Meso and macroscale internal fold complexity reflects deformation textures that are occurring on the microscale and reflect the two main styles of hydraulics that describe salt flow; (a) Poiseulle versus (b) Couette flow (Fig. 6.11) Poiseuille flow, typifies flows into a rising salt structure whereby flow is restricted by the viscous shear forces (frictional) acting along the boundaries of the salt, creating boundary drag. This means the salt is flowing faster in the central part of the salt layer than along its top and bottom. It means thin salt layers flow slower than thick ones and flow in a thick salt layer (>tens of meters) is slowed down as salt withdrawal reduces the deflating salt layer to thicknesses of less than a few tens of meters. This helps explain why there are residual salt pockets in many salt welds. The other type of flow Couette flow, which involves simple shearing within the salt layer as the overburden is translated relative to the substrate (Fig. 6.11b). Couette flow typifies salt layers acting as décollements and gravity glide planes. Theoretically, in Couette flow there is no boundary effect, while in Poiseuille flow there is; but the two types of flow may well be superposed in many subsurface settings. For a detailed analysis of the variable stress regime in flowing salt and the drilling problems it can induce, the interested reader is referred to Weijermars and Jackson (2014).

Salt structures are zones where salt has thickened relative to its original stratigraphic thickness and, by definition, salt must have flowed into this thickened structure. In salt pillows the sense of flow thickening, based on the outline of the whole feature is mainly horizontal, while in diapirs there is a much greater component of vertical flow. In typical Zechstein "pillows" the predominantly horizontal flow of halite is indicated by a gross morphology with a gentle nonpiercement style of thickening, but coring shows thickening of the salt structure was driven by stacked large scale flow-folds with near horizontal axial planes, as seen in the Anloo pillow in the Netherlands (Fig. 6.12; Geluk 1998). In the late "pillow" stage, the flow direction changes from predominantly horizontal to an even less predictable system as the salt starts to pierce its overburden.

Internal Complexity

Richter-Bernburg (1980) argues for high levels of structural complexity in all salt deposits and that even our expectations of internally-consistent layering in a sequence of stratiform salt beds may not be true. He cites the Silurian Salina Salt in the Whiskey Mine near Cleveland in Michigan where apparent isoclinal folds, with horizontal axial planes, are exposed on a 3 m-tall mine face in an area of the Canadian Shield where typical formation dips are less than 5°. An underground visit in 1984 by Professor Bernberg and me to another nearby mine in the Salina Salt with similar features lead to a discussion of whether these features were actually isoclinal folds or stacked, slumped and backfilled syndepositional erosional channels. However, in other salt basins with structures showing external geometries of pillowing or diapirism, the complexity of the internal structures that form in halokinetic salt is indisputable (Balk 1953; Talbot and Jackson 1987a; Richter Bernberg 1980).

By the diapir stage the morphology of the salt structure exterior shows that the sense of salt movement is

predominantly vertical and that salt appears to break through its cover. Diapiric salt is often mined, so its internal structures have been be mapped. By this stage, vertical fold axes (Fig. 6.14c; curtain folds) have[9]) been superimposed on the horizontal fold axes. Frictional interactions between the edges of the diapiric salt and adjacent strata drives even more complex fold patterns as flow vortices are created by irregularities in the thickness of the diapir neck. An analogy for this curtain-style of flow folding is that created when a handkerchief is poked up and through a napkin ring. Once the salt is at the surface it spreads as a series of salt glaciers (namakiers) and allochthons rolling and advancing over the surrounding landscape, much in the same way as a military tank rolls forward on its track.

In many diapiric structures the central part of the salt neck contains salt from the older (lower) part of the salt stratigraphy and the margins are made up of younger units. This is true for the diapirs of Dasht-i-Kavir (Fig. 6.13) and many Zechstein diapirs such as Benthe, Reidel, Winschoten and Zuidwending diapirs (Fig. 6.14a). But, as noted by Geluk (1998), this is a generalisation for there are many Zechstein diapirs where the reverse is true (e.g. Gorleben, Hänigsen and Pieterburen diapirs). Internal complexity is especially obvious in Zechstein diapirs where potash layers have been mapped as part of the extraction and ore control process (Fig. 6.14a, b). Characteristic flow folding and shearing is outlined by halite beds swimming or floating in isoclinally-folded carnallitite beds, as in diapirs in Miocene potash of Sicily and Poland and Zechstein of Germany.

In all these examples, areas of high strain are largely accommodated by the least competent layer, typically potassium salt or purer finer-grained rock salt units (Figs. 6.14b and 6.15). Some halite layers between these high strain intervals can remain relatively undeformed and even retain remnants of primary fabrics, such as megapolygons and microkarst pits. As the structure continues to deform and fold into a series of constriction folds and if flow continues the more competent layers ultimately brecciate or stretch into boudins (Fig. 6.14c). Finally, the halite layers pervasively recrystallise via pressure solution creep and no primary texture remains. Similar boudins and folded claystone or dolostone masses are folded can be imaged as stringers at the seismic scale using 3D techniques (van Gent et al. 2011; Kukla et al. 2011a, b).

The internal complexity of salt structures is such that the near-surface portions of salt diapirs may be divided into a number of zones showing differential movement and separated by shear zones. This was first demonstrated by Balk (1953) in a classic paper mapping the internal

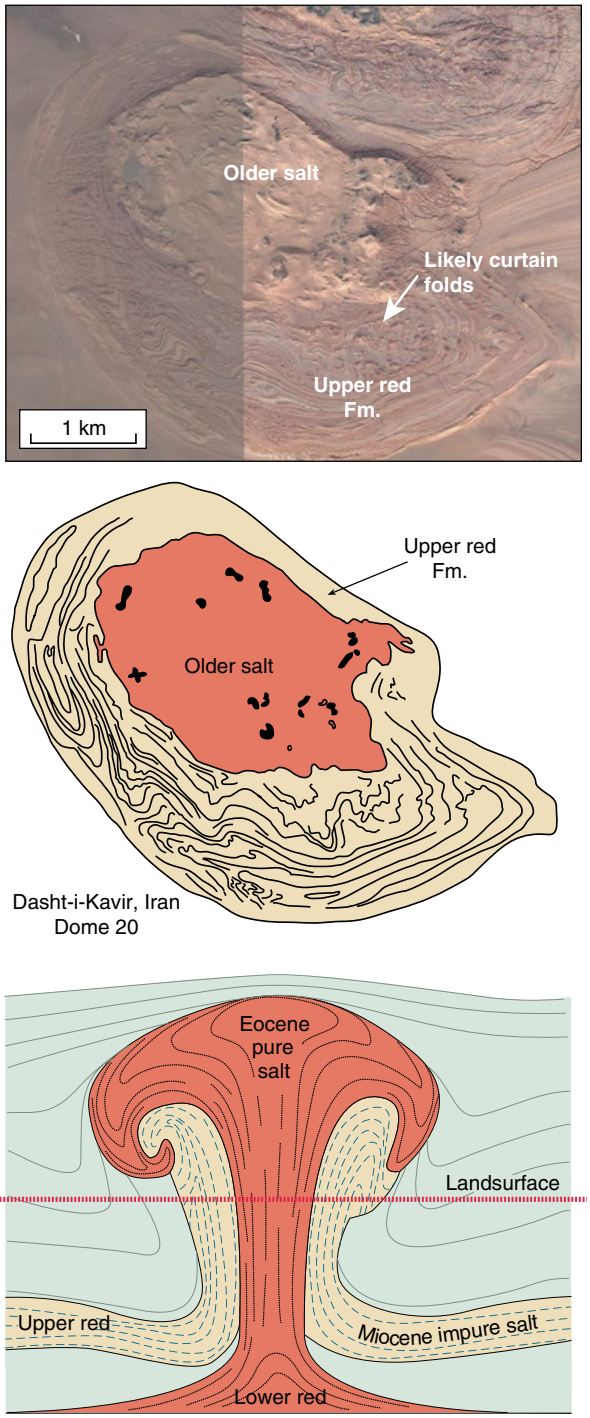

Fig. 6.13 Internal fabrics visible in salt structure outcrop (Dome 20 in the Dasht-i-Kavir, Iran). Its central portion is made up of Older Salt (Eocene), which is composed of relatively pure halite and is consider to be the halokinetic equivalent of the Lower Red Formation. Surrounding this, and making up the outer part of the dome, is the Miocene Upper Red Formation, which entrains alternations of clay, anhydrite and halite. These layers clearly outline the complex folding styles that characterises salt flow in the outer portion of the plug. The cross section illustrates the likely "curtain fold" style of this feature. *Red dashed line* indicates current landsurface level in the structure. Rafted blocks are also visible in the older salt mass (Bing® image mounted and scaled in MapInfo® software, (Schematic cross section is after Jackson 1990))

[9]Curtain folds are cylindrical fold having roughly radial axial trace and steeply plunging hinge within a diapir, possibly incorporating sheath folds originally formed in the source layer (Fig. 6.14c).

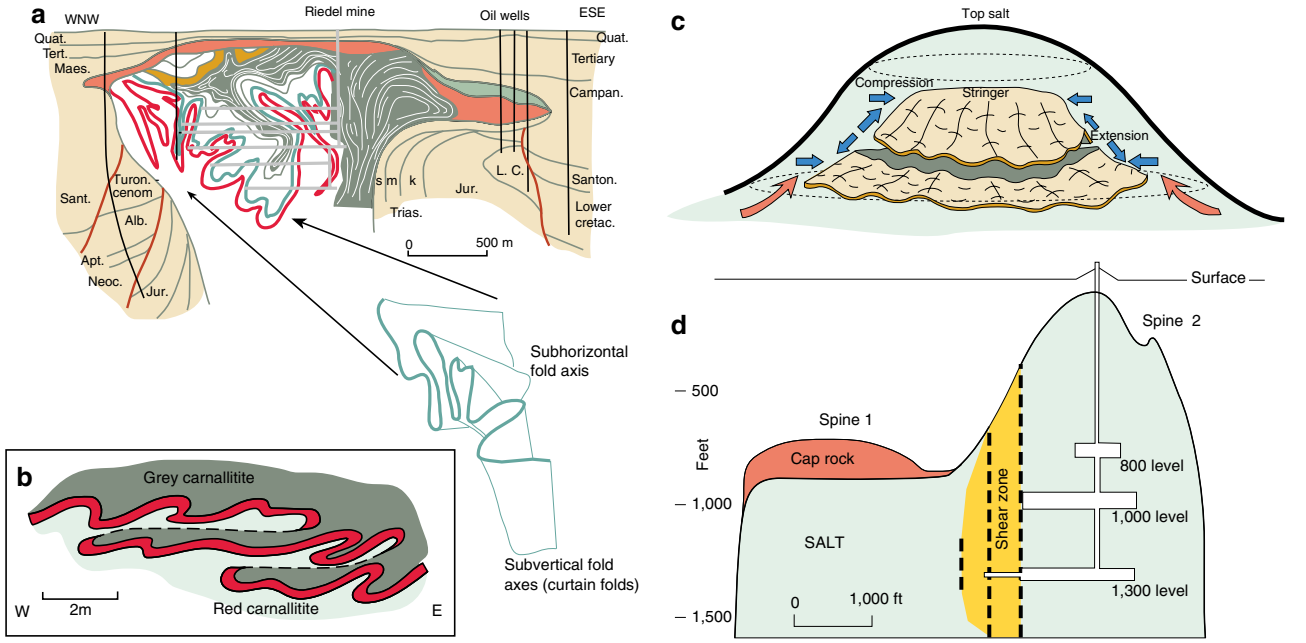

Fig. 6.14 Internal structures of salt diapirs, (**a**) Reidel diapir, Germany. The stratigraphically older part of the diapir (*grey*) of the structure sits atop the younger salt (*white*). Inset is a three dimensional diagram of the folds outlined by potash beds (ore horizon) in younger salt showing how axes of folds pass from a vertical orientation to a subhorizontal with depth. (**b**) Halite bed (*black*) defines sheath folds and shear planes floating in deformed carnallitic matrix in a potassic ore zone in the Krügershall Mine near Halle/Saale, Germany (After Richter-Bernburg 1980). (**c**) Formation of constriction folds (curtain folds) and concentric boudins due to flow into a salt dome. The combined effect of the tensile forces due to vertical extension and coeval horizontal compression due to the decrease in salt dome diameter results in the contemporary formation of contradicting structural styles (After van Gent et al. 2011). (**d**) Cross section through the Jefferson Island Salt dome, Louisiana, showing a wide boundary shear (black salt) separating an active salt spine from a less active caprock-capped part of the structural crest. North is to the left and the 800, 1,000 and 1,300 ft working levels of the mine are shown (After Kupfer 1976)

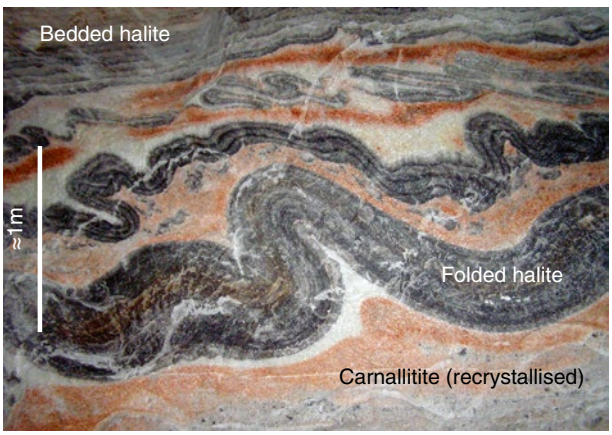

Fig. 6.15 Mine wall illustrating the varying response to differential stress in a number of halite and potash rich layers in a salt mine in Eastern Germany (Schofield et al. 2014)

complexities and shears in mined salt diapirs in the Gulf coast. Subsequent work by Kupfer (1976) on the same structures further refined notions of internal shear in diapirs. A shear forms where adjacent parts of a salt structure rise at different rates. This differential rise at the crest of a structure typically creates an active topographic high and a lack of thick caprock atop a rising spine, as is the case at Jefferson Island salt dome (Balk 1953; Kupfer 1976). The younger part of this salt stock is now 250 m (800 ft) higher than the adjacent flat-topped mass, which is also overlain by a cap rock (Fig. 6.14d). The boundary separating the spine from the less active portion of the crest is finer-grained and shale rich and it formed a limit to the former salt mining of the pure salt within the spine. Shale-rich shear zones at the edges of active spines and the clastic stain internal shears are sometimes called "black salt" by the miners and can show a greater propensity to leak water into a mine. The spine and its boundary shear are also seen in the Jefferson landscape, with a solution lake defining the zone of shallower salt created by the active spine. Shear zones within diapirs are potential problem zones if the crestal portions of domes are utilised for any type of fluid storage without an understanding of the significance of "black salt" (Fig. 13.48).

As a salt crystal moves in actively flowing salt, it recrystallises via various creep mechanisms. As it re-anneals, its outline stretches and deforms, leaving behind a strain memory of the stress regime in the various structures and crystal fabrics preserved in the diapir (Fig. 6.16a; Raymer and Kendall 1998; Talbot 1992a; Urai et al. 1986; Zak and Freund 1980). Studies

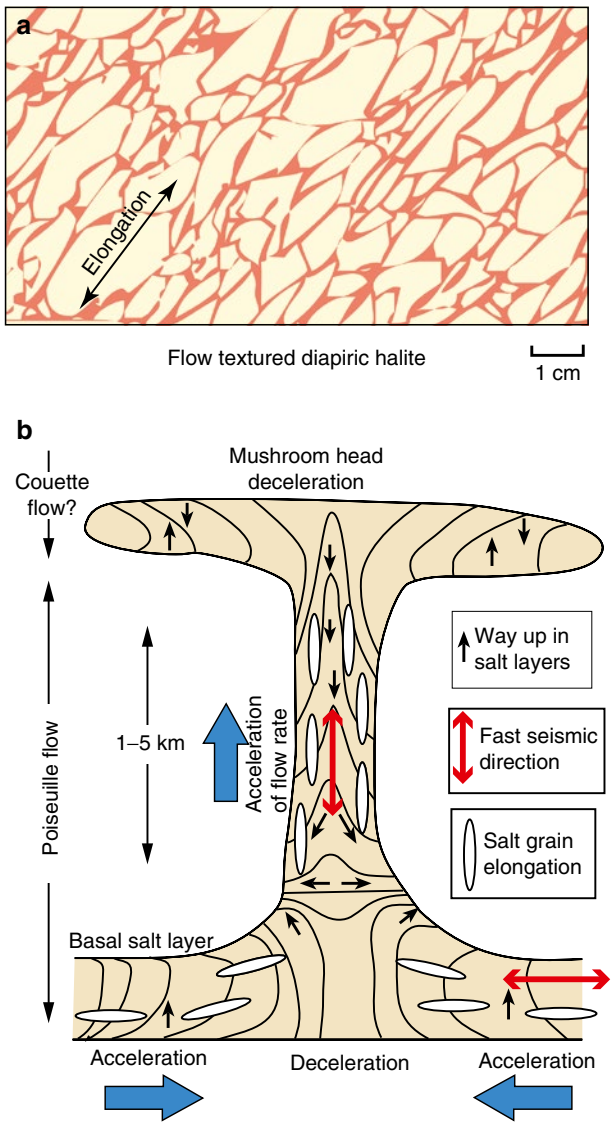

Fig. 6.16 Micro and macro scale flow texturing. (**a**) Digitised outline of flow textured halite crystals in a thin section of diapiric salt, no primary texture remains. (**b**) Schematic velocity fields in a flowing diapir derived from physical models. The deformed outlines of originally vertical markers are shown, as well as bed facing and salt elongation directions (After Davison 2013, Davison et al. 1996a, 2013)

of irradiated salt crystals show that the grains in flowing salt have such short strain memories that they rarely strain beyond length to width ratios of 4 or 5 before new flow aligned crystals are created and older sub-grain orientations are destroyed, like many other crystalline rocks in structurally complex lithologies, such as migmatites and mylonites (Figs. 6.5 and 6.7). A subgrain is a volume of crystalline material surrounded by subgrain walls composed of planar arrays of dislocations and are structures in halite best seen in irradiated samples (Fig. 6.17; Looff 2000). The subgrain walls separate crystalline material of the same composition with slightly misoriented crystal lattices (usually less than 1°).

Salt Crystal Size and Other Stress–Strain Indicators

Salt creep proceeds at stresses above a critical shear stress by glide and the multiplication of dislocations (Carter 1976). Dislocations are linear defects in the crystal lattice that divide slipped regions in the crystal from unslipped regions, allowing localized slip to occur and spread consecutively (Fig. 6.5a). With increasing deformation, dislocation density increases and work hardening occurs as the dislocations tangle and interfere with each other, limiting salt mobility. Recovery occurs by the diffusion of vacancies that allow dislocations to climb normal to their slip planes to avoid obstacles, and form stable subgrain walls (Fig. 6.17). Steady-state creep constitutes the bulk of the creep strain in naturally deformed deeper diapiric salt and occurs when the salt recovers at the same rate that it hardens, so that large creep strains can be achieved at constant stress and strain-rate (Carter 1976; Carter et al. 1993)

Hence, fine-scale grain-shape fabrics in confined flowing salt can record only the later stages of the strain history; its current and near current stress response. Total strains, resulting from superimposed deformations, are recorded by larger strain markers in the salt mass–primary anhydrite/dolomite layering or bedding, nodules, inclusions, and veins– all of which have much longer strain memories than individual halite crystals (Talbot and Jackson 1987a, b).

That is, constant readjustments and recrystallisation to the variable stress field experienced during flow does indicate the ambient stress field in a diapir (Fig. 6.5b). Most halokinetic salt crystals have long axes that are a few cm long and are steeply inclined to subvertical within a salt stem or wall (Fig. 6.16a). Between the elongate crystals are subgrain crystals with diameters that are a response to stress and can be approximated by an experimental power law equation noted by Carter et al. (1993) (see also Fig. 6.4a):

$$D(\mu m) = 214\sigma^{-1.15}$$

where D is the average subgrain size in microns and σ is differential stress in MPa.

This equation means crystal size in a diapir can be used to estimate differential stress in a salt mine or salt core. A detailed analysis of subgrain size immediately below the two-spined crest of the Weeks Island salt dome in Louisiana found differential stresses in the salt mass vary from 0.87 to 2.33 MPa at the 1,000 ft level (Fig. 6.18; Looff 2000). Higher stress levels and smaller subgrains indicate more actively moving salt. Finer-crystalline textures are generally associated with areas of salt spine beneath regions of higher surface topographic relief, while lows are tied to underlying zones of coarser-grained, recrystallised salt (Fig. 6.18).

Detailed mapping of internal mesoscale strain markers along with modelling experiments have clearly shown

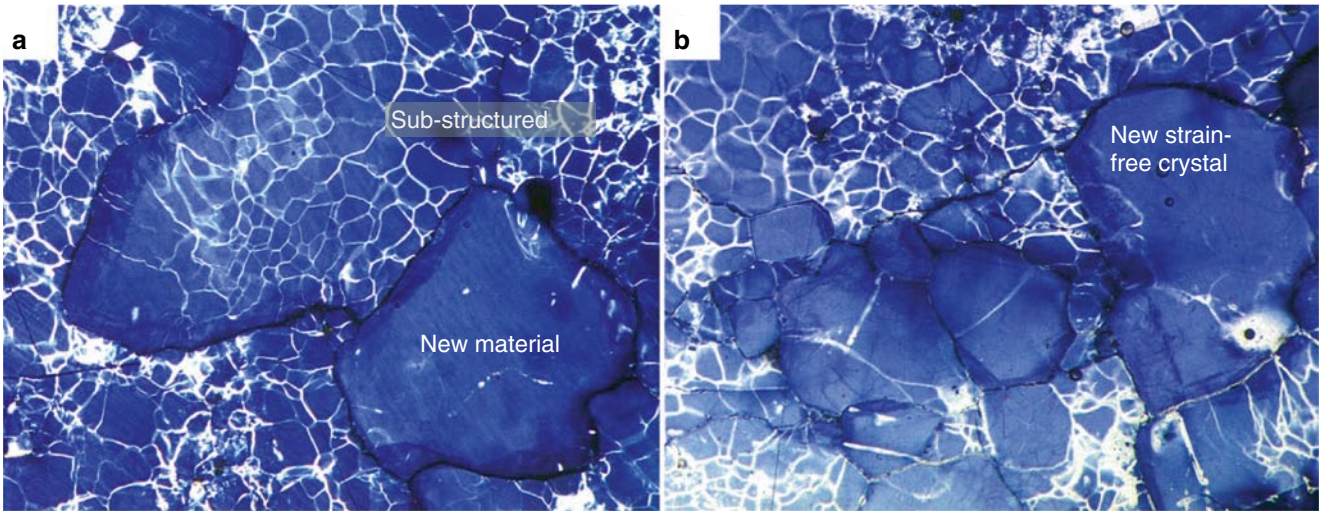

Fig. 6.17 Microstructures of sample from salt layer at a depth of 457.5 m in the Middle Triassic Rot Formation at Hengelo, Netherlands. Both are plane polarized transmitted light images of a salt sample from 475.5 m depth that was gamma-irradiated at 100 °C. (**a**) Migration of high angle grain boundaries as recorded by elongated subgrains, and strain-free new material, which grows at the expense of old, heavily substructured grains. Image width is 11 mm. (**b**) Strain-free grains that grew at the expense of deformed ones. The size of some of the new grains is comparable to that of subgrains. Image width is 7 mm (Both images courtesy of Zsolt Schléder; see Schleder and Urai 2005 for full details)

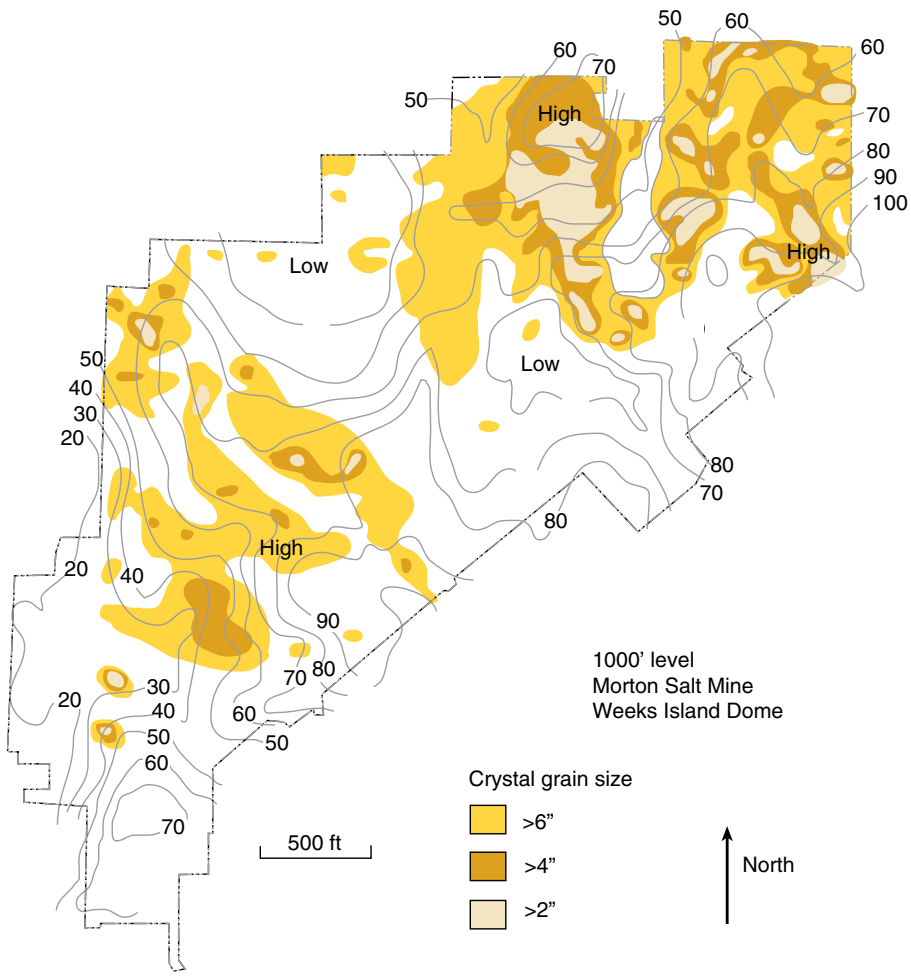

Fig. 6.18 Comparison of the salt grain size in the 1,000 ft level of the Morton Salt Mine, Weeks Island Louisiana, with surface topography over the mine. The finer-grained salt is generally associated with topographic high areas, while topographic depressions are associated with coarser-grained salt (After Looff 2000). See Fig. 13.48 for location of this the mine outline on Week Island

internal flow in deforming salt away from shear zone is not homogeneous (Kupfer 1976; Zak and Freund 1980; Burliga 1996; Davison et al. 1996a; Sans et al. 1996a, b; Smith 1996; Talbot and Alavi 1996; Geluk 1998; Schenk et al. 2006). Foliations in deformed salt in a diapir are often axial to folds that develop in the primary layering and to the flow folds that map local gradients in flow rates along internal stream lines and surfaces in the moving salt (Fig. 6.16b; Talbot 1979, 1992b). If these layers approach mechanical passivity then the flowing viscous salt "fluid" picks up internal flow folds wherever the salt slows and thickens to pass obstructions. Beyond the obstruction the flow accelerates and internal folds tighten and almost disappear in the narrowing flow before they refold at the next obstruction. If the internal markers are strain active, the slow (competent) layers fold, while fast (incompetent) layers mullion as they shorten within the slowing flow. Shears zones forming in a deforming salt body first grow in the least competent (usually potassic) horizons within the flowing salt mass. Between the shear zones, less deformed halite layers are carried laterally and upward into the diapir stem.

Davison et al. (1996a) show that fold wavelengths in Zechstein salt the North Sea (Fig. 6.76) are of the order of 20–30 km in layers with an original thickness of more than 1km and an overburden that is now more than 1km thick. The spacing of the folds controls the amount of salt that drains into any particular structure. With a circular drainage envelope of 10 km radius a 1.5 km-thick salt layer can supply of the order of 470 km^3 of salt to a single diapir. This is much greater than the volume of salt held in a typical North Sea diapir, which is around 25–75 km^3. It means there has been substantial salt loss by allochthon escape and crestal dissolution. The rate of salt supply is not constant throughout the drainage area as the rate of radial flow increases closer to the diapir. According to Davison et al. (1996a) the constriction associated with flow into the diapir neck creates strain within the neck up to 80 times greater than in the surrounding source layer. Thus, vertical flow in the centre of a diapiric neck produces extreme prolate strain textures that are in turn nullified at the top of the diapir where vertical flattening takes place via recrystallisation (Fig. 6.16b).

Various combinations of pressure solution creep and dislocation creep create the deformed, aligned and recrystallised halite textures seen in cores recovered from salt flows. Average halite grain size in cores from deformed recrystallised salt ranges between 5 and 10 mm in Zechstein salt in the North Sea and in Miocene salt in Mt Sedom in Israel and from 15 to 20 mm in Gulf Coast salt; all with L/S ratios typically greater than 1.5 (Davison et al. 1996a; Zak and Freund 1980; Talbot and Jackson 1987a).

Any interbedded sediment within the salt source layer strengthens a salt unit; it initially creates drag zones within the flowing salt, and so induces anisotropic strength and strain effects in the source layer as it moves toward the salt stem. This drag is often sufficient to generate small wavelength sheath folds. Once diapirism is more advanced, intrasalt beds (up to 40 m thick) in the mother salt are brecciated or boudinaged. Salt can then flow across former intervening layers, carrying along fragmented and fractured layer remnants, with the whole region then behaving like a pure salt mass. Thus, once the system attains diapiric status, the strength and resistance to flow created by more competent intrasalt beds is drastically reduced by boudinage and breakup. Once the intrasalt beds are broken, diapiric salt can develop internal vortices like a billowing cloud of smoke, which trap, encapsulate and lift the fractured blocks of intrasalt beds.

The captured fragments, usually dolomite, anhydrite or dolerite blocks, are referred to as "rafts" although they are not truly floating in the salt mass. Their density is typically higher than that of the salt. Rather, they are being swept upwards on a rising plume (Kukla et al. 2011a, b; Strozyk et al. 2012). Raft blocks can be porous and contain gas (including H_2S), oil or water and may create zones of unexpected overpressure when drilling salt. Once salt flow slows or ceases, blocks previously buoyed and caught up in the flowing salt mass of the diapir stem can sink back toward the base of the salt stem (Fig. 8.24a; Koyi 2001). The style of intrasalt boudinage depends on the degree of induration of the entrained sedimentary layers. Where the sediments are well indurated the breakup of intrasalt beds tends to create angular clasts, where less consolidated the beds tend to stream, streak and flow plastically, like the adjacent salt. Boudinaged and aligned angular clasts and blocks are a substantial component in any later halokinetic dissolution breccia (Figs. 7.29 and 7.30).

Microstructural Domains

There are predictable microstructural domains within this framework of flowing salt, as it migrates from the mother salt bed, through a diapir stem and into an extrusive structure, along with possible dissolutional reworking (Fig. 6.19; Urai et al. 2008). In undisturbed rock salt (position 1 in Fig. 6.19) the primary microstructures reflect the depositional conditions, with remnant fluid-inclusion-outlined chevron grains and microkarst textures. In regions of slightly deformed rock salt such as where the salt moves toward and first into the diapir stem (position 2), subgrains develop, together with incipient grain boundary migration zones. As migrating grain boundaries sweep through fluid-inclusion-rich primary crystals, the inclusion fluids collected at the grain boundary. Alternatively, salt solution-precipitation creep (pressure solution creep) is dominant in regions of finer grained flowing salt. Large contrasts in rheology are common in layered salt, even from the onset of tectonic deformation. As the salt

rises into the stem and deforms further (position 3), steady-state microstructures are produced after complete recrystallisation of the halite, although primary fluid-inclusions fluids are still preserved in intergranular positions. In the cooler portions of the diapir stem, high stress and small subgrains develop (position 4). On attaining the surface, weak mylonitic shear zones form and pressure solution mechanisms dominate (position 5), so allowing a namakier to flow downhill via gravity spreading, at unusually high strain rates compared to the stem and source levels (position 5). In the namakier, mesotextural indicators of Coutte flow are more common (Fig. 6.16b). Finally, at- and near-surface dissolution and ablation of the salt glacier edges occurs, typically driven by infiltrating rainwater, this facilitates halite recycling into ambient landscape sumps, which are often in rim synclines. In semi-arid to arid areas this leads to the formation of saline playas and chotts, where new salt crusts accumulate (Figs. 3.68 and 6.19). These are depositional sumps where the recycled salt can accumulate with primary bed (aligned-chevron) textures once more.

The change in salt crystal shape as it elongates in flow also produces seismic anisotropies within the flowing salt mass (Fig. 6.16b; Davison 2013). Pure halite has a seismic velocity of 4,500 ms^{-1}, which is often assumed to be a constant in velocity modelling of a salt mass. However, flowing salt bodies can contain varying amounts of anhydrite (velocity 6,500 ms^{-1}), or K-Mg-rich salts with velocities down to 3,500 ms^{-1}. A thick cap rock of anhydrite (up to 400 m) can occur due to salt dissolution along the top salt surface, so varying velocities are more realistic, even when used in initial velocity model testing in diapiric areas where the evaporite composition is unknown. All deformed salt bodies contain salt crystals that are preferentially elongated in the flow direction (Fig. 6.16a): they tend to be vertical in salt diapir stems and horizontal in source layers (Fig. 6.16b; Davison 2013). The P wave seismic velocity anisotropy has been measured at up to 7 % faster in the flow direction (Raymer et al. 2000). Individual interbeds of anhydrite and dolomite may also increase velocity anisotropy within the salt body if they maintain intact layers for long vertical distances. Currently, most seismic velocity models of diapiric salt do not encompass these known anisotropies.

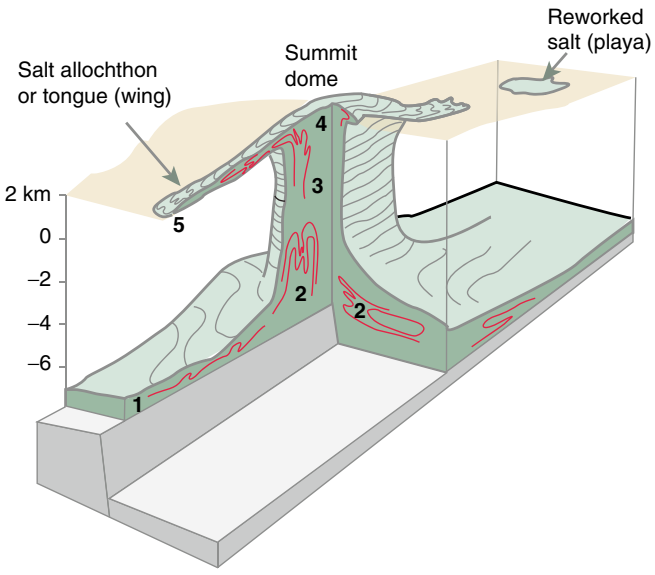

Fig. 6.19 Conceptual model of the rock salt cycle and associated rheological transitions and structures with respective microstructural domains (*1–5*). See text for detail (After Urai et al. 2008)

Triggers, Drivers and Outcomes of Salt Flow

We have seen that density inversion alone does not trigger salt flow; so what does? From our preceding discussion we know that pure salt is extremely weak compared to its surrounds (Fig. 6.7). Wet salt at or near the surface in a namakier or allochthon collapses under its own weight (gravity spreading) and so is capable of behaving like a Newtonian fluid across most geological time scales. In contrast any overlying or adjacent sediment responds brittlely in the same stress field. It seems salt structures in extensional basins that are accumulating sediment are triggered and driven by two main mechanisms; extension and differential loading. Both are derived from externally applied forces. Later in this chapter we shall look at salt flow in relation to external compressive forces, but for now we will focus on extensional systems.

Salt flow can be triggered syndepositionally by the accumulation and gravity-driven extension of overburden or by an externally imposed episode of regional extension and overburden foundering. Extension can be syndepositional with salt accumulation, or can occur long after bedded salt was first deposited and buried (Vendeville 2005; Hudec and Jackson 2006). Syndepositional movement was the case with the numerous early allochthons and minibasins in the Jurassic of the northern Gulf of Mexico and the Cretaceous of Santos Basin of Brazil. Initial halokinetic-sediment feedback began in the Mesozoic, yet further out in both basins flow continues today as allochthons of Mesozoic salt are emplaced atop Neogene deep-seafloor sediment. Over much of the current North Sea and NW Europe, salt flow was triggered by later regional extension. That is, flow of Zechstein salt (deposited in the Late Permian) began in the Triassic, some tens of millions of years after salt deposition had ceased. These Triassic extensional geometries were further complicated in the late Mesozoic to early Tertiary when there was a widespread episode of reactivated salt flow, triggered by compression tied to the Alpine orogeny (Mohr et al. 2007).

Studies of halokinesis conducted in the 1980s tended to place more significance on the triggering and driving effects of differential loading and gravity spreading (Trusheim 1960; Dailly 1976; Seni and Jackson 1983a, b; Jackson and Talbot 1986, 1991; Worrall and Snelson 1989; Nelson 1991). Studies in the early 1990s tended to emphasise the role of regional extension and gravity gliding (Duval et al. 1992; Vendeville and Jackson 1992a, b; Demercian et al. 1993; Jackson and Vendeville 1994). By the late 1990s, differential loading was physically modelled in the same way as extension had been and shown to be an equally valid mechanism for both triggering and driving salt flow in basins accumulating substantial volumes of sediment (Ge et al. 1997).

Now after more than three decades of detailed seismic mapping of salt structures in hydrocarbon-prone active halokinetic regions in the Gulf of Mexico, the Santos Basin, the North Sea and offshore West Africa, we know that both mechanisms can operate concurrently from the first onset of salt flow. Waltham (1997) argued that apparent differences in triggers (loading versus extension) are two end members of a response continuum, depending in large part on the thickness of the salt and the rate of deformation (Fig. 6.20).

Gravity gliding and gravity spreading are end-member modes of gravity tectonics, and both result in a decrease in gravitational potential energy. In gravity gliding, the driving energy causes motion parallel to the basal surface and is downdip along that surface (Fig. 6.21a). Gliding does not require internal deformation of the translating body, but a moving body with internal flow parallel to the basal slip surface is a variant of gliding. This means that sometimes a salt body that has experienced gravity gliding retains primary halite chevron textures away from the zone of translation or gliding (as is the case below salt-encased carbonate slivers in portions of the Ara Salt in Oman; *pers. obs*). The bottom surface must have a component of dip in the movement direction, whereas the dip of the top surface is not diagnostic of gliding: it may have no overall dip (or it may dip counter to movement. In gravity spreading, the driving energy causes motion of the material toward the basal surface (Fig. 6.21b), requiring deformation of the spreading body. Parts of the upper surface must have components of dip in the movement direction, but the dip of the basal surface may be opposite to this motion, or horizontal or in the same direction as the motion. That is, gliding is associated with a dip into the basin below the salt, spreading is often more tied to differential sediment loading.

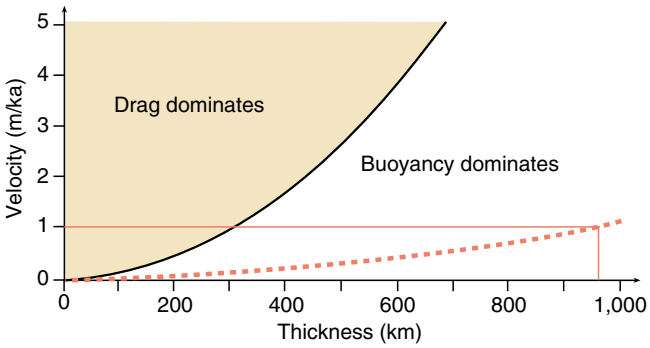

Fig. 6.20 Shaded interval shows the overburden velocity field where drag (largely a brittle response in the overburden) dominates over buoyancy contrast as a trigger of salt flow (viscosity is 1×10^{18} Pa.s). The dashed curve shows the overburden velocity field at which drag dominates over buoyancy if the viscosity is ten times higher (i.e. 1×10^{19} Pa.s). The crossline shows the salt thickness corresponding to an overburden velocity of 1 m/ka (After Waltham 1997)

Brun and Fort (2011) list the following sets of diagnostic structures useful in defining whether the dominant process sets were related to gliding or spreading. Good diagnostic structures for the dominance of gliding include sealed tilted blocks in the updip extensional domain and early folding and/or thrusting in the downdip contractional domain. Migration of the contraction is updip (landward) in settings dominated by gliding and seaward in pure spreading. Only if the seaward part of the salt basin is free of sediments, is early suprasalt rafting tied to ex tensional diapirism indicative of pure spreading. Otherwise, if rafting is synchronous with downdip contraction, then it indicates the dominance of gliding processes (Fig. 6.1b). Frontal salt nappes tend to form progressively in situations dominated by spreading processes, as a direct function of the amount of sediment deposited on top of the salt basin, but only if the seaward part of the salt basin is free of sediments. In situations dominated by gliding they form suddenly, after a long period of downdip contraction.

This paper by Brun and Fort (2011) and the reply by Rowan et al. (2012b) show there are still some fundamental

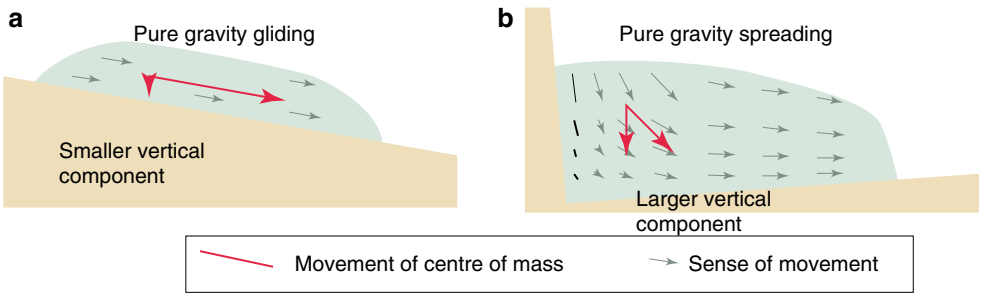

Fig. 6.21 (**a**) Gravity gliding versus (**b**) gravity spreading (See also Fig. 6.11)

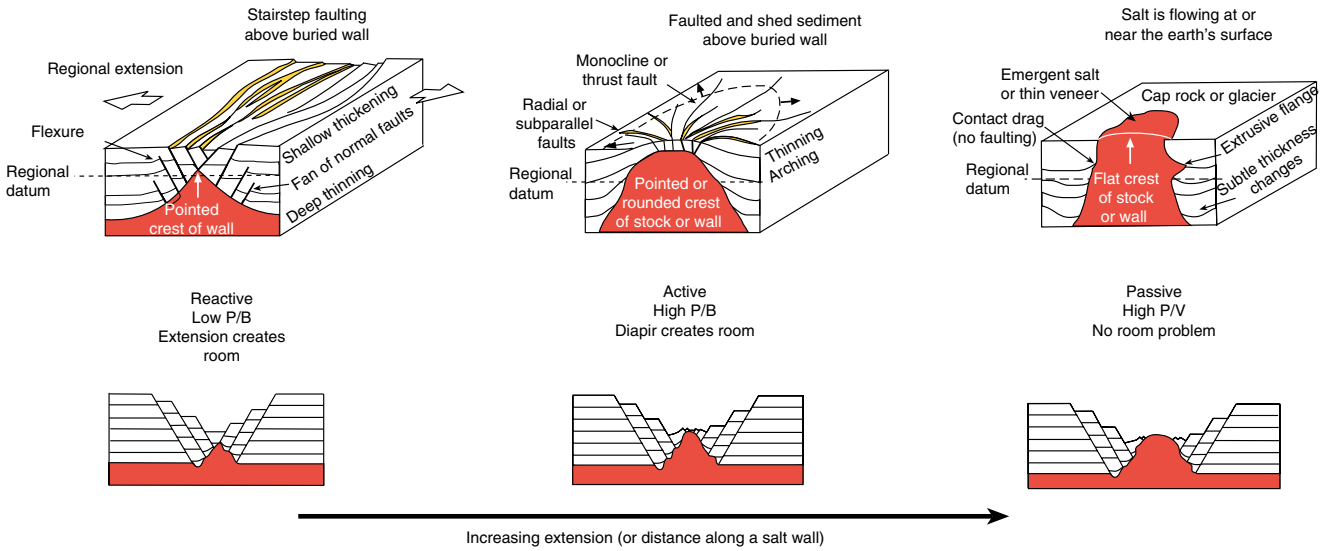

Fig. 6.22 Three piercement modes for diapirs (salt is red) and their characteristic structures. Regional datum is indicated by a *dashed line*). *P*, *V* and *B* refer to stresses due to salt pressure, salt viscosity and overburden brittle strength, respectively. Extension is accommodated by both graben-related faulting and diapir widening (In part after Vendeville and Jackson 1992a; Jackson et al. 1994a)

differences to be addressed in terms of dominant triggers and process sets driving salt tectonism. Brun and Fort (2011) argue that the dominant trigger for salt tectonics, at passive margins worldwide, is gliding down a margin dip. They go on to argue that salt tectonics triggered by differential sedimentary loading is a process that is difficult to reconcile with geological field evidence. Rowan et al. (2012b) argue the opposite.

Diapirs and Extension

During regional extension diapirs can "pierce" the overburden in three related ways: reactively, actively and passively (Fig. 6.22; Jackson et al. 1994a, b). A reactive diapir pierces by filling the space created by divergence of faulted overburden blocks. Reactive diapirism occurs during regional extension as salt approaches the surface beneath a subsiding graben in the thinned overburden. This surface graben is matched by development of an "inverse graben" at the underlying salt-sediment interface (isostatic balance). Salt fills the expanding space in the inverse graben and forms a reactive diapir that is triangular in cross section with flanking growth faults that become younger toward the diapir crest. If regional extension ceases before the onset of active diapirism, so does diapirism. Extension typically reflects a more regional set of tectonic processes such as gravity spreading or gliding of shelf and rise sediments in opening rifts. Diapiric salt at the reactive stage is not forcing aside overburden sediment, it merely reacts to regional stretching as it moves into space created by extension.

Extensional faulting is an effective mechanism for initiating diapirism in many situations, regardless of the prior overburden thickness, lithology or density (Fig. 6.22; Vendeville and Jackson 1992a, b). In such settings there is always a low ratio between salt pressure (Ψ) and brittle strength of the overburden. Reactive structures can be found either beneath newly-deposited thin overburden just starting to extend, or atop deeply buried salt beds in regions newly undergoing extension (Fig. 6.23).

An active diapir, by definition, lifts and shoves aside its overburden. Unlike reactive diapirism, this style of salt emplacement must deal with a "room" problem. It requires forceful intrusion to remove the roof of sediment atop the salt and is sometimes termed upbuilding. It is possible only if the overburden is relatively thin, whereby salt pressure exceeds the brittle strength of the overburden (Fig. 6.23). The roof must be thin enough for the pressure differential to lift it. For this to happen the roof is typically less than 20 % of the entire thickness of the overburden flanking the diapir (Jackson et al. 1994b). However, once initiated, a diapir can actively pierce each new increment of sediment that buries it. Repetition of active piercement events sheds successive episodes of thin cover sediment into a debris belt around the growing diapir.

Over time, an active diapir can pierce large cumulative thicknesses of sediment and create successive stacked unconformities about the diapir stem, which fade away with passage into areas above the withdrawal sink (rim syncline). Each unconformity defines an episode of active piercement. Fractures formed during shedding of crestal sediment in active diapirism are extensional, often filled

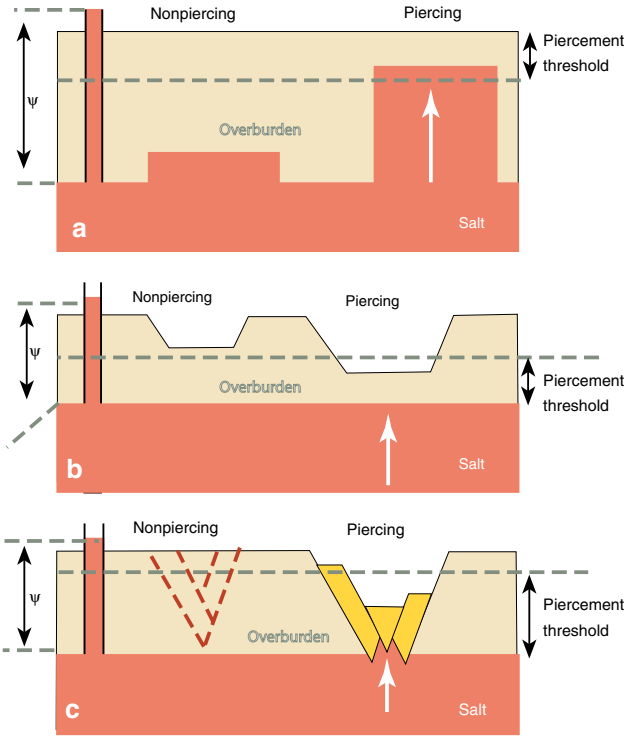

Fig. 6.23 Conditions for active piercement of salt (*red*) overlain by rigid brittle overburden (*brown*). Where the overburden is thinner than the piercement threshold, the salt can break through (*white arrows*) under non-extensional conditions above salt ridges (**a**) or below topographic troughs (**b**). In (**c**) the non-stretched salt roof is too thick to permit diapirism but where it is thinned by extension to below the critical thickness a diapir can break through. Ψ is the pressure head of salt (After Jackson and Vendeville 1994)

with infiltrated sediment and typically show little displacement of sedimentary layering on either side of the fracture (as is the case in fractured Lisan Fm. laminites atop actively flowing Sedom salt in the Dead Sea depression; Marco et al. 2002).

As well as active diapirism occurring by overthinning during extension (Fig. 6.22), there are numerous examples of compressional active diapirism driven by shortening or regional compression squeezing a salt structure and so forcing salt upward to uplift arch or intrude the roof, Regional tectonic forces typically are much greater the buoyancy forces active in extension, so compressional active diapirism can deform much thicker roofs than extensional active diapirism, as has occurred in numerous pierced anticlines in the Zagros belt, Iran (e.g., Fig. 6.32).

Once a diapir or salt wall emerges and flows onto the earth's surface it becomes a passive diapir, typically rimmed by salt allochthons; its edges spread and collapse under the weight of the extruded salt mass (Newtonian flow). A passive diapir crest maintains its position near the surface, while the adjacent sediment lows, along with the source salt layer they cover, subside. This is called downbuilding[10] with rim syncline maintenance and was first documented by Barton (1933). A passive diapir cannot continue to rise without ongoing sedimentation to load areas adjacent to the at-surface salt, but the area of the salt mound can widen and if extension continues will ultimately subside (falling diapir stage). A thin skin of sediment can form atop the salt high but it is continually breached, pierced, foundered and fragmented. Its remnants are erosively shed from the diapir crest, or carried away "conveyor belt style" by divergent lateral flow of the underlying salt allochthon. Thus little or no sediment accumulates atop the crest of a passive diapir. Most adjustments in the thickness of accumulating sediment in the adjacent subsiding basin is a response to the evacuation or withdrawal of salt at deeper levels below the accumulating sediment pile.

A lack of vertical constraint to the rising salt at the passive stage means there is no "room" problem; flanking strata need not be rotated, faulted or pushed aside as they must be during active diapirism. Faulting and folding are negligible in the sediments adjacent to passive diapirs, apart from a narrow drag zone along the salt-sediment contact (Fig. 6.22; Jackson et al. 1994a, b; Schultz-Ela 2003). Once the source layer is depleted, the diapir ceases to grow and is buried by further sedimentation. Shapes of passive diapirs are primarily a function of the ratio of salt flow rates to sedimentation rates. When balanced, the diapir stem grows vertically; when sedimentation rate is relatively slow, the salt leaks out over its surrounds to give flanges to the diapir and a more mushroom-like allochthonous aspect.

The sequence reactive -->active -->passive can be altered by changes in rates of extension, depletion of the source layer or changes in sedimentation rate, and so various evolutional paths are possible (Jackson et al. 1994a):

- Although a diapir may appear to be initiated passively, most likely it was reactive or active during its earliest stages. If the overburden was thin and unevenly deposited, the reactive and active stages are very brief, and the strata faulted during these very early stages can be too thin to be resolved seismically.
- A diapir that appears to have been passive may have passed through numerous cycles. Each cycle could have

[10]The process of downbuilding describes the situation where the rise of the salt relative to the source salt layer occurs coevally with further overburden deposition and loading, so the distance increases between the source layer and the surface of the basin, while the crest of the salt structure maintains the same position in earth space.

Its corollary is upbuilding, this describes the situation where salt rises after the overlying strata have already been deposited, thus the rising salt will warp and eventually break through overlying strata. The crest of the structure changes its position in earth-space as it grows.

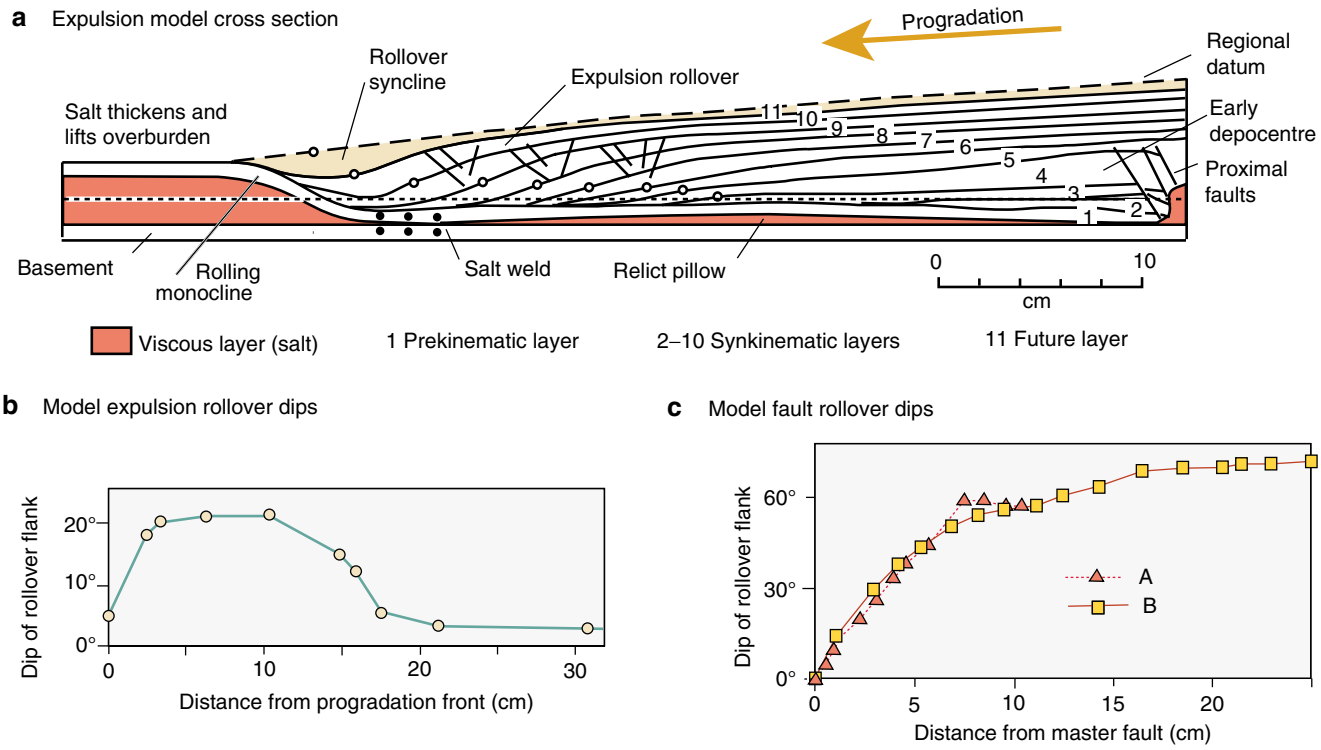

Fig. 6.24 Expulsion rollover characteristics. (**b**) Rollover plots of maximum dip associated with model illustrated in 6.24a. (**c**) Rollover plot of model experiments: result **a** is from experiment model 188 listed in Ge et al. (1997), result **b** is from experiment E30 in McClay (1990) (Modified from Ge et al. 1997)

comprised an episode of passive growth during slow sedimentation, followed by burial during a period of rapid sedimentation and be terminated by a brief active salt breakout. Each active stage removes the overburden roof by doming, local extension, entrainment, slumping, dissolution collapse and the creation of local unconformities.

- An active diapir can partially break through its roof, but never emerge, as: (1) the salt source layer may become depleted prior to breakout, (2) the salt source may be channelled off (pirated) by an emergent segment of an adjacent salt wall, or (3) without erosion or differential loading an active diapir only partially penetrates all but the thinnest roofs before reaching equilibrium (Schultz-Ela et al. 1993).

If a passive pluglike stock is later stretched during ongoing regional extension, the adjacent country rocks may also stretch, creating normal faults next to the diapir. But more typically the stretching is taken up in the much weaker salt body, so that passive elongated salt walls under extension are widened via ductile flow of salt. The much stronger flanking overburden may remain grossly intact and virtually devoid of normal faults at the scale of seismic resolution. An apparent absence of normal faults in sediments adjacent to a passive diapir wall means that even large amounts of regional extension may remain hidden within the expanding and deforming salt wall. This cryptic extension can be inferred by accurate reconstruction of cross sections backward in time. But this process is far from straightforward and requires additional constraints, such as independent data on the original length of the section or original thickness of salt (Schultz-Ela 1992).

Diapirism and Differential Loading

In a series of scaled physical models Ge et al. (1997) demonstrated the importance of progradation as a trigger for salt tectonics and formation of allochthonous sheets. They considered two end members in their modelling experiments. One group of experiments replicated salt with an underlying flat top to the basement (Fig. 6.24), while another group considered a basement with a stepped top, as would occur in a block faulted basement terrain (Fig. 6.25). Regional extension and contraction were excluded in their models.

The prograding wedges above a tabular, buoyant salt layer that was underlain by a flat basement top, expelled the salt basinward in a predictable sequence of structures. From proximal to distal they were: (a) sigmoidally distorted initially planar wedges, (b) relict salt pillows and salt welds, (c) basinward-dipping expulsion rollover and crestal graben, (d) rollover syncline, (e) landward-facing salt-cored monocline, and

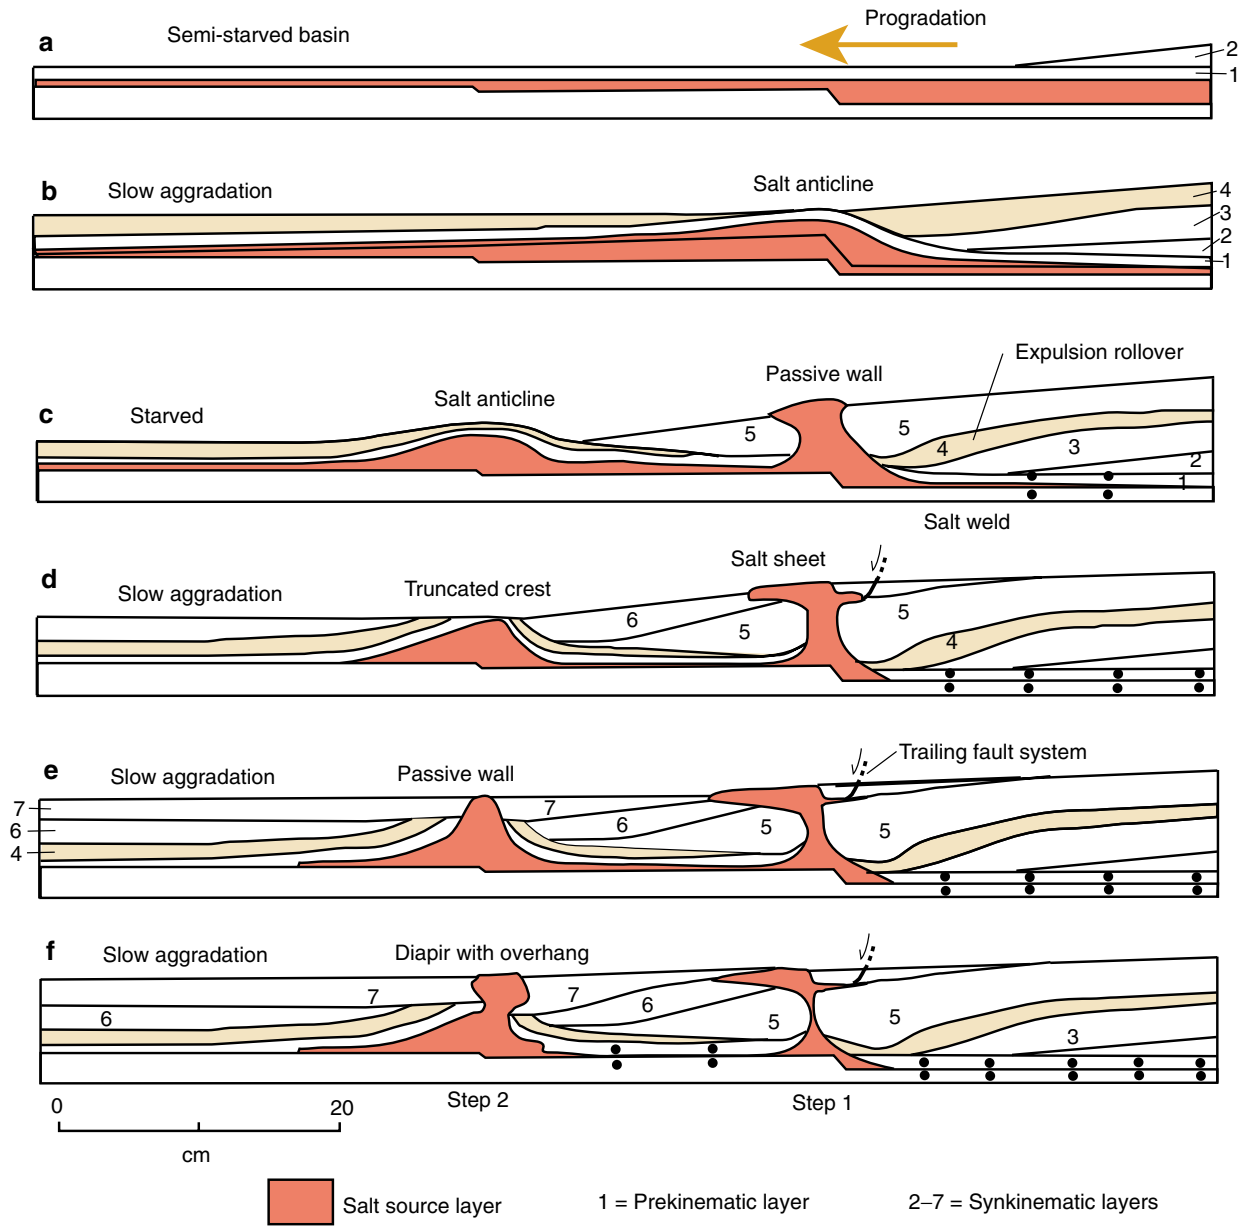

Fig. 6.25 Evolution of salt structures during progradation atop a salt basin that is underlain by a stepped basement. See text for detail on stages **a**–**f** (Modified from Ge et al. 1997)

(f) distal inflated salt layer (Fig. 6.24a). This deformation zone amplified and advanced basinward, together with the prograding sediment front. Complete evacuation of the salt left a basin-propagating salt weld below the prograding sediment wedge; incomplete evacuation left salt pillows as residual highs, but no diapiric salt structures were formed.

In contrast, modelling of progradation over a buoyant salt layer, which was underlain by landward-facing basement steps or fault escarpments (Fig. 6.25a), initially formed a broad anticline where the salt flow was focused across each basement step (Fig. 6.25b). Early on, differential loading by the prograding wedge expelled the salt basinward in an identical fashion to that which occurs in a basin with no basement steps. Then the lateral escape of the salt was altered as it was slowed across the friction point created by the basement step and salt backed up to form a broad asymmetric salt-cored anticline. Distal aggradation continued to pin the anticline and enhance differential loading. Next the anticline actively pierced its crest, which in the real world may have been thinned by faulting and erosion (Fig. 6.25c). Thereafter the diapir grew passively, locally sourcing allochthonous salt sheets. This deformation cycle repeated over each basement step so that the age, amplitude, complexity and maturity of salt-related structures decreased basinward (Fig. 6.25d–f).

As each allochthonous salt sheet was buried and evacuated by sediment loading, arcuate peripheral normal faults formed along the sheet's trailing edge, detached wrench faults formed along its lateral edges, and active piercement at

its leading edge allowed the sheet to break out and climb stratigraphic levels. This process formed a multi-tiered complex of salt sheets that migrated basinward with time. Ge et al.'s (1997) modelling clearly shows that immense landward-dipping (counter-regional) pseudofaults can arise entirely by salt expulsion rather than regional extension. Their physical model clearly shows that progradation alone can generate salt anticlines that mature into salt walls, stocks, glaciers or linked, multi-tiered complexes of evacuated sheets and salt welds. The prograding sediment wedge expels salt basinward regardless of density relationships. In such situations there is a relationship between underlying basement discontinuities and the location of salt diapirs and allochthons. A result that is not obvious in purely extensional regimes where the zones of diapirism tend to begin in zones of overburden thinning that can bear no relationship to subsalt discontinuities.

Salt can flow under both regional extension and progradation (loading). Both are typically present and interacting in a sedimentary basin where extension drives the subsidence that in turn creates accommodation space, which is then filled by sediment. Extension is perhaps the dominant mechanism triggering diapirism in deeply buried salt bodies, while progradation is a commonplace driving mechanism whenever salt is near the surface. Salt's propensity to flow means that diapirs, initially formed by early progradation of a wedge of continental shelf or platform sediment, can be later reactivated or overprinted during extensional or compressional regimes.

This leads to an obvious problem in distinguishing between expulsion rollover generated by progradation and a fault rollover in the hanging wall of a listric growth fault generated during extension. Ge et al. (1997) clearly show how dip analysis of the rollover plot can be used to help differentiate the two styles (Fig. 6.24b, c). They plot the maximum dip of each sediment wedge in the expulsion rollover (open circles in 6.24a, b) versus distance from the present progradation front. Maximum dip was measured on the basinward-dipping flank in the rollover syncline. The rollover plot is shaped like an asymmetric hill with dips increasing rapidly away from the front to a maximum and then decreasing less rapidly. The maximum dip corresponds to where the thickest salt was expelled. The oldest wedges preserved the initial depositional slope (5° in modelled system) and planar shapes, even though they were folded and then unfolded by the passage of the structural monocline that rolled through them as the salt evacuation front passed by.

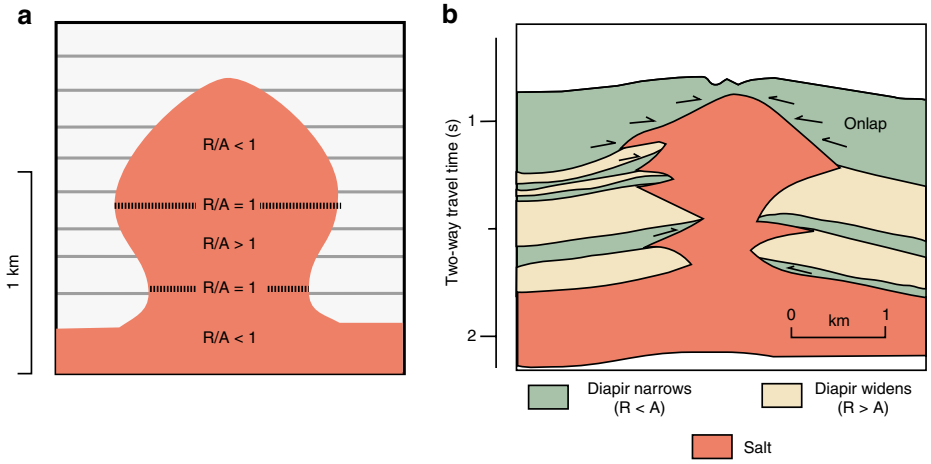
The plot of a fault rollover in the hanging wall of a simple listric fault is quite different and shows no decrease in dip away from the present progradation front (Fig. 6.24c). Dips of the hanging wall cut off abruptly and then gradually increase to reach a maximum value away from the surface trace of the listric fault. The constant maximum dip away from the fault corresponds to flattening of the underlying fault. This type of analysis can only be carried out on syn-kinematic strata, which are distinguished from prekinematic strata as they show local lateral variations in thickness. If a listric fault has multiple flats and ramps, the prekinematic strata generate a tail of data points that are not diagnostic and should not be used. See Ge et al. (1997) for a full explanation of this methodology and its application. Some workers subdivide the effects of sediment loading on salt flow into (1) systems with linear progradation fronts moving out over a salt mass (Vendeville 2005) versus, (2) more lobate styles of sediment loading (Gaullier and Vendeville 2005). The former are appropriate to linearly-loaded continental margins, as along much of the Atlantic slope-and-rise of South America and the Gulf of Mexico, while the latter models are more appropriate to lobate loaded margins, such as the Gulf of Lions and the Nile Cone.

Sedimentation Rate Controls Diapir Shape

Observations in seismic lines collected in the late 1980s, which for the first time were showing the base of salt, indicated a stepped base to the flowing salt mass (ramps and flats), rather than the previous assumption of flat or planform salt bases. It helped change the notion of salt allochthon emplacement from that of a salt sill injected into marine muds a few hundred metres or more below the seafloor into one of salt glaciers marching out over the seafloor via a combination of ramps and flats tied to sedimentation rates on the seafloor.

Interaction of upwelling salt and sediment accumulating on the diapir's flanks controls the geometry of a passive or downbuilding diapir and its salt tongues or wings. If the rate of salt rise is less than the sediment accumulation rate, then a passive diapir narrows upward as onlapping sediments encroach onto the diapir ($R/A < 1$; Fig. 6.26a, b). When a large volume of salt is supplied to the growing structure, the diapir rises faster than the surrounding sediment can aggrade. The resulting laterally unsupported salt ridge repeatedly overflows its unsupported margins (gravity spreading), thus creating a salt tongue that widens upward over time ($R/A > 1$; Fig. 6.26a, b). Eventually, all diapirs are buried by the slowing and eventual cessation of salt supply. This typically happens once the mother salt (source layer) is thinned or depleted by salt withdrawal and overburden touchdown.

The gross flow rate of salt in passive diapirs reflects a balance between driving forces, retarding forces and salt supply (Jackson et al. 1994a). Any change in sedimentation rate versus rate of salt supply controls the overall planform (at-surface shape) of a passive diapir. If, during extension, the sedimentation rate is high compared to the rate of regional extension, a reactive diapir evolves into a squat deeply buried salt roller bounded by a listric (upward steepening) fault. Conversely, if the sedimentation rate is low compared to the



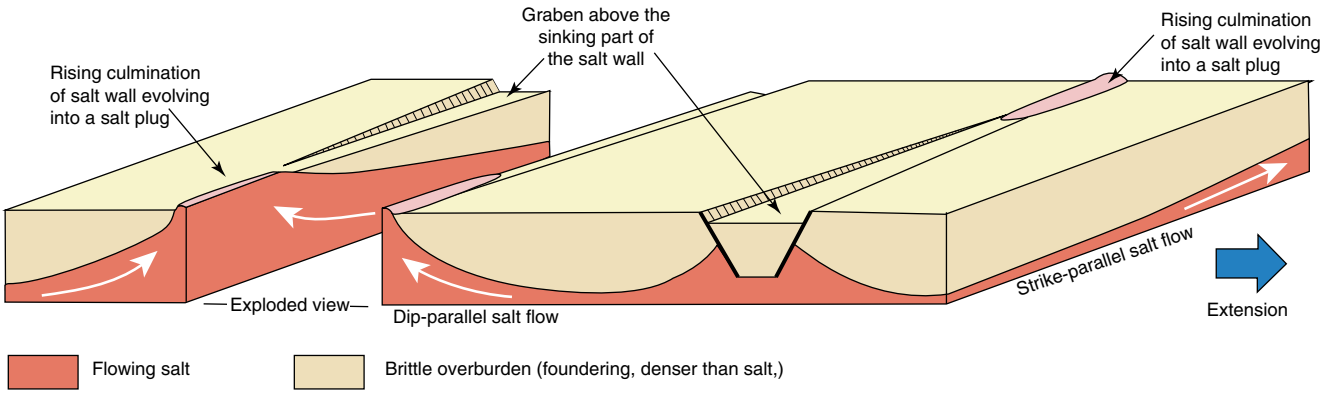


Fig. 6.26 Passive diapirs with extrusive flanges onlapped by overburden. (**a**) The shape of a diapir is controlled by the ratio of net diapiric rise R (incorporating the effects of dissolution), to aggradation rate (vertical accumulation of sediment). (**b**) A typical North Sea Diapir with allochthonous salt wings (After Jenyon 1986). (**c**) The stepped base of Mica (aka Mitchell dome) Garden Banks, offshore Louisiana, shows it was emplaced as an allochthon not a sill; high R/A causes salt flats (*SF*), low R/A causes salt ramps (*SR*) (After Vendeville and Jackson 1993)

Fig. 6.27 Once part of a salt wall begins to fall, subsidence can be enhanced by strike-parallel flow of salt from beneath the subsiding graben and toward parts of the wall that are still rising (After Vendeville and Jackson 1992b)

rate of regional extension, a reactive diapiric ridge evolves into a tall salt wall or a number of adjacent salt plugs that show steep or overhanging discordant contacts and shallowly buried crests (Vendeville and Jackson 1992a). Likewise, sedimentation rate also controls the form of advance of an allochthonous salt sheet (Fig. 6.26c). Salt flats indicate times of low sedimentation, while salt ramps indicate higher rates of sedimentation. Salt ramps are the remnants of an allochthon which was an active glacier moving across the seafloor. When the salt is completely evacuated the former ramp becomes a salt weld.

Within a single ovoid or elongate salt structure a diapir's rate of salt flux increases with increasing width. At the diapir's widest part, salt flow rates are high relative to sedimentation rates. Conversely, contact drag at the structure's extremities affects the narrower ends of an elliptical diapir more than at its wider parts. This slows the rate of rise at either end so creating relatively high aggradation rates. Thus salt spreads at the widest part of a diapir and retreats from its elliptical ends. Accordingly, an originally elongate salt wall evolves toward a string of pluglike passive stocks rising from the deeply buried reactive salt ridge (Fig. 6.27). The number of exposed plugs atop a salt wall declines as they exhaust their salt supply evolve into falling diapirs that are ultimately buried or evolve into mockturtle anticlines.

As a salt glacier is extruded onto the seafloor it can flow in any direction, depending on the local slope (gravity spreading); it can even flow landward into the depression atop an adjoining rollover syncline (rim syncline). Over time the breakout sites, where the salt climbs the section and

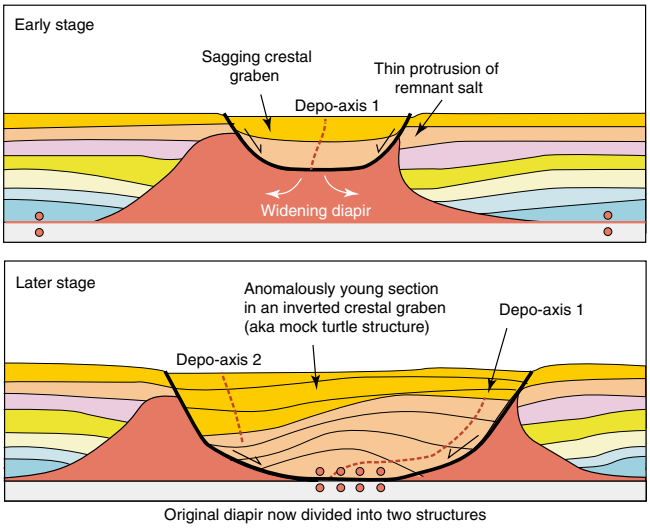

Fig. 6.28 Creation of an indented or falling diapir showing suprasalt depression that in its later stage develops into an inverted structure known as a mock turtle anticline

breaches to the surface, will ultimately shift basinward as salt is squeezed by the prograding basin fill (Fig. 6.25). Regionally, the depocentre of active diapirism in the Gulf of Mexico has been shifting basinward since the Jurassic when the mother salt bed, the Louann Salt, first breached the surface. As each newly-emplaced salt sheet is loaded by the prograding sediment pile, it carries its overburden basinward by gravity spreading. Thus, while a sheet evacuates into a new stratigraphic level it also generates halokinetic profiles atop it.

Extension, Falling Diapirs and Turtles

Salt-lubricated extension can initiate and maintain diapirism throughout the reactive, active and passive stages. When connected to an adequate salt supply, passive diapirs can widen between separating blocks of overburden, while still maintaining their crest at or near the surface (Vendeville and Jackson 1992b). That is, once it attains its maximum height, a reactive/passive diapir can continue to widen by viscous flow. Salt inflow fills an ever-widening gap between the extending fault blocks of overburden that are gliding apart on the salt source layer. Eventually the salt supply becomes restricted and ultimately depleted so that the passive diapir crest sags or falls as it evolves into a characteristic two-horned indented profile (Fig. 6.28 – early stage).

If the former diapir crest continues to sag, the crest inverts from a topographic bulge into a subsiding depotrough or graben, which is rapidly filled with sediment. This creates a sediment thick atop the diapir (Fig. 6.28 later stage). Slippage continues along the bounding faults of this deepening graben, but no new faults generally form within the graben. Such a crestal graben lacks the stair-step faults that characterise the smaller and shallower crestal graben of a reactive diapir. Adjoining the indentation are hornlike cusps of salt below each bounding fault of the graben.

That is, where extension continues after all salt supply to a passive-stage diapir is cutoff, overburden touchdown occurs in the position of the former passive diapir crest. The falling diapir overburden segments into two flanking triangular relics flanked by glide blocks composed of older overburden (Fig. 6.28 – later stage). The diapiric relics are now separated by deep, wide depocentres filled with younger sediments. If extension continues, the flanks of these diapiric relics subside until they too touchdown. Thus, ongoing extension and salt depletion causes even the young depocentre to subside until it too eventually inverts into a crestally-faulted arch, called a mock-turtle anticline. The creation of a mock turtle anticline can be accompanied by the creation of a number of crestal depocentres, rather than a single larger depocentre (see minibasins).

Turtle-structure anticlines, with crestal keystone grabens, form in the withdrawal sinks between falling diapirs and are a typical response to source-layer depletion under extension (Fig. 6.29a–e). Historically, turtle anticlines were attributed to the evolution of a salt pillow as it contracted into a upward-growing diapir (see Warren 1989 for dated discussion), but it is now known that they form during the falling diapir stage in an extending basin (Fig. 6.29c–e).

Once the salt supply to a diapir is restricted, more and more salt from the surrounds is withdrawn into the falling diapir (Fig. 6.29c). As this occurs the region of overburden touchdown forms creating an incipient turtle that then widens beneath the rim syncline sediments. Over time, the ongoing widening of this zone of salt withdrawal and touchdown causes the sediments of the rim syncline to invert into a turtle structure anticline, often with a keystone graben in the anticlinal crest (Fig. 6.29d).

The touchdown and inversion of the earlier rim syncline sediment pile can create a topographic high on the seafloor, which is a type of drape-induced anticline. Sediments deposited atop the anticlinal crest may be higher energy sands and carbonate buildups, as has occurred in the reefal carbonate reservoirs that characterise buildups in the James Limestone in the Gulf of Mexico (Fig. 10.55). Such depositionally enhanced potential reservoir intervals can be self-reservoiring, self-closing and self-draining petroleum systems.

In many diapiric settings, such as the North Sea and the Gulf of Mexico, salt walls can pass along strike from a section of the wall at the passive stage to a falling section of the wall marked by a thickening crestal graben. Once part of a salt wall begins to fall, subsidence can be enhanced by strike-parallel flow of salt from beneath the subsiding graben and toward parts of the wall that are still rising (Figs. 6.27 and

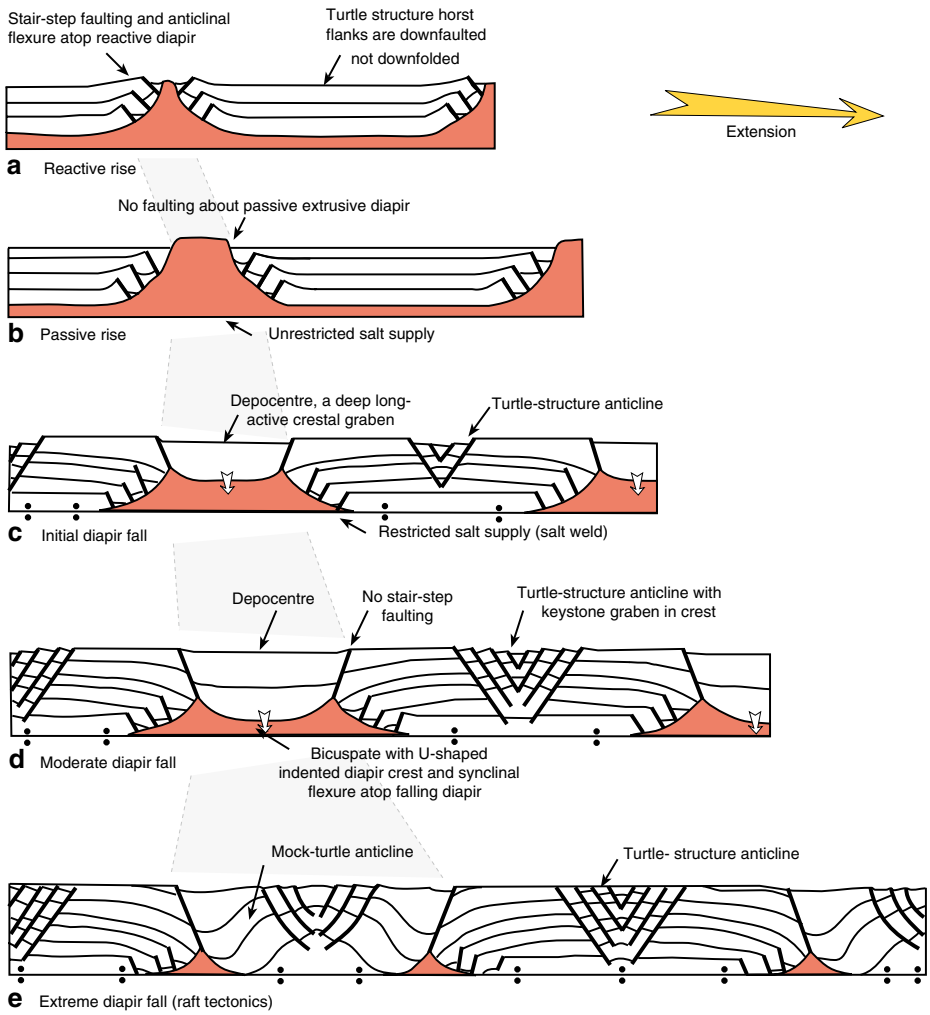

Fig. 6.29 Rise and fall of diapirs during synkinematic sedimentation and extension. The *dashed line* implies the various stages are not necessarily separate in time, but can be found along a single salt wall connected by strike -parallel salt flow (indicated by *grey shading* linking the profiles, see Fig. 6.27 for generalised 3D. See text for detail on stages **a**–**e** (after Vendeville and Jackson 1992b)

6.29). This effect is increased if the overburden filling the graben has an average density greater than that of the salt. Strike-parallel salt flow may keep parts of the wall emergent even after the salt source layer is exhausted.

In other words, stages a–e in Fig. 6.29 and time 1–4 in Fig. 6.30b, can occur along strike within a single salt wall. Where subsidence is accommodating regional extension, salt tends to move into the rising (reactive-passive) sections of the wall and away from subsiding depressions below the crestal grabens (Fig. 6.27). As salt flows into the intervening culminations along the wall they evolve from elongate walls into increasingly pluglike, rounded diapirs. If extension continues, these rising diapirs, which are commonly emergent, continue to widen and accommodate the regional extension without faulting. With sufficient extension, these diapirs ultimately exhaust their salt supply so that they too must subside and be buried.

Prior to the work of Vendeville and Jackson (1992b) on falling diapirs experiencing regional extension, many of the crestal indented structures produced by diapir fall were attributed to salt dissolution or forceful active intrusion at the crest; all three possibilities should be evaluated in any areas of crestal grabens or remnant salt cusps/rollers.

Falling Diapirs Drive Raft Tectonics

In some areas of falling diapirs the overburden becomes stretched to two or three times its original length by normal faulting, but the sub-salt basement is not involved. A weak intervening ductile layer or décollement of salt enables this prodigious extension of the overburden over a non-deforming basement. This style of overburden deformation is called raft tectonics and defines an extreme form of thin-skinned extension[11] or gravity sliding, whereby rigid sediment blocks slip downslope atop a décollement layer of evaporite or shale

[11] Thin-skin tectonics describes a situation where most of the deformation occurs in sediments above a regional décollement and structures in the basement below the décollement are different to those above. Sometimes called a "no basement" structural interpretation. Its corollary is "thick-skinned" tectonics, which involves related deformation of both basement and salt cover.

