systems (Fig. 10.64). These slope withdrawal basins are typically flanked by salt walls, with little fault rim development. Formation began with ponding of turbidites triggering loading and the creation of diapirs. Because of the great thicknesses of autochthonous salt involved, turbidite ponding is more or less continuous, so long as there is salt withdrawing from the basin. Should the depocentre shift during the diapiric phase, a salt wing forms during the hiatus and overflows the basin resulting in the formation of a salt canopy. Once the allochthonous salt has been evacuated, subsequent turbidite deposition bypasses the basin.

Regionally, within the Gulf of Mexico, these minibasin systems and associated trap types can be placed in a tiered system of primary and secondary minibasins, with much of the trapping occur-ring at the primary basin level (shaded

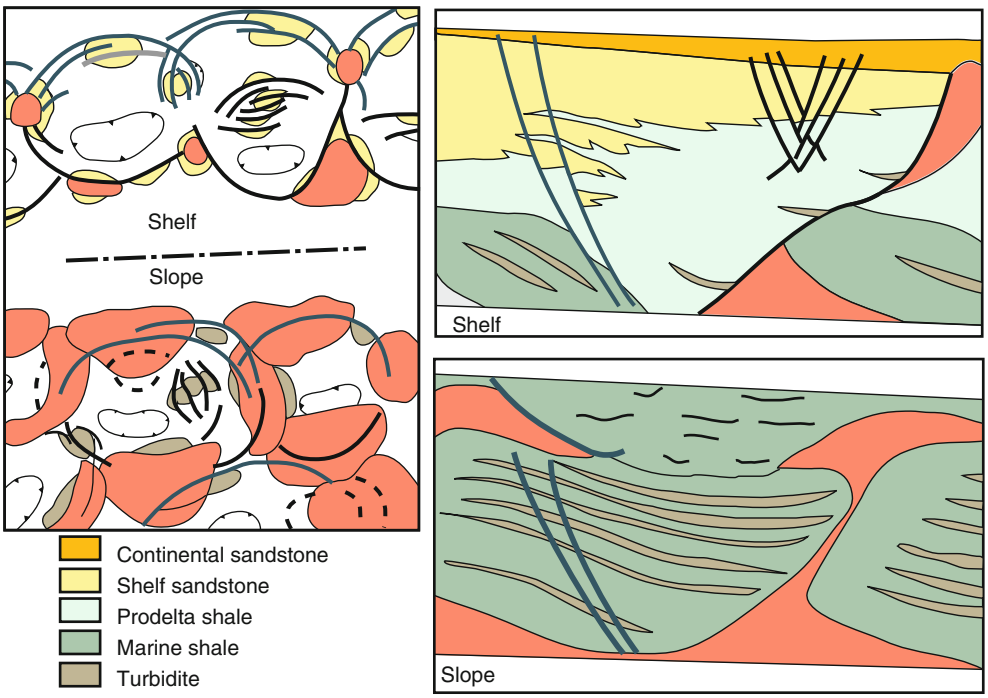

Fig. 10.64 Model of reservoir styles showing distribution of subsalt traps in both shelf and deepwater minibasin (primary basin) settings (After Karlo and Shoup 2000)

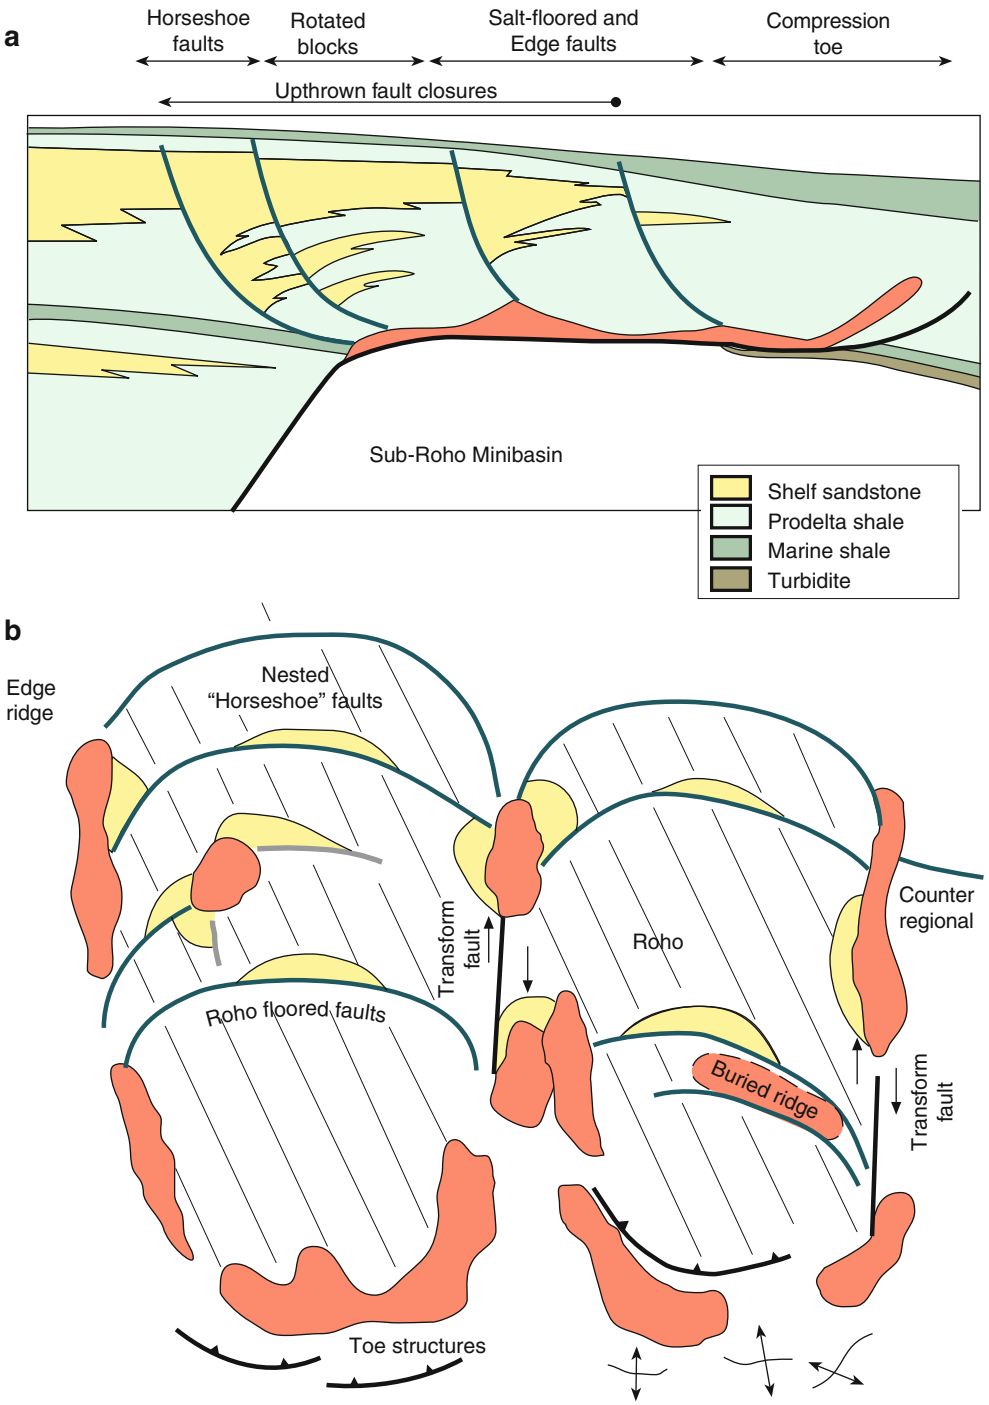

Fig. 10.65 Model of reservoir styles showing distribution of Roho (suprasalt) traps in both shelf and deepwater minibasin (primary basin) settings (After Karlo and Shoup 2000)

grey in Fig. 10.66; Pilcher et al. 2011). Most primary basins that trap hydrocarbons are encased entirely in salt or in some combination of salt and welds (Fig. 10.66c). Pilcher et al. (2011) notes most petroleum exploration in the deep-water Gulf of Mexico is currently focused on primary basin targets and increasingly those at their lateral boundaries. However, as these boundaries are usually poorly imaged, robust structural models are critical to interpretation of their evolution and relative petroleum system risk.

Using three-dimensional seismic data, Pilcher et al. (2011) define three tectonostratigraphic provinces that characterize primary basin depocenters: (1) a disconnected salt-stock-canopy province in Mississippi Canyon; (2) an amalgamated salt-stock-canopy province in northern Atwater Valley,

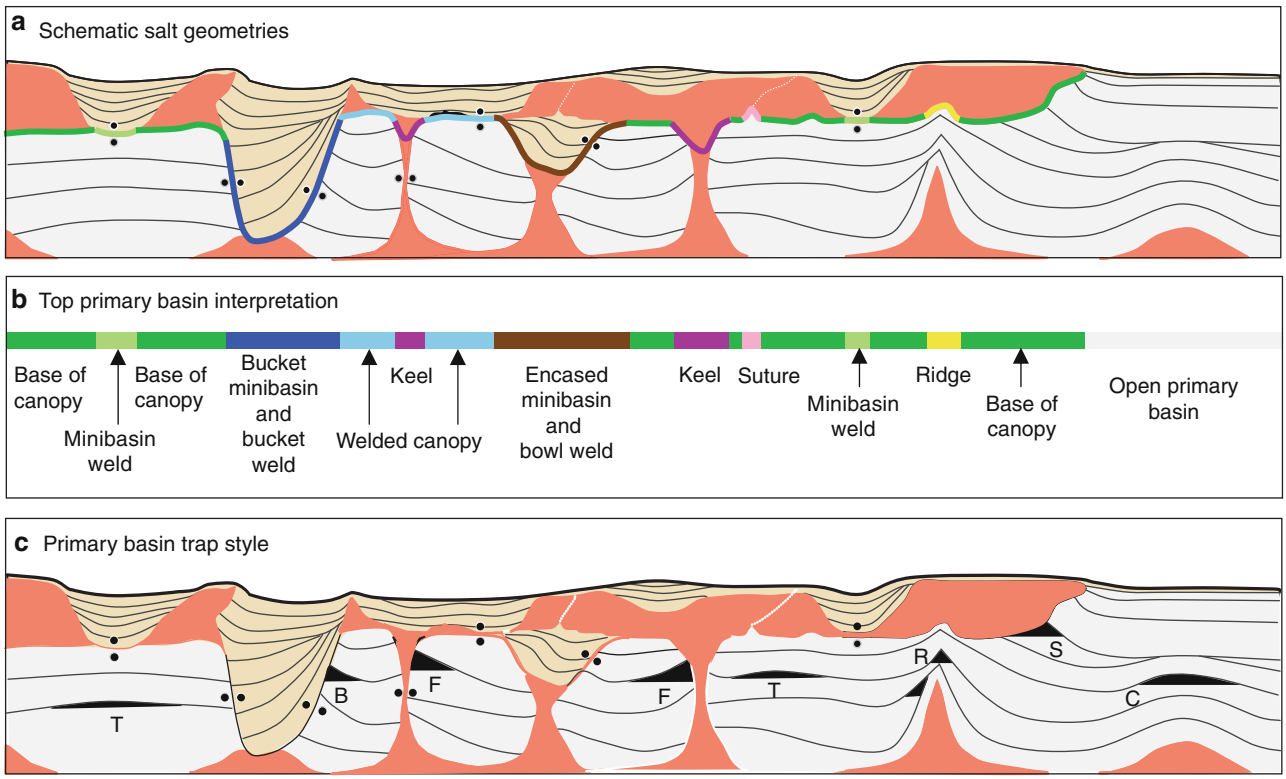

Fig. 10.66 Schematic representation of salt-related geometries in the deep-water Gulf of Mexico (After Pilcher et al. 2011). (**a**) Interpretation of top primary basin surface and distinction between primary and secondary basins. Salt is red, primary basins are gray, secondary basins are brown, and welds are indicated by paired *black dots*. (**b**) Classification of the top primary basin surface according to the nature of the surface. This classification allows primary basin bounding features such as feeders, ridges, and bucket welds to be mapped. (**c**) Schematic salt geometry highlighting primary basin trap types: turtle structure (*T*), bucket weld (*B*), salt feeder (*F*), salt ridge (*R*), base-of-salt truncation (*S*), and salt cored fold (*C*)

southeastern Green Canyon, Walker Ridge, and southern Keathley Canyon; and (3) a bucket-weld province in western Green Canyon, Garden Banks, and northern Keathley Canyon. They recognize six trap types in the primary basins (Fig. 10.66c): (1) autochthonous salt-cored folds, (2) turtle structures, (3) base-of-salt truncations, (4) salt feeders, (5) salt ridges, and (6) bucket welds. Most primary basin explorations to date have targeted traps in one of the first four styles. Future primary basin exploration will increasingly focus on the traps formed by bucket welds and salt-cored ridges. The contrasting evolution of these features has implications for reservoir continuity, charge access, and trap configuration. Of primary basin boundary trap types, salt feeders have the lowest petroleum system risk followed by bucket welds, with salt-cored ridges having the highest risk.

Intrasalt Halokinetic Plays

Known salt-associated reservoir distribution in the Gulf of Mexico is external to the salt mass, typically in subsalt or suprasalt positions in what is a tiered salt stratigraphy (Fig. 10.66) but there are a few situations worldwide where economic accumulations of hydrocarbons are trapped as intrasalt or salt-encased reservoirs. Usually the permeability of such accumulations is low and volumes of producible hydrocarbons are sub-economic. But, bedded masses of carbonate and porcellanite (silicilyte) in Infracambrian salt in the South Oman Salt Basin Oman are currently in production, extracting hydrocarbons from stringers (aka slivers) suspended in Infracambrian Ara Salt of the Huqf Supergroup (Fig. 10.67). The chronostratigraphic nomenclature of Oman is summarized in (Fig. 10.68).

Across the various Oman salt basins, wherever the Ara salt seal is breached, the Neoproterozoic organic-rich evaporitic sediments of the Huqf Supergroup have sourced most of the oil and gas stored in halokinetically structured suprasalt Phanerozoic reservoir sands in the Ghaba and Fahud salt basins (Fig. 10.67a; Terken et al. 2001) Likewise there is a concentration of large fields in Permian-age clastics along the dissolution edge (Eastern Flank) of the South Oman Salt Basin (Fig. 10.8b). Diapirs crop out across the Ghaba Salt Basin, while there are no such suprasalt diapir outcrops in the South Oman Salt Basin (Peters et al. 2003; Reuning et al. 2009). This distribution is a reflection of the migration pathways that

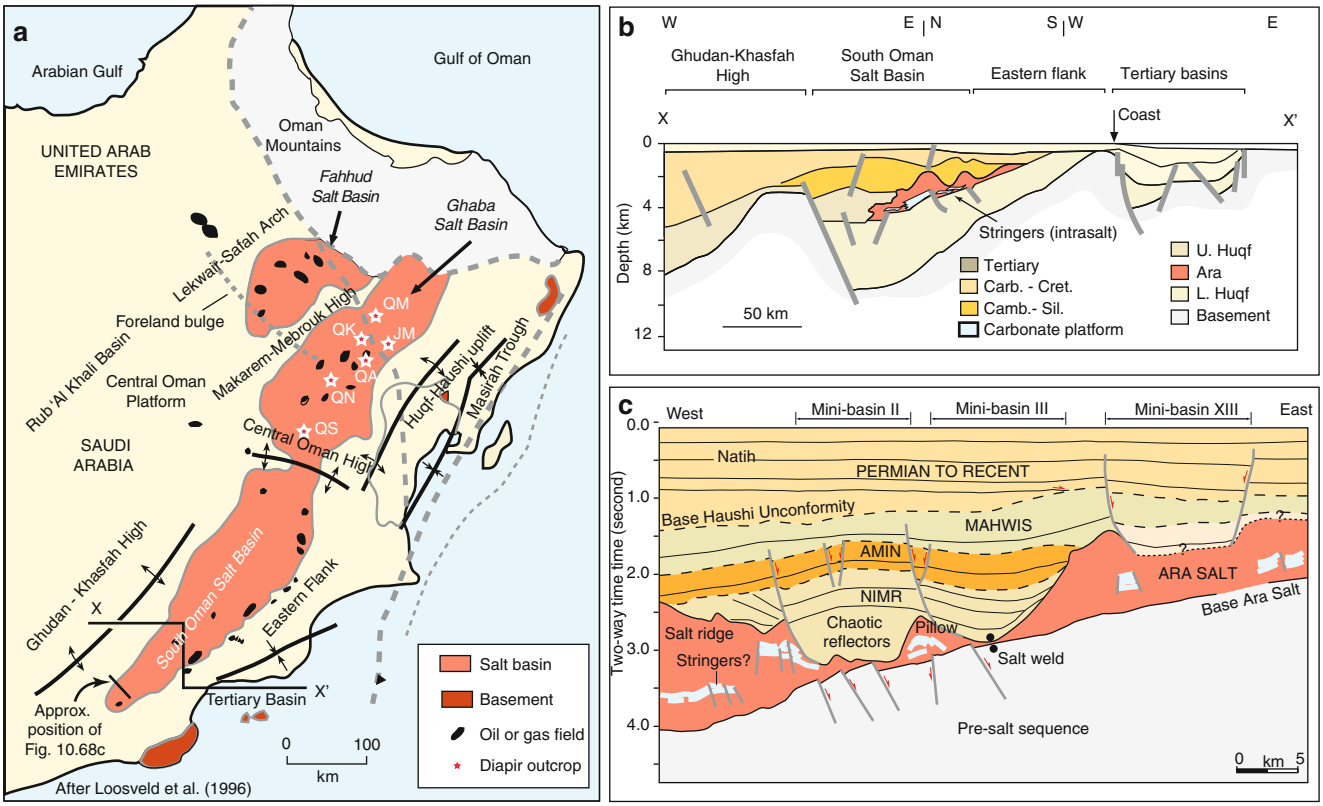

Fig. 10.67 Salt Basins of Oman. (**a**) Map view of three main salt basins. Palaeozoic strata capping the Ghaba Salt Basin and along the eastern flank of the South Oman Salt Basin are the main oil and gas producers, not Neoproterozoic platform carbonates or Athel Fm. silicilyte slivers, which host stringer reservoirs more toward the centre of the South Oman Salt Basin. Location of the six surface-piercing salt domes in the Ghaba Salt Basin (indicated by *star*) are: Qarn Sahmah (*QS*), Qarat Kibrit (*QK*), Qarat Al Milh (*QM*), Qarn Nihayda (*QN*), Qarn Alam (*QA*) and Jebel Majayiz (*JM*). (**b**) Cross section (X – X′) through the South Oman Salt Basin, schematically showing position of carbonate platform and stringers in the Ara Salt (After Loosveld et al. 1996 and Schröder et al. 2000a, b). (**c**) Section (seismic overlay) showing interrelationship between overburden loading (minibasins II, III and XIII) and distribution of carbonate reservoir stringers within the halokinetic Ara salt (After Al-Barwani and McClay 2008)

defines the two separate distribution styles of Phanerozoic age reservoirs in the two salt basins, Hydrocarbons in both basins were sourced in the Infracambrian Huqf Supergroup with generation from this ancient source rock beginning in the middle of the Cretaceous period (Fig. 10.8b; Terken et al. 2001).

Ara Group Intrasalt Reservoirs, Oman

The Neoproterozoic/Early Palaeozoic Ara-Group that hosts the various stringer reservoirs (carbonate and silicilyte) is the terminal subdivision of the Huqf-Supergroup of Oman (Fig. 10.68). Deposition of the Huqf spanned several tens of millions of years during the Vendian (Neoproterozoic) and early Cambrian and included deposition of the Ara Group salts. The Ara Group evaporites are a part of a broader penecontemporaneous Hormuz-Ara halite-hydrocarbon association that extended across the Middle East as a series of Neoproterozoic-Cambrian salt basins. Thick, variably halokinetic salt successions of this age occur in Oman (Ara salt in the South Oman, Ghudun, Ghaba and Fahud salt basins), in eastern Arabia and southern Iran (as the Hormuz salt in the Gulf Basins), in the Kerman region of Iran (Ravar Fm.) and across into NW India and Pakistan (Salt Range Fm.). Most of the salt bodies about the margins of these various salt basins show evidence of dissolution and salt flow-related withdrawal, suggesting that salt extent at the time the basins were actively accumulating halite was more widespread than it is today. All these basins constitute a series of basinwide evaporites precipitated in marine-fed seepage depressions or foreland sags created by the docking of continental masses at major subduction sutures. These systems were actively accumulating evaporites in regions of continental margin subduction that were tied to zones of active volcanism (Much like the Mediterranean in the Messinian and the Red Sea in the Middle Miocene). That there was an active volcanic influence at the time that Ara and Hormuz salt was accumulating is further evidenced by blocks of intrasalt rhyolitic volcanics and stringers in diapir outcrops in the Ghaba Salt basin (Fig. 10.67a; Reuning et al. 2009).

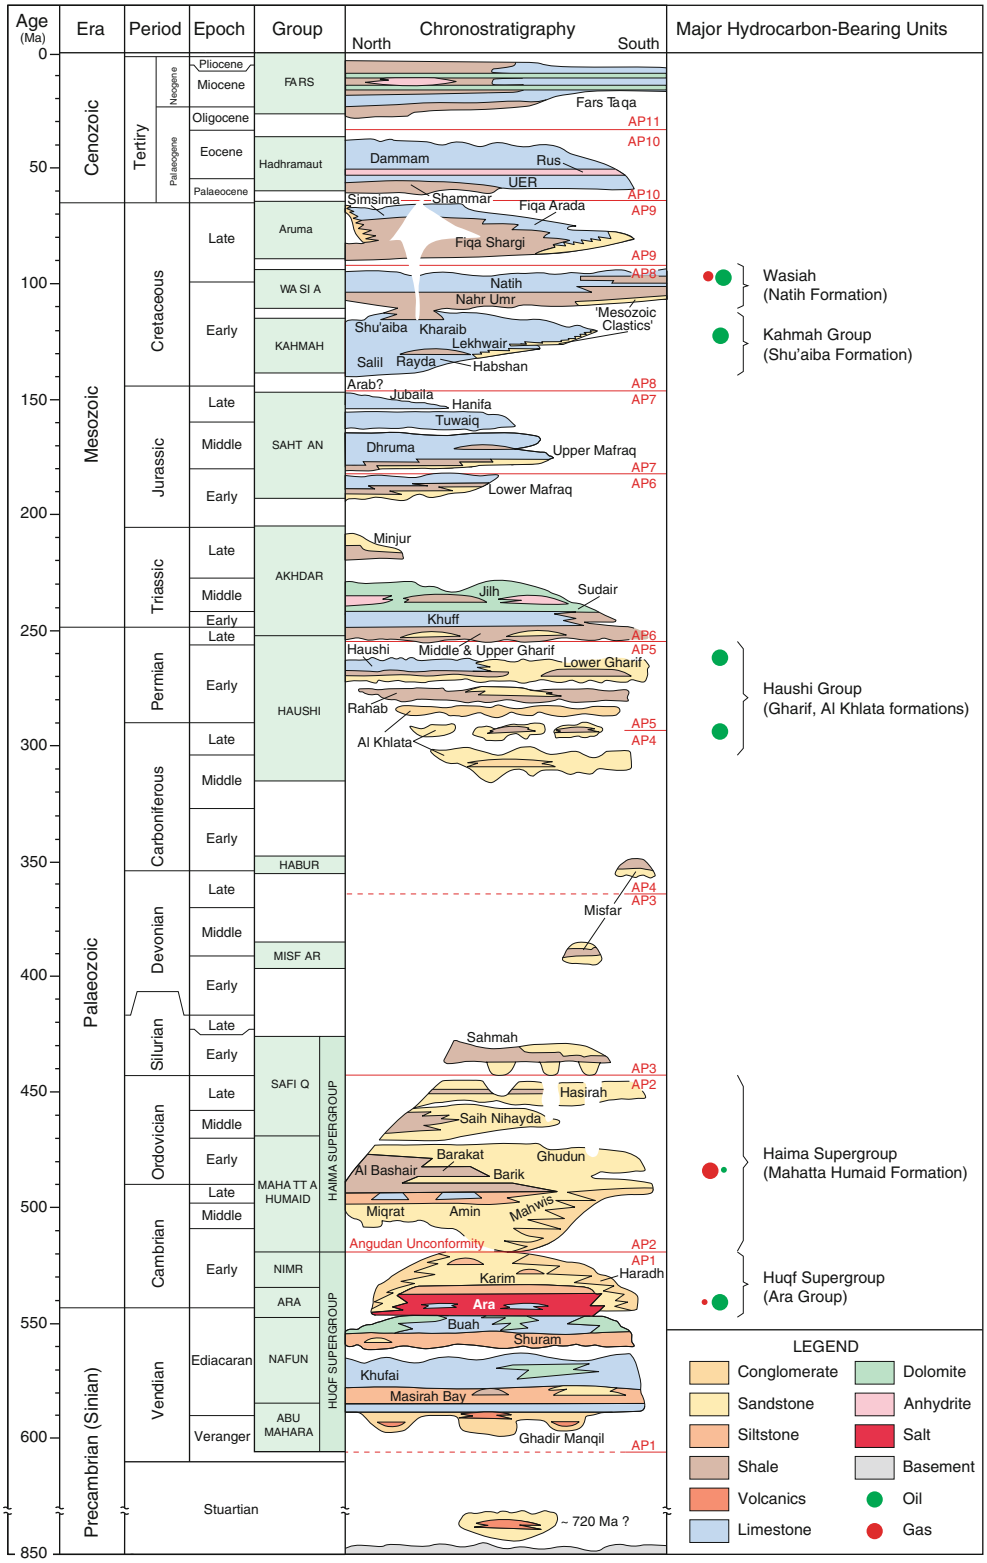

Fig. 10.68 Stratigraphy of Oman (After Sharland et al. 2001)

Carbonate Stringer Reservoirs in the South Oman Salt Basin

Depositional cycles within the Ara Group tend to be lithologically symmetric, with thick dolomitised carbonate platforms sandwiched between anhydrite, halite, and some thin intervals of potash salts. The Ara Group platform successions in the South Oman Salt Basin are conventionally broken down into five to six 3rd-order carbonate-evaporite cycles (Fig. 10.70; Schoenherr et al. 2007a, b, c; Schröder et al. 2000a, b, 2003, 2005; Gorin et al. 1982). Each depositional cycle starts with an erosion base often atop a dissolution breccia atop the salts of the previous cycle follow by variably dolomitised shelf carbonates (now somewhat disaggregated by halokinesis into salt-encased stringers with variable porosity) passing laterally and vertically in saltern anhydrites and up into halite at the top of the cycles. In parts of the Ara basin fill, the halite layers in cores collected between carbonate layers preserve aligned chevron depositional textures, while elsewhere thicker halite layers show widespread evidence of saltflow textures typified by pervasive biaxial flattened crystals and local stress-free mosaic (pers. obs.).

The regional subdivision of the South Oman Salt basin at a time of relative highstand in the various depositional cycles when carbonate deposition dominated is illustrated in Fig. 10.69. At that time the basin consisted of thrombolite-rimmed north and south carbonate platforms separated by a zone of deeper water carbonates or porcellanites (Fig. 10.69b). Better quality reservoirs tend be associated with the platform edges, but much of the original poroperm distribution has been strongly altered by a combination of dolomitisation, over-dolomitisation and variable intensities of pore fill by halite cement (Schoenherr et al. 2009). The stratigraphy of the stacked cycles defines what is a typical marine-fed intracontinental sag basinwide evaporite. In each cycle the carbonate is interpreted as representing the less saline highstand stage flood of the basin sump, with the subsequent progradation of a carbonate ramp prior to a basinwide episode of sulphate then halite-dominant evaporite fill. Today all the cored sulphate in the South Oman Salt Basin is platform anhydrite that is tied to the platform interior cycle, but it retains pseudomorphs after selenitic gypsum, showing it was originally deposited as a gypsum saltern atop thrombolite-rimmed platforms (Schröder et al. 2003).

Internally, the various carbonate and sulphate facies of the undeformed platform blocks are simple to interpret depositionally. Energy related facies developed in different water depths in an into-the-basin deepening ramp system, within what was an intracratonic rift or sag (Fig. 10.69b). Salt layers in the Ara Group are roughly time equivalent to cycles in the Hormuz Formation to the north (Schröder et al. 2003; Sharland et al. 2001). Finely laminated organic-rich dolomites and some thrombolite buildups of the carbonate platform facies occupied an outer to middle ramp setting, typified by lower energies and outcrop at the margins of the basin. Further out in the current basin they are overlain by shallow water platform mudstones, packstones, and evaporites (Fig. 10.69b).

I do not consider the Ara carbonate platforms, with thrombolites and stromatolites interlayered with salts, as indicators of an open-marine surface hydrographic connection to the ocean. Rather the thrombolites and stromatolites in the Ara stringers of the SOSB indicate times when an intrabasin drawndown water body possessed salinities suitable for the growth of marine-seepage-fed halotolerant biota (stromatolites and thrombolites). Thrombolites and stromatolites were widespread in marine waters of the early Cambrian marine waters of Namibia (Grotzinger et al. 2005), and this is the analog typically used for the Ara thrombolites. But, as we know from modern and Messinian and Silurian evaporite analogs the thrombolite/stromatolite association is not specific to open marine conditions (Chaps. 1, 4, and 5). Rather, throughout the Phanerozoic, the thrombolite-stromatolite association in evaporite basins (especially when interlayered with basinwide salts) is specific to episodes of microbial growth in the upper euphotic portions of salinity-stratified water masses. In this setting thrombolite capstones indicate times and places where basin salinity hovered around marine-like levels. The distinction is significant as it explains a lack of marine time equivalents to the Ara Group strata that would otherwise indicate a linkage and tie to succession to a worldwide eustatic curve. Ara Group thrombolite build-ups show more depositional affinity with subsalt lacustrine reservoir facies the typify the south Atlantic Aptian salt basins rather than any open-marine facies.

In evaporite basins the occurrence of salt-encased thrombolites and stromatolites does not indicate a time of a surface connection to the ocean, but relative intrabasin highstands with thrombolite mounds growing on water covered topographic highs (with positions controlled by the draping of underlying topographic highs). In the Silurian and Messinian the thrombolite stage indicates the onset of drawdown and the loss of a surface or hydrographic connection to the ocean. Today, in evaporitic waters, conditions where thrombolites flourish and come to dominate the halotolerant biota are typically in saline schizohaline lacustrine settings (e. g. Lake Clifton and Sleaford Mere in Australia) and not open marine settings. At times of restriction onset, healthy thrombolites and stromatolite populations flourished in the Messinian (Late Miocene) intrabasin highstands has seen during marine to evaporitic marine-seepage carbonate transitions into the various halite/gypsum-filled basins of Spain and Sicily. Likewise, stromatolites and thrombolites are growing today in a number of hydrographically isolated Holocene marine-seepage basin in southern and western Australia.

Conceptually, it is important to recognise that within the drawndown evaporite basin stage that defines Ara Group sedimentation, the Ara platform carbonates grew during episodes of higher relative water levels in the drawndown basin, when the waters atop the basinwide halocline were less saline. In contrast, thick Ara halites beds typify times of the lowest water

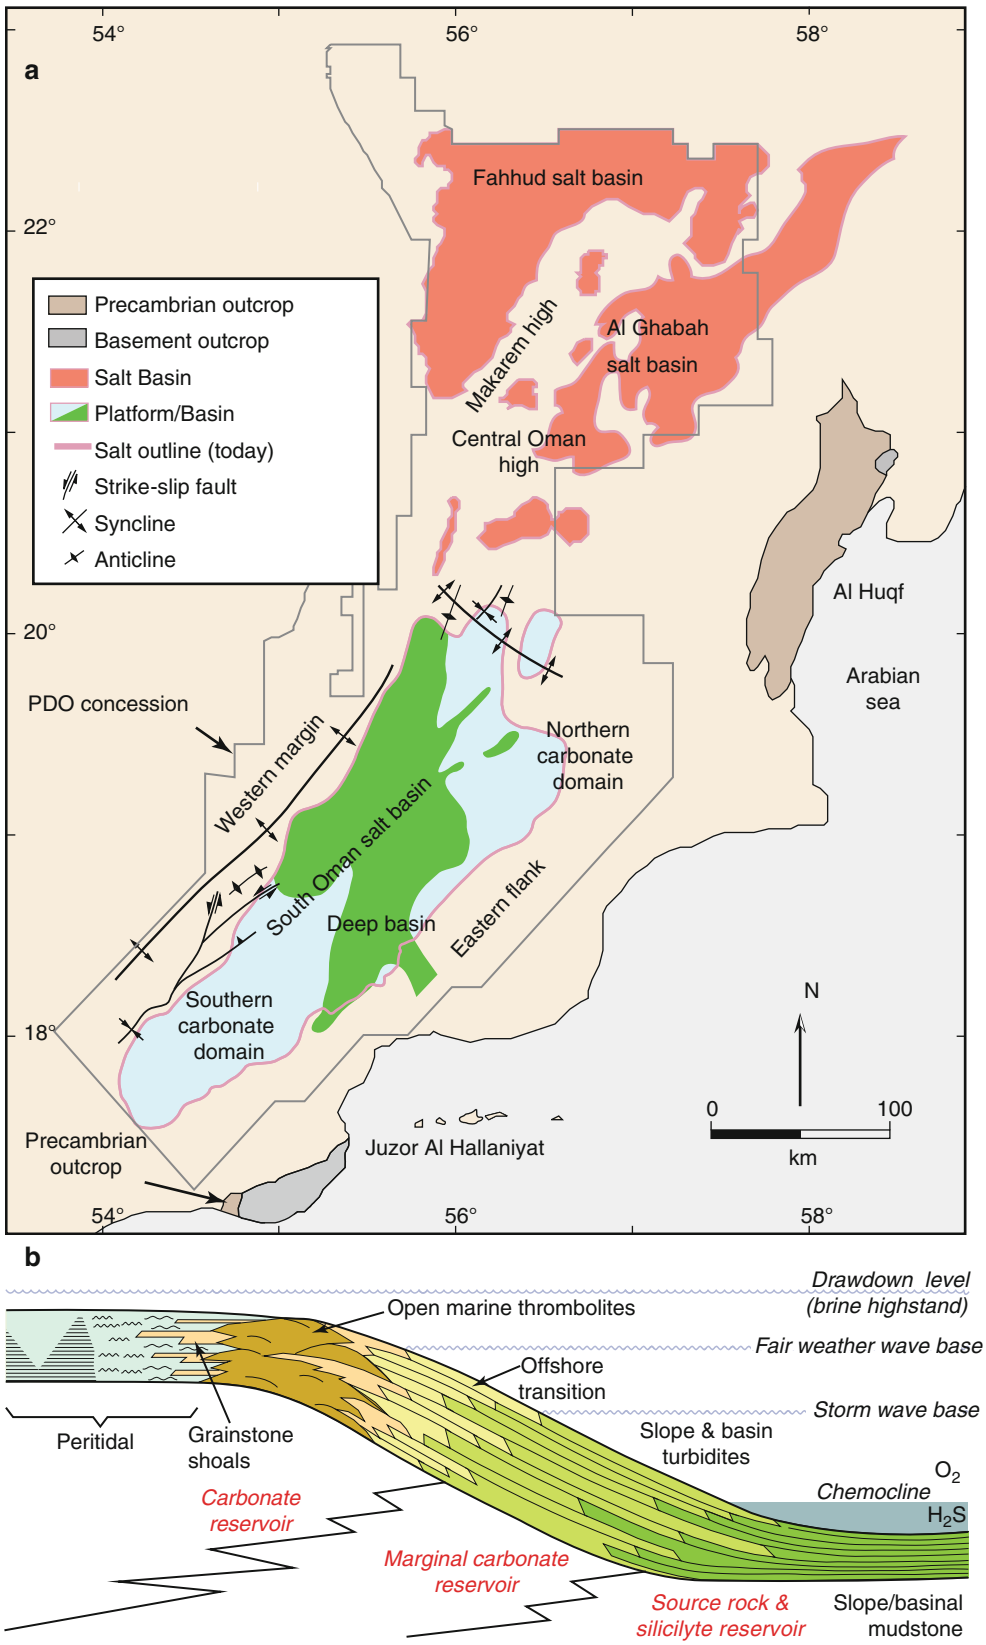

Fig. 10.69 Geology of the South Oman Salt Basin. (**a**) Distribution of the main depositional and tectonic elements. At the times of relative highstand in the deposition of the lower parts of the sequence cycles (illustration for cycle A3/4) the basin can be subdivided into two main carbonate platforms and a central deeper basinal section, where bacterial porcellanites (silicilytes) accumulated (After Al-Siyabi 2005). (**b**) Schematic showing facies distribution of an Ara carbonate platform and basin with interpreted reservoir and source rock occurrences during a relative highstand (fresher) in the drawndown South Oman Salt Basin at a time when thrombolite buildups were flourishing (After Al-Siyabi 2005). Later encased by "fill and spill" halite

levels in the basin, when basin sump water columns were holomictic and saturated, while anhydritic platforms define intermediary brine levels with basinwide anhydrite deposition requiring holomictic waters at $CaSO_4$ saturations (Chap. 5). This oscillating drawdown (fill and spill) hydrology has significant implications in terms of salt plugging of the carbonate stringer reservoirs and the timing of the synprecipitational dissolution breccias, which occur in the various cored Ara carbonate sequences and their outcrop equivalents (pers. obs.).

Even as each cycle was forming, earlier Ara halite-rich evaporite sections, laid down across this large drawdown basin, were exposed about the same basin edges by ongoing drawdown and lowering of the brine level. In these exposed areas intra-stringer halite was being recycled into the brine sumps to form a thicker purer cleaner halite that typifies the mostly halokinetic Al Noor Formation halites (Fig. 10.70). This purer cleaner halite unit is was loaded and deformed by the deposition of the Nimr-Mahwis succession (Fig. 10.67c) Prior to its deformation and edge dissolution the halite once extended all the way across the South Oman Salt Basin and probably beyond. It was thickest in the regions of the Waad and Waghald Basins, which were minibasin lows at the time the halite was accumulating (see silicilyte discussion). They were longterm brine sumps with positions controlled by an earlier basin topography inherited from Buah time. Widespread halite deposition slowed at the top of Birba Formation and so the background volcanism, which had periodically supplied epiclastic fine-grained sediments and tuffaceous ash layers throughout the precipitation of the Birba Formation came to dominate the depositional signature atop this salt. This was the time when the U shale and the Theleilat Formations were deposited in what were still saline, perhaps stratified, basinal successions within the intracratonic sump. Previously, this background volcanogenic sedimentation across the region had been swamped by the high rates of sedimentation associated with evaporite deposition. Much of the halite texture and geometry in the overlying Al Noor Formation halite is dominated by halokinetic textures induced by a combination of salt flow, sediment loading and salt dissolution.

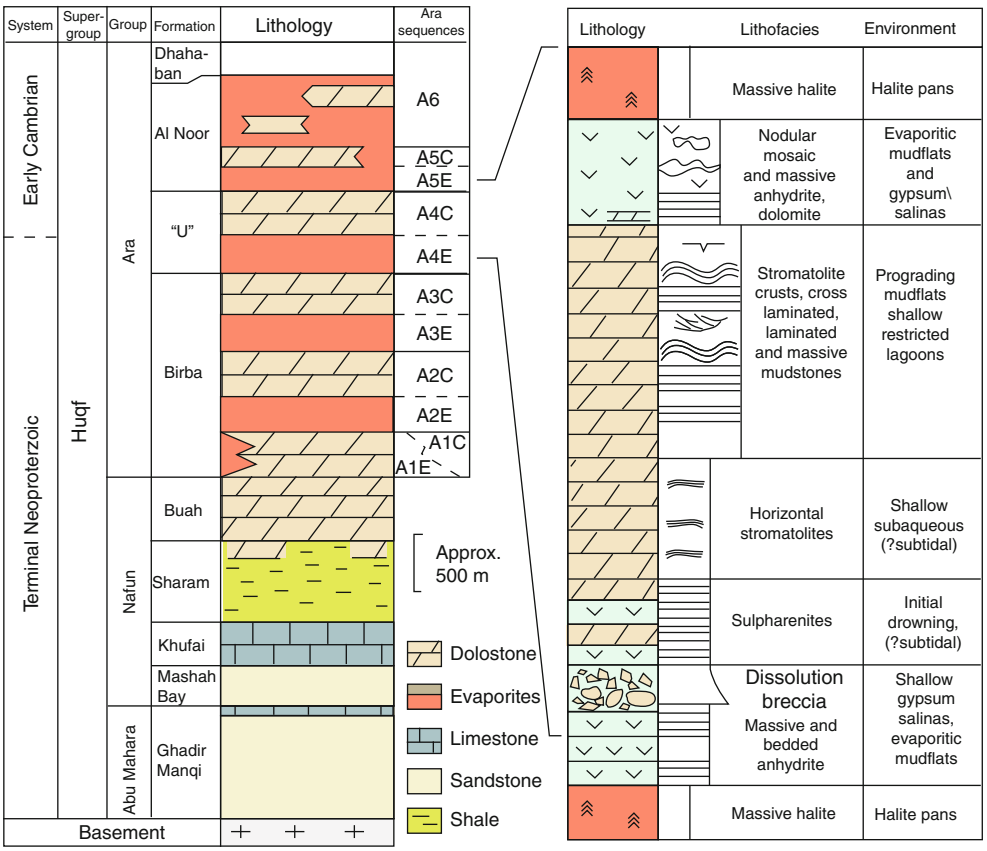

Fig. 10.70 Typical Ara carbonate platform cycle (A4) in the Neoproterozoic Ara Formation of the South Oman Salt Basin. Further out in the now chaotic central parts of the basin, some consider the Athel Silicilyte was originally deposited as a time-equivalent to the A4 carbonate, others argue that prior to halokinesis the silicilyte once lay immediately atop the unconformity capping the A3 carbonate (more likely). It can even be argued that in the original basin centre stratigraphy, prior to halokinesis, there was more than one level of mesohaline silicilyte deposition. This quandary could perhaps be resolved by more detailed determinations of basinwide versus platform evaporite signatures using wirelines and cores from across the basin (After Schröder et al. 2003, 2005) See also Fig. 10.69

In concert with the chevron textures preserved in the halite interlayers of the Birba formations (where salt has not flowed) there are well-preserved sedimentary structures (e.g. palmate gypsum morphologies and desiccation cracks) in the anhydrite layers of the Birba Formation cycles that suggest a shallow (<5 m deep) subaqueous environment for the various carbonate-sulphate platform cycles (Schröder et al. 2005). Sabkha deposits represent only a minor fraction of the total salt sulphate in each Birba cycle. Following times of basinwide saltern sulphate accumulation, brine depths shallowed further and thick beds of basin centre halite precipitated, along with rare thin beds containing rare potash salt cements. These beds rapidly aggraded to cover and seal the carbonate/sulphate platform. Bromine geochemistry in the halite beds show a consistent range of values between 40 and 150 ppm (Fig. 10.71; Schoenherr et al. 2009). The Br values likely indicate a first-cycle marine source to seepage brines precipitating the various Ara halite cycles, with some minor contributions from continental and/or hydrothermal waters. Interestingly the associated halite cements in the intervening carbonate layers are higher. This is indicative of the fact reservoir quality is not typically tied to depositional facies in the various Ara carbonate cycles. Rather reservoir quality is typically tied to varying intensities of dolomitisation and halite cementation (Fig. 10.72).

When porosity and permeability is tied back to position in the various carbonate layers it is immediately obvious that pore occluding halite cement is a major control on porosity and permeability, the other is dolomitisation (Fig. 10.72) The well permeability profile illustrated in Fig. 10.73 is typical of many of the low permeability wells that typify the Birba cycle carbonate layers and clearly shows the detrimental influence halite plugging on reservoir quality. In such low permeability wells the thrombolite and grainstone units tend to retain little or no permeability across zones of halite plugging. Locally there are zones of corrasion and this enhances porosity as seen in the high permeability spikes. Earlier work in the early 2000s tended to ignore the influence of halite cements and focused more on dolomitisation intensity and style. Dolomitisation is certainly another influence on reservoir quality and is vital in wells that lack halite cements However, when both these diagenetic factors are present, dolomitisation style is secondary to the degree of salt plugging. In almost all wells depositional porosity is lacking (Figs. 10.72 and 10.73)

There are two stages of dolomitisation in most carbonate layers and a later stage of post-dolomite corrasion (Fig. 10.72). The earlier episode of dolomite formation is related to brine reflux and the second to subsequent burial. Brine reflux dolomites tend to finely crystalline and mimetic. Later dolomites tend to be more coarsely crystalline. The separation of the two dolomite styles into earlier (somewhat

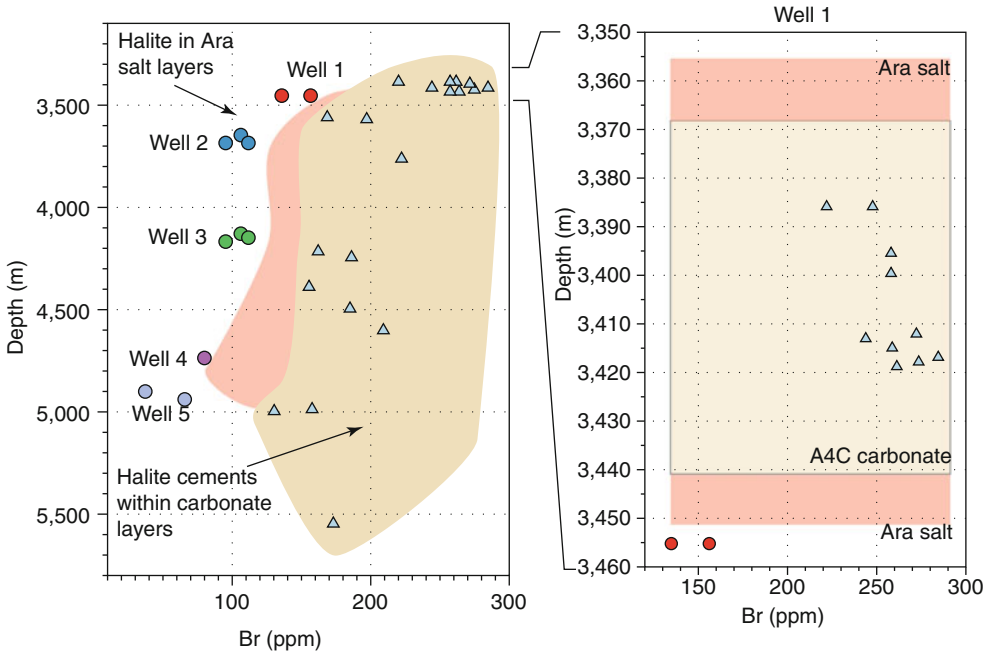

Fig. 10.71 Bromine values in the Ara Group. (**a**) Distribution of Br contents in pure Ara salt intervals and halite cements in various Ara carbonate stringers with depth showing most Br contents of the pure Ara salt (*red field*) are markedly below the Br values of the halite cements in associated carbonate stringers (*brown field*). (**b**) Detail of Well 1 values clearly showing that Br content of halite cements in the carbonate stringer A4C are some 150 ppm higher than Br contents of the underlying Ara salt. The two stratigraphically uppermost cement data points are from one halite vein. The remaining data points cluster around 260 ppm and are from early pore-cementing halites that degrade porosity in the carbonate bed (Replotted from values in Schoenherr et al. 2009)

lower temperatures) and later (warmer) diagenetic events is clearly seen in stable isotope C-O crossplots (Fig. 10.74). Finely crystalline dolomites dominate the matrix fraction while coarse dolomites tend to replace or encase the earlier finer crystals. The increasingly negative oxygen isotopes value seen in the dolomites indicates ongoing dolomite growth and replacement during increasingly warmer burial conditions (indicated by arrow in Fig. 10.73)

There is an interesting variation in the carbon isotope value plot field in a well that cored the A4C carbonate (Fig. 10.74-shaded region). Dating of associated ashfalls implies the A4C carbonate in this well straddles the Cambrian-Precambrian boundary (Al-Husseini et al. 2003; Amthor et al. 2003). A short-lived negative excursion in the carbon isotope composition of seawater is globally coincident with the Precambrian-Cambrian boundary. It is thought to indicate a mass extinction event within Terminal Proterozoic ecosystems at or very near the Precambrian boundary. This A4C carbonate interval is one of the few worldwide that preserves sediments across the Precambrian-Phanerozoic boundary. In A4C sediments below the isotope-defined boundary, the characteristic Proterozoic zone fossils *Cloudinia* and *Namacalathus* make their last appearance in the rock record.

Across much of the South Oman Salt Basin the Ara carbonate layers underwent a complex diagenetic evolution, typically with one stage of halite cementation occurring in a shallow (early) and another in a deeper (later) burial environment (Fig. 10.75). Early and late halite cements are defined by their microstructural relationship with a widespread pore-occluding solid bitumen phase. This bitumen phase includes locally abundant occurrences of the rare mineral whewellite ($CaC_2O_4.H_2O$). It is a known crystalline organic mineral, which can form as a low-temperature primary hydrothermal mineral in carbonate-sulphide veins, via oxidation of organic material in the surrounding rock. Whewellite typically shows an association with baryte, sphalerite, pyrite, bitumen and siderite in crosscutting veins (Fig. 10.75c).

The early phase of halite cementation is post-dated by this solid reservoir bitumen (with brecciated whewellite). This halite cement phase is most pervasive towards the top of carbonate stringers, where it plugs nearly all available porosity in facies with initially favourable poroperm characteristics (Figs. 10.73 and 10.75a, b). Bromine geochemistry reveals significantly higher bromine contents (up to 280 ppm) in the early halite compared with the late halite cement (173 ppm). Both intracarbonate halite cements show bromine values that

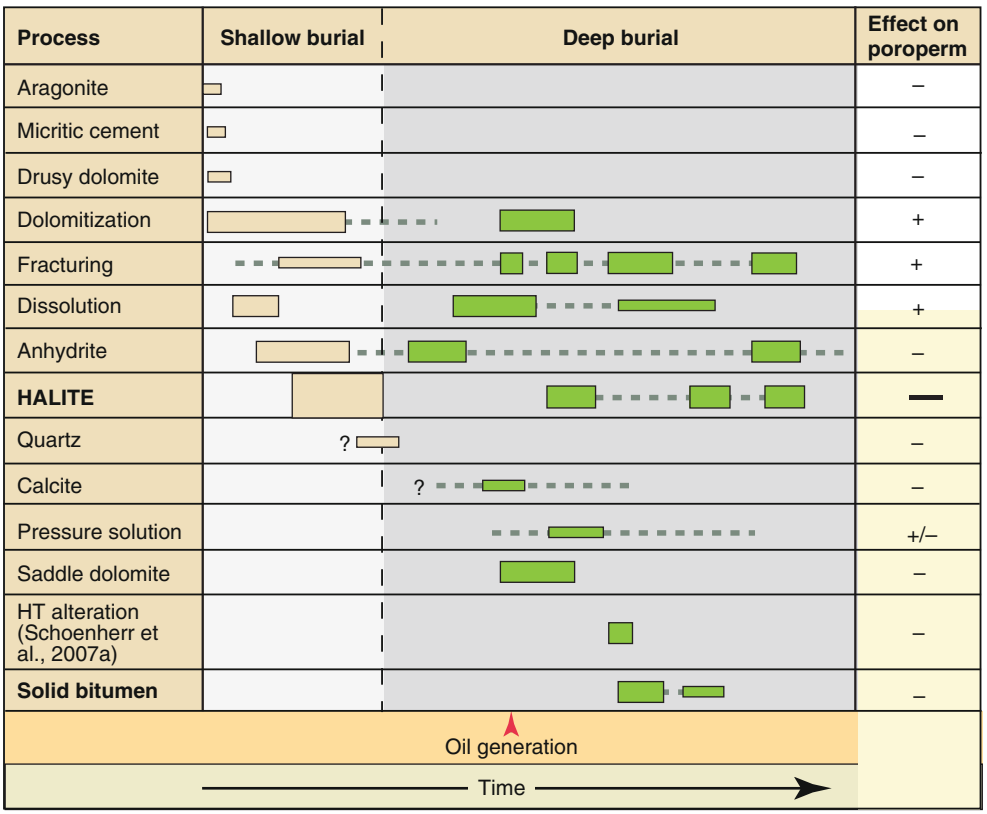

Fig. 10.72 Regional paragenetic sequence of reservoir quality controls in Ara stringer carbonates deduced from 190 samples from the A1C to A4C carbonate levels in 24 wells in the Greater Harweel and the Greater Birba Area (After Schoenherr et al. 2009). HT refers to hydrothermal alteration as described by Schoenherr et al. 2007a). *Thick coloured bars* indicate major diagenetic processes, *thin bars* indicate minor diagenetic processes; *dashed grey lines* indicate uncertainty of process duration. '+' denotes enhancement and '–' denotes degradation of the poroperm quality. Size of the symbol indicates relative importance in reservoir quality evolution

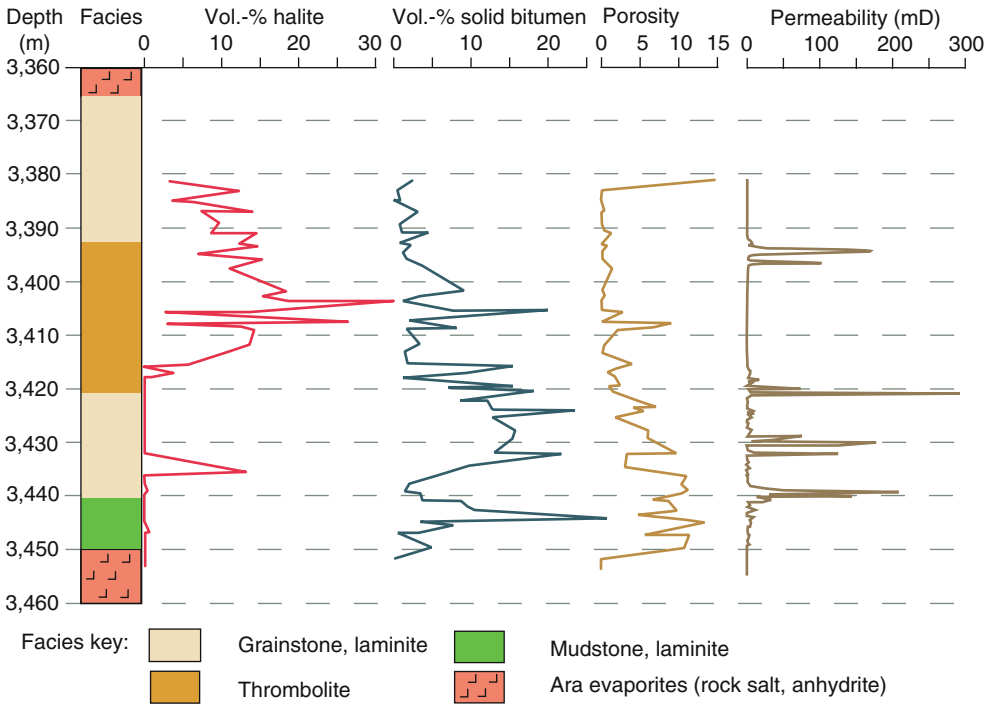

Fig. 10.73 Poroperm data and vertical distribution of halite and solid bitumen in the A1C cycle thrombolitic carbonate of a representative well. Core from 3,385 m is pervasively halite-cemented and also cross-cut by whewellite-cemented veins. Core from 3,399 m is a bitumen-cemented and halite-cemented thrombolite. Clearly, diagenesis related to the evaporite sealed and derived brines, play a significant role in the current reservoir quality. Depositional facies are secondary controls (After Schoenherr et al. 2009)

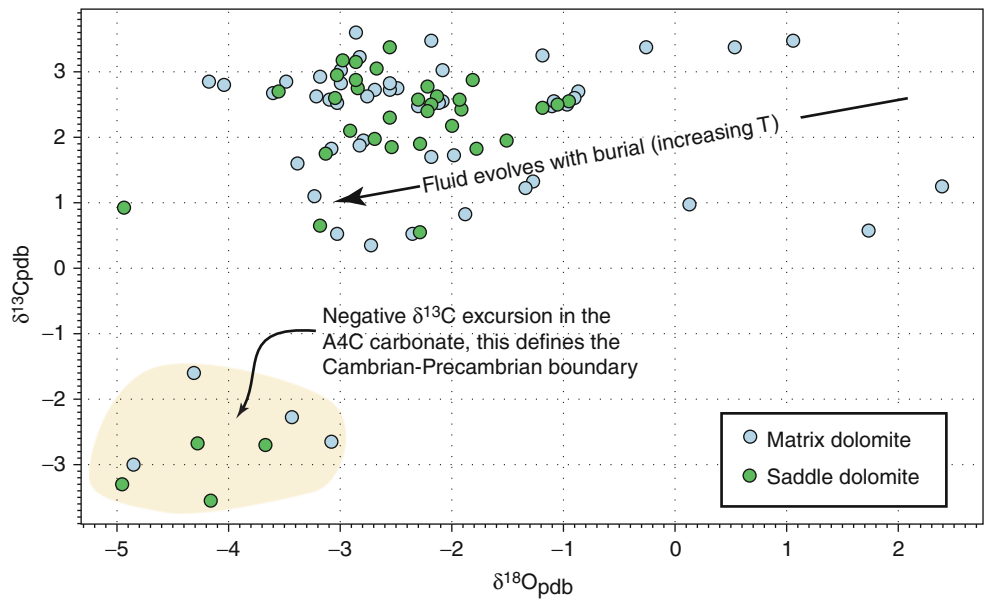

Fig. 10.74 Stable isotope data (covariant plot of $\delta^{18}O$ vs. $\delta\ ^{13}C$) in saddle and matrix dolomites from intra-salt Ara carbonate cycles. Shaded data within frame shows a shortlived negative $\delta^{13}C$ excursion in the A4C stringers at the Precambrian–Cambrian boundary (Replotted from Schoenherr et al. 2009)

are higher than the chevron halites preserves in the Ara Salt layers (Fig. 10.71).

The distribution patterns and the (high) bromine contents of early halite are consistent with precipitation caused by seepage reflux of highly saturated brines during deposition of the overlying rock salt interval (Fig. 10.75a). Later in burial history, relatively small quantities of early halite were dissolved locally and re-precipitated as indicated by inclusions of streaky solid bitumen within the late halite cements. Late halite cement also seals fractures, which show evidence for repeated reopening. Initially, these fractures formed during a period of hydrothermal activity and were later reopened

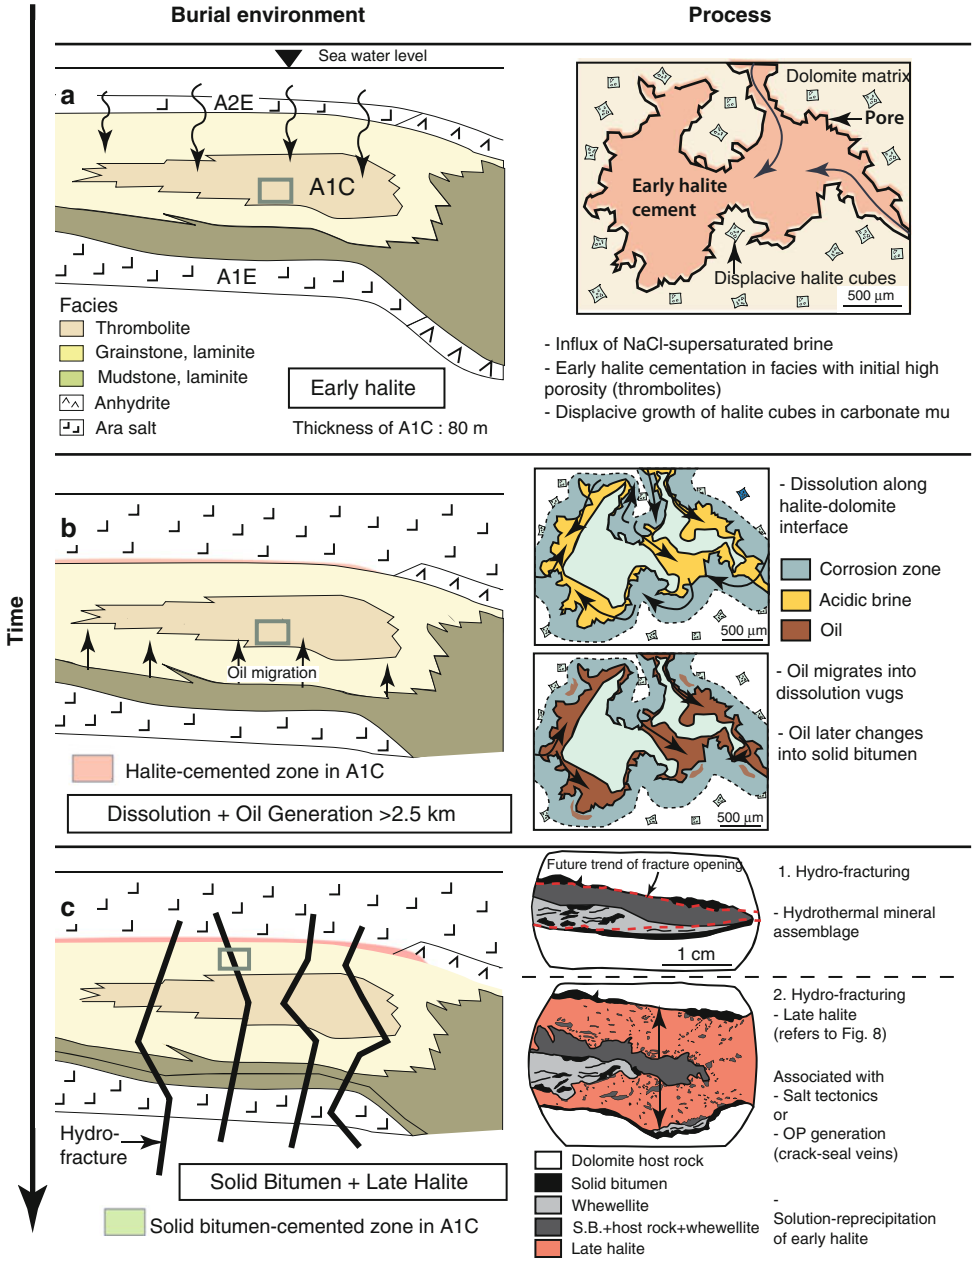

Fig. 10.75 Schematic illustrating the evolution of early and late halite cementation in the A1C stringer with time. Facies distribution of the A1C is adapted from Al-Siyabi (2005). Grey frames in burial environment of A to C represent corresponding micro-scale processes. (**a**) Early halite cementation in the A1C interval is due to infiltration of hypersaline brines, seeping from above during deposition of the overlying evaporite interval A2E. (**b**) This stage is marked by oil generation from the organic-rich mudstones and laminites. Because the upper part of the A1C was cemented by halite (*dashed zone*), oil migration is restricted to the lower portion. Oil migration was preceded by a 'roll front' of acidic brines which caused slight dissolution of the dolomite and the halite cements at their immediate contact. (**c**) The formation of fractures in the Ara Group was accompanied by strong overpressuring and the presence of hydrothermal fluids, causing solid bitumen formation. A second phase of overpressure (OP) build-up led to the formation of halite-cemented (crack-seal) veins

by a crack-seal mechanism caused by high fluid overpressures (Fig. 10.75b, c). Porosity plugging by early halite cements affects the poroperm characteristics of the Ara carbonates much more than the volumetrically less important late halite cement (Fig. 10.73). Schoenherr et al. (2009) argue that the formative processes and hydrologically controlled distribution patterns of halite cements in the South Oman Salt Basin can be generalized to other petroliferous evaporite drawdown basins.

In addition to the diagenetic complexity of carbonate reservoir pores, mostly occluded by early reflux halite cement spar, much of the halite in the Ara salt layers was variably recrystallised during halokinesis, especially in the halites of the Al Noor Formation in the Ara Group. Most of the deformation evident in the Ara Group has been taken up in intervals of flowing salt, rather than by internal deformation and folding of the platform carbonates and sulphate layers, which owing to greater mechanical strength tends to retain their integrity in the various stringers and blocks. Halokinetic salt also encases the silicilyte slivers or blocks in the more central portions of the South Oman Salt Basin and is why it is difficult to place the various slivers suspended in Ara salt into a depositional reconstruction of the basin (Fig. 10.67c). For example are the laminated organic-rich cherty slivers (Al Shomou Fm silicilytes that we discuss in the next section) still near their original somewhat deeper water depositional position in the basin palaeogeography, or have they slide tens of kilometres or more across the basin via salt-lubricated gravity gliding and raft tectonics? The latter scenario, which is likely, would create a more complex jumble of slithers with porosity distributions largely unrelated to current block orientations.

Athel (Al Shamou) Silicilyte Stringer Reservoirs

Intrasalt targets in the Athel Formation (Al Shomou silicilyte) represent one of the more complex deep oil exploration plays in onshore Oman and constitute a significant part of Petroleum Development Oman's undrilled prospect portfolio (Reinhardt et al. 1999; Peters et al. 2003). During the late 1970s to early 80s Petroleum Development Oman (PDO) drilled several significant oil and gas shows as intrasalt objectives within the more basinal parts of the Ara Salt of the South Oman Salt Basin, such as Marmul No. 7 (Fig. 10.76). These potential reservoirs were in porous (15–25 %), overpressured siliceous microlaminated sediments that were stratigraphically trapped and fully encased in halokinetic salt at depths of 3–4 km. Based on these intersections, the size of potential intrasalt pools was thought to be large, with individual slabs or slivers of possibly oil-saturated silicilyte seen in seismic to be up to 2×6 km across and more than 300 m thick (Amthor et al. 2005).

In 1989 and 1995, respectively, Al Noor and Al Shomou were drilled as two sliver prospects in the Athel Formation silicilyte (Figs. 10.76a and 10.77). The first two wells in the Al Noor Field encountered over 300 m of pay within low permeability fractured intervals that well tests showed had levels of 8–9 md/m. Reserves of 15.0×10^6 m^3 oil were calculated from these early intersections with an expectation of oil-in-place in the fields of up to 2 billion barrels (Wong et al. 2000). Oil recovered from the wells was attractive, although it was largely hosted in an unusual reservoir of microlaminated organic-rich chert or silicilyte, which contains up to 90 % microcrystalline silica and have a likely microbial source (Fig. 10.76b) Silicilyte is a general term for a fine-grained silica rock; porcellanite might be a more appropriate term as these cherts retain producible levels of microporosity. The chert was deposited at or near the Cambrian-Precambrian boundary (Ramseyer et al. 2013)

The produced oil is light (48° API) with a viscosity of 0.3–0.36 mPas^{-1} and a bubble point of 277 bar. The initial solution gas-oil-ratio was 400–550 m^3/m^3, with H_2S levels of 1.5 mol% and CO_2 levels of 3 mol%. It was recovered from wells with early flow rates of up to 8,800 bbls/day. Average well flow rates varied between 40 and 110 m^3/day prior to reservoir stimulation, post-stimulation figures have not been released. The silicilyte slivers define a play type worth pursuing, but a number of dry holes drilled after the initial successful wells defined inherent complexities with respect to reservoir quality prediction, hydrocarbon charge, production behaviour, and seismic imaging. Inherently high variability in the silicilyte permeability both vertically and laterally means successful future exploitation must involve targeted directional drilling and reservoir stimulation (Ramseyer et al. 2013).

The silicilyte play is an unusual basinal evaporite association, characterized by light and sour oil, hard overpressures and a high-porosity, low-permeability silica matrix (0.2–0.3 md) constituting a fine-grained microlaminated chert that is consistently rich in organic matter (Wong et al. 2000; Amthor et al. 1998; Amthor and Frewin 1999). Encasing halite has prevented hydrocarbon expulsion from the silicilyte, explaining inherently high formation pressures ≈19.8 kPa/m and high present-day oil saturations ≈65–90 %. The absence of oil expulsion is evident from Rock Eval data, which are characterized by high production indices. A good correlation between S_1 and the generative potential $S_1 + S_2$ suggests that hydrocarbons were indeed generated in situ and did not result from migration of hydrocarbons generated at deeper horizons. This also fits with the typical tight character of source rocks in style 1a basinwide evaporite settings (Chap. 9). As a source rock the Athel Formation silicilyte is also unique (Terken et al. 2001). Finely disseminated kerogen occupies up to 10 % of the rock volume, with a third of the organic matter concentrated in stylolites. Source rock extracts reflect the Infracambrian age of the formation, namely; light $\delta^{13}C_{PDB}$ of −37 to −35‰, a strong predominance of C29 over C28 steranes, and high 24-isopropyl/n-propyl

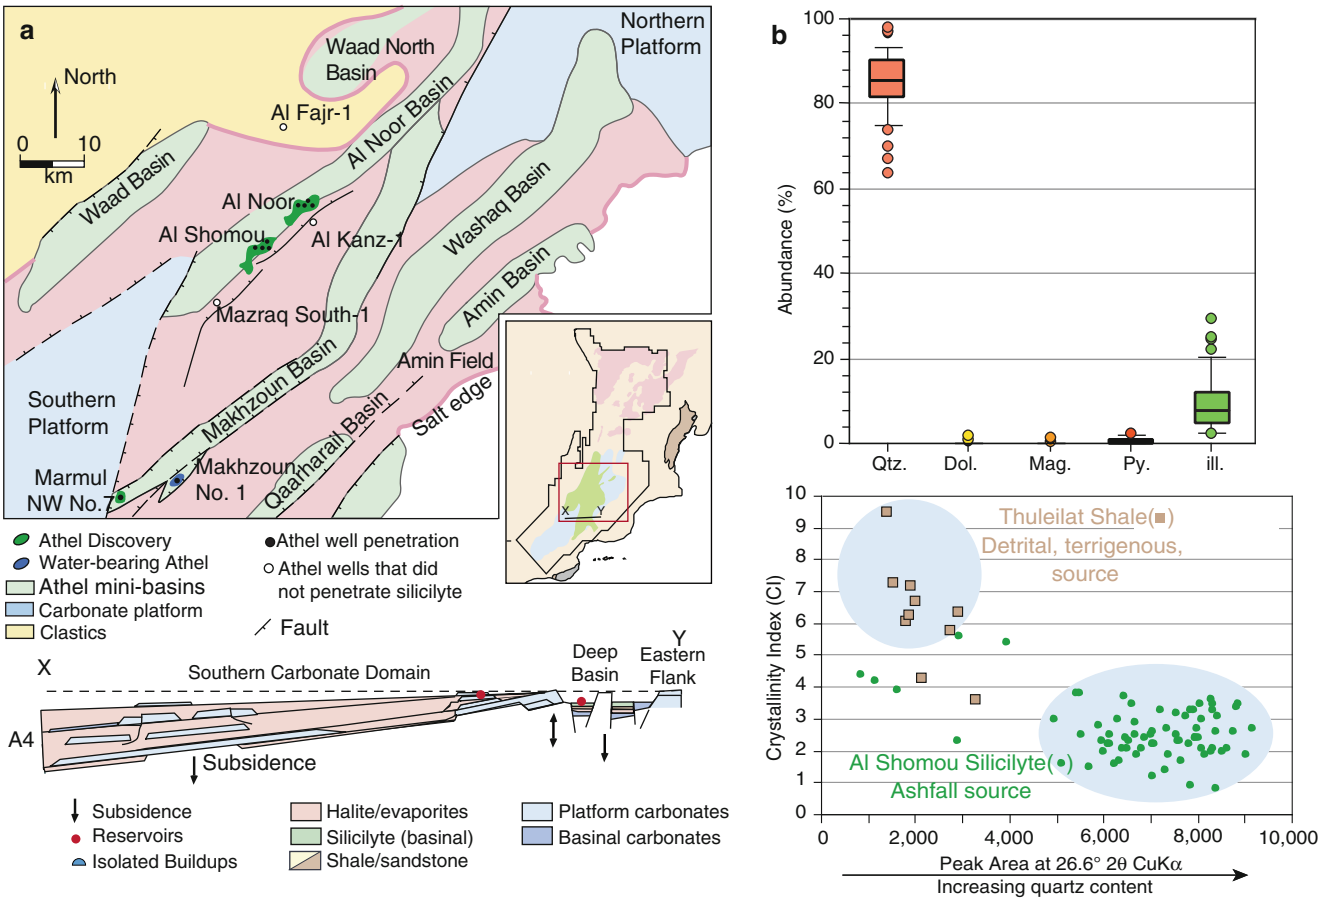

Fig. 10.76 Al Shomou (Athel) silicilyte. (**a**) Athel play map generated after drilling a number of unsuccessful penetrations illustrating the control of structural elements on the distribution of the Athel silicilyte in the SOSB. The occurrence of silicilyte in this model is restricted to lows between underlying Buah topographic highs which influence subsequent salt-cored seafloor topography. (**b**) Geochemistry of silicilyte showing X-ray determined mineralogical abundance and a crossplot of crystallinity index versus quartz content for samples from the Al Shomou Silicilyte and the Thuleilat Shale. Samples from the Thuleilat Shale have a higher crystallinity index and a lower concentration of quartz which is interpreted to reflect a higher detrital/authigenic ratio in the Thuleilat Shale (After Amthor et al. 2005)

cholestane ratios. The kinetic behaviour of the Athel is similar to that of the Miocene Monterey Formation, which, like the Athel, generates oil at low temperatures. Thin microfractures control production and much of the oil in fractures in this silicilyte reservoir is probably self-sourced from the adjacent matrix.

Varying thicknesses created by deep salt structures atop potential reservoir slivers, and the occurrence of reservoir slivers near the base of the thick halokinetic salt unit, has hampered reliable seismic positioning of these deep (>3,000 m) intrasalt reservoir objectives. Likewise, pressure transient tests in the intersected reservoir indicate an effective reservoir permeability that is one-tenth of that measured using cleaned core plugs (O'Dell 1998). The difference in well and plug determinations is likely caused by a combination of pressure-sealed fractures and the pervasive plugging effect of bitumen in the reservoir (bitumens are removed in standard plug preparation) Uncertainty in these and many other aspects of silicilyte understanding meant that until very recently the Athel Silicilyte or Al Shomou play was not pursued as a high value target within the PDO exploration portfolio. Improvements in seismic processing, targeted hydrofracturing, and geosteering technology, means it is possible to now pursue salt-encased permeable slivers as difficult but viable exploration targets.

Since the mid 2000s, wells in the two known silicilyte fields have been the successful subject of what was perhaps one of the largest fracture jobs in the region. PDO also instigated a number of detailed sedimentological and engineering studies to better understand what characterises reservoir versus nonreservoir associations in the silicilyte slivers (Ramseyer et al. 2013). Several factors are listed by Schröder et al. (2000b, 2003) as explaining the porosity dichotomy between Neoproterozoic platform carbonates and basin centre silicilytes:

- Downward circulation of saline brines caused mimetic dolomitisation and deterioration of reservoir characteristics in underlying platform carbonates. Any lithofacies close to overlying evaporites also suffered from evaporite

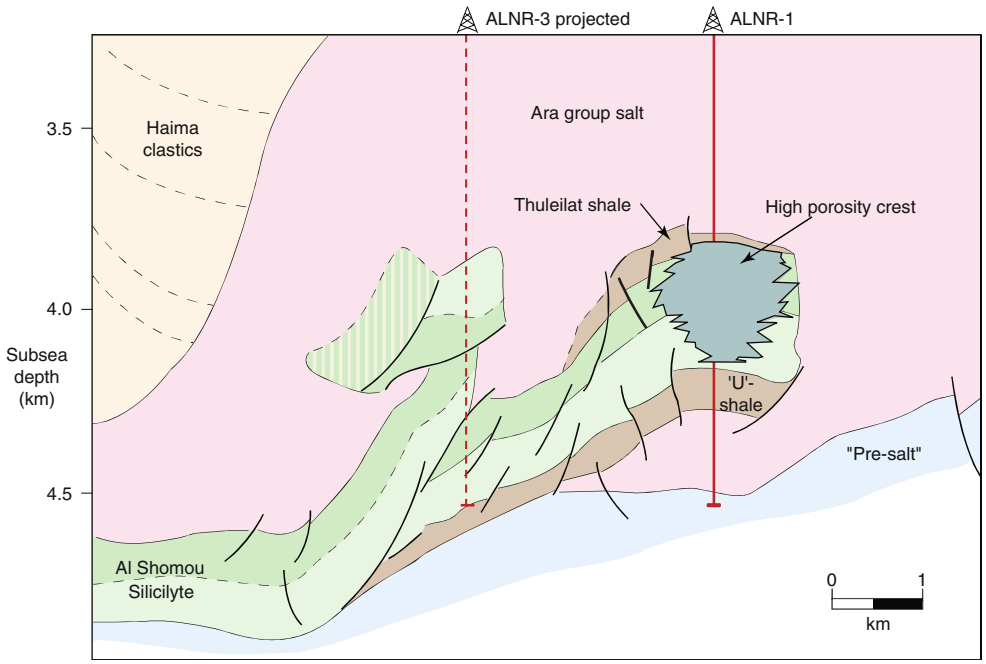

Fig. 10.77 Interpreted trace of seismic section across the Al Noor structure illustrating the positions of wells Al Noor-1 (ALNR-1) and Al Noor-3 (ALNR-3). Well Al Noor-1 (ALNR--1) targeted a thick intra-salt reflectivity package as part of the intra-salt carbonate stringer campaign. The well encountered a 400-m-thick, overpressured sequence of oil-bearing siliceous rocks. Well Al Noor-3 (ALNR-3) was drilled to appraise the down-dip extension of the proven oil column and to test a separate compartment of the Al Noor structure. The well did penetrate two Al Shomou Silicilyte slabs but encountered a significant deterioration in reservoir quality down-dip from the high-porosity crest (After Amthor et al. 2005)

cementation – i.e. shallow water carbonates at the top of stringers, as well as thin stringers.

- Early maturation of organic matter flushed the pore networks in the deeper water siliceous organic-rich laminites (silicilytes) with hydrocarbons that then prevented subsequent cementation by later carbonate and evaporite cements.
- Early reflux brines tended to flush the larger connected pores of the shallower and higher energy grainier carbonate units (e.g. thrombolite shoals) and so they were more easily filled with evaporite cements than the smaller hydrocarbon-rich pore networks of the basin centre silicilyte laminites.

Porosity evolution in the silicilyte laminites contrasts with that of thrombolite buildups and shallow water packstones where high porosities have been almost completely plugged by dolomite and halite cements, so typical of a depositional association with a basinwide evaporite unit. Thus production in Al Noor and Al Shomou fields comes from salt-encased organic rich blocks of chert of the Athel Silicilyte, not from platform dolomite sulphate successions (Peters et al. 2003).

Depositionally, the Al Shomou silicilyte is unusual compared to typical Phanerozoic marine cherts. It formed by primary silica precipitation of a marine-derived brine (as opposed to replacement of a carbonate or other mineral precursor) in an anoxic, sulphur-rich, stagnant and highly saline basin (Ramseyer et al. 2013). It is a primary hypersaline chert precipitated at the Neoproterozoic/Cambrian boundary. In core, the Al Shomou silicilyte is typically made up of metre-scale interlayers of finely microlaminated, porous silicilyte alternating with non-porous silica-cemented silicilyte. The latter act as vertical baffles to flow within the reservoir. In the absence of outcrop analogs, borehole-imaging logs are extensively used to delineate and to correlate reservoir units. FMI shows that more than 70 % of the lithofacies in the Athel Fm. are constituted of beds thinner than 1 m, along with cm-diameter dolomite nodules (possibly the result of bacterial sulphate reduction). Cemented fractures (some with fibrous halite fills) are locally common, typically reducing the horizontal connectivity. The rock matrix consists up to 80 % of microcrystalline quartz with high amounts of intercrystalline microporosity (up to 30 %). The very small modal crystal size of 2–3 μm and widespread bitumens in the silicilyte pore throats result in microdarcy levels of reservoir permeability (Ramseyer et al. 2013; Amthor et al. 1998; Peters et al. 2003). The present-day thicker (distal) silicilyte sections in the basin tend to have a higher average porosity than thinner (proximal) sections toward the platform.

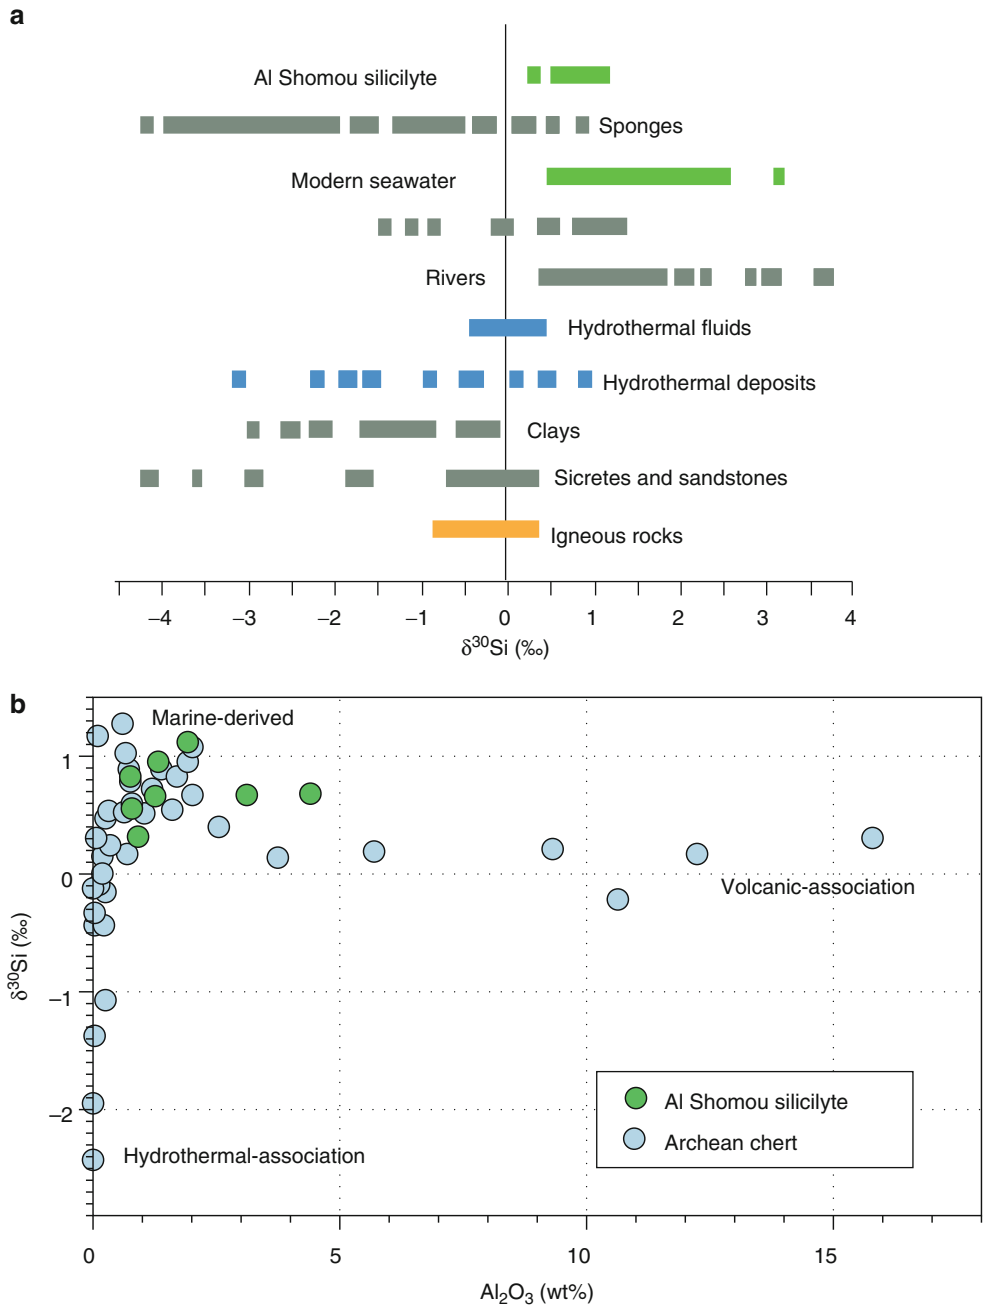

Fig. 10.78 Silica isotopes. (**a**) δ ^{30}Si composition of main modern Si reservoirs (**b**): δ^{30}Si composition of Early Cambrian silicilyte samples in comparison with Archaean chert samples (Data for both plots derived from Ramseyer et al. (2013) and references therein)

The homogeneous distribution and high values of stable Si isotope composition (avg. $\delta^{30}Si = +0.83 \pm 0.28$) coupled with a low molar Ge/Si ratio ($<0.25 \times 10^{-6}$) of the microcrystalline matrix quartz clearly reveal dissolved silica in seawater as the Si source, accordingly hydrothermal or biogenic (e.g. sponge-derived) silica can be excluded (Fig. 10.78a, b; Ramseyer et al. 2013). Silica precipitation from seawater was likely the result of a dramatic increase in salinity in response to salt dissolution atop and adjacent to the edges of transtensional depressions on the deep basin floor, thus markedly reducing the solubility of amorphous silica in these brine-filled seawater depressions (DHALs). This saturation triggered the formation of silica-gel, which accumulated at the basin floor forming a soft silica-rich layer on bacterial mats giving rise to a laminated sediment. The mean number of laminae is ≈32 per year suggesting that layering is non-annual and controlled

by processes such as fluctuations in nutrient supply, lunar driven re-mixing or diagenetic segregation. The transformation of the silica-gel to microcrystalline quartz occurred below 45 °C indicating a less than −4.5‰ $\delta^{18}O$ composition of the pore-water during microcrystalline quartz formation.

Based on the hydrology of all Phanerozoic evaporite basin drawdown settings, I would argue that the time of Athel Silicilyte deposition probably corresponded to a hiatus in the accumulation of the platform carbonates. The palaeogeographic setting at the time of silicilyte deposition was that of a relatively-shallow restricted marine-fed sag basin. Silicilyte probably accumulated in the somewhat deeper density stratified (meromictic) portions of this rift or intracratonic sag basin immediately prior to the onset of an episode of halokinetic halite emplacement across the central parts of the basin. At that time the basin was bound by exposed and hydrographically isolated carbonate-sulphate platforms along the basin edge. Silica levels in Neoproterozoic seawater were much higher than the biologically-limited silica chemistries of Phanerozoic seawater. Bottom stratification resulted in the preservation of substantial amounts of organic matter in the silicilyte and the formation of hydrocarbon source rocks of exceptional quality and thickness (SPI = 28–65 ton HC/m^2; Amthor et al. op. cits.).

Thick organic-rich basinal laminites are not uncommon in many marine-fed Proterozoic basins without an evaporite fill (e.g. oil and gas shales of the Velkerri Fm. of Central Australia; Warren et al. 1998; Craig et al. 2013). What makes the slivers in the Ara salt so economically interesting is that their organic maturation took place while encased in halite (Schoenherr et al. 2007c). The liquid fraction could not leak away, so the matrix permeability did not degrade to levels where it was subeconomic, unlike the Mesoproterozoic oil shales of northern Australia and many other Proterozoic oil shales.

Subsalt Reservoirs in Compressional Evaporite Provinces

There are more than twenty world-scale fold and thrust belts that have at some time slipped atop a layer of evaporites (Fig. 6.33; Davis and Engelder 1987). Such movement in a zone of horizontal compression often results in "thinskinned" or gravity-driven tectonics and the deposition of sediments atop salt-cored growth folds. Deformation in the overlying rocks produces seafloor or landscape topography and syndepositional inhomogeneity in overburden porosity and thickness, as well as stress instability in the salt bed. Both processes can initiate diapirism and allochthon breakout in a compressional terrain. Even when there is no development of piercement from salt-cored anticlines, folds show considerable anticlinal thickening in the salt layer, and associated synclinal thinning, as in the Jura and the SE Zagros. Any diapirism typically follows fault planes or tensional shears in the overburden (Figs. 6.86 and 6.88). Overburden deformation styles tend to have geometries that are controlled by the regional state of stress, and that geometry is frequently inherited by the salt structures. The close correspondence between the elongate salt structures of the North Sea and northern Germany to regional tectonic fabric clearly demonstrate this relationship (Fig. 6.76). Perhaps the best-studied hydrocarbon province controlled by salt-influenced folding and thrusting is in the Zagros Mountain region of the Arabian Gulf. In terms of hydrocarbon volumes, it is certainly the most prolific foldbelt in the world and holds as much as a third of the total reserves of the Middle East. Beydoun et al. (1992) estimated that there are more than 200 billion barrels of recoverable hydrocarbons in the Zagros foreland basin.

Zagros Foldbelt, Iran

Oil accumulations in anticlines of the Zagros Basin are the result of a Late Tertiary foreland basin foldbelt growing at the outer edge of the vast hydrocarbon-rich Palaeozoic-Mesozoic passive margin shelf of the Arabian plate (Fig. 10.79; Verges et al. 2011; Versfelt 2001; Beydoun et al. 1992). This foreland succession shares many of the same source rocks and salt seals as the relatively undeformed petroleum system of the Arabian Plate to the south. The two regions are separated across the Zagros deformation front. Compressionally driven folding and thrusting of the Zagros alpine belt began in the Eocene and continues today, still driven by the collision of the Arabian and Iranian plates. Miocene uplift of the growing alpine belt and subsidence of the adjacent foreland created a hydrographically isolated subsealevel depression in an arid climate (Fig. 5.32). The Fars/Gachsaran basinwide evaporite precipitated and today seals many of the giant and supergiant fields in the region. Compressional tectonics in this foreland foldbelt, especially in the Dezful Embayment, has formed some of the largest structurally-trapped oil fields in the world (Figs. 10.79 and 10.80). In Iran, mostly in the Dezful embayment, ongoing Late Tertiary folding, concurrent with deposition, means that the lower members of the basinwide evaporites of the Gachsaran Formation (seal) typically thin as they overlap or wedge out onto growth folds in the Asmari Limestone reservoir (Fig. 10.80b; Alavi 2004; Ala 1982 and references therein). Syndepositional compression led to the deposition of sandier units above the crests of growing thrust folds, and the sealing of these porous units by evaporites deposited within hypersaline seaways generated by the collision. In Iraq, mostly in the Kirkuk embayment, many of the reservoirs are in folded Mesozoic carbonates.

Late Tertiary collision of Africa and Eurasia did three things to create conditions that trapped enormous volumes of

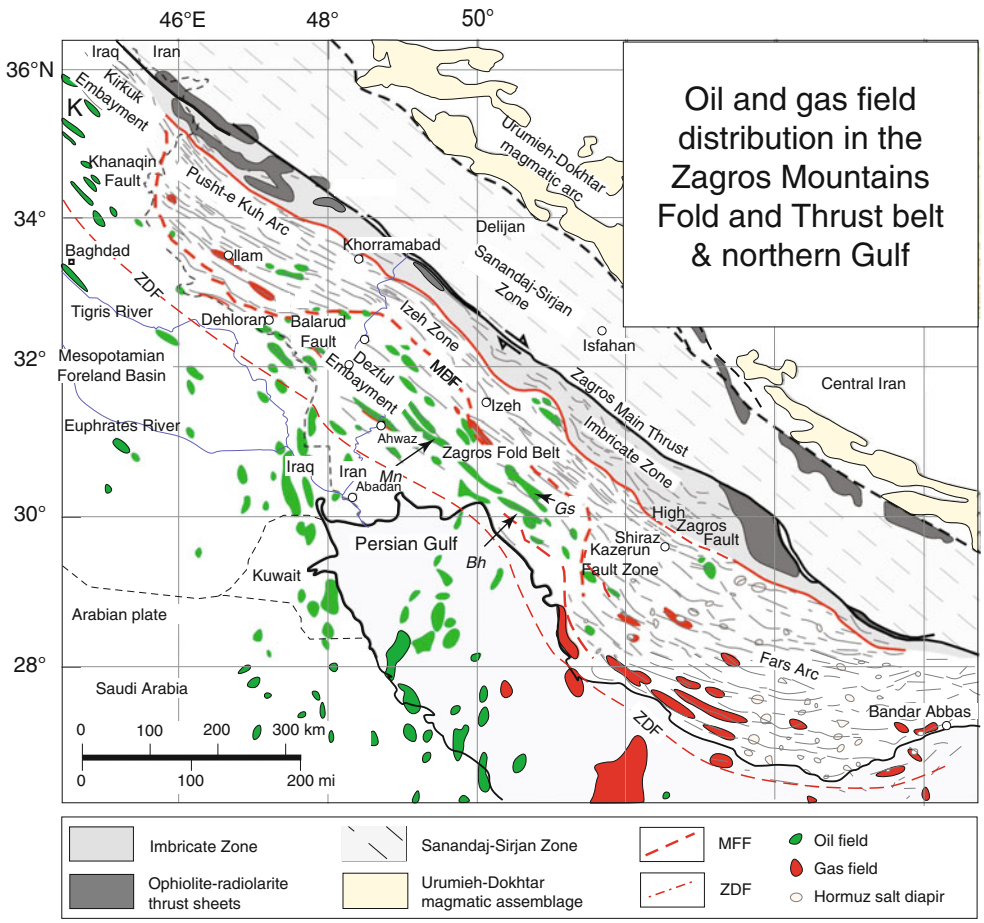

Fig. 10.79 Oil and gas fields in the Zagros and northern Gulf region plotted on a tectonic base of the Zagros Mountains (After Verges et al. 2011) showing the traces of anticlines in the Zagros fold belt, Mesopotamian foreland basin, and Persian (Arabian) Gulf. The imbricate zone, including ophiolites and volcanic arc outcrops, the Sanandaj-Sirjan zone, and the continental Iran block are also shown. Oil and gas fields display the northwest–southeast Zagros trend, and the roughly north–south Arabian trend, in the Abadan plains and Persian Gulf. The two domains are separated by the Zagros deformational front (ZDF) (*MFF* mountain front flexure, *Bh* Bibi Hakimeh, *Gs* Gachsaran field, *Mn* Marun field)

hydrocarbons in Iran and Iraq. First, it deformed a number of fracture-susceptible carbonate reservoirs into whaleback folds, which are world renowned for their huge amplitude and areas of closure; along-strike fold dimensions often exceed 160 km. These dimensions together with brittle fracture in the Asmari limestone reservoir have created fields such as Gach Saran and Bibi Hakimeh, which have estimated ultimate recoveries of oil of 12 and 8 billion barrels, respectively (Fig. 10.80a, b). They occur in a gently folded evaporite-sealed province that has recoverable reserves estimated at more than 87 billion barrels of oil and 514 trillion cubic feet of gas, and has produced more than 6 million barrels of oil per day (Burwood 1984; Beydoun et al. 1992).

Evaporite-sealed muddy limestones of the Asmari Formation and it equivalents (Fig. 10.79; Oligocene-Miocene), are the prime reservoir in this foreland foldbelt and provide the reservoir to something like 90 % of the oil in the oil fields of southwestern Iran (Dezful Embayment). There are lesser but still considerable volumes in Tertiary carbonate reservoirs in oilfields in the folded foothill belt of Iraq where it is known as the "Main Limestone" of the Kirkuk Group (Beydoun et al. 1992). Fractured Cretaceous carbonates of the Bangestan Group, along with minor eolian sand layers in some fields near the Kuwait-Iraq border, are primary reservoirs in Iraq and secondary reservoirs in Iran where they are often situated below Asmari production levels in the same wells in the same fold structures (multiple or stacked columns).

In its main producing area, the Asmari Fm. is predominantly a shallow-water non-reefal micritic platform limestone containing variable levels of dolomite and anhydrite plugging (Honarmand and Amini 2012; van Buchem et al. 2010; Mossadegh et al. 2009; Aqrawi et al. 2006). Matrix porosity and permeability are low in limestone matrices with typical porosities of up to 15 % and matrix permeabilities of up to a few millidarcies. Matrix porosities are significantly

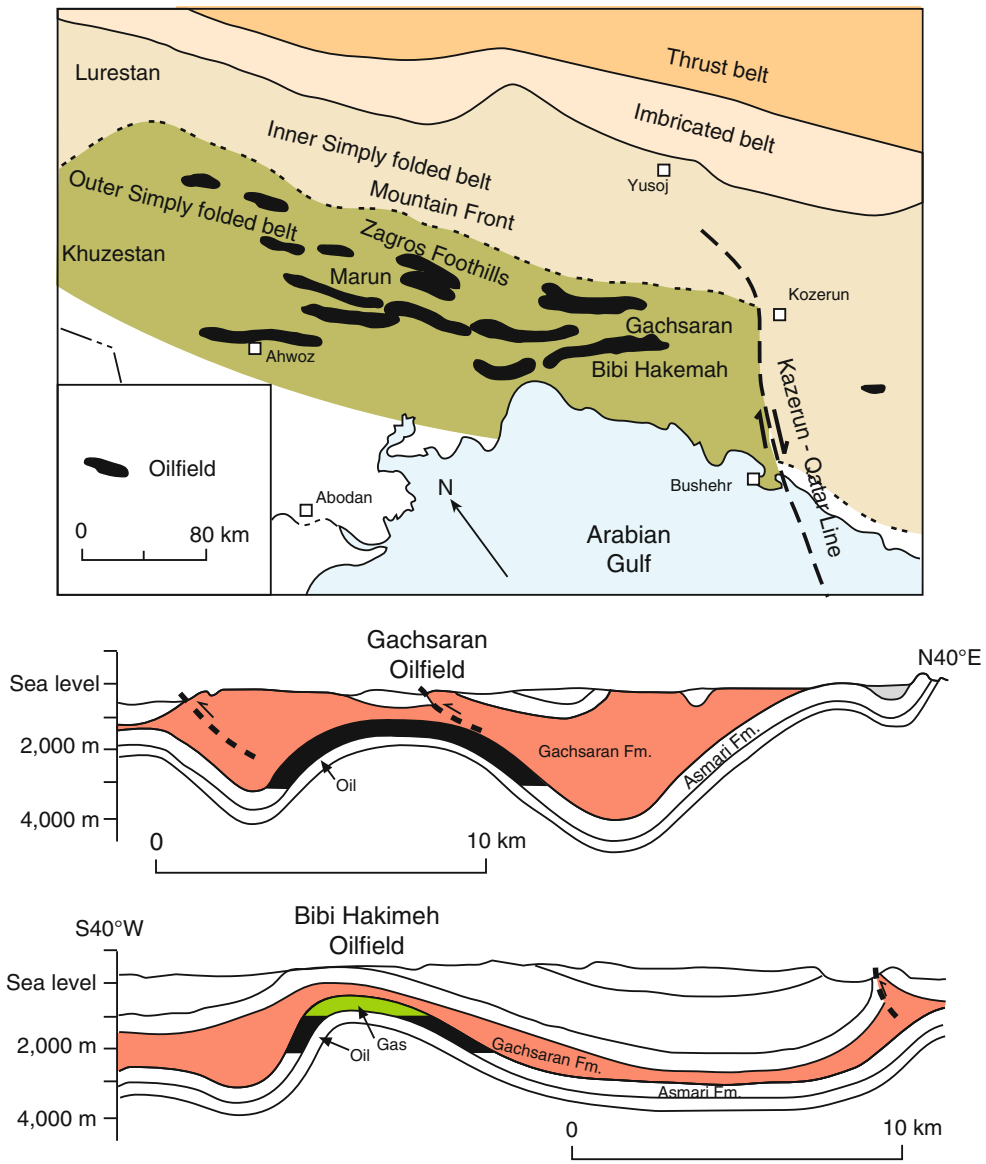

Fig. 10.80 (**a**) Oilfields in the foreland foldbelt of the Dezful Embayment in front of the thrust belt that is the Zagros Mountains, Iran. (**b**) Cross section through the Gachsaran and Bibi Hakimeh fields showing hydrocarbon storage in fractured muddy carbonates sealed by unfractured evaporites of the Gachsaran Formation (After McQuillan 1985)

higher when dolomitised, mostly as the result of brine reflux (Fig. 10.81a). Clearly dolomitisation, and the creation of intercrystalline permeability, improves storage capacity in Asmari reservoirs. Later burial dolomite spar tends to occlude porosity, and even in reflux settings some intervals can be overdolomitised (pers. obs.) Dissolution, first of aragonite allochems, and then mesogenetic corrosion of calcite also improves reservoir quality (Fig. 10.81b). Detritmental diagenetic processes related to $CaSO_4$ precipitation include reflux anhydrite and later burial anhydrite cement spars.

At the trap scale, the Asmari and its equivalents typically owes its excellent reservoir qualities to extensive brittle fracturing induced by Neogene compression beneath a ductile Fars/Gachsaran seal (Fig. 10.80). Wells intersecting fractured intervals of Asmari Limestone in the classic Gachsaran and Bib Hakimeh fields have tested at rates of up to 19,080 m^3/day (120,000 bbl/day) and have sustained production rates of 12,700 m^3/day (80,000 bbl/day), with estimated averages for wells producing from the fractured Asmari in various fields ranging from 3,180 to 3,975 m^3/day (20,000–25,000 bbl/day). Where wells fail to penetrate fracture intervals in the Asmari in the same fields they are essentially nonproductive (Fig. 10.82; McQuillan 1985; Beydoun et al. 1992).

Also, the continent-to-continent approach prior to final collision and suturing created a subsealevel soft suture belt that in the Miocene hydrographically isolated the foreland

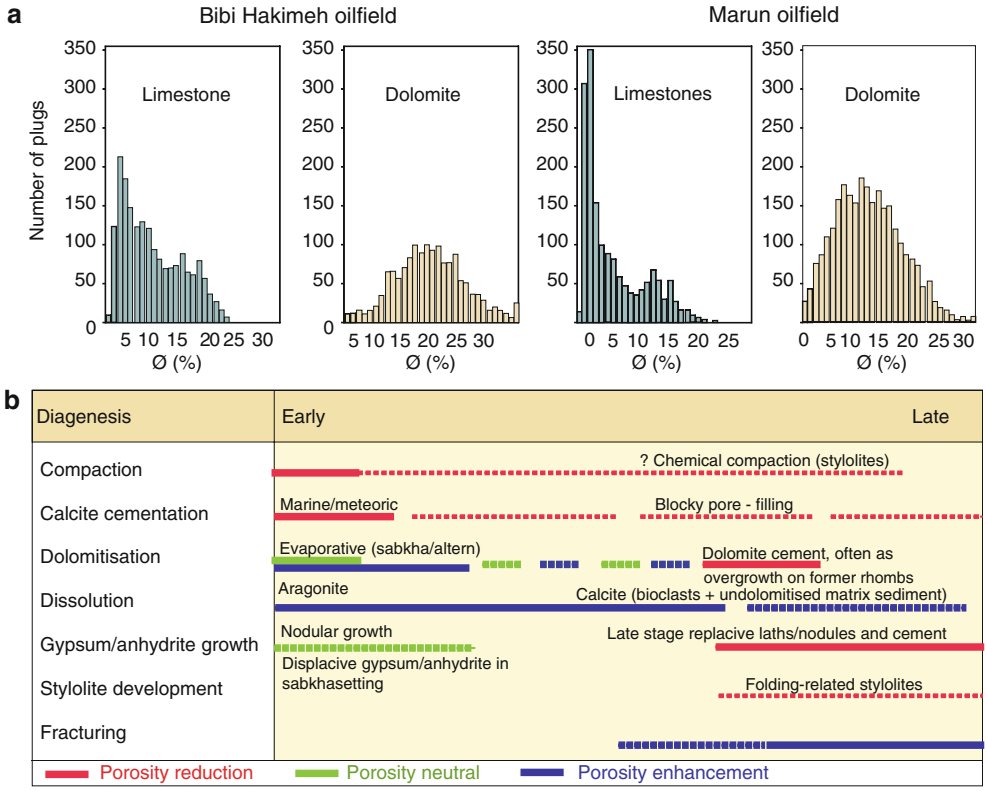

Fig. 10.81 Poroperm controls in the Asmari reservoirs of Iran. (**a**) Frequency histogram of core plug porosity (Ø) of limestones and dolomites in the Asmari Formation in the Bibi Hakimeh field (*left*), 1,660–2,130 m, and the Marun field (*right*), 3,000–3,700 m. The average porosity of dolostones is higher than that of limestones in both fields, see Fig. 10.80 for location. (**b**) Paragenetic summary of the main diagenetic processes which have influenced the reservoir quality (porosity) in the carbonates of the Asmari Formation (After Aqrawi et al. 2006)

basin sump from the open ocean and so deposited the Lower Fars or Gachsaran Formation as a marine-fed basinwide evaporite which subsequently acted as a longterm ductile seal to the growing folds (Kashfi 1983,1985). The presence of this impermeable unit, with its anhydrite base and halite top, is critical in sealing reservoirs in the Asmari Limestone and its equivalents and in maintaining seal integrity atop growing whaleback anticlines as underlying carbonates fractured and faulted. Erosion or nondeposition of the Lower Fars seal on growing folds to the northwest and southeast of the main producing Asmari folds in Iran and in parts of Iraq has destroyed the trapping potential of many otherwise suitable whaleback growth folds. In the SE portion of the Zagros Belt, continent-to-continent collision acted as a huge bellows to the underlying Hormuz salt which by flowing up toward the surface further exaggerated the structural closure of many existing nearsurface folds and also reactivated older Jurassic structures further out in the Gulf.

Although the presence of an evaporitic seal overlying a reservoir is always good news for sealing hydrocarbons, a thick underlying salt unit deformed into salt covered structures that breakout onto the surface is not always so useful in terms of accumulating large quantities of hydrocarbons in large broadly draining structures. Along-strike changes in the tectonic style of the Zagros Mountains demonstrate this point. The NW part of the Zagros foldbelt is the most prolific hydrocarbon area and is characterized by a thick and relatively deep section of fractured Asmari. It has been gently folded into whaleback anticlines and sealed beneath laterally continuous Gachsaran/Fars evaporites (Ala 1982; McQuillan 1985). There is no halokinetic surfacing of Hormuz Salt in the Dezful area to break up the continuity of these broad anticlines. Oil fields in this part of the outer Zagros foldbelt were relatively easy to define back in the 1920s by a combination of seeps and surface mapping and with development wells stepping out along anticlinal axes.

But salt-cored folds in the region of the Zagros foldbelt in southeast Iran in the region of Bandar Abbas are characterized by namakiers sourced in the underlying Hormuz Salt (Fig. 6.85). Most of the fields in this region are relatively small and gas prone (Fig. 10.79; Ala 1982; Versfelt 2001). There the Asmari is thinner and often outcrops as erosionally-breached salt-cored anticlines. In addition the Fars Gachsaran is less evaporitic and more carbonate rich in that area (Gill and Ala 1972). The style of deformation in this area is uplift with salt-cored transtensional shear faults and greater verti-

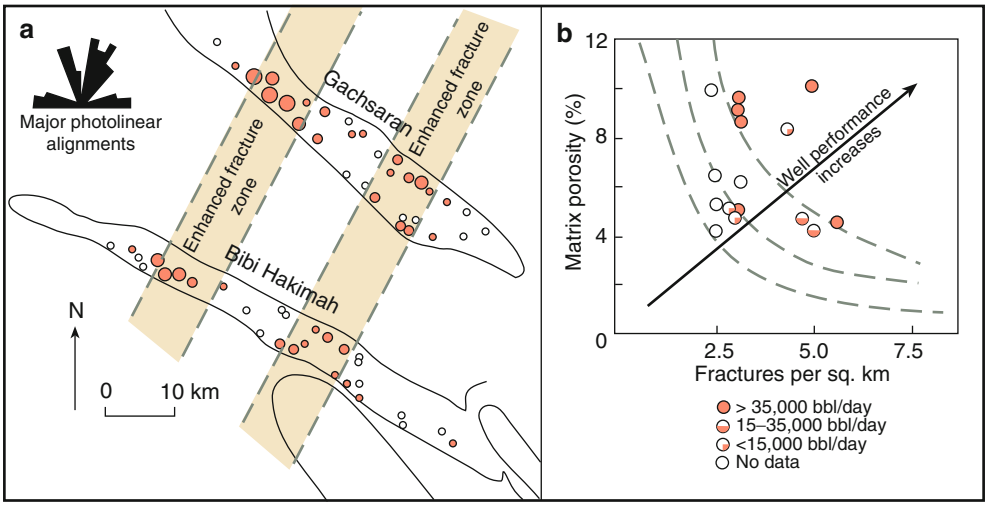

Fig. 10.82 Gachsaran and Bibi Hakimeh fields, Iran. (**a**) Formline map; areas of solid circles are proportional to maximum allowed production rates. *Open circles* are non-commercial or nonproducing wells. High production wells lie in zones of enhanced fracturing induced by deformation controlled by basement features. (**b**) Well production rates in Bibi Hakimeh Field as a function of matrix porosity and fracture density. See Fig. 10.80 for location (After McQuillan 1985)

cal components to the fault breaches compared to areas to the west. This greater intensity and verticality perhaps relates to withdrawal of thick successions of Hormuz salt into adjacent salt diapirs and glaciers. During ongoing periods of vertical uplift and diapir induced breaching many hydrocarbons either escaped through fractures in the exposed Asmari and its less evaporite-rich cap or underwent secondary migration, possibly becoming trapped on the western side of the Oman Mountains (Kashfi 1983). Gravity-driven shear faults developed in association with salt intrusions and a poor development of an evaporite seal, probably facilitated the migration and escape of hydrocarbons. The presence of a thicker Hormuz section in this part of the Arabian Gulf may well have prevented the transferral of the fracture system from the basement into the Asmari, the same fracture system that McQuillan (1985) uses in explaining the prolific production of the giant fields in the thrust belts further to the Northwest. Offshore from the Southern Zagros some large structural accumulations in the Tertiary strata may still remain to be discovered, but future onshore exploration will probably be for smaller stratigraphic or combination traps situated about and sealed by halokinetic structures.

The stacking of salt tiers in this region creates an interesting contrast in structures and related responses at potential reservoir levels compared to reservoir distribution in the extensional tiers in the Gulf of Mexico. Thick salt creates two mobile groups in the stratigraphy as well as thinner depositional salt beds occurring within the Competent Group (Fig. 10.83; Verges et al. 2011; Fard et al. 2011). These thin beds tend to focus zones of structural release and transfer in the Competent Group of units. Folds in the Pusht-e Kuh arc are exposed along the upper part of the 7-km (4.34-mi)-thick Competent Group level, which is folded between the main detachment at or near the base of the cover sequence (lower Mobile Group) and the Gachsaran evaporites (upper Mobile Group). Intermediate detachment levels, sometimes evaporitic (Triassic Dashtak, middle Cretaceous Garau and Kazhdumi, Paleocene Amiran, and middle Miocene Kalhur formations) within the Competent Group control the geometry of anticlines at surface as well as their variations with depth.

The Kabir Kuh anticline is the largest and highest anticline exposed in the Pusht-e Kuh arc (Fig. 10.83). Mapping of the anticline in its central part displays box fold geometry, characterized by a wide and rounded crestal domain, which is slightly tilted to the southwest. This geometry developed above an intermediate detachment at the level of 1.3-km (0.81-mi)-thick Triassic Dashtak evaporites within the Competent Group. Below this detachment, the geometry of the fold changes to more acute with a narrower crestal region. Although conjectural, Verges et al. (2011) propose low-angle thrusting forming a tectonic wedge to accommodate shortening at the deepest part of the anticline (Palaeozoic sequence). Subsidiary thrusts, related to fold tightening, likely reactivate axial surfaces, as well as local detachment levels, that propagate displacements of the crest of the anticline above its forelimb, as inferred along the southeastern segment of the Kabir Kuh anticline.

In terms of reservoir and structural understanding during exploration in a compressional salt-tiered region is notable that anticlines in the Passive Group may be displaced, sometimes by a few kilometers, from beneath anticlines in the Competent Group (potential deeper reservoirs). In the same way, the internal mechanically weak layers of the Competent

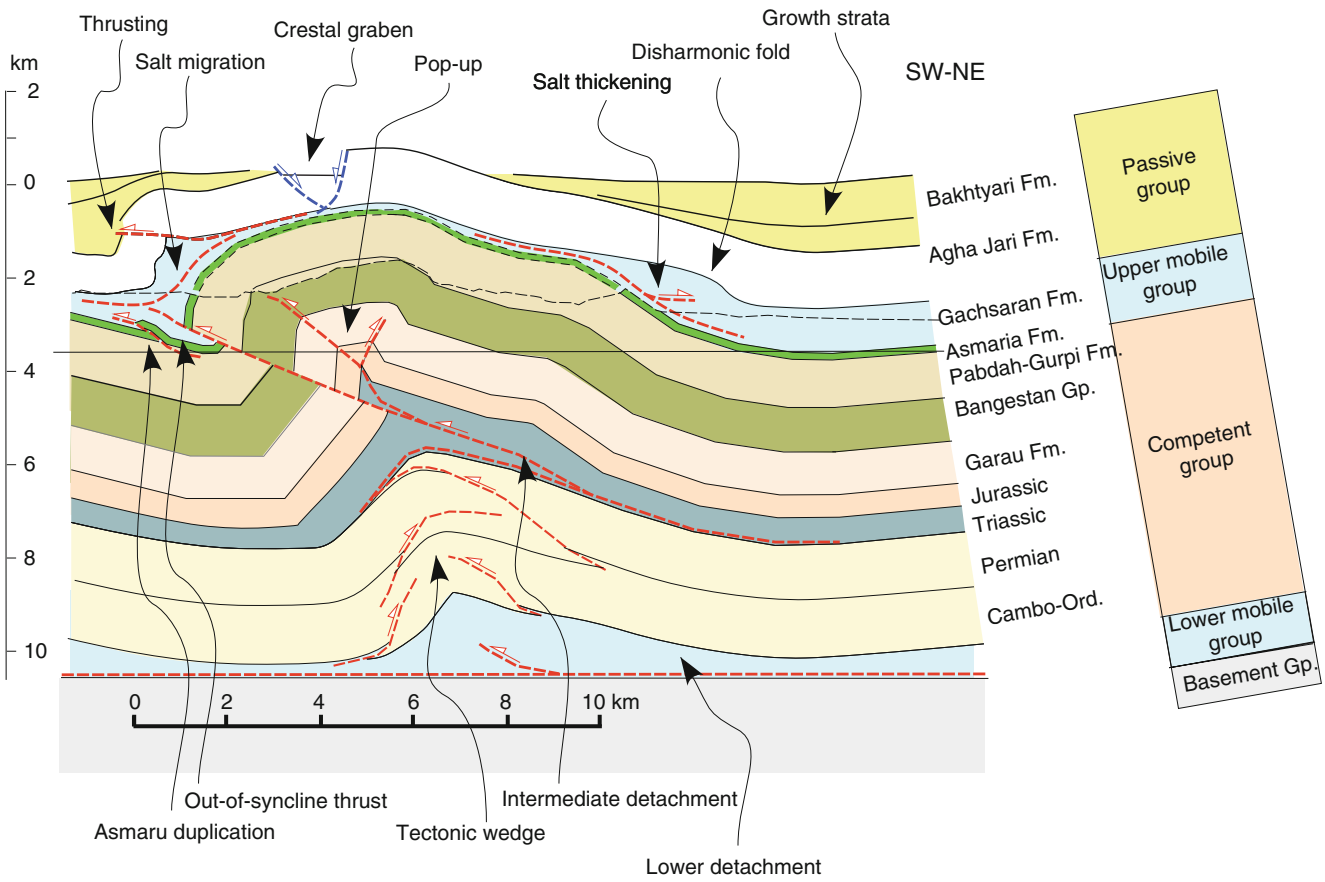

Fig. 10.83 Conceptual model of folding integrating observations from the Pusht-e Kuh arc (Competent Group) and Dezful embayment (Passive Group) tectonic domains (After Verges et al. 2011)

Group may form intermediate detachments that can produce a significant change in fold style with depth and displace the upper part of the structure, shifting again the position of the anticline crests.

Alpine Foldbelt in Albania and Romania

Giant salt-sealed highly deformed structures characterise onshore oil fields in the compressional Alpine fold and thrust belt (Albanides) of the Ionian basin in Albania. The Triassic evaporites form a regional detachment layer, but are also cut by thrust ramps that carry evaporites to the surface in their hanging walls (Fig. 10.84; Velaj et al. 1999; Graham Wall et al. 2006). Contraction of the Ionian zone reached a peak in the late Oligocene–Miocene Alpine Orogeny during an intense episode of overthrusting and major folding. The oil and gas fields in the region produce mainly from fractured Cretaceous–Eocene carbonates (e.g., Balshi-Hekal, Visoka, Gorisht-Koculi, Cakrani, Amonica, Finiq-Krane, and Delvina fields). Where a detachment is located at the top of the evaporite section, salts are dragged up in the footwall along thrusts. Faults develop both at the base and the top of the evaporite. Simple shear deformation along the thrusts causes greater than 80 % thinning of the evaporite, so that thinned salt sheets of only 40–200 m thickness are now preserved in regions where the original evaporite thickness was in excess of 2,000 m. Where thrust ramps cut through the evaporite and cause repetition of the complete evaporite layer, salt is remobilised into salt-filled compressional anticlines or it escapes at the surface to produce smeared-out allochthonous extrusions capable of sealing large volumes of hydrocarbons.

The most spectacular example of this is the Dumrea structure, where the mobilised evaporites have a complex shape that evolved from an overthrusted allochthonous sheet, which today subcrops at the modern landsurface (Fig. 10.84a). The Dumrea salt allochthon is up to 5.6 km thick, as proved by drilling, and has been displaced laterally by up to 25 km. It has the effective geometry of a giant sheath fold (Fig. 10.84b). Untested traps still exist below the allochthonous evaporites and good quality non-biodegraded hydrocarbons are possible at depth, as was the case in the Delvina Field in southern Albania (Fig. 10.84c). Shallower oil fields in the Albanides, not sealed by evaporites, typically contain very heavy oil due to ongoing bacterial degradation (e.g., Balshi-Hekali and Patos-Marinza fields).

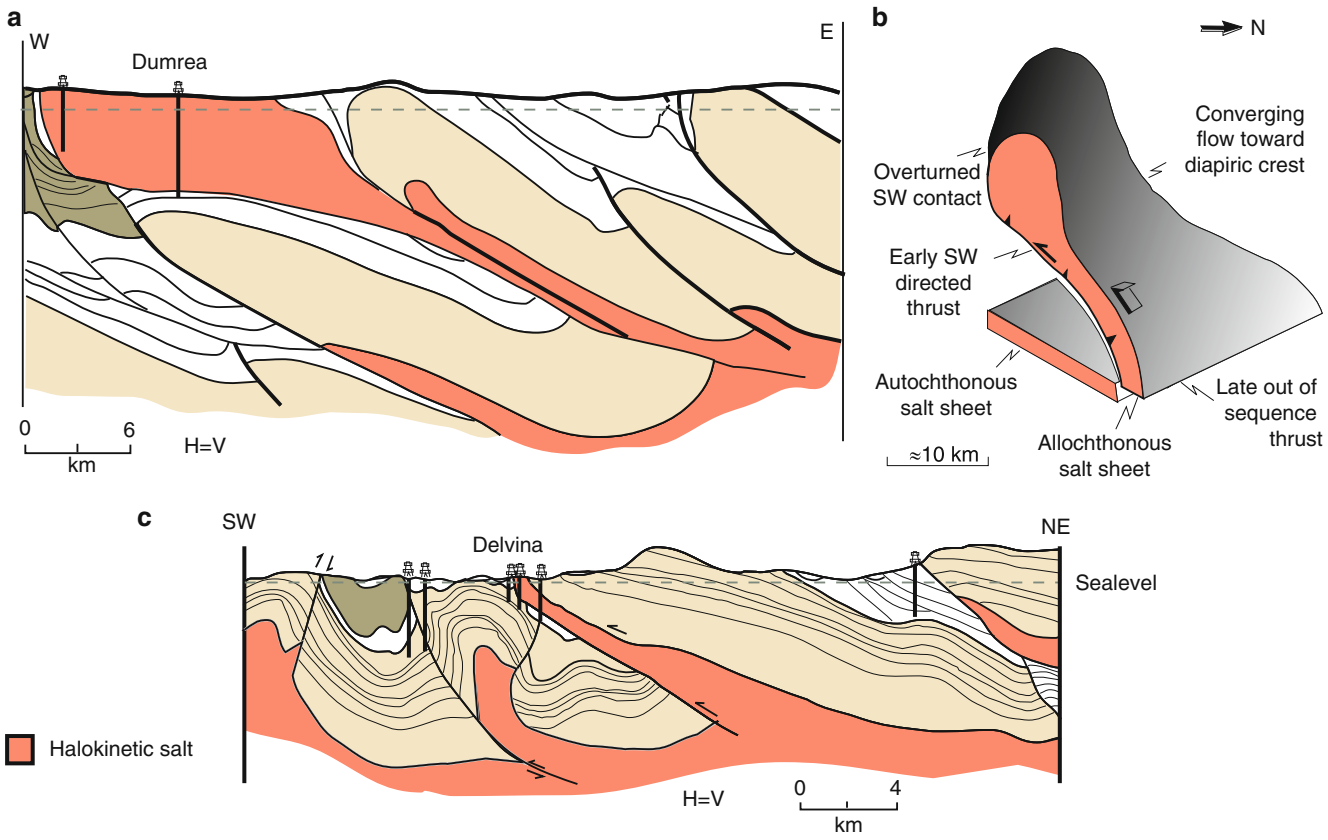

Fig. 10.84 Giant fields in the Albanides, Ionian Basin. (**a**) West-east–trending cross section through the Dumrea evaporite body showing the structure of Dumrea Field. (**b**) Three-dimensional block diagram of the Dumrea diapir. (**c**) Cross section of the Delvina gas condensate field trapped below a thrusted Triassic evaporite sheet (After Velaj et al. 1999; Velaj 2002)

The process of fracture and fault formation in carbonates of the Albanides fold-thrust belt was systematically documented by Graham Wall et al. (2006) using scaled studies of structural elements from hand sample, outcrop, and geologic-map scales. Calcite cement and bitumen distribution in these structures can be used as a paleoflow indicator of the various fluid migration stages in the evolving fracture and fault systems. Two prefolding pressure-solution and vein assemblages were identified: an overburden assemblage and a remote tectonic stress assemblage (Fig. 10.85a, b). Sheared layer-parallel pressure-solution surfaces of the overburden assemblage define mechanical layers. Shearing of mechanical layers associated with folding resulted in the formation of a series of folding assemblage fractures at different orientations, depending on the slip direction of individual mechanical layers.

Prefolding- and folding-related fracture assemblages together formed fragmentation zones in mechanical layers and are the sites of incipient fault localization (Fig. 10.85d–f). Further deformation along these sites was accommodated by rotation and translation of fragmented rock, which formed breccia and facilitated fault offset across multiple mechanical layers. Strike-slip faults formed by this process are organized in two sets in an apparent conjugate pattern. Calcite cement and bitumen that accumulated along fractures and faults are evidence of localized fluid flow along fault zones. By systematic identification of fractures and faults, their evolution, and their fluid and bitumen contents, along with subsurface core and well-log data, Graham-Wall et al. (2006) identified northeast-southwest-trending strike-slip faults and the associated structures as the dominant fluid (hydrocarbon) pathways at the reservoir and petroleum system scale in the compressional Albanides fold-thrust belt (Fig. 10.85f).

The nearby Romanian section of the Carpathians Mountains of eastern Europe is another collisional thrust-fold Alpine belt where hydrocarbon accumulation is intimately related to the presence of structurally-smeared basinwide evaporite seals, in this case of Lower Miocene age (Fig. 10.86; Paraschiv and Olteanu 1970). Most of the reservoirs are Pliocene lacustrine sands, interbedded with fine-grained marls. The latter may well have been both source and seal. Suitable Pliocene sands with sufficient thicknesses and favourable reservoir facies only occur in the Ploiesti area at the convexity of the Carpathian Bend. Like the Zagros Mountains and the Albanides this hydrocarbon

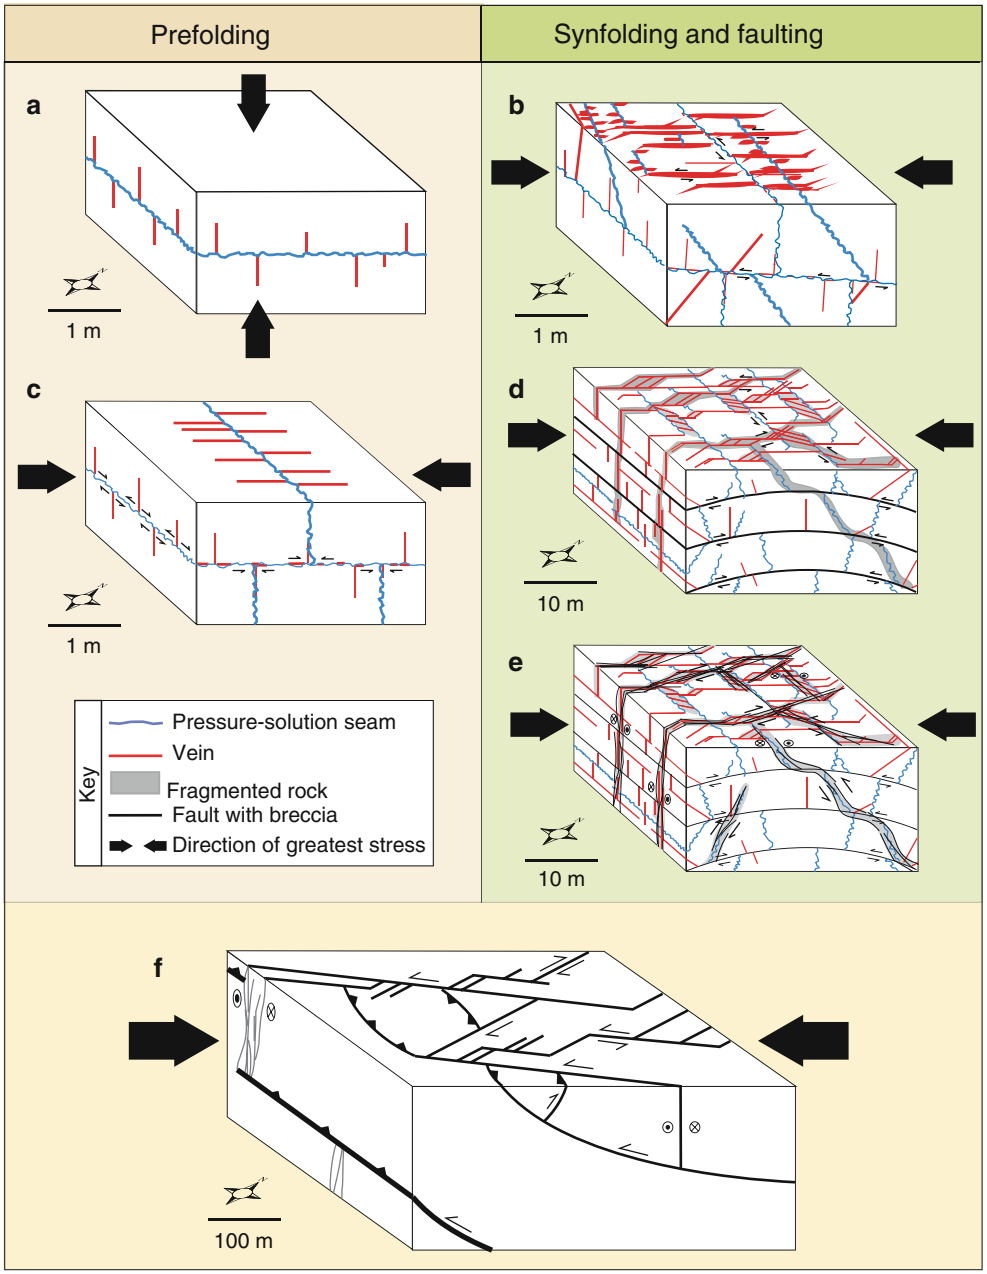

Fig. 10.85 Conceptual model of fault evolution in brittle carbonates of the Albanides involving prefolding and synfolding structural element development in response to mobile halokinetic deformation: (**a**) Overburden assemblage (prekinematic), (**b**) Remote tectonic stress assemblage, (**c**) folding assemblage, (**d**) the linkage of fracture assemblages to form localized fragmentation zones, (**e**) the linkage of fragmentation zones to form through-going faults, and (**f**) northeast-southwest–trending strike-slip faults formed through processes (**d**) and (**e**) with linkages visualized at the reservoir scale (After Graham-Wall et al. 2006)

province is another halokinetic province where the original basinwide evaporites have been squeezed into a compressive layer during large scale thrust movement. Where a thrust ramps toward the present surface the Miocene salt defines stocks, sills, dyke-like masses and other irregular shapes, whose original injection pathways were perhaps controlled by pre-existing diapirs, faults, folds and fault/fold intersections.

Rocky Mountain Foldbelt, USA

Deformed basinwide salt also plays a role in sealing the Nugget Sandstone reservoir in the Painter and East Painter fields of the Rocky Mountain thrust belt in the USA and the much more gently deformed sequence of Leadville Formation carbonates in the Lisbon Field, Utah. The Mississippian Leadville Lime-stone reservoir in Lisbon Field in the northern Paradox Basin, Utah, lies below a thick

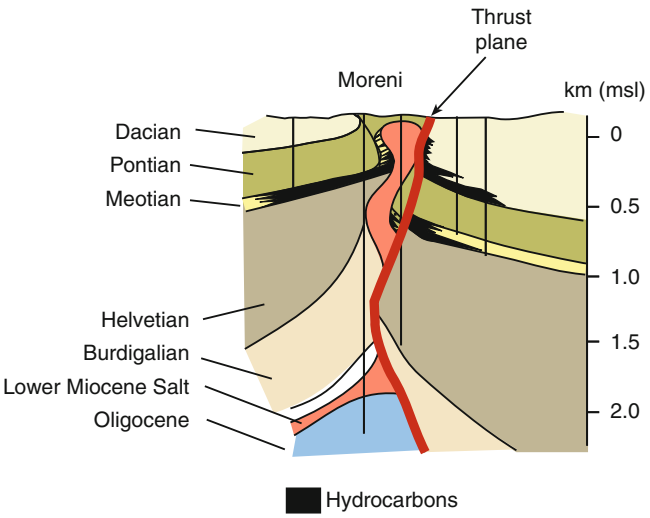

Fig. 10.86 Cross section through the Moreni-Gura Ocnitei oilfield, the largest field in the Carpathian foredeep. Productive sandstones are Pliocene in age. Structure is a sheared anticline where lower Miocene salt (*red*) has lubricated the thrust and now forms a lateral seal to multiple reservoir sands. Also note the greater concentration of oil on the right side of the thrust, which is the downthrown side of the principal fault (After Paraschiv and Olteanu 1970)

section of halokinetic Paradox salt and has produced some 50 Mmbl and 760 Bcfg since its discovery in 1959 (Fig. 10.87a). The trap is an elongate, asymmetrical, northwest-trending salt-cored anticline with nearly 600 m of structural closure (Fig. 10.87b; Miller 1985). The field is bound on its northeast flank by a major, basement-involved normal fault with nearly 760 m of displacement. A number of smaller northeast-trending normal faults dissect the reservoir into segments with fractured sweetspots located close to these secondary faults (Miller 1985).

The Leadville Limestone was deposited as an open-marine, carbonate-shelf system with local crinoid banks, mud mounds and peloid/oolitic shoals. Two dolomite types characterise the Leadville reservoir, a tight stratiform micritic mimetic dolomite and a later coarser saddle dolomite. Solution-enlarged fractures and breccias are also common in the reservoir interval. The dichotomy in dolomite type and the association of the saddle dolomite with faults and fractures is similar to the evaporite-focused occurrences seen in earlier in the various examples from the Middle East. But in the case of Lisbon Field the evaporite seal maintained its seal integrity even when the salt first underwent extension in the Palaeozoic and then compression during the Laramide orogeny. The oil in the structure is thought to be sourced from the overlying and now fractured Gothic Shale member in the Paradox Salt. Interestingly, such a subsalt trapping scenario may be a useful analog in exploration for sub-Ara Salt traps in the Proterozoic Buah Formation in the South Oman Salt Basin petroleum system.

More highly deformed salt levels in the Painter and East Painter fields maintain seal integrity atop the deformed and fractured reservoir intervals in the giant Painter and East Painter fields. Triassic salt also acts as the isolating décollement surface to the overlying overthrust plane (Fig. 10.88a; Dischinger and Mitra 2006). The Painter reservoir structure consists of a rounded asymmetric fold in the Jurassic Nugget Sandstone reservoir (eolian) sealed by the Gypsum Spring Member of the Twin Creek Limestone and the overlying salt. Significant thickening was accommodated in the underlying ductile Ankareh shales and the Thaynes limestones, which comprise the core of the structure (Fig. 10.88b; Mitra 2002). The forelimb of the structure is steep to overturned. A series of small-scale imbricates cut through this limb, but the displacement on these faults is relatively small and does not control the geometry and structural relief of the structure. The tightness of the structure also results in the formation of one or more out-of-syncline thrusts on the forelimb, which terminate upward within the salt unit and downward within the Twin Creek limestones. These out-of-syncline thrusts were folded during the later stages of deformation.

The East Painter reservoir structure is a west-vergent detachment fold, formed above the hanging-wall cutoff of the Mesozoic units atop the Cretaceous detachment (Fig. 10.88b). The steep frontlimb of this structure is also cut through by a west-vergent thrust. The convergence of the two opposite-vergent structures results in significant disharmonic folding within the Twin Creek limestones and the overlying salt. Interestingly, the hydrocarbons stored in the Nugget Formation sands were sourced in stratigraphically younger but now underlying Cretaceous mudstones (Lamb 1980).

Salt-Related Traps in the Tarim Basin, China

The Tarim Basin is one of the most important hydrocarbon-bearing evaporite basins in China. It retains four salt-bearing levels, the Middle and Lower Cambrian, the Mississippian, the Paleogene, and the Neogene, which have various thickness and areal distributions (Fig. 10.89). Salt levels define various intervals of stratigraphic discontinuity across the Tarim, they define important detachment layers and intensely affect structural deformation styles in the basin.

This is especially so in the Kuqa region in the northern part of the Tarim Basin. There the Kuqa depression is a subordinate structural unit typified by numerous salt-cored structures within the larger Tarim Basin. Salt overthrusts, salt pillows, salt anticlines, salt diapirs, and salt-withdrawal basins characterise the Kuqa depression. The source layer for the deformation is the Paleogene Kumugeliemu Formation. It contains a thick succession of halokinetic salt that was first deposited in a compressional foreland. This same compressional setting continued to be active post salt deposition and drove much of the structuration across this northern part of

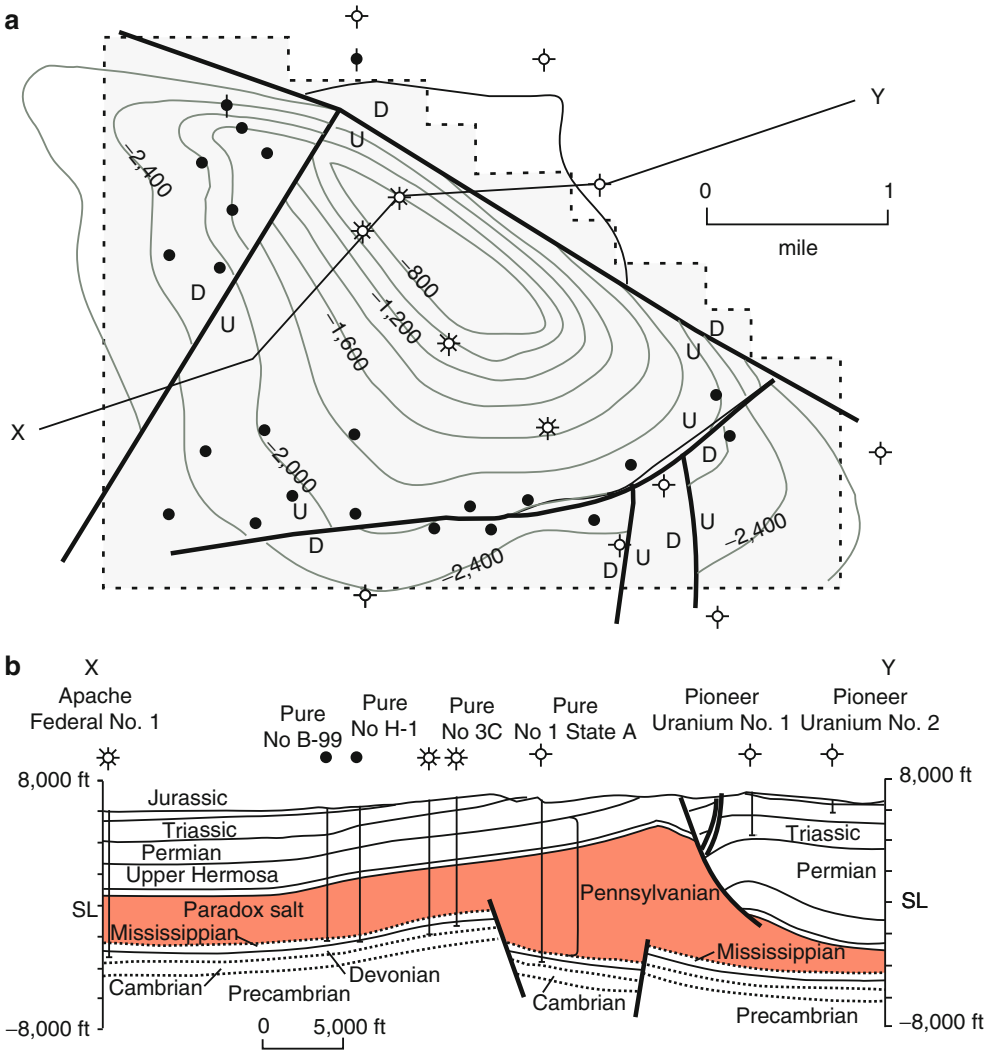

Fig. 10.87 Lisbon Field, Utah. (**a**) Depth to top of the Leadville Formation (Contours in feet subsealevel). (**b**) Regional cross section X-Y across the field showing its position beneath the seal of halokinetic Paradox Salt (After Miller 1985)

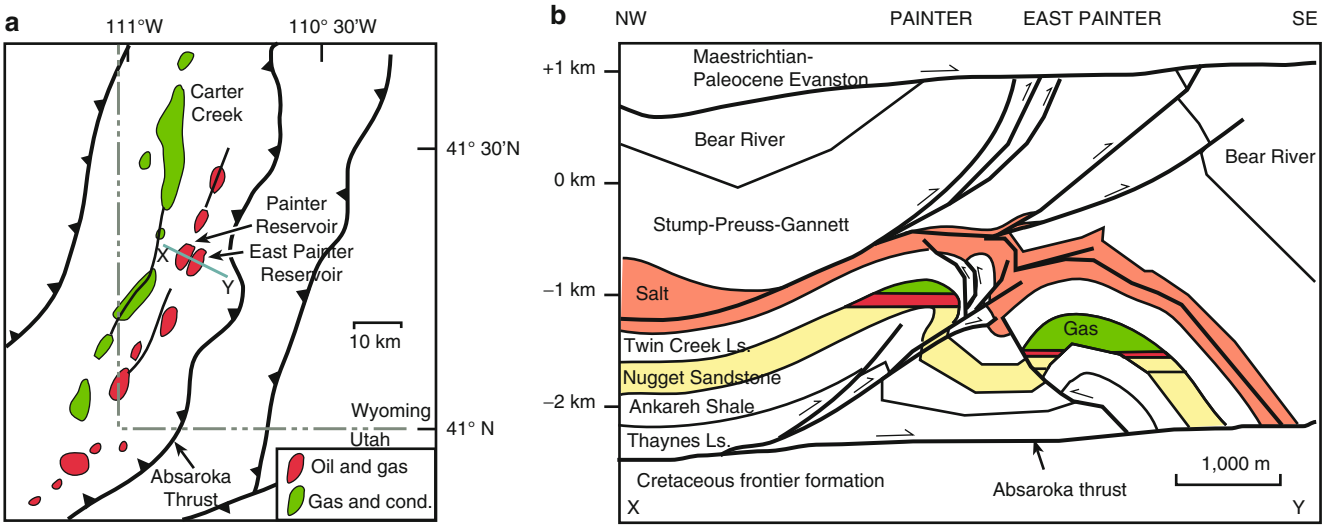

Fig. 10.88 (**a**) Geologic map of the Idaho-Wyoming-Utah fold and thrust belt showing some of the major oil- and gas-producing structures in the Absaroka thrust sheet. (**b**) Interpretive cross section through the Painter reservoir and East Painter reservoir structures (After Mitra 2002)

the Tarim basin, where a combination of salt-lubricated faulting and thrusting created the various traps, illustrated in (Fig. 10.90a–c).

Clearly, the contraction that resulted from ongoing orogeny plays a key function on the formation of various salt structures. Suprasalt growth strata thickening shows that intense salt structural deformation in the Kuqa depression occurred during the Himalayan movement from Oligocene to Holocene, with earlier structural deformation in the north and later deformation in the south of the depression. Growth sequences also record at least two phases of salt tectonism. In the Tahe area (as well as the Yingmaili and Tazhong areas) low-amplitude salt pillows are the most common salt structures, and these structures are commonly accompanied by thrust faults. There the faulting and uplifting of basement blocks controlled the location of salt structures. The differences in the geometries of salt structures in different regions show that the thickness of the salt sequences has an important influence on the development of salt-cored detachment folds and related thrust faults in the Tarim Basin (Yu et al. 2014).

Salt sequences and salt structures in the Tarim Basin are closely linked to hydrocarbon accumulations. Oil and gas fields have been discovered in the subsalt, intrasalt, and suprasalt strata. Salt deformation has created numerous potential traps, and salt sequences have provided a good seal for the preservation of hydrocarbon accumulations. Large- and small-scale faults related with salt structures have also given favorable migration pathways for oil and gas. For example, the trap style of the Dawanqi oil field in the Kuqa depression is a suprasalt faulted-anticline, controlled by salt tectonism (Fig. 10.90a). There the associated thick salt sequence is a good seal, which forces oil migrated along the Tuzimazha fault from the underlying Jurassic and Triassic source rocks into the sand reservoirs in the Neogene Kangcun Formation and moves oil into suitable reservoir sands as high as the Pleistocene sections.

But as in most oil accumulations worldwide, a subsalt trap tends to hold back larger hydrocarbon volumes. The Kela 2 structure is a subsalt imbricate pop-up structure, which is one of the largest gas fields in China with proven reserves of 284 billion m^3 and across its extent is sealed by the thick salt sequence of the Paleogene Kumugeliemu Formation (Yu et al. 2014). The structure allows the underlying Cretaceous section to fault and fracture, while the salt flows and maintains its seal integrity.

Although holding a smaller volume, the trap in Kela 3 gas field (also located in the Kuqa depression) is very interesting as it one of the few examples of a producing intrasalt field. The structure is a faulted anticline, where the reservoir is made up fine sandstones encased in the middle portion of the salt sequence in the Kumugeliemu Formation (Fig. 10.90c).

To the south of the Kuqa depression there are fields created by salt dissolution of the Mississippian-age salt of the Bachu Formation, such as the Tahe oilfield, which is mostly a subsalt hydrocarbon accumulation (Fig. 10.90d). Edge dissolution has driven overburden collapse and faulting, which is focused around the salt's dissolution edge. A salt edge allows hydrocarbons formerly draining laterally beneath a salt bed to move vertically in the overlying succession. Small-scale normal faults with 40–80-m (131–262-ft) throw are developed in the salt-edge sags in the Tahe These faults connect the deep source rocks and shallow reservoirs, and are important migration pathways (Yu et al. 2014).

Evaporite Dissolution

Collapse-related traps can form early within the depositional setting, or much later during catabaric salt removal. A dissolving subsurface salt unit creates zones of differential collapse, which can induce economic levels of fracturing in the overburden. Where the effects of a shallow dissolution edge reach the landsurface it creates a depression, which focuses deposition of sand, mud or even reefal buildups around its rim (Fig. 7.6; subsidence trough). If it does not reach the surface it still affects brittle overburden as it creates fractures that increase permeability. Either style of dissolution creates anomalous fluid movements, diagenetic haloes, and reservoir modification that can form a structural anomaly at the seismic scale. Salt dissolution breccias that define the position of former salt units or intervals of former salt cements can contribute to the permeability of the fractured overburden interval.

An association between salt collapse, fracturing and oil production is proven in the oil and gas fields of southeast Saskatchewan, southeastern Montana and southwestern North Dakota (Smith and Pullen 1967; Swensen 1967). Examples include reservoirs in Upper Devonian carbonates of the Hummingbird Field (Birdbear Formation), and the Dolphin, Fryburg, Kisbey, Flat Lake, Medoria-Scoria, Outlook, Star Valley, Tatagwa, Tule Creek, Walpole and West Hope fields. In their study of reservoir porosity in Devonian reef and bank carbonates of western Canada, Beales and Oldershaw (1969) make the observation that, "much of the so-called primary porosity in reef reservoirs may be evaporite solution porosity." Salt collapse depressions in the landscape also focused deposition of Cretaceous reservoir sands in the Mannville Formation in Westhazel Field. Subsurface salt bed leaching and collapse has also contributed to porosity distribution in various North Sea fields (Cartwright et al. 2007; Jenyon and Taylor 1983; Lohmann 1979) and to the fracturefocused creation of porosity in hydrothermal dolomites in the platform carbonates of the Rainbow/Zama Basin.

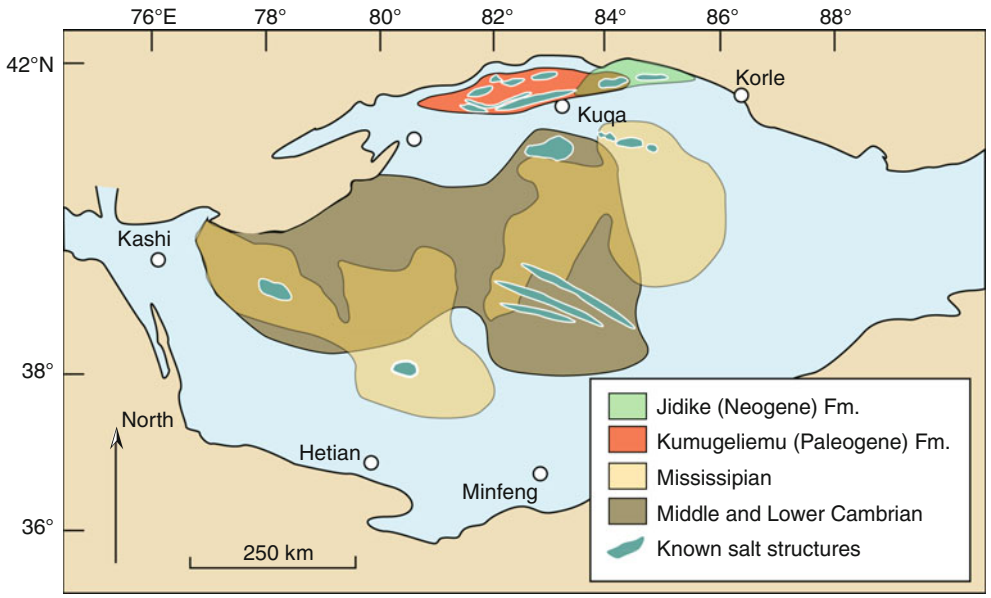

Fig. 10.89 Distribution of the 4 main levels of salt in the Tarim Basin, China, and the positions of the main salt structures (After Yu et al. 2014)

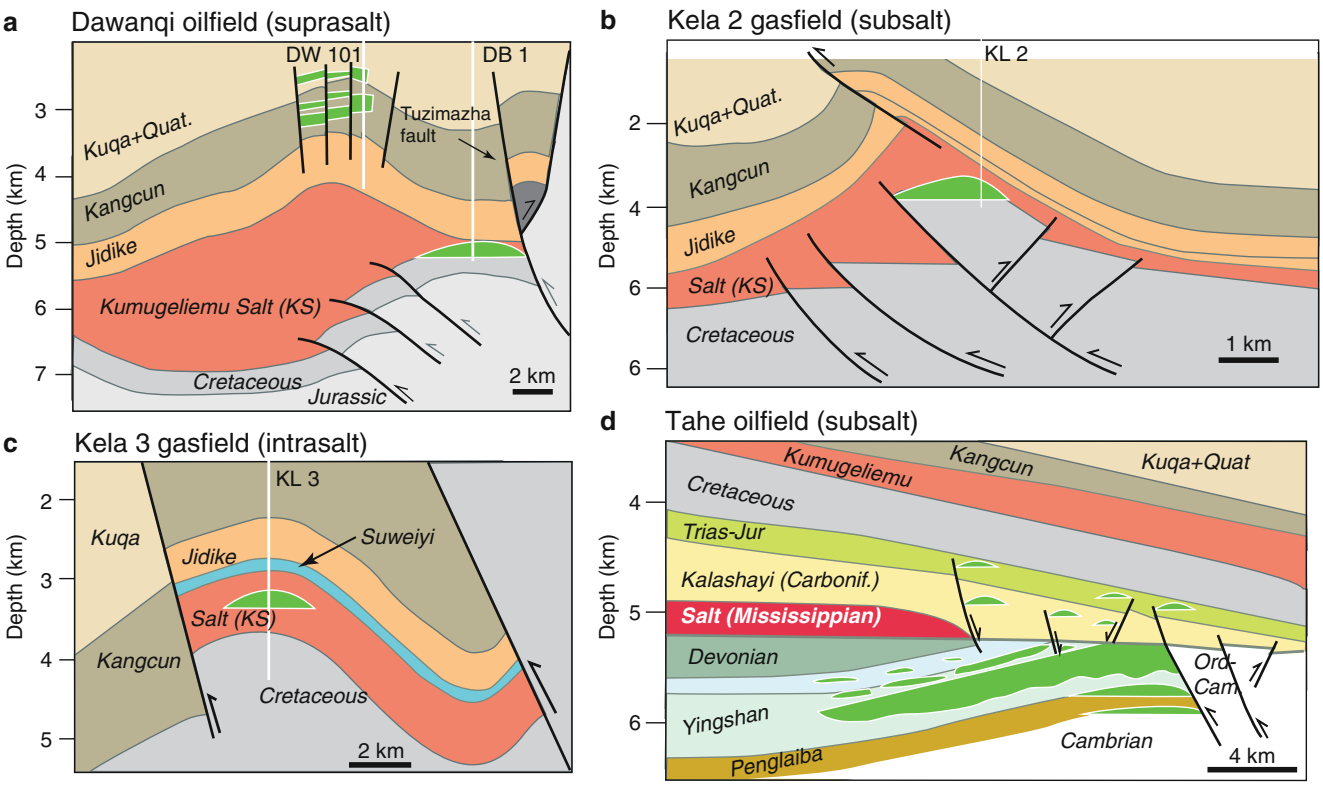

Fig. 10.90 Cross sections showing the trap styles in selected salt-related oil and gas fields in the Tarim Basin. (**a**) Dawanqi suprasalt oil field. (**b**) Kela 2 subsalt gas field. (**c**) Kela 3 intrasalt gas field. (**d**) Tahe subsalt oil field. **a** = **c** are related to the Paleogene salt that dominates the Paleogene Kumugeliemu Formation. The Tahe field is related to the dissolution edge of the salts in the Carboniferous Bachu Formation (After Yu et al. 2014)

The various salt collapse reservoirs in Devonian carbonates of Canada are typified by fractures and solution-enlarged vuggy to karstic pore systems in what are otherwise dense carbonates. These reservoirs have porosities exceeding 20–30 % and permeabilities in the range of darcies. The fields are small but their location makes them economic. Hummingbird Pool has produced more than 3 million barrels and Kisbey more than 1.6 million barrels. The Hummingbird oil pool was discovered in September 1966 on the northwest flank of the Williston Basin by drilling a semi-circular collapse-fill structure covering 2.6 km^2, thought to be a pinnacle reef prior to drilling (see Fig. 7.7 for location of Hummingbird Trough). Oil in the Hummingbird structure is produced from fractured 15 m-thick algal and bioclastic limestones of the Mississippian Charles Formation and 17 m-thick vuggy dolomites of the Devonian Birdbear Limestone. The structure was created by local solution collapse followed by complete regional dissolution during multiple episodes of Prairie Evaporite solution loss during the Late Devonian and Early Mississippian.

Synthesis of the various styles of dissolution induced traps in the Alberta Basin of Canada and the Williston Basin in the USA shows the dissolution process is broad ranging, variable in terms of timing and tied to the dissolving edge of the Prairie Evaporite (Fig. 7.7). Compactional drapes can create a rollover anticline that is closed over the dissolved edge of a residual salt body (Fig. 10.91a; Anderson et al. 1988; Anderson and Knapp 1993; Parker 1967). Local solution or collapse can form a sediment-filled sink that transforms to an inverted thick with the ongoing solution of the surrounding salt (Fig. 10.91b; a "pseudo-reef" – Anderson and Hunt 1964). Or subsidence can form a focused sand infill within a solution-induced depression on the land surface (Figs. 7.7 and 10.91c): or it can form as a remnant of a formerly widespread sand unit that was ultimately preserved only in sediment-filled depressions within the salt bed (Fig. 10.91d). Seismic is very useful in defining the lateral and vertical extent of many collapse anomalies and, if properly acquired and processed, can be used to define internal stratigraphy and reservoir development. Salt collapse structures can lead to focused oil entrapment in fractures in what otherwise may be a "tight" overburden lithology (Fig. 7.7). A breach in a dissolving salt bed can also create structural and stratigraphic closure in the overburden. This is especially so if the collapse anomaly occurs "on-salt", i.e. within a breach surrounded by, or adjacent to, the dissolving salt edge.

Ongoing fluid throughflow prior to oil emplacement in intervals above a dissolved salt bed or collapse chimney may have become pervasively cemented and thus rendered impermeable. Even so, the interval may then provide a seal for fractured and leached reservoirs still being created along the downdip side of the adjacent collapse basin. Collapse structures in the carbonate overburden may be multistage structures located "off-salt", i.e. in areas where all salt has been removed, as in the classic "Hummingbird" oil trap. Hummingbird drape was created by sequential collapse and its pinnacle-like appearance in seismic gave it the name "pseudo-reef" in early exploration programmes in the Alberta Basin (Fig. 10.91b). When dissolution is early, sediments often thicken above the areas of dissolution and thin in the areas over the remaining salt outlier. These overlying sediments can develop the same types of porosity patterns that form above salt ridges. Sometimes the salt dissolves in stages and so creates sequential thickened beds up section as the locus of salt dissolution shifts. In Fig. 10.91b, two areas of sediment thickening are created by salt dissolution; the first forms in stage 2, the second in stage 4. This and later differential compaction and drape can create reservoirs above salt remnants (high in stage 2) or by later differential compaction (stages 3 and 4). Other solution traps may be "on-salt," the result of compactional drape over a single stage fill of a salt solution trough such as at Kisbey Field (Fig. 10.91c, d).

Collapse has also created reservoirs in quartz sands such as Berry Field and the Westhazel pool in Lower Cretaceous fluvial sandstones of Alberta. These reservoirs were created by depositional focusing of fluvial sands at the migrating edge of the dissolving subsurface salt of the Prairie Evaporite (Hopkins 1987). Compared with most stratigraphic traps in Cretaceous sands in the region, the Berry Field is unusual in its occurrence on the flank of a local structural high within a larger regional structural depression. This unusual synclinal setting for the reservoir is a direct indication of its origin as a fluvial system within a landscape position controlled by salt solution.

The Westhazel General Petroleums Pool of west-central Saskatchewan, Canada, produces from the GP member of the Lower Cretaceous Mannville Group and is an excellent example of reservoir stacking in a salt dissolution trough (Fig. 10.92; Anderson and Cederwall 1993). The reservoir facies consists of fine- to medium-grained quartzose sandstones. The lateral uniformity and coarsening upward appearance of this unit and the uniform thickness of the underlying and overlying shales indicates that the General Petroleums Member was deposited in a relatively shallow, marine environment. The pool was discovered in 1971 and produced in excess of 60,000 m^3 (380,000 barrels) of heavy oil from the marine sandstones of the General Petroleums (GP) Member.

This reservoir is structurally closed across the updip, eastern dissolutional edge of the underlying Middle Devonian rock salt of the Leofnard Member of the Prairie Evaporite. The leaching of these salts occurred in post-Mannville time in the Westhazel area and caused the regional southwest dip of the General Petroleums member to be locally reversed

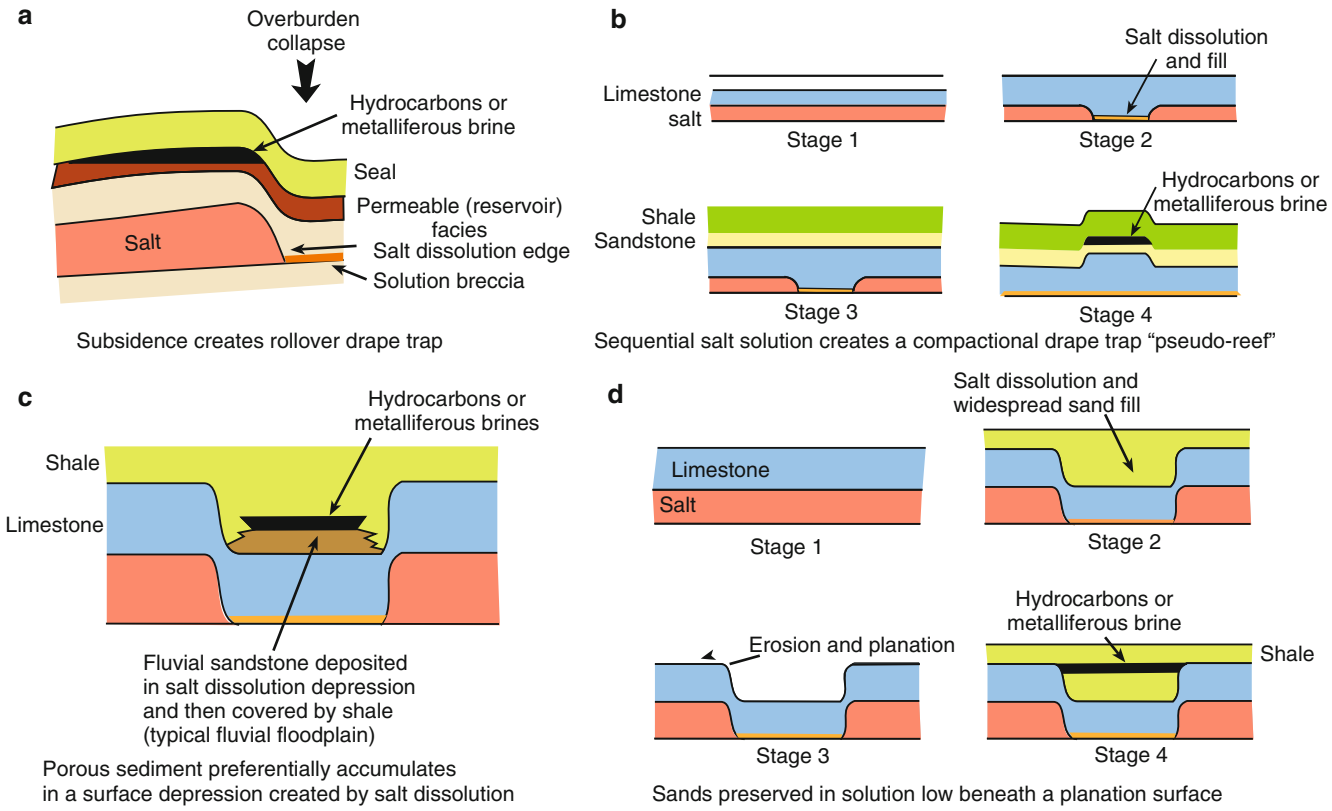

Fig. 10.91 Styles of structural and diagenetic trap created by localised salt solution (In part after Anderson et al. 1988). See text for detail of (**a**–**d**)

(Fig. 7.6). The thin, 10 m-thick reservoir facies at Westhazel does not exhibit a diagnostic signature on either seismic or gravity data. Rather, it is the updip edge of the salt, across which the reservoir is closed, that can be mapped using geophysical techniques.

On seismic data, the dissolutional edge of the Prairie salt is characterized by: (1) a subtle decrease in the amplitude and lateral coherency of the underlying Winnipegosis event; (2) a gradual thinning of key encompassing Palaeozoic intervals; (3) dip reversal along the Beaverhill Lake (Late Devonian) event; (4) dip reversal along the Mannville (Lower Cretaceous) event; and (5) time-structural "push down" of Lower Cretaceous and underlying reflections in areas of recent salt dissolution (salt is characterised by fast seismic velocities). On the gravity profile, the edge of the salt is manifested as a 1.5 mGal anomaly. The interpretation of both geophysical data sets is consistent with available geologic control. For more detailed information on salt solution traps the interested reader is referred to an excellent summary paper by Anderson and Knapp (1993).

Occasionally, the solution breccia created by the dissolution of salt can itself act as the reservoir rather than just fracturing and structuring the overburden. This is the case with Wolf Springs Field (north and south pools) and South Wolf Springs Field, located in Yellowstone County, Montana (Luebking et al. 2001). The Wolf Springs fields are unconformity-related combination structural and stratigraphic traps (Fig. 10.93; Luebking et al. 2001). The fields are located on a structural closure on the Custer anticline, where porosity and permeability development exhibits a northeast-southwest orientation perpendicular to structural strike of the anticline. The solution-collapse breccias pinch out laterally into either dense dolomites or anhydrite-plugged collapse breccias. The overlying shaly dolomite breccia of the Botts Member, located just below the Piper unconformity, and the Jurassic Piper Limestone together provide the top seal.

The Wolf Springs and South Wolf Springs fields were discovered in 1955 and 1957, respectively, and have produced more than 5.7 million barrels of oil from the Pennsylvanian Amsden Formation. Amsden reservoir rocks in the area are fractured and brecciated cherts and dolomites that occur in several laterally persistent and mappable zones (Fig. 10.93). The Amsden was deposited in a peritidal to sabkha setting, where evaporite minerals, mainly anhydrite, were once common. These evaporites were partly replaced by silica (chalcedony and chert) soon after deposition. Later dissolution of the remaining evaporites not long after the silicification event, or during the pre-Middle Jurassic unconformity, produced the solution-collapse chert breccias that now serve as

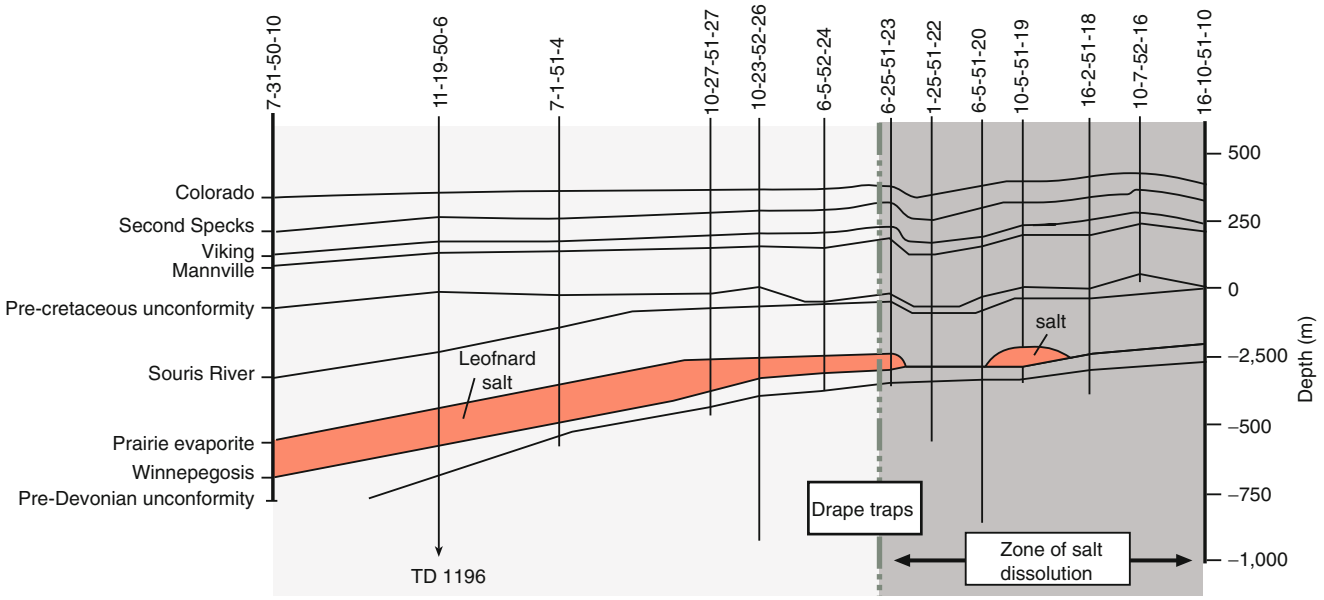

Fig. 10.92 Schematic section illustrating the eastern dissolutional edge of the Prairie Formation. The Westhazel study area straddles T50 and T51 in R23W3M – see Fig. 7.7 for location (After Anderson and Cederwall 1993)

the best reservoir facies in the field. Subtle variations in the diagenetic history of these breccias are a major factor in shaping reservoir quality. But the most impressive accumulation, worldwide, related to salt dissolution is the Athabasca oil (tar) sand accumulation.

Athabasca Tar Sands, Western Canada

The heavy-oil or bitumen reservoirs of northeast Alberta contain 1.8 trillion bbl of resources, the second largest known oil reserve after Saudi Arabia. Of this, almost 1 trillion bbl are contained in the Lower Cretaceous Wabiskaw and McMurray reservoirs of the Athabasca oil sands. The Athabasca oil sands lie close to the eastern edge of the Western Canada Sedimentary Basin (WCSB) at outcrop or a shallow depth of burial, and therefore, their location was known from direct observation even prior to the first descriptions by the Geological Survey of Canada (Fig. 10.94; Tozer et al. 2014; Broughton 2013).

The Lower Cretaceous Athabasca oil sands deposit, the largest of three in northern Alberta accumulated along a north-northwest oriented depression on the Devonian carbonate strata along the uplifted eastern margin of the WCSB. Pathways through the Devonian substrate controlled oil migrations into the overlying Cretaceous sands. The oil was subsequently biodegraded in situ into bitumen (7–9° API). The source rocks, timing of the oil migrations and bitumen formation are contentious, but there is a general consensus for the source rocks being Devonian strata to the west, and for Late Cretaceous to Early Tertiary (Laramide) oil migrations and biodegradation (Broughton 2013).

The northern one-third of the Athabasca deposit overlies a segment of a 150 km wide Middle Devonian salt dissolution trend that extends for 1,000 km along the eastern updip margin of the Middle Devonian Elk Point evaporite basin (Figs. 10.94 and 10.95). The northern Athabasca deposit and the easternmost margin of the Cold Lake deposit to the southeast are the only oil sands areas across northern Alberta to have been structurally impacted by the underlying salt removal.

Salt dissolution collapse-subsidence of Upper Devonian fault blocks underlying the Athabasca oil sands deposit has been widely accepted as the main control that configured the sub-Cretaceous paleotopography (Fig. 10.95) with multi-kilometer long troughs. This evaporite karst structuring fragmented and sagged the Upper Devonian strata, which gravity settled into salt withdrawal areas prior to the accumulation of the unconformably overlying McMurray Formation (Aptian) sands. Factors driving the collapse and the various mechanism of adjustment, such as fluvial capture in monoclinal sags, were discussed in detail in Chap. 7

The giant scale of the halite salt karst underlying the northern Athabasca deposit is widely known as one of the largest and thickest dissolution collapse-subsidence areas, as well as one of the worlds largest known stacked evaporite and collapse breccia karsts. Historically, within the industry, the salt edge is not typically modelled in terms of evaporite deposition and diagenesis, and is more generally recognized as a fault block subsidence terrain than as a

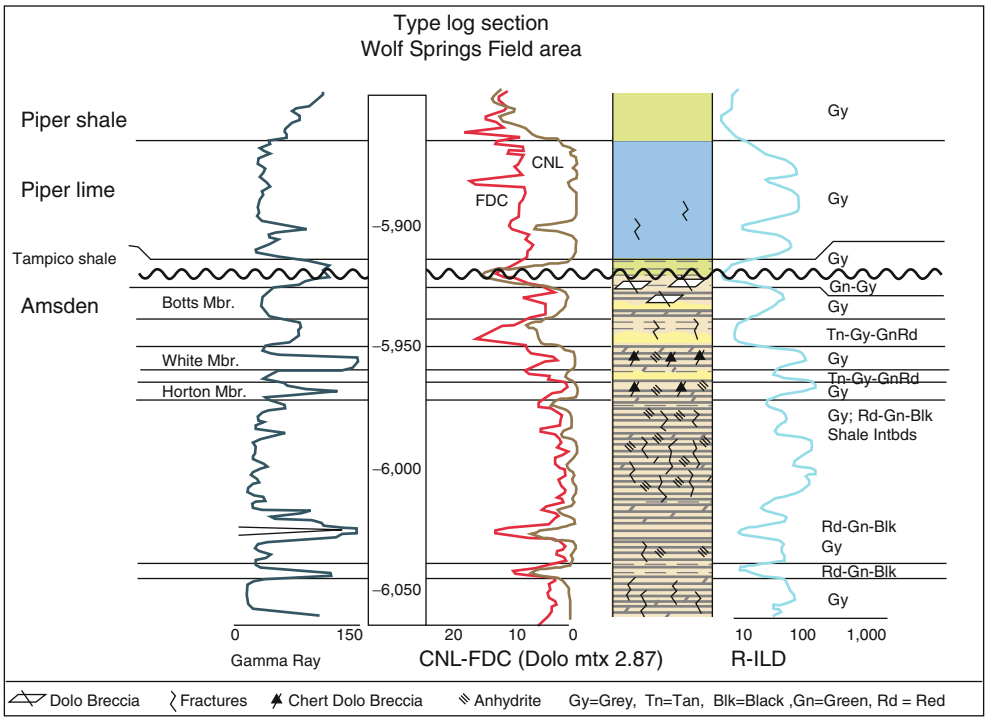

Fig. 10.93 Type log for the Wolf Springs Field area. The Botts, White, and Horton members of the upper Amsden are readily discernible as resistive kicks. The White and Horton members correspond to the zones of solution-collapse breccias. The Botts member is a shaly dolomite breccia. The lithologies shown in the Amsden and Piper formations represent compilations assembled from cores in the area (After Luebking et al. 2001)

system with pervasive faults originating as response to ongoing formation of evaporite collapse breccias. More recent work has begun to integrate the evolution of the salt dissolution edge into an improved understanding that will lead to more efficient recovery of this huge hydrocarbon resource and to better definition of subsurface areas suitable for brine waste disposal (Broughton 2013).

The sub-Cretaceous paleotopography beneath the Lower Cretaceous Athabasca oil sands, northern Alberta, shows an orthogonal lattice pattern of troughs up to 50 km long and 100 m deep between pairs of cross-cutting lineaments (Broughton 2013). These structures are likely inherited from a similar pattern of dissolution collapse-subsidence troughs in the underlying Middle Devonian salt beds. Removal of more than 100 m of halite via meteoric water crossflows has fragmented the overlying Upper Devonian strata into fault blocks and collapse breccias that subsided into the underlying dissolution troughs. An unusually low 1:2 to 1:3 thickness ratios of halite salts to the overlying strata resulted in Upper Devonian strata collapse-subsidence into underlying salt dissolution troughs being more cataclysmic during the first phase of salt removal. The second phase of slower but complete salt removal between the earlier troughs resulted in a more gradual subsidence of the overlying strata. This largely obliterated the earlier pattern of giant cross-cutting dissolution troughs bounded by major lineaments.

The collapse breccia fabrics underlying the earlier troughs differ from those areas between the troughs. Collapse breccias underlying the large troughs often have crushed fabrics distributed in zones that rapidly pinch out between fault blocks. Breccias between troughs developed as giant mosaics of detached carbonate blocks that formed breccia pipe complexes. Multiple sinkholes up to 100 m deep are aligned along multi-km linear valley trends that dissect the sub-Cretaceous paleotopography. These sinkhole trends form orthogonal patterns inherited from underlying lattice of NW-SE and NE-SW salt-structured lineaments. These cross-cutting sinkhole trends have a smaller 5 km scale reticulate pattern similar to the giant 50 km scale pattern of collapse-subsidence troughs. Other sinkholes developed as lower McMurray strata sagged when underlying Devonian fault blocks and breccia pipes differentially subsided.

Interestingly, not all hydrocarbon-reservoirs in salt entraining basins typified by stratiform breccias in carbonate platforms, are related to earth-bound dissolution processes. The Cantarell oil field in the Campeche Platform of Mexico, with a current daily production of 1.3 million barrels of oil, is probably the most voluminous oil-producing unit where reservoir fracturing is related to a bolide impact event. The K-T breccia reservoir itself, its ejecta horizon and its sealing muds are related to the same bolide event that wiped out the dinosaurs (Grajales-Nishimura et al. 2000).

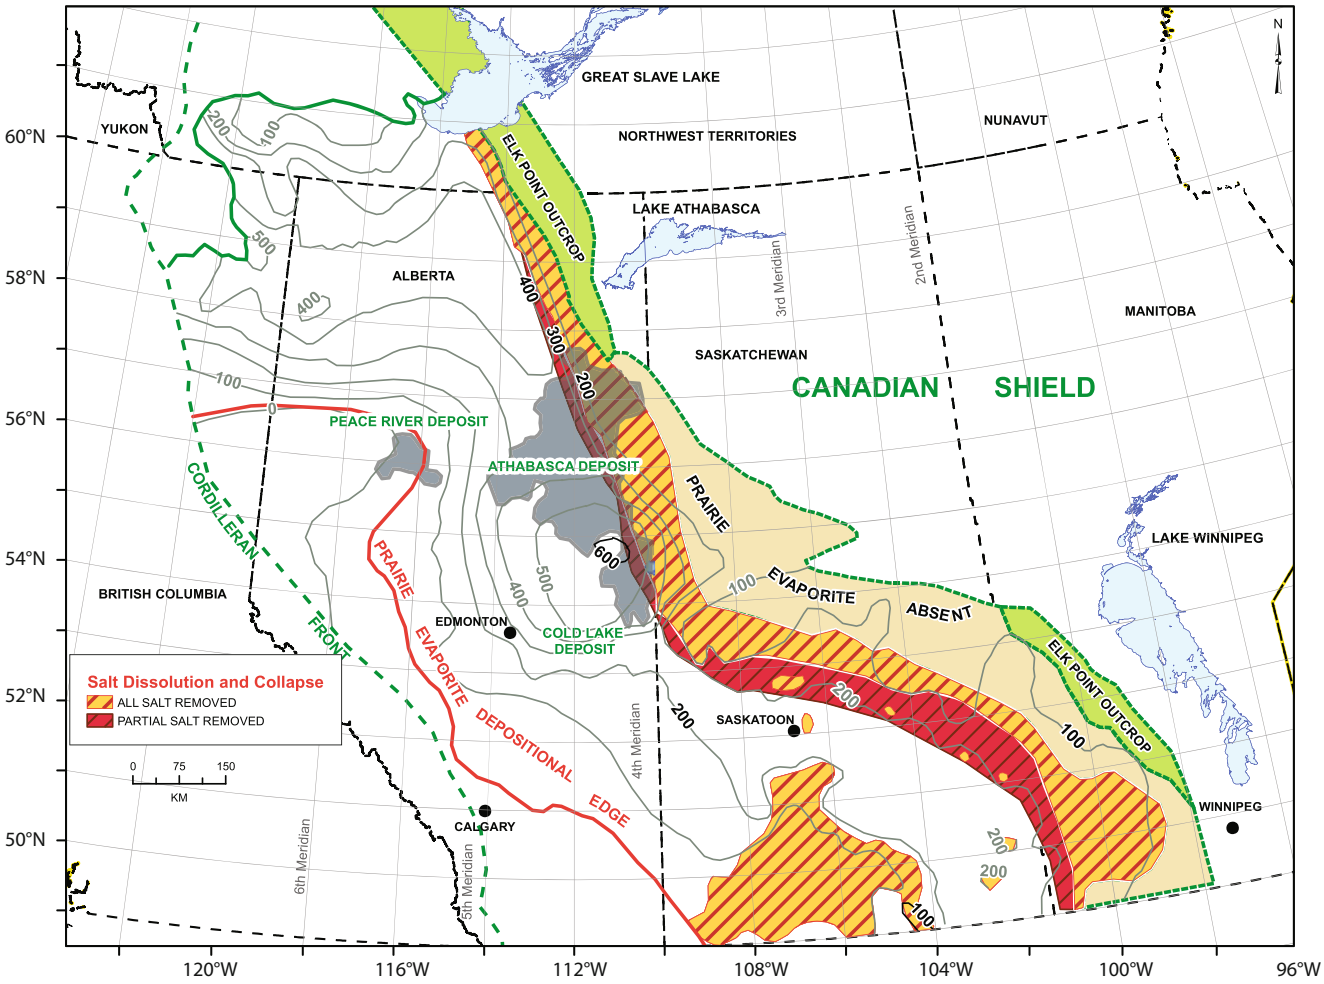

Fig. 10.94 Prairie Evaporite (Middle Devonian) salt basin extends across Western Canada with partial to complete salt removal trends typifying its salt dissolution edges. A 1,000 km long and 150 km wide salt dissolution trend underlies the northern one-third of the Athabasca oil sands deposit and the narrow eastern margin of the Cold Lake deposit to the south. Contours are 100 m (After Broughton 2013)

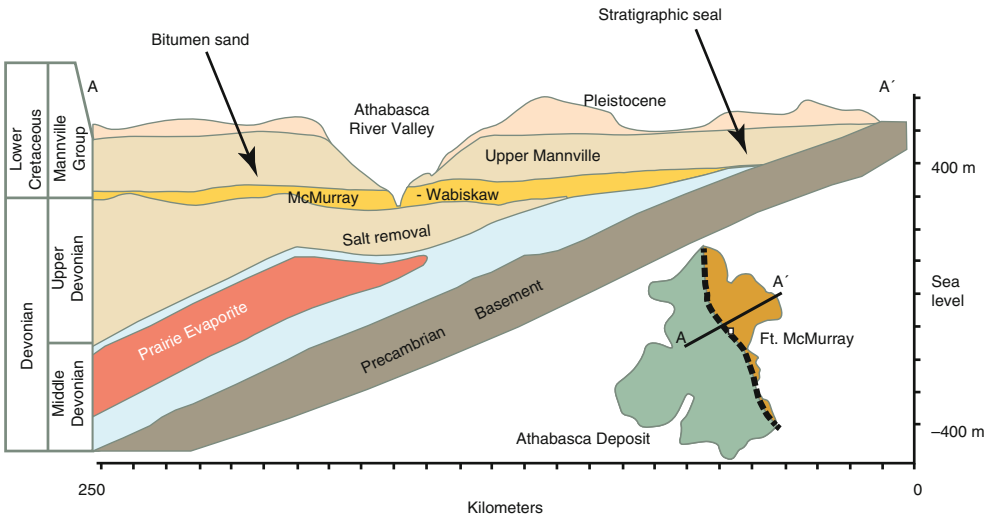

Fig. 10.95 Cross-section across the northern Athabasca oil sands deposit showing the sub-Cretaceous unconformity on the underlying Devonian strata and the salt removal from the Prairie Evaporite (After Broughton 2013; see also Chap. 7)

Potash Resources: Occurrences and Controls

11

Introduction

Natural potash evaporites are a typical part of a brine evaporation series, crystallizing at the higher concentration or bittern end, either at the surface (primary salts) or in the shallow subsurface (secondary salts). Today, bedded accumulations of primary potash evaporites are a relatively rare occurrence. Extremely high solubility of most potash salts means they accumulate in highly restricted, some would say highly continental, modern depositional settings (Cendon et al. 2003). Wherever Quaternary potash does occur naturally, as in the playas of the intermontane Qaidam Basin in China and in the Danakil Depression in the Afar Rift of Africa[1], carnallite, not[2] sylvite, is the dominant potash salt. This has led some to postulate that carnallite is the archetypal primary marine potash phase, while sylvite is a secondary diagenetic mineral formed by incongruent dissolution of carnallite. Others have argued that ancient sylvite was sometimes a primary precipitate, deposited by the cooling of highly saline surface or near surface brines and from seawater with ionic proportions different to those of today (Hardie 1996).

Phanerozoic potash salt series define two distinct time-related groupings of brines and associated minerals: $MgSO_4$-rich and $MgSO_4$-poor. Potash salts have not been recovered from Precambrian sediments, other than in minor amounts of intercrystalline cement in the latest Neoproterozoic evaporites of the Ara Salt Group of Oman and the Hanserian Evaporite Group (HEG) of the Nagaur-Ganganagar basin in India/Pakistan. No potash salt was recovered in Oman (inferred from wireline log), while the dominant potash mineral cored in the HEG is polyhalite, making it less attractive as an exploration target for fertiliser manufacture in that part of the world (Mohnot et al. 2005). All potash deposits rich in $MgSO_4$ accessories are composed of some combination of gypsum, anhydrite, polyhalite, kieserite, kainite, carnallite and bischofite. This group of $MgSO_4$-entraining salts typifies Quaternary salts in the Dallol depression of Ethiopia, the Miocene assemblages of the Ukraine and Sicily, as well as some Permian potash deposits in Europe and Russia and the few Eocambrian deposits known to exist. Potash deposits free of, or poor in, $MgSO_4$ minerals are dominated by some combination of halite, carnallite, and sylvite and typify much of the Phanerozoic rock record. This $MgSO_4$-depleted group constitutes the majority of known reserves of exploited potash, which are dominated by Devonian evaporites in Canada.

Potash is a collective term for a variety of ore-bearing minerals, ores and refined products, all containing the element potassium in water-soluble form (Table 11.1). The word "potassium" is derived from the word potash. In the 1800s the term "potash" was used to describe the mixture of potassium carbonate and potassium hydroxide crystals, which were recovered in heated iron "pots" from boiling the washings of wood or broad-leaf tree leaves "ashes," both these recovered potash salts are caustic. Lye meant sodium hydroxide and potash lye was potassium hydroxide, a higher grade product that has been used since the fifteenth century in the manufacture of higher-grade softer or facial grade soaps.

Potash minerals were mined from at-surface and nearsurface Quaternary salt beds in the Dallol region of the Danakil Depression as long ago as the fourteenth Century. In the western world, the Germans were the first to discovery subsurface quantities of potash salts in the 1850s in the Zechstein Basin and a few years later had determined the utility of potash as a fertiliser for improving plant production. The first documented use of potash as a soil fertiliser in the USA was in 1873, and since the start of the twentieth century potash

[1]The name carnallite comes from the German geologist Rudolph von Carnall (1804–1874).

[2]The name sylvite come from *sal digestevus Sylvii* (New Latin: digestive salt of Sylvius), named for the Dutch physician and chemist Franciscus de la Boë (1614–1672), a.k.a. Sylvius.

Table 11.1 Potassium ore salts and contaminants, with K_2O equivalents

Mineral	Composition	K_2O %	Comments
Chlorides			
Sylvite	KCl	63.2	Principal ore mineral
Carnallite	$MgCl_2 \cdot KCl \cdot 6H_2O$	16.9	Ore mineral and contaminant
Kainite	$4MgSO_4 \cdot 4KCl \cdot 11H_2O$	19.3	Important ore mineral
Sulphates			
Polyhalite	$2CaSO_4 \cdot MgSO_4 \cdot K_2SO_4 \cdot 2H_2O$	15.6	Ore contaminant
Langbeinite	$2MgSO_4 \cdot K_2SO_4$	22.7	Important ore mineral
Leonite	$MgSO_4 \cdot K_2SO_4 \cdot 4H_2O$	25.7	Ore contaminant
Schoenite (picromerite)	$MgSO_4 \cdot K_2SO_4 \cdot 6H_2O$	23.4	Accessory
Glaserite (aphthitalite)	$K_2SO_4 \cdot (Na, K)SO_4$	42.5	Accessory
Syngenite	$CaSO_4 \cdot K_2SO_4 \cdot H_2O$	28.7	Accessory
Associated minerals			
Halite	NaCl	0	Principal ore contaminant
Anhydrite	$CaSO_4$	0	Common ore contaminant
Bischofite	$2MgCl_2 \cdot 12H_2O$	0	Accessory contaminant
Bloedite (astrakanite)	$Na_2SO_4 \cdot MgSO_4 \cdot 2H_2O$	0	Accessory
Loewite	$2MgSO_4 \cdot 2Na_2SO_4 \cdot 5H_2O$	0	Accessory
Vanthoffite	$MgSO_4 \cdot 3Na_2SO_4$	0	Accessory
Kieserite	$MgSO_4 \cdot H_2O$	0	Common ore contaminant
Hexahydrite	$MgSO_4 \cdot 6H_2O$	0	Accessory
Epsomite	$MgSO_4 \cdot 7H_2O$	0	Accessory
Ores			
Sylvinite	KCl + NaCl	10–35	Canada, USA, Russia, Brazil, Congo, Thailand
Hartsalz	$KCl + NaCl + CaSO_4 + (MgSO_4 \cdot H_2O)$	10–20	Germany
Carnallitite	$MgCl_2 \cdot KCl \cdot 6H_2O + NaCl$	10–16	Germany, Spain, Thailand
Langbeinitite	$2MgSO_4 \cdot K_2SO_4 + NaCl$	7–12	USA, Russia
Mischsalz	Hartsalz + Carnallite	8–20	Germany
Kainitite	$4MgSO_4 \cdot 4KCl \cdot 11H_2O + NaCl$	13–18	Italy, Ethiopia, Belarus

has been increasingly used to enhance agricultural productivity worldwide. Today, our ability to feed the world's ever-expanding population is totally dependent on the use of various soluble potash salts as plant[3] fertilisers.

This change in potash usage from an ash product to an industrial chemical/fertiliser has changed the meaning of the term potash. Since the 1950s the terms, potash or potash salts, have been used commercially as general descriptions for potassium chloride (KCl or muriate of potash – MOP), potassium sulphate (K_2SO_4 or sulphate of potash – SOP), potassium-magnesium sulphate (K_2SO_4-$MgSO_4$ or sulphate of potash magnesia), potassium nitrate (KNO_3 or saltpetre), or mixed sodium-potassium nitrate ($NaNO_3 + KNO_3$ or Chilean saltpetre). Carnallite and sylvite are the most common naturally occurring potash mineral salts, with sylvite the most economically important. Other common potassium-entraining natural evaporite salts include: kainite, kieserite, langbeinite, leonite and polyhalite (Table 11.1). Of these, carnallite, kainite, langbeinite and polyhalite when processed, can constitute potash ore minerals. Today, langbeinite ore is economically exploited only in New Mexico.

Sylvinite, a mixture of sylvite and halite, constitutes the highest-grade ore source, while MOP constitutes some 96 % of the world's current potash production. Carnallite, when present in a sylvinite ore, is considered a contaminant. Muriate of potash is also a byproduct of the processing of the natural deposits of $NaNO_3$, which historically have been mined in significant volumes from soils in the hyperarid Atacama Desert of Chile. Potassium sulphate is produced

[3]Potassium increases plant resistance to drought, frost and to a number of diseases and pests, it is essential for the development of the root system, fosters nitrogen fixation in leguminous crops, and also it improves the size, colour and sugar content of crops, such as fruits. Natural reserves of soil-potassium diminish with each successive crop. This withdrawal or "soil mining" is greatly increased and accelerated by higher yields and more intensive cropping. For example, high-yielding, short-season rice varieties in a double-cropping annual system will remove up to 36 times more potassium from soil compared to a single crop of traditional varieties. Potassium uptake by rice in a triple-cropping system will be about 50 % more than extracted by two crops annually. Although some soils are rich in potassium, many are poorly endowed and crop production thereon is unsustainable if the potassium removed by cropping is not replenished in appropriate amounts.

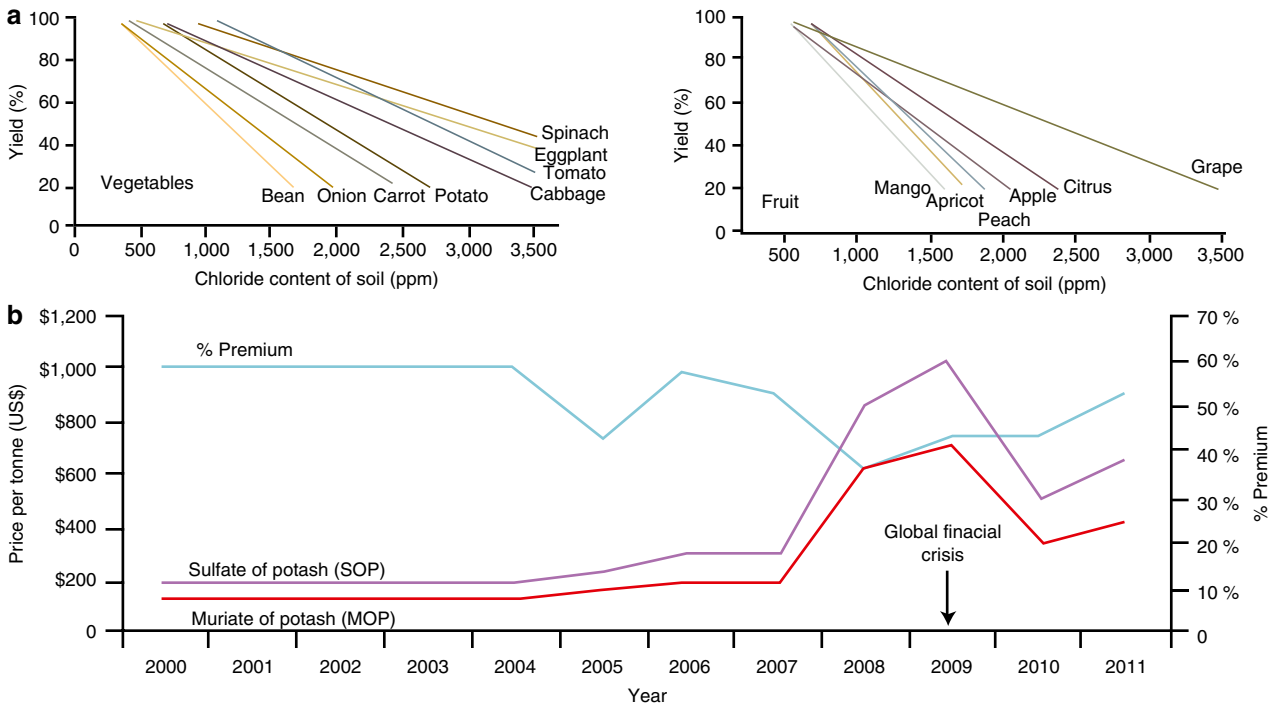

Fig. 11.1 Muriate of potash (MOP) and sulphate of potash (SOP). (**a**) Fruit and vegetables show decreasing yield with increasing chloride content in the soil. (**b**) Price comparison shown how SOP sells at a premium compared with MOP

from mined minerals in Germany and the USA and from processing of cool-climate lake brines in Canada, Chile, China, and the USA. In order to compare the various mineral sources of soluble potassium, the commodity is often listed and traded as K_2O equivalents (Table 11.1). No source of soluble potash for fertiliser actually contains K_2O as this form of potash is highly caustic and burns any plant in contact.

The fertiliser industry uses more than 90–95 % of produced potash, while the chemical industry uses the remainder in the manufacture of soaps and detergents, glass, ceramics, synthetic rubber and numerous industrial chemicals. As mentioned earlier, the main use of potash is as a source of soluble potassium, which is one of the three primary plant nutrients; the other fertilisers are fixed and soluble phosphorus and nitrogen. Mankind's use of these three nutrients, in commercial forms, started the "Green Revolution" in agriculture in the 1950s. More than 95 % of the world's potash fertiliser is today produced as muriate of potash (MOP-potassium chloride) and sylvite is the preferred ore mineral in most mines, due to relatively low processing costs. MOP fertilizer has a minimum requirement of 60 % K_2O content. Sulphate of Potash (SOP-Potassium sulphate) and Sulphate of Potash-Magnesia (SOPM-potassium magnesium sulphate), together make up around another 5 % of current fertiliser usage, and are required by some more sensitive crops where elevated chloride levels could be a problem (Fig. 11.1a). SOP has a minimum requirement of 50 % K_2O, while SOPM has a minimum requirement of 19 % K_2O content. Retailers sell potash, or potash blended with other fertilizers, in dry or liquid form.

Since 1960, the number of people on the planet has more than doubled, while the amount of arable land per hectare has halved (Fig. 11.2a). Yet the total crop or food production per capita has managed to exceed the growth in world population. Each year, potash fertiliser is used in the production of fruit and vegetables (17 %), maize (15 %), wheat (15 %), rice (14 %), sugar (4 %), cotton (4 %), soybeans (4 %) and palm oil (2 %). Our ability to continue to produce more food per capita is largely the result of the increasing use of potassium and other fertilisers and encapsulates the "Green Revolution".

Even so, the world's ever-expanding population means soil degradation now affects more than 15 % of the Earth's land area, resulting in 30 % of the world's cropland becoming increasingly unproductive, especially in the semi-arid climate belts of the Developing World, where many subsistence farmers cannot afford to buy fertiliser to boost yields (Rattan 2007). In addition, salt marshes of the temperate zones, heavily irrigated lands, and wetland rice soils are also increasingly saline, with elevated levels of sodium and chloride in the waters (Kendall and Pimental 1994; Timms 2005). Worldwide, soil degradation affects more than 15 % of the Earth's land area, resulting in 30 % of the world's current cropland currently becoming increasingly unproductive. This is mostly due to increasing soil salinity, especially in the

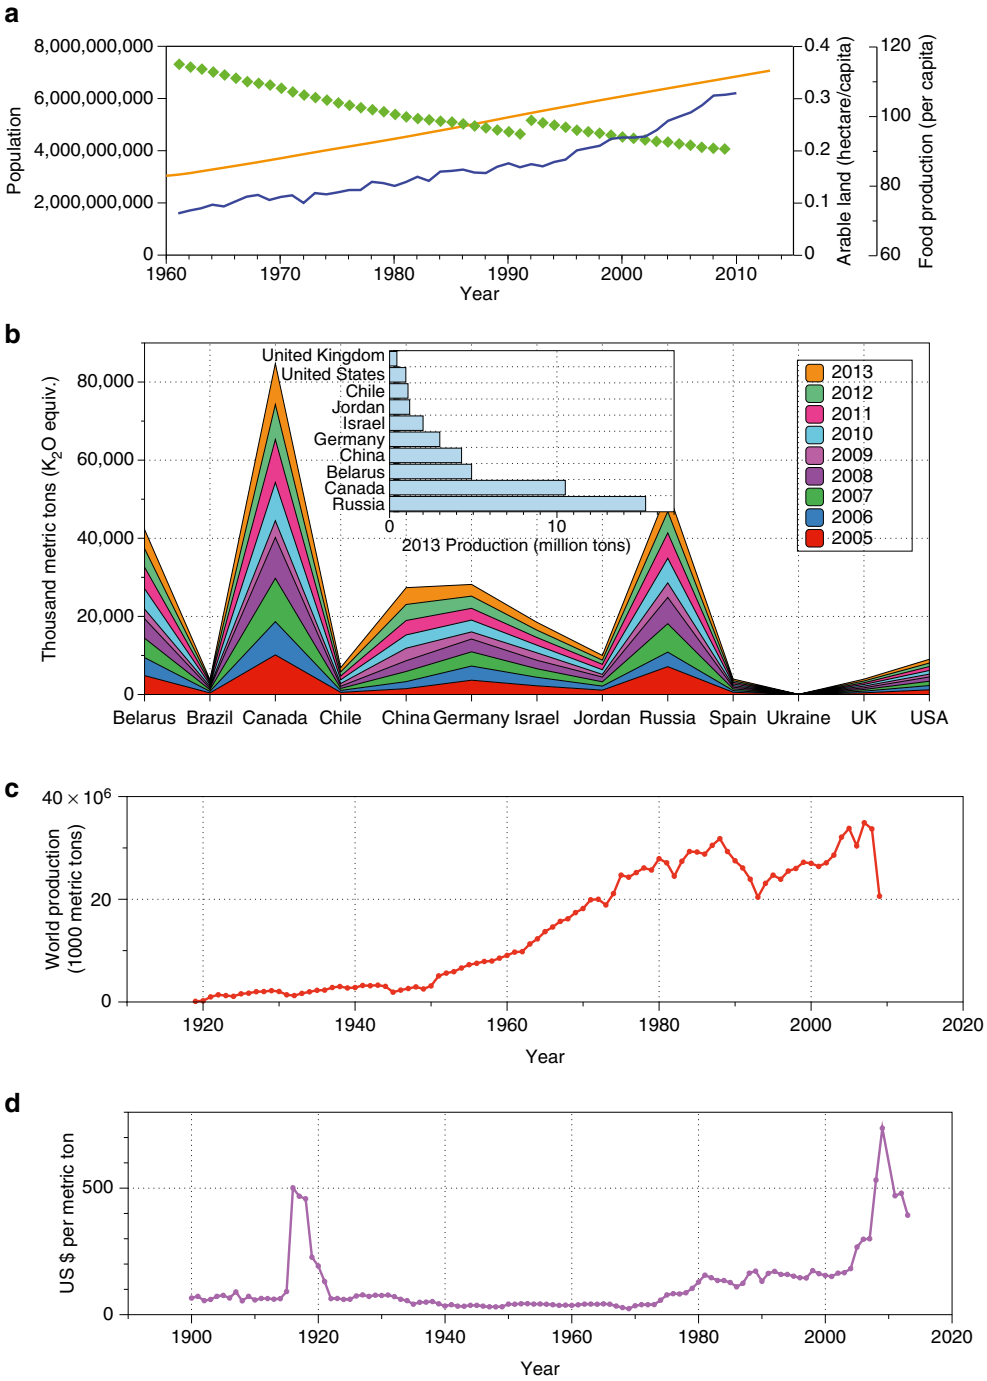

Fig. 11.2 World Statistics. (**a**) Trends since 1960 of world population (*gold line*), arable land per capita (*green diamonds*) and per capita food production (*blue line*), indexed to 100 and based on period 2004–2006 (From FAO database http://faostat3.fao.org accessed Sept 1, 2012). (**b**) Major potash producers for 1998–2010, the legend and chart match in their vertical order (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/pubs/commodity/potash/ last accessed 7 April, 2014). *Inset* shows 2013 production for top ten. (**c**) World potash production 1919–2010. (**d**) Price (annual average) of potash in US$ per metric ton. world's semi-arid climate belts where water access is limited and irrigation, coupled with application of fertiliser, drives a combination of salinisation and groundwater depletion (Rattan 2007). Salinity induced symptoms in a crop include reduced root growth, decreased flowering, and smaller leaf size (Fig. 11.1a). When applied to the soil, SOP has a lower salinity effect on soil quality compared to MOP (potash is carried to the soil and the plant roots as a soluble sulphate versus chloride salt), and therefore is the preferred fertilizer for many saline soils around the world. For this reason there is a 40–60 % price premium for SOP over MOP (Fig. 11.1).

Through the increasing use of potash and other fertilisers, we are currently winning the battle to supply enough food to support the world's growing population, even as the quality of some soil is subject to increasing salinisation. The major cause of famine today is not lack of food in the world, rather, regional famine is often due to a combination of war, ethnic and religious conflicts. The result is lack of required infrastructure and funding at the state and regional level needed to move large volumes of food into regions that require it.

In my opinion, over the longer term, ongoing unfettered population growth is driving what will likely be a catastrophic

collapse in the world's food supply. This is true whether or not one subscribes to claims of anthropogenically-induced climate change and the possible additional stresses this will add to an already depressing picture of the future health of the world's agriculture (Fig. 11.1a). Population growth is a problem that is much harder for the world's political class to address by giving speeches and putting in place a few legislative measures to reduce anthropogenic CO_2. It requires governments to address head-on the larger and more fundamental problem of too many mouths to feed. This is a situation created by a combination of human need and superstition, a lack of social systems to support the old, and by dogma inherent in the majority of the world's religions in their support of notions of large families, a lack of support for contraception and antithetic attitudes to homosexuality.

Production and Consumption

In 2013–2014 there were 14 potash producing countries, including smaller production volumes from the Ukraine, the UK and Chile. In 2013 Russian production exceeded that of Canada, other countries in the top ten in descending order were; Belarus, China, Germany, Israel, Jordan, Chile, USA and the UK (Fig. 11.2b and inset). The volume of produced potash has been steadily increasing since records are first available in 1919 (Fig. 11.2c). There were significant drops in world production in the late 1980s and in 2009, related to world financial crises. The price of potash in the period 1900–2013 shows a serrated rise since the 1950s, directly tied to the agricultural green revolution and increasing population pressure on the world's arable land (Fig. 11.1a). This is combined with rising middle class numbers in the developing world, along with increasing consumption of animal protein.

The sharp price spike during World War 1 (1914–1918) relates to the use of Chilean salt petre (potassium nitrate and sodium nitrate) in the manufacture of gunpowder (mixture of sulfur, charcoal and potassium nitrate) and to the fact that at that time the Germans exerted control of the world's potash production, which was focused in the Zechstein and Alsace basins (Fig. 11.2d). At that time extractable deposits in the caliche soils of the Atacama Desert were known as "white gold" (Fig. 12.62). Canada, historically the world's largest potash producer, holds more than 45 % of the world's known potash reserves (Fig. 11.3a) and recovers potash by mostly conventional underground mining of bedded sylvinite deposits. Production is centred on the Devonian Prairie Evaporite in the Elk Point Basin in Saskatchewan, with lesser production in the Carboniferous New Brunswick sub-basin in the Maritime Provinces (Table 11.5). Russia is the other major potash producer at the world scale, it holds some 35 % of known world reserves including significant potential for new discoveries in the East Siberian region. Currently, Russia extracts most of its potash from the Cis-Urals region, where sylvinite is conventionally mined from the Permian Upper Kama Basin in the Solikamsk region west of the Urals. Devonian potash is also mined in the Pripyat depression of Belarus, which holds 9 % of the world's known reserves. In terms of world potash resource, Canada once again tops the bill. A combined U.S. Geological Survey and Saskatchewan Geological Survey assessment (Cocker et al. 2010) estimate known potash resources in the Prairie Evaporite Deposit to be around 88.8 billion tonnes of potassium oxide (K_2O). This estimate is higher than various previous estimates ranging from 56 to 67 billion t of K_2O. If correct, the potash resource in Saskatchewan would be sufficient to mine for several thousand years at the current production level.

Significant volumes of Permian potash are still mined from the Zechstein of NW Europe (Germany, UK and the Netherlands), while smaller amounts are mined from the northern margin of the Delaware Basin in New Mexico, USA. Oligocene potash was formerly extracted from the Rhine Graben (Alsace Basin) in France, while Miocene potash was mined until a few years ago in the Stebnik area in the western Ukraine. In Spain, in the northern part of the Ebro Basin near the border with France, potash is produced from Eocene-Oligocene lake sediments. In Utah, potash is solution mined from the Carboniferous Paradox Formation deposits and recovered from Great Salt Lake brines by solar evaporation and flotation. Israel and Jordan use similar solar technology to produce large volumes of potash from Dead Sea brines created naturally from recycled marine Miocene evaporites and connate waters buried beneath the floor of the Dead Sea. In China, various combinations of KCl and/or K_2SO_4 are recovered by processing of saline lake brines from the Qarhan and Lop Nur salt flats. In California, potash and coproducts, borax pentahydrate, soda ash and saltcake, have been recovered from various subsurface playa brines using mechanical evaporation. KCl and K_2SO_4 are byproducts of lithium processing from salar brines in the Atacama Desert of Chile, South America.

Conventional underground mining typically requires an ore grade of 14 % K_2O or higher, and bed thickness of more than 1.2 m, with some 8-m of salt in the mine back or roof (Kogel et al. 2006; p 734). The 14 % rule was established in the 1930s by operations in the Carlsbad region of New Mexico. Last century, under centrally planned economies, the East Germans and the Russians utilized mined potash levels as low as 11 % K_2O. In the USA the Carlsbad producers operated with 80–85 % recovery in the mill (some producers operated with 92 % recovery by pulling pillars). Crystallizers were first installed in the back ends of potash mills by British and French operators to capture potash from waste liquors, before dispatching wastes to the slurry piles. This raised their recovery efficiencies to as high as 92 %.

Today there are 150 countries world-wide that use potash as a major agricultural component (Fig. 11.4a; FAO 2010).

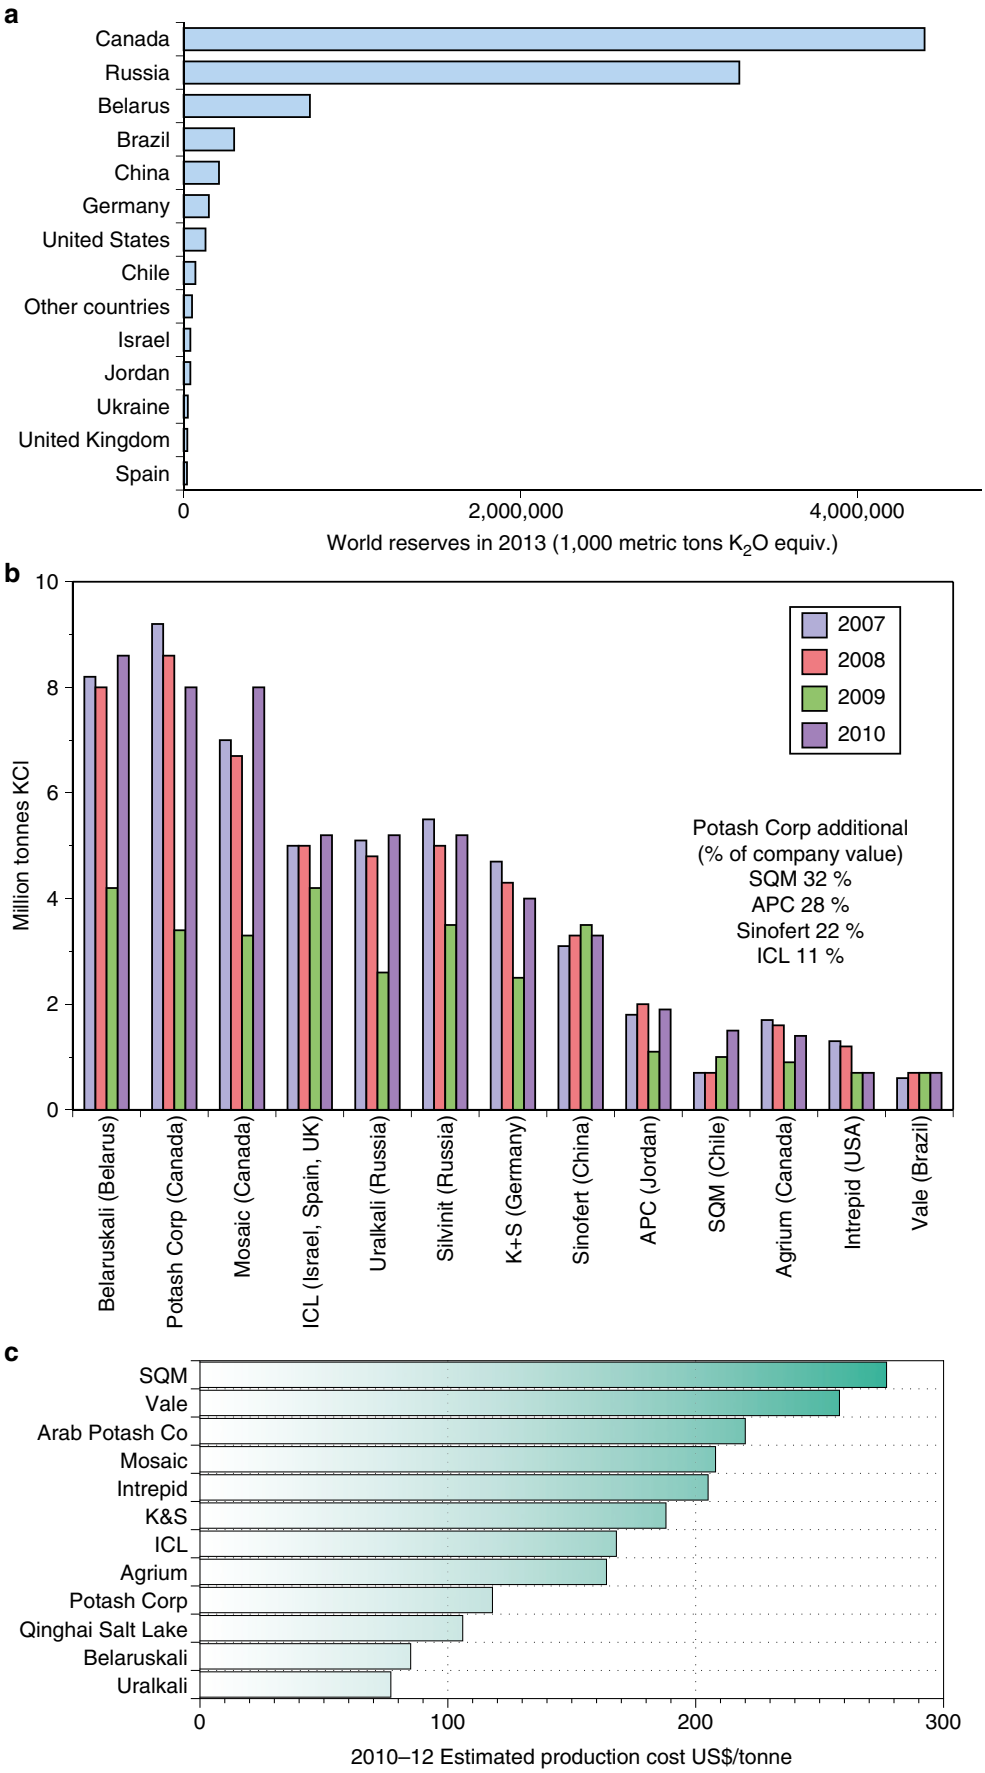

Fig. 11.3 Reserves and ownership. (**a**) World reserves as listed by USGS in 2011 in 1000 metric tonnes. (**b**) Major corporate producers of KCl in period 2007–2010, clearly showing the effects of the Global Financial Crisis in 2009. (**c**) Estimated averaged production costs (US$/tonne) for period 2010–2012, does not include freight costs and is broken down by major producers (extracted from various SaltWork database tables)

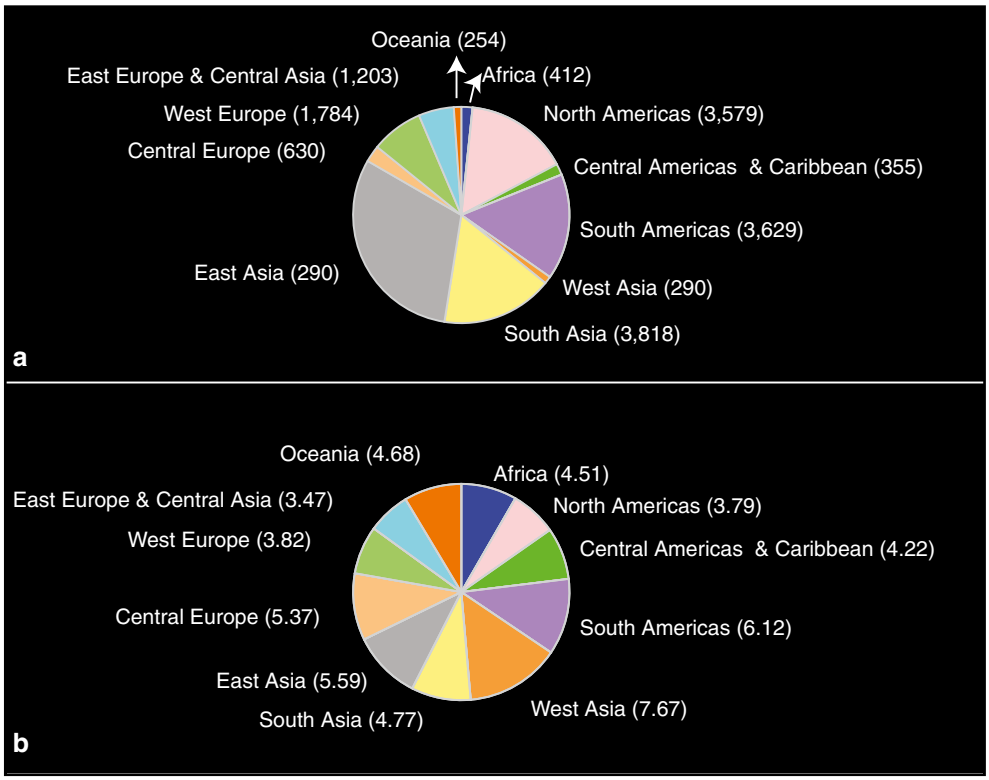

Fig. 11.4 Potash consumption. (**a**) Potash consumption by region in 2009 (in 1,000 metric tonnes). (**b**) Projected increase in demand, expressed as compound annual growth rate (%) in potash consumed (as K_2O) for the period 2010–2014 (Replotted from FAO reports 2010)

The United States is one the world's largest net consumers of potash, but produces only 23 % of the potash it consumes. Asian nations produce only 13 % of their potash demand. China and India and Brazil are the world's largest importers of potash and China's domestic production has risen over the past decade). Even so, all three have low levels of domestic production relative to demand and their rapidly growing population bases will fuel a world-scale increased demand for potash over the next decades (Fig. 11.4b).

Of current world production, just ten companies control some 90 % of the world's potash, and the five largest companies control more than 70 %, with a strong focus in ownership by Canadian and Russian companies (Fig. 11.3b). Canpotex is the world's largest exporter of potash, it was created in 1972 and is wholly owned by three Canadian potash producers (PotashCorp, Mosaic and Agrium). It even owns its own shipping fleet. Its overall share of the market is around 35 % with more than 130 customer groups in 60 countries. In 2011, Brazil, China, India, Indonesia and Malaysia accounted for some 70 % of its annual sales. In 2005, the Russian potash consortium Belarusian was formed by the merger of the Uralkali and Belaruskali (50 % stake) corporations. Until July 2013 the Belarusian Potash Company was the second largest supplier of potash to the world market and exports to more than 80 countries worldwide. Together the Canadian-Russian duopoly accounts for 70 % of global potash trade.

Historically, the world's supply of MOP has been held mostly by a few companies, whose coordinated actions in choosing to withhold supply has controlled prices. This ability to withhold supply is the result of the limited number of producers in the market and relatively high entry costs to construct a new mine (more than US$ 1–1.5 billion). Such marketing control, exerted by a few world-scale producers, is considered by some as a protectionist cartel, capable of artificially maintaining prices by controlling supply (see Javier Blas, Financial Times, London UK, August 19, 2010; al Rawashdeh and Maxwell 2014). Until recently the potash cartel was coordinated by two exporting consortia – Canpotex in North America (owned by PotashCorp, Agrium and Mosaic) and the Belarusian Potash Company in the Former Soviet Union (owned by Uralkali and Belaruskali). Through their size in the market they could act on State and Federal governments to prevent entry of new major competitors into their market. In November 2010, the Canadian potash industry successfully lobbied state and federal governments to block a $40 billion BHP Billiton bid to purchase PotashCorp (instigated in August, 2010). BHP Billiton has a worldwide policy of selling a commodity to world markets at current prices for all its commodities and to maximise the efficiencies of their operations when under price pressure. This was not a popular approach to Canpotex management in the sheltered Canadian marketplace, where historically the dominant producers have chosen to throttle production to maintain what they see as an acceptable potash price.

Unlike many other commodities such as gold and oil, which trade continuously on world markets, potash is sold

directly via negotiated contracts or by spot sales between producers and consumers, in a market where the sales price was dominated by the actions of the former duopoly. Farmers were at the delivery end of this largely consortia-controlled set of negotiations, but if they do not like the asking price, they could only choose not to fertilise their fields for 1–2 years. After this, there are substantial drops in productivity per acre. So, even when prices are high, agriculturalists must buy most years in order to maintain the required crop productivity. At times this lead to significant tensions in negotiations between suppliers and consumers of potash and to active exploration for potash outside of the holdings of the duopoly.

Each potash deposit has its own characteristics and associated mining problems that must be handled on an individual basis (Garrett 1995; UN Industrial Development Organization 1998). According to the Blas article in the Financial Times of London, mentioned earlier, not all potash operations are low cost, most high-cost production is outside of the conventional underground mines of Canada and Russia. It is in the hands of K+S in Germany, as well as mines in Spain, the UK and Israel Chemicals. Intrepid Potash, a US-based group, SQM and Vale of are also high-cost producers relative to the Canadians and the Russians (Fig. 11.3c).

Currently (mid 2014), after the vitriolic 2013[4] break-up of the Russian duopoly, Uralkali is undercutting the average world market price and is supplying bulk contract potash to India and China at around US$320–350 per tonne, leading to production cut-backs and layoffs in the Canadian industry and elsewhere (Fig. 11.3c). Over the past decade the price of potash has doubled but also fluctuated widely. At the beginning of 2008 the price rose rapidly from less than $200 a tonne to a high of $875 in February 2009. Then it dropped dramatically to an April 2010 low of $310, before recovering in 2011–2012, and relapsing again in 2013 (Figs. 11.1b and 11.2d). The potash price suffered less than other commodities during the 2009 global financial crisis, but current price projections for the next few years (2014–2016) are not optimistic, largely because of the July 2013 breakdown of the Russia Belarus cartel and the ongoing passage to the market of cheap potash. In the longer term, the per acre productivity of world agriculture must continue to increase in order to feed the world's burgeoning population, so the longterm price will slowly recovery.

Ore Extraction Technologies

There are three basic types of potash extraction in use today: (1) Conventional mining that, once the ore level is attained, can encompasses several standard mining methods, modified as necessary for specific subsurface situations, (2) Solution mining of ancient evaporites and (3) Solar processing of modern lake brines (Fig. 11.5). Solution mining typically requires lower upfront capital expenditure compared to conventional underground mining techniques, which requires significant mine development prior to production. Conversely, operating costs for underground mining techniques are generally lower, compared to solution mining and lake brine extraction processing methods, which can both be energy intensive.

Conventional Mining

For potash beds that are relatively flat and uniform in thickness, or for cutting entries to the ore zone, boring machines with two or four cutting arms have proven to be an effective and economic mining method. For moderately inclined, undulating and/or thickening-thinning potash seams, continuous miners with cutting "drums" mounted on one or two moveable arms are the most effective (Fig. 11.5). In general, two types of continuous mining machines are used: Borer miners and Drum miners. Borer miners apply uniform cutting pressure, have fixed cutting heads, and possess a higher capacity, though they only cut a fixed seam thickness and width. Drum miners have rotating cutting heads that cut sideways against the face and despite their lower capacity, are better able to adapt to changing ore thicknesses. For highly variable ore bodies, or ore with potential rock-bursts or other

[4]In July 2013, Vladislav Baumgertner, chief executive of the world's largest potash and cheapest producer, OAO Uralkali, suddenly announced, without prior warning, that he was removing his firm from one of the potash world's major price support cartels which his company had maintained with another firm, Belarusian Potash Company. As a result of his actions, Baumgertner has been ridiculed, reviled and even imprisoned for a month when he visited Belarus. Mining Weekly estimated that this decision had the effect of wiping out $18 billion in market capitalization of the major potash players, worldwide. The world of potash production and distribution has been thrown into major turmoil and a trade war between his home nation of Russia and neighbouring Belarus may very well have broken out. Baumgertner has explained his action was based on market forces (responding to cartel actions and changes in market share), which had led to a steady rise in his company's above-ground potash stocks. He believed the only way to work off those stocks was to stimulate demand by forcing prices lower. Naturally, agricultural consumers rejoiced somewhat, but for many potash producers, the decline in prices to US$325 per tonne by late October 2013 was a real profit-buster (see Table 11.3c).

Share prices of PotashCorp (POT) of Saskatchewan had been on a rollercoaster ride ever since the original price/tonne oscillations began in 2008, but, by 2013 stock prices appeared to be holding firmly between $40 and $45. This was so until the July announcement, upon which its share price immediately plunged by over 25 per cent to barely $30 per share. Part of POT's problem stemmed from their decision to dramatically increase brownfield production from 9,000,000 tonnes per year to a prodigious 17.1 million tonnes per year, by 2015. China moved swiftly to take advantage of the situation and purchased a huge block of Uralkali stock, thereby acquiring a 12.5 % ownership position and thereby gained market leverage in order to assure China of adequate potash supplies going forward.

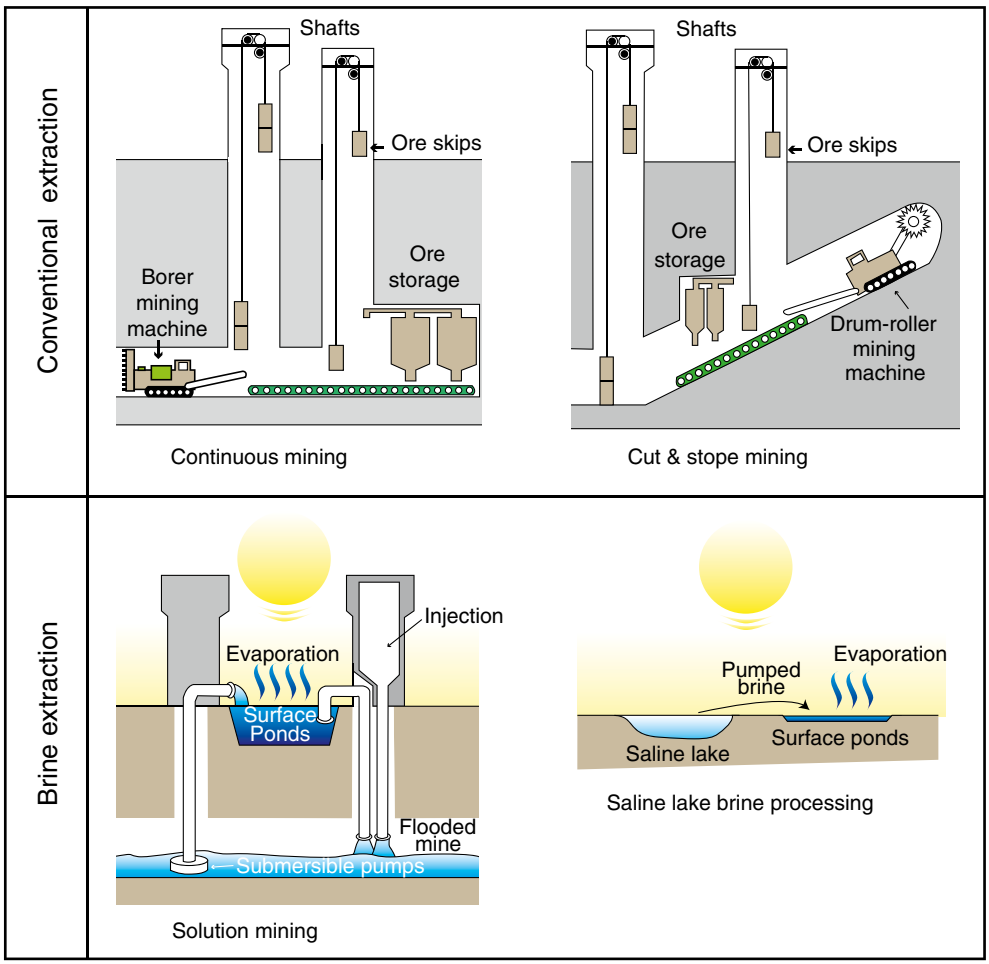

Fig. 11.5 Potash extraction techniques

special needs, drilling and blasting are still required. Blasting is most effective in managing mine sites with large variances in ore thickness, and requires less initial capital and maintenance than continuous mining, though generally results in higher costs overall.

Many potash mine configurations are conventional room and pillar designs. Stress-relief mining (multiple entries with outer yield pillars) has proven highly effective in deeper room and pillar mines, where there is a need to deal with plastic flow (of the ore and the adjacent salt host) or with unstable roof (mine back) conditions. The "room and pillar" method progresses along the potash seam, while pillars and timber are usually left standing to support the potash mine roof. Worldwide, in many shallower operations, where the original pillars collapse rapidly enough for the waste heaps to support the weight of the back, miners can return to extract ore from the pillars.

Sylvinite and langbeinite mining in Carlsbad, New Mexico, is room-and-pillar, while the Boulby mine on the eastern coast of England drives five panels with crossovers in a V-shape to redistribute the stress. Historically, Carlsbad, New Mexico potash mines (most of which are now exhausted) operated at depths between 270 and 430 m, recovered around 75 % of the ore on the first pass and attained 90 %, with the expectation of some surface subsidence on the retreating pass to mine out the pillars. Saskatchewan mines typically operate at greater depths (down to 1,000–1,100 m) with a 35–45 % recovery and typically do not utilise a retreating ore-recovery pass. Boulby mine UK also operates at a lower recovery rate (35 %) because of its greater operational depth, around 1,100 m and, due to its less than ideal back thickness, the ore zone is approached from below and ore is extracted using remote-control vehicles.

For those mines without high-pressure aquifers above the potash and with somewhat plastic overlying strata, the long-wall mining method, which allows the roof to gradually descend soon after the ore is cut, can provide very high ore recovery rates and result in high productivity. In the case of long-wall mining, the beds must be fairly uniform and continuous (very minor faulting, slumping) over the width and length of individual mining panels. Borers extract ore in very long galleries to take advantage of their cutting method, rather than room-and-pillar, which is the method typically used with drum mining. Some Canadian mines utilising

borers produce 1,200-m-long galleries with longwalls in between. Other Canadian mines use panels that have five entries per panel, with the outer two entries collapsing in 1 or 2 days (Kogel et al. 2006). Although long-wall mining can produce ores at relatively low costs per tonne, equipment and development costs can be high and the method is not as flexible as other methods. Yet, despite the high initial cost and substantial maintenance of continuous mining machines, they are incredibly efficient once in operation and are able to cut smoothly, provide low disturbance entry, and possess a very high extraction capacity. This places extraction costs in the Canadian mines of the Prairies at the cheaper end of the world's larger producers (Fig. 11.3c). In addition, the continuous mining method facilitates conveyor belt ore haulage, allowing for the near total automation of the entire ore extraction process.

For thicker or highly inclined potash seams, the open stope (successive horizontal cuts for thick beds) or cut and fill methods allow both a high ore recovery and an easy means of disposing of both waste produced underground and plant tailings (Kogel et al. 2006; Schultz et al. 2005). PotashCorp at its underground operation at Penobsquis, near Sussex in New Brunswick, Canada, mines with road headers in a cut-and-fill technique up one side of a salt anticline. Provincial environmental regulations require that no tailings pile remains on the surface, so all tailings are backfilled into the mine using a second conveyor belt system. Some German potash mines also use block-caving (benchmining and funnel-stoping) methods because potash ore is on the dipping flanks of salt domes and gangue can more readily be left underground.

Underground ore transport of potash (and in some cases the tailings return) is now accomplished almost entirely by conveyor belts. Conveyor belts may be suspended from the roof or set on the floor. For the highest capacity mines with continuous (borer or drum) mining machines, flexible belt conveyors attached to, or directly fed from, the miner, such directly feeding into a panel belt gives considerable savings. Some mines still employ either shuttle cars to take the ore from the mining machines to the feeder breaker at the panel belt, or load-haul-dump (LHD) machines that pick up ore from the floor and then haul it to a feed station. Most potash mines, because large cavities are cheaply and safely excavated in the salt host, typically have considerable underground ore storage capacity, this evens out the flow to the mill. Many of the large capacity operations also use feed bins where the ore is loaded into high-speed "skips" (elevator bins) that take the ore to the surface and dump it, with all aspects of the loading-lifting-dumping cycle now being done automatically. A few shallower mines can bring the ore to the surface with conveyor belts in long inclined tunnels.

The extraction costs of potash mining by conventional methods can vary tremendously (Fig. 11.3c). Mining is the major expense of potash production in operations that require more man-power because of low-grade ore or difficult mining conditions. For ore bodies and situations that allow high-capacity operations, mining can be somewhat less expensive than the costs of processing at the surface. Freight or transport costs are also significant, especially in markets located some distance from suppliers and is one of the major drivers for current greenfields potash exploration in Africa, Asia and South America.

Whatever the chosen production method, establishing a new conventional potash mine is associated with setup costs well in excess of a billion or more dollars (US$), so new players in the market are rare. The costs are high as the entry shaft for a new mine must be completed without water entry and is usually done via ground freezing. Once the vertical shaft is completed it is protected from water-bearing rocks by the use of tubbings, which are curved segments bolted together and sealed to form stacked rings that line the shaft. They are usually made from cast iron or steel-reinforced concrete. Such tubbed shafts generally have a diameter of 5–7 m, and can extend down to depths exceeding 1,000 m. Because of the very high costs involved in entry construction for a new potash mine, the proved amount of ore should be sufficient for at least 20 years of production (subject to a given mill size, mill recovery rate for a given ore depth and the density and origin of salt "horses"). Kogel et al. (2006) states the initial plant or mill annual capacity should be at least 300,000 t K_2O, in order to compete with a number of established plants with capacity in excess of 1 Mt.

High lead-in costs mean no significant greenfield potash project involving a conventional mine has been completed in the past three decades, although some brownfield expansion has taken place. In recent years a number of greenfield projects have been announced due to projected margin expansion and long term potash demand certainty (Tables 11.2, 11.3 and 11.5). For a conventional mine it takes 5–7 years to take a new greenfield project from conception to production. Currently the largest conventional mine in development is BHP-Billiton's Jansen project in Saskatchewan. Shaft excavation is currently underway and expected to be completed in 2016. When operational, the Jansen mine is projected by BHP -Billiton to be capable of production levels of up to ten million tonnes per year. Lead times for solution mining projects are typically shorter, on the order of 3–5 years. Currently the Legacy Facility, near Bethune Saskatchewan, is the largest greenfields solution mining plant under construction. Due to be completed by 2016, it has a projected mine life of at least 40–50 years, with a planned annual output from 2017 of 2.8 million tonnes per year (Table 11.2). Conventional brownfield mine expansion lead times are variable, most of the projects currently planned are projected to take less than 5 years. In the past few years, a lack of price stability and currently low ore prices have had a detrimental effect on the viability of some of the small to mid sized potash explorers.

Table 11.2 Active and projected solution mines that target potash extraction

Mine/property	Company	Target	Depth (m) to target	Product	Reserves (R) or inferred (I) resource or annual brine production and, where available, ore grade (K_2O %) Mt = million tonne	Extraction technique	Stage on ground in 2012
Patience Lake Solution Mine, Saskatchewan	Potash Corp	Sylvite	1,600	MOP	330,000 tonne/year 37 Mt (R)	Solution mining of flooded MOP mine	Active facility
Belle Plaine Solution Mine, Saskatchewan	Mosaic Corp	Sylvite	650	MOP	2.0–2.8 Mt/year 230 Mt (R)	Purpose-built solution mine in operation since 1960s	Active facility

Solution Mining of Potash

Solution mining entails the injection of brine solutions into underground potash-bearing salt seams (Fig. 11.5). The solution dissolves soluble potash-bearing minerals from the seam and the pregnant potash-bearing solution is then recovered to the surface for processing. Solution mining techniques, focused on caverns in halite, are discussed in detail in Chap. 13, this current section deals specifically with potash. Solution mining can substitute for conventional shaft mining in some potash deposits at depths of more than 1,100 m, which is the current limit for conventional potash mining. It is not an all-encompassing mining alternative to be used whenever potash zones are too deep or too variable for conventional mining methods. Currently, there are six active and a number of planned solution mining operations, focused specifically on potash recovery (Table 11.2). Thickness, mineralogy, and structure/ore-continuity, as well as other technical considerations of the mining operation, must be evaluated to determine the suitability of solution mining.

As well as purpose-designed facilities, a solution mining approach has been successfully employed in situations where a conventional underground potash mines was accidentally flooded and became unworkable. Of the three current potash solution mining plants in the North Americas, two recover brine from flooded mines, one in Canada (PCS-Patience Lake) and the other (Moab) in the United States. Water is injected as brine and circulated throughout the flooded mine workings, dissolving potash and salt from the original pillars and walls. The resulting dense brine sinks to the bottom of the water-filled mine cavity, is pumped back to the surface and into an evaporation pond or set of crystallizers. High capacity submersible pumps are used in these operations, for example in the PCS-Patience Lake solution mine each is pumping about 9,000 l/min.

Dissolution selectively picks up KCl over halite across the substantial surface area in the ore-zone focused flooded workings of the PCS Patience Lake Division Mine. The resulting dense brine is withdrawn from the mine sump and pumped to a large pond, which was formerly used for tailings, before being rebuilt as a set of holding and cooling reservoirs. This large pond operates each year as a cryogenic crystallizer from September through May. As warm brine from the mine flows into the pond, sylvite (not halite) crystallizes via exposure and rapid cooling of the brine beneath the cold winter air (Fig. 11.6). The sylvite precipitation process is predicated on the different temperature dependences of NaCl and KCl solubilities (Fig. 11.27). As the liquid in the surface pond cools, potash and salt crystals settle to the bottom of the pond. Residual cooled brine is then heated and reinjected into the mine to start dissolving potash again. The sylvinite slurry is harvested by floating dredges and sent to a nearby milling plant for drying, screening, and compacting.

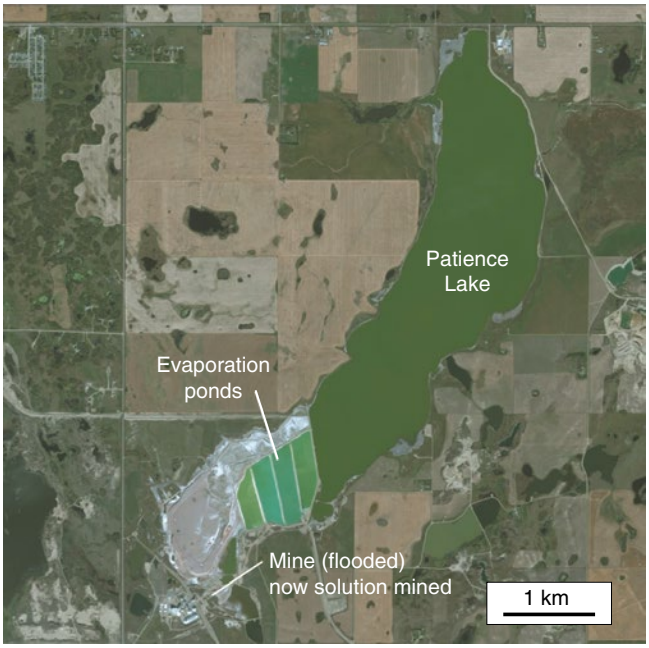

Fig. 11.6 Patience Lake – PCS solution mine, Saskatchewan, Canada

The other solution-mined facility in an intentionally flooded mine is the Moab Cane Creek Mine solution facility, Utah (USA). There potash brine is pumped to the surface to be solar evaporated and crystallize sylvinite. The sylvinite is the dry-harvested and sent to a processing plant for conventional flotation.

In contrast to the two postflood operations, the solution mine of Mosaic, near Moose Jaw, Saskatchewan (Canada), is a purpose-designed as a conventional 3-pipe string potash solution mining operation. The Moose Jaw (Belle Plaine) operation illustrates the success of a purpose-built facility as it can recover more than 2,700,000 tonnes of product a year, compared to 300,000–400,000 tonnes at Patience Lake and ≈60,000–100,000 tonnes of potash (and 210,000 t of by-product salt) at Cane Creek-Moab (Table 11.2).

The three-pipe-in-one-string solution method has an innermost pipe as the deepest pipe in the solution cavity and it is used to withdraw saturated brine from near the base of the cavity. The medial pipe is used to inject undersaturated brine into the cavity. The outermost and shortest pipe inserted into the cavity is used to maintain the uppermost pad fluid and so prevent the potentially destabilizing dissolution rise of the cavity roof (see Chap. 13 for more detail, especially Figs. 13.6, 13.7 and 13.8).

Brine production began in Moose Jaw facility the mid 1960s and was positioned to take advantage of a major thickening of the Belle Plaine Member at about 650-m depth. Brine from the well field is extracted, then evaporated in triple-effect evaporators to crystallize dissolved halite, and the brine is then cooled to crystallize the potash salts. The

residual brine is recirculated to the evaporators, although in the winter it is first sent to ponds to be further cooled and to precipitate additional potash salts.

Lake Brine Processing and Solution Chemistry

Potash is extracted from modern lake brines in two forms; MOP and SOP (Table 11.3; Fig. 11.5). In both cases, due to elevated levels of Mg or SO_4, sylvite is typically not the precipitated phase, making the production of sylvite from these facilities relatively expensive compared to conventional mines targeting sylvite ore from ancient bedded deposits (Fig. 11.3c). The largest set of lake brine potash operations is extracting sylvite from the processing of carnallitite precipitates in man-made solar ponds at the southern end of the Dead Sea. This and other lake brine operations, along with their brine chemistries, are discussed in detail later in this chapter.

Climate is critical for effective solar evaporation or cryogenic production from surface ponds, this is true whether ponds are fed modern lake brines or brines pumped from solution mine cavities. Brine brought to the surface at the Moab mine (Köppen climate BSk) evaporates completely in single ponds to precipitate a mixture of sylvite and halite. Because of its cool steppe arid climate, blue dyes added to pond brines increase solar energy adsorption and so increase brine temperature and rates of evaporation. The operations at Ogden and Wendover, Utah (Köppen Climate, Csa and BWh, respectively), use Great Salt Lake water (Ogden) or nearsurface brines and multiple ponds on the Bonneville saltflat (Wendover). Multiple fractionation ponds are used to establish brine densities for various K minerals at different stages. Efficient solar evaporation occurs during only 3 months of the year (June, July, and August) in the Utah region, with more than half the local evaporation occurring in July. During this 3-month period, low rainfall must combine with sufficient wind to keep the brine mixed and to enhance evaporation. In the potash-harvesting ponds at Moab and Wendover, both sylvite and halite drop precipitate out of the liquor. The harvest is then sent to a standard flotation-type beneficiation plant to separate the two salts.

In the Middle East, the two potash operations at the south end of the Dead Sea benefit from a hot arid climate that promotes evaporation throughout the year (Köppen climate, BSh) whereby carnallite and halite drop out of solution in harvesting ponds. In the nearby processing plant, $MgCl_2$ is leached away with freshwater, leaving a mixture of sylvite and halite. On the Israeli side, sylvite is separated from halite in three different processing plants. The oldest plant uses flotation technology. A more recent capacity expansion added a process that uses dissolution-recrystallisation. The newest plant uses a proprietary cold-crystallisation process that uses a low-heat crystallizer to produce KCl and makes the extraction process more energy and cost efficient (Fig. 11.3c).

Ore Beneficiation

With sylvite ores, the ore composition, the ore grade, the proportion of oversized particles required to allow separation of different minerals, and the type and the amount of insoluble slimes (such as clay, anhydrite, dolomite, silica, etc.) are different for different deposits and may perhaps even be highly variable within a single deposit. So, beneficiation of raw potash ore from different basins requires a somewhat different scheme and equipment for each MOP processing plant and ore source (Fig. 11.7; Perucca 2003; Schultz et al. 2005; Kogel et al. 2006; Gowariker et al. 2009). Four basic beneficiation techniques used to process MOP potash ore are: flotation, heavy media separation, electrostatic separation and thermal dissolution crystallization. The other techniques include ammoniacal leaching and gravity separation using shake tables. Ammoniacal leaching is costly and gravity separation gives only about 80 % pure concentrates.

The first step in the beneficiation of a solid potash ore is to reduce the particle size to a point where the potash is liberated from the other ore constituents, but doing so in an optimal fashion ensures crushing and grinding generates the minimum amount of fines (Fig. 11.7). Potash ore must be crushed because the sylvite (processing target) crystals are intimately intergrown with halite at the cm scale and so must be released by breaking down ore to the appropriate size (usually less than 4–5 mm). After crushing, fine particles of both ore minerals and insolubles are removed to the maximum possible extent (scrubbing and desliming), before potash separation begins.

Scrubbing involves flushing the crushed product with saturated brine. During this stage, enough fresh water is added to high carnallite ores to dissolve magnesium chloride (Perucca 2003). Scrubbing is usually accomplished in a series of highly agitated cells, normally run at high percent solids (60–70 % solids in a KCl-NaCl saturated brine), and also designed to liberate the insolubles attached to the potash particles. Two-stage scrubbing is common in mines with high levels of insolubles in the ore. After scrubbing, separation of the insolubles may be done with cyclones, siphon-sizers or wet screens, while the secondary separation is usually accomplished with hydro-separators, cyclones and thickeners. Desliming by flotation of insoluble slimes from the ore in two stages is also practiced. This method has the advantage of reduced capital expenditures for desliming equipment, but suffers the disadvantage of higher reagent costs. Successful desliming is critical, as a virtually slime-free product is necessary to optimise feed to the potash flotation stage, this minimizes reagent costs and ensures optimal potash recovery.

After desliming the feed to the flotation cells is typically chemically conditioned to further improve recovery. Coarse material is conditioned separately from fine material in order to optimise reagent usage and promote more effective coarse

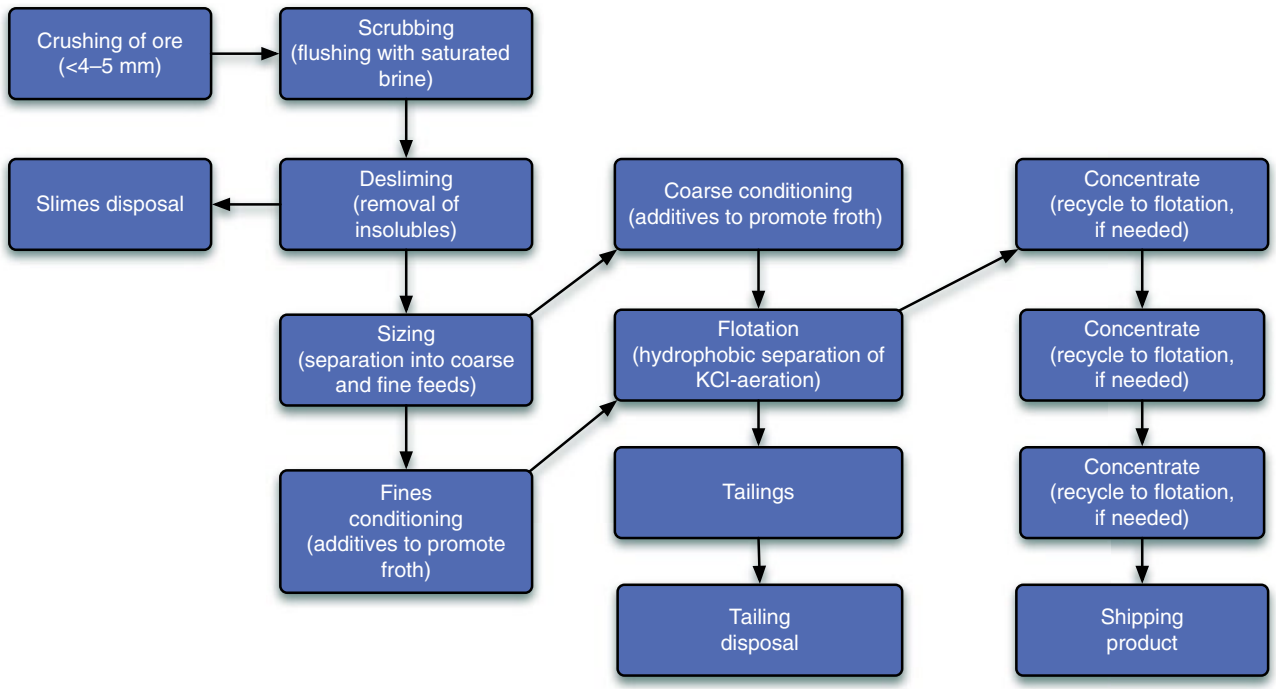

Fig. 11.7 Schematic block diagram of a conventional potash flotation plant (After Perucca 2003)

particle flotation. Both coarse and fine material is conditioned with a depressant and a potash collector. An extender oil is added to the coarse conditioner and various alcohols are normally added to promote frothing.

In potash flotation, the aim is to separate sylvite from halite using cationic collectors interacting with sylvinite feed, known as the pulp (Perucca 2003). Flotation is a selective beneficiation process that utilizes the differences in surface properties of various minerals. Sylvite (KCl) is hydrophobic and will therefore attach itself to air bubbles in an agitation cell and so can be separated from gangue material. The flotation process has advantages over hot leaching and crystallisation as it is not as energy intensive and so has a lower capital cost. In all flotation processes, the fine particles having high surface areas tend to adsorb excessive quantities of the flotation reagent, raising reagent costs and contaminating the product, hence the proportion of fines must be minimised. Post flotation, the residual slimes are finally thickened and sent to tailing areas for disposal. The most important reagents used in flotation are termed collectors. In the case of flotation of sylvinite ores, a cationic collector is added to the closely sized and deslimed ore slurry. The collectors for potash are mostly straight chain aliphatic amines derived from natural fats and oils that are neutralized by acetic or hydrochloric acid before use.

Frothers are another category of conditioning reagents used during flotation. They aid the formation and stabilization of flotation froth and typically are organic heteropolar compounds (e.g., pine oil and methyl isobutyl carbinol). Modifiers (or regulators) are another class of compounds added to the pulp to control the flotation process. In potash flotation, slime depressants such as starch, guar gum, dextrin and synthetic compounds are typically used. Once treated with a collector and a frother, the pulp is passed into an agitation cell where compressed air is introduced from the bottom. A froth of amine and entrained air bubbles carries the potash to the surface where it is mechanically swept over the side of the cell into a trough. Carnallite is avoided during mining due to its detrimental effect in the flotation process.

The concentrate from the flotation cells is made up of potash particles and brine, which are transferred to centrifuge to remove the brine. The potash solids are then moved to dryers, which heat the product to about 200 °C. The resulting dry mixture contains various sizes of product that are size-separated by huge mesh screens into standard, granular and suspension grade product. A portion of the finer product stream is typically fused under high pressure between two rollers. The resulting solid "board" is broken into pieces and sized to form additional granular potash. In some Canadian mills, finer product is dissolved in hot brine to release further small quantities of impurities. The brine is then cooled in vessels to produce a high purity white product, suitable for use in soluble fertilizer and in industrial markets.

When potash ore feeds contain sulphate minerals like kainite or kieserite, sulphate salts are floated using fatty acids or sulphated fatty acids as collectors. Potash flotation circuits

Table 11.4 Processes and costs in 2012 involved in various types of sulphate of potash (SOP) manufacture

Process method	World capacity	Process inputs	Products	Cost/t (US$)	Companies
Mannheim	60 %	MOP, sulphuric acid, energy	SOP, HCl	$700	Tessenderlo, Qingshang, Yara
MOP and Kieserite	25 %	MOP, Kieserite, energy	SOP, $MgCl_2$ brine	$350	K+S Kali
Salt lakes, Kainite-Schoenite slurry	15 %	Lake brines (saline), energy	SOP, $MgCl_2$ brine	$220	Luobupo Potash, SQM Compass Minerals
Polyhalite leach and solar concentration	In process	Polyhalite, water, energy	SOP, Kieserite	$160	IC Potash

always have both rough and clean cells. In the rough cells, as much potash as possible is made to float, while in the cleaner cells the purity of the floated product is the prime consideration. The coarse particles of the rough tailings and the tailings from the clean cells are usually re-ground to a smaller size and re-floated. With very fine ores, sometimes countercurrent flotation is used.

Another potash beneficiation process is heavy media separation, this is the technique used by the Mosaic Company in Saskatchewan. The process uses the difference in specific gravity of sylvite (SG = 1.9) and halite (SG = 2.13). In a liquid of intermediate specific gravity, halite will sink, while sylvite will float. Commercial heavy media operations use a very finely divided weighing agent, generally ferro-silicon or magnetite of 200 mesh, which is slurried to create an artificial heavy medium at the specific gravity required for separation. After separation, the magnetite or ferro-silicon is recovered by magnetic separation and recirculated to the system. In Carlsbad, one heavy media circuit separates sylvinite and langbeinite (SG = 2.83), then a second circuit separates sylvite from halite.

Electrostatic separation is a dry technique in which a mixture of minerals is differentiated according to their conductivity and is used when gangue materials are more conductive. Potash minerals are not naturally conductive, so with a potash ore feed the separation is preceded by a conducting step that induces the electrostatic charges of different magnitude for different minerals. For potash, fractional or triboelectric charging (charging via friction) is used via repeated physical contact between different materials. This separation technique was used by a number of German potash mines.

In Germany, potash ore is conditioned with aromatic and aliphatic monocarboxylic acids. The mixture is heated in a fluid bed and the relative humidity is adjusted to enhance the charging of particles. The ore is then fed to an electrostatic separator to give three fractions, namely, product, residue and middlings. The method has two advantages; cost and reduced environmental impact. Using a dry process to improve the product grade also eliminates the drying costs.

Thermal dissolution and crystallisation are possible because of the higher solubility of potassium chloride (KCl) in hot water than in cold water compared to that of sodium chloride (NaCl) which is slightly more soluble at 100 °C than at 20 °C. When a mixture of sylvite and halite is dissolved in water and heated to 100 °C, KCl is substantially in solution but not NaCl. The ore is crushed to minus 3 mesh and washed with cold water and a NaCl/KCl solution. Clays are removed by desliming and the clarified solution is then heated and used to dissolve the potash in the washed ore. Undissolved NaCl is discarded as tailings. The brine solution on cooling under vacuum separates out KCl, which is filtered, washed and dried. The remaining brine is recycled. It is once again recrystallised to meet the needs of high purity KCl.

Even though it was the preferred ore target in the 1860s in Germany, carnallite is not usually a targeted mine in any conventional mine, because; (1) Carnallite the mineral is deliquescent and so is unsuitable for use directly as fertilizer and so carnallite must be converted to sylvite, (2) Carnallite ores are lower grade (Table 11.2; K_2O of 17 %, compared with 63 % for pure sylvite), (3) Carnallite has unfavourable mechanical properties, compared to sylvite, making it more difficult to mine and, (4) Processing of carnallite to produce sylvite, produces large volumes of $MgCl_2$, which must be utilised or disposed of (Schultz et al. 2005).

Carnallite ore processing methods vary widely and depend upon accessory minerals that are associated with the ore. All the current dissolution and recrystallization methods used to convert carnallite to sylvite are energy intensive and relatively expensive. Processing of carnallite to sylvite is done commercially using carnallitite slurries produced in solar pans at the southern end of the Dead Sea. There the two general methods of carnallite processing are cold leaching and hot leaching. Cold leaching is carried at 20–25 °C, while hot leaching is done at 100 °C to dissolve $MgCl_2$, KCl and NaCl, if any (see later).

Unlike the cheaper MOP fertilizers, which can be recovered from a sylvinite ore feed by a combination of grinding and various relatively low cost flotation techniques with tailings disposal (Fig. 11.6), a conventionally mineable sulphate of potash (SOP) fertiliser ore source does not occur naturally (Perucca 2003; Gowariker et al. 2009). SOP is a commercially produced product that requires additional energy to manufacture from a potash ore source (Table 11.4). Most SOP is synthesized by heating MOP in the presence of sulphuric acid to temperatures around 650 °C in large continuous-feed furnaces (Mannheim Process). Some mines

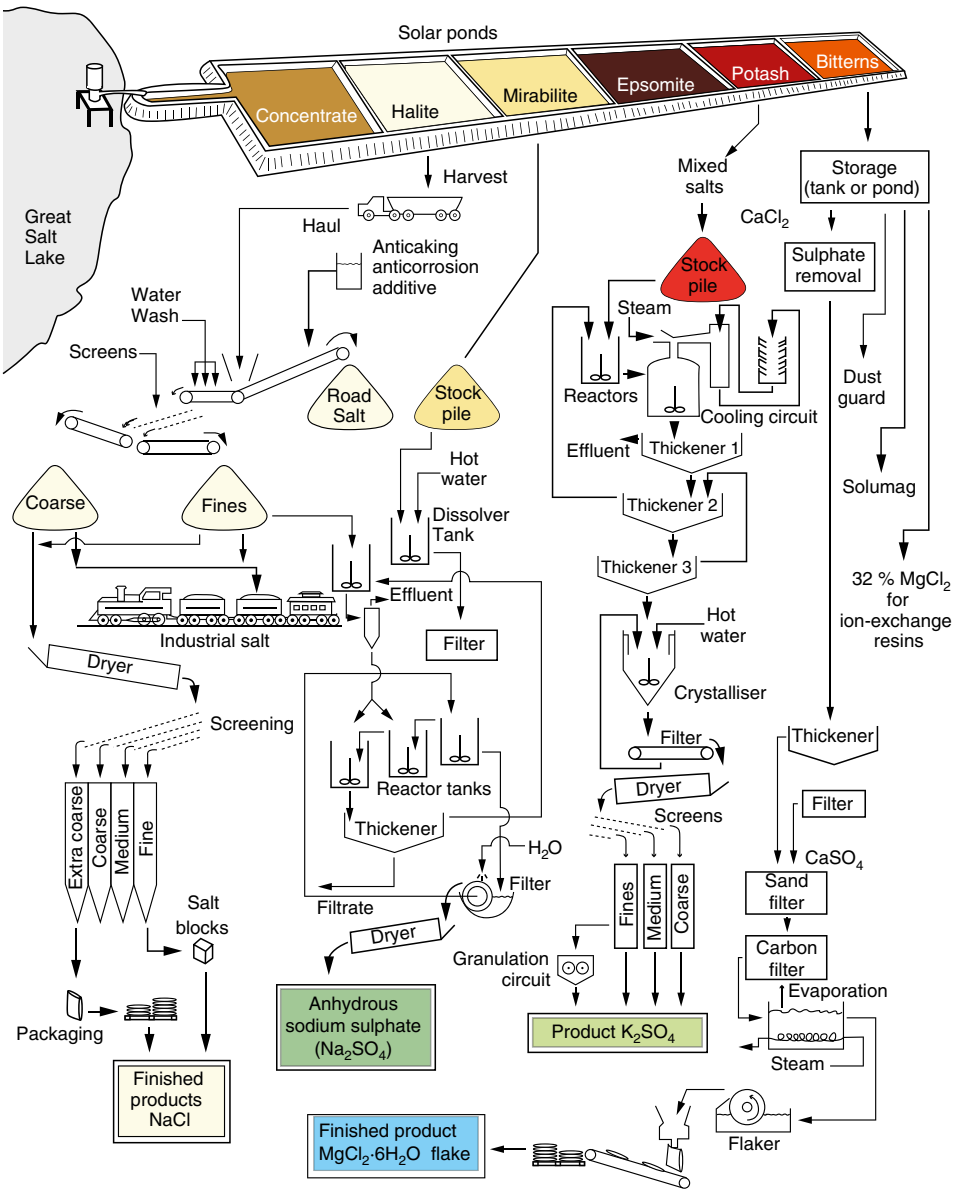

Fig. 11.8 Process stream for the manufacture of Sulphate of Potash in Great Salt Lake, Utah (After Butts 2007)

in Germany combine and process kieserite and sylvite to produce SOP. Currently the cost of production of SOP is $350–$700 per tonne using the Mannheim process, with the cost to purchase MOP making up $300–$600 per tonne of that cost.

SOP from a kainite/schoenite brine source (with lixiviation during processing) is produced from solar evaporators or crystallizers using saline Quaternary lake brines in Quill Lake in Canada, Great Salt Lake in USA, Lop Nor in China, and Salar de Atacama in Chile (where SOP production is a byproduct of lithium carbonate production). Production from three of these four lakes currently accounts for around 15 % of the world's SOP production, Quill Lake outputs are small compared to the other three. Once any halite is removed (typically via precipitation in earlier brine fractionation ponds), the kainite-schoenite slurry is processed so that kainite is converted to schoenite and then SOP crystallized from this schoenite source (Fig. 11.8). The volume of SOP production in all four regions is constrained by the chemistry the lake brines, that typically have relatively low levels of contained sulphate in the inflow waters. Because of a more favorable arid BSk climates in Salar de Atacama and Lop Nor regions, compared to the other two lake brine manufactures in Canada and the USA, it is likely that these two operations have SOP production costs of under $220 per tonne.

When langbeinite is targeted, as in the Carlsbad region today, it is separated from sylvite and halite by selective washing, froth flotation, or heavy media separation. Although processed langbeinite has a low K_2O content (23 %), it is marketed as a fertilizer or animal feed and as a source of K, Mg and S. It can also be used as a chemical feed and converted into other potash products such as SOP. Using a

mixture of mined sylvinite and langbeinite, SOP is today manufactured via a process of ion (base) exchange in the McNutt Potash region near Carlsbad, New Mexico. A drastic expansion of SOP manufacturing is proposed for the region, utilizing solar processing of a dissolved polyhalite ore.

Other than agricultural usage, soluble KCl is used as a drilling mud additive to stabilise reactive clays in oil well drilling. It is also used in aluminium recycling, in various steel heat-treating processes, metal electroplating, snow and ice melting, and water softening. Potassium chloride is used by the chlor-alkali industry to produce potassium hydroxide. The alkali potassium hydroxide is used for industrial water treatment and is the precursor of; potassium carbonate, several forms of potassium phosphate, many other potassic chemicals, and is the main ingredient in soap manufacture. The alkaline salt potassium carbonate is used with strontium and barium carbonate in the faceglass for televisions and computer monitors (used as radiation screen, but this is a decreasing use with advent of digital flatscreens), alkaline batteries, food products, pharmaceutical preparations, photography, some fire extinguishers, animal feed supplements, and as a catalyst for synthetic rubber manufacture.

The importance of potash to the future world agricultural economy means it is worthwhile gaining a detailed understanding of how potash salts accumulate in a variety of depositional and diagenetic settings. In the short term future the world's need for potash can only increase and more mineralogically diverse deposits will be utilized. Table 11.5 and Fig. 11.9 summarize the details of the various known potash occurrences that we shall discuss and interpret in the following pages. First, we shall look at some Quaternary lacustrine associations and then at the volumetrically more significant ancient (pre-Quaternary) sources of potash.

Quaternary Potash

Significant modern potash accumulations are rare: there are only two well documented examples of substantial Quaternary stratiform potash accumulating naturally, namely, the Qaidam Basin in China and the Danakil Depression in Ethiopia. Both basins, along with the anthropogenic potash pans of the Dead Sea basin are fed by calcium chloride brines with lower proportions of bicarbonate and sulphate, compared to brines derived by the evolution of modern seawater (Lowenstein and Risacher 2009; Katz and Starinsky 2009). Other modern examples, where carnallite or sylvite accumulates naturally are volumetrically minor and occur in continental lakes, playas and soils, either in ephemeral mineral efflorescences or in thin crusts Beds of potash salts can also accumulate in purpose-built pans. Such anthropogenic potash was precipitated experimentally as langbeinite by enhanced solar pond evaporation of seawater in Lake Macleod in Australia and by evaporation of continental lake and pore waters pumped into surface pans in the southern basin of the Dead Sea. In Canada, cryogenic pans are fed brines derived by solution mining and there are the dye-enhanced solar pans at Moab, Utah, which are also fed by solution-mined brines. Sylvite also occurs naturally as a widespread pedogenic salt along with nitrates in the hyperarid regions of the Atacama Desert in Chile.

Playas of the Qaidam Basin

The high plateau region of northern Qinghai-Xizang in west central China north of Tibet contains a number of large endorheic intermontane lake basins with thick fills of Mesozoic and Cenozoic nonmarine sediments (Fig. 11.10). The Qaidam (Chaidam) is one the larger such basins and its modern at-surface playas and salt lake sumps are subject to intense evaporation. Many of the drainage depressions in the basin are characterised by hypersaline brines with variable ionic proportions and, in some, there are accumulations of potash and borate-rich brines and salts. Lake Dabuxum and its surrounds in the southern Qaidam Depression is of special geological interest as it is one of the few localities in the world where quantities of potash salts are precipitating today in a number of laterally-limited groundwater sumps (Yang et al. 1995; Vengosh et al. 1995; Casas et al. 1992; Duan and Hu 2001).

Qaidam Basin is a large intermontane sedimentary and structural basin at the northern margin of the Qinghai-Tibet Plateau. With an area of 120,000 km^2, it has an extent that approaches that of some of the moderate to small ancient continental "saline giants," but the active-salt accumulating salt lakes are a much smaller proportion of the basin depression and only occupy its lower parts (Fig. 11.10). The Kunlun Mountains bound the plateau to the south, the Altun mountains to the west and the Qilian Mountains (which reach 5,000 m above sea level) bind the northern portion of the basin/plateau. Today the Qaidam Plateau (Qaidam Basin) is experiencing northeast-southwest compression, driven by the Himalayan Orogeny and expressed as active northwest-trending thrust faults, particularly along the Kunlun and Qilian Mountain fronts, with the basin sediments also cut by northeast-trending strike slip faults. The plateau centre has an average elevation of 2,800 m and contains numerous shallow to ephemeral saline lakes and dry saline pans. Its current hydrology is separated from the ocean by thousands of kilometers.

The Qaidam Basin first formed in the Jurassic, via extension in the Palaeozoic basement, when it was delineated by WNW-ESE faults. The basin was then filled by a 10-km thick succession of Mesozoic-Cenozoic terrestrial sediments. Lacustrine sedimentation began in the Early Cenozoic, but was limited to the western part of the current Qaidam

Table 11.5 Potash occurrences, listed by country, reserves listed in million tons (mt) or billion (Gt) metric tons of K_2O equivalent

Location, country	Age	Köppen	Brine source	Target unit	Comments/key reference
Potash in Congo and Gabon basins, Africa (Congo, Zaire, Angola)	Cret. Low.	–	Marine	Kouilou horizons	Carnallite, sylvinite in halite host, variable tachyhydrite (Aptian). Previously mined at Holle Mine (Republic of Congo) in 2 variable layers of 1.9 and 3 m thickness with K_2O contents of 18 and 38 % respectively with × mineable reserves of 17 and 26 mt K_2O respectively. Mine lost to flooding (breccia zone) in 1977. Future projected solution mine targeting of K and Mg brines in Kouilou evaporite horizons (De Ruiter 1979).
Neuquén and Mendoza Basins, Andes, Argentina	Cret.	–	Marine	Potash interval	Possible future solution mine. Sylvinite ore divided into 2 zones, upper zone about 3 m thick and lower about 11 m thick, average grade 20–25 % K_2O. A 1,000 m depth and high formation temperature (>50 °C) precludes conventional mine (Prud'homme and Krukowski 2006).
Pripyat Depression, Belarus	Dev., Upp.	–	Marine	Liven and Elets horizons	Livet (Frasnian) interval made up of four potash horizons with areas between 130 and 1,500 sq. km. Sylvite ore with minor carnallite in beds 4 cm to 1.5 m thick interbedded with muddy halite. Elets (Fammenian) interval >60 potash beds over 5,000 sq. km at depth of 200–3,000 m. Major potash production from Elets at average depth 480 m, grade 18 % K_2O.(Zharkov 1984).
Sergipe Basin, Brazil	Cret. Low.	–	Marine	Ibera member	Taquari-Vassouras mine targets sylvinite beds in Muribeca Fm. found in association with halite host, variable carnallite, tachyhydrite (primary textures in unit up to 90 m thick) constituting some 9 evaporite cycles deposited in an opening rift (Aptian). Tachyhydrite present (Wardlaw 1972).
Amazonas Basin, Brazil	Upp. Carb.-Perm, Low.	–	Marine	Nova Olinda Fm.	Two potential sylvinite deposits (sylvite cap to uppermost of 7 evaporite cycles) near Manaus ≈1,000 m depth, with average thickness of 2.7 m and grade 16.5 % K_2O. (Ufimian – Olenekian) (Szatmari et al. 1979)
New Brunswick Potash, Fundy Basin, Canada	Carb. Low.	–	Marine	Cassidy Lake Fm.	Formerly mined at depths 300-100 m in halokinetic salt wall, Mississippian sylvinite-halite sequence with local carnallite in Windsor Group in Moncton subbasin. (Visean) (Anderle et al. 1979; Wilson et al. 2006)
Alberta Potash Basin, Canada	Dev., Middle	–	Marine	Prairie Fm	Actively mined, some ten mines (2 solution mines) at depths between 800 and 1,000 m, region is world's major supplier of potash ore. Three potash horizons (sylvite, carnallite, halite) 20–25 m thick in upper part of Prairie Fm. (Esterhazy, Belle Plain and Patience Lake members). Dips gently to south at 1–8 m/km with potash level some 600–2,500 m below surface. Prairie Evaporite basin is a marine-fed foreland basin situated behind foreland bulge created by Antlerian orogen. (Givetian) (see text)
Quill Lake, Canada	Quat.	Dfb	Nonmarine	Recent	Saline depression in Quaternary glacial outwash. Supratill, sodium sulphate salts in lake floor beds, lake brine pumping and winter processing brine then combined with MOP (trucked in) to produce SOP (Eatock 1987).
Salar de Atacama brine, Chile	Quat.	BWk	Nonmarine	Recent	Brine Processing. Sylvinite and SOP is recovered as byproduct of lithium carbonate production (800 kt in 2004). Situated in Andean Altiplano at 2,250 m above sealevel (Garrett 2004).

Location, country	Age	Köppen	Brine source	Target unit	Comments/key reference
Dabuxum Lake (stratoid potash) Qahran Playa, Qaidam Basin, China	Quat.	BWk	Nonmarine	Recent	Carnallite (via solar processing of lake brine along with bishofite). Transtensional basin at 2,675 m elev. The Qahran playa region is main local supplier of potash to Chinese market (annual production of 1.2 Mt K_2O). Other Quaternary K-rich lakes in Qaidam Basin include Seni Lake and Tuanje Playa (see text and Fig. 11.31).
Lop Nur, China	Quat.	BWk	Non Marine	Recent	Natural lake evaporites are a nonmarine assemblages of mirabilite-glauberitepolyhalite-bloedite-gypsum-halite. Recent evaporitic stages of the lake fill in Lop Nur contain massive amounts of glauberite and polyhalite, compared to the other salts present. Their predominance, is indicative of pervasive backreactions, as is the presence of very minor amounts of carnallite and sylvite. Lake waters are processed to produce SOP (Ma et al. 2010; Dong et al. 2012). Annual capacity 1.7 Mt. Largest set of salt ponds in world.
Dallol Saline pan, Ethiopia	Quat.	BWh	Marine	Houston Fm.	Three members; uppermost is sylvinite member up to 10 thick; intermediate is 3–24 m thick with carnallite throughout, (sylvite at its top and kainite at its base) and lower member is kainite that is 4–13 m thick. It is a Pleistocene marine-fed unit that now lies beneath continental halite in a subsealevel (−115 msl) hydrographically-isolated marine-fed rift valley, region of active volcanism and hydrothermal overprints (Garrett 2004).
Mulhouse Potash Basin, Rhine rift, France	Eoc.-Olig.	–	Marine	Upper Salt Group	Main potash target is primary sylvite bed in Salt IV in Oligocene Rupelian succession at depths between 420 and 1,100 m. Basin was a consequence of Paleogene collision between European and African plates. Periodically mined for carnallite/sylvite ore. Subsealevel rift graben was active along western sidewall of the Alpine orogen during collision of the Apulian indentor with the European passive margin (Sannoisan) (Cendon et al. 2008).
Zechstein Potash Basin, Germany	Perm. Upp.	–	Marine	Zechstein Group	Actively mined at depths between 300 and 800 m, Zechstein comprises four evaporite cycles, with potash as five ore horizons in lower three (Thuringen, Hessen, Stassfurt, Ronnenberg and Riedel) (Tatarian). Tachyhydrite present in Stassfurt (Smith and Crosby 1979; Richter-Bernburg 1986).
Dead Sea brines, Israel and Jordan	Quat.	BSh	Nonmarine	Holocene anthrop.	Brine Processing (carnallite ppt. and converted to KCl) of lake brine pumped into a series of processing pans at southern end of Dead Sea. The Dead Sea brine contains an estimate 2 Gt of dissolved KCl, 1 Gt of $MgBr_2$ and 20 Gt of $MgCl_2$. Annual production of KCl ≈ 3.4 Mt ($MgCl_2$ is coproduct) Subsealevel transtensional basin with brine surface some 415 m below sealevel. (Recent) (Zak 1997; Garrett 2004)
Sicilian Basin, Italy	Mioc., Late	–	Marine	Solfifera Series	Inactive since mid 1990s. Kainite was dominant ore mineral (manufactured potassium sulphate). Other minerals in ore were sylvite, kieserite, and bischofite in 2–30 m thick beds dipping to 60°. Piggy-back basin in thrust belt. (Messinian).

Table 11.5 (continued)

Location, country	Age	Köppen	Brine source	Target unit	Comments/key reference
Pricaspian depression, Kazakhstan	Perm. Low.	–	Marine	Potash interval	Not mined. Potash interval contains polyhalite-halite, bishofite-carnallite, carnallite-halite, interval is strongly halokinetic in central part of basin. Oil wells intersected several potash horizons in this region. (Kungurian) (Volozh et al. 2003; Garrett 2004).
Solikamsk depression, Russia	Perm. Upp.	–	Marine	Iren horizon	Bezeneski and Solimgansk mines. potash interval lies at depths of 200–500 m and is divided into lower sylvinite and upper sylvinite-carnallite, little to no $MgSO_4$ salts. Av. lower interval thickness 21 m, upper interval 60 m (Kungurian) (Zharkov 1984).
Eastern Siberia Potash Basin, Russia	Camb. Lower	–	Marine	Chara horizon	Potash lies at depths of 600–900 m and contains some ore-grade sylvite intervals (>30 % K_2O) in Usolye and Angara Fm. Not currently exploited. (Botoman – Amgan) (Zharkov 1984)
Catalonia and Navarra Potash Basins, Spain	Eoc. upper	–	Marine		Transitional from marine evaporite to continental, deposited in two depocentres in Southern Pyrenean foreland. Sylvite + halite at base of unit, carnallite + halite toward top (Bartonian). Lower sylvite member is ore bed. $MgSO_4$-free (Rosell and Ortí 1981; Cendon et al. 2003).
Khorat & Sakhon Nakhon Potash Basins, Thailand, Laos	Cret. Upp.	–	Marine	Maha Sarakham Fm.	Possible sylvinite target on basin margin. Widespread massive halite, carnallite (with local zones of sylvinite), tachyhydrite and bischofite traces of priceite/boracite. Unconformable base, interbedded with three continental redbed successions and overlain by continental deposits. Variably halokinetic toward basin centre. (Albian-Cenomanian?) (Hite and Japakasetr 1979; El Tabakh et al. 1999a; Warren 2000c)
English Zechstein Potash Basin, UK	Perm. Upp.	–	Marine	Zechstein 3	Boulby Mine in UK extracts sylvinite ore from two 6 to 8 m beds at depths between 1,000 and 2,700 m, essentially no $MgSO_4$ phases. Water inflow and instability problems (Tatarian) (Smith 1996; Woods 1979).
Carpathian foredeep, Ukraine	Mioc. Middle	–	Marine	Tyras Suite	Stebnik mine and Kalush-Golyn region. Four evaporite cycles upper three with potash; exploited potash units composed of kainite, langbeinite, kainite–langbeinite, sylvinite and carnallite rocks with layers of rock salt or interbedded clays and carbonates. Fourth bed is polyhalite. (Burdigalian-Helvetian) (Hryniv et al. 2007).
Great Salt Lake region, UT USA	Quat.	Csa	Nonmarine	Rec.	Processing of lake brines in North Arm of lake and of shallow brines in Great Salt Lake desert (Bonneville Basin) at Wendover (MgCl is coproduct). Lake surface is 1,270 m above msl (Bingham, 1980; Garrett 2004).
Paradox Potash Basin, UT, USA	Penn. Mid.	–	Marine	Paradox Fm.	Solution mining of Paradox Fm. in converted conventional mine on Cane Creek anticline at a depth of 850 m. Middle Pennsylvanian collision basin related to Marathon-Ouchita orogeny, 18 of 29 halite cycles contain potash, mostly sylvite. (Moscovian) Tachyhydrite present (Desmoinian) (Hite 1961; Williams-Stroud 1994).

Table 11.5 (continued)

Location, country	Age	Köppen	Brine source	Target unit	Comments/key reference
Salado Potash Basin, NM, USA	Perm.-Upp. Lower Trias.	–	Marine	Salado Fm.	Resource now largely depleted, 12 potash horizons in part of Delaware Basin known as McNutt Zone (sylvite ore), few mines still active. Ore zones contain sylvite, carnallite, lesser amounts of sulphate minerals such as polyhalite and langbeinite (Tatarian – Olenekian) (Lowenstein 1988).
Michigan Basin, MI, USA	Sil. Low. -Upp.	–	Marine	Salina A-1 Evap.	Sylvinite and carnallite ore within central part of an intracratonic sag basin. Potash zone >30 m thick in central part of basin but ore concentration is erratic locally up to 40 % K_2O and as deep as 2,550 m but only solution mining is possible at these depths. (Wenlockian-Ludlovian). Tachyhydrite present (Matthews and Egleson 1974).

For overviews see Garrett (2004), Prud'homme and Krukowski (2006), Warren (2010) and references therein

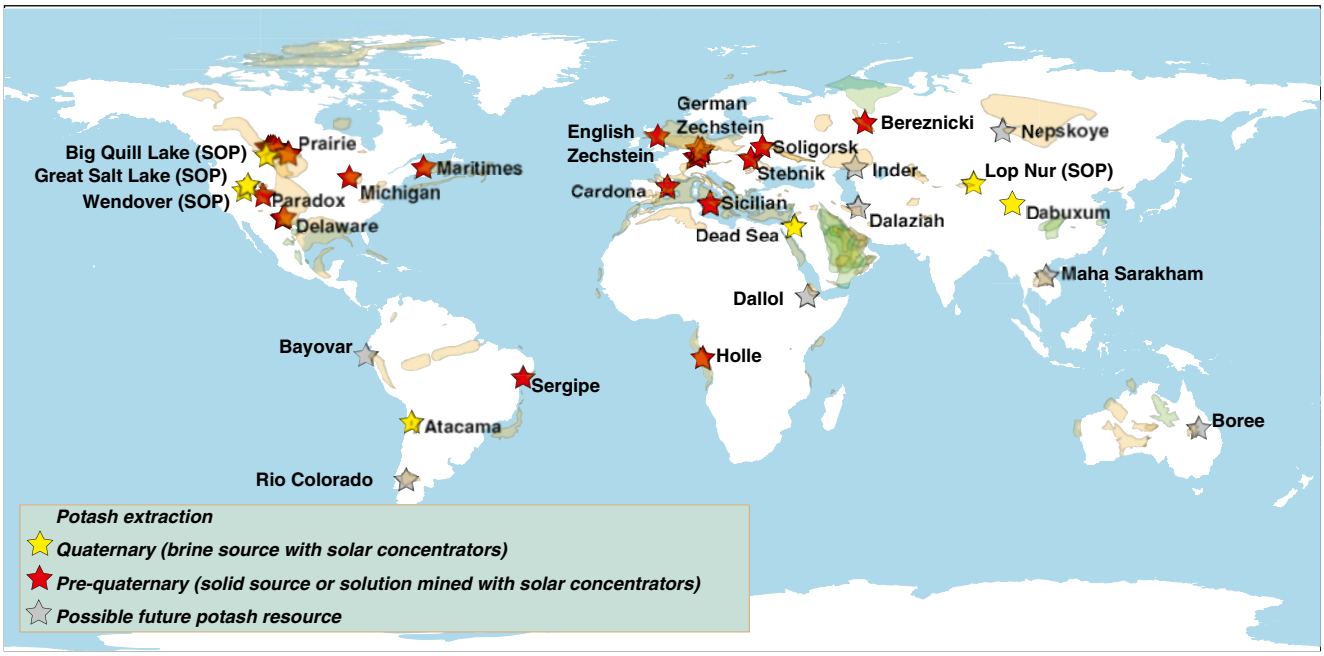

Fig. 11.9 World occurrences of potash; SOP indicates deposits where sulphate of potash is a significant part of the produced potash volume in that occurrence (occurrences and production details extracted from the SaltWork 1.8 database)

Basin (Duan and Hu 2001; Yin et al. 2008). In the Miocene the proto-Qaidam Lake expanded eastwards for some 300 km to attain its largest extent. Compressional tectonics, and the onset by 12 Ma of a relatively dry climate, broke the once continuous freshwater lake into many lacustrine sub-basins, a good proportion of which of which were saline sumps (Zhuang et al. 2011). Its active subsidence history, with more than 14 km of sediment deposited since the Oligocene, make it one of the deepest active sedimentary basins in the world (Wang and Coward 1990).

The present climate across the Qaidam Basin is arid to hyperarid (BWk), with an average annual rainfall of 26 mm, mean annual evaporation is 3,000–3,200 mm, and a mean annual temperature 2–4 °C in the central basin (An et al. 2012). Various salt lakes and playas are spread across the basin and contain alternating climate-dependent evaporitic sedimentary sequences. In the basin the various playas are surrounded by aeolian deposits and wind-erosion landforms. Overall the basin displays a typical exposed lacustrine geomorphology and desert landscape, related to increasing aridification. In contrast, the surrounding elevated highlands are mostly typified by a high-alpine tundra (ET) Köppen climate (Kottek et al. 2006).

The Qarhan saltflat/lake is now the largest hypersaline sump within the disaggregated lacustrine system that makes

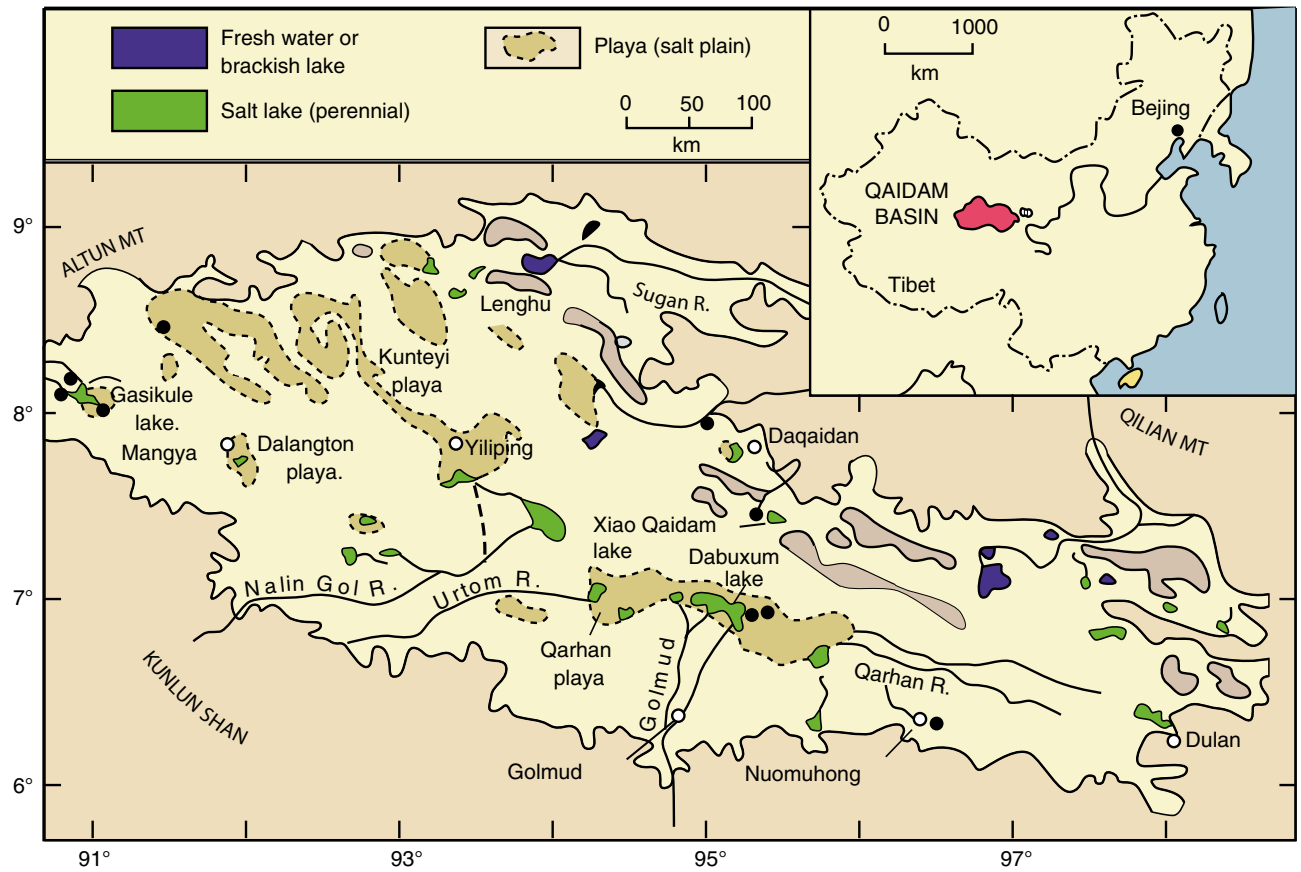

Fig. 11.10 Location of salt lakes, freshwater-brackish lakes and saltflat playas in the Qaidam Basin, China, with Dabuxum Lake located in Qahan playa in the central southern part of the map

up the Qaidam[5] hydrology. It has an area of some 6,000 km^2, is mostly underlain by bedded Late Quaternary halite (Fig. 11.11). The Qarhan depression is endorheic, fed by the Golmud, Qarhan and Urtom (Wutumeiren) rivers, and today is mostly covered by a layered halite pan crust. Below, some 0–1.3 m beneath the playa surface, is the watertable atop a permanent hypersaline groundwater brine lens.

The Qarhan Playa sump entrains nine perennial salt lakes: Seni, Dabiele, Xiaobiele, Daxi, Dabuxun (Dabsan Hu), Tuanjie, Xiezuo and Fubuxum north and south lakes (Fig. 11.11b). Dabuxum, which occupies the central part of the Qarhan sump, is the largest of the perennial lakes (184 km^2). Lake water depths vary seasonally from 20 cm to 1 m and never deeper than a metre, even when flooded. Salt contents vary from 165 to 360 g/l, with pH ranging between 5.4 and 7.85. Today the salt plain and pans of the Qahan playa are fed mostly from runoff from the Kunlun Mountains (Kunlun Shan), with a number of saline groundwater springs concentrated along the fault that defines an are of salt karst along the northern edge of the sump, especially north of Xiezuo Lake.

Bedded and displacive salts began to accumulate in the Qarhan depression some 50,000 years ago. Today, the surface salt crust consists of a chaotic mixture of fine-grained halite crystals and mud, with a rugged, pitted upper surface (Schubel and Lowenstein 1997; Duan and Hu 2001). Vadose diagenetic features, such as dissolution pits, cavities and pendant cements, form where the salt crust lies above the watertable. Interbedded salts and siliciclastic sediments underlie the crust to reach thicknesses of up to 75 m (Kezao and Bowler 1985).

Bedded potash, as carnallite, precipitates naturally in transient volumetrically-minor lake strandzone (stratoid) beds about the northeastern margin of Lake Dabuxum and as cements iLate Pleistocene bedded deposits in nearby Lake Tanje (Fig. 11.11a, b). Ongoing freshened sheetflow from the updip fans means the proportion of carnallite versus halite in the unit increases with distance from the Golmud Fan in both the layered (bedded) and stratoid (cement) modes of occurrence (Fig. 11.11c).

At times in the past, when the watertable was lower, meteoric inflow was also the driver for the brine cycling that created the karst cavities hosting the halite and carnallite cements. Solid potash salts are not present in sufficient

[5] "Qaidam" means salt marsh in Mongolian.

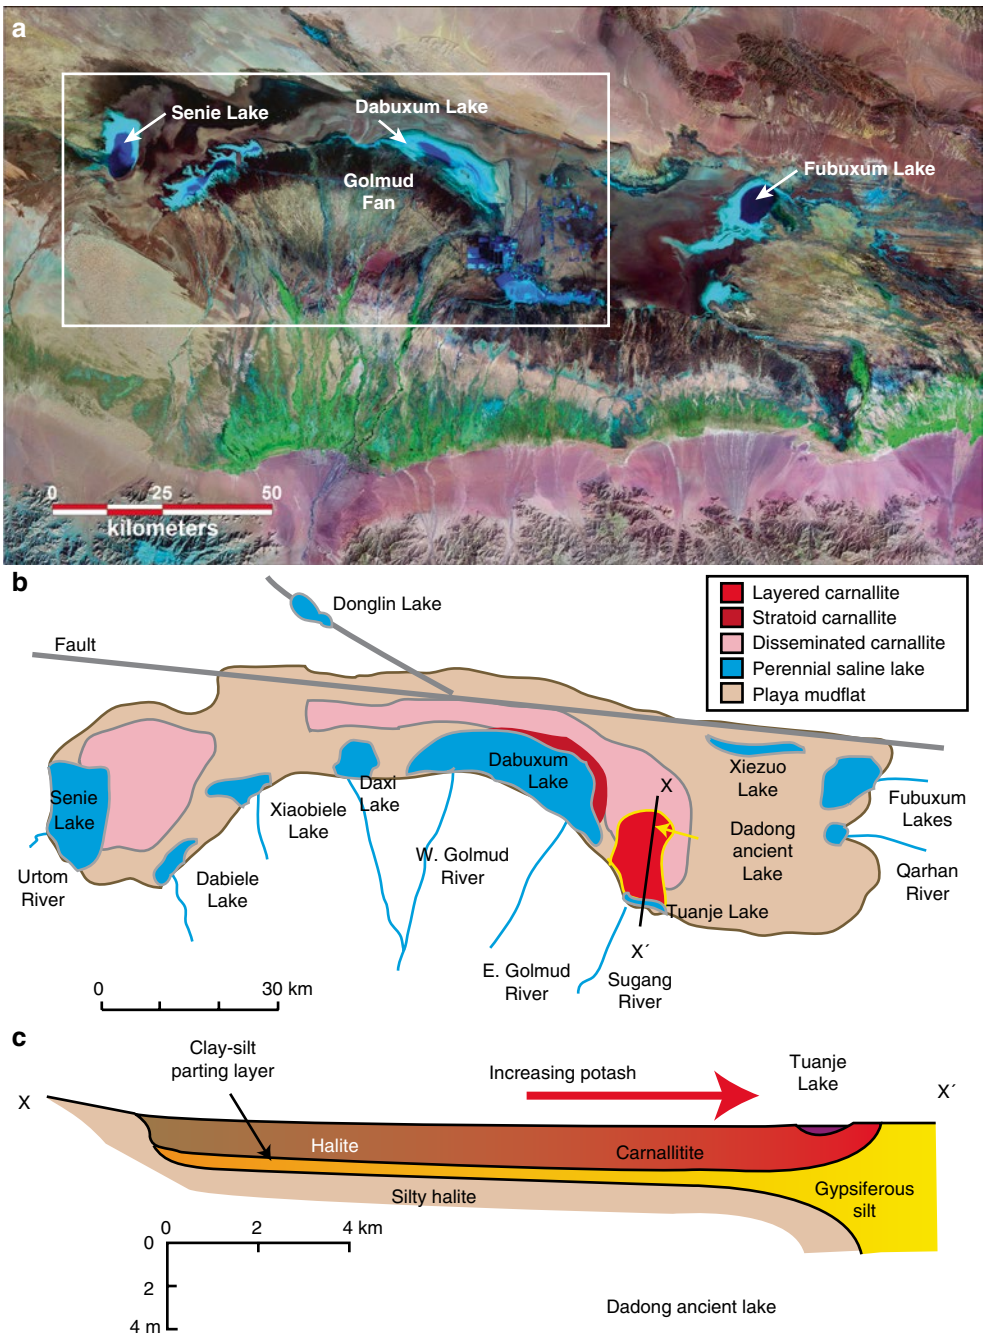

Fig. 11.11 Potash in the Lake Dabuxum region, Qarhan Playa, China. (**a**) locality map showing distribution of potash beds and lakes on the downflow side of the Golmud bajada (Landsat image courtesy of NASA https://zulu.ssc.nasa.gov/mrsid. (**b**) Potash geological plan, position indicated by white rectangle in (**a**) (After Duan and Hu 2001). amounts to be quarried and most of the exploited potash resource resides in interstitial brines that are pumped and processed using solar ponds.

Compositions of fluid inclusions in primary (chevron) halite beds hosting carnallite cements in the various Qarhan salt crusts represent preserved lake brines and indicate relatively wetter conditions throughout most of the Late Pleistocene (Yang et al. 1995). Oxygen isotope signatures of the inclusions record episodic freshening and concentration during the formation of the various salt units interlayered with lacustrine muds. Desiccation events, sufficient to allow halite beds to accumulate, occurred a number of times in the Late Quaternary: (1) in a short-lived event ≈50,000 ka, (2) from about 17–8,000 ka, and (3) from about 2,000 ka till now (Fig. 11.12). Modern halite crusts in Qahan playa contain the most concentrated brine inclusions, suggesting that today may be the most desiccated period recorded over the last 50,000 years. Measurements of inclusions in early diagenetic halite that formed from shallow groundwater brines (clear halite-spar void-fill between chevrons), confirm the climatic record derived from primary (chevron) halite. The occurrence of

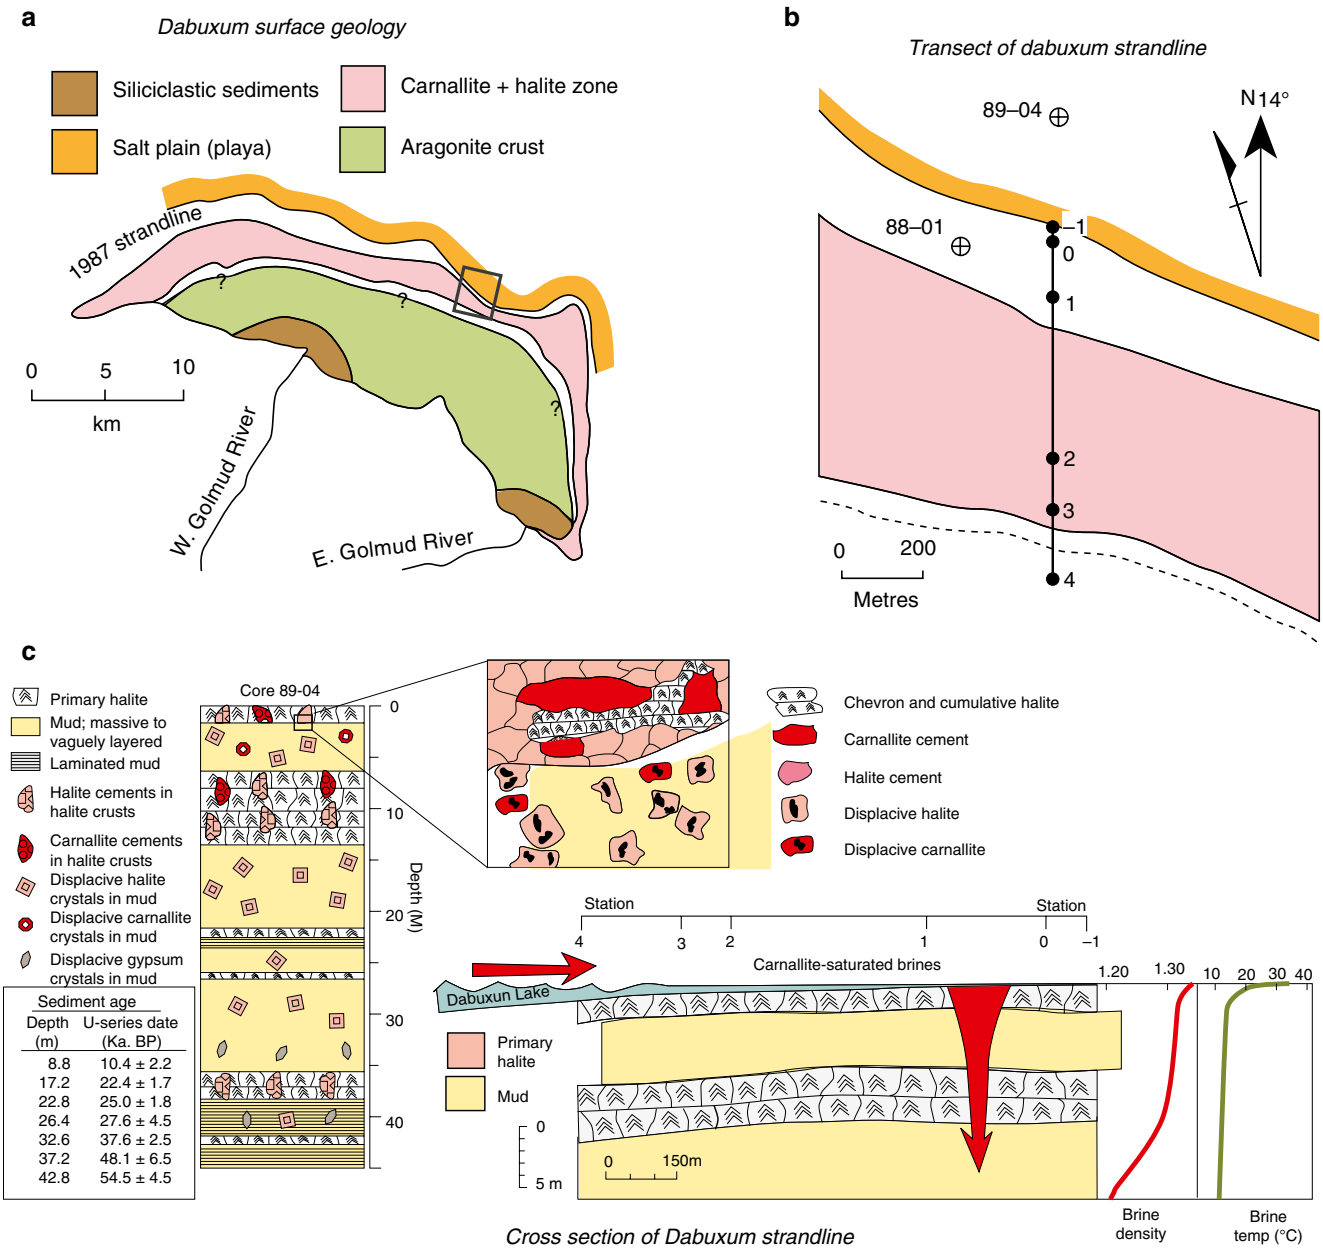

Fig. 11.12 Geology of carnallite in Lake Dabuxum area of the Qahan playa, Qaidam Basin. (**a**) Distribution of surficial sediment types also showing the position of enlarged region seen in **b** – see Fig. 11.11a for regional location. (**b**) Strandline geology of the northern shore of Lake Dabuxum showing position of coring traverse as shown as *inset* in **c**. (**c**) Cross section showing how the process of brine cooling forms carnallite cement in the karstic voids in shallow subsurface halite crusts and creates karst-filling cement textures (After Casas et al. 1992)

carnallite-saturated brines in fluid inclusions in the diagenetic halite in the top 13 m of Qahan playa sediments also imply a diagenetic, not depositional, origin of carnallite, which locally accumulated in the same voids as the more widespread microkarst halite-spar cements.

Transient surficial primary carnallite can accumulate along the strandline of Lake Dabuxum (Fig. 11.11a; Casas 1992; Van Gent et al. 2011). The greatest volume of water entering this lake comes from the Golmud River (Fig. 11.12a). Cold springs, emerging from a linear karst zone some 10 km to the north of the strandline and extending hundreds of km across the basin, also supply solutes to the lake.

The spring waters that discharge along the karst zone are chemically similar to the hydrothermal Ca–Cl sourced waters and are interpreted as subsurface brines that have risen to the surface along deep faults (Fig. 11.13; Lowenstein and Risacher 2009). Depths from where the Ca–Cl spring waters rise is not known; the subsurface of the Qaidam Basin in this region contains Jurassic and younger sediments and sedimentary rocks, up to 15 km thick, that overlie Proterozoic

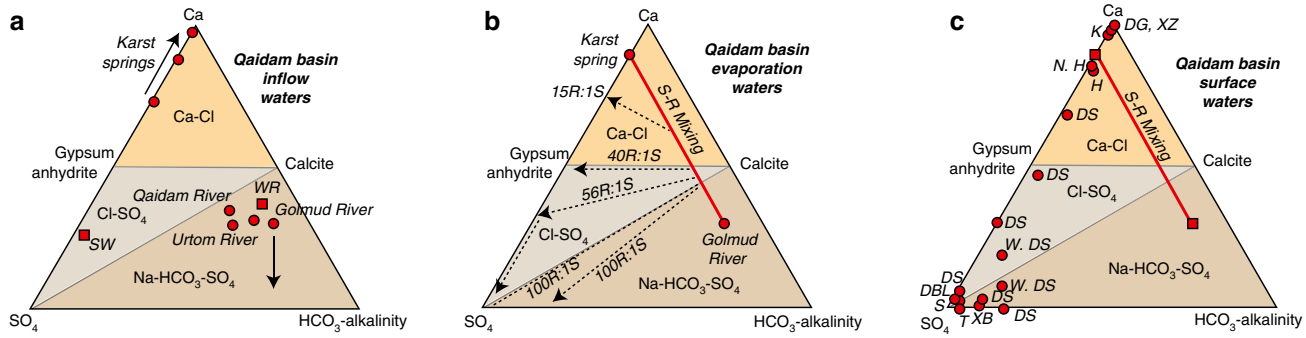

Fig. 11.13 Ternary Ca–SO_4–HCO_3 phase diagrams (After Lowenstein and Risacher 2009). (**a**) Qaidam Basin inflow water compositions. WR is world average river water, SW is Seawater. (**b**) Evaporation paths for mixtures of river water (Golmud River) and karst spring inflow. S–R is a spring water (karst spring) and river water (Golmud River) mixing line. (**c**) Qaidam Basin surface brine lake compositions (*DG* Donglin, *XZ* Xiezhuo, *NH* North Huobusun, *H* Huobusun, *K* karst brine pond, *WDS* West Dabuxun, *DS* Dabuxun, *S* Senie, *DBL* Dabiele, *XB* Xiaobiele, *T* Tuanjie)

metamorphic rocks (Wang and Coward 1990). It is also possible that Ca–Cl waters rise to the surface along a focusing permeability boundary between alluvial fan-dune sediments to the north and less permeable salt-mud sediments of Qarhan to the south. Spring inflow, whatever its flow path, has created an at-surface karst zone, focused along the main fault and defined by a series of depressions, where rising waters have dissolved soluble evaporites.

Several lakes located near this northern karst zone (Donglin, North Huobusun, Xiezhuo, and Huobusun) receive enough Ca–Cl inflow, more than 1 part spring inflow to 40 parts river inflow, to give these mixtures Ca equivalents >equivalents $HCO_3 + SO_4$ (Ca-Cl field in Fig. 11.13). With evaporation such waters evolve into Ca–Cl-rich, HCO_3–SO_4 -poor brines following precipitation of calcite and gypsum (much like seawater). The largest lake at Qarhan is Dabuxun, with its Na–Mg–K–Cl dominant brines and minor Ca and SO_4. These brines are interpreted by Lowenstein and Risacher (2009) to have formed from a mix of ≈40 parts river water to 1 part spring inflow, so that the equivalents of Ca ≈ equivalents $HCO_3 + SO_4$. Brines with this ratio of river to spring inflow lose most of their Ca, SO_4, and HCO_3 after precipitation of $CaCO_3$ and $CaSO_4$, and so form Na–K–Mg–Cl brines capable of precipitating carnallite and sylvite (Fig. 11.13). The chemical composition of surface brines in the various lakes on the Qarhan Salt plain appears to be controlled by the particular blend of river and spring inflows, which in turn is controlled geographically by proximity to river mouths and the northern karst zone with the formation of marine-like ionic proportions in some lakes.

Surface sediments of Dabuxum Lake are zoned (Fig. 11.12a, b). The southern part of the lake, closest to the Golmud River delta, is underlain by fine-grained siliciclastic sediments that pass lakeward into a centimetre-thick aragonite crusts, which floor much of the water-covered area of the lake. A small island in the centre of Dabuxum Lake is made up of mud and silt laminae coated by microcrystalline aragonite and mud chip breccias cemented with aragonite. Stacked halite pan crusts define most of the subaerial Qahan playa saltflats to the north of the perennial lake.

Surface efflorescent crusts of halite and carnallite accumulated along the edges of Dabuxum Lake from 1987 to 1989 with carnallite reaching thicknesses of up to 0.3 m along a strandline zone approximately 1 km wide. The water-covered lake area at that time was approximately 250 km^2 and waters were less than 1 m deep (Casas et al. 1992). The carnallite crust was brine-saturated, poorly cemented and had a mushy consistency. It was dominated by equigranular, anhedral carnallite crystals up to 5 mm in diameter. Thin sub-centimetre layers of very fine-grained (sub-millimetre) carnallite and siliciclastic mud occurred within the carnallite mush. Individual carnallite crystals in the mush were often linked with textures identical to rafts or films of fine-grained carnallite, which could be seen floating on the surface of the very shallow brines near the lakeshore. Rafts were being blown onto the strandline or left behind on the lake floor as the drying brine sheets retreated from the northern strand-zone of the lake. Strandline carnallites underwent extensive syndepositional diagenetic modification depending on daily temperature and weather conditions. In a single 2-week period, dominated by fine sunny weather with daily temperatures up to 35 °C, carnallite precipitated in the afternoon as rafts, or as centimetre-size, needle shaped skeletal crystals, or as efflorescent puffs of sub-millimetre crystals on evaporitic mudflats wherever the brine level was below the surface.

Light rains and strong southwest winds are common in the summer in Qaidam Basin. During such storms Dabuxum lake waters are blown over the halite-encrusted north shore and pond as thin brine sheets (Fig. 11.12b). For example, vigorous winds on 6 and 10 August 1988 shifted the northern lakeshore several hundred metres north (Casas et al. 1992).

These overlapping open lake waters were at or slightly below halite saturation and considerably below carnallite saturation. The carnallite strand zone was modified and partly dissolved after being covered by these waters, but was re-established during subsequent warm days. In a subsequent large flood, during July to September 1990, the Dabuxum Lake area expanded from 250 to 800 km^2, while the associated freshening of the expanded lake completely dissolved the carnallite crust. Clearly, surface carnallite along the north shore of Lake Dabuxum is an ephemeral strandzone sediment, with little or no preservation potential.

However, carnallite has been widely precipitated and preserved in the upper 13 m of the 45-m thick interbedded clay-halite succession that underlies the modern Lake Dabuxum strandline (Fig. 11.12c). These subsurface carnallites are diagenetic void-filling cements and displacive crystals, which indicate a carnallite distribution with a strong temperature control. As dense carnallite-saturated lake brines sank into the underlying sediment they cooled and so precipitated in pre-existing karst holes and pits in the halite bed (Fig. 11.12c; Casas et al. 1992). The voids in the halite were created by earlier lowerings of the watertable, alternating with times of freshening of the lake waters, with both events occurring numerous times prior to the accumulation of the present salt crust. This style of secondary nearsurface carnallite as early cements in the active phreatic zone is texturally analogous to much of the secondary carnallite and sylvite karst-fill fabric seen in ancient potash deposits in Thailand, Canada and the USA.

Because the majority of the carnallite in the Qarhan region is made up of patchy cement clusters hosted in bedded halite in karst cavities in the upper 13 m of the playa salt sequence is recovered via a brinefield pumping to a cluster of solar evaporators. The resulting crystal mush is scrapped and dredged from the pans by floating dredges to create the feedstock slurry for the nearby chemical processing plant that produces a combination of K_2SO_4 and KCl salt products.

Danakil Depression, Ethiopia

The Danakil Depression (aka Dallol Depression) of Ethiopia and Eritrea is an area of intense hydrothermal activity with potash occurrences related to rift magmatism, marine flooding, and deep brine cycling. It is part of the Afar Triple Junction and is located in the axial zone of the Afar rift, near the confluence of the East African, Red Sea and Carlsberg rifts (Fig. 11.14a; Holwerda and Hutchinson 1968; Hutchinson and Engels 1970; Hardie 1990). The depression is the northern part of the Afar depression and runs SSE parallel to the Red Sea coast but is some 50–80 km inland and separated from the sea by the Danakil Mountains. It is 185 km long, up to 70 km wide, with a floor more than 116 m below sea level in the deeper part of the depression. The Danakil Depression widens to the south, beginning with a 10 km width in the north and widening up to 70 km in the south (Fig. 11.14b, c). The basin floor in the northern part is the deepest and has elevations as low as 50–120 m below sealevel (Fig. 11.14c). A shallow volcanotectonic barrier behind Mersa Fatma on the coast prevents hydrographic recharge, or even substantial seawater seepage, into the current depression from waters of Howakil Bay, which is some 50–60 km WNW of Ito Aichil on the Red Sea coast.

In terms of daily temperature the floor of the Danakil is one of the hottest places on earth; year round the daily temperature is above 34 °C and in summer every day tops 40 °C, with some days topping 50 °C (Fig. 11.15). These high temperatures and a lack of rainfall place it at the hyperarid end of the world desert spectrum and make it a well known example of a BWh Köppen climate zone (Kottek et al. 2006).

A halite-floored elongate saltpan covers the deepest part of the Danakil Depression over an area some 40 km long and 10 km wide, (Figs. 11.14b, c and 11.16). The pan's position is asymmetric; it lies near the depression's western edge, some 5 km from the foot of the escarpment to the Balakia Mountains and the Ethiopian Highlands, but some 50 km from the eastern margin of the depression and today constitutes the deepest continental drainage sump of the Afar depression. The area in white shown in Fig. 11.15b, and located northeast of the main modern salt pan, is mostly an extensive gypsum plain. It defines a higher less saline lacustrine episode in the basin fill. Bedded Pleistocene evaporites may underlie the entire Danakil depression, but younger lava flows of the Aden Volcanic Series and alluvium washed in from the surrounding bajada obscure much of the older Pleistocene sedimentary series in southern part of the depression beyond Lake Assale (Fig. 11.14a).

Depositional Patterns in Outcrop

Surficial sediment distributions outline classic drawdown facies belts with a wadi fed alluvial fan fringe passing down dip into sandflats (local dune fields), dry mudflats (with springs), saline mudflats and shallow brine pans (Lake Assale). The fans are indented or locally covered by a mostly younger succession of constant-elevation marine, biochemical and evaporitic sediments fringes or "bathtub rim" facies (Fig. 11.16).

Pleistocene beds, exposed by local uplift, deflation and ongoing watertable lowering, outcrop about updip edges to the salt crusted parts of the northern Danakil, and form low flat-topped plateaus or mesas on the plain, they are the tops of alluvial fans aprons which are heavily dissected and eroded by occasional storm runoff and rainfall. This fan fringe contains relatively fresh water lenses in a desert setting that is one

of the world's harshest (Kebede 2012) Most of the active fans line the western margin of the basin. Many of the downdip fan edges are defined by a gypsum pavement, while others, such as the Musley fan, have flowed across the pavement level and into the lower parts of the depression (Fig. 11.16).

The Musley fan characteristics are documented by the potash explorers in the basin as it offers a reliable water source for potential ore processing and so has been cored by a number of proposed water wells. Internally the fan is composed of interfingering layers and lenses of sand, gravel and clay, with highly porous intervals in the sand and gravels. Depth to the watertable varies from >2 to 60 m, and salinities from 760 ppm to more than 23,400 ppm. The principal source of recharge is flash floods, originating in Musley Canyon draining the Western Escarpment, along with minor inflows from the adjacent uplifted volcanic block and local highly intermittent rains. Of six potential water wells drilled in the fan by the Parsons Company in the 1960s, four returned water of good quality (<2,000 mg/l) while the other two had waters with salinities in excess of 20 g/l. Pump test data indicate average transmissivity of the water-bearing beds around 870 m^2/day, with salinity in the fan increasing from west to east.

Overall, surface sediment patterns in the Danakil depression define a depositional framework of brine drawdown, related to basin isolation from an earlier hydrographic (at surface) marine connection to the Red Sea, followed by stepped evaporative drawdown. This is indicated by fringing topographically-distinct belts or rims of now inactive coralgal carbonates and gypsum evaporites (aka "bathtub ring" patterns) these were followed by the present drawdown saline-pan halite-dominant hydrology (Figs. 11.16 and 11.17a, b). The current hydrological package of sediments sits atop and postdates the Pleistocene potash hosting Lower Halite Formation and is probably equivalent to the uppermost part of the clastic overburden facies illustrated in Fig. 11.18.

In earlier work, some authors interpreted these fringing belts, especially the coralgal reefal belt, as being possibly of Pliocene or even Miocene age. However, when one looks at the stratiform nature of the outcrop trace of both the reef belt and the gypsum belt, and the carapace nature of its depositional boundaries in the field, it is immediately apparent they must be younger. Both the reefal and gypsum belts track horizontal hydrological intersections with the landscape, in

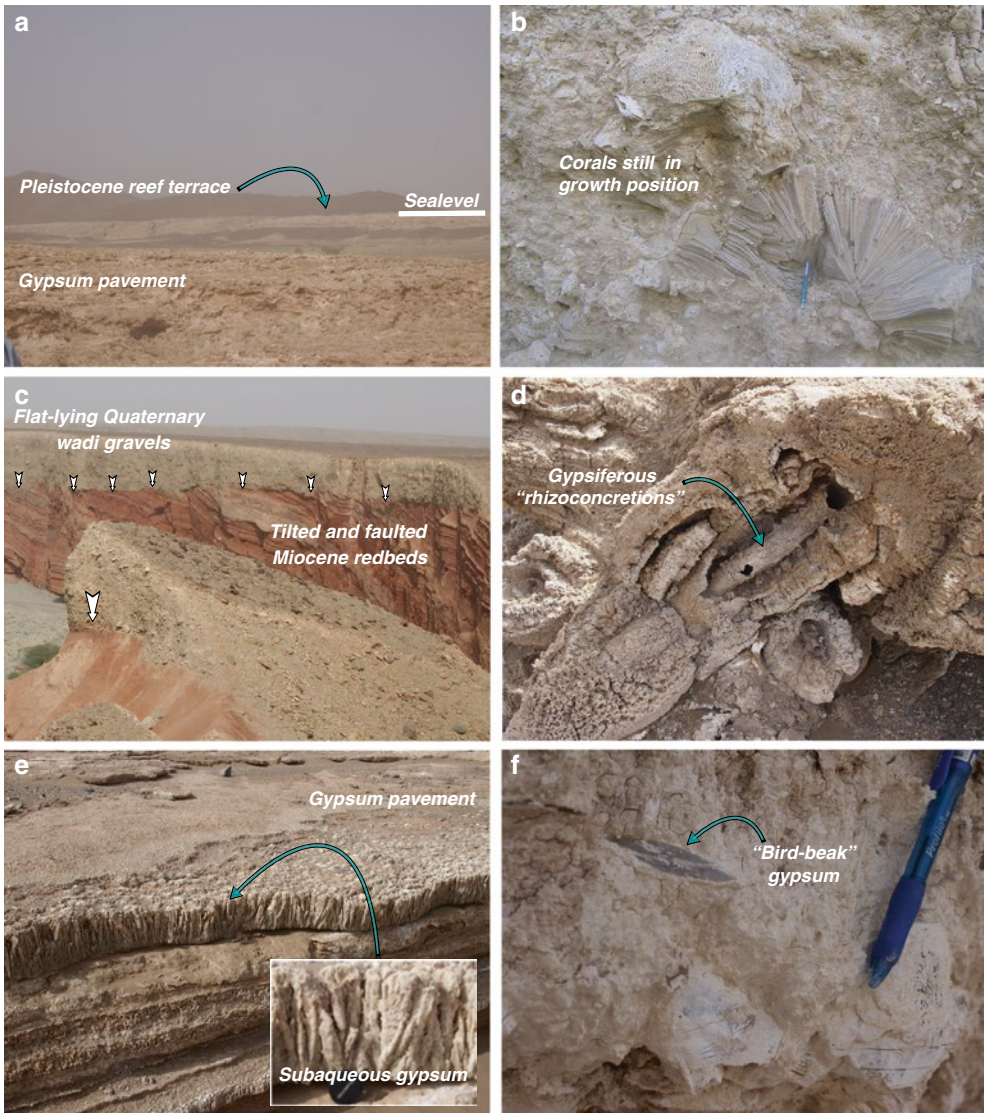

Fig. 11.17 Outcrop distribution and textures (**a**) View westward standing on the subsealevel gypsum pavement looking toward basin edge and the at-sea level Pleistocene coralgal rim (see Fig. 11.16a for map view of rim). (**b**) Coral heads in growth position in the reef rim facies. (**c**) Angular unconformity (*arrows*) separating tilted and faulted Miocene redbeds from overlying flat-bedded Quaternary wadi gravels. (**f**) Bird-beak displacive gypsum growing diagenetically in Pleistocene marls adjacent to rimming reef

what is an ongoing volcanogenic and tectonically active depression. When the reefal belt image is overlain by a DEM it shows the reef belt is consistently at sea level (Fig. 11.14c). If the outcrops of the reef belt and the gypsum pavement were older than late Pleistocene or Holocene, then ongoing episodes of tectonism and volcanism would have modified the elevations of the two outcrop belts in the landscape. Field visits to the Miocene section clearly show the influence of ongoing tilting and tectonism and hence why the flat-lying tops to the reef and gypsum belts imply a late Pleistocene-Holocene (Fig. 11.17c).

That is, the topographic distribution of the top of the reef facies, which lies within a metre or two of current sea level, implies that the Danakil depression had a relatively recent connection to the Red Sea. The pristine preservation of aragonitic corals and sand dollars in the adjacent marls suggest the connection was either related to the penultimate interglacial (around 104,000 years ago) or to an early Holocene transgression into the depression (Fig. 11.17b). My personal inclination is that this reef terrace is related to the penultimate sea level high (104 ka), when world sea level was a few metres above its present level. If so, there is no indication that since then the depression was ever connected at the surface to the Holocene waters of the Red Sea.

The coralgal reef terrace indicates normal marine water were once present in the Dallol depression, while the occurrences of the stratiform gypsum pavement are at a somewhat lower elevation (Fig. 11.17a). Like the reef rim, the gypsum pavement fringe defines a consistent elevated level, visible along the western margin of the present salt flat. It is the result of gypsum deposition during a period of drawdown associated with brine level stability, subsequent to the isolation of the depression from its former "at-surface" marine connection. During this time gypsum accumulated as a stack

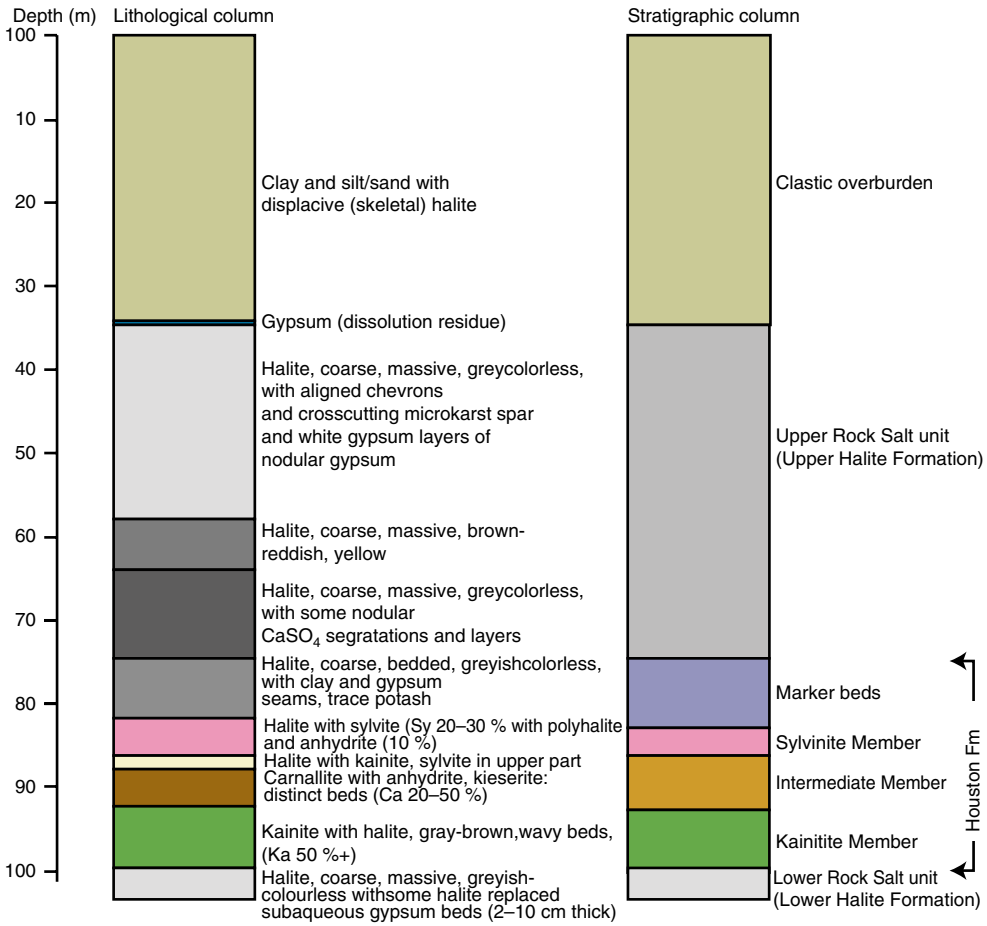

Fig. 11.18 Lithological column and stratigraphic column for the upper potash section in the Dallol depression (Based on personal study of cores and Ercosplan 2010). (See Fig. 11.20 for core-based textural details)

of subaqueous aligned gypsum beds, along with a series of gypsiferous tufas and rhizoconcretions in zones about the more marginward spring-fed parts of the gypsiferous lake margin (Fig. 11.17d, e). The evolution from marine waters that deposited the reefs and adjacent echinoid-rich lagoonal marls at a higher level in the depression (the lit zone) into a more saline capillary-fed system with no ongoing marine surface connection to the Red Sea is indicated by the diagenetic growth of large lenticular ("bird's-beak") gypsum crystals within the marine marls (Fig. 11.17f)

The current halite-dominant system is associated with even greater drawdown levels compared to the gypsum-dominant hydrology. Today's hydrology deposits a series of stacked brinepan salt sheets, which are still quarried by the local tribesmen using handtools and long trains of camels and asses to carry the mined blocks out of the quarry areas. The brine flats accumulate halite whenever the Lake Assele water line is periodically blown back and forth over the brine flat. Southerly winds occur quite often in the annual weather cycle and so the halite exploited by the tribesman is a renewable resource. Superimposed on this is occasional sheetflood event, driven by rare rainstorms and the deposition of a silt-mud layer sourced from the wadi belt. This brineflat hydrology is stable with respect to the current climate (groundwater inflow ≈ outflow). It means the current brine-flat of the northern Danakil low is accumulating salt at an even lower topographic level in the basin than the surrounding gypsum pavement, implying today's evaporites form under more arid conditions (less humid, more drawndown) than that of the gypsum pavement.

This stepped late-Pleistocene-early Holocene hydrology, captured in the modern surficial geology of the Dallol Depression, probably postdates a somewhat wetter (humid) climatic period indicated by the widespread deposition of the clastic overburden atop the Upper Halite Formation (UHF; Figs. 11.18 and 11.20). That is, the modern hydrology in present-day Lake Assale, and its adjacent saline mud flats, is not the same hydrology as that which precipitated the massive UHF cored the present clastic dominated saline pan. Texturally and hydrologically the UHF depositional system of stacked salt crusts that dominates the upper part of the UHF in the cored wells was similar to today, but a wetter moister period dominated by sheetflood clastic supply separates the two hydrological events in all the cored wells. A somewhat different marine-fed seepage hydrology formed the Lower Halite Formation (LHF) and its potash bittern cap (Houston Fm).

Table 11.6 Distinguishing features of the Lower and Upper Halite formations

Feature	Lower Halite Formation (LHF)	Upper Halite Formation (UHF)
Dominant halite style	Subaqueous, medium to coarsely crystalline, Chevron proportion increases upwards in formation.	Pan/mudflat, Coarser crystalline nearer base passes up into chevron dominate. Pristine textures.
Porosity	None to rare throughout	Yes, typically >10–15 %
$CaSO_4$ style	Anhydrite (?) crystal mantles and layers (subaqueous deposition some dissolution relicts)	Gypsum nodules with co-associated brine freshening – two styles (a) with detritals, (b) without detritals
Detrital styles (siliciclastic)	Minor aeolian settle-out, no sheetflood events	Sheetflood and rainstorm events with associated freshening and microkarsting truncations
Microkarst	Minor, only noted in halite immediately below transition to kainitite member	Multiple microkarst levels and subvertical cavity infill cements
Depositional style	Subaqueous marine fed system that shallows and brines upward into a potash association	Alternating saline pan facies, coarsely crystalline and chevron halite with increasing freshening upsection indicated by increasing levels of sheetflood clays
Potash association	Yes; depositional kainitite and reworked potash salts association (carnallite, primary and secondary, sylvite as early secondary potash minerals, with Mg salts kieserite, bischofites as co-associates)	No; little or no mineralogical evidence for bittern level salinities

Core-Based Geology

More than 970 m of halite-dominated Quaternary evaporites have accumulated beneath the present salt pan of the Northern Danakil, along with interbeds of gypsum, anhydrite and shale (Holwerda and Hutchinson 1968; Augustithis 1980). This km-thick subcropping Quaternary halite fill contains one and perhaps two or more dipping potash beds. The upper potash bed lies at a depth of 38–190 m and has been cored in a number of wells, while a lower inferred potash bed is at a depth of 596 m near the western end, but has been interpreted only from high API kicks in gamma logs run in deeper wells. The upper potash bed is the target zone for a number of minerals companies currently exploring for potash in the region. Regionally, both potash units dip to the east, and the deepest that indicators of the two units were encountered by the drill in a single well was at 683 and 930 m, respectively (Holwerda and Hutchinson 1968). The Quaternary age of the potash units, if they are marine-sourced, explains the high magnesium content of the potash bitterns depositing these evaporite as modern seawater contains high levels of Mg and SO_4 (Fig. 2.12).

My study of cores the intersected both the Lower and Upper Halite formations shows both the lower and the upper halite units retain pristine sedimentary textures with features and vertical successions that indicate distinct hydrologies during their deposition. There is no textural evidence of halokinetic recrystallization in halites any of the studied cores and published seismic also indicates consistent dips in the evaporites (Table 11.6; Figs. 11.19d, e and 11.20; Ercosplan 2010). Most of the textures in the cored potash interval indicate a subaqueous/phreatic environment, with brine reworking of a primary kainitite unit. The following paragraphs summarise my corebased observations and interpretations.

The *Lower Halite Formation* (LHF) is dominated by subaqueous halite textures and a lack of siliciclastic detritus compared to the upper Halite Formation (Fig. 11.19e). Overall, the formation is dominated by subaqueous textures and was most likely deposited in a marine-fed brine lake or seaway, which shallowed and brined upward via a gradational contact into the *Kainitite Member* (Fig. 11.20). Textures in the LHF are near identical to those in the Messinian of Spain and Sicily (Chap. 5). The mm-laminated Kainitite Member is a also subaqueous unit and was likely deposited on a pelagic bottom beneath a shallow body of marine-fed bittern waters, which never reached carnallite saturation. Above this are the variably present carnallitic *Intermediate and Sylvinitite members* and the overlying *Halite marker beds*. All retain pristine textures indicating mostly subaqueous deposition, soon followed by varying exposure and reaction to shallow phreatic brines moving across the top of Kainitite member. This shallow phreatic brine crossflow drove syndepositional mineral alteration and collapse.

Halite textures in the LHF show it did not experience this crossflow; beds are tight with primary bottom-nucleated textures dominated by coarsely crystalline beds, made up of cm-scale couplets dominated by upward pointing chevrons and mantled by thin $CaSO_4$ layers (Fig. 11.19e). This meromictic-holomictic textural association passes up into the upper part of the LHF with cm-scale alternating less-saline to more-saline episodes of evaporite precipitation, indicating an "on-average" increasingly shallow subaqueous depositional setting. The upward-shallowing, increasingly schizohaline trend is also indicated by an increasing proportion

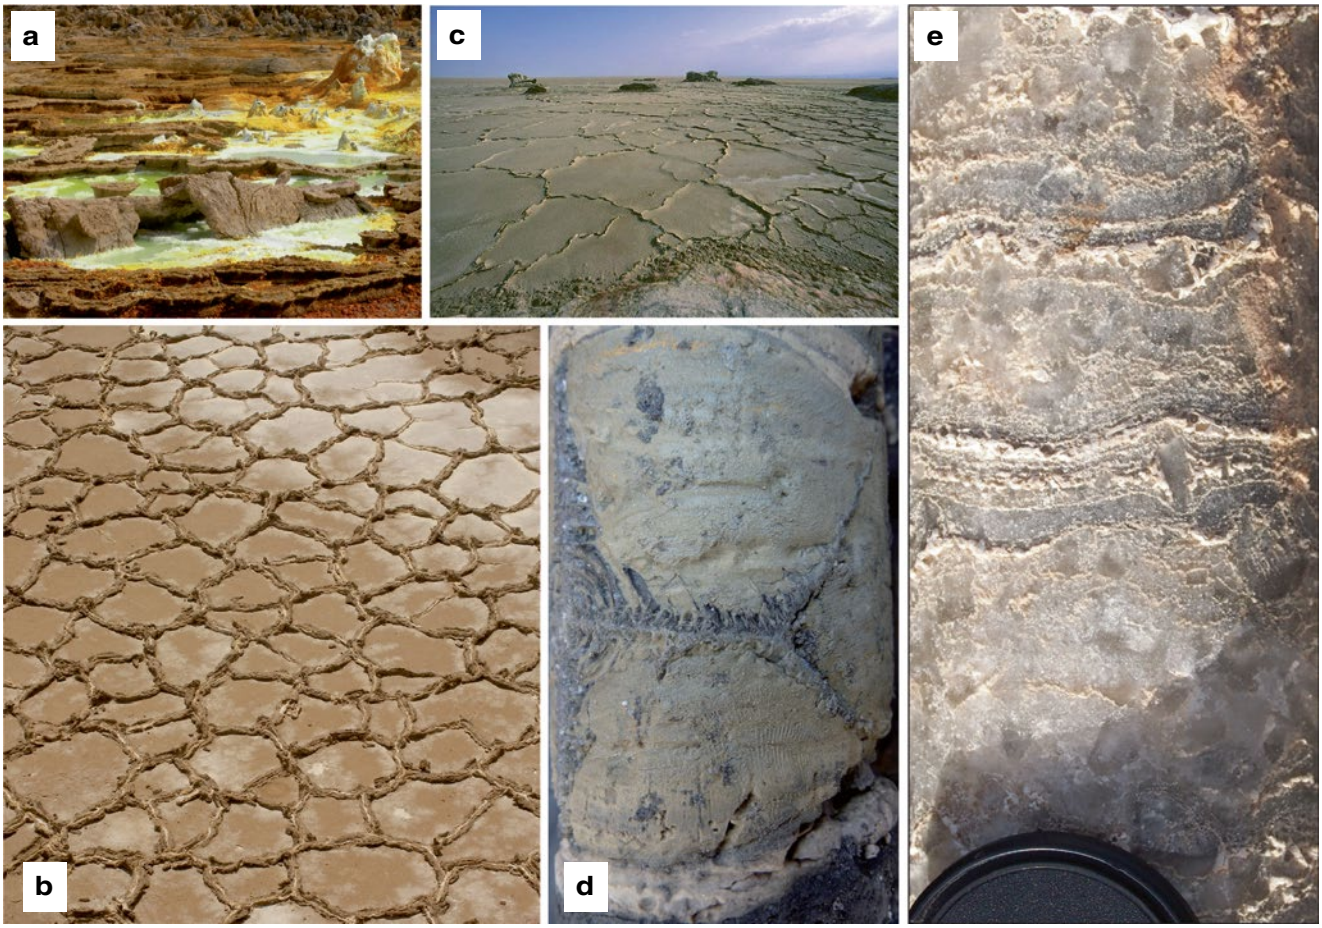

Fig. 11.19 Halite styles at the surface and in the subsurface in the Dallol depression, Ethiopia. of milky (brine-inclusion rich) chevron halite textures in the upper parts of the LHF (Fig. 11.20). The nature of the primary layering over the same interval changes from mantles (zig-zags) to flatter truncational laminae. The $CaSO_4$ layers mantle upward-aligned halites (Fig. 11.19e). The cubic crystal terminations on the halites encased in $CaSO_4$ show this is a primary texture, although similar features have been interpreted as replacive in the Permian of west Texas. Throughout the LHF there is little evidence of microkarsting (Fig. 11.20). In combination, all these pristine textures in the LHF indicate a perennial, periodically shallowing and freshening brine body. In the upper part of the unit, it shallowed to where the somewhat fresher upper water mass periodically touched down on the perennially-subaqueous depositional pavement.

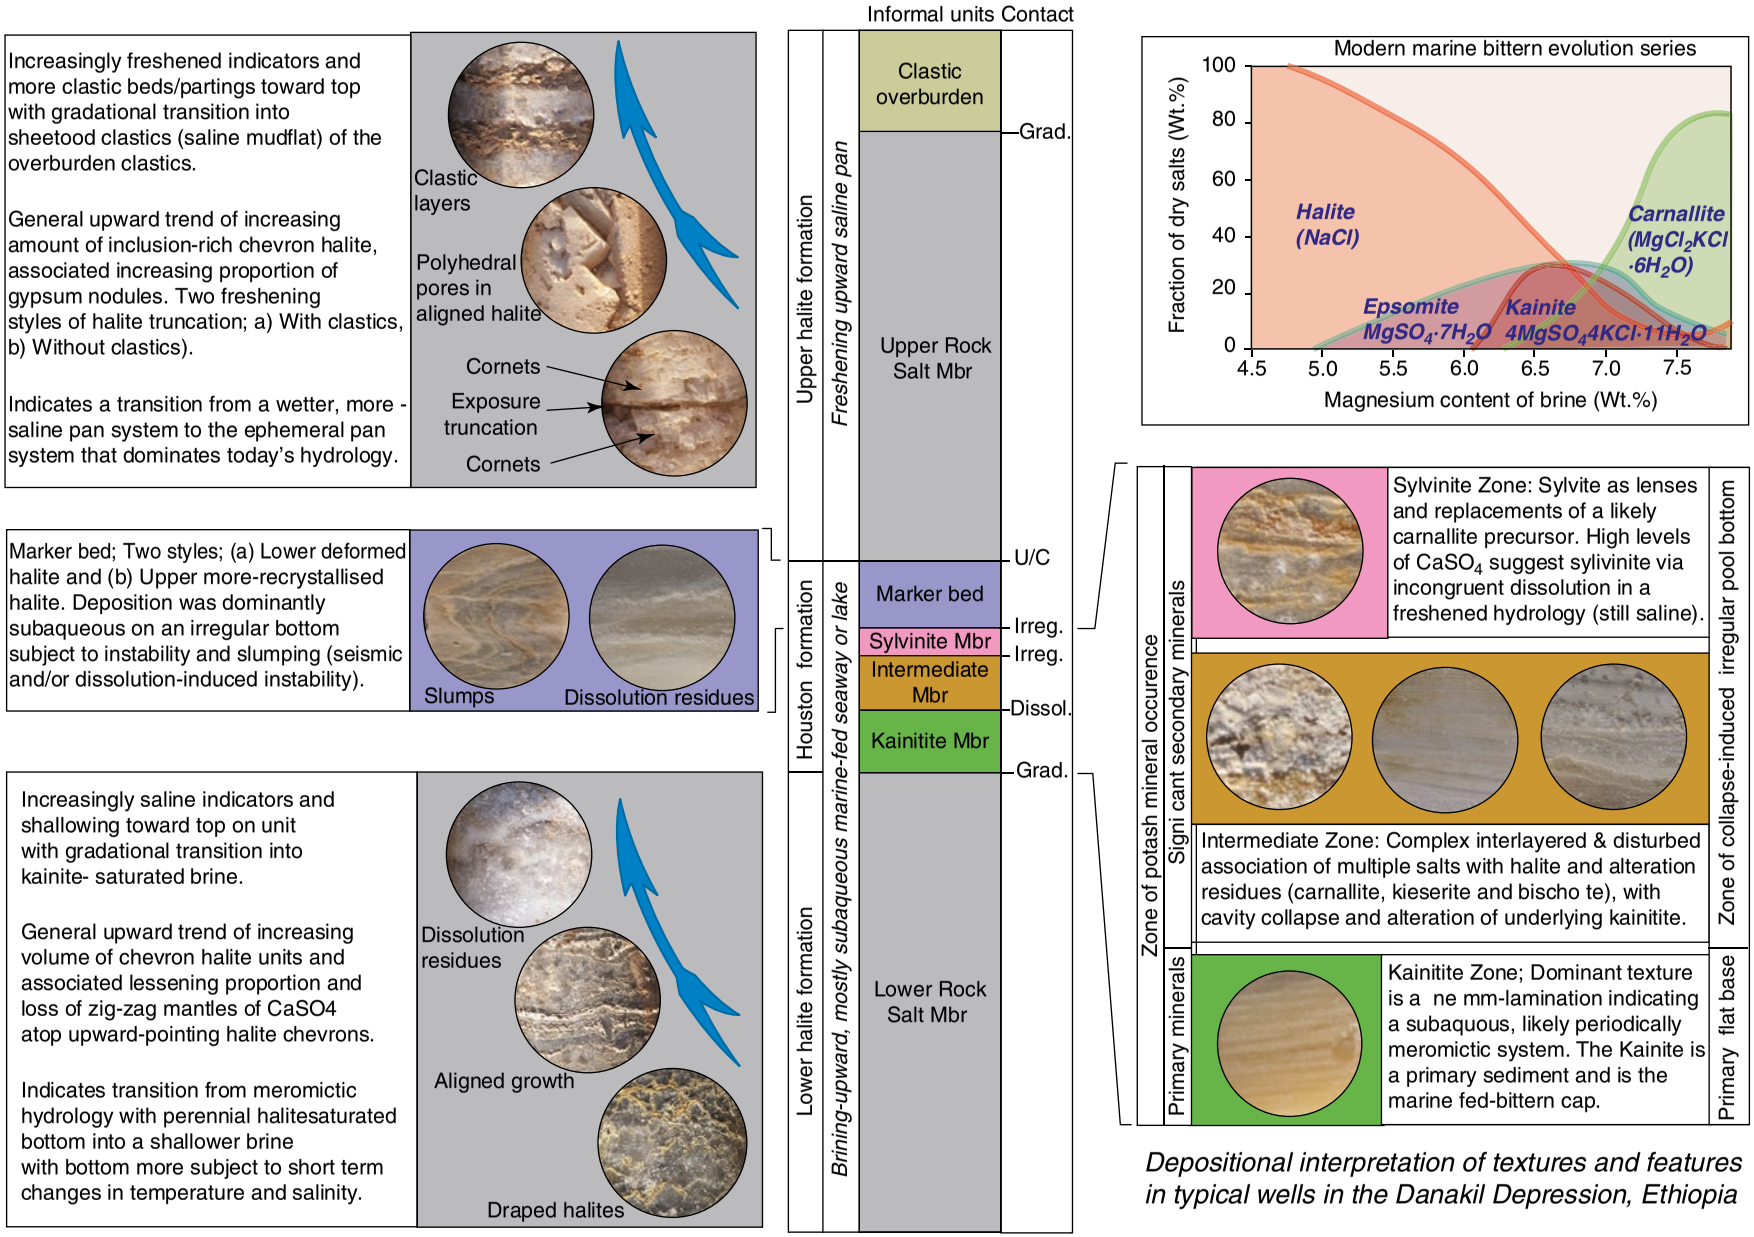
Between the UHF and LHF is the potash-entraining Houston Formation (Figs. 11.18 and 11.20). It has been drilled and cored extensively and is consistently between 15 and 40 m thick (Fig. 11.18). Stratigraphically, it consists of lower Kainitite Member (4–14 m thick) atop and in depositional continuity with the LHF (more than 500 m thick). The Kainitite Member is fine-grained, laminated, locally wavy-bedded, containing up to 50 % kainite in a halite background. It is overlain by what older literature describes as the "Carnallitite Intermediate unit" (3–25 m thick). More recent potash exploration drilling has shown the Intermediate Carnallitite Member is not always present within the Dallol depression and mineralogically is at best considered as variably developed. The lower part is a carnallite-halite mixture with some kieserite and anhydrite. This passes up or laterally into kainitite with sylvite. Above the Intermediate Member is the 0–10 m thick Sylvinite Member containing 20–30 % sylvite, along with polyhalite and anhydrite (up to 10 %). This passes up into a halite-dominated unit that is known as



Depositional interpretation of textures and features in typical wells in the Danakil Depression, Ethiopia

Fig. 11.20 Depositional summary of the significance of sedimentary textures in a representative potash-intersecting well, Danakil Depression, Ethiopia

the "Marker Beds" because of the co-associated presence of clay lamina and bedded halite, along with traces of potash minerals. This unit then passes up in the massive Upper Rock Salt unit across an unconformity at the top of the "Marker Beds." The bedded, and at times finely laminated textures in the magnesian bittern units, are used by many to argue that the kainitite and possibly carnallitite members are primary or syndepositional precipitates.

Cores through the sylvinite member sample a range of recrystallization rather than primary textures. Three types of barren zone occur within it and are possibly related to the effects of groundwaters and solution cavity cements within the carnallitite unit, perhaps precipitated before the deposition of the overlying halites. Barren zones in the Sylvinite member are regions where: (a) the entire sylvinite bed is replaced by a relatively pure stratiform halite, along with dispersed nodules of anhydrite, (b) zones up to 23 m thick and composed of pure crystalline halite (karst-fill cements?) that occur patchily within the sylvinite bed and, (c) potash-depleted zones defined by coarsely crystalline halite instead of sylvinite. Bedding plane spacing and layering in the halite in styles a and b are similar to that in the laterally adjacent sylvite bed. Contact with through flushing freshened waters probably created most of the barren zones in the sylvinite. Fluid crossflow may also have formed the sylvite of the upper member, via selective surface or nearsurface leaching of $MgCl_2$ from its carnallite precursor (Holwerda and Hutchinson 1968). Due to its secondary origin, the proportion of sylvite in the sylvinite member decreases as the proportion of carnallite increases, along with kieserite, polyhalite and kainite.

Beneath the sylvinite member, the variably-present carnallitite member contains a varied suite of non-commercial potash minerals that in addition to carnallite include, kieserite, kainite (up to 10 % by volume) and polyhalite, along with minor amounts of sylvite. Minor anhydrite is common, while bischofite and rinneite may occur locally, along with rust-red iron staining. Sylvite is more abundant near the top of the carnallitite member and its proportion decreases downward, perhaps reflecting its groundwater origin. Kainite is the reverse and its proportion increases downward. The sylvinite member and the carnallitite member also show an inverse thickness relationship. Bedding in the carnallitite member is commonly contorted with folded and brecciated horizons interpreted as slumps. The base of the carnallitite member is defined as the level where carnallite forms isolated patches in the kainite before disappearing entirely.

The kainite member is texturally distinctive and is composed of nearly pure, fine-grained, dense, relatively hard, amber-coloured kainite with ≈25 % admixed halite. Texture and colour are characteristic of the unit, but even more so are the distinct "ruler-straight" bedding planes in the kainite, a striking contrast to the wavy, contorted and irregular bedding planes of the overlying carnallitite and sylvinite members. Core study shows the lamina style remained flat-laminar (that is, subaqueous density-stratified with periodic bottom freshening) as the mineralogy passes from the LHF up into the flat-laminated kainitite member (Fig. 11.20). Throughout, the kainitite unit shows this finely sub-mm scale layering, with no evidence of microkarsting or any exposure of the kainitite depositional surface. That is, the Kainitite Member is a primary depositional unit, like the underlying halite and still retains pristine evidence of its dominantly subaqueous depositional hydrology. The decreased proportion of anhydrite in the Kainitite Member, compared to the underlying LHF, indicates a system that on-average was more saline than the brines that deposited the underlying halite. The preponderance of $MgSO_4$ salts means the Kainitite unit like the underlying LHF formed by the evaporation of seep-supplied seawater. This situation differs from the present "closed basin" hydrology of the Danakil Depression (Hardie 1990).

The top of the Kainitite Member is typically defined by a 2–3 m-thick zone of poor core recovery (brine-cavity zone?). Sediments of the what is known as the Intermediate Member occur immediately above this zone of poor recovery. The Intermediate Member is defined by the first appearance of carnallite in the well stratigraphy. Carnallite and kieserite, along with bischofite and some halite are co-associated mineralogies above the dissolutional top to the Kainitite Member (Fig. 11.20).

Textures in cores in all intervals above this poor recovery zone indicate deposition occurred on a more irregular bottom topography (e.g. pseudo-crossbeds in kieserite beds). Ongoing bottom instability is indicated by slumps and brecciation-induced collapse zones, along with pervasive lenticular bed styles. Taken together they indicate deposition in a subaqueous brine lake or seaway, but compared to the underlying LHF sediments this brine system had a more irregular and unstable, bottom topography. This was so throughout deposition of the Intermediate member, the Sylvinite member and the overlying marker beds. Together all these members atop the LHF constitute what is known as the Houston Formation (Fig. 11.20).

The amount of anhydrite increases in these beds compared to the underlying Kainitite Member, indicating a somewhat freshened (but still hypersaline) depositional/diagenetic brine hydrology that was capable of dissolving and reprecipitating potash and magnesia as it diagenetically reworked top of the Kainitite member. This inference of an early diagenetic component to the potash distribution is reinforced by the variable presence of bischofite (up to 200 m thick units of massive bischofite have been cored in some of the wells drill by Allana Potash). Interestingly, in terms of the somewhat mobile nature of $MgCl_2$ brines both past and present, there is today a bischofite-saturated brine pool active at the surface near Dallol. It contains brine at a temperatures of 132 °C and if a stick is placed in the brine and then extracted a coat of bischofite forms immediately on exposure to the air.

The zone of potash minerals in the two units atop the primary laminated textures of the kainitite show various

secondary potash textures (Fig. 11.20). It seems much of the potash alteration occurred in the shallow subsurface in zones subject to groundwater crossflows and collapse, possibly aided by seismically induced pulses of brine crossflow. All this hydrology was subject to long term brine reflux and the brine displacement backreactions that typify all evaporite deposition, past and present.

An observation of early ionic mobility in potash zone brines in the Danakil depositional system is also not unusual in any modern or ancient potash deposit. It should not be considered necessarily detrimental to the possibility of an extensive economically exploitable potash zone being present in the Danakil Depression. As we shall see in the later sections of this chapter, all the world's exploited potash deposits, including those in the Devonian of Canada and Belarus, the Perm of the Urals and the potash bed of west Texas, show evidence of syndepositional and shallow burial reworking of potash. Early potassium remobilization has created the ore distributions in these and other mined potash deposits. Likewise lack of knowledge in terms of evaporite textures and associated hydrological controls to explain such redistributions and their polycyclic nature explains many of the problems encountered in potash exploration and exploitation (Chap. 13; case studies).

Textures and mineralogies in the *Upper Halite Formation* (UHF) define a separate hydrological association to the marine-fed LHF and Houston Formation (Table 11.6). Compared to the LHF, the UHF has much higher levels of depositional porosity, lacks high levels of $CaSO_4$, has high levels of detrital siliciclastics. This is especially so in its upper part, which shows textural evidence of periodic and ongoing clastic-rich sheetflooding and freshening (Fig. 11.20). It was deposited in a hydrology that evolved up section to become very similar to that active on today's halite pan surface. The UHF contains no evidence of salinities or textures associated with a potash bittern event and is probably not a viable exploration target for solid potash salts.

The UHF lies immediately above the halite marker bed, which defines the top of the Houston Formation, where it is highly porous, with interconnected locally-high levels of effective intercrystalline polyhedral porosity. It is a likely a still-active basal aquifer to the Upper Halite Formation (Fig. 11.20). The lower part of the UHF is dominated by a relatively pure halite, with major impurities being occasional cm-sized nodules of gypsum or coats of clastics (mostly eolian transported). Halite crystals can be cm-scale meshworks and crosscut by still-open, partially-cemented subvertical dissolution cavities. Such microkarst textures indicate that during the formation of the pan halite crystals, the water level fell below the depositional surface numerous times to become a watertable. Higher in the UHF, especially in its upper 20–30 m the amount of clastic detritus (shale bands and beds) increases, with laminated clastic units tens of centimetres to more than a metre present in its uppermost part. Some of these beds entrain gypsum nodules and displacive halites, indicating periodic intrasediment capillary evaporite precipitation, tied to subaerial exposure of the sedimentation surface. This gradational transition upward into more siliciclastics indicates a UHF hydrological system that was overall freshening upward, with the effects of rainstorms and sheetfloods coming to dominate the depositional textures in its upper parts. This upward freshening of the UHF contrasts strongly with the upward brining hydrology that characterises the mineralogies and textures of the LHF. It means substantial volumes of preserved potash salts are highly unlikely in the UHF.

Up-section in the UHF the amount of mesocrystalline chevron halite increases at the expense of the more coarsely-crystalline halite, along with upward overall increases in numbers and thicknesses of detrital beds in the halites and increasing volumes of nodular gypsum. But gypsum never makes up more than a percent or two in any of the UHF halites. The chevron units that dominate the halites in the mid and upper parts of the UHF show two styles of truncation surfaces related to short-term freshening events in the pan hydrology. They are; (1) A relatively detrital-free $CaSO_4$ enriched layer where gypsum nodules formed after rainstorm-induced freshening of pan brine sheets, without substantial sheetflow transport of clays. These layers are composed of subhorizontally scattered nodules across a break in halite crystallisation. (2) A detrital-rich horizon or break that truncates the underlying halite chevron bed. These breaks in halite sedimentation are typified by cm-thick beds of siliciclastic muds that also entrain gypsum nodules These clastics define times of sheetflood clay transport out into the saline pan and were associated with times of wadi flooding. Both types of freshened surfaces are truncations not mantles in the background salt sedimentation and so indicate meteoric influxes in the pan history. Throughout chevron deposition they formed diurnally from thin sheets of brine subject to periodic freshening and desiccation (very different to the subaqueous holomictic-meromictic hydrology of the LHF with its resulting cm-layered anhydrite mantles).

Above the UHF is a clastic unit with significant amounts of and sometimes beds dominated by lenticular gypsum and displacive halite. The widespread presence of these diagenetic salts indicate high pore salinities as, or soon after, beds that stack into the clastic unit were deposited. Some of these early diagenetic evaporite are spectacular, as seen in the displacive halite recovered in a core from the lower portion of the clastic overburden some 45 m below the modern pan surface (Fig. 11.19d).

Today hot springs, rich in basinal $CaCl_2$ and depleted in $MgSO_4$, supply and maintain the active hydrothermally-fed brine pools and karst lakes in the solution depressions near the volcanic edifices that define Dallol Mountain

(Figs. 11.16b, c and 11.19a; Carniel et al. 2010). For example, there is a small carnallite deposit known as the Crescent deposit in the vicinity of this active hydrothermal region centred on the Dallol volcanic mound. Hydrothermally-driven groundwater activity has broken up the mineralogical continuity of the nearsurface salt beds in this region and drove the formation of natural regions of ground collapse, sulphurous and acidic springs and fumaroles along with the creation or water-filled chimneys and doline sags. Occasional intense storm-driven sheet floods drive renewed hydrothermal activity, as happened in the recent floods of February 2011, when a natural collapse doline tens of metres across formed on the depression margin. It is likely that hydrothermal circulation evidenced by these intra-saltflat dolines offers an explanation for some of the unusual mineral associations recovered in some wells such as a 200 m intersection of bischofite.

Some 60 km to the southeast of the Musley area, still in Ethiopia, is Lake Afrera (Lake Giulietti), with an area of 100 km^2, a water level some 102 m below sealevel and a water mass possibly 160 m deep (not confirmed) in the lake centre. It is located immediately southeast of the active Erta Ale volcanic field of the southern Danakil. Unlike the mostly alkaline waters of the majority of saline waters of the rift lakes to the south, its waters are acidic. Both the inflowing hot springs (40–50 °C) and the brines of the lake itself are rich in $CaCl_2$ and poor in $MgSO_4$. The modern lake waters are brackish and support a few species of halotolerant fish. Halite has been manufactured for centuries by concentrating lake waters in a series of anthropogenic pans that surround much of the lakeshore. Extensive concentration and desiccation of the waters in the lake may eventually lead to deposition of an $MgSO_4$-poor series of salts, dominated by carnallite, halite and $CaCl_2$ salts. Much in the same way these $MgSO_4$-deficient salts today dominate the surface salts of the Dallol salt pan. This will be in marked contrast to the thick underlying $MgSO_4$ -rich Pleistocene evaporites of the Musley area. It seems that seawater was much more important as a brine source in the Dallol in the Pleistocene than today.

In summary, it seems that the interaction between hot basinal groundwaters and volcanic bedrock is the likely explanation of the present inflow chemistry and groundwater-driven alteration of the original carnallitite beds. Fractional dissolution of the earlier highly soluble potash evaporites, in preference to the less soluble Mg-salts, plays an important part in the formation of sylvinite at a time after the deposition of the marine-fed lower Rock Salt Member and prior to the deposition of the overlying Upper Halite bed. Many hot modern brine springs, Some of which are at temperatures or more than 120 °C and precipitating bischofite in geothermally active areas in around Black Mountain and Dallol Mountain salt lakes are also rich in $FeCl_2$, sulphur and manganese (Carniel et al. 2010) This indicates ongoing hydrothermal interactions of saline groundwaters with volcanics and gives bright red-orange and yellow colours to many of the mineral assemblages precipitating in and about active springs (Fig. 11.14a).

Inland Chotts and Coastal Sabkhas in North Africa

Chott el Djerid in southern Tunisia is an endorheic playa where ephemeral carnallite accumulates as efflorescences and rare intercrystalline cements in the uppermost parts of ephemeral halite crusts in lowermost, more central portions of the saline pan facies (Fig. 11.21; Bryant et al. 1994a, b; Swezey 2009; Stivaletta et al. 2009). The chott, with an elevation typically more than 10 m below sea level on the saltflats, has an area of approximately 5,360 km^2 in a drainage basin with an area of 10,500 km^2. Mean annual rainfall for the area is 80–140 mm, the mean annual temperature is 21 °C and evaporation, which is highest between May and September, has a mean annual value of 1,500 mm. It has an elongated arm (Chott Fejej) that stretches eastward toward the coastal city of Gabes.

Chott el Djerid is the largest in a zone of chotts formed where a series of regional aquifers emerge to create a region of discharge playas along the northeast extremity of the Bas Saharan Artesian Basin (Fig. 11.22a; Rosen 1994). It is a groundwater sump region in a tectonically quiescent area of the North African craton. The encompassing chott-hosting depression extends over much of the Saharan desert into Morocco and Libya and encloses the northern end of the Grand Erg Oriental.

The zone of chotts defines the major discharge area of the "Complexe Terminal" aquifer system, which is made up of permeable Turonian dolomites and Upper Cenomanian limestones and intercalated evaporites, along with some Mio-Pliocene sands and conglomerates (Fig. 11.22b; Swezey et al. 1999). Discharging continental groundwaters seep into the chotts beneath the edges of thin Quaternary clay aquitards that also form the impervious bottoms to much of the playa areas. The same thin clay bed facilitates temporary ponding of waters supplied by winter floods onto the central playa facies. All the chotts in the "Complexe Terminal" occupy the lowest areas on the north African interior; Chott el Melrhir in Algeria is 40 m below sea level, while in their lowermost portions Djerid and Garsa are 16 and 21 m below sea level, respectively.

The lowest and more central part of the deflationary depression that is Chott el Djerid is now a halite pan outlined by a thin ephemeral halite crust atop Quaternary clays and sand aquifers that host saline pore waters. It is surrounded by a gypsum mudflat, which in turn pass marginward into a broad evaporitic mudflat and dry sandflat. Much of the

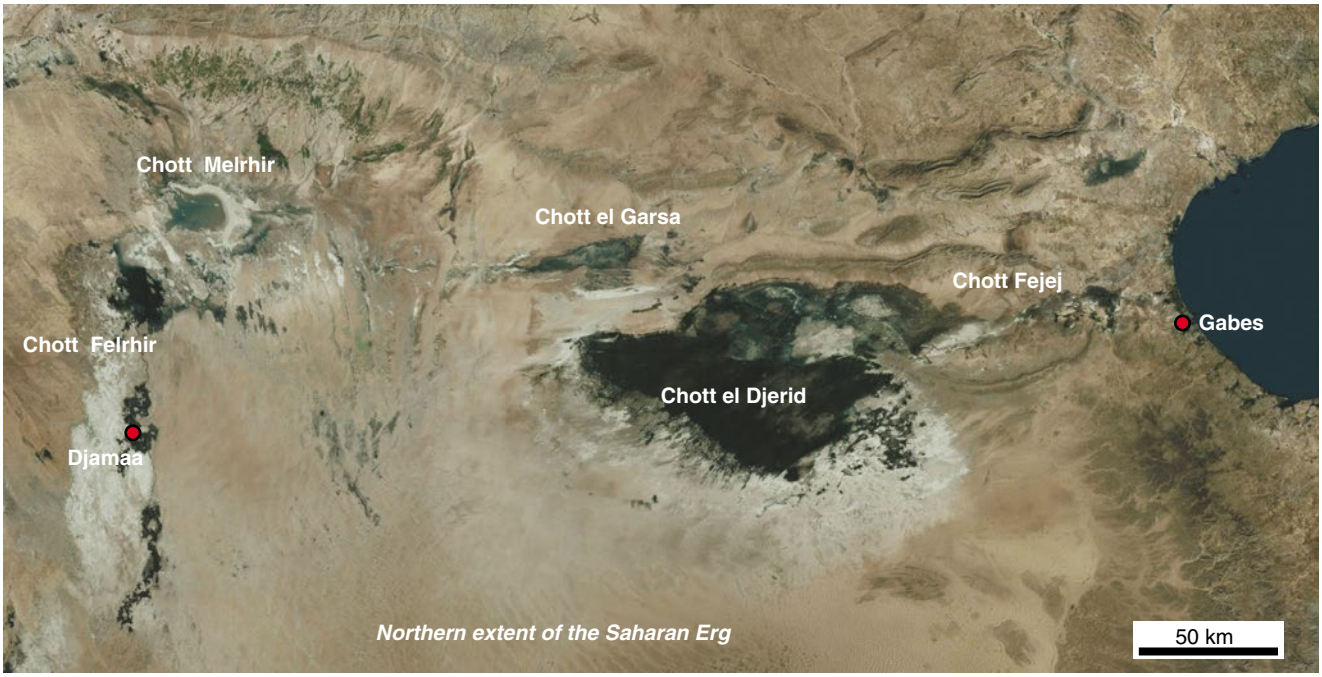


Fig. 11.21 Chott el Djerid, and other nearby chotts, Tunisia, showing the extensive saline mudflats that characterises the lowermost part of this inland depression. A surface geology map of the saline mudflat in northeastern portion of this region is given in Fig. 11.22c (Scaled Bing® image mounted in MapInfo®)

mudflat surface surrounding the halite-encrusted portion is covered by gypsum petees and adhesion ripples (Fig. 11.22c). Parts of the sandflat are transitional into aeolian-overprinted sediments with characteristic wind-blown sand streaks, wind-rippled sand sheets mounds and shadow dunes, all of which are cross cut by wadi channels that feed surface water into the central depression during times of flood. To the north, beyond the sands flats are the low-relief alluvial fans of the Atlas foothills. To the south of Chott el Djerid is the transition into the Great Eastern Erg of the Saharan Desert, the outer edges of which are characterized by low-relief, isolated sand mounds that mostly lack well-defined slip faces and are separated by interdunal sabkhas.

Like the interior salt lake basins along the southern edge of the Great Artesian Basin of Australia, the chotts are deflationary rather than accretionary depressions. They have lost something like 15–20 m of late Quaternary fill via eolian deflation to the adjacent Sahara desert erg (Blum et al. 1998). No evaporite beds occur in the 10 m of eolian-dominated Pleistocene sediments that lie atop the Miocene unconformity and beneath the ephemeral modern salt crust cap to the chott. This deflation-dominant outflow hydrology offers little preservation potential in terms of salts deposited in a surface salt crust. They cannot remain long enough in the stratigraphy to be buried. That is, periodic flooding and ongoing deflation mean there is no potential for potash preservation in this style of saline hydrology. Its sump hydrology is simply not saline enough, even though a thin salt crust cap extends for hundreds of kilometres over most of the chott surface.

Even though most of the present-day chott surface is deflationary, there is some local accretion around spring mounds, which are point sources of water escape from underlying artesian aquifers (Fig. 11.22c; Swezey et al. 1999; Stivaletta et al. 2009; Stivaletta and Barbieri 2009). Interestingly, the region around Chott el Djerid salt pan includes some of the most extensive gypsum beds in Africa (Drake et al. 2004; Barbieri et al. 2006). Regional chemical analyses show a marine signature to this pedogenic gypsum and by association the rare potash efflorescences (Gueddari 1984; Bryant 1999; Bryant et al. 1994a, b). The constituent sulphate ions are leached by deeply circulating meteoric groundwaters moving through Cretaceous and Triassic marine evaporite beds. That is, the ultimate salt source to the solutes in the nonmarine chott depression is seawater, it is just that the cycling of the marine solutes into the depression was delayed by more than 100–150 Ma, while the salt was stored in sediment beds (Drake et al 2004). In this sense the ion source to the North African gypcrete crusts are different from surface gypcretes about saline pans in the deserts of Namibia and Australia. There the recycling time from an oceanic atmospheric source is much shorter (contemporary to hundreds of years). Rare potash salts (mostly carnallite) that form ephemeral cements and efflorescences in upper parts of halite crusts and pans in Chott el Djerid have a similar longterm, ultimately marine, meteorically recycled ion sources (Bryant et al. 1994a).

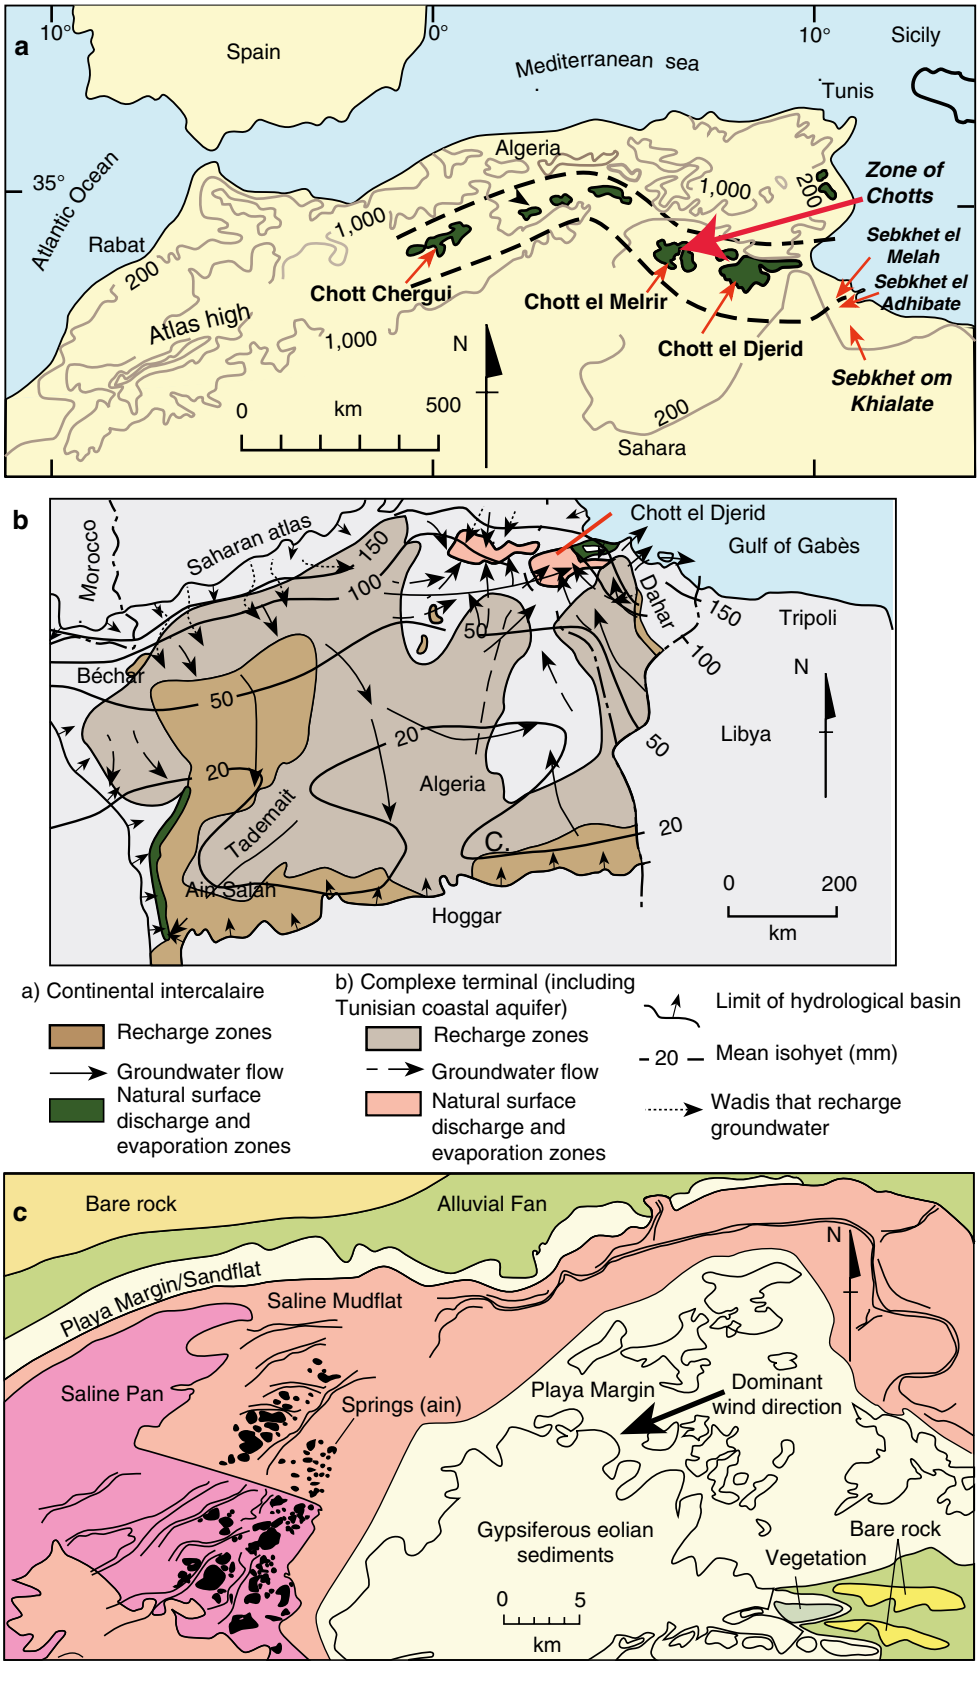

Fig. 11.22 Chott el Djerid. (**a**) Locality showing Zone of Chotts as regional groundwater outflow zone. (**b**) Regional hydrology. (**c**) Facies in northeastern corner of Chott el Djerid (After Bryant et al. 1994a)

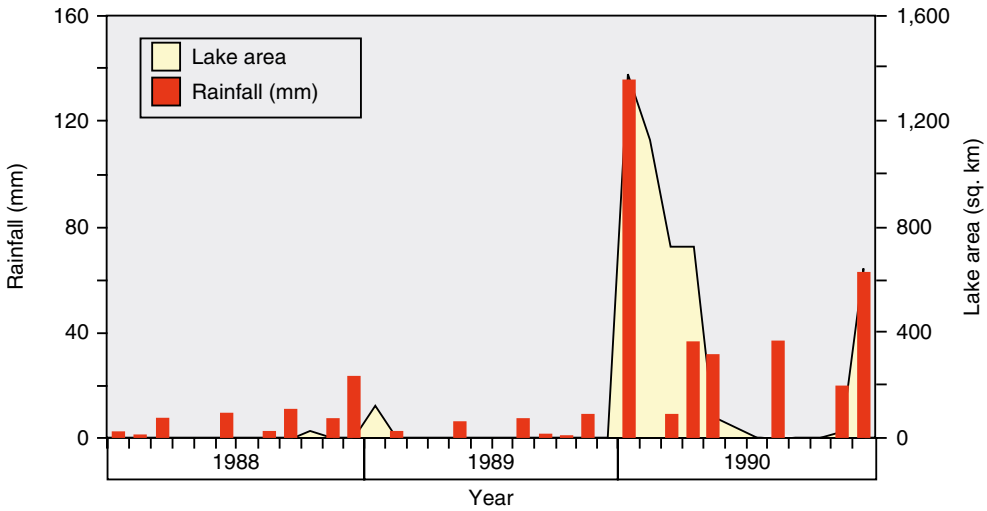

Fig. 11.23 Rainfall and lake areas recorded on the Chott el Djerid from 1987 to 1990 (After Bechtel et al. 1999)

After Kbir-Ariguib et al. (2001)

A flood occurred in the northeast portion of Chott el Djerid in January 1990 after an intense storm period when more than 120 mm of rain fell (Fig. 11.23). Its aftermath showed that Chott el Djerid undergoes four evolutionary stages as it recycles and concentrates its surface and nearsurface salts. The four stages define the evolution of the chott evaporites as it desiccates from a freshwater flood sheet to desiccated salinities where small volumes of potash salts precipitate as thin efflorescent crusts and pore cements in uppermost parts of the saline mudflat. The four stages are (Bryant et al. 1994a): (1) initial flooding, (2) evaporative concentration of lake waters, (3) the movement of concentrated thin brine sheets over the playa surface as a result of wind action, and (4) total desiccation of the lake by September 1990, some 9 months after the initial flood to precipitate halite crusts with minor bittern cements.

Surface waters and seeps in the chott have a consistent Ca–SO_4–Cl rich and HCO_3–CO_3 poor chemistry, reflecting the recycling of older (Pleistocene – Cretaceous) marine evaporites within the catchment area. As the lake desiccates and shrinks, these waters concentrate to produce a Na–Mg–K–Cl–SO_4 continental brine with ionic proportions similar to those of modern seawater (Table 11.7). But the brine source is continental not marine, and the contribution from modern marine aerosols is minor (Drake et al. 2004). During desiccation, saturation of surface water was reached first with respect to gypsum and then with halite and ultimately with potash minerals. The total brine volume in the chott is $\approx 5 \times 10^9$ m^3 and average shallow subsurface salinity ≈330‰.

Pore brines tend to be more potash-rich on the western side of the Djerid playa, where the waters are more saline, while they are more sulphate-rich on the eastern side (Kbir-Ariguib et al. 2001). After complete desiccation, the main mineral phases in the crystal mush on the floor of the many saline pans across the surface of the chott are gypsum and halite. Ephemeral carnallite (not sylvite) is present mostly as pore fills in thin cm-scale cemented halite crusts, within small hematite-stained areas near the centre of the various pan depressions on the chott floor, especially on the western (sump) side of the chott (Fig. 11.22c). The carnallite redissolves with each new flood of the chott. Its mode of occurrence is typical of the hydrologically decoupled mode of salt crusts in many modern artesian fed playas and its preservation potential is very low. Such systems are not Quaternary analogs to any substantial ancient accumulation of bedded potash.

Large scale pumping and evaporation tests have been made in the chott depression (Garrett 1995). Over much of its extent the chott surface is sandy, (with a great deal of poikilotopic gypsum, including frequent large desert rose and lenticular crystals growing at or near the watertable). Such a relatively porous substrate allows high pumping rates, but limits the area in the chott suitable for solar ponds, as does the decoupled hydrology.

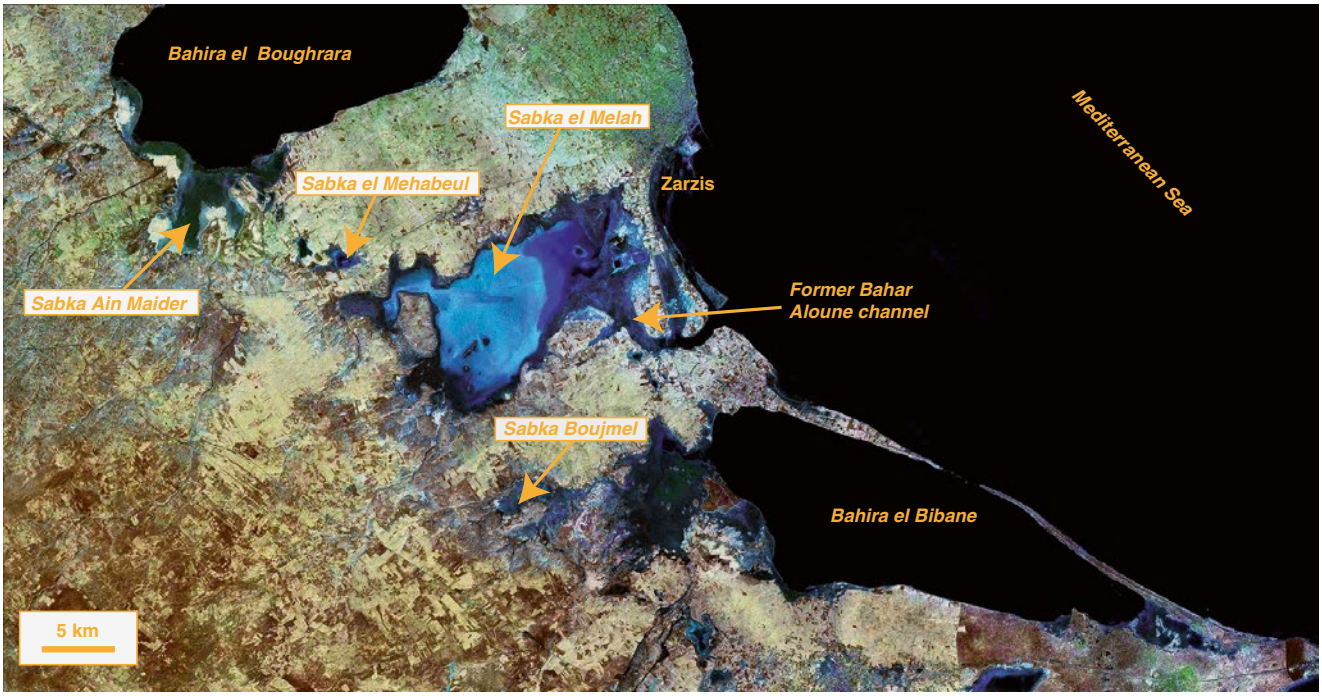

Fig. 11.24 Region of coastal sabkhas on the Tunisian coast near the town of Zarzis (Image base courtesy of NASA)

Sabkhat om Khialate with an area of 75 km^2 is another area of minor potash precipitation, once again as carnallite, not sylvite. It a small sabkha depression in the interior desert, well inland of the coastal plain and south of the coastal Sabkhat el Melah (Fig. 11.22a). Fed by continental waters, it is covered by a thin ephemeral salt crust a few decimetres thick, which contains a mixture of halite, gypsum, and thenardite (Na_2SO_4). Further toward the pan margin are thin efflorescent crusts made up almost solely of powdery thenardite with minute amounts of carnallite as a capillary precipitate.

Yet another modern area of ephemeral carnallite formation in North Africa is the near-coastal mudflats of Sabkha el Melah and the smaller nearby Sabkha el Mehabeul (Fig. 11.24; Perthuisot 1975; Garrett 1995). Both mudflats are situated on the northern edge of the Djeffara coastal plain near the town of Zarzis, Tunisia. Sabkha el Mehabeul is the more isolated of the Tunisian sabkhas; today it is a continental endorheic depression and has not been hydrographically connected to the nearby Mediterranean since the Late Pleistocene (Trabelsi et al. 2012). It retains preserved carnallite and kieserite interstitial cements in thin halite layers deposited in the last 2,000 years, along with minor occurrences of magnesite and huntite (Stengele and Smykatz-Kloss 1995; Schulz et al. 2002).

The larger Sabkha el Melah lies behind the coastal town of Zarzis and occasionally is hydrographically reconnected to the open sea by a channel that opens in times of flooding and turbulent seas (Fig. 11.24). The Holocene gypsum section beneath Sabkha el Melah is up 20 m thick and has been deposited in the last 4,000 years (Perthuisot et al. 1972; Lakhdar et al. 2006). Where freshened waters flow and seep as springs into the salt flat, typically near the sabkha edge, there are 6–8 m wide dissolution holes in the surface (moat facies). Wind action, in combination with ongoing gypsum intrasediment growth, has exposed large gypsum prisms and lenses in a deflationary crystal lag across much of the sabkha surface.

Sabkha el Melah was operated for bromine production during World War I, but no potash was recovered from their solar evaporation ponds. Brine was pumped from at least four of the larger springs into pans constructed on the sabkha surface. Garrett (1995) estimates the sabkha sediments down to about 10 m contain brines holding five million tons of equivalent KCl. However, like other sabkhas worldwide, permeabilities are inherently low and recovering the brine would be difficult. Phreatic brines in these coastal sabkhat are homogeneous and contain elevated magnesium and sulphate indicative of their marine source (Table 11.7).

Capillary evaporites in Djerid and the various coastal sabkhas are concentrically zoned within the uppermost few tens of cm of sediment beneath the ephemeral sabkha salt crusts. In all, the bittern salts only precipitate in the uppermost 0.5 m of sump sediments, via the processes of lateral capillary fractionation. Zonation is more evident in Sabkha el Melah where gypsum and anhydrite occur at the rim of the sabkha depression, while increasing amounts of halite with bitterns occurring in and beneath ephemeral crusts towards the centres (sumps) of local ephemeral saline pan depressions across the sabkha surface.

Traces of thenardite and carnallite can occur in the shallow subsurface sediments in the centres of some pans on the Melah sabkha (down to depths of a few tens of cm below the surface), but only in the innermost and lowermost sump zones of the saline pan facies. Polyhalite also occurs in the Sabkha el Melah sediments and, like similar occurrences in Ojo de Liebre Lagoon, Mexico, forms as a replacement of gypsum under the influence of increasingly saline capillary pore water (Perthuisot 1975; Pierre 1985).

The hydrographic separation of the Sabkha el Mehabeul from the ocean and Sabkha el Melah since the late Pleistocene has enabled a more advanced stage of diagenetic maturity and pore brine evolution in its sabkha fill. Anhydrite dominates over gypsum across the sabkha and the concentric zonation of the pan minerals into local depressions is much less obvious than the less saline Sabkha el Melah. Notably, in both these coastal sabkhas, carnallite, is no more than a minor mineral phase, is found co-associated with sulphate salts. All the bittern salts are dominantly part of powdery efflorescent crust salts.

To date, there has been no economic recovery of potash from saline brines held in marine coastal salt flats. This may be about to change. There are plans to develop a coastal brine recovery plant using brine held in coastal salt flats at Bayovar, Peru. Located in the coastal sandflats of the Sechura Desert (BWh climate). There the shallow coastal sediments are estimated to contain some 20 million tons of equivalent KCl, as a 0.1–0.8 % KCl brine (Garrett 1995). The higher grade reserves (0.4–0.8 % KCl) are estimated to be about half of the total reserves. Ample flat areas for the construction of solar ponds are available, but much of the shallow subsurface is quite permeable, or has many sandy beach berms zones. In mid 2012 a series of test brine wells are been pump-tested to ascertain the hydrological feasibility of potash production in a series of purpose-constructed lined pans.

The Bayovar project is unusual, and a lack of preserved bedded potash in all natural modern marine-fed depressions characterises Holocene coastal sabkhas and salinas, worldwide. Clearly, in terms of a marine-fed bedded potash deposits, the world's present day arid coastal sabkha and salina settings constitute a poor key to understanding widespread thick-bedded marine potash accumulations of the past. This relates to the fact we live in a time of icehouse earth, also lacking contemporaneous tectonically-induced saline giants.

Potash from Brine

There is no economic production from a Quaternary potash source by conventional mining anywhere in the world, rather potash is produced by brine processing in modern solar evaporation pans sourced in various saline continental lakes and playas. The world's largest Quaternary brine factories for MOP currently located at the southern end of the Dead Sea, Israel and Jordan, with a smaller MOP operation in the Dabuxum Lake area of the Qaidam Basin, China (Fig. 11.12). All locations utilise brines that are calcium-chloride rich and ultimately derived from hydrothermally-dominated inflows. These waters are pumped into solar concentrator brine pans, with a carnallitite slurry as the desired product. An even larger set of surface ponds than those of the southern Dead Sea have recently constructed for SOP production in Lop Nur region, China.

As mentioned earlier, a mother brine feed to a solar pan designed to precipitate potash salts can also be extracted by solution mining of potash horizons some hundreds of metres below the surface, as it is in operations near Moab, USA, and in the Belle-Plaine operation near Regina, Canada where a brine is recovered from the Prairie potash at a depth of 1,800 m. Often, such deep-sourced solution recovery exploits potash source beds not suitable for extractive mining due to great depth, structural complexity or propensity for water flood in a precursor conventional mine. The latter was the case at Patience Lake Mine in Saskatchewan, Canada, where two floods in the mid 1980s closed down the conventional mine operation. The former underground mine workings were abandoned and allowed to fill with water so that in 1988 the operation converted to a solution mining/brine recovery setup. Likewise, adverse mining conditions in the former Cane Creek mine led to a decision in 1970 to intentionally flood the mine and convert the subsurface operation into a solution-brine feed, sourcing saline waters for a series of at-surface purpose-built solar evaporation pans.

Dead Sea Potash, Middle East

Whatever the brine source, in order to recover potash once suitable brine is at the surface, it must be subjected to varying combinations of mechanical crystallization, natural crystallization (solar evaporation) and flotation. In the Southern Basin of the Dead Sea a series of linked fractionation ponds have been built to concentrate Dead Sea brine to the carnallite stage (Fig. 11.25a). On the Israeli side this is done by the Dead Sea Works Ltd. (DSW), near Mt. Sedom, and by the Arab Potash Company (APC) at Ghor al Safi on the Jordanian side. In both brine fields, muriate of potash is extracted by processing carnallitite slurries, created by sequential evaporation in a series of linked, gravity-fed fractionation ponds. After slurry extraction the residual brine, with a density of 1.34 g/cc, is pumped back into the northern Dead Sea basin water mass.

The area of the concentration pans is more than 130 km^2, within the total area of 1,000 km^2 that is the Dead Sea floor. The first stage in the evaporation process is pumping of Dead Sea water into header ponds to the gravity-fed series of artificial fractionation pans that now cover the Southern

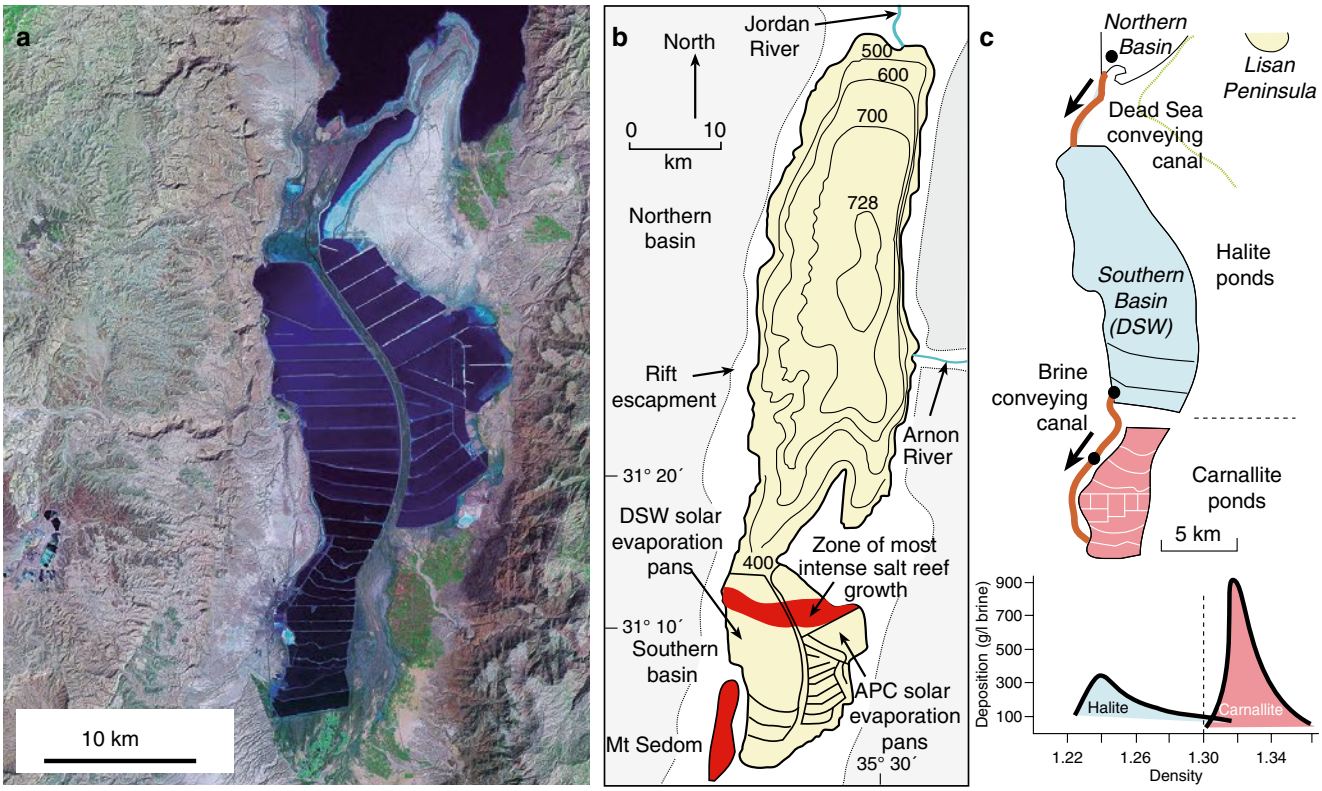

Fig. 11.25 Dead Sea Potash production. (a) Evaporation pans at the southern end of the Dead Sea (2000 Landsat image courtesy of NASA). (b) The water surface in the Dead Sea is around 417 m below sea level so the Southern Basin (elevation more than 401 m) is covered only by a thin controlled brine sheet up to 2 m deep, in a series of pans maintained by pumping of brines from the Northern Basin where waters attain depths of more than 300 m, seafloor isobaths are in metres below sea level. (c) Design of sequential evaporation pans at the Israeli Sedom plant, southern Basin of the Dead Sea colour coded to showing the relationship between increasing concentration (density) and the transition from halite to carnallite precipitation. ponds and the associated brine densities (After Karcz and Zak 1987)

Basin floor. With the ongoing fall of the Dead Sea water level over the past 60 years, brines from the Northern Basin must be pumped higher and over further lateral distances, resulting in a ongoing need for more powerful brine pumps. Saturation stages of the evolving brines are monitored and waters are moved from pan to pan as they are subject to the ongoing and intense levels of natural solar evaporation (Fig. 11.25b, c; Karcz and Zak 1987).

The artificial salt ponds of the Dead Sea are unusual in that they are designed to trap and discard most of the halite precipitate rather than harvest it. Most other artificial salt ponds around the world are shallow pans purpose-designed as ephemeral water-holding depressions that periodically dry out so that halite can be scrapped and harvested. In contrast, the Dead Sea halite ponds are purpose-designed to be permanently subaqueous and relatively deep (≈4 m). Brine levels in the ponds vary by a few decimetres during the year, and lowstand levels generally increase each winter when waste brine is pumped back into the northern basin.

As the Dead Sea brine thickens, minor gypsum, then voluminous halite precipitates on the pan floor in the upstream section of the concentration series, where the halite-precipitating-brines have densities >1.2 g/cc). As the concentrating brines approach carnallite precipitating densities (around 1.3 g/cc), they are allowed to flow into the carnallite precipitating ponds (Fig. 11.25c). Individual pans have areas around 6–8 km^2 and brine depths up to 2 m. During the early halite concentration stages a series of halite reefs or mushroom polygons can build to the brine surface and so compartmentalise and entrap brines within isolated pockets enclosed by the reefs, so preventing the orderly downstream progression of increasingly saline brines into the carnallite ponds, with the associated loss of product (Fig. 1.44).

When the plant was first designed the expectation was that halite would accumulate on the floor of the early fractionation ponds as horizontal beds and crusts, beneath permanent holomictic brine layers. The expected volume of salt was deposited in the pans each year (Talbot et al. 1996), but instead of accumulating on a flat floor aggrading 15–20 cm each year, halite in some areas built large numbers of macroscopic mounded salt reefs (aka salt mushrooms). Then, instead of each brine lake being homogenized by wind shear across these large subaqueous ponds, the salt reefs separated

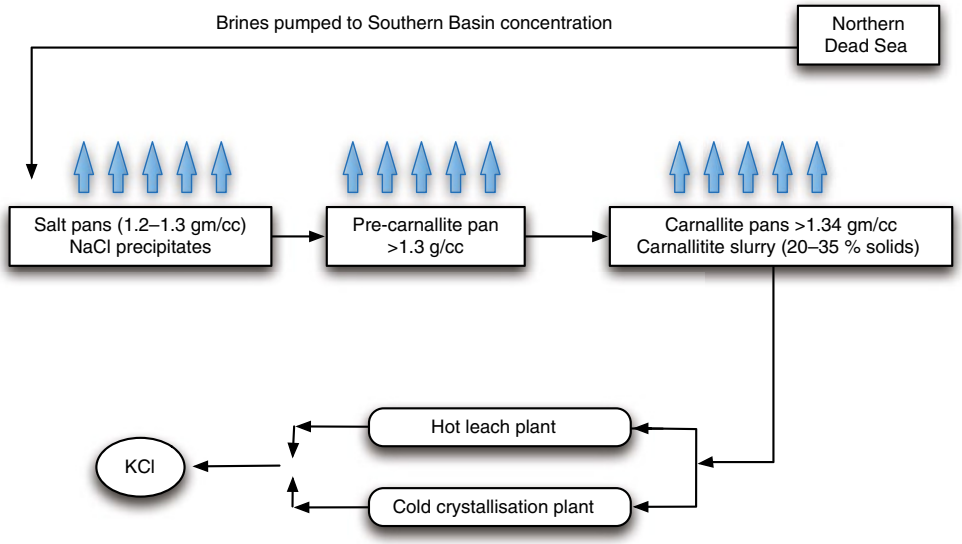

Fig. 11.26 Process stream for MOP manufacture in Dead Sea brine pans (*Blue arrows* indicate solar evaporation)

the larger early ponds into thousands of smaller polygonal compartments in which the isolated brines developed different compositions. Carnallitite slurries crystallized in inter-reef compartments from where it could not be easily harvested, so large volumes of potential product were locked up in the early fractionation ponds. Attempts to drown the reefs by maintaining freshened waters in the ponds during the winters of 1984 and 1985 were only partly successful. The current approach to the salt reef problem in the early fractionation ponds is to periodically breakup and remove the halite reefs and mushrooms by a combination of dredging and occasional blasting.

Unlike seawater feeds to conventional marine coastal saltworks producing halite with marine inflow salinities ≈35‰, the inflow brine pumped into the header ponds from the Dead Sea already has a salinity of more than 300‰. Massive halite precipitation occurs quickly, once the brine attains a density of 1.235 (≈340‰) and reaches a maximum at a density of 1.24 (Fig. 11.25c). Evaporation is allowed to continue in the initial halite concentrator ponds until the original water volume pumped into the pond has been halved. Concentrated halite-depleted brine is then pumped through a conveyance canal into a series of smaller evaporation ponds where carnallite, along with minor halite and gypsum precipitates (Fig. 11.25b). Around 300–400 mm of carnallite salt slurry is allowed to accumulate in the carnallite ponds, with 84 % pure carnallite and 16 % sodium chloride as the average chemical composition (Fig. 11.26; Abu-Hamatteh and Al-Amr 2008). The carnallite bed is harvested (pumped) from beneath the brine in slurry form and is delivered through corrosion-resistant steel pipes to the process refineries via a series of powerful pumps.

This carnallitite slurry is harvested using purpose-specific dredges floating across the crystalliser ponds. These dredges not only pump the slurry to the processing plant but also undertake the early part of the processing stream. On the dredge, harvested slurry is crushed, size sorted, with the coarser purer crystals separated for cold crystallization. The remainder is slurried with the residual pan brine and then further filtered aboard the floating dredges. At this stage in the processing stream the dredges pipe the treated slurries from the pans to the refining plant. On arrival at the processing plant, this raw product is then used to manufacture muriate of potash, salt, magnesium chloride, magnesium oxide, hydrochloric acid, bath salts, chlorine, caustic soda and magnesium metal. Residual brine after carnallitite precipitation contain about 11–12 g/l bromide and is used for the production of bromine, before the waste brine (with a density around 1.34 g/cc) is returned to the northern Dead Sea water mass. Israeli potash production currently exceeds 1.9 million tonnes per year while Jordanian production is more than a 1.7 tonnes per year. The production process continues 24 h a day, 365 days a year. The entire cycle from the harvesting to the MOP production takes as little as 5 h.

In the initial years of both DSW and APC operations, MOP was originally refined from the carnallite slurry by hot leaching and/or flotation. In the coarser-crystalline carnallitite feed, significant volumes of sylvite are now produced more economically in a cold crystallization plant (Fig. 11.26). The cold crystallization process takes place at ambient temperature and is less energy-intensive than the hot crystallization unit. The process also consumes less water but requires a higher and more consistent grade of carnallite feed (Mansour and Takrouri 2007; Abu-Hamatteh and Al-Amr 2008). Both hot (thermal) and cold production methods can be utilized in either plant, depending on the quality of the slurry feed.

Sylvite is produced via cold crystallization using the addition of water to incongruently dissolve the magnesium

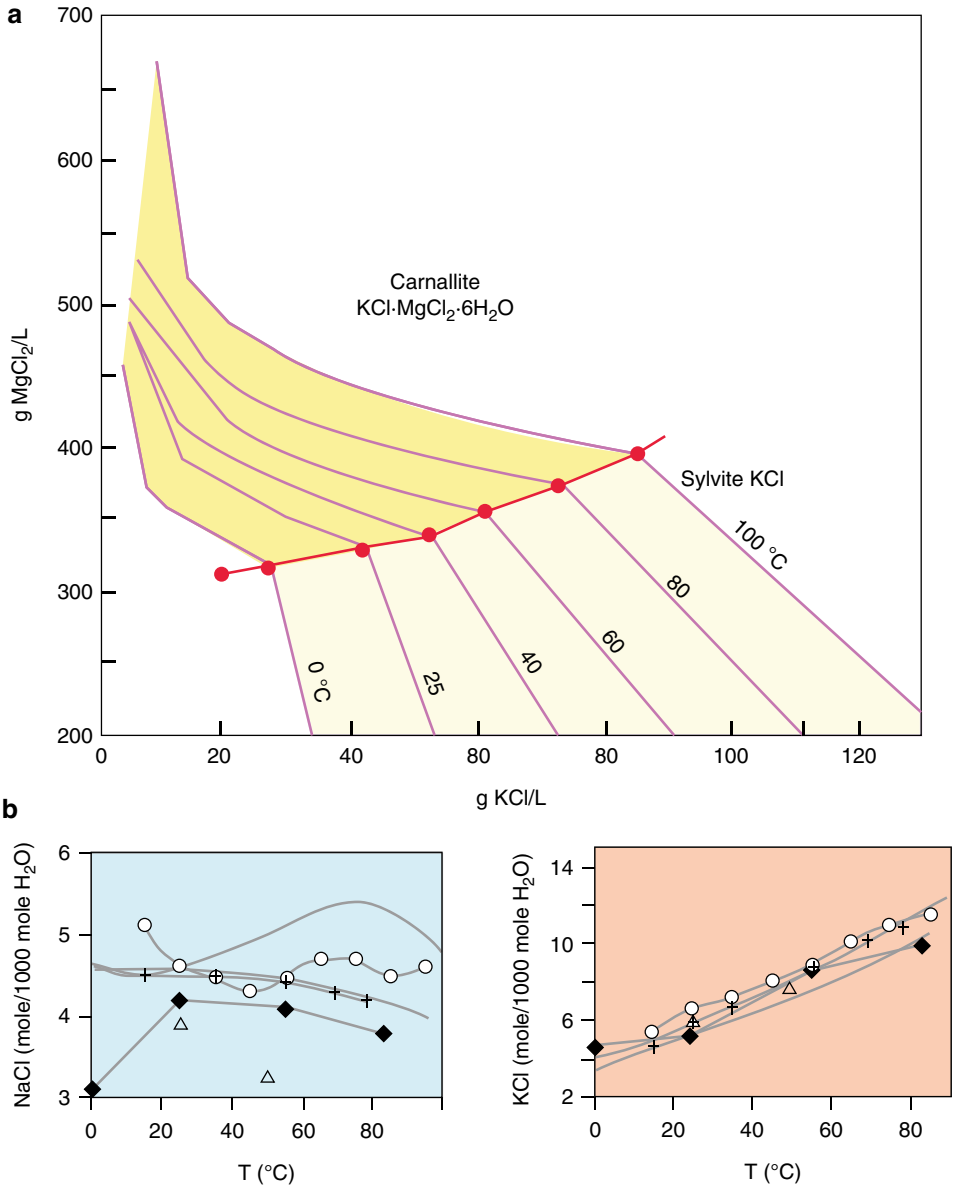

Fig. 11.27 Dead Sea potash production chemistries. (**a**) Cold Crystallization based on incongruent dissolution and illustrated by carnallite/KCl curve in the presence of 3 % NaCl (After Mansour and Takrouri 2007). (**b**) Hot or thermal crystallization is based on fact that halite solubility does not change greatly with temperature, while KCl solubility trebles over the same range (After Karcz and Zak 1987)

chloride from the crystal structure. If the carnallite slurry contains only a small amount of halite, the solid residue that remains after water flushing is mostly sylvite. As is shown in Fig. 11.27a, if the $MgCl_2$ concentration is at or near the triple-saturation point (the point at which the solution is saturated with carnallite, NaCl, and KCl), the KCl solubility is suppressed to the point where most of it will precipitate as sylvite. For maximum recovery, the crystallizing mixture must be saturated with carnallite at its triple-saturation point. If the mixture is not saturated, for example, it contains higher levels of NaCl, then more KCl will dissolve during the water flushing of the slurry. Industrially, the cold crystallizers are usually fed with both coarse and fine carnallite streams, such that 10 % carnallite remains in the slurry, this can be achieved by adjusting addition of process water (Mansour and Takrouri 2007).

Successful cold crystallization depends largely on a high quality carnallite feed. If a large amount of halite is present in the feed slurry, the resulting solid residue from cold crystallization is sylvinite, not sylvite. This needs to be further refined by hot crystallization, a more expensive extraction method based on the fact that the solubility of sylvite varies greatly with increasing temperature, while that of salt remains relatively constant (Fig. 11.27b). As potash brine is hot leached from the sylvinite, the remaining halite is filtered off, and the brine is cooled under controlled conditions to yield sylvite.

Residual brine from the crystallization processes then undergoes electrolysis to yield chlorine, caustic soda and hydrogen. Chlorine is then reacted with brine filtered from the pans to produce bromine. The caustic soda is sold, and the hydrogen is used to make bromine compounds, with the

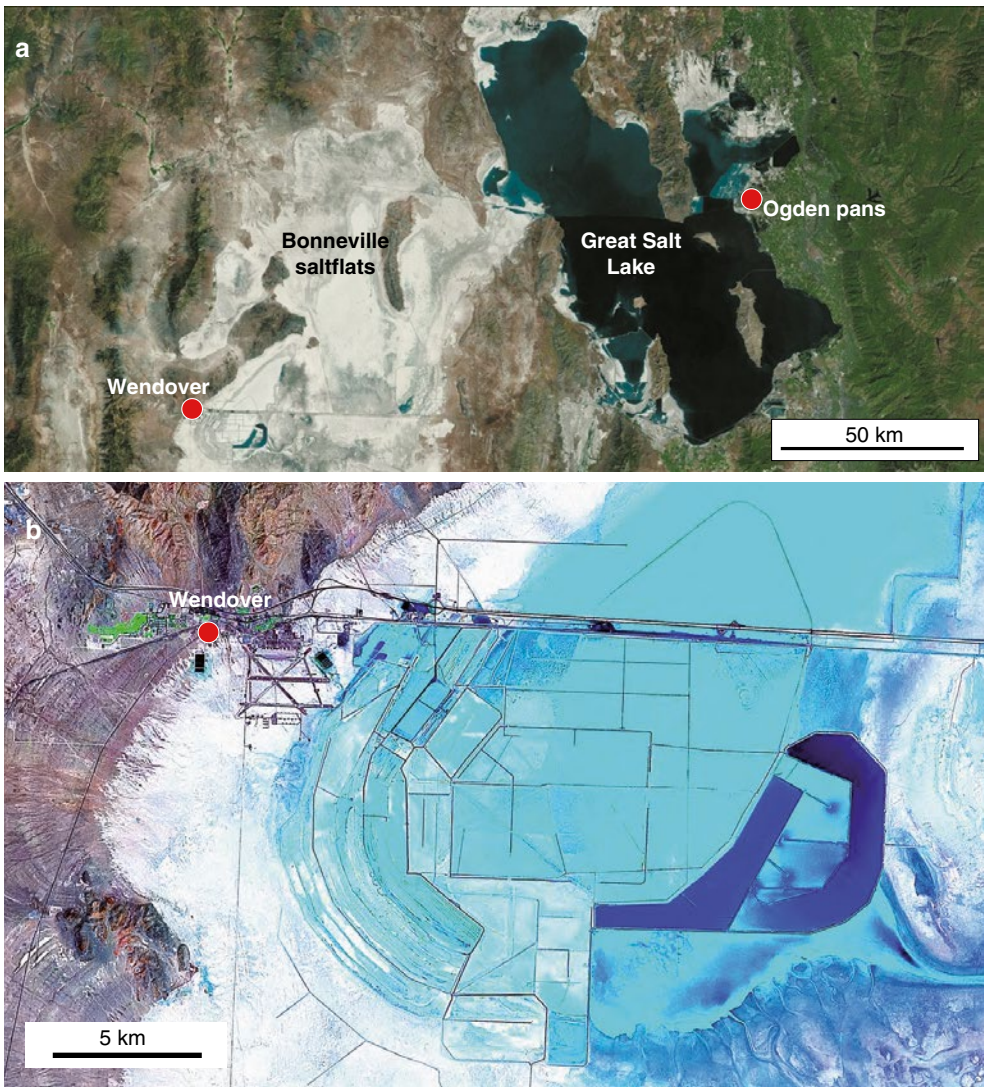

Fig. 11.28 (a) Regional map showing relative positions of Wendover (MOP) and Great Salt Lake (SOP) operations, Utah (b) Intrepid Mining's Wendover potash facility located in a drainage sump on the eastern edge of the Bonneville Salt flat, south of Interstate 80 and southeast of the town of Westover, Utah (Images courtesy of NASA and Microsoft Bing® mounted in MapInfo)

excess being burnt as fuel. Bromine distilled from the brine is sold partly as elemental bromine, and partly in the form of bromine compounds produced in the bromine plant at Ramat Hovav (near Beer Sheva). This is the largest bromine plant in the world, and Israel is the main exporter of bromine to Europe. About 200,000 t of bromine are produced each year. Residual magnesium chloride-rich solutions created by cold crystallization are concentrated and sold as flakes for use in the chemical industry and for de-icing (about 100,000 t per year) and dirt road dedusting. Part of the $MgCl_2$ solution produced is sold to the nearby Dead Sea Periclase plant (a subsidiary of Israel Chemicals Ltd.). At this plant the brine is decomposed thermally to give an extremely pure magnesium oxide (periclase) and hydrochloric acid.

In Israel, Dead Sea Salt Work's (DSW) production has risen to more than 2.9 Mt KCl since 2005, continuing a series of increments and reflecting and investment in expanded capacity, the streamlining of product throughput in the mill facilities, and the amelioration of the effects of salt mushrooms, and increased salinity of the Dead Sea due to extended drought conditions. On the other side of the truce line in Jordan, the Arab Potash Co. Ltd. (APC) output rose to 1.94 Mt KCl in 2010 (Fig. 11.2a). APC also has to remove salt mushrooms from its ponds, a process which when completed can increase carnallite output by over 50 000 t/year. The company is continuing with an expansion program aimed at increasing potash capacity to 2.5 Mt/year.

Potash from Solution Recovery Brine in Utah, USA

Potash extraction via solar pan concentration in Utah takes place near Ogden on the eastern edge of Great Salt Lake, on the Bonneville Salt Flats near Wendover, and the Cane Creek salt pans, near the town of Moab (Figs. 11.28a and 11.30). The Wendover MOP facility spans a BWk and BWh climate zone (Fig. 11.28b). The facility, owned since 2004 by

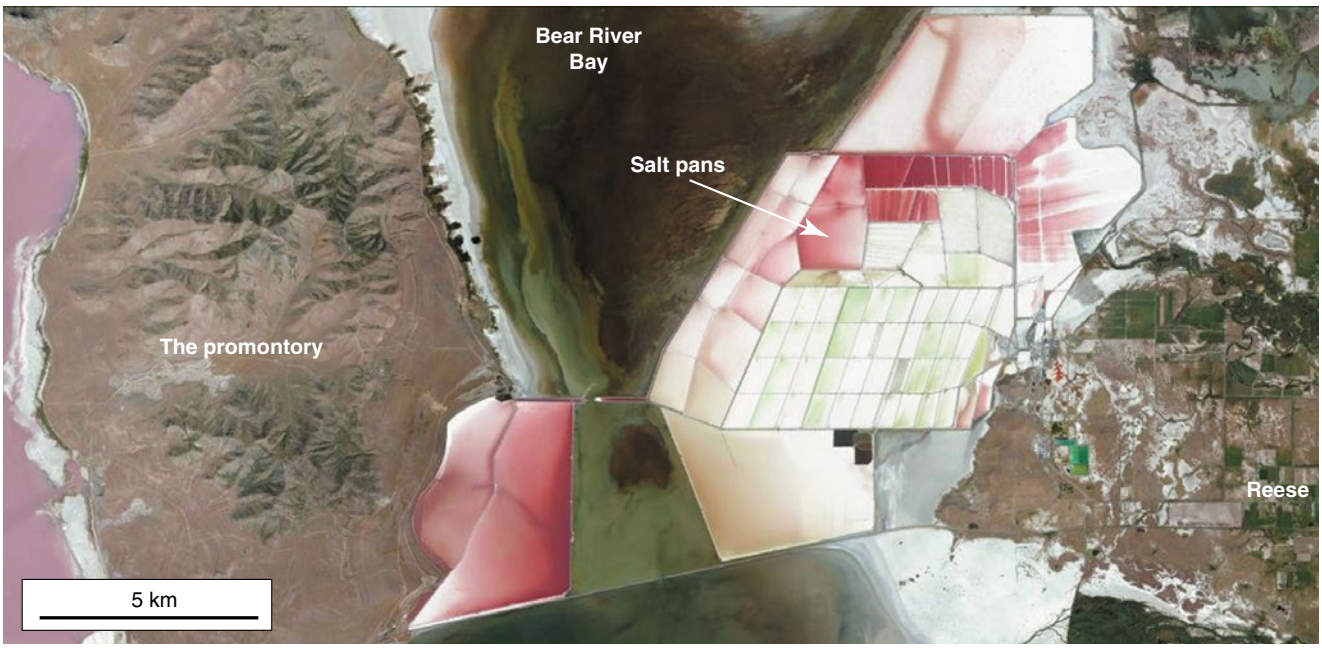

Fig. 11.29 Compass Mineral's SOP pans NE of Ogden, Utah on northeastern margin of Great Salt Lake (Microsoft Bing® image mounted and scaled in MapInfo®)

Intrepid Potash Inc., consists of a series of connected drainage ditches cut up to 2 m into the Bonneville saltflat. The saltflat occupies the western sump of a large playa located on the downdropped side of a Basin and Range boundary fault, which has more than 1,500 m of vertical displacement (Gwynn 2008; Turk 1973).

When the ditch water levels are pumped down, saltflat brines flow into the ditches as pore brines seep in from the adjacent saline lake sediments, driven by the artificially created brine head, which ranges from 1.6 to 4.5 m. Newly created ditch brine is then pumped from the collection ditches (made up of over 160 km of interconnected ditches across an area of more than 350 km^2) into concentrator ponds and allowed to season via solar evaporation. Once densities in the concentrators attain values in excess of 1.245 g/cc, they are then pumped into prepared evaporation/harvest ponds for KCl precipitation.

Sylvinite slurry, not carnallitite, is the precipitated salt in the harvest pond at Wendover (Bingham 1980). But the concentration process does not end with sylvite precipitation. Brine is pumped out of the sylvinite harvest pond into the adjacent carnallite ponds before the brine density attains values in excess of 1.257. This is the density that marks the onset of carnallite precipitation. Significantly, for the geological models of primary sylvite discussed later in this chapter, the Wendover facility is a brine fractionation system where sylvite crystallization precedes carnallite in the evaporation series.

The sylvite harvest ponds cover an area of some 3.2 km^2. Each sylvinite harvest concentrates more than 18 million cubic metres (5 billion gallons) of lake brine to make around 95,000 t of potash, making Wendover the largest single producer of potash in the United States. Once a sylvite harvesting pond is pumped down, the sylvinite mush is scrapped and transported to the processing plant for MOP manufacture via froth flotation and drying. The total period from ditch drawdown to harvest is around 180 days. Harvesting ponds are constructed with compacted floors and synthetic rubber liners. This prevents liquor loss during the seasoning cycle and allows conventional front end-loaders and scrapers to move across the sylvite-encrusted harvester pan floors, without sinking into water-saturated muddy sediments.

Prior to sylvite harvesting, residual brines are pumped into nearby carnallite ponds for further concentration and seasoning, resulting in highly concentrated brines that are then extracted and stored. These end brines in the carnallite ponds are very rich in $MgCl_2$ and are sold for use as a liquid de-icer.

The other Quaternary potash extractive facility in Utah is some 150 km from the Wendover facility and is operated by Compass Minerals (Fig. 11.28a). Brine ponds are located in two separate pond areas on the northwest and eastern shores of Great Salt Lake near Ogden, Utah and joined by a channel/levee system. Brines pumped in from Great Salt Lake are concentrated across more than 160 km^2 of ponds within a total area of some 4,100 km^2 (Fig. 11.29). Unlike Wendover, these brine ponds lie beneath a cooler Csa/Cfa Köppen climate zone, have much higher levels of sulphate in their brine feed, and utilise a seasonal brine chemistry that manufactures halite via solar evaporation in the summer and SOP from cryogenic brines in the winter.

During normal summer conditions, 90 % of the halite present in the brine is precipitated in the fractionation ponds with little contamination by other salts and it is harvested from the ponds for use mostly as de-iceing salt. Mirabilite can be a winter precipitate in the solar ponds that contain brine from ponds which had earlier precipitated halite. Once potassium salts begin to precipitate from the halite-depleted brine, it forms a complex mixture of double salts, such as kainite, schoenite and carnallite. At the same time magnesium can precipitate as bischofite, a highly hydrated magnesium chloride (Fig. 11.8). This salt sequence chemistry is one of the more complicated solar pond series of naturally-produced industrial salts in the world. Throughout the production phase of the various salts, ambient ionic compositions are monitored and brines are pumped and mixed from the various fractionation pans to maximise the production of both halite and potash salts. Ultimately the plant produces the following end products; sodium chloride, potassium sulphate, sodium sulphate and magnesium chloride hexahydrate.

Natural brines pumped into the pans from the Great Salt Lake are allowed to evaporate in a set of halite ponds until saturated with potassium salts. The residual brine is then transferred to a mixing pond where it is mixed with a second brine (from higher up the evaporation series, which contains a higher molar ratio of magnesium to potassium. This adjusted brine is allowed to evaporate to precipitate sodium chloride once more, until it is again saturated with respect to potassium salts. The brine is then transferred to another pond, is further evaporated and precipitates kainite (Fig. 11.8). Kainite precipitation continues until carnallite begins to form, at which time the brine is transferred to another pond and is allowed to evaporate further to precipitate carnallite. Some of the kainite-depleted brine is recycled to the mixing pond to maintain the required molar ratio of magnesium to calcium in the mixing pond. Once carnallite has precipitated, the residual brine is transferred to deep storage and subjected to winter cooling to precipitate additional carnallite. Cryogenically precipitated carnallite is converted to kainite by mixing it with a kainite-saturated brine.

Formerly, the salt solids were harvested from the Great Salt Lake pans using front-end loaders and trucks, similar to the Wendover facility, and transported to the processing plants (Fig. 11.8). More recently, the Behrens Trench was completed, this is a 35 km underwater canal on the floor of the Great Salt Lake that transports saturated brine product from the western shore solar ponds across the lake to its processing facilities on the eastern shore. Since 2000 the Great Salt Lake plant has produced more that 550,000 t of sulphate of potash. But, the earlier history of salt workings about the strandline of Great Salt Lake illustrate one of the major problems in solar pond extraction atop saline mudflats in continental lakes. Record floods in 1984 filled the solar ponds with fresh water and destroyed much of the levee infrastructure. Harvesting did not recommence until the early 1990s. Rapid and at times substantial changes in lake level are endemic to saline lacustrine systems and must be planned for in the development of a saltworks.

Fig. 11.30 Intrepid's Moab Potash Operation, Utah. Brines are pumped from the flooded workings of the former Cane Creek Potash Mine into the Moab solar pans, where they concentrate to sylvite saturation (Base image is courtesy of Microsoft Bing®)

Potash is also produced by evaporative concentration of solution-mined brine extracted from Pennsylvanian potash evaporites in the Paradox member of the Hermosa Formation in the now flooded Cane Creek mine, locate in an anticline in the northern part of the Paradox Basin in Utah near the town of Moab (Figs. 11.30) There are at least 29 evaporite cycles in the Hermosa Formation, which is dominated by varying combinations of limestone, dolomite, anhydrite and halite. Potash occurs near the top of 18 of these cycles, all located immediately above a thick halite bed (Raup 1966). Eleven of the 18 are of sufficient thickness and quality to be considered economic. Salt beds in the halokinetic Cane Creek anticlinal core are characterised by numerous folds discontinuities and faults, which can deepen, thicken or thin, and rotate the potash seam and alter the continuity of beds in the mine head (Fig. 11.31) The target potash bed, known as Bed 5, is a 3.4 m-thick sylvinite bed some 1,200 m below the surface in

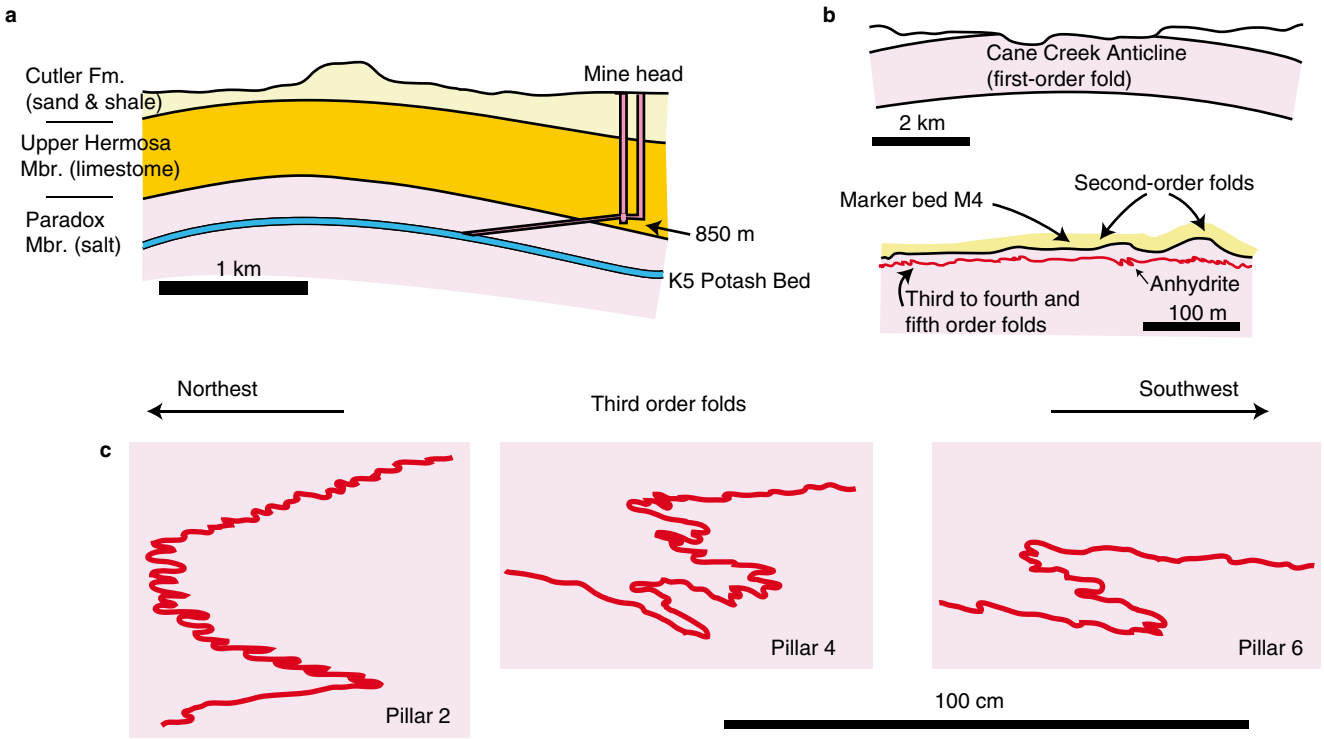

Fig. 11.31 Structural complexity in the original Cane Creek potash mine pillars before conversion to a solution feed operation (After Evans and Linn 1970). (**a**) Cane Creek stratigraphy and mine position on the anticline limb. (**b**) Fold orders in the ore zone of the Cane Creek Anticline. (**c**) Folds in anhydrite in the ore zone

the mine area and averaging 25–30 % K_2O. The depth to ore and its folded nature meant working conditions underground were difficult with mine temperatures around 35 °C or higher (Doelling and Chidsey 2000; Gwynn 1984).

The former Cane Creek mine, which began extracting ore in 1965, was never economically viable due to a combination of gassy bottom and the high degree of deformation of the target ore horizon. The target, Potash Bed K5, consists of variably dipping sylvinite layers 2.5–15 cm thick, alternating with folded anhydrite layers less than 3 mm thick. The ore horizon is overlain by 12 m of shaly dolomite and underlain by 43 m of halite. Fold wavelengths exposed in mine pillars are ≈30–120 m, with amplitudes ranging from 6 to 30 m (Fig. 11.31; Evans and Linn 1970). By 1963 some 550 km of 2.7×4.9 m rooms and entries had been completed. As well as the problems with structural complexity, a number of dangerous "gassy" intersections had occurred during the short operational life of the mine. On 28 August, 1963, 18 miners were tragically killed by a methane explosion, while constructing lateral access shafts. This calamity meant the mine was too dangerous to mine conventionally and the decision was made to convert to a solution mine.

The Moab Utah brine extraction operation began in 1972, after the conventional mine was abandoned in 1970, flooded and converted to the current solution-mined evaporation-processed operation. Colorado River water is now pumped through injection wells into the old mine workings to dissolve the potash and salt. The resulting dense brine is pumped out of sumps in the mine and piped to nearby solar evaporation ponds where the minerals are eventually harvested (Fig. 11.30).

It takes 2 years of brine seasoning in the Moab solar ponds under a BSk climate to make a potash crop. Evaporation proceeds to the point where halite drops out and the remaining potash-enriched brines are successively moved into the harvester ponds. A blue dye is added to some of the ponds to enhance solar absorption/evaporation and this makes the view from the site overview popular with photographers. There are 23 ponds, up to a metre deep, in four areas covering a total pan area in excess of 1.6 km^2 (Kogel et al. 2006). A sylvinite mixture forms in the final ponds and is harvested once a year per pond. The slurry is pumped north to the processing facility where the halite is separated from the potash by flotation. If the product cannot be harvested within 2 years the operational cycle becomes uneconomic. Potash production is roughly 60,000 t annually and around 200,000 t of halite are produced annually as a by-product.

Solution mining for potash is also profitable in other mines lost to flooding, as in Canada, where solution mining operations have been active in the abandoned Patience Lake Mine since 1988. The solution recovery process of PotashCorp in Patience Lake, Saskatchewan, uses a selective precipitation process that takes advantage of natural cooling (Kogel et al. 2006; p 735). One large final precipitation pond operates from September through May and produces around

0.4 million tonnes per year. As warm brine from the mine flows into the pond, only sylvite crystallizes on exposure to the cold winter air. Then the pond is dredged and the precipitated sylvite is dried for marketing. The process is predicated on the differing temperature dependence of NaCl and KCl solubilities (Fig. 11.27b).

Another method of potash recovery is used by the Mosaic Potash Company in Belle Plaine, Saskatchewan. This operation began in 1964 and was the world's first purpose-built solution mine operation. With an ore depth of 1,600 m it was too deep for a conventional mine. There the brine is processed using two trains of evaporators and crystallizers. Evaporators remove NaCl from the brine and KCl precipitates in the crystallizers. Annual production is 2.8 million tonnes per year. This process is more energy intensive than recovery by natural winter cooling in surface ponds.

Potash mining or recovery from brine is a possible technology of the future in areas where the potash has an $MgSO_4$ association, such as the eastern end Salt Range of Pakistan, where at a depth of 1,300 m a potash brine was recovered in a well. It is perhaps a relict bittern, first derived during deposition of the marine-fed halite beds and retained (Gill and Akhtar 1982). According to Garrett (1995) there are perhaps ten stacked potash beds within the 75 m thick upper salt formation of the Saline Series (Eocene) in the Salt Range, of the Punjab region, Pakistan. There are indications that the potash layers extend under much of the Salt Range and parts of the Potwar and Indus Plains. Drilling and salt mining operations show that the potash zones tend to be patchily distributed, occurring as lenses or beds up to 4 m thick. Kainite and langbeinite (combined) may total 80 % of the potash in some areas, with sylvite and smaller amounts of polyhalite. Astrakanite, epsomite and kieserite have also been reported. Volcanic rocks occur in the upper part of the saline series. Samples of the potash from Klewra and Nupur regions analyzed 10–14 % K_2O, 20–24 % $MgSO_4$ and 23–55 % NaCl (Garrett 1995).

Mineralogically similar, very thick, halokinetic halite deposits of Miocene age occur under the Red Sea's coastal plain between Jizan, Saudi Arabia (where they outcrop) to Safaga, Egypt, and limited potash beds have been found in some locations (Notholt 1983; Garrett 1995). Potash-enriched marine end-liquor brines characterise Red Sea geothermal springs, implying a more sizeable potash deposit may be (or once have been) present in this region. Hite and Wassef (1983) argue gamma ray logs in two drill holes in this area suggest the presence of sylvite, carnallite and possibly langbeinite.

Sulphate of Potash from Brine

Sulphate of potash is an attractive product as it does not salinise the soils as readily as muriate of potash. We have already seen how it is produced from the Ogden flats, and other continental brine lake settings. The most significant lake brine production volume comes from Lop Nur, China.

Lop Nur

Sulphate of potash (SOP) via brine processing (solution mining) of lake sediments and brines is currently underway in the Luobei Hollow region of the Lop Nur playa, in the southeastern part of Xinjiang Province, Western China (Fig. 11.32, Table 11.2). The recoverable sulphate of potash resource is estimated to be 36 million tonnes from lake brine (Dong et al. 2012). Lop Nur is in the eastern part of the Taklimakan Desert, China's largest and driest desert, and is in the drainage sump of the basin, some 780 m above sea

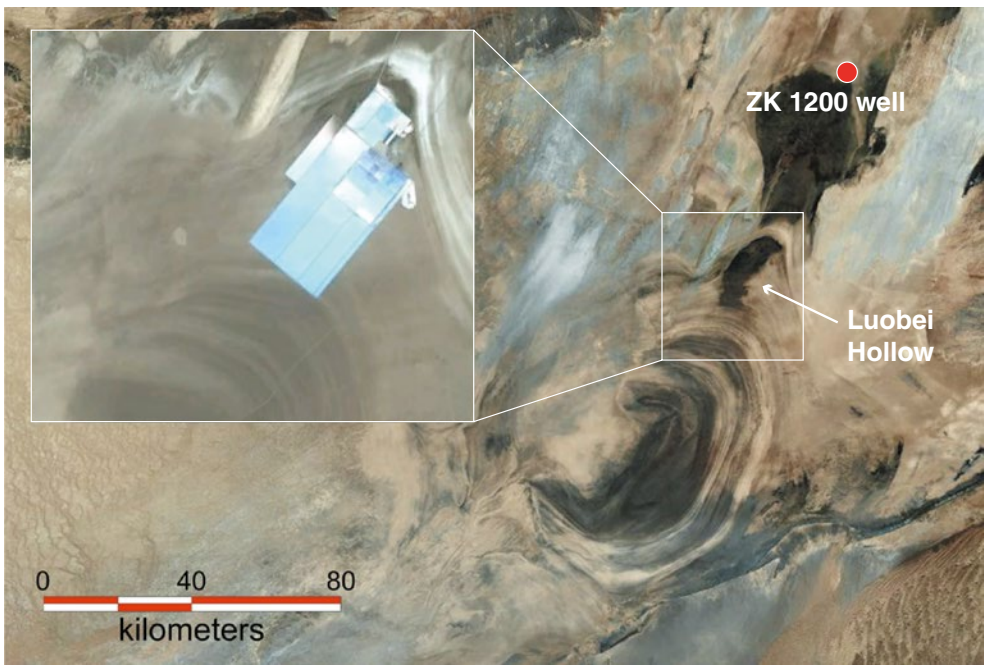

Fig. 11.32 Lop Nur playa (aka "great ear" region) eastern Tarim Basin, China before the construction of the sulphate of potash (SOP) facility. The concentric ring structure of the playa is created by successive strandline positions as the lake shrank. Inset shows the region of the SOP facility (as of July 2011) in the fault-bound Luobei sub-depression (Images courtesy of Google Earth and Bing® images, loaded into MapInfo®)

level and in a BSk climate belt. The Lop Nur depression first formed in the early Quaternary, due to the extensional collapse of the eastern Tarim Platform and is surrounded and typically in fault contact with the Kuruktagh (to north), Bei Shan (to east) and Altun (to south) mountains.

The resulting Lop Nor sump is a large groundwater discharge playa that is the terminal point of China's largest endorheic drainage system, the Tarim Basin, which occupies an area of more than 530,000 km^2 (Ma et al. 2010). The playa is the hydrographic base level to local and regional groundwater and surface water flow systems, and thus collectively captures all river and subsurface flow originating in the surrounding mountainous regions. The region has been subject to ongoing Quaternary climate oscillations, resulting in concentric strandzones on the playa surface over the last few hundred years, and widespread longer term (thousands of years) changes driving deposition of saline glauberite-polyhalite deposits, alternating with more humid lacustrine mudstones.

Presently, the Lop Nur playa lacks a longterm surface inflow and is characterized by desiccated saline mudflats and polygonal salt crusts. The upward capillary flux from the shallow groundwater helps to maintain a high rate of evaporation in the depression and drives the formation of a metre-thick ephemeral halite crust that covers much of the depression. Historically, prior to the construction of widespread irrigation systems in the upstream portion of the various riverine feeds to the depression and the diversion of water into the Tarim-Kongqi-Qargan canal, brackish flood waters periodically accumulated in the Lop Nur depression. After the diversion in flow, the terminal desiccation led to the formation of the concentric shrinkage shorelines, that today outline the "Great Ear" region of the Tarim Basin (Huntington 1907; Chao et al. 2009).

Climate is extremely arid; average annual rainfall is less than 20 mm and the average potential evaporation rates are ≈3,500 mm/year (Ma et al. 2010). The mean annual air temperature is 11.6 °C; highest temperatures occur during July (>40 °C) and the lowest temperatures occur during January (<20 °C). Primary wind direction is NE. The Lop Nor basin experiences severe and frequent sandstorms; the region is well known for its wind-eroded features, including many meso-yardangs along the northern, western and eastern margins of the Lop Nur salt plain.

Salinity and chemical composition of modern groundwater brine varies little in the "Great Ear" area and appears not to have changed significantly over the last decade (Ma et al. 2010). Dominant river inflow waters to the Lop Nor basin are of the Na–Mg–Ca–SO_4–Cl–HCO_3 type. In contrast, the sump region is characterized by highly concentrated groundwater brines (≈350 mg/l) that are rich in Na and Cl, poor in Ca and HCO_3+CO_3, and contain considerable amounts of Mg, SO_4 and K, with pH ranging from 6.6 to 7.2. When concentrated, the brine is saturated with respect to halite, glauberite, thenardite, polyhalite and bloedite (Ma et al. 2010). Groundwater brines in the northern sub-depression, the Luobei region, where potash is produced in a series of concentrator pans, is similar in chemistry and salinity to the Great Ear area (Hu and Wang, 2001). There, K-rich mother brines, that also contain $MgSO_4$, occur in pores of a widespread subsurface glauberite bed, with a potassium content of 1.4 % (Liu et al. 2008). These are the source brines pumped in to a large field of concentrator pans to produce sulphate of potash (Fig. 11.32).

Brine chemical models, using current inflow water and groundwater brine chemistries and assuming an open system hydrology, show good agreement between theoretically predicted and observed minerals in upper parts of the Lop Nor basin succession (Ma et al. 2010). Such modeling does not explain the massive amounts of glauberite ($Na_2SO_4{\cdot}CaSO_4$) and polyhalite ($K_2SO_4MgSO_4{\cdot}2CaSO_4{\cdot}2H_2O$) recovered in a 230 m deep core (ZK1200B well) from the Lop Nor basin (Fig. 11.33). Hydrochemical simulations assuming a closed system at depth and allowing brine reactions with previously formed minerals imply that widespread glauberite in the basin formed via back reactions between brine, gypsum and anhydrite and that polyhalite formed by diagenetic reaction between brine and glauberite. Diagenetic textures related to recrystallization and secondary replacement are seen in ZK1200B core, they include gypsum-cored glauberite crystals and gypsum replacing glauberite. Such textures indicate significant mineral-brine interaction during crystallization of glauberite and polyhalite.

Mineral assemblages predicted from the evaporation of Tarim river water match closely with natural assemblages and abundances and, in combination with a model that allows widespread backreactions, can explain the extensive glauberite deposits in the Lop Nor basin (Ma et al. 2010). It seems that the Tarim river inflows, not upwelling hydrothermal brines, were the dominant source throughout the lake history and that layered distribution of minerals in the cored sediments documents the evolving history of inflow water response to wet and dry periods in the Lop Nor basin. The occurrence of abundant glauberite and gypsum below 40 m depth, and the absence of halite, polyhalite and bloedite in the same sediment suggests that the brine underwent incomplete evaporation in the wetter periods Fig. 11.33). In contrast, the increasing abundance of halite, polyhalite and bloedite in the top 40 m of core from the ZK1200B well indicate relatively dry periods, where halite precipitated at lower evaporative concentrations (log = 3.15), while polyhalite and bloedite precipitated at higher evaporative concentrations (log = 3.31 and 3.48 respectively). Following deposition of the more saline minerals the lake system once again became more humid, until the anthropogenically induced changes in the hydrology over the last few decades.

Bloedite is replaced by polyhalite; *6*. Glauberite is replaced by bloedite; *7*. Halite is replaced by bloedite. Recrystallization: *1*. Undeveloped; *2*. Developed (After Ma et al. 2010)

The Lop Nur potash recovery plant and pan system, located in the LuoBei Hollow (Fig. 11.32, inset), utilises a brine source where the potash brine is reservoired in intercrystalline and vuggy porosity in a thick glauberite bed (as seen in Fig. 11.33). This makes the Lop Nur system unique in that it is the first large-scale example of brine commercialisation for potash recovery from a continental playa system with a non-KCl brine target. In the past similar glauberite-mirabilite hosted brines and beds have been use to recover sodium sulphate in both cryogenic and hot semi-arid desert scenarios, but these Quaternary-hosted brine systems did not target potassium sulphate (Warren 2010). In the case of the cryogenic systems in Quill Lake, Canada, small volumes of SOP are produced via mixing of a sylvite feed (trucked in to site) with a $NaSO_4$ lake brine, while the Great Salt Lake SOP brine chemistry and processing stream is described earlier in this module (Fig. 11.8).

SOP Brine Potential in the Amadeus Basin, Australia?

To the south of Alice Springs in the Amadeus Basin of Central Australia there are a number of small saline playas (areas <50 km^2) with thin ephemeral sylvite/glauberite crusts and efflorescences in an area centred on the Karinga Creek palaeodrainage (Fig. 11.34a; Arakel and Hong Jun 1994). In contrast, there are no documented sylvite or glauberite crusts in any of the larger playas of the same region, such as Lake Amadeus (area ≈ 750 km^2; Fig. 11.34b). The absence of potash precipitates in the larger playas reflects the variably decoupled nature of the inflow hydrologies to groundwater seeps in the region (Fig. 2.63; Jankowski and Jacobson 1990). Both types of playa experience the same arid (BWh) climate; median and mean annual rainfall in the region are 190 and 220 mm, respectively, mostly falling in summer (Dec.-Feb.); while annual evaporation is ≈ 3,300 mm. All the playas are ultimately supplied by a combination of surface runoff and seepage from a large regional groundwater outflow system, which discharges into this chain of playa lakes along an outflow zone that is some 500 km long (Fig. 11.34).

The difference in the mineralogy of the ephemeral surface salt crusts between the smaller and larger playas correlates with the depth to which the various playa groundwater systems tap into the regional hydrology. Throughout the artesian discharge zone, the various playa salt crusts form by capillary evaporation of resurging groundwaters. All the playa sediments entrain highly concentrated brines; typically, these are sodium-chloride rich waters with appreciable magnesium and sulphate and very low concentrations of calcium and bicarbonate. The larger playas in the chain, exemplified by Lake Amadeus, have dual shallow and deep groundwater inflow paths. The smaller playas, exemplified by Spring Lake and the Na_2SO_4 lakes of the Karinga Creek drainage system, have only shallow inflow paths. Brines in the larger playas such as Lake Amadeus are continually diluted by mixing with upwelling deep groundwaters tapping into the regional hydrology (Fig. 11.34b). This gives

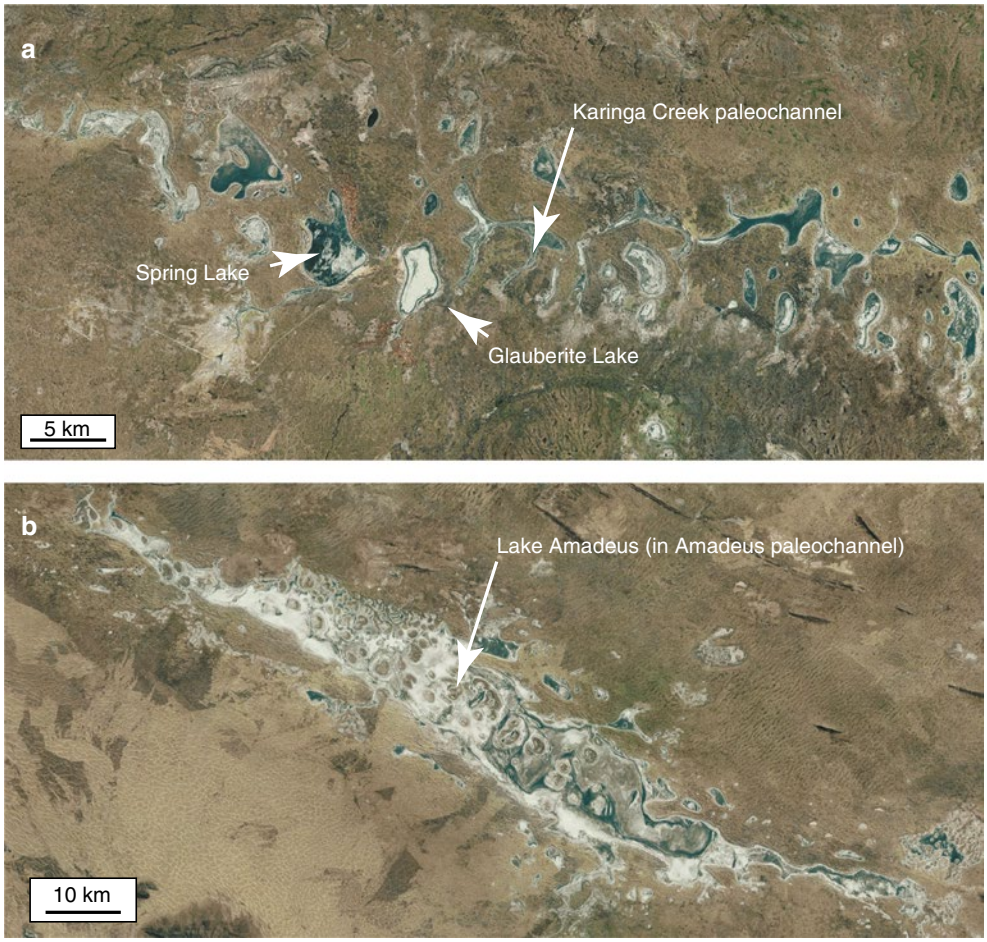

Fig. 11.34 Potash potential in palaeodrainage channels and lakes of the Northern Territory, central Australia. (**a**) Karinga Creek Palaeodrainage defined a series of local sumps with small playas draining the upper portion of the local hydrology (see Chap. 2). (**b**) Lake Amadeus; this large salt lake lies in a drainage chain that forms the central part of the 500-km long groundwater outflow belt (and palaeochannel network) along the northern edge of the Victoria desert and extends ESE into the Karinga Creek-Curtin Creek paleodrainages (Scaled Bing® images mounted in MapInfo®)

larger playas a stable recharge hydrology so that halite saturation rarely occurs within the playa sediments and thin ephemeral beds are short term features, thicker halite crusts cannot form.

In contrast, smaller playas tend to be uncoupled from the deep recharge system so pore saturation with respect to gypsum/halite is reached rapidly in the capillary zone of their mudflats (e.g. Spring Lake and Glauberite Lake). Subcropping groundwaters in both lake Amadeus and Spring Lake/Glauberite lake are undersaturated with respect to glauberite and sylvite. Yet both minerals accumulate as ephemeral efflorescent crusts about the edges of small salt lakes in the Karinga Creek palaeodrainage but not in Lake Amadeus due to its inherently higher local salinities and its rapidly transitioning lake surface, which because it is located well above the regional groundwater discharge level can attain short-term bittern saturation. The continual regional recharge from artesian waters beneath both small and larger playa depressions of this region means there is little longterm preservation of any salts, and zero potential for bedded potash preservation. However, the decoupled hydrology in the various salt lakes that define the Karinga Creek palaeochannel has the potential to supply brines that may suitable for sulphate of potash processing via anthropogenic solar pans, as is currently done in Lop Nor.

The hydrology of the large central Australian playas, and, for the same reasons, the artesian outflow hydrologies of other artesian-fed salt lakes/playas to the south such as Lake Eyre and Lake Frome are not suitable settings for the longterm natural accumulation of thick beds of potash salts. Their position in zones of regional meteoric outflow means they are too fresh and too deflationary, and the underlying groundwater prism is too fresh, to allow thick sequences of bedded salts to accumulate. Similarly decoupled seepage hydrologies are also why there are no substantial bedded accumulations of Quaternary potash in the Chotts of Tunisia. You need a deep depression with a saline feed and a stable hypersaline brine curtain to accumulate thick sequences of bedded salts, and in the case of potash salts that brine curtain must be maintained at the upper bittern end of the concentration range and preferable have a calcium chloride dominated hydrochemical makeup. Zones of shallow rising meteoric groundwaters, with typically higher levels of bicarbonate and sulphate, never underlie the sump hydrology of systems accumulating substantial volumes of potash salts (Hardie 1990).

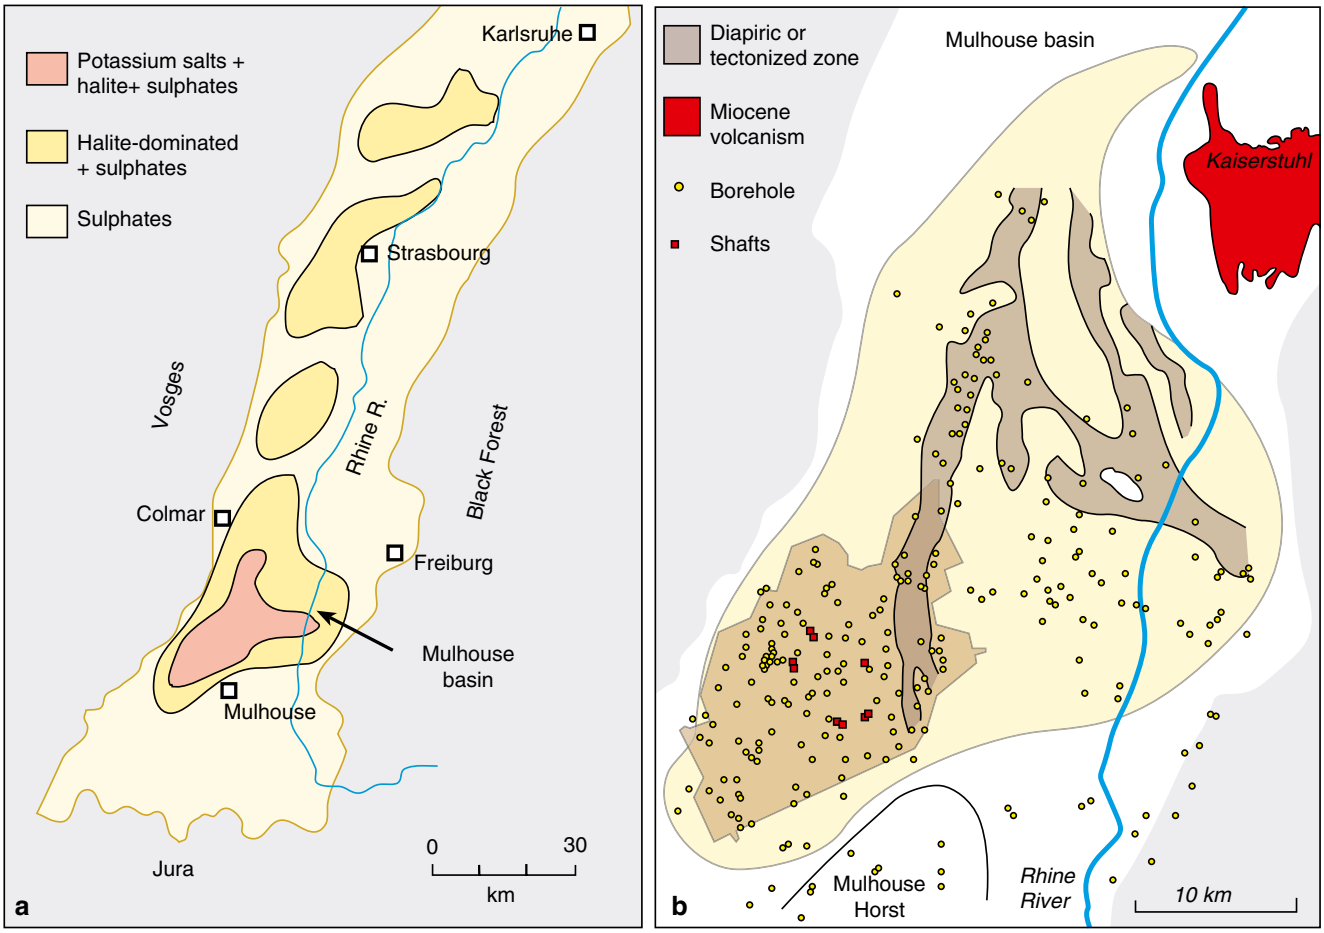

Fig. 11.35 Mulhouse Basin, Rhine Graben. (**a**) Regional distribution of salt basins showing how the potash dominant section is the southernmost of a number of small saline lacustrine deposits in the graben. (**b**) Detail of the Mulhouse (Alsace) Basin show how the exploited bedded potash area lay to the southeast of a more disturbed and diapiric zone (After Blanc-Valleron and Schuler 1997)

Ancient (Pre-Quaternary) Potash

Surface pan operations account for a little over 10 % of the world's annual potash production. The other 90 % comes from the extraction and mining of potash from ancient evaporite successions. Many ancient potash deposits accumulated as the bittern portions of marine-fed saline giants, with the larger examples forming during times of $MgSO_4$-depleted ocean chemistries and have no modern marine counterpart. We shall now look back progressively through time at some of the more important of the ancient potash occurrences.

Upper Rhine Graben, France

Until 2002 potash was conventionally mined in France in the Mulhouse basin. With an area of 400 km^2, the Mulhouse Basin (near Alsace, France) is the southernmost of a number of Lower Oligocene evaporite basins that occupied the upper Rhine Graben, which at that time was a narrow adiabatic-arid rift valley, experiencing a tectonic setting not dissimilar to the modern Danakil depression (Fig. 11.35a). The Rhine Graben is a Tertiary rift, some 150 km long and 10–25 km wide that straddles the Franco-German border as it runs from Basle in Switzerland to Frankfurt in Germany. Palaeogeographical reconstructions place a potential seaway seepage feed north or perhaps southeast of the Mulhouse basin, while marginal conglomerates tend to preclude any hydrographic connection with the ocean (Blanc-Valleron 1991; Cendon et al. 2008). Total fill of Oligocene lacustrine/marine-fed sediments is some 1,700 m thick and is dominated by anhydrites, halites and mudstones. The sequence is underlain by non-evaporitic Eocene continental mudstones with lacustrine fossils and local anhydrite. Bed continuity in the northern part of the basin are disturbed by diapiric and or erosional/fault movement and so were not considered economic targets for conventional mining (Fig. 11.35b).

The Paleogene filling of the basin is divided into 6 units; a pre-evaporitic series, Lower Salt Group (LSG), Middle Salt Group (MSG), an Upper Salt Group (USG – with potash),

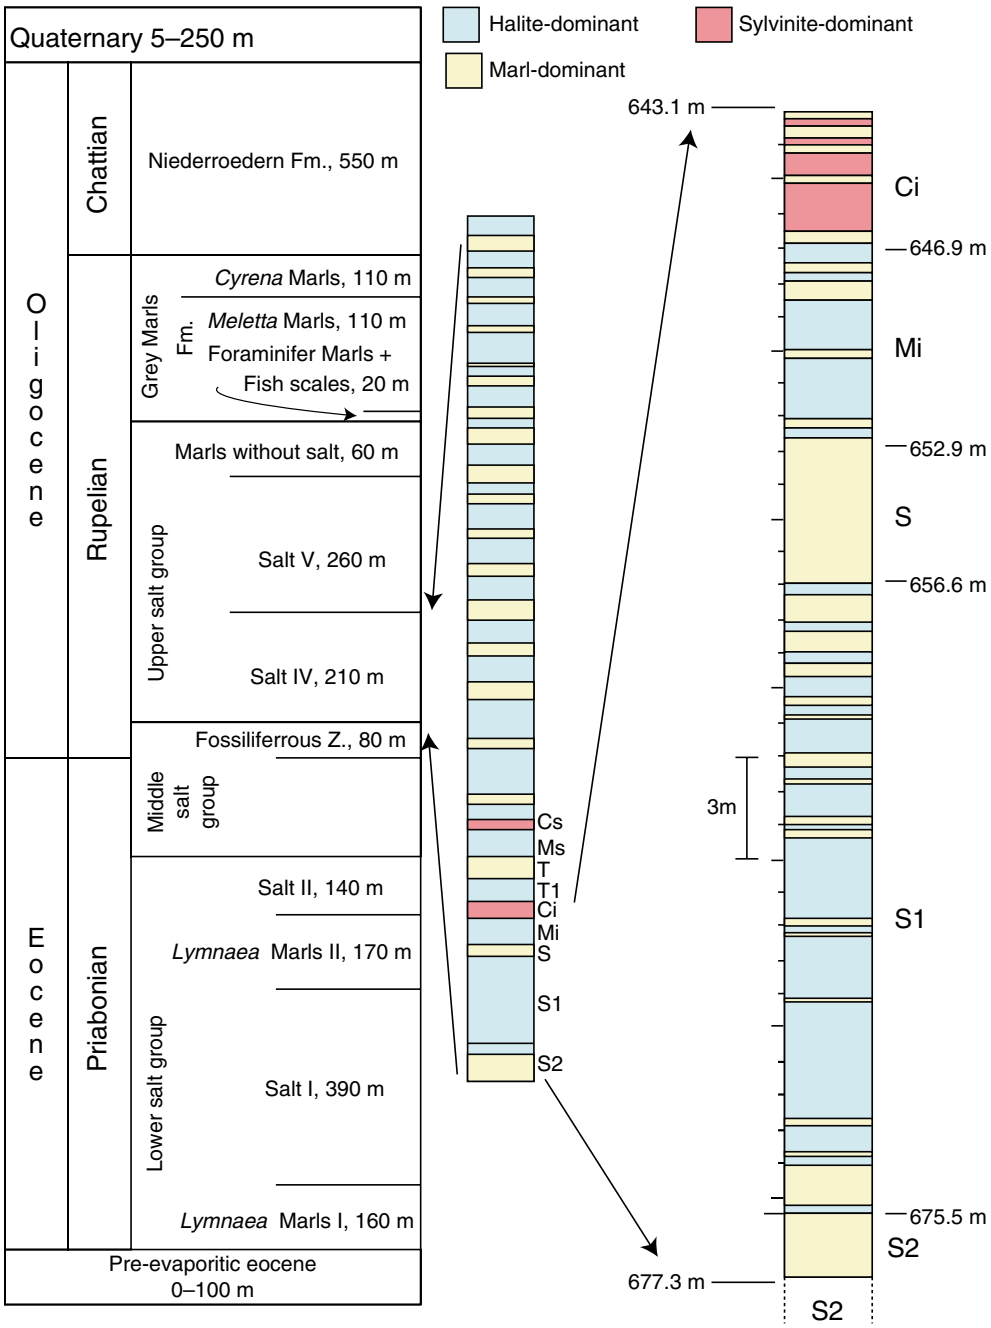

Fig. 11.36 Stratigraphy of the Mulhouse basin (After Cendon et al. 2008)

Grey Marls Fm., and Niederroedern Fm (Fig. 11.36; Cendon et al. 2008). The LSG and lower section of the MSG are interpreted as lacustrine in origin based on the scarce palaeontologic and geochemical data. However, based on the presence of Cenozoic marine nannoplankton, shallow water benthic foraminifera, and well diversified dinocyst assemblages in the Fossiliferous zone below Salt IV. Blanc-Valleron (1991) favours a marine influence near the top of the MSG, while recognizing the ambiguity of marine proportions with brackish faunas. Many marine-seepage fed brine systems have salinities that allow halotolerant species to flourish in marine-fed basins with no ongoing marine hydrographic connection. According to Blanc-Valleron and Schuler (1997), the region experienced a Mediterranean climate with long dry seasons during Salt IV member deposition.

In detail, the Salt IV member is made up of some 210 m of evaporitic sequence, with two relatively thin potash levels (Ci and Cs). The stratigraphy associated with this potash zone is, from base to top (Fig. 11.36):

S2 Unit: 11.5 m thick with well defined layers of organic-rich marls often dolomitic, with dispersed anhydrite layers.

S1 Unit: 19 m thick and made up of alternating metre-scale milky (inclusion-rich) halite layers, with much thinner marls and anhydrite layers. Marls show a sub-millimetric lamination formed by micritic carbonate laminae alternating with clay, quartz, and organic matter-rich laminae. Hofmann et al. (1993a, b) interpreted these couplets as reflecting seasonal variations. Anhydrite occasionally displays remnant swallowtail textures, which suggest that at least part of the anhydrite was primarily precipitated as gypsum. Halite shows abundance of growth-aligned primary textures, with abundant fluid inclusion banding (Lowenstein and Spencer 1990).

S Unit: Is 3.7 m thick and consists of thin marl layers and anhydrite, similar to the S2 Unit, with a few thin millimetric layers of halite.

Mi Unit: With a thickness of 6 m, it is mostly halite with similar characteristics to S1 Unit. Sylvite was detected in one sample, but its presence is probably related to the evolution of interstitial brines (Cendon et al. 2008).

Ci Unit ("*Couche inférieure*"): Is formed by 4 m of alternating marls/anhydrite, halite, and sylvite beds.

The Ti unit consists of alternating beds of halite, marl and anhydrite. The top of the interval is the *T unit*, which is similar in character to the *S unit* and consists of alternating beds of marl and anhydrite. Above this is the *Ms or upper Marl*, near identical to the *lower marl Mi.* The Mi is overlain by the upper potash bed *(Cs)*, a thinner, but texturally equivalent, bed compared to the sylvinitic Ci unit.

Thus, the Oligocene halite section includes two thin, but mined, potash zones: the Couche inferieure (Ci; 3.9 m thick), and Couche superieure (Cs; 1.6 m thick), both within Salt IV of the Upper Salt group (Fig. 11.36). Both potash beds are made up of stacked, thin, parallel-sided cm-dm-thick beds (averaging 8 cm thickness), which are in turn constructed of couplets composed of grey-coloured halite overlain by red-coloured sylvite. Each couplet has a sharp base that separates the basal halite from the sylvite cap of the underlying bed. In some cases the separation is also marked by a bituminous parting. The bottom-most halite in each dm-thick bed consists of halite aggregates with cumulate textures that pass upward into large, but delicate, primary chevrons and cornets. Clusters of this chevron halite swell upward to create a hummocky boundary with the overlying sylvite (Lowenstein and Spencer 1990).

The sylvite member of the couplet consists of granular aggregates of small clear halite cubes and rounded grains of red sylvite (with some euhedral sylvite hoppers) infilling the swales in the underlying hummocky halite. The sylvite layer is usually thick enough to bury the highest protuberances of the halite, so that the top of each sylvite layer, and the top of the couplet, is flat. Dissolution pipes and intercrystalline cavities are noticeably absent, although some chevrons show rounded coigns. Intercalated marker beds formed during times of brine pool freshening are composed of a finely laminated bituminous shale, with dolomite and anhydrite.

The sylvite-halite couplets appear to record unaltered settle-out and bottom-growth features of a primary chemical sediment that accumulated in a shallow perennial surface brine pool. The sylvite layers, like the halite layers, are interpreted as primary subaqueous deposits (Lowenstein and Spencer 1990). Based on their crystal size, the close association with cumulate halites in the sylvite layers, and the manner in which they mantle underlying chevron halites, sylvites are interpreted as precipitates first formed at the air-brine surface (or within the upper brine) that then sank to the bottom to form well sorted accumulations. Similar cumulate sylvite deposits form as ephemeral bottom accumulations on the floor of modern Lake Dabuxum in China during its more saline phases.

The current mosaic textural overprint in the Mulhouse sylvite layers was probably produced by postdepositional modification of the crystal boundaries, much in the same way as mosaic halite is formed by recrystallization of raft and cumulate halite during shallow burial. Inclusion studies in both the sylvite and the halites average 63 °C, suggesting solar heating of surface brines as precipitation took place (Cendon et al. 2008). Similar high at-surface brine temperatures are not unusual in many modern brine pools, especially those subject to periodic density stratification and heliothermometry.

Mineralogically, potash evaporites in the Mulhouse Basin in the Rhine Graben (also known as the Alsatian (Alsace) Wittelsheim Potash district) contain sylvite with subordinate carnallite, but lack the abundant $MgSO_4$ salts characteristic of the evaporation of modern seawater. The Rhine graben formed during the Oligocene, via crustal extension related to mantle upwelling. It was, and is, a continental graben typified by high geothermal gradients along its rift axis and in depositional setting is not dissimilar to the Quaternary Danakil and the Dead Sea during the deposition of the Sedom Fm. The role of its high temperature geothermal association in defining the $CaCl_2$ nature of the potash-precipitating brines versus a derivation from a $MgSO_4$-depleted marine feed is considered significant but is poorly understood (Hardie 1990). World ocean chemistry in the Oligocene is on a shoulder between the $MgSO_4$ -depleted $CaCl_2$-rich oceans of the Cretaceous and the $MgSO_4$ -enriched oceans of the Neogene (Zimmermann 2000b).

Recent work on the origin of the Mulhouse brines argues for an initial marine source but likely within a series of rift-valley basin depressions for which there was no direct hydrographic connection at the time the Middle Salt Member (potash entraining) was deposited (Cendon et al. 2008) That is, the general hydrological evolution of the Mulhouse basin is explained as a restricted sub-basin with an initial marine

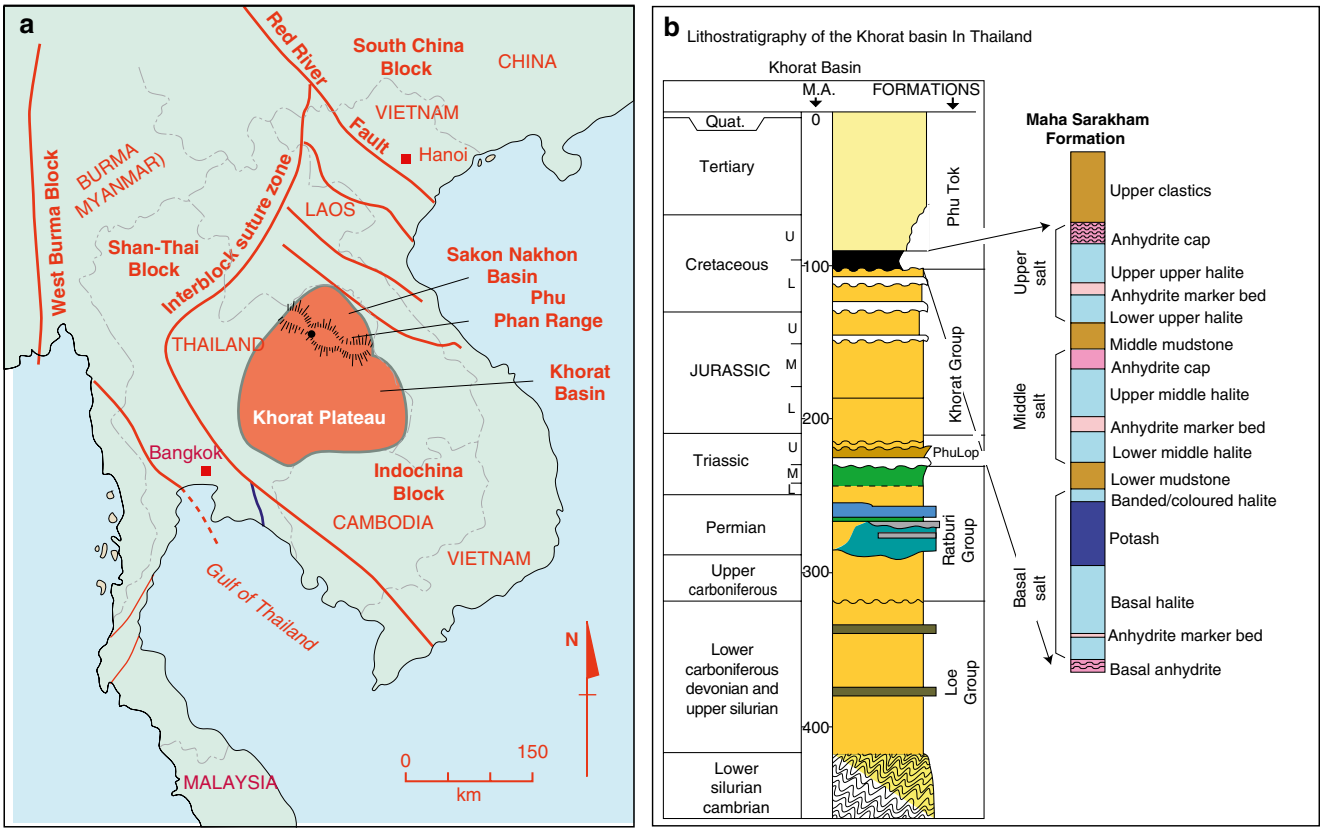

Fig. 11.37 Potash in Thailand. (**a**) Locality map showing location and tectonic setting of the Khorat Plateau, the Khorat Basin and the Sakon Nakhon Basin. (**b**) Stratigraphy of the Khorat Basin and the Maha Sarakham Formation (Albian-Cenomanian), NE Thailand (After Suwanich 1986; Mouret 1994; Racey 2009)

stage. This gradually changed to ≈40 % marine source at the beginning of evaporite precipitation, with the rest of hydrological inputs non-marine. The general proportion of solutes did not change greatly over evaporite precipitation. However, as the basin restriction increased, the originally marine inputs changed to continental or marine-modified inputs from neighboring basins north of Mulhouse basin.

Khorat Plateau, Thailand

Potash in the halite-dominated Cretaceous Maha Sarakham Formation is preserved within two structural basins: the northern Sakon Nakhon Basin (which also extends into Laos) and the southern Khorat Basin. These basins underlie much of the Khorat Plateau in NE Thailand and are separated by the highlands of the Phu Phan Range (Fig. 11.37a). It is likely that a single larger evaporite basin encompassing more than the current area of the present day Sakon Nakhon and Khorat Basins existed at the time of deposition. These deposits represent one of the last saline giants preserved in SE Asia and suggest an extreme arid period during Albian-Cenomanian time within a subsealevel marine-fed continental depression, possibly created by transpressional collision events that preceded the Himalayan Orogeny (see Morley 2012 and Racey 2009 for possible timing of various Mesozoic and Tertiary tectonic events). The evaporite sequence lacks $MgSO_4$ salts, consistent with our current understanding of the evolution of Cretaceous seawater chemistry.

The current margins of both basins are dissolutional, as are the upper and lower contacts of the salt units. If units of dolomite or anhydrite did form as platform wedges about the depositional edge of the basin, they must have been located outside the present structural/dissolution margins to the basin. More likely, thick units of dolomite or anhydrite were never present and these minerals only formed thin layers during times of short term freshening within the dominantly halite fill of the basin. Work by Racey (2009) suggests that the Khorat Group and the Maha Sarakham were originally deposited in a foreland basin setting rather than a thermal sag basin, following Late Triassic rifting. Moreover, the original site of deposition was to the north, somewhere in southern China, with the present-day location being the result of block movement along the Red River Fault coupled with a clockwise rotation of the Indochina Block (on which the Khorat Group sits) with respect to the South China Block.

In those parts of the stratigraphy largely unaffected by evaporite dissolution, the Maha Sarakham is composed of three salt beds –Lower, Middle and Upper Salt members– each overlain by a clastic mudstone –Lower, Middle and Upper Clastic members– (Fig. 11.37b). Where the Maha Sarakham has not been thinned, either by dissolution or salt flow, it is 250–300 m thick. In areas of salt dissolution it thins to <50 m, while in halokinetic regions it can be more than a 500 m thick (Figs. 7.40, 7.41a and 11.39). Evaporite minerals include halite; the sulphates gypsum and anhydrite, along with a variety of halite-hosted potash phases, dominated by carnallite and lesser sylvite with accessory tachyhydrite. Portions of the bedded halite display intricate depositional, dissolutional and diagenetic features that rank amongst the most pristine I have seen preserved in an ancient evaporite (Figs. 7.42 and 11.38).

Middle and Upper Salt members are generally flat lying and correlatable from well to well. In contrast, seismic and geomorphologic analysis shows that the Lower Salt of the Maha Sarakham has flowed in some parts of the basin so that thicknesses are much more variable from well to well (Fig. 11.39). Textures in the Lower Salt Member range from well preserved depositional textures in its upper part immediately below the potash entraining intervals to pervasive flowage features lower in the section. Petrographic evidence for salt flowage includes overburden-controlled elongate flattening of crystals and pervasive halite recrystallization that has destroyed original bedding features. In wells that sample deeper into the Lower Salt Member there is often a transition down core from pristine depositional textures into flowage textures, implying that flow into the pillows was fed mostly from the deeper parts of the Lower Salt Member. This is also consistent with the upper portions of the salt unit still being deposited while the lower parts of the same unit were flowing.

The potash interval in the upper part of the lower Halite unit of the Maha Sarakham in NE Thailand is dominated by carnallitite (up to 20–30 m thick), which forms a widespread stratiform unit along the western margins of both the Khorat and Sakon Nakhon basins. It is variably capped by sylvinite (<6 m) and typically covered by a bed of colour-banded red and grey halite (up to 6 m thick). This colour-banded halite preserves pristine depositional textures and is in turn overlain by the Lower Member.

A complete interval in the potash-entraining region at the top of the Lower Salt Member is divisible into (Fig. 11.37b):

(4) Uppermost colour-banded halite (0–6 m),
(3) Sylvinite zone (0–6 m),
(2) Carnallitite zone (0 up to 15–30 m),
(1) Lower zone of massive to bedded halite with traces of carnallite (50–300 m).

The lower zone (1), is dominated by massive, colourless, inclusion-free halite, which is made up of stacks of beds 0.2–0.5 m thick. The upper portion of this halite interval retains pristine depositional textures, including aligned bottom-nucleated chevron growth forms, clay dissolution stringers and microkarst and macrokarst pits. This halite zone is underlain by clean re-crystallized mosaic halite, which may stack into intervals that are hundreds of metres thick in halokinetic zones. Often this clean halite is dominated by biaxially flattened or necked and recrystallized lensoidal textures, a texture indicative of salt flow. Minor anhydrite stingers and nodules (≈1 cm thick) crosscut the axes of cores often with steep inclinations that also suggest flowage. This form of anhydrite is microcrystalline and lacks any of the original gypsum ghost structures so well preserved in thicker regional marker beds, especially those in the middle and upper halite members (Fig. 11.37b).

The carnallitite zone (2) is typically 15–25 m thick near the western edge of the current structural basin but can also disappear near the outermost parts of the basin where it has been dissolved by surface-driven crossflows of meteoric water. Three types of halite are found in the carnallitite zone: (a) inclusion-rich, cloudy, chevron halite; (b) clear, recrystallized, coarsely crystalline halite; and (c) granular, fine-grained halite. The first typifies preserved bottom-nucleated beds, the second typifies massive halite beds with poorly defined upper and lower contacts and suggests textures associated with macro and micro karstification, while the third type is found as disseminated halite in carnallite-filled voids. Anhydrite and other insoluble residues are scarce in the carnallitite zone. Halite that hosts carnallite is often crosscut by dissolution surfaces, clay stringers, collapsed halite beds and karst cavities can be coated with microcrystalline to coarsely crystalline carnallite (Fig. 11.38).

Many of the carnallite-filled voids are subvertical and narrow downward. In the older literature this texture was sometimes described and amoeboid potash. But much of this "amoeboid" texture is a syndepositional vadose karst fill, which prior to the precipitation of the carnallite cement was an open void. Textures in this part of the potash zone are identical to those found in the bedded potash deposits of the modern Qahan Playa and indicate the watertable was subject to large oscillations. Textures in the carnallitite interval in the Maha Sarakham show it was subject to syndepositional brine freshening, subaerial exposure and watertable lowering related to climatic changes and tectonic tilting in the depositional basin.

The sylvinite zone (a mixture of halite and sylvite) directly overlies the carnallitite zone and can be up to 6 m thick. It is not always present. Its contact zone is transitional with the underlying carnallitite zone, although sylvite crystal-clusters in the transition zone typically show sharp

Fig. 11.38 Typical multistage dissolution collapse and fill in Maha Sarakham Fm. by chevron halite. Cavities are sometimes filled by clear sylvite, not halite

non-horizontal edges. Sylvite is present in its halite host as: a) individual and small crystal clusters of up to 1 cm size, making up amoeboid-shaped forms; (b) coarsely crystalline massive beds up to 5 cm thick; (c) even layered, thick beds of up to 4 cm thick; (d) irregular medium to coarsely crystalline patches within massive halite beds and as patches sometimes rimming pre-existing carnallite crystals; and (e) massive sylvite units up to 25 cm across. In almost all cases, dark grey clayey matrix surrounds the larger sylvite crystals and/or alternates with the subhorizontal sylvite beds. Petrographically, sylvite crystals exhibit euhedral crystalline forms, either as individual crystals or as clusters of crystals.

At the transition between the carnallitite and sylvinite zones some dissolution cavities can be 25 cm across (in core) and filled with single clear sylvite crystals. Higher in the sylvinite interval the sylvite tends to occur as stratiform primary layers showing subhorizontal bedding, and ranges from 10 cm to 1 m thick. Individual primary sylvite crystals can reach up to 2 cm in size in the primary layers. Macroscopically, sylvite layers are not homogeneous and several types of sylvite may coexist within single layers along with fine clastic components and halite.

Halite beds alternating with sylvite layers range in thickness from 1 to 15 cm. Where not destroyed by the processes of dissolution and recrystallization, these halite beds can still exhibit relict bedding and occasionally are milky from inclusions in the preserved chevrons. But most of the halite in the sylvinite zone is clear and coarsely recrystallized, with geometries suggesting repeated episodes of dissolution followed by precipitation as passive void-fill cements. Traces of anhydrite are present throughout the sylvinite zone, along with traces of tachyhydrite. Anhydritic cm-diameter nodules are locally present, as are white nodules dominated by microcrystalline borate minerals (boracite and tyreskite).

More than one sylvite-rich interval may occur in the sylvinite zone. Workers in the region who have used a strict stratigraphic approach have often reported intervals with more than one sylvite layer as representing fault-repeat sections. Such an approach underscores the limitations of using a non-process based layer-cake stratigraphy in an evaporite succession. What is occurring is not associated with a fault-repeat of a single sylvite bed, but the vagaries of a sylvite-filled anastomose karst system being intersected a number of times in a single core. Contacts of many of the so-called repeat beds show classic insoluble-rich geopetal linings.

Colour banded halite (4) constitutes the uppermost part of the Lower Salt Member. It is coarsely laminated and retains pristine depositional textures (mostly chevrons) with little or no evidence of recrystallization. There is often a sharp upper dissolution contact with the overlying Lower Clastic Member, defined by a diagenetic horizon made up of anhydritic dissolution residues.

The origin of the richest sylvite zone (3) is related in part to the action of actively refluxing, possibly freshened brines working on an actively rising (pillowing) carnallite/halite precursor. For example, in the Khon Kaen region (Fig. 11.39), the Lower Salt Member has flowed into a pillow structure and the overlying strata are truncated beneath an alluvial cover. The synclinal structure associated with the rim of this pillow is also a zone where sylvinite thickens at the expense of the underlying carnallitite (Fig. 11.40a). This sylvinite is capped by the Lower Clastic Member, which is in turn capped by the

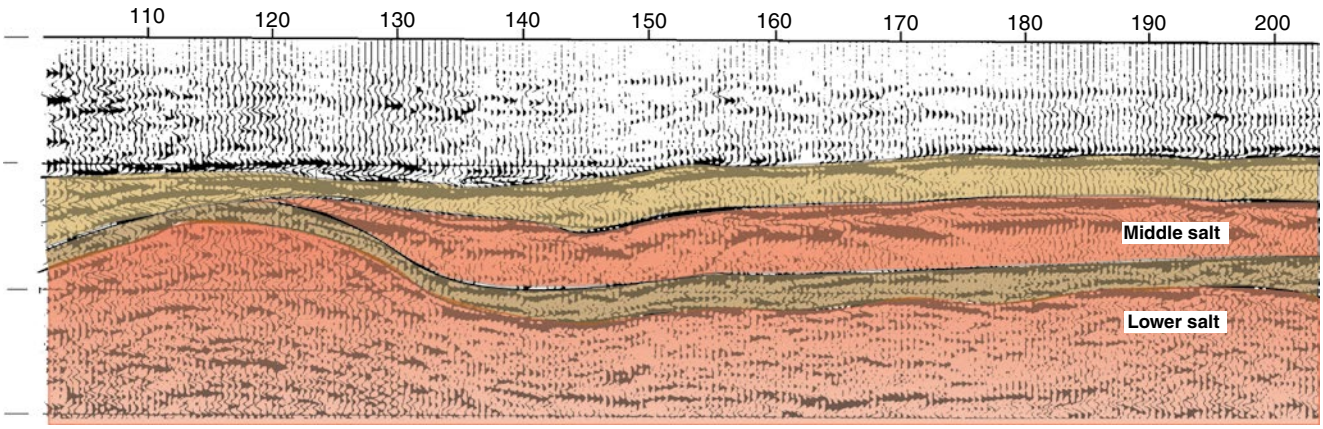

Fig. 11.39 Seismic image of Maha Sarakham Formation, from the Khon Kaen area showing a salt pillow in the Lower Salt Member and the syndepositional reduction in sedimentary thickness in units above this structure (seismic line supplied by CRA-RTZ)

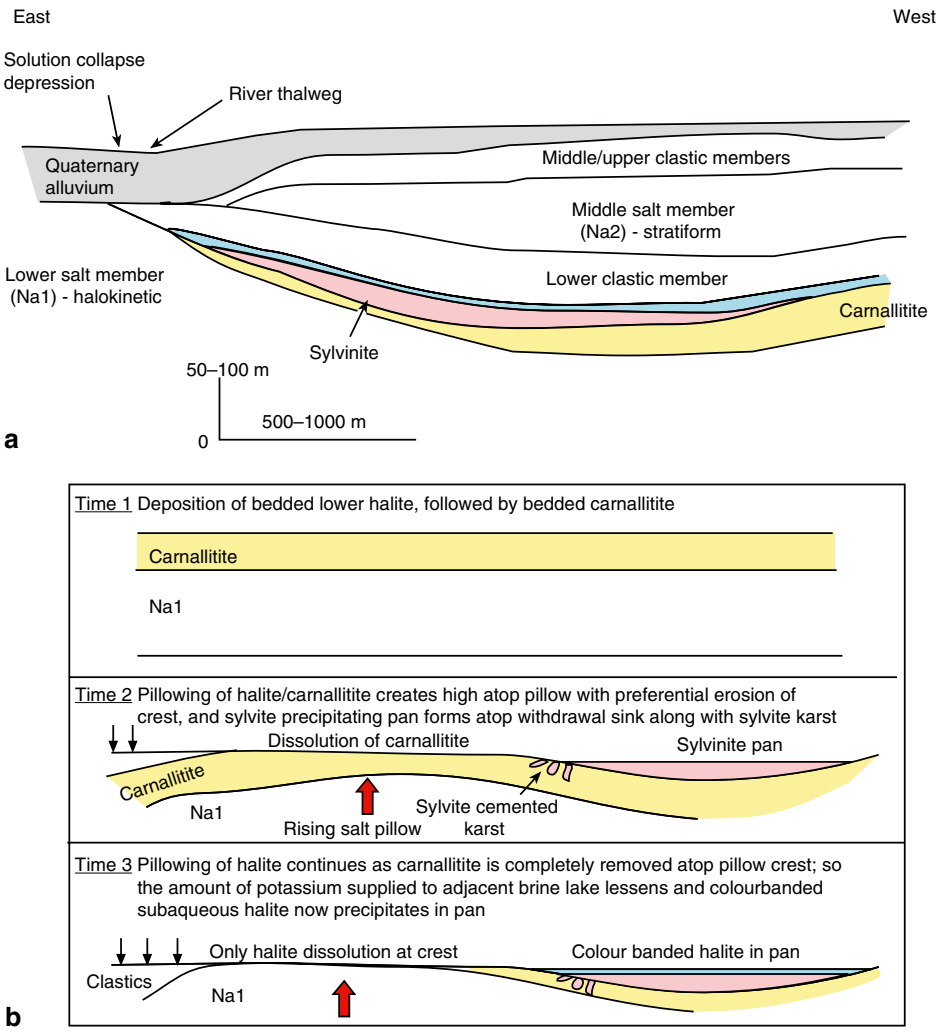

Fig. 11.40 Sylvite controls in the Maha Sarakham Formation along the western margin of the Khorat Plateau near Khon Kaen, Thailand. (**a**) Generalised schematic of current sylvite distribution based on well data in the region. (**b**) Sequential development of pillow and the erosion of crest facies controlling first the formation of sylvite and then the colour-banded halite within brine-entraining rim syncline depressions (see text for full explanation). Schematic based on author's research and field work in the region

Middle Halite Member. Core from the Middle Halite Member in this region shows predominantly undisturbed subhorizontal bedding and still retains perfectly preserved primary textures, such as chevrons and halite intercrystal karst, along with a regional dm-thick marker bed made up of subaqueous swallowtail gypsum pseudomorphed by halite/anhydrite (pers. obs. of core). At the regional scale, the halokinetic features follow curvilinear trends that are typically subparallel to

the present basin margin. Some pillows in the Lower Salt Member, especially those associated with sylvinite along the western margin of the basin, were probably syndepositionally initiated as they are truncated by sediments of the Lower Clastic Member (Fig. 11.39). Locally, other salt flow features are probably still active today, driven by laterally shifting surface river systems, including the Mekong and its tributaries. For example, $CaSO_4$ caprocks outcrop today in Laos in the erosional river-banks of the Nam Theun river one of the major tributaries to the Mekong (pers. obs.).

Initiation of the salt flow in the Maha Sarakham halite is probably diachronous and driven by sediment loading from various depocentres moving across the salt bed. In the Cretaceous the depocentres were tied to the deposition of the Lower Clastic Member and possibly the basin tilting related to the uplift of the Phu Pham ridge; today they are tied to the fluviatile deposits of the Mekong and its tributaries. Such feedback systems between depositional loading (sediment thicks) and salt buildups (pillows and anticlines) and salt dissolution characterise the western margin of the Maha Sarakham in the vicinity of Khon Kaen (Fig. 11.39). As well as being seen seismically, the relationship between surface landform and the underlying structuring of the salt can be imaged using currently available topographic maps, aerial photography and satellite imagery.

Like much of the halite in the Maha Sarakham, the petrography, depositional style and preservation quality of potash in the Lower Salt Member has been complicated by dissolution and halokinesis (Hite and Japakasetr 1979; Sessler 1990; El Tabakh et al. 1995; Utha-aroon et al. 1995). In terms of the potash minerals, carnallite dominates over sylvite through most the basin, while traces of tachyhydrite are also found preserved as enclosed euhedral to subhedral crystals in halite along with locally common boracite and priceite (up to 4 %).

Potash is widely dispersed as minor shows in the upper part of the Lower Halite unit across the basin. The only well studied and significant potash-rich zones are in the upper section of the Lower Salt Member along the western margin of the Khorat Plateau. Additional work has recently been publish by the Chinese on the equivalent marine fed potash units in the Khammuane regions of Laos (Zhang et al. 2013). Some Chinese authors assign a Paleocene (not mid Cretaceous) age for potash deposition (Tan et al. 2010). The isotopic evidence from the Laotian succession show the brine source is clearly marine (Fig. 11.41a). The actual age of the Maha Sarakham is contentious. Most workers in Thailand accept a Cretaceous age for the unit based on the assignment of a Late Cretaceous age to the overlying Phu Tok (Booth and Sattayarak 2011).

Around Vientiane, Lovatt-Smith et al. (1996) found evidence on seismic lines of an inversion event, which had created the Nam Leuk Uplift, an east–west trending feature that is bounded on its southern side variously by either a monocline

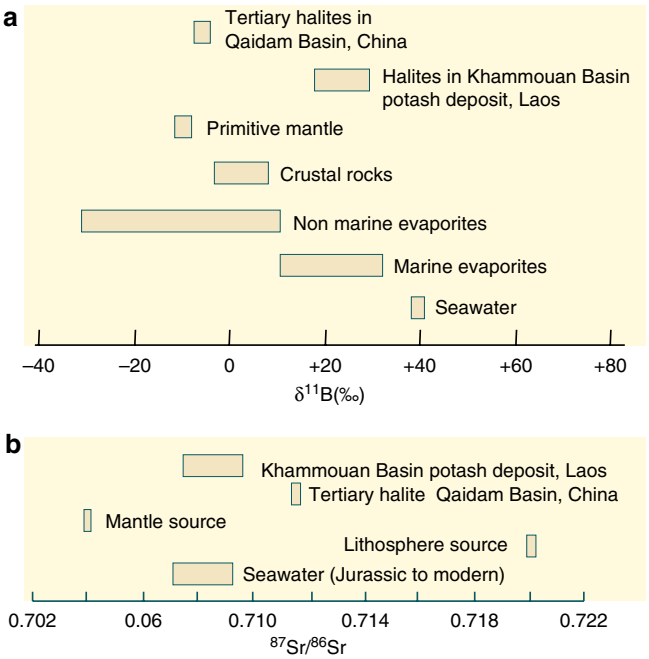

Fig. 11.41 Thangon Fm (= Maha Sarakham equiv. in Laos) isotope chemistry (**a**) Boron Isotopes. (**b**) Strontium isotopes (After Zhang et al. 2013)

or a high-angle reverse fault. They concluded that the evaporites of the Thangon Formation, which is the direct equivalent of the Maha Sarakham formation in Thailand, are essentially horizontally bedded and onlap the monocline in front of the Nam Leuk Uplift. On the basis of their seismic interpretation, which provided a mid-Cretaceous age for the Nam Leuk Uplift north of Vientiane. Lovatt-Smith et al. (1996) argued it was likely that the Phu Phan Uplift in Thailand had two stages of inversion: the first during this Mid-Cretaceous Event and the second during the Tertiary Himalayan Orogeny.

The presence of a regional unconformity at the base of the Maha Sarakham, Formation, as identified by Sattayarak et al. (1991), suggests that a deformational event did affect NE Thailand in the Mid-Cretaceous. However, although it is generally assumed that the Phu Phan Uplift was initiated in the Mid-Cretaceous, there is not yet any unequivocal evidence to support this contention. If such a regional unconformity is accepted, then the overlying Maha Sarakham and Phu Tok Formations should he regarded as separate from the Khorat Group.

The lower 100–200 m of the Phu Tok Formation (Booth and Sattayarak 2011) consists of a sequence of brick-red to red-brown clay-stones with minor siltstone and rare, thin, very fine-grained sandstone beds Overlying this is a sequence, at least 300 m thick, comprising thick beds of brick-red sandstone with large-scale high-angle cross-bedding. The lower claystone unit is interpreted to have been deposited in a very

low-energy fluvial environment, while the overlying sandstones are clearly aeolian. In many places the PhuTok Formation has been completely removed by Tertiary to Recent erosion, but in the centre of the basin seismic lines indicate that up to 500 m of section is still preserved. The original depositional thickness of the Phu Tok Formation is unknown. Hasegawa et al. (2010) have concluded from palaeomagnetic polarity studies that the aeolian beds are mid-Cretaceous (126- to 99–93 Ma), and that, at least in part the Phu Tok interfingers with the Maha Sarakham Fm.

There is little doubt that the large-wavelength folds of Khorat Group, which are such a notable feature of the surface geology of NE Thailand were initiated in the early Tertiary. The beginning of the uplift that accompanied the formation of these folds has been dated by Mouret et al. (1993) and Lovatt-Smith et al. (1996) using fission-track data at 65 Ma (earliest Palaeocene) and 60 Ma (Mid Palaeocene), respectively. Booth and Sattayarak (2011) estimate that the entire region of NE Thailand was uplifted and deeply eroded during the Tertiary, with some 1,000–1,250 m of section lost across the entire area and up to 3,000 m eroded off the Phu Ham high (which is a major inversion fold). The contentious question in terms of the Maha Sarakham age is whether its basinwide formation is related to the mid Cretaceous or Palaeocene tectonic collision event or were there aspects of evaporite deposition related to both events.

Facies geometries suggest that sylvite deposited along the western margin of the Khorat Plateau was: (a) precipitated after the deposition of the carnallitite; (b) deposited prior to deposition of the Lower Clastic Member; (c) influenced by lateral ground water inflows, probably driven by a potentiometric head generated by relative uplift of an adjacent growing salt pillow; (d) related to the cannibalisation of the uplifted carnallitite bed atop a growing salt pillow; (e) precipitated early, either as pond-bottom nucleates and floundered raft cumulates or as downward-fluxing karst-filling cements in the rising margins of the brine pool; and (f) then covered by subaqueous colour-banded halite, fed via the dissolution of halite from a now carnallitite-depleted pillow crest (Fig. 11.40b).

Sylvite precipitation was driven both by solar evaporation on the pond floor (as in the Mulhouse Basin) and by subsurface cooling of downward flushing potassium-saturated brines (as in the Qaidam Basin). Similar potash recycling into modern playa depressions in rim synclines is occurring around outcropping crests of diapirs fed by Miocene salt in the Qum Kuh region of central Iran (Warren 2008). The central Iranian potash is probably reworked from a Miocene source layer in the diapiric salt (Rahimpour-Bonab and Kalantarzadeh 2005). Diapiric potash is also hosted in the Pohl and Hormuz island diapirs in area of outcropping and subcropping Hormuz salt centred on the coastal city of Bandar Abbas. Iran. These namakier deposits present a number of problems in terms of stability and general safety if they are to be exploited using conventional mining techniques (Talbot et al. 2009a; b). Solution mining would be a more viable option.

In terms of potash exploration in Khon Kaen region and elsewhere in Thailand, it is important to note that the thickest potentially exploitable sylvinite fairways lie in rim synclines adjacent to syndepositionally breached salt pillows (Fig. 11.40a). They do not form laterally extensive horizons and are not akin to the Devonian sequences of Canada discussed later in this section. These pillows were deforming the carnallite zone and uplifting previously formed carnallite beds into a periodically freshened hydrological setting. Simultaneously, sylvite was precipitating on the pan floor and in karstic voids in the halite about the pan rim (Fig. 11.40b). It was the superimposed pillow hydrology that was karstifying the halite at the same time that the upper portion of the carnallite member was dissolving and supplying K-rich brines to the pool floor. The raising of the sedimentation surface, via pillowing, explains why some of the sylvite forms clear coarse-crystal fills in large karst holes in the halite, while other sylvite is a primary precipitate interlayered with primary halite.

The potash geology of the Maha Sarakham has a number of technological challenges for a conventional sylvite mining operation. Its geology should be carefully and publicly documented before the onset of any major mining operation. Maha Sarakham potash tends to occur in the upper part of the lower halite unit, and about the current dissolutional edge of the basin it is sometimes without a substantial thickness of halite atop the potential ore interval. Such a halite bed is a required back when mining, as it will support the mine roof as ore is extracted. Mine backs are typically more than 5–10 m of halite above the potash level in mines in Canada and New Mexico and 1–2 m in the robotically extracted potash ores of the Boulby Mine, UK. The overlying lower clastic unit in the Thai succession is typically not well-indurated sediment, so maintaining mine headwall stability will be a major consideration in mine planning.

Likewise, tilting, dissolution and flowage of the Lower Salt means some sylvite layers show bed inclinations of up to 70–80° to the drill core axis, implying sylvinite beds have dissolved or flowed. This means the bed thicknesses must be ascertained as a true thickness and not be indicated solely by assay thickness in core or wireline intersections in wells. Such high dips are also problematic in designing a mine plan utilising conventional mine equipment where access and assumptions of stratiform stratigraphy dominate.

There may be long term problems of ground subsidence and water entry in and above a shallow conventional mine within this area where depths to be mined are as shallow as 350–400 m and located a tropical Aw climate setting characterised by high seasonal rainfalls.

There is also the potential for unexpected intersection with brine-filled cavities. For decades, some of the local villagers near Ban Nonsaaeng, Sakhon Nakhon Province, have been extracting brine from cavernous regions above shallow diapir crests and using it to manufacture salt. The subsurface positions of shallow wells used in these cottage industry scale workings are largely undocumented and not subject to legislative controls. The associated at-surface solar pans are also subject to leakage that can degrade the underlying soils, drive subsidence that can damage adjacent rice paddies and aid in the formation of collapse dolines (Satarugsa 2011; Jenkunawat 2012).

To date, large-scale solution mining has not been the focus of any potash exploration programme in Thailand. All studies of the feasibility of extracting potash in the last three decades have focused on shallower areas of potash about the dissolution-overprinted basin edges, where potash tends to occur at depths more amenable to conventional mining (e.g. planned operations at Bamnet Narong and Udon Thani). Further out in both structural basins there may be some intervals of potash in the Maha Sarakham Formation that are more deeply buried and more amenable to solution mining. Some 45 km NE of Nakhon Ratchasima, there is a well-run salt solution operation (Pimai Salt Co. plant) that has sonar-monitored linked multi-pad wells that extract brine in a controlled manner to produce halite from the Maha Sarakham.

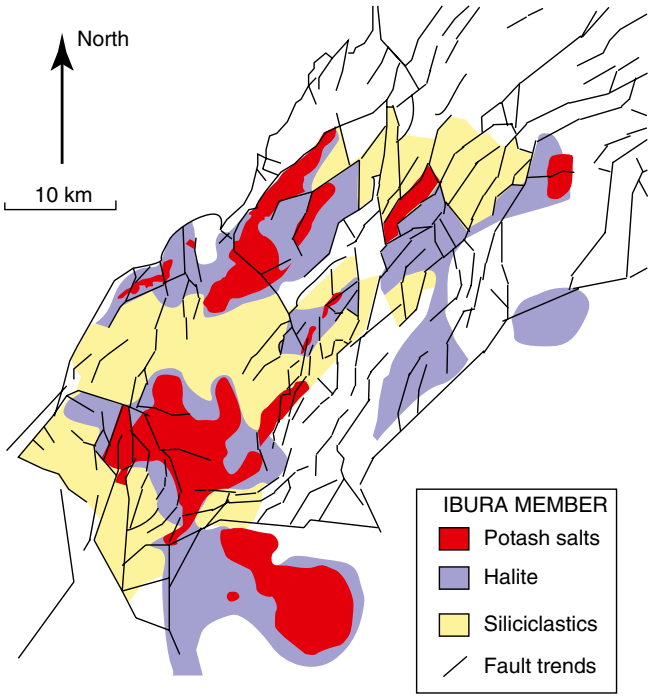

Fig. 11.42 Potash and halite distribution in the Sergipe region using a paleogeographic reconstruction (After Ecrosplan 2011b)

Cretaceous Trans-Atlantic Potash

Cretaceous (Aptian) evaporites, with bitterns, were deposited in a series of growing rifts created as Africa separated from South America. Today the remnants of these beds are to be found on opposite sides of the Atlantic in the Sergipe-Alagoas and Gabon-Congo basins (Chap. 5). In the Sergipe Basin the evaporite sequence (Ibura member of the Muribeca Formation) is a $MgSO_4$ -free potash deposit composed of stacked cycles of halite, carnallite and sylvite up to 800 m thick. Its distribution can be tied to deposition in a series of 10-km scale structural lows or sumps within a now halokinetic host and surrounded by siliciclastic aprons (Fig. 11.42).

More than 750,000 t/year of potash ore is extracted from the Ibura Member by the Companhia Vale do Rio Doce's at its conventional potash mine (Taquari-Vassouras mine) in Sergipe State. The deposit extent is relatively small and Mayrhofer (1985) estimated an *in situ* K_2O reserve of 11 million tonnes. The mine has a $174-per-ton operating cost and a projected productive life (as of 2012) of 9 years. It is owned by Petrobras, the state oil company, but leased and operated by Vale.

Depth to ore varies from 500 to 800 m, the thickness of the potash beds is uneven and ranges from 2 to 31.3 m (averaging 20.3 m). Sylvinite zones are mined as two separate layers, contain some carnallite and have an average grade around 25 % K_2O. Each layer is up to 11 m thick and they are separated by 3–6 m of barren halite. Several of the cycles in the Ibura Member are composed of thick halite (more than tens of metres thick) containing the highly soluble $CaCl_2$ mineral tachyhydrite (Fig. 11.43; Meister and Aurich 1972; Wardlaw 1972; Wardlaw and Nicholls 1972; Borchert 1977). The Sergipe deposits are characterised by thick cycles with a characteristic brining upward trend: halite (100 %) —>halite (35–90 %) + carnallite (10–65 %) —> tachyhydrite (5–100 %). Wardlaw (1972) showed that these deposits are primary as they contain bottom-growth features and primary bedding in the halite-carnallite units. Documented textures also suggest that there were episodes of syndepositional karstification and flowage within the carnallite, creating near identical textures to those seen in Thailand and the Qaidam Basin, but not yet documented as possible depositional analogs at the time when Wardlaw studied the Ibura sequence back in 1972.

In the upper part of the Ibura evaporite sequence a sylvinite bed sits atop a carnallite + halite bed and is overlain by a halite bed; a mineralogical evolution similar to that of the Thai and many other potash successions. The presence of a tachyhydrite layer just below a mine floor means that if tachyhydrite-entraining units are allowed to approach the mine floor, then there will likely be floor and mine-wall stability problems. This is always true of a tachyhydrite interval in a mined sequence, because tachyhydrite is

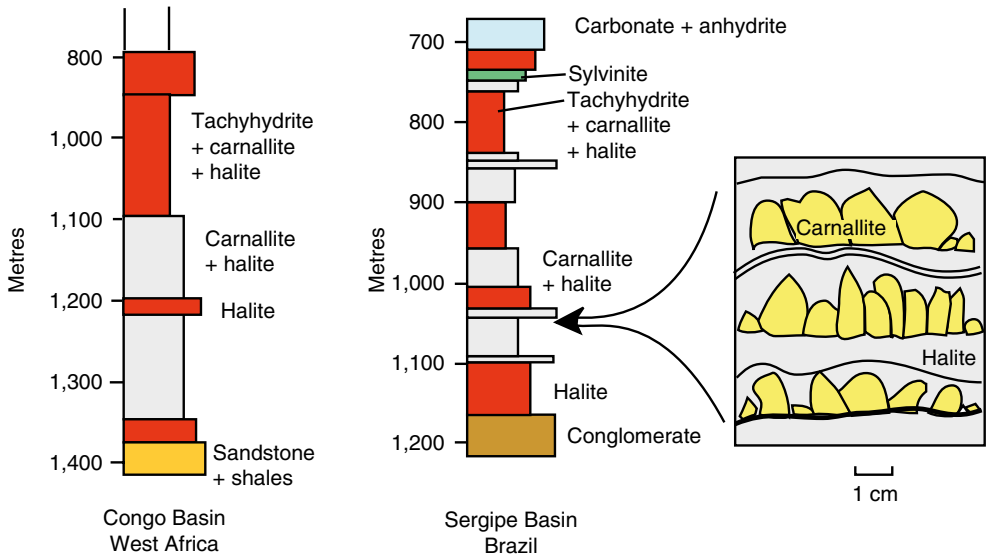

Fig. 11.43 Similarities in potash sequences from the Sergipe and Congo Basins (After Hardie 1990). *Inset* on the *right* shows primary layering and bottom-growth features of the Sergipe halite-carnallite subfacies (After Fig. 2 in Wardlaw 1972)

highly hygroscopic and has very low mechanical strength. Dangerous methane outbursts have also occurred in the Taquari-Vassouras mine when gas-filled dilation fractures were intersected (Davison 2009).

Today, away from the mined area, the various potash minerals in the Sergipe Basin show a systematic lateral zonation away from the anticlinal domes that also define the three main oil-producing structures in the Sergipe Basin. Oil-related drilling has shown that near the top of the anticlinal slope there is only rock salt, further out on the anticlinal arms there are intercalated sylvinitic layers, which in turn pass outward into carnallitic and tachyhydritic beds. There are no documented halokinetic structures beneath the anticlines and syndepositional uplift driving the leaching was perhaps related to drape over underlying horsts. This down-limb potash transition suggests that more soluble potash salts have been leached or escaped from the crests of the domes (Borchert 1977). In my opinion, given the similarity of the sequencing and layering to the Maha Sarakham and the preservation of detailed primary texture one can argue strongly for synprecipitational focusing of the ore via local halokinetic karstic reworking, as in the Maha Sarakham Fm.

Cyclic potash sequences constitute similar age beds on the African side of the Atlantic, there the beds are also free of $MgSO_4$ salts and include thick tachyhydrite or bischofite units. In and around salt domes, the Congo beds show a similar layering and downdip sequencing as in Brazil (Borchert 1977; De Ruiter 1979; Ercosplan 2007).

Within the Congo Basin the most extensive and thickest potash deposits occur in the coastal Kouilou region where ten evaporite intervals are recognised, with a cumulative thickness of potash beds of more than 100 m. Carnallite is the predominant potash mineral, while some cycles also contain bischofite and tachyhydrite, but lack substantial volumes of bedded sylvite (Fig. 11.44). The region is thought to be halokinetic, at least in part, and carnallite locally grades into sylvite in the upper parts of some beds. This implies transformation to sylvinite from a carnallitic precursor in zones of freshened water crossflow, either via incongruent dissolution, or synprecipitational karstic leaching from salt structure crests (as in the Maha Sarakham Fm).

Further inland, for 9 years in the 1970s, the equivalents of these carnallitic potash cycles were conventionally mined for sylvite in the Holle mine area in Republic of Congo, formerly Congo-Brazzaville (Fig. 11.45). Production was from uppermost sylvinite layers atop carnallite, with extraction rates around 360,000–450,000 tonne/year. Sylvinite was targeted in the second highest (9th) evaporite cycle in four separate beds. Two layers, beds 3 and 7/8 were mined at typical depths of 290–380 m, at an average grade of 18 % K_2O, over an area of 18 km^2. Bed 3, which was 10–20 below bed 8, had an average thickness of 3 m and a grade of up to 38 % K_2O with only 0.1 % insolubles.

Galleries were dug out below a 35-m to 55-m thickness of salt; the observed minimum mine head was 16 m. No faults or fractures were encountered over 8 years of operation. But on June 17, 1977, a flow ingress and a fall of materials with characteristic of the levels above the salt roof, occurred. At this specific location, the salt roof was some 70 m above the mine galleries. On June 20, a large water flow developed, and rocky blocks fell into the gallery; the inflow rate was 30 m^3/h, and the brine NaCl content had decreased drastically. By June 21, the flow rate was as much as 1,650 m^3/h and increased to 10,000 m^3/h or more on June 22. A large conical crater, 150 m in diameter and 20-m deep, developed at ground level above the mine. On June 20, 1977 water from a breached overlying aquifer termed a "clastic break-in" by the mine geologist had begun to enter the mine, accounting for the increased rate of inflow and with 36 h the mine was lost to flooding.

Prior to the final flooding ongoing geological and water problems prevented the Holle mine from ever being profitable

or reaching its target production level of 720,000 tonne/year. All operations at the site ceased in 1978. The shallow, discontinuous nature of the targeted sylvinite horizon in this deposit, probably means that the best way an economic recovery could be attained, in either the Kouilou or the Holle Mine areas, is via solution mining. The tropical climate of the region means energy-intensive crystallizers, rather than solar evaporite pans, would be needed to concentrate the return brines.

Interestingly, neither the Sergipe nor the Congo potash/tachy-hydrite mineralogies can be derived from the evaporation of modern day seawater. Yet both deposits retain bottom-nucleated halite crystal fabrics and widespread tachyhydrite, implying different seawater chemistry in the Cretaceous (Fig. 11.43).

Moroccan Meseta (Late Triassic)

Salt basins formed in Morocco as rifts evolved into subsea-level intracratonic sags during the Triassic breakup of the supercontinent Pangaea. As a result, nonmarine redbeds and evaporites fill the many Late Triassic (Keuper) to early Liassic half grabens, which make up the Moroccan Meseta (Fig. 11.46a). Thick basalt flows (up to 500 m) underlie and overlie these saline deposits (Van Houten 1977; Clement and Holser 1988; Lorenz 1988; Courel et al. 2003). In four of the sub-basins, including the Khemisset Basin, evaporites interbedded with basalts carry varying concentrations of potash, but as yet none are exploited commercially. Documented sylvinite occurrences in the Meseta Basin occur at depths of 490–790 m, tend to be low grade and erratically distributed (Tortochaux 1968). These potash intervals consist essentially of halite, carnallite, sylvite and rinneite, with less than 1 % of other minerals (anhydrite, kieserite, bischofite, douglasite;

Salvan 1972). Once again, like the Cretaceous examples just discussed, this is a $MgSO_4$ -depleted potash sequence and indicate a largely marine-derived Ca-Cl brine source with ionic proportions different from today.

The most detailed work on the stratigraphy of the evaporite intervals of the Meseta to date is by Courel et al. (Courel et al. 2003) and Et-Touhami (1996), who noted up to a kilometer of red-bed fringed halite in the thicker portions of the Khemisset Basin graben. Et-Touhami (1996) focused on potash-entraining strata in the centre of the Khemisset Basin, which are Late Triassic to Early Liassic and made up of five formations (from base to top); Lower Clay Formation, Lower Salt Formation, the Basaltic Formation, Upper Salt Formation and the Upper Clay Formation (Fig. 11.46b). Potash occurs toward the top of the Lower Salt Formation (LSF). The LSF is subdivided into two informal units known as L1 and L2. The lower unit (L1) is composed mostly of red-brown chaotic mudstone interbedded with red beds, especially toward its base. The upper unit (L2) is further divided into the L2.1 and L2.2 subunits (Fig. 11.46b). Subunit L2.1 is made up of black chaotic to massive banded salt with some local inclusions of potash. Subunit L2.2 is made up of massive banded halite with potash layers (sylvite and carnallite), along with thin stringers of anhydrite and polyhalite. As in Thailand and Brazil, the sylvite unit tends to occur near the top of a colour-banded halite unit and sits directly atop a carnallitite succession. Locally the halite crystals in the carnallitite unit retain relict chevron fabrics and vertically-elongate inclusion-free halites identical to those interpreted as syndepositional relicts in the Mallowa Salt of the Canning Basin, Australia (Cathro et al. 1992). Slumps and synprecipitational karstic textures also characterise the carnallitite. A bromine profile through the LSF shows the potash was precipitated in the most saline stage of the accumulation (Br >100 ppm; Fig. 11.46b).

The LSF in the Khemisset Basin is covered by vesicular to highly altered lavas and flows of the Basaltic Formation, which also retains local lenticular intercalations of claystones, limestones and evaporites. Atop this is the Upper Salt Formation, a unit composed of generally flat lying salt beds intercalated with siliciclastic mudstones and siltstones. It is divided into Units 1–3, with local potash inclusions sometimes found in Unit 3. The bromine profile of the Upper Salt Formation shows lower concentrations than the LSF and does not appear to have attained the bittern stage for long enough periods to accumulate thick beds of potash (Br <100 ppm; Fig. 11.46b). Hence, potash occurrences noted today in the Meseta tend to be low grade and erratically distributed.

Permian Potash

The Permian was a time of widespread epicontinental salt deposition across Europe, Russia and North America in basins driven by tectonics tied to the accretion of Pangaea. Like today, it was a time of $MgSO_4$ ocean chemistry. Most of the European Permian potash occurrences centre either on sumps in the large intracratonic thermal sag basin known as the Zechstein (Lopingian), or in foreland flexures located the east of the Cis-Urals collision suture (Kungurian). The Zechstein Basin stretched from northern Britain, southeast across the North Sea through the Netherlands, Denmark, Germany and Poland to the edge of the Hercynian massifs (Harz, Rhine and Bohemian mountains). North American potash was deposited in local sumps at a time of "fill and spill" in the aulocogen known as the Delaware basin (Lopingian stage). Chapter 5 discusses the tectonic and eustatic character of these various basins.

The Zechstein salt succession of NW Europe and its bedded potash was deposited in a Late Permian intracratonic thermal sag basin, within a tectonic relaxation or regional flexure setting, related more to the aftermath of the Hercynian orogeny than to the early stages of Mesozoic extension (Geluk 1999; Van Wees et al. 2000; Scheck et al. 2003). Zechstein salt deposition took place at the onset of a time of entry of marine waters in a period of thermal subsidence lasting from Permian to Late Triassic (Littke et al. 2008). This occurred after an initial volcanic rift-associated episode during Late Carboniferous to Early Permian. In the Late Triassic, a second extensional phase affected the Zechstein basin and halokinesis was widespread. This was followed by uplift of portions of the northern part of the basin in Late Jurassic–Early Cretaceous and a phase of compression during Late Cretaceous–Early Tertiary, both events reinvigorated salt flow and remobilized potash distributions within many salt structures.

Potash extracted from the Permian Zechstein evaporites provides 20 % of the world's potash. The Zechstein succession of NW Europe was deposited in a huge drawdown seaway extending across much of modern Europe and is today made up of four evaporite cycles: the Z1-Werra Series, Z2-Stassfurt Series; Z3-Leine Series and Z4-Aller Series. Each Zechstein series has a general sequence of clastics, carbonates, one or two phases of sodium and potassium salts, regressive halite or anhydrite, and carbonate. Potash beds of Z1 and Z2 are primarily composed of sylvite (KCl), carnallite ($KCl.MgCl_2.6H_2O$) and kieserite ($MgSO_4.H_2O$) and rapid lateral changes due to halokinesis are common. The Zechstein 2 potash bed interval locally attains a true thickness of about 15 m. Permian potash worldwide tends to be associated with $MgSO_4$ salts as the Permian was the penultimate time of a $MgSO_4$ ocean, prior to the current one (Warren 2010).

German Potash (Z1, Z2 and Z3 Potash)

Six mines are currently active in three German potash districts: the Hanover district in Lower Saxony, the Calvörder

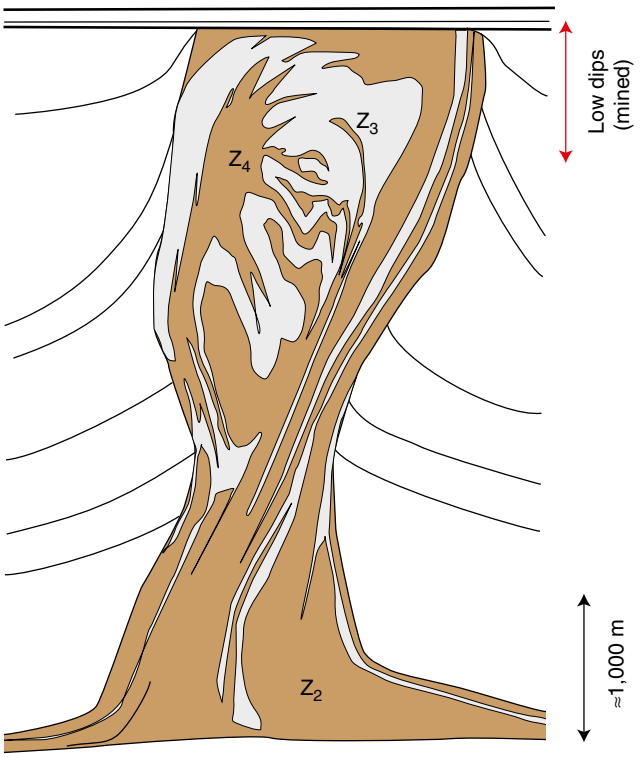

Fig. 11.47 Cross section showing geometries of the Permian Zechstein Z1–Z3 series in the salt structure that hosts the Mariaglück Mine, former West Germany (After Mayrhofer 1985)

district in Saxony-Anhalt and the Werra-Fulda district in Hesse and Thuringia. Some of these currently active German potash mines in the Stassfurt (Z2) and Leine (Z3) in the Saxony-Anhalt district are more than 100 years old. The Z3 seams are mostly sylvinite and ore zones are mostly free from higher levels of Mg-salts present in the Z2 series (carnallite and kieserite). In general, the average grade of halokinetic potash (sylvinite type) across Germany is 17–18 % K_2O, which is low by Canadian standards. However, the extracted products can be utilized economically due to proximity of the market, mining efficiencies, and high levels of government farming subsidies throughout the European community.

Two potash cycles are exploited in the Z1 in the Werra-Fulda Basin southeast of Kassel, while two potash beds in the Z2 and Z3 are mined near Hanover. Formations near Hanover in northwestern Germany occur in diapiric salt domes (Fig. 11.47). There, the salt and potash mines are located along salt walls that trend along strike for over 20 km and are 800–1,000 m wide. In the Hanover area, potash is mined between depths of 300 and 900 m, along a steeply-dipping seam some 2–30 m in width (the increased width is due to multiple, tight folds). In the southern potash-mining district of Werra-Fulda, two seams are mined at depths of 300–900 m with thicknesses of between 2 and 4 m. These seams are even lower in grade than in the Hanover area, but unit extraction costs are lower as seams gently dip and are steeply folded. However, the internal geometries of the various beds are complex and salts are usually extracted from those upper parts of the salt structures with dips that are relatively low angle (Fig. 11.47).

In Poland there are various occurrences of potash in the Zechstein series. For example, the Z1 is found at mineable depths north of Gdansk on the Leba upland, where it is made up of thin layers of polyhalite, with carnallite, kainite, glaserite and loeweite inclusions. Clay, anhydrite and gypsum are major components present with the polyhalite, which also contains smaller amounts of celestite, epsomite, halite and carbonate. In the central Polish depression the Z2 (Stassfurt) bed consists of up to 25 m of carnallite, but atop the Klodawa salt structure it has changed to 6–8 m of a high-kieserite sylvinite (Garrett 1995). Over the years many studies have been conducted on the possible utilization of these various halokinetic potash beds, but so far Polish potash has yet to be exploited commercially.

The nature of sylvite in the Polish Zechstein (Stassfurt Z2 and Leine Z3 cycles) is of broader interest than deposit occurrence, in that it illustrates the unusual thermal and reactive nature of potash salts encased in halite, both at deposition and in subsequent diagenesis. In a study of inclusion homogenization temperatures in chevron halite associated with sylvite layers, Vovnyuk and Czapowski (2007), found a thermal dichotomy in the inclusion data (Fig. 11.48). They interpret this as a combination of depositional and diagenetic signatures. The lower temperature band (53–60 °C) indicates primary halite and sylvite deposition via brine cooling within heliothermic salt lagoons and saltpan-salinas. Inclusion chemistry in the primary chevron-textured halite (group a) shows the bitterns were Na-K-Mg-Cl-SO_4 (SO_4-rich) waters, that is, brines typical of a marine oceanic source. The studied system differs in its elevated potassium contents compared to brines typical of many other primary-textured Zechstein halites. With diagenesis this has produced sylvite (also associated with daughter crystals in halite inclusions), via redeposition of locally generated potassium salts during inflow of fresh seawater into the sedimentary basin (i.e., sylvite layers via incongruent dissolution). The second brine group (group b), with somewhat higher temperatures of 85–135 °C, indicates subsequent diagenetic recrystallization of the buried halite and interlayered potash (Fig. 11.48).

Z3 – Boulby Potash, UK

Elsewhere in Europe, potash is solution mined from the Aller Series in the Veeder region of Netherlands and conventionally mined from the potash member of the Boulby Halite in the Teeside Group, with the mine located at the southeast

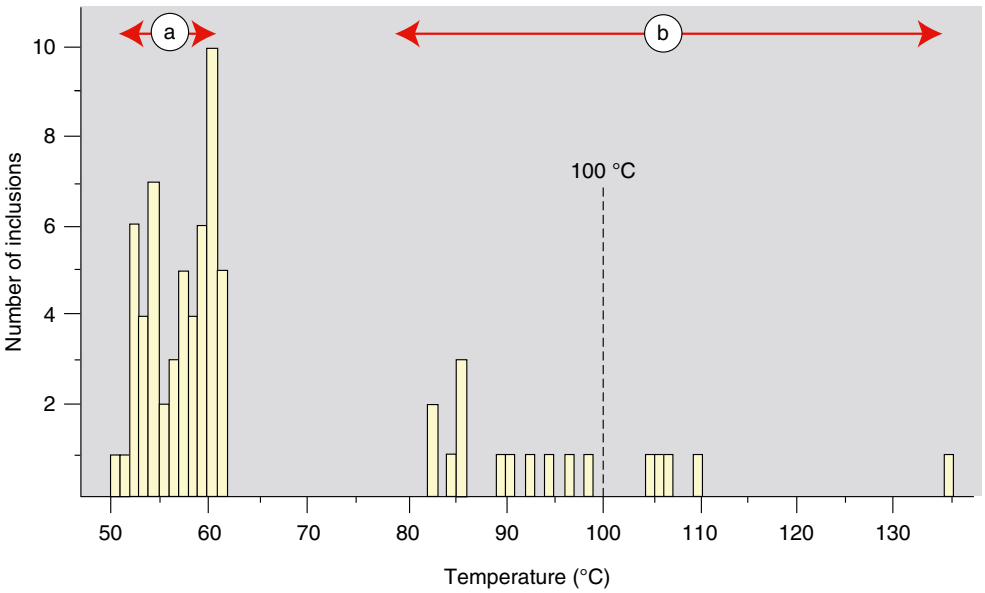

Fig. 11.48 Halite homogenization temperatures (*a*) indicate measurements that reflect the temperature of heliothemic-prone basin brines during precipitation, (*b*) homogenisation temperatures of inclusions in chevron halite from regions of halite/sylvite recrystallisation via diagenetic fluid overflow (After Vovnyuk and Czapowski 2007)

boundary of Cleveland County on the coast of NE England (Figs. 11.49 and 11.50). The Boulby mine has more than a 1,000 km of tunnels over an area measuring 8 km by 5 km, with around 50 km of new tunnels added each year. Workings extend more than 5 km under the North Sea. Today, the mine is the only exploitation of Zechstein potash in England,

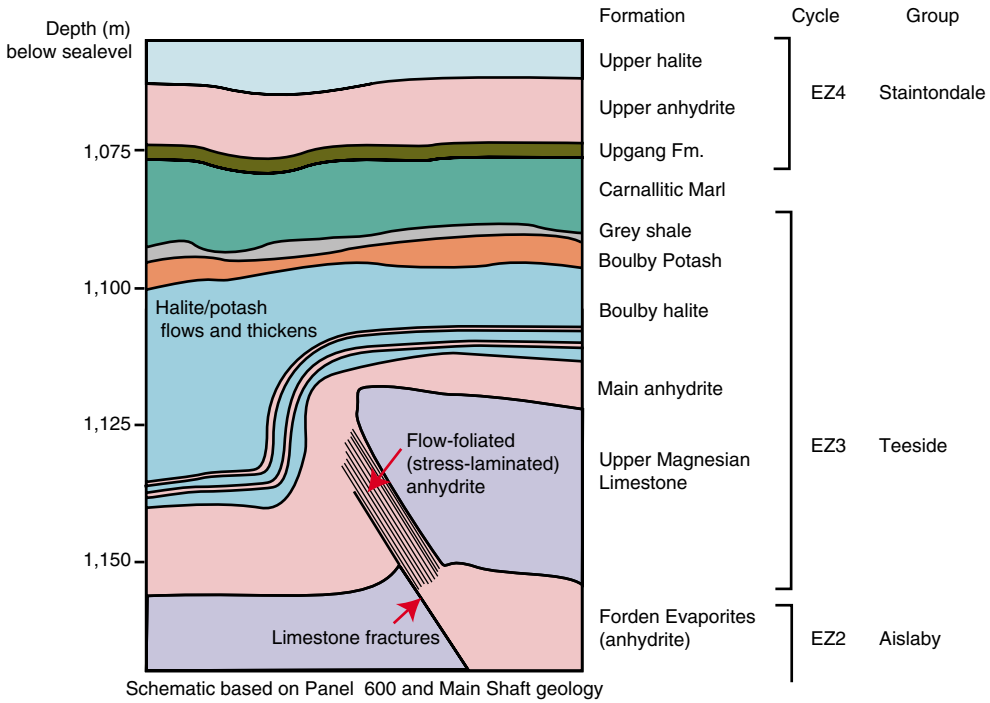

Fig. 11.50 Effect of reverse faulting (Mesozoic-Tertiary compression on the Boulby Evaporite Succession where salts tend to flow and thicken, while brittle carbonates fracture (After Talbot et al. 1982; Davison 2009)

although new mines in the same coastal region are currently under consideration. Cleveland Potash Ltd (CPL), a business unit of ICL Fertilizers, has operated the Boulby Mine for over 35 years, currently producing over one million tonnes per annum of refined KCl and 0.5 Mtpa salt. The operation extracts sylvinite from between 850 and 1,350 m and is operating is near the limit for conventional underground potash mining. It processes the ore by conventional froth flotation techniques and in April 2011 the mine also began to extract and process a polyhalite ore.

The Boulby deposit lies at the extreme western edge of the Zechstein Basin and marks one of the deeper zones of the Zechstein 3 and 4 potash (Garrett 1995). The English Middle (or Boulby) Potash bed is assumed to be a Zechstein 3 equivalent, and the Upper Potash bed (not found at the Boulby mine) to be Zechstein 4 (Smith and Crosby 1979). This consensus correlation is still used today, even though some consider the Zechstein series of England to be depositionally distinct from Germany and Poland. The Boulby Potash bed deepens to the south of the current mine workings, where the "Upper Potash" bed (Z4) is also present. Potash ore is underlain by a thick sequence of mildly halokinetic halite, which makes up the majority of the Boulby Formation (Fig. 11.49). This halite is in turn underlain by the Billingham Main Anhydrite and Upper Magnesian Limestone Formations of the Teeside Group.

The targeted Boulby Potash interval is a sylvinite with gneissic and augen-like flow textures, along with tectonically-rounded rock fragments from adjacent intrasalt beds (Figs. 11.49 and 11.50; Woods 1979; Talbot et al. 1982; Smith 1996; Davison 2009). The sylvinite has a variable bed thickness ranging from less than 1 to 20 m over lateral distances of 20–30 m, with mined units generally ranging between 0 and 8.5 m in thickness. The ore horizon essentially lacks soluble magnesium or sulphate salts, and so is an ore feed lacking many of the processing problems inherent to more magnesian potash ores currently extracted on the European mainland.

There are five distinct Boulby ore types across the more than 40 km^2 of the mine workings, all of which exhibit flow-related rapid lateral changes. An ore type can predominant over mine areas more than a kilometer across (Garrett 1995). In some zones an ore with low insolubles is found, with the gneiss-like texture of sylvite crystals being elongated in a ratio as high as 3–1, and generally with a near-horizontal bed orientation (Woods 1979). This is the ideal ore. The sylvite can be red to white, and the halite may contain considerable anhydrite and clay, or be quite pure and apparently recrystallized (Fig. 11.51). The second type of ore is similar in quality, but found in areas with folds, overturned folds (recumbent; often with a near-horizontal axis), or sheet-like with a horizontal surface (nappes). Some of the overlying salt clay, or underlying halite may occasionally be incorporated into the overfolding. The ore may be as much as 20 m thick and have a KCl content of over 50 %, probably because of sylvite's differential flow character compared to halite.

The next three ore types have purer sylvinite at their base for 0.5–1.5 m, with grey anhydritic shale on top of it. The shale contains a high percentage of crystallized or fibrous veins of sylvinite. In one of these types, shale is usually

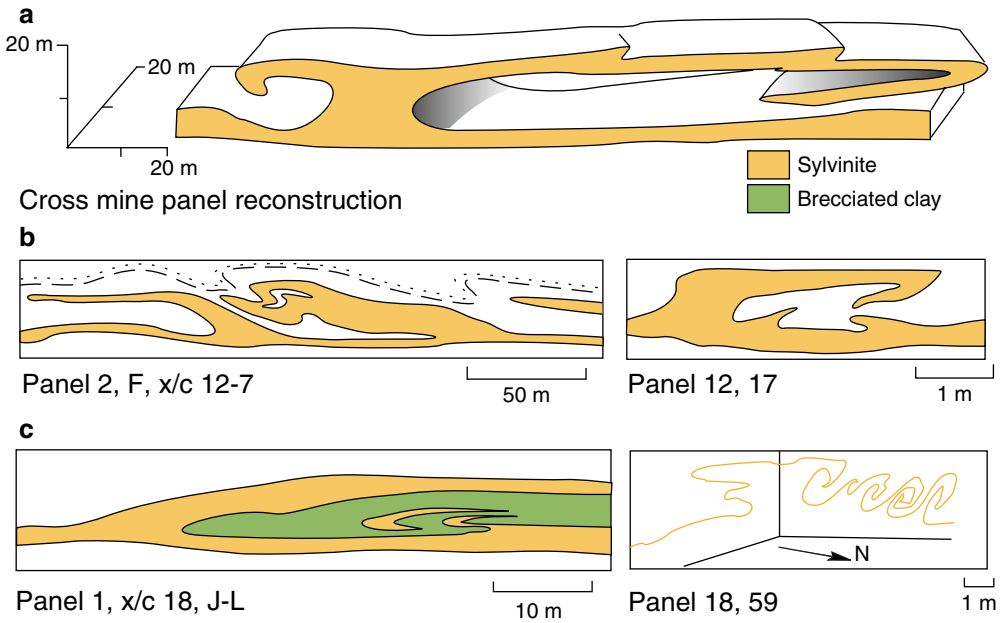

Fig. 11.51 Structural complexity of the sylvinite ore as mapped in the mine panels (After Talbot et al. 1982)

topped by the salt clay, but a displaced halite zone may also be present. The next type is similar, except sylvinite also occurs above highly veined shale, and folds and nappe structures occur, resulting in a much thicker deposit. Ore grades there often exceed 40 % KCl. The final type is also similar, but has a greater portion of halite in the upper sylvinite.

The average KCl content in the exploited parts of the Boulby Halite is 26 % KCl. As in the New Brunswick ores of eastern Canada, Boulby sylvinite ore is characterized by marked thickness changes reflecting flow thickening, related to the high differential stresses created by halokinesis in potash encased in halite (Fig. 11.50). The flow thickening of highly mobile potash intervals has locally enriched several of the ore beds to grades in excess of 50 % KCl in a process sometimes called "flow or stress refining". The same potash-related thickening is seen seismically in North Sea diapirs (Jenyon 1986).

The first of two shafts at Boulby was completed in 1973 (Fig. 11.49). It quickly became apparent that ore grade in this potash deposit, which sits atop the thick halites of the Boulby Halite Formation, was characterized by postdepositional textures indicating both brine-controlled mineral migration (early karst) and gravity-induced plastic flow especially in the sylvinite bed (Fig. 11.51). From core studies related to mine definition, Stewart (1965) estimated that the sylvite (or at least 50 % of it) in the Boulby Potash zone was derived from carnallite. This interpretation was based upon the presence of abundant halite pseudomorphs after carnallite in one core, with lesser, but still considerable volumes of similar pseudomorphs seen in each of the other three cores he examined.

Bromine analyses appear to further indicate that the Boulby sylvite was formed from carnallite (Garrett 1995). It seems that the carnallite was converted to sylvinite soon after deposition, since there is no evidence of the overlying sediments settling or being distorted by the carnallite-to-sylvite volume change. There is a distinct red halite zone in the underlying Boulby Halite, where perhaps red carnallite was converted to sylvite and then, because of a period of shallow subsurface epsomite leaching, the associated sylvite was also fractionally dissolved, leaving the zones of red halite with associated red halite-cemented caverns in the host halite. This leaching and alteration must have occurred soon after deposition because of the Upper Halite's relatively undisturbed bedding planes and structure. Calcium and magnesium-containing brine also seeps from cuts in the halite bed at the access level in the mine (below the potash level), further indicating the early removal of the last traces of kieserite by precipitation with shallow-burial dolomite conversion brines.

Deformation of the potash bed is ongoing today and has led to a number of mining problems over the years, exacerbated by high temperatures of 40 °C or more at the deepest workings (≈1,200–1,300 m below land surface), and the occurrence of local highly pressurised nitrogen gas pockets in the salt. Past mine problems include one gas blowout (in 1976) with sufficient pressure to turn a continuous miner onto its side and the need to cope with the inherently unstable geology of the salt-clay head to the mine workings. However, the high-grade of the ore, its relative simple mineralogy (no sulphates) and low dips even though halokinetic (Fig. 11.51) make processing straightforward and so the

deposit is economic. The virtual absence of magnesium minerals is particularly relevant to economic processing of the ore stream.

Locally, clay content in a projected ore zone can be anomalously high due to a combination of halokinesis and karst, which can exert a major detrimental effect on ore grade, as do unexpected elevated levels of anhydrite, magnesite, pyrite, quartz and boron minerals, which together can locally exceed 15 %.

The Carnallitic (Rotten) Marl Formation of the Staintondale Group, composed primarily of dehydrated clay minerals and halite, overlies the Boulby Halite Formation. As the name implies the Rotten Marl is a "salt-clay" bed. It tends to be structurally incompetent as it lacks any significant cementing mineral binding the soft clay. The bed is further weakened in some parts of the mine area by steeply dipping discontinuities created by a combination of flow and dissolution features. It must be well characterised before mining can proceed safely. A minimum of 1.5–2 m of salt in the mine back (roof) is maintained to ensure no significant roof collapse and the ore zone is always approached from below, not above. The Carnallitic (Rotten) Marl Formation sits in sharp contact with the overlying Upgang Formation, which in turn is overlain by the Upper Anhydrite Formation and Upper Halite Formation of the Zechstein Cycle 4 of the Staintondale Group. The Staintondale Group is in turn overlain by more than a kilometer thick Upper Permian and Triassic marine and continental clastic sediments, which include highly pressurised brines in sands of the Triassic Sherwood Formation, a unit which required expensive specialised linings when the shafts were first sank to enter the ore level (Fig. 11.49).

The Boulby potash zone is worked using a variation of the room and pillar method. Ore is extracted from the rooms (potash panels) using "continuous miner" equipment, similar to that used in coal mines. Mine development work is carried out in relatively thick stable halite beds, located some 30 m below the potash ore. Ramps are then driven upward from the development roadway level into the potash zone, which is less structurally stable. Even the access roads are liable to instability due to high lithostatic pressures at these 1,000 m + depths, so long horizontal slots are cut into roadway walls for stress relief. Although the basic concept of roadway development in salt to access room-and-pillar potash panels was sound, determining the most efficient mining system proved difficult and it was not until 1984 that mining costs were sufficiently reduced to achieve profitability. By the mid-1990s, output had stabilized at 16,000 t/day – 2.8 Mt/year from 6 production sections. To cope with greater stresses in the ore below 1,200 m and to raise output above 3 Mt/year, in 2001 the miner-operator (ICL Fertilizers; Cleveland Potash) converted its continuous miners to remote-controlled operation (so they can be used safely without prior blasting and gas relief in shaly, gassy sections of the potash ore level).

New Mexico Potash, USA

Potash is mined from McNutt Member of the Salado Formation in the Carlsbad Potash District of the Permian Basin of New Mexico (251 Ma – Lopingian). Now largely depleted the area once produced more than 70 % the potash mined in the United States. Potash was first discovered in this region in the mid 1920s during drilling for oil and the first potash mine was opened in 1931. Various potash minerals occur in 11 ore zones numbered 1–11 (in ascending order) in a 215 m thick cyclic interval known as the McNutt interval located in the middle of the Salado Formation and atop some 400–700 m of halite (Fig. 11.52: Adams 1970; Lowenstein 1987b). Zone 1 is the richest, but is now exhausted. More recent production in the 1980s and 1990s was mostly from zones 3, 5, 7 and 10, where the proportion of langbeinite is higher but, in terms of conventional mining, these levels too are now largely depleted. The areal extent of the potash is both highly irregular and in some ore zones is patchy and scattered. The number of ore beds in a vertical section can vary considerably, and their shape and location is only roughly similar. This is so even within the 1,100 km^2 area underlain by shallow, high-grade ore and designated the "Potash Area" or "Carlsbad Potash District" in 1934 by the Secretary of the Interior (this is the area in New Mexico where oil and gas drilling is largely banned). It lies at the centre of a larger 140,000 km^2 area underlain by low grades of potash and centred on the towns of Hobbs and Carlsbad, New Mexico (Fig. 11.53a). Throughout the "Potash Area", the potash ore beds are relatively flat lying, making them amenable conventional mining targets. Beds can mildly-to-moderately undulate at the sub-km scale, and locally, at a scale of tens of metres or less, there can be gradual-to-steep displacement and folding in the targeted ore beds, related to dissolution and mineralogical transformation.

Major ore minerals are sylvite and langbeinite, with accessory leonite, kainite, carnallite, polyhalite, kieserite, bloedite, halite and anhydrite (Fig. 11.52). A typical ore in zone 1 ran 60 % halite, 30 % sylvite, 5 % langbeinite, and 2 % of polyhalite and insolubles. Langbeinite ore is produced from zone 4 and mixed sylvite-langbeinite from zone 5. For example, in the former IMC Global Inc operation (now the Mosaic Potash Facility), the ore on the 900 ft (275 m) level (zone 5) is primarily sylvinite with some langbeinite. The 260 m (850 ft) level ore is langbeinite (zone 4). The 244 and 213 m (800 and 700 ft) level ores are a mixture of the two. Currently, in a nearby operation at its "East Mine," Intrepid Potash produces muriate from sylvinite ore, and sulphate of potash -magnesia from langbeinite and MOP combinations.

The potash ores in New Mexico are $MgSO_4$ associations and lie above and immediately at times basinward of the older Permian basin margin, as defined by the position of the underlying Capitan Reef (Fig. 11.53a). This location corresponds to a likely surface depression and water sink at the

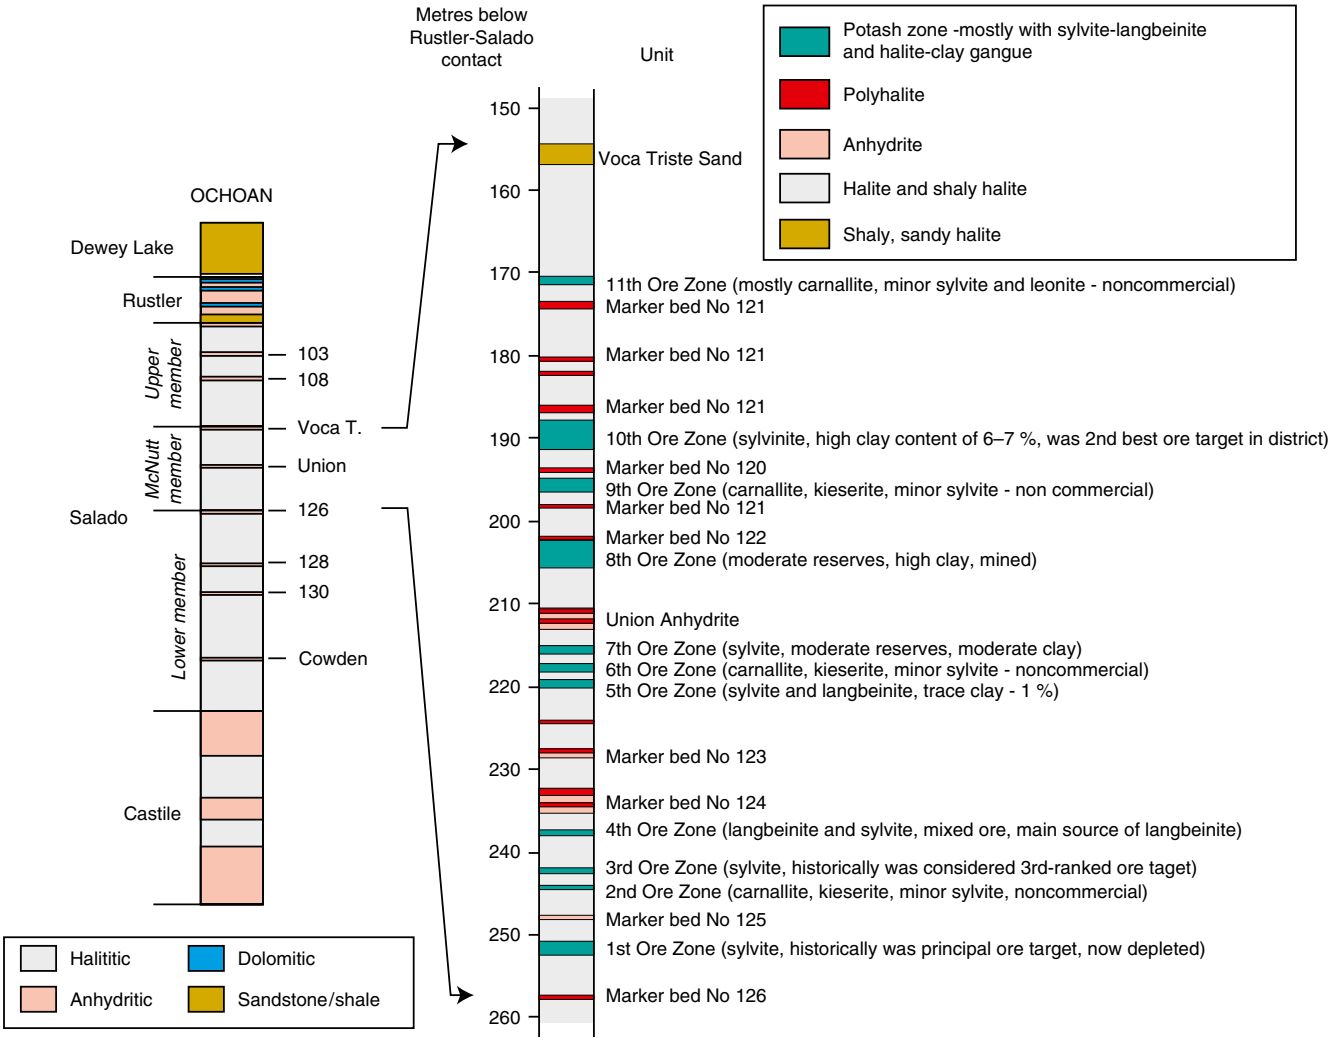

Fig. 11.52 Stratigraphy of the McNutt Potash zone in the Salado Fm, based on the main ore zone near Hobbs New Mexico (Comments on mineralogy from Griswold 1982)

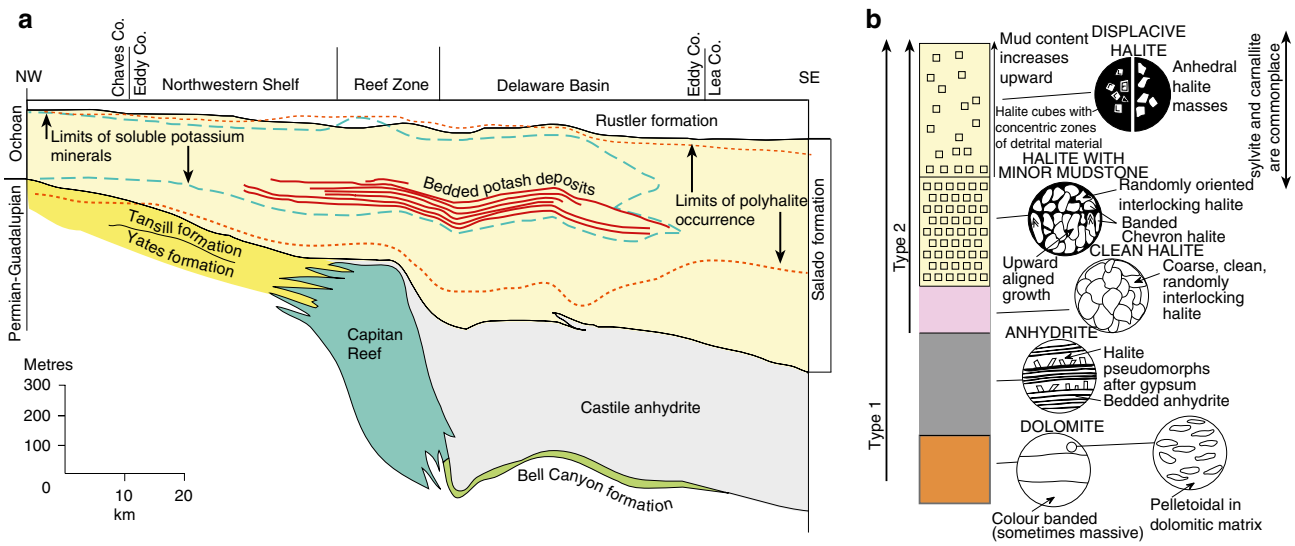

Fig. 11.53 Potash in the Carlsbad Potash District, New Mexico. (**a**) Stratigraphic section in southeastern New Mexico showing distribution of bedded potash (McNutt ore zone) about basin margin (After Bates 1969). (**b**) Idealised halite-dominated depositional cycles that host the ore beds (After Lowenstein, 1987b)

time of deposition. At the time the potash was emplaced, it was probably a zone of differential subsidence in the underlying sediment, located at the hinge between indurated platform edge carbonates and muddier basin-centre evaporites. It was also the spill point of the aggrading basin-filling evaporite cycles that make up the basinwide evaporites of the Castile and Salado formations as well as a focus for later upwellings of deeply circulated meteoric waters. The significance of fill and spill hydrology as loci of changes in evaporite mineralogy was discussed in Chap. 5 in Warren 2006. The nearby underlying Capitan Fm. reef crest acted as a focus to any subsequent rise of artesian or escaping basinal waters.

Two types of sedimentologic cycles dominate ore zones in the Carlsbad Potash District (Fig. 11.53b; Lowenstein 1987b). Type I cycles begin with mixed siliciclastic carbonate (magnesite) mudstone, followed by anhydrite-polyhalite with gypsum crystal pseudomorphs, overlain by halite and capped by muddy halite. Type II cycles begin with halite that grades transitionally upsection into muddy halite and pseudomorphs after gypsum, which retain subaqueous bottom-aligned growth habits or mechanically deposited sedimentary structures (ripples, cross beds, etc.). In the anhydrite-polyhalite parts of the cycles there are many pseudomorphs of primary gypsum textures that are now replaced by anhydrite, polyhalite, halite or sylvite. Sylvite and carnallite are most common in the muddy halite parts of the cycles where they occur as millimetre- to centimetre-sized anhedral crystals.

Both blood-red sylvite and the purple carnallite colours in the ore zones come from micrometre-sized plates of hematite (Sonnenfeld 1995). The same potash crystals may be internally zoned; with dark hematite-rich bands developed at the crystal rims, and progressively lighter bands, depleted in hematite, in the cores of the crystals. Ore zones are hosted in stacked halite beds, up to 1 m thick and contain up to 50 % sylvite and carnallite. Thin sections of the ore show poikilitic textures, with several halite crystals encased in single carnallite or sylvite crystals. The sylvite and carnallite occupy areas equivalent in size and shape to the void spaces in modern saline pan halites and are interpreted as pore-filling cements (Lowenstein and Spencer 1990).

Given that Quaternary halite beds lose porosity by 100 m depth, it is likely that the bulk of the stratiform potash ores within the McNutt potash zone were emplaced syndepositionally or very early during shallow burial. A study of the ore emplacement temperatures using brine inclusions in chevron halite near sylvite in a number of primary textured zones shows that the bulk of the crystals formed at temperatures ranging upward from 30 °C (Fig. 11.54a, b). Lowenstein and Spencer (1990) suggest that the ore-hosting halite crystallized from warm surface brines rich in KCl and that syndepositional cooling of these brines just below the surface achieved supersaturation with respect to sylvite. They concluded that the Salado sylvite did not form by incongruent dissolution of carnallite. Others have suggested that the widespread langbeinite with carnallite and the associated discontinuities in the ore beds, along with evidence of early karst features, implies that warm (>55–60 °C) geothermal brines where present at or soon after deposition of the primary salts (Fig. 11.54b; Garrett 1995).

Harville and Fritz (1986) document textures in three cores from two of the high-langbeinite beds in the third and fourth ore zones. In two of the three cores, the langbeinite conversion from sylvinite was essentially complete, but in one considerable sylvinite remained, probably because of reduced brine circulation. In one core some early diagenetic kainite was formed, typically as a rim to langbeinite, implying it formed as residual brines cooled. In all cases the adjacent anhydrite was converted to polyhalite, and the langbeinite crystal size was large, as would result from slow, intruding brine crystallization rather than primary langbeinite. We shall return to this topic of the relative importance of incongruent dissolution versus primary precipitation of carnallite verses primary sylvite as an ore-forming set of processes later in the chapter.

That the ore is early is reinforced by an argon date of 250 ± 0.6 Ma for deposition obtained from langbeinites in the McNutt ore zone, with subsequent local recrystallization events at 245 and 94 Ma (Renne et al. 2001). Like their more recent analogs, this Permian Salado potash precipitated as stratiform units in depressions in a saltern to mudflat terrain subject to exposure and shallow karsting in bedded halite beds. Much of the initial ore precipitation was driven by cooling of warm refluxing shallow brine. Later in its burial history the ore zones were subject to recrystallization from fluid crossflows (descending or ascending), most likely driven by local or region tectonic events. This explains the irregular distribution of the stratiform Carlsbad potash salts and a general lack of fine original texture in halite hosts, which away from the ore zone still retain the original chevron halite texture. It is also why the stratiform Salado potash zone ores usually cross depositional boundaries in the primary halite beds (Fig. 11.53a).

Upper Kama Potash Region, Cis-Urals Russia

The largest potash occurrence currently mined in Russia is in the Upper Kama Basin in the Perm region of Russia, some 250 km north of the town of Perm, adjacent to the Kama River and the Ural Mountains. This deposit is second in size only to the Saskatchewan deposits in Canada (although perhaps also smaller than the under explored Nepskoye potash district in Siberia to the west). In Russia the region is often called the Ural or Verkhnekamskoye potash ore district (Kovin 2011). The potash is part of the Iren Fm (Kungurian-

(**b**) Temperatures of dissolution of sylvite daughter crystals in 119 primary fluid inclusions in chevron halite from ore zones that contain sylvite (After Lowenstein and Spencer 1990)

Permian) and covers about 3,000 km^2 near the shallow edge of a somewhat larger megasulphate basin that is the upper part of Cis-Ural Trough (Figs. 11.55 and 11.56a, b). In the potash ore district there are 13 potentially mineable beds at depths of 200–500 m. Ground collapse and water influx are ongoing environmental problems in areas of the Kama Basin where the exploited intervals are within a few hundred metres of the landsurface; as seen in the Solikamsk 2 mine collapse in 1995 and the collapse in the 3rd Berenzki mine in 1986 (Chap. 13; Whyatt and Varley 2008).

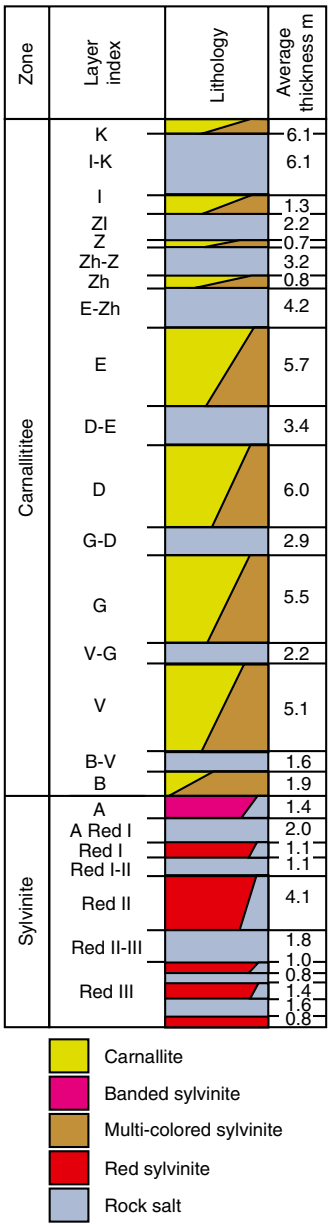

Fig. 11.55 Stratigraphic subdivision of the potash zone (After Kudryashov 2001)

Historically, the deposit's major extraction areas have been centred about the towns of Solikamsk, Bereznki and Romanovo. Annual capacity in the region is around 850,000 t/year and total mineable reserves are thought to be in excess of 3.8 billion tonnes (Fig. 11.2). The two largest potash producers in the area, both semi-privatised state enterprises, merged in 2011 to create a US$ 15 billion enterprise. The Joint Stock Company (JSC) "Uralkali", headquartered in city of Bereznki, operates in the southern part of the potash deposit, and the Joint Stock Company "Silvinit", headquartered in Solikamsk, operates in the northern area.

The Upper Kama potash deposit lies in central part of the Solikamsk (Solikamskaya) depression of the Pre-Ural foreland basin. This horizontally bedded evaporitic formation, up to 500 m thick, is composed predominantly of halite with substantial interbedded sylvinite, carnallite, clay, and anhydrite layers (Fig. 11.55). Regionally, the lower rocksalt is 250–400 m thick and is overlain by the potash-hosting sequence with a thickness of 30–125 m (Figs. 11.55 and 11.56c; Mayrhofer 1985). The Iren Fm. evaporites were deposited after the rise of the Ural Mountains in the late Carboniferous as a result of the continental collision between the East-European platform and West-Siberian plate (Kovin 2011). The evaporite formation is underlain by 2–3 km of clastic Proterozoic rocks, a Devonian reef sequence, a dominantly carbonate Carboniferous sequence, and Lower Permian sediments of up to 1 km in thickness. The Lower Permian molasse (flysch) wedge, consisting of conglomerate, sandstone and argillite beds, underlies the eastern part of the potash deposit (Fig. 11.56b). The uppermost 80–120 m of evaporite formation contains economic deposits of potash salt, which include 13 sylvinite and carnallite mineable beds and interbed halite layers.

The potash zone overlies a thick halite deposit and most recovered ores are medium grade (16–23 % K_2O). Four sylvite-rich beds (referred to as A, Red I, Red II and Red III) in the lowest part of productive strata are the principal mineable beds with typical ore grades in the medium quality range of 16–23 % K_2O (Kovin 2011; Figs. 11.55 and 11.56c). Nine carnallite beds (namely B, V, G, D, E, Zh, Z, I, K) along with halite interlayers lie on top of the 4 beds of the sylvinite layer and form a carnallite zone that ranges in thickness from 38 to 80 m. A halite layer some 20 m thick, termed the overlying rock salt, covers the potash beds, unless breached or dissolved (Kudryashov 2001). The Middle Permian terrigeneous-carbonate complex with multiple aquifer layers overlies evaporites. This aquifer system typically overlies and locally penetrates the evaporite strata with water pressures of up to 3.5 MPa, while the ore deposit depth varies from 75 to 450 m (Mayrhofer 1985).

Six of the thirteen potash beds are intermittent over 15–35 % of this area, and the principal bed that is mined, Red (KrII), has now been depleted across significant portions of the defined ore district. The ore zone dips to the west and is lost via complete dissolution to the east along a halite basin edge that has captured the Glukhaya Vil'va River (Fig. 11.56b). Even so, the remaining mineable reserves of K_2O in the ore district are still estimated to be in excess of two billion tonnes. Regionally within the Upper Kama basin there is a general tendency for the potash zone to contain 5–13 % more KCl to the south than in the north, and 1–1.5 % more KCl in the east than in the west at Solikamsk, and 5–6 % more in the east than in the west in the southern district (Garrett 1995). For example, the four beds of the Red II layer near Solikamsk average 5.2 m with 23 % KCl, and the

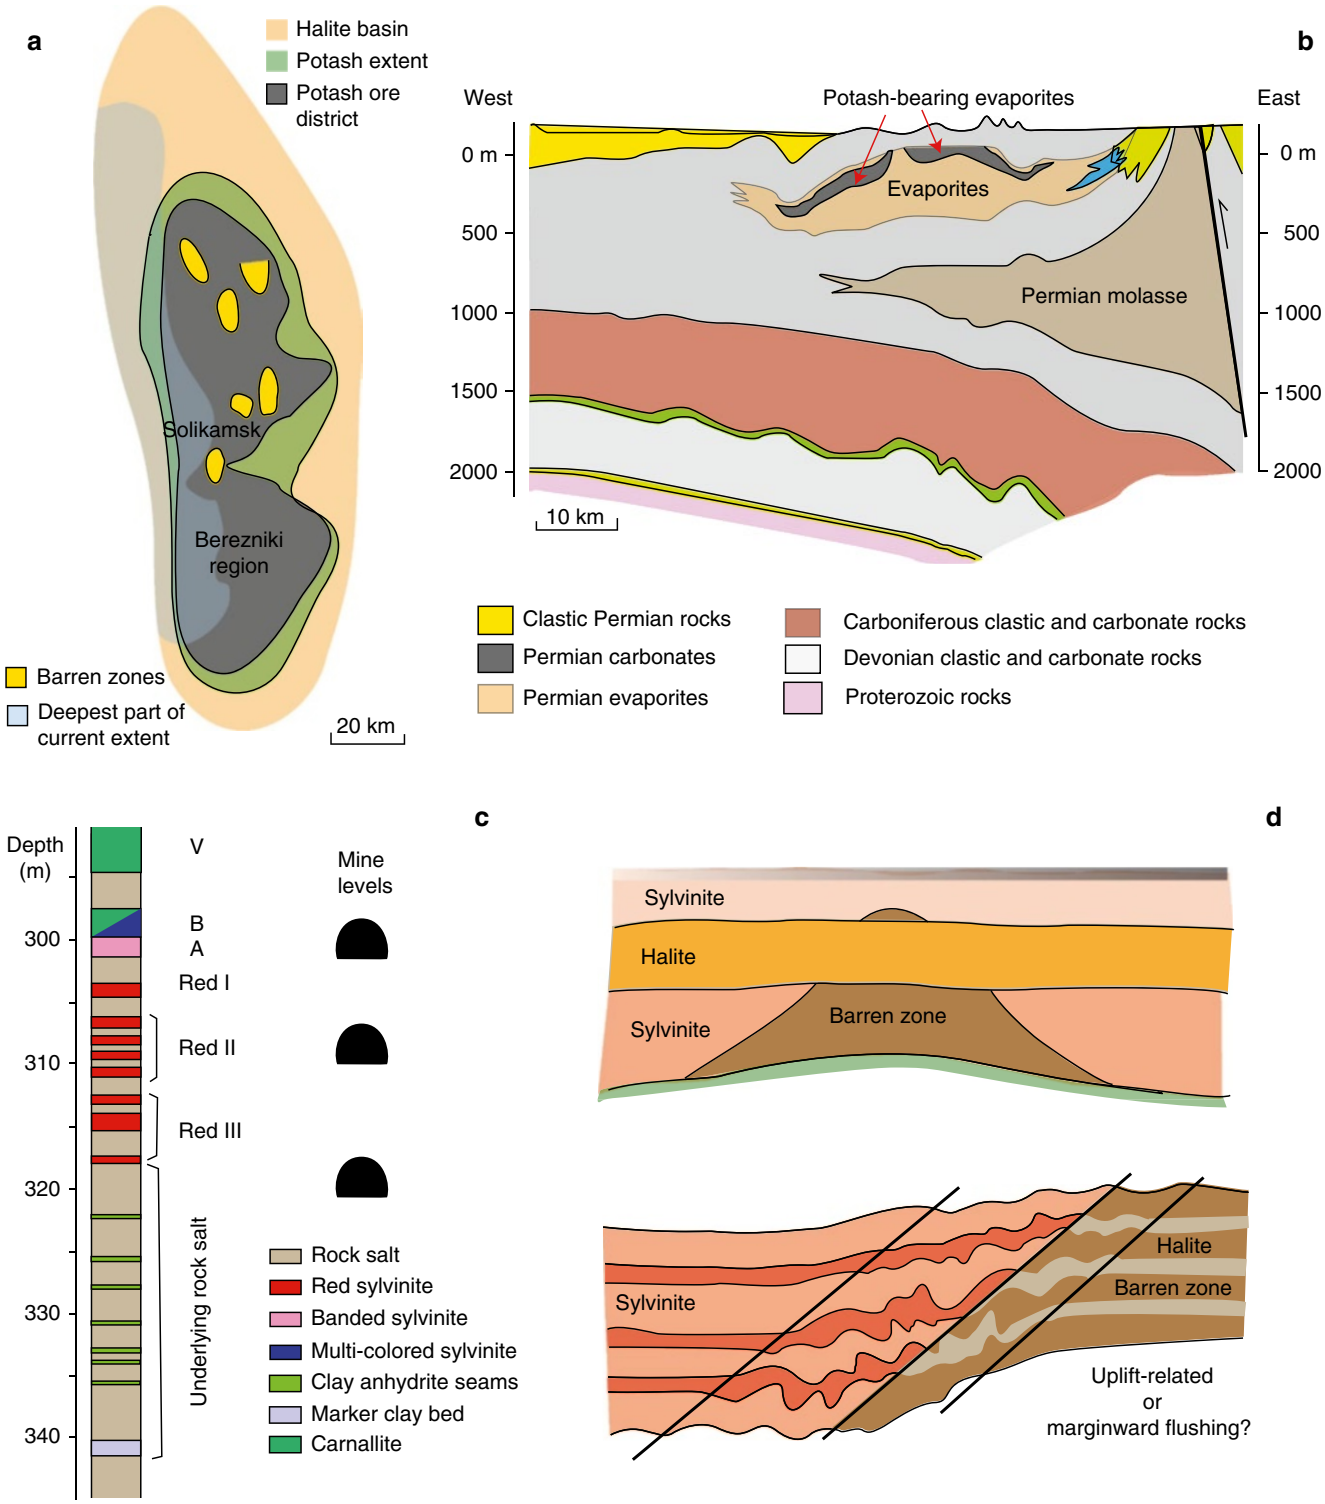

Fig. 11.56 Potash distribution and style in the Kama Basin, Cis-Urals, Russia. (**a**) Map of halite basin extent (**b**) East-west cross section showing control on faceies exterted by Urals suture. (**c**) Ore zone stratigraphy. (**d**) Geometries of barren zones (After Kovin 2011; Tret'yakov 1974; Garrett 1995)

A layer averages 1.4 m with 29 % KCl, while near Bereznki the comparable figures are 4.8 m and 32 % KCl, and 1.5 m and 43 % KCl respectively (Fig. 11.55; Garrett 1995).

The upper part of the potash deposit along with the overlaying marl, halite, clay, anhydrite, gypsum and carbonate beds of the transitional series is left un-mined to form a water

protective barrier above the mine. The average thickness of impermeable strata is 70–90 m. Insolubles are present in the ore succession, mostly as thin centimeter-scale parting seams composed of clay and anhydrite. The 1–2 m thick carbonate clay layer (referred to as "Marker Clay") located in the underlying rock salt, some 20 m below sylvinite zone, is the most stable stratigraphic marker at the Upper Kama deposit (Kudryashov et al. 2004).

Most of the historically mined beds have very gentle dips of from 0 to 4°, but folds do occur, influencing continuity of strata, as do occasional cavities and numerous barren zones (Fig. 11.56d). For example, folds in bed V have been found between 2 and 9 m in height, with a width of 8–30 m and length of 50–150 m (Garrett 1995).

The salt roof to the ore zone, averaging about 25 m, is a sometimes entirely sub-eroded. In its place is an alternating sequence of originally existing rocksalt, now mostly sub-eroded, and claystone, which changes substantially in thickness (0–80 m). This then passes up to the upper Kungur member, a lime-sand and clay-sand stratum, which is about 25 m thick. Within the mined potash beds, small quantities of trapped brines occur frequently, and there are locally significant quantities of methane and hydrogen. There are also brine-filled poorly documented disturbances in the uppermost portions of the saline formations, the watery residues from former poorly-controlled long-term solution mining of rock salt in the Soviet era (see Chap. 13; case histories). Patchy distribution of highest-grade ore, and abrupt lateral transitions are reflective of the shallow nature of the ore zone across the district, so that controlling water entry and preventing or minimising salt-karst related collapse are ongoing problems.

As previously noted, there are major zones of ore impoverishment in the Kama deposit, and the two most common styles are illustrated in Fig. 11.56d. Tret'yakov (1974) considers them to have been formed in; (1) Regions of the basin that were structurally higher during or soon after the potash deposition or perhaps located in zones that were more severely leached when the basin was reflooded, or (2), Areas where there has been later fault or karst-related fluid movement, allowing intruding formation waters to enter the deposit and leach the potash, replacing it with halite. In these barren zones the bedding planes are often missing, and the structure is that of recrystallized salt similar to the salt horses of New Mexico and Carlsbad (Tret'yakov 1974). Garrett (1995) noted that the sylvinite is thought to be richer in the areas of the deposit where there was no syndepositional subsidence (or there was even a slight upwarping), and less rich where settling (or downwarping) occurred during deposition.

The Upper Kama deposit has been subjected to major compressive regional tectonic, gravitational and mining induced forces. Extensive folding of variable amplitudes and wavelengths is characteristic of evaporite formation of the Upper Kama deposit (Kovin 2001). Predominantly, tectonic movements in the adjacent orogens governed the folding deformation of the evaporite, so that the main folds in the Upper Kama potash deposit have submeridianal orientations, perpendicular to principal lateral E–W tectonic stress caused by the Uralian Orogen. Locally, a superposition of a major tectonic stress and stress from the faults and numerous uplift structures leads to deformation reorientation or overlapping the deformational structures with different trends (Fig. 11.56d). Because of their inherently high plasticity, brittle deformation is not common in the potash zones, but occurs locally when tectonic, gravitational or mine induced stress exceeds the strength of the rock mass.

A number of discrete natural fractures and fracture systems of various scales have been observed, especially in the central part of the Upper Kama deposit. Most of these fractures are effectively healed and can be visually observed only in the non-annealed clay–anhydrite layers. Open fractures are encountered mostly in the sylvinite–carnallite zone. They usually develop with meridianal and NW–SE direction. The most intense deformations are seen in the carnallite zone, where very steep folding, tectonic brecciation and blocks of interbed rock salt are present (Kovin 2011).

Canadian Maritimes (Mississippian of Nova Scotia and New Brunswick)

The Carboniferous geology of the Maritime Provinces and Quebec is characterised by a series of northeast trending fault-bound grabens or half grabens containing clastics and evaporites (mostly halite) up to 10 km thick (Roberts and Williams 1993). The Windsor Group (Visean) in Nova Scotia and New Brunswick hosts $MgSO_4$ -poor potash evaporites of the Cassidy Lake Formation in several continental intermontane basins that were created by extension-driven post-Acadian strike-slip faulting with the salt then subject to halokinesis first by extension and then subsequent compression. The same evaporite unit that hosts the potash ore also acts as a seal to MVT deposits at Gays River and Jubilee (Fig. 11.57).

Salt deposits were first utilized in the Sussex area in the early 1800's when area residents tapped local salt springs, dried the brine to produce halite, which they then used in food preservation. Exploitable subsurface potash at New Brunswick near the town of Sussex was discovered in the 1970s by the New Brunswick Mineral Resources Branch of the Geological Survey, with the first intersection occurring in 1969–1970 during a drilling program designed to define a halite resource suitable for hydrocarbon storage. Two mines were built near the town, one in Penobsquis (aka Sussex Mine), 8 km east of Sussex, and another at Cassidy Lake (aka Potocan Mine or Clover Hill Mine), some 10 km

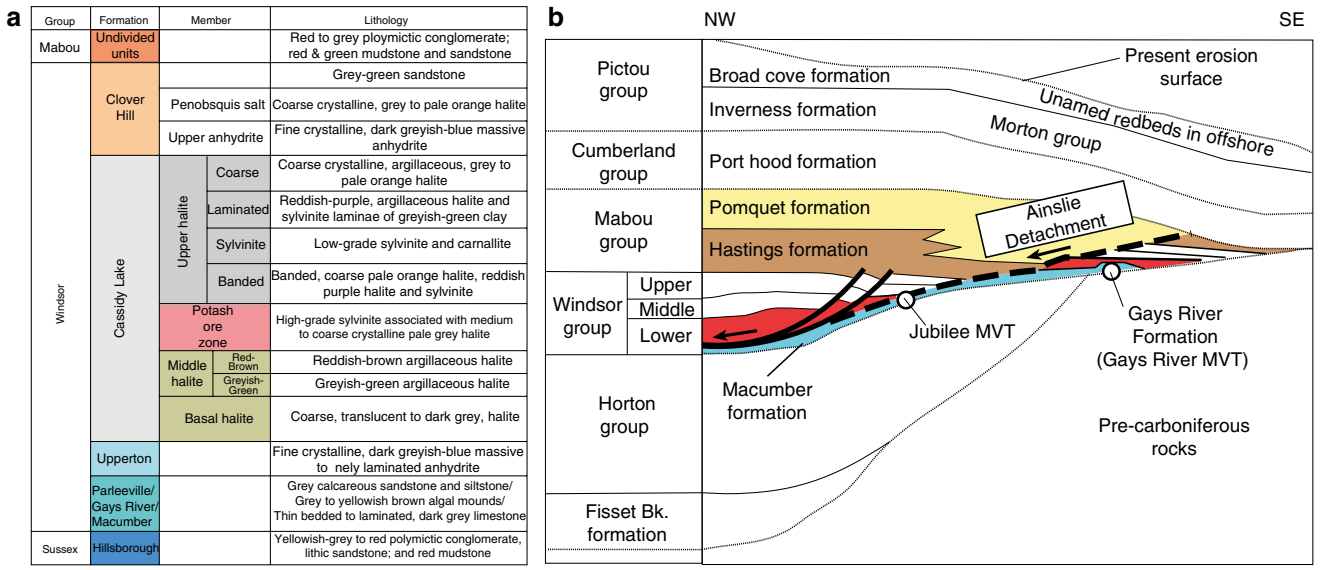

Fig. 11.57 Potash in the Cassidy Lake Formation of the Lower Windsor Group, New Brunswick and Nova Scotia. (**a**) Cassidy Lake Fm and Potash ore Stratigraphy (After Wilson et al. 2006). (**b**) Schematic cross-section of the stratigraphy and position of the regional Ainslie Detachment, in Nova Scotia, a major allochthon feature associated with salt flow and gravity gliding into the basin. Lubricating evaporites of the lower Windsor Group (Carrols Corner Formation) are shaded grey. Note the salt raft tectonics geometry with thickening of the Mabou Group in the salt-withdrawal sink. Jubilee-style base metal deposits are hosted in the salt tectonites created by the detachment. In contrast, the Gays River-style of deposit is formed at the evaporite-encased underbelly contact adjacent to the salt-encased reefal buildup. In the case of the Jubilee deposit it was focused by the feather edge of the salt unit (After Lynch et al. 1998; Warren 2000b)

southeast of the town of Sussex. Following creation of the Penobsquis Mine under the auspices of Potash Corporation of America, the Port of Saint John potash shipping terminal was constructed and potash was first shipped from New Brunswick in 1983.

The Penobsquis Mine continues in operation to the present time under the ownership of PotashCorp, which acquired the project from PCA in 1993 and until the first half of 2014 produced potash at a rate of over 700,000 tonnes per year. Cassidy Lake mine was brought into production in 1985 by Denison Mines Ltd. and Potash Company of Canada and actually outproduced the Penobsquis Mine, attaining an annual production rate of around one million tonnes of potash per year. However, massive underground flooding caused the permanent closure of the mine in 1997. In 2002, drillers for natural gas intersected another major potash deposit near Penobsquis, presently known as the Picadilly Deposit. PotashCorp has developed Picadilly to the point where a major mine is under development with production scheduled to beginning in second half of 2014. Due to lower potash prices in the second half of 2013, PotashCorp will cease production at its Penobsquis mine sometime in 2014 as it focuses future activities in the Picadilly mine and the nearby wet mill.

Of particular interest for potash extraction in New Brunswick is the Cassidy Lake Formation of the Moncton Sub-basin (Fig. 11.57a). It entrains structurally complex potash ore and, with variable dips ranging to subvertical and ore thicknesses ranging from 0 to 45 m, is much more deformed than the conventionally mined bedded potash occurrences of Saskatchewan (Fig. 11.58). Seismic and borehole evidence from the Windsor Group shows that the Cassidy Lake Formation (rock salt and potash) is separated from the underlying Upperton Formation (anhydrite) by a low-angle décollement surface marked by the presence of mylonitic salt and cataclastic limestone and anhydrite. Much of the halokinetic deformation occurred above the regional décollement separating the Cassidy Lake Formation from the underlying Upperton Formation. Deformation was syntectonically mobilised by gravity sliding, thrusting and folding atop the regional décollement surface, with the most intense deformation being taken up in the highly deformable sylvinites. Flow has been complex within the salt body itself, resulting in structural repeats of the salt stratigraphy through recumbent to inclined isoclinal folds and sheath folds (Fig. 11.58).

The Potash Ore Member in the Cassidy Lake Formation consists of cm-scale beds of halite and halite + sylvite and minor rinneite and polyhalite. The exploited ore is sylvinite, running 20–30 % K_2O with 0.5–5.0 % insolubles. Grade at Penobsquis is around 26 % K_2O and 28 % K_2O at the former Cassidy Lake mine. The Upper Halite Member atop the potash ore is between 2.5 and 20 m thick and composed of interlayered thin beds and laminae of argillaceous halite, sylvinite and claystone-anhydrite (Anderle et al. 1979). Because of structural thickening in this halokinetic salt, it entrains what is perhaps the thickest exploited bed of KCl salts in the world in a domelike anticline fold with a highly complicated

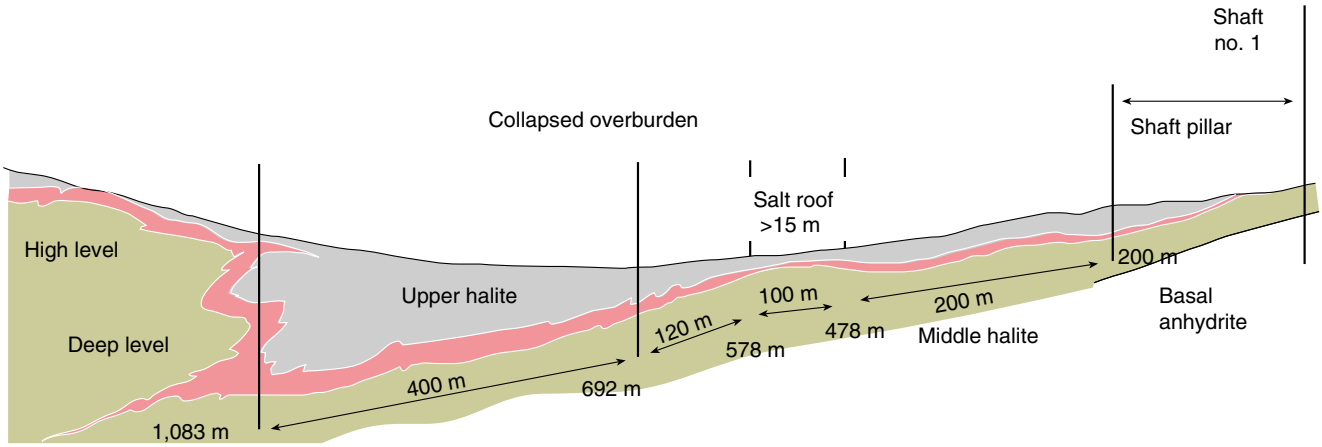

Fig. 11.58 Distribution of sylvinite ore zone (*pink*), encased in halokinetic halite an anticlinal structure in a New Brunswick potash mine. See Fig. 11.57a for stratigraphy

internal structure dominated by isoclinal and sheath folds (Roberts and Williams 1993).

The depth to ore in this structure ranges from 580 to 850 m below the surface and in thickness the ore zone ranges from a few metres to 30 m. The variable inclination and thickness of the ore zone means mining procedures are more variable than those used in extracting potash from the Prairie Evaporite. In intervals where the ore zone is relatively flat, continuous front procedures are used, similar to Saskatchewan. Where the ore zone is more steeply inclined, classic drill and blast techniques are used to extract the ore.

Salt, not potash, is the main product from Pugwash Mine, Nova Scotia, within equivalent age evaporites, but the operations in the halite show a similar structural complexity in the salt to the New Brunswick operation. Fig. 11.59 shows a refolded fold in the Pugwash Mine: the axial plane of the initial antiform (axial trace 1) was folded and the nose (axial trace 2) of the resultant synform was folded (axial trace 3). The axial planes of each of the folds have the same axial orientations as the axial plane traces of the other two clearly demonstrating an inherently high degree of plasticity during deformation (Evans 1967).

Borates are commonplace coprecipitates in particular horizons in the Cassidy Lake Formation: for example, danburite occurs in the Basal Halite; while boracite, hydroboracite, szaebelyite, hilgardite and ulexite are found in the Upper Salt Member of the Windsor Group (Roulston and Waugh 1981). Where the Clover Hill Formation overlies the Cassidy Lake Formation the contact is typically a thin "residual" bed made up of laminated clayey anhydrite, borates and quartz grains. It is not a depositional contact but the result of ongoing post deformational "sub-rosion" at the evaporite-nonevaporite interface, similar to that documented at the upper and lower contacts of the Maha Sarakham Fm. in Thailand.

In 1997, Potocan was forced to close the 890,000-t mine at Cassidy Lake, because of flooding related to intersection

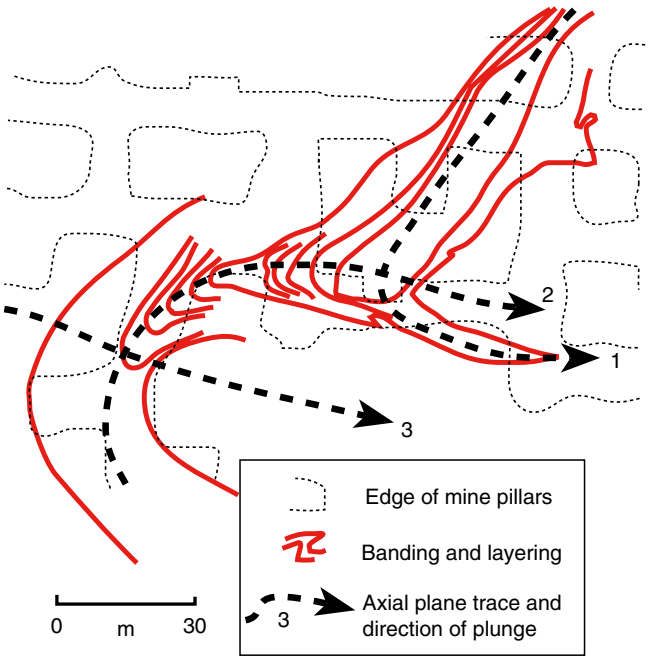

Fig. 11.59 Refolded fold in sylvite-halite, Pugwash Mine, Nova Scotia (After Evans 1967)

of an unexpected salt "horse." This leaves one conventional mine (Sussex Mine or New Brunswick Facility) currently exploiting the New Brunswick potash ore in this structurally complex region. Construction of two new shafts and an expanded mill is underway at the Sussex Mine and expected to double the current annual output by 2015 when it will become possible to produce more than two million tonne per year. There is also the possibility of a new mine in the Millstream area where there is a known 500 m thick halite with several sylvinite and carnallite intersections.

In 1998 Potash Corporation of Saskatchewan Inc. purchased both the Cassidy Lake and Sussex Mine

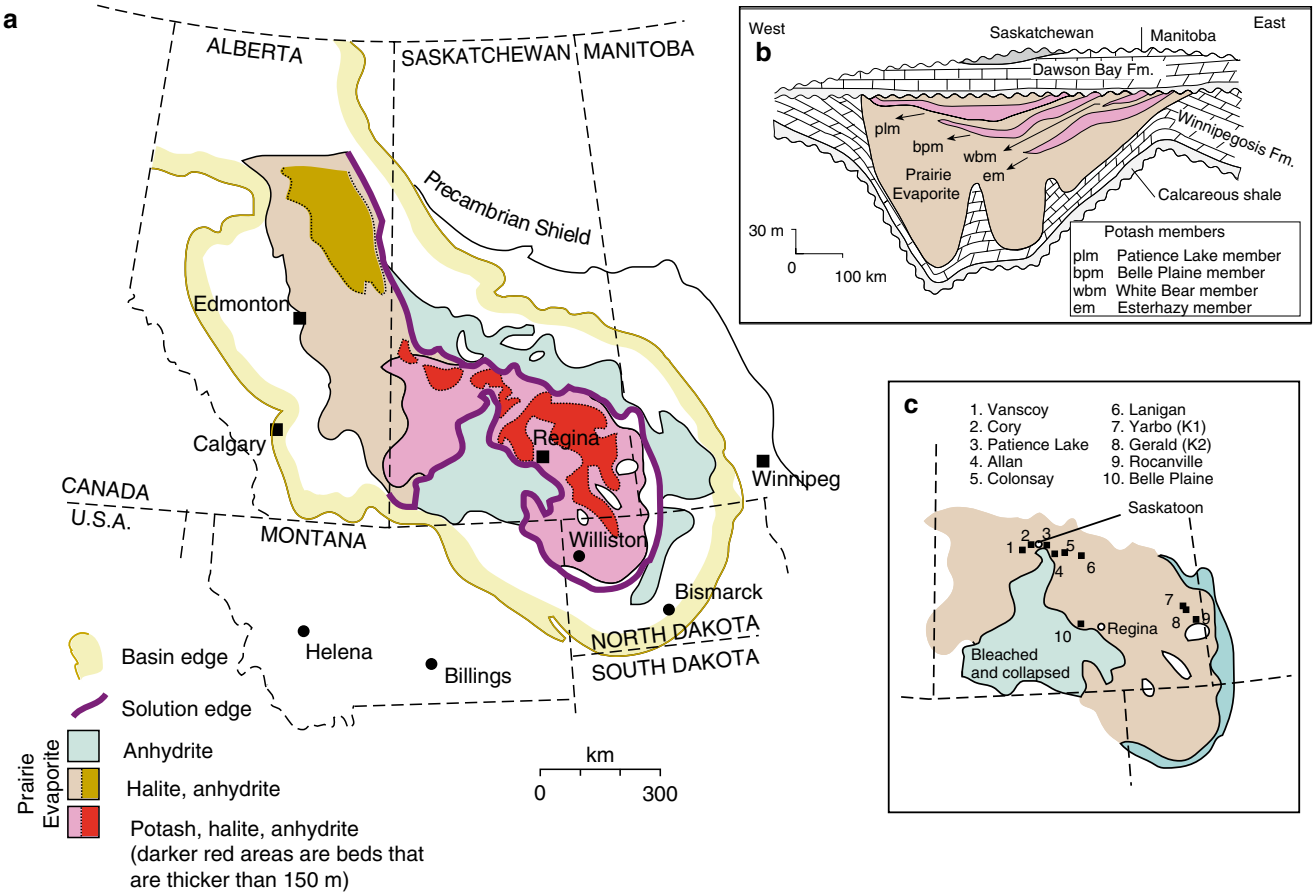

Fig. 11.60 Potash in the Elk Point Basin, western Canada. (**a**) Regional geology showing thickest salt and potash intervals in the Prairie Evaporite and its dissolution edge. (**b**) Cross section of basin showing distribution of potash members. (**c**) Map of potash mines in the basin (Compiled and modified from Worsley and Fuzesy 1979; Fuzesy 1982; Boys 1993)

properties – a flooded mine and a functioning mill. The flooded mine was renamed the Cassidy Lake Division of PCS. Today the Cassidy Lake mine acts as a brine storage facility for the nearby Penobsquis Mine. At the Cassidy Lake brine facility a small group of employees manage the company's brine pipeline to the Bay of Fundy. Each day some 300–350 tanker truckloads of brine from the Sussex mine arrive at the Cassidy Lake storage facility. The brine is a slurry of potash and brine that has been brought to surface to alleviate any water inflow problems in the Penobsquis Mine. The brine is pumped into slurry-holding lagoons where the brine is taken off and pumped via a pipeline into the Bay of Fundy near Giffin's Pond, south of St. Martin's.

West Canadian Potash (Devonian)

The Middle Devonian (Givetian) Prairie Evaporite Formation is a potash-entraining halite sequence deposited in the Elk Point Basin, an early intracratonic phase of the Western Canada Sedimentary Basin (WCSB; Chipley and Kyser 1989). It is the world's predominate source of potash. The flexure that formed the basin and its subsealevel accommodation space was a distal downwarp to, and driven by, the early stages of the Antler Orogeny (Root 2001). Devonian halite constitutes a large portion of the four formations that make up the Elk Point Group: (1) the Lotsberg (Lower and Upper Lotsberg Salt), (2) the Cold Lake (Cold Lake Salt), (3) the Prairie Evaporite (Whitkow and Leofnard Salt), and (4) the Dawson Bay (Hubbard Evaporite). Today the remnants of the Middle Devonian Prairie Evaporite Formation constitute a bedded unit some 220 m thick, which lies atop the irregular topography of the platform carbonates of the Winnipegosis Fm. Extensive solutioning of the various salts has given rise to an irregular thickness to the formation and the local absence of salt (Fig. 11.60a).

The Elk Point Group was deposited within what is termed the Middle Devonian "Elk Point Seaway," a broad intracratonic sag basin extending from North Dakota and northeastern Montana at its southern extent north through southwestern Manitoba, southern and central Saskatchewan, and eastern to northern Alberta (Fig. 11.60a). Its Pacific

coast was near the present Alberta-British Columbia border, and the basin was centred at approximately 10°S latitude. To the north and west the basin was bound by a series of tectonic ridges and arches; but, due to subsequent erosion, the true eastern extent is unknown (Mossop and Shetsen 1994). In northern Alberta, the Prairie Evaporite is correlated with the Muskeg and Presqu'ile formations. Hydrographic isolation of the intracratonic basin from its marine connection resulted in the deposition of a drawndown sequence of basinwide (platform-dominant) evaporites with what is a uniquely high volume of preserved potash salts deposited within a clayey halite host. The potash resource in this basin far exceeds that of any other known potash basin in the world (Fig. 11.2).

Above the Prairie Evaporite Formation is a series of cyclic Devonian limestones, dolomites and evaporites that make up the Dawson Bay, Souris River, Duperow and Nisku Formations. Together the Dawson Bay Formation and overlying Souris River constitute the informally named Manitoba group. The presence of the "Manitoba Group" above any potential mine is important as it entrains two halite beds: (1) the "Hubbard Salt," which is the uppermost bed of the Dawson Bay, and (2) the "Davidson Evaporite" composed of two halite beds separated by an anhydrite bed. Where present, the evaporites of the Manitoba Group form a flood protection zone, separating the Prairie Evaporite potash mining horizons from the water and brine aquifers present within the overlying Mesozoic sands. Its absence, especially of its halites, implies dissolution and removal processes have been active, so creating potential head and lateral stability difficulties in a conventional underground mine. Lying unconformably on the Dawson Group are the Lower Cretaceous sands of the Mannville Group, which are in turn overlain by younger Cretaceous shales and capped by Quaternary glacial sediments.

Potash Geology of the WCSB

Potash deposits mined in Saskatchewan are all found within the upper 60–70 m of the Prairie Evaporite Formation, at depths of more than 400–2,750 m beneath the surface of the Saskatchewan Plains. Within the Prairie Evaporite there are four main potash-bearing members, in ascending stratigraphic order they are: Esterhazy, White Bear, Belle Plaine and Patience Lake members (Fig. 11.60b). Each member is composed of various combinations of halite, sylvite, sylvinite, and carnallitite, with occurrences of sylvite versus carnallite definable with wireline signatures (once calibrated to core or mine control – Fig. 11.61; Fuzesy 1982). The Patience Lake Member is the uppermost Prairie Evaporite member and is separated from the Belle Plaine by 3–12 m of barren halite (Holter 1972). Its thickness ranges from 0 to 21 m and averages 12 m, its top 7–14 m is made up halite with clay bands and stratiform sylvite. This is the targeted ore unit in conventional mines in the Saskatoon and Lanigan areas and is the solution-mined target, along with the underlying Belle Plaine Member, at the Mosaic Belle Plaine potash facility. The Belle Plaine member is separated from the Esterhazy by the White Bear Marker beds made up of some 15 m of low grade halite, clay seams and sylvinite, The Belle Plaine Member is more carnallite-prone than the Patience Lake member (Fig. 11.61). It is the ore unit in the conventional mines at Rocanville and Esterhazy (Fig. 11.60b) where its thickness ranges from 0 to 18 m and averages around 9 m. In total, the Prairie Evaporite Formation does not contain any significant $MgSO_4$ minerals (kieserite, polyhalite) although some members do contain abundant carnallite. This mineralogy indicates precipitation from a Devonian seawater/brine chemistry somewhat different from today's.

As early as 1860, salt springs and seepages near the edge of the Elk Point Basin indicated the presence of widespread salt in Western Canada. Rock salt was first sampled in 1907, while potash beds were intersected in Saskatchewan in 1942 during the sinking of oil and gas wells. The potential of commercial grades of potash mineralisation was not recognized until 1946. Canadian potash deposits are among the richest and largest on earth, containing around five billion tons of ore in a mineable band up to 50 miles wide, which stretches some 725 km (450 miles) across the province (Fig. 11.60a). Canada today supplies more than 30 % of the world's annual potash production (Fig. 11.2).

The Prairie Evaporite Fm. is nonhalokinetic throughout the basin, it is more than 200 m thick in the potash mining district in Saskatoon and 140 m thick in the Rocanville area to the southeast. The Patience Lake member is the main target for conventional mining near Saskatoon. The Esterhazy potash member rises close to the surface in the southeastern part of Saskatchewan near Rocanville and on into Manitoba. This is a region where the Patience Lake Member is thinner or completely dissolved (Fig. 11.60b). Over the area of mineable interest in the Patience Lake Member, centred on Saskatoon, the ore bed currently slopes downward only slightly in a westerly direction, but deepens more strongly to the south at a rate of 3–9 m/km. Mines near Saskatoon are at depths approaching a kilometer and so are nearing the limits of currently economic shaft mining. The main shaft for the Colonsay Mine, which took IMC Global Inc. more than 5 years to complete through a water-saturated sediment column, finally reached the target ore body at a depth of 960 m. Such depths and a southerly dip to the ore means that the conventional shaft mines near Saskatoon define a narrow WNW-ESE band of activity (Fig. 11.60c). To the south potash is recovered from greater depths by solution mining; the Belle Plaine operation leaches potash from the Belle Plaine member at a depth of 1,800 m.

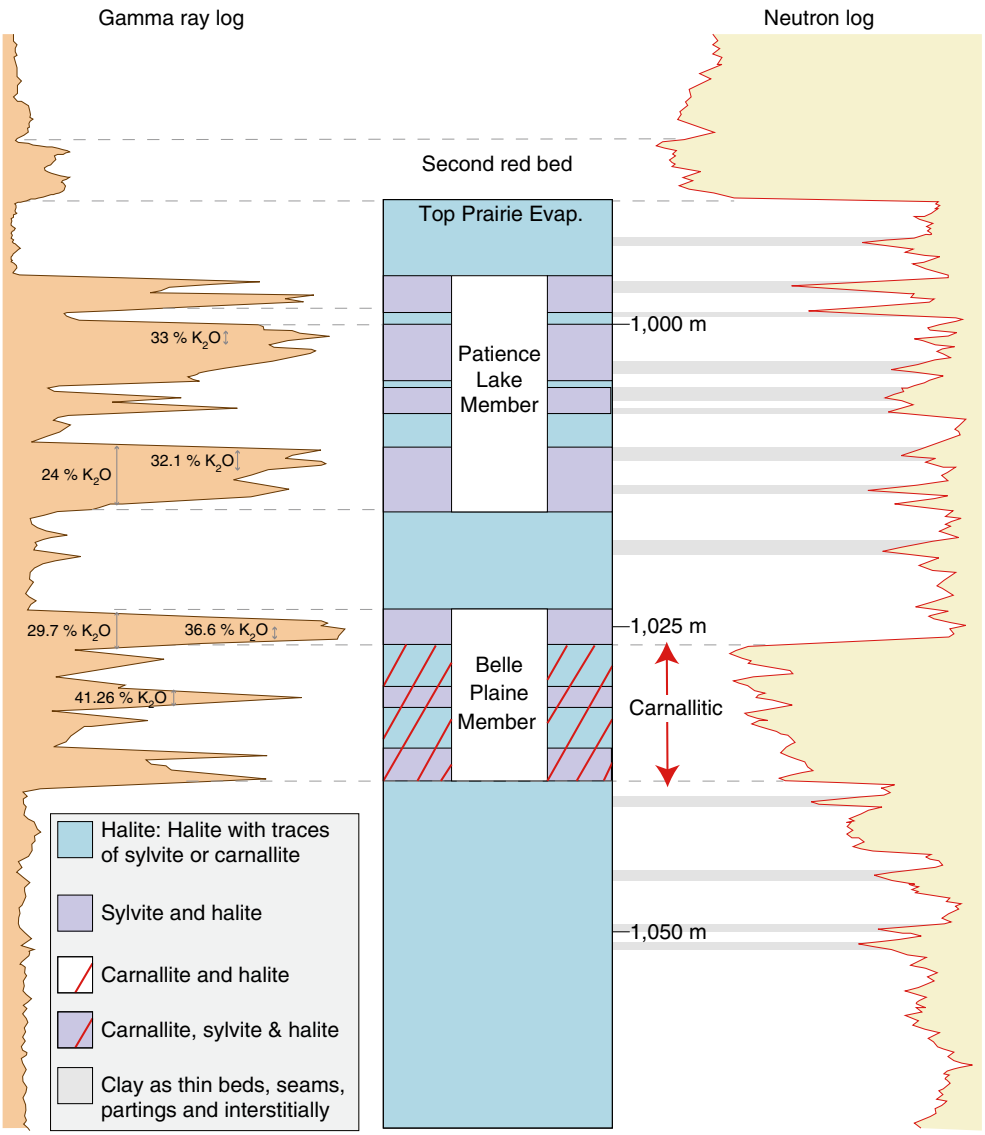

Fig. 11.61 Typical ore grades, thicknesses and wireline characteristics of the potash members in the Upper Prairie Evaporite (After Fuzesy 1982)

The Prairie Evaporite typically thins southwards in the basin; although local thickening occurs where carnallite, not sylvite, is the dominant potash mineral (Worsley and Fuzesy 1979). The Patience Lake member is mined at the Cory, Allan and Lanigan mines, and the Esterhazy Member is mined in the Rocanville area (Fig. 11.60c). Ore mined from the 2.4 m thick Esterhazy Member in eastern Saskatchewan contain minimal amounts of insolubles (≈1 %), but considerable quantities of carnallite (typically 1 %, but up to 10 %) and this reduces the average KCl grade value to an average of 25 % K_2O. The converse is true for ore mined from the Patience Lake potash member in western Saskatchewan near Saskatoon, where carnallite is uncommon in the Cory and Allan mines. The mined ore thickness is a 2.74–3.35 m cut off near the top of the 3.66–4.57 m Prairie Lake potash member. Ore grade is 20–26 % K_2O and inversely related to thickness (Fig. 11.62). The insoluble content is 4–7 %, mostly clay and markedly higher than in the Rocanville mines.

A typical sylvinite ore zone in the Patience Lake member can be divided into four to six units, based on potash rock-types and clay seams (Figs. 11.61 and 11.62a; M1–M6 of Boys 1990). Units are mappable and have been correlated throughout the PCS Cory Mine with varying degrees of success, dependent on partial or complete loss of section from dissolution. Potash deposition appears to have been early and related to syndepositional reflux. So it is cyclic, expressed in the repetitive distribution of hematite and other insoluble minerals. Desiccation polygons, desiccation cracks, microkarst pits and chevron halite crystals indicate that the Patience Lake member that entrains the potash ore was deposited in and just beneath a shallow-brine, salt-pan environment (Fig. 11.62b).

Clay seams form thin stratigraphic layers throughout the potash ore zone(s) of the Prairie Evaporite, as well as disseminated intervals, and constitute about 6 % of the ore as mined.