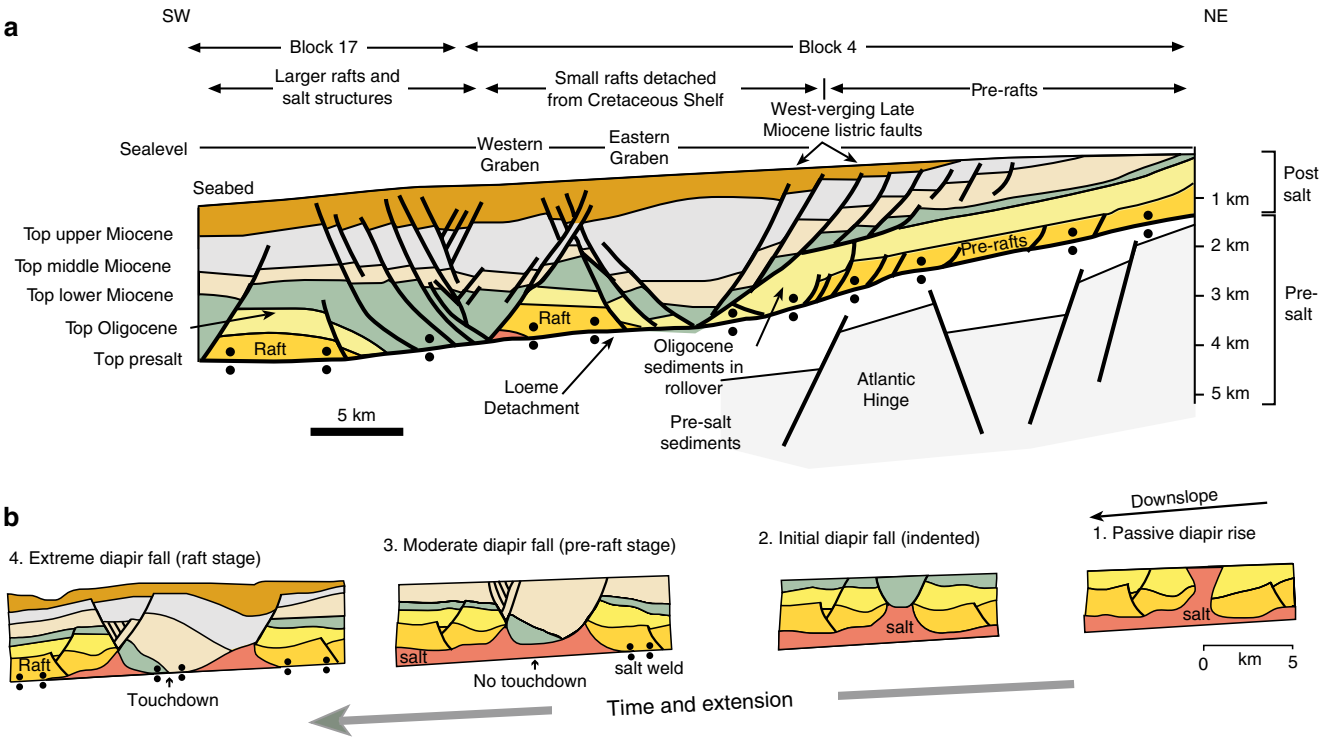

Fig. 6.30 Raft Tectonics, Angola. (**a**) NE-SW section through the Block 4 region of the Lower Congo Basin (Anderson et al. 2000). West-dipping listric faults affect the late Cretaceous sediments in the east of the block. Further west, Miocene extensional faults and associated grabens separate an isolated Cretaceous fault block (raft) from the equivalent Cretaceous sediments on the shelf. A similar structural style, characterised by thin-skinned faults, exists to the west but with relatively simple Cretaceous roll-over anticlines. Each of these isolated fault blocks is separated from neighbouring fault blocks by Miocene grabens (Eastern and Western grabens). The Miocene faults flatten downwards onto a salt detachment in the Loeme Formation. (**b**) Restoration model of a falling diapir in the zone of raft tectonics of the Kwanza Basin, Angola (After Schultz-Ela 1992 and based on a seismic line in Duval et al. 1992)

(Figs. 6.1b and 6.8a; Spathopoulos 1996; Cramez and Jackson 2000; Fort et al. 2004; Morley et al. 2011).

Raft tectonics characterises areas of large-scale extension where the hanging wall of an extensional salt-soled fault separates completely from the footwall, creating a fault weld via coherent slippage along the salt detachment surface (Fig. 6.30a; Duval et al. 1992). In other words these rafts are allochthonous fault-defined overburden blocks that have slipped downdip to become so far apart they are no longer in mutual contact across the growing fault that once separated them. Rafts characterise extensional geometries beneath the modern shelf and rise of Brazil in South America, Angola in central West Africa and the Gulf of Mexico (Fig. 6.1b; Anderson et al. 2000; Fiduk et al. 2004; Dutton and Trudgill 2009). Similar large rafts characterise blocks of Zechstein sediment in the NW Permian Basin of the North Sea (Clark et al. 1998). In this case, the blocks of sediment are composed of platform anhydrite, which slid into the basin atop a halite lubricated sole.

With less extension the fault blocks are called pre-rafts as they remain in mutual contact across the fault and parts of the hanging wall still rests on its original footwall. Rafting movement produces listric faults and sediment-filled grabens atop a deflating salt mass. Sediment-filled grabens separating raft blocks can be substantial structures; the Quenguela Graben in the Kwanza Basin is 20 km wide and 90 km long, the nearby Gaivota Graben is 15–20 km wide and 225 km long (Cramez and Jackson 2000).

With initial extension between two overburden blocks, a salt wall first rises passively to fill the increasing gap (Fig. 6.30b; time 1). Once the supply of salt can no longer keep up with demand, the diapir starts to fall. The crest of the sagging diapir becomes a subsiding trough that fills rapidly with sediment (Fig. 6.30b – time 3). While stretching and décollement are active the thickness of the evaporite layer is reduced both by downslope gravity drainage of the salt and ongoing dissolution. Once most of the salt is removed from under the sliding blocks, they ground or weld on the presalt layers and the downslope movement of the blocks stop (Fig. 6.30b – time 4). Stretching or extension that drives raft tectonics can usually be attributed to gravity gliding. Gravity gliding drives the translation of fault blocks down a gentle slope, driven by the downslope shear stress component of gravity on a tilted mass atop a mobile layer.

Regionally, salt basins characterised by raft tectonics can usually be divided into two different stress regimes (Fig. 6.1b;

Spathopoulos 1996; Cramez and Jackson 2000): an updip extensional regime located under the shelf and upper slope where salt décollement has facilitated the breakup of overlying sediments into raft blocks, and a downdip compressional or contractional regime typically under the lower continental slope where the up dip extension is taken up in a fold or thrust province (Fig. 6.1b). Raft tectonics requires the creation of substantial lateral space into which the overburden can expand during stretching. Downdip space is generated by: (1) formation of a downdip fold or thrust belt, (2) down dip displacement of autochthonous salt into allochthonous salt sheets that climb the stratigraphy, and (3) generation of new oceanic crust by a spreading ridge with allochthonous salt allowing overlying blocks to slide (Duval et al. 1992). Downdip compressional terrain is discussed in more detail later in the chapter.

Salt as Sheets, Allochthons and Breakouts

Allochthonous salt sheets are flowing salt masses that have been moved by low temperature tectonic processes, so that the front edge of the salt flow overlies younger strata and it is typically no longer connected with the mother salt bed. Allochthons have areas measured in hundreds of square kilometres and salt thicknesses ranging up to several kilometres. They typically indicate into-the-basin translation of the salt mass and its overburden. Salt allochthons typically lie at or very near the surface when actively inflating with salt (Fig. 6.31). Some authors draw a distinction between an allochthon and a namakier, using namakier to describe the structure created by the extrusion of allochthonous salt onto a continental landsurface, as exemplified by salt landforms in Iran. Others use the terms salt allochthon and namakier interchangeably.

In contrast to an allochthon, an autochthonous salt structure extends continuously down to the primary source layer and may not have experienced substantial lateral translation (Rowan et al. 1999). Allochthonous salt sheets characterise the present day continental margins of offshore Brazil, the Gulf of Mexico, West Africa, the North Sea and the Red Sea and outcrop as namakiers or their remnants in Iran, Algeria, Yemen, Mexico and Australia (Hudec and Jackson 2006). The recognition of allochthons as potential traps in deepwater petroleum provinces has opened up possibilities of prodigious subsalt hydrocarbon reservoirs, particularly in continental slope and rise sediments in the various circum-Atlantic salt basins (Chap. 10).

Over the past four decades, proposed mechanisms for salt allochthon emplacement include: recumbent folding, deep intrusion, shallow intrusion and surface extrusion (Fig. 6.31; Schultz-Ela and Jackson 1996). In all categories, a massive basinward flow of salt is a major part of the

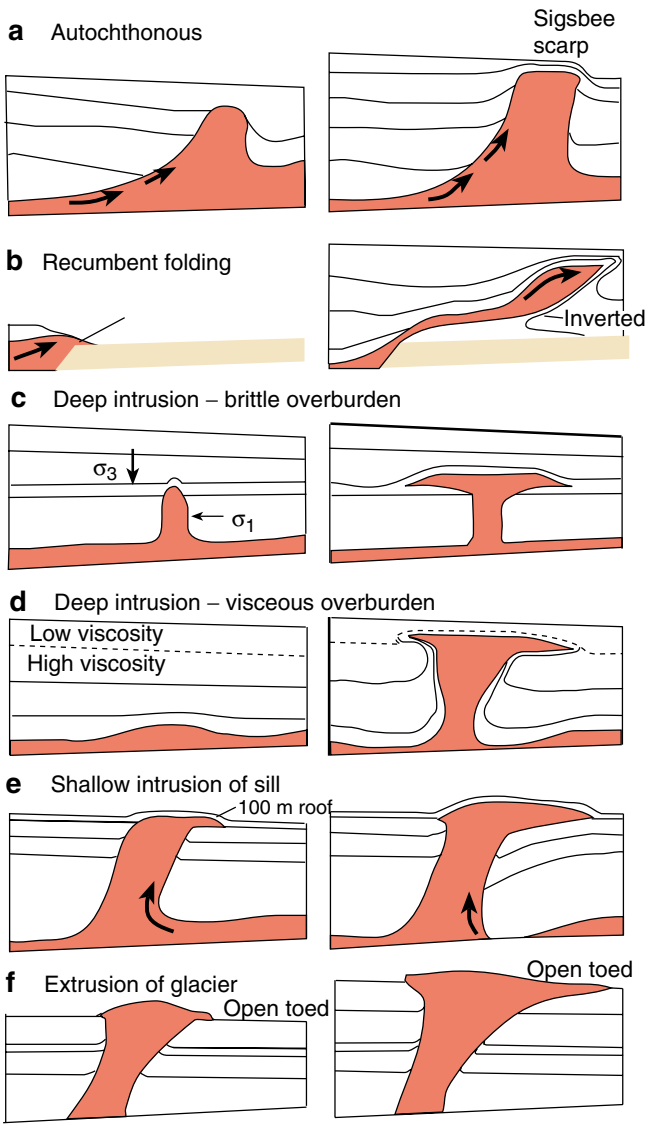

Fig. 6.31 Various hypotheses proposed for the emplacement of allochthonous salt sheets. See text for explanation of styles **a**–**f** (Modified from Schultz-Ela and Jackson 1996)

emplacement process in both subaerial and submarine settings (gravity gliding and gravity sliding). Ewing and Antoine (1966) envisaged the allochthonous Sigsbee Scarp was the basinward flowing edge of an autochthonous diapir (Fig. 6.31a). We now know their original interpretation, limited by the state of the seismic art at that time, was not correct in terms of its vertical connectivity to the mother salt bed. Amery (1969) discovered that the Sigsbee Scarp was the leading tip of a wedge of an allochthonous salt tier (Fig. 6.2).

Jackson and Cornelius (1987) modelled allochthonous salt sheets as flowing salt bodies ramping up to the nearsurface from a buried sub-salt step. On reaching the nearsurface the suprasalt wedge then spread rapidly under gravity

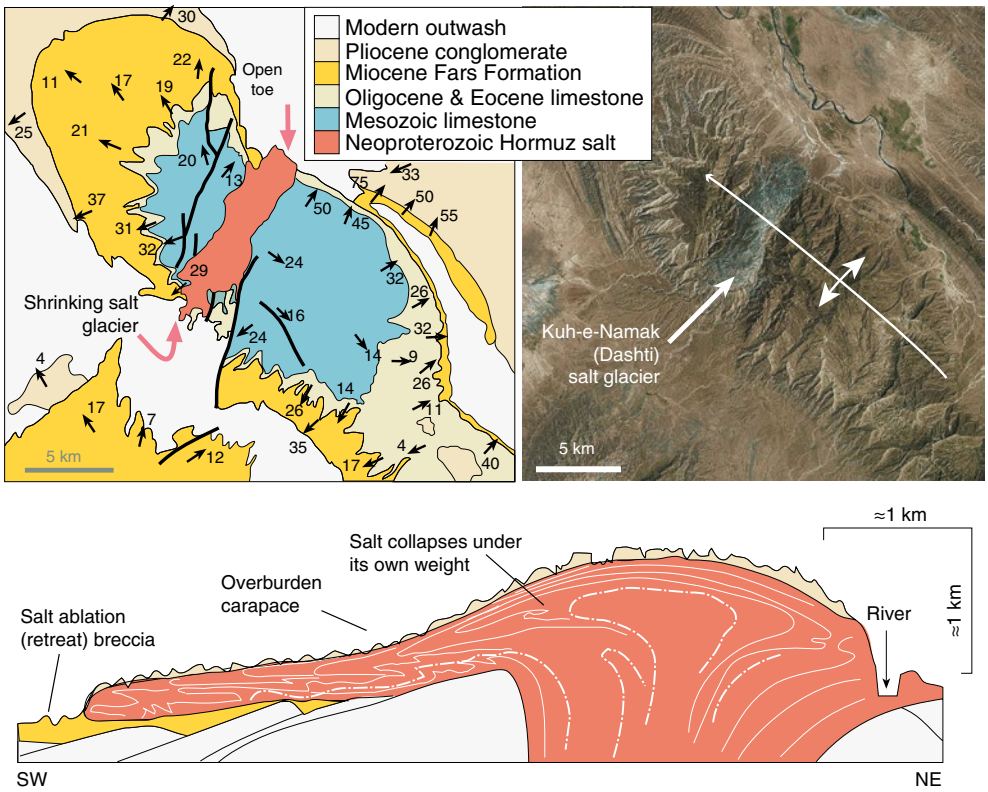

Fig. 6.32 (**a**, **b**) Surface geology (*left*) and Landsat image (*right*) of Kuk-e-Namak salt plug (Dashti Province), Iran, 28°16′N, 51°42′E. Faults, intersecting the plunging anticlinal dome, facilitated salt breakout and drove the formation of a surface salt glacier, or namakier, which is flowing away from the salt-core anticlinal ridge (see also Fig. 6.34). *Black arrows* indicate bedding dip and azimuth in the anticlinal beds. (**c**) Schematic cross section showing likely internal folds show how salt flows over the landscape like the rolling track of a military tank (After Kent 1958; Talbot 1979, 1998; Bing® image mounted in MapInfo® software)

as a recumbent fold anticline. Based on their modelling and analogs in the namakiers of Iran, they argued the allochthon edge advanced like a tank track rolling out over itself, creating a core of allochthonous salt and a laterally sliding carapace of deformed sedimentary overburden in a flow process know as tank-track advance or frontal rolling. This occurs when the advancing upper surface of a salt sheet moves faster than its base. Thus it advances and it rolls over and the lower portion adheres to the substratum below the salt. This advance lengthens the base of the salt, so forming a series of recumbent folds (Fig. 6.31b). As such an allochthon rolls out over the landscape it carries with it the veneer of accumulating and deforming sediment known as a carapace. When later buried and drilled, carapace sediments atop a salt sheet may be older than those below. This is case in the Vermilion #356 well drilled through a Gulf of Mexico salt sheet by Amoco in 1988. The highly overpressured section beneath the salt sheet is younger than the condensed suprasalt section in the same well (Harrison and Patton 1995).

D'Onfro (1988) modelled allochthonous salt sheets as dykes and sills that were intruded in areas of local compression, such as the toe regions of growth faults (Figs. 6.31c, d). Podladchikov et al. (1993) modelled asymmetric salt sheets as intruding laterally from a diapiric salt mass at depths of approximately 1 km depth. This level, according to the authors, lies just above an abrupt 1,000-fold downward increase in the viscosity in what otherwise are uniformly viscous sediments (Fig. 6.31d). Amery (1969, 1978) envisaged shallow allochthonous intrusion of the spreading salt layer as occurring beneath a thin sediment roof that was no more than 200–300 m thick. He visualised the salt as coming from an autochthonous diapir source. Nelson (1991) stated that most salt sheets in the Gulf of Mexico had been emplaced shallow at depths of around 100 m and never more than 300 m (Figs. 6.7b and 6.31e). Talbot (1993) pointed out the resemblance of salt sheet profiles to viscous fountains spreading laterally into unconsolidated surface muds (Figs. 6.31f). The stepped base to many salt allochthons attest to their emplacement as surface rather than shallow subsurface features (Fig. 6.26c). At-surface stepped allochthon emplacement mechanisms and associated salt flow textures were first supported by studies of salt features various Kuh-e-Namak outcrops in Dashti province and the Great Kavir regions of Iran (Fig. 6.32, Kent 1958; Talbot 1979; Jackson et al. 1990).

Periodic salt breakout is a consequence that is inherent to shallow or at-surface styles of allochthon emplacement. Breakout describes a process or place where a buried salt sheet is exposed by erosion or roof extension and where an exposed pressurised salt mass advances by extrusion and gravity spreading (Jackson et al. 1994a, b). The advancing sheet is termed open-toed when salt moves as an at-surface tongue or namakier with no more than a thin veneer of residual sediment, which is carried along by the expanding sheet as it flows toward topographic lows. This is illustrated by the

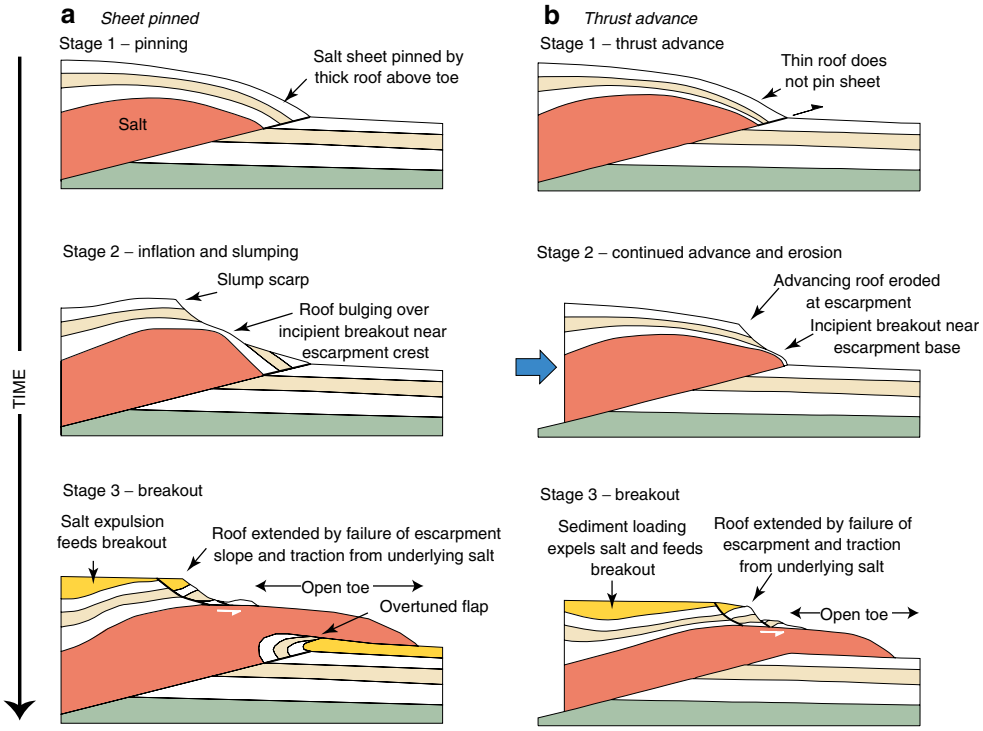

Fig. 6.33 Salt Breakout. The geometry of breakout at the toe of a salt sheet depends on whether the roof is thick and strong enough to pin the toe of the sheet (Hudec and Jackson 2006)

Kuh-e-Namak outcrop in Dashti Province, Iran (Fig. 6.32). This namakier is also interesting as in the same at-surface salt mass it exhibits simultaneous salt ablation retreat rims on the more extensive south-western margin and an open toe allochthon, maintained by river erosion and suffusion carapace removal, on the northeastern edge of the salt tongue (Fig. 6.32c).

There are two ways salt can breakout (sheet-pinned versus thrust advance) and they are dependent on whether or not the roof is thick and strong enough to pin the toe of the sheet (Fig. 6.33; Jackson et al. 1994b; Hudec and Jackson 2006). If the roof is thick and strong enough to pin the toe of the sheet, then the minibasins subsiding into the rear of the sheet and mostly off section in the illustration can laterally expel underlying salt, which then inflates (pressurises) the toe of the sheet (Fig. 6.33a- stage 1). This steepens the frontal escarpment, causing slope failure of its upper part (Fig. 6.33a-stage 2). Salt breaks through the thinned roof near the crest of the escarpment. Roof strata at the escarpment below the breakout are inverted to form an overturned flap (Fig. 6.33a-stage 3). If, however, the roof is not strong enough to contain the sheet, as illustrated in Fig. 6.33b, then the roof and salt sheet advance together as a thrust. If the leading edge of this thrust is sufficiently eroded, salt breaks out near the base of the escarpment, via a process known as thrust advance and open-toed advance begins.

During times of active extrusion a salt sheet forms a topographic or bathymetric high, with up to several hundred metres of relief above the surrounding seafloor. A feedback occurs between the rate at which salt is pumped to the surface and the rate at which meteoric or marine waters dissolves the salt. The rate of salt pumping is thought to be many times greater than the sedimentation rate during peak growth periods of the allochthon (Fig. 6.26). Expanding salt sheets are protected from dissolution by a combination of: (1) a sediment veneer or carapace, (2) an insoluble residue (caprock) of relatively impervious anhydrite/gypsum, and (3) an overlying layer of saturated pore brines where circulation of meteoric or marine pore water is locally restricted. If continuously deposited, a low-permeability sedimentary roof, alone, can protect underlying salt, even if the roof is continuously breached by deformation and erosion.

Historically, ancient equivalents of salt glaciers were not widely recognised in the rock record. Now, with our improving understanding of salt tectonics and the different styles of salt dissolution, ancient counterparts have been documented at increasing numbers of surface and subsurface locations, which include; Kazakhstan, Algeria, Tunisia, Yemen, Australia, Mexico and NW Europe (Volozh et al. 1994; Vila et al. 1994, 2002; Davison et al. 1996b; Dyson 1998; Giles and Lawton 1999; Mohr et al. 2007, respectively). Figure 6.34 illustrates an autochthonous salt tongue sourced in Permian Zechstein salt and emplaced onto an arid Triassic (Upper Keuper) landscape (Mohr et al. 2007). Through its partial dissolution at the time it was emplaced it supplied brine to adjacent playa sumps to form salt beds in the hyperarid Triassic desert (Warren 2008).

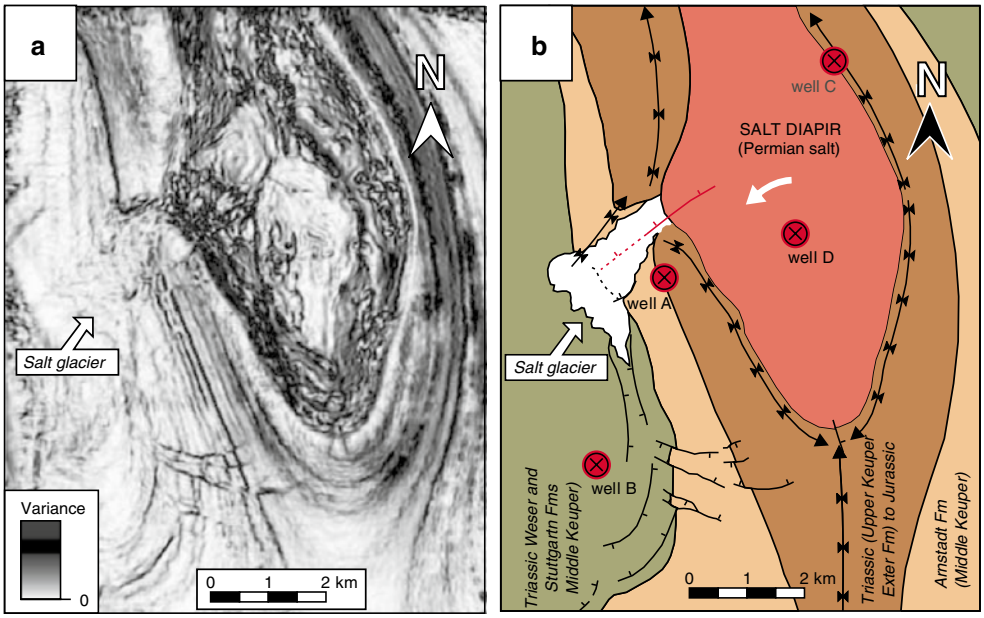

Fig. 6.34 Salt sheet emplacement in the Triassic (Keuper Sediments of Germany (After Mohr et al. 2007). (**a**) Variance map some 50 m below unconformity at base of the Cretaceous. It displays the uppermost salt extrusion as fan-like structure. There are three levels of salt tongue in this section of the salt wall. (**b**) Geological interpretation of **a** showing location geometry of Late Triassic salt glacier as well as the location of the wells used to verify the seismic interpretation and nature of the salt distribution

As any salt glacier or allochthon sheet spreads out over the surrounding landscape or seafloor, it also laterally transports and deforms its roof. Flow also induces drag folds and overturned flaps in subsalt sediments, to ultimately create transition zones known as basal shears. With the exception of the namakiers of Iran, most areas where allochthons outcrop are no longer characterised by salt actively flowing at the surface. Rather, the former presence of thick flowing sheets of salt are indicated by dissolution breccias and welds and associated deformation in the cap and the surrounds of the former sheet (Figs. 6.32, 7.29 and 7.30).

Inflation, Deflation, Welds and Basal (Subsalt) Shear Zones

There are two major stages in salt allochthon emplacement (Montgomery and Moore 1997): (1) Initial inflation and local loading of a salt mass, which then generates zones of salt withdrawal and diapir formation (Fig. 6.35a; times 1–3); and (2). Subsequent widespread suprasalt loading and salt deflation, which creates complex salt welds and suprasalt growth faults usually classified as regional or counterregional faults (Fig. 6.35a; times 3–5).This second stage creates salt tiers in levels of the stratigraphy that lie well above the primary salt level. Salt emplacement at all stages involves a combination of syndepositional dissolution and shearing at the allochthon contacts. Emplacement can be associated with gravity spreading and/or coalescence of a number of salt sheets to form a salt canopy, which is in turn evacuated by later sediment loading (Fig. 6.35b). Once emergent, an allochthonous salt sheet expands its area at the same time it is deflating, loading and segmenting into smaller second-generation structures via loading. The top and bottom contacts of the initial salt sheet come closer and closer together until touchdown occurs and the amalgamation surface becomes a salt weld.

Salt Inflation and Extrusion

There are four types of salt inflation or allochthon development possible in a sedimentary basin (Fig. 6.36; Hudec and Jackson 2006), they are; (a) Extrusive advance, (b) Open-toed advance, (c) Thrust advance, and, (d) Salt-wing intrusion. The style that dominates the allochthon at any time in its history depends on the source of the salt, the tectonic setting, and the sedimentary environment. Consequently, a wide range of evolutionary sequences or possible allochthon evolution lineages are possible Most common emplacement styles are plug-fed extrusions, plug-fed thrusts, and source-fed thrusts, which are defined by the geometry of the feeder structure and by their initial mode of advance (Fig. 6.37). Each lineage involves an evolution from extrusive advance, through open-toed advance, and then thrust advance. Allochthons can become pinned (forward advance slowed) via deposition of the wedge of thick overburden until salt breakout occurs and extrusive or open-toed advance takes over once more. Typically, the allochthon sheet stops moving into the basin when salt deflation cuts off the salt supply. It may then dissolve completely or be buried.

Plug-Fed Extrusion

A plug-fed extrusion or allochthon forms when a sheet extrudes from the top of a vertical or steeply dipping diapir (Figs. 6.36a and 6.37b). Plug-fed thrusts form when a diapir having a thick roof is shortened. The roof is too thick to be immediately disrupted, so the sheet initiates in the hanging wall of a diapir-roof thrust. If shortening continues, the sheet may breakout at the surface and evolve into an open-toed sheet. Given sufficient suprasalt sedimentation rates, this sheet is eventually buried. Compressional reactivation of

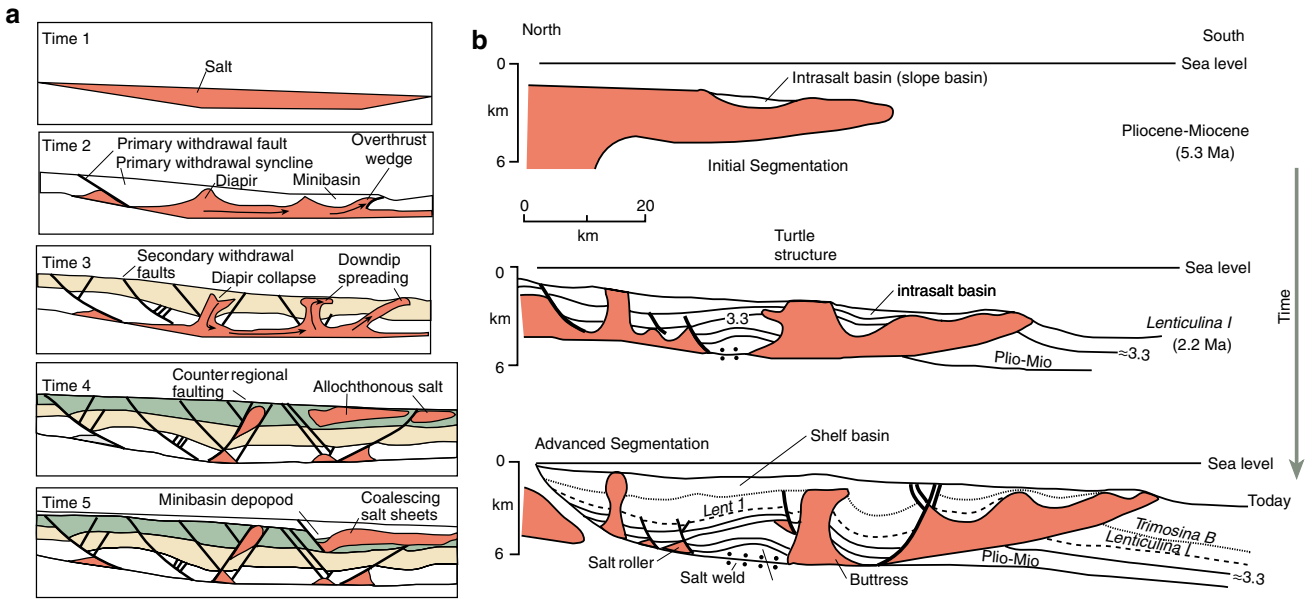

Fig. 6.35 Salt allochthon evolution. (**a**) Evolutionary model of the creation of allochthonous salt sheets in the Gulf of Mexico (After Montgomery and Moore 1997). (**b**) Schematic of evolution of eastern Green Canyon, Gulf of Mexico. At 5.3 Ma the salt sheet was extruded. From 6.3 to 3.3 Ma the ongoing basinward extension of the sheet promoted differential loading within half grabens. From 3.3 to 2.2 Ma the largest intrasalt basin displaced all the salt below it to create a salt weld and a structural inversion that was created by a turtle structure. Subsequently the sheet was further deformed as it continued to flow basinward and climb the stratigraphy (Modified from Seni and Jackson 1992a, b)

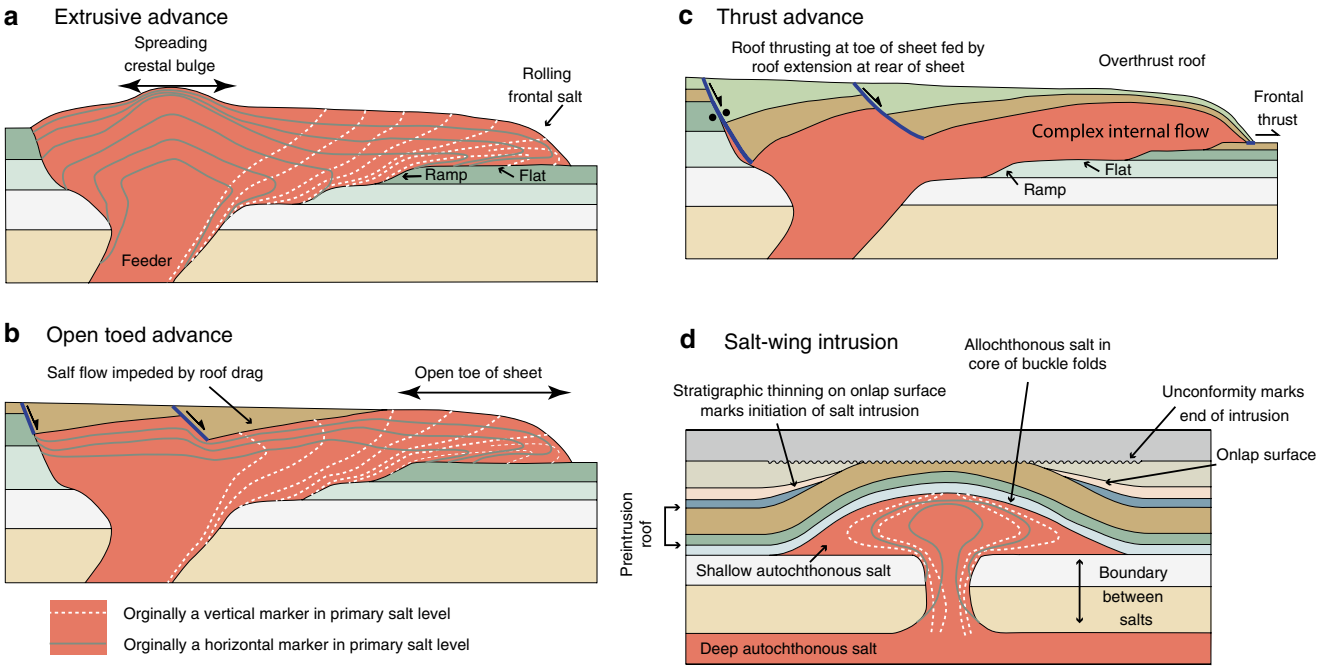

Fig. 6.36 Emplacement of salt sheets. Salt sheets can advance in four ways. In extrusive advance (**a**), an exposed salt sheet spreads at the surface without a roof. The salt flows outward by gravity, spreading from a summit formed by a dynamic bulge above the feeder. Deformation of passive marker lines here illustrates frontal rolling, which is common above lithified bedrock but less typical above unlithified subsalt strata. In open-toed advance (**b**), the sheet is extrusive at its toe but is partly buried by a roof strong enough to modify the underlying salt flow. The roof resists salt flow. Traction exerted on the roof by flow of the underlying salt may extend a sufficiently weak roof. In thrust advance (**c**), a buried sheet advances along with its roof in a thrust hanging wall. The roof is separated from peripheral sediments by a roof-edge thrust fault that projects from the tip of the salt to the surface. During salt-wing intrusion (**d**), a wedge of salt is emplaced along a thin delaminating stratigraphic layer in the flanking country rock. The roof is typically uplifted as a detachment anticline during regional shortening. This arching typically leads to onlap or erosion of the roof strata. These processes can occur sequentially during growth of a sheet to produce salt-sheet lineages as illustrated in Fig. 6.33 (After Hudec and Jackson 2006)

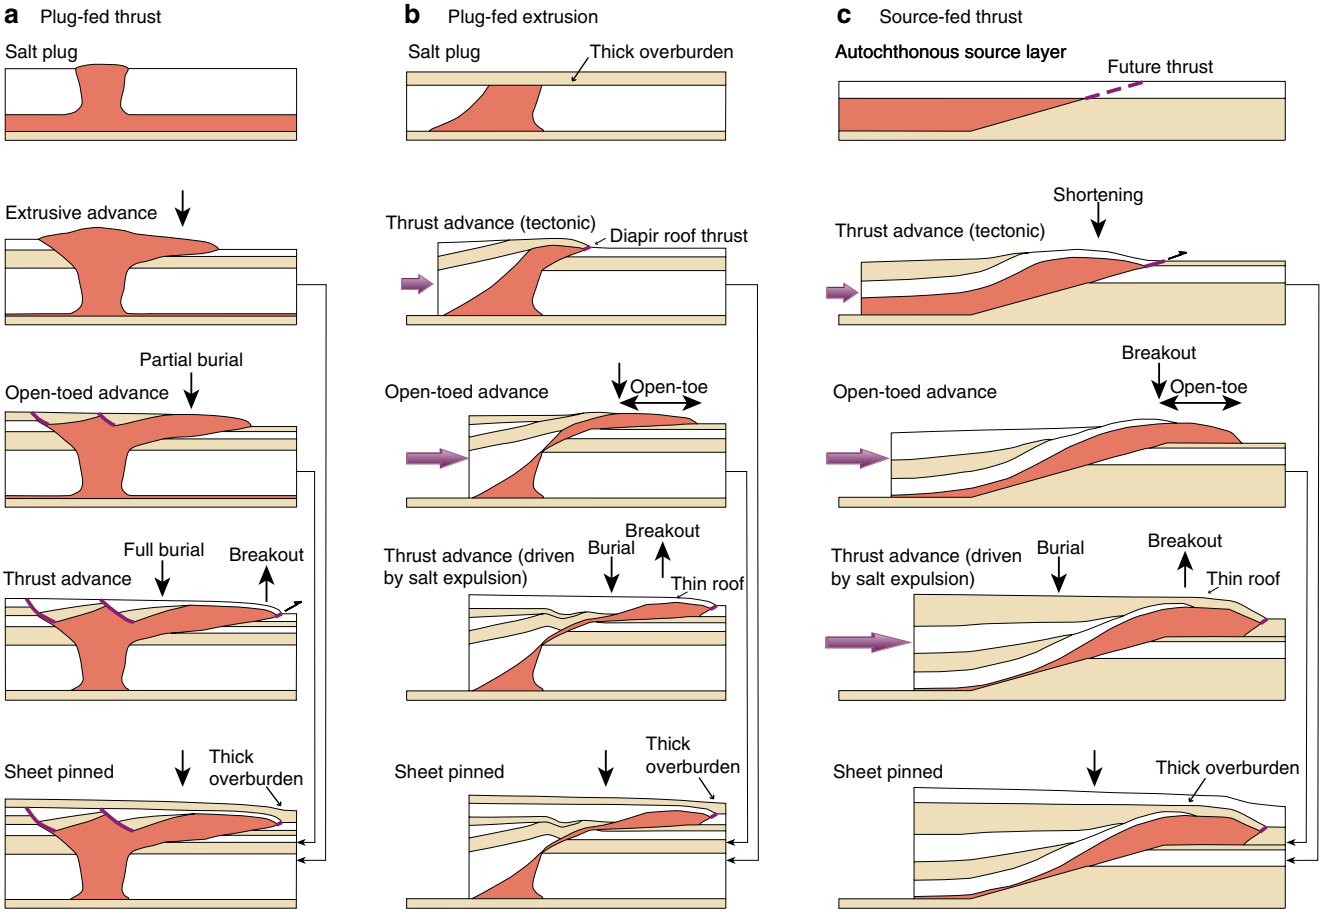

Fig. 6.37 Emplacement of salt sheets. Most salt sheets advance by a time related sequence of extrusion, open-toed advance, and thrusting. These modes may combine in many ways over the life span of a salt sheet, but three evolutionary sequences (or lineages) are particularly common. (**a**) Plug-fed extrusions. (**b**) Plug-fed thrusts, and (**c**) Source-fed thrusts. See Fig. 6.38 for 3D reconstruction of plug-fed versus source-fed styles (After Hudec and Jackson 2006)

buried diapirs is common in orogenic belts that involve salt basins and in some compressional provinces in deep-water passive margins (Mohr et al. 2007; Ventisette et al. 2005; Saintot et al. 2003). The term "salt plug", as used by Hudec and Jackson (2006) encompasses both salt stocks and salt walls (see Fig. 6.1a), although most plug-fed extrusions are sourced from stocks. Plug-fed extrusions are probably the most common type of salt sheet feeder, worldwide, and form in both passive margins and orogens.

Extrusive salt sheets spread whenever salt in a downbuilding diapir rises faster than dissolution, erosion, and sediment aggradation can remove or contain it (Fig. 6.26b). Plug-fed extrusion is typically initiated by decreases in dissolution, erosion, or sediment aggradation rates or an increase in salt-rise rate. Decreased aggradation can result from decreased sedimentation associated by changes in sea level, climate, source-area tectonics, or sediment-transport systems. Alternatively, slow aggradation may be caused by increased subsidence in local basins adjacent to the diapir. Slower sediment aggradation allows salt to spread more rapidly along a base-salt flat (Fig. 6.26c). Regional sediment starvation can therefore simultaneously initiate extrusive sheets from many domes. These sheets can eventually coalesce to form salt canopies, as in the continental rise of the Gulf of Mexico (Hudec and Jackson 2006).

Onshore, when salt is near to or at the surface, extreme aridity can retard salt dissolution and the extruded or open-toed allochthon's passage into thrust-advance or sheet-pinned styles. Limiting dissolution and allochthon passage into thrust-advanced and sheet-pinned styles is more difficult in subaqueous settings. Even an accumulation of a thin roof or carapace of caprock or sediment can retard dissolution in subaqueous settings. These sediment veneers tend to be ephemeral because vigorous, multidirectional spreading of a salt sheet tends to dismember any roof or cap rock. However, rapid sedimentation or cap-rock formation can create a new impermeable layer faster than the old one is disrupted. This can retard dissolution and the transition into deflation even in an actively spreading sheet. Mechanical erosion of evaporites is likely to be more important in spreading of the salt

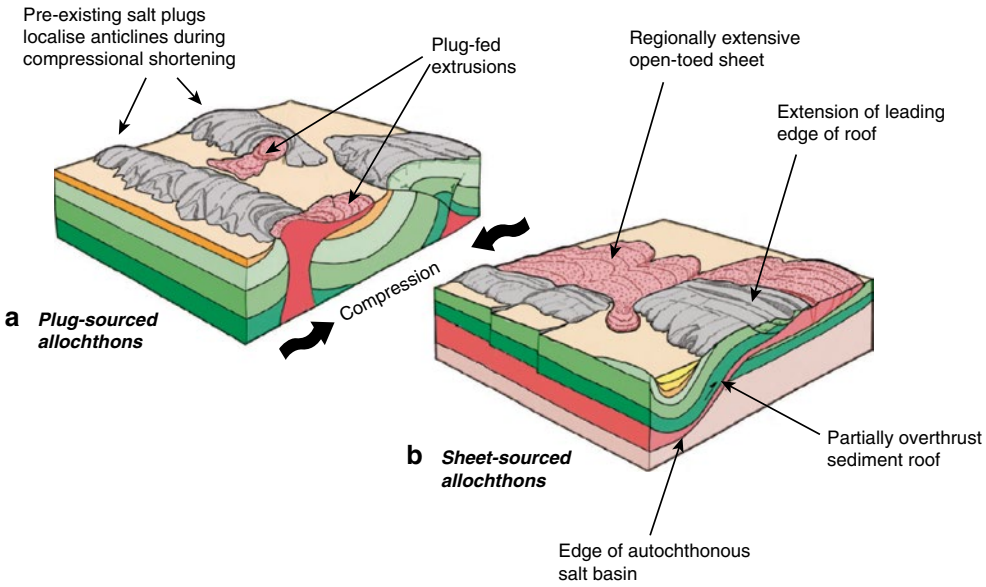

Fig. 6.38 Varying salt source geometries. (**a**) Plug sourced salt sheets. (**b**) Source-fed thrust décollement that broke out to form open-toed salt sheets (After Hudec and Jackson 2006)

sheet in arid or polar settings, where dissolution is less effective (Chap. 7). In humid or subaqueous environment the transition to deflation and gravity spreading is rapid if the load on the source layer is high (a viscous salt blowout). A sheet produced by a salt blowout, where salt escapes under elevated pressures, is more likely to have a flat base over a broad area because the sheet advances much faster than the sediments can aggrade. This effect is enhanced if the blowout occurs during a sedimentary hiatus.

Lateral shortening of a dome is especially effective in triggering a plug-fed extrusion (Fig. 6.37a). In addition to any salt blowout caused by the disruption of the plug's roof, inward convergence of the walls displaces salt from the diapir. As for sheets triggered by roof disruption, regional compression typically causes the rapid advance of sheets, which results in a flat base of salt.

Roof Deposition or Salt Burial

The flow of an unbuttressed extrusive sheet is typically radially outward, with a preferred direction down the local slope (Fig. 6.38a, b). This outward salt flow continually dismembers the roof sediment. Deposition of a permanent roof does not typically begin until either the sheet advance slows markedly, or the salt streamlines become parallel instead of radial (Fig. 6.36b). This transition can occur for three reasons (Hudec and Jackson 2006) and for each, a salt supply deceleration or change from radial spreading allows a continuous roof to accumulate.

First, sheet advance slows if salt supply from the feeder is reduced. This can occur if the source layer is depleted enough that increasing boundary drag (edge friction) slows salt flow, or if the feeder stops shortening under compression, or if the feeder pinches off. Diminishing salt supply marks the transition from a salt fountain to a salt droplet; a salt fountain comprises a summit dome that feeds one or more salt glaciers; a salt droplet continues to spread until the relief of the former summit dome dissipates, resulting in an extrusion having a flat-topped profile and steep margins (Figs. 6.1a and 6.36)

Second, sheet advance will slow even if the salt feeder and fountain remain active, simply because radially spreading sheets require a progressively greater volume of salt for each additional increment of advance. This requirement explains why the measured advance rate of salt glaciers tends to decline toward their terminus (Talbot et al. 2000).

Finally, a sheet will slow where it meets a buttress. Some buttresses are sedimentary and an extrusive sheet advances most slowly where aggradation is most rapid. Pre-existing topography, such as mountains, anticlines, or scarps, can create other buttresses, especially onshore. Sheets can also be buttressed against adjacent sheets during salt suturing as a canopy forms. Thus, a radially spreading sheet becomes constrained to flow more unidirectionally if it sutures on each flank to become part of a canopy.

In most sedimentary environments, but especially in prograding margins, a roof does not accumulate uniformly over the entire salt sheet. Thus, open-toed advance typically follows extrusive advance (Fig. 6.36a transition into to 6.36b). The style of deposition above the salt sheet (synclinal minibasin, roho, or counter-regional) varies with the depositional environment and geometry of the sheet. All three styles expel salt from beneath the sinking minibasins (see next section). Salt expulsion can drive sheet advance by recycling salt even if the feeder no longer supplies salt. Open-toed advance continues until the sheet toe is buried (Fig. 6.36c), which happens in two ways. First, sedimentation can bury the toe while the sheet is still advancing. If so, the sheet will most likely continue to advance by thrusting, as is true along nearly all of the modern Sigsbee Escarpment in the northern Gulf of Mexico (Fig. 6.49; Hudec and Jackson 2009).

Second, the sheet may continue to advance as an open-toed sheet for a long period before being buried by a permanent roof. Salt expelled from beneath subsiding basins flows into a variety of salt structures. Some salt flows into rising diapirs; some is trapped as relics along a basal weld; some is dissolved; and some may feed continued advance of the sheet. The amount of salt available for sheet advance ultimately diminishes to exhaustion. Once the toe is buried, there may not be enough salt to feed any further advance by thrusting. Counter-regional salt systems behave like this, as do the later stages of some roho systems.

Thrust Advance

Once completely buried, a salt sheet may advance as a thrust as long as forces driving sheet advance can overcome the strength of the roof (Fig. 6.36c). Bigger sheets tend to advance by thrusting for a longer time. For example, the giant Sigsbee Escarpment has, in places, advanced more than 5 km since the burial of its toe (Jackson and Hudec 2004). In contrast, small, isolated sheets like the Mica salt sheet (centred on Mississippi Canyon, Block 166, northern Gulf of Mexico) have advanced at most a few hundred meters since burial (Fletcher et al. 1995). Thrust advance becomes more difficult as the roof thickens and strengthens, and so even the largest sheet should eventually be pinned in place by its overburden.

During thrust advance, mass wasting may re-expose parts of a sheet's leading edge and allow salt breakout (Fig. 6.33, stage 2). In contrast to source-fed thrusts (see below), where salt breakout is important, the only known examples of present-day breakout from diapir-fed sheets along the Sigsbee Escarpment are small and insignificant. Because of their small size, the exposed parts of these toes are likely to be soon reburied and the salt sheets will then resume advance as thrusts.

Plug-Fed Thrusts

Plug-fed thrusts form when a diapir's overburden is shortened by thrusting, carrying a sheet of salt from the diapir in the base of the thrust hangingwall (Fig. 6.37a, b). The style of deformation occurs during regional shortening if a thick, strong overburden prevents a laterally shortened salt plug from piercing to the surface. Thrusting is facilitated if the plug is inclined because slip along the more gently dipping diapir flank may nucleate the fault. Sheets of this type occur in orogenic belts and in deep-water fold and thrust belts. Many sheets of this type never progress beyond their initial thrusting stage.

If the overburden is kilometres thick when shortening begins, salt is unlikely to pierce to the surface without substantial erosion (Fig. 6.23). Structural style typically changes abruptly along strike from a salt sheet near the plug to a salt-free thrust fault away from the plug. Where diapirs predate shortening, transpressional thrust networks can form oblique to the regional shortening direction (Jackson et al. 2004). Such thrusts tend to form parallel and adjacent to the flanks of salt walls even if this direction is strongly oblique to the regional maximum compressive stress.

Some plug-fed salt-cored thrusts, however, have overburden thin enough to be eroded off during shortening. Erosion of the overburden above the thrust allows the salt to break out. If vigorous salt flow overcomes dissolution and sedimentation, open-toed sheet advance can begin (Fig. 6.36b). Extrusion can be rapid because salt is pressurized by tectonic compression or by a location at the foot of a slope.

After breakout, an open-toed sheet extruding from a plug-fed thrust advances over the sediment surface until its feeder is completely pinched shut, or the source layer is depleted of salt. The sheet then evolves through stages typical of open-toed advance: progressive burial, possible thrust advance (driven by gravity spreading of the sheet instead of by regional shortening), and eventual pinning. This postbreakout history can obscure an origin as a plug-fed thrust, especially if most of the prekinematic roof has been eroded.

Source-Fed Thrusts

A source-fed thrust forms when a thrust imbricate detaches on autochthonous salt and carries a slice of salt in its hanging wall (Figs. 6.37c and 6.38b). In Hudec and Jackson's (2006) terminology, "source" refers to the autochthonous salt layer, the source level for all the salt structures in the basin. Source-fed thrusts range from thin slivers in the hanging walls of small thrusts to salt-cored nappes involving kilometre-thick salt sheets displaced by many kilometres (Fig. 6.38b). The largest thrust-fed breakouts form near the edges of salt basins, where the salt-lubricated detachment stiffens by facies changes, thins, or disappears. Here, translation, aided by a subhorizontal salt detachment, must be accommodated beyond the salt by thrusts or folds in the overburden. Thrust systems fringing salt basins can extend along strike for hundreds of kilometres. Examples include the Angola salt nappe (>900 km long), the Guadalquivir allochthon (350 km long), the Salt Range allochthon (230 km long), and the Mesozoic nappe on which the Atwater foldbelt is detached in the northern Gulf of Mexico (160–240 km long).

Small source-fed thrusts may be too small to expose salt sheets at the surface. These sheets are preserved in the thrust-advance stage. However, many basin-edge structures have tens of kilometres of slip. Examples with large slips include; the Guadalquivir allochthon (25 km roof overthrust), the Salt Range allochthon (as much as 35 km roof overthrust), the Angola salt nappe (>20 km roof overthrust), and the West Lufilian allochthon (65 km roof overthrust). Coupled with uplift and erosion of the roof, this displacement allows salt to break out at the sediment surface to form open-toed sheets that are partly covered by the overthrust sedimentary roof

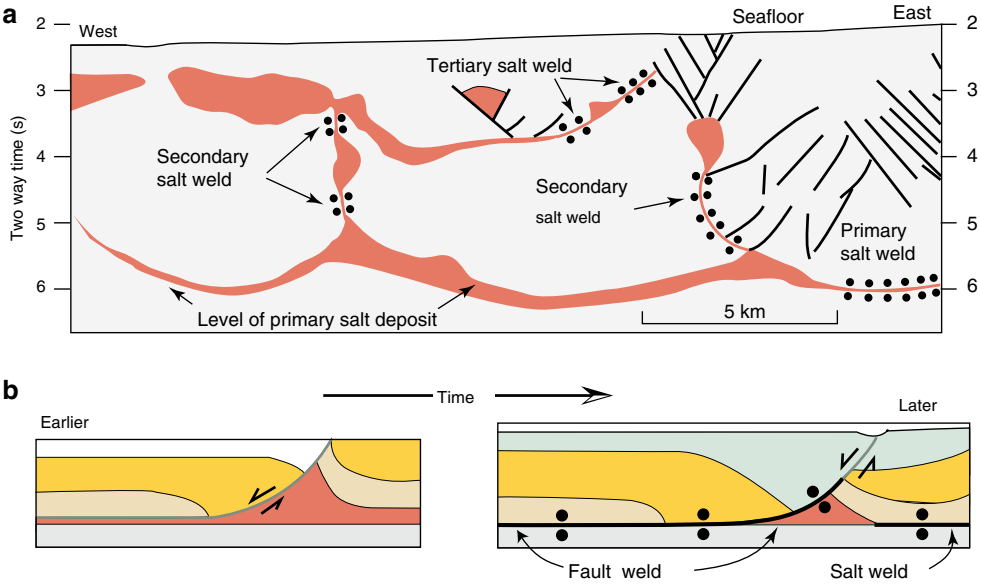

Fig. 6.39 Welds (**a**) Salt weld classification (see text for detail on weld types). This schematic cross section is based loosely on the geology of offshore Angola. (**b**) Salt weld versus fault weld (fault weld displacements can be normal or reverse-thrusted)

(Fig. 6.38b). Because shortening pressurizes salt, any breakout is likely to extrude rapidly as a salt blowout. An extrusive salt apron ahead of the thrust allochthon creates an excellent detachment for translation of the roof, which continues to advance. This detachment is so effective that the roof may extend while advancing over the lubricating sheet, as in the Scotian salt nappe, the Salt Range allochthon and the Rif allochthon in Morocco. Over time, the roof may advance completely across the salt, obscuring its origin as a salt breakout. Jackson et al. (2003) interpreted this style for the Neoproterozoic West Lufilian allochthon (Democratic Republic of Congo). There the evaporite sheet appears to have been extruded rapidly across a 65-km long flat, followed by more gradual overthrusting and buckling of the roof and burial by synorogenic sediments.

Large breakouts can obscure the origin of a sheet as a source-fed thrust. In orogenic belts, thrust ancestry is typically obvious from the regional setting (as in the Guadalquivir and Salt Range allochthons). However, on passive margins, some basin-edge nappes may have extruded out of the basin prior to deposition of a mechanically significant roof, driven by sediment loading farther updip and seaward tilting. If so, this would constitute another lineage: the source-fed extrusion. This origin has been proposed for the Mesozoic nappe below the Atwater foldbelt in the northern Gulf of Mexico.

Remembering that Hudec and Jackson's (2006) lineage classification, illustrated in Fig. 6.37, is based on the initial mode of sheet advance, the distinction between source-fed thrusts and source-fed extrusions must depend on roof thickness at the time of sheet initiation. This can be difficult to define as the evidence can be disturbed or obliterated by subsequent salt movements. A structure is a source-fed thrust if a mechanically significant roof was present at the onset of deformation, because the earliest phases of movement were by thrust advance. Breakout may have occurred very early during thrust advance if the roof was thin, but this does not change the classification of the sheet, as illustrated in Fig. 6.37c. Conversely, the structure is a source-fed extrusion if no mechanically significant roof was present when the sheet started to advance.

Given that most candidate structures for source-fed extrusion are deeply buried at the downdip ends of passive margins, little is known regarding the details of the preadvance roof. Hudec and Jackson (2006) recognize source-fed extrusions as a possible style, but think it is premature to recognize them as a common lineage until more details are available concerning their early history.

Salt Deflation and the Formation of a Weld

A salt weld forms when the salt sheet or primary bed is so thinned by withdrawal (deflation) that salt is no longer resolvable on seismic profiles (Fig. 6.39; Wagner III and Jackson 2011). Salt welds are also called evacuation surfaces, overburden touchdown scars, salt scars (literally *cicatrice salifére* in the French literature), or simply touchdowns. A salt weld is usually, but not always, marked by a structural discordance. Another distinctive feature is the common presence of a structural inversion above the salt weld, which often defines some sort of broad anticlinal structure (e.g. turtle and mock-turtle structures; Fig. 6.29). Subsurface welds are readily imaged in modern seismic surveys, but the temporal resolution of today's reflection seismic surveys is still too coarse to display the internal structure of welds (resolution is typically greater than ~30–50 m of halite for peak frequencies of ~10–30 Hz; Wagner III and Jackson 2011).

The term salt weld encompasses a zone that may or may not retain tens of metres of remnant evaporites and insoluble residues within the amalgamation interval that originally contained the halokinetic salt mass (Fig. 6.39). The position

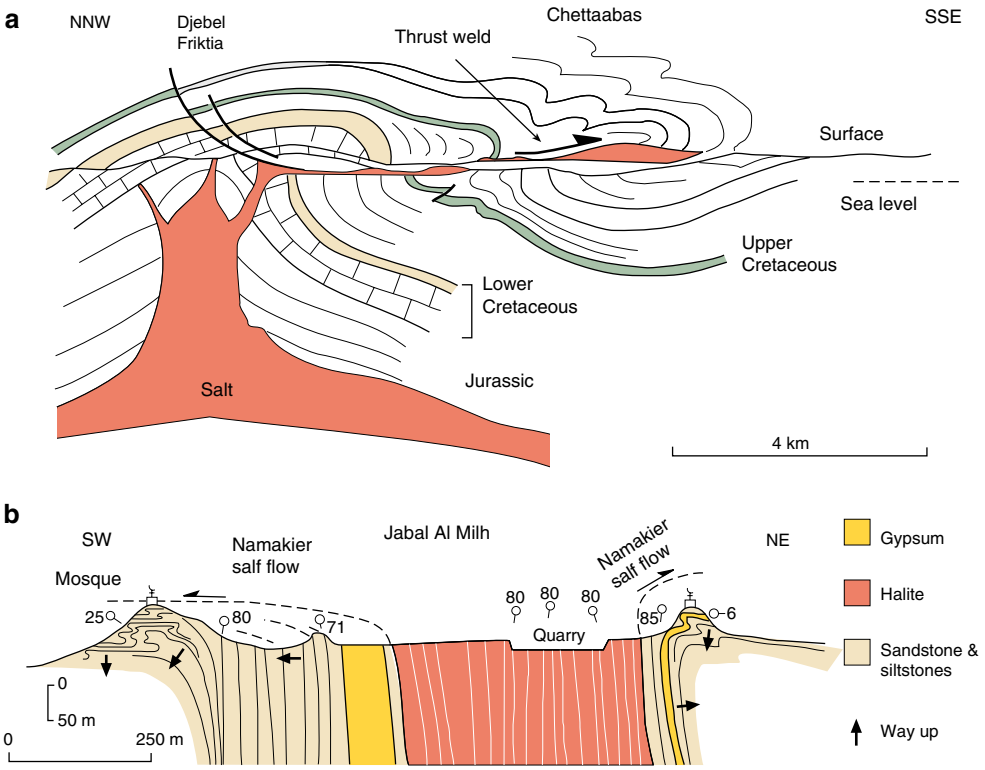

Fig. 6.40 Cross sections through outcropping salt allochthon terrains. (**a**) The Djebel Friktia allochthon, Algeria, shows how breakout of salt into the next allochthon tier typically evolves into a gravitational collapse 'thrust' off the original salt wall. This thrust is a gravitational adjustment to "down to the basin" extension in the overburden. Breakout occurs in areas where pressurized salt rises faster than extension and sedimentation can accommodate. (**b**) Recumbent folding and thrusting are the main deformation features observed in the siltstones and gypsum layers of the dissolution disturbed overburden at the margins of the Jabal Al Milh diapir, Yemen (After Davison et al. 1996b)

of a weld is usually, but not invariably, marked by structural discordance across the weld, as in the Friktia thrust weld (Fig. 6.40a).

A salt weld is a always surface joining strata originally separated by autochthonous or allochthonous salt (Fig. 6.39a. Lithologies on either side of the weld are in direct or near-direct contact, not separated by significant evaporite thicknesses or primary interlayered material. A primary weld joins strata originally separated by gently dipping autochthonous bedded salt at the level of primary salt deposition or mother salt bed (Fig. 6.39a). Secondary welds join minibasin or depopod strata originally separated by steep sided salt diapirs (walls or stocks). Tertiary welds join strata originally separated by gently dipping allochthonous salt sheets.

Each side of the weld can slip relative to the other, as it can in a more steeply inclined fault that is lubricated by salt. The latter structure is termed a fault weld, although all welds are tied to some sort of translation or shearing of strata above and below the salt sheet (Fig. 6.39a, b). A fault weld is a simply a recognisable fault surface or fault zone joining strata originally separated by autochthonous or allochthonous salt (Fig. 6.39b). Thus a fault weld can be a salt weld along which there has been obvious faulting or shearing. Faults styles and associated welds are discussed in detail later in this chapter.

As salt evacuates to form a weld, evidence of local salt loss is always recorded in overlying sediments via variable thicknesses, dispersal patterns, and facies distributions. An incomplete salt weld is a zone joining strata originally separated by autochthonous or allochthonous salt and still separated by up to 50 m of remnant evaporites and interlayered insolubles. A discontinuous weld is a salt body that is welded in places, but in other areas retains more than a 50 m thickness of evaporites and interbedded material. An apparent weld is a salt body that appears welded at the scale of observation, but which may actually contain more than 50 m of evaporites and interbedded material.

Better-documented geological examples of weld textures do not come from the subsurface but from outcrops of salt-cored structures in arid regions such as the Flinders Ranges Australia, Monterey region, Mexico and the Zagros and Qom foldbelts in the Middle East (Dyson and Rowan 2004; Rowan et al. 2012a; Morley et al. 2009). Figure 6.41 illustrates an outcropping example of a primary salt weld, left after dissolution/evacuation of Miocene salt, as studied by the author in central Iran. It outcrops in a succession of thrusted and overturned Miocene redbeds to the west of the Qom city and immediately south of the Indus thrust fault. The weld today is exposed as a near vertical (slightly overturned) outcrop pattern, marking the position of the former primary salt bed. Seismic across the outcrop into the adjacent Qom Basin to the south shows the outcrop is equivalent to a stratigraphic position once occupied by a 100 m plus-thick salt halokinetic mother salt bed (Morley et al. 2009). The outcrop consists of a central massive claystone residual

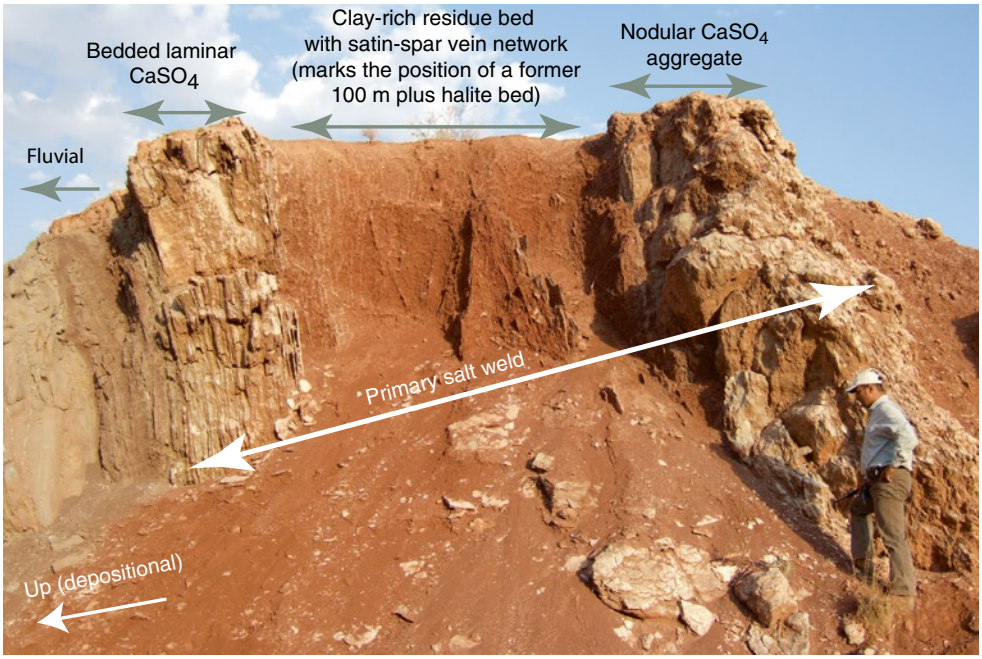

Fig. 6.41 Outcropping primary salt weld in thrust-upturned Miocene redbeds, located to the west of Qom City, Iran

bed, now crosscut by a network of cm-scale satin-spar veins. This unit is all that is left of the once 100+ m thick salt mass at the level of the primary mother salt. Either side of this residue claystone are stratabound beds of gypsum (anhydrite in the subsurface). Both these gypsum units are fractionated residuals formed as the salt flowed and dissolved in the subsurface. The lower gypsum bed is a nodular aggregate, with cm-scale textures indicative of a basal anhydrite, as exemplified by the diagenetic $CaSO_4$ bed (basal anhydrite) defining the underside of the Cretaceous Maha Sarakham salt, Thailand (Fig. 7.45). In contrast, the upper $CaSO_4$ bed is dominated by laminar textures similar in character to laminar $CaSO_4$ textures recovered in core from many Gulf of Mexico diapiric capstones.

Another example of a salt weld, visible in outcrop, comes from the La Popa basin, near Monterey, Mexico, there a subvertical salt weld is exposed for 25 km along its strike (see Fig. 6.106 and associated text for full geological detail; Rowan et al. 2003, 2012a). Traverses across the la Popa weld indicate significant strike-parallel variability in both weld structure and the geometry of adjacent strata. In some places the weld is a 2–4 m wide fault zone with brecciated and sheared siliciclastics, no remnant evaporites, and evidence of extensive fluid alteration adjacent to the weld. In other places, the weld contains up to 30 m of remnant gypsum, either massive or sheared, that locally contains inclusions of meta-igneous rocks or Jurassic dolostones that were carried up in the diapir. The La Popa weld ends in the west at an outcrop of gypsum several hundred metres in diameter that represents a remnant salt stock. In contrast, the weld trace is truncated in the southeast by an intra-Maastrichtian unconformity (see later in this chapter for geological detail).

Flow Edges, Basal Shearing and Salty Gumbos

Shearing associated with the margins of salt diapirs has long been recognised as creating shale sheaths and shear-defined cylinders of differential salt movement within downbuilding subvertical diapirs (Hanna 1953). This is especially obvious within subvertical salt structures that have been mined or crop out (Balk 1953; Kupfer 1976; Talbot and Jackson 1987a; Zak and Freund 1980). What differentiates classic subvertical diapir models from the lateral flow emphasis of more recent allochthon models is an understanding of the development of minibasins and listric faults in supra-allochthon sediments and the typical creation of a sheared interval at the basal sediment-salt contact (Fig. 6.42a).

Once an allochthonous salt sheet is detached from its source layer, pods of condensed sediment are deposited as a roof carapace (e.g. palaeontological equivalent of unit 5 in Fig. 6.42a). This suprasalt region loads and splits into a number of growth-fault defined suprasalt depopods (layers 1–4 in Fig. 6.42a). Sediment accommodation space is created at the up dip end of this expanding depopod system via growth faulting, while thrusting and erosion is occurring at the same time at the downdip end (Figs. 6.36b, c and 6.42b). The rotation of the suprasalt sediment prism as it accumulates is facilitated by the lateral migration of salt. Internal shear in the advancing salt sheet is greatest in the salt's basal shear zone.

Sediments beneath the base of subhorizontal allochthon sheets or the subsequent welds typically preserve shear features that encompass both external and internal shear zones. They include; evidence of sediment pressurization, entrainment of country rock within the salt body and structurally induced drag folds (Fig. 6.42a; Harrison and Patton 1995;

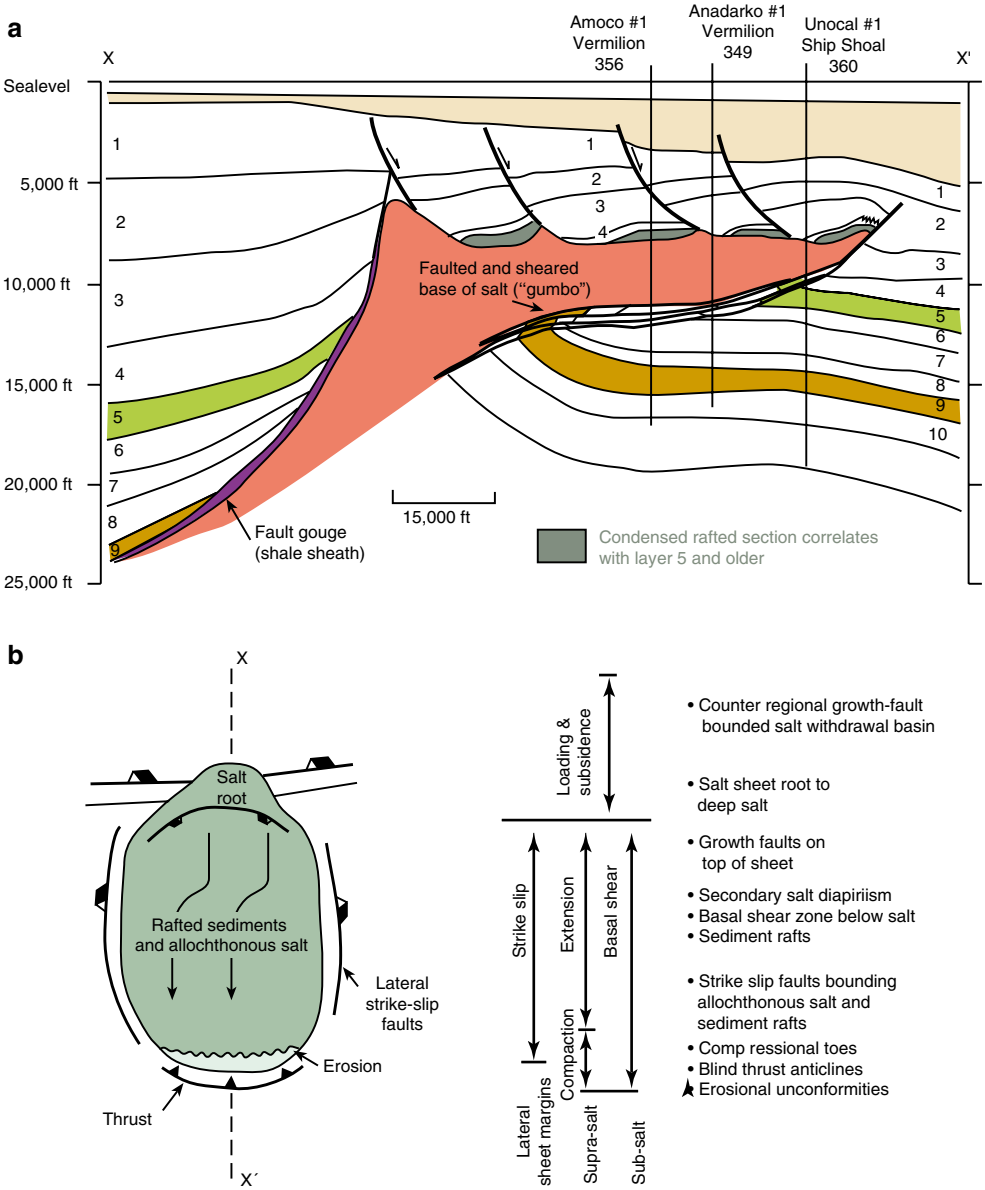

Fig. 6.42 Basal shear model (After Harrison and Patton 1995). (**a**) Cross section view with a thrust fault defining the rising compressional nose of the salt sheet. Relevant Gulf of Mexico wells are placed schematically on this section. (**b**). Map view. Down-to-the-basin translation of the composite salt/sediment glacier forms strike slip shears at the depopod margins. The compressional toe is a complex combination of normal fault and eroded blind-thrust anticlines (see later)

Alsop et al. 1996). Basal shear zones of allochthons are also called transition zones, gumbo zones[12], unconsolidated rubble zones, and can be considered as a subhorizontal type of shale sheath.

The basal shear zone is a response to thrusting along and within the base of the salt allochthon as it is emplaced at or near the sea floor (Harrison and Patton 1995). Consequent sediment loading atop the sheet drives further salt withdrawal and suprasalt sediment deformation (Fig. 6.42a). Salt flow within the salt sheet occurs via internal shear and pressure solution creep. The salt sheet remains impermeable as it experiences no brittle response to flow deformation as it rolls and extrudes out over its substrate.

As the sediment carapace thickens over the salt sheet, overpressures develop in the subsalt transition zone. The resulting anomalously high pore fluid pressures facilitate simple shear beneath the sheet by reducing the effective normal stress, thereby allowing lateral slippage of the sheet and its sediment carapace (gravity gliding; Baud and Haglund 1996). Whether shearing occurs within the salt sheet or in the immediately adjacent subsalt sediment is determined by which interval has the lower shear strength. Baud and Haglund (op. cit.) believe post first-emplacement shearing occurs within the salt sheet, at least until anomalously high pore pressures develop in sediments below the sheet.

[12]The term gumbo is used mostly by Gulf of Mexico drillers to describe the appearance of the large, pliable sticky and clumped cuttings that come up in the mud returns, whenever these basal salt transition zones are intersected. Gumbo is actually a thick seafood-based soup or stock that originated in the eighteenth century in the Creole region of southern Louisiana and is still a very popular dish in the southeast of the USA.

Measured pore pressures in the basal shear zone of Gulf of Mexico allochthons can be much higher than regional pore pressures and approach lithostatic fracture-inducing pressures in some subsalt shales. Measured gradients as high as 0.88 psi/ft or balanced mud weights of 17 ppg can characterise subsalt Gulf of Mexico drilling (Table 8.4; Harrison and Patton 1995). Field evidence cited in House and Pritchett (1995) indicates that the hyper-pressured interval below a salt sheet is typically 300–600 m (1,000–2,000 ft) thick and its upper part is likely to entrain the lithologically distinct "gumbo" or transition zone. In the Gulf of Mexico, "gumbo" zone are encountered beneath salt sheets emplaced into Pliocene, upper Miocene and middle Miocene age sections, but hyper-pressurised cells in the "gumbo" have been documented only below allochthons emplaced into Pliocene and upper Miocene sections (House and Pritchett 1995; Shaker 2008). This may indicate that hyperpressures are a geologically transient allochthon phenomenon and that, with sufficient time, a pressure equilibrium gradually re-establishes itself.

On passing through the salt allochthon the Amoco #1 well, Vermilion Block 356, immediately intersected such a pressured disturbed transition or "gumbo" zone (Fig. 6.42a). Cuttings from the gumbo zone documented a change with increasing depth below base of salt from a grey soft shale with pyrite traces into a firmer, medium to dark shale. Deep resistivities were less than 0.2 ohm.m in the shale in the first 120 m (400 ft) below the salt and increased to 0.4 ohm.m in the next 180 m (600 ft) possibly indicating decreasing pore water salinities or increasing organic content. The lowest resistivity zone corresponded to a wireline density $\approx$ 2.10 g/cc, which increased to 2.25 g/cc by 300 m below base of salt. RFT-measured pressures in thin sands in the disturbed (gumbo) zone were some 16.7 ppg equivalent, while in the same well, measured pressures were 16.1 ppg equivalent several thousand feet below the gumbo.

The South Marsh Island Block 169 Amoco #1 well in a transition zone immediately below its salt sheet intersected pressure gradients of 17.4 ppg equivalent. This pressure level is only 0.3 ppg less than the calculated fracture gradient for the matrix (House and Pritchett 1995). Below the "gumbo", pressure gradients decreased to more typical regional values of 16.5 ppg equivalent. Pressure data divide this well into a high-pressure zone (hyper-pressure cell) some 335 m (1,100 ft) thick immediately below the salt sheet and an underlying pressure transition zone some 245 m (800 ft) thick. Pressures below the transition zone were equivalent to regional overpressures.

Abnormally high pressures in transition zones (gumbo) typically indicate hydrologic isolation of this shale-rich section and a lack of hydraulic continuity (these shales do not readily dewater). Wireline image data show soft sediment deformation features, with higher levels of contortion in proximity to the allochthon contact. A similar style of disturbance is seen in outcrops in the former transition zone of Jabal Al Milh diapir, Yemen (Fig. 6.40b) and in subsalt thrust folds that define the Upper Cretaceous section of the Jebel Friktia allochthon (Fig. 6.40a). In situations where extruded salt is advancing across the seafloor, the initial soft-sediment disturbance textures in gumbo zones probably represent material slumped off the bathymetric scarp above the toe of salt and subsequently overridden as the salt extrudes basinward (McGuinness and Hossack 1993; Fletcher et al. 1995).

Jackson and Hudec (2004) have expanded on Harrison and Patton's notion of basal thrusting (Fig. 6.40a) by arguing that as salt allochthons continue to advance over the seafloor as a series of flats and ramps, they act much in the same way as a glacial ice sheet advances and ploughs over glacial till pushing a piling sediment at its nose. That is, as the allochthonous salt rides up over its underburden it pushes, deforms and thrusts portions of this water-saturated substrate. This in turn creates thrust ramps and duplexes in the subsalt "gumbo" sediments immediately beneath the salt sheet.

Once covered by extruded salt, a variably deformed subsalt transition (gumbo) zone typifies the lower contact of most active allochthon sheets. Before natural pressure bleed-off occurs it is outlined by abnormal pressure and temperature gradients. Differential translation is concentrated at and immediately below the base of the salt sheet. Salt-lubricated slivers line up as sub-parallel thrust planes along the pressurised base of the allochthon, as do repeat sections and recumbent subsalt folds (Fig. 6.42a; Harrison and Patton 1995). A lack of fluid movement in a disturbed zone due to low permeability can lead to anomalously low temperature gradients in this interval, with a low thermal gradient halo typically characterising the interval immediately below the thick, thermally conductive salt sheet. Thermal gradients in this halo gradually increase downward until a more normal regional gradient is achieved.

The laterally variable low temperature, high-pressure (gumbo) interval that occurs below most allochthon sheets is a potential problem zone for the drilling engineer (Chap. 8). Although not all intersected gumbo zones remain pressurised in the subsurface, prior to drilling, a basal shear zone in most active allochthon provinces is best considered as a potentially thick, highly pressured, faulted and folded interval, and planned for accordingly. Fluids in this deformed zone may migrate along fault planes, but typically not within the blocks of disturbed sediment matrix, which like the overlying salt, act as vertical barriers to fluid flow. Pressure build-ups within the gumbo shales probably lead to periodic matrix fracturing and bleed-off of elevated pressures (seismic pumping).

When pressurised, the base of salt or gumbo zone tends to act as a permeability barrier to rising basinal fluids, as does the overlying salt (House and Pritchett 1995). When rising fluids impinge on this zone they are forced to flow laterally, subparallel to the base of salt and through or beneath the gumbo until they encounter a breach point or the feather

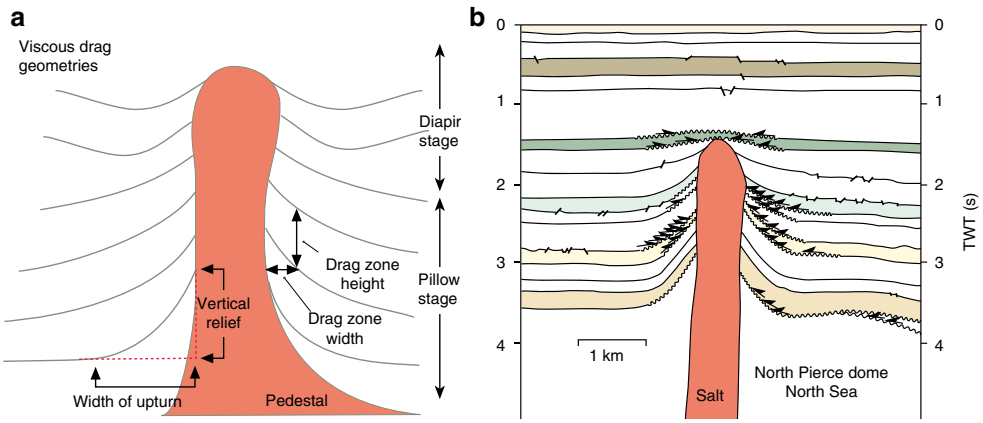

Fig. 6.43 Circum-diapir drag folds. (**a**) Dimensions and parameters of the diapir drag zone (After Davison et al. 2000b). (**b**) Interpreted onlap surfaces in the "drag-zone" or rotated drape-fold zone vicinity of North Pierce dome, North Sea (After Schultz-Ela 2003)

edge of the salt sheet (Chap. 8). But not all "gumbo" transitions are anomalously pressured and pressure character of the transition zone is not easily predicted ahead of drilling. For example, instead of being impervious, extra permeability can be created in a gumbo or transition zone via periodic salt evacuation from salt feeder stocks below an allochthon canopy.

Depending upon its local character, a gumbo zone can be a seal, or it can be a path for hydrocarbon migration, or even a potential reservoir. When pressurised a gumbo zone provides a potential trapping mechanism, much like a pressure-sealing fault. Hydrocarbons migrating laterally through a highly-pressured transition zone can be injected into low-pressured underlying sands and trapped due to the pressure differential. Or a transition zone can trap hydrocarbons migrating upward through subsalt sands as overpressures in the transition zone prohibit fluid invasion. If not overpressured, a fracture-susceptible gumbo zone can provide a permeability pathway for hydrocarbons migrating upward along base of a salt feeder as buoyant fluids move through the transition zone. Hydrocarbons can also migrate upward through suballochthon sands and then leak into the transition zone wherever the sand and transition zone contact one another. Lastly, subsalt transition zones could prove to be reservoirs themselves, as widespread leakage of hydrocarbons from below, or lateral migration of fluids through the gumbo, can saturate them. But most subsalt transition or "gumbo" zones are probably not of reservoir quality and observed log character shows most are disturbed and shale prone (LeBlanc 1994). Fluid modelling, based on allochthon-focused subsalt flow, has implications for the pulse-like fluid emplacement in suprasalt hydrocarbon traps (Fig. 8.28 and discussion) as well as mineralisation episodes and the development of footwall alteration haloes in many base metal deposits (Fig. 15.87 and discussion).

Developing pre-drill seismic techniques that can reliably define which welds seal and which leak, is still an expanding topic in salt basin research (Taylor et al. 2011). For example, below the salt canopy in Walker Ridge and Keathley Canyon in the Gulf of Mexico, variations in both pore pressures and elastic rock properties are highly correlated to age and lithology and so are seismically resolvable. Sub-salt geopressure increases there are typically associated with regional marls (high velocity, indurated lime-rich mudstones), which cap sequences of thick, low velocity, overpressured shale. As a result of their anomalous acoustic properties, these high-pressure indicator marls can readily be tied to seismic events and often mapped over extensive areas (seismic data quality permitting).

Near-Diapir Suprasalt Shear (Drag Zones)

Halokinetic deformation can create substantial faulted external or drag zones, not just in the gumbo and shale shear zones immediately adjacent to the deforming salt, but in broader intervals of nearby sediment. As it faults brittle strata, drag can also rotate neighbouring beds into steeply dipping attitudes that lie subparallel to the walls of the salt diapir (Schultz-Ela 2003; Alsop et al. 2000). Rotations can be as steep as 90° and can even overturn beds. Deformation in drag zones is driven by a variety of processes including downbuilding, differential compaction, grain boundary sliding, microfracturing, larger-scale faulting and pressure solution. The abutment of an inclined drag zone against a near-diapir fault can form intervals of stacked and compartmentalised oil and gas reservoir sands. Drag-induced stacking of inclined sand beds circumferential to the diapir stem explains why, in the early days of their production, reservoir sands adjacent to sub-vertical portions of onshore salt structures in the Gulf of Mexico constituted some of the most productive acreage (bbl equiv./km^2) in the world's oil fields (Fig. 10.54).