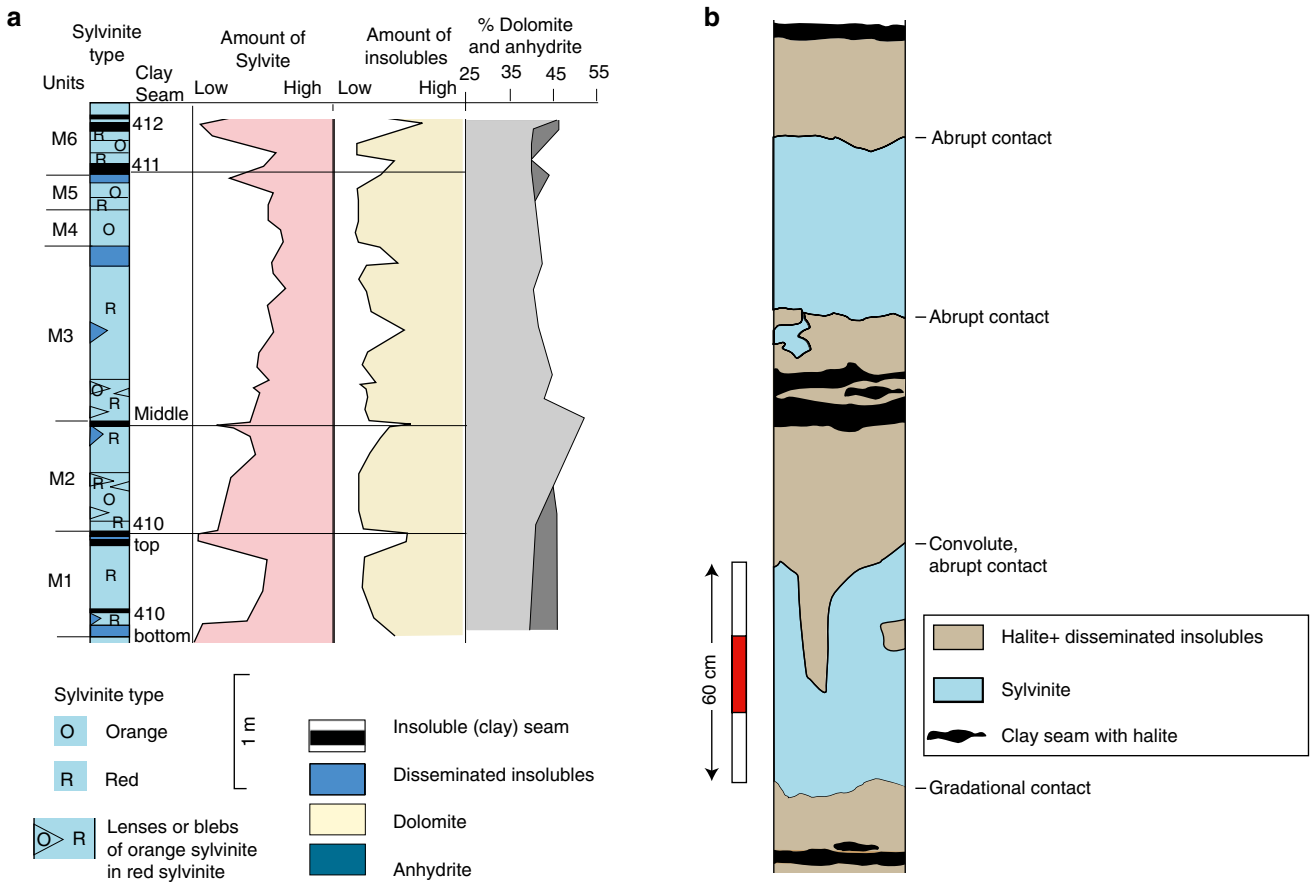

Fig. 11.62 Mineralogy and textures in the ore section in the Patience Lake member of the Prairie Evaporite Formation in the PCS Cory potash mine. (**a**) Typical mineralogy in cycles (units). (**b**) Contacts in two ore cycles showing early karst outlines (Redrawn and modified based on Boys 1990)

Insoluble minerals found in the PCS Cory samples are, in approximate order of decreasing abundance: dolomite, clay [illite, chlorite (including swelling-chlorite/chlorite), and septechlorite], quartz, anhydrite, hematite, and goethite. Clay minerals make up about one-third of the total insolubles: other minor components include: potassium feldspar, hydrocarbons, and sporadic non-diagnostic palynomorphs (Boys 1990).

Potash salts probably first formed as syndepositional secondary precipitates just beneath the sediment surface and were modified to varying degrees by ongoing fluid flushing in the shallow burial environment. The cyclic depositional distribution of disseminated insolubles was possibly due to a combination of source proximity and the strength of the winds blowing detritals out over the brine seaway. Possible intrapotash disconformities, created by dissolution of overlying potash-bearing beds, are indicated by an abundance of residual hematite in clay seams. Except in, and near, dissolution and collapse features, the secondary redistribution of insolubles, other than iron oxides, is insignificant.

Bedded halite away from the ore zones generally retains primary depositional textures typical of halite precipitation in shallow ephemeral saline pans (Brodylo and Spencer 1987). Crystalline growth fabrics, mainly remnants of vertically elongate halite chevrons, are found in 50–90 % of the halite from many intervals in the Prairie Evaporite. Many of the chevrons are truncated by irregular patches of clear halite that formed as early diagenetic cements in syndepositional karst.

In contrast, the halite hosting the potash ore layers lacks well defined primary textures. From the regional petrology and the lower than expected Br levels in halite in the Prairie Evaporite Formation, Schwerdtner (1964), Wardlaw and Watson (1966) and Wardlaw (1968) postulated a series of recrystallization events forming sylvite after carnallite as a result of periodic flushing by hypersaline solutions. This origin as a secondary precipitate is supported by observations of intergrowth and overgrowth textures (McIntosh and Wardlaw, 1968), large-scale collapse and dissolution features (Gendzwill 1978), radiometric ages (Baadsgaard 1987) and palaeomagnetic orientations of the diagenetic hematite linings associated with the emplacement of the potash (Koehler et al. 1997).

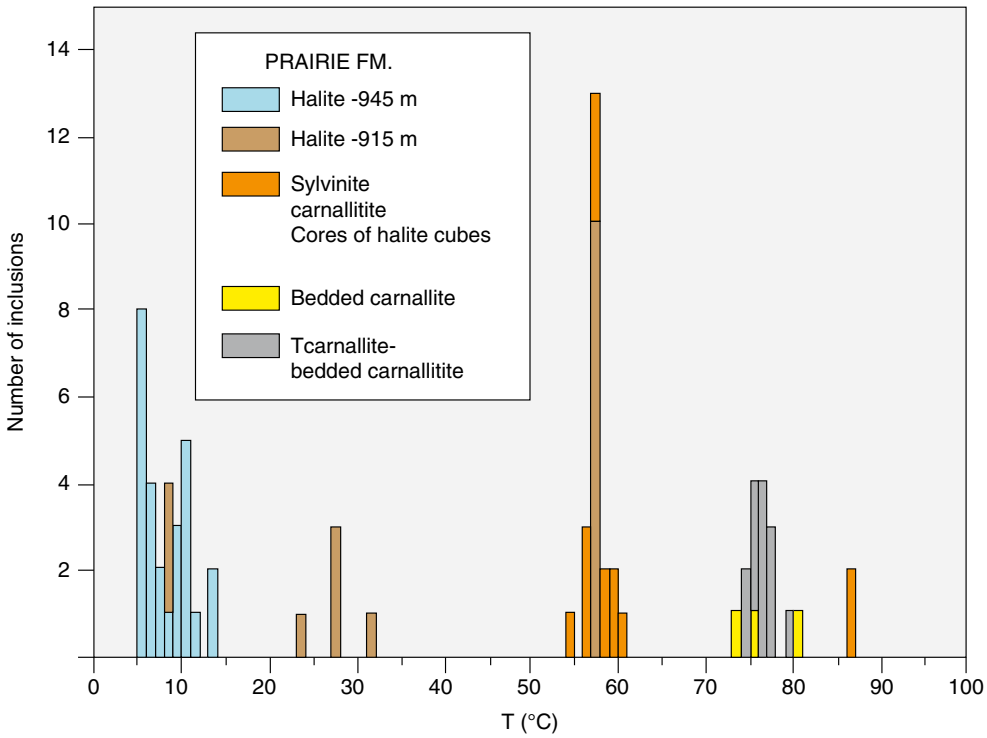

Fig. 11.63 Histogram of the temperature of dissolution of sylvite daughter crystals in fluid inclusions in halite of the Prairie Fm. from the Winsal Osler well at 915 and 945 m; sylvite daughter crystal dissolution temperatures from fluid inclusions in the cloudy centres of halite crystals associated with potash salts from other cores and sylvite and carnallite daughter crystal dissolution temperatures from fluid inclusions in fluid inclusion banded halite from bedded halite-carnallite (After Lowenstein and Spencer 1990)

Dating of clear halite crystals associated with the ore zone shows that the exceptionally coarse and pure secondary halites forming pods in the mined potash horizons may have precipitated as soon as early burial or have formed as late as Pliocene-Pleistocene. Even today, alteration and remobilisation of the sylvite and carnallite appears to be an ongoing process, perhaps related to the encroachment of the current dissolution edge or the ongoing stoping of chimneys fed by deep artesian circulation.

Halite-sylvite (sylvinite) rocks in the ore zone show two end member textures, the most common is a recrystallized polygonal mosaic texture with individual crystals ranging from millimetres to centimetres and sylvite grain boundaries outlined by concentrations of blood-red halite. The other end member texture is a framework of euhedral and subhedral halite cubes enclosed by anhedral crystals of sylvite. This is very similar to ore textures in the Salado Formation of New Mexico interpreted as early passive precipitates in karstic voids.

Petrographically, the halite-carnallite (carnallitite) rocks display three distinct textures. Most halite-carnallite rocks contain isolated centimetre-sized cubes of halite enclosed by poikilitic carnallite crystals. The halite cubes are typically clear, with occasional cloudy crystal cores that retain patches of syndepositional growth textures (Lowenstein and Spencer 1990). The second texture is coarsely crystalline halite-carnallite with equigranular, polygonal mosaic textures. The third type, which is rare, contains interlayered halite and carnallite with a primary bedding style similar to that in the Oligocene potash of the Rhine Graben. In zones where halite overlies anhydrite, most of the halite is clear with only the occasional crystal showing fluid inclusion banding.

Fluid inclusions support the notion of primary textures in the low formations temperatures in chevron halite in the Prairie evaporite and an associated thermal separation of non-sylvite and sylvite associated halite (Fig. 11.63; Lowenstein and Spencer 1990). Most fluid inclusions found in primary, fluid inclusion-banded halite associated with the Prairie potash salts contain sylvite daughter crystals at room temperature or nucleate them on cooling (halite at 915 and 945 m depth in the Winsal Osler well) In contrast, no sylvite daughter crystals have been observed in fluid inclusions outlining primary growth textures from chevron halites away from the potash deposits. This establishes that potash salts occur in stratigraphic intervals where syndepositional surface brines contained high concentrations of potassium ions and at least a portion of the potash salts formed as passive pore filling cements in a meshwork of halite. Whether the cement was sylvite or carnallite is open to interpretation (Lowenstein and Spencer 1990).

Clay minerals, which tend to occur as long continuous seams or markers in the potash zones, are mainly composed of detrital chlorite and illite and authigenic septechlorite, montmorillonite and sepiolite (Mossman et al. 1982; Boys 1990). Of the two chlorites, septechlorite is the more thermally stable. The septechlorite, sepiolite and vermiculite very likely originated as direct products of settle-out or early diagenesis under hypersaline conditions of what was

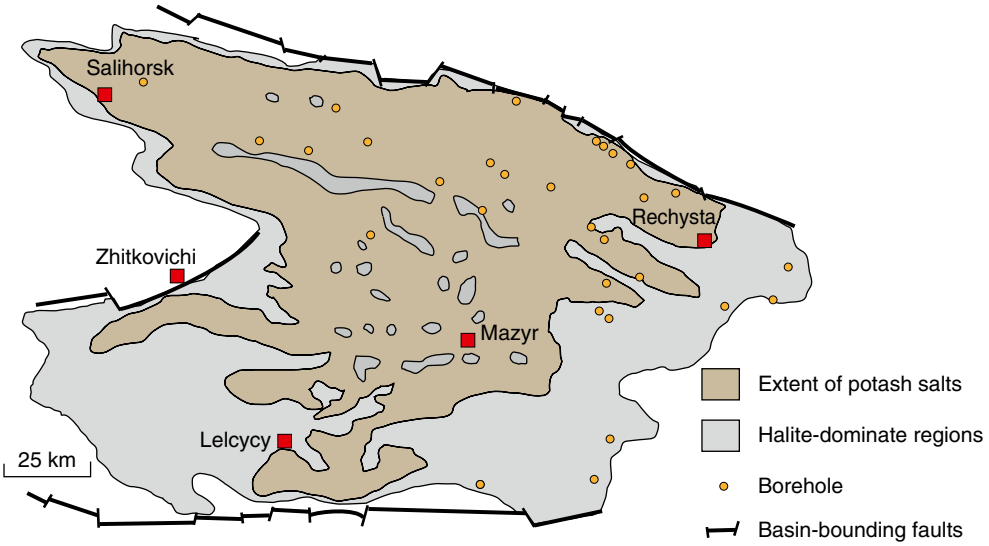

Fig. 11.64 Salt and potash extent in the Pripyat Basin (After Peryt et al. 2007)

originally eolian dust settling into a huge brine seaway. Absence of the otherwise ubiquitous septechlorite from Second Red Beds west of the zero-edge of the evaporite basin supports this concept.

The WCSB Fluids

Analysis of subsurface waters from various Canadian potash mines and collapse anomalies in the Prairie Evaporite suggest that, after initial potash precipitation, a series of recrystallising fluids had access to the evaporite minerals at various times throughout the burial history of the Prairie Formation (Chipley 1995; Koehler et al. 1997). Likewise, the Rb-Sr isotope systematics of crystal layers in both halite and sylvite indicate that the Prairie Evaporite was variably recrystallized during fluid overprint events at 371, 284, 241, 185, 147, 85, 35 and 0.5 Ma. These ages are all more recent than original deposition and correspond to ages of various tectonic events that influenced the western margin of North America.

Chemical compositions of inclusion fluids in the Prairie Evaporite, as determined by their thermometric properties, reveal at least two distinct waters played a role in potash formation: a Na-K-Mg-Ca-Cl brine, variably saturated with respect to sylvite and carnallite; and a Na-K-Cl brine that is the result of fluidrock interaction and did not result from simple evaporation of seawater to sylvite bitterns (Chipley 1995). This is supported by δD and $\delta^{18}O$ values of inclusion fluids in both halite and sylvite, which range from −146 to 0‰ and from −17.6 to −3.0‰, respectively. Most of the various preserved isotope values are different from those of evaporated seawater, which should have δD and $\delta^{18}O$ values near 0‰. Furthermore, the δD and $\delta^{18}O$ values of inclusion fluids are probably not the result of precipitation of the evaporite minerals from a brine that was a mixture of seawater and meteoric water. The low latitude position of the basin during the Middle Devonian (10-15° from the equator), the required lack of meteoric water to precipitate basinwide evaporites, and the expected δD and $\delta^{18}O$ values of any meteoric water in such a setting, make this an unlikely explanation. Rather, the δD and $\delta^{18}O$ values of inclusion fluids in the halites reflect ambient and evolving brine chemistries as the fluids in inclusions in the various growth layers were intermittently trapped during the subsurface evolution of the Prairie Formation in the Western Canada Sedimentary Basin. They also suggest that nonmarine pore water has been a major component of the crossflowing basinal brines throughout much of the recrystallization history (Chipley 1995).

Pripyat Basin (Devonian) Belarus

Pripyat Basin is the northwestern part of a larger linear sedimentary trough made up of the Pripyat, Dnieper-Donets and Donbas (foldbelt) basins (Ulmishek et al. 1994). The Dnieper-Donets and Pripyat Basins are separated by the Brahin-Loeu High. The northern and southern boundaries of the Pripyat Basin are defined by the boundary faults of a Devonian rift that was active as the potash hosting evaporites were deposited (Fig. 11.64). The basin is considered a classic example of an aulocogen and has a current area in excess of 10,000 km^2 entraining a two layered Devonian salt succession containing more than 30 potash beds, made up of sylvite and carnallite (Peryt et al. 2007; Mayrhofer 1985).

Basement to the Pripyat is an Archaean to lower Proterozoic crystalline craton sequence, which is unconformably overlain by Devonian rift-fill and later post-rift sediments (Fig. 11.65a). The thickness of Pripyat sediment fill is up to 6.5 km, thinnest in the west where it is only 2.9 km thick. There are three evaporite intervals in the Pripyat, with the halite dominant section occurring as two

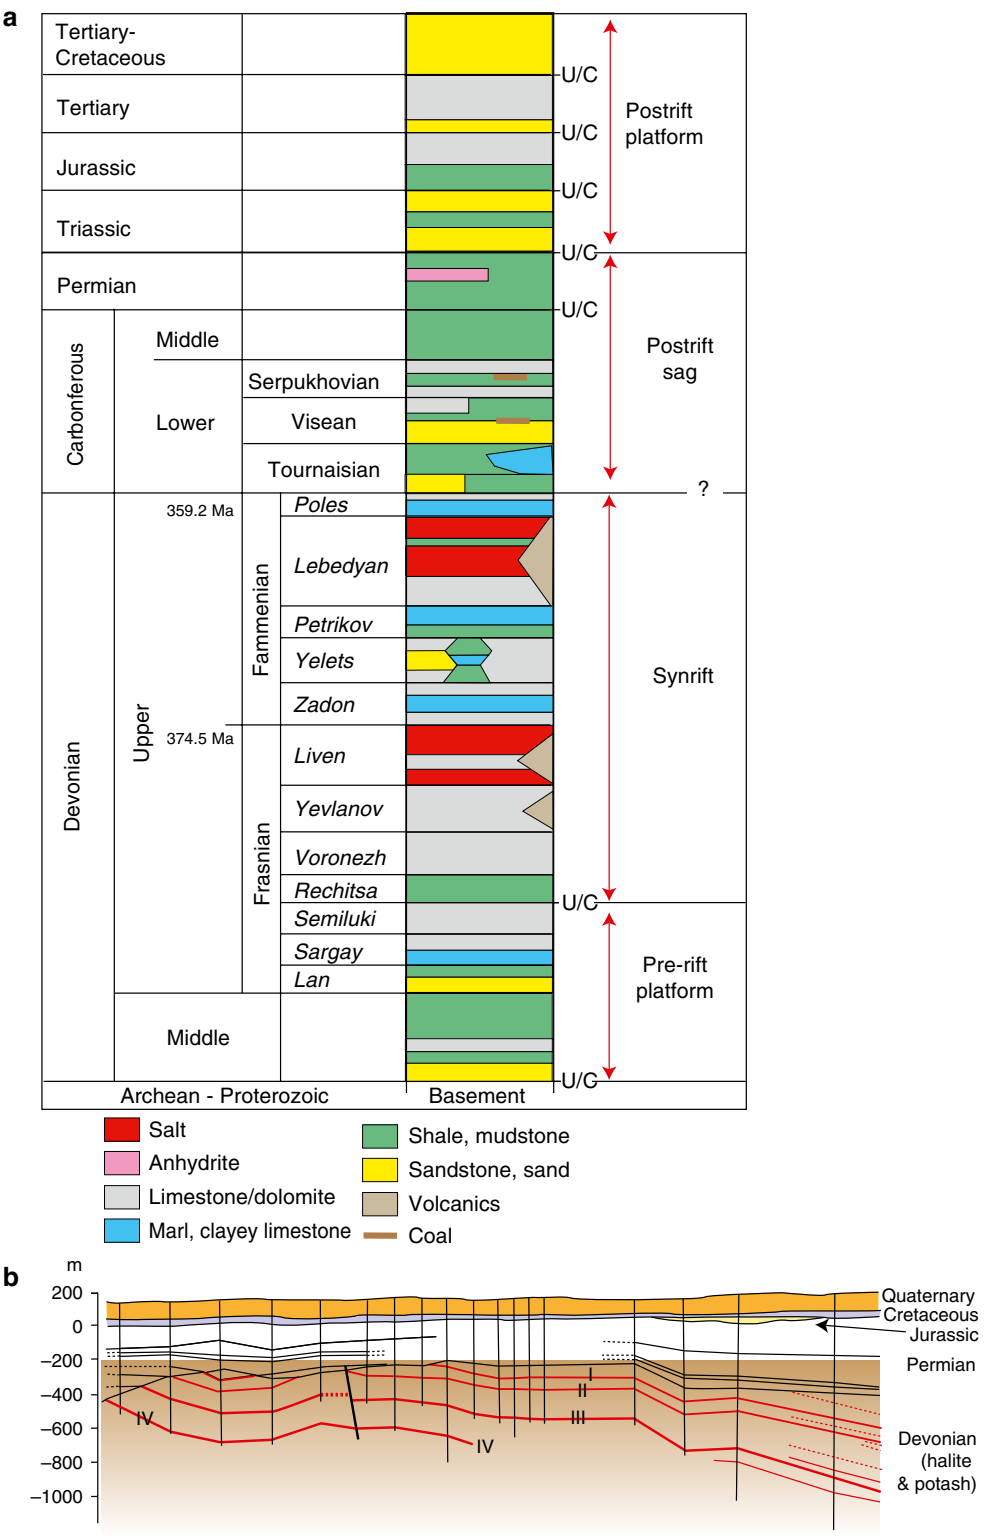

Fig. 11.65 Evaporites in Pripyat Basin, Belarus. (**a**) Basin stratigraphy. (**b**) Cross section showing potash ore layers in the upper salt unit (After Peryt et al. 2007; Mayrhofer 1985)

halite units separated by a succession of Devonian carbonates. The later Permian evaporite is an anhydrite-dominant sequence formed in association with the Uralian orogeny.

The synrift halite-dominant sequences constitute two salt formations of Late Frasnian and Late Famennian age. These salts were deposited in a hydrographically isolated stage of a deepwater marine basin, with marine brine supplied from the vast nearby epicontinental sea covering much of the East European Platform (Zharkov 1984). In contrast to the lower halite (Famennian) sequence, which contains numerous carbonate/anhydrite interbeds, the upper (Frasnian) sequence is purer in terms of its halite content and so is characterized by

more pronounced salt tectonics, with well-developed salt domes, plugs, and swells (Fig. 11.64; Khutorskoi et al. 2010). The Famennian evaporite basin was restricted to the NW part of the depression, while the Late Frasnian evaporite deposition terminated with potash salts of sylvite composition (lack $MgSO_4$ salts).

In the northeastern part of the basin, sedimentation was accompanied by active faulting and volcanic activity, so sedimentary-volcanic sequences and alkali basalts are coeval with the evaporite sequences (as was the related hydrothermal circulation and seismicity). In contrast to the lower halite sequence, the upper sequence is characterized by more pronounced salt tectonics with well-developed salt domes, plugs, and swells.

The potash beds I-IV can be traced continuously from 485 to 1,488 m depth in the Soligorsk region as the depth to potash increases from NW to SE (Fig. 11.65b). The current mining area is situated in the northwest corner of the basin centred on Soligorsk and is divided into four large mining fields covering 640 sq km (Mayrhofer 1985). Future mines (including solution mines) are planned for the Starobin region. Potash beds (I-IV) in the Soligorsk region are no more than slightly inclined, and practically flat with respect to the potash beds II and III, which are the targeted ore beds (Fig. 11.65b). Mayrhofer (1985) estimated ore reserves in excess of 100 Mt for the region. Considerable mine-roof stress problems must be dealt with in day-to-day operations, due the clay-carnallite alternations above the lower mined section, and the ore over most of its extent has a high content of insolubles, as much as 10.7 %).

Other Significant Deposits

In addition to the exploited deposits discussed in the preceding section, there are a number of bedded or halokinetic deposits of potash that are yet to be considered economic opportunities. For example, in Nagaur-Ganganagar evaporite basin of India there are seven halite cycles of Late Precambrian or Early Cambrian age (Dasgupta et al. 1998; Banerjee et al. 1998). Sylvinite horizons are known to occur between 592 and 681 m depth, with intersections averaging 0.5 m in thickness and containing 2.5–19.2 % K (Garrett 1995). In two adjacent halite beds polyhalite occurs in layers 0.1–8.8 m thick with 0.75–8.7 % K.

By far the largest known bedded potash deposit in Russia, which is not yet produced, occurs in an immense Lower Cambrian age basin in the Siberian Platform (Table 11.8;

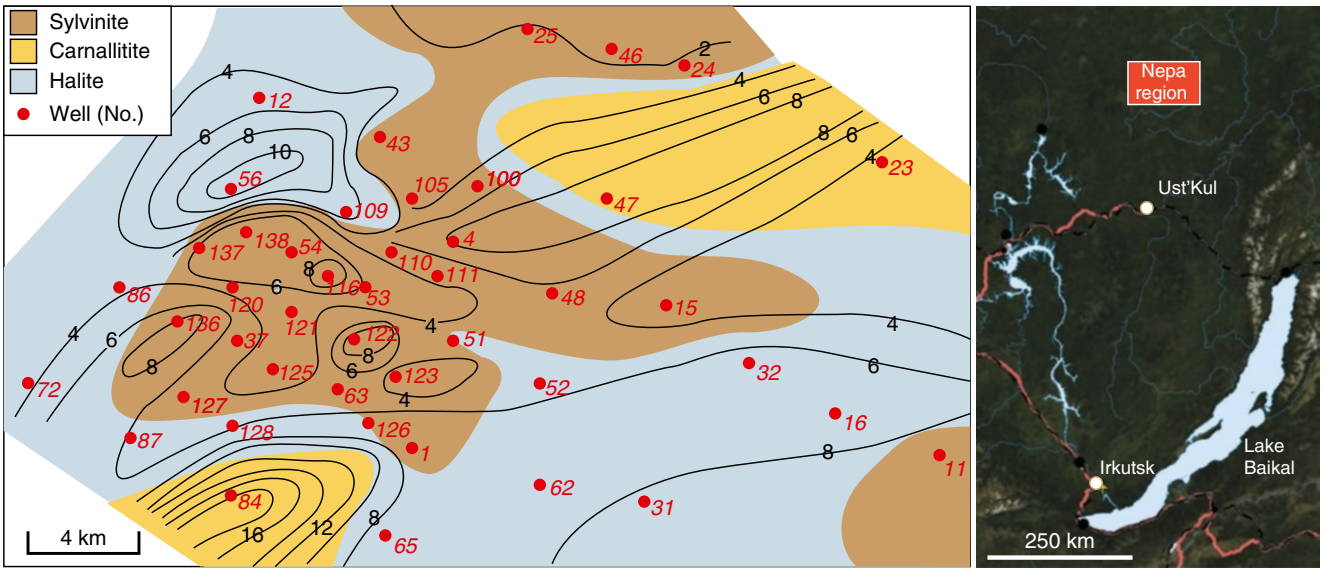

Fig. 11.66 Potash occurrence at the base of the Cambrian Angara Formation in the Nepa Region of Siberia. Note that the region posted as sylvinite carnallitite and halite is the K1 level and is isopached at the level of the K2 potash zone, this region is only some 30 km across and occurs within the red rectangle indicating the potash-rich Nepa Region (After Andreev et al. 1986; Garrett 1995)

Garrett 1995). Potash salts occur at the base of the Angara formation in what is called the sixth halite series. This basin is one of the larger potash-entraining salt deposits in the world, several times larger than the Upper Kama deposit and approaching the Prairie Evaporite in aerial extent. Plans were made in 1986 under the old Soviet regime to initiate a mining program in a section of this basin called the Nepskoye deposit, but were never implemented (Fig. 11.66; Andreev et al. 1986).

The proposed development region is near the towns of Nepa and Ust-Kut (300 km apart) in Irkutsk State. High-grade sylvinite was intersected at depths of 600–1,000 m in beds some 1.5–5 m thick over an area of more than 1,000 km^2 (Garrett 1995). The lower Bur or K1 bedded potash horizon lies at a depth of 750–960 m and is 2–18 m thick (4–6 m in the central area (Fig. 11.66; Table 11.8). Two sylvinite zones in this horizon were mapped, with the central one being 16–26 km long and 6–8 km wide. In the lower horizon (K1) the sylvinite was 1.5–3 m thick, and averaged 15–50 % KCl, 0.05–0.5 % $MgCl_2$, with 0.5 % insolubles. The overlying K2 potash zone also entrains several sylvinite beds and is some 679–880 m deep and 2.5–20 m thick. It has a 15–45 % KCl content and comparatively low $MgCl_2$ and insoluble contents. This zone represents the major potash reserves of the deposit. In the upper potash beds (K2) the sylvinite strata becomes more discontinuous, but some reasonably thick, high grade and extensive zones exist (Andreev et al. 1986).

To the south and west, between Taseyevo and Irkutsk, other large potash occurrences have been reported in the same general but poorly delineated evaporite basin. For instance, in the Kanak-Taseyevo basin, potash beds containing 3–24 % K_2O have been intersected at depths of 1,240–1,415 m (Garrett 1995). Potash beds at these depths would require a solution mining methodology, but the at-surface climate would mean either cryogenic pan processing or evaporators, making recovery more difficult and expensive.

Another significant, as yet poorly delineated, set of potash occurrences occur in the Amazon Basin, Brazil (Szatmari et al. 1979). The Amazon Basin is an intracratonic sag basin, some 2,100 km long and 300 km wide, located in the central zone of the Amazon Craton (Fig. 11.67a). It contains a number of stacked megasequence cycles ranging in age from Lower Ordovician (Autaz Mirim Member of Trombetas Formation) to Lower Permian (Andirá Formation; Gonzaga et al. 2000). The basin has a widespread Upper Cretaceous cover (Alter do Chão Formation) and was affected by widespread tholeiitic magmatic activity (Penatecaua dolerites) at about 150 Ma, making seismic-based exploration difficult especially as much of the basin still lies beneath thick jungle. Because of the recognition of this widespread igneous overprint, hydrocarbon exploration efforts were subdued since the late 1970s.

However, this large sag basin is developed on the same scale as the Alberta basin of Canada and entrains the Carboniferous (Pennsylvanian, ≈305 Ma) Nova Olinda Formation, which is made up of a large laterally extensive set of cyclic evaporite beds, dominated by interbedded combinations of anhydrite and halite (Gonzaga et al. 2000). These evaporites occur within the Carboniferous-Permian megasequence, known as the Tapajós Group, which can be up to 1,600 m thick (Fig. 11.67b: Milani and Zalan 1999). The lowest part of the megasequence is a blanket of eolian sandstones (Monte Alegre Formation), which is covered by marine-influenced carbonates and evaporites (Itaituba and

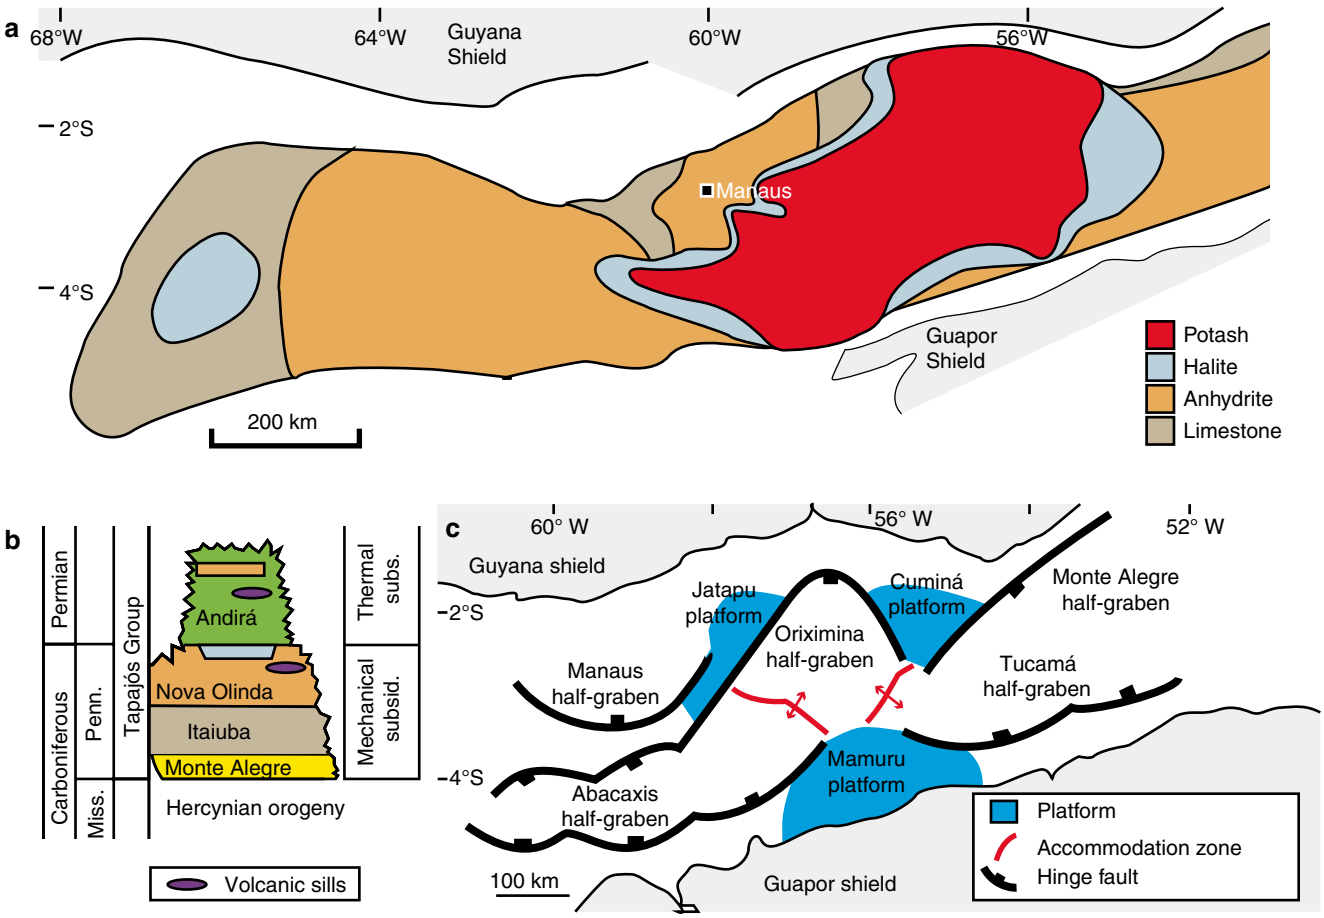

Fig. 11.67 Amazon Basin, Brazil. Amazon Basin, Brazil. (**a**) Distribution of potash and other evaporite salts in the Nova Olinda Fm (After Szatmari et al. 1979). (**b**) Relevant stratigraphy. (**c**) Basin architecture in the main evaporite area (After Gonzaga et al. 2000)

Nova Olinda Formations, respectively), along with subordinate sandstones and shales. The Tapajós megacycle is closed by a suite of Permian continental redbeds (Andirá Formation) of Permian age. Subsequent east-west regional extension facilitated a pervasive intrusion of magmatic bodies during the Early Jurassic (Penatecaua dolerites and equivalents).

Individual halite beds in the Nova Olinda evaporite cycles are 20–80 m thick, while the Nova Olinda Fm. has an average thickness of 900 m. Because of the high levels of entrained anhydrite beds in the Nova Olinda Fm., evaporite layers are not halokinetic, but are subject to collapse and flow about the basin margin in areas of intense dissolution.

Early Petrobras drilling programs conducted in the Amazon Basin from 1953 to 1963, defined the presence of halite, but did not appreciate that a number of the beds of NaCl in The Nova Olinda Formation are capped by sylvinite/carnallite beds. During the late 1960s and 1970s, higher resolution gamma ray logging tools were used, along with better mud technology and associated narrower caliper measures. This work identified a number of (0.5–2 m thick) layers of sylvinite, capping the halites (Szatmari et al. 1979). For example, the fifth and seventh depositional cycles define isolated salt sub-basins that accumulated significant potash salts in Fazendinha and Arari regions. KCl contents of these beds are between 28 and 33 % in beds some 2.47–2.65 m thick (Garrett 1995). As well as carnallite and sylvite, the potential ore intervals contain anhydrite and kieserite, but reserves are interpreted to be very large (Szatmari et al. 1979; Garrett 1995). The average ore depth at Fazendinha, the larger of the known potash area, is 1,050 m. Much of the halite and potash distribution is controlled by the underlying Basin architecture (Fig. 11.67c).

So, How Does Mineable Potash Form?

According to Braitsch (1971, p. 120), "The incongruent alteration of carnallite is probably the most important process in the alteration of potash salts." Incongruent dissolution" of carnallite is the process whereby carnallite alters to sylvite via the loss of magnesium chloride in the reaction

$$KMgCl_3.6H_2O \rightarrow KCl + Mg^{++} + 2Cl^{-} + 6H_2O$$

The reaction generates magnesium and chloride, it has been used to explain diagenetic bischofite and dolomite found is proximity to the newly formed sylvite. Bischofite is a highly soluble salt and may be metastable in many of the subsurface settings where incongruent dissolution is deemed to have occurred. In many such hydrologically active systems it may be flushed by associated brine crossflow.

Sylvite, interpreted to have formed from incongruent dissolution of primary carnallite, is reported from the Late Permian Zechstein Formation of Germany (Borchert and Muir 1964), Late Permian Salado Formation of New Mexico (Adams 1970), Early Mississippian Windsor Group of Nova Scotia (Evans 1970), Early Cretaceous Muribeca Formation of Brazil and the Gabon Basin, West Africa (Wardlaw 1972; Wardlaw and Nicholls 1972; Szatmari et al. 1979; De Ruiter 1979), Late Cretaceous of the Maha Sarakham Formation, Khorat Plateau, Thailand and Laos (Hite and Japakasetr 1979), Pleistocene Houston Formation, Danakil Depression, Ethiopia (Holwerda and Hutchinson 1968), and Middle Devonian Prairie Formation of western Canada (Schwerdtner 1964; Wardlaw 1968).

This rich literature base supports a long-held notion that there is a problem with primary sylvite as a marine salt Lowenstein and Spencer (1990)). Put simply, sylvite does not crystallize via evaporation of modern seawater at 25 °C, except under metastable equilibrium conditions (Braitsch 1971; Valyashko 1972; Hardie 1984). The sequence of bitterns crystallizing from modern seawater bitterns is illustrated in Fig. 11.68a.

The notion of sylvite via incongruent dissolution at depth is further supported by the thermodynamics of connate brines with ionic proportions of modern seawater (Fig. 11.68b; Koehler et al. 1990). Carnallite precipitating from a modern seawater bittern crystallises from a solution that has an ion activity product (IAP) within the carnallite stability field, at 1 bar pressure and approximately 30 °C (shown as point A in Fig. 11.68b). Increasing pressure, as carnallite is buried, moves the stability point into the sylvite + solution field as the carnallite sylvite boundary attains higher values of K. At a pressure of 1 kilobar, which corresponds to a lithostatic load equivalent to 2–3 km burial, the IAP position of the connate solution that first precipitated the carnallite at 1 bar, now lies in the sylvite + solution field. If equilibrium is maintained, the carnallite can react incongruently to form sylvite + solution.

So, based on this short geochemical discussion, and what we observed in our discussion of the various examples of sylvite occurrence, it seems the dilemma of primary sylvite can be solved in one of three ways. Historically, most workers have interpreted widespread sylvite as a diagenetic mineral formed by the incongruent dissolution of carnallite. Then there is the interpretation that some sylvite beds, perhaps associated with tachyhydrite, were the evaporite bittern part of a basin hydrology fed by $CaCl_2$-rich basinal

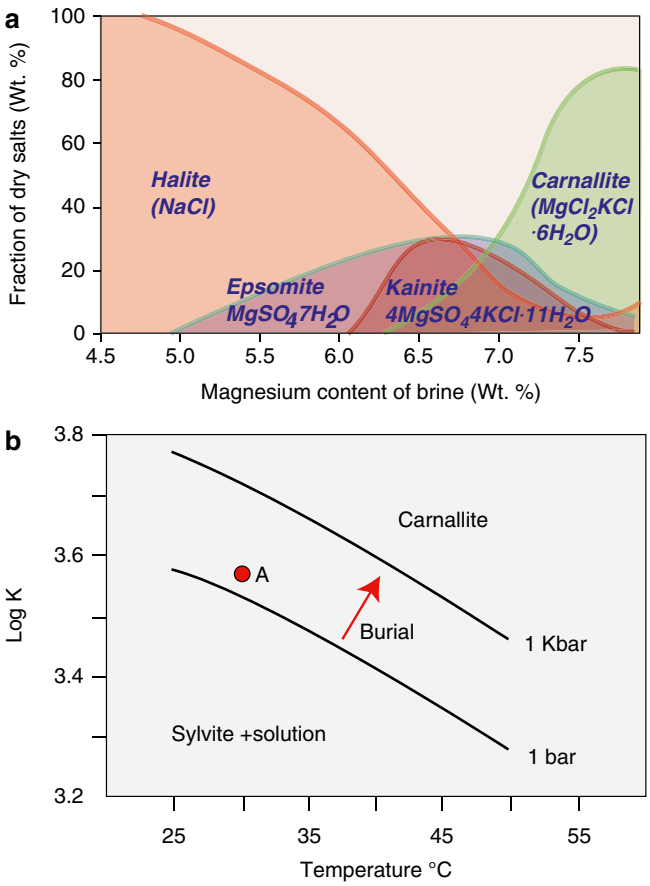

Fig. 11.68 Marine bitterns and incongruent dissolution. (**a**) Typical bittern sequence precipitated from modern seawater (After Garrett 1970a). (**b**) Phase relationship between the equilibrium constant (K) and temperature for the incongruent dissolution of carnallite to sylvite at 1 bar and 1 kbar pressures (After Koehler et al. 1990). The ion activity product (IAP) is related to the product of the concentration of Cl^- and Mg^{++} in the solution and is equal to K along the boundary between carnallite and sylvite stability fields

hydrothermal waters (Hardie 1990). The third, and increasing popular explanation of syndepositional sylvite, well supported by brine inclusion chemistry of co-associated halite, is that the chemistry of Phanerozoic seawater has evolved so that there were times in the past when $MgSO_4$ levels were lower and sylvite was a primary marine bittern precipitate (Lowenstein et al. 2001).

All views are valid within their relevant geological contexts but, if used exclusively to explain the presence of sylvite, are perhaps a little too dogmatic. My own view is that, owing to its high solubility, the various textures found in ancient potash salts reflect variegated and evolving origins that are dependent on how many times and how pervasively in its burial history an evolving brine chemistry came into contact with the potash beds (Warren 2000c). In other words, various forms and textures of potash may dissolve, recrystallise and backreact with each other from the time a potash salt is first precipitated until it is exploited.

Textural and mineralogical evolution depends on how open is the hydrology of the system at various stages during its burial evolution. Alteration can occur syndepositionally, in brine reflux or during later flushing by compactional or thermobaric subsurface waters. Tectonism (extensional and compactional) during the various stages of a basin's burial evolution acts as a bellows driving fluid flow within a basin, so forcing and speeding up the focused circulation of potash-altering waters.

A similar, but less intense, textural evolution can also be seen in the burial history of the less soluble salts. For example, $CaSO_4$ can flip-flop from gypsum to anhydrite depending on temperature, pore fluid salinity and the state of uplift/burial. This means that, as in gypsum/anhydrite sequences, there will be primary and secondary forms of both carnallite and sylvite that can alternate during deposition, during burial and during any deep meteoric flushing.

In Thailand, both primary potash precipitation and shallow diagenetic backreactions seem to have worked simultaneously with hydrologies that were first driven by early salt diapirism, that were also associated with the formation of shallow karst. Then alteration continued into deeper burial and finally during uplift, driven by the regional gravity drive of throughflushing fluids whose flow was focused along nearby clastic aquifers. The Canadian examples show how carnallite/sylvite has continued to evolve with the evolution of basinal and deeply flushing suprasalt and subsalt meteoric waters, as they came into contact with variably dissolving salt units. The Canadian potash deposits are unique in terms of their size and relative stratabound continuity, so, as part of this discussion on what make or destroys ore grade potash, we must consider why the Western Canadian Sedimentary Basin has so much more potash than any other.

Whatever model, or combination of models, is used to explain the origin of the world's major potash salts, the most important economic corollary is that, wherever a potash bed is in contact with mobile pore fluids, these highly soluble salts are continually subject to dissolution, mobilisation and reprecipitation. When trying to understand the distribution of potash ore in a halite-dominated sequence in various sedimentary and tectonic settings, the ability of the potash salts to flow, dissolve, alter and reprecipitate must be accounted for in order to create a predictive exploration model or development programme. So let us look first at controls on ore grade at the deposit scale and then at the basin and world tectonic scale.

Controls on Potash Quality: Anomalies, Leaching and Problematic Mine Waters

Just as the first rule for safe conventional halite mining is "stay in the salt," problem areas encountered in most potash mines are related to thinning or disappearing ore seams in zones showing evidence of water-related dissolution and solution collapse (Fig. 11.69; Boys 1990, 1993; Woods 1979).

Uncontrollable water inflow is the greatest threat to any operating potash mine, as can be seen in a history of loss of operational potash mines over the past four decades. In 1970 the decision was made to allow the Cane Creek (Moab) potash mine to flood, after 5 difficult years trying to deal with unexpected water inflows and ore-grade problems. In 1977 The Holle Mine in West Africa was lost to flooding. In 1986 Uralkali's Mine 3 was abandoned due to flooding. In early 1987 the Patience Lake potash mine was closed due to uncontrollable flooding. Water inflows were first encountered there during routine mining in 1975 and after a number of years of trying to cope with the inflows the former conventional underground mine was closed, allowed to flood, and a new solution mine started in 1988. The Cassidy Lake (Potacan) potash mine in New Brunswick, closed in October 1997 because of irreparable damage from severe flooding, at the time its capacity was 1.3 million tonnes. In October 2006, Uralkali's (URKA–RT) Mine 1 was closed due to flooding, with associated ground collapse, resulting in the loss of some 3 % or 1.2 million tonnes/year of global production. Today, Mosaic's Esterhazy K1 and K2 facilities are still dealing with ongoing water inflow problems. A flood at the Esterhazy complex (current capacity of 5.3 million tonnes/year) would affect some 9 % of current global capacity and it probably represents the most credible known current risk for a potash mine to flood.

In all these situations, other than intersecting old open well bores in the potash ore zone, most episodes of flooding, including the complete loss of working mines, stem from uncontrolled water inflows that follow an unexpected intersection with an anomalous non-ore zone. So in order to understand both the controls on potash ore grade and a mine's susceptibility to water inflow we must study how groundwater interacts with any potash intersection.

Increased water inflows in Saskatchewan potash mines are consistently linked to salt anomalies, that is, to natural areas of little or no potash within the potash ore bed (Gendzwill and Martin 1996). Geology of potash ore quality in three salt anomalies were studied by Boys (1990) in the PCS Cory mine, Canada, which extracts potash from the Patience Lake member of the Prairie Evaporite Formation. He defined five postburial facies in the vicinity of the salt anomalies, all related to a current or previous crossflow of water undersaturated with respect to potash (Fig. 11.69a). Where undersaturated groundwater continually interacts with a sylvinite bed it ultimately dissolves all the salts to leave behind only insoluble residues in a solution collapse breccia (facies 1). This potash-free interval is at the one end of the facies continuum defining salt anomalies in the PCS mine (Fig. 11.69a; facies 1 through 5). At

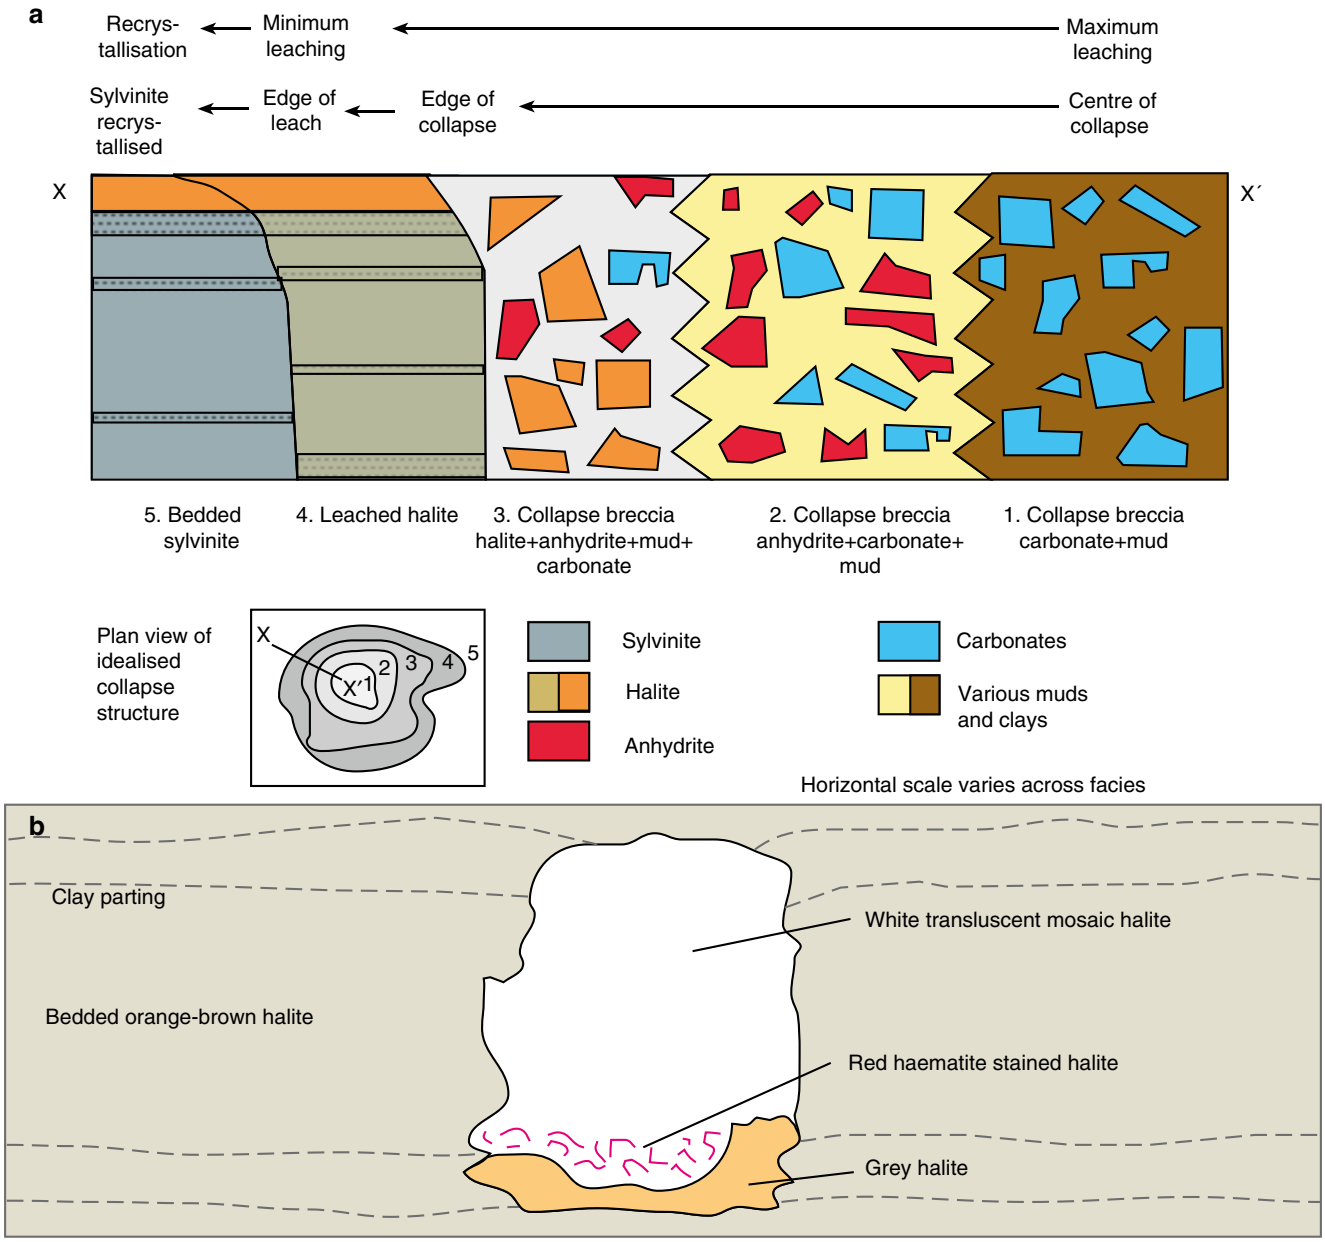

Fig. 11.69 Potash solution features. (**a**) Cross section A–A′ through half of an idealised collapse structure in the Prairie Evaporite Formation, Variable scale from 100 to more than 500 m across (After Boys 1990, 1993). (**b**) Recemented solution cavity in the Boulby Halite, Boulby Mine, UK. This interval is located below the main potash zone (After Woods 1979)

the other end of the groundwater-potash interaction spectrum are beds composed of completely recrystallized and often potash-enriched sylvinite (facies 5). These sweet spots lie adjacent to leached beds where recrystallized halite (facies 4) passes laterally into collapse breccias with blocks of anhydrite and halite (facies 3 and 2; solution residues made up of the less soluble salts), which in turn pass laterally into the most mature dissolution breccias of facies 1, where no evaporite salts remain. When a drive or a test hole passes out of the ore into facies 1 the potential for water problems is high.

In his model, salt anomalies indicate proximity to collapse structures that act as conduits for overlying (or possibly pressurised underlying?) formation waters. The crossflow drives a halo of pervasive leaching and recrystallization in the Prairie Evaporite Formation. The same fluids that cause widespread recrystallization, and possibly enrichment of the potash salts at the outer edge of the salt anomaly, also dissolve water-filled cavities in the more central parts of the anomalies. The intensity of the leaching and the geometry of the leached halo is variable, while the timing of major leaching events in the Prairie Evaporite is still poorly constrained. Boys (1990) pos-

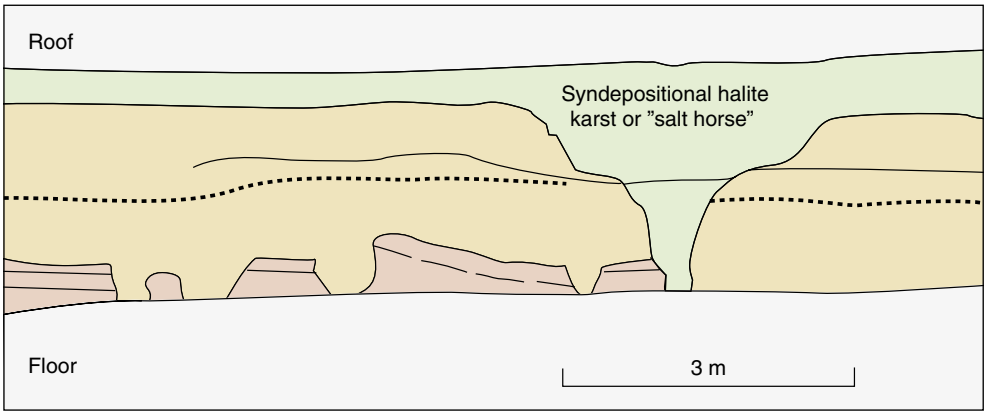

Fig. 11.70 Sedimentary structures showing the abundance of vadose textures including a downcutting "salt horse" from halite cavern infill in the Salado Formation of the Delaware Basin, as exposed in the WIPP shaft, USA (After Hovorka et al. 2007)

tulates at least two major water crossflow events in the PCS mine, possibly driven by uplift and tectonism: one occurred in the Late Devonian, the other in the Cretaceous, both are tied to the gravity-driven descent of undersaturated waters.

Similar leached solution cavity-fill features that create salt anomalies occur in the Boulby Potash Mine in the UK, although most of the features are now halite-cemented and consist of lenses of coarse pure translucent secondary halite (Fig. 11.69b). Intersected zones are up to 2 m across and typically overlie a band of halite encrusted with red hematite (Woods (1979)). The amount of anhydrite at the base of many cavities is greater than would accumulate as a simple insoluble residue implying they formed from waters close to $CaSO_4$ saturation. According to Woods (1979), the cavities formed in the subsurface from $CaSO_4$ -saturated brines that were involved in dissolving the carnallite and sylvite. The resulting brines became supersaturated with respect to $CaSO_4$ causing halite to precipitate and accumulate on the cavity floor.

At a smaller scale, I have observed similar $CaSO_4$-floored dm-scale cavities in core from the Maha Sarakham potash intervals in Thailand and in this case they formed early, syn-precipitationally to bedded sylvinite in adjacent salt withdrawal depressions (Fig. 11.38). It seems that vadose and shallow phreatic dissolution is commonplace in many potash intervals worldwide. The infill, however, is not always halite; and in Thailand, in the heavily recrystallized sylvinite zones, some of these anhydrite-floored cavities have been filled by coarse-grained clear sylvite made up of single crystals that can be more than 30 cm across.

Salt anomalies (barren zones in potash ore) also form crosscutting intervals in the Permian potash ores in New Mexico (Linn and Adams 1966). Locally called "salt horses"[6], these crosscutting irregular zones range from 0.3 to 100 m in width and 3–200 m in length. Beds in salt horses are thinner than the equivalent beds in ore. Contacts between salt horses and ore are sharp and colour of the clay changes from grey in ore to brown in salt horses, perhaps indicating more oxygenated crossflushing waters. Pods and lenses of langbeinite, leonite, kainite, recrystallized halite, and recrystallized sylvite occur in McNutt ore near the salt horses, while disseminated polyhalite of the typical marker bed is locally concentrated into intergranular seams and pods in or near horses.

According to Linn and Adams (1966) the NaCl-saturated brines creating the horses entered the ore zone from below and formed horses by the selective metasomatic leaching of sylvite. Fluid entry from below is not unreasonable in the New Mexico situation, as the potash evaporites occur along the western margin of the Delaware Basin and sit atop an aquifer that entrains deeply circulating meteoric waters. However, based on three decades of detailed geological study in the same area, both at the WIPP site and the surrounding potash mines, Hovorka et al. (2007; p. 351) conclude that the large 'salt horses' composed of relatively pure halite encountered in Salado ore zones are perhaps large halite-filled synsedimentary dissolution pits (Fig. 11.70) They go on to state that a least a proportions of geometrically similar large pits (anomalies of Boys 1993) that have been mapped in various potash mines in the Devonian Prairie evaporite may also be synsedimentary.

Effects of the leaching events that produce the salt anomalies and loss of potash in Canada or elsewhere, range from weak to strong, from selectively preserving delicate laminae and chevron textures, to deforming and destroying salt beds (Boys 1990). Good preservation of iron oxides in halite may indicate that the leaching was weak or of short duration. In many leach anomalies fed from above, salinity indicator minerals increase downward evolution in a structure, possibly because fluids exit downward and NaCl-saturated fluids tend to follow the chemical gradient provided by potash beds. Or, in my opinion, it zones downward because all

[6]"Horse" is possibly a miner's corruption of the term horst. In mining the term typically refers to a block of country rock entirely encased within a mineral lode. Horse is also a broader geological technical term to describe any block of rock completely separated from the surrounding rock either by mineral veins or fault planes.

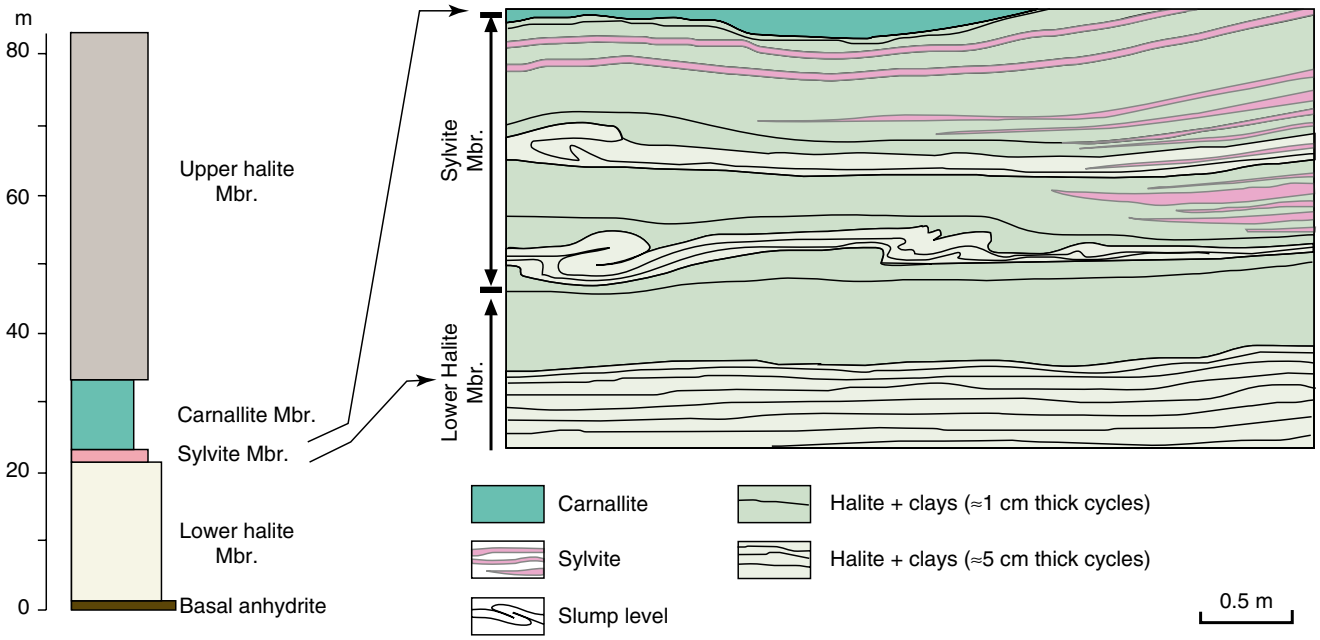

Fig. 11.71 Stratigraphy of Upper Eocene potash section based on sequence cored in Biurrun borehole and tied to a mine wall sketch from Subiza Mine, showing barren body made up of two superimposed slump structures with corresponding upper sections, where the overlapping sylvite beds evolve from absent to continuous (After Cendon et al. 1998)

brines tend to density stratify and the denser more saturated waters in a downward growing dissolution feature would tend to have ponded in its bottom (or synprecipitational sump). Early stages of stratification are seen in the perched waters on blind-bottomed sub-vertical karst holes in Mt Sedom, Israel.

Identifying proximity to a salt anomaly is obviously important in terms of ore quality and mine safety (Boys 1990). Geological indicators of proximity to a halite anomaly include: a change in insoluble seam colour from greenish-grey to mottled brown and greenish-grey (probably corresponds to increasingly oxidised fluids in the crossflow structure), unusual local increases in ore grade, large patches of sylvite-poor potash crosscutting units near the top of the ore zone, and drops in topography >10 m of the marker seams across an anomaly. For example, within 5 m of a large salt anomaly, Boys (1990) found large blebs (>200 cm^2 on the mine wall) of sylvite-poor potash that crosscut the units of an incomplete potash cycle near the top of the main ore zone. Anhydrite, a less soluble salt, is also more common in a salt anomaly than in the adjacent ore. Once into the anomaly facies, possible indicators of a nearby major collapse feature include: stretched clay seams; folded beds; small collapse features (1–20 m scale); and split clay seams with salt appearing to be injected into the seam.

In a study of "barren bodies" in the Subiza Mine, Navarra, Spain, Cendon et al. (1998) recognised a syndepositional mechanism of "salt horse" formation (Fig. 11.71). It was controlled by brine pool stratification, not various diagenetic processes tied to subsurface crossflow. The Subiza potash deposit contains a 100 m thick Upper Eocene succession of alternating claystone and evaporites (sulphate, halite, and sylvite). The evaporites accumulated in an elongated basin that is one of the depocentres within the 250 km long South Pyrenean foreland basin. Slope instability along the margin of the basin, perhaps promoted by tectonism, created mass wasting of the evaporite beds. This formed subaqueous mounds 0.5–2 m high and tens of metres across. As evaporation progressed, a stratified brine system formed and encroached over the mounds. Halite precipitated at the air-brine interface and sank to the bottom of the basin, along with terrigenous clays. Sylvite, however, precipitated only from the cooling of a lower denser bottom hugging brine. This brine was warm where it formed about the basin edge and cooled as it seeped into the deeper parts of the basin floor. As many mound crests extended into the upper less saline brine, the sylvite could not precipitate over these subaqueous highs. With progressive accumulation, the lower brine ultimately covered the mounds as sylvite beds overlapped the mound tops.

This model, however, is in my opinion problematic in terms of its hydrological restraints: it requires a hydrological system that encapsulates sylvite saturation and precipitation in the cooling lower brine with simultaneous halite precipitation in the upper brine. Such a system is extremely difficult to maintain over time frames that allow metre-thick beds of evaporites to accumulate. A more likely hydrology is perhaps a desiccating and concentrating single brine body,

which reached halite saturation at the "pond full" stages while the mounds were still covered with brine. It did not reach sylvite saturation until ongoing drying of the brine lake had lowered the level to where the crests of the mounds were exposed. Whichever model is accepted, what is most important in terms of potash geology is that breached syndepositional salt horses or barren zones are less likely to possess subsequent subsurface hydrologies that will flood mines, as compared with horsts induced by later subsurface leaching, as defined by Boys (1993). The Navarra type of salt anomaly would not be tied to a zone of potential inflow in an active mine. Using and applying it as an interpretation of salt anomalies in an ore zone outside of the region where it was documented has significant implications in terms of mine safety.

Intersecting unexpected salt anomalies, especially those associated with flowing undersaturated brines should always be noted and dealt with as early as possible in a mine plan. Otherwise these zones can impair or destroy a potash mine. In the 1970s the Patience Lake potash mine operation, located on the eastern outskirts of Saskatoon, encountered a natural collapse structure. Grouting managed to control the inflow and mining continued. Then, in January of 1986 the rate of water inflow began to increase dramatically from the same fractured interval (Fig. 11.72; Gendzwill and Martin 1996). At its worst, the fractures associated with the structure were leaking 75 m^3/min (680,000 bbl/day) of water into the mine. The water was traced back to the overlying Cretaceous Mannville and possibly the Duperow formations. Finally, in January 1987 the mine was abandoned. It took another 6 months for the mine to fill with water. Subsequent seismic shot over the offending structure suggested that the actual collapse wasn't even penetrated; the mine had merely intersected a fracture within a marginal zone of partial collapse (Gendzwill and Martin 1996). Part of the problem was that the water was undersaturated and quickly weakened pillars and supports, so compromising the structural integrity of the workings. The unexpected intersection of one simple fracture system resulted in the loss of a billion dollar mine.

Patience Lake mine now operates as a solution mine by pumping KCl-rich brine from the flooded mine workings to the surface (Fig. 11.6). The operation has a capacity to produce more than a million tonnes of potash annually. It works by circulating heated brine through the flooded mineshaft into the former workings, which extend up to 18 km from the main shaft. Heated recovered potassium-rich brines are pumped into surface crystallization ponds where the liquor evaporates and cools. Sylvite, potash, and other salt crystals form and settle to the bottom of the pond. This potash sludge is pumped from a floating dredge to the processing plan, while the cooled NaCl-saturated pond brine is reheated and re-injected into the mine to repeat the process.

Prugger and Prugger (1991) documented the successful treatment of an underground inflow into the Rocanville mine that occurred in 1984 (Fig. 11.73). In this case the mine was saved. It began when a mine entry accidentally penetrated a salt collapse structure that then began to leak brine into the mine at rates exceeding 10 m^3/min (90,576 bbl/day). Seismic showed that the structure was roughly circular and relatively

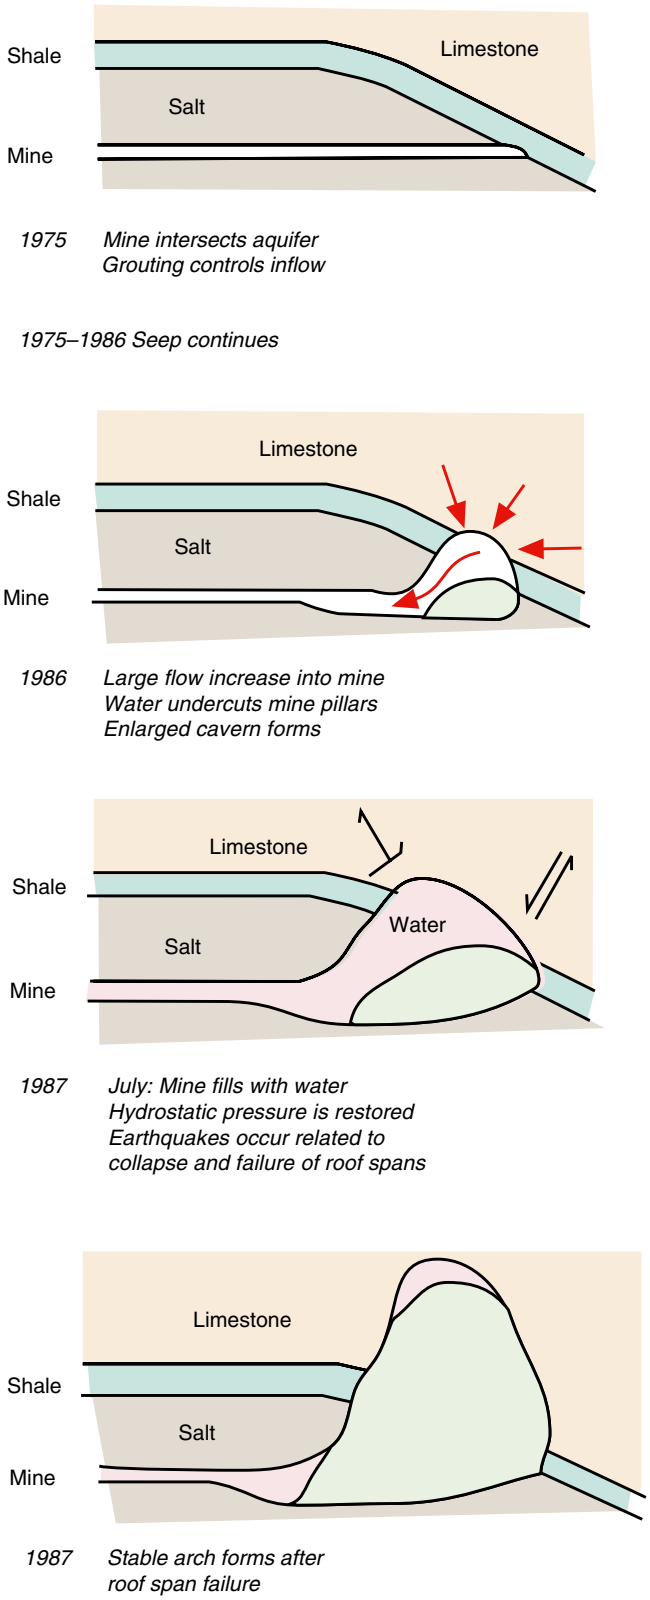

Fig. 11.72 Sequence of events controlling the flooding of the Patience Lake Mine (After Gendzwill and Martin 1996)

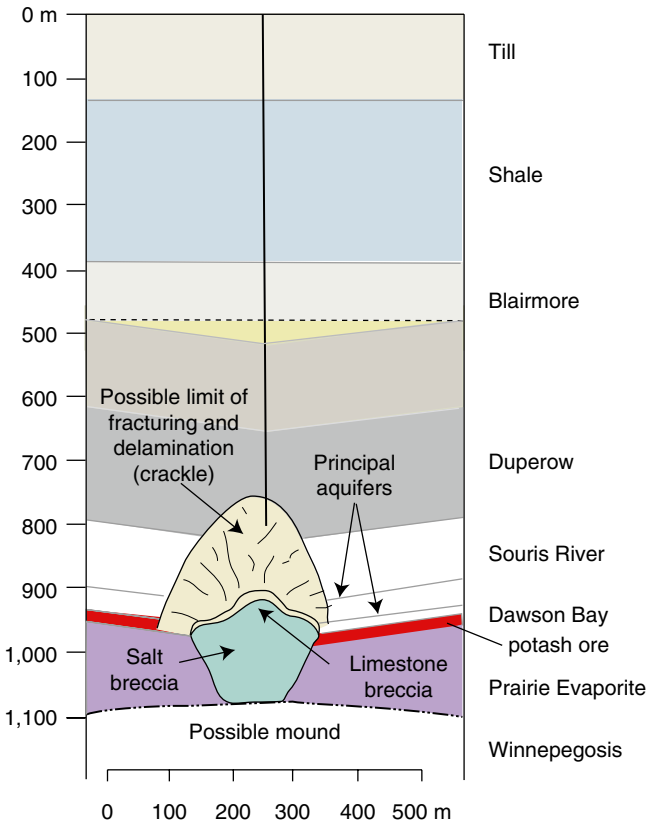

Fig. 11.73 Dimensions of the salt collapse chimney that was breached in the Rocanville Mine in 1984 (After Prugger and Prugger 1991)

small in size (300 m in diameter), and was isolated from other collapse structures. A grout well was drilled from the surface and encountered the collapse upon penetrating the carbonates of the overlying Duperow Formation, suggesting that fracturing associated with the collapse structure had extended as a blind chimney a considerable distance up from the Prairie level. Unlike the Patience Lake Mine flood, a combination of grouting and bulkhead emplacement in Rocanville succeeded in sealing off the inflow, thus saving the mine. Also unlike Patience Lake, the brine from the breached structure was halite-saturated so limiting the amount of dissolution damage. Different outcomes between the loss of the Patience Lake Mine and recovery from flooding in the Rocanville Mine may reflect the difference between intersecting a chimney that made its way to the Cretaceous landsurface and is now overlain by a wide-draining set of sediments versus intersecting a blind chimney that never broke out at the landsurface.

The notion of ore continuity in the sylvinite units of the Prairie Evaporite in the potash area of the Western Canada Sedimentary Basin is a commonly stated precept. But when the actual distribution and scale of salt horses are mapped as a mining operation proceeds it is obvious that many small 10 m-scale discontinuities are present. Sometimes they thin and degrade (Section A–A_1–A_2), other times locally enrich the ore grade (B–B_1). They are much more widespread than often considered to be present in what is the richest potash ore deposit in the world and exemplified for the lateral continuity of the ore zones (Fig. 11.74; Baar 1974). It seems that unexpectedly intersecting a salt anomaly in an ore zone can have a range of outcomes ranging from the inconsequential to the catastrophic, in part because there is more than one type of salt anomaly or "salt horse."

Figure 11.75 summarises what are considered the three most common salt anomalies and their occurrence styles are in part time-related (Boys 1990). Washouts are defined as… "salt-filled V- or U-shaped structures, which transect the normal bedded sequence and obliterate the stratigraphy" (Fig. 11.75a; Mackintosh and McVittie 1983, p. 60). They are typically enriched or filled by insoluble materials in their lower one-third and medium-coarse-grained halite in the upper two thirds. Up to several metres across, when traced laterally they typically pass into halite-cemented paleo-sinks and cavern networks (e.g. Fig. 11.75b). Most washouts likely formed penecon-temporaneous with the potash beds they transect, that is, they are preserved examples of synkarst with infilling of the karst void by a slightly later halite cement. They indicate watertable lowering in a potash rich saline sump. This was followed soon after by a period of higher watertables and brine saturations, when halite cements occluded the washouts and palaeocaverns. Modern examples of this process typify the edges of subcropping and contemporary evaporite beds, as about the recently exposed edges of the modern Dead Sea. As such, "wash outs" tend to indicate relatively early interactions of the potash interval with undersaturated waters, they may even be a part of the syndepositional remobilization hydrology that focused, and locally enriched, potash ore levels.

In a leach zone, the stratabound sylvinite ore zone has been partially or completely replaced by barren halite, without significantly disturbing the normal stratigraphic sequence (Fig. 11.75b). Some loss of volume or local thinning of the stratigraphy is typical in this type of salt horse. Typically saucer-shaped, they have diameters ranging from a few metres up to 400 m. Less often, they can be linear features that are up to 20 m wide and 1,600 m long. Leach zones can form contemporaneously due to depressions and back-reactions in the ore beds, or by later low-energy infiltration of Na-saturated, K-undersaturated brines. The latter method of formation is also likely on the margins of collapse zones, a situation typically classified as a leach-collapse anomaly (Mackintosh and McVittie 1983; McIntosh and Wardlaw, 1968).

Of the three types of salt anomaly illustrated, leach zone processes are the least understood. Historically, when incongruent dissolution was the widely accepted interpretation for loss of unit thickness many leach anomalies were considered metasomatic. Much of the inherent metasomatic interpretation was based on decades of detailed work in the various salt mines of the German Zechstein Basin. Intellectually, evaporites were considered more akin to metamorphic rocks and the term metasomatic alteration was commonly used

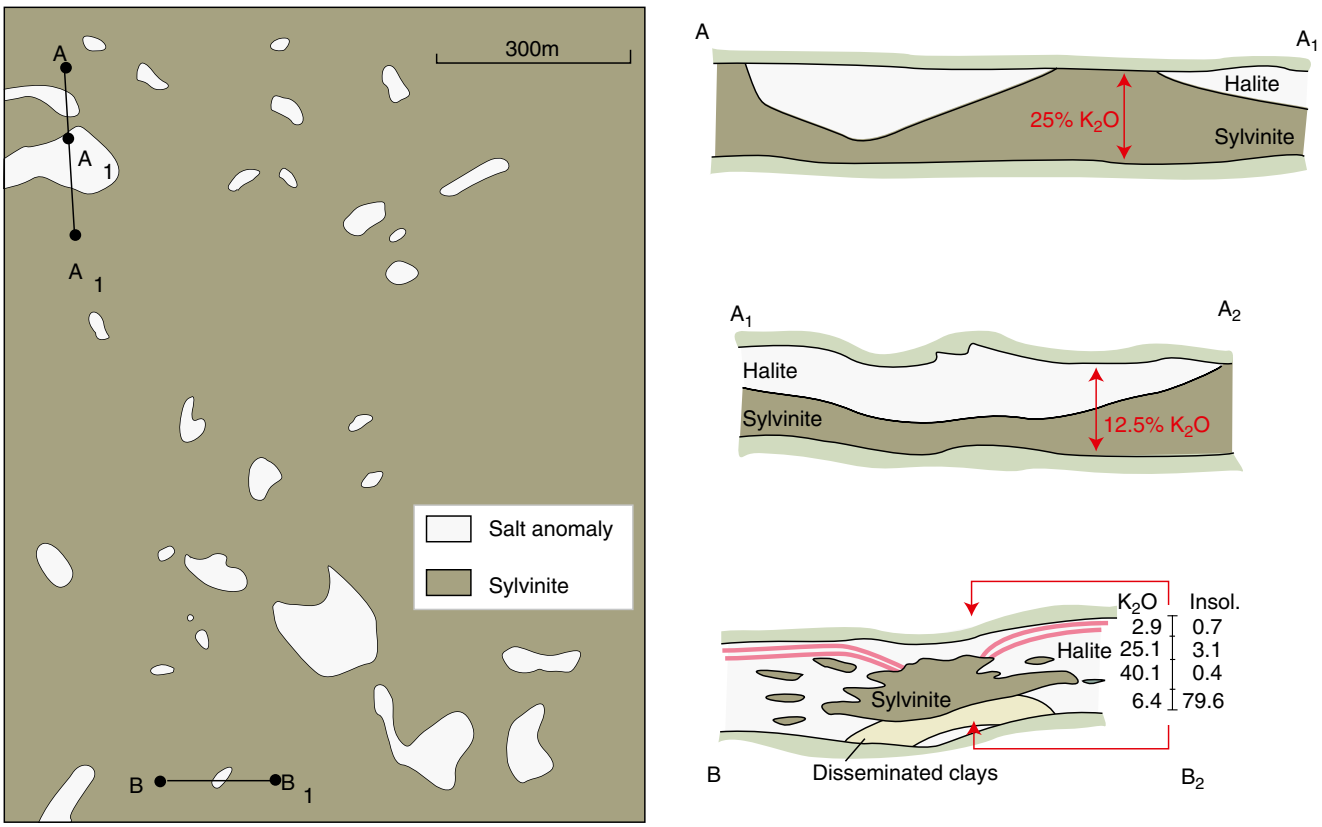

Fig. 11.74 Salt horses mapped in an ore level in a potash mine near Saskatoon, Canada (After Baar 1974). (**a**) Subsurface distribution of small scale salt anomalies mapped during mining. (**b**) Scaled cross sections of salt anomalies and associated K_2O

when explaining leach anomalies. In the past two decades, widespread observations of the preservation of primary chevron halite in most bedded evaporites have led to a reduced use of notions of widespread metamorphic-like metasomatic or solid-state alteration processes in bedded evaporites. There is just too much preserved primary texture in the bedded salt units to invoke pervasive burial metasomatism. So how do leach anomalies, as illustrated in Fig. 11.75b, occur in nonhalokinetic settings? A possible explanation is given by the depositional salt horse textures documented in the Navarra Potash Province (Fig. 11.71). There, the underlying and overlying salt stratigraphy is contiguous, while the intervening sylvite passed laterally into a syndepositional "salt horse."

On the other hand, in halokinetic situations (which characterises much Zechstein salt) solid-state alteration via inclusion related migration in flowing salt beds is a well-documented set of texture-altering processes (diffusion metasomatism). Most workers in such halokinetic systems would agree that there must have been an original stratiform potassium segregation present during or soon after deposition related to initial precipitation, fractional dissolution and karst-cooling precipitation. But what is controlling potassium distribution now is a totally recrystallised and remobilised set of textures that preserve little or no crystal-scale evidence of primary conditions. The complex layering in such deposits may preserve a broad depositional stratigraphy, but the decimetre to metre scale mineral distributions are indications of complex interactions of folds, overfolds, and disaggregation with local flow thickening.

Collapse zones are characterized by a loss of recognizable ore strata, which is replaced by brecciated, recemented and recrystallized material, with the breccia blocks typically made of the intrasalt or roof lithologies (Fig. 11.75c), so angular fragments of the Second Red beds and dolostones of the Dawson Bay Formation are the most conspicuous components of the collapse features in the Western Canada Sedimentary Basin. When ore dissolution is well developed, all the halite can dissolve, along with the potash salts, and the overlying strata collapse into the cavity (these are classic solution collapse features). Transitional leached zones typically separate the collapsed core from normal bedded potash. Such collapse structures indicate a breach of the ore layers by unsaturated waters, fed either from below or above. For example, in the Western Canada Sedimentary Basin, well developed collapse structures tend to occur over the edges and top Devonian mud mounds, while in the New Mexico potash zone the collapse zones are related to highs

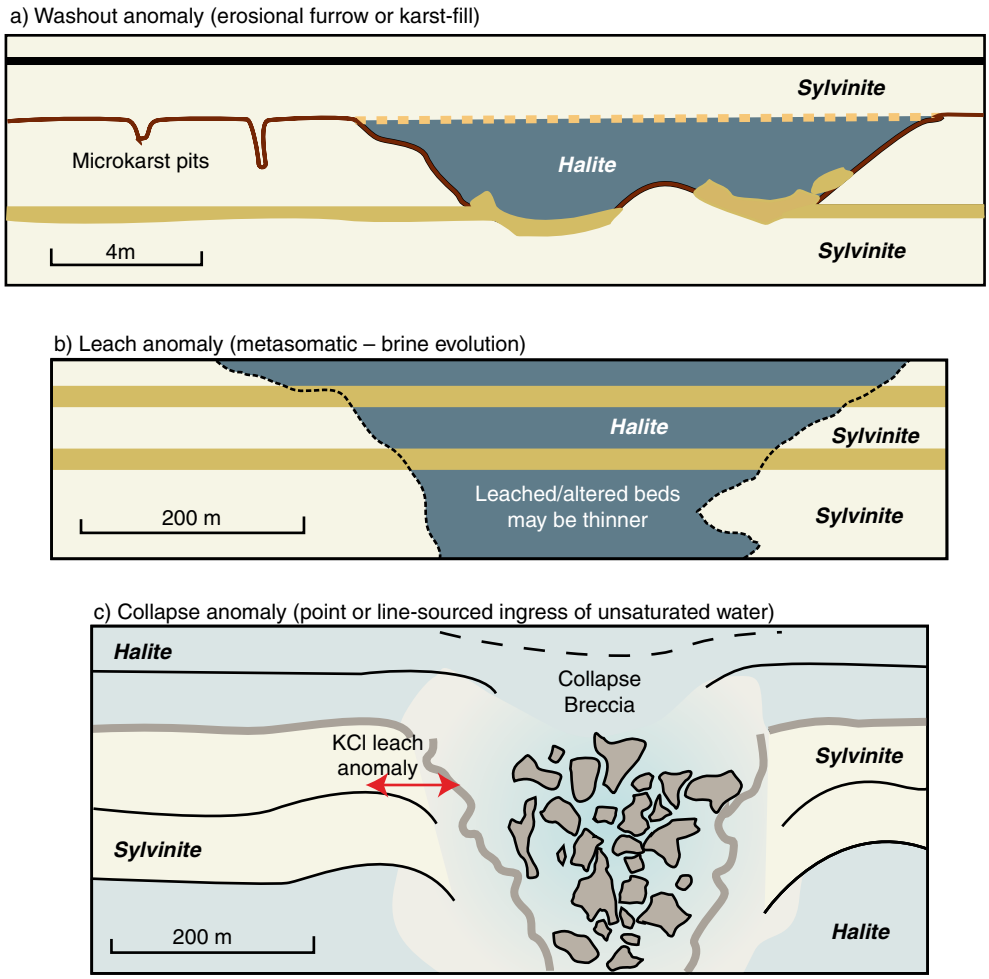

Fig. 11.75 Three main types of salt anomalies or salt horses (Based on Boys 1990 and Mackintosh and McVittie 1983)

in the underlying Capitan reef trend. Leaching fluids may have come from below or above to form collapse structures at anytime after initial deposition. When connected to a water source, these are the subsurface features that when intersected can quickly move the mining operation out of the salt into and adjacent aquifer system, a transition that led to flooding in most of the mine-lost operations listed earlier.

Clearly, identifying at the mine scale the set of processes that created a salt horse has implications in terms of its likely influence on mine stability whatever decision is made on how to deal with it as part of the ongoing mine operation. Syndepositional karst fills and leach anomalies are least likely to be problematic if penetrated, as the aquifer system that formed them is likely no longer active. In contrast, penetration or removal of the region around a salt-depleted collapse breccia may lead to uncontrollable water inflows and ultimately to loss of the mine. Unfortunately, in terms of production planning, the features of the periphery of a leach anomaly can be similar if not identical to those in the alteration halo that typically forms about the leached edge a collapse zone. The processes of sylvite recrystallization that define the edge of collapse anomaly can lead to local enrichment in sylvite levels, making these zones surrounding the collapse core attractive extraction targets (Fig. 11.69a; Boys 1990, 1993). Boundaries of any alteration halo about a collapse centre are not concentric but irregular making prediction of a feature's geometry very difficult, if not impossible. The safest course of action is to avoid mining salt anomalies but longwall techniques make this difficult and they must be identified and dealt with. There are a number of features that should be monitored in an active potash mine to help identify proximity to a salt anomaly or salt horse and minimise associated problems related to maintaining a constant ore-grade feed to the mill (Table 11.9).

Potash Occurrence and Quality at the Worldscale

The solubility of potash salts controls how and where beds are economic at the extraction scale, but are the same sets of processes, namely dilution and reprecipitation, also

Table 11.9 Features that should be monitored and mapped during both exploration for, and development of a potash deposit/mine

Feature	Problem	Related observations
Structure of the ore horizon	Faulting. folding or flowage of ore horizon complicating or precluding room-and-pillar mining method.	(a) Correlation of stratigraphy between boreholes (b) Examination of core for evidence of deformation and recrystallisation.
Stratigraphy	Incorrect correlation of ore horizons; salt thicknesses above ore are insufficient to protect deposit from water influx; slabbing, and ore dilution from clay beds above ore horizon.	Detailed core logging and correlation of beds between drill holes.
Ore depth	Low mine extraction or excessive development and mining costs.	Mining method and size of mine openings designed on basis of rock mechanics and geology.
Ore thickness	Local systematic or random thinning of ore zone.	(a) Isopach maps of stratigraphic units and mineralisation in ore zone. (b) Inspection of core for evidence of metasomatism and potash leaching, i.e., recrystallised halite, clay in intergranular clots, and horizontal mineral zoning.
Ore mineralogy	Assemblages incompatible with proposed mill circuit; certain assemblages reduce stability of mine openings, high insoluble content requires extra desliming capacity.	Determinative mineralogy of core.
Ore grade	Grade may be too low or erratic to maintain acceptable mill feed, recoverable K_2O may be significantly less than total K_2O.	Correlation and interpretation of drill hole data, comparison of chemical analyses with determinative mineralogy.
Ore continuity	Erratic barren or thin areas in ore zone.	Correlation of stratigraphic units and mineralisation in ore zones, inspection of core for evidence of recrystallisation and horizontal mineral zoning.
Ore crystallinity	Inclusion of contaminants within potash minerals, fine-grained assemblages requiring finer grind.	Correlation of microscopic examination of ore samples with chemical analyses of mineral separates.
Ore reserves	Insufficient reserves or excessive mining and milling costs.	Accurate geological description of deposit for mining and metallurgical studies.

After Adams and Hite (1983)

significant in controlling potash texture and distribution at the basin scale and defines which tectonic associations are likely to be optimal for the development of basins that entrain relatively undeformed, mineable, potash horizons?

First let us consider the some documented Quaternary potash deposits (Table 11.10), these systems can be subdivided into those where the potash minerals occur naturally at the present day landsurface, namely, Salar Gorbea-ET, Quinghai (Dabaxum)-BWk, and Chott el Djerid-BWh. Aridity in these settings ranges across polar tundra, to desert steppe, to hot dry desert. In all three cases the modern potash precipitate is carnallite, not sylvite, and it is either precipitated as ephemeral efflorescences, or occurs as a karst fill cement in a bedded halite host. In no case is Quaternary potash a marine-sourced mineral, in only two regions (Qinghai and Danakil) is the potash present in sufficient volumes to be exploited, and in neither case is the potash present as extensive at-surface beds, rather it occurs in discontinuous karst-influenced cement clusters, hosted in primary textured halite beds. In all the other listed Quaternary examples there is no natural precipitate of potash, it is anthropogenically produced in salt factory facilities operating as brine concentrators, with inflow brine feeds derived either from modern lake brines or recovered by the solution mining of ancient evaporites.

Mineralogically and topographically, there is a distinct schism in Quaternary potash associations. Muriate of potash is the dominant phase produced, or expected to be produced, in the Dead Sea and the Danakil depressions. Both deposits are forming in extreme endorheic lows on the Earth's surface (some 415 and 115 m below sea level, respectively), both are in adiabatic deserts in regions of drastic subsidence, both have brine inflows with chemistries and ionic proportions substantially influenced by the dissolution of older marine evaporites. The slightly milder BSh (hot desert steppe) setting of the southern Dead Sea versus the BWh (hot arid desert) setting of the Danakil, which encompasses the hottest place (year round) on the earth's surface, may explain why carnallite is a at-surface precipitate in the Danakil and a manufactured salt in the desert steppe climate of southern Dead Sea pans (Warren 2015a,b).

In contrast to the two listed muriate of potash occurrences, for the SOP examples the various combinations of mixed sulphate of potash salts are the precipitated precursor salts in the briney lake sediments, as well as being the manufactured product. In Lop Nur, for example the natural lake evaporites are a nonmarine assemblages of mirabilite-glauberite-polyhalite-bloedite-gypsum-halite. The evaporitic stages of the lake fill in Lop Nur contain massive amounts of glauberite

Table 11.10 Quaternary potash occurrences and producers, listed by country

Location	Tectonic setting (orogeny)	Köppen	Elevation (m msl)	Commodity (est. reserve Mt) or occurrence	Comment
Big Quill Lake, Brine plant, Canada	Canadian plain, Foreland basin to Rockies	Dfb	500	Sulphate of potash (small)	Small SOP operation near Wynyard, Saskatchewan, combines trucked-in KCl with Mg_2SO_4 from Quill Lake brine to produce K_2SO_4, for specialty fertilizers. Capacity 40,000 t/year
Salar Gorbea, Chile	Convergent. Intermontane (Andean)	ET	3,946	Local occurrence (not economic)	Carnallite cements in marginal salt crusts in two adjacent salars (Gorbea and Ignorado) with waters that are acidic, almost all other South American salars are neutral or alkaline
Salar de Atacama, Chile	Convergent. Intermontane (Andean)	BWk	2,250	Sulphate of potash (250) and MOP	Solar evaporation of brine, SOP recovered from brine field during $LiCO_3$ concentration. Capacity 650,000/year
Lop Nur, China	Convergent, Intermontane (Himalayan)	BWk	789	Sulphate of potash (36, expanding)	World's largest SOP pan facility at eastern end of Takla Makan Desert in Playa atop former delta of Tarim River
Quinghai Salt Lake, China	Convergent, Intermontane (Himalayan)	BWk	2,672	Muriate of potash (220)	Active solar evaporation of lake brines to precipitate carnallite which is processed to produce KCl
Danakil depression, Ethiopia and Eritrea	Rift (East African-Afar rift)	BWh	−115	Prospect (possible resource more than 600)	Salt mineralogy indicates a brine feed that transitioned from partial Pleistocene marine seepage to modern hydrothermal nonmarine. Active plans to solution mine and open pit mine parts of the deposit
Dead Sea, Jordan and Israel, Middle East	Transform, rift (Palestinian Transform)	BSh	−416	Muriate of potash (1,000)	Brine processing since 1955 (carnallitite slurry), Dead Sea (Israel and Jordan) supplies 10–12 % of world potash (Mg as byproduct). Ongoing problem with halite mushrooms in concentrator pans
Bayovar, brine pilot, Peru	Convergent, marine coastal (Andean)	BWh	2	Prospect	Located in coast part of Sechura Desert. Pilot plant for potash production in operation in coastal evaporators using pumped in solution brines
Chott El Djerid, Tunisia	Intracratonic sag (stable craton)	BWh	15	Local KCl effloresences (not economic)	Small hematite stained crystals of carnallite form atop 10 cm thick halite crust (documented occurrence on Sept. 1990)
Great Salt Lake, USA	Basin and Range	Csa	1,270	Sulphate of potash	Kainite, schoenite and halite in artificial concentrator pans on lake flat pans fed lake brine, slurry processed to produce SOP. Annual capacity 400,000 t
Bonneville Salt Flats, USA	Basin and Range	BSk	1,280	Muriate of potash	Output from lake flat brine trenches pumped into concentrators, brine has less sulphate and magnesium than Great Salt Lake
Cane Creek Mine (Moab salt pans), USA	Basin and Range	BSk	1,390	Muriate of potash	Solution mine in a former mine facility intentionally flooded in 1970, solution mine (Colorado river water injected, recovered mine brine now feeding solar evaporators precipitating carnallitite/ sylvinite in nearby Shafer basin. Capacity 180,000 t/year

See also Table 11.2

and polyhalite compared to the other salts present, and their predominance, is indicative of pervasive back-reactions, as is the presence of very minor amounts of carnallite and sylvite (Ma et al. 2010; Dong et al. 2012). In Great Salt Lake the SOP is produced by processing a slurry of kainite and schoenite that is the prime winter precipitate after halite has formed in

Table 11.11 Some of the world's larger ancient potash ancient potash accumulations, as discussed in this chapter and listed by age of deposit (reserves listed are in million tonnes of *in situ* K_2O, as estimated by Mayrhofer, 1985 – the Salado *in situ* estimate comes from the USGS and includes Paradox reserves)

Host formation and location	Age	Synsalt tectonics	Post-salt tectonics	Halokinesis (reserves)	Mineralogy	Comment
Prairie Evaporites in Western Canada Sedimentary Basin	Devonian (Givetian)	Intracratonic sag that was a distal foreland basin to early stages of Antler Orogeny	Ongoing distal flexural responses Laramide Orgeny	No (507,218)	Sylvite ocean	Extensive ongoing edge dissolution/recycling throughout its history.
Liven Fm., Soligorsk or Starobin deposit, Belarus, Pripyat Basin	Devonian (Frasnian)	Devonian intracratonic synrift passing into aulocogen sag basin	Polyphase former intracratonic sag inverted in Cretaceous-Tertiary	Yes (444)	Sylvite ocean	Synrift salt is actually two separate thick beds Liven (late Frasnian) and Lebeyan (Late Fammenian) Fm
Iren Fm., Upper Kama Basin, Pre Urals Trough, Russia	Permian (Kungurian)	Intracratonic sag basin related to Uralian orogeny	Polyphase, former sag inverted in Mesozoic and Tertiary	Yes (10,822)	$MgSO_4$ ocean	Currently very shallow mining operation with associated groundwater entry considerations
Zechstein salts, NW Europe	Permian (Lopingian)	Intracratonic thermal sag (post Hercynian relaxation)	Polyphase, former intracratonic sag inverted in Cretaceous-Tertiary	Yes (1,620)	$MgSO_4$ ocean	Former more extensive potash beds have been broken up by extensional and compressional halokinesis
Salado Fm., Delaware Basin	Permian (Lopingian)	Intracratonic basin flexure (downwarp) due to closure of Gondwana against Laurentia	Ongoing distal flexural responses Laramide Orgeny	No (800)	$MgSO_4$ ocean	Potash sedimentation in a fill-and-spill transition over old Capitan reef/basin margin
Brazil	Cretaceous (Aptian)	Small isolated rift-margin basin (open of South Atlantic)	Halokinesis via combination of loading and tectonic extension	Yes (100)	Sylvite ocean	Small and discontinuous, stability problems related to nearby tachyhydrite
Carpathian basin, Ukraine	Middle Miocene (Badenian)	Foreland basin form in response to Alpine orogeny	Halokinesis via combination of loading and compression tectonics	Yes (129)	$MgSO_4$ ocean	Problematic ore mineral ores association and patchy ore distribution
Brine producers	(See Table 11.6).					

the summer in the earlier concentrator pans. In Quill Lake, Canada, SOP is produced by the mixing of $MgSO_4$-rich lake brines with sylvite trucked to the lake processing plant.

In the Moab pans, muriate of potash is the product after solar evaporation, dye injection and slurry processing. The brine feed to the solar pans is not a Quaternary lake brine, but is derived from the pumped-in waters of the Colorado River, which are heated, pumped into, and flow through the flooded workings of the former Cane Creek Potash Mine, before being piped into the at-surface solar pans. In Salar de Atacama there are two potash brine processing streams in the evaporation pans, both are fed from a brine field located in the nearby natural sump: (a) One of the pan processing stream produces a KCl precipitate (sylvite and carnallite) as it is concentrated to a lithium chloride brine stage; (b) The other potash processing stream in the pans precipitates SOP with boric acid as a manufactured byproduct. The hyperarid climate at Atacama facilitates year round solar-driven production of the salts. Both the Moab and Atacama occurrences and all the other SOP Quaternary examples listed in Table 11.11 are situated in cool arid (BWk) or desert steppe (BSk) climates, or, in the case of the Great Salt Lake and Quill lake, even milder temperate seasonally arid climates. None of the SOP climates are as extreme as the MOP forming areas in the Danakil and the Dead Sea. Yet these two, and all of the Quaternary lacustrine settings manufacturing SOP, have hydrologies that are fed nonmarine brine inflow with ionic constituents very different from modern seawater.

If we look at Quaternary potash occurrences worldwide, it is clear that all modern potash is a nonmarine salt, as are many of the other economic salt-based feedstocks to the chemical industries of the world (salt cake, soda ash, borates, $CaCl_2$ and lithium brines – Warren 2010). That is, to state the obvious, all Quaternary potash producing environments are

defined by markedly nonmarine sets of environments of deposition. We should not use them as same-scale analogs for ancient marine-associated potash occurrences.

Phanerozoic potash salt beds comprise two distinct associations: $MgSO_4$ -rich and $MgSO_4$ -poor (Table 11.11). Ancient potash deposits, rich in $MgSO_4$, are composed of some combination of gypsum, anhydrite, polyhalite, kieserite, kainite, carnallite and bischofite. Potash deposits free of, or poor in, $MgSO_4$ are dominated by some combination of halite, carnallite, and sylvite. This latter group constitutes a majority of the known "*in situ*" potash reserves of the world, and is very much dominated by the Devonian evaporites of western Canada. Other than minor amounts of sylvite in the halokinetic structures in Late Neoproterozoic-Early Cambrian Ara Salt of Oman, potash salt remnants have not been recognized in Precambrian sediments. In contrast, to the markedly nonmarine locations of potash recovery from the Quaternary sources, almost all pre-Quaternary potash operations extract product from marine-fed basinwide ore hosts during times of $MgSO_4$ depleted and $MgSO_4$ enriched oceans. This time-based dichotomy in potash ore sources with nonmarine hosts in the Quaternary deposits and marine evaporite hosted ore zones in Miocene deposits and older, reflects the simple lack of basinwide marine deposits since the late Miocene (Warren 2010). As for all ancient marine evaporites, the depositional system that deposited ancient marine-fed potash deposits was one to two orders of magnitude larger and the resultant deposits were typically thicker stacks than any Quaternary potash settings. The last such "saline giant" potash system was the Solfifera series in the Sicilian basin, deposited as part of the Mediterranean "salinity crisis".

So, what are the factors that favour the formation of, and hence exploration for, additional deposits of exploitable ancient potash? First they are all basinwide, not lacustrine deposits. Within the basinwide association it seems that intracratonic basins host significantly larger reserves of ore, compared to systems that formed in the more tectonically-active plate-edge association. This is a reflection of: (1) accessibility – near the shallow current edge of a salt basin, (2) a lack of a halokinetic overprint and, (3) the setup of longterm, stable, edge-dissolution brine hydrologies that typify many intracratonic basins. Known reserves of potash in the Devonian Prairie evaporite in West Canadian Sedimentary Basin (WCSB) are of the order of 50 times that of next largest known deposit, the Permian of the Upper Kama basin, and more than two orders of magnitude larger than any other of the other known exploited deposits (Table 11.11).

Part of this difference in the volume of recoverable reserves lies in the fact that the various Canadian potash members in the WCSB are still bedded and flat-lying. Beds have not been broken up or steepened, by any subsequent halokinesis. The only set of processes overprinting and remobilizing the various potash salts in the WCSB are related to various styles and timings of aquifer encroachment on the potash units, and this probably took place at various times since the potash was first deposited, largely driven by a combination of hinterland uplift and subrosion. In contrast, most of the other significant potash basins listed in Table 11.11 have been subjected to ongoing combinations of halokinesis and groundwater encroachments, making these beds much less laterally predictable. In their formative stages the WCSB potash beds were located a substantial distance from the orogenic belt that drove flexural downwarp and creation of the subsealevel sag depression. Like many other intracratonic basins the WCSB did not experience substantial syndepositional compression or rift-related loading.

Non-Potash Salts: Borates, Na-Sulphates, Na-Carbonate, Lithium Salts, Gypsum, Halite and Zolites

12

Introduction

In Chap. 11 we focused on potash deposits and concluded that the larger accumulations of potash that dominate the rock record are marine-derived. That is, the larger potash deposits that are conventionally mined across the world accumulated in ancient tectonic (megahalite) basins with no Quaternary counterpart. We shall now discuss various accumulations of other evaporite salts and related products that are exploited as economic resources, namely the borates, Na-carbonates, Na-sulphates, lithium salts and zeolites, along with short considerations of exploited gypsum and halite deposits (Table 12.1). Other than gypsum and halite, they are typically lacustrine precipitates or brine products, formed by the evaporation of waters with nonmarine ionic proportions and in supra-sealevel depositional settings that do have same-scale pre-Quaternary counterparts (Warren 2010). The marine-derived megahalite and megasulphate deposits, which have no same-scale modern counterparts, were the focus of much of the discussion in earlier chapters. Aspects of these halite and gypsum deposits are only mentioned in passing in this chapter, via a discussion of their annual production volumes and uses, but they are the highest ranked deposits in terms of the weight utilized as mineable or extractable natural resources (Table 12.2). Next in terms of extracted volume is soda ash, then the potash salts, then with an order of magnitude less is salt cake and the borate salts.

This chapter focuses on those industrial salts derived in large part from extraction and processing of evaporite salts or associated brines. There are other industrial commodities, such as bromine, iodine and sulphur that, although intimately tied to evaporites in their natural settings, are no longer extracted via quarrying and mining. Rather these commodities, along with increasing proportions of gypsum, are synthetic byproducts of other industrial processes.

Borate Salts (Tincals)

Borate salts are least in terms of annual volumes extracted of naturally occurring nonmarine salts and of the same order of magnitude as sodium sulphate or salt cake (Table 12.2). Borate production is dominated by a few nations, with Turkey as the largest producer, followed by the USA (Fig. 12.1). Seventy five percent of the market is controlled by the two major producers, Etimine, based in Turkey, and Rio Tinto Borax with its main mine at Boron in California. The rest of the market is made up of half a dozen or so minor producers. The market is, to all intents and purposes, a duopoly. Due to economies of scale and other factors the two main suppliers have low cost bases and the other suppliers higher costs, some significantly so. The lower cost producers can compete on a worldwide basis because they can absorb the transportation costs, while the higher cost producers are mostly restricted to a geographical area, again to a greater or lesser degree determined by their underlying costs. In all world markets the two major producers are the price setters and can determine the price according to the market penetration to which they aspire. There is one very significant difference between the two major producers. Rio Tinto Borax is well into the latter part of the Boron mine life cycle, whereas Etimine's mines are in the relatively early stages of theirs. According to the Turkish Ministry of Energy and Natural Resources, Turkey has over two thirds of the world known boron resource totaling over 950 million tonnes while remaining known US resource is somewhere around 80 million tonnes.

Character, History and Processing

Boron (from the Arabic *Buraq* or the Persian *Burah* meaning white, or to glitter or shine) is a highly dispersed element in nature – averaging 3–20 ppm in the earth's upper crust, as estimated by various authors, and 4.6 ppm in seawater. It is

Table 12.1 Uses of evaporite salts, byproducts and brines

Type	Mineralogy	Source	Uses
Rock-salt (halite)	NaCl	Halite, brine processing	Chloralkali industry for manufacture of chlorine, sodium hydroxide and other related industrial chemicals and industrial products, road de-icing, food processing, water softening, swimming pool additive, stockfeed additive
Gypsum	$CaSO_4$	Gypsum, including secondary after anhydrite	Construction industry, mostly in wallboard and plaster products, cement retardant, agricultural soil enhancer, high purity forms used in wide range of industrial processes including glass manufacture and smelting
Potash (mostly sylvite)	KCl, KNO_3, K_2SO_4	Sylvite, sylvinite, brine processing	Fertiliser (main usage), use as feedstock to chemical industry to manufacture KCl, KOH, K_2CO_3, several forms of potassium phosphate, many other potassic chemicals, drilling muds, also used in recycling alumina, electroplating, etc.
Borates	B_2O_3	Borax (tincal), boracite, colemanite, hydroboracite, kernite, ulexite	Glass, ceramics. fiberglass, textile manufacture, agricultural chemicals, pharmaceuticals, flux cleansing agent, detergents, water softener, preservative and fire retardant
Sodium carbonate (soda-ash)	Na_2CO_3	Trona, solvay process, brine processing	Glass manufacture, chemicals, soap and detergents, pulp and paper manufacture, water treatment, and flue gas desulphurization
Sodium sulphate (salt-cake)	Na_2SO_4	Mirabilite, thenardite, glauberite, brine processing	Filler in soap and detergent powder, textile and glass manufacture, pulp and paper industry, carpet fresheners
Lithium	Li	Brine Processing, hectorite in some saline clays	Production of ceramics, glass, and primary aluminium, battery technology, pharmaceutical
Calcium Chloride	$CaCl_2$	Brine processing	Deicing, dust control, road stabilization, concrete curing, oil well drilling, tire ballasting
Magnesium carbonate, Magnesium oxide, Magnesium sulphate	$MgCO_3$, MgO, $MgSO_4$	Brine Processing, magnesite, electrolytic processing	Majority used for refractories. A constituent in aluminium-base alloys, used for packaging, transportation, and other applications. Remainder is consumed in agricultural, chemical, construction, environmental, and industrial applications
Bromine (sodium bromide)	Br_2, NaBr	Brine Processing	Additive
Iodine	I_2	Brine Processing	Animal feed supplements, catalysts, inks and colourants, pharmaceutical, photographic equipment, sanitary and industrial disinfectant, and stabilizers
Ammonium chloride Ammonium sulphate	NH_4 Cl, $(NH_4)_2SO_4$	Brine Processing	Fertiliser, industrial additive

NH_4 salts are not further discussed in this paper

both a volatile and mobile element and so tends to be enriched in the later stages of both magmatic crystallization and volcanic eruptions and a few small economic deposits are found in skarns where late-stage magmas have intruded carbonates. When these primary sources are weathered in arid settings, borate evaporites can form.

Boron is the fifth element of the periodic table and is the only electron-deficient nonmetallic element. Thus, boron

Table 12.2 World production of industrial salts, all values are in 1,000 metric tons

Year	2006	2007	2008	2009	2010	2011
Salt (halite)	261,000	266,000	276,000	279,000	280,000	286,000
Gypsum	160,000	167,000	157,000	148,000	147,000	147,000
Soda-ash	43,700	46,200	47,000	44,400	48,100	51,300
Potash (K_2O eqv.)	30,400	34,900	33,700	20,800	34,100	36,400
Boron (B_2O_3 eqv.)	3,620	4,200	4.480	3,710	4,050	4,550
Salt-cake	No reliable published data; annual production is ≈4 million metric tons

Production figures compiled from USGS on-line data tables downloaded from. Since 2005, production data for USA in (**a**) is not listed by USGS, supposedly for reasons of commercial confidentiality needed by US companies mining borate

has a high affinity for oxygen and so forms strong covalent-bound salts known as borates. In the chemical industry borate salts are defined as minerals containing boric acid or boron-oxygen molecules (Kogel et al. 2006). As such, their purity can be expressed on the basis of B_2O_3, in combination with a major cation (typically Ca, or Na) and so borates as a

Table 12.3 Commonplace sedimentary (and metasedimentary) borate minerals with B_2O_3 equivalents

Borate Mineral	Composition	B_2O_3%	Remarks
Na Borates			
Borax (tincal)	$Na_2B_4O_7{\cdot}10H_2O$	36.5	Major ore mineral in USA, Turkey and Argentina
Kernite	$Na_2B_4O_7{\cdot}4H_2O$	51.0	Major mineral in USA, often converts to borax
Tincalconite	$Na_2B_4O_7{\cdot}5H_2O$	47.8	Intermediate or accessory mineral + manufactured endproduct
Na-Ca Borates			
Ulexite (cottonball)	$NaCaB_5O_9{\cdot}8H_2O$	43.0	Major ore mineral particularly in Turkey and South America
Probertite	$NaCaB_5O_9{\cdot}8H_2O$	49.6	Secondary/accessory mineral
Ca Borates			
Colemanite	$Ca_2B_5O_{11}{\cdot}5H_2O$	50.8	Major ore mineral, particularly in Turkey. Secondary after inyoite
Meyerhoffite	$Ca_2B_5O_{11}{\cdot}7H_2O$	46.7	Intermediate ore mineral, rarely survives at surface
Priceite (pandermite)	$Ca_2B_4O_{10}{\cdot}7H_2O$	49.8	Ore mineral in Bigadic, elsewhere minor
Inyoite	$Ca_2B_6O_{11}{\cdot}13H_2O$	37.6	Minor ore mineral
Danburite	$CaB_2Si_2O_8$	28.3	Ore mineral (borosilicate) in evaporitic skarns in Russia
Datolite	$Ca_2B_2Si_2O_9{\cdot}H_2O$	21.8	Ore mineral (borosilicate) in evaporitic skarns in Russia
Other Borates			
Sassolite	$B(OH)_3$ or $B_2O_3{\cdot}3H_2O$	56.4	Natural boric acid (fumarole, hot springs), once extracted in Italy
Ludwigite	$(Fe,Mg)_4Fe_2B_2O_7$	17.8	Accessory mineral (meta-evaporitic) association
Hydroboracite	$CaMgB_6O_{11}{\cdot}6H_2O$	50.5	Secondary ore mineral
Szaibelyite (ascharite)	$Mg_2B_2O_5{\cdot}H_2O$	41.4	Ore in Russia and China (meta-evaporite)
Suanite	$Mg_2B_2O_5$	46.3	Ore mineral Russia/China (meta-evaporite, hydrates to szaibelyite)
Boracite (strassfurite)	$Mg_3B_7O_{13}{\cdot}Cl$	62.2	Associated with potash especially in Zechstein of Europe
Pinnoite	$MgB_2O{\cdot}3H_2O$	42.5	Secondary to minor ore mineral in some saline lakes, China
Inderite	$Mg_2B_60_{11}{\cdot}15H_2O$	37.3	Commonplace in ore from Lake Inder deposit, Kazakhstan
Howlite	$Ca_2SiB_5O_9(OH)_5$	44.5	Accessory mineral
Bakerite	$Ca_4B_4(BO_4)(SiO_4)_3(OH)_3{\cdot}H_2O$	42.1	Accessory mineral
Tunellite	$SrB_6O_9(OH)_2{\cdot}3H_2O$	55.1	Accessory mineral
Tertschite	$Ca_4B_{10}O_{19}{\cdot}2H_2O$	65.1	Accessory mineral
Kurnakovite	$Mg_2B_5O_{11}{\cdot}15H_2O$	37.3	Accessory mineral

commodity are sold on the basis of their boric oxide content (Table 12.3). Only a few of the range of naturally occurring borate salts are stable over the long term (Birsoy and Özbaz 2012). Four minerals comprise more than 90 % of the borate salts used by the borate industry; the sodium borates – borax (tincal), kernite, the calcium borate – colemanite, and the sodium-calcium borate – ulexite. Water content of the various borate salts tends to decrease with burial and to increase with exposure and weathering. Borax is the primary mineral in many US deposits, but with burial and dewatering it converts to tincalconite and kernite. If kernite is exposed to weathering or crossflowing groundwater it reconverts to borax.

Currently, borax (tincal) is the preferred sodium borate ore as it needs little processing, crushes freely and dissolves readily in water with a rate of solubility that increases steeply with increasing temperature. "Tincal" is the old general name for borax in the chemical industry and is sometimes used to distinguish the naturally occurring borax ore mineral (tincalonite) from the chemically identical manufactured salt called tincal. Kernite (a source for boric acid manufacture) is present in large tonnages in the USA and Argentina. It is less

suitable as an ore salt than borax or tincalonite despite its high B_2O_3 content. Kernite has excellent cleavage, but crushes into fibres that tend to mat and clog handling equipment. It also is much less soluble in water than borax and so is less suitable as a feedstock for the manufacture of pentahydrate. Colemanite is the preferred calcium-bearing borate; it is the least soluble of the commercial borates and only slowly dissolves in water, but is highly soluble in acid solutions. Szaebelyite, a magnesium borate is the main ore mineral in the Proterozoic meta-evaporite ores of the Liaoning Province, China, while datolite was the principal ore salt in the borate skarns of Dalnegorsk in Russia (Fig. 12.2).

Because most borate salts are soluble in water, most exploitable Neogene deposits of at-surface or near-surface borate salt beds involved lacustrine deposition in arid settings that were strongly influenced by volcanic activity at the time of lake sedimentation. These deposits, which make up the majority of the world's borate reserves, tend to have abundant tuffs and basalts in the drainage basin, to have formed beneath a semi-arid climate and a precipitated from saline continental brines (Fig. 12.3). A protective layer of other impervious less-soluble evaporite salts, such as gypsum or anhydrite, typically forms a carapace that prevents subsequent redissolution.

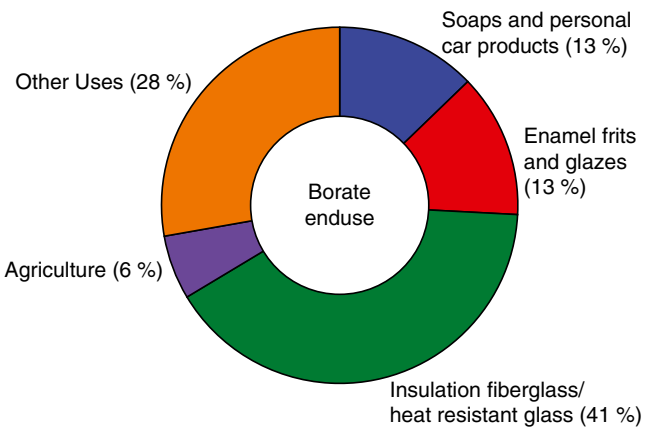

Fig. 12.2 End uses of mined borates (After Butts 2007)

In terms of dollar value, the most commercially significant boron salt is the pentahydrate ($Na_2B_4O_7{\cdot}5H_2O$; tincal), which is used is in the manufacture of borosilicate glass (fibre-glass and heat-resistant glass). Next in importance is borax ($Na_2B_4O_7{\cdot}10H_2O$; sodium tetraborate decahydrate), which is used principally in laundry products. Borax's mild alkalinity means it can emulsify oil and grease and also reduces the surface tension of water which aids in the loosening of dirt particles. It also reacts with some organics to produce esters, making it a mild bactericide. This means it has a strong but gentle cleansing action, making it suitable for personal and fabric cleansing (Fig. 12.2). Borax is also used in the manufacture of abrasives and refractories; some boride compounds have a hardness around 9 on the Moh scale and also exhibit high thermal and electrical conductivity. In agriculture boron is essential to plant growth and one of the 16 basic plant nutrition although in higher concentrations it is toxic. Use of borax as a mild antiseptic is minor in terms of both dollars and tons. Amorphous boron is used in pyrotechnic flares to provide a distinctive green colour, and in rockets as an igniter. Other boron compounds show promise in treating arthritis.

In the field of nuclear energy, boron (the ^{10}B isotope) protects personnel from the harmful effects of reactors. It has the unique property of absorbing neutrons produced by nuclear reaction without the emission of harmful secondary gamma radiation and is sold as an organic borate, made by combination with paraffin, for nuclear shielding. The elemental form of boron is also incorporated into polyethylene and rubber. Ammonium pentaborate is used in a 'poison' charge in atomic submarines. Another organo-sodium borate (Liquibor) is now in use in hydraulic brake fluids in cars to provide lower volatility and built-in corrosive protection. Boron, also, confers a low co-efficient of expansion, increases the resistance to mechanical and thermal shocks and gives a bright and pleasing appearance to glass. Borax and boric acid are used together in the manufacture of a number of boro-silicate glasses of low alkali content. Between 15 and 50 parts of borax are used to each 1,000 parts of a glass-sand batch to give enhanced properties to glass.

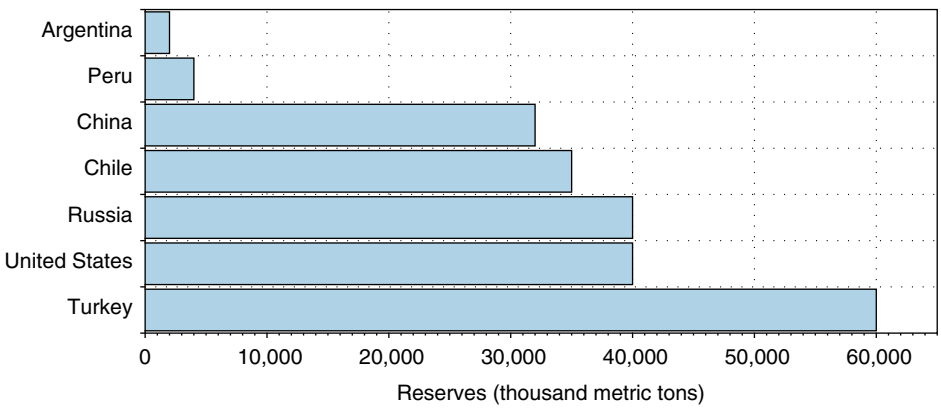

Fig. 12.3 World borate reserves as listed by USGS (http://minerals.usgs.gov/minerals/index.html last accessed April, 2014)

Boron nitride can be used to make a material almost as hard as diamond. Cubic boron nitride, commercially called 'Borazon' can withstand temperatures which are more than twice the temperature limit of a diamond (about 900 °C) and so is used as a flux in the manufacture of artificial gems. The nitride also behaves like an electrical insulator but conducts heat like a metal. It also has lubricating properties similar to graphite. Boron hydrides are easily oxidized with considerable energy liberation, and have been studied for use as rocket fuels and ignitors for fuels. Demand is increasing for boron filaments, a high-strength, lightweight material chiefly employed for advanced aerospace structures. This form of boron is similar to carbon in that it has a capacity to form stable covalently bonded molecular networks.

Historically, borates (as a component of natron salts) were used 4,000 years ago in mummification. Subsequently, borax (in a purer form than natron) was imported from the Far East for use as a gold and silver flux, first used by the ancient Babylonians. The word tincal comes from the Babylonian *tincar* meaning "Far East" and the Malay word *tingkal* meaning borax.

By the eighth century AD, the Arabs around Mecca, Medina and Baghdad were using imported borax (tincar) as a kiln additive or flux to braze or harden precious metals, especially gold. Borax glazes were used in China from AD 300, and boron compounds were used in glassmaking in ancient Rome. By the Middle Ages, borax from Tibet was regularly imported into Europe. At the time borax was very expensive, and this limited its use principally to the precious metal trade where goldsmiths used it as a soldering agent and in the refining of metals and assaying of ores. Quantities traded were small, its method of production was a tightly held secret of the alchemist's guild, and its source in the borate pavements precipitated in the salt lakes of Tibet remained a mystery until the second half of eighteenth century.

At the time of Marco Polo's travels, Tibetan borax was transported over the Himalayas into India in bags tied to the necks of sheep. Marco Polo claimed to have brought the first borates from China to Europe and his homeport of Venice became a centre for refined arts in gold, ceramics and glassware. This use of borate was a closely held Venetian "trade-secret". The price of borax remained high for hundreds of years, with refined borax fetching $3/oz in London, as late as 1790. Tibet continued to be the source of most borate into Europe until the beginning of the nineteenth century when sassolite was discovered around fumaroles in Larderello, near Pisa, Italy and production began there in 1808. Sassolite is natural boric acid and is a volcanic product that occurs in association with sulphur in the craters of volcano. As well as the Lardello deposits it was found in the Lipari Islands, southern Italy and the Tuscan lagoons, between Voltena and Massa Marittima. In all cases the boric acid condenses naturally in water and separates in large sassolite flakes which contain about 50 % of the acid.

Subsequent borate salt discoveries in the desert playas of North and South America in the 1860s to 1880s brought large volumes to the market and prices fell as manufacturing volumes increased for this once rare commodity. Today, borate's supply routes are more mundane, but the volumes consumed in the chemical industries are huge (Fig. 12.1c), with major present or past production centres in northern Argentina, Chile, southern Bolivia, Peru, southern California, eastern Russia, Turkey, and China.

US Borax, a member of the Rio Tinto Borax Group, is the largest global miner of B_2O_3, mostly of tincal ore. The company is also the world's largest manufacturer of refined borate products. US Borax supplies almost half of the world's demand for industrial and specialty borates from its Kramer borate deposit at Boron in southern California's Mojave Desert. Turkey is the world's largest producer of borate ore, mining more than 1 Mt (1.1 million st) of salable product each year (Fig. 12.1a) including refined materials from Kirka and Bandirma. This makes Turkey the second largest producer of refined boron compounds after the USA. The government organization, ETI Holding A. S., is the sole producer of Turkish borate compounds through its subsidiary Etibank A. S. Combined production of Turkey and the US accounts for more than 90 % of the global borate output.

During ore processing, advantage is taken of the solubility of borate salts, especially borax and kernite, in separating clayey material by water washing and recrystallization. Refined borax is produced by dissolving the crude material in hot water under pressure. The insoluble impurities are filtered off and the liquor is crystallized to give borax, or if boric acid is to be manufactured, the hot water solution is reacted with sulphuric acid. The reaction that takes place is as follows:

$$Na_2B_4O_7 \cdot 10H_2O + H_2SO_4 \Rightarrow 4H_3BO_3 + Na_2SO_4 + 5H_2O$$

The ulexite or colemanite mined in Turkey is shipped to many European countries for processing into boric acid and borax. Ulexite and colemanite are treated in the same manner with sulphuric acid to convert them into boric acid. If borax is to be prepared, the boric acid is added to a soda ash solution. Borax is also produced from colemanite via boiling the powdered mineral with a sodium carbonate solution for about 3 h. After filtering, the solution is allowed to crystallize to yield crude borax. Borax is recovered from the Searles Lake deposits as a by-product of potash recovery.

Geology of Borates

The major commercial borate deposits occur in a limited number of Neogene to Holocene non-marine evaporitic settings (Garrett 1998; Helvaci et al. 2012). They are always

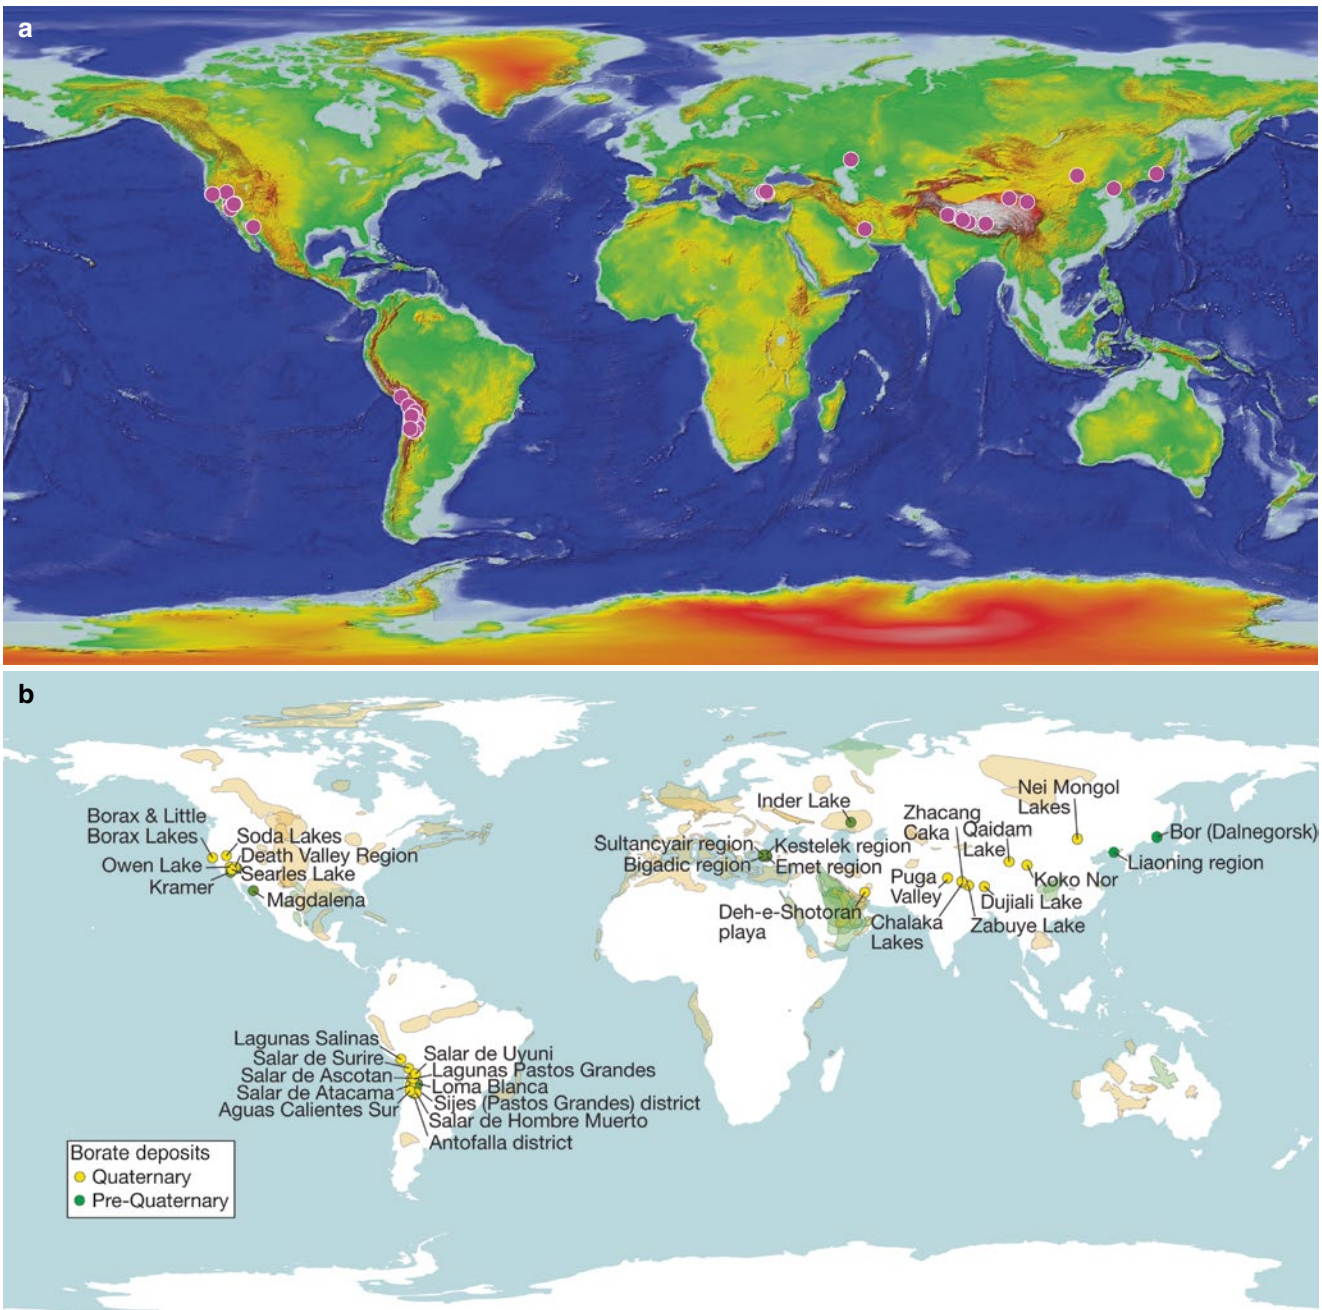

Fig. 12.4 Borate deposits. (**a**) Deposits plotted on a world topographic/tectonic base (Table 12.4). (**b**) Deposits plotted on a marine evaporite basin base, where brown shading indicates halite-dominant and green indicates megasulphate basin (After Warren 2010). Plot shows that borate deposits are better developed in volcanic-associated, active orogenic collision belts and zones of fractured continental crust. They do not occur atop or within large marine-fed mega-evaporite basins

related to volcanic rocks and pyroclastic deposits and closed-basin alkaline lakes or playas fed by hydrothermal sources (Fig. 12.5b). Borax, and to a lesser extent kernite, is open-pit mined today at the Kramer mine near Boron in California, the Sarikaya mine in Kirka ore district (Eskisehir Province, in Turkey), and Tincalayu in northern Argentina (Fig. 12.4, Table 12.4; Briggs 2007). These three saline lacustrine regions, plus the brines from Searles Lake, California, furnish the majority of the sodium borates used by chemical industry (Fig. 12.1a). Sodium borates ores are easily soluble in water, making them preferable feedstock for many end uses. Most of the larger extractive facilities also produce boric acid at nearby refineries. Colemanite is mined from several deposits in the Emet and Bigadic basins of western Turkey, one former Death Valley deposit, and small deposits in northern Argentina. This calcium borate is used in boron

Table 12.4 Borate deposits of the world, listed by country, areas and Köppen climate for Quaternary playas/salars

Location	Age	Elev. (m)	Köppen	Mineralogy/setting/comments
Loma Blanca, Argentina	Miocene (7 Ma)	3,970	–	Borax, lesser inyoite and ulexite, some kernite, minor colemanite in Sijes Fm (2.7 mt). 30 m of borate is interlayered with green-grey tuffites and clays and overlain by volcaniclastics. Active open pit. (Alonso et al. 1988; Helvaci and Alonso 2000)
Salar de Hombre Muerto, Argentina (565 km^2)	Quaternary	4,300	ET	Ulexite on playa surface and shallow subsurface, also large brine reserves (second largest playa after Arizaro in Argentine Puna region). Borate recovered as byproduct during lithium recovery (3 mt). Typical lake brine contains 230 ppm B and 540 ppm Li. Low Mg/Li. Lithium largely sourced via leaching of surrounding volcaniclastics (Garrett 1998; Vinante and Alonso 2006; Godfrey et al. 2013)
Sijes district (Monte Amarillo, Monte Verde, Esperanza, and Santa Rosa deposits), Argentina	Miocene, 5.7–6.8 Ma	4,050	–	Bedded colemanite [Monte Verde, Esperanza (upper beds)], inyoite [Monte Verde (middle beds)], and hydroboracite [Monte Amarillo (lower beds)] within the Sijes Formation (4 mt). Deposited in more than ten 1–4 km^2 sub-basins as a chain of lakes, fed via thermal springs probably opened by emplacement of the Quevar volcanic complex. Deposits change laterally from borates to gypsum (or anhydrite) to clastics or pyroclastics and are folded and dip to the east. Open pit mining (Garrett 1998; Orti and Alonso 2000).
Tincalayu, Argentina	Miocene, 5.86 Ma	3,938	–	Borax (4.8 mt) in Sijes Fm, occurs as limited zones of kernite in lower part of ore bed, or veins, ulexite nodules in clays occur above ore. Irregular borate member (folded) lies atop a halite unit (that is less than 100 m thick) and is covered by 25 m-thick pelitic member. (Ericksen 1993; Helvaci and Alonso 2000)
Lagunas Pastos Grandes, Bolivia (100 km^2)	Quaternary	4,430	ET	Brine, ulexite. Lithium and potassium recovery from lake brine is possible. This salar is slightly southwest of Uyuni, in Bolivia. There is also a Pastos Grandes in Argentina. Typical lake brine contains 230 ppm B and 540 ppm Li. (Muessig 1966; Jones and Renaut 1994; vanderVoort 1997)
Salar de Uyuni, Bolivia (9,654 km^2)	Quaternary	3,650	BWk	Ulexite (10 mt). Surface salt crust in the southern area is being mined for its ulexite content (in 1996 at a rate of 5,000 t/month), and salt has been mined from the central area since the 1500s. Typical lake brine contains 320 ppm B and 187 ppm Li (Garret 1998, 2004; Risacher and Fritz 2000)
Aguas Calientes Sur, Chile (76 km^2)	Quaternary	3,770	ET	Ulexite. Previously mined. Lake brines have elevated levels of both boron (474 ppm) and lithium (152 ppm). Possible future lithium resource. (Garrett 1998; Chong et al. 2000)
Salar de Ascotan, Chile (232 km^2)	Quaternary	3,960	ET	Ulexite. It was first Puna salar to be mined (1852), but there was no significant production until the 1880s, by 1900 it was among the world's largest producers, reaching a peak in 1913 and almost totally stopped from 1967 to 1978. Harvesting resumed in late 1990s. (Garrett 1998; Chong et al. 2000)
Salar de Atacama, Chile (3,065 km^2)	Quaternary	2,300	BWk	Natural ulexite nodules on or near parts of salar surface. Borate as byproduct during potash and lithium production via brine processing (10 m). Previously mined for borates in early part of last century. Lake brine contains up to 440 ppm B and 1,570 ppm Li. (Bobst et al. 2001; Boschetti et al. 2007)
Salar de Surire, Chile (141 km^2)	Quaternary	4,250	ET	Ulexite (5 m). Perennial lake with hot springs below, still producing ulexite via open pit method. Sporadically mined since 1880s. Lake brine contains up to 1,820 ppm B and 340 ppm Li. (Garrett 1998; Chong et al. 2000)

Table 12.4 (continued)

Location	Age	Elev. (m)	Köppen	Mineralogy/setting/comments
Liaoning Borate region, China	Paleoproterozoic	500	–	Szaibelyite (ascharite) and szaibelyite-ludwigite, with some suanite. Metasediments and metavolcanics in Liaoning and Jilin provinces. 55 underground and open pit mines in 112 separate borate deposits (12 contained 98 % of the reserves) in the Liaoning area (40 mt). (Peng and Palmer 2002)
Numerous lakes and flats, Tibet Plateau, China (>50–100 km^2)	Quaternary (<40 ka)	3,200	Dwc	Numerous (>60) low carbonate-borate lakes on Qaidam-Ziqang flats (e.g. lakes Koko and Qinghai) with B potential via brine processing. Lake waters up to 2,000 ppm B and 310 ppm Li. See Xiao Chaidam and Dujali Lake for representative deposits) Borate nodules in Qaidam saltflats are more extensive than in water-covered lake beds. (Vengosh et al. 1995; Li et al. 2001; Zheng and Liu 2009)
Xiao Chaidam (Qaidam Lake), Chaidamu Basin, China (Tibet) (51 km^2)	Quaternary	3,154	BWk	Pinnoite, ulexite, halite, minor mirabilite in perennial lake beds on edge of Quidam Basin. Upper 2.5–3.5 m are porous with gypsum and mirabilite beds, next 1–2 m contain ulexite with gypsum and lentiform mirabilite, below is 1–2 m of gray-to-black mud with gypsum. Lake brines contain up to 3,600 ppm B and 280 ppm Li. (Garrett 1998; Zheng 1997)
Dujiali Lake (Guojialin), China, (Tibet) (480 km^2)	Quaternary	4,632	ET	Borax, tincalconite. Section made up of thin beds of borax interlayered with mirabilite and trona. Lake was a major borate supplier to Medieval Europe (gold flux), salt crusts are still periodically harvested. Lake brine contains 1,540 ppm B. (Garrett 1998; Zheng 1997)
Nei (Inner) Mongol Plateau Lakes, China (up to 990 km^2)	Quaternary	998	BSk	Borax/Boric acid (byproduct of soda-ash production at lakes Chaganor (aka Qagan Nur) and Ordus lakes). Numerous borate springs in region. Lake beds typically composed of two alternating layers, one of natron, mirabilite, halite and trona, which is interbedded with black mud containing illite, some gaylussite, dolomite and calcite. (Garrett 1998; Zheng et al. 1993, 1997; Zheng and Liu 2009)
Zabuye (Chabyer) Salt Lake, China (Tibet) (251 km^2)	Quaternary	4,426	Dwc	Borax. High concentrations of the alkali metals (K, Li, Rb, and Ce) as well as borax, sodium, chloride, sulphate, and carbonate. Similar to Searles Lake. Lake brine contains 1,760 ppm B. Lithium carbonate (zabuyelite) is a natural salt precipitate in the lake. Operational lithium plant. (Wang et al. 2004; Zheng et al. 1993, 1997; Nie et al. 2009)
Zhacang Salt Lakes (Zhacang Caka), China (Tibet) (26 km^2)	Quaternary	4,962	ET	Mirabilite in uppermost sediments, as well as kurnakovite, pinnoite, inderite, ulexite. A large playa basin in interior of the Tibetan Plateau. There are three salt lakes (Lakes I, II and III) in playa, with areas between 23 and 58 km^2, and salt depths of 30 cm to 2 m. (Xiyu 1984; Zheng et al. 1993)
Puga Valley, Kashmir. India	Quaternary	4,400	ET	Kernite crusts periodically removed since 1860s. Hot springs with kernite crusts, is part of the extensive Ladakh borax spring zone. (Garrett 1998)
Deh-e-Shotoran playa, Iran	Quaternary	1,806	BSk	Ulexite. Minor occurrences of ulexite precipitated in halite-rich saline depressions in a region draining tourmaline-rich granites. (Garrett 1998)
Inder Lake, Kazakhstan (106 km^2)	Quaternary	−25	BSk	Hydroboracite is main ore mineral, also borax, colemanite, inyoite, sylvite, ulexite. Receives drainage from the borate-containing Inder salt dome and has formed a porous, 36-m deep brine-filled lake atop salt mass (1 mt) with borate veins in salt dome caprock. (Garrett 1998)

(continued)

Table 12.4 (continued)

Location	Age	Elev. (m)	Köppen	Mineralogy/setting/comments
Magdalena, Mexico	Mid-Tertiary (Miocene?)	850	–	Howlite veins in Tertiary lacustrine sediments, minor meyerhofferite and priceite. Colemanite in subsurface (high arsenic levels make processing difficult). 50 % of veins are 10–30 cm thick in pale red-green tuffaceous shales, 40 % are 1- to 20-cm beds in finegrained silty sandstone, 10 % are 1- to 80-cm beds in zeolitic or lithic tuffs (Lefond and Barker 1979)
Laguna Salinas, Peru (110 km^2)	Quaternary	4,400	ET	Inyoite, ulexite. It becomes partly flooded (50 cm deep) after the winter rains (December-March) and dries rapidly to form surface crusts containing ulexite, halite, glauber salt and thenardite. Beneath the surface are irregular 10- to 100-cm beds or lenses of ulexite (3 t). (Muessig 1958)
Bor (Dal'negorsk), Russia	Triassic?	270	–	Datolite and danburite. Rhythmically banded pyroxene-wollastonite skarn (3 stages) in Triassic limest. and siltstone intruded by Cretaceous granodiorite; Ore body is 2 km long, <500 m wide, > 1,000 m deep. Boroslilicates can occur as "giant crystals" and are cogenetic with the Pb-Zn-Ag skarns and replacements in the same worldclass ore field. Mined as open pit (54 mt) (Obolenskiy et al. 2007) Likely nomarine evaporite source for boron Baskina 2008; Dubinina et al. 2011)
Bigadic region, Turkey	Miocene, 17 Ma	444	–	Ulexite and colemanite, minor but locally significant probertite and hydroboracite, Borate beds (0.2–0.5 m thick) alternate with marl, tuff, claystone mudstone. Ulexite sits atop colemanite (330 mt) (Helvaci 1995)
Emet region, Turkey	Mid-Oligocene	1,028	–	Colemanite with minor ulexite, hydroboracite, intercalated claystones. Borate zones mostly discontinuous, nodular in beds 2–20 m thick (200 mt). (Helvaci and Alonso 2000). Proberite diagenetically replaces ulexite in the lake margins during flooding episodes of the tuff flats and there is a biogenic (bacterial) dolomite association in the lake carbonates (García-Veigas et al. 2011b).
Kestelek region, Turkey	Miocene, 17.4 Ma	748	–	Colemanite, ulexite, and probertite predominate, with coarse hydroboracite. Nodular colemanite in 5 m thick zone intercalated with volcaniclastic claystones (3 mt). (Helvaci 1994)
Kirka region, Turkey	Miocene, 17 Ma	1,000	–	Main borate minerals is borax, with lesser ulexite and colemanite (140 mt). Borate lacustrine interval is up to 145 m thick and hosts the only sodium borate orebody in Turkey, with a B_2O_3 content of 20–25 % (Helvaci and Orti 2004)
Sultancyair region, Turkey	Miocene, 20 Ma	210	–	Priceite in gypsum-clay matrix, minor howlite. District with first (1865) borate mine (underground mine) in Turkey, region is now depleted. (Helvaci 1994)
Borax Lake, California, USA (1.2 km^2)	Quaternary	500	–	Layered borax grits some 0.6–1 m below lake floor clays. Small (100 ha) shallow perennial lake, adjacent to active hot spring in recently active volcanic area. First commercially exploited deposit in US (1860s). (Garrett 1998)
Death Valley region, California, USA (54 km^2)	Quaternary	−24	BWh	Ulexite is common on the modern halite playa, along with halite, thenardite, and trona. (Crowley 1993)
Death Valley Borate deposits, California, USA	Miocene, 6–7 Ma	950	–	Colemanite with ulexite and proberite in central core. 23 deposits in area. Borates interbedded with lacustrine clays, tuffaceous mudstones, mainly in Black Mountain tectonic block (8 mt; deposits include; Biddy-McCarthy; Billie; Boraxco; Corkscrew-DeBely; Gertsley; Grand View Mine). (Tanner 2002)

Table 12.4 (continued)

Location	Age	Elev. (m)	Köppen	Mineralogy/setting/comments
Hector (Fort Cady area) Ca, USA	Miocene -Pliocene?	900	–	Colemanite intersected in a 58-m drillhole interval at 410 m depth as stacked <60 cm thick beds of spherulitic crystals in a tuffaceous clay or anhydrite rock host. Some secondary veins of clear colemanite or anhydrite and minor howlite (potential 7 mt) (Garrett 1998)
Kramer, Boron, California, USA	Miocene, 19 Ma	800	–	Borax, colemanite, kernite, tincalconite. Lacustrine deposit underlain and overlain by arkoses with Saddleback Basalt as base to deposit (46 mt) (Garrett 1998)
Little Borax (Hachinhama) Lake, California, USA (0.1 km^2)	Quaternary	400	Csb	Borax from solar evaporators on edge of small shallow (>1 m deep) perennial saline lake in volcanic crater. Operational only from 1869 to 1872, could not compete with playa ulexite deposits (Garrett 1998)
Owens Lake, California, USA (278 km^2)	Quaternary	1,081	BSk	Trona is the dominant primary sal preserved in the surface crust, also borax, some burkeite, mirabilite, natron, and thermonatrite. In winter considerable natron, glauber salt, and borax crystallize, but largely melt in the warmer summer brine (Smith and Friedman 1998). From 1915 to 1953 soda-ash was produced from brine evaporators with borax byproduct. Salts derived from leaching of nearby active geothermal springs (3 mt) (Alderman 1985; Garrett 1998)
Searles Lake, California, USA (132 km^2)	Quaternary	493	BWk	Trona is the dominant salt, also borax, some burkeite, mirabilite, natron, and thermonatrite. In winter considerable natron, glauber salt, and borax crystallize, but melt in summer. Mother brine via dissolution of buried glauberite (43 mt) (Garrett 1998; Smith 1979)
Soda Lakes, Nevada, USA (0.16 km^2)	Quaternary	1,000	BWk	Borax as minor byproduct of soda-ash brine operations in 1860s. Is a small playa adjacent to Big Soda Lake. (Garrett 1998)

See Fig. 12.4 for locations (reserves in mt (million metric tons) of B_2O_3 after Garrett 1998; for overviews see Warren 2010, Carpenter and Kistler 2006, and references within

endproducts that have a low sodium requirement, and in making boric acid.

Ulexite is the common playa (salar) or hypersaline marsh borate. It is produced commercially from numerous salars in South America and playas in the Provinces of Quinghi and Xizang (Tibet) in western China. Ancient saline lacustrine deposits 5–20 million years old— are the source of Turkish ulexite, it is found in Death Valley and in some of the ore produced in Argentina. Much of this material is ground and used as a crude product in agriculture or to manufacture boric acid.

The less easily refined magnesium borates of China occur in the Palaeoproterozoic metasediments of Liaoning peninsula adjacent to North Korea. These are mined by underground methods and refined in small, local plants to produce sodium borates and boric acid for domestic use. A unique borosilicate skarn deposit (datolite and danburite) near Dal'negorsk in fareastern Russia is open pit mined to produce boric acid. Triassic carbonates were intruded by Cretaceous granodiorites to create the borosilicate skarn. Borates from this source were once shipped by rail to western Russia and eastern Europe, when they were mines operated under the auspices of the Former Soviet Union, but more recently ore products are shipped through local ports to markets in the Far East.

Other borate deposits, some of which were once mined commercially, include the Inder region of Kazakhstan, the Stassfurt district of eastern Germany, as well as parts of northern Iran, and Yugoslavia. Numerous smaller lacustrine playa deposits are known in western United States, western Turkey, and in South America. Some of these Holocene playa deposits were extensively exploited by pioneer producers in the late nineteenth and early twentieth centuries, but are not currently in production (Garrett 1998; Warren 2010). We shall now discuss the geological detail of the more significant of these borate deposits.

Turkish Borates

Turkey has the largest known reserves of natural borate in the world. The borate region of western Anatolia has five districts, from west to east they are: Bigadic, Sultancayir, Kestelek, Emet, and Kirka, with the Kirka district containing the most mature borate mining operations (Fig. 12.5a; Helvaci and Orti 1998, 2004; Helvaci and Alonso 2000;

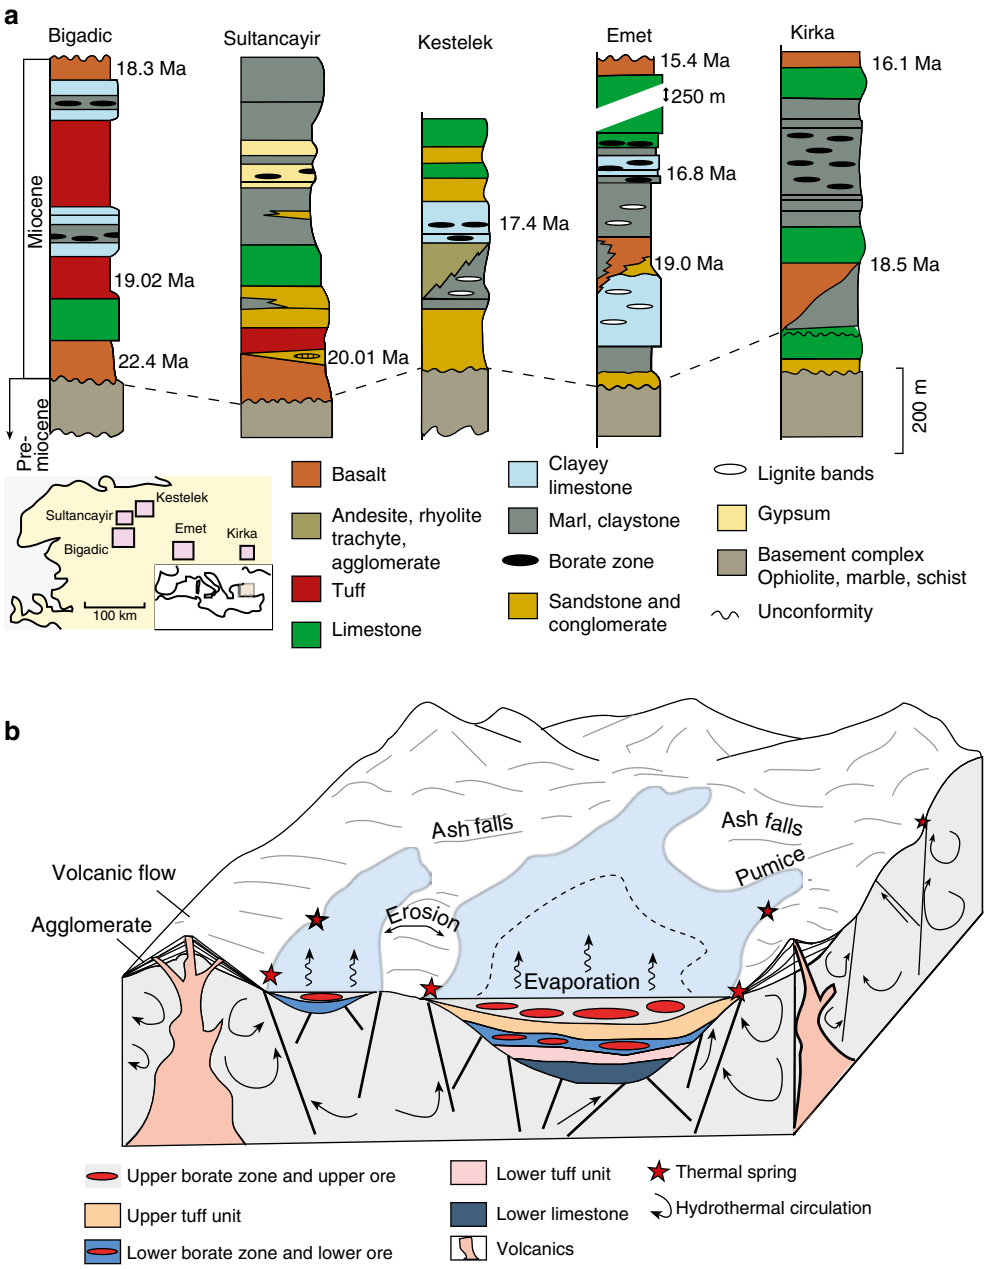

Fig. 12.5 Turkish borate deposits. (**a**) Representative sections of the various Miocene borate deposits in western Turkey. All occur in local extensional rifts in a volcanogenic continent-to-continent collision setting (After Helvaci and Alonso 2000). (**b**) Classic playa stage of the Bigadic Deposit (After Helvaci 1995). Deposition occurred under arid to semi-arid conditions within separate or interconnected shallow perennial saline lakes located in an active volcanic area within lakes, fed by borate-rich thermal springs and surrounded by saline mudflats

García-Veigas et al. 2011b; García-Veigas and Helvaci 2013). Turkish borates have been mined for the last fifteen centuries. Proven borate reserves are 532 million tonnes with total estimated reserves of 987 million tonnes. Colemanite is the major ore mineral at Bigadic, Emet, and Kestelek, ulexite at Bigadic, and tincal at Kirka. Borax and colemanite ores are refined and concentrated at the Kirka and Bandirma plants. Bigadic borates are extracted from what is likely the largest colemanite/ulexite deposit in the world, with high-grade colemanite and ulexite ores running 30 % and 29 % B_2O_3, respectively.

The Kirka stratigraphic succession comprises borates that are intimately interbedded with and penetrating into marls, claystones, zeolitized tuffs and tuffaceous epiclastic materials in bedded lacustrine sediments (Fig. 12.5a). The main boron mineral is borax with lesser amounts of colemanite, ulexite and other borate minerals. Volcano-sedimentary rock units in the Sultancayir deposit include borate-bearing gypsum intercalated in a sandy claystone unit. Calcium borates, mainly pandermite (priceite) and howlite, but also colemanite and bakerite, are interspersed within the Sultancayir gypsum. The Kestelek deposit is 27 km southeast of the town of Mustafa Kemalpasa in the province of Bursa. The borate ore zone there makes up part of an interbedded lacustrine succession of marl, limestone, tuffaceous limestone, tuff and borate layers (Fig. 12.5a; Helvaci and Alonso 2000). Borate

layers are typically hosted in clays. Colemanite is present as nodule to boulder size masses (up to 1 m in diameter), and as thin layers of fibrous and euhedral crystals. Colemanite, ulexite and probertite predominate and sparse hydroboracite is also present locally.

All the exploited Turkish borate ores were originally precipitated as early Miocene (16–20 Ma) perennial saline lake sediment within a series of northeast-southwest-trending elongate basins, which are underlain by a Palaeozoic and Mesozoic basement composed of ophiolites, marbles and schists (Fig. 12.5b; Helvaci 1995). The Bigadic, Emet and Kirka lacustrine basins of western Turkey are hosted by Tibet-type extensional graben structures. The grabens developed during Miocene continent-to-continent collision along the Izmir-Ankara suture zone, where calc-alkaline volcanism was simultaneous with borate sedimentation. This volcano-sedimentary sequence consists of (from bottom to top) basement volcanics and volcaniclastics, lower limestone, lower tuff, lower borate zone, upper tuff, upper borate zone and olivine basalt (Fig. 12.5b). Borates in the upper zone occur in units up to 30 m thick beneath a sediment cover that is 25–410 m thick, while the lower borate zone is up to 65 m thick and is found at depths between 150 and 950 m.

All these Neogene borate deposits have thin sedimentary covers and have never been deeply buried (Helvaci and Orti 1998). Borate precipitation occurred mostly in shallow to at-surface brine saturated settings, in saline lake systems encompassing a range of evaporitic settings, from stable playa mudflats to deeper perennial lakes, the latter typically preserve shoaling suceessions, changing from shallow lake to playa and mudflat. Shallowing-upward cyclicity typifies all ore beds in these deposits, which accumulated as lacustrine deposits in a hydrothermally active volcanogenic terrain (Fig. 12.5b). Colemanite tends to occupy the deposit's depositional margins, while laminated borax is more common in the centres of the lacustrine basins, with a zone of ulexite separating the two (Inan et al. 1973). This mineral zonation is syndepositional and cannot be ascribed to later burial diagenetic processes.

When details on these obviously primary to very early secondary (sabkha) deposits began to come to the world scientific literature in the mid 1970s the prevailing notion of borate ore zones as thermal replacements (mesogenetic) during somewhat deeper burial were challenged (thermal replacement models were largely based on the US deposits and the work of Foshag 1921 and Christ and Garrels 1959). When details of the primary borate textures in South American deposits became known in the mid 1980s (next section in this chapter) even some of the strongest proponents of the thermal or mesogenetetic replacement model for borate ores began to admit the possibility of a primary or syndepositional origin for the ore zonation for most of the world's borate deposits.

Borate minerals at Bigadic form two ore zones, now separated by thick tuff beds that have been transformed to montmorillonite, chlorite, and zeolites (mainly heulandite) during diagenesis (Figs. 12.5b and 12.6; Gundogdu et al. 1996; Helvaci and Orti 1998). Colemanite with lesser ulexite predominates in both zones: but other borates, including howlite, proberite, and hydroboracite are present in the lower borate zone; whereas inyoite, meyerhofferite, pandermite, tertschite(?), hydroboracite, howlite, tunellite, and rivadavite are found in the upper borate zone (Helvaci 1995). Calcite, anhydrite, gypsum, celestite, K-feldspar, analcime, heulandite, clinoptilolite, quartz, opal-CT, montmorillonite, chlorite, and illite are also found in the Bigadic deposit.

Nodules of colemanite and ulexite predominate in both borate zones at Bigadic (Fig. 12.6). Agglomerated colemanite and ulexite nodules construct alternating bedded horizons with relatively sharp boundaries. Because these minerals are readily dissolved and reprecipitated, early secondary masses of pure and transparent colemanite and ulexite are often encountered in cavities, nodules and cracks in the same ore hosts. Some nearsurface colemanite and ulexite beds are now so weathered they are completely replaced by calcite.

Colemanite nodules in both ore zones first formed as widespread secondary syndepositional precipitates in concentrated pore brines within unconsolidated gypsiferous sediments (Fig. 12.6; Helvaci and Orti 1998). Colemanite and ulexite formed mostly as interstitial growths under syn-sedimentary conditions, either as mineralogically primary or as displacive and cementing lithofacies. All crystals were later affected by waters tied to progressive compaction and the conversion of gypsum to anhydrite. Heliothermal conditions may have favoured the precipitation of colemanite over ulexite on the shallow bottom or just below the sediment surface in some density-stratified lakes. Locally, some colemanite is a secondary precipitate emplaced during early burial, its precipitation was possibly driven by compactional pore water crossflow via the (macroscopic) replacement of precursor ulexite. Early formed nodules continued to grow as the sediments were compacted to give septarian-like fracture fills. Later generations of colemanite and ulexite are found in vugs and veins and as fibrous margins of early-formed nodules. Burial diagenetic changes in the main borates include the partial replacement of colemanite by howlite and hydroboracite, and replacement of ulexite by tunellite. It is unlikely that substantial volumes of Turkish colemanite ever formed by dehydration of inyoite or by a burial driven thermal replacement of ulexite.

Proberite bands at Bigadic are found in some ulexite horizons, especially in the lower borate zone. It formed in the same chemical environment as ulexite, and according to Helvaci (1995) indicates short periods of extreme desiccation and possibly short periods of subaerial exposure within the lake centres. Euhedral tunellite formed during dissolution

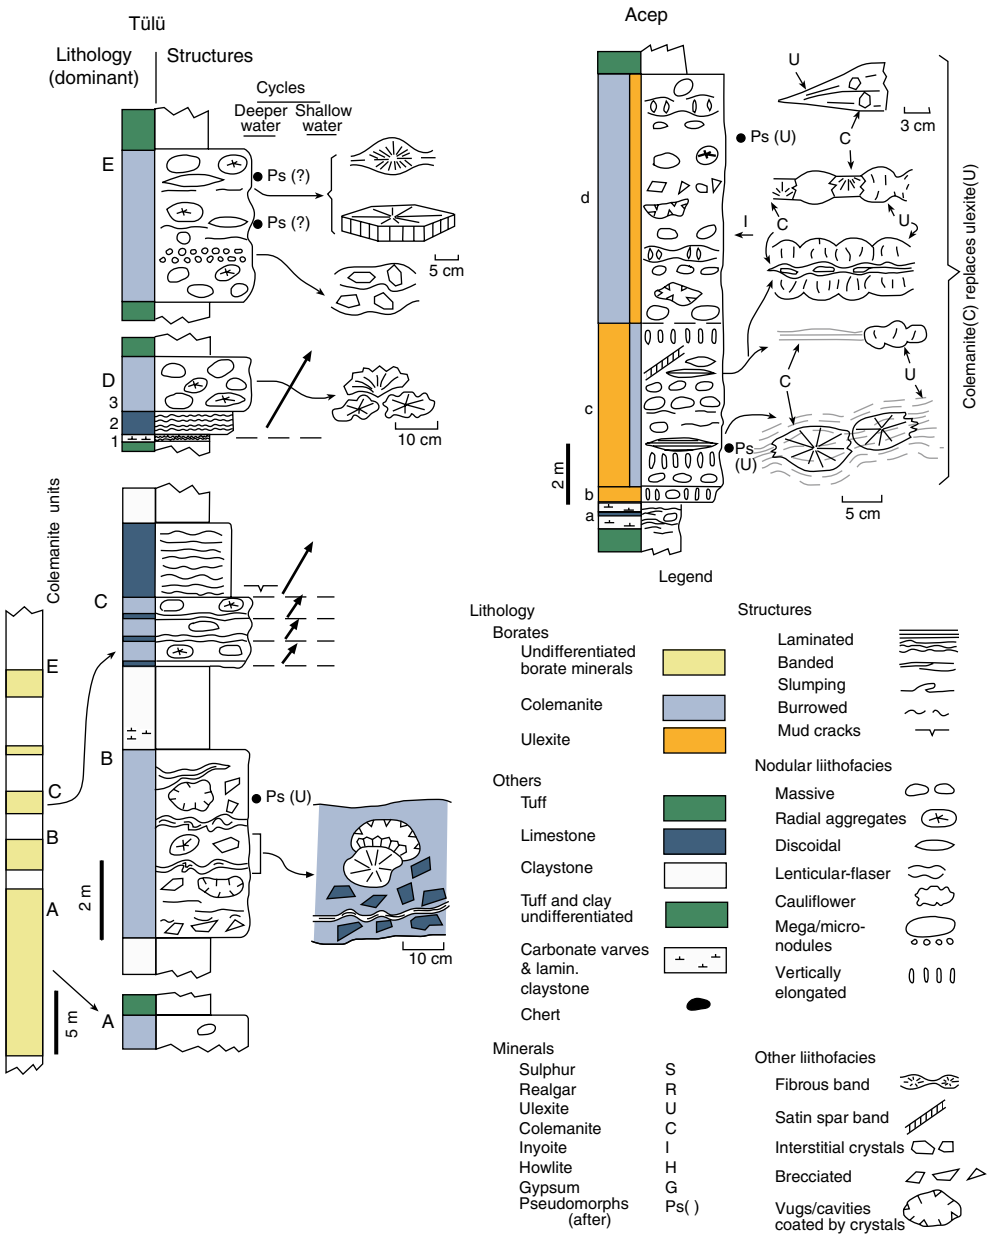

Fig. 12.6 Detailed stratigraphic sections of Tülü (lower borate unit), and Acep (upper borate unit) open pits, in the Bigadic ore district, Turkey, showing details of lithofacies, rock units, carbonate-borate depositional cycles, and the replacement of ulexite by secondary colemanite (After Helvaci and Orti 1998)

and recrystallization of some Sr-rich ulexite horizons. In the Bigadic deposits, hydroboracite formed by replacement of colemanite, with Mg ions supplied from adjacent tuffs and clays by ion exchange. Howlite grew in clay bands alternating with thin colemanite bands and coincided with periods of relatively high silica concentrations. Diagenetic processes also produced small howlite nodules embedded in unconsolidated colemanite nodules.

In contrast to the colemanite-ulexite dominance at Bigadic, laminated lacustrine borax is volumetrically and economically the most important zone in the Kirka borate deposit (Helvaci and Orti 2004; García-Veigas and Helvaci 2013), The deposit is symmetrically zoned in a lateral sense with a central body of Na borate (borax), an intermediate zone of Na–Ca borate (ulexite), and a marginal zone of Ca borate (colemanite; Fig. 12.7). The same mineral zonation is also developed in a vertical sense, although it is somewhat asymmetrical because of the presence of a discontinuous Mg borate horizon overlying the central body of borax. Older studies, based on analogies with US borate deposits, attributed the zonation to a diagenetic overprint on the margins of the original syndepositional boraxclay laminates of the lake (Inan et al. 1973). More recent work has shown that the Kirka sequences are depositionally fractionated and that the zonation represents a hydrologically controlled separation of evaporite minerals in a lake basin actively accumulating sediment (Fig. 12.7b; Helvaci and Orti 2004; García-Veigas et al. 2011b). Lateral gradients in salinity in the mudflats

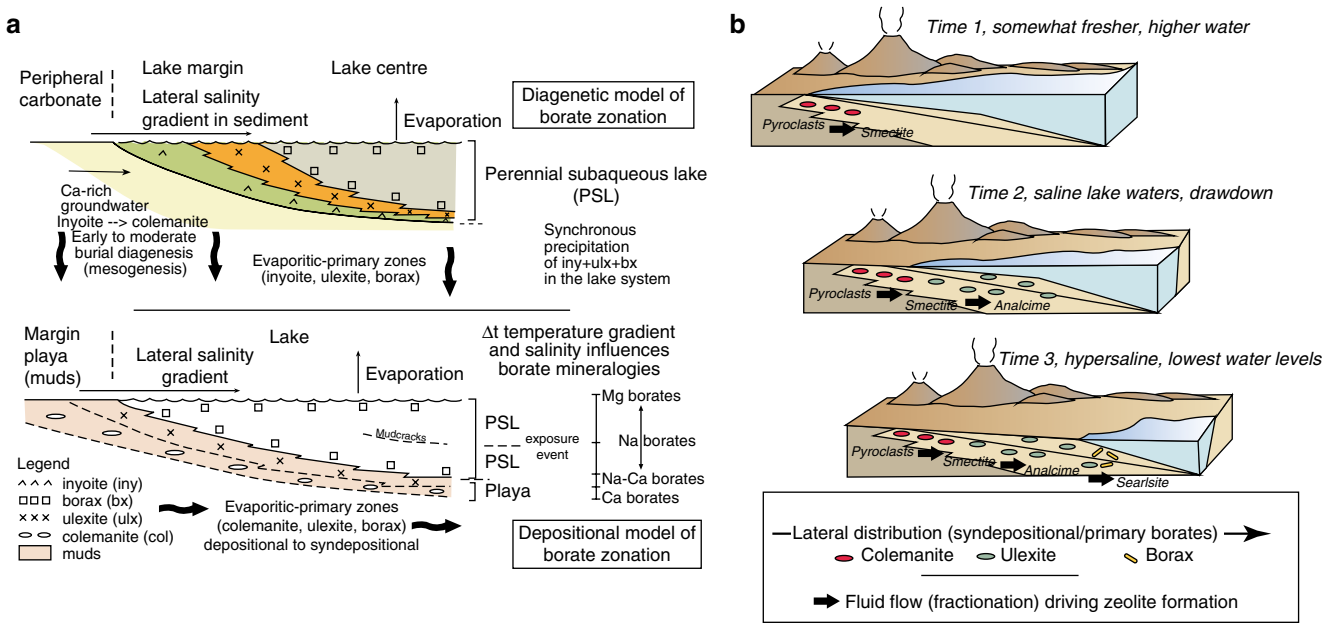

Fig. 12.7 Depositional setting and zonation of Turkish borate deposits. (**a**) Two endmember models used to explain the zonation of Turkish borates; one uses diagenetic flushing by Ca-rich subsurface waters (After Inan et al. 1973), the other explains the zonation as a depositional separation (After Helvaci and Orti 2004). (**b**) Current model that integrates depositional aspects (borates) and diagenetic aspects (zeolites) used to explain mineralogies in the various Turkish borate deposits (After García-Veigas and Helvaci 2013)

passing into the perennially subaqueous centre conditioned the concentric pattern of the facies at Kirka. Thus, the various borax lithofacies zones (chemical, clastic, mixed) seen in the central ore body reflect surface and near-surface borate precipitation in a lake that evolved with subsidence and climate. Conditions oscillated from predominantly subaqueous with variable brine depths (perennial lake stage), to an interstitial sabkha or mudflat setting (playa-lake stage). The evaporative concentration of the boratiferous waters in the lake, together with the periodic changes in temperature of the water mass, are the main controls on the crystallization of borax.

Helvaci and Orti (2004) found no petrographic evidence for a thermally induced inyoite-to-colemanite transformation, as previously proposed by the diageneticists and went on to argue that the moderate burial depths in all the various Turkish borate deposits are insufficient for the generalized transformations required by the diageneticists (Fig. 12.7a). Rather the Mg borates represent evaporitic precipitates from the fractionation of the initial boratiferous inflow, they are not burial driven reaction products between pre-existing borates and groundwaters. Thus the mineral zonation in Kirka is primary, not only for borax and ulexite in the subaqueous dominated parts of the lake, but also for both the colemanite forming the marginal playa dominated zones and for the Mg borates overlying the central body of borax in Kirka (Fig. 12.7b). This same argument of syndepositional not burial flushing can be applied to Bigadic, which is then seen to be a deposit accumulating under predominantly playa conditions (Fig. 12.5b).

Almost all workers now accept that the borax-clay laminite texture that dominates the core of the Bigadic deposit is subaqueous. Crystal outlines have a characteristic growth-aligned borax (palisade) texture in mm-cm thick layers separated by clay segregations. This is a texture similar in many ways to the hydroboracites of South American salars (Fig. 12.9) and the Kramer deposit in the USA. Borax crystals in the lower portions of the lower borate unit in Kirka show zigzag tops mantled by clay, while borax layers in the upper parts of the same unit show erosional tops. The same textural transition from zig-zag to truncation is seen in meromictic gypsum lakes as the depositional surface aggrades across the zone of saturation in a permanently subaqueous brine lake (Fig. 2.72). The nodular Turkish borate ore of the playa margin is more enigmatic; it may be an early diagenetic playa mudflat precipitate or it may be an early alteration halo created by centripetal flushing of the borax core by shallow subsurface waters. These same early pore brines that are laterally fractionating the mudflat borates are also driving clay mineral alteration of the volcanic hosts. This creates classic bull's distributions in the authigenic zeolites (Fig. 12.7b). The ultimate products are analcime and searlesite and processes involved in their formation are discussed later in this chapter

Initial volcanogenic waters that fed the alkaline perennial saline lake(s) were low in Cl and SO_4, and high in boron and Ca, with subordinate Na. Boron isotope data from the Turkish deposits are consistent with colemanite being precipitated from a more acidic brine than ulexite, with borax being

precipitated from a brine that was more basic (Helvaci 1995; Palmer and Helvaci 1995, 1997). Borax precipitation and replacement to create ore grade beds typically occurred in a laminated gypsiferous host, either syndepositionally or in very early burial, perhaps in or immediately beneath stratified brines, where solar-derived brines mixed with upwelling boron-rich hydrothermal solutions. With further burial, the anhydritization of gypsum began at depths that were less than 250 m. At the same time, anhydrite can replace some of the earlier formed more reactive borates (priceite, bakerite and howlite), along with associated celestite precipitation. Subsequent uplift and exposure of some parts of the sequence has rehydrated nearsurface anhydrite to secondary gypsum and partially transformed priceite and howlite into secondary calcite.

South American Borates

In the Andes of South America there are more than forty borate deposits hosted in Neogene volcanogenic-sedimentary rocks across an 880-km-long stretch paralleing the common borders of Argentina, Bolivia, Chile and Peru (Fig. 12.4). This area is high plateau created in the late Cenozoic in the compressional/subduction orogen that created the Andes. As in Turkey, the Andean borate province sits on a major plate suture zone. Most deposits are small aprons or cones of borax and ulexite near volcanic vents, with reserves measured in thousands of tonnes. But in the larger endorheic basins, where volcanogenic brines can pond and concentrate, there are beds of ulexite, borax and inyoite in modern and ancient salars ranging up to hundreds of square kilometers in area, with reserves measured in millions to tens of millions of tonnes. They occupy groundwater sumps formed during arid to hyperarid conditions that have prevailed in most of the Andean intermontane lows since the Miocene and appropriate sumps continue to focus borate precipitates, even today (Strecker et al. 2007; Oveyero-Toledo et al. 2009).

Two main textures typify the borate salts, both modern and ancient; (1) nodular borate locally known as "papas" (potato or cottonball borate), and (2) bedded borates usually interbedded and intermixed with lacustrine muds and locally known as "barras or bancos" (meaning beds or banks). Nodules are the preferred texture to mine as they tend to create a purer product when cleaned and air dried (can be >28 % B_2O_3; Garrett 1998).

Extraction from modern and Quaternary salars utilises ulexite or brine, while ancient (Miocene) ore is dominated by borax or tincal (see inset in Fig. 12.8a). The main ancient borate reserves lie in the Argentinian Andes, mostly in the Pastos Grandes Basin within the 1,500-m-thick volcaniclastic and lacustrine stratigraphic unit known as the Sijes Formation (Fig. 12.8). There were three major pulses of borate generation during deposition of the Miocene Sijes Formation. These pulses are easily identifiable in the central part of the basin but become indistinct and tend to thin out toward the edges (Helvaci and Alonso 2000). Along its approximately 30 km outcrop belt, the Sijes Formation is characterized by a string of variably overlapping borate lenses and is not one continuous bed. Borate-bearing members of the Sijes formation from the base to top are as follows: Monte Amarillo (Fig. 12.8b; mostly hydroboracite), Monte Verde (colemanite-inyoite) and Esperanza (colemanite). The Tincalayu and Loma Blanca areas are important regions of older borate salt units (typified by borax occurrences). Modern active salars, such as Salar di Rincón and Salar di Surire are typified by ulexite plus borax as the dominant borate salts (Helvaci and Alonso 2000; Oveyero-Toledo et al. 2009). Ulexite is also the first evaporite to precipitate in the Pleistocene Blanca Lila Formation near Salar Pastos Grandes, followed by gypsum then halite (Vandervoort 1997).

Typically, ancient South American salars with substantial borates have a central zone, consisting of a relatively thick halite, surrounded by a thinner marginal sulphate zone consisting of a variety of sulphate minerals, as well as variable amounts of halite, ulexite and other borates (Fig. 12.8a; Ericksen 1993; Helvaci and Alonso 2000). Salars that are filled mostly with gypsum lack this zonation. The borate zoning may be symmetrical (bull's-eye pattern) with sulphate surrounding a central halite core, or asymmetrical with the halite zone crowded against one side of the salar. This is also the situation in modern Salar de Atacama where tectonic tilting has displaced the lowest part of the brine sink to the southern end of the playa (see Fig. 12.51). Both the halite and sulphate zones are typically underlain by gypsum and this in turn by siliciclastics. Alternating arid and pluvial climatic episodes in the Andes since the mid-Miocene, means the playas are filled by alternating salt beds and siliciclastics (Figs. 3.48 and 3.49).

Most Neogene borate-rich salar deposits in South America have undergone relatively minor deformation since they were first emplaced. As a result, borates are extracted from a number of open pit operations in the Andean Altiplano (Alonso 1991). Borax Argentina, a member of the Rio Tinto Borax Group, extracts sodium borate ores at its Tincalayu Mine, high in the Argentinian Andes Mountains (altitude of 4,100 m). Nearby, hydroboracite is extracted at Sijes, and ulexite from two modern dry lakebeds, Salar Cauchari and Salar Diablillos, all in the Salta province. Originally developed in 1976, Tincalayu is now Argentina's largest open pit operation measuring more than 1.5 km (1 mile) across and 100 m (330 ft) deep and extracts ore at a rate of 100,000 t per year. In Bolivia, ulexite is extracted from mines in the Salar de Uyuni (Fig. 3.43). In Chile, borates are extracted from Salar de Surire; the largest Quaternary ulexite deposit in the world, with reserves reported to be ≈1.5 million tonnes of 35 % boron oxide. The salar is located some 4,250 m above

sealevel and within the borders of the Monumento Natural de Surire national park of Chile.

Borate salts occurrences in South America are variously described as depositional or diagenetic, or perhaps syndepositional replacements of gypsum. A significant portion of the bedded hydroboracite is thought to be a primary precipitate in the Sijes Formation (Miocene, central Andes, NW Argentina), which is the major exploited Neogene ore target (Orti and Alonso 2000) and encompasses the largest known hydroboracite accumulation in the world. At outcrop, sulphate minerals in the Sijes Fm, are mostly secondary gypsum and minor anhydrite, while the borate minerals are hydroboracite with subordinate inyoite and colemanite, and some ulexite. Regionally, the Sijes Formation (Miocene) has four members; three of them are fine-grained siliciclastic, tuffaceous, and chemical-evaporitic in nature (the Monte Amarillo Member, the Monte Verde Member, and the Esperanza Member), while the other member is dominantly a coarse-grained siliciclastic (the Conglomerate Member). The overlying Blanca Lila Formation (Pleistocene) is made up of claystone and evaporites (including borates). Much of the exploitable hydroboracite resides in the Monte Amarillo member.

The Monte Amarillo Member accumulated in two coeval, shallow lacustrine Miocene subbasins (Fig. 12.8a): (1) The Monte Amarillo hydroboracite subbasin, and (2) The Santa Rosa hydroboracite subbasin. The Monte Amarillo hydroboracite subbasin encompasses the borate districts to the south of the Sijes village and is an area where hydroboracite has been mined since 1985. This district is located at an altitude of 3,900 m and lies near the paleogeographic centre of the Monte Amarillo subbasin. The Santa Rosa hydroboracite subbasin, includes the borate districts to the north of the Sijes village and is located at an altitude of 3,900 m. This subbasin occupies a marginal position with respect to the Monte Amarillo subbasin. In these subbasins, the hydroboracite layers are fine-grained, light brown, and difficult to break with a hammer. Because of these characteristics, they had for a long time been confused with limestones. In both subbasins, gypsum accumulated in the margins and the hydroboracite in the centres, the intermediate zones being characterized by mixed gypsum hydroboracite layers.

The type section of the Monte Amarillo Member is 317 m thick, contains an inyoite unit 36 m thick at the base, which is overlain by a hydroboracite unit 137 m thick (Fig. 12.8b; Alonso 1986). This hydroboracite unit has variable amounts

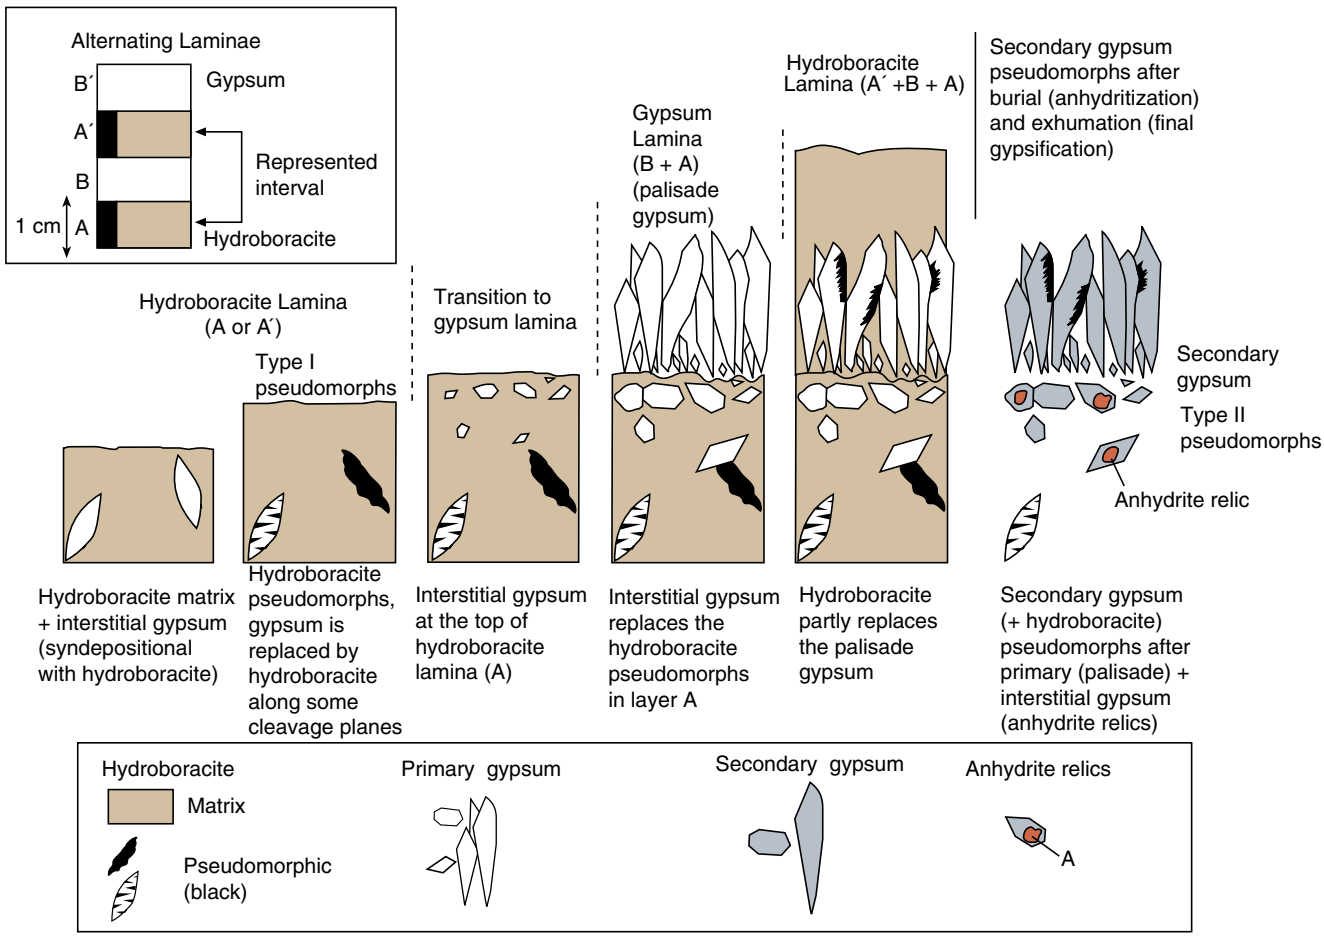

Fig. 12.9 Syndepositional formation of hydroboracite pseudomorphs after gypsum in primary hydroboracite successions composed of alternating cm-scale beds of hydroboracite and gypsum precipitates. Most of the hydroboracite is primary, not secondary (After Orti and Alonso 2000)

of inyoite and ulexite. Gypsum layers are ubiquitous in the Monte Amarillo Member. Samples of two tuff levels located close to the base and at the top of this section were dated as 6.81 ± 0.18 and 6.25 ± 0.15 Ma, respectively, which indicates a depositional period of about 630,000 years for the Monte Amarillo Member during the Upper Miocene (Alonso 1986).

Alternations between gypsum and hydroboracite laminae are present in the transition from gypsum units to hydroboracite units in the Monte Amrillo member and contain fabrics that indicate both the borates and the gypsum-anhydrite were primary or syndepositional precipitates. Fine-grained hydroboracite matrix commonly cements and partly replaces the precursor gypsarenite crystals in the gypsum laminae (Fig. 12.9; Orti and Alonso 2000). In addition, micronodules of hydroboracite can displace or replace gypsum laminae. Two styles of pseudomorphs after interstitially grown (precursor) gypsum are preserved at the mm-scale in hydroboracite laminae. Type I corresponds to hydroboracite pseudomorphs after euhedral, lenticular or tabular gypsum crystals. Many of these pseudomorphs are thin, curved, lenticular or slightly deformed, and now composed of fine-grained hydroboracite crystals. Others are made up of parallel prisms of hydroboracite that project inward from the boundaries of the pseudomorph with the centre commonly occupied by secondary gypsum bearing anhydrite relics. Parallel arrangement of the prisms suggests replacement of the precursor gypsum along the main cleavage plane (010). Type II corresponds to secondary gypsum pseudomorphs after equant to prismatic, commonly zoned (precursor) gypsum crystals. These pseudomorphs are located in the uppermost parts of hydroboracite laminae and grade into secondary gypsum pseudomorphs that constitute the overlying gypsum lamina. Type II pseudomorphs crosscut and replace type I pseudomorphs suggesting that type II pseudomorphs postdate type I.

Alternations between gypsum laminae (with aligned crystal outlines) and hydroboracite laminae imply bottom precipitation in a shallow subaqueous environment, where fine-grained, soft hydroboracite mud encased the gypsum in the laminated gypsarenites. The prevalent microcrystalline or fibrous textures of hydroboracite suggest a primary origin for these alternations in which precipitating conditions

oscillated from gypsum to hydroboracite. Hydroboracite matrix appears to have precipitated interstitially within the open fabric of the (precursor) gypsarenite under synsedimentary conditions (Orti and Alonso 2000). This precipitation, together with associated partial replacement of (precursor) gypsum crystals, occurred during the sedimentation of the overlying hydroboracite lamina (Fig. 12.9). In the hydroboracite laminae, type I pseudomorphs seem to correspond to (precursor) gypsum crystals that grew interstitially in the hydroboracite matrix when the borate concentration of the brine was relatively low. It appears that these crystals were very soon (syndepositionally) replaced by hydroboracite matrix. Flow deformation of the pseudomorphs that are formed by fine-grained hydroboracite occur between flat laminae suggesting that the replacement process took place in a soft matrix under synsedimentary conditions. However, when this replacement occurred as a growth of prisms along the gypsum cleavage planes, the pseudomorphs remained undeformed and consistent. In general, this mechanism was less penetrative, and many pseudomorphs had a mixed hydroboracite–gypsum composition. Presumably, in these mixed pseudomorphs, the anhydrite replacement of the gypsum postdates the partial hydroboracite replacement. These pseudomorphs changed to hydroboracite–anhydrite during burial, and to hydroboracite–secondary gypsum in final exhumation. Type II pseudomorphs seem to correspond to (precursor) gypsum crystals that grew interstitially toward the tops of the hydroboracite laminae during precipitation of the overlying gypsarenite layer, once again a syndepositional diagenetic process.

Beds dominated by primary gypsum (gypsarenite) and syndepositional anhydrite were first precipitated during deposition of the Monte Amarillo Member, in association with limited amounts of calcium borates (colemanite, inyoite). This was soon followed by beds containing hydroboracite (calcium/magnesium borate) and alternating gypsum and hydroboracite layers also formed. The hydroboracite at this level in the stratigraphy is mainly a primary mineral, although it also replaced some gypsum under synsedimentary conditions (Fig. 12.9). The formation of colemanite, which occurred during early diagenesis, is linked to brines precipitating calcium sulphates (gypsum and anhydrite), whereas inyoite coexisted with brines precipitating both calcium sulphate and magnesium-bearing borates. Transformations among the various borate minerals during later burial diagenesis were not detected by Orti and Alonso (2000). Primary gypsum was transformed into anhydrite from the onset of early diagenesis through to moderate burial diagenesis. The boron source of these deposits is volcanic/hydrothermal activity in the central Andes during the Miocene. Likewise, borate salt deposition in the modern salars, such as Salar el Rincón, is also syndepositional (Oveyero-Toledo et al. 2009, inset table in Fig. 12.8a and depositional detail in Chap. 3).

North American Borates

The United States is the world's largest producer of boron compounds and the second largest producer of borate ore with California' largest open pit mine working the Kramer deposit and supplying almost half of the world's borate needs. Other US producers exploit saline brines and bedded playa deposits, such as Searles Lake in California (Smith 1979) or Tertiary counterparts at Boron and the much smaller conventionally mined deposits in the nearby Death Valley area (Kistler and Smith 1983). An excellent history of the Californian borate industry is given by Beeby (2002).

The Kramer deposit (aka Boron deposit) is huge and located near Boron, California, in the Mojave Desert, some 140 km north northeast of Los Angeles and midway between the towns of Barstow and Mojave (Fig. 12.4). The total borate area (including the ulexite and colemanite[1] rims) is 8 km (east–west) by 1.6 km (north–south). The deposit within this area is about 1,600 m long, 800 m wide by 100 m thick, and consists of a lenticular central mass of borax/kernite with interbedded montmorillonite-smectite clay. Borate ore reserves exceed 100 Mt (110 million st). The original borax target was 45–305 m deep and dipped 10–15° to the south. The deposit was discovered in 1913 and was developed as an underground operation during the 1920s. It was converted to an open-pit operation in 1957. Since that time, the operation has grown to become the largest mining operation in California and is operated today by Rio Tinto Borax. The mine open cut is now more than 2.8 km wide, 3.2 km long and 230 m deep (Fig. 12.10b). Ores are part of the shale member of the Kramer beds, which include an arkose member above and the Saddleback Basalt below (Fig. 12.10a, c).

The age of the deposit is 19 ± 0.7 Ma and it defines a small subbasin in a much larger Tertiary lacustrine basin. It is encased in arkosic sands, silts and minor volcanics and limestones. Sedimentation in the basin was interrupted by flows of acidic lava (olivine basalt to latite) known as the Saddleback Basalt, it constitutes the base to the borate ore zone and also interfingers with other sediments of the basin fill. The upper part of the basalt in the mine area has fractures filled with ulexite and searlesite and its contact with the overlying sediments is defined by an "apple green" siliceous shale that contains ostracod carapaces. The colour of the shale reflects its creation by the basalt reacting with lake waters.

Barnard and Kistler (1966) defined the sedimentology of borate beds above the Saddleback Basalt (Fig. 12.10). First is a 7.6–15 m thick footwall shale, further divisible into an initial barren (≈3.7 m) shale and then a ulexite zone. This is a

[1]The mineral name colemanite is named after one of the early miners in the Death Valley region, Mr. William T. Coleman. Ulexite was named for the German chemist Georg Ludwig Ulex (1811–1883) who first discovered it.

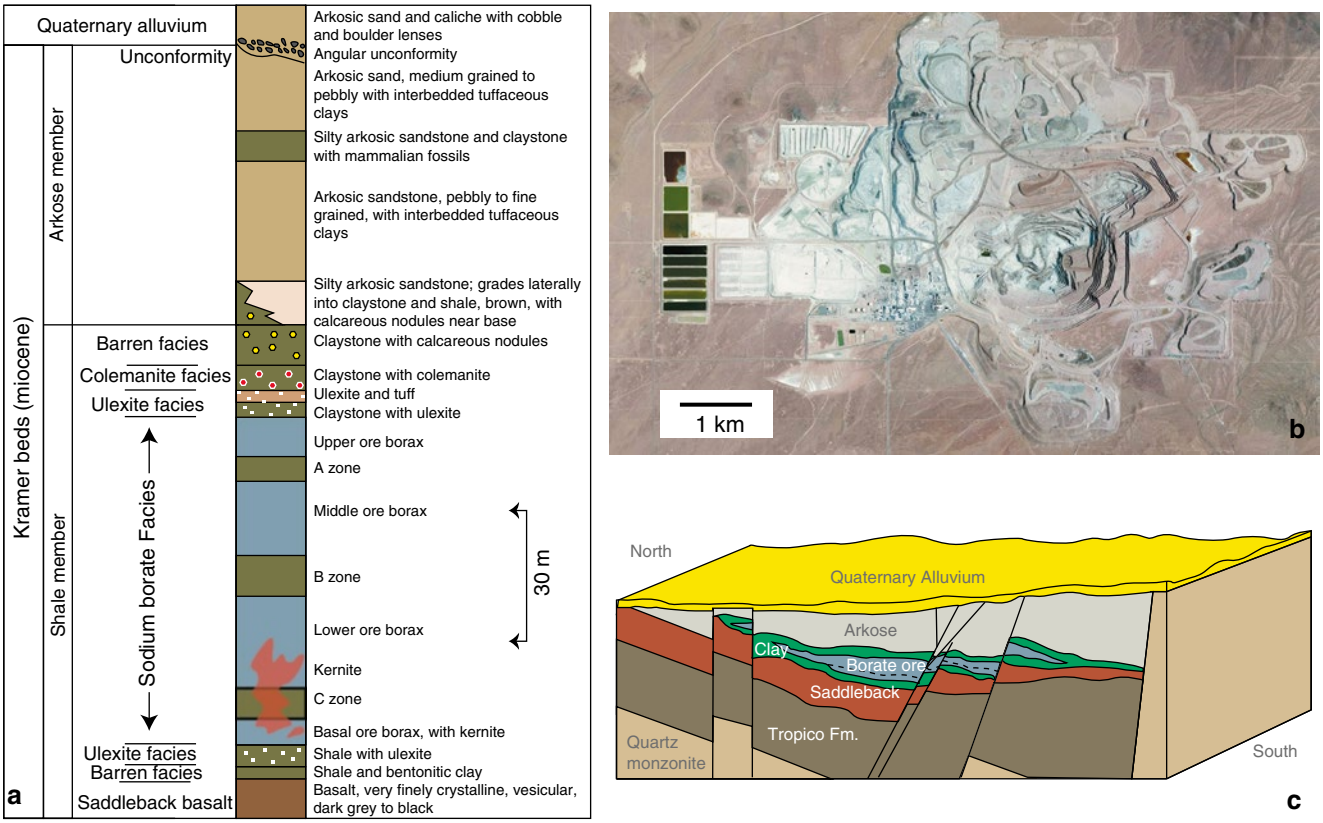

Fig. 12.10 Kramer Borate deposit, near Boron, California. (**a**) Vertical sequence in the mine pit. (**b**) Aerial view of Kramer Pit. (**c**) 3D-schematic showing borate ore distribution with respect to adjacent geology, dashed line indicates inferred extent of kernite (irregular mass in lower part of ore zone; in part after Barnard and Kistler 1996; Bowser and Dickson 1966; Siefke 1991)

layer of greenish-gray at times black fissile shale that is thinly laminated, micaceous and at times contorted. Locally it encloses lenses of arkosic sandstone and coarse conglomerate. Above this are the borax beds interbedded with clay and shale along with some beds and lenses of tuff, arkosic sand and conglomerate. The low permeability of these lacustrine shales is thought to have helped preserve the borax by preventing entry of groundwaters. Laterally and vertically away from the deposit's borax/kernite core, the borate facies changes to ulexite and colemanite, and the levels of shale interbeds and clay impurities in the borates become more significant (Bowser and Dickson 1966).

The deposit is believed to have formed in a shallow Mid-Miocene saline lake, fed by Na- and B-rich thermal springs, a response to the later stages of volcanism. Saline sodium-borate-bearing thermal spring waters, being denser, sank to the lake bottom, cooled, and precipitated borax as they cooled. The original lake position was controlled by faulting contemporaneous with the accumulation of the borax. Continued fault movement, associated with the middle Pliocene uplift of the Mojave Block, tilted and dropped the lake sediments, which are now buried by more than 760 m of late Miocene and Pliocene arkosic sediment. Older models argue that deeply buried portions of the borax deposit were altered, via water loss, to kernite at this time. Renewed movement in late Pliocene–Pleistocene uplifted the deposit and drove some erosion of the original borate so that the outer portions of the kernite facies were rehydrated at that time. The deposit was then covered by 9–21 m of Pleistocene and Recent sands and gravels (Barnard and Kistler 1966; Siefke 1991).

As well as 19 Ma Kramer deposit, across the Death Valley area, borates were also deposited 6 Ma and there are more than 23 known deposits (Garrett 1998). In all, the borate ore is contained in the lower 150 m of the 2,100 m thick Pliocene Furnace Creek Formation. The interiors of most of the ore deposits preserve unaltered bedding planes and uniform depositional patterns. There are few to no indicators of syndepositional alteration (slumps, pseudomorphs) in the centres of the deposits but considerable evidence for alteration and replacement about the deposit's edges. The agglomerated nodular structure composed of masses of acicular crystals in much of the originally exploited ore meant that earlier miners in Death Valley area described the various exposures of borate ore as cottonball or cotton-tail (like the fluffy tail of a cottontail rabbit). Regionally a series of projected shoreline

features can be traced from the Billie to the Boraxo to the Sigma-White Monster mines and residues of ancient geothermal spring mantle deposits are locally present (Garrett 1998).

One of the largest deposits in the Death Valley area was the Billie orebody (an underground mine, now abandoned), a 1,100 m long lens of ulexite, proberite and colemanite, interbedded and surrounded by limey laminated lacustrine mudstone and shale. Fault activity controlled the position of the lake-bed borates and some beds now have local dips of upwards of 45°. The Billie orebody has an average thickness of 45–55 m, a width of 220 m, and a regional dip of 20–30° toward the southeast. Reserves were of the order of 2,700,000 metric tons of ulexite-proberite at 27 % B_2O_3 and 11,000,000 metric tons of colemanite at 21 % B_2O_3 (Garrett 1998).

The borate ore zone at Billie Creek is hosted by shales of the Furnace Creek Formation and is made up of metre-scale units of nodular borate, mainly colemanite, interbedded with laminated mudstones deposited in a saline lacustrine environment during extension of the basin. The hosting laminites lack features of syndepositional exposure or wave-reworked deposition, indicating that the borate-hosting sediment first accumulated on the floor of a density-stratified perennial lake (Tanner 2002). The presence of interbedded sulphate minerals in this facies suggests that salinity in this lake was elevated. Metre-scale mounds of porous limestone with a clotted-micritic fabric define spring-apron tufas that formed where groundwater discharged along fault-fed outflows about the edge of a more saline water mass.

The exploited massive borate facies in the various Death Valley deposits are made up of thick, massive borate layers, locally containing host rock clasts with sharp to diffuse boundaries. Borate formation first took place at or below the sediment/water interface. The composition of the borate deposits in Death Valley varies from mainly colemanite to zoned accumulations, with colemanite surrounding a core of probertite and ulexite.

Many older models for the formation of colemanite in the Kramer and Death Valley deposits, prior to the 1960s argue for burial (thermal) replacement of ulexite and inyoite via flushing by "intruding warm borax solutions." High Ca/Na ratios favoured primary deposition of hydrated Ca-borates, which early workers argued were subsequently transformed by diagenetic dehydration to colemanite (Foshag 1921; Christ and Garrels 1959). This meant the gradual depletion of Ca and decreasing Ca/Na ratios in the mother brine resulted in Na-Ca-borate precipitation, while any renewed onset of elevated Ca/Na ratios again caused Ca-borate deposition.

But these older burial/thermal fluid models never clearly addressed a number of textural and conceptual problems (Garrett 2001). Namely, (1) Where did these conversion liquors come from? (2) How did they maintain their chemical uniformity? (3) How did they totally and completely pervade and replace what were impermeable salt units? (4) What was the required voluminous Ca source needed to accomplish the transformation? (5) Where did the residual brine go? In addition, why are there no widespread disruption texture and slumps structures both within and above the bedded salts and why are commonplace colemanite alteration minerals like, priceite, ginorite, nobleite and gowerite, absent?

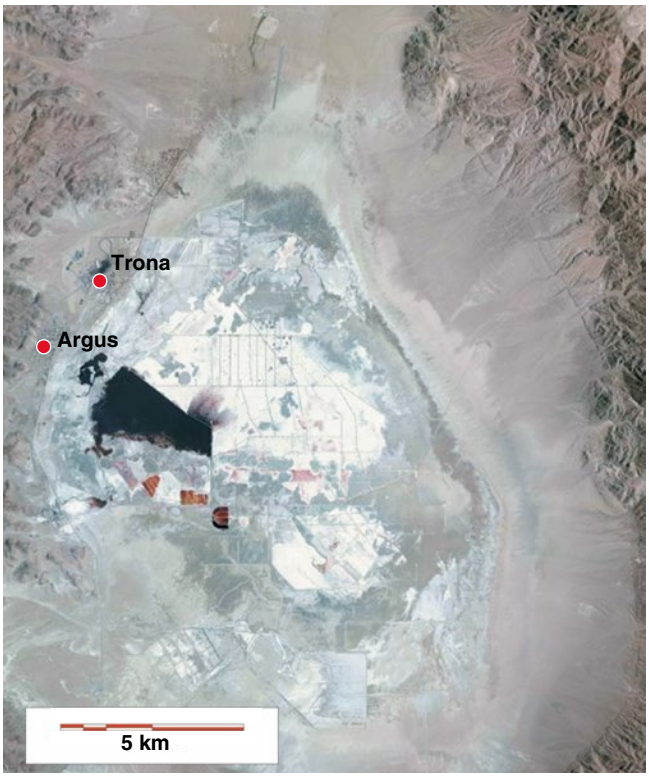

Fig. 12.11 Searles lake, California, showing that it is a endorheic basin in the Basin and Range of the USA

A similar set of problems beset the notion that the dehydration of borax to kernite indicates a deep burial conversion process. The problem as to deposition versus burial replacement for the Kramer deposit is yet to be resolved to the satisfaction of all. But, given the widespread preservation of depositional features in the Kramer and Death Valley deposits, the clearly primary nature of the various less compacted borate salt beds in Turkish deposits as likely analogs, syndepositional controls for the Kramer and Death Valley deposits are favored. This places colemanite, for example, as forming in the capillary zone of a saline lacustrine mudflat, with inyoite in the more saline perennial centre of the sump (e.g., Fig. 12.7).

Searles Lake in southeastern California is located in the lower central portion of a small block-faulted desert valley with a drainage area of 1,600 km^2 and located midway between Boron and Death Valley (Fig. 12.11). It is a likely Pleistocene counterpart to the lacustrine evaporites that

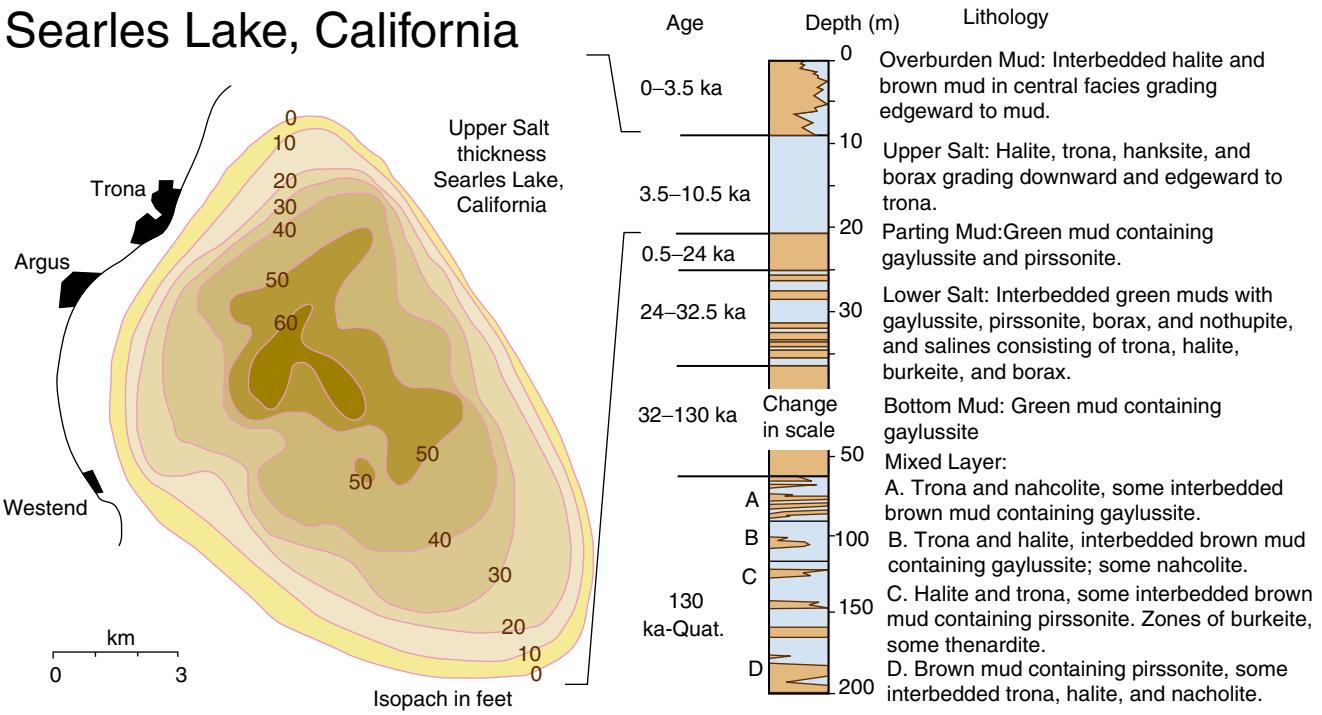

Fig. 12.12 Searles Lake, California showing isopach of the "Upper Salt" in feet as well the stratigraphy of the three salt layers and intervening clays (After Smith 1979). Note the change in scale in the vertical section at around 50 m

entrain the exploited Neogene deposits of Boron and Death Valley. The central pan, some 103 km^2 in extent, overlies a crystalline mush of mixed salts dominated by sodium carbonates, but also with borax, clays, and hypersaline interstitial brines. The brine recovery operation is a multicomponent chemical system and borax is only one of the products recovered; others include sodium sulphate, lithium compounds, potash, bromine and other salts. Boron was supplied to the lake via thermal springs along the Sierra Nevada frontal faults in Long and Owens Valleys (Smith 1979).

There are two main solution-mined salt horizons beneath the central pan: the "upper salt," some 9–27 m thick (averaging 15 m), with a brine content averaging 1.0 % B_2O_3; and the "lower salt," some 8–14 m thick, (averaging 12 m), with a brine content averaging 1.2 % B_2O_3. The upper salt is overlain by a surficial mud and salt-crust unit some 7–9 m thick and is separated from the lower salt by 3–6 m (average 4 m), of relatively impervious clays called the "parting muds" (Fig. 12.12). The upper two salt beds accumulated in the period 3.5–40 Ka. There is also a much deeper salt bed with a mineralogy dominated by trona-nahcolite-halite with lesser amounts of burkeite-thenardite.

The salt mush in both the upper and lower salt beds is quite porous (0.35–0.40) and the stored brine is pumped via a series of wells into adjacent saltworks where borate, sodium bicarbonate and sodium sulphate salts are recovered. A constant resupply of brine to the mush beds is maintained by natural recharge and percolation of dilute refinery effluent, which is pumped back into the mush beds. The two salt horizons are pumped separately as they differ somewhat in chemical makeup and therefore require different plant treatments. Historically, until 1979, the upper salt was the solution-mining target, since then the lower salt has been mined as a trona target and processed using carbonation.

Other Borate Deposits

Borates in China are found in many salt lakes on the Qinghai-Xizang (Tibet) Plateau, in cold arid conditions in lakes such as Zhacang Caka and Zabuye Caka. There typical lake waters contain 85 mg/l of boron oxide and are co-associated with elevated lithium levels (Fig. 12.55; Sun and Li 1993; Zheng and Liu 2009). The maximum value of boron oxide in such lake brines is around 1,500 mg/l. The saltflats in lakes such as these, and their borate crusts, were the original suppliers of borate salts to Medieval Europe.

However, today the largest economic borate reserves in China occur not in Quaternary/Tertiary saline lakes but in the Precambrian meta-evaporitic borosilicates in Liaoning Province. Reported reserves are 44 million tonnes of boromagnesite with 8.4 % boron oxide content. The deposits in the Liaoning Province represent 64 % of the country's total boron resources and 90 % of these deposits are associated with banded iron formations. There are more than 112 separate borosilicate deposits (12 contain 98 % of the known reserves)

in the Liaoning area on the Liaoning Peninsular in northeast China. The main ore mineral is szaibelyite (aka ascharite), along with ludwigite, with some suanite. All are Mg-borates and are hosted along with magnesite and magnetite in fractured marbles. Deposits are thought to be meta-evaporitic skarns, originally deposited as lacustrine borates interbedded with volcanic tuffs (Peng and Palmer 2002). These deposits are discussed in detail in Chap. 14 (Fig. 14.44).

The world's only exploited marine borate deposit is in the Inder district of Kazakhstan (former USSR), north of the Caspian Sea. Now-depleted mined borates formed bedded lenses up to 3 m thick and were hosted in the gypsiferous caprock in the 100+ km^2 crest of a large Permian salt dome. Ores are magnesian borates, rather than the more commonplace sodian-calcian borates typically found in modern continental salars and playas. Mineralization is centred on fractures near the top of the dome, where borates have precipitated in a matrix of gypsum, clay and anhydrite. The fluids precipitating borate are thought to be derived from geothermal springs (Garrett 1995). Boron is also periodically extracted from the brines of nearby Lake Inder. This salt lake has a m-thick surface salt crust underlain by some 30 m of brine-saturated salt, which contains potassium chlorides and bromides as well as borax (Kistler and Smith 1983). Unlike the other economic borate deposits of the world, this deposit is sourced by dissolving Permian marine salts, hence the association with the magnesian salts, and is not tied to volcanism.

Its marine origin is obvious in its boron isotope signature, which is clearly much more enriched in ^{11}B than nonmarine sediments (Fig. 2.39c; Swihart et al. 1986). The clear separation of nonmarine and marine borate salts using boron isotopes is also used to define parentage of various meta-evaporitic tourmalines in the meta-evaporites of Liaoning, China. Isotope analysis is a useful technique for determining boron source long after the original salts have evolved into lattice components of high temperature and high pressure minerals (see Chap. 14).

Borate minerals do occur in marine evaporites other than the Inder deposit, but are not known in sufficient amounts to be economic targets. For example, potash ore processing of the Zechstein potash ores in Germany leaves behind borates in the mud residues. At times this borate has been recovered as a small-tonnage byproduct (Garrett 1998). Marine borates such as priceite and howlite are present in minor amounts in the Cretaceous marine evaporites of the Maha Sarakham Fm. in Thailand, in the Mesozoic evaporites of the Atlantic margin in Nova Scotia, Brazil and West Africa, and in the Permian evaporites of the Delaware Basin, USA (Chap. 7). In all cases it seems that the levels of boron in the marine bitterns were never sufficient to create economic levels of borate salts. That seems to requires hydrothermal circulation, usually in a volcanic basin.

Evaporitic Borates and the Evolution of Life

Associated with the earliest borate minerals of the Hadean and the earliest Archaean in a period of time known colloquially as the RNA World, there is an esoteric, but nonetheless interesting, association of borate salts and evolution of the earliest lifeforms. RNA World hydrochemistry is thought to have been an important link between purely prebiotic (≈3.7 Ga) chemistry and modern DNA/protein biochemistry. Given the ambient atmospheric and hydrospheric chemistry of that time, one major concern in the evolution of early life, is the geochemical stability of ribose, which is the sugar moiety of RNA and the precursor to true DNA-based life. Prebiotic stabilization of ribose by solutions associated with borate minerals, notably colemanite, ulexite, and kernite, has been proposed by a number of workers (Fig. 12.13; Grew et al. 2011).

Although the oldest reported colemanite and ulexite are 330 million years old, and the oldest reported kernite, 19 Ma, boron isotope data and geologic context are consistent with an evaporitic borate precursor to 2,400–2,100 Ma borate deposits in the Liaoning and Jilin Provinces, China, as well as to tourmaline-group minerals at 3,300–3,450 Ma in the Barberton belt, South Africa (Fig. 12.13). The oldest boron minerals for which the age of crystallization can be determined are derived from metamorphic tourmaline species, schorl and dravite, in the Isua complex, Greenland (metamorphism between 3,650 and 3,600 Ma). Whether borates such as colemanite, ulexite and kernite were present in the Hadean (≈4,000 Ma) at the critical juncture when prebiotic molecules such as ribose required stabilization depends on whether a granitic continental crust had yet differentiated. In its absence there appears to be no means for boron to be sufficiently concentrated for low temperature borates to precipitate; the discussion continues.

Sodium Sulphate Salts (Salt Cake)

Sodium sulphate salts are similar to borates in terms of volumes extracted of naturally occurring nonmarine sodium salts (Table 12.2). Sodium sulphate salts typical of ore mineral assemblages include combinations of: thenardite, mirabilite [also called glaubers salt], glauberite, astrakanite (also called bloedite) and burkeite (Table 12.5).

Character and History

Sodium sulphate mineral assemblages show interesting stability relationships with respect to salinity and temperature, with corresponding affects on crystallization assemblages in

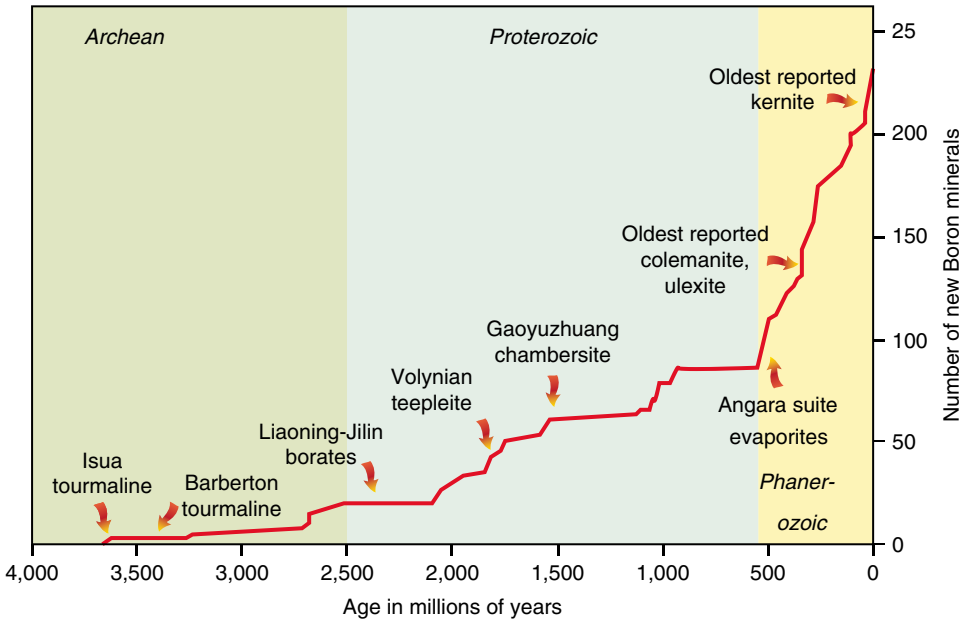

Fig. 12.13 Cumulative plot for 263 boron minerals based on reported occurrences and age determinations (After Grew et al. 2011)

Table 12.5 Minerals that contain Na_2SO_4 and percent Na_2SO_4

Mineral name	Composition	%
Thenardite	Na_2SO_4	100
Hanksite	$9Na_2SO_4{\cdot}2Na_2CO_3{\cdot}KCl$	81.7
D'ansite	$9Na_2SO_4{\cdot}MgSO_4{\cdot}3NaCl$	81.2
Lecontite	$(Na,NH_4K)_2SO_4{\cdot}2H_2O$	<79.8
Vanthoffite	$3Na_2SO_4{\cdot}MgSO_4$	78
Hectorfloresite	$4Na_2SO_4{\cdot}NaClO_3$	74.1
Sulphohalite	$2Na_2SO_4{\cdot}NaCl{\cdot}NaF$	73.9
Burkeite	$2Na_2SO_4{\cdot}Na_2CO_3$	72.8
Eugsterite (Fritzche's salt)	$2Na_2SO_4{\cdot}CaSO_4{\cdot}2H_2O$	62.3
Darapskite	$NaNO_3{\cdot}Na_2SO_4{\cdot}H_2O$	58.0
Hydro-glauberite	$5Na_2SO_4{\cdot}3CaSO_4{\cdot}6H_2O$	57.9
Glauberite	$Na_2SO_4{\cdot}CaSO_4$	51.1
Loeweite	$Na_2SO_4{\cdot}MgSO_4{\cdot}2.5H_2O$	46.2
Ferrinatrite	$3Na_2SO_4{\cdot}Fe_2(SO_4)_3{\cdot}6H_2O$	45.6
Mirabilite (Glauber's salt)	$Na_2SO_4{\cdot}10H_2O$	44.1
Bloedite (astrakanite)	$Na_2SO_4{\cdot}MgSO_4{\cdot}H_2O$	42.5
Kroehnkite	$CuSO_4{\cdot}NaSO_4{\cdot}2H_2O$	42.1
Nickelbloedite	$Na_2Ni(SO_4)_2{\cdot}4H_2O$	40.3
Sideronatrite	$Na_2Fe(SO_4)_2{\cdot}OH{\cdot}3H_2O$	38.9
Caracolite	$Pb(OH)Cl{\cdot}NaSO_4$	35.4
Palmierite	$(K,Na)_2Pb(SO_4)_2$	<31.9
Tychite	$Na_2SO_4{\cdot}2Na_2CO_3{\cdot}2MgCO_3$	27.2
Aphthitalite (Glaserite)	$Na_2SO_4{\cdot}3K_2SO_4$	21–38
Tamarugite	$Na_2SO_4{\cdot}Al_2(SO_4)_3{\cdot}12H_2O$	20.3
Natrochalcite	$Cu_4(OH)_2(SO_4)_2{\cdot}NaSO_4{\cdot}2H_2O$	18.8
Almerite	$Na_2SO_4{\cdot}Al_2(SO_4)_3{\cdot}5Al(OH)_3{\cdot}H_2O$	15.9
Mendozite (soda alum)	$Na_2SO_4{\cdot}Al_2(SO_4)_3{\cdot}24H_2O$	15.5
Natrojarosite	$Na_2Fe_6(OH)_{12}(SO_4)_4$	14.7
Noselite	$3Na_2Al_2Si_2O_8{\cdot}NaSO_4$	14.3
Slavikite	$(NaK)_2SO_4{\cdot}Fe_{10}(OH)_6(SO_4)_{12}{\cdot}63H_2O$	<4.6

Salt cake is defined as anhydrous sodium sulphate with purity less than 98 %

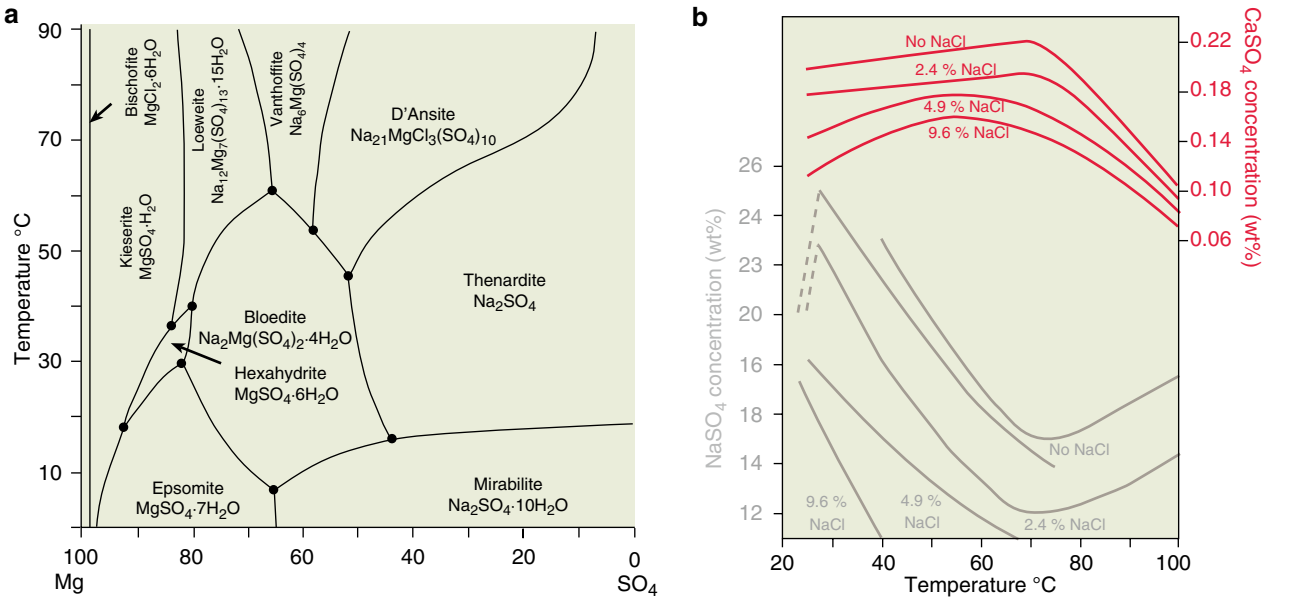

Fig. 12.14 Sodium sulphate chemistry. (**a**) Temperature dependency of Na_2SO_4 minerals in an NaCl-saturated NaCl–Na_2SO_4–$MgCl_2$–H_2O system (After Braitsch 1964). (**b**) Solubility of sodium sulphate and calcium sulphate (different scales) when glauberite and gypsum/anhydrite are both present at 20–100 °C, and with 0–9.6 % NaCl, wt% (After Garrett 2001)

natural and processed brines (Fig. 12.14a, b). Thenardite and mirabilite, respectively, are the anhydrous and decahydrate single-sodium sulphate salts and are the commercially important ore salts, with lesser production from glauberite and bloedite (astrakanite) ores. Thenardite, named for the French chemist Louis J. Thenard, is a colourless to white mineral with a specific gravity of 2.67 and a hardness of 2.5–3.0. It is stable below 33 °C and is extremely hygroscopic below 25 °C, converting to the decahydrate mirabilite (Fig. 12.14a). This mineral contains 55.9 % water of crystallization and forms opaque to colourless needle-like crystals sometimes referred to as Glauber's salt. Common nongeological usage of the term Glauber's salts can be confusing, it usually refers to mirabilite rather than glauberite (named after the seventeenth century German iatrochemist, Johann Glauber). The mineral name mirabilite comes from the Latin *sal mirabilis* or "miracle salt" possibly referring to its pharmacological use as a cathartic or laxative in the Middle Ages and its utility in treating a wide variety of gastric complaints. The mineral glauberite and Glauber's salt are two separate minerals; Glauber's salt is the industrial name for the mineral mirabilite.

Essentially all commercial deposits of natural sodium sulphate are the result of the accumulation and evaporation of continental surface waters and groundwaters in arid endorheic basins, all located in hot or cold, arid to semiarid, desert regions. Exploited Na_2SO_4 deposits can be further classified into; (1) those extracted from Quaternary-age brines hosted in crystalline beds containing mirabilite or glauberite; and (2) those found as older (Pre-Quaternary) bedded accumulations of thenardite, glauberite and associated minerals. The first category includes most of the principal economic deposits of the world. Notable among them are, the lake deposits of western Canada; the vast mirabilite-glauberite deposits of Karabogazgol on the eastern shore of the Caspian Sea, the mirabilites of Great Salt Lake, Utah; the brine deposits of Laguna del Rey in western Mexico and Searles Lake in the western USA. All these Quaternary lacustrine systems require brine reservoiring for exploitation, some also require dredging. Commercial deposits of the second category, that is, the Pre-Quaternary bedded ores, are relatively rare occurrences. Miocene saline lacustrine deposits of thenardite and glauberite are mined in Spain, while thenardite was mined at Camp Verde, Arizona, and Rhodes Marsh near Mina, Nevada. Conventional mining techniques are, or were, used for ore extraction in this group of deposits.

Quaternary sodium sulphate brines show an interesting climatic dichotomy, one group is characterised by the formation of mirabilite via brine freezing (cryogenic salts), the other by glauberite/bloedite created by the evaporation of continental brines in saline groundwater sumps in warm to hot arid deserts.

The dichotomy reflects the fact that sodium sulphate solubility in water changes as a nonlinear function of temperature (Fig. 12.14a). Below 1.2 °C, ice and mirabilite

tend to precipitate as seawater or a saline brine freezes. As the temperature increases above 0 °C, increasing amounts of hydrous sodium sulphate (as the decahydrate, mirabilite) become soluble, while the hydrous form (thenardite) becomes the precipitative phase in brines saturated with respect to the sodium sulphate salts. At 32.4 °C in pure water, a transition point on the solubility curve is reached, whereby mirabilite melts in its own water of crystallization and thenardite crystallizes. Presence of other dissolved salts changes the transition temperature and solubility characteristics of sodium sulphate due to the double salt effect. Figure 12.14b plots solubility versus temperature in terms of $NaSO_4$ and $CaSO_4$ in various NaCl solutions. It clearly shows the retrograde solubility of both salts and in part explains why glauberite is a common low temperature replacement of gypsum/anhydrite in many salt-cake beds (see discussion of double salt effect in Chap. 2).

Natural temperature drops in sodium sulphate-saturated brines in cooler climates are sufficient to allow mirabilite to crystallise in Canadian salt lakes during the autumn transition to winter, and even during cooling on summer nights in higher altitudes. In many places, mirabilite crystals redissolve into the lake brine with the next passage to warmer temperatures, this can be on the next day, or with the passage of winter into spring. This is also true of the brines in Great Salt Lake and Karabogazgol.

Natural sources of sodium sulphate make up over 60 % of world production, the balance is a synthetic byproduct of various chemical and waste recovery processes, including the manufacture of rayon, dichromate, phenol and potash. Mexico and Spain are the world's highest tonnage miners of natural sodium sulphate, followed by a group comprising the USA, Canada, Turkey and Iran (Table 12.6, Fig. 12.15). The Chinese probably manufacture the largest volume of synthetic salt-cake, although figures are not released. The

Table 12.6 $NaSO_4$ deposits, listed by country

Location (area)	Age	Elev. (m)	Köppen	Mineralogy/setting/comments/key references
Hobbs mirabilite area, Antarctica	Quaternary	174	EF	Pure bedded mirabilite to mirabilite-cemented till of Hobbs Glacier in region between glacial nose and coastline. Mainly sourced by freezing of seawater-influenced aerosols. Not exploited (4 mt). (Bowser et al. 1970)
Cerro Blanco, Argentina	Pliocene	3,926	–	Thenardite, small deposit (1.2 mt) in Upper Member of Rodeo Fm. Hosted in clay, shale, gypsum and volcanic ash. (Garrett 2001)
Florentino Ameghino, Argentina (13 km^2)	Quaternary	122	BSk	Mirabilite, halite. Four "mineralized levels" (beds) containing multiple lenses (several metres long and up to 10 cm thick) associated with similar sized lenses gypsum after anhydrite. Numerous springs. (Garrett 2001)
Rio Grande Salar, Argentina (67 km^2)	Quaternary	3,630	ET	Mirabilite/thenardite, bedded salar salts, occasional extraction (≈6,000 t/year) via trenching in Salta Province. (Garrett 2001)
Sua (Sowa) Pan, Botswana (3,306 km^2)	Quaternary	892	BSh	Brine processing active in Makgadikgadi playa. Salt-cake is possible future byproduct from brine carbonation in existing soda-ash facility. Estimated there is ≈110 mt of $NaSO_4$ in brine stored in pan aquifer. (Low et al. 2000; Eckardt et al. 2008)
Canadian saline lakes on the Great Plains Canada	Quaternary	650–712	BSk	Mirabilite/thenardite. Supratill depressions, some lakes with permanent mirabilite beds, others with ephemeral mirabilite (winter) recovery by various combinations of dredging and brine processing. Ingebright Lake (2.8 km^2, BSk) had largest reserves of the Canadian lakes (11.7 mt). Other exploited and now depleted lakes (in BSk and Dfb climate) include Big Quill Lake (7 mt), Chaplin Lake (3 mt), Dead Moose (1.6 mt), Freefight Lake (1.3 mt), Horseshoe Lake (3.7 mt), Sybouts Lake (3.3 mt), Whiteshore Lake (6.5 mt). (Last 2002)
Submergent coastal lake basins, Sachs Harbor, Canadian Arctic	Quaternary	−1.0	ET	Freezing of seawater excludes salts, generating dense brines that sink to the basin bottom (Mirabilite Lakes 1&2). Progressive freezing increases salinity of residual brines to the point of mirabilite saturation, and as a result sedimentary deposits of mirabilite (1 m-thick beds) accumulate on the basin floors. Brine formation also leads to density stratification and bottom water anoxia (Grasby et al. 2013).

Table 12.6 (continued)

Location (area)	Age	Elev. (m)	Köppen	Mineralogy/setting/comments/key references
Weldon, New Brunswick, Canada	Lower Carboniferous	4	–	Glauberite (25 mt) at 344 m depth in the lacustrine Gautreau Formation. Overlies at least 60 % of halite extent and grades into, a 13 km^2 halite deposit in the small nonmarine Weldon-Gautreau Basin. Not exploited, ≈ 25 mt. (St. Peter 2006; Webb 1977)
Salars inland of Antofagasta (>100 salars), Northern Chile (<10 km^2)	Quaternary	1,400	BWk	Mirabilite/thenardite in small playas of Atacama and Central Valley. Bedded salar salts, occasional extraction via trenching, association with pedogenic nitrate (1,200 mt). (Garrett 2001)
Chaganor Salt Lake, China (Inner Mongolia) (21 km^2)	Quaternary	968	BSk	Brine processing. Nine porous brine-filled beds of salts with 11.3 mt of sodium carbonate, and 4.5 mt of sodium sulphate. Beds of natron, mirabilite, halite, burkeite and trona interbedded with black mud containing illite, some gaylussite, dolomite and calcite. (Zheng 1997)
Beida Lake (Wadi Natrun), Egypt (1.2 km^2)	Quaternary	−23	BWh	Massive 1-m-thick thenardite below 0.5 m halite bed. Lowest lake in Wadi Natrun chain, which are spring-fed depressions sourced in Nile. No brine-based salt-cake production, historically mined (1.1 mt). (Atia et al. 1970; Nakla and Saleh 1985; Shortland 2004)
Lake Qarun, Egypt (226 km^2)	Quaternary	5	BWh	Thenardite via brine processing in El Faiyum depression, possibly not implementable as lake brine is very dilute (4 mt). (Rasmy and Estefan 1983)
N. Aral Sea, Kazak. and Uzbek. (400 km^2)	Quaternary	40	BWk	Mirabilite/thenardite in shallow bed up to 60–70 cm thick beneath 1.5–2 m gypsiferous silt in Lesser Northern Sea, processing required. Seasonal mirabilite precipitation (≈200 mt). (Crétaux et al. 2009; Zavialov et al. 2009)
Tien Shan region, Kyrgyzstan	Tertiary Late?	1,500–2,200	–	Halite with glauberite (after thenardite as it sits atop glauberite). Lenses up to 5 m thick that aggregate to a several hundred metre thick saline section hosted in more than 2,000 m of Miocene sediment. Found in various intermontane sub-basins in Kochkorka, Kegen Dzhamgol, Frunze and Naryn regions (≈4,000 mt). (Garrett 2001; Wünnemann et al. 2007)
Bacadehuachi Valley, Sonora (includes Oro Blanco Pit), Mexico	OligoMiocene	700	–	Thenardite, lesser mirabilite, hosted in fine-grained, vitreous lacustrine tuff beds, beneath dissected alluvial fan conglomerate. Lenticular beds 20 m thick, outcrops in Baucarit Group, ore zone that is 4 km wide, area 13 km^2, in block-faulted basin in Occidental Sierra Madre Mountains (100 mt). (Austin and Humphrey 2006)
Laguna del Rey, Mexico (40 km^2)	Quaternary	1,000	BWh	Targeted horizon has 50 % glauberite and 20 % astrakanite (bloedite), lesser halite, minor mirabilite. Richest bloedite is 8 m below top of salt bed Shallow lake beds ≈10 km long, 4 km wide and 35 m thick in centre. Recovery via brine pumping and processing (350 mt). (Sanchez-Mejorada 1986)
Otjiwalunda playa, Namibia (95 km^2)	Quaternary	900	BSh	Thenardite (dominant) and significant trona (lesser burkeite). 80 mt of salt-cake and 40 mt of trona. Surface salts constitute a surface and nearsurface old massive playa bed, probably strip mineable with simple flotation separation. Most of the potential ore has 2–3 % insolubles. Lies 80 km to the west of Etosha Pan. (Garret 2001)
Laguna Salinas, Peru (4.4 km^2)	Quaternary	4,200	ET	Mirabilite/thenardite (3 mt) within surface crusts on playa floor, along with halite and ulexite. Is partially flooded in winter, then dries as surface crusts form. High altitude intermontane depression in Southern Peru, potential but not developed, primary target would be borates. (Garrett 2001; Muessig 1958)
Kuchuk Lake (Ozero Kuchukskoye), Russia (178 km^2)	Quaternary	92	Dfb	Brine processing; there are also two" glassy mirabilite beds in the lake partially converted to thenardite. Upper bed is 3 m thick. Mirabilite crystallizes in winter and on cool summer evenings (converts to thenardite). Problems due to fluctuating lake levels (540 mt). (Lebedeva et al. 2008)

(continued)

Table 12.6 (continued)

Location (area)	Age	Elev. (m)	Köppen	Mineralogy/setting/comments/key references
Madrid, Ebro and Calatayud basins, Spain	Miocene, Lower	500		Thenardite, glauberite. e.g. El Castillar Mine via pillar and room mine on 5–8 m thick (Lower Saline unit) thenardite bed, processed in evaporation plant (Total 2,500 mt of $NaSO_4$; economic 272 mt). (Ordonez and Garcia 1988; Salvany et al. 2007)
Cayirhan mine (aka Kimir or Beypazari deposit), Turkey	Miocene Upper	700		Thenardite, glauberite (possibly after mirabilite). Hosted in Kirmir Fm. (up to 250 m thick) intercalated with gypsum and claystones, sits atop trona in Hirka Fm. and atop lignite deposit. (65 mt) (Orti et al. 2002; Gungdogan and Helvaci 2001)
Acigol, Turkey (Extent: Spring 100 km^2, Summer 35 km^2)	Quaternary	836	Csa	Mirabilite/thenardite via solar evaporators. Intermontane, ephemeral saline pan beds, brine ponding and processing (12.5 mt; possible 82 mt resource). Production also in nearby Lakes Tersakan (56 km^2) and Bolluk (20 km^2) within the Tuzgolu depression (10 mt). (Mutlu et al. 1999)
Kara Bogaz Gol, Turkmenistan (18,000 km^2)	Quaternary	−29	BSk	Glauberite/astrakanite via groundwater flushing (mirabilite precursor). Speculated resource of 2 billion tons of salt-cake in the Gulf (10 mt under production via brine processing). Saline lake floor beds are widespread, especially along northern margin of the gulf, which is a post-collision lacustrine foreland basin. (Kosarev et al. 2009; Kurilenko et al. 1988)
Bertram, CA, USA	Neogene	−27	–	Discontinuous thenardite/astrakanite beds, sporadically mined. Ore hosted in highly deformed gypsiferous lake beds, occasional extraction (2 mt). (Garrett 2001)
Owens Lake, USA (278 km^2)	Quaternary	1,081	BSk	Brine processing (10 mt). Dry playa in block-faulted Basin and Range valley (anthropogenic increased salinity). Natron, mirabilite and borax are all winter precipitates in lake. Trona is dominant salt in salt bed, which is some 3,500 years old, about same age as upper salt bed in Searles Lake. Was a perennial saline lake until 1917 and inflow diverted in LA aqueduct, was dry by 1922. (Alderman 1985)
Searles Lake, USA (132 km^2)	Quaternary	493	BWk	Brine extraction from two buried saline playa salt beds (halite, trona, hanksite, borax, thenardite). Both beds less than 35 ka. Brine pumping and processing (carbonation), mirabilite formerly produced by winter spraying, concentrated brine now largely depleted (434 mt). (Smith 1979)
Great Salt Lake, USA (4,998 km^2)	Quaternary	1,270	Csa	Mirabilite, brine processing (408 mt). Buried fault-bound Pleistocene mirabilite bed deposited when brine level fell rapidly at end of Provo Level time. $NaSO_4$ is also a byproduct of brine processing in Northern Arm of Lake). (Garrett 2001; Colman et al. 2002)

Reserves in million metric tons (mt) of $NaSO_4$ after Garrett 2001 (for additional overviews see Austin and Humphrey 2006; Butts and Bush 2007)

world's largest and purest exploited brine sources of Na_2SO_4 salts (as documented in the literature) occur in two saline, but climatically contrasting, Quaternary playas/lakes in arid deserts, namely; cryogenic salt in Kara Bogaz Gol in Turkmenistan (BWk) and hot desert evaporites in Laguna del Rey in Mexico (BWh; Fig. 12.16). In both, the prime target beds are dominated by glauberite/halite with lesser astrakanite (bloedite). Searles Lake in California (BWk) constitutes a third Quaternary saline lacustrine system where $NaSO_4$ is recovered via brine extraction and solar processing from a Late Pleistocene trona/halite bed that contains significant thenardite, but soda-ash, not salt-cake is the primary product. Today, all three of these deposits are in an extraction phase where brine pumping and processing rather than mining of the solid salt drives the economics. Then there are the ancient (Tertiary-age) lacustrine deposits of Spain and Turkey where glauberite and thenardite are the main ore minerals and the modern pedogenic deposits in the Atacama Desert of Chile.

Although commercial production figures and reserves are not released by the Chinese Government, it is likely that in 2012 China was the leading exporter and producer of natural and synthetic sodium sulphate in the world. Jiangsu Province is the major area for sodium sulphate production. According to the USGS it is anticipated that this area will produce 4.8 million tons of sodium sulphate annually by the end of 2014.

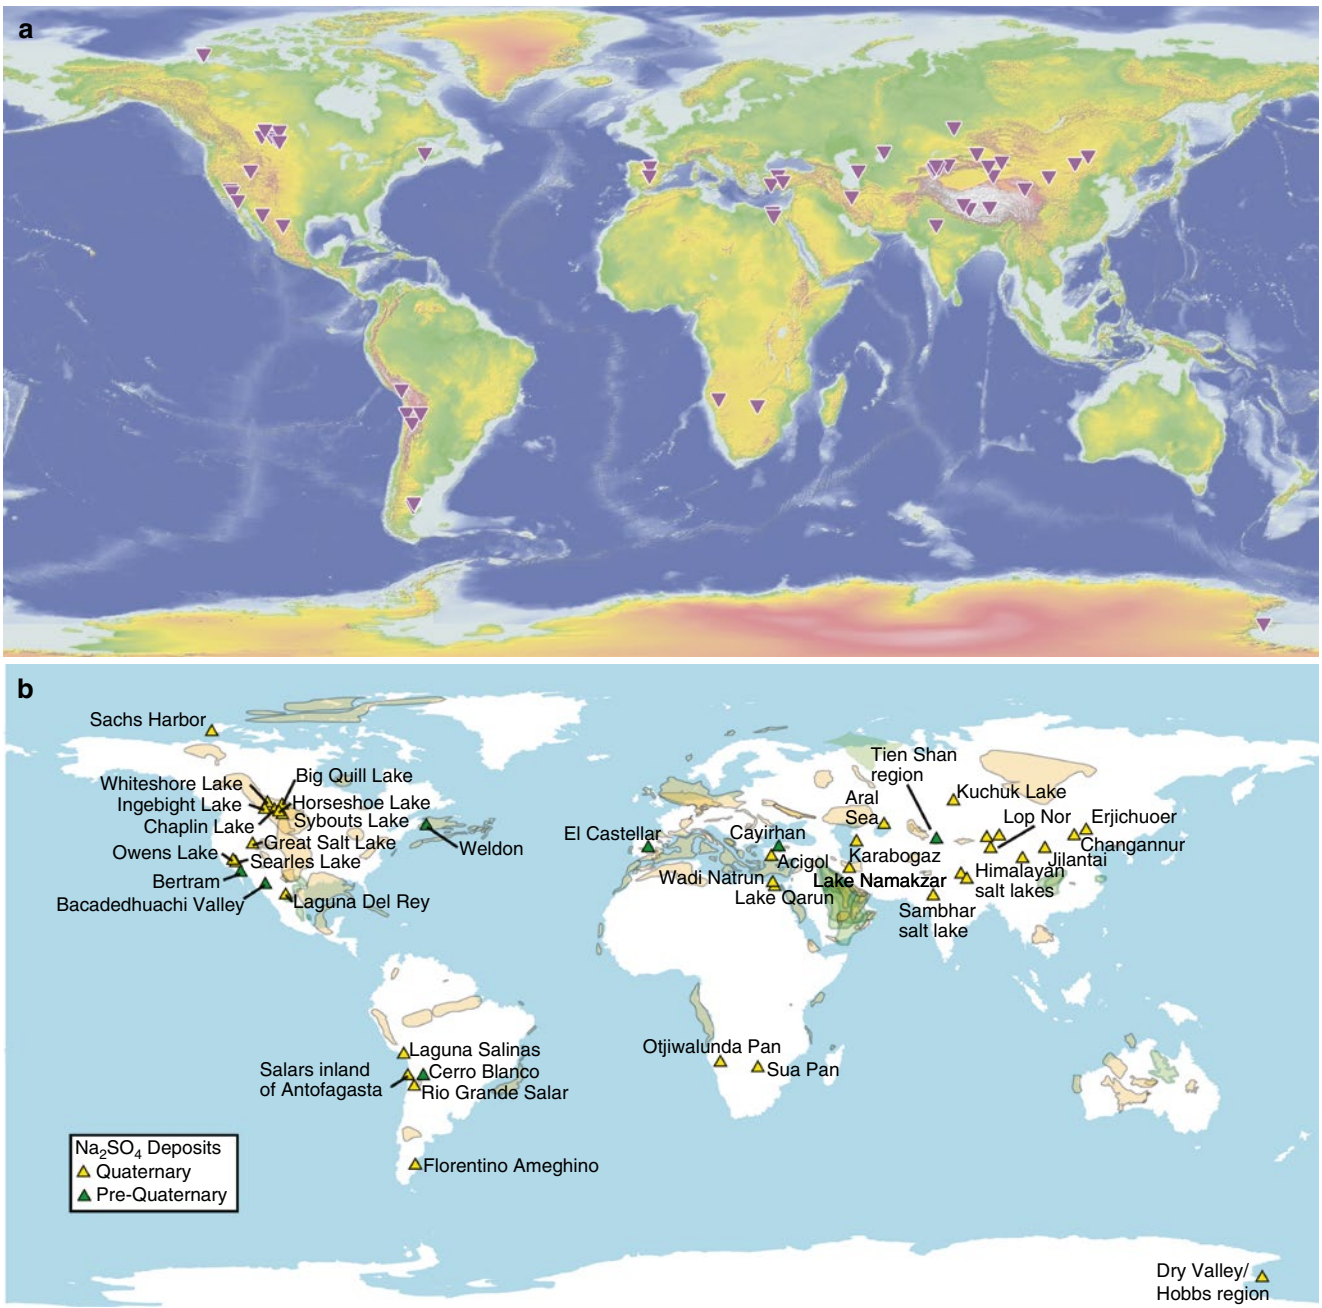

Fig. 12.15 Na_2SO_4 deposits. (**a**) Deposits plotted on a world topographic/tectonic base (Table 12.6). (**b**) Deposits plotted on a marine evaporite basin base, where brown shading indicates halite-dominant and green indicates megasulphate basin (After Warren 2010). Plot shows that borate deposits are better developed in volcanic-associated, active orogenic collision belts and zones of fractured continental crust. They do not occur atop or within large marine-fed mega-evaporite basins

As of 2008, it was estimated China represented about three-fourths of world production capacity of saltcake and more than 70 % of world production (Kostick 2012). Although data on mine production for natural sodium sulphate are not available, total world production of natural sodium sulphate is estimated to be about 6 million tons (Fig. 12.16). Today in the United States, more than one half of the total domestic sodium sulphate output is a by-product of various manufacturing processes or products including ascorbic acid, battery reclamation, cellulose, rayon, and silica pigments (Austin and Humphrey 2006). In addition, there is sizable production of sodium sulphate from other chemicals (primarily salt and sulphuric acid). Total world production of byproduct sodium sulphate is estimated to be between 1.5 and 2.0 million tons. World sodium sulphate production from natural sources probably peaked around 1970

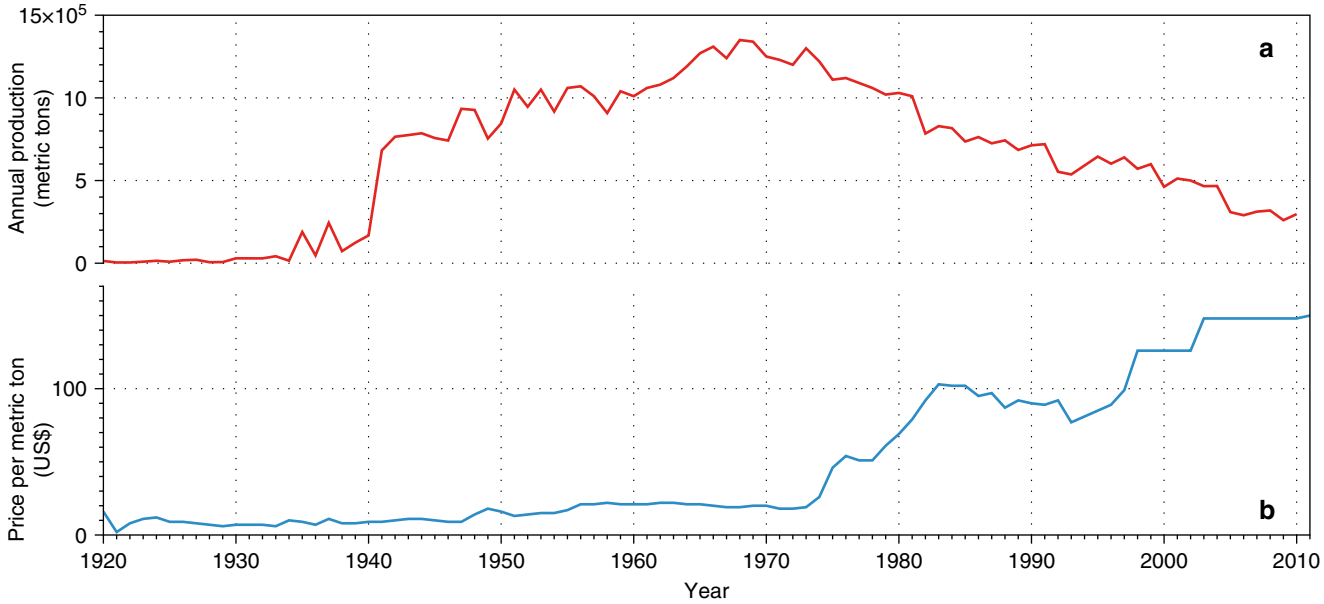

Fig. 12.16 World Production of $NaSO_4$. (**a**) Annual production in metric tons. (**b**) Price per metric ton in US dollars (**a**, **b** are replotted from USGS on-line data tables, downloaded from http://minerals.usgs.gov/minerals/index.html, last accessed May 5, 2014)

Table 12.7 World reserves of natural Na_2SO_4

Country	Reserves (1,000 metric tons)
United States	860,000
Canada	84,000
China	Not available
Mexico	170,000
Spain	180,000
Turkey	100,000
Other countries	1,900,000
World (rounded)	3,300,000

After Kostick 2012

(Fig. 12.16a) and although the absolute price shows a consistent rise since then, in terms of inflation corrected value per ton, the price has risen little since 1970. Reserves of natural Na_2SO_4, other than in China, are given in Table 12.7.

Canadian Brine Extraction

The number of saline lakes in the moraine plain of central Canada is staggering. Estimates vary from about one million to greater than ten million, with densities in some areas being as high as 120 lakes/km^2, creating a concentration and diversity of salt lake environments unequalled in the world (Last and Ginn 2005). Virtually all brine types are represented in these lakes, with Na-Mg-SO_4 chemistries dominant. Over 80 species of endogenic precipitates and authigenic minerals have been identified as lake precipitates, the most common being calcium/calcium-magnesium carbonates (calcite/dolomite) and sodium/sodium-magnesium sulphates (mirabilite/gypsum) (Fig. 12.17).

All the present and former Canadian production of sodium sulphate in southern Saskatchewan and southeastern Alberta comes from deposits that are the result of present day or earlier Holocene late autumn- early winter cooling/freezing of playa brines. Cryogenic precipitates in the ore salts are mostly mirabilitic, which may convert to thenardite with warming. Saltcake ore formation in Canada is a cryogenic, not solar evaporative, process. Most of the mirabilite-accumulating lakes are small (<100 km^2), shallow (brines <3–20 m deep), with permanent salt beds found only in the lowest portions of some of the hydrologically-closed meromictic depressions (Last 1989a, 1994). Around a hundred lakes have salt reserves of more than 100 kt of Na_2SO_4 and their combined recoverable reserves prior to ongoing exploitation were around 80–100 Mt (Fig. 12.18; Garrett 2002; Last and Ginn 2005).

Large tracts of hummocky and icethrust moraine dominate the saline lakes region where cryogenic salts precipitate in landscape sumps. In combination with the limited efficacy of fluvial processes under a subhumid to semiarid temperate climate, this geomorphology results in more than 45 % of the region being endorheically drained into perennial saline lakes in depressions in the glacial drift. Some of these depressions are elongate and probably occupy pre-ice age river valleys (Fig. 12.17; Little Manitou Lake), others were created as kettles by the melting of huge relict blocks of ice left in the moraine after the main front of the ice sheet had retreated (Fig. 12.19a, b; Freefight Lake, Ingebright Lake). Groundwater seeping from the surrounding moraine, through the underlying

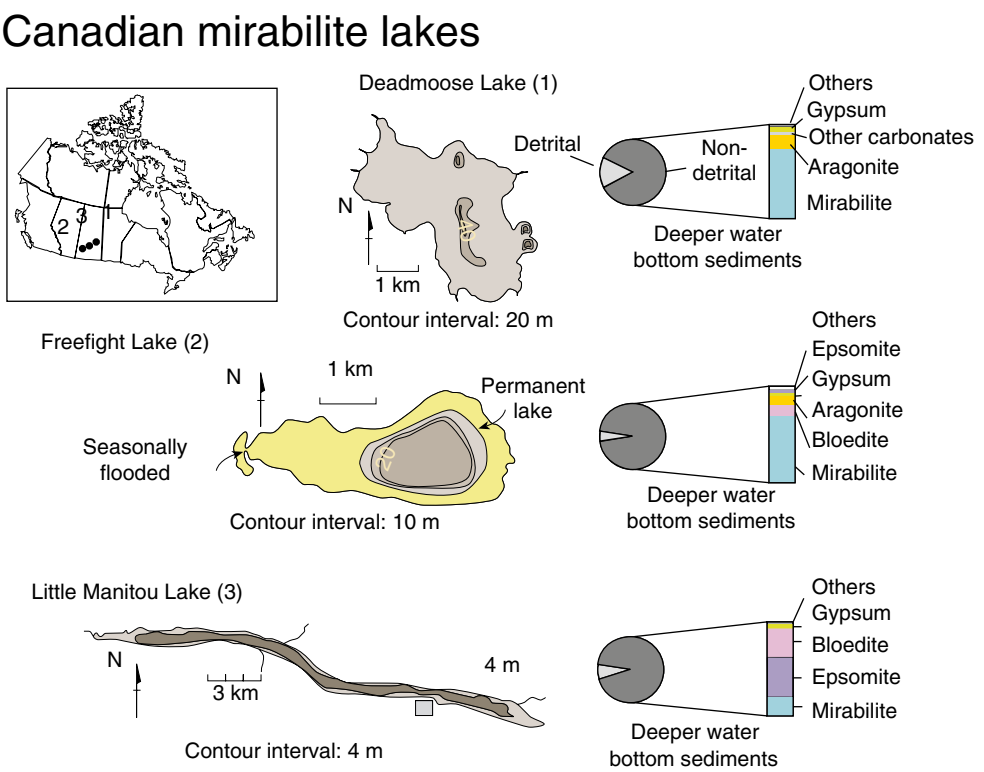

Fig. 12.17 Sodium sulphate lakes, Canada. Selected mirabilite lakes in the plains of Canada, showing bathymetry and bottom sediment composition in deeper subaqueous parts of lake floor (After Last 1994)

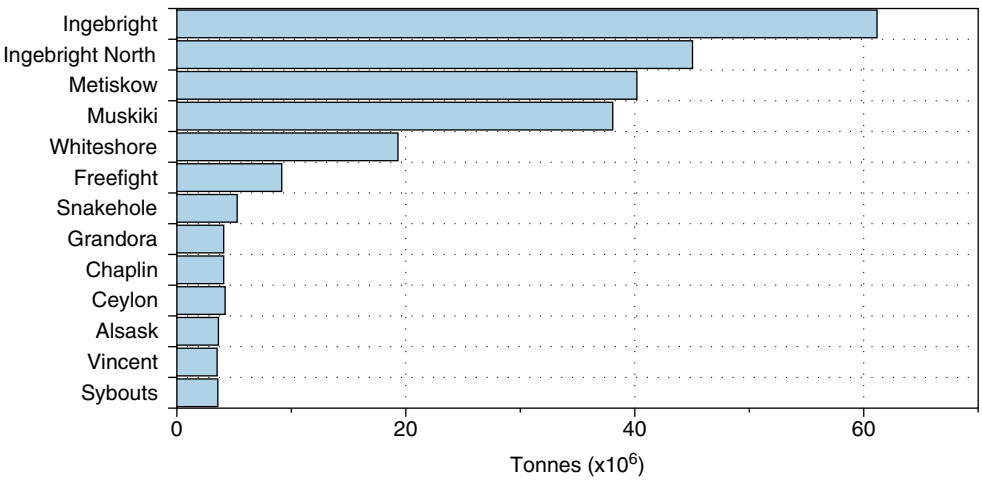

Fig. 12.18 Reserves of anhydrous sodium sulphate in the twelve largest lacustrine deposits in the northern Great Plains of western Canada. Ingebright and North Ingebright deposits have been separated but geologically are one contiguous deposit (After Last and Ginn 2005)

valley sands and across underlying bedrock, supplies much of the dissolved content, but there is still no consensus as to the ultimate origin of the sodium and sulphate (Last 1989a). The geographic coincidence of many of the more productive lakes to the subsurface solution edge of the Devonian Prairie Evaporite lead Grossman (1968) to suggest dissolution-derived salt-rich resurging groundwaters were the ultimate source. Others have argued that weathering and leaching of pyritiferous glacial flour is the likely source for the ions, independent of the underlying Devonian salts (Wallick 1981).

Before the mirabilite crusts redissolve with the passage in to the warmer lake waters of spring, these coldwater saltcake crystals can be dredged each year from suitably saline lakes. Thicker-bedded crystalline thenardite deposits (transformed from primary mirabilite) have accumulated over hundreds to thousands of years on the bottom of some of these lake depressions. Each year, they retain a saturated brine layer from few centimeters to metres deep, but the bottom waters in the shallower stratified are typically subject to seasonal warming sufficient to convert some mirabilite to thenardite/bloedite. Waters in the upper water mass of all the deeper perennial lakes are replenished annually by spring melt. Cryogenic cycling, whereby some of the mirabilite redissolves due to heating, can produce lake-bottom brines with

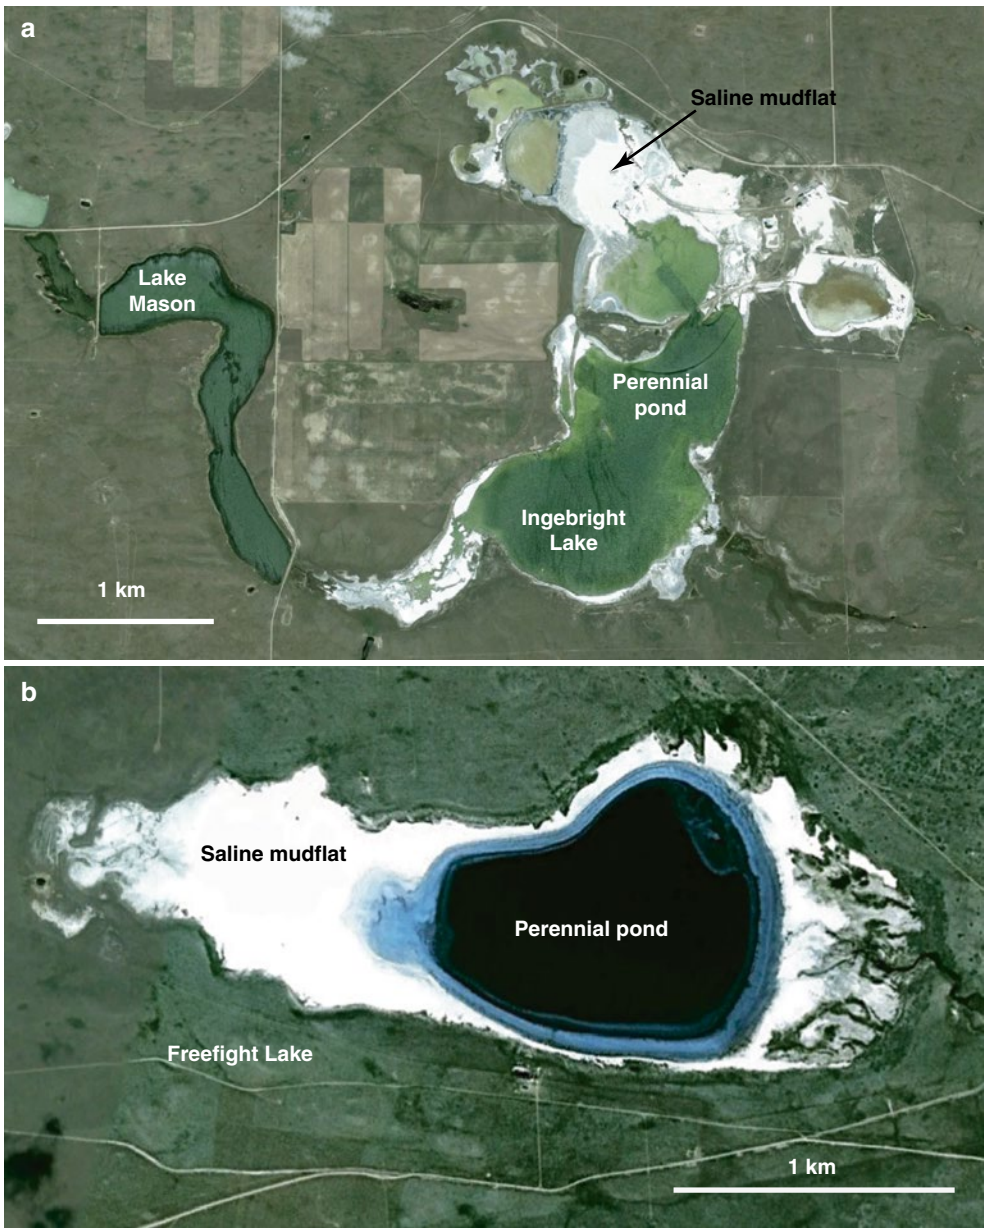

Fig. 12.19 Canadian cryogenic Lakes. (**a**) Ingebright Lake, (**b**) Freefight Lake, Saskatchewan, Canada, showing perennial lake areas and surrounding saline pan – mudflat. Two of numerous such $NaSO_4$ lakes in the Canadian Great Plain (See Fig. 12.17 for geological detail)

salinities that may exceed 400‰. This maintains a perennial curtain or plume of saturated pore brines that preserve thick saltcake beds in the lower parts of the lake depression (Fig. 12.17).

The saline lakes region of Saskatchewan encompasses some of the largest (Quill, Old Wives) and deepest (Freefight), perennial hypersaline lakes in North America, capable of accumulating bedded salts more saline than evaporitic carbonate. Ingebright Lake in southern Saskatchewan, although it is small in area (<2 km^2) has, at 25–40 m-thick, the thickest Holocene evaporite bed in North America and it is dominated by primary precipitates of thenardite, Mg-carbonates and gypsum. Ingebright Lake had the largest reserves of the various $NaSO_4$ salt lakes recently in production, but in 2005 extraction facilities were mothballed. Bed thickness once averaged 6.7 m of permanent salt, and reserves once exceeded 60 million tonnes beneath a lake area of 280 ha (Fig. 12.17; Garrett 2001). The lake and its drainage area is not large and no modern streams flow into it although it does define the termination of a glacial paleodrainage channel (Fig. 12.19a). Today, it is fed by numerous saline springs and seeps about the lake edge, including five large springs that flow year round, so supplying a dilute high-sulphate medium carbonate/bicarbonate water to the upper water mass (TDS of 2,800 ppm; Cole 1926). Subaqueous springs also cut up through the mirabilite bed that covers the lake floor. Springs tend to be cold (7 °C) in the northern part of the lake, and warmer (15–18 °C) and more saline in the south. Each winter

these more saline southern springs precipitate large ephemeral mirabilite mounds that are up to 3 m tall and 6 m across.

The fresher nature of the water supply to the northern springs means they are capable of dissolving all the mirabilite on their rise to the lake floor and so are defined by mud pipes or chimneys cutting up through the mirabilite ore bed (Last 1993a). The metres-thick mirabilite bed, which covers the perennially subaqueous lake floor, is compact and friable. In the northern part of the lake it contains numerous clay layers that are mostly cm-scale, but as thick a 1 m at the 7.6–9.1 m level in the lake (Cole 1926). In the south there is much less mud in the salt and it is more indurated. In the thicker ore bed of the southern part of the lake there are two zones where the mirabilite bed is thicker than 30 m and one borehole intersected more than 42 m of relatively pure sodium sulphate.

Two recognizable brine styles drive $NaSO_4$ precipitation and accumulation in the various Canadian lakes; intermittent saturation and permanent saturation (Last 1994). Intermittent brines form seasonally on the bottom and along the shores of the lakes. There, cryogenic mirabilite crystallizes and largely redissolves with each seasonal cycle of cooling and warming. Mirabilite precipitation-dissolution cycles in such lakes can occur in a matter of hours, but as winter sets in, redissolution wanes, causing the crusts to become thicker and more compact. Spring meltwaters in a few lakes with such intermittent brine hydrologies carry in sufficient volumes of fine detritus to mantle salts in the shallower parts of the lakes and so preserve some of the lake precipitates year round. Such beds range in thickness from less than one to several metres, they are relatively impure, and made up of thenardite interstratified with thin layers of mud, clay, and organics.

Thicker purer beds of $NaSO_4$ tend to accumulate and be preserved beneath the permanent meromictic waters of the deeper lakes. Hence, Deadmoose, Little Manitou, and Freefight Lakes are lacustrine depressions in the moraine plain where soluble and sparingly soluble $NaSO_4$ salts accumulate beneath relatively deep permanent brine bodies (up to 20 m deep; Fig. 12.17). Both Deadmoose and Freefight Lakes are hypersaline and meromictic systems, with strongly anoxic hypersaline bottom waters. Little Manitou is also hypersaline, but the seasonal density and chemical stratification in the water column usually breaks down in early to midsummer, so allowing mixing of the upper and lower water masses down to the sediment surface.

There are four distinct styles of salt occurrence in these perennial mirabilite lakes: (a) crusts and hardgrounds of the lake edge, (b) massive and bedded salts of the lake centre, (c) spring or seep deposits, (d) subsurface and groundwater related interstitial and replacive cements (Last 1989a, b). Relatively thick sections of subaqueous evaporites (mostly mriabilite/thenardite) have accumulated on the bottoms of some of these deep perennial lakes making them one of our better examples of textures in modern "deepwater" evaporites

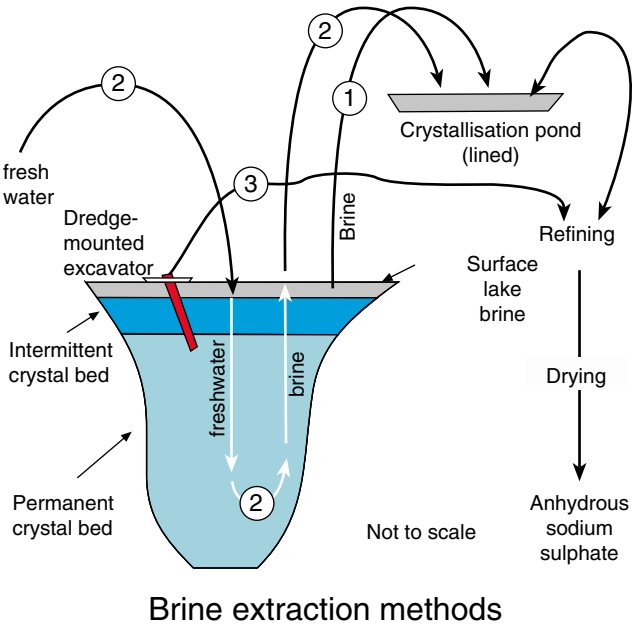

Fig. 12.20 Extraction methods in various Saskatchewan sodium sulphate deposits (After Garrett 2001); (*1*) Evaporative concentration of lake brine in crystallization pond, followed by precipitation of crystals of Glauber's salt (mirabilite) as the brine cools in autumn; (*2*) Solution mining of thick crystal beds. The return brine is treated as in *1*; and (*3*) Dredging of lake bottom crystal beds

(Last 1994). These deepwater salts are generally coarsely crystalline, massive to thickly bedded, and interfinger laterally with laminated organic-rich clays and poorly sorted carbonate-clastic debris washed in from nearshore areas. As in the Dead Sea, it seems that the deep water signature to a salt body accumulating in deeper hypersaline waters is not a laminate, but an aggregated bed of coarse crystals growing at the base of a holomictic brine column as crystal meshworks showing little or no preferred growth direction.

Today, the mirabilite extraction industry in Canada is in decline after peaking in the 1970s, most remaining commercial lakes are small, intermittently exploited and located in southern Saskatchewan. Most of the richer bedded Quaternary salt-cake has been mined. In the early days of the 1950s and 60s, operators merely mined mirabilite by scraping or blasting, later some of the mirabilite was solution mined (Garrett 2001, 2002). Traditional brine extraction involves pumping of surface brines into storage reservoirs during the summer and then allowing the lower autumn and winter temperatures to precipitate mirabilite (Fig. 12.20). The mirabilite was then trucked to the processing plant, where water of crystallization is removed and product then dried to salt cake in a rotary kiln. The largest problem for the Canadian operators was maintaining a high purity economic product that was comparable to the cheaper but higher purity product from dry playa brine leachate operations at Laguna Del Rey and the low-cost brine production and synthetic recovery plants of China.

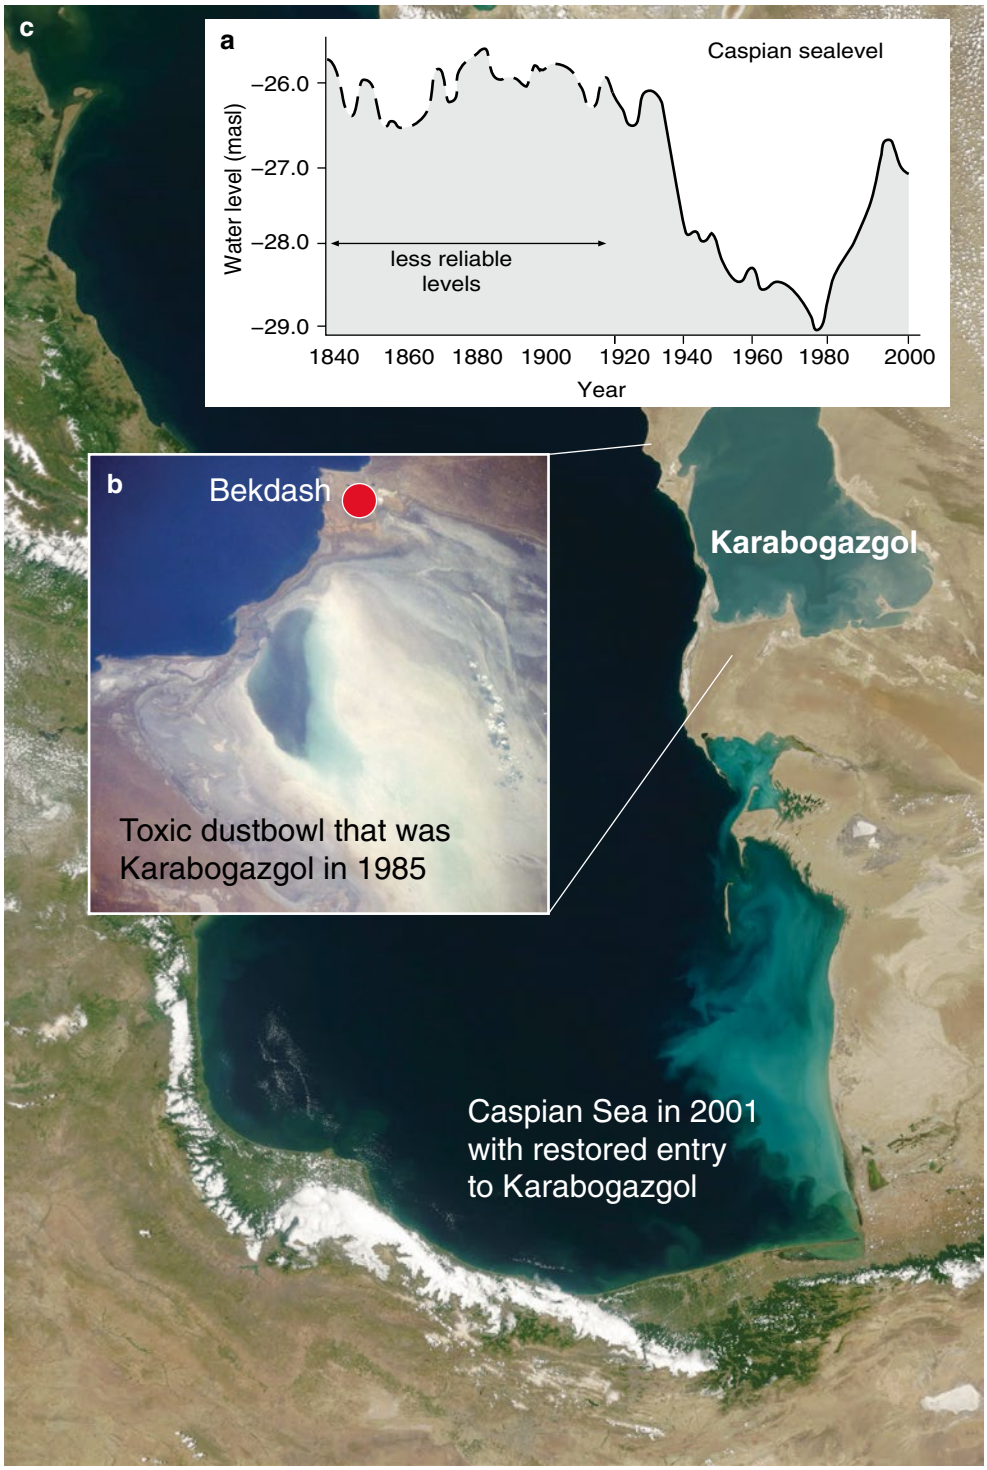

Fig. 12.21 Karabogazgol and the Caspian Sea. (*A*) Variation in the level of the Caspian Sea with the low in the period 1960–1990 driving the hydrographic isolation of Karabogazgol. Karabogazgol Brines, Turkmenistan

Sodium sulphate occurs as mirabilite-glauberite beds in the shallow subsurface of the Karabogazgol. Karabogazgol, along with the adjacent Caspian Sea, is a lacustrine foreland remnant of the former Tethyan seaway. Kara Bogaz lies in the cool arid steppes of Turkmenistan at the edge of the Caspian Sea with a brine surface some 29 m below sea level (Fig. 12.21a). The speculated total resource beneath the lake/playa is some 2–4 billion tonnes of salt-cake (Garrett 2001). The waters of Karabogazgol are derived from the Caspian Sea via a narrow inlet that gives the Gulf its name. In the past 100 years water levels in Karabogazgol have been a metre or so less than the adjacent Caspian surface, which has fluctuated between 25 and 29 m below sea level (Fig. 12.21a).

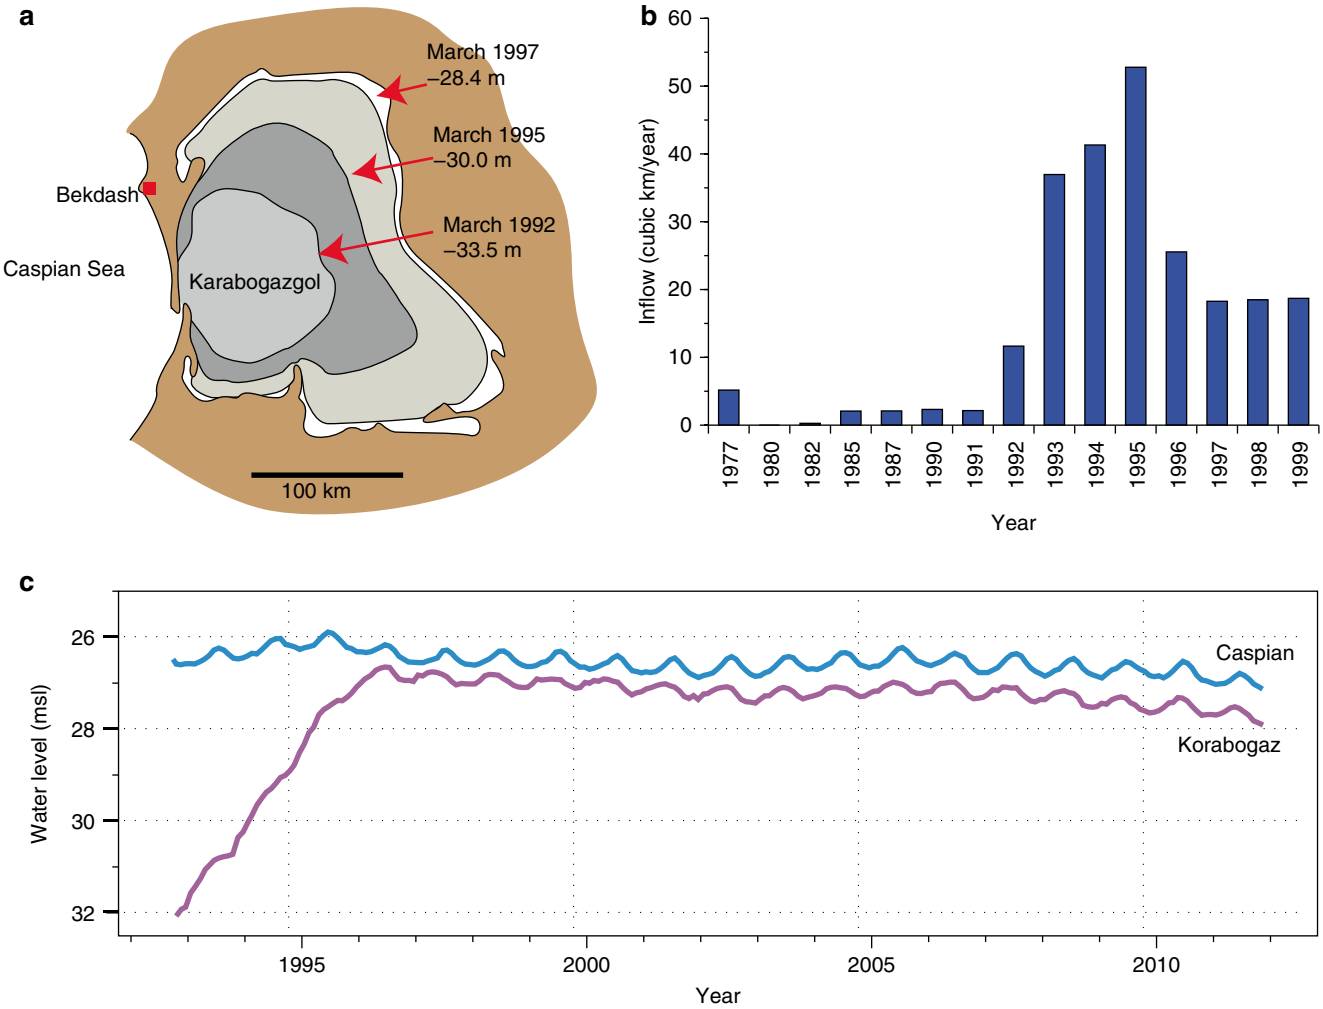

Fig. 12.22 Karabogazgol recovery. (**a**) Successive annual extents of water levels in the Gulf 1992–1997. (**b**) Annual inflow volumes through Karabogaz inlet 1977–1999. Note there was no inflow in 1980 (After Leroy et al. 2006). (**c**) Water levels in the Caspian and Korabogaz Bay in the period 1999–2011 (Replotted from data downloaded from http://www.legos.obs-mip.fr/soa/hydrologie/) (See Crétaux et al. 2011)

For much of the Holocene, Karabogazgol (Bay) has been connected via a narrow 500 m-wide inlet to the Caspian Sea, which flows water from the Caspian to Karabogazgol at a rate of 25–44 m/min. Natural inflow from the Caspian replaces water lost by evaporation from Karabogazgol (Bay) and when this happens the drawndown water level in the gulf is consistently 0.5–3 m below that of the Caspian Sea. This makes it one of the few modern examples of a drawdown basin with a highly restricted hydrographic connection between one isolated seaway and another (A_o:A_i = 2 × 10^7; Fig. 2.80). It is sufficiently restricted to allow gypsarenite to accumulate today on the brine-covered lake bottom. Water level in the Caspian Sea levels have varied considerably over the 10,000 years and so Karabogazgol repeatedly lost its hydrographic connection with the Caspian whenever water levels fell below the entrance sill. In earlier times of cooler temperatures that allowed winter freezing of a perennial water body, beds some 3–8 m-thick containing cryogenic sodium sulphate formed and are today composed of varying amounts of calcite-hydromagnesite-gypsum-halite-epsomite-mirabilite-glauberite (Fig. 12.23).

In Turkmen, Karabogazgol means "lake of the black throat," so named because the gulf is continually gulping down the waters of the Caspian. There is an interesting anthropogenic aspect to the natural loss of water from the Caspian to the Gulf and the periodic salting of Karabogazgol. Early last century (prior to 1929) the Caspian sealevel was around −26 masl and Karabogazgol was almost entirely water-filled (as it is today; Figs. 12.21a, b and 12.22a). The water-covered surface area was around 18,000 km^2 and its maximum water depth was around 9 m. The annual volume of water flowing through the inlet was high, somewhere between 18 and 26 km^3 and the difference in level between waters of the Caspian and Karabogazgol was around 0.45 m. From 1929 until 1940 there was a 1.8 fall in the level of the Caspian Sea and by 1948 the Caspian level was −27.87 m. The volume of inflow to the Gulf fell to 12–14 km^3/year by the late 1940s

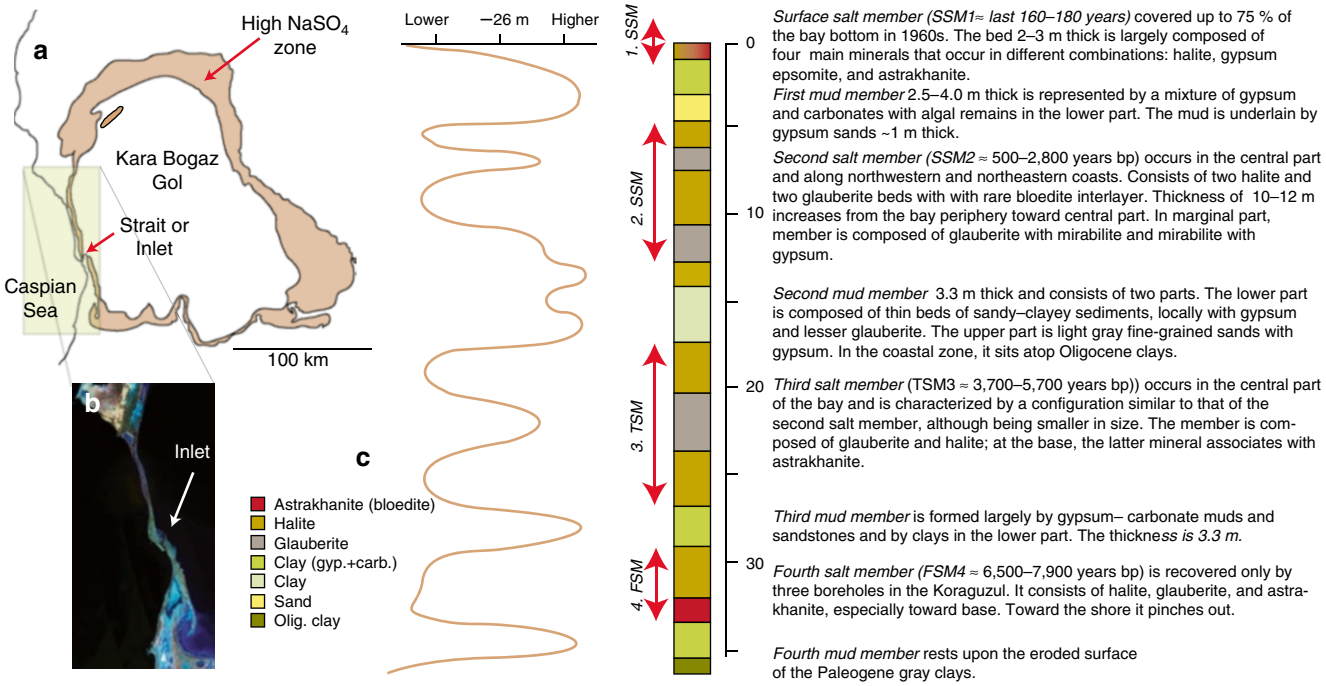

Fig. 12.23 Kara Bogaz Gol, Turkmenistan. (*A*) Plan view showing distribution of second salt member zones with higher $NaSO_4$, which tend to occur about bay margin (After Strakhov 1970). (*B*) The Landsat image insert shows detail of the narrow inlet allowing surface entry of Caspian Seawater into bay. (*C*) Typical lake stratigraphy showing thickness, relative water levels and Holocene ages of the four salt members that define the saline successions in the bay (In part after Karpychev 2007)

and to 8 km^3/year in 1956. Differences in water level between Caspian and the Gulf increased to 3.17 m in 1947 and 3.80 m in 1955. By 1957–1959 the water-covered area in Karabogazgol had fallen to around 13,000 km^2. By 1977 water level in the Caspian was −29.02 masl, it had fallen fell by more than 3 m since 1929 (Fig. 12.21a). The 1977 water surface in Karabogazgol was 4.5 m lower than the Caspian and the strandline of southern Karabogazgol had retreated by 50–60 km in 50 years. This ongoing drop in water level in Karabogazgol since 1929 meant fisheries were threatened on the Caspian side and numerous salt works had developed in the increasingly exposed and accessible brine flats.

The ongoing fall of the Caspian Sea level from 1929 and well into the 1970s, was thought by the Russian Government to be related to the continuous loss of water from the Caspian to Karabogazgol. After all, the climate in the Karabogazgol was arid, the annual evaporation rate was 1,000–1,500 mm and annual rainfall around 70 mm. Russian government scientists argued that damming the entryway would stop the Caspian spilling into the Gulf and so arrest the fall in the Caspian water level and the threat to fisheries. This notion of interfering in a natural saline system was opposed by a number of Turkmeni scientists who argued that the rise and fall of the Caspian and the variable filling in Karabogazgol were natural processes and had been noted in the texts of ancient Islamic scholars living in the region.

Ignoring the argument that rise and fall of brine level in isolated saline waters bodies, such as the Caspian, was the normal situation, a decision was made in 1977 by the central administration in Moscow that the entryway would be damned. Central administration scientists had concluded that sufficient water would remain in Karabogazgol after damming to allow the salt industry to continue its operations. The dam was not actually constructed for another 3 years. Ironically, the natural fall in the level of the Caspian had reversed in 1977 and had began to rise once more, with a corresponding rise in waters levels in the Gulf. From 1977 until 1995 the Caspian level rose by the same 3 m it had dropped since the 30s. However a decision had been made back in 1977 to dam the entryway, so in 1980, even though the Caspian water level was rising once more, Russian engineers dammed the entry strait between the Caspian and Karabogazgol.

This complete loss of hydrographic connection to the Caspian did not have the desired effect, which was by then an irrelevancy, but egos and the authority of the Russian Empire was involved. Rather, the damming of the inflow resulted in rapid desiccation of Karabogazgol, so that by 1983 only a small brine-covered area remained in the lowest part of the gulf depression (Figs. 12.22a, b and 12.23). Much of the former brine lake floor had turned into a saline dust bowl, blowing high levels of sodium salts onto downwind irrigated pasture lands. By 1984 the villages surrounding Karabogazgol had turned into ghost towns. In 1984, in an attempt to restore the ecosystem, eleven large diameter pipes were laid across the dam so that Caspian water could be pumped back into Karabogaz at a

controlled rate. In 1992, after the fall of the Soviet Empire, this approach was abandoned and the dam was completely demolished by order of the president of the newly independent Turkmenistan. As it refilled from 1992 to 1995, the gulf water level rose by some 6 m and since then its water level has once again matched that of the Caspian Sea and it is once again fulfilling its role as a natural desalinator of the waters of the Caspian (Fig. 12.22; Leroy et al. 2006; Crétaux et al. 2011).

Today, with the entryway connection to the Caspian restored, the water chemistry of the main open water body in the centre of the gulf is an Na-Mg-Cl brine, with a density of 1.2 g/cm^3, and pH values that range between 7.2 and 9 (Giralt et al. 2003). Surface water temperatures range from 4 °C in December to 25 °C in July. These temperature fluctuations are seen in the precipitation of different mineral phases during the year. Calcite, aragonite and perhaps hydromagnesite usually precipitate from lake waters in spring, gypsum in summer (via solar evaporation), and rafts, blown shoreward, into stacked crusts of cryogenic mirabilite and halite accumulate on the shores and mudflats of the embayment edge throughout the winter. Gypsum (as lenticular sand-sized grains) is the only permanent sulphate phase seen in cores sampling surface sediments from beneath today's central embaymnt water body (Giralt et al. 2003).

Below this modern hydrology, $NaSO_4$ salts occur in 4 main beds (Salt members 1–4), dominated by glauberite/astrakanite, with alteration textures suggesting a mirabilite precursor (Fig. 12.23). Three separate glauberite layers are present, a fourth lowermost layer is dominated by bloedite: the upper layer is at a depth of 0–0.3 m and is up to 3 m thick; the middle layer is at a depth of 5–8 m; and the lower layer is at a depth of 14–18 m. Gypsiferous-carbonate muds separate the salt layers by 2–5 m.

Depending on the water salinity in Kara Bogaz, the following succession of various salts have precipitated in response to increasing salinity and temperature fluctuations: carbonates–gypsum–mirabilite–glauberite–halite (in the summertime) and mirabilite (in the winter) -epsomite–astrakanite. Today, although mirabilite precipitates each winter across the Gulf, much of it is redissolved with the passage into warmer weather and drying of much of the Gulf floor. Hence, across the central parts of the Gulf, mirabilite is not currently contributing large volumes of precipitates to the at-surface gypsum bed (Fig. 12.23).

Each of the four underlying $NaSO_4$ beds is a likely remnant from cooler climatic periods over the last 10,000 years (Karpychev 2007). Then large amounts of mirabilite formed each winter, much like today but, unlike today, the cooler more humid glacial climate meant the bay was not as subject to summer desiccation. Dense residual bottom brines were perennially ponded and so preserved a summer-halite sealing bed. This allowed the underlying mirabilite/epsomite winter precipitates to be preserved across the lake floor. During the following winter the process was repeated as mirabilite/epsomite/halite beds stacked one atop the other to create a future ore horizon. In time, the combination of groundwater and exposure, especially nearer the Gulf's strandzone, converted most of the mirabilite, along with epsomite, to astrakanite, and then both phases to glauberite in the upper three beds. This explains the association of the richer glauberite zones with the lake edges (Fig. 12.23a; Strakhov 1970). Water of crystallization is released by the mirabilite to thenardite conversion, then it slightly dilutes any strong residual brine, so facilitating a high sodium-sulphate mineral and brine composition across the bay (Kurilenko et al. 1988).

Even today, a portion of the air-brine winter mirabilite precipitates do not sink, but form crystal rafts that are blown by prevailing winds to stack into crusts fringing the lake shore. Early last century the resulting strandzone mirabilite/epsomite beds were harvested by the local peasantry. In contrast to the current complete loss of mirabilite from the lake floor each summer, cooler earlier Holocene conditions favoured retention of bottom-cumulates much like winter salting in saline lakes in Canada today (Fig. 12.23). Today's gypsum/glauberite/thenardite fringes form during the summer transformation of the mirabilite, epsomite and bloedite that accumulated as windblown fringes each previous winter about the edges Karabogazgol. That is, because the climate and bay hydrology has changed over the last few thousand years, the present is not a direct key to immediate past textures and extents.

During the anthropogenic dust-bowl stage of the lake in the 1960s to 1980s a glauberite/bloedite/mirabilite/gypsum windblown mineralogy formed as capillary efflorescences were exposed across the whole exposed floor of the gulf. At that time the Karabogazgol depression was converting to a saline perennial dust bowl. But since 1992, with a return to the high water levels of today, glauberite no longer accumulates on the floor of the lake, only gypsum. The only glauberite/thenardite forming today is that accumulating about the exposed margins of the gulf where each summer high-calcium groundwaters dissolve and transform earlier winter precipitates of astrakanite, epsomite and mirabilite into capillary precipitates of glauberite/thenardite.

Natural winter precipitates of sodium sulphate salts in this natural evaporation basin have been used commercially since at least the 1920s. Back then, the produced[2] commodity was

[2]In the first decades of the twentieth century the mining of Korabogazgol (Bay) raw materials for the Russian chemical industry was based on natural processes. Year-round the upper layers of water in the bay contained sodium chloride NaCl, magnesium chloride $MgCl_2$, and sodium sulfate Na_2SO_4. Every year, in late November, when the water temperatures dropped to 5.5–6 °C, the water became saturated with sodium sulfate, and mirabilite ($Na_2SO_4{\cdot}10H_2O$) precipitated as colorless crystals on the bay bottom that were then transported by wind and wave action to the shorezone, especially during winter storms. In mid-March when the bay waters were heated to over 6 °C, the mirabilite on the bay floor began to redissolve. By July–August the entire precipitated mirabilite crop out in the bay had re-dissolved. The period from November through March was a period of "harvesting" mirabilite on the bay shores. In summer with its arid climate the remaining strandzone salt converted to thenardite Na_2SO_4 that was gathered at the end of each summer.

just whatever accumulated on the shore from winter wave action, especially on the southern shores of the Gulf during winter (Kosarev et al. 2009). The salt was scraped and harvested by hand and shipped to the Caspian using animals and barges. In the early 1930s, the port town of Karabogazgol was established on the Caspian side of the entryway, in order to trans-ship salt from the barges to the Caspian and its population grew to a peak of 7,000 in 1936. By the late 1930s, the gulf was too shallow for barge traffic and the port town of Karabogazgol was abandoned in 1941. The falling water levels in the gulf also meant that by the end of the 1930s manual collection of naturally formed salt in the southern part of the gulf had stopped as well. The industry had to shift north to its present centre located inland of the town of Bekdash, which is a town of about 10,000 people on the shores of the Caspian Sea.

Canals were built inland of Bekdash on the increasingly exposed mudflats that defined the strandzone of the Gulf. The canals were designed to feed gulf waters into large salt settling basins, which were filled with lake brines in the summer and left to cool in winter when mirabilite precipitated. Bekdash eventually became the centre of the salt-cake industry of Karabogazgol and in the 1960s and 70s supplied chemical feedstock to much of the Russian chemicals industry in the satellite states surrounding the Caspian Sea. By the end of the 1930s, the falling water level drove increased salinities and a shift toward higher volumes of sodium chloride precipitates from ponded gulf waters, an unwanted by-product in the sodium sulphate industry. Profitability fell, and the salt pan-based industry waned through the 1940s. In the 1950s, production technology shifted to extraction and processing of subsurface brines, Bekdash was reinvigorated as it had been connected to a major brine extraction site via a 24-km pipeline.

In 1963 construction began at Bekdash on a modern plant for increased year-round production of salines, independent of natural evaporation. This plant was completed in 1973. The brines for the processing plant were extracted from the buried glauberite/bloedite/epsomite beds beneath the margin of the gulf. These beds still constitute a huge potential resource containing more than 3 Gt of sodium sulphate. Currently, sodium sulphate brines are solution mined which in the 1980s used a single high capacity captive well and a mine planning approach that is a leftover from excesses of the former Soviet Union. Unlike the monitored gentle extraction of 113 l/s of intercrystalline sodium sulphate brine spread over more than 70 wells in Laguna del Rey brinefield (next section), a single well into the Karabogaz salt layers blasted out 126 l/s to a pipeline feeding the processing plant. Within the first 10 years of the brinefield operation it had largely drained all the high salinity brines from the immediate vicinity and created a short circuit for less saline brine entry into the well bore. Ongoing drawdown and associated coning meant brine strength supplied to the plant dropped to almost unusable levels. Once set up, coning from overpumping is difficult to reverse.

The highly competitive state of today's sodium sulphate industry probably means that, without new capital injection for a better planned and monitored set of brinefields and extraction wells, the Karabogaz salt industry will continue to shrink. By the end of the 1980s recommendations were being made to alleviate the problem; Kurilenko et al. (1988) proposed the following changes to the local brine industry; (1) locating and developing production wells based on optimum hydrogeology and stratigraphy, (2) lowering the brine output of every well from 500 to 250 m^3/h, and reinjecting end liquors from the plants to recharge and stabilise pay horizons.

Other substantial modern saline lakes with cryogenic saltcake potential are relatively common in the former USSR and extend from the Black Sea to western China (Fig. 12.15). Examples include Selenga Lake in the eastern Transbaikal, Lakes Azhbulat, Ebeity and Tengis in Kazakhstan, and the Batalpashinsk and Tambukan Lakes between the Black and Caspian Seas. The enormous salt cake potential of these deposits is illustrated in Lake Azhbulat where some 40 Mt of mirabilite is deposited each winter. On the Kulunda Steppe, western Siberia, lacustrine deposits consist of sodium chloride in the upper layers and mirabilite below. The largest sodium sulphate lake in the region, Lake Kuchuk, 320 km southwest of Novosibirsk, covers an area of some 150 km^2. It contains an estimated 600 Mt of sodium sulphate in brines and underlying strata and each winter between 380,000 and 640,000 tonnes of mirabilite drop out of solution.