Drag zones develop sequentially; initial salt pillowing creates a broad gentle overburden flexure that increases in intensity as the structure evolves into a diapir (Fig. 6.43; Davison et al. 2000b). By the diapir stage the width of a drag zone is approximately equivalent to the width of the diapir at the diapiric base and decreases to 25 % of the diapir width toward the diapir crest. Vertical relief of the upturn in a bed

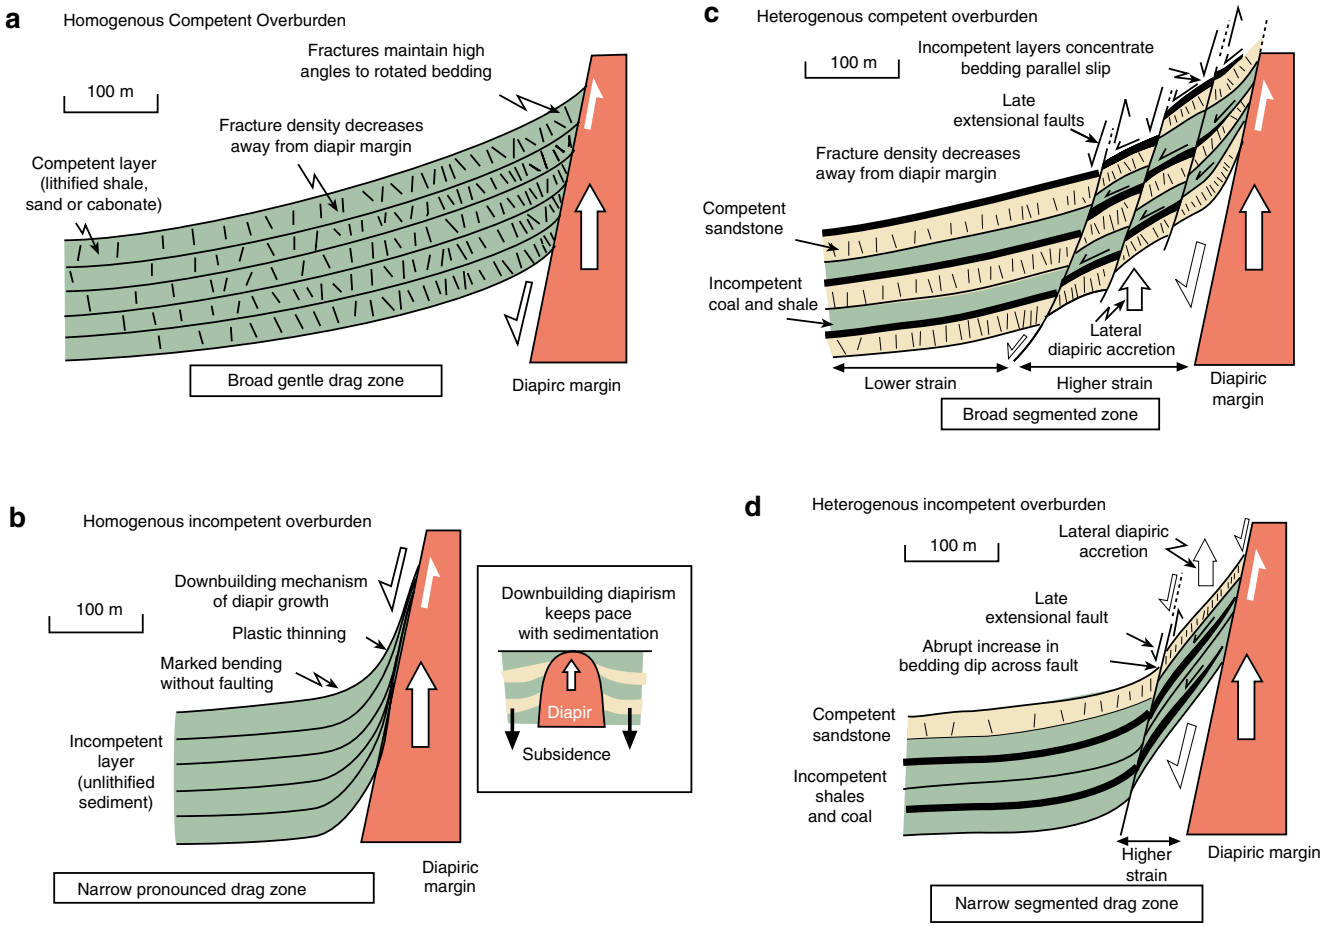

Fig. 6.44 Schematic profiles of diapir drag zones (After Alsop et al. 2000). (**a**) Broad drag zone within homogenous competent overburden. (**b**) narrow drag zone with incompetent inhomogeneous overburden. (**c**) Broad segmented drag zone within homogenous incompetent overburden. (**d**) narrow segmented drag zone within heterogenous incompetent overburden with marked internal competency contrasts. (**c**, **d**) also illustrate the process of lateral diapiric accretion where fault-bound material moves upward with the flanks of the diapir relative to sediments further out in the rim syncline

also decreases upward. Vertical relief is some 5 % of the diapir height near the crest and increases to 30 % near the diapir base, a consequence of the greater relative movement across the pre-movement and early syn-movement layers situated near the base of the diapir stem. The width of the drag zone increases proportionally with increasing diapir size and diapir height, while the total amount of bed upturn increases proportionally with the width of the drag zone.

In one of the few outcrop studies of the characteristics of diapir drag zones Alsop et al. (2000) relate variation across the drag zone to overburden competence (Fig. 6.44a–d). Their work focused on an outcropping diapiric province in Cape Breton Island, Nova Scotia, where five Visean-age salt diapirs penetrate Upper Carboniferous (Namurian-Stephanian) conglomerates, sandstones, shales and coal seams. The width of diapiric drag zones varies from 70 m up to 500 m. Narrow drag zones are a response to the low mean competence of shales and siltstones, which were probably shallowly buried and poorly lithified at the onset of diapirism (Fig. 6.44b). Broader drag zones are dissected by two sets of extensional fractures, together with major faults, suggesting that the overburden was semi-lithified and displayed greater flexural rigidity at the time of salt flow (the beam effect; Fig. 6.44a). Overburdens with high internal competency contrasts (e.g. interbedded sand-shale) generated strain localization and partitioning, with pervasive granulation seams and minor faults developed in the more competent sandstones and bedding-parallel shears in the coal and shale horizons. The various drag zones are segmented by steep outward-dipping faults associated with decametric, asymmetric drag profiles (Fig. 6.44c, d). These faults facilitate the upward movement of material and effectively enlarge the diapiric process into the adjacent overburden a process that Alsop et al. (2000) call lateral diapiric accretion.

In the subsurface, seismic of varying quality is usually all that is available to interpret drag zone geometries. Steep dips and irregularities in the distribution and density of adjacent salt means that the shape and extent of the diapiric drag zone is poorly defined in the inner shear zone area, especially when the diapir is bulbous. The width of the upturned zone

caused solely by frictional drag is difficult to estimate, as a large section of the upturned interval can be due to the salt pedestal effect (Vendeville and Nilsen 1995). The increased permeability around zones of fracture adjacent to diapirs means that drag zones can act as preferential conduits for fluids escaping from deeper levels. Pervasive fracturing in broader drag zones formed by more competent beds helps explain the pervasive entry of ferroan brines into adjacent carbonates and fracture defining haloes as is seen in the outcropping Proterozoic diapiric province of the McArthur Basin, Australia (Warren 1999). There the salt has long gone and only siderite/brunnerite diagenetic replacement haloes remain around fault welds and salt welds.

With prekinematic overburden, substantial drag-induced folds only form in exceedingly weak rock (Schultz-Ela 2003). Even then, most folding develops by nearsurface upward and outward rotation. Protrusions of overburden into a diapir, where the contact dips shallowly outward, are most susceptible to folding due to frictional drag created by the crossflow of salt. Based on modelling experiments, Schultz-Ela argues synkinematic sedimentation is much more likely to engender large and broad folds in the drag zone because onlapping wedges may be continually produced during downbuilding (Fig. 6.43b). These syndepositional folds can even form in strong layers. He argues folding of onlaps over rising salt is really drape[13] folding, so "drag" fold is actually a misnomer. Local gravity fold is perhaps a better descriptor of this style of deformation. Episodically deposited layers further enhance the potential for onlap folding.

For the same average aggradation rate, pulsed deposition of thick layers generates larger folds than do continuously deposited thin layers. Variation in thickness and timing of deposition increases the likelihood of multiple wide onlaps that evolve into substantial folds. Older layers tend to form the broadest and tallest folds because those layers prograded farthest across the diapir crest. As the salt contact steepens, the folded zone narrows as younger layers onlap onto older folds or the salt. Onlap folds can only form for a limited range of relative salt rise and deposition rates. Deposition much faster than the net rate of salt rise buries the diapir. Deposition that is too slow creates steep contacts or salt spilling onto the sediment surface, both of which result in little "drag" folding.

In three dimensions, outcrop and 3D seismic studies have shown that both radial and concentric faults occur in drag/drape zones around diapirs, and that the fault patterns are lithologically dependent and can rotate during the life of a diapir (Davison et al. 2000a, b). Ongoing drag or drape deformation can facilitate the creation of a hydrocarbon-bearing column adjacent to a diapir that is more than a km tall. Many fault patterns are approximately sub-radial due to the intersection of multiple fault trends and many faults curve to become roughly tangential to the diapir face to produce cuspate salt outlines in plan view (Chap. 10). In the context of rotated faults some types of Christmas-tree[14] diapirs are of interest. Christmas-tree diapirs are typically interpreted as indicators of stacked salt allochthon wings, however, Varela and Mohriak (2013) have suggested stacked salt wings may also be indicative of rotated salt-cored crestal faults which have rotated into a position lateral to the main salt mass via the ongoing rise of salt (Fig. 6.45).

Welds, Loading Detachments and Growth Faults

Many regional growth faults in salt allochthon provinces sole out onto residual fault welds, which can be many tens of kilometres in length. The link between growth faults and salt welds is an inherited relationship whereby sediment loading of a salt sheet or layer where one evolves or passes into the other (Jackson et al. 1994b; Fletcher et al. 1995; Wagner III and Jackson 2011). A thick salt sheet present before welding decouples faulted zones above and below it as it flows and deforms. This decoupling means most large suprasalt faults sole out into the level of the former sheet (Fig. 6.39b).

Burial of an evacuating salt allochthon beneath loading sediment typically occurs after pinch-off from the feeder diapir (Fletcher et al. 1995). This allows the former sea floor high created by the glacier to relax (deflate), especially at the updip end of the sheet. Sediment can then prograde across the sheet beginning at its updip end (Figs. 6.36 and 6.42). Even during burial of its updip end, an evacuating salt sheet typically retains several hundred metres of relief on the downdip end. Thus the downdip sheet continues to advance as a composite salt-sediment glacier. Sediments atop the allochthon are deformed, along with the flowing salt, as the gliding movement creates extensional breakaway zones at the updip end. In turn this initiates fault-bound minibasins at the updip end of actively flowing salt sheets (Figs. 6.36 and 6.39). Ongoing slippage creates a growth fault rollover anticline as salt continues to extrude at the downdip or compressional end.

The same salt mass can recycle multiple times as tiers ascending into ever-higher stratigraphic levels (Fig. 6.46). Each time salt activity is transferred to a higher level, a largely welded smear of salt (salt weld) with a vestigial salt

[13] In salt tectonics, a drape fold describes a zone of upturned strata adjacent to a diapir. Upturning results from arching of the diapir roof above flanking strata and is an important process in the formation of halokinetic sequences and is also known as a flap fold.

[14] Repeated extrusions can create stacked salt wings, so forming a serrated salt contact known as a Christmas-tree structure. Some can also form via fault rotation, not stacking of successive extrusive salt wings and tongues.

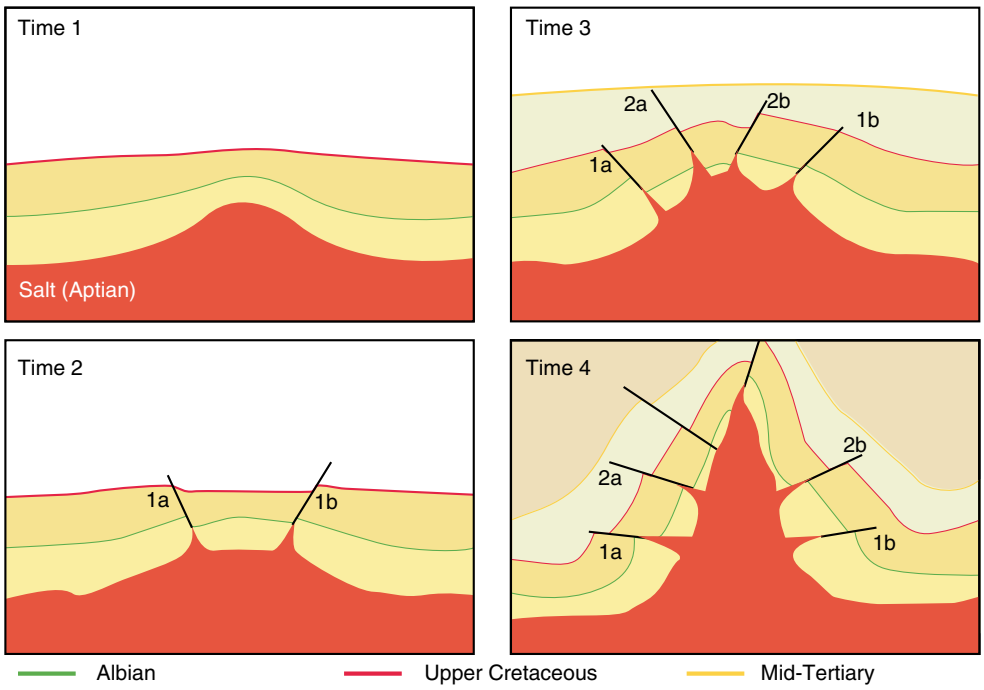

Fig. 6.45 Christmas-tree diapirs via fault rotation, not stacked extrusion (After Varela and Mohriak 2013). Time (*1*) Initial doming. Time (*2*) Crestal collapse graben with extensional faults; incipient salt intrusion along fault planes. Time (*3*) Crestal faults migrate to the diapir flank and have their dip angles reduced, whereas the bedding dips increase. New sets of crestal faults are formed toward the center of the structure. Time (*4*) Subhorizontal faults characterized by bedding with high dip angles; salt stringers forming an intrusive Christmas tree structure. Part of the salt in the apophyses may be squeezed back to the salt diapir because of the weight of the overburden or dissolved by formation waters

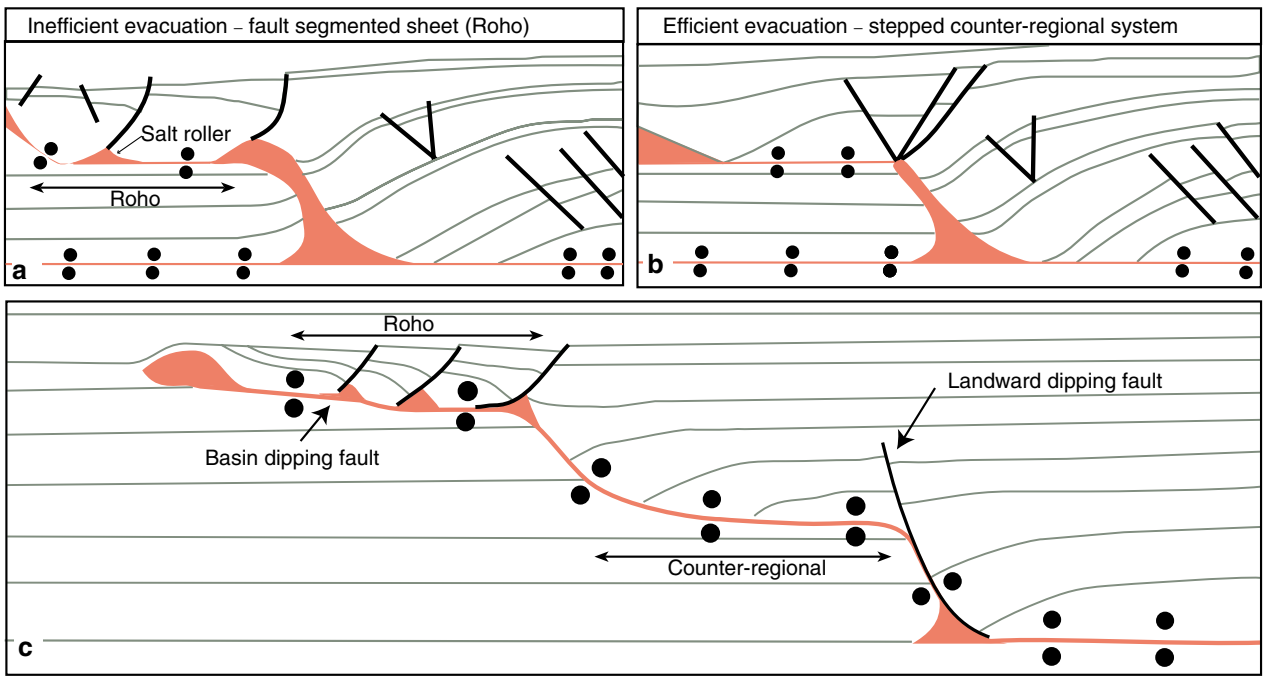

Fig. 6.46 Efficiency of evacuation is reflected in the suprasalt structuring. (**a**) With inefficient salt evacuation a fault segmented (Roho) system forms. (**b**) With efficient evacuation a counter-regional system is created. (**c**) Shows how the two systems can be created by the same salt body. See text for explanation, *black circles* define salt welds (In part after Jackson et al. 1994b; Rowan 1995)

structure (salt roller) is left behind at the lower levels. Substantial volumes of salt are lost via dissolution each time the salt approaches the seafloor or is bathed in less saline pore fluids. Thus, the ascending salt mass cannot recycle indefinitely and the driving mechanism is lost once a salt weld or overburden touchdown is created beneath the minibasins.

A salt sheet that is isolated from its feeder stock can advance further only by cannibalising its trailing edge (Fig. 6.42a; Fletcher et al. 1995; Schuster 1995; Jackson et al. 1994b). If the salt is inefficiently withdrawn from the trailing edge, the salt becomes progressively sequestered into residual smaller bodies and the overall structure is called

a fault-segmented sheet. In the Gulf of Mexico this is also called a "Roho"[15] or a listric weld system (Fig. 6.46a). Roho systems are characterised by major, listric, basinward dipping (down-to-the-basin) growth faults, that can sole out onto an allochthonous salt sheet, allochthonous salt canopy, or allochthonous weld. Sediment wedges in the fault blocks dip and thicken landward but become younger seaward. In the Gulf of Mexico systems that sole into allochthonous salt evacuation surfaces are also known as tertiary salt welds, as opposed to primary and secondary salt welds (Fig. 6.39a).

During shelf progradation over a salt sheet or a salt "wing" on a salt plug, the rear (landward) margin of the salt sheet gradually segments and deep withdrawal structures are enhanced. At shallower levels, vestigial salt forms a train of sequestered salt walls formed by the partitioning of a formerly continuous sheet of salt. Each residual salt structure is typically in the footwall of a normal fault or is separated from its neighbour by a syncline. Each residual wall is generally overlain by a splay of extensional faults, which are commonly listric.

If salt is more efficiently withdrawn from the deflating trailing margin shelf progradation then a stepped counter-regional system results (Fig. 6.46b). A counter-regional system is made up of landward-dipping, largely welded salt system whose upper part is a weld, remnant diapir, or normal fault. Sediment wedges dip and thicken seaward. The lower part of the system may ramp continuously down to the source layer or may include flat-lying segments. If the system has more than one ramp, it is a stepped counter-regional system. Strata above the deflating salt sheet gently subside to form a shallow flat step along the weld of vanished salt. The step resembles a landward dipping growth fault (Fig. 6.45c). However, the step can be merely a pseudo-fault, like the contiguous deeper step created by upward evacuation of the original diapir. In three dimensions the shallow step fault is the axis of a partly evacuated sheet that is shaped like a tongue with curled up lateral margins (Fig. 6.46b). Along the deepest axis of the tongue lies the deepest, most evacuated part of the salt sheet below the thickest overburden.

These two structures —the fault-segmented sheet (Roho) and the stepped counter-regional system— are end members of a load-induced evacuation series where the counter-regional systems define welds where salt has been completely evacuated and a Roho system defines less efficient evacuation. It is possible that as the salt climbs the stratigraphy the same salt body can create both Roho and counter-regional systems or welds depending on the efficiency of evacuation (Fig. 6.46c).

[15] The detachment surface for these into-the-basin "Roho" growth-faults is inefficiently evacuated salt. With 1960s and 1970s vintage seismic data, it was not possible to image below the salt evacuation surface (tertiary weld). An early seismic stratigrapher in Shell, Chuck Roripaugh, after being instructed to map to the Moho below areas of salt, jokingly labelled his map of the salt evacuation as "Roripaugh's Moho" which was later contracted to Roho. This in-house joke has since escaped into the public literature.

Minibasins, Canopies and Welds

Differential loading, created by the emplacement of a depositional lobe atop a salt allochthon, induces a differential fluid pressure in the salt below. Salt squeezes laterally into flanking areas and a bathymetric high, which dams the accumulating sediment, forms a rim adjacent to the sediment accumulating in the growing minibasin (Fig. 6.47a). A minibasin is an suprasalt depositional basin underlain and surrounded by allochthonous salt. The term intrasalt basin is sometimes also used to described salt-floored minibasins or depopods. In my opinion this is confusing as intra means within, these basins are never within, when depositionally active they are initially atop and laterally restrained by salt. Then in more mature extensional and compressional terrains, where most of the salt in a former salt wall has been largely squeezed from the system, the remaining adjacent depopods can be in lateral contact across a salt weld and floored by a salt weld (e.g. Fig. 6.40a). I use the term intrasalt to describe features completely encased in salt, as in the carbonate stringers of the South Oman Salt Basin.

A feedback process is created as the sediment-loaded minibasin floor subsides by pushing salt aside, so allowing the basin to receive additional sediment. The process continues until the minibasin floor touches down on the subsalt strata to form a salt weld (Fig. 6.47a). At that time, minibasin subsidence ceases. Once the minibasin touches down, subsidence shifts from the centre of the minibasin to its flanks, which are still underlain by salt. Both flanks subside, creating an anticlinal turtle structure. Subsequent depocentres form on both sides of the early depocentre (Fig. 6.29). At the same time, if there is sufficient salt supply then the level of the suprasalt minibasins may first fuse and then be covered by a salt canopy (Fig. 6.48 – Stage a). Ongoing loading by the expanding minibasins and their fills (or extensionally-driven minibasin foundering) drives a transition of the salt geometries from joined ridges and walls separating the basins, into isolated diapirs, encased and separated by a level made up of merged merging minibasins (Fig. 6.48 – Stage b). With enough salt supply a new salt canopy can form higher in the stratigraphy, while the former underlying salt tier is marked by welds (Fig. 6.48 – Stage c).

Intrasalt minibasins that form above tabular salt allochthons typically entrain a sediment fill that indicates an evolution from slope basins to shelf basins (Fig. 10.66). They are typically bound by arcuate growth faults formed largely by downslope salt withdrawal. Initially, the allochthon acts as a deflating cushion that accommodates sediment deposited in minibasins. After time, loading or extension, the original salt sheet transforms into thin but broad welds, which then act as major subhorizontal detachments for deep growth faults

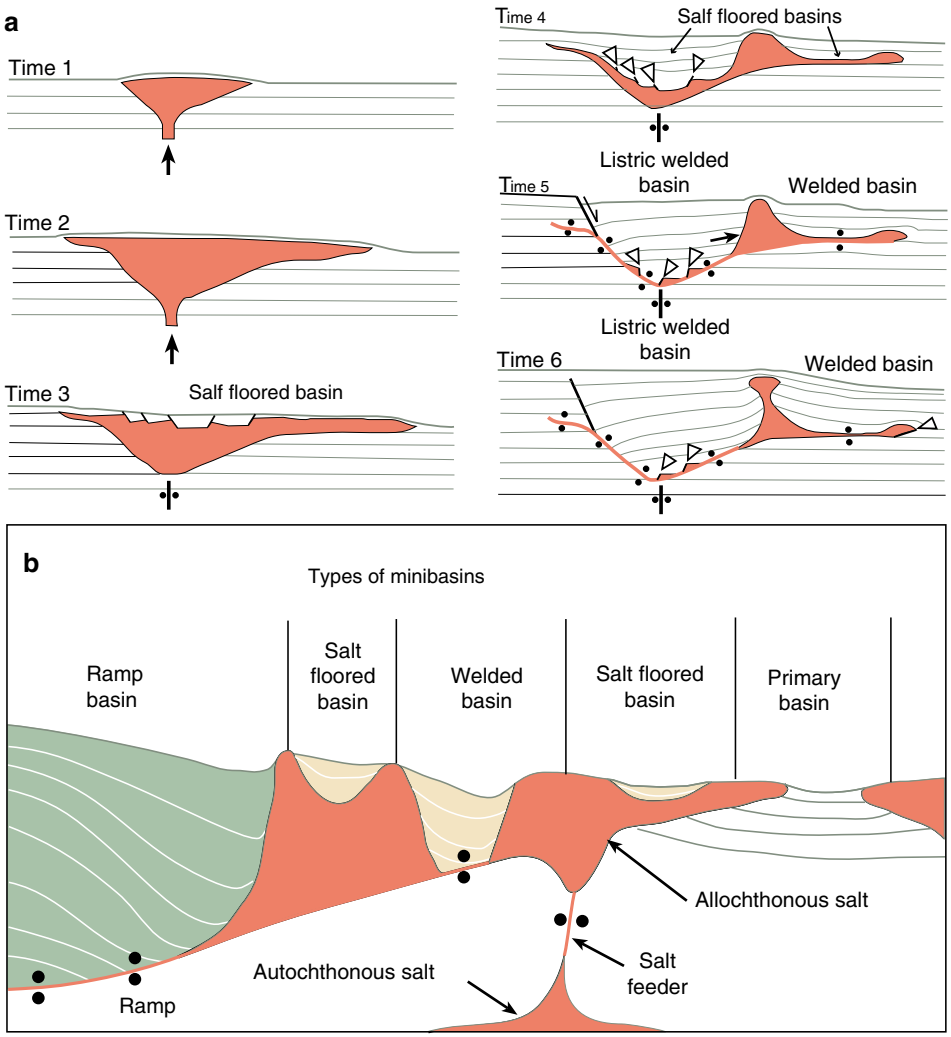

Fig. 6.47 Evolution of minibasins atop salt allochthons based on the northern Gulf of Mexico (as in Fig. 6.49). (**a**) Evolution of a minibasin as sediment loads a salt allochthon (After McBride et al. 1998a). (**b**) Types of minibasins (After Koch et al. 1998)

whose slip creates space for further sedimentation. Ultimately, the sheet itself is segmented into discrete salt structures separated by salt welds and fault welds. Second or third cycle tiers of salt structures can rise from these deformed sheets (Fig. 6.46).

Minibasins can contain upwards of 5 km of sediment fill, and in the northern Gulf of Mexico are divided into five types based on the relationship of the fill to the presence or absence of a underlying salt weld (Fig. 6.47b; Koch et al. 1998):

- Ramp (atop counter-regional)
- Salt-floored minibasin
- Welded minibasin
- Welded listric minibasin (Roho)
- Primary basin (seaward of the allochthon)

Ramp basins predominate on the slope in Garden Banks and Green Canyon of the Gulf of Mexico. They are characterized by a set of south-bounding, north-dipping salt welds (Fig. 6.35b). Most ramp basins have young thick depocentres adjacent to the counter regional ramp. Ramp basins tend to be asymmetric and larger in areal extent than the other types of minibasins. Welded basins were previously underlain by allochthonous salt that has been fully or partially evacuated. In the northern Gulf of Mexico they increase in frequency southward into the Walker Ridge and Keathley Canyon protraction areas where there is still a substantial volume of salt in the allochthon stratigraphy.

Welded listric (Roho) basins in the northern Gulf of Mexico have south-dipping arcuate faults that sole into the evacuating salt. Welded basins have a multitude of internal fault patterns and sediment fills, some are symmetrical with bowl-shaped fills, others have multiple depositional axes and bidirectional stratal fills. Primary basins in the Gulf of Mexico show no evidence of allochthonous salt and display continuous sedimentary fill from Cretaceous to Recent. Salt-floored basins are underlain by continuous allochthonous salt, which typically shields them from the underlying petroleum kitchens. Salt-floored basins occur along the down dip edge of allochthonous salt near the Sigsbee escarpment and above very young salt sheets in Garden Banks and Green Canyon (Figs. 6.1 and 6.49).

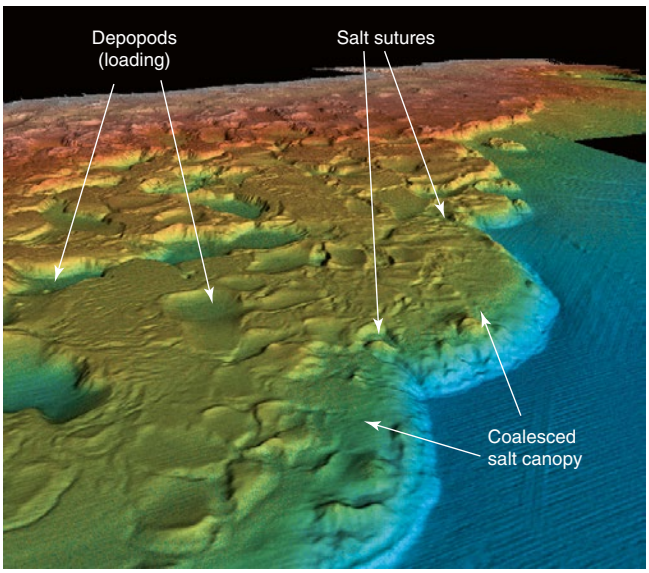

Fig. 6.49 Salt canopy including part of the Sigsbee Scarp located along the continental slope of rise of the Northern Gulf of Mexico. Image shows a series of salt-floored minibasin depressions atop a coalesced salt canopy with a thrusted front (Image courtesy of Martin Jackson). See Fig. 6.61 for location

As basin fill changes through geologic time, each of the five types of basin have differing capabilities for receiving and internally distributing the hydrocarbons supplied from mature more deeply buried source rocks. In general, hydrocarbon entry points to basin strata in the Gulf of Mexico salt basins are controlled through time by salt movement and carrier bed geometry. Koch et al. (op. cit.) argue ramp basins have attractive plumbing for hydrocarbons as well as an enhanced trapping focus (Chap. 10). Welded and welded-listric basins are dependent on the evacuation of the salt floor and leakage across the weld for any supra-weld hydrocarbon charge to occur in the minibasin sands; therefore, the age and areal extent of the weld are factors is assigning prospectivity. Primary basins appear to have access to underlying mature sources but may lack effective migration pathways and trapping geometries. Salt-floored basins are the lowest ranked basins due to separation from a mature subsalt source.

Within the four areas of minibasin development studied by Koch et al. (1998), most discoveries were in ramp and welded minibasins (about 1 BBOE in each basin type). Primary and salt-floored minibasins show minor discoveries and none of significant size. The feedback between allochthon style, deposition of potential reservoirs sands and hydrocarbon maturation is discussed in detail later in this chapter and in Chap. 10.

A widely used explanation for the subsidence that accommodates minibasin sediment is that salt is forced from beneath the sinking basin by the weight of its sedimentary fill and so the basin accumulates further sediment (i.e. depositional loading drives salt flow). At the broader scale the system is driven by into the basin gravity gliding. Loading as the explanation is valid if the average density of the minibasin fill exceeds that of salt, which in the Gulf of Mexico requires at least 2,300 m of siliciclastic fill to ensure enough compactional density (Fig. 6.50a). However, as noted by Hudec and Jackson (2009) most minibasins start sinking and accumulating sediments when overburden thicknesses are much thinner than this. They argue that our understanding of the driving mechanisms for minibasin creation and evolution is incomplete and identify five mechanisms, in addition to density-driven subsidence, that can create minibasins. They are: (1) Diapir shortening which occurs as squeezed diapirs inflate, leaving the intervening minibasins occupying bathymetric depressions (Fig. 6.50b); (2) Extensional diapir fall, when stretching of a diapir causes it to sag, producing a minibasin above its subsiding crest (Fig. 6.50c); (3) Decay of salt topography (deflation), occurs as the dynamic salt bulge subsides in response to the slowing of the upward flow of salt, this lowers the salt surface below the regional sediment surface and so permits sediment infill (Fig. 6.50d); (4) During

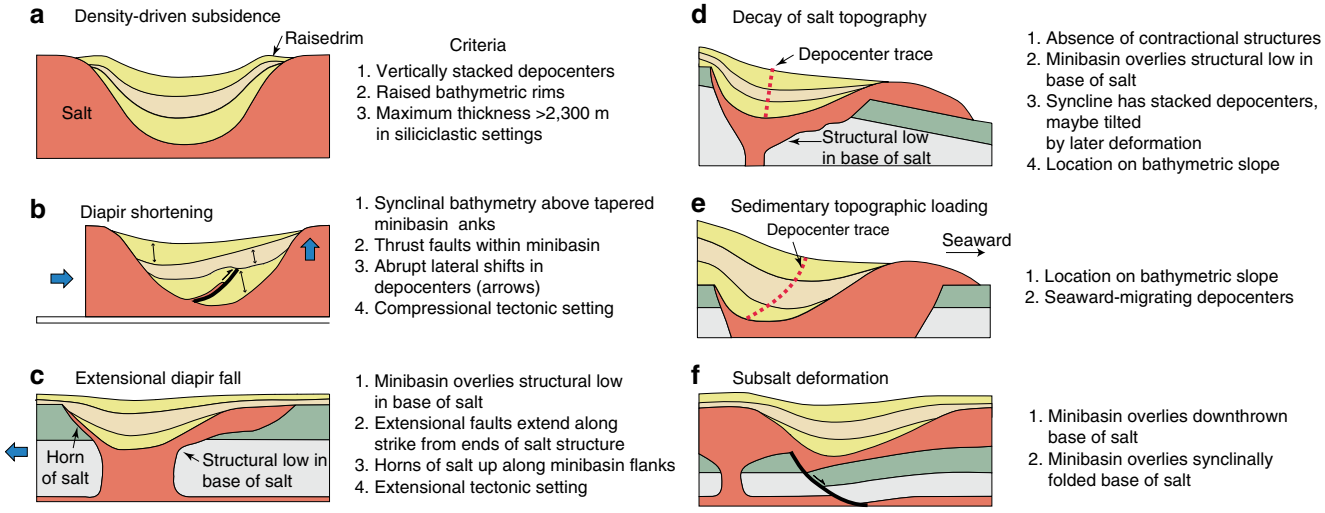

Fig. 6.50 Summary of minibasin-subsidence models and criteria used to distinguish them. See text for explanation of stages **a**–**f** (After Hudec and Jackson 2009)

sedimentary topographic loading, sediments accumulate as a bathymetric high above salt (Fig. 6.50e). (5) Lastly, subsalt deformation in the base of salt may produce relief at the top of salt (Fig. 6.50f).

All six mechanisms (including density-driven subsidence) produce different positions of the bathymetric lows, with respect to the flowing salt mass, which interacts with sediment transport to produce different facies patterns in each type of minibasin, each with characteristic recognition criteria (Fig. 6.50). The particular mechanism driving minibasin subsidence depends on the tectonic environment, regional bathymetry, and sedimentation rate, while their spatial variation on a continental margin creates provinces in which a given minibasin style is dominant.

At broader scales than individual minibasin sags, salt sheets can spread laterally as they deform until they eventually coalesce with neighbouring salt sheets. Collectively they create a salt canopy, a feature that dominates much of the foot of slope in the northeastern Gulf of Mexico (Figs. 6.48 and 6.49; Talbot 1993; Wu 1993). There individual lobate sheets coalesce westward into an extensive salt canopy whose leading edge is the Sigsbee Scarp. Adjoining salt sheets merge into canopies along salt sutures. The formation of a more or less continuous salt canopy must entail the upward and lateral movement of vast quantities of salt carrying with it an expanding overburden made up of minibasins actively accumulating sediments.

Canopies form as allochthonous salt sheets come together or coalesce with the position of merging defining canopy suture. Suture can occur beneath thin or thick roofs (Fig. 6.51a, b). Once formed a canopy can be loaded with sediment and then segments as the overlying minibasins merge (Figs. 6.51 and 6.48). When the canopy roof is thin, the adjoining sheets are salt glaciers, with a thicker roof confining the edges of adjacent sheets, the roof lies beneath

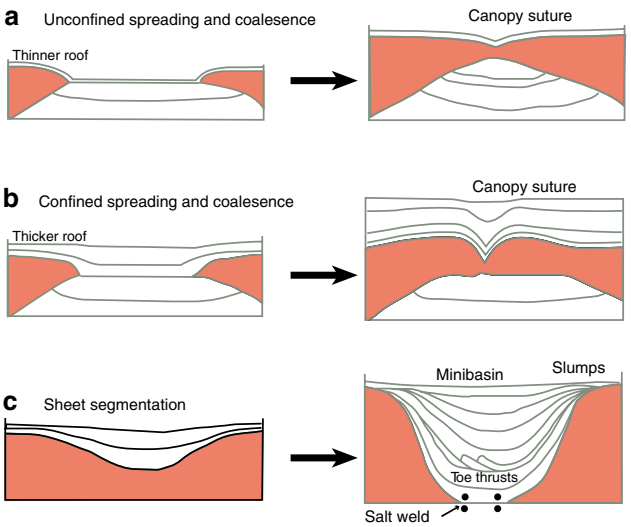

Fig. 6.51 Comparison of structures produced by (**a**) coalescence of unconfined salt glaciers, (**b**) coalescence of confined, buried salt sheets, and (**c**) segmentation of salt sheets by loading suprasalt minibasins (Jackson et al. 1994b)

cuspate sediment-filled synclines associated with small thrust faults and kinks (Jackson et al. 1994b).

Dooley et al. (2012) integrate and categorise notions of salt canopy evolution. At the broad scale of interactions within and between the canopy salt sheets where they touch they define autosutural and allosutural styles (Fig. 6.52a, b) An allosuture is formed by the two coalesced salt sheets fed by separate feeders, while an autosuture forms at the contact of two lobes fed from a single salt sheet, including any trapped sediments. Dooley et al. also refine the terminology that is applied to canopy sutures utilising, plan views and map views of an idealised sutural contact (Fig. 6.52c).

Autosutures can form in two ways. An overriding autosuture is produced when part of a salt sheet overrides its

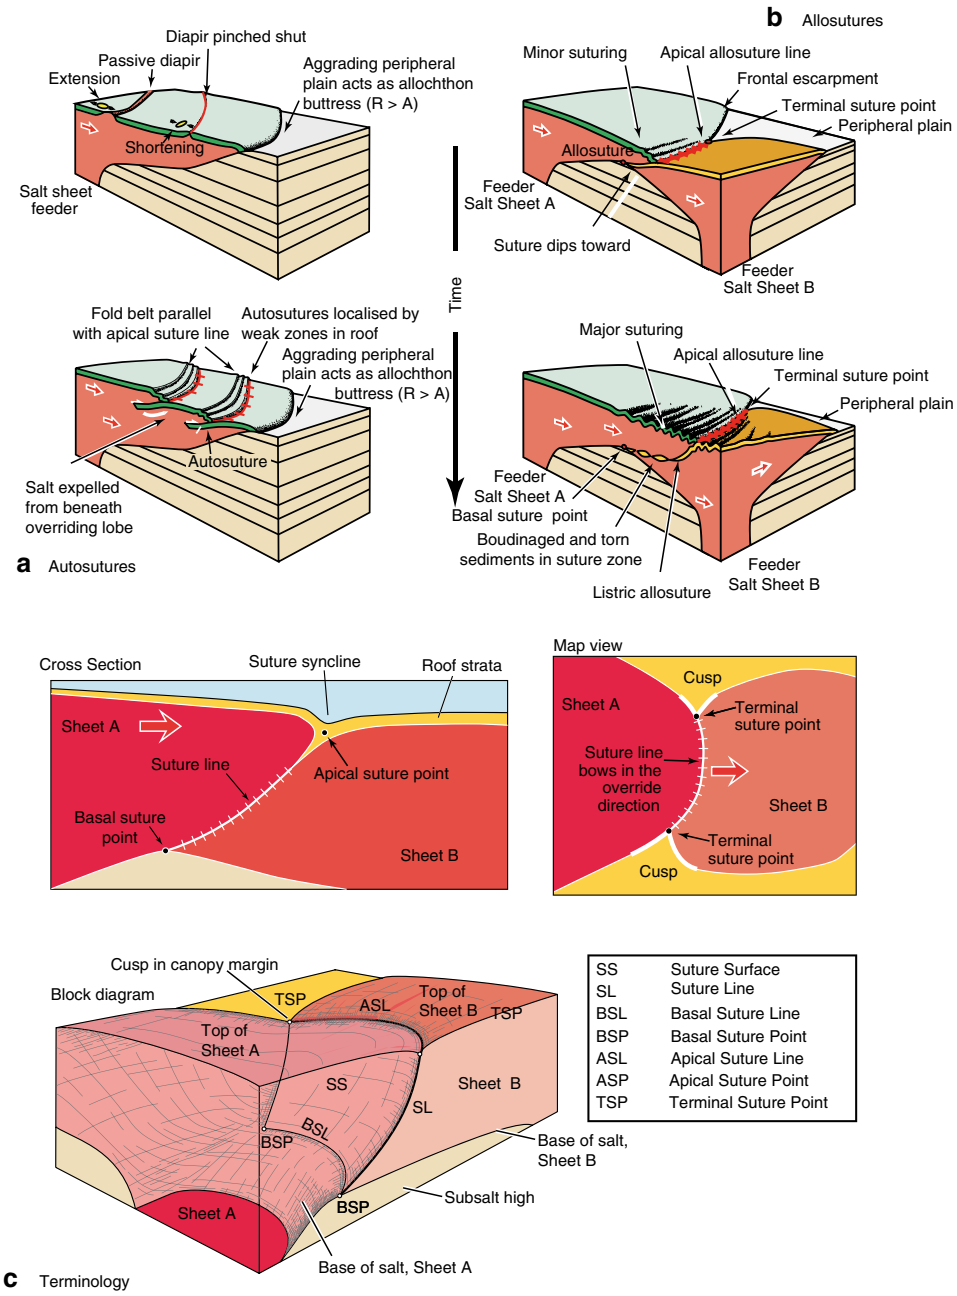

Fig. 6.52 Salt canopies and their sutured edges (After Dooley et al. 2012) (**a**) Autosutures. The roof of a salt sheet shortens where sheet advance is buttressed by peripheral plain or by another sheet. Overriding autosutures may initiate at any zone of weakness in the roof, especially pre-existing reactive diapirs formed by previous stretching as the salt sheet spreads. As it is overridden from the rear, the front of the roof is depressed into the salt. (**b**) Asymmetric allosutures. As one salt sheet overrides the other, sediments in the suture are depressed, stretched, and dismembered to form boudins in the salt. These sediments eventually tear off from the basal suture line. (**c**) Terminology for describing salt-sheet sutures in cross section, map view, and in three dimensions. Note that, in the block diagram, the sides around sheet A are transparent. The side showing sheet B is solid in order to illustrate a cross sectional view

neighbour in the direction of salt movement. The overridden roof subsides into the salt sheet, and these trapped sediments appear as intrasalt reflections on seismic data. An encircling autosuture forms when two lobes of a salt sheet separate to bypass an obstacle and then rejoin on the downstream side of the obstacle. Encircling autosutures tend to be short and parallel to the dominant salt-flow direction.

Allosutures separate sheets sourced from two different feeders. If neither salt sheet overrides the other, the resulting suture is symmetric, forming an upright zone of roof sediments trapped between the two sheets. More typically, one salt sheet is more vigorous (generally the larger sheet or the one whose feeder is farther updip) and overrides the other. Sediments trapped in an asymmetric allosuture are mostly from the roof of the overridden sheet. The overriding sheet shears and extends the roof of the overridden sheet, detaching it from the base of the canopy and obscuring its origin.

Based on their physical modelling and analysis of canopies in the Gulf of Mexico, Dooley et al. (2012) argue that if the type of canopy suture can be classified then it can be used to better understand geological evolution to its current state. Encircling autosutures have the clearest origin (Fig. 6.53a).

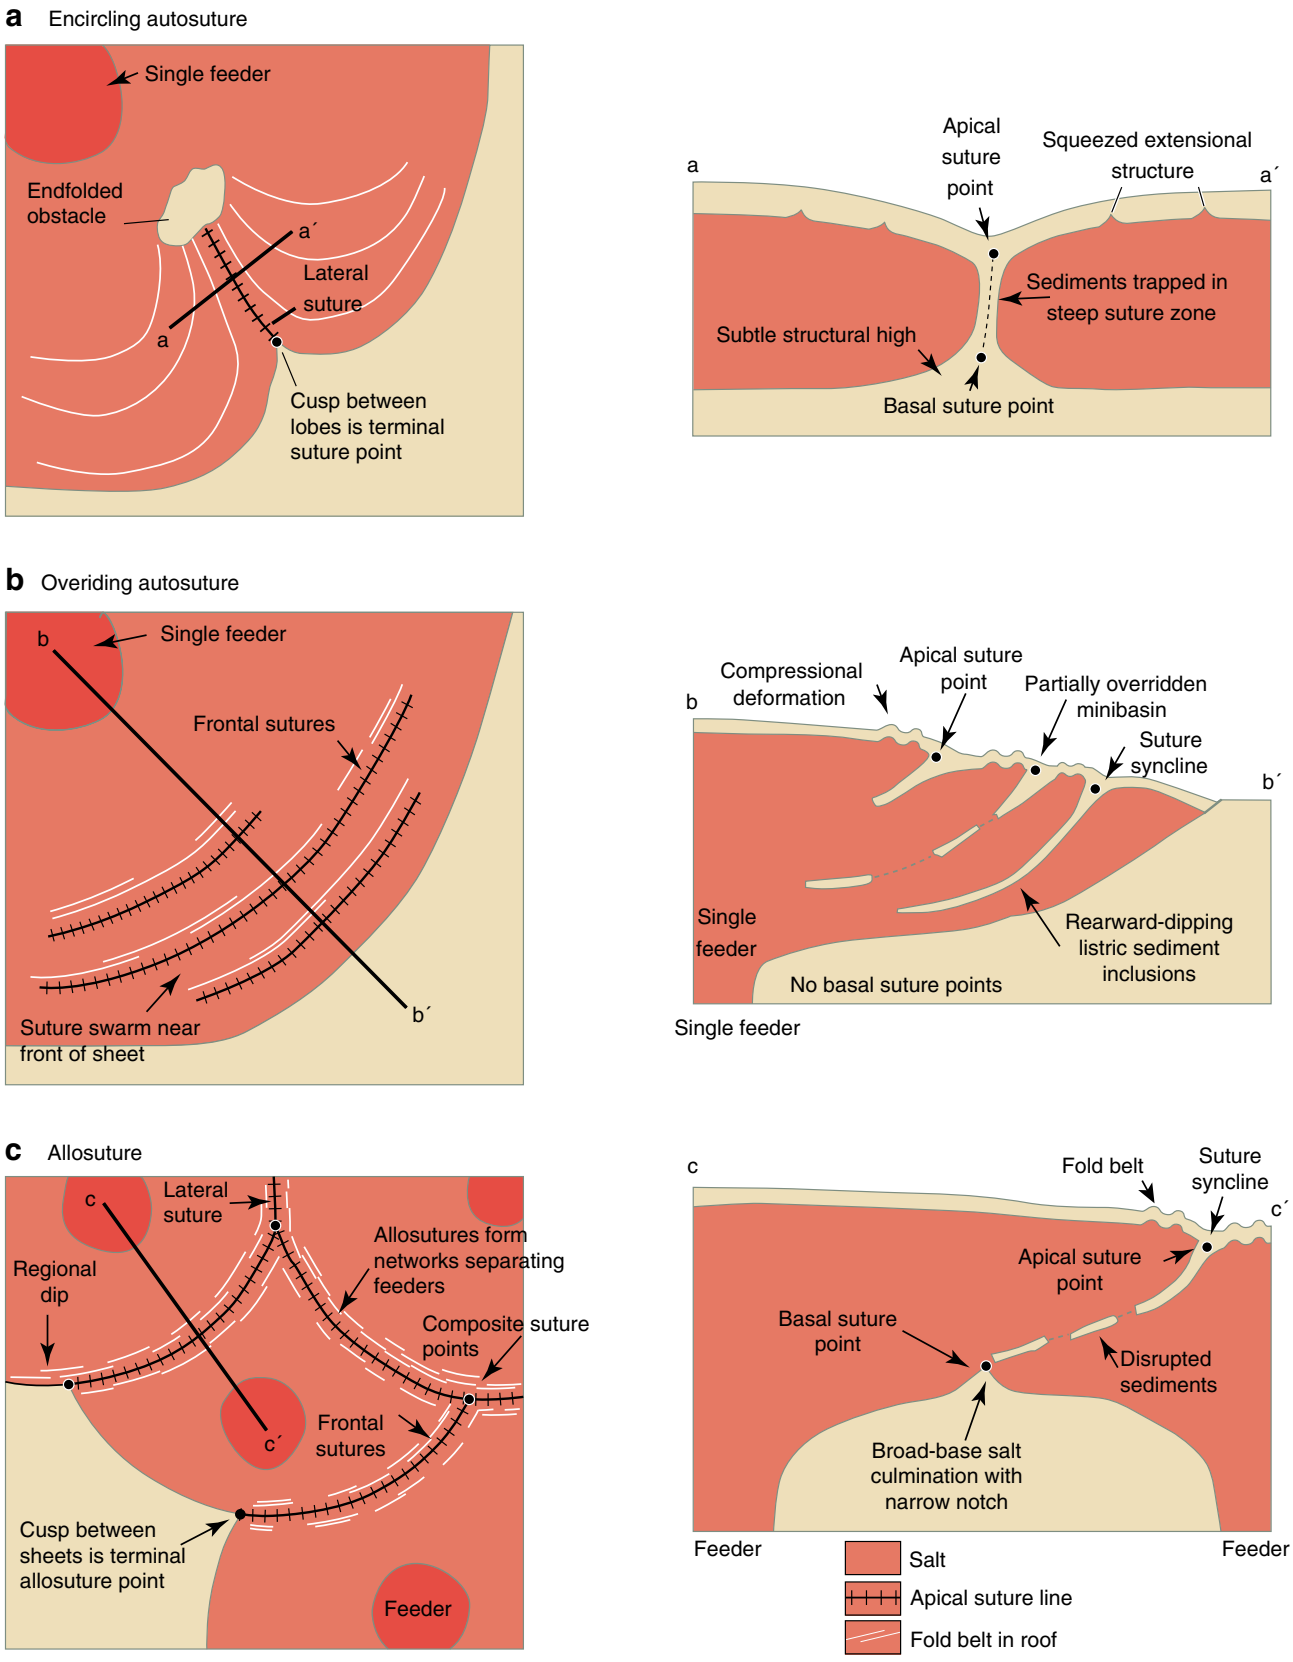

Fig. 6.53 Criteria for recognizing suture types (After Dooley et al. 2012)

Encircling flows typically meet as a short lateral suture just downdip of an enfolded obstacle, which is typically a grounded minibasin. Structural fabrics in the top of salt or roof reflect salt flow encircling this obstacle. The autosuture is merely an ornament on the periphery of a single sheet whose edge first divides into two small lobes and then sutures. Because encircling autosutures normally do not override much, sediments trapped in the suture typically remain connected to the basal suture line. Overriding typically forms one or more frontal autosutures near the toe of a salt sheet slowed by another sheet or by aggradation of the abyssal plain (Fig. 6.53b). Sediments trapped in the autosuture form a rearward-dipping, listric, intrasalt reflector that commonly terminates into a partly overridden minibasin along the apical suture line (Fig. 6.53b). Overriding autosutures may occur in swarms, resembling an imbricate thrust belt. Because an overriding autosuture forms by imbrication of the saltsheet roof, no basal suture line exists.

Allosutures are generally easy to identify, although they share aspects of both encircling and overriding autosutures (Fig. 6.53c). Because allosutures separate two independently sourced salt sheets, they are marked by a broad base-salt culmination below the basal suture line. These culminations, together with salt-sheet edges, form a regional network separating canopy feeders from one another. Most lobe boundaries in the canopy margin are terminal allosuture points (Fig. 6.48), although a few may instead be associated with encircling autosutures.

Finally, roof sediments trapped in allosutures may extend in a near-continuous band from basal to apical suture lines, if sheet override has been minor. However, these sediments may tear from the basal suture line after major override, which can be difficult to distinguish from an overriding autosuture.

Two factors can complicate suture interpretation. First, sutures are not the only sources of intrasalt reflections in canopies. Material originally interbedded with the salt, igneous intrusions, foundered roof material, and coherent seismic noise may also produce intrasalt reflections. In many cases, sutures can be distinguished from these by their association with lobe boundaries, apical and basal suture lines, or location with respect to feeders. However, this distinction may not be possible in cases where intrasalt reflections are highly dismembered as, for example, in the Zechstein and Ara salt masses. Second, subsalt structures may deform the base of a salt canopy, creating structural highs and lows in the base of salt that are unrelated to salt emplacement. According to Dooley et al. (2012) care must be taken to map subsalt structure as well as the base of salt so as to determine whether base salt highs and lows are related to canopy emplacement (ramps and flats) or to subsequent deformation.

As salt canopies spread, prior to merging and coalescing, they interact with adjacent and underlying sediments in four main ways, all of which drive compressive/ thrust deformation responses in the adjacent strata (Fig. 6.54; Hudec and Jackson 2009). In all situations, gravity spreading of a salt canopy produces thrust faults around the canopy rim. These thrusts may form by shear along the base of the salt (Fig. 6.54a), by frontal rolling of the canopy (Fig. 6.54b), by expulsion of underlying sediments (Fig. 6.54c), or by submarine landsliding off the canopy's frontal escarpment (Fig. 6.54d).

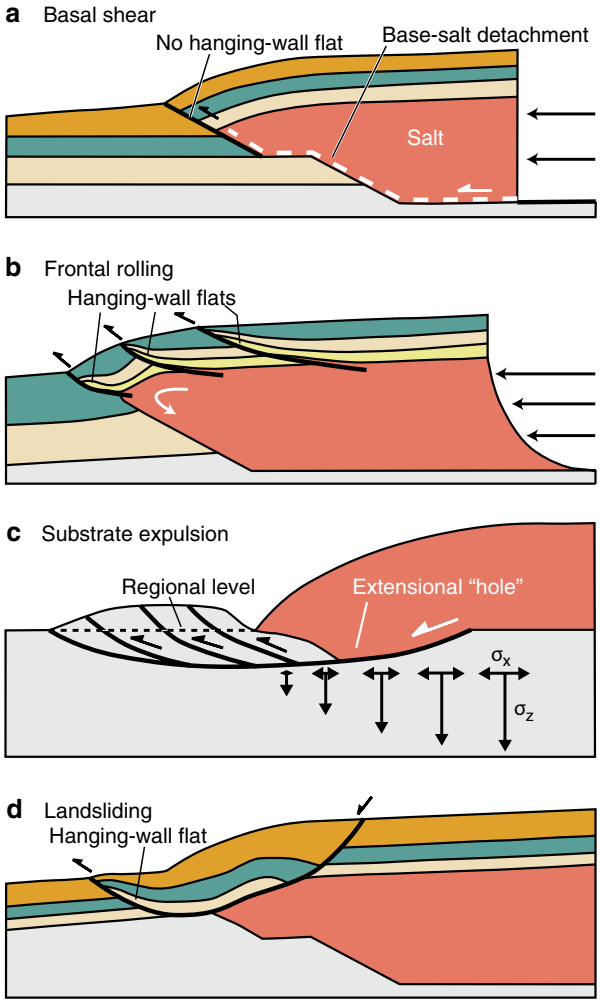

Fig. 6.54 Cross sections showing possible origins of canopy-margin thrust systems. See text for explanation of stages **a**–**d** (After Hudec and Jackson 2009)

Each mechanism has a characteristic structural style, providing clues to processes of shortening in canopy-margin thrust systems (Table 6.2). Canopy-margin thrust systems along the Sigsbee Escarpment in the deepwater Gulf of Mexico have three parts although all three may occur in any particular salt edge location (Fig. 6.55). First, nearly all canopy-margin systems include a roof-edge thrust, which cuts upsection from the tip of the salt canopy and separates condensed strata in the canopy roof from thicker sections on the adjoining peripheral plain. Second, roughly one-third of roof-edge thrusts overlie an imbricate wedge, which telescopes

Table 6.2 Salt advance mechanisms for salt canopies, as inferred from canopy margin thrusts

Thrust type	Key observations	Compatible advance mechanisms	Inferred advance mechanism[a]
Roof-edge thrust	Single thrust Thrust connects to salt tip Hanging-wall flats are rare Footwall cutoffs intersect base of salt	Basal shear, frontal rolling, landslide Basal shear, frontal rolling, substrate expulsion, landslide Basal shear, substrate expulsion Basal shear, frontal rolling	Basal shear
Imbricate wedge	Basal décollement of salt-floor wedges connect to base of salt Strike transitions between salt-tip and salt-floor wedges Imbricate wedges associated with roof-edge thrusts No significant structural lows in the base of salt updip of wedges	Basal shear, substrate expulsion Basal shear, substrate expulsion Basal shear Basal shear, frontal rolling, landslide	Basal shear
Salt-roof thrust	Thrusts are behind salt tip Significant hanging-wall flats	Frontal rolling Frontal rolling, landslide	Frontal rolling

After Hudec and Jackson (2009)
[a]Salt advance mechanism that is common to all key observations

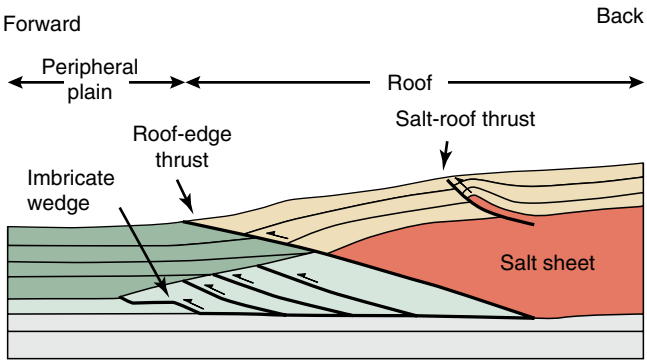

Fig. 6.55 Schematic cross section illustrating the three types of canopy-margin thrust. The diagram illustrates the proposed reference frame for salt-canopy margins: "forward" refers to the direction of canopy advance, and "back" is toward the interior of the canopy. Usage of forward and back in the literature is not yet consistent when describing the sense of salt flow with reference to the peripheral plain (After Hudec and Jackson 2009)

sediments on the peripheral plain above a bedding-plane décollement. Third, in a few areas, salt-roof thrusts shorten the roof of the salt sheet. Because roof-edge thrusts and imbricate wedges both form by shear along the base of the salt allochthon, their abundance along the Sigsbee Escarpment implies that basal shear is the primary mode of advance there. Despite the dominance of basal shear, however, the Sigsbee Escarpment exhibits a wide range of structural styles. Hudec and Jackson (2009) speculate that this range reflects variations in relief on the canopy margin, thickness of the roof above the canopy toe, strength of the base-salt zone, and strength of sediments on the peripheral plain.

Fault Families in Allochthons

In the past three decades our understanding of gravity gliding, gravity spreading and salt flow in the Gulf of Mexico, the Santos Basin of offshore Brazil, the Kwanza Basin of offshore Angola has improved to where linkages between faults, welds and salt-related anticlines in allochthon provinces can be predicted at the continental margin scale (Fig. 6.1b). Linkages between anticlines and extensional faults predominate, but links to contractional faults and strike-slip faults can also be predicted within a prograding sediment prism (Figs. 6.56, 6.57, and 6.58). The observed diversity of structuration reflects the linked nature of gravity-driven deformation in zones where sedimentary overburden spreads under its own weight and slides basinward atop salt detachments (Rowan et al. 1999; Hudec and Jackson 2006). These passive margin salt-floored systems are a subset of near-field[16] stress driven type 1 fold and thrust belts that includes shale detachments as well as salt-lubricated systems (Morley et al. 2011, 2014).

Linked gravitational systems, floored by salt, can range in scale from small, isolated, allochthonous salt sheets to the entire continental margin as it detaches and slides above autochthonous salt. Extension characterizes the landward and middle parts of salt-linked continental margin systems, while contraction usually occurs near the basinward limits of allochthonous salt (Figs. 6.1b). Strike-slip deformation typically connects these two domains. Where frontal contraction is not observed, downslope translation is usually accommodated by extrusion of allochthonous salt tongues.

Using a synthesis of existing seismic, Rowan et al. (1999) reclassified the salt-associated faulting and welding in the Gulf of Mexico into related families (Fig. 6.56). The classification is strictly geometric, without reference to kinematics, dynamics, or genesis but can be linked to the allochthon evolution outlined by Hudec and Jackson (2006); compare evolution streams

[16]Distinction between near-field and far-field is typically assumed, rather than defined. Far-field typically refers to continent-scale influences (e.g., continent-continent collision), while near-field refers to more local-scale stresses such as those involved in gravity gliding.

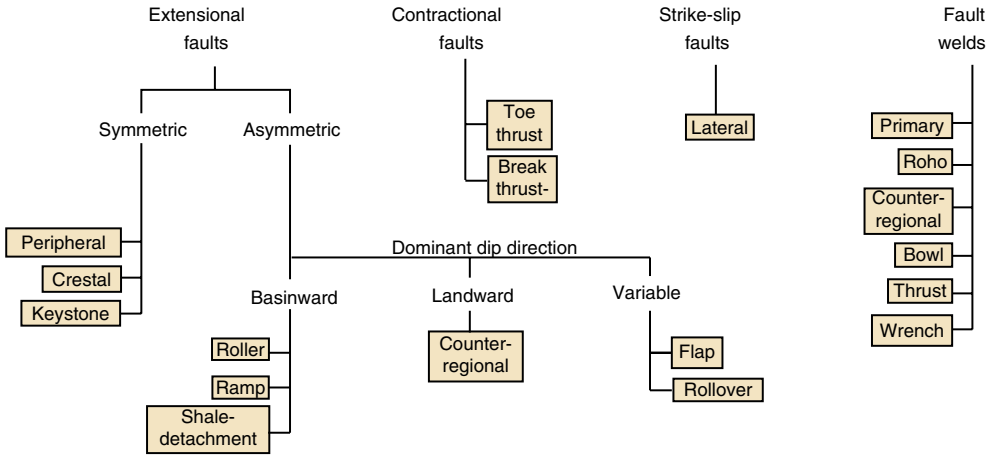

Fig. 6.56 Classification system based on fault families and fault welds observed in the northern Gulf of Mexico (After Rowan et al. 1999)

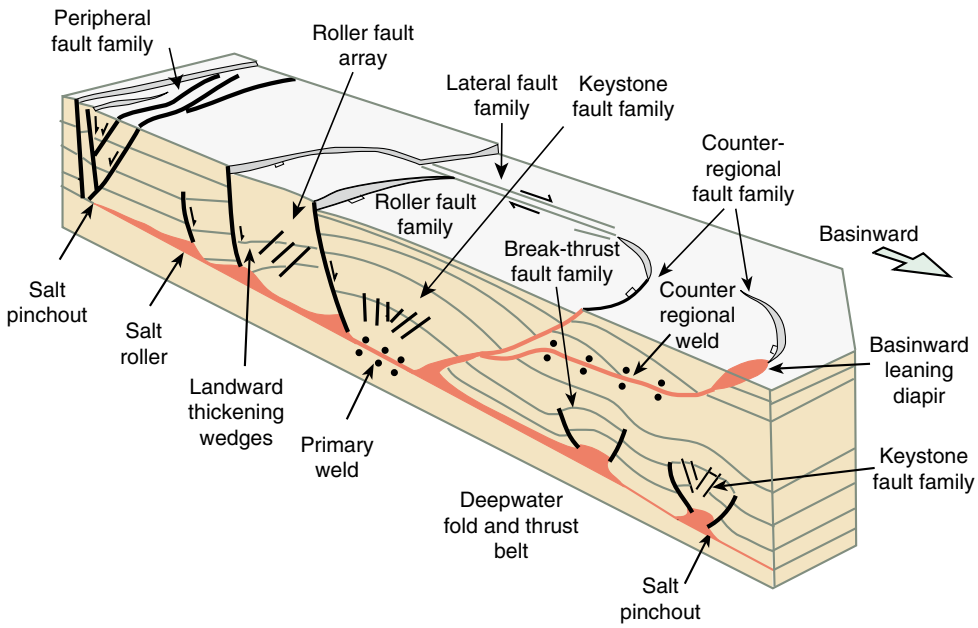

Fig. 6.57 Fault families in areas of salt flow centred on the primary salt level (autochthonous salt), which evacuates to leave behind the primary weld (After Rowan et al. 1999)

in Figs. 6.37 and 6.58. Like the evolution of the salt allochthons that drive them, the different fault families are connected by linked fault systems (inheritance), which, in turn, are associated with different types and stages in the gravity-driven evolution of flowing salt shelf systems. The transition from one fault family into another is related to position of the salt allochthon within the continental margin sediment prism (Fig. 6.56). Each fault family is an array of faults having similar three-dimensional form and geometric relationships with deformed strata and associated salt. A fault family can include not only a dominant style (e.g., a basinward-dipping, listric, growth geometry), but also smaller faults that accommodate the strains and displacements induced by the primary faults. These subsidiary elements include antithetic faults, whose dip is opposite to that of the primary faults, and faults at high angles to the dominant trend. The various fault families and fault welds are tied to five varieties of salt systems: autochthonous salt, salt-tongue systems (both stepped counter-regional and Roho evacuation styles), salt-stock canopies, and salt nappes.

Autochthonous salt tectonics: Autochthonous salt flow is centred on the level of the primary weld (Fig. 6.57). In the Gulf of Mexico the formation of the faulting is driven by two related mechanisms: gravity gliding and gravity spreading. Early salt flow is dominated by gravity gliding and association extension of the suprasalt strata. Oceanic spreading in the Gulf of Mexico began during the Callovian, around the same time the Louann Salt accumulated. The timing of oceanic spreading versus salt deposition in the proto Gulf of Mexico is contentious; some argue they were contemporaneous, others such as Hudec et al. (2013a) argue salt deposition preceded seafloor spreading by 7–12 million years and that oceanic spreading broke up the continuity of the original salt body.

Whatever the timing, subsequent cooling of the lithosphere during differential thermal subsidence probably tilted basinward the proto-Gulf of Mexico continental margin, so driving gravity gliding of the thin overburden above autochthonous salt. Increased clastic input along the continental

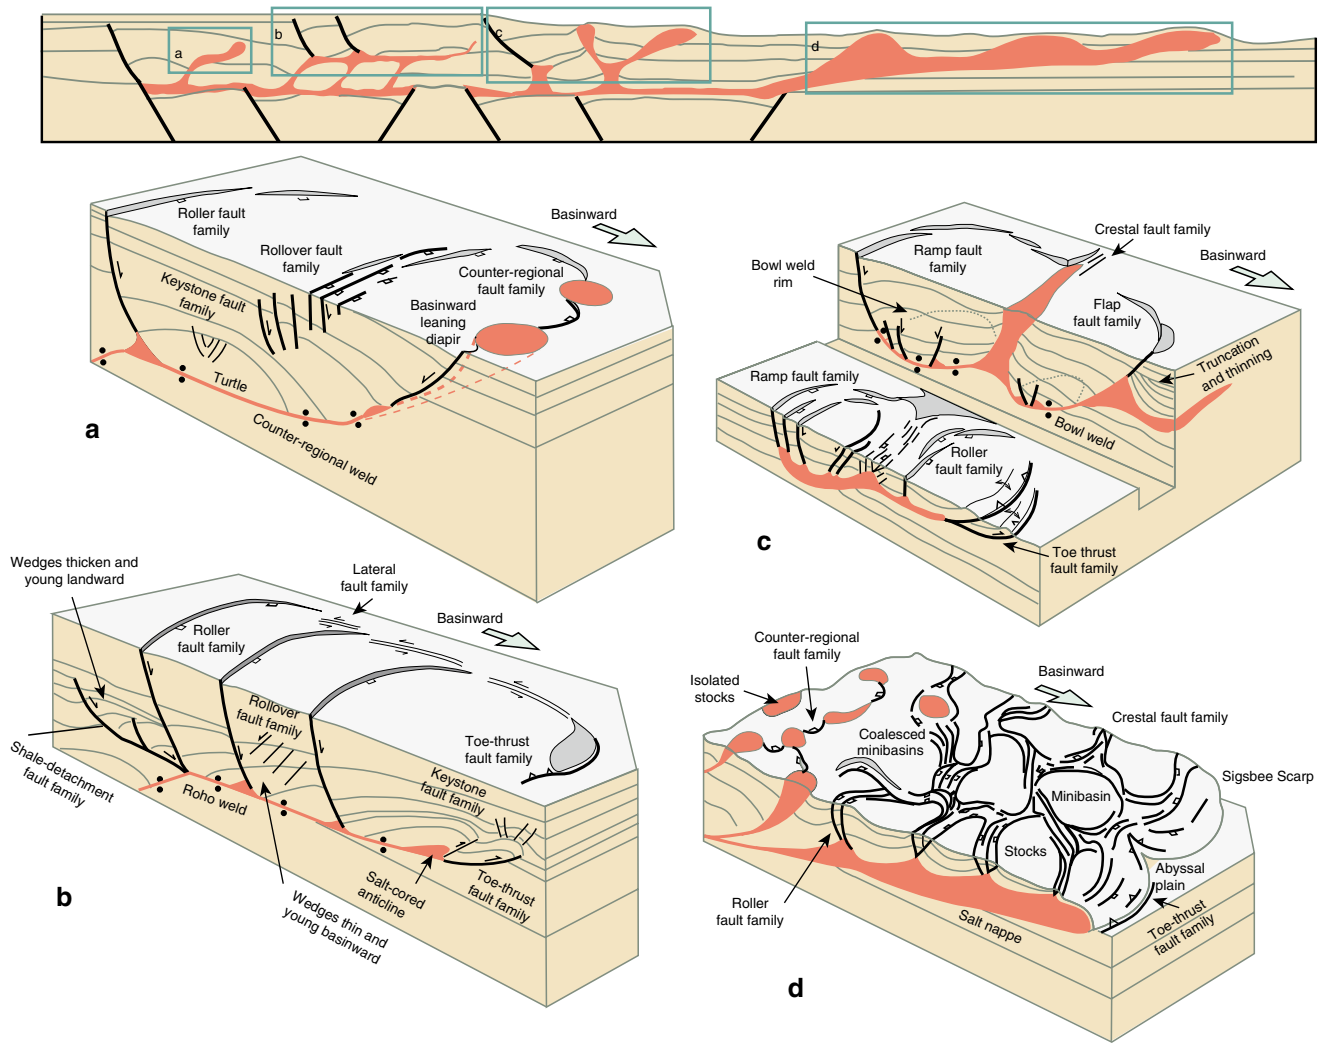

Fig. 6.58 Fault families in salt allochthon provinces, based on the Gulf of Mexico (After Rowan et al. 1999). (**a**) Typical assemblage of fault families and salt or fault welds in a stepped counter-regional allochthonous salt system. Roller faults are less common than the other types. (**b**) Typical assemblage of fault families and fault welds in a Roho allochthonous salt system. (**c**) Typical assemblage of fault families and salt or fault welds in an allochthonous salt-stock canopy. The frontal section shows a partially evacuated salt stock; the back cutout shows two coalesced stocks that have been completely evacuated. (**d**) Typical assemblage of fault families in a salt nappe advancing over the abyssal plain. The basinward area shows an immature stage of evolution; the more landward area shows more highly evolved structures

margin created a depocentre that flexed the underlying crust. This flexure probably reversed the basinward tilt of the autochthonous salt below the continental slope, thereby ending gravity gliding at this level in the stratigraphy; however, the continental margin remained gravitationally unstable and spread under its own weight, especially during Cenozoic clastic progradation. Thus, some of the structures established during early gravity gliding probably were reactivated during subsequent gravity spreading related to ongoing sediment loading and associated local inflation related to salt extrusion.

As a squeezed salt mass climbs the stratigraphy it separates from the primary salt level to become allochthonous salt. Ongoing allochthon loading and flowage forms the same spectrum of faults seen in autochthonous structures but now at levels above those of the mother salt bed (right side of Fig. 6.57). Peripheral and roller fault families accommodate basinward extension at the landward margin of the basin and throughout the salt basin, respectively. Early reactive diapirism can create crestal fault families in this extensional zone. The extension is balanced by a combination of distributed salt extrusion and contractional deformation at the basinward limit of salt. Salt extrudes mainly from basinward-leaning salt diapirs (overlain by counter-regional fault families), but also from more vertical salt stocks. Contraction at the toe of the system creates detachment folds and break-thrust fault families. Folding, whether due to slip on extensional roller faults, collapse of seaward-leaning feeder diapirs, or contraction, generates a combination of rollover and keystone faults. Lateral fault families segment extensional regimes, possibly

controlled by the geometry of faults in the rifted basement (e.g., Watkins et al. 1995; Rowan 1997). Remnant salt or primary welds provide the common link in autochthonous salt systems.

In a landward to basinward traverse, allochthonous fault associations break down into four interrelated fault families, which are shown in basinward order in Fig. 6.58a–d.

Stepped Counter-regional Salt System: Salt-tongue systems comprise subhorizontal salt sheets fed by one or more basinward-leaning feeder diapirs (Fig. 6.58a; Rowan et al. 1999). These systems can evolve as stepped counter-regional systems (Schuster 1995), consisting of a deep feeder weld, an intervening evacuated salt sheet, and higher level basinward-leaning diapirs and landward-dipping salt welds. The linked fault system associated with this counter-regional weld is relatively simple. It is dominated by a counter-regional fault family and associated rollover and keystone fault families. Additionally, a second counter-regional fault family may overlie the deep feeder (not shown). If there were any basinward translation during evacuation of the sheet, there may be a roller fault family detaching on the secondary weld,

Roho Salt System: Salt-tongue systems can also evolve as Roho systems (Fig. 6.58b; Schuster 1995). These are generally longer in the downdip direction than are stepped counter-regional systems. The extra length creates a greater elevation head for the salt and thus more gravity spreading. The result is a linked fault system dominated by a roller fault family. In places, shale-detachment fault families merge into the landward or lateral edges of the salt layer or weld. The extension on the combination of roller and shale-detachment faults is accommodated by salt extrusion or shortening along a toe-thrust fault family. Extension and contraction are linked by lateral fault families and a Roho weld. Minor structures include rollover fault families in the hanging walls of the roller faults and keystone fault families in the crests of contractional folds.

Salt-Stock Canopy System: Salt-stock canopies can be true or apparent depending on whether amalgamation occurred during stock growth or stock evacuation, respectively. In both, a complex linked fault system can develop with the link provided by remnant allochthonous salt and bowl welds (Fig. 6.58c; Rowan et al. 1999). Partly or fully evacuated stocks can have ramp fault families at the landward margins, flap fault families at the basinward margins, and older roller fault families in the central areas. Where the canopy feeds a subhorizontal salt tongue, reactive diapirs and crestal fault families can form at the stretched hinge between the stock and tongue. Translation above the tongue can create roller and toethrust fault families linked by lateral fault families.

Salt-Nappe System: Salt nappes are large allochthonous salt bodies that advance tens to hundreds of kilometres basinward over long periods of time (Worrall and Snelson 1989; Rowan 1997; Morley et al. 2011). The front of a salt nappe is an arcuate lobe of salt covered by a generally landward-thickening clastic skin. In its most immature, distal regions, the structure is dominated by circular to elliptical minibasins up to 40 km wide. They subside into the salt and are separated by reactive diapirs formed during radial gravity spreading of the salt nappe (Jackson and Vendeville 1994). Thus, the linked fault system is dominated by a polygonal pattern of crestal fault families (Figs. 6.58d). Toe thrusts can occur at the front of the nappe. Landward, the regular polygonal pattern degrades as minibasins coalesce. Interaction between salt deformation and sedimentary loading may result in various fault families (e.g., counter-regional, roller, flap, lateral) and welds; however, the three-dimensional geometry of fault families in mature salt nappes is unknown because mature examples have not yet been identified.

Linking Allochthons at the Basin Scale

Clearly, salt flow in a loading and extending halokinetic basin creates a number of predictable geometries, rollovers and fault patterns that are related by variations in rates of extension and loading as prograding suprasalt sediments evolve into ramps and welded basins (Fig. 6.59). In the Gulf of Mexico it is important to distinguish between the more landward intervals of salt flow, which are sourced in autochthonous salt and by definition are still linked to the primary salt level, and the more basinward flows sourced in allochthonous salt where the salt slug is no longer necessarily connected to the primary weld (Fig. 6.59a; Rowan et al. 2001). At this broad continental margin scale of flow, Karlo and Shoup (2000) argue that the thickness of the primary salt bed (Jurassic Louann Salt in the Gulf of Mexico) is what separates regions of autochthonous and allochthonous salt flow. Allochthonous salt tends to be sourced in the thickest portions of the primary salt, while autochthonous flow tends to be sourced in the thinner areas of the primary source bed (Fig. 6.59a). The resulting salt features and associated withdrawal basins make up an ordered but gradational sequence of structural styles across the shelf and slope (Karlo and Shoup 2000).

The sequence progresses from updip autochthonous basins with static diapirs that aborted and were buried, to the most downdip withdrawal basins that have been active at various levels in the stratigraphy since the Mesozoic and are related to an amalgamated and fully allochthonous salt canopy. They argue that differences in depositional thicknesses of the Louann Salt mean the thicker eastern half of the Gulf of Mexico basin has a full progression of salt-related structural styles, while the western half of the basin has a wide area lacking major salt structures that then abruptly juxtapose against tabular salt. The gravity slide detachments characteristic of the western half of the basin are superimposed over salt-related structures where original

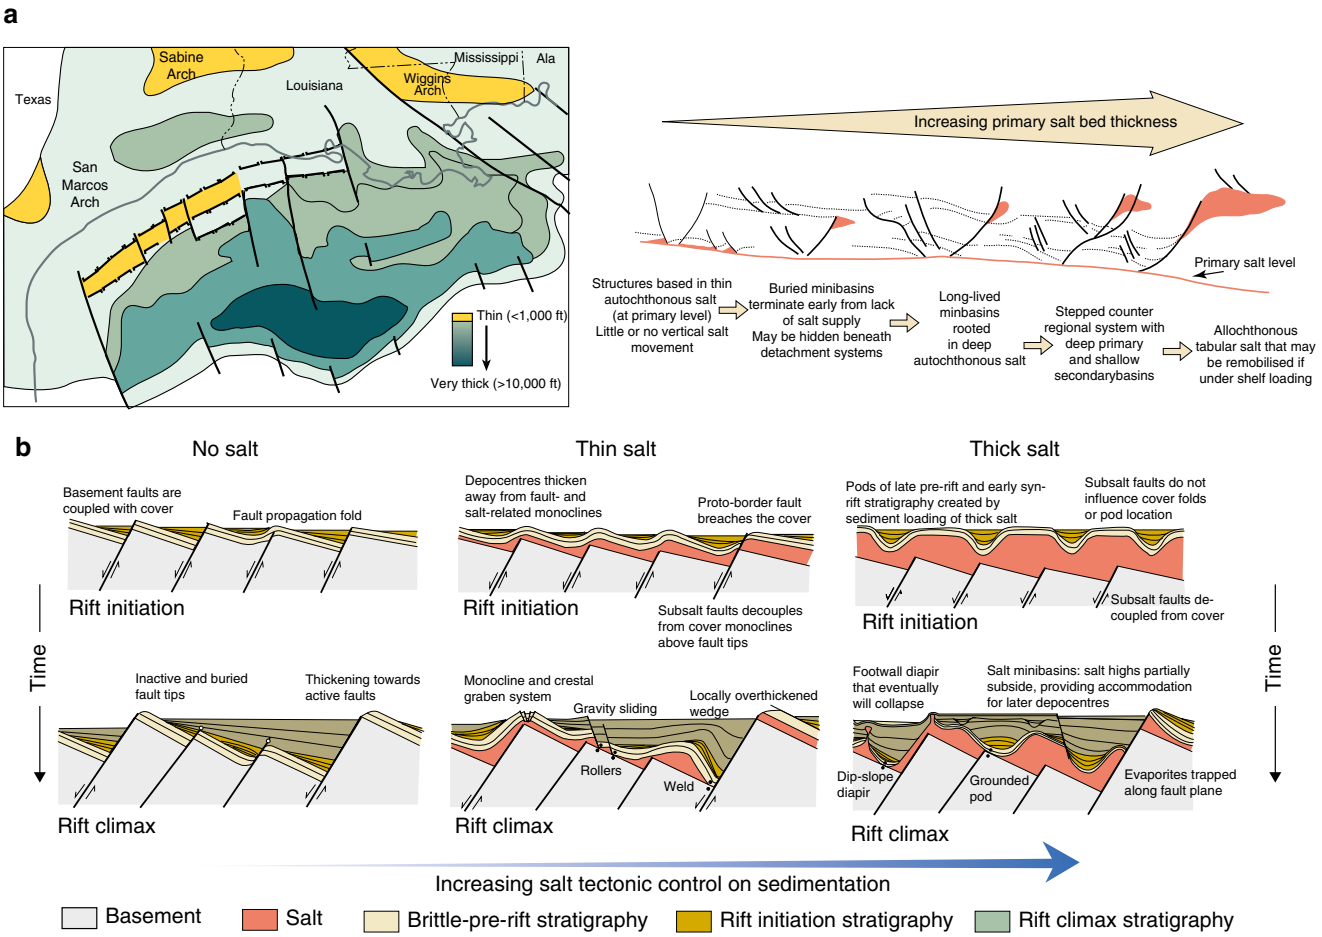

Fig. 6.59 Salt tectonic style is controlled by original thickness of the primary salt layer. (**a**) Approximate salt thickness at the time of deposition of the Jurassic Louann Salt whereby schematic cross section shows that autochthonous salt deformation tends to occur in zones of thinner primary salt. Allochthonous salt deformation is favoured by areas of thicker primary salt (After Karlo and Shoup 2000). (**b**) Tectonic evolution of salt geometries and minibasins in three situations seen in various North Sea grabens of; (i) no salt, (ii) thin salt, (iii) thick salt (After Duffy et al. 2013)

salt thickness was insufficient to maintain structural growth at higher levels.

The early work of Karlo and Shoup (op cit.) is supported by the results of Hall (2002) who found that most of the deep-water region of the northern Gulf of Mexico was underlain by an inflated mother salt layer during the Cretaceous to middle Miocene. The southern edge of this mega-pillow was either the depositional edge of the salt or a basement structure. Partial deflation of this mega-pillow during Late Miocene-Pleistocene sedimentation resulted in the formation of large structures overlying the mother salt level. The process of 'deep' structuring was synchronous with progressive emplacement of shallow (allochthonous) salt to form the Sigsbee canopy in the southern part of the present-day deepwater area.

A similar relationship between salt thickness and deformation style is seen in the Danish Central Graben (Fig. 6.59b; Duffy et al. 2013). Syn-rift basins lacking salt display classical half-graben geometries bounded by thick-skinned faults. In contrast, grabens that entrain increasing thickness of salt show a corresponding evolution in suprasalt depositional style with increasing degrees of structural decoupling between sub-Zechstein structure and cover fault and fold systems. The addition of mobile evaporites to the rift results in: (i) complex and spatially variable modes of tectono-stratigraphic evolution; (ii) syn-rift stratal geometries which are condensed above evaporite swells and over-thickened in areas of withdrawal; (iii) compartmentalized syn-rift depocentres; and (iv) masking of rift-related megasequence boundaries (Duffy et al. 2013). Evaporites clearly exert a significant influence upon rift structural style, the distribution and thicknesses of syn-rift units and the formation of allochthonous salt units higher in the stratigraphy.