Laguna Del Ray Brines, Mexico

Quimica del Rey, SA, a subsidiary of Industrias Peñoles, SA de CV, produces sodium sulphate from brines extracted from a playa of Laguna del Rey, located in the State of Coahuila in northern Mexico, some 150 km north of Torreon. The precipitation of the mother salt beds occurred in a hot arid desert setting and is not a cryogenic association. The brine processing plant on the lakeshore is the world's largest sodium sulphate brine facility outside of China (Fig. 12.24). Spent brine from the plant is used as raw material for the production of magnesium oxide. The playa is one the world's larger exploited bedded sodium sulphate deposits and Mexico's major sodium sulphate resource.

Today the lake is a dry playa some 10 km long and 4 km wide. It contains a captive brinefield that solution mines

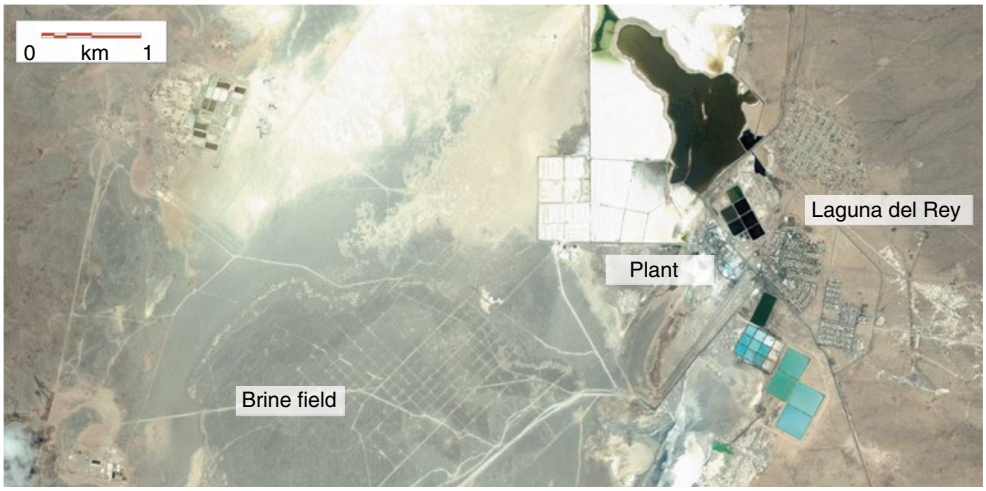

Fig. 12.24 Laguna del Rey, Mexico. Plant and brine field

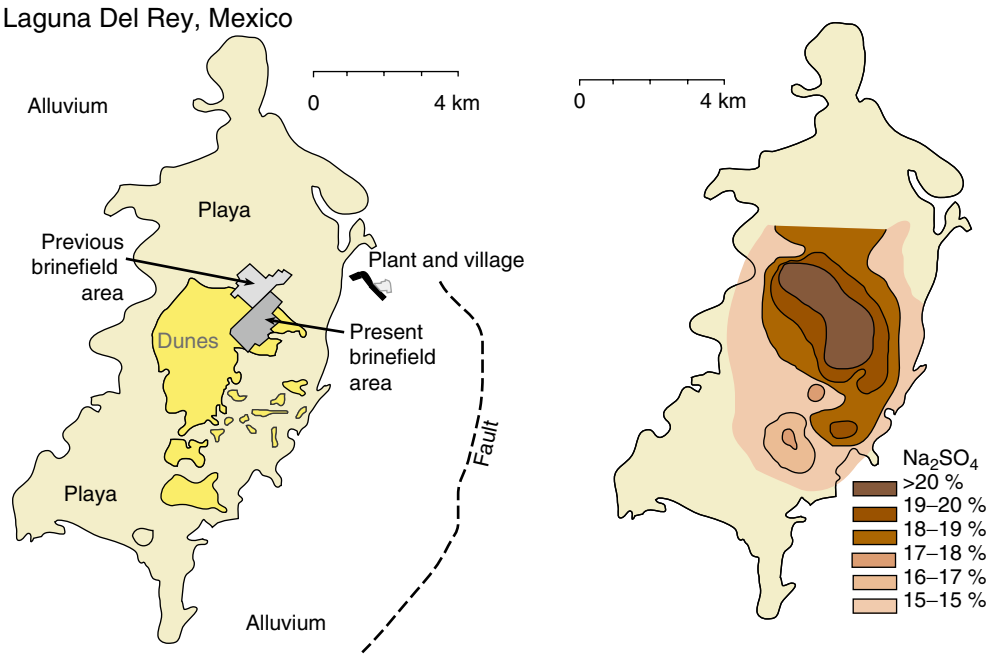

Fig. 12.25 Laguna del Rey, Mexico showing distribution of surface features and the distribution of Na_2SO_4 in brines in the exploited shallow subsurface salt bed (After Garrett 2001)

brine from a Na_2SO_4 bed containing 50 % glauberite, 20 % bloedite (astrakanite), 28 % clay and various other sodium and magnesium salts, including 1 % halite. Minor mirabilite and epsomite are locally present as a cement between the glauberite crystals (Garrett 2002). The salt body lies some 1–2 m beneath the present playa floor, with porosity around 25 %, is lenticular in cross section, dips slightly to the east and thickens to the south. It has a maximum thickness of 35 m and an area of 40 km^2 and contains a resource of some 350 million metric tons of sodium sulphate and 77 million metric tons of magnesium sulphate.

The lower parts of the modern flat playa surface, its sumps, are marked by an ephemeral halite crust, broken in places by relicts of a now largely inactive dune field. Above the halite crust is a green clay containing abundant gypsum and lesser glauberite and halite. Below the green clay is a red clay bed that immediately overlies the target salt bed. A similar, but much thicker, red clay also underlies the main salt mass. Porosity in the salt bed is filled with a brine that when pumped from this salt bed contains more than 26 % sodium sulphate (Fig. 12.25). A brinefield of more than 70 wells pumps brine to the surface from depths down to 24–25 m below the playa surface. Wells are gravel packed for the lower 12 m and the brinefield pumps around 113 l/s of 25 °C 200 g/l sulphate to the recovery plant (Garrett 2002). The ultimate source of the ions now accumulating in the playa

depression is thought to be halokinetic gypsum-capped marine evaporites and carbonates that subcrop in the surrounding highlands. Possibly this was followed by ion exchange on saline clays of calcium for sodium. The oxidation of sulphides from the large silver-lead deposit at Sierra Mojada (to the north) must have augmented the proportion of sulphate in the drainage, along with leaching some of the dolomite in the drainage area's soil, to form the high-magnesium parent brine (Sanchez-Mejorada 1986).

Brine processed at Quimica del Rey. S.A. de C.V. plant on the playa shore is hypersaline and probably saturated with more than 26 % sodium sulphate and appreciable amounts of chlorides and magnesium (Kogel et al. 2006). The brine temperature entering the plant is around 25 °C before precooling with the spent brine. The cooled brine is fed to a vacuum crystallizer where it is further cooled to 9 °C by evaporative cooling, causing Glauber's salt to crystallize. The resulting slurry is then thickened, filtered, and melted. Evaporation is accomplished in multiple-effect evaporators. Final drying is in co-current-fired rotary kilns. Part of the mother liquor is processed further for recovery of magnesia products and the balance goes to waste.

Spanish Glauberite Mines

Tertiary lacustrine sediments are the major source of sodium sulphate in Spain within three large Tertiary basins (Madrid, Ebro and Calatayud basins) that together contain as much as 3 Gt in the form of glauberite or thenardite (Table 12.8; Salvany et al. 2007; Garrett 2001). Spain probably has the largest glauberite-thenardite deposits in the world, except perhaps for the less well known Tien Shan (Kyrgyzstan) deposits. Deposits in the Madrid and Ebro basins are very well defined and many of the richer deposits are largely depleted, while the Calatayud Basin still has potential.

Spanish operations recover solid ores for processing, not brine. Ore is mined via room and pillar methods or in-situ leaching extracted via planned face retreat. The "El Castillar" mine in Toledo Province yields mostly thenardite from an ore averaging 67 % Na_2SO_4, 19 % $CaSO_4$ and 12 % clay and marl. The ore bed thickness averages 9 m and it lies atop a 13 m-thick halite bed. Glauberite is extracted also at Cerezo de Riotirón, Burgos Province, where the deposit is practically horizontal, undisturbed and made up of glauberite in four beds hosted in Miocene lacustrine marls.

The exploited salts have a primary paragenesis of glauberite + anhydrite + dolomite ± chalcedony; the secondary minerals related to hydration and incongruent dissolution of glauberite are mainly gypsum and calcite (Menduina et al. 1984; Salvany and Orti 1994). Glauberite ore types are varying combinations of: (1) massive glauberite within fining-upward sequences containing nodular anhydrite; (2) millimeter-scale glauberite layers alternating with dolomicrites; (3) single glauberite crystals dispersed in dolomicritic matrix (Fig. 12.26a). There is no mirabilite phase preserved in these deposits.

A 'perennial saline lake' model with warm extensive continental saline mudflats is typically used to explain the various glauberite deposits (Fig. 12.26b; Salvany and Orti 1994; Salvany et al. 2007). Solutes were derived from the phreatic dissolution of Mesozoic evaporites, mainly Ca-sulphates and halite, in the nearby mountains (Pyrenees and Iberian Ridge).

The concentration sequence was: carbonate, gypsum-anhydrite, glauberite, halite-polyhalite. Indicators of backreactions of glauberite with gypsum/anhydrite are commonplace via dissolution-driven interactions of primary precipitates with less concentrated (meteoric) brines and seeps from the basin margin, supplemented by occasional storm runoff. That is, some of the glauberite, anhydrite and polyhalite in the ore units is made up of early diagenetic minerals, formed via backreactions with a solid precursor (typically nodular gypsum) during early diagenesis, others are primary (Fig. 12.26; Salvany et al. 2007).

The brines that drove early alteration reacted with the solid precursor in two ways: (1) reaction of the concentrated

Mineral abbreviations: *H* halite, *Ph* polyhalite, *Th* thenardite, *Gb* glauberite, *An* anhydrite, *G* gypsum (primary), *Mg* dolomite, *Ar* aragonite, *Qz* quartz. Primary gypsum (G) refers to the deduced original mineral association. The presence of secondary gypsum in all the formations is omitted (After Salvany et al. 2007)

brine with the solid phase precipitated during episodes of lowered salinity (e.g. anhydrite alters to glauberite; glauberite alters to polyhalite), and (2) reaction of dilute brines with solid phases precipitated in episodes of higher salinity (e.g. glauberite alters to anhydrite, polyhalite alters to glauberite or anhydrite). Burial led to further transformations of gypsum to anhydrite and, during exhumation and exposure, all pre-existing sulphates (anhydrite, glauberite, polyhalite) were transformed near the surface into gypsum, which now dominates the weathered cover or carapace atop many ore profiles (Fig. 12.26a).

However, the relative proportion of primary versus secondary textured glauberite in the extracted ore, and where in the basin depositional setting was syndepositional alteration most likely, has always been a point of discussion. Detailed petrographic analysis by Salvany et al. (2007) on core from glauberite intervals in two wells sampling the Zaragoza Gypsum Formation has gone some way to defining a resolution (Fig. 12.27). They document two glauberite-halite lithofacies associations, A and B: (1) Association A is a combination of bedded cloudy halite and minor amounts of massive and clastic glauberite; (2) Association B is made up of laminated to thin-bedded, clear macrocrystalline, massive, clastic and contorted lithofacies of glauberite, and small amounts of bedded cloudy halite. Transparent glauberite cemented by clear halite, as well as normal-graded and reverse-graded glauberite textures, are common in Association B. This type of transparent glauberite is interpreted as a primary, subaqueous precipitate. Gypsum, thenardite or mirabilite are absent in either association. The depositional environment is interpreted as a shallow perennial saline lake system, in which chloride brines (association A) and sulphate-(chloride) brines (association B) are developed at different lake levels and salinities, much like the gypsum and halite facies are indicative of higher and lower lake levels in the Pleistocene evaporites of the Danakil Depression.

The geochemical study of halite crystals (bromine contents and fluid inclusion compositions) demonstrates that conditions for co-precipitation of halite and glauberite, or for primary precipitation of Na-sulphates (mirabilite, thenardite) were never fulfilled in the Zaragoza saline lake system. In my opinion, this absence of phases that had by some earlier workers been interpreted as likely co-precipitates, relates to the need for holomictic brine conditions for synchronous across-basin subaqueous halite deposition.

Weathering products of these glauberite-entraining Miocene evaporites are sometimes recycled into saline sumps in the modern landscape. For example, salt crusts covering the surface of the Salda Mediana, a seasonally dry saline lake in the arid part of the central Ebro Basin in northern Spain, consist predominantly of bloedite ($Na_2SO_4{\cdot}MgSO_4{\cdot}4H_2O$) atop a succession of evaporitic sediments dominated by gypsum (Fig. 12.28; Mees et al. 2011). In the various modern Spanish lakes, bloedite tends to occupy the sump centre, while epsomite tends to dominate the borders to the sump (Sanchez-Moral et al. 1998). The genesis of bloedite is perhaps explained by a rapid early diagenetic alteration of the previously precipitated epsomite

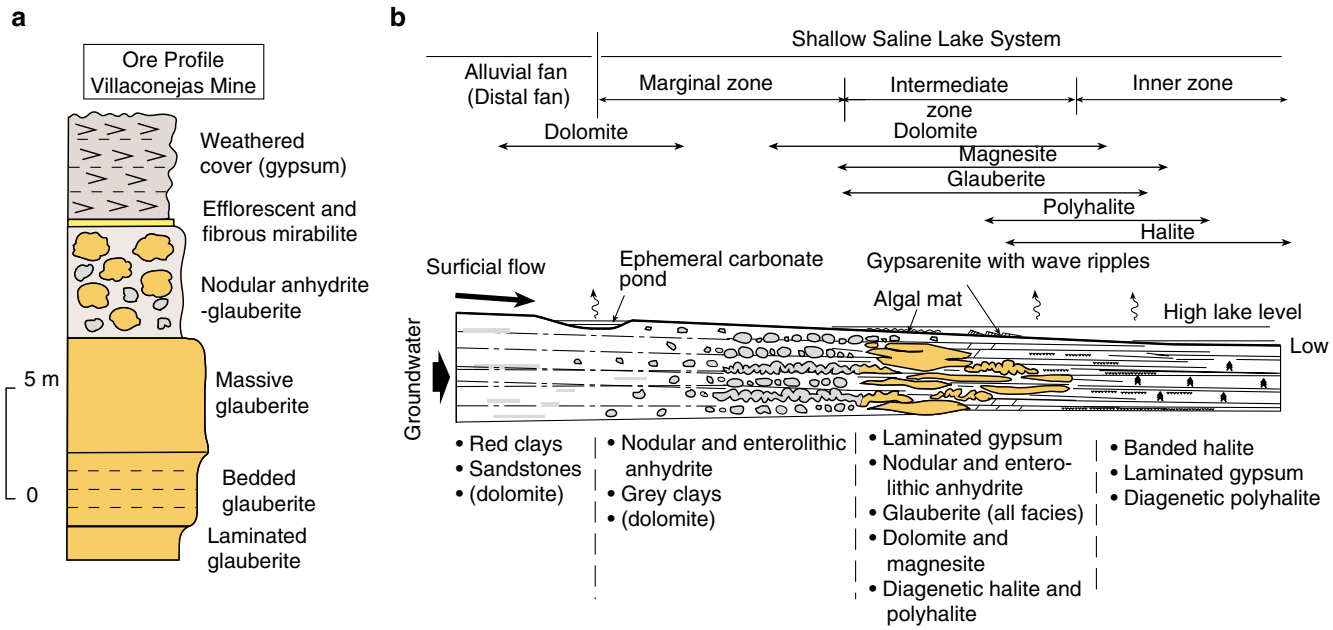

Fig. 12.26 Miocene glauberite in Spain. (**a**) Profile of the ore zone in the Villaconejas Mine, Spain. (**b**) Sedimentological model for deposition of Spanish glauberite deposits (After Salvany and Orti 1994)

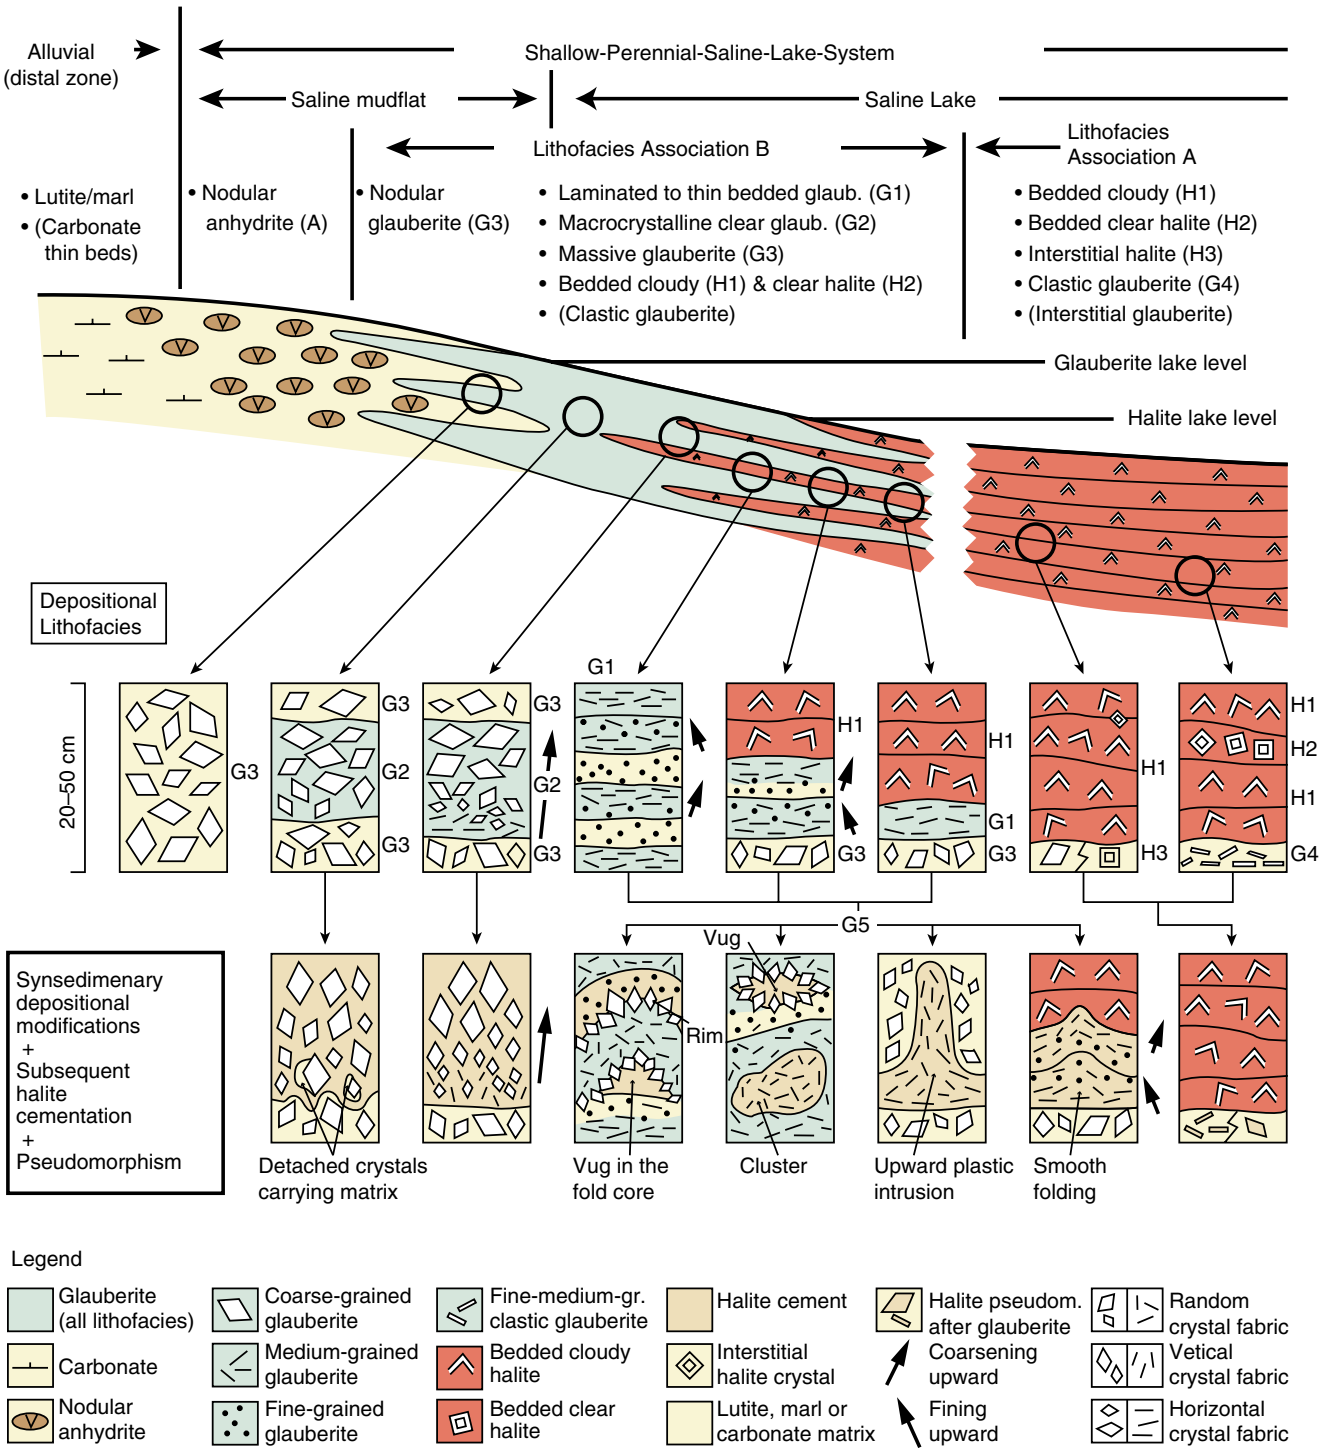

Fig. 12.27 Deposition and diagenesis in the Zaragoza Fm, Ebro Basin, Spain (After Salvany et al. 2007)

that had accumulated at the bottom ("bloeditization"), by means of a reaction with a crossflowing brine enriched in Na^+ and Cl^-. It means the replacement of epsomite, as well as some previously precipitated halite, by bloedite in the accumulated saline deposit, had also released magnesium chloride and water to the brine.

Turkish Deposits

Sodium sulphate salts are extracted from the Upper Miocene Kirmir Formation at Cayirhan Mine, Turkey (Fig. 12.29; Orti et al. 2002). Unlike the Spanish ores, thenardite (after mirabilite) is thought to be a significant depositional component of

the bedded $NaSO_4$ salts in this lacustrine ore association. However, none of the primary mirabilite remains as it has since converted to thenardite with moderate burial. The Evaporite Member of the Kirmir Formation, which is composed of secondary gypsum at outcrop, can be subdivided into a bedded lower unit and a massive upper unit (Fig. 12.29a). Most of the current outcropping and subcropping gypsum of the bedded lower unit has been transformed to gypsum during exhumation from a glauberite parent. Glauberite layers ("clear glauberite") still remain at depth, as in the Cayirhan mine, where textures suggest it was deposited as a primary, subaqueous, cumulate precipitate on the saline lake floor (Fig. 12.29b). But more typically, the glauberite textures are nodular, suggesting it was an early (syndepositional to precompaction) interstitial precipitate, indicating crystal growth occurred just below the sediment surface as passive and displacive crystals within a poorly lithified clayey magnesitic matrix. Thenardite layers in the glauberite beds in the Cayirhan mine, show disruption structures created by synsedimentary dissolution and infill (Fig. 12.29c). These structures, together with their pseudomorphic textures, suggest mirabilite was the original sodium sulphate lakefloor precipitate. If so, the current thenardite ore is a secondary phase, formed by mirabilite dehydration during early to moderate burial.

The massive upper unit, in which evidence of any sodium-bearing minerals is absent, is characterized by laminated to banded gypsum, with nodular gypsum dominant in the marginal areas of the evaporitic basin. Thick, clast-supported gypsum

breccias prevail in the northern, deeper part of the basin. The brecciation of these calcium sulphate layers possibly occurred as a result of synsedimentary, gravitational slumping into the deeper parts of the perennial lake during times of lake flow instability driven by active tectonism (Orti et al. 2002).

Sodium sulphate minerals are also widespread co-precipitates with borates and glauberite, but in the Emet Basin of Turkey are diagenetic associations (García-Veigas et al. 2011b, 2013). They are part of a complex mineral association in which probertite, glauberite, and halite constitute the major primary phases (without mineral precursors) precipitated in a saline lake placed in a volcano-sedimentary context (Fig. 12.30a). Other sulphates (anhydrite, gypsum, thenardite, celestite and kalistrontite), borates (colemanite, ulexite, hydroboracite, tunellite, kaliborite

Fig. 12.31 Anthropogenic pans at the northern end of Tersakan Golu (near Tuz Golu), Turkey, used by Alkim Alkali Kimya A.Ş to precipitate thenardite (Bing® image mounted and scaled in MapInfo®)

and aristarainite), and sulphides (arsenopyrite, realgar and orpiment) are attributed to early diagenesis. So far, the Doganlar deposit is the most important deposit of probertite known in Turkey and perhaps worldwide (Fig. 12.30b).

Chemical changes in the groundwater inflow led to the precipitation of Ca-bearing borates (colemanite) in the tuff-flat environment surrounding the lake, while Na-Ca sulphates and borates (glauberite and probertite) precipitated in the centre of the lake. Fluid inclusion compositions in halite indicate that the advanced brines correspond to the Na-K-Cl-SO_4 type. During restricted stages of the saline lake, the residual brines seeped through the tuff-flat sediments, leading to transformations of previous precipitates that resulted in the formation of K-bearing minerals (Fig. 12.30b). The abundance of coccoidlike biogenic dolomite, colloidal arsenopyrite and the isotopic composition of sulphates are indicative of bacterial sulphate reduction. In contrast, arsenic sulphides are attributed to acidophilic micro-organisms in oxidizing conditions. Fluctuations of redox conditions in both free and interstitial brines control the biological influence in some diagenetic transformations.

As well as these ancient $NaSO_4$ resources, there are three Turkish playa lakes where sodium sulphate is produced from winter brine; they are Acigol, Tersakan and Bolluk and all three use the same basic production method (Fig. 12.31). Surface brine is pumped into a series of solar ponds or small depressions on the lake floor in the summer and autumn. The inflow in some is supplemented by spring or aquifer waters, as well as interstitial brine from lake bores, or seepage trenches in areas on the lake floor outside of the pans. Salinity of brine in the pans is monitored so that it does not become saline enough to precipitate halite nor fresh enough to dissolve the pan floor where a seed bed some 20–30 cm thick of thenardite (with minor mirabilite) was left from the previous year's salt harvest. As the concentrated brine cools from October to December, a 50–60 cm thick layer of mirabilite crystallizes in the centre of the ponds. From January and on into early spring the residual brine and any spring rainfall is drained from the pan. The flush of this fresher water through the lower part of the now metre-thick salt bed helps re-establish the integrity of the seed layer that will be left behind after harvesting. Any mirabilite slowly dehydrates and by the end of June the bed is largely composed of thenardite, which is scraped from the lake surface and loaded into bags.

The textural transitions associated with this process are interesting and as it ultimately forms a vadose product with textures that are somewhat different to the perennial lakes of Canada but more analogous to the Tertiary-age deposits just discussed. The mirabilite has two forms, either large thin interlocking elongate hoppers or fine radiating spherules made up of acicular crystals (Garrett 2001). The 0.6 m-thick mirabilite crust precipitated each winter is characterised by a thin uppermost layer or lamina of thenardite-mirabilite crystals, with some astrakanite. This is underlain by downward-pointing dog-tooth spar crystals of mirabilite, which constitute the bulk of the winter precipitates. They are downward-pointing as mirabilite tends to form rafts or hoppers at the contact between cool air and brine and not to grow upward from the lake floor. Below the coarse crystalline mirabilite is a thin layer of smaller equant mirabilite crystals defining the base of the winter precipitate layer. As the mirabilite bed dehydrates in the following summer, it forms small powdery crystals that are easily blown about in the wind and escape the pans. As summer temperatures reach 30–35 °C the mirabilite bed "melts" leaving behind some 15 % of its former mass as thenardite and a saturated sodium sulphate solution that then continues to precipitate more thenardite. The resulting thenardite layer is composed of hard compact transparent crystals, which can contain numerous solid phase inclusions.

Other Sodium Sulphate Deposits

Most US production of sodium sulphate comes from multi-component brine processing in Searles Lake, California. As discussed earlier in the section dealing with borates, this brine

resides in the interstices of the lake's salt beds, which contain some 369 million metric tons of Na_2SO_4 and 65 million metric tons of K_2SO_4, representing ≈35 % of the total lake brine (Fig. 12.12). These volumes rank Searles Lake as one of the world's larger exploitable sodium sulphate brine accumulations. Brine processing began in 1873 and the first sodium sulphate from brine was produced in 1914. Searles Valley Minerals, Inc. (a subsidary of the Indian Company Nirma) today operates two facilities near Searles Lake, the West End plant and the Argus plant. The West End plant is North American's only source of sodium sulphate recovered as the primary product, along with secondary soda ash and borax. Mixed brines are processed (carbonated) with carbon dioxide to precipitate sodium bicarbonate, which is then removed by filtration. The decarbonated brine is cooled three times to produce two successive batches of borax and one of Glauber's Salt (mirabilite). By heating, the sodium bicarbonate is converted to soda ash and the borax is either crystallized as a hydrate or dehydrated to its anhydrous form. The Glauber's salt is washed, melted, and recrystallized as anhydrous sodium sulphate; 99.3 % purity can be obtained in this process.

In the saline waters of the Great Salt Lake, Utah, about 12 % of the dissolved salt is sodium sulphate, representing about 400 million tonnes of potential resource. The precipitation process begins in December when brine temperatures can drop below −4 °C and mirabilite crystals begin to form as rafts atop the cold lake brines. Some sink to the lake bottom, others are blown to shore. Where the mirabilite sinks to the bottom it can by late winter form a layer, some 0.15–0.30 m thick, that extends over large portions of the lake floor, but redissolves with warming and the passage into spring. When mirabilite rafts are blown to the lake shore, it can form strandzone banks, some 0.9–1.2 m thick, extending up to 60 m inland of the lake shore and standing some 0.3–0.5 m above the water line. Due to their low density (≈1.5 g/cc) and the elevated density of the underlying formative brine (1.22–1.25 g/cc), mirabilite rafts have the propensity to form strandzone banks, both in the Great Salt Lake and, as described earlier, in Karabogazgol. By late winter, a strandline bank of mirabilite can become quite solid and resemble a large lake-edge snowbank. Then, as the spring meltwaters flood the lake and the brines warm, most of the mirabilite redissolves (Adams 1993).

Beneath the south and southeast parts of the lake there are permanent metre-thick mirabilite beds below some 0.5 m of oolitic sand. To the north, immediately west of Promontory Point, there is a much thicker accumulation of bedded mirabilite making up an irregular, 21-m-thick, mirabilite deposit, which is interlayered with clay beds between 4.5 and 9.1 m thick (Fig. 12.32). This more substantial mirabilite accumulation probably accumulated as bedded salt during colder conditions of the last glacial (probably under a meromictic hydrology similar to that in Ingebright Lake today or to Karabogazgol in an earlier glacial period). Historically, the Great Salt Lake mirabilite bed has been blasted and dredged in different parts

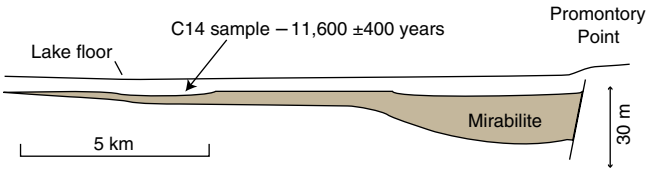

Fig. 12.32 Distribution of the mirabilite bed under the railway embankment at the northern end of Great Salt Lake (After Eardley 1962). See Fig. 4.21 for location

of the lake and a purpose-built Na_2SO_4 processing plant was set up on the shores of the lake in the 1930s and 40s.

In the recent past, the Great Salt Lake Minerals and Chemicals Corp. (Compass Minerals) made use of the annual cooling in its Great Salt Lake brine pans to manufacture sodium sulphate salts as secondary product, with sulphate of potash as the primary product (Fig. 11.28). Today the operation produces potassium sulphate, halite and magnesium chloride; sodium sulphate is no longer produced, but can be stockpiled if ever required. The first sodium sulphate production from Great Salt Lake took place in 1970 and had ceased by 2005.

Brine is pumped from the Great Salt Lake into solar evaporation ponds where sodium chloride precipitates in the summer and is also a natural summer precipitate in the lake (Adams 1938). When winter weather cools the residual brine in the pans to −1 to −4 °C, sodium sulphate crystals precipitate as mirabilite in a fairly pure state. Crystals can be picked up by large earth-moving machinery and stored outdoors each winter until further processing takes place. The harvested salt is melted and anhydrous sodium sulphate precipitated by the addition of sodium chloride to reduce its solubility through the common ion effect. The final product was 99.5 % pure $NaSO_4$. Thus, sodium sulphate can be produced in Great Salt Lake as a byproduct of the halite and potash production process (Fig. 11.8), but low Na_2SO_4 prices meant it has not been harvested for the last decade.

Ancient lacustrine deposits in the USA containing bedded sodium sulphate are considered non-commercial today, but have been mined in the past at Camp Verde, Arizona and Rhodes Marsh near Mina, Nevada, all mining ceased in 1934. The thenardite deposit at Camp Verde is the only large well-defined ancient sodium sulphate deposit in the USA, it has projected reserves ≈100 Mt (Garrett 2002). The Camp Verde deposit is unusual, because pure anhydrous sodium sulphate occurring in solid crystal form is rare (Austin and Humphrey 2006). The deposit consists of layers of thenardite and other sodium salts interbedded with clay, which form a part of the Verde Formation. The total thickness of the beds is at least 46 m. Camp Verde also has the distinction of probably being the oldest mining operation in the United States. A tunnel in one of the halite beds at the base of the deposit yielded Indian artifacts around 2,000 years old. During the fourteenth and fifteenth centuries, it was mined more intensively by the Mesa Verde and Rio Verde cliff dwellers, who removed a few thousand cubic metres.

An anhydrous natural sodium sulphate operation in China, with an annual capacity of 200,000 t, came onstream in mid 2003. The plant, operated by Dayang Chemical Limited Company, is located in Xishunhe Town, Hongze County, Jiangsu Province. The company, which is a joint venture between a Chinese company and an Indonesian firm, extracts mirabilite from a large sodium sulphate deposit in east China. Little has yet been published on the geology of this lacustrine deposit. It has a proven area of more than 8.4 km^2, and a likely reserve of up to 150 million tons. It operates, in combination with a second facility, with an annual capacity of up to 600,000 t, and has been in production since the year 2000 (operated by Jiangsu Nanfeng Chemical Co. Ltd., which is a joint venture between Shanxi Nanfeng Group and Hongze Chemical Group, which is the Chinese operating arm of the Spanish Crimidesa Group). Sodium sulphate also occurs in several of China's large soda ash deposits, such as at Chaganor (Austin and Humphrey 2006). This Pleistocene deposit is located in the central part of the Inner Mongolia Autonomous region, 80 km south east of Erlianhot. The deposit covers 21 km^2, with nine porous brine-filled beds of salts containing about 11.3 Mt of sodium carbonate and 4.5 Mt of sodium sulphate. In combination, this now makes China the world's largest natural sodium sulphate producer, with a combined capacity of some 800,000 t per year.

Sodium Carbonate Salts (Soda ash)

Worldwide, in terms of naturally-occurring salts, sodium carbonate is next to gypsum in terms of annual volumes extracted (Table 12.2). The dominant ore salt is trona. The word trona is an aphaeretic form of natrun, derivative of the Arabic word *natrun*, from which we also derive the English word natron. Mineralogically natron (not *natrun* as originally used by the ancient Egyptians and then the Arab alchemists) describes the decahydrate form of sodium carbonate and is one of a number of evaporitic sodium carbonate minerals (Table 12.9).

Table 12.9 Minerals containing sodium carbonate

Mineral	Formula	Na_2CO_3 (equiv.%)
Trona	$NaHCO_3{\cdot}Na_2CO_3{\cdot}2H_2O$	70.4
Thermonatrite	$Na_2CO_3{\cdot}H_2O$	85.5
Nahcolite	$NaHCO_3$	63.1
Bradleyite	$Na_2PO_4{\cdot}MgCO_3$	47.1
Pirssonite	$CaCO_3{\cdot}Na_2CO_3{\cdot}2H_2O$	43.8
Northupite	$Na_2CO_3{\cdot}NaCl{\cdot}MgCO_3$	40.6
Tychite	$2MgCO_3{\cdot}2Na_2CO_3{\cdot}Na_2SO_4$	42.6
Natron	$Na_2CO_3{\cdot}10H_2O$	37.1
Dawsonite	$NaAl(CO_3)(OH)_2$	35.8
Gaylussite	$CaCO_3{\cdot}Na_2CO_3{\cdot}5H_2O$	35.8
Shortite	$Na_2CO_3{\cdot}2CaCO_3$	34.6
Burkeite	$Na_2CO_3{\cdot}2Na_2SO_4$	27.2
Hanksite	$2Na_2CO_3{\cdot}9Na_2SO_4{\cdot}KCl$	13.6

Character and Extraction History

Modern sodium carbonate end usage is mostly in glass manufacture followed by chemicals, soap and detergents, pulp and paper manufacture, water treatment, and flue gas desulphurization. One of sodium carbonate's prime uses in ancient Egypt, in the form of *natrun* (a trona-halite-sodium sulphate mix) quarried from salt lakes, was as an integral part of the mummification[3]

[3] Ancient Egyptians are famous for their perfection of the art of mummification. A key ingredient in the process was *natrun*, which is composed of halite + trona + sodium sulphate (Edwards et al. 2007). The ancients knew its preservative properties rivalled those of halite and, as it also absorbs water readily, it is an excellent desiccant/ preservative of organic material. *Natrun* is found in large quantities in the beds of several Egyptian playa lakes (e.g. Wadi Natrun and El Kab, as well as Behiera in the nearby Libyan desert) and has been mined and traded from these localities for thousands of years. Writings as old as the reign of Rameses III (1198–1166 B.C.) refer to these deposits. The preservative qualities must have been immediately apparent to the ancient Egyptians from its effects on any wild life, which had died in these lakes. There is some evidence that the Egyptians artificially precipitated *natrun* by isolating shallow basins of lake waters for faster evaporation, as is still done in parts of the depression today. For purification and preservation, *natrun* was preferred over halite because it chemically attacks and destroys grease and fat and so is a superior drying agent (as is sodium borate). It is found not only in tombs and in pits, along with other discarded embalming materials, but also forms nodules and residues in the mummies themselves.

There is some debate over the method in which the *natrun* was used for mummification by the ancient Egyptians. Some argue it was used in a way similar to the contemporary method for "salting" fish. Dry *natrun* would be sprinkled over the body, perhaps with sawdust, or spread with linen cloths. Others with a more prosaic bent, believe the body was immersed in vats containing a *natrun* solution. Such a wet method would have been odiferous and accelerated putrefaction, thus counterproductive to the preservation of the body, although it makes for good Hollywood images. A dry body is also more readily bandaged as well as being more amenable to the attachment of amulets and other jewelry. Although mummification has supernatural trappings in popular culture and ancient religions, its basis is rooted in simple chemistry and processes as mundane as salting fish.

Mummification also occurs naturally in halite and trona is not necessary, although it improves preservation. In 1593 AD and again in 1616 AD several tombs encased in salt were exposed by natural salt weathering and collapse in the Hazel Mountains. When the coffins were opened by the local people of Hallein and Hallstatt, there was astonishment that the bodies inside had very well preserved soft tissues. It was the result of the hyperarid encasement in a Neolithic salt mine, but frightened religious locals insisted of prompt reburial with additional efforts to create effective seals. There was a similar popular response in 1734 AD when the salt preserved body of a man wearing mountain clothing (possibly a miner) was discovered. Fearful locals insisted on immediate reburial with no further study or observations on the remains (Aufderheide 2011). First in the winter of 1993 and later in 2004, in the modern Chehr Abad Salt Mine, near Hamzehloo, Zanjan Province of Iran, at total five salt-preserved male bodies were found in a collapsed tunnel of a former salt mine, which was active around 400 BC. The first discovery in the winter of 1993 was a salt encased bearded head and some artifacts, the later discovery, beginning in November 2004, was of the remaining bodies. It is likely all five men died in earthquake induced collapses in the salt mine (Pollard et al. 2008). Encasement in the hyperarid atmosphere of the collapsed salt mine tunnel led to mummification of the bodies.

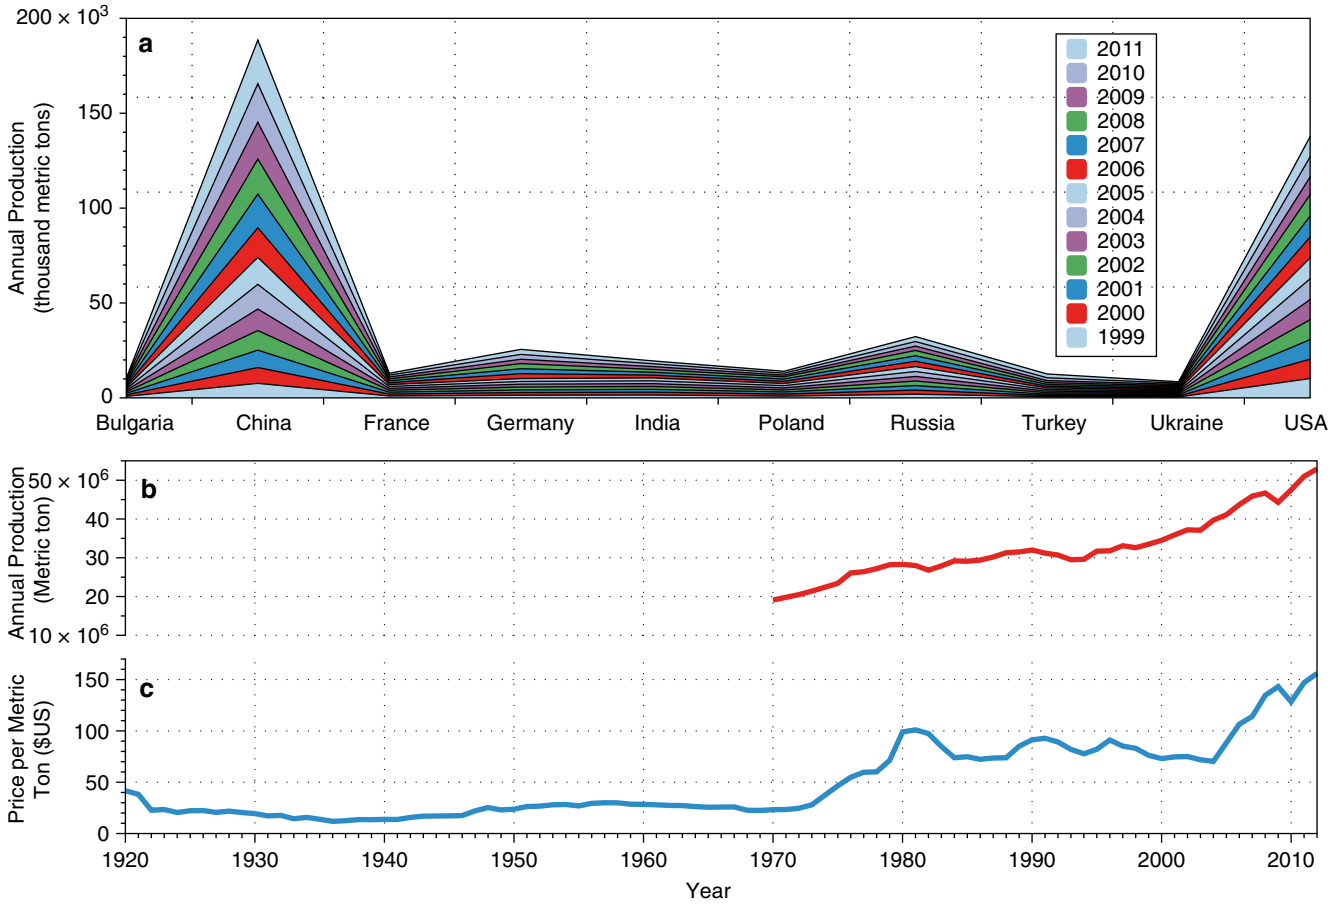

Fig. 12.33 World production of synthetic and natural soda ash. (**a**) Cumulative area plot of top producing countries, (**b**) World production (1,000 metric ton), (**c**) Price per metric ton in US dollars (Plots compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed September 3, 2014)

process so body and soul could re-unite in death. Natron was also used as a flux in glassmaking in Egypt since the Badarian Period (early 4th millennium BC), indicated by the very low potash contents of glasses from that time (Dotsika et al. 2009; Shortland et al. 2006). The use of natron as a soda flux in glass manufacture is increasingly apparent in glass chemistry since the 1st millennium BC. Glass from the tomb of Nesikhons in Egypt has a low content of potash, magnesia and lime implying that the soda flux was derived from natron. Other evidence of natron use in the same period is in the chemistry of blue glass manufactured in eighth to ninth century BC at Nimrud, Iraq. Likewise, the Roman glassmaking industry seems to have been based on natron, as indicated by the low-magnesia content of Roman glass.

Until the ninth century AD, natron continued to be the basic flux material in glassmaking in the Levant, the Mediterranean, and Europe. Use of natron as the flux in glass production declines in Near East and in Europe in the ninth century AD, when it was replaced by soda-rich plant ash as a flux (Shortland et al. 2006). However, natron continued to be harvested at al-Barnuj in the Western Nile Delta, Egypt until the eighteenth century AD. From the 1920s onwards, natron was collected in the same sump area by the Egypt Salt and Soda Company. A natron occurrence in ancient Greece was mentioned by Plato in the fifth century in his writings on the Republic (Testimonium 1), it was likely harvested from Lake Pikrolimni (Dotsika et al. 2009).

Today, in many countries local supply of sodium carbonate (aka soda ash) is synthetic, created using the Solvay process, which utilizes halite and limestone as raw materials with an ammonia catalyst within the carbonating towers. Annually, roughly twice as much soda ash is produced worldwide by the Solvay process than by bedded trona extraction. Major producers using the Solvay method include; China, Germany, India and Russia (Fig. 12.33a). In 2003 Chinese production of soda ash exceeded that of the USA for the first time, and this has been the situation since then. In 2010, world soda ash production was estimated to be 47.5 Mt, which was a 7 % increase from that of 2009, indicating a rebound from the global financial crisis. The top five soda ash-producing nations accounted for 79 % of world

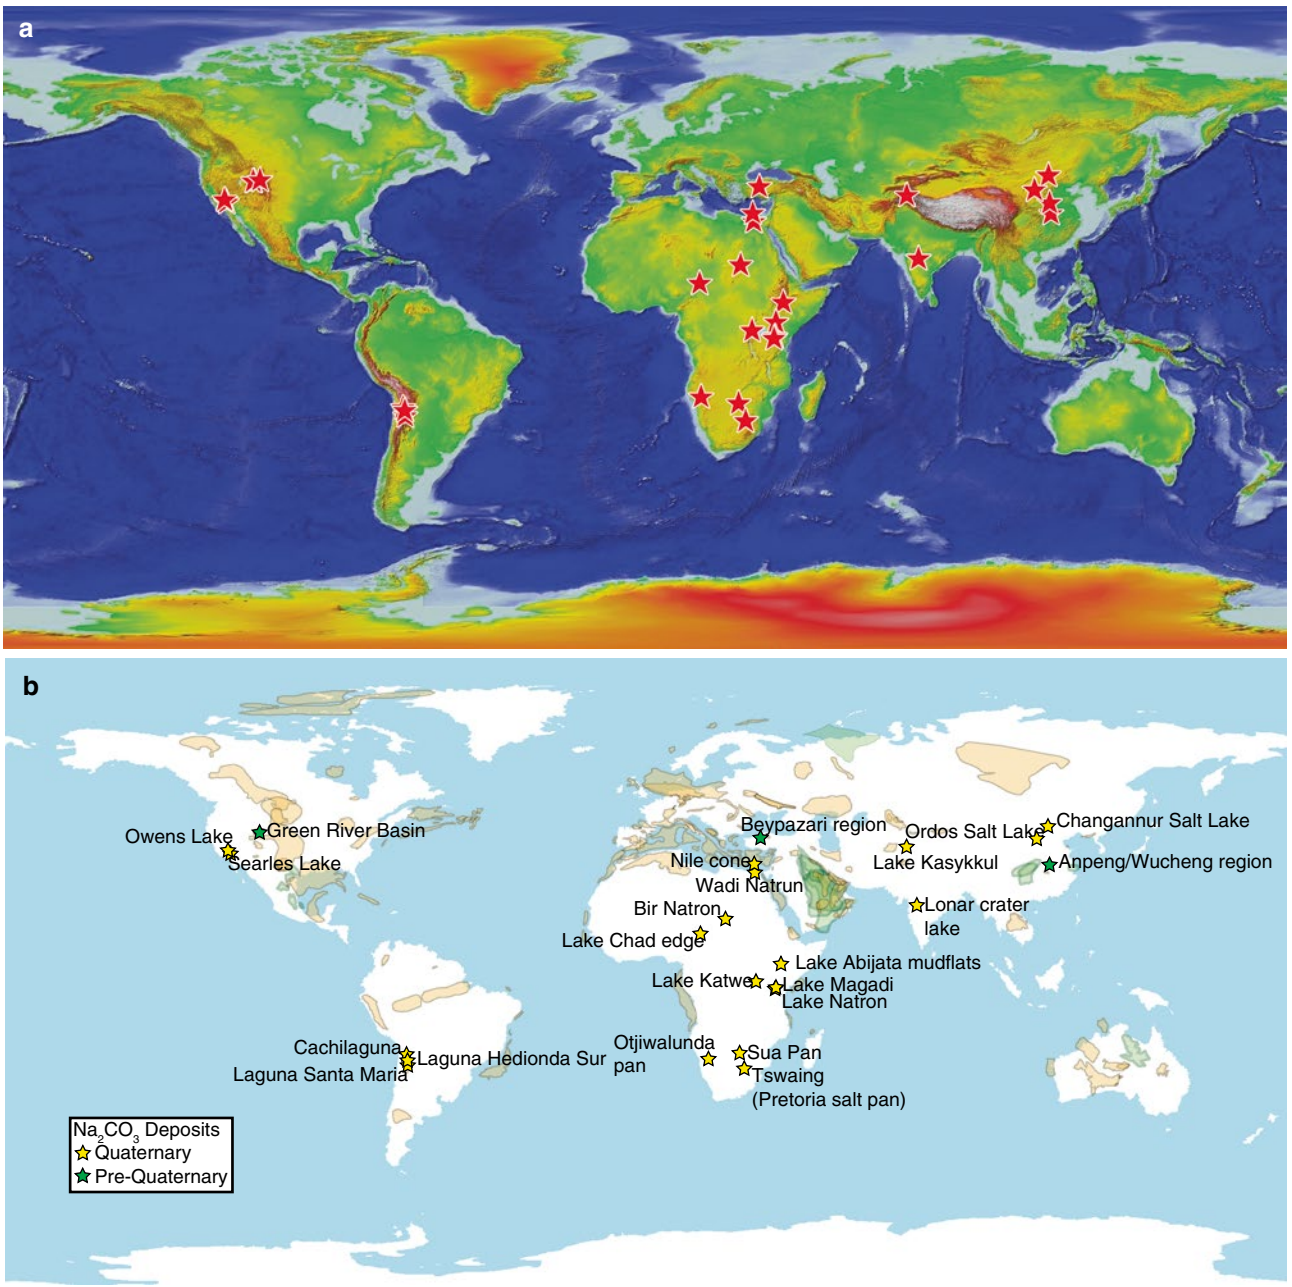

Fig. 12.34 Sodium carbonate occurrence. (**a**) Deposits plotted on a world topographic/tectonic base (see Table 12.10). (**b**) Deposits plotted on a marine evaporite basin base, where *brown shading* indicates halite-dominant and *green* indicates megasulphate basin (After Warren 2010). Plot shows that soda-ash deposits do not occur atop or within large marine-fed mega-evaporite basins

production in 2011 (Fig. 12.33; Kostick 2011). Of the 29 countries that produce natural and synthetic soda ash in 2011, the United States was the world's second-ranked producer, accounting for 22 % of total world output and producing around 10.6 million metric tons of natural soda. The USA, China and Russia combined have a 65 % share of installed world capacity. India, Germany, Ukraine, France, the United Kingdom, Italy, Bulgaria and Romania also have significant capacity.

Only Botswana, China, Ethiopia, Kenya, Turkey, and the United States produce significant quantities of soda ash from natural sources (Fig. 12.34; Table 12.10); the remaining 23 nations manufacture synthetic soda ash through various chemical processes, primarily the Solvay process. Total world natural soda ash production represented about 26 % of combined world soda ash production. A number of naturally occurring evaporite minerals contain Na_2CO_3, but only trona is economically extracted or solution mined at this time.

Table 12.10 Selected sodium carbonate occurrences, listed by country, reserves listed in million (mt) or billion (Gt) metric tons of sodium carbonate equivalent

Location	Age	Elev. (m)	Köppen	Mineralogy/setting/comments/key references
Laguna Santa Maria, Argentina	Quaternary	4,300	ET	Thin trona beds in a moderately small (19 km^2) alpine deposit some 5 km from border with Chile.
Cachilaguna (Laguna Cachi), Bolivia	Quaternary	3,650	ET	Trona, small (1.5 km^2) alkaline brine lake, brine depth ≈17 cm. Salts precipitated when lake brine freezes in winter to form a 6 to 10 cm thick crust of trona and thermonatrite (Ahlfeld and Muñoz Reyes 1955)
Laguna Hedionda Sur, Bolivia	Quaternary	4,572	ET	Trona, small (2.8 km^2) alkaline brine lake (pH 10.46) covering, average brine depth 75 cm. (Ahlfeld and Muñoz Reyes 1955)
Laguna Honda Sur, Bolivia	Quaternary	4,636	ET	Trona, small alkaline brine lake (pH 9.88) covering 30 ha (0.3 km^2), average brine depth only 10 cm. (Ahlfeld and Munoz-Reyes 1955)
Sua (Sowa) Pan, Makgadikgadi Basin, Botswana (3,307 km^2)	Quaternary	892	BSh	Deepest of a three pan complex separated by dune covered ridges. Pan surfaces of brine-saturated sand and clay layers with surface efflorescence of trona and halite. Seasonally flooded by Nata River. Trona, brine processing plant commenced operations in 1991. Salt-cake as possible byproduct. Produces 300 kty of soda-ash and 600 kty of halite for South African market. (360 Mt) (Low et al. 2000; Eckardt et al. 2008)
NE Lake Chad, interdunal pans, Chad (22,351 km^2)	Quaternary	264	BWh	Evaporation of groundwaters to form trona-halite-gaylussite crystals crusts and efflorescences in the capillary zone of interdunal depressions. Some pans with natron mixed with halite, small anthropogenic crystallizer pans in interdunal depressions (<5 km^2), NE Lake Chad. Low quality product for local consumption. (Eugster and Maglione 1979)
Anpeng Basin Trona Mine, China	Eocene	1,266		Nahcolite, trona, mirabilite, gypsum. Solution-mined, 17 nahcolite beds (0.6–3.6 m thick) mixed with sulphate- and carbonate-bearing layer in a depth of around 1,310–2,520 m. Located near Anpeng, about 35 km NW of Tongbai (Wang 1987)
Wucheng Basin Trona Mine, Henan Province China	Neogene	142		Trona, halite, lesser nahcolite (minor northupite and shortite), 36 trona beds (693–974 m deep), lower 15 beds are 0.5–1.5 m thick, thickest 2.38 m; upper 21 beds are 1–3 m thick, maximum 4.56 m, hosted and underlain by dolomitic oil shales of Wulidui Fm. Actual ore body re body contains about 77 % trona and 23 % nahcolite, and lies 650–970 m deep in beds 0.3–3.0 m thick (Youxun 1985)
Chaganor Salt Lake (Qagan Nur), China (Nei Mongol) (21 km^2)	Quaternary	968	BSk	Trona in nine porous brine-filled saline beds containing 11.3 million mt of sodium carbonate, and 4.5 million mt of sodium sulphate. Beds <10,000 years. Current lake area of 21 km^2 consisting of smaller northeastern sub-basin (East Chagannur) and a larger southwestern sub-basin (West Chagannur) joined by a narrow channel (Zheng 1997; Yu et al. 2001)
Wadi Natrun. Egypt (500 km^2)	Quaternary	−23	BWh	Natrun beds with burkeite, gaylussite, trona, halite, northupite, pirsonite, thenardite in various lakes in the depression. Exploited by ancient Egyptians. (Shortland 2004)
Nile Cone (Outer Egyptian Shelf) Mediterranean	Quaternary	down to −2,345	Marine	Trona and thenardite occur in Late Quaternary sediments cored on the outer Egyptian Shelf and the Rosetta Fan of the Nile Cone. Their distinct spatial–temporal distribution suggests emplacement by resedimentation (Stanley and Sheng 1979).
Lake Magadi, Kenya (110 km^2)	Quaternary	696	Aw	Trona, nahcolite, burkeite, magadiite, kenyaite. Contains up to 30 billion tons of trona in Holocene unit 74 km^2 area and 15–40 m thick. Current production ≈350 kty (via dredging) with ≈200 kty renewed (Jones et al. 1977)

Table 12.10 (continued)

Location	Age	Elev. (m)	Köppen	Mineralogy/setting/comments/key references
Lake Natron, Tanzania (561 km^2)	Quaternary	538	Aw	Trona/nahcolite/burkeite. A 2,100 km^2 area of northern part lake is covered by a 1.5 m thick trona bed (≈150 mt resource). (Manega and Bieda 1987)
Sasykkul Lake, Tajikistan (Pamir)	Quaternary			Small, heliothermal lake with local halite and trona precipitation. Similar alpine association to Bolivian trona lakes (Volkova 1998)
Beypazari region, Turkey	Miocene 21.5 Ma	738		Trona, halite, minor nahcolite (in lake margin). Areal extent of the trona deposit is estimated to be 8 km^2. Deposited as two fault-bound lensoidal trona bodies within a 70- to 100-m-thick zone in the lower part of a lacustrine oil shale (Lower Hirka Fm.) Total of 33 trona beds: 16 in the lower trona lens and 17 in the upper. Total thickness of the lower sequence is 40–60 m; upper trona ≈40 m. The interval between the lower and the upper trona sequence is 30–35 m. There is $NaSO_4$ in overlying Kimir Fm (Helvaci 1998; Suner et al. 2003)
Green River Fm., WY, USA	Eocene	1,900		Trona, halite, shortite, dolomitic oil shale of Wilkins Peak Member of Green River Fm over some 31,000 km^2 made up of 42 layers of crystalline trona in basin, 25 of which exceed 1 m thickness. World's largest exploited natural deposit (127 Gt of trona). Nearby in the Piceance Creek basin (18,700 km^2) is the worlds second largest known $NaCO_3$ occurrence, some 27 Gt of nahcolite and 17 Gt of dawsonite in the lower part of the Piceance River Formation (see text)
Owens Lake, CA, USA (278 km^2)	Quaternary	1,081	BSk	Trona/burkeite/thermonatrite/halite. Small playa valley in block-faulted Basin and Range region (anthropogenic salinity). (≈52 mt of sodium carbonate equivalent). (Alderman 1985)
Searles Lake, CA, USA (132 km^2)	Quaternary	493	BWk	Trona-nahcolite-halite. Two saline beds with trona-nacholite dominant in lower salt bed. Soda-ash via brine extraction and processing, salt-cake as byproduct. Playa in blockfaulted Basin and Range valley (estimated 1.06 Gt of sodium carbonate equivalent) (Smith 1979)

Nahcolite shows promise as another mineral that may be solution mined commercially in the near future (Table 12.10).

Until the 1960s, soda ash in the USA was almost totally derived from Solvay plants situated near industrial markets in the country's northeast. Today the position in the USA is reversed and natural extraction dominates due to lower extractive costs and lesser environmental impact. Trona in the USA is mined from the Eocene Green River Basin, Wyoming, or processed from lacustrine brines in Searles Lake and Owens Lake, California. The large-scale subsurface operations in Wyoming extract trona using various conventional combinations of room-and-pillar, longwall and shortwall extraction methods.

In contrast, solution mining and multicomponent recovery methods process brines extracted from trona beds in Searles Lake (Fig. 12.12). Dilute sodium hydroxide (NaOH – commonly called caustic soda) is typically injected into the lake beds to dissolve trona. The recovered solution is treated with CO_2 gas in carbonation towers to convert the sodium carbonate (Na_2CO_3) in solution to sodium bicarbonate ($NaHCO_3$), which precipitates as nahcolite and is filtered out. The crystals are again dissolved in water, precipitated with carbon dioxide, and filtered. The product is then calcined to produce dense soda ash. Sodium bicarbonate, sodium sulphate, potassium chloride, potassium sulphate, borax, and other minor minerals are produced as coproducts from sodium carbonate production from brines in Searles Lake, California. Likewise, sodium bicarbonate, sodium sulphite, sodium tripolyphosphate, and chemical caustic soda are manufactured as coproducts during processing of mined trona at several of the Wyoming soda ash plants.

There is a common misconception among some geologists that the presence of thick-bedded trona indicates a carbonatite-rift source area. Certainly, there are some geologically scenic trona deposits in the African rift, which are surrounded by volcanoes spewing natrocarbonatites; but these are volumetrically minor deposits, even in terms of the volume of rift sediment fill in the rift sump and, especially when compared to the volumes of ancient lacustrine Eocene trona in Wyoming and China, or the trona (long since

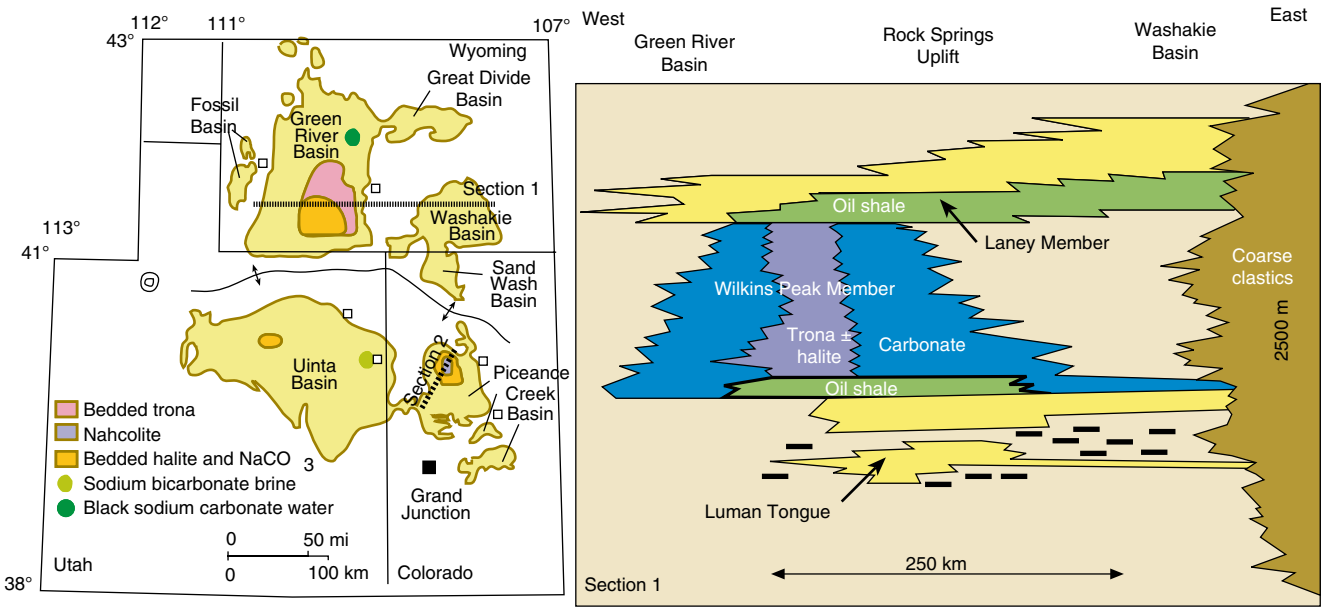

Fig. 12.35 Green River Formation. (**a**) Areal distribution and the locations of sodium carbonate deposits in Utah, Colorado, and Wyoming. (**b**) Stratigraphy of the Eocene Green River Formation showing interrelationships between various members and facies in the Green River Basin (After Dyni 1996)

dissolved) that once precipited in evaporitic seaways of the Archaean. Even today, all that is needed to form sodium carbonate brine is a suitably alkaline inflow water, depleted in sulphate and chloride. Most continental ground waters in metamorphic, volcanic, or igneous terrains can produce alkaline solutions upon evaporation (Hardie and Eugster 1970). The relative absence of chloride and sulphate in these types of rocks permits solutions to become relatively enriched in Na and HCO_3 and so follow the appropriate "closed basin" concentration pathway leading to trona/nahcolite (Fig. 2.19; pathway I). Mechanisms driving the appropriate chemical evolution leading to trona are varying combinations of mineral precipitation, selective dissolution of efflorescent crusts, degassing of brines, and/or redox reactions (Jones et al. 1977).

Groundwater percolating through siliceous soils, such as those developed on granite or windblown sand, can become highly alkaline and enriched in sodium carbonate (Garrels and Mackenzie 1981). Alternatively, very high carbon dioxide concentrations (up to 10 % in soil gas) can be the result of intense biological activity in the precipitative brine. The Pretoria pan and the Sua Pan in Botswana are examples showing elevated sodium carbonate in soil waters, so the construction of solar evaporators using this water can produce substantial volumes of trona each dry season. In soda lakes such as Lake Magadi and Lake Natron, the deposition of monomineralic beds of trona is be aided by the continual generation of biogenic CO_2 from the halobiota flourishing in alkaline lake waters (Chap. 9; The Flamingo connection).

In regions characterised by an abundance of limestone or dolomite, or even a drainage basin leaching older marine evaporites, the inflow waters to the saline depression typically contain too much chloride, sulphate, and calcium to produce a trona brine. Even in some areas draining igneous and volcanic terrains, the inflow waters mix with other basinal waters or with other rock and soil types to create a hybrid chemistry where trona cannot precipitate.

Trona in North America

The lacustrine Green River Formation (Eocene) in the Green River Basin in Sweetwater County, southwest Wyoming contains the world's largest known resource of natural sodium carbonate in the form of bedded trona (Fig. 12.35). The scale of current extraction, and the possibility for future expansion using conventional mining techniques for the various Wyoming operations is huge. For example, General Chemical's Green River Basin plant has identified trona ore reserves of more than 500 million tonnes and currently maintains more than 200 km of underground workings. Total identified trona resource in the basin is more than 47 billion tonnes, dwarfing any other known natural trona resource. For comparison, the combined identified total resource for Searles and Owens lakes is slightly in excess of 815 million tonnes. America today produces over 10 million tonnes of trona per year and is a net exporter of product.

The Eocene Green River Formation is divided in ascending order into the Tipton Shale, Wilkins Peak Member, and

the Laney Shale. The trona resource lies wholly within the lacustrine Wilkins Peak Member. The Wilkins Peak ranges from about 183 to 410 m (600 to 1,350 ft) in thickness and consists of marlstone, oil shale, trona, siltstone, mudstone, and numerous laterally persistent thin layers of tuff. These sodium carbonate-rich sediments were deposited in two large lakes that occupied several lacustrine sedimentary-structural basins in Colorado, Wyoming, and Utah (Figs. 5.12 and 12.35; Dyni 1996; Smith et al. 2008; Tanavsuu-Milkeviciene and Sarg 2012). These Eocene basins include the Green River, Washakie, and Sand Wash Basins in southwest Wyoming and northwest Colorado, the Piceance Creek Basin in northwest Colorado, and the Uinta Basin in northeast Utah. Eocene Lake Gosiute is the northern lake that once occupied the Green River, Washakie, and Sand Wash Basins. The southern lake, Eocene Lake Uinta, occupied the Uinta and Piceance Creek Basins in Utah and Colorado (Fig. 12.35a). The Uinta Mountain Uplift, an east–west positive structural element, separated the two lakes, although they may have been connected during part of their existence on the east side of the uplift. At its maximum extent, Lake Uinta covered about 57,000 km^2 (22,000 square miles), and Lake Gosiute, about 38,850 km^2 (15,000 square miles).

During much of Green River time, the lakes were hydrographically-closed with no surface outlets. The Green River Formation consists of a variety of lacustrine sedimentary rocks, including sandstone, claystone, shale, dolomitic marlstone, oil shale, and numerous, generally thin beds of volcanic tuff (Dyni 1996). Typically, the Green River sediments grade from fine-grained sandstone, mudstone, claystone, and shale in shoreward areas of the lakes into carbonate-bearing sediments enriched in organic matter toward basin centre (Dyni, op. cit.). The lateral transition from siliciclastic to carbonate-enriched rocks is also reflected in vertical sequences of the Green River Formation and equivalents in the Green River, Piceance Creek, and Uinta Basins. This indicates increasing salinity of remaining alkaline lake waters as divalent cations of calcium and magnesium were precipitated as calcite, Mg-calcite, and dolomite in lake fringe mudflats, while dissolved sodium, bicarbonate, and chloride continued to accumulate in surface and near-surface waters in saline pans in the lower parts of the basin. A lack of sulphate in the trona pans perhaps reflects bacteriogenic sulphate reduction in the lake brines, as in modern lakes in the African rift valley. Associated hydrolysis of detrital silicate minerals and glassy volcanic ash (zeolites) also contributes additional dissolved bicarbonate, sodium, and other ions to the lake brines. Tuffaceous debris amounts to roughly 5 % of the total sediments in the Green River Formation.

During drier periods these Eocene lakes shrank and large volumes of saline sodium bicarbonate minerals were deposited, either as bottom nucleates in shallow brine sheets or as displacive intrasediment nodules in mudflats. The more abundant sodium salts include trona, nahcolite, shortite, dawsonite, halite, and less commonly eitelite and wegscheiderite. The most important lake desiccation event occurred during Wilkins Peak and Parachute Creek time when vast deposits of trona and nahcolite were precipitated in the Green River and Piceance Creek Basins, respectively (Figs. 12.35 and 12.36). During two later desiccation events, nahcolite was deposited as nodules and possibly some thin beds in the Birds-nest zone in the eastern Uinta Basin, Utah. Finally, during a later desiccation event, bedded sodium salts were deposited in the Uinta Basin near Duchesne, Utah (Dyni 1996). Interbedded dolomitic oil shales separate these desiccation events and represent biochemical deposition from relatively dilute lake waters during expanded lake phases. Trona beds were deposited in the lowest sectors of the various basins during times when surface waters were extremely shallow to ephemeral with brine chemistries akin to those in modern Lake Magadi (Surdam and Wolfbauer 1975; Fischer and Roberts 1991). Centripetal groundwater inflows subsequently dissolved some of the sodium salts, as evidenced by the presence of solution breccias and solution cavities in cores collected in marginward parts of the Green River Formation. At least two areas today contain sodium carbonate brine pools of unknown size, but that are possibly exploitable brine resources (Fig. 12.35).

Currently mined trona ore in the Green River Basin is restricted to the Eocene Wilkins Peak Member of Wyoming. Culbertson (1966) defined 42 beds of trona, up to 14 m thick in the member, at depths ranging from 120 m to over 1,000 m. He numbered the thickest and economically most important of these beds from 1 to 25 in ascending order (Fig. 12.36). These trona beds are remarkable for their purity and continuity compared to other large lacustrine trona deposits elsewhere in the world. Sulphate minerals are essentially absent, and other than halite, the chief impurities are thin dolomitic marlstone stringers and vertical seams of mudstone created by extension and injection of water saturated mud. Faults cutting the trona are rare and bed dips are typically less than a degree, making them eminently suitable for mining. Toward the depocenter in the southern part of the basin some of the trona beds grade laterally into mixed halite and trona (south of dashed line in Fig. 12.36). Nahcolite is abundant in some beds in the lower part of the evaporite stratigraphy making them less suitable mining targets. Dyni (1996) also notes that nahcolite, wegscheiderite, northupite, and possibly shortite become locally abundant, as well as quartz, toward the depositional centre of the mixed halite and trona interval in bed 17 when it is traced into the southern part of the basin. Bed 17 is one of the most important ore targets as it has the greatest area in the basin.

The Wyoming trona district currently produces about 8.2 million mt (9 million tons) of refined soda ash annually from five underground mines that extract a total of about 16.3 million mt (18 million tons) of trona ore (Dyni 1996). Trona

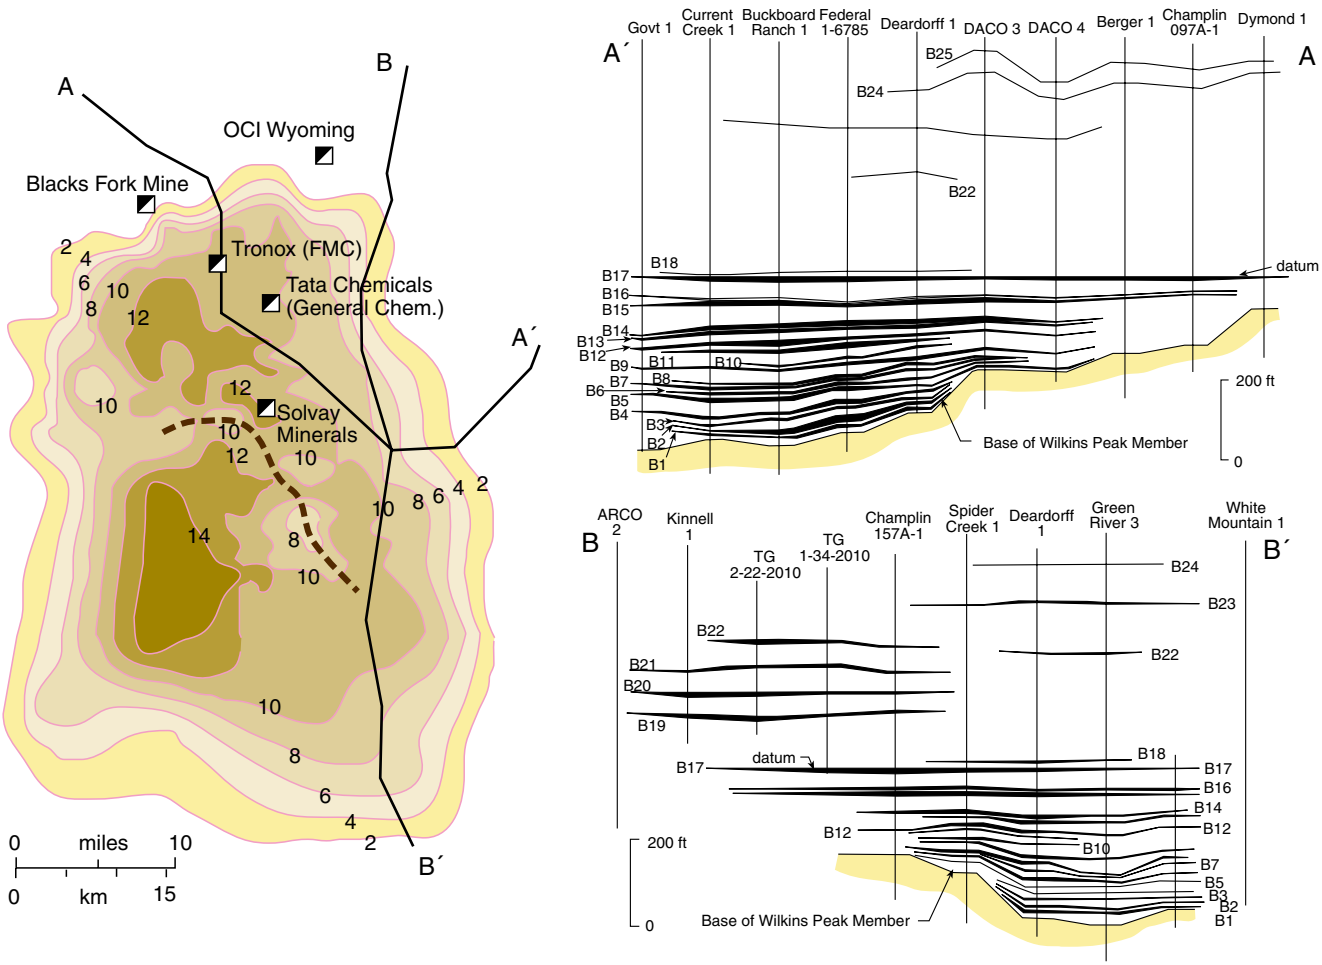

Fig. 12.36 Trona distribution in the Wilkins Peak Member of the Eocene Green River Formation in Wyoming. Isopach is of Bed 17 and is in feet. *Heavy dashed line* indicates approximate northern extent of halitic facies. Cross sections use Bed 17 as a datum; halitic facies are not shown and the wells are equally spaced in the cross sections (After Dyni 1996 and Wiig et al. 1995)

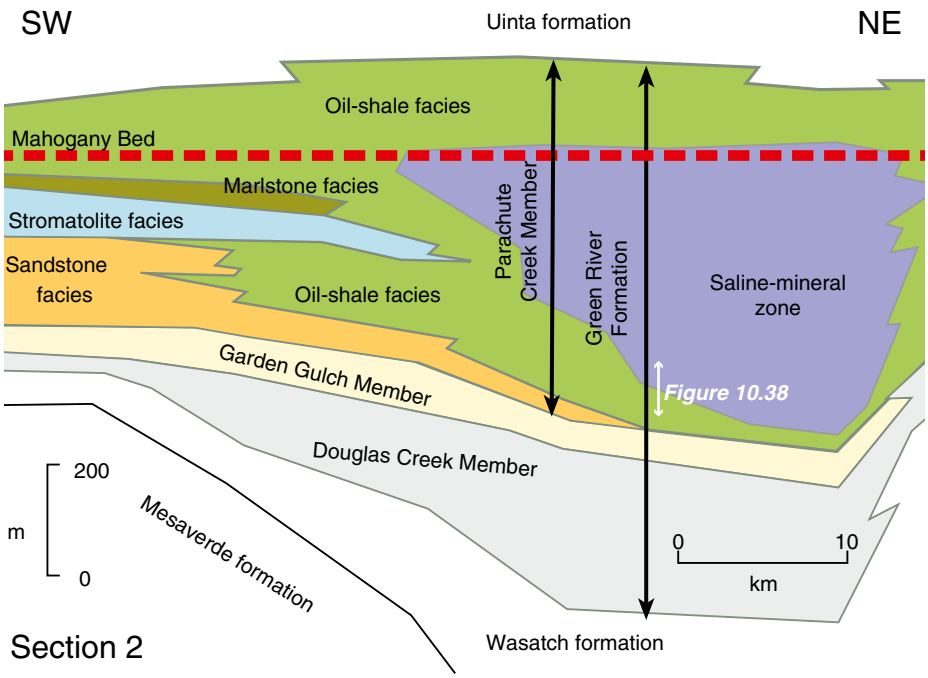
bed 17 where it is more than 1.2 m (4 ft) thick, underlies about 2,000 km^2 (775 square miles) of the basin and ranges from 1.2 to 5.2 m (4–17 ft) in thickness (Fig. 12.36; Dyni 1996). Twenty-two of the 25 numbered beds listed by Dyni (1996) are estimated to contain 115 billion mt (127 billion tons) of trona ore, or 69 billion mt (76 billion tons) of trona in beds containing less than 2 % halite. These 22 beds, where they are 1.2 or more metres (4 or more feet) thick, underlie areas ranging from 130 to more than 2,000 km^2 (50 to more than 775 square miles) at depths of 200–915 m (650–3,000 feet) below the surface. The trona contains 70.3 wt% sodium carbonate and it takes about 2 t of trona ore to produce 1 t of soda ash. Currently, Tronox (formerly FMC), Tata Chemicals, and Solvay Chemicals mine trona bed 17, Blacks Fork mines bed 20, and OCI Wyoming (formerly DC Chemicals) mines beds 24 and 25.

Mining is conventional, using vertical shafts to access the ore level and then room-and-pillar, short- and long-wall techniques (Dyni 1996). At three mines, additional sodium carbonate is recovered from wastewaters from the processing plant, which are used to slurry tailings to abandoned parts of the mines. These same waters dissolve additional trona from the pillars and are then pumped back to the surface to recover the additional sodium carbonate. This post-mining brine recovery/recycling technique has proven to be economical and will probably soon be employed by other mines in the district. Earlier attempts to solution mine trona from vertically drilled holes have been unsuccessful due to nahcolite 'blinding' (Fig. 13.11).

At the end of the millenium, a small-scale solution mining operation began in the Parachute Creek member in the Piceance Creek Basin using horizontally drilled holes with nahcolite, not trona, as the planned feed source. If the blinding problem is solved a similar horizontal drilling method may be especially useful in the southern part of the Uinta basin where the trona beds are thicker and lie at greater depths. By mid 2004 operations at this facility were scaled back and today there are no active extraction or processing activities focused on nahcolite in this area.

The Parachute Creek Member in the deeper northern part of the Piceance Creek Basin contains a saline facies,



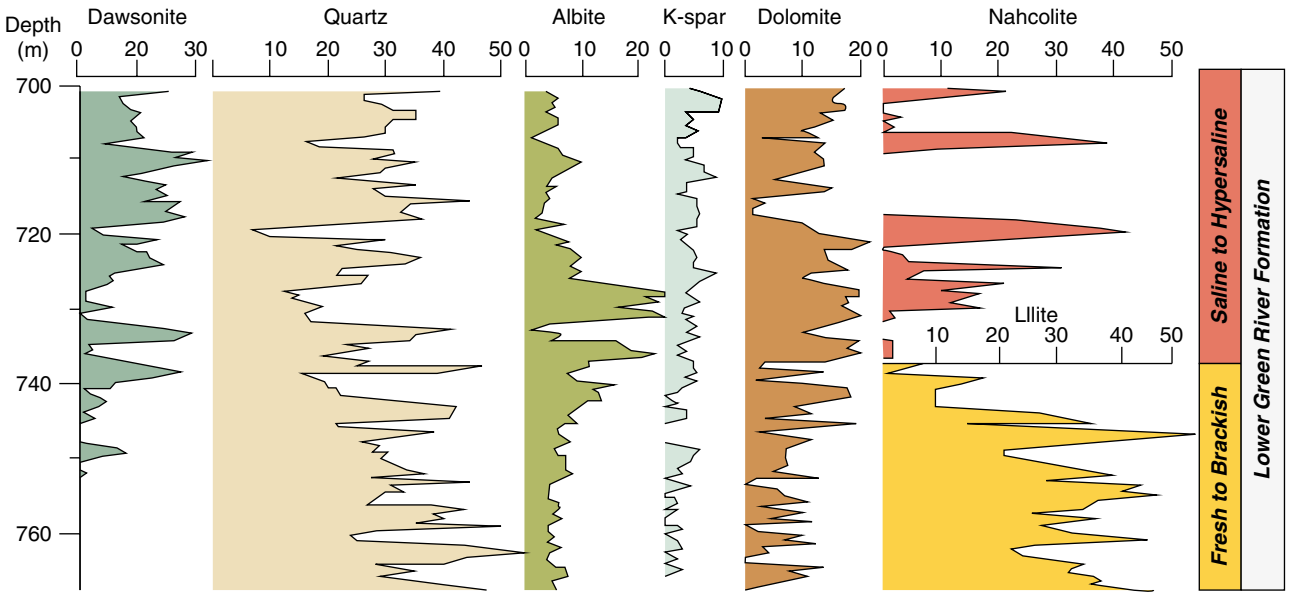


Fig. 12.37 Stratigraphy of the Eocene Green River Formation showing interrelationships between various members and facies in the Piceance River Basin (section 2). Locality of section indicated on Fig. 12.35

Fig. 12.38 Salinity-related transition to saline nahcolite-precipitating brines in Lower Green River Formation in core from the Juhan 4–1 well, Piceance Creek Basin, Colorado. Note the upward decrease then disappearance of illite as the first sodium carbonate minerals, nahcolite and dawsonite appear. The increasing salinity is indicated also by increases in dolomite and albite and a decrease in the level of quartz (After Dyni 1998)

which includes beds of nahcolite and some halite, along with scattered crystals, nodules, and coarse-crystalline aggregates of nahcolite commingled with high-grade oil shale (Fig. 12.37; Dyni 1996, 1998). Also included in the saline facies is dawsonite as microscopic crystals in the microcrystalline matrix of the oil shale. The transition into saline oil shales and into the sodium carbonate minerals nahcolite and dawsonite in the Piceance Creek Basin is a transition from brackish into saline waters, accompanied by a loss of detrital illite and an increase in dolomite and albite (Fig. 12.38; Dyni 1998).

The top of the nahcolite-bearing oil shale in the Piceance Creek Basin is a dissolution surface above which meteoric waters have dissolved nahcolite and halite forming a "leached zone" of vuggy brecciated oil shale (collapse breccia), which is up to several hundred feet thick. The leached zone extends upward into the lower part of the Mahogany oil-shale zone, a unit of high-grade oil shale traceable throughout the basin

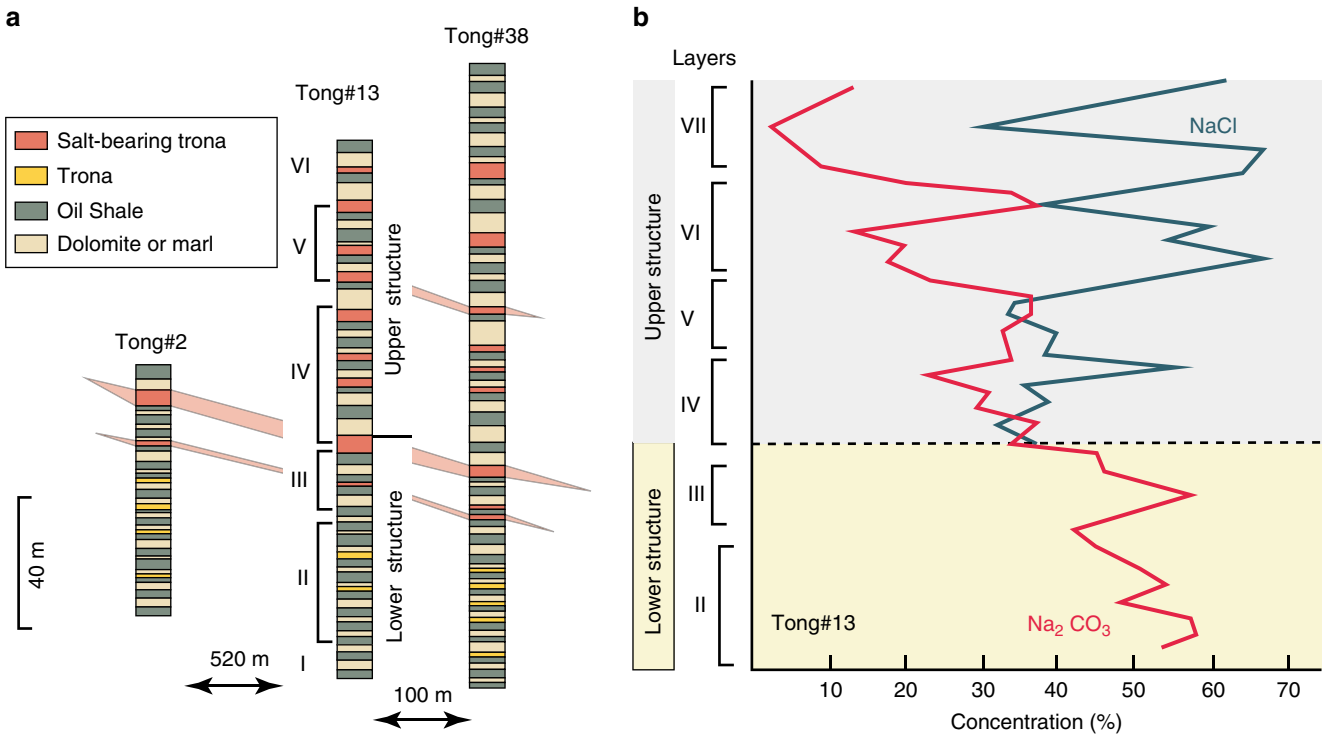

Fig. 12.39 Eocene lacustrine trona at Wucheng, China. (**a**) Layering across 3 wells in the Wucheng deposit showing purer trona in the "Lower Structure" interval of the deposit. (**b**) Detail illustrating loss of halite and increase in trona in the *lower part* of the Tong#13 borehole (After Zhang 1998)

(Fig. 12.37). The top of the leached zone is defined by the stratigraphically highest occurrence of the solution breccia (Dyni 1981). This top can be considered to be the top of the original bedded saline facies in the Parachute Creek Member, although crystal cavities and vugs are found scattered through the upper part of the Parachute Creek Member well above the Mahogany oil shale in a zone 168–335 m (550–1,100 ft) thick.

The potential nahcolite resource in the Piceance Creek basin is estimated at between 29 and 32 billion short tons (26–29 billion mt; Dyni 1996). It is unlikely that this resource will be exploited as associated oil shale cannot be removed or damaged under current sodium leasing regulations. The major part of the potential nahcolite resource, which occurs as crystalline aggregates scattered through oil shale, will be difficult to economically mine for soda ash alone. Any solution mining of nahcolite beds in this part of the basin may render portions of the overlying oil shale unsuitable for future in situ or underground mining.

Natural Soda Ash in China

In China, synthetic sources dominate the country's total soda ash production, but lesser volumes of natural soda ash are extracted via solution mining of two Eocene deposits (Wucheng and Anpeng) and winter extraction in two Quaternary salt lake systems (Lakes Changnor and Ordus; Zhang 1998).

The Wucheng trona deposit in southern Henan Province, 18 km west of Tongbai County was discovered in 1971 during petroleum exploration. This Eocene deposit lies in the central part of the Paleogene faulted Wucheng basin (Zhang 1998). Trona beds cover an area of 4.66 km^2 at depths of 643–974 m. Based on NaCl content is divided in two units: (1) The "upper structure" consists of 21 salt-bearing trona beds with thicknesses ranging from 1 to 3 m (Fig. 12.39a). The beds of the upper structure contain an average of 34.0 % total sodium carbonate and 45.6 % sodium chloride. (2) The "lower structure" consists of 15 trona beds with low halite content and thicknesses ranging from 0.5 to 1.5 m. The ore (trona beds) of the lower structure contains an average of 55.0 % total sodium carbonate and less than 0.3 % sodium chloride (Fig. 12.39b). Resources of the Wucheng trona deposit total 36.8 Mt sodium carbonate and 17.8 Mt sodium chloride.

Sodium carbonate-bearing minerals in Wucheng are mostly trona and nahcolite, typically associated with lesser amounts of shortite, northupite, and $NaCl{\cdot}Na_2CO_3{\cdot}(MgFe)CO_3$. Halite is a commingled mineral in both the upper and lower units but present in much lower proportions in units of the lower structure. The floor and roof strata of the ore units and gangue interbeds are composed of oil shale, dolomite, and marl. A representative cross section based on three

boreholes through the Wucheng trona deposit is presented as Fig. 12.39a, while sodium carbonate and sodium chloride variations within layers in the Tong #13 borehole are illustrated in Fig. 12.39b.

A trona bed in the lower structure of the Wucheng trona deposit is the target for solution mining extraction. This trona bed is made up of 38.63 % Na_2CO_3, 47.72 % $NaHCO_3$, 0.53 % NaCl, and 13.12 % H_2O (without insoluble matter). The calculated optimum concentration and consumption of caustic soda used for solution mining for this bed is optimised for various subsurface temperatures across the deposit (Chap. 13). This trona bed is separated by 450 m of impermeable dolomite, marl, and oil shale from upper aquifer strata; the floor strata are also impermeable.

The Wucheng trona deposit shows no obvious faults. Surface distance between the injection and production wells is about 100–150 m, The trona was fractured at an injection pressure of 15 megapascals (MPa), and the operating pressure kept at about 2.5 MPa. Under normal conditions, solvent is injected with a caustic soda concentration of 4–5 %. The solution obtained at the production well has a sodium carbonate content of 14–16 %. The flow rate proportion of produced solution to injected solvent is about 0.85.

The nearby Anpeng nahcolite deposit is located 60 km southwest of the Wucheng trona deposit and was discovered in 1976 during petroleum exploration (Zhang 1998). The deposit lies in the southeastern part of the faulted Paleogene Biyang basin and like Wucheng also formed as saline lacustrine precipitates in the Eocene at a time when CO_2 levels in the atmosphere were much higher than today (≈1,125 ppm; Lowenstein and Demicco 2006). The deposit consists of 17 nahcolite beds with thicknesses ranging from 0.6 to 3.6 m across an area of 8 km^2 at depths of 1,310–2,520 m. Ore targets are located in the middle, proximal middle, and upper parts of the Lower Tertiary Hetaoyuan Formation. Northwest of the main exploited area of the nahcolite beds, brines containing sodium bicarbonate and sodium carbonate occur in porous and permeable lacustrine dolomites in five layers with thicknesses ranging from 1 to 5 m. Solid minerals in the Anpeng deposit are mainly nahcolite and wegscheiderite ($Na_2CO_3 \cdot 3NaHCO_3$). The floor and roof strata and evaporite interbeds consist of dolomite, oil shale, and sandstone. The Anpeng nahcolite deposit has a likely reserve of 55 Mt sodium carbonate, of which about 2–3 % occurs in brine.

Solution mining of the Anpeng nahcolite deposit is similar to that of the Wucheng trona deposit, utilising a set of injectors and producer wells. Surface distance between injection and production wells is about 168–215 m. The dolomitic floor and roof stratum have a higher strength than nahcolite, enabling effective longterm solution mining. With injection of a 3 % caustic soda solution as a solvent, the produced solution has a sodium carbonate content of 8.5–10.1 %. The flow rate proportion of produced solution to injected solvent is about 0.82. Some nahcolite ore is contaminated by petroleum, which influences the dissolving effect. The pumped solution can contain some sodium carbonate crystals. Recently, there have been local saline groundwater breakouts that are related to escaping solution mine brines causing environmental problems via contamination of local aquifers and soil salinisation in the vicinity Cao Village (see Chap. 13; Shi et al. 2013).

The Chaganur (Chagonnor) soda ash lake deposit, discovered in 1966, is located in the central part of the Inner Mongolia Autonomous Region, some 80 km southeast of Erlianhot (Fig. 12.40a). At an elevation of 1,000 m, it is a lacustrine sump in the lowest part an arid deflation basin situated at an erg edge in the cool arid steppes (BSk) of the Inner Mongolian plateau. It is made up of a smaller northeastern sub-basin (East Chaganur) and a larger southwestern sub-basin (West Chaganur) joined by a narrow channel. Two intermittent rivers discharge into the lake, one from the northeast and the other from the southeast. The lake is also fed by direct precipitation. Chagannur is the largest of a series of 16 alkaline salt lakes in the region (e.g. Hushunur, Wulannur, Huguonur, Halefushuyingnur, Muyingnur, Wulannur, Wenduobunur, South Chaganur) that are relicts of a formerly more extensive lake (palaeolake Chagannur).

At its maximum extent, which is thought to have been during the early to mid- Holocene, this palaeolake occupied an area around 2,640 km^2. The total area of the various lakes in the basin today is ca 156 km^2 and the area of the current catchment is 2,800 km^2. The basin, which is controlled by two faults running SW-NE, is a tectonic sump with a Cretaceous bedrock of sandstone and mudstone. Annual evaporation today is ten times that of precipitation. The natural soda beds in the Chaganur lake accumulated during climatically-induced shrinkage events and occupy an area of 21 km^2 and are under-lain by some 20 m of sandy clay. The targeted deposit consists of nine soda beds with interstitial hypersaline brines that are interlayered with black muds (Fig. 12.40a).

The main minerals in the soda beds are natron and trona, with associated mirabilite and halite, and small amounts of northupite and gaylussite. The Chaganor deposit has a reserve of 11.3 Mt of sodium carbonate and 4.5 Mt of sodium sulphate. After the topsoil is removed, trona levels are quarried, bed by bed. Interstitial brine is pumped off in advance of bed removal via pumping into solar ponds where halite is recovered in the summer and burkeite in the autumn. Earthern walls are constructed to prevent surface floods entering the worked areas.

The Ordus (Ordos) alkali lakes are located on Ordus Plateau in the southwestern part of the Inner Mongolia Autonomous Region. Some of these alkali lakes are among the earliest worked natural soda ash deposits in China. The lakes lie in the Ordus Plateau region, at an elevation of

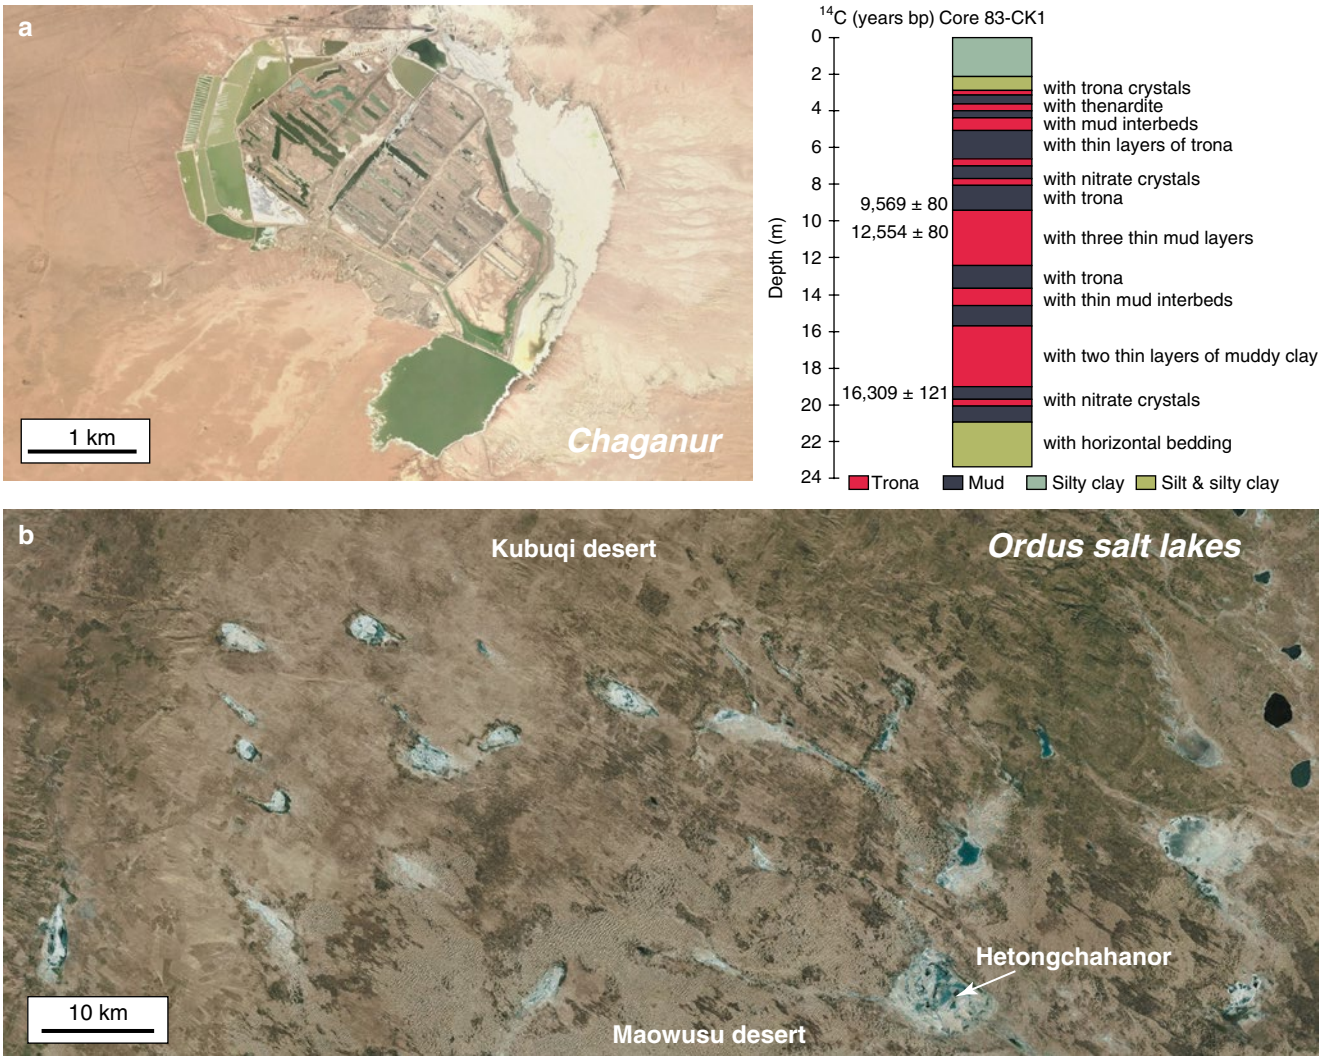

Fig. 12.40 Quaternary trona lakes, Inner Mongolia autonomous region, China. (**a**) Chagannor Lake, with geological detail of core 83-CK1 collected in the lake. (**b**) Regional view of the Ordus Salt lake system (Bing® Images mounted in Mapinfo®)

1,268–1,412 m, at the margin of the Gobi Desert in a corridor that separates two sandy deserts called Kubuqi and Maowusu. Climate is cool arid (BSk), with annual evaporation levels some seven times that of precipitation. Around ten significant alkali lakes are distributed over the two desert margins (Fig. 12.40b).

Like the other lakes of the Ordus system, the largest lake Hetongchahanor-occupies a deflation depression and is located in the northern extent of the Maowusu desert, 110 km southwest of Dongsheng. The Hetongchahanor alkali lake has an area of 29 km^2, and contains 0.4–1.0 m of perennial alkaline surface water. The ore target consists of one natural soda bed and its interstitial brine. This soda bed covers an area of 6.14 km^2, with an average thickness of 1 m, and is underlain by 1–1.5 m of sandy clay. Hetongchahanor alkali lake contains a reserve of 1.7 Mt sodium carbonate. Principal minerals are natron and trona with associated mirabilite and halite, and a small amount of gaylussite. Solar ponds have been used at Hetongchahanor to recover trona in the summer and natron and mirabilite in the winter.

Trona in the African Rift

Outside of the USA, the largest documented production of natural soda ash in Quaternary sediments is from Lake Magadi, located some 120 km southwest of Nairobi, Kenya (Chap. 4). The lake is situated in the lowest part of the East African Rift Valley and has a total area of 100 km^2, it lies in an Aw climate belt with a net evaporation rate in excess of 400 mm per year in the lake vicinity. The deposit contains more than 30 billion metric tons of trona in a bed between 7 and 40 m thick and believed to have formed in the last 9,000 years. Thermal springs, driven by the area's volcanic

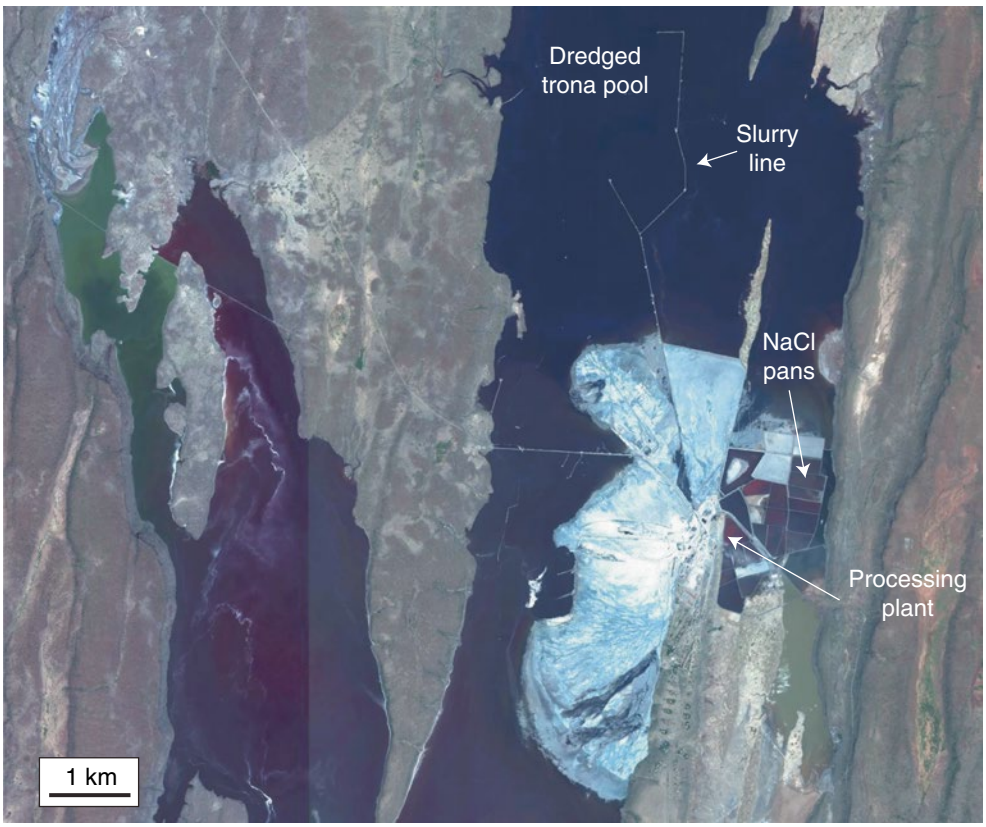

Fig. 12.41 Lake Magadi, extraction and processing areas

activity, are the major source of sodium in the lake and are sourced from a deep actively circulating groundwater reservoir. Trona precipitates in the more central areas of Lake Magadi as a bottom-nucleated crystal pavement. The annual crop is estimated at 1.5 million tonnes/year, although the bulk of this crop (≈75 %) redissolves each wet season. When trona-saturated surface brines in Magadi dry up, the brine level stays close to the trona pavement surface. Even during exceptionally dry years the brine surface drops only 1 or 2 cm into the trona bed.

Trona in Lake Magadi has been mined since 1914 and is currently quarried from the central pavement using dredging barges. Today, the facility is owned and operated by Tata Chemicals Magadi Ltd and produces around 350,000 tonne/year. As the solid material is removed by a digger belt, liquor from the surrounding trona pavement drains into the resulting cavity, forming a pool or 'paddock' in which dredges float and move forward (Fig. 12.41). Crystals of trona produced by the dredges are coarse crushed, mixed with lake liquor and pumped as a slurry back to the factory where the liquor is discarded and the crystals washed and centrifuged. Water washing reduces the sodium chloride level associated with the liquor from 11.5 % to around 0.33 %. The damp crystals are then fed into calciner plant. The crushed refined soda is then conveyed to the calciner plant. There it is fed into two large rotary kilns and subjected to a continuous flow of hot gases across a reaction bed to chemically decompose the trona (sodium sesquicarbonate) into soda ash, carbon dioxide and water vapour. This calcined material is conveyed to the grinding and screening plant, where the physical grading of the product takes place, before the product is conveyed to the storage silos, followed by packaging and transport to market.

If for any reason a dredging barge breaks down for more than a day or two, trona precipitating in the paddock about the base of the barge can lock the barge in place. This trona has to be physically chipped away before dredging operations can continue. Replenishment of trona in the lake is so rapid that at present extraction rates the Magadi trona could be considered a renewable resource.

The Lake Magadi facility also produces NaCl in a series of purpose-constructed solar evaporation ponds use to concentrated natural lake brines pumped into the pans (Fig. 12.41). Lake brines are typically saturated, with a total dissolved solids (TDS) content of approximately 32 %. Of this, sodium chloride content varies from 30 to 34 %, the rest being almost exclusively sodium carbonate compounds with some sodium fluoride in small quantities (Chap. 4).

Lake brines are pumped to pre-concentration ponds where mostly sodium carbonate monohydrate precipitates. When the remaining brine contains a 50:50 ratio of sodium chloride and sodium carbonate, it is transferred to the salt-making ponds and left to cure. With more evaporation a mixture of soda ash and halite precipitates as a 1-cm-thick layer. This

layer is manually harvested and transported to the factory for processing into various grades of sodium chloride for different salt markets.

There is additional trona production and occurrence on the African continent (Table 12.10): (1) An industrial brine processing plant on the Sua Pan in the Makgadikgadi Basin in NE Botswana (annual production around 300,000 tonne), (2) Minor production of an impure product, mostly for local consumption, from interdunal pans on the NE edge of Lake Chad, (3) Minor production form the Wadi Natrun region of Egypt, some 80 km NW of Cairo, where varying mixtures of trona + halite precipitate each summer in a series of most ephemeral lakes, including Lakes Hamra and Beida (Shortland 2004), (4) Minor production from small ephemeral lake and sodium carbonate brine occurrences spread across the rift valley of Ethiopia, especially toward the southern end of the Ethiopian rift, as in the Lake Abijata mudflats (Tadesse et al. 2003). (5) Lake Katwe, a volcanic cone lake in Uganda, which may also be suitable site for the production of small volumes of potash salts. (6) Lake Logipi, Kenya, (7) The Pretoria Salt Pan (Tswaing), South Africa, (8) Bir Natron (Al 'Atrun) in the Sudan, and (9) A poorly understood noneconomic occurrence of trona crystals recovered in a core taken from sediments of the Nile cone at water depths down to 2,500 m (Stanley and Sheng 1979). Worldwide, other natural trona and sodium bicarbonate brine occurrences include: the saline lakes of the high Andes (including, Laguna Santa Maria, Cachilaguna, Laguna Hedionda Sur, Laguna Honda Sur); Pikrolimni Lake, Greece; Lonar Crater Lake, India; and Sasykkul Lake in Tajikistan (Fig. 12.34, Table 12.10).

In summary, at the worldscale, exploited trona deposits can be grouped into two major and three minor subdivisions (Fig. 12.34, Table 12.10): (1) Eocene-Miocene lacustrine deposits formed in intermontane depressions within actively subsiding foreland depressions with relatively high relief surrounding drainage terranes, and, (2) Quaternary lacustrine deposits at the termina of hydrographically-closed drainages and further divisible into: (a) Intermontane depressions surrounded by relatively high topographic relief in the drainage basin where either (i) hot arid conditions allows bedded $NaCO_3$ to accumulate (Lake Magadi, Lake Natron, Searles Lake) or, (ii) high altitude conditions where seasonal brine freezing facilitates the formation of trona crusts (high altitude lakes of South America and the Pamirs and Nei (inner) Mongolia). Cryogenic soda-ash deposits tend to be marginally economic unless the sodium carbonate phase is a byproduct of other brine processing operations. (b) Terminal pans in lower-relief hot arid cratonic settings where a $NaCO_3$ resource resides within annually replenished $NaCO_3$ brines, often in combination with $NaSO_4$ (SuaPan, WadiNatrun, Lake Chad). Elevated CO_2 levels are common to all $NaCO_3$ settings modern and ancient; nahcolite was a typical bedded co-precipitate with trona during the peak Eocene greenhouse period when atmospheric CO_2 levels more than double that of today (Lowenstein and Demicco 2006).

$CaSO_4$ and NaCl

The depositional, diagenetic and geological settings of halite (rock salt) and gypsum/anhydrite (the most commonplace evaporite salts) were discussed in detail in earlier chapters, and will not be repeated here, only aspects relevant to economic exploitation and production are presented.

Calcium Sulphate (Gypsum)

The predominant use of gypsum since ancient times has been as a construction material (Kogel et al. 2006). The word gypsum is derived from the Greek word *gupsos* and the Arabic *jibs*, both meaning "plaster" and used in reference to calcined gypsum. The deriviation probably comes from the ancient Greeks; the Greek words "*epseo*" means burning or cooking and "*ge*" means earth ("*gepseos*" originally meant chalk).

Character and Extraction History

Gypsum's utility to the construction industry stems from its hydrated character. When gypsum is calcined at 160 °C it loses 1.5 mol of its combined water to form calcium sulphate[4] hemihydrate ($CaSO_4 \cdot 1/2H_2O$); stucco or "Plaster of Paris." When mixed with water the hemihydrate can be spread, cast or molded into the desired form, which then sets to a rocklike hardness. The name "Plaster of Paris" comes from gypsum quarries in the Montmartre district of Paris, which have furnished calcined gypsum to much of Europe since the Middle Ages. When calcined gypsum is added to water, spread between sheets of heavy paper and allowed to set, it makes the plasterboard or wallboard used worldwide in the "dry wall" industry. Uncalcined finely crushed gypsum and anhydrite are used as retarding agents in Portland cement; the set of the cement is slowed, but the tensile strength is not lessened.

The oldest traces of plaster renders are 9,000 years old, and were found in Anatolia and Syria. We also know that 5,000 years ago, the Egyptians burnt gypsum in open-air fires, then crushed it into powder, and finally mixed this powder with water to make jointing material for the blocks of

[4]Calcium sulphate has several forms, ie, calcium sulphate dihydrate ($CaSO_4 \cdot 2H_2O$; commercially known as gypsum), calcium sulphate anhydrous ($CaSO_4$; anhydrite), calcium sulphate hemihydrate ($CaSO_4 \cdot 1/2H_2O$), present in two different structures, α-hemihydrate and β-hemihydrate (commercial name of β-form: stucco or plaster of Paris).

their monuments, such as the Cheops Pyramid in 3500 BC. The writer Theophraste (372–287 BC) described quite precisely the fabrication of plaster as it was done at that time in Syria and Phoenicia. Hydraulic gypsum mortar was used in medieval times in castles and fortresses in what today is Germany. Remnants of walls constructed with hydraulic gypsum mortar have existed for centuries in the Hartz Mountain region of Germany. The ancient Greeks also used gypsum, in particular large plates of clear gypsum as temple windows. When the sun is viewed through relatively large plates of clear gypsum it takes on the appearance of the moon, hence the term selenite to describe this form of gypsum.

The industrial development of gypsum plasters is difficult to trace, but by the late 1800s a commercial process had been developed to slow the setting times, thereby allowing widespread use of finishing plaster in the construction industry. Prefabricated wallboard panels were developed in 1918, but were not widely used until the great construction boom after World War II (Adams 1993). Before that time, plastered walls were more common in residential and commercial construction.

Production

Global crude gypsum production in 2009 was estimated by Crangle (2009) to be 149×10^9 metric tonnes, representing a decrease of 5 % compared with that of 2008, when production totaled 157×10^9 metric tonnes (Fig. 12.42; pre world global financial crisis). In 2009, 87 countries produced significant quantities of gypsum, 10 of which accounted for 74 % of the total world production (Fig. 12.42a). In 2008 (the last year reliable worldwide end use data is available), cement manufacture accounted for up to 60 % of worldwide gypsum consumption, while plaster products, including wallboard, accounted for approximately 30 % of all consumption.

China was the leading producer of crude gypsum in 2011 with an estimated 45 Mt, followed by Iran with 13.0 Mt, Spain with 11.5 Mt, the United States with 10.4 Mt, Thailand with 8.5 Mt, Mexico and Japan with 5.8 Mt each, and Italy with 4.1 Mt (Fig. 12.42a). Given the likely longterm ongoing expansion in China's economy and its respective construction and infrastructure demands, China will likely continue to be the world's leading gypsum producer in the near future. Much of the Chinese production is an industrial byproduct

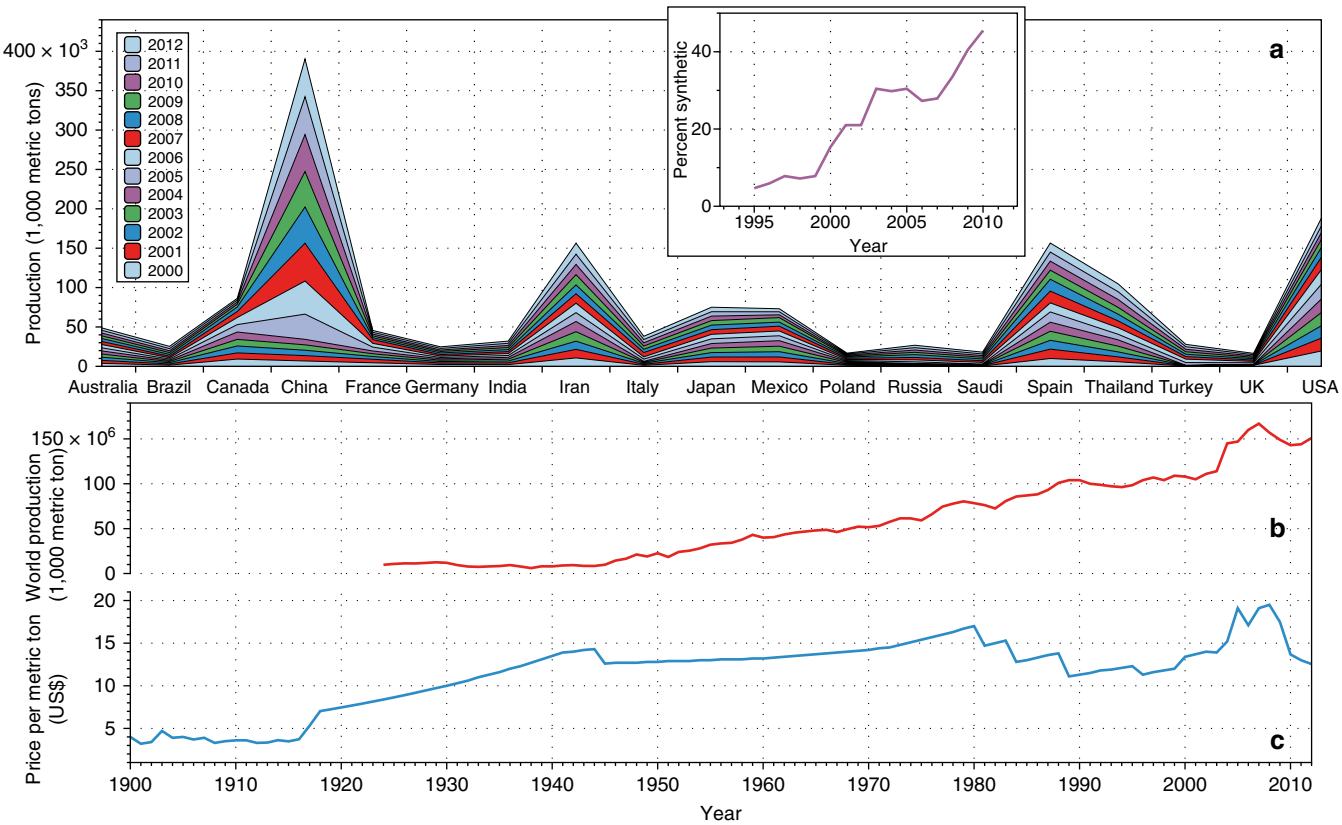

Fig. 12.42 Gypsum Production. (**a**) Cumulative area plot of annual production of top producing countries (in 1,000 metric tons). The drastic increase in Chinese production since 2004 is not as large as it seems in the figure, but indicates a more realistic set of estimates of China production by USGS since that time. Inset shows percent of world production that is synthetic (largely in China). (**b**) World production from 1924 to 2012 (1,000 metric tons), (**c**) Price per tonne in US dollars from 1910 to 2012 (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed April 18, 2014)

and Chinese utilization of synthetic gypsum in wallboard and other construction material is increasing.

Use of gypsum wallboard is increasing worldwide, but only industrialized nations have the majority of their gypsum consumed in the manufacture of wallboard products. In developing countries, especially in Asia and the Middle East, the majority of gypsum is consumed in the production of cement or plaster products. Because some gypsum producers, especially in the developing world, manufacture gypsum products onsite, or nearsite, and intermittently, this product volume goes unreported. Accordingly, Crangle (2011) notes that world production levels are probably underestimated in USGS compilations, as illustrated in Fig. 12.42.

Use of gypsum plaster or wallboard in the construction industry also acts to improve fire protection in a building. Back in the 1600s, Louis XIV issued an edict stipulating that all wooden buildings must be covered inside and out with a layer of gypsum plaster. It is doubtful the mechanism of fire protection by gypsum was fully understood at the time, but considerable protection of the building ensued. At the very least, gypsum plating leads to compartmentalization of a fire, which in the typical wooden dwelling of the seventeenth century was a tremendous advance in fire protection and control.

When applied as soil conditioners, gypsum and anhydrite can have beneficial effects. They decrease the salinity of salty soil, improve the permeability of clayey soil and provide sulphur, calcium and catalytic support, so decreasing fertilizer use and maximizing the economics of crop production. Uncalcined gypsum is also used as a filler in a diverse range of products including paint, paper and toothpaste, as a flux in the smelting of certain nickel ores, in the manufacture of crayons, in asbestos packing gaskets and when in the form of alabaster[5] as a medium for sculpting. Other minor uses for calcined gypsum include dental plaster, modelling casts, moulds, surgical casts and drilling mud additives. Gypsum is also added to tofu to improve its stability and is probably one of the main sources of calcium for many people in SE Asia, who tend not to consume large volumes of dairy products.

Natural anhydrite is also crushed to less than 7 mm (30 % of which is dust), then mixed with water and an accelerator (Fe_2SO_4 and K_2SO_4), to form quick-setting, high strength roadside packs. Aerated anhydrite products are sometimes used to fill cavities in mines or in spaces above road arches. Anhydrite has also been used as a filling and packing material in the coal mining industry of West Germany since the mid 1960s.

Current natural $CaSO_4$ production is either from quarrying or mining. In North America and Europe, gypsum is mined at relatively shallow depths in areas where ancient buried anhydrite beds or diapir caprocks have reconverted to gypsum during uplift and erosion. The Maritimes region of eastern Canada and the USA produces the most gypsum from a single area in the world, with more than 6 million metric tonnes extracted each year from Mississippian strata of the Windsor Group. There is also substantial US production from Tertiary playa deposits in the Salton Trough, California. Spain is Europe's leading gypsum producer, with the main production from bedded Tertiary lacustrine deposits. In Germany, the greater volume of its gypsum is mined from the rehydrated caprock crests of near surface salt structures of Permian Zechstein salt. Secondary targets are the Middle Muschelkalk and minor production comes from the Keuper. In the UK, the most important beds are Permo-Triassic in age, except for those in Sussex, which are Jurassic.

In the southern Hemisphere, substantial volumes of high-grade gypsum are quarried, processed and shipped from Holocene coastal lakes in southern (>1,000,000 tonnes/year) and western Australia (300,000–500,000 tonnes/year). This production supplies the construction industry of Australia and many other parts of Southeast Asia. Small amounts of coarsely crushed gypsum are used as a cheap aggregate to pave unsealed minor roads in many places in southern Australia. Under the region's semi-arid to arid climate gypsum aggregate tends to compact and set into a hard flexible crust.

Synthetic gypsum is produced by a variety of industrial processes (Kuntze 2009). Most synthetic gypsum is the result of a neutralizing reaction between sulphate and calcium ions, as in the manufacture of phosphoric acid or titanium dioxide. Likewise, most chemical processes that use sulphuric acid to digest rocks result in acidic fluids that must be neutralised before they can be recycled or safely discarded. Limestone is the most common neutralising agent and synthetic gypsum is typically produced in the neutralising process. As mentioned previously, synthetic gypsum is chemically identical to natural gypsum and has the same crystal structure. Usually it has a higher dihydrate content and purity than most natural gypsums, but its impurities distributions are different and in some synthetic gypsums that can be of environmental concern.

Hence. despite the availability of synthetic gypsum as an industrial byproduct for more than half a century, there was an initial reluctance in North America and other places in the developed world to use synthetic material in wallboard manufacture. Nevertheless, over the past 20 years, due to increasing availability there has been a considerable change in attitude toward the use of synthetic gypsum, especially that sourced by desulphurization of flue gases at coal-fired power plants.

The price of crude gypsum fell in 2009 as the gypsum industry is closely tied to the construction industry (Fig. 12.42c). Even as the world economy improves, post the

[5] Alabaster is a form of gypsum that is massive, fine-grained, granular and compact; the name is related to a place in ancient Egypt called Alabaston, where this mineral was quarried for sculpturing.

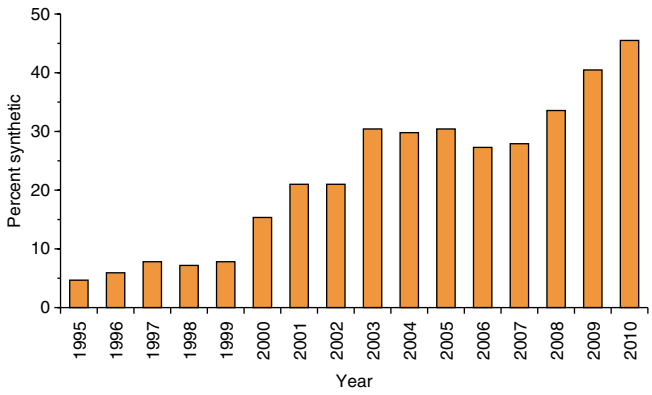

Fig. 12.43 Synthetic gypsum as a percentage of total gypsum ore used to manufacture gypsum panels in the United States 1995–2010 (Replotted from data on http://www.gypsumsustainability.org/recycled.html)

2009 financial crisis, it is unlikely there will be any substantial increases in price. This is because the market is being increasingly supplied and saturated by cheap synthetic gypsum. Increasing long-term use of synthetic gypsum derived from flue gas desulphurization (FGD) will continue to increase worldwide as more coal-fired electric powerplants convert their desulphurization processes to produce marketable gypsum (Crangle 2011). For example, most coal-burning powerplants in the United States are required by the U.S. Environmental Protection Agency to install sulphur dioxide scrubbing systems. This has created a significant source of gypsum, at a lower price than the cost of its mined counterpart, and in the past two decades has led to the construction of wallboard production facilities adjacent to coal-fired powerplants across the USA (Fig. 12.43). An estimated 250 million metric tons per year of synthetic gypsum is generated worldwide (Crangle 2011). Synthetic gypsum that is suitable for use in wallboard includes flue-gas desulphurization (FGD) gypsum, fluorogypsum (byproduct of fluoric acid manufacture), citrogypsum, and titanogypsum. Phosphogypsum (byproduct of phosphoric acid manufacture from apatite or phosphorite) on the other hand must be disposed of rather than used, due to unacceptable levels of deleterious impurities, such as radon and radionuclides.

Rock and Pan Salt (Halite)

The word halite comes from the Greek *hals* meaning salt. Annual world production of salt has today reached more than 280 billion tons (Fig. 12.44). Approximately one third of the total is produced by solar evaporation of seawater or inland brines; another third is obtained by mining of rock salt deposits. The balance is obtained from processing of recovered brines, mainly via solution mining.

Usage History

Sodium chloride (halite), the most common industrial evaporite salt, is used in some form by virtually every person in the world. There are more than 14,000 reported usages of halite and more than 30 references to salt in the Bible. Halite has long played a very important role in human affairs. Some 3,200 years ago Bronze-Age Celtic miners were extracting salt near Hallstatt in Austria, from a network of several kilometres of galleries up to 300 m below the surface. Two thousand seven hundred years later some ten pages deal with salt in the "De Re Metallica" by Georgius Agricola (Georg Bauer), both in terms of mining it and producing it from seawater. Published in 1556, his was the first book on mining to be based on field research and observation. Until the nineteenth Century and the advent of refrigeration, salt's main uses were as a preservative and as a much sought after additive to flavour foodstuffs (Kurlansky 2002). Without salt, the human metabolism cannot function. Even today, most people think of salt in terms of sprinkling it on their food, or in colder climates they may also think in terms of road de-icing. These are in fact lesser modern usages of halite; its main use is as a feedstock in the chemical industry.

The human body's need for salt gave it military significance; the earliest recorded war over access to a supply of salt was over a salt lake in China in 3000 BC. The words, 'war' and 'peace' originate from the words for salt and bread in ancient Hebrew and Arabic. In the American Civil War the salt production facilities in Saltville, Va., Virginia's Kanawha Valley and Avery Island, Louisiana, were early targets of the Union Army. The North fought for 36 h to capture Saltville, Va., where the salt works were considered crucial to the Rebel army – so crucial that Confederate President Jefferson Davis offered to waive military service to anyone willing to tend coastal salt kettles to supply the South's war effort. In addition to dietary salt, the Confederacy needed this precious mineral to treat wounds, tan leather, dye cloth for uniforms and to preserve meat and other foodstuffs. Thousands of Napoleon's troops died during his retreat from Moscow, because, for lack of salt, their wounds would not heal.

Early hominids lived on the edge of the saline Lake Olduvai (Hay and Kyser 2001) and salt was part of their diet. In ancient Greece it was so valuable that the slave trade involved an exchange of salt for a slave and gave rise to the expression, "not worth his salt." Some 4,700 years ago the Peng-Tzao-Kan-Mu was published in China. It is probably the earliest known treatise on pharmacology, with detailed discussions of the palliative and curative powers of more than 40 kinds of salts, including descriptions of two methods of recovering usable salts from brine. In 2200 BC the Chinese emperor Hsia Yua declared than Shandong Province must supply the Imperial Court with salt. An ancient Chinese philosopher once called salt "the sweetest thing on earth."

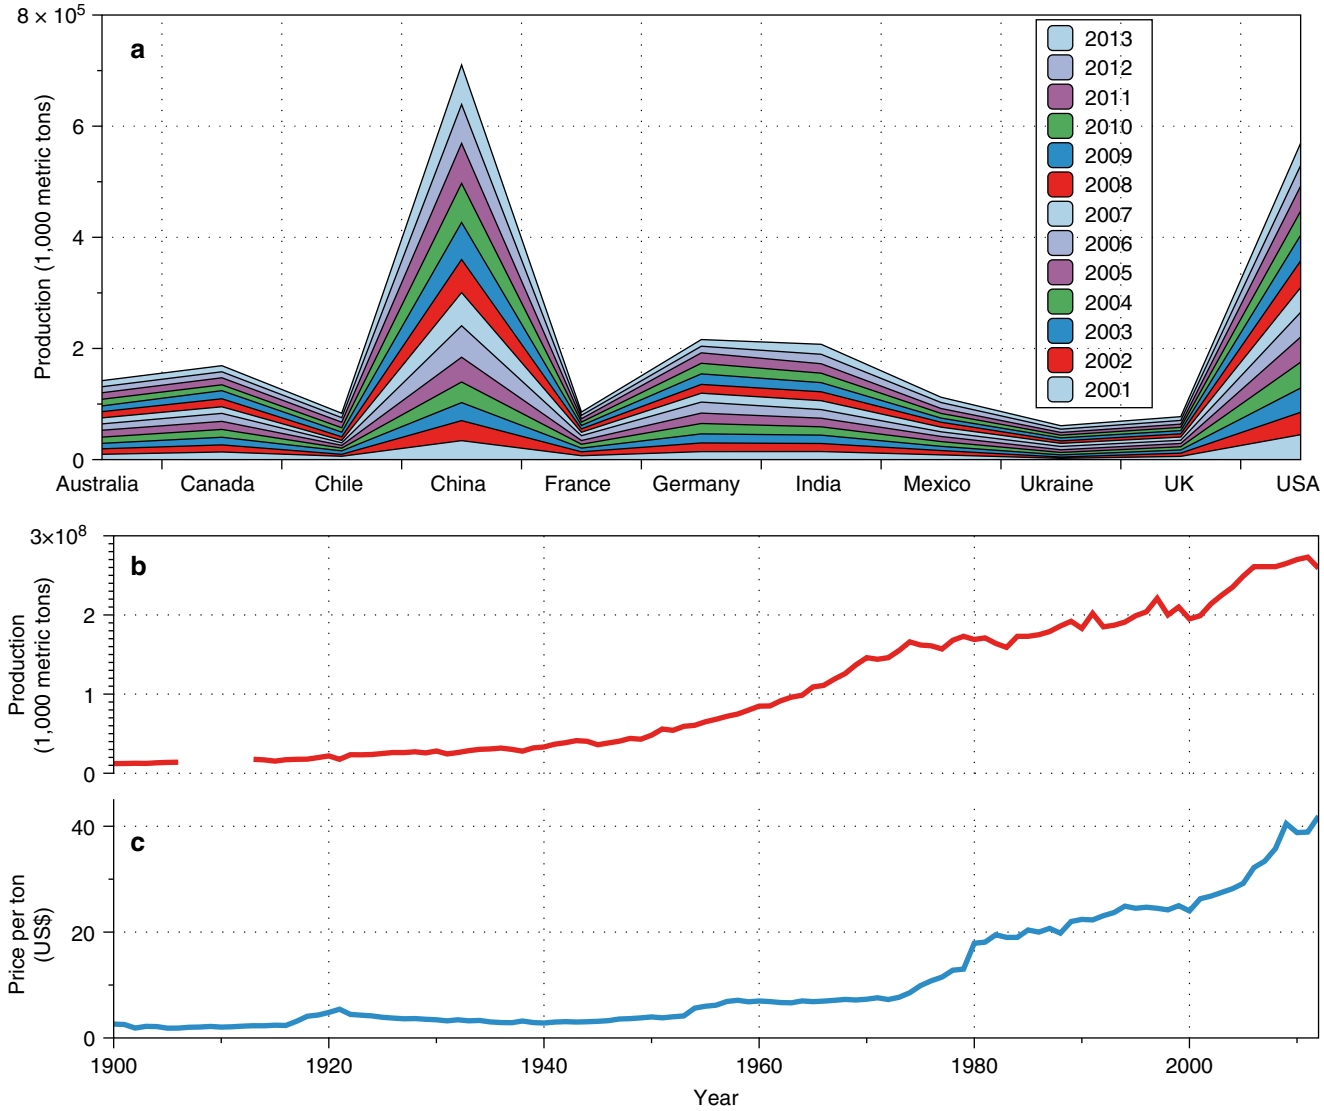

Fig. 12.44 Salt Production. (**a**) Cumulative area plot of top salt-producing countries (1,000 metric tons). (**b**) Salt production from 1900 to 2012. (**c**) Price per tonne in US dollars (Charts compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed April 10, 2014)

In Europe, the first recorded industrial production of pan salt took place in Italy some 2,500 years ago when Ancus Martius, one of the early Roman kings, began letting seawater into an enclosed basin, then allowing the sun to evaporate the water to create a salt residue. The importance that Rome attached to the salt works and port at Ostia was such that the main highway along which the salt was carried to Rome was called the Via Salaria. Like Venice after it, the city of Rome based much of its early commerce on trading salt. Special salt ration equivalents, paid to early Roman soldiers, were known as "salarium argentum", the forerunner of the English word "salary." With a near monopoly on supply to Rome, the traders in the port of Ostia raised the salt price so high that the state was forced to take over the industry in 506 BC.

When Julius Caesar landed in Britain in 55 BC, he brought his salinators with him, but found that even the backward Britons were extracting salt by pouring brine on to hot stones. The Romans, however, used iron pans in which they boiled the brine, and Caesar established a brine-based salt works in Cheshire and subsequently in other localities. The towns in Britain where salt was made can be distinguished to this day by the termination "wich", an Anglo-Saxon descriptor for a place where salt was made and includes towns like Greenwich, Ipswich, Droitwich, Northwich and Middlewich.

Merchants in twelfth-Century Timbuktu in Africa, the gateway to the Sahara Desert and the seat of renowned scholars, valued salt as highly as books or gold. In Tibet, Marco Polo noted that tiny cakes of salt, manufactured from salt lakes in the high plains of Tibet were pressed with images of

the Grand Khan and used as coins. Salt is still carried by camel trains and still used as money among the some of the nomadic tribes of the Sahara and Ethiopia's Danakil Plains. The ancient Maya made salt at Salinas de los Nueve Cerros, Guatemala, an area where natural salt springs flowed into a river gully, giving easy trading access to downstream customers. This site was the only large-scale source of salt for the interior Lowland Maya. Maya technology included solar evaporation and firing of brine from salt springs in special large ceramic bowls that are the largest receptacles ever found in any Maya sites.

Salt's economic value meant it was taxed by governments from the ancient Chinese and Romans to late medieval Europe. In 2200 BC the Chinese Emperor Hsia Yu levied a salt tax as one of the world's first documented taxes. Mary Queen of Scots was perhaps the first European head of state to have the idea of making salt a source of governmental revenue. She granted a patent to an Italian to make salt in Scotland and then placed a heavy tax on it, which she appropriated to herself. Elizabeth, Queen of England, and Mary's lifelong "dear sister" and eventual executioner, thought this an excellent idea and likewise taxed English salt making. Salt tax was a source of great resentment to everyone, English and Scots alike, and smuggling grew to alarming proportions. In 1785, the Earl of Dundonald wrote that every year in England, 10,000 people were arrested for salt smuggling. During Queen Anne's reign, the salt tax rose to £30 a ton, an enormous amount of money in those days. The whole of England arose in rioting protest, with the result that the salt tax was finally abolished.

In Burgundy, salt was taxed at more than 100 % as it came from the salt-works. This tax was extended to the whole of France when Burgundy was absorbed and the notorious salt tax "la gabelle" became a necessary input to the government's finances. Cardinal Richelieu said that salt was as vital to France as American silver was to Spain. The repeal of the salt tax was a major goal of the revolutionaries of 1789, but Napoléon restored the salt tax to pay for his foreign wars as soon as he became Emperor and the impost continued until 1945 to feed French government coffers. It is said that income from a salt pan in southern Spain largely financed Columbus' voyages. The Erie Canal, an engineering marvel that connected the Great Lakes to New York's Hudson River in 1825, was called "the ditch that salt built" as salt taxes paid for half of the cost of construction. The "Great Hedge of India," the mid-eighteenth century colonial equivalent of the Great Wall of China, stretched 3,700 km from the western border of Punjab down to the Bay of Bengal. It was manned by 12,000 men and planted by the British to minimise salt smuggling into Bengal and enforce the collection of the Indian salt tax. As late as the 1940s, the people of India under the leadership of Mahatma Gandhi protested British taxes on salt supply. In 1930 he led a 200-mile march to the Arabian Ocean to symbolically collect untaxed salt for India's poor.

Salt, because of its value in the ancient world, still has religious significance. Ancient Greek worshippers consecrated salt in their rituals. Jewish temple offerings included salt; on the Sabbath, Jews still dip their bread in salt as a remembrance of those sacrifices. Covenants in both the Old and New Testaments were often sealed with salt, explaining the origin of the word "salvation." In the Catholic Church, salt was or is used in a variety of purifying rituals. Jesus called his disciples "the Salt of the Earth", a statement that was commemorated by the Catholic church until Vatican II, by placing a small taste of salt on a baby's lip at his or her baptism. In Leonardo Da Vinci's famous painting, "The Last Supper," Judas Escariot has just spilled a bowl of salt – a portent of evil and bad luck. In Buddhist tradition, salt repels evil spirits. That's why in some Asian cultures it can still be customary to throw salt over your shoulder before entering your house after a funeral: it scares off any evil spirits that may be clinging to your back. In 1933, the Dalai Lama was buried sitting up in a bed of salt. Shinto religion also uses salt to purify an area. Before sumo wrestlers enter the ring for a match – which is actually an elaborate Shinto rite – a handful of salt is thrown into the centre to drive off malevolent spirits. In the American Southwest, the Pueblo worship the Salt Mother. Other Native American tribes had significant restrictions on who was permitted to eat salt. Hopi legend holds that the angry Warrior Twins punished mankind by placing valuable salt deposits far from civilization, requiring hard work and bravery to harvest the precious mineral.

Today, halite is a cheaply produced commodity extracted either from mines or saltpans. In the production of table salt, processing, packaging and marketing are the major costs. An exception to the low sale price of modern salt is "Fleur de Sel de Geurande" a delicate gourmet form of white seasalt that is still hand-produced (for the correct "feel on the tongue") in the fens along the coast of Brittany. It costs ≈ US$40–50/kg and is produced by "paludiers" only on suitable summer days when halite rafts can be raked from the brine surface of specially maintained coastal salt pans, which are floored with grey clay. According to the local legend it only forms when the wind blows from the east (from the sea). It and the cheaper grey salt (sel gris), which is scraped from the pan floors and also prized by gourmands, has been produced this way since Pre-Roman times. Impurities like this clay are called grey spot or black spot in highly efficient mechanised production plants elsewhere in the world and are considered undesirable in the end product. It says something about our notions of luxury, French culinary marketing skills, and perhaps the gullibility of middle-class gourmands with too much money and time on their hands, that each year the gourmet industry successfully markets dirt-polluted variable-quality salt for top prices.

Production

The largest volumes of salt production are concentrated in 15 nations, which together produce more than 80 % of the world's total production (Fig. 12.44a). China today is the dominant salt producer, followed by the United States. In 2012, estimated salt production in China was about 70 million tonnes, or about 26 % of total world output compared to the US with 14 % of the world's production. Most countries possess some form of salt production capability, with production levels set to meet their own domestic requirements and with additional quantities available for export to other countries.

World resources of rock salt and sea salt are practically unlimited and total production levels continue to rise as the human population rises (Fig. 12.44b). The majority of usage worldwide is in the chemical industry, some 60 % of total rock salt production is processed to supply sodium and chlorine chemicals that are then used to manufacture a multiplicity of products (Kogel et al. 2006). The principal basic chemicals, chlorine and sodium hydroxide (caustic soda) are manufactured from brine via electrolysis. Sodium chloride is reacted with limestone in the Solvay process to produce sodium carbonate (soda ash), and with sulphuric acid to produce hydrochloric acid and sodium sulphate (salt cake). The chloralkali industry also uses substantial quantities of salt. Most of its output is polyvinyl chloride and vinyl chloride monomers; chlorine is another product. The second largest user of salt is mankind itself. Humans metabolise around 30 % of the total salt produced to support their physiological functions and eating habits. Salt for food is probably the most "taken for granted" commodity in the world today, available from thousands of sources in hundreds of qualities as table, cooking and industrial salt for food production. Salt usage in the northern hemisphere increases in the winter months when salt is used to de-ice frozen roadways (≈10–15 % of world annual production).

Important commercial rock salt deposits are found in the Silurian of northeastern North America; the Devonian of western Canada (also a major producer of potash); the Permian of Russia, western Europe, the midwest of North America, the Jurassic of the US Gulf Coast and the Miocene of the Middle East. In Europe and North America the salt is recovered either by hard rock mining (mostly room and pillar methods) or by solution mining. In warmer climates, such as Australia, Spain, Mexico and the inland deserts of China, large volumes of salt are recovered by solar evaporation of seawater, or less commonly of inland playa waters. The term sea salt is sometimes applied to this type of salt to distinguish it from rock salt, which tend to be mined,

The advantage of salt manufacture via large scale marine-fed solar evaporation ponds in arid coastal settings is the ability to control purity and consistency of the feedstock flowing to the processing plant, as well as the relatively low energy costs involved in sea-salt manufacture (sun and wind) compared with conventional mining techniques used to extract rock salt. Modern computer-configured and -monitored saltworks in Australia and Mexico used automated logger measurement of the salt pan climate and the state of the brines in the various pans in order to a produce a high quality, high volume, consistent NaCl feedstock. These high volume industrial sea-salt plants in Mexico and Australia supply a consistently high volume, high quality, low-impurity product to the world's chemicals industries. Smaller "cottage-industry" pans or saltworks are commonplace around the world, but with lesser quality monitoring, they tend to produce a range of lower volume and lower quality salts.

Climate distributions plotted against annual production of coastal solar saltworks suggests a relatively narrow climatic range for the more efficient high-volume producers. The majority of the high volume saltworks (with annual production more than 1–2 million tonnes) are located in arid coastal climates typified by hot arid desert (BWh) or hot arid steppe (BSh) zones (Table 12.11, Figs. 12.45 and 12.46).

The largest and most efficient producers of seasalt are located in the BWh climate zones of Mexico and NW Australia, and significant cumulative production also comes from numerous but smaller coastal salt farms in BSh zones along the Gujarat coast of India (Fig. 12.45). In the past, much of the Indian coastal salt production on the Gujarat coast and in southern India has been a village industry, with little control on overall quality or volume of output. That is changing, but not without local political implications, as the Indian salt industry moves toward larger more efficient pans and less labour intensive modes of harvesting.

Outside of these three main regions of high volume production, there are other salt plants with significant annual production volumes, also located in hot coastal desert steppe settings (BSh), as in the Macau region of coastal Brazil and Shark Bay, Australia (Fig. 12.46; illustrates regions with $>10^6$ tonne/year production, the background zone with these higher production volumes is shaded brown in the figure). Unlike the cooler climates of the suprasealevel nonmarine evaporites (that constitutes the natural sources of saline borates, soda ash and salt cake), the cooler arid coastal climates (BWk and BSk) do not host the huge production volumes that are accomplished in the hot arid coastal deserts and steppes. Even so, locally some large volumes are possible in somewhat cooler coastal climes, as in the Cabo del Gata plant (BSk) in the Almeiria region of Spain (Table 12.11). The Morton Saltworks on Great Inagua Island (Aw) with annual production near 1 million tonnes is the largest producer in an oceanic seasonal semiarid climate zone that typifies the south Caribbean and the Netherland Antilles.

Any salt harvest in a cooler BSk or Cs coastal climate is more subject to vagaries in meteoric inflow volumes and

Table 12.11 A list of active halite production facilities in sea-fed anthropogenic salt pans tied to Köppen climate at the site and its annual production (tonne/year)

Key	Name	Country	Köppen	Annual production (tonnes)

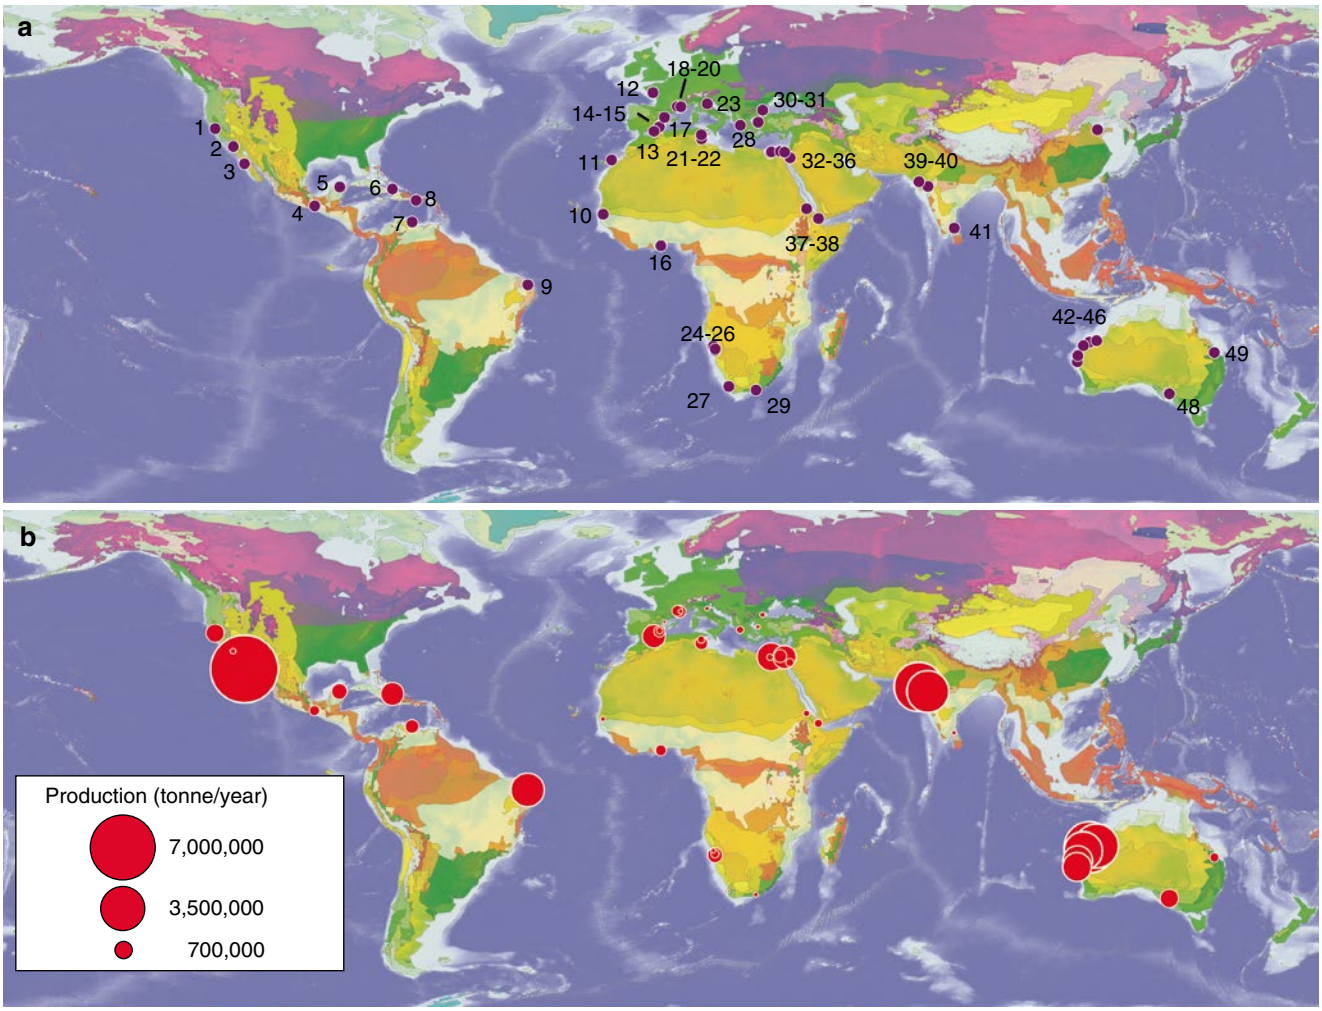

Fig. 12.45 Anthropogenic seawater-fed coastal salt pans. (a) Locations of salt pans, numbers refer to key code listed into Table 12.11. (**b**) Annual production of salt (NaCl) at various sites, as listed in Table 12.11. Base is colour-coded Köppen zones. Data extracted and replotted from SaltWork database, version 1.7, with permission

lower evaporation rates, so many of the viable saltworks in these somewhat cooler moister coastal climates are compensated by proximity to markets. For a transport-cost controlled product these lower-volume manufacturing facilities can be economic, even though they must deal with a more impure product and a longer time to harvesting.

Usually, there are semipermanent dm-cm thick natural salt crusts along BWh coastal regions in regions of low permeability seepage mudflat sumps areas outside the landscaped anthropogenic pans. These coastal sabkha crusts remain until waters from an occasional cyclone or hurricane passing over the area supplies enough surface runoff to dissolve the surface salt, including potential harvest salt in the nearby crystallizers. After the flood, this dissolved halite then reprecipitates a few months later. In contrast, in milder and moister BSk and Cs regions, any remnant halite in a crystallizer after a salt harvest, along with any natural salt efflorescences covering mudflats outside the crystallizer pans, dissolve each year with the onset of seasonal rain and will not reform until the next dry season.

Time to harvest from first inflow lagoons (pre-concentrators) to crystallizer pans gets longer as the climate gets milder. For example, in the solar saltworks that operated in South San Francisco Bay (Csb) it took 5 years to move seawater from the initial concentrator lagoons to the final crystallizers. In the BWh settings of Mexico and NW Australia it takes less than a year. Longer residence times can detrimentally affect the quality and volume of the halite product and salt from these plants typically has higher levels of impurities. As coastal climates where salt is manufactured get cooler and wetter it may require more expensive artificial means (e.g. fans, lifting pumps and cyclonic dryers) to maintain conditions suitable for salt precipitation (Fig. 12.45b).

This is why older and climatically less efficient salt plants in the northern Mediterranean and southern France cannot compete with the chemical quality (consistent product purity)

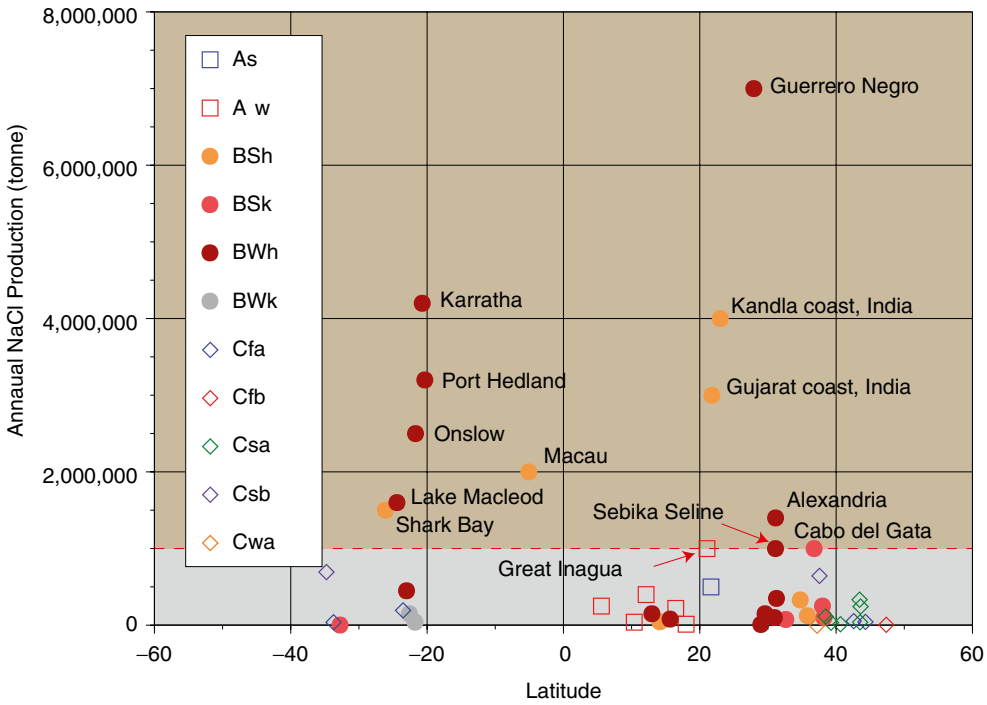

Fig. 12.46 Annual production versus latitude and Köppen climate setting of anthropogenic seawater-fed salt works listed in Table 12.11 and illustrated in Fig. 12.45

of the industrial product maintained by high volume suppliers of NaCl in the BWh climate belts. Many of the NaCl manufacturers in solar saltworks, based in small coastal pans in less climatically efficient areas, today emphasize their "green" and "buy local" credentials. Their inflow concentrator lagoons are mostly monitored wildlife sanctuaries in part to maintain subsidies and other governmental support. In some regions of Europe the remaining local salt industry maintain an even more labour-intensive high-value cottage-industry with a specialised consumer-quality image for their sea salt manufacture (paludiers). As mentioned earlier, annually they harvest small volumes of high-value gourmet salt for specialized use in the food industry (marketed as flaked salt, grey salt and Fleur del Sel). Chemically these products are less pure than that of the larger volume industrial manufacturers, but to a gourmand a little clay in the final product and a variable crystal size, with many of the larger halite hopper rafts preserved, gives it "on-the-tongue character" for which they are more than happy to pay a premium price.

Worldwide, all the high volume saltworks with annual production of more than a million tonnes/year are located on coasts in the Trade Wind belts, which are latitudinally-limited arid regions beneath bands of cool dry descending air in the subtropical arms of Hadley cells. Such regions sit on either side of the equatorial divergence as two BW climate bands, meandering along in two subparallel arid belts centred on regions some 20–35° north and south of the equator (Fig. 12.46; see also Chap. 2).

Today, there is only one high volume solar seasalt producer (output more than 1,500,000 tonnes/year) located outside the Trade Wind belt. It is centred on the Salinor saltworks in the Nordeste region near Macau, on the coast of NE Brazil and is only some 5° south of the equator, but is located in a local BSh setting (Fig. 12.46). There is another even hotter and drier anomalous coastal zone (BWh) outside the Trade Wind belt at 6°S south of the Equator on the coast of the Sechura Desert of NE Venezuela. There the Bayovar solar brine plant is in the early stages of construction and pilot solar plants have already recovered sylvite and carnallite from pans that focused and ponded shallow mudflat brines. Both the Bayovar and Macau regions are considered anomalous in terms of a north-to-south latitudinal zonation in the earth's broad scale climate zones. The Nordeste region, with its relatively high population density, has been classified as an El Niño "hotspot" in that drought stress is an ongoing climate hazard.

Both regions are arid responses to seasonal changes in oceanic circulation interacting with onshore climate. In either region the precise causes driving aridity are not fully understood, like much of our understanding of the controls on long and short term variations in the world's climate. Aridity in the Nordeste region involves the seasonally changing position of the subtropical high-pressure system over the Atlantic Ocean, the position of the advance and retreat of the intertropical convergence zone or ITC (hence the El Niño designation of the Nordeste climate hazard, even though it is on the Atlantic Ocean – Oliver 2005, p. 678) and the interaction of air circulation patterns with local topography. Causes of aridity over the Bayovar region are equally problematic. The location is such that onshore trade winds, local

mountains, and the anticipated presence of the ITC should provide copious rainfall, but it does not. In spring (the driest season) a deep easterly air flow prevails with a divergence up to at least 2,000 m elevation to give rise to subsidence of a dry air mass. In summer the ITC is absent and the subsidence continues, although not as severe as in the spring, and some rain can fall (Oliver 2005). Winter, like autumn can be somewhat moister in the Bayovar region, but subsidence still continues to minimize the influx of moisture-carrying air from the oceanic side, hence the formation of the Sechura Desert.

Reasons for the tie between large volumes of bedded seasalt production and hot arid coastal desert climates in both natural and anthropogenic marine fed saltworks are axiomatic (Table 12.11 and Fig. 12.46). The corollaries are also of geological interest. By definition, a marine seepage system has continual access to a huge isochemical brine reservoir (the sea). But water cannot flow uphill, so providing a linking aquifer exists to a closed subsealevel natural coastal depression (coastal salina) (or in the case of anthropogenic salt pans a pumping station to pump seawater uphill into the pans), then the water supply to a marine-fed hydrology is not a limiting factor. Seepage resupply continues until the coastal inflow system attains a sediment level and a natural hydrological equilibrium where inflow = outflow, as in modern Lake Macleod, which is the largest natural halite-filled coastal salina in the world, there the natural sediment surface has stabilised at around 0.5–1 m below mean sea level.

Interestingly, Quaternary continental salt sumps are five to ten times larger in area and the salt volumes much greater than Quaternary coastal systems (Chap. 5). Also, unlike coastal anthropogenic and natural halite-filled salinas that accumulate the greatest salt volumes in hot arid coastal deserts (BWh), our most voluminous natural lacustrine examples accumulating bedded salts are located in high-altitude high-relief, steppe climates (BSk), such as Salar di Atacama and Salar di Uyuni. Large volumes of halite and other salts do not accumulate in hot arid continental-interior deserts (BWh). This is because in terrestrial BSk sump settings, the ponded moisture input levels are higher than in terrestrial BWh settings, evaporation rates are less and at- or near-surface residence times of saturated brines are longer. Hence, no marine-fed modern natural coastal salina or a continental interior saline lacustrine system can offer a same-scale analog to the inflow hydrology of an ancient marine seepage-fed evaporite drawdown basin (Chap. 5 – basinwide and saltern systems).

Lithium and $CaCl_2$ Brines, Iodine and Bromine

So far we have considered salt resources as dominantly solid salt systems where targeted beds (various borates, $NaSO_4$ and Na_2CO_3 salts) are present, while their interstitial brines are saturated with the same set of ions. Production is both by extraction of the solid product (ore) and/or the extraction and processing of associated interstitial brines to produce the targeted salts. But there is another group of subsurface-derived saline products where, due to high levels of the targeted cations in the hypersaline interstitial waters, the targeted element or its salts, can be extracted from the processed brine, even though no solid salt of the targeted product is present in the ore horizon. These targeted products are lithium carbonate and calcium chloride brines, iodine and bromine. Figure 12.47 plots distribution of current and future resources for lithium and calcium chloride brines.

Lithium Brines

Historically, until the electronic revolution, lithium located near the top of the periodic table, was of little economic interest. With an atomic number of 3 and a atomic weight of 6.9, lithium is exceptionally small and light, with a high charge/radius ratio. Lithium compounds are consumed in the production of ceramics, lubricants, glass, and primary aluminium (Fig. 12.48). Its high specific heat capacity and high electrochemical potential, make lithium ideal in heat transfer technology where it is used in welding and metallurgical applications. High electrochemical potential and light weight make it amenable to battery applications. Compared to nickel metal hydride batteries, the type of battery currently powering most hybrid electric vehicles, Li-ion batteries are lighter, less bulky, and more energy efficient. Lithium batteries have three times the energy of nickel hydride at one-third of the weight, and they operate at very low temperatures with a longer battery life. Growing use of lithium in batteries for electric vehicles is expected to make this usage the main market for lithium in the twenty-first century (Kesler et al. 2012; Grosjean et al. 2012).

Production

Lithium occurs in more than 140 minerals, with conventionally mined production of lithium ore concentrates mostly from nonevaporitic spodumene ($LiAlSi_2O_6$) and petalite ($LiAlSi_4O_{10}$) in pegmatites. Currently, there is no known economic process for extracting lithium from lithium-bearing clays, but if the technology develops these too may be future conventional mining targets. The breadth of mineral occurrences of lithium is seen in the etymological derivation of lithium. It comes from lithos (Greek for stone) and -ium referring to the fact that this element was first found in minerals, while its cognates sodium and potassium were first found in plant ashes (Senning 2007). Three major lithium miners supply the majority of worldwide demand for solid lithium ore concentrates (Table 12.12). They are; Sons of Gwalia in Australia (largest), Tanco in Canada, and Bikita

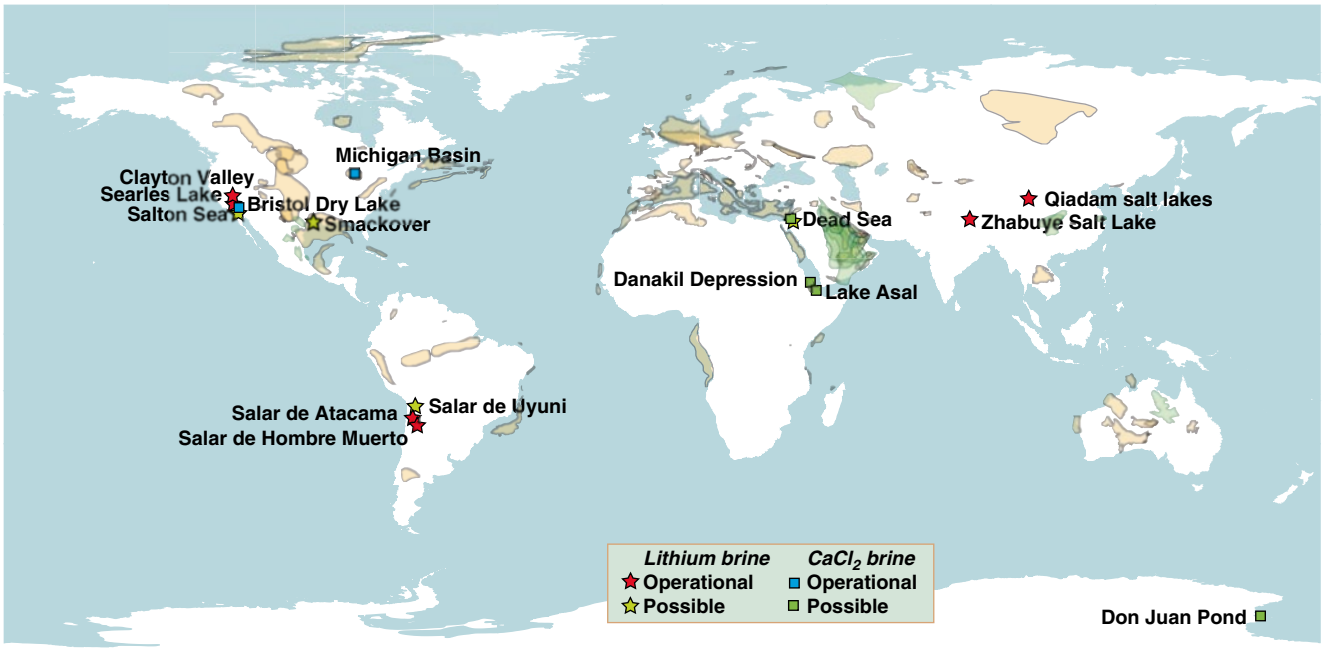

Fig. 12.47 Lithium and $CaCl_2$ brine occurrences. Red stars indicate operations that are extracting (or have extracted) lithium brines in a saline setting. Green stars indicate locations of possible future lithium brine resources. Blue square indicates an active $CaCl_2$ brine operation, *green squares* indicate other sites of $CaCl_2$ that may be a future possible $CaCl_2$ brine resource. The *brown and green shaded zones* indicate the positions of ancient marine halite and sulphate basins, respectively (See Tables 12.12, 12.13 and 12.14 for occurrence details)

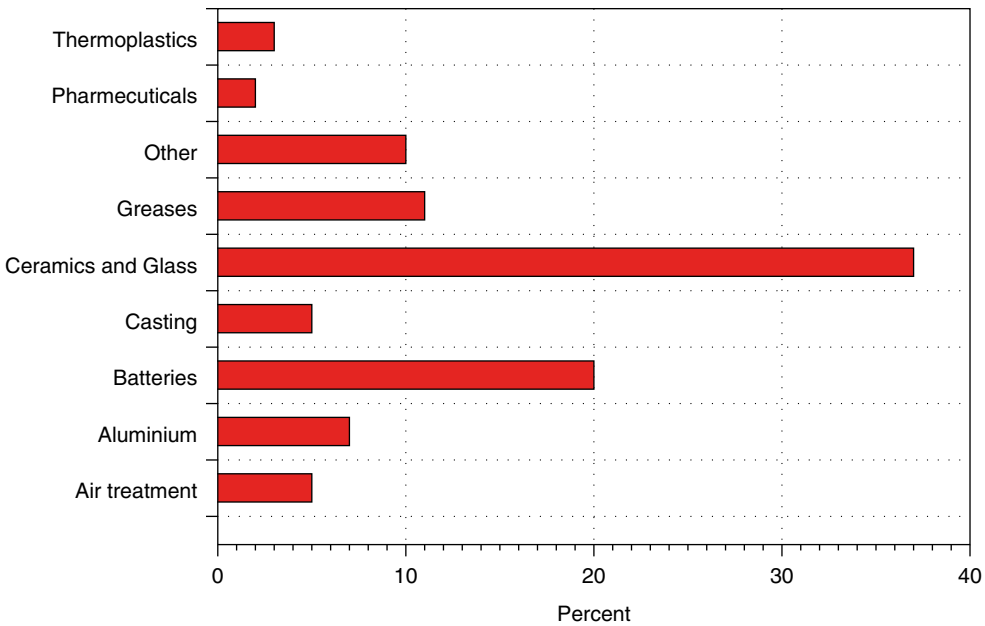
Fig. 12.48 Current lithium uses



Minerals in Zimbabwe, with combined production form these sources in 2010 at more than 350,000 t.

To produce lithium carbonate from spodumene, the material is pulverized, calcined at 1,100 °C, treated with sulphuric acid, dissolved in water, separated from aluminium, and precipitated with soda ash. Energy expended in the heating and dissolution required in this processing stream make it more expensive compared to lithium brine processing. However, this cost differential is somewhat ameliorated by the higher concentration of lithium in pegmatites compared to brines.

In his 1992 book "La Industria del Litio en Chile," P. Pavlovic estimated the cost to produce a kilogram of Li_2CO_3 from Bessemer City spodumene pegmatite (North

Carolina), hectorite-hosted Silver Peak brine (Nevada) and Salar de Atacama halite-hosted brine (Chile) as US$2.45, $1.65 and $1.10, respectively. Today, the even higher costs of energy compared to solar evaporation make it relatively much more expensive to process spodumene. But, compared to suitable rock (spodumene) sources, the distribution of known suitable lithium-entraining brine lakes is limited. In addition, the future exploitation of solid versus liquid sources will depend on the world's need for lithium batteries, versus conventional hydrocarbon-derived energy. Likely, the known pegmatite sources will continue to be exploited for the foreseeable future and a number of the larger solid ore deposits, compared to brine sources, are located in regions that are less susceptible to issues of sovereign risk (Kesler et al. 2012).

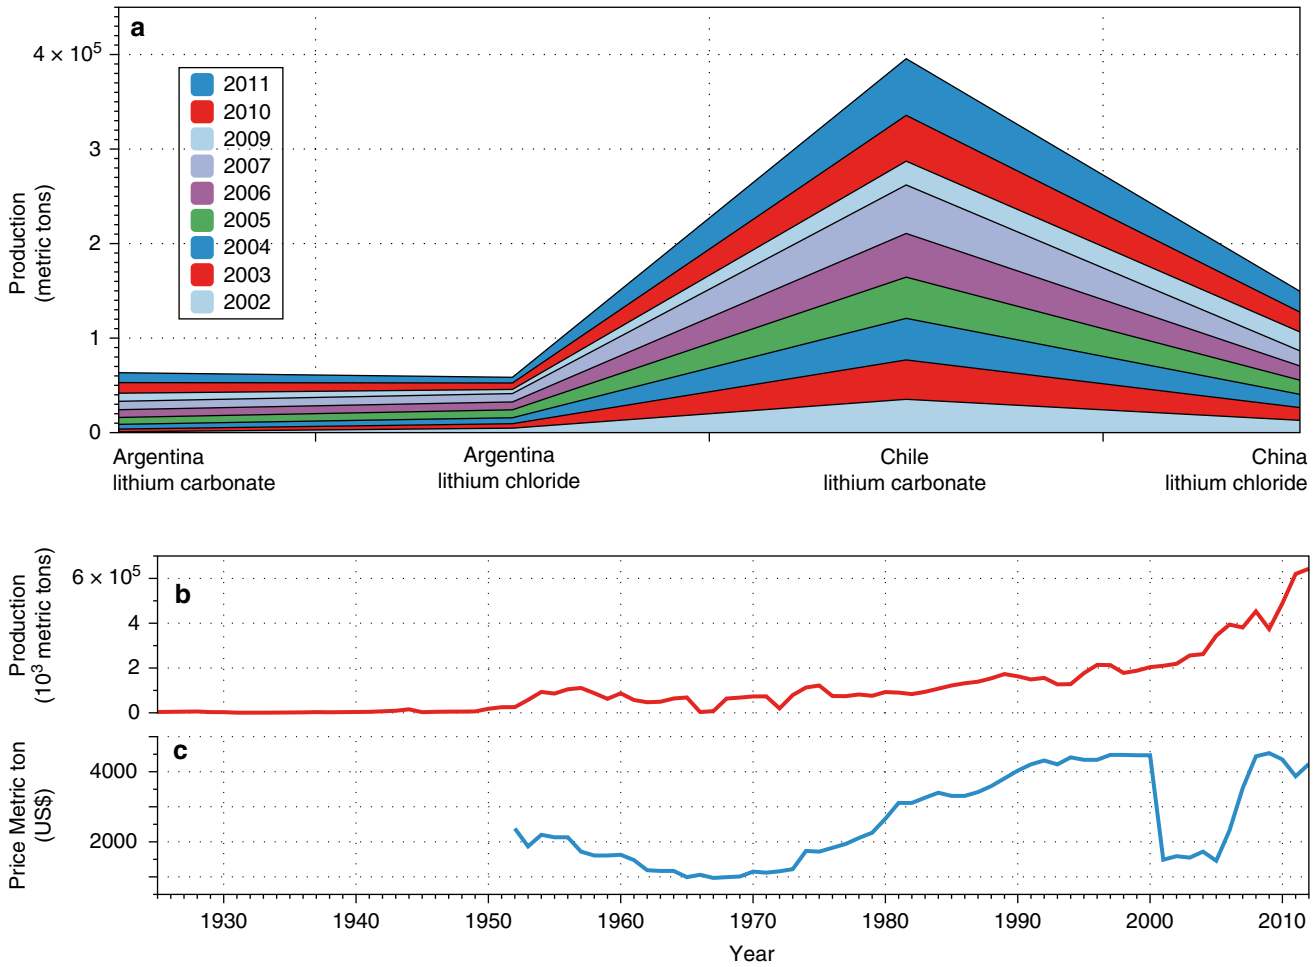

Fig. 12.49 Lithium brine production. (**a**) Cumulative area plot of annual production of lithium salts from brine producing countries in metric tons. USA also produces lithium from brine, but figures not made public, they are less than other countries listed. (**b**) World production from 1925 to 2011 (metric tons, includes both brine and spodumene sources), (**c**) Price per metric ton in US dollars from 1954 to 2010 (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed April 28, 2014)

The price of lithium carbonate (in adjusted or relative dollars) steadily declined from 1954 to 1998, as new South American production began at Atacama in 1984 and Hombre Muerto, Argentina, in 1997. Beginning in 2003, the price of lithium carbonate (in relative dollars) increased until 2008 (Gruber et al. 2011). In 2009, however, the price of lithium carbonate decreased by 25 %, likely due to decreasing demand and possibly due to SQM's September announcement that it would reduce the price of lithium by 20 %.

Cheaper prices and abundant supply in the previous decade meant there was a move away from ore to brine as the major source of lithium. Today, Chilean and Argentinian salars, along with Chinese (Tibetan) salt lakes are the dominant brine sources, with significant brine reserves in Salar de Atacama (Figs. 12.49a–c and 12.50a, b; Tables 12.12 and 12.13). Today there are substantial lithium carbonate brine operations in Salar de Atacama, Chile and Salar del Hombre Muerto, Argentina, and Dabuxum Salt Lake in China, along with smaller volumes recovered from multicomponent brine operations in Searles Lake, California, and Clayton Valley, Nevada (Figs. 12.49 and 12.50). Salar operations in South America can now produce lithium throughout the year, whereas historically the brine extraction operations were seasonal and subject to downtime related to periodic salar floods.

The highly competitive nature of the current supply market makes some published lithium figures suspect. It is a market where availability of known reserves exceeds projected needs by a ratio of more than 2:1 and lithium carbonate from brine is perhaps now supplying as much as 60–80 % of the world's needs. A ready cheap supply of lithium from brine operations led to a fall in the real price of lithium by up to 50 % in the late 1990s. Increasing use in battery manufacture accounts for much of the price recovery since the mid 2000s (Fig. 12.49b, c). Even so, the market today is still highly competitive with some more expensive spodumene operations and low capacity brine operations closing each year. United

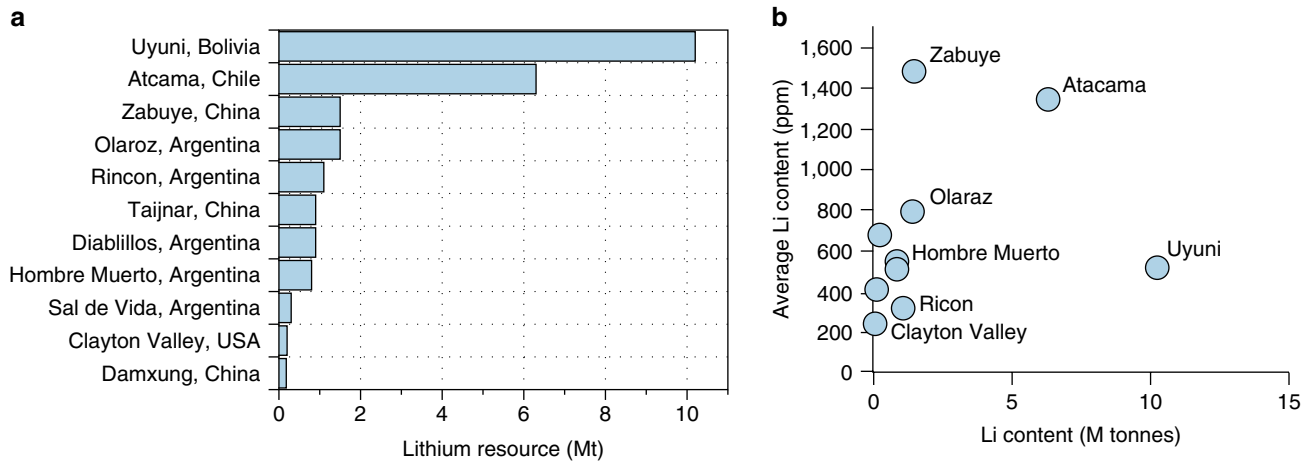

Fig. 12.50 Lithium resource. (**a**) Estimated lithium resources (Mt Li) for brine deposits. (**b**) Average lithium concentration vs. lithium content (endowment) for brine deposits based on Kesler et al. (2012)

Table 12.13 Lithium-enriched brine occurrences, mostly in Quaternary saline settings (many lithium-rich brine occurrences are closely association with saline borate deposits, as listed in Table 12.4)

Location, Country (area)	Elev. (msl)	Köppen	Comments
Salar de Hombre Muerto, Argentina (565 km^2)	4,300	ET	Lithium carbonate brine processing; Rather than solar evaporation, FMC use a proprietary alumina adsorption system to directly extract lithium from the salar brine. Nodular ulexite is commonplace on the salar and in shallow subsurface. A porous halite bed (15 % Ø) some 40–50 m thick extends across much of the salar. Pore brines are principally sourced from lithium-containing hot springs and seeps, fed by groundwaters that leached surrounding volcaniclastics. Average Li levels in the brine ≈520 ppm. Brine in the salar is usually within 20 cm of the salar surface, and appears to be relatively constant in composition to depths of at least 15 m. (Vinante and Alonso 2006; Godfrey et al. 2013)
Salar de Uyuni, Bolivia (9,654 km^2)	3,650	BWk	Planned lithium carbonate brine processing facility. Typical sediment thickness is 121 m, made up of 11 variably porous (0–30 % Ø) halite beds separated by layers of mud and sand. Ulexite is present. The upper halite bed is porous and is the currently targeted bed, it is around 11 m thick across much of the salar. Brine is always within 5–20 cm of the surface and contains 80–1,150 ppm of lithium, averaging 321 ppm Li; a limited area in the southeast corner averages 625 ppm. Pore brines are principally sourced from lithium-containing hot springs and seeps. Mg/Li ratios are three times that in Salar de Atacama making Li extraction much more difficult. A similar processing problem occurs at the nearby Salar de Rincon, where Admiralty Resources plan to pretreat the raw brine with calcium hydroxide to reduce the magnesium content before pan evaporation commences. Compared to Atacama and de Hombre Muerto, the lesser thickness of porous halite (11 m versus 35 m), the lower Li, and higher Mg content in the brines have made this salar a less attractive resource. (Risacher and Fritz 2000; Ericksen et al. 1978; Risacher et al. 2003)
Salar de Atacama, Chile (3,065 km^2)	2,250	BWk	Lithium carbonate extraction via solar concentration of extracted and ponded salar brine. Sediment fill thickness is more than 950 m of intercalated halite and lacustrine muds. Nearsurface salt unit is very porous (30, 20, 15 and 5 % at 0–0.5, 0.5–2, 2–25 and 25 m depth, respectively; average of 18 % in upper 25 m), and brine-filled from about 0.6–35 m. The porosity decreases rapidly to nearly zero after about 35–40 m depth. The brine is saturated with halite, and contains variable concentrations of lithium, potassium, magnesium, sulphate and borate in different locations in the Salar; Lithium concentration varies from about 1,000–4,000 ppm, and averages over 1,500 ppm for the two commercial lithium operations on the Salar. SQM's production costs estimated $1,260 per ton of lithium carbonate, historically it has sold that ton for up to $12,000. Unusual compared with other Puna salars as it contains no borate beds. (Boschetti et al. 2007; Risacher et al. 2003).

Table 12.13 (continued)

Location, Country (area)	Elev. (msl)	Köppen	Comments
Zabuye (Chabyer) Salt Lake, western Tibet, China (251 km^2)	4,426	Dwc	Currently under expansion, a 5,000 tpy $LiCO_3$ plant began operations in 2005. Complex perennial brine; Li from 500 to 1,000 ppm, the lake centre brine is saturated with both halite and potassium sulphate, during solar evaporation lithium starts to crystallize around two-fold concentration. Unique saline lacustrine system in that $LiCO_3$ is a natural precipitate about lake strandzone. (Zheng and Liu 2009; Nie et al. 2009)
Dabuxum/East Taijinaier Lakes, China (350 km^2)	3,200	Dwc	Potash brine operation via extraction and solar concentration since mid 1980s, a 35,000 tpy $LiCO_3$ plant began operations at Golmud in 2007, but will not reach full capacity for a number of years. A 8–13 ppm Li brine is pumped into solar evaporation ponds where the final potash end-liquors (carnallite) contain around 120 ppm Li. (see text and Yu et al. 2013)
Dead Sea, Israel, Jordan (1,023 km^2)	−415	BSh	Possible future resource. The $MgCl_2$-rich lake brine is currently pumped into large solar ponds to produce potash (carnallite) and magnesia in both Israel and Jordan (Mg and Br as byproducts). Pond end-liquors contain about 30 ppm Li, but high Mg content make Li extraction problematic. (Garrett 2004)
Clayton Valley Playa, Nevada, USA	1,300	BWk	Lithium carbonate operation started in 1966 (then Li in brine was 360–400 ppm, today ≈230 ppm). Brine level (WT) was sometimes as low as 15–76 m beneath the playa floor. Brine wells were pumped into solar ponds where Li concentration reached 5,000 ppm, then sent to Li recovery plant. Current lower Li levels make this operation unattractive compared to South American salars. Hectorite clays ($Na_{0.33}(Mg,Li)_3Si_4O_{10}(F,OH)_{2)}$ found in playa formed by interaction of playa brine with smectitic clays (Davis et al. 1986)
Great Salt Lake, USA (4,998 km^2)	1,280	Cfa	Possible future resource. The lake brine Li concentration varies widely with the climate cycle, the southern brine contains up to 18 to 43 ppm Li, and the northern brine from 40 to 64 ppm Li. The commercial magnesium plant's solar pond end-liquor often contains about 600 ppm Li, while the potassium sulphate plant has achieved values of 700–1,600 ppm Li, but high Mg content make Li concentration and extraction problematic from either brine source. (Garrett 2004)
Searles Lake, USA (100 km^2)	490	BWk	Lithium carbonate manufacture as byproduct from salt-cake and soda-ash processing via brine extraction from two porous halite layers and subsequent solar concentration. Li plant operated from 1951 to 1978. In the central section of the lake the brine contained an average of 50–80 ppm Li, which graded to 10–70 ppm Li near the lake edges. The high salinity brine resource beneath the lake is now largely depleted, Li content is probably too low and volumes too small to make this a viable future $LiCO_3$ resource. (Garrett 2004)
Salton Sea, USA	−70	BWh	Possible future resource, situated in a very large geothermal brine field hosted in porous saline sediments at a depth of about 500–3,000 m. Brine is a hot (100–400 °C) NaCl solution carrying elevated levels of metals, including from 100 to 400 ppm Li (200 ppm average). Many difficulties to be overcome in terms of rigid environmental restraints, elevated Mg and other metal content in the concentrated brines and land access needed to construct solar evaporators. (McKibben et al. 1987; Garrett 2004)
Smackover oilfield brines, Arkansas, USA	–	–	Possible future resource, Smackover reservoirs in both Texas and Arkansas have Li content of 50–572 ppm, in one zone in Texas the brine averages 386 ppm Li, while Arkansas a brine averages 365 ppm. Brines occur at 1,800–4,800 m depth and are currently commercially processed to extract bromine before re-injection (these brines currently account for 40 % of world Br production). (Garrett 2004)

For additional overviews see Garrett (2004), Kunasz (2006) and Kogel et al. (2006)

States production from brine was surpassed in 1998 by Chile and today only one lithium carbonate focused brine operation is still active in the USA. The United States remains the world's largest consumer of lithium.

Production from pore brines in South American salars dominates current world lithium brine production, with Chile and Argentina producing some two-thirds of the documented brine production (Figs. 12.48a and 12.49a, b). Most lithium

Table 12.14 Lithium contents of some salar and playa brines

Location	Country	Lithium (ppm)	Reference
Salar de Atacama	Chile	1,000–7,000	Risacher and Alonso (1996)
Salar del Hombre Muerto	Argentina	100–700	Saller and O'Driscoll (2000)
Salar de Uyuni	Bolivia	100–500	Risacher and Fritz (2000)
Lake Zabuye	Tibet	700–1,000	Chen (1986)
Clayton Playa, Nevada	USA	100–300	Davis et al. (1986)
Searles Lake, Ca	USA	70	Kunasz (1983)
Great Salt Lake, Utah	USA	30–60	Kunasz (1983)
Qinghai Lake	China	100	Kunasz (1983)

salts are highly soluble in natural brines and tend stay in solution although some can be to be absorbed on playa clays, as in the hectorite beds in Clayton Playa, Nevada. Interestingly, lithium carbonate (zabuyelite) is a natural precipitate from the high-altitude hypersaline waters of Lake Zabuye in Tibet.

Geological Setting of Li Brines

Only the geology of the brine sources and associated saline sediment host is discussed in detail in this section, the interested reader is referred to Garrett (2004), and Kesler et al.(2012) for a full discussion of all lithium raw materials. Subsurface lithium in playa sediments typically occurs either as a brine component (Tables 12.13 and 12.14; Fig. 12.50) or as lithium bearing minerals in saline clays such as hectorite [$Na_{0.33}(Mg,Li)_3Si_4O_{10}(F,OH)_2$] a clay mineral of the smectite group where the replacement of aluminium by lithium and magnesium is essentially complete or jadarite [$LiNaB_3SiO_7(OH)$], a newly recognized mineral with up to 5.7 % Li and 14.7 % B. Jadarite[6] is associated with borate salts such as colemanite in the Oligocene-Pliocene host lacustrine sediments in its type area in the Jadar Valley in Serbia (Stanley 2007). Hectorite is probably associated with crossflows of moderate salinity hydrothermal waters, while jadarite requires hypersaline hydrothermal waters to form. To date an economic technology for extracting lithium from saline clays, rather than brine, is yet to be developed.

Hectorite is still mined periodically (not as a lithium source) in its type area, near Hector, California. It has a soft, greasy texture, a candlewax-like appearance and feels like modelling clay when squeezed between the fingers. As a colloid, hectorite's unique thixotropic properties for emulsion stabilizing, gelling, suspending, binding, bodying and disintegrating, means it sells for more than US$2,000 a ton. Associated authigenic clays include stevensite and saponite and in its type area it lies adjacent to a colemanite deposit. Hecorite, along with associated authigenic clays and zeolites, is the diagenetic result of alkaline brines flushing highly labile volcaniclastic playa sediments. A similar moat/fault genesis explains the lithium-rich hectorite clays in King Valley, Nevada. There, layers of hectorite occur in a sequence of sedimentary and tuffaceous rocks in moat sediments along the western side of the McDermitt caldera (Kesler et al. 2012). As in the type area in California, hectorite is the main clay mineral in a sequence of altered volcanic ash beds that are interbedded with lake sediments and travertines, along an 8 km fault zone. King Valley hectorite again formed through hydrothermal alteration of volcanic ash by moderately saline hydrothermal fluids moving up fault zone. None of the clay-bound lithium occurrences are currently exploited as a lithium source.

Lithium in Andean Salars

The situation is very different with respect to lithium-entraining saline lacustrine pore brines. In the last two decades Chile has emerged as the most important lithium carbonate producer from a lake brine, largely through the exploitation of Salar de Atacama, Chile (Figs. 12.51 and 12.52) followed by China with operations focused in the Qaidam Basin. Salar de Atacama lies on the Tropic of Capricorn at an altitude of 2,300 m in the Desierto de Atacama, some 200 km inland from Antofagasto. In its more central portions this salt-encrusted playa contains a massive halite unit (nucleus) that is more than 900 m thick, with an area ≈1,100 km^2. Fringing saline muds, with an area ≈2,000 km^2, surround the nucleus (Fig. 12.51a, b).

The current salt crust atop this halite nucleus contains a sodium chloride interstitial brine that is rich in Mg, K, Li, and B (Alonso and Risacher 1996). Lithium contents of the pore brines range from 200 to 300 ppm in the marginal zone, some 500–1,600 ppm in the intermediate zone and 1,510–6,400 ppm in the salt nucleus (Fig. 12.51c). The nucleus zone averages 4,000 ppm lithium and is asymmetric with respect to the salar center due to the sump offset via ongoing faulting (Chap. 3). Main inflows to the salar

[6]Jadarite was discovered by Rio Tinto in November 2006, in drill core from the Jadar Valley, Serbia. Jadarite's chemical formula is very close to the formula ("sodium lithium boron silicate hydroxide with fluorine") invented for the fictional substance kryptonite in the 2006 film *Superman Returns*, although jadarite lacks fluorine and is white not green. This coincidence in chemistry attracted significant mass-media attention, following its discovery.

drain volcanic formations of the Andean Highlands located to the east of the basin. Salts dissolved in inflow waters have a double origin. Weathering of volcanic rocks supplies K, Li, Mg, B and, to a lesser extent, Na and Ca. Leaching of ancient halokinetic evaporites sourced in a mother salt layer beneath the volcanic formations provides additional amounts of Na, Ca, Cl, SO_4 to the most saline inflow waters. The mass-balance of the upper halite nucleus in the salar shows a strong excess of NaCl with respect to the bittern solutes Mg, K, Li, B. According to Alonso and Risacher (1996) this suggests that the nucleus did not originate from evaporation of inflow waters similar to the present groundwaters. Rather the excess of NaCl is due to NaCl-rich inflow waters that formerly drained the Cordillera de la Sal, a Tertiary-age evaporitic ridge along the western rim of the present-day salar.

Although annual salt accreation rates in the nucleus facies can be as high as 5–6 cm/year (Ruch et al. 2012), the average sedimentation rate of halite in the lake centre is ≈0.1 mm/year, based on the age of an ignimbrite interbedded with the salt. This slow aggradation rate implies a climatic setting of long dry periods and inactivity alternating with short wet periods during which large amounts of water, and so large amounts of salt, accumulated in the basin centre. The lack of peripheral lacustrine deposits and the high purity of the salt also suggest that the main salt unit is not the remnant of an ancient deep saline lake, but originated mostly from evaporation of waters supplied by subsurface and subterranean saline seeps.

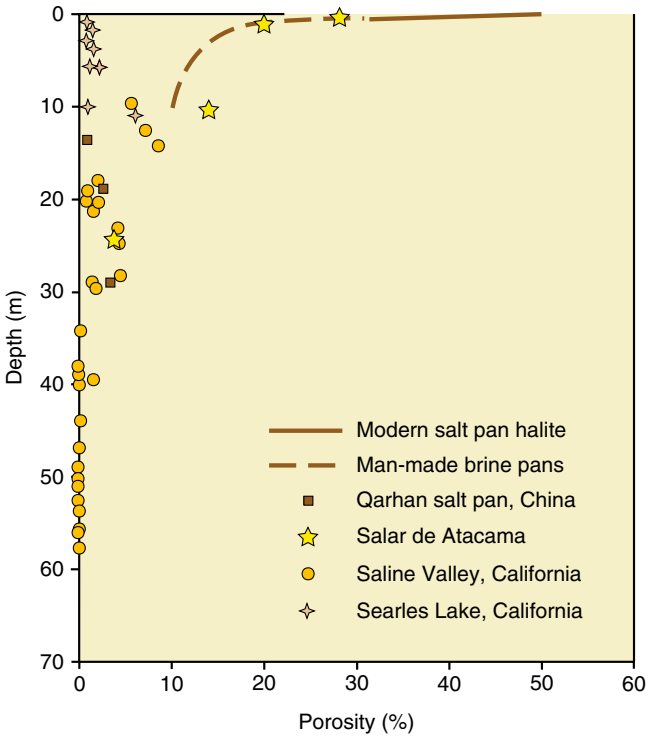

Fig. 12.53 Porosity loss with depth in bedded halite from saline pan and salar deposits (In part after Casas and Lowenstein 1989)

Brines are pumped from 30 m deep boreholes in the salt nucleus into solar evaporation ponds. In the ponds the liquours are concentrated by a factor of 25, generating a final brine strength of 4.3 % Li. During evaporation processing and the production of potassium chloride and potassium sulphate the ion ratios are constantly monitored and adjusted to avoid the precipitation of lithium potassium sulphate. When soda ash (sodium carbonate) is added to the concentrated brines, lithium carbonate drops out (Fig. 12.55c). The high initial lithium content of the Atacama brines and the extremely arid setting (3,200 mm pan evaporation and <15 mm precipitation) means that only 90 ha of evaporation ponds are required for one of the current brine operations on the salar, this is only 5 % of the area required at Clayton Valley, Nevada (Fig. 12.52a). Borate (as perborate) is recovered at levels of 0.84 g/l during lithium extraction. Increasing volumes of lithium are also produced by new salar brine processing facilities in Salar de Hombre Muerto, Argentina and Salar de Uyuni, Bolivia. In Lake Zabuye, China, the seasonal cooling of lithium-rich lake brines leads to the natural precipitation of lithium carbonate (Fig. 12.55d).

Porosity levels in a host halite aquifer are a major constraint on potential economics of any salar or salt lake lithium brine resource. Most halite units lose their effective porosity and permeability by depths of 50–60 m (Fig. 12.53). Thus, most Quaternary lithium brine operations hosted in a halite bed/aquifer will have an economic basement to brine recovery at around this depth. It is unlikely that recovery operations in Salar de Atacama and planned projects in Salar de Uyuni can recover economic brine volumes at much greater depths. There may be a 900 m thick halite-dominant succession infilling Salar de Atacama and a number of halite beds to a depth of 120 m in Salar de Uyuni, but economic porosities in the halite will likely only be present in the upper portions of the halite fill in both salars.

Postulating likely lithium resources, in a salar of a salt lake, to depths greater than 50–60 m should only be done after salar-hydrology-aware drilling has established the presence of economic permeabilities in the hosting halite aquifer and this is likely related to the presence of active faults (see below). Such measurements require drilling and sampling equipment that facilitate reliable "in-situ" determinations of porosity and permeability in the halite mass and Li measurements in the brine that are related to actual content at the level of measurement, with minimal contamination by waters from outside the measured horizon.

Clayton Valley, Nevada

Lithium carbonate is still produced from playa brines in Searles Lake, California and Clayton Valley (Silver Peak playa), Nevada. Historically, the Clayton Valley playa produced about one-third of the US lithium requirements, but its economic viability is now suffering from fierce market competition and a largely depleted brine supply. Originally, the central valley area contained 100–800 ppm Li, and the discovery well at 229 m depth contained 678 ppm when pumped at 450 gpm (Garrett 2004). The average brine analysis when commercial production of lithium carbonate began in 1966 was about 400 ppm (Fig. 12.54). Since that time it has been slowly declining, and in 1998 the concentration was about 100–300 ppm Li (averaging 160 ppm, Harben and Edwards 1998).

The Silver Peak playa has an area of 50 km^2 and an elevation of 1,300–1,400 m (Fig. 12.54). It lies in the rain-shadow of the Sierra Nevada, with an annual rainfall ≈130 mm and an evaporation rate of ≈1,380 mm. Near surface sediments consist of a mixture of clays (smectite, illite, chlorite, kaolin) and salts (halite and gypsum) and widespread pedogenic calcite. Lithium in the brines is from weathering and leaching of volcaniclastics in Tertiary Esmeralda Formation and Quaternary ash-fall tuffs (Davis et al. 1986). Lithium content is highest on the eastern side of the playa adjacent to the outcropping marls of the Esmeralda Fm. Before it is leached, lithium is held in the clay fraction of the playa sediments and is probably part of the clay structure (hectorite is a widespread minor component in the Clayton Valley clays).

Lithium-rich brine feed to the plant, averages 0.023 % (230 ppm) lithium in a background NaCl concentration of

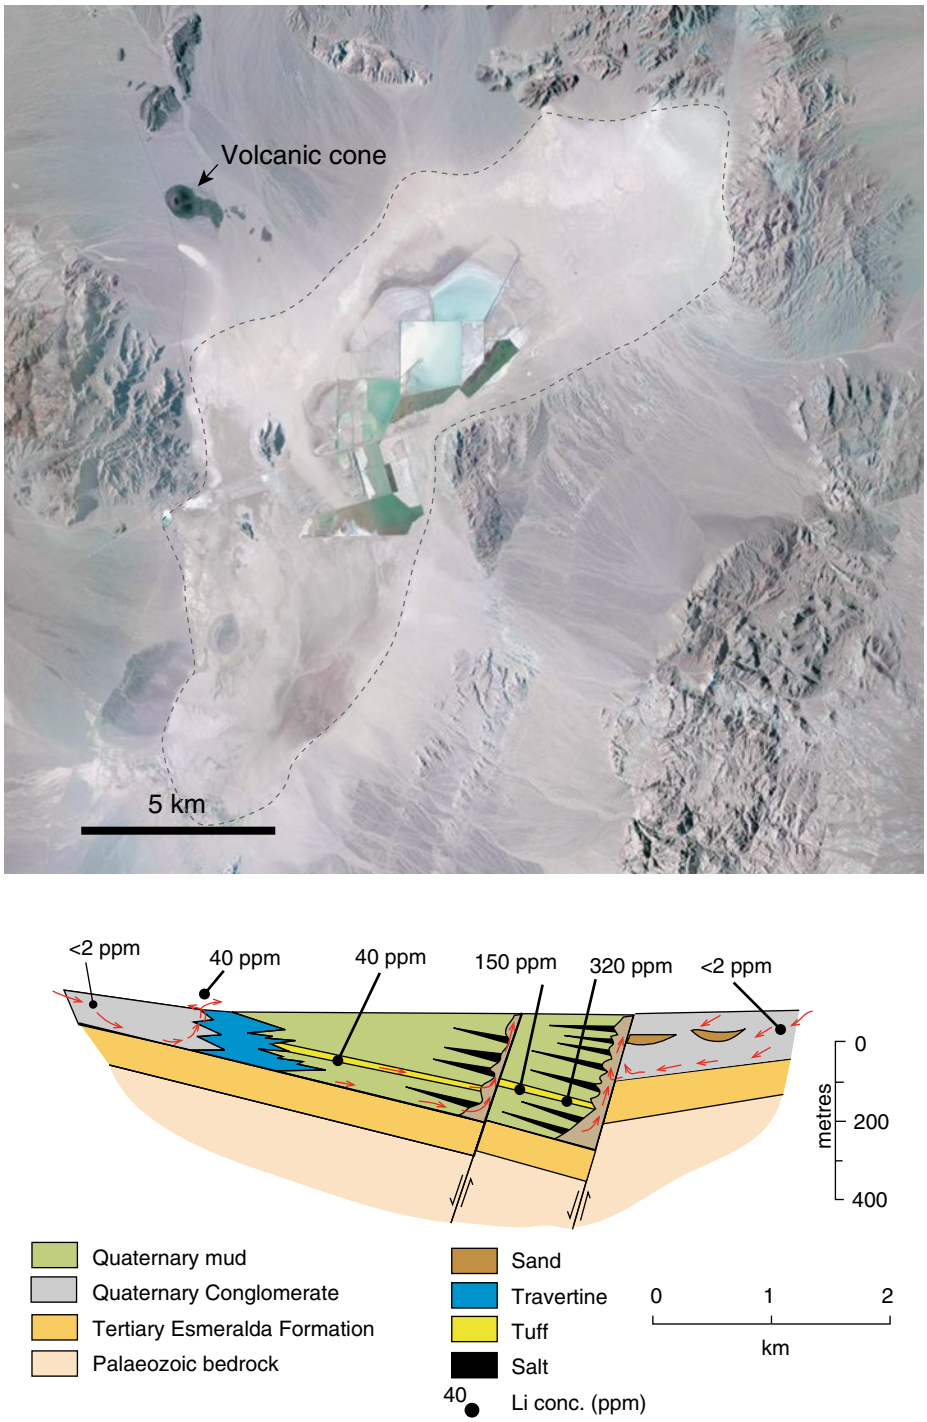

Fig. 12.54 Plan view and generalised cross section of Clayton Valley (Silver Peak) Playa, Nevada. Basin is hydrographically closed with a recent volcanic cone in bajada to northwest of playa depression. Cross section shows the relative position of the major tuff-bed aquifer, inferred directions of groundwater flow and representative lithium concentrations (ppm) in the various aquifers and springs (In part after Davis et al. 1986)

200,000 ppm, is pumped from depths of 100–300 m in the Clayton Valley (Silver Peak) playa via a number of gravel-packed wells. The lithium (and potassium) in the deposit probably originated from currently flowing hot springs along the Silver Peak Fault, with the current brine composition being a blend of evaporated water from these springs and surface and ground water that drains into the basin (Garrett 2004). Springs flow at 10–20 gpm and contain 9,280–10,000 ppm Na, 786–826 ppm K and 24–43 ppm Li (Fig. 12.54; Table 12.14). Unusually high brine temperatures in some areas of the deposit (up to 44 °C at fairly shallow depths ≈25 m) tend to support a geothermal origin for the lithium. Some of the brine feed shows elevated levels of radon gas.

Pumped brine progresses through a series of fractionating evaporation ponds (Fig. 12.54; Zampirro 2004). Lithium

concentration in the liquor increases to 6,000 ppm over the course of 12–18 months in the solar evaporation pans. When the lithium chloride level reaches optimum concentration, the liquor is pumped to a recovery plant and treated with soda ash to precipitate lithium carbonate, which is then removed through filtration, dried, and shipped. Lithium from brine, when the Clayton valley first produced product in the 1970s, was a unique deposit. It established the technology and economic viability of lithium recovery from brine that led to the development of brine production from the salars of South America, which now dominate world production of lithium from brine.

Lithium in Chinese Salt Lakes: Zabuye and Qaidam Basins

The lithium brine resource of China is held mostly stored in two saline lake regions in high altitude zones, Lake Zabuye on the Tibetan Plateau and four salt lakes in the Qaidam Basin on the Mongolian Plateau (Figs. 12.47 and 12.50). Something like 80 % of brine lithium resource found in China is contained in the four salt lakes of the Qiadam: Bieletan (BLT), DongTaijinaier (DT), XiTaijinaier (XT) and Yiliping (YLP). Zabuye lake on the Tibetan Plateau is probably the most geologically interesting as the Li content of the lake waters are so elevated that it is the only know lacustrine location where lithium carbonate, zabuyelite, is an exploitable natural precipitate (Nie et al. 2009).

Lake Zabuye, is located some 1,000 km west of Lhasa, the Tibetan capital and lies in the ET Köppen high altitude climate zone of the Tibetan Plateau (Fig. 12.55a). When artificially concentrated, the crystallization sequence of primary salts from Zabuye lake brine at 25 °C is (Fig. 12.55b):

$$\begin{aligned}&\text{halite}\left(\text{NaCl}\right) \rightarrow \text{aphthitalite}\left(3\text{K}_2\text{SO}_4 \cdot \text{Na}_2\text{SO}_4\right)\\&\quad \rightarrow \text{zabuyelite}\left(\text{Li}_2\text{CO}_3\right) \rightarrow \text{sylvite}\left(\text{KCl}\right)\\&\quad \rightarrow \text{trona}\left(\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}\right) \text{and}\\&\qquad \text{thermonatrite}\left(\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}\right)\end{aligned}$$

The lake's brine is naturally supersaturated with NaCl and other salts, so millions of metric tons of halite, potash, trona, and other minerals have accumulated on the bottom of the lake in the past few thousand years (Zheng et al. 1987; Zheng and Liu 1989). Zabuye Lake is of significant economic value as it is a new type of exploited saline lacustrine deposit that contains lithium and borate salts in addition to significant volumes of potash, halite, natron and Glauber's salt. Lake waters also retain elevated levels of caesium, rubidium and bromine. Lake levels can vary by metres each year; in 2008 the water level was some 4,422 m above sea level. At this level, the lake's area is approximately 247 km^2 and its salinity varies from 360 to 440‰, depending on seasonal differences in water input and evaporation rate. Lithium carbonate and sylvite precipitate, via a combination of brine concentration and cooling, but can also be induced by the addition of soda ash (Fig. 12.55c, d).

Detailed sedimentologial and hydrological work in the Qaidam by Yu et al. (2013) has shown that: (1) Some 748.8 tonnes of lithium is transported annually into the lower catchment of the four salt lakes via the Hongshui-Nalinggele river (H-N river in Fig. 12.55e), which is the largest river draining into the Qaidam Basin, (2) Li^+-rich brines are formed only in those salt lakes in the Qaidam that are associated with inflowing rivers with Li^+ concentrations greater than 0.4 mg/L, and (3) the water Li^+ concentration is positively correlated with elevated levels in both the inflowing river and the associated subsurface brine. Their findings clearly show that long-term input of Li^+ from the Hongshui-Nalinggele river controls the formation of lithium brine deposits. They conclude that the source of the lithium in the lake brines is ultimately from hydrothermal fields where two active faults converge in the upper reach of the Hongshui River. These hydrothermal fields are associated with a magmatic heat source, as suggested by the high Li^+ and As^{3+} content water in geysers. Based on the assumption of a constant rate of lithium influx, they estimate that the total reserves of lithium in the Qaidam were likely formed since the postglacial period. Their field mapping and coring indicates that lithium reserves in each of the four salt lakes depend on the influx of Li^+-bearing water from the H-N River. The data also suggest that during the progradation of the alluvial Fan I, the Hongshui-Nalinggele drained mostly into the Bieletan salt lake until the Taijinaier River shifted its watercourse to the north and began to feed the salt lakes of the DongTaijinaier, XiTaijinaier and Yiliping salt lakes, while also driving Fan II progradation (Fig. 14.55e). One of their major findings in terms of Lithium enrichment is the importance of the contrasting hydroclimatic conditions between the high mountains containing ice caps and the terminal salt lakes. The greater than 4,000 m of relief in the watershed enables a massive amount of ions, such as K+, to be weathered and transported, together with detrital material from the huge, relatively wet alpine regions to the hyperarid terminal basins, where intense evaporation rapidly enriches the lake water, resulting in evaporite deposition and associated K+ and Li^+ rich brine deposits.

In summary, characteristics that appear to be essential to define a potential lithium carbonate brine resource are; (i) an arid climate and, (ii) a closed, tectonically active basin e, with significant elevation and tectonically active that can entrain brines with elevated lithium contents (Fig. 12.56a; Bradley et al. 2013; Yu et al. 2013). Sources of lithium can be deeply circulated magmatic or basinal fluids. Magnesium levels in the brine should not be too high as this complicates brine processing. A co-occurring potash resource, extractable from the same brine, if present typically reduces processing costs. Another possible requirement—or at least a favourable characteristic—is elevated heat flow, as evident from young volcanoes or hot springs and the associated increase in Li-rich juvenile waters flushing the surrounding

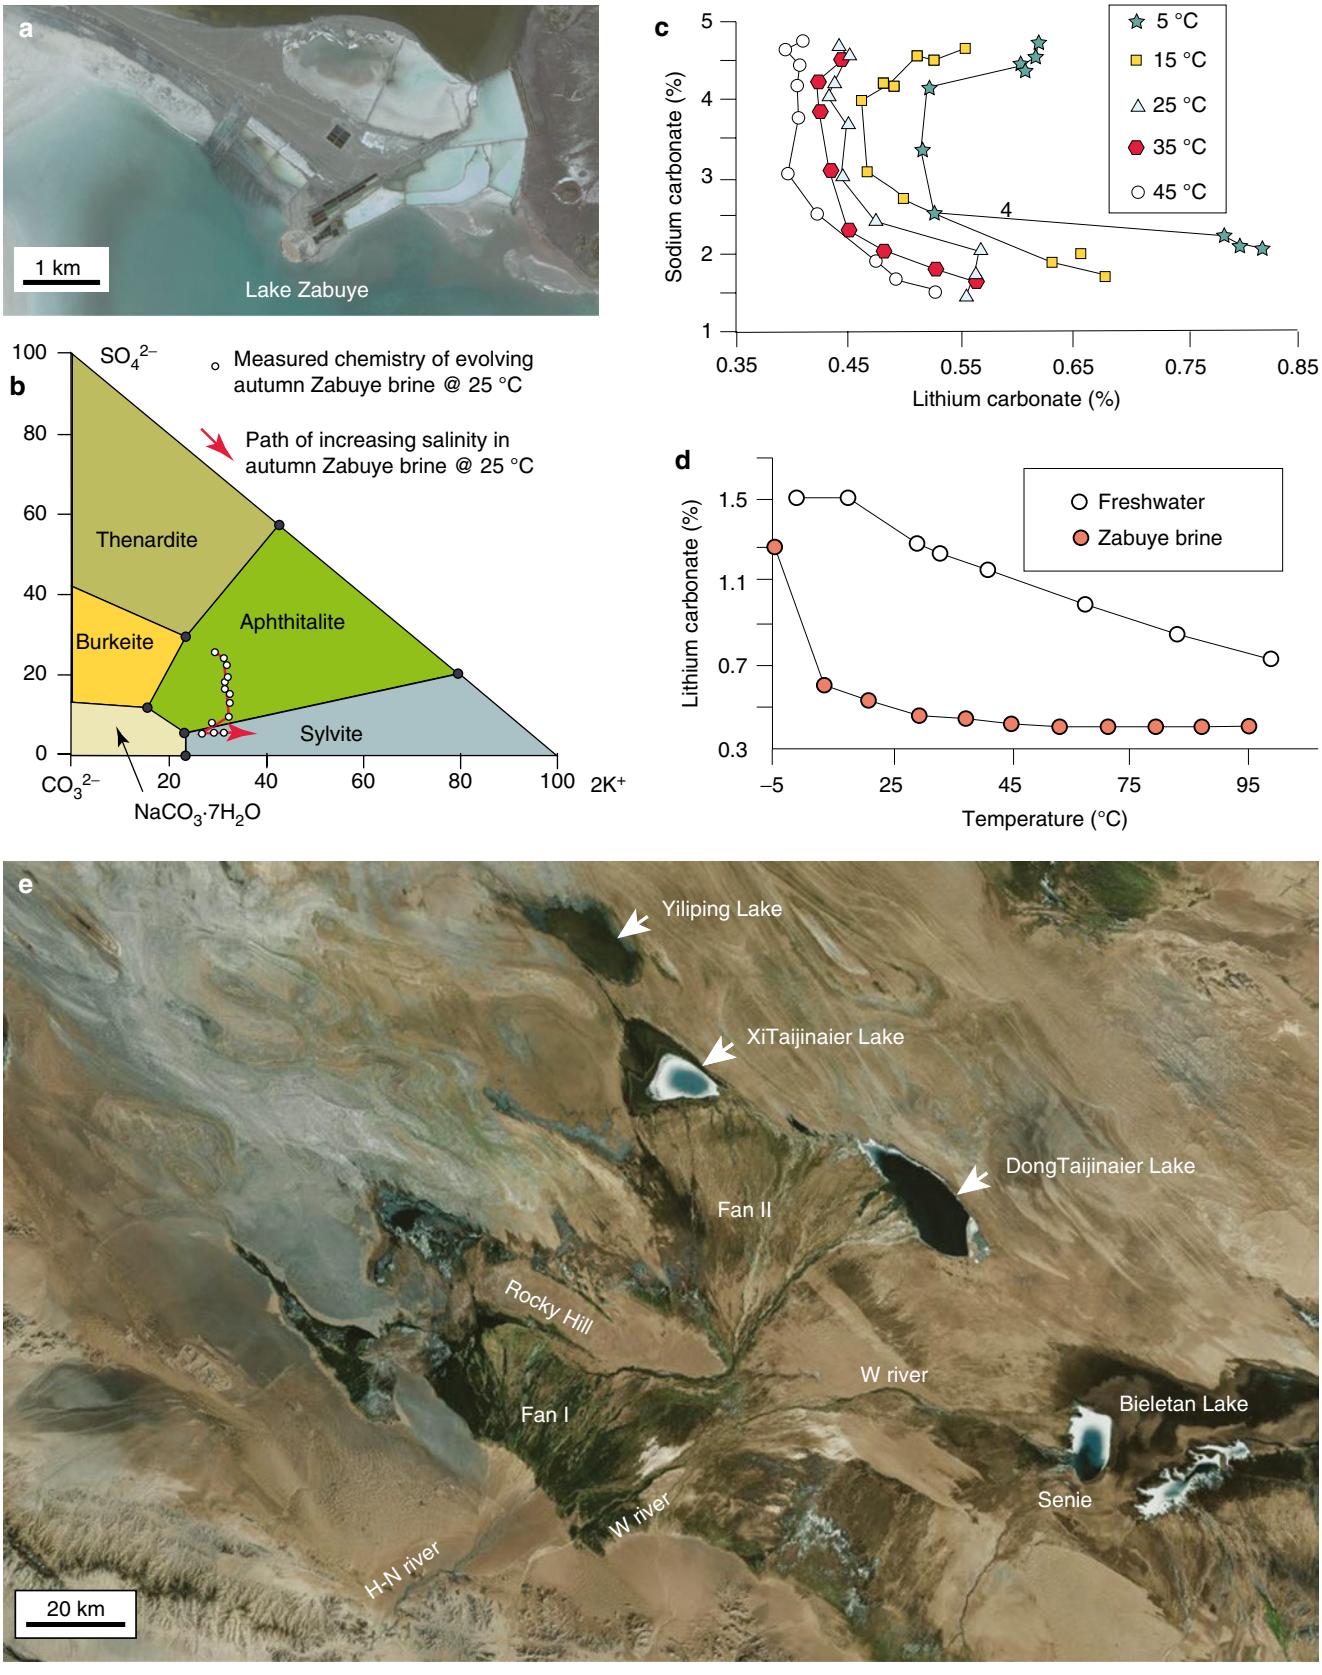

Fig. 12.55 Lithium brine lakes China. (**a**) location of Li plant on northern shore of Lake Zabuye, Tibetan Plateau. (**b**) Brine evolution pathway (After Nie et al. 2009). Fig. 12.56 Lithium controls and distribution. (**a**) Summary of mechanisms controlling lithium in a salar setting. (**b**) Latitudinal distribution of modern lithium brine occurrences (Replotted with permission from SaltWork database version 1.6- see also Fig. 12.47)

drainage basin beneath the Andean Altiplano. Volcanigenic source rocks in the lake drainage, such as felsic, vitric tuffs that have abundant and readily leached lithium are favourable, but perhaps not essential, since lithium is present in most crustal rocks at tens of parts per million (ppm). Another possible favourable indication of lithium brines is the existence of hectorite or jadarite in associated clays in the bajada rims. Active faulting appears to be involved in forming a suitable spring-fed hydrology for all known economic lithium brine basins. Fault-related subsidence also creates accommodation space, without which only a thin veneer of arid basin sediments and brines can accumulate. Thus, a thick basin fill is needed to provide an aquifer of sufficient volume to hold a viable lithium brine resource.

In contrast, shallow, superficial basins in intracratonic regions such as the Sahara Desert and most inland Australian deserts largely lack active fault control and associated rapid subsidence and so are not known to be prospective for lithium brines. As well as the aquifers, salt fills in some lithium basin sumps are cut by active intrabasinal faults (known from boreholes and seismic) but have no surface expression due to rapid infill and levelling of the accommodation space by salt precipitation. Significantly, the brine pools in ClaytonValley, Salar deAtacama and the Qaidam sumps are localized along active intrabasinal faults, which also control the distribution of aquifers and influence groundwater movement patterns, as well as the position of maximum stacking of concentrates and brines in the halite nucleus, along with porosity retention levels in the subsurface halite host (Chaps. 2 and 3; Zampirro 2004; Jordan et al. 2002). A plot of known Quaternary-hosted lithium brines also shows that these accumulations are latitudinally restricted to cool arid belts within endoheic brine sumps that are surrounded by high altitude drainage basins (Fig. 12.56b; Warren 2010).

$CaCl_2$ Brines and Minerals

Calcium chloride is produced in commercial amounts using many different procedures: (1) refining of natural brines, (2) reaction of calcium hydroxide with ammonium chloride in Solvay soda ash production, and (3) reaction of hydrochloric acid with calcium carbonate. The first two processes account for over 90 % of the world's total calcium chloride production Historically, natural brines sources have been the dominant source. There is currently an excess of capacity in the

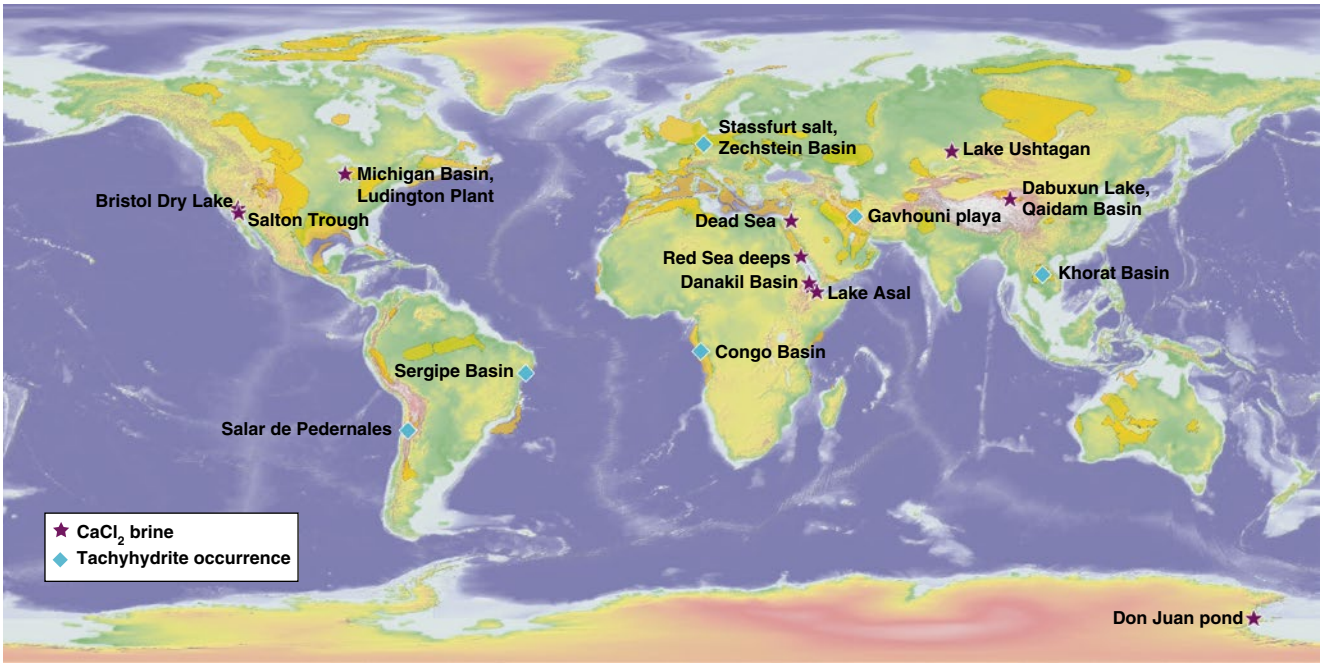

Fig. 12.57 Occurrences of tachyhydrite and calcium chloride brines. Only the Cretaceous occurrences in circum Atlantic Salt basins and the Maha Sarakham are sufficient to be considered bedded or stratabound

calcium chloride industry, a situation which is only expected to become more acute as additional synthetic or byproduct capacity increases.

More than 50 % of $CaCl_2$ use is for deicing during winter, roadbed stabilization, and as a dust palliative during the summer. It is also used as an accelerator in the ready-mix concrete industry, where there is concern about its usage because of possible chloride-induced corrosion of steel in highways and buildings. Calcium chloride is also widely used to increase mud fluid densities in oil- and gas-well drilling.

Most natural calcium chloride brines are derived from a hydrothermally-modified marine waters or from resurging deep basinal brines/formation waters. Volumetrically, the largest volumes $CaCl_2$ occur in relatively dilute, oceanic $CaCl_2$ brines that are the result hydrothermal circulation and thermally-driven alteration of mid-ocean ridge lithosphere. These $CaCl_2$ waters occur in and near active fracture zones, wherever seawater interacts with labile basalt (oceanic crust) at elevated temperatures and coverts a connate hydrothermal brine from a Na-Mg-Cl water into a low-salinity Na-Ca-Cl brine, depleted in Mg and SO_4. Similar hydrothermally-driven alterations of continental basalts, driven by deeply circulated seawater, forms modern $CaCl_2$ brine feeds to the active continental Danakil rift valley where potentially economic volumes of potash are found. The only current commercially, exploited natural $CaCl_2$ brine source is in Bristol Dry Lake, California (Fig. 12.57, Table 12.15).

Found in association with some highly-saline calcium chloride brines are two indicator $CaCl_2$ evaporite minerals, namely tachyhydrite and antarcticite. Bischofite is sometimes a co-precipitate with tachyhydrite and is indicative of mother brines with higher $MgCl_2$ contents (Fig. 12.57). Halite-encased tachyhydrite ($CaMg_2Cl_6{\cdot}12H_2O$) is a rare bittern mineral phase in some evaporites across much of the Phanerozoic. Along with carnallite ($KCl{\cdot}MgCl_2{\cdot}6H_2O$) and bischofite ($MgCl_2{\cdot}6H_2O$), it typifies highly saline marine bittern assemblages in some, but not all, ancient basinwide potash-rich evaporite systems that are $MgSO_4$ poor. They include: Silurian potash of Michigan Basin; Carboniferous potash in the Canadian Maritimes and the Paradox basin; Permian Zechstein 2 Stassfurt potash seams in Stassfurt, Germany; Triassic Saharan potash of North Africa; Cretaceous potash evaporites in Brazil, Gabon and Thailand and Oligocene potash in the Rhine Graben. Outside of these deposits, tachyhydrite-bearing successions are much less common within this broader $MgSO_4$-poor group of ancient potash deposits (see Chaps. 2 and 11 for the detail).

To form antarcticite ($CaCl_2$)$\cdot 6H_2O$ at the bittern stage, a $CaCl_2$ brine must be depleted in Mg, otherwise tachyhydrite forms, along with carnallite and bischofite. These three chloride bittern salts are not part of the bittern suite precipitated from today's $MgSO_4$ oceans, where sulphate and magnesium levels are too high relative to calcium. But carnallite and tachyhydrite were more common precipititates in the bittern stages of ancient $CaCl_2$ or $MgSO_4$-depleted oceans at times when rates of seafloor spreading, and hence volumes of through-circulated seawater, were greater than today (Fig. 2.45). It seems that most the highly saline calcium chloride brines form in sedimentary basins with a thick evaporite

Table 12.15 $CaCl_2$ brines in Quaternary saline settings; $CaCl_2$ brines and tachyhydrite in ancient evaporite deposits tend to typify times of $CaCl_2$ oceans, as listed in Fig. 12.57

Location, Country (area)	Elev. (msl)	Köppen	Comments
Don Juan Pond, Lake Vanda, Antarctica (<1 km^2)	90	EF	Very small saline lake (<1 km^2) and only of academic interest. Unusual association of low $MgCl_2$ levels in this $CaCl_2$ brine. Calcite, gypsum, mirabilite, antarcticite are lake floor precipitates. See earlier mirabilite discussion for deposit details. (Torii and Ossaka 1965; Horita 2009)
Lake Asal, Djibouti (54 km^2)	−155	BWh	Possible future resource. Lake precipitates halite and gypsum and is fed in east by hydrothermally-altered $CaCl_2$-rich modified seawater (Manda springs; 40–80 °C) seeping through recent fault zones in Dahla Basalt ridge (salinities >100,000 ppm). Lake waters are less enriched in Ca relative to springs due to widespread precipitation of subaqueous gypsum on perennial lake floor. (Stieljes 1973, Castanier et al. 1992; Garrett 2004)
Danakil depression, Ethiopia	−77 and −118 resp.	BWh	Possible future resource. Lake Afrera (Lake Giulietti; −77 m, 115 km^2) is largest perennial saline lake in Danakil depression, water depth of over 100 m situated in an actively rifting area in the centre of the Danakil Depression and surrounded by active volcanic peaks. A number of calcium chloride-containing hot springs (40–50 °C) flow into the southwest edge of Lake Afrera, and the lake appears to occasionally drain into the nearby Dallol Salt Pan (−118 m, 344 km^2). Inflow water is hydrothermally-altered seawater. In the northern portion of the Danakil Depression, bischofite and carnallite precipitate from a 130 °C $MgCl_2$ brine that emerges from the Black Mountain hot spring, although bischofite quickly deliquesces to sylvite upon exposure to the atmosphere. (Hutchinson and Holwerda 1968, Augustithis 1980)
Dead Sea, Israel, Jordan (1,023 km^2)	−415	BSh	Possible future resource. Ca and $MgCl_2$ brine tied to carnallite and bischofite precipitate stages in artificial pans and then can be used to manufacture $MgCl_2$. Dead Sea is a nonmarine, fault-bounded evaporite basin that contains $CaCl_2$-rich and SO_4- and $CaCO_3$-poor waters, supplied by the Jordan River and a number of hydrothermal springs., Most of the solutes come from hydrothermal spring waters that have leached earlier Miocene marine evaporites. These hydrothermal brines are enriched in $CaCl_2$, have a chlorinity that is eight times that of seawater, and are rich in the heavy metals; iron, manganese, lead and zinc. (Gavrieli et al. 2001)
Bristol Dry Lake, California, USA (200 km^2)	180	BWk	Active $CaCl_2$ brine extraction and processing. Unusual nonmarine association of low $MgCl_2$ levels in a $CaCl_2$ lake brine. Main evaporites are gypsum, anhydrite, and halite with rare antarcticite, celestite ($SrSO_4$), bacterial calcite, and possibly chlorocalcite ($KCaCl_3$). Bristol Dry Lake is mined for its chloride brines and is thus covered with pits and trenches. Antarcticite was identified in one trench that was 3 m deep, 20 m long, and contained a 10–25 cm deep pool of $CaCl_2$ brine. The base of the pit was a massive halite deposit with acicular groups of antarcticite protruding outward from the halite and within the brine. Evaporative concentration of this brine in the arid cool winter climate with temperatures well below 30 °C allowed antarcticite to precipitate. (Dunning and Cooper 1969; Garrett 2004)

For additional overviews of geology of deposits see Garrett (2004) and Kogel et al. (2006)

near the base of the sediment fill. But, as Fig. 12.57 illustrates, not all are basins with highly saline $CaCl_2$ brines are co-associated with bedded tachyhydrite occurrences in the buried and dissolving evaporite units.

Textures recovered in core, and visible in mine walls in Brazil, indicate this tachyhydrite was a primary bedded precipitate in those circum-Atlantic Cretaceous evaporites with stratiform tachyhydrite units in these potash beds (Fig. 11.43;

Wardlaw 1972). The Cretaceous world ocean at the time this tachyhydrite precipitated was typified by $MgSO_4$-free marine bitterns. Yet, as Fig. 12.57 shows, tachyhydrite does not occur as a bittern phases in many other potash sequences deposited in basinwide settings at other times of $CaCl_2$ oceans (e.g. the Devonian of Canada, the Silurian of the Michigan Basin). This has led to the argument that stratabound tachyhydrite in potash beds indicates a hydrothermal/basinal source for the mother brine; as such the presence of tachyhydrite is not necessarily indicative of a $MgSO_4$-depleted marine feed to the basin (Hardie 1990).

Today, large volumes of relatively dilute, oceanic $CaCl_2$ brines form via hydrothermal circulation and thermally-driven alteration of mid-ocean ridge (MOR) lithosphere. These $CaCl_2$ waters occur in and near active fracture zones, wherever seawater interacts with labile basalt (oceanic crust) at elevated temperatures and coverts the circulating fluid from a Na-Mg-Cl water into a low-salinity Na-Ca-Cl brine, depleted in Mg and SO_4. Similar hydrothermally-driven alteration of continental basalts via deeply circulated seawater interactions forms modern $CaCl_2$-rich brine seeps, for example, within the thermally active continental Danakil rift valley (Hardie 1990).

There may be an additional factor at work here in terms of our recognition of tachyhydrite's basin-by-basin distribution and that is tachyhydrite's high solubility in most subsurface waters and drilling muds. Even the name, tachyhydrite, was chosen from the Greek *tachy hydros* for "*swift water*" to indicate its rapid deliquescence on exposure to atmospheric conditions. This property means that any ground-up remains (rock chips) of tachyhydrite in the return mud stream of a conventional drilling operation typically do not make it to the surface. So, there may be more tachyhydrite occurrences in deeply buried basin evaporites than the few currently documented. Ancient tachyhydrite has only been found encased in halite in recovered cores and mine walls, never drill cuttings, and its presence or absence can be easily misinterpreted in wireline logs, especially when drilling through thick salt masses in the search for oil and gas (companies tend to run a more limited log suite in thick salt units).

Tachyhydrite's lack of shear strength and extremely high solubility makes mining the associated potash difficult, it leads to head beam and floor stability problems in conventional underground mines in Brazil and West Africa. Holle, a West African potash mine in the 1970s, was never economic and was lost to flooding after a few years of conventional mining and the Brazilian mine has ongoing floor and wall stability problems ties to tachyhydrite-induced heave. Today, solution mining is proposed and a more effective means to exploit areas of Cretaceous potash associated with tachyhydrite beds, as in Aptian halite-potash associations on both sides of the Atlantic.

Not only is tachyhydrite highly soluble, it is highly reactive whenever in comes into contact with subsurface bitterns. Based on its occurrence in the Permian Stassfurt series in Germany, D'Ans (1961) suggested that much of the widespread polyhalite found in the $CaCl_2$ brine-rich parts of the Zechstein Basin was a reaction product indicating former tachyhydrite. He noted that, at temperatures higher than room, there is a reaction between gypsum/anhydrite, sylvite and tachyhydrite-bischofite, or their dissolution-related brines, which removes tachyhydrite to form diagenetic polyhalite and calcium chloride brines;

$$CaMg_2Cl_6 \cdot 12H_2O + 4KCl + 8CaSO_4 \rightarrow 2CaSO_4Mg(SO_4)4(H_2O)_2 + 5CaCl_2 + 4H_2O$$

This was the mechanism suggested by Manheim (1974) to explain the lack of tachyhydrite and the formation $CaCl_2$-rich brines that characterize hydrothermal pore waters circulating in sediments associated with buried Miocene evaporites along the deep axial trough of the Red Sea.

Natural modern tachyhydrite is documented only in a few hypersaline settings and never in a bed with primary precipitation textures. Tachyhydrite occurs seasonally as a minor interstitial cements and efflorescences, along with antarcticite (the hexa-hydrate form of calcium chloride), in the modern ephemeral halite crusts, atop sabkhas, of the Gavkhoni Playa (BWk), southeast of Isfahan, Iran (Pakzad and Ajalloeian 2004) and perhaps the Abu Dhabi sabkha (Wood et al. 2005). One occurrence of the dihydrate form of calcium chloride (sinjarite; $CaCl_2 \cdot 2H_2O$) has been documented as small rare pink crystals in wadi sediments of Sinjar town, west of Mosul city, Iraq (Aljubouri and Alddabbagh 1980).

Much of the elevated ionic content of various Iranian playas in the Great Kavir is due to salt dissolution of the crests of nearby at- or near-surface diapirs and namakiers, where the mother salt sourced in halokinetic Miocene marine salts (Warren 2008). These outcropping diapirs have carried carnallite and sylvite remnants to the namakiers that now reside at the surface (Rahimpour-Bonab and Kalantarzadeh 2005). Tachyhydrite is also found as white feathery efflorescences within waste piles at an abandoned borate working along the southwestern margin of Salar de Pedernales, Chile (a BWk location very near the ET climate boundary; Ericksen and Salas 1989).

It seems that tachyhydrite's high solubility means it has little or no preservation potential as a solid salt in any modern at-surface depositional setting; in the Peruvian case it is a winter precipitate that disappears with the end of winter. In Abu Dhabi it, along with other highly soluble salts in the salty surface efflorescences, can disappear in morning dew (Warren, pers. obs.). In both the Iranian and the Peruvian setting the climate is cool and elevated. The arid desert

environments where bedded subaqueous-textured tachyhydrite accumulated in the drawndown Aptian seepage basins of the opening Atlantic were very different to its occurrence in the evaporite settings of today.

The purest $CaCl_2$ mineral precipitates (antarcticite and sinjarite) are rare occurrences as crystalline beds anywhere in today's hypersaline lakes. None have been documented in ancient salts, except as a volumetrically insignificant mineral phase in brine inclusions in both sediments and igneous rocks, even in basins with highly saline $CaCl_2$-rich pore fluids. Antarcticite in Holocene occurrences in saline settings requires a Ca-enriched mother brine that is completely depleted in sulphate. Otherwise gypsum precipitates, and in so doing removes all the calcium from concentrating brine, well prior to the bittern stage. There are only two known modern hypersaline saline deposits where the pure $CaCl_2$ mineral antarcticite ($CaCl_2{\cdot}6H_2O$) is present as thin crystal beds and effloresences; they are, Bristol Dry Lake (BWh) in California and Don Juan Pond (EF) in the Dry Valleys, near Lake Vanda in Antarctica (Dunning and Cooper 1969; Horita 2009). Both saline lakes possess similar $CaCl_2$-enriched, $MgCl_2$-depleted chemistries and are fed by hydrothermal waters. In Bristol Dry Lake the concentration process is driven by solar evaporation, while cryogenesis is the main driver in Don Juan pond. Only in Bristol Dry Lake is a $CaCl_2$ brine is commercially extracted.

The high solubility of $CaCl_2$ minerals means that, with the exception of some parts of the Aptian Atlantic potash association, even in past times of likely $CaCl_2$-rich oceans, calcium chloride minerals are relatively rare as primary-textured occurrences in solid salt beds. On the other hand, $CaCl_2$ brines are commonplace in basinal or formation waters in many Phanerozoic sedimentary basins entraining thick sequences of dissolving ancient salt. For example, since 1914, $CaCl_2$ brines have been extracted from Silurian strata adjacent to Salina Salt of the Michigan Basin USA (Garrett 2004). These brines are recovered from Detroit Group sediments that overlie the Silurian Salina evaporites. Based on fluid inclusions in primary halite chevrons in the Salina Salt, the Silurian was a time characterized by a $CaCl_2$-enriched $MgSO_4$-depleted ocean (but no tachyhydrite is known from Silurian strata – see Chap. 2). The porous 0–90 m thick Sylvania Sandstone lies at the base of the Detroit River Group, while the remainder of the Group consists of 0–350 m of variably porous carbonates (Garrett 1995, 2004). Both contain $CaCl_2$-rich brines and extend across some 40 % of the Michigan Basin at depths of from 300 to 1,400 m. Brine concentration and the relative amount of $CaCl_2$ increases with depth. Typically, the brines are only considered to be of economic importance below about 880 m. In carbonate hosts, the $CaCl_2$ content varies from 3 to 23 % and KCl from 0.2 to 2.9 %, usually increasing in concert with concentration, as the NaCl content decreases. $CaCl_2$ content in the Sylvania Sandstone varies from 14 to 22 %, KCl from 0.6 to 2.1 %, and both are more uniformly concentrated compared to the carbonate hosted brines (Fig. 12.43; Garrett 2004).

Historically, before micro-inclusion studies of chevron halite showed that the ionic proportions of seawater likely varied across the Phanerozoic, the various $CaCl_2$ basinal brines occurrences in Silurian and Cretaceous strata were explained as an indicator of widespread dolomitisation and other diagenetic reactions, which preferentially extracted magnesium from pore waters. Since then, some authors have argued that $CaCl_2$ enrichments in many ancient basinal brines, including brines in the Detroit group are partial leftovers of primary seawater chemistries (Lowenstein and Timofeeff 2008). That is, Ca-enriched ($MgSO_4$-depleted) pore brines are indicators of ancient $CaCl_2$ oceans, with the pore brines being remnants from time the enclosing evaporitic and marine sediments were deposited (relict or connate brines). Others, such as Houston et al. (2011), conclude this is not necessarily so, they agree that there are two end-members typifying highly saline subsurface brines. But they conclude that end member chemistries relate to either substantial subsurface halite dissolution, or to preservation of early reflux-related seawater. Houston et al. (2011) go on to argue that $CaCl_2$-enriched formation water chemistries from many basins worldwide, including the Michigan Basin, do not support an interpretation[7] of variation in ionic proportions in seawater across the Phanerozoic. They find that $CaCl_2$-rich brines formed either by dissolving bittern salts in the subsurface, or simply lost water in the subsurface after significant rock-fluid interaction had taken place. Water loss might be achieved by interaction with a gas phase in the elevated temperatures of deep burial or, alternatively, water may have been lost to clays. Both these mechanisms would have the effect of dehydrating (concentrating) the brine.

However, whatever the mechanism, it does seem that there is a Quaternary continental/pre-Quaternary marine dichotomy in the nature and distribution of $CaCl_2$ brines and the associated antarcticite/tachyhydrite minerals, as there is for the world's potash deposits ($MgSO_4$-enriched versus $MgSO_4$-depleted). There are no documented examples of pre-Quaternary bedded antarcticite. Today antarcticite either precipitates in the hot-arid Bristol Dry Lake or the icecap-polar setting of Don Juan Pond, neither is associated with brine sourced in seawater or derived by the recycling of older ("connate") marine evaporite successions. Other present-day examples of regions with somewhat enriched $CaCl_2$ surface waters, lack both tachyhydrite and antarcticite precipitates,

[7]In the context of past seawater chemistries it is important to note that this discussion of brine origin concerns interpretation of proportions of ions present in porous non-evaporite sediment hosts. It is totally separate to interpretations of past seawater chemistries based on analyses of inclusions held in primary chevron halite crystals sampled from a impermeable bedded salt mass. In this latter case the ionic proportions of the ambient seawater concentrate are unequivocally preserved.

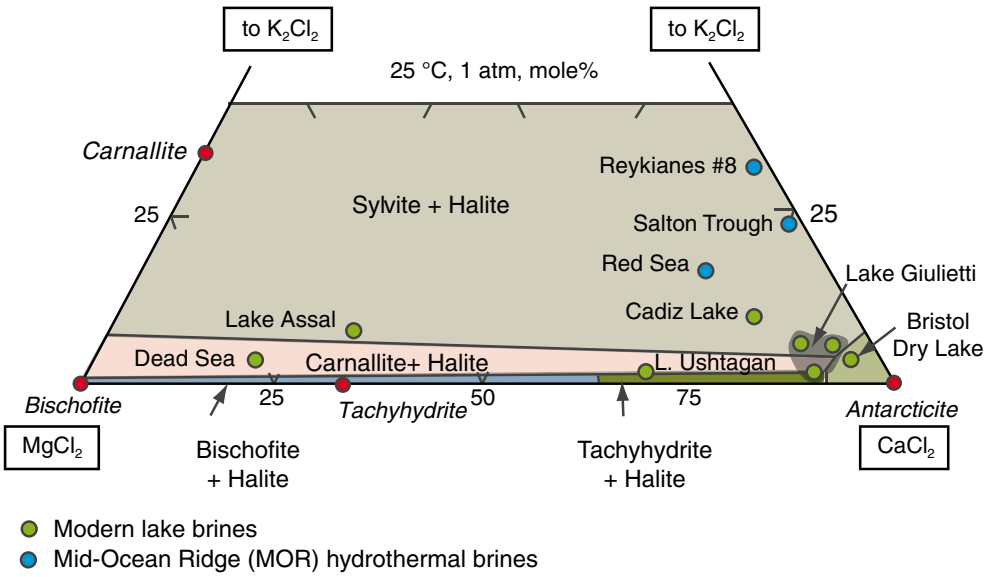

Fig. 12.58 Phase relations and brine chemistry of modern $CaCl_2$ brine associations in the system $CaCl_2$-$MgCl_2$-KCl-NaCl-H_2O at halite saturation, 25 °C, and 1 atm total pressure (After Hardie 1990)

and contain higher levels of Mg that are tied to deeply circulated marine/hydrothermal waters and variable interactions with $MgSO_4$-enriched marine salts (Fig. 12.58; e.g., Lake Asal and the Dallol Salt Pan). $CaCl_2$ brines of the Dead Sea and the Red Sea show even more elevated levels of $MgCl_2$ as they are derived, at least in part by the fractionated dissolution of bedded and halokinetic Miocene marine evaporites. The Mg-rich clay palygorskite is co-associated with these brines in the subsurface of the Red Sea and the Dallol.

In contrast, tachyhydrite in some ancient marine-fed basinwide evaporite associations is found as somewhat rare, but at times bedded, units in the bittern-rich portions of the halite succession (Fig. 12.57; Table 12.14), as in the Cretaceous basinwide evaporites of Brazil, the Congo and Thailand, and as a cementing phase in the Permian Stassfurt 2 in the Zechstein (where it is commercially extracted in association with $MgCl_2$ brines). All the ancient tachyhydrite examples mentioned above, are associated with the presence of widespread potash within adjacent salt beds. However, there are many other even larger ancient potash deposits, such as the intracratonic Alberta and the Kama basins where no tachyhydrite is documented. It seems that the precipitation of bedded tachyhydrite is not just favoured by times of $CaCl_2$ oceans, it also requires additional input from saline hydrothermal/basinal waters. Such settings are most likely in the transition phases in an actively-opening hydrothermally-influenced continental rift as passes into the marine seepage realm at a time when the adjacent ocean was a $MgSO_4$ -depleted system.

Iodine

The name iodine comes from the Greek word *iodes*, for "violet-like." Iodine was discovered by Bernard Curtois toward the end of 1811 or early 1812 when, while attempting to minimise pot corrosion in a seaweed processing saltpetre factory where he was employed, he decided to understand the violet vapours he observed rising from heated saltpetre pots and associated purple crystals sublimating on cooler surfaces (Lauterbach 2007).

Iodine at 0.46 part per million in the Earth's crust is one of the scarcest of nonmetallic elements in the total composition of the earth; it is the sixtieth element in order of world element abundance. Although not abundant in terms of quantity, iodine can be found almost everywhere on the earth. It is present in rocks, soils, water-bodies, plants, animal tissues, and foodstuffs. Natural commercial surface deposits contain iodates such as lautarite $Ca(IO_3)_2$ and dietzeite $Ca(lO_3)_2$. (CrO_4). Except for the possible occurrence of elemental iodine vapour in the air near certain iodine-rich volcanic springs, iodine never occurs naturally in its elemental form. It is always found in combination with other elements, either as inorganic salts or rather complex organic compounds, such as thyroxin. Organic-rich sedimentary rocks represent the Earth's dominant iodine reservoir and marine organic matter contains high ppm-levels of both I and Br (Collins et al. 1971; Kendrick and Burnard 2013). Ongoing subsurface fluid interaction with organic matter does not influence salinity but represents the dominant control of fluid I/Cl, and can exert a significant influence on the Br/Cl ratio.

Wherever iodine occurs naturally, its quantities are generally exceedingly small, and very sophisticated chemical methods are required to detect it. Only a few natural substances characteristically contain iodine in relatively large quantities (Lauterbach 2007). These are: marine seaweeds and sponges, subsurface waters in deep oil wells or mineral springs and in natural deposits of sodium nitrate, ("caliche ore" or saltpetre) in the northern part of Chile. In all natural

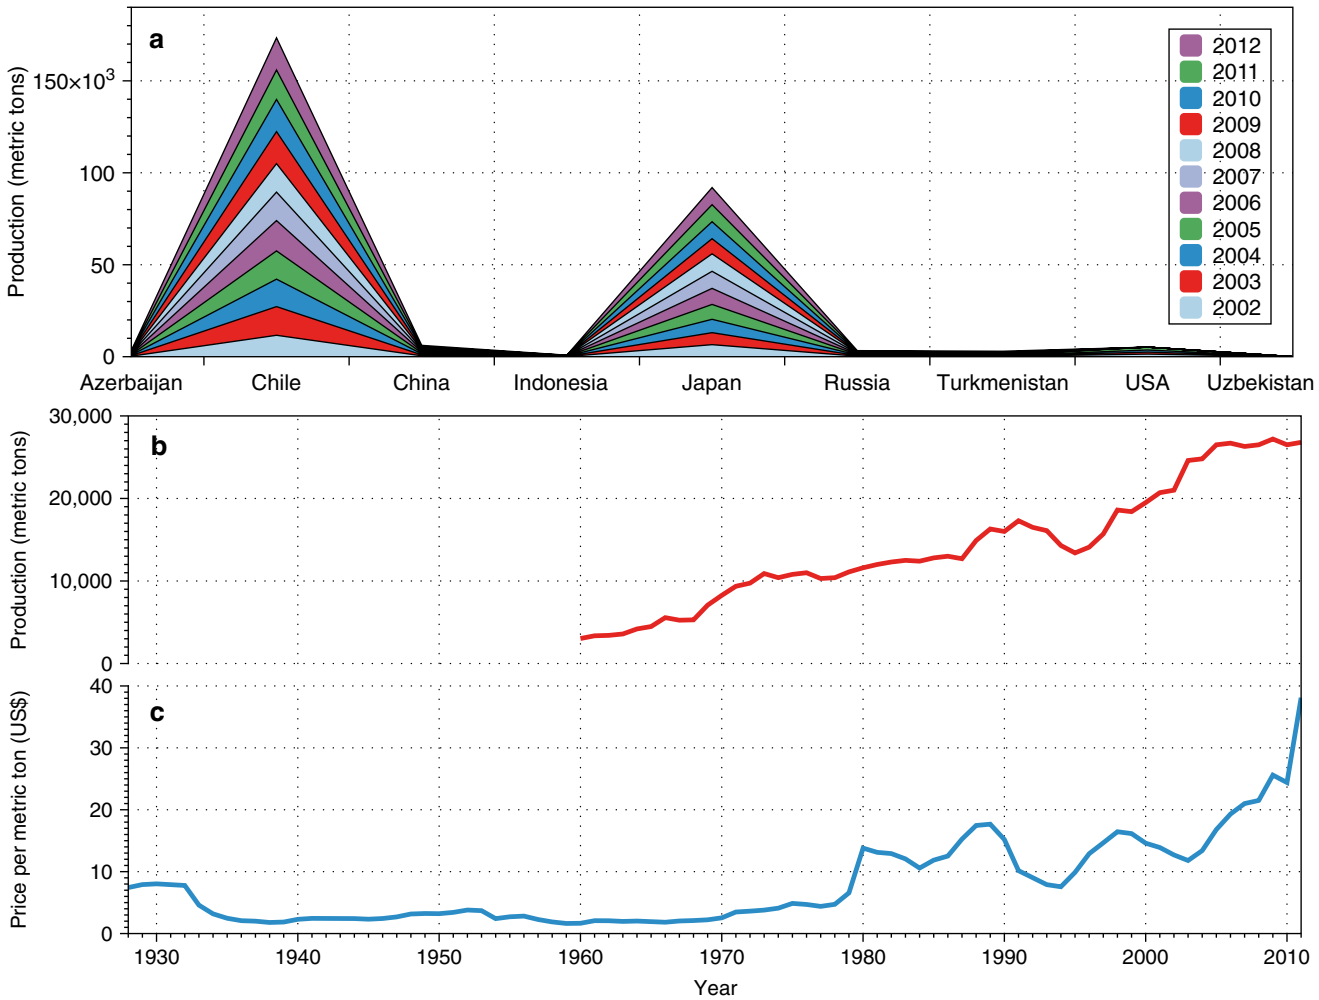

Fig. 12.59 Iodine production. (**a**) Cumulative area plot of annual production of major iodine producing countries in metric tons. USA figures not made public since 2006. (**b**) World production from 1960 to 2011 (metric tons), (**c**) Price per metric ton in US dollars from 1927 to 2011 (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed September 4, 2013)

examples, other than the Chilean iodates in caliche, the proportion of iodine is small, rarely exceeding 2,000 ppm (Lauterbach 2007). Oilfield brines in Louisiana, California, and Michigan contain 30–40 parts per million iodide, while some Japanese subsurface brines contain up to 100 parts per million. Iodine makes up only 0.05 ppm in seawater, but some seaweeds concentrate iodine up to 0.45 % (4,500 ppm) of their dry weight.

Iodine is quarried and extracted from hypersaline lakes and saline desert soils of the Atacama Desert in Chile, or recovered from saline subsurface brine associated with natural gas production (e.g. southern Kanto gasfield, Japan) and from deep highly-saline oilfield brines in the USA (e.g. Woodward Shale, Oklahoma: Moran 1996). Chile today controls around 58 % of the world iodine capacity, Japan 21 %, and the USA around 5 % (Fig. 12.59). In 2012, global crude iodine production was estimated at around 28,700 metric tons and was carried out in only nine countries: Chile, Japan, USA, China, Turkmenistan, Azerbaijan, Indonesia, Russia and Iran (Fig. 12.59a). Chilean reserves are vast, but producers can experience climate-related or other anthropogenic variations in ore quality that can affect production costs and iodine price (Angulo 2011).

High levels of Na_2SO_4 in the Chilean processing feedstock can be detrimental and this delayed the opening of the new iodine processing at the Aguas Blancas mine in northern Chile. Reserves of iodine-rich brines are also huge in Japan, and considered near-inexhaustible at current extraction rates. Japanese production is limited. however, by problems of land subsidence and the occasional earthquake. Compared with Japanese and Chilean reserves, the US reserves are much smaller, but are still estimated to be sufficient for domestic use for another century at current production rates. Mid nineteenth century, small, but commercial, amounts of iodine were produced from the ash of seaweed collected of the coast of Great Britain (Rosenfeld 2000). World iodine

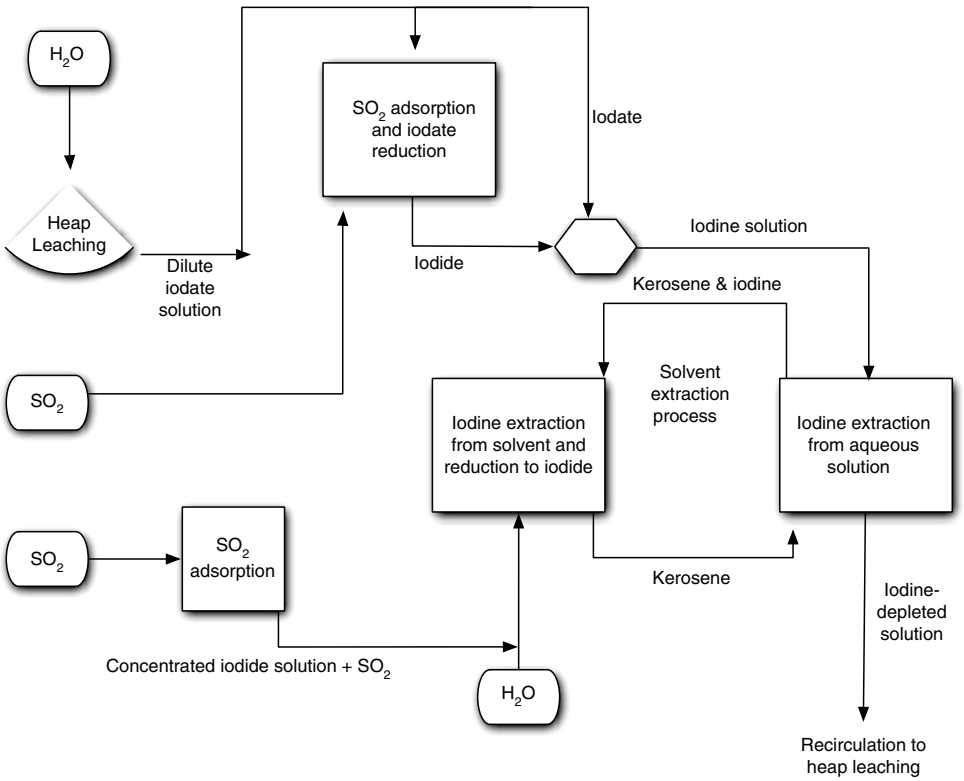

Fig. 12.60 SQM's heap leaching of caliche tailings for iodine recovery from dilute iodate solutions in the Atacama Desert, Chile (After Lauterbach 2007)

production has not risen greatly since the mid 2000s, current annual world production is about 28,000 metric tons (Fig. 12.59b; Angulo 2011).

The method of iodine extraction depends on the source of the iodine. From Chilean saltpeter beds, sodium iodate is dissolved by an alkaline solution, converted to iodide ion by reaction with sodium hydrogen sulphite, and iodine is then precipitated by adding iodate solution (Fig. 12.60). From brines, the iodide ion is converted to iodine by reaction with chlorine. Air blown in through the solution collects the iodine, which then precipitates, while purification is by resublimation. In an alternate method the iodide ion is precipitated with silver ions, reacted with iron to make iron iodide, and reacted with chlorine to produce iodine. Another method uses an ion-exchange resin to collect the iodine after it has reacted with chlorine.

Iodine prices were largely stable around US$32/kg throughout 2010 and the beginning of 2011 (Fig. 12.59c). In March of that year, prices went from US$33/kg to US$97.5/kg on the spot market because of the Japanese earthquake and a later a seasonal production drop off in South America. A further factor was that Cosayach of Chile idled a significant proportion of its capacity because of lack of water, following the closure of illegal water wells.

Chile is the largest producer of iodine in the world and the sole producer of commercial quantities of natural iodine from a non deep-brine source, namely naturally occurring iodate salts (Table 12.16). Historically, iodine in Chile was recovered either as a byproduct in the processing of nitrate saltpetre deposits, or by leaching of nitrate tailings heaps (Fig. 12.60; e.g. at Coya Sur, in northern Chile- see nitrates in following section). Today iodates in the Atacama, rather than nitrates, can be prime target in some Atacama operations as at Aguas Blancas. The nitrate fields are mostly located in the Central Valley of Chile, called Pampa del Tamarugal, which lies between the relatively low Coastal Range to the west and the high Andes mountains to the east (Fig. 12.62).

The most likely ultimate source of Chilean iodine is thought to be iodine-rich organic films on the ocean surface. This organic scum is carried inland, along with nitrogen, as aerosols and sea spray (Fig. 2.29). Alternatively, some have argued the dominant iodine source in the Atacama caliche is from the gases and sublimates associated with Andean volcanism others have argued it is sourced by the weathering of uplifted Jurassic sediments. Once at or near the hyperarid land surface, iodates and nitrates are leached and transported by groundwaters to ultimately concentrate in pedogenic profiles (Ericksen 1993). Iodine salts in caliche ores, are largely present as the oxidized iodate minerals; lautarite (CaI_2O_6) and dietzite ($7CaI_2O_6{\cdot}8CaCrO_4$) (Table 12.16). Ore layers are 1–3 m thick and overburden is less than 1 m. The nitrate deposit in the Atacama Desert, with which it is associated, is huge, measuring some 15–75 km across and paralleling the coast for more than 720 km (Fig. 12.62). Processing of the quarried nitrate ore to produce an iodate concentrate involves

Table 12.16 Typical iodate, nitrate, borate and other minerals in the Atacama Desert, Chile

Halides	
Halite	$NaCl$
Nitrates	
Nitratite (soda nitre) -main ore	$NaNO_3$
Nitre (saltpetre) – secondary salt	KNO_3
Darapskite – Minor salt	$Na_3(SO_4)(NO_3)\cdot H_2O$
Humberstonite – Minor salt	$K_3Na_7Mg_2(SO_4)_6(NO_3)_2\cdot 6H_2O$
Iodates and chromates	
Lautarite	$Ca(IO_3)_2$
Bruggenite	$Ca(lO_3)_2\cdot H_2O$
Dietzeite	$Ca(lO_3)_2\cdot(CrO_4)$
Hectorfloresite	$Na_9(IO_3)(SO_4)_4$
Fuenzalidaite	$K_3(Na,K)2Na_3Mg_5(IO_3)_6(SO_4)_6\cdot 6H_2O$
Tarapacaite	K_2CrO_4
Lopezite	$K_2Cr_20_7$
Borates	
Ulexite	$NaCaB_5O_9\cdot 8H_2O$
Probertite	$NaCaB_5O_9\cdot 5H_2O$
Ginorite	$Ca_2B_{14}O_{23}\cdot 8H_2O$
Hydroboracite	$CaMgB_6O_{11}\cdot 6H_2O$
Kaliborite	$HKMg_2B_{12}O_{16}(OH)_{10}\cdot 4H_2O$
Colemanite	$Ca_2B_6O_{11}\cdot 5H_2O$
Sulphates	
Thenardite	Na_2S0_4
Glauberite	$Na_2Ca(SO_4)_2$
Bloedite	$Na_2Mg(SO_4)_2\cdot 4H_2O$
Kieserite	$MgSO_4\cdot H_2O$
Epsomite	$MgS0_4\cdot 7H_2O$
Gypsum	$CaSO_4\cdot 2H_2O$
Anhydrite	$CaSO_4$
Bassanite	$2CaS0_4\cdot 0.5H_2O$
Polyhalite	$K_2Ca_2Mg(S0_4)_4\cdot 2H_2O$

crushing, leaching with fresher water, thickening, filtration, and calcium iodate (with sodium nitrate) precipitation. Many of the iodine plants use solar evaporation ponds to thicken the leachate prior to processing (Fig. 12.60).

Like the coastal desert association of iodine in the hypersaline Chilean deposits, most of the iodine in highly saline subsurface brines of marine sedimentary basins ultimately comes from an organic source (Worden 1996). In fact, many such subsurface waters are enriched in iodine by up to three orders of magnitude relative to modern seawater evaporated to the same concentrations. Iodine enrichment in brines is often tied to proximity to hydrocarbon pools and iodine increases in concentration in pore waters with increasing depth of burial at a faster rate than bromine (Martin et al. 1993a).

Iodine is used in a diverse range of applications by a wide variety of industries. Around half is used in applications directly related to human health, for example x-ray contrast media, iodophors (biocides) and iodine supplements and pharmaceuticals. Most of the remainder is in industrial applications such as optical polarising film (OPF) for liquid crystal displays (LCDs), catalysts, heat stabilisers and the production of fluorine derivatives, along with animal feed supplements, catalysts, inks and colourants. For the next 5 or so years, world demand for iodine is forecast to rise due to expanding usage mostly in the x-ray contrast media, OPF and biocide markets. Demand for iodine in OPF will continue to grow until the end of the decade, but after that LCDs are expected to face increasing competition from technologies that do not use OPF such as OLED.

Healthwise, a worldwide effort is underway to eliminate iodine-deficiency disorders by fortifying world salt supply with iodine. Iodine deficiency[8] is the Developing World's leading cause of mental health problems along with more subtle associated problems such as clumsiness, lethargy, and reduced learning capacity. Endemic cretinism manifested in mental retardation, deaf muteness, blindness, crosseye, and growth lag, are created in areas where pregnancy occurs in the presence of an iodine deficit. Globally, more than 2.2 billion people live in iodine-deficient areas, especially in mountainous areas located well away from the sea coast. Iodine is an essential part of the thyroid hormone, a substance that contributes to brain development during foetal life and later metabolism.

In Tibet for example, some remote mountain villages have birthing data that show 13 % of newborns suffer from cretinism. This is because of low iodine levels in the soils and the fact that local salt is harvested from salt lakes where glaciation and deep weathering have long ago removed iodine from soils and associated salts. Unlike seasalt, the present soil waters and runoff, that ends up collecting and evaporating in the salt lakes, contains little or no iodine (Lee 2001). Salt harvested from the Tibetan lakes, when carried to the villages and sold, is 50 % cheaper than salt that has been fortified (sprayed) with iodine. A lower cost makes natural local salt a more attractive product to peasants in the villages, most of whom are subsistence-level farmers. Harvested salt is usually bartered or exchanged for an equivalent weight in rice. In an attempt to improve the health of the people, selling non-iodised salt has been made illegal by the Chinese government. But a lower price and the fact that the salt

[8]The human body contains approximately 5 mg of iodine, which functions only in the iodine-containing thyroid hormones. In 1990, the United Nations and WHO estimated that about one billion people are at risk for iodine deficiency disorders (IDD), 211 million with goiter (enlargement of the thyroid gland), 5.1 million with severe cognitive and neuromotor deficiencies (cretinism), and many more with less severe neuropsychological defects.

harvesters usually barter their salt for an equivalent weight in rice, and have done so for hundreds of years, make the harvested natural salt more attractive than the more expensive iodized product. To maintain their own subsistence level livelihoods, the salt harvesters have spread and encouraged rumors that animals and people fed iodized salt will be infertile.

In rural China and Mongolia, the Chinese government's policy of introducing iodized salt to the agrarian population has been much more successful than in religious regions of Tibet. In the 1980s the rates of goiter (indicated by an enlarged thyroid and an indicator of iodine deficiency) in the general population of China were as high as 40 %. By making non-iodized salt illegal and keeping the price of the iodized salt low, the current rate of goiter in the general Chinese population is now somewhere near 5 %.

Iodization programs in salt and milk products in the western world since the 1920s had largely eliminated the problem of iodine-deficiency by the 1960s. Ironically, in some in parts of the western world now lacking a government-enforced iodine program, the populist anti-science "new-age" push for healthier back-to-nature, vegan and organic food products is an evergrowing and ever more profitable market trend. Accordingly, there has been a move away from iodized salt and iodized milk to make it more "natural." Now the rate of incidence of iodine-deficiency in the general population, and in children especially, is growing once more in many parts of the developed world.

For example, in Australia in 2003 the iodine intake in the population was half what it was 5 years earlier, but most Australian adults were unaware they were recreating the problem of iodine-deficiency in their children (Li et al. 2001). Based on a more recent 2010 WHO study, it appears the problem in Australia has grown even further (Sydney Morning Herald Newspaper, Oct 10, 2010). The WHO study, which focused on almost all the babies born in the state of Victoria from 2001 to 2006, found clear signs of iodine deficiency in many Australian newborns. About 26,000 of the 368,000 newborns, or about seven per cent, were found to have elevated concentrations of thyroid-stimulating hormone (TSH) caused by the body's compensatory response to a poor intake of iodine. A smaller NSW-based study found 5–8 % of newborns in that state from 1998 to 2000 were iodine deficient. The WHO considers a population to be iodine deficient if more than three per cent of neonatal blood samples show elevated TSH concentrations. New-age anti-science and anti-industrial mantras, now followed by an increasingly scientifically-uninformed proportion of the Australian adult population, have returned the status of Australia's newborn population to that of "iodine deficiency." Some states in Australia are now considering legislation to make iodized flour mandatory in bakery products.

Bromine

Bromine has an abundance of 2.5 parts per million in the Earth's crust, ranking it forty-sixth in order of abundance of the elements. It is more prevalent in the oceans, at 65 ppm. The name bromine comes from the Greek *bromos* meaning stench. Bromine was discovered in 1825 when Antoine Balard extracted it from seawater bitterns. The United States and Israel dominate the world's elemental bromine output of about 5.2 million tonnes (5.7 million st). Azerbaijan, Ukraine, France, United Kingdom, China, Japan and India contribute most of the rest. Bromine is recovered from modern brines in Searles Lake and the Dead Sea, as well as from formation waters in the Gulf of Mexico and the Michigan Basin, and seawater in Japan and Spain (Fig. 12.61). For example, a brine averaging 5,000 ppm Br is recovered for processing from depths around 2,500 m in the upper Reynolds Oolite Member of the Upper Jurassic Smackover Formation in Union Co, southern Arkansas (Kyle 1991). The elevated Br content in this brine indicates natural leaching of the underlying Louann Salt.

Since 1957 bromine has been produced at Beersheva, Israel, as a byproduct from bitterns associated with potash, chlorine and caustic soda production. There, and in the Jordanian salt works on the other side of the border, solar evaporation concentrates lake brines pumped from the Dead Sea ($Br \approx 4{,}000$ ppm). After the potash slurry is processed, residual bitterns are treated with chlorine to recover bromine. Bromine-free bitterns are then further processed to recover magnesium. The Dead Sea effluent feed-brine for bromine recovery contains 11,000–12,000 ppm of bromine and is one of the richest bromine brine feeds currently in commercial operation. Brine reserves are huge, with the Dead Sea waters containing more than 1 billion tonnes of bromine. In Germany, bromine is produced as a byproduct of potash mined from the Zechstein salt.

Since 1973, when the United States produced 71 % of the world supply, its market share has decreased; a result of local environmental constraints and the emergence of Israel as the world's largest producer. Israel, the United States, Jordan, China, Japan, and Turkmenistan, in descending order, had the leading bromine production capabilities in 2010, although none of these countries operated at capacity in that year (Fig. 12.61; Ober 2011).

Traditionally, the major market for bromine was in the production of ethylene dibromide; a lead scavenger in gasoline antiknock compounds. However, this market has been in decline over the past four decades, and is now very small, as more and more countries legislated to require catalytic converters in all new cars and the use of lead-free gasoline. Flame retardant is now the largest end use and accounts for more than 30 % of the US bromine market. Other uses include intermediates in chemical manufacture of dyes,

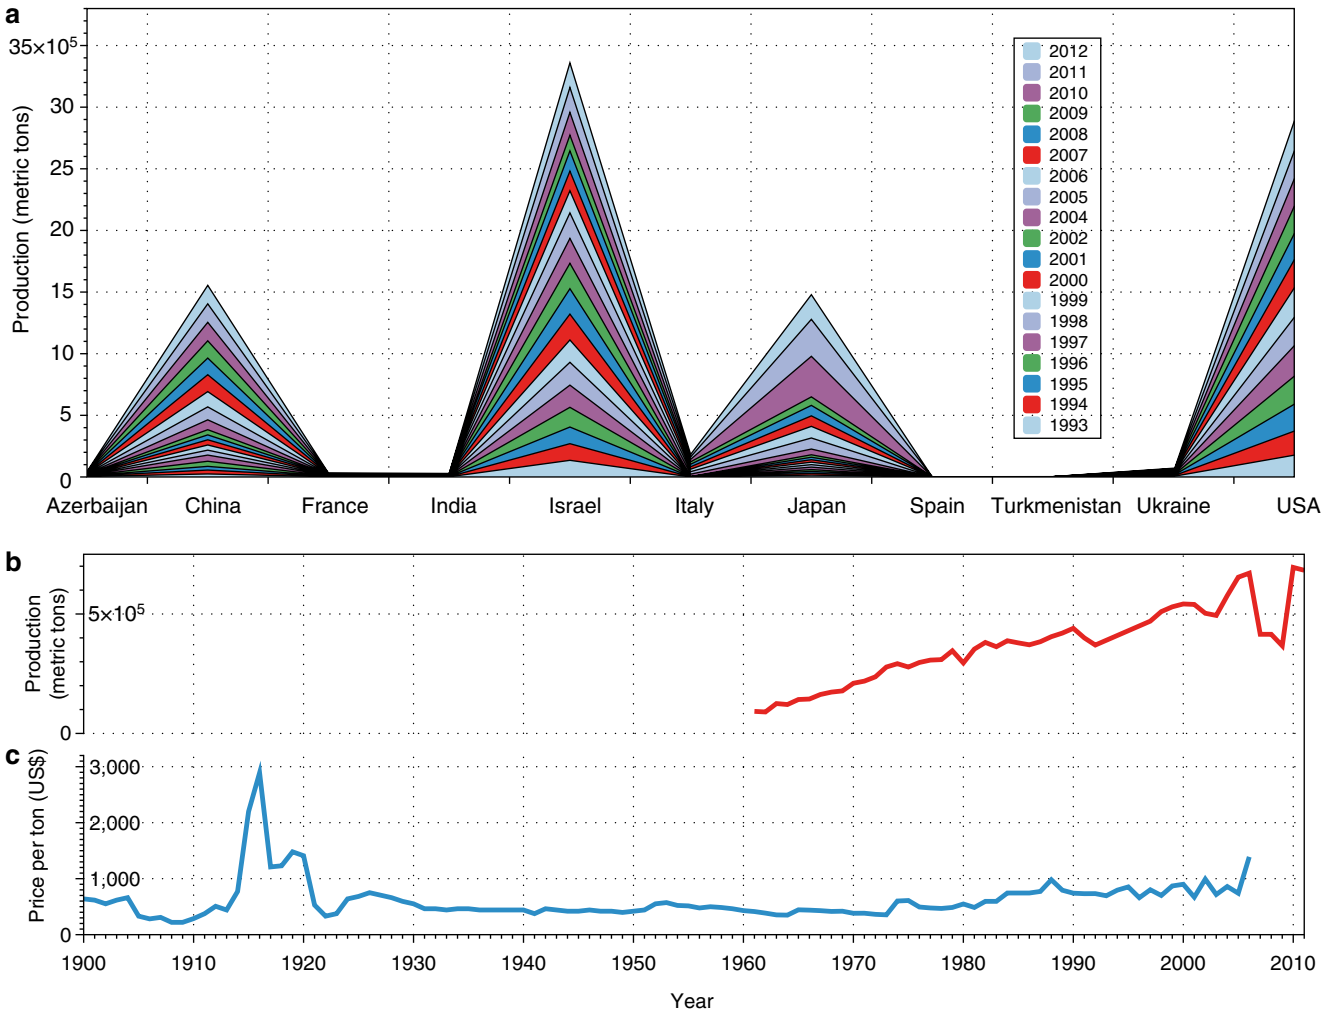

Fig. 12.61 Bromine production. (**a**) Cumulative area plot of annual brine production of major producing countries in metric tons. USA figures not made public since 2006 and so not plotted. (**b**) World production from 1960 to 2011 (metric tons), (**c**) Price per metric ton in US dollars from 1900 to 2006, since 2006 prices withheld for reasons of commercial confidentiality (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed April 21, 2014)

fragrances and pharmaceuticals; it is also used in photographic compounds, as bleach, as an additive in drilling fluids, and in the production of methyl bromide, a pre-plant soil fumigant. The market potential for bromide-based technologies to remove mercury emissions at coal-fired powerplants is an area of potential growth for the industry. Bromine use in commercial film processing continues to decrease as digital photography expands.

Nitrate Salts (Nitratite and Saltpetre)

The word nitre and the entomological derivatives nitrogen and nitrate ultimately come form the ancient Egyptian for nitre salts, *ntry*. Nitrogen is abundant on and near the earth's surface where it makes up 78 % of the world's atmosphere. It, along with potassium and phosphorus, make up the three essential plant nutrients driving the "green" agricultural revolution of th past 60 years. Natural deposits of nitrate are rare because of the extreme solubility of nitrate salts in water; synthetic sources of nitrate today far outweigh the natural sources, with natural sources today supplying less than 0.3 % of the world's nitrogen needs.

Nitrate salts precipitate as efflorescent crusts in several of the world's deserts including; the Egyptian and Namibian Deserts, the Gobi desert, the Abu Dhabi sabkhas and deserts of the Mojave and Death Valley. Small amounts of nitrate salts have also precipitated in the cryogenic deserts of Antarctica. Natural nitrate salts are only present in mineable quantities in the Atacama Desert of Chile, where deposits occur in a narrow zone between the low-lying Pampa del Tamarugal to the east and the hills of the Coastal Range to the west (Fig. 12.62a; Table 12.16; Ericksen 1981, 1983; Searl and Rankin 1993). This area contains nitrate-rich soft

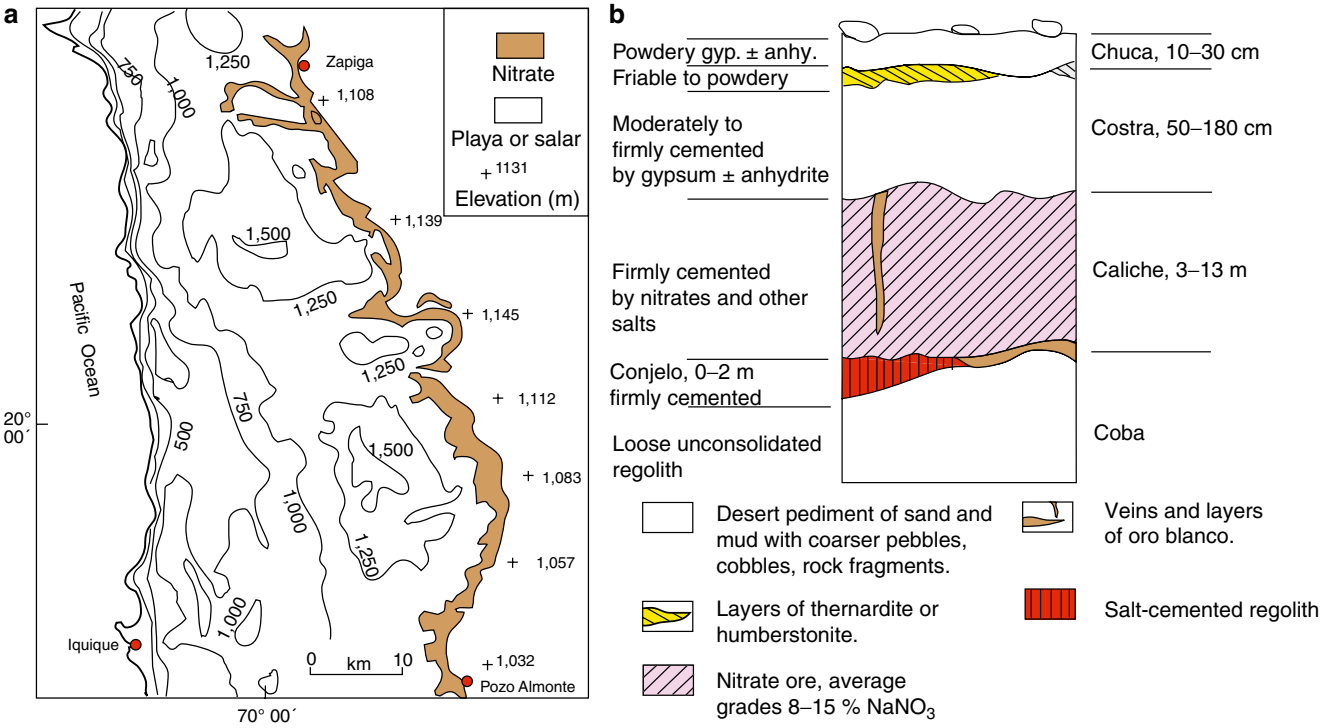

Fig. 12.62 South American nitrates. (**a**) Sketch of northernmost Chilean nitrate field, which is located along the eastern side of the Coastal Range, and marginal to salars and clay playas on the western side of Pampa del Tamarugal. (**b**) Typical regolith profile through alluvial-type nitrate deposits in a Chilean nitrate field (After Ericksen 1993; Ericksen and Mrose 1972)

soils, as well as surfaces encrusted with nitrate-bearing salts, saline-cemented regolith, and nitrates accumulating in closed basin playas or salars. Commercial concentrations develop in and atop weathered rock types ranging from granite to limestone and shales. Nitrates can be found in all topographic positions from hilltops to hillsides to playa and valley floor. The richest accumulations tend to be on the lower slope of hills situated marginal to salars and playas (Ericksen 1993).

Prior to the invention of synthetic nitre sources by Germany in the First World War, the Chilean nitrates were the main source of salt petre[9] in dynamite, and other explosive nitrate-based derivatives like nitroglycerine or glycerol tri-nitrate, nitrocellulose, nitroglycol, ammonium nitrate, etc. At its peak in the first 20 years of last century there were more than 250 actively mined concessions in the Atacama Desert, with production of 4 million tonnes/year and a local population of more than 250,000 people. At the time, the local name for the nitrate ore was "*oro blanco*" or white gold. By the 1960s synthetic worldwide production of nitrate and ammonia fertilizers meant there was no longer a viable economic base in the Atacama sufficient to support the nitrate boom towns of the first 20 years of last century; the last major mining town in the Atacama closed in 1960. Since then, the mining towns of Humberstone and Santa Laura have been declared World Heritage Sites. Total nitrate production from 1830 to 1970 in this region amounted to 135 million tonnes of $NaNO_3$. By 1980 the Chilean nitrates were only 0.14 % of the world market for fixed nitrogen.

Two major types of nitrate ore have been recognized in the Atacama desert (Ericksen 1983; Ericksen and Mrose 1972): (1) Regolith cement ("alluvial caliche") and (2) Impregnated bedrock ("bedrock caliche"). A typical alluvial caliche consists of various zone, at the top is *chuca*, a powdery to poorly cemented surface layer up around 10–30 cm thick (Fig. 12.62b). This consists of friable silt, sand, rock fragments and some gypsum and anhydrite. It is a surface soil from which a large portion of the soluble saline material has been leached and to which eolian silts have accumulated. It may contain a layer of soluble salts, including thenardite, bloedite and humberstonite. Beneath this, typically, is the 0.5–2.0 m thick transitional *costra* zone, which is moderately

[9]Nitre (sometimes called saltpetre) is a naturally occurring nitrate. The name saltpetre comes from medieval Latin "sal petrae" meaning "stone salt". The saltpetre terminology can be confusing as there are types of saltpetre, namely, (1) Ordinary saltpetre, or potassium nitrate (KNO_3) and generally referred to as 'saltpetre' without any prefix – it was the active gunpowder component that in Medieval times was derived from dung heaps and other decomposing organic material; (2) Chilean saltpetre or "cubic nitre" or "soda nitre" or "nitratine" or sodium nitrate ($NaNO_3$), this is the focus of our discussion as it is the predominant nitrate salt in the Atacama Desert; (3) Lime saltpetre or wall saltpetre or calcium nitrate [$Ca(NO_3)_2$] or Norgessalpetre (Norwegian saltpetre) or kalksalpetre – a rare efflorescent salt in natural state.

to firmly cemented with polygonal or "ped" structures. It in turn is underlain by the 1–3 m thick '*caliche*' zone, which is firmly cemented and contains layers of high-purity, white, nitrate-rich material called "caliche blanco". The caliche grades downwards into *conjelo* (saline-cemented regolith containing little sodium nitrate) or into *coba* (loose, uncemented regolith).

In contrast, bedrock caliche consists of saline impregnations and layers (from a few centimeters to several tens of centimeters in thickness) where crystallization processes have gradually forced open cracks and fissures in the matrix (Ericksen and Mrose 1972). In some cases the fractured bedrock may be so altered that it has converted into a mosaic of isolated rock fragments in a matrix of "caliche blanco".

There are a few small-scale nitrate mines still operating intermittently in the Atacama Desert, including Santa Maria, which is an open pit scrape extracting nitrate ore from stratiform pedogenic seams, just below the desert surface (Callao et al. 2002). Ores are hosted mostly by breccias or sandstones (volcaniclastics and tuffs) with the ore minerals occurring as mm-metre scale rinds about breccia or sandstone clasts. Nitrate contents in the ore seams vary between 7.5 and more than 20 wt% and NaCl between 8.6 and 40 wt%. Locally abundant are the sulphates thenardite, anhydrite, bloedite, polyhalite, hexahydrite and glauberite, which reflect part of 7.5–19.7 wt% content of Na_2SO_4. Other salts present as minor contents include a variety of sulphates (kieserite, woodwardite, loeweite); nitrates (humberstonite, darapskite and nitre); borates (calciborite, strontio-borite); chlorides (sylvite, nantokite) and iodates (bruggenite). The IO_3 content varies between 0.026 and 0.074 wt%. Other intermittently active nitrate quarries in the northern Chilean desert include Pedro de Valdivia and Pampa Blanca.

The micromorphology of nitrates from the Antofagasta region is described and illustrated by Pueyo et al. (1998), but overall the amount of information available on this aspect of caliche deposits is modest. The main features that can be noted are: (a) frequent complex mixing of crystals of different composition, with, for example, layers of that mixtures of relatively pure sulphate minerals (humberstonite, bloedite, etc.); (b) evidence for multiple episodes of precipitation and dissolution (e.g. solution cavities), and formation of desiccation polygons; (c) evidence for repeated fracturing and displacive growth, including the incorporation of microscopic fragments of saline minerals into larger crystals or grains of soda niter and halite; (d) incorporation of silt and other detrital material, together with remains of birds (feathers, guano, egg fragments, etc.; Ericksen 1981, p. 18); (e) presence of veins of purer nitrate (Ericksen and Mrose 1972); (f) evidence of extensive fracturing in the vicinity of faults; (g) formation of hard, spheroidal cakes of anhydrite, called *losa*, probably produced at the surface by prolonged slow leaching (Ericksen 1981); an (h) presence of small, length-slow chalcedony nodules.

Chilean nitrate ores have an average composition of: 7–10 % $NaNO_3$; 4–10 % NaCl; 10–30 % Na_2SO_4; and 2–7 % Mg, Ca, K, Br, and I (Ericksen 1983; Searl and Rankin 1993). The dominant nitrate in the Atacama is mostly nitratite (aka soda nitre or Chilean saltpetre, as distinct form KNO_3 known as saltpetre or common saltpetre). A number of other unusual highly soluble salts have also accumulated in the caliche ore, along with the nitrates, and include iodates, perchlorates, chromates and dichromates, as well as the more familiar borates, sulphates and chlorides (Table 12.16). The Atacama is the only known region in the world that contains natural perchlorate. Salts form at the more saline end of a vadose/phreatic precipitation sequence made up of progressively more soluble evaporitic minerals: silicates (zeolites); calcite; Ca-, Na-, (K-) and Mg-sulphates; Na- and K-Mg-nitrate-sulphates; nitratine; and small amounts of iodates, Na- and K-Mg-iodate-sulphates, chromates, borates and perchlorates (Pueyo et al. 1998). Two specific precipitation trends were distinguished within this more general regional sequence; a Na-trend characterised by an association of glauberite-darapskite-(hectorfloresite), and a K-Mg-Na-trend related to bloedite-polyhalite-humberstoniteniter-(fuenzalidaite).

What is most amazing about the Atacama nitrates is the age of the desert host and stability of its geomorphic features; some nitrate soils are thought have been at the surface since the mid-Miocene, so allowing the gradual buildup of large volumes of pedogenic and atmospheric salines in the soils including the exploited nitrates (Alonso et al. 1991). The Atacama Desert is one of the driest places on Earth, its hyperaridity is the result of the rainshadow effect of the High Andes and the strong atmospheric temperature inversion along the coast (Chap. 2). Average annual rainfall in the Atacama Desert is less than a centimetre, and as much as 20 years can pass between rainstorms, with similar conditions prevailing since the middle Miocene.

The unusual mineralogy of the nitrate ore reflects the extreme chemical evolution of the precipitating brines through multiple episodes of salt precipitation and remobilization during transport to the nitrate horizons. The ultimate source of the nitrate is atmospheric nitrogen, first carried inland as nitrate in sea fogs (Rech et al. 2003; Ericksen 1993). These dense coastal fogs or low clouds, locally known as *camanchaca*, sweep inland from the Pacific Ocean, covering the nitrate area nearly every night-early morning during the winter months of June to August, and usually precipitating some condensate on the soil surface (Garrett 1985). The fogs in most areas generally do not extend farther east than the central valley of Pampa del Tamarugal but do fairly completely cover the nitrate zone (Fig. 12.62a). The marine biogenic nitrates and iodates carried inland by these fogs are then mobilised from the soil moisture zone into the vadose (caliche) zone during rare but perhaps intense rainfall events that occasionally flood this hyperarid desert.

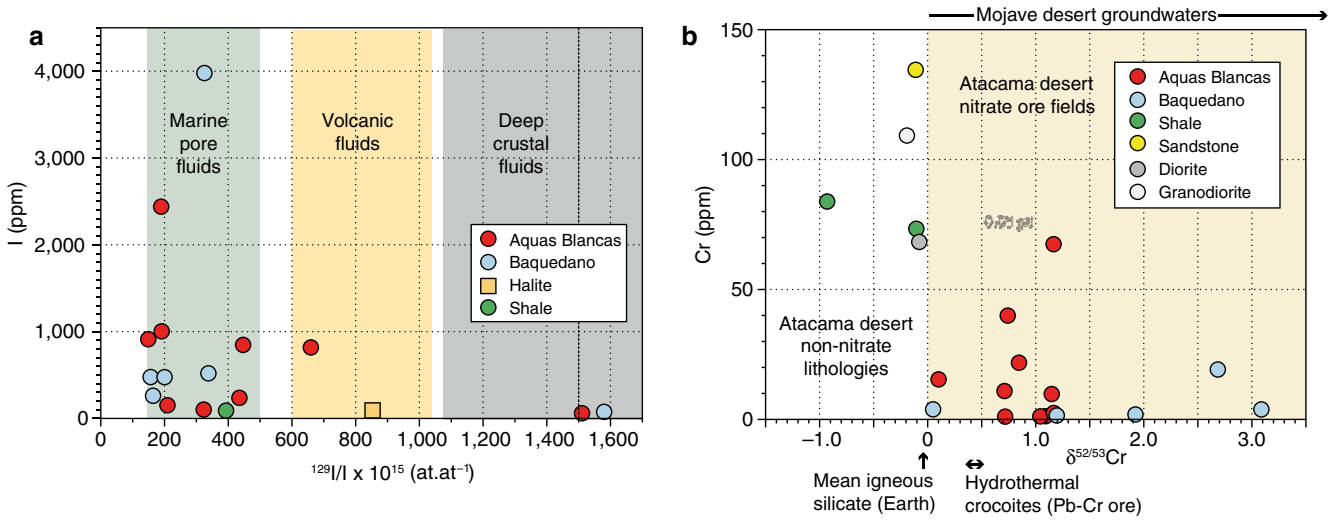

Fig. 12.63 Isotope indicators in nitrates of the Atacama Desert, northern Chile. (**a**) $^{129}I/I$ ratios of nitrate sample (AMS—accelerator mass spectrometry) plotted against iodine levels (ppm). Vertical dashed line shows pre-anthropogenic surficial/atmospheric iodine ratio ($1{,}500 \times 10^{-15}$). (**b**) $\delta^{53/52}Cr$ of nitrate samples plotted against Cr levels (ppm). Also plotted are Mojave Desert (western USA) groundwater values as well as mean values for igneous silicate earth and hydrothermal crocoites (Plots are compiled from geochemical spreadsheets stored in GSA data repository for Pérez-Fodich et al. 2014)

Upwelling coastal waters off Chile, and associated coastal fogs, can contain high concentrations of nutrients and dissolved solutes. The average concentration of dissolved solutes in Chilean coastal fog are: 9.1 ppm SO_4; 0.8 ppm NO_3; 1.8 ppm Cl; 4.81 ppm Na; 0.4 ppm K; 1.0 ppm Ca; 0.6 ppm Mg. Sea spray moves these solutes as aerosols into the coastal fog, while the sulphate in sea spray comes mostly from outgassing of biogenic marine sulphur (Chap. 2). As sea fog moves inland over the Atacama, it settles and evaporates, so depositing its dissolved solutes into the soil moisture zone, which are then fractionated by pedogenic and downslope meteoric processes. To form an ore grade nitrate buildup in the soil requires multiple pedogenic fractionation episodes that are driven by dissolution, reprecipitation and recrystallisation within hyperarid desert soils. Millennia of these processes vertically separates the highly soluble nitrate salts from less soluble sulphate salts in the overlying profile (Fig. 12.62b).

Once the nitrates and iodates arrive in the soil moisture zone via a combination of sea fogs, runoff and volcanic sublimates, they are reworked into the groundwater system. The parental brines for the richer nitrate deposits are the hypersaline discharge portions of the regional vadose/phreatic system, which Pueyo et al. (1998) consider to be older than 6 Ma. At that time the main physiographic features were similar to today, but the climate was more humid. Precipitating parental waters were derived from a variety of meteoric sources: westward flowing Andean groundwater, coastal fogs, occasional rainfall and Andean-derived surface floodwaters. Evaporation in a background of shallow watertables and hyperaridity was involved in the nitrate paragenesis; it is the only mechanism effective enough to saturate a brine with these very soluble supersaline minerals (Garrett 1985). Nevertheless, most of the nitrate ores do not show typical displacive nodular and enterolithic evaporitic textures, rather, the salts tend to passively infill veins, fractures or pre-existing matrix porosity and the various salts have largely accumulated through passive growth. Locally, some of the host silicate and carbonate lithologies have also undergone a small degree of active salt replacement.

Isotopes of iodine and chromium indicate multiple and complex sources for the various elemental components in the Atacama nitrate ores (Fig. 12.63; Pérez-Fodich et al. 2014). Isotopic ratios of iodine held in the nitrate ores ($^{129}I/I \approx 150$–600×10^{-15}) share similarities with deep sedimentary (marine) pore waters and shales, and are significantly different from the pre anthropogenic atmospheric iodine ratios (Fig. 12.63a; $^{129}I/I \approx 1{,}500 \times 10^{-15}$). Such dominantly low ratios in the majority of nitrate ore values, likely rule out a prevalent atmospheric/eolian source for most of the I and point toward an old I source. It is likely that much of the iodine in the nitrates was leached from Jurassic marine sediments that are exposed along the eastern margin of the Atacama Desert. The few samples showing higher $^{129}I/I$ ratios (~600–$1{,}580 \times 10^{-15}$) are perhaps indicative of the influence of meteoric water with high pre-anthropogenic $^{129}I/I$ ratios, related to infrequent moisture and flooding events, associated with increased precipitation in the High Andes, as occurred 16–10 ka and led to increased groundwater recharge.

The positive and highly fractionated $\delta^{53/52}Cr_{SRM979}$ values (+0.7‰ to +3‰) are indicative of Cr enrichment relative to

Table 12.17 Sedimentary minerals and deposit types used as a source for magnesium oxide or magnesium metal

Mineral	Formula	Deposit exploited
Magnesite	$MgCO_3$	Sparry or cryptocrystalline
Dolomite	$Ca_{(1-x)}Mg_x(CO_3)_2$	Not utilized
Brucite	$Mg(OH)_2$	Weathering byproduct
Brunnerite	$Mg_{(1-x)}Fe_x(CO_3)_2$	Sparry (magnesite associated)

the mean value of silicate Earth reservoirs (Fig. 12.63b; Pérez-Fodich et al. 2014). This highly fractionated Cr isotope signature in Atacama's nitrates, with respect to common Cr sources such as igneous rocks and marine shales is strong evidence of extensive Cr redox cycling from its source to the final deposition in the nitrate salts. This set of highly fractionated $\delta^{53/52}Cr_{SRM979}$ values are comparable to groundwater $\delta^{53/52}Cr_{SRM979}$ values in the arid hydrology the Mojave Desert, California and argues for a similar origin.

Pérez-Fodich et al. 2014 use isotope values in the Aguas Blancos and Baquedano nitrate ores to argue for a multisource genetic model. If so, extensive pedogenic nitrate accumulations are the result of long-lived, near-surface mineral precipitation, driven by groundwater evaporation (chromates, iodates) coupled with dry atmospheric supply (nitrates, perchlorates) and sea spray inputs (sulphates, chlorides), deposited by an evaporite hydrology triggered by increasing aridity and tectonic uplift in the late Miocene to early Pliocene. That is, the unique nitrate deposits that constitute a large and near-continuous, 700-km-long by 20-km-wide pedogenic salt belt are the result of an unusual convergence of common physical-chemical processes where an ideal combination of geologic, tectonic, hydrologic, and climatic has occurred. The nitrate belt defines the hyperarid portion of a convergent margin, undergoing rapid uplift since the late Miocene to hinterland elevations sufficient for exhumation and weathering of Jurassic marine sequences, and enhanced large-scale groundwater flow toward the Central Basin.

Magnesite and Magnesia Salts

Magnesium is the eighth most abundant element in the earth's crust (2.4 %) and is widely distributed in numerous minerals. Magnesium is named after ancient *Magnesia*, a district in Thessaly, Greece. Among the more commercially important magnesium minerals are magnesite, brucite, dolomite, olivine, talc and serpentine (Table 12.17), as well as the magnesium sulphate and chloride salts recovered from natural brines and concentrated seawater (e.g., epsomite, bischofite, carnallite). World resources of magnesite, dolomite and magnesium-bearing evaporite minerals are enormous. Magnesium-bearing extractable brines are estimated to constitute a potential resource measured in billions of tonnes, and in the near future magnesium will be economically recovered from seawater off arid coasts.

As well as being extracted by concentrating seawater, magnesium is also produced by processing of continental evaporitic and subsurface basinal brines in the USA, the Netherlands, Israel and Mexico. In the Netherlands the brine is formed by solution mining of magnesium/potassium-bearing horizons (carnallite, bischofite and kieserite) in the Permian Zechstein section (Fig. 13.6). Mg-rich continental brines of the Dead Sea are also processed for magnesium after bromine is extracted. When pumped into the saltworks, Dead Sea brine already contains 42,430 ppm of magnesium (30 times seawater levels), which when evaporated and processed produces caustic-calcined and dead-burned magnesia,[10] along with small amounts of magnesian chloride.