Worldwide, detailed analysis of halokinetic basins, ranging from salt-floored passive margins to tectonically-induced contractional basins (with a concentration of detailed seismic coming from the hydrocarbon regions of the circum-Atlantic and Mediterranean), has shown there is a predictable timebased formative relationship in allochthon/minibasin associations. The common evolution to the various continental margins experiencing gravity-driven salt

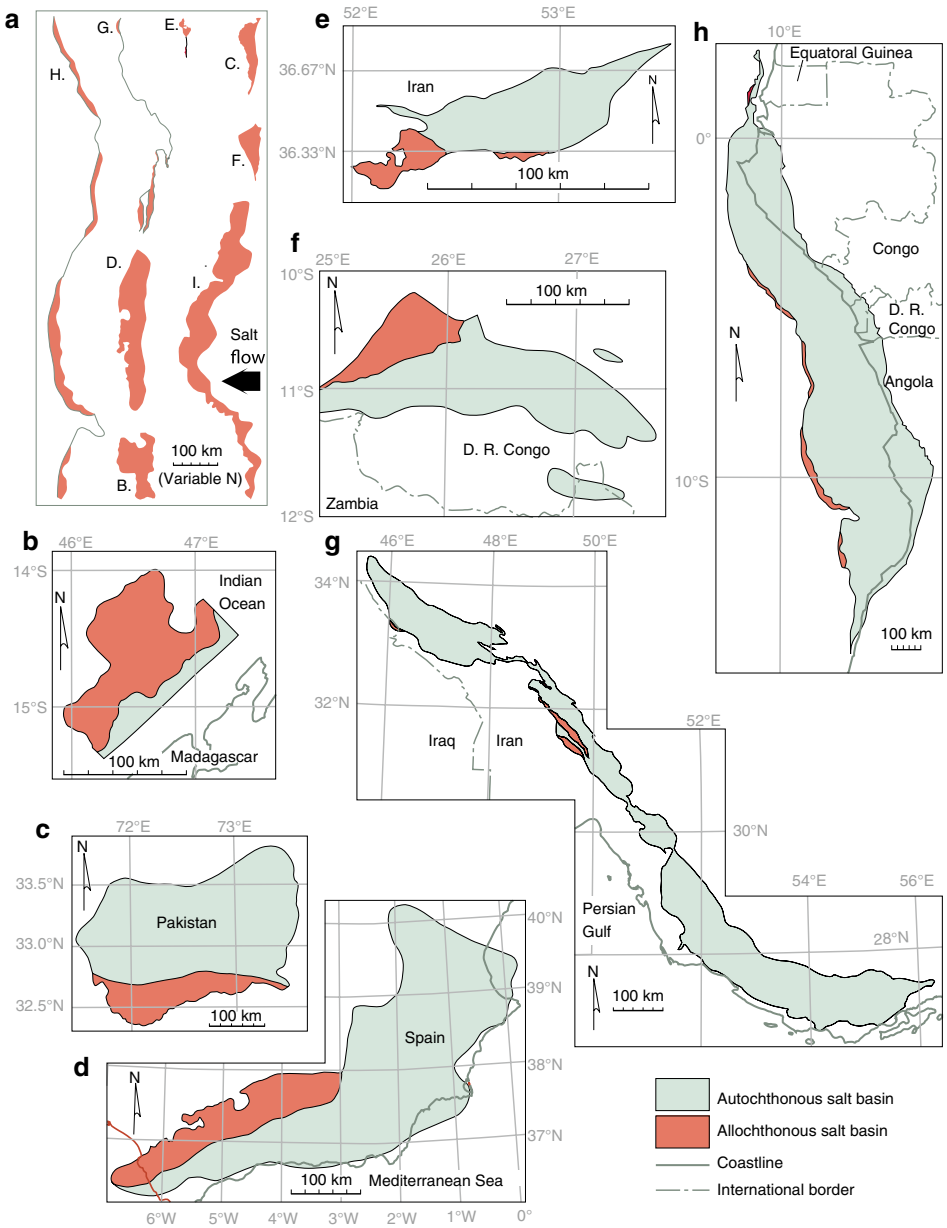

Fig. 6.60 Maps showing source-fed allochthonous fringes in evaporite basins across the world (After Hudec and Jackson 2006 and references therein). In each map, evaporite sheets have spread beyond the autochthonous salt basins (*shaded green*), which typically also contain additional allochthonous parts in them (not differentiated). (**a**) Compilation of selected allochthonous fringes (*A–I*) at a uniform scale but with variable North to show the wide range of allochthon sizes. Each allochthon fringe is oriented so that the dominant flow of the salt sheets is from left to right (indicated by *thick black arrow*) left. The deep-water allochthonous fringe of the Gulf of Mexico's passive margin (labeled I) is also shown in A but not shown in rest of diagram (see Fig. 6.61) for the detail of this allochthonous thrust fringe that is I. The autochthonous interior of the Gulf of Mexico fringe comprises mostly plug-fed sheets supplied by stocks. All other maps (B through H) are at different scales, indicated by 100 km scale bar, and have north to the top. (**b**) Majunga Basin, northwestern Madagascar passive margin; evaporites of probable Jurassic age. (**c**) Salt Range, Himalayan foreland, Pakistan; Punjab evaporites of Neoproterozoic–Cambrian age. (**d**) Guadalquivir Basin, Betic foreland, southern Spain; Keuper (Carnian-Triassic) evaporites. (**e**) Garmsar Basin, Alborz foreland, northern Iran; Eocene and Miocene Upper Red evaporites. (**f**) Katanga Basin, Lufilian foreland, Shaba Province, southern D. R. Congo; Neoproterozoic Roan evaporite residues (rauhwacke). (**g**) Gachsaran Formation, Zagros foreland, southwestern Iran; Miocene evaporites; many allochthonous salt sheets, derived from the Neoproterozoic–Cambrian Hormuz Formation are also present in much of this region. (**h**) Aptian salt basin, Angolan passive margin, offshore Equatorial Guinea to Angola

tectonics is characterised by; (1) an underlying initially thick 100–200 m + autochthonous salt bed (now with overlying plug and wall-fed allochthonous layers) and (2) a source-fed allochthonous margin or fringe to the autochthonous system, which is located along the downdip continental slope/edge (Fig. 6.60; Hudec and Jackson 2006).

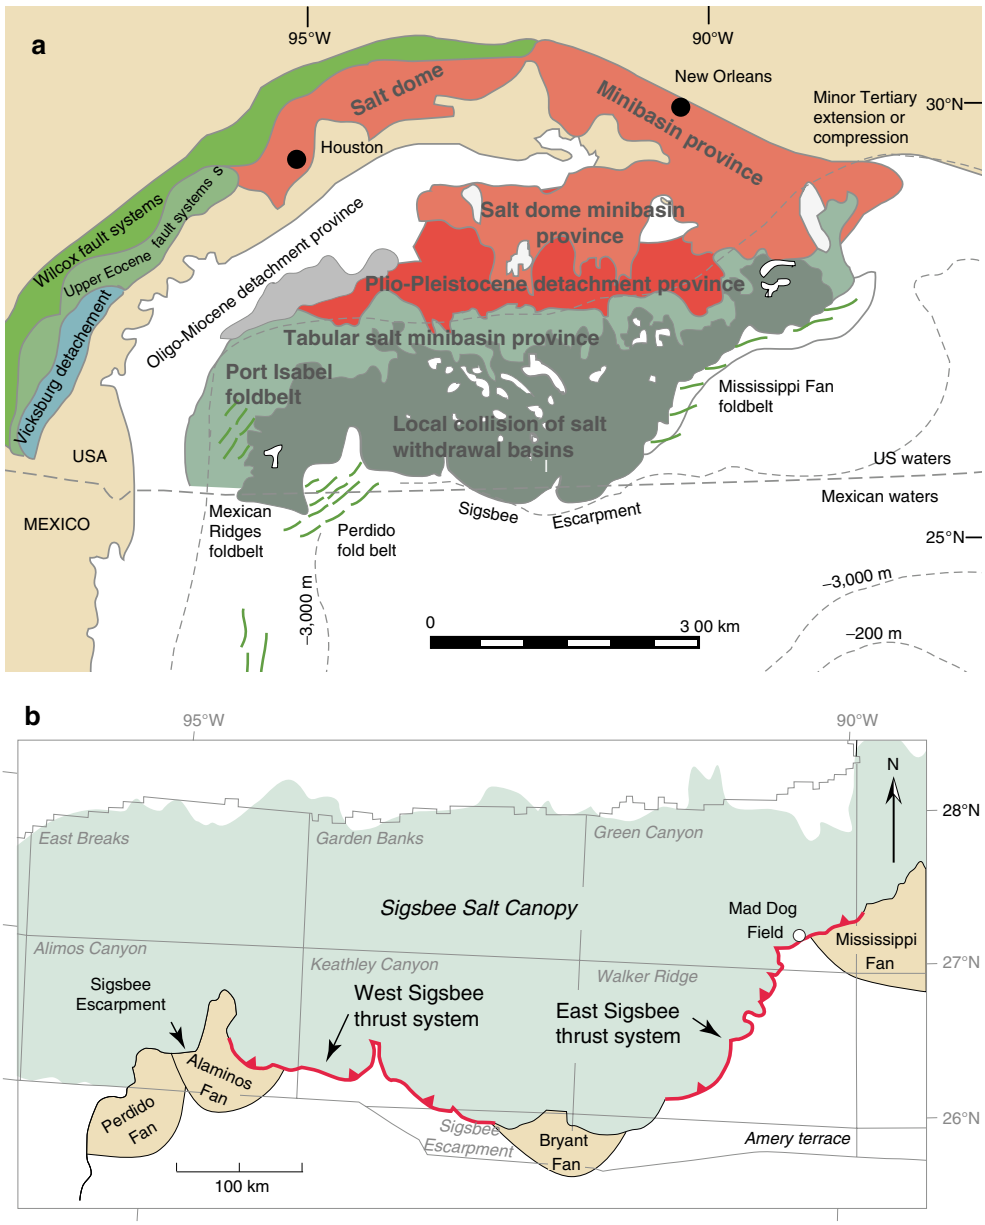

Fig. 6.61 Salt and allochthon distribution in the Gulf of Mexico. (**a**) Distribution of thrusts in the context autochthonous and allochthonous salt basins (After Hudec and Jackson 2006). (**b**) Map showing main structural units salt distribution and water depths, based on Morley et al. (2011)

Salt basins with this linked autochthon-allochthon style of salt tectonism range in scale from the supergiant 1,000 km-long salt canopy systems of the larger of the circum-Atlantic salt basins to the 100 km long systems of offshore Madagascar (Fig. 6.60). In the Gulf of Mexico, as in many salt floored continental margins, the allochthonous downdip basin margin links a deepwater fold and thrust belt to a deepwater thrusted edge to the allochthon and its latest canopy area (Fig. 6.61). Interestingly, the downdip canopy edge overlies oceanic, not transitional, crust and is a strong indication of how far downdip the Louann Salt has migrated (been thrust) as it climbed the basin stratigraphy (compare Fig. 5.56 and 5.57 with 6.61b)

Compressional Salt Tectonics

Contractional or tectonically shortened salt basins are numerous and can be loosely classified into three conceptually shingled compressional styles (Figs. 6.62 and 6.63; Letouzey et al. 1995):

- Zones of shortening at the toe of prograding and gravity-gliding systems (thin-skinned; Fig. 6.62a),
- Thin-skinned deformation in fold and thrust belts (Fig. 6.62b),
- Intracratonic inverted basins with or without wrench components – thick-skinned with basement involved in the compression (Fig. 6.62c).

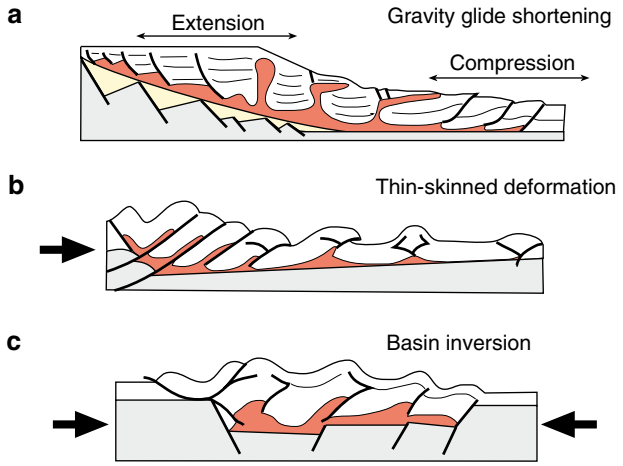

Fig. 6.62 Compression tectonics. (**a**) Gravity glide shortening at the toe of the continental slope. The basement is not involved in the deformation. (**b**) Thin skinned deformation in front of the fold and thrust belt where subduction is the driving mechanism in the inner foldbelt. (**c**) Intracratonic inverted basin. Driving mechanism is regional contraction, which is orthogonal or oblique to the pre-existing graben. Basement, salt and overburden are all shortened together (After Letouzey et al. 1995)

Contractional salt tectonism is produced either by convergent (including transpressive) plate tectonics, or is restricted to the seaward portions of divergent continental margins, where downslope gravity-sliding stacks and thrusts overburden blocks against each other as they slide basinward atop a salt décollement. Contractional salt tectonics require either the minimum principal stress (σ_3) to be vertical (so creating shortening) or the intermediate principal stress (σ_2) to be vertical (resulting in transpression; Jackson and Talbot 1994). Compression in a salt-entraining basin tends to thicken both salt and its overburden units. This increases overburden strength and laterally squeezes the feeding stem of any existing diapir, while the increased overburden strength tends to impede piercement. Shortening or squeezing of diapirs, that earlier formed in extension, is an under-recognized process in many gently-shortened salt basins.

Shortening with Gravity Gliding

Belts of upslope extension are paired or linked to downslope compression on rapidly prograding shelf-slope systems along salt-cored passive continental margins. Overburden sediment slides downslope atop a lubricating salt layer, with the translation largely driven by the increasing weight of sediment accumulating atop the salt (Fig. 6.62a). Shortening and gravity-driven compressional structures typify the toes of such systems, while extensional features and welds occur in the upslope position. Areas of extreme extension in the upslope regions evolve into regions of raft tectonics. In the zone between areas of extension and compression some large plates of sediment (up to tens of kilometres across and a kilometre or more thick) can shift or translate downslope with little intraplate evidence of migration until the downslope edge starts to experience compression and pop-up structures form, such as squeezed diapirs.

Salt-cored rising growth folds and active thrusts typify the compressional toes of such regions of into-the-basin salt translation. Compressional foot of slope examples, lubricated by salt décollement, include (Fig. 6.63): the Perdido and Mississippi Fan foldbelts in the Gulf of Mexico (Schuster 1995), the deep Campos and Santos Basins of offshore Brazil (Cobbold et al. 1995, 2001), offshore west Africa (Duval et al. 1992; Cramez and Jackson 2000; Brun and Fort 2004), the eastern Mediterranean adjacent to the Nile Deep Sea fan (Sage and Letouzey 1990), and offshore Yemen (Heaton et al. 1995). The salt in all the areas, with the exception of the Mediterranean, was precipitated in early post-rift time with consequent thermal subsidence generating a basinward tilt of the continental margin (typically > 1°–3°). The tilt was an early contributing factor to the décollement and gravity gliding, and is a likely triggering mechanism (Brun and Fort 2011). The other likely trigger is differential loading tied to the rapid progradation of the up-dip shelf margin sediments; (Rowan et al. 2012b). Compressional toe-thrust and diapiric systems are not the sole province of salt-floored systems, but also occur in fold and thrust belts along the deepwater edges of mud-rich evaporite-free continental margins, such as the Neogene fluvio-deltaic wedge of Brunei and the Niger Delta of Africa (Morley et al. 2011).

Because salt-floored extensional domains on active passive margins tend to lie in a more proximal shallower water positions they are, to date, better studied than the associated downdip compressional terrain. Contractional or compressional domains tend to lie in deeper water further out into the basin at the foot of a continental slope or a prograding delta front. Many of these offshore compressional areas are covered by waters that are still too deep to be exploited with current drilling technology.

Shortening in gravity-glide salt belts is usually accommodated in salt-cored compressional foldbelts with growth-folds near the toe of the salt layer or at the base of the continental slope. Contractional growth folds are the near-surface subseafloor expression of a ramping thrust fault at the downdip end of an inflating salt allochthon. If the crest of a salt-cored fold is eroded or weakened enough by crestal faulting, salt may burst through as an active diapir. Once it reaches the surface, it can continue to grow as a passive diapir instigating a new allochthon-floored stratigraphic level of into-the-basin gliding.

The Mississippi Fan or Atwater Foldbelt lies 200 km SSE of New Orleans and is defined by a such a series of ENE trending thrust-associated growth-anticlines down dip of the current allochthon salt sheet canopy and is sourced in the

Fig. 6.63 Worldwide occurrences of compressive deformation that involves salt sequences (In part after Letouzey et al. 1995; Davis and Engelder 1985, and SaltWork version 1.6)

Jurassic Louann Salt (Fig. 6.64; Rowan 1997). Today it is a zone of compressional response to updip loading and associated gravity spreading/sliding along a salt detachment, linked to updip normal faults. Faults and folds are dominantly south vergent, although symmetric box folds and backthrusts exist[17]. Updip, the shallow allochthonous salt sheets of the Sigsbee Nappe have over-ridden the landward portions of this same foldbelt to create a number of hydrocarbon targets. Thickness variations in sediments above the Top MMR and a lack of such variations in more recent sediments and the presence of an erosional unconformity atop the Mississippi Fan unit suggest structures actively grew near the seafloor prior to the current episode of Tertiary-age shortening.

Profile X-X′ shows a seismic interpretation of one such asymmetric faulted detachment fold cored by the Louann Salt (Fig. 6.64a; Rowan 1997). Data from the Shell 471–1 Atwater well constrain the interpretation in the upper part of the section. The frontlimb of the fold is cut through by a

[17] Backthrust describes a thrust fault that dips opposite to the general dip of thrust faults in a thrust belt and results in displacement toward the hinterland of the belt.

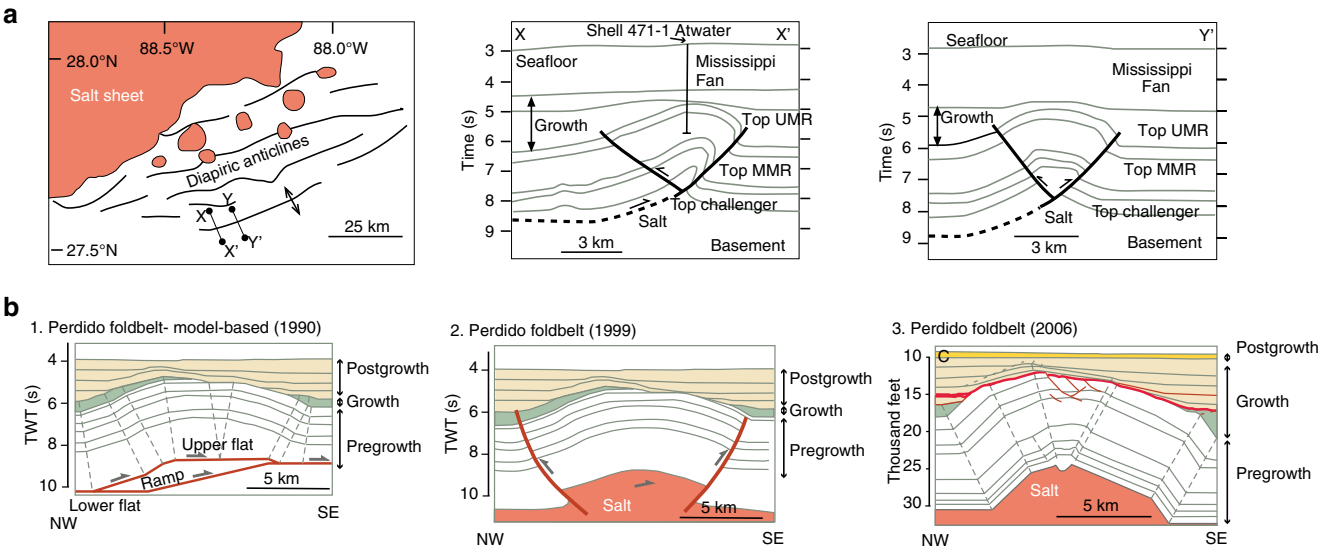

Fig. 6.64 Fold belt structures. (**a**) Thrust folding in downslope compressional belt, northern Gulf of Mexico (After Rowan 1997). Map shows the location of presumed salt-cored anticlinal structures in the Mississippi Fan foldbelt and locations of interpreted sections. X–X′, interpreted seismic section profile' through a salt-cored anticline showing an asymmetric faulted detachment fold. Y–Y′ Interpreted seismic section profile further along strike through the same structure, showing a symmetric faulted detachment fold. *UMR* Upper Mexican Ridges, *MMR* Middle Mexican Ridges. (**b**) Evolving interpretations of the Perdido foldbelt. (*1*) Duplex-cored fault-bend fold model (Mount et al. 1990), (*2*) Reverse-faulted salt-cored detachment fold model (Trudgill et al. 1999), and (*3*) Unfaulted kink-style detachment fold (After Camerlo et al. 2006) *TWT* two-way traveltime

major thrust fault, which is truncated up section by unconformable units of the Upper Mexican Ridges. A possible back thrust is interpreted as cutting through the backlimb and terminating against the main thrust fault. Both thrusts are characterized by fault to fold transfer, although the displacement of individual units can vary up-section. The overall geometry, fold-fault relationship, and the nature of the stratigraphic section, which consists primarily of alternating shales, chalk, marls, and turbidites, are all suggestive of an asymmetric faulted detachment fold (Mitra 2002). The upper part of the Upper Mexican Ridges (UMR) consists of growth units, which are strongly thinned and eroded on the crest of the structure, suggesting that the folds formed primarily during the deposition of these units (growth-fold deposition). The growth units thin onto the crest of the structure on both limbs and also are truncated on the backlimb.

The salt cored structure shown in profile Y–Y′ is located further east along the same ridge (Fig. 6.64a; Rowan 1997). It is interpreted as having a more symmetric pop-up geometry with a relatively flatter fold crest. Thrust faults on both limbs terminate upward within the Upper Mexican Ridges and downward within the Louann Salt. The thrust fault on the southern limb has a larger displacement; however, the difference in displacement on the two thrusts is smaller than in profile X–X′. Once again thickness changes in the upper part of the Upper Mexican Ridges (UMR) unit show it is also a growth fold, with fold-related seafloor topography controlling depositional patterns on the seafloor. The structural characteristics of this part of the fold ridge are suggestive of the symmetric faulted detachment fold model of Mitra (2002), with thrust faults propagating through rotated segments on both limbs.

However, a subsequent paper by Camerlo et al. 2006, dealing with the Perdido foldbelt, argues that an interpretation of a toe thrust and backthrust within the fold, much like the Mississippi foldbelt, may not be appropriate (Fig. 6.64b). The thrust interpretation with a thrust and backthrust, as made by Trudgill et al. 1999, Camerlo argues is not correct, rather the thrust interpretation is an artifact of the poor seismic imaging that occurs at depth with sloping beds. He asserts that the most likely interpretation, given the nature of the overburden, is not faulting but folding and that the folds are unfaulted kink-style detachments. That is, The Perdido foldbelt is composed of detachment folds flanked by megascopic-scale kink bands (Fig. 6.64b). The kink bands are seismically poorly imaged zones of low signal-to-noise ratio and low reflectivity. These seismic artefacts result from problems related to steep dip, primarily dip bias of amplitude and the sensitivity of positioning and coherence of dipping events to migration velocity. The kink-band interpretation is supported by the substantial width of the low-reflectivity zones on the flanks of the folds; the subparallel edges of the low-reflectivity zones; the formation of the low-reflectivity zones at a high angle to layering; the absence of backlimbs that would help to support blind reverse faults at depth; and

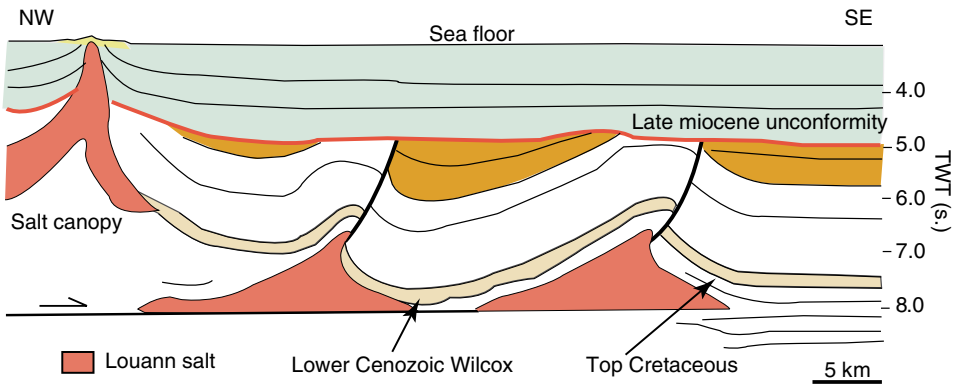

Fig. 6.65 Section across the Mississippi Fan Fold Belt, based on seismic line in Meyer et al. (2005). Indicates regional late Miocene salt inflation

the illumination of steeply dipping bedding in the low-reflectivity zones through improved seismic imaging efforts compares to the 1999 vintage data.

Both interpretations are quite distinct from the earlier interpretation of Mount et al. 1990 (Fig. 6.64b). It was made at a time when only the upper portion of the foldbelt could be seismically imaged. Their interpretation of a ramping thrust duplex was based on section balancing techniques, which largely ignore the influence of the salt cores, as they were too deep to be reliably imaged at that time The three models shown in Fig. 6.64b show substantial differences in the relative thickness of pregrowth, growth and postgrowth successions across the three interpretations. It underlines the difficulties in balancing sections when flowing salt is involved in the reconstruction.

At a somewhat broader scale, there are three main salt-formed compressional deepwater fold belts in the Northern Gulf of Mexico, the Perdido, Mississippi Fan and Port Isabel fold and thrust belts – DWFTB's (Fig. 6.61a). Meyer et al. (2005, 2007) and Morley et al. (2011) provide reviews of deepwater exploration in these trends, and their discussions are summarised in the following paragraphs. A cluster of deepwater hydrocarbon development projects (BAHA, 2002; Trident, 2001; Great White, 2002; Silvertip, Tobago) exist in the Perdido Fold Belt, but more numerous development projects are associated with the Mississippi Fan Fold Belt. Major discoveries in the Mississippi Fan Fold Belt include Neptune (1995), Mad Dog (1999), Tahiti (2002), Knotty Head (2005), Genghis Khan (2005) and Big Foot (2005). Thunder Horse (1999) is the largest of the DWFTB fields, with an estimated mean size of one billion barrels of oil equivalent (Chap. 10). It is the largest producing deepwater asset in the world. Conversely, the Port Isabel Fold Belt as has no discoveries (Cossey 2004).

The northwestern Gulf of Mexico contains the deepwater Perdido fold and thrust belt (Camerlo and Benson 2006). This belt is, however, just the external portion of a more extensive belt of contraction that includes the Port Isabel fold belt and the salt canopy area (Fig. 6.66; Morley et al. 2011). Up-dip extension of 60+km suggests the down-dip fold and thrust belts, and the salt canopy must accommodate a similar amount of contraction, of which the Perdido fold belt only accommodates 5–10 km. The Perdido fold belt mainly underwent deformation during the lower Oligocene, but minor deformation continued until the Middle Miocene. In map view, the folds range from linear, to more dome shaped, fold length appears to be limited in places by underlying NW-SE trending syn-rift basement structures (Trudgill et al. 1999).

A switch in depositional systems with time resulted in abandonment of the Perdido fan fold belt, and formation of the Mississippi Fan fold belt during the Miocene–Pliocene (Fig. 6.65 Wu et al. (1990a, b); Weimer and Buffler 1992). The two fold belts are separated by a wide region without demonstrable contractional deformation (Diegel et al. 1995). The Mississippi Fan Fold Belt is characterised by broad, upright folds to asymmetric, offshore and landward verging folds, cut by thrusts with wavelengths of about 8–12 km. They are salt-cored detachment anticlines, with welds at the base of the synclines (Rowan et al. 2004; Grando and McClay 2004; Figs. 6.64 and 6.65).

Precursor, small wavelength salt pillows formed in places during the Late Jurassic–Cretaceous in response to early contractional deformation, and later helped control the positions of Cenozoic age folding (Grando and McClay 2004). The Mississippi Fan fold belt is partially overlain by the Sigsbee Salt Nappe, whose emplacement is responsible for the withdrawal of salt along the basal detachment of the fold belt. This situation contrasts with the thick salt detachment of the Perdido Fold Belt (Trudgill et al. 1999).

Both fold belts underwent a late oceanwards tilting as a result of a wedge of salt being injected into, and inflating, the basal detachment (Fig. 6.66). In the context of the foldbelt it is important to note it inflates once the higher-level allochthon belt is welded (Stage 2 in Fig. 6.67). A complex system of extensional detachments exists up-dip, with detachments forming at different levels partly in response to large salt sheets migrating up through different stratigraphic levels over time (e.g., Diegel et al. 1995).

Regionally, the style and extent of the compression across a salt-lubricated toe of the slope system is largely controlled

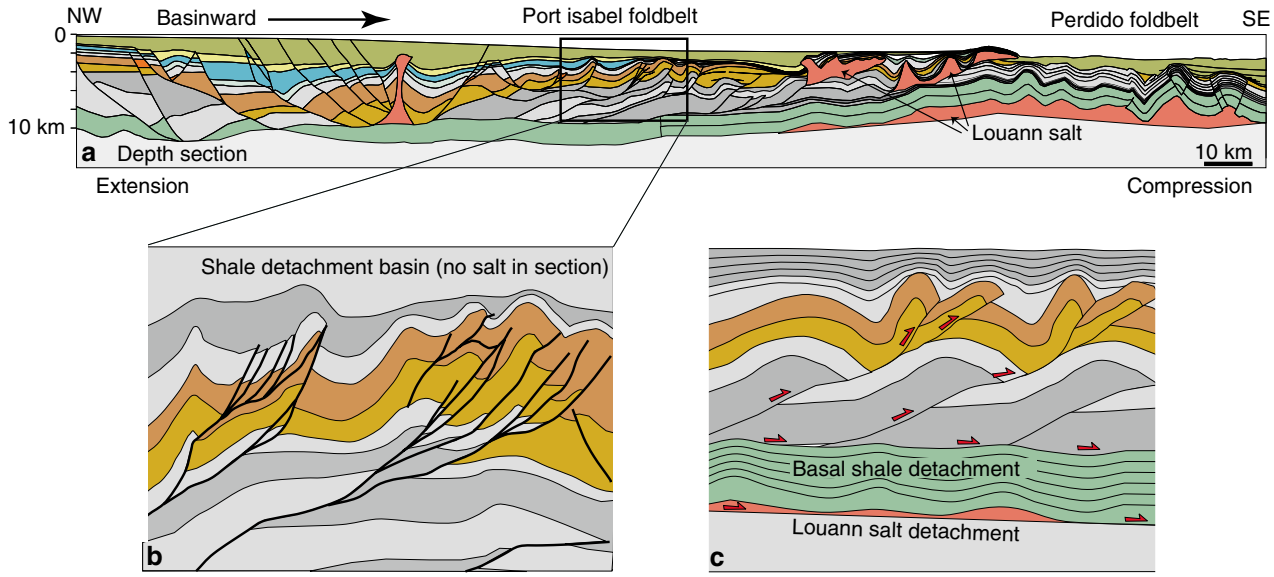

Fig. 6.66 Port Isabel Foldbelt, northwestern Gulf of Mexico. (**a**) Regional depth section showing linked proximal extension and distal contraction. Shortening (compression) is accommodated in: the Perdido Foldbelt above the Jurassic Louann Salt; extrusion of, and translation above, allochthonous salt; and the Port Isabel Foldbelt, detached on Eocene shales (2×1 vertical exaggeration). (**b**) Seismic interpretation of the Port Isabel Foldbelt, showing multiple shale detachment levels and associated fault-bend and fault-propagation folds. (**c**) Schematic cross section (not to scale) showing the relationship of the Port Isabel shale detachments (at the top of the green unit and higher) and the underlying, autochthonous Louann Salt detachment (After Rowan et al. 2004; Morley et al. 2011). See Fig. 6.61a for location

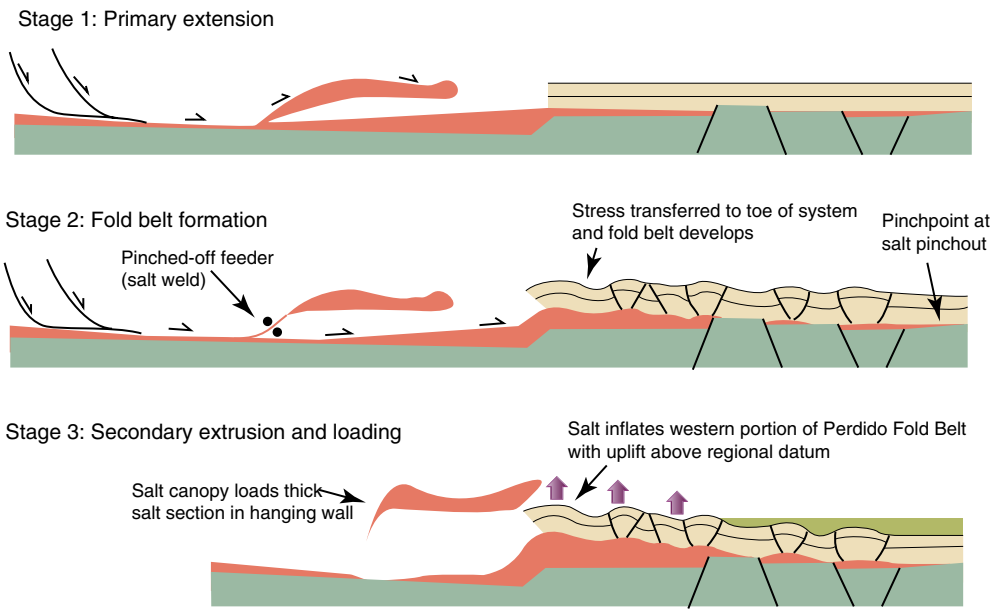

Fig. 6.67 Cross-sectional schematic illustrating the development of the Perdido fold belt via regional gravity spreading linked to up-dip extension. *Stage 1*: Paleogene initial loading and extension caused primary extrusion of salt and the development of a regional allochthonous salt canopy. *Stage 2*; Closure of the feeder salt diapirs transferred stress to the toe of the system, causing development of the Perdido fold belt. *Stage 3*: Further salt movement resulted in inflation of a salt wedge along the Perdido fold belt detachment (After Trudgill et al. 1999; Morley et al. 2011)

by the extent of the salt layer and the position of the salt edge or pinchout on the down dip side of the basin (Fig. 6.68; Letouzey et al. 1995). If the mother salt layer extends well out into the basin, with the salt pinchpoint beyond the zone of significant compression, the system tends to form a fold-belt dominated by salt-cored buckle folds with little or no evidence of thrusting. If, on the other hand, the salt layer pinches out near the toe of the slope, the friction coefficient at the base of the contracting sediment pile is greatly increased and forms a narrower thrust-faulted zone.

The degree of shortening in such compressional thrust terrains can be substantial. In the deep water Santos Basin, Brazil, the downdip section is shortened by up to 50 % of its original length as the seaward margin of the salt belt flows out over the backstop basalts of oceanic basement (Fig. 6.69). Many of these thrust blocks show typical contractional salt

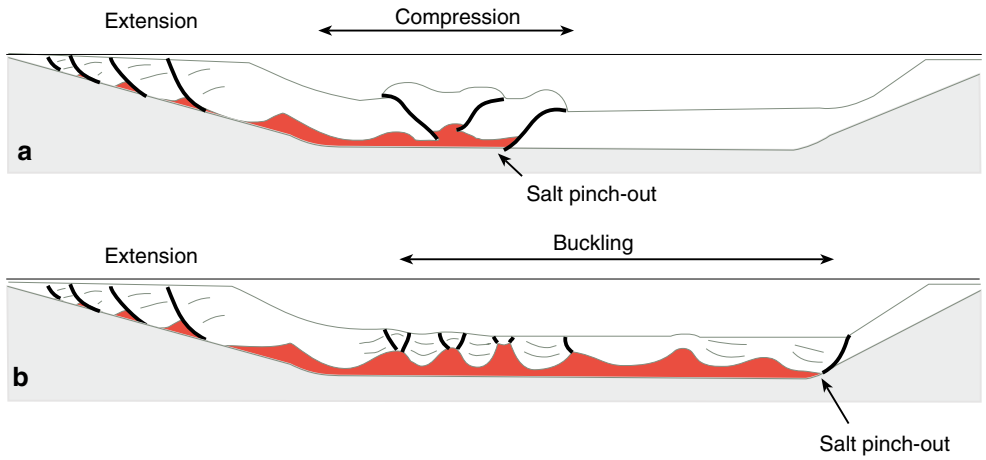

Fig. 6.68 Location of basinward pinchout of the salt layer controls the style of contractional/ compressional structures. (**a**) Where the salt layer does not extend out far past the foot of the continental slope, the frictional resistance increases at the base of the sedimentary pile and interferes with further basinward movement. This can create an imbricate thrust zone on the updip side of the salt pinchout. (**b**) Where the salt layer extends across the basin and well out from the foot of the continental slope, the contraction is taken up in a series of buckle folds with crests that tend to lack thrust zones (After Letouzey et al. 1995)

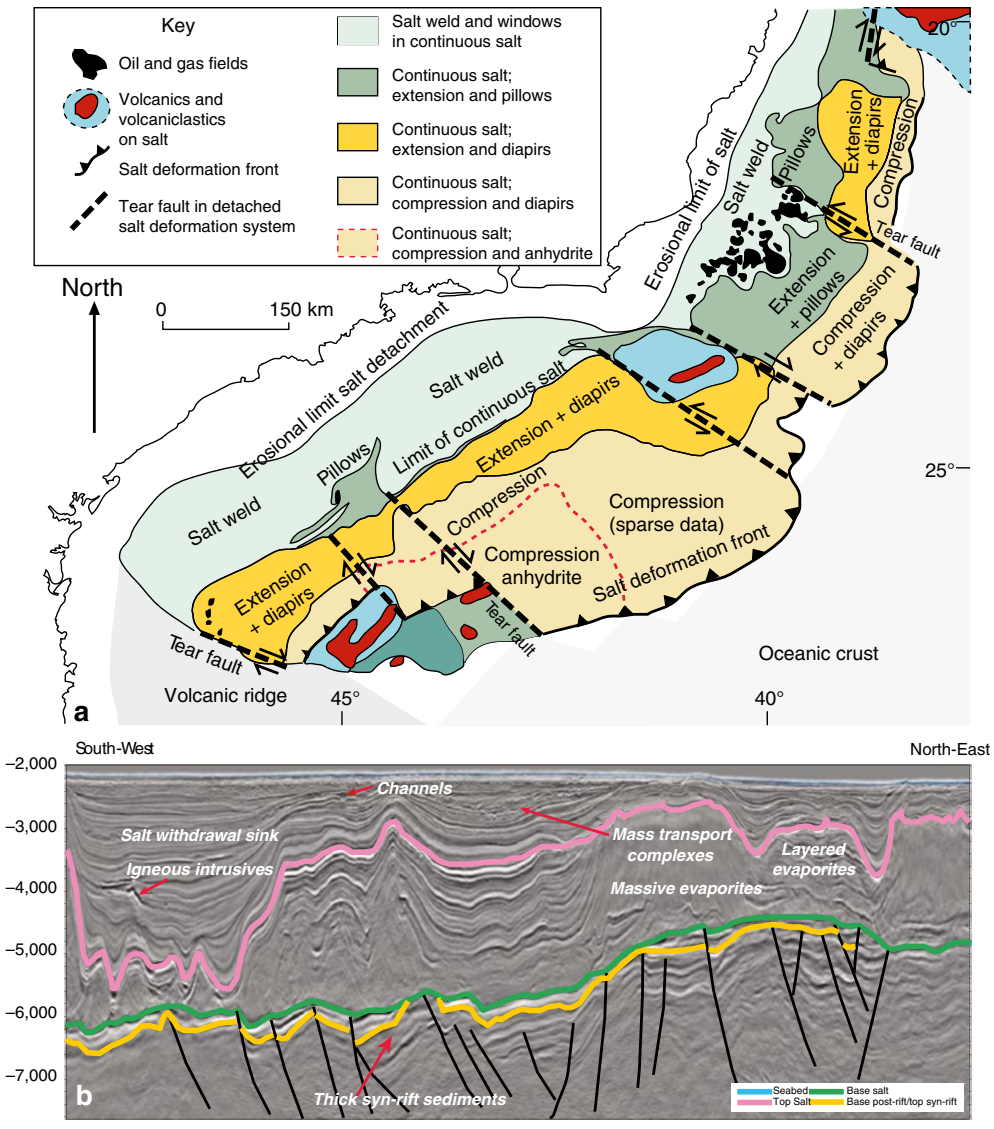

Fig. 6.69 (**a**) Map showing relationships between the various salt-detached basins in the Santos and Campos basins of offshore Brazil. Oil and gas fields in the northeast tend to occur updip of the limit of continuous salt in suprasalt turbidite reservoirs that are sourced from sub salt lacustrine sediments (After Meisling et al. 2001) In the southeast (Santos Basin) are subsalt, typically on basement highs capped by porous lacustrine carbonates as illustrated in (**b**) Typical subsalt relationships in the vicinity of Libra Field (Santos Basin) showing layered versus massive character of Aptian salt in this region (Seismic image courtesy of CCG)

thrust assemblages of sediment wedges in their footwall and chronologically older (Aptian) salt in their hanging walls. Interestingly, the giant oilfields of the Campos Basin and the fields of the Santos Basin only occur atop salt breakout windows on the inboard side of the belt of continuous salt or atop the zone of salt welds. This reflects the high seal integrity of continuous salt sheets, which prevent hydrocarbons generated in the mature subsalt salt source from reaching the suprasalt turbidite reservoirs (Fig. 6.69; Meisling et al. 2001). It is a very positive indicator of the possible presence of large subsalt traps some distance further offshore where halokinetic salt sheets constitute more continuous layers, including structures similar to Tupi.

At the scale of salt flow in passive margin sediments along the edge of a widening ocean basin there is also the process of increasing shelf edge to ridge distance to be considered. Over time this will create an increasingly broad compressional zone in the zone of transitional crust at the foot of the continental slope. This is clearly illustrated in the expanding compressional belt down dip of the zone of raft tectonic in the seaward margin of the Kwanza Basin, Angola (Fig. 6.70; Fort et al. 2004). A thick sequence of Cretaceous (Aptian) salt was laid down atop lacustrine sediments in the opening rift, followed by a transition into marine sediments the passive margin. Three groups of sediments make up this marine wedge; The Pinda Group (Albian to Late Cretaceous), consists of a carbonate platform followed by sedimentation increasingly dominated by marls and clays. The Iabe-Landana Group (Late Cretaceous to Eocene) consists of dominantly siliciclastic sediments, with locally significant carbonates. Most of these deposits are located on the current platform, pinching out seaward into condensed sections, indicating a long-term highstand during the Late Cretaceous. The Malembo Group (Oligocene to the present day) corresponds to a large, prograding clastic wedge. The salt has acted as a décollement allowing updip extension and downdip compression. The extensional domain is characterised by oceanward-sealed tectonic blocks, rollovers and diapirs, while the downdip compressional terrain is characterised by growth folds, squeezed diapirs and thrusts (Fig. 6.70).

The compressional zone is divisible into; (1) an inner more upslope subdomain characterised by formation of contractional diapirs by the compression of former extensional diapirs (squeezed diapirs) and (2) an outer more downdip subdomain characterised by growth folds and thrusts. The upper subdomain indicates the expansion of the compressional domain in a more upslope direction as formerly extensional suprasalt sediments slides and piles at the foot of slope (Figs. 6.69 and 6.70). The ductile diapir salt in the Kwanza salt style is trapped and pinched in anticlinal cores, leading to the formation of contractional diapirs that typically do not necessarily extrude at the surface but are stopped and sealed by further sedimentation. This type of updip extension and downdip compression indicates an initial salt geometry that wedged or thinned in both seaward and landward directions at the end of the margin-rifting stage (Aptian; Fig. 6.69a). Postrift cooling of the lithosphere then induced a seaward tilt in the margin and the development of gravitational instability, creating a seaward-gliding system with an extensional upper end and a compressional downdip end (Fig. 6.70b passing to 6.70c). The increasing into the basin tilt due to thermal subsidence drives an updip migration of the zone of compression or contraction (Fig. 6.70c). Over time diapirs that formed by extensional processes become squeezed and take on the structural and trap morphologies of diapiric structures indicative of this compression (see later).

Thin-Skinned Fold and Thrust Belts

Widening salt-floored rift basins are subject to later closure (Wilson Cycle; Fig. 5.32), so, independent of early glide-induced compressional stacking at foot of slope, compressional deformation is often later superimposed on originally extensional halokinetic margin by regional plate-driven collision (Fig. 6.62b) or its aulocogen counterpart in the continental interior (Fig. 6.62c). Salt acts as a lubricant to any consequent thrust sheet as it pushes landward. Thin-skinned fold and thrust belts form in orogenic chains where the basement is not involved in the deformation and evaporite layers are preferred detachment horizons (Letouzey et al. 1995). Resultant structures are predominantly oriented parallel to the intermediate stress direction and perpendicular to the maximum shortening. Examples of thin-skinned fold and thrust belts include (Fig. 6.63): the Parry Islands Foldbelt in Arctic Canada (Harrison 1995), the European Jura (Philippe 1994), the Spanish Alps (Flinch et al. 1996), the Lufilian foldbelt of Central Africa (Jackson et al. 2003), the Adelaidean foldbelt of southern Australia (Marshak and Flottmann 1996), the Kuqa foldbelt of Tarim Basin of NW China (Liang-Jie et al. 2004) and the Zagros Foldbelt of Iraq and Iran (Talbot and Alavi 1996).

The style of compressional deformation is dependent largely on the friction coefficient acting along the detachment level(s). The lower the basal friction level, the further the thrusts propagate out and so the wider the thrust belt, the thinner the cross section of deformation and the lower the critical taper angle (Fig. 6.71: Davis and Engelder 1985, 1987; De Celles and Mitra 1995). The critical taper angle in the thrust wedge (φ_c) is defined as the sum of the surface slope angle (α_n) and the detachment slope angle (β). The observed critical taper of a given fold thrust belt depends on the material strength of the thrust wedge, the resistance to sliding across the basal detachment, and the ratio of fluid pressure to overburden pressure, both in the wedge and across the detachment (van der Pluijm and Marshak 2004).

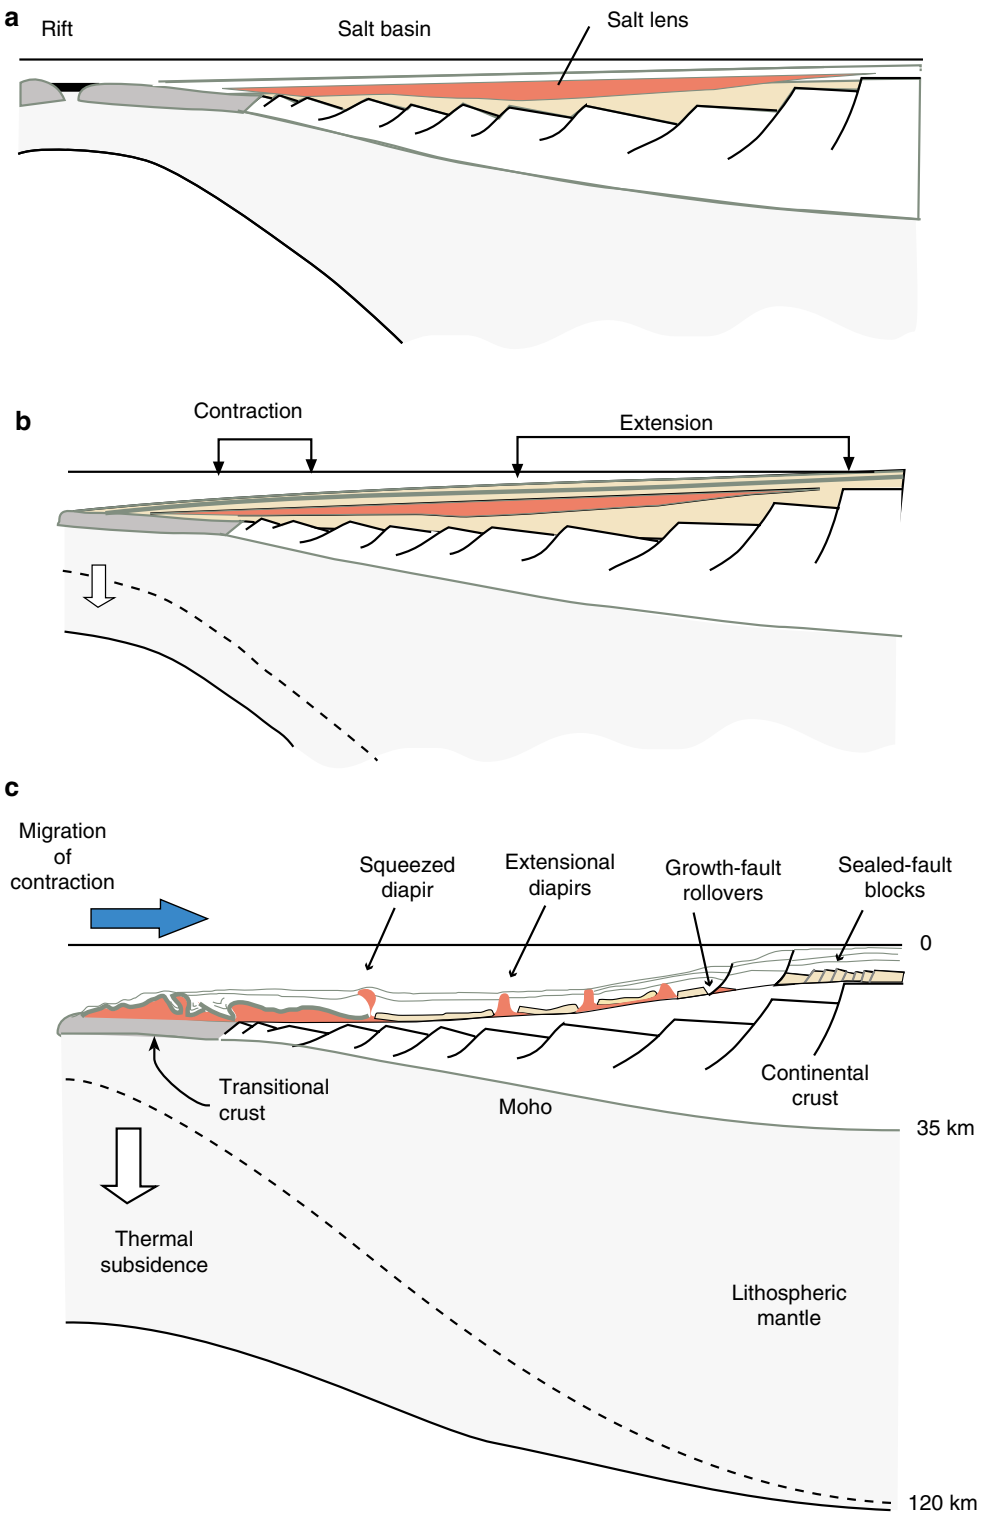

Fig. 6.70 Evolutionary model of gravity spreading above salt in a passive-margin tectonic setting, at lithospheric scale based on the offshore region of Angola, central Africa. (**a**) Initial stage following continental breakup. The salt basin is entirely covered by sediments that overlie oceanic crust. (**b**) Synchronous initiation of contraction downslope and extension upslope. The compressional domain initiates at some distance from the salt wedge toe. (**c**) Major displacement of extensional and compression domains during spreading. Compression migrates both downslope and upslope. Downslope migration reaches the salt toe. Upslope migration reaches the downslope part of the extensional domain, thus inducing diapir squeezing. Slope increases during spreading as a consequence of lithospheric cooling and subsequent subsidence (Fort et al. 2004)

If the effective strength of the wedge is increased (either by increasing rock strength or by decreasing fluid pressure), then the critical taper angle decreases. If the resistance to sliding on the basal detachment is increased (either by increasing the coefficient of sliding friction or by decreasing the fluid pressure), then the critical-taper angle increases. Fold-thrust belts basal detachments in salt are very weak and have a critical taper angle as low as 1–2°, whereas fold-thrust belts that have detachments in stronger rocks may have critical taper angles as high as 8–10° (Fig. 6.72).

Interestingly, regions of shale tectonics in offshore Brunei and offshore Barbados lie on this salty boundary, although

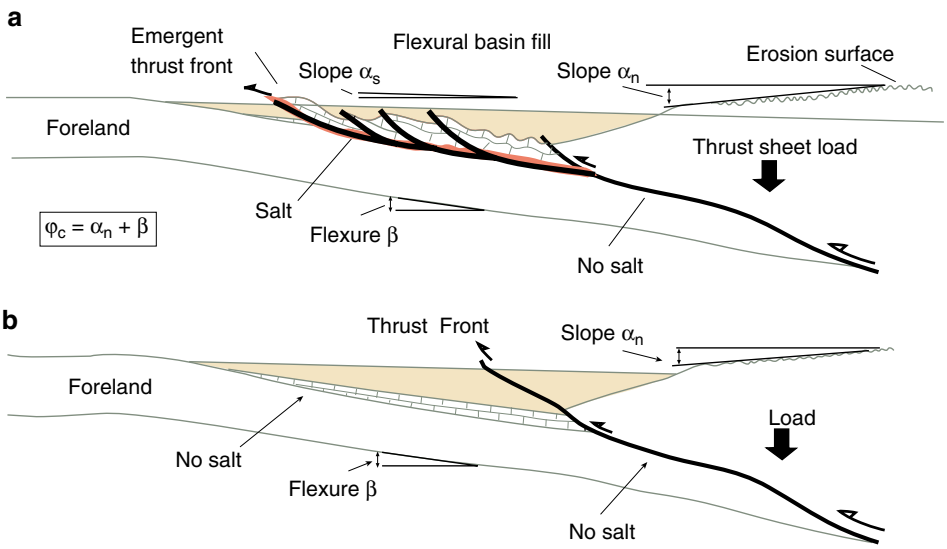

Fig. 6.71 Characteristics of thrust propagation and critical taper angle in a salt cored and nonsalt cored thrust (**a**) Salt lubricates thrust sheets. (**b**) No salt to lubricate thrust sheet. Salt cored thrusts are wider, show more extensive thrust propagation, thinner thrust cross section and critical taper angles ϕ_c <2°; while those deforming over other rock layers are narrower, with critical taper angles φ_c nearing 8–10° (After Davis and Engelder 1985, 1987; van der Pluijm and Marshak 2004)

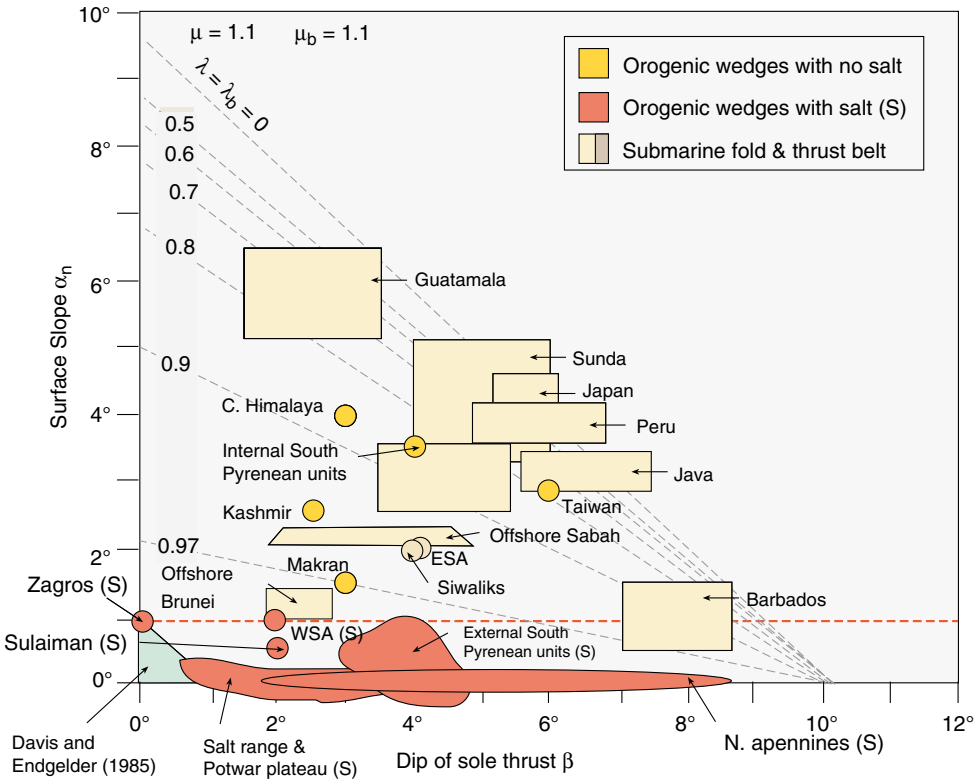

Fig. 6.72 Pressure and wedge character showing the relationship between surface slope (α), basal detachment dip (β), and pore-fluid ratio for orogenic wedges and submarine fold and thrust belts at critical taper, assuming a Coulomb material behavior (After Ford 2004; Morley 2007a, b; Warren et al. 2011). Orogenic belts with salt entrained in the décollement are indicated by (S). *μ* postulated coefficient of internal friction for the wedge, *μb* coefficient of internal friction at the base of the wedge, *λb* ratio of pore-fluid pressure to lithostatic pressure at the base of the wedge, *ESA* east Swiss Alps, *WSA* west Swiss Alps. The *green triangle plots* the region of the low basal friction wedge of Davis and Engelder (1985). As shown by Ford (2004), the region of low basal friction created by a salt décollement extends beyond the region indicated by Davis and Engelder (1985) and is indicated by the interval below the *dashed red line* (surface slopes <1°)

neither sediment wedge entrains salt. This is an indication of a muddy and highly pressured character in both prisms. Morley (2007b) argued that the very low surface slopes (1–2.5°) and basal detachment dips (2–5°) in the Brunei offshore wedge require basal pore-fluid pressures that must be near lithostatic for the wedge to propagate at such angles. That is, shale pressures approaching lithostatic in the mud-dominant wedge that is the continental margin of offshore Brunei is capable of near-Newtonian fluid-like behaviour. It is responding to gravity in a fashion similar to that of continental margins underlain by deforming and gliding salt (Warren et al. 2011).

A salt décollement in a compressional thrust terrain also enhances the development of major backthrusts and greater outward migration of the deformation front (Luján et al. 2003; Velaj et al. 1999). Pre-existing faults and salt welds in a halokinetic prism on a passive margin can be a major zone of weakness in the development of subsequent compressional structures. Hence the very close association between pre-existing faults and the current elongated salt structures of the southern North Sea (Fig. 6.76).

A fundamental consequence of salt weakness in many salt-detached thrust foldbelts is an absence of a preferred

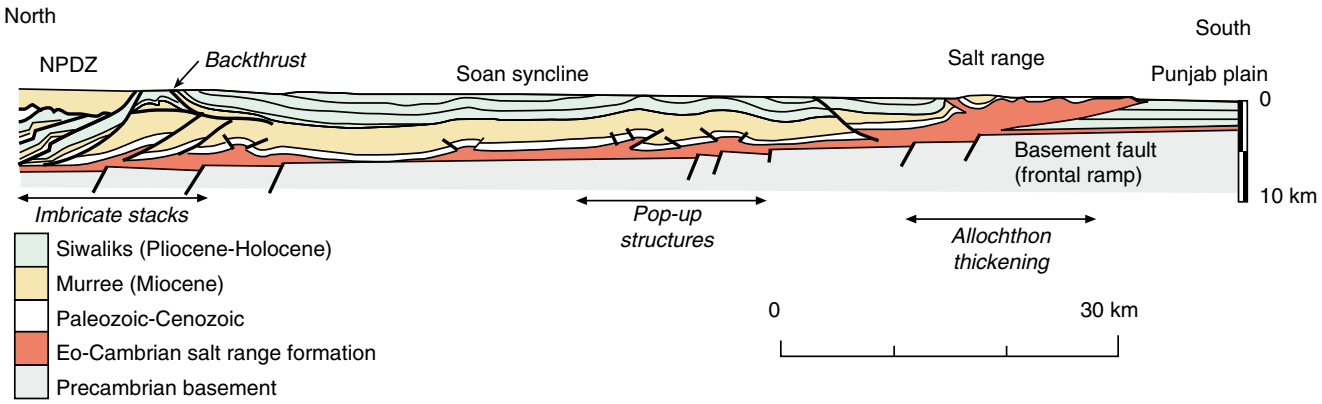

Fig. 6.73 North–south cross section in Pakistan across the Northern Potwar deformation zone (*NPDZ*), Soan syncline, and Salt Range (After Cotton and Koyi 2000). Three deformation zones can be seen: an imbricate stack (*NPDZ*) forming a wedge at the rear northern part; a zone of broad anticlines and synclines with pop-up and/or pop-down structures in the middle; and a zone of thickened allochthonous salt (Salt Range) in the south

direction of thrust transport (Davis and Engelder 1987; Harrison 1995; Bahroudi and Koyi 2003; Luján et al. 2003). The geometry of individual thrusts and anticlines reveals little or nothing about the location of the tectonic hinterland without some independent understanding of the regional geology. Angular folds (box folds, chevron folds and mitre folds) and backthrusts can predominate in a buckling thin-skinned salt-cored thrust belt, reflecting internal deformation of anisotropic multilayers above the thin, ductile salt substratum. If the deforming salt substratum is thicker, the multilayers tend to buckle as a single unit into large sinusoidal folds, with consequent loss of fold angularity. Mixtures of forethrusts and backthrusts are common even in individual salt-cored anticlines.

An active example of this style of thin-skinned thrust, lubricated by salt, is found in the Salt Range region of Pakistan (Fig. 6.73). The Salt Range and Potwar Plateau are the external and most recent expression of Himalayan shortening. This thin-skinned fold-and-thrust belt is detached upon thick Lower Cambrian evaporites of the Salt Range Formation. This basinwide evaporite unit underlies the Potwar Basin and is roughly equivalent in age to the Hormuz Formation in the Zagros Belt of the Arabian Gulf. The presence of thick salt facilitated rapid thrust propagation of the basal detachment before the main fault plane rose to form the Salt Range thrust above a basement frontal ramp at the southern termination of the basin.

A dextral wrench zone defines the western limit of the Salt Range and corresponds to the edge of the halokinetic Infracambrian evaporite (Cotton and Koyi 2000). There are three main zones of deformation across the Salt Range and Potwar Plateau: from north to south, these are the Northern Potwar deformation zone, the Soan syncline, and the Salt Range (Fig. 6.73). Deformation in the Northern Potwar deformation zone is characterized by the development of an imbricate duplex in the footwall of the Main Boundary thrust of the Himalayas. Deformation of the overlying Main Boundary thrust sequence constrains development of the Northern Potwar deformation zone to younger than 10 Ma. The northern limb of the Soan syncline marks the southernmost limit of uplift in the Northern Potwar deformation zone. The northern limb of the Soan syncline is steeply upturned, forming a monocline. A sequence of salt cored pop-up structures and broad anticlinal swells accommodated shortening formed to the south of the Soan syncline axis and have created a number of structural traps for hydrocarbons.[18] The contrast in deformation styles between the Northern Potwar deformation zone and the Soan syncline, seen in Fig. 6.73, is attributed to the lubricating effect of the Infracambrian evaporite sequence (Salt Range Formation).

The Salt Range today forms an approximate east–west hanging wall in a thrust that accommodates ~25–30 km of shortening (Baker et al. 1988; Aamir and Siddiqui 2006). The majority of deformation was accommodated within the hanging wall with some minor imbrication of the footwall. Deformation in the Salt Range area is considered to have occurred in two pulses, commencing ca. 5 Ma with a later pulse at 2 Ma. Lag time between pulses is attributed to breakback thrust development in the northern limb of the Soan syncline. The anomalous thickness of salt that has accumulated beneath the hanging wall of the Salt Range thrust is a result of differential loading by a prograding basin fill and

[18]The Potwar Basin is one of the world's oldest oil provinces. The first commercial discovery was made in 1914 at Khaur. Eastern Potwar region is an important oil- and gas-producing area. Discoveries in the eastern part of the Potwar Plateau, located southeast of the Soan syncline, are mostly from NE-SW elongated anticlines.

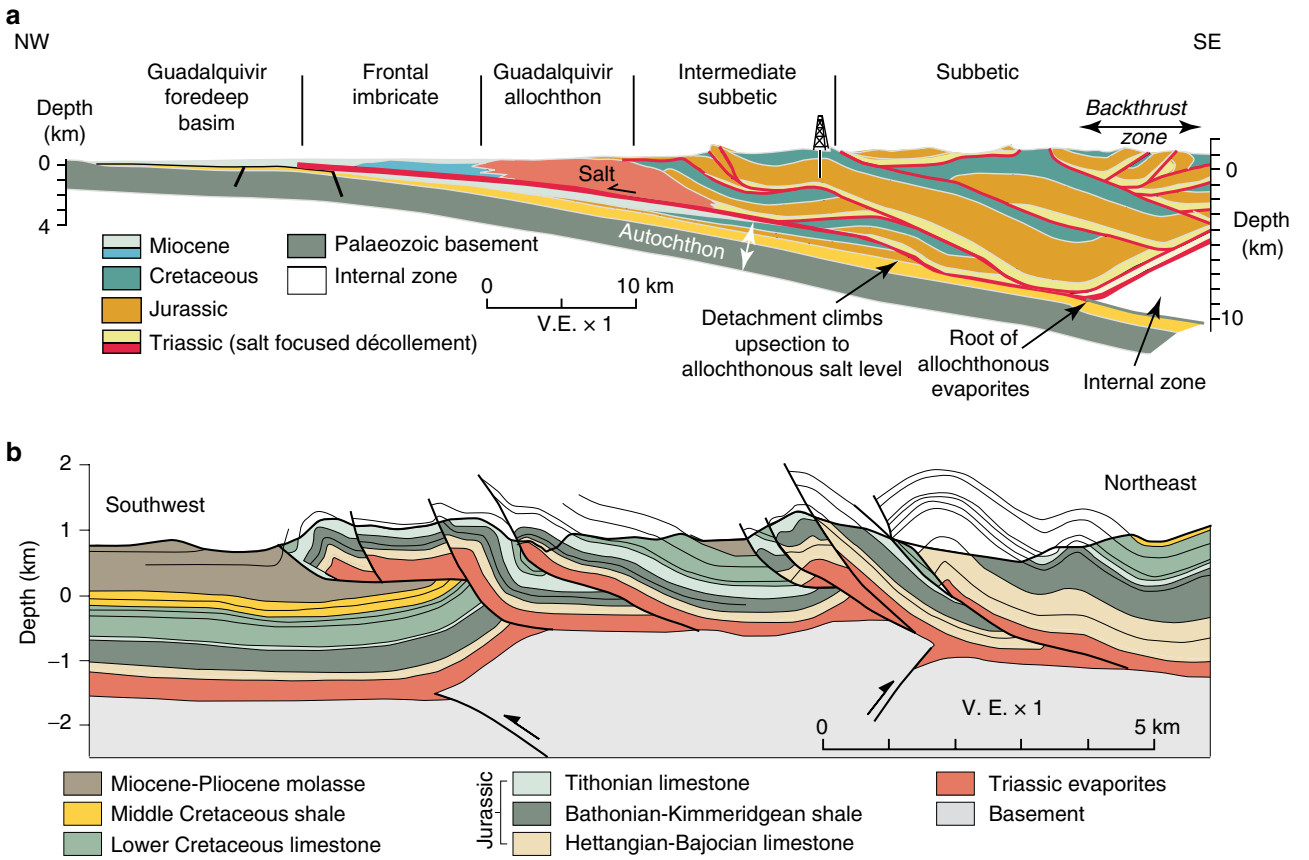

Fig. 6.74 Inversion focused by décollement in Keuper (Triassic) salt belts. (**a**) Exposed Keuper evaporites of the Guadalquivir allochthon at the leading edge of the Betic orogen southern Spain. Shortening expelled salt northwestward over lower to middle Miocene strata. The autochthonous Triassic evaporite basin sourcing the evaporite nappe is thought to be deep beneath the orogen, at least 30 km inboard of the exposed salt (After Berastegui et al. 1998). (**b**) Triassic salt sheets emplaced in thrust hanging walls by orogenic shortening, Digne, Barréme, Rhodanian Basins, southern Subalpine chains, southeast France (After Lickorish and Ford 1998)

deformation front moving south from the growing Himalayas. This combination of sedimentary and tectonic loading caused a southward migration of the Salt Range Formation (like squeezing toothpaste) to where the Neoproterozoic to Eocene sediments in the Salt Range are thrust over the Quaternary sediments of the Punjab Plain (Baker et al. 1988). Thickening has been assisted in the central Salt Range by the buttressing effect of a major basement fault in front of the southward-migrating salt (Fig. 6.73).

Another well-documented example with more than 200 km of salt-lubricated translation characterises the Triassic section of the external domain of the Betic Cordillera, near Gibraltar in the Mediterranean, where the thrust block is rootless and allochthonous (Fig. 6.74a; Berastegui et al. 1998; Luján et al. 2003). The frontal accretionary wedge of the Guadalquivir allochthon consists of Triassic evaporites and red beds that in outcrop form a gypsum-cemented melange/residual mixed with Upper Cretaceous-Palaeogene deepwater sedimentary rocks. Throughout the unit, Jurassic rocks are absent. The widespread Triassic evaporites of the Guadalquivir allochthon were originally emplaced as gravitational allochthonous masses or salt sheets at the foot of the Betic continental slope. This occurred originally in a passive-margin gravity glide setting, much like the present day emplacement of allochthonous sheets of Jurassic Louann Salt atop Neogene sediments in the Texas-Louisiana Gulf Coast or Aptian salt in the Santos Basin of Brazil. Later, during Neogene formation of the Gibraltar Arc, the Spanish evaporites were overthrust as an accretionary wedge to form the Guadalquivir allochthon. This explains the lack of Jurassic sediments within the melange of Guadalquivir allochthon. Triassic halokinetically pierced strata were thrust back up onto the former passive Betic margin, a lateral distance of some 200 km, from an area that lacked Jurassic deposits. Thus the Guadalquivir allochthon ended up atop sediment that was originally located well landward of the Guadalquivir prism (Fig. 6.74a).

The Tertiary foreland basin of the southern Subalpine chains preserves a stratigraphic record of late Alpine salt-associated deformation, both ahead of the thrust front in the Valensole basin, and in a series of thrust-sheet-top basin remnants. Stratigraphy and growth structures in these basin

remnants are used by Lickorish and Ford (1998) to identify the location and timing of deformation and hence to constrain the sequential restoration of a cross section through the region. They conclude the thrust belt developed as a single large thrust sheet riding on a weak Triassic evaporite layer (Fig. 6.74b). Minor breaching thrusts occur, in particular at inverted Mesozoic normal faults. The Digne thrust sheet show a dominantly SW direction of tectonic transport. Where some of the reactivated structures lie at a slightly oblique angle to the southwest transport direction there has been a partitioning of deformation into SW-directed thrusting and a component of dextral strike-slip taken up on minor faults. The total shortening across the fold and thrust belt is 21.5 km.

Deformation within the Digne sheet occurred in three stages. Firstly, during the late Eocene, Alpine collision in the hinterland caused flexure of the foreland plate to generate a simple broad marine foredeep. Slight detachment above the Triassic evaporites allowed gentle buckling of the floor of the foredeep. Secondly, in the Early to Mid-Oligocene overthrust shear associated with the SW emplacement of the internally derived Embrunais-Ubaye nappes into the foredeep caused substantial deformation in the underlying Digne sheet. A component of flattening strain was associated with overthrust shear beneath the nappes, but ahead of the nappe front gentle, upright folding and thrusting continued. Sedimentation stepped westward, became dominated by continental facies and confined to small thrust sheet top basins (e.g. Barréme). The Mio-Pliocene stage of deformation involved a change from thin-skinned to a thick-skinned out-of-sequence deformation when basement blocks were uplifted on deepseated structures across the region (e.g. Dôme de Chateauredon). Shortening associated with the uplift of the main Argentera basement massif at the internal boundary of the external fold and thrust belt was transferred onto the Triassic detachment from below, and transferred forward to reactivate the frontal edge of the Digne sheet, which was thrust out over the Valensole basin. A similar across-salt transfer from shallower thin-skinned thrusts to thick-skinned compressional thrusting below the Triassic salt (Ionian thrust) is seen in the offshore region between the mainland of western Greece and Zakynthos Island (Kokkalas et al. 2013)

Some of the Tertiary thrusting in the Digne region may have overprinted an earlier episode of Triassic salt flowing on the Jurassic seafloor. Graham et al. (2012) identified a completely overturned, highly condensed Jurassic section near Barles village that resembles the elevated roof of a Triassic salt body in a deep-marine basin. They argue this carapace became overturned as a flap in the Middle Jurassic when salt broke out at the seafloor and overran the inverted flap as an allochthonous extrusion, comparable to those seen in the deepwater Gulf of Mexico or Angola. Later, Alpine compression exploited the weakness of the salt sheet as the Digne Thrust moved over the inverted flap (Fig. 6.74b). Although the flap is in the footwall of the thrust, evidence of soft-sediment deformation and other anomalous structures within the flap suggest that it did not originate as an overturned footwall syncline.

Inverted Salt Basins

Varying degrees of inversion are common in many intracratonic basins, which tend to evolve into a compressional regime some time after subsidence of the initial extensional rift/sag has ceased (Figs. 6.62c). Salt-floored inverted basins typically pass laterally into a thin-skinned thrusted terrain. By the time inversion occurs much of the sediment atop the primary salt interval is indurated and the basin is laterally confined. Examples of salt-entraining inverted basins include (Fig. 6.63); the relatively mild effects of Tertiary shortening of Palaeozoic and Mesozoic sediments in the southern and central North Sea Basins (Hooper et al. 1995; Stewart and Coward 1995; Eggink et al. 1996; De Jager 2003; Rossland et al. 2013), through to more extreme basin overprints as seen in the Cretaceous shortening of Triassic basins in the Atlas foldbelt of north Africa and the offshore Spain (Vially et al. 1994; Zouaghi et al. 2005; Matias et al. 2011), the Palaeozoic shortening of Neoproterozoic basins in the Flinders Ranges and the Amadeus Basin in central Australia (Stewart et al. 1991), and the Eocene-Miocene shortening of Palaeozoic and Mesozoic basins in the Zagros of central Iran (Jackson et al. 1990; Callot et al. 2012).

Under a regional shortening event that is orthogonal or oblique to pre-existing structures, the inversion typically squeezes hanging wall blocks upward, as the original extensional normal faults become compressional (Fig. 6.75). Basement, salt and overlying sediments are all shortened with pre-existing salt structures (pillows, diapirs and walls) frequently taking up much of the initial compression.

Where the horizontal compressive stresses are near orthogonal to pre-existing extensional structures and where these are bound by high angle normal faults, much of the inversion above the salt layer is accommodated by forced folding rather than slip along the former faults (Letouzey et al. 1990). New low-angle reverse faults are firmly rooted in the décollement salt and typically originate at the crest of the upthrown basement block, and so passively transport the former high-angle normal fault planes (Fig. 6.75). This initiates short-cut[19] thrust geometries. If the horizontal

[19]Footwall shortcut thrusts: A low angle thrust fault developed in the footwall of a steep thrust fault. The resultant lower angle fault trajectory is kinematically and mechanically more feasible for large displacement than the high angle fault trajectory (McClay 1992)

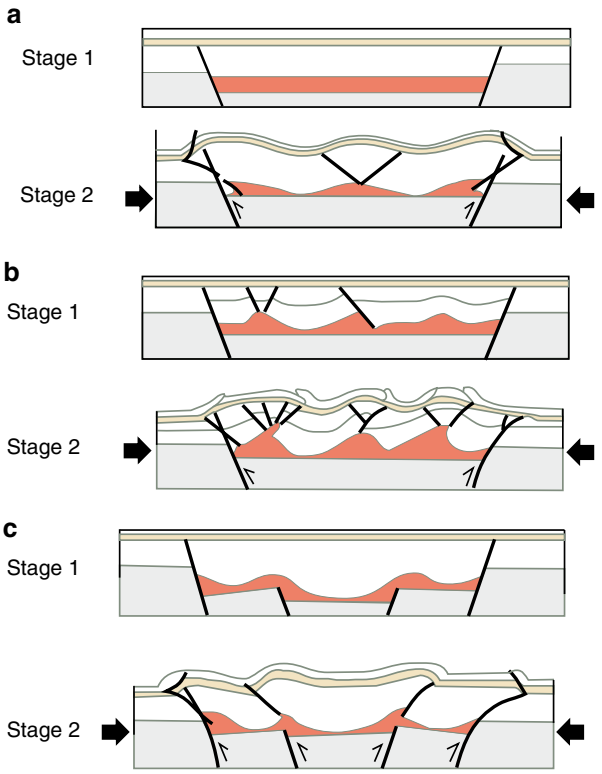

Fig. 6.75 Structural evolution of an inverted basement graben varies according to structures present in pre-existing graben (salt is *red*). (**a**) Folds and short-cut faults develop in homogeneous strata above inverted basement faults. Fold hinges in the graben are perpendicular to the regional compression. (**b**) Thrusts and folds are localised by pre-existing salt structures. (**c**) Thrusts and folds are localised by reactivation of basement faults (After Letouzey et al. 1995)

compression is oblique to the former normal fault, a strike-slip component is induced that can reactivate former high angle normal faults. In addition to conventional inversion features, such as forced folds (i.e. fault propagation folds over inverted basement blocks) and short cut faults over basement faults, strike slip will also form *en echelon* synthetic faults in the hanging walls of preexisting basement faults (Letouzey et al. 1995). Such *en echelon* systems define the basin edge of the Sahara flexure in Algeria (Vially et al. 1994).

Lateral pressures on a fluid salt décollement horizon undergoing compression promotes decoupling of the overburden and so create the following associations:

- Folding is more common than thrusting,
- Folds and thrusts lack consistent vergences, being commonly expressed as box folds and backthrusts;
- The cross sectional taper is typically low angle, which results in extremely broad fold and thrust belts;
- Complex three-dimensional edge effects form at the lateral boundary of the salt substratum.

Mild Shortening in Tectonically Confined Basins

Salt flow occurs within basins confined on either edge and subject to varying degrees of compression. Pre-existing basement structure is an obvious broad scale control on the development and location of the various salt features in these basins while formerly extensional diapirs experience compressional shortening. Salt walls and ridges of Permian salt in the southern North Sea Basin are type examples of extension followed by basin shortening and inversion. Many ridges tend to follow well-defined trends that parallel reactivated basement faults (Fig. 6.75c and 6.76: Remmelts 1995; Stewart et al. 1997; de Jager 2003). In other words, the present suprasalt patterns in much of the southern North Sea Basin are not decoupled from subsalt structure, unlike the current gravity glide systems of the Gulf of Mexico. Zechstein salt structures in NW Europe and the southern North Sea tend to first develop as extensional features atop the high of the upthrown basement block and are slightly offset but parallel to the controlling basement fault. At the same time salt was rising into these features, into-the-basin flow of salt was also creating downslope compressional buckles. Both these features typically first formed in the early Mesozoic, many millions of years after the Zechstein salt deposition had ceased (Mohr et al. 2004). Many such extensional diapirs were then further altered during subsequent late Mesozoic compression and inversion.

There are three salt domains (defined by parallel salt ridges) in the southern North Sea (Fig. 6.76; Remmelts 1995). The first, in the north, are elongate salt structures oriented north to northeast in a province that runs from the Central North Sea Graben to northern Germany. The second encompasses the region from English waters to onshore Netherlands where the salt structures are elongated northwest and made up of both pillows and walls. The third encompasses onshore southern Germany where an eastward trend is more obvious and encompasses both pillows and low salt walls. Small structures, with no preferred orientations, separate the three domains. The domains defined by the various salt ridges correspond to the structural grain in the basement.

Triassic extensional faults that strike north to north-northeast in the northern part of the basin form the boundary of the Central North Sea Graben, the Horn Graben and the Glückstadt Graben, while in onshore Germany this same orientation defines the Ems Low and the Weser Depression. Further south, extension was accommodated by transtensional slip in a northwest direction. Not only are the orientation of salt ridges and fault trends related across the domains, but so is the timing of salt movement and faulting. Salt piercement and basement fault movement is dominantly Triassic in the northern part of North Germany, while in the

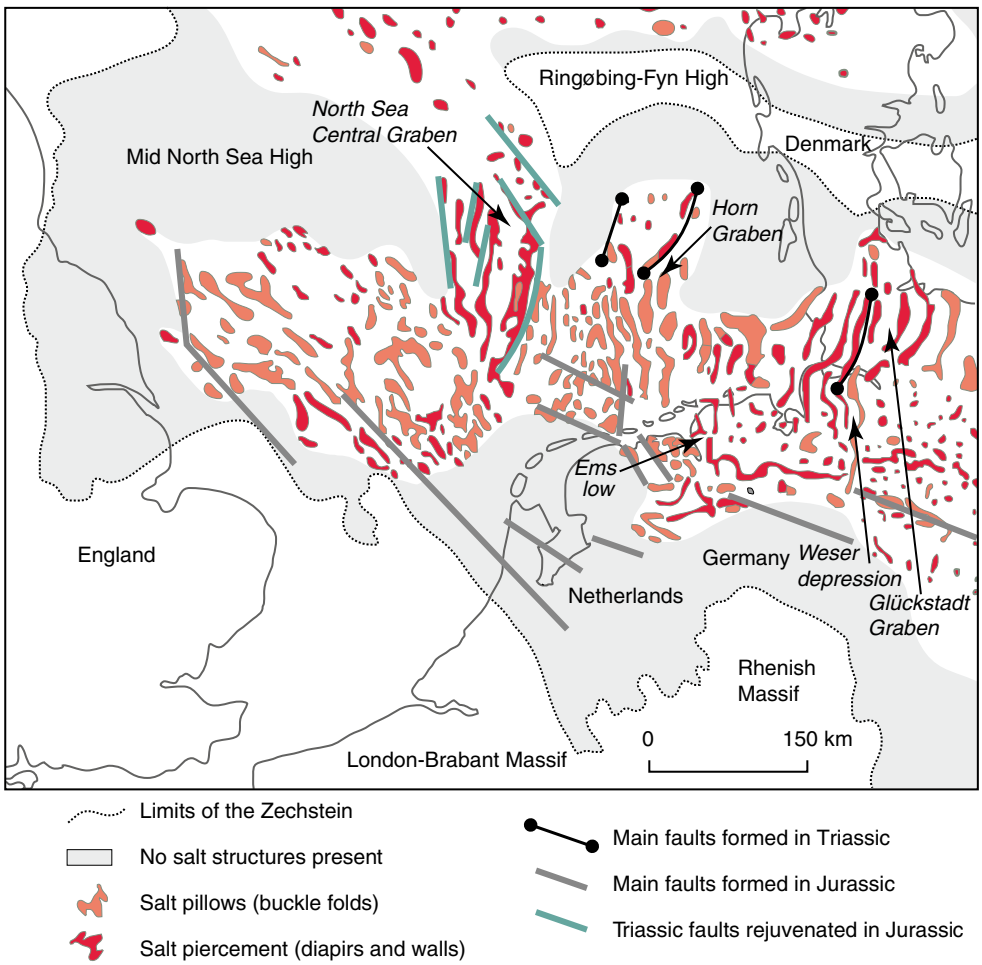

Fig. 6.76 Salt structures in the southern North Sea showing that salt flow tends to be restricted to the basin centre. The various structures show a regularity of ridge spacing and there is an association with the major fault directions in the basin (After Remmelts 1995)

south a Jurassic age prevails. Piercement is mostly Late Jurassic in the Central North Sea Graben, as is the main tectonic phase. Many Zechstein diapirs in onshore and offshore NW Europe were initiated along extensional faults that defined half-graben edges in Triassic to Jurassic times (Fig. 6.77a). The lack of primary rim synclines indicates that many of the structures became diapiric without going through a pillow phase immediately atop the primary Zechstein salt layer (Fig. 6.78). In extension, diapirs grew mainly by asymmetric downbuilding with salt rise focused on the upthrown block adjacent to the fault, probably with sporadic periods of bathymetric relief created at diapir crests (Fig. 6.78). The associated hanging wall tilt drove gravity gliding of the post-salt section, with resultant low-angle extensional faulting upslope and salt-cored buckling downslope with structural trends following basement grain (Fig. 6.77b; Thomas and Coward 1996).

The extensional half-grabens were subsequently tightened or compressed by a phase of thin-skinned inversion, associated with back-steepening of the margin fault system and a resulting reactivation of the extensional detachment system. The effects of this inversion have been noted in many parts of the northern North Sea, clearly post Early Cretaceous and Tertiary history of the southern North Sea Basin is compressional, not extensional. This is expressed as changes in basin tilt and in reverse slip on individual faults so that parts of the North Sea basin now tilt to the northeast, a reversal of the original Jurassic tilt direction in the UK section of the southern North Sea Basin (Fig. 6.79; Stewart and Coward 1995). This is especially obvious in thrust faults and structures that fringe the Broad Forties basin (Hayward and Graham 1989) but is seen across the North Sea Graben (Thomas and Coward 1996) and much of the southern North Sea Basin (Remmelts 1995; Stewart et al. 1997). Within the South Viking Graben, shortening estimates vary between 14 and 18 % and are expressed on seismic data by localized hanging wall folds and the back-steepening of faults along the fault complex of the western margin of the graben, together with out-of-graben thrusting up the hanging wall dip-slope.

In order to fully explain the elongate salt walls and pillows of the southern North Sea Basin the effects of both extension and inversion must be considered in the final analysis of the salt structure geometry. Recognition of significant

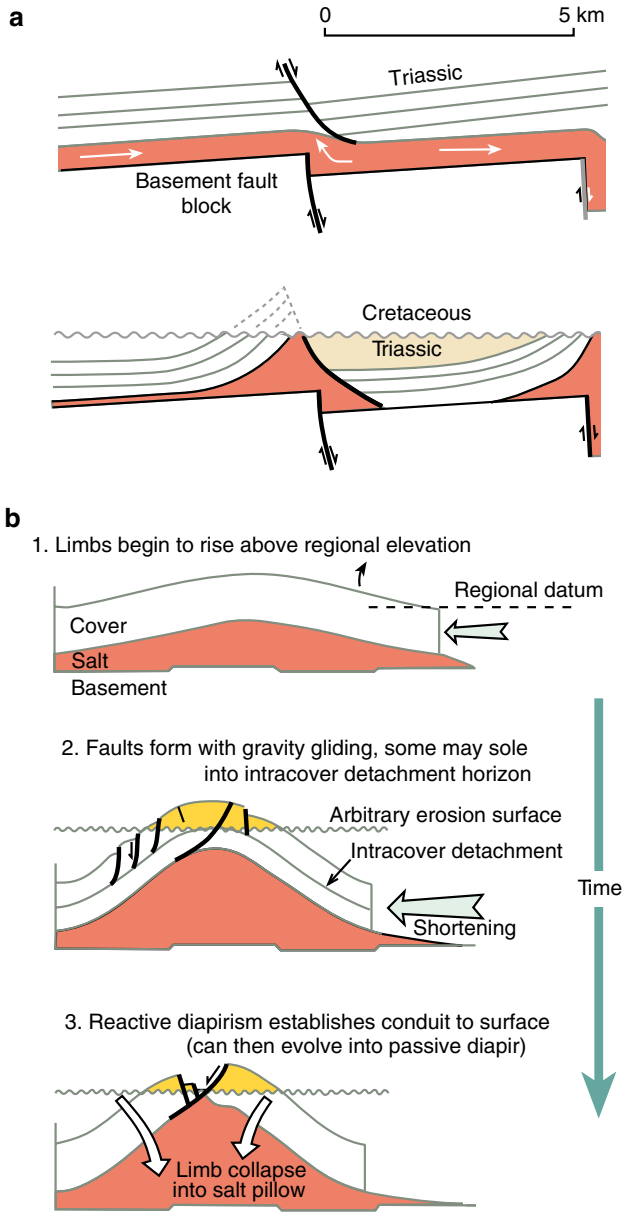

Fig. 6.77 Extension and conversion structures, North Sea. (**a**) Evolution of the Step Graben in the North Sea. Triassic extension focused the formation of salt structures atop normal faults in Sub-Zechstein basement. Early block faulting and accompanying rotation causes bedding plane parallel salt flow and pillowing atop the fault plane. This is followed by compression (shortening and inversion), tied to the Cretaceous unconformity and deposition of overlying sealing shales. Shortening drove oversteepening and flow reactivation during the Cretaceous Tertiary inversion (After Remmelts 1995). (**b**) Buckle fold evolution with crestal erosion culminating in diapirism (After Coward and Stewart 1995). See also Fig. 6.79

inversion can change the interpretation of some elongate salt-cored anticlines from salt pillows/swells to compressional buckle folds and squeezing of earlier extensional structures (Fig. 6.79). Clearly, any precontractional salt tectonics strongly influences the location of subsequent thrusts and folds (Letouzey et al. 1995).

During contraction and inversion, folds and thrusts are initiated where thickness variations in the salt were already present in the overburden (Fig. 6.77a; Vendeville and Jackson 1992a, b; Nalpas and Brun 1993). Erosional thinning of the overburden over salt ridges or salt walls also localises thrusts and folds, even when they are not related to basement normal faults (Fig. 6.77b). Décollement atop the compressed salt also induces normal-fault offsets on the top of salt that then localise thrusting and facilitate subsequent reactive diapirism (Fig. 6.77b).

Distinguishing Downbuilt and Reactivated (Mildly Squeezed) Diapirs

The preceding discussion of salt terrains where compression follows extension is both a response to gravity gliding in a passive margin and also occurs when continents collide (a corollary of the Wilson Cycle). It explains why many extensional diapirs suffer later horizontal shortening (squeezed diapirs). Examples are found in all three compressional terrains, namely; (a) thin-skinned fold and thrust belts at the toe of gravity-spreading systems on divergent margins, as in the South Atlantic, (b) thin-skinned fold and thrust belts driven by plate convergence, as in the foreland foldbelt of the Zagros Mountains, and (c) inverted, thick-skinned extensional basins, such as the North Sea. Styles range from salt structures that merely acted as foci of mild compression induced folding and faulting to diapirs that underwent considerable rise of salt or reactivation (Fig. 6.80).

Shortening squeezes salt in the diapir stem and so contributes to a short-term increase in salt supply. But this increase is temporary and decreases sharply, once shortening closes and empties the feeding stem of the diapir (Fig. 6.80). During shortening diapirs act as stress concentration zones where new folds/thrusts may form and propagate (Koyi 1998). Thrusts can propagate from the salt pedestal and so cut the feeding stem of the diapir. These diapirs sag with time, implying that some of the inactive diapirs in the Zagros mountain belt may have their feeder stems cut-off during the Zagros orogeny.

In the mildly compressed autochthonous salt region of the southern North Sea, the importance of Tertiary compression after Mesozoic extension was largely ignored until the early 1990s. Many diapirs cutting through the Tertiary section of the Central Graben, North Sea and the onshore basins of Germany, are now known to be rejuvenated diapirs with later episodes of salt flow driven by compression (Davison et al. 2000a, b; Scheck et al. 2003; Mohr et al. 2007; Dooley et al. 2009). Similar sets of rejuvenated diapirs can be also found nearby in the southwestern Nordkapp Basin (Henriksen and Vorren 1996). In all these basins diapirs first formed in Triassic extension and were rejuvenated during Late Cretaceous to Middle Tertiary shortening. It was an event that helped form the many Danian chalk reservoirs of the North Sea basin region offshore from Norway and Denmark.

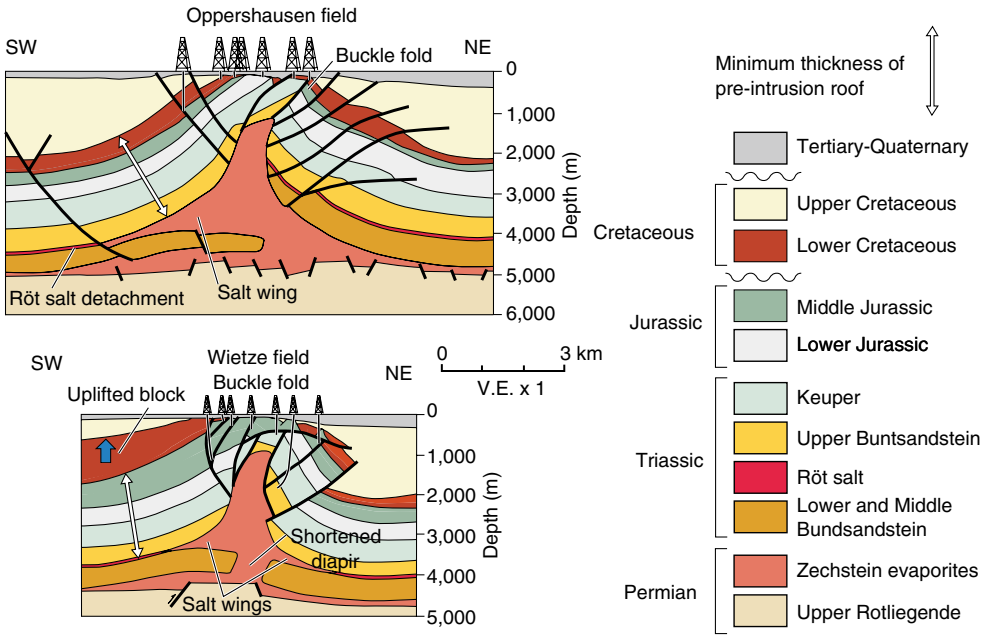

Fig. 6.78 Examples of compression-driven salt-wing intrusion from the Zechstein Basin, northwest Germany. Permian Zechstein salt wings were emplaced into the Triassic Röt salt layer during Late Cretaceous shortening. Shortening buckled strata above the Röt salt. Zechstein salt was emplaced passively into the cores of these detachment anticlines (After Baldschuhn et al. 2001)

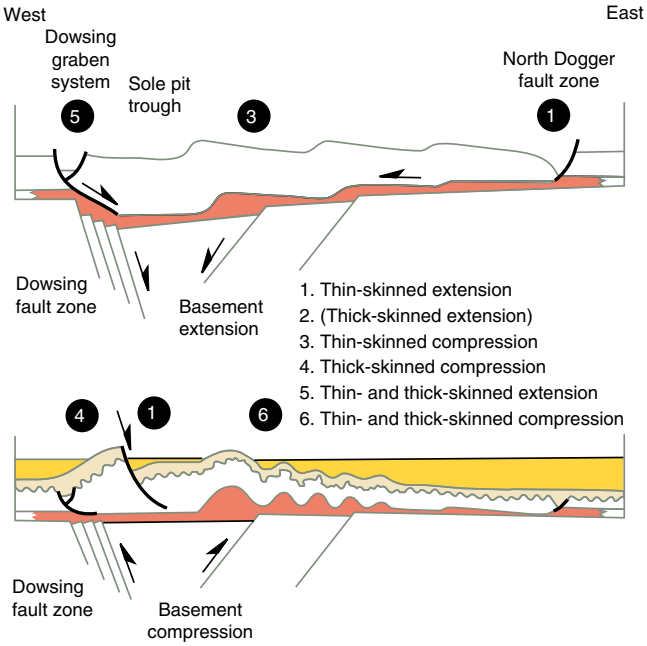

Fig. 6.79 Driving mechanisms for the evolution of suprasalt features atop the Zechstein salt in the western part of the southern North Sea Basin. All listed mechanisms, except thick-skinned extension, played a role. Salt structures evolved as the basin tectonics evolved from extension (*upper diagram*) to compression (*lower diagram*) and there is always an element of detachment tectonics, such as buckle folding, in the current distribution of the salt layer (After Coward and Stewart 1995)

Diapirs reactivated in compressional settings typically show common set of features (Table 6.3 and Fig. 6.81; Vendeville and Nilsen 1995; Davison et al. 2000b; Dooley et al. 2009); (1) Growth was episodic rather than continuous, allowing thick sets of strata to be deposited flat and horizontal as a thick roof atop the diapir crest during periods of diapiric quiescence, (2) Reactivated and compressed diapirs tend to have narrow or pinched-off stems, (3) Strata adjacent to the diapir are little deformed as most of the deformation is taken up in the diapir salt, (4) Many reactivated and squeezed diapirs show a triangular-shaped basal pedestal. A lack of primary rim synclines around these diapirs during times of tectonic quiescence indicates that the structures went diapiric without necessarily going through a pillow phase.

Most rejuvenated structures grew by localised downbuilding associated with crestal extension and near-crestal gravity sliding with sporadic periods of bathymetric relief at the active diapir crest. For example, salt-cored sea-bed relief controlled the deposition of Palaeocene and Eocene turbidite sandstones in the North Sea, which today thicken away from the compressionally re-activated diapir crests to form potential reservoir sands from 0 to 300 m thick (Fig. 6.100). The effects of compression on autochthonous salt structures in the North Sea tend to be most obvious in the vicinity of the diapirs and not in the interdiapir areas. Compression in the Central Graben of the North Sea was driven by downslope sliding of overburden above the Zechstein salt on the Eastern Platform area during late Palaeocene, and by regional Alpine shortening across the whole of the Central Graben during middle Miocene times. The various re-activated diapirs of the North Sea are much less deformed than those described in the Triassic-salt cored décollements of Spain and the French Maritime Alps (Fig. 6.78b; Roca et al. 1996; Dardeau and Graciansky 1990) or the Cegonha and similar compressional structures in offshore Angola (Fig. 6.70; Duval et al. 1992; Fort et al. 2004).

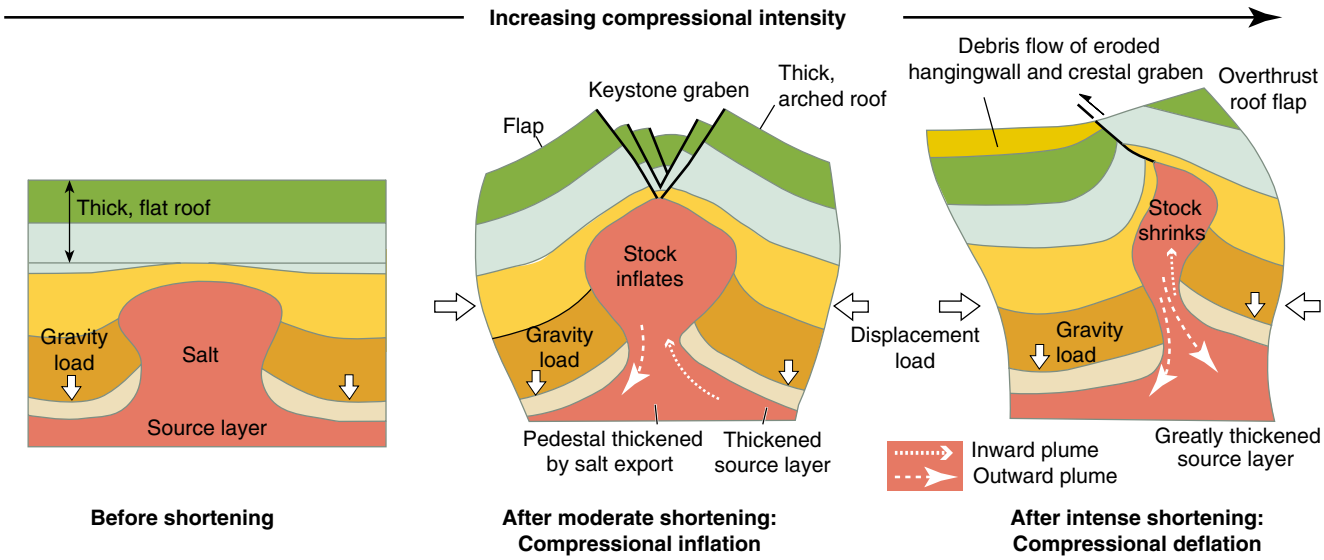

Fig. 6.80 Schematic showing gradual squeezing of a salt stock during regional shortening. After an early stage of salt inflation, diapiric salt is forced down into the source layer to thicken the pedestal, and the squeezed diapir shrinks (After Dooley et al. 2009)

Table 6.3 Criteria for separating downbuilt diapirs from diapirs which have been reactivated by regional compression

Criteria	Downbuilding	Rejuvenation driven by compression
Stratal thickness	Thick beds on the flanks thin over the salt, consistent with the syngrowth sedimentation patterns of Trusheim (1960) and Seni and Jackson (1983a, b).	Uniform bed thickness over crest when not tectonically thinned. Large thickness of overburden folded above crest. High angle onlap onto pre-inversion unconformity.
Lithological variation	Thick beds on the flanks thin over the salt, consistent with the syngrowth sedimentation patterns of Trusheim (1960) and Seni and Jackson (1983a, b).	Less concentric lithological variation produced when diapir inactive before inversion period.
Layer parallel shear	Normal sense of movement away from crest, caused by material sliding off crest.	Reverse sense of movement toward the crest.
Faulting	Small displacement normal faults on diapir shoulders, dipping away from the diapir. Crestal graben. Large listric growth faults along part of the salt contact.	Convex upward thrusts in the overburden on the shoulder of the diapir. Crestal horst as well as graben. Normal faults, strike-slip faults and thrust faults directly above the diapir e.g. Withjack and Scheiner (1982).
Drag zone geometry	Narrow and high relief.	Broad and lower relief.
Regional deformation	Regional extension faults.	Regional folds and thrusts and inverted extension structures in the cover.
Fold geometry of concordant overburden	Geometry moulds to the diapir.	Broad at top or, fold shapes unrelated to the underlying diapir shape.
Withdrawal basin	Primary and or secondary rim syncline sometimes present.	Absent when diapir is growing by compression. Diapir continues to grow even when source is severed by welding.

After Davison et al. (2000b), Vendeville and Nilsen (1995)

Specific features in the overburden atop a North Sea diapir, which may help in determining whether a diapir was rejuvenated by later compression after an earlier phase of extensional downbuilding, are illustrated in Fig. 6.81a (see also Letouzey et al. 1995; Vendeville and Nilsen 1995; Guglielmo et al. 2000; Dooley et al. 2009). Sediments atop rejuvenated North Sea diapirs exhibit some or all of the following characteristics: (a) localised unconformities with high angles of onlap above the unconformity; (b) thick lid of overburden strata (>300 m) updomed above the diapir; (c) reverse layer-parallel slip or concentric thrust faults localised at the diapir shoulders; (d) central horst block uplifted above diapir; (e) continued upward movement of the diapir even when pinched off from the source. The presence of layer-parallel reverse-slip and concentric reverse faults may not occur together. In experiments on active diapirs Schultz-Ela

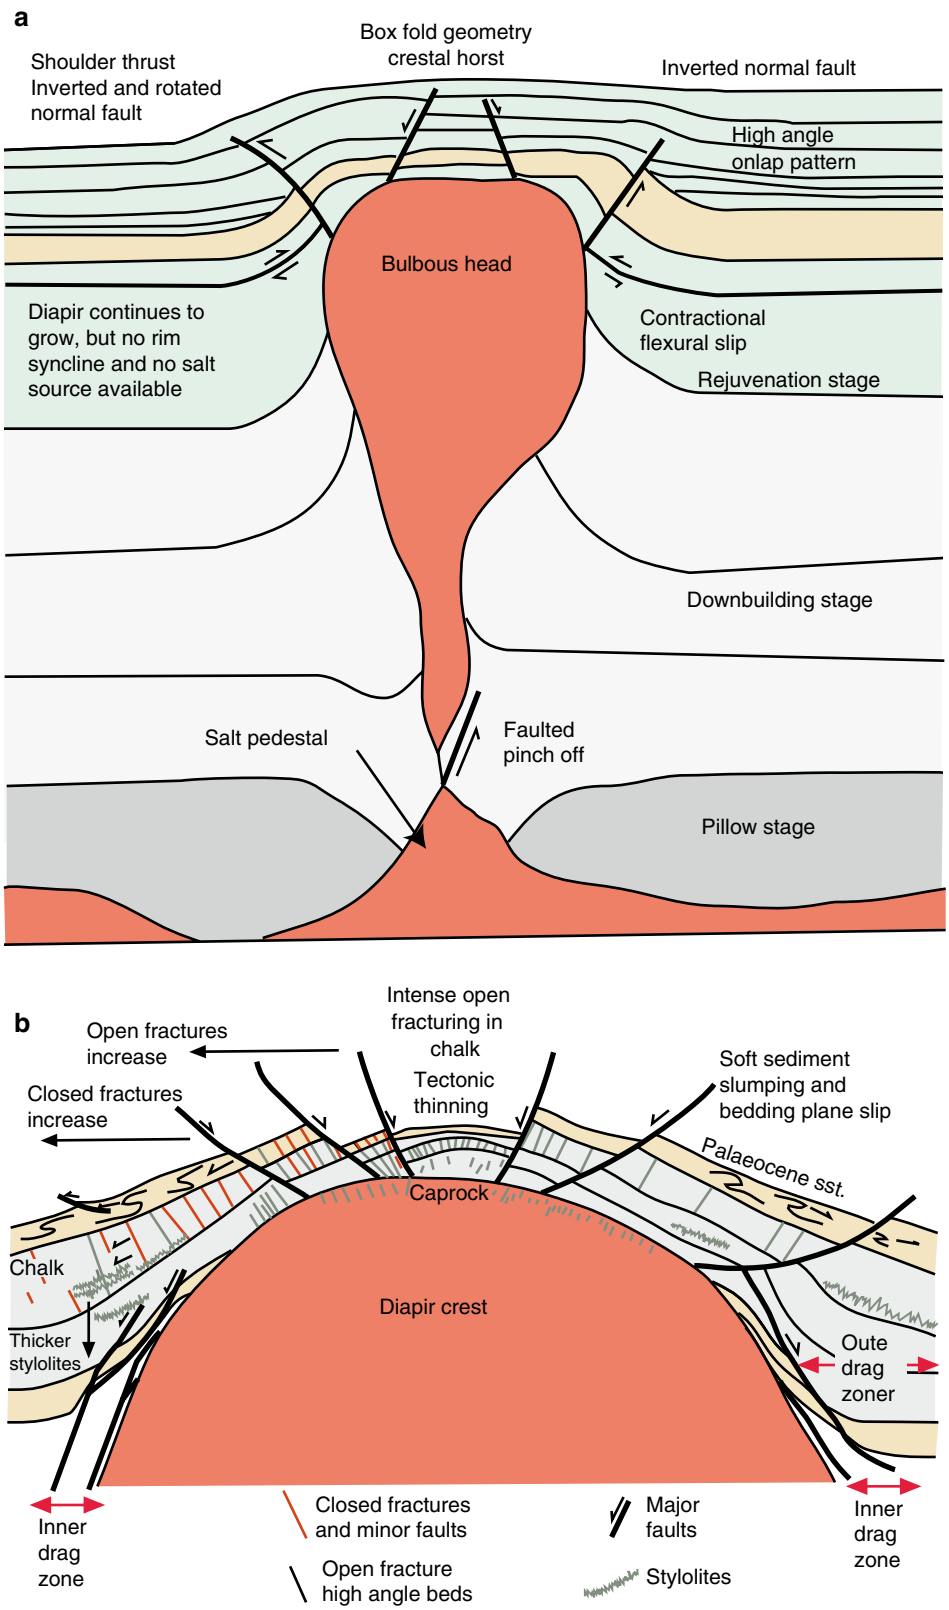

Fig. 6.81 Rejuvenated diapirs and suprasalt deformation. (**a**) Typical diapir crest showing deformation style in fractured chalks and Palaeocene sandstones (After Davison et al. 2000a). (**b**) Seismic scale geometry of diapirs affected by late compression with (a) compressional fold in overburden, (b) reverse layer-parallel slip, (c) wide drag zone, (d) thrust faults on shoulders, (e) lack of rim synclines (f) localised unconformities and high angle of onlap above unconformity restricted to immediate diapir vicinity, and (g) thick updomed strata above the diapir (After Davison et al. 2000b)

et al. (1993) showed that layer parallel slip occurs in overburden, which is anisotropic, and thrust faults at diapir shoulders occur in isotropic overburden. Crestal collapse grabens also occur above some rejuvenated diapirs, but crestal horst structures have only ever been produced in physical models of upbuilt diapirs (Davison et al. 1993). The

significance of the various fault patterns associated with the inversion of the diapir is discussed further in terms of hydrocarbon trapping in Chap. 10.

Suprasalt doming influenced the distribution of chalk and sandstone overburden in the North Sea via crestal thinning associated with intense extensional faulting, tensile fracturing, gravity sliding and pressure solution (Fig. 6.81b; Davison et al. 2000a). Salt buoyancy created topographic relief about the flanks of the thinned chalk layers, resulting in semi-indurated chalk sliding off the crests of the diapirs as shown by soft-sediment slump folding and bedding-parallel shear zones in the chalk in most producing offshore fields. For example, debris flows in the Kyle field carry clasts of caprock anhydrite indicating that the salt crest was exposed or was near the seafloor. Lithified angular clasts in the same debris flows indicate that chalk was already indurated and cemented at the time of extrusion, but nevertheless the diapir was able to actively break through and shed this lithified material. Topographic relief of several tens to hundreds of metres above the surrounding seafloor had developed atop reactivated diapir crests during the Late Cretaceous to Palaeocene period.

An associated flow of squeezed pore fluids through the chalk reservoirs in Banff, Machar, Kyle and North Pierce fields in the North Sea resulted in interconnected vuggy fractures filled with calcite. This calcite was probably derived from pressure solution, but much of the dissolved chalk atop the Machar diapir has since been removed from the system, with dissolution waters possibly escaping directly into the sea along major faults. A combination of all the rejuvenation effects produces what is an apparently intrusive single-event geometry. In reality, the overburden was tectonically thinned episodically and removed by gravity sliding, rather than actively pushed aside by rising salt in one event. Typical deformation patterns observed in chalks above a reactivated diapir are summarised in Fig. 6.81b.

Palaeocene sands overlie chalks in many diapiric fields in the Central Graben. Bedding-plane slip surfaces, with at least 10 m of displacement, are common in the Palaeocene siliciclastic rocks from South Pierce field in the North Sea (Fig. 6.81b; Davison et al. 2000a). Like the chalks, these overlying clastic sediments slid away from the diapir crest to accumulate on the diapir flanks as stacked and slumped deepwater sandstones. Sliding and shedding preferentially took place along mudstones, which preserve commonplace slump folds and polished faulted surfaces. Similar soft-sediment folds are not always present in the sandstones, which rode on the muddy slides and some coherent sandy blocks were translated large distances without any internal deformation. Thicknesses of the Tertiary sandstone packets increase from zero near the crest to 300 m on the flanks and indicate a combination off-crest channel stacking/ponding and crest-induced slumping. Davison et al. (2000a) argue that build-ups of tens of metres of supracrestal sediment were followed by up-doming of the salt diapir crest, which was accompanied by faulting and rotation of the strata until a critical angle was reached and then overburden slid off the diapir. Hence, as for their chalky precursors, these episodically active compressional diapirs were close to or at the seafloor during the Palaeocene to Eocene period, producing bathymetric highs that periodically shed their siliciclastic sediment cover (Fig. 6.100).

The notion that salt is susceptible to multiple episodes of deformation is not just seen in the North Sea. It also influences salt distribution in the Dniepr-Donets salt basins and large parts of the Zagros Belt. It is probably universal observation. Salt flow is driven by initial extension and then reactivated by later compression, which can be mild or intense. This set of compression driven structures may be subject further extension events. The various deformation events reactivating flow may be tens or even hundreds of millions of years apart. That is, salt structures in tectonically complex regions subject to ongoing externally applied stress will have responded by multiple episodes of deformation.

For example, the Ukrainian Dniepr-Donets Basin (DDB) is a Late Palaeozoic intracratonic rift basin, with sedimentary thicknesses up to 19 km, displaying the effects of salt tectonics during its entire history of formation, from Late Devonian rifting to the Tertiary (Stovba and Stephenson 2003). Hundreds of concordant and discordant salt structures formed during this time. Salt movement began during the Devonian synrift phase of basin development and exerted controls on the later distribution of salt structures although the geometry of basement faults is not solely responsible for the regular spacing of salt structures (Fig. 6.82). Postrift salt movements in the DDB occurred episodically. Episodes of salt movement were triggered by ongoing tectonic events, specifically two extensional events during the Carboniferous, an extensional reactivation at the end of Carboniferous-earliest Permian, and a compressional event at the end of the Cretaceous. Extensional events that induced salt movement were "thick-skinned," (i.e. basement involved in deformation) rather than "thin-skinned" (Fig. 6.82). Most overburden deformation related to salt movements was ductile regardless of sedimentary bulk lithology and degree of diagenesis, while the deformation of sedimentary cover in areas where salt is absent was mainly brittle. This implies that the presence of salt can change the predominant mode of deformation of overlying sedimentary rocks. Episodes of salt movement lasted longer than the periods of active tectonics that initiated them.

According to Stovba and Stephenson (2003), buoyancy, erosion, and differential loading all played a role in driving halokinesis once tectonic forces had pushed the salt-overburden system into disequilibrium; among these factors, erosion of overburden above growing salt structures acted as a key self-renewing force for development of salt diapirs.

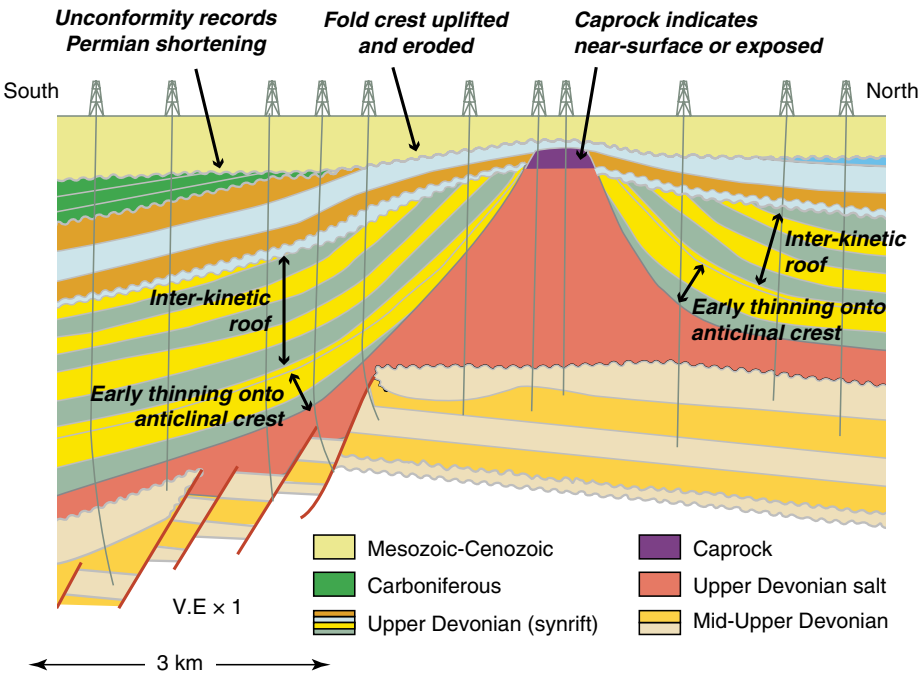

Fig. 6.82 Early thinning onto the crest of the structure suggests that the diapir originated as a low-relief salt anticline shortly after Late Devonian salt deposition. This anticline was then buried beneath a thick constant-thickness package (interkinematic section) before being reactivated and breaching its roof later in the Devonian. Signs that this reactivation was compressional are (a) the uplifted and eroded crest, (b) a thick interkinematic roof, and (c) a short-lived uplift. However, any shortening in the Late Devonian is counter to the consensus that the Late Devonian was a time of extension, volcanism, and basin formation (compare with section in the adjacent Dnieper-Donets Basin). This anticline suggests a previously unrecognized tectonic event in the Pripyat Trough. Alternatively the bedding geometries are inaccurate. A second episode of shortening in the Permian further amplified the structure and caused renewed crestal erosion (After Stovba and Stephenson 2003)

Very high sedimentation rates (related to high post-rift tectonic subsidence rates), particularly during the Carboniferous, were able to bury diapirs and to load salt bodies such that buoyancy, erosion, and differential loading forces eventually became insufficient to continue driving diapirism, until the system was perturbed by an ensuing tectonic event. In contrast, some salt anticlines and diapirs developed continuously during the entire Mesozoic because of much-reduced tectonic subsidence rates (and sedimentation supply) during this time. However, the Lower Permian salt series and overhangs of buried diapirs in the Dniepr-Donets played an important role in preventing overburden piercing (and fracturing) during the Mesozoic and, specifically, during the Late Cretaceous salt diapirism phase.

Before leaving the topic of basin inversion, it is instructive to return to the notion of how ambiguous some salt structures can be when trying to interpret their origin from shape alone (as needs be in most seismic interpretation). Figure 6.83 maps the distribution of some of the various salt valleys in the Canyonlands region of Utah. Did these salt structures, sourced in the Permian Paradox Formation, initiate and grow during contraction related to the Uncompahgre Uplift, or are they the result of subsequent Mesozoic sediment loading and extension? Elongated salt walls dominate, but more circular diapirs also occur. The salt walls seem to follow the NW–SE trend of long-lived basement faults (thick-skinned), while younger collapse-related faults occur in the overburden. Did these salt structures initiate and grow during contraction or extension? Simple questions are sometimes hard to answer. The valley system is further complicated by deep dissolution of the salt, which may obliterate the morphological evidence of contraction or extension (Chap. 7). Likewise, the Silver Pit structure in the North Sea is enigmatic and has been interpreted as both a squeezed diapir and as an impact crater (Underhill 2009) as has the Upheaval Dome in the Canyonlands of Utah (Jackson et al. 1998 vs Kriens et al. 1999).

Salt Extruding Today?

With enough time, halokinetic salt settings evolve from extensional to compressional and when tectonically active flowing salt can be near or at the landsurface in either setting. This can occur relatively early, a result of gravity gliding in the downdip portion of a passive continental margin, or it can occur later, the result of a transition from rift to drift to collision in continental margin sediments. Both are inherent transformations in continental edges that underline the Wilson Cycle (e.g., Zechstein diapirs of NW Europe). Halokinesis can be associated also with the set up of transpressional or transtensional zones along salt-floored strike-slip basins (portions of the Dead Sea transform, and parts of the Zagros collision belt).

Most examples of contemporary at-surface salt flow are in areas of active regional compression, in arid deserts, and especially in the Horse Latitudes of the Middle East. Regions where salt flows have been recently active are distributed more widely than the Middle East, but restricted to arid settings with limited liquid water, and so as well as deserts can include the frozen tundra of the Canadian Archipelago (Fig. 6.84a). Of the various examples, Iran is the premier region to study outcrops of active salt flows (Figs. 6.84b and

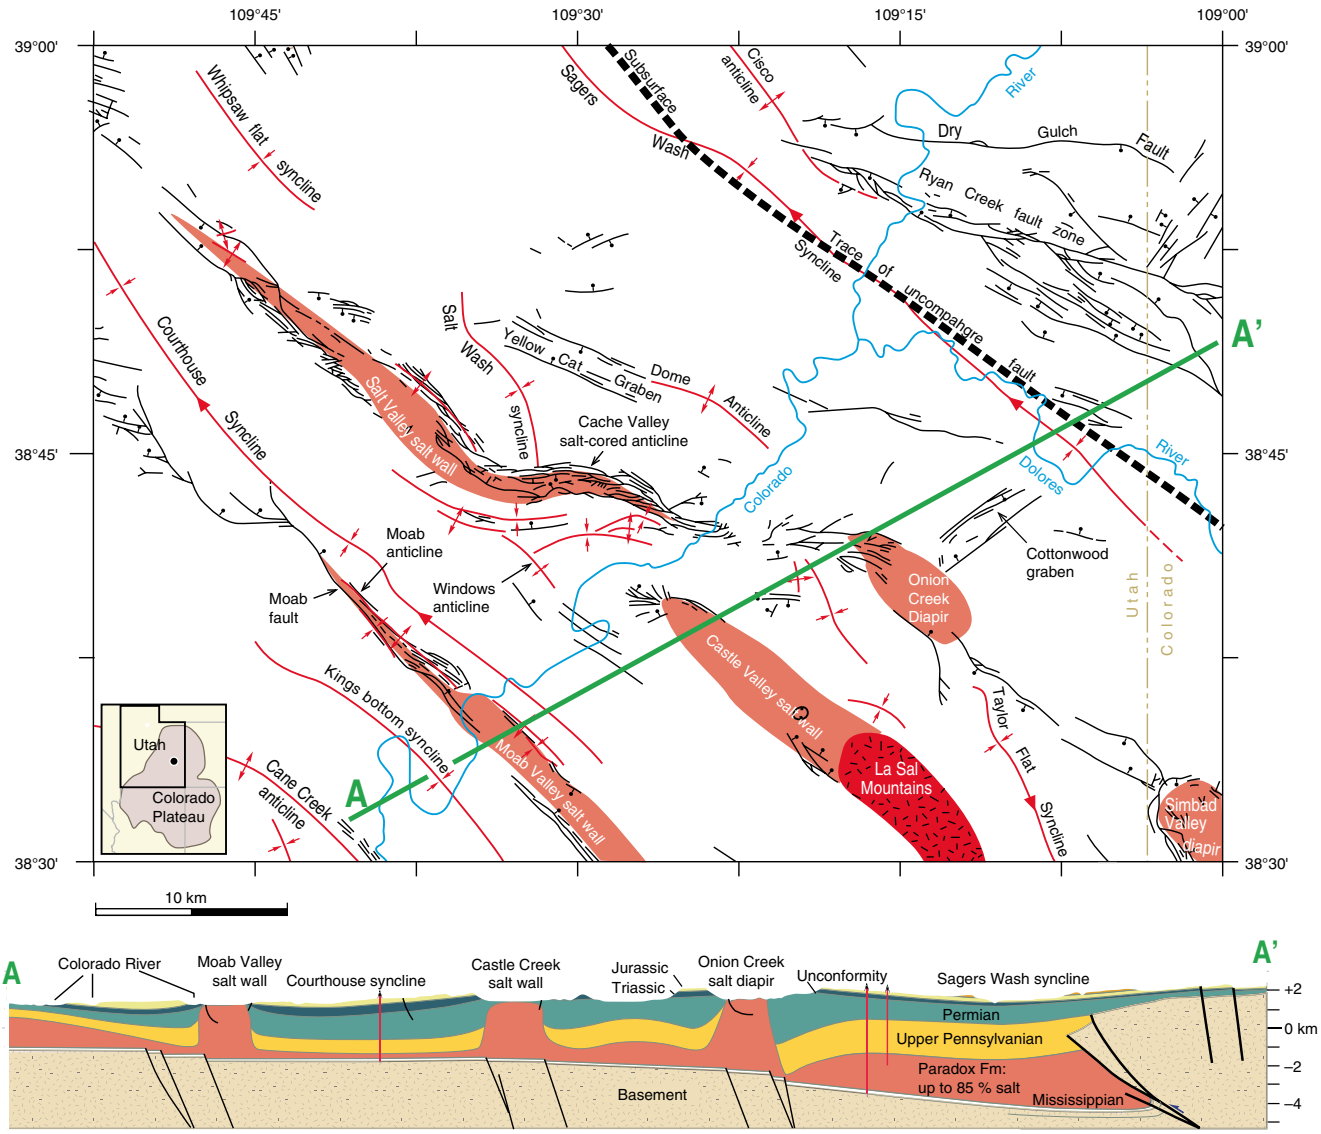

Fig. 6.83 Salt structures in the Moab area of southeast Utah in map view and cross-section. Elongated salt walls dominate, but more circular diapirs such as Onion Creek also occur. Figure based mainly on Doelling (2001) and Fossen (2010)

6.85). The common theme to all these examples is tectonic inversion and/or compression that is either active now, or was so in the recent past. Only in settings where the compression is ongoing, is salt flowing at the modern landsurface.

Free-flowing namakiers in Iran occur in two tectonic zones, the Alborz and the Zagros fold and thrust belts. The salt caught up in the tectonism of the Zagros is the Infracambrian/Cambrian Hormuz salt and its equivalents (Kent 1979), while that in the Alborz zone it is the salt of the Miocene Lower and Upper Red formations, first deposited in tectonically-induced collision basins and then caught up in the subsequent deformation (Morley et al. 2009). In both settings ongoing continent-continent compression drives lateral shortening, via buckling, which encourages thickening of salt in anticlinal cores. Some fold crests are erosionally thinned, others are cut by faults so that the anticline leaks salt to the surface along the fault intersection ("slicing the bladder"). With crestal erosion, this drives a loss of structural integrity allowing for buoyant (pressurised) salt emergence ("popping the pimple"), possibly aided by pinch-off from the mother salt layer. Similar buckled salt-cored anticlines, which are no longer active, constituted the source for ancient salt flows in the Nordkapp Basin in the southern Barents Sea (Dooley et al. 2009), the Dniepr-Donets Basin in Ukraine and in the Zechstein of NW Germany (Mohr et al. 2007). Once salt is extruded, the original salt-cored anticlinal source is subject to collapse and erosion, especially if the mother supply lessens or it is cut off by closure of the salt neck (Figs. 6.80).

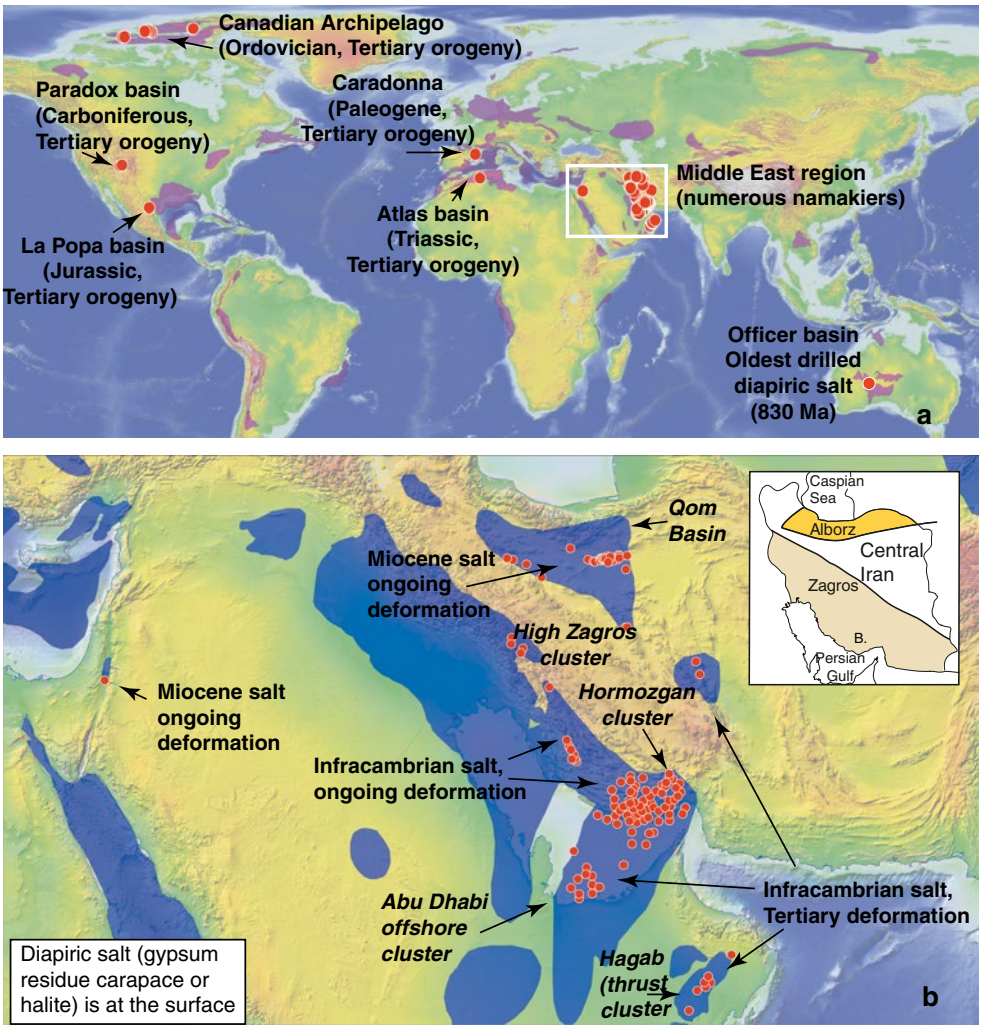

Fig. 6.84 Plot of selected documented examples where salt is at or very near the modern landsurface. Examples in Iran have salt flowing at the surface (namakiers). The remainder are recently active flows where salt is now in dissolutional retreat, marked by salt ablation breccias and brecciated dissolution carapaces typically with residual gypsum. (**a**) World; (**b**) Middle East. Plots also show the position of underlying halite basins with thick salt successions (Extracted with permission, from SaltWork database – Version 1.7)

As it has for interpreting triggers in salt under extension (Brun and Fort 2011), physical modelling of salt under compression creates a quandary as to whether buckling and thickening of salt in an anticline can build sufficient pressure to initiate active diapirism. This is especially so if the salt in the buckle-fold core is still connected to the mother salt layer. That is, physical models of a buckling compressional system using brittle overburden and a viscous salt-analogue silicone gel layer do not show breakout at the thickening anticlinal crests (Vendeville and Jackson 1992b; Letouzey et al. 1995; Koyi 1998). The silicone gel initially thickens in the rising anticlinal cores, then is squeezed out back down into the mother salt layer (the squeezed salt/gel takes the path of least resistance compared with breaking through the brittle overburden), or the gel is dragged along thrust planes. In all cases it does not emerge, but stays in normal stratigraphic contact with the overlying thrust sheet. Only when there is a preexisting diapir stem, or there is crestal erosion, or if the salt core is pinched off from the original mother salt level, is salt extruded and this episode is typically short lived ("popping the pimple").

And yet the scale of such flows can be impressive. In Iran, there are 300-m high glaciers of Miocene or Infracambrian salt flowing across today's landscape, both in the Qom Gamsar Basin region in the Alborz Tectonic zone and in the eastern foldbelt of the Zagros, respectively (Fig. 6.84b; Morley et al. 2009; Alsouki et al. 2011). The ubiquity of salt glaciers (namakiers) in both tectonic zones of Iran (Alborz and Zagros) clearly shows salt does breach salt-cored anticlines within regionally compressed and/or transtensional terrains. The question is; "When and how does it flow?"

The most impressive region for observing salt flowing at the surface is the Hormuzgan district, situated north and east of Bandar Abbas (Fig. 6.85a; Jahani et al. 2007) There, those Zagros folds with active namakiers tend to be located atop elongated symmetric whalebacks or box-shaped anticlines with crests generally aligned in a NW-SE direction and the main thrust detachment at the level of the Precambrian Hormuz salt (Alavi 2004).

The Zagros front is still advancing and every stage in the evolution of a namakier (from fountain to ruin) outcrops in this active mountain belt, which is still shortening at ca.

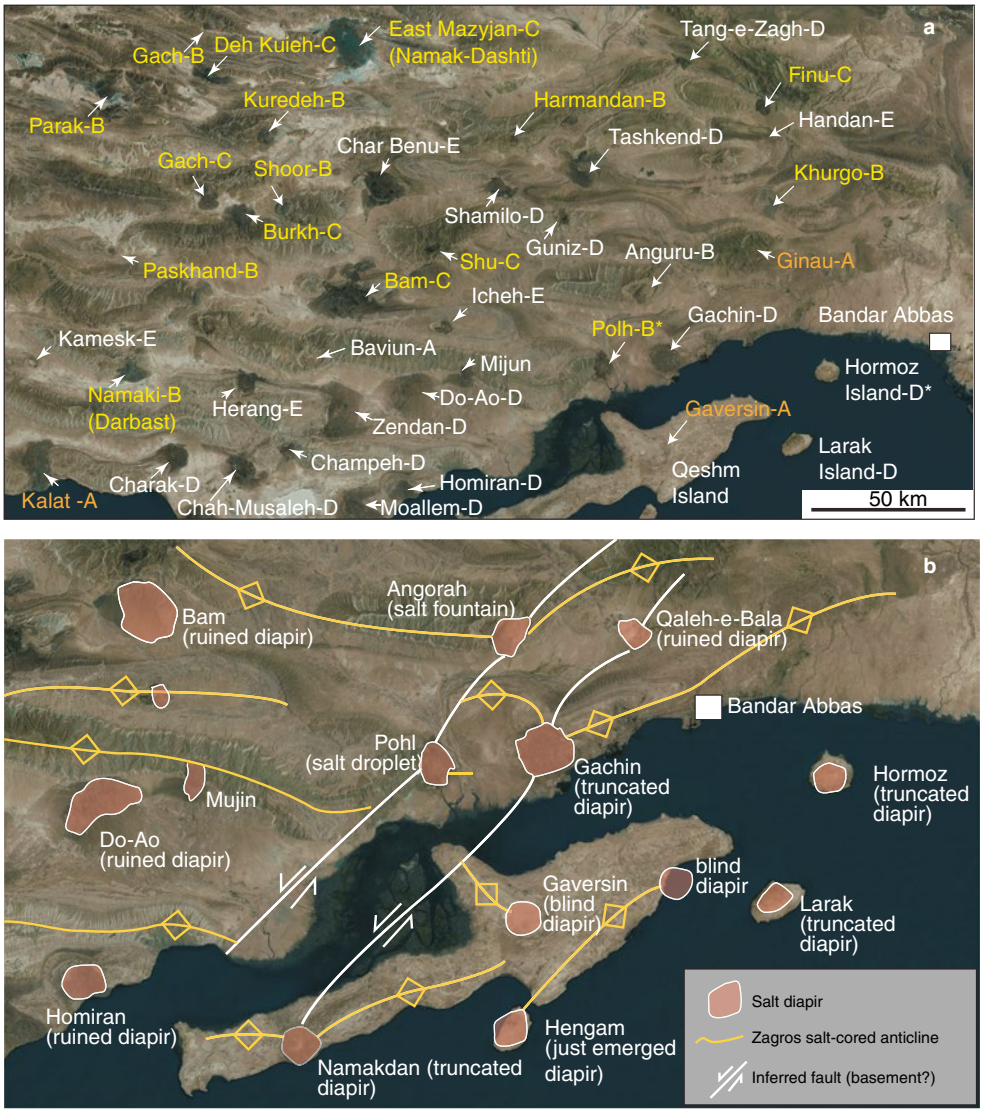

Fig. 6.85 Namakiers of Eastern Iran. (**a**) Salt glaciers (dark blebs) of Hormuz Salt flowing across the landscape of Iran north and east of the coastal town of Bandar Abbas, offshore islands are also cored by salt diapir and with now inactive glacier residues at surface. Classified A–E is indicative of stage of development; a = pre-piercement bulge, b = Exposed salt plug, c = salt namakier at surface, may be in retreat, d = namakier with near complete dissolution, e- degraded and dissolve core with little or no visible salt., That is, orange = pre breakout, yellow lettering = salt at surface, white = little or no salt remains only residues – see Chap. 7 for details on evolution Asterisk indicates a salt feature known to contain potash. Note that the name "Gach" appears more than once as it means gypsum in Farsi. (**b**) Diapirs in the vicinity of Bandar Abbas showing regional deformation structures (in part after Fürst 1976; Talbot et al. 2009a, b – Bing® images mounted and scaled in Mapinfo)

20–25 mm a^{-1} (Hessami et al. 2006). Regionally, the SW advance of the Zagros front, and the halokinesis associated with it, is extensively documented (Talbot and Alavi 1996; Talbot et al. 2009a, b). Diapirs, pressurized by their overburden and the stresses associated with the arrival of the Zagros front, burst out of their overburden to extrude as salt-cored islands in the Gulf or salt mountains onshore (Fig. 6.85). The southward migration of the Zagros front is still forming successive thrust anticlines and spawning reactive syn-Zagros diapirs that decrease in age southward along the N–S trending pre-Zagros pillows of Hormuz salt (Talbot and Alavi 1996). The regional stress field rotated slightly in late Neogene times at ca. 5 Ma (Lacombe et al. 2007; Jahani et al. 2007) and previously thin-skinned largely salt-floored deformation now involves a thick-skinned component with reactivation of faults in the basement (Molinaro et al. 2005). This is indicated by most modern active diapirs aligning along faults oblique to the Zagros fold axes (Fig. 6.85b and 6.86; Talbot and Alavi 1996). For example, the Zagros fold system in the Firuzabad region is overthrusted along, and cut off by, the Zandan Thrust, a branch of the Zagros Main Thrust, approximately 75 km east of Bandar Abbas. Salt breakout in the salt-cored anticlines there does not occur unless the crest of the anticline is faulted or eroded. Hundreds of kilometres to the northeast from the Hormuzgan district, in the hydrocarbon rich section of foreland foldbelt in the Fars district, the Miocene evaporites of the Fars/Gachsaran Formation can act as a secondary detachment level whereby pairs of shallow thrusts are rooted with opposite vergences toward the crest of the anticline (Figs. 10.79 and 10.80).

Bosak et al. (1999) and Fürst (1976) note that outcropping salt plugs and associated namakiers are mostly associated with sigmoidal bends in fold axes (these are the circular plugs noted by Fürst 1976) or occur near terminations of anticlines (plunge turnovers). Many active flows are sourced on anticlinal flanks and not in axial crests (Figs. 6.86 and

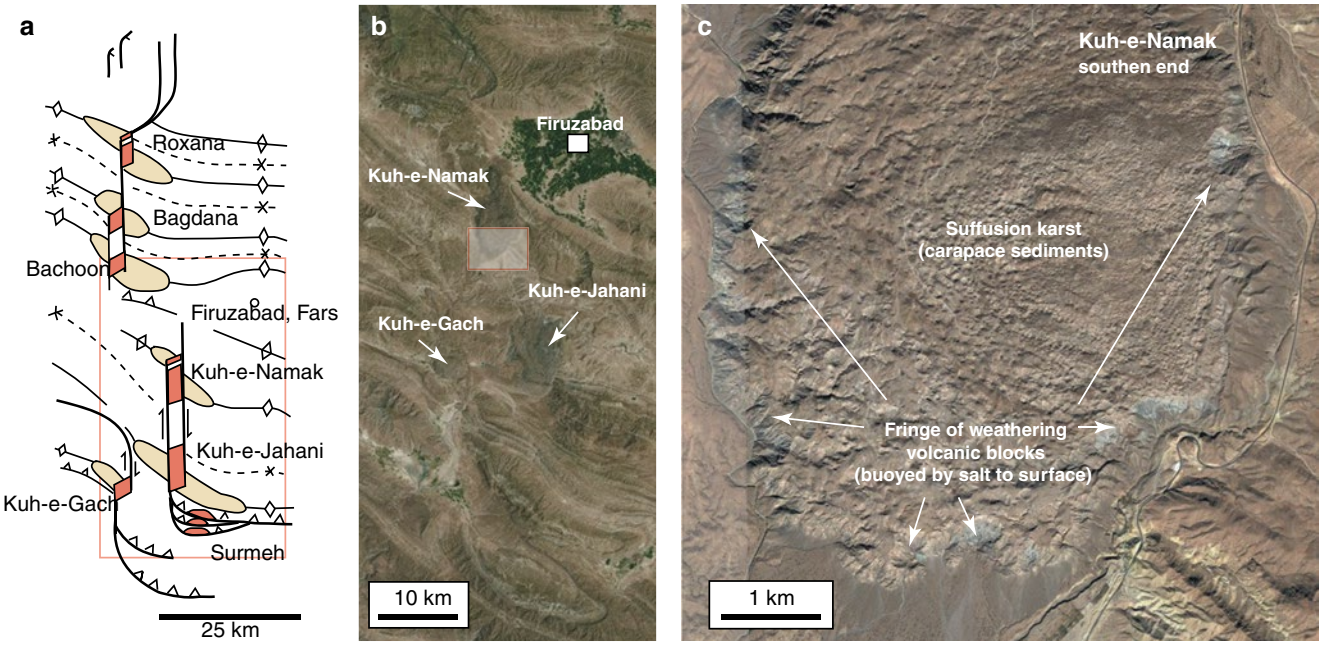

Fig. 6.86 Current kinematics of Mangarak fault zone, Firuzabad region, Zagros tectonic zone, Iran, showing the location of present and former salt extrusions (*red*). They occur in zones where a fault zone crosses salt-cored anticlinal culminations, shown as rhombic areas (After Talbot and Alavi 1996)

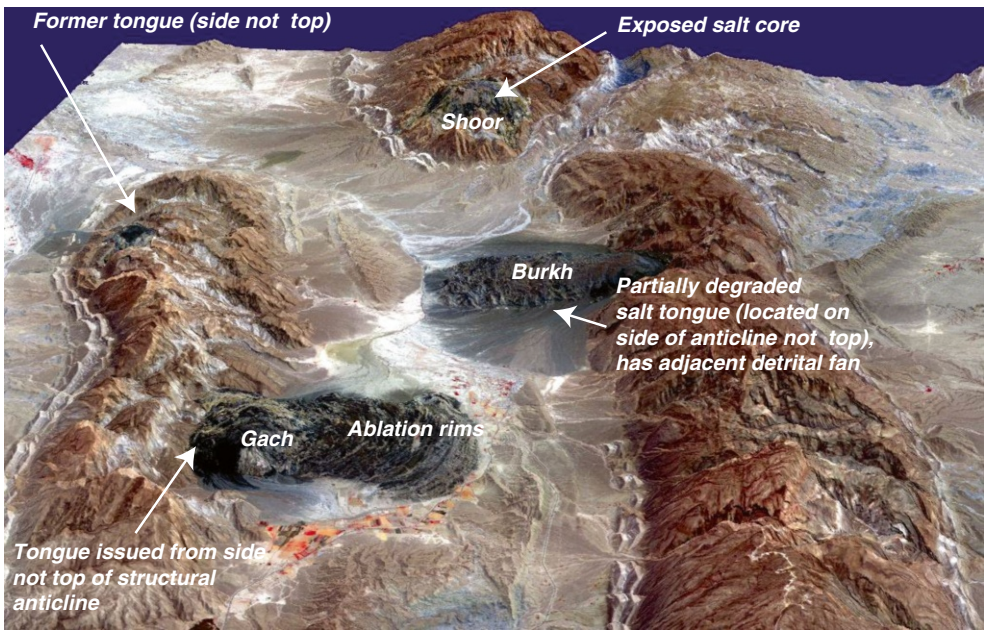

Fig. 6.87 Lateral view looking east across the Gach – Shoor namakier region, clearly shows the bladderlike nature of namakier flow – see text (Image courtesy of NASA, NASA/GSFC/ METI/ERSDAC/ JAROS, and the U.S./Japan ASTER Science Team; see http://asterweb.jpl.nasa.gov/gallery; accessed June 17, 2013)

6.87). Apparently, zones of fault-induced extensional shear are more important in controlling the site of salt emergence, rather than the zone of extension across the culmination of anticlinal crests (once the surface is breached via active diapirism salt drains out of the sides of sliced structures not the crests; in most Zagros namakiers we are slicing bladders, not popping pimples!). A few of the salt plugs on the anticlinal flanks lie closer to the synclinal axis than to the anticlinal axis. But in some of the less active namakiers the site of the original emergence can be difficult to define. Extruded salt always rolls downslope, so if it is cut off from its source, it will end up occupying flanks and synclinal axes, even if the source was the anticline crest.

Even so, the following generalizations can be made; (1) most salt plugs outcrop in bends or faulted displaced offsets of the anticlinal axes, (2) salt typically does not breakout in areas of straight (unfaulted) anticlinal axes. This led Talbot and Alavi (1996) to argue that Hormuz salt typically emerges

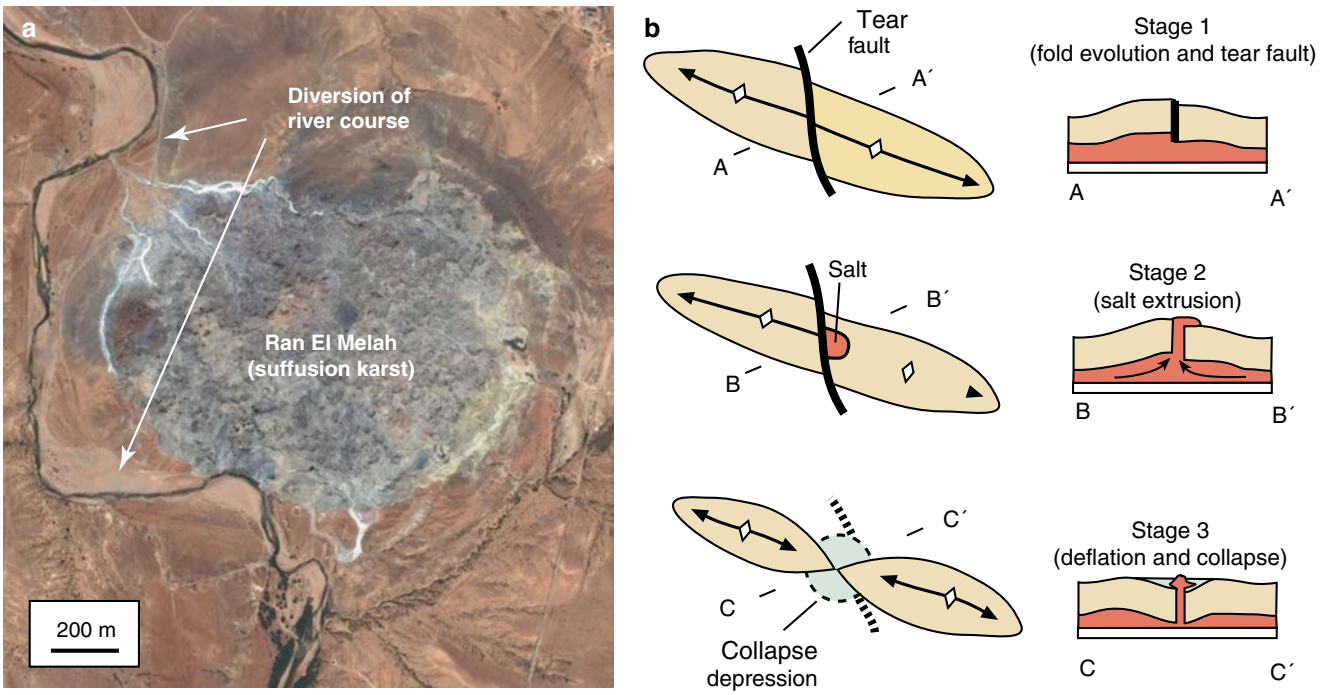

Fig. 6.88 Ran El Melah, Algeria. (**a**) Suffusion karst in a gypsum carapace, now outlining the namakier. Notice how the landscape high, created by the namakier has diverted the river course. (**b**) Schematic based on Ran El Melah and other Algerian examples showing how salt extrusions tend to occur where tear faults intersect salt-cored anticlinal culminations and the successive stage of dissolution and collapse the occur once supply to mother salt is cut off (After Letouzey et al. 1995)

as namakiers where the salt cored anticlinal crests are cut by faults, such as in the Kazerun and Mangarak fault zones (Figs. 6.85b and 6.86). A similar system of extensional tear faults across salt-cored compressional anticlines also explains emergent salt in Triassic salt now forming namakiers such as Ran Al Melah in the Atlas ranges of Algeria (Fig. 6.88; Talbot and Aftabi 2004; Vially et al. 1994). Ran Al Melah was the first active salt glacier documented in the geological literature (Ville 1856).

Other than faulted and eroded anticlinal buckle folds, additional salt or salt breccia-defined outcrops in compressional settings populate salt-lubricated thrust planes, some showing a strong strike-slip sense of movement. Examples include Miocene salts in the Carpathians of Romania, Triassic salts in Alpine thrust belts in southern France and Spain, the Neoproterozoic Roan breccias of the Lufilian foldbelt of Central Africa and the Callana Formation breccias of the Flinders Ranges of South Australia (Chap. 7).

Once again, this style is best seen in Iran, in the regional faults that define the margins of the Miocene section in the Qom Basin of central Iran (Fig. 6.89a). The Central Basin of the Iran Plateau lies between the geologically better-known regions of the Zagros and Alborz Mountains. Hydrocarbon exploration in the Central Basin has revealed the details of the late Eocene – Holocene evolution of the basin based on seismic reflection data, geological fieldwork, basin modelling, and satellite interpretation (Morley et al. 2009). The multistage basin history commenced with broad sag-type subsidence and isolated normal faults during Oligocene-early Miocene time. Short periods of hydrographic isolation allowed thick sequences of marine-fed salt to be deposited at this time. The basin evolved to an extensional or transtensional basin in the early-middle Miocene, with as much as 4–5 km of Upper Red Formation section (including continental evaporites) being deposited in some parts of the basin during this stage.

The upper part of the Upper Red Formation is associated with a change to transpressional deformation, with the development of thrusts and folds. This latest (probably middle and/or late Miocene-Holocene) deformation is transpressional, and includes a mixture of basement-involved strike-slip and thrust faults and thin-skinned folding and thrusting detached on the Oligocene halite dominant evaporites. Local detachment levels higher in the stratigraphy also exist some centred on the Upper Red Fm. continental evaporites (Fig. 6.88b). Subsidence in mini-foredeep basins and strike-slip fault bounded basins occurred during the transpressional stage, and several kilometres of Upper Red Formation were deposited in the main depocentres.

Northwest-southeast to north-northwest-south-southeast, striking dextral strike-slip to compressional faults dominate the area, with subordinate east–west and north–south fault orientations also present. These different fault sets combine in places to form major strike-slip duplex geometries. The

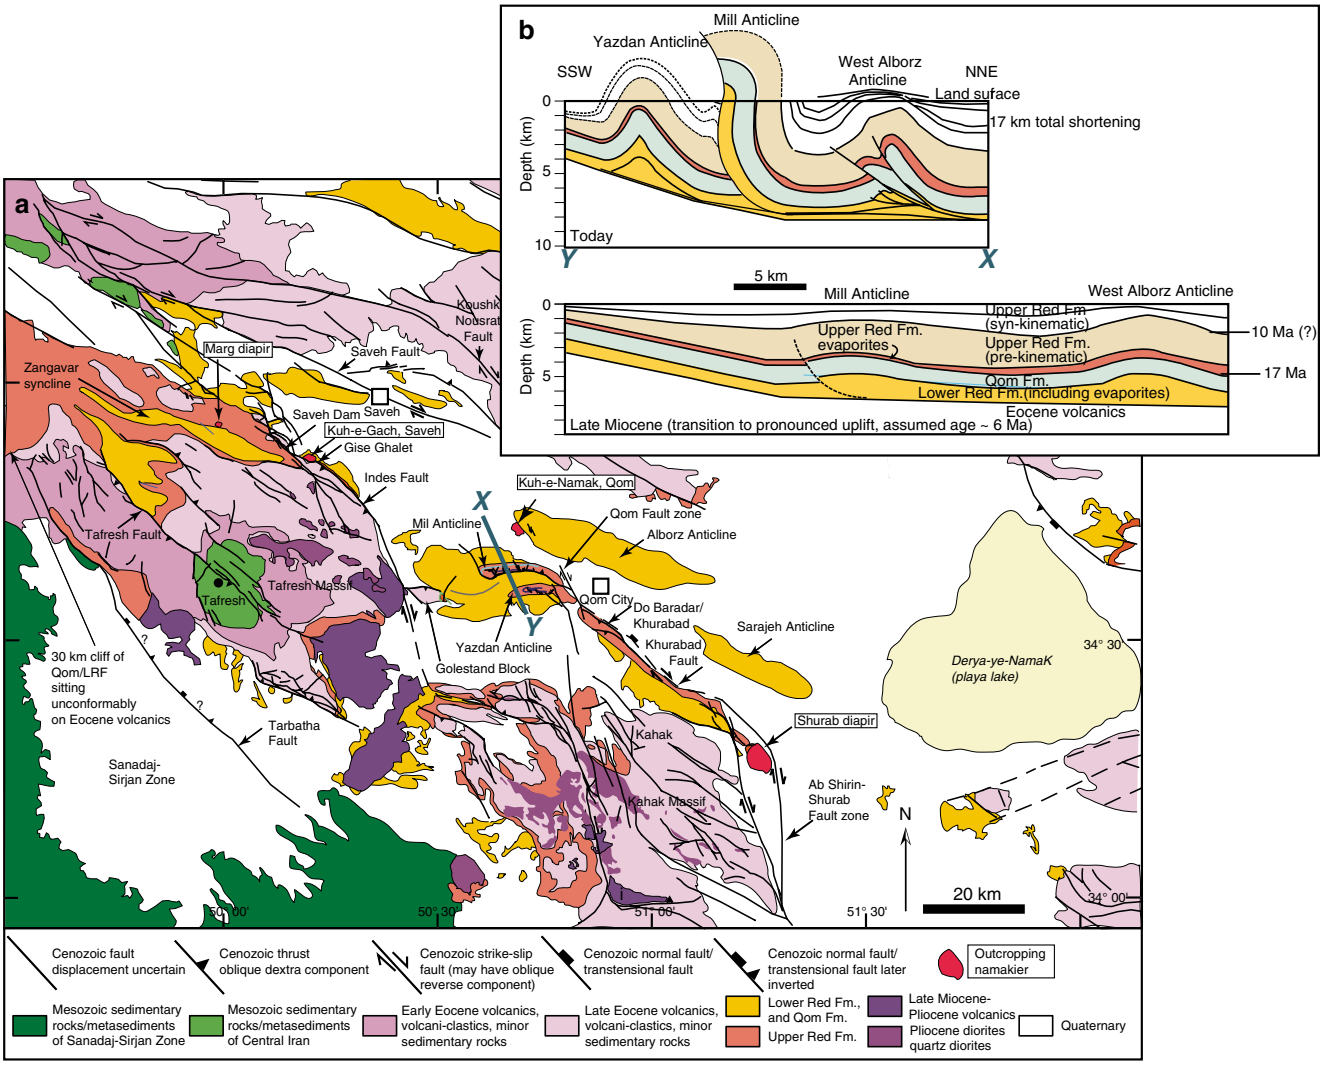

Fig. 6.89 Regional geology of central Iran, based on geological maps, satellite interpretation, and ground site checking. (**a**) Regional geological map. (**b**) Cross-section X–Y showing there has been at least 17 km of shortening/inversion since the Miocene in this saline basin with much of the compressional décollement focused into salt rich layers in the Miocene stratigraphy (After Morley et al. 2009)

Eocene volcanic belt (Urumieh-Dokhtar zone) along the southern margin of the basin forms a chain of massifs as much as 3 km high, the outcrops of which were exhumed by movement along major thrusts from 5 to 6 km depth between the middle Miocene and present day.

The Central Basin-Urumieh-Dokhtar zone forms a distinctive transpressional belt that underwent a minimum of 38 km shortening between the late Miocene and Holocene. The Central Basin and the Zagros and Alborz Mountains all indicate that the onset of widespread crustal shortening in Iran occurred late (latest early Miocene or later), relative to the initial collision of the Arabia Peninsula with Eurasia during the late Eocene or early Oligocene. Uplift of the Central Basin surface from approximately sea level to 900–1,000 m occurred during the middle or late Miocene, after deposition of the marine Qom Formation.

Within this complex milieu of deposition and interacting structure, local transtensional rhombs along the major faults have allowed pressured salt be pumped to the surface. One of the most impressive examples of salt emergence is the Kuh-e-Qom salt fountain (Figs. 6.89 and 6.90). Qom Kuh is one of four salt diapirs emergent along releasing bends pulled apart along major dextral transpressive faults crossing the Qom Basin in the central plateau of Iran. The others are Shurab, Kuh-e-Gach and Marg, indicated by rectangular boxes in Fig. 6.89a. Of the four, Kuh-Qom is the most active and is still actively flowing, while the other three are in varying stages of collapse and dissolution. Qom-Kuh is located on a releasing bend of an offset in the Qom Fault that cross-cuts the plunging nose of the Alborz Anticline (Fig. 6.90a). The Qom Fault intersects a number of normal faults in the vicinity of Kuh Qom which are exposed to the east of Qom

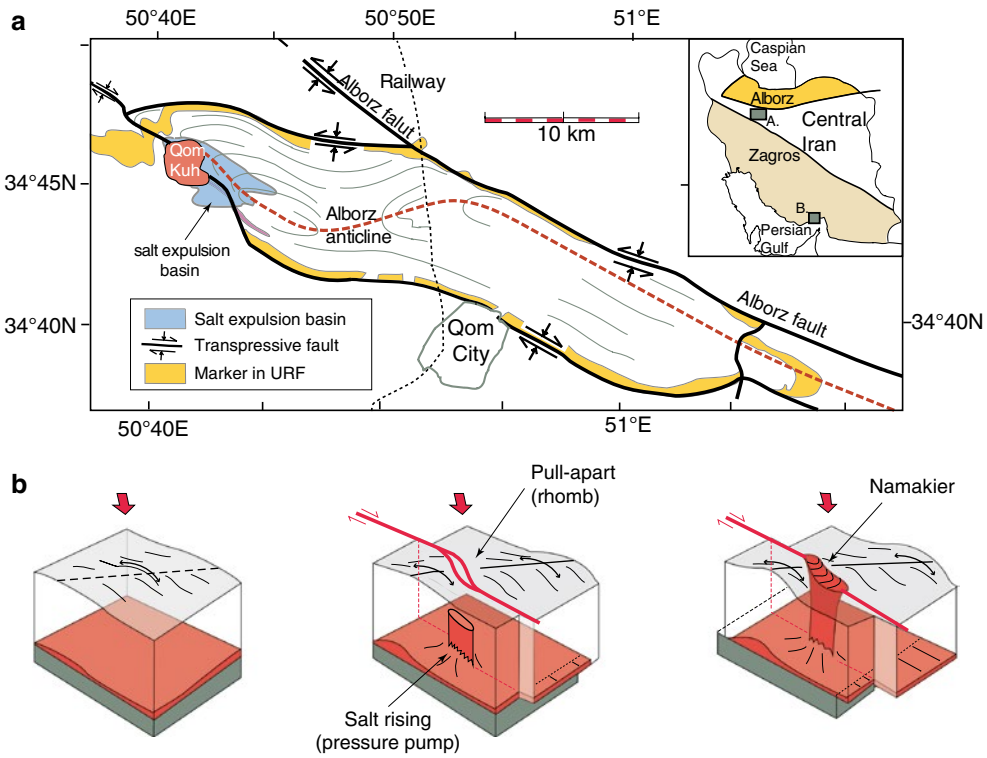

Fig. 6.90 Kuh-e-Namak, Qom. (**a**) Geological setting of Qom-Kuh with *inset* showing location in Iran in the framework of the Alborz and Zagros tectonic zones of Iran (After Emami and Hajian 1980; Talbot and Aftabi 2004). (**b**) Emplacement occurs as a transtensional lens escaping via a strike-slip rhomboid pull-apart. See Fig. 6.91 for regional geology of Kuh Qom

Kuh where it extends beneath alluvium to the northwest of the diapir (Fig. 6.91). Splays of oblique-reverse and oblique-normal faults offset the nearby asymmetric thrust anticline, known as the Alborz Anticline. These faults are well exposed in the 60 m-high river cliff that defines the eastern flank of Qom Kuh and in the adjacent river bench that has bevelled in Upper Red Formation marls at the 920 m above sea level (Fig. 6.91b). The faults are clearly seen in the zone separating the diapir from the hill created by the northern limb outcrop of the anticline. The largest of these faults has an irregular trace that was superimposed on a ductile dextral strike-slip shear zone before it offset the river bench some 1.5 m down to the east (Fig. 6.90d).

The salt fountain of Qom Kuh rises to 1,235 m asl and is 315 m above the surrounding plateau (Fig. 6.91d). The Qom Kuh namakier can be divided into two main components: (1) a smooth hemispheric dome or summit with a diameter of 2.5 km and surrounded by, (2) a slightly dissected apron of salt allochthonous atop Upper Red Formation and Recent gravels (Fig. 6.91b, d). Steps in the salt topography indicate that the extruded salt overflows a collar of Upper Red Formation up-tilted around the inferred diapiric vent. This raised collar is highest beneath the NE shoulder of Qom Kuh, where it is exposed in windows up to 1,100 m asl and lowest in its SW corner (Talbot and Aftabi 2004; Cosgrove et al. 2009). The river cliff truncates the eastern end of this bedrock collar (Fig. 6.91a, b). The apron of allochthonous salt is up to 200 m thick and about 0.75 km long to the west of the summit, and some 2 km to the south (Fig. 6.91d). The rhombic vent through which Qum Kuh extrudes was pulled apart between normal faults hard-linking a releasing offset along a regional transpressive strike-slip fault that trends west–east (Fig. 6.89b; Talbot and Aftabi 2004). In profiles though the summit, Qum Kuh can be considered as a pile of recumbent fold nappes of gneiss-like and mylonite-like Oligocene and Miocene salts that have extruded from depth and then gravity spread over recent alluvial gravels (Fig. 6.91c).

An ephemeral stream still flows anticlockwise around most of Qom Kuh, and is still eroding the cliff on the east side of Qom Kuh. Broken pottery lying on the river-bevelled bench to the east, and exposed by wind-deflation of the soils overridden by the southern namakier, suggest that the river eroded the salt of Qom Kuh in historical times (≈10,000 years according to Talbot and Aftabi 2004). Salt dissolved from the Qom Kuh namakier is now being re-precipitated as Holocene evaporite beds in the adjacent playa low, which is possibly situated atop an active salt withdrawal basin (Figs. 6.90b and 6.92b).

The rhombic transtensional nature of the salt neck to this graben structure that allows salt supply to Kuh-Qom salt fountain is seen more clearly in a rhomboid neck that now outcrops as Kuhe-Gach, Saveh, a highly dissolved namakier remnant (Figs. 6.89a and 6.92). Only the gypsum carapace and the reducing brine halo remain below the position of the former namakier (Fig. 6.92a–d). The leaching of the namakier creates reducing brines that colour the underlying redbeds grey, as it converts iron from its ferrous to ferric state

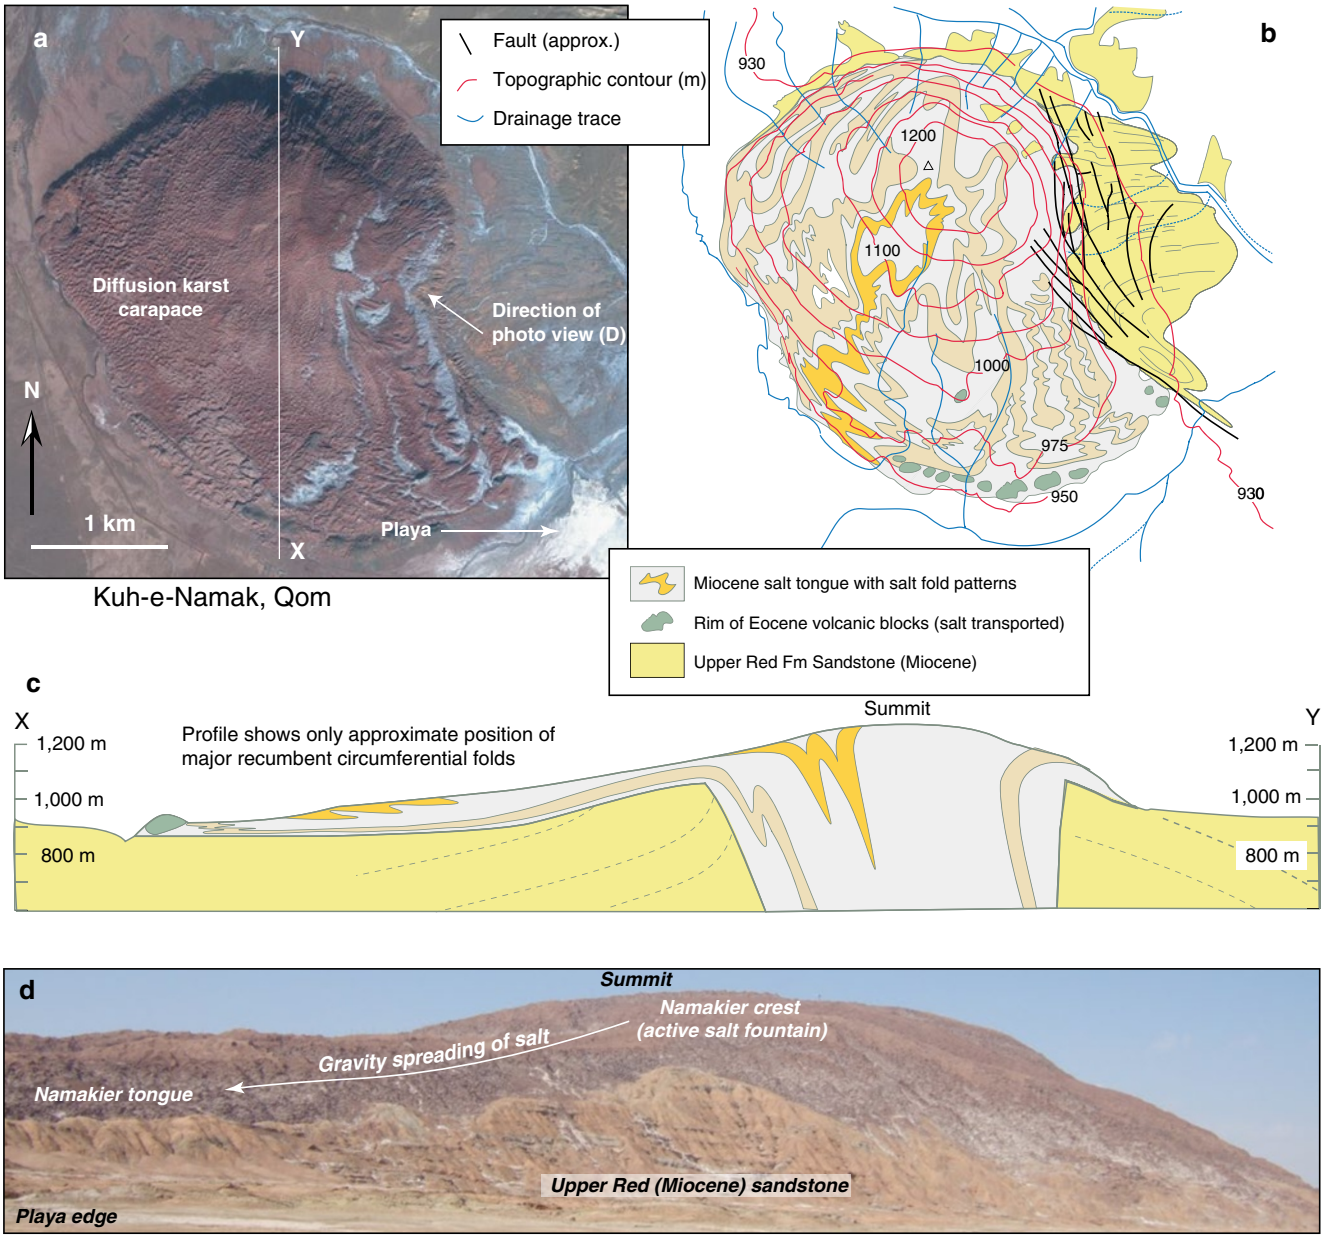

Fig. 6.91 Kuh-e-Namak Qom, Iran. (**a**) General plan view of namakier showing radial flow of salt away from the crest of the active salt fountain define by the summit of the kuh (Bing® image. **b**) geological interpretation of the namakier flows. (**c**) schematic section of the flow (X–Y). (**d**) Field photo showing the tongue lies atop salt inflated Upper Red Formation and how salt is flowing away from the summit (After Talbot and Aftabi (2004) and author's work in the region; see also Morley et al. 2009)

(Warren 2008). The topic of textures indicative of namakier weathering and retreat is discussed further in Chap. 7.

The regional work of Morley et al. (2009), based on a detailed field mapping program, assigns a mainly Oligocene age to the salt in this part of the Qom Basin. This is somewhat older than the dominantly Miocene age assigned by Talbot and Aftabi (2004). The nearby salt-thrust sealed Qom carbonate sediments of the Alborz anticline are famous, in 1956 they were the site of the of the world's largest uncontrolled oil well blow-out. The wildcat well (Alborz 5) blew out on August 26 1956 and leaked more than five million barrels of oil before it naturally bridged on November 18, 1956 (Mostofi and Gansser 1957; Gretener 1982). This drilling accident underlines the way in which a highly efficient salt seals can hold back substantial pressures, which in the case of the salt-sealed thrust fault to the Alborz anticline probably approached lithostatic (Fig. 6.89a; Chap. 8).