Electrolytic processes recover much of the world's currently produced magnesium. The majority of magnesium compounds are used for refractories in the die casting industry. Due to an inherent high strength to weight ratio, usage in the automobile industry is expected to double in the next decade. Currently, the aluminium industry is the largest consumer of magnesium, where it is a constituent in aluminium-base alloys used for packaging, transportation, and other applications. The remainder is consumed in agricultural, chemical, construction, environmental, and industrial applications. Annual world magnesia production (from magnesite) is more than 3.1 Mt (3.4 million st), mostly from China, USA, North Korea, Russia and Turkey. Although no specific production figures are available, China and the United States probably account for more than one-half of the world's capacity for the production of magnesium compounds from seawater and brines.

Geological occurrences of magnesite are either microcrystalline (micritic) or macrocrystalline (sparry), as illustrated in Table 12.18. Within this classification framework there are four end member types (named using European examples, Pohl 1989). They are; Kraubath, Bela Stena, Greiner and Veitch.

[10] *Dead–burned magnesite* (or refractory magnesia) refers to the granular product produced by firing magnesite, magnesium hydroxide, or other materials reducible to magnesia at temperatures in excess of 1,450 °C.

Calcined magnesia is the result of 800–1,000 °C heat being applied, frequently in a rotary kiln, to magnesite or other materials reducible by heat to magnesia. It is heated to such a degree that less than 10 % ignition loss remains and the product displays absorptive capacity or activity. *Fused magnesia* is produced by heating high grade magnesite to a molten state for up to 6 h in electric arc furnaces to temperatures approximately 3,000 °C. The resultant product, at 96–98 % MgO, has a favorable high density of 3.50 g/cc and relatively high chemical stability, strength, and resistance to abrasion.

Table 12.18 Classic styles of magnesite occurrence, based on type settings in Europe

	Ultramafic-hosted	Sediment-hosted
Ultrafine-grained (cryptocrystalline to microcrystalline)	Kraubath	Bela Stena
Coarse-grained (sparry)	Greiner	Veitch

After Pohl (1989)

1. Kraubath-type, consisting of cryptocrystalline (or microcrystalline) high-purity, snow-white, magnesite forming veins and stockworks related to hot spring alteration of ultramafic rocks (e.g. Neogene alpine fault zones in southern Europe).
2. Bela Stena-type, consisting of fine-grained, high-purity, nodular, massive, banded, brecciated or vuggy magnesite forming lensoidal or irregular bodies grading into well-defined seams (less commonly sinter deposits) within mainly clastic lacustrine Tertiary-age sediments developed close to ultramafic outcrops.
3. Greiner-type, consisting of sparry, ferroan magnesite–talc or ferroan magnesite–chlorite assemblages (up to 70 % granular magnesite) formed by carbonation of ultramafic rocks.
4. Veitch-type, consisting of sparry, high-purity magnesite associated with bedded siliciclastic and carbonate rocks, and commonly forming very large deposits (130 Gt in Liaoning deposits in China) and depositionally related typically to original marginal marine deposition (e.g. partial analogies to Coorong area in South Australia), typically with regional metamorphism or hydrothermal replacement of a limestone precursor (with dolomite as an intermediate stage).

Overlaying this classic subdivision based on the geology of type magnesite deposits, there are three geologic modes of sedimentary-associated magnesite occurrence: (1) Small scale micritic deposits accumulating in Quaternary alkaline lake and mudflats in climates ranging from hot arid to cold temperate (Table 12.19); (2) Laterally continuous, stratiform sedimen-thosted deposits, which can be cryptocrystalline (micritic) or coarsely crystalline (sparry). Sparry deposits tend to occur more frequently in Precambrian strata; (3) Clustered hydrothermal deposits that form sparry magnesites at or near ultramafic complexes of all ages. Weathered cryptocrystalline magnesite stockwork deposits (Kraubath style) hosted in serpentinites and dunites are commercially exploited in the Yerakini mine, Greece. Similar cryptocrystalline deposits, hosted in dunites, are mined in southern Salem district of Madras state, India. Further discussion of style 3 (Kraubath and Greiner styles) and variably developed pedogenic textures lies outside the evaporite focus of this book and the interested reader is referred to Pohl (1990).

Sparry style 2 occurrences constitute a large portion of current refactory magnesia ores. Style 1 deposits offer small-scale analogs for the sort of low temperature brine chemistry that has produced many sedimentary magnesite deposits. It suggests a requirement of waters enriched in magnesium, commonly hypersaline, and an association with microbes (Table 12.19). Within Style 2, magnesite occurs in two commercially exploited forms, coarse crystalline (sparry) magnesite -Veitch style- and cryptocrystalline magnesite -Bela Stena style- (Table 12.18; Pohl 1989). Sparry magnesite deposits tend to be larger and purer (70–90 % $MgCO_3$) than most cryptocrystalline magnesite deposits (purity <12 %$MgCO_3$) and are the preferred ore deposit style, worldwide. Much of the world's sediment-hosted coarsely crystalline magnesite is Precambrian and typically occurs as variations on a theme of fault-controlled, high temperature, hydrothermal alteration of dolomitic shelf sediment.

Modern cryptocrystalline sedimentary magnesite occurrences are nonmarine bedded, micritic, laterally limited and lacustrine; most ancient sedimentary magnesites are marine-associated, stratiform, microsparry to sparry, laterally and vertically extensive, and diagenetically altered. As with ancient evaporitic dolomite and ancient marine-fed evaporites, there are fundamental problems when comparing brine chemistries of recent and ancient sedimentary magnesite deposits. Today cryptocrystalline magnesite is mostly a nonmarine saline lacustrine precipitate with precipitation increasingly being interpreted and bacterially mediated (Table 12.19; Gierlowski-Kordesch 2010; Armenteros 2010; Sanz-Montero and Rodriguez-Aranda 2012). For an excellent and readily accessible summary of precipitative settings of modern magnesian carbonates see Deelman (2011).

Magnesite is easily manufactured in the lab using inorganic chemical techniques, but as for inorganically produced dolomite, natural magnesite requires temperatures much too high to be realistic in a modern marine sedimentary system. Likewise there are intrinsic problems with comparisons of scale and diversity modern and ancient, leading to interpretations of ancient magnesite origins in terms of "solving the magnesite problem." Some authors have suggested that Precambrian magnesite was a primary evaporitic marine carbonate, or even a normal marine mineral (Frank and Fielding 2003).

Major Phanerozoic cryptocrystalline sedimentary magnesite deposits occur in Australia and Turkey, where most occurrences are considered potential, rather than actual, ore deposits. Worldwide, almost all Phanerozoic cryptocrystalline magnesite sediments are either sepentinite-hosted stockworks (Kraubath style) or lenses of evaporitic lacustrine sediments in serpentinite terrains. The huge Tertiary lacustrine/pedogenic cryptocrystalline lacustrine deposits in the vicinity of Rockhampton, Australia, are a possible exception, as are the Neogene huntite-magnesite-hydromagnesite lacustrine deposits in the Kozani Basin, Northern Greece, the Bela

Table 12.19 Selected examples of Holocene occurrences of sedimentary magnesite

Location	Style	Reference
Coorong lagoon, southern Australia (Csb)	Primary magnesite precipitates (with magnesian dolomite) in a number of hypersaline-schizohaline coastal lakes fed by continental brines. Nearby lakes contain hydromagnesite-aragonite associations.	Alderman and von der Borch (1963), Warren (1990)
Clipperton Atoll, Pacific Ocean (mid oceanic; BSh?)	Magnesite occurs at the bottom of the atoll lagoon. Some 2,850 years ago the lagoon became sufficiently isolated to be density stratified. At present the upper 14–15 m of the water column has a salinity of 14‰, while the underlying water mass up to a maximum depth of 34 m is marine (salinity of 33–34‰).	Bourrouilh-Le Jan et al. (1985)
Lake Bonneville, Great Salt Lake depression, Utah (BSk)	Magnesite was found in association with aragonite and dolomite in five cores taken through saline laminites near the shore of former Lake Bonneville. The dark layers contain about twice as much magnesium as the light layers. The light-coloured laminations contain more clay minerals than carbonate.	Graf et al. (1961), Bissell and Chilingar (1962)
Lake Yao, Chad (BWh)	Magnesite occurs in beaches of Lake Yao, a saline lake in northern Chad. Occurs in a sequential paragenesis going from the lake up to the beach: changes from calcite, aragonite, magnesium calcite, dolomite, huntite, magnesite, sodium carbonates (nahcolite, thermonatrite, trona), sodium sulphates (burkeite, thenardite), halite and sylvite. Accompanying brine has pH ≈ 10.	Gac et al. (1977)
Lake Walyungup, (coastal lake) Western Australia (Csa)	Hydromagnesite in the littoral zone replacing aragonite, particularly within the mesoclot fabric of stromatolites, but also in sediments (strandline and dune sand, crusts) derived by erosion of stromatolites.	Coshell et al. (1998)
Playa Pito, Playa Gualla, and Laguna Gallocanta southeast of Zaragoza, Spain (Cfb)	Diagenetic association with dolomite, calcite, gypsum, halite, thenardite, and bloedite, increases with depth (from 5 to 30 %). Tends to form in mixing zone about playa edge where hypersaline lake brines mix with brackish groundwaters.	Pueyo-Mur and Inglés-Urpinell (1987)
Tuz Gölu, Turkey (Csa)	Magnesite and huntite are early diagenetic minerals in saline mudflat formed by transformation of dolomite in the presence of pore fluids with a high Mg/Ca ratio.	Irion and Mueller (1968), Camur and Mutlu (1996)
Sabkha El Melah, Tunisia (BSh)	Minor phase in coastal sabkha, probably replacing aragonite.	Perthuisot et al. (1972)
Sabkhat of Abu Dhabi (BWh)	Magnesite is a minor phase (possibly after huntite) found only in the upper 10–20 cm of the Abu Dhabi supratidal.	Kinsman et al. (1967), Bush (1973)
Salda Gölu, Turkey (Csa)	Extensive areas of hydromagnesite shorelines and basin centre turbidites formed by mechanical breakdown of hydromagnesite microbialites.	Braithwaite and Zedef (1994), 1996
Saline lakes, British Columbia, Canada (Dfc)	Simple monomineralic biolaminated carbonate or sulphate layers as well as beds and mounds composed of complex mixtures of aragonite, magnesite, hydromagnesite, mirabilite, gypsum, epsomite, and/or bloedite.	Last and Vance (1997), Power et al. (2014)

Stena region of southeastern Serbia and the lacustrine magnesites in the Acıgöl Basin, southwestern Anatolia, Turkey (Stamatakis 1995; Alçiçek 2009). Extensive drilling in eastern Australia in the 1980s, centred on Rockhampton, outlined several large lacustrine magnesite deposits, namely; Marlborough, Kunwarara, Merimal and Yamba. Of these, the largest, but as yet not yet fully realized, economic accumulation is the Kunwarara deposit (Fig. 12.64). It contains some 550 million tonnes of potential magnesite ore, including 260 million tonnes in a soil-covered nearsurface "blanket" ore composed of 40–45 % cryptocrystalline magnesite.

The Kunwarara deposit, situated some 60 km northwest of Rockhampton, has a proven area of 31 km^2 making it one of the world's largest deposits of cryptocrystalline magnesite, and is the only major source of lacustrine magnesite in Australia. The deposit, which has been intermittently mined

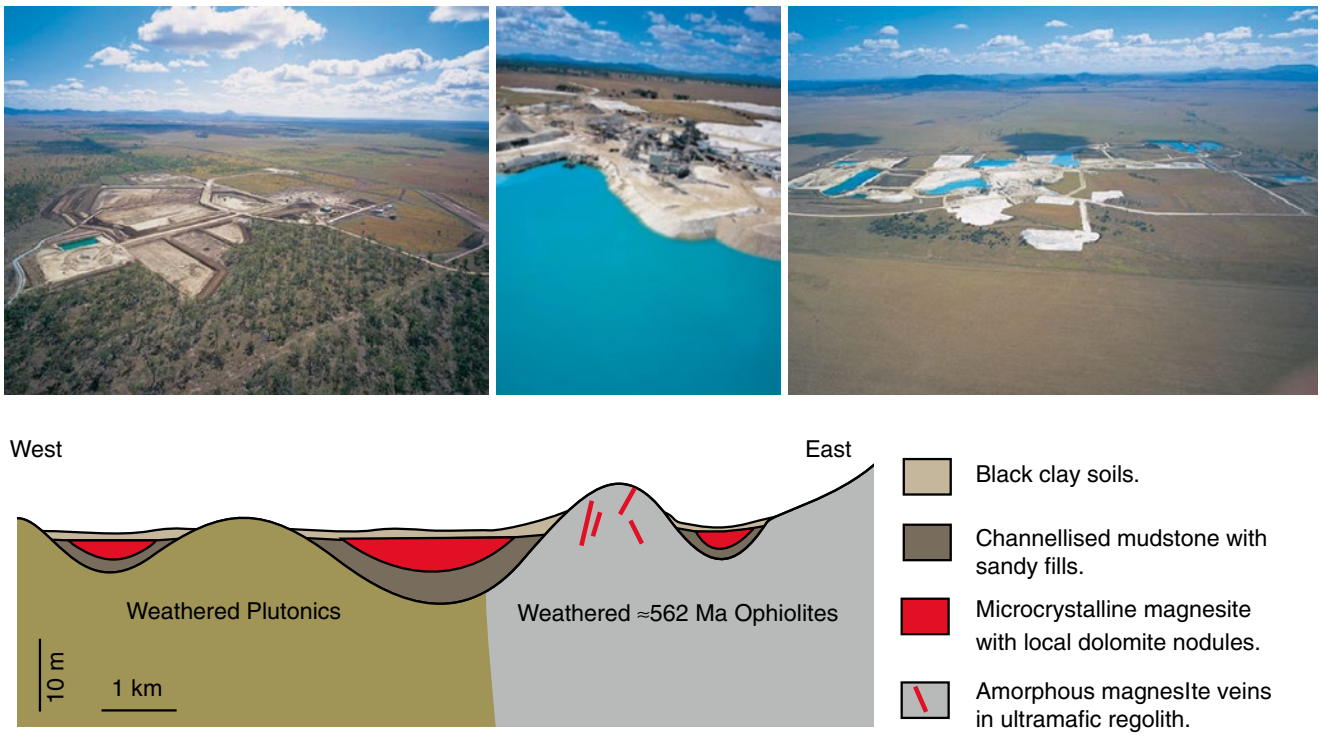

Fig. 12.64 Kunwarara magnesite, Queensland, Australia, showing general mine views and a magnesite distribution schematic cross section of regolith over the Marlborough ophiolite complex

on a small scale since 1991, has an inferred resource of 1.2 billion tonne magnesite concentrate at 20 % $MgCO_3$ cutoff, for 345 mt Mg (Milburn and Wilcock 1998). All this magnesite is stratiform, micritic and shallow, making it readily accessible to open pit access (Fig. 12.64). It is a blanket deposit varying in thickness from 1 m to 26 m, with an average thickness of 7.75 m. It lies below a humus-rich black clay ranging in thickness from 0.4 to 12 m, with an average thickness of 7.75 m (Fig. 12.48; Burban 1990; Hill 1993; Milburn and Wilcock 1998).

Most of the Kunwarara magnesite is in mm-metre diameter nodules and lumps, in a matrix of soft magnesitic mudstone, which is underlain by dolomitic mudstone, sandstone or gravel. The deposit is thought to have formed via secondary alteration of magnesian-rich lacustrine sediments. In the Marlborough area, economic magnesite occurrences are more lenticular and occur in paleochannels in the regolith, as well as in nodules, veins and stockworks in the weathered zone of ultramafic basement rocks. The formation of all the Queensland magnesite deposits involved erosion of deeply weathered lateritic soils on magnesium-rich serpentinites with subsequent deposition as fluvial/lacustrine sediments, which were then subject to further evaporatively-driven pedogenic enrichment.

A partial modern analogue for Kunwarara is the magnesite-rich lake sequence of Salda Golu in southern Turkey (Fig. 4.32; Schmid 1987). Based on this comparison, the following conditions are thought to have formed the Kunwarara deposits:

- Deep weathering of primary stockwork-bearing serpentine rocks and subsequent erosion by heavy rains.
- Water and groundwater transport of eroded and dissolved magnesian materials into a lake depression.
- Deposition and crystallization of magnesite muds in an ephemeral mudflat (capillary evaporation). Agglomeration of material into cryptocrystalline nodules.
- Periodic waves and sheet flooding carries away non-crystallized impurities such as SiO_2, Al_2O_3 and CaO.
- Flushed impurities deposited in adjacent shallow lakes, which, with a lowering of lake levels, then acted as matrix for later magnesite nodules.
- Magnesite layers were compacted and covered by soil. Pedogenesis also formed a silica-rich skin on the nodules, while pedogenic magnesite continued to crystallise in the nodular horizons.

In contrast to the meteoric supply and precipitation of micritic magnesite in Tertiary lake depressions, much of the cryptocrystalline sedimentary magnesite in Precambrian sediment is thought to be a primary precipitate from marine-fed brines. The "Magnesite Problem" is most obvious when comparing the disparity between the abundance of primary or syndepositional cyptocrystalline magnesite in

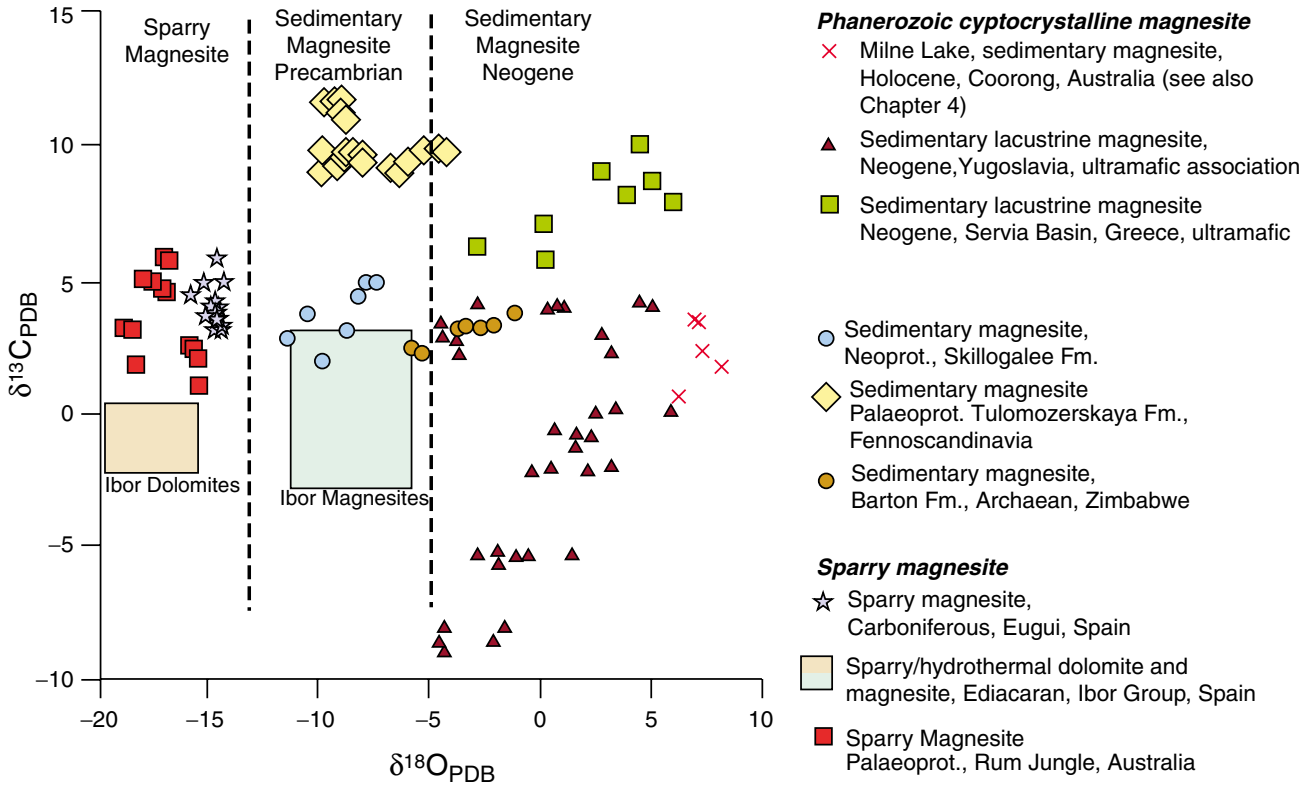

Fig. 12.65 Stable isotope signatures of sparry, lacustrine and cryptocrystalline Precambrian magnesites (In part after Melezhik et al. 2001; Herrero et al. 2011)

Precambrian restricted-marine settings and the paucity of cryptocrystalline magnesite in similar modern marine-fed evaporitic settings. The disparity probably reflects differences in the ionic proportions in Precambrian and modern oceans, especially the relative lack of sulphate and calcium, as well as extreme carbonate saturation in Precambrian oceans (Chap. 2).

Well-documented examples of widespread Precambrian magnesite are the Paleoproterozoic Tulomozerskaya Formation of the Fennoscandinavian Shield (Melezhik et al. 2001), the Ediacaran Ibor Group of western Spain (Herrero et al. 2011) and Neoproterozoic Skillogalee Formation of the Flinders Ranges in southern Australia (Frank and Fielding 2003). The latter is intermittently exploited in a small way (≈10,000 t/year). In the vicinity of Leigh Creek an inherently high purity gives the Skilogalee the potential for much higher levels of exploitation (Keeling and Mauger 1998). Outcrops of Skillogalee magnesite across the Flinders Ranges show very well preserved primary structures. In contrast, metamorphism and coarser recrystallization has destroyed more of the fine primary detail in the Fennoscandinavian magnesite strata. Yet, both areas still retain abundant textures from their primary marine-fed evaporite association (stromatolites, mudcracks, tepees, evaporite pseudomorphs, intraclastic horizons, dissolution breccias).

Some highly metamorphosed Precambrian sparry ore deposits are huge; a single magnesite-bearing zone in Liaoning Province of China is approximately 60 km long and has an outcrop width of 1–2 km. It is known to continue further to the north-east and reportedly contains some 2.5 Gt of ore (Qiusheng 1988). There are 17 moderate to large deposits and many smaller ones in the district. The magnesite bodies are stratiform, concordant with the bedding in the host dolomites, and have an average thickness of 100 m. Minor amounts of talc, tremolite, quartz, dolomite, calcite and pyrite accompany the magnesite. The magnesia content is very uniform. This, and the excellently preserved sedimentary structures, such as hail pits on bedding surfaces and slump folds, that have been found, and stable isotopic investigations, suggested to Qiusheng (1988) that the deposits are of primary saline sedimentary origin. They are associated with the siliceous metaborate marble-hosted meta-evaporites discussed in Chap. 14.

A comparison of stable isotope signatures from various types of magnesite deposits shows a clear separation in oxygen isotope signatures between Neogene lacustrine magnesites, Precambrian cryptocrystalline magnesites, and Precambrian sparry magnesites, with each group showing successively more negative values (Fig. 12.65). This difference, at least in part, reflects the higher hydrothermal

temperatures that characterise the sparry magnesite association. Within the cyptocrystalline magnesites it also reflects the likelihood that Precambrian carbonates have in general experienced higher burial temperatures for longer periods than Neogene lacustrine precipitates (Melezhik et al. 2001). Carbon isotope signatures are much more variable and relate in part to the variable supply of carbon from pre-existing carbonate minerals, levels of organic contribution and amounts of meteoric input.

Sulphur Salts (Brimstone)

Sulphur, a nonmetallic element, is the second element of Group 16 (VIA) in the periodic table, coming below oxygen and above selenium. In massive elemental form, sulphur is often referred to as brimstone. The name comes from the ancient Latin *sulpur*, referring to it as the stone that burns. Sulphur is one of the most important raw materials of the chemical industry and of prime importance to the fertilizer industry. Its consumption is generally regarded as one of the best measures of a nation's industrial development and economic activity (Anonymous 2007). Sulphur may be found alone as native or elemental sulphur, or as a gregarious element in combination with many other elements, including metal sulphides and evaporitic sulphates. In nature it is a common byproduct of bacterial and thermochemical sulphate reduction with the sulphate supplied by dissolving anhydrite or gypsum. In the chemical industry it is mostly a byproduct of metallurgical and hydrocarbon processing.

Usage History and Industry Trends

Native sulphur was known to the ancients as brimstone or "the stone that burns," in Christian mythology it was said to "fuel the Fires of Hell." Much of the following discussion of sulphur's historical uses comes from Wilburn et al. (2001). Early man used sulphur as a colourant for cave drawings, as a fumigant, in medicine, and as incense. By 2000 BC, the Egyptians began using sulphur in the bleaching of linen textiles. Homer refers to its use as a fumigant in the Odyssey. During the Peloponnesian War, in the fifth century BC, the Greeks used burning sulphur and pitch to produce suffocating gases. The Romans combined brimstone with tar, pitch, and other combustible materials to produce the first incendiary weapons. This technology was lost in the "Dark Ages." Muslims, through the use of alchemy during the "Golden Age of Arabic Science" around AD 700, probably were the first to produce sulphuric acid and this is today the major use of sulphur. Sulphuric acid is a chemical workhorse throughout the world's chemical industries. Early uses of sulphur were relatively limited in terms of quantities and the small quantities needed were mined, typically from volcanic vent deposits.

Sulphur is a necessary ingredient in gunpowder, which was developed by the Chinese during the time of Confucius (557?–479 BC). Crusaders returning from the Holy Land in the early 1300s brought with them the knowledge of gunpowder. Gunpowder was first used effectively in Europe at the Battle of Crécy (1346). Its introduction led to profound social and political changes and for the first time made sulphur an important tradeable mineral commodity. Sicilian sulphur deposits, hosted in Messinian evaporites, satisfied European demand throughout the Renaissance and continued to supply much of the world's sulphur into the last century. But attempts to stabilize the price of Sicilian sulphur at high levels by French controlling interests in 1838 led to the development and use of alternative sources.

In 1833, a French chemist, Michel Perrett, developed an economical method of obtaining sulphur dioxide by roasting pyrite. His invention led to the development of a rotary furnace in 1870 that made pyrite a profitable raw material for sulphuric acid production. By 1880, sulphuric acid throughout the world was being produced from pyrite, except in the United States where import tariffs on iron and copper sulphides prevented a shift away from native sulphur. These import tariffs were removed in 1890 and 1894 respectively, and by 1900 burnt pyrite had become the principal acid–making material in the United States.

Native sulphur deposits occur in a number of evaporite basins in America and Europe, and several attempts were made to mine sulphur from salt dome cap rock in Louisiana between 1870 and 1890 using conventional underground mining techniques. These efforts were all frustrated by the patchy nature of caprock sulphur ore and collapse-prone overburden. In 1894, Herman Frasch developed a method of recovering native sulphur using hot water and compressed air. It is a form of chemically-targeted solution mining and comprises a well made up of three concentric pipes (casing) ending in the ore zone. Pressurized superheated water is pumped down the outermost pipe in the string. The resulting steam melts the sulphur, while air pressure applied via the innermost pipe forces the molten sulphur to the surface via the intermediate space in the pipe string. Sulphur was first commercially obtained using the Frasch method in 1895 by the Union Sulphur Company at Sulphur Mines dome, Calcasieu Parish, LA. The Frasch method was also employed in 1912 at Bryan Mound, Brazoria County, Texas, and later at many other domes scattered about the US Gulf Coast.

Worldwide, documented resource of elemental sulphur amounts to about 5 billion tonnes (Fig. 12.66). It occurs in evaporite and volcanic deposits, or as sulphur associated with natural gas, petroleum, tar sands, and metal sulphides. Current uses for sulphur are: phosphate fertilizer production – 70 %;

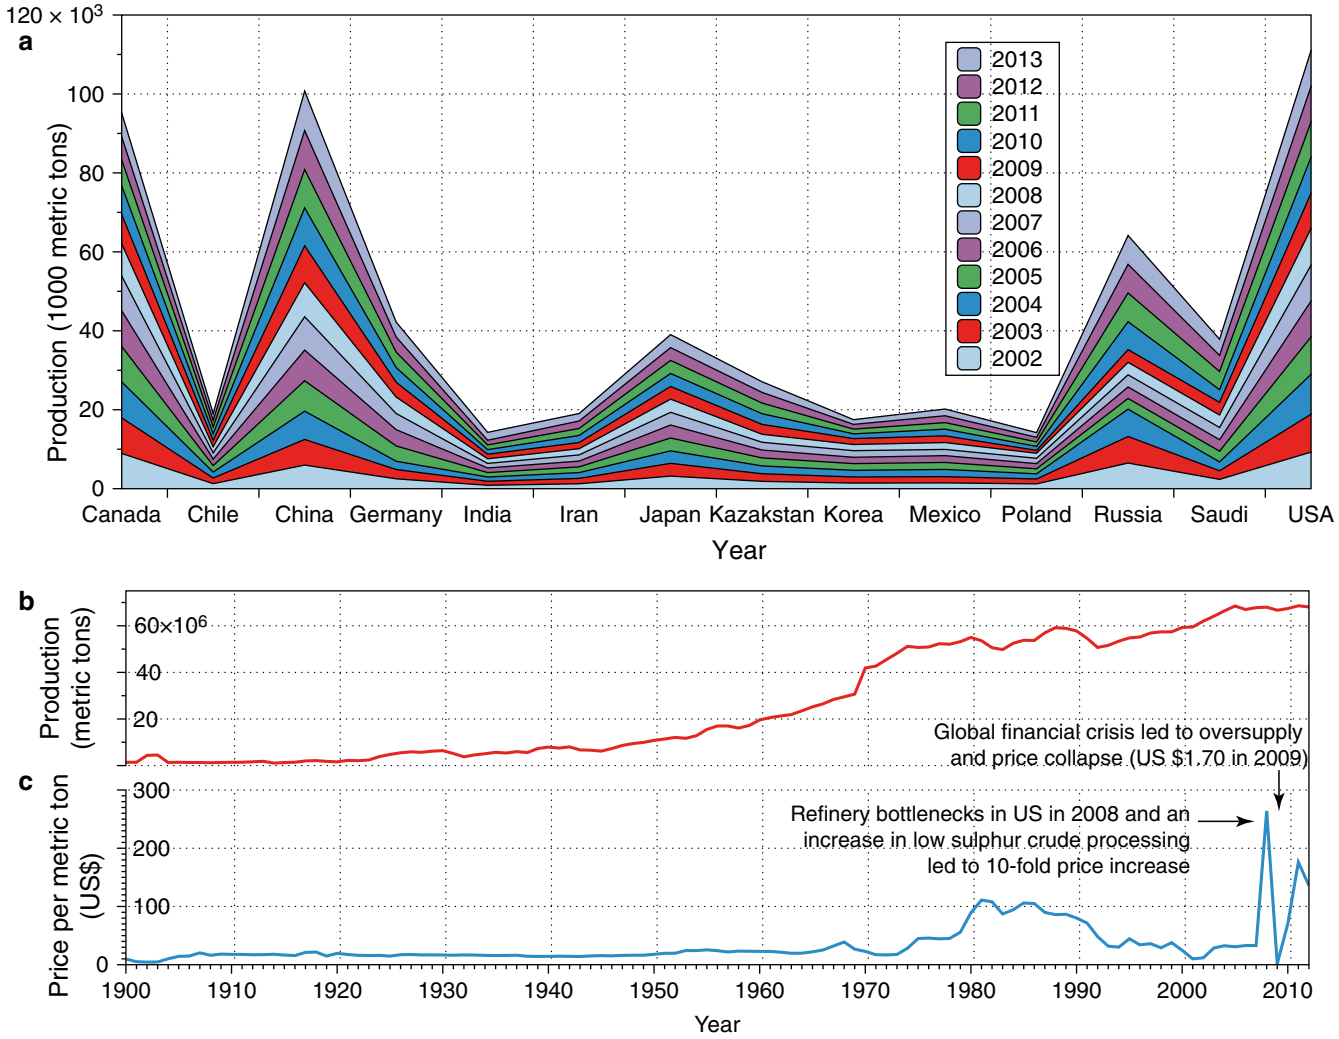

Fig. 12.66 Sulphur production mostly as byproduct of petroleum processing. (**a**) Cumulative area plot of annual production in major producing countries in metric tons (See Fig. 12.67 for manufacture-process proportions). (**b**) World production from 1900 to 2011 (metric tons), (**c**) Price per metric ton in US dollars from 1900 to 2012 (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed April 29, 2014)

petroleum alkylation catalysis (the conversion of one kind of hydrocarbon into another) – 15 %; metals industry processes (leaching and pickling) – 7 %; chemicals – 4 %: and other uses – 4 % (Fig. 12.67; Ober 2000).

Worldwide, the production of mined or extractive sulphur has been falling since the mid 1980s, as has the price per ton. During 2009 and the global financial crisis, the price per ton at $1.70 reached a record low but has since recovered (Fig. 12.66c; Apodaca 2012). Most sulphur is today produced either as a byproduct in hydrocarbon processing or as a metallurgical byproduct (Fig. 12.67). Poland is the only country still producing substantial quantities of native sulphur from evaporite-related deposits, using either the Frasch method or conventional mining. In August 2000, Freeport Sulphur closed its Main Pass Mine, offshore Louisiana, which was extracting sulphur from diapiric caprock, this facility was the last remaining Frasch mine in the USA. At the time it ceased operation it was the largest offshore structure in the Gulf of Mexico and the largest mine worldwide utilising the Frasch process.

In the previous year, Freeport had closed the Culberson Mine in West Texas, which was the last mine in the onshore of the USA using the Frasch method to recover sulphur from bacteriogenic deposits hosted in bedded Permian evaporites. Polish Frasch sulphur production still hovers around 1,000 metric tons per year, although this production is now threatened by low international prices, due to saturation of the market with byproduct sulphur. Today, small quantities of native sulphur are still mined in Asia, Europe, and North and South America. The use of pyrite as a sulphur source has significantly decreased in the last two decades because of pollution concerns. China, South Africa, and Spain are now

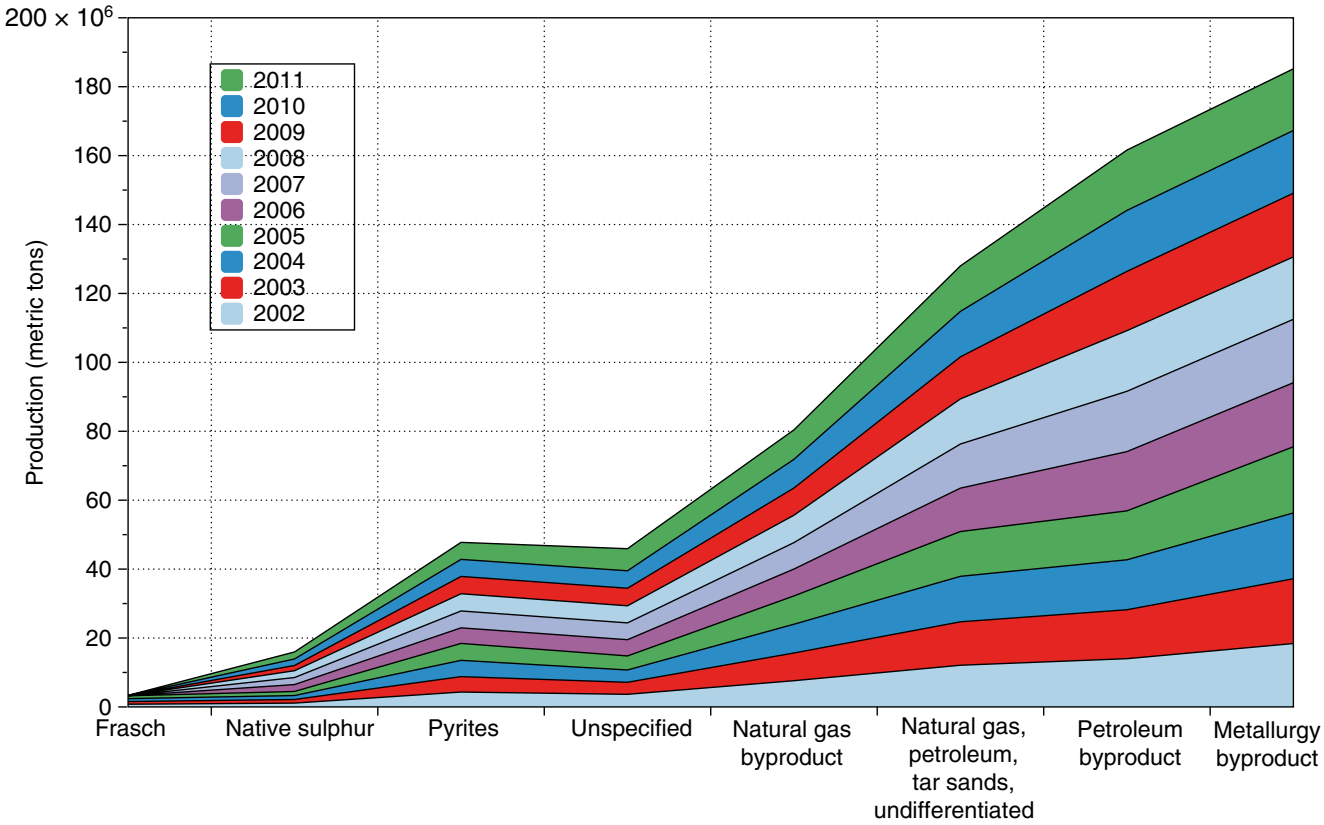

Fig. 12.67 Processes of sulphur manufacture – worldwide from 2002 to 2011 (in 1,000 metric tons). Dominance as a product of hydrocarbon and matallurgical processing is clear (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/index.html last accessed April 29, 2014)

the only countries in the top 15 sulphur producers whose prime sulphur source is pyrite; together these three nations account for more than 80 % of all pyrite-based production (Apodaca 2012).

Although mined sulphur production is decreasing worldwide, world production of recovered (byproduct) sulphur is increasing (Fig. 12.67). The growth comes mostly from sulphur recovery from sour gas processing plants and from the refining of sour crude oils, especially the sulphur-rich hydrocarbons of the Middle East and Canada. Chemically recovered elemental sulphur is now the predominant sulphur source in Canada, France, Germany, Iran, Russia, Saudi Arabia, and the United States, and an important sulphur source in Japan and Mexico (Fig. 12.66a). In many countries this form of sulphur is recovered in compliance with environmental regulations that restrict the sulphur content of the fuels sold or used by a processing facility. Growth in sulphur recovery continues to outpace sulphur demand, resulting in increased stocks worldwide, as increasingly stringent environmental regulations force producers to limit atmospheric emissions of sulphur dioxide.

In addition to the currently known native sulphur resource, the amount of natural sulphur held as sulphate in gypsum and anhydrite is almost limitless. Some 600 billion tonnes are contained in coal, oil shale, and shale rich in organic matter, but low-cost recovery methods are lacking.

Types of Natural Sulphur Deposits

Most large nearsurface accumulations of natural sulphur are the results of chemoautotrophic bacteria living on hydrocarbons or organic matter and dissolving anhydrite/gypsum, either in diapiric caprocks or in stratiform layers near the dissolving edges of anhydrite/gypsum beds (Ruckmick et al. 1979). Such deposits are classified as bio-epigenetic and are intimately linked to the formation of microbial calcite. Bacteriogenic production can take place up to a kilometer or more below the landsurface. The same bacterial sulphate reduction process also forms much smaller volumes of native sulphur in modern anoxic marine or lacustrine muds, termed biosyngenetic deposits by Ruckmick et al. (1979). Thermogenic deposits of molten sulphur precipitate as via thermochemical sulphate reduction at much higher burial temperatures in association with

natural sour gas (Chap. 9). There are also deposits of native sulphur in volcanic terrains, usually as vein and fracture fills; a few still are mined in a small way and may be locally important, especially in the developing world. Lastly, there is oxidative native sulphur, which according to Ruckmick et al. (1979) is widespread but typically creates small sulphur occurrences. This type of sulphur forms wherever hydrogen sulphide (regardless of origin) is oxidized. An example would be the dispersed native sulphur that occurs in the Carlsbad and Lechuguilla caves in New Mexico. We shall only discuss bioepigenetic occurrences in this chapter. Thermochemical sulphur occurrences are typically to deep to have ever been viable extraction targets and the formative mechanisms were discussed in detail in Chaps. 7 and 9.

Biology of Native Sulphur

Native sulphur is microbially produced from calcium sulphate via bacterial degradation (sulphate reduction) of anhydrite and gypsum in the presence of organic matter or hydrocarbons at temperatures of up to 110 °C;

$$CaSO_4 \cdot 2H_2O + \text{hydrocarbons} \rightarrow H_2S + CaCO_3 + H_2O$$

Sulphate-reducing bacteria chemoautotrophically metabolise migrating hydrocarbons and sulphate minerals within the evaporites to produce hydrogen sulphide and vuggy bacteriogenic calcite. Infiltrating meteoric water then oxidises the H_2S to form elemental sulphur. The reaction takes place in the mixing zone between shallow meteoric waters and deep basin fluids in both bedded and diapiric $CaSO_4$ precursors (Aref 1998b). Fine specks of sulphur and calcite replace gypsum in the early stages. With increasing replacement, sulphur and calcite form networks and patches within the gypsum (rehydrated anhydrite), which expand until gypsum remains only as relict splotches in a massive vuggy bioepigenetic calcite with pores lined with sulphur.

Dominant species of sulphate-reducing bacteria acting on the $CaSO_4$ change with salinity and temperature (Chap. 9); *Desulphovibrio desulphrican* is active at shallow subsurface temperatures, *Desulphovibrio orientis* is active at moderate burial temperatures and *Clostridium nigrificans* dominates in hotter conditions. These bacterial reducers consume organics or hydrocarbons as a source of energy, but use sulphur instead of oxygen as a hydrogen acceptor and so produce hydrogen sulphide, calcite and water as byproducts. In addition to West Texas and the Gulf of Mexico, large deposits of bioepigenetic sulphur replacing gypsum/anhydrite occur in the Mishraq sulphur deposits (Barker et al. 1979), in the Polish sulphur deposits (Pawlowski et al. 1979), and in the Gulf of Suez (Youssef 1989; Aref 1998b). In the past all these deposits have been mined.

Occurrences and Textures

In sulphur-entraining caprocks atop diapirs in the Gulf Coast and Mexico, the $CaSO_4$ ore host is first created by dissolution of halite in the rising salt stem (Chap. 6). This leaves behind a residual carapace or caprock of anhydrite that phreatic groundwater flushing then converts to gypsum at shallower depths (Fig. 12.68a; Ruckmick et al. 1979). In the stratiform sulphur ore district of Culberson County, West Texas, requisite ore-forming fluids, including basinal hydrocarbons and deeply circulating meteoric groundwaters, migrated upward from underlying carrier beds, along steeply dipping normal faults, into the Salado Formation host (Fig. 12.68b). Likewise, native sulphur occurs in the Red Sea Coast at Ras Gemsa, where an uplifted horst block, containing middle Miocene oil and gas bearing strata, is overlain and sealed by evaporite-carbonate layers (Youssef 1989). In all cases, the native sulphur resides in pores and vugs of bio-epigenetic limestone beds.

In its unaltered subsurface state the Castile Formation of the Delaware Basin is made up of stacked laminar anhydrite beds. The unit's underside acts as a seal and a focus for hydrocarbons seeping up from the oil kitchen in the deeper parts of the Delaware Basin and for deeply circulating meteoric waters (Fig. 12.68b). Previously mineralised castiles now outcrop and subcrop about the edge of the Delaware Basin. The trap was naturally prepared for sulphur accumulation by a series of faults and collapse anticlines, activated or reactivated by evaporite dissolution about the basin edge. These extensional fractures acted as hydrological foci during the creation of porous dissolution collapse breccias or chimneys that crosscut the anhydrite beds of the Castile and the overlying Salado and Rustler formations (Fig. 12.68b). Once a dissolution breccia/karst system was created toward the basin margins, it focused the ascent of petroleum-bearing waters from the underlying carrier beds (Bell Canyon Sandstone aquifer). As hydrocarbon-bearing waters flushed through the breccia, sulphate-reducing bacteria converted anhydrite to limestone and deposited sulphur in newly created fractures and vugs.

Locations of stratiform sulphur in this style of deposit are always structurally controlled and initiated during regional bathyphreatic speleogenesis (Stafford et al. 2008a, b). Individual sulphur deposits in West Texas are generally small, although the now closed Duval Mine in Culberson County, Texas, had original sulphur ore reserves of more than 55 Mt, between depths of 70 and 380 m (Davis and Kirkland 1979). The Fort Stockton Mine in Pecos County was located on the culmination of a leaky northwest-southeast trending anticline in the Salado Formation with a structural closure of 20 m (65 ft) in mine area (Fig. 12.69; McNeal and Hemenway 1972). Sulphur ore was largely confined to diagenetic limestone hosts that made up the A, B, and C units. Tops of the B

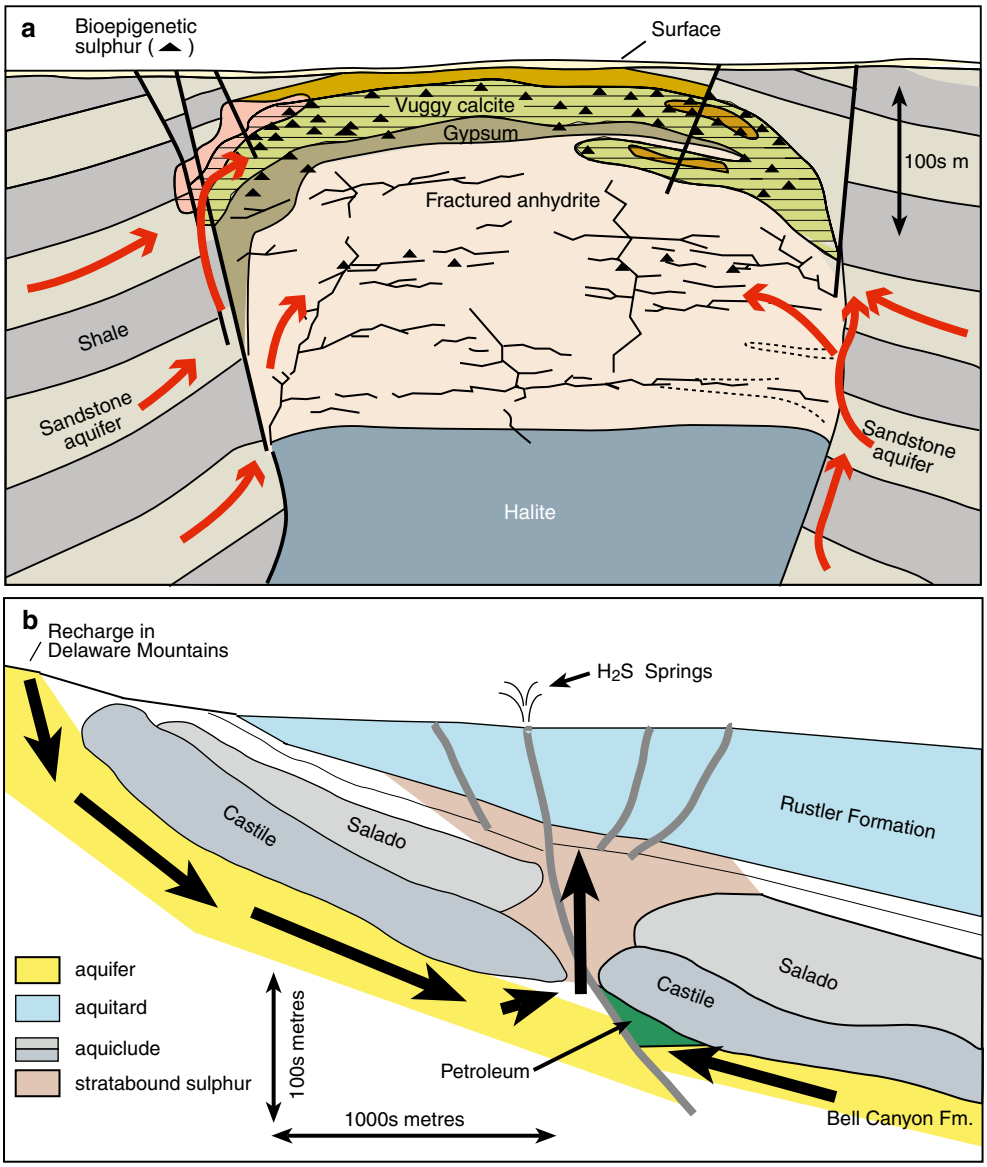

Fig. 12.68 Conceptual models for the origin of evaporite-related elemental sulphur. (**a**) Genetic model for diapir caprocks. (**b**) Genetic model for stratabound or stratiform sulphur and the formation of subsurface castiles in the Permian Castile Formation of West Texas and New Mexico (After Ruckmick et al. 1979)

and C units were defined by radiogenic clay marker beds and the top of the A was defined as the top of the Salado Formation. Sulphur in the ore zones sat mostly within dispersed vugs, fractures and fenestra in solution collapse breccia units, so it was more amenable to Frasch processing rather than conventional mining. As the ore was mined by steam injection, the more permeable megavug, mesovug and megafenestral ore zones were prime targets in the steam-mined interval. Intervals with mesointercrystalline and mesofenestral porosity greatly increased the efficiencies of recovery by facilitating improved steam circulation through sulphur-impregnated intervals.

Similar stratiform sulphur occurs along the Red Sea coast of Egypt where accumulations range from small and non-commercial (Gebel Abu Gerfan and Ras Dip) to economic deposits (Gemsa; Aref 1998b). Sulphur crystals vary in morphology, colour, and size, it forms fine disseminations at Abu Gerfan, Gemsa and Gebel El Zeit; fracture and cavity fillings at Gemsa and Little Zeit; and sulphur nests at Gemsa and Shagar. The size of the sulphur aggregates ranges from a few millimeters to 5 cm diameter and crystal morphologies range from anhedral to subhedral to euhedral orthorhombic. Occurrences vary in colour from clear or turbid yellow crystals that may be encrusted with bitumen, to brown or black bitumen-stained sulphur varieties. Within outcropping calcite castiles along the Red Sea coast these epigenetic sulphur crystals can fill vugs or fractures in the host rocks, or they can replace gypsum or anhydrite along cleavage planes or intercrystalline crystal boundaries. They also may pervasively replace gypsum and calcite units to form network or meshwork patterns.

Bio-epigenetic sulphur was mined in Poland as early as the fifteenth century, and although declining, annual sulphur

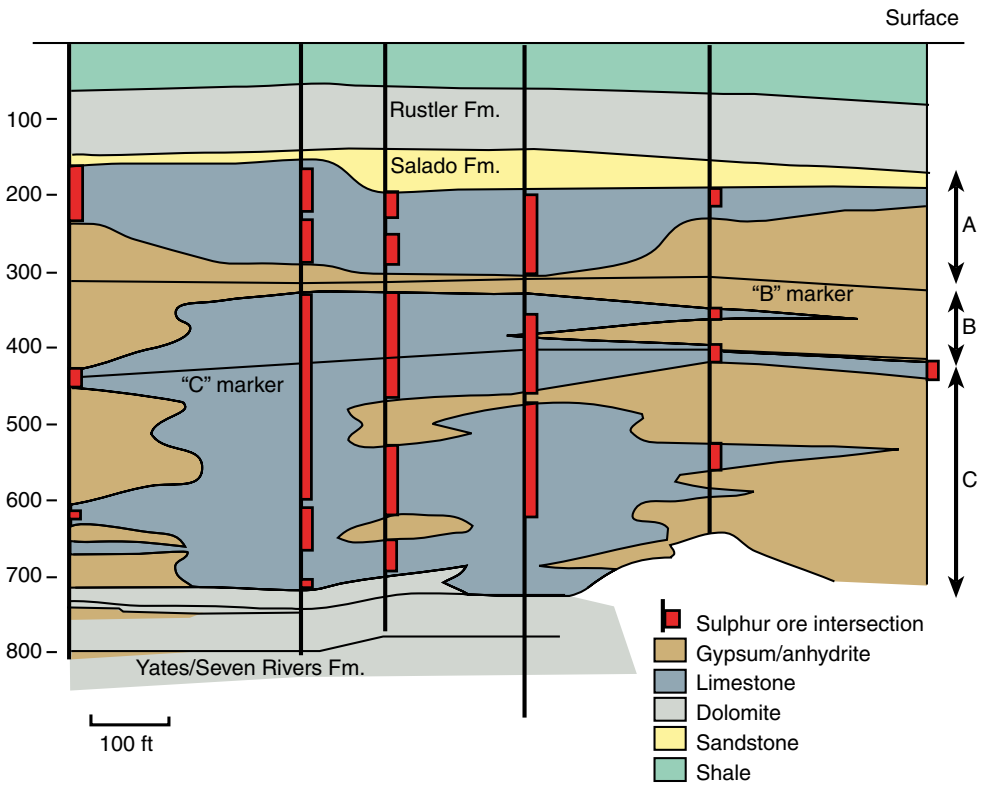

Fig. 12.69 West-east cross section through the Fort Stockton anticline showing sulphur occurrence is largely confined to the dissolved and bacteriogenically reworked remnants of the Castile and Salado Formations (After McNeal and Hemenway 1972)

production in Poland still exceeds a million metric tons. Native sulphur deposits today occur beneath fluvioglacial outwash in the Vistula Valley, some 190 km south of Warsaw, and in the area around Lublin. All deposits lie within a Middle Tortonian gypsum host and are part of the 3,000 m thick fill of Miocene sediments that accumulated during the Alpine Orogeny in the foredeep north of the Carpathian Front (Chap. 12).

Polish sulphur is either extracted by conventional open-pit mining or by the Frasch hot-water/steam method (Pawlowski et al. 1979). The sulphur occurs in several styles; the most commercially important is as disseminated microcrystalline sulphur in a fine-grained poorly lithified calcitic marl host. This form of sulphur makes up 15 to 80 % of the exploited rock mass and averages 30 %. It is pale coloured and may occur in rounded concretionary masses, in thin irregular stringers, or in thick masses of high purity. A secondary ore mode is as coarser recrystallized forms that are bright yellow and typically occurs as crystals lining vugs and along fractures and seams. Masses of this coarsely crystalline form commonly grade into the microcrystalline form. Non-commercial occurrences constitute finely divided sulphur in interstices in growth-aligned bottom-nucleated gypsum crystals and as dispersed sulphur cements in sandstone beds. Both styles contain less than 15 % sulphur in forms that are difficult to concentrate.

The main difference between North American, Polish and Red Sea sulphur occurrences is that the ore host is rehydrated and exhumed anhydrite in North America, while the Polish and Red Sea ore hosts have never been sufficiently buried to convert primary gypsum to anhydrite. This is also the case in the sulphur deposits of Sicily, which are hosted in Messinian gypsum with immature hydrocarbons bleeding from the mine walls (pers. obs.).

Bacterial reduction of sulphate in all native sulphur ore hosts causes significant depletion of $\delta^{34}S$ in H_2S relative to the parent sulphate and a similar depletion in the sulphur derived from it (Thode and Monster 1973). Reoxidation of sulphide to sulphate or sulphur by O_2 in the fluid mixing zone does not cause significant isotopic fractionation. Hence the lighter sulphur isotopic composition of oxidative sulphur in Guadalupe Mountain caves ($\delta^{34}S_{CDT} = -25.8$) and in the stratiform sulphur of the Culberson mine (–4.7‰) (Hill and Forti 1997). The light carbon isotope signature of epigenetic calcite in the Culberson mine also indicates a hydrocarbon source ($\delta^{13}C_{PDB} = -44.2$ to –18.6‰; Hill 1995). The depleted $\delta^{13}C_{PDB}$ values are significantly lower than would be expected in marine carbonates, which typically fall in the range –4 to +4‰.

Zeolites – Molecular Sieves

Zeolites are aluminosilicate minerals that occur as low-temperature (generally less than 200 °C) alteration products of volcanic and feldspathic rocks. Like clays, zeolites are hydrated aluminosilicates made up of alkaline and alkaline

Table 12.20 Properties of some important zeolites

Mineral structure (channel size in angstroms)	Typical unit cell content	Void volume	Specific Gravity	CEC (meq/g)
Group 1: Single 4-ring				
Analcime (1.6 × 4.2; irregular)	$Na[AlSi_2O_6]\cdot H_2O$	0.18	2.24–2.39	4.54
Phillipsite (4.2 × 4.4)	$(K,Na,Ca_{0.5},Ba_{0.5})_x[Al_xSi_{16-x}O_{32}]\cdot 12H_2O$	0.31	2.15–2.20	3.87
Laumonite (5.0 × 5.3)	$Ca_4[Al_8Si_{16}O_{48}]\cdot 18H_2O$	0.34	2.20–2.23	4.25
Group 2: Single 6-ring				
Erionite (3.6 × 5.2)	$K_2(Na,Ca_{0.5})_8[Al_{10}Si_{26}O_{72}]\cdot 30H_2O$	0.35	2.02–2.08	3.12
Group 3: Double 4-ring				
A (Linde: 4.2)	$Na_{12}[(AlO_2)_{12}]\cdot 27H_2O$	0.47	1.99	3.12
Group 4: Double 4-ring				
Chabazite (3.7 × 4.2)	$(Ca_{0.5},Na,K)_4[Al_4Si_8O_{24}]\cdot 12H_2O$	0.47	2.05–2.10	3.81
Group 5: Complex 4–1, T_5O_{10}				
Natrolite (2.6 × 3.9)	$Na_2[Al_2Si_3O_{10}]\cdot 2H_2O$	0.23	2.20–2.26	5.26
Group 6: Complex 5–1, T_8O_{16}				
Mordenite (2.9 × 5.7)	$(Na_2,Ca,K_2)_4[Al_8Si_{40}O_{96}]\cdot 28H_2O$	0.28	2.12–2.15	2.29

earth metals. Their varying tetrahedral structures break them down into seven related aluminosilicate groups, each with some non-claylike properties (Table 12.20). Most clays have a layered crystalline structure and are subject to shrinking and swelling as water is absorbed and removed between the expanding and contracting lattice layers. In contrast, zeolites lack this expandable layered lattice. Rather, they have a rigid, 3-dimensional crystalline structure consisting of a network of interconnected tunnels and cages, separated by tetrahedal latticework. Water moves freely in and out of these pores, while the zeolite framework remains rigid. A dehydrated zeolite framework, with its honeycomb of passageways, is capable of absorbing large quantities of fluids and gases in place of the removed water, without ever changing volume. In fact, the word zeolite comes from the Greek *zein* meaning "to boil" (lit. *boiling rock*) and was given its name by Swedish mineralogist Axel Fredrik Cronstedt who had seen water boiling out of the rock pores when it was heated, but without obvious changes in rock volume.

As of 2008, 175 catalogued unique zeolite frameworks had been identified, 40 of which are naturally occurring. Their rather unusual cage- or sieve-like lattice structure gives zeolites some useful characteristics (Table 12.20: Breck 1974):

- a high degree of hydration;
- a rigid structure with a low density and large void volume when dehydrated;
- a stable crystal structure when dehydrated;
- a set of mineral specific cation exchange properties;
- a set of uniform molecular-sized channels in many dehydrated crystals;
- a controlled variable set of physical properties such as electrical conductivity;
- an ability to adsorb selected gases and vapours;
- catalytic properties.

Because each member of the zeolite family has a unique aperture size, the molecules admitted to the framework are restricted to those of appropriate dimensions. This selective nature of the various zeolite structures makes them extremely useful as molecular sieves, with numerous industrial applications.

Zeolites also have the ability to exchange cations, whereby one charged ion is exchanged for another in the crystal structure. The ability of a zeolite to do this is measured by its cation exchange capacity (CEC; Table 12.20). Compared to clays, zeolites have high CEC's, which are lattice specific and reflect varying degrees of alumina substitution for silica in the lattice tetrahedra to create lattice specific zones of surface charge. Exchange sites on natural zeolites are primarily occupied by three major cations: potassium (K), calcium (Ca), and sodium (Na), although other elements such as magnesium (Mg) may also be present. Exchange sites on a particular zeolite may contain nearly all K, nearly all Na, some Ca or Mg, or a combination of these, and this controls which zeolites are suitable for a particular application.

Usage and Production

The primary use for zeolites is in laundry detergents. The mineral's porous nature allows particles of dirt and contaminants to be captured in the wash cycle and then rinsed away

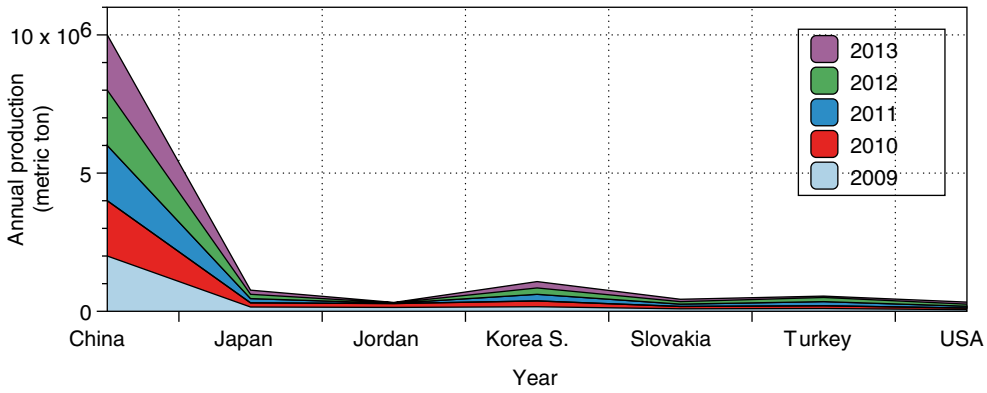

Fig. 12.70 Estimates of country by country annual production of zeolites. Subject to error as some countries producing substantial zeolite volume do not compile estimates (Compiled from USGS on-line data tables downloaded from http://minerals.usgs.gov/minerals/pubs/commodity/zeolites/ last accessed May 5, 2014)

in the rinse cycle. Other common household uses are as aquarium filters and cat litter. Zeolites are also used extensively within the medical profession as sieves to filter and purify air to make medical grade oxygen. In agriculture, zeolites are used as preservative agents (desiccants), soil conditioners, fertilizer extenders, herbicides, pesticide and fungicide carriers, animal food additives and odor controllers. Zeolites with K exchange sites are useful as longterm K-release fertilizers. Other uses include dimension stone, lightweight aggregate, pozzolan and numerous filtration/treatment uses, such as natural gas purification, nuclear waste treatment and disposal, and oil spill, sewage and effluent cleanup. Chabazite is used to remove CO_2 and H_2S from sour natural gas, while clinoptilolite can remove ammonia in tertiary sewage treatment and is also used for odor control in pet-litter. It also relieves ammonia stress in cud-chewing animals and it can strip base metals from effluents. Clinoptilolite is also highly effective in the cleanup of radioactive waste as it strongly adsorbs strontium and caesium, two of the longest-lived radioactive ions. It was used in the cleanup of Three Mile Island spill and was fed to children affected by the Chernobyl disaster.

World reserves of natural zeolites have not been reliably estimated and plots of production, as in Fig. 12.70 are subject to error (Vitra 2014). Deposits occur in many countries, but companies rarely, if ever, publish reserve data. Further complicating estimates of reserves is the fact that much of the reported world production includes altered volcanic tuffs that contain low to moderate concentrations of zeolites. These typically are used in high-volume construction applications, and therefore some deposits should be excluded from reserve estimates because it is the rock itself and not its zeolite content that makes the deposit valuable.

Countries mining large tonnages of zeolites typically use them in low-value applications. The ready availability of zeolite-rich rock at low cost and the shortage of competing minerals and rocks are probably the most important factors encouraging its large-scale use. It is also likely that a significant percentage of the material sold as zeolites in some countries is ground or sawn volcanic tuff that contains only a small amount of zeolites. Examples of such usage are dimension stone (as an altered volcanic tuff), lightweight aggregate, pozzolanic cement, and soil conditioners. Where zeolite figures are more reliably estimated the reserves are substantial. For example, some 120 million tons of clinoptilolite, chabazite, erionite, mordenite, and phillipsite is present in near-surface deposits in the Basin and Range province in the United States (Vitra 2014). Resources in the United States may approach 10 trillion tons for zeolite-rich deposits.

Geological Controls on Saline Zeolitisation

There are six major geological settings where zeolites are found, of which saline lacustrine settings are one (Table 12.21). Most zeolites are altered volcaniclastics, with the larger number of exploited zeolite deposits formed by groundwater flushing of volcaniclastics within saline lacustrine settings (Surdam 1981). These are ideal settings as they are characterised by hydrologies that force alkaline lake and pore brines to interact and alter trachyte glass (Fig. 12.71). Zeolites are not preserved in rocks where metamorphic grade exceeds zeolite facies and so their occurrence decreases with age. More than 30 different zeolite minerals have been identified in Cenozoic rocks, only 7 in Mesozoic strata, 2 in the Early Palaeozoic, 4 in the Late Palaeozoic, one in the Neoproterozoic and none in the Archaean (Iijama 1980). The interested reader is referred to Mumpton (1983) or Iijama (1980) for a full discussion of all the geological settings forming zeolites, in the following section we shall only consider natural zeolites formed in saline lacustrine settings.

Natural zeolites in saline settings typically form via the reaction of pore waters with labile material, typically volcanic glass, but also with poorly crystalline clay, plagioclase or silica. Factors influencing zeolite mineralogy are salinity, pH, ratios of alkali and alkaline-earth ions in the pore waters, along with temperature, pressure and partial pressure of water in the fluid-filled pore spaces. Zeolitization is favoured by higher pH in waters interacting with volcanics and by elevated ratios of Mg compared to Na, K and Ca, conditions

Table 12.21 Geological occurrence of some natural zeolites

Mode of occurrence	Temp. (°C)	Zeolite species	Examples
Alkaline saline lake and percolating groundwater, semi arid (in basic tephra)	20–50	Ph, Cp, Ch, Er, Mo, Gi, Fa, Go, Na, An, (He)	Zeolitic tuffs of ancient Lake Tecopa, Shoshone, California
Percolating groundwater in a semi-arid setting (in acid tephra – vitric tuff)	20–50	Ph, Cp, Er, Mo, Fe, Th, Me	Altered tuffs of the John Day Formation, central Oregon
Nearshore or deep sea volcaniclastic sediment halmylosis	4–50	Ph, Cp, (An)	Massive, clinoptilolite-rich tuff near Kurdzali, Bulgaria
Shallow burial diagenesis (low-temp. hydro-thermal)	25–100	Sc, He, St	Massive, clinoptilolite-rich tuff near Kurdzali, Bulgaria
Deep burial diagenesis (mod. temp. hydro-thermal)	100	La, An	Massive, clinoptilolite-rich tuff near Kurdzali, Bulgaria
Low grade metamorphic (high temp. hydro-thermal)	>200	Wa, Yu, An	Altered tuffs and sandstones Wairakei, New Zealand
Magmatic primary	high	An	Nishi-Iburi District, Hokkaido, Japan

that typify saline groundwaters in many closed hypersaline basins, especially in tectonically active depressions (continental rifts and collision belts). A preponderance of sodic-rich zeolites such as analcime, mordenite, phillipsite, natrolite and clinoptilolite is probably a more common outcome in evaporitic, compared to nonevaporitic, zeolite associations, reflecting high levels of Na in most saline brines. Chemical composition of the protolith glass, grain size and permeability of the host vitric tuff, are additional factors controlling the mineralogy of a zeolite, pH of the flushing solution is the most important (Hay 1981; Hall 1998).

Volcanic glass in a saline mudflat hydrology is most readily altered near the watertable as alkalinity increases via evaporative pumping and an aluminosilicate gel forms. Once pore brines become alkaline (pH >9–10), zeolites begin to crystallise (Fig. 12.71). Mariner and Surdam (1970) showed experimentally that the rate of dissolution and hence alteration of rhyolitic glass increases 20-fold as the pH is raised from 8.5 to 11.5. Initial surface waters and groundwaters in many volcanic areas are acidic, but zeolitisation requires neutral to alkaline (bicarbonate-bearing) conditions. Before zeolitisation can take place, acidic interstitial water must be removed or neutralized. This can occur via deposition or redeposition of ash in a standing body of alkaline water (not uncommon in saline depressions), or if there is reheating of ash via hydrothermal circulation pushing alkaline saline groundwater through the ash bed. Alkaline water can come from leaching of overlying or neighboring limestone. Arid hypersaline depressions are associated with density-induced circulation cells that favour the replacement of original acidic pore water with more alkaline brackish to hypersaline brines (Fig. 12.72).

Saline-alkaline lake chemistry evolves through time. Clinoptilolite forms early or more marginally in the region of more dilute waters, which tend to contain Ca^{++} along with K^{+} and Na^{+}. As the lake waters become more alkaline, due to ongoing evaporation and precipitation of Ca^{++}- bearing minerals, chabazite, phillipsite and erionite become stable digenetic products. The proportion of clinoptilolite decreases as lake waters become more enriched in K^{+}. As the waters continue to evolve and become richer in Na^{+}, analcime becomes stable (Fig. 12.71). This creates a bull's-eye pattern of

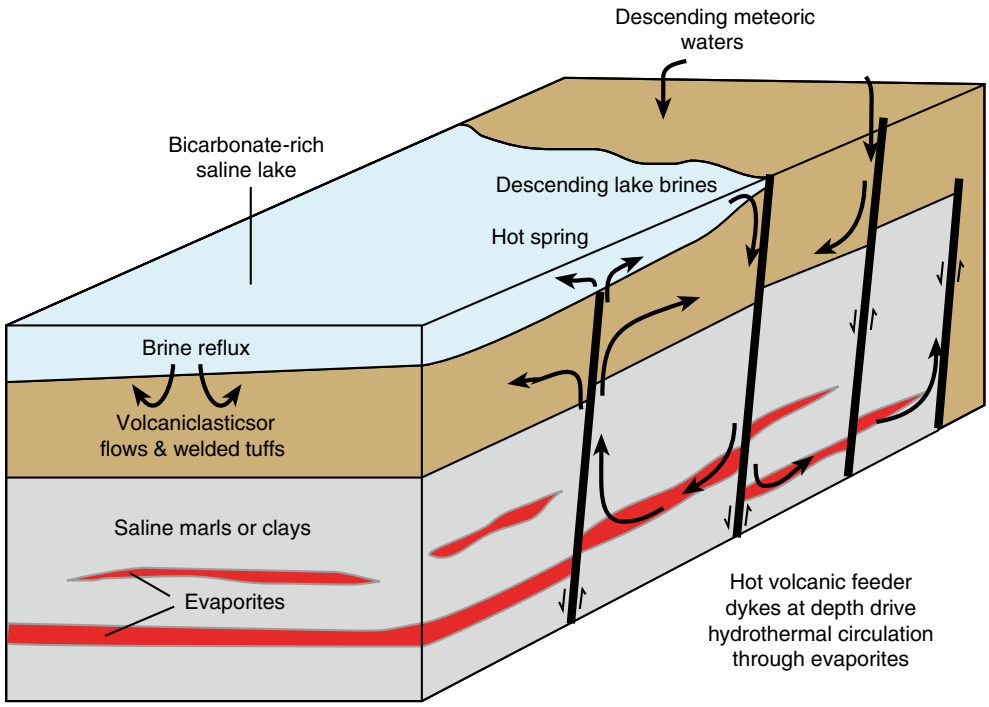

Fig. 12.72 Schematic showing possible circulation mechanism in a saline lacustrine system where volcanics are altering and weathering to various zeolites

zeolites in the saline lake. Phillipsite is stable at lower silica activities, in equilibrium with quartz, while erionite requires silica activity equivalent to cristobalite. Erionite, phillipsite and clinoptilolite are replaced by authigenic orthoclase (K-feldspar) where the K^+ concentration is high.

Zeolites can also form rapidly in alkaline soils not directly flushed by lake waters, but wherever vadose flushing tends to reduce the amount of acidic pore water (Hay 1963; Renaut 1993). The reaction of volcanic glass with crossflowing water can itself conducive to a rise in pH as the dissolution mechanism involves cation exchange reaction at the glass surface, whereby H_3O^+ enters the glass from the solution, while Na and K enter the solution from the glass (Casey and Bunker 1990).

Saline lacustrine zeolites are commonplace in: (1) endorheic alkaline basins in block-faulted terrains (such as the Basin and Range province of the USA; Sheppard and Gude 1968), (2) in trough valley depressions associated with rifting (such as Lake Magadi or Lake Bogoria in the Eastern Rift Valley of Kenya; Surdam and Eugster 1976), or (3) in Tibet-type grabens forming depressions in compressional terrains (such as Emet and Kirka basins, Turkey; Gundogdu et al. 1996). Most saline Neogene basins that retain exploitable volumes of zeolites still retain large volumes of highly reactive, silica-rich, vitric, volcanic material and evaporite beds. Bedded evaporite levels or their dissolution residues in a volcanic terrain are the product of a density-driven through-flushing brine system that displaced the original acidic waters. Hence, in terms of exploration for zeolites, evaporite horizons are excellent pointers in a basin to a level in the stratigraphy where ash alteration and zeolites are likely.

Zeolites precipitate in volcanic hosts in timeframes measured in thousands to hundreds of thousands of years, depending on brine alkalinity, the precursor mineralogy and the climate (typically semi-arid rather than hyperarid). Groundwaters driving zeolite formation in saline settings are typically sodium-rich, often with elevated carbonate-bicarbonate contents and a pH level maintained above 9 (soda lakes). Favorable hostrocks are freshly deposited rhyolitic to dacitic, vitric tuffs, especially those levels of the volcaniclastic succession time equivalent to alkali-rich saline mudflats and saline pans. Saline aluminosilicate gels (kenyaite, magadiite) can form pointer minerals at these levels and can act as zeolite precursors. Associated saline rocks can be bedded evaporites (trona, halite, borate), with interlayered mudstones, oil shales, diatomites (which can be an additional silica source in many alkaline lakes), bedded or nodular Magadi-style cherts and volcaniclastic conglomerate/sandstone.

Zeolitic alteration haloes in exposed marginward saline sediments of Lake Bogoria in the Kenya Rift Valley provide a useful Quaternary analog for many older saline lacustrine zeolites (Renaut 1993; Owen et al. 2008). Late Quaternary fluviolacustrine siltstones, mudstones and claystones (Loboi Silts) make up the northern margins of this saline, alkaline lake and contain up to 40 % authigenic analcime and minor natrolite (Fig. 12.73a). The zeolitic sedimentary layers are reddish brown and up to 1 m thick. The amount of analcime increases upward in the profile, but decreases with distance from the saline lake (Fig. 12.73b). Altered sediments hosting the zeolites show many pedogenic features including; zeolitic

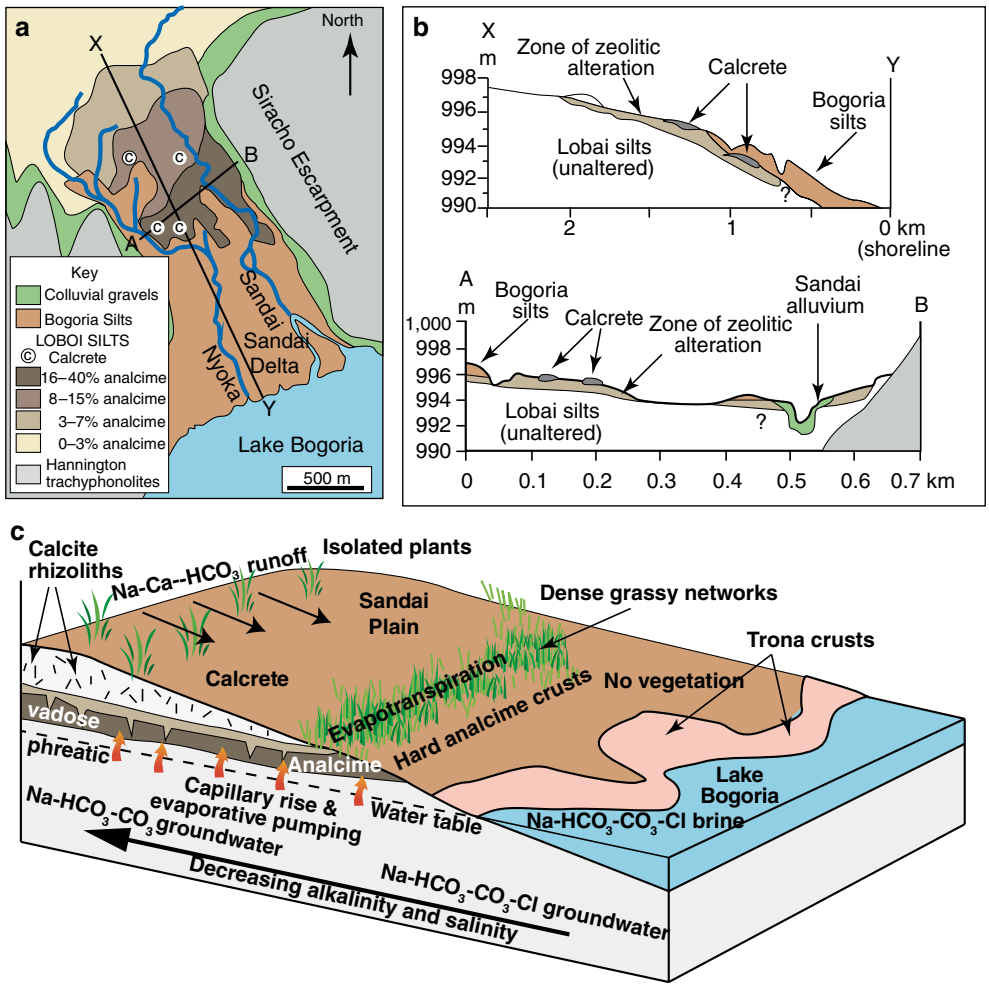

Fig. 12.73 Lake Bogoria, African rift. (**a**) The Sandai Plain, showing the sediment distribution and the variation of analcime concentration in the upper 10 cm of the Loboi Silts. (**b**) Cross-sections show thickness of zeolitic alteration and relationship of the zeolitic profile to the Bogoria Silts. (**c**) Schematic showing zeolite and rhizolith formation on Sandai Plain. Saline, alkaline groundwater is subject to capillary rise and evaporative pumping. In upper profile vadose waters react with labile clastics to produce zeolites. Infiltrating Ca-bearing surface waters precipitate calcite upon mixing with saline alkaline waters, or following evaporative concentration and CO_2 degassing (After Renaut 1993; Owen et al. 2008)

root mats, rootmarks, concretions and carbonate rhizoliths. Residual patches of calcrete locally cap the zeolitic rocks. The zeolitic profile about the edge of Lake Bogoria is interpreted as an exhumed palaeosol, which defines a former landsurface on the saline mudflat of the paleolake, no some 10 m above the present water level.

Analcime in the Bogoria mudflat is made up of submicroscopic (0.5–2.5 μm) subhedral and euhedral crystals, which have an average Si/Al ratio of 2.33 (as determined by X- ray micro-analysis) or 2.18 (as determined from the d-value of analcime peak). Analcime formed diagenetically in these lake-marginal sediments via reaction of silicate detritus with alkaline Na_2CO_3 rich pore waters, which had concentrated during sabkha-like capillary evaporation and evapotranspiration.

Poorly ordered clay minerals were probably the main matrix reactants. Authigenic illite may have been a byproduct of the reactions forming the analcime. The saline pore waters of the mudflat probably supplied additional Na, and possibly K and SiO_2 to the process of zeolitisation. Calcrete and rhizoliths formed during or shortly after the main period of zeolitisation with the Ca sourced by dilute runoff and seepage waters (Fig. 12.73c). Authigenic smectite was precipitated in open pores following analcime formation. Zeolites have formed in similar saline mudflat settings in other nearby alkaline lakes such as Lake Magadi, where zeolites are associated with magadiite nodule.

Microcrystalline zeolite-bearing vitric tuffs, chiefly composed of analcime, chabazite, clinoptilolite, mordenite, phillipsite and sometimes erionite, are typical of mined saline lacustrine zeolites worldwide. Ore deposits are typically layered and may consist of one to several stacked zeolite layers separated by sub-economic or barren beds. Cutoff grade for zeolite ore varies greatly depending on mineralogy and cementation intensity. For example, a 10–20 cm thick ore bed at Bowie in North America contains 60–80 % chabazite. This zone would not be economic if the main ore mineral was clinoptilolite. Most commercial clinoptilolite deposits contain between 50 and 90 % zeolite.

Large-scale commercial exploitation of saline lacustrine zeolites currently takes place in the Basin and Range province of the United State (Surdam and Sheppard 1978), the Andes (Hartley et al. 1991) and in Tibet. For example, zeolites are extracted from saline lacustrine strata in the San Simon Valley, Arizona. The valley is underlain by 700 m of Pliocene

to Holocene flat-lying fluviatile and lacustrine rocks. Ore horizons occur within what is known as the "older alluvial fill," which is a zeolitized Pliocene tuff and part of a more regional tuff marker bed within the Green Lake Beds (Sheppard et al. 1978). Thickness of individual zeolitic tuff layers ranges from 10 cm to 10 m with areal extents from tens to hundreds of square kilometers. The most common zeolites in this succession are chabazite, erionite and clinoptilolite, with small quantities of analcime in the southern part of the deposit. Parent materials include volcanic glass, biogenic silica, clays, plagioclase and quartz. Non-zeolite authigenic minerals in the tuff include smectite clays, calcite, halite, gypsum and/or thenardite. Chabazite, the main commercial mineral, constitutes up to 80 % of the bed in the ore zone.

These zeolites crystallized after the accumulation of volcanic ash as throughflushing saline alkaline groundwaters reacted with the ash in the lake mudflat (Fig. 12.71). Factors controlling intensity of alteration in the Green Lake Beds included the original lake bottom topography, depth and cation content of the saline-alkaline lake waters and proximity to postdepositional erosion surfaces (Eyde and Eyde 1987). Zeolitic alteration ceased when an extensive system of younger paleochannels deeply eroded the Green Lake Beds. Erosion indicates a change in the base level and a fall in groundwater level that removed the beds from the zone of active saline flushing. Erosion left only a few dissected remnants of the original tuff marker so that the "high grade zeolite bed" now outcrops in the various channel walls, where it is now mined. Former channels and the Green Lake Beds are now overlain by a section of halite-cemented brown mudstone known as the Brown Lake Beds, which largely prevented any later surface-driven meteoric alteration of the zeolites.

Throughflushing saline waters will first generate analcime and then K-feldspar with more complete alteration. In ancient zeolitized lacustrine deposits this is reflected in a commonplace transition from unaltered finely crystalline volcaniclastic glass and tuff near a palaeostrandline, through a series of immature alkaline silicic zeolites to analcime to potassic and sodic authigenic feldspars in the lake centre (Eugster 1986; Hay et al. 1991). Volcanic glass is initially converted to zeolites such as clinoptilolite and mordenite before being altered to analcime. Under ultrasaline conditions when the K/Na activity ratio is sufficiently high (from earlier halite precipitation), analcime is then converted to K-feldspar. Tuff beds deposited during the most saline and alkaline phase of Lake Gosiute in the Eocene Green River Formation typically exhibit such K feldspar alteration. Beds that remain soaked in somewhat less saline brines still remain at the analcime alteration stage (Smith et al. 2003).

Likewise, basin-centre Quaternary deposits in the various saline east African rift valley lakes typically exhibit more alteration toward the lake centres, suggesting that as Pleistocene saline lakes shrank and concentrated, sediments in the lowest (central) positions were more exposed to increasingly saline and alkaline fluids. For example, in Lake Naivasha, Kenya, low lake levels are represented by the presence of chabazite and phillipsite, with even greater aridity indicated by clinoptilolite and analcime (Trauth et al. 2001). Analcime is also common in sodium-rich alkaline desert soils.

Such pointers to the intensity of alteration also outline Cretaceous Lake T'oo'dichi' in the Four Corners region of the USA (Fig. 12.74; Turner and Fishman 1991). This large alkaline saline lake occupied the entire eastern part of the Colorado Plateau region during deposition of the Brushy Basin Member of the Upper Jurassic Morrison Formation. At its maximum it extended from Albuquerque, New Mexico, to Grand Junction, Colorado, and occupied a region that encompassed the San Juan and ancestral Paradox basins, making it one of the largest ancient alkaline, saline lakes known; it was more than twice the size of Eocene Lake Uinta. As yet, zeolites have not been found in sufficient quantity to be exploited in this ancient lake system.

The lake was typically shallow and frequently evaporated to dryness, although the watertable was probably never far beneath the surface and widespread bedded salt did not form (Fig. 12.74; Turner and Fishman 1991). Intermittent streams carried detritus from source areas to the west and southwest far out into the lake basin, a reflection of a low depositional gradient and the ephemeral brackish nature of the lake. Prevailing westerly winds carried silicic volcanic ash to the lake basin from an arc region to the west and southwest. A lateral hydrogeochemical gradient, characterized by increasing salinity and alkalinity from the margin of the lake to the centre, developed in pore waters of the lacustrine sediments and resulted in alteration of the ash to a variety of authigenic minerals that define concentric zones within the lake basin. The basinward progression of diagenetic mineral zones is smectite to clinoptilolite to analcime ± potassium feldspar to albite in the lake centre. A concomitant lateral zonation of mixed-layer illite/smectite developed, from highly smectitic in the outermost zones to highly illitic in the central zone (Fig. 12.74).

Authigenic albite and illitic mixed-layer clay, minerals typically thought to require elevated temperatures for formation in non-saline burial settings, crystallized during early diagenesis at syndepositional temperatures in the lacustrine sediments of Lake T'oo'dichi'. Other examples of syndepositional authigenic albite are documented in saline lacustrine sediments of the Eocene Green River Fm. (Cole 1985), Miocene tuffs near Boron, California (Williamson 1987) and albite rims to evaporite pseudomorphs in the Triassic lacustrine mudstones of the Passaic Formation of the Newark Basin (El Tabakh et al. 1997).

Throughout burial, and on into the zone of metamorphism, zeolites can continue to react with evolving pore

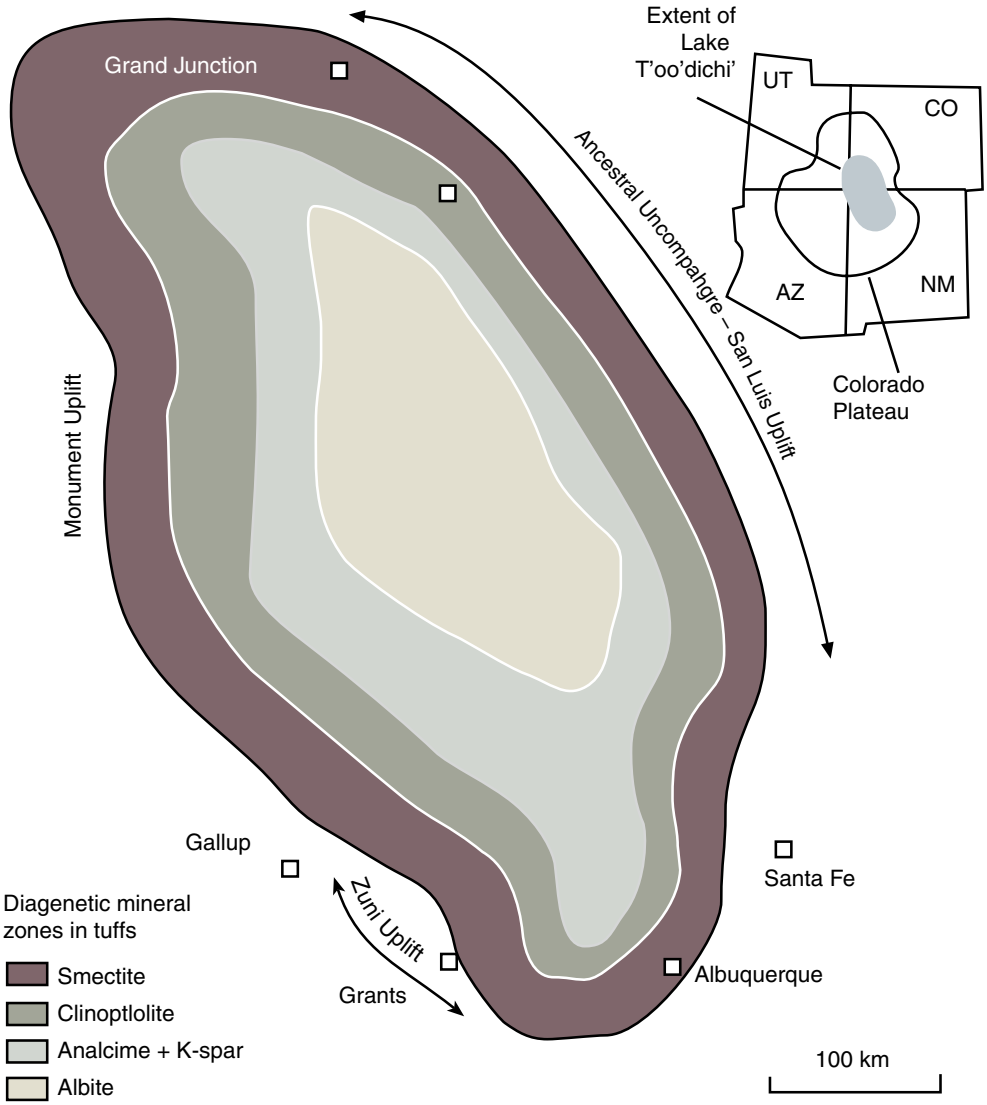

Fig. 12.74 Basinward progression of concentric alteration haloes in the tuff lithofacies in the lacustrine Brushy Basin Member of Jurassic Lake T'oo'dichi' (After Turner and Fishman 1991) This ancient alkaline lake occupied the combined San Juan-Paradox Basin area and was bound by structurally active uplift areas (related to an active volcanic arc that lay to the west)

fluids as new minerals are formed by the replacement of earlier zeolites. Ongoing alteration in deep burial also explains the abundance of albitised metasediments and metavolcanics in meta-evaporitic settings and the loss of natural zeolites with increasing geological age.

But not all sodic zeolites in saline lakes need labile volcaniclastic precursors. Analcime occurs in the basal anhydrite of the Navarra potash in a late Eocene basin that contained no volcaniclastics. Rosell and Orti (1980) interpreted it as a result of the interaction of highly concentrated brines with detrital clays. Likewise, authigenic analcime (±morganite) is forming today in early to mid Pleistocene playa muds in deflation playas, such as Lake Lewis in central Australia,. The zeolites are hosted in endorheic saline clays, within saline hydrologies that do not interact with labile volcaniclastics (Fig. 12.75; English 2001). Lake Lewis playa in the Northern Territory lies in a hydrologically closed intermontane basin in a low relief terrain in which clay-rich paleolacustrine sediments are infused with highly evolved sodic brines. Near-stagnant lake waters, fed by groundwaters flowing through the Proterozoic Arunta granite-gneiss terrain and through arkosic alluvium and its weathering products, source the silica and sodium needed to precipitate analcime. Supersaturation of groundwaters with respect to SiO_2 and the availability of catalytic ions, coupled with high rates of evaporation, favours precipitation of opal and chalcedonic silica from solution near the groundwater discharge zone about the lake strandline. Moganite, a distinctive silica polymorph that is commonly associated with evaporites, is amongst the various silica species precipitated in association with the analcime (Chap. 7).

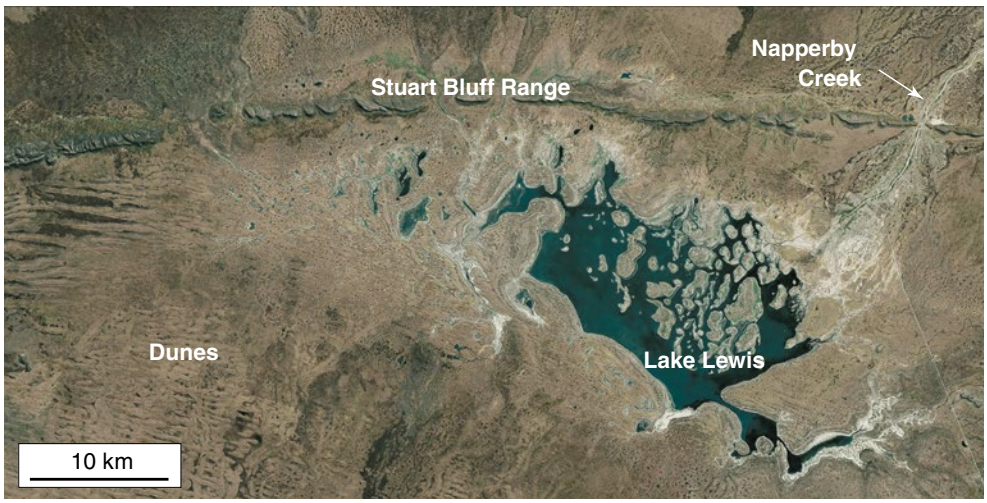

Fig. 12.75 Lake Lewis, Central Australia, where analcime and moganite are precipitating in the Early to Mid Pleistocene Anmatyerre clay (Bing® image mounted and scaled in MapInfo)

Downgradient from the zone of silica precipitation, beneath the playa proper, the brines become SiO_2-deficient. Long periods of weathering and diagenesis of the lacustrine clays, immersed in semi-stagnant brines, has transformed detrital minerals into amorphous or gelatinous aluminosilicates. Hence, various aluminosilicate phases have become metastable in the longterm presence of evolved SiO_2-deficient interstitial brine. Analcime is stable in this relatively stagnant Na-rich brine and is crystallizing authigenically below the watertable from these amorphous and gelatinous aluminosilicates in the more central parts of the lake depression. No volcanic rocks or pyroclastic sediments are involved in this diagenetic occurrence of analcime. The appearance of analcime in Lake Lewis probably commenced within the last 100,000 years and is ongoing (English 2001).

Summary

The greater majority of nonpotash bedded salt resources (borates, sodium carbonates or sodium sulphates) accumulated in continental lacustrine or playa settings. They owe their existence to the unusual ionic compositions that come from groundwater leaching under highly arid conditions, in appropriate bedrock terrains. Quaternary continental examples have same scale and same ionic proportions in the brines as their ancient lacustrine counterparts (Chap. 5).

Simple marine geochemistry shows that these types of lacustrine deposits can not form by simple evaporation of Phanerozoic seawater. Phanerozoic seawater simply never had the ionic proportions necessary to precipitate borates, nitrates, sodium carbonates or sodium sulphates. This chemical evolution can only happen with nonmarine brines, typically where nonmarine waters drain into an arid, highly isolated depression in the continental landsurface. The effect of isolation and concentration in producing appropriate brine chemistries is often enhanced by the presence of nearby mountains. Mountains act both to form a rain shadow zone and to create topographic head, which drives deep circulation of meteoric groundwaters. In endorheic continental lakes in both extensional rift valleys and collision belts, the creation of the mountains is tied to an active tectonic regime and volcanism, which in turn tends to create enhanced hydrothermal circulation and labile volcaniclastic aquifers in hydrographically closed depressions where the saline waters are ponding. Borates, for example, form via the lacustrine concentration of spring inflows that have passed through active volcanogenic terrain. Likewise, the trona beds of Lake Magadi reflect nonacidic groundwater and hydrothermal/basin brine leaching (low sulphate, high bicarbonate waters).

Most of the non-potash deposits discussed in this chapter are nonmarine lacustrine associations, and so are a distinct association from the ancient marine-fed potash deposits discussed in the preceding chapter (Table 12.21). This situation is most obvious in the various South American salars that contain economic brine associations of boron and lithium. They lie in intermontane depressions with floors that are thousands of metres above sea level, yet they drain and pond hypersaline waters for long periods of time, sufficient to allow salt beds hundred of metres thick to accumulate. Likewise, mountains and volcanoes influenced local climate and helped create the Neogene successions of NE Turkey and the Basin and Range playas in the USA. Long-term aridity for more than 6 Ma tied to rain shadow effects, in combination with offshore upwelling, explains the hyperarid nitrate regolith of Atacama Desert.

The high solubility of the nonpotash salt resources, and their formation as lacustrine, not marine, precipitates explains their limited thicknesses, their mostly Neogene ages and their relatively small size compared to marine evaporites (Table 12.22). Self-evidently, a lacustrine depositional setting, with its inherent lack of a huge isochemical brine reserve (seawater), means

Table 12.22 Summary of non-potash evaporite characteristics

	Commodity	Hydrologic situation	Brine source	Depositional associations	Exploration characteristics
NONMARINE (lesser ancient evaporite systems)	Borate	Suprasealevel intermontane hydrographically closed continental depressions ACTIVE SAME-SCALE AS PRE-QUATERNARY COUNTER PARTS	Nonmarine brine, typically with volcanogenic leachates	Neogene lacustrine underfilled basin in cooler but arid conditions, generally in high elevation intermontane fault-bound depressions. A few borate deposits also found in older meta-evaporitic and igneous associations	Continental interior lacustrine. Best developed in Neogene continent-continent collision belts and/or continent/ocean plate subduction zones with active magmatism. Not located within or atop ancient marine mega-evaporite basins
	Sodium Sulphate (salt-cake)		Nonmarine brine	Neogene lacustrine underfilled basin. (1) Solar concentration of surface brines with associated increasing temperature in endorheic continental playa depressions, (2) The winter onset of saline brine cooling in local depressions	Continental interior lacustrine. Not located within or atop ancient marine mega-evaporite basins. Basin drainage must be high sulphate, e.g. from dissolution of older evaporites, cation exchange, volcanics or pyrite oxidation.
	Sodium Carbonate (soda-ash)		Nonmarine brine with elevated CO_2 levels	Neogene lacustrine underfilled basin. (1) Eocene-Miocene intermontane depressions in actively subsiding foreland depressions with relatively high relief surrounding drainage terranes, (2) Quaternary lacustrine deposits at termini of hydrographically-closed drainages in: (a) Intermontane depressions surrounded by relatively high topographic relief and, (i) hot arid conditions or, (ii) high altitude conditions. (b) Terminal pans in lower-relief hot arid cratonic settings where $NaCO_3$ resource resides within annually replenished $NaCO_3$ brines, often in combination with $NaSO_4$.	Continental interior lacustrine. Not located within or atop ancient marine mega-evaporite basins. Sodium must be present (ionic exchange) with appropriate labiles in abundant quantities along with elevated levels of CO_2. Nahcolite was a typical bedded co-precipitate with trona during the peak Eocene greenhouse period when atmospheric CO_2 levels more than double those of today. Trona-nacholite, along with halite and not gypsum, were the dominant Early Archaean evaporite salts.
	Lithium Brines		Nonmarine	As for borates	As for borates

(continued)

Table 12.22 (continued)

	Commodity	Hydrologic situation	Brine source	Depositional associations	Exploration characteristics
MARINE (dominant ancient evaporite systems)	Mega-evaporite (especially thick halite intervals) but also mega-sulphate and mega-potash beds	Subsealevel, hydrographically-closed marine-seepage depressions, occasional breaching of barrier NO CURRENTLY ACTIVE SAME-SCALE QUATERNARY COUNTER PART	Marine brine. Alternating $MgSO_4$ and $CaCl_2$ ocean chemistry in the Phanerozoic tied to variable rates of seafloor spreading and platform dolomitisation	Continent-continent proximity. Megahalite and megasulphate beds deposited in: (1) Soft suture collision basin (2) Opening rift to incipient ocean basin (3) Intracratonic sag basin (4) Strike-slip depression (smallest of the associations)	Marine mega-evaporite basins in zones of appropriate tectonics and climate, Late Neoproterozoic to Neogene at plate margins or intracratonic sags. Thick halite beds in this association subject to early halokinesis due to syndepositional tectonics, rapid subsidence and sediment loading (except in intracratonic settings where superimposed tectonism drives salt flow).
	Mega-sulphate			(1) Periplatform saltern and mudflat beds intercalated with open marine platform/shelf carbonates (2) Intracratonic sag with 10 m + thick sulphate typically intercalated with halite and evaporitic carbonates of equivalent or greater thickness	Epeiric platforms favouredby greenhouse eustasy.
HYBRID	$CaCl_2$ brines	Subsealevel or basinal	Marine/hydrothermal	Low Mg $CaCl_2$ salts in underfilled continental lacustrine depression. High Mg $CaCl_2$ salts in marine evaporite association	Typical subsurface connate association with marine evaporites, especially if ancient salts from a $CaCl_2$ oceans are present.

total bed thicknesses and salt volumes will always be less than that of bedded salts accumulating in marine-fed saline giants. Inherent high solubility of lacustrine salt beds (trona, mirabilite, glauberite) in a hydrology susceptible to drastic changes in water supply and watertable, means lacustrine salts are rarely found in rocks with pre-Cenozoic ages. The Proterozoic borates of Liaoning Province are an obvious exception. The impervious nature of this succession, its metavolcaniclastic host, and the formation of a silicified envelope around the borates, relatively soon after their precipitation, allowed these salts to be preserved, although as a meta-evaporite.

As a rule of thumb for salt exploration for borates, soda ash, salt cake, lithium brines and zeolites in a frontier area, those arid basins with post Mid-Tertiary ages should be considered much more prospective than any older basins. You should not expect to find trona or thenardite or other soluble lacustrine phases preserved in large volumes in Palaeozoic saline successions and will probably not find them at all in Precambrian strata, at least not without a meta-evaporite silica-genesis and a co-transformation of host mineral phases into tourmalines white micas and scapolites.

Solution Mining and Salt Cavern Usage

13

Introduction

Salt solution mining is just what it says, the mining of various salts by dissolving them and pumping the resulting brine to the surface where it is concentrated or processed to recover the desired chemical products. Actual dissolution and recovery methodology is predicated on the solubility of the targeted salt, A "rule of thumb" in the solution mining industry is that every 7–8 m^3 of freshwater pumped into a cavity will dissolve 1 m^3 of halite. Water or undersaturated brine is injected through a purpose-designed well drilled into a salt mass to etch out a void or cavern. The resulting "almost saturated" brine is then extracted for processing. The technique usually targets salts at depths greater than 400–500 m and down to 2,000 m (Fig. 13.1). The current deepest salt solution operation is in the Barradeel concession in northern Netherlands in Zechstein Z2 salts and operating at depths around 2,800 m (Geluk et al. 2007). At depths greater than 2,000 m ongoing salt creep tends to reduce cavern size. Some operating brinefield caverns are as shallow as 150 m, but this can lead to catastrophic chimneying and stoping in sediments above cavity. With deeper operations the landsurface tends to subside into a bowl of subsidence, as it does above many conventional mines. Cavern shape and the upward rise of the cavern roof is today controlled by an inert fluid blanket pumped in and maintained at the top of the zone of active brine creation. Early solution wells did not use this blanket technology. In the 1800s and extending into first half of last century many brinefield operators perceived surface sinks, collapses and regular abandonment of caved wells as normal, during the operational life of a saltfield. Attitudes in the mining community today, across all types of exploration and production, are much changed.

In a solution mining saltworks, where production of various chemical salts is the main aim, saline brine is withdrawn from the expanding cavern and often pumped into solar evaporation pans to manufacture salts of designated grade, mineralogy and quality. Brine product from the pans, either solids or slurries, or a brine feed direct from the solution cavern, is piped to a nearby chemical processing plant designed for particular chloralkali, magnesia or other chemical products. Wells located near the site of a chemical plant and designed to capture brine of a particular chemistry are called captive brine wells.

The advantage of solution mining over conventional salt mining or surface evaporation pans is that product quality and the extraction operation is not as subject to the vagaries of climate or rock strength. Specific subsurface mineralogies can be targeted by the well bore to obtain a specific feedstock or chemical product, without the need to get men and equipment from the surface to the mine face. Solution mining can exploit folded and disturbed beds or deep-lying salt strata, situations not easily mined using conventional techniques. The main limitation of the solution mining method is an inherent outcome of a need for a significant volume of undersaturated water to be pumped into a salt bed and returned to the surface for processing. There is always a need to manage spent brine in an environmentally aware manner (Yanosky and Kappel 1997).

As well as halite, which historically has been the most common commercial target, other solution-mined salts include; potash (sylvite, sylvinite, carnallite), trona/nahcolite (sodium carbonate/sodium bicarbonate), borates (borax, ulexite, colemanite), sodium sulphates (mirabilite, thenardite) and magnesium chlorides. Today the cavern produced by solution mining can have a greater value than the extracted brine, particularly for a ubiquitous salt like halite. If appropriately designed, a cavity can be used for hydrocarbon or waste storage and even for energy storage/generation. In the future it is likely salt caverns will be used for hydrogen storage as part of an energy storage grid, fed by renewable energy sources (e.g., storage of energy output from wind and solar energy; Ozarslan 2012).

Diapiric salt masses tend to be the preferred medium for solution mining as the salt mass undergoing designed dissolution is typically large, thick and tends toward internal homogeneity. This makes it easier to purpose design in terms of both cavern shape and volume. Bedded salts tend to be less vertically homogenous and so more subject to differential caving and roof collapse in the life of a cavern. Ongoing improvements in directional and horizontal drilling mean bedded deposits can now be more reliably exploited. Rather than the brine product, more and more the cavern itself and its use as a storage vessel, is the rationale for solution mining. Many salt masses, especially in regions of relatively shallow salt or hydrocarbon interest have been drilled and exploited for more than a century and a half. In the 1800s and the first half of last century, well positions, completions and abandonment procedures were poorly documented and controlled. This has led to many of ground stability problems discussed later in the chapter.

The Solution Mining Process

Solution mining is an alternative to mechanical excavation of salt ores (Richner et al. 1992). Since most waste components in solution mining are not soluble they are left behind to settle to the bottom of the expanding cavern, as the brine product is removed to a surface processing facility. Unlike conventional mining, there are no large above-ground waste piles and tailings impoundments. However, the possibility of collapse and karstification atop brinefields means contamination and brine leakage into nearsurface and surface waters are potential problems. Monitoring of landsurface stability reduces the possibility of uncontrolled cavity collapse and associated environmental degradation.

History of Salt Solution Wells

The Chinese have been using brine wells and a form of salt solution mining, for more than 2,000 years (Flad et al. 2005; Kuhn 2004; Zhong and Huang 1997; Vogel 1993; Yoshida 1992; Yuanxiong and Chengxun 1983). Designed-use shaft wells were sunk as early as 220 BC in the Szechuan and Yunnan provinces (Table 13.1). By 1035 AD the Chinese in the Szechuan area were using percussion drilling to recover deep brines, a technique that would not come to the West for another 600–800 years (Fig. 13.2). European travellers to China in 1400–1700 AD reported salt and natural gas production from dense networks of brine wells. Some of the wells had been sunk deeper than 450 m and at least one well was more than 1,000 m deep (Table 13.1). Salt production in China at that time was prodigious, with more than 10,000 wells in operation. Marco Polo reported annual production in a single province of more than 30,000 t.

Practically all the materials used in Chinese brine recovery wells, including ropes, casing and derricks, were made from wood or wood fibre, mostly bamboo. Bamboo is salt resistant, while salt and brine kills microbes and algae that would otherwise cause it to rot. Pipeline joints were sealed by mud or a mixture of lime and tung oil. Manpower was used both to power the drilling process and to raise the brine. A sharp iron wedge bit (resembling a spade or shovel) was suspended on a levered rope at the end of a bamboo cable so that it kept pounding and pulverising the rock at the bottom of the drill hole (Fig. 13.2a inset). At the surface the drilling

Table 13.1 Maximum well depths attained since 221 BC using bamboo drilling technology in China

Royal empire	Time period	Well depth (m)
Qin Dynasty	221–206 BC	30.0
Han Dynasty	206 BC–220 AD	138.2
Tang Dynasty	618–907 AD	248.8
Song Dynasty	960–1280 AD	276.5
Ming Dynasty	1368–1644 AD	311.0
Qing Dynasty	1736–1796 AD	530.0
	1796–1821 AD	797.8
(Xinghai well)	1821–1851 AD	1,001.4
	1851–1861 AD	1,045.0
	1875–1908 AD	1,119.0

(**a**) Man-powered percussion drilling using a human-weighted lever system to raise the drill bit. *Inset shows* typical spade like iron drill bit that was suspended on bottom of bamboo drill string. (**b**) Animal-powered hoisting of brine from a salt well showing use of flexible bamboo cable wrapped on spindle. (**c**) Transfer of brine to iron pans for boiling of the brine product and recovery of salt. Boiling plants often using piped natural gas (No bamboo piping from well head to boiling house is shown in this image) (From the annals of Salt Law of Sichuan Province)

tool and drill string (flexible bamboo cable) were suspended from the end of a "spring pole." The raising and lowering of the percussion head at the base of the hole was supplied either by workmen running up a short incline and jumping down, one after the other, onto a small platform attached to the spring pole or by a single workman alternately standing on a wooden lever pole and stepping off (Fig. 13.2a; Deutsch 1978). As the drill assembly was raised after each descent another worker rotated the drill string assembly so it would strike the base of the hole in a different position. After 3–5 years, a successful well could have penetrated up to several hundred metres to intersect a brine or natural gas target. In 1835, the Xinhai well reached a depth of more than 1 km using this bamboo percussion technology (Table 13.1). Interestingly, the deepest percussion well in Europe around the same time was in Germany, where a percussion well reached 535 m in 1835. A likely reason for this shallower depth was that the Europeans used rope to suspend the drill tool, while the Chinese used flexible bamboo cable.

Periodically, pulverised rock was bailed from the base of the deepening hole. This was done by pouring water down the hole to create a slurry. The slurry was extracted by lowering a weighted hollowed-out bamboo pipe with an interior leather flap on its lower end. When lowered into the slurry the flap would open and jigging the pipe up and down when on the base of the hole forced rock slurry into the pipe. Then the pipe was raised with the weight of the slurry forcing the leather flap closed.

Later, once the hole had achieved its target depth, brine in the Szechuan area was often recovered from the well by the same means, namely, using a long bamboo bailer with a leather valve at its bottom. When a brine-filled tube was suspended over a nearby storage tank, a poke from a stick would open the valve releasing the brine (Fig. 13.2b). Alternatively, a section of bamboo with pith left in place was cut by a series of holes located just below each pith level creating a series of small buckets. The weighted bailer was lowered into the brine pooled at the base of the brine well and brine flowed into the holed pith sections. Then the bailer was raised and inverted over the storage tank.

Often the storage tank was connected by bamboo piping to the salt boiling house (Fig. 13.2c). Other bamboo pipes, located just below a natural gas wellhead were used to capture escaping methane and pipe it to the boiling house to fire the salt crystallisers (iron pans).

From the flexible bamboo pipe (cable) technology developed at the Szechuan brine works, Chinese throughout the country learned to build irrigation and plumbing systems (Kurlansky 2002; Zheng and Palmer 2009). Farms, villages, and even houses were fitted with bamboo plumbing. By the time of the Norman conquest of England, Su Dongpo, a bureaucrat born in Sichuan, was building sophisticated bamboo urban plumbing networks. Large bamboo water mains were installed in Hangzhou in 1089 AD and in Canton in 1096 AD. Holes and ventilators were installed for dealing with both blockages and air pockets.

In Europe, near Lorraine, France, much simpler designed-usage brine shaft wells were sunk by hand as early as 858 AD (something the Chinese had been doing since at least 250 BC). In 1381 AD the Duke of Lorraine, the Bishop of Metz and the Duke of Bar, formed a salt cartel that operated brine wells at Chateau-Salins and Salonne (Deutsch 1978). By 1740 brine was raised in the region using horse-driven pumps and in 1758 steam-driven pumps were drawing brine from wells that were more than 100 m deep. By 1839 salt was being directly mined in an underground operation at Dienze that employed over 400 miners. By 1830 in the USA there were more than 60 brine wells in operation in Kanawha region near the confluence of the Kanawha and Ohio rivers. Numerous brine wells were in operation in New York State by 1880, while large-scale brine recovery operations in the various playas of the Basin and Range were underway by the early 1900s. Today, steel-cased brine wells are consistently drilled to depths of more than 1–2 km to extract brine product or to excavate custom-built salt caverns for hydrocarbon or waste storage.

Well and Cavern Design

The design of a salt solution well consists of two or more columns of steel pipes (casing strings) with the smaller inside the larger. Fresh water or undersaturated brine (feed solvent), needed to drive the solution process in an expanding cavern, is pumped into the well to create a cavity in the targeted salt. The resulting brine is then returned to the surface for processing and recovery.

The first step in solution mining salt is to drill an appropriate diameter borehole, large enough to accommodate all the required pipes (casing). This means solution wells are wider than most oil and gas or water wells. Near the surface, the borehole is widest to allow for installation of several concentric layers of pipe casing (Fig. 13.3). The outermost layer of casing, known as the surface casing, is cemented in place to prevent any leakage and contamination of nearby groundwaters. Surface casing does not typically extend all the way down to the cavern roof. The final casing string (or long string casing), which is also cemented in place, is set at some depth below the top of the target salt so that during dissolution a reasonable thickness of salt remains in place as a salt roof to the expanding solution cavity. In modern wells there is another string immediately inside the outer casing string that controls the thickness of the fluid blanket.

Generally, one or more non-cemented casing strings, the tubing strings, are placed inside the final casing string. In modern designed-use caverns, non-cemented casing or

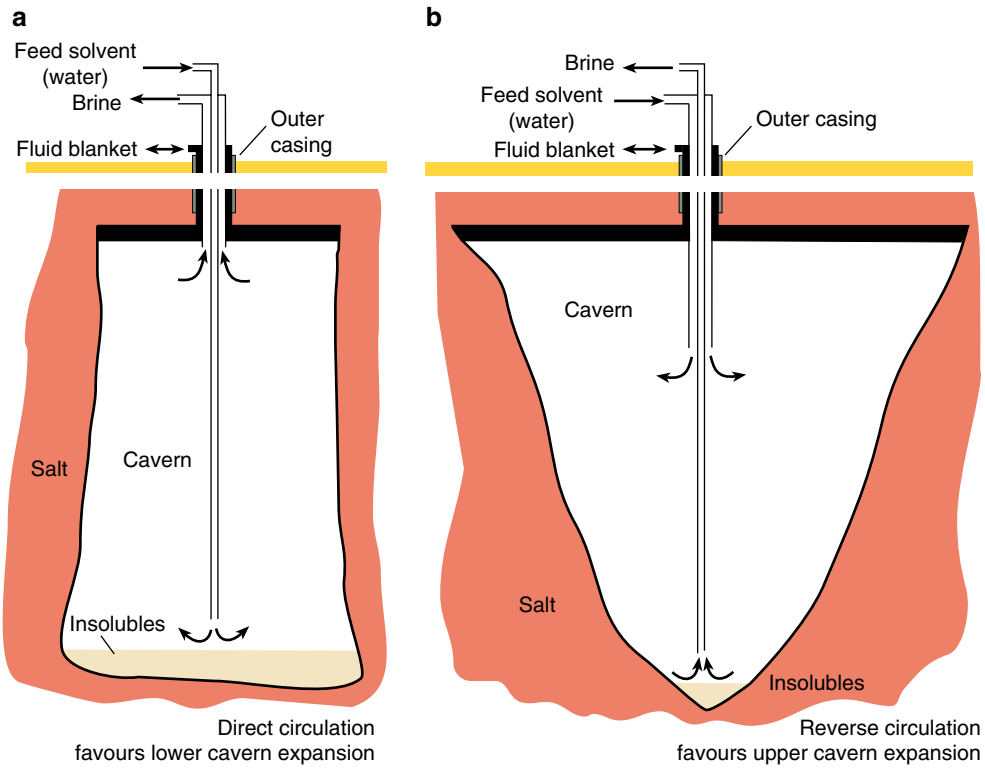

Fig. 13.3 The solution mining process. (**a**) Direct brine circulation where feed solvent is injected through the tubing string and brine is withdrawn through the annular space between the tubing string and the final casing. Cavern shape tends toward cylindrical with slightly expanded lower section. (**b**) Reverse-circulation where the feed solvent enters the cavity through the annulus and brine is withdrawn through the tubing string. Cavern tends to be wider at top than base ("morning glory"). In both cases the outermost casing allows feed of the blanket solution into the uppermost part of the cavern, so protecting the cavern roof. Varying the volume of blanket in the cavern can be used to help shape the cavity

tubing strings first extend to a depth near the planned based of the cavern. Under this design scenario, strings can be rotated and raised (snubbed or pulled) as the cavern grows and the bottom fills with insoluble debris. Depending on the size of the cavern and the amount of impurities present, more than 20 m of impurities (dolomite-anhydrite residues and fragmented roof blocks) can sit on the bottom of an active solution cavern (Crossley 1998; Tomasko 1985). Some older interconnected multi-well brinefields did not have non-cemented strings in each well.

Salt subjected to undersaturated crossflow in an expanding solution cavity tends to leach 1.5–2 times faster vertically than horizontally (fresher water is less dense than brine and tends to accumulate in the upper part of a cavity). Vertical leaching tends to be even faster if there are gas inclusions in the cavity waters, giving it even greater buoyancy. An inert low-density fluid blanket is usually pumped into a solution cavern to prevent rapid upward stoping and ultimate collapse of the cavern roof into the growing cavity, along with its cemented casing string. Roof blanketing, sonar imaging and designed cavern shaping typify most contemporary commercial solution mining operations.

Blanketing fluid is inert so it does not dissolve the target salt, and is always less dense than the feed solvent or the produced brine. It always floats to the top of the cavern where it insulates the roof from the effects of dissolution. Older blankets were one of a number of different types of oil, typically diesel or crude, but today are increasingly composed of other fluids including LPG, nitrogen and compressed air. Nitrogen and less often compressed air tend to be the fluids of choice as they do not have the environmental and safety issues associated with a hydrocarbon blanket. Generating a blanket requires the addition of a devoted column of pipes in the well string and the blanket is usually pumped in/out via the annular space between the outer and middle casing pipes (Fig. 13.3).

There are several methods for developing and shaping caverns. In the direct circulation method, feed solvent is injected through the tubing string and brine is withdrawn through the annular space between the tubing string and the final casing (Fig. 13.3a). In the reverse-circulation method, feed solvent enters through the annulus and the brine is withdrawn through the tubing string (Fig. 13.3b). As less dense water in a salt cavern tends to float on a more concentrated brine, a "morning glory" type cavity with a much wider top than base is likely to be formed by what is called reverse circulation, especially in cavities grown without the aid of a fluid blanket. A more cylindrical cavity is formed by direct circulation. During cavern excavation, the volume of the blanket fluid is increased or decreased to help shape the cavity.

Detailed discussion of the engineering aspects involved in well design and cavern shaping is largely outside the geological focus of this book. Various authors, such as Remson et al. (1966), have outlined the general procedures for controlling the shape of the solution mine cavities, and many articles, such as that of Shock (1985) and Jacoby (1974),

have been written on basic solution mining techniques for various salts. Extensive bibliographies also have been prepared on solution mining, such as those by Dahl (1985) and Nigbor (1982). Combinations of these various methods and other more complicated solution mining approaches are now well understood and can be used to obtain any desired cavern geometry or well-to-well interconnections (API 1994).

If a particular brine product is the goal of a solution mining operation, rather than the cavern itself, then the extracted brine typically is evaporated or treated at the surface to produce a crystallized product. In this case an "almost saturated" brine product is mandatory in the rising casing string. Dilute brine is too expensive to process, while supersaturated brine can block the raising string with unwanted precipitates. When a single hole solution mining well is first drilled, the flow rate through the cavity and up the pipe is usually kept very low to maintain higher levels of brine concentration. As the surface area of the cavity and the cavity volume increase with time, the extracted brine flow rate can be progressively raised. In a year or so comparatively high flow rates can be maintained. The life of a successful brine well can be quite long, up to 30–40 years. If the solution process is maintained from a single well the area around the well will eventually subside, or the borehole roof carrying the casing strings will weaken and cave, disrupting the brine flow. Even if the roof doesn't cave, salt will dissolve from around the casing string and it will eventually corrode and fall into the cavity.

Historically, until the 1950s in the West and much later in the former Soviet Union, captive wells designed for brine recovery and not for storage were expected to be abandoned or to fail. Most such wells started out as reasonably good producers, but ultimately failed by breakage or damage to the casing string by corrosion, by roof caving or by subsidence-related shearing/collapse of the casing string (Deutsch 1978). Failure could occur soon after a well evolved into a high-capacity performer or decades later. Most brinefield operators learnt that many of their oldest wells were their most reliable producers. Many captive brinewells "die" during their "infancy," but if they live through the usual "childhood diseases" of roof collapse and casing shear, the chance of failure lessen as they get older. Some older brinefield wells in bedded salts, that is, wells that had produced for 20–30 years, seemed to be immune to caving and were abandoned only when the target salt layer was exhausted.

Predicting which wells survive in a brinefield is difficult. An analysis of some 60 wells drilled between 1,887 and 1,925 clearly shows this trend of long-lived survivors (Fig. 13.4). One possible explanation for "long-life" wells is that early cave-ins distributed fallen rock in such a way that the lowest part of the tubing string was protected from damage by later cave-ins. Alternatively, as the roof of a growing salt cavity reached a greater and greater span, it could either cave with serious results for the well, or it could very gradually subside

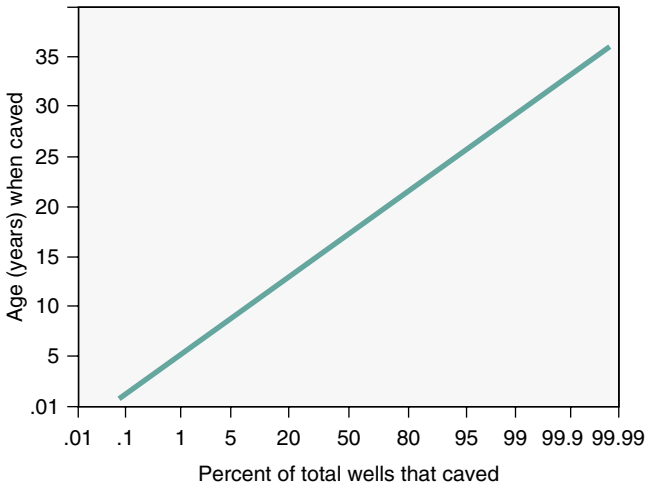

Fig. 13.4 Schematic of the "life expectancy" of a set of brine wells (Deutsch 1978)

until it was supported by silt or projections and debris at the bottom of the cavity. A brine well in the latter situation would continue to be a good producer, even with a very shallow cavity. Well failure or poor performance is somewhat random in nature, and can occur unexpectedly. Consequently, and because of slow initial production rates, most captive brinefield operators employ many wells, abandoning nonproducers and bringing new ones on-line.

In all cases, mud and other insolubles, as well as some salt falls accumulate as muddy breccias at the base of the expanding cavity. In wells where salt layers other than halite are the target and are encased in thick halite, the initial borehole is typically drilled through the target bed(s) to some distance into the underlying halite mass. As the cavity then expands, it creates a sump below the target bed where insolubles can accumulate. In any solution cavity it will be necessary to raise the bottom casing string (snubbing) above the level of the insolubles, otherwise the well will need to be plugged and abandoned. This is also true if the casing has been severely bent or damaged by the rock-falls from the roof. Normally these problems occur very slowly, and the cost of the initial capital and well operation is such that the total mining expense is very low compared to conventional room and pillar extraction.

Many land areas above brinefields, which were active in the eighteenth or nineteenth centuries and were over-exploited, are today subject to collapse. But few records of well placement or even the position of the brinefield were kept in older areas of extraction (as in Hutchinson, Kansas – see case histories later in this chapter). This leads to all manner of environmental and civil engineering problems in the vicinity of many former brinefields. But not all engineering and subsidence problems in areas of nearsurface salt are anthropogenic (Table 7.10). Salt dissolves and the large collapse cavities form naturally at the landsurface in time scales measured in days or

weeks. Outside of areas atop poorly managed or historical brinefields, separating anthropogenic sinkholes from natural dissolution cratering is very difficult. A cynic might conclude that many causative interpretations depend in large part on which interest group is paying the consultancy bill.

Solution Well Styles

Various techniques have been employed in brinefields over the last 150 years to improve brine production costs and to increase the amount of brine produced per well. Today the dissolution process for single wells can involve multiple concentric or independent tubing strings, various fluid injection/production depth combinations, as well as several different roof-protection combinations involving blankets of different types of hydrocarbons including crude oil, LPG, and gases such as nitrogen and CO_2. Blanket design now also includes solids such as floatable cements and hollow spheres (Richner et al. 1992). Multiple-well interconnections can be achieved in a planned manner using appropriate geological understanding along with combinations of roof padding, well deviation/ horizontal drilling and hydraulic fracturing.

Expert design of solution wells is for the most part dependent on geological understanding of the salt to be exploited. Required knowledge includes: dip and thickness variations of the target bed; mineralogical composition, homogeneity, insoluble levels and dissolution behaviour of the target salt bed and adjacent salt layers; distribution and mineralogy of intrasalt beds; structural integrity of confining beds. Caverns engineered in salt domes tend to be more reliable and predictable structures than caverns engineered in bedded salts and are more suited to product storage especially if the product is stored under pressure. Compared to dome salt, bedded salt in the vicinity of a solution well tends to be thinner and bound above and below by more permeable formations. Bedded salt is also more likely to enclose layered intrasalt beds with varying levels of solubility and fracture intensity (anhydrite, shale and dolomite intrabeds) and so tends to supply significantly higher quantities of impurities to the cavity floor. The most stable cavern shape for purpose-designed storage resembles a giant carrot or cucumber embedded deep in a mass of salt. This ideal shape is next to impossible in bedded salt, and to continue the vegetable garden analogy, jack-o-lantern pumpkins are a more likely outcome.

Historically, the earliest single wells had top injection (reverse circulation) and no roof pad or blanket. This style of well is known as a "Tully method" well and also are described as "top-injection," "casing-injection," "direct-circulation" and topwater injection" wells. Tully-method wells had the advantage of low investment costs along with rapid development of saturated brine flow (Richner et al. 1992). Unfortunately, this technique tended to create unstable morning-glory caverns subject to roof failure and their design inherently limits brine recovery to the upper portions of any targeted salt mass. Casing damage was likely even in the very early stages of cavern growth. "Tully" wells are not used today and belong to a time in human history when landscape damage was seen as a positive indicator of "progress." In the 1920s and 30s "Detroit-method" wells, with direct circulation via a bottom tubing injection, became the preferred method for excavating single well brine producers as they tended to create more stable cylindrical caverns, less subject to early collapse and loss of the well. Detroit-method wells are also referred to as "bottom water injection," "tubing injection" or "reverse circulation" wells.

In the 1930s the "Trump" method, a multiple well technique, was introduced to exploit bedded salts. It involved direct circulation and the use of a roof pad or blanket (Fig. 13.5. Multiple wells were completed near the base of the targeted salt formation. The aim was to create large diameter undercuts near the base of the target salt bed and then allow the undercut caverns to expand beneath their blankets until adjacent cavities met. Historically, wells utilising the Trump method were between 61 and 183 m apart. Once an interwell connection occurred, the wells were changed from two independent circulation wells, into two-well or multiple-well operations. One (or more) well(s) became the injector(s) for feed solvent and the other(s) became the brine producer(s) (Fig. 13.5). In this way the salt formation between the two wells was more efficiently recovered by the rising cavity roof and the per well brine production rates and tonnages were markedly improved compared to the older single "Tully" method wells. Using the Trump method entails a 12–24 month period of cavern development during which arrangements must be made for the usage or disposal of unsaturated brine.

Henderson (1974) reviewed this multiwell method of solution mining for halite targets. For maximum efficiency, he recommended a 91 m well spacing in bedded salt and about 18 months from the onset of feeder brine pumping to a time when an appropriate and consistent quality brine product could be recovered. He noted that cavity development and brine field subsidence in general can be controlled to a greater degree using the "Trump" procedure rather than a single Tully well. It entails relatively low production costs and high flow rates per mature well. However, the padded rising roof of the cavity is not a structurally competent shape, and roof falls ultimately occur. Constant raising of the casing is often required, especially in the downdip feed wells. The production or uphole wells are particularly vulnerable, and generally weaken and fail first (see the Romanian SALROM disaster in case studies).

Specific examples of the mining of very thin beds of salt using one- or two-hole methods were reported from a brinefield in China by Yuanxiong and Chengxun (1983). Single-well, nonblanketed, production of a salt bed 1–6 m thick at a

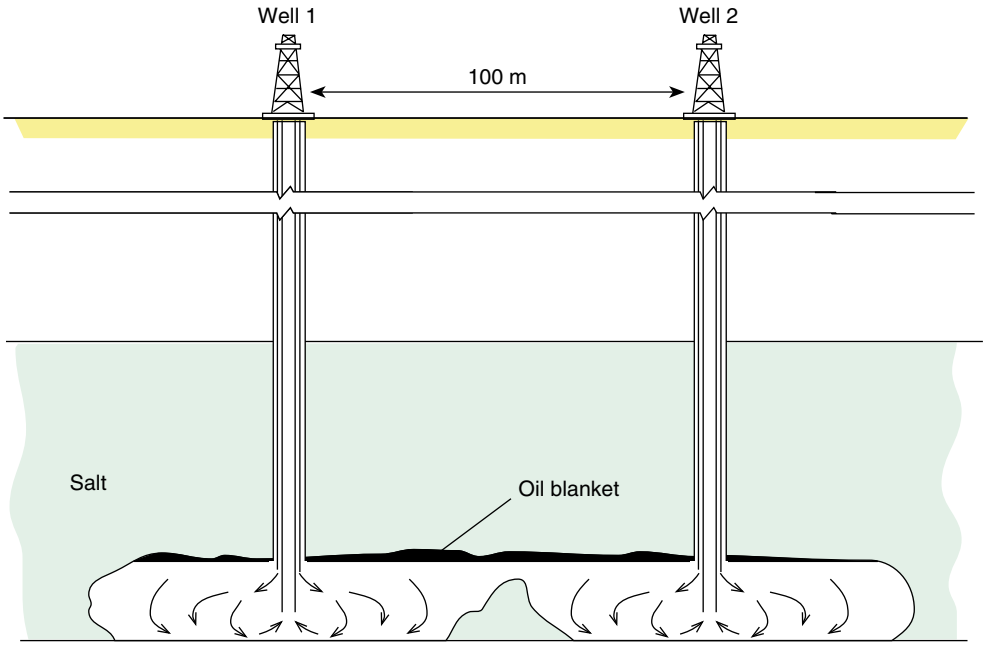

Fig. 13.5 Solution mining by joining wells by using an oil pad or blanket in combination with reverse circulation (After Henderson 1974)

depth of over 1,000 m in 12 wells over a 5-year period averaged 20,000–30,000 t/year of salt per well (maximum 70,000 t/year), with a well life of 4–8 months. Both the casing and tubing tended to deform, bend, and break from roof falls. Well life was longer in zones with a more stable roof. However, when oil pads were employed on a single two-pipe well 935 m deep within a 17-m-thick salt, the well was fairly quickly producing 50 t/day of salt as a saturated brine. Well life and productivity were much improved. Two other wells were then connected by using oil pad control to test against the single well extraction method. The wells were 1,042 m deep, 71.7 m apart, and operating in a salt bed some 17–20 m thick. Cavity height during excavation was maintained about 2 m above the base of the salt. By 100 days the flow rate in each well was 10 m^3/h with an "almost saturated" exit brine, and in 500 days the wells were interconnected. In a third set of wells at 1,004 m depth, 16-m-thick salt, and 68-m spacing, it only took 180 days to make the connection. About 26,000 t of salt were "wet mined" in making each cavity, and the daily salt output was 300–400 t/day per well at the end of this period. Blanketed reverse circulation (top injection, bottom production) was employed to better control roof height and allow faster horizontal cavity growth. Over 50 % recoveries of the entire thin salt beds were obtained with excellent economics and minimal surface subsidence using this procedure.

Today, most single well solution mining operations utilise a modified annular injection method, known as variable point injection, where both the tubing string and the casing string are positioned near the lowermost level of salt to be dissolved. Undercuts of more than 100 m diameter are achieved using a gaseous or liquid roof pad. In captive wells, brine production rates of more than 13 l/s have been obtained once the blanket is withdrawn. As solution proceeds both the tubing string and the casing strings are raised clear of the accumulating insolubles (snubbed). This type of well is also capable of achieving planned-cavity shapes suitable for waste storage.

An interesting test of the efficiency of both single-well and two-connected-wells solution mining systems targeting a thin bed of sodium borate was described by Taylor (1970). An 8.8-m thick layer of borate ore, which was 107 m below the land surface with a 72 % ore grade, was solution-mined in a series of tests. At the completion of the tests the cavities were physically mined (entered) and inspected. No roof padding was employed during the tests. Hot water at 102–110 °C was injected as a feed into the 21 °C formation and a 15 l/min flow produced an "almost saturated" borax solution with an exit temperature around 77 °C. As the test progressed, feed temperature was steadily decreased and the allowable flow rate of the saturated solution steadily increased. On later cavern entry it was found that broad morning glory holes had formed and large amounts of insolubles had accumulated on the cavern floor. Clay and shales from the roof had fallen as intraclasts with a "sand and gravel" structure. Cavity bottoms were dominated by this material, rather than by fine bottom slimes usually postulated to dominate cavity bottoms. Some slabs of borate remained encased in the pile of insolubles, where they remained buried as unleached blocks.

Techniques in Potash Operations

Texas Gulf solution mines potash-rich brine from deformed salt beds in the Paradox Formation at Moab, Utah and then uses solar concentrators to achieve a product appropriate for

processing Fig. 11.30). The IMC Kalium operation near Moose Jaw, Saskatoon, recovers potash brine by solution mining a sylvinite bed (Belle Plain Member) 9–15 m thick at a depth of 1,650 m using a patented solution and recovery method (Fig. 11.61). To capture the ore, hot undersaturated brine feed is pumped into the dissolution cavity. Concentrated potash brine is then returned to the surface processing plant, which uses a sequential evaporation-crystallization process to recover potash and recycle hot NaCl-rich brine to the subsurface for another leach cycle. In the dry steam driven evaporation stage in the processing plant, moisture is removed and the recovered brine is brought to saturation point. But halite and sylvite have different temperature responses (Fig. 11.68b). Halite is crystallized first by evaporating the recovered brine, then potash is recovered by cooling the remaining hot, saturated solution.

In conventional solution mining of potash intervals, all of the halite in the dissolution cavern must be leached along with the potash in order to keep the face of the solution cavity open and dissolving rapidly. Otherwise, a buildup of salt and insolubles on the active dissolution face cause blinding. Bottom casings are raised (snubbed) periodically to keep above the buildup of insolubles. In all solution brine operations, including those targeting potash intervals, flow rates are kept low enough to produce a transparent "almost saturated" brine. Because the targeted potash bed is typically thin with respect to the halite host, well capital and operating costs are comparatively high, but are reported to be still less than conventional potash mining. Relevant published potash solution mining articles and processing patents include; Bach et al. (1985), Day (1967), Dillard et al. (1975) and Schlitt (1982) (Fig. 13.6).

Carnallitite, like trona, shows incongruent solubility so that in beds composed of mixtures of carnallite, sylvite and halite, the sylvite tends to be left behind as a less soluble component that can slow the rate of dissolution (surface blinding; Fig. 13.7). Furthermore, the solubility of halite, sylvite, and kieserite is very low in strong $MgCl_2$ solutions and this limits exploitation in intervals where these minerals are co-associated.

The NedMag solution mining facility near Veendam in the Nederlands produces magnesium from magnesium chloride brine by solution mining a Zechstein salt dome, targeting beds that are a mixture of carnallite ($KCl \cdot MgCl_2 \cdot 6H_2O$), bischofite ($MgCl_2 \cdot 6H_2O$) and halite (NaCl), with some sylvite (KCl) and kieserite ($MgSO_4 \cdot H_2O$). Target intervals at Veenham average 100 m (combined) thickness at depths, dipping around 20°, at depths between 1,400 and 1,800 m. About a 100 m of halite lies above the target magnesium salts and more than 1,400 m

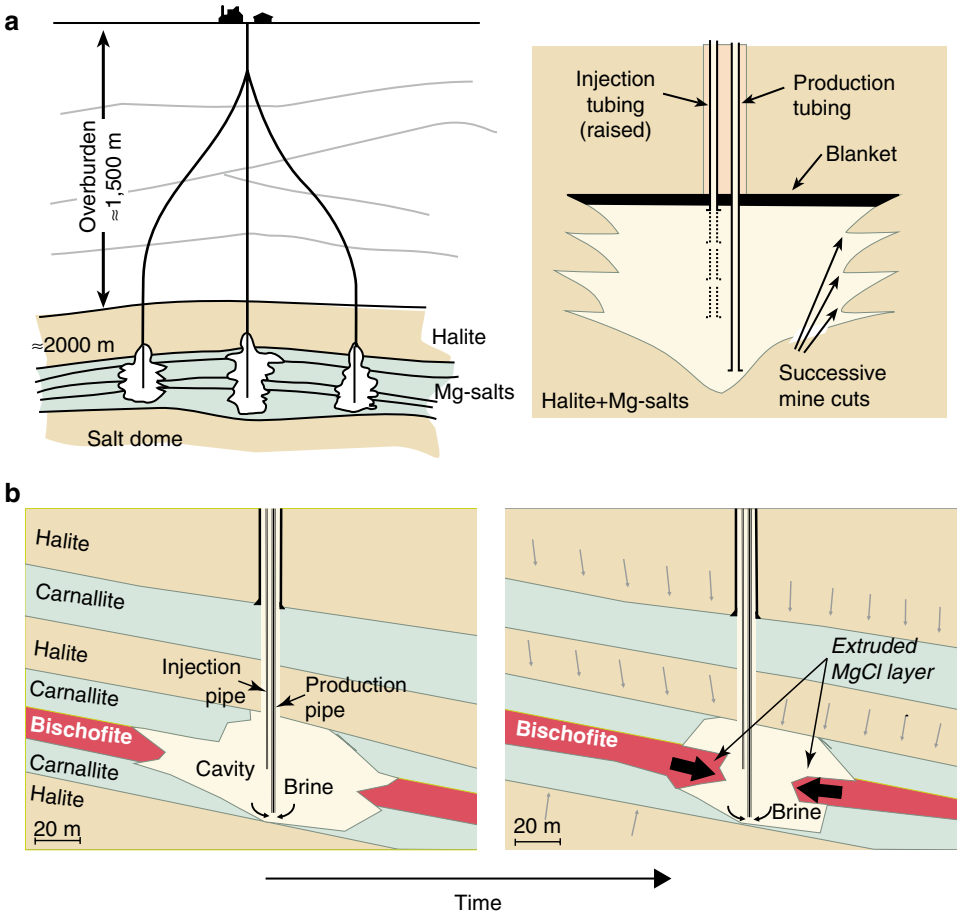

Fig. 13.6 Squeeze mining (**a**) Schematic of deviated wells in magnesium salts at the NedMag plant in Veendam, Netherlands, showing solution mining method of upward retreating successive cuts with positions controlled by the blanket (After Currie and Walters 1985). (**b**) Squeeze mining method utilised at Veendam targeting bischofite layers (in part after Drijkoningen et al. 2012)

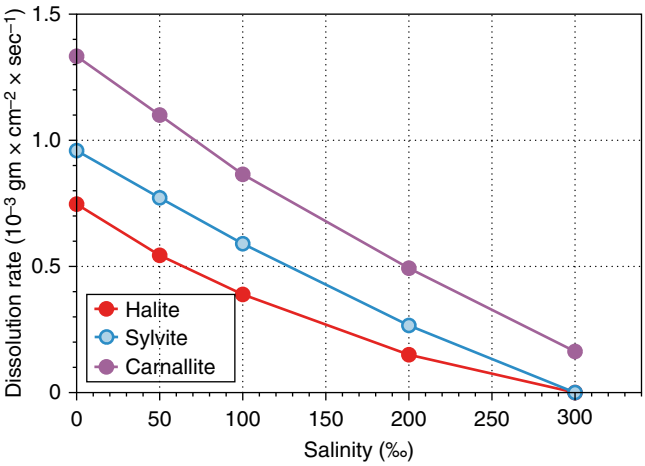

Fig. 13.7 Solubilities in water of the three main potash minerals at 25 °C

occur below (Fokker 1995). Beds were accessed by a total of 12 solution wells drilled between 1972 and 1991. Nine of these wells were still operational in 2000 with average brine production per well around 25 m^3/h. NedMag has recently excavated one of the deepest solution mining cavities in the world at 2,890 m. Each year the NedMag plant produces in excess of 200,000 tonnes of high purity synthetic dead-burned magnesia and more than 70,000 tonnes of magnesium chloride in liquid or solid form. A similar solution-mined operation producing $MgCl_2$ brine by targeting bischofite beds is planned for a large deposit near Volgograd in Russia.

The mining procedure at Veendam utilizes a backstepping solution cavity method (Fig. 13.6a; Fokker 1995). Cavity extent is limited to ≈ 100 m diameter (perhaps now extended to 150 m), and the brine is maintained at the original downhole (lithostatic) pressure. Wells are designed to be plugged and abandoned at full pressure. During production the magnesium salt-rich layers are preferentially dissolved, leaving behind many halite balconies on the cavity walls. Eventually the balconies collapse. This creates considerable insoluble rockfall and mud deposition on the cavity floor, compared to conventional cavities that target homogenous halite. Dealing with this extra volume of collapse debris requires frequent raising of both the injection (to control the cavity diameter) and the withdrawal pipes (to prevent blockages; Fig. 13.6a).

Cavern pressures are kept relatively low in the producing caverns (average of 10 MPa or 100 bars) and well below the far field rock stresses. This facilitates salt creep into the cavern, but the lower viscosity of the magnesium salts compared to halite means they are preferentially squeezed like toothpaste into an active solution cavern at a rate far greater than the creep of the adjacent halite (Fig. 13.6b). Hence, the bischofite beds supply far greater volumes to the dissolution cavern than the adjacent halite beds, with convergence rates contributing 30–40 % of the produced MgCl-brine volume. This method has been called "squeeze mining" and the brine product from squeeze caverns can be very pure. For example, four wells producing brine from "squeeze caverns" at Veendam are almost saturated with respect to bischofite, rendering a high quality brine product with less than 1 % by weight of non-magnesium chloride salts.

Although the degree of creep is not well understood, it has been established that halite shows a much lower creep than carnallite, which in turn shows a much lower creep than bischofite (Fig. 13.6b; Drijkoningen et al. 2012). Although the strain rate depends on differential stress, the strain rates can be estimated very roughly, in order of magnitude, as 1:10:100, respectively. The bischofite will therefore creep towards the caverns, resulting in a gradual thinning of the salt layer. Bischofite will creep due to pressure difference between lithostatic pressure depending on the depth and the pressure applied in the cavern.

In the development of cavities it is important to note that squeeze mining has a different effect than conventional solution mining under lithostatic conditions, because part of the created brine is replaced by solid salt. This enables production of more salt from the same cavern (Drijkoningen et al. 2012). A counter-effect is that squeeze mining leads to a more rapid surface subsidence than conventional lithostatic mining, in which there is no net volume change in the salt layers. The squeeze mining leads to extra deformation of the overburden, which in turn causes extra subsidence of the Earth's surface. Dutch regulations now impose a maximum subsidence of the surface of 65 cm for this mine, limiting production in the future.

By carefully maintaining the proper $MgCl_2$ concentration in the Veendam cavern brines and monitoring solution flow rates using variably pressurised waters, NedMag has minimised blinding in bischofite beds (Steenge 1979). For successful magnesium chloride recovery, the solution rate, the dissolving surface and the produced brine at Veendam must be maintained at all times at an 'almost saturated" condition. The operations at Veendam are a worldclass example of targeted and monitored solution mining with a set of process technologies specifically designed for the brine product. Historically, high levels of carnallite in some potash beds in the Zechstein have made them a poor choice for a KCl targeted beds in both solution and conventional mining operations. But NedMag has recently begun to use a patented process to produce brines that are also saturated with respect to carnallite from carnallitic beds previously considered subeconomic.

Lithology Effects Shape

So far, much of our discussion of shapes of solution cavities has assumed that the thick salt targeted for dissolution is relatively homogenous. But halite masses typically contain

thinner intercalated layers, composed either of less soluble salts, such as anhydrite or dolomite, or of more soluble salts, such as carnallite or bischofite (as at Veendam). An assumption of target bed homogeneity in solution planning can lead to problems during the leaching process.

With less soluble salt layers intersecting a cavern edge there is a tendency to form unsupported ledges and bevels, which eventually collapse to the floor of the expanding cavity. This can damage the roof in the vicinity of the feeder pipe, break the drill string, or force the operator of a suitably designed well to raise the well pipe off the former cavity floor (snubbing). In the case of more soluble beds, their rapid solution can leave behind blocks of unstable halite, which have a propensity for collapse, or it can lead to cavity shapes that become enlarged in one direction and encroach on the structural integrity of the well design, especially when there are adjacent solution cavities.

The best-studied and modelled examples of lithology variation effecting cavity shape come from the monitored cavities in the Zechstein salts of onshore Germany (Wilke et al. 2001). Of the four major Zechstein formations in the northwest European Zechstein basin, the Stassfurt formation (Zechstein 2) occurs in sufficient thickness (more than 800 m), to flow in to salt pillows and diapirs and so is the most important target unit for solution-leached caverns in this part of Europe. The underlying units of Werra formation, along with older salt units of the Rotliegende, are typically inactive and many beds are still attached to the basement. Salt of the overlying Leine formation (Zechstein 3) contains relatively thick beds of anhydrite and dolomite. It has an original thickness of 200 m, lies above the Stassfurt formation and is typically caught up in the Zechstein flows, but it needs the underlying thick halite of the Zechstein 2 to flow and carry it along.

High quality documentation of the internal structures of the German diapirs during potash mining has produced an excellent data set on which to model the likely geological complexity of these Zechstein structures (Fig. 11.47). This work caused the German salt experts, Richter-Bernberg and Horfrichter to conclude that of the Z2 and the Z3 series, the Hauptsalz member of the Stassfurt formation is most suitable for designed-use cavern construction and that the upper part of Stassfurt be avoided where possible due to inherently higher proportions of highly soluble potash and magnesium layers. Likewise, the overlying Hauptanhydrit of the Z3 has a propensity to create unstable anhydrite blocks during halite leaching and is not considered suitable for controlled cavity creation. Since their pioneer work, the goal has been to avoid solution mining in this transition zone between Zechstein 2 (Stassfurt Formation) and Zechstein 3 (Leine Formation). Nevertheless, several caverns have been leached in these strata, some without any problems, others with intensive preferred leaching directions (Fig. 13.8a, b; Wilke et al. 2001).

Structural elements in salt diapirs, largely crystal size and anhydrite distribution patterns in non-potash containing intervals lead to slight changes in cavern development. For this reason a sonar-measured cavern shape can be used to re-interpret a preexisting geological map. For example, the horizontal section in Fig. 13.8c outlines the contact between the Kristallbrockensalz (Z2A-HS3) and the Streifensalz (Z2-HS2), which leaches slightly faster due to its finer halite crystal size and more widely dispersed insolubles. Figure 13.8a, b are examples of preferred leaching along a relatively undisturbed potash seam. It lies several metres above a previously interpreted contact between the Kristallbrockensalz (Z2-HS3) and the Streifensalz (Z2-HS2). This later geological interpretation along the borehole provoked concerns that the potash layer would be intersected as cavern proceeded and led to a modified plan for cavern creation.

Experience in this terrain has shown that where potash layers of the Kaliflöz Stassfurt cross the drill axis a number of times it is not possible to perform a controlled leaching in one step. Rather, the leach design has to be planned as a number of mining steps to avoid a premature achievement of the maximum allowed cavern diameter in the vicinity of the potash layers (Wilke et al. 2001).

Such a controlled leaching program, tied to lithological variation, is called blanket management and proceeds in a series of back steps as described by Wilke et al. (2001); Fig. 13.9:

- Blanket depth is kept below the 50° dipping potassium seam at a distance such that the expanding cavern wall will not touch the seam while it is expanding towards the maximum allowed diameter.
- After reaching 80 % of the planned cavern volume below the seam, the blanket is raised to a position slightly above the dipping seam to allow some upwards leaching along its occurrence.
- After some weeks of development of the original borehole, the blanket is pumped down to once again cover the more soluble part of the leached section.
- Continue leaching and continuously add "oversize" amounts to the blanket to be sure the more soluble section is covered.
- Raise the blanket to prepare a new leaching step, before snubbing the pipes. Maintain the blanket in the section of the potassium seam to continue protecting that area.
- Change the injection point depths shortly before the maximum diameter is reached below the seam and while the production point is still sufficiently deep to approach to the maximum allowable shape in this part of the cavern. All the upper section of the cavern is then allowed to expand toward planned diameter.

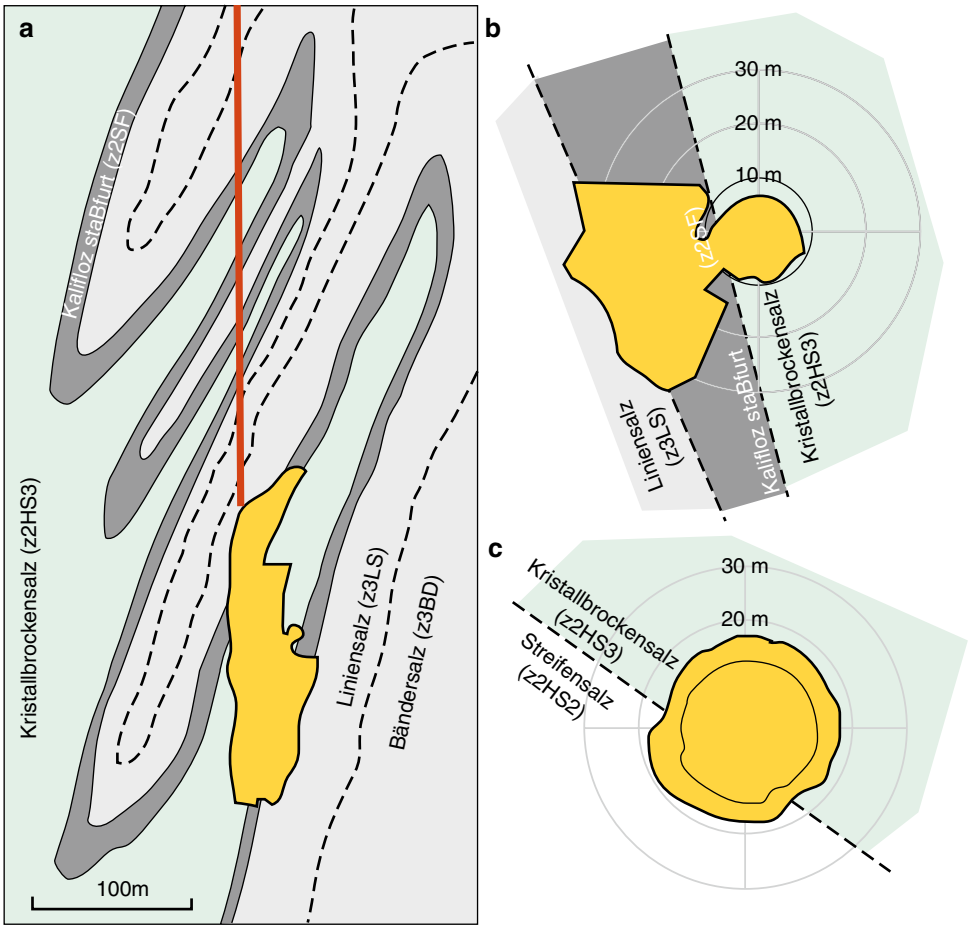

Fig. 13.8 Effect of salt geology on cavern shape in diapiric Zechstein Salt. (**a**) Vertical section through a cavity in Zechstein Salt in Germany showing preferential enlargement into potash-rich Kaliflöz Stassfurt horizon (*shaded grey*). (**b**) Horizontal slice showing strongly asymmetrical shape formed as cavity develops preferentially into the potash facies of the Kaliflöz Stassfurt. (**c**) Horizontal slice in a cavity in two halite lithologies where differences in crystal size and proportion of insolubles create a slight asymmetry that is maintained during growth (After Wilke et al. 2001)

In the case of caverns intersecting highly soluble intrasalt beds it is especially important to create "as much as possible" cylindrical caverns below the level of any seam. This approach means that the largest allowable storage volume is created inside the project's rock mechanical parameters. At the same time the cavity shape must be monitored often enough to avoid uncontrolled expansion in the highly soluble (potash) layers.

Well Pad Design

Some modern brinefields and storage sites are made up of single wells with concentric casings extending into individual caverns. Others consist of several adjacent brine wells extending into a single large cavern. Yet others create multiple caverns off a cluster pad. Brine is withdrawn either through the outer concentric casing in a single well cavern, or through a separate casing in a multiple well cavern. Once active, the size and shape of solution-mined caverns can be measured and controlled with cavern sonar and operating techniques (Crossley 1997, 1998).

Single drill pads typically sit atop vertical wells, they offer maximum flexibility in cavern depth range and minimisation of hole damage (Fig. 13.10). Snubbing or pulling pipe is relatively straightforward in a vertical well due to low frictional losses. There is minimal borehole contact and good control on any twisting of the drill string needed to free it if it has become stuck. In all solution wells the initial borehole shape is important as it can strongly influence the shape of the subsequent cavern. Vertical holes suffer minimal borehole asymmetry, which is often created by excessive one-sided hole wear during the drilling phase of an inclined well.

Cluster well pads allow multiple caverns to be created beneath a large pad and are a cheaper alternative to single well pads (Fig. 13.10b). They have lower infrastructure costs and land area requirements, they need only a single access road, one field pipeline for the brine product, one set of power supply cables to the pad, and the surveillance of only one site. However, compared to single well pads, they suffer from less flexibility in ongoing planning and maintenance. The need for directional drilling and the degree of deviation means it may be difficult or even impossible to turn the leaching strings or the cables after a cluster pad well is activated. Rotating a tubing string is a technique frequently used to free the coupling on the last cemented casing shoe if it has become stuck during production.

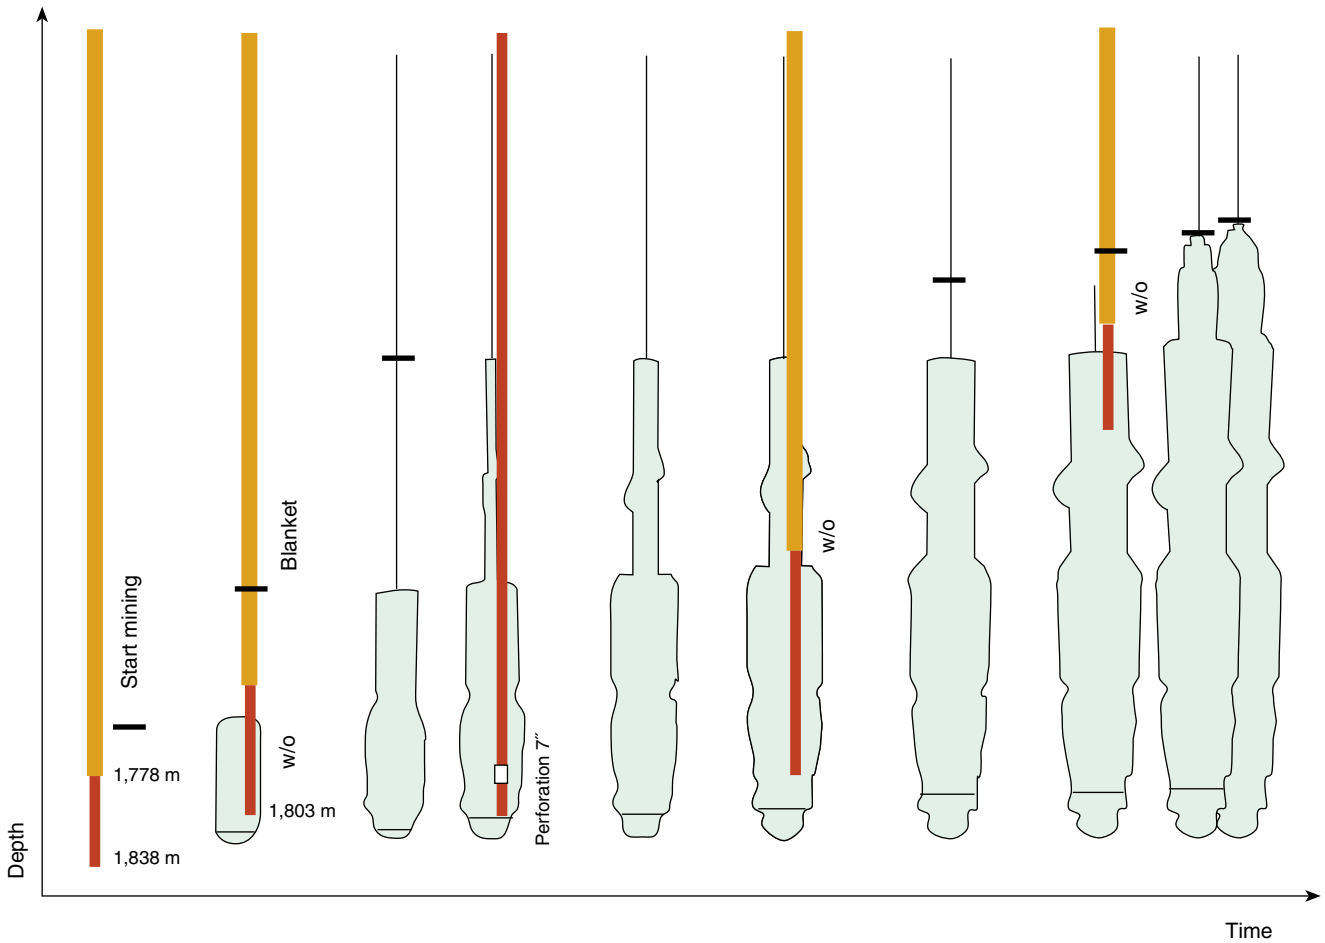

Fig. 13.9 Solution mining for a gas storage cavern using a blanket management plan designed to control breakout across an inclined potash bed that cuts the storage cavern twice along its planned length (as shown in Fig. 13.8a). The scheme uses a combination of blanket management and sequential snubbing. See text for details (After Wilke et al. 2001)

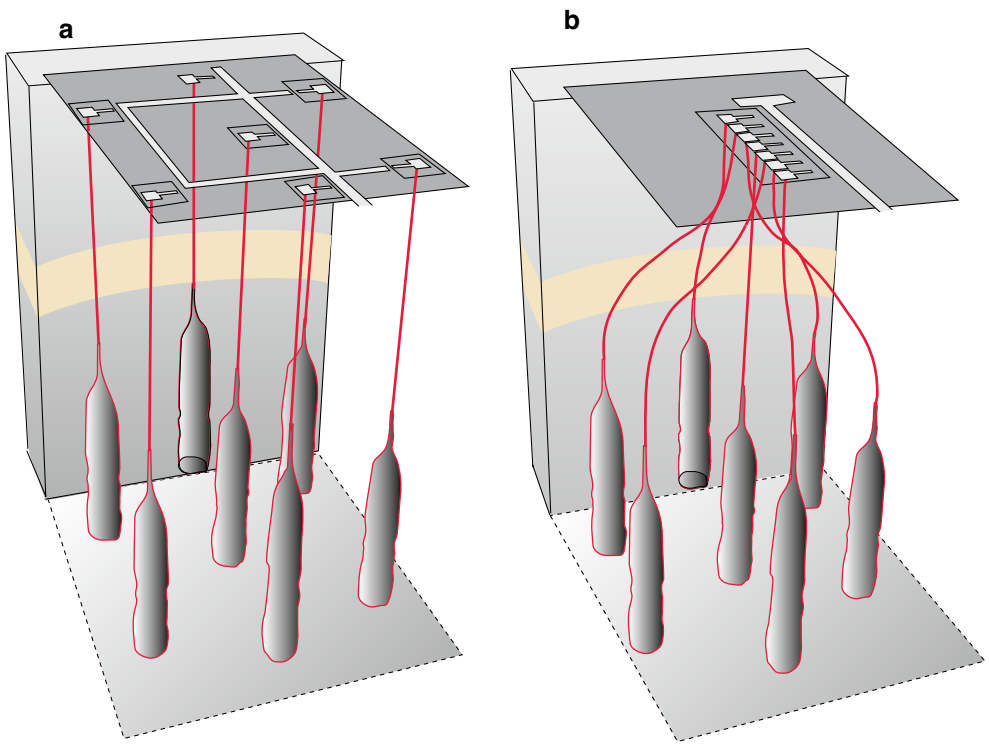

Fig. 13.10 Well pad design. (**a**) Single well pads. (**b**) Cluster pad

Once a cluster well group is completed is difficult to later modify production casings, but this can be an ongoing need in some hydrocarbon storage caverns. Cluster wells, which require an S-shaped drilling path, may not be feasible in regions where the targeted salt is shallow. Cluster pads only work if target salt bodies are more than 600–700 m below the surface. A rough rule of thumb is that directed drilling can give deviations of some 1.5° every 10 m of vertical depth.

Casing couplings should be engineered in the early stages of well completion design and are a critical feature in most cluster pad wells, especially those used for hydrocarbon storage. Once operational, it is virtually impossible to turn the leaching string in a deviated well. To compensate, the outermost leaching casing should be fitted with an integral coupling below the casing shoe of the last cemented casing string. That way, couplings do not stick in the vicinity of the casing shoe. When a cavern is to be used for gas storage the more expensive option of integral couplings should be included in design of the brine withdrawal string. This prevents the sticking of casing in the vicinity of the production-string casing shoe. If a cavity is to be used for gas storage, the brine withdrawal string must be raised under gas pressure as the cavern is first filled with gas.

Deciding on single well pads versus cluster pads influences the design of the casing string and the completion specifications. With a cluster pad the likely depth and homogeneity of the target salt must be known prior to the commencement of drilling. Successful directional drilling of S-shaped wells is best achieved using measurement while drilling (MWD) techniques. MWD techniques are now standard methods in the oil and gas industry and should perhaps be more widely considered for single well pads. MWD allows the operator to better deal with any unexpected deviations encountered during the drilling of vertical or inclined wells.

Blinding and Phase Chemistry

Halite is the targeted salt for most solution-mined brinefields and is one of the simplest chemical systems to cope with in the subsurface. Thick halite deposits, if associated with only carbonate and calcium sulphate impurities, are chemically well behaved during dissolution and their basic brine chemistry was discussed in Chap. 2. But today, there are a growing number of solution mining operations that target salts with more complex dissolution chemistries, such as the borate or sodium carbonate salts, where covering or blinding the cavern surface with a layer of less soluble salts is a strong possibility.

All non-halite salt targets require a predictive understanding of brine phase chemistry. The intricacies of phase chemistry of brines and salts is largely outside the evaporite focus of this book and a detailed consideration of the various precipitation outcomes requires a book in its own right (see Usdowski and Dietzel 1998). To illustrate what is possible we will look at some of the complexities and possible problems using current understanding of simple phase equilibria and dissolution kinetics for trona (After Haynes 1997). Searles Valley Minerals (Nirma) currently solution mines soda ash at Trona, California and until recently American Soda operated a directionally drilled solution mine facility for a nahcolite target bed in Colorado.

Phase Chemistry – Trona Solution Mining

The ternary phase equilibria of the sodium carbonate system Na_2CO_3–$NaHCO_3$–H_2O is temperature dependent (Haynes 1997 see also Fig. 2.20a). When trona is dissolved in pure water it follows the dissolution path A-A' (Fig. 13.11a). If the system is at 40 °C, an undersaturated brine following the trona dissolution path will encounter the 40 °C isotherm at X. Further trona dissolution means the brine is now supersaturated with respect to nahcolite. At some point this mineral begins to drop out of solution, while the brine follows the path X – Y. At Y, solid nahcolite, solid trona and a brine liquor corresponding to point Y (17 % Na_2CO_3 and 5.6 % $NaHCO_3$) are all in equilibrium. A similar precipitation sequence will occur at other temperatures from 25 to 87 °C, showing that sodium carbonate solubility doesn't change much over this range, while the wt% of bicarbonate doubles in the residual brine (Y to Z). Wegscheiderite forms above 87 °C (Fig. 13.11b). The formation of the less soluble nahcolite is the reason many early field tests attempting to solution mine trona typically mention "blinding" of the dissolution surface whereby a coat of nahcolite forms atop the dissolving trona, slowing or preventing further dissolution.

"Blinding" problems can be avoided if temperatures for brine extraction are kept high or if the feed solvent is not pure water but a solution of Na_2CO_3. The effect of high temperature can be seen as a byproduct of shale-oil recovery experiments conducted by Shell Oil in the Piceance Creek Basin. In 1970–72, the Company experimented with warm water and steam injection in an attempt to recover oil from nahcolite-bearing oil shales of the Parachute Creek Member on a 10-acre site in Rio Blanco County, Piceance Basin Colorado. In addition to the expected oil, Ireson (1990) reported that large amounts of sodium carbonate brine were co-produced at higher recovered brine temperatures (Fig. 13.12).

In 1990, solution mining of Boies nahcolite bed began near Rifle, Colorado. Where mined, the Boies bed is about 7.6 m (25 ft) thick and at a depth of 610 m (2,000 ft; Day 1974). Such a thin target bed means solution mining is most efficient if it involves directional drilling. A vertical hole is sunk to a 100 m or so above the target bed, the hole is then turned so it enters the target bed at a slight angle and then is drilled horizontally along the base of the bed. Hot water is then injected into the bed to dissolve the nahcolite and form an expanding cavity. Sodium carbonate brine is recovered

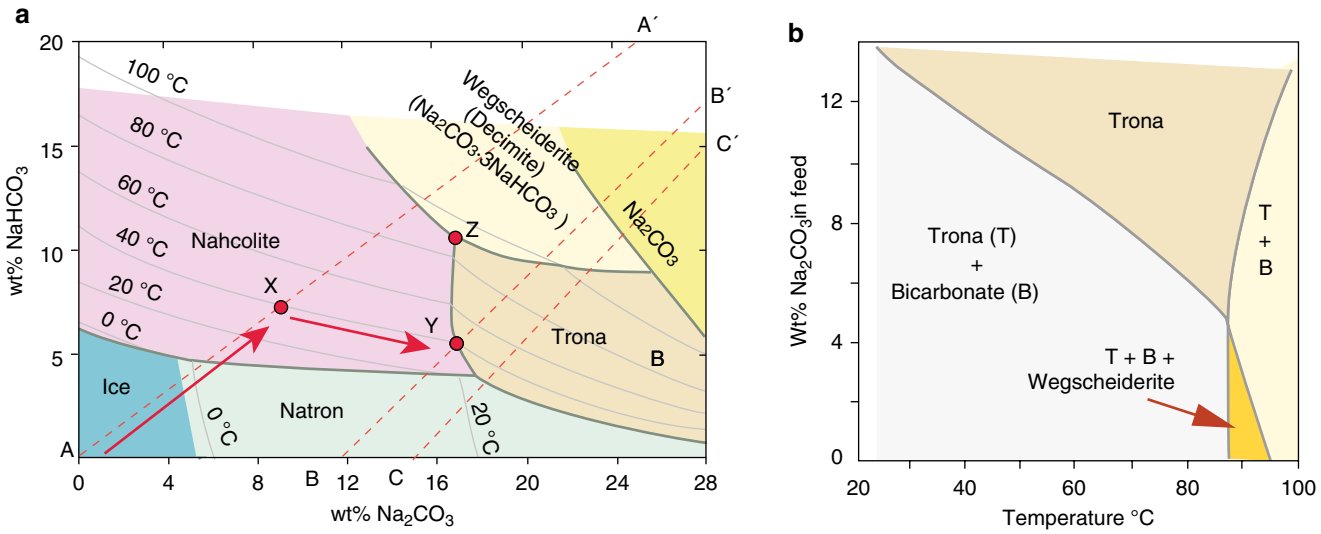

Fig. 13.11 Trona stability (After Haynes 1997). (**a**) Stability of major sodium carbonate minerals in the temperature range 0–100 °C. (**b**) Stability fields of various precipitates, trona is in excess in all phases

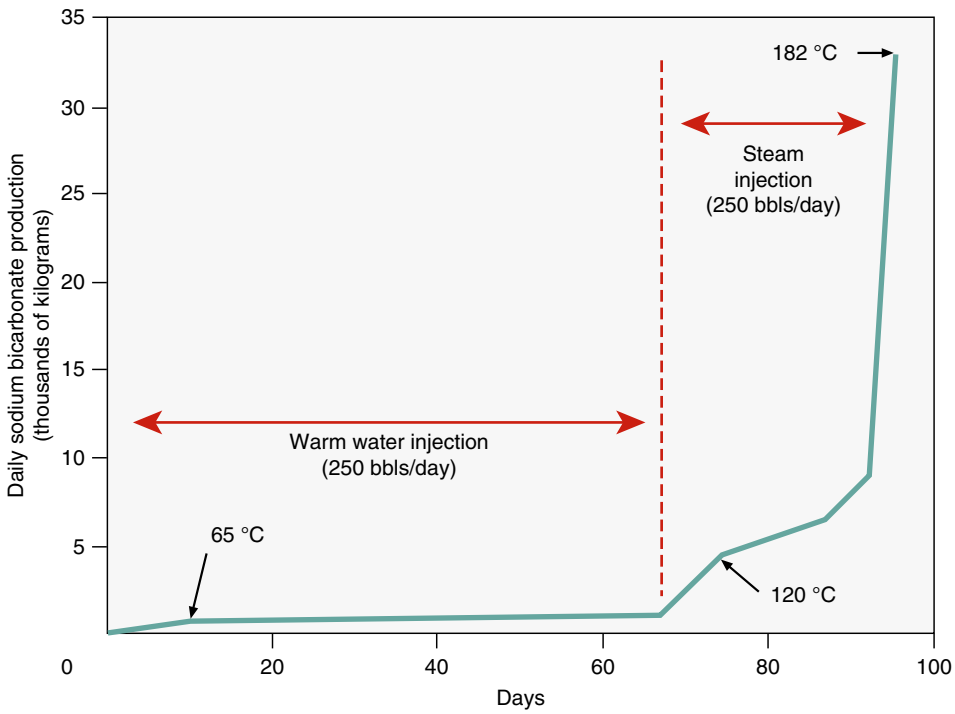

Fig. 13.12 Daily production of sodium bicarbonate from Shell's shale-oil recovery experiment in the Piceance Creek Basin, Colorado (From Ireson 1990)

from another vertical hole drilled into the cavity some hundreds of feet from the injection hole.

Until 2004, American Soda PPL solution mined nahcolite using this hot extraction method on a lease near Parachute, Colorado and adjacent to White River Nahcolite's property. First, pressurized hot water was injected into bedded nahcolite at depths of some 450–600 m subsurface. Nahcolite was returned to the surface as a highly saturated $NaHCO_3$ solution. In the first quarter of 2002, the company drilled 26 wells but anticipated that as the solution cavities expanded, production would be maintained using half that number. Idle wells were to be held in reserve to ensure an uninterrupted source of feed brine. At the brinefield plant, CO_2 was stripped from the well liquor ahead of pipeline transport. This created a brine solution more suitable for pipeline transport and also gave a relatively low-cost source of CO_2. Brine was pumped 70 km (44 miles) from the brinefield to the Parachute Creek processing plant using an insulated, pressurized, closed-loop pipeline. At the plant, the incoming brine passed through crystallisers, was dried and packaged for shipping. Recycled

hot water from the processing plant was then piped back to the minesite to leach more nahcolite. The 1,000-acre upper site was the prior location of Unocal's shale oil upgrading plant and much of the former infrastructure was used by American Soda. Unfortunately, the operation was deemed uneconomic and was shut down in late 2004.

Solution mining nahcolite in the Piceance Creek Basin suffers some unusual problems that can be expensive to control (Dyni 1996). Problems include: (1) Cavern shapes in the Boise must be tightly controlled and regularly monitored as the Boise bed is very close to a natural dissolution surface in the immediate overburden, a breakthrough into this overlying water-bearing leached zone would be detrimental to controlled solution mining in the target bed; (2) The Boise bed actually consists of two nahcolite beds, the lower one is thinner and also contains halite, so exact bed targeting is very important both during directional drilling and in cavity expansion during production; (3) The Boies bed grades laterally into mixed halite and nahcolite toward the basin's chemical depocentre, accidentally dissolving halite in this region would contaminate brine product with high levels of sodium chloride; (4) Oil shale which overlies the Boise Bed cannot be mined or damaged under current sodium leasing regulations. Given the major part of the known nahcolite resource today occurs as crystalline aggregates scattered through oil shale, it difficult to target mine for soda ash alone. Current legislation makes the solution mining of soda ash difficult, if not impossible, over much of the extent of the Boise Bed as it could render parts of the overlying oil shale unsuitable for future in situ leaching or underground mining. Under current legislation, any oil shale that is damaged by solution mining must be stockpiled for future oil recovery.

A possible future method to solution mine trona, not nahcolite, could use an initial feed solvent that contains Na_2CO_3 in solution (Haynes 1997). For example, a 15 wt% Na_2CO_3 solution proceeds along the line C-C' in Fig. 13.11a. This intersects the 40 °C isotherm well into the trona stability field and no sodium bicarbonate (nahcolite) will form. The line B-B' separates fields at 40 °C where nahcolite and trona are likely precipitates and corresponds to a value of 11.9 wt% Na_2CO_3 on the abscissa. This is the minimum feed solvent composition that will insure that no nahcolite is precipitated during the dissolution process. Critical "excess carbonate lines" were similarly determined by Haynes (1997) at other temperatures and are plotted as the solid phase existence fields of Fig. 13.11b. Trona is present in all stability fields as it is the excess phase.

Another way to avoid nahcolite blinding in a trona target bed is to maintain a caustic solution for the feed (Haynes 1997). The phase relationships in Fig. 13.11 are well known to the trona industry but their utility is greatly lessened in situations where impurities are present in the dissolving trona or in situations where other reagents need to be introduced to the solvent feed (see Haynes 1997 for details). Clearly, an understanding of the phase equilibria and temperature susceptibility of any targeted salt system is fundamental to any successful solution mining operation.

Use of Salt Caverns

Subsurface salt is an appropriate medium for enclosing and storing of a range of materials from artwork, to hydrocarbons, to industrial and nuclear waste to CO_2. Former salt mines offer a constant temperature and low humidity in which waste, munitions, paper and computer records, and works of art may be stored. For example, Winsford Mine in Cheshire, with around 26 million m^3 of space, is used for the secure, long-term and 'active' storage of a wide range of documents and sensitive or fragile materials (Evans et al. 2009). Part of Winsford Mine is also used for the disposal (and is therefore regulated as a landfill site) of up to 100,000 tonnes of selected hazardous wastes such as contaminated soils and residues from the nonferrous metals and chemicals industries.

Less and less the rationale to create a solution mined salt cavern is the production of brine or a particular chemical feedstock. In the past few decades, the number of purpose-built storage caverns, shaped using solution mining techniques, has expanded rapidly and an industry centred on the construction of salt caverns for hydrocarbon and waster storage has evolved and continues to expand (Thoms and Gehle 2000a, b). Today's commercial brine producers are also aware of potential storage opportunities, they still use controlled solution mining techniques to produce their required brine feed, but at the same time their ultimate goal is to produce a tight cavern suitable for future hydrocarbon or long-term waste storage (Table 13.2).

Energy Liquids & Compressed Air Storage

Crude oil or unrefined petroleum and light hydrocarbons can be safely stored below ground in liquid form in brine-compensated salt caverns (Table 13.3; Veil et al. 1996; Grappe 2000; Thoms and Gehle 2000a). Light hydrocarbons currently stored in salt caverns include propane, butane, ethane, ethylene, and other products extracted by refineries that can be transported and stored as liquids. In recent years natural gas[1] has been stored in salt caverns in increasing volumes, this entails much higher storage pressures and a greater need

[1]Natural gas is a naturally occurring mixture of hydrocarbon gases, principally methane with lesser quantities of ethane, propane, butane, and other gases.

Table 13.2 Use of salt caverns as storage facilities

Cavern Usage	Product stored	Distribution and specifications	Operational mechanism
Hydrocarbons	Liquid hydrocarbons-Crude oil, distillate, naptha, etc.	More than 16 storage sites encompassing more than 190 caverns. Largest volume stored in USA (SPR), storage also in France, Mexico and Germany.	Due to reduced compressibility but relatively low density of product and immiscibility with water, caverns are operated by a brine compensation mechanism. This requires above ground facility (ponds) for storing excess brine when the caverns are filled with hydrocarbons. Brine compensation enlarges the cavern during each recovery cycle, hence cavern shape must be continually monitored throughout life of facility. Less pressure variation occurs in caverns used for liquid storage compared to gas, so caverns can be much larger for liquid storage (more than 1 million m^3) in a single cavern. Salt creep is less critical for liquid storage compared to gas.
	Liquefied hydrocarbons-LPG, ethylene, ethane	Around 110 storage sites with over 190 caverns. Major sites in Sarnia (Canada) and Mount Belvieu (USA). Sites also in Morocco, France and Germany.	
Compressed air storage	Energy generation via electrical demand-peak shaving	Two plants currently in operation worldwide- Huntorf Germany and Alabama Electric Cooperative, USA.	Air is compressed and stored in a salt cavern using cheap electricity. Then stored air is expanded through a gas turbine to produce high value, peak electricity. Caverns cycle daily.
Waste storage	Industrial waste	Limited number of facilities in operation in USA and Europe, most caverns used to store oil-field wastes or industrial chemicals.	Waste is stored as a "final repository" hence cavern must be emptied prior to filling with pelleted waste (avoids groundwater contamination), or an inert blanket of suitable density must be used to separate waste (pasty consistency) from the brine. Waste is also stored as both "inerted" bulk material and in containers in old salt mines in Germany.
	Nuclear waste	Operational site at WIPP, New Mexico, USA. Waste is isolated by plugs made from a crushed mix of salt and compacted clay.	Purpose built facility using conventional mining in a salt bed rather than a solution-leached cavern in a salt dome as there is a legislated requirement for reversibility of nuclear storage and site stability for at least 10,000 years.

After Grappe (2000)

Table 13.3 Hydrocarbon storage (1,000 m^3) in salt caverns, xxxx indicates storage but volumetric data is not available

After Thoms and Gehle (2000a)

for pressure integrity in the access well(s) and couplings compared to liquids storage. Natural gas is a clean burning energy source and has become a prime source of energy worldwide, especially in gas-fired power plants, which now constitute some 25 % of gas usage in the United States (Thoms and Gehle 2000a). Earlier last century natural gas was flared as a oilfield byproduct. By the 1970s it was thought to be in short supply, but it is now known to exist in adequate volumes for the foreseeable future.

As early as 1916 there was a German patent taken out to cover the solution mining of salt caverns for the storage of crude oil and distillates. The earliest oil storage in caverns was in bedded salt in Canada early in World War II. A few years later, by 1949, liquefied petroleum gas (LPG) was stored in caverns in bedded Permian salts near Kermit, Texas. Crude oil was stored in salt caverns in England during the "Suez Crisis" in the 1950s. In 1975, the US Congress created the Strategic Petroleum Reserve (SPR) program to provide sufficient petroleum reserves to reduce the impact of interruptions to future oil supplies. The SPR today consists of more than 60 caverns in domal salt bodies across the United States, with a total capacity of 680 million barrels (108×10^6 m^3).

The first storage of natural gas in a salt cavern was at Unity Saskatchewan in 1959, followed soon after in 1961 in Marysville, Michigan USA. Gas storage caverns were first purpose engineered in 1963 in Saskatchewan, Canada, in bedded Devonian salt at depths of 1,100 m. This was followed in 1964 by the first purpose-engineered gas cavern in a salt dome at Eminence, Mississippi, at a depth of 1,740–2,040 m (Fig. 13.1). European gas storage in salt domes began in Tersanne, France in 1970 at depths of 1,400–1,500 m and near Kiel, Germany in 1971 at depths of more than 1,300 m.

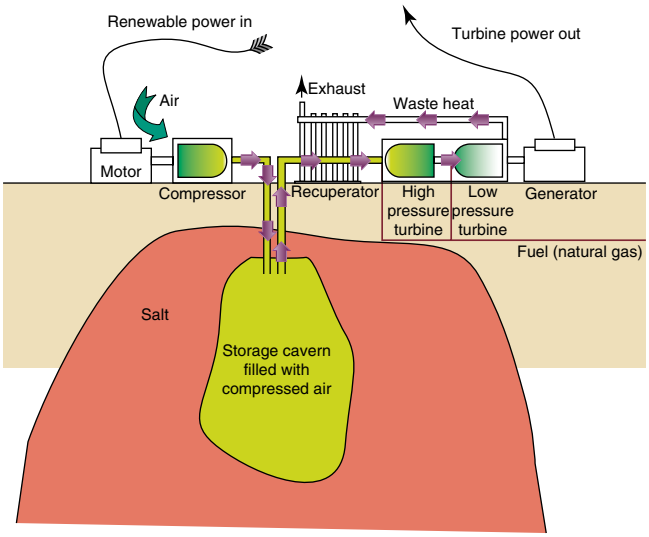

Fig. 13.13 Schematic of processes in a compressed air energy storage facility

Compressed air energy storage (CAES)[2] for peak electricity generation began in 1978 in as purpose built salt cavern Huntorf dome near Hamburg, while in 1991 a second CAES plant was commissioned in the McIntosh salt dome, near Mobile, Alabama (Fig. 13.13). Huntorf was designed for peaking and black-start[3] applications, it was initially designed with a storage volume capable of 2 h of rated output. The plant has since been modified to provide up to 3 h of storage and has been used increasingly to help balance the rapidly growing wind output from North Germany. The 110 MW Macintosh plant was built by the Alabama Electric Cooperative on the McIntosh salt dome in southwestern Alabama It was designed for 26 h of generation at full power and uses a single salt cavern (560,000 m^3) designed to operate between 45 and 74 bar. Although the McIntosh plant experienced significant outages in its early operation, the causes were addressed through modifications of the high pressure combustor mounting and a redesign of the low pressure combustor. These changes enabled the McIntosh plant, over 10 years of operation, to achieve 91.2 and 92.1 % average starting reliabilities with 96.8 and 99.5 % average running reliabilities for the generation and compression cycles, respectively.

[2]Compressed air energy storage (CAES) is a way to store massive amounts of renewable power by compressing air at very high pressures and storing it in large underground caverns (or depleted fields or aquifers). Compression and underground storage takes place at times of excess energy generation (aka peaking). The compressed air is later released and run through turbines to generate power when wind turbines and solar plant outputs are reduced and power is needed.

[3]Black start is the ability of a plant to start up during a complete grid outage. Because nuclear power stations require some power to resume operation, the Huntorf plant was built in part to provide black-start power.

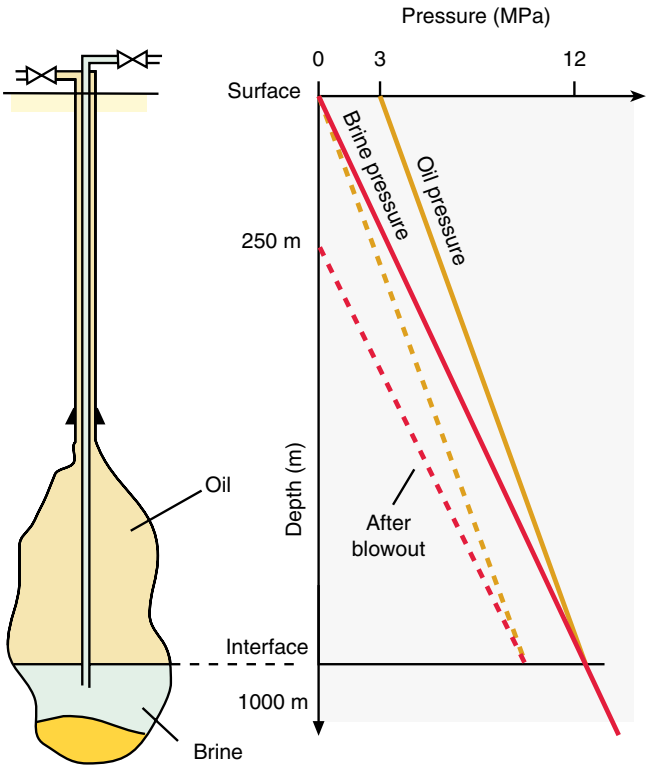

Fig. 13.14 Typical pressure regime in a salt cavern used for oil storage. Situation after a blowout is graphed as dashed lines (After Bérest and Brouard 2002)

Hydrocarbons in a salt cavern are stored in what is in effect a pressure vessel, where high pressure fluids are contained within a stiff impervious envelope using a system of pipes and valves that allow fluids to be placed, sealed and periodically withdrawn from the cavity. Salt caverns differ from standard surface storage tanks in the following way (Bérest and Brouard 2003):

1. The "container" consists of the access well and the cavern proper. Typically, the height (depth) of such a system is ≈ 1 km. The access well(s) is equipped with several casing strings or tubes, one inside the other, containing fluids (brine and hydrocarbons) at different densities. Even small differences in fluid densities result in very different column weights within the concentric annuli that make up the well. At the same depth, the gap between fluid pressures in adjacent annuli can be several MPa (Fig. 13.14). If the concentric fluids accidentally come into direct contact it creates unstable situations where accidents, such as blowouts and spills, are more likely.
2. The volume of a storage cavern is very large (up to 1,000,000 m^3). Even a small pressure drop in the cavern results in a significant change in the volume of the stored product. Liquid compressibility, a typically negligible consideration in most above-ground storage tanks, plays a significant role in the safe operation of large underground caverns.

Interactions between these two factors explain most industrial accidents involving hydrocarbons in salt caverns (see case histories).

Storage facilities for liquids (oil, naphtha, kerosene, gasoline) and liquefied hydrocarbons (LPG, ethylene, propylene) are operated by the "brine compensation" method. As brine is injected through a central tube at the bottom of the cavern, an equivalent volume of product is withdrawn through the annular space between the steel cemented casing and the central brine tube. When the cavern is idle, the brine is at atmospheric pressure at ground level. In the brine tube, however, the pressure is in proportion to the depth and specific density of brine, which is around 1,200 $kg \cdot m^{-3}$ (Fig. 13.14). If the interface between the oil and brine is 1,000 m below ground level, the pressure in the brine column at this point is approximately 12 MPa. Brine pressure and product pressure are equal at the interface in the cavern between brine and product. Above this point, the pressure in the product-filled annular space reduces gradually, and more slowly than in brine because the density of the stored product is lower (of the order of 900 $kg \cdot m^{-3}$ for oil, and 500 $kg \cdot m^{-3}$ for LPG).

Thus at any given depth, the pressure in the annular space containing the product is higher than the pressure in the central brine-filled tube. The difference is greatest at ground level, where in a 1 km deep example it is 3 MPa (for oil storage) or 7 MPa (for LPG storage). At the wellhead, the stored product applies pressure to the valve controlling the annular space. If this valve fails, the product is ejected suddenly, and the brine level in the central string drops until a new pressure balance is reached (see West Hackberry blowout in case histories).

For a valve failure in an oil-storage cavern, with an oil density of 900 $kg \cdot m^{-3}$ and with the initial brine oil storage interface at a depth of 1,000 m, the top level of the brine in the central tubing will come to rest at a depth of 250 m below the surface (Fig. 13.14; Bérest and Brouard 2003; Bérest et al. 1999). The weights of the brine column and the oil column will then be equal at the interface depth in the cavern. If both fluids were incompressible, the volume of expelled oil following valve failure would be small because the central tube capacity in the access well is only a few tens of litres per metre length of casing. In reality, due to differences in liquid compressibility in oil and brine in the cavern itself, much more oil is expelled. The compressibility factor of brine is $Bb = 2.7 \times 10^{-4}$ MPa^{-1}; the compressibility factor of the cavern is $Bc = 1.3 \times 10^{-4}$ MPa^{-1} (this figure can vary, depending on the elastic properties of rock salt and the cavern shape; see Bérest et al. 1999.); and the compressibility factor of the oil is $\approx Bo = 6 \times 10^{-4}$ MPa^{-1}. If y is the ratio between the stored-oil volume and the cavern volume, the global compressibility is;

$$B = B_c + yB_o + (1-y)B_b.$$

Following the wellhead valve failure, the pressure of the entire body of stored fluids (oil and brine) will be reduced by $\Delta P = 3$ MPa (in a 1 km deep example). If the cavity contains $V = 500{,}000$ m^3 of oil and very little brine ($y \approx 1$), then, because of the compressibility, the amount ejected will be;

$$B \cdot V \cdot \Delta P = \left(6 \times 10^{-4}\ MPa^{-1} \times 500{,}000\ m^3\right) \times 3\ MPa = 900\ m^3.$$

For liquefied product, a limited amount of LPG would first be expelled in liquid form. (However, this amount will be larger than in the case of oil, as the compressibility factor of LPG is larger, $Bp = 3 \times 10^{-3}$ MPa^{-1}). This liquid would evaporate gradually after running over the ground, and a heavier-than-air gas cloud would form. Accidental ignition of such a gas cloud is likely (see Brenham explosion in case histories).

Brine pumped into a cavern to compensate for displaced product must be less than totally saturated with respect to the encasing salt. This prevents any salt crystallising in the access casing, but it also leaches salt from the cavern wall. Regular product cycling using brine compensation increases the size of a salt cavern. Caverns used by oil storage companies in North America typically increase in size by about 1–2 % a year. Some of the older caverns in the USA and Canada are now twice as large as when they were first filled (Figs. 13.14 and 13.15).

Unfettered enlargement of a storage cavern can evolve into a stability problem as the retreating salt roof and walls are increasingly susceptible to sloughing, caving, fusion and associated damage to the long casing string. Cavern expansion has led to industrial accidents at some storage facilities and during the 1980s emphasized the need for better legislative definitions of safe storage and cavern life in the USA (see Mineola fire in case histories). The worst case expansion scenario is total roof failure and the formation of a sinkhole connecting the surface to the underlying storage cavern. This is highly unlikely in modern, well-maintained and monitored storage facilities around the developed world. The recognition of such a possibility required the complete drainage of the former SPR facility on Weeks Island, Louisiana (see case histories).

Natural gas storage caverns operate under much higher pressures than those storing liquid hydrocarbons. Internal pressure not brine compensation cycles the stored product. Purpose designed salt caverns are ideal for the storage of natural gas, especially when excavated in salt domes. They are stable and will not disintegrate in an explosion. They are safe and out of sight and so can be located near demand centres. They act as huge pressurised cavities with low gas

cushion[4] requirements of around 33 % of the total storage volume (Table 13.4). Unlike other gas storage facilities above and below ground, a salt cavern also offers very high deliverability and rapid product cycling. Caverns deal readily with peak demand, gas shaving and any rapid demand fluctuations. Operators can change from injection to withdrawal in 15 min and back to injection in 30 min. The main disadvantage to natural gas storage in a solution cavern is the relatively high cost of construction compared to other forms of underground storage using depleted oil and gas fields or suitable aquifers (Barnes and Levine 2011). But purpose-built salt cavity facilities are consistently safer and cleaner than all other types of underground and above-ground storage. The relative proportion of gas that is stored in salt caverns in the United States is increasing over volumes stored in aquifers and depleted fields (Fig. 13.16).

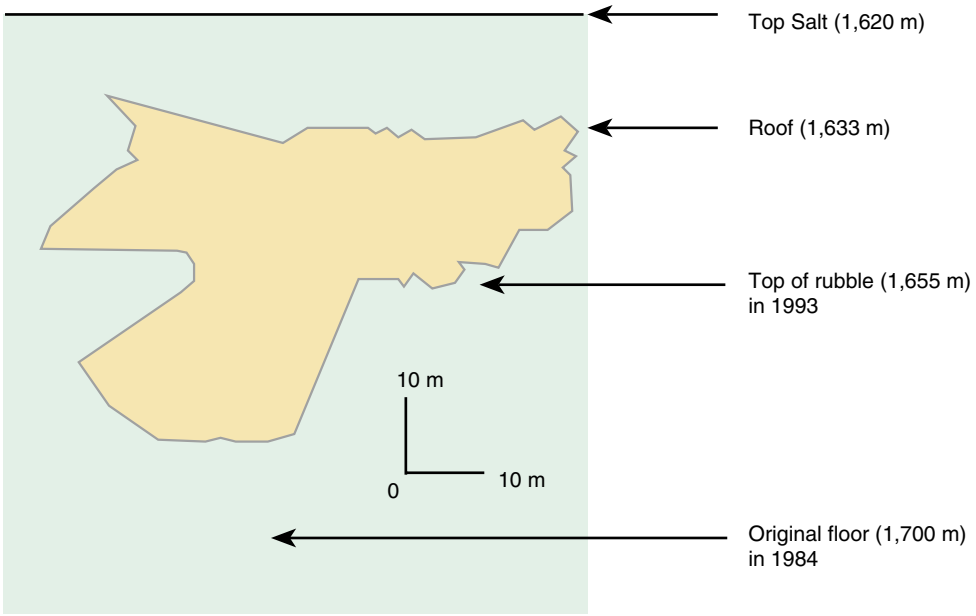

Fig. 13.15 Outline (cross section) as of 1993 of Cavern 5, Regina South, leached into the bedded salt of the Devonian Winnipegosis Salt, Canada. It is one of a number used for brine-compensated gas storage. Changes in floor level show how its shape has changed since 1984 (After Crossley 1998)

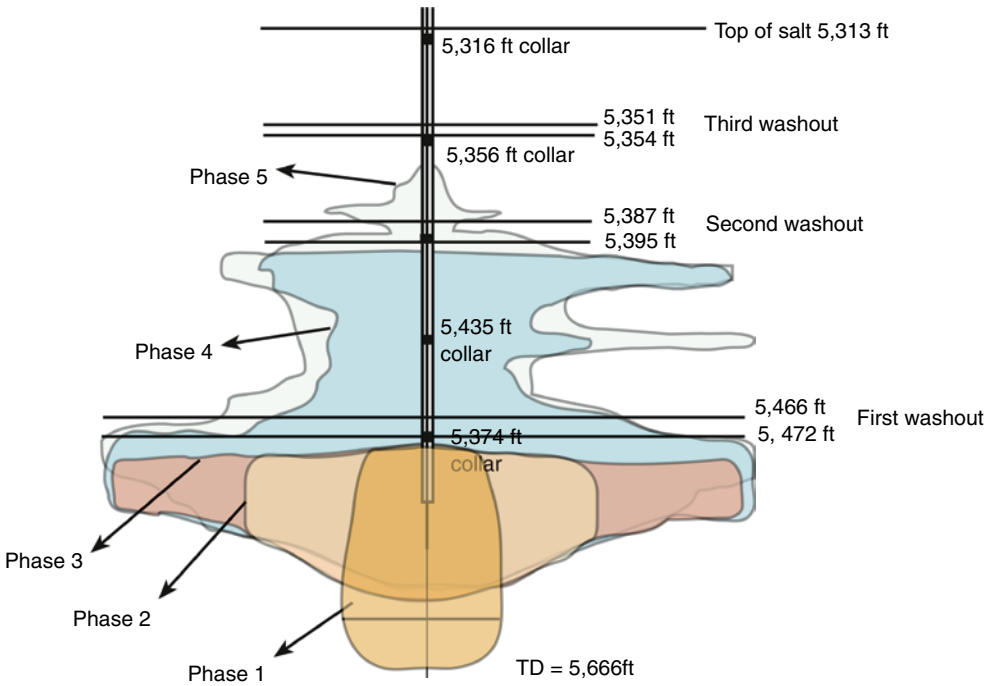
[4]Cushion gas is the volume of gas needed to fill a subsurface storage facility to where the gas pressure is sufficient to supply a significant flow of gas to the surface.



Outline (cross section) of Cavern 5, Regina South cavern field, leached into the bedded salt of the Devonian Winnipegosis Salt, Canada. Shows changes in cavern shape over time (Phase 1–5) due to ongoing brine compensation (After Crossley 1998)

Table 13.4 Cushion and cycle time requirements for underground gas storage operations

Type	Cushion to working gas ratio	Injection period (days)	Withdrawal period (days)
Aquifer	Cushion is 50–80 %	200–250	100–150
Depleted oil/gas reservoir	Cushion 50 %	200–250	100–150
Salt cavern	Cushion 20–30 %	20–40	10–20

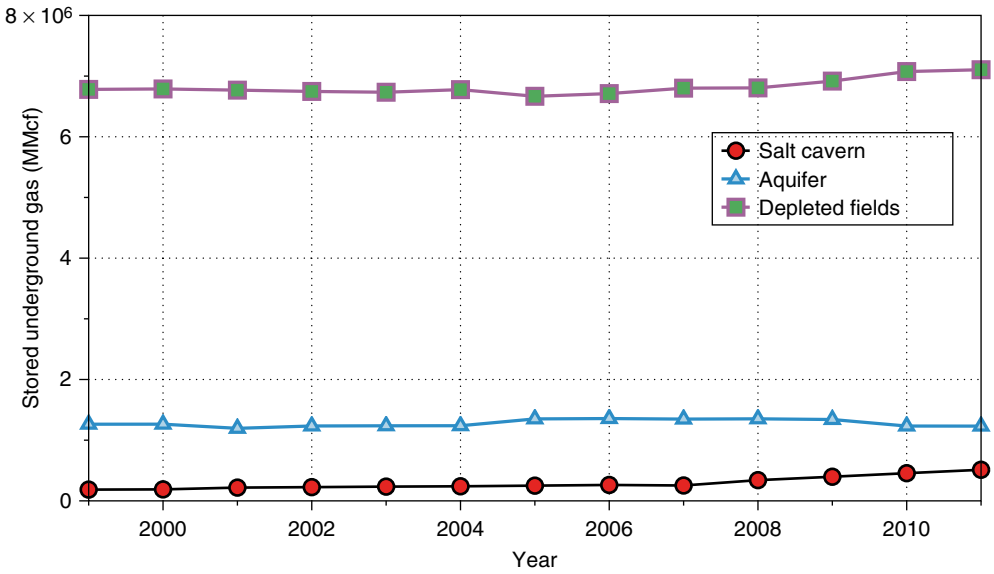


Fig. 13.16 History of the volume of natural gas stored underground in the USA and contributions of different modes of storage (Replotted from data downloaded from the US Energy Information Administration website <http://www.eia.gov>. Last accessed September 15, 2013)

As an example of cost, consider the purpose built "Big Hill" storage facility in Texas; completed in 1992, it is a 14.3 million cubic metre, solution-mined cavity operated under the U.S. Petroleum Reserve. The leaching cost (in 1992 dollars) was ≈$1.80 per cubic metre of salt excavated, and the total cost of the project (including land acquisition, design, site development, pipeline development, drilling, hydrocarbon interfaces, etc.) was $21.80 per cubic metre. Part of the higher cost for salt caverns reflects the need for controlled circulation and safe disposal of large volumes of cycled water required during the construction stage. But construction and maintenance costs are low compared with above ground storage facilities, which also suffer from much lower cycling rates, storage volumes, a higher likelihood of catastrophic damage during an accident and a need for higher gas cushions.

Hence, once in operation, a gas storage cavern has several advantages over depleted oil/gas field or aquifer storages. Purpose engineered salt caverns are integral structures that allow very little of the injected natural gas to escape from storage unless specifically extracted. If well designed with an adequate salt buffer between cavities, the walls of the salt cavern are strong and impervious to gas over the lifespan of the storage facility.

However, salt caverns are usually much smaller than depleted gas reservoir and aquifer storage facilities. A salt cavern facility may occupy only 1 % of the area taken up by a depleted gas reservoir facility. Consequently, salt caverns cannot hold the large volumes of gas necessary to meet base load storage requirements. Deliverability from salt caverns is, however, much higher than for either aquifers or depleted reservoirs, making them more cost effective. This high deliverability allows the gas stored in a salt cavern to be withdrawn and replenished more readily and quickly. This quick cycle-time is useful in emergency situations or during short periods of unexpected demand surges.

Life expectancy of a storage cavern may be as little as 40 years for existing caverns made with older solution leach technologies, or a century or more in purpose-engineered facilities constructed with current technologies. Deep caverns in thicker relatively homogenous salt bodies (as typifies many salt domes) are the safest hydrocarbon storage facilities currently known for natural gas and liquids.

Waste Disposal

Salt caverns can be used for the safe disposal of various types of hazardous waste (Table 13.2; Grappe 2000; Dusseault and Davidson 1999). Until recently, the major users of solution caverns as waste repositories were within the same salt-based and hydrocarbon-based industries that generated the cavities.

Nonradioactive Waste Disposal

Since 1959, alkali wastes from local "soda ash" production has been pumped back into "worked out" solution caverns of the Holford brinefield, located some 30 km south of Manchester, England. The Holford brinefield operator is authorised to dispose of 200 t per day of brine mud solids from the purification of crude brine, and 250 t per day of alkali wastes from local soda ash production. In addition, the operator is authorised to dispose of organic residues from the production of perchloroethylene, trichloroethylene, and other related chlorohydrocarbons into specially designated caverns that contain alkaline material designed to neutralise any free acid in the wastes. Brine displaced from the caverns by the emplacement of solids is used to slurry additional solids back to the caverns. The US salt mining industry also disposes of impurities generated during above-ground brine purification processes into salt caverns. Wassmann (1983) reported that the Dutch pumped wastes from a brine purification plant in to a nearby salt cavern. Concentrated magnesium chloride brine has also been stored in caverns in the Nederlands. In Mexico, sulphate purged from salt evaporators is being disposed of in salt caverns.

In addition to brine wastes, salt caverns are now also used to dispose of oilfield wastes. The state of Texas recently legislated that six salt caverns can be used for the disposal of nonhazardous oilfield waste and one cavern for the disposal of naturally occurring radioactive waste. The states of Louisiana and New Mexico are developing similar legislation. Canada has recently authorised disposal of oil field wastes into several caverns near Edmonton and Unity, Saskatchewan. Oil field products slated for disposal in salt caverns include; used drilling fluids, drill cuttings, completion and stimulation waste, produced sand, tank bottoms, and soil contaminated by crude oil or produced water.

Disposal caverns used in hydrocarbon waste disposal act like large oil/water/solids separators. The solids in the incoming waste settle to the bottom of the cavern while the lighter oils and hydrocarbons rise to the top of the cavern, where they can be removed. Incoming waste displaces clean brine, which is either sold as a product or disposed of. Cavern pressure integrity in a cavern to be put to such a use should be defined, tested and access controlled before the cavern is filled with oil field waste. It should be regularly monitored throughout the waste emplacement cycle, and optimally, for some period of time after waste emplacement has ended and before the cavern is finally sealed.

The main concern in any waste liquid storage is what will be the longterm response of the cavern once it is filled. Will it maintain its integrity for hundreds or even thousands of years? In a detailed study of rock property responses based on more than a decade of detailed rock mechanics studies in the laboratory, in the field and in abandoned salt cavities, Bérest and Brouard (2001) concluded that storing hazardous waste in salt caverns is an appealing solution when the toxicity of the waste vanishes after a few decades or centuries.

A suitable selection of cavern fluid pressure in the storage cavity will prevent too fast a convergence rate and allow a small amount of rock-mass fluid flow to be directed toward the cavern, preventing any fluid seepage from the cavern. Bérest and Brouard (2001) recommend that such storage facilities be shallower than 1,000 m to minimise the effects of creep and published cavern convergence curves for both a brine and a fuel-oil support medium (Fig. 13.17). As is to be expected, cavern convergence or creep rates are much higher when less dense fuel oil rather than brine is the support medium in the cavern.

Radioactive Waste

Radioactive waste disposal in salt caverns is much more problematic as toxicity can remain for millennia and stability must be maintained across such timeframes. Such timelengths include the possible to and fro of icesheets over much of North America and Europe. A key question to be resolved is whether medium and high level waste should be stored above or below the watertable.

Mainland Europe has adopted rigorous technical regulations for hazardous waste management. Germany, for example, requires that all waste, which cannot be stored for extended periods above ground without posing a serious threat to the biosphere, even after undergoing treatment, should be stored underground in suitable geologic formations. In the early 1960s the German Federal Government (former West Germany) decided that radioactive waste is to be stored exclusively in deep geological formations of the continental crust. Whereas the German nuclear industry was to be responsible for waste processing, intermediate disposal and conditioning, the German Government was to be responsible for final disposal. To this end the German Government contracted DBE, a company especially founded for this purpose in 1979, to plan, construct and operate the final radioactive waste repositories of the German Government. Until unification, DBE activities centred on the Gorleben and Asse salt domes and on the Konrad iron ore mine. Up to 1979, the Asse facility was also used as an experimental final repository for low-level wastes. In the following two decades the focus of experimental studies shifted to the purpose-designed Gorleben facility in the Gorleben salt dome.

Since March 1999, the WIPP site in New Mexico, USA, has been receiving radioactive waste for storage. This is a purpose-built salt cavern constructed by conventional mining techniques in bedded salt, not by solution mining. Like an unpressurized solution cavern, it is subject to the same creep, closure, temperature and pressure considerations and its depth of some 500 m below the surface places it in a depth range where karst penetration and lateral discontinuities including upward stoping chimneys are possible, if highly

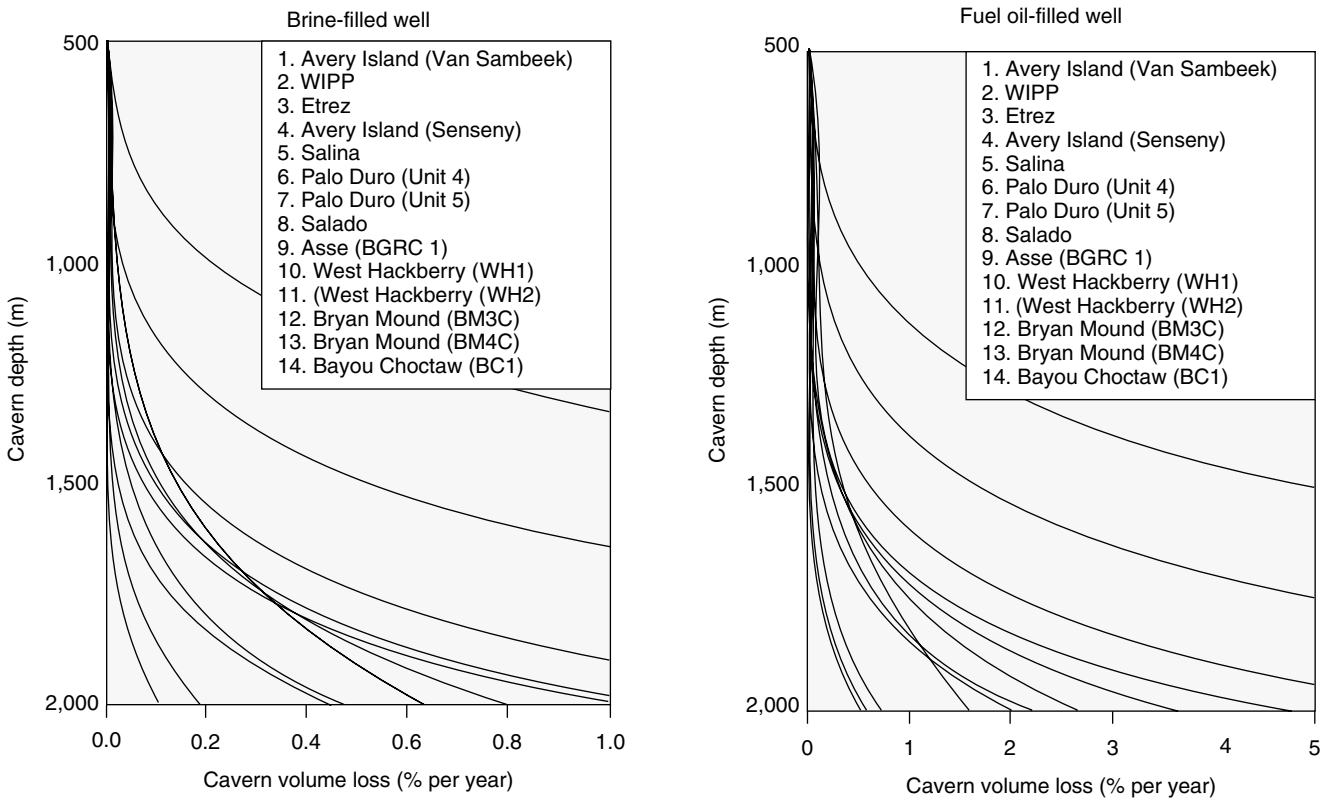

Fig. 13.17 Calculated annual convergence of a sealed salt cavern filled with brine or fuel oil and expressed as percent volume loss (Bérest and Brouard 2001)

unlikely, in the next few hundred millennia. At this stage no salt solution cavern is used for nuclear waste storage in the USA, because of a legislated requirement for reversibility (Grappe 2000). Unfortunately in some ways, much of the research effort by the DOE in the USA has focused on the relatively shallow WIPP site in a region of chimneying and deep subsalt artesian circulation and not on the development of deep purpose-built storage caverns in diapiric salt. Then again, no-one wants a radiogenic waste storage facility in their backyard across the much more highly populated Gulf of Mexico rim where salt structures subcrop.

In the context of the ability of diapiric salt caverns to safely store nuclear waste in a cavern space with adequate confinement and salt cover it's worthwhile looking at the response of salt caverns to nuclear detonations (Thoms and Gehle 2000a). Two 5-kt devices were detonated in salt as events within the "Ploughshare" and "Project Dribble" test programs. The event "Gnome" of Ploughshare took place in 1961 in bedded salt near Carlsbad, New Mexico, and the event "Salmon" of Project Dribble occurred in 1964 in the Tatum Dome near Hattiesburg, Mississippi. Three additional events involving explosions of natural gas were performed in the cavity in the Tatum salt stock first created by the Salmon event. The salt stock completely contained all the blasts and the original cavern was only enlarged by 17 m (55 ft) by the original nuclear explosion. To date no leakage of radioactivity has been reported atop the Tatum dome. It seems salt domes maintain seal integrity even when subject to the rigours of nuclear explosions within the cavern!

The suitability of purpose-built caverns deep in salt domes for the disposal of hazardous chemical and even low level nuclear wastes has been recognised by governments and companies worldwide, but applications to construct such waste disposal facilities have also raised such strong public objections that few permissions have been given anywhere in the developed world. As that famous German, Chancellor Bismarck, once said, "When a man says he approves of something in principle, it means he hasn't the slightest intention of putting it into practice."

Problems in Salt Solution Mines, Conventional Mines, Well-Bores and Storage Facilities

Dissolution and collapse of nearsurface and at-surface salt is a natural and ongoing process. When such salt bodies are penetrated by drilling or parts of the salt mass are extracted in a poorly supervised fashion, the resulting disturbance can speed up natural solution and collapse, sometimes with

Fig. 13.18 Locations of some of the anthropologically-facilitated problem areas in the circum-Atlantic that are discussed in the following pages. This map does not show that these areas are more subject to problems than other areas in the world that are underlain by shallow salt. Only that in these areas the political systems are such that it allows public documentation and discussion of the potential problems. All these areas are also in regions where natural salt collapse is ongoing

unexpected environmental consequences (Fig. 13.18; Table 13.5). In this context, and as a justification for the following section, it is of interest to quote part of the introduction in a paper by Zuber et al. (2000) dealing with flooding and collapse events in Polish salt mines.

"Catastrophic inflows to salt mines, though quite frequent, are seldom described in literature and consequently students of mining and mine managers remain, to a high degree, ignorant in this respect. Contrary to common opinion, inflows are seldom caused by unavoidable forces of nature. Though some errors were unavoidable in the past, modern geophysical methods are, most probably, quite sufficient to solve the majority of problems (e.g., to determine a close presence of the salt boundary). Detailed study of the recent catastrophic floods, which happened in Polish salt mines, shows that they usually occur, or have strong negative impacts, due to human errors. Most probably similar human errors caused catastrophic inflows to salt mines in other countries. It seems that a knowledge of the real history of catastrophes, better education of mine engineers and the application of modern geophysical methods could lead to the reduction of floods in salt mines."

Case Histories: Caving Brinefields

Abandoned brine fields can be areas with major environmental problems as many old wells are undocumented and unmonitored. Like areas of natural solution collapse (Tables 7.9 and 7.10), they can become zones of catastrophic ground failure, this is especially problematic if located near cities or towns (Table 13.5). Some of the most outstanding examples of how not to solution mine a resource and how not to control ground subsidence effects are to be found in east European countries that are still trying to deal with the environmental outcomes of being former satellite states of the Soviet Union. But caving problems have been tied also to mines and boreholes in the United States and Canada, once again human error, greed or ignorance has created many of these problem structures.

Ocnele Mari Brinefield, Romania

SALROM, a government-owned company, solution mines Badenian (Miocene) halite in the Valcea Prefecture of Romania (Fig. 13.19). Production from Field 2 was shut down on March 5, 1991, when earth vibrations were noted by SALROM workers. A subsequent sonar survey showed that poorly monitored brinefield leaching between 1971 and 1991 had created a gigantic merged cavern as salt pillars separating adjoining caverns were inadvertently dissolved (Fig. 13.20); the upper parts of the captive boreholes 363, 364, 365, 366, 367 and 369 had merged into a common cavern. The cavern was filled with some 4.5 million cubic metres of brine, was less than a hundred metres below the landsurface, was more than 350 m across and was overlain by loosely consolidated sandy marls (von Tryller 2002; Zamfirescu et al. 2003). The cavern was overlain by a bowl of subsidence and, even though mining operations in the region of the cavern completely stopped in 1993, the ground above continued to subside to a maximum of 2.2 m prior to the September 2001 collapse. In the period 1993–2001 the cavern continued to enlarge and the northern part of the cavity expanded by some 25–35 m (see inset in Fig. 13.20 showing sonar surveys 1995–2001).

The 1993 sonic survey of the cavern showed it was so large and shallow that its roof must ultimately collapse, predicting when was the unknown. The fear was that if it collapsed catastrophically, it could release a flood of at least a million cubic metres of brine. Brine could be released either

Table 13.5 Collapse and subsidence vents associated with brinefields

Location	Timing and size	Explanations & implications	Reference
Ocnele Mari Brinefield, Romania	Partial collapse of the roof of a much larger solution cavern occurred on 12 September 2001, it formed a large collapse crater and forced a brine flood down a nearby valley. Subsequent collapse and flooding occurred on July 15, 2004.	Poorly monitored salt leaching under the former Soviet regime between 1970 and 1993 created a gigantic cavern as salt pillars separating adjoining caverns were inadvertently dissolved and the cavern roof migrated toward the surface. The resulting cavern was filled with 4 million cubic metres of brine and was more than 350 m across. It broke through to the surface at its northern end in 2001, with further collapse in 2004.	von Tryller (2002)
Ground subsidence in brinefields near Krakow, Poland (Lezkowice/Barycz brinefields)	At the Barycz brinefield, 33 sinkholes up to 27 m wide and 27 m deep appeared between 1923 and 1993, the region is subject to numerous landslides.	A large deep sinkhole formed between 1984 and 1986 above the Lezkowice brinefield. Pollution of the groundwater system via poorly managed wells and broken pipes allowed high salinity waters to reach the nearby Raba River. In 1983 the river salinity reached 206 mg/l.	Garlicki (1993), Zuber et al. (2000)
Collapse at Compagnie des Salins Gellenoncourt saltworks near Lorraine, France	On March 4, 1998, a sinkhole more than 50 m across and 40 m deep formed atop the SG4 and SG5 brinefield caverns, France. It was an induced collapse.	The SG4 and SG5 caverns, drilled in 1967, unexpectedly joined in 1971. By 1982 the salt cushion in the roof had dissolved out putting the cavity roof in direct contact with a 25 m thick marl. In October 1992 the marls broke free, exposing a large section of the cavity roof to direct contact with the brittle Dolomite de Beaumont. Collapse was induced by enlarging the cavity by injecting 300,000 m^3 of fresh water.	Buffet (1998)
Cargill saltworks collapse, near Hutchinson, Kansas	Collapse started on October 21, 1974. Within 4 h the crater was 60 m across and after 3 days had created a circular depression some 90 m in diameter and nearly 15 m deep.	Uncontrolled brine extraction since 1888 certainly contributed to the Cargill collapse. Post-mortem analyses showed that several warning signs, especially an enlarging bowl of subsidence, had been noted, but ignored. After the collapse the brine field and the loss of part of the saltworks infrastructure the brinefield was abandoned.	Walters (1978), Hendron and Lenzini (1983), Dyni (1986)
Brinefield sinkholes at Windsor, Ontario and Point Hennepin, Michigan	On February 19, 1954, near Windsor, a water filled depression some 120–150 m across and up to 7.5 m deep formed within a few hours, destroying much of the surface plant. On January 9, 1971 at Point Hennepin the first collapse crater formed, after a few months it stabilized with a diameter of 65 m. A second crater developed in April and May 1971 measuring some 120 m across, with a depth of 35 m.	The similarity in the geology of the Windsor and the Detroit sites as well as the rapidity of the collapse, along with the size and steepness of the collapse craters, led Nieto and Russell (1984) to question the collapse mechanism of Terzaghi (1971). They argued his notion of steep upward caving from more than 300–400 m below the surface and centred on solution caverns in the Salina Salt could not explain the craters or their subsidence history. Instead, they proposed a collapse scenario based on a loss of cohesion in pressurised Sylvania sandstone and in the presence of water.	Terzaghi (1971), Nieto and Russell (1984)
Retsof Mine collapse, New York State	Loss of the Retsof Salt Mine began with a magnitude 3.6 earthquake in the early morning hours of March 12, 1994. Two large, circular collapse features some 100 m apart developed a month apart at the land surface above two collapsed mine rooms.	Catastrophic breakdown driven by collapse of a small pillar and panel section in the mine some 340 m below the surface. Collapse of the "back" was accompanied by an initial inrush of brine and gas (methane) into the mine and by a sustained inflow of water via the overlying fractured limestone. A month later on April 18 an adjacent mine room collapsed.	Gowan and Trader (1999), Payment (2000)

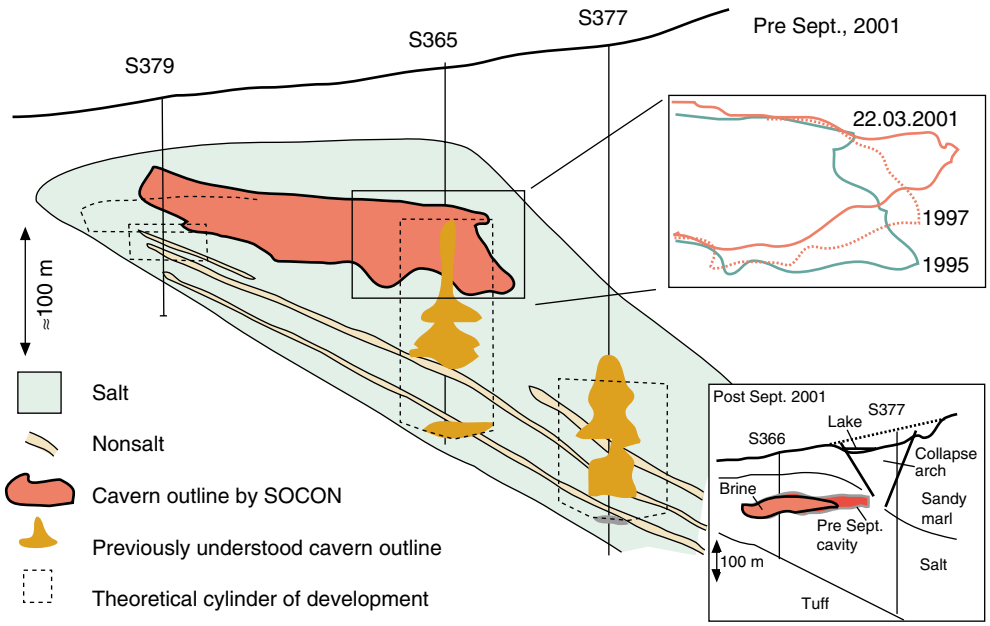

Fig. 13.20 Ocnele Mari brinefield, Romania. Interpretive cross section showing locality of cavern and proximity to land surface, the *inset shows* sonar defined outlines and the upward migration of the cavern from 1995 to 2001. This ultimately led to a partial collapse of the cavern roof in this zone on September 12, 2001, as seen in *lower inset* (Redrafted from SMRI data files at <http://www.solutionmining.org>, von Tryller (2002), Zamfirescu et al. (2003))

over several hours (least damaging scenario) or instantly forming a wave of escaping water several metres high that would flood the nearby Sarat River valley for many kilometres downstream. There were 22 homes on top of the cavern that would be immediately affected; also at risk were the hundreds and perhaps thousands of residents in the area of the saltworks and river valley below, as well as the local ecology and the civil/industrial infrastructure. Ongoing brine delivery from other nearby operational SALROM caverns to the large Oltchem and Govora chemical plants would also be disrupted. When collapse did ultimately occur (twice in the period 2001–2004), each episode took place over a number of hours and so a catastrophic wave of water did not eventuate.

According to SMRI (Solution Mining Research Institute), there was no good engineering solution to prevent the Ocnele cavern roof from collapsing. Prior to collapse, brine in the cavern exerted pressure against the roof helping to hold it up; removing even a small amount of brine would remove hydraulic pressure that could possibly trigger a catastrophic collapse. Nor was it practical to fill the cavern with sand and industrial wastes as suggested by the Romanian government. It would take too long and it was unsafe to place men and equipment on top of the still expanding cavern. Even if it could be done, only the areas directly below the injection wells would be filled. The best solution was to construct a dam as close to the cavern as possible, and then perhaps trigger a controlled collapse by pumping out the cavern brine.

A partial collapse of the cavern roof atop well 377 occurred on 12 September of 2001, the ensuing brine flood killed a child and injured an older man. The collapse began at 7 pm with brine spilling out of wells 365 and 367. Southward of well 377 a collapse cone some 10 m across started to form and fill with brine. The cone continued to expand and fill with water until its southern lip was breached. Water spilled out of the cone and down the hill slope. The flow rate of the expelled flow reached a maximum of 17 m^3/s at 3 am on September 13th, with flow continuously exceeding 10 m^3/s for a period of more than 6 h around that time. By 7 am flow was down to 4–5 m^3/s and by 7 pm, 24 h after the flow began the flow rate was 0.4–0.5 m^3/s. Some 24 h after the onset, roof collapse had formed a water-filled lake with an area of 2.4 ha (Fig. 13.19; Zamfirescu et al. 2003).

A second roof collapse occurred on July 13, 2004. Realitatea Romaneasca, Romania, reported that ground collapse occurred on 9:30 pm July 13, 2004, possibly triggered by heavy, recent rains. The wellhead of bore 365 was destroyed in this collapse and many other well heads in Field 2 had been destroyed by ongoing subsidence in the period 2001–2004. This collapse was the culmination of a series of collapse-related events that began on Monday July 11. It was planned that a purpose-built earthern dam would contain the brine flood. But when the roof fall occurred at 9:30 pm, the dam was breached 30 min later by some 250,000 m^3 of salt water. Flow rate through the breach reached a maximum of 6 m^3/s. Collapse did not occur until just after local authorities had evacuated people from 50 homes in the area around the cavern. Most of the brine forced out by the roof collapse escaped into the Sarat (Olt) River. The government attempted to dilute the effects of this flush of salt water by releasing fresh water into the river from nearby dams. Fortunately, unlike the 2001 event, there was no loss of life.

Subsidence in Old Belvedere Spinello, Italy

The Old Belvedere Spinello brinefield is located near Crotone, in southern Italy and exploited the salts of the Messinian series and is transgressively covered by a number of Plio-Pleistocene alternating sandy clay units. Originally the Belvedere Spinello brinefield was operated via brine wells interconnected by hydraulic fractures. This area, now referred to as the "Old Mine," was operational in the 1970s and 1980s, exhibits subsidence effects ranging from sinkholes to bowl subsidence and landslides (Fig. 13.21). Salt strata do not outcrop in the valley and are folded in an anti-

Fig. 13.21 Sinkholes in an anthropogenically-induced cone of collapses in the "old mine area" in the upper valley of the former Belvedere Spinello brinefield, Italy (Scaled Bing® Image mounted in MapInfo)

cline with a NNE to SSW oriented axis. The brinefield, which is no longer active, sat atop this anticline and was located over two main Messinian salt layers, the first or upper, was targeted for solution mining. It is made up of breccia (clayey marl, gypsum, etc.), cemented by salts, mostly halite; it has a halite percentage of about 60 and an average thickness of about 150 m. The depth from the ground level of the surface to this layer varies from 200 to 600 m (Fig. 13.22). The brinefield occupies a valley atop a salt anticline which is asymmetrical; its western side is vertical, or locally overturned, while the eastern side grades eastward with an inclination of 15–20° (Fig. 13.22b). The character of the exploited salt varies down the valley from a modestly deformed bi-crested salt anticline in the "Old Mine" area to a laterally compressed and thickened domelike anticline lower down the valley in what is called the "New Mine" area. Brinefield mining began in the 1970s over the less deformed salt in the upper valley and gradually moved down the valley toward thicker more deformed salt (indicated by the southern area dominated by Ba-numbered wells in Fig. 13.22).

Relatively strong formations overlie the less deformed salt of the "Old Mine" brinefield area. Over the more recently mined domelike salt targets, located further down the valley, these brittle formations are replaced by relatively weak overburden strata. For a short distance on one side of the valley near the "Old Mine area" the crest of the salt anticline lies against a fault running beneath the toe of a steep hill. From this point the top of the salt dips steeply in the direction of brine wells located some distance away in the valley axis.

The first sinkhole surfaced in January 1983 around well 5. After the collapse, a circular doline opened in the ground, with a diameter of 50 m and an area of about 2,000 m and filled with brine to a depth of 6 m. Subsequent erosion of the soft materials of the walls progressively refilled much of the doline. The initial volume of brine was about 20,000 m^3, with a TDS of 30 g/l (Gisotti 1991).

A second sinkhole (now filled) appeared in April 1984, to the east of Colle Barretta, near the south-western edge of the brine field and more than 360 m from the nearest active brine well of the "Old Mine" area. It formed at the foot of the hilly slope of Barretta Hill, causing a catastrophic landslide into the water-filled sinkhole, with consequent violent expulsion and projections of a significant volume of brine. Around 100,000 m^3 of brine was released in this flood, first into the river bed of Fosso Barretta, then onto the plain of the Neto River, extending across an area of some 120 ha. Brine flowed into the fluvial stream of Neto River, polluting it, and also polluting the local ground waters via percolation. The salinity of fluvial waters, immediately after the brine flood, reached values of 19.7 g/1. Step by step, the salinity has returned to normal values.

This destructive sinkhole formed along the Timpa del Salto fault, so putting into contact the "marly clay of Cutro" (that suffered the majority of the sliding), on the downthrown side, to the "Molasse of Scandale" on the upthrown

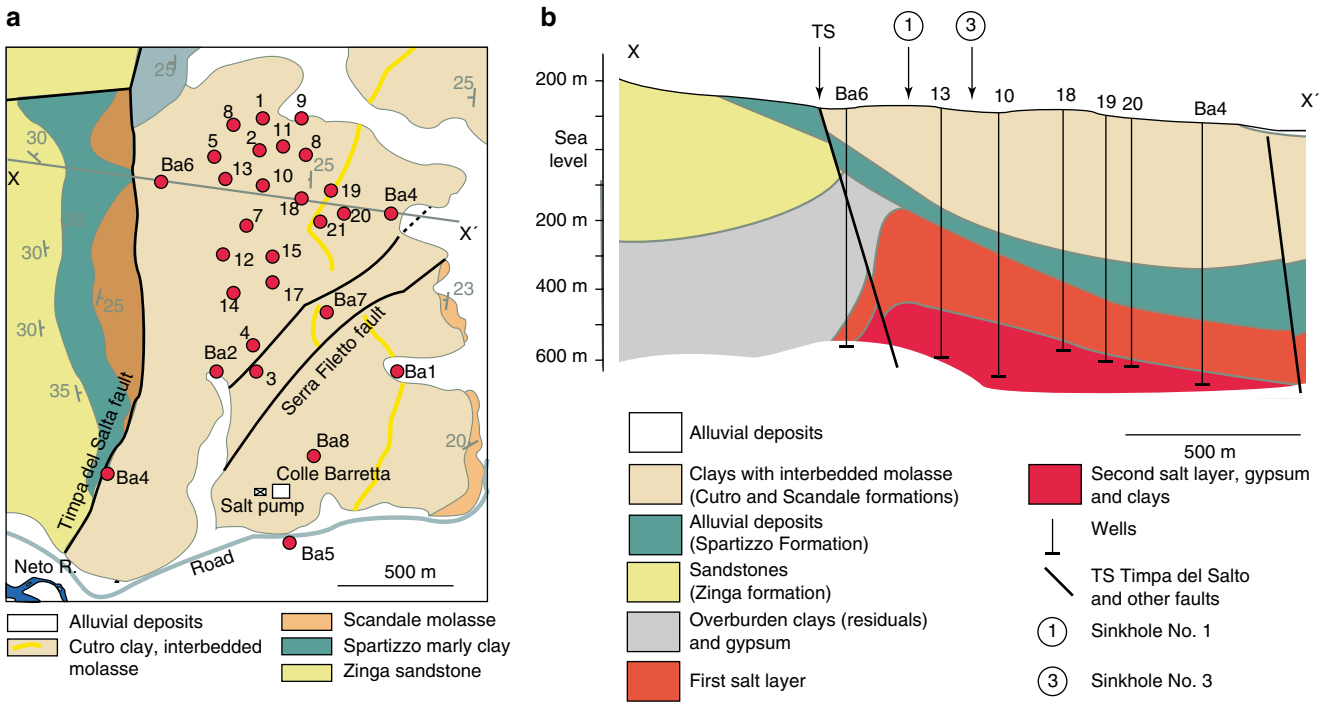

Fig. 13.22 Belvedere Spinello brinefield, near Crotone, Italy. (**a**) Geological map. (**b**) Geological cross section X-X′ (After Gisotti 1991)

side. Material caught up in the landslide had a volume less than the landslide body; meaning that the missing rock filled the sinkhole in response to the collapse of the stoped roof to the induced subterranean cavity. The centre of this collapse was not immediately above any of the producing wells; salt solutioning had apparently migrated within the salt formation for a considerable distance laterally from the brine wells to where it had dissolved a large cavity at the toe of the hill. After the landslide and the consequent brine flood, saltworks operations were interrupted, and began again in the first months of 1987 with improved monitoring of all wells.

In September 1986, a third sinkhole formed on a quite steep hilly slope in the area of Barretta Asciutta of the Old Mine" area, located in a triangle with vertexes defined by the wells 13, 10 and 7 (Gisotti 1991). This new collapse doline (Sinkhole 3) was 200 m away from the first sinkhole, which was close to the well 5, and once again located in the "marly clays of Cutro" (Fig. 13.22). Initially, the collapse doline diameter was ≈ 30 m and the bottom was covered by a small brine lake, with a depth to the surface of this water body some 20 m below the doline edge. The width of the sinkhole increased because of subsequent collapses, and the brine dispersed back underground and so that the diameter of the hole evolved to about 50 m, with an area of about 8,000 m^3 and a depth around 25 m. Today all these dolines in the "Old Mine" area are water filled (Fig. 13.21). No further sinkholes appeared in the more recently mined end of the brinefield, probably due to its relatively weak overburden. Instead, gradual bowl subsidence dominates this part of the field. Solution mining continued until 2008 in what was called the new Belvedere Spinello Brinefield using a number of single-well, sonar-monitored salt caverns (Guarascio, et al. 1995). The brinefield is no longer active.

Brinefield and Mine Collapse Near Krakow, Poland

A former salt mining region, including the World-Heritage Wieliczka Mine, lies close to Krakow in south of Poland, has been mined since the thirteenth century. There are two main problem sites, Barycz/Wieliczka and Lezkowice. The Lezkowice site is east of Krakow and lies about 10 km east of Wieliczka city. The Barycz site, located to the immediate west of Wieliczka Mine, covers an area of one square kilometre, and is two kilometres wide at its maximum extent (Fig. 13.23). It was first solution mined in 1923. Miocene salt at Barycz is relatively flat lying, around 30 m thick, and some 230–280 m below the land surface. Salt at Lezkowice is steeply dipping and can be found as patchy subcrops as shallow as 40 m below the surface. Salt was solution mined at Lezkowice from the nearsurface to depths of more than 450 m. Both sites are covered by 15–20 m of unconsolidated Quaternary sediments (sands, gravels and peats).

At its most active the Barycz brinefield consisted of more than 900 solution wells about 50 m apart. In 1993 after 70 years of exploitation the field had produced some ten million tons of salt, equivalent to a unit 3 m thick across the whole of the exploited area. There was significant surface subsidence in the brinefield from the onset of solution mining, with ground displacements of 10–30 cm noted between 1926 and 1934. Thirty three sinkholes up to 27 m wide and 27 m deep appeared in the brinefield between 1923 and 1993, and the region was subject to numerous landslides. By 1993, the brinefield was exhausted and the landsurface was pock-marked by stagnant brine-filled subsidence cones and sinkholes, often centred on abandoned wells. As the land is considered unusable for agricultural purposes, it is currently used as a waste dump by the nearby town of Krakow (≈800,000 inhabitants) (Fig. 13.23).

Fig. 13.23 Location of former Barycz brinefield (*shaded*) and the Wieliczka salt mine. Bing® image mounted and scaled in MapInfo®

Unfortunately, although the Barycz and Wieliczka areas are separated by a shallow salt ridge, the world heritage Wieliczka Mine with its unique salt sculptures and carvings in the upper levels of the mine, lies less than a few kilometres from the Barycz brinefield. Throughout its history, the mine has been subject to flooding and freshwater influx. Even though a dehumidification program for the mine air has now removed the sculptures and carvings in the mine from the endangered sites list, it is in a constant state of possible destruction by flooding (Zuber et al. 2000). Exploited Miocene salt in Wieliczka mine is made up of two intervals: the lower one consists of layered salt which was strongly tectonically deformed, while the upper interval consists of salty clays with large salt blocks (Fig. 13.24). The salt deposit, and the adjacent flysch sediments were overthrust from the south and are relatively well documented by the mining operations. Tertiary-age water-bearing Chodenice beds make up the northern boundary of the deposit and are much less well studied. They consist mainly of clays, slightly cemented sandstones and sandstone conglomerates that were probably strongly fractured during Miocene folding (Fig. 13.24). The main water inflow into the mine network occurs along the southern boundary with the Chodenice beds.

Seven centuries of exploitation in the Wieliczka Mine, beginning in the thirteenth century, has created more than 2,000 chambers with the total volume of about 7.5×10^6 m^3 and over 190 km of galleries in nine main levels and several local midlevels. Throughout the 700 years of mine history there were many catastrophic intrusions of water and loose sand, largely caused by a lack of knowledge of the boundary of the salt and the high permeability of adjacent rocks.

Zuber et al. (2000) gives a simplified historical record of inflow rates to the mine in m^3 day^{-1} as: 6 in 1381–1819, 31 in 1820–1919, 50 in 1925–1960, 135 in 1960–1971,

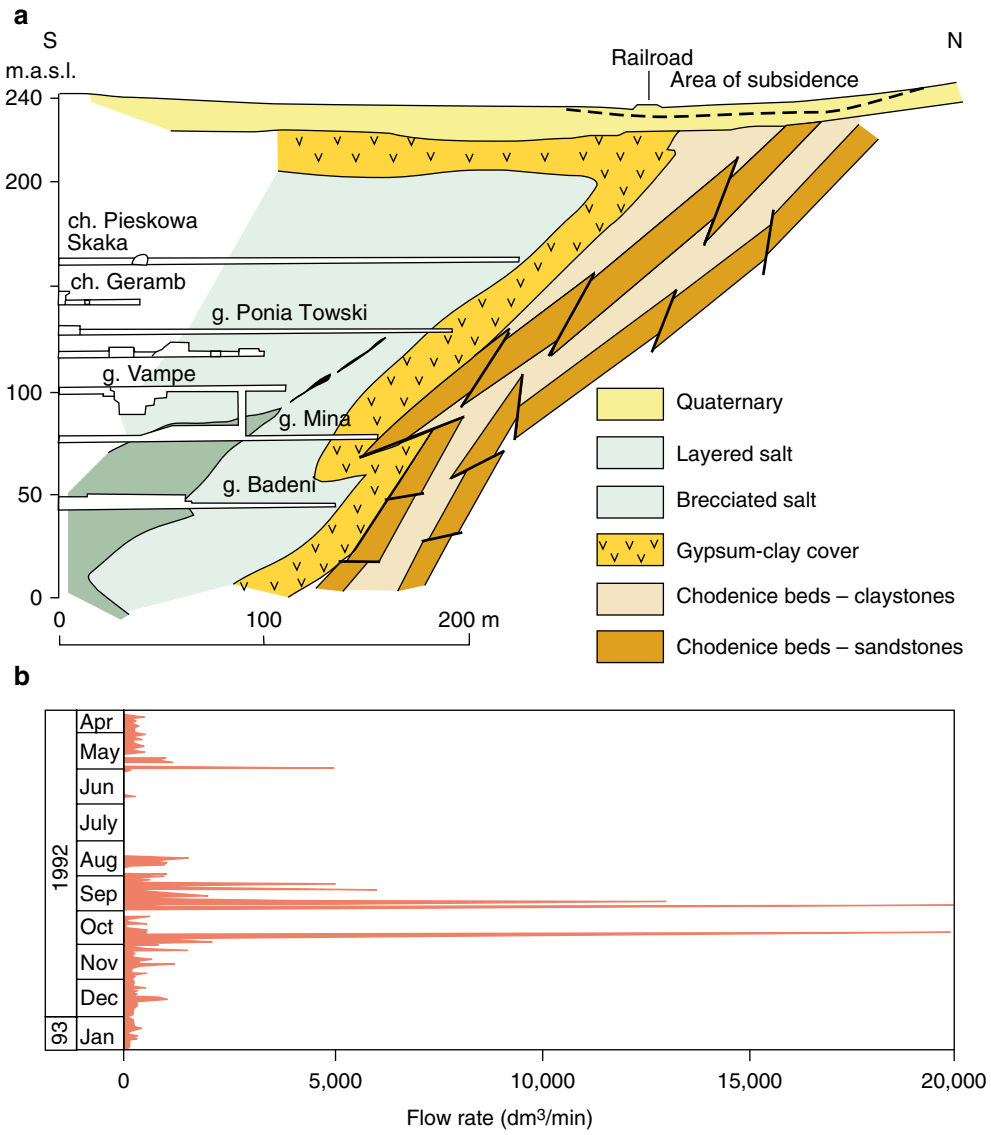

Fig. 13.24 (**a**) Wieliczka Mine cross section through the northern boundary in the region of the Mina Gallery. (**b**) Inflow rates into the Mina Gallery during 1992–93 (After Garlicki and Wilk 1993; Zuber et al. 2000)

500–418 in 1972–1991, and about 900 in 1992. In 1991, there were about 260 inflows with very low flow rates and several larger inflows at the fourth, fifth, sixth and seventh mine levels. These large inflows considerably increased the total water inflow to the mine in the last several decades. One of the most catastrophic inflows started in 1992 in the Mina gallery at the fourth level and was so intense that the lower flooded sections of the mine had to be abandoned (Fig. 13.24b). Shortly before the First World War that gallery had crossed the salt boundary and stopped 20 m beyond the salt deposit in gypsum and clay cover (Fig. 13.24a). After the Second World War, the gallery was not accessible due to rock falls, and slag used to fill in the Dunajewski chamber cut across the Mina gallery. Water was seeping downward through the slag deposit and exiting at the fifth level (Badeni gallery) at a rate of 4–5 l per minute and TDS of 300 g/l (Zuber et al. 2000).

Serious trouble with inflows started during a reconstruction of the Mina gallery aimed at ponding the inflow behind a dam where it could be pumped from the mine. A catastrophic influx began on the night of 13 April 1992 when the flow rate increased to 200–300 l per minute (290–430 $m^3\,day^{-1}$), i.e., nearly equal to the sum of all other inflows to the mine at that time. Pumps then in use were not able to pump it out. In consequence, the gallery was filled nearly to the ceiling with water and mud, but the water drained or was pumped out after a few days. An even more catastrophic flood began on September 13, 1991 and overwhelmed the pumps and the newly constructed dams. Influxes exceeded 10,000 l per minute. Inflows to the Mina Gallery continued to show a similar pulsing, well into 1993 (Fig. 13.24b). Operations in the lower levels ceased soon after and the mine today is no longer exploiting solid salt although brine pumping still takes place. This extraction is expanding the proportion of cavities in the lower levels of the mine and will ultimately destabilise the tourist areas. But if brine is not removed and processed, the resulting rising waters will also enter the tourist levels of the mine.

The pore pressure release created by the flooding drove considerable subsidence at the surface (Zuber et al. 2000; Perski et al. 2009). Walls surrounding a historic Franciscan monastery partially caved and huge cracks appeared in the walls of the buildings both inside the monastery itself and around it, making some sites structurally unsafe. In October 1992 the surface subsidence in the wake of the successive floods was as deep as 0.5 m.

The pulsed nature of the inflow prior to the final flood argues for more than one water source to the Mina level (Zuber et al. 2000). Initially, the Chodenice beds in the vicinity of the Mina gallery were drained of water, then either waters stored in the Chodenice beds west and east of the Mina gallery were drained, or there was a hydraulic contact established with the sands of the Tertiary Grabowiec beds (Fig. 13.24a). The Grabowiec beds are mostly confined aquifers filled with Holocene waters. In any case, the increased influx at the Minas level did not influence the flow rate of other inflows, and the local recharge, especially within the subsidence cone atop the mine, was negligible.

The pulsed character of the measured inflow was probably driven by natural instability of adjacent rocks, and by unsuccessful attempts to stop the inflow. Wash out (suffosion) periods occurred during times with high inflow rates. These were followed by land subsidence, which led to clogging (colmatation) when the flow rates and hydraulic pressures dropped (Zuber et al. 2000). A temporary colmatation lead to an increase of the watertable level in the Chodenice beds, this drove an increase in hydraulic head until pressure breakout occurred and the whole cycle repeated.

That the pulsing process is quite complicated is shown by differences in water levels observed in a number of boreholes in the northern region of the mine adjacent to the Mina gallery (Garlicki et al. 1996). In general, when the water pressure builds-up sufficiently, dams, or any other anthropogenic sealing structures in this area of the mine are easily destroyed or moved from their positions because they cannot be anchored in stable rocks. The Chodenice beds are naturally unstable and additionally deformed and weakened by ongoing exposure to water crossflows. If the exiting water is recharged indirectly through the Grabowiec sands, the inflow rate to the mine can perhaps be reduced, but only if their basal sections are sealed in the region of the contact with the Chodenice beds. If the water comes from the distant parts of the Chodenice beds, the inflow rate can be reduced by pumping in wells installed at distances sufficient to avoid further rock destabilization in the vicinity of the gallery. Undoubtedly, any such operation would be a very expensive undertaking.

When the inflow to the Mina gallery developed to catastrophic dimensions in the early 1990s, the mine management showed a remarkable lack of scientific or engineering sophistication and no understanding of simple hydrological principles. They called on and paid generously for dowsing and witching methods to solve the flooding problem. The dowsers claimed that an underground "river" flows through the mine at the rate of 1.5 m^3/s. Following the advice of witches and dowsers, a 100-m-long trail was buried about 1 m below the ground surface, it was supposed to stop the inflow of the underground "river" at a depth of 170 m, and to change the "rivers" flow direction upwards (Zuber et al. 2000). Today, the flooding of the lower mine continues, the tourist region of the mine area is still under constant threat of renewed flooding, but the witches and dowsers are happy and counting their spare zlotys.

Depletion of the Barycz brinefield meant that in order to maintain a feedstock for nearby chemical industries the saltworks needed to shift to the Lezkowice site in 1968. There the brinefield wells were sited 35 m apart with a 300 m wide

"exclusion" zone between the brinefield and the nearby Raba River (Fig. 13.25). Brine well production was supposed to be limited to 8–10 years and the cavities monitored by sonar to prevent the problems experienced at Barycz. Exploitation actually continued unabated for 20 years until January 1988 when the brinefield was finally shutdown. Over-exploitation led to the fusion of numerous cavities, the unfettered escape of brine into the environment and the nearby Raba River. Some 5.1 million tons of salt were extracted over the 20 year life of the brinefield (corresponds to 17 million cubic meters of brine product). In an attempt to prevent further ground collapse, loam and ash waste from a nearby power station were injected into some of the cavities. Even taking into account the re-injection of some 1.10 million cubic meters of waste, the cumulative volume of the cavities remaining beneath the Lezkowice site in 1990 was of the order of 1.45 million cubic metres.

Subsidence measurements were made at Lezkowice from the beginning of the exploitation in 1968. Measurements carried out between 1974 and 1988 show two principal zones where subsidence exceeds 80 cm (Fig. 13.24a; Garlicki 1993). The most significant area of subsidence lies at the centre of the brinefield, but extends beyond the exploited zone, in particular in the northeast. Subsidence reaches 1.20 m in the brinefield centre. The second major subsidence zone, where subsidence was higher than 80 cm, is located in the northern part of the brinefield. There is a third zone of subsidence with depressions of more than 50 cm to the east of the former brinefield.

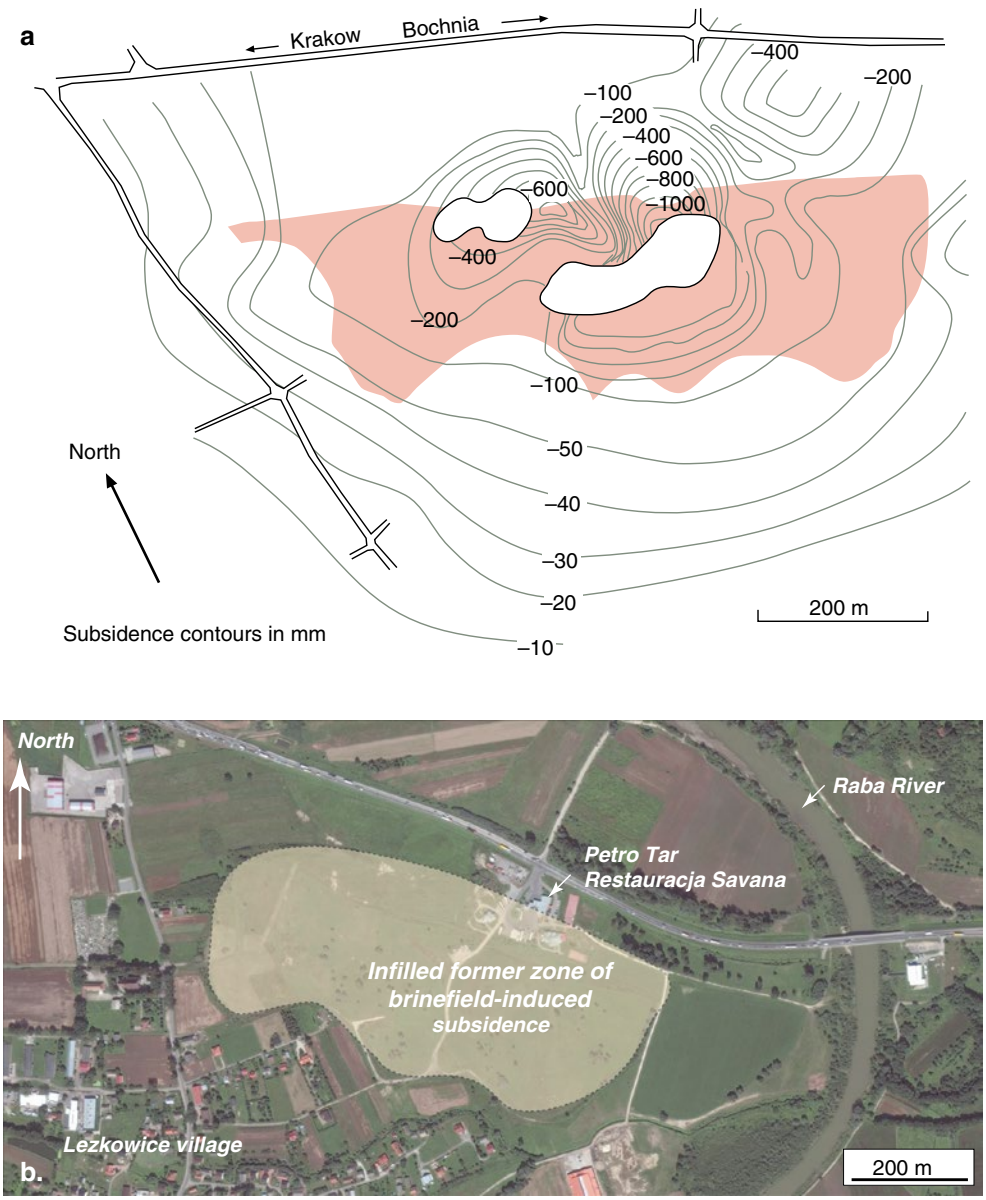

Fig. 13.25 Lezkowice brinefield site, Poland. (**a**) Subsidence at the between 1974 and 1988, contours in mm. Area of the former brinefield is shaded pink (After Garlicki 1993). (**b**) Situation in 2012 following infill of subsidence cone and construction of commercial sites (including a roadside petrol station) above the former cone of subsidence. Bing® image mounted and scaled in MapInfo®

Between August 1988 and June 1991, subsidence increased by 40 cm in the western part, and 80 cm in the central part; sagging in the central part had lengthened along an east-west axis and the depression bowl had migrated 150 m east. The first large deep (22 m) sinkhole at Lezkowice started to form in 1984, and continued to grow until 1986. After the first few months, the sinkhole was filled by the brinefield operator with more than 250,000 m^3 of sandy and argillaceous waste materials. Another large sinkhole formed nearby between 1988 and 1989, but it was no more than 3 m deep. Still more sinkholes appeared between 1988 and 1990 with a total a volume of more than 300,000 m^3, all were filled using waste residues.

Garlicki (1993) estimates that the large deep sinkhole, which formed between 1984 and 1986, was a response to the uncontrolled dissolution of a steeply dipping layer of salt that lay no more than a few metres beneath the Quaternary cover. There was significant salinization of the Quaternary aquifer in the region due a combination of brine leakage from poorly maintained pipelines and casings, and the uncontrolled solution flushing of shallow salt. The resulting brine percolated through sands and gravel aquifers and easily breached the "exclusion" zone to reach the River Raba. River salinity reached 206 mg/l in 1983 but returned to lower levels after the operator drilled drainage sumps.

Induced Collapse, Gellenoncourt Saltworks, France

Gellenoncourt is one of three sites that exploit halite beds of the Lower Keuper in the eastern part of the Paris Basin. The deposits extend from Cezanne in the west to Nancy with a length of 250 km and a width of 50–70 km. Salt production utilising solution mining techniques is focused on three sites along the Meurthe river, which all lie immediately to the east of Nancy.

On March 4, 1998, a sinkhole more than 50 m across and 40 m deep formed atop the SG4 and SG5 brinefield caverns in the Gellenoncourt saltworks near Lorraine, France (Fig. 13.26; Buffet 1998). It was an induced collapse designed to prevent a possible uncontrolled future ground collapse. The problem started in 1967 with the beginning of the exploitation of Triassic salt layers in the Keuper Fm. In total the Keuper is more than 150 m thick with five salt layers at its base, passing up into variegated and poorly consolidated marls and sandstones and capped by the Dolomite du Beaumont. The top of the salt is some 220 m below the surface and divided into 5 beds numbered 1–5 from top to bottom, with the solution mining program designed to leach beds 1 through 3 in the region of SG4 and SG5 caverns (Fig. 13.27). Five wells, SG1 to SG5, were joined using hydrofracturing in February 1967. Theoretically, the process was designed to leave a substantial salt pillow atop all the cavities and so separate the solution cavities from the overlying marls (Fig. 13.27; 1967–1971). The SG4 and SG5 caverns unexpectedly joined in 1971. Brine injection to these two wells was stopped, but crossflowing brines flowing to the producing SG1 well continued to excavate these two caverns. By 1982 the salt cushion in the roof of the SG4-SG5 cavern had completely dissolved away, placing the cavity roof in direct contact with the base of the marls.

From 1982 until October 1992 there was no further upward growth of the cavern roof. Then a 25 m-thick section of the variegated marls in the roof broke free and fell to the

Fig. 13.26 Gellenoncourt brinefield, France. Shows the position of the induced collapse dolines in the region of the former SG4 and SG5 brine wells (Bing® image mounted and scaled using MapInfo® software)

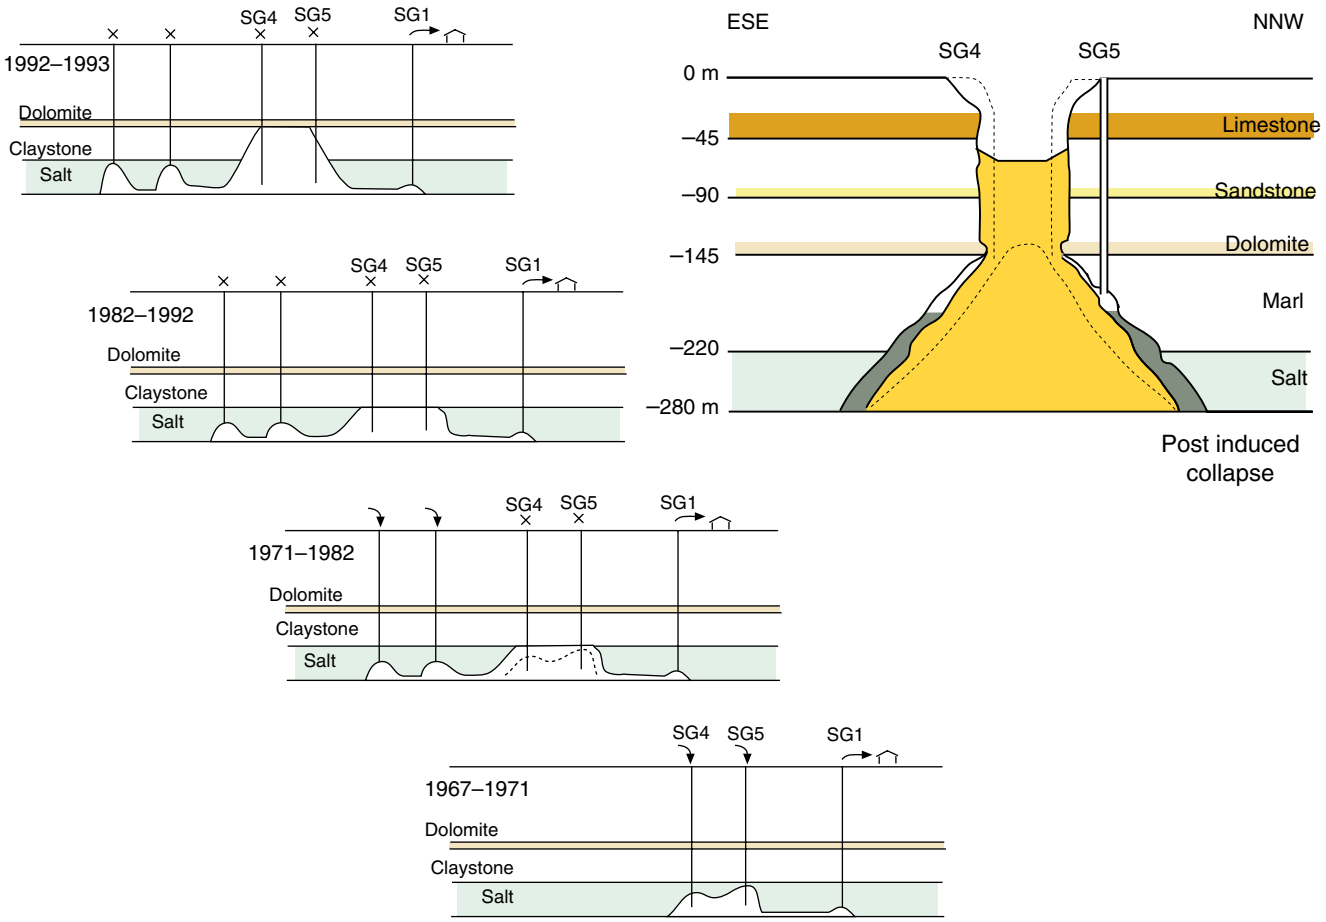

Fig. 13.27 Series of chronological panels showing the evolution of the SG4-SG5 cavity in the Gellenoncourt saltworks, France. The larger panel shows the shape and size of the final induced collapse crater (After Buffet 1998)

cavern floor, leaving a large section of the cavity roof in direct contact with the brittle Dolomite de Beaumont. This stiff dolomite layer prevented any further immediate collapse of the roof and consequent propagation of the cavity to the surface. But continued growth of the roof span beneath the dolomite would mean a later, larger, perhaps catastrophic collapse. In 1995 the operator tried to induce a controlled collapse by placing a submerged pump in the cavity and pumping out brine to create an exposed upper face. But this didn't work. The next approach was to further enlarge the roof span by injecting 300,000 m^3 of freshwater into the cavity. Collapse occurred on March 4, 1998, forming a 50 m wide crater. To protect the surrounding countryside from any brineflood damage a dam was constructed to capture any brine overflow, but in the actual event it was not needed.

Solution Mining Induced Ground Collapse, Tusla

Salt mining induced ground subsidence is a major hazard in the city of Tuzla (Northeastern sector of Bosnia and Herzegovina) and its surroundings since 1950, when salt solution mining began (Fig. 13.28; Mancini et al. 2009).

The exploited salt is a Tertiary bedded deposit (Eocene to Miocene) with five salt horizons lying at an average depth of 300 m. It covers a limited known area of only 1.5 km^2 (Fig. 13.28). In the 1990s the original Tusanj site in Tuzla was expanded to include the Tetima brine field, which was known to have high quality and large thicknesses of salt down to depths of 900 m, separated from one another by interbeds of banded marls, impure salt and clay horizons. The mining operations had been conducted for hundreds of years at depths starting from 170 m, but it was the large volumes extracted in the 1990s that caused massive surface subsidence and damage.

Analysis of topographical data collected during two periods: from 1956 to the Balkan War, and from 1992 to 2003 shows cumulative subsidence as high as 12 m across the whole period. It has damaged buildings and infrastructure across an area that includes a large portion of the historical town. Human-induced subsidence, with rates up to 40 cm/year in the most developed areas, were documented by GPS-based monitoring that began in 2004. It defines a decrease in subsidence rate to 20 cm/year in the past few years, and this decrease is directly related to reduction in rates of salt exploitation.

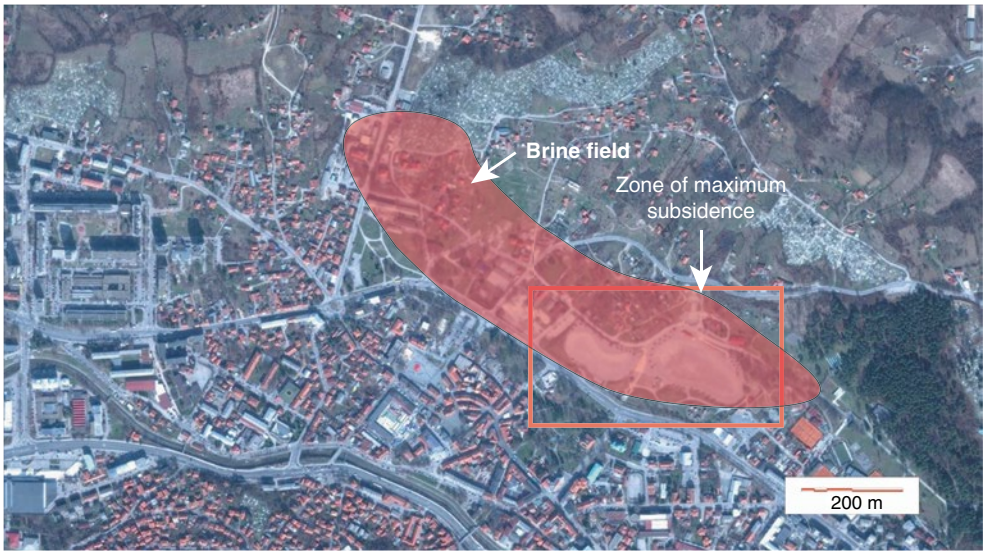

Fig. 13.28 Tusla city, Bosnia-Herzegovina, showing zone of maximum solution induced subsidence (*rectangle*) in relation to the brine field (Based on information in Mancini et al. 2009). Bing® image mounted and scaled in MapInfo®

That is, Mancini et al. (2009) show that there is close correlation between the average subsidence rate and the annual amount of salt extracted. The most intense period of damage occurred under Soviet domination and so destructive events are poorly documented in the state records. Something like 2,350 apartments were demolished by 1979 and 10,000 people lost their homes with a further loss of 1,500 buildings in the following 2 years. Today, the same region of maximum subsidence has been converted to public space with the subsidence depression in the zone of maximum subsidence used as a swimming pond, surrounded by parklands (Fig. 13.28).

Solikamsk and Bereznki Mine Collapses, Russia

Collapse of the Solikamsk-2 potash mine, Verkhnekamsky deposit, in the Upper Kama district of western Ural, Russia, resulted in a 4.7 magnitude seismic event on January 5th, 1995 and 4.5 m of surface subsidence (Fig. 13.29a, b; Whyatt and Varley 2008; Malovichko et al. 2001). Underground, the mine roof collapsed over an area measuring 600 m by 600 m. The event released an estimated 900,000 m^3 of gas (a mix of methane, hydrogen, carbon dioxide, carbon monoxide and other gases) that in turn led to gas explosions on the following day. Timely placement by the operators of a "significant volume" of backfill is credited with preventing further catastrophic consequences. There were subsequent collapses nearby in 2007 and 2014 (see www.saltworkconsultants.com).

The mined salt is of Middle Permian (Kungurian) age and located in one of six sub-basins extending from the Urals foreland to the Caspian basin. Sylvinite (potash) in the collapse area was extracted from 2 to 3 beds, with 10–16 m of total extraction height (Fig. 11.56). The mine used a panel system of rooms and pillars under 200–400 m of overburden. Rooms were 13–16 m wide and pillars 11–14 m wide by 200 m long.

A "rule of thumb" used across the Upper Kama district is that surface subsidence typically reaches 50 % of excavation

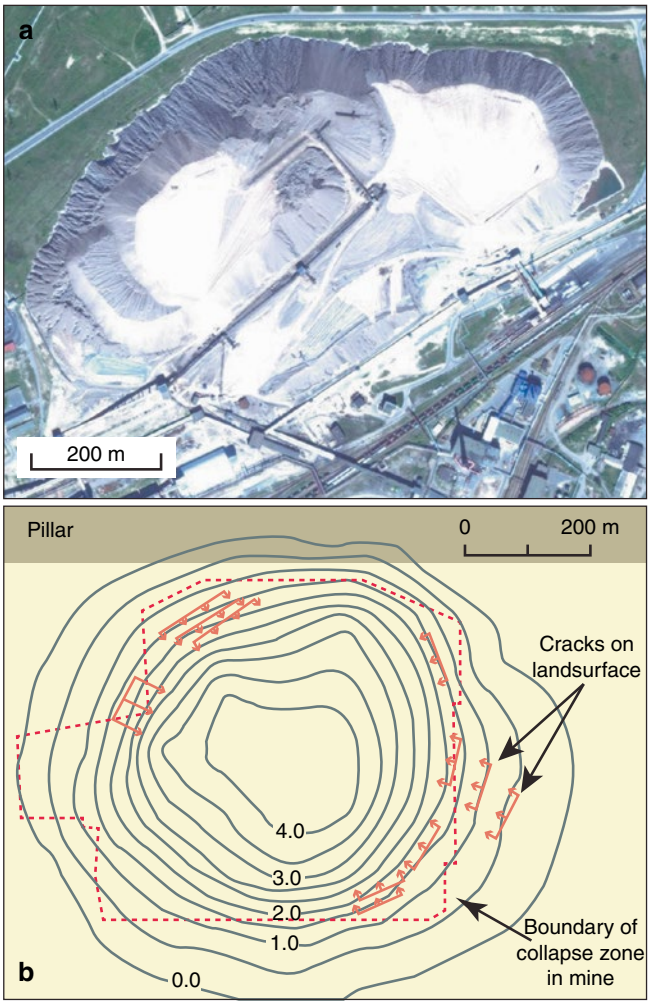

Fig. 13.29 Solikamsk-2 collapse, Urals. (**a**) View of collapse crater (Bing® image mounted in Mapinfo®). (**b**) Landsurface collapse contours in metres and the extent of the collapse zone in the mine (After Malovichko et al. 2001)

height 48 months after excavation. The collapse event in 1995 occurred 15 years after mining began, and 7 years after mining was completed beneath the collapse area. The unusual delay in subsidence implies extensive bridging of overburden, consistent with the uncommonly high release of seismic energy. The next largest collapses occurred in 1993 and 1997 with seismic magnitudes of 2.6 and 2.8, respectively.

An earlier collapse in the nearby 3rd Bereznki potash mine in July 25, 1986 is another interesting case of sinkhole formation from a mine operating at relatively shallow depths (Andrejchuk 2002; Whyatt and Varley 2008). Potash extraction was active at depths of 235 and 425 m below surface, where the targeted ore zone was overlain by a 100 m thick "salt complex" made up of halite and carnallite beds, overlain in turn by clays, carbonates, aquifers and sediments. Mining created "yield pillars," with 5.3 m wide rooms, 3.8 m wide pillars and a 5.5 m mining height. After mining, conditions in mined-out areas were described as, "pillars crushed and roofs sagged."

Observations of significant brine leakage into the 3rd Bereznki potash mine workings at a depth of 400 m indicated a loss of hydraulic control as early as January of 1986 (Andrejchuk 2002; Andrejchuk et al. 2000). This was a prelude or warning of massive dissolution occurring in the 90 m interval of salt overlying the potash level. Some 7 months later a large cavity had formed in the sandstone/limestone overburden, which was nearly 200 m thick. In the mine it appeared the water inflow situation remained relatively stable, at least until July. Failure of the mine head then occurred, the result of a cavity that had migrated vertically through more than 300 m of limestones, mudstones and sandstones. Final stoping was indicated by the near instantaneous appearance of a caprock sinkhole, which was 150 m deep and 40–80 m across and located at the top of a stoping breccia pipe or chimney of the same dimensions. Failure of this sequence began at 18:30 h with "clearly felt underground shocks" culminating with a final collapse at midnight, which was accompanied by an explosion with "flashes of light." Roof stoping over the pipe in the final stages before the cavity daylighted took only 12 days to migrate through the last 100 m of mudstone (Waltham et al. 2005). This very high rate of stoping was aided by structural weakness in a fracture zone along a local fold axis.

Retsof Mine, New York State, USA

The 1994 flooding of the Retsof Mine, New York State USA, took place over a period of weeks. Prior to abandonment, the 24 km^2 area of subsurface workings made it the largest underground salt mine in the USA and the second largest in the world (Figs. 13.30 and 13.31). It had been in operation since 1885, exploiting the Silurian Salina Salt and each year it produced a little over three million tons of halite. It supplied more than 50 % of the total volume of salt used to deice roads across the United States.

The eventual loss of the Retsof Salt Mine began in the early morning hours of March 12, 1994, with a magnitude 3.6 earthquake. The quake was caused by the catastrophic breakdown of a small mine pillar and panel section some 340 m below the surface and was accompanied by surface collapse of an area atop the mine that was some 180 by 180 m across and 10 m deep. This all occurred at the southern end of the mine near the town of Cuylerville. A month later, on April 18, an adjacent mine room collapsed to form a second collapse crater (Fig. 13.30). The initial March 12 collapse in the mine was accompanied by an inrush of brine and gas (methane) and by a sustained intense inflow of water at rates in excess of 70 m^3/min, via the overlying now fractured limestone back (Gowan and Trader 1999).

In a little more than a month, two steep-sided circular collapse features, some 100 m apart, had indented the landscape above the two collapsed mine rooms (Fig. 13.31). The northernmost feature, which was more than 200 m across, included a central area that was about 60 m wide and had subsided about 6–10 m. The southernmost feature, which was about 270 m in diameter, included a central area that was about 200 m wide and had subsided about 20 m (Fig. 13.30).

Fig. 13.30 Location of the collapse dolines atop the former Retsof Mine to the east of the town of Cuylerville. The doline occupies a pre-existing low that had also captured Beard Creek (Bing® 2012 image mounted and scaled in MapInfo®)

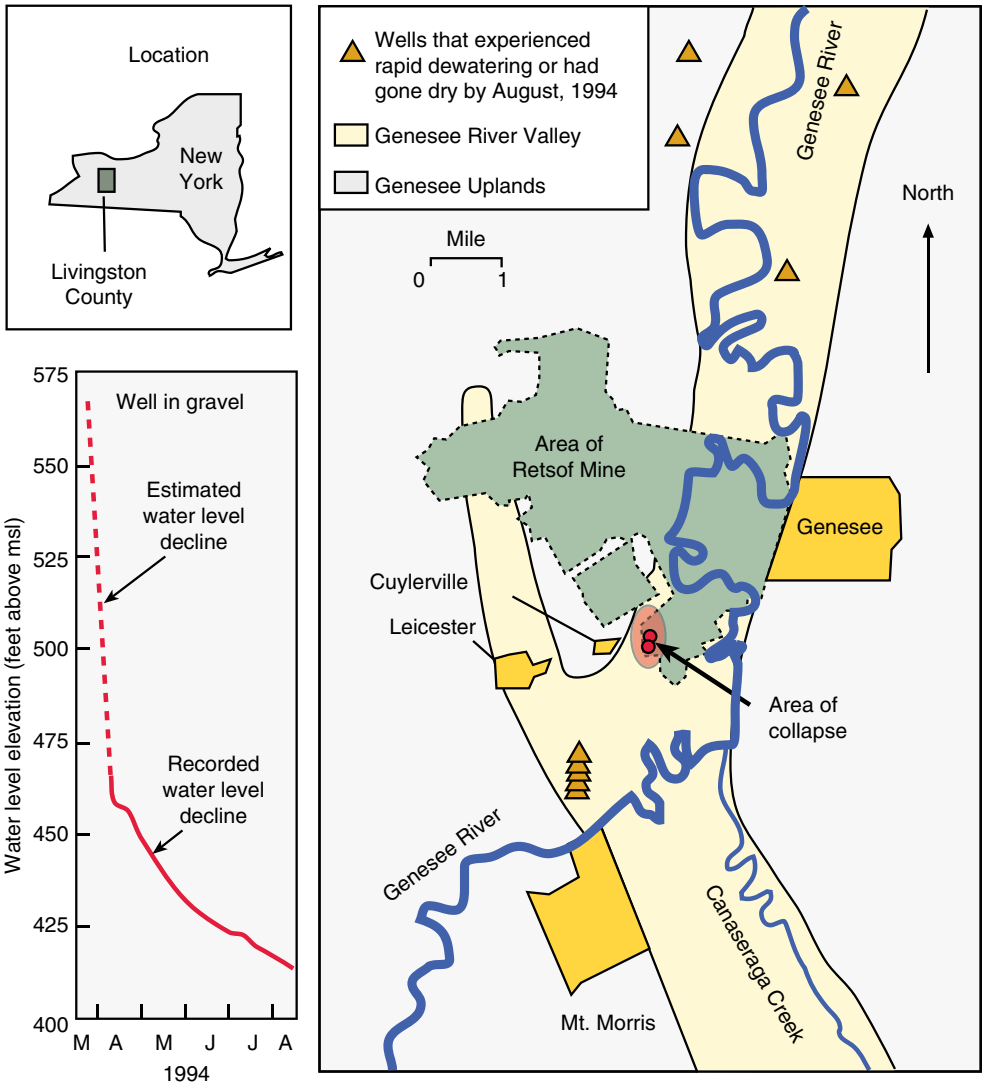

Fig. 13.31 Locality plan of the Retsof mine and the area of collapse along with a selected hydrograph from a well in the Genesee River valley (March 12 to August 12 1994; after Tepper et al. 1997)

Fractures extending up from the broken mine back created hydraulic connections between aquifers, which previously had been isolated from each and so provided new high volume flow routes for rapid migration of perched groundwaters into the mine level.

Water flooded the mine at rates that eventually exceeded 60,000 l per minute and could not be controlled by pumping or in-mine grouting. Within weeks the entire mine was flooded. Associated aquifer drawdown caused inadequate water supply to a number of local wells in the months following the collapse; some dried up (Fig. 13.31; Tepper et al. 1997). Aside from the loss of the mine and its effect on the local economy, other adverse effects included abandonment of four homes, damage to other homes (some as much as 1.5 km from the sinkholes), the loss of a major highway and bridge, loss of water wells and prohibition of public access to the collapse area. Land subsidence, possibly related to compaction induced by aquifer drainage to the mine, even occurred near the town of Mt. Morris some 3 miles southwest of the collapse area.

Post-mortem examination of closure data from the two failed mine panels showed an anomalous buildup of fluid pressure above the panels in the period leading up to their collapse. The initial influx of brine and gas following the first collapse coincided with the relief of this excess pressure. Gowan and Trader (1999) demonstrated the existence of pre-collapse pressurized brine cavities and gas pools above the panels and related them to nineteenth-century solution mining operations. They also documented widespread natural gas and brine pools within Unit D of the Syracuse Formation approximately 160 ft above the mined horizon in the Retsof Mine. The satellite image also shows the collapse occurred along the landscape low that was the Beard Creek valley (Fig. 13.30). Brine accumulations apparently formed in natural sinks, long before solution mining began in the valley, driven by the natural circulation and accumulation of meteoric waters along vertical discontinuities, which connected zones of dissolving salt to overlying fresh water aquifers.

Sinkhole Problems Cargill Saltworks, Kansas

A number of sinkholes appeared in the 1950s and 1970s around brine wells near Hutchinson, Kansas, an area where numerous wells and mines were extracting brine from bedded Permian salts as long ago as 1887. The Cargill south collapse sink near Hutchinson, Kansas, started to form on October 21, 1974. Within 4 h it was 60 m across, after 3 days it had created a circular depression some 90 m across and nearly 15 m deep (Fig. 13.32). The initial collapse left the tracks of the Missouri-Pacific Railroad spectacularly suspended 6 m above the water that accumulated in the sinkhole. There was no loss of life at the site.

Fig. 13.32 Location of the 1974 collapse doline to the south of the Hutchison Salt Mine (2012 Bing® image mounted and scaled in MapInfo®)

The Permian Hutchinson salt at this site is about 105 m thick and occurs at a depth of some 130 m (Martinez et al. 1998). The salt is overlain by 110 m of Permian shales, and these, in turn, are covered by about 20 m of water-saturated, loose Quaternary sands (Fig. 13.33a, b). Locations of some of the earliest brine wells in this property are unknown, and the early dissolution methods were not documented (see Hutchinson gas explosion). The sink developed in an area that was part of an active brine field at the time of collapse and would have included both operating and abandoned wells. Embraced within the sinkhole itself was a captive brine well that was drilled in 1908 and plugged and abandoned in 1929.

Earlier uncontrolled brine extraction in the region since 1888 certainly contributed to the Cargill collapse (Fig. 13.33a). Post-mortem analysis showed that several warning signs, especially an enlarging bowl of subsidence, had been noted, but ignored. Post-event drilling revealed a large elongate solution gallery underlay the crater (Dyni 1986; Hendron and Lenzini 1983; Walters 1978). The cavern paralleled a line of brine-producing wells that were hydraulically connected. Prior to collapse the span of the cavern roof was more than 400 m long and a little less than 90 m wide.

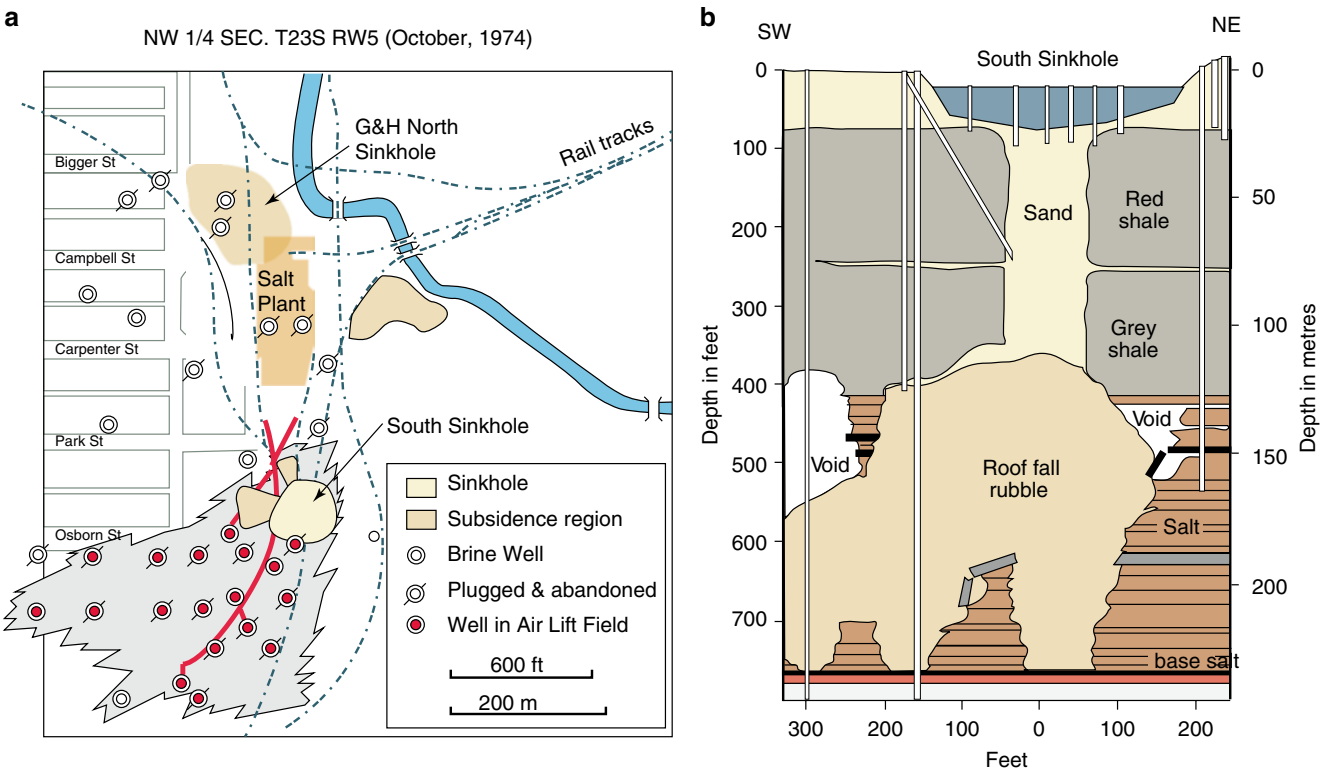

Fig. 13.33 Cargill Salt collapse. (**a**) Plan view of the collapse at the time the South Sinkhole formed in October, 1974. Grey shaded area outlines the approximate extent of the Air Lift brinefield. (**b**). Cross section through South Sinkhole at the Cargill collapse site showing the fused solution voids in the Permian Hutchinson Salt, which led to catastrophic cavern roof collapse (After Walters 1978)

This growing roof span had ultimately exceeded the bridging capacity of overlying Permian shales. Successive overlying rock layers collapsed into the stoping cavity atop the salt, forming an expanding bowl of subsidence at the surface, until the uppermost shale layer finally dropped into the water-filled void. At this point, loose water-saturated Quaternary sands quickly sank into the cavity, creating the surface sink. The sand continued to flow until it filled a subsurface chimney some 30 m in diameter (Fig. 13.33b).

This, and other nearby sinkholes in the Hutchinson region, formed atop breached salt caverns where bedded salt lay at shallow depths in areas with easily broken shaly overburden. As a result of numerous collapses, the State of Kansas now requires caverns created by solution wells to be acoustically monitored and a salt roof of at least 12 m be maintained over captive brine caverns.

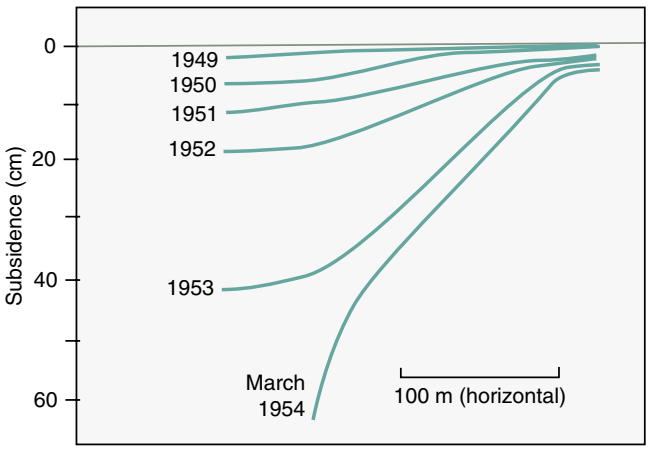

Fig. 13.34 Subsidence profile over the margin of the collapse zone in Windsor, Ontario (After Terzaghi 1971)

Brinefield Subsidence, Windsor, Ontario

Subsidence identified in 1948, followed by collapse in 1954, destroyed a portion of the suprastructure in the brinefield of the Canadian Salt Company near Windsor, Ontario. It was the end result of solution mining of the Silurian Salina salt for a period of 50 years. The first well in the brinefield was drilled in 1902, but intensive exploitation began in 1922, from 1922 to 1953 some 25 wells were drilled. Most were completed in the "Lower Salt" at depths around 480 m (Terzaghi 1971). Wells were typically cased and cemented to depths below the base of the "Middle Salt," between 370 and 390 m. All of the early captive wells circulated water without a blanket, so dissolution tended to be rapid, upward stoping and poorly constrained.

Prior to the 1954 collapse, an area that was some 300 m across had subsided some 40 cm over a period of 5 years. Cracks in several buildings on the site were first noted in 1948 and measurements were then made of the subsidence cone up until the collapse. During the first 2 years of monitoring (1948–1950) maximum subsidence was 6.3 cm (Fig. 13.34). The general trend over the 5 years of monitoring was that the cone of subsidence was becoming increasingly deep at increasing speed. By the fifth year of monitoring the depth of the basin had increased another 23 cm making for a total drop of 40 cm in the landsurface since the beginning of monitoring. The rate of subsidence climaxed on February 19, 1954 with a catastrophic failure when a water-filled depression, some 120–150 m across and up to 7.5 m deep, swallowed much of the surface plant. Prior to the 1954 collapse an estimated 4.25×10^6 m^3 of salt had been dissolved. Contrary to the initial expectations voiced in 1948, collapse was not centred on wells of the brinefield, but beneath the saltworks itself.

The February 19, 1954, collapse event was spectacular, the 9 h it took to pass to completion shows how quickly such events can proceed, once the collapse chimney reaches the land surface. The first signs of a pending collapse were noted between 8 and 9 am with small ground tremors and vibrations. By 10:30 am it was obvious a crater was forming in the centre of the bowl of subsidence, which was visibly sagging. Around midday the crater started to fill with water, first by draining a nearby marsh and later with water from broken pipes. Around 1:15 pm there was a rapid 1 m drop in the ground defining the edge of the crater, accompanied by a 1.2 m high water spout issuing from a crack along part of the crater edge. Throughout the early afternoon other cracks and water jets appeared. The escaping waters were black and smelt of H_2S. By the mid afternoon the collapse had ceased and had constructed a 150 m wide water-filled sinkhole in the middle of a 600 m wide cone of subsidence.

Sinkholes in the Detroit River

Early in 1971 several sinkholes developed in and around Hennepin Point and on nearby Grosse Isle in the brinefield of the BASF Wyandotte Corporation (Landes and Piper 1972). Both sites are located next to the Detroit River, SE Michigan, near Detroit and 10 km downriver from the Windsor collapse site. The sinkholes were the result of 30 years of solution mining of the "Lower Salt" of Silurian Salina Group salts at depths of more than 320 m. Production of brinefield salt at Point Hennepin began in 1943 using unblanketed brine wells. Salt cavities quickly met to form larger cavities. The largest was made up of two galleries called the Northern gallery and Central gallery. Ground subsidence atop this large cavity was first noticed in 1960. The rate of subsidence was constant until the end of 1967. From then it accelerated until the first collapse crater formed above the Northern Gallery on January 9, 1971. Its subsidence history is near identical to the 1954 Windsor site. After a few months of expansion, this first crater stabilized with a diameter of 65 m. In April and May 1971 a second crater then developed above the Central gallery. This crater, some 120 m across and up to 35 m deep, was larger than that above Northern gallery. By May, another companion crater, some 60 m in diameter, had formed next to the larger sinkhole.

The similarity in the geology of the Windsor and the Detroit sites, as well as the rapidity of the collapse, along with the size and steepness of the collapse craters, led Nieto and Russell (1984) to question the upward caving or stoping collapse mechanism of Terzaghi (1971). They argued his notion of steep upward propagation and caving from more than 300–400 m below the surface could not explain the steepness of the three surface craters or their rapid, near catastrophic subsidence. Instead, they proposed a collapse scenario based on loss of cohesion in the Sylvania sandstone layer some distance atop the Silurian salt bed. Their collapse scenario is now accepted for both the Windsor and Point Hennepin events (Fig. 13.35).

Intensive solution leaching of the lower layer of Salina salt, and to a lesser degree the two other salt beds in the Salina Group, formed a basin of subsidence in the overlying strata. At the landsurface this cone of subsidence was initially small and slowly evolved outward. It became unstable when it had attained surface slopes of more than 2 mm/m and a diameter of more than 500 m. As the cone expanded out and up, strata atop the growing cavity salt cavity responded by downwarping elastically into the underlying cavity and then fracturing, but not necessarily collapsing. Downwarping created compressive stresses in the higher part of each cohesively downwarping overburden unit. Expanding joints in the lower part of each unit took up the corresponding tensile stress. Compression increased in the higher part of each layer until it reached its compressional limit, the layer then fractured. Like the adjacent carbonate beams, the Sylvania sandstone bed initially deformed elastically until a rupture, driven by internal compression, formed in the higher part of the bed.

What was different in the collapse-response in the Sylvania layer compared to the limestone beams atop the cavity was its fracture response to compressional stress. When plugs of the Sylvania sandstone were subjected to triaxial compression testing, it was found the plugs failed by pervasive grain rotation, not by fracture (in contrast, plugs of the underlying dolomites all failed by fracture). Instead of a cracked plug at the end of a test, what was left in the stress jacket after a test of Sylvania Sandstone was freeflowing sand grains. In the real world, a network of growing fractures and solution channels in the underlying Bois Blanc and Bass Island formations allowed the disaggregated Sylvania sands to infiltrate into the saltwork galleries. Collapse of overburden into resulting cavities in the Sylvania then followed. The catastrophic collapse of the landsurface was facilitated by expanding shallow cavities in the sandstone, not the deeper cavities in the Salina Salt. A similar pervasive loss of mechanical strength can occur in oil reservoir intervals across zones that were formerly partially-cemented by halite and where significant volumes of hydrocarbons were extracted to be replaced by undersaturated pore waters (pers.obs.).

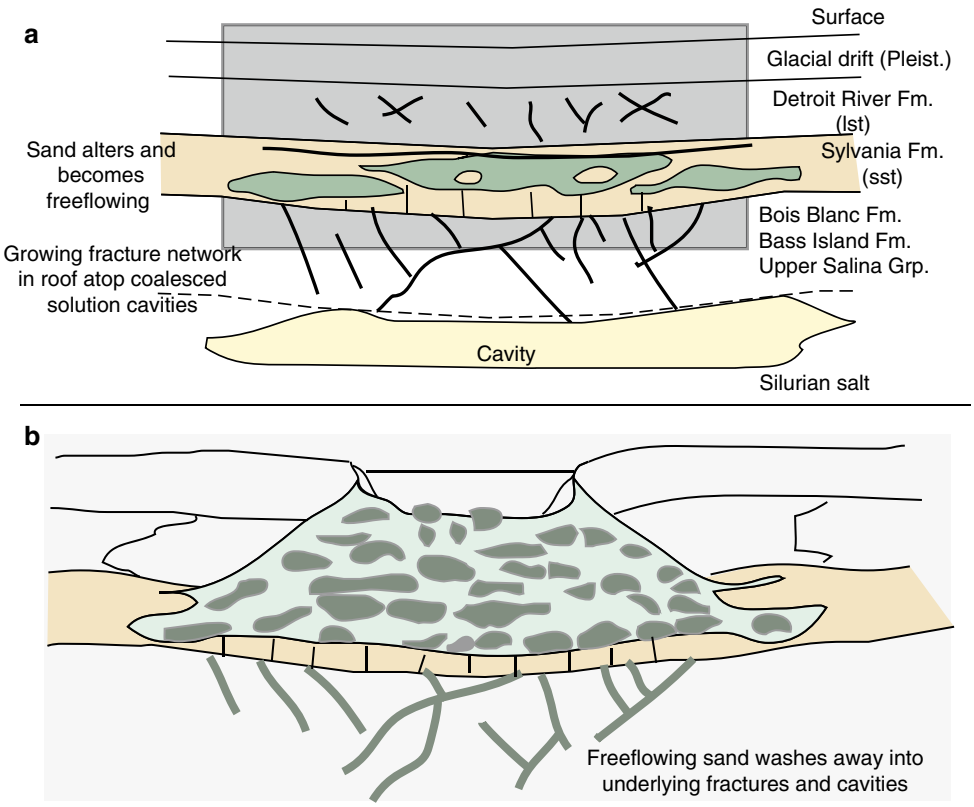

Fig. 13.35 Collapse mechanism for the Windsor and Detroit events. (**a**) A growing cone of subsidence causes fractures in the carbonate overburden and pervasive disaggregation and cavity growth in the Sylvania sandstone. (**b**) Catastrophic collapse of the overburden into cavities in the Sylvania sandstone not into cavities in the Salina salt drives sinkhole formation at the landsurface (in part after Nieto and Russell 1984)

Case Histories: Caving and Leaking Wells

Petroleum-industry activities have unintentionally aided and produced dissolution cavities via exploration, production or brine disposal wells drilled in, or through, subsurface salt units (Table 13.6; Martinez et al. 1998). Ongoing corrosion of access wells to storage caverns, or the continued expansion of caverns as stored product is cycled, can have unexpected and sometimes devastating results. If a storage cavity becomes too large for the roof to be self-supporting, successive roof failures may cause cavities to migrate upward and breach the land surface. Documented surface collapses and sinks, which can be directly related to oil drilling and poor brine disposal practices, tend to involve boreholes drilled long ago, typically in the 1920s to 1950s. This was at a time of different public perceptions of development and long before the application of modern engineering safeguards pertaining to drilling-mud design, casing placement and the use of salt-tolerant cements. It can be more than 30 or 40 years after a well was plugged and abandoned before the problem becomes obvious at the surface. In the future there will be more problems related to old wells that intersected evaporites.

Permian Basin, Ground Stability Problems, Southwest USA

Wink Sink (aka Wink Sink No. 1 sinkhole), located 3 km north of the town of Wink in Winkler County, Texas, formed in early June, 1980, and is centred on an abandoned oil well within the giant Hendrick oilfield (Fig. 13.36). Hendrick 10A had produced oil from 1928 to 1951 and was the foci of the sink crater, while a second nearby operational oil well was plugged and abandoned, soon after the collapse began (Fig. 13.37). Wink Sink No. 1. first formed on June 3, 1980 and within 24 h had expanded to a maximum width of 110 m. Two days later, the maximum depth of the sinkhole was 34 m with a volume estimated at 159,000 m^3 (Johnson 1987, 1989). The collapse was the surface expression of an underlying dissolution cavity that had migrated upward by successive roof failures until it breached the land surface. The instigating cavity had first developed in halite beds of the Permian Salado Formation, some 400 m below (Fig. 13.37).

The location of Wink Sink atop the Guadalupian Capitan Reef trend (pressurised artesian aquifer) places it in a region of natural ongoing dissolution of salt and associated chimneying, which first occurred atop the reef aquifer as early as Salado time (Fig. 7.12). Wink Sink lies in an evaporite karst region where water filled sinkholes as large as, and larger than, Wink Sink are a natural part of the landscape of the Permian Basin (e.g. water-filled sinkholes that make up the various lakes in Bottomless Lakes State Park, New Mexico). Such structures were collapsing long before the arrival of man. Sediments in collapse chimneys in the vicinity of Wink Sink indicate salt-related caving events had occurred at various times from the late Permian, to Triassic, to the Cenozoic (Johnson 1987; Baumgardner et al. 1982). But the natural processes of salt dissolution, cavity growth and resultant chimney collapse were perhaps accelerated by drilling and inappropriate well management practices in the immediate area of the Wink sinkhole centred on the Hendrick 10A well.

Drilling and completion of the Hendrick well 10A during the late 1920s was consistent with standard industry practices of the time (Fig. 13.37a). But in retrospect, several factors and events related to the drilling and ongoing exploitation of the borehole probably contributed to development of a surface sink, centred on the well. These include the probable use of a fresh-water drilling fluid, use of nitroglycerine to straighten the hole, the strong possibility of poor cement jobs that inadequately sealed off the salt beds behind the casing, possible corrosion of casing and cement fretting by salt water, and the removal of some critical casing during the final plugging of the well in 1964.

Poor cement jobs and fractures in cement linings behind the well casing opened a vertical pathway for movement of undersaturated fluid up or down the borehole surrounds (Baumgardner et al. 1982). Surface casing in the well was originally set at a depth of 122 m, approximately at the base of the Santa Rosa fresh-water aquifer. If the casing were set too shallow to seal off the aquifer, or if undersaturated waters were present in some of the siltstone or sandstone beds of the underlying Tecovas Formation, undersaturated waters would have leaked into the borehole surrounds (Fig. 13.37b). Also, the cement job at the base of this surface casing in 1928 was probably not suitable for the subsurface conditions. It was done at a time when salt-tolerant cements were not yet in use. Fracturing of the original cement possibly occurred during later workover, re-entry, and plugging operations. Fractures could have focused water flow from the Santa Rosa into the borehole surrounds at the level of the Salado Salt (Fig. 13.37c).

Baumgardner et al. (1982) pointed out that the absence of cement plugs or cement linings in the Hendrick 10A borehole below a depth of 669 m during the period from 1928 to 1951 would have allowed water to move upward under artesian pressure from the Guadalupian aquifer at the base of the Salado Formation. In my opinion, this is the more likely mechanism driving dissolution as it creates a density inversion in the hydrology that moves fresher waters upward into the salt. Contamination from above requires the less saline (lighter) waters of the Santa Rosa aquifer to displace brine (denser). Casing in the well may have also been perforated by corrosion. In addition the pumping of large amounts of saline water between 1928 and 1951, when it was used as a brine well, would have caused a substantial crossflow of undersaturated water and aided further corrosion of the casing (Hendrick Field brines ranged from 5,000 to 48,000 ppm dissolved solids; Johnson 1987).

Table 13.6 Events associated with oil wells or storage

Location	Timing and size	Explanations and implications	Reference
Haoud Berkaoui oilfield, near Ouarlaga, Algeria	In October 1986 a crater 200 m in diameter, 75 m deep formed. It has expanded until now, when the cavity is more than 230 by 600 m across. Its outward progression is still continuing at a rate of 1 m per year (denoted by environmentalists to be the "largest anthropogenic sinkhole in the world").	In 1978, an oil exploration well with a 2,500 m Ordovician target was abandoned because of stability problems in Triassic salt at a depth around 650 m. The well was abandoned without casing near the bottom of the well. A second well was drilled in 1979 located 80 m from the previous well. In March 1981, the lining of this well broke because of cavity formation at around 550 m, which is the level of salt. In October 1986 a surface crater formed, centred on these two wells. Dissolving salt may be salinising the crossflowing artesian waters, leading to undocumented, but possible, degradation of freshwater oases in the region.	Morisseau (2000)
Wink Sink, Texas, and Whitten Ranch Sink, New Mexico	On June 3, 1980 the Wink Sink formed a 110 m wide and 34 m deep collapse crater. It was centred on the Hendrick 10 A well in the Hendrick oil field. Whitten Ranch Sinkhole or collapse crater formed sometime between August 31 and September 5, 1998 and was up to 23 m wide and 33 m deep.	It appears likely that the natural processes of salt dissolution, cavity growth and resultant chimney collapse atop the Permian Capitan reef were accelerated by oil drilling and extraction activity in the immediate area of the sinkholes in the early part of last century. Large water filled sinkholes (as in the "Bottomless Lakes" of New Mexico) are a natural part of the landscape in the region and were collapsing long before the arrival of man.	Baumgardner et al. (1982), Powers (2000), Johnson (2001)
Panning Sink, Kansas	It formed in April 1959 with a diameter of 90 m and had a water surface more than 18 m below the sinkhole lip.	Formed by subsidence and collapse around an already tilted and abandoned salt-water-disposal (SWD) well – Panning 11A.	Walters (1978, 1991)
Lake Peigneur, Jefferson Island Louisiana	On November 20, 1980, Lake Peigneur disappeared in hours as it drained into an underlying salt mine cavern. Within hours, a collapse sink-hole 0.91 km^2 in area developed in the SE portion of the lake and in 12 h the underlying mine had flooded, some 2 days later the lake had refilled with water.	An oil well being drilled from barges and platforms in lake intersected an abandoned part of an active salt mine in the salt dome that underlies the lake. Water from the lake and the intervening natural collapse features entered the mine workings. Peigneur Lake itself is a natural dissolution depression.	Autin (2002), Thoms and Gehle (2000b), Thoms and Gehle (1994)
Sinkhole atop Weeks Island, storage facility, Louisiana	An active sinkhole some 10 m across and 10 m deep, first noted near the edge of the SPR facility in May 1992. A second, much smaller sinkhole was noticed early February 1995, but it lay outside the area of cavern storage.	The sinkhole led to the decision to drain the facility of its hydrocarbons. Drainage and remediation was completed in 1999 at a cost of US $100 million. This facility was not purpose built, but was an old salt dome mine facility. In hindsight, based on an earlier event, one might fault the initial DOE decision to select this mine for oil storage. A groundwater leak in the mine in 1978 may have been a forewarning of events to come. Injection of cement grout into the flow path controlled the leak at that time, but it could just as easily have become uncontrollable and formed a sinkhole.	Neal and Meyers (1995), Bauer et al. (2000)
Mont Belvieu sinkhole, Texas	July 30, 1993 a sinkhole crater formed between two brine storage wells. The crater stabilized in a few hours with a diameter of 12 m and a depth of 6 m. It was filled with sand a few days later.	Large volumes of brine are periodically cycled in and out of the brine cavern in the caprock. It is used to drive the withdrawal of the stored hydrocarbons in other deeper storage caverns. Using a system that stores saline brine in a caprock, even without the possibility of the collapse of a brine well, means there is a possibility of groundwater contamination from leaked storage brines.	Cartwright et al. (2000)

See text for full description of these and other sinkholes

Fig. 13.36 Sinkhole breakouts in the Wink sinks, Permian Basin, West Texas. Wink Sink No 1 reached the landsurface in 1980, No. 2 in 2002 (Bing® image mounted in MapInfo® software)

Wink Sink No. 1, which broke through to the surface in 1980 was largely inactive for the next 20 years, but in May, 2002 a new sinkhole formed less than 2 km south of Wink Sink No. 1. It was named Wink Sink No. 2 and was significantly larger than its predecessor, with a maximum width of 238 m and an estimated total volume of 1.3 million cubic meters (Fig. 13.36). It developed some 400 m west of a number of existing natural dolines and caprock collapse sinkholes. Both Wink #1 and #2 sinkholes are assumed to have formed by dissolution of salt beds in the Upper Permian Salado Formation.

The problem of rapid wellhead collapse and sinkhole formation continues throughout many areas of New Mexico and Texas typified by shallow Permian salt and poorly monitored brine solution cavities (Land 2013). For example, around 8:15 on the morning of July 16th, 2008, a driver for Jim's Water Service, a local oil field service company based in Carlsbad, NM, was inspecting a brine well (BW-005) located on state trust land, near Artesia, some 35 km northeast of Carlsbad. While on location, the driver noticed a significant amount of dust in the air in the vicinity of the well, he then heard a rumbling noise and saw a large ground crack propagating toward him. He quickly vacated the site. Minutes later, a large sinkhole (now known as the JWS sinkhole) abruptly formed, engulfing the brine well and associated infrastructure (Fig. 13.38).

The well operator had been solution mining the Salado Formation by injecting fresh water and circulating it through the 86 m thick section of halite until the water reached saturation. The resulting brine was then sold as oil field drilling fluid. BW-005 was originally drilled as an oil and gas exploration and production well in 1955 with cable tools to a total depth of 1,191 m (3,909 ft). The well was plugged and abandoned in 1955. The well was reentered and recompleted as a brine well in 1978. The Salado Formation was encountered at approximately 121 m (397 ft) below ground surface (BGS). BW-005 was operated as a single well system with a single tubing configuration using direct circulation until 1986, when it was switched to reverse circulation (Fig. 13.3). No sonar surveys were ever run to map the cavern. Based on incomplete production data, the New Mexico Oil Conservation Division (NMOCD) estimated that the total brine production at BW-005 was approximately 8 million barrels and that the cavern volume was approximately 1.3 million barrels.

Initially, JWS sinkhole, was several tens of meters in diameter and filled with water to a depth of ~12 m below land surface (Land 2013). Large concentric fractures developed around the perimeter of the sink, threatening the integrity of County Road 217, some 100 m away (Fig. 13.38). By July 24 the originally vertical walls of the sinkhole had begun to collapse, and the sink continued to grow in diameter over the course of the next 2 weeks. By July 28, the walls of the sink had developed an angle of about 45° to within ~10 m below ground level, above which the sides of the sink were vertical, and the water originally visible in the base of the cavity had subsided into the subsurface. As there are no significant sources of groundwater at shallow depths in the immediate vicinity of the JWS sink, the water is assumed to have been solution mining fluid that was forced up the stoping debris chimney in the initial stages of collapse. The same water is now stored in pore spaces of the resulting collapse breccia, and in shallower porous zones of the overlying Rustler and Dewey Lake Formations. By end July, the sinkhole had attained a diameter of ~111 m and a maximum depth of ~45 m. It has since been filled by the operator.

On November 3, 2008, less than 4 months after the JWS collapse, another brine well-centred sinkhole broke out at the surface north of the small community of Loco Hills, in northern Eddy County, New Mexico. Centred on the Loco Hills Water Disposal Service (BW-021) brine well, it formed a sinkhole of similar dimensions to the JWS doline, it is now

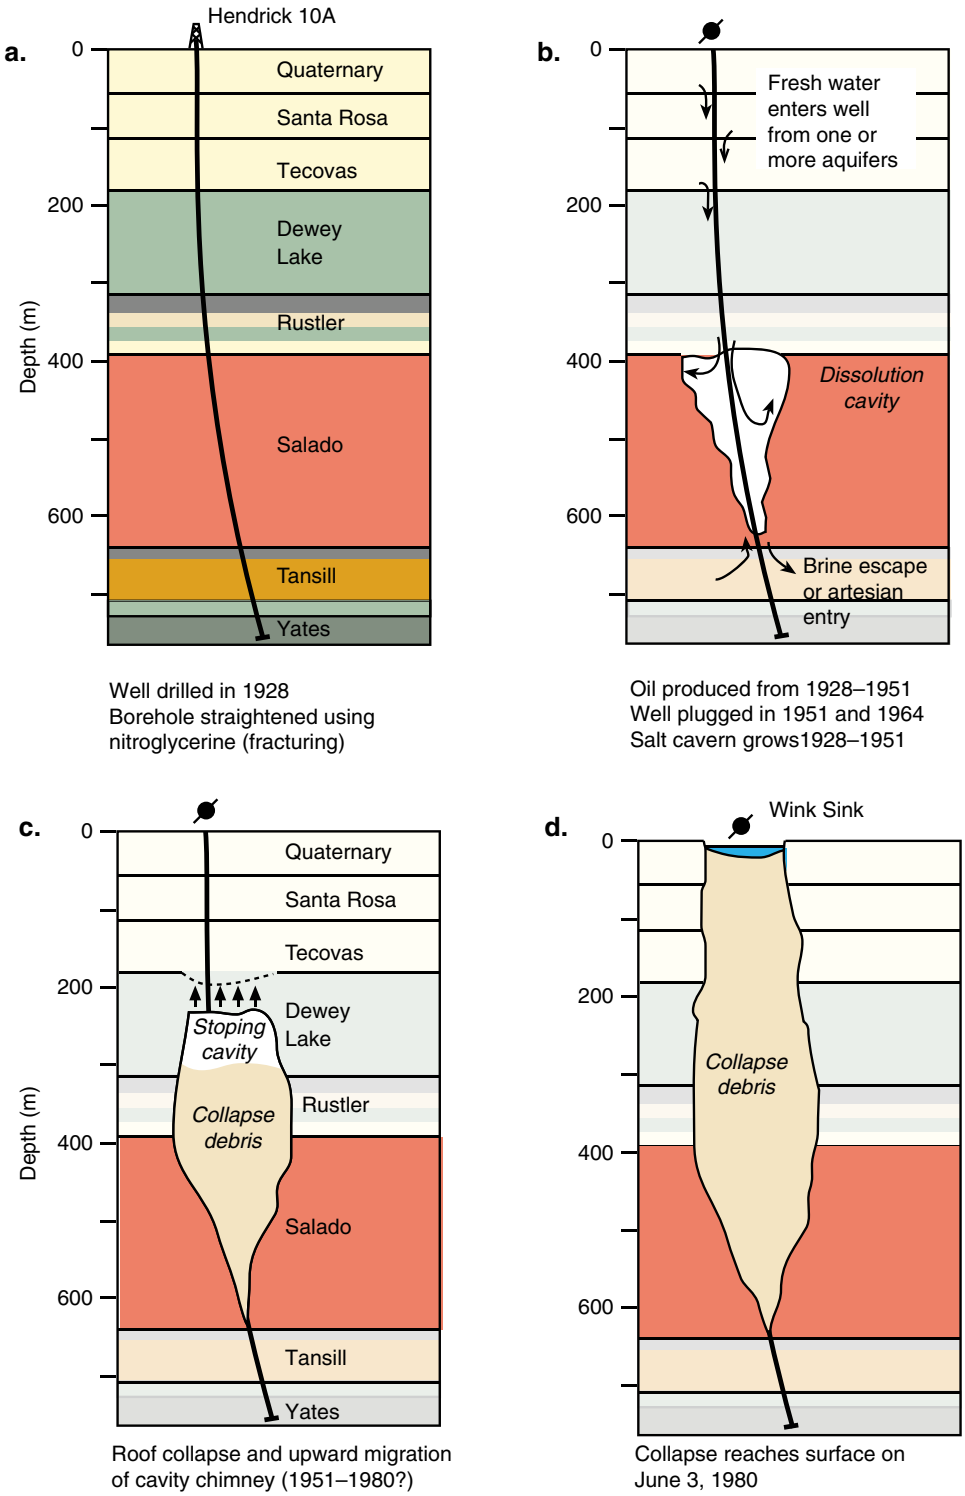

Fig. 13.37 East–west section through Hendrick well 10-A in Wink Sink, West Texas (After Johnson 1987). Undersaturated meteoric and artesian water circulated along borehole margins to dissolve the salt and create a salt cavern, which migrated to the land surface by successive roof failures ("chimneying"). See text for detailed discussion of stages (**a**–**d**). See Fig. 7.12 for location of the Wink Sink

back-filled. The BW-021 well was originally drilled as an oil and gas exploration and production well and was converted into a brine production well approximately 25 years ago. It was operated as a single well system with a single tubing configuration using reverse circulation. The casing shoe was set at 126 m (415 ft) BGS above the salt, which occurs at 143 m (470 ft) BGS. (It is not clear whether the exploited salt was part of the Rustler or Salado Formation, or both). The production tubing was set at 274 m (900 ft) BGS. The last sonar log of the well was completed on February 7, 2001. Based on incomplete production information, NMOCD estimates that the total brine production at BW-021 was

approximately eight million barrels and that the cavern volume was approximately 750,000 barrels.

BW-021 was plugged and abandoned at the time of the collapse and was being visually monitored for subsidence.

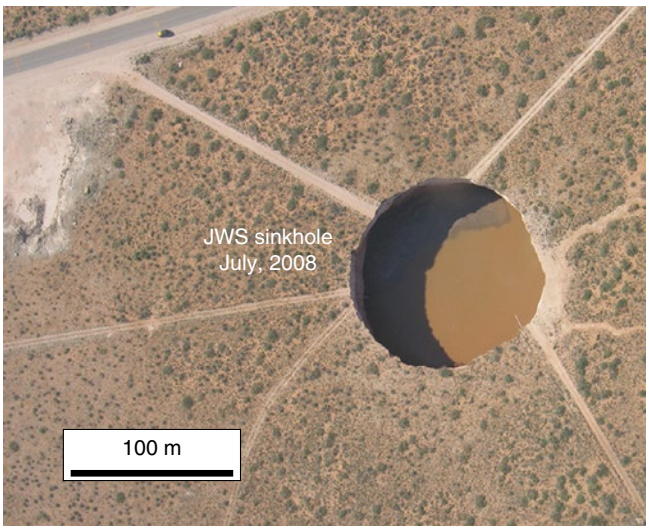

Fig. 13.38 JWS collapse doline, New Mexico, soon after collapse when solution brines are still visible in base of collapse. Bing® image mounted and scaled in MapInfo®

NMOCD had ordered the operator to plug and abandon the well. The well had failed an formation integrity test on June 18, 2008, as part of a statewide review of brine wells conducted in the aftermath of the JWS collapse. The well had previously passed a 5-year MIT of the casing in 2006 (Land 2012, 2013).

Like the JWS collapse, the Loco Hills sinkhole was likely a result of overly aggressive solution mining of the Salado Formation using unblanketed circulation methods. Then in July, 2009, another sinkhole abruptly formed near Denver City, Texas, ~115 km east of Loco Hills. The Denver City sinkhole was also the product of a solution mining operation.

During a well review program across New Mexico, instigated by the JWS sinkhole, the I & W brine well facility was identified within the city limits of Carlsbad as a potential problem, it had a similar geologic setting and pumping history to the already collapsed JWS and Loco well heads (Fig. 13.39a). The I & W brine facility originally involved two wells, which conducted solution mining of the Salado Formation almost continuously since 1979. Eugenie #1 well was drilled first with the intent of being a single-well brine producer. However, after a short period of poor production, Eugenie #2 was drilled approximately 100 m to the north-

(**b**) Subsidence monitoring at the TRail site from January 2009 to early 2012

west as a freshwater injection well. The two wells were connected by hydraulic fracturing, and brine was produced from Eugenie #1. After June 2000, Eugenie #2 was shut in, and solution mining was conducted as a single-well operation through Eugenie #1, wherein freshwater was injected through the annulus and brine withdrawn through suspended tubing (Goodman et al. 2009). This is the ideal set-up to created poorly controlled upward stoping "morning glory" cavities (Fig. 13.3).

Unlike the JWS and Loco Hills sinkholes, which are located in relatively remote areas in northern Eddy County, the I&W operation is sited in a more densely populated area within the city of Carlsbad, near the BN&SF rail line and the intersection of two major highways known as the "South Y." The Carlsbad Irrigation District (CID) South Canal is approximately 50 m south of the Eugenie #1 wellhead, and the immediate area also includes a feed store, truck stop, mobile home park, and Jehovah's Witness church (Fig. 13.39a). A catastrophic collapse in this area would inflict extensive damage to individual property and civic infrastructure. Following the collapse of the JWS sinkhole, the New Mexico Oil Conservation Division ordered closure of the I&W brine well and initiated site characterization, which has determined the likely presence of a significant solution cavity beneath the region. As yet, possible still-rising solution cavities have not surfaced or created any damage to the town's infrastructure, but ongoing ground monitoring and emergency procedures are now in place (Fig. 13.39b).

Market value of brine is relatively low, but is a steady source of income in an oilfield region, when nearby wells are being drilled. In New Mexico, extracted brine typically sells for less than two dollars per barrel and monthly statewide brine production in 2011 in New Mexico exceeded 200,000 barrels per month. Brine extraction operations there have almost exclusively been owned and run by trucking companies. Oversight of brine wells by the Oil Conservation Division was accomplished under provisions of the federal Underground Injection Control program and the New Mexico Water Quality Control Commission regulations. Both these enforcement mechanisms are primarily concerned with the protection of groundwater quality, not cavern monitoring. In the "reverse" circulation method, fresh water is injected down the annulus and the brine is extracted through the tubing. The reverse circulation method was rationalised as more protective of any fresh water zones above the Salado Formation because in the event of a casing leak, fresh water would leak into the fresh water zone rather than brine. However, as mentioned earlier, in imperfectly monitored situations, this is the ideal set-up to created poorly-controlled upward-stoping "morning glory" cavities.

It is not just oil and gas related wells in New Mexico that can facilitate ground stability problems in areas of shallow evaporite karst. Water wells can also focus the formation of sinkholes. Powers (2000) argues it was an improper casing seal in an artesian water well that focused rising waters and instigated the Jal collapse doline, New Mexico. This was the Skelly Jal Water System #2 well, which penetrated the Salado Formation to access the pressurised Capitan Reef aquifer at around 100 m. It was the centre to the Jal sinkhole (aka Whitten ranch Sinkhole), which was some 25 m across and located 13 km north-northwest of the township of Jal. Local ranchers Jimmy and Linda O'Rear noticed a small surface opening on August 31, 1998, at the site of the collapse. On the morning of September 5, they discovered the full-sized sinkhole (Fig. 13.40).

Clearly drilling, completion, plugging and brine extraction procedures in the Permian Basin can combine to create borehole-focused conduits that enable fresh water to better circulate in the vicinity of the well and so dissolve salt. This is

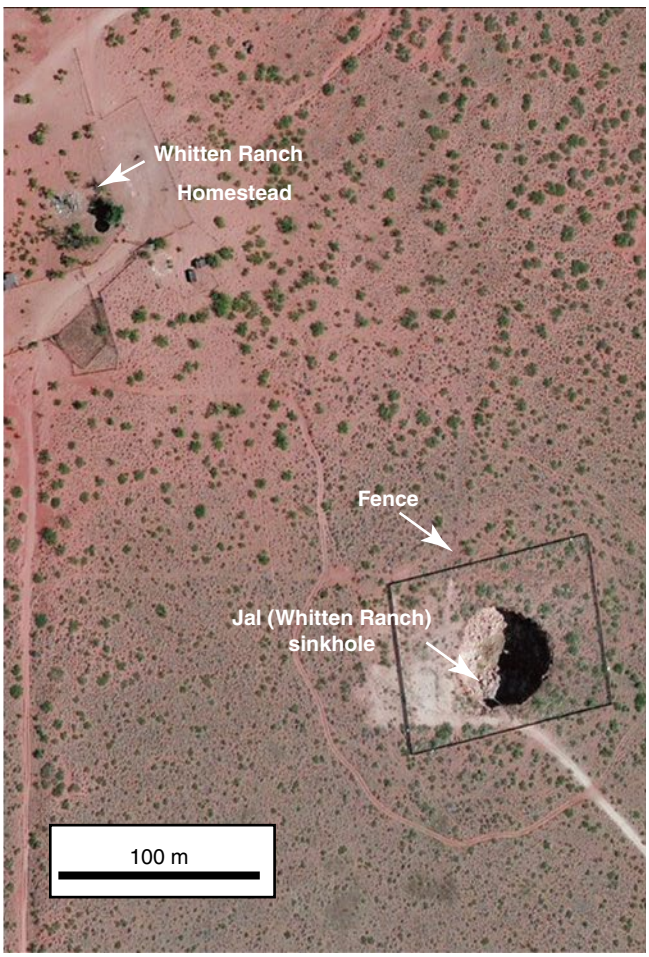

Fig. 13.40 Jal (Whitten Ranch), New Mexico, sinkhole reached the landsurface in 2008 (Bing® image mounted in MapInfo® software)

especially so in unmonitored and poorly regulated brine extraction scenarios without suitable geological overview. The potential for surface collapse is greater in hydrological settings of subsalt pressurised (artesian) aquifers. When an expanding dissolution cavity is large enough, the roof fails and overlying strata collapse, often catastrophically into the cavity. The collapses in Texas and New Mexico underline the importance of having legislation in place that defines and enforces appropriate well design specifications, reliably monitors solution cavity maintenance during well life, and emphasizes the need for adequate plugging and abandonment procedures, specifically designed for wells passing through salt intervals.

Panning Sink, Barton County, Kansas

Panning Sink on the Panning Lease reached the surface on April 24, 1959 in an area of subsidence and collapse, centred on an already tilted and abandoned salt-water-disposal well (Fig. 13.41). The Panning 11A well had been abandoned in the previous January because of uncontrolled well-head tilting. Walters (1978) reported that the 90-m-wide water-filled sinkhole formed in about 12 h, with a water surface more than 18 m below the lip of the sinkhole. Four days later the diameter of the sinkhole had not increased, but the water surface was only 3.5 m below the crater edge.

The suspect well, originally drilled as an oil producer in 1938, penetrated 91 m of Permian Hutchinson salt at a depth of 298 m on its way to the Arbuckle Group reservoir. Freshwater drilling fluids used in drilling the well dissolved the salt in the borehole to an excessive diameter (≈1.4 m) and this washed-out zone was not cemented behind the 15.2-centimeter-diameter casing. Conversion of the borehole to an salt-water-disposal well from 1946 to 1958 injected a large quantity (≈1.6 × 10^6 m^3) of unsaturated oilfield brines (with a total concentration around 28,000 ppm) into the well and so further dissolved the salt behind the well casing. Disposal was supposedly into the Arbuckle Group dolomite at a depth of 995 m. In 1949, the tubing was removed, and water was injected directly down the 15.2 cm casing. Ongoing exposure to this undersaturated brine formed a large cavern, and with successive roof falls as the void migrated upward to ultimately cause the surface crater.

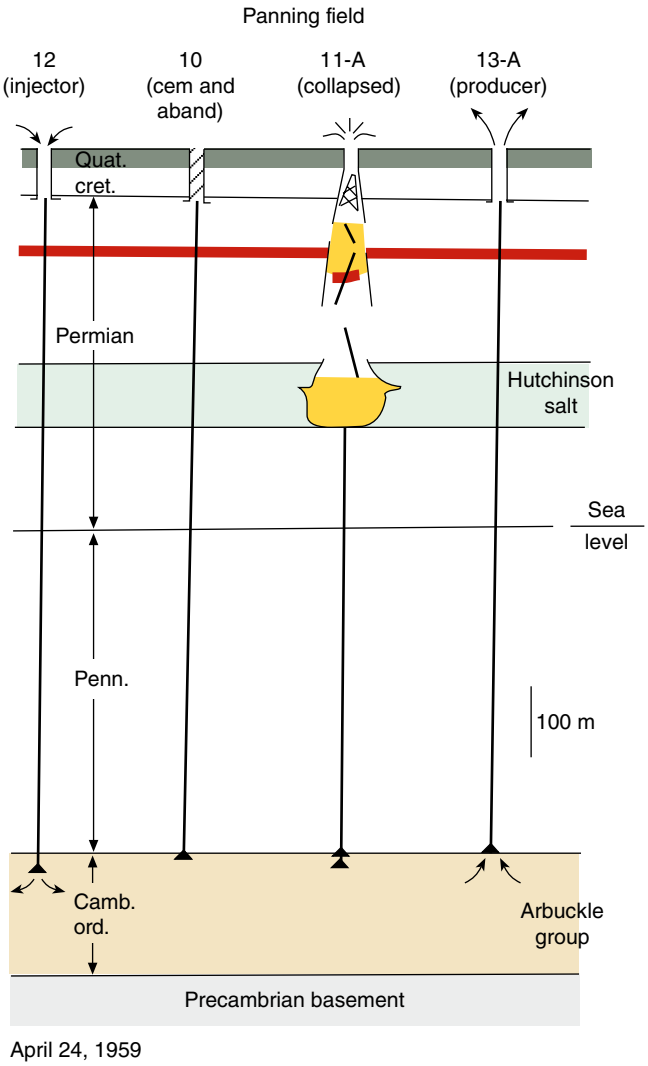

Fig. 13.41 Schematic cross section through Panning Field, Kansas, showing the situation on April 24, 1959 (After Johnson 2001; Walters 1978)

Gorham oil Field and I-70, Russell County, Kansas

Gorham oil field, a former giant field in Russell County, Kansas, is the site of slow subsidence of a major highway (Interstate 70) above salt-dissolution zones in the Permian Hutchinson salt (Fig. 13.42a; Croxton 2003; Walters 1991; Knapp et al. 1989). A series of oil wells, drilled on four-hectare spacing in the 1920s through the 1940s, penetrated 75 m of salt at a depth of 390 m (Fig. 13.42b). Gorham field produced more than 100 million barrels and the wells are now plugged and abandoned. Corroded casing has been left in some of the boreholes at depths above, within, and below the salt unit. As a result of what appears to be improper plugging of these abandoned oil wells, unsaturated water probably has flowed down some of the boreholes and has dissolved large volumes of the salt. Subsidence was further aided by disposal of waste oilfield brines that were re-injected when unsaturated with respect to halite.

Initial studies of the area (before road construction) did not reveal subsidence along the proposed alignment of 1–70 through the Gorham oil field, and final grading for the new highway was completed in 1966 (Fig. 13.42; Croxton 2003). Subsidence of 1–70 pavement subsequently occurred at several sites along the highway, with principal sites being the Witt sink and the Crawford sink (located some 5–6 km east of the town of Gorham). Subsidence had occurred at rates of 10–15 cm/year, and by 1971, the lanes had dropped so much that they had to be

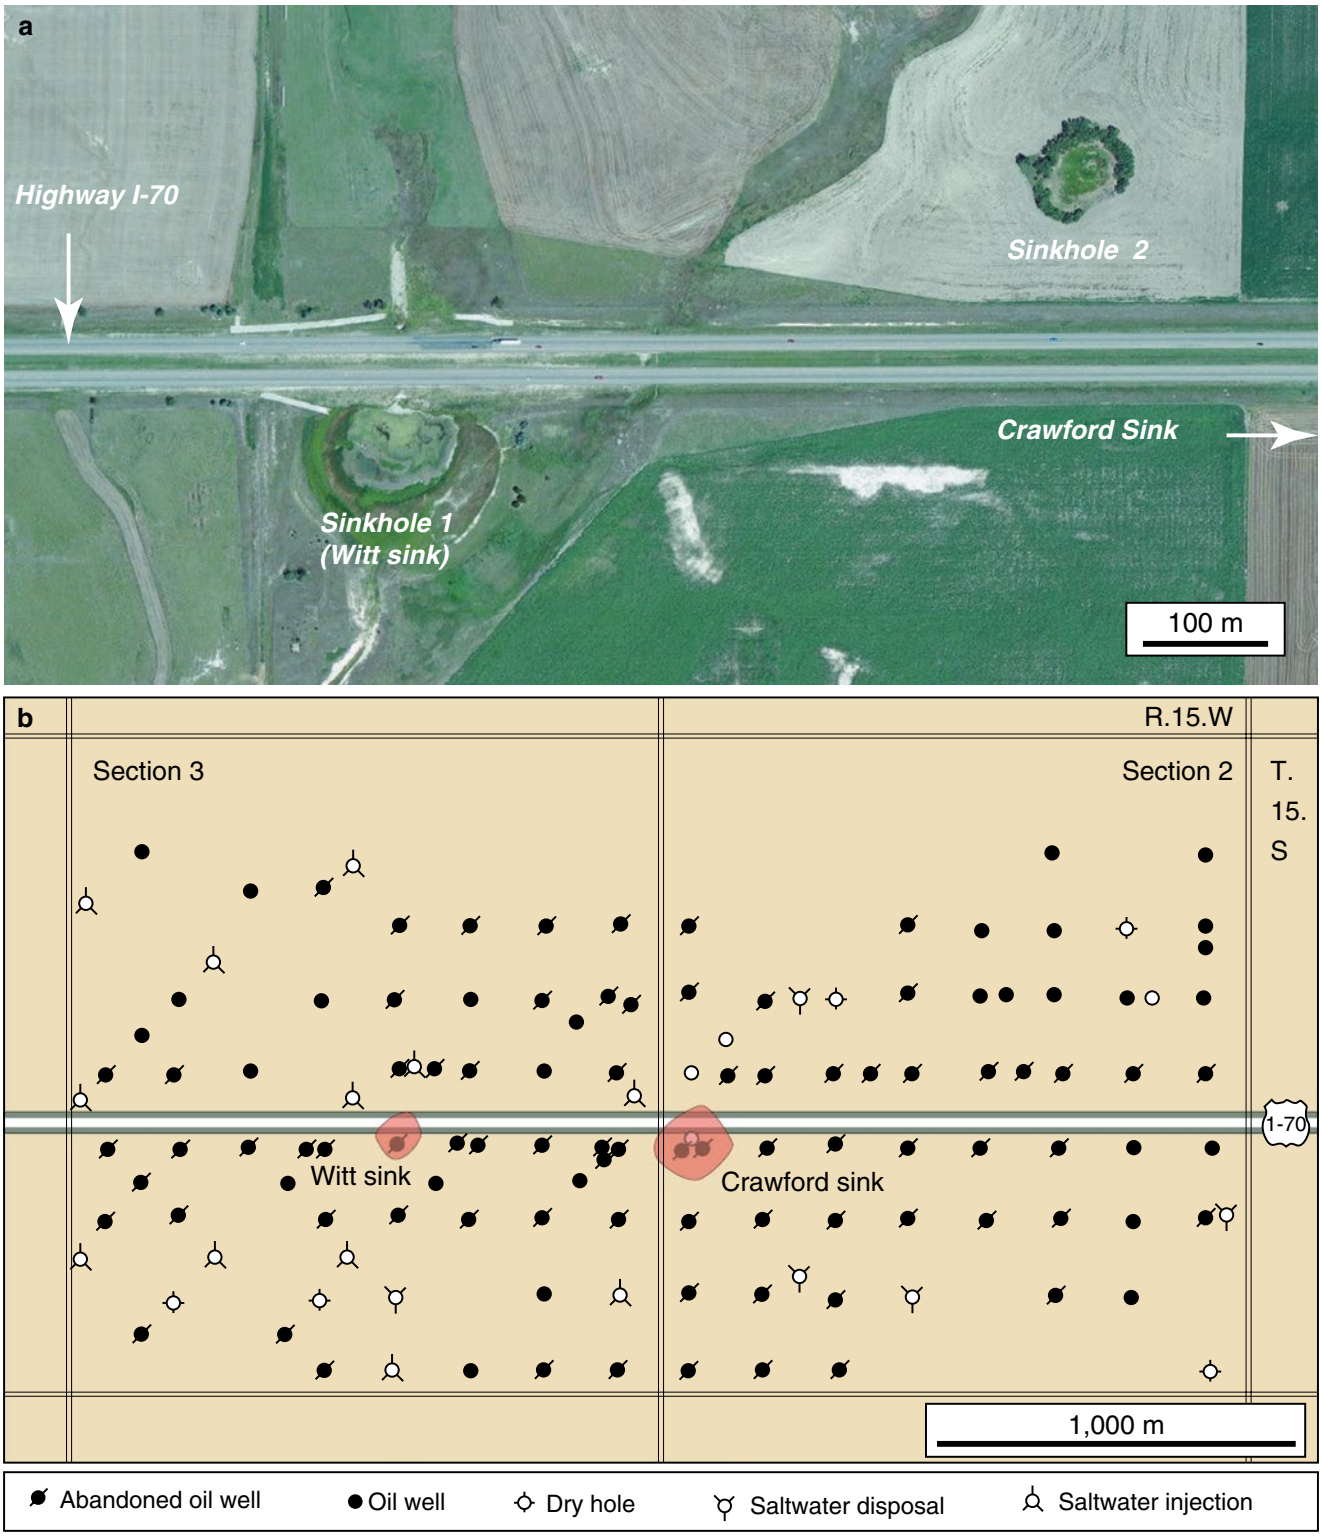

Fig. 13.42 I-70 sinkholes east of Gorham city. (**a**) Sinkholes in a cone of subsidence defined by where Witt Sink intersects Interstate-70 (scaled Bing® image mounted in MapInfo® software). (**b**) Distribution of Gorham and Witt sinks with respect to the various wells of the now depleted Gorham oilfield, some 6 km east of Gorham, Kansas (in part after Knapp et al. 1989)

regraded; paving was raised by some 1.5 m at both sinks, at a cost of US$220,000. By 1984, the lanes at the Witt sink had again subsided nearly 2.5 m and a line-of-sight problem arose because cars down in the sink could not be seen by oncoming traffic. Witt sink was again regraded and repaved in 1986 at a cost of nearly US$500,000.

Further attempts to remedy the problem were carried out in 1986 and 1988 when a borehole was drilled adjacent to the abandoned oil well thought to be the cause of the Witt sink. Cement with additives was injected into the well to try to plug the old well at the base of the salt. Although the plugging appeared to stop the settling for about 6 months, subsidence then resumed at a rate of 12–15 cm/year. Present plans call for continuing to regrade the lanes of 1–70, as needed, because an economical solution to the subsidence problem has not been found (Croxton 2003).

The highway in the vicinity of the Witt sink can be regraded as many times as necessary. The highway in the vicinity of Crawford sink is a different matter as it is located near where a local road passes over the interstate, via a road bridge. This section of highway cannot be successively regraded because of clearance and line-of-sight requirements under the nearby bridge. The bridge is sinking, too; one end has dropped over 6 ft since it was built in 1965. At the south abutment, the east curb is now 2 ft higher than the west curb. Yet, about the only indication that the bridge is under any stress at all are narrow cracks in the curbs just over the piers. Something will eventually have to be re-engineered at the Crawford sink site. This will probably happen when the bridge finally subsides enough to become a sight distance problem for traffic on I-70, or water will begin to cover the highway during storms.

In a geophysical study of this, and other areas of Kansas subject to salt-related subsidence, Knapp et al. (1989) note that poor well completion and disposal practices tend to exacerbate a natural set of subsidence problems that predate human settlement, let alone the activities of the oil industry.[5]

[5]On completion of this section of highway, and the subsidence that followed, the press and the locals were quick to blame the subsidence on the oil industry and poor drilling practice, with subsequent questions as to the competency of the engineering studies done prior to highway construction. When geology crews began their preliminary studies for this section of 1–70 in the early 1960s, there was a large pond along the right-of-way, some six miles west of Russell. They noticed that the pond appeared rather deep, and although it was situated in a streambed, apparently it had no dam. Asking around among local residents, Highway Commission geologists were told that the pond had always been there. An 83-year-old woman who had lived in the area all of her life reported that there had been a pond in that location ever since she could remember (pre-oilfield!). So little additional planning as to its origin was given. During construction, the Crawford and Witt sinks were filled in and the highway was built, along with a nearby bridge to carry county traffic over the interstate. Final grading for the new lanes was finished in the spring of 1966 and the subsidence problems began.

Despite these and other salt-related problems, incidents of rapid dissolution induced subsidence atop wells drilled through the Hutchison (Wellington) Salt and equivalents are rare events. In Kansas the ratio of wells intersecting salt and being associated with at-surface subsidence is something like 1:10,000 (Walters 1978, 1991).

Sinkholes at Bayou Corne (2012) and Bayou Choctaw (1954) Domes, Louisiana

In spring 2012, residents of a rural community near Bayou Corne in Louisiana's Assumption Parish noticed gas bubbles rising to the surface in some bayous. Shortly thereafter, a series of small earthquakes shook the area, prompting state officials to investigate. In early August 2012, a sinkhole, some 110 m across, surfaced adjacent to in the property of the Texas Brine Company, which operates the surrounding brine extraction (solution mining) facility (Fig. 13.43). On August 3, 2012, Louisiana Governor Bobby Jindal declared a statewide emergency, and local officials in Assumption County ordered the mandatory evacuation of about 300 residents from more than 150 homes located about a half-mile from the sinkhole. The sinkhole is unusual in that the salt breach has occurred on the sidewall of the intradome solution cavity, not the typical sinkhole position above a solution cavity (Jones and Blom 2014).

The cause of the sinkhole is likely related to uncontrolled stoping or a wall breach in one of two Texas Brine LLC's storage caverns, located near the edge the Napoleonville Salt Dome. The top of the dome is some 210 m below the surface. Much of the attention has been focused on the Oxy Geismar Well No 3, and associated solution cavity, as being the likely facilitator of the collapse (Jones and Blom 2014; Nunn 2013). The Oxy Geismar Well No. 3 was first permitted on April 15, 1982 for the mining of salt water brine from the Napoleonville Salt Dome. A 2007 sonar survey indicated the top of cavern was around 1,031 m, the base of cavern around 1,707 m with a cavern diameter of more than 61 m.

In early September 2010, Texas Brine began reworking the cavern well, milling a section of salt higher than the existing cavern roof, then at 1,036 m, to test if the upper strata could be solution mined and so expand the storage capacity. A Louisiana Department of Natural Resources (LDNR) permit for that work was issued in May 2010. In 2011, the well failed a pressure test implying that the integrity of the well had been lost. It has since been interpreted that the solution cavity was likely in a previously unrecognised salt overhang. Texas Brine LLC sent a letter to LDNR

Once again it seems Hutchison Salt in the Gorham region likely was dissolving naturally with a typical landscape sink expression. If word of mouth recollection was correct, then sinks were present in the area prior to both the oil field and highway construction. Then again, as all lawyers know, it is hard to sue mother nature.

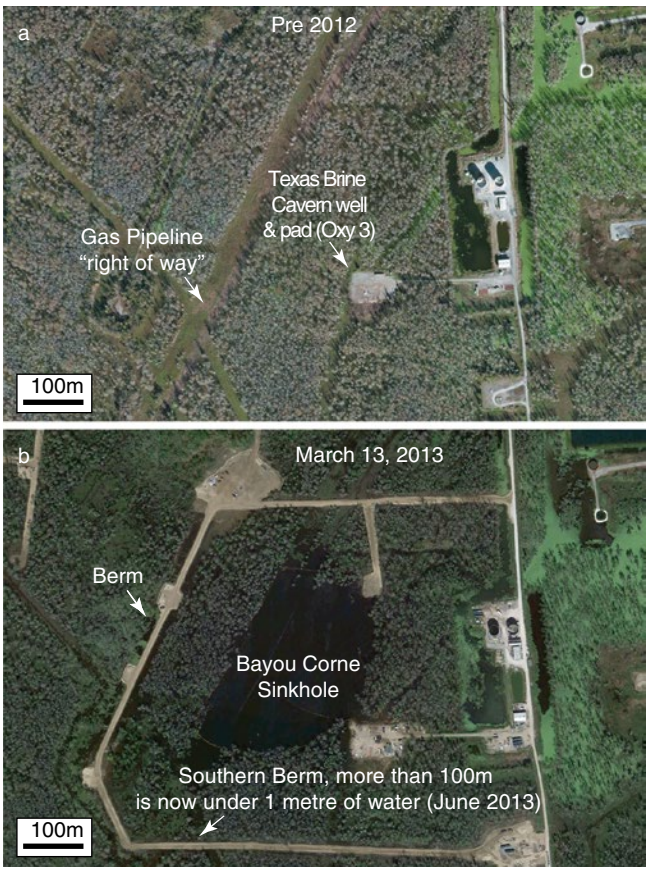

Fig. 13.43 Zone of subsidence and collapse in water saturated Bayou Corne region, Louisiana. (**a**) Situation pre the sinkhole breaching the surface. (**b**) Situation on and after March 13, 2013 (Bing® base images mounted and scaled using MapInfo® software)

reporting the failed test and expressing concern over the possibility that "a breach out of the salt dome appears possible." On June 6, 2011, the well bore above the cavern was plugged with cement.

On August 13, 2012 the LDNR-Injection and Mining Division approved Texas Brine LLC's permit to drill a new well into the company's abandoned brine cavern in order to determine the structural status of the cavern and what pressures, gas or brine it contained. Sonar, run on September 24, confirmed that the cavern floor was at 1,220 m, some 400 m above the depth recorded prior to the closure of the cavern in 2011. On September 24, 2012, Texas Brine LLC issued a statement claiming that regional seismic activity had caused the cavern failure. On September 25, USGS consensus was that the seismic activity detected in the area was a consequence of the cavern collapse, not the cause of the collapse and the formation of the sinkhole/slurry area.

As of early 2015, the sinkhole is still actively subsiding and expanding (Fig. 13.43). On June 4, 2013 a 100 m long portion of a berm, constructed to help retain sinkhole waters, slipped into the sinkhole. Earlier an excavator platform was swallowed by the expanding sinkhole. In May 2013, the deepest part of the sinkhole collapse cone was some 53 m deep. The lawyers have yet to have their day in court, nor has the scientific work been completed on cause of the collapse, so a fact-based final understanding of the sinkhole, and how much the driving force for the at-surface cavity was anthropogenic versus enhanced natural, has yet to be finalised. It does appear that seismic monitoring and geological assessment lacked some finesse and the remilling of Oxy 3 was perhaps more driven by profit than any forward looking technical understanding (Newsweek, 20 Dec., 2013) Unfortunately, this brine extraction facility has drawn into question the integrity of the much larger Napoleonville storage cavern region. Once again, we see what can happen when a solution cavity (or a drive in a mine) is allowed to approach the edge of a salt mass.

In January 1954, there was a similar collapse when the "No. 7 brine well" atop the Bayou Choctaw salt dome, Louisiana, collapsed during brine production, probably because of loss of its salt roof atop a growing solution cavern. It is one of the few caverns in domal salt that has failed completely and catastrophically and, along with Lake Peigneur, its documented collapse is one of the most dramatic. In 1954, it occurred at a time before sonar monitoring and controlled brining, when landscape damage was an expected consequence of solution mining.

Immediately prior to its collapse the cavern generated by Brine Well No. 7, Choctaw Bayou, had no salt roof and a "morning glory" dissolution cavity had leached upward through the caprock, allowing the overburden to collapse directly into the cavern. It didn't take more than about a day for a water-filled 240 m (800 ft) diameter collapse doline/sinkhole to form. A rig that was producing brine at the time fell into the collapsing depression and was never seen again. (Stanczuk, et al. 1976; Neal et al. 1993). Today it is still a circular structure, filled with bayou water, and known as Cavern Lake. It defines the northeastern corner of the area occupied by the facilities of the Choctaw Bayou Strategic Petroleum Reserve (Fig. 13.44).

Grand Saline Sinkhole, Texas

On April 26, 1976 the Grand Saline sink emerged at the surface within the city of Grand Saline, Texas (Dunrud and Nevins 1981). The sink occurred at the site of a former brine well, which had penetrated the top of the Grand Saline salt dome at a depth of 60 m, and had produced brine from 1924 through 1949. The salt is overlain by some 50 m of Eocene claystones and 10 m of unconsolidated Quaternary silt and clay. Failure occurred in two stages. First a sinkhole 4–6 m in diameter and more 15 m deep opened at 24 Tremont Street. Second, the hole rapidly widened as rim slabs toppled in and in a few hours the collapse reached an at-surface diameter of 15 m. The sink displaced a total volume of 8,500 m^3 of silt and clay into the underground cavity. A house was

Fig. 13.44 A zone of subsidence and collapse occupies the crest of Bayou Choctaw salt dome. Visible in the image are Cavern Lake, which is the water-filled circular structure that occupies the former position of brine well No. 7. It is located northeastern edge of the Choctaw Bayou Strategic Petroleum Reserve facility (Bing® base image mounted and scaled using MapInfo software)

endangered by this collapse and, during the collapse, a pipeline broke and sewage flowed into the sinkhole. Earlier, in 1948, a similar-sized sinkhole had formed just to the east of the Grand Saline Sink.

Haoud Berkaoui Oilfield, Algeria

Located in the Sahara, some 32 km southwest of Ouargla City, the Haoud Berkaoui oilfield is an area of subsidence where numerous exploration and development wells were completed in the 1970s. Of these, the OKN32 and OKN32BIS wells have collapsed into an expanding collapse doline. It surfaced in October 1986 when a crater, some 200 m across and 75 m deep, formed (Morisseau 2000). Today the solution cavity continues to expand and is now some 230 by 600 m across. Its outward progression is continuing at a rate around 1 m per year. The collapse is centred on two oil wells drilled in the late 1970s. The problem began in 1978, when the OKN32 oil exploration well was abandoned because of stability problems in Triassic salt at a depth around 650 m. The target was an Ordovician sandstone at a depth of 2,500 m. Because of the technical problems associated with significant caverns at the level of the salt, the well was abandoned without casing being set in the salt, probably facilitating the escape of artesian waters (Morisseau 2000; Bouraoui et al. 2012).

When it reached the 600 m level, the well had already passed through 50 m of anhydrite (220–270 m depth) along with interbedded anhydrite clay and dolomite 270–450 m depth). These are evaporite sediments that, in their undisturbed state, can act as aquicludes or aquitards to any access by unconfined phreatic groundwaters, although at such shallow depths the evaporite beds are likely also to be variably overprinted by active-phreatic dissolution processes. Prior to drilling it was thought that the Senonian halite extended continuously to a depth of 600 m in the well and in turn was underlain by 50 m of anhydrite (600–650 m depth). Below the halite-anhydrite is an artesian aquifer (Albian) with a natural hydraulic head that is larger than the surface aquifer head by 2.5 MPa (Morisseau 2000)

In 1979 a second well, OKN32BIS, was drilled located some 80 m from the previous well and it successfully obtained its Ordovician target. But in March 1981, the lining of this second well broke, probably because of cavity collapse at a level around 550 m (once again the regional level of salt) and the well was lost. Five years later, on October 1 1986, a large surface crater formed, centred on these two wells. The initial at-surface diameter was 200 m and it was 75 m deep, today it is even larger (Fig. 13.45). Cavern diameter below the stope breakout at that time was estimated to be 300 m and water flows to be around 2,000 m^3/h.

Since the initial stope breakout, leaching has become progressively less effective and expansion rates have slowed (Morisseau 2000). This is because cavern growth and water outflow flow are thought to take place preferentially near the centre of the collapse, which is now far from the collapsing cavern walls Dissolving salt may be salinising the crossflowing groundwaters, leading to undocumented, but possible, ongoing degradation of freshwater oases in the region. Continuing expansion is evidenced by the development of fresh centripetal cracks about the expanding collapse margin. Using MT-InSAR analysis, Bouraoui et al. (2012) documented ongoing subsidence near the crater, with an average subsidence of 4 mm per year (between 1992 and 2002). The zone of current zone of subsidence is centred on the OKN32 location and is slowly migrating north east.

Fig. 13.45 Haoud Berkaoui collapse doline in 2010. Note the centripetal fracture mesh indicting subsidence and collapse is ongoing (Image from Microsoft ®Bing mounted and scaled in MapInfo®)

As in the USA, the loss of these wells, in this case during their active life, emphasizes the need for caution when planning well abandonment in a salt bed, especially when it is highly likely that the salt is acting as a seal, or at least an aquitard, to a regional artesian system. The fact that the first well (OKN32) was lost during drilling argues that a natural breach or cavity was already present in the salt bed and perhaps was already stoping its way to the surface. It is also possible that the inappropriate completion and cementation of casing levels, prior to the well's abandonment, may have accelerated cavity expansion. In hindsight, the loss of the second well some 5 years later was highly likely as was catastrophic cavity collapse 5 years after that; the OKN32BIS wellhead was situated only 80 m from OKN32 and was dealing with the same cavern-ridden salt geology.

Lake Peigneur, Louisiana

On November 20, 1980, one of the most spectacular sinkhole events associated with oilwell drilling occurred atop the Jefferson Island dome just west of New Iberia. Lake Peigneur disappeared as it drained into an underlying salt mine cavern and a collapse sinkhole, some 0.91 km^2 in area, developed in the SE portion of the lake (Fig. 13.46; Autin 2002). In the 12 h following the first intersection the underlying mine had flooded and the lake was completely drained.

Lake Peigneur is a natural water-filled salt solution depression atop the Jefferson Island salt dome, which is one of the salt-cored islands in the Five Islands region of the Gulf Coast (Fig. 7.18a). The lake is about 2.4 km in diameter, has a bean-shaped configuration, with a topographic promontory along the southeast shore of the lake rising to more than 23 m above sea level and the surrounding delta plain. Nearby was the site of the infrastructure of the Jefferson Island salt mine (Fig. 13.47a).

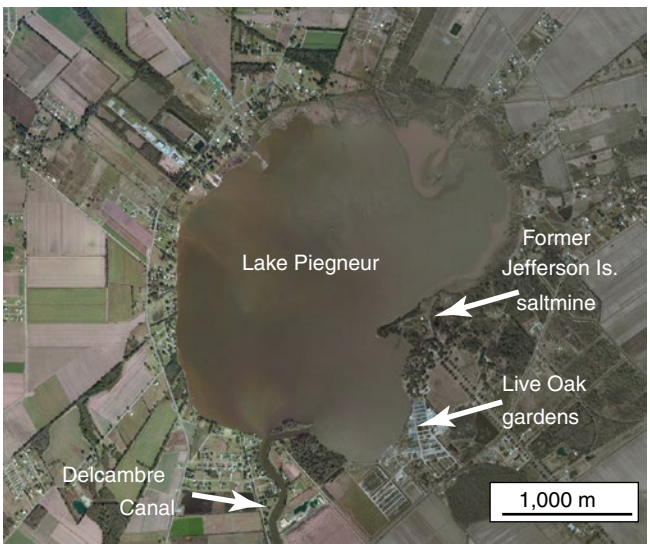

Fig. 13.46 Lake Peigneur, Louisiana (Scale ®Bing image mounted in ®MapInfo)

Drainage and collapse of the lake began when a Texaco oilrig, drilling from a pontoon in the lake, breached an unused section of the salt mine some 1,000 ft (350 m) below the lake floor (Fig. 13.47b). Witnesses working below ground described how a wave of water instantly filled an old sump in the mine measuring some 200 ft across and 24 ft deep. The volume of floodwater engulfing the mine corridors couldn't be drained by the available pumps. At the time of flooding the mine had 4 working levels and one projected future level. The shallowest was at 800 ft, it was the first mined level and had been exploited since 1922. The deepest part of the mine at the time of flooding was the approach rampways for a planned 1,800 ft level. In 58 years of mine life some 23–28

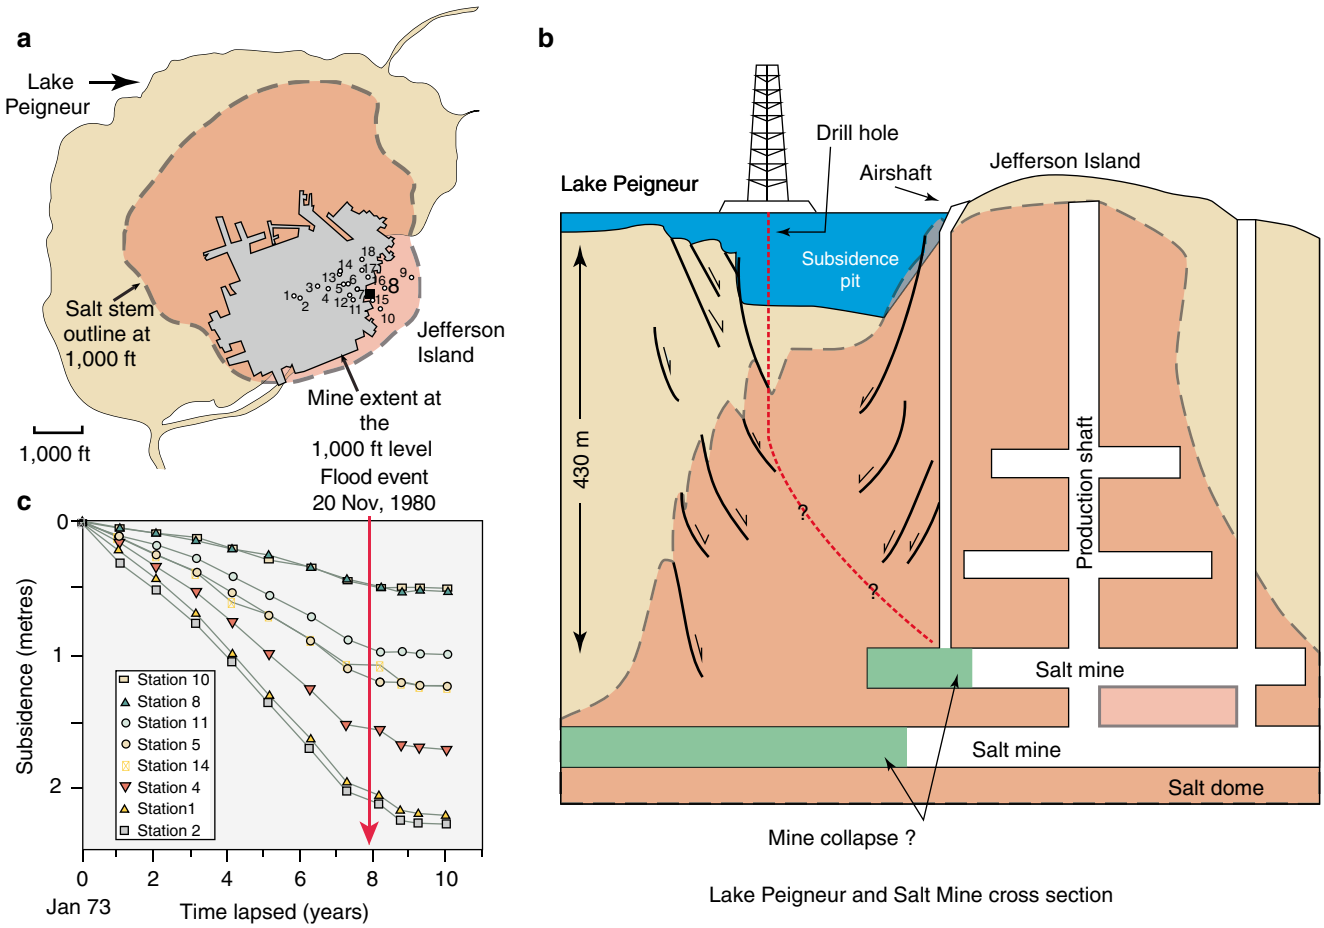

Fig. 13.47 Lake Peigneur, Jefferson Island, Louisiana. (**a**) Plan view showing the extent of Lake Peigneur and the position of the surface monitoring stations (1–18) with selected data plotted as (**c**). Also shown is the extent of the mine workings at 1,000 ft subsurface and the outline of the salt stem at the same level. *Black square* indicates the position of the now flooded No. 1 production shaft. (**b**) Cross section showing the cause of the flooding of the mine and the temporary draining of the lake (in part after Keller and Blodgett 2006) (**c**) Ten years of surface subsidence data showing the drastic decrease in subsidence that followed the flooding of the mine workings (see Fig. 7.18 for locality; after Thoms and Gehle 1994)

million m^3 of salt had been extracted. Prompt reaction to the initial flood wave by mine staff allowed all 50 personnel, who were underground at the time, to escape without anything more than a few minor injuries.

The rapid flush of lake water into the mine, probably augmented by the drainage of natural solution cavities in the caprock below the lake floor, meant landslides and mudflows developed along the perimeter of the sinkhole, and that the lake was enlarged by 28 ha. The surface entry hole in the floor of Lake Peigneur quickly grew into a half-mile-wide crater. Eyewitnesses all agreed that the lake drained like a giant unplugged bathtub—taking with it trees, two oil rigs (worth more than $5 million), eleven barges, a tug boat and most of the Live Oak botanical gardens. It almost took local fisherman Leonce Viator Jr. as well. He was out fishing with his nephew Timmy on his fourteen-foot aluminium boat when the disaster struck. The water drained from the lake so quickly that the boat got stuck in the mud and they were able to walk away! The drained lake didn't stay dry for long, within 2 days it was refilled to its normal level by Gulf of Mexico waters flowing backwards into the lake depression through a connecting bayou (Delcambre Canal, aka Carline Bayou). But, since parts of the lake bottom had slumped into the sinkhole during the collapse, the final water level in some sections was higher than before relative to previous land features. It left one former lakefront house aslant under 12 ft of water.

Of course, an anthropogenically induced disaster like this attracted the lawyers like flies to a dead dingo. On 21 November 1980, the day after the disaster, Diamond Crystal Salt filed a suit against Texaco for an unspecified amount of damage. On 25 November, Texaco filed a countersuit against Diamond Crystal. The Live Oak Gardens sued both Diamond Crystal and Texaco. Months later, the State of Louisiana was brought into the suit since the incident occurred on state land. One woman sued Texaco and Wilson Brothers (the

drillers) for $1.45 million for injuries (bruised ribs and an injured back) received while escaping from the salt mine. Less than a week before the scheduled trial, an out-of-court settlement was reached between the major players. Due to human error, related to a triangulation mistake when siting the drilling barge, Texaco and Wilson Brothers agreed to pay $32 million to Diamond Crystal and $12.1 million to the Live Oak Gardens.

An ongoing environmental catastrophe that was anticipated by environmental groups at the time of the accident never materialized. The lake quickly returned to its natural freshwater state and with it the wildlife was largely unaffected. Nine of the barges eventually popped back up like corks (the drilling rigs and tug were never to be seen again). The torrent of water helped dredge Delcambre Canal so that it was 2–4 ft deeper. And of course, the former 1 m deep Lake Peigneur was now 400 m deep in the vicinity of the borehole!

Interestingly, the filling of the mine workings with water drastically slowed the rate of land subsidence atop the mine (Fig. 13.47c). Measurements had been carried out between 1973 and 1983, some 7 years before the accident and continued for 2 years afterwards (Thoms and Gehle 1994). Slowing reflects the post-accident reduction in the total pressure exerted on the roof of the mine to half its pre-accident levels. Prior to the accident there was no hydrostatic pressure to alleviate some of the lithostatic pressure exerted by the weight of the overburden and so land subsidence above the mine workings was relatively rapid.

Although this incident is not directly related to any solution mining operation and no human lives were lost (although three dogs perished), it clearly illustrates the speed of potential leakage following a breach in a cavern roof in any shallow storage facilities filled with low density fluids. It also illustrates the usual cause of such disasters – human error in the form of a lack of due diligence, a lack of forward planning and a lack of communication between various private and government authorities. It also illustrates that filling a solution cavity with water slows the rate of subsidence atop a large salt cavity and that waters after the disturbance will return quietly to a state of density stratification.

The incident had wider resource implications as it detrimentally affected the profitability of other salt mines in the Five Islands region (Autin 2002). Even as the legal and political battles at Lake Peigneur subsided, safe mining operations at the nearby Belle Isle salt mine came into contention with public perceptions questioning the structural integrity of the salt dome roof. Horizontal stress on the mine shaft near the level where the Louann Salt contacts the overlying Pleistocene Prairie Complex had caused some mine shaft deterioration. Broad ground subsidence over the mine area was well documented and monitored, as was near continuous ground water leakage into the mine workings. The Peigneur disaster meant an increased perception of continued difficulty with mine operations and an increased risk of catastrophic collapse was considered a distinct possibility. In 1985, a controlled flooding of the Belle Isle salt mine was completed as part of a safe closure plan.

Subsidence over the nearby Avery Island salt mine (operated by Cargill Salt) has been documented since 1986. This is oldest operating salt mine in the United States and has been in operation since the American Civil War; and after the Lake Peigneur disaster the mine underwent a major reconstruction and safety workover. Mine management and landowners did not publicly disclose the technical details of rates of subsidence, but field observations revealed the nature of the subsidence process. Subsidence along the mine edge coincided with a topographic saddle above an anomalous salt zone located inside the mined salt area, ground water had seeped into the mine, and there were a number of soil gas anomalies associated with the mine. Small bead-shaped sinkholes were initially noticed in the area in 1986, then over several years, a broad area of bowl-shaped subsidence and areas of gully erosion formed (Autin 2002). Reconstruction has now stabilised this situation. Much of the subsidence on Avery Island was a natural process that occurs atop any shallow salt structure. Dating of middens and human artifacts around salt solution induced water-filled depressions atop the dome shows dissolution-induced subsidence is a natural process that extends back well beyond the 3,000 years of human occupation documented on the island.

Compared to the other salt domes of the Five Islands, Cote Blanche Island has benefited from a safe, stable salt mine operation throughout the mine life (Autin 2002). Reasons for this success to date are possibly; (i) mining operations have not been conducted as long at Cote Blanche Island as other nearby domes, (ii) the Cote Blanche salt dome may have better natural structural integrity than other islands, thus allowing for greater mine stability (although it too has anomalous zones, a salt overhang, and other structural complexities), and (iii) the salt is surrounded by more clayey (impervious) sediments than the other Five Islands, perhaps allowing for lower rates of crossflow and greater hydrologic stability.

Groundwater Breakout Tied to Anpeng Trona, China

At a depth of more than 2,000 m, the Anpeng trona salt mine, China, exploits the deepest and second largest trona deposit yet discovered in the world. The mine is located in hilly country and is solution mining Eocene sediments in the fault-bound Biyang depression, via a linked series of injector and extractor wells (Chap. 12). Since October 2008, groundwater bursting or breakout has occurred, even under rainless weather conditions in and around Cao Village, Anpeng, Tongbai County. These saline breakouts have caused severe

salinization of the land, which currently has an area of over 300,000 m^2. Water from some drinking wells has also become contaminated and nonpotable.

A systematic study of the geological conditions, operation of the mines, the hydrogeochemistry of groundwater bursts shows leaked solution waters are the source of the groundwater bursts (Shi et al. 2013). Over the 40 years of mine operations, natural and induced fractures, cracks, faults, and leaking brine wells have formed connections with one another. Previously unrecognised water leakages of saline mine waters have welled up and recharged shallow aquifers, before finally reaching the ground surface as groundwater bursts, where pressurised escaping waters can form fountains up to a metre tall.

Case Histories: Storage Cavern Problems

The world's demand for fuel means it must be held in sufficient quantities near centres of distribution so as to insure security of supply. Deciding where and how mankind stores substantial volumes of hydrocarbons (or in the future the much more volatile hydrogen) in or near populated areas will always be a problem. There have been a few accidents in below ground storage facilities and some are described in this section. However, when the environmental and safety records of above and below ground fuel storage facilities are compared, the below ground facilities are an order of magnitude safer and less environmentally hazardous. Problems with storage caverns in salt hosts are related either to the utilisation of non-purpose built caverns or to human error and poor management practices (Fig. 13.7).

Weeks Island, Louisiana

The Weeks Island Strategic Petroleum Reserve (SPR) facility on Weeks Island, Louisiana, is some 30 km SE of Jefferson Island (Fig. 7.18). Like other salt-cored islands, the landscape shows a variety of surface features indicative of ongoing salt dissolution such as dolines and linear valleys atop shear zones (Fig. 13.48a). It utilized abandoned room and pillar caverns of the Morton Salt Company mine and so was unusual compared to other purpose-built storage caverns of the Strategic Petroleum Reserve (SPR). It was purchased in the 1970s, a time that was early in the annals of the SPR and at the height of the 1970s oil crisis. Occupying a former salt mine it was the shallowest of all the SPR facilities across the USA (150–220 m below the land surface). It was not a custom built facility, nor was it constructed by solution mining technologies.

Following oil fill in 1980–1982, the facility stored some 72.5 million BBL of crude oil in abandoned mine chambers. Then in November 1995, the Department of Energy (DOE)

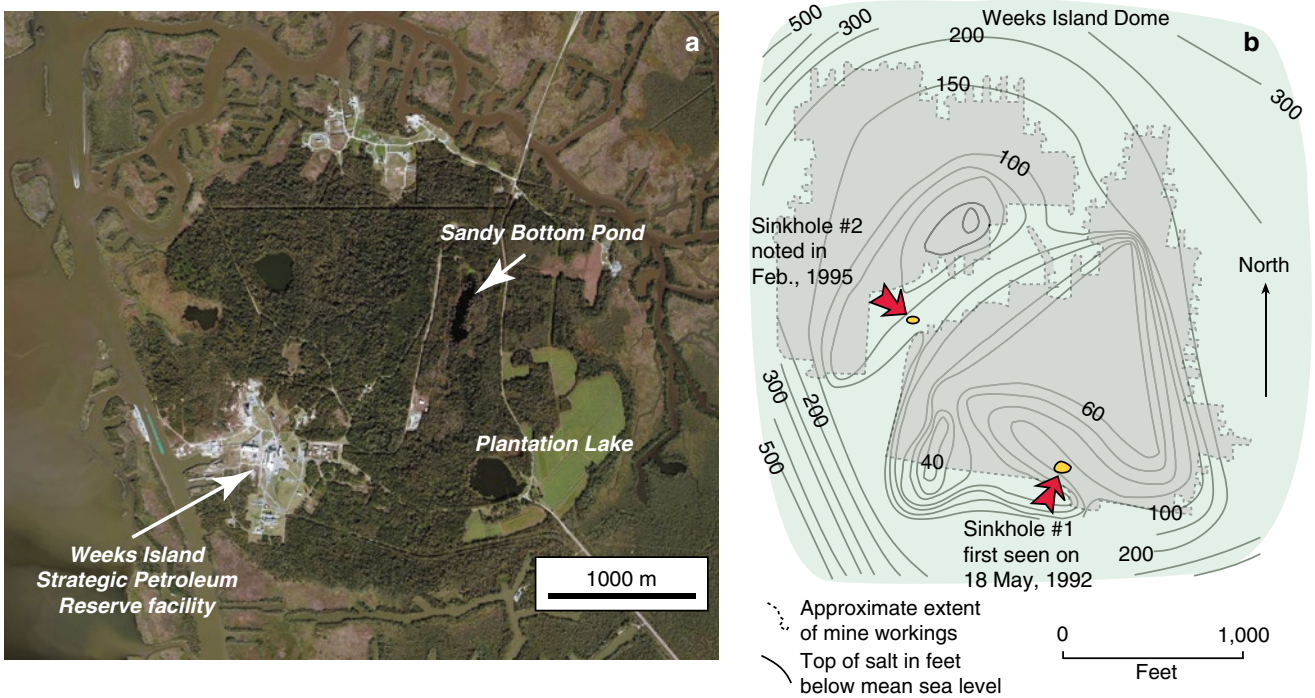

Fig. 13.48 Strategic Petroleum Reserve facility, Weeks Island, Louisiana. (**a**) Location of SPR facility and the presence of natural water-filled collapse dolines. Bing® image mounted and scaled in MapInfo®. (**b**) Top of salt contours showing how sinkholes developed in depressions atop the upper part of the salt. The sinkholes occur in regions near the edge of the cavern, with the potential for foundering of the cavern roof into the chambers of the former Morton Salt mine

initiated oil drawdown procedures, along with brine refill and oil skimming, plus numerous plugging and sealing activities. In 1999, at the end of this recovery operation, about 98 % of the crude oil had been recovered and transferred to other SPR facilities in Louisiana and Texas; approximately 1.47 MMBL still lies in the now plugged and abandoned cavern system.

The cause of this drainage and abandonment was an active sinkhole some 10 m across and 10 m deep, first noted near the edge of the SPR facility in May 1992 and perhaps reaching the surface about a year earlier. However, the growing depression was located on the south-central portion of the island, directly over a subsurface trough, which is obvious in the top-of-salt contour based on mine records (Fig. 13.48b; Neal and Myers 1995). Earlier shallow exploratory drilling around the Department of Energy service and production shafts in 1986 had identified the presence of irregularities and brine-filled voids along the top of salt in this region. A second, much smaller sinkhole was noticed in early February 1995, but it did not constitute a serious threat as it lay outside the area of cavern storage.

Neal (1994) pointed out that Kupfer's 1976 map of that part of the mine located beneath the first sinkhole showed black salt. Regionally, black salt in Gulf Coast salt mines is often associated with anomalous leach-zones, indicating zones where salt was subject to unpredictable movement and sometimes to collapse. The volume of this sinkhole (estimated as 650 m^3 when first noted), its occurrence over a trough in the top of salt, and its position directly above the oil-filled mine caverns, meant it was of concern to the SPR authorities, especially in terms of the stability of the roof of the storage cavern. This feature did not form overnight, it lies atop a shear zone that formed during the diapiric rise of the salt and capped by a rockhead valley containing Pleistocene sediment fill. Salt extraction probably created tension across the shear zone, thereby favouring fracture enlargement, as early perhaps as 1970 (Fig. 13.49; Waltham et al. 2005). Eventually, an incursion of undersaturated groundwater traversed the fracture zone across some 107 m, from a level equivalent to the rockhead down to the mine where it emerged. Over time, ongoing dissolution enlarged a void at the top of the salt, creating the collapse environment for the sinkhole that was noted at the land surface in 1991. Investigations undertaken in 1994 and 1995 into the cause of active at-surface sinkholes verified that water from the aquifer above the Weeks Island salt dome was seeping into the underground oil storage chamber at the first sinkhole site (Figs. 13.48 and 13.49; Neal and Myers 1995; Neal et al. 1995, 1997). Drainage and decommissioning of the Weeks Island facility followed.

Beginning in 1994, and continuing until abandonment of the facility, saturated brine was injected directly into the throat of first sinkhole, which lay some 75 m beneath the surface. This essentially arrested further dissolution and

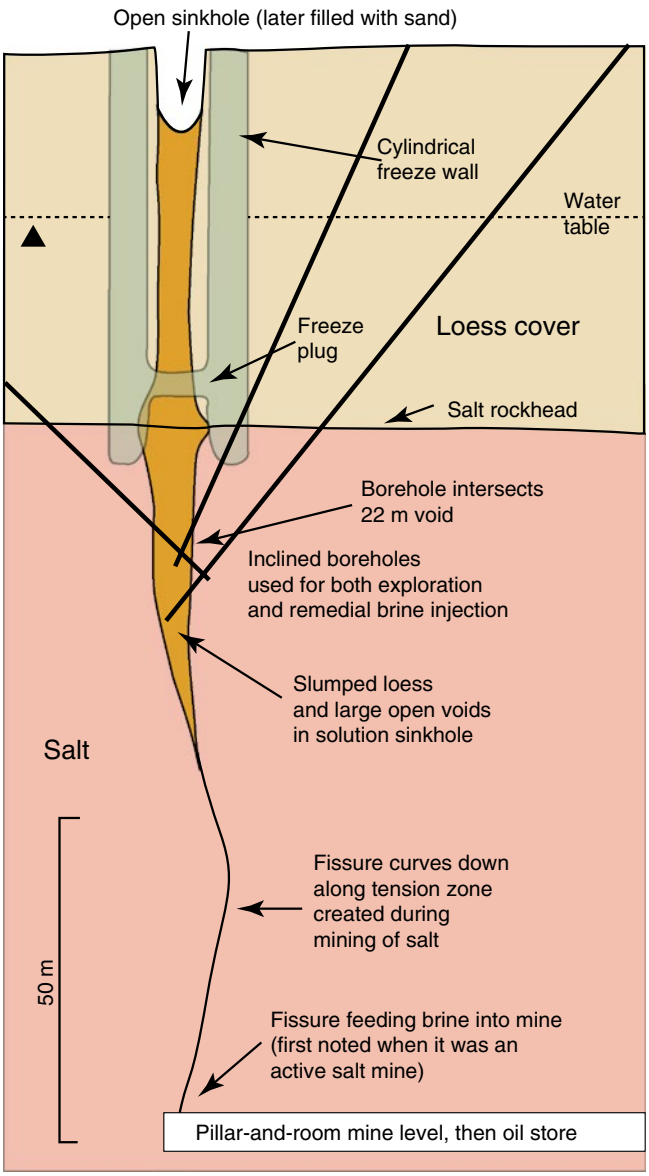

Fig. 13.49 Schematic section through the main Weeks Island sinkhole and its remedial freeze curtain (After Waltham et al. 2005)

bought time for DOE to prepare for the safe and orderly transfer of crude oil to another storage facility. To provide added insurance during the oil transfer stage, a "freeze curtain" was constructed in 1995. It consisted of a 54 well installation around the principal sinkhole, which froze the overburden and uppermost salt to a depth of 67 m (Fig. 13.49; Martinez et al. 1998). Until the mine was completely filled with brine and its hydrocarbons removed, this freeze wall prevented groundwater flow into the mine via the region of black salt around the sinkhole. Dealing with this sinkhole was costly. Mitigation and the removal and transfer of oil, including dismantling of infrastructure (pipelines, pumps etc.), cost a total of nearly US$100 million; the freeze curtain itself cost nearly $10 million.

In hindsight, based on an earlier leak into the mine, while it was an operational mine, and the noted presence of black salt in a shear zone in the mined salt, one might fault the initial DOE decision to select this mine for oil storage. In 1978 groundwater had already leaked into a part of the mine adjacent to the sinkhole and this was forewarning of events to come (Martinez et al. 1998). Injection of cement grout into the flow path controlled the leak at that time, but it could just as easily have become uncontrollable and formed a sinkhole then. But in 1978 the technology needed to understand the salt physics, salt solution and mine conditions and so predict future events had not been developed. The world, and the United States, was in the middle of an oil crisis and as a former US President once observed, "It's hard to drain the swamp when you're up to your arse in alligators!"

Gas Escape, Explosions and Fires from Cavern Leaks

Almost all the explosions and fires described in this section are caused either by human error, poor forward planning, a lack of due diligence by the storage company or operator or a combination of these factors (Table 13.7; Yang et al. 2013). In all cases the salt caverns themselves did not fail. In spite of these accidents, cavern storage is still one of the safest ways to store what are very large volumes of highly explosive materials. Consequences are far graver, and death rates orders of magnitude higher, when explosions and fires have occurred in above ground fuel storage tanks and facilities (Evans et al. 2009).

The West Hackberry Explosion

On September 21, 1978 a blowout and explosion occurred at the West Hackberry salt dome storage facility in southern Louisiana (USA). It killed one worker, released 10,000 m^3 of oil to the surface and cost US $14–20 million (1980 dollars) in cleanup and remediation. The incident occurred during workover operations on one of the access wells to the No. 6 cavity.

Understanding the causes of the explosion requires a few background comments on casing strings in the well and the workover specifications (Fig. 13.50). The well completion was made up of an outer 12.75-in (32.4 cm) casing string cemented to a depth of 2,632 ft (816 m). Cemented inside was another 9.62-in (24.4 cm) diameter casing string some 2,603 ft (807 m) long. This was probably added after the "initial" completion to improve oil tightness when the cavity was converted to oil storage. An innermost 5.5-in (14 cm) diameter pipe string was used to withdraw brine whenever oil was pumped in to the cavity (see Fig. 13.50).

On the day of the explosion the workover consisted of withdrawing the 5.5-in innermost tubing string, repairing a leak on the 12.75-in casing, and reinforcing the wellhead equipment. To accomplish this, the annular space between the innermost pipe string and the 9.62-in casing had been filled with high viscosity mud. This was designed to bring wellhead pressure in the oil string to zero. Once the annular space was filled, a packer was set at the bottom of the 5.5-in brine pipe to seal it off from the cavity. Work then commenced on pulling the innermost 5.5-in pipe; however, after 14 pipe lengths had been stacked, the packer slipped as increasing differential pressure started to push it up to the surface. As the packer rose, the pressure (brine to oil differential) on it increased. Soon the packer shot up and out on to the surface, forming an oil geyser (blowout) that continued until the pressure differential had dissipated. By that time an estimated 72,000 barrels (10,000 m^3) had shot up into the air, caught fire and killed one of the drilling crew.

A poor understanding of the pressure distribution in the fluid columns when the workover was designed is the main reason for the incident. As planned, the workover was extremely delicate, it was attempted without drawing down the oil pressure in the cavern. As the oil was under high pressure (sealed in by viscous mud in oil feeder casing) as the workover began it was liable to expand violently if any mishap upset the status quo. Injecting the viscous mud at the top of the well was a good precaution against any failure of the topside valve on the oil-filled annular space, but it had absolutely no effect on the dangerous situation at the bottom of the cavity and if the packer failed, which it did, there was no way of preventing a blowout.

A comprehensive but simple precaution would have been to release the pressure on the oil in the cavity by drawing down the top surface of the brine in the access well to about one quarter of its total original height. The volume of oil needed to be withdrawn was, of course, exactly equal to the volume that was expelled in the blowout. This relatively small volume of oil could easily have been stored temporarily in another cavity on the site. So doing would have rendered the workover situation entirely safe.

The Brenham Explosion

A disastrous explosion occurred on April 7, 1992, following the outflow of LPG onto the surface from a well atop a storage cavern in the Brenham Salt Dome. The blast occurred some 110 km northwest of Houston. It killed a 6-year old boy and two adults, injured 21 persons, damaged more than 40 homes and snapped trees like matchsticks, while denuding acres of rolling farmland. In all it caused an estimated US$ 9 million in damage to property within a 5 km radius. Seismographs at three Texas universities within 120 km of the scene recorded surface tremors ranging from 3.5 to 4.0 on the Richter scale. Windows were rattled in homes more than 200 km away.

The Brenham storage facility consisted of a 380,000-bbl (60,000-m^3) cavern filled with LPG (a mixture of propane, ethane, n-butane and other gases). The cavern was linked to

Table 13.7 Accidents associated with oil and gas storage facilities

Storage cavern	Time and place of accident	Reserve resource	Accident description	Accident cause	Economic loss	Number of casualties	Influence scope
Petal City	1974, Mississippi, USA	Liquid butane	Fire & explosion	Human error leading to overfilling	Homes destroyed within 7 km	24 injured	Influence range was 7 km, 3,000 evacuated
West Hackberry	1978, Louisiana, USA	Petroleum	Fire & blowout	Packer failure during repair of casing	72,000 bbls (about 11,446 m^3) crude oil leaked, US $ 14–20 million loss in total	1 fatality, 1 injured	Influenced area was 90,000 m^2, environment polluted
Mont Belvieu	1980, Texas, USA	Liquid propane	Fire & explosion	Casing failure-corrosion	23 million m^3 of propane loss	At least 1 fatality	75 families (300 people) evacuated for 180 days
Conway	1980–2002, Kansas, USA	Liquid propane	Gas leaking into the groundwater	Hydrated cap rock	Gas found in wells and local groundwater possibly caused by wet rockhead	None	Area near the storage cavern, 30 homes bought, 110 people relocated
Mont Belvieu	October, 1984, Texas, USA	Liquid propane	Fire & explosion	Casing failure	Several million US $ loss	None	
Mont Belvieu	November, 1985, Texas, USA	Liquid propane	Fire & explosion	Transmission pipeline cut off	110 m^3 of propane consumed and a large amount of propane leaked	2 fatalities	More than 17,000 evacuated
Viriat	1986, France	Ethylene	Gas cloud	Ground facilities broken	All gas leaked	None	
Teutschenthal	1988, Halle, Germany	Ethylene	Surface dome and crack	Casing broken	60–80 % of ethylene leaked	None	An area of approximately 8 km^2 evacuated
Clute	1988–1989, Texas, USA	Ethylene	Gas escaping	Drilling operation resulting in tightness failure	About 20,000 m^3 of ethylene loss	None	10 families evacuated
Brenham	1992, Texas, USA	Liquefied petroleum gas (LPG)	Fire & explosion	Overfilling and valve failure	332,000 barrels (about 52,500 m^3) US$5.4 million & US$1.38 million punitive damages awarded	3 fatalities, 23 injured	About 3 km radius of plant, 26 homes destroyed
Mineola	1995, Texas, USA	Propane	Fire underground and on the surface	Pillar cracks	Cavern cycling connected adjacent cavities, pressure buildup and casing leak	None	The two caverns and region within 15 m on the surface
Yaggy	2001, Kansas, USA	Natural gas	Fire & explosion	Casing bend and damage	About 5,600,000 m^3 natural gas loss. Gas surfaced in old brine pipeheads. US$800 million law suit	2 fatalities	Part of the town influenced, some 250 people evacuated
Fort-Saskatchewan	2001, Saskatchewan, Canada	Ethylene	Fire lasting 8 days	Failure of pipeline connecting two caverns	14,500 m^3 ethylene loss in	None	Area near the plant
Magnolia	2003, Louisiana, USA, near Napoleonville	Natural gas	Gas escaping	Casing crack	More than 1,000,000 m^3 natural gas leaked	None	About 30 people evacuated from Grand Bayou
Odessa	2004, Kansas, USA	Liquid propane	Gas escaping	Ground facilities broken	More than 100 t (about 90,000 kg) liquid propane leaked	None	
Clute	2004, Texas, USA	Ethylene	Fire & explosion	Drilling operation resulting in tightness failure		None	10 families evacuated
Moss Bluff	2004, Texas, USA	Natural gas	Fire & explosion (300 m high flame)	Brine pipe corrosion, well casing separation	At least 36 million US $ loss in gas inventory	None	Influence range was 120 m, 1,000 people within 5 km evacuated

After Yang et al. (2013), Evans et al. 2009)

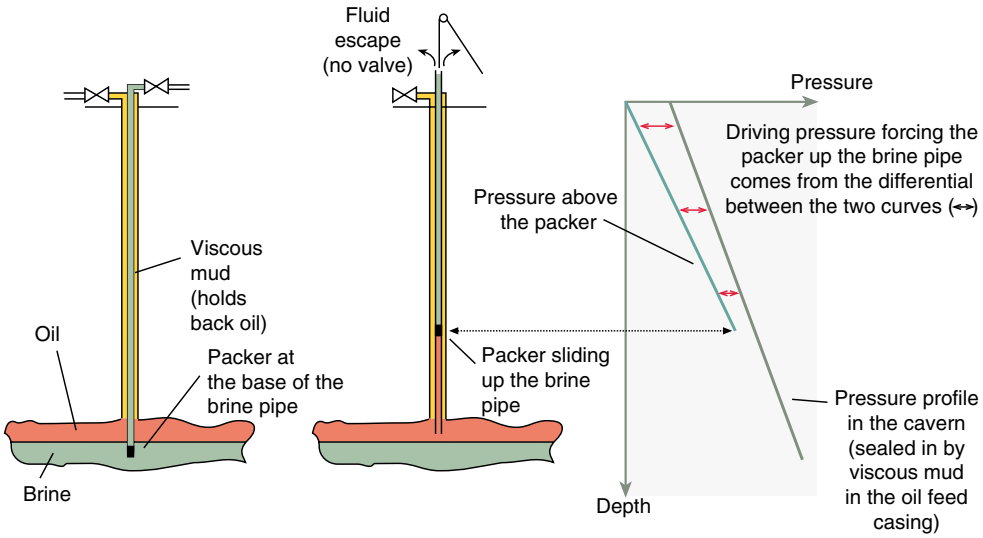

Fig. 13.50 Schematic of the pressure differentials that caused the West Hackberry blow out and explosion (see also Fig. 13.14)

ground level by a 13-3/8-in diameter, 2,702-ft long cemented casing (Fig. 13.51). A central brine pipe (2,871-ft long) allowed injection and withdrawal of brine. LPG was injected into, or withdrawn from, three distinct pipelines. Brine was provided by two above-ground brine ponds. The wellhead was equipped with a shutdown valve. The Brenham station was operated remotely by a dispatcher in Tulsa, Oklahoma (Bérest and Brouard 2003).

At 5:43 am on April 7, 1992, additional LPG was injected in the cavern. The brine/LPG interface unexpectedly reached the 1-in diameter weep hole located in the lower part of the central tubing, some 1 ft above the tubing base. The weep hole was supposed to provide warning in case of imminent overfilling. LPG flowed into the central brine tubing, leading to lower density in the fluid in the central column, partial vaporization and expansion of the lighter gases, a pressure drop in the cavern and, ultimately, a large flow of gas through the weep hole and the tubing base alike.

Brine, followed by liquefied gas, daylighted at the brine pond surface. Back-calculation proved that 3,000–10,000 bbl (500–1,600 m^3) of liquefied gases were expelled via the ponds. The release of gas into the atmosphere activated gas detectors at ground level. (Such activation was apparently a relatively frequent event at this station, and alarms were often unrelated to an actual gas leak). The dispatcher in Tulsa was not able to interpret correctly the somewhat confusing information delivered by the telemetric system – a unique signal was sent, whatever had activated a number of detectors. The shutdown valve (or cavern safety valve) was assumed to have immediately reacted to the high pressure level (100 psi) in the brine tubing at the wellhead, but the system failed.

A subsequent National Transport Safety Board (NTSB) investigation confirmed the local operator had overfilled the storage cavern to where LPG had escaped into an adjoining brine storage pit through the brine injection system via an open valve. Product had then evaporated and, being heavier than air, formed a low-lying cloud 30 ft high and several hundred yards long. At 7:08 am the "mushroom-shaped" vapour cloud was ignited by an automobile driving into the foggy cloud near the storage facility.

According to the NTSB report, Mapco (the operator of the facility) was not aware of the volume of product in storage at the site. Some 338,995 barrels were actually stored instead of the 288,000 bbl estimated by Mapco. NTSB concluded that the management procedures had lacked oversight adequate to confirm employee measurements. Nor did the company have the ability to balance cavern receipts against withdrawals. In addition, employee measurement procedures did not adequately take into account specific gravity variations of the NGLs in storage.

Aside from the computation errors, NTSB said other contributing factors included:

(a) Inadequate positioning of the brine pipe weep hole – in a post accident redesign it was moved to 6 ft above the base of the brine pipe,
(b) A lack of several fail-safe features on the cavern's shutdown system – this system had included a brine pressure-sensing line designed so that when a large pressure build-up was sensed in the brine line it switched a spring that, when triggered, sent an electrical signal in a chain containing a fusible link whose fusion should have closed the brine safety valve and so prevented product leakage back up the brine pipe. It is extremely likely than one or two manual valves were closed on this sensing line at the time of the explosion, isolating it from the main body of the brine pipe, so making the emergency shutdown system ineffective. Ironically, the shutdown valve was activated when heat from the explosion burned

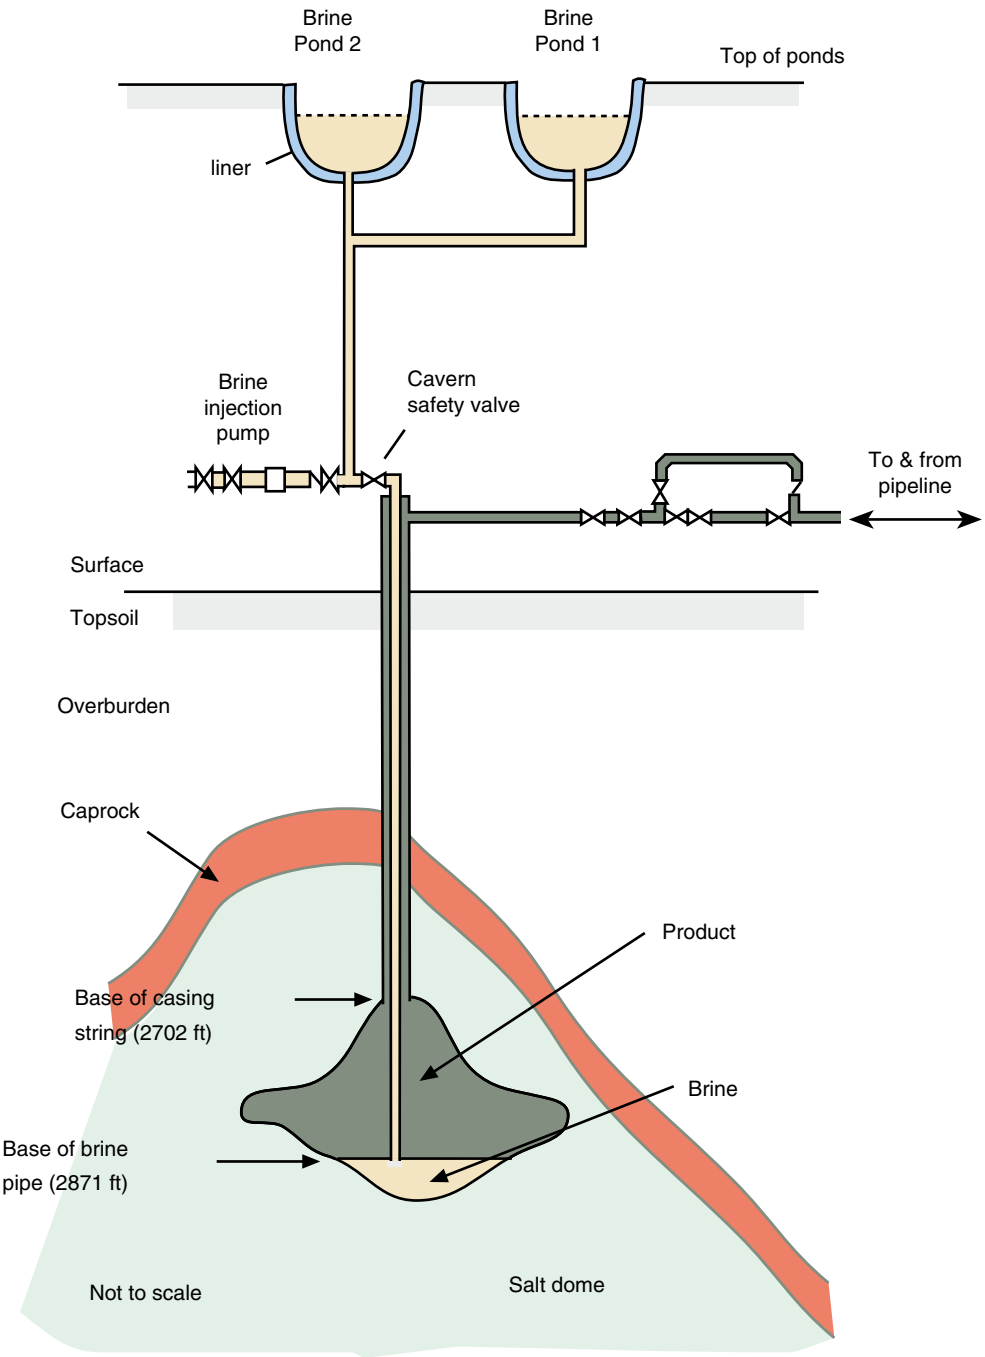

Fig. 13.51 Schematic of the situation at the time of the Brenham explosion

the fuse and triggered valve closure (it shut the barn door after the horse had bolted).

(c) Inadequate emergency response training and procedures, along with poor communication among Mapco employees responding to the alarms and to the obvious surface emergency.

Early media coverage sensationally reported that "A Salt Dome Has Blown Up". However the cavern storing the leaked liquids later passed a mechanical integrity test and is still in use today. It was operational supervision and safety procedures that failed dismally, not the cavern. After this accident, the Railroad Commission of Texas issued new regulations (effective in 1994) mandating that LPG storage caverns be protected by at least two overfill detection and automatic shut-in methods.

Barber's Hill Explosion and Collapse

On October 3, 1980 a gas-fed explosion occurred in a residence in Mont Belvieu, a Texan town that sits atop the Barbers Hill diapir, some 60 km west of Houston. Barbers Hill dome is the largest subsurface LPG storage facility in

the U.S. with over 126 active solution-mined caverns storing between 75 and 300 million barrels of light hydrocarbon products. The explosion was ignited by a woman who sustained burns when turning on her dishwasher. A spark from the dishwasher had ignited gas that had accumulated in the foundation of the house.

Two weeks earlier, on September 17, 1980, a drop in pressure had been recorded in one of the nearby cavities storing liquefied petroleum gas (70 % ethane, 30 % propane). The cavern was emptied of product and filled with brine. Subsequent investigation showed a leak had occurred through a corroded casing joint in the access well in the vicinity of the porous anhydrite caprock (Fig. 13.52). The well in question had originally been drilled in 1958. Leaking gas seeped through the surrounding soil to accumulate in the foundations of the residence where the explosion occurred. In the days that followed, gas daylighted haphazardly in residential areas around the site of the original explosion. Holes were drilled into the watertable to find and vent pockets of gas. Residual gas saturations in the soils forced the evacuation of 73 families for nearly 7 months and a drastic fall in property values.

Because of its low density, propane tends to rise to the surface, either through the cement along the outside of the casing or by dispersing in the overlying ground surrounding a breach (Bérest and Brouard 2003). This happens, for example, if escaping gas intersects a sufficiently pervious water-bearing layer just below the surface. The gas can accumulate in building foundations, emerge at streams and similar low-lying ground or come up through faults and joints, daylighting at the surface several hundred meters from the well head. To minimise this potential problem, the architecture of the access well is of utmost importance. In the Mount Belvieu situation, if the two last cemented casings been anchored in the salt formation and not into the anhydrite cap, the propane leak would have been channeled in the cemented annular space between the two casings, with considerably lesser consequences (Thoms and Kiddoo 1998).

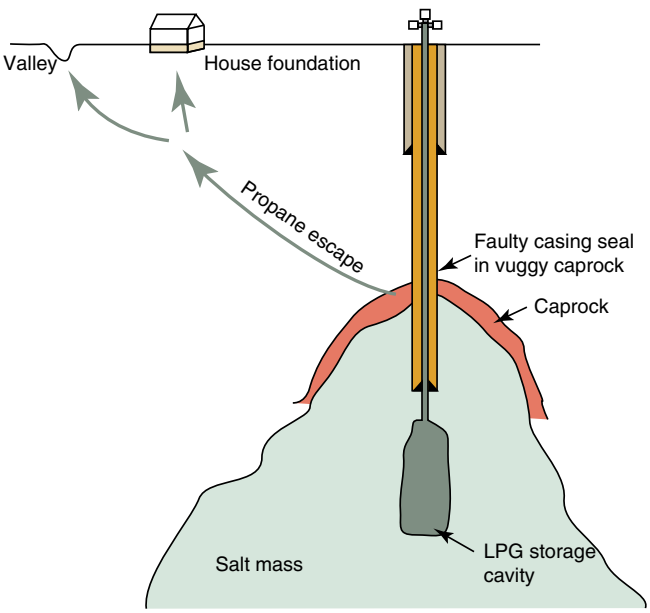

Fig. 13.52 The Mont Belvieu (Texas) 1980 accident. After 22 years of operation, the last cemented casing became leaky. In Texas, more recent wells must be equipped with two casing strings into the salt (After Bérest and Brouard 2003)

A few years later, on July 30, 1993, there was another event that further lowered Mont Belvieu property values. In a few hours a sinkhole crater formed between two brine wells in the EGP Fuel Storage facility (Cartwright et al. 2000). The crater stabilized with a diameter of 12 m and a depth of 6 m. A well that was near the problem site had to be abandoned after the sinkhole formed. It was not a hydrocarbon storage well so the environmental implications of a collapse-induced abandonment were not as significant it would have been for a failed hydrocarbon cycling well. The cause of the sinkhole is contentious but it is thought that brine cycling in the two wells may have contributed to the collapse. Detailed subsidence work in the cone of subsidence about the sinkhole suggest that it was probably there prior to the collapse and, if it had been monitored, the data could have been used as an indicator of the likelihood of collapse (Cartwright et al. 2000).

Brine injection that drives brine compensated withdrawal of the stored hydrocarbons periodically requires large volumes of brine in short time frames. But in Mont Belvieu there was not sufficient above ground infrastructure to store the large volumes of brine needed for product cycling. To give access to large volumes of brines quickly, brines were pumped down dedicated brine storage wells with bases in shallow caprock caverns. Wells adjacent to 1993 Mont Belvieu sinkhole were two such wells that had stoped toward the landsurface, perhaps facilitated by ongoing brine cycling.

Mineola Propane Fire

In 1995 there was an underground fire that burned for several days at a salt dome storage cavern operated by Suburban Propane near Mineola in East Texas, some 145 km east of Dallas. The cavern in which the blow-out occurred extended from 1,200 to 2,500 ft (350–750 m) subsurface. The blowout occurred when a salt wall separating two storage caverns had become so thin from the enlargement associated with brine compensation (product cycling) that it cracked (Gebhardt et al. 2001). This allowed stored propane product to flow from one cavern to an adjacent cavern that was empty of product and undergoing testing. Pressurised nitrogen was being injected into the adjacent brine filled cavern as part of a standard mechanical integrity test. The testing may have contributed to the penultimate pressure buildup that allowed propane product to leak into shallow depths via a casing leak

(Bérest and Brouard 2003). The leaking well had originally been drilled as an oil producer in the late 1950s, four decades before the accident. Liquified gas escaped through the soil in a halo that extended as far as 100 ft from the well. The escaping gas ignited and burned releasing heavy black smoke. Extinction of the fire was not a viable option, as dangerous re-ignition and flash back was likely. The innovative kill techniques applied to this well are described in Gebhardt et al. (2001).

There are potential problems with longterm intercavern integrity as all salt caverns will enlarge during product cycling, so the Texas Railroad Commission now legislates what is an acceptable degree of enlargement before a storage cavern must be plugged and abandoned.

Hutchinson Explosion

On January 17, 2001, a gas explosion and fire destroyed two businesses in downtown Hutchinson in central Kansas (Allison 2001). The next day in the Big Chief mobile home park 3 miles away another explosion occurred and 2 residents died of injuries received. The explosions were tied to geysers spewing gas and water, and their appearance caused the excavation of hundreds of Hutchinson residents. Pathways to the landsurface at both explosion sites and to the various active geysers across town were directly tied to undocumented and abandoned wells that were once used to solution mine the Hutchinson Salt.

The January 17–18, 2001 eruptions of gas and brine, driving 30-ft (10 m) geysers in the town, resulted from the loss of 143 MMcf of gas from the Yaggy natural gas storage facility located 7 miles down the road from the town community of 40,000 people (Fig. 13.53). Oneok Inc., owned and operated the Yaggy field through a subsidiary company called KGas. Upon review of pressure records, KGas officials realized that the S-1 cavern had probably been leaking at a low level, at least since the pod of caverns had been refilled with natural gas on January 14, and perhaps much longer, perhaps since the initial well workover in the 1990s. At the time of the refilling, technicians did not think much of a minor pressure drop, as it was a routine situation associated with filling the cavern. When the caverns are pressurized, the natural gas is compressed, raising its temperature. Once in the caverns, the pressurised gas begins to cool and condense, resulting in a slight pressure decrease. It was common practice to then "top off" the cooled caverns with additional gas to fill the caverns to the final storage pressure.

The Yaggy field of salt caverns was originally developed in the early 1980s to hold propane. Wells were drilled to depths of about 650–900 ft (200–300 m), into the lower parts of the Hutchinson Salt Member and cased with steel. The roof of each cavern was about 40 ft (12 m) below the top of the salt layer. The company had difficulty making a financial success of the operation and eventually ceased operations. All of the storage wells were filled with brine and then plugged by partially filling them with concrete. KGas acquired the facility in the early 1990s and converted it to natural gas storage (by definition this is a pressurized storage system). Plugged wells were drilled out to return the feeder

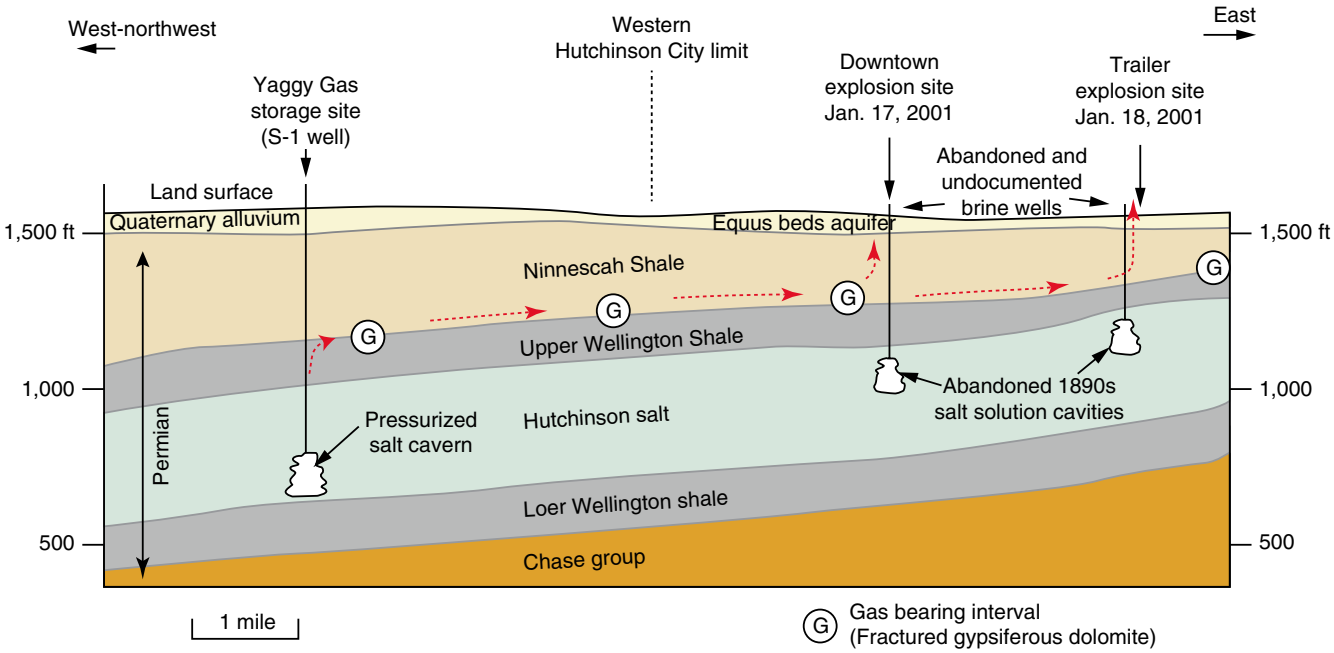

Fig. 13.53 Hutchinson, Kansas January 2001 gas explosion, explanatory cross section (Redrafted and modified from image downloaded on June 4, 2013 at <http://www.kgs.ku.edu/Hydro/Hutch/GeneralGeology/index.html>)

wells and caverns to use. At the surface the wells in the Yaggy facility are 300 ft (90 m) apart. At the time of the crisis, Yaggy had about 70 wells, of which 62 were feeders to active natural gas storage caverns. More than 20 new wells had been drilled and were being used to create new caverns for expansion of the field storage capacity.

At full capacity, the field could hold 3.5 billion cubic feet (Bcf) of gas at pressures of about 600 lb per square inch and at the time of the accident it was supplying up to 150 MMcf (million cubic feet) of gas per day. Yaggy is the only natural gas storage field in salt caverns in the state of Kansas. Other salt caverns in Kansas are used for brine-cycled storage of liquid hydrocarbons, such as propane, at much lower pressures than the natural gas at Yaggy.

Records show that when KGas drilled the concrete out from the well casing in S-1 well to return the well to operation, they encountered a steel casing coupler that was dropped into the concrete in the well during the plugging operations (Allison 2001). During the workover this object may have deflected the drill bit against the side of the well casing damaging and weakening it. A post accident down-hole video in S-1 shows a large curved slice in the casing at that depth. The city's geological consultant described it as looking "like a kitchen knife cutting into a can." Prior to the Yaggy facility approval by state authorities the S-1 had a satisfactory casing pressure test, as required by the Kansas Department of Health and Environment. The test was though to demonstrate the integrity of the casing at that time. However, the well at the depth of the leak was never tested to the maximum pressure that would be experienced in service.

The route followed to the surface by the escaping gas is not completely documented. Initial seismic surveys in early February 2001 at first indicated a possible subsurface sand channel through which the escaping gas flowed up from the storage facility. But that was not borne out by a study of regional well logs or the 22 % success rate in drilling for suspected gas pockets (Watney et al. 2003) or subsequent seismic interpretation (Nissen et al. 2004). The most likely candidate carrier is thought to be a fractured intrasalt gypsiferous dolomite layer that pinched out northwest against the tight shales, and so facilitated drainage to the crest of the anticlinal culmination that underlies the town of Hutchinson (Fig. 13.53).

There are more than 600 NGL-LPG salt storage caverns in bedded Hutchinson salt in the state of Kansas, the most of any state in the USA. Kansas also has plans for more natural gas storage caverns, although Gulf Coast salt dome caverns are 10–20 times larger. The mix of bedded salt and permeable rock formations (perhaps even intrasalt) around Hutchinson region, the presence of natural dissolution irregularities and the fact that Hutchinson has been an area of solution mining since the late 1800s is a real problem for storage of high-pressure fluids. Once the S-1 well was breached, numerous unplugged brine wells that were long ago drilled within the Hutchinson Salt and abandoned, without appropriate documentation, routed the escaping gas to the surface. Such wells are directly tied to the downtown fire that first heralded the problem, and to the two deaths that occurred in the explosion in the mobile home park a few days later. Work since the explosion has pointed out numerous problems to be addressed in a region of bedded salt that appears in many ways not to be a suitable site for future natural gas storage projects. Even so, the salt storage cavern itself did not leak, the access piping was the problem due to well workover damage.

After the accident, poor regulation and the small inspection staff numbers in the state of Kansas (compared to neighboring states) were incriminated by several experts (Bérest and Brouard 2003). New sets of regulations were discussed and legislated, including mandatory double casing in wells, corrosion control, well conversion restrictions (salt caverns designed to store LPG should not be converted to store natural gas, and cavern wells that have been plugged cannot be reopened and used again), maximum pressure limit of 0.76 psi/ft ($1.73\ 10^{-2}$ MPa/m) and new testing requirements, such as a leak test should be performed every 5 years.

CO_2 Outburst, Menzengraben Potash Mine, E. Germany

An intense outburst of carbon dioxide took place on 7 July 1953 in the vicinity of the Menzengraben potash mine of the former East Germany (Hedlund 2012). This disaster occurred in a salt mining region known to be gassy, and prone to CO_2 rock-burst problems (Table 13.8). The gas escaped from the #2 Shaft House immediately after a scheduled underground blast at 11:35 pm on the evening of July 7, 1953. As a result of the gas escape some 12 people died above ground from CO_2 -induced asphyxiation, many died in their sleep. No-one died underground as, due to the gassy nature of the extracted salt, it was standard practice to bring all staff above ground prior to a blast. For 25 min after the scheduled blast, a large amount of CO_2 blew with great force out of the mine shaft. Outside, it was a still night with no wind, allowing concentrated CO_2 to accumulate in a nearby valley, leading to multiple asphyxiation casualties.

Based on a review of concentration-response relationships, the location of victims, and other information, Hedlund (2012) concluded that concentrations of 10–30 % carbon dioxide occurred up to 450 m from the point of release at the shaft house, for at least 45 min, with some 1,100–3,900 tonnes of CO_2 blown out of the mine, at "blow-out" intensities estimated to be 4 tonnes per second. The majority of the gas escaped via a near-vertical high-velocity jet, with only little loss of momentum due to impingement. The nature of the escape and the ability of the gas to pond is relevant to planned CO_2 sequestration facilities, worldwide. The largest natural CO_2 induced

Table 13.9 Problems in pressurized storage caverns (see text)

Storage cavern	Time and place of accident	Reserve resource	Accident description	Accident cause	Economic loss	Influence scope
Kiel	1967, Germany	Natural gas & hydrogen	Volume lost 12.3 % after 45 days	Excessive creep of salt, operating at too low pressure	Cavern failure (reduced capacity)	The cavern
Eminence	1970–1972, Mississippi, USA	Natural gas	Volume lost more than 40 %	Excessive creep of salt, operating at too low pressure	Cavern failure (reduced capacity)	The cavern
Stratton Ridge	1990s, Texas, USA	Natural gas	Cavern abandoned, ground subsidence, settlement rate 40 mm/a	Excessive creep of salt and in wet condition	Cavern failure	Ground above the caverns
Bayou Choctaw	1954, Louisiana, USA		Cap rock collapsed, ≈245 m diameter lake formed on the surface	Human error	Cavern failure	Ground above the caverns
Clovelly	Louisiana, USA	Oil storage	Cavern in salt overhang dissolved into cap rock	Thin cap rock, inadequate salt buffer	Cavern abandonment	The cavern
Napoleonville Bayou Corne	2012-ongoing, Louisiana, USA	Brine cycling	Cap rock with large voids, unexpected shale layers in salt edge leading to collapse	Cap rock failure, inadequate salt buffer	Cavern abandonment, loss of brine storage	The cavern and ground above

disaster occurred in 1986 in the vicinity of Lake Nyos (Cameroon), when a CO_2 plume was released from lake bottom sediments. The gas plume had a likely volume of 1.5 million tonnes and spread up to 25 km from the release point, hugging the lower parts of the landscape and killing an estimated 1,700 people, along with large numbers of livestock.

Recognising and Preventing Potential Cavern Problems

Three factors can contribute to the breaching and collapse of solution-mined cavities, namely creep, uncontrolled leaching, and the presence of anomalous zones in what had been assumed to be homogenous salt (Table 13.9). Anomalous zones may be unexpected regions of highly soluble salts (potash salts), of fractured intrasalt beds, or zones of much older natural leaching (e.g. black salt), which may contain pressurized brine or gas (methane or nitrogen). In brinefields and some salt mines the anomalous zones tend to occur near intersections with poorly documented older well bores. The same set of factors generates many of the operational problems in conventional salt mines (Chaps. 11 and 12).

Salt Creep

The principal factors influencing the rate of salt creep are; (a) cavern depth and overburden characteristics; pressure and temperature gradients, (b) internal cavity pressure, (c) cavern shape,

(d) salt properties (e.g., variations in halite crystal size, moisture content). Left alone, and not subject to fresh water incursion, salt (especially carnallite and bischofite salt) will creep into an unbreached storage cavern until differential pressures are equalised. Salt cavities in homogenous halite hosts are generally stable at depths between a few hundred metres and about 2,000 m depth (Figs. 13.1 and 13.54). Below that depth there is an elastic-plastic transition zone for salt behaviour somewhere below 1,000–2,000 m. Cavities below this can be relatively unstable and show large volume decreases through rock creep; with the transition depth depending on the composition of the salt, the geothermal gradient and the overburden pressure. Effects of salt cavity creep, due to inadequate internal pressuring, were first noted in the 1970s by the operators of some large purpose-built storage caverns. The Eminence cavern in Mississippi, built at 1,700–2,000 m, lost 40 % of its volume in just 2 years post-construction, while Tersanne in France lost 30 % to salt creep (Fig. 13.55). Such losses in storage capacity were potentially expensive, but when adjustments were made to cavern depths and minimum gas storage pressures, the volume loss stopped. Today both facilities are still operational and have recovered much of their initial volume loss (Thoms and Gehle 2000a). Salt creep occurs at slower rates above the transition zone; measured rates are mm – cm per year in salt mines in Kansas and Texas with depths up to 600 m.

Like mines, salt cavities built above or within the transition zone can be extremely stable and when properly located, designed and operated may lose only a few percent

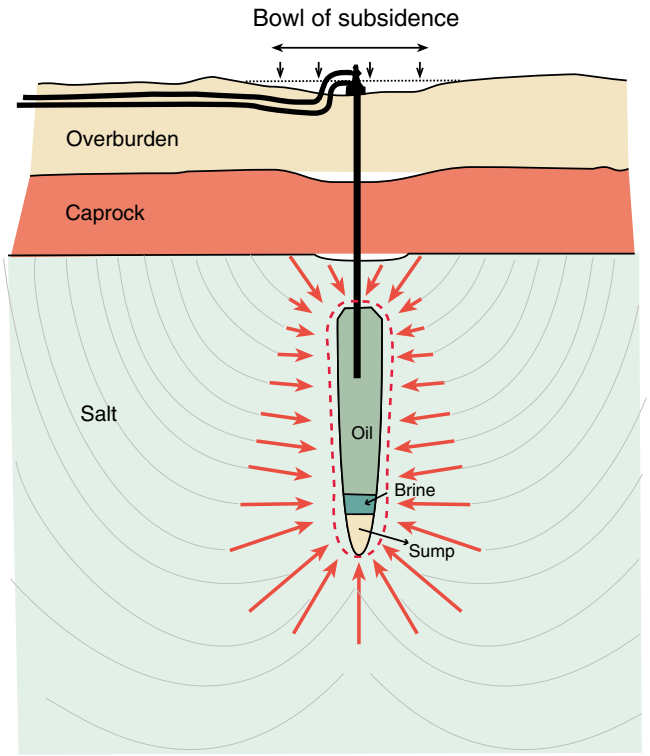

Fig. 13.54 After the cavern has formed and is filled, salt creep causes the cavern to shrink from its original size (*dashed shape*) into a somewhat smaller configuration. This induces subsidence and possible collapse in the zone above the cavern. At the surface this process forms a "bowl of subsidence" (in part after Thoms and Gehle 2000a)

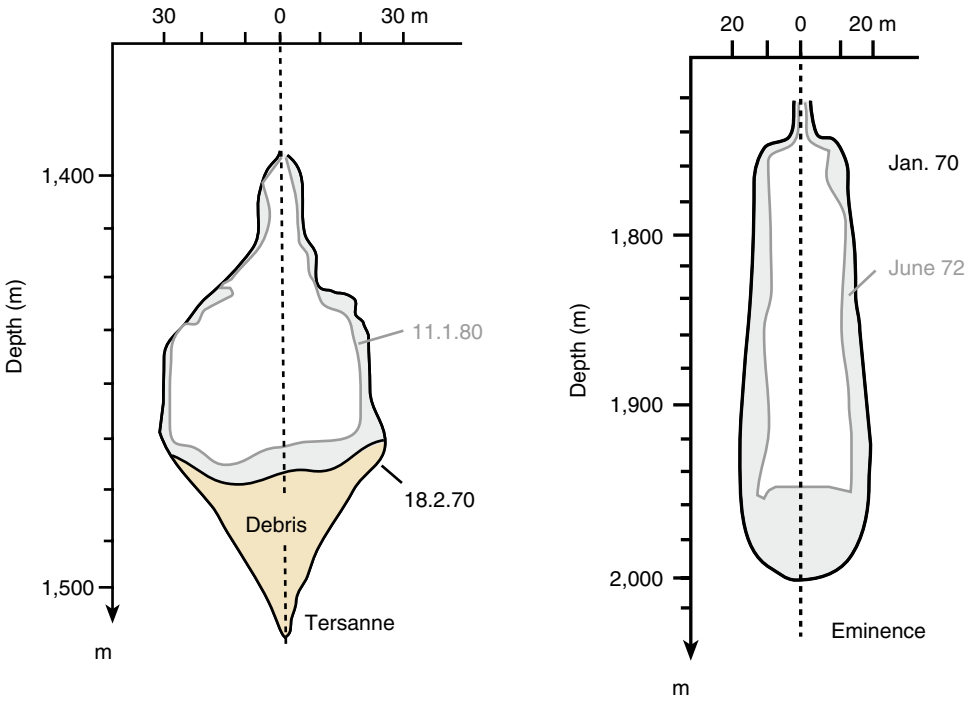

Fig. 13.55 Creep effects in Tersanne (France) and Eminence (Mississippi) showing shrinkage with time (*Brown shading* indicates the distribution of insolubles in the Tersanne cavern)

volume a year. Some cavities in salt above the transition zone can remain remarkably stable even if emptied of product. For example, in the 1950s, a lenticular cavern with a roof span 366 m was excavated by solution mining in the Bryan Mound salt dome in Texas, which is also the site for the later Strategic Petroleum Reserve programme. The cavern has an unusual shape compared to the "carrot" shape of later purpose-designed caverns in the Mound. It had an average depth of 550 m, a cavity height of 55 m and an unsupported span of more than 360 m After excavation, it was filled with LPG but subsequently lost wellhead pressure and so was abandoned (emptied). Thirty years later, measurements indicated that this cavern is still remarkably stable, having lost only about 4 % of it total volume since abandonment.

Salt creep is accelerated by large differences between natural lithostatic pressure (in the salt) and the pressure in the cavern. The rate of creep also depends on variations in the proportions and physical properties of the various salt minerals and the configuration of nearby nonevaporites (e.g. carbonate, anhydrite or potash beds in halite). To minimise creep, operational pressures in a fluid-filled storage cavern should be as high as allowed, this is especially true in facilities used to store natural gas. But this may encourage leakage and gas loss in facilities lacking structural integrity (see Hutchinson explosion in case histories).

When a cavern is active, overburden creep will typically drive ongoing subsidence at the landsurface in the form of a subsidence bowl or depression (Fig. 13.54). The length of the delay between creep into a cavern and its expression at the surface depends upon cavern depth, mode of cavern operation, thickness of salt cover and character of overburden materials or roof beams (Neal 1991). Ground effects atop shallow caverns usually show up more quickly than those above deeper caverns, subsidence over some storage caverns has been detected only after a decade or more of operation (Thoms and Gehle 2000a).

Salt Falls Versus Roof Collapses

Salt fall from the cavern roof, as distinct from catastrophic roof collapse and chimneying, occurs frequently in most caverns especially in bedded salt. In a storage cavern it is part of the preliminary construction/leaching phase and also occurs during later storage cavern expansion driven by product cycling. Providing an adequate salt pillow is left as part of the cavern's design, roof falls are not considered detrimental by most operators, as they generally do not greatly affect containment volume. They may sometimes damage casing strings "hanging" from the roof of the cavern.

Most damaging to a salt cavern and possibly to the surface environment is total collapse of a cavern's roof span. It may ultimately lead to the formation of a collapse sinkhole at the landsurface. Such surface expressions atop a brinefield may be delayed for some time after operations have ceased. Typical causes of sinkholes in brinefields are uncontrolled solution leaching, the unexpected of intersection of soluble (potash-rich) seams in the salt roof, or the presence of natural brine lenses from natural karstification near the outer parts of a salt mass (see case histories).

Figure 13.56 illustrates the range of probabilities for salt fall and collapse in salt cavities: (a) is an intact cavern with adequate salt cover – salt falls are a part of the operational running of the cavern, (b) is a breached cavern with a strong roof, still capable of spanning the cavern – ultimately ongoing salt solution it will drive it into a breached system, while (c) illustrates a breached cavern system that may soon develop into a sinkhole at the surface – it is the result of total salt removal beneath a weak cavern roof.

Ongoing brine compensation (product-cycling) means any storage cavern has the potential to expand until it collapses. To prevent potentially dangerous collapses and product leakage, the shape of a storage cavern must be monitored throughout its life. Some materials found above salt formations, such as reactive shales exposed to brine, may take time

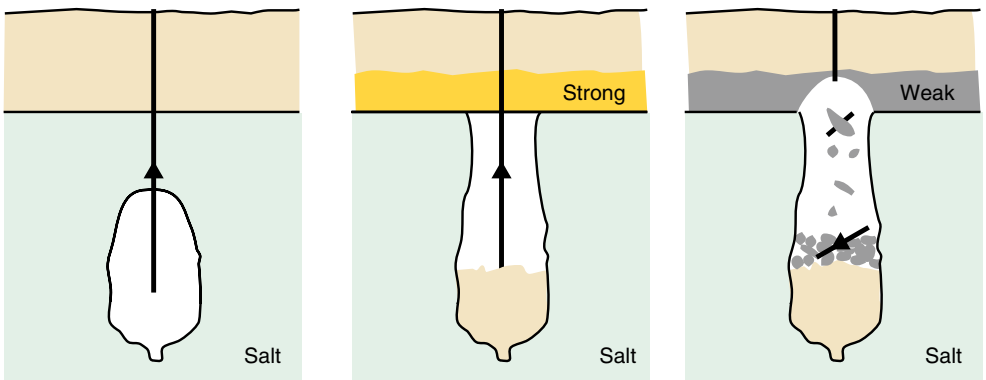

Fig. 13.56 Preservation of a salt roof or the presence of strong overburden spanning the cavern roof makes cavern collapse less likely

to weaken. This means there will be a delayed collapse event, it can occur years after the cessation of solution operations. Occasionally the salt roof to a cavern in stage (b) may be taken out with the intent of instigating collapse (see the SG4 case history). Deliberate oversolutioning is being considered to create desirable wetlands via sinkholes in the former ICI brinefield near Teeside, England.

Ground Subsidence

Salt creep means the ground surface over an intact cavern will deform into a shape resembling a wide shallow bowl, hence the name bowl subsidence. Bowl subsidence over intact salt caverns is a response to movements at depth, which are transferred to the surface with diminishing amplitude over a wide cone of influence. Subsidence of the landsurface above a salt cavern is normal and to be expected, especially above shallower storage caverns (Fig. 13.57; Table 13.10). This surface response is similar to "trough subsidence" at the surface above "long-wall" or "room and pillar" mining operations. As the boundaries of such mines advance the accompanying ground movements manifest as moving linear depressions in the landscape called areas of trough subsidence by mining engineers. Bowl subsidence above a salt cavern is not a problem unless the roof span breaches and the rate of ground subsidence increases.

Measured land subsidence rates vary above salt caverns constructed for storage of US Strategic Petroleum Reserve (SPR). Rates atop storage domes in the 1980s ranged up to 40–50 mm/year in SPR facilities in Texas and Louisiana (e.g. Fig. 13.57a). Rates above the much deeper Tersanne cavern in France are much lower ≈6–8 mm/year than those of the Gulf Coast (Fig. 13.57b), even after the cavern had shrunk relatively rapidly in the 1970s (Fig. 13.55). Since the late 1980s, almost all purpose-built storage caverns have been filled and maintained at higher pressures than in the 1970s. Pressurizing has mitigated salt creep and surface subsidence effects in land areas atop many of these domes (Thoms and Gehle 2000a).

For example, the Bryan Mound Dome, located southeast of Houston on the Texas Gulf Coast, was one of the first domes to host SPR caverns. The SPR site's subsidence rate was 24.4–36.6 mm per year from 1982 to 1988; when subsequently pressurized from 1988 to 1994 the subsidence rate fell to 6.1–24.4 mm per year; and was 3.1–15.2 mm per year from 1994 to 1999. That is, the median subsidence rate atop Bryan Mound decreased by 70 % following the increase in cavern pressure. Rates at the more recently constructed Big Hill SPR site ranged from 6.1 to 15.2 mm per year from 1989 to 1994; and from 6.1 to 9.1 mm per year from 1994 to 1999. By contrast, the subsidence rate at another SPR site, West Hackberry, was still high, approximately 76.2 mm per year

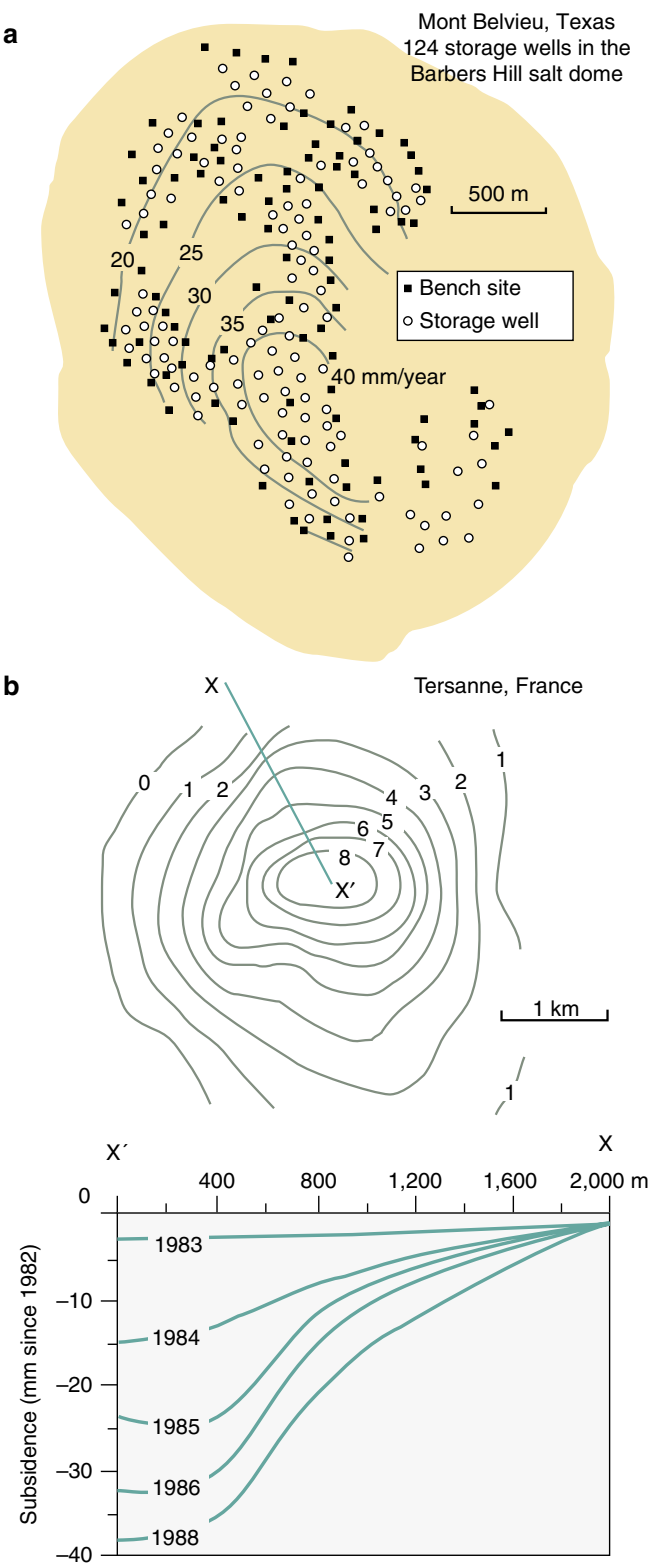

Fig. 13.57 Landsurface subsidence above storage caverns. (**a**) Subsidence contours in mm/year atop the Barbers Hill salt dome in the vicinity of Mont Belvieu, Texas (After Ratigan 1991). (**b**) Subsidence contours in mm/year atop the Tersanne storage cavern, France. Lower panel plots successive subsidence profiles from 1983 to 1988 along the line X-X' (After Bérest and Brouard 2003; Durup 1991)

Table 13.10 Examples of ground subsidence problems above salt caverns

Storage cavern	Time and place of accident	Reserve resource	Depth	Accident description	Accident cause	Influence scope
West Hack-berry	1970s, Louisiana, USA	Petroleum	750–1,400 m	Surface settlement rate 75 mm/a	Excessive creep of salt	Influence range about 750 m
Tersanne	1970–1980, France	Natural gas	1,860 m on average	Effective volume loss 35 %, settlement rate 40 mm/a	Excessive creep of salt	Influence range about 2,000 m
Bryan Mound	1982–1998, Texas, USA	Petroleum	640–1,250 m	Surface settlement rate 36 mm/a	Excessive creep of salt	Influence range about 600 m
Mont Belvieu	1988–1993, Texas, USA	Liquid propane	750–1,700 m	Surface settlement rate 20–40 mm/a	Excessive creep of salt	Influence range about 1,500 m
Big Hill	1989–1999, Texas, USA	Petroleum	1,350 m on average	Surface settlement rate 90 mm/a	Excessive creep of salt	Influence range about 1,000 m

After Yang et al. (2013)

after pressurization. The reason for the much lower rate at Big Hill is thought to reflect the very thick (300 m +) brittle caprock covering the Big Hill salt stock (Linn and Culbert 1999; Bauer 1999).

Estimates of rates of acceptable bowl subsidence atop product cycling caverns can be calculated using influence functions based on linear elasticity, the same mathematics used by mining engineers. This works well if the displacements are small, continuity prevails, and if appropriate effective reaction moduli can be estimated for the various inhomogeneous overburden materials above the caverns. Assumptions of mathematical linearity are often incorporated into methods for fitting subsidence models to existing databases in order to predict future trends of subsidence over cavern fields. But different leaching rates and inhomogeneous distributions of subsurface features means predictions are often of limited use. Sophisticated three dimensional finite element computer programs have been used to analyse subsidence over brinefields incorporating closely spaced caverns with relatively complicated subsurface geometries (see Kunstman and Mazur 2000). More recently 4D seismic approaches (Drijkoningen et al. 2012) and ERS radar interferometry (Raucoules et al. 2003) have been found to be feasible monitoring techniques.

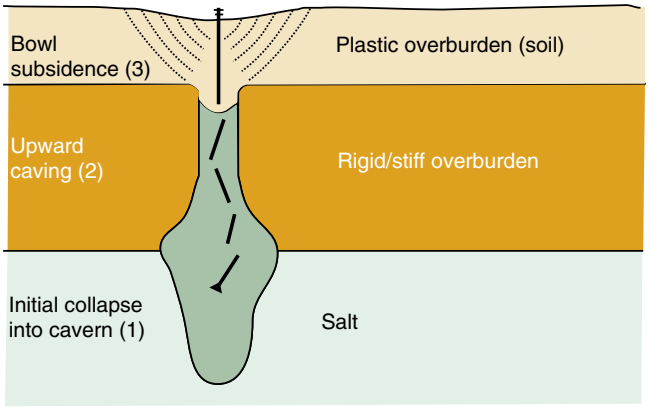

Fig. 13.58 Three stages of cavern collapse and sinkhole growth (After Thoms and Gehle 2000a)

Surface Indicators of Breached Caverns

Measuring subsidence above an active storage cavity over a number of years is a useful tool to monitor the state of the cavern and the likelihood of any sinkholes appearing at the surface. Subsidence over breaching caverns, where the integrity of the roof span is finally lost, generally involves three stages (Fig. 13.58; Thoms and Gehle 2000a): (1) initial overburden collapse into breached cavern; (2) upward caving via "chimneying" through indurated strata (which engineers sometimes describe as "stiff soils"), and (3) transition to bowl subsidence in more plastic soils near the surface. Following initial roof span collapse, local conditions determine whether caving or bowl subsidence will dominate. After an initial breach and collapse, Stage 2 caving stopes vertically through indurated strata as an upward migrating cavity atop a growing chimney. The cavity diminishes in height as it rises because of the bulking of caved materials into the stoping chimney. In Stage 3 the caving mechanism transforms into bowl subsidence as more plastic horizons (weathered strata and soils) are encountered nearer the surface. Breached caverns typically manifest at the surface as relatively deep subsidence bowls, sometimes with sinkholes near their centres.

Stage 2 caving can be bypassed or be arrested if the breached cavern is overlain only by plastic overburden or the cavern is too small to contain all the bulking debris from the overlying strata. In the latter case, the bulking materials fill the cavity to where they can support the roof once more, so arresting further upward migration. Localized bowls of subsidence will usually be seen at the surface over the arrested cavity. With time, the bulked materials may consolidate and allow some additional upward migration of the cavity, and so drive additional subsidence.

Among the various subsidence features, sinkholes are of greatest concern as they are rapidly expressed surface features of typically downdropped plugs of surface material encircled by near vertical sides. They occur when Stage 2 caving dominates all the way to the surface. Concentric fissuring and collapse of the landsurface atop a sinkhole can form within hours of the structure first breaking through to the surface. Overburden materials rapidly slip and fall into the growing water-saturated core with a huge potential for property damage and even loss of life (see case histories).

Monitoring and Minimizing Collapse

Subsidence effects, and even active sinkholing were once ignored by brinefield operators but changes in rates of subsidence, along with sonar monitoring of cavern shape, are now used as indicators of the state of the cavern. Responsible operators now conduct periodic or continuous subsidence surveys, and if anomalous effects are recognised, preventative action can be taken.

Routine monitoring of subsidence over storage cavern fields can be performed with conventional land surveying methods. A network of reference points or bench monuments is set up that effectively spans a brinefield or storage facility (Figs. 13.57a). A tie-in is often made to an established reference point located some distance away from the influence of the field. Differences in elevations of points over time intervals between surveys can then be interpreted as velocities of vertical movement (Fig. 13.57b). It is important to perform surveys at about the same time each year to minimize effects of natural seasonal factors, e.g., soil temperature and rainfall. For some cavern fields, it may be more efficient to make use of the Global Positioning System (GPS) for subsidence monitoring. Regulatory agencies often require that subsidence over storage caverns be routinely monitored and reported. Standard techniques for this purpose are given in Swarts (1993), Watts (1991) and Wong (1982).

More sophisticated automated methods for monitoring subsidence are justified when there is a significant risk of environmental or property damage, as in an area where there is a high probability of sinkhole development in close proximity to residences or storage pipelines and other infrastructure. Such a system might consist of an array of strategically placed tiltmeters, geophones, and inclinometers, with remote read-out and telemetry components (as is currently done for the subsidence cone associated with the Eugenie wells in Carlsbad, new Mexico). This system should be capable of collecting and sending data to a comprehensive analysis station at selected time intervals or when activated by a precursor event. Significant events may consist of accelerating localized surface movements, microseisms, and fissures.

Monitoring ground subsidence and cavern shape allows a cavern operator to minimize the effects of subsidence by:

Minimising subsidence from salt creep – As noted earlier, salt creep into caverns causes longterm bowl subsidence at the surface. It follows that bowl subsidence can be mitigated by minimizing salt creep in caverns. The most direct method for minimizing salt creep in existing hydrocarbon storage caverns is to operate them at the highest practical pressures at all times. The determination of the highest practical cavern pressures and operating schedules will involve consideration of site-specific cavern rock mechanics, economic and regulatory factors, as well as the potential impact of subsidence (Rokahr et al. 1998).

Maintaining adequate salt cover – In order to avoid possible collapse that might ultimately lead to sinkholes, an adequate salt cover must be maintained over salt caverns during solution mining and product cycling. Regulatory agencies generally now require that caverns be monitored to ensure that an adequate salt roof is maintained above caverns. Downhole "wireline" logging technology, e.g. sonar, is available to periodically check shapes and sizes of caverns and the location of the salt roof (Crossley 1998).

Natural or Anthropogenic Subsidence?

Figure 13.59a, b illustrates the long-term and ongoing effects of salt extraction and the utility of surface mapping in defining potential problem sites associated with long defunct solution mining. It is a subsidence map of the of the Muttenz-Pratteln area, Switzerland, a region where the solution mining of Triassic Keuper Salt ceased more than a century ago, yet ground subsidence is ongoing (Zechner et al. 2011). Recent land subsidences were surveyed at six separate locations, diameters of the affected surface areas ranging from 100 to 1,500 m, and corresponding subsidence rates reaching more than 100 mm/year (Fig. 13.59a). Of the six sites, three sites could be outlined where land subsidence was likely due on ongoing responses to salt solution mining. The others including the Lachmatt area were subsidence is greatest are likely responses to natural processes. For the natural occurrences, the authors conclude the most sensitive factor for the dissolution rate and related subsidence rate is the structure or dip of the halite formation, which leads to an increase of dissolution rate with increasing dip. This is due to the increased density of the brine, an intrinsic meteoric flow dynamic develops, which follows the direction of the dip.

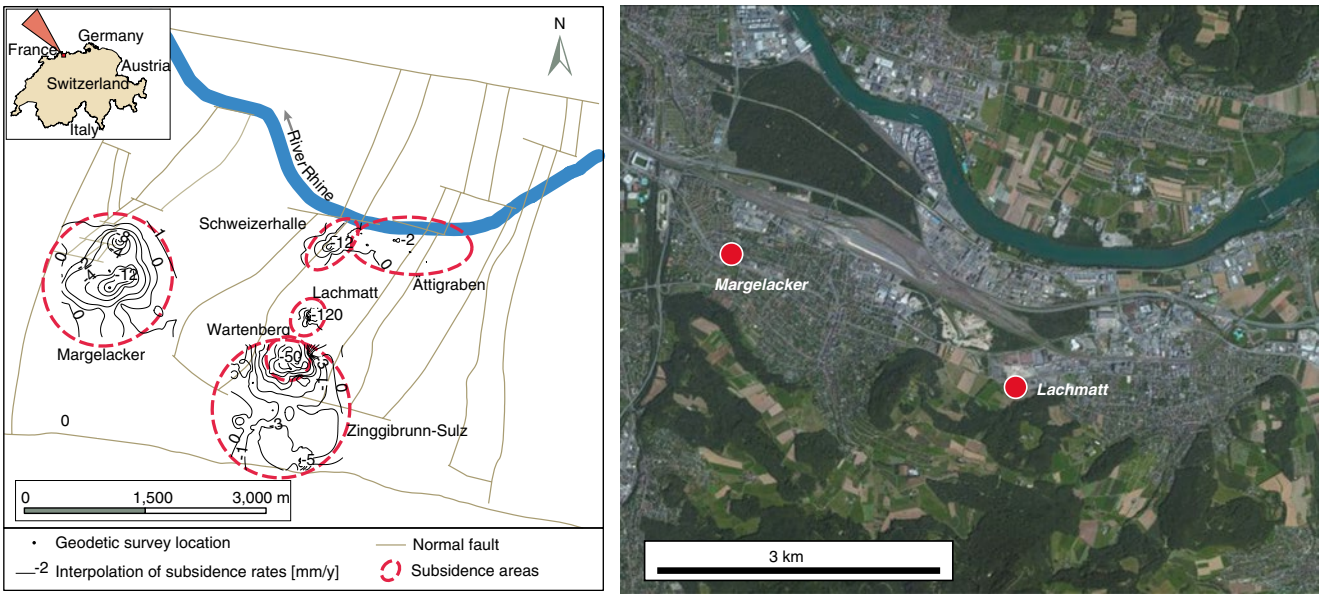

Fig. 13.59 Map of the Muttenz-Pratteln area, Switzerland. Solution mining in the area largely ceased 100 years ago. Interpolation of subsidence rates between 1975 and 2000 (averaged over 25 years), showing zone of greatest subsidence is centred on the Lachmatt area, a region with a subsidence cone unrelated to sites of former solution mining (After Zechner et al. 2011). So How Stable is a Storage Cavern?

Sites that are most suitable for a storage cavern lie within relatively homogenous regions of salt located deep in a diapiric salt mass, typically more than a kilometre below the landsurface and hundred of metres below the upper surface of the salt. Even today, many salt caverns used for various types of storage were first used for the commercial production of brine or hydrocarbons, although the number of purpose-built facilities increases year by year. Some older caverns now have shapes and spans or are at shallower depths that make them marginally suitable for future storage or waste disposal. Likewise, the access wells to these caverns were drilled some time ago and suffer the effects of chemical corrosion and older cement technologies. These older non-purpose built caverns do however make excellent "in-situ" laboratories to test the strength and integrity of salt formations. For example one brine cavern in the Bryan Mound Dome in Texas has a roof span of 335 m, yet it has not collapsed (Thoms and Gehle 2000a).

Natural gas storage caverns, with their inherent need for the deep cycling of internal pressures, place much greater demands on the integrity of the surrounding salt than caverns used for liquids storage. Salt cavities for natural gas storage were first designed with relatively small storage volumes but designs over the last three decades have increased in size. In Germany the maximum permitted volumes of gas for storage in salt caverns started at 350,000 m^3, increased to 500,000 m^3 and for the past 10 years has been set at 700,000 m^3. In the US cavern volumes for gas storage are not specifically regulated, but a design-specified cavern for natural gas storage with a volume of 15 MM bbl (6.5 Bcf) and a roof span of more than 100 m is now underway in the Napoleonville Dome in south Louisiana.

Cavern Plugging

The are a number of factors related to prior use and to long term salt creep that must be considered in designing effective closure or cavern plugs. For example during its operational life, episodes of low storage pressure can accelerate creep closure of a cavern, transmitting tensile strain to the casing. High storage pressure can cause increased permeability of the salt, by induced microcracks, which can result in migration of the stored gas into the salt, and possibly macro-fractures or casing shoe fracture. Hence, when a salt cavern used for hydrocarbon storage reaches the end of its life, it must be plugged in a way that does not allow for any later environmental degradation.

Wells creating and/or feeding a salt cavern can not be plugged using the same relatively straightforward methods used to seal an oil or gas well that has reached the end of its useful life. Oil and gas wells are usually sealed by simply installing a "plug" of alternating intervals of different grouts. Sealing and abandoning a brinewell or a salt cavern is not the same as plugging an oil and gas well for two main reasons (Fig. 13.60; Ratigan 2000):

1. Brine wells are generally completed with much larger casings than oil and gas wells.
2. The fluid pressure in the abandoned salt cavern is still joined to the casing string and it rises after plugging.

The first is not a significant deterrent to plugging and abandoning a storage well, appropriate modern grouts and methods are offered by most service companies. Essentially all of the uncertainties associated with cavern sealing and abandonment are a direct result of the second factor, rising fluid pressure and its effects on the access well(s).

Once a cavern is sealed and abandoned, salt begins to flow or creep into the opening and continues to flow until pressure differences between the salt and the cavern interior vanish. Plugs in former access wells to abandoned caverns must be capable of maintaining seal integrity and of holding back this pressure, otherwise brine or stored waste product may be squeezed back up the well bore via microcracks and seals. Fluid flow paths out of the cavern are schematically depicted in Fig. 13.60, while Table 13.11 summarizes the effects of the various processes contributing to fluid flow and pressure changes in a sealed salt cavern (Ratigan 2000).

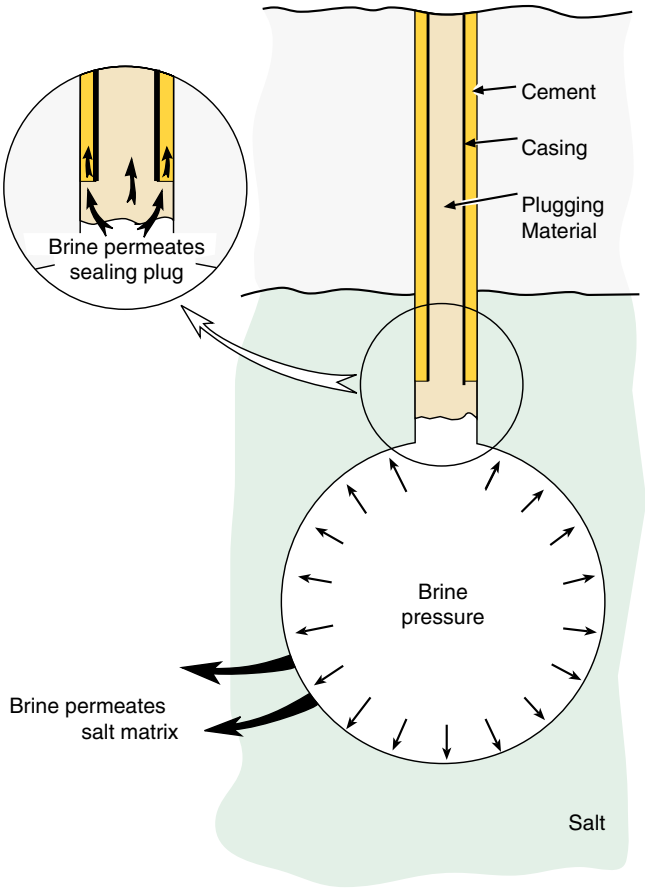

Fig. 13.60 Factors influencing cavern integrity once a cavern has been plugged and abandoned (After Ratigan 2000)

It is not just salt creep that increases the fluid pressure in an abandoned cavern. Solution mining and product cycling results in a significant disruption of the thermal environment in the salt. Feed solvent injected into the formation to create the cavern is almost always cooler than the salt formation, as is most stored product or waste. Continual leaching of a cavern to its final shape can result in a significant cooling of the salt surrounding the cavern, particularly near the cavern boundary. Unless a cavern has been inactive for a long period of time (tens of years), the fluid in the cavern will be at a lower temperature than the "pre-cavern" temperature of the rocksalt. Thus, when the cavern is sealed, heat will flow from the salt mass to the cavern fluid and its temperature will rise in response. A rise in fluid temperature expands the fluid volume and, since the cavern is sealed, the cavern fluid pressure will rise.

Unless the cavern was idle for some years prior to its plugging, cavern fluid is not 100 % saturated with sodium chloride. Salt dissolution may occur after a cavern is sealed and tends to lessen the effects of pressure rise. So, even after sealing, dissolution of the cavern wall continues until the enclosed fluid approaches halite saturation. This increases the cavern volume and so tends to decrease the cavern fluid pressure. Salt dissolution is an endothermic chemical reaction, which further reduces the temperature of the fluid, and so further reduces fluid pressure in the cavern.

A number of other interactive processes can effect the stability of a storage cavern and its plugged entry hole, depending on the nature of any waste stored in a sealed cavern. Differential settling and compaction cause the various wastes

Table 13.11 Factors influencing fluid pressure in a plugged cavern

Process	Influence on fluid pressure	Time scale
Salt creep	Increases cavern fluid pressure at a monotonically decreasing rate	Majority of the pressure rise occurs years to tens of years after sealing
Fluid heat transfer between salt and cavern	Causes cavern fluid expansion and increases cavern fluid pressure at a decreasing rate	Majority of pressure rise within tens of years to many tens of years after sealing
Salt dissolution and cavern fluid saturation	Increases cavern volume and decreases fluid temperature, which in turn, causes a decrease in fluid pressure	Majority of pressure decrease within years after sealing
Cavern fluid escape into salt	Decrease in cavern fluid pressure	Continues indefinitely
Cavern fluid escapes via sealing plug/or casing cement	Decrease in cavern fluid pressure	Continues indefinitely

After Ratigan (2000)

pumped into the cavern to separate into layers. Various chemical reactions can then occur within or between layers of waste, or between the waste and the surrounding salt. All can cause unexpected pressure build-up and so drive fluid penetration of the plug seal. Gas can also be produced in a sealed storage cavern, either by bacterial degradation of waste materials or by natural degassing corrosion of the surrounding salt. This too leads to a buildup in fluid pressures and places increased stress on the cavity plug and the cavern walls.

Even though salt has extremely low permeabilities, pressurised cavern fluid may slowly seep into the surrounding salt. This will reduce the volume of fluid in the cavern, and thus help ameliorate the pressure exerted on the salt by the cavern fluid. However, the entry of cavern fluids into the salt will also alter the salt matrix stresses, increase the rate of creep and the intrinsic permeability of the salt.

Before a cavern is sealed, the amount of cavern fluid that permeates the salt cavern walls is negligible. After the cavern is sealed and the cavern fluid pressure rises, the amount of cavern fluid that permeates the cavern wall must increase, both because the pressure gradient (driving the fluid transport) increases and because the salt permeability increases. If the cavern fluid pressure cannot be reduced sufficiently through the diffusional flow it is possible that fractures could develop in the salt. This would in turn reduce the cavern fluid pressure, but obviously increases the likelihood of a possible leak of cavern fluid into adjacent formations. Whether or not a fracture or fractures develop depends on the rate of cavern fluid pressurization. Low pressurization rates would not be expected to result in fracturing of the salt, rather the salt would flow and anneal. Very high rates of pressurization might well produce a brittle fracture.

But, as mentioned earlier, the salt itself is probably not the weakest link in terms of seal integrity. Pressurized cavern fluid will tend to first breach or fracture the sealing plug/casing shoe. Diffusional or fracture-induced flow could then occur through the sealing cement plug or the cement between the salt borehole wall and the deepest casing (Fig. 13.60 inset).

As well as dissolution creating potential seal problems, there is also the longer term problem of ongoing local rise of smaller salt spines within a diapir, which can shear casing and allow a breach to form in the well string. This was the situation in the at-surface well collar in well S-5 in the Sour Lake oilfield atop the Sour Lake diapir in Hardin County, Texas (Looff 2001). In 1998 the well casing sheared, driven by a rising spine of salt in what was overall a degrading or dissolving diapir crest. The 13 5/8-in. casing string, set in salt caprock, was being pushed upward inside the 16 in. casing. This fractured the cement between the two strings and the 16-in. casing string, that had been welded to the wellhead, which was sheared off its foundation as it was displaced upward by several inches.

Storage in salt creates a complex situation with various processes and mechanisms driving cavern pressures in opposite directions. A study of the stability of such systems is a study in multivariate rock mechanics, grout physics and pore fluid chemistry, well beyond the geological/sedimentological emphasis of this book (see Munson 1997; Lee and De Souza 1998 for a discussion of some of the basic considerations). As yet, our models of salt and grout response of time frame of hundreds or even thousands of years do not allow us to reliably predict exact conditions under which pervasive fracturing or leakage will occur. Accordingly, most storage facilities are "over-engineered" to reduce the possibility of longterm failure (Ratigan 2000).

Summary

Solution mining with appropriate monitoring and timely plugging offers major advantages in generating chemical feedstock compared to room-and-pillar mining techniques. Drilling injection and production wells cost less than sinking deeper shafts and opening underground workings. It also provides safer operating conditions as underground miners are not needed.

In terms of problems with solution cavities and storage facilities it is important to note that a salt mass used for storage has never failed or leaked. The weak point in these systems is wherever "the outside has access to the inside," so problems tend to be mostly in the well, its casing and its grout, or where uncontrolled cavity expansion breaches a salt edge. Almost all the problems related to well and cavity failure are more a matter of human error, either by negligence, or a lack of understanding by on-the-ground personnel. There is the same general rule of thumb when it comes to salt cavities and salt mines and that is, "keep it in the salt!" Most failures and breaches occur when a leaching or a mining operation allows the cavity to contact the edge of the salt. There undersaturated water crossflows can exaggerate any uncontrolled dissolution problems.

The rapidly expanding technologies of deep purpose-built and monitored storage caverns located well within geologically suitable salt masses, will lead to future safer storage of hydrocarbons and hazardous wastes. Almost all the problems documented in the USA and elsewhere come from storage operations utilising caverns constructed by earlier less-defined solution methods. Even so, in all the incidents related to various storages in salt caverns the integrity of the cavern has never been threatened by any accident. All incidents to date can be traced back to poor management practises or utilisation of facilities that are not necessarily suitable. Purpose-built salt caverns are probably one of the safest ways to store hydrocarbons and dispose of hazardous materials.

Meta-evaporites

14

Introduction

Evaporite salts can survive well into the metamorphic realm, but are altered, recrystallised or transformed into new minerals. And so, beyond the early greenschist phase, little or nothing of the original sedimentary mineral phase remains with the possible exception of anhydrite (Table 14.1; Spear 1993). Consider "the before and after" situation as a sequence of evaporite-entraining sediments passes into the metamorphic realm. Under a likely "before" regional metamorphism scenario, a typical buried marine evaporite body occupies a continental margin position, is hundreds of metres thick, tens to hundreds of kilometres wide, perhaps with halokinetic geometries and an extensively tilted and faulted overburden. Halite typically makes up more than 60–80 % of the total rock salt volume in a basinwide unit. This halite is likely to be interlayered with anhydrite, bitterns, magnesian carbonates and siliciclastic clays. "After" metamorphism, typically driven by subduction and continent-continent collision, the end product of this once dominantly NaCl body of rock is a series of sodic and magnesian aluminosilicates, magnesites, calc-silicates and marbles with local zones of potassic enrichment. The immediate question is, where did all that salt and the associated volatiles (Cl, CO_2, SO_3) go?

Some salt components may still reside in meta-evaporite indicator minerals, such as sodic or magnesian talc, lazurite, marialitic scapolites or tourmalinites. The remainder went elsewhere, perhaps as the transforming evaporite mass generated metalliferous volatile-entraining brines. The presence of volatiles and their mobilization in metamorphic transformation is typical of meta-evaporite associations. A relatively open system of hydrofractures and shear strength contrasts in the form of fault/shear-related fluid/volatile conduits was already present in the evaporitic protolith and encouraged by the polyhedral transformation of the NaCl lattice as it enters the greenschist pressure realm.

Such a "leaky" prognosis is a somewhat different subsurface scenario from the classic isochemical paradigms and closed chemical system assumptions that permeate much of the older metamorphic literature. More recent work has challenged and displaced the classic "no loss" and homogeneity assumptions in metamorphic mineral phase evolution (Yardley and Graham 2002; Putnis and Austrheim 2010). This is especially so when evaporites enter the contact, dynamic, hydrothermal and regional metamorphic realms. So first, a few definitions relevant to the metamorphic realm, then we shall consider in detail the role of evaporite salts as they evolve, dissolve, transform and release volatiles within the metamorphic milieu.

Dynamic metamorphism is associated with localised zones of high to moderate strain, such as fault zones, with textures that evolve with greater depth and pressure (Fig. 14.1a). Cataclasis, crushing and grinding of rocks into angular fragments, occurs in dynamic metamorphic zones, engendering a variety of evolving cataclastic textures. Salt bodies are an exception as a salt body is already ductile within tens of metres of the earth's surface (Chap. 6). Textures of dynamic metamorphism in the non-evaporites experiencing ever greater burial are dependent on the depth, while the temperature and confining pressure determine the deformation mechanisms which predominate (Fig. 14.1a). Generally, at depths less than 5 km, dynamic metamorphism is not operating in non-evaporites because the confining pressures are too low to produce frictional heat. Instead, brittle deformation dominates and zones of breccia or cataclasites can form as the mother rock is locally milled and broken into random fragments. At greater depths, the angular non-evaporite fragments in faults transit into ductile shear textures and into mylonite zones. Within a depth range of 5–10 km pseudotachylite can form in non-evaporites under shear, confining pressures are now enough to prevent brecciation and milling, but energy is still largely focused into discrete fault planes. Frictional heating in this case may locally melt the rock to form pseudotachylite glass. Within the depth range of 10–20 km, deformation is governed by ductile deformation conditions extending beyond the confines of individual fault damage zones and hence frictional heating is dispersed throughout shear zones. This results in a

After Spear (1993)

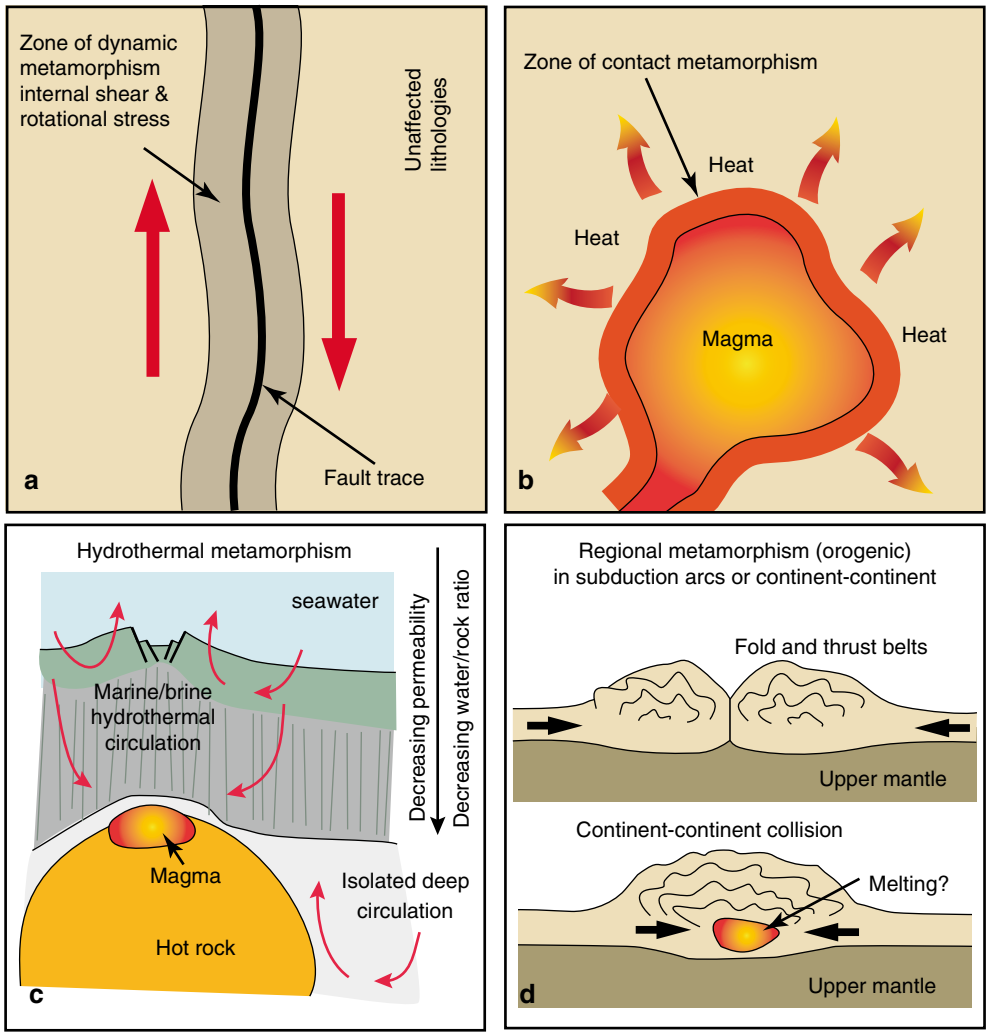

Fig. 14.1 Types of metamorphism. (**a**) Dynamic metamorphism. (**b**) Contact metamorphism. (**c**) Hydrothermal metamorphism. (**d**) Regional metamorphism. The various types are not mutually exclusive. (**a**, **b**) Tend to be more local features (tens of metres to tens of kilometres) (**c**, **d**) develop at the plate tectonic scale (tens to hundreds of kilometres)

weaker local thermal imprint and distributed more deformation. Here, deformation forms mylonite in the nonevaporites, with dynamothermal metamorphism occasionally driving the growth of porphyroblasts in the mylonite zones.

Contact metamorphism occurs typically around intrusive igneous rocks as a result of the temperature increase caused by the intrusion of magma into cooler country rock. The area surrounding the intrusion where the contact metamorphism effects are present is called the metamorphic aureole. The resultant metamorphics are typically classified as hornfels (Figs. 14.1b and 14.2).

Hydrothermal metamorphism is the result of the interaction of a rock with a high-temperature fluid of variable composition (Fig. 14.1c). The difference in composition between existing rock and the invading fluid triggers a set of metamorphic and metasomatic reactions. The hydrothermal fluid may be magmatic (originate in an intruding magma), circulating groundwater, or ocean water. Convective circulation of hydrothermal fluids in the ocean floor basalts produces extensive hydrothermal metamorphism adjacent to spreading centres and other submarine volcanic areas. The fluids eventually escape through vents in the ocean floor known as black smokers (Chap. 16).

Regional or Barrovian metamorphism covers large areas of continental crust typically associated with mountain ranges, particularly those associated with convergent tectonic plates or the roots of previously eroded mountains. The collision of two continental plates or island arcs with continental plates produce the extreme compressional forces required for the metamorphic changes typical of regional metamorphism. These orogenic mountains are later eroded, exposing the intensely deformed rocks typical of their cores. The conditions within the subducting slab as it plunges toward the mantle in a subduction zone also produce regional metamorphic effects and constituent the setting where many of the examples discussed in this chapter were formed (Figs. 14.1d and 14.2).

What effect did the flow/loss of significant volumes of metasomatic fluid/brine have on surrounding lithologies as they were released by the transforming evaporite minerals?

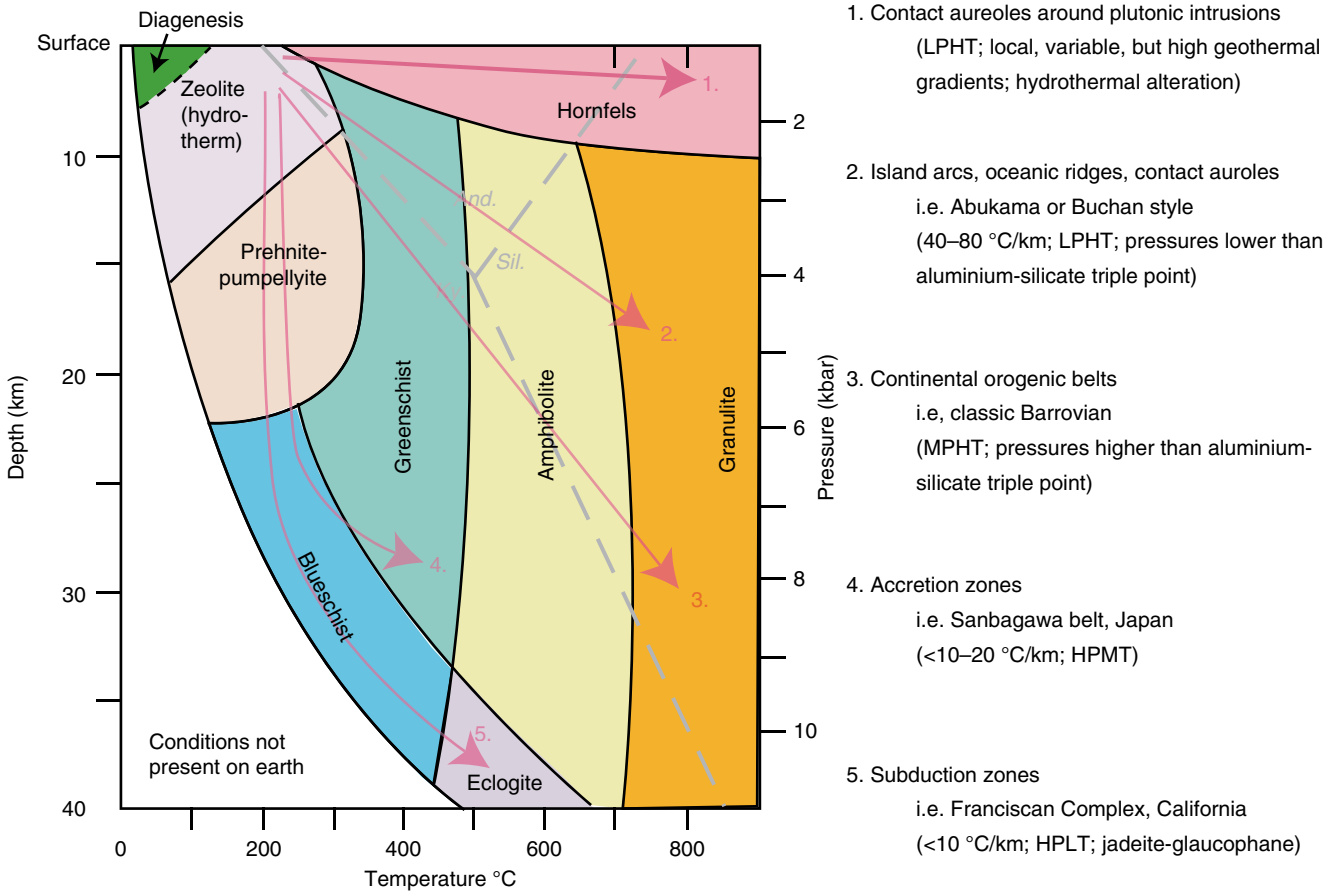

Fig. 14.2 Metamorphic facies in a depth, pressure temperature framework. *Numbered arrows* and the *adjacent listing* indicate typical facies evolution pathways (tied to geothermal gradients). *Dashed grey lines* indicate Kyanite (*Ky*) Andalusite (*And*) and Sillimanite (*Sil*) stability fields often used to help assign metamorphic grade. Refer to Table 14.1 for typical mineral associations in these facies (note this figure is constructed with isochemical or closed system assumptions)

Where, when and how did diagnostic meta-evaporite minerals precipitate? This chapter attempts to address some of these questions, while Chap. 16 addresses matters related to sulphide mineralization associated with meta-evaporites and contact/hydrothermal metamorphism.

It must be noted that the relevant literature base dealing with the "after evaporite" is sparse when compared with the mainstream literature in metamorphic petrology, and is at times contradictory (e.g., whiteschist discussion in Gebauer et al. 1997). Much of the metamorphic literature, and the associated structural literature, in meta-evaporite terranes seems to assume that prior to metamorphism all evaporitic protoliths were flat bedded, stratabound and little altered. This does not reflect the sedimentological reality that, prior to the onset of metamorphism in evaporitic basins there were:

- Steeply dipping blocks and folds in the brittle overburden and many of these structures were decoupled from basement features across widespread extensive low and high angle shear zones (décollements and shears, minibasin peripheries).
- Widespread breccias and alteration haloes defined the position of former salt units (dissolutional, halokinetic, fault plane breccias, welds and rauhwacke).
- Prior to the onset of metamorphism, pervasive alteration haloes (generally ferroan) had already formed, typically with nonstratiform geometries. They outlined hydrological conduits associated with salt sheets and welds, diapirs and faults.
- Magnesium and iron were replacing and altering adjacent sediments, with alteration beginning the time the evaporites were first deposited (e.g. reflux dolomites, ferruginized haloes, zeolites) and continuing into the metamorphic realm.
- Sodic and potassic alteration haloes in adjacent finer-grained sediments were already widespread, as were burial cements and replacements within coarser-grained non-evaporite units.

To make better sense of the influence of evaporites in some all types and scales of metamorphism of dynamic, contact hydrothermal and regional, these sedimentologic axioms need to be integrated into metamorphic/structural mineral evolution models and paradigms.

World-Scale Tectonism

Metamorphism occurs once the thermobaric regime, and associated diagenetic realm, passes with depth and increasing temperature and pressure, into the zone of metamorphism. Figure 14.2 encapsulates the pressure and temperature fields of the metamorphic regime (Yardley 1996). I have reversed the depth and pressure axes in this and some other P-T-Depth figures in this chapter from those used by some metamorphic petrologists to make it more familiar to the burial perspective to a sedimentologist (y axis goes from shallow to deep).

Regional zones of increasing metamorphic grade can be classified into metamorphic facies that represent limited ranges of burial depth, temperature, pressure, and water content in the crust. Zones of local or contact metamorphism are encapsulated in the hornfels (granofels) facies. Five major metamorphic facies of regional metamorphism are recognized (Fig. 14.2). The zeolite facies is characterized by the development of zeolite minerals in sediments and volcanics and reflects temperatures generally less than 200–250 °C and burial depths up to 10–15 km (Chap. 11). The succeeding greenschist facies is characterized by the development of chlorite, actinolite, epidote, and albite in mafic volcanics, and muscovite -biotite in pelitic rocks (Table 14.2). Albitization is also a widespread meta-mineral phase where halite and sodium bicarbonate salts are transformed within the greenschist realm.

Blueschist-facies assemblages tend to form in subduction zones with archetypal high pressures (>6–8 kbar[1]) and low temperatures (<400 °C); typical minerals are glaucophane, lawsonite, and jadeite. The amphibolite facies is characterized by kyanite, staurolite, and sillimanite in metapelites and plagioclase and hornblende in mafic rocks. The highest-grade rocks occur in the granulite facies, which is characterized by the sparsity or absence of hydrous minerals and the appearance of pyroxenes and a lack of preserved sedimentary evaporite salts, with the possible exception of anhydrite.

Clearly there are different geothermal gradients tied to different regional metamorphic associations (indicated by arrows 1–5 in Fig. 14.2). Within a plate tectonic paradigm, subduction and accretion terranes are typified by high pressure and high to moderate temperatures (arrows 5 and 4, respectively). Continental orogenic belts (continent-continent collision zone) are characterised by high temperatures and moderate pressures (arrow 3), while island arc metamorphism is characterised by high temperatures and low pressures (arrow 2). Zones of contact metamorphism (hornfels) show a wide range of temperatures at relatively low pressures and shallow depths (arrow 1). Variable temperatures and pressures in the zone of contact metamorphism can drive some types of hydrothermal circulation and associated precipitation and alteration haloes. The influence of evaporites, and associated saline basinal brines, in this setting is well documented, for example, by Barton and Johnson (1996).

In terms of thick widespread masses of evaporites evolving into meta-evaporites, the prime zones of interest are areas of hydrothermal circulation associated with contact metamorphism and zones of continent-continent collision. Thick widespread salts tend not to form in Proterozoic and Phanerozoic marine island arcs as the conditions are not typically hydrographically restricted, and likewise evaporites are not found in deepwater open marine settings (Chap. 5). That is, masses of sedimentary evaporites (or consequent meta-evaporites) are typically not part of any sediment pile found in open marine island arc/accretionary orogens (unless the suture zone was a restricted zone between two or more microcontinents, which facilitated hydrographic isolation).

Regionally extensive meta-evaporites are typically derived from thick widespread evaporite protoliths first deposited in the early stages of continental rifting or later in foreland basins tied to zones of continent-continent collision. Such thick sedimentary salt masses tend to form at the world-scale in predictable positions within the Wilson Cycle; early rift or continent-continent collision. Both are tectonic regions where substantial volumes of magma emplacement are likely. Then there is a third region of broad scale metamorphism, namely anorogenic prograde metamorphism. These are typically regions of high temperature, low pressure characterised by temperatures in excess of 600 °C, with pressures less than 5 kb. This third metamorphic grouping is typically tied to long-lived thermal anomalies tied to a mantle plume acting as the primary heat source. This third grouping is considered to have been the driver for the creation of many Archaean granite terranes such as in the eastern Yilgarn Block, Australia

During Phanerozoic and Proterozoic continental orogenies (continent-continent collision), lateral movements of the Earth's crust moved segments of continental crust into highly deformed and thickened regions known as orogenic belts (arrow 3 in Fig. 14.3). But there is a dilemma within this tripartite metamorphic frame that shades the interpretation paradigm for many meta-evaporites successions, namely, more than 50 % of the documented meta-evaporites are older than Neoproterozoic (Fig. 14.4). They occur in host successions where the precursor salts are long gone and plate tectonic models are less secured in the processes and rate of today's geosystem. That is, seems that the further back in time we look, the earth's crustal process paradigm is more and more related to a hotter mantle and a less evolved atmosphere/ocean and a somewhat different set/rates of plate tectonic paradigms.

[1]Pressure units: 1 bar = 100 kPa = 0.987 atmospheres and 1 kilobar = 1,000 bars = 100 MPa

Table 14.2 Examples of some meta-evaporite processes and indicator minerals

Process (indicator mineral)	Example	Reference
Scapolitization (scapolite) $(Na,Ca)_4[(Al,Si)_4O_8]_3(Cl,CO_3)$	Betic Cordilleras, southern Spain	Torres-Roldan (1978), Gómez-Pugnaire et al. (1994)
	Corella and Staveley Formations, Mt Isa Block, Australia	Oliver (1995), Stewart (1994a, b)
	Seve Nappe Complex, northern Sweden	Svenningsen (1994), Frietsch et al. (1997)
	Proterozoic Bamble and ModumKongsberg sectors, South Norway	Engvik et al. (2011)
	Wernecke breccia complex, Yukon Canada	Hunt et al. (2005), Kendrick et al. (2008)
	Paleoproterozoic magnesites, Ceara, NE Brazil	Parente et al. (2004)
	Granulite complex, Dronning Maud Land, Antarctica	Markl and Piazolo (1998)
	Zambesi Orogenic Belt, Zambia	Hanson et al. (1994)
Albitization (albite) $NaAlSi_3O_8$	Proterozoic Paranoa Group, Goias, Brazil	Giuliani et al. (1993)
	Olary Block, Australia	Cook (1992), Cook and Ashley (1992)
	Starra Gold deposit, Cloncurry region, Australia	Davidson et al. (1989)
Sodic talcs and/or phlogopites	Metapelites, Tell Atlas Algeria	Schreyer et al. (1980)
	Manganese-rich talc, Fowler Talc Belt, New York	Ayuso and Brown (1984)
	Sodic talc- kyanite, Sar-e-Sang, Afghanistan	Schreyer (1977)
	Permian evaporites, New Mexico and Carboniferous evaporites, Nova Scotia	Bailey (1949), Evans (1970), Gresens (1978)
Stratiform anorthositization (plagioclase) $(Na,Ca)Al(Si,Al)Si_2O_8$	Grenville Series, New York	Gresens (1978)
	Oaxacan granulite, Mexico	Ortega-Gutierrez (1984), Dostal et al. (2004)
Tourmalinitization (tourmaline) $Na(Mg,Fe)_3Al_6(BO_3)_3(Si_6O_{18})(OH)_4$	Barberton Greenstones, South Africa Willyama Supergroup, Broken Hill Block, Australia Liaoning borates, China	Byerly and Palmer (1991) Slack et al. (1989) Plimer (1988) Peng and Palmer (1995)
Lapis Lazuli (lazurite) $(Na,Ca)_8(AlSiO_4)_6(SO_4,S,Cl)_2$	Sar-e-Sang whiteschists, Afghanistan Baffin Island, Canada Edwards, New York	Faryad (2002) Hogarth and Griffith (1978) Hogarth (1979)
Columbian emerald (gem-tourmaline)	Columbia, S. America	Giuliani et al. (1995)
Marble-hosted rubies in Southeast Asia	e.g. Jegdalek Fm (Afghanistan); Mogok Fm. (Myanmar)	Garnier et al. (2008)

Although this table lists separate examples of indicators, most examples have multiple indications in the same deposits for example, scapolite and albitite are common co-associated mineral phases

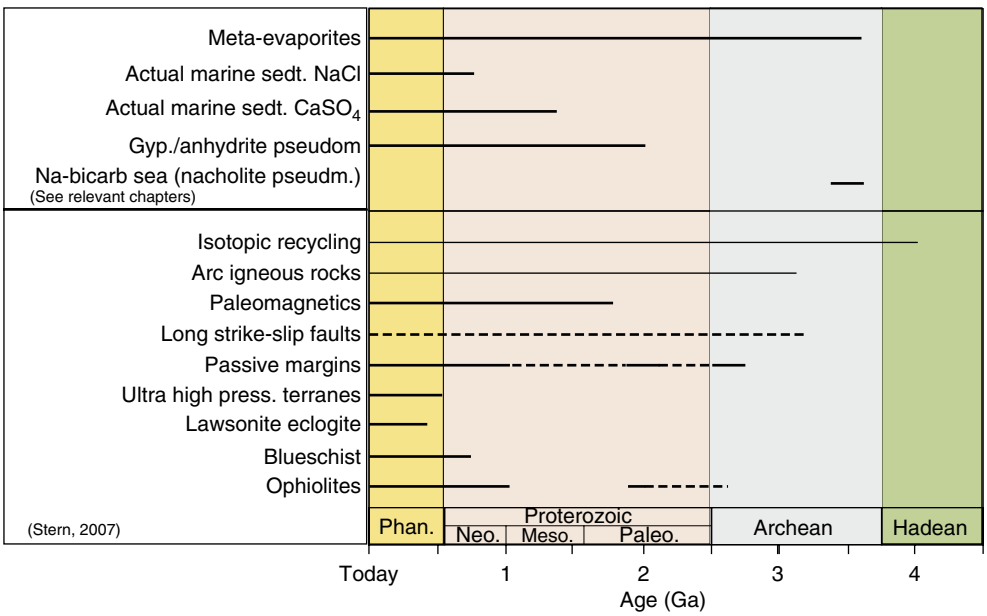

Fig. 14.3 Plate tectonic indicators and evaporite occurrences through time. *Solid lines* indicate features that are well documented, *thin lines* indicate more ambiguous indicators of plate tectonics that are well dated. *Dashed lines* indicate lesser degrees of confidence about the indicator and/or its timing (In part after Stern 2007)

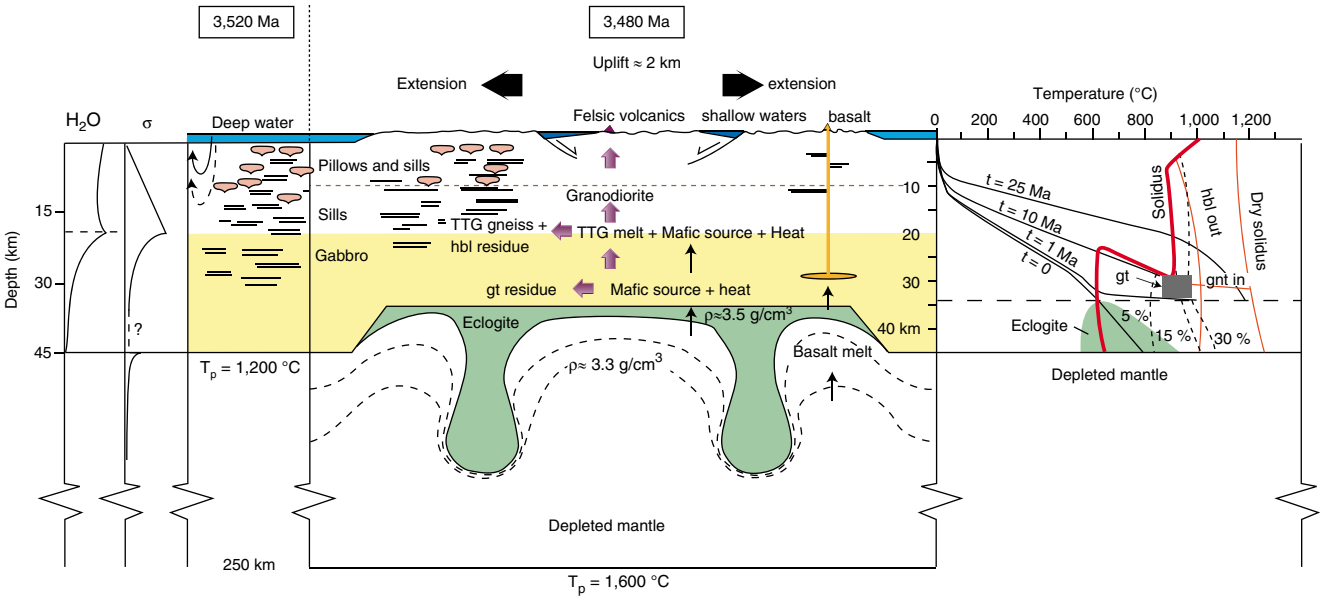

Fig. 14.4 Model for delamination of thick oceanic crust in the Middle Archaean based on Pilbara Craton geology, Australia (After Zegers and van Keken 2001). Partial melting in mantle with potential temperature (Tp) of 1,600 °C leads to thick oceanic crust (45 km) and thick depleted mantle (200 km), shown on left. Oceanic crust, corresponding to 3,520 Ma Coonterunah Succession in Pilbara craton, is hydrothermally altered by circulation of seawater. Qualitative water content is shown as a plot of H_2O. At ca. 3.49 Ga, lower oceanic crust, which has been metamorphosed to eclogite, delaminates from ductile middle crust. Eclogite is replaced by depleted mantle, forming basaltic melt by pressure-release melting. Overlying oceanic crust is intruded by these melts and conductively heated, resulting in melting of mafic protocrust to form TTG (tonalite, trondhjemite, and granodiorite) melts. Delamination of 10 km of eclogite results in ~2 km of uplift and associated extension in brittle upper crust. At right, solidus and melt contours are shown for dehydration-melting of amphibolite (*hbl*) in combination with estimated geotherms (based on conductive heating) in thick mafic protocrust before delamination, directly after delamination, and 10 and 25 m.y. after delamination. Garnet (*gt*) is formed in residue indicated by shaded rectangle in pressure-temperature condition diagram

Many Meta-evaporites are Pre-Neoproterozoic

Phanerozoic is the time frame encompassing almost all examples of preserved salts and known variations in oceanic chemistry and well-documented plate tectonic paradigms controlling metamorphic setting (Chap. 5). But more than 50 % of documented meta-evaporites are older than 1 Ga and occur within Precambrian mobile belts circumferential to Archaean craton cores. These are regions where no preserved primary salt remains. So, before discussing meta-evaporites in detail, we must consider the relevant time-based process/tectonic frame and ask; (a) What is a craton and, (b) How do models of craton formation and accretion relate to evolving styles of plate tectonism and evaporite metamorphism across deep time?

Precambrian cratonic regions have long been recognized as an important part of continental crust evolution, but looking back though a complex polycyclic igneous/metamorphic veil in order to interpret formative processes for older metaevaporite successions, means cratonic origin and accretionary evolution must be understood. Formation and preservation of cratons is a topic of ongoing and sometimes fierce geological debate. For example, in the Archaean terranes at Isua in Greenland, textures long considered as indicating the earliest sedimentary conglomerates and quartzites in the world, are now considered by others to be the relicts of tectonism and myolinitisation and not sedimentary remnants at all (see Eriksson et al. 2004; Chap. 2.2). If so, then arguments of the timing and origin of the hydrosphere using these rocks are even more enigmatic than the initial contentious argument of Appel 1984 that the stratiform tourmalinites at Isua indicated an evaporitic boron-rich precursor.

Cratons constitute the cores of today's continents and are characteristically composed of ancient crystalline basement crust, dominated by lightweight felsic igneous rocks, such as granites and granodiorites. The term craton (from the Greek, *kratos* for strength) describes old and stable parts of the continental crust that have survived the merging and splitting of continents and supercontinents (plate tectonics) and so encompass the world's oldest rocks. Cratons have thick lithospheric roots and are underlain by anomalously cold mantle corresponding to lithosphere more than twice the typical 60-mile (100 km) thickness of mature oceanic or non-cratonic, continental lithosphere (Condie 2004). But if cratons encompass the world's oldest rocks (>3.5 Ga), why were cratonic cores not destroyed by the dynamism of the recycling process that is inherent in modern plate tectonics?

Condie and Kröner (2008) argue that modern plate tectonic processes were operational, at least in some places on the planet, by 3.0 Ga, or even earlier, and that they became widespread by 2.7 Ga. They explain scarcity of complete ophiolite sequences before 1 Ga as indicating thicker oceanic crust, with preservation of only the upper, basaltic unit. They also argue that the apparent absence of blueschists and ultrahigh-pressure metamorphic rocks before ≈1 Ga indicates steeper subduction geotherms and slower rates of uplift at convergent margins.

In contrast, Stern (2007) defines plate tectonics as the horizontal motion of Earth's thermal boundary layer (lithosphere) over the convecting mantle (asthenosphere), and so it is a world-scale system or set of processes mostly driven by lithosphere sinking (subduction pull). He argues that the complete set of processes and metamorphic indicators, associated with modern subduction zones, only became active at the beginning of the Neoproterozoic (≈1 Ga). Stern interprets the older record to indicate a progression of tectonic styles from active Archaean tectonics and magmatism (greenstone belts), to something akin to modern plate tectonics at around 1.9 Ga. If so, then modern world-scale plate tectonics only began in the Neoproterozoic, with the advent of deep subduction zones (blueschists) and associated powerful slab pull mechanisms (Fig. 14.3). Flament et al. (2008) argue that the world's continents were mostly flooded (water-covered) until the end of the Archaean and that only 2–3 % of the Earth's area consisted of emerged continental crust by around 2.5 Ga.

It is very likely that the Archaean Earth's surface was broken up into many smaller plates with volcanic islands and arcs in great abundance (greenstone terranes). Small protocontinents (cratons) formed as crustal rock was melted and remelted by hot spots and recycled in subduction zones. There were no large continents in the Early Archaean, and small protocontinents were probably the norm in the MesoArchaean, when the higher rate of geologic activity (hotter core and mantle) prevented crustal segregations from coalescing into larger units (Figs. 14.3 and 14.4). During the Early-Middle Archaean, Earth's heat flow was almost three times higher than it is today, because of the greater concentration of radioactive isotopes and the residual heat from the Earth's accretion (Eriksson et al. 2004). There was considerably greater tectonic and volcanic activity; the mantle was much more fluid and the crust much thinner (Zegers and van Keken 2001; Ernst 2009; Flament et al. 2008). This resulted in rapid formation of oceanic crust at ridges and hot spots, and rapid recycling of oceanic crust at subduction zones with oceanic water cycling through hydrothermally active zones somewhat more intensely than today. Felsic protocontinents (cratons) probably formed atop Archaean hot spots from a variety of sources: mafic magma melting more felsic rocks, partial melting of mafic rock, and from the metamorphic alteration of felsic sedimentary rocks. Although the first continents formed during the Archaean, rock of this age makes up only 7 % of the world's current cratons; even allowing for erosion and destruction of past formations, evidence suggests that only 5–40 % of the present continental crust formed during the Archaean.

Whatever and wherever the onset of Archaean evaporite deposition, all agree that the mechanisms and aerial proportions world-scale plate tectonism were different in early earth history compared to the Phanerozoic. The current argument as to how different is mostly centred on when earth-scale plate tectonic processes became similar to those of today. Give much higher crustal heat flows, it is likely that hydrographically isolated subsealevel depressions, required to form widespread marine evaporites, were more localised in the Archaean than today and possibly more susceptible to hydrothermal metamorphism. Appropriate restricted brine sumps would have tended to occur in magmatically-induced uplift zones, with crestal subsealevel grabens, which were hydrographically isolated by their surrounds created by supra-sealevel uplift. Once deposited, the higher heat flow in Archaean crust and mantle would also have meant evaporites masses were more rapidly recycled by diagenetic and metamorphic processes than today.

By definition, a craton is an isostatically positive and tectonically stable portion of the world's continental crust, relative to adjacent orogenic belts. This is why evaporite masses, with a need for subsealevel seepage are not typically found atop cratons throughout the Phanerozoic (with the exception of the aulocogen zones in the Amazonian and the Siberian cratons). To have survived without being recycled, a craton core must have deep roots that extend down into the mantle. Mantle tomography shows that cratons are underlain by anomalously cold mantle, corresponding to lithosphere more than twice the approximately 100 km thickness of mature oceanic or noncratonic continental lithosphere. With roots at that depth, it could be argued that some cratons might even be anchored in the asthenosphere. Mantle roots must be chemically distinct because cratons have long-term neutral or positive buoyancy, and an intrinsically low density required to offset any density increases due to geothermal contraction across billions of years. Otherwise, cratons would have been destroyed/recycled by ongoing Proterozoic and Phanerozoic plate tectonism.

Samples of these mantle roots are contained in peridotites, delivered to the intracratonic surface as inclusions in diamond-bearing kimberlite pipes. These inclusions have densities consistent with a low density craton composition and are composed of mantle material that are residuals from high degrees of partial melt (Fig. 14.4). For example, harzburgite peridotites represent the crystalline residues after extraction of melts with compositions indicative of basalt and komatiite. The question is, how did these low density

mantle roots, now below the cratons, form, and what types of processes instigated them and allowed their longterm preservation?

Models based on the uniformitarian extrapolation of present-day arc volcanic and mantle plume processes to a hotter early Earth do not adequately explain the geology of early to Middle Archaean cratons. Alternate plate-scale mechanisms are needed to explain the formation of the earliest continental crust. In the Archaean the formation of continental crust was probably driven by delamination of the lower eclogitic part of an oceanic plateau-like protocrust, which was much thicker than today's oceanic crust. Such delamination resulted in local uplift, extension, and the production of tonalite, trondhjemite, and granodiorite (TTG) suites, as recorded in Middle Archaean cratons of NW Australia and South Africa. These are both areas where trona pseudomorphs typify meta-evaporite phases in the adjacent greenstone sediment suites (Chap. 2).

In the Pilbara craton the delamination occurred ≈3.49 Ga, just before the production of voluminous TTG melts between 3.48 and 3.42 Ga (Fig. 14.4; Zegers and van Keken 2001). Delamination resulted in rapid uplift, extension, and voluminous magmatism, which are all features of the 3.48–3.42 Ga Pilbara succession. As the delaminated portion was replaced by hot, depleted mantle, melts were produced by both decompressional melting of the mantle, resulting in high-MgO basalts (this is the Salgash Subgroup in the Pilbara craton), and melting of the gabbroic and amphibolitic lower crust, so producing TTG melts. Partial melting of the protocrust to higher levels can be envisaged as a multistep process in which heat was conducted to higher levels and advection of heat occurs by intrusion of partial melts in subsequently higher levels (indicated by purple arrows in Fig. 14.3). TTG melt products that were first intruded were subsequently metamorphosed and possibly partially melted, as can be inferred from the migmatitic gneisses of the Pilbara. This multistep history explains the complex pattern of U-Pb zircon ages of gneisses and granodiorites found within the Pilbara batholiths and the range in geochemical compositions of the Pilbara TTG suite.

Simple mass- and heat-balance considerations suggest that delamination of a 10-km-thick eclogite layer would have led to up to 2 km of crustal uplift and that the conducted and advected heat would allow mid-crustal melting and TTG production within 10–20 m.y. after delamination, which is consistent with the geologic evidence in the Pilbara and Barberton cratons (Fig. 14.4; Zegers and van Keken 2001). To produce 10 km of TTG melt from 30 km of mafic protocrust, an average of 30 % partial melting is required. Melting contours in Fig. 14.4 show that the 30 % melt contour is exceeded with the high temperatures reached in the lower and middle crust.

Between 875 and 980 °C, garnet is formed in the residue after partial melting of amphibolite (indicated by grey rectangle in Fig. 14.4), and depending on the garnet content, the residue can have a density of 3.35–3.50 g/cm^3. This high density will lead to a renewed delamination event and subsequent uplift, extension, and magmatism. At lower depth, the residue will consist of hornblende, plagioclase, and clinopyroxene. TTG production will eventually cease when the heat effects of delamination have dissipated and when no new garnet residue is produced to cause further delamination, because the crust is too thin (<30 km) to be in the garnet stability field. In the Pilbara craton, the entire range of U-Pb ages of the TTG event spans from 3.49 to 3.42 Ga in the TTG suites and volcanic rocks, but two age spikes at 3.47 and 3.45 Ga may each represent a delamination event, the second one indicative of a garnet residue event.

The eclogite-delamination model of Zegers and van Keken (2001) explains a wide range of observations in Middle Archaean cratons that have been insufficiently explained when subduction models and modern plate tectonic analogs are applied to these ancient cratons. Delamination explains; (1) the compositional difference between subcratonic Archaean and post-Archaean lithospheric mantle (as sampled in peridotites) and the spatial and temporal link between Middle Archaean crust and depleted mantle, (2) the seismically inferred thinner continental crust and absence of the basal high-velocity layer in Middle Archaean cratons (i.e. the deep roots), (3) coeval TTG melt occurring over large areas (>20,000 km^2 in the Pilbara), (4) substantial uplift, extension, and core-complex formation during intrusion of TTG suites and juxtaposition of high-grade gneisses with low-grade greenstones with preserved shallow water textures and meta-evaporites (that would have required hydrographically isolated depressions), and (5) the nonlinear arrangement of volcanic rocks, structures, and metamorphism (including the creation of highly sodic meta-evaporitic protoliths).

Key to the formation of early Archaean evaporites, which indicate a sodium bicarbonate ocean at that time (Fig. 2.48) is the observation that delamination led to up to 2 km of crustal uplift. This would have driven some regions of what were submarine sedimentary systems into suprasealevel positions, so creating the potential for hydrographically isolated – subsealevel marine seepage sumps in those portions of the uplifted crust above the zones of delamination. It also explains the centripetal nature of much shallow marine sedimentation of that time. This is cardinal at the broad tectonic scale when comparing the distribution of Archaean and Phanerozoic evaporites. Most Archaean evaporites are underlain by layered igneous complexes that were dominant across the greenstone seafloor. Uplift and the local accumulation of sodium carbonate evaporites occurred in a depositional setting that was dominated by volcaniclastics,

hydrothermal vents and extensional tectonics. Tectonic patterns in these settings have a strongly vertical flavor. In contrast, Phanerozoic salts formed from marine waters with a NaCl dominance with minor bicarbonate compared to calcium, and located mostly in subsealevel sumps formed at interacting plate margins where the dominant tectonic flavor is driven the lateral movement of plates atop a laterally moving asthenosphere.

Across the Earth's 3.5 Ga sedimentary record, not only has ocean chemistry evolved (Chap. 2), the earth's lithosphere/plate tectonic character has also evolved (Eriksson et al. 2013). The further back in time, the less reliable is the application of the current plate tectonic paradigm with its strongly lateral movements of crustal blocks and associated plate-scale evaporite basin controls. This is a system where subsealevel continental rifts and continent-continent collision belts favour the formation of mega-evaporite basins (Fig. 14.3). Instead, in a substantial portion of the 2 billion year history that is the Archaean, evaporite deposition was favoured by hydrographic isolation created by stronger vertical movement of earth's crust related to upwelling mantle plumes. There is still no real consensus as to actual time when plate tectonics, as it operates today, actually began but there is consensus that the present (in terms of plate tectonics and evaporite distribution) is not the key to much of the Archaean (Stern 2007; Rollinson 2007).

Protoliths Across the First 2 Billion Years

Key to the understanding the formation of Archaean meta-evaporites is whether the Archaean Earth was a waterworld in which only a few small landmasses (mafic or felsic) breached the surface of a global ocean; or did higher mantle temperatures and more vigorous convection produce more extensive networks of emergent mountain ranges and plateaus, possibly emergent atop mantle plumes, zones of delamination, or along the mid-ocean ridges? Whatever scenario is correct, tectonic settings, sedimentation styles, mineral proportions and lateral extents of marine evaporite protoliths were not the same in the Early-Middle Archaean as in the Phanerozoic. They evolved though time into associations more akin those at the surface of a cooler and increasingly oxygenated surface that typifies the Neoproterozoic and Phanerozoic earth (Ernst 2009). Yet there is clear evidence of evaporite episodes in the metasediments of Early Archaean greenstone terranes, both as meta-evaporite minerals (e.g. stratiform scapolites, tourmalinites and albitites) and nahcolite/trona/halite pseudomorphs in chert masses and mudstone hosts (Fig. 14.5). Archaean evaporite mineralogies reflect precipitation under much hotter surface and mantle conditions beneath a CO_2-enriched atmosphere (Chap. 2; Lowe and Tice 2004).

Very thick sections of mostly submarine mafic, and subordinate ultramafic, volcanic rocks, and mostly younger subaerial and submarine felsic volcanic rocks and sediments were oppressed into complex synforms between rising young domiform felsic batholiths mobilized by hydrous partial melting in the lower crust (Hamilton 1998). Upper-crust granite-and-greenstone terrains underwent moderate regional shortening, decoupled from the lower crust, during compositional inversion accompanying doming, but cratonization soon followed. Tonalitic basement is preserved beneath some greenstone sections but supracrustal rocks commonly give way downward to correlative or younger plutonic rocks. Stable convective mantle plume cells probably did not yet exist in the early to mid Archaean, and developing continents were concentrated in cool regions. Hot-region upper mantle was partly molten, and voluminous magmas, mostly ultramafic, erupted through many ephemeral submarine vents and rifts focussed at the thinnest crust. Surviving Archaean crust is typically from regions of cooler, and more depleted, mantle, wherein greater stability permitted uncommonly thick volcanic accumulations from which voluminous partial-melt, low-density felsic rocks could be generated.

Within this predominance of various types and styles of lava flows and magmas, four types of sediments typify Archaean greenstones that were the at-surface areas both between and onlapping the proto-sialic crust (Lowe 1994). In order of decreasing importance, they were; volcaniclastic, chemical, biochemical, and terrigenous sediments. Volcaniclastic sediments (including greywackes) range from mafic to felsic in composition and were typically deposited as turbidites, implying subaqueous sedimentation beneath an extensive hydrosphere. Whether the subaqueous setting of the early Archaean was marine in the sense of a large contiguous mass of water covering much of the earth's surface or whether surface water was present as more localized "super-lakes" perhaps residing in huge bolide depressions, is a still a matter of debate, as is when in the Early Archaean the world's surface hydrography can first be called truly oceanic (Awramik and Buchheim 2009).

Layered chert and banded iron formation are the most important nonclastic sediments in Archaean greenstone belts. Relict detrital textures in some cherts indicate that many Archaean cherts are silicified clastic sediments and volcanics. This style of hydrothermally driven chertification/silicification is not as prevalent in the cooler sedimentary basins of today. Few, if any, Archaean cherts appear to represent pelagic "marine" biochemical sediments, which today are the dominant modern style of sedimentary chert precipitation. Many Archaean cherts are local lenses and were probably tied to hydrothermal vent deposits. Low $\delta^{18}0$ values in many Archaean cherts support such a volcanogenic/high temperature origin (Knauth and Lowe 2003). A lack of sulphate in the world's anoxic oceans probably meant

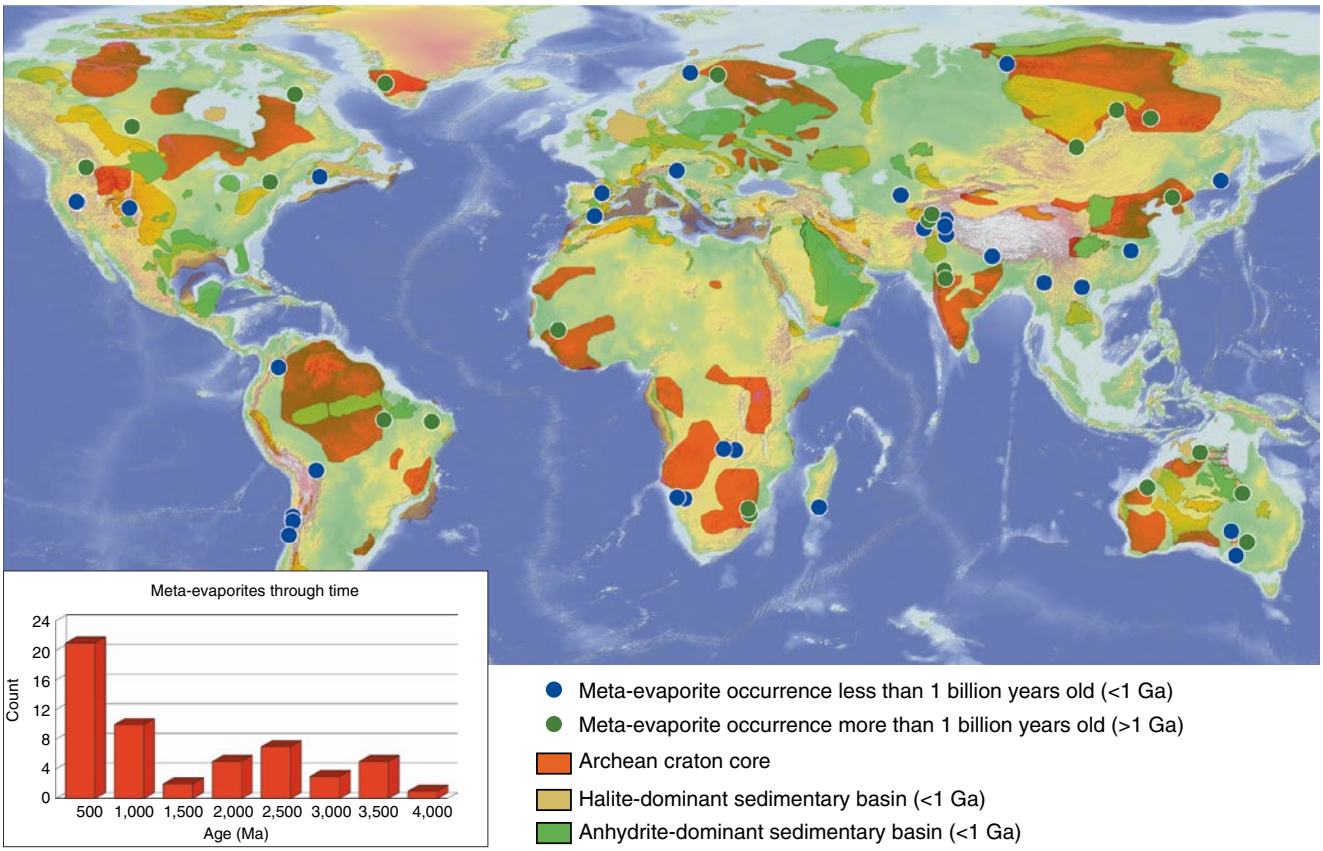

Fig. 14.5 Meta-evaporite occurrences, older and younger than 1 Ga, overlain on distribution plots of Archaean cratons, halite-dominant and anhydrite-dominant sedimentary basins. *Inset* shows age distribution of the occurrences in 500 million year blocks (Data replotted, with permission, from SaltWork database version 1.6. Details of individual plots are given in the various tables in this chapter)

marine hydrothermal anhydrite was less common as a convective oceanic salt than in modern marine hydrothermal vents and VHMS deposits.

Worldwide, the most widespread Archaean depositional environment, especially in early Archaean greenstone terranes, was the mafic plain environment (Condie 2004; Lowe 1994). In this setting, large volumes of basalt and komatiite were erupted to form widespread mostly submarine mafic plains characteristic by ubiquitous pillow structures in the lava interlayers. A second significant sedimentary environment was a deepwater, nonvolcanic setting, where chemical and biochemical cherts, banded iron formation, and carbonate laminites were deposited. The typical lack of evaporite indications in these mostly deepwater sediments indicates an ongoing lack of hydrologic restriction while the sediments were accumulating (waterworld association). The third association, a greywacke-volcanic association becomes more widespread in late Archaean greenstones, which typically sit stratigraphically atop mafic plain units. This association is composed chiefly of greywackes and interbedded calc-alkaline volcanics. It was perhaps deposited in or near island arcs and it too typically lacks widespread indicators of former marine evaporites. Fluvial and shallow-marine detrital sediments, were probably deposited locally in Archaean pull-apart basins, and mineralogically mature sediments (quartz arenites, etc.) typified the shallowest to emergent parts of continental rifts that constructed the last two of the three sedimentary environments within greenstone terranes.

Also associated with a surfacing seafloor, in regions such as the Pilbara, are particular chert and volcaniclastic layers that preserve evidence of shallowing in the form of mud cracks, wave ripples, tidalites interbedded with hyaloclastics, vuggy cherts, banded iron formations, carbonates and thick now-dissolved and altered evaporite masses (breccias), perhaps residues of beds formerly dominated by sodium carbonate salts. Strelley Pool chert in the Warrawoona Group, preserves many silicified examples that retain fine detail of primary textures such as mud cracks, oolites, and evaporite crystal casts and pseudomorphs, all indicating shallow-water to emergent deposition atop the mafic plain. In terms of crystal outlines there are rare casts of possible gypsum crystals (Chap. 2), more typically, they indicate bladed bottom-nucleated nahcolite, trona and in some instances, halite pseudomorphs (Fig. 14.6). These cherty units must have risen, at least locally, to shallow near-sealevel depths and at time become emergent, allowing local hydrographically-isolated

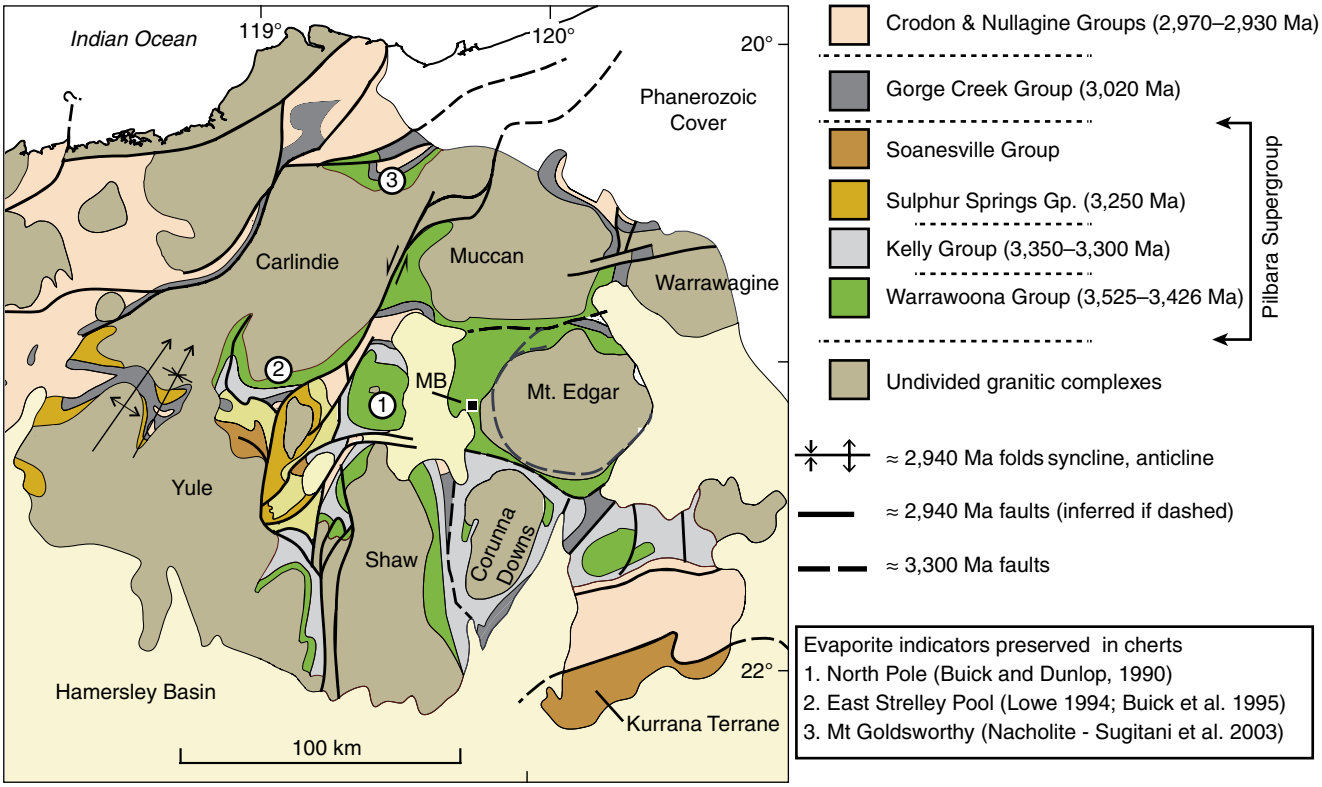

Fig. 14.6 Simplified geological map of the East Pilbara terrane, northwest Australia, showing main granitic domes and the Archaean synformal sediment fills in the interdomal regions (*greenstone*). Also illustrated are documented occurrences of evaporite indicators in chert (In part after Van Kranendonk et al. 2007)

lacustrine/rift evaporite deposition or precipitation of local seepage drawdown salts (Fig. 7.98). Associated primary-textured carbonate and baryte layers interbedded with the cherts are typically minor, bottom-nucleated baryte textures that may represent hydrothermal vent deposits.

High solubility of any sodium bicarbonate and/or halite salts in what was a hotter burial system strongly influenced by hydrothermal circulation, meant most original evaporite salts were not preserved, unless silicified in early burial. But their presence as pseudomorphs in less altered greenschist terranes intercalated with volcanics, such as in the Yilgarn, Pilbara and Kaapvaal cratons, clearly shows two things; (1) at times in the early Archaean there was sufficient hydrographic restriction to allow marine sodian carbonate and sodian chloride evaporites to form and (2) this marine restriction/seepage inflow was probably driven by ongoing volcanism and associated uplift, with evaporites restricted to particular basinwide stratigraphic indicator levels.

In the East Pilbara, the early Archaean evaporite stratigraphic level is the Strelley Pool chert, in the Warrawoona group (Fig. 14.6). This is also the level with some of the earliest indications of cellular lifeforms (Wacey 2009). For the evaporites, it marks the hydrological transition from open marine seafloor to a restricted hydrographically-isolated marine-fed sump basin, surrounded by granite-cored highs with the required uplift likely driven by delamination at the level of the mantle transition (Figs. 14.4 and 14.6). Given the intimate association of chemical sediments to volcanism in early Archaean greenstone basins, and the sodium bicarbonate ocean chemistry then, compared to the Phanerozoic evaporite hydrochemistries, we can expect a higher proportion of CO_2 volatilization and a higher boron content (tourmalinites) in early Archaean and perhaps even Paleoproterozoic meta-evaporite assemblages.

Some authors have noted that there are no widespread marine evaporites in the Archaean and in the sense of actual preserved salts, this is true. But when one considers that the Archaean crust was much hotter than today and hydrothermal circulation was more active and pervasive, then burial preservation seems highly unlikely. Even in the Neoproterozoic, only minor volumes of the original salt masses remain (Hay et al. 2006). The lack of preserved salts in earlier Precambrian strata is more a matter of great age and polycyclic metamorphic alteration. The mode of alteration associated with the nahcolite-dominant marine systems associated with a sodium-chloro-bicarbonated ocean versus the halite-$CaSO_4$ dominated marine evaporites associated with the Na-(Mg)-Cl-(SO_4) ocean of the Proterozoic and

Phanerozoic is still not widely discussed or understood. We shall come back to this topic of Archaean versus Proterozoic-Phanerozoic meta-evaporites and their alteration dissolution later in this chapter and in subsequent chapters dealing with controls on the formation of Precambrian base and precious metal deposits.

Metamorphism: Onset and Evolution

The temperature separating the diagenetic from the metamorphic realm is thought to be ≈200 °C. Conceptually, it is difficult to separate the high temperature end of the zone of diagenesis from the zone of metamorphism. In the more advanced stages of burial diagenesis many clays become unstable as they convert to interlayered mixtures of chlorite and illite, often associated with kaolinite. These mineralogical changes in clays occur in both the late diagenetic and the early metamorphic realms and are associated with the ongoing loss of pore fluids, including generation of volatiles such as CO_2, H_2S, Cl and CH_4. Hence the rock matrix chemistries, especially in evaporitic settings, cannot be interacting isochemically at this time; there must be a flow of fluid and ionic components in and out of the system.

Thrust Belts; Dynamic or Regional Metamorphism

Some metamorphic petrologists use the term anchizone (anchimetamorphic) to describe the subsurface region where chlorite-illite diagenesis is transitional into the prograde metamorphic realm, and the term epizone for the succeeding lowest grades of prograde metamorphism in which illite is largely replaced by muscovite or white mica in a process described as sericitization. Very fine-grained white micas of epizonal slaty rocks are known as sericites, with the dominant constituent typically phengite, a variety of muscovite. The degree of illite[2] crystallinity is often used by metamorphic petrologists to help define the early stages of metamorphism.

Where studies of illite crystallinity (IC) have been conducted on evaporite-encased clay samples, the outcome, while fitting the general paradigm of increasing illite crystallinity with regional temperature gradient, is a little more complicated due to various combinations of salt-edge fluid focus, halokinesis and higher thermal conductivity in NaCl masses. Spötl (1992) studied clay mineral assemblages in Upper Permian evaporites (Alpine Haselgebirge Formation) of the Northern Calcareous Alps in Austria. Using fresh samples from a salt mine from Hall in Tyrol, he found that illite crystallinity was strongly dependent on the host lithology (Fig. 14.7). Illite from muddy halite indicated an incipient anchizonal overprint (boundary is defined by $\Delta°2\theta$ mean $= 0.42 \pm 0.02$). Illites from intercalated mudrocks and sandstones were less crystalline and averaged higher $\Delta\ °2\theta$ values of 0.47 ± 0.01 and 0.56 ± 0.03, respectively. Thus, illites in these lithologies are significantly less evolved compared with intercalated muddy halite samples and indicate nonmetamorphic (diagenetic) conditions. Spötl postulates that the crystallinity in the muddy halites reflects either higher potassium content and hence greater supersaturation with respect to muscovite transformation in highly saline pore brines, or, a thermal anomaly tied to nearby diapiric ascent.

In a subsequent related study, Spötl and Hasenhüttl (1998) compared IC values and levels of vitrinite reflectance across a number of Haselgebirge localities, mostly using samples collected in salt mines, including the Hallstatt Mine site (Fig. 14.7b). They identified a general relationship between the two determinations, showing that decreasing IC values were tied to increasing temperatures of alteration/diagenesis/onset metamorphism, indicated by the higher vitrinite values. Across the Haselgebirge there were significant ranges of both values, as is to be expected given the tectonic melange origin of the Haselgebirge. As we saw in Chap. 7, it contains a mixture of clasts and fragments in a flowing salt matrix, some clasts had experienced greater degrees of thermal alteration before being mobilised as the surrounding tectonised salt moved to a shallower cooler depth.

When illite crystallinity was measured in bedded Permian–Triassic sediments (Bellerophon/Weren) of varying carbonate/siliciclastic content, recovered in the Gartnerkofel-1 Core (Carnic Alps, Austria), values appropriate to the anchizone (onset of metamorphism) were restricted to the oolitic carbonates of the Tesero horizon (Fig. 14.7c; Schramm 1991). In general, below the PermoTriassic contact, samples with lower carbonate contents had lesser IC values, and most sampled sediments had yet to reach the metamorphic realm. The exception occurs at the Permo-Triassic boundary in the 6.5 m thick Tesero Horizon. Schramm (1991) notes that regional burial and heatflow cannot explain these elevated values, especially as IC values in the underlying Bellerophon Fm are not anchimetamorphic. He concludes the IC values in the Tesero Horizon were inherited from detrital micas, which had retained anchi-metamorphic IC values. A possibility of evaporite-focused thermal fluids is mentioned as another possible explanation but Schramm went on to favour the detrital

[2]The illite lattice is structurally very similar to muscovite and it tends to transform to muscovite with increasing metamorphic grade. The Illite crystallinity or Kübler index is experimentally determined by measuring the full width at half maximum for the X-ray diffraction reflection peak along the (001) crystallographic axis of the illite sample. This value is an indirect measurement of the thickness of illite/muscovite packets, which denote change in metamorphic grade.

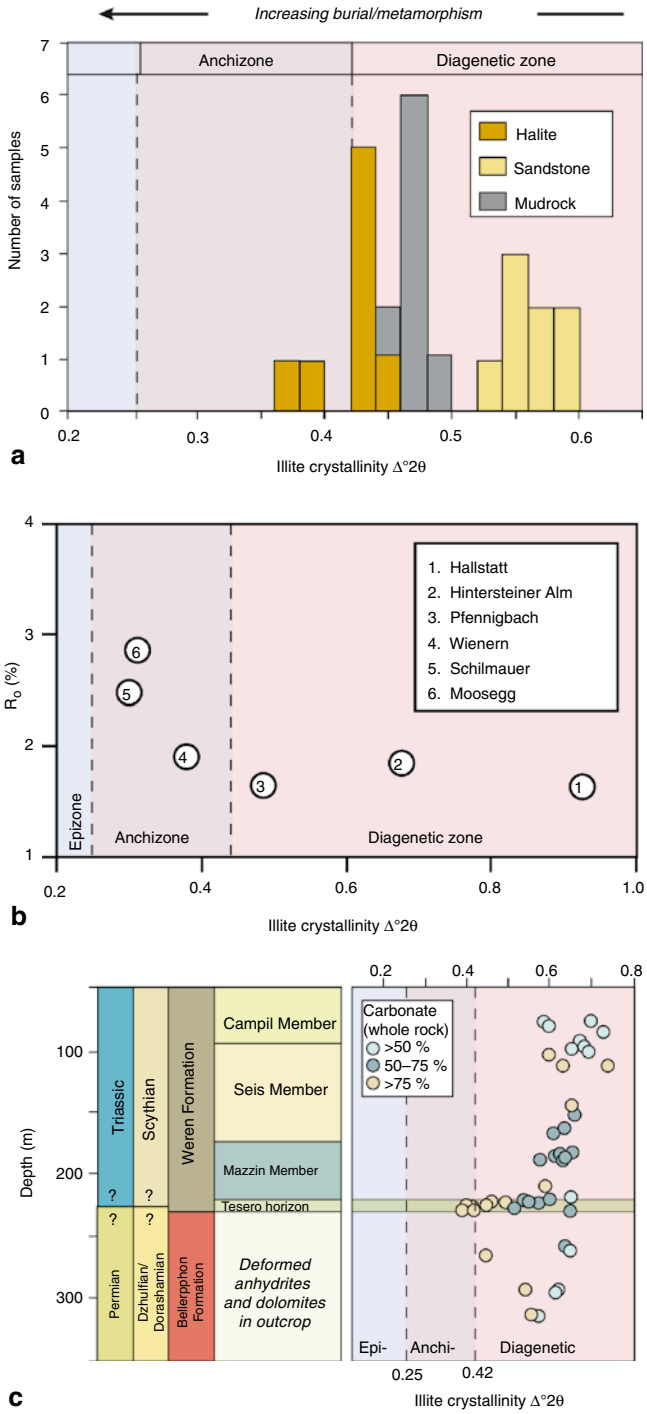

Fig. 14.7 Illite crystallinity (Δ °2θ) (**a**) From the <2 μm fraction of samples from evaporitic facies in Hall in Tyrol. Note that different lithologies from the same region show distinct crystallinities (After Spötl 1992). (**b**) Comparison of IC and vitrinite reflectance values for the six localities of the Haselgebirge mélange in the Alps (After Spötl and Hasenhüttl (1998). (**c**) IC values in core from Gartnerkofel-1 well, (Carnic Alps, Austria) sampling the contact between the deformed anhydrites residues and dolomites of the Permian Bellerphon Formation and the overlying Triassic succession with anchiomorphic values restricted to the oolitic carbonates of the Tesero Horizon (After Schramm 1991)

inheritance mechanism. In my opinion, evaporite focusing of thermal fluids is the more likely explanation, making it an example of focused hydrothermal metamorphism or alteration. The Tesero Horizon sits directly atop the Bellerophon evaporitic succession and the contact would have acted as a relative aquifer, focusing crossflows of hot halokinetic/dissolution brines as they rose along the tectonically active contact.

In contrast to higher temperature indications in anchizonal halites, as seen in Fig. 14.7a, inclusion-derived temperature measurements in halites in nearsurface exhumed evaporites in the Himalayas are preferentially overprinted by exhumation effects (telogenesis). They tend to indicate the cooler recrystallization temperatures associated with exhumation-related meteoric flushing and so do not indicate maximum burial temperatures. Maximum burial indicators are better preserved as illite crystallinity indices in the shales, which unlike the salts do not so readily transform during uplift and recrystallisation in the telogenetic realm.

In parts of the Himalayan foldbelt, Neoproterozoic evaporites and intercalated clays, which have passed through the early greenschist realm, now constitute outcrop and subcrop in the Chamba and Kashmir regions (Singh and Singh 2010). Depositionally, these Neoproterozoic evaporites were coeval with the Hormuz-Ara salts of Pakistan, Iran and Oman. The evaporite-bearing succession crops out as an association of phyllite, quartzite and carbonate, adjacent to the main boundary thrust of the Lesser Himalayas. The illite crystallinity index (KI), measured from the illite peaks of the clay minerals in beds that are separate from the evaporite rocks indicate near epizonal conditions and a maximum temperature ≈300 °C, as do the anhydrites (Fig. 14.8a). Microthermometric measurements on fluid inclusions in intercalated dolomites show a range of homogenization temperatures from 220 to 280 °C, well within the temperature range of anchizone metamorphism (Fig. 14.8b). The dolomites also show highly negative $\delta^{18}O_{PDB}$ signatures (av. = −15.5‰), which probably relate to diagenetic overprints during deep burial.

In contrast, the associated halite intervals, which were texturally transformed a number of times after their precipitation, have retained only the those temperature indicators developed during last one or two phases of telogenetic alteration, deformation and recrystallisation (Fig. 14.8b). As we saw in Chap. 7, this is an indication of an inherent high degree of shallow subsurface reactivity and solubility in halites flushed by shallow subsurface and surface meteoric waters. An inclusion-derived final temperature range of 42–78 °C in these outcropping gypsums and halites gives a thermal approximation that is not in concordance with the thermal history of the basin, but is related to telogenetic conversion of anhydrite into gypsum and pervasive recrystallization of halite during exhumation.

Using highly saline inclusions in vein quartz in the Apuan Alps metamorphic complex of Northern Italy, Montomoli et al. (2005) document the migration of halite-derived brines into subthrust sericitized metamorphic lithologies. Fluid inclusions, which are trapped in quartz crystals in syn-tectonic veins, are oversaturated in NaCl at room temperature with salinities ranging from 29.5 to 37 wt.% NaCl equiv. The isochore of the earliest trapped fluid inclusions (type IA; primary inclusions in fibrous quartz of A veins), coupled with mineralogical geothermometric data, constrains the pressure temperature conditions of the quartz to around 325–300 MPa and 370–380 °C during the late-D1 phase. Subsequent trapping of inclusion types IIA, IIB, IIIA, IIIB and VB in the two vein sets probably occurred during a pressure-temperature decrease, down to 220–245 MPa and 260–270 °C, at a lithostatic thermal gradient of 30 °C/km (Fig. 14.9a). Type IVB inclusions were probably trapped at even lower pressures (between lithostatic and hydrostatic conditions) during cementation driven by transient pressure drops resulting from fault-valve action.

The resulting fluid circulation model proposes that the high-salinity fluids found in the syn-tectonic veins, along with the high-salinity and NaCl-rich nature of the trapped fluids are the result of the original metamorphic fluids interacting with evaporite levels present at the base of the Tuscan Nappe, which overlies Apuan Alps metamorphic units (Fig. 14.9b). These hypersaline evaporite-derived fluids had infiltrated downward during metamorphism, possibly through shear zones crosscutting the stratigraphic sequence, into the syn-tectonic veins and interacted with the host-rocks to produce local element mobilization and their precipitation in the vein minerals, which reflect the quartz dominant mineralogy of the host-rocks.

Instead of illite crystallinity, the diagenetic to metamorphic transition is sometimes defined as the subsurface interval where all sedimentary porosity and permeability is lost (Phillips et al. 1994). That is, at burial depths where sedimentary porosity is significant, diagenetic fluids are likely to dominate. Once compaction and authigenic cementation occludes this porosity to negligible levels, there is little capacity to retain either diagenetic fluids or significant permeabilities and so the strata pass into the realm of metamorphism.

This definition is based on the assumption that in metasediments, unless there is evidence to the contrary, one generally assumes that with the loss of diagenetic permeability, the system can be approximated as a near isochemical closed system. Evolving mineral phases then reflect successive equilibria tied to changes in temperature and pressure, with little change in the molecular components that make up the whole rock chemistry. This is, after all, the basis for the application of phase diagrams in classic metamorphic petrology. More recent work has showing that most metamorphic systems have some degree of fluid throughput, especially those involving metasediments and decarbonation reactions or within protoliths containing high levels of other volatiles such as coals or evaporites (Yardley and Lloyd 1995; Yardley

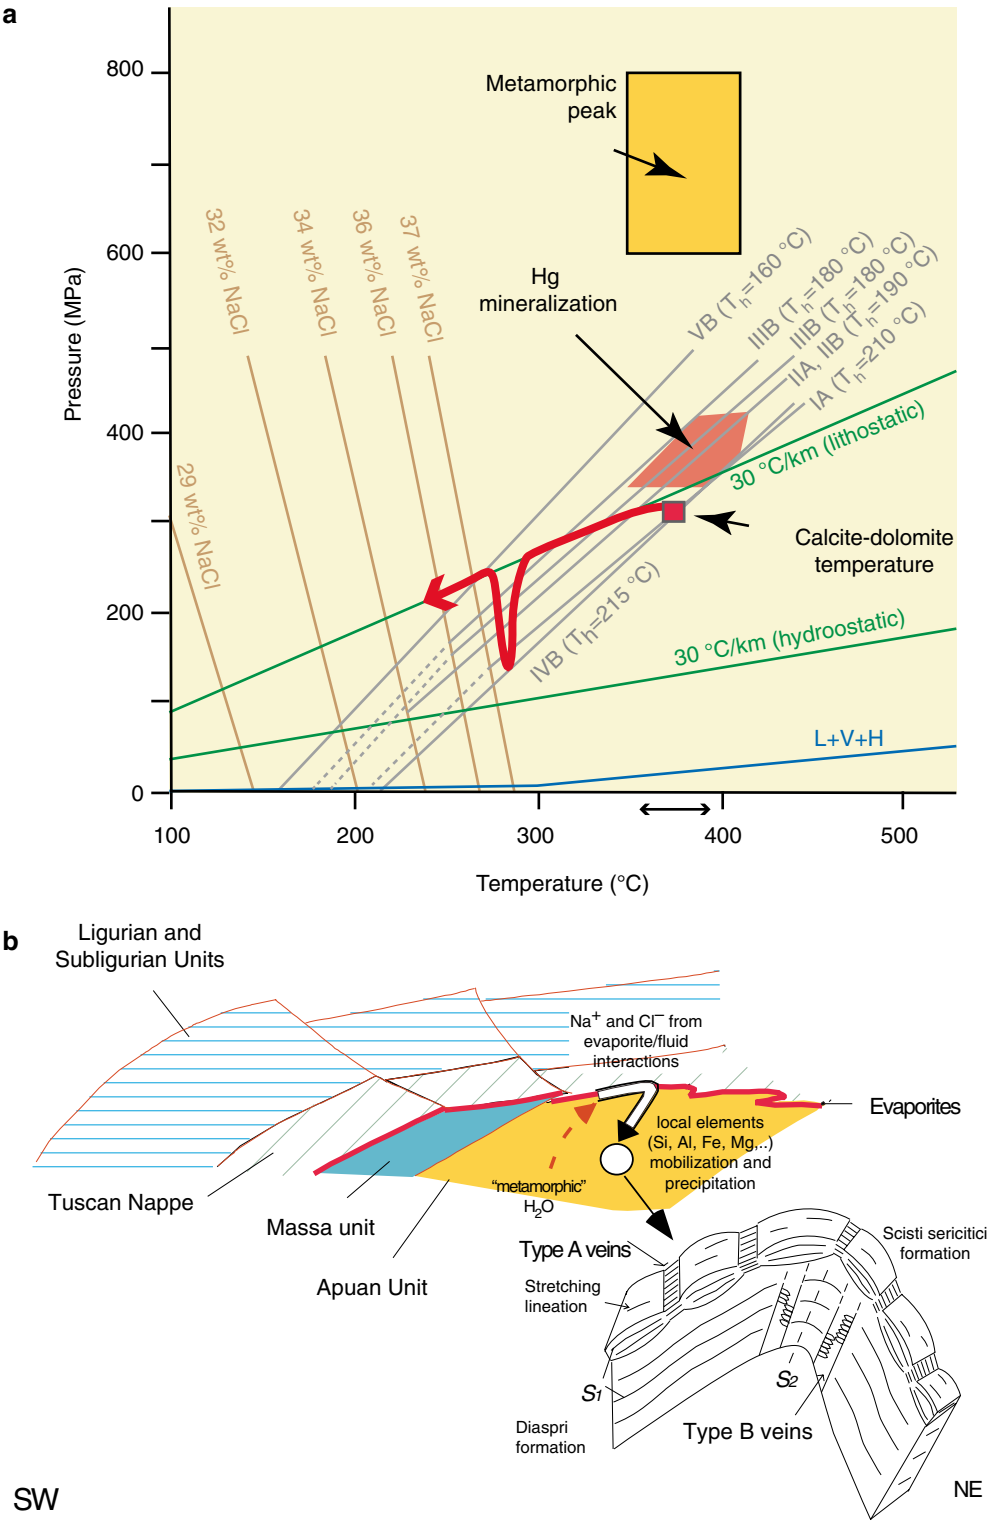

Fig. 14.9 Saline brine geothermometry, Apuan Metamorphic Complex, Italy (After Montomoli et al. 2005). (**a**) Pressure–temperature diagram from quartz vein inclusions (Types I-V) showing the representative isochores (*dashed lines* in the halite + liquid field, *light continuous lines* in the liquid field), the halite liquidi (*grey lines*) for the average salinities of the different inclusion types, and the liquid + vapour + halite (L + V + H) curve. The 30 °C/km lithostatic and hydrostatic gradient (*green lines*) are plotted as are the temperature ranges computed using the chlorite geothermometer (*black double-ended arrow*) and estimated temperature ranges for the D1-phase in the central-northern part of the complex calculated using the calcite–dolomite geothermometer (*red double ended arrow*). The *red square* indicates the pressure–temperature conditions determined from the IA-fluid inclusion representative isochore and from geothermometric estimates for the late-D1 phase. The *thick red arrow* indicates the proposed pressure–temperature evolution of the metamorphic fluids flowing in the syn-tectonic veins. Temperature-pressure field at peak metamorphism in the complex is also shown. (**b**) Schematic showing the fluid migration path for the high-salinity fluids of the Apuan Alps. Schematic block diagram (*bottom right*) shows relationship between the two vein types and the main structural elements (*S1* foliation associated to the first folding phase, *S2* foliation associated to the second folding phase)

2013). The loss of volatiles from metamorphosing evaporites, described in the first paragraphs of this chapter, means an assumption of a closed system is not appropriate for areas adjacent to, or interbedded with, thick successions of evaporites entering the realm of metamorphism.

Porosity and permeability loss in the diagenetic realm is directly related to increasing burial in all sediments, except for some evaporite salts, where permeability is lost very early but regained at greater burial depths. In bedded halite, all effective porosity and permeability in a halite bed is lost

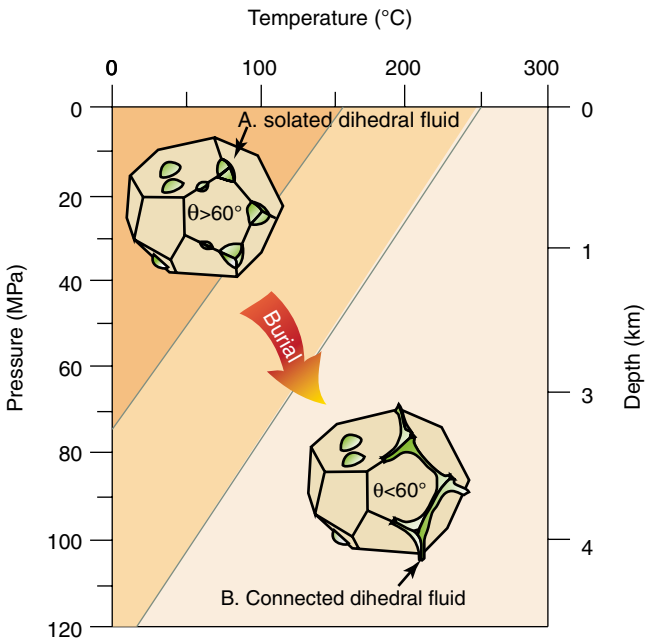

Fig. 14.10 Effect of dihedral angle on pore connectivity in texturally equilibrated monomineralic and isotopic polycrystalline mosaic halite. *Background shading* shows two polyhedral porosity fields and transition zone calculated for the Ara Salt (black salt or leaking halite plots in transition zone), Oman. (**a**) Isolated porosity for dihedral angle >60°. (**b**) Connected polyhedral porosity for dihedral angle <60° (After Lewis and Holness 1996; Kukla et al. 2011b)

by 100 m burial at temperatures that are less than 50 °C. Anhydrite beds are typically tight by 500–1,000 m depth. This, and halite's ability to flow rather than fracture, is why evaporites constitute such excellent hydrocarbon seals throughout the diagenetic realm (Chap. 10).

More deeply buried halite may regain permeability during halite recrystallization due to a change in the halite-brine dihedral angle at depth (Lewis and Holness 1996). At temperatures <100–150 °C the contact angle between halite and brine is 70 °C (Fig. 14.10a). Under laboratory conditions this contact angle equates to maintenance of closure of grain polyhedral boundaries by halite precipitation, and so at such low temperatures salt is impermeable (Schenk and Urai 2004; Lewis and Holness 1996). In this temperature range the small amounts of brine present in the salt are distributed in micrometer-sized isolated fluid inclusions. At temperatures >100 °C and pressures of 70 MPa or more, the dihedral angle decreases to values <60 °C, driving a redistribution of the fluid into a thermodynamically stable network of connected, fluid filled channels at grain boundary triple junctions. This transition may be related to the observation by Peach and Spiers (1996) that during natural deformation of rocksalt at great depths it undergoes natural hydraulic fracturing or dilatancy. The transition is also used to explain the occurrence of black (bitumen-charged) salt in the Ara Salt of Oman (Kukla et al. 2011b).

Once this recrystallization occurs, mosaic halite loses its ability to act as an aquitard and may instead act as a permeable conduit for escaping formation waters (Fig. 14.10b). According to Lewis and Holness, the depth at which the recrystallization occurs may begin as shallow as a few kilometres. But, their pressure bomb laboratory-based experiments did not completely encompass the ability of natural salt to pressure creep and self-seal by longer-term diffusion-controlled pressure solution (Chap. 6). Even if the changing dihedral angles alter and open up permeability at such shallow depths, there is no guarantee that subsequent flowage associated with pressure solution will not re-anneal these new pores. The ability of salt to continue to act as a highly effective hydrocarbon seal to depths of 8–10 km means, in my opinion, that bedded salt does not become a relative aquifer until depths of 6–10 km or more, and probably at burial temperatures that mean the sequence is entering the greenschist realm. In extreme overpressured situations the transition can be much shallower, as in the 40–50 m thick black salt rims that typify the salt-encased hydrocarbon-charged carbonate stringers in the Ara Salt of Oman (Kukla et al. 2011b). Once it does transform into polyhedral halite, a former aquiclude becomes an aquifer flushed by chloride-rich brines, likely carrying other volatiles.

A release of entrained inclusion (±intercrystalline) water at temperatures >300–400 °C (early greenschist) influences the textures of deeply buried halite. Most of the inclusions in chevron halite and other inclusion-rich cloudy primary salts are due to entrained brine inclusions and not mineral matter. Figure 14.11 plots the weight loss of various types of halite during heating. It clearly shows cloudy (inclusion-rich) halite releases up to five times more brine (0.2–0.5 wt%) than clear coarsely crystalline halite. An analysis of all fluids released during heating shows carbon dioxide and hydrogen contents are much lower than the water volumes: $CO_2/H_2O < 0.01$ and $H_2/H_2O < 0.005$. Organic compounds, with CH_4, are always present (<0.05 % H_2O), and are twice as abundant in cloudy halite. There are also traces of nitrogen and, in some samples, hydrogen sulphide and sulphur dioxide (Zimmermann and Moretto 1996).

Nitrogen is released below 240 °C and is probably of atmospheric origin. Most of the water is expelled from 330 to 410 °C, corresponding to the decrepitation of inclusions (Fig. 14.11). Likewise, CO_2 liberation occurs mainly between these temperatures. Above 420 °C an additional part of the weight loss comes from carbonate dissociation through heating. Hydrogen is extracted continuously from 200 to 460 °C, even though an evolving salt crystals water content is less than 0.5 %. Most of the hydrogen originates from dissociation of organic matter present in the halite crystals as well as from water reduction during heating (inclusion release; Zimmermann and Moretto 1996).

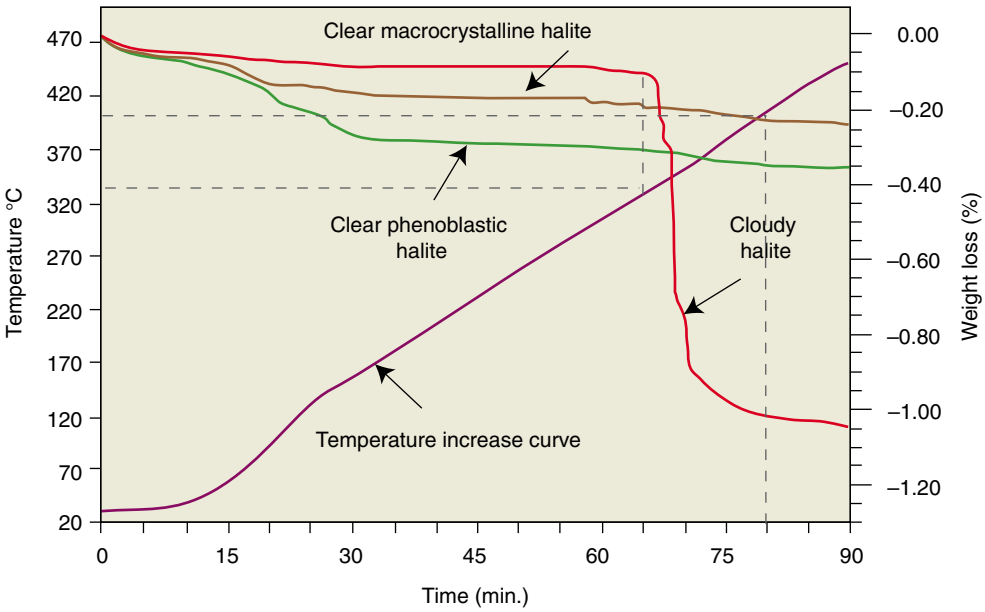

Fig. 14.11 Weight loss of three pure halite samples upon heating from ambient temperature to 470 °C. Most of the weight loss corresponds to water loss from entrained inclusions, which are more common in cloudy halite (After Zimmermann and Moretto 1996)

Halite as a distinct mineral phase is rarely recovered from metamorphic rocks beyond the early greenschist realm and is no more than an extremely rare mineral phase in granulites (Newton et al. 1998). Both the polyhedral transformation and the dehydration/alteration of cloudy salts may explain why, even though the associated temperatures in granulites are well below halite's melting point of 750–800 °C. As halite recrystallizes, via compaction-related generation of intercrystalline polyhedral porosity, the increasingly permeable halite bed is being flushed by waters from adjacent devolatising and altering meta-sediments. These waters further aid in removing and altering the highly soluble halite phase. Through its dissolution and metamorphism, halite can generate zones of extensive sodic metasomatism in nearby meta-sediments. The same chloride-rich fluids may also flush metals from adjacent beds and then carry them into contact with reducing intervals, such as graphitic schists, where metal sulphides or oxides crystallize in suitably prepared ground or pressure shadows. We shall discuss the economic significance of this transformation in detail in the next chapters, which deal with the genesis of ore deposits associated with present and former evaporites.

A thick anhydrite mass does not dissolve or transform as readily as halite entering a greenschist zone, recrystallised anhydrite is known to survive into high grades of metamorphism (Butchins and Mason 1973; Serdyuchenko 1975; Markl and Piazolo 1998). For example, hornfelsic anhydrite, interbedded with anhydrite-cemented shale breccias formed by evaporite solution collapse, is found at 1 km depth in the Magmamax 11 well in the central part the Salton Sea geothermal system (McKibben et al. 1988a, b). Massive anhydrite is found in association with copper mineralisation in the Mt Isa inlier (Wilde et al. 2006). Thick beds of recrystallised sedimentary anhydrite occur in amphibolite grade Mesoproterozoic metasediments at Balmat, New York (Whelan et al. 1990) and granulite grade Neoproterozoic metasediments in Central Dronning Maud Land in East Antarctica (Markl and Piazolo 1998; MacGregor et al. 2013). Nonevaporitic anhydrite can also form as a hydrothermal precipitate from heated seawater, and will be discussed fully in Chap. 16, this chapter focuses on metasedimentary anhydrite.

As noted earlier, evaporite-associated rock matrix chemistries cannot be interacting isochemically: there must be a flow of fluids and ionic components in and out of the system to explain the near-complete loss volatiles (Cl, CO_2, SO_3 and H_2O) during metamorphic transformation of evaporite salts. However, the presence of a likely meta-evaporitic mineral assemblage, such as NaCl-scapolite with dravite-uvite tourmaline, does not, by itself, indicate an undeniable evaporite protolith. Hydrothermal waters associated with late cooling stages of magmatic intrusions can also drive sodic alteration and scapolitization, as well as dissolve and mobilise salts in the adjacent country rock. Ideally, there should be further evidence to support a meta-evaporitic interpretation such as:

- Strict stratigraphic/halokinetic control on the occurrence of meta-evaporite mineral phases and haloes (Hietanen 1967; Sharma 1981);
- The presence of recognisable salt pseudomorphs, such as hoppers, in less metamorphosed stratigraphic equivalents (Grotzinger 1986a, b);
- Hypersaline fluid inclusions in the assemblage (Roedder 1984a, b);
- The occurrence of abundant associated Mg- and Cl-rich biotite (Moine et al. 1981).

A. Encloses all athe low salinity fields of formation waters, springs and metamorphic fluids hosted by sequences of oceanic or accretionary prism origin.

Fig. 14.12 Temperature–salinity plot for formation waters and metamorphic fluids hosted by sequences deposited in epeiric seas and at continental margins (After Yardley and Graham 2002). Boxes reflect the range of data from each of the numbered sources listed, many of the meta-evaporite examples are discussed later in this chapter The box, designated A, clearly shows that meta-oceanic and meta-accretionary wedges lack high NaCl/salinity waters. The *red arrows* show (i) the typical dehydration trend in metamorphic successions lacking a widespread evaporite protolith and (ii) the high salinity rehydration trend within deeply buried successions subject to the elevated temperatures and high salinities created in volatiles released during by eclogite formation (not necessarily evaporitic protolith)

Ongoing progressive regional metamorphism of an evaporitic halite-entraining sequence leads to a removal of water, CO_2, Cl and other volatile components. The greatest expulsion volume of volatiles from an altering rock salt mass and the ultimate disappearance of halite occurs in the lower grades of metamorphism (greenschist). The H_2O, CO_2, Cl°, CH_4, etc. then migrates, as the fluid carries away large quantities of dissolved ions, particularly Na^+ and Cl^-. Fluid released during devolatilisation of meta-evaporites is typically saline and chloride-rich with an innate ability to leach and transport base and precious metals as chloride complexes. The resulting metamorphic minerals, dominated by sodic phases, can create zones of widespread scapolitization or albitization (Kwak 1977; Moine et al. 1981; Rozen 1979). These same metamorphic associations tend to entrain minerals and inclusions with high NaCl contents (Fig. 14.12; Yardley and Graham 2002).

What is most interesting from the work of Yardley and Graham (2002) and illustrated in Fig. 14.12 is that with nonevaporitic protoliths the salinities of metamorphic fluids show some overall trend to lower values at higher metamorphic grades, but in evaporite-bearing protoliths, the opposite trend is present. Sedimentary sequences deposited in oceanic and accretionary settings invariably yield low-salinity metamorphic fluids (<7 % wt.% NaCl; Box A in Fig. 14.12). In contrast, sedimentary sequences deposited mostly on continental crust, and including products of shallow water deposition, typically (though not invariably) give rise to relatively saline metamorphic fluids. Yardley and Graham's conclusion, that the general pattern of pore fluid salinities persists from the diagenetic into the metamorphic realm, has important implications for both metamorphic and ore-forming processes in the crust. Firstly, interpretations of metamorphic phase equilibria should consider the nature of the original sedimentary sequence; for shallow water sequences, it is essential to test for possible high fluid salinities, since these give rise to substantial deviations from the simple mixed-volatile fluid model normally used by metamorphic petrologists. Secondly, salinity is a fundamental control on the ability of fluids to transport many ore-forming elements. They go on to state that this difference is almost certainly related to the original distribution of evaporites and/or connate brines in the protolith.

In terms of migration of metals complexed by chloride and leading to the formation of base metal deposits, it is more likely that high-chloride diagenetic and metamorphic waters derived from alteration of evaporites, will tend to occur in metamorphosed saline passive-margin and intracratonic sediments. Evaporite influences are less likely in pore waters systems in oceanic and accretionary orogenic prisms. There the volatiles will tend to come from seawater and magmatic/hydrothermal sources. In the next two chapters we will focus on the importance of understanding the likely nature of the protolith when developing base and precious metal exploration models in metamorphic terranes. For now, let us now look at some of the more common evaporite indicator minerals and associations in the metamorphic realm.

Meta-evaporite Mineral Associations

Generally, metamorphic minerals with an evaporite protolith tend to be enriched in minerals entraining sodium, potassium and magnesium. They can entrain high levels of volatiles (Cl, SO_3 and CO_2) as well as elevated levels of boron, all features, along with high salinity in the associated metamorphic fluids, which are indicative of their evaporitic origins (Table 14.2; Fig. 14.12). Sodium tends to come from the dissolution of salts, such as halite or trona; while magnesium tends to be remobilized from earlier diagenetic minerals, such as reflux dolomites and magnesium-rich evaporitic clays. Boron in tourmalinites may have come from a colemanite/ulexite lacustrine precursor. Once direct evidence of a salty protolith is largely removed via fluid dispersion and ongoing loss of volatiles, the palaeo-evaporite indications are largely restricted to mineralogic associations, along with an occasional textural relict of an evaporitic breccia bed, rauwacke or salt weld.

Evidence of early stages in a evaporite-fed sodic transformation can be seen in the sodic phlogopites (phlogopite = magnesian mica) and sodian aluminian talcs in the metapelites of the Tell Atlas in Algeria (Schreyer et al. 1980). Evaporitic sulphate crystals are pseudomorphed in the NaCl-scapolite-dominated sequences of the Cordilleras Beticas of Spain (Gómez-Pugnaire et al. 1994). Rocks of higher temperature and pressure facies, such as the massive stratiform anorthosites in the Grenville Precambrian Province of North America, have been interpreted as possible meta-evaporites (Gresens 1978), as have the anhydrite-containing Mesoproterozoic calcsilicates in the Oaxacan granulite complex in southern Mexico (Ortega-Gutierrez 1984) and the pervasive scapolites in the Neoproterozoic Zambesian orogenic belt of Zambia (Hanson et al. 1994). Subsequent work on the Grenville and Limpopo anorthosites, although still allowing for a metasedimentary protolith, have concluded an igneous source of volatiles is more likely (Barton 1996; Moecher et al. 1992; Peck and Valley 2000; Glassley et al. 2010). Defining the likelihood of a evaporite protolith becomes increasing difficult as the metamorphic grade increases. Once a metamorphic rock enters the granulite facies, its protolith interpretation is typically much more contentious (e.g. the evaporite versus carbonatite interpretations in the Oaxacan granulites, Mexico).

Scapolite and Scapolitization

Like feldspar, the term scapolite describes a solid solution series. The sodium-chloride-rich end member is called marialite [$Na_4(Al, Si)_{12}O_{24}Cl$] and the calcium-carbonate-rich end member is meionite [$Ca_4(Si, Al)_{12}O_{24}(CO_3,SO_4)$]. The sulphate ion shown in the meionite formula is typically barely more than a trace, even in meta-evaporites; but is found in far greater percentages than the occasional fluorine or hydroxide interlopers in the scapolite lattice. The structure of scapolite is similar to some feldspathoids in that it is composed of large open spaces in the framework of silicate and aluminium tetrahedrons. These open spaces are large enough to cage large diameter ionic groups. So, a scapolite lattice can be described in terms of four-membered tetrahedral rings [(Si,Al)—O], linked together to form an open chain framework that is parallel to the c axis. A large subspherical opening is located at the fourfold axis and is surrounded by four oval shaped channels running parallel to the c axis [001]. This large cage is occupied by the Cl, CO_3, and SO_4 anions, whereas the channels host Na, Ca, and minor K cations (Fig. 14.13a).

In general, for each metamorphic grade, the variation in the amount of Cl in the scapolite suggests a local control (Table 14.3). In a scapolite-biotite assemblage, elevated levels of Cl indicate a high NaCl activity at the time of their crystallization from a likely evaporitic/feldspathic precursor (Orville 1975; Ellis 1978; Vanko and Bishop 1982; Mora and Valley 1989).

Marialitic scapolite grows at temperatures around 400 °C and NaCl-H_2O fluids, containing more than 40 mol% NaCl, are needed to stabilize the marialite (Vanko and Bishop 1982). The Na and Cl in the scapolite lattice may have been derived from sedimentary halite, or introduced from an outside source such as Cl-rich hydrothermal or sedimentary brines.

The distribution of scapolite lenses and layers in outcrop is often the best evidence for the origin of the scapolite (Hietanen 1967). Scapolites derived from hydrothermal brines tend to be in haloes around intrusives, while basinal brine chlorine tends to form replacement fronts associated with faults, shears and other conduits (Owen and

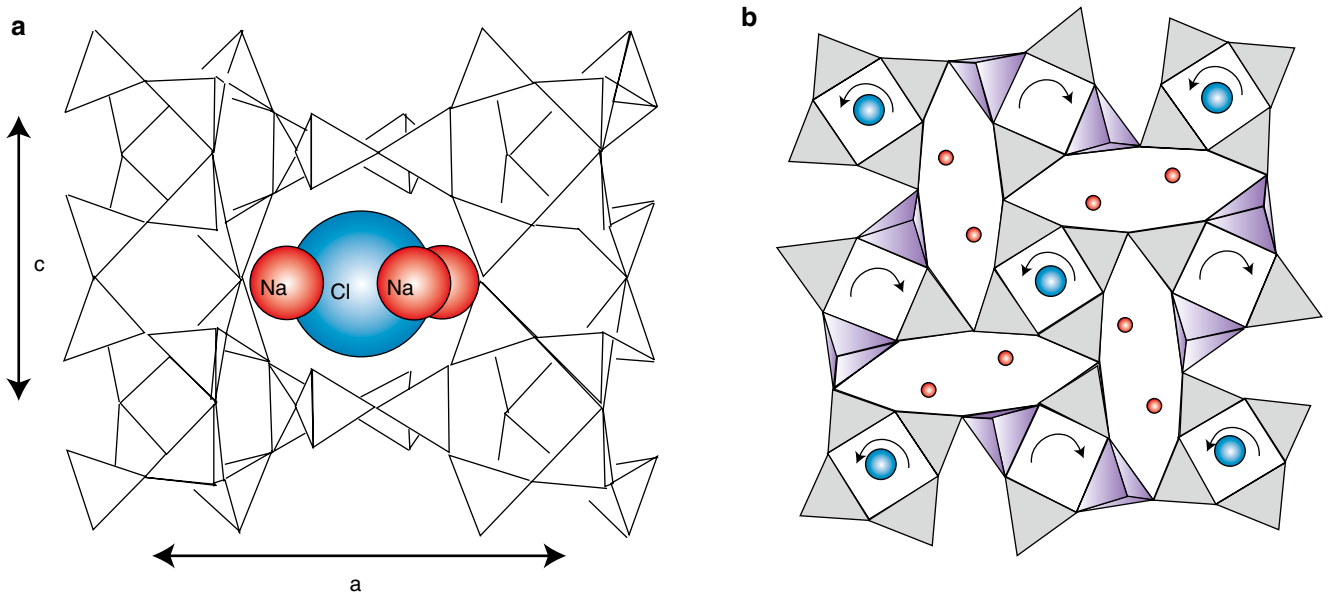

Fig. 14.13 Scapolite structure. (**a**) The [100] projection of the structure of marialite showing the cage-like structure and the linkage of the (Si,Na)—O tetrahedra parallel to the c axis. (**b**) [001] projection of the crystal structure of scapolite. Small circles represent cations (Na), larger circles represent anions (Cl). The *arrows* indicate the sense of rotation of the four-membered tetraheda rings with increasing pressure, this compaction releases the Na and Cl ions from their lattice cages (Modified from Comodi et al. 1990)

Greenough 1999). Conversely, where scapolite is distributed as fine-scale interbedded units of scapolite-bearing and scapolite-free layers that differ only in their Cl content, it argues strongly for an *in situ* salt precursor. This section will focus on scapolites interpreted as metaevaporites in continental regions with a significant sedimentary halite protolith (Table 14.3). For scapolite-anhydrite exhalites formed in seawater-influenced hydrothermal systems, Jiang et al. (1994) or Kribek et al. (2002) are good starting points, for nonevaporitic scapolitic skarns see Pan et al. (1994).

Its cage-like lattice structure means that scapolite acts as a source or sink for a number of volatile species in the metamorphic realm (Cl^-, CO_3^{2-} and SO_4^{2-}). Once a metasedimentary sequence passes beyond the early greenschist stage, scapolite takes over from halite as the most likely potential source for chloride volatiles. As metamorphic grade increases, pressure increases, and the lattice compresses by rotating its tetrahedra (Fig. 14.13b; Comodi et al. 1990). As this happens the Cl^- content of the scapolite decreases as the squeezed lattice releases Cl^- and other stored volatiles in the large diameter lattice cages. Meier (1979) highlighted the importance in Precambrian terranes of scapolite, scapolite-diopside, and scapolite-diopsideamphibolite-feldspar assemblages as ongoing saline (volatile) sources, long after halite disappeared in the early greenschist realm. Mora and Valley (1989) rejected the notion that most scapolitic assemblages were the result of Cl-rich fluid infiltration/metasomatism mostly tied to late-stage magmatic brines, instead they concluded that most metamorphic scapolite formed by the reaction of plagioclase with calcite and halite.

Whatever the ultimate Na and Cl source, most scapolite forms via the metamorphic alteration of plagioclase feldspar. As a consequence, albitization and scapolitization are typically co-associated metamorphic outcomes. The entire scapolite series can be considered to be analogous to the plagioclase series (Fig. 14.14a). If the formula of marialite is written as $3(Na(Al, Si)_4O_8)NaCl$, it is clear how well it matches the formula of the sodium-rich plagioclase, albite, $NaAlSi_3O_8$. A similar look at meionite's formula, $3(Ca(Al,Si)_4O_8)CaCO_3$, shows that it too is near three times the formula of anorthite, $CaAl_2Si_2O_8$. Along these lines, Reinhardt (1992) noted the formation of scapolite in metaevaporitic terranes of the Mary Kathleen region, Australia, can be expressed by end member reactions noted in Orville (1975):

$$3\text{Albite} + \text{NaCl} \leftrightarrow \text{Marialite}$$

$$3\text{Anorthite} + \text{CaCO}_3 \leftrightarrow \text{Meinonite}$$

$$\text{Anorthite} + \text{CaSO}_4 \leftrightarrow \text{SO}_3 - \text{Meinonite}.$$

Addition of the extra sodium chloride or calcium carbonate occurs during metamorphism, as do substantial alterations of the original lattice structure during ongoing compression. Although nearly pure albite and anorthite specimens are sometimes found in nature, pure forms of meionite and

Table 14.3 Worldwide examples of scapolites and scapolitization

Occurrence	Age	Features	Reference
Scapolite-bearing Rocks from Lapis Lazuli Deposits at Sar e Sang, Afghanistan	Neogene cooling	E. Scapolite and other halogen-rich minerals (phlogopite, amphibole, apatite, titanite and clinohumite) occur in some high-pressure amphibolite facies calc-silicates and orthopyroxene-bearing rocks. Peak P-T metamorphic conditions are 750 C and 1.3–1.4 GPa. Protolith was evaporite-bearing carbonates now indicated by scapolite, F- or Cl-rich apatite, and amphibole forming bands and layers or hosted in veins crosscutting sodalite group minerals, including lapis lazuli	Faryad (2002)
Contact metamorphicmetasomatic halo, Italian Mountain granite intrusion, Gunnison Co., Colorado	Eocene (latest)	E. Near- vertical Pennsylvanian black shales and carbonates along the west margin of the intrusive were converted to phlogopite-diopside-andalusite hornfels and scapolitediopside skarns with minor analcime Dissolution of once nearby halite or saline surface waters or shallow groundwaters moving south from the Eagle Basin supplied the NaCl	Mauger (2007)
Andean Iron belt southwest of Mendoza, Argentina.	Cretaceous	Granite-related skarn overprints the earlier diorite-related skarn and consists of garnet + clinopyroxene + scapolite (Me_{28-36}) quartz alkali feldspar endoskarn and a zoned exoskarn with proximal garnet clinopyroxene quartz, intermediate green garnet + clinopyroxene, and distal scapolite (Me_{25-36}) ferroactinolite pyrite veins	Pons et al. (2009), Franchini et al. (2007)
Andesitic volcanics in the Ningwu terrestrial basin, East China	Cretaceous	E. Iron oxide-apatite deposits with abundant scapolite in albitized breccia skarn zones composed of diopside-magnetite-scapolite, magnetite-apatite-diopside-calcite, quartzpyrite-hematite-kaolinite-anhydrite-carbonate Overlain by evaporitic Triassic lacustrine redbeds	Mao et al. (2008)
Magnetite iron ores, Anatolia region, Turkey	Cretaceous	E. Volcanic or subvolcanic rocks and are associated with a voluminous scapolite ± amphibole ± biotite alteration, derived from Late Mesozoic brine infiltration	Marschik et al. (2008)
Cordilleras Béticas, Spain	Alpine metamorphism	E. Permo-Triassic pelite-carbonate rock series (with intercalated evaporites and metabasitic rocks) in the, was metamorphosed during the Alpine metamorphism at high pressures (P_{min} near 18 kbar) Scapolite, rich in NaCl (Ca/(Ca + Na) mol% 24–40) and poor in SO_4, with Cl/(Cl + CO_3) ratios between 0.6 and 0.8, formed as porphyroblasts, sometimes replacing up to 60 % of the rock in a late stage of metamorphism (between 10 and 5 kbar, near 600 °C)	Gómez-Pugnaire et a. (1994)
Muzkol metamorphic complex in the Central Pamirs, Tajikistan	Alpine metamorphism	E. Calcite marbles contain corundum together with muscovite, scapolite, and biotite, with the scapolite is rich in marialite (60–75 mol %). The isotopic-geochemical characteristics numerical simulations of the fluid-rock interactions indicate that the corundumbearing metasomatic scapolitic rocks developed after originally sedimentary Phanerozoic carbonate rocks, with the desilicification of the terrigenous material. Neogene cooling age in Archaean-age host	Dufour et al. (2007)
Humboldt lopolith, N.W. Nevada	MidJurassic	E. Scapolite occurs: (1) as a pervasive replacement of plagioclase in gabbro, diorite and extrusive rocks; (2) as a poikiloblastic mineral in scapolite dykes; and (3) as a fracturefilling mineral with analcite, albite and sphene in scapolite veins. The likely source of Na and Cl is pre-existing evaporites or evaporite brines derived from wallrocks. Salinity may have been increased sufficiently to stabilize scapolite by hydration of dry magmas, possibly aided by hydrothermal boiling. Marialitic scapolite grew at temperatures around 400 °C from NaCl-H_2O fluids having more than 40 mol% NaCl (conditions needed to stabilize the scapolite)	Vanko and Bishop (1982)
Scapolite pegmatite from the Minas fault at McKay Head, Nova Scotia	Carboniferous	E. Pegmatite cutting chlorite schist in the Minas fault at McKay Head, Nova Scotia, consists of Cl-rich (2.7–3.8 wt.% Cl) marialitic scapolite (EqAn(21–32)) with interstitial, apparently primary analcite, hematite and rutile, and later (including vug-lining) analcite, pyrite, chlorite, titanite and calcite, and cross-cutting epidote veins. Derived from highly sodic hydrothermal solutions from early Carboniferous evaporites of the Windsor/Horton groups. Compositionally-similar fluids, also related to an evaporite source, may be responsible for a regional, early Carboniferous Na-metasomatic event that altered a suite of alkaline granitoid intrusions shortly after their emplacement	Owen and Greenough (1999)

Dolomite marble, Prosetin (Olesnice Unit, Moravicum), Czech Republic	Late Palaeozoic	E. Scapolite ($Me_{41–49}$) in Is rich in Cl (1.30–2.20 wt. %), does not contain SO_3 and forms small as nests, containing also phlogopite and zoisite. Host-rock mineral association suggest prograde metamorphic growth and support a meta-evaporitic origin of the plagioclase-muscovite-scapolite rocks. See also, Kribek et al. (2002)	Opletal et al. (2007), Bacik et al. (2012)
Scapolites in the Metamorphic Mozambique Belt, Africa	Neoproterozoic	E. Scapolitic meta-evaporites intercalated with metasomatized graphitic rocks such as graphitic gneiss and calc-silicates. Tsvorite gemstone association	Feneyrol et al. (2013)
Ketri Copper Belt, Rajasthan, NW India	Neoproterozoic	E. A 50 km wide by >100 km zone of calc silicate and albite-hematite alteration overprints and cross-cuts metamorphic fabrics. Calc silicate alteration comprises coarsegrained clinopyroxene – hornblende – epidote – apatite – scapolite – titanite – magnetite, whereas albite – hematite alteration comprises assemblages of albite – amphibole hematite – magnetite – calcite, with variable K-feldspar, biotite, epidote, scapolite, titanite, apatite and fluorite, and locally abundant pyrite and chalcopyrite. Calc silicate alteration occurs on the margins of the Khetri Copper Belt, whereas albite-hematite alteration forms a central core to the Belt and locally overprints calc-silicate assemblages	Knight et al. (2002)
Mary Kathleen Foldbelt, Queensland, Australia	Mesoproterozoic	E. Intrusion of Wonga Batholith and equivalents were emplaced between 1,760–1,720 Ma coincident with the Wonga extension. This was accompanied by widespread NaCl scapolitization, skarn development and Na-(Ca)-K metasomatism. The highly evaporitic Corella Fm was the source of salt driving the chemistry of this metasomatic event	Ramsay and Davidson (1970), Oliver et al. (1992), Hammerli et al. (2014)
IOCG associations, Fennoscandian Shield, Norway	Mesoproterozoic	E-Scapolite formed during repeated extensional and compressional events at 3.1–1.8 Ga, and is part of an iron ore province characterized by regionally developed albite and scapolite alteration and the occurrence of world class Fe-oxide (e.g. Kiirunavaara)	Martinsson et al. (2008), Frietsch et al. (1997)
Sveconorwegian metamorphic event, Southern Norway	Mesoproterozoic	E. Scapolitization was associated with veining, and was followed by albitization, transforming metagabbros pervasively over large areas. Plagioclase was replaced by Cl-rich scapolite (Me_{19-42}) reflecting Cl-saturation, while K- and Mg-saturation produced phlogopite, enstatite, sapphirine and rare corundum The sodic brines responsible for this alteration were probably evaporite derived and remobilised	Engvik et al. (2011)
E. Blackbird District, East-Central Idaho, USA	Mesoproterozoic	E. Thrust faulting juxtaposed meta-evaporite layers in the Mesoproterozoic Yellowjacket Formation over Blackbird district host rocks that facilitated chemical exchange between juxtaposed units resulting in leaching of critical elements (Cl, K, B, Na) from meta-evaporites to produce brines, mineralisation and scapolites	Lund et al. (2011)
Wernecke Breccia, Wernecke Mountains, Canada	Mesoproterozoic	E. Scapolites in the regionally-distributed brecciation in the; associated with hydrothermal alteration with saline brines from former salt décollement, now rauhwacke	Kendrick et al. (2008)
Lutzow-Holm Complex, East Antarctica	Paleo to Mesoproterozoic	E. Spectacular reaction textures in poikiloblastic scapolite boudins, within outcropping marbles. Core composition of scapolite poikiloblasts (Scp(I)) are marialitic (Cl = 0.7 apfu) whereas rims in contact with biotite or clinopyroxene are meionite rich. Finegrained recrystallized equigranular scapolite (Scp(II)) shows prominent chemical zoning, with a marialitic core and a meionitic rim (Cl = 0.36 apfu). Scapolite poikiloblasts are traversed by Scp(III) reaction zones along fractures with compositional gradients	Satish-Kumar et al. (2006)
Aravalli metasediments, NW India:	Paleoproterozoic	E. Scapolite occurs in succession dominated by amphibole-bearing dolomitic marble and albite-rich quartzo-feldspathic rocks (QFR). The presence of vugs, believed to be after dissolution of halite patches, coupled with the development of scapolite-bearing assemblages in dolomite marble, occurrence of tourmaline-rich mineralized rocks and very high Na content of carbonates and QFR indicate hypersaline depositional environment for the protolith	Golani et al. (2002)
Carajas Mineral Province, Brazil	Archaean	E. Tourmaline pre-dates mineralization, and is abundant as coarse porphyroblasts or fine-grained layers alternating with albite, quartz, and scapolite in sodic-altered mylonitic metavolcanic rocks. These rocks have been subjected to an early sodic alteration (albite and scapolite) followed by more pervasive and widespread potassium and chlorite alterations, silicification, carbonatization, and minor epidotization. K alteration is accompanied of magnetite formation	Xavier et al. (2008)

E indicates a meta-evaporite association

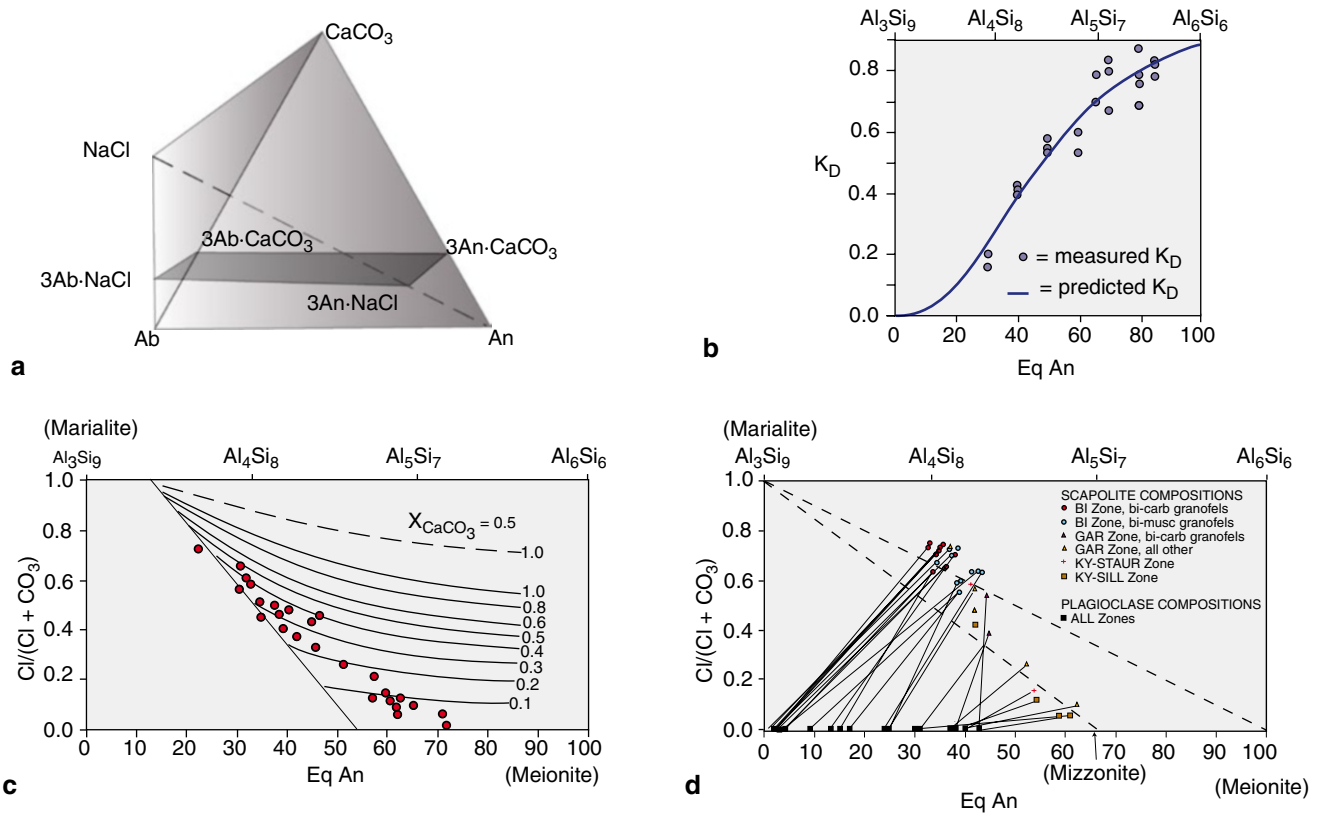

Fig. 14.14 (**a**) Compositional space for marialite-meionite. The shaded region is the theoretically possible plane of scapolite compositions (*Ab* albite, *An* anorthite). (**b**) Measured values of K_D for the reaction $NaCl_{(scap)} + CaCO_{3(fl)} = CaCO_{3(scap)} + NaCl_{(fl)}$ at 750 °C and 4,000 bar plotted against EqAn. The predicted line $LnK_D = (-0.0028)[Al/Al+Si]^{-5.5580}$ is shown for comparison. (**c**) The correlation between scapolite composition and fluid composition at 750 °C and 4,000 bar predicted by the equation $LnK_D = (-0.0028)[Al/Al+Si]^{-5.5580}$. Lines of equal $NaCl/(NaCl+H_2O)$ in coexisting fluid are shown. The compositions of natural scapolites are shown as *black dots*. (**d**) Compositions of coexisting scapolite and plagioclase in the Wallace Formation, Idaho. Plagioclase compositions are plotted along the horizontal axis. *Dashed lines* are solid solutions between marialite, meionite and mizzonite. In general, Cl in scapolite decreases with increasing metamorphic grade; but compositional variations within each grade suggest local control of fluid and scapolite compositions (**b** and **c** after Ellis 1978; **d** after Mora and Valley 1989)

marialite are unknown. Natural scapolites have compositional limits between 17.4 and 87.3 % of the meionitic component (Me) calculated as

$$Me = \frac{[Ca + Mg + Fe + Mn + Ti]}{[Ca + Na + K + Mg + Fe + Mn + Ti]}$$

Marialite corresponds to the compositions $Me_{0\text{-}20}$, and meionite to $Me_{80\text{-}100}$. Intermediates $Me_{20\text{-}50}$ and $Me_{50\text{-}80}$ are known as dipyre and mizzonite, respectively.

Minerals of the scapolite group have received considerable attention in metamorphic petrology due to their rather wide field of stability, which extends from late diagenetic to high temperature and high pressure crustal conditions. An understanding of variations in NaCl-scapolite (marialite) and $CaCO_3$-scapolite (meinonite) mineralogy is useful when studying the relationships between scapolite-plagioclase-halite reactions, metamorphic conditions, and the nature of the fluid phase.

Ellis (1978) considered the equilibrium between scapolite and a fluid, for a scapolite of fixed EqAn content, from exchange of the NaCl components:

$$NaCl_{(scapolite)} + CaCO_{3(fluid)} = CaCO_{3(scapolite)} + NaCl_{(fluid)}$$

at 750 °C and 4 kbar:

$$KD = \left[\left(X^{Scap}_{CaCO_3}\right)\left(X^{fluid}_{NaCl}\right) / \left(X^{Scap}_{NaCl}\right)\left(X^{Calcite}_{CaCO_3}\right)\right]$$

where X^i_j is the mole fraction of NaCl or $CaCO_3$ (i) in the respective phases (j). This he fitted to an expression

$$\ln K_D = -0.0028\left(X_{Al}\right)^{-5.5580}$$

where X_{Al} is the atomic Al/(Al+Si) ratio in scapolite (Fig. 14.14b). He went on to suggest that if the mixing is ideal, the activity of NaCl in fluids coexisting with scapolite grown at

temperatures and pressures, other than those of the experiment, can be calculated from this equation for K_D (Fig. 14.14c). This implies that Cl-poor natural scapolites coexisted with fluids low in NaCl and that regional occurrences of Cl-rich scapolites are likely to represent metamorphosed evaporite sequences.

Experimental results of Ellis (1978) were used by Mora and Valley (1989) and Oliver et al. (1992) in studies of meta-evaporite paragenesis to estimate the salinity of the metamorphic fluids based on the composition of Cl-bearing scapolite. Mora and Valley found that abundant Cl-rich scapolite and biotite in the Wallace Formation, Idaho, indicate high Cl activities during greenschist-through amphibolite-facies regional metamorphism of evaporite entraining metasedimentary rocks (Fig. 14.14d).

In general, Cl in scapolite decreases with increasing metamorphic grade; but compositional variations within each grade suggest local control of fluid and scapolite compositions probably related to the original distribution of halite in the sequence. The abundance of Cl-rich phases decreases abruptly with the appearance of zoisite-bearing assemblages, suggesting infiltration of low-Cl H_2O at higher metamorphic grades. The occurrence of buffered activity gradients in Cl, as indicated by scapolite and biotite compositions, also suggests that metamorphic fluid flow was highly channelized and aqueous fluid-rock interaction was limited. Similar channelisation defines scapolite distribution in the meta-evaporitic Corella Formation in the Mt Isa inlier.

Scapolite is a common mineral in the Lower Proterozoic metamorphic rocks of the Mary Kathleen area, Queensland. Australia (Ramsay and Davidson 1970). There, its occurrence in a wide range of host rock compositions, calcareous and non-calcareous metapelitics, acid and basic metavolcanics, and metadolerites, made it one of the first areas where the detailed relationships between scapolite composition and saline rock compositions were explored. The grade of metamorphism throughout is amphibolite facies. Calcareous metapelites are very sodic, and scapolite in the calcareous metapelites is more marialitic than that in intercalated low-calcium equivalents. The scapolite composition in all groups of meta-igneous rocks in the region varies through a similar range and is opposite to that of the metasedimentary group. Ramsay and Davidson (1970) concluded that the metasedimentary scapolite originated by isochemical metamorphism of shales and marls containing evaporitic halite, the local abundance of which was the main control on the composition and distribution of the scapolite. Thus the calcareous shales, which contained considerable halite, crystallized as marialitic scapolite (Me_{32}-Me_{52}), while the low-calcium equivalents formed a meionitic scapolite (Me_{50}-Me_{60}). In contrast the scapolite in the meta-igneous rocks formed metasomatically during regional metamorphism by the introduction of volatile-rich fluids derived from the adjacent evaporitic sediments (see later for more detail).

In applying geothermic postulates to their Cl-rich scapolites, Mora and Valley (1989) recognized limitations in the work of Ellis (1978), such as too high a temperature in the experiment for many meta-evaporites, and the high degree of uncertainty in terms of the nature and composition of the NaCl-H_2O-CO_2 fluid including the degree of immiscibility.

Generally, at temperatures up to 400–500 °C, the NaCl in scapolites may be derived directly from solid halite or associated highly-saline NaCl waters, that is, it is associated with the reaction:

$$\text{NaCl} + \text{plagioclase} + \text{calcite} \rightarrow \text{scapolite}.$$

At higher temperatures, the production of H_2O and CO_2 from devolatilisation reactions in adjacent metasediments tends to dissolve the remaining solid halite (Skippen and Trommsdorff 1986; Oliver et al. 1992). Scapolite growing in palaeo-evaporitic metapelites at temperatures above 400–500 °C is probably not in equilibrium with halite but with a halite-undersaturated NaCl-bearing fluid. Some minor dispersed halite may remain up to the melting point of halite at 750–800 °C. For example, minor solid inclusions of halite have been found in several samples of calcsilicate rocks from Switzerland and northern Italy that have been metamorphosed to lower amphibolite grade, with the development of talc and tremolite. Such idiomorphic crystals and dendrites of halite have been analysed and show a range of compositions in the system NaCl-KCl, which indicate temperature maximums greater than 500 °C and pressures of 2 kbar or higher (Trommsdorff et al. 1985).

Gómez-Pugnaire et al. (1994) found that the existing well-studied relationships and assumptions of the alliance between scapolite, calcite and plagioclase (e.g. Aitken 1983) were not the explanation of the meta-evaporitic scapolites of the Cóbdar region of Spain. There biotite, not albite, was involved with halite in scapolite formation and the scapolite is a retrograde mineral phases. This Permo-Triassic pelite-carbonate rock series (with intercalated metabasitic rocks) in the Cordilleras Beticas, Spain, was metamorphosed during the Alpine metamorphism with peak metamorphism at eclogite facies with high pressures (P_{min} near 18–22 kbar) and relatively low temperatures (≈650 °C). These evaporitic metapelites have a whole rock composition characterised by high Mg/(Mg + Ca) ratios >0.7, variable alkaline and Sr, Ba, contents, but are mostly K_2O rich (<8.8 wt%). The F (<2,600 ppm), Cl (<3,600 ppm), and P_2O_5 (<0.24 wt%) contents are also high. The pelitic member of this series is a fine-grained biotite rock, where kyanite-phengite-talcbiotite clusters in pseudomorphs developed in the high pressure stage. Albite-rich plagioclase was formed when the rocks crossed the albite stability curve in the early stages of the uplift. Scapolite, rich in NaCl [Ca/(Ca + Na) ≈ 24–40 mol%] and poor in SO_4, with Cl/(Cl + CO_3) ratios between 0.6 and 0.8, formed as porphyroblasts, sometimes replacing up to

60 % of the rock in the later decompressional stage of metamorphism (between 10 and 5 kbar, near 600 °C).

That is, the Spanish scapolites are rich in Na and poor in CO_3. Plagioclase is not consumed by scapolitization; but biotite, the most important matrix material, almost completely disappears in areas of scapolite blastesis. Gómez-Pugnaire et al. (1994) conclude that these Spanish scapolites formed during retrograde metamorphism from a biotite precursor by the reaction:

$$\text{Al-biotite} + \text{CaCO}_3 + \text{NaCl} + \text{SiO}_2 = \text{Al-poor biotite} + \text{scapolite} + \text{MgCO}_3 + \text{KCl} + \text{MgCl}_2 + \text{H}_2\text{O}$$

The rocks, even though at amphibolite grade, still retain well preserved sedimentary indicators of former evaporites, such as pseudomorphs after sulphate evaporites, which are now composed of talc, kyanite-phengite-talc-biotite, and quartz. In addition, there are relicts of baryte, anhydrite, NaCl and KCl still present in the rock matrix. All the metasedimentary evidence indicates a salt-clay mixture as the protolith, which was dominated by illite, chlorite, talc, and halite. Calculated fluid composition in equilibrium with scapolite indicates varying salt concentrations in the fluid, and the distribution of Cl and F in biotite and apatite also indicates varying fluid compositions possibly inherited from the metasedimentary protolith.

Br/Cl ratios were recognised by Pan and Dong (2003) to closely reflect those of its co-existing melts and fluids and so are useful indicators of likely scapolite protoliths and sources of any associated ore-forming fluids, even at amphibolite grade metamorphism. Cl/Br values of marialite in the Tieshan deposit are considerably higher than seawater, but can be explained by the dissolution of halite and sylvite as the mode of origin of the hydrothermal metamorphosing brines (Fig. 14.15a). Likewise, Cl/Br values of scapolite-group minerals in exoskarns of the Nickel Plate deposit are close to those of the Tieshan deposit, and according to Pan and Dong (2003) indicate a similar meta-evaporitic origin. Interestingly, the Nickel Plate gold deposit, some 240 km east of Vancouver, is one of the largest and most important gold-skarn deposits in British Columbia, having produced some 49 tonnes of gold, which is approximately half of all the gold produced from skarns in British Columbia (Pan et al. 1994). The increase in Cl/Br from endoskarn to exoskarn in the deposit is readily attributable to an increased involvement of magmatic H_2O in the former, while the exoskarn values indicate involvement of metamorphosed Triassic evaporites. Similarly, a wide variation in Cl/Br in scapolite-group minerals from the Grenville deposits of Ontario (Fig. 14.15b) is consistent with varying degrees of mixing of

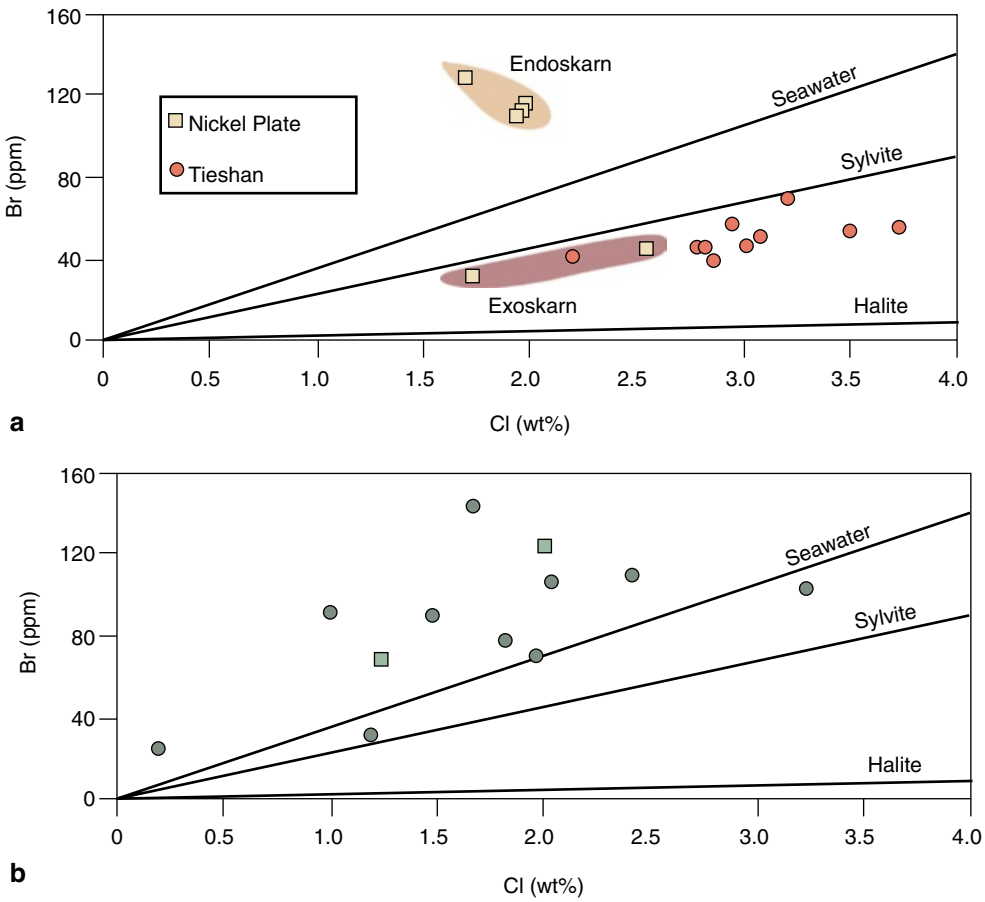

Fig. 14.15 Br (ppm) versus Cl (wt%) plots illustrating scapolite group minerals from: (**a**) the Tieshan, China and Nickel Plate, British Columbia, skarn deposits, and (**b**) the Grenville, Ontario-Quebec, pegmatite, skarn, and vein deposits (Replotted from Pan and Dong 2003)

hydrothermal fluids derived from magmatic sources and associated variably evaporitic sedimentary rocks. In a recent study of scapolites in the Mary Kathleen region, Hammerli et al. (2014) used Br/Cl signatures to refine brine origins and likely protoliths in this amphibolite-grade terrane (see later).

Albitites and Albitization

The process of albitization describes any system of sodic alteration (secondary mineral formation) where the effected rock is partly or completely replaced by albite. Albite-rich rocks are typically termed albitites, but are sometimes referred to as "adinole," "albite felsite," "albite fels" and "alitolite" (Kalsbeek 1992). Albitization can overprint all rock types, sedimentary, metamorphic and igneous, and the sodic solutions driving the albitization can be derived from magmatic solutions or an evaporitic protolith (e.g. Frietsch et al. 1997; Oliver et al. 2004). Oliver et al. (2004) argues albitization, as it is tied to sodic fluids that leached metals, is part of the ore-forming process in the metasedimentary section of the Cloncurry region. Worldwide, albitites occur in intimate association with Iron-Oxide-Copper-Gold (IOCG) deposits and with mineralised zones in the Broken Hill and Cloncurry regions (Chap. 16). As such, there are numerous widespread examples of albitites in Proterozoic and Archaean terranes (Table 14.4).

Albite, the mineral, is one end-member of the plagioclase feldspar series with anorthite constituting the other (Fig. 14.16a). Other members of the plagioclase series (oligoclase, andesine, labradorite, bytownite and anorthite) are defined by variable rations of Na/Ca. Albite is also one end member of the alkali feldspar series with orthoclase as the other, with constituent members of the alkali series being anorthoclase and sanidine and subdivided based on the Na/K ratio. Albitization is a worldwide replacement mechanism and albitites have formed throughout earth history in a wide variety of igneous, hydrothermal and metasedimentary settings (Table 14.4). Albite's thermal stability field, like scapolite, is now thought to encompass temperatures ranges from the early diagenetic (≈40–60 °C) well into the amphibolite facies (≈600 °C). Albitite is often associated with scapolite and mineralogical similarities between the two mineral series were noted in the previous section.

Proposed sources for the Na-rich brines that drive albitisation in the metamorphic realm include: (1) leaching of halite from exhalatives (Bierlein et al. 1996); (2) Dissolution of evaporites (Bierlein et al. 1996); (3) Dehydration reactions (Clark et al. 2005); (4) Magmatic fluids; (5) Fluids derived form the devolatilisation of volcanics; (6) Seawater interactions; (7) Intraformation Na-rich brines (8) Surface-driven infiltration of dense hypersaline brines. Much of the following discussion is centred on albitites tied to evaporites and hypersaline brines, my intention is not to make the case that the majority of the world's albitites are tied to evaporites, clearly there are numerous examples where they are not; but the focus of this chapter is meta-evaporites and for this book is evaporites. For a broader discussion of albitites in a metasomatic[3] framework see Yardley (2013), and work without a focus on deposits tied to evaporites and their dissolution/alteration products, the reader is referred to papers such as Castorina et al. (2006), or Azer et al. (2010) and the references therein.

In the diagenetic realm, halite dissolution supplies much of the sodium for albitization, while the albitisation of pre-existing sedimentary feldspars is an important source of Ca to basinal brines. These brines continue to be important in the metamorphic realm (Fig. 14.12; Yardley 2013). Ramseyer et al. (1992) noted that deeply buried plagioclase grains in sandstones are commonly albitised, especially when bathed in more-saline basinal brines. For example, massive albitization of feldspars (both plagioclase and alkali feldspar) occurred during burial diagenesis at depths greater than 4,000 m in the Oligocene Frio Formation (Texas) over much of its extent in the Gulf of Mexico. Albitization was intimately associated with the circulation of Na–Ca–Cl basinal brines and is tied to its sodium supply via massive dissolution of deeply buried salt (Land and Milliken 1981). Albitization has developed in several other sandstone formations of the Gulf Coast Tertiary between 2,500 and 2,870 m depth at temperatures between 110 and 120 °C and can supply Ca to the basin brines (Fig. 14.16b; Boles 1982). Quartz and albite also formed diagenetically in Devonian limestone's of the Belgian Ardennes during burial diagenesis at temperatures less than 90 °C (Molenaar and de Jong 1987).

Albitization did not begin in Tertiary clastic reservoir sandstones in the North Sea at depths less than 2,000 m and at 65–145 °C (Saigal et al. 1988; Aagaard et al. 1990; Morad et al. 1990). Consequently plagioclase albitization is seen from a sedimentological viewpoint as occurring during in burial diagenesis and is driven by the circulation of saline basinal brines at temperatures between 75 and 160 °C (Ramseyer et al. 1992; Saigal et al. 1988; Aagaard et al. 1990; Morad et al. 1990; Ben Baccar et al. 1993). These sodic brines tend to be well developed in basins with thick deeply buried halite masses subject to burial dissolution (e.g. examples 1–6 in Fig. 14.12).

[3]Metamorphism and metasomatism both involve the re-equilibration of mineral assemblages due to changes in pressure, temperature and/or chemical environment. Both processes involve material transport but on different length scales, so every metamorphic reaction is metasomatic on a local scale. Fluids provide a transport mechanism which is orders of magnitude faster than solid state diffusion and induce re-equilibration through dissolution of parent phases and reprecipitation of products (Putnis and Austrheim 2010).

Table 14.4 Worldwide examples of albitites

Time	Africa	Americas	Asia	Australia	Europe and adjacent
Mesozoic/ Cenozoic	Hercynian of northern Africa (Hill 2003)	Chilean coastal batholith (E – Chiaradia et al. 2006); Chilean Coastal Cordillera (Hopper and Correa 2000) Hanging wall association to Columbian emerald occurrences (Branquet et al. 1999)	Ningwu Basin, Cretaceous, China (Mao et al. 2008); Mlakawa albitite, NE Iraq (Mohammad et al. 2007)	–	Stratabound Zechstein Copper deposits, Poland (E – Kucha and Pawlikowski 1986); Morvan Massif, France (*E* – Parcerisa et al. 2010) Volcaniclastics in vicinity of the Gemsbach fault zone (E – Brockamp et al. 1994); Northeast German Basin (Paulick and Breitkreuz 2005); Streltsovka U-deposit (Chabiron et al. 2003)

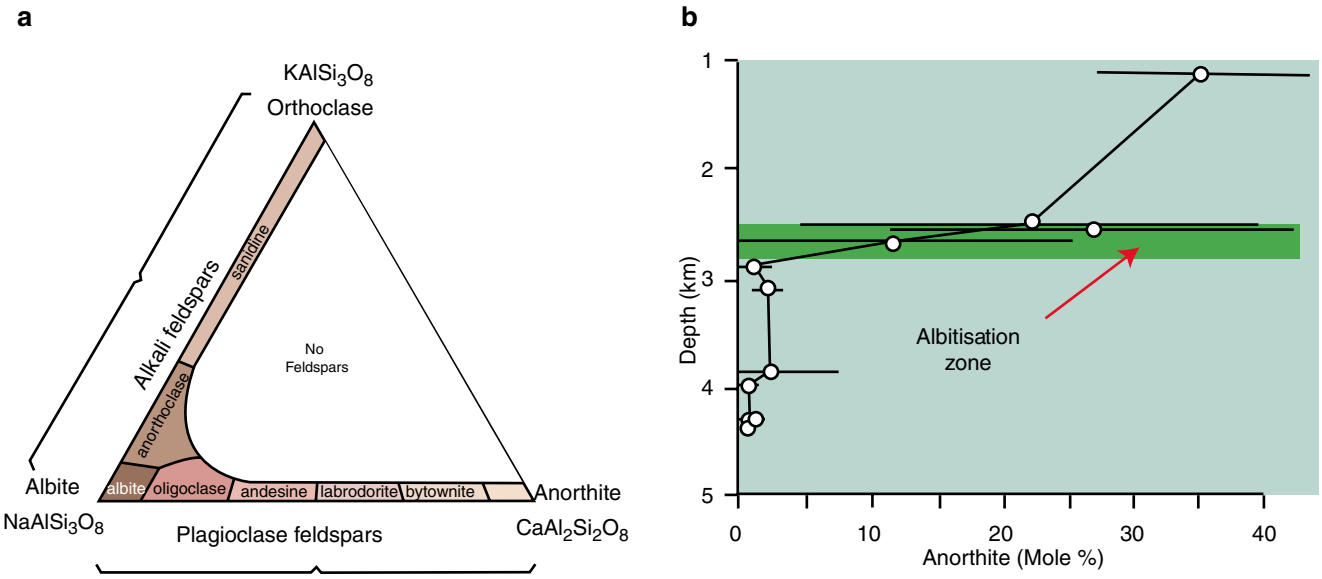

Fig. 14.16 Feldspar and albitisation. (**a**) Feldspar mineral series. (**b**) Increasing albitization of anorthite feldspar with depth in the Frio and Wilcox sandstones, Gulf of Mexico. Significant increase in albitization at 2,500–3,000 m depth (After Boles 1982)

An interesting variation on this burial diagenetic sedimentary story is seen in igneous strata that make up the Hercynian Morvan Massif (Parcerisa et al. 2010). The Massif, in the northern part of the French Massif Central, consists of granite and some rhyolite. A Triassic erosional unconformity sits atop the massif, which is in turn covered by Mesozoic sediments of the Paris Basin (Fig. 14.17). Igneous rocks of the Morvan Massif show strong alteration via; (1) the pseudomorphic replacement of the primary plagioclases with albite, (2) the pseudomorphic replacement of primary biotite with chlorite and, (3) minor precipitation of neogenic minerals like albite, chlorite, apatite, hematite, calcite and titanite. The geometry and arrangement of these alterations indicates the likely diagenetic control on their development. Some altered facies are pervasive in the massif; others are restricted to centimetric to metric-wide joints and imply fluid-flow phenomena. Moreover, the alteration facies show a clear depth-related succession with strongly altered facies at the top of the massif and immediately below the unconformity, while the intensity of alteration weakens with depth. This points to a genetic relationship of albitization to the Triassic unconformity.