In summary, there is now widespread agreement that salt in compression plays a fundamental role in controlling the fold style and amount of shortening in thin-skinned

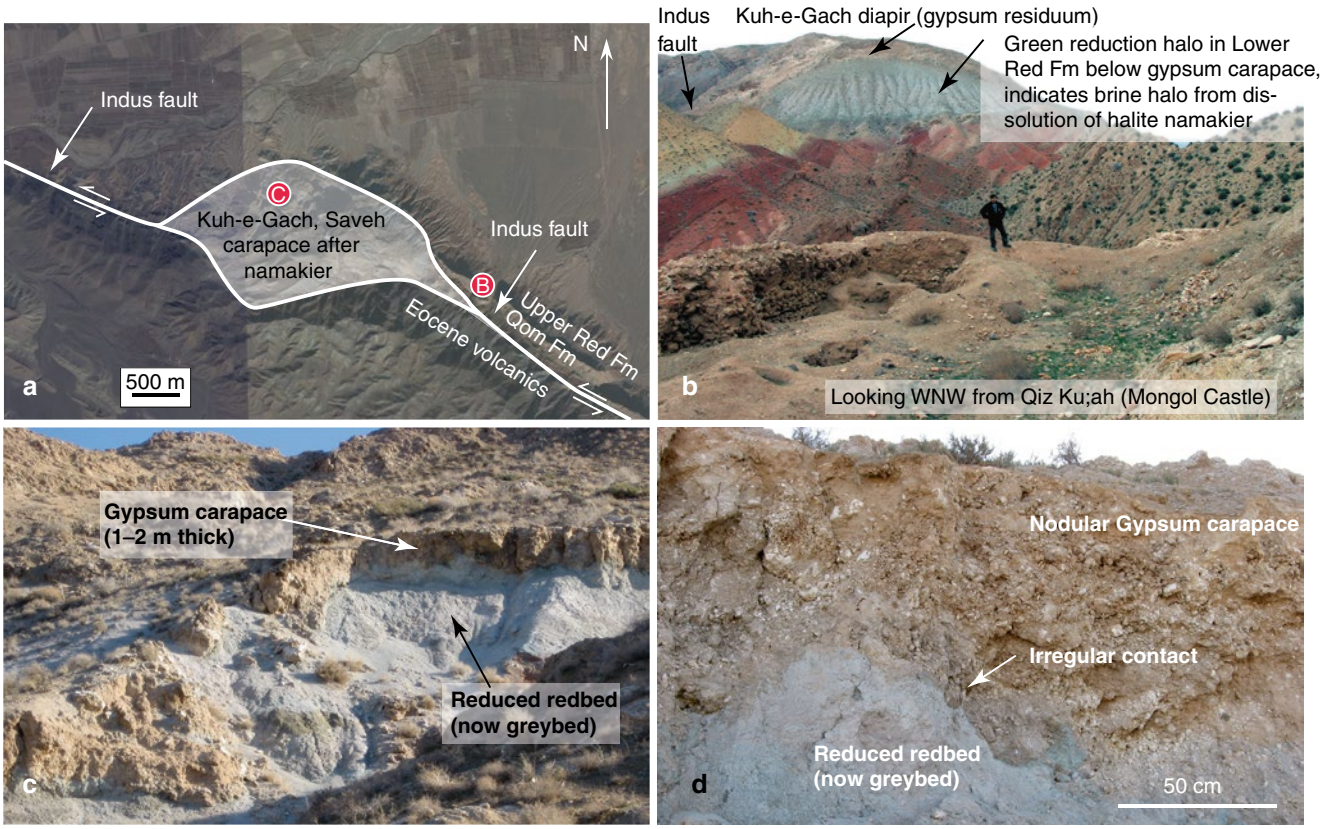

Fig. 6.92 Kuh-e-Gach, Saveh. (**a**) Interpreted Bing® image showing the releasing bend in the Indes Thrust Fault with a possible tear fault that allowed salt to escape to the surface from near the base of the Lower Red Formation. (**b**) View to north from Qiz Kaleh (Mongol Castle) showing diapir is a residuum after dissolution of former halite namakier and is now made up of a relatively thin carapace of gypsum (1–2 m) atop a green alteration zone in the Lower Red Formation red beds. (**c**) View of the carapace showing it is a veneer atop reduced (*grey*) shales that were once red. (**d**) Close-up of carapace-greybed contact

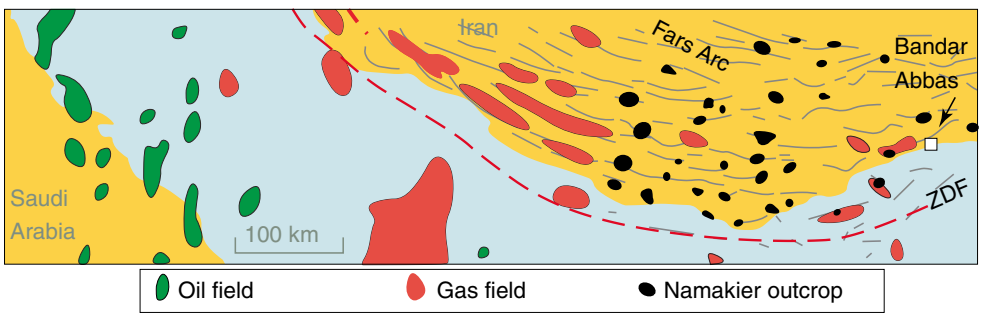

Fig. 6.93 Relationship between oil and Gas distribution and the Zagros deformation front (*ZDF*) which controls the WNW-ESE tend in Onshore Iranian gas field versus the N-S trends in Saudi Arabia. Notice the lack of gas fields in the zone where salt has breached the landsurface (to the west of Bandar Abbas)

salt-entraining thrust provinces. Outcomes range from mild inversion of an previously extensional system (such as modified pillow structures in the North Sea) to fully developed salt-cored, detached fold-and-thrust belts in the various alpine chains of Europe, North Africa, the Middle East, Southwest Asia and central Australia. It seems the presence of an at-surface namakier, as in the Hormuzagan region, indicates the likelihood of a loss of seal integrity via fault leakage; abundant active namakiers and significant gas filled anticlinal structures are for the most part mutually exclusive (Fig. 6.93; Chap. 10).

Browne Formation Oldest Known Salt

Neoproterozoic halokinetic sediments in the Officer Basin extend across in arid interiors of much of Western and South Australia, across some 320,000 km^2, and are largely concealed beneath sediments of the Gibson and Great Victoria Desert (Apak et al. 2002). Approximately 2/3 of the Officer Basin lies in Western Australia (Figs. 6.63 and 6.94a). Extensional faults have been recognised in Late Proterozoic and early Cambrian sequences of the northeastern part of the Officer basin (Southgate et al. 1989). Subsequent southward-

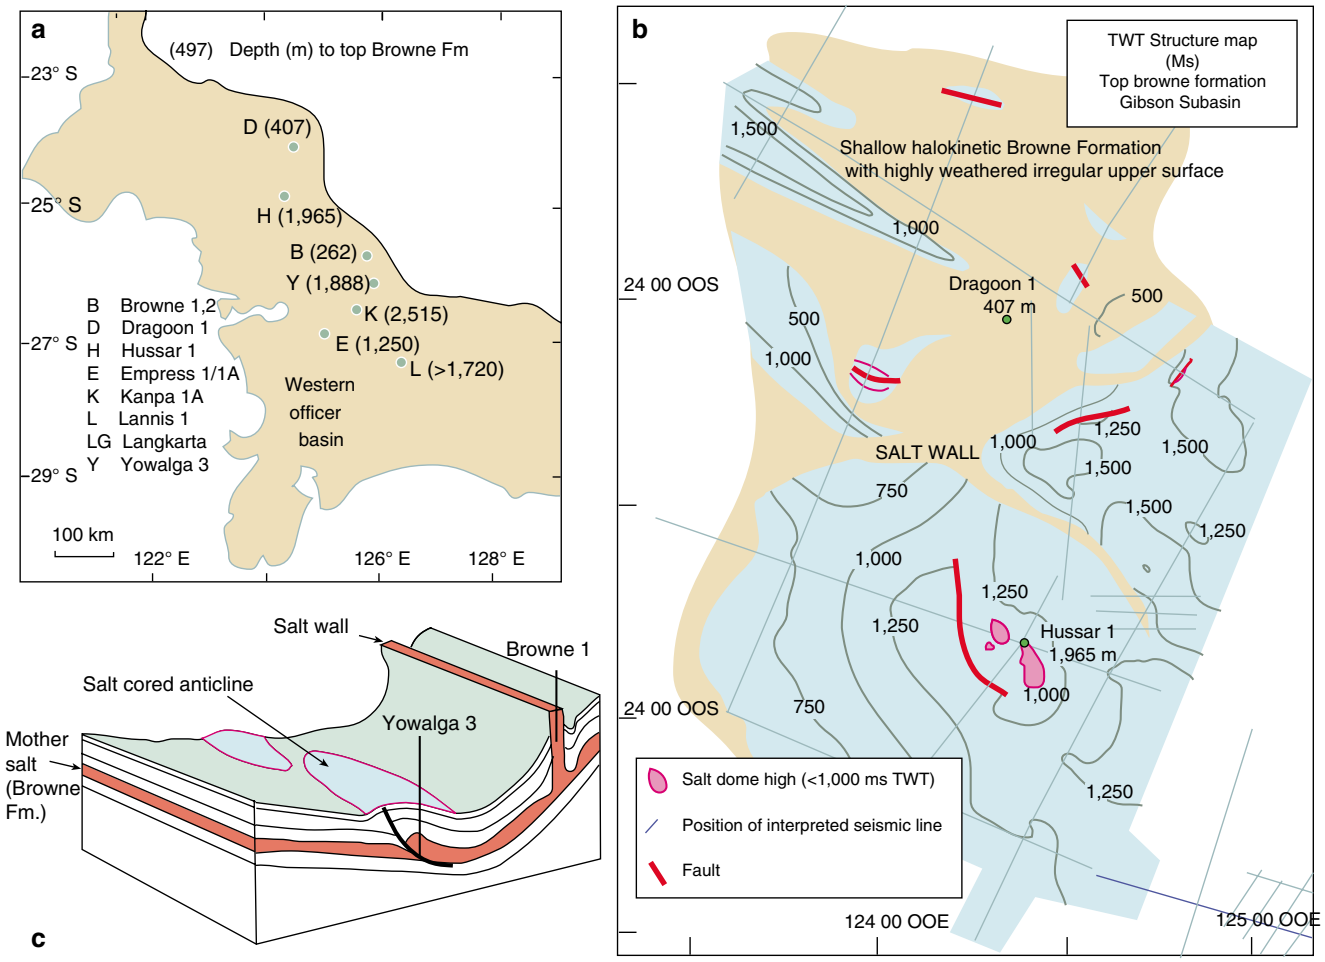

Fig. 6.94 Salt in the Browne Fm (830 Ma) Western Officer Basin, Australia. (**a**) Well positions and depth to top Browne Fm. intersection. (**b**) Interpreted Two Way Time (*TWT*) structure map of the top of the Browne Formation in the Western Officer Basin. Note the closed anticlinal feature cored by Hussar 1 and the poorly imaged northern region characterised by widespread relatively shallow and dissolved salt of the Browne Formation. This region is sampled by the Dragoon 1 well. (**c**) Interpreted styles of salt-induced deformation in the Browne Formation, Officer Basin. Note the penetrative salt walls, which approach the landsurface, and the deeper non-penetrative thrust-cored anticlines (After Apak et al. 2002; Simeonova and Iasky 2005)

directed thrusting of the Musgrave Block along the northern margin of the Officer Basin has long been recognised; for example, in the late 1980's seismic lines outlined several salt cored thrusts in the northern part of the Officer Basin that dip shallowly to the north. These thrusts have affected Cambrian sequences and may be equivalent in age and style to the Alice Springs Orogeny.

Shallow and subcropping halokinetic salt in the Officer Basin is centred on thick halite beds in the 830 Ma Browne Formation in the Western Officer and its as yet undrilled counterparts in the eastern Officer Basin (Fig. 6.94a). Highly leached outcrops of sulphate caprocks of the Browne Fm., equivalent to the Neoproterozoic Bitter Springs Formation in the Amadeus Basin, were first drilled in the 1960's in the Woolnough area during reconnaissance mapping of the region (Table 6.4). Outcrops near these wells (e.g., Browne 1 & 2 wells) are dominated by large blocks of Proterozoic dolomite and Permian sandstone up to hundreds of metres in diameter. They outline the various brecciated and weathered diapir tops, which drilling shows passes down into gypsiferous/anhydritic capstones that are hundreds of metres thick. The blocks indicate the brecciation of units emplaced as part of a series of salt flows, with blocks left as a residue on the ancient Australian landsurface, once the encasing more soluble evaporite minerals weathered away. The elongate orientation of many diapir crests in the western Officer Basin indicate emplacement as salt walls or salt-cored thrust anticlines, rather than isolated diapir stems (Fig. 6.94b). Equivalent salts have been recovered in the subsurface in various oil wells drilled through the top of the Neoproterozoic Browne Formation over much of the Western Officer Basin (Table 6.4; Simeonova and Iasky 2005).

Shallow drilling recovered a variety of actual evaporite salts, including halite, beneath outcropping diapir crests in

anhydrite-dolomite. Its texture suggests solution and recrystallisation processes have overprinted any original biaxially-stressed morphologies in the precursor halokinetic salt. Finely crystalline anhydrite and quartz are also scattered throughout the clear halite crystals.

Diapiric and pillow geometries, some of which have closed anticlinal crests in the outcropping Neoproterozoic section are seen in regional seismic lines, defining salt walls and salt-cored anticlinal thrust ridges in both the western Officer (Fig. 6.94b; Craig et al. 1984; Townson 1985), and in the Eastern Officer Basin (Sukanta 1993). Figure 6.94c illustrates the two dominant styles of salt geometry, based on seismic interpretation of salt-related structures in the western Officer Basin. The Empress 1A cored a 275 m thick section of interbedded halite dolomite and shale with individual halite beds up to 10 m thick. Thicker halokinetic salt sections of the Browne Formation were intersected in various wells to the north of this well (Table 6.4). The Browne Formation is 1,152 m thick in Kanpa 1A and more than 2,316 m thick in Yowalga 3, where the well bottomed while still in the salts Browne Formation (Fig. 6.94c). Wireline interpretation in Kanpa 1A shows much of the intersected halite is made up of stacked 10 m scale beds with one bed at a depth of 3,100 m being more than 100 m thick. Halite beds in Yowalga 3 are somewhat thicker but most are still no more than 30–40 m thick, although one bed at around 3,500 m depth is more than 150 m thick.

A Two Way Time (TWT) structure map to Top Browne is presented as Fig. 6.94b. The area can be subdivided into a northern zone of shallow Browne and a southern zone of deeper Browne Fm. Seismic quality is low in the northern area. The lack of identifiable reflectors is due to the relatively shallow position of the top of the Browne and its long term disturbance by deep meteoric flushing. In this region there are only a few resolvable zones showing interpretable sediment cover. Modelling using very approximate conversions for time to depth suggest some of these narrow sediment-filled troughs in the northern zone contain more than 1,000–2,000 m of post-Browne sediment. The steep sides to these zones clearly show the Browne to be halokinetic. In the southern zone the top of the Browne is seismically resolvable and it is covered by conformable layers of later sediments. There are also closed domes in this area, where the top Browne is deeper than 1,500–2,000 m. Two wells were drilled in the region covered by this seismic, Dragoon 1 and Hussar 1. Dragoon 1 is located on a closed structure in a halokinetic setting that appears to be a thrusted anticline, near identical in halokinetic setting to Yowalga 3. When drilling ceased Dragoon 1 was still in evaporites, after intersecting more than 80 m of salt in the Browne Fm. The upper contact of the Browne appears conformable with the overlying Hussar Fm. Dragoon 1 intersected the top of the Browne Formation at 407 m and passed through 200 m of dissolution residues before intersecting more than 1,400 m of interbedded halites and mudstone sequences until it TD'd at 2,000 m where it was still in the Browne Formation. Some of the halite interbeds in this well are more than 200 m thick.

Sediments and Flowing Salt

Wherever flowing salt approaches the land surface in both continental and offshore positions it creates topographic relief in the landscape and so influences the style and pattern of deposition (Table 6.5). Historically, sedimentological studies of this phenomena focused on predicting suprasalt deposition and its utility in predicting associated porosity trends (see summary in Warren 1989). Conclusions as to the position of sands, reefs and porosity belts in relation to salt structure highs in the landscape are still valid, but our understanding of mechanisms driving salt flow have substantially changed. With increasing recognition of the importance of lateral flow in allochthonous salt, the sedimentology of subsalt systems has become as important a topic to model and predict.

Reactive diapirism typically forms a graben or low atop the diapir crest. Active diapirism, passive diapirism and

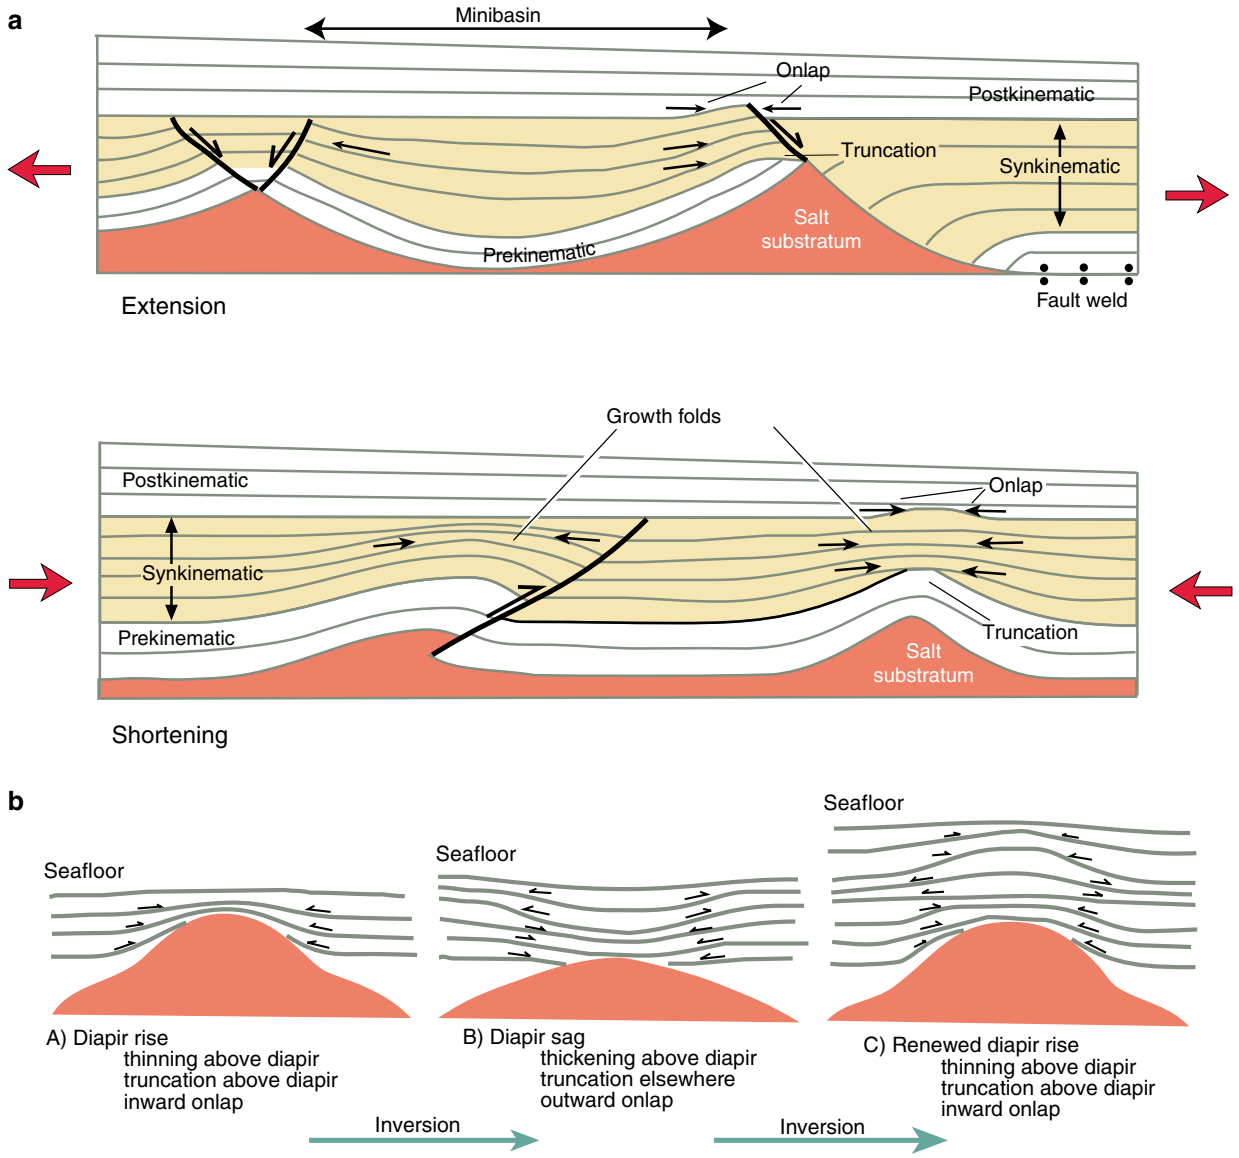

Fig. 6.95 Sedimentary record of salt flow. (**a**) Synkinematic during extension (*upper panel*) or shortening (*lower panel*). The prekinematic layer was deposited before salt movement began. The synkinematic layer was deposited during salt flow and includes many internal onlap or truncation surfaces. The postkinematic layer was deposited after salt flow ceased. Its base may onlap or truncate originally exposed surfaces in the synkinematic layer (After Jackson and Talbot 1994). (**b**) During two episodes of structural inversion caused by subsidence and renewed uplift of a diapir. The inversions are recorded by changes in bed thickness and onlap directions indicated by *barbed arrows* (After Jackson and Talbot 1994; Nelson 1991)

compressional growth folds are all marked by topographic highs about the crest of the salt body. Salt flow rates are in turn influenced by loading (sedimentation rates) and tectonics (rates of extension or compression). Interaction creates feedback whereby the geometry of a growing salt body is influenced by, and feeds back into, the depositional rate/water depth of the adjacent sedimentation setting. Once rising salt is sufficiently close to the surface to influence its topography, sedimentary feedback at the depositional surface typifies all styles of halokinesis. At the scale of seismic resolution this is recorded in changes in bed thickness (e.g. formation of suprasalt/intersalt basins or minibasins, thickness changes approaching active diapirs ridges and growth folds), as well as varying onlap and offlap relationships, and changes in bed attitude as the salt body is approached. At the lithofacies scale, it is recorded in changing styles of shallowing or deepening of the sequence (sanding or shaling upward parasequences), the development or the drowning of reefs and shoals, syndepositional bed disturbance, slumping and faulting, as well as the formation of local unconformities and karsting.

At the broad scale of seismically resolvable suprasalt sediment geometries, the style of sedimentation can be broken down into three groupings: prekinematic, synkinematic and postkinematic (Fig. 6.95a; Jackson and Talbot 1994). The

prekinematic layer records sedimentation before salt movement or any other deformation. A prekinematic sediment layer is an interval of strata where initial stratigraphic thickness is constant above a salt structure or its adjacent rim. That is, the prekinematic sediment layer is isopachous or its depositional thickness varies only as much as would be typical for the same sedimentation style in a region where no salt was present.

In contrast, the synkinematic layers record sediment thickness and facies changes related to salt-cored highs and crestal sloughing. Synkinematic layers thicken above withdrawal basins or locally thin against rapidly rising structures. For example, in the East Texas Basin in the Gulf Coast, the percentage of stratigraphic or seismic-stratigraphic thinning of synkinematic strata ranges from 10 to 100 % in units influenced by the flow of Jurassic Louann Salt (Seni and Jackson 1983a, b). Changes in bed thickness are frequently recorded by onlap or truncation at all levels of the synkinematic layer (Figs. 6.95a, b).

The postkinematic layer is the interval of strata deposited by sedimentation after salt flow, or any other deformation, has ceased. Basal postkinematic strata can onlap an underlying, uneven deformed surface but show no thickness changes that can be directly ascribed to deformation induced by local salt-flow. The postkinematic layer typically overlies the synkinematic layer.

Truncations (unconformities) are particularly useful in distinguishing the three suprasalt packages. Removal and termination of dipping deformed strata by subaerial or subaqueous erosion forms a truncation or sequence boundary. Truncations cutting across anticlines or fault blocks indicate that the structures had surface relief at the time of erosion (Fig. 6.95a). Undeformed truncations mark the base of the postkinematic layer. Where a truncation is itself folded or faulted, it marks an episode of deformation of the synkinematic layer.

Various terms have also been coined to describe synkinematic basins that fill with sediment as they load and subside adjacent to or atop relatively thick allochthonous or autochthonous salt, which ultimately evacuates to leave behind weld and ramp basins (Fig. 6.47). An older term for a sediment-filled basin atop a salt allochthon is a depotrough. In its strictest definition depotrough describes a basin filled with deepwater, mass flow or turbiditic deposits that uplap a diapir margin (Spindler 1977). The term depotrough is used by some as equivalent to depopod. But a depopod can also be a basin filled with shallow water deltaic deposits draping over or against a flanking salt diapir. In many prograding shelf situations a depotrough passes upward into a depopod. A better term to describe sedimentary basins created by the coming and going of flowing salt is minibasin. It has no genetic implications. Also, without drilling, there should be no assumption of predominant water depth or lithology accumulating during the fill of a minibasin. In much of the current literature there is a strong bias toward Gulf of Mexico models of sediment fill by deeper water siliciclastics passing up into fluviodeltaics. This bias reflects the excellent, but geographically localised, work that has been widely published on the slope and rise allochthons of offshore Gulf of Mexico. It has led some authors to discuss suprasalt reservoirs solely in terms of siliciclastic models. Outside of the Gulf of Mexico, modern and ancient minibasins are filled by other lithologies; such as chalks in the North Sea, or by shallow water lagoonal mudstones, grainstone shoals and reefs, as well as Mesozoic sabkhas and salterns in the Middle East.

Sedimentation and Evolving Salt Structures

The crestal positions of shallow salt structures in extensional regimes are intimately associated with faulting in the first two of the three evolutionary stages of diapirism (reactive and active versus passive). The reactive diapir is triggered by faulting in the extending brittle overburden whereby the hanging wall of an initial fault sinks into the source layer until resisted by increasing pressure forces in the salt source layer and the bending resistance of the overburden (Jackson et al. 1994a). Continuing expansion is accommodated by subsidence as new faults form repeatedly along the expanding axis of the graben. The central fault block or graben sinks and dwindles, while the diapir rises below it, regardless of overburden density. Progressively smaller fault blocks are supported by fluid pressure of the salt at progressively higher levels flanking the triangular diapir. Syndiapir sedimentation keeps diapirs in the reactive phase longer by continually filling the graben floor with new layers of sediment (Fig. 6.96). Reactive diapirism is controlled by the rate of regional extension; whenever regional extension ceases, a reactive diapir stops growing. In contrast both active and passive diapirs are strongly influenced by sedimentation rates and the deposition of sediment wedges (Ge et al. 1997).

At the time a reactive diapir is forming there is an active depression or graben atop the extending structure (Fig. 6.96). There are three depositional settings that can supply sediment to that depression: continental, marine shelf, and deepwater slope to basin. If the extensional graben or depression atop the reactive diapir is in a continental situation, then any surface waters, lakes or rivers, will tend to occupy that depression. In hydrologically-open settings, the deposits of a series of stacked fluvial channels may infill the lower parts of the depression. In more restricted to hydrographically closed scenarios the graben fills with deposits from a series of elongate saline lakes and mudflats. If the graben depression forms in a marine shelf setting it may fill with somewhat deeper water lagoonal muds while shoal water sediments and reefs occupy the very shallow waters atop the edges of the faulted graben margin. If the reactive stage creates a graben depression in deeper waters on the upper part of the

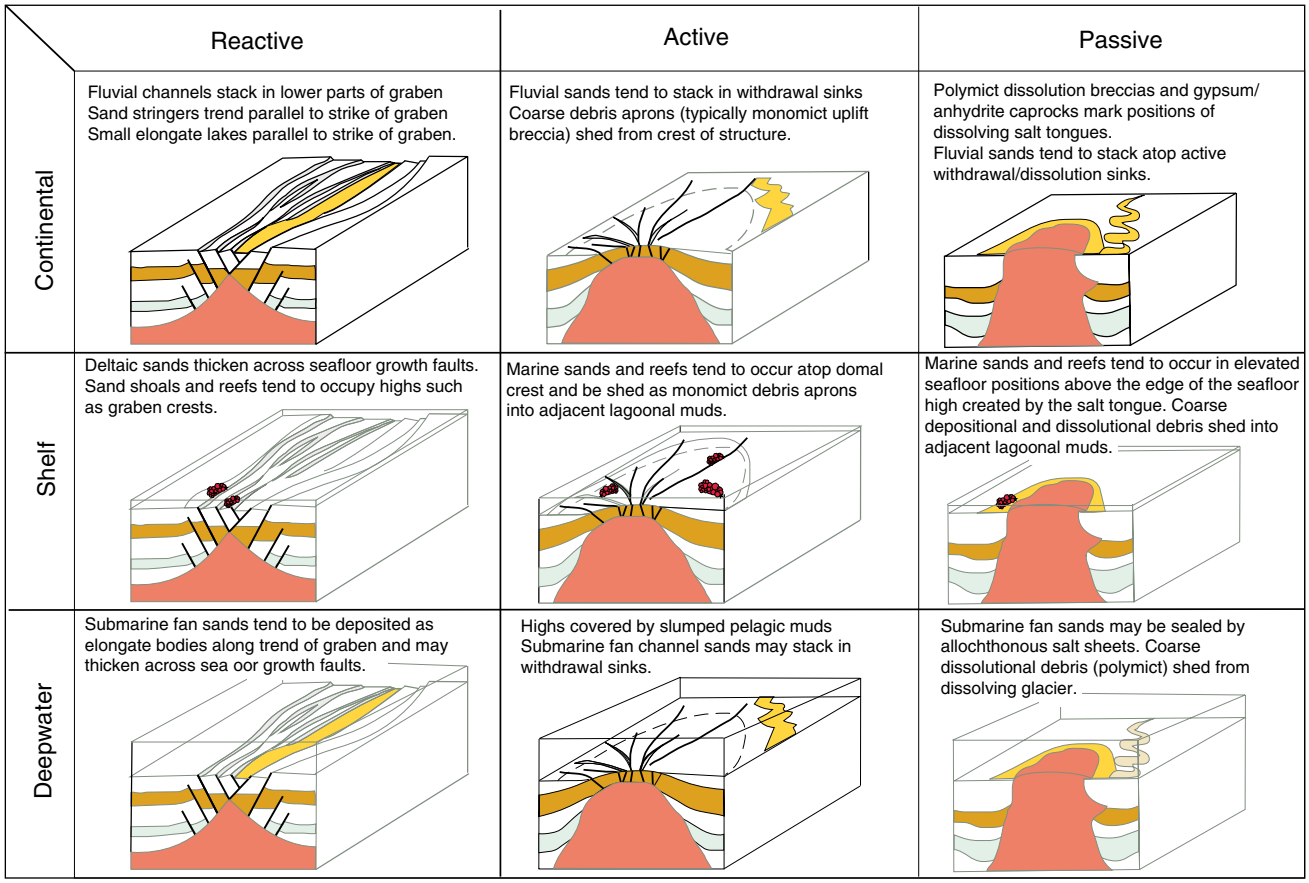

Fig. 6.96 Schematic cross sections showing the control exerted by shallow salt (topographic high) on the distribution of sands and reefs in synkinematic sediments. Sand distribution changes with the stage of salt structure and water depth in the depositional setting (Modified in part from Warren 1999). This sequence of schematics is drawn using a diapir outline, but similar depth-related sediment patterns also form about the seafloor highs created by nearsurface salt allochthons or atop turtle structure anticlines in interdiapir areas

continental slope, then a series of growth faults amid thickened deltaic sand traps may occur and help load the system. Conversely the graben may create a deep seafloor depression that stacks successive episodes of submarine channel and fan sands.

Once a reactive diapir becomes sufficiently tall and its roof sufficiently thin, then pressure at the diapir crest impels the system into the active stage. The diapir lifts its roof, as it rotates, breaks through and shoulders aside its overburden. Crestal erosion and near-crest sloughing then disperses the fragmented roof materials as a series of monomict debris aprons composed of sediments that formerly overlay the diapir crest. Throughout this time, and during the following passive stage, the area above and about the diapir or salt wall is a topographic high that does not accumulate sediment. In the continental realm, fluvial channel sands may stack into the depression created by any adjacent salt withdrawal sink. In the marine realm, the high often lifts the sea floor above wavebase and into shallow euphotic waters suitable for carbonate growth. The higher energy realm about a high on the open marine shelf means muds are winnowed to leave behind sands and gravels. In the transitional continental marine setting, the high-energy shorezone tends to lap up onto the edge of the high and wave-action reworks and winnows the debris apron of the active stage into well-sorted shorezone sands. Later in the passive stage the shorezone also picks up and redeposits exotic blocks derived by the dissolution of extruded salt to create polymict breccias and conglomerates.

Once salt is emergent at the land surface or on the seafloor the diapir has evolved into its passive stage (Fig. 6.96). At this stage the salt is extrusive and any thin sediment roof that may periodically develop atop the salt has little mechanical influence and is destroyed by ongoing active salt breakout. Dissolution of a salt sheet on or near the seafloor creates anhydrite/gypsum carapaces and may also supply a cap of exotic blocks that have been dragged up from greater depths. In some Neoproterozoic salt allochthons in Northern Australia, the transition from active to passive salt structure can be seen in a change of the debris apron constituents from monomict to polymict breccias. The increase in the variety of clasts is driven by dissolution of namakier salt, leaving behind a much broader range of clasts (pers. obs.). If the

breccias are not recognised as salt allochthon-generated, such units are easily misidentified as the outcome of long distance transport driven by tectonic uplift. In Proterozoic and Archaean salt allochthons the salt carrier has typically dissolved, even in the feeders to many of these breccias. All that remains are characteristic alteration haloes around salt and fault welds and indicators of the former presence of salt in the matrix of the breccia itself (Chap. 7). This has significance to many base metal deposits and exploration models (Warren 2000b). For example, in sedex exploration it is the difference between a predictive layered brine-pool model as the control on prepared ground for subsequent mineralisation, versus no discernable control other than a general notion of fault proximity (Chap. 15).

A salt-induced high on the seafloor can develop substantial relief over the surrounding region. A rich biota of bioherms and associated grainstone flats can form in shoalwater tropical seafloor settings. In the deeper water settings of the allochthons in the Gulf of Mexico the areas atop extrusive salt tongues have a relief measured in hundreds of metres above the surrounding seafloor (Table 6.5; Fletcher et al. 1995). Such deep seafloor highs tend to channel turbiditic sands into the relative lows along the allochthon edge. While the salt is replenished (salt fountain stage), the region about the salt remains a topographic high. The maintenance of the salt at or near the sedimentation surface by periodic overburden shedding means that both the active and the passive stages are characterised by many unconformities, debris aprons and thinning of strata in the vicinity of the diapir crest.

Three-thousand-year-old coral reefs that now lie some 18 m above sea level along the onshore portion of the active Al Salif diapir, Yemen (Davison et al. 1995, 1996b). This active stage diapir has lifted its roof and continues to do so today. The nearby Jabal al Milh diapir is the much-reduced remnant of a formerly active extrusive structure on a Pleistocene carbonate shelf (Fig. 6.40b). In both, the highs atop the structures strongly influence the facies distribution of nearby carbonate and evaporite sediments. Offshore from this region are a number of depositionally similar islands and grainstone shoals that likely indicate sea floor shoaling atop other diapirs and salt walls in the same Miocene salt.

Topographic lows form above peripheral sinks created atop areas of salt withdrawal. These are often areas of preferential sedimentation, that is, sediment thicks. Loading associated with accumulation of sediment in the sinks drives further salt flow. The lows persist until the salt is completely evacuated and a salt weld forms. Salt-flow induced highs and lows in the sedimentation surface persist until the diapiric ridge or crest is cut off from its supply by the formation of welds or touchdowns. Then the diapir and allochthon crests are buried by sediment that continues to aggrade until its thickness exceeds the piercement potential and the structure is no longer active.

Even though coal is not a sediment typically associated with evaporites, an ongoing low created during the formation of a suprasalt minibasin has preferentially accumulated a thick coal succession in the Pennsylvanian Joggins Formation, in the Cumberland Group of Nova Scotia (Waldron and Rygel 2005). This 1.5-km-thick coal-bearing unit is famous for upright fossil lycopsid trees, and is preferentially preserved in the Athol syncline in the western Cumberland basin. Seismic profiles show that the Athol syncline sits atop a salt weld and that the Joggins Formation thins on the flanks of adjacent evaporite-cored anticlines. During deposition of the Joggins Formation, at least 1 km of syndepositional subsidence was facilitated by flow of underlying salt into the adjacent anticlines.

Both subaerial and submarine glaciers are topographic highs at the time of salt emplacement so the syndepositional surface adjacent to a glacier is subject to slumping and mass wasting. Like a glacier of ice, a salt allochthon or namakier can spread out over its own moraine, so that the lower contact of a preserved allochthon is disturbed even while the salt rolls out over its own lower surface (Fig. 6.91). It seems that the preservation potential of salt wings and allochthons are higher if emplaced as a submarine glacier compared to a subaerial salt glacier (Peel et al. 1995). Submarine salt glaciers form in passive margin settings and are protected from pervasive dissolution by a thin membrane of supersaturated salt mud, which maintains its suprasalt position as the salt sheet is loaded and minibasins form in the relative quiescence of the sub-wavebase seafloor. Subaerial salt glaciers tend to form in compressive continental terrains where the salt source is more limited and their carapaces are exposed to the continuous rigours of subaerial weathering and rainfall dissolution. Caprocks atop salt glaciers in both settings can form either as biological precipitates or as accumulations of insoluble weathering products.

Siliciclastic Patterns

When a diapir crest is near the surface in a continental deltaic or fluvial setting it is a local topographic high focusing sand deposition into a series of stacked interdiapir channels. Even in a mature salt province, such as the modern siliciclastic Texas Gulf coast, salt structures are capable of maintaining a degree of topographic relief at the land surface and so act as a focus for off-structure fluvial sand accumulations (Fig. 6.97) and as a focus for sand distributions further out on the modern siliciclastic-dominated shelf (Morton and Suter 1996).

Through time, the salt crest's position in earth space is maintained by the withdrawal of salt from an adjacent rim syncline, with the creation of a topographic low in the landscape atop the sediment-accumulating rim syncline. The effect of this topographic differential explains the 10–100 % syndepositional thinning of lower Cretaceous Paluxy sands

over the Van and Hawkins salt pillows and the Hainesville diapir in east Texas and the associated stacking of fluvial sands in the interdiapir areas (Seni and Jackson 1983a). A net sandstone map shows that salt crestal areas contain between 5 and 20 % less sand as Cretaceous Paluxy sands were focused into withdrawal sinks between highs in the landscape created by the growing autochthonous salt structures (Fig. 6.98a). Sand pinchout and lateral passage into floodplain muds atop the various salt structures clearly shows that the thinning of the Paluxy sands onto the various salt structure crests is depositional, rather than a response to active piercement. Likewise, sand body distribution in the Paleocene-Eocene Wilcox Group around Bethel and Oakwood domes in the southern East Texas Basin indicate the effects of dome induced topography on coeval fluviodeltaic sedimentation in this Tertiary landscape (Fig. 6.98b; Seni and Jackson 1983a). To illustrate, there are four stacked channel-fill sands, each more than 15 m thick, in the rim syncline immediately east of the Bethel Dome. In contrast, there is only one sand body more than 15 m thick in the strata over the Bethel Dome, yet the percentage of sand in the thinned crestal succession is only slightly lower than in the stacked sands. Paluxy sands in the East Texas Basin were deposited around the basin margin as part of the Lower Cretaceous Trinity Group. At the same time, but further out in the basin, shelfal sediments were dominantly carbonates of the James Limestone and the Glen Rose Formation. There seafloor highs atop salt structures and turtle structures controlled local patterns of carbonate reef and shoal sedimentation (Fig. 10.55).

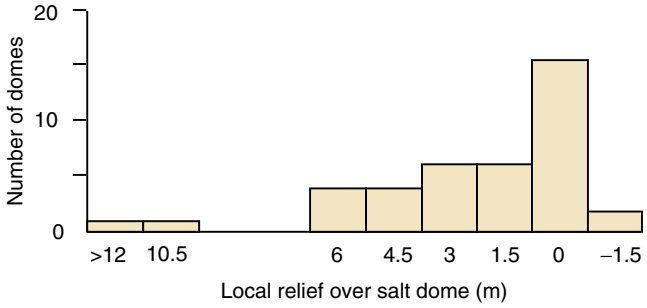

Fig. 6.97 Topographic relief developed over buried salt domes in the uppermost Texas coast (Beaumont-Port Arthur area; after Seni and Jackson 1983a)

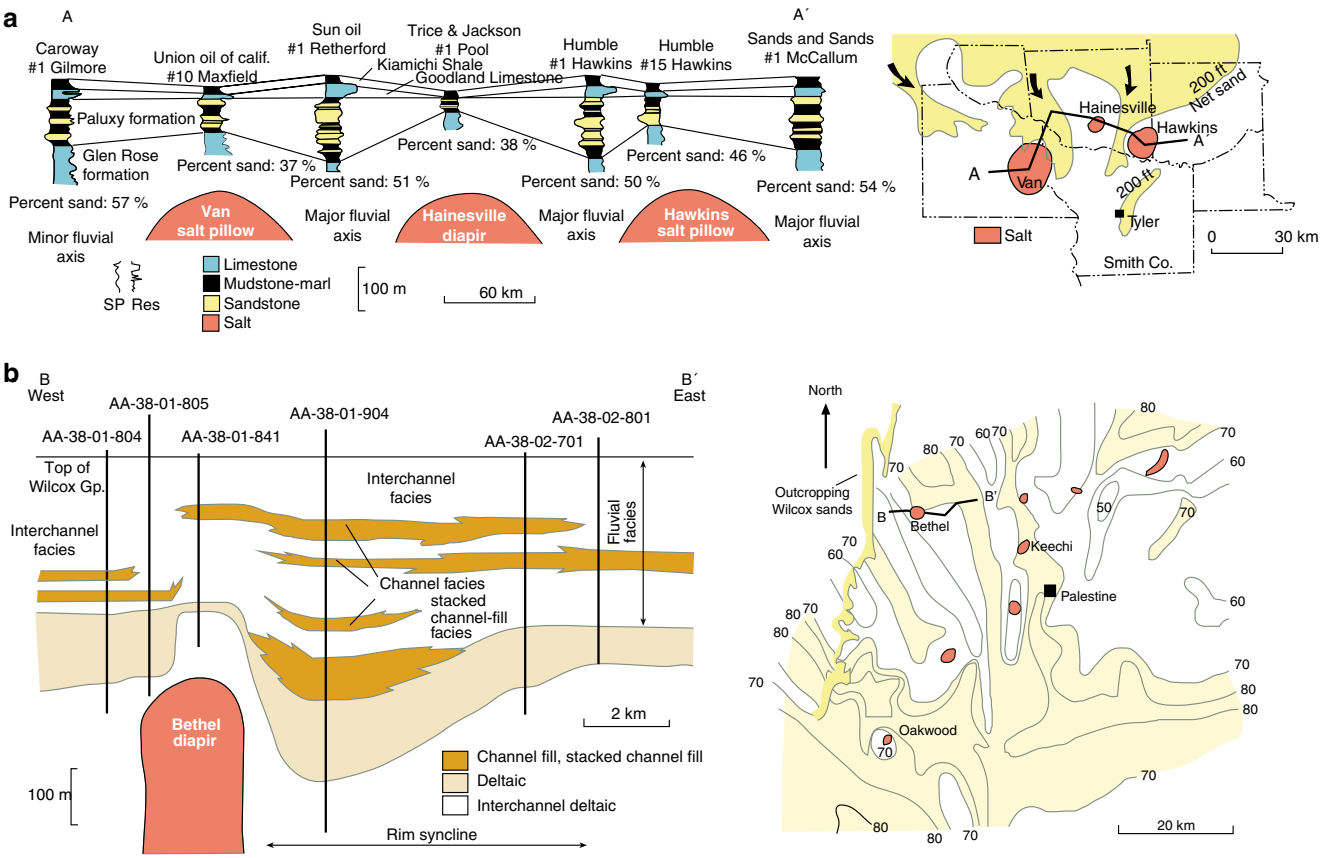

Fig. 6.98 Interaction of fluviodeltaic sedimentation and diapirism. (**a**) Decreased thickness and sand percentage over Van, Hainesville and Hawkins salt structures in East Texas Basin indicate that fluvial systems bypassed topographic swells over salt structures during Paluxy deposition. (**b**) Cross section across top of Bethel diapir and a percentage sandstone map showing how stacked fluviodeltaic sands of the Eocene Wilcox Group in the southern part of the East Texas Basin pinch out over the crest of the structure (After Seni and Jackson 1983a)

Salt squeezing at the basin scale created minibasins patterns that captured first cycle arkosic sediments in depositionally-loaded suprasalt "Haima pods" of the Thumrait region in the southern part of the South Oman Salt Basin (Fig. 6.99; Al-Barwani and McClay 2008). Palaeozoic fluvial depositional loading drove deformation of the thick sequence of underlying early Cambrian Ara. It created the various Haima "pods" or minibasins atop the loading and deflating salt mass. Syn-kinematic, predominantly clastic units of the Nimr and overlying Mahatta Humaid groups were deposited in these mini-basins. An interplay between depositional loading and salt withdrawal explains the marked lateral thickness variations of up to 1,000 m over 10 km laterally. Seismically, the underlying Ara Salt is typically opaque, with internal character obscured by multiples, generated by sub-horizontal reflectors higher in the section. Where internal salt geometries are imaged, complex internal structures are observed.

The main depositional stages and associated salt loading/deformation was driven mainly by pulses of sediment progradation sourced from the tectonically active upland to the west and northwest of the basin. Four main evolutionary phases for the mini-basins were defined by Al-Barwani and McClay (2008). Pre-existing basement topography and regional faults played a role in triggering and delineating the regional salt trends. That is, many of the salt ridges and salt walls parallel the main basement trends as seen in the regional aeromagnetics. This part of the South Oman Salt Basin has retained much the same facies distribution atop the salt since the Devonian, when clastic loading largely ceased. In contrast, in northern Oman, six salt domes have pierced the surface due to the reactivation of major basement faults and their caps still retain Ara salt as outcrop (Peters et al. 2003; Schoenherr et al. 2007a, b).

In a similar fashion, the fluviolacustrine sediments in the Triassic Chinle and Moenkopi formations, Paradox Basin, Utah responded to changes in the rate of accommodation space creation, driven by the interplay between climate, the rate of rise of salt walls and sediment loading (Fig. 6.99b; Matthews et al. 2007; Banham and Mountney 2014). Fluviolacustrine strata (mostly braidplain reservoirs) host significant hydrocarbon volumes in salt-confined minibasins, characterized by syndepositional growth of passive salt walls and diapirs. Two predictive models were identified

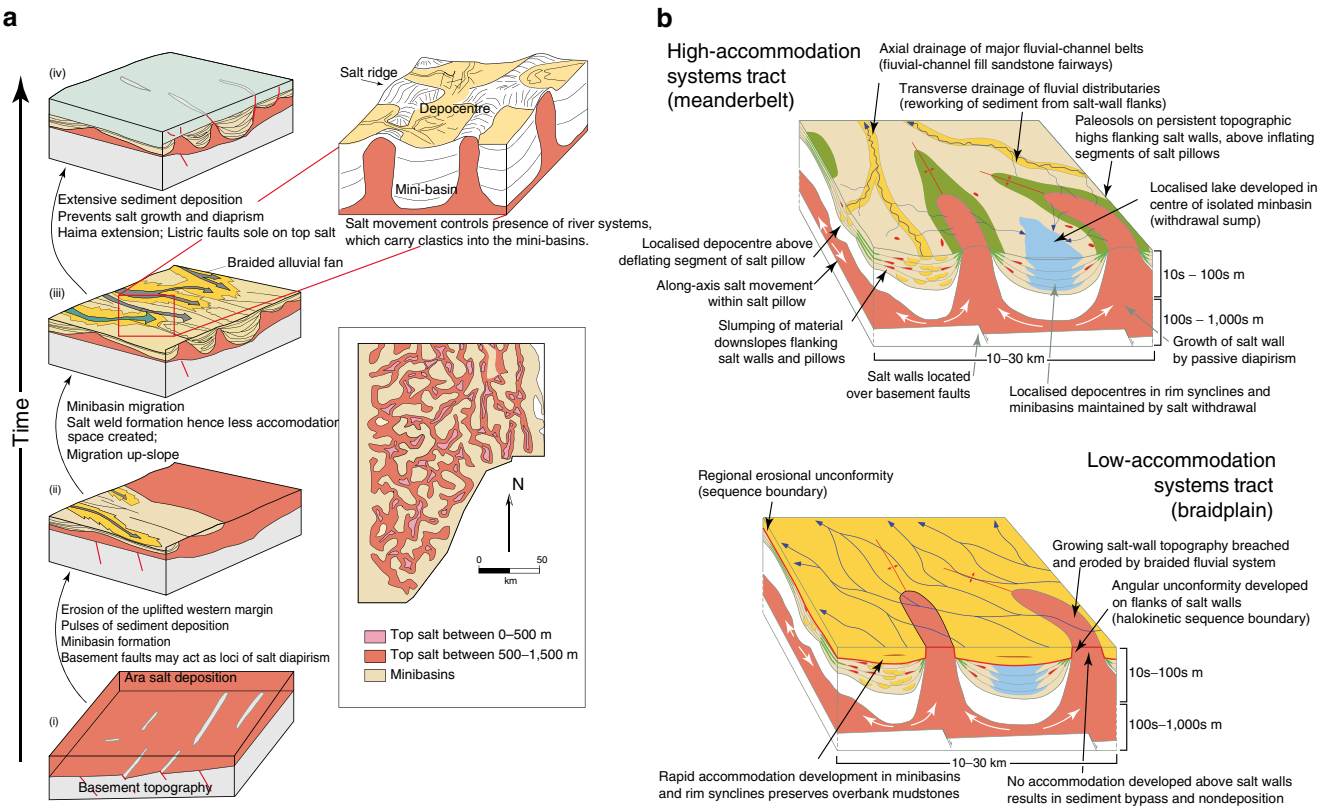

Fig. 6.99 Interactions between braid plain sediments and salt structures. (**a**) Basin scale schematic showing how pulsing sediment loading drove the formation of minibasins in the Thumrait area, Oman. Haima Group siliciclastics filling the various salt-floored minibasins show strong lateral thickness variations. The inset shows the actual scale and distribution of the numerous suprasalt minibasins in relation to top of the Ara salt (After Al-Barwani and McClay 2008). (**b**) Sequence stratigraphy in the Chinle Form, Utah and the differences in deposition style at times of high accommodation (meanderbelt) and low accommodation space creation (After Matthews et al. 2007; See text for detail)

(Fig. 6.99b; Matthews et al. 2007): (1) Low-energy fluvial systems and/or relatively high regional accommodation regimes (high-accommodation systems tracts) were controlled by localized, salt-induced topography. Fluvial sand fairways are confined to the axes of rim synclines, minibasins, and deflating salt-pillow segments (i.e., areas of salt withdrawal) that were occupied by regional fluvial-drainage systems; (2) High-energy fluvial systems and/or relatively low regional accommodation regimes (low-accommodation systems tracts) exhibit less local variability because rivers could breach and erode salt-induced topography. Such strata are characterized by widespread sheet sandstones, which thicken in areas of salt withdrawal.

A similar system of salt-related subsidence controls the stacking of fluvial channels in withdrawal sinks (minibasins) in Permian clastics of the southern Urals, Russia (Newell et al. 2012). There, calcrete carapaces tend to occupy intervalley highs atop buried saltwall crests.

Reactivation of pre-existing salt structures in parts of the North Sea, driven by the Alpine orogeny in the Cretaceous and early Tertiary, has squeezed diapir crests. In places along the continental slope they became topographic highs as deep seafloor sediment was accumulating. The syndepositional high then influenced deepwater sand distribution patterns (Figs. 6.80). The squeezed diapir's shape and its freeboard height above its surrounds influenced flow directions, current speeds, and thickness of turbidite sands accumulating as various fan lobes atop withdrawal sinks adjacent to the squeezed diapir high.

This was the case in the Eocene during the deposition of the deepwater Tay sand, which now constitutes the main reservoir in the various Gannet fields (Fig. 6.100a; Armstrong et al. 1987). Reservoir sands are broken down into three units; the lower, middle and upper sands, all deposited in a shoaling submarine fan complex. The area is underlain by various squeezed diapirs and some, like the Gannet North diapir, have exerted a major control on sand thickness and sand distribution. The seafloor highs, generated by areas of shallow reactivated Zechstein salt structures, created sand pinchouts as salt-cored highs deflected dense turbidity flows away from their edges (Fig. 6.100b). This minibasin system shows a classic vertical transition from stacked sheet to channel-levee geometries.

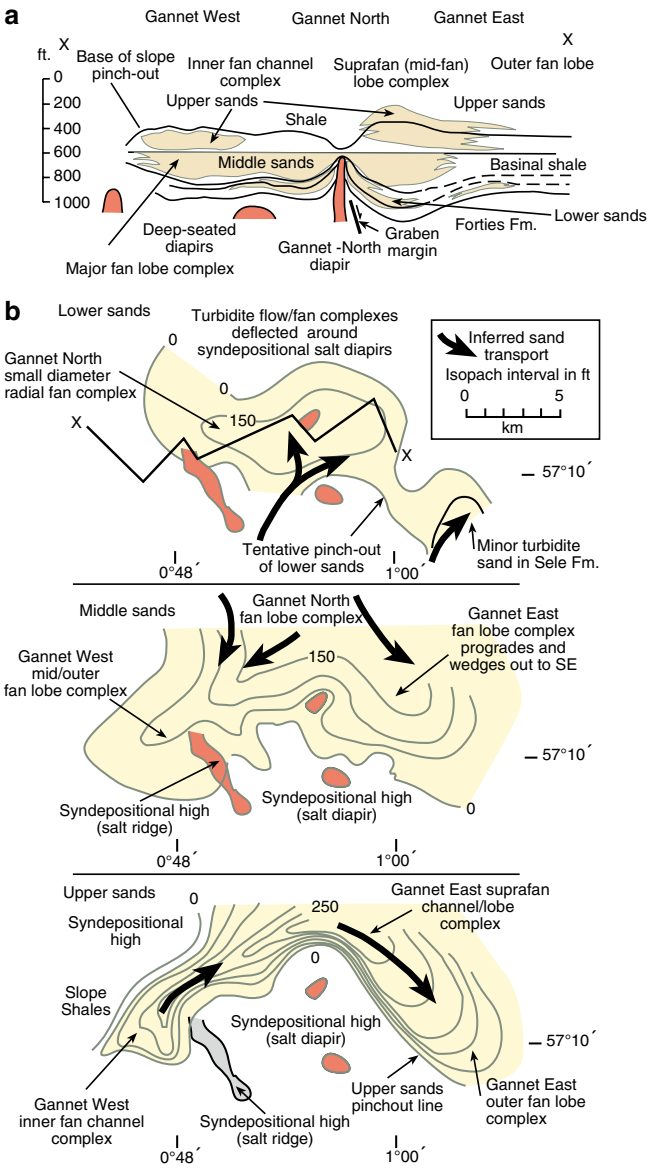

Fig. 6.100 Eocene Tay Sands of the Gannet area of the North Sea. (**a**) E-W cross section showing a strike section through the lower and middle sands and a proximal to distal section through the upper sand. Note the influence of reactivated diapirs on sand distribution. (**b**) Palaeogeographic reconstruction for lower, middle and upper sand intervals showing the effects on sand/fan distribution of diapir-induced syndepositional seafloor highs (After Armstrong et al. 1987)

Carbonate Patterns

The multiplicity of depositional settings above and around reactivated salt-cored highs in the Arabian Gulf gives an insight into the geometries of carbonate sands and porosity distribution in squeezed salt structures that are no longer extruding salt (Fig. 6.101; Warren 1989). Salt-cored seafloor highs surrounded by deeper gulf waters do not show the effects of widespread current reworking. These structures simply shed shallower water sediments centripetally into deep sub-wave base depths (Fig. 6.102). Facies patterns tend to form concentric rings, with the best-sorted sediments at or near the crest of the now buried structure. Sediment patterns tend to become more elongate and stream in the direction of current transport once the depositional surface lies above wave base. In the case of the various grainstone and rudstone shoals of the Great Pearl Bank this largely reflects waves driven by the Shamal. When exploring for porosity in an ancient counterpart one would drill on or near the crest of the structure, as identified in seismic.

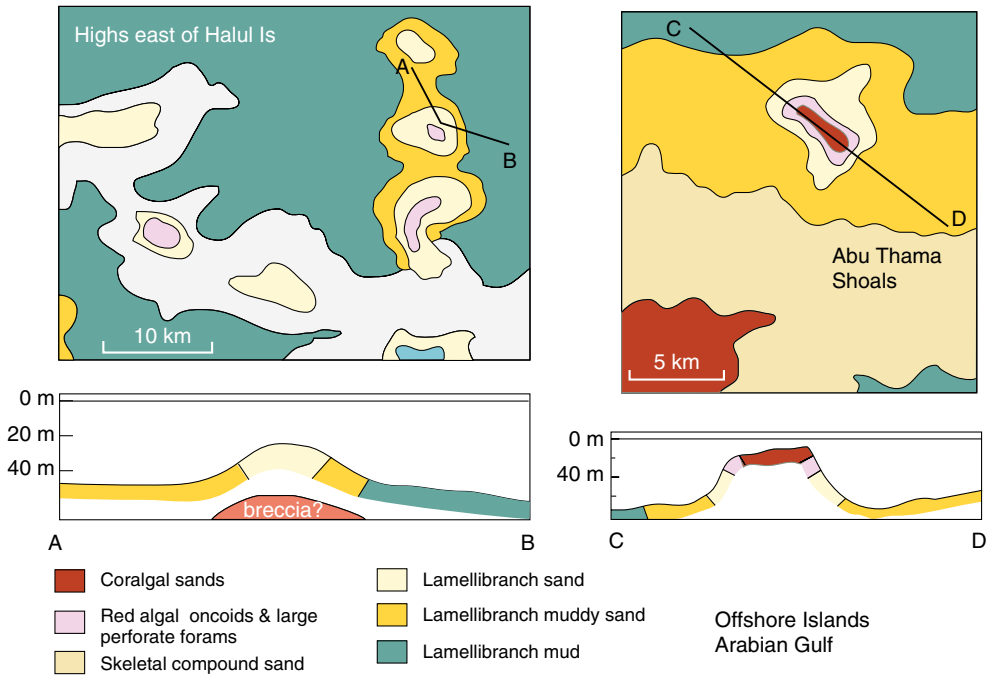

Fig. 6.101 Sediment distribution on sea floor shoals atop buried salt structures on the floor of the Arabian Gulf (After Purser 1973 a, b). See also Fig. 7.30

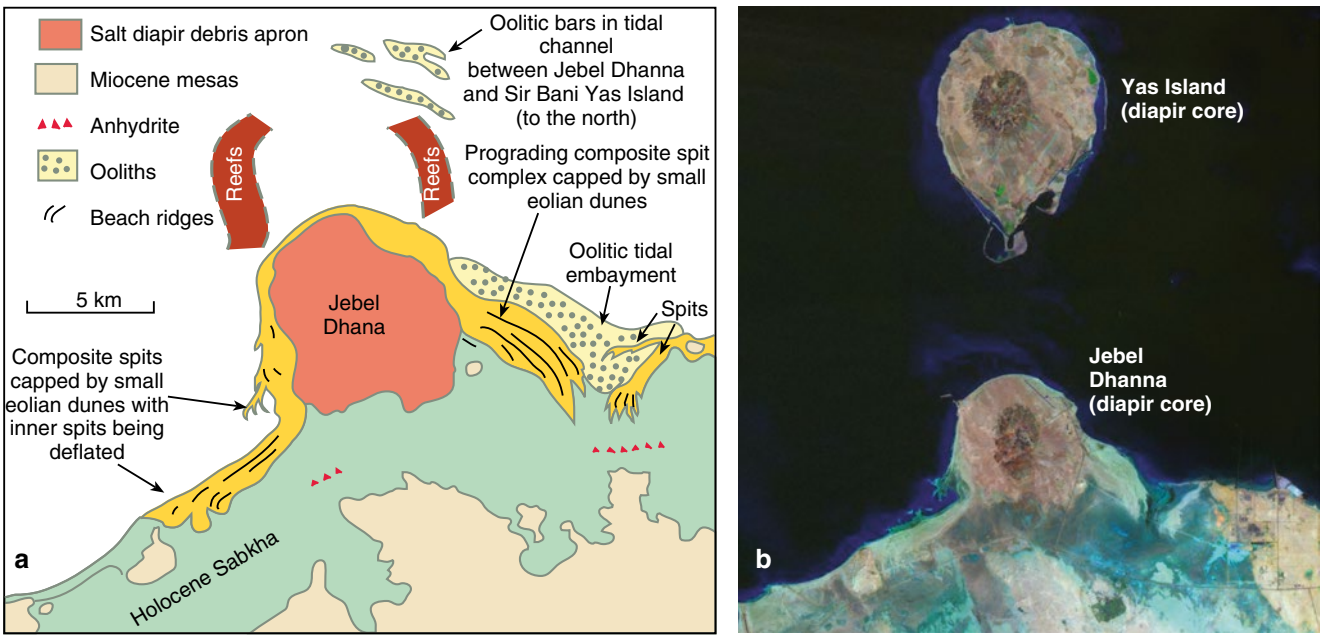

Fig. 6.102 Sediment distribution controlled by the near coastal and coastal shoals created by Jebel Dhanna and Yas Island diapirs, coastal Abu Dhabi, see Fig. 3.3a for location. (**a**) Holocene sediment coastal patterns and tails in the vicinity of Jebel Dhanna (In part after Kirkham 1997). Note that seaward extension of active reefs and offshore oolite bar thicks are both controlled by the position of the diapir. (**b**) Landsat 2000 image of coastal zone clearly shows diapir breccias forming cores to both diapiric outcrops (Image courtesy of NASA; the surface is now (2015) overprinted by refinery infrastructure)

Intermediate water depth highs in the Arabian Gulf are surrounded by waters of moderate to somewhat greater depths. Sediment shed from the carbonate high is reworked by tides and other currents, both across the high and into the shoal water areas surrounding the high. Often, this type of structure generates a down current sediment tail, creating a strong asymmetry to any reef or sand buildup on the structure itself. Sediment tails can be quite thick and extensive; off Dalma Island in the Arabian Gulf the modern downwind grainstone tail attains thicknesses of 20 m and is measured in kilometres. Exploring for relict primary porosity on the ancient equivalent of this type of marine platform structure

involves drilling both on or near the crest of the structure, as well as expecting and drilling sand trends that cut across the structural crest (Lomando et al. 1984; Lomando 1999).

The observation that sediment tails about Arabian Gulf salt structures tend to trend in the same direction as the prevailing winds of the region is a useful predictive tool. Once the position and trend of any ancient grainstone shoal is established about an individual salt structure, likely grainstone orientation and position of potential reservoirs about other time equivalent diapirs in the region can be predicted as likely to occur in the same quadrant. In the case of the Great Pearl Bank the region about the salt structure highs with the highest probability of sand occurrence lies south to southeast of the salt-cored seafloor high (Figs. 6.101 and 6.102).

In near coastal settings in the southern Arabian Gulf the windwave sediment trend is often modified by coastal parallel (longshore) transport processes. Leeward sediment tails often extend from the high to the shoreline, generating a progressive shallowing between the high and the mainland that ultimately create a tombolo. Studies of the peritidal sand tail that extends from Yas Island onto the mainland at Jebel Dhanna show that shallowing increases the velocity of tidal currents. This causes the sequence to shoal upward from bioclastic grainstones and wackestones into oolite shoals that trend at an oblique angle to the trend of the sediment tail (Fig. 6.102; Warren 1989). The Jebel Dhanna diapir-cored high also controls the seaward extension of Holocene sabkha in the coastal plain behind the headland. Such tombolo links between diapir-cored island shoals is not restricted to tropical shallow carbonate seaways. The modern siliciclastic sand shoals joining diapir-cored Magdalen Islands in the Gulf of St. Lawrence, Canada, are another such diapir-linked tombolo system. In this case they are located in a cool-temperature seaway at a latitude of 47°N.

In the modern Gulf of Mexico, a reef system is actively accumulating coarse biogenic sediment atop a salt cored high in the Flower Gardens Bank. Upper-slope siliciclastic deepwater muds completely surround the reef-capped high. Carbonate buildups top the Flower Garden Bank because of the shoaling effects of salt just below the seafloor. A brine lake occupies the central part of East Flower Garden Bank (Rezak and Bright 1981). Collapse foundering over the crest of the structure generated the graben that houses the lake, while ongoing salt dissolution and the focused escape of basinal brines maintain the dense waters of the lake. Healthy growing corals surround the lake, except where a canyon cuts a brine lip across the bank to the deep open seafloor. Halokinesis beneath the Flower Garden Banks has converted an otherwise muddy siliciclastic platform into a region suitable for carbonate reef growth. Shoaling lifted the seafloor into a clear, well-lit environment and has created a carbonate buildup in what is otherwise a muddy, siliciclastic province. Brine seeps atop salt allochthons, located in much deeper waters at the foot of the continental slope, have allowed chemosynthetic mussel communities (biostromes) to flourish at water depths that are a kilometre or more below the base of the euphotic zone (Chap. 9).

Ancient counterparts to the salt-cored islands in carbonate seaways, that is areas where carbonate sedimentation patterns are controlled by seafloor shoaling, occur in numerous diapir provinces ranging in age from Proterozoic to Neogene. Hydrocarbons and base metals have accumulated in brine lake laminites associated with some of these buildups (Warren 2000b; Chap. 15). For example, a series of Neoproterozoic stromatolite reefs fringe the western edge of the Enorama Diapir in the central Flinders Ranges (Fig. 6.103; Lemon 2000). The enclosing stratigraphic unit, the Enorama Shale, is the locally-named interglacial succession, lying between the Sturtian and Marinoan (Varanger equivalent) glacigenic units, thereby placing reef growth within the upper Cryogenian. A reef core facies of cumulate stromatolite domes first formed as mounds, which interfingered with the surrounding sediments, then as reefs, which stood well above the sea floor. Many mounds formed preferentially atop large debris blocks carried to the surface by diapiric salt.

The Enorama diapir breccia blocks are typical of many diapir remnants (stems and welds) in the Central Flinders Ranges (Lemon 2000). The breccias atop former salt stems and their surrounding debris aprons are made up of red and grey shales, sandstone blocks with halite casts, yellow dolomites with chert pseudomorphs of gypsum and anhydrite, and large blocks of amygdaloidal basalt and dolerite. All these blocks were carried up through the stratigraphy by allochthonous – autochthonous salt sources in the mother salt bed in the Callanna Group. Interaction with the surrounding sediments and inclusion of breccia fragments in the reefs and mounds shows continual movement and exposure of the diapir occurred throughout the deposition of the lower two thirds of the Enorama Shale. Lenses of diapir-derived polymict conglomerate are common along the flanks of the Enorama diapir and many of these show extensive evidence of shorezone reworking. Pebbles of conglomerate in cobbles of conglomerate within boulders indicate several phases of deposition followed uplift and erosion. The conglomerates commonly have a dolomicrite matrix, which cements very early to allow the reworking to be recorded. Thickening of the Enorama Shale towards the Enorama Diapir is particularly evident in the stacked halokinetic sequences at the northern end of the diapir. Associated stacked conglomerate lenses that thicken toward the diapir stem, show this was an area of ongoing aggradation and syndepositional growth of the diapir stem as it fed salt into various allochthon sheets, salt wings and Christmas-tree diapirs (Dyson 1998).

As the edge of the active diapir was unstable at times, not all mounds progressed to reefs. The maximum size of a mound plus reef at Enorama is $\approx$ 50 m high and 200 m across

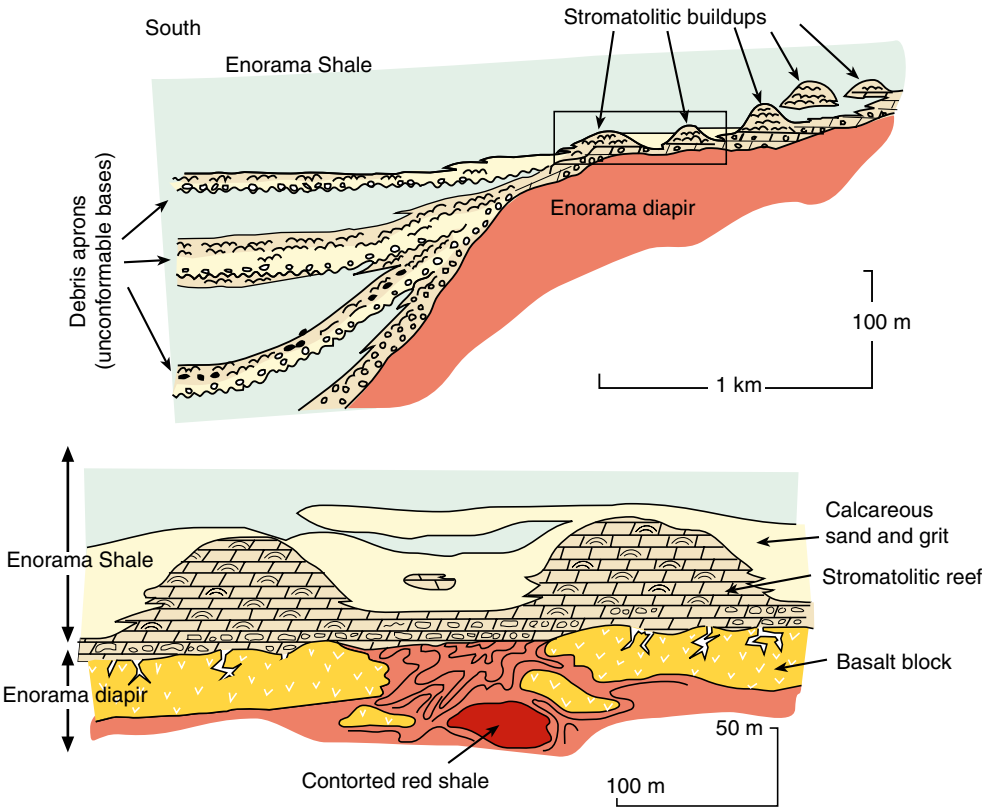

Fig. 6.103 Palinspastic reconstruction of part of the western Neoproterozoic margin of the Enorama diapir, Flinders Ranges, Australia Lower figure shows detail of contact of reef with diapiric breccia (After Lemon 2000)

the base. Syndepositional diapir activity is indicated by tilting of the surrounding sediments and by inclusion of insoluble debris shed from the diapiric island. Progressive movement is shown by cannibalisation and reworking of coarse shoreline conglomerates (Fig. 6.103). Diapir movement continued after deposition of the reefs ceased so that the entire succession in the drag zone close to the diapir is tilted up to near vertical in what would be called the shale-sheath position in a siliciclastic interval.

Enorama reefs interfinger with both shallow water limestones of the Etina Formation and deep water siltstones of the Enorama Shale. The base to the middle of the Enorama Shale is a transgressive systems tract, deposited during a steady rise in sea level. Onlap onto the diapiric island is marked by backstepping of each reef higher in the section (Fig. 6.103). Backstepping occurred as a number of pulses, each marked by channels of conglomerate shed from the diapir and by progressive convergence of local angular unconformity surfaces. Small pulses of salt uplift caused reefs to recolonise on higher ground, sometimes on previous reef growths, sometimes establishing a new mound. The reefs drowned as the sea floor next to the diapir subsided into the peripheral sink that flanked the diapir. On a mesoscale, the reefs are composed of a series of stromatolite mounds up to 6 m high and 15 m long. Lamination within the mounds is wrinkled and quite unlike nearby isopachous stromatolites that are characterised by smooth laminated micrites. The latter grew in shallow water as Etina limestones and are interbedded with the older parts of the widespread reef complex. The microscale wrinkly structure of the reef has a distinctive clotted texture with filamentous linkages, reminiscent of calcareous alga like *Epiphyton* or *Renalcis*. The entire reef complex has been completely dolomitised, probably by solutions emanating from the diapir. Early dolomite cement has allowed mimetic preservation of sedimentary textures and some minor porosity.

In summary, the reefs grew during a time of sea level rise and show a close relationship with rises in the Enorama Diapir, with each deepening upward reef succession being a response to a pulse of diapir growth. The diapir provided an area of shallow water around an island at a time when deeper water marine shale was being deposited in the rest of the basin. The mound to reef transition shows 'catch up' and 'keep up' growth habits, but the sudden demise of each individual reef appears related to a subsequent pulse of salt movement on the diapir, not to broader eustasy.

Sediments Tied to Salt Basin Evolution

There is an ongoing interaction between near-surface and at-surface flowing salt in sedimentary basins and consequent landscape elevations. This is seen in the resulting suprasalt or intersalt sedimentation patterns.

Suprasalt Clastic Sedimentation

Alexander and Flemings (1995) documented the spatial and temporal distribution of siliciclastic sand within an evolving Pliocene-Pleistocene salt-withdrawal shelf minibasin in the Gulf of Mexico; the Eugene Island Block 330 field. Part of it is a giant oil and gas field in offshore Louisiana and is located immediately landward of the deeper water Green Canyon area. The minibasin evolved through three phases: prodelta, proximal deltaic, and fluvial (Figs. 6.104). In the prodelta phase, bathyal and outer neritic shales and turbidites loaded and mobilised the underlying salt sheet (Fig. 6.104a). During the proximal deltaic phase, salt continued to withdraw from beneath the minibasin, and lowstand shelf margin deltas remained focused at a regional growth fault zone on the northern margin of the minibasin (Fig. 6.104b). Sediment accumulation and fault slip rates were high, as thick sequences of deltaic sands were deposited adjacent to the fault system. During the final fluvial phase, salt withdrawal waned; consequently, the creation of accommodation space within the minibasin ceased (Fig. 6.104c). The basin filled and, during lowstands, deltaic systems prograded southward. Unconformities developed in the minibasin during these lowstands. During transgressions, thick packages of shallow-water deltaic and fluvial sands (capped by shales) were deposited on top of the unconformities.

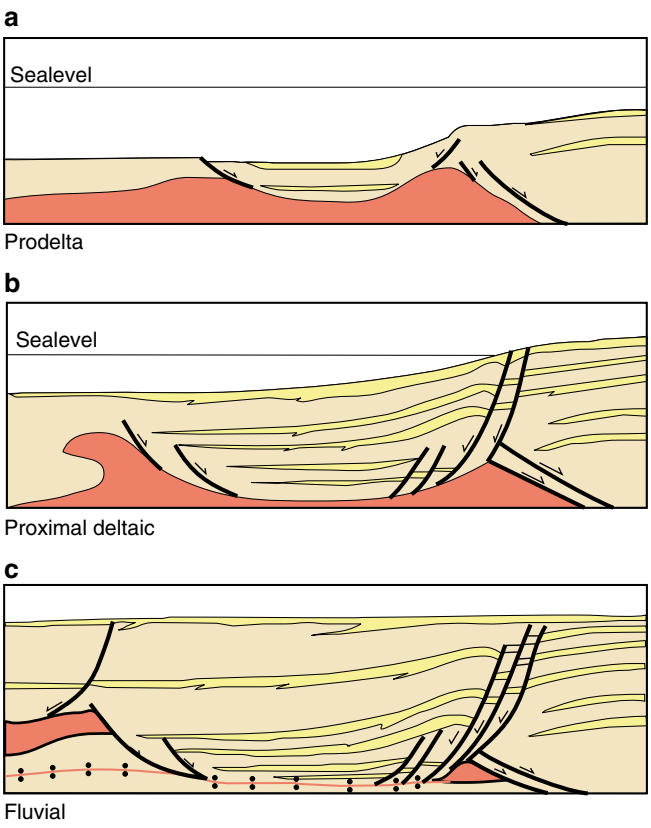

Fig. 6.104 Schematic of three-phase depositional evolution of intrasalt basin fill in the 330 Block, Gulf of Mexico (Alexander and Flemings 1995). Evolution began prior to 2.8 Ma and continues today

On a salt-floored continental margin that is being loaded by fluvio-deltaic wedges, the transition from deep water, when the floor of the minibasin first begins to subside as it is loaded, into a shelf and deltaic system is a natural evolution. The sedimentation model documented by Alexander and Flemings (1995) has a wider application to other salt-floored passive margins. Some authors in the Gulf of Mexico prefer to divide minibasin sedimentation into shelf-loaded and slope-load subcategories, but recognise it is all part of a feedback between basinward salt flow of the allochthon sheet and sediment loading (Figs. 6.42). Once the salt is evacuated from beneath a minibasin the basin can no longer subside and the depositional locus shifts basinward into the next minibasin atop the next tier of the allochthon. In the case of the Eugene Island minibasin this did not occur until the basin was filling with shelf sediments. In other basins this can happen while turbidites are still accumulating in the withdrawal sink. In this case the basin no longer accumulates turbidites, which now bypass the basin on their way downslope to the next active depopod.

Turbidite fill in Gulf of Mexico minibasins of the northern Green Canyon and Ewing Bank areas has been modelled by Rowan and Weimer (1998). They found that at the highest order of scale, external factors dictated the volume and type of systemwide clastic input. Regional factors, such as nearby salt structures and the position of deltas, then controlled the dispersal of the clastics to the continental slope. Local factors, such as the thickness of underlying salt, influenced minibasin-specific evolution. In the deepwater slope setting these factors interact at three scales: (1) a broad transition from sand-rich ponded settings to shale-dominated bypass settings during the Pliocene-Pleistocene, (2) fluctuations over periods encapsulating several sequences creating highly variable stratigraphic stacking patterns, and (3) a progression from ponded to bypass facies within individual sea level cycles. The most sand-rich gravity flows in an ideal sequence are deposited in the minibasin at the beginning of a sealevel cycle (i.e. during the lowstand) giving rise to sheetlike geometries. A transition to more mud-rich gravity flows leads to the formation of a channel levee system, where flows tend to be channelized and more organised. The gradual decrease of sediment volume within individual gravity flows during a sea level cycle increases the hemipelagic content (mixed pelagic and gravity flows) and eventually passes into a condensed section typified by pelagic mud-rich sediments or foraminiferal-rich oozes. The idealised fining upward succession is complicated by varying rates of salt withdrawal from the minibasin, which influences the volume of accommodation space within the minibasin. The distribution of accommodation space can be further complicated if the crest of a diapir undergoes dissolution to create a potential zone

for further sediment accumulation. Slides and slumps can occur anywhere within a sequence; they can originate from local slope failures or from oversteepened delta fronts and can be triggered by salt movement, dissolution or can be seismically induced.

Suprasalt Carbonate Sedimentation

La Popa Basin, Nuevo Leon, Mexico, is a salt influenced foreland basin near Monterey in Mexico, with excellent exposures of halokinetically influenced sedimentation around three salt stems (La Popa, El Papalote and El Gordo diapirs) and along the 25 km La Popa salt weld/wall (Fig. 6.105; Giles and Lawton 1999; Giles and Goldhammer 2002; Shelley and Lawton 2005; Buck et al. 2010). As in the Flinders Ranges, reef growth is a halokinetic response to pulses of diapir growth. A number of thick (<600 m) coral, sponge, red algal reefs, exposed as a series of carbonate lentils, are the most obvious sediments associated with halokinetic seafloor shoaling. These carbonate buildups, the La Popa, San Jose, El Toro and El Gordo lentils, developed as shoals atop significant seafloor highs created by the passive rise of salt diapirs during the Cretaceous and Lower Tertiary in what was a dominantly fine-grained siliciclastic shelfal environment.

The La Popa structure is interpreted as a 25 km long salt weld with parallel flanking synclines, previously it was

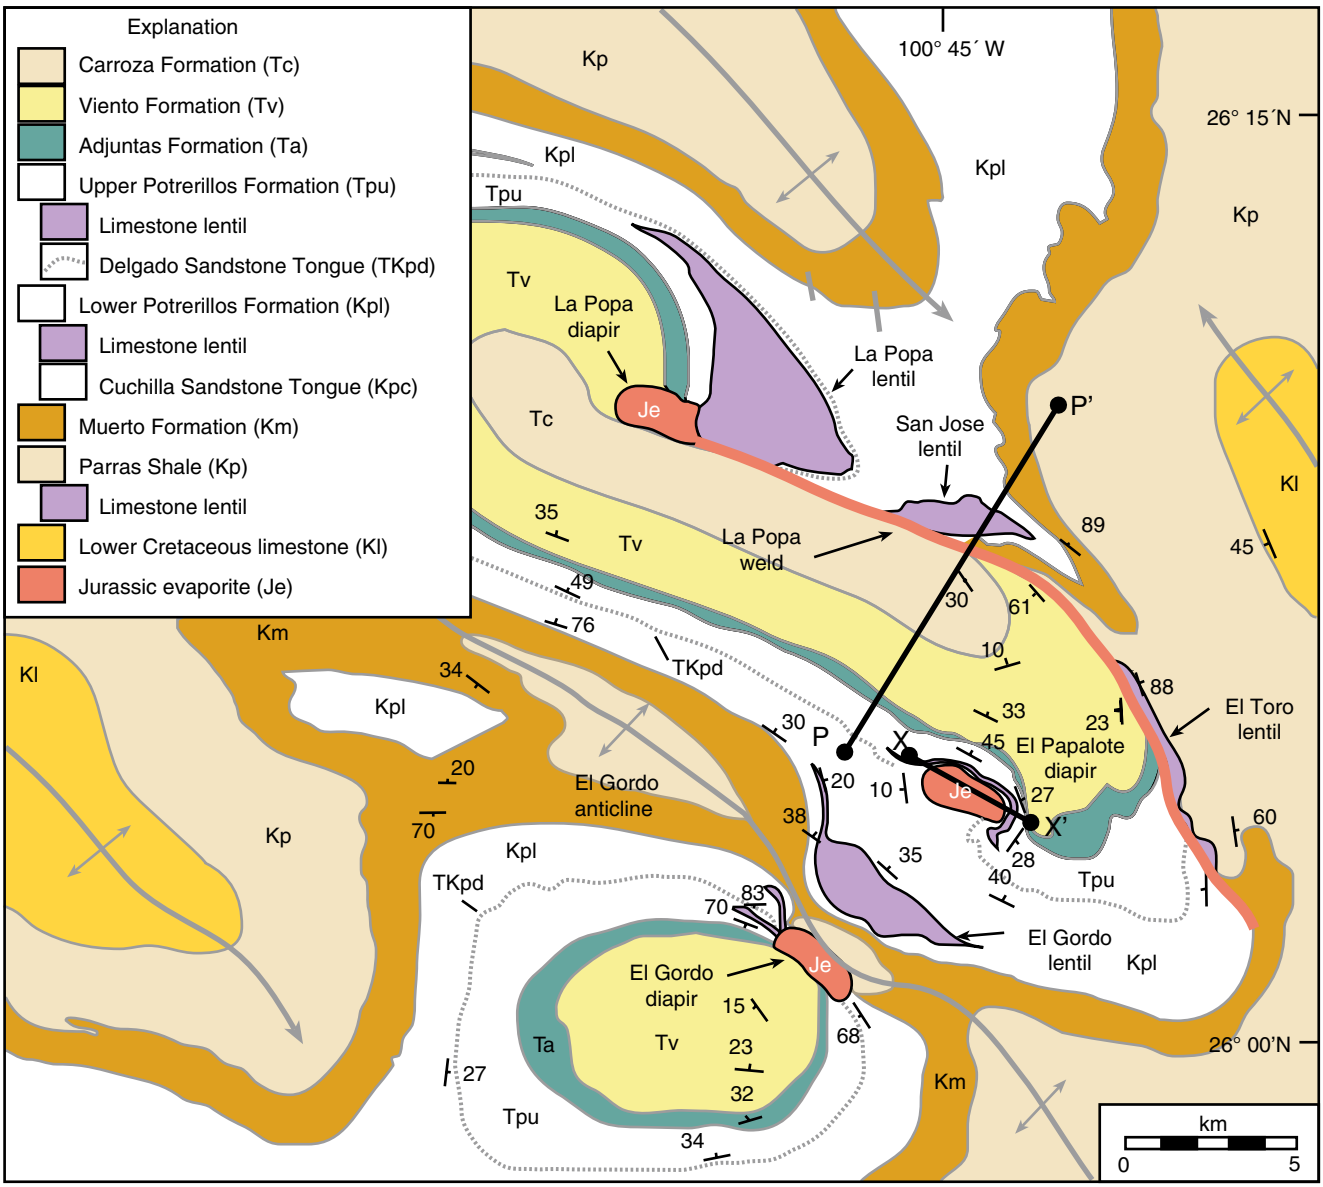

Fig. 6.105 Geologic map of the La Popa Basin, Mexico. Anticlinal fold axes indicate structures attributed to the Hildagoan (Laramide) shortening (After Giles and Lawton 2002). P–P′ and X–X′ are the locations of cross sections in Figs. 6.106 and 6.107

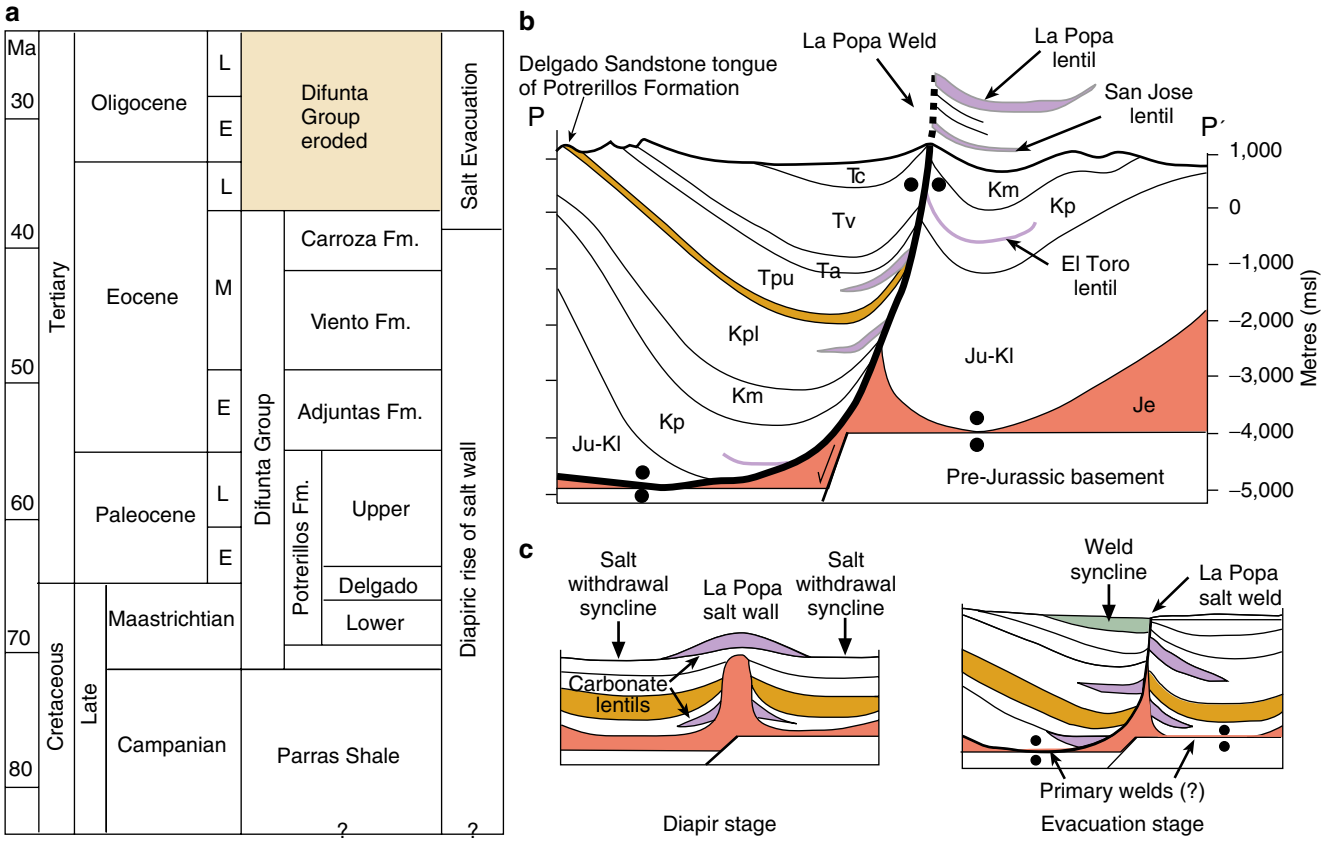

Fig. 6.106 The La Popa salt weld. (**a**) Stratigraphy of the La Popa Basin during the time when salt flow occurred (*L* Lower, *M* Middle, *U* Upper). (**b**) Cross section of the La Popa weld (see Fig. 6.105 for position). (**c**) Interpreted evolution of the La Popa structure (After Giles and Lawton 1999)

considered to be a reverse fault (Fig. 6.106a, b; Giles and Lawton 1999). The displacement surface is convex to the southwest and dips south to southwest. Stratigraphic displacement at the surface is zero at either end, and increases to ≈ 5 km halfway along the trace of the structure. The structure is the result of hangingwall subsidence during evacuation of Jurassic salt along a former diapiric salt wall. Sedimentation patterns on either side of the weld indicate the La Popa structure experienced a two-phase history in Late Cretaceous to Eocene time: (1) A diapiric phase marked by rise of an elongate, arcuate salt wall that was symmetrically flanked by withdrawal synclines; (2) a subsequent evacuation phase recorded by substantially increased subsidence of the hanging wall relative to the footwall and the stratigraphic "welding" of footwall and hanging wall along a steep planar discontinuity (salt weld) created as salt withdrew from the former diapir.