Regionally, the distribution of the alteration halo, which overprints a variety of Carboniferous igneous and volcanic formations beneath the Jurassic sedimentary cover, is tied to the presence the Triassic unconformity (Fig. 14.17b, c, but not 14.17a) and not to fluids from the emplacement of the granite massif. Parcerisca et al. (2010) noted an even more interesting result; the alteration haloes are Triassic (not Hercynian), and so have the same age as the unconformity not the emplacement time of the basement. Taking into account all these geological constraints, and the widespread evidence of former now dissolved Keuper halite beds atop the unconformity, Parcerisca et al. (2010), proposed that albitization of the Morvan Massif was developed under low temperature diagenetic conditions, which were tied to a brine hydrology related to the Triassic paleosurface and not to contact metamorphic fluids related to the emplacement of the granite massif (Fig. 14.17c).

Across the metamorphic realm, examples of albitization abound, especially in the Precambrian, some with their sodium supply tied to meta-evaporites, others tied to magmatic fluids (Table 14.3). Compared to Phanerozoic examples, a direct tie to evaporites is less obvious in most of the Precambrian cases listed in Table 14.3. There are a number of reasons for this. First, the further back in time, and/or the higher the metamorphic grade or temperature of formation, the less likely it is that *prima facie* evidence is preserved of the primary mineral phases that tie to the source the sodic solutions responsible for the albitization. Second, beyond the Paleoproterozoic, the less likelihood there is of direct analogs to models within a framework of modern plate tectonic analogs to explain the source of sodium; this is true for both the igneous and meta-sedimentary fluid explanations. Third, as yet, there is no consensus in terms of world-scale models of plate movement and driving forces for basin scale sodic fluid movement in the early Archaean world (Ernst 2009 and earlier discussion in this chapter).

But there is direct evidence in preserved metasediment-volcanic greenschist associations that the Archaean greenstone world was a much more volcanigenically-driven system than today, and that Na-carbonates were likely the dominant evaporite marine precipitates. The question to be considered in the various Precambrian albitite associations is

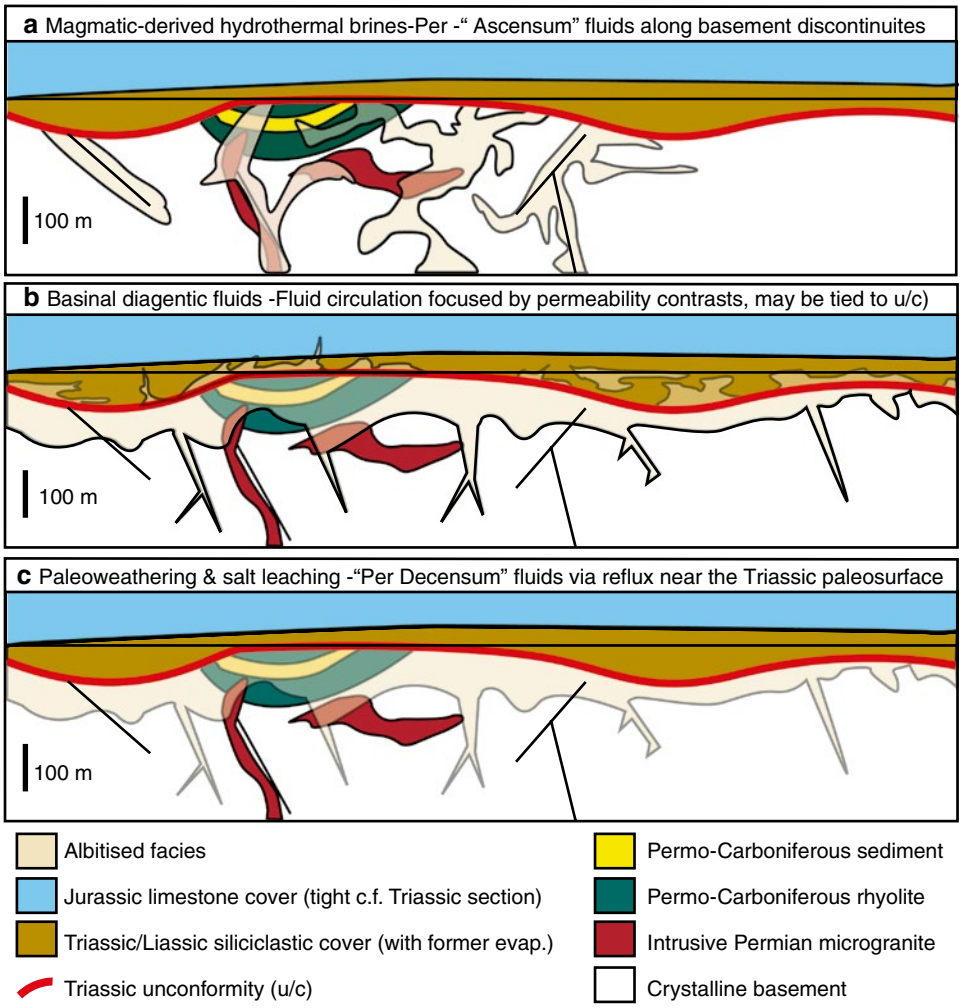

Fig. 14.17 Distribution of the albitised facies relative to three possible hypotheses as to the origin of the albitization: (**a**) Sodic solutions are hydrothermal brines associated with later stages of emplacement of igneous bodies and formed prior to the formation of the unconformity and deposition of Triassic sediments. Albitite geometries are related to fault and shear discontinuities within the basement and do not need to be located near the Triassic unconformity, (**b**) Sodic solutions are associated with Na-Ca-Cl basinal brines derive from deep subsurface dissolution of salt. Solutions flow preferentially along permeable sands beneath a relative seal created by the overlying Jurassic carbonates. Albitite geometries are preferentially developed near the contact of the sandstone aquifer and the crystalline basement. (**c**) Sodic solutions are derived via early salt leaching or supergene solutions, so the albitites form a reflux halo at the upper part of the massif, immediately below the unconformity and/or the position of former Keuper salt beds (In part after Parcerisa et al. 2010)

how important was an evolving and very different seawater chemistry to the volume of salts precipitated. Unfortunately, we are trying to decipher a system where time and metamorphism means that primary sodic salt phases and or igneous indicators have long since passed into the realm of polyphase metamorphism, within the various cratonic blocks that now constitute the cores of the world's continents.

Within this metamorphic cloud, Proterozoic albitite associations perhaps retain textural and chemical associations that are more indicative of the primary origin of many albitites that the Archaean association. It may be that the Proterozoic associations, formed in a plate tectonic system more akin to that of today, are also more readily interpreted in terms of formative processes than albitites of the Archaean greenstone world. For example, the Paleo- and Mesoproterozoic metasedimentary/metavolcanic units of the meta-evaporitic Willyama Supergroup of the South Australian Curnamona Province are considered prime examples of regional scale Proterozoic albitization. Petrographic, geochemical and SEM-BSE/edx studies by Schmidt-Mumm and Conor (2008) and Heimann et al. (2013) show that mineral replacement in the albitised units in this succession initially affects plagioclase, followed by K-feldspars, micas and finally Fe-oxides. Replacement thereby progressively reduces K, Ca, Mg, Fe and Ti, the traces of lithophiles (Ba, Sr, Rb, Th, Nb), siderophiles (Co, Ni) and chalcophiles (Cu, Zn, Pb) by orders of magnitude. With progressive intensity of albitization, the light REE are depleted preferentially over the heavy REE, but in intense albitization all REE are depleted.

At the same time, Na (and Al) are enriched while the mobility of Si is conservative and dependent on the affected lithologies, Zr appears the least mobile element. Endproducts of progressive replacement are trace element poor, Na-rich end-member albites and a highly charged, metal-rich fluid. The subsurface course these fluids take can be traced in the form of breccia pipes and dykes with a distinct FeOx-rich, calc-silicate (actinolite, clinopyroxene) bearing matrix. In my opinion, some of these breccias, where I have visited field sites in the Olary Province, do not preclude a halotectonic rather than a purely structural focus during formation. Such breccias, with analogous occurrences in the Cloncurry (Qld, Australia) and Wernecke Mts (Canada), are distinctly

enriched in Fe, Mg, Ca and K and are strongly positively anomalous in Ba, Sr and Rb, Cu, Pb and Zn as well as the REE elements, emphasizing the mineralising potential of the involved fluids. Electron microprobe and Laser Ablation ICP-MS analysis show that these metasomatic reactions gradually affect individual grains, while the influx of Na-rich fluids occurs along microfractures and crystal cleavage plains.

The effects of albitization are well documented in the Olary region, but the driving mechanisms for Precambrian albitization are not (see discussion in Conor and Preiss 2008). The same is true for other areas of Proterozoic and Archaean albitization (Kalsbeek 1992; Dreher et al. 2008). We shall return to this question of sources of sodic solutions when discussing specific Proterozoic and Archaean meta-evaporite examples later in this chapter.

Tourmaline and Tourmalinisation

Tourmaline precipitation encompasses temperatures of ≈150 to >900 °C, pressures of ≈6 MPa to >6 GPa and it can equilibrate with a wide range of geological fluids from the diagenetic to metamorphic, and precipitation sites can include low temperature caprocks atop salt allochthons such as the Challenger Knoll (Henry et al. 2008; Henry and Dutrow 2012). Boron in tourmaline in many meta-evaporite associations comes from the borate salts, while boron is ultimately produced by cosmic ray spallation and not by stellar nucleosynthesis. Hence, B is a low-abundance element in both the solar system and the Earth's crust and is concentrated by the water-solubility of its more common naturally occurring compounds, namely, the borate minerals (such as; borax. colemanite and ulexite – Chap. 12).

Tourmalinite is a common gangue in many massive sulphide and sedex deposits, where hydrothermal alteration associated with seawater convection can be a significant mineralization process (Chap. 16; Palmer and Slack 1989). Tourmaline as dravite and schorl occurs in tourmalinite in the Isua complex, Greenland, which with an age of some 3,650—ca. 3,600 Ma (metamorphic age) is probably the oldest boron mineral reported to date. Tourmaline, the mineral, is typically classified as a semi-precious stone, and gemstone forms come in a wide variety of colours from black to green to red to blue. The name tourmaline comes from the Sinhalese word "*Thuramali*," which is applied to different gemstones found across Sri Lanka.

Borate evaporites (the ultimate borate source for much metaevaporitic tourmaline) are today associated with lacustrine depressions created within zones typified by convergent continental tectonics (Chap. 12). Convergent tectonics is also a commonplace association for tourmaline precursor fluids in metavolcanic and meta-igneous deposits. But, as for albitite, there is a time-based dichotomy in the relative abundance of tourmaline, with tourmalinites with metasedimentary associations being more common in Precambrian protoliths. This is another line of evidence that there were differences in plate tectonic settings and boron fluid distributions in the early Precambrian compared to the Phanerozoic.

Tourmaline, the mineral, encompasses a complex series of aluminium borosilicates with the general formula: $XY_3Al_6Si_6O_{18}(BO_3)_3(OH,F,O)_4$. X represents large cations such as calcium, sodium and/or rarely potassium, while the Y cation represents smaller cations such as iron (+2 and/or +3), magnesium, aluminium, lithium and/or manganese (Table 14.5; Fig. 14.18). The aluminium in the Al_6 site can be substituted for, on a limited basis, by iron and more rarely chromium or vanadium. Fluorine and oxygen substitute for hydroxide in a few of the members and then only to a limited extent. For a full discussion of the various petrogenetic indicators in the tourmaline lattice see Henry and Dutrow (2012).

Table 14.5 Typical members of the tourmaline mineral series

End member	Formula
Schorl*	$NaFe^{2+}Al_6(BO_3)_3Si_6O_{18}(OH)_4$
Dravite*	$NaMg_3Al_6(BO_3)_3Si_6O_{18}(OH)_4$
Oxy-dravite*	$Na(MgAl_2)(MgAl_5)(BO_3)_3Si_6O_{18}(OH)_3O$
Povondraite*	$NaFe^{3+}{}_3Fe^{3+}{}_4Mg_{2)}(BO_3)_3Si_6O_{18}(OH)_3O$
Tsiliasite	$NaMn_3Al_6(BO_3)_3Si_6O_{18}(OH)_3$
Elbaite	$Na(Li,Al)_3Al_6(BO_3)_3Si_6O_{18}(OH)_4$
Ferridravite	$NaMg_3Fe^{3+}{}_6\ (BO_3)_3Si_6O_{18}(OH)_4$
Buergerite	$NaFe^{3+}{}_3(BO_3)_3Si_6O_{22}F$
Liddicoatite	$Ca(Li,Al)_3Al_6(BO_3)_3Si_6O_{18}(OH)_4$
Uvite	$CaMg_3(MgAl_5)(BO_3)_3Si_6O_{18}(OH)_4$

Minerals marked with an asterisk are considered by Henry et al. (2008) to be significant in many meta-evaporitic tourmaline associations

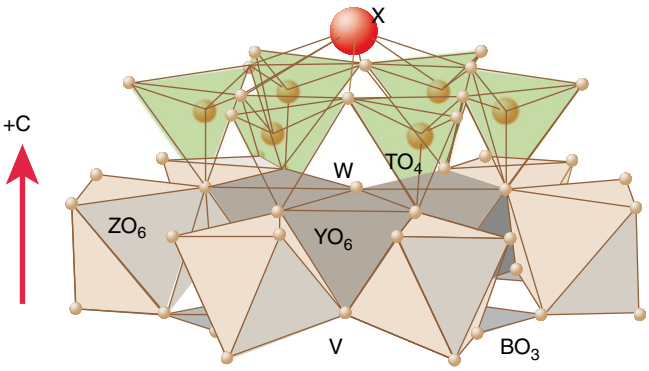

Fig. 14.18 Lattice structure of tourmaline as viewed perpendicular to the c-axis. Tetrahedra (TO_4) of the six-membered ring point in the same direction, parallel to c, to produce the crystallographic asymmetry. The polyhedra, X cation and V/W anions are labeled consistent with the structural formula. Octahedra, YO6 and ZO6, are shown together with the BO_3 site (After Henry and Dutrow 2012)

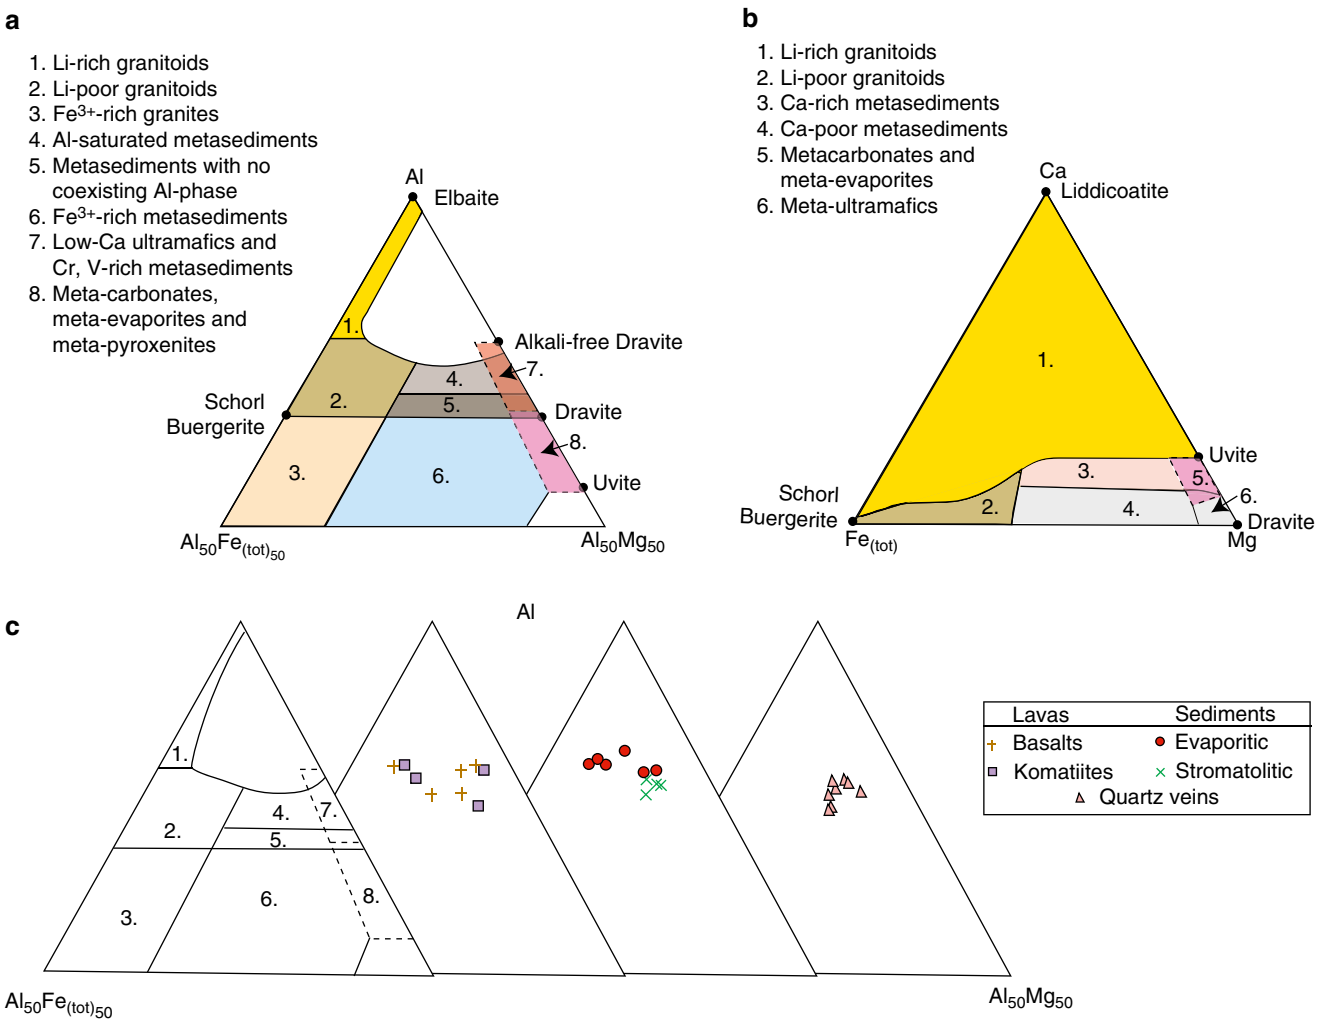

Fig. 14.19 Tourmaline composition. (**a**) Al-$Fe_{(Tot)}$-Mg diagram in molecular proportions for tourmalines, showing compositional range of various metasedimentary and igneous rock types, note overlap of fields 4 and 5 with field 7 (After Henry and Guidotti 1985). (**b**) Ca-$Fe_{(tot)}$-Mg diagram in molecular proportions for tourmalines showing compositional range of various rock types, note overlap of field 4 with field 6. Note povondraite previously called ferric dravite (After Henry and Guidotti 1985). (**c**) Compositional variations of various Barberton craton rocks using plot of A for comparison (After Byerly and Palmer 1991)

Three solid solution series characterise the most common tourmalines in nature (Fig. 14.19a, b):

- Between the Fe-rich (schorl) and the Mg-rich (dravite) tourmalines,
- Between schorl and the Li-rich (elbaite) tourmalines, and,
- Between dravite (Na>Ca) and uvite (Ca>Na) tourmalines.

The dravite-uvite series, is typical of tourmalines with metaevaporite and/or metacarbonate affinities and has end member compositions: dravite [$NaMg_3Al_6Si_6O_{18}(BO_3)_3(OH)_4$], and uvite [$Ca(Mg,Fe)_3MgAl_5Si_6O_{18}(BO_3)_3(OH)_4$]. Ayuso and Brown (1984) and Henry and Guidotti (1985) also demonstrated that tourmalines associated with meta-evaporites and metacarbonates in Precambrian sequences in North America are Mg-rich members of the schorl-dravite series, with significant Ca-uvite components.

Henry et al. (2008) note that the meta-evaporitic tourmalines are generally sodic, magnesian, moderately-to-highly depleted in Al, and enriched in Fe^{3+} and O-W^{2-} (calculated). They typically follow a trend along a join between "oxy-dravite" [$Na(Mg_2Al)(Al_6)(Si_6O_{18})(BO_3)_3(OH)_3O$] and povondraite [$NaFe_3^{3+}Fe_4^{3+}Mg_2Si_6O_{18}(BO_3)_3(OH)_3O$] (Fig. 14.19a). Tourmalines occurring in the highly magnesian high-pressure rocks (whiteschists and pyrope-coesite rocks) are distinctly more magnesian and fall close to the dravite and "oxy-dravite" compositions. These latter tourmaline compositions likely reflect the metasomatic processes that produced these more unusual bulk compositions and/or the influx of a reactive fluid that eliminated any earlier chemical signatures of meta-evaporitic fluids or protoliths.

As for stratabound tourmalinites, any restriction of these boron-rich minerals to particular stratiform units in a layered metamorphosed sequence strengthens a likely metasedimentary, possibly evaporitic, protolith (Abraham et al. 1972). However, even in meta-evaporitic settings, the boron ultimately captured in stratiform tourmalines may have come from:

(i) The diagenetic or regional metamorphic alteration of originally bedded borate mineral deposits (e.g., meta-borates in eastern Liaoning, China: Peng and Palmer 1995);
(ii) From hydrothermal activity in areas underlain by dissolving continental evaporites, such as early rift basin activity (such as in the Willyama complex: Slack et al. 1993); and
(iii) From ongoing submarine fumarolic and hydrothermal activity (exhalites) independent of any evaporitic contribution (Byerly and Palmer 1991).

Tourmalinite association (i) may well pass to (ii) as a continental rift basin evolves into a passive continental margin and then into convergence/collision (Wilson Cycle). Association (iii) can occur in volcanogenic rifts with or without the presence of borate evaporites.

The utility of tourmaline end-member concepts and compositional field divisions, as illustrated in Fig. 14.19, is only as good as our understanding of the chemical system that they represent. The tourmalines in sediments and lavas from the Archaean Barberton greenstone belt in South Africa are typical of the compositional variations seen in Precambrian metamorphics from across this region (Fig. 14.19c; Byerly and Palmer 1991). Using a standard Al-$Fe_{(tot)}$ -Mg plot places many of the Barberton samples in the field of immiscibility between dravitic and elbaitic tourmalines (Fig. 14.19c). The remainder plot in the Al-saturated metasedimentary field and are well away from the uvite compositional field. Only the Barberton tourmalines associated with meta-stromatolites and quartz veins show a degree of Mg enrichment and largely plot outside the standard metaevaporite-metacarbonate field, yet they occur in metasedimentary hosts that are considered evaporitic based on associated scapolites, evaporite pseudomorphs and isotopic compositions.

In my opinion, this quandary underlines a difficulty that seems to pervade the metamorphic literature, namely simplistic notions of the homogeneity of the sedimentary protolith. In terms of a tourmaline precursor, not all borate evaporites contain high levels of calcium, and most mined borate salts contain little or no magnesium (see borates in Chap. 11). This means the magnesium component in the protolith to meta-evaporitic tourmalines comes mostly from the host sediments that entrain the borate salts. There can be only a very minor contribution from the borax salts. If the host matrix contains dolomites and other carbonate minerals and the borate salts are dominated by colemanite or ulexite (major ore minerals in Turkey) then there will be a high level of Mg and Ca in the system and Mg-Ca rich sodic tourmalines minerals will form. But, it is worth noting that there is not any calcium in lacustrine borates composed of borax or kernite (major salts in the US borate deposits). In many borate deposits the host volcanogenic matrices are labile, and so are altered to be dominated by aluminosilicate clays (such as smectite), with some zeolites. Analcime, a common alteration product, for example, contains no Mg (see Chap. 11). Without evaporation of appropriate low salinity bicarbonate-rich inflow waters in the depositional basin, the levels of magnesium and calcium carbonate in the protolith matrix may be quite low. When borate salts in such a systems start to metamorphose and supply ions that will precipitate tourmaline, there may be little or no Ca or even Mg supplied to the system. The result will be meta-evaporitic tourmalines that do not plot in field 4 of Fig. 14.19b.

A more reliable way to determine a likely meta-evaporite protolith to some tourmalines and tourmalinites, based on chemical composition, is perhaps via a Na, Fe^{3+}, ^{W}O crossplot. Henry and Dutrow (2012) found low-temperature tourmalines that developed in hypersaline environments (e.g. salt dome caps) have distinct chemical characteristics of high Na, Fe^{3+} and ^{W}O (i.e. the W site occupied by oxygen as illustrated in lattice structure in Fig. 14.20), and follow a trend between oxy-dravite, and povondraite (O-P trend) (Fig. 14.20a, b). They argue this compositional trend can be used as a guide to indicate tourmaline development within low-temperature hypersaline environments and appears to be diagnostic of an oxidizing environment with high Na in the fluid and high salinity with the resulting reduction of the activity of H_2O. The same O-P trend is retained in some meta-evaporite deposits that are relatively high grade, as in Namibia (Fig. 14.20c). The same signature is also found in tourmalines from some types of economically important precious metal deposits, typically tied to meta-evaporites (see later).

But perhaps the most reliable method to distinguish between possible origins of meta-evaporitic tourmalines and tourmalinites is to measure their $\delta^{11}B$ isotopic signature (Fig. 14.21). Palmer and Slack (1989) described how boron isotopic signatures vary in a predictable manner in deposits ranging from primary borate salts to meta-evaporites. Tourmalinites associated with marine evaporites have a positive $\delta^{11}B$ signature near +10‰, tourmalinites associated with mafic volcanics have a signature near −2‰, tourmalinites from continental margin sediments have values near −15‰, while tourmalinites derived from nonmarine evaporites have very negative isotopic signatures near −20‰.

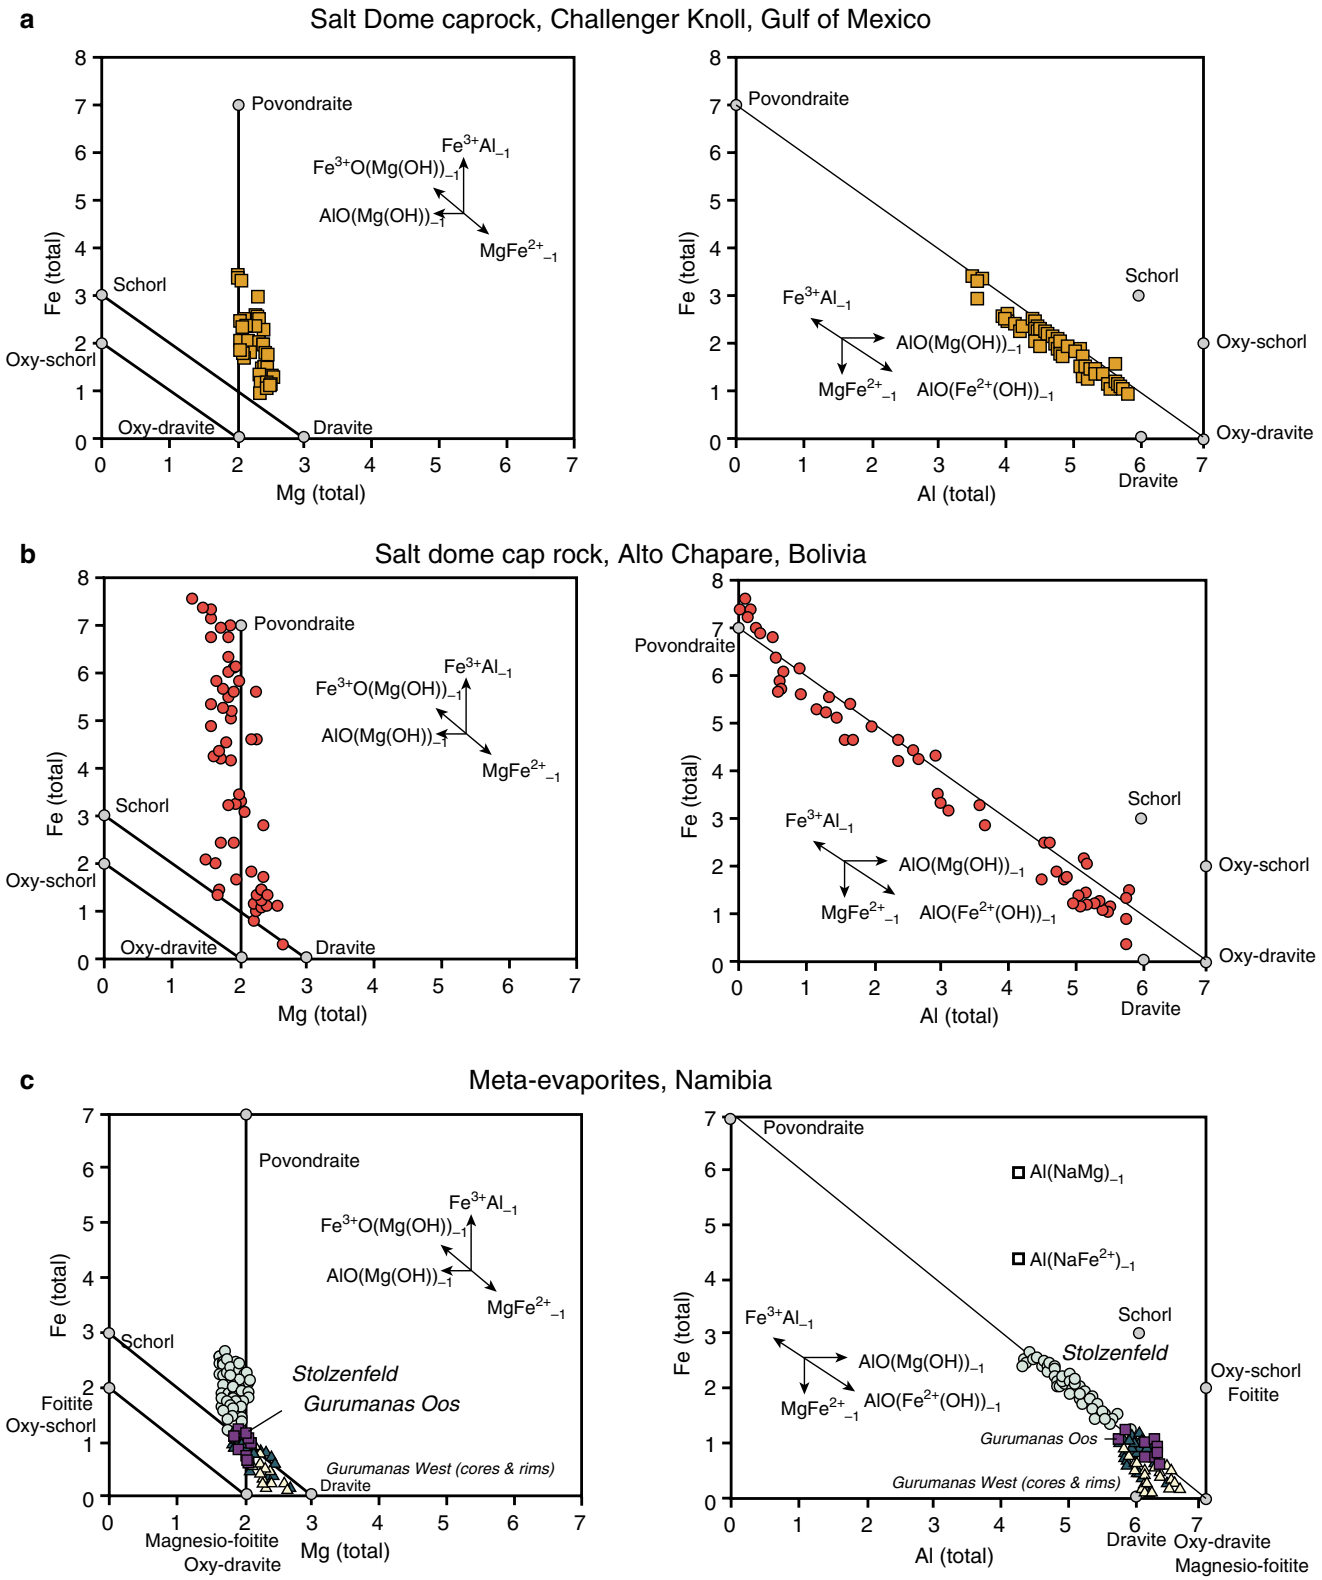

Fig. 14.20 Tourmaline components indicative of evaporite association (After Henry and Dutrow 2012). The covariant lines represent joins between selected tourmaline end members – indicated compositions cover the complete range from "oxydravite"/dravite to povondraite -see text. (**a**) Compositional variations Mg vs. Fe(total) and Al vs. Fe(total) diagrams of low-temperature tourmaline (<150 °C) found in the cap rock of the Challenger Knoll salt dome in the central Gulf of Mexico. (**b**) Compositional variations Mg vs. Fe(total) and Al vs. Fe(total) diagrams of low-temperature tourmaline found in the cap rock of the Alto Chapare salt dome, Bolivia. (**c**) Compositional variations Mg vs. Fe(total) and Al vs. Fe(total) diagrams for tourmaline found in three tourmalinite localities associated with metamorphosed evaporite deposits in Namibia. The three meta-evaporite localities are labeled and have different symbols. The green triangle for the Gurumanas West locality represents generation-2 rim compositions. As in (**a**, **b**), the array of data is generally along the "oxy-dravite"–povondraite join and is most consistent with operation of the $AlFe_{-1}$ substitution except for the Gurumanas West rims that exhibit $Mg(OH)(Fe^{3+}O)_{-1}$ and $MgFe_{-1}$ substitutions as well. These Namibian tourmalines are mostly classified as "oxy-dravites", but some are dravites

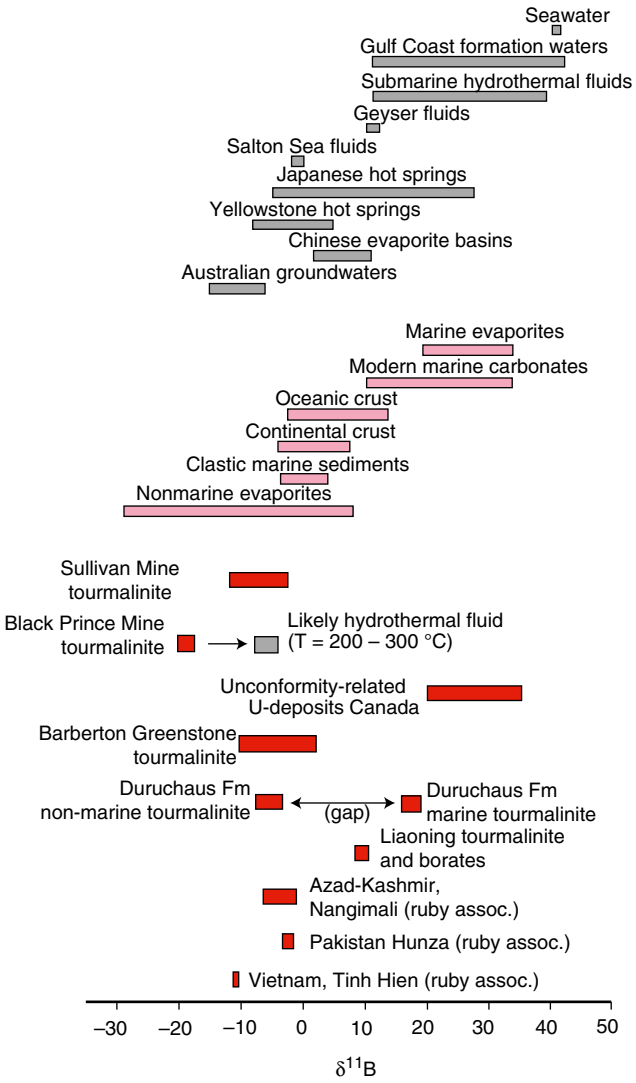

Fig. 14.21 Boron isotopic composition of tourmalines in the Black Prince Mine, Broken Hill District, Australia, the Barberton greenstone belt, South Africa, the Duruchaus Fm, Namibia and the Lianong region, China and various ruby associations in SE Asia (*solid red boxes*) compared with typical values for various boron sources; *Grey boxes* indicate fluids, *pink boxes* indicate solids (After Slack et al. 1989; Byerly and Palmer 1991; Peng and Palmer 1995; Sun 2007; Garnier et al. 2008)

Using this approach implies a likely nonmarine evaporite protolith for the Paleoproterozoic tourmalinites of the Black Prince Mine in the Broken Hill District, while samples from the Barberton Greenstone Belt indicate a mixed volcanic and sedimentary protolith. Sun (2007) showed how stratabound tourmalinites in the Neoproterozoic Duruchaus Fm of Namibia preserve separate marine and nonmarine meta-evaporite signatures. The nonmarine Duruchaus tourmaline association is tied to the early rift stage of the protolith basin, while the marine signature is related to later meta-evaporites formed in the incipient oceanic setting of the widening rift. A similar "rift-to-drift" evolution was used to explain the dichotomy of boron isotope values in the Houxianyu meta-borates of the Liaoning region, China (Jiang et al. 1997).

One of the more interesting examples comes from the Sullivan Mine in British Columbia (Fig. 14.22; Jiang et al. 1999). The Sullivan Pb–Zn–Ag deposit is a giant, SEDEX-type sulphide orebody lying conformably within clastic metasedimentary rocks of the Middle Proterozoic Aldridge Formation in the Belt–Purcell Supergroup. The orebody is divided by an irregular transition zone into a western massive sulphide body and an eastern body of bedded sulphides and intercalated clastic metasedimentary rocks. Underlying this orebody is a large, funnel-shaped tourmalinite alteration pipe. The shallow part of this pipe, <30 m from the base of the massive orebody, comprises tourmalinized fragmental breccia and conglomerates, which locally contain disseminated or stockwork of the same composition as the underlying metasedimentary rocks; no foreign clasts have been identified, implying the breccia is locally derived. Chlorite–pyrrhotite alteration is present in the uppermost portion of the tourmalinite pipe, just below the massive pyrrhotite body. The chlorite–pyrrhotite-altered rocks are in contact with, and locally cut, the footwall tourmalinites (Fig. 14.22b). The most abundant altered rock overlying the deposit contains an albite–chlorite–pyrite assemblage that forms an irregular alteration zone that overprints hangingwall tourmalinites and massive sulphides. Shortly after deposition of the Aldridge Formation, a series of gabbroic sills and dykes intruded into the partly consolidated sediments and the zircons in the sediments give a U-Pb age of 1,468 ± 3 Ma. The regional metamorphic grade at Sullivan is middle to upper greenschist, with inferred temperatures and pressures of 450 °C and 3.8 kb, respectively. Toumalinites not only typify the footwall they also occur, though in lesser volumes, in the hanging wall.

The $\delta^{11}B$ values across the footwall and hanging wall range from −11.1 to −2.9‰ (Fig. 14.23a). Jiang et al. (1999) conclude that the major control on the overall $\delta^{11}B$ values in the Sullivan tourmalinites is boron source. As can be seen in Fig. 14.23a, boron isotope data at Sullivan are consistent with possible boron derivation from leaching of footwall clastic sediments. However, the great abundance of tourmaline in the Sullivan deposit suggests that the local clastic sediments were not the most important source of boron, Jiang et al. argue that nonmarine evaporites, once buried deep below the orebody, are the most viable source of this additional boron. They go on to note that some of the spread in boron isotope values may reflect a degree mixing of boron from these two sources.

Another illustration of the utility of boron isotopes in deciphering the evolution of tourmalines comes from the Jaduguda U (–Cu-Fe) deposit, Singhbhum shear zone, India (Fig. 14.23b; Pal et al. 2010). The ≈200 km long and ≈1–5 km wide Singhbhum shear zone occurs close to the

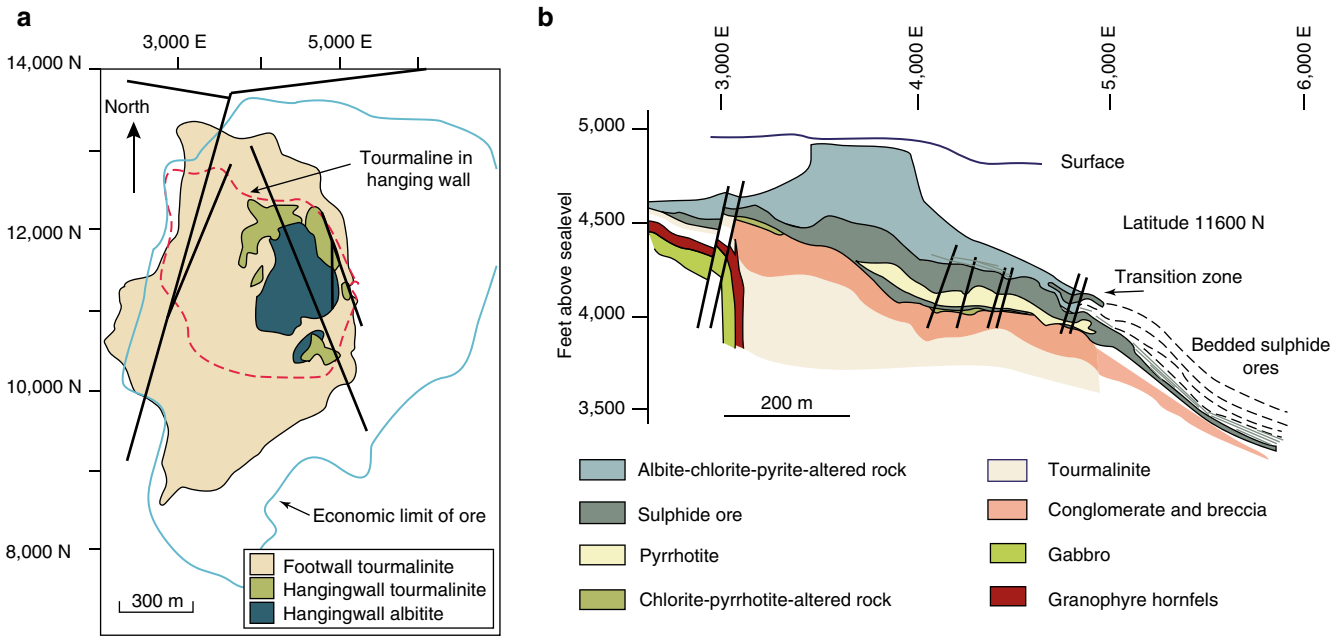

Fig. 14.22 Geology of the Sullivan Pb–Zn–Ag deposit, British Columbia (After Jiang et al. 1999). (**a**) Simplified plan of the deposit showing the projected distribution of hanging wall and footwall tourmalinites, and hanging wall albitites. Fig. 14.23 Frequency histogram of boron isotope compositions of tourmalines. (**a**) Sullivan Mine, British Columbia with separate plots in samples from the hanging wall, the shallow footwall <30 m below the sulphide orebody and the deep footwall, see Fig. 14.22b) for geological section (After Jiang et al. 1999). (**b**) Jaduguda U-(Cu-Fe) deposit, India, with separate plots from the footwall U-bearing quartz–tourmaline rock, the U–Cu zone and the hanging-wall U-bearing metaconglomerate. Note the similarity in isotopic compositions of Tourmaline-1 in all zones and a distinctly lighter isotopic signature of Tourmaline-2 (rims/fracture-filling) in the Cu–U zone. Tourmaline 1 boron is interpreted as having a marine evaporitic source. Post deformation Tourmaline-3 displays similar isotopic compositions as that of Tourmaline-1 (After Pal et al. 2010)

boundary between the Archaean Singhbhum cratonic nucleus (3.3–3.5 Ga) on the south and the Proterozoic North Singhbhum Fold Belt on the north. Along the shear, polymetallic ores are hosted in altered, sheared and metamorphosed volcano-sedimentary rocks, and the associated geological complexity has lead to a confusion of ore genetic models for the Jaduguda deposit. A characteristic of the mineralization is the presence of tourmalinite, which is spatially associated with U and Cu mineralization in all rock types, with tourmaline locally exceeding 50 vol.%. The chemical and B-isotopic variations in the tourmalines provide important constraints on fluid source(s) and ore deposit affinity. Tourmaline grew in three different stages across the U-Cu ore zone and adjacent footwall and hanging wall meta-sedimentary rocks. Pre-kinematic tourmaline-1 is represented by fractured and porphyroblastic grains, it is ubiquitous in the wall rocks and the U-Cu zone. Syn-kinematic tourmaline-2 and post-kinematic tourmaline-3 are found exclusively in the U-Cu zone, where intense shear deformation has focussed fluid flow, alteration and metamorphism. All tourmalines belong to the alkalic group and most are dravitic.

The overall range of $\delta^{11}B$ values from −6.8 to +17.2‰ is broad and relatively undiagnostic. However, when broken down by tourmaline type, the positive values of tourmaline-1 are irrespective of host rock and ore association (U or U + Cu), and range between +2.3 and +17.2‰ (n = 44). The calculated $\delta^{11}B$ values of fluid in equilibrium with this tourmaline (for mineralization temperatures of 300–450 °C) range from +4 to +20‰. The $\delta^{11}B$ values of syn-kinematic tourmaline-2 are much lower than tourmaline-1, between −6.8 and +4‰ (n = 7) and the corresponding fluid $\delta^{11}B$ values are −4.8 + 6‰. The high values of $\delta^{11}B$ for tourmaline-1 and associated early fluid suggest a marine evaporite or basinal brine was the source of boron, and this fits with abundant mineralogical and geochemical evidence for highly-saline fluids during mineralization (Pal et al. 2010). The isotopically lighter fluid associated with tourmaline-2 and related syn-kinematic mineralization/mobilization was likely derived from the metamorphic volcano-sedimentary rocks with high fluid/rock ratios in and around the shear zone. Postkinematic tourmaline-3 is compositionally and isotopically $\delta^{11}B$ = +4 to +11.1‰ (n = 5) similar to tourmaline-1 in the same samples, suggesting it formed by local recrystallization of the earlier tourmaline or from a renewed influx of saline fluids, similar to those which formed the pre-kinematic mineralization. Given the complexity of deciphering primary fluid sources in metamorphic terranes, clearly the isotopic method is the better tool compared to bulk mineral composition.

At the world scale of plate boundary interactions, it is clear that tourmaline is a common occurrence in Phanerozoic and older hydrothermal systems in both marine and nonmarine settings. This is also indicative of the distribution of boron in the lithosphere Phanerozoic systems where the higher boron content of melts and associated exhalative associations is the result of melting of accretionary wedge sediments. There, in accretionary wedges, absolute boron levels are elevated by the photosynthesizing activities of plankton. Hence, boron tends to accumulate in pelagic sediments, compared with oceanic crust (boron is one of the seven food elements required by all phytoplankton; Park and Schlesinger 2002).

When this accretionary prism sediment is subducted it releases aqueous fluids as it moves deeper and ultimately into the zone of melting. The derived melts move boron back to the earth's surface and into renewed zones of intermontane deposition, via hydrothermal springs and seeps, especially in zones of active fluid circulation within rhyolite/andesite terranes. It is in these intermontane depressions that continental borate evaporites tend to accumulate with their characteristically negative $\delta^{11}B$ signatures (Chap. 12).

There is a relationship between boron isotope composition and depth to the Benioff zone. Field studies in subduction zones from Izu-Bonin, the Kuriles, Eastern Kamchatka, and the Central Andes consistently show that boron concentrations and $^{11}B/^{10}B$-ratios in volcanic arcs are high close to the trench and systematically decrease across the arc with increasing distance from the trench, corresponding to increasing depth of the Wadati-Benioff zone (Wunder et al. 2005). For each subduction zone, there is a systematic variation of $\delta^{11}B$ in the volcanic arc versus depth to the Wadati-Benioff zone (Fig. 14.24). In old cold slabs, such as Izu-Bonin and the Kuriles, the trend is significantly flatter, compared to the younger, hotter slabs of Eastern Kamchatka and the Central Andes. These trends are interpreted as resulting from continuous dehydration reactions within the slab and may trace the particular thermal structure of each slab.

Within the zone of metamorphism related to the subduction zone in accretionary orogens it seems that, because of its high modal abundance, potassic white mica (containing up to 270 ppm B), is probably the most important boron reservoir during subduction of oceanic sediments and altered basalts. It dominates the boron budget within the subducting slab, even in the presence of tourmaline and amphibole, which can contain B-concentrations up to 63 ppm (Wunder et al. 2005 and references therein). Moreover, this white mica is stable to depths of 300 km in cold subducting slabs where, with enhanced subduction, its modal amount is continuously decreased and its composition shifted towards phengitic mica as boron is released.

Thus, it seems Phanerozoic marine tourmalinites, based on a study of boron distribution in modern ridge and subduction settings, typify accretionary orogenies (Fig. 14.24). However, the listing of older documented metasedimentary

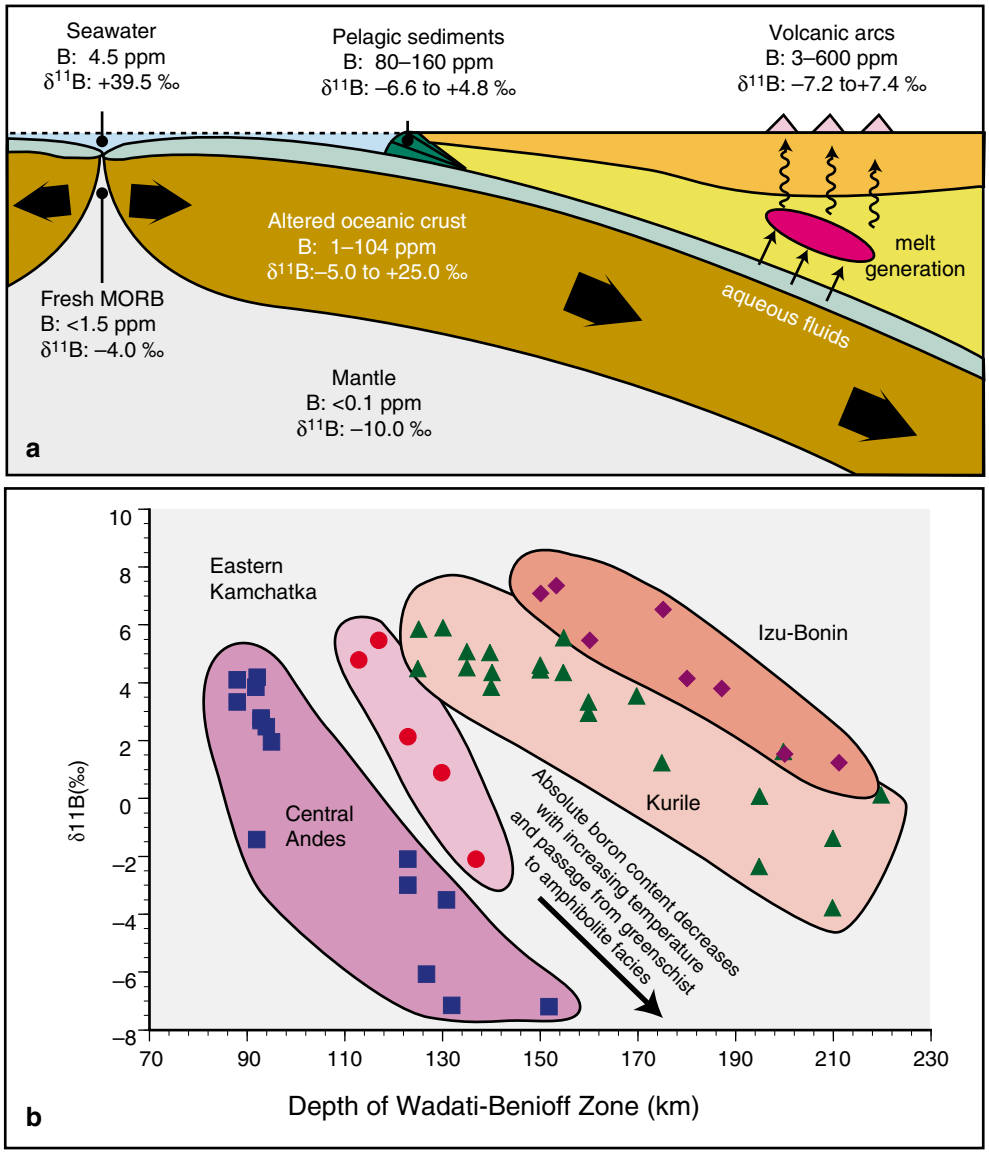

Fig. 14.24 Boron redistribution in subduction/accretionary orogeny. (**a**) Schematic cross section through a subduction zone with ranges of boron concentrations and $\delta^{11}B$-values typical for mantle, oceanic crust and convergent margin reservoirs. (**b**) Plot of $\delta^{11}B$-values of volcanic arcs versus depth of the respective Wadati-Benioff zone for four subduction zones. Izu-Bonin, Kuriles, Eastern Kamchatka, Central Andes (After Wunder et al. 2005)

tourmalinites in the same table shows a correlation of older boron/tourmalinite occurrences with Precambrian meta-evaporites, meta-carbonate and metavolcanic associations many of which are not tied to subducting oceanic plates. Rather many older tourmalinite/boron deposits occur in association with what appear to be massive sulphides in continental extensional rifts, as well as with some Proterozoic IOCG deposits, which tend to form in continental anorogenic settings (Chap. 16). Neither are directly tied to arc subduction, but rather to early extensional phases, or to zones of continent-continent collision (Table 14.6). Analogs to these settings would be perhaps be the African rift and the Alpine-Zagros orogenic belts. In addition, the numerous occurrences of metasedimentary tourmalines in Early Archaean terranes, and once again raises the question of what were the controls on boron levels and its distribution within a much hotter Archaean earth interior, prior to the evolution of the nitrogen fixation process in phytoplankton?

Table 14.6 Worldwide examples of toumalinites

Time	Africa	Americas	Asia	Australia	Europe and adjacent
Mesozoic/ Cenozoic	–	(E) Tourmaline in salt diapir caprocks, Challenger Knoll, Gulf of Mexico (Henry et al. 1999). (E?) Jurassic Light Creek Stock (Stephens and Dilles 2008)	Tourmalinite (Jurassic) from Chitral, northern Pakistan (Zahid and Moon 1999). Tourmalinite, Yozgat Batholith, Central Anatolian core complex, Turkey (Isik et al. 2004)		(E) Triassic NevadoFilábride Complex, SE Spain (Torres-Ruiz et al. 2003a, b). (E) Tourmalinite pebbles from Lower Triassic and Upper Cretaceous of W. Carpathians, Slovakia (Bacik et al. 2008)
Palaeozoic	–	(E) Tourmaline in Locotal Breccia, Alto Chapare, central Bolivian Andes (Zacek et al. 1998)	(E) Caledonian tourmalinites in Sar-e-Sang region, Afghanistan (Grew 1988). E indicates tourmalinites with a meta-evaporite association

Sodian Phyllosilicates and Talc

In the Triassic meta-evaporites from Derrag, in the Tell Atlas of Algeria, sodian phlogopite occurs naturally as an unusual meta-evaporitic product in a sugary dolomite matrix, which also hosts other magnesian phyllosilicates, as well as large porphyroblasts of albite, dravite-uvite tourmalines, quartz, scapolite, magnesite, rutile and pyrite (Schreyer et al. 1980). There the phlogopite[4] has a microprobe-determined chemical formula that is close to ideal $NaMg_3[AlSi_3O_{10}](OH)_2$, with some possible addition of lithium. Crystals are invariably coated with thin rims of the more typical potassium phlogopite and these rims probably prevented the retrograde hydration of the sodian phlogopite. The phlogopite coexists with an enigmatic talc-containing phase called kulkeite.

Kulkeite is an unusual sodian phyllosilicate mineral in this Triassic sequence, and it appears to be associated with the metaevaporites. It is an ordered 1:1 chlorite/talc mixed-layer mineral that forms platy, colourless, porphyroblastic, single crystals in its low-grade sugary dolomite host (Schreyer et al. 1982). From microprobe analysis kulkeite's empirical formula is $(Na_{0.38}K_{0.01}Ca_{0.01})(Mg_{8.02}Al_{0.99})[Al_{1.43}Si_{6.67}O_{20}](OH)_{10}$ with some variation in Na, Si and tetrahedral Al.

Both the sodian phlogopite and the kulkeite formed during low grade metamorphism of an evaporite protolith at temperatures that did not exceed 400 °C. According to Schreyer et al. (1980, 1982) these meta-evaporitic aluminosilicates are the first known natural examples of sodian phlogopite and the first documentation of an aluminosilicate showing a regular mixed interlayering between chlorite and talc (Fig. 14.25a). Both occur in dolomites interbedded with clays and thick salts, which were originally buried to depths varying from 2 to 10 km and then returned to the surface by halokinesis. The close proximity of clastic silicate rocks with dolomite and salt (mostly halite but with some K, Mg salts), as well as deep burial prior to exhumation, are thought to have been responsible for this meta-evaporite association. It is a somewhat more evolved metamorphic-halokinetic system than that in the Flinders Ranges, Australia (Chap. 7).

Sodic talc- kyanite is another likely meta-evaporite indicator in the Derrag (Schreyer 1977; Schreyer and Abraham 1976). Once again, fluid-driven chemistries of meta-evaporitic sequences do not fit easily into a conventional isochemical analysis of regional metamorphism. Meta-evaporites in the Sar-e-Sang region of Afghanistan exhibit mosaic equilibria across small volumes (in the cm^3 range) within a talc-kyanite schist (whiteschist) host. The microscale mineral variations are characterised by variations in mineral assemblages conventionally attributed to vastly different pressure/temperature conditions during regional metamorphism.

On the basis of petrographic and microprobe studies, these assemblages are attributed to three consecutive stages of metamorphism of a chemically exceptional rock with a composition that falls largely into the model system MgO-Al_2O3-SiO_2-H_2O (Fig. 14.25b; Schreyer and Abraham 1976). Stage 1, typified by Mg chlorite-quartz -talc and some paragonite, was followed during stage 2 by talc-kyanite, Mg gedrite-quartz[5] and the growth of large dravites. Microprobe analyses of the phases gedrite and talc indicate variable degrees of sodium incorporation into these phases according to the substitution NaAl— >Si. In stage 3, pure Mg cordierite formed with or without corundum and/or talc, and the kyanite was partly converted into sillimanite. Pressure and temperature during this final stage of metamorphism was near 5–6 kb and 640 °C.

Schreyer and Abraham (1976) concluded that chemical variations in the metamorphic fluids were generated by progressive metamorphism and mobilisation of an evaporite deposit. Relict anhydrite and gypsum still occur in the Sar-e-Sang area. Whiteschists and the associated lapis lazuli deposits of the region are part of a highly metamorphosed evaporitic succession (see discussion of lapis lazuli in the gem section of this chapter). Salts have largely vanished due to ongoing melting and volatilizations. The preservation of the three stage succession of mineral assemblages, across such small scales and yet related to each other through isochemical reactions, means that the main factors governing the metamorphic history of this whiteschist were compositional changes of the coexisting fluids with time. Under this scenario any pressure-temperature variations were subordinate and the chemistry of the fluids evolved as the evaporites underwent metasomatic alteration.

The sedimentary pelitic layers of this evaporitic sequence first underwent a period of metamorphism in which fluid pressures approached lithostatic (stage 1). Subsequently at higher metamorphic grades, with the beginning of mobilisation of the salts, the metamorphic fluids became increasingly enriched in ions such as Na^+, Mg^{2+}, Cl^-, SO_4^{2-}, BO_3^{3-}, etc., so that water fugacity dropped considerably. This period is represented by stage 2 of the whiteschist metamorphism and was characterised by strong metasomatism that led, for example, to the growth of dravite and the amphibolite, gedrite. The physical and chemical character of stage 3 is less clearly defined. Kyanite/sillimanite inversion requires an increase in temperature or a decrease in pressure, or both; but changes in the composition of a coexisting gas phase may have played an additional role in the formation of cordierite.

[4]Phlogopite is a yellow, greenish, or reddish-brown member of the mica family of phyllosilicates that is also known as magnesium mica.

[5]Gedrite is a silicate mineral of the amphibole group with formula: $(Mg;Fe^{2+})^2[(Mg;Fe^{2+})3Al_2](Si_6Al_2)O_{22}(OH)_2$

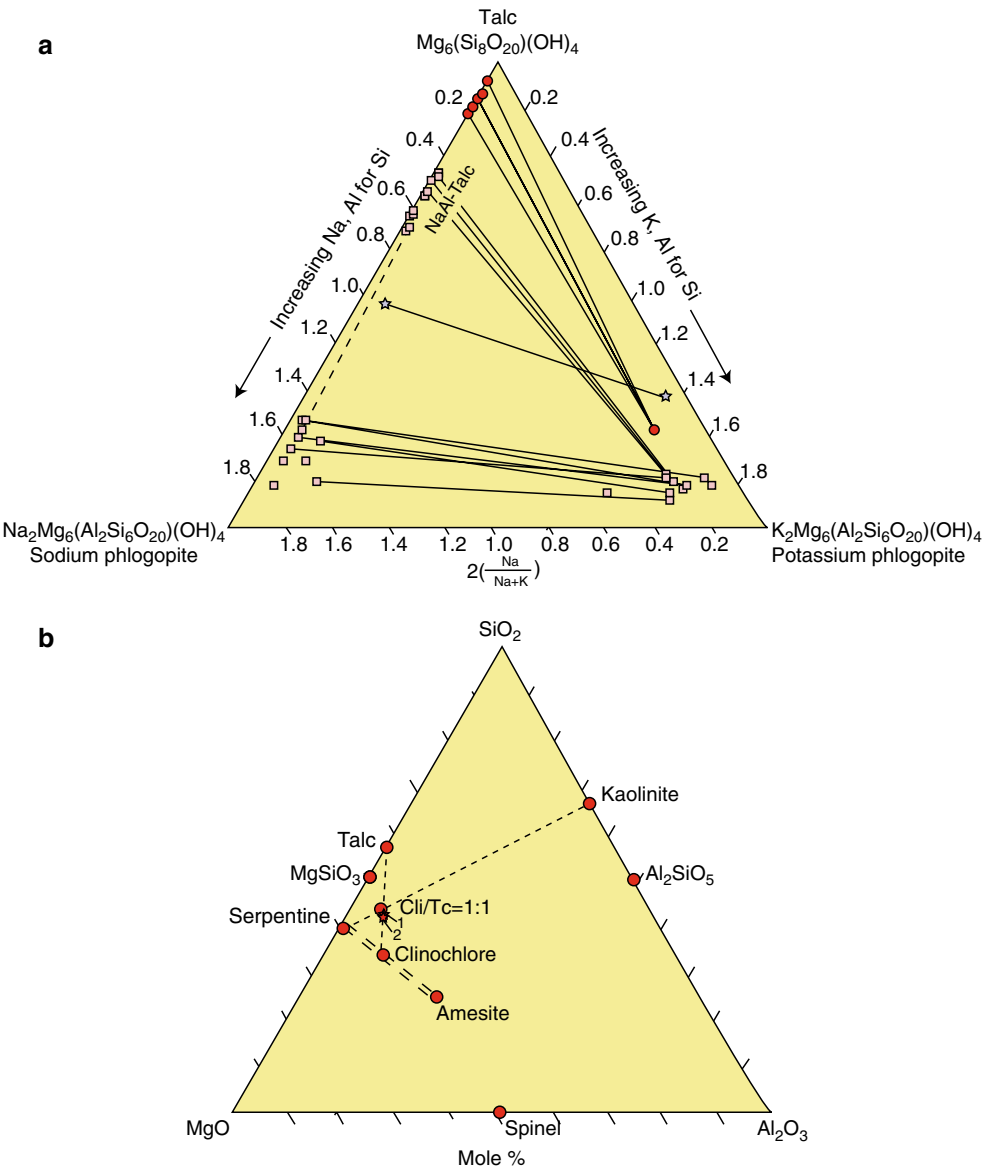

Fig. 14.25 Sodian phlogopite, talc and kulkeite. (**a**) Ternary system sodium phlogopite – potassium phlogopite talc. *Squares* represent the 10 analyses from phlogopitic micas and the sodian aluminian talc. *Circles* indicate minerals from the Sar-e-Sang, Afghanistan, whiteschist (Schreyer and Abraham 1976), *stars* plot one set of coexisting micas from Post Pond, Vermont, metavolcanics. *Solid lines* connect coexisting phases, while the *dashed tie line* between talc and a sodium phlogopite represents the assemblage spread before the growth of potassium phlogopite (After Schreyer et al. 1980). (**b**) Ternary plot of the system MgO-$A1_2O_3$-SiO_2-H_2O projected onto the water-free base showing some relevant crystalline phases, the location of a theoretical 1:1 clinochlore/talc mixture, and the analysed compositions of kulkeite indicated by *stars 1* and *2* (After Schreyer et al. 1982)

The meta-evaporite-derived assemblage in Afghanistan may in a single thin section entrain mineral assemblages that conventionally would be assigned to the greenschist facies, the hornfels facies, and to a high pressure (amphibolite) regime. The assemblages are in effect a mosaic equilibria that reflects changes in fluid composition generated from a metamorphosing evaporite pile over time and only to a lesser degree by regional evolution of total temperature and pressure. Once again, evaporites generate unusual responses compared to the general responses of metasediments.

In a refinement paper discussing the likely relationships between evaporites and whiteschists, Franz et al. (2013) note that whiteschist mineral assemblages are stable up to pressures of more than 4 GPa, but may already form at pressures of 0.5 GPa. Their formation largely depends on the composition of the protolith and requires elevated contents of Al and Mg as well as low Fe, Ca, and Na contents, as otherwise chloritoid, amphibole, feldspar, or omphacite are formed instead of kyanite or talc. They go on to note that the stability field of a whiteschist mineral assemblage strongly depends on XCO_2 and fO_2: at low values of XCO_2, CO_2 binds Mg to carbonates strongly reducing the whiteschist stability field, whereas high fO_2 enlarges the stability field and stabilizes yoderite [$Mg(Al, Fe^{3+})_3(SiO_4)_2O(OH)$].

The scarcity of whiteschist is not necessarily due to unusual P–T conditions, but to the restricted range of suitable protolith compositions and the spatial distribution of these protoliths: (1) continental sedimentary rocks and (2) hydrothermally and metasomatically altered felsic to mafic rocks. They argue continental sedimentary rocks that may

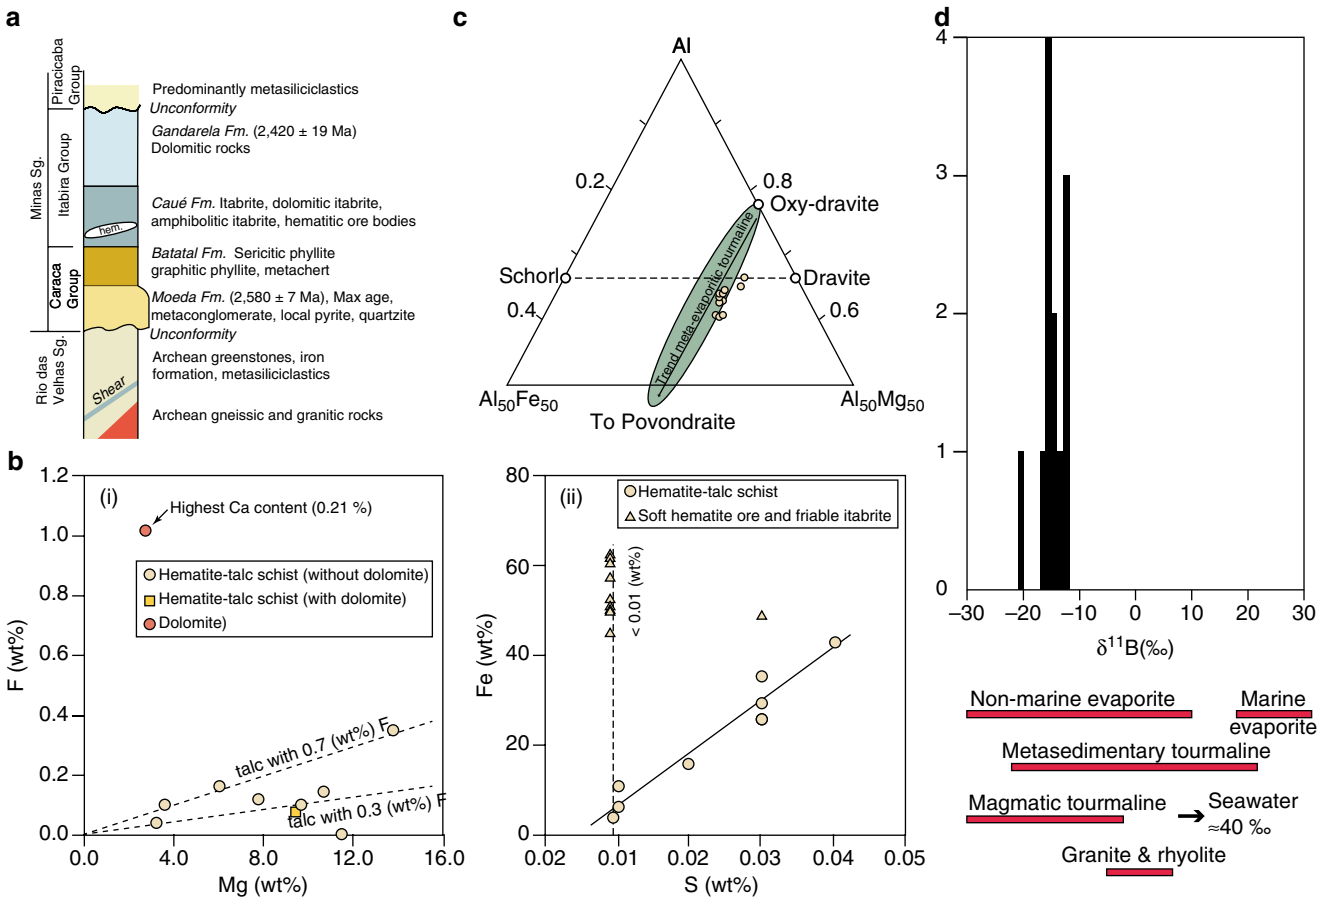

Fig. 14.26 Talc-tourmaline interrelationships in the Gongo Soco deposit, Minas Gerais, Brazil (After Cabral et al. 2012). (**a**) Lithostratigraphic column emphasising the Caraça and Itabira groups of the Minas Supergroup. (**b**) Diagram for whole-rock contents of Mg vs. Fluorine. Talc is the dominant F-bearing mineral and most samples plot within, or near, the limits defined by the *dashed lines* in (*i*). These lines represent the minimum and maximum contents of fluorine measured. (*ii*) Diagram for wholerock contents of S vs. Fe. The elements show a strong positive correlation (regression line) in samples of hematite–talc schist. Other Fe-rich rocks from Gongo Soco, which were previously analysed using the same analytical techniques, are plotted for comparison as triangles showing the S-Fe relationship only typifies the hematite-talc schist. (**c**) Upper portion of an Al–Fe–Mg ternary diagram for tourmaline within the hematite–talc schist. Meta-evaporitic tourmaline typically follows a trend along the join line between "oxy-dravite" and povondraite (see Fig. 14.20). (**d**) Histogram of tourmaline $\delta^{11}B$ value for hematite–talc schist in Gongo Soco, compared to $\delta^{11}B$ some in some known reservoirs (see Fig. 14.21). Tourmaline composition illustrates a range of negative $\delta^{11}B$ values, and this together with the abundance of fluorine- bearing talc at Gongo Soco, favour a nonmarine evaporitic reservoir supplying the talc-mineralising fluid system

produce whiteschist mineral assemblages typically have been deposited under arid climatic conditions in closed evaporite basins and may be restricted to relatively low latitudes. These rocks typically contain large amounts of palygorskite and sepiolite. Franz et al. (2013), conclude whiteschist assemblages typically are only found in settings of continental collision or where continental fragments were involved in subduction.

Talc, $Mg_3Si_4O_{10}(OH)_2$, is typically interpreted as a high-temperature mineral that forms from hydrothermal alteration or metamorphism of Mg-rich and ultrabasic rocks (Tosca et al. 2011). Lower temperature reactions can also produce talc-bearing assemblages, for example through the weathering of serpentinite deposits. It can also occur as an authigenic component in evaporites that have yet to experience metamorphic grade burial temperatures and pressures. Talc has been recorded in Permian evaporites from New Mexico (Bailey 1949; Bodine 1983), in Carboniferous evaporites in Nova Scotia (Evans 1970) from the Eskdale boreholes in NE Yorkshire (Scrivener and Sanderson 1982) and in Neoproterozoic carbonate successions (Tosca et al. 2011).

In Yorkshire it occurs as minor quantities of isolated flakes in the halite-rich parts of four evaporite breccia beds that also contain minor anhydrite, dolomite and quartz. In the Yorkshire deposit, the mineral is always enclosed by halite, but in New Mexico it is also found in the cleavage cracks of sylvinite and polyhalite. Both of

these localities are associated with magnesium-bearing salts such as carnallite and kieserite. In the case of the Yorkshire deposits, the nature of the sediments enclosing the evaporites and in the breccia suggests a salt flat or sabkha environment of deposition. There is no evidence that the talc is depositional and Scrivener and Sanderson (op. cit.) suggest that postdepositional hypersaline conditions permitted the diagenetic reaction of dolomite with silica to form talc (Bodine 1983). Given the appropriate seawater brine chemistry, as occurred at times in Neoproterozoic carbonate platforms, talc may also form during very early diagenesis of marine carbonate sediments independent of the need for hypersaline Mg- and silica-rich high-pH brines (Tosca et al. 2011).

Meta-evaporitic talc mineralisation has formed a hematite–talc schist between soft hematite ore and dolomitic itabirite[6] at Gongo Soco, Quadrilátero Ferrífero of Minas Gerais, Brazil (Cabral et al. 2012 Fig. 14.26). Hosted in the Archaean Caué Formation, it is one of numerous iron-ore deposits of the Quadrilátero Ferrífero situated in the southernmost part of the São Francisco Archaean craton, which is edged by orogenic belts of Brasiliano age, i.e. ~0.6 Ga. The talcose schist is enriched in F and has a constant Fe/S ratio (Fig. 14.26bi, bii; respectively). Electron-microprobe analyses indicate trace amounts of S in different generations of hematite. The whole-rock Fe/S ratio possibly represents sulphate S from hematite-hosted fluid inclusions. Fluid inclusions in foliation-overprinting hematite and chlorite geothermometry from talcose rocks suggest, respectively, temperatures from <200 to ~300 °C. Tourmaline, a rare mineral in the hematite–talc schists, belongs to the alkali group and falls in the dravite compositional field and plots along the meta-evaporitic "Oxy-dravite-povondraite" trend (Fig. 14.26c). Boron-isotope determinations of tourmaline crystals, using secondary ion mass spectrometry, vary from −20 to −12‰ $\delta^{11}B$ (Fig. 14.26d). This compositional isotopic range, the fluorine rich nature of the talc and the trend in tourmaline chemical composition, all suggest a meta-evaporitic origin. That is, a non-marine evaporitic setting is the most likely source of acidic, highly oxidising fluids, which resulted in the abundant F-bearing talc and the presence of otherwise immobile Ti in the hematite. Oxidising brines were channelled along shear zones and converted dolomitic itabirite into the Gongo Soco soft hematite and the talc mineralisation. The latter is envisaged as the hydrothermal wall-rock alteration of dolomitic itabirite, which gave rise to the soft hematite ore (Cabral et al. 2012).

[6]Itabirite, is a banded-quartz hematite and hematite schist, constituting a laminated, metamorphosed oxide-facies iron formation in which the original chert or jasper bands have been recrystallized into layers made up of distinct crystals of quartz and the iron is present as thin layers of hematite, magnetite, or martite.

Precious Stones as Meta-evaporites

Base and precious metals are not the only ore deposits formed in association with meta-evaporites, some gemstones can also have meta-evaporite affinities. We have already seen that tourmaline is a semi-precious stone. Precious stones[7] and gems are rare by definition and need exceptional geologic conditions that give rise to gem-quality materials. These conditions may include the availability of sometimes uncommon major constituents, the presence of adequate chromophores[8] limited concentrations of undesirable elements, open space, an environment conducive to forming crystals of sufficient size and transparency. This general statement of requirements to form a precious stone also encapsulates why some gems have meta-evaporitic associations. As we have seen, halite and most other evaporite salts disappear or transform into other mineral phases by the early greenschist phase. As this happens the dissolution/transformation releases a pulse of hot basinal chloride waters that can leach/carry elements such as beryllium, chromium and vanadium (chromophores) from any adjacent organic-rich shales. Trace elements also tend to be enriched in the more evolved depositional brines that precipitated the latter minerals in any evaporite precipitates. At the same time as halite dissolves or transforms, anhydrite layers and masses typically remains into the more evolved portions of the metamorphic realm (amphibolite-granulite facies). The volume loss associated with the dissolution/transformation of meta-evaporites facilitates the formation of open space (sometimes pressurized) as veins and fractures that then allow the free growth of the precious stone or gem material.

Many natural gemstone settings are not evaporite-associated, the following section discussed those that are. Interestingly, the common link between most natural gem-forming environments is a hydrous, typically saline to hypersaline, solution that is able to precipitate a crystal in a void from a fluid that contains elevated and unusual levels of particular constituents, including chromophores; hence pegmatites, volcanics and meta-evaporites are the most typical hosts for natural gemstones.

[7]The Ancient Greeks, distinguished between precious and semi-precious stones; similar distinctions were made in other ancient cultures. In modern usage, the precious stones are diamond, ruby, sapphire and emerald, with all other gemstones being semi-precious.

[8]Chromophore; is the part of a gem lattice responsible for its colour. A gem's colour arises when a molecule absorbs certain wavelengths of visible light and transmits or reflects others. It is a structural feature in the lattice indicative of the presence of a gem-specific electron configuration of the ions in its crystal lattice; such as transition metal ions (Cr, V or Fe) occupying several different coordination sites. For example, ferrous iron (Fe^{2+}) or ferric iron (Fe^{3+}), the ferrous ion in peridot causes the green colour and ferric ion causes the yellow colour in chrysoberyl. This colour effect has important uses in heat-treatment gemstones such as blue colour in heat-treated sapphire.

Lapis Lazuli

Lapis lazuli is made up not of a single mineral but an accumulation of minerals; it is mostly composed of lazurite $(Na,Ca)_8(AlSiO_4)_6(S,SO_4,Cl)_{1-2}$ typically 30–40 % (Table 14.7). Lapis gemstones also contains calcite (white veins), sodalite (blue), and pyrite (gold flecks of colour). Dependent on metamorphic history and protolith chemistry, other common minerals in lapis include; augite, diopside, enstatite, mica, haüyanite, hornblende, and nosean. Some specimens also contain trace amounts of the sulphur-rich mineral lollingite (*var.* geyerite). Lazurite is a member of the sodalite group of feldspathoid minerals (Table 14.7). Feldspathoids have chemistries that are close to those of the alkali feldspars, but are poor in silica. If free quartz were present at the time of formation it would react with any feldspathoid precursor to form a feldspar. Natural lazurite contains both sulphide and sulphate sulphur, in addition to calcium and sodium, and so is sometimes classified as a sulphide-bearing haüyne (Fig. 14.27a). Sulphur gives lazurite its characteristically intense blue colour, it comes from three polysulphide units made up of three sulphur atoms having a single negative charge. The S_3- ion in the sulphur has a total of 19 electrons in molecular orbitals and a transition among these orbitals produces a strong absorption band at 600 nm, giving a blue colour with yellow overtones. The intensity of the gem's blue is increased with increasing sulphur and calcium content, while a green colour is the result of insufficient sulphur (O'Donoghue 2006, p. 329).

Other members of the sodalite group include sodalite and nosean (Table 14.7). Sodalite is the most sodium-rich member of the sodalite group and differs from the other minerals of the group in that its lattice retains chlorine. Interestingly, sodalite can be created in the laboratory by heating muscovite or kaolinite in the presence of NaCl at temperatures of 500 °C or more. In the literature, the commonly accepted origin of lazurite is through contact metamorphism and metasomatism of dolomitic limestone. Such a metasedimentary system also requires a source of sodium, chlorine and sulphur; the obvious source is interbedded evaporites in the protolith, as is seen in plots of its molecular constituents (Fig. 14.28; Aleksandrov and Senin 2006).

Lapis lazuli from the Precambrian of Baffin Island, Canada (Fig. 14.27a), and from Edwards, New York, are metaevaporites, as are the lapis lazuli deposits at Sar-e-Sang in the Kokcha valley, Afghanistan and the lapis deposits in Liadjuar-Dara region ("River of Lazurite") at an altitude of 5,000 m in the Pamir Mountains, Tajikistan (Webster 1975). Throughout history its bright blue colour has made lapis, mostly from Sare-Sang, a valued gem commodity. First mined 6,000 years ago, the Sar-e-Sang lapis was transported to Egypt and present day Iraq and later to Europe where it was used in jewellery and for ornamental stone[9] Europeans even ground down the rock into an expensive powdered pigment for paints called "ultramarine".

Lapis deposits in Lake Harbour on Baffin Island and in the Edwards Mine, New York, were produced by high grade metamorphism of an evaporite-marble protolith (Hogarth and Griffin 1978). The anhydrites preserved near Balmat are also part of this sequence and are discussed separately later in this chapter. On Baffin Island the two main lapis lazuli lenses, some 1.6 km apart, lie at the structural top of two sequences of dolomitic marble, the thicker lens being approximately 150 m across (Fig. 14.27b). The elongation of both lenses parallels the local layering and foliation and shows a well-developed layering parallel to the regional foliation, implying a sedimentary protolith to the deposits. The Main and Northern bodies constitute diopside–lazurite rocks of variable gem quality and are localized in marbles among biotite gneisses. The Main (Southern) occurrence is as long as 170 and 6 m thick. In these deposits, sheets of high-quality lazurite (up to 1 m thick) contain variable amounts of relict diopside and plagioclase, as well as newly formed haüyne, nepheline, or phlogopite. The quantitative proportions of these minerals define the colour of the rock, which becomes more intense with heating. The Northern occurrence (25 × 36 m in size) is less productive than the Main occurrence and consists of small (no more than 1 m) lenses with disseminated lazurite, which imparts a bluish green colour to the polished surface of the rock. Chlorine and sulphur in the various lazurites, accessory pyrite, and pyrrhotite were

[9]Lapis is the Latin word for "stone" and lazuli is the genitive form of the Medieval Latin *lazulum* meaning blue, which was taken originally from the Persian *lāžaward*, the name of a place where lapis lazuli was mined. Taken as a whole, lapis lazuli originally meant "stone of Lāzhward." With time, the name of the place came to be associated with the stone mined there and, eventually, with its bright blue colour. Lapis lazuli's use as jewellery can be traced back to the 5th millennium B.C.E. with the discovery of beads at a cemetery outside the temple walls of Eridu (Sumer) in southern Babylonia (Von Rosen 1990). To the ancient Egyptians, it was considered a gem representing the skies or heaven, thus was thought to denote light, truth and wisdom. It was thus often shaped into eye-shaped gems and was worn by judges in ancient Egypt. A lapis amulet graced the brow of Ra. Lapis is noted in Revelations in Christian mythology as a stone in the Breastplate of Aaron. In China, lapis was worn during the Manchu dynasty for services in the Temple of Heaven. The Romans and Greeks used it as a cure for fever and melancholy.

The Sar-e-Sang region has supplied much of the gem quality lapis to the world. One of the first European explorers to the region (Wood 1841) described mining methods in use at that time. Camel-thorn and tamarisk twigs were collected from the valley below and carried up the steep path to the mine. When sufficient fuel had been collected, it was piled against the rock face and a fire was lit. When the rock was hot, cold water, which also had to be carried up the steep 350 m ascent from the valley floor, was thrown onto it. The rock cracked and split, enabling further work to be done with the primitive tools available (pick, hammer and chisel) in order to extract the lapis lazuli from its marble host rock.

Fig. 14.27 Lapis Lazuli and Baffin Island. (**a**) Collateral compositional diagram, showing the relation between chlorine, iron, alkalies and sulphur for lapis lazuli from Baffin Island and Slyudyanka as well as alkalic igneous rocks and typical Permian evaporites for comparison. (**b**) Baffin Island, map of the Main (South) occurrence shows the lapis lazuli distribution is stratiform within its dolomitic marble host. Also listed are major and minor mineral phases for the Main (South) and North occurrences (After Hogarth and Griffin 1978)

derived from metamorphosed gypsum-, anhydrite-, and evaporitic-carbonate protoliths (Hogarth and Griffin 1978).

In the Lake Baikal lazurite occurrences, there is once again a strong association between marble of the Perval'na Group and lazurite occurrence (Fig. 14.28a). For example, the Slyudyanka deposit is hosted in diopside skarns and spinel–forsterite calciphyres developed from metamorphically evolved evaporitic dolomites (Aleksandrov and Senin 2006). The Slyudyanka deposit shows clearly pronounced metasomatic zoning, which was associated with the prograde magnesian skarn stage and was overprinted by retrograde postmagmatic assemblages, which were formed together with lazurite-bearing rocks under the influence of saline alkaline S–Cl-bearing hydrothermal solutions. These solutions also caused microclinization of blocks of leucocratic granite with the formation of lazurite in the some of the inner skarn zones. Potassium solutions caused phlogopitization of the host rocks.

Likewise, scapolite and magnesian whiteschists are typically saline mineral phases in the classic deposits of the Sare-Sang District (Fig. 14.28b; Faryad 2002). There the lapis is composed of a combination of lazurite, diopside, calcite and pyrite and occurs in beds and lenses up to 4 m thick within a scapolitic magnesian-marble skarn near the centre of the

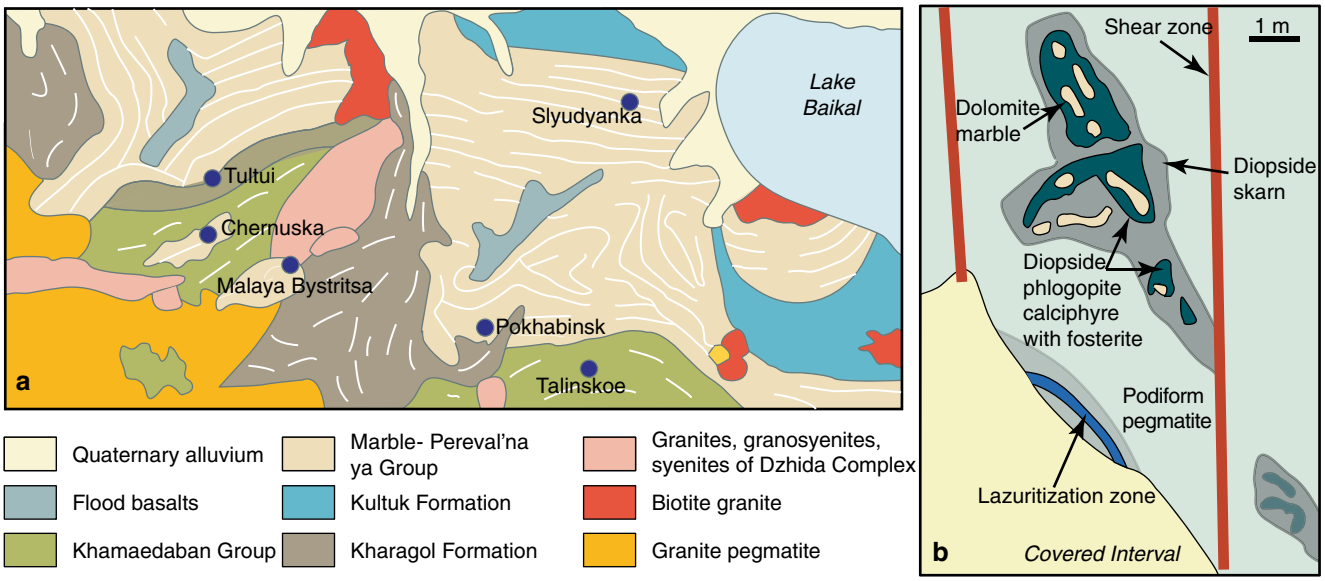

Fig. 14.28 Lapis Lazuli geological setting. (**a**) Geological map of the lazurite-bearing region in the southwestern Baikal area, also showing positions of main deposits and structural trend lines. (**b**) Geological detail of a lapis occurrence at Sar-e-Sang Afghanistan (After Aleksandrov and Senin 2006)

Hindu Kush granitic massif. It is typically interlayered with, or forms veins and lenses within its gneissic and pegmatitic host. Lens-shaped lodes are typically hosted in orthoclase–microcline–perthite hornfels containing albite and quartz (Fig. 14.28b). Lazurite bodies at the Sar-e-Sang deposit are associated with diopside metasomatites bearing nepheline, pale blue haüyne, and blue lazurite. Some lazurite-rich zones can contain up to 40–90 vol % lazurite. The rocks also contain diopside, haüyne, afghanite, and nepheline, as well as disseminated pyrite replaced by pyrrhotite. Pockets of near pure lapis lazuli can be up to 40 cm across and occasionally up to a metre.

Lapis lazuli in the North Italian Mountains of Colorado occurs in impure marbles in a meta-evaporitic skarn near the contact with the Eocene-age quartz monzonite and quartz diorites of the Italian Mountain stocks (Hogarth and Griffin 1980; Mauger 2007). There near vertical Pennsylvanian black shales and carbonates along the west margin of the intrusive have been converted to phlogopite-diopside-andalusite hornfels and scapolite-diopside skarns with minor analcime. Compared to Sar-e-Sang, lapis in this lapis in this skarn deposit is of inferior quality. It forms as deep blue lazurite granules in fine-grained forsterite-Ti phlogopite-calcite skarns and calcite marbles with diopside, Ti-phlogopite and pyrite. The hosting sediments along the NE margin of the pluton are Mississippian limestones and Devonian sandstones, while the NaCl came from dissolution of once nearby halite or dissolution-derived saline surface waters and shallow groundwaters moving south from the Eagle Basin.

High quality lapis is also mined from a limestone-granite skarn contact in the Chilean Andes (3,500 m elevation) in the headwaters of the Cazadero and Vias river, Ovalle, Coquimbo, Chile. The lapis there is good quality, although somewhat paler than Sar-e-Sang and, like the Baikal lapis deposits of Russia, is associated with wollastonite not diopside, making it a less attractive gem. The Chilean lapis occurs in an association of phlogopite, sodalite, calcite and pyrite (Coenraads and de Bon 2000).

Columbian Emeralds

Colombian emeralds[10] are meta-evaporitic gems formed via mixing of fault-focused hypersaline basinal solutions released during the subsurface dissolution and alteration of evaporites (Ottaway et al. 1994; Giuliani et al. 1995, 2000; Branquet et al. 1999; Banks et al. 2000; Groat et al. 2008). Emeralds occur within carbonate-silicate-pyrite veins and breccias hosted in black shales and limestones, tied to occurrences of hydrocarbons/bitumens. Gem fields constitute two zones, the eastern and western emerald zones, some 80 km apart in the Eastern Cordillera of Columbia (Fig. 14.29). The Columbian emerald fields supply more than 60 % of the world market (Groat et al. 2008).

The western zone crops out in the core of the Villeta anticlinorium (Fig. 14.29a; Branquet et al. 1999). The sedimentary series that enclose the emerald deposits (Fig. 14.29b) are a few hundred meters thick and are composed of, from bottom to top: (1) micritic, largely dolomitic limestones (Rosablanca Formation, Valanginian-Hauterivian); (2) calcareous black shales (Hauterivian); and (3) siliceous black shales that form the base (Hauterivian) of the thick mudstones (Barremian-Aptian) of the Paja Formation. Most of the emeralds are found in hydrothermal breccias or in

[10] Emerald is a brilliant, grass-green variety of beryl [$Be_3(Al,Cr)_2Si_6O_{18}$], highly favoured as a gemstone. Green colour is caused by trace of chromium (Cr^{3+}) and vanadium (V^{3+}) ions.

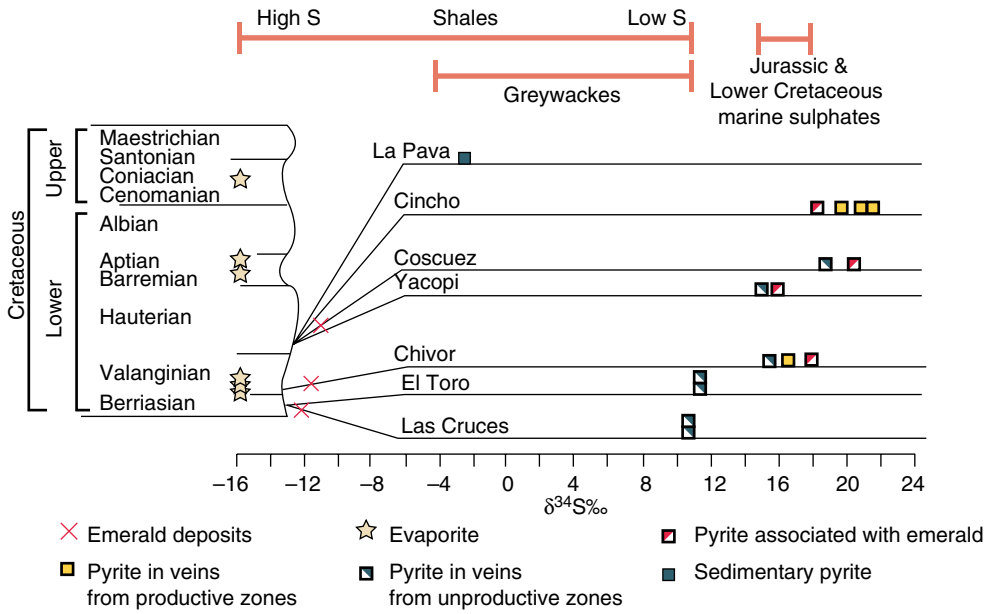

Fig. 14.30 Lithostratigraphic chart locating the main emerald deposits from eastern and western Columbia. Sulphur isotope $\delta^{34}S_{CDT}$ values of pyrites within productive and unproductive intervals plotted against potential sources of sedimentary sulphur (After Giuliani et al. 1995)

carbonate-pyrite veins developed within both dolomitic limestones and calcareous black shales.

The deposits are hectometer-sized at most and display numerous folds, thrusts, and tear faults. All the tectonic contacts are marked by centimeter-to meter-thick hydrothermal breccias that are cataclasites with clasts of black shales and albitites (i.e., massively albitized shales) within a carbonate-albite-pyrite cement. These breccias derived from a fluid-rich pulp (Branquet et al. 1999). Part of the overpressured fluid escaped and triggered intense hydraulic fracturing in surrounding rocks, especially along tear faults. In each deposit, there is evidence of complex deformation that resulted in polyphase duplex structures. For example, in the Coscuez deposit, the ore-hosting N30°E verging folds and thrusts were a response to movement on the sinistral N20°E trending Coscuez tear fault (Fig. 14.29c).

In the eastern zone (Fig. 14.29d), Andean thick-skinned tectonics are responsible for the main deformation observed on regional cross sections through the Eastern Cordillera and adjacent Llanos foothills. This Andean deformation corresponds mainly to reverse faults (with an overall vergence to the southeast) and folds affecting the Palaeozoic basement and its Cretaceous-Tertiary sedimentary cover. Some of these faults are inverted Early Cretaceous growth faults. The Esmeralda fault likely represents the preserved part of an Early Cretaceous normal fault (Fig. 14.29d). As the result of Andean thick-skinned tectonics, the Chivor emerald deposit is located on a gently northwest dipping monocline situated on the western flank of a large, N30°E-trending, upright fold, devoid of cleavage.

The enclosing sedimentary series (Fig. 14.29e) correspond to the upper part of the Guavio Formation (Berriasian), which unconformably overlies the Palaeozoic basement and is overlain by the shales of the thick (2,900 m) Valanginian Macanal Formation. The series hosting the emerald-bearing veins and associated hydrothermal breccias are composed of, from bottom to top: (1) shales and siltstones that are locally massively albitized (lower albitites); (2) a 1–10-m-thick, stratiform brecciated level, largely made of hydrothermal breccia after a former evaporite level; (3) an albitized and carbonatized sequence (upper albitites) that is white and initially contained anhydrite beds (as evidenced by phantom nodules, chicken-wire, and tepee structures); and (4) bioherms of micritic or shelly limestones grading vertically and laterally into black shales intercalated with calcareous pebbly mudstones and olistostromes.

Within the brecciated level, disrupted blocks of the hanging wall (albitites, black shales, limestones) and caving structures are evidence for the collapse of the roof. Thus, the dissolution of an evaporitic horizon (probably initially dominated by halite) appears to be a major process controlling the formation of the brecciated level. The stratiform association of evaporites, limestones, albitites, and the brecciated level is consistent across tens of kilometres around the Chivor deposit, owing to its folding by the Andean phase. All the emerald deposits of the Chivor mining district are located within or just above this regional level, and so define a stratigraphic emerald horizon (Fig. 14.29f).

Mineralizing fluids were derived via interaction of low-salinity fluids with primary halite and anhydrite, tentatively assigned to the Carib Halite Formation (Higgs 2009). The source of beryllium is thought to be the encasing black shales, while the sulphide-sulphur is evaporitic (Fig. 14.30). Organic matter, including bitumen, occurs both in the black

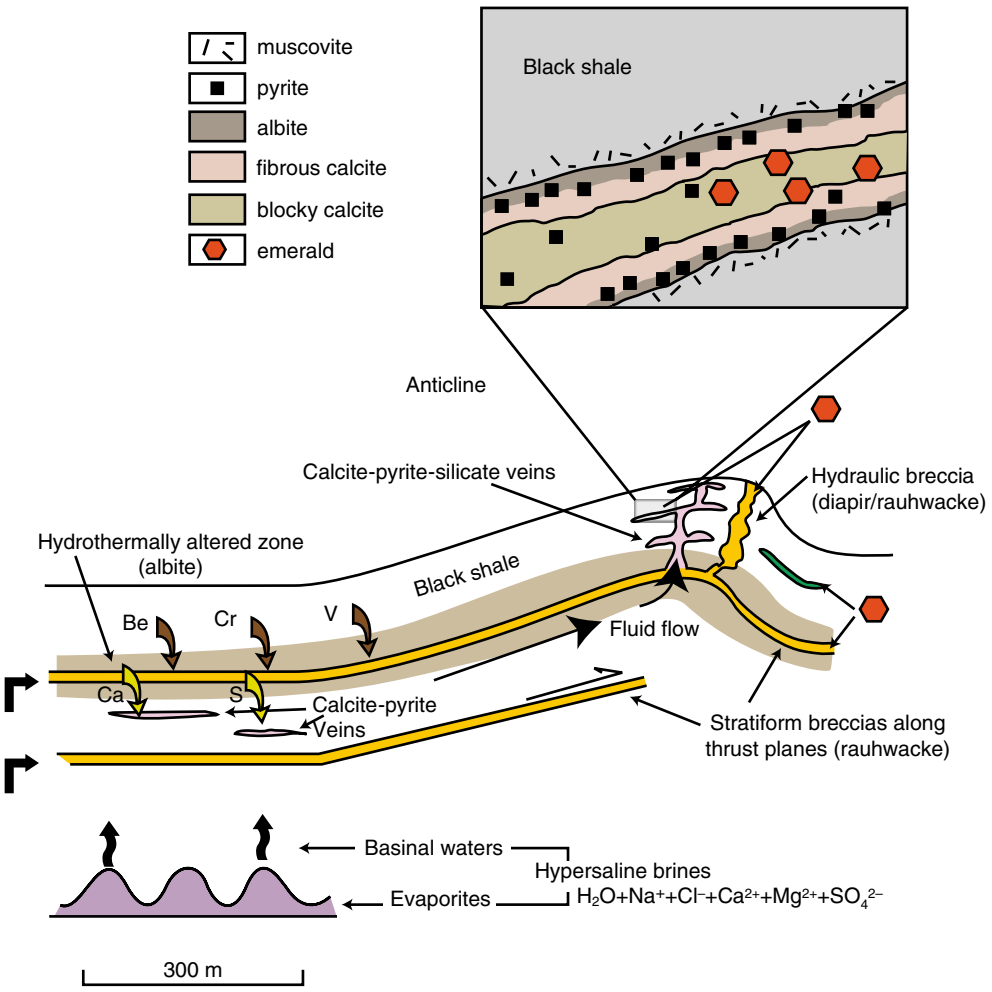

Fig. 14.31 Model of formation of Colombian emeralds. Emeralds were hydrothermally formed during thrusting and folding of black shales in a salt lubricated rauhwacke system. Highly reactive hypersaline brines, generated by circulation of hot basinal waters passing through and dissolving halokinetic evaporite beds, meant chloride-rich brines passed from thrust planes to drive wall-rock metasomatic alteration in zones immediately adjacent. By this process, Be, Cr and V were mobilised, and could then precipitate emeralds in extensional veins and hydraulic breccias (rauhwacke), which are also rich in calcite and pyrite (Compiled from sketches by Ottaway et al. (1994) and Cheilletz and Giuliani (1996))

shales and in the emerald-bearing hydrothermal veins. Organic matter is found in hydrothermally altered and unaltered forms and in primary fluid inclusions in the emeralds. Infrared microscopy of the hydrothermal bitumens revealed the absence of aliphatic and aromatic bands and the disappearance of oxygen functional groups. Rock-Eval analyses (hydrogen index (HI) <1; 19< oxygen index (OI) <61), as well the elemental H/C ratio (HI <1) of the bitumens, confirm the intense cracking suffered by the original organic matter during thermal alteration associated with emerald formation.

Fluids trapped as inclusions in the emeralds, dolomites and pyrites consist predominantly of Na-Ca-Cl brines, with some KCl. The Na-Ca-K chemistry of the inclusions supports an evaporitic parent for the hydrothermal fluids; fluid inclusion salinities in the emeralds range from 25 to 40 NaCl wt% equiv. (Giuliani et al. 2000; Banks et al. 2000). Emerald mineralization in the western zone is dated at ≈35 Ma, while eastern zone mineralization is 30 Ma older. Crush leach analyses of electrolytes in fluid inclusions within emeralds, quartz, calcites, dolomites and fluorites from both zones, demonstrate that parent brines in each region range between two extremes (fluid 1 versus fluid 2) with many samples yielding intermediate compositions. Fluid 1, found mainly in emerald-hosted fluid inclusions, is dominated by NaCl with high Cl:Br ratios indicating that the salinity was derived by dissolution of halite, most probably from local, now dissolved, salt beds. Fluid 2, found mostly in quartz hosted-fluid inclusions, is of similar salinity but contains less Na and significant concentrations of Ca-K-Fe-Cl and other cations. It has lower Cl:Br ratios, and so is more comparable with formation waters, but is inferred to have obtained part of its salinity by halite dissolution.

Bivariate plots of most cations show linear or sublinear trends, regardless of the mineral hosting the inclusions or the locality from which the samples originated, demonstrating that mixing of the two saline fluids has occurred. Because the same two fluids occur in both eastern and western zones, despite the difference in space and time for the mineralization, it is inferred that fluid compositions were rock-controlled via similar interactions with dissolving evaporites and black shales in both instances. It is proposed that beryllium was transported as Be-F complexes in the NaCl-fluid,

and was precipitated as emerald after mixing with the calcic brine caused precipitation of fluorite (CaF_2) and parisite, $[(Ce,La)_2Ca(CO_3)_3F_2]$.

The $\delta^{34}S$ values of H_2S in solution is in equilibrium with pyrite from six emerald deposits ranging from 14.8 to 19.4‰, whereas sedimentary pyrite from the enclosing black shales yields a $\delta^{34}S$ of −2.4‰ (Fig. 14.30; Giuliani et al. 1995). The narrow range in $\delta^{34}S_{H2S}$ between the different deposits suggests a uniform and probably unique source for the sulphide-sulphur. Elevated $\delta^{34}S_{H2S}$ values suggest non-participation of magmatic or Early Cretaceous black-shale sulphur sources. Salt diapirs occur in the emeraldiferous areas and the most likely explanation for high $\delta^{34}S$ involves the reduction of sedimentary marine evaporitic sulphates (Fig. 14.31). This emerald-deposit type is a mesothermal meta-evaporite deposit (300 °C) produced through thermochemical reduction of diapir-derived sulphate-rich brines to hydrogen sulphide by interaction with organic-rich strata.

Emeralds grew hydrothermally during thrusting and folding of black shales in a salt lubricated rauhwacke system. Highly reactive hypersaline brines, generated by circulation of hot basinal waters passing through and dissolving halokinetic evaporite beds, created chloride-rich brines that passed from thrust planes to drive wall-rock metasomatic alteration. By this process, Be, Cr and V were mobilised, and could then precipitate emeralds in extensional veins and hydraulic breccias (rauhwacke), which are also rich in calcite and pyrite.

A similar mesothermal metamorphic model is used to explain emeralds hosted in the Red Pine Shale, within the South Flank fault zone of the Uinta Mountains of Utah (Keith et al. 1996). The host rock is a 1 km thick, black (organic-bearing) Proterozoic shale sequence, with thin interbedded arkoses. As in Columbia, abundant pyrite, baryte, vein quartz, blocky and fibrous calcite veins, along with bleached shale and green mica, are present along and about the fault zone, and within the Cr-rich (up to 200 ppm) Red Pine Shale. As in Columbia there are no granitoid or intermediate intrusions within 50 km of the area, and no geophysical evidence to indicate that the alteration is associated with concealed igneous activity (Keith et al. 1996).

The isotopic composition of pyrite from the South Flank fault zone ($\delta^{34}S = +4.6$ to $+4.2$‰) is similar to the isotopic signature of sulphur in nearby Tertiary oil field brines (≈ +5‰). These brines are present near the base of the Uinta Basin succession, within the Wasatch Formation and the highly evaporitic Green River Formation. The deepest portion of the asymmetric Uinta basin is bounded by normal and reverse faults that were active during uplift of the Uinta Mountains. Consequently, the hydrothermal fluid, responsible for alteration of the Red Pine Shale, may be similar to that forming the Colombian emeralds. According to Keith et al. (1996), their data suggests that an external hydrothermal fluid (a highly saline, probably Tertiary age basinal brine) mixed with other subsurface waters along the fault zone. As these basinal fluids reacted with feldspar or calcite cements, they formed the sparse emerald and other alteration products now found in their Proterozoic host shales.

Rubies in SE Asia

Ruby is the red-pink transparent gem form of the mineral corundum ($2[Al_2O_3]$), with intensity of its red colour related to trace amounts of chromium[11] oxide. The coloured gem varieties of corundum include; white sapphire (colourless), ruby (red), pigeon's blood (deep red), sapphire (blue), golden sapphire (yellow), green sapphire (green), as well as olive green, purple and violet (violet sapphire). Corundum is found as highly valued rubies in Myanmar and Thailand, and as sapphires in Sri Lanka and Cashmere-India, as well as in lesser quality gem deposits in Australia, Tanzania, Cambodia, Russia, Thailand, Malagasy, Nepal, Malawi, and the USA (Manutchehr-Danai 2005).

Marble-hosted ruby deposits today represent the most important source of coloured gemstones in Central and South East Asia (Garnier et al. 2004, 2008). These deposits are located in the Himalayan belt and formed during the Tertiary collision of the Indian plate in its northward movement into the Eurasian plate (Fig. 14.32a). SE Asian rubies are spatially related to granitoid intrusions and are hosted in evaporite-entraining platform carbonates that have experienced high-grade metamorphism. All occurrences are located close to major tectonic features active during Himalayan orogenesis, either directly in suture zones in the Himalayas, or in shear zones that guided extrusion of the Indochina block after the collision in South East Asia. Ar-Ar dating of micas syngenetic with the rubies, and U-Pb dating of zircon inclusions in the rubies, show that these deposits formed during Himalayan orogenesis and associated extensional tectonics active between the Oligocene and the Pliocene, in a belt from Afghanistan to Vietnam. These ruby-bearing marbles lie in the amphibolite facies (T = 610–790 °C and P ≈6 kbar).

[11] Chromium is the chromophore in both ruby and (most) emerald. In ruby, the details of the atomic environment and local charges around the chromium ion result in a strong interaction, equivalent to a small "cage" around the ion. This induces light absorption at high energy, and hence most of the transmission is at low energy, in the red part of the visible spectrum. The opposite occurs in emerald, in which the local environment is more relaxed, resulting in a looser "cage" around the chromium ion. The absorption is at lower energies, which results in the well-known emerald-green colour (Groat and Laurs 2009).

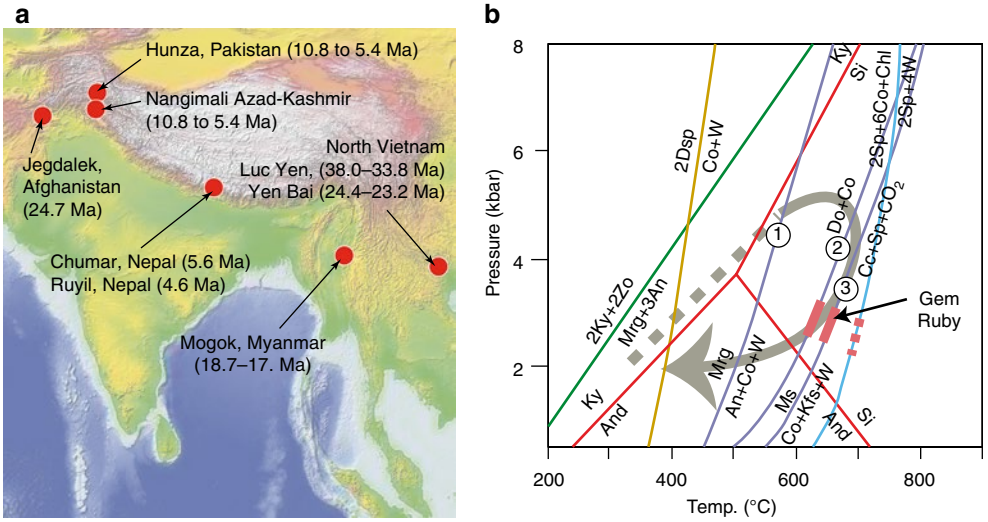

Fig. 14.32 Meta-evaporitic rubies in SE Asia (After Garnier et al. 2008). (**a**) Location and age of various gem ruby fields in SE Asia. (**b**) P-T evolution showing corundum formed during the prograde metamorphic P–T path (*dashed thick grey line*) and then during the retrograde stage (*solid grey line*) from the destabilization of different mineral assemblages as drawn in this P–T sketch: *1* from margarite, then *2* from micas, and *3* from spinel. At this stage, corundum is destabilised at lower temperature and pressure in margarite and then diaspore. Gem ruby formed at a pressure between 2.6 and 3.3 kbar and temperature between 620 and 670 °C (*pink rectangles*). Abbreviations: *An* anorthite, *And* andalusite, *Cc* calcite, *Co* corundum, *Do* dolomite, *Dsp* diaspore, *Kfs* K-feldspar, *Ky* kyanite, *Mrg* margarite, *Ms* muscovite, *Si* sillimanite, *Sp* spinel, *W* water

Fluid inclusions in the various gem rubies from the Jegdalek, Hunza and northern Vietnamese deposits indicate retrograde metamorphism; 620< T <670 °C and 2.6 <P <3.3 kbar (Fig. 14.32b; Garnier et al. 2008). Whole rock analyses of nonruby-bearing marbles show they contain enough aluminium and chromiferous elements to produce all the ruby crystals that they host. As protolith, these carbonates contained Al- and chromiferous-bearing detrital materials, probably clays, which were deposited on the platform as the same time as the mostly carbonate matrix along with locally enriched levels of organic matter.

In addition, the consistency of (C, O)-isotopic values of carbonate in the marbles shows marbles developed in a closed fluid system, and were not infiltrated by externally-derived fluids. The carbon isotopic composition of graphite in the marbles underlines its organic origin and that it exchanged C-isotopes with the adjacent carbonates during its metamorphic evolution. Earlier, less evolved examples of this isotopic exchange, with temperatures still in the upper diagenetic realms are seen in Permian Carbonates of the Saraburi region, Thailand (Warren et al. 2014). Moreover, the O-isotopic composition of ruby across SE Asia was buffered by metamorphic CO_2, released during devolatilisation of marble, while the H-isotopic composition of associated mica is consistent with a metamorphic origin for water now in equilibrium with the micas. The boron isotopes from tourmalines associated with the rubies indicates a likely nonmarine evaporite source for the boron (Fig. 14.33; Garnier et al. 2008).

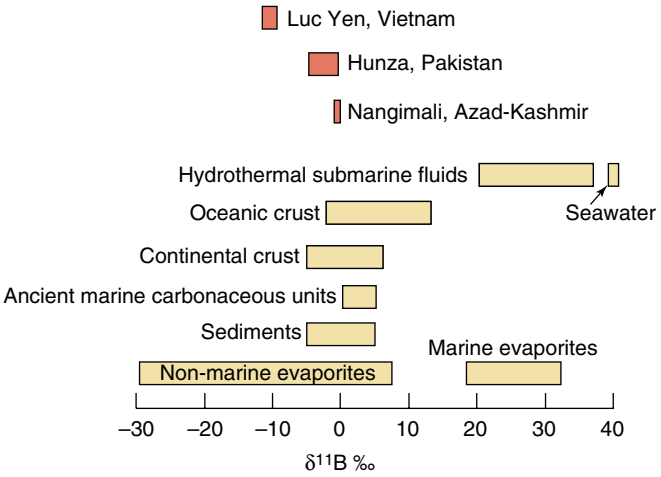

Fig. 14.33 Boron isotopic compositions of tourmaline associated with ruby in marbles compared to other typical boron sources and associations (After Garnier et al. 2008)

Garnier et al. (2004, 2005) note that the ruby-bearing marbles from Nangimali, in the Azad-Kashmir deposits of Pakistan, contain, besides phengite, atypical mica intergrowths with paragonite, phlogopite and aspidolite (sodium phlogopite). Both phlogopites, although intimately linked and coexisting with paragonite, are fluorine rich, in contrast to the phengite and paragonite. The phengite is either associated with phlogopite or can be isolated. The presence of aspidolite in these ruby-bearing marbles,

together with NaCl solid inclusions and the presence of anhydrite, further strengthen the notion that evaporites were involved in the genesis of these gem corundums.

In summary, Southeast Asian rubies formed during the retrograde portion of the metamorphic path, mainly by destabilization of muscovite or spinel. The metamorphic fluid system was rich in CO_2 released from devolatilisation of carbonates, and in fluorine, chlorine and boron, probably released from molten and altering Cretaceous or Precambrian and even Permian salt masses (NaCl, KCl, $CaSO_4$) caught up in the orogeny. Garnier et al. (2008) emphasise that evaporites are key to explaining the formation of rubies and emeralds in this gem-rich region of southeast Asia. Molten salts mobilized the *in situ* Al and metal transition elements that were contained in the host marbles, leading to crystallization of the rubies.

Tsavorite and Tanzanite

Tsavorite,[12] the vanadian variety of green grossular garnet, is a high value semi-precious gemstone. Currently it is hosted exclusively in metasedimentary and largely meta-evaporitic formations within the Neoproterozoic Metamorphic Mozambique Belt (Feneyrol et al. 2013). Deposits are mined in Kenya, Tanzania and Madagascar and other occurrences in the belt are located in Pakistan and East Antarctica. All are located within metasomatized graphitic rocks, such as graphitic gneiss and calc-silicates, intercalated with meta-evaporites. Tsavorite is found as primary deposits either in nodule (type I) or in quartz vein (type II), and in placers (type III). The primary mineralizations (types I and II) are controlled by lithostratigraphy and/or structure (Fig. 14.34).

For the African occurrences, the protoliths of the host-rocks are either anhydrite or baryte, both hosts were deposited at the beginning of the Neoproterozoic within a saline marine coastal sabkha environment, deposited at the margin of the Congo–Kalahari cratons. Subsequently, during the East African–Antarctican orogeny, these saline sediments experienced high amphibolite to granulite facies grade metamorphism, with the formation of the tsavorite occurring between 650 and 550 Ma. Nodules of tsavorite formed during prograde metamorphism, with calcium supplied by metamorphosing sedimentary sulphates and carbonates, whereas the alumina, silicates, vanadium and chromium come from a clay-chlorite protolith (Fig. 14.34). Veins formed during deformation and shearing of the metasedimentary platform were partially filled with tsavorite and other metamorphic phases. Further metasomatism occurred subsequent retrograde metamorphism with ongoing reactions with pore waters.

All the metasedimentary sequences today are still characterized by the presence of evaporitic minerals, such as gypsum and anhydrite, and scapolite. Evaporites are essential to tsavorite as they provide calcium and facilitate the mobilization of all the chemical elements for tsavorite formation. The H_2S–S_8 metamorphic fluids characterized in primary fluid inclusions of tsavorites and the $\delta^{11}B$ values of coeval dravite consistently around $-20‰$ confirm the marine evaporitic (high salinity) origin of the fluids. The V_2O_3 and Cr_2O_3 contents of tsavorite range respectively from 0.05 to 7.5 wt.%, while their $\delta^{18}O$ values are in the range of 9.5–21.1‰.

The genetic model proposed for tsavorite is metamorphic, based on chemical reactions developed between an initial assemblage composed of gypsum and anhydrite, carbonates and organic matter deposited in a sabkha-like sedimentary basin (Fig. 14.34; Feneyrol et al. 2012, 2013). Two kinds of nodules were likely precursors to tsavorite and both were hosted in an evaporitic protolith: (i) nodules Type N_I were initially anhydrite concretions within silica-rich shales; (ii) nodules Type N_{II} were initially baryte concretions located within calcareous shales. Both types of shales contained V(−Cr)-rich clays and organic matter.

At the beginning of the prograde metamorphism (stage 2), the hosting shales turned into schists, and V(−Cr)-rich clays and organic matter transformed into respectively V(−Cr)-rich micas and graphite. For the crystallisation of tsavorite in nodules Type N_I, Si and Al come from the schist, and V and Cr from the clays and transported into the anhydrite core where it forms tsavorite utilising Ca from the evaporitic sulphate, following the equation;

$$3CaSO_4 + 2Al_3 + 3SiO_2 + 6H_2O \rightarrow Ca_3Al_2\left(SiO_4\right)_3 + 6O_2 + 3H_2S + 6H^+.$$

H_2S is trapped in fluid inclusion cavities during the growth of tsavorite, while the sulphur is expelled into the schist to form pyrite. At the end of the prograde metamorphism, most of the anhydrite had been replaced by tsavorite, which is also present as small crystals scattered in the evaporitic rims. During retrograde metamorphism, these crystals are rehydrated and change in the rims into vanadian zoisite.

[12] Tsavorite (also spelled tsavolite, and tsavolithe) is a transparent, bright green to emerald green variety of grossular garnet $Ca_3Al_2(SiO_4)_3$ coloured by chromium and vanadium. RI: 1.734–1.744. SG: 3.68. H: 6½–7. Originally discovered in 1967 by British-born gemmologist Campbell Bridges and described from the Tsavo National Game Park in Kenya, from which it took its name, this green vanadium-bearing (goldmanite-component) grossular garnet, with minor chromium, is more prevalent in Tanzania, with current production from Tunduru, Ruangwa, Umba, Merelani Hills and Komolo, which has outstripped production from Kenya. Also found at Gogogogo, Madagascar, and in the Swat region, Pakistan. In 2009, Campbell Bridges was ambushed and killed by a Kenyan mob, who were illegally mining the gem on his property.

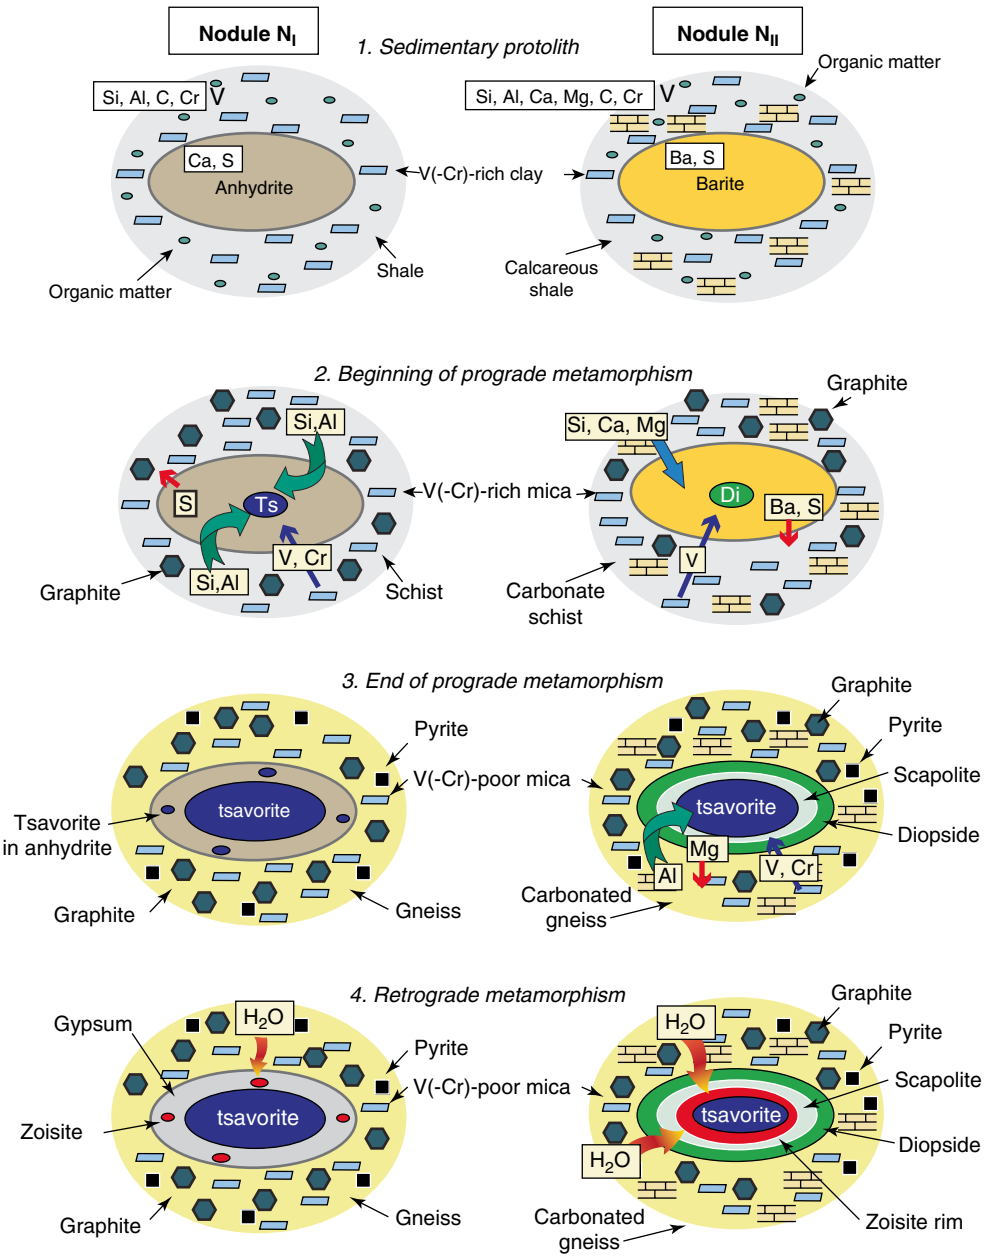

Fig. 14.34 Schematic representation of the formation of tsavorite-bearing nodules (type I and II). See text for details (After Feneyrol et al. 2013)

For the crystallisation of tsavorite in Type N_{II} nodules, Ca and Mg came from the carbonates and Si is transported towards the central part of the nodule, replacing baryte with diopside. A minor amount of vanadium is sourced from the micas and had been incorporated into the diopside core. Ba and S were expelled into the schist, the latter forming pyrite. Then the diopside core increased until replacing all the baryte. Transport of Al, V and Cr from the schist into the core led to the formation of tsavorite following the reaction;

$$3CaMgSi_2O_6 + 2Al_3^+ \rightarrow Ca_3Al_2\left(SiO_4\right)_3 + 3SiO_2 + 3Mg^{2+}.$$

Tsavorite and diopside interacted then to form scapolite following the reaction;

$$2CaMgSi_2O_6 + 2Ca_3Al_2\left(SiO_4\right)_3 + 2SiO_2 + 2CO_2 + 4Al_2O_3 \rightarrow 2Ca_4Al_6Si_6O_{24}CO_3 + 2MgO.$$

Hence, primary deposits of tsavorite are of two types, both with predictable occurrence positions in the field, which can be used to construct useful exploration paradigms (Fig. 14.35). Type I nodules occur in meta-evaporite beds creating stratiform units, intercalated within the metamorphic series and more precisely in Ca-dominated rocks such

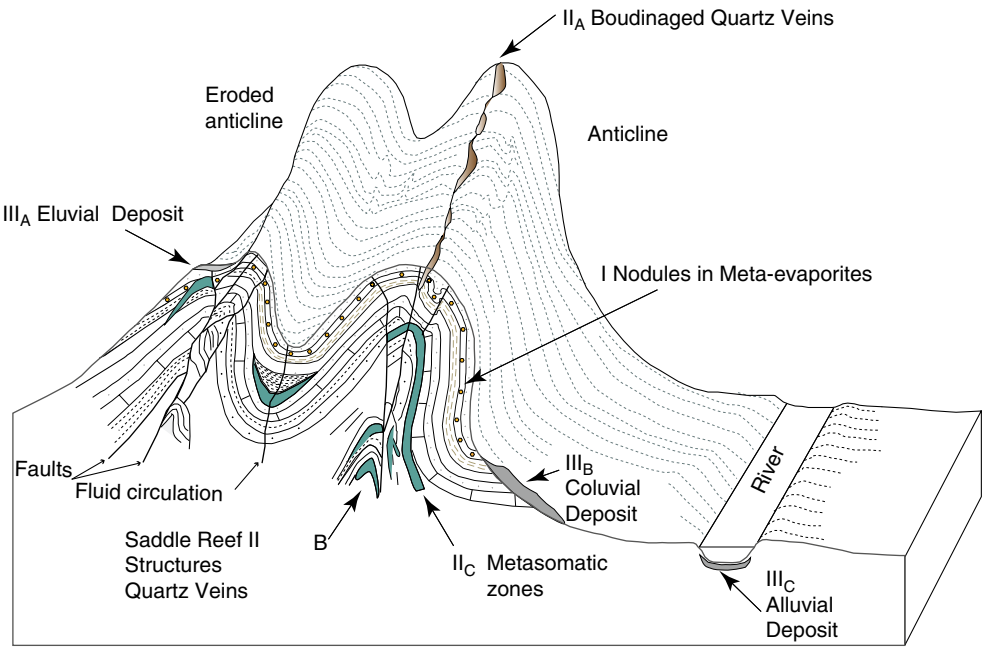

Fig. 14.35 Schematic cross-section of the different types of tsavorite deposits in the Neoproterozoic Metamorphic Mozambique Belt (After Feneyrol et al. 2013, and references therein)

as carbonate gneiss and calc-silicates with intercalations of marble (as in Kenya, Madagascar, part of Tanzania and Antarctic deposits). Type II associations occur where the metamorphic formations are affected by tight ductile isoclinal folding and shearing. The tsavorite occurs in quartz veins located at the hinges of the sheared isoclinal folds (Type IIA) and within 'saddle reef' structures (Type IIB). In this situation, deformation and shearing are associated with fluid circulation and percolation in the tectonically-opened structures. The metamorphic rocks undergo metasomatic phenomena such as pyritisation, graphitisation, silicification and carbonatisation, sometimes with precipitation of tsavorite (Type IIC). This type of deposit is found in the Lelatema area and Ruangwa in Tanzania, and in Pakistan.

Secondary tsavorite deposits (Type III) result from the erosion of the primary ones. Three secondary (reworked) sub-types are described: (i) sub-type IIIA corresponds to eluvial deposits such as those found in the Merelani area and in Kenya; (ii) sub-type IIIB is colluvial deposits such as those located in the Merelani area and in Kenya; (iii) sub-type IIIC is alluvial deposits forming the placers of Tunduru and Umba in Tanzania.

During retrograde metamorphism, hydration of both tsavorite and scapolite can lead to the formation of zoisite ($4[Ca_2Al_3(O/OH/SiO_4/Si_2O_7)]$), a member of the epidote group, which can become another gem mineral, known as Tanzanite.[13] In the Merelani region of Tanzania, veins containing tanzanite and tsavorite garnet have resulted from pegmatitic and hydrothermal fluids reacting with medium- to high-grade meta-evaporitic rocks along the crests of folds (Fig. 14.35). The faceted crystal form of many of the tanzanites is a result of their growth into dissolution cavities in the anhydrites and gypsums, fed by undersaturated mineralizing solutions and free of interference from other minerals. The zone of mineralization with such excellent gems is only a few metres wide but extends for about 9 km and includes other spectacular gem growths such of chrome tourmaline and chrome diopside. To date the known occurrences of gem quality tanzanite are restricted to the Merelani area.

Elevated Magnesium Levels in Metasediments

So far in our discussion of mineral phases that imply an evaporite protolith, we have largely focused on those mineral phases that retain evidence of the actual ionic components of the original evaporite salt; scapolite (Na, Cl, S from SO_4) albite (Na) and tourmaline (B and Na), sodian phlogopite and kulkeite. But there are also a number of commonplace metamorphic minerals, derived from an

[13] Tanzanite; a commercial term for cut zoisite; transparent blue to violet gem, pleochroic variety of zoisite, which exhibits strongly trichroic properties in deep blue, deep red, and greenish yellow. Optics; α:1.692, β:1.693, γ:1.700. Birefringence: 0.009. Dispersion: 0.019. SG;3.38. H;6–7. Currently, high quality gem forms are considered to be a thousand times rarer than diamond, but its relative softness keeps the price (hundreds to thousands of dollars per carat) far below that of fine diamond. Tiffany & Co. coined the name tanzanite for blue zoisite as they considered the term "zoisite" sounded too much like "suicide."

Fig. 14.36 Al-Mg-Ca diagram (milliatoms) showing the discrimination between the studied evaporitic rocks and shales and marls from common platform series (indicated by density occurrence isopachs of 120 samples). The evaporitic argillites and marl clearly exhibit higher Mg contents due to abundant magnesian clays while dolomite is the main carbonate. Sulphate-bearing rocks trend toward the Ca apex (calcite-anhydrite) and follow a trend (*dashed lines*) indicating the high Mg content of their clay fraction compared with nonevaporitic platform sediments (After Moine et al. 1981)

evaporitic protolith, that do not retain evidence of elevated levels of the ionic components in the salt protolith. Rather these meta-evaporites retain evidence of their genesis in the form of elevated levels of magnesium, which was originally deposited as magnesian interbeds (e.g., dolomite cements in interbedded clays or palygorskite) or in the periphery of the actual chloride salt mass. Such associations are much more enigmatic in terms of deciphering their meta-evaporitic protolith.

In a attempt to better define the significance of this association, Moine et al. (1981) geochemically analysed a selection of evaporitic and nonevaporitic sediments and then plotted the results as a Ca-Mg-Al triangular plot. They chose these three apices as they felt these were components that would be the least affected by subsequent metamorphism. Volatiles and the alkali elements were considered more likely to enter into a fluid phase and so perhaps lost from the system. Their triangular diagram (redrafted as Fig. 14.36) locates clay minerals along the Al-Mg edge, while the most widespread minerals in common shales, i.e. illites, smectites and kaolinite, fall near the Al corner. Chlorite, corrensite and attapulgite are located in the centre of the Al-Mg edge, while sepiolite, talc, Mg-smectite and magnesite lie close to the Mg apex. The location of dolomite, calcite and gypsum/anhydrite cluster in their respective Ca and Mg:Ca = 1:1 positions.

From their analyses, it is clear that, except for sulphate-bearing rocks, samples from evaporitic sedimentary series (red dots) are readily distinguished by their higher Mg contents from the non-evaporitic platform sediments (indicated by occurrence isopleths). The boundary between the two sets lies in the area occupied by the non-evaporitic dolomitic marls (where illite is the most common clay mineral). Where some of evaporite samples plotted in the field occupied by the non evaporite population (right side of triangle), they tend to be argillites and calcitic marls deposited along the borders of the various evaporitic basins (Moine et al. 1981). The presence of alkalis in some highly terrigenous or volcano-sedimentary formations complicates matters when isochemical comparisons are made to meta-evaporite geochemistry.

As expected, sulphate-bearing evaporitic sediments are mainly situated in a zone departing from the above-mentioned population and trending towards the Ca apex. When considering only the Al, Ca and Mg components, they seem to have the same composition as numerous common marls and

carbonate rocks. Nevertheless, as shown in Fig. 14.36, there is a definite trend for sulphate-bearing sediments to be related to variable proportions, of calcium sulphate and magnesium-rich clay minerals (indicated by field enclosed in dashed lines).

Interestingly, when meta-evaporite geochemical components are plotted using the same the same triangular axes (points 12 through 17 in Fig. 14.36) they overlap the geochemical fields of the unmetamorphosed evaporitic sediments and do not plot in the Al rich region of the nonevaporites (see Tables 1–4 in Moine et al. (1981) for the full geochemical breakdown of samples from sites 12–17). Assuming an isochemical transformation from an evaporite precursor, Moine et al. (1981) argued this Mg-dominant distribution strengthens an interpretation of a likely evaporite protolith. It should not be used as a sole indicator of a metamorphic rocks parenthood and should always be supplemented with other lines of argument.

Meta-evaporite Examples

The preceding discussion clearly shows that meta-evaporite interpretations are typically not based on the presence of actual salts but on the recognition of alteration products related to the mobilisation, volatilizations and dissolution of the precursor salts. What follows is a discussion of a number of meta-evaporitic terranes. The order of presentation is not chronological but rather in terms of the strength or the reliability of the meta-evaporite interpretation. Ancient meta-evaporite localities range from archetypical occurrences, with excellent preservation of the evaporite salts or their pseudomorphs, along with widespread sodic and potassic aluminosilicates, through to inferred areas with little more evidence for meta-evaporites than the presence of occasional sodic, magnesian and chloride-rich mineral phases. Broadly, a separation between examples where the tie to an evaporite protolith is obvious, versus examples where the tie to an evaporite protolith is more subtle, roughly corresponds to meta-evaporites in the greenschist versus the amphibolite/granulite realms, respectively.

Examples in the Greenschist Realm

Metasediments in the greenschist realm tend to retain many of the sedimentary and diagenetic indicators of their evaporite protolith including: lamination, bedding, silicified and calcified evaporite casts, salt residues, dissolution breccias, salt welds, mineral haloes and halokinetic/rauhwacke geometries; making the tie to an evaporite protolith quite obvious. This is especially so when there are abundant mineralogical daughter products, such as scapolite, tourmaline and phlogopite/talc associated with stratabound zones entraining these textural indicators. Because of their obvious ties to evaporites, some examples of chloride-rich greenschist realm meta-evaporites were discussed in the rauhwacke section of Chap. 7. Such examples include the Roan breccias of the Katangan copperbelt and the Callanna breccias of the Flinders Ranges, these examples will not be considered again here.

Anhydrite in Greenschist Conditions, Salton Sea

The Salton Trough is a continental rift zone at the head of the Gulf of California (Fig. 9.73a), It defines the transition from the offshore divergent tectonics of the East Pacific Rise to the onshore strike-slip dextral tectonics of the San Andreas Fault System (Fig. 14.37a; Patrick Muffler and White 1969; McKibben et al. 1988a, b; Osborn 1989). Infilling of the rift by the bi-polar Colorado River delta for the past 4 Ma has isolated the northern part of the trough, forming the closed Salton Basin in an orographic desert (McDougall 2008). The current Salton Sea was created anthropogenically in 1905 when a canal, designed to bring irrigation water from the Colorado River into the Imperial Valley, was breached during spring floods. The entire volume of this large river was then channelled into the Salton Sink, which at the time was an evaporitic mudflat/pan with a surface more than 100 m below sea level. It was 2 years before the breach was plugged and the river diverted back to its natural course, but, by that time the Salton Sink had become the Salton Sea, a huge saline inland lake extending over several hundred square kilometres. Much of the salinity was the result of dissolution of the salt crust that previously occupied the lower portions of the sink.

Although this transformation was anthropogenic, the underlying Quaternary fill preserves a similar set of pan to saline lake alternations. High evaporation rates combined with an extremely variable hydrologic budget resulted in episodic infill by saline lake and lacustrine evaporite sediments. Within the Salton Sea geothermal system (SSGS), rapid subsidence and rift-related magmatic intrusions at relatively shallow depth make up an arc of five Quaternary rhyolite domes. Related convective heating has flushed Plio-Pleistocene and younger sediments (fluvial and lacustrine deltaic matrices in a rift fill up to 1–4.5 km thick) with hypersaline chloride- and metal-rich brines, containing up to 26 wt% of dissolved solids (Fig. 14.37a, b). Seeps of mud, gas (CO_2) and dominantly polyaromatic hydrocarbons are common in this geothermal field, where wells drilled for geothermal power record temperatures of up to 350 °C at depths ranging from 1,500 to 2,500 m (Svensen et al. 2007; Mazzini et al. 2011). Hydrocarbons appear to originate from hydrothermal heating rather than

thermal maturation of organic compounds via burial (Svensen et al. 2007).

In 1962, over a 3-month period, fluid discharge from Salton Sea boreholes at temperatures of 130–170 °C precipitated several tonnes of sulphide minerals and opaline silica having a bulk composition of up to 20 % Cu, 7 % Ag, and 7 % Fe (Weissberg et al. 1979). An estimate of the size and content of the saline brine reservoir by White (1981) gives the following: 5 Mt of Zn metal, 9 Mt of Pb, 120,000 t of As, 60,000 t of Cu, 20,000 t of Cd and 10,000 t of Ag, contained in a brine volume of about 11.6 km^3 to a depth of 3 km and with a mean reservoir temperature of 300 °C. The relevance of this meta-hydrothermal hydrology to sedex systems is discussed in detail in the next chapter.

Where flushed by hot hydrothermal waters, saline Salton Sea sediments are metamorphosed, typically to greenschist facies mineral assemblages: actinolite-quartz-epidote-biotiteandradite (Fig. 14.37c; Patrick Muffler and White

1969). Cores recovered from a depth of 3 km or more contain dual-amphibole assemblages marking the transition from greenschist to amphibolite facies, as well as intergranular hydrothermal anhydrite. Calcic amphiboles with up to 2.7 wt.% Cl occur in meta-sandstones, metabasites and veins at depths between 3,100 and 3,180 m where the temperatures are in excess of 350 °C (Enami et al. 1992). There the Cl-bearing amphiboles range in composition from hastingsitic (Cl >1 wt.%) to actinolitic (Cl <0.5 wt.%). These amphiboles formed by reactions involving high-salinity geothermal fluids, with 15.4–19.7 wt.% total dissolved Cl. Coexisting phases include quartz, plagioclase, K-feldspar, epidote, clinopyroxene, apatite, and titanite.

Gypsum/anhydrite are significant components in the shallow relatively-impervious 200–300 m thick caprock to the Salton Sea Geothermal System (SSGS; Younker et al. 1982). Stratiform calcium sulphate units are commonplace in drill cores recovered in the upper few hundred metres of the SSGS. They were deposited in various playa-sabkha subenvironments, with laminated to massively bedded sulphates deposited subaqueously in perennial and ephemeral saline lakes. Gypsum (now pseudomorphed by anhydrite) was precipitated within fluid-saturated sediments in lake-fringing saline mudflats and nodular sulphates were formed in the capillary zone of surrounding dry mudflats (McKibben et al. 1988a, b).

Gypsum is the only primary evaporitic sulphate found in the SSGS, but it undergoes dehydration to anhydrite at 80–105 °C and is largely converted by burial depths of 200–250 m. The resultant interlocking texture in the anhydrite beds lowers permeability and enhances the sealing qualities of the caprock. Diagenetic anhydrite dominates the $CaSO_4$ phase to the base of the SSGS caprock at depths of 340–370 m. Below this depth, the anhydrite and calcite proportions lessen as the proportion of the cementing metamorphic minerals epidote and silica increase (Younker et al. 1982).

Fluid inclusions in the gypsum contain 4–12 wt.% equivalent NaCl fluids (Osborn 1989). Gypsum dehydration apparently dilutes these fluids, forming inclusions in anhydrite that contain <4 wt.% equivalent NaCl fluids. Fluid inclusion homogenization temperatures closely parallel the thermal profile measured in boreholes, implying continual recrystallization of anhydrite to maintain thermal equilibrium with the prevailing geothermal gradient. Continuous recrystallization allows heterogeneous mixing of relatively dilute fluids from inclusions with more concentrated geothermal brines, producing inclusions containing fluids ranging from 13 to 25 wt.% equivalent NaCl. These coexist spatially with 25 wt.% equivalent NaCl geothermal brines.

The initial result of increasing temperature is a hornfelsic to granofelsic recrystallization texture in the anhydrites, which are evolving into hydrothermal anhydrites. Bedded anhydrite is still present as a 0.6 m unit at a depth of 1,000 m and a temperature of 305 °C in the Magmamax 11 well (McKibben et al. 1988a). At that depth most of the remaining anhydrite is made up of interlocking granular anhedral grains (burial anhydrite), which alternate with marly and pelitic laminae that surround small anhydrite nodules and clusters (Fig. 14.37c). Any original small-scale sedimentary growth banding and other depositional textures in the original evaporites has been largely obliterated by hydrothermally-driven metamorphic recrystallization. Shales in a 0.8 m thick section immediately below this anhydrite are extensively brecciated, forming angular fragments cemented by clean, coarse anhydrite. The angular nature of the shale breccia fragments, their sharp contact with the anhydrite cement and the lack of fine matrix between them implies that they were brecciated after lithification of the original mudstone. The burial-related breccia is interpreted as the result of halite dissolution and is thought to indicate the process that sourced much of the high salinity chloride brine beneath the caprock in the SSGS (McKibben et al. 1988a). The notion of the dissolution at depth of former halite beds to supply much of the deeper high salinity brine is further reinforced by the work of Bozkurt (1989). He recognized widespread halite relicts in calcite at 1,240 m depth and interpreted this halite as a remnant of once more-extensive beds.

Below the breccia zone in the Magmamax 11 well is a 4.7 m thick sequence of thin interbedded anhydrite and shale. The layers of anhydrite are composed of a mosaic of interlocking grains. Isolated coarse crystals of anhydrite occur scattered throughout the shale layers, possibly representing hydrothermal porphyroblasts or pseudomorphs formed in place of former gypsum crystals.

The Salton Sea geohydrology demonstrates a system where diagenesis and metamorphic interactions are tied to the temperature regime, which is ultimately a response to magmatic heating. It shows how not only is evaporite recycling an integral part of the evolution of the metamorphic fluids but the hot temperatures in young sediment drives hydrothermal cracking and so creates hydrocarbons as one of the volatile components in the metamorphic milieu, aiding in the leaching and transport of redbed metals (Fig. 14.38). Igneous emplacement sets up a number of hydrogeochemical effects and metamorphic alteration haloes in adjacent evaporitic sediment columns, as seem in the SSGS. This has significance in understanding precipitation mechanisms for some base and precious metals, so we shall return to this topic in Chap. 16.

Metaplaya Sequences, Damara Orogen (Namibia)

Evaporitic metaplaya strata, up to 1,000 m thick, typify the Neoproterozoic rift sediments of the Duruchaus Formation in the Damara Orogen, Namibia (Behr and Horn 1982; Schmidt-Mumm et al. 1987). The Damara is part of the principal PanAfrican orogenic belt in south-

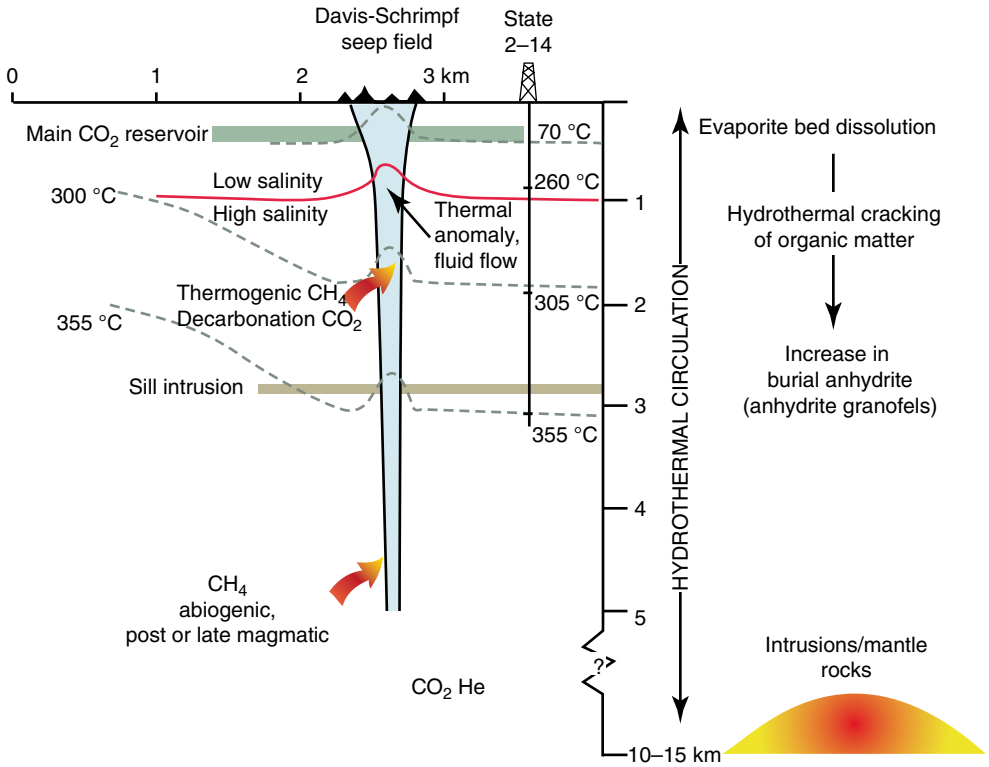

Fig. 14.38 Schematic section of the geothermal regime in Salton Sea, southern California, showing distribution of burial anhydrite and likely sources of the seep gases. Hydrothermally driven circulation of shallow meteoric fluids and dissolution/interaction with buried evaporites and associated brines controls much of the pore fluid geochemistry. A minor proportion of pore waters may have a deeper (juvenile?) origin (In part after Mazzini et al. 2011)

western Africa, reaching from the West Congo Belt in the north to the Lufilian/Zambezi, Kaoko, Damara, Gariep and finally the Saldania Belt in the south. Across the paleo-Atlantic, it faced the Ribeira-Brasilia belts and possibly the Cuchilla Dionsio-Pelotas magmatic terrane (Fig. 14.39; Frimmel et al. 2011). Its geological evolution preserves evidence Neoproterozoic breakup of Rodinia when the evaporites were formed, followed by the Cambrian accretion of Gondwana that in combination define one of the most significant supercontinent cycles in Earth history.

Evaporite deposition occurred in a widening aulocogen as a consequence of the initial breakup of the Rodinian supercontinent, some 870–740 Ma, and took place in lacustrine, playa-lake and arid fluvial settings, while overthrusting of the same evaporite deposits occurred later during the Pan-African Orogeny, 650–450 Ma. This orogenic belt, like the nearby Lufilian (Katangan) copper belt, shows an association of meta-evaporites with base metal mineralization (Chetty and Frimmel 2000), this aspect will be discussed in the following chapters.

Microthermometric fluid inclusion studies in these rocks show that two distinctly different fluid systems were active during the tectogenesis of the Damara Orogen, resulting mainly in (a) the emplacement of large bodies of quartz-dolomite plugs and dykes, and (b) the support of the extensive nappe tectonics (Naukluft Nappe, Kudos Nappe) and related mineralisations (Schmidt-Mumm et al. 1987). As a first approximation, the two systems are considered a low-salinity and a high-salinity system, which can be related to different formational conditions (Fig. 14.40). The low-salinity system is related to metapelites and metapsammites, derived from the thick geosynclinal (deeper water) sequence that was deposited in the Damara trough. The high salinity system is derived from dewatering of a sedimentary sequence containing significant continental rift/playa evaporites and cyclic pelitic-dolomite layers, intercalated with psammites (Nosib Group, Duruchaus Facies, Kamtsas Facies).

The likely continental rift playa protolith is indicated by morphologically well-preserved pseudomorphs of Na-carbonates (shortite, trona, gaylussite), borates (borax, colemanite, ulexite) and sulphates (thenardite, gypsum, baryte). All indicate a meta-evaporitic sodium bicarbonate entraining precursor, as do laterally extensive albitites and tourmalinites (Fig. 14.41). All of the pseudomorphs are now composed of microcrystalline albite with varying amounts of dolomite, calcite, tourmaline, rutile and chloritoids.

Ferroan dolomite is the most important carbonate phase in the region and at least five generations of dolomite can be distinguished in the area (Behr et al. 1983). The oldest is micritic dolomite, which is subsequently overprinted by successive coarser-grained dolospars. The composition of the dolomites varies markedly. Groups of $Ca_{90}Mg_{10}$, $Ca_{70}Mg_{30}$ and $Ca_{55}Mg_{45}$ carbonates were identified that also contained 5 % to more than 10 % FeO. Calcite occurs only locally and appears to be a product of dedolomitisation or

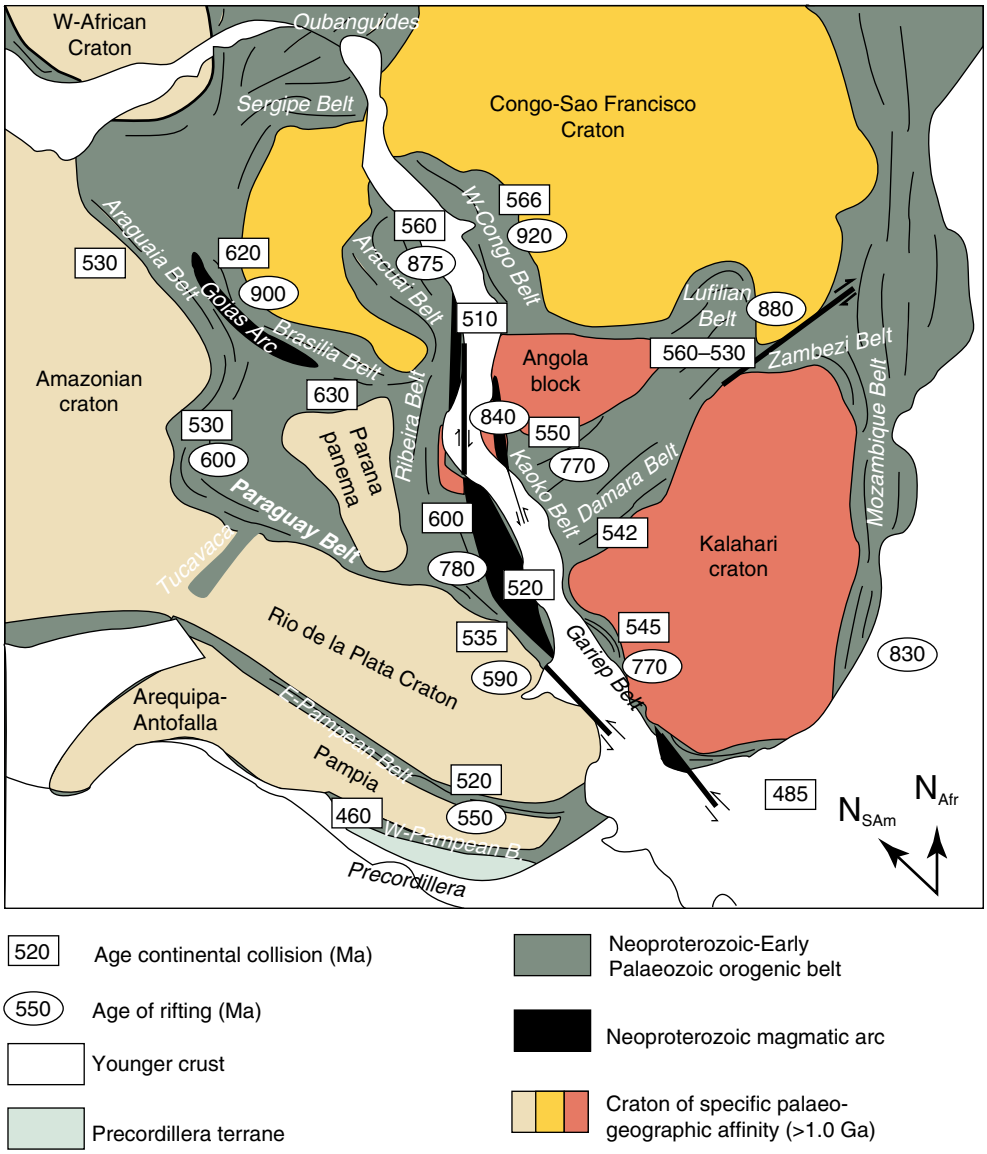

Fig. 14.39 Position of Neoproterozoic fold belts and magmatic arcs between the various cratonic blocks of southwestern Gondwana. The timing of basin opening and closure in each belt is indicated. Note that the cratonic affinity of the Parana-Panema Block is unresolved and shown here only tentatively (After Frimmel et al. 2011)

hydrothermal alteration associated with the later stages of dolomitisation

A high NaCl content in the protolith is indicated by numerous horizons dominated by Cl-scapolite with thicknesses up to several metres (Fig. 14.41a). Scapolite is best developed in dark grey dolomitic mudstones in the upper part of the Duruchaus Formation (Facies E). It is associated with albite, phlogopite and quartz; dolomite exceeds albite, and phlogopite can comprise up to 30 % of the total rock. Individual scapolite crystals are subhedral, up to 2 cm long and can make up to 80 % by volume in some layers. The scapolitic dolomites still preserve mud cracks, depositional laminae and ripples. The scapolite typically replaces calcite and phlogopite and is often associated with newly formed sparry dolomite. Average make-up is SiO_2 52–54 %, Al_2O_3 21–25 %; Na_2O 8–9 %, CaO 9–10 %; SO_3 0.7 %; Cl 2.5 %. Meionite content is calculated as 45–50 %. Behr et al. (1983) postulate the reaction:

$$\text{phlogopite} + \text{albite} + \text{NaCl}_{(aq)} + \text{calcite} \rightarrow \text{scapolite} + \text{dolomite}$$

Both the chlorine and the sodium were supplied by the metamorphism of calcareous shales containing varying amounts of halite, and were not from a magmatic source.

Laminated albite-dolomite rocks (albitites or albitolites) are also commonplace and are characterised by albite crystals up to 5 cm long (Facies D). Albite can make up more than 80 % of the rock by volume, and dolomite proportions range up to 40 % of the rock volume. Quartz, minor biotite and metamorphic muscovite are the other rock-forming minerals. Lamination is often distorted and brecciation is also widespread, possibly indicating the removal of former evaporites. The albite is usually crypto-

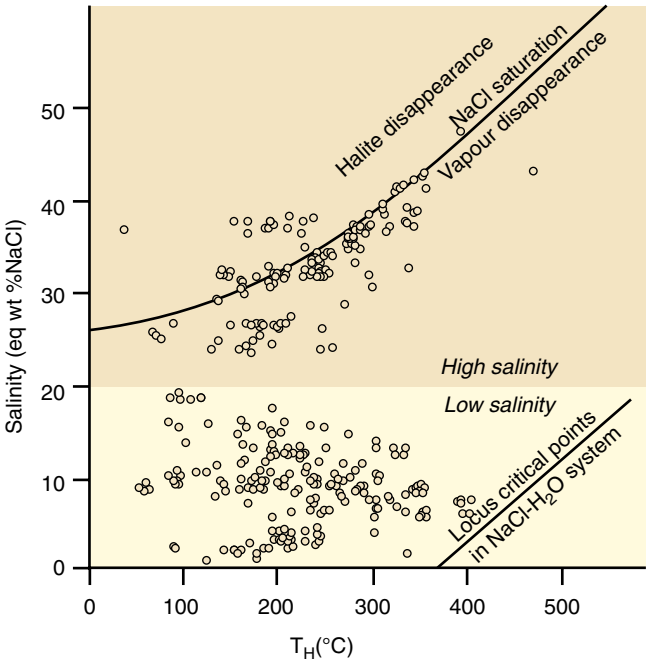

Fig. 14.40 Salinity versus total homogenisation temperature (*TH*) in the low- and high-salinity fluid systems the Damara Orogen. For highly-saline inclusions (>20 %) homogenization temperatures of daughter minerals of *cubic shape* were used to determine the salinities. For low-salinity inclusions (<20 %) values were determined from freezing data (After Schmidt-Mumm et al. 1987)

to microcrystalline (10–30 μm) and is almost pure (CaO ≈0.3 %; K_2O ≈0.1 %). Occasional larger albite crystals occur as lath-like forms (up to 500 μm) in brecciated zones. Only simple albite twins have formed and Roc-Tourne twins, so common in authigenic albites, were not found in the region. Albite is thought to have formed during late diagenesis and the onset of metamorphism in the evaporite successions from: (1) clay minerals, (2) evaporites and (3) the alteration of tuffs (Behr et al. 1983). Albite can form in the presences of saline highly alkaline waters in the following fashion:

$$\text{illite} + \text{NaCl}_{(aq)} + \text{SiO2}_{(aq)} \rightarrow \text{NaAlSi}_3\text{O}_8 + \text{HCl}_{(aq)} + \text{H}_2\text{O} + \text{KCl}_{(aq)}$$

The liberated HCl was buffered by carbonates in the matrix as the protolith was replaced by albite, a similar evolution to that documented in Triassic salts of north Africa (Kulke 1978). This style of albitization is largely restricted to the pelitic sediments of the Duruchaus Formation, and these albites typically includes relics of sericite.

Primary sodic salts in alkaline playas, such as gaylussite and trona, typically transform during dewatering to pirssonite and then to shortite. As burial proceeds and

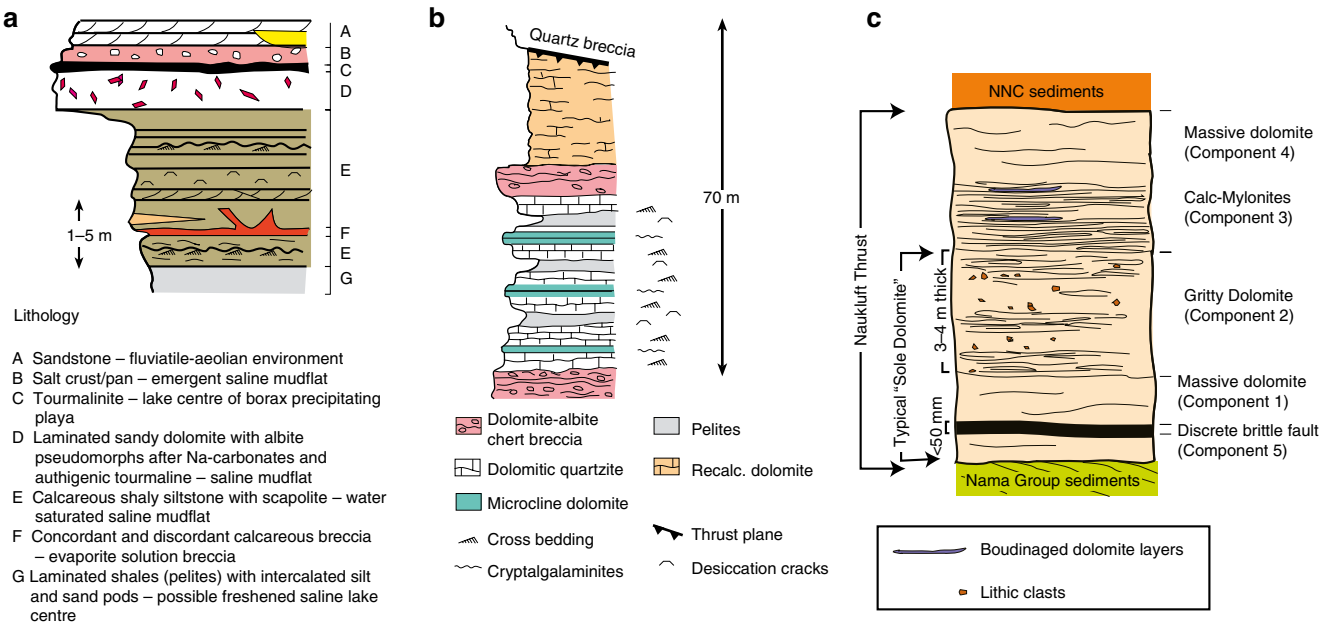

Fig. 14.41 Stratigraphy of the metasediments and thrusts associated with the Duruchaus Formation, Namibia. (**a**) Idealised vertical sequence of the metaplaya sequence, Geelkop Dome, Damara showing distribution of meta-evaporite indicators in the profile. (**b**) Generalised section of the Naos Farm dolomite sequence showing position of microcline dolomite and breccias, which indicate former evaporite horizons (**a**, **b** after Behr et al. 1983). (**c**) Schematic tectonostratigraphic section showing the five components of the Naukluft Thrust (After Miller et al. (2008). The Sole Dolomite is represented by *components 1 & 2*. Not all five components are always present and the "brittle" fault (*component 5*) may cut through at any tectonostratigraphic position, although it typically occurs within *components 1 & 2*

temperatures increase, the shortite typically transforms to albite via:

$$Na_2Ca_2(CO_3)_2 + 2Al_3OOH_{(aq)} + SiO_{2(aq)} \rightarrow 2NaAlSi_3O_8 + 2CaCO_3 + H_2O + CO_2$$

Carbonate liberated by this reaction is typically preserved as calcite and dolomite within albite pseudomorphs of the former sodium salts.

Albitites with a tuff precursor typically form dm-thick albite layers and tend to be associated with volcanics on the southern Damara margin, a similar genesis has been proposed for the widespread albitites of the Broken Hill – Olary region in Australia (see later). The pervasive recrystallization associated with this transformation means relict shard textures or analcime and other zeolites are no longer present. However, this form of albitite typically retains elevated levels of detrital rutile and biotite. The proposed reaction is:

$$\text{tuffitic glass} + \text{Duruchaus brines} - (\text{pH} > 9) \rightarrow$$
$$\text{Na - Al - Si(gel)} \rightarrow \text{zeolites} - (+\text{Na}) \rightarrow$$
$$\text{analcite} - (90^\circ\text{C}; + SiO_2) \rightarrow \text{albite 2}$$

Microcline is another conspicuous mineral in Duruchaus sediments and is especially obvious in the Naos dolomite sequence that occurs toward the top of the Duruchaus Formation (Fig. 14.41b). Microcline is present in a number of forms: (1) as microcrystalline anhedral crystals in the albite-phlogopite-quartz matrix of the pelites; (2) as rosette-like pseudomorphs after gypsum in evaporitic mudflat facies sediments; these crystals are up to 3 cm long and are often arranged perpendicular to bedding planes in cryptalgal laminites; (3) as planar, up to 1 cm long crystals in dolomite layers of calcareous shales; (4) as crystal linings in quartz-filled shear fractures; and (5) as hydrothermally formed stratiform veins, opened by hydrofracturing and the intrusion of a carbonate mush. Most of the microcline has an adularian habit with individual crystals having a dirty core and clear rims. It is interpreted by Behr et al. (1983) to have formed via hydrothermal crystallization at the end of deformation stage.

Also within this meta-evaporite sequence are stratiform tourmalinites up to several metres thick that can be traced over areas measured in tens of kilometres and extending continuously for more than 20 km (Facies C; Behr et al. 1983; Sun 2007). Electron microprobe analysis shows that they are dravites with a significantly high Mg content [average Fe/(FeO + MgO) = 0.28]. The sedimentary precursor of these tourmalinites is seen in their well-preserved finely laminated primary bedding along with preserved dewatering and cross-bedded structures, with some intervals also associated with albitites containing pseudomorphs. Some of the tourmalinite is made up of fine alternating laminae of tourmaline and albite. These units are interpreted to indicate times of hot spring activity and were associated with times of widespread borate deposition in the playa. Tourmalinites are of high economic significance in the area as they are commonly associated with stratabound accumulations of Cu, Au, Ti, U and megaquartz (Chetty and Frimmel 2000).

Metamorphism of the playa sediments, as deduced from the biotite isograd of the intercalated pelitic siltstones, and temperature-depth estimates, indicated by the CO_2 and H_2O-NaCl isochore intersections, attained temperatures of 550 °C at depths of 5–8 km burial (middle-upper greenschist facies). During this rise of temperature the large fluid volume in the enclosing dolosparite caused, by aquathermal pressuring, a mechanical destruction of the grains and a liberation of the fluid phases (Behr and Horn 1982). Additional fluids were liberated by the dehydration of the Na-carbonates, Na-silicates and Na-sulphate minerals that were concentrated in particular layers. This abnormal fluid pressure broke up the palaeoevaporite layers to form a highly mobile cataclastic sludge. Preserved fragments within the sludge range from several cubic micrometres to metres.

This process of palaeo-evaporite fluidization seems to have been initiated by the rapid overthrusting of nappes composed of hot (≈540 °C) metasediments that were squeezed out of the Khomas Trough during the Damara Orogeny. Nappe emplacement formed a hot lid some 5 km thick atop the cooler meta-playa sediments (Fig. 14.42). The underlying mobile carbonate sludge, enriched with palaeo-evaporite pseudomorphs, was partly squeezed into the thrust plane of the Khomas Nappe. Three sequential stages of brecciation were distinguished (Behr et al. 1983; Schmidt-Mumm et al. 1987):

1. A stratiform breccia formed by dewatering of water-rich evaporites in layers now enriched in palaeo-evaporitic pseudomorphs.
2. With increasing mobilisation of the saline fluids a stronger style of brecciation occurred. It was associated with aquathermal pressuring due to abnormal pore pressures and it created strongly and mostly internal hydrofractured concordant units.
3. At the final stage a very ductile discordant breccia containing xenoliths of the wall rock formed. It intruded the wallrock along faults, fissures and bedding planes.

A further breccia evolved from the type-(c) breccia that, along with diapiric ascent of the breccia mush, was intruded into the contact zones with the basement nappes. By acting as a lubricant it re-initialised or further enhanced the southwest-directed movement of the nappes (Fig. 14.42). The associated flushing of large volumes of hypersaline and alkaline solutions resulted in a strong hydrothermal and metasomatic alteration of the country rock along with mineralization of large quartz-

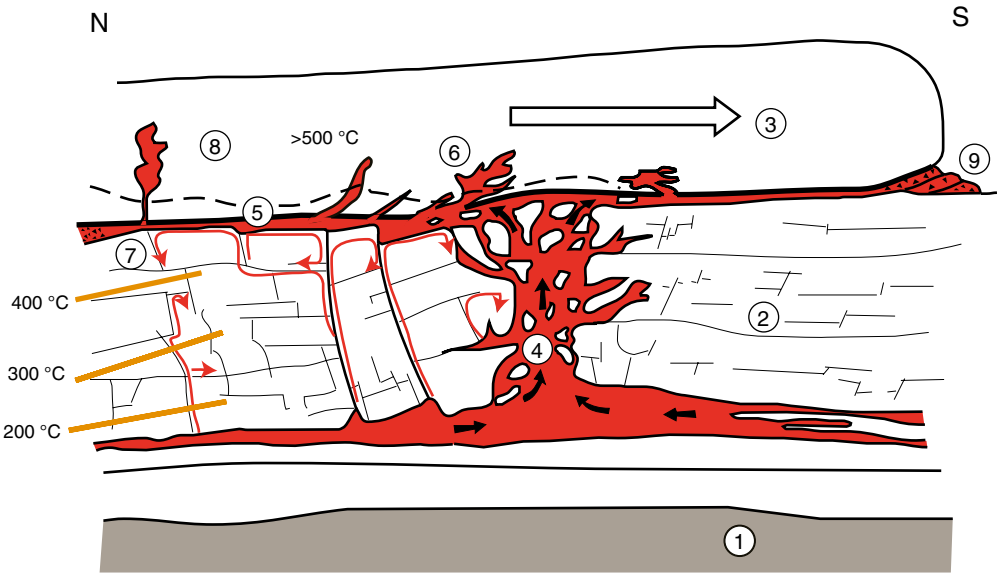

Fig. 14.42 Processes associated with the hot Kudis Nappe (>500 °C) overriding the somewhat cooler Duruchaus Formation. *1* basement, *2* Duruchaus Formation, *3* Kudis Nappe, *4* discordant breccia, *5* carbonate-quartz breccia and sole dolomite, *6* breccia injected into faults and shear planes of Kudis rocks, *7* zone of strong hydrothermal metasomatic reactions liberated by dewatering of evaporite horizons, *8* pipes plugs and veins filled by quartz precipitates derived from highly saline hydrothermal solutions, *9* breccias generated by overriding nappes (After Schmidt-Mumm et al. 1987)

carbonate bodies. Single quartz crystals within these mineralizations can have crystal faces up to 50 m across and are intergrown with large dolomite crystals up to a metre long.

In a related study, Viola et al. (2006) examined the Naukluft Nappe Complex (NNC), which forms a far-travelled fold and thrust belt klippe in the southern Pan-African Damara Belt in central Namibia, with a SE-directed displacement between 50 and 80 km. This section is less metamorphosed than the equivalent Duruchaus Fm to the north. The entire nappe stack was thrust along an out-of-sequence, nearly planar, horizontal structure, the Naukluft Thrust. The thrust zone consists of several distinct lithological components whose typical distribution, when all present, from bottom to top is (1) a massive, ochreyellow weathering dolomite; (2) a polymict gritty dolomite (called in the past Sole Dolomite), (3) strongly foliated and isoclinally folded calc-mylonites, and (4) an upper massive dolomite. In addition, a discrete (<50 mm thick, often >10 mm thick) planar brittle crosscutting fault association (component 5) can occur at any level within this sequence (1–4) but is most typically found in a basal position (Fig. 14.41c). Viola et al. (2006) concluded that the gritty dolomite formed by progressive cataclasis of a massive dolomite. They note that clasts of gritty dolomite are observed randomly oriented within a similar gritty dolomite matrix, suggesting multiple pulses of brecciation and self-brecciation (or, in my opinion, the loss of a substantial volume of pressurized halokinetic halite that once occupied the thrust plane). The gritty dolomite locally forms injection veins into the calc-mylonites, and these veins are themselves boudinaged, which they interpret as the result of broadly coeval cataclastic and ductile deformation. The evolution of structures within the thrust zone is linked to the presence and flow of overpressured pore fluids.

Based on their field observations, Viola et al. (2006) suggest that there were several pulses of fluid-induced brittle deformation that were overprinted, in a cyclic fashion, by ductile structures formed during the emplacement of the nappe edifice. Their interpretation is not related to the notion of a salt lubricated thrust and they did not consider that most of the textures in this association are classic rauhwacke, with numerous indicators of the former presence of evaporites within and about the thrust planes. Their paper is a very good example of how interpretations in thrust terranes in metamorphic settings, even low grade metamorphic settings, tend to ignore ubiquitous sedimentological analogue evidence of transcurrent and diagenetic textural overprints, now so well documented in salt allochthon terranes.

Miller et al. (2008) studied the same thrust using an isotopic approach to better understand the nature of the Naukluft Thrust (Fig. 14.43). They too found that the thrust tectonostratigraphy comprises three dolomitic components, a calc-mylonite horizon, and a discrete brittle fault (Fig. 14.41c). Stable isotope data indicate that the leading edge of the thrust is characterized by positive $\delta^{13}C$ values, whereas the trailing edge is characterized by negative $\delta^{13}C$ values. There is also a significant range in the $\delta^{18}O$ values over 15‰ in different sections, with the leading thrust edge showing a larger range than the trailing edge. The measured $\delta^{18}O$ values are characteristic of burial dolomites and secondary dolomitisation, as indicated by the presence of dolomite networks above and below the Naukluft Thrust zone. They interpret the large range in $\delta^{18}O$ values and variations in $\delta^{13}C$ versus $\delta^{18}O$ patterns to be the result of interaction between the precursor to the Naukluft Thrust zone dolomites and fluids derived from different footwall lithologies.

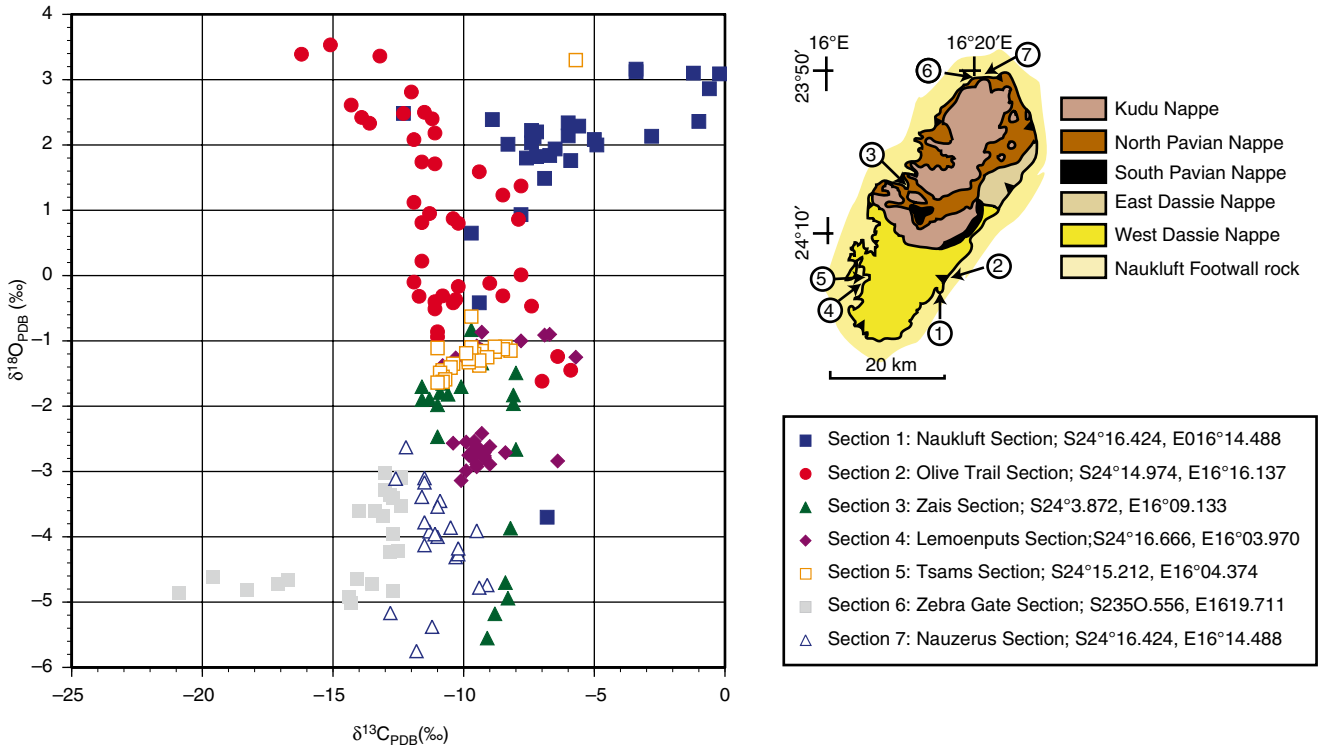

Fig. 14.43 Stable isotopes, Naukluft thrust, Namibia. Leading edge of thrust (*sections 1 &2*) show positive carbon values compared to trailing edge (*sections 3–7*). *Inset* shows Geology of the Naukluft thrust (Isotopic values replotted from Table 2 in Miller et al. (2008))

$^{87}Sr/^{86}Sr$ isotope ratios indicate that some portion of the dolomitizing fluids was derived from the basement. Although their model of the thrust and the associated dolomitisation does recognise the likely role of dissolved evaporites and multicyclic generation of the dolomitizing fluids, once again, the strong likelihood that the thrust plane was a former salt-lubricated allochthon surface is largely ignored. Their conclusion was that an original carbonate-dominated horizon existed prior to thrusting and that the basal thrust of the nappe complex exploited this horizon.

The Damara region is an interesting meta-evaporite terrane for a number of reasons: it provides excellent evidence of how sodic metasomatism is controlled by former evaporites; it offers outcrop examples of crosscutting evaporite-derived hydrothermal breccias with both diapiric and thrust-lubricated (rauhwacke) geometries; and it shows how dravite-tourmalines and albitites in greenschist facies successions can be directly related to former borate, sodium sulphate and halite salts in lacustrine settings. What is yet to be considered is how much of the metasomatism, brecciation and diapirism was related to replacement and haloes set up during the rift stage then overprinted and reworked during the subsequent orogeny. This distinction has obvious economic implications in terms of localities of prepared ground for sulphide emplacement as discussed in the next chapters.

Examples in the Amphibolite/Granulite Realm

Remnants of sedimentary evaporite salts, with the possible exception of exception of sedimentary anhydrites, do not seem to occur in metasediments that have reached amphibolite or granulite grade. It may be that the mechanical buoyancy and high solubilities of halite beds prevent them from reaching the deep-crustal milieu (Newton et al. 1998) or it may be that evaporites were transformed to meta-evaporite daughter products on attaining the greenschist realm (this chapter). It is also likely that disseminated salts or diagenetic apatite in metasediments are important sources of saline fluids capable of flushing and carrying metals in rocks that attain the amphibolite and granulite grades (see next chapter for details). This would explain observations, such as those by Touret (1985), who noted that hypersaline fluid inclusions in metamorphics of the Bamble granulite terrane in southern Norway are more abundant in marbles, metapelites and metavolcanics, compared to orthogneisses in the same terrane.

Borates of Eastern Liaoning, China

Paleoproterozoic boron deposits in eastern Liaoning, China, are now considered to be meta-evaporites that have formed with little or no fluid input from the granites of the region (Peng and Palmer 1995; Jiang et al. 1997). The borate minerals of economic interest are suanite ($Mg_2B_2O_5$),

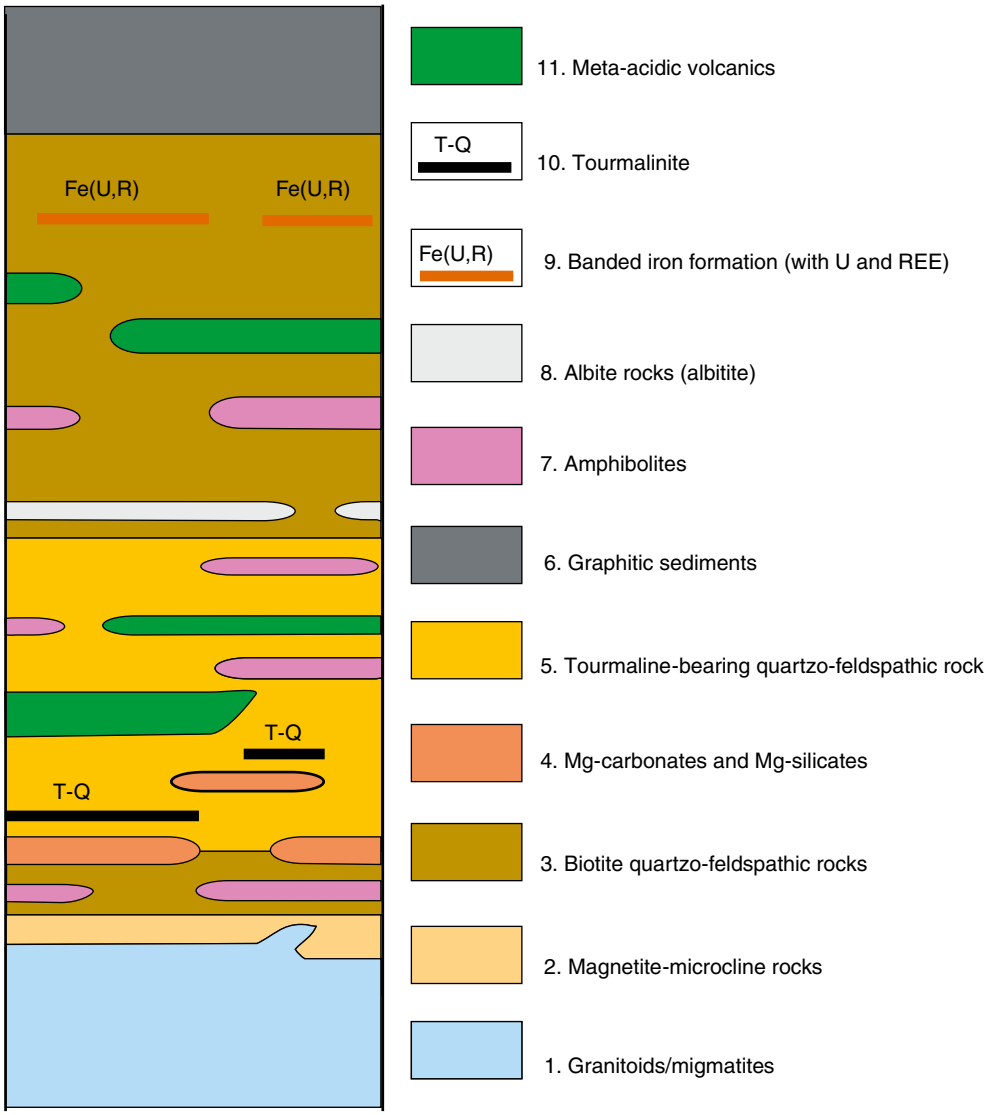

Fig. 14.44 Generalised stratigraphic section through the Liaoning borate deposits (After Peng and Palmer 1995). Various proportions of the numerically listed lithologies (1–10) make up the metamorphic facies types I (lowest) through VI (highest)

szaebelyite or ascharite ($Mg_2B_2O_5{\cdot}H_2O$), and ludwigite [$(Fe, Mg)_4Fe_2B_2O_7$]. The borates are hosted within crystalline Mg-silicate and Mg-carbonate rocks, but exhibit laminar textures implying a sedimentary precursor.

A generalized stratigraphy (from the base up) in of the Liaoning area is comprised of (Fig. 14.44; Peng and Palmer 1995): (I) Magnetite-microcline rocks (that have undergone varying degrees of metamorphism) – this unit forms the base of the borate-bearing sequence, it is dominated by microcline and contains up to 5 % magnetite. (II) Biotite-quartz-feldspar (largely microcline) rocks, and where biotite is more abundant are locally termed leptite or leptynite (≈granulite). The leptites and leptynites are remarkably K- and Na-rich, with the two elements negatively correlated. In a Na/Al–K/Al diagram, the rocks fall along the line of Na/Al = 0.9 and K/Al = 1.0 (Fig. 14.45), which is consistent with evaporite-related clastic meta-sediments (Moine et al. 1981; Cook and Ashley 1992). Tourmaline may be present locally, but only in trace amounts. (III) Mg-silicates (that have undergone varying degrees of serpentinisation) intercalated with magnesite marble – these marbles are the exclusive hosts to the borate ores and range in thickness from 15 to 160 m. In some areas the borates are present as breccias within otherwise bedded rocks and many of the blocks are laminated. Phlogopite is present in both marbles and Mg-silicate rocks and can be up to 10 % by volume of the rock. (IV). Tourmaline-bearing biotite-quartz-feldspar rocks are locally common – except for the abundant tourmaline, this lithology has the same mineralogy as the underlying leptites and leptynites. Units with abundant tourmaline tends to overlie borates and are used as an indicator of nearby ore. (V) Albite rocks may contain up to 90 % albite (albitites). They overlie the tourmaline-bearing unit and define the upper limit of the boron-bearing sequence. (VI) Graphitic gneisses – an unconformity may separate this unit from the borate bearing sequences. It is sometimes finely laminated and is interpreted as having a sedimentary

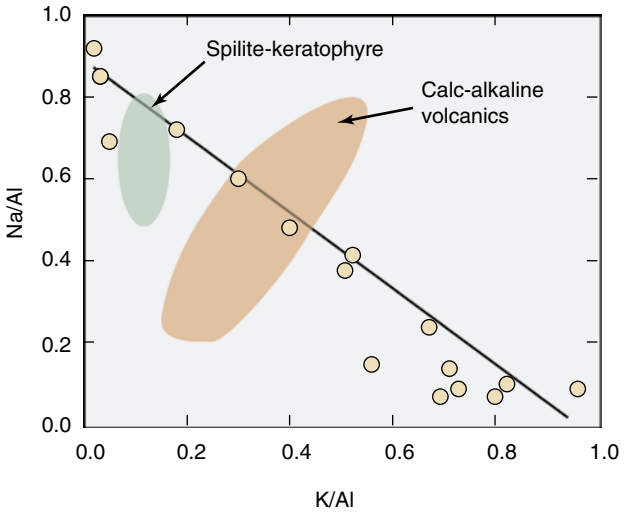

Fig. 14.45 Na/Al vs K/Al diagram of the evaporite-brine influenced pyroclastic assemblages in the Liaoning borate deposits. For comparison the general plot fields of -calc-alkali volcanics and spilites and kerotophyres are also shown (After Peng et al. 1998)

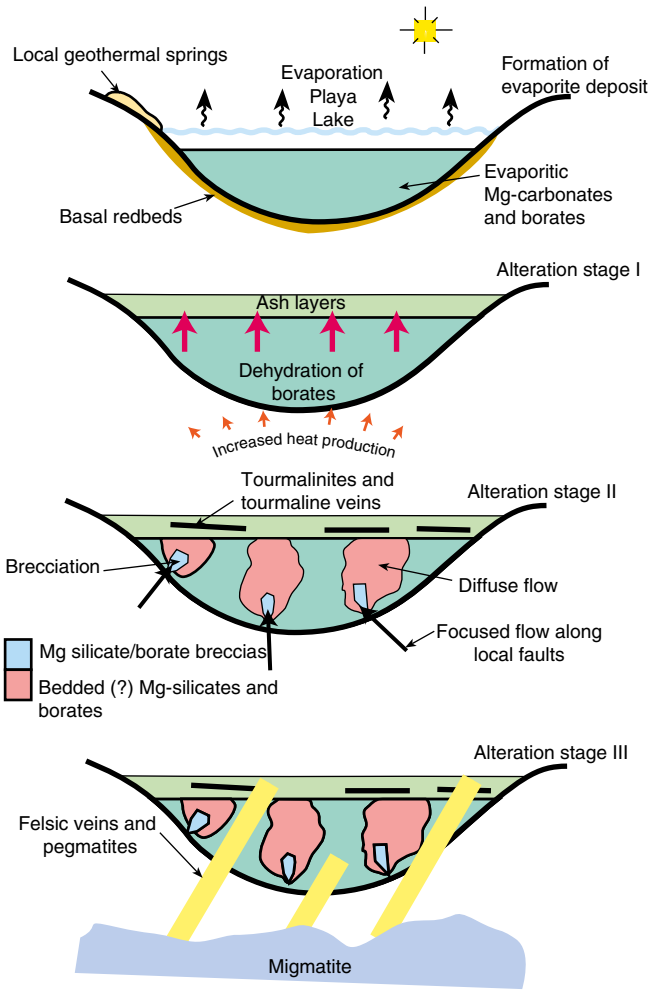

Fig. 14.46 Alteration model of lacustrine borates, Precambrian Liaoning borate deposits, China (After Peng and Palmer 1995, 2002)

protolith. Amphibolites are intercalated throughout the sequence but rarely exceed 10 m in thickness and consist almost entirely of hornblende and albite.

The borate-bearing rocks comprise much of the Liaohe Group and are overlain by graphitic gneisses with intercalations of dolomitic marbles of the Gaojiayu Formation. The thicknesses of the units vary considerably between different areas as the whole sequence has experienced intense folding and faulting, such that the true nature of the original stratigraphic column is often obscured at individual sites.

The Liaoning borates experienced several postdepositional metamorphic episodes (Fig. 14.46):

- *Stage I* The first of these prograde metamorphic events was associated with the widening of the rift basin, which led to increased geothermal gradients.
- *Stage II* This resulted in expulsion of Si-rich brines from the underlying sediments to form Mg-silicates by the alteration of lacustrine magnesite. In some places this alteration was via vigorous focused flow, which led to the development of fluidised breccias. Elsewhere in the deposits, where the fluid flow was more diffuse, this led to the replacement of carbonate in the bedded carbonate-borate evaporites on a lit-par-lit basis.
- *Stage III* At the height of metamorphism felsic veins cut through the deposits producing tourmaline-quartz rims to the veins. Subsequent deformation led to intense faulting and folding of the ore bodies.

Parental fluids for the borate and carbonate evaporites may have been originally derived from the evaporation of surface waters fed by geothermal springs associated with local volcanic activity. They have strong affinities both with the Tertiary borate deposits of Turkey (see Chap. 11) and the metasediments of the Damara Orogen (Jiang et al. 1997). Previously the Liaoning deposits were considered to have formed as skarns or as metamorphosed volcanogenic exhalative deposits. A skarn origin is now known to be incompatible with their boron isotopic signature (Fig. 14.21; Peng and Palmer 1995). A direct volcanogenic exhalative model is unlikely, as borate minerals are simply too soluble to precipitate directly into a standing fresh to marine water body fed by non-evaporated hydrothermal fluids. A concentration phase associated with solar evaporation is needed to explain the borate protolith.

In summary, Peng and Palmer (2002) reported geological, geochemical, and boron isotope data in the Liaoning-Jilin area that defines a plate-scale tectonic scenario overprinting a non-marine evaporite protolith deposited in playa lakes some 2,400–2,100 Ma ago. These evaporites were recrystallised under greenschist- to amphibolite-

facies conditions around 2,100–2,000 Ma to form siliceous borate assemblages dominated by szaibélyite, suanite and ludwigite. The protolith first experienced subduction of oceanic crust below an Archaean craton, then continental collision and lastly development of extensional basins analogous to the Cenozoic basins that contain evaporitic borates in Turkey and Argentina (Peng and Palmer 2002). Liaoning borate ore bodies differ from economic borate deposits elsewhere in the world in two important respects. First, the deposits are Precambrian, whereas most of the world's other major exploited borate deposits are located in Neogene (or younger) lacustrine sediments. Second, these borates are siliceous meta-evaporites and, with the exception of a few small skarn deposits in Russia, all other major economic boron deposits in the world are sedimentary (Chap. 12).

Grenville Complex, St Lawrence County (USA)

Northwest of New York, beneath the Adirondack Lowlands, is a 5–6 km thick Mesoproterozoic Grenville Series of metasediments and metavolcanics (Whelan et al. 1990). It is part of the Grenville Orogenic belt, a remnant of a large hot long-duration collisional orogen (Rivers 2009). At the orogen scale, Grenvillian metamorphism can be subdivided into two spatially and temporally distinct orogenic phases, a relatively high temperature Ottawan (c. 1,090–1,020 Ma) phase in the hanging wall of the Allochthon Boundary Thrust, and a relatively lower temperature Rigolet (c. 1,000–980 Ma) phase in the hanging wall of the Grenville Front (Fig. 14.47; Krauss and Rivers 2004; Rivers 2009).

The Grenville Series in the Balmat region is made up of the Upper and Lower Marbles separated by some 750 m of the Popple Hill Gneiss and underlain by the Hyde School Gneiss (Fig. 14.48a; Doe 1960; Whelan et al. 1990). Amphibolite to granulite facies metamorphism of the Grenville Series occurred about 1,050 Ma, along with emplacement of the sulphide ores, with peak conditions near the town of Balmat reaching 6.6 kb and 625 °C. There are four phases of deformation in the Balmat region. The Grenville Series is host to some unusual iron-sulphide-rich metasediments with some intervals of more than 10 m thick exceeding 70 % pyrite and containing significant stratiform anhydrite (Zimmer 1947). There are also numerous small-scale Pb-Zn occurrences in the region, which are interpreted as metamorphosed and partially remobilized MVT deposits (Fig. 14.48b; see Chap. 14).

In addition to preserved anhydrites, the Upper Marble also contains a number of other indicators of meta-evaporites, including magnesian tourmalines and local scapolites. But the most impressive are stratiform sections that are more than 50 % recrystallised anhydrite. Detailed mapping in the Balmat mine and associated drilling allows the Upper Marble to be subdivided into 16 units, numbered from oldest to youngest (Fig. 14.48a, b). In general, the sequence is composed of alternating fairly pure dolomites and quartzose calcsilicate-rich dolomitic marble. Units 1, 3, 5, 7, 9 and 12 are typically >95 % dolomite (Whelan et al. 1990). Lenses and layers of anhydrite occur in unit 6 and 10 through 14, and may be up to 50 % of the unit by volume. Brownish in unit 6, elsewhere the anhydrite is usually pale to deep lavender. Quartz and diopside may be present in the lenses, along with minor tremolite, talc, calcite, phlogopite and pyrite. The thickest lenses occur near the base of unit 6 (15–20 m) and unit 11 (40–60 m). Plastic deformation has thickened the lens in unit 11 to more than 300 m in the hinge zone of the Fowler syncline (Unit 11a in Fig. 14.48b). The anhydrite lenses in units 10, 12, 13 and 14 are 1–15 m thick. $\delta^{34}S_{anhy}$ values in the oldest anhydrite lens (Unit 6) average 8.2‰; while progressively younger lenses average 19.6, 27.2, 26.8 and 19.1‰ (Fig. 14.49; Units 10, 11a 12 and 13/14, respectively; Whelan et al. 1990). The thickest and isotopically heaviest lens (unit 11a) displays a coincident up section increase in $\delta^{34}S_{anhy}$ (24.1–30.2‰) and $\delta^{18}O_{anhy}$ (19.8–22.5‰) values. These increases and the overall ^{34}S enrichment indicate the evaporitic anhydrite precipitation was concurrent with widespread bacterial sulphate reduction in the depositional basin. A similar increase in $\delta^{34}S$ values of biogenic pyrite (total range, −31.6 to 12.9‰) and decrease in $\delta^{13}C$ values (total range, −3.7 to 5.1‰) of the marble carbonate are also consistent with bacterial reduction. Whelan et al.

Fig. 14.48 Geology of the Upper Marble. (**a**) Stratigraphy of the Upper Marble. (**b**) Cross section of the Upper Marble, also showing location of the many Pb-Zn ore bodies in the region (*black*). Where unit 11 is more than 50 % anhydrite it is shaded *red* (After Whelan et al. 1990)

(1990) interpret the isotopic data as indicating a protolith of biogenic-sulphide rich sediments. The anhydrite lenses were deposited in a restricted basin, which was also the site of accumulation of highly saline brines and extensive bacterial sulphate reduction. The low $\delta^{34}S$ and high $\delta^{18}O$ in unit 6 are interpreted as episodes of oxidation of biogenic H_2S in the surface waters. They also infer a likely sedex setting for the precipitation of the widespread sulphides.

In a later study, Hauer (1995) argues that mineral composition, trace element and isotopic (O, C, and Sr) data show that the largely dolomitic rocks below the main anhydrite horizon (unit 11a of the Upper Marble) experienced open-system diagenesis, whereas the rocks above unit 11a experienced closed-system diagenesis. This diagenesis was accomplished penecontemporaneously by seawater-dominated fluids. Differences in the history of the Upper

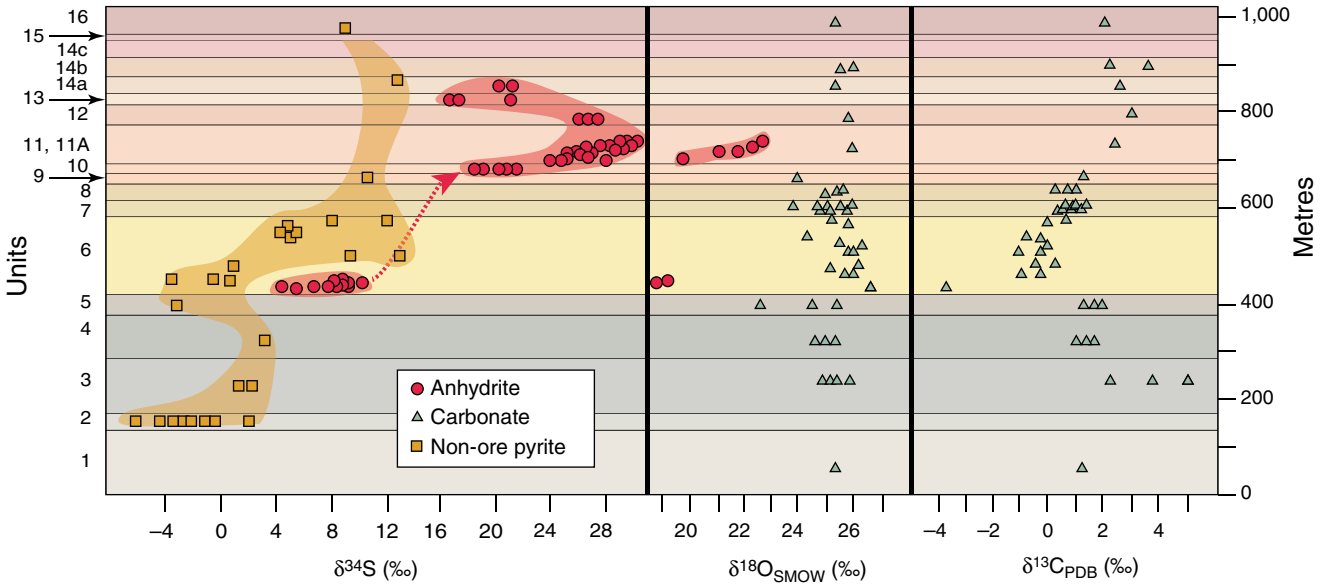

Fig. 14.49 The $\delta^{34}S$, $\delta^{18}O$ and $\delta^{13}C$ values of anhydrite, non-ore sulphide and carbonate within the Upper Marble in the Balmat stratigraphy (see Fig. 14.48) (After Whelan et al. 1990)

Marble below and above 11a are supported by differences in published Pb data for sphalerite in the Balmat Zn-Pb ores. Hauer (op. cit.) also concludes that most Upper Marble quartz originated as early diagenetic chert and that increases in aluminosilicate mineral abundances just below unit 11a are related to the tectonic events that caused the basin restriction and also drove anhydrite deposition.

Anhydrite presence has also played a significant role in the highly remobilised distribution of the ore bodies (Corriveau et al. 2007). The Balmat Pb-Zn orebodies occur within an overturned isocline in which the anhydritic units (11–13) show clear evidence of significant flow-related changes in thickness compared to other units in the metamorphic strigraphy (Fig. 14.48b). Large ductility contrasts between anhydrite and calc-silicate units led to the development of axial planar macrofractures that evolved into tectonic slides (de Lorraine 2001). Conformable massive sphalerite-pyrite-quartz lenses and layers contained with the three hosting stratigraphic units probably served as the loci for development of some of the minor or parasitic folds and the tectonic slides associated with the main syncline. Sphalerite was extremely mobile during peak metamorphism (650–700 °C and 6.5 kb) and locally flowed from the massive sulphide "parent" bodies into thin but extensive, cross-cutting ductility-contrast-induced "macrofractures" at points where macrofractures happened to transect the parent stratiform bodies. Spectacular excursions or remobilizations of "daughter" ore into macrofractures occurred locally with sulphide apparently flowing radially outward as far as 2 km away from source bed or parent ore masses. The bulk of remobilized sulphides remained within 0.5–1 km from the parent orebodies. According to Corriveau et al. (2007, 2009), such spectacular ore remobilization may have framed current perception that metamorphosed orebodies are remobilized significantly, however, this is not the norm as exemplified by well preserved stratigraphy even in marble successions (Gauthier et al. 2004) and is probably indicative of a propensity for greater mobilisation in the near fluid milieu created by deforming evaporites.

Mt Isa Inlier, Northern Australia

The Mount Isa Inlier is an extensive area of exposed midProterozoic rocks in northwest Queensland, that is part of a broader mineralised Proterozoic association extending southeast from the Pine Creek region, across the McArthur Basin the Lawn Hill Platform and into the Mt Isa Inlier (Fig. 14.50) the geology is attributed to attributed to early–mid Proterozoic tectonostratigraphic cycles (Fig. 14.51; Murphy et al. 2011; Blenkinsop et al. 2008). It contains a number of large Pb-Zn and copper accumulations, including the worldscale Mt Isa deposit. In this section we shall document the meta-evaporite nature of much of the ore-hosting matrix in the various blocks of the Mt Isa Inlier. In Chap. 15, the mineralisation aspect is discussed further, as it relates to halokinesis along with halite dissolution breccias after salt allochthon tiers, and the narrow polycyclic timing of mineralization, focusing on less metamorphosed examples, especially, the HYC deposit in the McArthur River Basin and the Century Deposit on the Lawn Hill Platform.

The Mt Isa inlier has conventionally been divided into three north–south trending tectonic units on the basis of major faults or fault zones (Fig. 14.50; Blake and Stewart

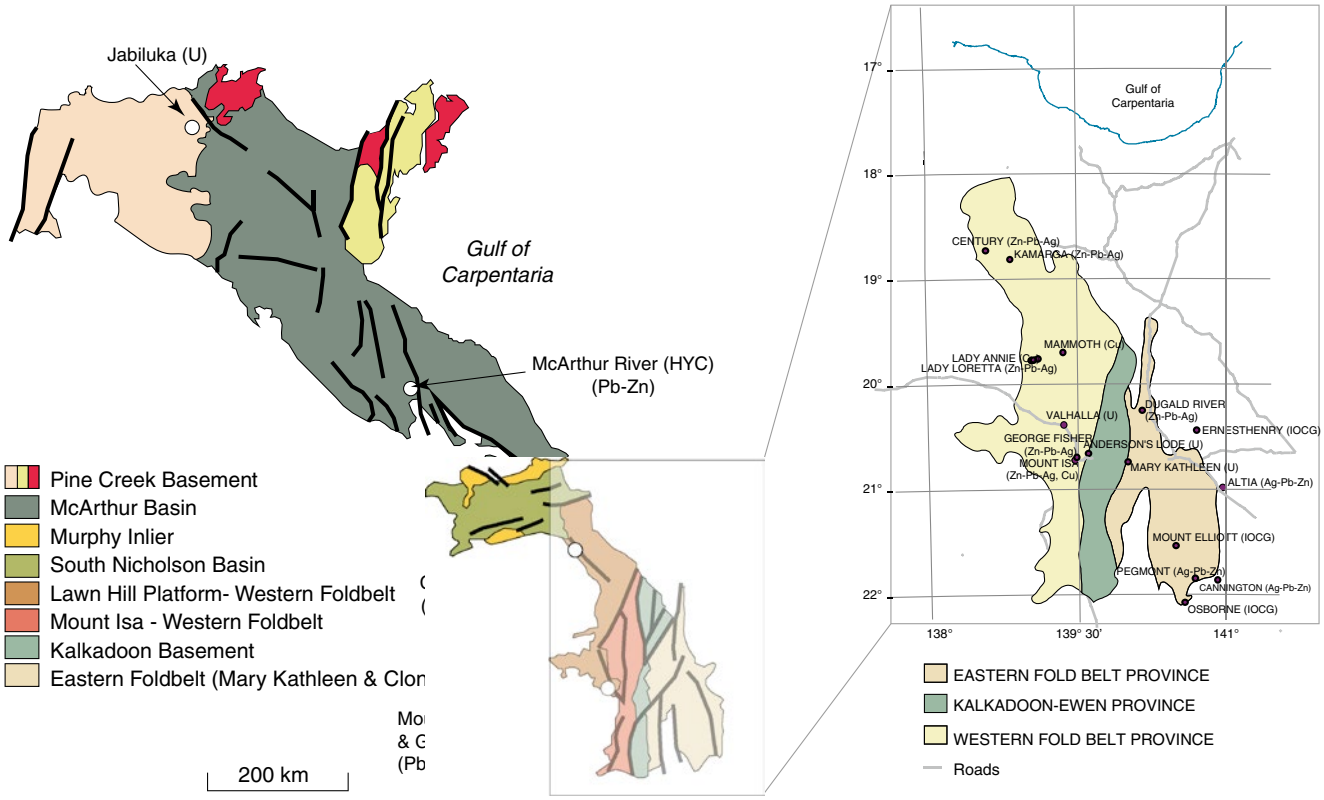

Fig. 14.50 Geological associations and provinces in the Mt Isa – McArthur Basin – Pine Creek region (Refer to Fig. 14.51 for space-time summary). Expanded view shows distribution of significant metalliferous occurrences in the region of the Mt Isa Inlier, which is made up of a central Kalkadoon-Leichhardt basement block, flanked by the eastern and western foldbelts, with significantly higher metamorphic grade defining the eastern foldbelt (After Hutton et al. 2012; Wilde 2011)

1992), namely: the Western Foldbelt (comprised of the Lawn Hill Platform and the Leichhardt River Fault Trough); the central KalkadoonLeichhardt Belt; and the Eastern Foldbelt (higher metamorphic grade, made up of the Mary Kathleen and Cloncurry districts). Across the region, remnants of the first depositional cycle form the basement to the Isa Inlier and were metamorphosed to amphibolite facies during the Barramundi Orogeny at ca. 1,900–1,870 Ma (Fig. 14.51).

The 'Barramundi Orogeny' rocks underlie the "cover sequences," which historically within the Inlier were considered to make up the "Eastern Fold Belt" and the "Western (foldbelt?) Succession" ranging across 1,550–1,800 Ma rocks. Recent geochronological, sequence stratigraphic and structural studies within the western half of the inlier have revealed that basin formation and sedimentation was more complicated than the three sequences model and that mineralization across the region is hosted in metasediments that were deposited within a relatively narrow age range between ca. 1,680 and 1,590 Ma (Foster and Austin 2008; Southgate et al. 2013). The succession is now regarded as a series of superposed basins: the 1,800–1,750 Ma Leichhardt, 1,730–1,670 Ma Calvert and 1,670–1,575 Ma Isa superbasins (Jackson et al. 2000).

Current understanding of the chronostratigraphic breakdown at the group level, and the associated igneous and orogenic events, is summarised in Fig. 14.51. This space-time plot shows a lithological spread across space-time of the three superbasins that constitute the McArthur- Mt Isa region, namely the Leichhardt, Calvert and Isa Superbasins, for which there is a spread of interpretations as to basin genesis (Murphy et al. 2011 and references therein):

1. Intra-continental rifting, punctuated by contraction, with a mantle plume that generated the flood basalts in the Leichhardt Superbasin;
2. Continental back-arc setting, punctuated by contraction due to accretion events along the plate boundary. In support of this model, trace-element geochemistry of mafic rocks mostly indicate a subducted slab component;
3. Rift to rift-drift and passive margin development, not punctuated by contraction, but by differential uplift and block rotation, particularly during the Calvert Superbasin;
4. Later in the history, ramp and strike-slip basins developed during Isa Superbasin infill, this was related to subduction in the south or

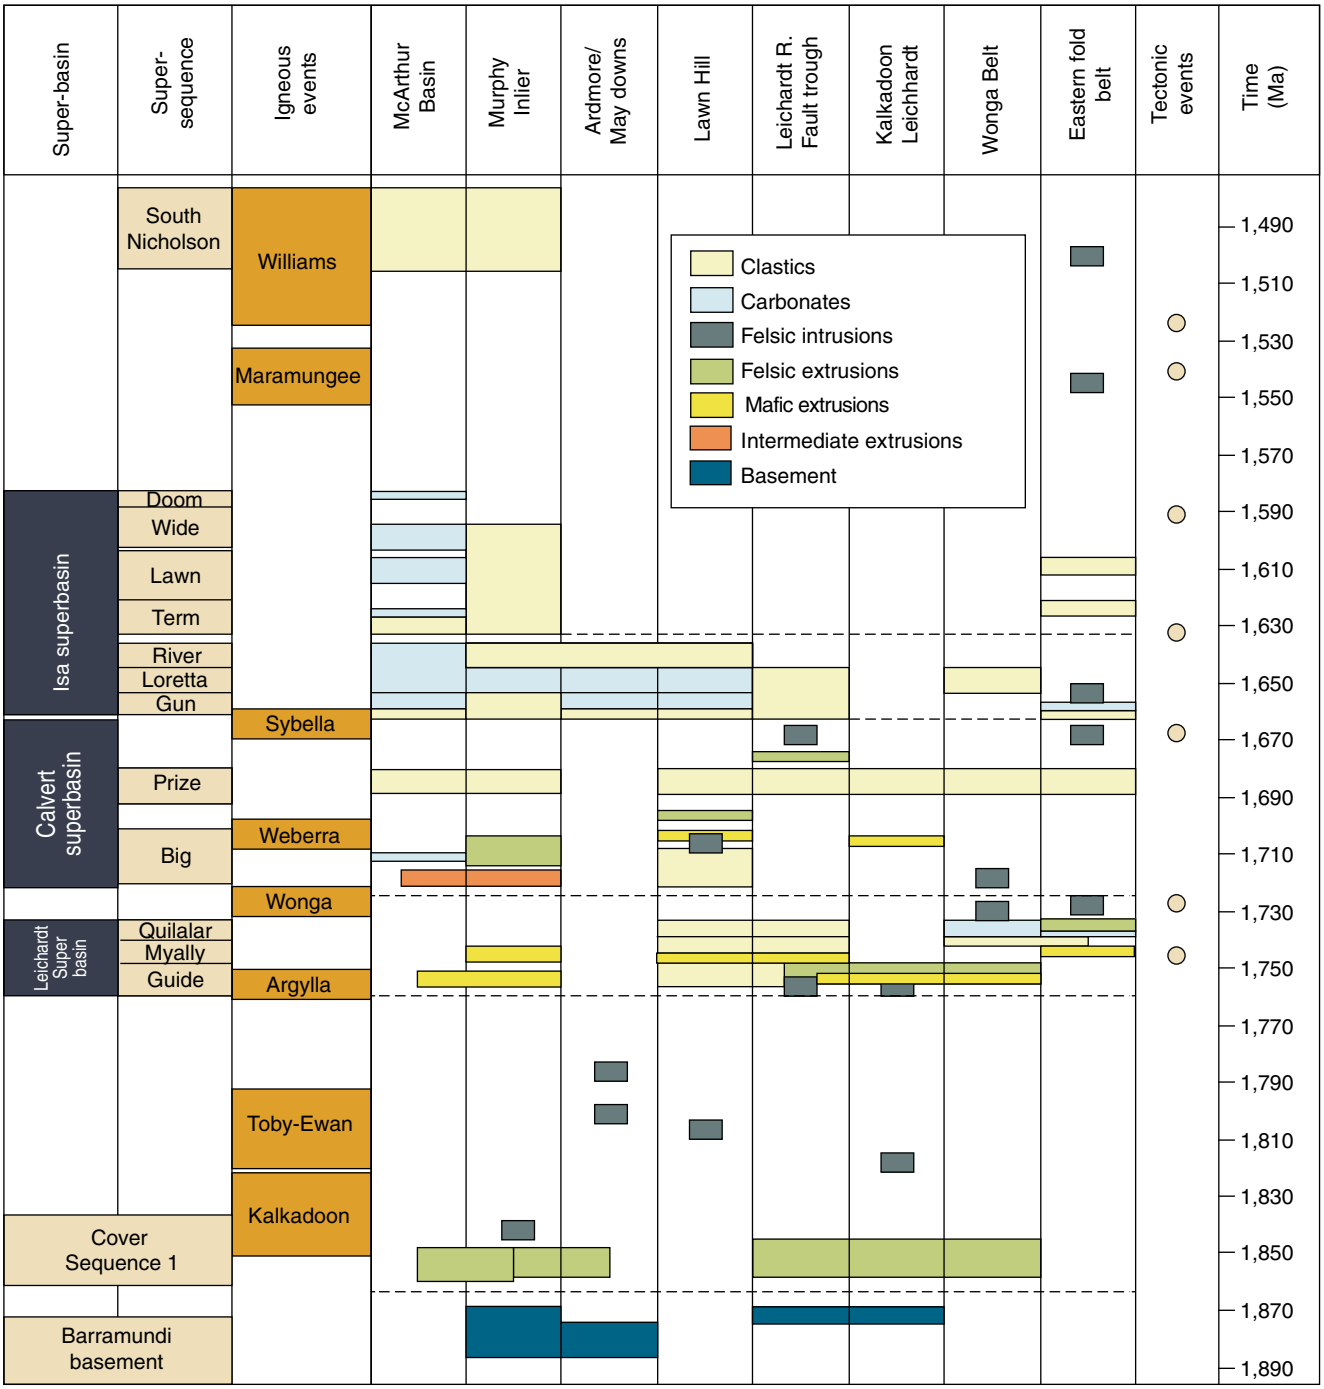

Fig. 14.51 Tectonostratigraphic evolution of the successions of the Mt Isa -McArthur River region (After Murphy et al. 2011)

5. Foreland basin development during deposition of the upper part of the Isa Superbasin. This was related to continental collision during the Isan Orogeny.

The Mount Isa Pb-Zn-Ag-Cu deposit is located in the Leichhardt Fault Trough, in the Gun Group, and hosted in the laminites of the Urquhart Shale. It contains a global resource of 255 Mt at 3.3 % Cu; while the Pb-Zn-Ag deposit contains 150 Mt at 7 % Zn, 6 % Pb, 150 g/t Ag in 10 strata-bound lenses in an en echelon arrangement around the silica-dolomite hosted copper deposits. The deposit contains 10 strata-bound Zn-Pb-Ag orebodies in an en echelon array. According to Davis (2004) the extremities of the orebodies correlate with F4 folds, and high-grade shoots are centred on F4 hinges and short limbs that contain older F2 folds (Fig. 14.52a).

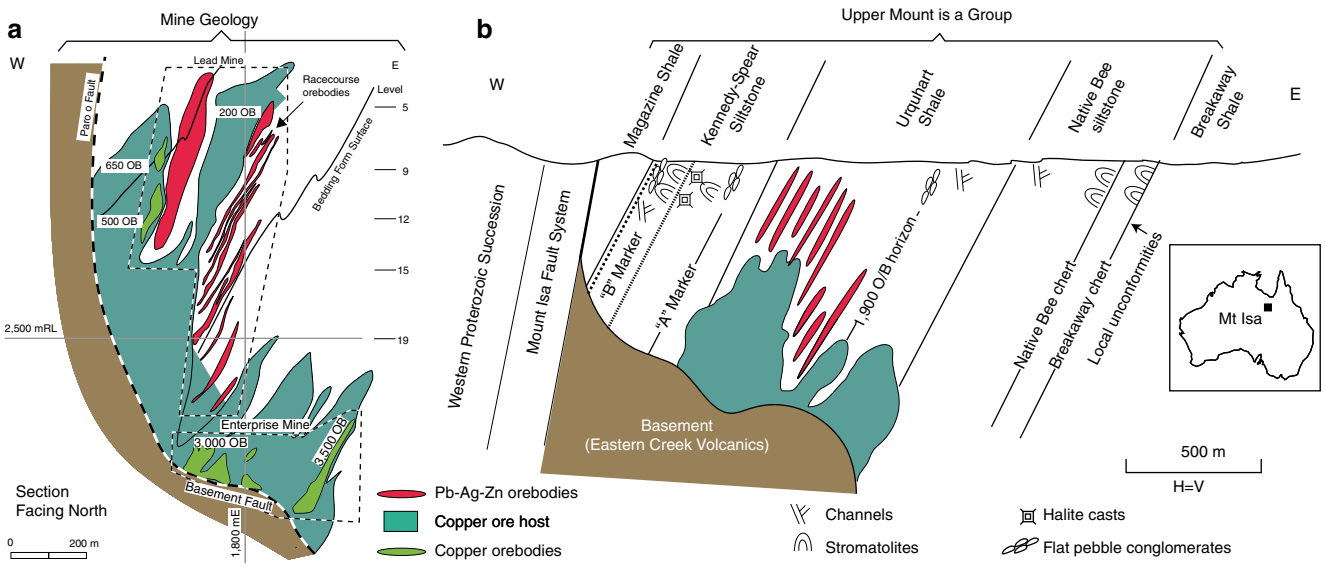

Fig. 14.52 Geology of the Mt Isa Cu-Pb-Zn ore deposit. (**a**) Ore distribution in a north-facing mine section (After Davis 2004). (**b**) Idealised E-W cross-section through Upper Mt Isa Group formations hosting the showing occurrences of various evaporitic indicators in the sequence (After Neudert 1986). *Inset*: locality map

Several major sedimentary sequences in the Mt. Isa inlier, including the ore-hosting Urquhart Shale (calcareous siltstones and shales at greenschist grade) in the western Succession and the more metamorphosed Corella Fm. and Staveley Fm. in the eastern foldbelt, all contain relict evaporite pseudomorphs or meta-evaporites indicators (Stewart and Blake 1992; Stewart 1994a, b). The sequence in the vicinity of the Mt Isa mine (Western Succession) has undergone several deformations within low greenschist facies (chlorite grade) metamorphic conditions (McClay and Carlile 1978). The deformations were not penetrative and a slaty cleavage is only well developed in the more argillaceous beds. Thus primary bedding and many other sedimentary textures are still visible in the Urquhart Sahle and adjacent lithologies, including widespread evaporite pseudomorphs, and other hypersaline indicators, such as tepees, stromatolites and dissolution breccias, (Fig. 14.52b; Table 14.8; Neudert and Russell 1981; Neudert 1986). The influence of evaporites in the Mt. Isa Inlier Cu-Pb-Zn mineralization was ongoing from the diagenetic into the metamorphic realms. Large anhydrite-baryte bodies remain in the subsurface at the northern end of the Mount Isa copper ore body (Wilde et al. 2005a, 2006). There is ongoing debate as to whether this anhydrite is a recrystallised depositional relict or is a hydrothermal anhydrite.

Likewise there is ongoing debate as to the nature of the Paroo Fault, which is widely accepted as having acted as the main conduit/focus for mineralising fluids in the Mt Isa ore (Fig. 14.52a; Long 2010). But, whether these solutions arrived when the Paroo Fault was a bounding fault to a deep seafloor minibasin, with a salt allochthon focused transport mechanism, or if was independent of any evaporite influence and was a purely structural feature focusing mineralising fluids is not yet resolved.

Mary Kathleen (Eastern) Foldbelt

The lowermost part of the Eastern Succession stratigraphic sequence (Argylla Formation, Ballara Quartzite, Corella Formation) is intruded by the Wonga Batholith, comprising bimodal intrusive rocks in the Mary Kathleen Fold Belt (Fig. 14.53a; Hammerli et al. 2014). The batholith crops out in a north– south linear zone about 200 km long and 10–20 km wide. Intrusive rocks of the batholith are subdivided into two groups based on their deformational style. The strongly foliated Wonga Granite Suite occurs in the central part of the batholith (the Wonga Belt), and is interpreted as intruding high-strain zones below a regional detachment (i.e. the lower plate). Lower plate magmatic rocks were intruded contemporaneously with shearing and the overprinted results of this process encompass various granites as well as dykes of metadolerite (now amphibolite). These rocks have experienced varying degrees of ductile deformation and some are extensively mylonitised. Mylonitic fabrics give either a top-to-the-north (Holcombe et al. 1991, 1992) or top-to-the-south sense of shear (Pearson et al. 1992; Gibson et al. 2008) and indicate amphibolite-facies conditions as they formed.

In contrast, deformation in the upper plate was accompanied by development of more brittle structures, including normal faults that root downward into the mid-crustal detachment. Metamorphism associated with initial upper-plate extensional deformation rarely exceeded greenschist facies,

Table 14.8 Sedimentary features at Mt Isa and their significance

	Tepees	X			X						

with subsequent amphibolite-facies metamorphism related to later events. Along with the intervening detachment, upper and lower plate rocks were deformed into a series of upright, north–south trending D2 folds during east–west shortening accompanying the ≈1,600 Ma Isan Orogeny (Fig. 14.53b). This event post-dates extensional shearing by more than 100 Ma. By contrast, the flanking and less-foliated Burstal Igneous Suite is located in the lower strain and originally also less intensely metamorphosed upper plate above the regional detachment (Holcombe et al. 1992). Wyborn (1988) interpreted magmatism as occurring in both domains from about 1,760–1,720 Ma during an episodic period of extension known as the Wonga Extension Event.

Work by Neumann et al. (2009) refined the duration of this extension event to between 1,780 and 1,740 Ma. They demonstrated that the initial stages of this tectonomagmatic event are coincident with mafic magmatism, basin formation and rapid sedimentation of the ≈1,780–1,765 Ma Myally Supersequence of the Leichhardt Superbasin in the adjacent Leichhardt River Fault Trough. That is, deposits of the Ballara Quartzite and Corella Formation represent a period of sag-phase sedimentation during the later part this event, and that these units are likely equivalent to the Quilalar Supersequence of the Leichhardt River Fault Trough (Fig. 14.51). These correlations permit the equivalent sections of the Eastern and Western Successions of the Mt Isa Inlier to be correlated from 1,780 Ma. Locally, the Corella Formation is intruded by 1,740 Ma granites, suggesting that at least the lower parts of this package were deposited during the 1,780–1,740 Ma extensional event. That is the original evaporites, now seen as meta-evaporite remnants in the Corella Formation in the eastern foldbelt were originally deposited as "rift to drift" evaporites.

So, regionally, the Mary Kathleen Foldbelt (Eastern Succession) is composed of: (1) meta-evaporites and meta-carbonates of the Corella Formation (deposited 1,738–1,750 Ma), or (2) meta-granites and metadolerites (Oliver and Wall 1987; Foster and Austin 2008; Neumann et al. 2009). Metamorphic grade ranges from upper greenschist to upper amphibolite and the succession is intruded by batholithic late- to post-tectonic granitoids. Evaporites and carbonates (their bitterns and their daughter products) in these metasediments acted as ongoing sources of saline fluids during a protracted series of tectonothermal events and were integral to the creation of widespread hydro-brecciated textures. One wonders how much of the brittle to ductile

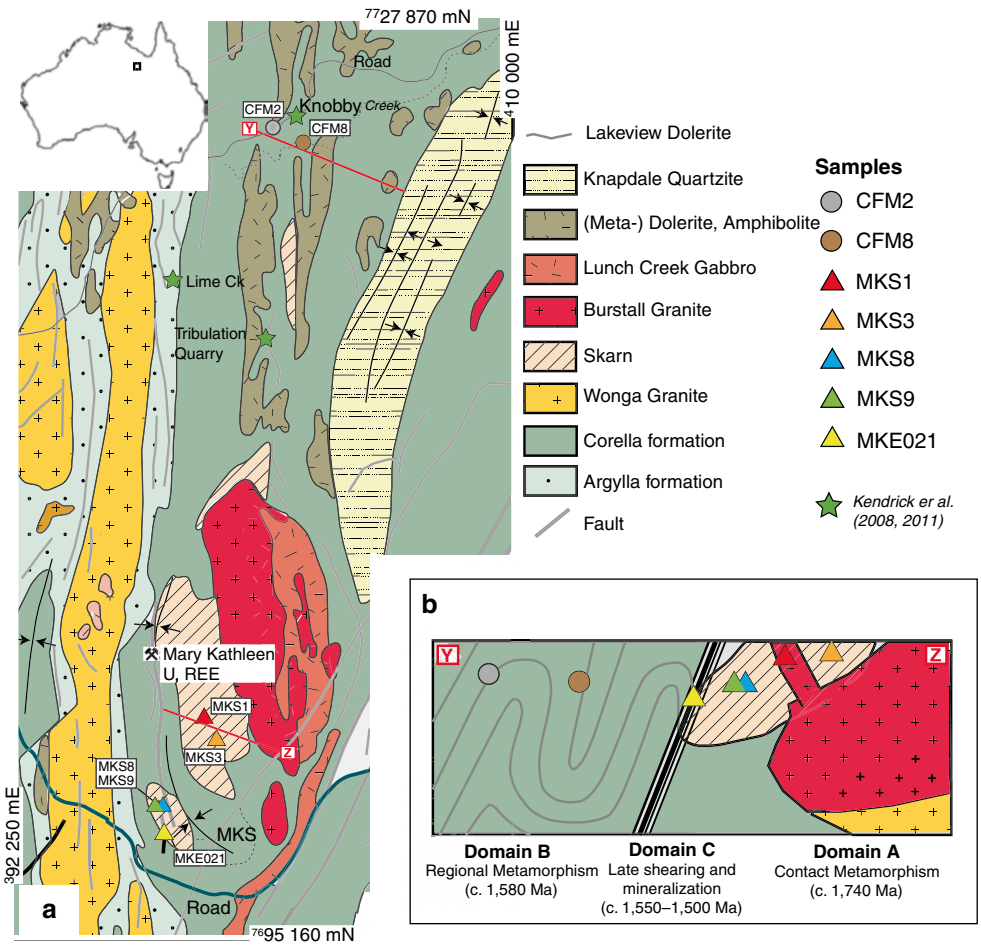

Fig. 14.53 Geology of the Mary Kathleen Foldbelt. (**a**) Map. (**b**) Section (After Hammerli et al. 2014)

transition at the base of the Corella reflects, at least in part, the influence of a brittle-ductile discontinuity associated with the presence of a thick former salt unit at the transition boundary.

For example, the fluid evolution history in the Cloncurry district is characterized by early high temperature and low salinity to late low temperature and high salinity fluids given an association that is distinct from many intrusion-related hydrothermal systems elsewhere in the world (Xu 2000). The ubiquitous presence of low-temperature (T <200 °C) $CaCl_2$-bearing inclusions is a remarkable feature of the mid-Proterozoic Cloncurry hydrothermal system (Fig. 14.54). It is interpreted to be a result of the interaction between widespread dissolving metaevaporites and downward penetration of deeply-circulating meteoric water. The transition from early hotter magmatic and/or metamorphic fluids to cooler late meteoric water is ascribed by Xu (2000) to the shift of the crustal level during exhumation.

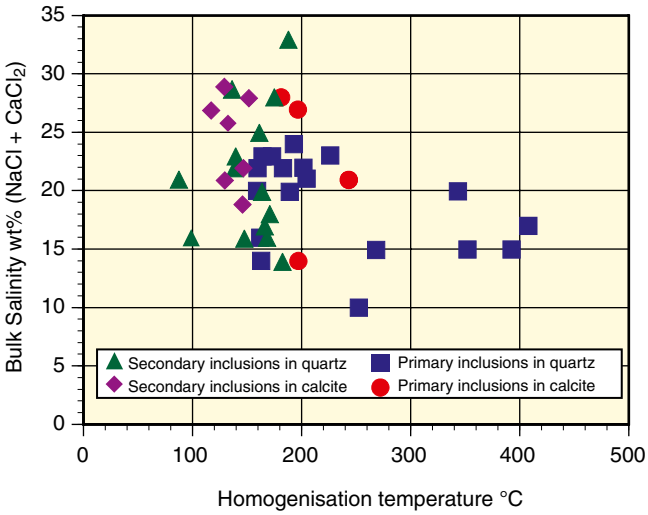

Fig. 14.54 Plot of homogenization temperatures T_h versus bulk salinities (wt.% NaCl + $CaCl_2$) of $CaCl_2$-bearing inclusions. Note the overall negative correlation between them and rapid change in Th, illustrating a fluid mixing between hot magmatic fluid and downward circulating cold $CaCl_2$ brines (After Xu 2000)

Diagenetic sulphides, Corella evaporites and associated bitterns have been extensively remobilized so that only meta-evaporite indicators, such as scapolites, albites and tourmalines, remain (Phillips et al. 1994; Oliver et al. 1994). Accordingly, the assignment of an evaporitic protolith to particular levels in this metasedimentary succession is more contentious than the Urqhardt Shale in the Leichardt Fault trough. However, noble-gas and halogen data suggest evaporite-sourced bittern brines in the sedimentary portion of the Corella protolith were significant contributors during late-Isan Orogeny albitisation in the Mary Kathleen Foldbelt and were present throughout much of the Cloncurry District during the Isan Orogeny (Fig. 14.55; Kendrick et al. 2008, 2011).

An evaporitic origin for the metasediments of Corella Formation was first postulated by Ramsay and Davidson (1970). High fluid salinities in the Corella Formation are indicated by Cl-rich biotite, amphibole, and scapolite (Fig. 14.56; maximum Cl contents: 0.60 wt%, 1.24 wt%, 3.67 wt%, respectively). Some SO_3 is present in almost all samples implying the former presence of $CaSO_4$. Reinhardt (1992) showed that the Corella Formation in the Rosebud Syncline now consists of interlayered Al- and Mg-rich metapelites, Ca-rich rocks, feldspathic schist, and scapolite schists that were originally deposited as pelite-carbonate-evaporite sequences in a Mid-Proterozoic ensialic rift basin. Widespread evaporite deposition took place in the final stage of rift sedimentation within a hypersaline shallow-water

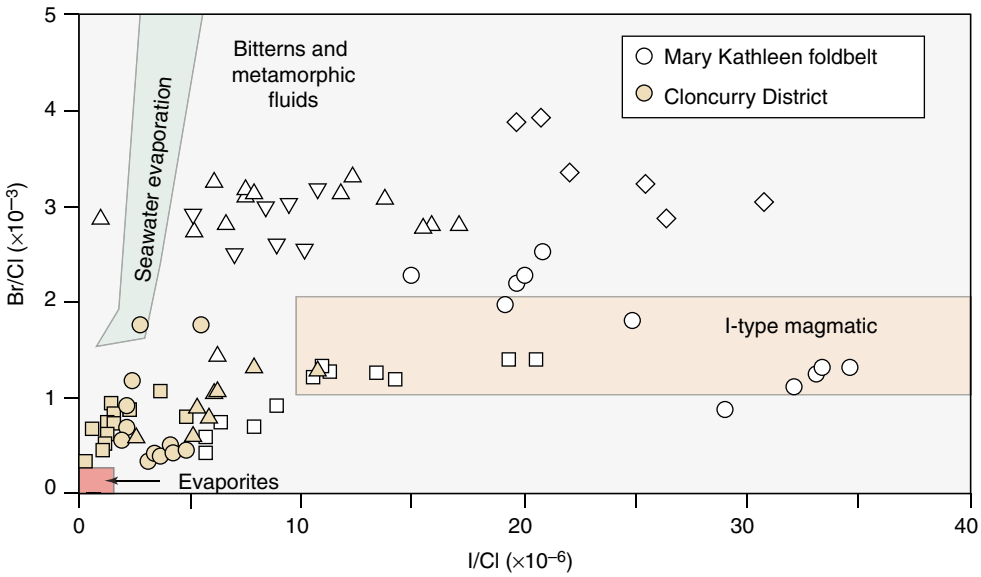

Fig. 14.55 Fluid inclusion halogen signature associated with albitisation in the Mary Kathleen Fold Belt (*open symbols*) and Cloncurry District (*closed symbols*). The Cloncurry District fluids have fractionated halogen signatures characteristic of fluid interaction with meta-evaporitic scapolite (After Kendrick et al. 2008)

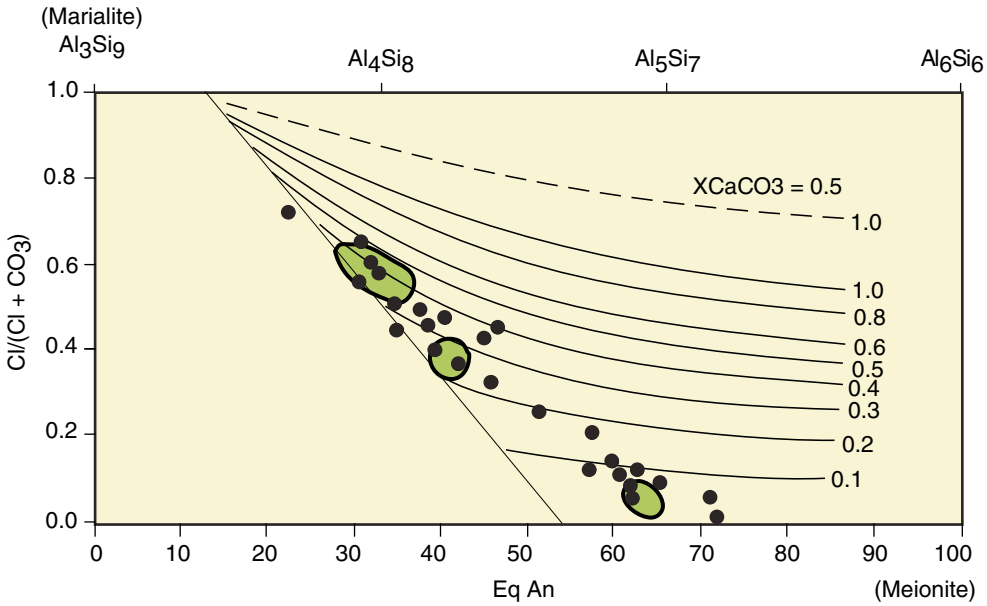

Fig. 14.56 Compositions of scapolites (low F/R group) from a single outcrop (*shaded zones*) in the Mary Kathleen Foldbelt are plotted on the equivalent anorthite/fluid salinity plot. *Black circles* are data points from Ellis 1978 (After Oliver and Wall 1987)

environment (Neumann et al. 2009). The compositional variation of scapolite in the Rosebud Syncline on a layer-to-layer scale excludes large scale infiltration of externally derived fluids in the metasediments, but suggests variable proportions of evaporitic minerals in different layers and small scale variations of fluid salinity during metamorphism.

With burial, the Corella Formation evolved in concert with its distinctly saline fluid suite under P-T conditions that initially were perhaps close to those of peak metamorphism. This pulse of sodic immersion first occurred during the extension phase (1,760–1,730 Ma), and was coincident with intrusion of voluminous granitic and doleritic magmas (Wonga Suite) at ≈5–10 km depths into the carbonate-evaporite-dominated Corella Formation (Fig. 14.57a; Oliver et al. 1994; Oliver 1995). Widespread high-temperature metasomatism ensued, involving scapolitization in dolerites, formation of albite-scapolite shear zones in granite, exo- and endoskarn formation, and a zone of K-Na-Ca alteration in the lowermost Corella Formation.

Granites and dolerites were altered to an unusual Na-Ca-rich bulk composition, reflecting infiltration of highly saline, chemically reactive externally-derived sodic fluids. The alteration products and their distribution suggest not only reaction of magmatic/aqueous fluids with the saline country rocks but also extensive halite alteration/dissolution and hydrothermal recirculation of saline fluids back into the intrusive bodies. According to Oliver and Wall (1987) the bulk of fluid flow occurred at high temperatures (500–700 °C), and the major element and isotopic fronts within the metasediments were generally not smoothed out by the effects of temperature gradients.

Oliver and Wall (1987) divided the lithologies of the Mary Kathleen Foldbelt into two distinct groups: a low fluid/rock (F/R) group and a high F/R group. The low F/R group is comprised of large areas of pristine metasediments showing evidence for internal buffering of fluid composition, as shown by $\delta^{18}O$ and $\delta^{13}C$ signatures typical of metamorphosed marine carbonates. In these low F/R metasediments the progress of calcsilicate reactions, and scapolite compositions vary greatly between adjacent layers. In contrast, the high F/R group is an assemblage developed in pretectonic intrusive rocks, as well as in metasomatic zones of calcsilicates around the margins of the intrusives (Fig. 14.57b). This group is characterised by scapolitised metadolerites, albitised calcsilicates, and large calcite pods and veins with ^{18}O- and ^{13}C-depleted values. This group indicates localized throughput of predominantly externally-derived hypersaline fluid, at high F/R ratios. It accompanied the initial metamorphic peak of 560–630 °C and 3–4 kbar and subsequent cooling.

Scapolitic layers in the foldbelt comprise approximately 40 % of the metasedimentary sequence (low F/R group; Unit A and B in Fig. 14.57b). and scapolitic modes are typically in the range 5–35 %, with average chlorine contents ≈1.5 % (Fig. 14.56). Plots of Mary Kathleen Foldbelt metasediments compared with plots from the experimental work of Ellis (1978) indicate that fluids in equilibrium with the chloride-rich scapolites must have been hypersaline, particularly in calcite-bearing metasedimentary assemblages, with >30 mol% NaCl equivalent (Fig. 14.56; Oliver and Wall 1987). Abundant three-phase halite-bearing primary fluid inclusions in scapolite, amphibole and quartz are further evidence of synmetamorphic hypersaline conditions. The Cl content in units A and B (low F/R) varies widely, even in individual outcrops, indicating small-scale salinity gradients associated with the original Cl content of

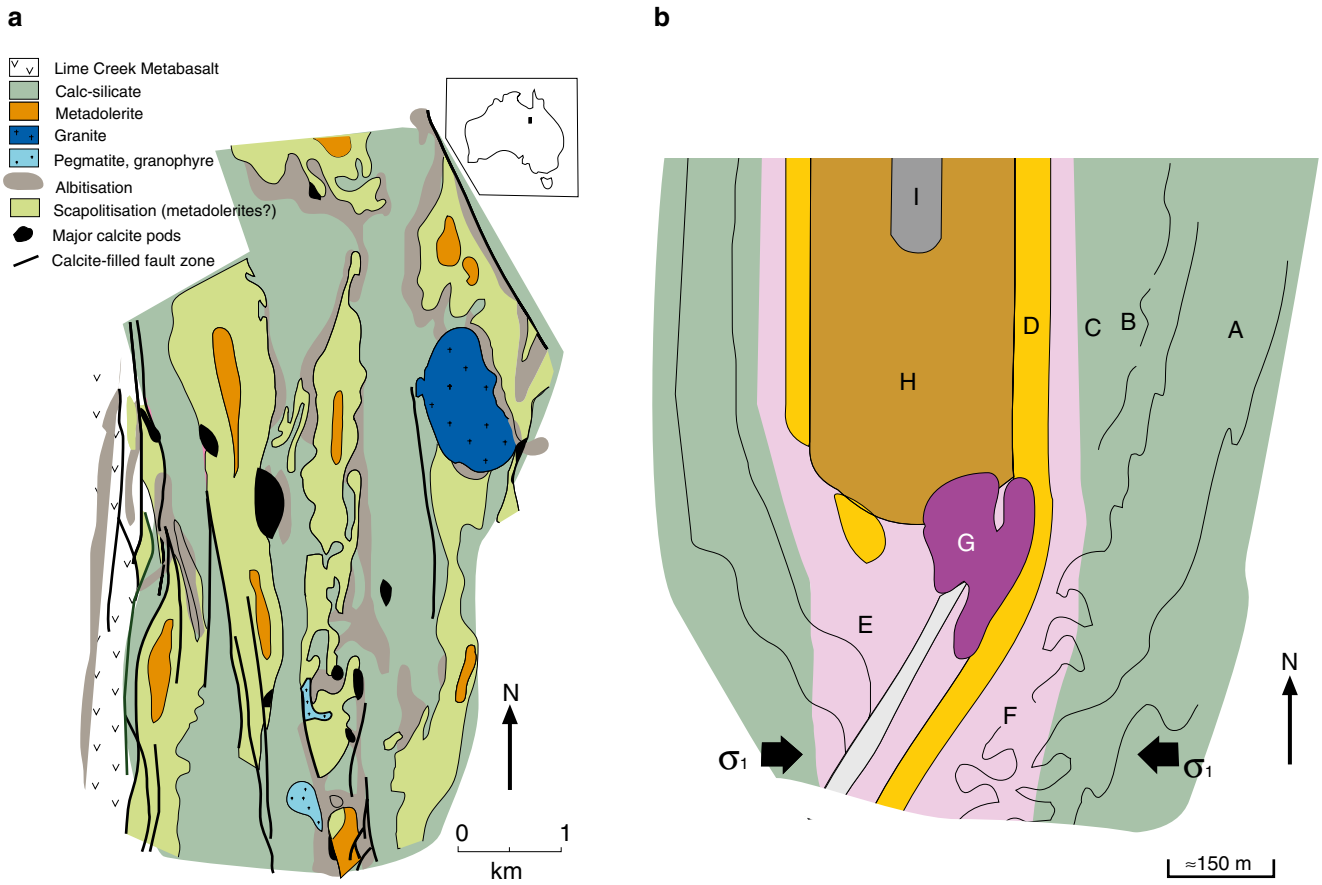

Fig. 14.57 Geology of Mary Kathleen Foldbelt. (**a**) Portion of the foldbelt showing distribution of pristine calcsilicate relative to albitised equivalents, shear zones, and scapolitised metadolerites. *Inset* shows locality of foldbelt. (**b**) Model of influence exerted by competent meta-intrusive units on localisation of fluid flow. Unit *A* is pristine calcsilicates; *B* is zone of boudinage and minor veining in zones of high differential stress; *C* is albitised and brecciated calcsilicates (failure adjacent to shear zone); *D* is albite-calcite shear zones; *E* is strain-shadow zone – abundant calcite veins and albitite breccia; *F* is refolded brecciated folds in albitised calcsilicates; *G* is large calcite pods in tensile and shear zones; *H* is scapolitised orthoamphibolite; *I* is scapolite poor metadolerite (After Oliver and Wall 1987)

the metasedimentary protolith are still retained in the sequence (Fig. 14.57). Similarly, the highly variable Cl content in the biotites in units A and B suggests a protolith differential in the low F/R group. The original proportion of halite was at least 15 % of the sedimentary sequence and probably much higher, especially if the effects of diagenetic dissolution and the likely inefficiencies of halite incorporation into scapolite are considered.

Major competency contrasts between meta-intrusive and calcsilicate metasediments of the Corella Fms influenced stress and strain patterns around the igneous bodies, which in turn controlled fracture permeability and the focusing of the interacting metamorphic fluids (Fig. 14.57b). The relatively brittle behaviour of the meta-intrusive rocks favoured the development of small-scale fracture permeability and consequent pervasive alteration of these bodies. Calcite vein systems (Units C and D) and intensely albitised calcsilicate breccias (Unit E) are localized in shear zones and dilatant areas around the meta-intrusives, either where shear stresses were high or where all stresses were low, resulting in shear and tensile failure, respectively (Units F and G). Thus, permeability enhancement, and the development of major fluid pathways during regional metamorphism of the terrane, is systematically related to variations in the stress field accompanying deformation. Oliver et al. (1994) favour a model where fluid was preferentially channelled along specific permeable conduits, including former evaporite layers, before interaction with the now exposed altered rocks. Fluid was probably driven by both convective circulation and dilatancy-related deformation accompanying emplacement of magmas into a major crustal extensional décollement.

Regionally, the halites and subsequent scapolites of the Corella Formation evaporites played an ongoing role over more than 600 million years of metasomatic alteration in the Mary Kathleen Foldbelt. There were four phases of deformation-related hydrothermal activity in the region (D1-D4), which occurred over a time range from at least 1,750–1,100 Ma, and all were associated with evaporite-derived

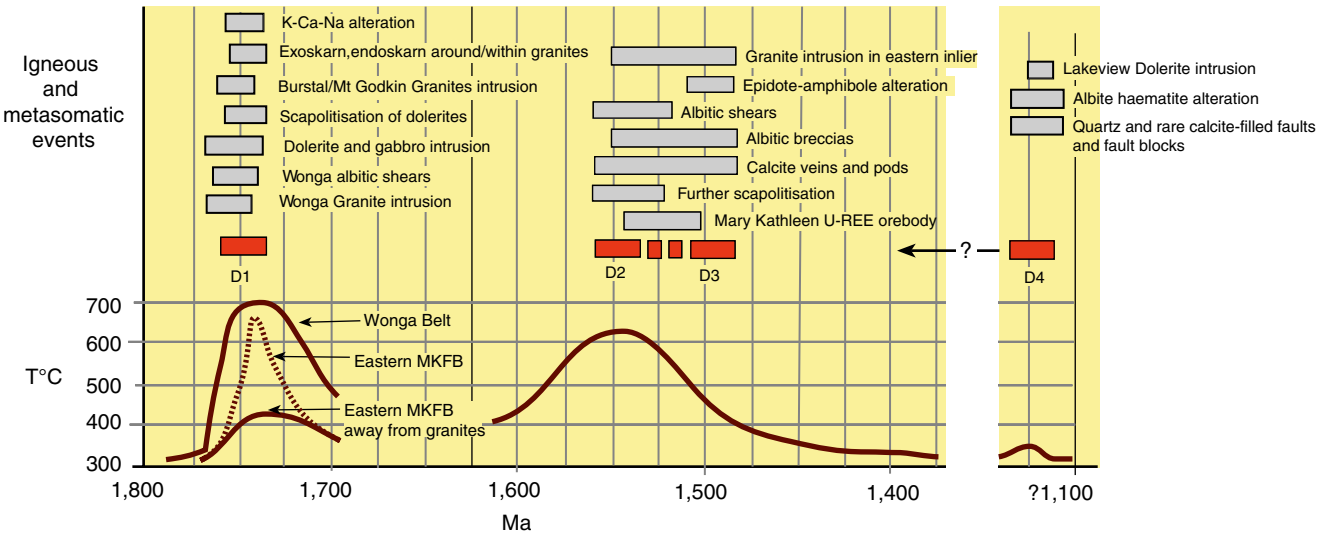

Fig. 14.58 Hydrothermal history of the Mary Kathleen Foldbelt (MKFB), the time-temperature lines are poorly constrained by available geochronological data and are schematic (After Oliver 1995)

saline fluids (Oliver 1995). The Na–Cl brine source of much of these highly saline metasomatic fluids was halite in the Corella Formation, its halokinetic derivatives, and subsequent scapolites.

In Phase 1, deformation, contact metamorphism, and metasomatism, accompanied the emplacement of the Wonga Batholith along with related mafic and felsic intrusives (1,750–1,730 Ma; Fig. 14.58). This occurred not long after the deposition of the volcano-sedimentary package that included the evaporitic protolith to the Corella Formation (1,750–1,738 Ma; Foster and Austin 2008). It involved fluid pathways related to emplacement of intrusions in and above a major crustal subhorizontal extensional shear zone where a predominantly ductile lower plate -Wonga Belt- was flanked by a predominantly brittlely deformed upper plate -Corella Formation. Intrusive rocks and contact aureoles formed discrete kilometre-scale bodies within the Corella Formation during Phase 1. As a consequence, fluid flow during Phases 2 and 3 (regional deformation and amphibolite-facies metamorphism) was localized around the boundaries of these very competent Phase 1 intrusions and contact metamorphic aureoles (Fig. 14.57b). Fluids infiltrating the rocks during Phases 2 and 3 were complex externally derived $NaCl$-$CaCl_2$-KCl-H_2O-CO_2 brines that may have undergone phase separation. This fluid flow culminated in the formation of widespread calcite vein systems (with copper) and the Mary Kathleen U-REE vein-style orebody. Mineralization was sufficiently localized by the pre-existing structural heterogeneity that many parts of the Corella Formation did not experience significant fluid flow at this time (perhaps a reflection of intrinsically lower permeability in meta-evaporite intervals not adjacent to the intrusive). Phase 4, post-metamorphic oxidising alteration (D4), was localized around major predominantly crosscutting strike-slip faults. These faults are very large with apparent strike-slip displacements of 5 to >40 km and define the most obvious crosscutting regional geological features.

Using halogen ratios in the metamorphic and hydrothermally derived scapolite from a range of rock-types in the Mary Kathleen fold belt, Hammerli et al. (2014) argue that the dominant metamorphic interactions were between bittern-grade formation waters and magmatic-hydrothermal fluids derived from granite plutons (Fig. 14.59). They conclude that halite-dissolution supplied at best only minor chlorine to fluids in the foldbelt. Chlorine/bromine ratios in metamorphic scapolite indicate that fluids were dominantly derived from basinal brines formed from sub-aerial evaporation of seawater beyond the point of halite saturation. This bittern fluid infiltrated the underlying sedimentary sequences prior to regional metamorphism. Zoned scapolites in a major late-metamorphic mineralized shear-zone record three discrete pulses of magmatic and metamorphic fluid, and suggest that fluid mixing assisted mineralization along and around this shear-zone (Fig. 14.57b). This interpretation is predicated on their conclusion that Cl and Br do not fractionate when incorporated in scapolite. Furthermore, they found unaltered rims of heavily retrogressed scapolite show indistinguishable Cl/Br signatures compared with fresh grains from the same sample, indicating retrograde metamorphism did not significantly affect Cl and Br signatures in scapolite group minerals, hence the halogen ratios are indicators of the protolith (Fig. 14.59; Hammerli et al. 2014).

Staveley Formation

The Staveley Formation (Eastern Foldbelt) was once thought to be part of the Mary Kathleen Group and indicated a conformable meta-evaporitic (middle-upper greenschist to amphibolite) transition between the Corella Fm and the Marimo Shale (Stewart 1991, 1994a, b; Krcmarov and

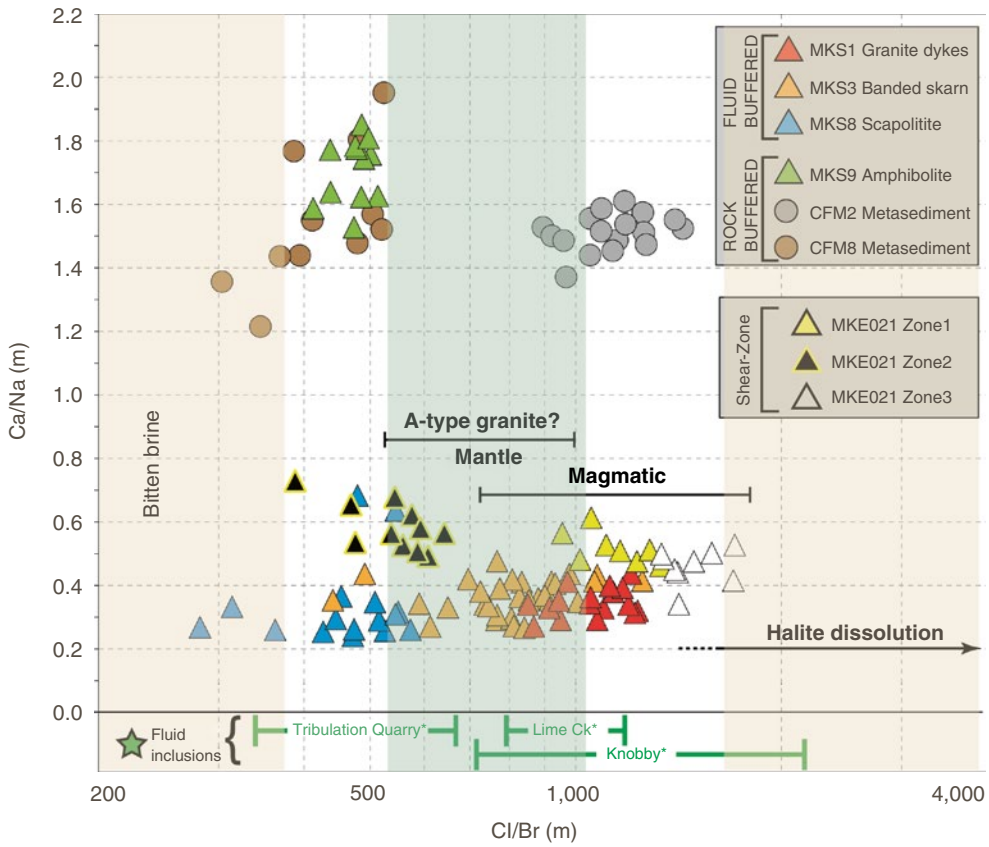

Fig. 14.59 Molar Ca/Na ratios v. molar Cl/Br ratios of fluid-buffered scapolite samples (MKS1, MKS3 and MKS8) and rock-buffered scapolite samples (MKS9, CFM2 and CFM8). Rock buffering leads to high Ca/Na ratios in scapolite. The Ca/Na variation in sample CFM8 might be due to small-scaled local equilibria. The fluid-buffered scapolite compositions fall on a fluid mixing trend between magmatic and bittern brine fluid. Plot fields of molar Cl/Br ratios of typical magmatic fluids, mantle fluids, Br-enriched bittern brine fluids and typical halite dissolution fluids are shown as shaded areas. (Figure is after Hammerli et al. 2014; Data on fluid inclusions shown in the lower part of the figure are from Kendrick et al. 2008, 2011)

Stewart 1998). More recent work by Foster et al. (2008) has shown that it is probably younger (1,610–1,675 Ma) and should be removed from this lower evaporitic grouping. It is now considered equivalent in age to the Urquhart Shale of the Western Foldbelt that hosts the Mount Isa mineralisation.

South of Cloncurry, chalcopyrite (cobaltiferous)-pyrite mineralization occurs as disseminations in pre- and syntectonic breccias in the Staveley Formation, and within disaggregated silica pseudomorphs (after thinly bedded evaporitic sulphate beds) that are associated with dolomitised limestone-calcilutites. Although this mineralization may be partly diagenetic in origin, the 200 m-thick meta-evaporitic packages are also host to a locally widespread (2–4 km long and 200 to >500 m wide) and pervasive 'redrock' styled microcline-dolomite ± hematite alteration. Within this gross alteration package there also seems to be a consistent association with narrow (10–100 m wide) linear (stratabound) semi-massive magnetite-hematite-microcline and quartz-chalcedony replacement zones. The economic significance of mineralised haematitic intervals (ironstones) in evaporitic terranes and gold deposits, such as Starra, is discussed further in Chap. 16.

Like much of the Corella Formation, the meta-evaporitic Staveley Formation experienced dissolution/alteration, paleosolution karsting (breccias), and tectonic brecciation, such that the precursor lithological details were progressively obliterated even prior to entering the metamorphic realm. The post-diagenetic to post-tectonic fluid pathway development and metasomatic alteration history of this important lithostructural package of rocks in the Eastern Succession has been traced by Stewart (1994a, b). He proposes that both the base of the Marimo Shale and parts of the underlying evaporitic-limestone dololutite have acted as conformable fluid pathways for hydrothermal and (perhaps) diagenetically derived, Cu-Au-(±Co ± As)-K-Na-Ti-REE bearing fluids and brines.

Evidence for the evaporite protolith in this amphibolite grade sequence, where the actual salts have long since disappeared, is not just mineralogical but also textural. Stewart's (op. cit.) documented evaporite indicators in the Staveley Formation include (Fig. 14.60):

1. Disaggregated chert nodules: 2–6 cm thick beds of 2–3 cm spheres comprising a collection of fragment-supported chert discoids, shingles, 'shards' and nodules with an ankerite feldspar matrix.
2. Enterolithic layers: chert nodule trains and contorted cherty nodule layers with overlying feldspathic dolomite laminae draped around nodules and slumped between them.
3. Beds of disseminated nodules and angular chert fragments with a sparry dolomite-quartz cement.

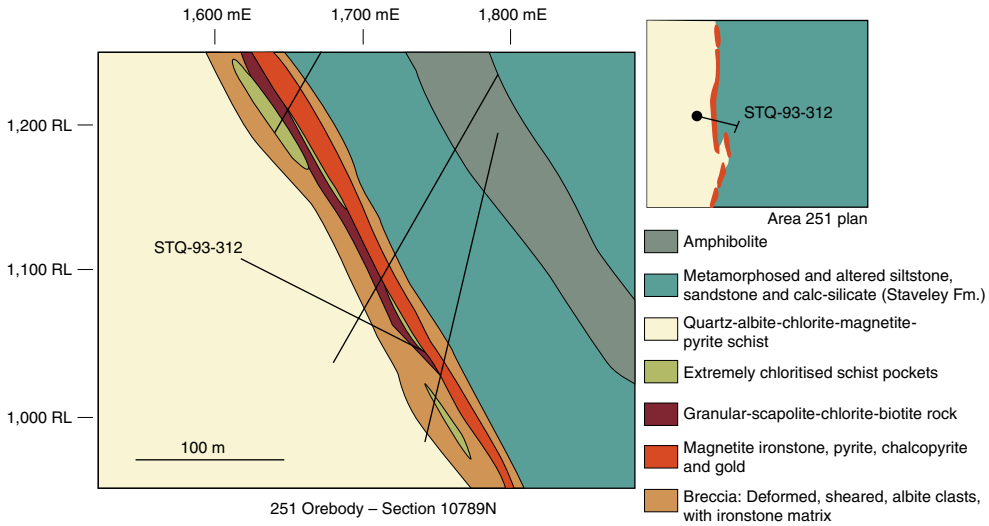

Fig. 14.60 Starra Cu-Au deposit. Cross section through 251 orebody, drill hole STQ-90-312, showing relationship between Staveley Formation, brecciated shear, ironstone lenses and Cu-Au mineralisation (After Rotherham 1997)

4. Cauliflower-textured and embayed nodules with contorted internal bands of cryptocrystalline (20 μm sized) chert.
5. Abundant hypersaline fluid inclusions (including halite crystals).
6. Displacive upward growth textures of nodules and discoids, alignment of nodule shards along low-angle cross bedding.
7. Lenticular and discoidal voids in shales. Shingle beds. Chickenwire or cottage cheese textures. Desiccation cracks. Soft sediment slumping.
8. Halite and scapolite pseudomorphs.

He shows how shallow-marine? evaporitic sulphates of the Staveley Fm. underwent Ca-Mg-Fe carbonate metasomatism and copper enrichment during diagenetic disintegration of the sulphate forms prior to general silicification.

To date workers on the various Mt Isa inlier lithologies, including the Staveley Fm., have largely ignored the possibility that halokinetic horizons in the protolith form long-lived zoned of ductility contrast (including primary and secondary salt welds, as well as fault welds) that focused various fluid conduits and channel-ways (Chaps. 15 and 16).

Willyama Supergroup: Olary and Broken Hill

The Mesoproterozoic Willyama Supergroup is part of the Curnamona Province and straddles the border between far western New South Wales and eastern South Australia (Fig. 14.61). It entrains Early to Middle Proterozoic metasedimentary and minor meta-igneous rocks that have a total stratigraphic thickness estimated at 7–9 km. It is subdivided into several structural blocks dominated by the Broken Hill and Euriowie Blocks in NSW and the Olary Block in South Australia (Figs. 14.61 and 14.62; Stevens et al. 1988). Late Proterozoic (Adelaidean) sedimentary cover separates the Euriowie and Broken Hill Blocks, while the Broken Hill and

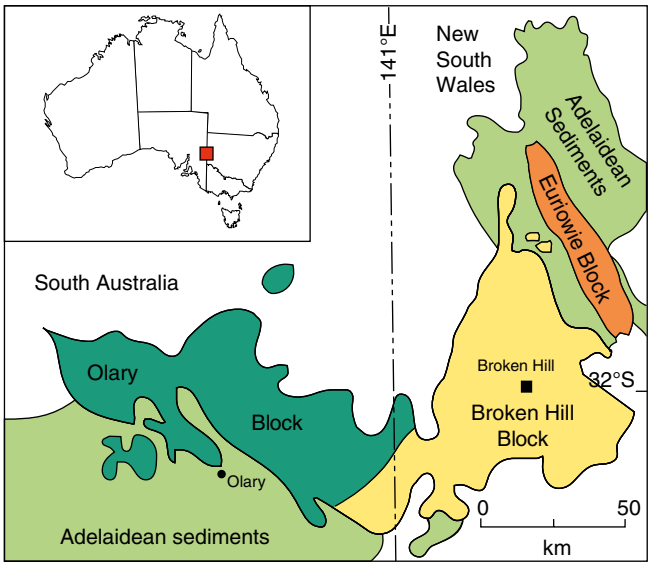

Fig. 14.61 Location of the Willyama Block, made up of the Olary Block and the Broken Hill Block

Olary Blocks are separated by Cenozoic cover in the north and an inferred fault in the south.

As well as being pervasively metamorphosed (amphibolite to granulite facies), the Willyama Supergroup is intensely mineralised. In the Olary Block copper and uranium deposits are the most significant, with lesser iron, barium, cobalt, tungsten, gold and fluorite. In the Euriowie Block tin deposits are the most significant and common, while minor deposits of lithium, niobium, tantalum, copper and iron are also present. The Broken Hill Block is dominated by deposits of lead, zinc and silver with lesser tungsten, copper, iron, cobalt, gold, nickel, platinum, tin, beryllium, uranium and fluorite. This block includes the 250 Mt of ore in Broken Hill lead-zinc-silver body, which is also the world's largest known Pb–Zn–Ag deposit.

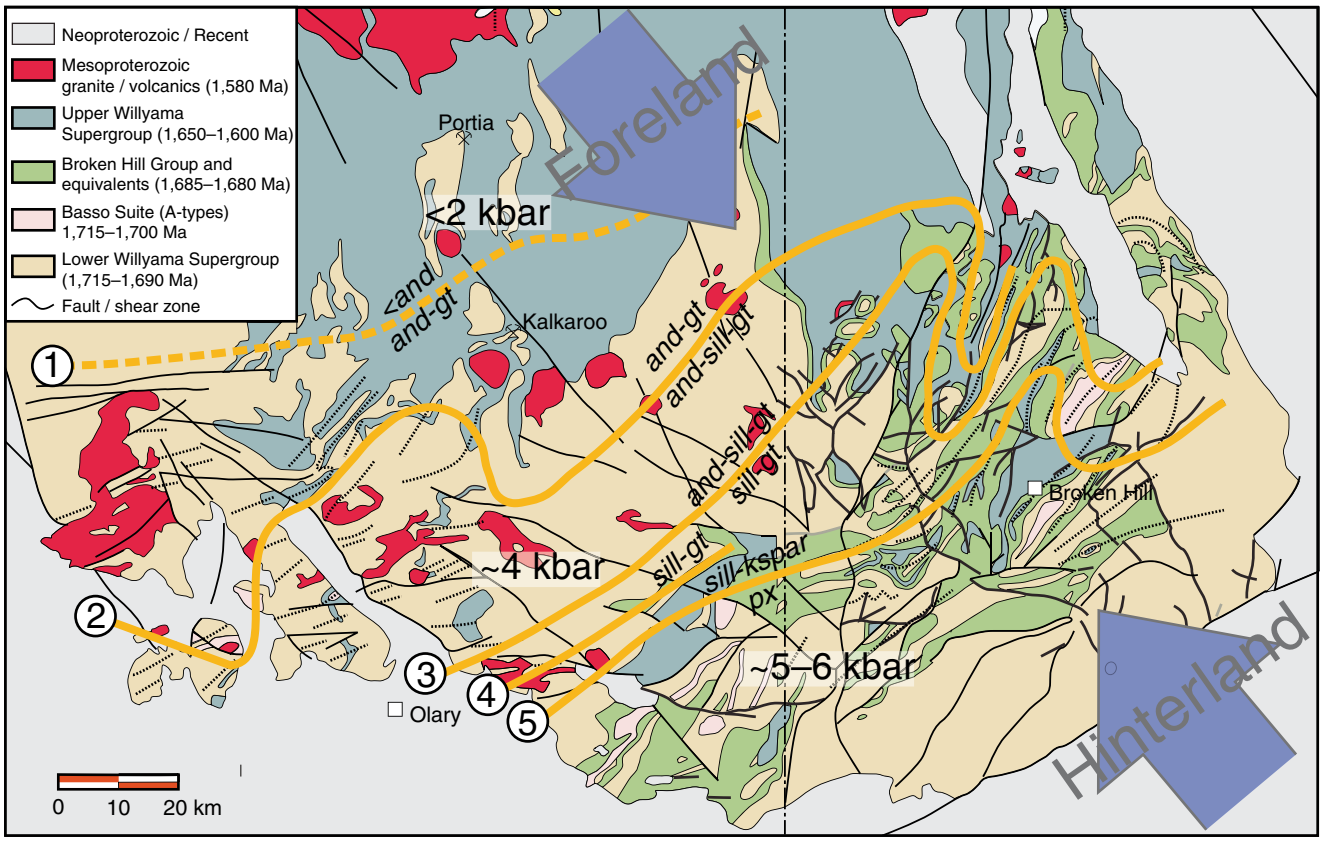

Fig. 14.62 Map of southeastern Curnamona Province showing the distribution of deformation and metamorphism associated with the 1,600–1,580 Ma Olarian Orogeny. The intensity of tectonism decreases toward the NW, suggesting the orogen may have had a NW–SE component of tectonic transport. The *dotted black lines* indicate axial traces of D2 folds which have upright to reclined orientations and deform earlier low-angle large-scale folds that invert large areas of the stratigraphy. The numbered lines (1–5 represent isograds of increasing metamorphic intensity. The ≈1,580 Ma granites immediately postdate the penetrative deformation (*and* andalusite, *gt* garnet, *Kspar* K-feldspar, *px* pyroxene, *sill* sillimanite) (After Hand et al. 2008)

The Willyama Supergroup metasediments are thought to have been deposited in an ensialic intracontinental rift zone (Conor and Preiss 2008; Barovich and Hand 2008). Multiple tectonic episodes during the ≈1,600 Ma Olarian Orogeny and the ≈500 Ma Delamerian Orogeny have dismembered and inverted the stratigraphy and metamorphosed the succession well in to granulite facies (Fig. 14.62). Lithologies in the Olary Block indicate rift margin-related conditions, whereas the majority of lithologies in the Broken Hill Block indicate more central and deeper water portions of perhaps the same progressively developing rift system (Willis et al. 1983; Plimer 1984, 1985; Vernon and Williams 1988; Slack et al. 1989; Cook and Ashley 1992; Cook 1993; Bierlein et al. 1995; Barovich and Hand 2008). Due to pervasive intense deformation and high grade regional metamorphism any primary evaporites in the rift and halokinetically mobilised into the deeper water slope and rise sediments have long since been destroyed and only subtle indications remain (Cook and Ashley 1992), such as boron isotope signatures in tourmalines (Slack et al. 1989) and the meta-evaporite associations in some stratiform scheelites (Plimer 1994).

Olary Block

The Willyama Supergroup in the Olary Block, west of the Broken Hill Block, consists of upper greenschist to amphibolite grade metamorphosed sedimentary and minor igneous rocks. The sequence is dominated by meta-clastic and meta-chemical sediments (evaporites and exhalites; Lottermoser and Ashley 1996; Conor and Preiss 2008; Heimann et al. 2013). Using lithological, geochemical and fluid inclusion data, Cook and Ashley (1992) first demonstrated the widespread importance of meta-evaporite associations within the Willyama Supergroup in the Olary Block.

The stratigraphic succession in the Olary Block displays a change in general composition from quartzo-feldspathic at the base through calcsilicate-rich to pelitic at the top (Fig. 14.63; Clarke et al. 1987; Forbes 1991; Cook and Ashley 1992). The Composite Gneiss Suite is the basal unit and is made up of crudely layered coarse-grained quartz-feldspar-biotite ± sillimanite ± garnet gneiss (migmatic). It grades into psammopelitic and pelitic schists, implying a sedimentary precursor; but there are zones exhibiting complete conversion, via *in situ* migmatites, into banded, migma-

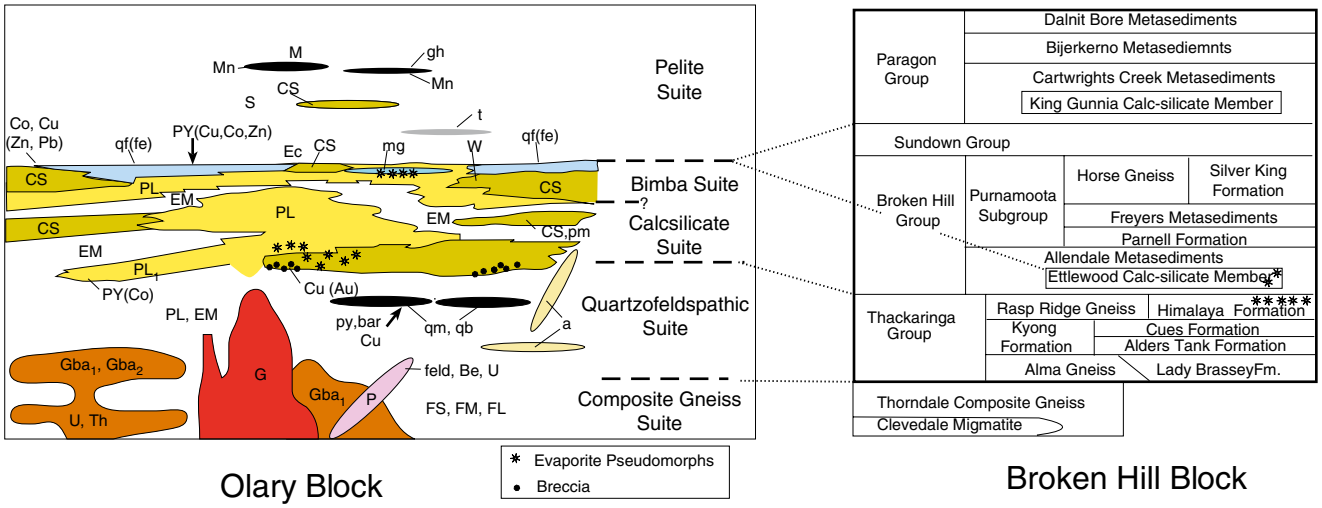

Fig. 14.63 Mineralisation types and stratigraphic sequences in the Olary Block and Broken Hill Block comprising the Willyama Supergroup (After Cook and Ashley 1992). Abbreviations; *S* psammitic schist, *M* psammopelitic schist, *EM* psammopelitic and pelitic rocks, *PL* plagioclase rock (albite-quartz rock), *PL1* pyritic albite-quartz rock, *FS* psammite-rich composite gneiss, *FM* psammopelite-rich composite gneiss, *FL* composite gneiss with leucocratic layers, *CS* calcsilicate rock, *PY* pyrite-rich rock, *Ec* carbonaceous pelite, *P* pegmatite, *G* post-tectonic granite, *Gba1* early syntectonic granite (pink porphyritic), *Gba2* early syntectonic granite (sodic), *a* amphibolite, *qf(fe)* quartz-Fe sulphide rock (Bimba horizon), *mg* magnetite-garnet rock, *qm* quartz-magnetite rock, *qb* quartz-baryte rock, *gh* garnet-quartz rock, *W* scheelite, *t* tourmalinite, *pm* piemontite-bearing rock

titic and locally massive leucocratic granitoids with intrusive characteristics (Fig. 14.64; Cook and Ashley 1992).

This is overlain by the laterally extensive Quartzofeldspathic Gneiss Suite, which is dominated by massive to layered quartz-albite and quartz-K-feldspar gneiss. These rocks have a felsic volcaniclastic precursor (Cook and Ashley 1992) and are locally intercalated with pelitic mica schists, quartzites and calcsilicate-rich layers. Radiometric U-Pb dating of zircons gives ages of 1,699 ± 10 and 1,703 ± 6 Ma for samples from a felsic metavolcanic rock and a co-magmatic granitoid (Cook 1993). Minor rock types include quartzite, laterally discontinuous horizons of quartz-magnetite-hematite and quartz-magnetite-baryte rocks along with rare amphibolite and tourmalinite.

The overlying Calcsilicate Suite is characterised by calcsilicate-bearing albitites, grading into pure calcsilicate rocks. Unusual chemical sediments of possibly exhalative hypersaline origin, such as scheelite-bearing rocks, hematite-rich banded iron formations and Mn-rich rocks, are common in this laterally extensive suite. Cook and Ashley (1992) proposed an evaporitic origin for the albitite- and calcsilicate-rich metasediments on the basis of their textures, mineralogy and calcsilicate pseudomorphs after dolomite and gypsum. Rocks of sodic composition abound, represented by albite-quartz-rich rocks (+calcite, actinolite, epidote, garnet, clinopyroxene), and are inferred to represent metamorphosed analcite-rich strata of felsic volcaniclastic provenance, with variable proportions of evaporitic carbonates. Rocks in the Olary region thought by Cook and Ashley (op. cit., p. 218) to be meta-evaporitic carry a distinctive suite of minerals including; albite, K-feldspar, amphiboles, clinopyroxene, scapolite, garnet, calcite, phlogopite, tourmaline, titanite and apatite, with several phases rich in fluorine and chlorine. Zoned amphibole grains (e.g. core-rim variations of F: 0.3–0.4 %, Cl: 0.04–0.22 %, Na_2O: 0.76–1.56 %, K_2O: 0.32–1.41 %) coexisting with pyrite indicate substantial enrichment of dissolved volatiles in the fluid phase during prograde metamorphism, presumably derived from the breakdown of former Na-, K-, and Cl-rich minerals. Phlogopite and titanite contain up to 3.50 and 2.31 %F, respectively. Scapolites are Cl-rich, containing up to 2.66 % Cl (mean 2.46 %). Feldspars are near end-member albite (usually exceeding Ab_{97}) and microcline, with the latter containing up to 4 % celsian.[14] Garnet composition is principally dependent on whole-rock Mn content, due to the strong partitioning of Mn into the garnet; low Mn rocks contain grossular-andradite types, whereas manganiferous samples (>0.8 % MnO) contain spessartine-grossular-andradite + calderite. Amphibole compositions include actinolite, edenite, and various hornblendes and clinopyroxenes are of the diopside-hedenbergite series. Tourmaline is dravite-schorl and occurs with end-member fluor-apatite. In addition, gypsum was recognized as pseudomorphic moulds and as epidote pseudomorphs in the rocks of the Calcsilicate Suite and in Bimba Iron Formation.

Whole rock analyses where substantial alkali enrichment is evident provide additional support for evaporitic condi-

[14]Celsian is an uncommon feldspar mineral, a barium aluminosilicate, $BaAl_2Si_2O_8$. It is a metamorphic mineral that may indicate an exhalative hydrothermal precursor.

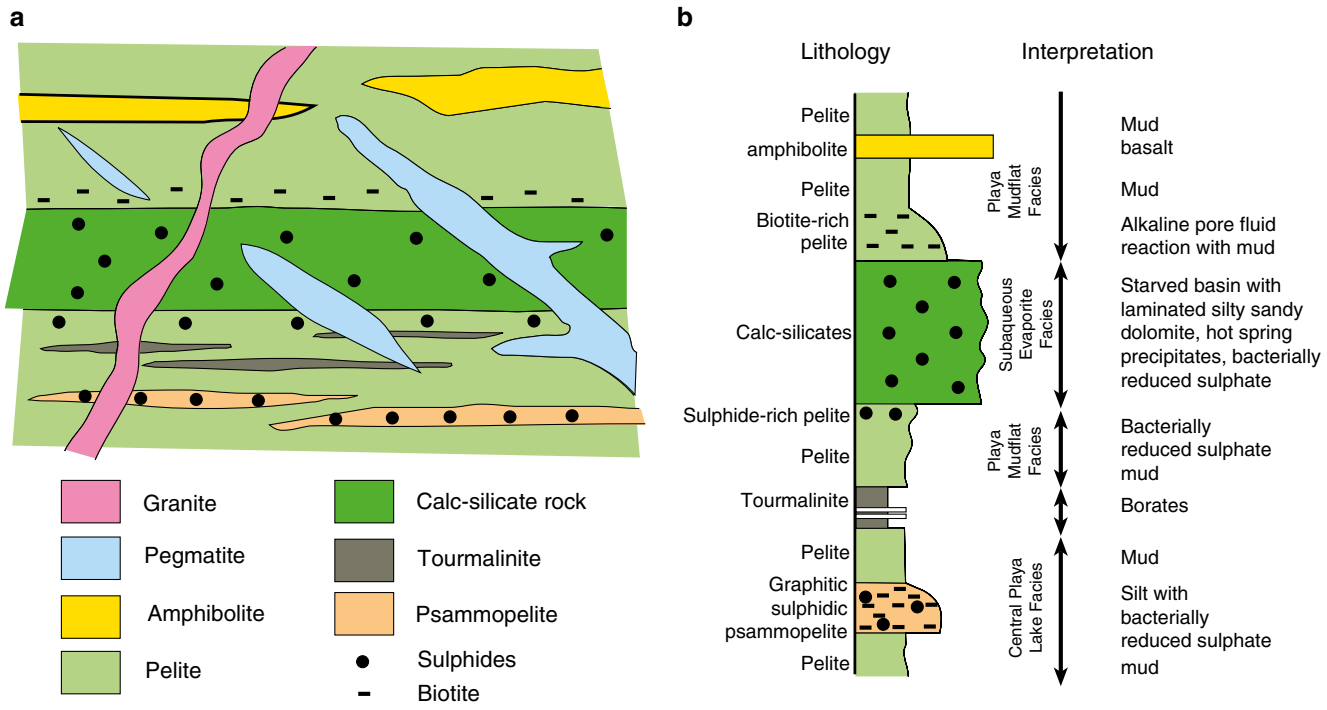

Fig. 14.64 (**a**) Schematic of stratigraphic relationships between the stratiform scheelite-bearing calcsilicate rocks and other lithologies in the Lakes Nob region of the Broken Hill Block. (**b**) Palaeolimnological interpretation of the observed sequence in the Allendale metasediments and the Ettlewood Member at Lake Nob (After Plimer 1994)

tions during deposition of some strata, other elements typically vary as a function of dilution by SiO_2 (Cook and Ashley 1992). Pseudomorphs after carbonate were also observed in calcsilicate-bearing quartz-albite rocks of lower metamorphic grade and interpreted to be pseudomorphs after dolomite that was transformed during prograde metamorphic reactions. The presence of halogen-rich minerals in a distinctive sodic mineral assemblage, in addition to hypersaline fluid inclusions, pseudomorphic voids and minerals after gypsum and carbonate, tourmalinites with isotopically light boron, imply a nonmarine evaporite protolith.

A transition from generally magnetite-bearing to sulphide-bearing strata defines the passage from the Calcsilicate Suite into the overlying quartz-feldspar-calcsilicate-carbonate-sulphide-bearing Bimba Suite. The Bimba Suite is a thin (<50 m), laterally continuous unit that, due to the widespread occurrences of stratiform Fe-dominated sulphides, is the focus of metal exploration interest in the Olary Block. Oxidation of sulphides (dominantly pyrite and pyrrhotite), calcsilicates and carbonates has led to distinctly gossanous surface exposures typically associated with anomalous Cu, Zn, Pb, Co, As, Ag, Au, Mn, Ba, W, Mo, Bi and U.

The uppermost unit of the Willyama Supergroup metasediments in the Olary Block is the widely distributed Pelite Suite. It is made up of quartzmica-garnet-andalusite-sillimanite-tourmaline schists, which are interbedded with layers of coarser-grained quartzo-feldspathic meta-siltstone and quartzite. Lenses of Mn-rich banded iron formations and garnet-quartz rocks occurring at the base or within the lower parts of the Pelite Suite imply continuing exhalative activity during deposition of this unit (Cook and Ashley 1992).

In addition to recognizable metasediments, at least four phases of widespread emplacement of granitoids have been identified, ranging from pre- through syn- to post-high grade metamorphism in age (Cook and Ashley 1992). Five deformational episodes (D_1-D_5) are recognized throughout the Olary Block (Berry et al. 1978; Clarke et al. 1987). Events D_1-D_3 only affected the Willyama Supergroup and some granitoid units. They occurred during the Middle Proterozoic Olarian Orogeny at about 1,600–1,580 Ma. Events D_4-D_5 also deformed the Adelaidean sequence during the Delamerian Orogeny (500 Ma; Preiss 1987).

Broken Hill Block

The Willyama Supergroup in the Broken Hill Block has undergone regional low-P/high-T prograde metamorphism. A series of prograde metamorphic zones is present, grading from upper greenschist to lower amphibolite. As in the Olary Block, the presence of former widespread evaporites in the district can only be inferred on the basis of indirect lithologic, chemical, and isotopic data (Slack et al. 1993). Lithologic evidence for former evaporites includes the occur-

rence of bedded albitites in the Himalaya Formation at the top of the Thackaringa Group, which are believed to represent clastic sediments or tuffs that were largely altered to analcime in an alkaline lake setting (Fig. 14.64; Plimer 1977; Stevens et al. 1988). Other evidence for evaporites and/or nonmarine depositional settings comes from (Slack et al. 1993):

- The presence of abundant scapolite locally in the Ettlewood Calcsilicate Member at the base of the Broken Hill Group, which in correlative rocks of the adjacent Olary Block in the South Australia and contains up to 2.7 % Cl (Cook 1992; Cook and Ashley 1992);
- Abundant magnetite disseminated in some quartzofeldspathic rocks of the Thackaringa Group suggesting protoliths of oxidised red beds;
- Quartz-muscovite nodules in the Rockwell area (Himalaya Formation) that have crystal forms suggesting pseudomorphic replacement of gypsum by silica in nonmarine evaporitic environments.

Quartz-albitites in the Thackaringa Group occur below the Broken Hill Main Lode (Fig. 14.63), while psammopelitic units occur above and below the quartz-albitites. The albitites are light coloured and comprise uniformly grained quartz + plagioclase (An_{8-15}) + minor biotite and pyrite locally interlayered with micaceous paragneiss. They have unusually high SiO_2, Na_2O contents, and very low CaO, MgO, K_2O (all <1 %), Pb and Zn (<20 ppm) contents compared to surrounding units. Complex zircon populations occur in the quartz-albitites (Love 1992; Nutman and Ehlers 1998). The protolith of these rocks has been subject to longterm debate, although hypersaline fluids figure in most accounts. Suggested protoliths include: rhyolites, tuffs, clastic sediments (arkoses) or evaporites, with tuffs flushed by hypersaline brines the most popular model. Altered rhyolite or rhyolitic tuffs are a possible protolith, but they would have had a very special composition (to justify the unusually high Si and Na content of the consequent quartz-albitites). An igneous precursor does not easily account for the detrital zircon populations that occur within the albitites. An arkosic protolith can account for the detrital zircons, but would require an unusually albite-rich source region or extensive post-depositional alteration.

Whatever the precursor, metasomatism and/or analcimitization have altered significant portions of the protolith. Analcimization is common in saline lakes and analcimization of tuff was first suggested for the Broken Hill albitites by Plimer (1977). An analcime-rich saline precursor is attractive as it explains the high Na content along with the occurrence of scapolite and saline fluid inclusions and the detrital zircons. Prograde metamorphism (at T >200 °C) of a quartz-analcime rock would readily produce a quartz-albitite. However, analcime-rich rocks can be produced from tuffs, argillic or arkosic sediments (rhyolite *sensu stricto* probably being too massive to react). A mix of unanalcimized tuffs and arkosic sediments in a saline continental lacustrine rift setting explains most of the characteristics of the quartz-albitites in the Broken Hill Olary region.

The former presence of evaporites at the time of albitite formation is also suggested by the occurrence of chemically unusual halide minerals in the main Pb-Zn-Ag lodes at Broken Hill (Slack et al. 1993). The oxidised ores of the main lodes are famous for containing an unusual suite of secondary halides including: ioargyrite [AgI], bromargyrite [AgBr], marshite [CuI], miersite [(Ag,Cu)I], and embolite [Ag(Cl,Br)]. These halides were reportedly concentrated at the base of the gossan, above the supergene ores and formed following the weathering of the main ore loads in the Permian and/or Tertiary. Most workers have assumed that the source of the Cl, Br, and I within oxidised ores in such desert environments is from exotic groundwaters or seawater-derived salt spray, with little if any contribution from the protolith. Similar iodine and nitrate accumulations in the soils of the hyperarid Atacama Desert, South America, are discussed in Chap. 11. Slack et al. (1993), argue that in the case of Broken Hill a local bedrock or protolith source is equally plausible, if not compelling. They also contend that much of the sulphur in the Pb-Zn-Ag ores may also have come from nonmarine evaporites.

Tourmaline-rich rocks are widespread, but minor, lithologies within the Early Proterozoic Willyama Supergroup in the Broken Hill district (Fig. 14.64a). Tourmaline concentrations occur in stratabound and local stratiform tourmalinites, clastic metasedimentary rocks, quartz-gahnite lode rocks, stratiform Pb-Zn-Ag sulphide ores, garnet quartzites, stratabound scheelite deposits, quartz-tourmaline nodules, discordant quartz veins, and granitic pegmatites. Most of the tourmaline-rich rocks are within the Broken Hill Group that hosts the main Pb-Zn-Ag ores.

Combined field and geochemical data indicate that the tourmalinites represent normal clastic sediments that were metasomatically altered by boron-rich hydrothermal fluids at or below the sediment-water interface. Slack et al. (1993) suggest the hydrothermal system(s) acquired abundant boron by leaching evaporitic borates within the Thackaringa Group, the stratigraphic sequence that underlies the Broken Hill Group and hosts most of the tourmaline concentrations. They argue that evaporites of the Thackaringa Group provided a source of readily extractable boron for formation of the tourmalinites and also acted as a source for the fluoride, sulphur, and perhaps the carbonate in the main lodes; such evaporites may have been critical for increased metal chloride complexing and transport necessary for deposition of the high-grade Pb-Zn-Ag ores.

Plimer (1994) interprets scheelite ($CaWO_4$ and an ore of tungsten) in the Willyama Supergroup -Allendale calcsilicates-

to be part of a metamorphosed sequence of intracontinental rift sediments, volcanics and hot spring precipitates. Scheelite and the calcsilicate host, which is enriched in F and Zn, constitute a conformable sequence of carbonaceous-sulphidic metabolites, tourmalinites, and amphibolites. It overlies a gneiss-metasediment sequence, part of which (Ettlewood calcsilcates) is interpreted as meta-evaporitic (Fig. 14.64b). The distribution of scheelite is unrelated to syntectonic pegmatite or posttectonic granitic rocks. The scheelite underwent only minor remobilization during tectonism. Plimer (op. cit.) interprets the calcsilicate rocks as dolomitic limey sediment that formed part of a playa-lake sequence into which B, W, Zn, and F-rich alkaline hot springs debouched (Fig. 14.64b). Coeval sudden deepening, an increased geothermal gradient, deposition of the Broken Hill Pb-Zn-Ag sulphide orebodies, and siliceous exhalite deposition all occurred after deposition of the evaporite sequence. Thus components for the highly saline Broken Hill Pb-Zn-Ag ore fluid may have been leached from the underlying evaporites and redeposited higher in the stratigraphy.

Although not considered in the current interpretations of the Broken Hill Block, it is interesting to postulate, what was the evaporite distribution in the Broken Block prior to its entrainment and alteration/destruction in the metamorphic realm? Much of meta-sediment in the Broken Hill Block is interpreted as accumulating in a deepwater setting within an evolving rift to passive margin association. If evaporites were part of this association, it is highly likely that at the time of such widespread deep water sedimentation any subjacent salt masses were allochthonous halite tongues, as was the case in the Mt Isa Inlier (Warren 2000a). These salts were sourced from a thicker older halokinetic mother salt horizon deposited in an earlier stage of rifting. Prior to onset of its flow, it was a unit situated deeper in the rift fill and perhaps updip in the basin fill, leading to gravity-glide shear-related emplacement, much like the Louann Salt in the modern Gulf of Mexico and the Aptian-sourced salt allochthons of offshore Brazil, or the Atlantis II deep region in the Red Sea.

Pine Creek Inlier, Northern Territory

The Pine Creek Inlier is a major mineral province in the Northern Territory, Australia, and covers an area of some 66,000 km^2 (Fig. 14.50 for location). It entrains Archaean and Paleoproterozoic rocks surrounded by subhorizontal strata of several intracratonic sedimentary basins that range in age from Mesoproterozoic to Mesozoic. It entrains the Alligator River, Rum Jungle and South Alligator Valley uranium provinces and the overlying Pine Creek Gold mineralization (Needham 1988; Pirajno and Bagas 2008; Hollis and Wygralak 2012). Pine Creek metasediments record four phases of moderate to tight folding, including two isoclinal folding events. An eastward increase in metamorphic grade is also apparent (Ferguson 1980). Lower greenschist facies metamorphism was coincident with folding in the western and central parts of the Inlier, but reached regional amphibolite (Barrovian) facies grade in the western region of the Inlier adjacent to the Kakadu Shelf in the final folding phase (≈1.8 Ga). There the metasediments were migmatised to form the gneissic outer parts of the Nibuwah Complex (Worden et al. 2008).

Evaporite pseudomorphs after gypsum (lenticular) and halite (cubic) were noted in the coarsely crystalline magnesite and dolomite rocks in the Rum Jungle and Alligator Rivers uranium fields Northern Territory; in the Celia and Coomalie Dolomites at Rum Jungle, and the Cahill Formation in the Alligator Rivers region of the Pine Creek Geosyncline (Fig. 14.65a; Crick and Muir 1980; Muir 1987).

These rocks are now marbles in the middle to upper greenschist facies, but they still retain recognisable sedimentary features including algal bioherms. Stratiform and domal stromatolites are common, with some domes reaching 1.5 m in height with a similar diameter; *Conophyton* bioherms are also well developed. The stromatolites may also preserve evaporite casts after gypsum and are interbedded with non-stromatolitic carbonates that contain crossbeds, ripples, scour surfaces, intraclast breccias and tepee structures (Fig. 14.65a). Possible evaporite casts in the magnesite marbles are characterised by blade shapes and discoidal shapes up to 1 cm long. Cruciform and swallowtail twin forms are also present in the magnesite marbles. Orthorhombic shapes and cubes after halite are also abundant.

However, Bone (1983) in a study of inclusions in the discoidal forms of magnesite from Rum Jungle concluded that the discoids and the cube shapes were a high temperature form of magnesite that formed above 150 °C and not evaporite pseudomorphs. Muir (1987) countered this argument with the observation that identical discoidal pseudomorphs after gypsum can be found in the Amelia Dolomite in the McArthur Basin in strata that have never been subjected to temperatures of more than 100 °C. Further evidence for an evaporite association is adduced from the co-presence of lutecite, a variety of length-slow quartz that pseudomorphs anhydrite.