Superb exposures (over 10 km along strike) of the largest reef complexes along the northern side of the La Popa Weld show that during the diapir stage these Paleocene lentils initially accreted as coral, sponge, red algal reef and oyster biostrome complexes atop and immediately adjacent to the La Popa salt wall (Fig. 6.106c). Large, steep (200 m relief over 0.5 km) forereef clinoforms indicate northward (downwind) progradation of the La Popa lentil away from seafloor high created by the La Popa salt wall. With a probable lowering of the local rate of salt induced uplift near this part of the salt wall, this reefal system was subsequently truncated, onlapped and possibly overlapped by a southward prograding grainstone bar complex. This shoal was derived from a separate source to the north, perhaps from another salt-related bathymetric high tied to the La Popa Diapir. To the north and west of the La Popa diapir, the two carbonate complexes coalesced through time to generate a continuous carbonate sheet that now defines the La Popa lentil. It extended more than 5 km within what was at edge of a low created by a salt withdrawal/contractional syncline as salt was evacuated into the rising salt wall (Fig. 6.106c). Carbonate strata thin and become siliciclastic away from the La Popa salt wall and are intercalated with siliciclastics in the footwall syncline. The Delgado Sandstone Tongue of the Potrerillos Formation is a shelfal sandstone/siltstone that was deposited during salt wall growth as a complex, wave-dominated, eastward-prograding deltaic depositional system. Typical parasequences in the siliciclastic section comprise offshore shales overlain by lower to upper

shoreface sandstone. The Delgado Sandstone contains a lower, progradational parasequence set; it is part of a high-stand system tract that is in turn part of the underlying Middle Siltstone Member of the Potrerillos Formation. It also contains an upper retrogradational set, which is part of a transgressive system tract that persisted into the Upper Mudstone Member. The two system tracts are separated by an erosional sequence boundary that incises up to 10 m of underlying strata and locally preserves a lowstand system tract within the incised valleys.

During growth of the salt wall in the Early Tertiary, thick prodeltaic and tidally-influenced shoreface siliciclastics periodically accumulated in the adjacent withdrawal syncline (Buck et al. 2010). Flute marks on bases of turbidite beds and channel axis orientations indicate a dominant palaeoflow along synclinal axes, with a component of flow away from the salt wall. Siliciclastic units thin and fine toward the salt wall, near which they are upturned and contain numerous synkinematic angular unconformities. During evacuation the volume of the wall declined, causing the synclinal hinge of the hanging wall to migrate laterally toward the developing weld. Hangingwall strata deposited during the evacuation phase thicken, rather than thin, toward the weld. They define the weld syncline where sand-rich fluvial channels are concentrated directly adjacent to the weld.

To the south of the La Popa salt weld are the El Papalote and El Gordo diapirs, they have similar dimensions and are located 5 km apart (Fig. 6.105). The at-surface diapiric material in both diapirs and portions of the weld is today a complex mixture of gypsum, anhydrite and salt-transported exotic blocks of metamorphosed mafic intermediate igneous rocks and Jurassic carbonates (Garrison and McMillan 1999). The gypsum is created by rehydration of the anhydrite caprock atop the Jurassic salt of the diapir core. Petrology and geochemistry of the meta-igneous blocks indicate derivation from partial mantle melting during Jurassic rifting with greenschist facies metamorphism dated at 146 Ma ($^{40}Ar/^{39}Ar$ dating of biotite and potassium in meta-plutonic blocks). This date is younger than that of the hosting Minas Viejas evaporite beds suggesting high heat flow from the basement continued into the latest Jurassic. The various sedimentary and volcanic blocks were likely intercalated in bedded salt prior to halokinesis, while the plutonics were intruded into the syn-rift fill and all were fragmented by extensional tectonics and salt flow. Vitrinite values in the suprasalt sediment in the vicinity of the El Gordo diapir show a high degree of asymmetry, with the highest R_o values ($\approx$1.44 %) immediately northwest of the diapir, possibly indicating differentiated fluid histories in the diapir periphery.

El Papalote diapir is located on a major fold limb and has experienced approximately 100 m of net shortening, whereas El Gordo is located along the axis of the same fold and has accommodated over 2 km of shortening (Rowan et al. 2001). The corresponding halo of diapir-related drape folding, which is at most 800 m wide at El Papalote, is up to 2 km wide at El Gordo. Carbonate lentils, which formed over the bathymetric highs associated with both diapirs, are overall shallower, thicker, broader and record fewer halokinetic sequences at El Gordo than at El Papalote. Sandstone units start thinning within 300–800 m of the edge of El Papalote but within 1,000–1,500 m at El Gordo. Differences in style and distribution of halokinetic strata about the two diapirs imply that the uplift histories of the two features were different and that the buildup atop the El Gordo structure more closely approached sealevel (Rowan et al. 2003).

Sediments flanking the El Papalote diapir have been studied in more detail than the other two structures with a view to defining typical successions in an ancient withdrawal sink and to test if such successions are amenable to sequence stratigraphic analysis (Figs. 6.107 and 6.108; Giles and Lawton 2002). At the time sediments were accumulating, diapir-flanking strata thinned toward the diapir and were characterised by abrupt lateral facies changes and intense local deformation. Strata can be broken out into a series of "halokinetic sequences," which are defined as unconformity-bounded strata, genetically related to halokinetic processes.

Each halokinetic sequence contains a basal debris-flow bed overlying an unconformity, which is angular directly adjacent to the diapir and becomes disconformable to conformable with increasing distance from the diapir. Debris-flow or mass wasting beds contain polymict clasts derived from the diapir and material that mantled the diapir (Fig. 6.108). At the various times these beds were forming the diapir crest was exposed at the sediment-water interface and shedding carapace debris into the surrounding sediments. These mass wasting deposits are dominated by carbonate clasts. They are interlayered with autochthonous reefal and biostromal strata and together constitute the lentils mentioned earlier. Hence, debris and mass wasting beds grade upsection into oyster- and red algal-rich carbonate banks. This carbonate section is then onlapped by black basinal shales and capped by upward-shallowing and coarsening, lower shoreface siliciclastic strata, which lack diapir-derived detritus (Fig. 6.108). This lack of diapir detritus indicates that the diapir crest was no longer at the surface or had insufficient seafloor relief to act as a sediment source. Lower shoreface deposits are abruptly overlain by outer shelf shales, which in turn underlie the angular unconformity of the next halokinetic sequence.

Each halokinetic sequence was generated by the waxing and waning of an episode of salt fountaining and salt glacier flow (Figs. 6.106c and 6.108; Giles and Lawton 2002). Periods of salt rise and salt glacier advance followed by retreat create unconformities near the salt structure. They

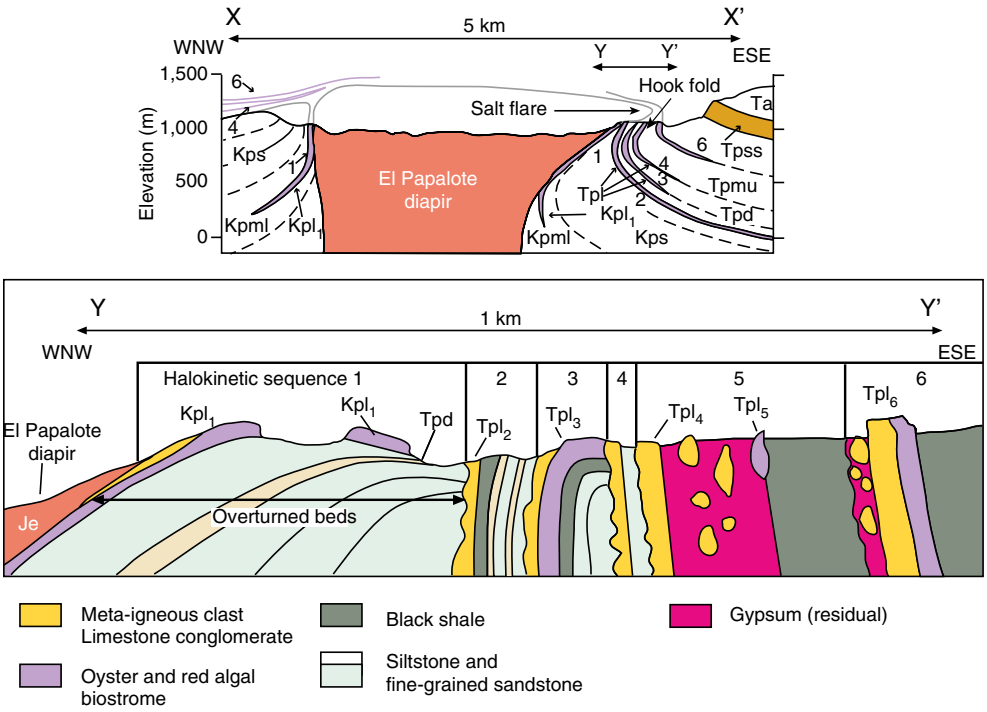

Fig. 6.107 Cross sections X-X′ and Y-Y′ through the El Papalote diapir (After Giles and Lawton 2002). Locality of cross section X-X′ is shown on Fig. 6.105

correspond to times of slow sedimentation and regional black shales in interdiapir withdrawal sinks. These black shales perhaps reflect basin deposition during deepening (maximum flooding events). Advances of glaciers over diapir-flanking beds provided a mechanism of deforming and overturning strata that underwent subsequent local truncation via subaqueous erosion processes during glacial retreat.

As in the modern Gulf of Mexico, glacial salt advance was also marked by development of a siliciclastic "shadow zone" on the downcurrent flank of the salt diapir high. Glacier advance at El Papalote is only displayed by strata on the east side of the diapir, indicating a down gradient flow of seafloor salt into the regionally extensive withdrawal syncline created by asymmetric salt supply to the adjacent and inflating La Popa salt wall. Quaternary counterparts to these carbonate debris aprons have been documented in weathering haloes about salt structures in the Arabian Gulf, while older counterparts occur in the Neoproterozoic salt structures in the Flinders Ranges of Australia. For example, Lemon (1985) documented and modelled similar asymmetric salt withdrawal controls on sedimentation about the Neoproterozoic Oratunga diapir in the Flinders Ranges, Australia.

Internally, the various halokinetic sequences show stratal onlap and thinning of beds toward the diapir. Adjacent to the diapir stem each halokinetic sequence is tightly folded and angular unconformities have truncation angle as high as 90° (Fig. 6.108b). The intensity of deformation and angle of truncation decrease rapidly away from the diapir and sequences are typically conformable by a distance of 250 m from the diapir and are known as hook[20] folds. The geometry resembles the hook of the letter 'J' (e.g. Sequence 3 in Fig. 6.107; Rowan et al. 2003). These 'J' hook folds and associated unconformities terminate directly against the diapir and outline salt cusps created by a combination of drape folding and fault reactivation during halokinesis. The amount of fault reactivation on these unconformities can be significant with the unconformity/fault preserving evidence of brittle shear and sense-of-shear indicators showing older beds were displaced away from the diapir.

Away from zones directly influenced by the diapirs and 'J' unconformities sediments tend to lack evidence of mass wasting and the interdiapir lows were filled by facies that shallow upward, from middle shelf lower shoreface shales to upper shoreface foreshore sandstones and tidal-lagoon sequences. These sequences do not terminate at the diapir but are spatially separated by a thick/wide package of older more tightly folded drag-zone strata (Figs. 6.107 and 6.108).

[20]Hook folds are defined by basal sequence boundaries that curve sharply upward within 50–200 m of the diapir contact and is truncated at up to 90° by an overlying unconformity marking the base of the next younger sequence (Fig. 6.107). Mass-wasting deposits are common at the base of the sequence, and facies change abruptly near the diapir. In contrast a wedge halokinetic sequence gradually taper toward the diapir and typically terminate against a truncating younger halokinetic sequence. The zone of drape folding is 300–1,000 m wide, angular truncation is typically less than 30°, mass-wasting deposits are less common than in hook halokinetic sequences.

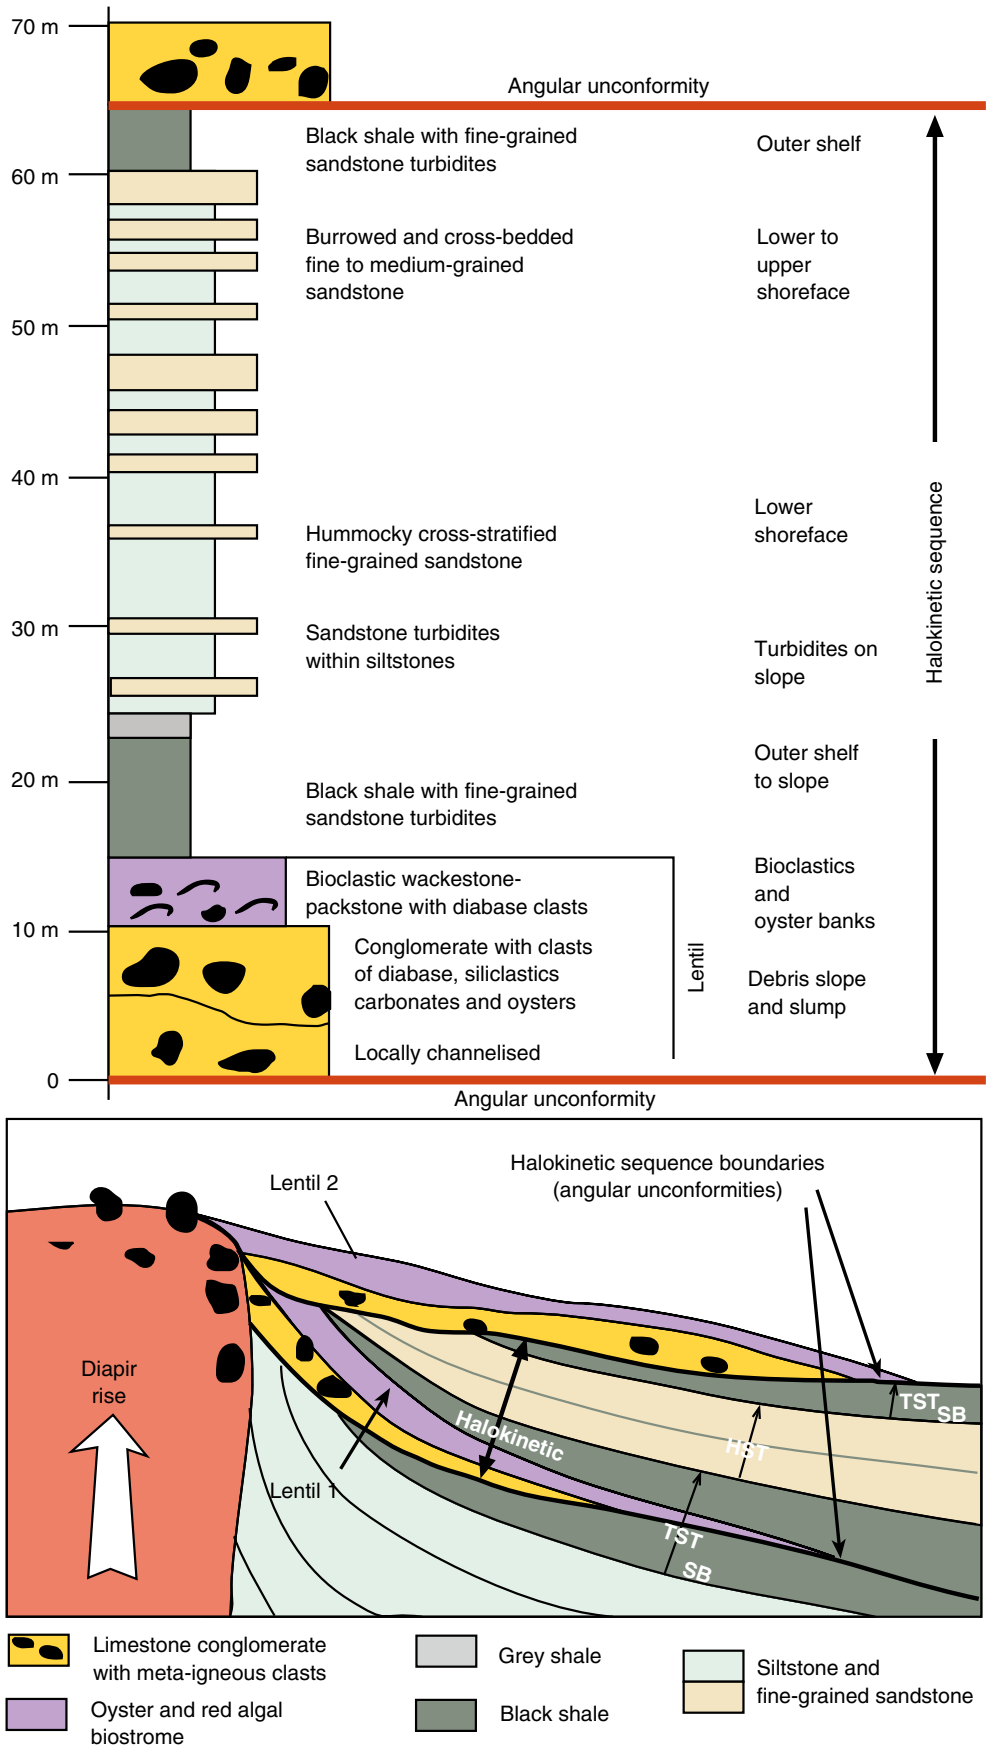

Fig. 6.108 Halokinetic sequence in a marine shelf setting, based on the stratigraphy of the lentil and associated sediments in the vicinity of the El Papalote diapir. Lower figure also shows the interpreted relationships between sediments and angular unconformities tied to diapir rise and to the sequence stratigraphic interpretation of the surrounding shelf and slope sediments. *SB* sequence boundary, *TST* transgressive system tract, *HST* highstand system tract (After Giles and Lawton 1999)

Subsalt Sections

Subsalt sediments, originally deposited adjacent to a seafloor allochthon and subsequently sealed beneath overflowing salt and its basal shear zone, have been studied extensively in the Gulf of Mexico, where numerous exploration wells have been drilled with subsalt targets (Chap. 10). Sub-allochthon sands in the Gulf of Mexico are mostly Miocene-Pleistocene deepwater-slope submarine fan channel and levee settings. The sandstones were deposited by turbidity currents associated with channel-levee systems carrying sediment from the outer shelf into bathyal water depths in the middle to lower continental slope (Snyder and Nugent 1995; Pilcher et al. 2011). Drilled facies vary from thick fining upward channelized deposits to thinly bedded levee sands and overbank splays. Sands range from friable to moderately consolidated, very fine to fine-grained, moderately to well sorted and slightly calcareous. Channel orientations can be strongly influenced by the seafloor topography generated by nearby salt allochthons. Once deposited the sands were then overridden and sealed by lateral flow of the allochthon sheets. The encroachment of the salt allochthon is associated with the creation of a salt-sealed gumbo or basal shear zone and defines one of four positions where subsalt sandy reservoirs are likely (Fig. 6.109). Economic and stratigraphic aspects of this very important subsalt-hydrocarbon association are discussed in detail in Chap. 10.

Caprock Formation (Diagenesis of Salt)

Caprock is a limestone/anhydrite carapace found atop many buried diapirs and allochthons (Fig. 6.110a; Halbouty 1979;

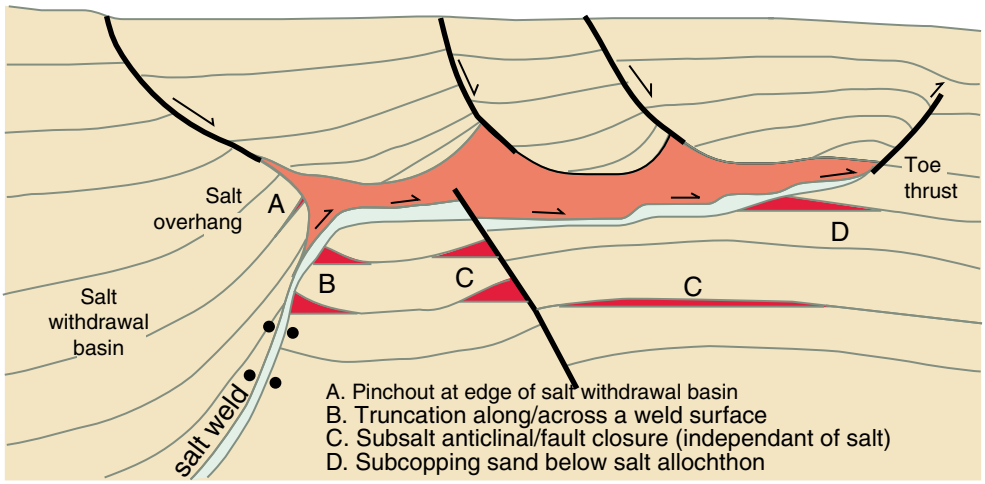

Fig. 6.109 Subsalt sediments buried beneath an encroaching allochthon is one (Style D) of four subsalt trap styles discussed in Snyder and Nugent (1995). See Chap. 10

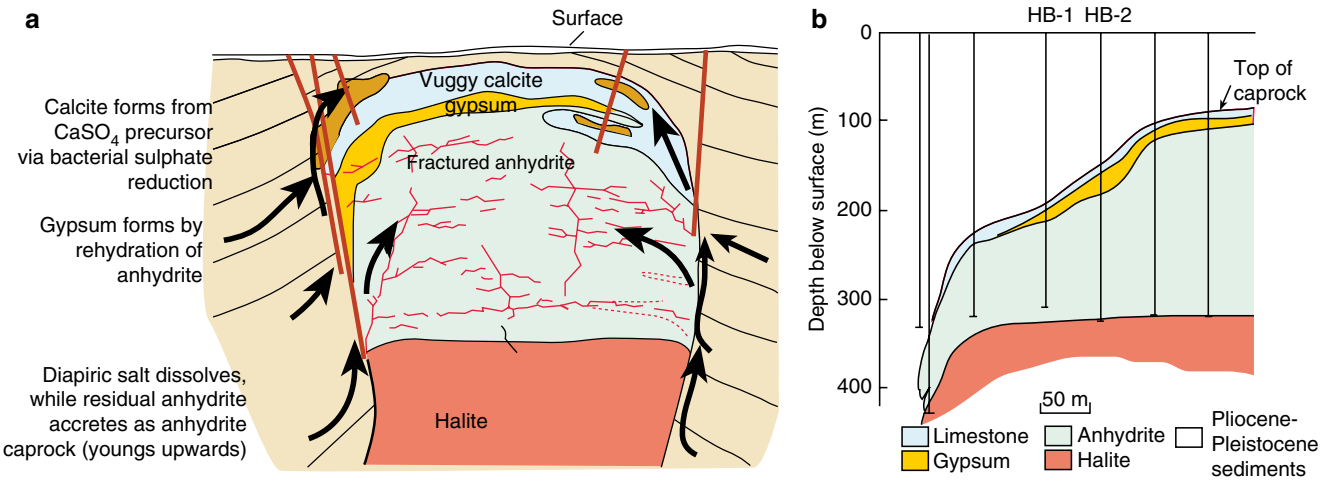

Fig. 6.110 Caprock zonation. (**a**) Caprock forms by the dissolution of the upper part of a salt structure once salt supply dwindles the rate of rise slows and it is flushed by undersaturated phreatic waters (*black arrows*). Dissolution of the halite leaves behind anhydrite that then accretes into an anhydrite caprock. The upper portion of the anhydrite unit rehydrates to gypsum that is then converted to limestone by bacterial sulphate reduction. (**b**) Section of Hockley dome caprock showing relative thickness of the caprock zones and depth below the landsurface based on drilling (After Hallager et al. 1990)

Prikryl et al. 1988; Kyle and Posey 1991; Light and Posey 1992; Jaworska 2010). It forms as a dissolution residue atop and on the flanks of diapirs, seafloor allochthons and even buried subaerial namakiers. Suprasalt caprocks thicken once salt supply starts to dwindle and the head of the salt plug or the top of any residual salt sheet is buried to depths where it can no longer actively pierce/breakout and shed sediment. The edge of any buried salt mass feels the increased effects of dissolution via the undersaturated crossflow of phreatic waters. Atop a buried, but still buoyant diapir, halite preferentially dissolves from the upper part of the salt mass/stem and a $CaSO_4$ unit accretes via underplating. The caprock underbelly has a continued supply of anhydrite residues as the top of the rising and dissolving salt stem is dissolved (Fig. 6.111; Hallager et al. 1990). In zones of longterm fluid crossflow and ongoing slow salt supply, this interface becomes a widespread laminar sulphate carapace, encasing a salt mass with caprocks some tens to hundreds of metres thick.

Caprock is most common and thickest on diapir crests that are currently close to the earth's surface but can be found atop and lateral to structures buried as deep as 3,000 m. Most diapir capstones are 100–150 m thick, but can be thicker than 300 m. Caprock is typically thicker over the crest of shallowly buried diapiric spines and thins along the flanks. Oil drilling over the Hockley dome, near Houston Texas, clearly defines a mineralogical layering of diagenetic products that is typical of caprocks worldwide (Fig. 6.110b). At its crest the Hockley Dome caprock is covered by only 30 m of Plio-Pleistocene sediments. The upper part of the caprock is a calcite unit up to 30 m thick. Over the crest the calcite is underlain by a gypsum zone up to 30 m thick. Further toward the flanks and somewhat deeper the gypsum unit is absent or patchy and the calcite is in direct contact with anhydrite. The calcite zone grades downward across a transition zone into a laminar anhydrite capstone up to 244 m thick. The Hockley caprock thins toward its edge and disappears, but in some

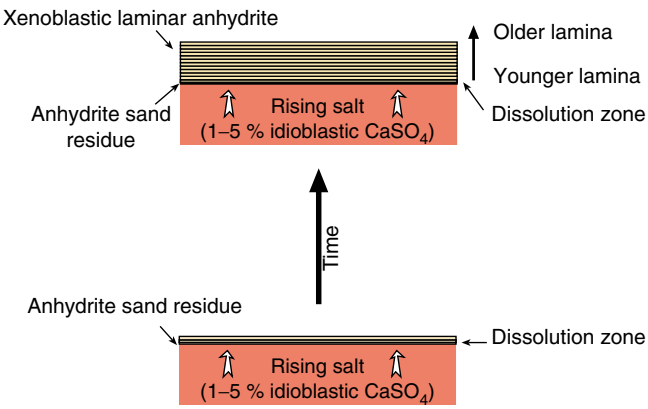

Fig. 6.111 Development of laminar anhydrite caprock via underplating across a zone of periodic dissolution at the halite-anhydrite contact

other nearby Gulf of Mexico diapirs the steep vertical walls of the diapir stem are also mantled with caprock.

Caprock extent reflects hydrodynamics about the upper part of the salt stem. The gypsum and limestone intervals in a caprock tend to be fractured and vuggy, typically containing accessory minerals such as baryte, celestite, strontianite, metal sulphides, rare tourmaline and fluorite derived from ascending basinal brines (Fig. 6.110a, b). Sulphur forms in vugs and fractures in the upper parts of caprocks where H_2S is oxidised by crossflowing waters (Figs. 12.68 and 12.69). Reactivated salt flow and associated carapace destruction means earlier allochthon and namakier residues can be carried to the margins and shed to become part of a polymict debris flow aprons that are perhaps parts of a unit that is termed a lateral caprock (in contrast to a "crestal" caprock).

The bulk of an actively accreting caprock is laminated and composed of unoriented, interlocking xenoblastic anhydrite crystal mosaics. Laminae are defined by thin intervals of dark sulphide/ bitumen accumulations or by intervals of more intense pressure-solution-sutured anhydrite. Deformed, banded anhydrite clasts are also contained locally within cm-spaced lamina (Ulrich et al. 1984, 1985). The laminar nature of a caprock reflects its formation via underplating, whereby the less soluble anhydrite and a few carbonate rhombs are left behind as undersaturated groundwaters dissolve halite from the upper part of the buoyant diapir stem (Fig. 6.111; Ulrich et al. 1985).

Anhydrite and carbonate typically comprise 1–5 % of the original undissolved salt massif in Gulf of Mexico diapirs. The salt/anhydrite contact tends to be subhorizontal to undulose, with local cm-thick metres-wide pockets of unconsolidated idioblastic anhydrite sand (euhedral grains freed from their encasing halite matrix). Above the halite contact and its sand pockets the anhydrite is laminated and consists of tightly interlocked xenoblastic crystals (Ulrich et al. 1985; Hallager et al. 1990). The transition from euhedral idioblastic anhydrite sand to xenoblastic anhydrite mosaics occurs in the first few centimetres above the salt stock. Outside of the sand pockets the porosity and permeability are consistently low to negligible.

Enclosed coarsely crystalline halite pockets, still with disseminated idioblastic anhydrite, can occur along some horizons in the caprock, especially in the lower portions of the anhydrite zone. Pocket shapes vary from tall and thin to broad and squat, maximum dimensions range from less than 0.5 m to about 2.0 m. These moundlike halite structures are mega-inclusion in the caprock anhydrite and are remnants of former zones of salt spine penetration along the salt-anhydrite contact. As the halite spine dissolves through several cycles of dissolution and accretion, a laminated anhydrite mound is preserved that sometimes contains minor amounts of base metals. Other clasts within the laminar anhydrite caprocks are remnants of anhydrite beds first deposited along with

mother salt, and then deformed and boudinaged into anhydrite "pencils" during salt flow (Hoy et al. 1962).

Gypsum forms sporadically along the upper side of the anhydrite portion of a caprock by hydration and is driven by the crossflushing of cooler less saline waters. Depending on permeabilities, this gypsum band is variably developed on and through the anhydrite, but deeper caprocks in the onshore Gulf of Mexico may lack a gypsum zone. Given the relatively high salinities and elevated temperatures that characterise the zone of onset of caprock formation, it may well be that gypsum formation postdates the formation of most calcite and sulphide minerals in the caprock and requires the pervasive entry of cooler meteoric water or seawater.

The calcite portion of the caprock occurs in hydrocarbon-bearing zones, mostly in the anhydrite zone where anaerobic SO_4-reducing bacteria break down the $CaSO_4$ phase into $CaCO_3$ and H_2S. Like the anhydrite zone, a calcite cap rock exhibits horizontal banding defined by alternating dark- and light-coloured layers of calcite that formed along the prevailing anhydrite/calcite contact during dissolution of anhydrite, coupled with SO_4 reduction (e.g. Prikryl et al. 1988). Dark calcite bands consist of fine-grained and typically pelletoidal calcite containing minor amounts of Fe, Zn, and Pb sulphides and bitumen. Light-coloured bands consist of coarse-grained euhedral calcite that apparently precipitated in open spaces and can also fill vugs.

In terms of porosity and permeability, it has long been assumed that most porosity and permeability occurs in the calcite layer in a caprock, and that the anhydrite and halite zones below this are tight. However, more detailed studies are showing that significant portions of the anhydrite zones in a caprock can be fractured and permeable. Lacazette et al. (2007) found that a caprock fracture system developed in the Sour Lake structure during caprock growth and was linked to salt-dome movement. The caprock was fractured both by faulting and extensional fracturing, resulting from dome emplacement and by mineral volume changes occurring during conversion of anhydrite to calcite. Isotopic data from the caprock limestones ($\delta^{18}O_{PDB}$: −4 to −8‰, and $\delta^{13}C_{PDB}$: −11 to −31‰) suggest that fluids evolved from deep bacterial to mixed meteoric during dome ascent.

Paleostress analysis based on fault-slip kinematics and extensional fracturing shows that caprock strain was due to dome inflation and that this expansion bears an overprint of the neotectonic (present-day) stress field. They document previously unrecognised pockets of fractured limestone occurring deep within the Sour Lake anhydrite layer and that these pockets constitute a significant part of the salt dome caprock volume. Some of these pockets were sampled by wells and imaged on the crosswell tomography. The fractured limestone pockets within the anhydrite likely resulted from bacterially-mediated diagenetic reactions which occurred when petroleum and brine flowed along faults created by dome inflation. The anhydrite portion of a caprock carapace should be considered potentially permeable intervals at geological time scales.

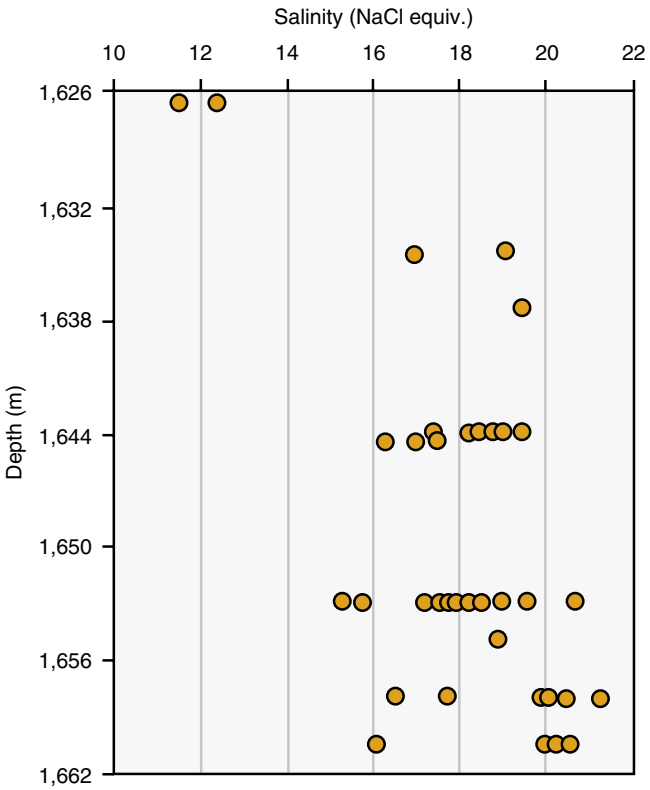

Fig. 6.112 Plot of fluid inclusions-based salinities in baryte and celestite in calcite cap rock versus depth (ft) in the Hockley Dome, Texas (After Saunders and Thomas 1996)

Massive amounts of the Sr minerals celestite ($SrSO_4$) and strontianite ($SrCO_3$) can occur in the lower portions of some calcite cap rocks, primarily in the light-coloured bands, along with minor amounts of baryte. Sulphide minerals can also be locally abundant in the lower portions of calcite cap rocks. The calcite cap rock at the Hazlehurst salt dome in Texas is approximately 30 m thick in the 2 drill holes that fully penetrated it (Saunders and Thomas 1996). The upper half of the cap rock consists of banded calcite similar to other Gulf Coast salt domes. Numerous near-vertical banded calcite-sulphide veins are also present in this part of the cap rock. The lower part of the calcite cap rock consists of horizontal sulphide + calcite bands that alternate with coarse-grained (white) calcite bands. Locally, sulphide-rich zones are more than a metre thick and consist principally of marcasite and pyrite, with minor amounts of sphalerite, galena, pyrrhotite, celestite, baryte and strontianite. Sulphate minerals are commonly intergrown with sulphides.

Fluid inclusion data in the calcite caprock of Hockley Dome, Texas, indicate that baryte and celestite precipitated at temperatures less than ~60 °C, from brines averaging around 200,000 mg/l total dissolved solids (Fig. 6.112; ~ 18 % NaCl

equiv.; Saunders and Thomas 1996). Fluid inclusion salinities in caprocks do not vary significantly with depth, suggesting that brine salinity did not change dramatically over time. Sulphur and carbon isotopic evidence also supports a biogenic origin for both carbonate and sulphide minerals in calcite cap rocks (Saunders and Swann 1994) or a combined basinal and biogenic origin (Hallager et al. 1990).

In the last two decades there have been a growing number of studies dealing with mineralised portions of caprock and the results are used to improve geological understanding of processes that create Mississippi Valley Type (MVT) base metal deposits (Chap. 15; Kyle and Price 1986a, b; Bechtel et al. 1999). In Tunisia, some of these mineralised caprocks the associated biolaminated muds and the iron-rich haloes adjacent to the salt stems contain sufficient lead, zinc or siderite to be mineable (Bechtel et al. 1998; Warren 2000b). Porosity in biogenic calcite caprocks can be as high as 40 %, with porosity types ranging from pinpoint to fracture to vuggy to cavernous. Caprock reservoirs[21] are shallow and so were attractive targets in the early heyday of drilling in Texas and many of the famous early discoveries were in caprocks; examples include Spindletop, Sour Lake, and Humble. Caprock reservoirs tend to be relatively small; the most difficult thing about working them in the early 1920s was their lack of predictability.[22]

The earliest-formed anhydrite lies at the top of the anhydrite zone, and the oldest calcite lies at the top of the calcite zone (Fig. 6.110). In other words the anhydrite and calcite caprock units grow from the bottom up and can be thought of as having a half life, like the basal anhydrites of the Maha Sarakham Fm. in Thailand (Fig. 7.45). That is, the thickness of any caprock zone is dependent on the rate of fluid flushing at the lower contact where it is forming and, at the upper contact, where it is being converted to another mineral phase or is dissolving. Ultimately, if crossflow continues, all that will be left of a caprock is a dissolution breccia or a weld.

Paleomagnetic age measurement of stratiform laminae of pyrrhotite and other sulphides in anhydrite cap rock, over a sampled section that represents about two thirds of the total anhydrite thickness in the Winnfield salt dome in northern Louisiana, indicate it formed between 157 and 145 Ma (latest Jurassic; Kyle and Gose 1991). Accumulation rates from these data indicate that the average rate for the oldest cap rock sampled is 5.7 m/m.y. and decreases to 2.8 m/m.y. for the younger lower parts of the caprock, indicating a waning rate of salt supply. The nearby 285 m-thick Hockley Dome cap rock is believed to have developed within the last 45 Ma giving same order of magnitude for the caprock accumulation rate (≈6 m/m.y.)

Caprocks are residuum responses to throughflushing waters atop and about largely inactive and buried salt structures. Historically they were interpreted as a diagenetic response to largely continental meteoric hydrologies imposed on dissolving diapir crests. Halbouty (1979), for example, noted that only 5 of 77 offshore wells drilled in diapiric crests intersected a caprock, but this analysis was done before any notions of allochthon shedding had been developed. Without doubt, actively forming caprock is found onshore wherever the active meteoric phreatic comes into contact with the upper part of a buoyant diapir crest (Schelkes et al. 2001). Yet, caprocks also form in offshore halotectonic slope-and-rise realms atop largely inactive salt structures that have not experienced substantial meteoric crossflow.

For example, a core through the Eureka dome, a structure located in the upper slope of the Gulf of Mexico, encountered 36 m (117 ft) of anhydrite caprock above the salt massif (Lehner 1969). Assuming an anhydrite content of around 5 % in the Louann Salt, this thickness of caprock requires the dissolution of more than 700 m of salt. Burk et al. (1969) reported caprock in core recovered from the Challenger Knoll in the Sigsbee abyssal plain. Authigenic tourmaline is anther mineral forming there (Chap. 13).

The allochthonous Sigsbee salt mass overrode the abyssal plain sediments and its upper surface was at or near the seafloor throughout the entire Cenozoic era and was probably never in contact with large volumes of meteoric waters. Apparently, circulating meteoric water is not necessary for salt dissolution and caprock formation. If such pore water is present, its relatively low salinity compared to phreatic seawater does accelerate the process of caprock creation. Substantial caprock can even form subaerially and active salt glaciers in Iran have a brownish laminated gypcrete capstone that can be 3–10 m thick over the actively flowing parts of the salt (Bosak et al. 1999).

The term "cap" may be somewhat of a misnomer as layered $CaSO_4$ dissolution residues also form offshore in the Gulf of Mexico, the North Sea and Thailand in zones of

[21] The early oil history of Gulf Coast, USA, has an interesting aside. Oldtime drillers found that drilling wells in graveyards led to a significant number of successes. High success rates associated with "graveyard-tology" meant that early last century the church elders and many still-living relatives developed a sudden if somewhat belated attachment to long-since-departed great aunt Maude. Bitter legal battles, fraught with claims along the lines of being the bastard child of aunt Maude, were fought over the percentage of royalties that one would receive for part of, or even a distant ownership of, a small piece of "Boot Hill." A reason exists for these early success rates. Many early east Texas fields were salt-structure associated, with the shallow reservoirs (vuggy and fractured caprock) lying directly over the crest of the structure. The surface expression of an underlying salt structure in the Texas Gulf coast is a small topographic high or hill, and since John Wayne was a whippersnapper, graveyards have been "up on Boot Hill." The first oil discovered in southern Louisiana in 1901 came from a similar salt-formed topographic feature known as Jennings Hill about 100 km west of Baton Rouge.

[22] The Spindletop discovery well blew out at a depth of 311 m (1,020 ft) and in 8 days it is estimated some 800,000 bbls of pressurized oil had escaped from the well.

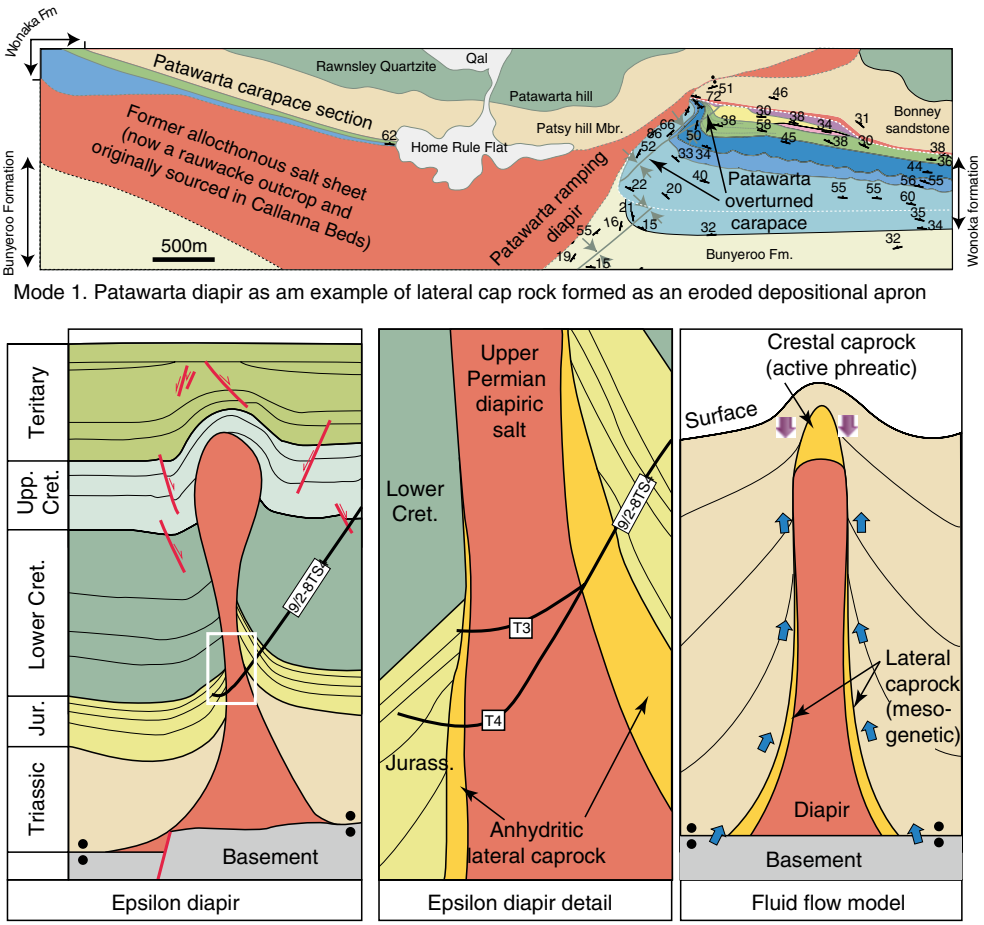

Fig. 6.113 Lateral caprock modes of formation. *Mode 1*: cross section based on Patawarta diapir, Flinders Ranges, South Australia, indicating formation via ongoing crestal erosion during downbuilding. *Mode 2*: cross section based on the Epsilon Diapir, illustrating formation via fractional dissolution of diapir salt in contact with undersaturated mesogenetic waters (*blue arrows*). Crestal caprock formed via active phreatic waters, eogenetic when sub seafloor, meteoric on land (*purple arrows*) (Adapted from Jackson et al. 2013; Kernen et al. 2012)

active fluid flushing on the margins and undersides of salt beds and allochthon sheets (see fractionated dissolution discussion in Chap. 7 and Jackson and Lewis 2012). For example, cores taken from the base salt contact in the Amoco #1 SL 12878 well in Plaquemines Parish, Louisiana, sampled a mineral assemblage of calcite, euhedral dolomite, ferroan dolomite, anhydrite, banded diagenetic calcite and trace sulphide minerals, the typical mineral association of a Gulf Coast caprock (House and Pritchett 1995). The notion of diagenetic anhydrite as residues from salt dissolution has led to a discussion of the major processes that form "lateral caprocks" about diapir edges that have experienced little or no exposure to meteoric waters and perhaps formed in settings that may not have approached the landsurface (Giles et al. 2012 vs Jackson et al. 2013).

The proponents of the drape-fold model of lateral caprock formation base their interruptions on mapping of field relationships in exposed salt structure margins in the La Popa, Mexico, Canyonlands, Utah and especially in the Flinders Ranges of South Australia (Giles et al. 2012; Kernen et al. 2012). There Neoproterozoic Patawarta salt sheet displays a laterally extensive (>10 km) dolomite caprock assemblage preserved in both subsalt and suprasalt positions along the sheet margins (Fig. 6.113; Mode 1). This caprock is 3–100 m thick and contains massive, laminated, and crackle breccia textures. The near-vertical to overturned subsalt caprock parallels steeply dipping strata of the Bunyeroo Fm in a tapered composite halokinetic sequence (CHS). The caprock terminates upward at an angular unconformity marking the upper boundary of the CHS. Basal strata of the overlying Wonoka Fm onlap the truncated caprock and contain conglomerates of caprock-derived detritus indicating that the caprock formed in a suprasalt position prior to deposition of the Wonoka, which forms another CHS but without caprock. The authors note similar, but not as well exposed, relationships in caprock and adjacent Permian and Mesozoic strata flanking the Castle Valley diapir in the Paradox Basin, Utah and the La Popa region of Mexico (Fig. 7.17).

They argue flanking and subsalt caprock forms via four steps: (1) caprock develops in a crestal position by crossflow waters; (2) continued diapiric rise and minibasin subsidence cause drape folding of roof strata and competent caprock, which detaches from the underlying halite-dominated diapir and rotates off the diapir top into a flanking position;

(3) topography generated by diapir inflation as diapir-rise rates exceed sediment-accumulation rates result in erosional thinning of the roof to create an angular unconformity that truncates the underlying CHS and flanking caprock; (4) increasing rates of sediment accumulation relative to diapir rise lead to onlap of the overlying CHS, which may or may not develop a new crestal caprock assemblage.

Contrasting with this dominantly sedimentary reworking mode of lateral caprock is the mesogenetic-diagenetic mode as outlined in Warren (2006) and Jackson et al. (2013). This mode of formation is created by the contact of a salt mass with an adjacent undersaturated water mass. This is the situation active on the basal edge of the Maha Sarakham evaporite mass, creating a diagenetic edge to the salt mass known as the "basal anhydrite" (El Tabakh et al. 1998a) and has formed the "lateral anhydritic caprock" to the Epsilon diapir and others in the North Sea (Mode 2 in Fig. 6.113). These diagenetic units are associated with a warm saline plume of pore fluids that typify the sediments adjacent to the salt edge.

Using a combination of seismic and wireline data from the Epsilon Diapir, Jackson et al. (2013) demonstrate that a weld is beginning to develop diagenetically via mesogenetic dissolution of halite along the squeezed diapir stem leaving bend an anhydritic residue. Borehole data indicate the structure today consists of an inner, ≈1,500 m thick, halite-dominated inner zone, and an outer, ≈250 m thick, anhydrite-dominated sheath or lateral caprock. This "lateral caprock" formed late in the basin history in response to the migration of NaCl-poor fluids up the margins of the diapir. Dissolution of large volumes of halite from the margins of steep-sided salt structures by the focused rise of deep, warm, basinal brines has implications for understanding the patterns and vigour of groundwater flow in sedimentary basins and the location of economically important metals (Chaps. 8 and 15, respectively).

Complications of Shale Diapirism

Both salt and shale form diapiric structures that, without drilling, can appear somewhat similar in seismic sections, especially in compressional settings (Fig. 6.114). Morley et al. (2014) and Warren et al. (2011) discuss the similarities and differences present in "diapiric" salt and shale provinces and outline ways of distinguishing the two styles (Table 6.6). Both salt and shale have sufficiently low permeabilities to allow units within folded and deformed compactional settings to create and hold back overpressured fluid columns ($k < 10^{-18}\ m^2$; Sibson 2003). In some situations, flowing shale ridges (argillokinesis) and flowing salt (halokinesis) can occur in the same basin stratigraphy, as in the Port Isabel and Mexican Ridges fold-belt provinces of the western Gulf of Mexico (Fig. 6.66; Rowan et al. 2004; Salomon Mora et al. 2011).

A key difference is where the overpressure resides and the effect of the structure's evolution on seal integrity. Salt's mobility is a inherent material property; so that structures in an active salt-cored fold and thrust belt continues to evolve until the salt is completely dissolved or ongoing salt withdrawal produces sufficient overburden touchdowns to stop further salt flow. While salt is flowing, it tends to maintain seal integrity whether or not there is an overpressured underbelly, which there typically is. Shale, on the other hand, only "flows" while it is overpressured. Whenever the main shale body depressurizes it freezes. While a shale is mobile (overpressured) it can generate a progression of kinematic geometries similar to those generated by the reactive and active phases of salt diapirism (Fig. 6.114a; Morley and Guerin 1996; Van Rensbergen et al. 2003). The presence of a mud diapir or volcano approaching the seafloor indicates a breach zone in an otherwise pressurized mud seal.

To illustrate the nature of a shale-cored fold and thrust belt let us look briefly at the highly visible set of thrust-cored ridges at the foot of slope of offshore Brunei (Fig. 6.115a). Modern growth faults are located near the present shelf-slope break of Brunei are prograding over older, inactive innermost deeper water folds (Plio-Pleistocene section in Fig. 6.115b). The average dip of the modern slope is between 1 and 1.5° toward the deepest region of the South China Sea, the northwest Borneo Trough. The slope is affected by an extensive train of folds, spaced between 5 and 15 km apart, that verge offshore (Fig. 6.115c). They are mostly fault-propagation folds that sole out into one or more detachments. These active thrust-cored growth anticlines outcrop or underlie much of the Brunei slope and rise and act as seafloor sediment baffles and catchment dams (Fig. 6.115c). Anticlines are cored by mud volcanoes (also called mud diapirs), while between the growing ridges are several northeastward-trending sediment-filled depressions that parallel the shelf margin and range from 2 to 10 km wide and 20 to 60 km long. These growth folds are the result of a downslope gravitational compression, which started in the upper Miocene and continues today (Morley et al. 2012). The remainder of the slope and rise area illustrated in Fig. 6.115c is a relatively flat terrain, mostly covered by a mass transport complex or landslide (Gee et al. 2007). This flow complex represents a catastrophic event that occurred in the relatively recent past and was perhaps emplaced as a single landslide, not as a series of time-separate debris flows. The collapsed headwall of this mass transport complex lies updip and immediately offshore from the Baram Delta (Fig. 6.115a).

Integrating the data (core sedimentology, organic character and isotope data) collected from a set of more than 100 piston cores over the area, shows the nature of the fluid system in and around mud volcanoes in the slope and rise of Brunei (Warren et al. 2011). Site 110 is one of a number of sites on the growth anticline crests where pressured fluids are

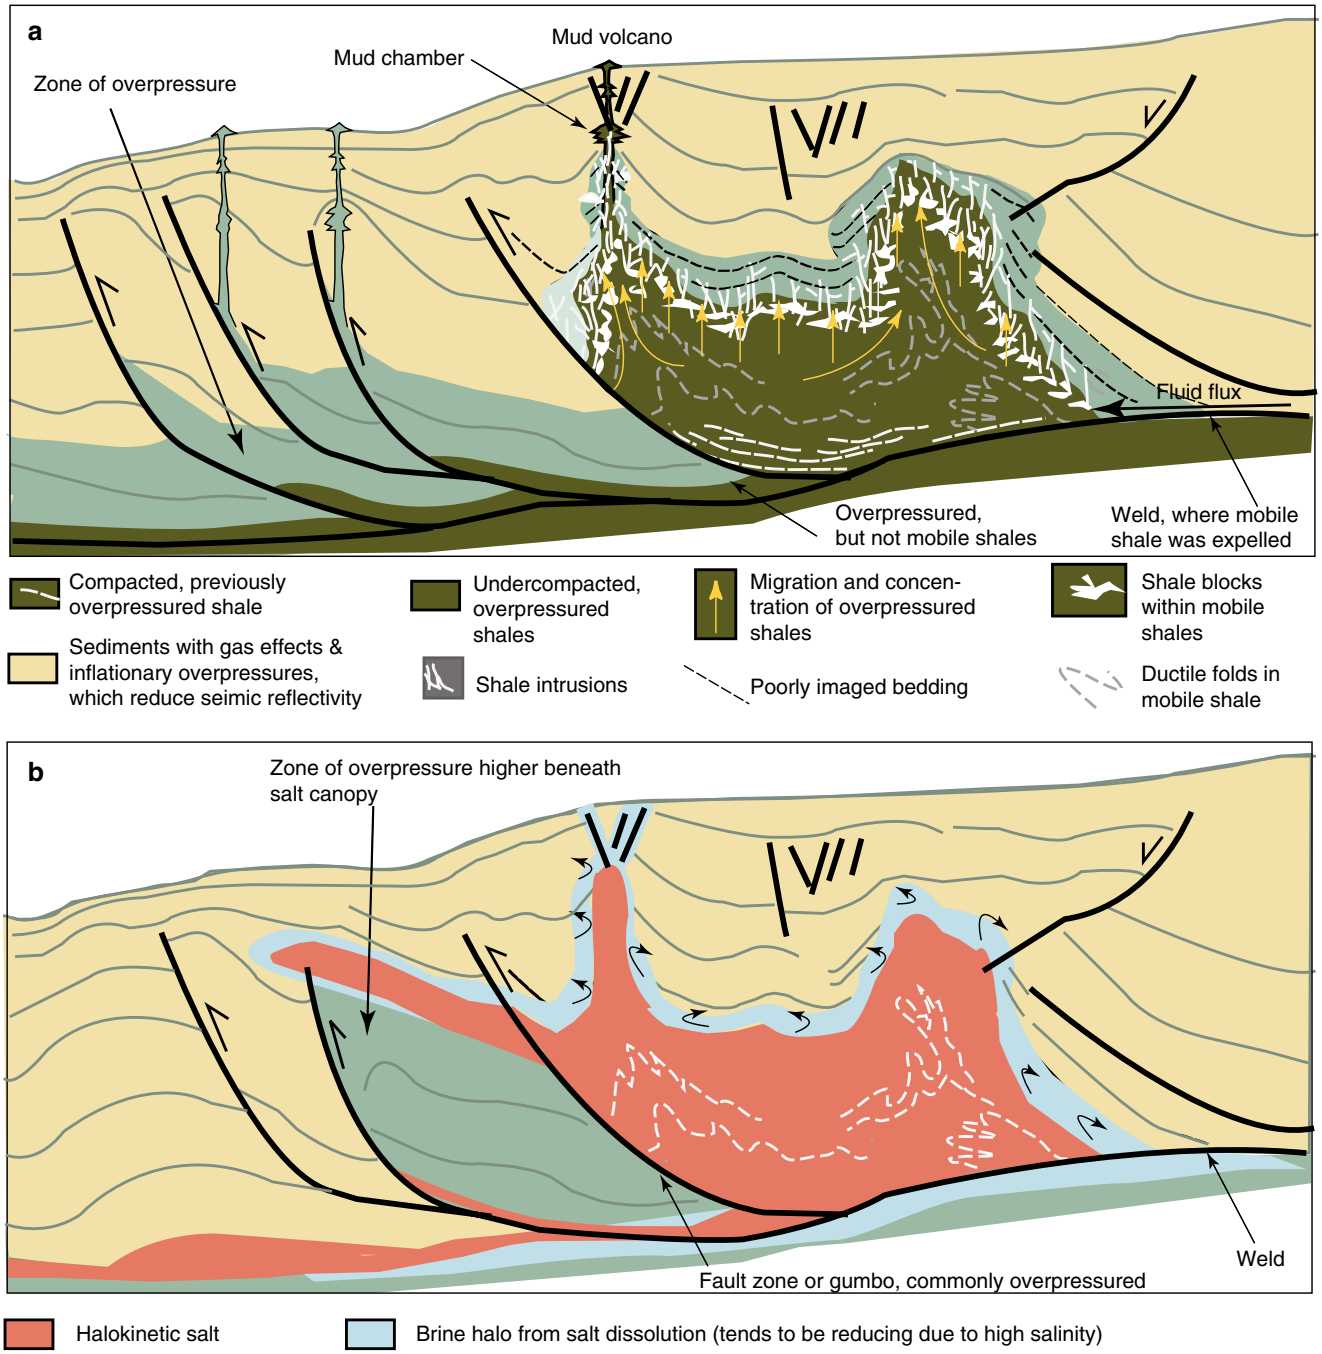

Fig. 6.114 Comparison of signatures of mud and salt diapirism. (**a**) Mud diapirism indicates a zone of fluid-charged overpressured fine-grained sediment (mostly mud). It can rise via stoping subvertical mud chimneys and periodically break out onto the sea floor. The seismic signature indicates zones of active or former fluid charge. The diapir as seen in the seismic signature is not a lithology but typically a gas effect. As such, the diapir zone can expand and encapsulate or cannibalize adjacent sediments without disturbing the bed orientation. (**b**) Salt diapirism indicates a zone of flowing impermeable salt (halokinesis). There is both a vertical and horizontal component to this flow and a strong response to sediment loading, and, on salt reaching the sea floor, it is tied to downslope gravity spreading. The seismic signature of a salt diapir or allochthon is a direct indicator of the salt mass, which is always impermeable. Flow sets up a mobile mass of impervious salt with edges subject to dissolution (like a block of ice). This mass and its brine halo focus fluid flow and overpressuring about its edges (After Morley et al. 2011, 2014)

on their way to the surface and forming mud chimneys and mud volcanoes (Fig. 6.116). It lies atop a thrust-cored growth anticline where rising overpressured fluids are causing the reflectors to rise and outline diapir-like convex-upward chimney geometries. These indicate fluid anomalies that are on their way to creating pressurised mounds on the sea floor. Seismic across other sites show collapse cones and pocks where the pressure has vented (Warren et al. 2011).

Table 6.6 Features typical of mud diapirism and salt diapirism

		Mud diapir (argillokinetic)	Salt diapir (halokinetic)
Tectonic setting where argillokinesis and/or halokinesis occurs	Rift to drift (passive margin (extensional) with depositional loading)	Yes, gravity-driven fold belt (especially in toe of slope) Examples: Mexican Ridges and Port Isabel foldbelts of western Gulf of Mexico; foldbelts in the Sergipe Alagoas and Pára-Maranhao basins of Brazil, Niger delta foldbelt; McKenzie delta foldbelt, Arctic Canada; Yangtze delta, East China Sea.	Yes, gravity-driven fold belt (especially in toe of slope) Examples: Slope and rise foldbelts of the circum-South Atlantic salt basins and the northern Gulf of Mexico; foldbelts in the Yemeni Red Sea; Nile deep sea fan; Rhone deep sea fan; Scotian Margin, eastern Canada.
	Collisional accretionary belts, transpressional belts, both can overprint a former passive margin	Yes (forearc and backarc basins) Examples: Barbados accretionary prism; Mediterranean Sea and Tethyan Belt, spanning from south of Greece over the Black and Caspian Seas into Azerbaijan, the Crimea and Taman Peninsulas, Iran, and Turkmenistan into the Makran coast; Borneo; South China Sea.	Yes (especially in zones of continent-continent collision, compression can reactivate former extensional salt diapirs). Examples: Qom Basin and Zagros foldbelt, Iran; Kuqa foldbelt, Tarim; Betics; Carpathians; Apennines; Sierra Madre; Neuquen, Argentina.
	Intracratonic sag	No.	No (unless basin inversion occurs – e.g. Amadeus).
Depositional Association	Marine	Typical of muddy continental slope and rise.	Typical of continental slope and rise, also shelf
	Lacustrine	Foreland basin.	Foreland basin.
Movement style and drivers		Requires overpressure. Shale can pass from ductile to fluidized, and back to ductile numerous times as the structure oscillates between inflation (gas explosions & diapir wings) and deflation (collapse after landsurface is breached). Overpressure is caused by combination of burial compaction, diagenesis of clay, organic maturation and compressive tectonics. Overpressure is lost when fluid-charged mass reaches the surface and there is typically only a relatively minor lateral sediment flow component when the fluid escapes onto the surface. Mud diapir provinces can form zones of extremely rapid subsidence atop salt withdrawal zones even if the mud source interval is not overpressured (Fort Isabel foldbelt).	Thick beds of wet salt undergoing loading or extension can be autokinetic, almost from the time of deposition. Salt continues to move in response to extension or loading and maintains its flow until overburden touchdown occurs. Salt in compression will fold but not pierce overburden, except under particular circumstances. When the salt reaches the surface there is a strong lateral component (downslope) to flow (allochthons and namakiers), salt flow can continue via gravity spreading for many kilometers way from vent. Overpressure is often focused beneath an allochthon as the salt mass is an excellent seal. Overpressure is also common in suprasalt minibasins where the feedback between loading and salt withdrawal facilitates rapid sedimentation until touchdown.
Causes of collapse of overburden or sediment immediately adjacent to structure		Structural collapse, typically occurs via venting/mud volcanism, which acts as a drain to overpressure and as breach zones to mud seals.	Dissolution or deflation of salt feature as it flows up and ultimately out of the subsurface to landsurface/seafloor. At surface flow slows then ceases as the allochthon is cut off from mother salt supply layer.

(continued)

Table 6.6 (continued)

	Mud diapir (argillokinetic)	Salt diapir (halokinetic)
Pockmarks	Indicate zones of pressure release often in zones of fluid escape through a zone of methane hydrate on basin floor.	Indicate zones of salt dissolution or of escaping fluids released to basin floor near the feather edge of salt sheet or above zones of overburden touchdown (welds).
Breccias in and around vent	Mud can carry blocks that assimilate into rising plume with diameters of several to hundreds of metres. Large blocks are also captured by crestal collapse.	Salt can carry blocks with diameters of kilometers. Blocks typically were originally intercalated with mother salt or source layer.
Fault association	Yes – shale diapirism initiated by faults that weaken the overburden. Pressurized mud then intrudes into the overlying sedimentary rock and may or may not reach the surface.	Yes – close association between fault welds and salt welds. Much synkinematic activity is driven by feedback between loading, salt withdrawal and creation of further accommodation space.
Fluid association	Warm subsurface fluids (typically gassy) escape along active faults or chimneys and carry mud with indicators of organic maturation. Thermal pools may or may not be present on seafloor. Overpressuring feeds hydrocarbons to the surface (seeps associated with volcanoes). The sense of fluid flow is dominantly vertical and there are no traps associated with lateral mud flow at the seafloor.	Warm subsalt fluids escape at feather edge of salt or atop active salt transecting faults or above zones of overburden touchdown. Fluids can carry mature hydrocarbons. Brine pools are present at zones of topographic closure on basin floor. Methane seeps are commonplace. Once salt is at seafloor it spreads under influence if gravity and there are a broad range of subsalt traps associated with lateral flow of salt.
Hydrocarbon traps	Detachment folds, diapir toplap, diapir top drape or rollover rims, radial faults, tilted fault blocks, erosional truncation and associated unconformity traps, lateral mini-anticlines, and downbuilt anticlinal flank traps. Mud volcano indicates a breach to a muddy seal interval	Detachment folds, diapir toplap, diapir top drape or rollover rims, radial faults, tilted fault blocks, erosional truncation and associated unconformity traps, lateral mini-anticlines, and downbuilt anticlinal flank traps, suballochthon traps, intra-salt traps. Salt acts as seal.

After Warren et al. (2011)

The convex-upward character of reflectors that pass into the rising fluid columns and the convex-upward sea floor atop the rising plumes (no collapse cones yet exist) imply that the pressured fluid column is yet to breach the sea floor from below site 110, but has reached the sea floor nearby (Fig. 6.116). For example, the plume that rises all the way to the sea floor in the mound downdip of site 110 and the lack of layering or a BSR in the plume position feeding this mound (indicated by purple arrow) imply that seepage of fluids onto the sea floor near site 110 occurs. The two intersecting section lines illustrate the precursor and the active phase of a rising fluid plume that will evolve into a mud volcano. What is so distinctive about the system is that, unlike a salt-cored system where the salt is flowing near or onto the seafloor (Fig. 6.116b), in a mud cored fold and thrust belt we are dealing mostly with gassy fluids leaking onto the seafloor not a flowing mass of shale (Fig. 6.116a).

Halokinetic flow in a salt province builds diachronous levels and tiers of allochthons all the way up through the basin stratigraphy to the seafloor. Salt flows and evolves into higher levels in the stratigraphy, long after the original salt level has become a primary weld. Movement of a shale diapir tends to be much more episodic and related to particular overpressuring events within the shale-dominated section of a prograding typically deltaic continental margin (e.g. load-driven compaction or thermobaric release of water or hydrocarbon generation). The "shale" freezes once the pressurised set of fluids in a shale, which defines the "shale diapir" mass,

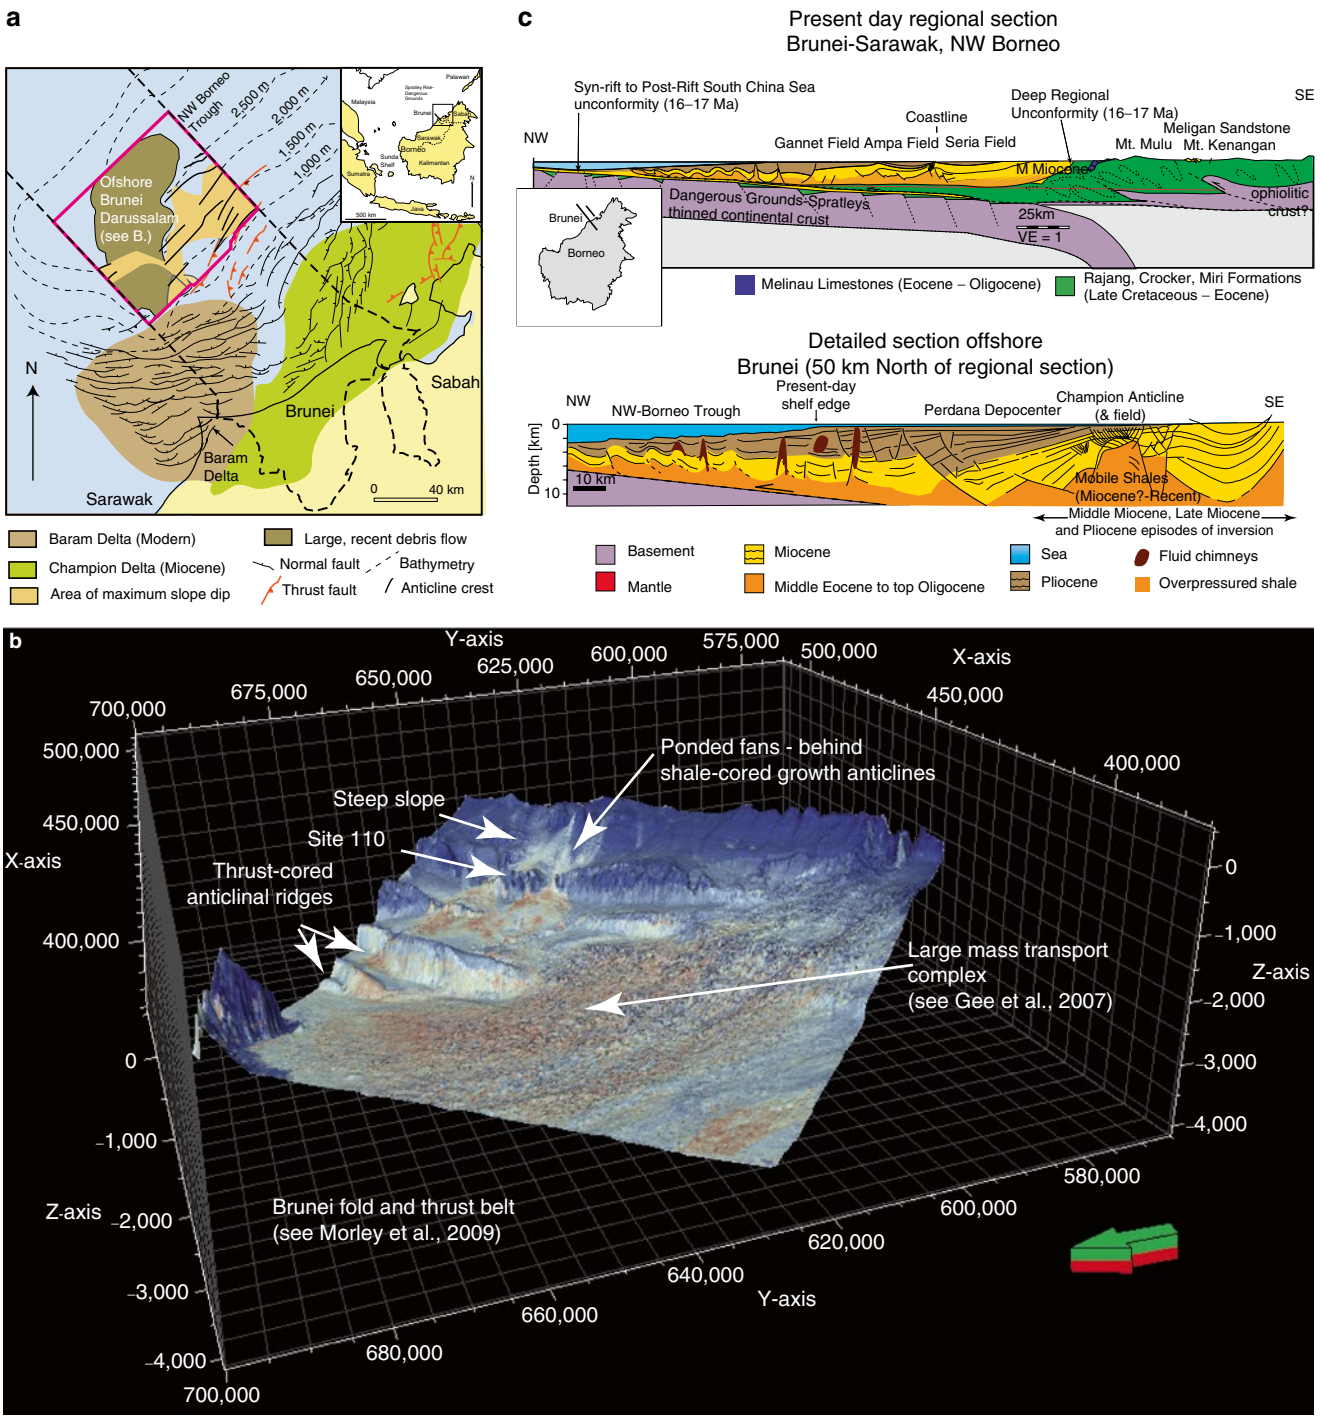

Fig. 6.115 Regional summary for offshore Brunei Darussalam (After Warren et al. 2011). (**a**) Regional sea-floor map showing Brunei-Malaysia borders (*dashed line*), the outline of study area (*pink rectangle*, centered on 5.718 N, 113.168E), and the dominant depositional styles (After Morley 2007a). (**b**) Sea-bottom map of the study area. Seismic amplitude extractions of the water bottom draped over the bathymetry of the deep-water slope and rise of Brunei showing the location of anticlinal ridges and the mass transport debris apron to the south (arbitrary z-axis scale; x and y scales UTM in m). The colour range represents a range of root mean square (RMS) amplitudes. Generally, the higher the RMS amplitude, the more consolidated the sediments. Areas in brighter orange are typically active sediment flow paths (channels, downslope of deep-sea fans, and fault scarps), lighter areas indicate a more compacted mud, whereas gray indicates a relatively stable ground. *Arrow* points north. (**c**) Regional and local cross sections of offshore Brunei Darussalam showing dominant down to basin style of gravity-driven sedimentation atop an inactive subduction zone (After Hall and Morley 2004). The pattern shows the overall progradation in a region of updip extension and growth faulting that passes downdip into compressional ridges and sediment dams and minibasins

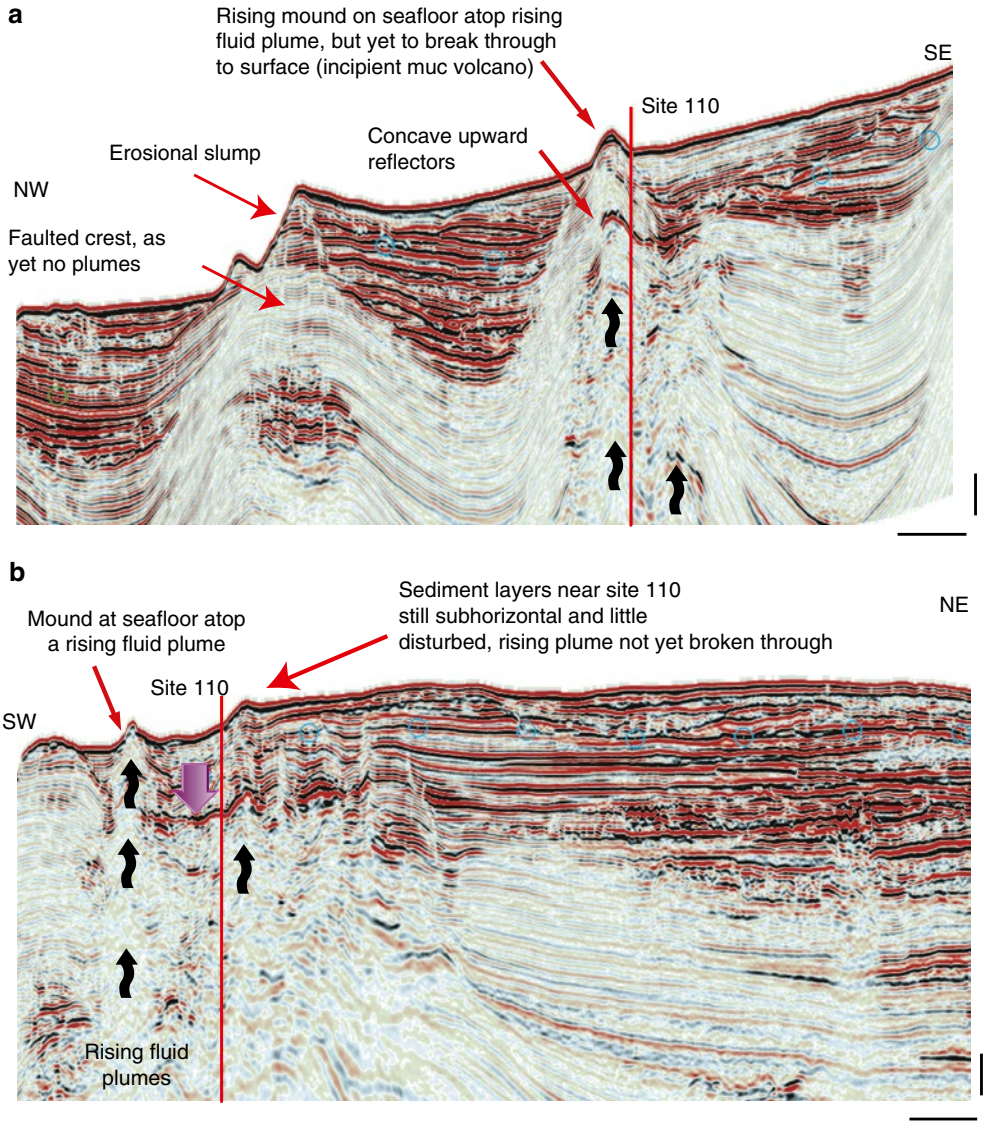

Fig. 6.116 Incipient mud volcano, in the slope and rise of the fold and thrust belt of offshore Brunei (After Warren et al. 2011). *Vertical red lines* indicate where inline and crossline seismic, illustrated in this figure, intersect one another (Horizontal bars = 1 km (0.6 mi); vertical bars = 1 ms. See Fig. 6.113= for the site location)

approaches the surface and the pressure buildup is released via mud volcanoes.

Mud "diapirs" are not created by the same digenetic mechanisms as salt diapirs, even if they occur in fold and thrust belts that show similar patterns of gravity-driven compressional folding. There is a basic distinction to be made between the actual volume of "sediment" flowing in a mud "diapir" or allochthon, versus the distribution of overpressured mud leaking pore fluids and imaged in seismic. What we resolve seismically as a "mud diapir" is not sediment that has experienced Newtonian flow. Rather, it is muddy and gassy sediment that is disturbed because it contains, or once contained, overpressured fluid. This is not the same as a body of flowing salt in a salt allochthon. This is why there are no equivalents to salt canopies and tongues in regions of mud diapirism. Rather there are local, often relatively narrow and cylindrical structures (mud volcanoes and chimneys) that define the vent and escape positions of overpressured fluids rising though the growth anticlines from below. Allochthons and diapirs in halokinetic systems act as a focus to fluid flow, in mud diapirs and walls they are the zones of fluid flow (Fig. 6.116 and Table 6.6).

For the same reason, shallow allochthons and widespread raft tectonics atop thin shallow décollement layers are much less common in mobile shale belts. Most shale diapirs show affinities to autochthonous rather than allochthonous salt systems. Laterally-limited shale allochthons do occur in the Niger Delta, where they form imbricate thrusts that pass down dip into gravity flows and slumped blocks of shale derived from the exposed mobile shale.

Where salt diapirs act as a focus to fluid flow in suprasalt sediments they can create seafloor effects similar to those in shale diapir provinces, as evidenced by (Cartwright et al. 2007; Camerlenghi et al. 2009): (1) localized development of

mud mounds above diapirs in the Gulf of Mexico (Roberts and Carney, 1997); (2) shallow gas anomalies clustered around and above salt diapirs in the North Sea (Heggland 2004), large pockmarks above diapir margins in west Africa and pockmarks on the deep sea floor in the Adriatic (Geletti et al. 2008) and (3) localized salinity anomalies around salt diapirs, as in offshore Louisiana (Esch and Hanor 1995). In the North Sea, gas chimneys in the Tertiary overburden are widely observed above salt diapirs; there and elsewhere salt-focused gas escape zones contribute to imaging problems at depth and to drilling hazards in the shallow subsurface (Heggland 2004).

A significant difference between salt and shale diapiric provinces lies in the permanence of the contact between the flowing unit and adjacent strata (Fig. 6.114). While flow in halokinetic terrains only takes place within the salt unit, shale "mobility" (the zone of pressured fluid) can spread out into adjacent beds as the overpressured interval spreads, this is why conformable layers are sometimes visible in a diapiric mud. That is, while overpressured, a stressed ("mobile") shale interval can facilitate fluid migration that cannibalises (overpressures) adjacent shale strata and so cut across time/bed boundaries giving an overpressured shale interval a chaotic indistinctly-layered appearance in seismic (Fig. 6.114a).

Morley and Guerin (1996) record how these differences in mechanical behaviour lead to differences in structural style. They note that prekinematic and synkinematic structures occur in both provinces, but much of the prekinematic deformation in mobile shale deltas, such as the Niger Delta of Africa and the Baram/Champion systems of Brunei, are destroyed by aggrading cannibalisation of the overpressured shale. Not recognising this cannibalising effect can lead to the inappropriate placement of the lower portions of growth faults during seismic interpretation of shale diapiric belts (Fig. 6.114a; Van Rensbergen and Morley 2000).

Fault-dominated minibasins occur above the flowing unit in both salt and shale mobile belts. Likewise, in the shale-dominant Niger Delta, the interval of overpressured shales beneath the actively accumulating delta prism varies from relatively thin intervals to massive chaotic zones some 4–6 km thick. The maximum minibasin thickness is the thickness of the mobile shale, plus the thickness of the overlying pregrowth fault strata (i.e. some 4–8 km). Such thicknesses are similar to those in salt-induced minibasins in the Gulf of Mexico.

Classic autochthon geometries are common to both salt and shale provinces, as are normal fault haloes that are created during reactive diapirism (Fig. 6.114). Early counter-regional faults and toe thrusts are early controls on the formation and position of subsequent minibasins in both settings. Salt has the potential to completely evacuate as it evolves into salt welds or overburden touchdowns. Mobile shale deformation may also create local touchdown areas (shale welds), but complete shale collapse is uncommon and large volumes of immobile dewatered shale are usually left after diapirism has ceased.

Van Rensbergen et al. (2003) go on to note that due to the requirement of overpressure for shale mobility and the need for hydrocarbon generation to instigate overpressuring, a gas-charged mobile shale can forcibly stope upward though its overburden via the process of shale cannibalisation. This tends to create narrow near vertical pipes, typically issuing pressurized fluids and some liquefied sediment onto the landscape as mud volcanoes. There are no equivalent narrow pipe-like cannibalistic stoping or diatreme-like features in the realm of salt flow, except where pressurised subsalt fluid breaches a salt layer and creates a similar set of mud diatremes.

Compressional growth anticlines cored by salt or overpressured mud can influence the distribution of deepwater sediments in the continental slope and rise in both settings. Such an anticlinal dam the shale diapiric zone of offshore Brunei is illustrated in Figs. 6.115 and 6.116. The geometry can be compared with similar fold and thrust anticlines, but with salt cores, in the Gulf of Mexico and Angola (Table 6.6).

Occasionally, mud diapirs can be underlain by active salt diapirs, as in the case in the Mercator mud volcano (MMV) in the Gulf of Cadiz (Haffert et al. 2013). As well as focusing upward fluid migration, this mud volcano is also an important zone for fluid and mineral diagenesis and the occurrence of authigenic gypsum and anhydrite crystals in the volcano muds. Modern near-surface muds in its vicinity show extremely high salinities (up to 5.2 M of NaCl) with pore brines sourced from underlying Triassic diapiric and evaporitic halite dissolution. The strong increase in salinity in the mud volcano pore fluids raises the gypsum-anhydrite transition zone from $\approx$1 km regionally to about 400 m sediment depth in the vicinity of the mud volcano. This transition is further shifted to immediately below the seafloor during intervals of active mud and fluid expulsion when the sediment surface temperature is heated up to at least 30 °C.

As a consequence, precipitation of authigenic gypsum near the sediment surface (1–2 m depth) is linked to the dissolution of evaporites below the MMV. Mechanisms generating supersaturation in the ascending gypsum-saturated MMV fluids are: (1) The slow and constant cooling of these fluids along the geothermal gradient during their ascent leading to formation of ubiquitous micro-crystals; and (2) The more rapid cooling after a heat pulse or transport from greater and warmer depths during an active mud volcano phase leading to the precipitation of cm-scale gypsum crystals or even fist-size concretions. The MMV fluids approaching the salt diapir from farther below have experienced a genesis similar to those of other mud volcanoes in the Gulf of Cadiz located above deep-rooted pressurised faults. These broader scale processes include clay mineral

dewatering, thermogenic degradation of organic matter and deep high-temperature leaching of terrigenous sediments or continental crust.