Work by Aharon (1988) on the same magnesites showed that they are replacement fronts. Magnesite beds up to 700 m thick from the Lower Proterozoic rocks of the Rum Jungle Uranium Field yielded $\delta^{18}O$ and $\delta^{13}C$ compositions of +11.2 to +14.6‰ (SMOW) and +1.0 to +5.8‰ (PDB), respectively (Fig. 14.65b). Dolomites in the same region yield $\delta^{18}O$- and $\delta^{13}C$-values of +11.7 to +21.9‰ and −4.0 to +2.9 ‰, respectively, and show an ^{18}O enrichment gradient away from the magnesite. Fluid-inclusion homogenization temperatures, used in conjunction with the isotope determinations and an approximate magnesite-water equation, indicate that magnesites were formed in the temperature range of 100–200 °C from fluids that became progressively enriched in ^{18}O. He argues the results support an epigenetic-metaso-

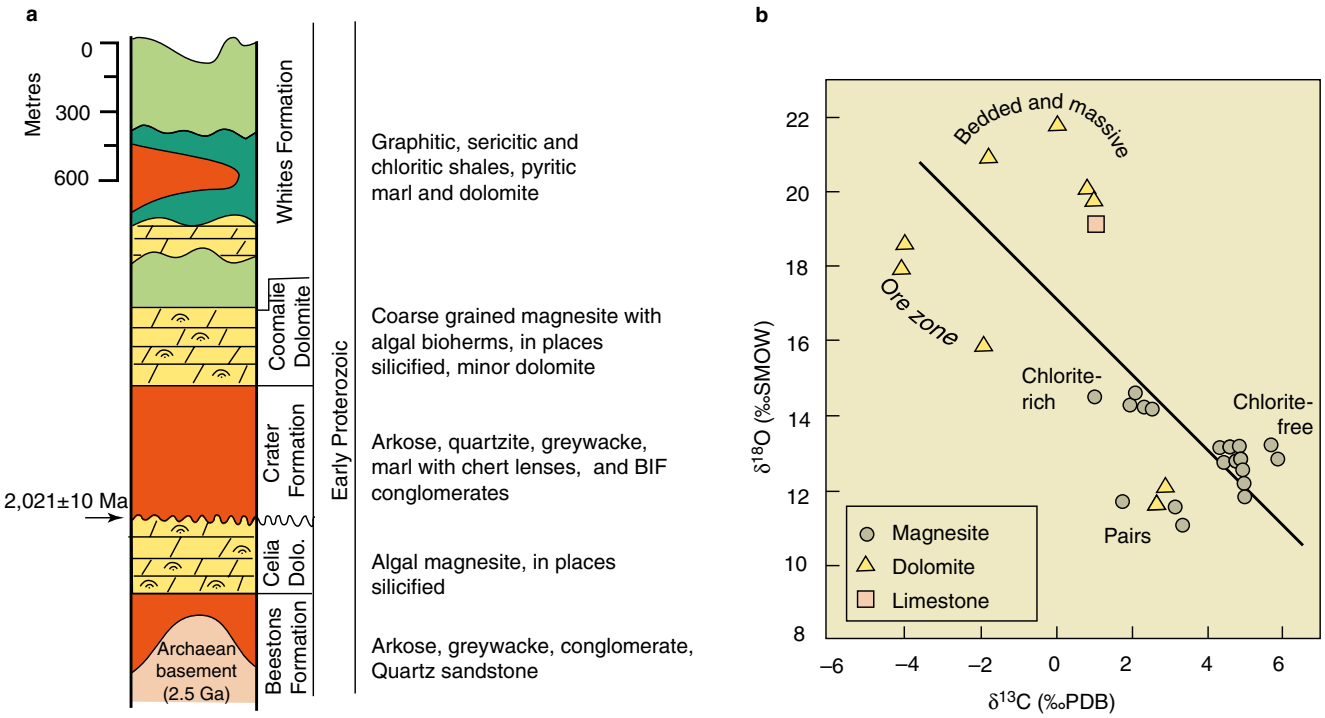

Fig. 14.65 Magnesites in the Rum Jungle Uranium Field, Northern Territory, Australia. (**a**) Stratigraphic column. (**b**) Carbon and oxygen isotope crossplots of magnesites and coeval dolomites (After Aharon 1988; Worden et al. 2008)

matic replacement model of dolomite by magnesite under the influence of invasive hot Mg-rich basinal fluids.

My own work on Proterozoic sparry magnesite elsewhere in northern Australia supports the conclusions of both Aharon and Bone. That is, the discoidal magnesites are a diagenetic replacement in a nonevaporitic platform carbonate host. In addition, my proprietary work, in selected areas also implies that these sparry magnesites are ultimately tied to evaporites. They likely do not indicate the depositional magnesite association postulated by Crick and Muir (1980). Rather, they are related diagenetic alteration fronts driven by deep subsurface dissolution of halokinetic evaporites that then supplied metalliferous chloride brines into fault conduits. In my opinion these sparry magnesites are hydrothermal pinolitic structures that were fed via fault conduits, many of which were created or reactivated by the flow of underlying salt as the basin underwent extension (Chap. 15). Similar pinolitic carbonate cements and replacements associated with faults, tied to rifting episodes, occur in other Precambrian basins in Northern Australia and the Flinders Ranges, South Australia. There are also strong similarities with Phanerozoic peridiapiric metasomatic cements in North Africa and Europe.

There are also tourmalinites in the lower metasedimentary sequence in the Rum Jungle region of the Pine Creek Inlier, mostly within the Beestons Formation, but also in the marbles of the Celia Dolomite (Fig. 14.66; Bone 1988). Although common in these Archaean metasediments, Rum Jungle tourmalinites can be difficult to recognise in the field, leading to misidentification in the Rum Jungle as amphibolites, mafic schists, actinolite schists, chert and, in the case of the leucocratic tourmalinites at the base of the Crater Formation, scapolite. In the Beestons Fm. it occurs as a conformable banded quartz-tourmaline lithological unit comprising at least 15 % and as much as 50 % of the rock. Within what are the oldest recognisable metasediments (arenites of the Beestons Fm and magnesites of the Celia Dolomite) it occurs as distinct lenses, as facies equivalents of quartz-magnetite units and mafic schists (tuffs?) and distal equivalents of polymetallic sulphides. Distinct layering, slump folding, rip-up clasts and the association with diagenetic pyrite suggest a sedimentary protolith. At the micro-scale the en-echelon fracturing of the fine-grained, light green tourmaline crystals supports pre-deformation formation. The crystals are optically and chemically zoned parallel to the c axis, with irregular growth lamellae width — which supports a pre-regional metamorphic origin. Analyses show the tourmaline to be the Mg-rich variety “dravite”.

In terms of depositional setting, parallels are drawn with tourmalinites showing a similar age and metasedimentary association in the metasediments of the Broken Hill Block (Bone 1988). The tourmalinites in the Pine Creek Inlier indicate a borate-rich protolith, possibly a lacustrine, shallow water, evaporitic setting in the sumps of a continental rift. Suitable B-bearing fluids were generated by hot spring activ-

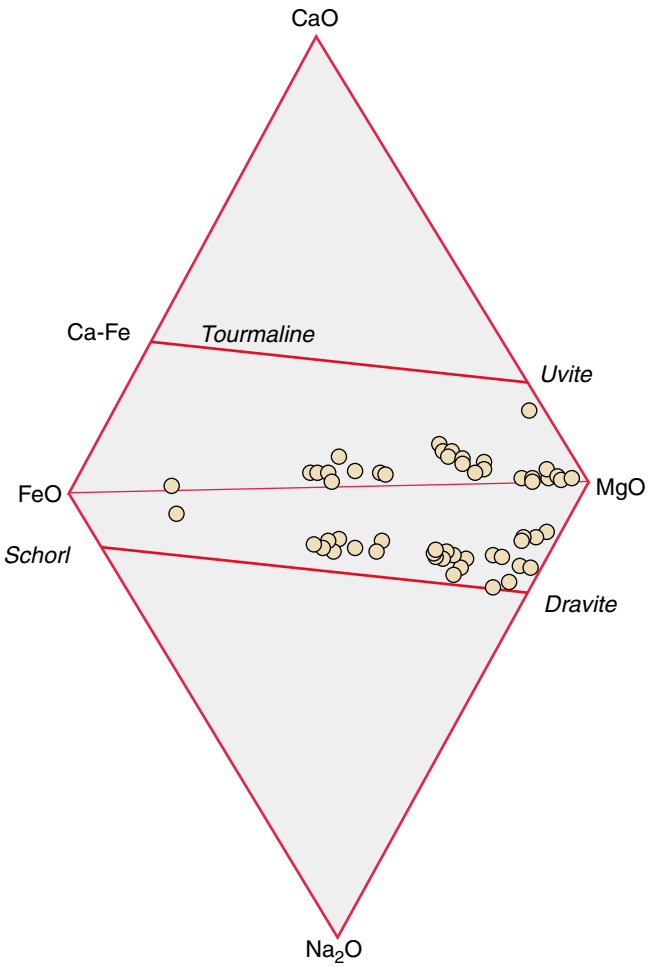

Fig. 14.66 Rum Jungle tourmaline geochemistry (After Bone 1988)

ity and mobilized by CO_2-rich fluids. Localised hot-spring activity contributed B-bearing fluids which precipitated chemical sediments according to the pertaining pH, temperature etc. Thus, diagenetic metaevaporitic alteration produced the stratabound tourmalinites of the Pine Creek Inlier

Meta-evaporites, Seve Nappe, Sarek Mts., Swedish Caledonides

The Seve Nappe Complex in the Scandinavian Caledonides preserves a portion of the fragmented Neoproterozoic continent-ocean transition between Baltica and the Iapetus Ocean. This passive margin was fragmented and thrust eastwards over the Baltic Shield during subsequent Caledonian orogenesis. The individual thrust sheets in the Seve Nappe Complex went through different P-T-depth evolutions, resulting in dramatic metamorphic contrasts where eclogite-bearing nappes are juxtaposed with nappes showing no evidence of Caledonian deformation or metamorphism in their interiors (Svenningsen 2001).

Such a nappe, with little or no evidence of Caledonian deformation, is the Sarektjåkkå Nappe. There, in the Caledonides of northern Sweden, meta-evaporitic stratiform magnesite and scapolite are hosted by diabase and amphibolite derived from diabase, (Fig. 14.67a, b: Svenningsen 1994). The Sarektjåkkå Nappe is dominated Nappe is dominated by a metasedimentary sequence, the Favoritkammen Group, that has been intruded by vast amounts of diabase as single or sheeted dykes, which now constitute up to 70–80 % of the nappe (Fig. 14.68; Svenningsen 1995). The diabase yields a Sm-Nd isochron of 573 ± 74 Ma and is related to the 608 Ma opening of the Iapetus seaway (Nystuen et al. 2008). Because the Sarektjåkkå Nappe largely escaped penetrative Caledonian (Silurian) deformation, it still preserves recognizable igneous and sedimentary elements that are linked to the evolution of the pre-Caledonian rift margin, while the sheeted dyke complex is interpreted to represent the early stage of seafloor spreading.

Magnesite and scapolite layers in the Favoritkammen Group are part of the Spika Formation. Locally the Spika Formation retains sedimentary structures, such as cross-lamination in psammitic beds, dewatering pillars and soft sediment convolute folds in former calcarenite layers. More typically, the ductility of the carbonate bed and contrast between layers of differing compositions of scapolite dolomite and magnesite means that pervasive deformation and shearing has destroyed much of the primary sedimentary structures.

The purest magnesite in Sarek is found in the Äpar Quarry, situated in a carbonate/calcsilicate lens on the northern slope of the Äpar massif (Fig. 14.67b). There it is composed of pure sparry white magnesite and has a visible area of 2,500 m^2 and has the shape of a 120 by 40 m flat-lying cigar. The Äpar magnesite is hosted by massive grey diabase and is the only known deposit of pure magnesite in the region.

Two horizons of the Spika Formation in the Äpar Magnesite Quarry contain matrix-supported intraformational breccias with intraclasts, which are interpreted as evaporite solution collapse breccias (Svenningsen 1994). This is supported by the presence nearby of carbonate pseudomorphs after anhydrite nodules. The magnesite rock is conformable with the underlying calcsilicate layers and the contacts are gradual, indicating that the magnesite was not created by metasomatic alteration derived from the diabase. Rather, the rock reflects an original sedimentary magnesite deposited in what was a Coorong-Marion Lake like hydrology.

The Spika Formation was deposited in an evaporative setting characterised by alternating influxes of continental (magnesian carbonate) and marine-fed evaporites (halite and anhydrite/gypsum) in rift-related Neoproterozoic basins (Svenningsen 1995). The overall stratigraphy of the Favoritkammen Group indicates a progressively deepening, increasingly marine-fed basin, consistent with deposition in a developing rift basin.

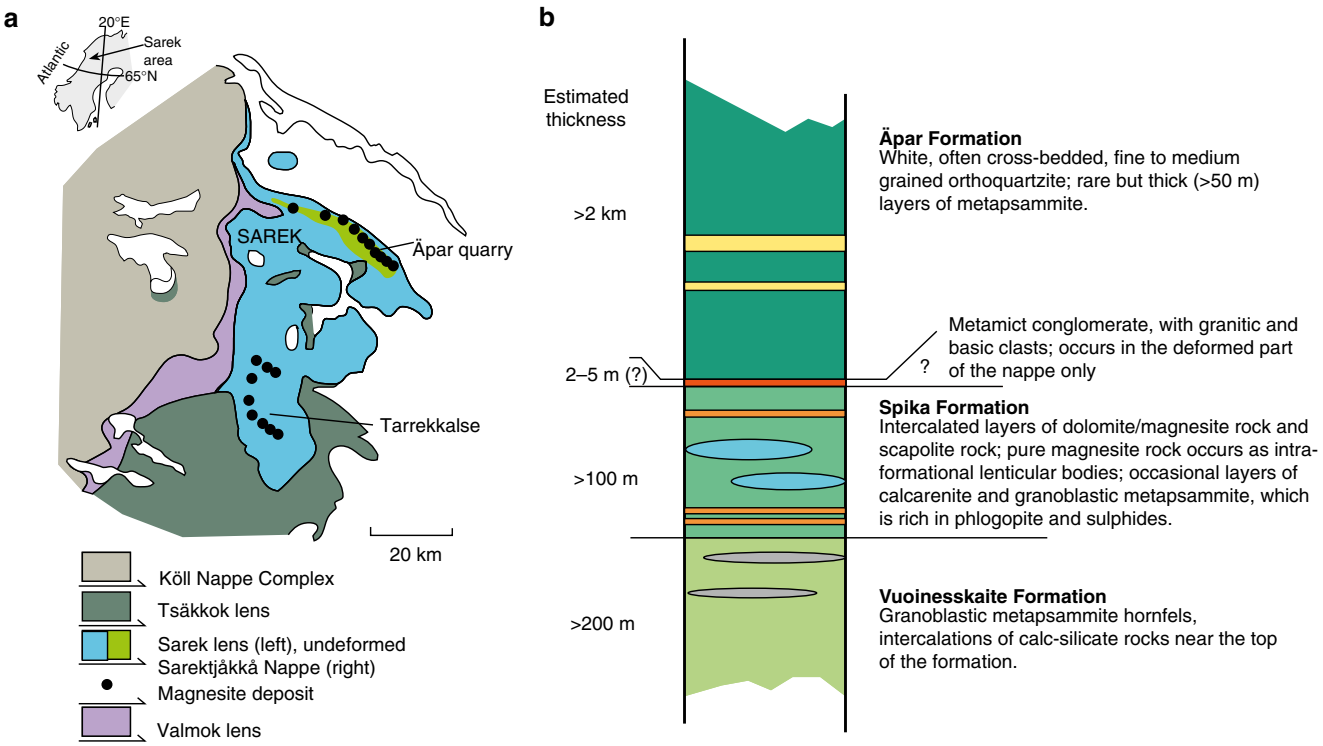

Fig. 14.67 (**a**) Tectonostratigraphic and location map of the Sarek National Park and adjacent areas. All the magnesite deposits occur in the Sarektjåkkå Nappe. (**b**) Generalised stratigraphy of the Favoritkammen Group. The sequence is dismembered by enormous quantities of diabase dykes, and so thicknesses are no more than estimates (After Svenningsen 1994)

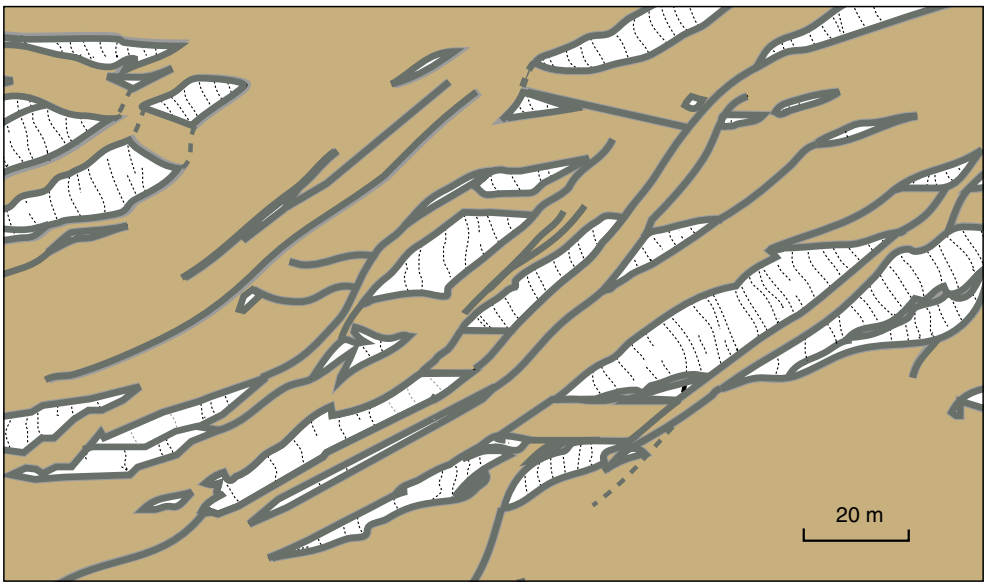

Fig. 14.68 Typical sediment-dyke pattern from the central, undeformed part of the Sarektjåkkå Nappe (Favoritkammen Ridge east of Äpar quarry). Diabase dykes are stippled *grey*, with chilled margins. Vertical bedding attitude in sediment (Äpar Formation) is also indicated. Diabase is more than 70–80 % of rock volume, yet bedding is still recognizable in metasediment blocks (After Svenningsen 1994)

The evaporitic sequence was altered to scapolitic marbles during subsequent thermal metamorphism. Diabase dykes that cut the Spika Formation drove regional thermal metamorphism, but were not responsible for the magnesite formation. The magnesites were recrystallised during thermal metamorphism but were perhaps a product of the Neoproterozoic magnesite ocean, perhaps akin to sedimentary magnesites so prevalent in similar age lithologies in the Flinders Ranges of South Australia (Frank and Fielding 2003). In summary, the metamorphic lithologies of the Sarektjåkkå Nappe record the evolution of a Neoproterozoic rift passing into a passive margin. That passive margin was subsequently detached and thrust over the Baltic Shield during the Caledonian (Silurian) Orogeny.

Oaxacan Granulites, Mexico

Two origins have been proposed for Oaxacan calcareous rocks in the ~1 Ga Oaxacan Complex of southern Mexico: (1) a meta-sedimentary origin with an evaporitic protolith first deposited in a passive-margin tectonic setting (Ortega-Gutierrez 1984); or (2) a meta-igneous origin as carbonatites (Melgarejo and Prol-Ledesma 1999). Metasomatism is a third possibility (Dostal et al. 2004).

The Oaxacan calcareous rocks contain from 10 to >90 vol% carbonate and were subdivided by Ortega-Gutiérrez (1984), using modal composition, into marbles (>50 vol% carbonates) and calc-silicates (10–50 vol% carbonates). Layers in this high grade (granulite) sequence constitute either concordant (<200 m thick) or discordant bodies up to 4 m thick. Discordant calcareous rocks are dyke-like mostly marble intrusions with xenoliths of calc-silicate and/or host rocks, whereas the concordant bodies are made up of both calc-silicates and marbles.

These calcareous bodies occur with in the upper "paragneiss" thrust slice that dominates the northern Oaxacan Complex (Fig. 14.69a; Dostal et al. 2004). This slice was intruded by within-plate, ≥1,140 Ma charnockites and meta-syenites (Keppie et al. 2003) and was involved in two tectonothermal events, the ~1,100 Ma Olmecan event, and the ~1,005–980 Ma Zapotecan event. The latter involved polyphase deformation under granulite-facies metamorphic conditions (Fig. 14.69b; Solari et al. 2003). Peak granulite facies metamorphism reached 700–750 °C and 7.2–8.2 kbar. The concordant calcareous lenses contain Zapotecan foliations and folds, and although the discordant bodies cut across these ductile structures, they record the granulite facies metamorphism, indicating that the high-grade metamorphism outlasted the deformation. Titanite and phlogopite from these discordant calcareous bodies have yielded ages of 968 ± 9 Ma (concordant U-Pb age) and 945 ± 10 Ma ($^{40}Ar/^{39}Ar$ laser fusion analyses), respectively, which have been interpreted as dating cooling through 660–700 °C and ~450 °C.

Host rocks in the thrust slice are of mostly mafic and felsic granulite anhydrous phases and include quartz, plagioclase (typically antiperthitic), hypersthene, clinopyroxene, garnet, alkali feldspar (perthite and mesoperthite), opaque minerals (ilmenite), and a variable amount of titaniferous hornblende and biotite. Hydrous phases, including hornblende and biotite, are in textural equilibrium with the anhydrous minerals (Mora et al. 1986). In places, the Oaxacan rocks are composed of mineral assemblages containing biotite, amphibole, plagioclase and opaques, indicative of only upper amphibolite facies–grade metamorphism.

High abundance of meionitic scapolite, dolomite, phlogopite, albite, and K-feldspar in the Oaxacan carbonate bodies supports a saline precursor, but all traces of primary salts have been lost by partial melting and volatile expulsion during attainment of the successions high metamorphic grade (granulite). The marialitic nature of the scapolite minerals implies the presence of Cl and Na in the protolith. Albite, K-feldspar, phlogopite, and cancrinite contain elevated concentrations of alkalis, whereas, dolomite, forsterite, clinopyroxene, and amphibole are rich in Mg, and sulphides are rich in sulphur. Rare anhydrite, now mostly present as gypsum pseudomorphing the anhydrite, remains in these metasediments, with outlines indicating that the anhydrite was in textural equilibrium with granulitic carbonate (Ortega-Gutierrez 1984).

Tourmaline is absent in Oaxacan rocks and has its absence has been used by those favouring non-evaporitic precursor for the required high salinity fluids. It is true that borates are enriched in the salts that are some of the last minerals to precipitate from seawater, but most substantial accumulations of borate salts tend to be in a nonmarine continental volcanogenic association (Chap. 11). A lack of tourmaline in the Oaxacan assemblages may indicate an evaporite protolith that was marine and never contained high levels of boron. An alternative explanation for the absence of tourmaline in the Oaxacan Complex may be thermal instability of the tourmaline under the low water pressures characteristic of granulite facies (Dostal et al. 2004). Boron, if originally present, perhaps migrated with the fluid and melt phases to lower temperature and wetter zones of the orogen. Low contents of boron may also indicate that the source of the Oaxacan carbonate rocks was non-granitic. The marbles were probably derived from impure limestones and evaporites whereas the protolith to the calc-silicate rocks were calcareous sediments with higher contents of silicates (Fig. 14.70). The common presence of spinel may indicate some silica-poor, bauxitic component in the clay fraction, and thus probably highly weathered source rocks (Dostal et al. 2004).

Scapolitic Meta-evaporites, Rajasthan, India

Paleoproterozoic metasediments of the Aravalli group (2.2 Ga) of the Aravalli craton and contain a sequence of granulites that likely have an evaporite protolith (Sharma 1981; Golani et al. 2002; Knight et al. 2002; Fareeduddin et al. 2010). The Aravalli Craton preserves an uninterrupted Archaean succession from 3.3 to 2.5 Ga as well as two significant intersecting Proterozoic foldbelts; the Paleoproterozoic Aravalli foldbelt and the younger Meso-Neoproterozoic Delhi foldbelt. The 60-km long Salumber Ghatol belt constitutes the easternmost sector of the Aravalli foldbelt. It has undergone polyphase deformation and a single metamorphic recrystallisation event at greenschist grade. It contains several Cu-Au deposits, including; Bhukia, Dugocha, Hinglaz, Mata, Timran Mata, Manpur, Kukra and Rajpura.

Electron-microprobe analyses of coexisting phases from a scapolite-garnet-epidote-calcite-plagioclase-amphibole-pyroxene (sphene-hematite-magnetite) rock of the Aravalli group in Karera area show that chlorine is an important con-

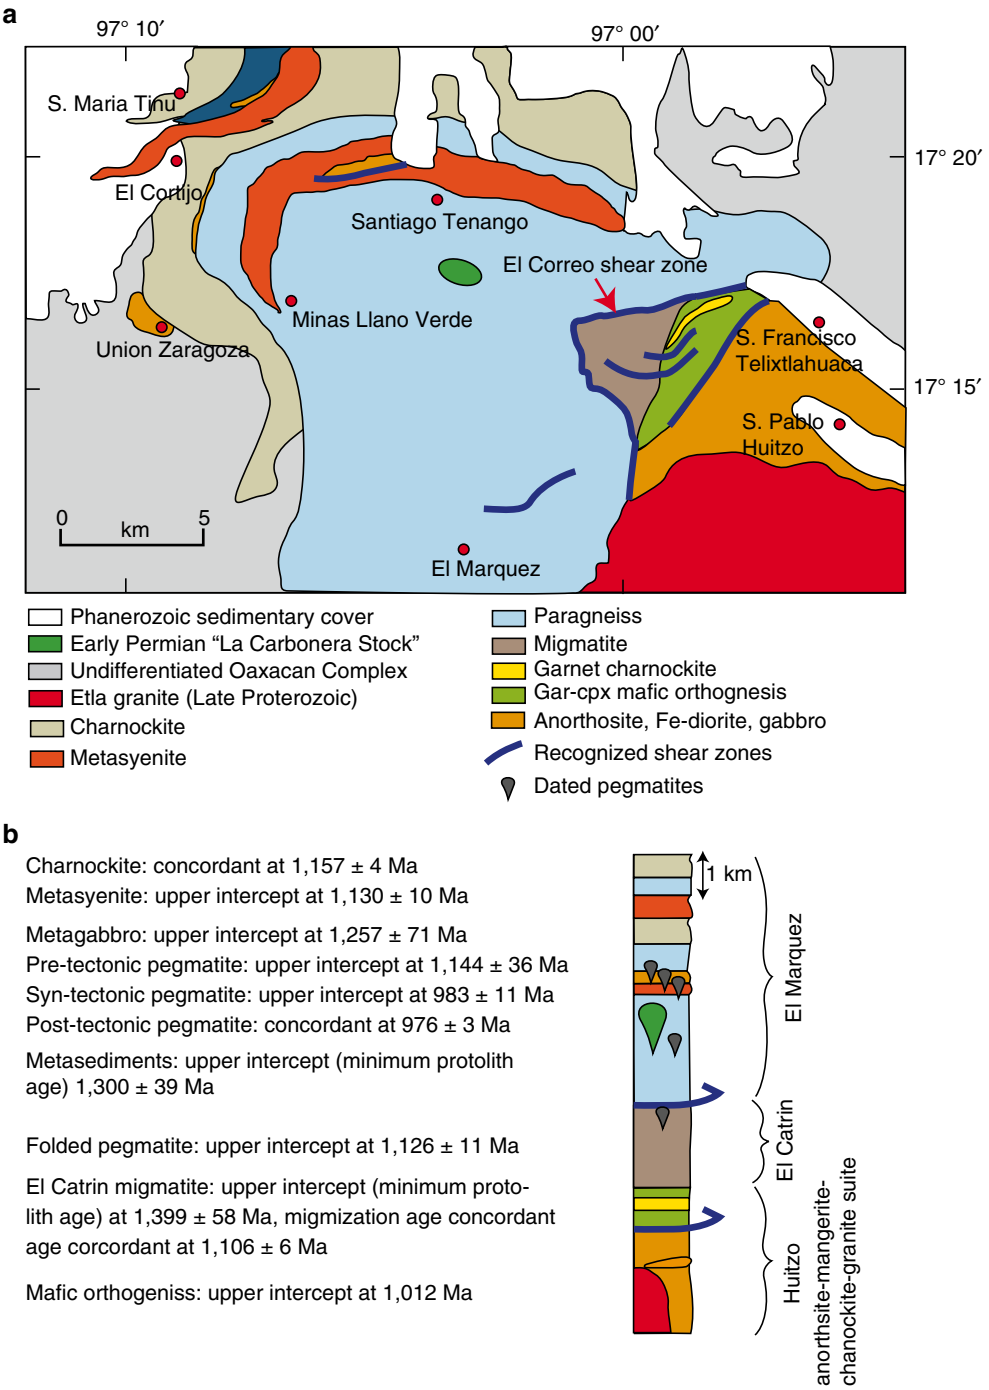

Fig. 14.69 Geology of the Oaxacan Complex. (**a**) Geological map of the northern Oaxacan Complex (**b**) Structural section of the northern Oaxacan Complex showing the location of the sampled calcareous intrusions; Huitzo, El Catrin and El Marquez refer to three thrust sheets of the Oaxacan Complex (Modified after Solari et al. 2003; Dostal et al. 2004)

stituent of both scapolite ($Me_{71.3}$) and amphibole in this succession (Sharma 1981). The amphibole also contains an unusually high K_2O (3.7 wt.%), and is a chloro-potassian hastingsite. The epidote contains 41 % pistacite and shows complete substitution of Al by Fe^{3+} in the M_2 site and to some extent also in M_1 and/or M_3 sites. The garnet is also rich in ferric iron and has a molecular composition $Pyr_{23}Alm_{8.5}Gro_{13}And_{54.5}Sp_{1.0}$. The pyroxene is dominantly a hedenbergite.

Geothermometry, based on the fractionation of Na and Ca between scapolite and plagioclase, yields metamorphic temperatures of around 700 °C, which are in agreement with those obtained by other mineral equilibria in the associated pelitic assemblages. Sharma (1981) argues that phase relations and textural as well as geological criteria exclude metasomatic processes or a magmatic source. He favours equilibrium recrystallization of the scapolite-bearing assem-

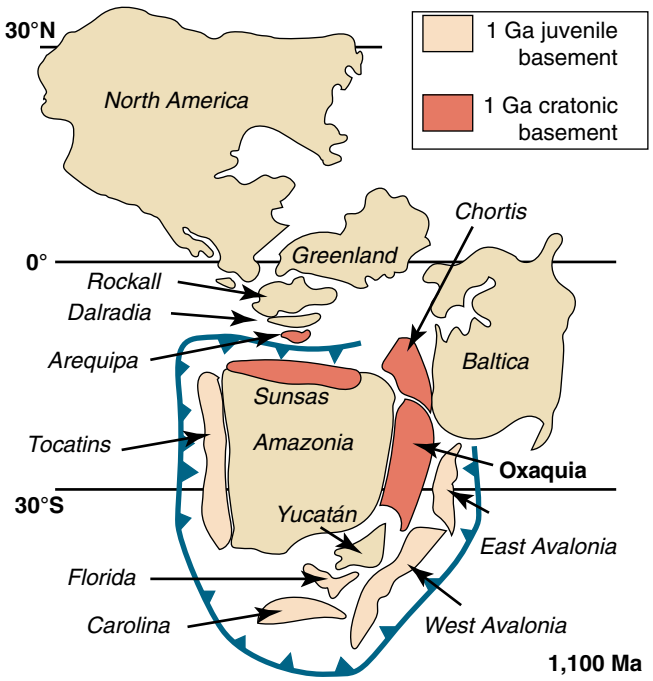

Fig. 14.70 Reconstruction of Rodinia around 1,100 Ma, showing the location of Oaxaquia, Mexico as part of a 1 Ga belt on the margin of Amazonia. Note that meta-evaporitic carbonates in Oaxaquia lie between 10° and 35°S encompassing the latitudinal limits for the formation of Phanerozoic marine evaporites, as discussed in Chap. 5. The *barbed line* define the relevant subduction zone with triangles on the upper slab (After Dostal et al. 2004)

blage with the chlorine derived from an evaporite unit in the Aravalli protolith.

The interpretation of an evaporitic protolith to the Aravalli metamorphics is strengthened by Golani et al. (2002) in their detailed geochemical and isotopic study of marbles associated with the Bhukia gold prospect. Their evidence for meta-evaporite includes:

1. Presence of dissolution 'pits' and cavities in the dolomitic marble, and a Na content (Av. = 5,013 ppm) that is significantly higher than the 1,000–3,000 ppm range for hypersaline and evaporitic (sabkha) environments and much above the 1,000 ppm level reported for normal marine sedimentary carbonates. High Na/K ratio of Bhukia rocks is comparable to carbonate lithologies in some of the large soda lakes of the world. High sodium content is also a characteristic feature of the QFR (quartzo-feldspathic rock) unit. The possibility of non-evaporitic soda metasomatism in the carbonate-QFR (±tourmalinite) litho-association is ruled out on the strength of; (a) well-bedded nature of lithological units, (b) consistent presence of Na throughout the deposition of host-rock litho-association and, (c) purity of albite feldspars, all features considered to be diagnostic of sedimentary feldspars in evaporitic settings.
2. Mineral analyses of brown biotite, a common mineral in the Bhukia Gold Prospect rocks, show that it is phlogopitic in composition. Phlogopite has been cited as an important index mineral in most of the meta-evaporitic sequences (Moine et al. 1981).
3. Development of widespread scapolite-bearing calc-silicate assemblages in Bhukia carbonates indicate an evaporitic affinity (Serdyuchenko 1975).
4. Presence of tourmaline, its common occurrence as disseminations in the quartzo-feldspathic facies and in thin tourmalinite bands, indicates a high boron flux in the protolith; as is also the case in meta-evaporites of China (Peng and Palmer 1995) and Australia (Cook and Ashley 1992). The extremely low Fe/Al ratio (mean 0.15) in the Bhukia tourmalines is far below the 38.5 level (range 10.5–62.2), reported for submarine hydrothermal deposits, but similar to values from Proterozoic meta-evaporitic sequences of China with Fe/Al ratio ranges from 0.29 to 0.87 (Fig. 14.71a; Av. = 0.48; Jiang et al. 1997).

Likewise, the geochemistry of the Ghagri tourmalinites, which are interlayered with copper sulphides, indicates a likely metaevaporitic precursor (Fareeduddin et al. 2010). These tourmalinites include a major povondraite component and follow an 'oxydravite' – povondraite crystallization trend indicative of a hypersaline saline precursor (Fig. 14.71b, c), as defined in Namibian meta-evaporitic equivalents (Henry et al. 2008).

Isotopic compositions of the Bhukia meta-sediments also support the notion of an evaporitic protolith, but also contains evidence of mixing with mantle derived fluids (Fig. 14.71d; Golani et al. 2002). Bhukia carbonates are characterized by $\delta^{18}O$ values ranging from +15.3 to +26‰$_{SMOW}$, which are slightly depleted when compared to typical Palaeoproterozoic marine carbonate compositions (Golani et al. 2002). The C- and O-isotopic compositions are non-correlative, however, the $\delta^{13}C$ values show a bimodal distribution ranging from −4.1 to +0.3‰$_{PDB}$, allowing the discrimination into two groups (Fields I and II) each with closely similar C-isotopic ratios (Fig. 14.71d). The narrow range of C isotopic ratios for Field II carbonates indicates unmodified compositions, while the spread in O-isotopic ratios for Field I indicates slightly modified $\delta^{18}O$ values as a result of evaporative conditions (trend A) and high temperature burial and/or exposure to meteoric waters (trend B; Golani et al. 2002). The Field I carbonates with similar C- and O-isotopic ratios are interpreted to best approximate the unmodified marine sedimentary carbonate signatures and closely compare with values in the Aravalli stromatolitic phosphate-bearing carbonates of Udaipur area.

In the absence of any evidence of algal activity in the Bhukia area, the Field II representing 'lighter' carbon component (mean value −3.1‰$_{PDB}$) may either indicate

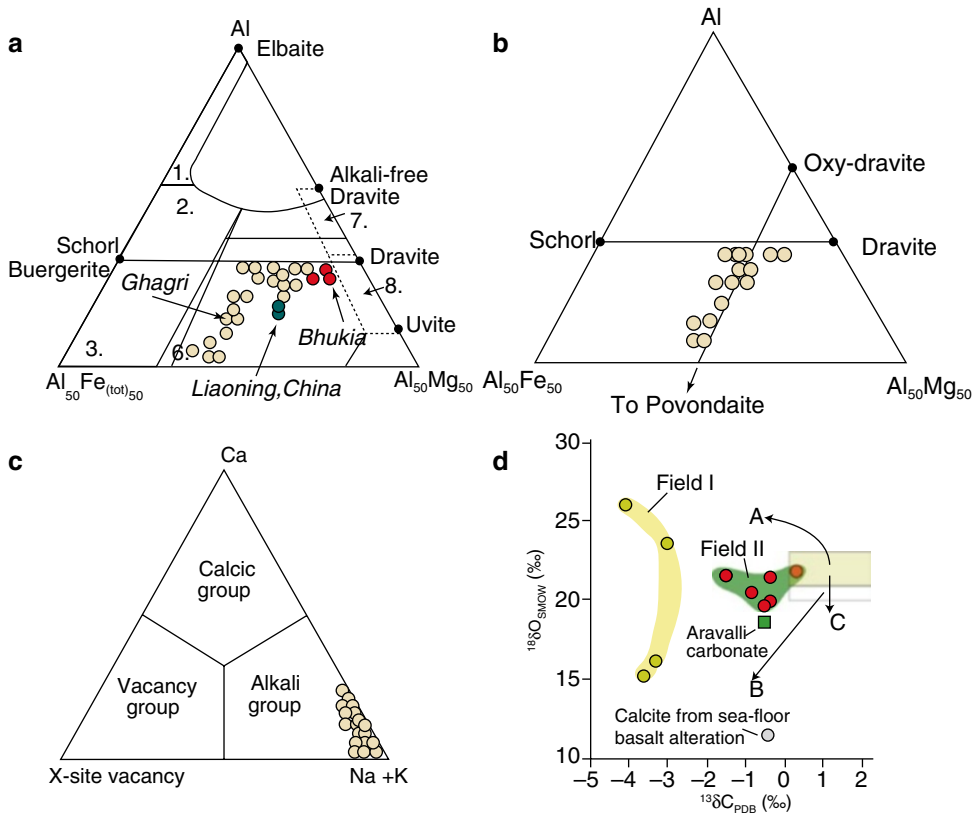

Fig. 14.71 Geochemistry of Aravalli metasediments (After Golani et al. 2002; Fareeduddin et al. 2010). (**a**) The Al-Fe-Mg (molecular proportions) plot for tourmaline of Bhukia and Ghagri areas. Note a similarity with meta-evaporitic tourmalines from Liaoning, China (see Fig. 14.19 for explanation of fields 1–7). (**b**) Ghagri values plot on the Oxy-dravite to Povondraite line indicating a meta-evaporite protolith. decarbonation due to thermal metamorphism or a mantle-derived carbon component. Despite evidence of high-grade metamorphism, such as development of spherulitic graphite in arsenopyrite (Golani et al. 1999) and occurrence of rare fine graphitic flakes in QFR unit, Golani et al. (2002) interpret the negative $\delta^{13}C$ values in terms of mantle affinity as, being homogeneous, they can be considered unmodified. Bhukia $\delta^{18}O$ values (mean +20.6‰$_{SMOW}$) are close to the low-grade Proterozoic evaporitic carbonates of Lomagundi (+22.6‰) and Karnataka (+21.6‰). Thermal decarbonation would normally result in lowering of both $^{13}C/^{12}C$ and $^{18}O/^{16}O$ ratios (Shieh and Taylor 1969; Bottinga 1969).

It is clear from the foregoing discussion that the metasedimentary host-rocks of gold-sulphide mineralization were deposited in a hypersaline to evaporitic environment (Field I). In contrast, the $\delta^{13}C$-depleted Bhukia carbonates of field II appear to be consistent with values in other Archaean greenstone- hosted gold deposits (Groves et al. 1988). These more $\delta^{13}C$ negative values are attributed by Golani et al. (2002) to a mantle source. They argue that this mantle flux emanated through palaeofaults and ultimately derived either from the granite–greenstone substratum or through the coeval carbonatite magmatism (2.27 Ga) in the adjacent areas. We shall deal with the copper-gold-metaevaporite association in more detail in the next two chapters.

Sulphide-Anhydrite Archaean Carbonates, Brazil

Anhydrite occurs in Archaean carbonates that host sulphidesulphate phases in high-grade metamorphics in the Caraíba gneiss-granulite complex in central Bahia State, Brazil (Fig. 14.72a; Leake et al. 1979; Oliveira and Tarney 1995). The region includes the Caraíba Mine, the largest copper deposit in Brazil. Caraíba metasediments (marbles, calcsilicates, metapelites) are crosscut by younger granitic gneisses (≈2.0 Ga) and by K-rich zones. The anhydrite-

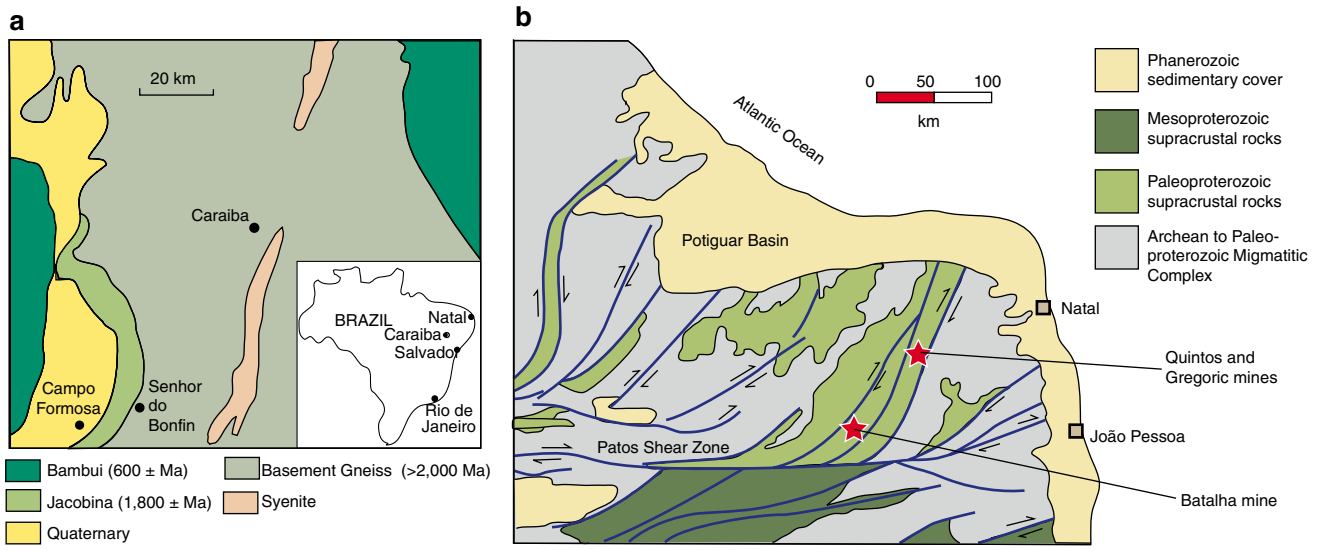

Fig. 14.72 Geological setting of the Paleoproterozoic/Archaean meta-evaporites and tourmalines in the Brazilian craton. (**a**) In the vicinity of the Caraíba copper mine in Archaean basement gneiss (After Leake et al. 1979). (**b**) Tourmaline mines in the Serido foldbelt (*red stars*) (Scares et al. 2008)

entraining metasedimentary sequence is dominated by calcsilicates with varying mineral assemblages (Sighinolfi et al. 1980):

1. diopside (≈90 %), green spinel, apatite and sphene;
2. diopside, calcite microcline;
3. diopside, anhydrite microcline;
4. diopside, anhydrite, calcite, forsterite.

Assemblages (2)–(4) contain varying amounts of phlogopitic marble and scapolite occurs locally. The anhydrite-bearing assemblages occur as layers (0.05–0.5 m thick) within the metasedimentary sequence. The anhydrite forms large crystals in the layers or forms fine-grained aggregates that fill cracks and microfractures. Textural evidence shows the anhydrite growth was associated with formation of phlogopitic mica (Sighinolfi, et al. 1980). The common occurrence of anhydrite in both marble and diopsidite led Leake et al. (1979) and Sighinolfi et al. (1980) to propose an metaevaporitic protolith.

Almost all the high grade metamorphic rocks in the Caraíba area have been heavily metasomatised and deformed, so that determining the ultimate origin of the anhydrite is beset with difficulty. The textural evidence is inconclusive. Anhydrite distribution in the layers appears sometimes to have been little affected by metamorphism, but there is also extensive anhydrite crystallization along cracks and fractures. The abundance of the anhydrite-mica association indicates its active participation in metasomatism but does not directly infer an evaporite protolith. The additional possibility of hydrothermal anhydrite has not been addressed.

Lindenmayer (1981) described relict cumulus textures in some gabbros associated with the Cu-bearing norites-hypersthenites in the Caraiba Mine area and found possible clinopyroxene exsolution lamellae in hypersthene. On the basis of chemical data and cross-cutting relationships deduced from drill cores, she concluded that the ore-hosting rocks are intrusive and evolved through fractional crystallization of a previously differentiated Fe-Ti-rich tholeiitic liquid, and that the hypersthenite-norite-gabbroanorthosite sequence might well represent the original igneous stratigraphy. She also suggested that some anhydrite-bearing marble and calcsilicate-rocks could have supplied sulphur to form part of the sulphides. The influence of entraining evaporites on magma sulphide chemistry is discussed in more detail in Chap. 16.

Interestingly, many different coloured tourmalines are found in the Paleoproterozoic meta-evaporitic successions in Bahia State to the northeast of the Caraiba Mine (Fig. 14.72b; Scares et al. 2008). Today the pink, blue and green gems are particularly popular. In 1988, miners discovered gem tourmaline in pegmatite veins of the Batalha Mine that were unlike any that they had ever seen before (Wilson 2002). The new type of tourmaline, which soon became known as Paraiba tourmaline, comes in incredibly vivid blues and greens, related to elevated levels of Cu (±Mn) in the lattice. The demand and excitement for this new material grew in the early 1990s when better specimens were soon fetched more than US$10,000 per carat, today better specimens can fetch in excess of US$20,000 per carat.

Implications

Meta-evaporites are not simple rock systems, their interpretation involves more than just recognising sodic or magnesian metamorphic minerals. This must be done in conjunction with a full description of the geometries of these phases and the recognition that the evaporites and their subsequent minerals are altered many times during their metamorphic history, often in ways that do not fit the isochemical paradigms of classic metamorphic petrology. The following questions should always be asked of potential meta-evaporite sequences:

- Are the minerals distributed in a fashion that reflects a stratiform or a halokinetic precursor?
- Are breccias present that contain nodules and other textures indicative of former evaporites?
- Do the breccias reflect a halokinetic precursor or was the brecciation a later fluidisation event (rauhwacke), perhaps associated with compression and overthrusting centred on evaporite -rich horizons that were undergoing metamorphism?

Evaporites undergoing metamorphism release large volumes of volatile-rich fluids, which are typically saline chloride solutions with elevated levels of sodium and magnesium as well as chromatophore metals that may colour gemstones growing in ductile meta-evaporitic hosts.

Many of these fluids have the capacity to mobilise and flush metals from adjacent strata that often include metalliferous metabasites. Thus meta-evaporites or their residues are often part of a metallisation series in a metamorphic terrane. The processes and styles of these evaporite-metallogeny associations are discussed further in the next chapters.

Lower Temperature Metals in an Evaporitic Framework

15

Introduction

Most subsurface evaporites ultimately dissolve and, through their ongoing dissolution and alteration, can create conditions suitable for metal enrichment and entrapment in subsurface settings ranging from the burial diagenetic through to the metamorphic and igneous realms. Within this framework, this chapter explores relationships between evaporites and lower temperature ore deposits, where ore is defined as a mineral, or an aggregate of minerals, from which a valuable constituent, especially a metal, can be profitably mined or extracted. The next chapter explores the significance of dissolving and altering evaporites in ore deposits formed in the higher temperature igneous and metamorphic realms.

An overview of a selection of the large-scale ore deposits associated with hypersaline brines and dissolving/altering salt masses, plotted on a topographic and salt basin base, shows that the many evaporite-associated ore deposits lie outside areas occupied by actual evaporite salts (Fig. 15.1). Rather, they tend to be at or near the edges of a salt basin or in areas where most or all of the actual salts have been long gone (typically via subsurface dissolution or metamorphic transformation). This is why the metal-evaporite association is not widely recognised by the economic geology community. Without the conceptual tools to recognise the former presence of evaporites (Chap. 7) and meta-evaporites (Chap. 14) the significance of disappearing salt masses, in focusing and enhancing metal precipitation via the creation of chloride-rich brines, is not obvious.

We have already discussed ore deposits where the evaporite minerals constitute the ore, or have transformed into gemstones (Chaps. 11, 12, and 14). Earlier papers by Kirkham 2001 and have noted parts of this association in the metals realm (Fig. 15.1), but have focused on the ore deposits themselves. This chapter and the next will approach this problem a little differently. We shall place the various base and precious metal deposits in the framework of our deeper understanding of evaporites and their residues and then use this understanding to pigeonhole the deposits. So, in this chapter we will focus on stratabound Cu, Pb-Zn and U associations in the low temperature realm (diagenetic and lower end of greenschist grade ores). The next chapter will focus on metalliferous ores (both gold and base metals) formed in those higher temperature igneous and metamorphic realms that have interacted with evaporites.

Let me clearly state at the outset of this discussion that I am not saying all large metal accumulations require evaporites or the highly-saline subsurface fluids that they can generate, although some recent papers do argue for a widespread role of evaporites in the Pb-Zn association (Fusswinkel et al. 2013; Wilkinson et al. 2009). This and the next chapter are only about those deposits where evaporites have contributed to the metal accumulation in some way. However, as the various tonnage-grade plots in this chapter and the next show, many accumulations with an evaporite association tend to plot at the larger end of their respective groupings.

High levels of metals in all ore deposits, like thick salts in evaporite basins across the sedimentary realm, are responses to unusual conditions, related to fortuitous associations of local and plate-scale tectonics and fluid systems. To become an ore deposit, metals need to build, at specific precipitation sites, to levels well above that of their background presence in the carrier brines. This typically requires a chemical interface that can be related to salinity/oxidation levels, or cooling/heating interfaces. As such, it is no surprise that the same process sets created by conductivity and salinity/oxidation levels tied to dissolution and reprecipitation of minerals are likely to be associated with conduits created by the passage of pore waters from altered buried evaporites and hydrothermal salts (e.g., Fusswinkel et al. 2013). As for the salts that accumulate in ancient evaporite basins, we can place ore deposit frequencies in a time and plate tectonic framework and so perhaps better understand and predict occurrences (Fig. 15.2; Groves et al. 2005).

Not all sediment-associated ore deposits are associated with evaporites. Only in those ore deposits that are classified as anorogenic and/or continental margin can subsurface evaporite masses be involved in the same unusual

Fig. 15.1 A selection of metalliferous ore deposit provinces where formation is tied to the presence of hypersaline brines and/or evaporites (In part after Kirkham 2001; see also Table 15.1 and text in this chapter and the next for further explanation of the various deposits). Also, positions of the world's larger halite-dominated basins are plotted as *orange-coloured* areas, anhydrite-dominated as *green*

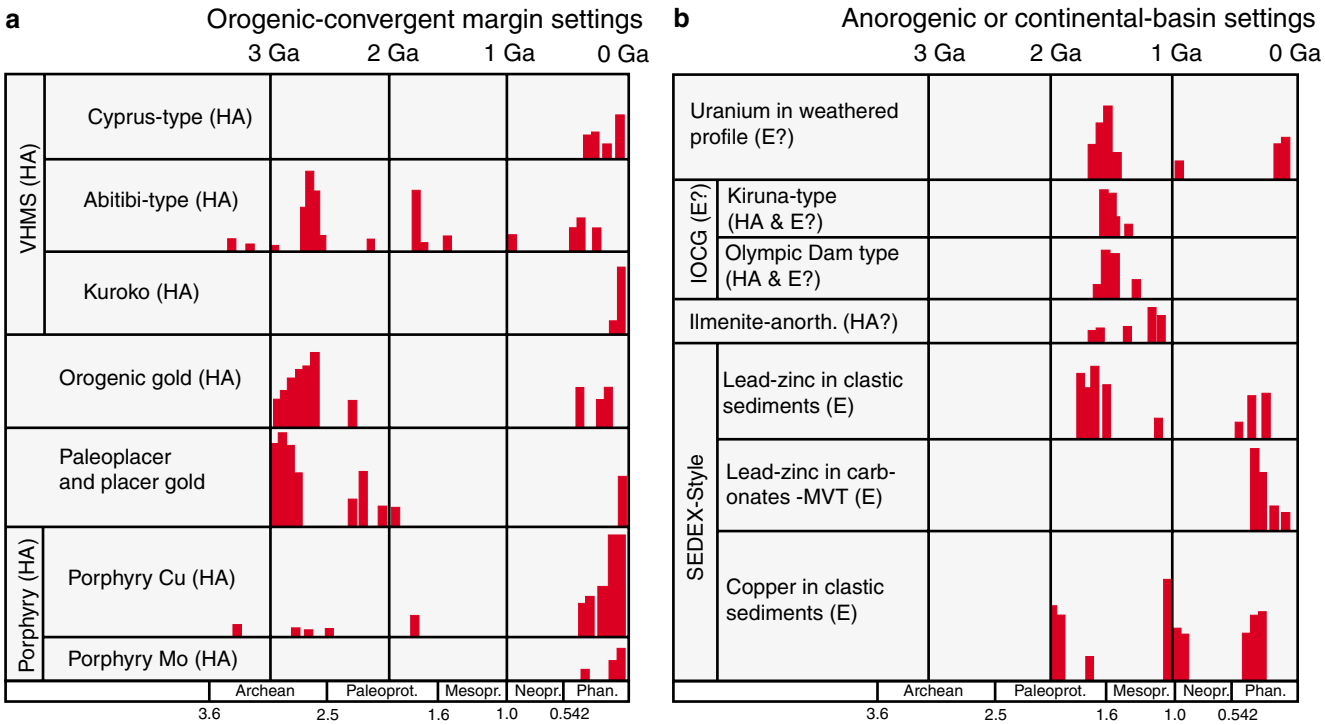

Fig. 15.2 Ore deposit occurrences across geological time (Modified from Groves et al. 2005; see Meyer 1988 for more detail and other igneous subsets). (**a**) Orogenic convergent margins, (**b**) Anorogenic or basin collision settings. *E* indicates direct evidence of evaporites or derived brine in the formative processes associated with some of the examples of this deposit style. *E?* indicates the presence of hypersaline brine associated with the formative ore process. Such brines may be magmatic or sedimentary/hydrothermal. *HA* indicates the presence or former presence of hydrothermal or igneous anhydrite precipitated by non evaporitic processes

concentration and alteration conditions that lead to the creation of metalliferous ore deposits (indicated by E in Fig. 15.2). At other times mineral salts, such as anhydrite, can be an integral part of the ore accumulation, but their occurrence may be unrelated to aridity. Rather, they are burial or magmatic hydrothermal salts formed by high salinity conditions inherent to the ore forming environment, as in the formation of carbonatites (e.g. Afrikanda and Bayan Obo; Wu 2008) and pegmatites (hydrothermal anhydrite is indicated by HA in Fig. 15.2). In such hot subsurface settings the role of any buried "true" evaporite may be, via its dissolution or alteration, to aid in the

creation of highly-saline high-temperature basinal brines. These brines can then act as either enhanced metal carriers or fixers.

The role of evaporites creating metalliferous ores is twofold; (1) In solution (halite-dominant precursor) they can act as chloride-rich metal carriers and (2) Locally, as beds or masses (especially of $CaSO_4$), their dissolution products, especially if trapped, can supply sulphur (mostly as bacteriogenic or thermogenic H_2S) and also set up chemical interfaces that act as foci in the setup of brine mixing conditions suitable for precipitation of metal sulphides or native elements. Hence, many evaporite-associated ore systems tend to be epigenetic, rather than syngenetic (Table 15.1). Subsurface salt beds and masses are merely the solid part of a large ionic recycling system, dissolved metals are another part and zones of mixing between the two are typically sites where ores tend to accumulate.

At the world-scale, both systems are driven by plate tectonics. Halite-dominated sequences, deposited in the drawdown basin centres, tend to dissolve in burial, and so supply chloride ions to the brine system. Salt beds that are thick enough tend to flow and so focus the upward and centripetal passage of basinal and hydrothermal fluid flows. Dissolving gypsum or anhydrite beds, typically deposited higher on the basin platform or diagenetically accumulated along salt dissolution edges and touchdowns can supply sulphur, via bacterial or thermochemical sulphate reduction, while simultaneously focusing metalliferous brine flows into the precipitation interface.

When the chemistries of the dissolving salt beds and the metal carriers interact so that redox fronts, salinity contrasts, and other precipitative interfaces are set up, an ore deposit can form. Thus, in base and precious metal exploration in evaporitic terranes, we are ultimately searching for those parts of a subsurface ionic cycling system where the salt dissolution, salt beds and metal systems have interacted to create economic levels of metalliferous precipitates.

Conceptually, this evaporite-related notion of regional fluid flow in a sedimentary/metasedimentary host is somewhat different to the internal process and local mineralised

Table 15.1 Classic classification of ore deposits into epigenetic and syngenetic (e.g. as used by Evans 1993). The effects of evaporites within this type of classification ranges across many subdivision -see text

Epigenetic Mineral deposit formed much later than the rocks which enclose it	Porphyry Large, low grade, usually associated with porphyritic intrusive body	Cu-Mo Cu (−Au) Mo (−W)
	Skarn Deposits formed by replacement of limestone by ore and calc-silicate minerals, usually adjacent to a felsic or granitic intrusive body	W-Cu (−Zn, −Mo) Zn-Pb-Ag (−Cu, −W) Cu (−Fe, −Au, −Ag, − Mo) Fe (−Cu, − Au) Sn (−Cu, −W, −Zn) Au (−As, −Cu)
	Vein Fracture filling deposits which often have great lateral and/or depth extent but which are usually very narrow	Hypothermal –Cu (−Au) Mesothermal –Cu-Pb-Zn-Ag-Au Epithermal –Au-Ag (−Hg)
	Mississippi Valley Type Named for the region where they were first described, these deposits formed within porous carbonate rocks (limestone reefs or caves)	Pb-Zn deposits with low Ag values
	Stratiform sediment-hosted redbed Cu	Cu
Syngenetic Mineral deposit which formed at the same time as the rocks that enclose it	Volcanic Massive Sulphide (VMS) These deposits formed as massive (over 60 % sulphide) lens-like accumulations on or near the sea floor in association with volcanic activity	Felsic volcanic hosted –Cu-Pb-Zn-Ag-Au Mafic volcanic hosted –Cu (−Zn, −Au) Mixed volcanic/sedimentary – Cu-Zn (−Au)
	Sedimentary Massive Sulphide (SedEx) Deposits formed by hydrothermal emanations on or near the sea floor in association with the deposition of sedimentary rocks	Pb-Zn-Ag Ba
	Magmatic-layered mafic intrusion During the crystallization of a magma, usually mafic or ultramafic, heavy, metal-rich liquids settle and accumulate at specific sites, often at the base, within the intrusion	PGM (Platinum group metals) Chromite Ni-Cu (−PGM)
	Placer Formed within sediments by the concentration of heavy resistant minerals by stream or wave action	Au, diamond, cassiterite

halo models that dominate our understanding of those world-class ore deposits related to the interior workings of igneous systems. The latter are known as orthomagmatic systems and encompass the majority of the deposits listed in Fig. 15.2a. There, interior igneous processes of fractional crystallisation and liquid immiscibility largely control ore formation in a framework of the evolution of world-scale tectonics across time, from Archaean greenstones to those of present-day plate tectonism. Examples where buried evaporites have been assimilated into a magma chamber are discussed in the next chapter. Then there are the various ore deposits that are external to (paramagmatic) or unrelated to the emplacement of igneous bodies (nonmagmatic). In both cases, the mineralisation is typically part of an ongoing longterm sedimentary burial history, tied to dissolving and flowing masses and associated hydrothermal circulation.

So, this chapter focuses on nonmagmatic ore deposits. The conceptualization of metal sources in a framework of orthomagmatic versus paramagmatic versus nonmagmatic is important as it either ties the deposit style to times and locations of magmatism and associated metal/heat brine sources or, in nonmagmatic settings, it does not.

Evidence for hydrothermally-induced low-moderate temperature mineralisation is often best preserved in textures in the hydrothermally altered rock matrix, typically located outside the actual ore deposit (in its hydrothermal alteration halo). From the hydrothermal perspective, one should see the role of evaporites and metal sulphides as each contributing its part to a larger scale "mineral systems" paradigm, much in the same way as, in a petroleum system, the integration of concepts of source, carrier, seal and trap are fundamental requirements to understand and predict economic oil and gas accumulations.

This ore systems approach is not fully encompassed in a number of economic geology studies that use sequence stratigraphic sedimentological approaches for ore deposit prediction in greenschist terrains (Ruffell et al. 1998; McConachie and Dunster 1996). In my opinion, this approach can shift the interpretation paradigm too far into the depositional realm. The problem with classic sequence stratigraphic approaches, when trying to understand ore genesis, is that sequence stratigraphy does not handle well the concept of a mobile ephemeral subsurface salt body that climbs the stratigraphy via autochthonous and allochthonous process sets (halokinesis). As the salt flows, it dissolves and so brings with it the associated epigenetic influences of brine-driven diagenesis and metasomatism. Current sequence stratigraphic paradigms in the economic geology realm are dominated by the assumption that the geometry of the units in the depositional system, and associated fault characteristics, are relatively static within the buried sediment prism. Yet, in terms of most sediment-hosted hypersaline ore deposits, what is most important in understanding the metal-evaporite association is the understanding of; (1) evaporite dissolution and halokinesis, (2) Migration of subsurface fluids, (3) creation of nearsurface redox fronts along with, (4) the opening and closing of fault/shear focused fluid conduits, typically tied to, the coming and going of bedded and halokinetic salts. These factors, rather than primary sediment wedge geometries, are the dominant controls as the mineralising system passes from the diagenetic into the metamorphic realm.

It is interesting that in a benchmark paper, discussing and classifying the world's ore deposits in a plate-tectonic-time framework, Groves et al. (2007) list almost all the major ore categories shown in Fig. 15.2b as belonging to the group of "…sediment-hosted deposits of non-diagnostic or variable geodynamic setting." Into this category they place all stratiform to stratabound sediment-hosted deposits with variable proportions of Pb, Zn, Cu (including Zambian Copper belt, Kupferschiefer and SedEx deposits). They go on to note (p. 26) that, although there is general agreement that the majority of these various deposits formed during active crustal extension, either in intracratonic rift basins or in passive margin sediment hosts, there is considerable controversy concerning their broader scale tectonic setting at the time of mineralisation and the driving force for hydrothermal fluid flow at the time of their mineralisation.

Perhaps this lack of model specificity in the varied interpretations of sediment-hosted deposits reflects the fact that one piece of significant information is missing from many ore genesis models. Namely, that the greater majority of these poorly classified sediment-hosted deposits sat atop, or adjacent to, or beneath, what were once thick evaporite sequences. It was the dissolution of these salt masses, either bedded or halokinetic-allochthonous, that focused much of the ore-fluid flow in the sedimentary-diagenetic realm. The loss of salt as the basin sediments passed from the low temperature diagenetic into the metamorphic realm, and as metalliferous fluid flow was focused into permeable conduits about or above the dissolving and retreating, or flowing salt edges, is how salt-related ore deposits form.

This is why the majority of these deposits tend to occur outside salt basins that retain substantial salt masses still in the diagenetic realm (Fig. 15.1). They are a response to the dissolution of evaporites, or the residual seawater bitterns created in underlying and subjacent settings as the salt beds were deposited, not the presence of evaporites. As we saw in the previous chapter in our discussion of Proterozoic and Archaean meta-evaporites, in most Precambrian evaporite associations the original salt mass is long gone from the hosting succession, via varying combinations of halokinesis, dissolution and metasomatism. Ore deposits of this age tend to be linked to evaporite alteration products and residues and rarely preserve actual sedimentary salts (other than local remains of hydrothermal anhydrite). In younger Phanerozoic

deposits, such as Kupferschiefer, the Atlantis II deep and Dzhezkazgan, portions of actual salt (brine source) remain in the more deeply buried parts of the basin.

Metal sulphide precipitates are not rare or unique in the subsurface diagenetic fluid milieu, what is important in prediction of ore-grade levels of metal sulphide buildups is understanding where and why the metal precipitation system was focused into particular structurally-controlled positions. That is, evaporite associated ore deposits are no more than ancient subsurface hydrology-specific associations where the precipitation system was stable enough, for long enough, to allow ore-grade levels of metals sulphides to accumulate from carrier brines. As such, they are part of the ore-forming process set, spread across the epigenetic and syngenetic realms (Table 15.1). They were part of the regional evolution of the fluid plumbing from time of deposition, into burial, and on into the realm of metamorphic transformations. This means to holistically understand the ore system in an evaporite-entraining system one must integrate local ore paragenesis with various aspects of the basin-scale geology, sedimentology, sequence stratigraphy, diagenetic metamorphic-igneous facies, fluid flow conduits and structural evolution of the evaporitic basin.

A Little Classification/Exploration Philosophy

Personally, I do not find much benefit in trying to create an exploration paradigm using the currently accepted somewhat generalised SSC, MVT or SedEx groupings that capture most low temperature base metal deposits. All the current compilations of Stratabound Sedimentary Copper (SSC), Mississippi Valley Type (MVT) and Sedimentary Exhalative (SedEx) deposits tie a very broad range of range of stratiform deposit styles into general association of metal precipitation occurring in sediment hosts, which may be redbeds, shelfal carbonates or deeper/quieter water laminites (as an example see the excellent compilation of Cox and Singer 2007). All these deposits are thought to form in low temperature settings, still largely in the thermal range of diagenetic (not metamorphic) geosystems, and are fed and bathed in cross-flowing basinal basement brines. Once formed, subsequent structuration and metamorphism can enhance ore quality.

Some SSC, MVT and SedEx models have the fluids escaping from the basin during basin subsidence, others call upon deep meteoric circulation driven by basin collision and uplift of the basin margin, still others draw upon the convection of basinal brines beneath evaporite seaway sediments and or the mixing of basinal and basement brines. None are rock texture specific, so making the use of applied targeting approaches problematic, if based on textures seen in outcrop, or recovered in core.

I am not saying the varied interpreted process sets, that explain the SSC, MVT and SedEx deposits, are wrong, only that the current classification sets are so broad that, when exploring, they lack the ability to make specific on-ground target predictions. Other than a general notion that most of these deposits are typically tied to faults acting as fluid conduits, there is little commonality in rock textures and lithologies across the host rock spectrum. That is to say, most of the host rock textures are extensive, but the faults are local, so we tend to target the fault or a set of fault trends, hoping to find mineralisation. Geochemistry of various sorts is the tool used to highlight areas of "on ground" interest and specify more targeted drilling; typically host rock textures do not play much of a role as part of the exploration paradigm.

But, if we can establish that evaporites (bedded or halokinetic) or their residues acted as foci to mineralisation in some types of SSC, SedEx and MVT deposits then, through recognition of positions of former evaporites either in outcrop or core we can establish additional targeting parameters to define where these masses have intersected or interacted with fluid-carrying faults. This gives us an improved ability to predict that ores are more likely to be found at or near the intersections between faults and evaporites or their residues. So for a subset of SSC, MVT and SedEx deposits (the evaporite-related subset) we then have the ability to more reliably locate and orient drilling sites and drilling grids.

Unfortunately, modelling paradigms in classic economic geology typically concentrate on particularized ore parageneses and the detailed measurement of trace/rare-earth element constituent levels, which are tied to metal sulphide emplacement, within and about an ore deposit (aka the "indicator halo"). When exploring for new deposits, this halo understanding and associated data trends are used in designing geochemical and remote sensing approaches. Inherently, this approach is most fruitful in brownfields expansion studies, it gives the more localised understanding needed to predict ore extensions and hence where to extend the current mining operation. But in greenfield areas, where predictive regional models are needed, it leads to less predictive ore exploration paradigms, other than a general concept of… "let's grid-drill (typically air-drill) around that fault with the gossan, or in the region of the associated soil anomalies, and see what we get back in the plots of the geochemical analyses of the rock flour".

With this in mind, I propose a somewhat different classification for those sediment-hosted (this chapter) and igneous-related (next chapter) ore deposits that can be linked to evaporitic associations, which are indicated by remnant salt bed and masses, their residues or their alteration products. It focuses on the nature of the evaporite, or former evaporite, (bedded or halokinetic residues) and the

ore deposits position relative to the former salt bed or salt mass. When classifying these ore deposits at the intrabasin scale, I ask; where in earth-space were these evaporite-associated metalliferous ore deposits located (within the diagenetic and early metamorphic evolution of the evaporite mass)? And I answer in terms of the following criteria:

(i) Is the ore deposit related to stratiform or halokinetic (allochthon) salt beds/masses and/or their residues?
(ii) Is the ore deposit in a; subsalt (below a thick >50–100 m salt bed/mass), intersalt (interbedded with ≈2–10 m thick salt beds) or suprasalt position (above a thick >50–100 m salt bed/mass)?
(iii) What was the likely dominant mineralogy in the former now dissolved salt mass (halite, anhydrite, trona, nahcolite, etc.)?

For the plate tectonic framework, I ask:

(i) What was the plate tectonic setting at the time these ore deposits formed; convergent, divergent, intracratonic sag or strike slip?
(ii) Does it relate to the plate tectonic association of the interacting evaporites? If yes, then: What was the depositional style of the host sediments (shallow or deep water; marine or nonmarine)? This also relates to the style, scale and geometry of the salt-related plumbing at the time of interaction/ dissolution: Was it a saltern or a basinwide salt unit, was it interbedded, massive stratiform or halokinetic? If halokinetic, was it autochthonous or allochthonous?
(iii) Was there a single metalliferous fluid or multiple fluids linked to the mineralisation/diagenetic history? Was the fluid source a burial water, or a magmatic or a metamorphic fluid, or was it some type of hybrid?
(iv) Was the deformation history of the deposit simple or complex and does it relate to the metamorphic grade or early structural controls, including halokinetic structuration of the salt overburden?

The resulting illustrative listing of some nonmagmatic deposits given in Table 15.2 is by no means comprehensive. It showcases only some of the more well-known Phanerozoic and Proterozoic examples where actual salts, or obvious residues, are still present. In the next chapter I shall expand on it as we develop paramagmatic and orthomagmatic models. For the deposits listed in Table 15.2 the depositional and diagenetic conditions are reasonably well understood in terms of atmospheric, marine and subsurface pore fluids conditions, most of these examples formed within subsurface basin chemistries somewhat similar to those seen today.

Evaporite-Related Metalliferous Brines?

Before we classify and discuss evaporite-linked ore deposits, we need to discuss in general terms how metals are sourced, transported and fixed in the various subsurface fluids found in sedimentary basins containing thick successions of dissolving evaporite salts. Chloride complexes, not organometallic or bi-sulphide complexes are what transports the greater volume of base metals through the pore spaces in the diagenetic realm of today's sedimentary basins (Kharaka and Hanor 2003). Through the inherently high pore brine densities created by subsurface halite dissolution, such high-chloride basinal brine densities can drive metal leaching waters deep into the understrata, including crystalline basement (Chap. 8; Koziy et al. 2009; Fusswinkel et al. 2013).

Also aiding the creation of metalliferous brines in the diagenetic realm is the sequential release of a metal series as organic-rich shales are subject to burial compaction under increasing temperature and pressure (Table 15.3; Wallace et al. 2002). The evolution parallels the maturation/generation of first liquid and then gaseous hydrocarbons (Chap. 9). Released metals are dissolved in the basin's aqueous (chloride-rich) fluids via a sequence of thermochemically controlled metal-maturity windows. That is, metals are released from maturing shale/mudstone source rocks in a progressive sequence, determined by ion concentrations and degree of association of ion complexes (Helgeson 1969), so that metals of similar ionic strengths and ionic diameters are released together. The temperatures at which these metal suites are released overlap, but the release from the shaly diagenetic sources follows a consistent pattern with increasing depth of burial.

As well as this grey-bed leaching, metals can also be leached diagenetically via redbed alteration in evolving saline oxidised nonmagmatic brine systems. In paramagmatic systems, igneous bodies can act as an additional source of brine products, as can leached volcaniclastics. Once released, as in a petroleum system, there must be carrier beds for the metalliferous brines, along with focusing mechanisms and then traps and seals to focus accumulations. As we shall see throughout this chapter and the next, this is how subsurface salt masses make substantial contributions to the formation of an economic metal accumulation. Before, or as, subsurface evaporite salts disappear, they generate various brine chemistries that can transport, seal, trap, focus and precipitate ore. Thus, a buried evaporite unit can act as:

(i) *An ionic source* – As the salt dissolves or alters it acts as a brine or volatile source feeding into the basin hydrology. It can supply economically important ions that, depending on the dissolving mineralogy, may be chloride-rich or a source of sulphur and so act as both a leacher and transporter of metals.

Table 15.2 Classic ore deposit breakdown (stratiform redbed-related Cu versus MVT Pb-Zn deposits) of some of the many Phanerzoic-Neoproterozoic base-metal deposits formed in the diagenetic realm in association with bedded, dissolving and flowing evaporites, mostly in situations where actual salts or remnant salts are still present. More comprehensive lists and discussions of less obviously evaporite-linked ore deposits are discussed later in this chapter and the next

Deposit, location (age of host)		Reserve (10^6 tonnes)	Cu (%)	Pb (%)	Zn (%)	Evaporite role (relative position and mechanism)	Evaporite association
Deposits associated with bedded evaporites or their residues							
Redstone River, Canada (Neoproterozoic)	Stratiform -sediment hosted copper (redbed) deposit	Small	2.7	–	–	Intersalt stratabound with subsalt focus to upwelling brine	Redbeds with bedded algal limestone host and abundant nodular $CaSO_4$
Creta, Oklahoma, USA (Permian)		1.9	2	–	–	Intersalt bedded (breccia), adjacent redox precipitates	Redbed – evaporitic mudflat host with abundant nodular $CaSO_4$
Corocoro, Bolivia (Eocene)		≥7	≈5	–	–	Intersalt bedded (breccia), brine reductant	Redbed – greenbed host with gypsum and baryte in veinlets and disseminated nodules
Nanisivik, Baffin Island (Mesoproterozoic)	Mississippi Valley Type deposit	6.5	–	1.5	12	Intersalt?, bedded	Host is a stratiform karst cavern: evaporites and pseudomorphs in lateral equivalent beds
San Vincente, Peru (Triassic – Jurassic)		12	–	1	12	Intersalt, bedded. Local supplier of sulphur via TSR	Ore hosted in cryptalgal laminites with pseudomorphs after $CaSO_4$ in barrier-lagoon host
Cadjebut, NW Australia (Devonian)		3.8	–	17 % (Pb + Zn)		Intersalt, bedded (breccia). Local supplier of sulphur via TSR	Bedded anhydrite as lateral equivalent to each ore lense and linked by evaporite dissolution breccias
Largentiére, France (Triassic)		9.6	–	0.7	3.7	Intersalt	Disseminated $CaSO_4$ cements and nodules within evaporitic lagoonal beds
Peridiapiric deposits associated with halokinetic evaporite masses or their residues							
Atlantis II Deep, Red Sea (Holocene)	Stratiform redbed -related copper deposit	150–200	0.8	Yes	5–6	Suprasalt allochthon acts as focus to resurging Cu-Zn-Cl brine (salt partially covers ridge basalts)	Dissolving salt allochthon underbelly supplies Cl-rich metalliferous brine to deep seafloor brine lake. Hydrothermal anhydrite is interbedded with laminites
Kupferschiefer-style, Lubin, Poland (Permian)		≈2,000	>2	–	–	Subsalt, stratiform with brine focus creating the Rote Faule contact and adjacent redox precipitates	Anhydrite and halite in Zechstein hangingwall and anhydrite in Rotliegende footwall – redbed ore source
Kupferschiefer-style, Mansfeld, Germany (Permian)		≈7.5	≈2.9	–	±1.8	Subsalt, stratiform with brine focus	Anhydrite and halite in Zechstein hangingwall and anhydrite in Rotliegende footwall – redbed ore source
Dzhezkazgan, Kazakhstan (Carboniferous)		≈400	1.5	0.1–1.0	–	Suprasalt diapiric, anticlinal focus to brine flow	Interbedded redbed and greybed host with $CaSO_4$ and halite in underlying salt anticline and lateral equivalents
Dongchuan deposits, China (Mesoproterozoic)		10–100	1.0–1.5	–	–	Suprasalt allochthon or intrasalt breccia. Allochthon acts as focus to resurging metalliferous brine	Stratabound ore in cryptalgal laminites adjacent to diapiric breccia
Lisbon Valley, Utah, USA (Cretaceous)		Small >0.15	1.4	–	–	Suprasalt allochthon, salt movement creates orehosting faults in overburden	Ore in vein and pore fills adjacent to faults created by halokinesis
Jubilee, Nova Scotia (Carboniferous)	Mississippi Valley Type deposit	Not economic	n/a	n/a	n/a	Subsalt allochthon (tectonic breccia) stratiform, subsalt focus to brine flow	Interstratified fractured carbonate and anhydrite ore host created by regional salt-induced gravity slide
Gays River, Nova Scotia (Carboniferous)		2.4	–	8.6	6.3	Subsalt with subsalt focus to upwelling brine. Local supplier of sulphur via TSR	Anhydrite both within main ore zone and as cement in disseminated ore
Bou Grine, Tunisia (Cretaceous)		7.3	–	2.4	9.7	Suprasalt, peridiapiric, brine focus via halokinesis	Ore in peridiapiric organic-rich pyritic laminates adjacent to halite allochthons
Gulf Coast USA (Tertiary)		Not economic	n/a	n/a	n/a	Suprasalt allochthon capstone, brine focus via halokinesis	Anhydritic caprock undergoing bacteriogenic alteration in association with reservoired hydrocarbons

Table 15.3 Temperature ranges associated with various metal releases in an organic-rich shale undergoing burial diagenesis

Metal maturity window	Temperature (°C)
U-V-(Th)	35–100
Au-PGE	60–110
Cu-Ag	60–120
Pb-Zn	70–180
Au-Co-Au	175–275

After Wallace et al. (2002), Helgeson (1970)

(ii) *A seal and* trap – Thick evaporite units act as a seal, limiting or preventing the free vertical escape of basinal, hydrothermal, hybrid or upwelling meteoric waters. Given the right geometry, an evaporite unit can also act as a fluid barrier that, until it is breached, can pond or hold back buoyant metalliferous basinal waters and hydrocarbons.

(iii) *A* precipitative *focus* – Breach points or brine mixing zones tied to the edges of a dissolving evaporite mass (i.e. the edge of bed or the edge of a salt body created by flowage, décollement, or faulting). The edge to an impervious salt mass tends to focus the escape/mixing of pressured subsurface waters into the zones above, within or sometimes even below the breach (Chap. 8). Additionally, hot metalliferous basinal water, escaping via a breach or conduit into a nearsurface and surface setting, can create brine ponds and replacement haloes about, near or atop the escape conduit.

Even after the actual salts have long gone, a zone of dissolution residues can act as an aquifer or focus for ongoing metalliferous brine flow. Recognising the process and timing under which an evaporite disappears or its residues become an aquifer is often the most important step in understanding the evaporite ore deposit link. This is especially true of ore deposits hosted in Proterozoic and Archaean rocks and metasediments where no actual salts remain, only indicators of the former evaporite protolith. Such saline metalliferous flow paths may at times be indicated by the presence of hydrothermal zebra dolomites (Diehl et al. 2010).

To better define the role of the various metal-carrying chloride brines in evaporitic basins, we will first discuss the nature and chemistry of modern subsurface basinal brines, then chemistries suitable for metal precipitation and then look to likely examples of resultant ore deposits in the sedimentary and greenschist realms.

Modern Basin Brines: Composition

Sampled deep formation waters, in particular oilfield brines, vary widely in salinity, composition and their metal-carrying capacity (Chap. 8). Most deeper saline brines, even if not carrying hydrocarbons, tend to be anoxic or, at best occasionally dysaerobic. That is, levels of dissolved oxygen in subsurface petroleum-related waters are always low and typically undetectable (Collins 1975, p. 159). Shallower, primary reflux brines can retain somewhat higher oxygen levels, but, significant dissolved oxygen levels in a brine occur only where subsurface waters are in hydrodynamic connection with the surface and are actively receiving a surface-recharge (Collins 1975, p.301). Kuznetsov (1957) measured the dissolved oxygen content in brines from wells in the Groznyv oil district and found up to 10.6 mg/l at a depth of 249 m. He also found that in general, dissolved oxygen was found only in the zone of active water circulation (surface recharge) and was lacking in zones of stagnant phreatic waters and below. This general observation has important implications in understanding depth-related controls on distribution of Rote Faule related ore zones, such as in the Kupferschiefer copper deposits of NW Europe (discussed later).

In the deeper portions of most saline basins, the dominant anion is Cl and the dominant cations Na and/or Ca (Houston et al. 2011). Elevated levels of chloride in modern basinal brines are typically created by some combination of subsurface dissolution of halite (aka secondary brines; Land 1995a, b) and infiltration of subaerially evaporated seawater (aka primary brines or reflux brines; Carpenter 1978). Both are subject to further alteration in ionic proportions in response to other ongoing water-rock interactions, such as albitisation at lower salinities and dolomitisation at moderate salinities (Houston et al. 2011).

In general, the salinity of modern basinal brines increases with depth, especially in basins entraining thick deeply-buried salt masses (Fig. 15.3; Kharaka and Thordsen 1992). Basinal pore water salinities are typically higher than seawater (35 g/l) and range to over 350 g/l in basins with thick partially-dissolved basal salt units. In some basins there is a progressive increase in salinity with depth, in others, especially in Tertiary basins with thick dewatering shale units, there may be a reversal of this trend with depth (California and South Louisiana basins in Fig. 15.3). The salinity of a Na–Cl or Na–Ca–Cl brine can be estimated from its chlorinity by the relationship; salinity $\approx$ 1.7 chlorinity. This is the basis for most of the salinities estimated from oilfield waters and plotted in Fig. 15.3 (Hanor 1996).

Inorganic (Halogen) Components in Basinal Brines

Most basinal brines of moderate salinity are dominated by dissolved Na and Cl and, as salinity increases, there is a progression from Na-Cl to Na-Ca-Cl to Ca-Cl brines (Kharaka and Hanor 2003; Houston et al. 2011). Chloride is the dominant anion in formation waters with salinities greater than 20,000 mg/l, while a transition zone between 20,000 and 10,000 mg/l defines a total dissolved solid (TDS) boundary

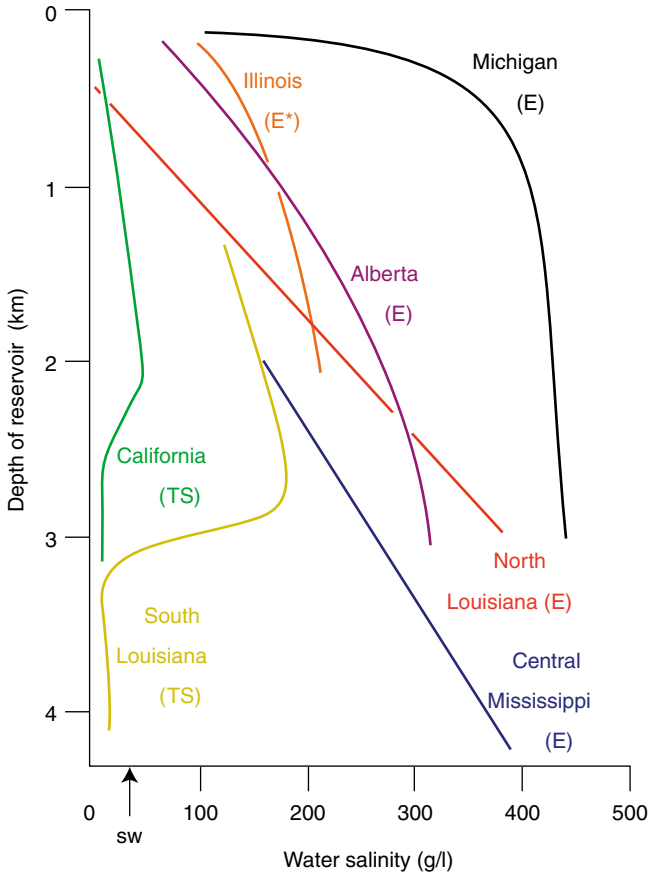

Fig. 15.3 Salinity to depth profiles in selected basins (After Kharaka and Thordsen 1992) *E* evaporitic, *E** former, now dissolved evaporite, *TS* Tertiary shale-rich basin. *Sw* indicates seawater salinity

below which the dominant anion is either bicarbonate, sulphate, or acetate (Fig. 8.40). Sodium is the dominant cation in basinal brines with salinities less than 300,000 mg/l. In general, the relative proportion of Na to K, Ca, or Mg decreases with increasing salinity and Ca becomes the dominant cation in basinal brines having salinities in excess of 330,000 mg/l TDS. Between 300,000 and 330,000 mg/l TDS, the dominant cation is either Na or Ca. Houston et al. (2011) show that most highly saline oilfield formation waters have cation chemistries controlled by chemical equilibration with the host rocks. Thus basinal fluids are almost invariably enriched in Ca relative to Na, when compared to evaporated modern seawater of similar chlorinity. This is the result of ongoing diagenetic mineral-fluid interactions in the subsurface and $CaCl_2$ brines are the result.

Evaporites are important contributors to the major ion chemistry of basinal brines through a combination of early brine reflux, ongoing nearsurface and, more importantly, subsurface dissolution/alteration (Houston et al. 2011; Hanor and McIntosh 2007). The chemical make-up of a subsurface brine depends on the mineralogy of the dissolving salt sequence and labile components in other sediments in the basin. Thick beds of dissolving halite (the most common Phanerozoic evaporite salt) generate regional chloride-rich brines. Leached anhydrite/gypsum successions are likely to develop sulphate- or sulphide-enriched waters, depending on the oxidation state of pore waters at the site of dissolution. Associated brine reflux during subsurface dissolution can drive convective circulation cells, as well as leach and transport metals, within and through the adjacent sediments. Ongoing reaction of this reflux brine with the nonevaporite matrix in nearby beds modifies overall brine chemistry (see Chap. 8).

Ongoing interaction with a dissolving salt mass is seen in the halogen water chemistry (Cl, Br, F, I) of Phanerozoic sedimentary basins. According to Worden (1996), the key geological parameters influencing chlorine and bromine (and possibly fluorine) concentrations in the basinal waters are, in order of importance: (1) Presence of salt in the basin, (2) Age of the aquifer unit, and (3) Kerogen type within any significant organic-rich rocks in the basin. Worden concluded the presence of salt in a basin means that any connate water contributing to the basin water chemistry is hypersaline. More importantly, he showed that most high chlorinity subsurface waters are not connate (i.e. not preserved seawater), but are generated though pore-water salt bed interaction during burial (e.g., Ferguson et al. 1992, 1993; Land 1995a, b).

Worden 1996 found that brines in Tertiary-age basins typically have much lower chlorine and bromine concentrations than pore waters in Mesozoic or Palaeozoic rocks. This age separation may simply reflect the different amount of time the basinal waters had to interact with any buried salt beds or that the effects of shale dewatering tends to dominate in rapidly subsiding mud-rich portions of Tertiary sedimentary basins (Fig. 15.3; California and South Louisiana basins).

Dominance of type II marine kerogen in a basin leads also to a higher bromine concentration in the basinal waters. According to Worden this may reflect the dominance of marine influences in a type II entraining basin, which in turn is more likely to lead to greater volumes of salt deposition compared with a basin dominated by terrestrial/meteoric inflows. Iodine concentrations in subsurface waters are independent of all these parameters. He found that other geological parameters, such as depth of burial, temperature, basin-forming mechanism and reservoir lithology, exerted no recognisable influence upon halogen concentrations.

In general, the pH of subsurface waters decreases with increasing salinity from values of approximately 8 for salinities near 20,000 mg/l to values between 3 and 4 for halite-saturated brines with salinities near 330,000 mg/l, thus most Na–Cl and Na–Ca– Cl brines have a pH in the 4–8 range (Fig. 8.40). Acidity, and hence the ability to leach and carry metals, can be augmented by the presence of dissolved organic acids, and CO_2, but the proportion of both, relative to

chlorinity, tends to drop off with increasing salinity (Fig. 15.5a). Outside of oilfield waters, true *in situ* pH values in deep subsurface brines are not well known, nor are the relative contributions of the various diagenetic processes that create and maintain acidity. Whatever the other possible carriers in a basinal or hydrothermal water it has been known for 40 years that elevated salinity (chlorinity) is the key to metal transport in the sedimentary diagenetic realm.

Metals, Ligands and Salinity

Oil field brine chemistry, including Holland's (1972) now-classic experiments, show that the solubility of metals such as Pb, Zn, Mn, and Fe varies as an exponential function of the chloride ion (Cl^-) concentration or salinity of the fluid and temperature (Figs. 15.4 and 15.6a). Both natural pore fluid chemistry and laboratory experiments show aqueous solutions tend to contain other dissolved ingredients that metals can bond to, thereby promoting metal dissolution. For example, the solubility of a mineral such as galena (PbS) in pure water, even at high temperatures, is extremely small. Wood and Samson (1998) calculated that the amount of Pb that could be dissolved in an aqueous solution (with 10^{-3} molal H_2S and in equilibrium with galena at 200 °C) would be a trivial 47.4 ppb. If 5.5 wt% NaCl is added to this solution, the solubility of Pb at the same temperature increases significantly to 1,038 ppm and will continue to rise with increasing temperature (Fig. 15.4).

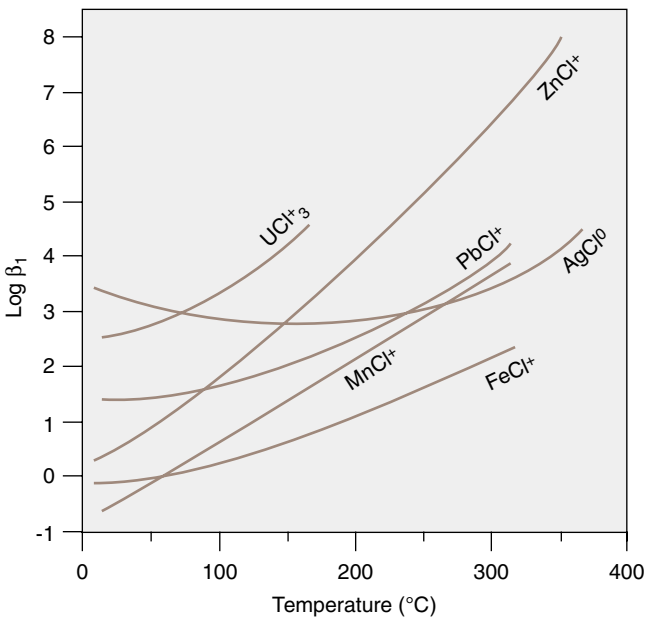

Fig. 15.4 Plot of the effective stability of a metal complex (expressed in terms of β_1, which is the equilibrium formation constant) versus temperature (After Seward and Barnes 1997). The stabilities of metal–chloride complexes shown increase by several orders of magnitude as temperature increases, as will their solubilities in aqueous solution (Redrawn from Robb 2005)

In addition to Cl^-, a variety of different ligands (electron donors or electronegative ions with lone pairs of valence electrons) will affect the solubility of metals in solution (Robb 2005). Ligands (particularly those that are chloride-associated in the high salinity sedimentary realm) combine with metallic ions by the formation of a coordinate bond, which is a type of covalent bond where the shared electron pair is provided by one of the participating molecules (the ligand in this case) rather than the normal situation where the shared electrons are supplied from each of the two participating components. A ligand that promotes the formation of complexes by coordination bonding will typically increase the solubility of metals in aqueous ore-forming solutions (Fig. 15.4).

How metals go into solution in basinal and hydrothermal fluids can be understood using the concept of Lewis acids and bases (Robb 2005). Conventional acids and bases are defined as substances capable, respectively, of contributing H^+ ions to, or taking up H^+ ions from, a solution. In contrast, Lewis acid/base concepts are applicable to subsurface fluid situations where H^+ ions are not present, and this has particular relevance to geological situations (Gill 1994). A Lewis acid is defined as an atom or molecule that can accept a lone pair of valence electrons, whereas a Lewis base can donate an electron pair to a bond.

"Hard" Lewis acids are strongly electropositive metals (with high charges and/or small atomic radii) such as the alkali and alkaline earth metals (e.g. Na^+, K^+, Mg^{2+}, Ca^{2+}) that form ionic bonds with strongly electronegative elements, like oxygen (O^{2-}). "Soft" Lewis acids have an abundance of easily accessible electrons in their outer shells and prefer to form covalent bonds with soft bases (Table 15.4, Robb 2005). Soft acids are typified by the chalcophile metals (i.e. those that have an affinity with sulphur, such as Cu, Pb, Zn, Ag, Bi, Cd), which tend to form covalent bonds with ligands of low electronegativity, such as S^{2-}. The principle stating that, in a competitive situation, hard metals (acids or electron accep-

Major ligands in basinal and hydrothermal waters shown in bold italic text

tors) will tend to complex with hard ligands (bases or electron donors), and soft metals with soft ligands, is commonly referred to as Pearson's Principle, and underpins the solubility behaviour of metals in hydrothermal and basinal waters and the notion that different leach lithologies provide different metal proportions in the leachate fluids, which is the basis for Fig. 15.4.

A "borderline" category is added to accommodate the fact that some metals (such as Fe and Pb) can complex readily with both hard and soft ligands, forming a range of minerals such as sulphides (pyrite FeS_2, galena PbS) and carbonates (siderite $FeCO_3$, cerrusite $PbCO_3$). Likewise, Cl^- can be an effective complexing agent for both hard and soft metals, and therefore promotes the solubility of a wide range of metals in hydrothermal aqueous solutions.

The classification of aqueous ionic species into hard and soft Lewis acids/bases assists considerably in understanding the nature of metal–ligand complexation, and, therefore, the controls on solubility, in basinal/hydrothermal solutions (Robb 2005; Seward and Barnes 1997; Wood and Samson 1998). In addition, it is well known that temperature plays a very important role in determining the degree to which metals enter solution. In most cases stabilities of metal–ligand complexes such as $PbCl^+$ and $ZnCl^+$ will increase by several orders of magnitude as temperature increases from ambient values to 300 °C (Seward and Barnes 1997). This is illustrated, together with data for other metal–chloride complexes, in Fig. 15.4. By contrast, an increase in pressure will have the opposite effect to temperature and the stabilities of metal–ligand complexes will tend to decrease because of bond dissociation and the formation of free metal ions. In general, however, the effect on solubilities of pressure increases are minimal and more than offset by the significant changes associated with temperature increases (Seward and Barnes 1997).

So let us now consider the significance of Lewis principles in the transport of the base metals (Cu, Zn and Pb) in the lower temperature sedimentary brine settings discussed in this chapter. In subsurface brines, copper occurs in both Cu^+ and Cu^{2+} valence states, although the monovalent state is predominant in most hydrothermal and basinal fluids (Robb 2005). It is a relatively soft Lewis acid and forms stable Cu^+ chloride and Cu^+-bisulphide complexes, as well as Cu^+-hydroxide complexes if other ligands are not available. Movement of copper in basinal solutions occurs under a wide range of conditions and is most likely to carried as Cu^+–chloride complexes in the form $CuCl^{2-}$. Although copper–bisulphide complexes will form in high-sulphur environments, they are not likely to play a significant role in most hydrothermal/basinal brine ore-forming environments where chloride dominates.

The dominant divalent zinc cation, Zn^{2+}, is a borderline Lewis acid that complexes with a variety of ligands, including Cl^-, HS^-, OH^-, HCO_3^-, and CO_3^{2-} (Robb 2005). At relatively low temperatures and high pH, and in fluids with high bisulphide concentrations but low salinities, a variety of Zn^{2+}-bisulphide complexes are stable, including $Zn(HS)_2$, $Zn(HS)_3^-$, and $Zn(HS)_4^{2-}$. In contrast, at higher temperatures and salinities and under more acidic conditions, a host of chloride complexes predominate, including $Zn(Cl)^+$, $Zn(Cl)_2$, $Zn(Cl)_3^-$, and $Zn(Cl)_4^{2-}$.

Lead is the softest of the borderline Lewis acids and forms stronger bonds with Cl^- and HS^- ligands than with OH^- or HCO_3^-. The valence state and complexing behaviour of lead is very similar to that of zinc. Pb^{2+}-bisulphide complexes are more stable than chloride complexes in low temperature, neutral to alkaline, low salinity solutions. Different Pb^{2+}-bisulphide complexes form as a function of pH, and these include $Pb(HS)_2$ under acidic conditions and $Pb(HS)_3^-$ at higher pH (i.e. >6). At higher temperatures and lower pH, however, a variety of Pb^{2+}chloride complexes form and these include $Pb(Cl)^+$, $Pb(Cl)_2$, $Pb(Cl)_3^-$, and $Pb(Cl)_4^{2-}$. Pb^{2+}-carbonate or Pb^{2+}-bicarbonate complexes can form in CO_2-bearing fluids but their solubilities are typically low and they are unlikely, therefore, to have relevance in ore-forming processes.

There is also compelling evidence that lead, and to a lesser extent zinc, can be transported by organo-metallic complexes (Table 15.5), especially in relatively low temperature environments such as those related to the formation of some Mississippi Valley type Pb–Zn deposits, where the hydrothermal/basinal fluids are known to contain hydrocarbons. The acetate ligand (CH_3COO^-) is one of a number of organic molecules that have been implicated in base metal transport, others include thiols and sulphur-bearing organic compounds.

Organic Components in Metalliferous Brines

Concentrations of carboxylic acid anions in modern petroleum field brines are highly variable with respect to their major known controls, including age and temperature of reservoir rocks, type and amount of kerogen in source rocks, and the nature of metastable equilibria and water rock interactions that characterize organic-matter interactions in the reservoir (Seewald 2003). Although concentrations vary with temperature and reservoir depth for any given petroleum field, maximum values are generally present in Cenozoic-age reservoir rocks of moderate salinities in the temperature range 80–120 °C (Fig. 15.5a, b; Kharaka and Hanor 2003; Seewald 2003). Within such brines, monocarboxylate anions (mainly acetate, propionate, butyrate, n-valerate) and dicarboxylate anions (mainly malonate, succinate, glutarate, maleate) are the dominant organic acid species. These organic acids are typically detected in moderate salinity formation waters, associated with petroleum, and mostly reside in reservoirs with temperatures ranging from 20° to 200 °C

Table 15.5 Modern oil field brines constituents and their Pb-Zn contents

Parameter	Low ΣH_2S, high trace metal content (brine 1)	Low ΣH_2S, low trace metal content (brine 2)	High ΣH_2S, low trace metal content (brine 3)

Pb (mg/l)	5 to 70 (cluster)	<1.0 (cluster)	<0.1 (cluster)
Pb (mg/l) range	1 to 111	BDL to 0.9	BDL to 0.9
Zn (mg/l)	15 to 250 (cluster)	<1.0 (cluster)	<0.1 (cluster)
Zn (mg/l) range	1 to 575	BDL to 0.9	BDL to 0.9

After Giordano (2003)
Cluster indicates most common values observed for modern petroleum field brines not the total range
BDL below detection limit, usually less than about 0.01 mg/l
Explanation of selected parameters
[a]Total dissolved inorganic sulphide defined as $\Sigma H_2S = H_2S + HS^-$ (mg/l) and $\Sigma m_{H_2S} = m_{H_2S} + m_{HS}$ (mol kg21)
[b]Total dissolved sulphate is defined as the sum of all dissolved sulphate species in mg/l (ΣSO_4) and as the molal sum of all dissolved sulphate species (Σm_{SO4}) in mol kg^{-1}
[c]Total monocbx = sum of monocarboxylate anions, as listed by Giordano (2002) in mg/l (Σmonocbx), while $\Sigma m_{monocbx}$ = total molality of dissolved monocbx in mol kg^{-1}
[d]dicbx = sum of dicarbonxylate anions, as listed by Giordano (2002) in mg/l (Σdicbx), while [e]Σm_{dicbx} = total dissolved dicbx in mol kg^{-1}

(Kharaka et al. 2000). At higher temperatures they are destroyed by various decarboxylation reactions with CO_2 as the ultimate byproduct (Seewald 2003)

Plots of organic acid (carboxylate anions) concentration versus salinity in this temperature range show a pronounced decrease in organic acid concentration with increasing salinity (Fig. 15.5a; Hanor 1994a, b). Highest concentrations are found in pore waters with salinities less than 30,000 mg/l, while these species do not appear to be major constituents of petroleum field brines having salinities that exceed 100,000 mg/l. The total concentration of monocarboxylate anions ($\Sigma_{monocbx}$) in modern petroleum-field brines is generally less than 100 mg/l, however, many brines have concentrations in the 100–5,000 mg/l range (Table 15.5). The dominant monocarboxylate anion in most petroleum-field brines is acetate, followed in order of decreasing concentration by propionate, butrate, and valerate. The highest concentration of acetate reported in a subsurface water is 10,000 mg/l but values above 5,000 mg/l are very rare (Lundegard and Kharaka 1994; Kharaka et al. 2000).

Typically acetate comprises 80–90 % of the total monocarboxylate species (Giordano and Kharaka 1994). The dominant dicarboxylate species in modern petroleum-field brines are malonate, succinate, and glutarate. Each of these species is not likely to have concentrations greater than about 100 mg/l, but controversially high values for oxalate (494 mg/l) and malonate (2,540 mg/l) have been reported (MacGowan and Surdam 1988). Reported total dicarboxylate anion concentrations (Σ_{dicbx}) range from 0 to 2,640 mg/l but values higher than 300 mg/l are very rare.

Typically, brines high in dicarboxylate anions are also high in monocarboxylate anions; however, brines high in monocarboxylate species are not always enriched in dicarboxylate anions. The total dicarboxylate anion concentration is typically less than 5 % of the total carboxylate concentration for modern petroleumfield brines. Thus, the ratio of total monocarboxylate anions to total dicarboxylate anions ($\Sigma m_{monocbx}/\Sigma m_{dicbx}$) for modern basinal brines is nearly always greater than 20 and even higher in some brines with high trace metal contents (Table 15.5).

Basinal Brines: Metal Carrying Capacity

The presence of halite (or indicators of its former presence) in a basin fill announce that, if metals were present in sufficient volumes in adjacent strata to become leachates, then

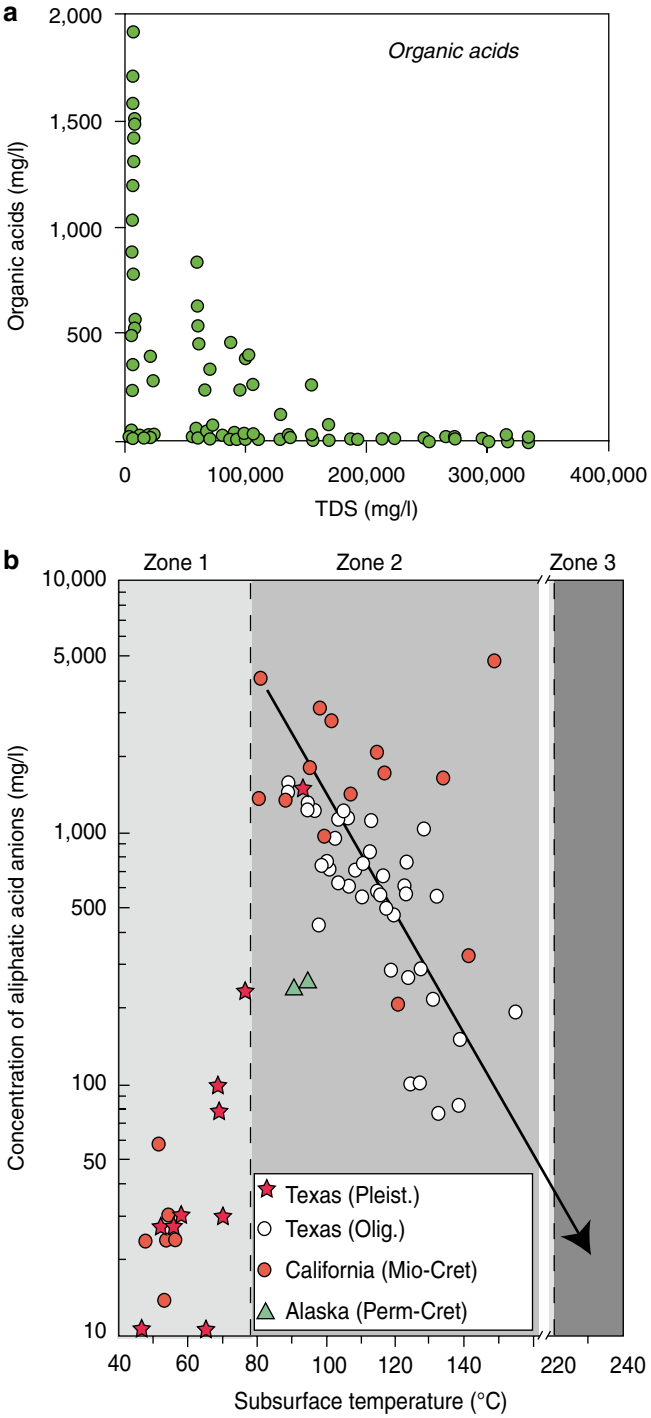

Fig. 15.5 Organics in basinal brines. (**a**) Organic acids in saline brines (After Hanor 1994a, b). (**b**) Concentrations of aliphatic acid anions (C_2–C_5) in formation waters from three sedimentary basins typified by moderate salinities. The highest concentrations are at 80–120 °C and then decrease with increasing temperatures, as indicated by *arrow*, note the scale break at 160 °C (After Kharaka and Hanor 2003)

metal transport as chloride complexes in high salinity brines was highly likely at some stage in the diagenetic history of the basin. Modern basinal pore brines, located near dissolving evaporites, are chloride-rich, somewhat acidic and in some settings, slightly oxidising. They can carry elevated levels of metals as they become more saline, and so act as potential metal "leachers and carriers" in the subsurface hydrology. In order to qualify as a potential ore carrying fluid, a basinal fluid must contain on the order of 1 mg/l or more of the dissolved metal in question (Eugster 1989; Hanor 1994a, b). Most basinal brines that achieve Pb, Zn or Cu values at or above this level have pore salinities that are typically in excess of 200,000 mg/l, with their entrained base metals carried as chloride complexes (Fig. 15.6a). These saline waters also tend to be acidic and have lower levels of organic acids when compared to their less saline counterparts (Fig. 15.5a).

Sediments as Metal Sources

Much of the base metal content, including copper, in low temperature ore deposits in sedimentary basins has an intrabasinal nonmagmatic source. Some researchers propose that the metals in basinal brines are derived either from the alteration and leaching of feldspars and clays that supply most of the iron, lead, barium and strontium, or from the alteration of carbonates to supply most of the zinc (Land and Prezbindowski 1981; Sverjensky 1986; Kharaka et al. 1987). Others workers conclude that leaching of iron-oxide-hydroxides from a redbed parent can source many metals (Carpenter et al. 1974). When incorporated as detritus in first-cycle redbeds, copper-rich mafic rocks such as basalt, or copper-rich mafic minerals (such as hornblende, pyroxene, biotite, oxides and sulphides) in felsic rocks, are ideal copper sources (Fig. 15.7; Kirkham 1989; Brown 2005, 2006). Flushing of metals sequestered into organic-rich evaporitic mudstones are yet another possible source for base-metals (Table 15.3).

Dissolving evaporite beds themselves have also been evoked as possible metal sources. Thiede and Cameron (1978) argued that Cu remains in solution during the initial evaporation process; whereas Pb and Zn enter solid precipitates, such as gypsum and anhydrite. Later dissolution of such evaporites generates a metal source enriched in Pb and Zn and depleted in Cu. More recent models have proposed it is not the evaporites, but the residual bitterns, that have sank (refluxed) into underlying and adjacent sediments, which act as the source of metals in diagenetic-realm base-metal accumulations for lead and zinc in MVT style deposits; for example, in Ireland and Arkansas, (Wilkinson et al. 2009; Kendrick et al. 2011).

Sverjensky (1989) further refined earlier brine transport models by demonstrating that significant water-rock interaction takes place as warm, subsurface chloride-rich brines traverse and interact with various deep aquifers. He concluded that, depending on the dominant lithology of the aquifer traversed by the chloride-rich brines, a single highly saline

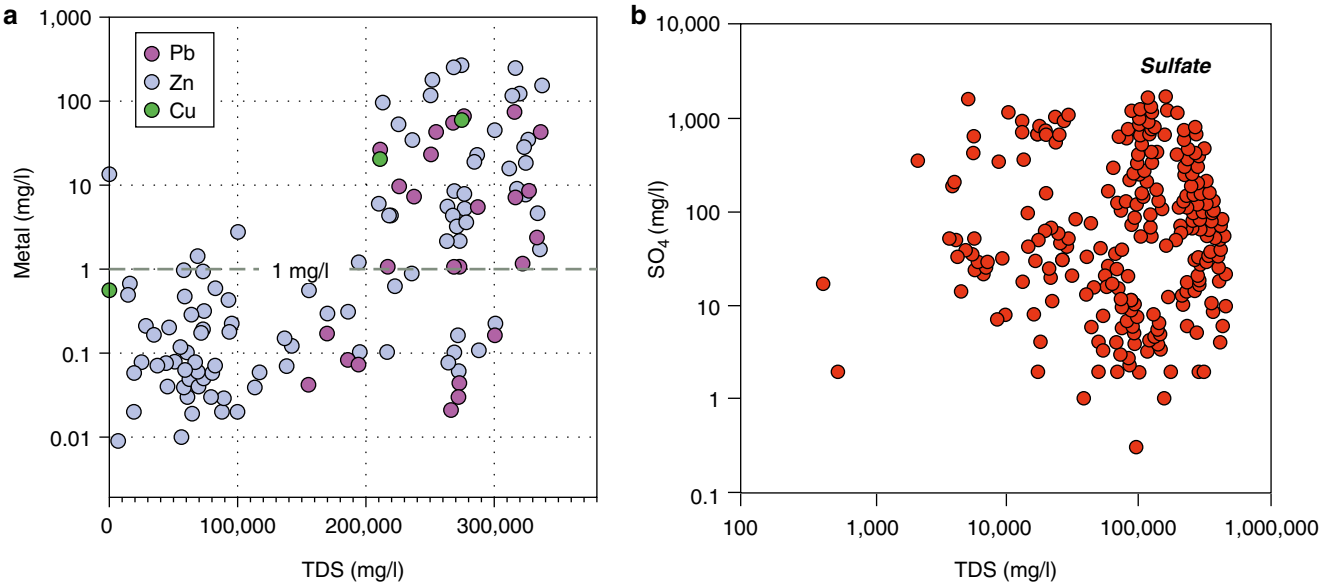

Fig. 15.6 Components of high-salinity basinal brines (After Hanor 1994a, b). (**a**) Metal content of subsurface waters showing elevated metal contents (>1 mg/l) in more saline (chloride-rich) pore waters. (**b**) Sulphate as a function of salinity

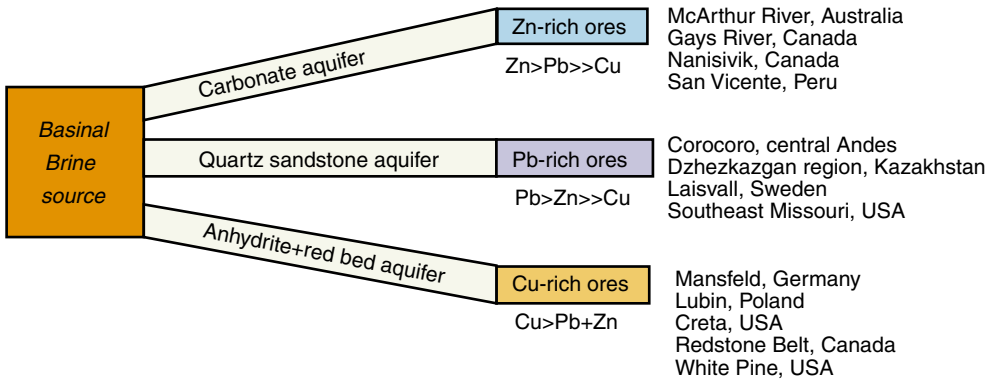

Fig. 15.7 Influence of flushed matrix mineralogy on the base metal precipitated (After Sverjensky 1989)

basinal brine may evolve chemically to become the ore-forming fluid for a wide range of sediment-hosted base-metal sulphide deposits. Migration through carbonate, quartz sandstone, or anhydrite + redbed aquifers could result in the formation of Zn-, Pb-, or Cu-rich deposits, respectively (Fig. 15.7).

As a starting point he considered a typical chloride-enriched basinal brine that was initially saturated with galena, chalcopyrite, muscovite, kaolinite and quartz, but undersaturated with respect to sphalerite, with up to 1 mg/l Pb, 0.1 mg/l Cu and 5 mg/l Zn. Passage of this fluid through a carbonate-cemented aquifer produces a metalliferous brine characterised by high Zn/Pb and (Zn + Pb)/Cu ratios. Transport of the same fluids through a quartz-cemented sandstone exhausts the buffering capacity of the aquifer relatively quickly, so that any mineral accumulations precipitated from the resulting waters are galena-rich. Maintenance of the oxidation state in a typical basinal brine near the hematite-magnetite buffer prevents copper mobilisation (solubility of Cu in a typical basinal brine is ≈ 0.07 mg/l).

Geochemical sampling by Wilde et al. (2005b) in the Canning Basin of West Australia confirms the theory outlined by Sverjensky (1989). Lead isotope and permeability/porosity data indicate that Carboniferous and Devonian feldspar-rich sandstones and siltstones are the most likely reservoirs for ore-forming brines and metals in the various Pb-Zn deposits of the eastern Canning Basin. The Anderson Formation and Tandalgoo Sandstone are characterized by extreme depletion in Pb and Zn relative to Cu (Fig. 15.8). Conversely, limestones and dolomites in the Devonian and Carboniferous rift-fill are enriched in Pb and Zn relative to Cu. This enrichment, is interpreted as due to hydrothermal circulation of chloride-rich waters derived from deep dissolution of the Mallowa salt mass. If so, it explains the numerous MVT deposits hosted in carbonate rocks of the eastern margin of this Carboniferous-Devonian rift-fill.

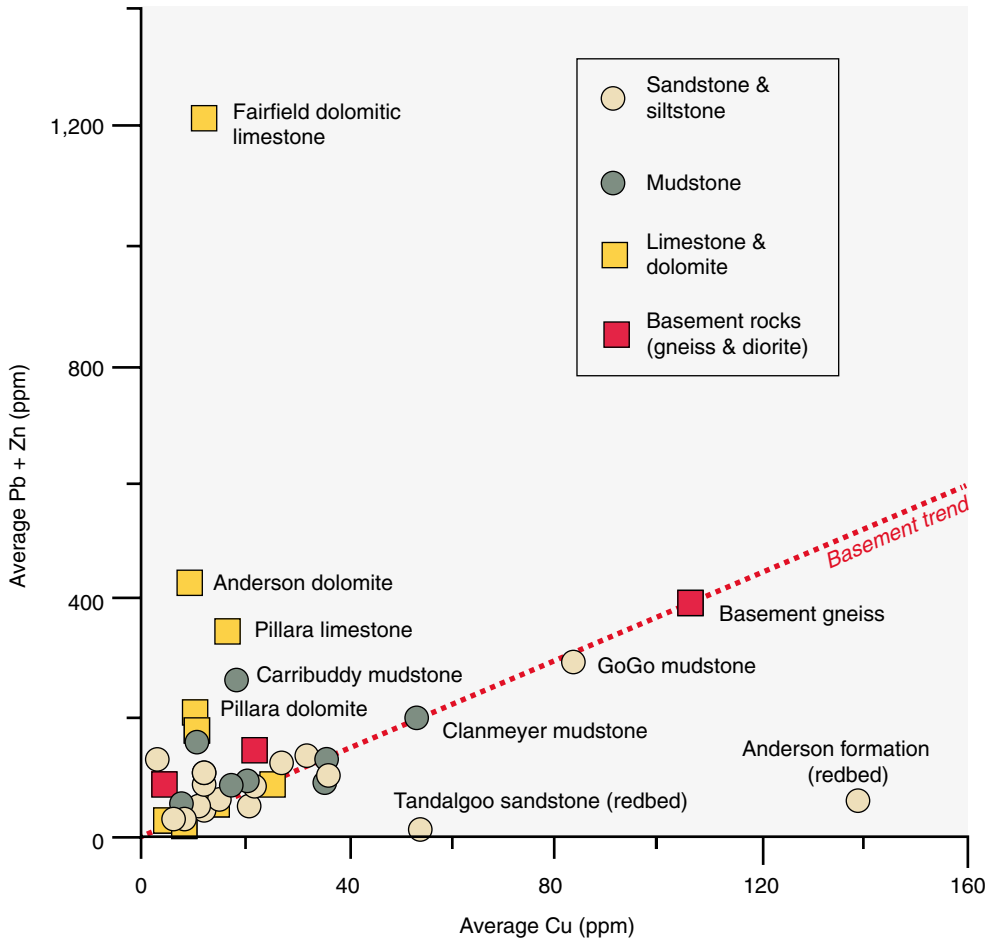

Fig. 15.8 Average base metal concentrations in various stratigraphic units of the Fitzroy Trough and Lennard Shelf in the Canning Basin, Australia (Wilde et al. 2005b)

In a variation on the same theme of metalliferous saline brines tied to leached sediments, and the corollary that magmatic heat may enhance convective circulation of basinal brines, but not supply the metals in some paramagmatic sediment-hosted ore deposits, Tornos and Heinrich (2008) have shown that shales interacting with highly saline chloride-rich basinal brines are the main suppliers of metals to the massive sulphide deposits of the Iberian Pyrite Belt (Fig. 15.9). Historically, these deposits were interpreted as volcanogenic-hosted massive sulphide (VHMS) deposits, and related to hydrothermal oceanic-rift analogs, such as the Tag Mound or the massive sulphides of Cyprus, where the metals have a magmatic source. But veinstyle deposits and other indicators of magmatically-sourced fluids, typically associated with this style of VHMS deposit, are largely lacking in the massive sulphides of the Iberian pyrite belt. Tornos and Heinrich (2008) argue that the deposit hydrology and textural/geochemical signature is more akin to that of the Sullivan and McArthur River styles of ore deposit. There, brine pools tied to focused upwelling and venting of hypersaline basinal waters into closed depressions on deep seafloor were the driving mechanisms creating the SedEx deposits.

Mildly reducing redox conditions, imposed by equilibration with a muddy metal source was most critical factor in the formation of such an effective ore-forming fluid system (Fig. 15.9). Relatively metal-rich, but organic-poor, pyrite-bearing shales, undergoing dewatering and interaction with hypersaline saline pore fluids created an effective source for the generation of sulphur-deficient, but relatively iron and base metal-rich, chloride brines (Fig. 15.9a). When temperatures are in excess of 330–340 °C, even copper becomes highly mobile in high salinity subsurface waters passing through compacting shales (Fig. 15.9a and Chap. 16). Thus, Tornos and Heinrich (2008) proposed that the giant deposits of the Iberian Pyrite Belt owe their existence not to exceptionally metal-enriched magmatic fluids, but to the existence of a fairly ordinary, but volumetrically large (with depletion ratio of 1:200), metal source in these reactive fine-grained (high grain-surface areas) siliciclastic sediments, flushed by chloride-rich evaporite-dissolution-derived basinal brines. The convective fluid flow system may be tied to an underlying igneous heat source driving the regional fluid flow, but ore focusing and metal transport is more dependent on a particularly efficient mechanism of sulphide precipitation, driven by mixing and reduction of the metalliferous brine

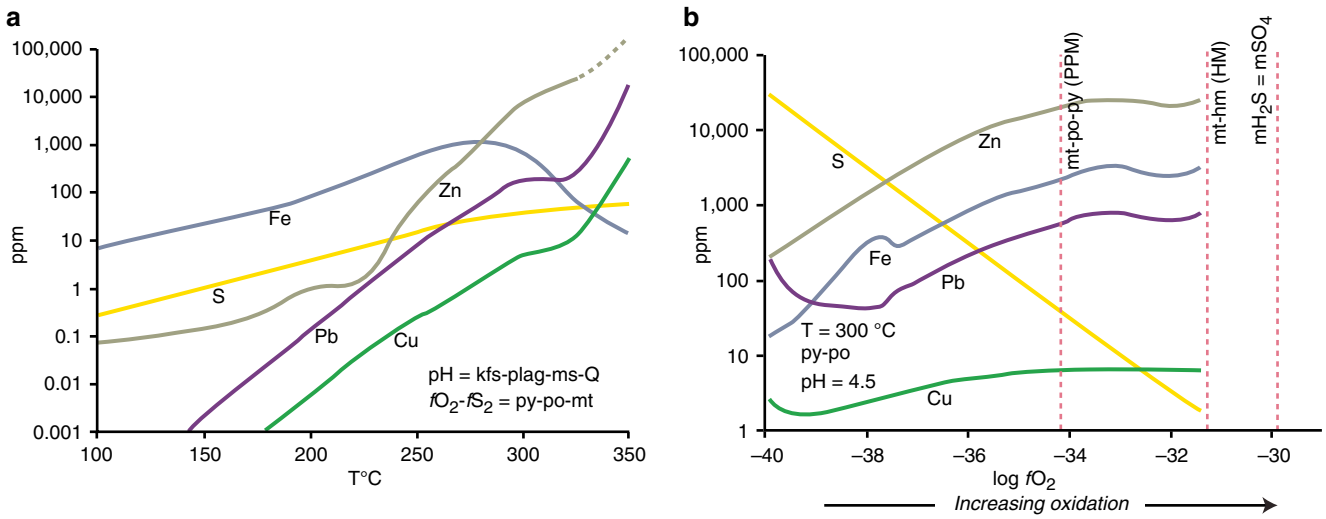

Fig. 15.9 Metal solubility and fixation in shale as related to sulphur presence (After Tornos and Heinrich 2008). (**a**) Base metal and sulphur solubility as a function of temperature between 350 and 100 °C at a pH buffered by the mineral assemblage observed in shales, for a total salinity of 9 wt.% NaCl equivalent and the fO_2 –fS_2 conditions defined by the pyrite–pyrrhotite– magnetite equilibria. Base metal solubilities are calculated in equilibrium with excess sphalerite, galena and chalcopyrite. Mineral abbreviations are; *hm* hematite, *mt* magnetite, *py* pyrite, *po* pyrrhotite, *kfs* K feldspar, *plag* plagioclase, *Ms* muscovite, *Q* quartz. (**b**) Reduced sulphur (*S*) and metal solubility in a shale-buffered reservoir at 300 °C showing the strong dependence on the redox conditions. Calculations performed at a constant pH of 4.5 and the fS_2 controlled by the pyrite–pyrrhotite equilibrium. The H_2S:SO_4 boundary is that defined by equal molalities of reduced and oxidized sulphur species

with H_2S-rich fluids at or near the seafloor (Fig. 15.9b; see later SedEx discussion). We shall come back to this notion of chloride-rich basinal brines transporting and fixing metals a number of times in this chapter, as we develop arguments in support of dissolving salt masses aiding in the focusing and trapping of brines and their outflows.

Similar redox-controlled mineral equilibria are imposed when saline chloride-enriched basinal fluids are buffered by typical continental basement rocks (Fig. 15.7). This is how copper can be mobilised and leached from the sediment, along with Pb and Zn. At redox conditions near and above the hematite–magnetite buffer, sulphate becomes the main sulphur species. This defines another diagenetic fluid environment proposed by Cooke et al. (2000) for base metal transport in sediment-hosted deposits overlying oxidized sequences, as at McArthur River (Australia). Leaching of retrograde minerals and possibly residual salts from a magmatic or metamorphic protolith are expected to generate similar, variably metal-rich, but relatively sulphide-deficient, fluids. Thus, according to Tornos and Heinrich (2008) the existence of mildly-reducing saline sedimentary brines in sedimentary hosts, not magmatic waters, can be the dominant chemical control in sourcing metalliferous fluids linked to many volcanogenic, Irish-type or SedEx deposits. Many of these brine-related deposits are known to precipitate their metal load in response to biogenic or thermochemical sulphide addition at the ore deposition site. Typically this took place within depressions on seafloor with their downslope precipitative positions maintained by a combination of extension, gravity gliding and halokinesis, and sometimes by more updip via interaction with bedded platform anhydrites.

At the contact of an evaporitic sedimentary basin with its underlying basement, dense chloride brines derived from dissolution and reflux beneath thick salts can leach metals from the underlying basement and then convectively transport them into a metal-fixing redox front. Such brines leach a variety of metals from underlying igneous and metamorphic rocks and worldwide are responsible for a number of large unconformity-associated uranium deposits and SedEx deposits (Fusswinkel et al. 2013; Wilkinson et al. 2009; Boiron et al. 2010; Koziy et al. 2009).

Carrier Brines (Eh, pH and Chlorinity/Salinity)

Numerous experimental studies have shown that chloride complexes are effective ligands for Zn and Pb in low temperature basinal brines. Bisulphide and organic complexes are less effective, particularly in moderate to highly saline pore fluids in sediments in the presence of abundant Na and Ca (Giordano 1985; Barrett and Anderson 1988; Sicree and Barnes 1996). The presence of reduced sulphur in MVT and other basinal brines (typically a H_2S association) greatly reduces the solubility of chloride-complexed Pb and Zn (Fig. 15.10b and Table 15.5; compare Pb and Zn contents with respect to ΣH_2S in brines 1 and 3). Hence, the widely accepted model for formation of MVT deposits via saline basinal brines transporting metals to local areas containing reduced sulphur where the metals are fixed as solid metal sulphide phases (Anderson 1983; Anderson and Macqueen 1988).

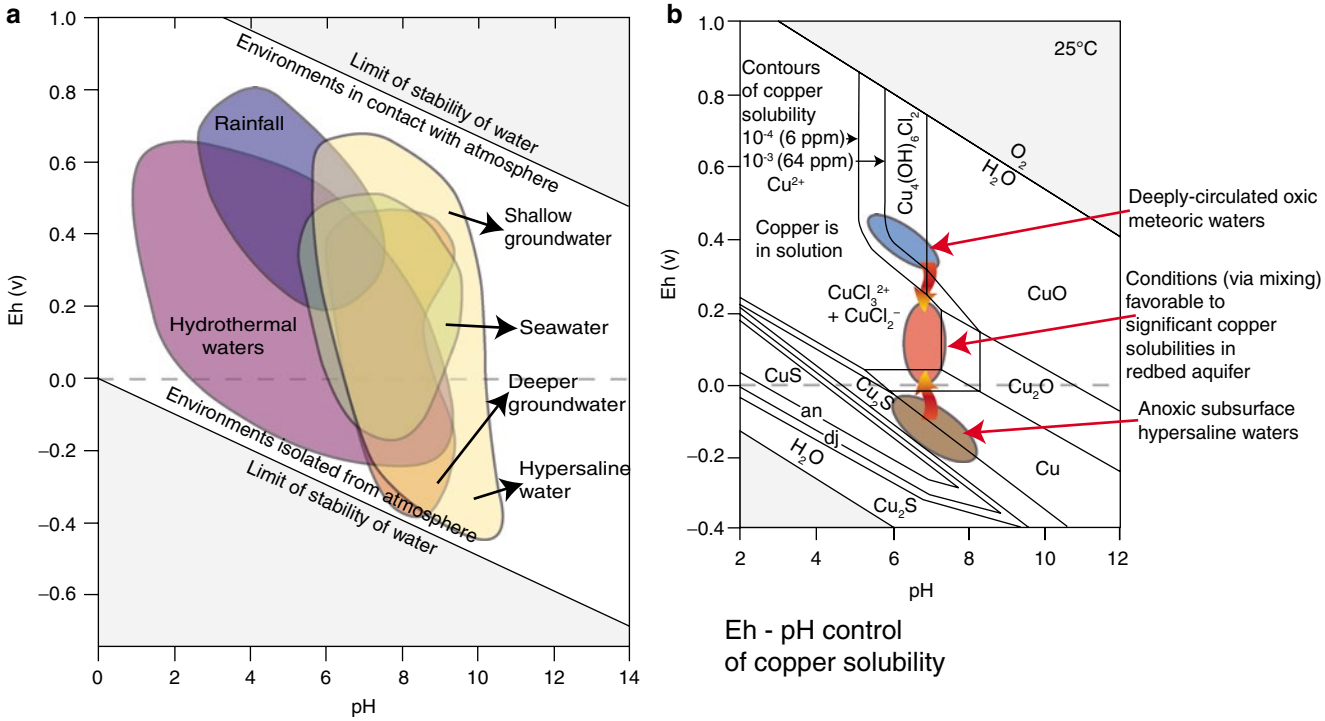

Fig. 15.10 Redox and copper solubility. (**a**) Eh-pH diagram with occurrence fields of various surface and subsurface waters plotted. (**b**) Solubility of copper as cuprous chloride complexes in a low-temperature brine, showing how a Cu-transporting brine(slightly oxidising and neutral pH) in a redbed succession is in part created by mixing of deeply circulating oxygenated meteoric and anoxic saline subsurface waters (In part after Rose 1976; Brown 2006). *CuS* covellite, *Cu_2S* chalcocite, *Cu* copper, *Cu_2O* cuprite, *CuO* tenorite, *$Cu_4(OH)_6Cl_2$* malachite

In terms of potential Pb and Zn carriers, there are three main types of basin brine in today's sedimentary basin, only one carrier has elevated levels of Pb and Zn (Table 15.5; Giordano 2003). The table shows the specific inorganic and organic fluid parameters that influence the concentration of Pb and Zn in these subsurface waters. Modern oilfield brines are bimodal in terms of total reduced sulphur content (ΣH_2S). Low H_2S brines have ΣH_2S values less than 1.0 mg/l, with the majority showing values less than 0.02 mg/l and often showing values below the detection limit (Giodarno 2003 and references therein). Not all low H_2S chloride-rich brines carry elevated levels of Pb and Zn, only those that have passed through strata containing leachable levels of these base metals.

High H_2S brines have ΣH_2S concentrations greater than 1.0 mg/l, with the highest concentrations approaching 1,000 mg/l, especially in the vicinity of active fault conduits carrying these H_2S-rich waters (see Wade et al. 1989; Moldovanyi and Walter 1992). In high H_2S formation waters, the most commonly observed ΣH_2S values are in the 10–600 mg/l range (see also Chap. 9). Total sulphate concentrations in modern petroleum-field brines rarely exceed 1,000 mg/l and are more typically in the 0.1–250 mg/l range (Fig. 15.6b; Kharaka and Hanor 2003). There is no statistical correlation between the concentration of SO_4 and chlorinity or salinity, although there appears to be a broad inverse correlation between ΣH_2S and ΣSO_4, indicating a likely relation to subsurface sulphate reduction (Fig. 15.6b; Hanor 1994a, b).

The ability of chloride-rich basinal brines to become ore forming fluids, capable of carrying and precipitating Pb-Zn minerals, is well illustrated by the Na-Ca-Cl oil field brines in the Cheleken region of Turkmenistan (Lebedev 1972). These brines contain up to 10 mg/l Zn + Pb and deposit native lead, sphalerite, galena and pyrite in the well pipes and holding tanks at rates considered analogous to ore formation. Some Na-Ca-Cl oil field brines in Jurassic and Cretaceous formations in the Salt Dome Basin of central Mississippi, USA, have total dissolved solid contents up to 350,000 mg/l, densities that exceed 1.2 g/ml, and contain up to several hundred mg/l of Pb + Zn (Fig. 15.6a; Carpenter et al. 1974; Kharaka et al. 1987). Both these highly metalliferous brines systems occur in regions underlain by thick dissolving evaporites with dissolution plumes moving through adjacent metal-carrying sediments (Chap. 8).

Similarly, sphalerite and galena scale is forming today in the pipes of producing geothermal wells in the Asal Rift in the Republic of Djibouti, Africa (D'Amore et al. 1998). Sulphide precipitation starts at the flash level (where hot pressurised water converts to steam), located at 850 m depth where temperatures are close to 260 °C, and extends deeper into the main reservoir. The main geothermal reservoir is located at depths

between 1,000 and 1,300 m with temperatures between 260 and 360 °C. Seawater seepage, with additional ionic input from dissolving salt beds, is the main source for the chloride-rich metalliferous brines in the field. As a result of sulphide precipitation, about 90 % of H_2S is removed from the original fluid before it is discharged at the surface. Brines produced in the Asal thermal field all have salinities in excess of 100,000 ppm, with a low gas content of the order of 0.6 mmol/mol.

If the subsurface brine migrates though a red bed succession that contains hematite and/or anhydrite, the oxidation state and the SO_4^{2-}/H_2S ratio of the fluid is increased by mixing of oxygenated groundwaters and anoxic brines and by reactions such as:

$$CaSO_4 = Ca^{++} + SO_4^{2-}$$

$$4Fe_2O_3 + H_2S + 14H^+ = 8Fe_2^{+} + SO_4^{2-} + 8H_2O$$

The migration of this moderately oxidising saline fluid through a red bed can then scavenge the necessary Cu, Zn and Pb to form a mineralising fluid with elevated Cu content where Cu > Pb + Zn (Fig. 15.10; see also Rose 1976; Brown 2006). Redox conditions of $\log f_{O2} > -46$ at 125 °C are necessary in the brine to mobilise copper as cuprous chloride complexes (see Rose 1976 for relevant discussion). This explains the common association of copper sulphides with redox haloes adjacent to leached redbeds in evaporitic basins (see later).

So far, we have discussed slightly-acidic metal-rich saline chloride brines. However, high salinity in a subsurface water, by itself, does not guarantee a high dissolved metal content, nor are metals always carried in the subsurface as chloride complexes in saline acidic brines. A large number of saline basinal brines and formation waters are low in metals and high in dissolved sulphides (Table 15.5). Figure 15.6a clearly shows that many highly saline subsurface waters in sedimentary basins worldwide contain <1 ppm metal. Such waters become metal-rich and sulphide-poor only when they flush germane metalliferous sediment, such as redbeds, metal-rich shales or hydrothermally altered basalts (Ellis 1968; Coveney 1989). Metal leaching and chloride transport from such metal sources involves desorption of loosely bound metals, release of metals on mineral recrystallisation or replacement, or release of metals to the brine from metal-organic complexes through thermal alteration or thermal destruction of such complexes (Carpenter et al. 1974; Gize et al. 1991).

Acidification is an essential step in the acquisition of metals in brines during dissolution or alteration of aquifer minerals. Chloride-rich, high salinity basinal fluids may become acidified by pyrite oxidation, by decomposition of organic matter, or by the precipitation of Mg silicates, such as smectite or chlorite. Organic acids may also play an important role in leaching the metals from metalliferous source beds (Raiswell and Al-Biatty 1992). In contrast, Eugster (1985, 1989) argued that not all metalliferous brines are acidic. He notes that in a Green River style of ore deposit (a category in which Eugster includes the Mt Isa and Dugald River deposits of Australia) the brines were alkaline, with pH values of up to 11. If so, then metals were carried not as chloride complexes, but as hydroxy or carbonate-complexes. Such non-chloride waters are generated today in saline continental rift lakes where sodium bicarbonate evaporites dominate, there is no primary gypsum, and the lake evolves by the evaporation of source waters that drain adjacent basic igneous or metamorphic terranes (see Chaps. 2 and 3 for a discussion of nonmarine brine evolution).

So far this discussion is largely theoretical or based on analogy with modern basinal and oil field brines. But with improvements in microsampling and laser-ablation inductively-coupled plasma mass spectrometry techniques it has become possible to study the hydrogeochemistry of metal precipitating brines by analysing the chemical makeup of individual brine inclusions in zoned quartz and sphalerite crystals and so map the evolution of the metal reprecipitating brines (Wilkinson et al. 2009; Fusswinkel et al. 2013). A study of fluid inclusions in sphalerite and a comparison with co-associate inclusions in quartz crystals from two geographically separate Pb-Zn MVT deposits in Ireland and Arkansas showed that the metal contents of the sphalerite are up to two orders of magnitude higher than associated quartz (Fig. 15.11). The difference between sphalerite and associated quartz is much higher than previously thought and strongly suggests ore formation is linked to an influx of anomalously metal-rich fluids into subsurface systems, dominated by basinal fluids that are otherwise barren of metals. It could be argued that the fluid inclusions in quartz represent spent ore fluids, trapped after sulphide precipitation had already taken place. This is thought to be unlikely in the Irish deposits because the quartz was sampled from largely barren vein systems that formed beneath the ore deposits, in hydrothermal upflow zones, and the fluids show no signs of having substantially cooled or mixed (Wilkinson et al. 2009). A metal-pulse model for ore fluids has now been shown to be true of MVT deposits based on inclusion chemistry at the microscale, rather than just inferred, as was done in many previous mineralisation transport models.

In the Tri-State MVT district, Wilkinson et al. (2009) found sphalerite- and quartz-hosted brine inclusions show distinct halogen signatures, indicating that the fluids had separate origins. Fertile ore fluids appear to have originated during strong evaporation of seawater at Earth's surface, before later burial and expulsion. This contrasts with the barren fluids that evolved from less strongly evaporated seawater. The metalliferous fluids were linked to the arid paleoclimate and the specific characteristics of the sedimentary aquifer within which they were trapped.

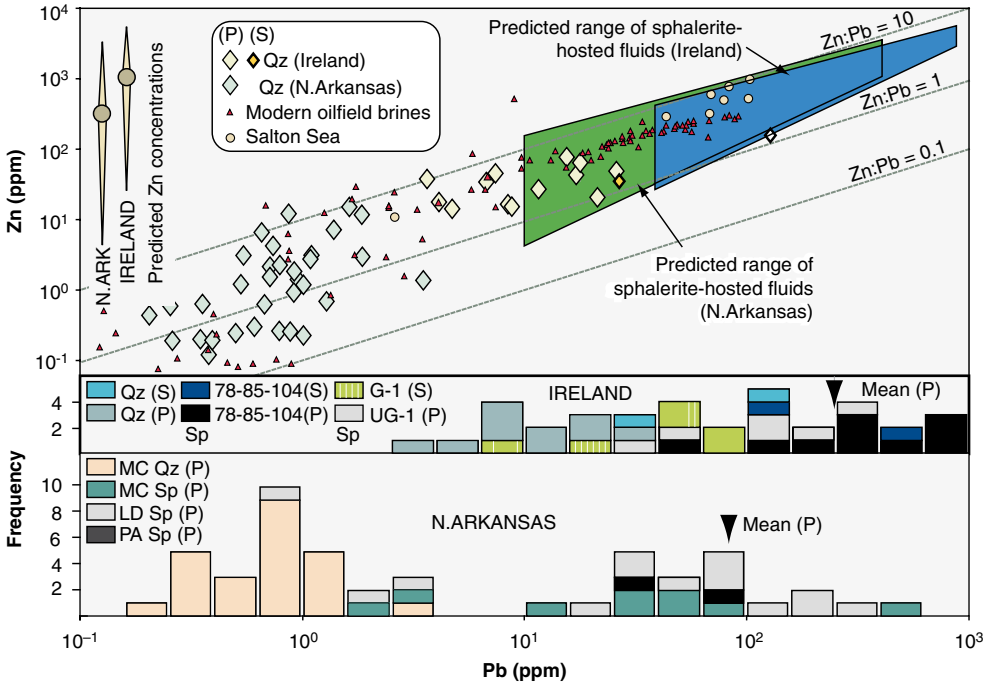

Fig. 15.11 Metals concentrations in natural subsurface waters (After Wilkinson et al. 2009). Concentrations of Zn versus Pb in quartz-hosted fluid inclusions and histograms showing measured Pb concentrations in quartz- and sphalerite-hosted inclusions from Irish and North Arkansas MVT deposits, compared with natural brine data from broadly analogous environments (subsurface Salton Sea and oilfield waters). Predicted Pb-Zn covariation for sphalerite-hosted inclusions indicated by shaded fields, based on the extrapolation of empirical Pb-Zn concentrations. All data sets have values that fall in the "high-metal" fluid fields, suggesting that they are anomalously metalliferous and indicative of viable ore-forming fluids. Typical Zn:Pb ratios (by mass) for natural fluids are in the range of 1–10 (*dashed grey lines*) are shown and all tend toward higher values at elevated concentrations. Also plotted are data points from the Northern Arkansas MVT dataset with low detected Pb are inferred secondary inclusions (S vs P for primary inclusions). *Qz* quartz, *Sp* sphalerite, Deposits plotted are *MC* Monte Cristo, *PA* Philadelphia, *LD* Lucky Dog

In a refinement of this halogen approach to the interpretation of the nature of ore fluids in quartz-fluorite-baryte-Pb-Zn vein system, Fusswinkel et al. (2013) concluded mineralisation can be related to the mixing of two evaporite-related brines (Fig. 15.12). Post-Variscan Mesozoic vein-type Pb-Zn mineralization is widespread in large parts of western and central Europe, including Variscan basement complexes of Germany, France, England, and Spain. In Germany, the vein-hosting crystalline basement is unconformably overlain by Permian and Lower Triassic redbed sedimentary rocks and Middle Triassic to Jurassic carbonates with intercalated claystones and evaporites. Utilising laser ablation analysis of inclusion trails in zoned vein quartz crystals they found evidence of two end-member hypersaline brines, one was metal rich, the other metal poor (Fig. 15.12a).

They determined simultaneously the ore metal concentrations and the Cl/Br ratio in texturally well constrained inclusion assemblages from this basement-hosted quartz-fluorite-baryte-Pb-Zn vein system. There is an inverse correlation between the Pb + Zn concentrations and the Na/Ca and Cl/Br mass ratios in the fluid inclusions, respectively (Fig. 15.12b, c). This is clear evidence of mixing of a basement-derived metal-rich hypersaline brine and a metal-poor formation brine that acquired its salinity from halite dissolution in Triassic evaporites of the sedimentary cover (high Cl/Br and Na/Ca ratios are indicative of brines derived from subsurface halite dissolution, see Chap. 8). This mixing of two distinct brines with comparable salinity is recorded during the growth of individual quartz crystals containing small galena inclusions, demonstrating the transient and episodic nature of fluid mixing during mineral deposition. Once again, this reinforces the observation of Wilkinson that at the microscale there is a pulsing of metal supply in an ore precipitating system in the diagenetic realm. It points to the importance of syndepositional metalliferous bitterns sinking into the underbelly sediments as salt successions precipitate in saline giant settings (the brine curtain – Chap. 5).

Metal Fixers

Metal transport-precipitation models breakdown into three end-members; (1) Mixing model, (2) Sulphate reduction model and, (3) Reduced sulphur model

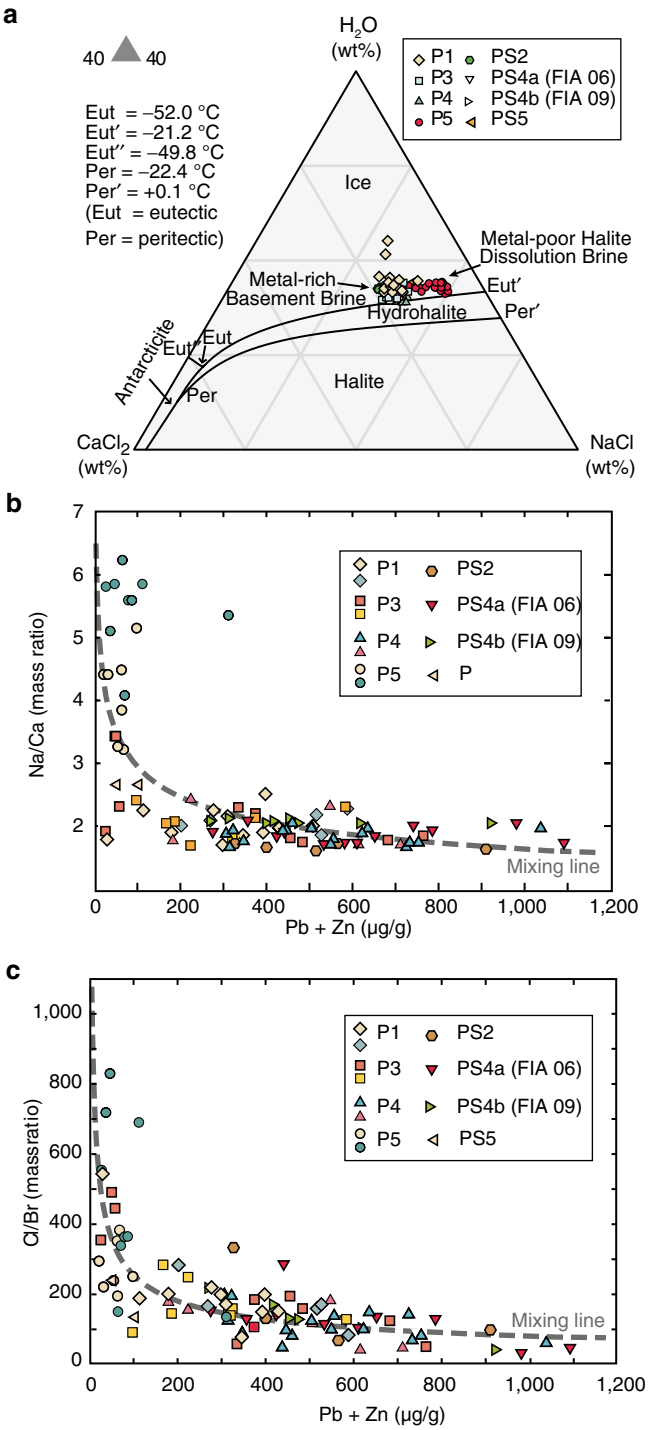

Fig. 15.12 Evaporite brine mixing creates metalliferous brines (After Fusswinkel et al. 2013). (**a**) Fluid composition in ternary H_2O-NaCl-$CaCl_2$ system as determined by microthermometry, showing close overlap of two brine end members (metal-rich and metal-poor) in terms of their major element composition. *P* primary, *PS* pseudosecondary, *FIA* fluid inclusion assemblage. (**b**) Microanalysis of single fluid inclusions shows close correlation between total base metal content (Pb+Zn) and Ca/Na ratio. *P* primary, *PS* pseudosecondary, *FIA* fluid inclusion assemblage. (**c**) Close correlation between Pb+Zn and Cl/Br ratio, resulting from mixing of two brines with similar total salinity (**a**). (**c**) Major variation of total metal content at constant Pb/Zn ratio reflects mixing of metal-bearing brine with metal-depleted fluid. Upper and lower paired symbol shapes denote laser ablation analyses performed with full and reduced element suites, respectively

Table 15.6 Widely accepted models for transportation and precipitation of base metals in low temperature (<250–300 °C) basin burial settings

Transportation of ore-forming constituents	Precipitation mechanisms
Mixing model Base metals transported by saline Cl-rich fluids without significant sulphur content	(i) Mixing with fluids containing H_2S (ii) Replacement of diagenetic iron sulphides (iii) Thermal degradation of organic compounds releasing sulphur (iv) Mixing of two hypersaline Cl-rich brines, one is metal-depleted the other is metal-rich
Sulphate reduction models Base metals transported together with sulphate in the same fluid	Reduction of sulphate by reactions with organic matter or hydrocarbons, especially methane (bacterial of thermogenic sulphate reduction)
Reduced sulphur model Base metals transported together with reduced sulphur in the same solutions	(i) Cooling (ii) Dilution (iii) Change in pH

(Sverjensky 1986; Table 15.6). According to the most commonly accepted mixing models, base metals are transported in one fluid and sulphide is transported separately in another fluid, while precipitation occurs where the two fluids mix (e.g. Anderson 1975; Beales and Jackson 1966). Related theories, encompassed by the mixing model, hypothesize that the source of reduced sulphur encountered at the precipitation site was in the form of H_2S, diagenetic iron disulphides, or sulphur associated with petroliferous materials. In the sulphate reduction model, base metals are transported in fluids along with sulphate, rather than sulphide, and precipitation is driven by a sulphate reduction reaction, whereby sulphate is reduced to sulphide, typically via oxidation of organic matter or methane (e.g. Anderson 1983; Powell and MacQueen 1984). According to the third model, the reduced-sulphur model, base metals and reduced sulphur are transported together in the same fluid, with precipitation driven by varying combinations of pH change, cooling, dilution (e.g. Helgeson 1970; Anderson 1973; Sverjensky 1989). All three precipitation interfaces in these models are typically tied to redox fronts and often relate also to pore water salinity/density mixing interfaces.

Copper minerals precipitated at a diagenetic redox front are predominantly Cu-sulphides (covellite (CuS), chalcocite (Cu_2S), chalcopyrite ($CuFeS_2$), and bornite (Cu_5FeS_4), depending on the concentration of ions in solution and Eh–pH conditions (Fig. 15.10a: Rose 1976; Wodzicki and Piestrzynski 1994; Brown 1997; Robb 2005; Asael et al. 2009). Subsequent reoxidation of the sulphides may lead to the formation of Cu(II) minerals, such as; malachite ($Cu_2(CO_3)(OH)_2$), paratacamite, ($Cu,Zn)_2(OH)_3Cl$), brochantite ($Cu_4(SO_4)(OH)_6$) and chrysocolla $(Cu,Al)_2H_2Si_2O_5(OH)_4{\cdot}n(H_2O)$. Typically, the formation of redox fronts is attributed to the interface between a fresh meteoric and a saline water mass (Fig. 15.10b). But as

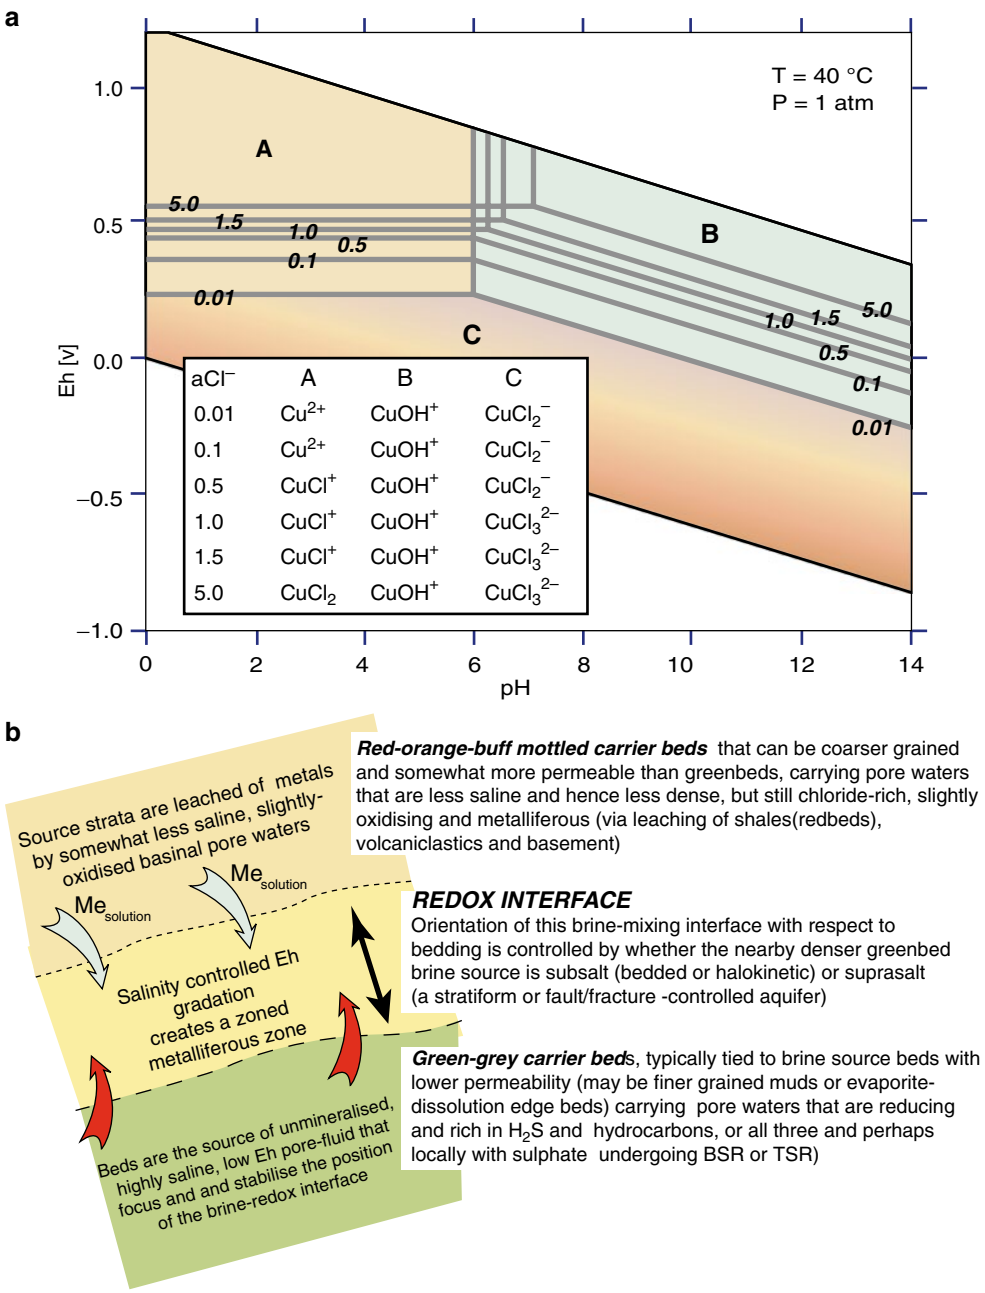

Fig. 15.13 Metal sulphide 'fixing' at redox interfaces (**a**) Eh–pH diagram showing the changes in the copper-chlorine speciation in solution and the position of the equi-concentration boundaries between the different copper complexes (ligands) at varying values of the chlorine activity aCl^- (After Asael et al. 2009). (**b**) Brine mixing between two saline water masses that are typical in the vicinity of buried and dissolving evaporites. One brine is less dense, metalliferous, somewhat acidic and slightly oxidising, the other somewhat more saline, denser, anoxic and likely carrying hydrocarbons and H_2S. (also does not destroy any organic matter in carrier beds as it is a "pickling" brine -Chap. 8)

the variations in the a, and c plot fields in Fig. 15.13a show, they can also be set up at interfaces between,; (1) dense highly saline reduced brine masses (in the immediate vicinity of a dissolving salt mass) and (2) an adjacent, still saline, but somewhat less so, chloride-dominant basinal brine that is also slightly oxidising and slightly acidic and capable of leaching copper. For example, compare the saline plot fields in Fig. 15.10b and their positions in 15.13a when aCl^- is in the range >4–5. This notion of dissolving evaporites contributing to the leaching, transport and fixing of copper sulphides is not new, aspects of it were detailed by Rose (1976).

Redox fronts and density-driven mixing interfaces in the shallow to deep subsurface are consistently located about the edge of dissolving salt beds and halokinetic salt masses, or the related brine plumes (Chap. 8). These interfaces play a significant role in localising and focusing metal precipitation in many evaporite-associated metal accumulations (Fig. 15.13b). For example, the inherent highly saline and reducing conditions adjacent to and beneath a salt bed, salt structure or an at-surface brine pool are created by the high salinity of the pore fluids in the vicinity of an evaporite unit and the likely co-occurrence of elevated levels of organics (Chap. 9). Further away from the dissolving salt mass the pore waters are typically still saline, although in some cases can be lower salinity waters, that are somewhat more acid and slightly oxidising (e.g. Fig. 15.13b). Thus, the conditions suitable for the fixing of metal sulphides in zones of mixing between the two water masses, where redox interfaces form,

can be present from the time of deposition of the sedimentary host through to the metamorphic realm. This dissolution/density style of redox front precipitation is relevant to most sediment-hosted ore deposits found in evaporitic basins and encompasses formative mechanisms in stratiform Mississippi Valley-type Pb-Zn, redbed-related base metal, and salt allochthon related base metal accumulations.

Redox fronts are typically indicated by a greenbed-redbed halo (reduced-oxidised iron) adjacent to a dissolving salt bed or its dissolution breccia. When such a redox interface is set up, between a reduced brine halo and slightly more oxygenated and acidic set of somewhat less saline basinal waters, it creates redox conditions suitable for base metal precipitation (Fig. 15.13b). For example, the reflux underbelly and edges of dissolving sequences of bedded or halokinetic salt masses tend to focus and deflect the escape of basinal or meteoric water along the underside or the feather-edge of a dissolving evaporite (see Rote Faule discussion in next section). At the same time, ongoing dissolution maintains a stable and continually renewed source of reduced anoxic brine, a near salt edge situation which survives as a relatively stable interface until the evaporite bed is leached or breached. Ongoing halokinesis, which tends to maintain salt supply over longer time frames than a dissolving salt bed edge, can further stabilise the long term position of the dissolution front in earth-space. Dissolving BSR- or TSR- sulphate evaporite sites, pyrite, or hydrocarbons on the reducing side of such redox fronts are possible sources of sulphur.

In this context it is important to note that redox fronts are not unique to evaporite dissolution zones. But what is unusual about subsurface evaporite-dissolution zones in terms of any associated mineralised redox zones is the long term chemical stability it maintains. Even as evaporites are precipitating, they are associated with a bittern or reflux underbelly that can persists for long periods, long after salt deposition has ceased (Chap. 8). And, once buried, the dissolving salt edge of a thick halokinetic salt bed or mass can maintain a redox interface in subsurface earth space over long time intervals, via replenishment from inflowing salt. Likewise, the same salt flow can maintain seismically-pumped suprasalt extension faults. At the same time, away from the salt edge or touchdown weld, dissolution of the underbelly of the salt mass aides circulation and high chloride content in density-driven convective brine flows (Fig. 8.18). Salt-floored extensional faults passing out into the upper side of a salt mass can also act as conduits for significant volumes of dense anoxic brine that also supply seafloor brine lakes or sumps (DHAL). The sump positions are stabilised by their location atop salt withdrawal sinks and so create stable seafloor positions for the formation of the laminites that constitute the prepared ground for many SedEx deposits.

In my opinion, this stabilization of the redox/mixing front may explain why, worldwide, in a plethora of subeconomic to small scale examples of redox-related Cu-segregations and small-scale Pb-Zn associations, almost all giant stratiform redbed copper and Pb-Zn deposits can be tied to structures with current, or former, evaporite-induced redox interfaces, typically located near or adjacent to present or past halokinetic salt masses. Brines from dissolving evaporites are not the source and, sometimes, not even the carriers of metals. Rather, dissolving evaporite masses are the stabilisers, both geographically and chemically, for the chemical/density subsurface interfaces that precipitate the various metals and/or act as hydrological termination sites to carriers of sulphur to the precipitation site.

Low Temperature Sediment-Hosted Ore Deposits (Evaporite-Related)

Work over the past four decades has shown many sediment-hosted stratiform copper deposits are closely associated with evaporites, or indicators of former evaporites, as are a number of SedEx and MVT deposits (Fig. 15.1). Some ore deposits discussed in this chapter still retain the actual salts responsible for the association, especially gypsum or anhydrite relics, in close proximity to the ore. Such deposits include the Zambian and Redstone copperbelts, Creta, Boleo, Corocoro, Dzhezkazgan, Kupferschiefer (Lubin and Mansfeld regions), Largentière and the Mt Isa copper association. All these accumulations of metals are associated with the formation of a burial diagenetic redox/ mixing front, where either copper or Pb-Zn sulphides tended to accumulate (Fig. 15.14).

However, examples discussed in detail in the remainder of the chapter and the resulting classification of low-temperature base metal associations is not inclusive of all styles of base metal associations in stratiform sediment-hosted Cu, SedEx and MVT settings. It only considers examples where a tie to evaporites and associated brine fluid sourcing or focusing is obvious (Table 15.2).

One of the metalliferous deposits with an obvious tie to evaporites is the modern metalliferous deep of the Red Sea, focused on the Atlantis II Deep. It is a modern example of a metalliferous laminite forming in a brine lake sump on the deep seafloor where the brine lake and the stabilisation of the precipitation interface is a result of dissolution of adjacent halokinetic salt masses. Most workers classify the metalliferous Red Sea deeps as SedEx deposits, but the low levels of lead and high levels of copper, along with its stratigraphic position atop seafloor basalts, place it outside the usual Pb-Zn dominant system that typifies SedEx deposits. Some economic geologists use the Atlantis Deeps as analogs for volcanic massive sulphides and some argue it even illustrates aspects of some stratiform Cu accumulations. Many such economic geology studies have a propensity to ignore the elephant in the room, that is the Red Sea deeps are the result

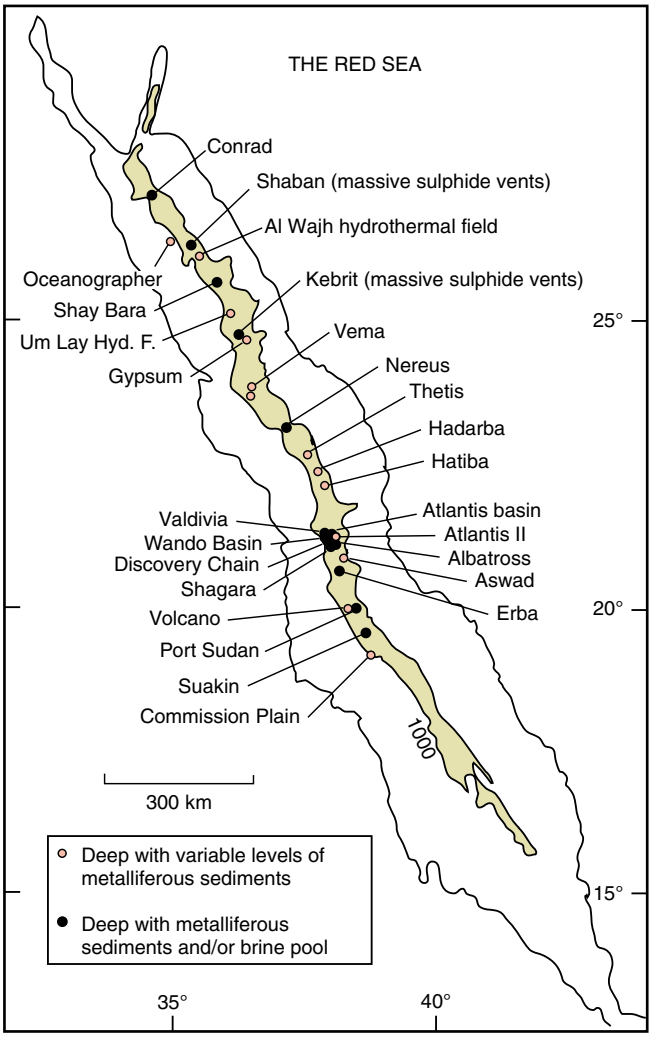

Fig. 15.14 Locality map of deeps along the Red Sea showing different characteristics, metalliferous versus brine (In part after Blum and Puchelt 1991)

of a large Tertiary-age halokinetically plumbed seafloor brine association.

In my mind what is most important about the brine lakes on the deep seafloor of the Red Sea is the fact that they exist with such large lateral extents only because of dissolution of the hosting halokinetic slope salt mass. Seismic surveys conducted in the past decade in the Red Sea show extensive salt flows (submarine salt glaciers) along the whole of the Red Sea Rift (at least from 19 to 23°N; Augustin et al. 2014). In places, these salt sheets flow into and completely blanket the axial region of the rift. Where not covered by namakiers, the seafloor comprises volcanic terrain characteristic of a mid-ocean spreading axis. In the salt-covered areas, evidence from bathymetry, volume-balance of the saltflows, and geophysical data all seems to support the conclusion that the sub-salt basement is also basaltic in nature and represents oceanic crust (Augustin et al. 2014).

The variably metalliferous seafloor deeps or deepsea hypersaline anoxic lakes (DHAL) are part of a world association of DHALs that form in association with shallowly-buried dissolving salt masses. But, what makes the Red sea deeps unique is that they can host substantial amounts of metal sulphides. And, as Pierret et al. (2010) show, a Red Sea deep without the seafloor brine lake, is not significantly mineralised. It is the intersection of the DHAL setting with an active midocean ridge (ultimate metal source) that explains the size and extent of the Atlantis deposit. Its salt-dissolution related hydrology changes the typical mid-ocean massive-sulphide ridge deposit (with volumes usually around 300,000 and up to three million tonnes; Hannington et al. 2011) into a more stable brine-stratified bottom hydrology, which can fix metals over longer time and stability frames, so that the known sulphide accumulation in the Atlantis II Deep has a reserve that exceeds 90 million tonnes.

The Atlantis II deep offers an evaporite-specific exploration paradigm for large-scale ancient counterparts. Accordingly, we shall discuss modern metalliferous laminites in the Red Sea DHALs separately to other evaporite-associated Cu, Pb-Zn and U deposits described in this and the next chapter. I offer it as our first example of the importance of nearby dissolving evaporites in stabilising the mineralisation interface in this case in a region adjacent to a volcanogenic/rift/hydrothermal heat source.

Red Sea – Modern Metalliferous Brine Lake Laminite Beds

The Red Sea is a young intracratonic basin atop a region of the crust that is currently transitional from continental to oceanic rift. It contains a thick sequence of middle Miocene evaporites formed in the early stages of ongoing rifting that is separating the African and Arabian plates. This same rifting facilitates formation of new basaltic ocean floor below the axis of the growing rift basin (Ehrhardt et al. 2005). Beneath waters more than a kilometre deep, along the deep rift axis there are numerous brine pools and deeps, some of which are underlain by metalliferous sediments (Fig. 15.14; Blanc and Anschutz 1995; Blum and Puchelt 1991).

Economically, the most important brine pool is the Atlantis II Deep; other smaller deeps, with variable development of metalliferous muds and brine sumps, include; Commission Plain, Hatiba, Thetis, Nereus, Vema, Gypsum, Kebrit and Shaban Deeps (Fig. 15.14). Laminites of the Atlantis II Deep are highly metalliferous, while the Kebrit and Shaban deeps are of metalliferous interest in that fragments of massive sulphide from hydrothermal chimney sulphides were recovered in bottom grab samples (Blum and Puchelt 1991). All brine-filled deeps are located in depressions or brine sumps along the spreading axis, in the region

of the median valley. Most of these axial troughs and deeps are also located where transverse faults, inferred from bathymetric data, seismic, or from continuation of continental fracture lines, cross the median rift valley in regions that are also characterised by halokinetic Miocene salt. Not all deeps contain brine sumps and not all brine sumps overlie metalliferous laminites.

The Conrad Deep, one of the northernmost deeps, illustrates the plate tectonic transition from continental rift to open ocean seafloor and the transition to a passive margin. Seismic across the deep shows how new seafloor ridge basalts have interacted with and penetrated the halokinetic Miocene salt mass (Fig. 15.15; Ehrhardt et al. 2005). Likewise, the Thetis and Atlantis II deeps are intimately tied to halokinesis (Mitchell et al. 2010; Feldens et al. 2012). Of the three well-studied deeps or DHALs along the Red Sea axis, only Atlantis contains significant volumes of metalliferous laminites. Interestingly, where seismic is available it clearly shows diapiric salt, not basalt underlies the deeps (Fig. 15.15a). This is in marked contrast to the typical basalt-dominant understory interpetations that dominate older pre-seismic schematics in the economic geology literature (e.g., Fig. 5.16b).

Three conditions favour the formation of the brine-filled deeps: (1) The Red Sea is a narrow depression only 200 km wide, with water circulation to the south limited by a shallow subsea sill near the connection with the Indian Ocean. (2) The surrounding hot arid desert hinterland facilitates a low levels of clastic and nutrient input so clastic and pelagic accretion rate are very low along the axial part of the rift; this prevents clastic dilution of DAHL sediments and allows hydrothermal solutions and their precipitates to be important aspects of sedimentation in the deeps. Hydrothermal outflows are perhaps focused by transverse-fault damage zones interacting with mobile gravity glide salt masses to influence the topography of the seafloor and create hydrographically open or closed seafloor depressions. (3) Nearby dissolving halokinetic salt contributes huge volumes of chloride-dominant hydrothermal and basinal brine into the irregular bottom topography it creates (Ehrhardt et al. 2005; Mitchell et al. 2010; Feldens et al. 2012). Many deeps are filled by permanently-stagnant brine pools, derived either directly from the dissolution of nearby evaporites or overspill from adjacent brine pools. Others deeps, filled by episodic hydrothermal brine seeps, may have been intermittently influenced by

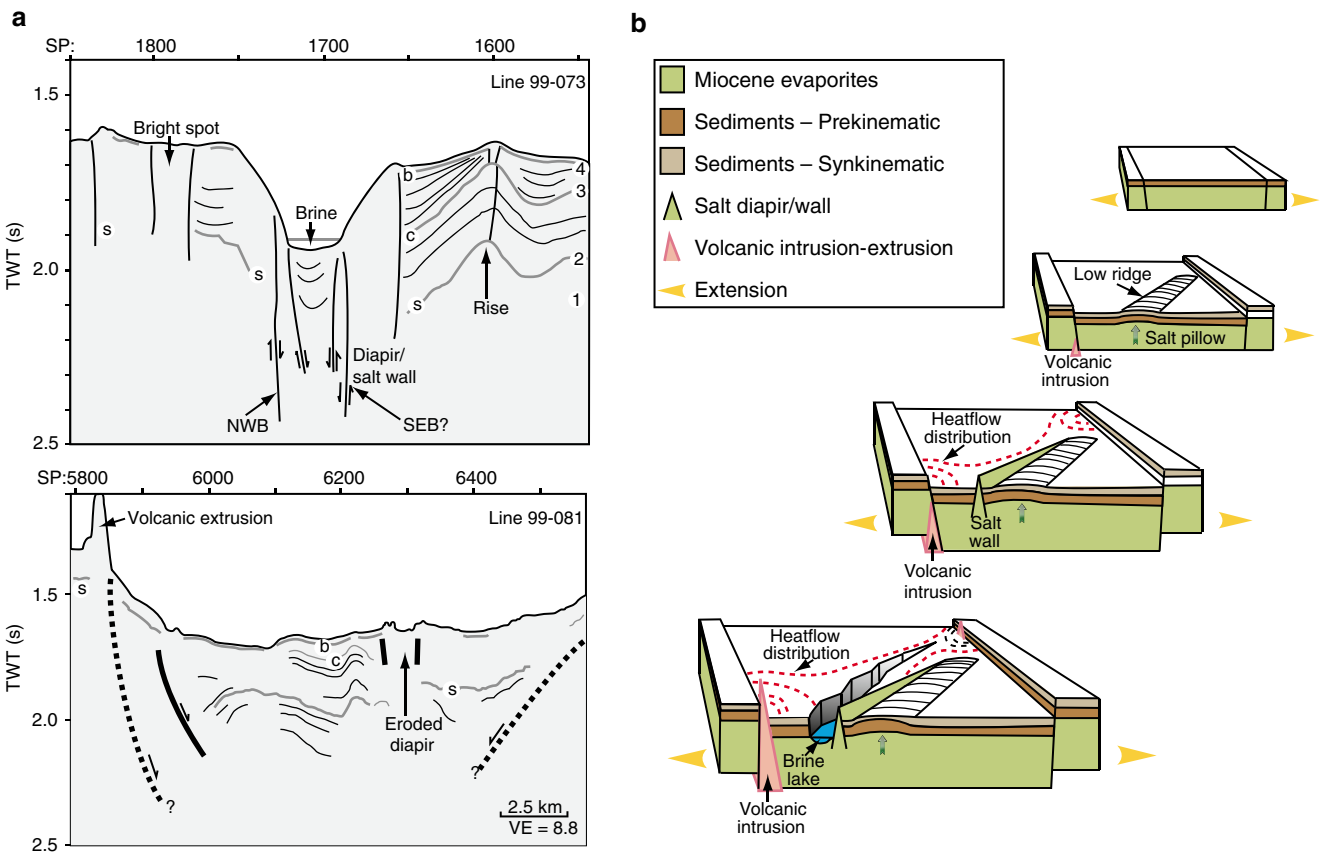

Fig. 15.15 Conrad Deep at the northern end of the axial rift in the Red Sea. (**a**) Representative seismic showing the association of extension, diapirism and volcanism as the deep forms. Some structures are active some are collapsing. Collapsed structures probably contribute to formation of brines and brine pools. (**b**) Evolution of the features in the Conrad Deep as it experiences ongoing extension (After Ehrhardt et al. 2005)

hydrothermal convection within the bottom brine mass. Still others, such as Thetis deep, show little evidence of ever acting as a seafloor sump for ponded brine.

Atlantis II Deep, Red Sea

The Deep is roughly elliptical in shape, 14 km long, 5 km wide and is located in the most geothermally active part of the central Red Sea (Fig. 15.14). The bottom of the brine pool is 2,200 m below sea level and is surrounded by thick sequences of halokinetic Miocene evaporites and thin veneers of Pliocene Recent clastics (Fig. 15.16a). Through subsurface dissolution and convective flushing, these Miocene evaporites supply ions to the seafloor and to high salinity brines caught up in hydrothermal flow cells beneath the flowing and dissolving underbelly of the salt units. Hot hybrid brines ultimately discharge onto the floor of the Deep, and settle into the lower part of the main depression to form a two layered brine pool that is some 200 m thick and is underlain by hypersaline metalliferous muds (Fig. 15.16b). For example, the southwest portion of the Atlantis II Deep contains 150–200 million tonnes of unconsolidated mud averaging 5–6 wt% Zn and 0.8 wt% Cu on a dry salt free basis. These tonnages rival some of the larger SedEx deposits in the world and represent the only known deposit of Fe, Mn, Zn, Cu, Ag and Au of economic proportions currently forming on the sea bottom (Shanks III 1983; Backer and Lange 1987).

The Deep was first discovered in 1966, it contains about 5 km^3 of brine, stratified into distinct dense and convective layers of differing temperature and chlorinity. The lower brine body has an area of 1.8 km^2 and is about 150 m thick atop a sea bottom as deep as 2,040 m (Figs. 15.16b). Distribution of bottom sediment facies is directly tied to the properties of the overlying brine column (Fig. 15.16b). In 1977 the bottom brine had a temperature of 61.5 °C, a chlorinity of 156‰, and contained no free oxygen. The overlying 50-m-thick brine layer, called the Transition Zone, was at 50 °C with 82‰ chlorinity. This partially oxygenated upper brine was a transitional zone of mixing between the lower brine and overlying normal seawater. (Anschutz and Blanc 1996; Hartmann et al. 1998).

Since the 1960s the temperature of the lower brine mass has been steadily rising. By 2008 the temperature in the bottom brine of the SW basin was 67.5 °C (Fig. 15.17). The structure of the lower transition zone, between about 1,990 m water depth and highly saline bottom brine has changed significantly, by the mid 1990s, when it contained two convective layers with nearly constant internal temperatures (61° and 55 °C, respectively). Since then temperature in the thick lower convective layer in the Atlantis II Deep has continued to increase but at a somewhat lower rate of 0.1 °C/year. Clearly, the temperature of all four convective layers in the deep have increased since the 1960s at the same rate across all four layers (Fig. 5.17). Based on the observed changes, Swift et al. (2012) concluded that diffusive vertical heat flux between the various convective layers is rapid on time scales of 3–5 years and that heat is being continually lost from the brine pools to overlying Red Sea Deep seawater. Heat budgets suggest that the heat flux from hydrothermal venting has today decreased from 0.54 GW to 0.18 GW since 1966.

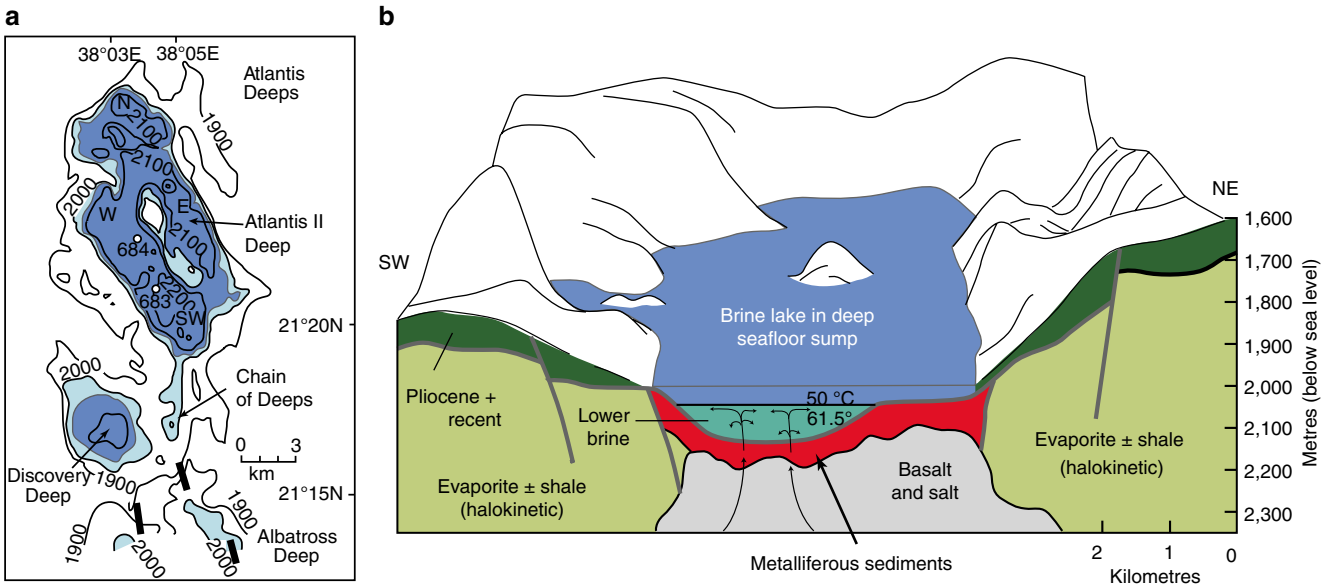

Fig. 15.16 Atlantis II Deep region, Red Sea. (**a**) Bathymetry of the Atlantis II deep and adjacent seafloor depressions, contours in metres (After Anschutz and Blanc 1995). (**b**) Schematic showing relationship of Atlantis brine lake (DHAL) to adjacent dissolving masses of halokinetic Miocene salt (After Anschutz and Blanc 1995)

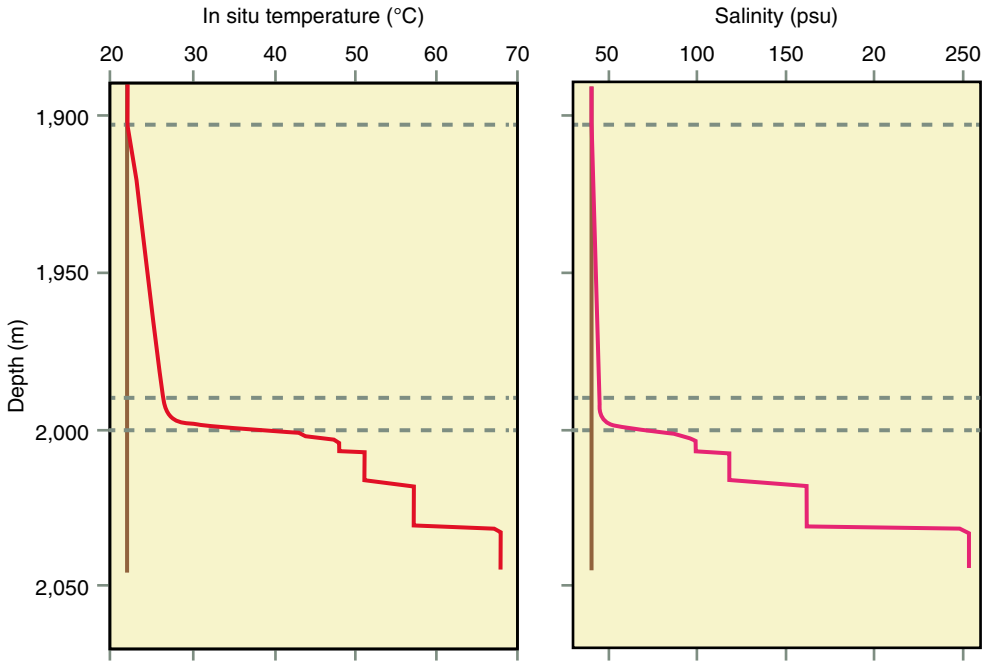

Fig. 15.17 Temperature and salinity profiles in 2008 in the Atlantis II Deep (After Swift et al. 2012). *Dashed lines* indicate the depths of bottom ridges controlling the brine lakes

Clearly, the venting of highly saline hydrothermal brines into the brine lake over the past 40 years has been continuous, but at a variable rate.

What is most significant geologically and mineralogically is the long term stability of this dense halokinetically-derived lower brine mass, with temperatures favouring anhydrite over gypsum precipitates, and its ongoing hydrochemical isolation from the overlying normal seawater column. For the last four decades, almost all additional heat and salt supplied to the Deep has been confined to the depression sump and it drives an increase in temperature in bottom waters. That is, very little heat is dispersed into the overlying seawater (Anschutz and Blanc 1996; Swift et al. 2012). The rate of heat input to the Deep was near constant during the period till 1996 and amounted to 0.54×10^9 W, which drove the documented rise in bottom-brine temperature. Salt input from the hydrothermal influx was also constant, and equalled 250–350 kg/s.

The effect of longterm brine pool stability is the precipitation of sulphide minerals at the Deep's redox interface, which is defined by the halocline contact with the overlying seawater column, and the subsequent accumulation of some rather unusual sulphide-rich saline bottom sediments. Interestingly, base metal laminites are not present on the floors of other deeps, such as Thetis, which lack a longterm brine sump (Pierret et al. 2010). The laminated nature of metalliferous sediment on the deep sea floor in the Atlantis II Deep is directly related to the oscillating nature of the overlying brine and its halocline interface (Fig. 15.18).

In the last 28,000 years some 10–30 m of the oxidic-silicatic-sulphidic laminites, along with hydrothermal anhydrites, have accumulated beneath the Atlantis brine lake, atop a basement composed of a mixture of basaltic ridges and halokinetic salt (Shanks III and Bischoff 1980; Pottorf and Barnes 1983; Anschutz and Blanc 1995; Mitchell et al. 2010; Feldens et al. 2012). Metalliferous sediments beneath the floor of the deep are composed of stacked delicately banded mudstones with bright colours of red, yellow, green, purple, black or white, indicating varying levels of oxidised or reduced iron and manganese related to varying oxidation levels and salinities in the overlying brine column. Sediments are typically anhydritic and very fine grained, with 50–80 % of the sediment less than 2 μm in size. Intercrystalline pore brines constitute up to 95 wt% of the muds, with measured pore salinities as much as 26 wt% and directly comparable to the salinity/density of the overlying brine (Fig. 5.18; Pottorf and Barnes 1983).

The sulphide-rich layers are a metre to several metres thick and form laterally continuous beds that are several kilometres across. Sulphides are dominated by very fine-grained pyrrhotite, cubic cubanite, chalcopyrite, sphalerite, and pyrite, and are interlayered with iron-rich phyllosilicates (Zierenberg and Shanks III 1983). Sulphur isotope compositions and carbon-sulphur relations indicate that some of these sulphide layers have a hydrothermal seawater component, whereas others were formed by bacterial sulphate reduction centred in the interface. Ongoing brine activity began in the western part of the Deep some 23,000 years ago with deposition of a lower and upper sulphide zone, and an amorphous silicate zone (Fig. 15.19). The metalliferous and nonmetalliferous sediments in the W basin accumulated at similar rates, averaging 150 kg/k.y./m^2, while metalliferous sediments in the SW basin accumulated at a higher rate of

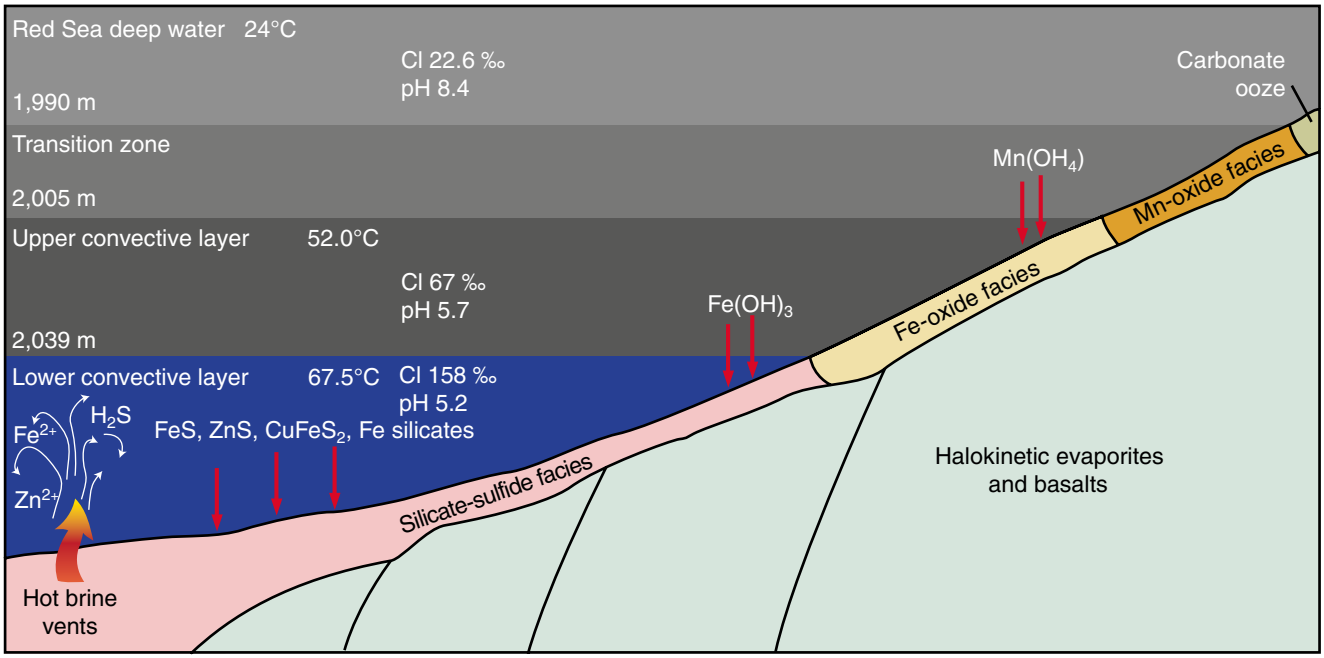

Fig. 15.18 Summary of the oceanographic and physical conditions in the Atlantis II Deep, Red Sea; not to scale (After Hovland et al. 2006b)

700 kg/k.y./m^2 (Fig. 15.19; Anschutz and Blanc 1995). The lowermost unit in the pile in the W basin consists mainly of detrital biogenic carbonates, with occasional thin beds of red iron oxides (mostly fine-grained hematite) or dark interbeds entraining sulphide minerals.

Hydrothermal anhydrite in the Atlantis II sediments occurs both as at-surface nodular hydrothermal beds around areas where hot fluid discharges onto the sea floor and as vein fills beneath the sea floor (Degens and Ross 1969; Pottorf and Barnes 1983; Ramboz and Danis 1990; Monnin and Ramboz 1996). White nodular to massive anhydrite beds in the W basin are up to 20 cm thick and composed of 20–50 μm plates and laths of anhydrite, typically interlayered with sulphide and Fe-montmorillonite beds. The central portion of individual anhydrite crystals in these beds can be composed of marcasite. The lowermost bedded unit in the SW basin contains much more nodular anhydrite, along with fragments of basalt toward its base. Its 4-m + anhydritic stratigraphy is not unlike that of nodular sekko-oko ore in a Kuroko deposit, except that any underlying volcanics are basaltic rather than felsic (see Chap. 16).

The anhydrite-filled veins that crosscut the laminites act as conduits by which hot, saline hydrothermal brines vent onto the floor of the Deep. Authigenic talc and smectite dominate in deeper, hotter vein fills, while shallower veins are rich in anhydrite cement (Zierenberg and Shanks III 1983). The vertical zoning of vein-mineral fill is related to heating haloes tied the same ascending hydrothermal fluids, with stable isotope ratios in the various vein minerals indicating precipitation temperatures ranging up to 300 °C.

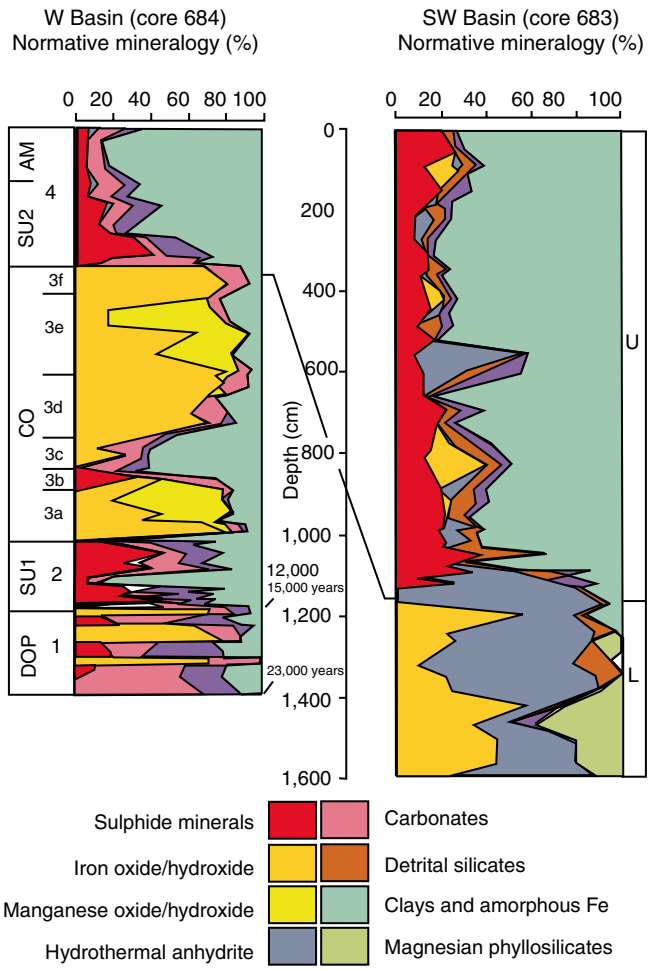

Fig. 15.19 Atlantis II Deep, Red Sea showing mineralogical proportions in cores from W and SW basins (After Anschutz and Blanc 1995)

Because of anhydrite's retrograde solubility, it can form by a process as simple as heating hydrothermally-circulating seawater to temperatures in excess of 150 °C. Pottorf and Barnes (1983) concluded that the bedded anhydrite of the Atlantis II Deep, like the vein fill, is a hydrothermal precipitate. Based on marcasite inclusions in the anhydrite units, it precipitated at temperatures down to 160 °C or less. At some temperature between 60 and 160 °C, probably close to 100–120 °C, hydrothermal anhydrite precipitation ceased. Thus, anhydrite distribution in the Atlantis II deep is related to the solution mixing and thermal anomalies associated with hydrothermal seawater circulation.

The fact that Holocene sediments in the Atlantis II Deep contain sulphate minerals and that particulate anhydrite is still suspended in the lower brine body strongly suggests that anhydrite is stable in the temperatures found at the bottom of the water column or is at least only dissolving slowly. These conclusions were clarified by Monnin and Ramboz (1996), who found that the Upper Convective Layer (UCL; or Transition Zone) of the Atlantis II hydrothermal system was undersaturated with respect to hydrothermal anhydrite throughout their study period, 1965–1985. The system reached anhydrite saturation in the lower brine only for short periods in 1966 and 1976.

What distinguishes the hydrothermal salts and sediments in the Atlantis II Deep from the much smaller hydrothermal accumulations in volcanogenic hosted massive sulphide (VHMS) deposits (Chap. 16) is that the hot metalliferous brines now found on the seafloor achieved their elevated salinities, temperatures and acidic saline chemistries via hybrid hydrothermal circulation through both seafloor basalts and dissolution of the edges and underbellies of halite in nearby halokinetic Miocene salt masses. Heat to drive this circulation probably came from the hot basaltic rocks emplaced in the slowly spreading axial zone, while most of the chloride and fluid focusing was due to circulation of marine-fed hydrothermal brines with significant, if not dominant contributions from nearby dissolution of halokinetic salt tongues. Thus, a seawater/brine flushing of newly formed basalts, as well as of Miocene evaporitic sediments atop and below the halokinetic salt, both contribute metal to the brine pool. This is clearly seen in studies of lead isotopes in the brine pool laminites, which indicate that a substantial portion of the lead came from the Miocene evaporites and their associated clastics and not from the basalts (Dupre et al. 1988).

As in anoxic halokinetic brine pools (DHALs) that typify halokinetic brine sumps on suprasalt seafloors elsewhere in the world (such as in the Mediterranean and the Gulf of Mexico), the reduced sulphur in the shallow pore brines and the bottom brine layer in the deep were mostly derived from bacteriogenic reactions, using seawater sulphate and entrained organic matter. This created conditions suitable for widespread metal sulphide precipitation at the halocline, in the brine column, and in brine-saturated sediments beneath areas covered by stable anoxic H_2S-enriched brines. Brine pool stability and an associated lack of mixing with overlying seawater (due to density/salinity stratification) allowed metal sulphides to accumulate as laminites across large areas of the brine pool floor and not just near vent localities. Hence, the larger volume of the metal resource and the greater dispersal of metal sulphides in the Atlantis II Deep compared to the much smaller near-vent precipitation sites typical of VHMS deposits, such as TAG Mound, the smokers of the east Pacific rise, and Kuroko- and Cyprus-style deposits (see Chap. 16). It is the hydrological and hydrogeochemical effects of the dissolving halokinetic evaporites that distinguish this style of hydrothermal "SedEx" precipitate from less stable seafloor brine pools, tied to much smaller open marine VHMS deposits.

Kebrit and Shaban Deeps, Red Sea

Massive sulphides dredged from the Kebrit Deep (Arabic for sulphur) represent black smoker fragments, novel to most Red Sea brine pool deposits (Fig. 15.14; Blum and Puchelt 1991). TV camera observations at 1,366 m depth in the Kebrit Deep, and just above the seawater/brine interface at 1,370 m, imaged some 40+ inactive smokers. Brines below the interface in Kebrit Deep at a depth of 1,373 m have a temperature of 24.3 °C and a salinity of 256‰, making this pool as saline but somewhat cooler (in the gypsum, not anhydrite, temperature field) than the Atlantis II deep. Above the interface the Kebrit brine has a temperature of 21.5 °C and a salinity of 41.9‰. According to Hartmann et al. (1998) there were no significant changes in temperature, brine level or chlorinity over the preceding 23 years. The transition in the column from high saline bottom brine to normal seawater salinity probably extends over a depth of only a few decimetres or less. As in the Atlantis II Deep, the dissolution of nearby Miocene evaporites accounts for the very high salinities in the bottom brine layer.

Piston core sampling in the Kebrit Deep revealed stratified somewhat metal-enriched sediments in the upper portions of the sedimentary column, while box and dredge sampling recovered specimens of elemental sulphur, sulphide and sulphates. These recovered sulphides consist primarily of Fe- Zn- and Pb-bearing phases that can be tar and asphalt impregnated. They were probably derived by hydrothermal cracking of organics held in adjacent sediments, where TOC values are more than 4 % in Kebrit and can be higher than 8 % in Shaban cores (Fig. 15.20 – see also Chap. 9). The sphalerite typically forms banded colloform nodules. Concentration of Ni in discrete bravoite [$(Fe,Ni,Co)S^2$] aggregates points to brine leaching of nearby basalts as a source for at least some of the metals in the brine pool. Unlike the Atlantis II Deep, Cu-sulphides are virtually absent from the paragenesis. This, and the presence of gypsum

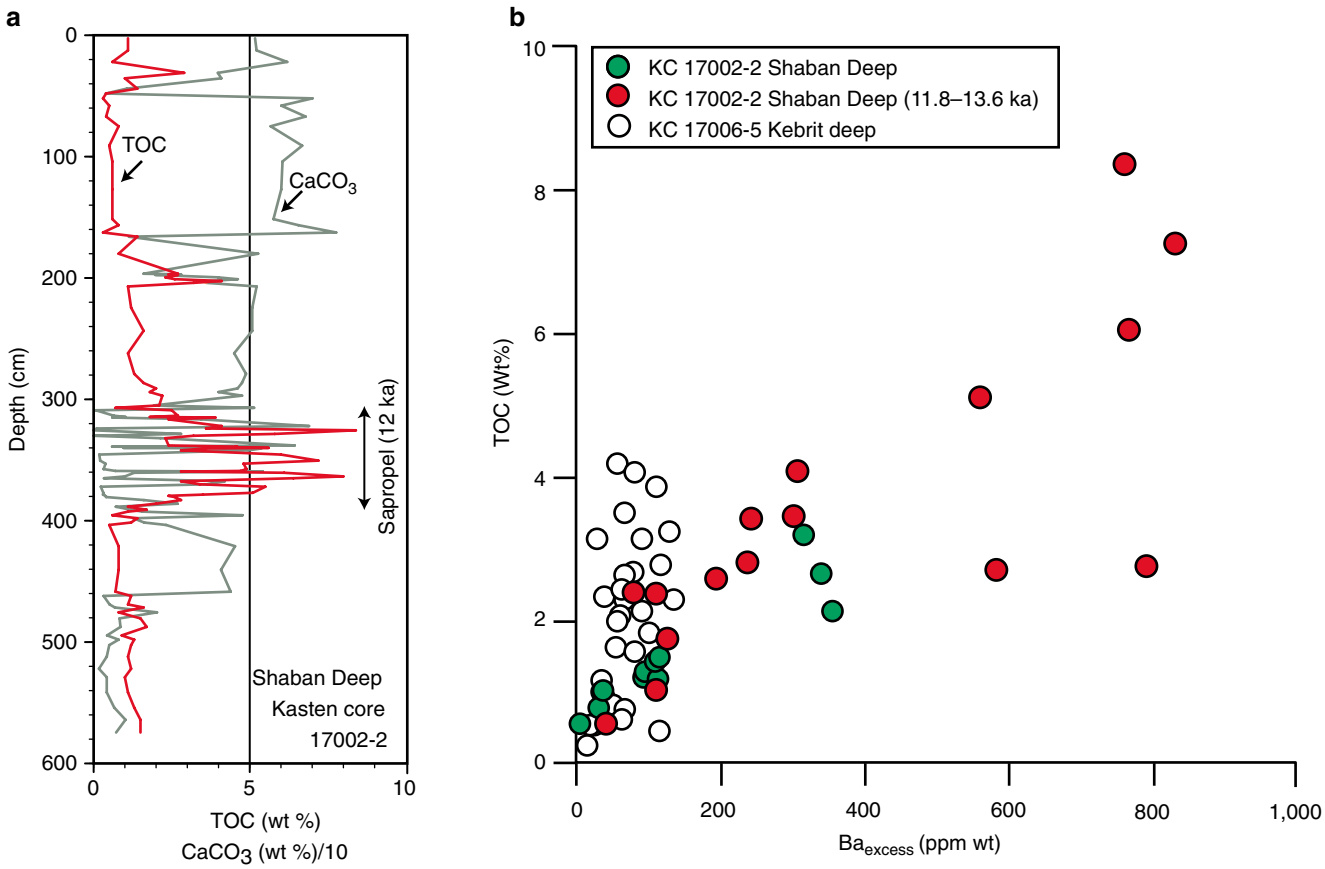

Fig. 15.20 Organic matter in the Shaban and Kebrit deeps. (**a**) TOC and $CaCO_3$ contents in the upper 6 m of the KC 17002–2 core from Shaban deep showing elevated content in the laminites (deposited 11.8–136.6 ka). (**b**) Crossplot of TOC versus Ba_{excess} in select core intervals (After Botz et al. 2007)

rather than anhydrite interlayers in chimney fragments points to formation of metal sulphides at lower temperatures compared to the Atlantis II Deep. Sulphide layering in the chimneys shows classic zonation, with Zn-bearing phases preferentially lining the interiors of the chimneys while pyrite is dominant in the outer portions.

The bottom brine layers in the Shaban Deep in the northern part of the Red Sea are 200 m thick, but the brines are only 2–3 °C warmer than the normal bottom waters (Cocherie et al. 1994). An insignificant decrease in temperature (to about 24.1 °C) occurred in the upper brine since detection of the Shaban Deep in 1981 and no changes were found for the brine-seawater level (Hartmann et al. 1998). The bottom sediment in the Shaban Deep is somewhat unusual compared with other brine pool sediments in the Red Sea in that the sediment consists almost entirely of biodetrital silicate mud (diatomaceous), with occasional volcanic glass fragments and only a thin (4 cm thick) hydrothermal sediment layer, along with intervals with more than 50 % biodetrital carbonate (Fig. 15.20a; note the plotted $CaCO_3$ values are reduced by an order of magnitude to allow plotting on the same scale as the TOC values). This biodetrital lithofacies is similar to the more oxidised layer in the western part of the Atlantis II Deep that lies beneath the metalliferous sediments and similar to the biogenic sediments found on the deep seafloor above the zone defined by the more saline portions of the brine lake (Fig. 15.18). This biogenic layer in the Shaban Deep overlies a tholeiitic ferro-basalt with transitional affinities, it too is different from the typical tholeiite basalt found further south. Thus, the Shaban Deep, the northernmost deep in the Red Sea rift, represents a very recent stage of oceanic opening. The lack of pervasive hydrothermal signature in the Shaban Deep compared with the Atlantis II Deep is also seen in both the Sr-Nd isotopes and the rare earth element signatures (Cocherie et al. 1994). Metal sulphides in Shaban Deep are less frequent than those in Kebrit, with framboidal pyrite being the dominant ore mineral.

Gypsum occurs in the bottom sediments of both the Shaban and Kebrit deeps, as both euhedral prisms and lenticular forms, up to several centimetres across. Crystals often interpenetrate the sediment layering to construct classic "desert rosette" morphologies, especially in the Kebrit Deep, where gypsum is commonplace. Deeper coring has yet to be undertaken in either of these deeps, but it is likely that this gypsum forms atop areas of subcropping and dissolving autochthonous salt in the same way morphologically

identical gypsum forms in sediments atop areas of dissolving halokinetic salt in DHAL settings worldwide.

Sulphur isotopes from gypsum in the rosettes in Kebrit Deep have values in the range +25.1‰ to +30.0 ‰. These values exceed those of normal seawater-sulphate-derived gypsum and imply a significant input of bacteriogenically fractionated residual seawater sulphate. Some samples show intimate intergrowths of idiomorphic gypsum and spongy sulphide, pointing to coprecipitation of both minerals from the same hydrothermal fluid in the presence of possible bacterial mediators. Inclusion studies show rather low sulphide and sulphate precipitation temperatures of 110–130 ° C in the Kebrit brine pool and 100 ° C in the Shaban Deep. In either deep, the gypsum, like the anhydrite in the Atlantis II deep, is not a true solar-derived deepwater evaporite, but a hydrothermal or burial salt.

There is a very interesting organic-rich laminite in the Shaban Deep with TOC values in excess of 5 wt%, qualifying it as a sapropel (Fig. 15.20a). The same interval also shows cemented carbonate layers between the organic-rich layers and elevated levels of Ba tied to elevated TOC (Fig. 15.20b). The organic signature in this 11,800–13,600 year old sapropel is largely unoxidised as it is bathed in hypersaline pore waters (Botz et al. 2007). The excellent correlation between TOC content and barium content suggests the sapropel formed via a productivity pulse in the basin arguing organic productivity not hydrothermalism controls the organic and Ba content of the Shaban sediments.

Red Sea Summary

Stable stagnant brine pools have developed in sea floor depressions along the medial ridge of the Red Sea, in close association with dissolution of adjacent thick halokinetic evaporites. Hot metalliferous brines focused by salt allochthons and escaping into the lower convective layers of these pools become widely dispersed across the extent of the deepwater brine pool with the richest metalliferous laminites (Atlantis II Deep), corresponding to a brine lake (DHAL) positioned in the most geothermally active position in the axial trough. The Atlantis II brine lake also contains the hottest brines. During active venting of metalliferous brines, the presence of a longterm brine pond facilitated stable anoxia at the sea bottom, as well as intra-brine-pool convection and the dispersal of metalliferous brine away from the immediate vent area. Diffusive mixing at the halocline atop the brine pool precipitated metal sulphides, mostly as pyrite framboids that then sank to the bottom carrying with them dispersed organic water. Thus, the longterm presence of a stable bottom brine lake increases the area of prepared ground for any subsequent Fe, Pb, Zn and Cu emplacement.

Ongoing dissolution of adjacent thick halokinetic masses not only enhances the permanency of the brine pool, it also raises the metal-carrying capacity of chloride-rich hydrothermal brines as they convect through and flush adjacent sub-salt and suprasalt sediment and volcanics, before ultimately venting and residing in the brine lake. That is, the high chloride levels in the circulating brine increases the reaction rate of any saline fluids flushing metals from the basaltic basement and suitable first-cycle sediments. The presence of a dissolving salt aquiclude atop seafloor basalt also focuses reflux driven hydrothermal vent fluids into the outflow zones about the edges of the stable brine pools. The now increasingly documented role of salt allochthons as the dominant control on the location of the deeps on the Red Sea floor, means it is likely that synkinematic salt gliding drives restriction and brine focusing on the sea floor depressions. However, the presence of salt allochthons is a focus for the mineralisation site (trap or seal), but salt focusing is not directly sourcing the metals found in some of the Deeps. If it was then sediment fills in all brine-filled deeps along the Red Sea axis would be metalliferous. Rather there is still a need for a focused deeper mantle-source convection to source the metals ultimately held in this type of deposit.

Stratiform Copper Deposits (Salt-Related)

Sediment-hosted stratiform copper deposits comprise disseminated to veinlet Cu and Cu-Fe sulphides hosted in siliciclastic or dolomitic sediments. In this chapter I am using the term "sediment-hosted stratiform copper" (SSC) as defined by Kirkham (1989). It encompasses a group of Cu deposits that are not truly stratiform in that they may cut the stratigraphy either locally or regionally. Yet, locally, most of these deposits are not only stratabound (confined to a particular stratum), but are more or less concordant or peneconcordant, either with bedding or with the edge of a salt mass or its residues (stratiform).

SSC deposits worldwide rank second only to porphyry copper deposits in terms of copper production and they represent the most important global source of cobalt (Figs. 15.21 and 15.2). Together, SSC deposits account for some 23 % of the world's Cu production and known reserves, as well as being significant sources of Co and Ag. Small SSC deposits of various ages are commonplace, but large sediment-hosted stratiform copper deposits are rare (Hitzman et al. 2005; Brown 1997). Within the supergiant grouping, three evaporitic basins, that contain enormous Cu deposits, dominate (>24 million metric tons -Mt), they are; (1) the Permian Basin Kupferschiefer of central Europe, (2) the Neoproterozoic Katangan Basin in central Africa, and (3) the Paleoproterozoic Kodaro-Udokan in Siberia (Fig. 15.21 and Table 15.7). Ore hosts in this group of supergiant deposits span lithologies that range from carbonates to siliciclastics and all the larger accumulations are associated with halokinetic evaporites or their residues.

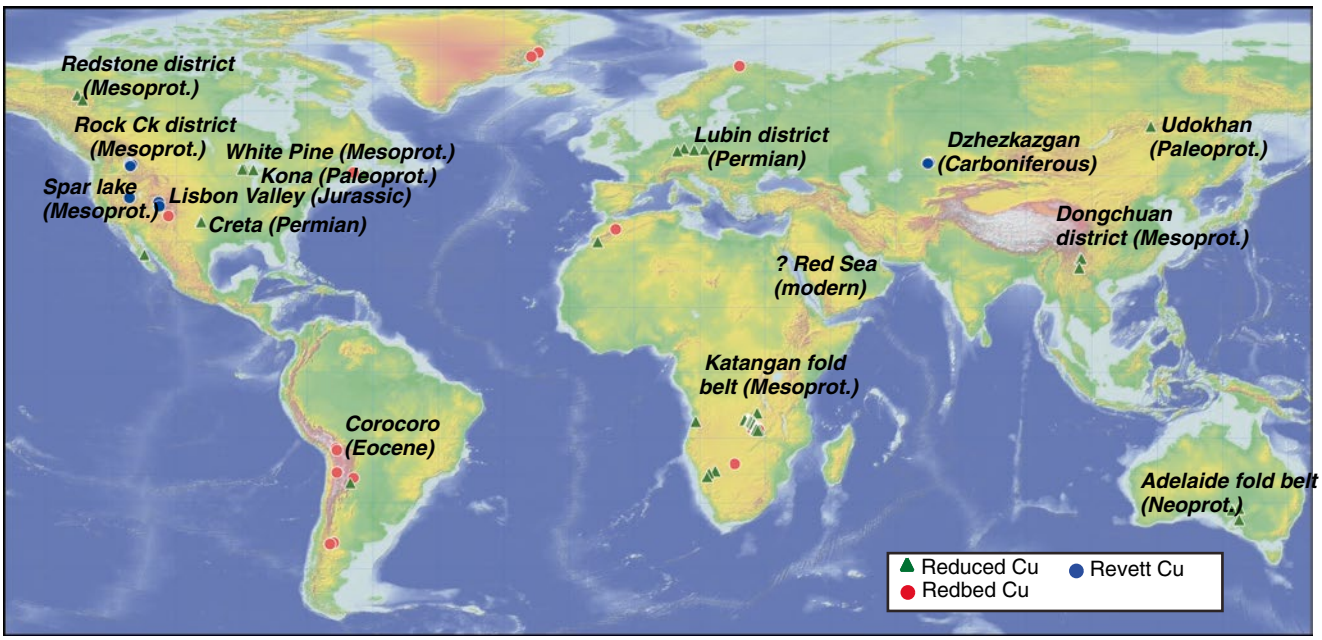

Fig. 15.21 Sediment-hosted stratiform (SSC) Cu deposits with Cu reserves of more than 1 million tonnes and discussed in this chapter (see also Fig. 15.22) (Data points extracted from Cox et al. 2007 and Salt Work database version 1.6)

Table 15.7 Selected evaporite-related sediment-hosted stratiform Cu (SSC) deposits related to salt style and position relative to the salt mass. In many cases the salt bed or mass is partially or completely dissolved and only residues remain. Only deposits still in the diagenetic realm were selected in this listing

Ore deposit position	Bedded salt	Halokinetic (peridiapiric) salt
Suprasalt and or its residues		Lisbon Valley Utah Flinders Ranges, South Australia Dongchuan, China Dzhezkazgan, Kazakhstan
Inter or lateral to salt edge and/or its residues	Corocoro Redstone, NWT	Katangan Copperbelt (Kipushi) Atlantis II Deep?
Subsalt or its residues	Creta, USA	Kupferschiefer (Lubin district)

The problem with exploration-based targeting of this group of copper deposits, especially when they are associated with now dissolved evaporites, is that we are looking at metal precipitation mechanisms that are diagenetic and dynamic. Ore positions are typically a reflection of a once rapidly evolving basin/ brine hydrology, which now is much less active. Accordingly, the various copper ore precipitates are concordant with paleopermeability trends and chemical interfaces, but they are not always concordant with regional depositional bedding. Thus, to predict positions of likely evaporite-associated stratiform copper occurrences within a basin, one must understand not just local depositional geometries, but also the subsequent diagenetic history, as well as likely focusing and trapping geometries created by interactions between redox interfaces and dissolving evaporite masses. The latter, now largely dissolved, evaporite masses were likely halokinetic in the case of the larger deposits and some masses were possibly allochthonous, as they are in a number of the larger SedEx deposits. The positions of former salt masses are now likely indicated by residues and alteration products, rather than actual salts.

Current classifications of SSC deposits do not place them in an understood evaporite framework, and the proximity of most larger deposits to halokinesis at some time in their burial evolution, is rarely noted. Many current classifications do, however, note the typical association of redbed Cu with present or former evaporites, but then tend to mismatch brine settings and associations, making the noted evaporite association useless as a pointer to mineralised positions. So, to simplify and better understand the diagenetic processes associated with copper ores tied to evaporite evolution, I have decided to steer away from the classic subdivisions of sediment-hosted Cu deposits; other than noting at the start of this section that this group of SSC deposits is currently subdivided in the literature into Reduced copper, Redbed copper and Revett copper (as illustrated in Figs. 15.21 and 15.22). According to Cox et al. (2007) these are three subtypes of sediment-hosted copper deposits show significant differences in tonnage and copper grade which can be used to help separate the three groups. In their world GIS compilation of SSC deposits they list 56 reduced-facies Cu deposits, 32 redbed Cu deposits, and 15 Revett Cu deposits. They conclude that the three types differ in the strength and efficiency of the reductant at the site of

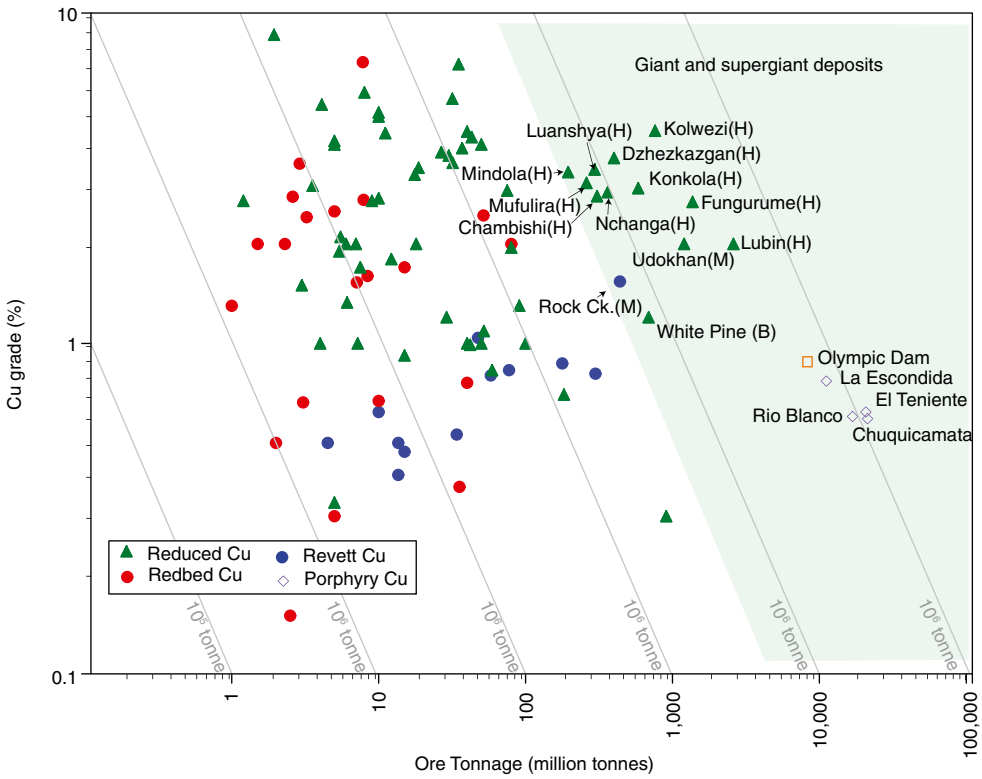

Fig. 15.22 Resource plot for sediment hosted stratiform copper deposits. Halokinetic association indicated by *H*, bedded evaporite association by *B* and metamorphic evaporite association by M (Plotted data values were extracted from Cox et al. 2007, integrated with the SSC evaporite association GIS base and classification extracted from the SaltWork database version 1.6). Also shown is Olympic Dam (IOCG) and the four largest Porphyry-Cu deposits

deposition. In classic SSC classifications, the reductant the reduced-facies deposits is a marine or lacustrine fine-grained sediment, containing abundant organic matter. In redbed deposits, the reductant is more weakly distributed, usually represented by patches of organic debris in sandstone. In Revett Cu deposits, the reductant is broad and diffuse and in some Phanerozoic deposits can be shown to be gaseous or liquid hydrocarbon, or sulphide-rich sour gas.

I shall not use this three part terminology in this chapter as it does little to improve our understanding of the role of dissolving salt in focusing and trapping processes associated with ore creation within the group of salt-related copper deposits that we will discuss. In terms of understanding how these deposits relate to evaporite-derived brines and dissolution foci, the classic classifications confuse a significant factor of prime exploration importance, namely where did the deposit form in relation to the associated evaporite mass and the redox front created by subsurface salt dissolution.

So, instead, I shall subdivide and discuss representative stratiform Cu deposits using an understanding of halokinetic and bedded salt associations. It is based on the geometry of the adjacent salt mass, or its residues, and the relative position of the ore deposits with respect to the salt mass (Tables 15.2 and 15.7; subsalt, intrasalt or suprasalt). I shall consider the halokinetic examples first, as they tend to be worldclass and currently exploited. Accordingly, the three dimensional aspects of many of the facies and structural indicators for associated salts in the halokinetic group are well mapped, if not well understood in terms of process significance.

Typing a deposit to its evaporite style makes it easier to illustrate and understand the formative brine fluid hydrologies. Interestingly, almost all the world's giant and supergiant SSC's have a halokinetic evaporite basinwide association, rather than a bedded platform evaporite association (Fig. 15.22). After discussing the various halokinetic associations, I will consider sediment-hosted Cu deposits tied to the bedded salt associations. This latter group tend encompass much more numerous, but smaller, examples of copper accumulations. Worldwide, they are patchily distributed, so deposit details are not as well documented (Fig. 15.21).

By itself, this two-part breakdown into halokinetic versus bedded and the understanding of extension, compression, and structuration that is associated with an evaporite/brine genesis, become exploration pointers or paradigms. So, as a rule of thumb in a greenfield area, when looking for the larger SSC's, one should first focus on localities where the "prepared ground" units (organic shales or former hydrocarbon traps) lie adjacent to stable halokinetic salt or rauhwacke masses, not to stratiform bedded salt associations. The latter tend to be smaller. We shall revisit this observation, but with understanding, after we have studied some representative examples (Table 15.7).

Stratiform Cu Halokinetic-Salt Associations

Within the sediment-hosted Cu association there are two styles of halokinetic salt: (1) Deposits where substantial volumes of the halokinetic salt are nearby, such as the

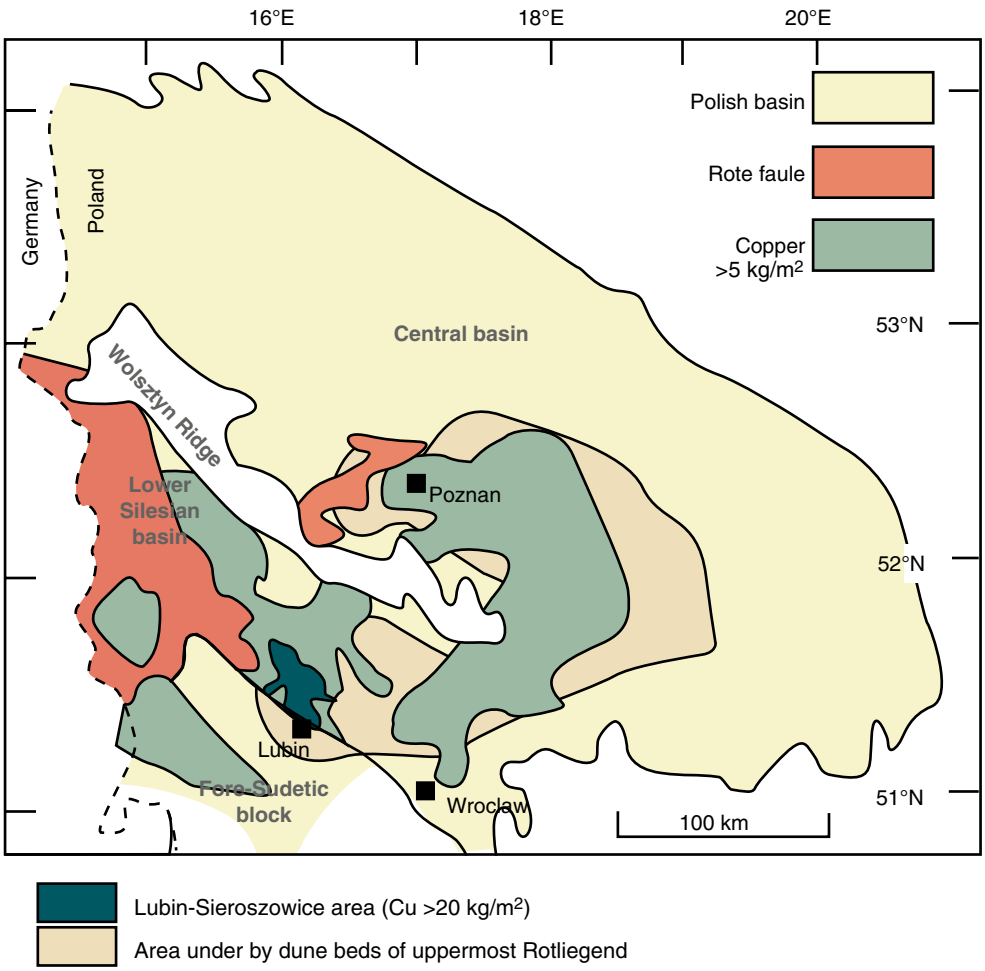

Fig. 15.23 Distribution of the Kupferschiefer copper deposits in Poland (After Oszczepalski and Blundell 2005)

Kupferschiefer, Lisbon Valley and the Dzhezkazgan deposits and, (2) Deposits where flowing salt was once present but now is indicated by dissolution remnants, typically now in thrust terranes, but often showing evidence of an early gravity gliding stage of mineralisation later overprinted compressional thrusting, given a rauhwacke association to the current outcrop/subcrop expression. Widespread examples of type 2 deposits, where salt is no longer present, typify the Katangan copperbelt, copper in the Mt Isa mine region and the numerous small suprasalt Cu occurrences in the Flinders Ranges, South Australia (see Chaps. 6 and 7 respectively for the geological background to these rauhwacke associations).

In this section I have chosen worldclass examples to illustrate Cu accumulations where dissolving halokinetic salt masses played a role, both in generating metalliferous saline brines, and in focusing the ore precipitation process at a salt-dissolution induced stable redox front. They are (Table 15.7);

(a) Subsalt – Kupferschiefer in Poland and Germany.
(b) Suprasalt -Dzhezkazgan and Lisbon Valley.
(c) Intersalt or halokinetic salt residue associated – various examples in the Donchuan District and Katangan Copper belt and their more metamorphosed equivalents (Udokhan)

Kupferschiefer/Rote Faule, Lubin Region, Poland

The world's largest sediment-hosted stratiform copper accumulation is a subsalt copper association, centred on the Kupferschiefer shales in the Lubin-Sieroszowice copper district, Poland (Fig. 15.23). Near the ore zone, is a partially dissolved thick mass of halokinetic Zechstein salt. Facies distribution preserves *prima facie* evidence of the influence of a salt mass, both deeper in the basin where it acts as a source of dissolution-related basinal brines and nearer the basin margin where it focused the set-up of a halokinetically-stabilised brine-mixing redox front.

Mineralisation typically occurs in reduced, Zechstein-capped beds at the top of a thick continental volcanic and redbed Rotliegende sequence, which was deposited within a continental Permian rift basin known as the Polish Trough. This is a generally north-west trending basin and is the south-eastern extension of the main evaporite-filled

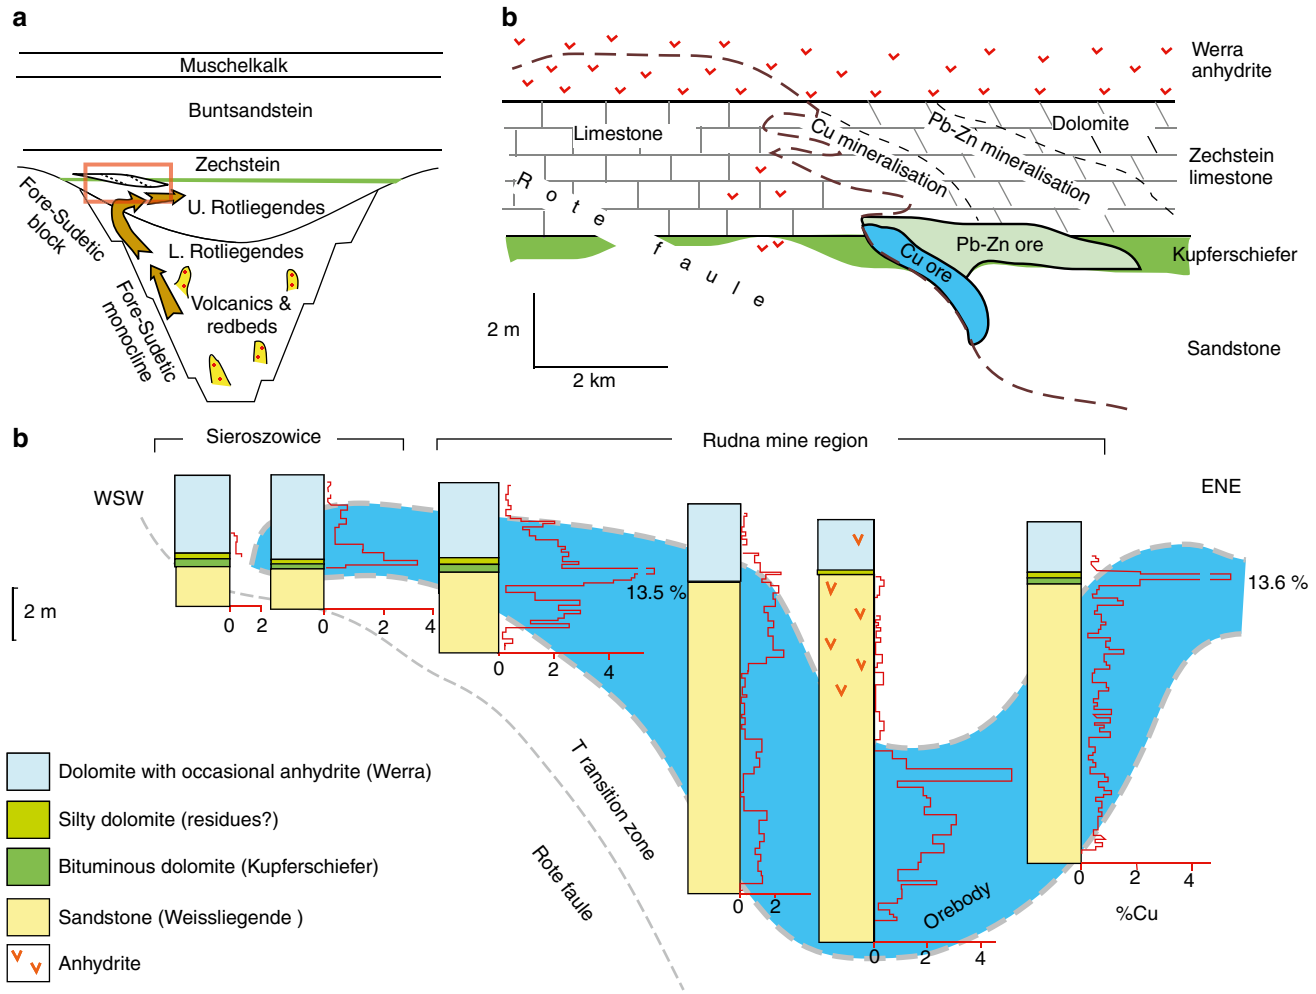

Fig. 15.24 Rote Faule and its influence on Kupferschiefer mineralisation in the Lubin copper district, Poland. (**a**) Regional schematic showing focus of upwelling of convective basinal waters toward basin edge and the Rote Faule Zone. (**b**) Enlargement of Rote Faule area outlined in **a**, showing how the resultant mineralisation cross cuts the stratigraphy. (**c**) Distribution of Cu in the Lubin ore zone, shows higher Cu enrichment in Kupferschiefer with Cu values in excess of 13 %, but the greater thickness and volume of ore in the Lubin district resides in the Upper Rotliegende sandstone, beneath a Werra Anhydrite seal (Modified from Jowett 1992; Vaughan et al. 1989; ore assays and associated stratigraphy after Wodzicki and Piestrzynski 1994)

(Zechstein Series) halokinetic Southern Permian Basin (Fig. 15.23; Krzywiec 2004). The mineralised district lies along the southern edge of the halokinetic Zechstein sequence and is also proximal to the basin margin of the Lower Silesian Basin to the south. The ongoing ability of flowing salt to maintain its seal capacity and its diagenetic interfaces in earth-space adjacent to a basement high, even as the salt was dissolved and deformed, is in my opinion the reason why the Lubin-Sieroszowice District is world-class. It has 2,369 Mt of ore, made up of 47.07 Mt Cu @ 1.3–2.6 %, 135,000 t Ag @ 30–80 g/t (Oszczepalski and Blundell 2005).

Stratabound Cu–Ag Kupferschiefer deposits were long considered classic examples of syngenetic mineralisation, driven by syndepositional bacterial sulphate reduction (e.g., Wedepohl 1964). However, detailed work in Poland in the last few decades has shown that the Cu mineralisation cuts depositional boundaries (Fig. 15.24). Levels of mineralisation in the Kupferschiefer Rote Faule interval in the Lubin-Sieroszowice district are typically far higher than background levels in the Kupferschiefer shale (Fig. 15.24c) It should be pointed out that the using term shale in this context to imply a terrigenous sediment is a misnomer, the Kupferschiefer is actually a finegrained (micritic) organic-enriched, finely laminated dolomite mudstone, often with no more than minor amounts of terrigenous material.

Locally, mineralisation transgresses depositional boundaries as it is tied to the Rote Faule/saline brine interface and not to the depositional pattern or solely to the distribution of the Kupferschiefer shale. Thus copper ore in the Lubin

district is not just hosted in the organic laminites of the Kupferschiefer and the Zechsteinkalk, it also occurs in parts of the Weissliegend aeolian sandstone, a unit that at the time of deposition in a desert sand sea was exceptionally free of organics, organic laminites and pre-ore sulphides (Figs. 15.23 and 15.24b, c).

To the dismay of many syngeneticists, this depositionally organic-clean aeolian sandstone hosts half the economic Cu-sulphides in the Lubin-Sieroszowice copper district. That is, the richest intervals of mineralisation define low-angle transgressive metal zones tied to the redox edges adjacent to diagenetic Rote Faule units (Jowett et al. 1987; Jowett 1987, 1989, 1992; Oszczepalski 1989, 1994; Vaughan et al. 1989; Hammer et al. 1990; Kucha 1990; Bechtel and Hoernes 1993; Wodzicki and Piestrzynski 1994; Bechtel et al. 1995; Heppenheimer et al. 1995; Speczik 1995; Sun et al. 1995; Large et al. 1995; Large and Gize 1996). The overlying evaporitic Zechstein sediments enhanced and focused the precipitation of base metals, both by forming prepared ground at the time of deposition (pyritic and organic-rich evaporitic laminite host), and by creating a stable dissolution hydrology during diagenesis, which focused the greater volumes of economic mineralisation into a redox zone immediately below the main evaporite mass and adjacent to the Rote Faule boundary.

The mesohaline setting of the Kupferschiefer laminites created much of the "prepared ground"- organic-rich laminites below thick salt that would later control much of the mineralising fluid flows and interfaces. Away from the zone of organic degradation associated with the Rote Faule, the degree of methylation of 2-methyl-2-trimethyl-tridecylchromans (MTTC) in the shales indicate original euryhaline to mesohaline (30–60‰) salinity during subaqueous laminite sedimentation. An abundance of biomarkers, derived from green/purple sulphur bacteria, suggests H_2S saturation of the anoxic bottom waters and maximum water depths below 100 m. These organisms lived near the boundary between the photic zone and the anoxic (euxinic) bottom water at depths of 10–30 m. Primary production in the upper water column was dominated by photosynthetic cyanobacteria or green algae. In the sediment, sulphate reduction was driven by the availability of abundant sulphate and organic detritus settling from the overlying water column. Methanogenesis was active mostly during early Kupferschiefer deposition; it is indicated by the light carbon isotopic composition of the organic matter that originated from recycling of CO_2, which was generated by methane-oxidizing bacteria in the water column (see Chap. 9 for detail).

Kupferschiefer matrix was deposited mostly from suspension load in density-stratified subaqueous lacustrine/restricted marine-fed brine lakes and seaways with reducing anoxic bottom waters (Glennie 1989a, b). Higher energy sediments were deposited in shallower shorezone areas about the basin edge or atop basement highs. The anoxic organic-rich laminates of the deeper water areas quickly became the hosts to syndepositional bacterially mediated pyrite framboids (Sawlowicz 1992). Regionally, much early metal sulphide precipitation was dominated by this pyrite. Only locally was there any early Cu or Zn enrichment as this pyrite and the associated organics were replaced by base metal sulphides, which were further concentrated in regions adjacent to Rote Faule intervals (Sawlowicz 1992). This type of enrichment is sometimes call a two-fluid or multiple-fluid ore forming process.

The high mineral content of the Kupferschiefer was attained via a three-step process (Sun and Püttmann 1997): (1) framboidal pyrite and pyrite precursors were precipitated by bacterial sulphate reduction during deposition of the sediment; (2) pyrite and pyrite precursors were largely replaced by mixed Cu/Fe minerals and by chalcocite during early diagenesis; and, (3) in those intervals with very high Cu contents (>8 %), the amount of reduced sulphur from Fe-sulphide precursors was not sufficient for precipitation of Cu and other trace metals. In this part of the profile, thermochemical sulphate reduction (TSR) occurred after pyrite replacement, as is indicated by the presence of pyrobitumen and sparry calcite.

The maturation profiles of the kerogens in the ore zone and the adjacent Rote Faule show the Rote Faule kerogen to be highly oxidised and degraded compare to kerogens in the ore zone (Fig. 15.25a; Bechtel et al. 2002). Likewise, the stable isotope profiles across the mineralised zone imply increasing oxidation in the Rote Faule (Fig. 15.25b). Biomarker profiles within the mineralised zones also imply hydrothermal alteration has occurred within locally elevated temperature regimes. Some aspects of the profiles are similar to those of hydrothermal-cracked hydrocarbons in the modern Guayamas Basin (Rospondek et al. 2007). All this is consistent with the model of Brown (2006) arguing for a mixing of reduced metalliferous basinal fluids and surface-derived, somewhat more oxidised, saline waters and indicated by Rote Faule (Fig. 15.24). According to Brown, the descending oxidising waters become more saline by coming into contact with buried evaporites (in this case it would have been the underside of the adjacent Zechstein salt seal), or in some cases he argues the surface-derived fluids are reflux brines.

Rote Faule ("red rot") describes a non-mineralised diagenetic zone and loosely encompasses barren red-coloured rocks typically found in the vicinity of high-grade ore. That is, it describes an oxidised haematitic interval that is adjacent to reduced highly mineralised intervals throughout the Lubin-Sieroszowice copper district. Levels of mineralisation in the Kupferschiefer adjacent to a Rote Faule interval are typically far higher than background levels in the

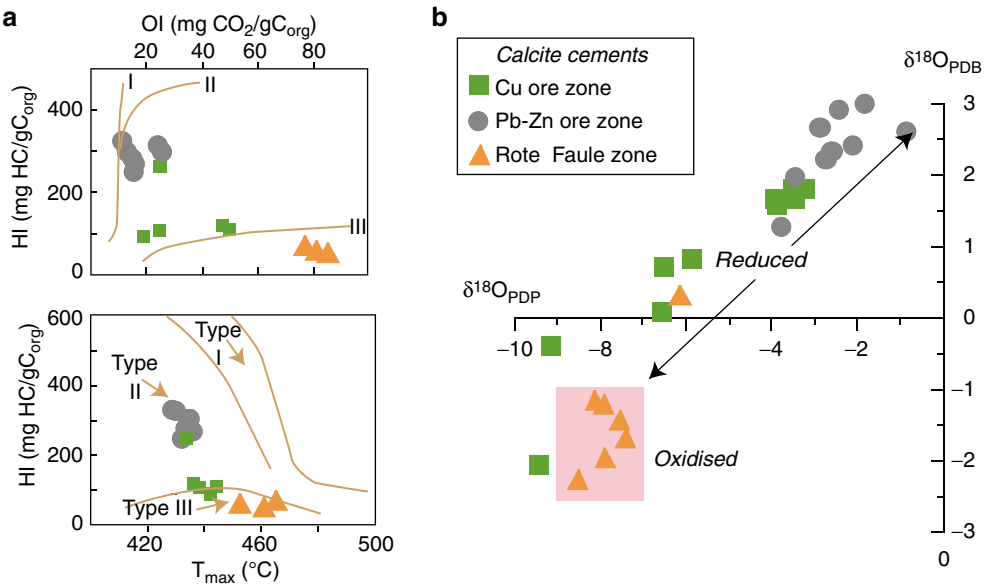

Fig. 15.25 Organic character in the vicinity of Rote Faule. (**a**) Upper figure is a modified van Krevelen diagram plotting Rock-Eval pyrolysis of samples from Kupferschiefer strata Lower figure shows relationship between hydrogen index (*HI*) and temperature as measured by maximum pyrolysis yield (*Tmax*) of the same Kupferschiefer strata. Maturation pathways typical for the different kerogen types are shown in both figures (**b**) $\delta^{13}C$ versus $\delta^{18}O$ plots of calcite cements in the Kupferschiefer in the vicinity of the Rote Faule of SW Poland (After Bechtel et al. 2002)

Kupferschiefer shales (Fig. 15.24c). Rote Faule is a diagenetic unit that is not formation specific and occurs in the Weissliegend, Kupferschiefer and Zechsteinkalk strata, wherever various types of red colour ("red rot") have been created by the diagenetic formation of disseminated authigenic hematite and goethite. Pyrite, and the original organics of the Zechstein carbonate and the Kupferschiefer mudstones, are oxidised and largely removed in Rote Faule intervals, while the economic sulphides of Cu and Pb-Zn have been largely leached and deposited in adjacent areas (Oszczepalski 1989). The organic degradation associated the development of more oxidised and leached Rote Faule is clearly seen in the degradation of the kerogen within this zone (Fig. 15.25a).

The development of Rote Faule interval indicates the oxidised portion of a redox front. In Poland, it is located near the basin margin at the top of the thick redbed sequence, which during burial dewatering was flushed by upwelling basinal waters (Fig. 15.24a). Ore sulphides occur on the far side of this subhorizontal oxidation-reduction front (Fig. 15.24b; or, in the words of the poet Byron, "a gilded halo hovering around decay"). Thus Rote Faule zones outline redox interfaces, centred immediately updip of the outflow positions of salt-seal focused hydrological conduits which carry ascending, highly saline, basinal chloride-rich brines. They define the mixing zones between ascending basinal waters and telogenetic waters of the basin margin, so that the sulphides are arranged in three distinct haloes around "Rote Faule", in the order Cu, Pb and Zn (Fig. 15.24c). Thus, around and above the Rote Faule, base metals are zoned laterally and vertically in successive mineralisation belts of chalcocite, bornite, chalcopyrite, galena and sphalerite.

Mineralisation in Kupferschiefer-style deposits transgresses depositional facies as it is tied to the Rote Faule/upwelling saline brine interface and not to the depositional pattern. That is, Kupferschiefer shales may constitute the richest prepared ground in terms of their inherently high organic content, but volumetrically are not necessarily the best ore hosts. The likely seal to gases (mostly methane), trapped in the Weissliegend sandstones, was the overlying Zechstein evaporites. Throughout Europe, and in the offshore southern Zechstein Basin in North Sea, the Weissliegend is a significant gas reservoir. In Poland, the entrained gases are mainly methane and nitrogen and are often found in the same localities as significant sulphide concentrations (Peryt 1989). These deposits cannot be mined unless vented by Alpine-age faults, as they have been in the worldclass Lubin district. Venting of this gases is tied to the dissolution-driven destruction of the Zechstein salt seal. As in the rest of Europe, the methane was largely sourced in the underlying Carboniferous coal beds and variably trapped beneath the Zechstein evaporite seal.

Geometries of mineralisation show that the underside of the Zechstein evaporites acted as a longterm seal, which focused and locally ponded or trapped the upwelling basinal waters within the immediately underlying Kupferschiefer or its lateral equivalents in the Weissliegend (Fig. 15.24c). It also acted as a pressure seal that aided hydrofracturing within the maturing organic laminates of the Kupferschiefer, as evidenced by numerous sulphide-calcite veinlets in the Kupferschiefer. An inherent lack of permeability in widespread thick evaporites also meant the upper side of the Zechstein salt beds prevented vertical/downward percolation of fresh oxygenated waters, which would otherwise have destroyed the stability of the redox interface (mixing zone) along the edge/underside of the dissolving salt bed (the "block of ice" model for salt dissolution).

Dissolving Zechstein evaporites (including basinwide sulphates) atop the Kupferschiefer laminates acted both as a

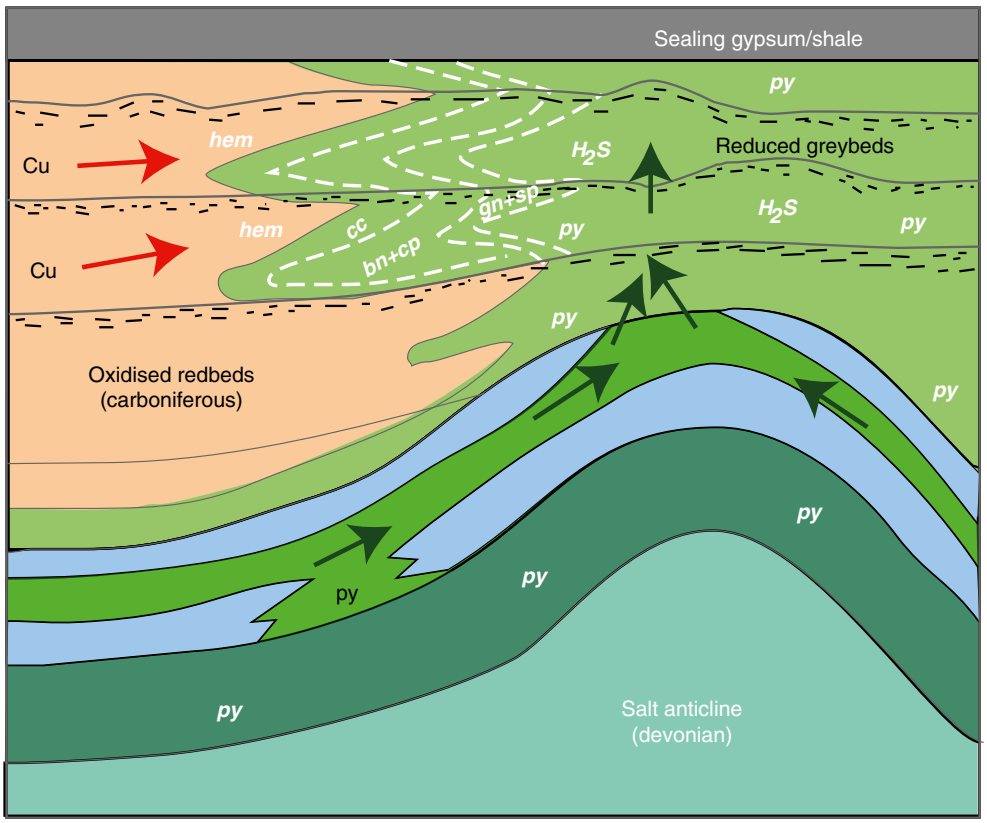

Fig. 15.26 Highly schematic cross section of the Dzhezkazgan region showing Cu zonation at the redbed/greybed interface (After Kirkham 1989)

burial seal to escaping basinal brines (and gases) and as an ongoing focus to descending oxidised brines. The mixing zones (often structurally controlled by reactivated faults), were not where the most significant regional mineralisation took place. It was the presence of an adjacent slowly dissolving salt mass that enabled longterm maintenance of the redox interface between the anoxic hydrology of the Kupferschiefer laminates and the more oxidising metalliferous water of the Rote Faule and so created the worldclass ore deposits of the Kupferschiefer. Similar evaporite-enabled focusing of redox interfaces have created the somewhat smaller ore zones of the Harz Mountains and the Spessart ore district, Germany (Wedepohl and Rentzsch 2006; Wagner et al. 2010).

Dzhezkazgan Region, Kazakhstan

The Dzhezkazgan copper deposit is a halokinetically focused suprasalt sandstone-hosted deposit (Fig. 15.26 and Table 15.7). It is located in a graben near the southern closure of a PermoCarboniferous basin, at the northern edge of the first-order Chu-Sarysu Basin of central Kazakhstan. The Basin contains several stratabound Cu and also Pb-Zn and U zones (Cu mineralisation is present in stacked sandstone beds throughout a 70 km long belt with an area of 600 km^2) of which the Dzhezkazgan ore field is the largest. Ores are hosted in Middle to Late Carboniferous continental successions of conglomerate, sandstone, shale and evaporites (Gablina 1981; Susura et al. 1986). Reserves estimates for the Dzhezkazgan deposit, but based on questionable Soviet era data, are around 400 million tonnes, with a copper grade of 1.5 % (Kirkham 1989). The depositional setting of the host was an intermontane closed-basin, which was made up of deltaic-lagoonal, alluvial and saline lake sediments.

Hosts to the ore are siliciclastic redbeds that are laterally equivalent to bedded evaporites and underlain by Early Carboniferous organic-rich sediments (presumed source rock) and sealed by shaly carbonates. The main copper sulphide and pyrite orebodies are tied to fault feeds that occur on or near the greenbed crest of an anticlinal trap, located along the flanks of a basement high, and sitting atop a salt ridge (Fig. 15.26). The host redbed sandstones become more evaporitic basinward and coarser-grained toward a pinchout along the basement highs. The mineralised sandstone is pyritic, with reduced pore fluids created by entrained hydrocarbons and high salinities. In contrast, the interbedded shales are red due to more oxidising pore fluids. These redbeds were in part derived from continental volcanics.

The mineralised system is carried by 10 cupriferous stratabound bands, within the 380 m thick Dzhezkazgan Formation. Only a limited number of these mineralised bands are of ore grade at a given point in the regional Cu trend. The mineralised system covers an area of approximately 120 km^2, extending down dip to a depth of 1,000 m

Table 15.8 Stratigraphic column of the Dzhezkazgan copper district

	Unit	Comments
Permian	H5	30–2,500 m thick – marl, and interbedded marl and interbedded 20–30 m thick salt beds. A major 1,000 m thick salt bed found in the middle of the unit. This unit is widely developed above and to the south of Dzhezkazgan.
	Black pyritic unit	Average 0.2 m thick – a Kupferschiefer type pyritic and carbonaceous (2–5 % TOC) shale layer. This unit is absent at Dzhezkazgan, but is found in the Tengiz Basin, 350 km to the north, where it contains Cu mineralisation. In the Dzhezkazgan area the units above and below the position of the absent shale are red and lacustrine
	H4	600–800 m thick – red beds, which have the same ratios of conglomerate: sandstone: siltstone as the Dzhezkazgan Formation, but with no reduced grey or green intervals and patches. There are also no carbonates. Halite and sylvite layers are found low in the unit in the main basin to the south of Dzhezkazgan, while some methane, helium and nitrogen accumulations have also been encountered within it, less than 30 km to the south of the mine;
	Sulphate unit	0–100 m thick – a discontinuous gypsum rich band up to a maximum of 100 m in thickness, containing 3–5 % $SrSO_4$
	H3	Dzhezkazgan Fm. to 380 m thick – which hosts the Cu mineralisation of the major Dzhezkazgan orebodies. This unit comprises a red, continental sequence of conglomerates, sandstones and siltstones, which has been locally reduced to a grey or greenish-grey colour in the vicinity of the orebody. The reduced beds consist of compact, uniform, fine-, medium- and coarse-grained rocks with a grey and greenish-grey colour. They contain angular 0.25–0.6 mm, and rarely up to 1 mm, clasts of feldspar and quartz in a fine siliceous-carbonate matrix. The grey sandstones are characterised by a clear stratification, emphasised by intercalations of the red varieties. Grey siltstones are rare. The red siltstones and sandstones are distinguished only by the somewhat smaller clasts and by the clay-carbonate content of the matrix. The ratio of green: red lithologies is approximately 1:1. The ratio of sandstone: siltstone is 1:1, and conglomerate:sandstone 1:30. Variable amounts of 'gypsum' impregnate the sandstones. Conglomerates are present as both intra- and inter-formational varieties. The former are generally 0.8–2 m thick, locally grading laterally into sandstone and sometimes into siltstone. The clasts are usually 0.5–1 cm in diameter and rarely up to 5 cm, comprising locally sourced rock, in a matrix of the enclosing sandstones. The interformational conglomerates have angular exotic clasts
Carboniferous	H2	Lower Member, 3,000 m thick – marine limestone to clayey-limestone or marl, with minor intercalated dolomite. Amorphous pyrite occurs within the marls. – Upper Member, 200–500 m thick – shallow water, terriginous-derived, fine grained calc-siltstone and mudstone, grading to calcarenite. In the top sections lenses of Cu mineralisation up to 20 cm thick may be found at the contact with the overlying Unit H3. This interval is characterised by thin banding and black sandstones;
	H1	Marine limestone – up to 3,000 m thick
	Transition bed	A thin, discontinuous dolomite found at the transition from the Devonian to the Carboniferous, marking the beginning of marine conditions. There is minor Pb/Zn mineralisation and concentrations of Ba and Sr on its lower contact
Devonian	F4	2,000–2,500 m thick – red terrigenous sandstone and siltstone with salt beds and domes
	F3	800–1,200 m thick – andesite, basalt and rhyolite belonging to the middle Devonian volcanic arc
	F2	Continental red beds
	F1	Rhyolite, andesite and basalt, resting on lower Devonian granites
Unconformity		
Ordovician		Grey marine sediments of indeterminate thickness

After Porter (2004)

on its southern margin. Within the cupriferous bands, there are a series of large, elongated, partially overlapping orebodies, developed at a number of different levels, covering much of an approximately 9×6 km area. In that area the ore-bearing Middle-Upper Carboniferous Dzhezkazgan Suite comprises rhythmically alternating gray and red lithic sandstone units that change facies laterally into saline siltstone.

The paleo-environment is interpreted by Gablina (1981) as a closed saline intermontane basin with alluvial, deltaic-lagoonal and saline lake facies. There are 50+ red-gray interbedded cycles in the Dzhezkazgan Formation, each 2–42 m thick, with variable colouration and mineralisation attributed to post-lithification basin brines moving updip along with hydrocarbon and H_2S. The source of Cu is unclear, typically it is attributed to the saline leaching of the regionally distributed Devonian-Lower Carboniferous andesitic volcanics of the Central Kazakhstan Andean-type margin (the Balkhash porphyry-Cu province), which is broadly contemporaneous with the Cu sandstones and located several hundred kilometres further east (Table 15.8). The mineralisation/depositional association shows some affinities with the Eocene Corocoro copper-hosting system in the Andes. The hosting sedimentary strata are gently open-folded and block faulted with much of the structuration in the area controlled by halokinesis.

Interestingly, there is a strong laterally and vertically zoned impregnation of gypsum and halite within mineralised sections of the Permo-Carboniferous cover sequence. Within the Dzhezkazgan area, the red units contain appreciable 'gypsum' within Unit H3, the Dzhezkazgan Formation (Table 15.8; Porter Geoconsultancy 2004). Away from ore, on the shared limb of the Dzhezkazgan Syncline and the adjacent Zhaniu Anticline, where the sequence is almost completely oxidised, all ten units that are mineralised within the ore zone contain abundant 'gypsum.' However, within the sulphide-bearing reduced rocks in the immediate vicinity of Dzhezkazgan, there is little to no gypsum, although it is present within interbanded red lithologies, particularly in the section above the orebodies. Within the sulphide-bearing reduced rocks the cement is mainly carbonate, rather than gypsum. This is taken to imply that the sulphur of the 'gypsum' has been consumed in the formation of sulphides.

There is also a lateral 'primary' variation in authigenic gypsum content. To the south into the Dzhezkazgan Saryzu Trough, the proportion of the red sequence containing gypsum decreases, as does the gypsum content. Similarly, to the north into the Dzhezkazgan Syncline the number of units and thickness of gypsum impregnation decreases, although on the margins of the syncline appreciable amounts are still present. Mineralisation is also present in these same zones. However, despite the drop in levels, regionally 'gypsum' is a relatively constant component of Unit H3.

Within Unit H3, the 'gypsum' is pseudomorphed by $SrSO_4$, with the sequence containing 6–8 % of celestite over thicknesses of 50–80 m. Higher in the sequence, at the base of the exclusively red bed Unit H4, a thick band of gypsiferous marl contains 3–5 % $SrSO_4$. Higher still, in Unit H5, halite and sylvite are abundant, with little or no associated gypsum.

According the Porter Geoconsultancy (2004) it is likely that there is a relationship between the development of sulphides and the presence of pre-existing authigenic sulphate, which is possibly also concentrated in structural positions. Little hydrocarbon remains in the sulphide zone, probably also having been consumed in the production of carbonates and sulphide through the thermochemical reaction/combination with the sulphates. Hydrocarbons are exploited within the main Dzhezkazgan Saryzu Trough to the south, trapped within Unit H4.

Gablina (1981) suggested that an early salt weld juxtaposed fluids of the marine/evaporitic rocks and lowermost redbeds that overlie the salt anticline. Bed geometries illustrated in Fig. 15.26 suggest this weld is halotectonic. The breach allowed hydrocarbon-bearing basinal waters to migrate vertically into the overlying redbeds, where H_2S was produced by thermochemical or bacterial sulphate-reduction. Extensive precipitation of copper and other metals occurred at the regional redox front separating reducing evaporite-fed brines and adjacent red beds.

If so, the role of the catagenically dissolved evaporites was to supply reduced brines and to create precipitation foci, atop a halokinetically controlled salt anticline. The precipitation mechanism and the metal zonation is the same as in the Kupferschiefer model, but in this case the relative position of the evaporite and the redbeds are adjacent and domal, rather than salt dissolution edge. The main evaporite bed lies below the redbeds, which are the ultimate source of the metals. Although the mineralised beds are stratiform, this deposit is really a result of halokinesis; a similar, but less economically significant, analogue is to be found in the Lisbon Valley, USA.

Copper in the Lisbon Valley, Utah

The ore deposits of the Lisbon valley are another example of halokinetic suprasalt deformation controlling structure and hence the position of redox mineralisation. Compared to Dzhezkazgan, the deposits are much smaller (34 Mmt @ 0.53 %). Cu(±Ag). Ores in Lisbon Valley occur along suprasalt extensional faults, in redbed sediments of the Paradox Basin and in coal-bearing horizons of the overlying Cretaceous Dakota Sandstone in SE Utah and SW Colorado (Fig. 15.27a). Deposits of this type occur at Salt Valley and Paradox Valley, with the largest deposits in the Lisbon Valley (Fig. 6.83; Morrison and Parry 1986). Cu is found as vein fillings, sandstone pore fillings, and as replacement of coalified plant fossils. The deposits are clearly related to halokinetically-induced faults (Fig. 15.27b, c). The largest deposits, Big Indian and Blackbird, occur along the Lisbon Valley fault in coaly horizons of the Cretaceous Dakota Formation. Almost all the mineable copper ore occurs within several hundred metres of either the Lisbon Valley fault or other major suprasalt fracture zones.

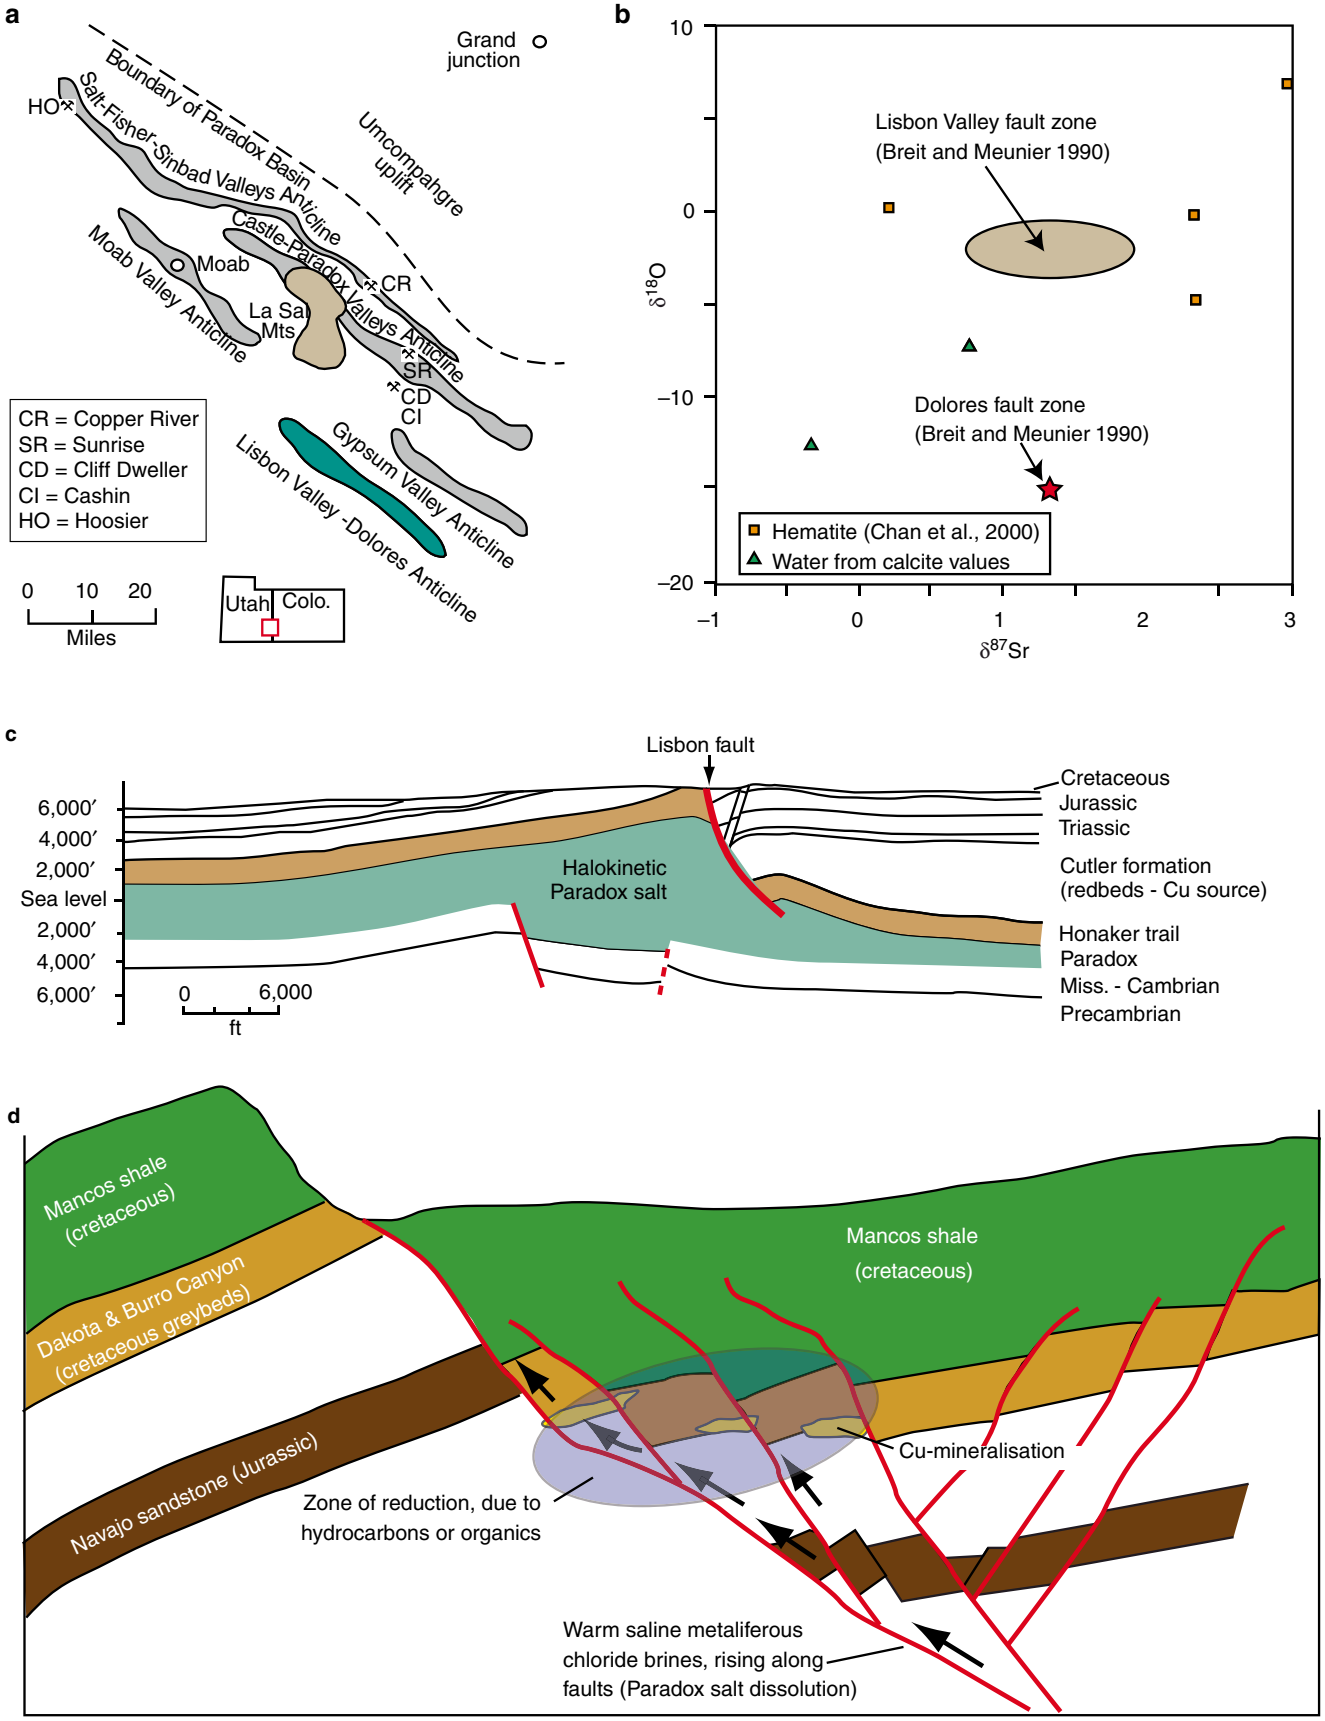

Fig. 15.27 Copper in Lisbon Valley salt anticline, Utah. (**a**) Regional distribution of salt anticlines (see also Fig. 6.83), (**b**) Isotope character of hematite and calcite. (**c**) Cross section of Lisbon Valley salt anticline. (**d**) Detail of crestal position of Lisbon Fault showing distribution of Cu ore (After Morrison and Parry 1986; Kirkham 1989)

All the deposits in the area are related by geologic setting as well as ore and gangue mineralogy (Morrison and Parry 1986). Fluid inclusions, mineral chemistry, and C-O stable isotopes in calcite gangue associated with Cu ores at Lisbon Valley suggest they formed via subsurface mixing of two diagenetic waters. Fluid temperatures ranged from 72 to 103 °C, while salinities were 5–20 equiv. wt % NaCl during calcite deposition. Saline, salt dissolution-influenced basinal fluids migrated upward along fault zones, and upon mixing with shallower reduced Ba-rich groundwater deposited ore and gangue minerals. Mineral precipitation was induced by the combination of reduction and dilution of upwelling basinal brines.

The metal-carrying fluid probably originated in the redbed aquifers of the Permian Cutler Formation. The brines may have equilibrated for long periods in these Cutler Formation aquifers and only been released during faulting driven by halokinetic activity during the Late Cretaceous – Early Tertiary Laramide orogeny. Then faults, such as the Lisbon Valley Fault, breached the redbed aquifer and so allowed pressurised, heated metalliferous fluids to escape upward along the faults until they encountered permeable units replete with reductants, such as in the Dakota and Wingate Sandstones (Kirkham 1989).

In my opinion, the role of salt has not been given the importance it deserves in the explanation of mineralisation in a Lisbon-Valley style deposit. The style of faulting that focuses the mineralisation is a response to movement on the underlying active salt structure (Fig. 15.27b, c). The ongoing dissolution of this underlying salt also supplied the chloride-rich brines that maintained the interface with leached the metals from adjacent redbeds. It also created the thermal and brine density contrasts that drove the convection and metal enrichment of this brine. Without halokinesis and salt dissolution there would be no focusing into this structurally controlled deposit. Nor would there be any long-term maintenance of the redox haloes about the faults that allowed this deposit to accumulate. Without the underlying halokinetic salt, economic levels of copper sulphides simply would not be there. As is to be expected, this cupriferous flow regime is very similar to, although less prolific than, those of the Dzhezkazgan region. The patchy ore distribution means the various Lisbon Valley deposits are classified as Revett- style Cu deposits.

The same brine-related redox hydrology is also responsible for a number of uranium deposits in the area (Lisbon Valley, White Canyon, Monument Valley) totalling some 42.5 Kt of produced uranium (Dahlkamp 1993). Tabular uraniferous orebodies are peneconcordant with bedding and located in channel sandstones rich in coalified plant trash, mostly in the in fluvial channels of the Shinarump Sandstone member of the Triassic Chinle Formation, with some reworking into exposed or subcropping positions atop the salt anticline into the Permian Cutler sandstones (Reynolds et al. 1985).

Dongchuan Copper, China

Stratabound sediment-hosted copper deposits, associated with a widespread halokinetic breccia unit, occur in a 450 km long rift in the Yunnan Province of China (Huichi et al. 1991). The Dongchuan area is the largest of five copper mining districts in this north-trending rift, which contains sandstone, shale, and carbonate rocks of the Dongchuan Group, deposited in this late Paleoproterozoic rift as it was transitioning into a passive margin (Fig. 15.28; Zhao et al. 2010; Wang and Zhou 2014).

Deposits in the area range from 10 to 100 million tonnes of ore with ore grades of 1–1.5 %. Three formations, totalling some 1,200 m, contain the copper deposits mostly in the lower part (Fig. 15.29). They are from top to bottom: the Etouchang (Heishan) Formation, mainly a carbonaceous slate; the Laoxue Formation, mainly a stromatolitic dolostone; and the Yinmin Formation, chiefly purple slate and sandstone. These formations are crosscut by breccia and mafic igneous rocks.

Numerous transtratal breccia bodies occur in the Dongchuan Group, particularly within the Yinmin Formation, and are collectively known as the Yinmin Breccia (Fig. 15.29). They are made up largely of clasts derived from the Yinmin Formation that are cemented in a matrix of rock flour and possibly hydrothermal minerals (e.g. quartz, feldspar, carbonate and biotite). The mechanism of brecciation is still unclear, but is likely due to halokinesis sourced in what were once thick mother salt beds in the lower part of the Yinmin Formation. Post emplacement, there were one or more leaching/dissolution episodes (coupled with a hydrothermal overprint), creating textures similar to, but more metamorphically evolved than seen in the Neoproterozoic diapiric breccias exposed in the Flinders Ranges, Australia. Another example of halokinetic focusing in China, but in a much more highly metamorphosed milieu is seen in the Palaeoproterozoic Fe-Cu sulphide and borate deposits in eastern Liaoning, Northeastern China (Chap. 14; Wang et al. 1998a).

Clasts of igneous rocks are locally present in the Yinmin breccia, suggesting that at least some breccia bodies postdate the igneous intrusions and were carried higher into the stratigraphy via salt flow. This is consistent with field relationships in which a number of gabbro bodies appear brecciated (Zhao et al. 2010). It is also consistent with the common association with gabbros and dolerite blocks in halokinetic breccias that define outcrops of Miocene salt in the Middle East (Chap. 7). The position of the former mother salt mass in the Yinmin Fm redbeds is also consistent with it once being a basinwide halite bed that formed during the rift to drift transition indicated by the passage from rift redbeds of the Yinmin formation to passive margin marine carbonates of the overlying Luoxue Formation.

Numerous sedimentary-hosted stratiform copper deposits, known as the “Dongchuan-type” Cu deposits in Chinese literature, are hosted within dolomites, typically near the

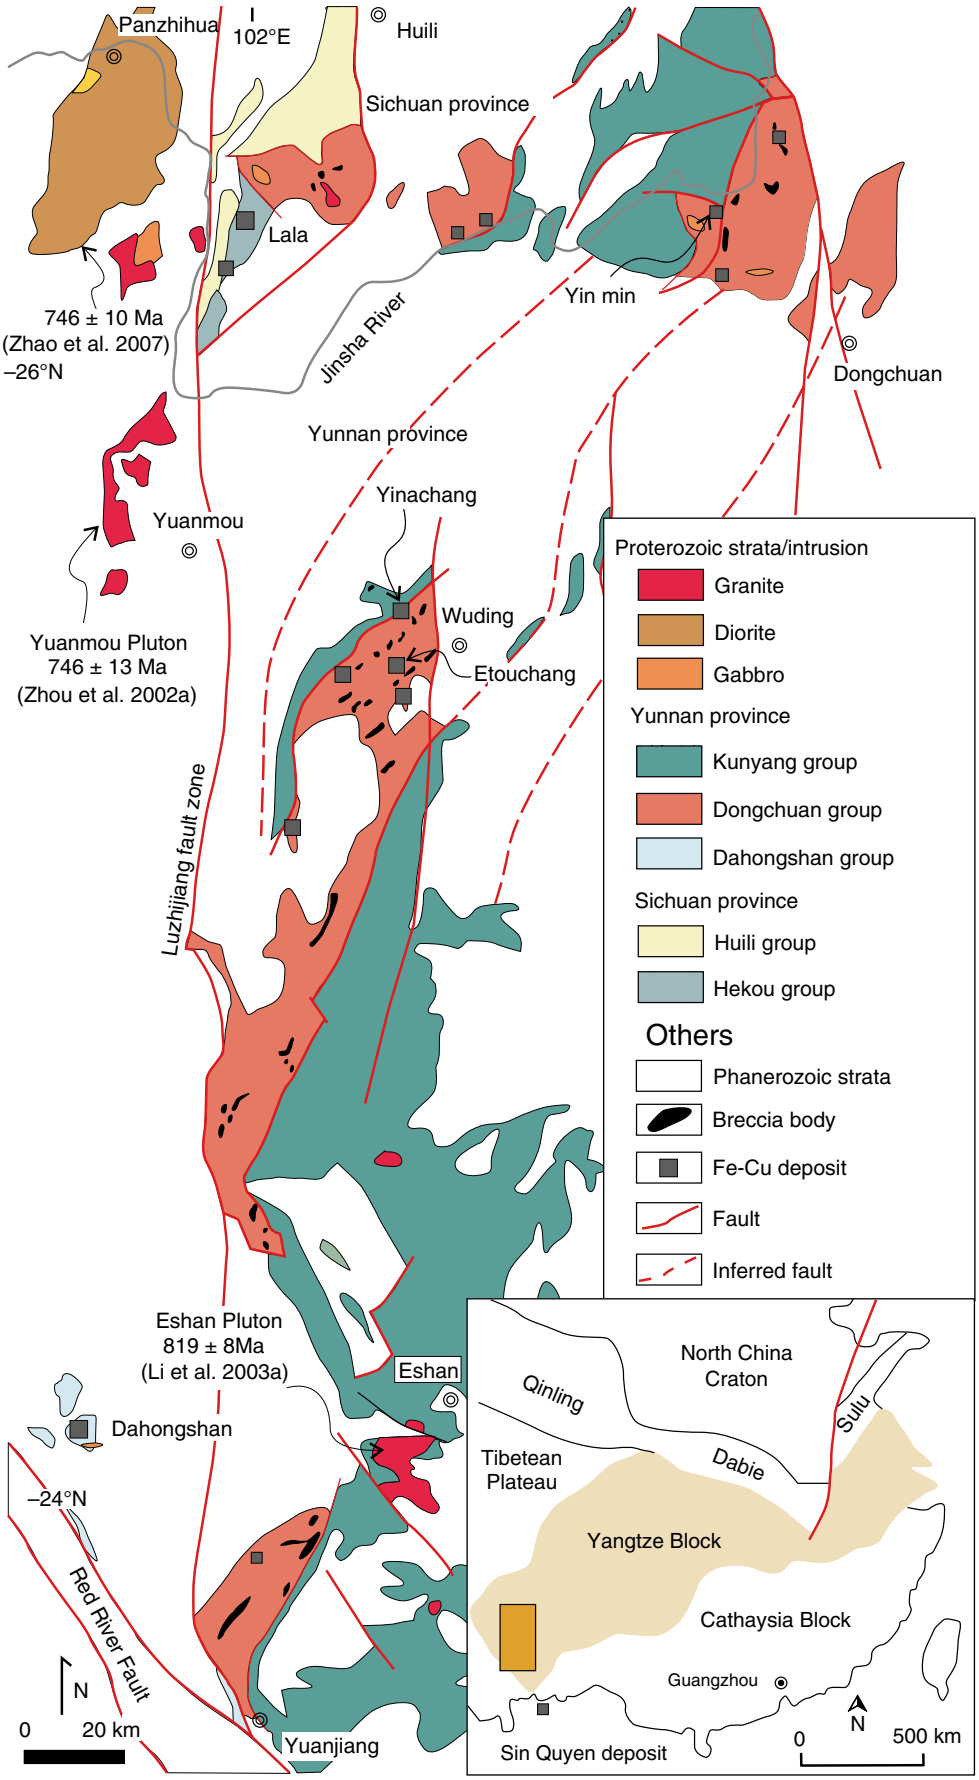

Fig. 15.28 Geological map showing the distribution of Proterozoic strata, granites and gabbros in the SW Yangtze Block, of southeastern China, while inset shows position of the Yangtze block in a simplified tectonic map of China (After Zhao et al. 2010)

contact between the Yinmin and Luoxue Formations and often associated with Yinmin breccia. Vein type ore bodies account for only 3 % of the total ore reserves in the area. Stratabound ores characteristically occur as disseminations of sulphides along stromatolitic algal layers. Locally, highgrade vein-type ores crosscut the dolostone. Both ore types contain bornite, chalcopyrite, chalcocite, and other minerals. Fluid inclusions in quartz veinlets contemporaneous with the copper mineralisation contain liquid, vapour and daughter minerals: NaCl, $CaCl_2$, KCl and $BaCl_2$. The inclusions homogenise between 200 and 280 °C.

Hot reducing chloride-rich brines, circulating and cycling upward along the flanks of the diapir, leached copper from the oxidised Yinmin Formation and carried it to the base of the overlying Laoxue Formation (Huichi et al. 1991; Wu Moude and Li Xiji 1981). There sulphide-rich fluids were formed by reaction of evaporitic sulphates with decayed organic matter in the dolostones. Copper sulphide deposition in the dolostones resulted from the mixing of these fluids. Continued circulation leached all of the remaining salt from the diapir, and the overlying and surrounding rocks collapsed to form the current breccia masses.

Cu-sulphides were precipitated at two sites: (1) as breccias, lenses, and veins around fluid-venting centres tied to the breccias; and (2) as stratiform pyrite-chalcopyrites, which are associated with anhydrite located distal to the salt domes (Fig. 15.30). Within each mining district the proximal ores are associated with brecciated, albite-and tourmaline-rich metasediments. The sulphides in the proximal ores have $\delta^{34}S$ values of 14.6‰–12.7‰, whereas the distal ores have $\delta^{34}S$ values of 2.6‰–14.5‰ for the sulphides and 7.9‰–19.0‰ for the anhydrite; suggesting a sulphate-dominated sulphur source, with the pyrite $\delta^{34}S$ variations arising mainly from decreasing temperatures away from the

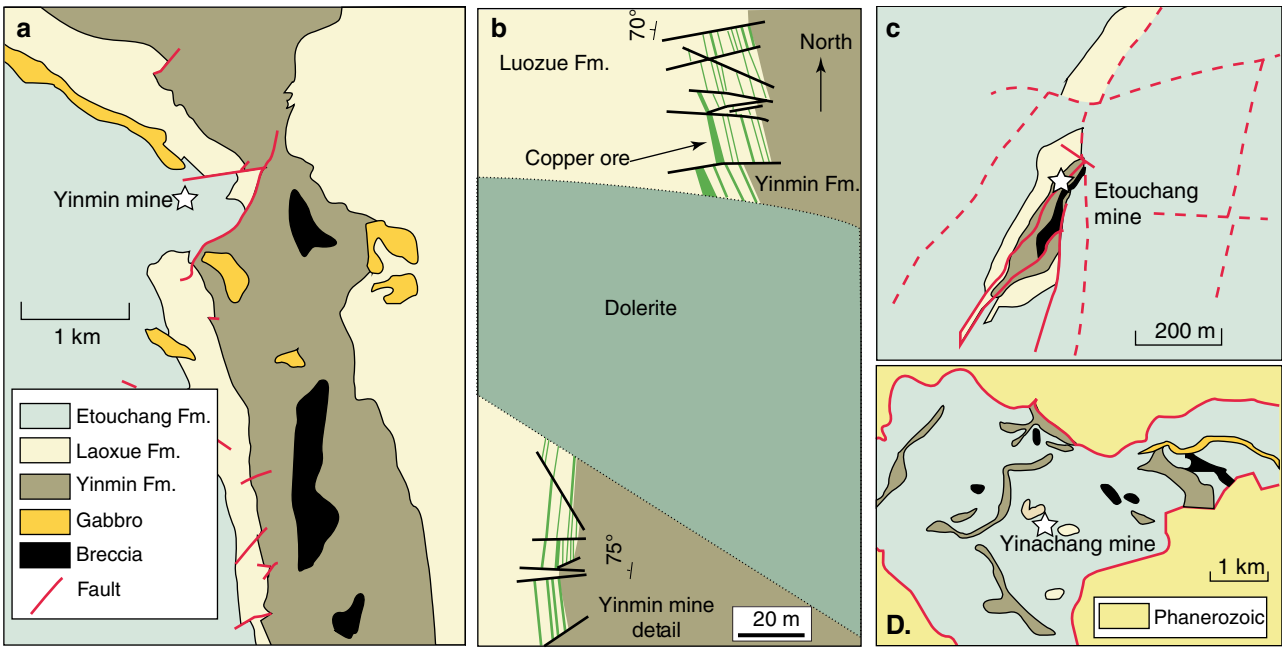

Fig. 15.30 Geological map of (**a**) Yinmin mine in Dongchuan area, (**b**) Detail from an audit in the Yinmin mine, (**c**) Etouchang mine area, (**d**) Yinachang mine area (After Zhao et al. 2010, 2013)

centres of the deposits. According to Wang et al. (1998a) the origin of the deposits is best described by a model in which sulphate-carbonate rocks were deposited in peridiapir sinks during salt diapirism. The salt domes then acted as foci for subsequent hydrothermal venting of chloride-rich metalliferous fluids and the adjacent peridiapir sediments became the centres of sulphide mineralization. The sulphides precipitated during interaction of the reduced, metal-bearing hydrothermal fluids with the *in situ* sulphates, which acted as the major *in situ* source of evaporitic sulphur.

At the broader scale the Dongchuan deposits can be related to the Dahongshan deposits, via a common paragenetic history, constituting a wider group of Paleoproterozoic Fe-Cu deposits, in the Kangdian region of SW China (Fig. 15.28; Zhao and Zhou 2011). The Dongchuan Group is composed of siltstone, slate, and dolostone with minor volcanic rocks, whereas the Dahongshan Group has undergone lower amphibolite facies metamorphism and consists of quartz mica-schist, albitite, quartzite, marble and amphibolite with local migmatite. Deposits in the Dongchuan Group are commonly localized in the cores of anticlines, in fault bends and intersections, and at lithological contacts. Orebodies are closely associated with breccias, which are locally derived from the host rocks. Fe-oxides (magnetite and/or haematite) and Cu-sulphides (chalcopyrite, bornite) form disseminated, vein-like and massive ores, and typically fill open spaces in the host rocks. The deposits have extensive albite alteration and local K-feldspar alteration overprinted by quartz, carbonate, sericite and chlorite.

Deposits in the Dahongshan Group have orebodies subparallel to stratification and show crude stratal partitioning of metals. Fe-oxide ores occur as massive and/or banded replacements within the breccia pipes, whereas Cu-sulphide ores occur predominantly as disseminations and veinlets within mica schists and massive magnetite ores. Ore textures suggest that Cu-sulphides formed somewhat later than Fe-oxides, but are possibly within the same mineralization event. Both ore minerals predated regional Neoproterozoic metamorphism. Both orebodies and host rocks have undergone extensive alteration of albite, scapolite, amphibole, biotite, sericite and chlorite. Silica and carbonate alterations are also widespread. Ore-hosting strata have a LA-ICP-MS zircon U–Pb age of 1,681 ± 13 Ma, and a dolerite dyke cutting the Fe-oxide orebodies has an age of 1,659 ± 16 Ma. Thus, the mineralization age of the Dahongshan deposit is constrained at between the two.

All ores from the Donchuan and Dahongshan groups have high Fe and low Ti, with variable Cu contents. Locally they are rich in Mo, Co, V, and REE, but all are poor in Pb and Zn. Sulphides from the Fe–Cu deposits have $\delta^{34}S$ values mostly in the range of +2 to +6 per mil, suggesting a mix of several sources due to large-scale leaching of the strata, with the involvement of evaporite-derived brines across all ore types (Zhao and Zhou 2011). Isotopic dating and field relationships suggest that these deposits formed in the late Paleoproterozoic. Ore textures, mineralogy and alteration characteristics are typical of IOCG-type deposits and thus define a major IOCG metallogenic province with an evaporitic association. We shall come back to evaporitic associations in some IOCG deposits in the next chapter

The Paleoproterozoic rift-related sedimentary sequences of the Dongchuan Group, South China, today constitute one of the largest SSC districts in the world (Zhao et al. 2013). One of the largest deposits in the Donchuan district, is the Yinmin deposit, which shows stratiform Cu orebodies intruded by dolerite dykes, which have a U-Pb age of 1,701 ± 28 Ma (Fig. 15.30a, b). This is slightly younger than the ore hosting strata which include a tuff with a zircon U-Pb age of 1,742 ± 13 Ma. Sulphides in the ore yield ages around 1,600 Ma, thus the Yinmin mineralisation and by inference other Cu deposits in the Dongchuan district correspond to a late Paleoproterozoic rifting event, likely tied to the breakup of the Columbia supercontinent (Wang and Zhou 2014). Zhao et al. 2013, argue this timing further supports the notion of genetic and temporal links between episodes of more intense formation of SSC's and the breakup of supercontinents. In my mind, this also supports the redox interface association with proximity to flow and dissolving halokinetic salt acting as deposit foci to adjacent leached redbeds. Thick and widespread halite supergiants are tied to supercontinent rifting events, last seen in the Phanerozoic in the Pangean break-up (Chap. 5) and by default to depositional systems that have redbeds and thick halokinetic-salt masses at the base of the rift succession

Zn-Cu-Pb Kipushi Deposit, Africa

The Neoproterozoic metallogenic province of Central Africa contains rich stratiform concentrations of Cu and Co in both the Shaba Province (Shaba cupriferous arc – Zaire) and Congo-Zambian copper belts (Cailteux 1994; Kampunzu et al. 2009). Both provinces retain substantial evidence of meta-evaporites. For example, scapolite is widespread in amphibolite-grade calcsilicate rocks and marbles in Katangan rocks of the copper belt and in the central provinces in Zambia. Ramsay and Ridgway (1977) point out that "scapolite is rarely found in such abundance and Zambia must be one of the major scapolite provinces in the world." Munyanyiwa (1990) argues for an evaporite precursor to this scapolite, he also notes that metasedimentary anhydrite is still present in parts of the Katangan succession in the copper belt. We shall look in detail at the Kipushi deposit, but it is indicative of facies association in many other similar perhaps more metamorphosed copper deposits in the region. Much of the following description is taken from Kampunzu et al. (2009), Van Wilderode et al. (2013), (Heijlen et al. 2008) and references therein.

The Kipushi Zn-Pb-Cu deposit, hosted in Nguba Group strata is located in the northern extension of the central African Copper Belt in southeastern Zaire. Kipushi is perhaps the most significant Zn–(Cu)–Pb carbonate-hosted deposit in the Copperbelt of Central Africa with total metal production of 6,622,116 t Zn and 4,082,275 t Cu from 1922 to 1993 when operations were suspended. The in-situ ore grade averaged 11.03 wt.% Zn and 6.80 wt.% Cu. Ore has been proven to a depth ≈ 1,800 m, but mine development stopped at 1,250 m depth. The remaining ore resources down to the 1,500 m level are estimated at >5 Mt Zn, >500,000 t Cu, and >100,000 t Pb from ores averaging 21.4 wt.% Zn, 2.1 wt.% Cu and 0.88 wt.% Pb with additional trace metals of Cd (763 ppm), Co (100 ppm), Ge (68 ppm), Ag (28 ppm) and Re (3 ppm) (Cailteux 1986, 1994). Other rare metals include As, Ga, Mo, Bi, Hg, Ni, Sb, Se, Sn, Te and V.

The Kipushi deposit is hosted on the northern flank of a regional NW–SE trending anticline characterized by a faulted axial core filled with a transtratal megabreccia known as the "Axial Breccia" (Fig. 15.31a). The dip is 60–70° SW on the southern flank and 75–85° NE on the northern flank. The Axial Breccia is barren and consists of a heterogeneous layer-parallel breccia made up of highly strained and brecciated or rounded fragments of Roan and Nguba Group rocks as well as dolomites and meta-evaporites, and also includes arkosic sandstones and metabasic rocks along with white talcose dolomites (Table 15.9). Near identical Roan breccias underlie most Katangan thrusts and are interpreted as a rauhwacke, where much of the salt is long gone, leaving only pseudomorphs and patchy anhydrite (e.g., Jackson et al. 2003; Warren 1999, 2000b).

The ore is a discordant body, parallel to the former salt flow margin (transtratal) at the contact between a halokinetic breccia body and adjoining host rocks of the Upper Proterozoic Lower Kundelungu Group of the Katangan System (Fig. 15.31b; De Magnee and Francois 1988; Heijlen et al. 2008). It is currently exposed at the surface at the northeast margin of a large plunging anticline. The halokinetic breccia in the core of the anticline contains large blocks (up to 100 s of metres across) of Roan Supergroup rocks of several lithologies, as well as large blocks of gabbro. Much of the breccia at Kipushi is made up of fragments of white sparry dolomite, which are thought to have originally been derived from the halokinetic and solution induced break-up of the Dipeta Dolomite. The gabbro (now completely amphibitolised) is thought to have originally been emplaced as a sill in the Dipeta Dolomite within the Roan Supergroup (Fig. 15.31c).

Most workers accept there is an association with former evaporites and the Kipushi deposit breccias which host, or are adjacent to, mineralisation. Roan Supergroup sediment once contained several evaporite intervals (De Magnee and Francois 1988; Jackson et al. 2003; Heijlen et al. 2008). Regionally these former salt intervals are defined by evaporite dissolution breccias. Such solution breccias occur in the lower part of the Katangan System and are interlayered with alternating sparry dolostones, black shales, and chlorito-talcose dolomitic siltstones (Fig. 15.31). Prior to dissolution, the evaporites are thought to have acted as the mother salt bed for the Kipushi allochthon and other halokinetic features in the region. The upper part of the Katangan System is made up of the Lower and Upper Kundelungu Supergroup and is composed mostly of siliciclastics with some limestones, which are locally dolomitised.

Portions of the Katangan System are now intensely folded in the copper belt, with a disharmonic style reminiscent of the salt-cored European Jura. Cores of many anticlines in the copper belt are formed by megabreccias, containing blocks of Roan metasediment. Regionally, some of the larger clasts contain sufficient stratabound Cu-Co sulphides to be actively mined. The matrix between the blocks is a dolomitic metasiltstone, which also contains gypsum and anhydrite pseudomorphs (De Magnee and Francois 1988). Regionally, the megabreccias cut into the flanks of many megabreccia cored anticlines and reach into Upper Kundelungu strata. This is the case at Kipushi (Fig. 15.31a).

The megabreccia and its crosscutting relationships are very similar to outcropping halokinetic breccias in the Neoproterozoic Callanna Group megabreccias of the Flinders Ranges, South Australia (Chap. 7). There, many of the breccia geometries reflect the falling or deflation stage of diapir evolution and are located along regional extensional faults. Breccias in the Katangan System also follow major faults, which De Magnee and Francois (1988) called extrusion faults. If analogies to the Flinders Ranges are valid, some of these "extrusion faults" may be examples of outcropping fault welds. Once a basin undergoes inversion, such faults are often reactivated and can be easily misinterpreted as solely due to late-stage thrusting.

The Kipushi structure is interpreted as a salt diapir/allochthon that, after emplacement, was subject to ongoing dissolution of the more soluble salts, along with associated collapse brecciation. According to De Magnee and Francois (1988) and Chabu (1995), this dissolution process played an essential role in the base metal mineralisation, as it supplied an ongoing focus for the saline chloride-rich brines that leached and transported the heavy chalcophile metals. The matrix dolomites adjacent to the mineralising show little evidence of thermal effects and only the gangue dolomite indicate the elevation saline fluid temperatures associated with mineralisation (Fig. 15.32, Van Wilderode et al. 2013). De Magnee and Francois (1988) went on to argue that sulphur and organic matter must also be present to form a mineral deposit, as well as a high lateral thermal gradient to set up the circulation cells and an appropriate permeability structure to channel the ascending hydrothermal solutions.

Table 15.9 Stratigraphy of the Neoproterozoic Nguba Group at Kipushi and indication of the kinematic and sedimentological setting

		Formation	Lithology at Kipushi	Kinematic and sedimentological setting
Nguba Group	Bunkeya Subgroup	Monwezi	Dolomitic sandstones, siltstones and pelites	Transgressive clastic sequence prograding over the cap carbonates. Persistence of northern proximal facies and southern open basin
		Katete	"Serie Recurrente" Top (30–40 m): alternation green chloritic shales with nodules (e.g. gypsum) and white dolomites Middle (120–130 m): irregularly bedded greyish shales and white dolomites Bottom (60 m): grey dolomites and shales containing dolomite nodules	
	Muombe Subgroup	Kipushi	Black carbonaceous dolomite with oolites, cherts and shungite (100 m)	
		Kakontwe	Upper (20–50 m): irregular bedded and carbonaceous dolomite with black cherts. Middle (60–70 m): bedded dolomite with oolites and algal structures Lower (180–250 m): massive fine-grained grey dolomite	Cap carbonates. Proximal facies in the north, open basin towards the south
		Kaponda	Top (90 m): dolomites with cherts at the base, some shales Middle (30 m): lenticular or massive, limonitic dolomite Bottom (0–80 m): carbonaceous dolomitic shale – "Dolomie Tigree"	
		Mwale	Grand Conglomerat (300–500 m): green-grey, unsorted matrix supported conglomerate	Sturtian glaciation and transition from intracontinental rift into proto-oceanic basin with further basin widening

After van Wilderode et al. (2013)

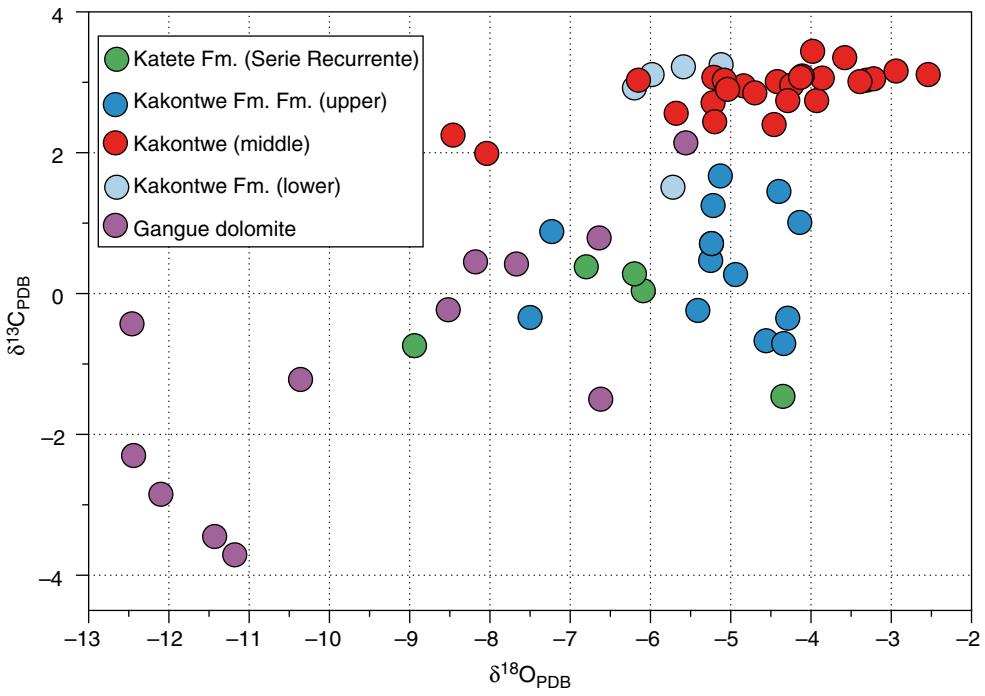

Fig. 15.32 Covariant carbon-oxygen stable isotope crossplot broken down by host formation dolomites using values extracted from Table 2 in Van Wilderode et al. (2013). Clearly illustrates the hotter fluid origin (indicated by more negative carbon and oxygen values of the gangue dolomites)

At Kipushi these conditions were created by a huge slab of silty dolomitic shale (Kundelungu Group), which lies alongside the wall of the halokinetic breccia and forms the current roof of the ore body. De Magnée and Francois go on to draw parallels with peridiapiric mineralised laminites in north Africa.