Summary

With the increasing use of 3D seismic for oil exploration in Phanerozoic basins, it has become obvious that models of predominantly vertical movement of salt from a mother salt bed into thumb-like autochthonous appendages are limiting. We now know that huge salt sheets (allochthons) can climb the stratigraphy as a series of predominantly subhorizontal sheets or tiers that are continually moving and squeezing as they are loaded by ongoing sedimentation. The end result is a feedback system where flowage creates withdrawal lows that fill with sediment, while at the same time the filling of the low with sediment triggers further salt flow. The upper side of the deforming salt sheet can also flow into more classic thumb-like styles of diapir geometries.

Prior to the advent of forward-modelling techniques in seismic processing and the gathering of 3D data networks we could not image beneath salt bodies and so tended to interpret the upper salt surface as the primary level of the salt body (Roho's moho). We now know this is not the case, many deforming salt beds flow into laterally extensive allochthons and canopies, which become rootless once the connection to the primary source or mother salt bed is converted to a salt weld or a fault weld. A salt weld forms as salt migrates or dissolves away to allow the former upper and lower contacts of the salt to come together or touchdown to form a salt weld. A fault weld forms where salt that was once within or lubricating a fault or shear plane is lost and the two sides of the fault come together. When a thrust plane is lubricated by salt that is subsequently lost by migration or dissolution, the plane may convert to a characteristic nearsurface dissolution breccia called rauhwacke (Chap. 7).

The end result of salt allochthons climbing through an aggrading and prograding shelf sequence is a layered and faulted stratigraphy with former sheets left as salt welds and fault welds, rather like a slug leaves a slime trail as it moves through a pile of leaf debris. The amount of salt left behind in the basin stratigraphy depends on the efficiency of salt evacuation. When the evacuation of the allochthonous salt sheet is efficient, all that is left behind is a series of stepped counter-regional fault welds and associated landward dipping faults. When the evacuation is less efficient the result is a series of salt rollers along the salt weld and an overlying fault-segmented sedimentary sheet cut by dominantly basin-dipping growth faults (a Roho system).

Wherever a salt allochthon is near the seafloor it can load, deform, coalesce or disaggregate as it continues its climb through the aggrading stratigraphy. Sediment loading atop a deforming allochthon creates fault-defined suprasalt basins or minibasins, often interacting with salt glaciers on the seafloor. Minibasins typically fill with a characteristic upward shoaling pattern of sediments passing from initial deeper-water laminated shales and mud to shallow water sands and carbonates. Processes of ongoing halokinesis and minibasin formation cease once the salt allochthon is sufficiently thinned, dissolved or buried. Thus, throughout the sedimentation history of a passive margin that is underlain by early thick salt beds there are many intervals where thick sheets of flowing allochthonous salt are present just beneath the deep sea floor and sandwiched into what are otherwise normal deeper marine bottom sediments.

Salt tectonics is also active in compressional terrains, which can occur at the foot of a gravity-glide sheets basinward of the continental slope. Flow is especially obvious in ancient foreland fold and thrust belts and inverted basins where weak subsurface salt acted a décollement layer and, if it makes it to the surface, the salt can create namakiers. The resulting growth anticlines are narrow and salt-cored, while the intervening synclines are broad. Most of the thrusts are blind and backthrusts typically occur in association with forward directed thrusts. Much of the salt in the cores of the anticlines is strongly folded and diapiric; although the notion that compressional diapirs can breach their overburden, without being erosionally thinned or disrupted by tear faults, has yet to be proven. There is now an appreciable body of evidence that many compressional diapirs feeding salt to the surface are actually reactivated extensional structures.

Salt Dissolution and Pointers to Vanished Evaporites: Karst, Breccia, Nodules and Cement

7

Introduction

Given enough time all subsurface evaporites eventually dissolve. Even in the subsurface sedimentary realm there are probably more intervals of dissolution residues than there are beds of salts. The rate of evaporite dissolution changes with temperature and rate and volume of crossflowing undersaturated pore waters (Fig. 7.1) Solubility of the chloride salts consistently increases with increasing temperature (prograde solubility), with the sulphates and the sodium carbonates it initially increases, but can then decrease at higher temperatures (retrograde solubility). Dissolution typically begins in the shallow subsurface as the edges of salt beds are flushed by meteoric or marine waters and continues deeper in the subsurface, wherever and whenever bed edges are flushed by undersaturated basinal brines. Partial dissolution, whereby crystals of more saline salts (typically halite and bitterns) are flushed, leaves behind residues of the less saline salts (typically gypsum-anhydrite, as in many caprocks).

Solubility varies from salt to salt (Table 7.1). For example, gypsum is moderately soluble in nearsurface meteoric waters with a saturation concentration of around 2,500 ppm at 40 °C. Halite is much more soluble, its saturation concentration is ≈350,000 ppm at 25 °C and, unlike the calcium sulphate salts, its solubility consistently increases with rising temperature (Fig. 7.1). Limestone dissolves more slowly than gypsum or halite, with a saturation concentration that varies according to ambient pH and CO_2 levels, but typically in the range 50–400 ppm.

When exposed to meteoric crossflows, gypsum is one to two orders of magnitude as soluble, while halite is more than three orders of magnitude as soluble as limestone. For example, in temperate-zone caves Klimchouk and Aksem (2000) used gypsum tablets of standard lithology and size (40–45 mm diameter, 7–8 mm thick), and placed them so they were exposed to surface precipitation (640 mm), cave air in zones of condensation, percolation, and static or semi-static

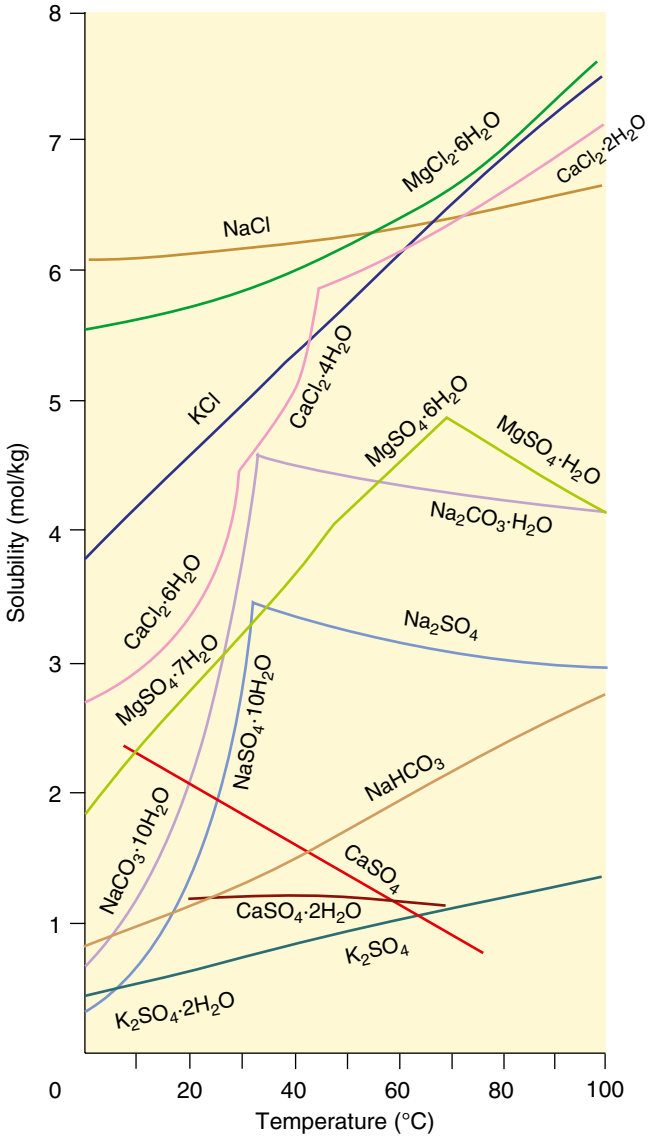

Fig. 7.1 Solubility of common salts in pure water as a function of temperature, expressed in mole anhydrous salt per kg H_2O, (After Braitsch 1964)

Table 7.1 Solubilities in freshwater of various evaporite salts in comparison to limestone at 25 °C (relative solubility calculated from molar concentrations)

Mineral name	Composition	Solubility in freshwater (moles/l)	Solubility with respect to limestone
Limestone	$CaCO_3$	0.00014	1
Magnesite	$MgCO_3$	0.001	7.1
Gypsum	$CaSO_4{\cdot}2H_2O$	0.014	100
Nahcolite	$NaHCO_3$	1.22	8.7×10^3
Mirabilite	$Na_2\ SO_4{\cdot}10H_2O$	1.96	14.0×10^3
Natron	$Na_2\ CO_3{\cdot}10H_2O$	2.77	19.8×10^3
Epsomite	$MgSO_4{\cdot}7H_2\ O$	3.07	21.9×10^3
Thenardite	$NaSO_4$	3.45	24.6×10^3
Hexahydrite	$MgSO_4{\cdot}6H_2O$	4.15	29.6×10^3
Sylvite	KCl	4.78	34.1×10^3
Bischofite	$MgCl_2{\cdot}6H_2O$	5.84	41.7×10^3
Halite	NaCl	6.15	43.9×10^3
Kieserite	$MgSO_4{\cdot}H_2O$	6.25	44.6×10^3
Antarcticite	$CaCl_2{\cdot}6H_2O$	7.38	52.7×10^3

water in caves and boreholes. Aggressive groundwaters were able to dissolve gypsum tablets at rates up to 26 mm/year; the solution rate under active unconfined circulation averaged about 11 mm/year; whereas in the bulk aquifer the solution rate was about 0.1 mm/year. At Ripon in Yorkshire, a 3 m cube of undercut gypsum that fell into the River Ure was completely dissolved in 18 months and the nearby gypsum face was undercut another 6 m in the next 10 years (Cooper 1998).

Rates of gypsum dissolution can increase where there are significant amounts of halite dissolving nearby, this is attributed to the ionic strength effect (Fig. 2.18b; Ford and Williams 2007; Waltham et al. 2005). This can be an important booster to gypsum karstification where halite is intercalated with anhydrite or gypsum. Dissolution of exhumed anhydrite is often associated with a transformation to gypsum, its "in situ" measured dissolution rate is approximately 20 times slower than that of gypsum, essentially because the latter is precipitating onto the anhydrite surface as molecules dissociate there (Ford and Williams 2007, p. 71).

Rates of halite karst can only be measured where halite is at or near the landsurface. This tends to be in zones of halokinesis in arid areas, otherwise halite is long dissolved before it can approach the surface. In the 14 km^2 area of the active salt diapir of Mount Sedom in Israel, in a region with an annual rainfall around 50 mm, Frumkin (1994a) estimated the regional karst denudation rate to be about 0.50–0.75 mm/year, with most of this occurring within the subsurface rocksalt mass rather than near the surface.

Whatever the mineralogy, an evaporite mass will rapidly dissolve when in contact with a crossflow of meteoric or undersaturated basinal water. So, unlike carbonate karst, the effects of nearsurface evaporite solution on cavern formation and land surface subsidence are obvious in time frames measured in years, not millennia and the associated visible effects of this rapid collapse can be impressive[1] at the human perception scale.

This chapter deals with subsurface and near surface regions where hypersaline depositional and burial hydrologies are replaced by pore waters undersaturated with respect to the various evaporite salts. This situation is ubiquitous, it occurs wherever ancient evaporites are exhumed and once again enter the active phreatic (telogenetic) zone. Dissolution is also typical of evaporites in the deeper subsurface (mesogenetic realm) wherever undersaturated basinal waters are flushing the edges of impervious evaporite beds (Chap. 8). Dissolution leaves behind solution breccias and other indicators of the former presence of now-leached evaporites (vanished evaporites or "the salt that was").

Even as an evaporite bed accumulates, or soon after its deposition ceases, pore waters in the depositional environs can be periodically freshened, either by climatic excursions or by progradation of sheetwash/fluvial/marine flood sediment. In this scenario karstification is part of the ongoing

[1]The cluster of water-filled sinkholes atop dissolving evaporites and locally known as "Hell's Kettles" (Lat 54.492655, Long −1.567459) located to the south of Darlington, UK, formed in 1179 AD via a catastrophic collapse of the landsurface. A twelfth century annalist describes their formation as follows:

"In the reign of Henry II, the earth rose high at Oxendale, in the District of Darlington, (Oxendale is now Oxney flat) in the likeness of a lofty tower, and so remained from nine in the morning until evening, when it sank don with a terrible noise, to the terror of all that heard it, and being swallowed up it left behind a deep pit."

After the collapse the local clergy had a field-day; the "Hell's Kettles" dolines have long been reputed to be bottomless pits, said to harbor the tortured souls of the sinful dead.

depositional story and explains many microkarst textures described in Chap. 1. In one of the first uses of the term "the salt that was," Schreiber and Schreiber (1977) described Miocene gypsum beds in Sicily where early halite layers were seasonally dissolved, even as the gypsum bed was accreting. This is an example of the syndepositional end of a salt dissolution spectrum that extends into much longer time frames that encapsulate the burial and metamorphic realms.

At a millennial time scale, periodic evolution of a syndepositional hypersaline hydrology into a less saline groundwater system creates karst effects and textures at the contact between the evaporite bed and its overburden. This can drive freshened pore water ingress and karstification of the upper few metres of an accumulating evaporite bed. This scenario is typical of many continental playas where fluvial and bajada sediments periodically build out over a saline pan, or where marine transgressions pass over saltern beds. Its effects are discussed later in this chapter in the section dealing with syndepositional karst. But most of the chapter deals with the various outcomes and indicators of longer time frames where overburden is indurated and the dissolution process effects deeper subsurface (meso-genetic) and uplifted (telogenetic) bedded and diapiric salts.

Because of their high solubility, exhumed ancient evaporites outcrop best in arid or frozen regions of the world. These are areas with lower crossflow volumes of liquid groundwater and so are zones where even halite can make it back to the shallow subsurface, before complete disintegration (Fig. 6.84). Exhumed anhydrite typically converts to gypsum some tens to hundreds of metres below the landscape over those areas of the world featuring subcropping and outcropping evaporites. This telogenetic gypsum has a fresh set of textures that make it difficult to interpret its original depositional fabric. Subcropping halite, with its much higher solubility, tends to dissolve completely before reaching the surface. In all but the most arid environments, gypsum, not halite or anhydrite, is the commonplace outcrop expression of an underlying evaporite mass, be it bedded or halokinetic.

Outcropping gypsum caprock, with well-developed karst, encases salt diapirs in the Middle East, north Africa and central Australia and defines halite subcrop in the Qinghai (Tibetan) plateau, the Pecos Valley of West Texas, the Magdalen Islands in the Gulf of St. Lawrence, Canada, and in the Sierra del Fraile, in northeastern Mexico (Fig. 7.2). Gypsum capstones can occasionally outcrop in humid tropical regions. For example, a gypsum caprock sporadically outcrops along the erosional banks of the Nam Theun River in Laos. This site lies within the axis of an evaporite-floored synclinal trough, it is surrounded by tropical pine forest, and caps an actively dissolving residual mass of stratiform Cretaceous halite (*pers. obs.*). Halite can reach the surface in arid zones where salt is actively flowing into diapirs and allochthons, as at Mt Sedom in the Dead Sea Valley and in the salt glaciers (namakiers) of Iran (Fig. 6.84).

Individual exposures of outcropping salts are usually no more than a few square kilometres, whereas dissolution breccias, insoluble residues and their characteristic subsidence terrains such as blind-valleys and suffusion karst, subcrop more widely, as do many other indictors of evaporites (Fig. 7.2). The mining of rock salt, or the drilling of boreholes into or through rock salt, have accidentally intersected or created caverns leading to a number of large, anthropogenically-enhanced collapse sinks, subsidence cones and subrosion[2] features, which are discussed further in Chap. 13. Natural karst hazards are discussed later in this chapter.

Complete evaporite dissolution means no salt remains, while partial or preferential dissolution means the vertical or lateral extent of the remaining salt sequence is reduced and the more soluble salts have gone. Salt bed dissolution can be syndepositional, as can nodule and crystal replacement, or can occur later during shallow burial with vadose or shallow phreatic groundwater flow driving cavern formation and overburden collapse. Bed alteration and solution can occur much later under deeper phreatic basin hydrologies, where circulation is driven by compactional and thermobaric flushing. It can occur later still, when uplifted salts beds are once again flushed by deeply circulating meteoric waters during collision, inversion and overthrusting (Table 7.2; Fig. 1.9).

Dissolution also occurs in the more enigmatic meta-evaporitic and igneous realms, where it is accompanied by deep burial mineral transformations such as scapolitisation, albitisation and tourmalinisation (see Chap. 14 for details). Evidence for vanished evaporites can remain in the rock record long after the actual salts have gone. This is why many indicators of ancient evaporites plot outside known salt basins (Fig. 7.2).

Brines generated at an evaporite dissolution front can seep into adjacent sediments where new authigenic evaporite cements and nodules precipitate. Dissolution brines can rise along brine escape conduits, such as faults and fractures, into the higher portions of the sediment pile, where they cool or mix with waters of differing chemistries and so precipitate authigenic cements. Although dissolutional hydrology is transitory, the evidence of former evaporite beds –the evaporite that was– is permanent and ranges from dissolution breccias and residues, to replaced evaporite crystals and nodules, to authigenic evaporite cements near flow conduits such as unconformities, faults and fractures.

[2]The term subrosion refers to the burial-related dissolution of salt.

Evaporite Landforms

As salt dissolves in the shallow subsurface it creates void space into which overlying strata can drape or brecciate to create characteristic landforms at both local (m to km) and regional (km to tens of km) scales (Fig. 7.3). We can divide solution-related landforms into two styles: active karst and palaeokarst. Paleokarst refers to ancient karstic features that are no longer active and were tied to basinal flushing hydrologies or landsurfaces no longer present. Active karst is responding to the ambient hydrology and typifies the landscapes discussed in the following section.

Local Scale Karst

Regions underlain by an evaporite subcrop exhibit dissolution landforms similar to carbonate karst and so include many varieties of karren, sinkholes (dolines), blind valleys and poljes (Ford and Williams 1989). Bedrock exposures of gypsum or salt at a finer scale are sculpted into irregular surfaces called rillenkarren and other solution flutes (Macaluso and Sauro 1996; Stenson and Ford 1993). Local-scale karst features that define subsidence basins range in lateral extent from the metre-scale cones of suffusion karst to kilometre-scale doline depressions (Fig. 7.3).

Dolines or Sinkholes

Dolines (aka sinkholes) are closed circular to elliptical hollows or depressions, often funnel shaped, with diameters ranging from a few metres to a few kilometres and depths from a metre or so to hundreds of metres (Fig. 7.3; Ford and Williams 2007). They indicate subsidence and collapse of underlying salt or carbonates. Valley sides may be steep and can expose karstified gypsum, or be gentle and covered by desert soils. Active sinkholes atop shallow bedded evaporites typify terminations of dry arroyos in many deserts. Larger sinkholes may enclose one or more smaller sinkholes and can be further subdivided into collapse, suffosion and solution dolines (Fig. 7.3). A collapse sinkhole forms by the collapse of a roof span into an underlying solution cavity. Suffosion dolines are smaller features (1–5 m diameter) covered and filled with soils and debris washed into its fissures by rainfall or sheetflood. They indicate that the dissolving salt mass is close to the landsurface. Solution (subsidence) dolines tend to be larger downwarped doline craters or bowl-like subsidence depressions. Compared to collapse and suffusion dolines they have lower slopes into the deeper parts of the doline, the doline walls are usually hosted in nonevaporites and the dissolving salt bed can lie some distance below the landsurface. At the larger end of the scale of doline development a subsidence doline merges into a subsidence basin. This is a large solution hollow that creates enough accommodation space to be considered a small sedimentary basin, which is filling with varying combinations of fluvial and lacustrine sediments.

Dissolution, collapse and suffosion are more active, more rapid, more frequent and more obvious in evaporite compared to carbonate terranes. In the Perm and Bashkir regions of Russia, Gorbunova (1979) reported doline densities atop weathering evaporites and carbonates of 32 and 10/km^2 respectively, although densities up to 1,000/km^2 can occur in many evaporite-cored fold axes or at contacts of evaporites with other lithologies. Densities of 1,100–1,500/km^2 have

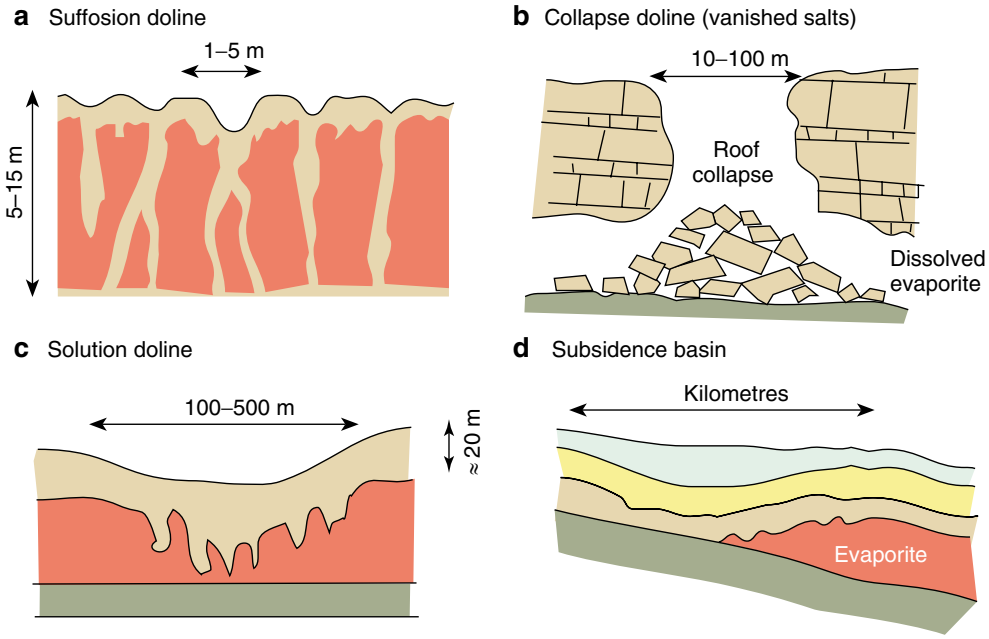

Fig. 7.3 Typical scales and origins of evaporite karst features formed at the land surface, atop a dissolving evaporite unit (*red*). See text for details of **a**–**d**

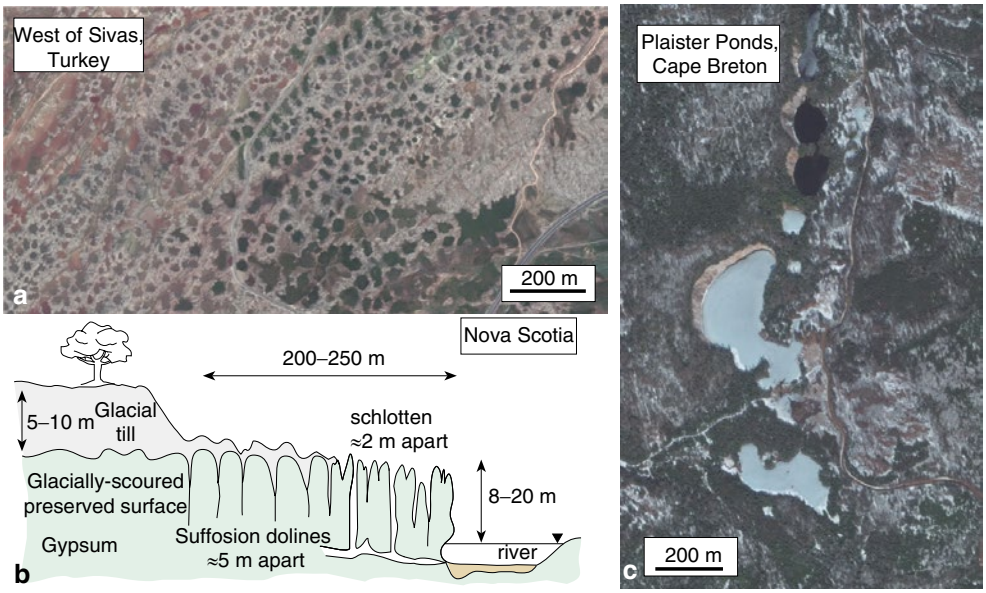

Fig. 7.4 High densities of dissolution depressions on evaporites. (**a**) Karst polygon terrane atop a Miocene gypsum outcrop (Hafik Fm.), some 20 km west of Sivas, Turkey. (**b**) model of suffosion karst development on subcropping till-covered gypsum (Carboniferous) in Nova Scotia, Canada. (**c**) Natural water-filled steep sided collapse dolines known as Plaister Ponds, near Baddeck on Cape Breton Island (Scaled Bing® images mounted and scaled in MapInfo)

been documented in evaporite karst in the Italian Alps and in regions to west of Sivas, Turkey (Fig. 7.4a). Such high densities occur in regions of high hydraulic gradients and mean the dolines have diameters around 5 m or less (Belloni et al. 1972). The inherently high solubility of evaporite salts also explains densely-packed schlotten depressions and large karren shafts seen in gypsum karst of the Sivas region of Turkey and Antigonish County, Nova Scotia, where extrapolated doline densities in the latter case range up to 10,000/km^2 (Fig. 7.4a, b; Kacaroglu et al. 1997; Martinez and Boehner 1997). Extrapolated, because such dense networks do not extend over any more than a square kilometre or two and are typically found near retreating escarpment edges underlain by shallow subcropping salts.

Suffosion Dolines

High levels of dispersed impurities (mostly clays and muds, often dolomitic) in a rapidly dissolving evaporite mass, means a soil or carapace of insoluble residues quickly covers the subcropping top and edges of a dissolving salt mass (Figs. 7.3a and 7.4a). This carapace is continually undermined by ongoing rapid solution so that residual debris is washed into the doline crevices. This creates characteristic soil-covered dimpled landscapes that typify high-density doline terrains. Suffusion is a form of mantle karst where the dissolving salt bed is never more than a few metres below the landsurface.

Collapse Dolines

Collapse dolines are steep-sided sinkholes, often defined by cave entrances (Fig. 7.3b). They form when solution of an underlying evaporite bed creates a roof span in the regolith that can no longer be supported by the overlying lithology. Doline walls are frequently asymmetrical; one wall is steep and the other one is gentle. Steep-sided collapse dolines are typical of regions with unconsolidated overburden, such as glacial till (Fig. 7.4c). Doline floors, when not water covered, tend to display either concave-up or flat geometries. Apart from blocks of the collapsed roof span, active doline floors can be veneered by thin collapse breccias. The high density of dolines in areas of evaporite subcrop and the ubiquity of the associated breccias indicates the inherently higher solubility of the evaporite salts compared with interbedded and overlying carbonates.

Solution Dolines

Larger sinkholes (subsidence dolines) with characteristic low angle widespread edge flexures and slopes indicate deeper, more widespread salt dissolution compared to collapse dolines and are linked to the creation of a bowl of subsidence (Fig. 7.3c). They occur in most regions of deeper evaporite karst including; Italy (Belloni et al. 1972; Burri 1986; Ferrarase et al. 2002), Spain (Gutiérrez 1996) and the Pecos Valley of West Texas and New Mexico (Gustavson et al. 1982; Davies 1984a, b; Quinlan et al. 1986). In contrast to the numerous small steep-sided suffosion and collapse dolines formed atop shallow subcropping shallow evaporites, these larger, bowl-like dolines can have diameters of 100–500 m and depths of 10–20 m. Most have a soil cover and a thick sediment fill, with dissolving salt units at depths measured in tens to hundreds of metres below the land surface. They are mature dissolution forms and are transitional to subsidence basins where even thicker more widespread sediment fills are to be found (Fig. 7.3d).

Following the definitions of Waltham et al. (2005), Gutiérrez (2010), constructed a nongenetic evaporite-related

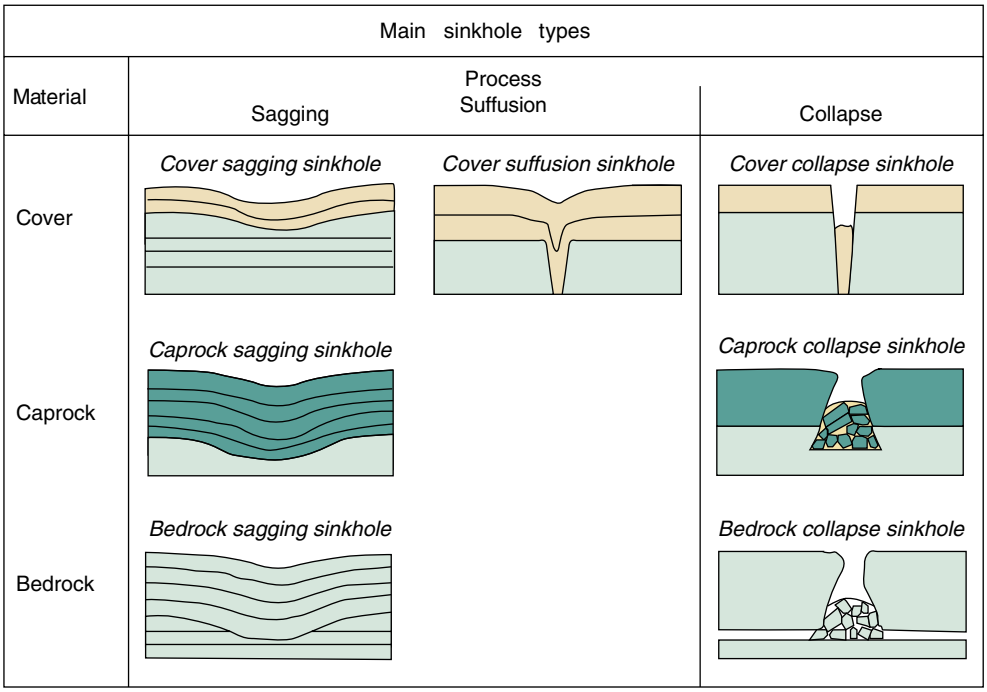

Fig. 7.5 Doline (sinkhole) classification for features found in a landscape underlain by dissolving evaporites, indicated by *light green* (After Gutierrez 2010; Waltham et al. 2005)

subsidence dolines or sinkholes classification based on terms that refer to the material affected by downward gravitational movements (cover, bedrock or caprock) and the main type of process involved (collapse, suffosion or sagging; Fig. 7.5). The classification also applies to carbonate karst. The term "cover" refers to allogenic unconsolidated deposits or residual soil material, bedrock to karst rocks and caprock to non-karst rocks. Collapse indicates the brittle deformation of soil or rock material either by brecciation or the downward migration deposits through conduits and its progressive settling, while sagging is the ductile flexure (bending) of sediments caused by the lack of basal support. In practice, more than one material type and several processes can be involved in the generation of sinkholes. These more complex sinkholes can be described using combinations of the proposed terms with the dominant material and/or process followed by the secondary one (e.g. cover and bedrock collapse sinkhole, bedrock sagging and collapse sinkhole),

The cover material may be affected by any of three subsidence mechanisms. The progressive corrosional lowering of the rockhead may[3] cause the gradual settling of the overlying deposits by sagging, producing cover sagging sinkholes. An important applied aspect is that the generation of these sinkholes does not require the formation of cavities. These depressions arc commonly shallow, have poorly defined edges and may reach several hundred metres across.

Cover deposits may migrate downward into fissures and conduits developed in the rockhead by action of a wide range of processes collectively designated us suffusion: downwashing of particles by percolating waters, cohesion-less granular flows, viscous gravity flows (non-Newtonian), fall of particles, and sediment-laden water flows. The downward transport of the cover material through pipes and fissures may produce two main types of sinkholes depending on the rheological behaviour of the mantling deposits. Where the cover behaves as a ductile or loose granular material, it may settle gradually as undermining by suffosion progresses. This creates sags and slumps in the overburden materials. Where cover behaves in a more brittle manner, collapse breccias form.

Sinkholes that result from the combination of several subsidence processes and affect more than one type of material are described by combinations of the different terms with the dominant material or process followed by the secondary one (e.g. bedrock sagging and collapse sinkhole). The mechanism of collapse includes any brittle gravitational deformation of cover and bedrock material, such as upward stoping of cavities by roof failure, development of well-defined failure planes and rock brecciation. They define suffosion as the downward migration of cover deposits through dissolutional conduits accompanied by ductile settling. Sagging is the ductile flexure of sediments caused by differential corrosional lowering of the rockhead or interstratal karstification of the soluble bedrock. Sag plays an important role in the generation of sinkholes in evaporites (not included in previous genetic classifications mostly based on carbonate karst). They conclude collapse processes are more significant in extent and rate in areas underlain by evaporites than in carbonate karst, primarily due to the greater solubility of the evaporites and the lower mechanical strength and ductile rheology of gypsum and salt rocks.

[3]Rockhead is the buried interface between the underlying bedrock and its soil cover.

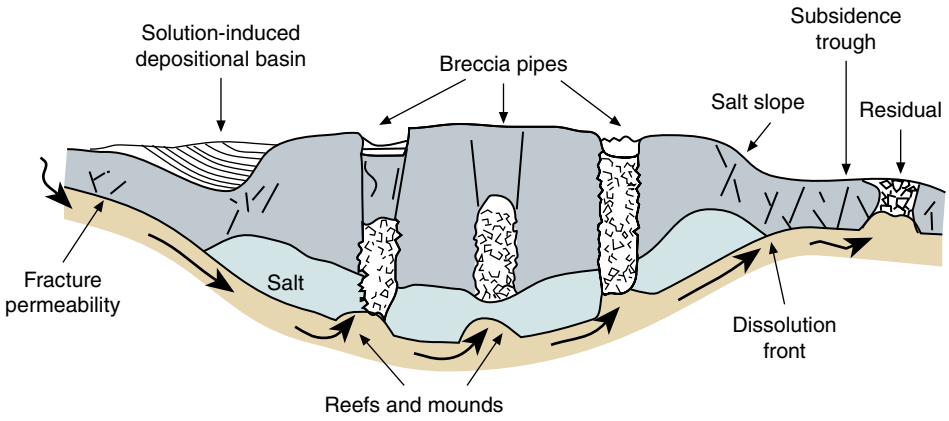

Fig. 7.6 Interrelationships between larger scale dissolution features, artesian flow and various types of upward stoping breccia pipes (not to scale; in part after Ford and Williams 1989)

Breccia Chimneys and Pipes

Breccia pipes develop as steep-sided chimney-like features on the same scale as collapse dolines or sinkholes and show typically circular outlines at the surface. Some consider them a subset of caprock collapse dolines and tie them to a specific process set namely formation by progressive upward stoping from the base of the salt bed, not its upper portions. This contrasts with the subsidence/sag-dominated set of process set that creates most meteoric suprasalt dolines. In regions of thick evaporites the stoping process is driven by the focused upward escape of undersaturated basinal or deeply circulating meteoric waters leaking from levels below the sealing evaporite bed. Waters creating a stoping pipe can be focused into point or line sources via underlying biogenic buildups or fracture networks (Fig. 7.6). Quinlan (1978) reviewed the nature and distribution of more than 5,000 breccia pipes within or atop salt or gypsum in the United States. Pipes ranged from 1 to 1,000 m in diameter and up to 500 m in depth. Similar crosscutting pipes in halite of the Devonian Prairie evaporite interrupt workings of potash mines in Saskatchewan, where they may propagate from depths as great as 1,200 m, and may lie beneath a thousand or more metres of cover strata (Figs. 7.7). Unexpected intersection with a breccia pipe in an exploited bed can lead to catastrophic flooding and ultimate loss of a mine (Figs. 11.69 and 11.75).

One of the most impressive regions of widespread and well-documented breccia piping is seen in the coal mine regions of northern China. There, more than 2,800 breccia pipes have been recorded in the mines of Shanxi and Hebei regions (Lu and Cooper 1997). The pipes originate in Ordovician gypsum, interbedded with limestones, and passing upwards through the Permo-Carboniferous coal measures. Vertical transmissivity in the pipes creates a major mining hazard due to large volumes of entrained water, which are more than sufficient to flood a mine. Pipes vary in diameter from tens of metres to hundreds of metres, with the larger pipes transecting more than 500 m of overburden. Some have reached the modern landsurface, others are blind chimneys. Pipe densities reach 70 per km^2 in the Shanxi coal basin, where more than 1,300 pipes occur. Interestingly, most of the pipes are located about the margin of the coal basin and none are known in the deeper parts of the Shanxi basin centre.

Breccia pipes in an evaporite mass may exhibit one of four possible states (Fig. 7.6): (a) Active, and propagating upwards towards the surface, but not yet expressed there – a blind chimney; (b) Active or inactive, expressed at the surface as a closed depression or a depression with a surface outflow channel; (c) Inactive, and buried by later strata – paleokarst chimney; (d) Inactive and standing up as a positive relief feature on the landsurface because the breccia (probably cemented) is more resistant to weathering than the upper cover strata – a residual pipe. Downward flexure in the uppermost strata atop a growing pipe forms a bowl of subsidence and sinkhole.

In some intrasalt pipes the halite or gypsum is entirely removed, leaving only an accumulation of insolubles and collapsed breccia blocks. In others, portions of the less soluble salts remain in the pipe. Mature pipes are typically filled by a jumble of intrasalt and suprasalt breccia blocks. In some, a lower brecciated zone is succeeded by an upper zone in which the overlying strata failed as a coherent block, settling downwards via a cylindrical pattern of steep to vertical faults with downthrows of up to 200 m.

Landscape Residuals; Karst Domes and Castiles

Karst domes remain as features of positive relief once the surrounding evaporite mass has completely dissolved. Unlike chimneys, the cores of evaporitic karst domes can expose blocks from below, as well as above the original salt level. Some evaporitic karst domes are related to the stratigraphic level of former bedded salt, others are the remains of now dissolved salt thrusts, diapirs and allochthons (see diapiric breccias and rauhwacke). Domes and residuals are dramatic landscape features in the gypsum terrain of northern Alberta, Canada (Wigley et al. 1973; Tsui and Cruden 1984) and the Arkhangelsk gypsum karst region inland of the Barents Sea coast of Russia (Korotkov 1974). Canadian karst domes range from 10 to 1,000 m or more in length or diameter, and can rise up to 25 m above the surrounding land surface.

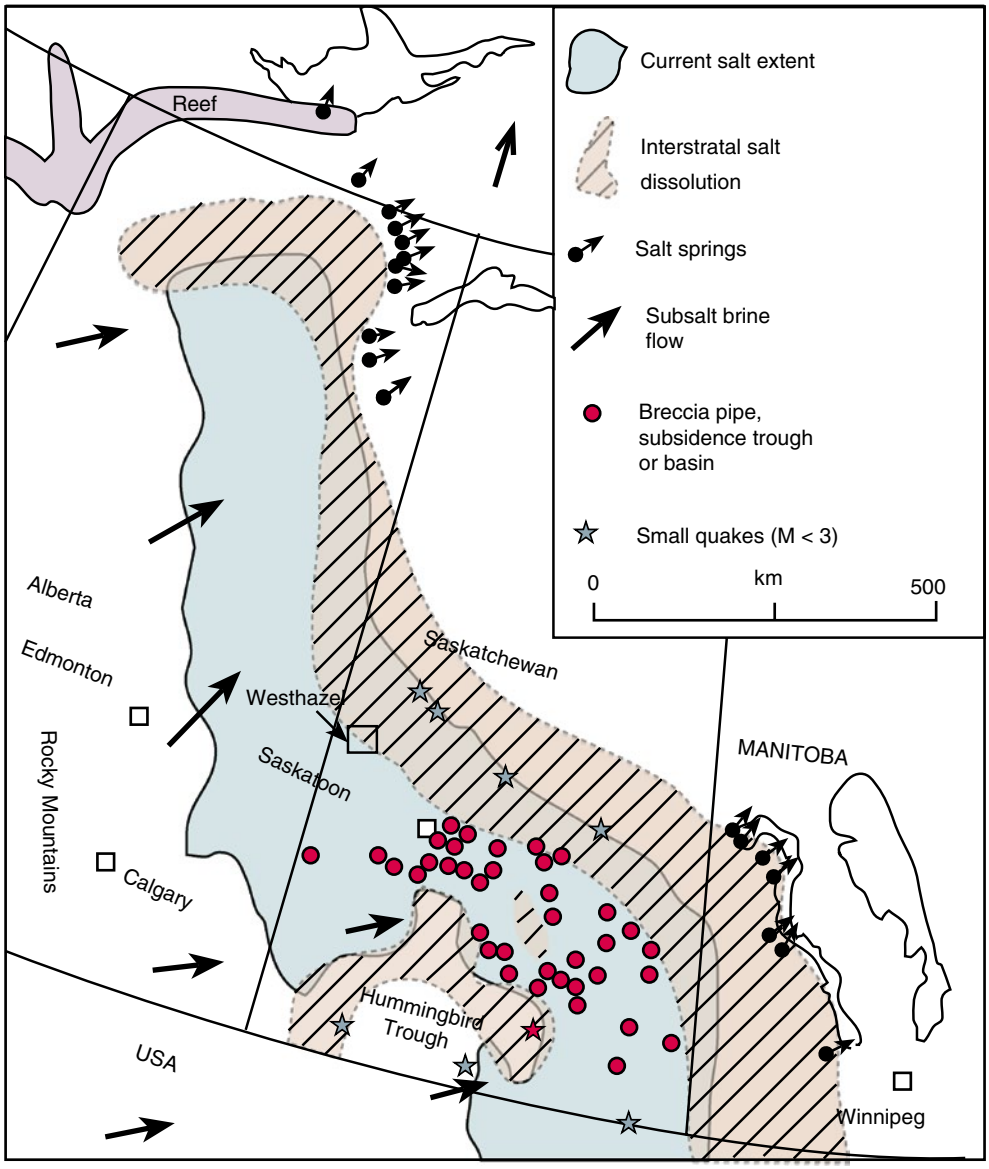

Fig. 7.7 Regional distribution of evaporite karst features in the Prairie Provinces of Canada, including a large subsidence basin known as the Hummingbird Trough. These features were created by the dissolution of thick widespread Prairie Evaporite at various times from the Devonian to the present (In part after Ford and Williams 1989)

Many domes are highly fractured, with individual overburden blocks displaced by heaving and sliding, with the residual gypsum showing well-developed flow foliation.

At the extreme end of disturbance and dissolution the domes are megabreccias; positive relief features made up of upthrust jumbles of large blocks the size of houses. The largest reported Canadian example is in a steep-limbed anticline that extends along the shore of Slave Lake for a distance of 30 km, it is up to 175 m in height with a crest that is marked by a 'chaotic structure and trench-like lineaments' (Aitken and Cook 1969). These spectacular karst domes occur in regions of widespread permafrost so that accumulation of ground ice in initial fractures in the evaporite layer probably contributes to the heaving, folding and other displacement of breccia fragments in the dome. Tsui and Cruden (1984) attributed the examples that they studied in the salt plains of Wood Buffalo National Park Canada (Lat. 59–60°N) to hydration processes operating on subcropping bedded gypsum during the postglacial period. Ford and Williams (1989) argued such features indicate local injection of gypsum residuals during times of rapidly changing glacial ice loading. Whether they are created by glacial unloading/reworking or are a type of gravitationally-displaced dissolution breccia in a permafrost region is debatable; that they are a type of evaporite residue is not. They characterise parts of the region defined by dissolution of shallow subcropping Devonian salt in Northern Alberta.

Residuals composed of cemented sinkhole or breccia pipe fillings can create hills surrounded by lower relief remnants of the former host bed (Fig. 7.6). More than a thousand such hills occur on the gypsum plains of western Oklahoma (Fay and Hart 1978). Those karst mounds or hills with a doughnut

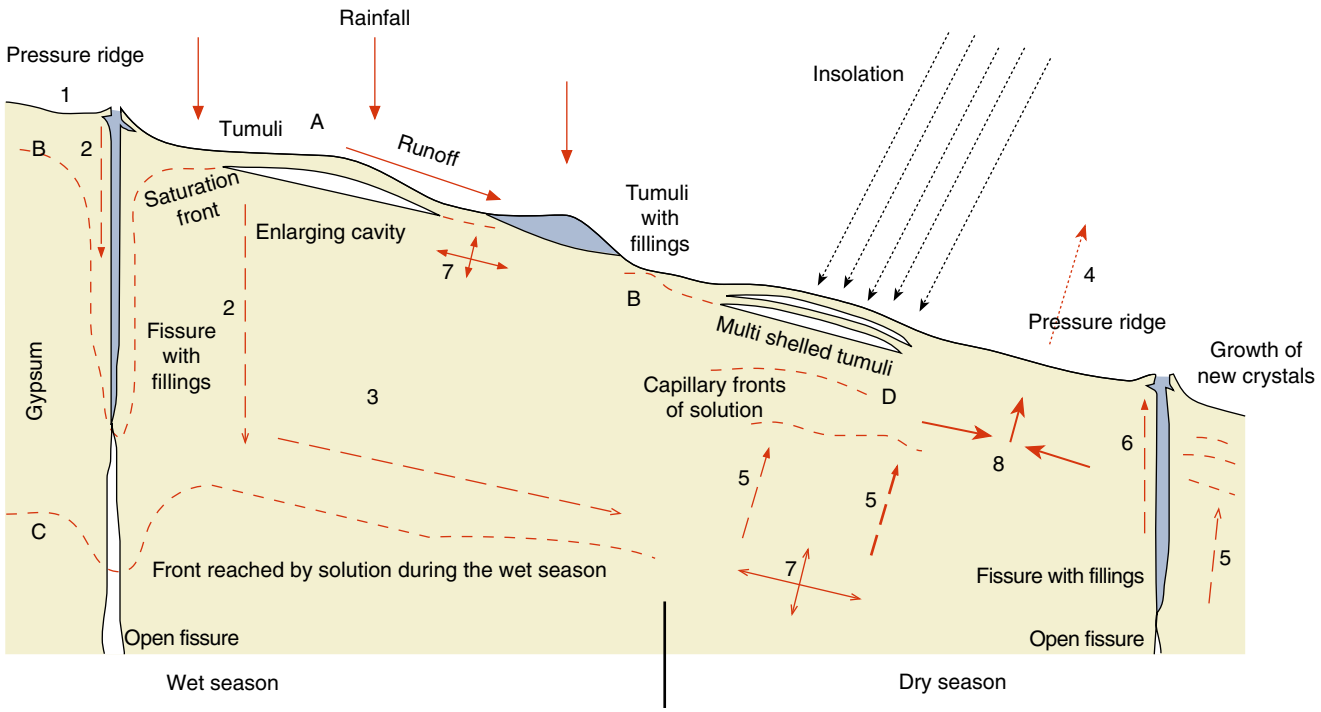

Fig. 7.8 Main processes occurring inside an outer gypsum layer directly exposed to the atmosphere in a typical Mediterranean climatic regime. During wet winters, rainfall drives an overland flow and the water dissolves the gypsum at the surface (*A*) while a portion of the runoff manages to penetrate inside the intercrystalline pores of the rock. The water reaches saturation (with $CaSO_4$) at the surface and a few decimetres into the rock (the *B* line (dashed) may be considered a saturation front). The solution continues to penetrate both inside the pores and along fissures and joints (*2*), creating a downward reaching front of newly arrived meteoric water (*C*). Nearsurface water in this front can also flow laterally (*3*). During the dry season, the pores lose water by evaporation (*4*). The inner solution becomes oversaturated and moves by capillary action towards the surface (*5*). In the *D zone*, there is precipitation of gypsum both by evaporative loss and by brine heating as it approaches the landsurface (gypsum has retrograde solubility). In the fissures and cavities, the pore fluids now migrate upwards (*6*) and new gypsum crystals may develop. The mass transfer from the inner towards the outmost zone results in pressure relaxation (*7*) in the *C zone*, where open fissures may exist, and in pressure increase (*8*) in the *D zone*. In soil-covered gypsum settings, runoff inside the sediment cover causes solution of the underlying gypsum both at the interface and in the fissures and other discontinuities of the rock. In this way, covered solution pavements and expansion tumuli can develop below the landsurface, and only become obvious after erosion of the soil cover (After Ferrarase et al. 2002)

form (a central depression), rather than a rounded form, are believed to be cemented expressions of former sinkhole fills within bedded evaporites, rather than residual breccia pipes (Myers 1962). Hills made up of cemented breccia pipe residuals are typically a few tens to hundreds of metres in diameter and can rise 5–40 m above their surrounds.

Castiles are another exhumed feature in a gypsum karst terrain. In their type area of the Delaware Basin, south of Carlsbad Caverns, NewMexico, they make up steep-sided hills and mesas rising 3–30 m above the Gypsum Plain (Kirkland and Evans 1976, 1980). They are composed of calcite, now exposed by the preferential dissolution of the surrounding bedded gypsum, in an area near the solution edge of the sulphate facies of the Castile Formation (Fig. 7.12). Similar features occur in areas of exhumed Miocene evaporites along the margin of the Red Sea (Aref 1998b). Castiles first form in the subsurface as a byproduct of the metabolic activities of sulphate-reducing bacteria, which locally replace gypsum with biogenic calcite (Figs. 7.63 and 9.65).

Evaporite Expansion Morphotypes at Outcrop

As well as the classic karst features, which are a response to dissolution and volume loss, some outcropping gypsum beds, especially in regions of anthropogenically induced rapid soil erosion, indicate local volume changes; as in parts of Sicily and Spain where weathered late Miocene gypsum is now exposed at the landsurface (Fig. 7.8). Such regions are characterised by extensive alteration and recrystallisation of the gypsum regolith and soil textures that indicate repetitive cycles of expansion and contraction of the nearsurface gypsum. The gypsum has evolved into pedogenic mounds and polygons related to exhumation into an active hydrology some millions of years after its deposition (telogenesis). The resulting medium-sized dome-like hills are covered by a mosaic of smaller landforms, related to different types of karren and of "expansion" forms such as tumuli and polygons. According to Ferrarase et al. (2002), the various gypsum morphotypes can be classified into two main categories: those that originated by solution and those that originated through recrystallisation.

Fig. 7.9 Gypsum tumuli, 1–3 m in diameter (colloquially known as "igloos"), growing in a capillary fringe on the margin of Salar de Agua Amarga, in the high altitude desert belt of the Andes. The host gypsum bed is Late Quaternary and predates the current halite system. (**a**) Field of Tumuli. (**b**) Close up of one the tumuli mounds shown in **a** (Photos courtesy of Tom Carpenter)

Outcrops of gypsum lacking soil cover and influenced by alternating seasonal water conditions of surplus and deficit are affected by both solution and recrystallisation processes. During the wet season, the water soaks into the rocky subcropping gypsum mass, filling all the fissures and pores of the outer layer from a few centimetres to some metres below the surface. During the dry season, there is a capillary-driven upward motion of the water solution. Near the surface, gypsum precipitates from the oversaturated solution, increasing the crystal size or forming new crystals. In this way, during the dry season, there is a pressure increase in the outer gypsum layers, which is responsible for the development of a "gypsum weathering crust." It is characterised by many different expansion forms such as gypsum tumuli, pressure ridges and pressure humps.

Tumuli (aka bubbles, tents or "igloos") are hollow subcircular domes, developed in pre-existing coarsely crystalline gypsum crusts in the uppermost stratum of the gypsum regolith. They vary from a few centimetres to several metres in diameter and reach maximum heights of a little over a metre (Fig. 7.9a, b; Ferrarase et al. 2002; Pulido-Bosch et al. 2004). Thicker crusts (≈1 m thick) support the development of mega-tumuli and dome-like hills 10 m or more across. Earlier studies in the Mediterranean and Canada interpreted tumuli doming as an indication of volume expansion related anhydrite rehydration. This is clearly not the case in the modern active examples illustrated in Fig. 7.9b where the host crusts retain its bottom-nucleated texture. Today, tumuli are interpreted as indicative of volume addition via capillary rise and not anhydrite alteration.

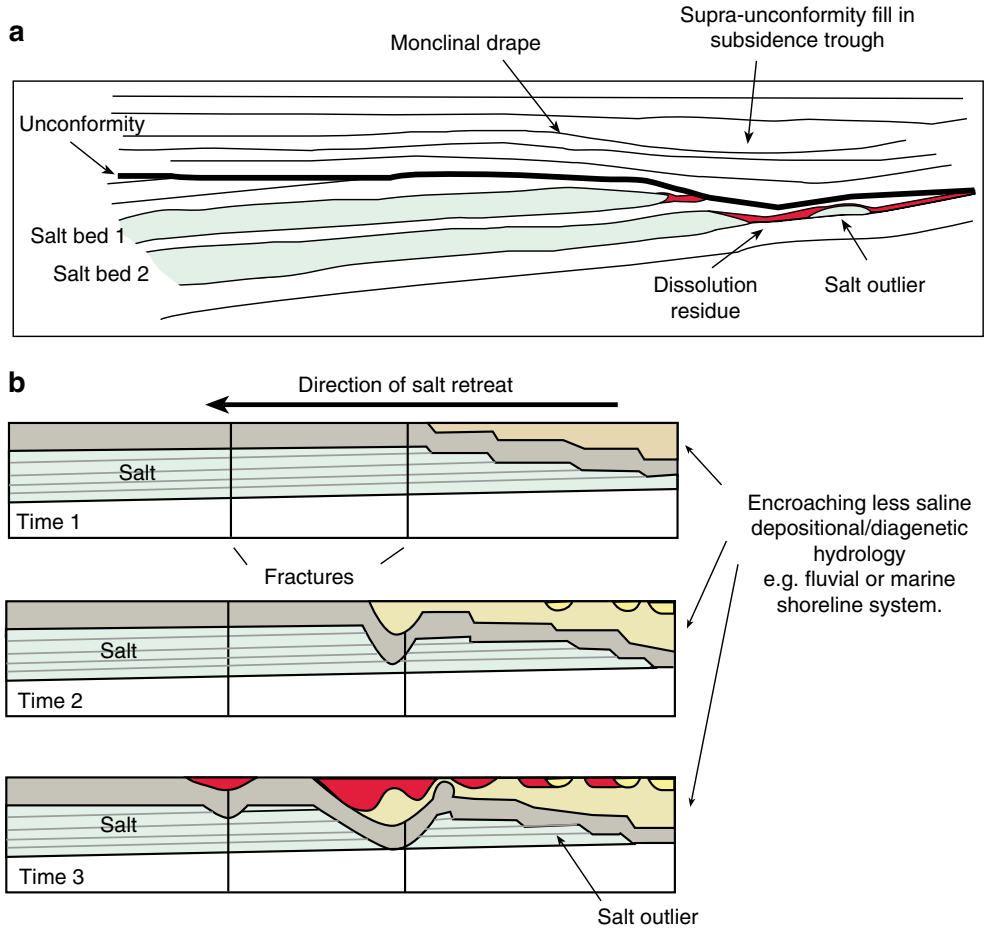
Stenson (1990) studied fresh development of tumuli in the floor of a gypsum quarry in Nova Scotia that was abandoned some 35 years earlier. In an area of a few hectares there were 69 new tents (inverted-v) or tumuli (rounded), ranging 0.8–8.2 m in diameter. Crustal hydration was apparent, but here the process may have been aided by mechanical 'pop-up' due to lithostatic pressure release in an artificial excavation. Development of dome-like tumuli-overprinted hills does not seem to be controlled by variations in strike, dip, or fissuring of the gypsum beds. Their evolution seems to be linked to the fact that on most of the tumuli surfaces the weathering crust is evolving through a nearly isotropic field of stresses, which is a result of capillary-driven volume increase in the outer gypsum layer giving an "igloo-like" appearance to some tumuli fields (Fig. 7.9; Ferrarase et al. 2002).

Regional-Scale Karst

The distribution of landscape features above an actively dissolving salt mass depends on the extent and depth of the underlying salt. That is, at the regional scale is the dissolving salt bedded or diapiric? Elongate depressions, known as subsidence troughs, tend to define the subcropping edges of shallow gently-dipping salt beds. In contrast, smaller zones of circular sinkholes, solution lakes and cenotes tend to form atop the crests of shallow diapiric salt. In regions where the crest of the halokinetic salt is still rising, there is ongoing retention of positive relief atop the structure, even though sinkholes and capstones are continually forming within this zone of positive relief. Salt dissolution and loss of volume facilitates gravitational extension in the overburden and can be expressed as active normal faults intersecting the land surface. In some cases these faults can be misinterpreted as tectonically, not sedimentologically, driven features (Gutierrez et al. 2012).

Subsidence Basins or Troughs

Subsidence troughs are large-scale elongate depositional depressions created by interstratal solution along the dissolving edge of shallow salt bodies. The largest solution-induced depositional basins tend to occur along the margins of the great interstratal halite deposits, creating a solution form that may be represented by a shallow salt slope at the surface (Fig. 7.6) They can be filled or partly filled by clastic sediments (Figs. 7.10a–c and 7.11; Olive 1957; Quinlan 1978; Simpson 1988). Salt-edge leaching of the shallow dipping



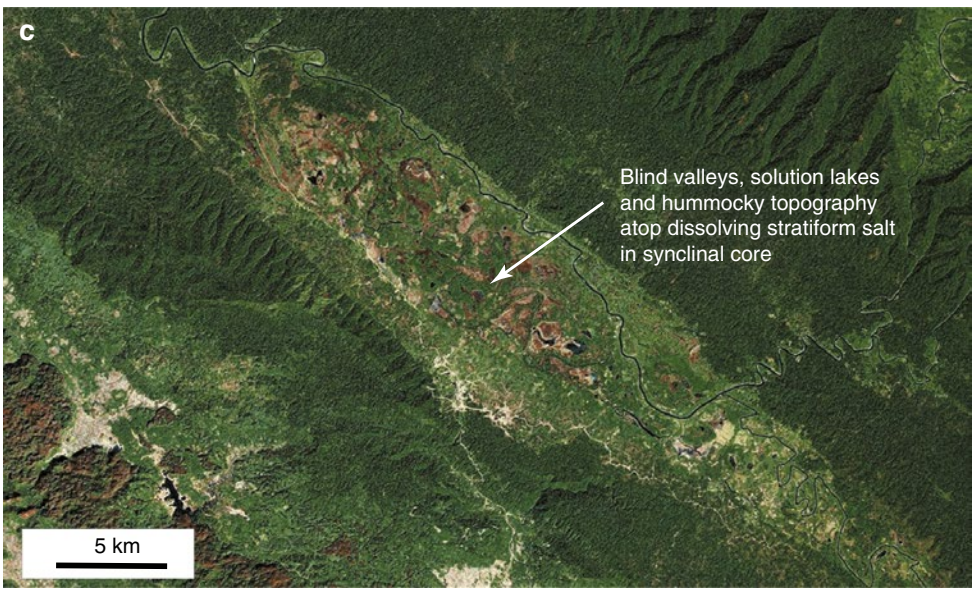


Fig. 7.10 (**a**) Subcrop salt dissolution creates characteristic sag geometries visible in seismic reflectors. (**b**) Schematic dip section showing the sequential development of a regional subsidence trough, based on studies of the Hutchison Salt Member, Kansas (Modified in part from Anderson et al. 1994a). (**c**) Nam Theun syncline, Laos, with Nam Theun River running along the northeastern edge of a dissolving stratiform salt mass that is equivalent to the Cretaceous Maha Sarakham salt of Thailand (17.709056 N, 105.22245 E; Landsat image courtesy of NASA)

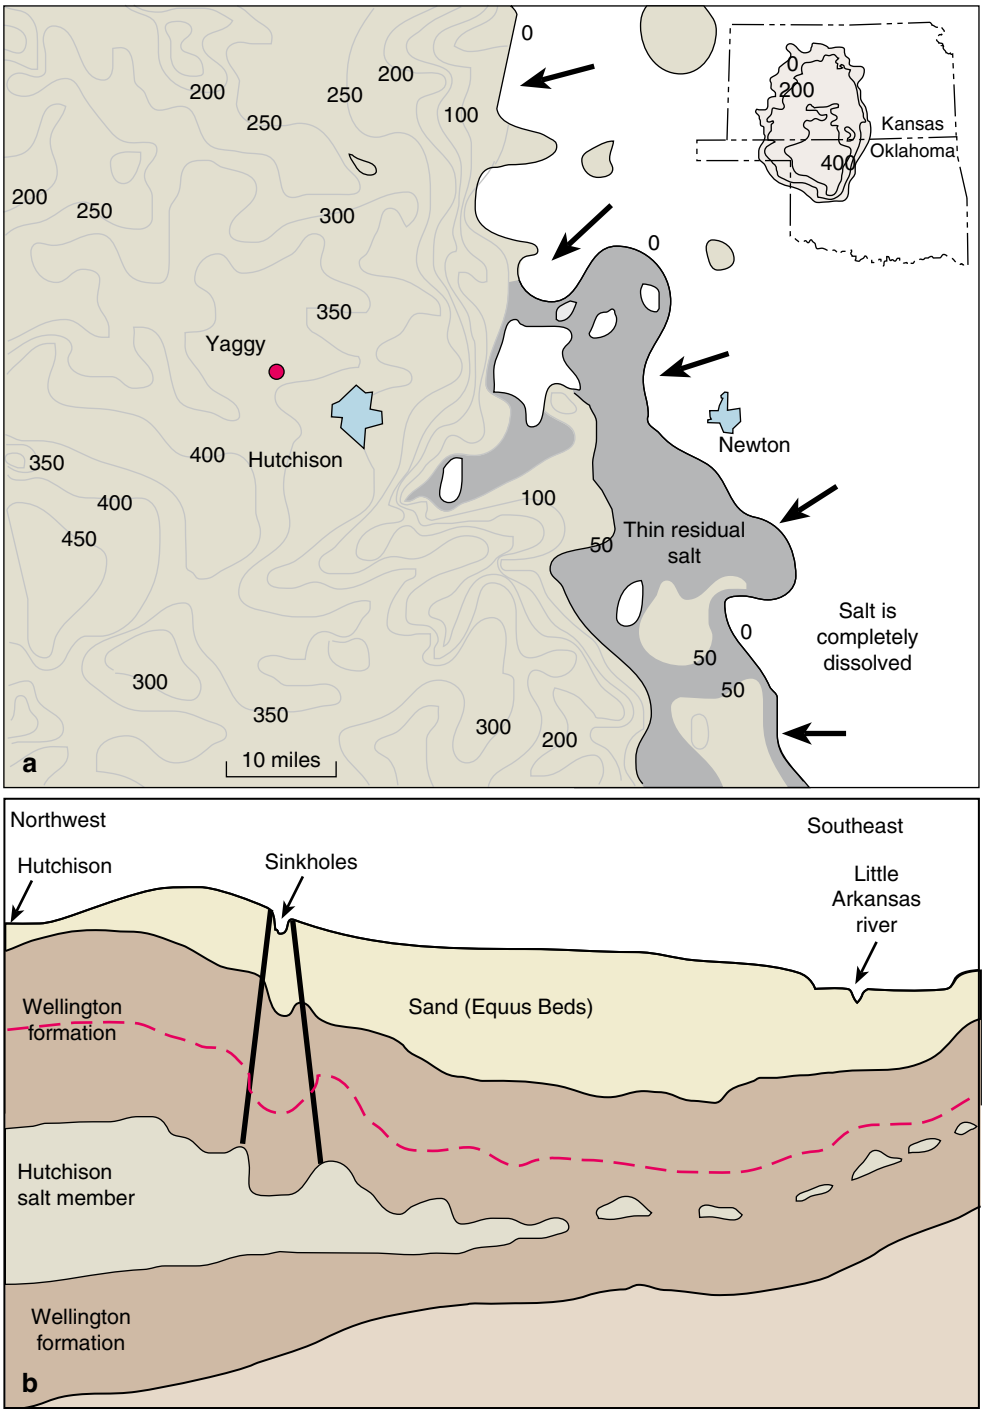

Fig. 7.11 Karstified edge of Hutchison Salt Member. (**a**) Thickness of the Permian Hutchison Salt, Kansas. *Arrows* indicate the direction of retreat of the dissolution feather edge of the salt body, Thickness is in feet and *grey shading* indicates salt thicker than 50 ft. Note the remnant outliers to the east of the dissolution edge (In part after Walters 1978). (**b**) Schematic east-west section in the vicinity of the town of Hutchison (After Watney et al. 2003)

salt underscores a set of self-perpetuating processes. Fractures created by the collapse of overburden and intrasalt beds into accommodation space (generated by salt cavities) provide new fissures and sinks that act as additional conduits for further percolation of meteoric or upwelling of undersaturated basinal waters into the salt. This in turn instigates yet more salt solution in the vicinity of the collapse and typically creates an elongate corridor of subsidence at the surface.

Large solution-induced depositional basins and monoclines outline the edges of the great interstratal salt deposits of the world. Depression corridors some 5–500 km long, 5–250 km wide, with up to 100–500 m of subsidence induced relief and sediment fill define saline karst plains along the edges of bedded and dissolving saline giants in the Devonian subcrop of Canada (Tsui and Cruden 1984), the Permian Basin of New Mexico, Oklahoma and Texas (Bachman

1984), the Perm region of Russia (Gorbunova 1979) and the Jurassic Hith region of Saudi Arabia (Amin and Bankher 1997a, b). Associated sediment infill typically reduces the regional solution edge landscape to a few tens of metres of relief. For example, the Rosetown Low and the Regina Hummingbird Trough accumulated more than 100 m of depression trough sediment during interstratal dissolution of the underlying Prairie salt (Devonian) in southern Saskatchewan (Fig. 7.10b; DeMille et al. 1964). The concurrence of a supra-unconformity thick, adjacent to the sub-unconformity feather-edge of a bedded salt sequence, is at a scale that is easily recognised in seismic and constitutes one of the classic signatures of a salt collapse-induced hydrocarbon trap (Figs. 7.10a and 10.91).

A solution depression tends to capture rivers that, via seepage loss, tend to be losing streams in the vicinity of the solution front, so encouraging further salt solution and collapse. Examples of modern fluvial capture by subsidence troughs include the nearsurface edges of the Hutchison Salt Member in Kansas, the Maha Sarakham Formation in NE Thailand and along the Nam Theun valley in Laos (Fig. 7.10c; Anderson et al. 1994a; Supajanya and Friederich 1992) and rivers in the Ebro Basin, NE Spain (Benito et al. 2000; Guerrero et al. 2013). The associated accumulation of fluvial and other sediments rapidly fill most modern solution troughs, so that surface relief is usually no more than metres to tens of metres across the subsidence corridor. Pleistocene and Holocene sedimentation rates in active US and Canadian subsidence corridors are ≈5–10 cm/1,000 years. The Uralian troughs of the former Soviet Union are no longer active and so show somewhat lower rates of 0.3–3 cm/1,000 years.

Interestingly, the foci of many small recent Saskatchewan earthquakes (magnitude <3–4 on the Richter scale) are located near the dissolving edge of the Prairie Evaporite salt (Fig. 7.7; Gendzwill and Unrau 1996). As bedded salt dissolves, support is removed from the overburden, which then slumps. If the overburden is weak or extensively fractured, it settles quietly. However, if the overlying rock is an indurated carbonate, it may resist movement, forming a bridge over the growing cavern. The roof span can fail violently when the undermined area gets large enough, so causing a small earthquake. Dissolution of the salt is possibly localized by faults and fractures, which provide seepage paths for the entry of undersaturated ground waters. Landscapes above many of the small Saskatchewan earthquakes lack extensive solution lakes, implying they may be sites upward stoping breccia pipes that have not yet breached (blind chimneys). Similar scale earthquakes can also define times of catastrophic failure in some salt mines and brine fields. On March 12, 1994 a 3.5 M quake documented the collapse of a mine panel in the Retsof Mine near Cyberville, New York state. Ensuing flooding caused the loss of the mine, which was until then the largest salt mine in the United States (Fig. 13.31).

Hutchison Salt, Kansas

As well as their vertical expression being maintained by dissolution, subsidence troughs also migrate laterally, mirroring the retreat of the dissolving salt front (Figs. 7.10b and 7.11a). The westward-dipping Hutchinson Salt Member of the Permian Wellington Formation is 50–90 m thick and underlies much of central and south-central Kansas. Ongoing edge dissolution since the late Tertiary has created a subsidence corridor with contemporaneous valley-fill of Quaternary alluvium. In places, the alluvial fill extends more than 25 km to the east of the present-day edge of the main body of contiguous rock salt. The salt margin has receded this distance over the past several million years. Subsidence and collapse atop the active dissolution front creates numerous sinks, blind valleys and other salt karst features in the land surface and a pockmarked irregular thickness in the shallower parts of the salt bed (Fig. 7.10b).

Oil well drillers call this region of dissolution cavities and fractures the "Wellington Lost Circulation Zone" and it extends for more than 100 miles N-S parallel to the dissolution edge of the salt bed (Fig. 7.11a). Hutchison Salt is leaching vertically from the top down, and horizontally inward along the outer edge of the salt shallow dipping salt bed. Dissolution is driven by sustained contact with a crossflow of unconfined and undersaturated groundwater. As a result, over distances of 5–15 km westward, the eastern margin of the dipping and dissolving salt bed thickens by up to 90 m (from east to west). Locally, the salt member is preferentially leached along NNE-trending palaeoshear/fracture zones to leave behind thick stepped outliers (Fig. 7.11b). Walters (1978) calculated an average lateral retreat of 3.2 km per million years since the late Pleistocene. He also pointed out that this rate is not constant. Dissolution was more rapid in the Early Pleistocene as the salt front was shallower. Now, when the front affecting the shallow dipping beds is deeper, groundwater crossflow and associated dissolution is slowing.

Natural subsidence and the rapid appearance of collapse dolines atop the dissolving Hutchison Salt Member has resulted in periodic ponding of surface waters in numerous dolines, abandonment of at least one oil well, and ongoing damage to numerous county roads (Figs. 13.42 and 13.53). Because this damage can be in the vicinity of an oilfield, much of the surface subsidence has been popularly attributed to poorly controlled drilling and development by unscrupulous oil companies. Any subsidence that occurs significant distances from any known well site is popularly attributed to unrecorded abandoned wells or complex asymmetric patterns of salt dissolution that originates at a drillhole. To test the validity of this widely accepted anthropogenic salt-dissolution model, so popular with the environmental movement, a 4 km seismic reflection profile was acquired along an east-west-oriented county road adjacent to an abandoned oil

well (Anderson et al. 1998). The expectation was that the residual Hutchinson Salt Member would be anomalously thin near an area of historical subsidence such as near the Burton oilfield. It should be thicker away from intensely drilled areas. Contrary to expectations, the residual Hutchinson Salt Member is relatively thick (20–30 m) below areas of significant recent surface subsidence.

Nor is there any evidence of recent surface subsidence at locations along the seismic profile where the rock salt edge has been totally leached. Dissolution and subsidence at these sites largely predates European settlement of Kansas. Sinkhole development via catastrophic collapse is a natural phenomenon and should be expected along this irregular salt dissolution front that forms atop and beneath a salt unit. Anderson et al. (1998) concluded that no modern catastrophic sinkhole development in the area has a clear-cut anthropogenic cause. As in the Prairie Evaporite, it seems focused collapse is largely a natural process influenced strongly by pre-existing geologic conditions. But, the rate and extent of collapse can be anthropogenically enhanced, typically in the vicinity of a few poorly completed wells, abandoned prior to the 1950s when the industry and society in general had a very different attitude to the landscape. These anthropogenic hazards combined with pressurized gas storage in shallow bedded salt in the presence of old poorly-documented brine solution wells has had some tragic outcomes (see Hutchison gas explosion; Chap. 13).

Natural salt karst collapse occurs quickly, well within a human lifetime. We cannot greatly influence the process of salt karst collapse, so we should plan geographic placement of infrastructure so that as much as possible it avoids it.

Delaware Basin, West Texas

The Delaware Basin of West Texas and southeast New Mexico, in the southwest portion of the Permian Basin, contains bedded evaporites of the Late Permian Castile, Salado and Rustler Formations. Outcrops and subcrops of these three formations constitute an area of widespread subsidence troughs, collapse sinks, dolines and breccia chimneys, all created by ongoing removal of underlying bedded Permian salts. The Delaware is an eastward-dipping basin, largely surrounded by the Capitan Reef and its equivalents (Fig. 7.12). The area called the "Gypsum Plain" of Texas lies to the west of the Pecos River and comprises about 2,600 km^2 of subcropping gypsum of the Castile Formation (Olive 1957; Quinlan 1978; Kirkland and Evans 1980; Anderson 1981; Stafford et al. 2008a, b; Holt and Powers 2010). South of Carlsbad and Carlsbad Caverns, the plain exhibits many small examples of solution subsidence troughs, typically 0.7–15 km in length, 100–1,500 m wide, but no more than 5–10 m deep (Fig. 7.12: Stafford et al. 2008a). The plain is also where the "Castile" landforms, mentioned earlier, are to be found. Additional gypsum outcrops are present to the east in the Rustler Hills and to the north in Reeves County, Texas.

In the centre of the Delaware Basin the thick evaporites of the Castile and Salado Formations and the thinner evaporites of the Rustler Formation are underlain by relatively permeable carbonates and siliciclastics, including some prolific hydrocarbon reservoirs in Permian backreef of the Central Basin Platform (Fig. 7.13). Reef mounds, fractures and faults in these underlying sediments have provided focused conduits for upward stoping chimneys through the buried evaporites as well as the subsurface formation of now-exhumed Castiles to the west. An eastward-flowing deeply-circulating regional artesian hydrology, in combination with centripetal escape of buoyant hydrocarbon-rich basinal waters, drives the formation of these features, with their surface expressions occurring in areas such as the Wink Sink (chain of breached chimneys) and the Gypsum Plain (Castiles). The ongoing flushing of the basin fill evaporites by this confined hydrology means only 30–40 % of the original halite volume remains in the basin (Anderson 1981).

The upper sides of the shallow dipping salt beds are also affected by the hydrologies of the zone of active phreatic circulation. The Pecos River has migrated back and forth across the top of subcropping evaporites for much of the Tertiary. Its ancestral positions drove substantial salt dissolution, now evidenced by large sediment-filled subsidence basins and troughs in the centre of the Delaware basin (Figs. 7.12 and 7.13). The regional eastward dip of the Delaware basin sediments means first halite and then gypsum has disappeared along the updip eastern edge of the basin. Relatively undisturbed salt remains along the more deeply buried western side of the basin that abuts and covers the Central Basin Platform. Bachman and Johnson (1973) estimate the horizontal migration rate of the dissolution front across the basin as high as 10–12 km per million years, while Anderson (1981) concluded more than 40 % of the original halite is gone. Multiple smaller examples of sediment-filled subsidence troughs occur at the edge of the gypsum plain of the Delaware Basin south of Carlsbad Caverns, where depositional troughs, 0.7–15 km in length, 100–1,500 m wide and no more than 5–10 m deep, are well documented, as are subsidence sinks within the subsidence swales, such as Bottomless Lake and region where the watertable intersects a subsidence chimney (Fig. 7.13a, b; Quinlan et al. 1986).

The San Simon swale is a 25 km^2 depression defining a residual karst feature atop the Capitan Reef on the northeastern margin of the Basin (Figs. 7.12 and 7.13a). San Simon Sink, atop a subsidence chimney within the swale, is the lowest point in the depression and is some 30 m deep and 1 km^2 in area. It in turn encloses a secondary collapse sink some a few hundred metres across and 10 m deep (Fig. 7.13b). During a storm in 1918 a sinkhole formed a gaping hole about 25 m

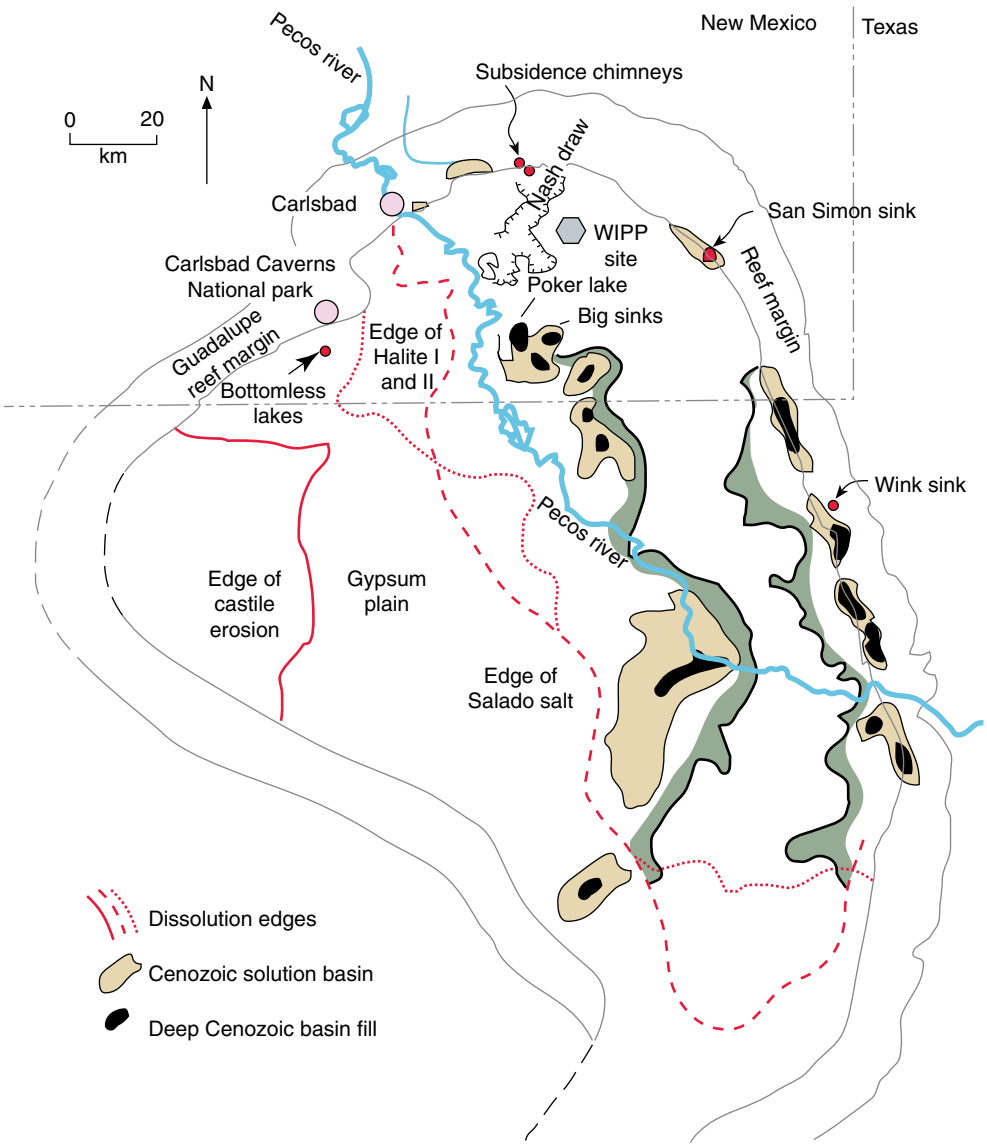

Fig. 7.12 Karst features in the Delaware Basin and the positions of dissolution edges of various salt units, USA (After Anderson 1981; Davies 1984a, b)

across and 20 m deep in the sink. In one night, nearly 23,000 cubic metres of soil and bedrock disappeared into the cavern. Annular rings that cut the surface around the San Simon sinkhole today suggest ongoing subsidence and readjustment of the sinkhole is still occurring in response to earlier collapses. The position of the San Simon sink over the Permian reef crest led Lambert (1983) and many others to suggest that the sinkhole originated as a groundwater cavity breakthrough, atop a series of stoping reef-focused breccia pipes. Sinkhole breakouts, which can emerge in a matter of hours, continue to form across this dissolution basin, in some case aided by poorly-monitored brine extraction operations and improperly-cased water wells. But the majority of the sinkholes are natural, not anthropogenically enhanced (Land 2013).

Nash Draw is a southwesterly trending depression or swale, some 25 km long and 5–15 km wide, at the northern end of the Delaware Basin with its sump in a salt lake (Poker Lake) at the southern end of the draw (Fig. 7.12). The underlying evaporitic Rustler Formation and parts of the Salado Formation has largely dissolved so that more than 100 caves, sinks, fractures, swallow-holes, and tunnels make up a complex local karst topography, which is still active today (Bachman 1981). An extensive drilling program conducted for the nearby WIPP site (now a low level radioactive waste repository) showed that natural dissolution of halite in the Rustler and upper Salado formations is responsible for the subsidence and overall formation of Nash Draw (Lambert 1983; Holt and Powers 2010).

To the west of Nash Draw the WIPP/DOE drilling program clearly defines the formation of a solution trough in the Dewey Lake Redbeds, created by preferential leaching of halite beds in the Rustler Formation, with interstratal

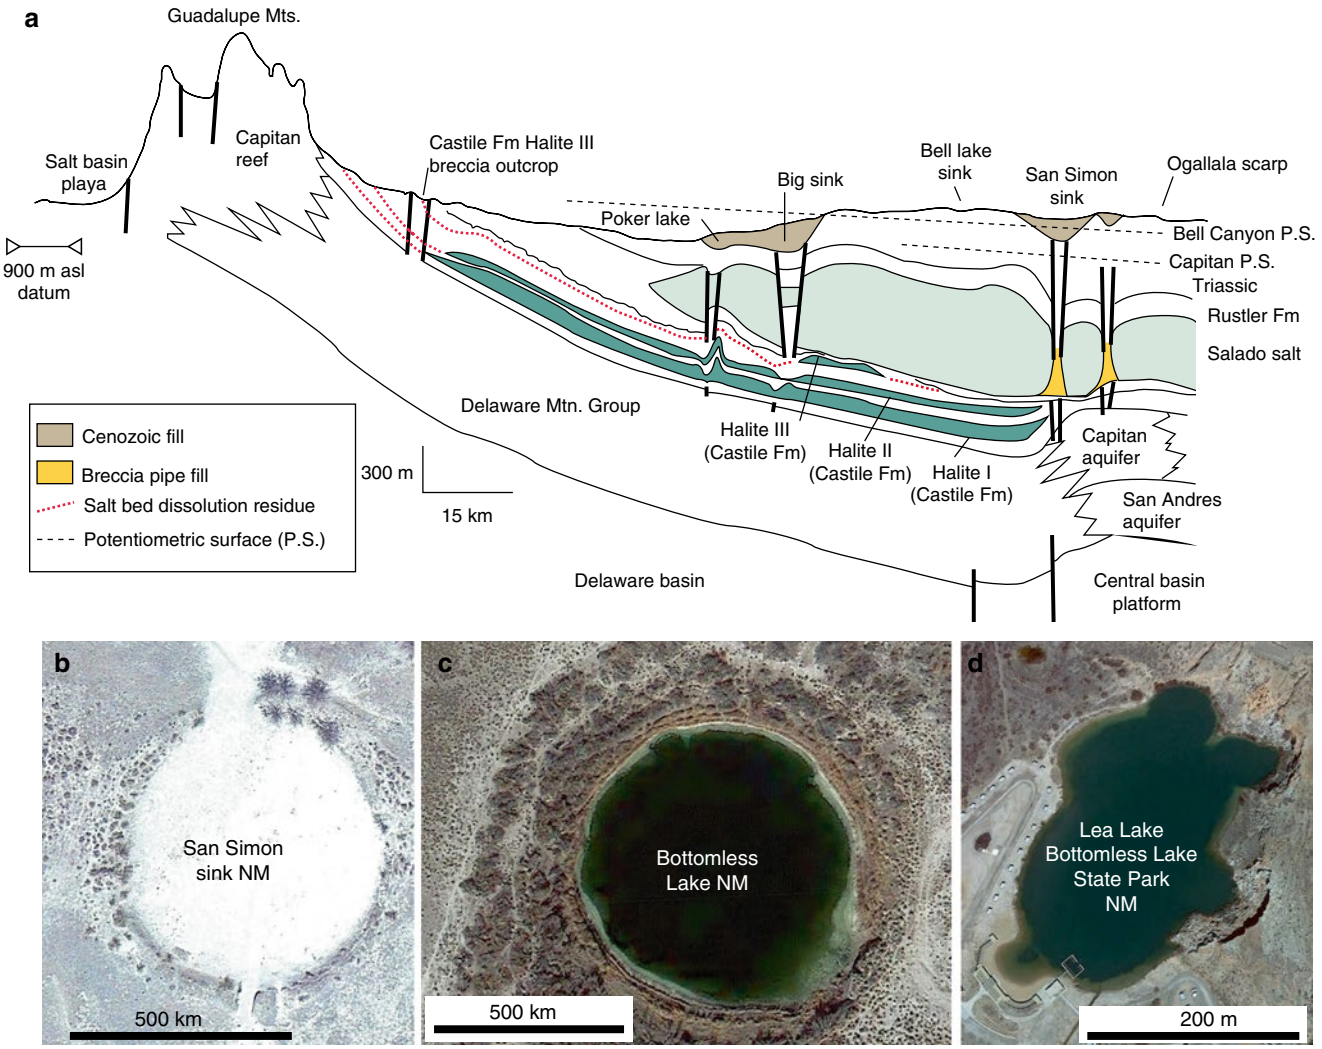

Fig. 7.13 Salt dissolution features, New Mexico. (**b**) San Simon Sink, New Mexico. (**c**) "Bottomless" Lake, south of Carlsbad, New Mexico. (**d**) Lea Lake, Bottomless Lakes State Park, near Roswell, New Mexico. Refer to Fig. 7.12 for geographic locations

anhydrite and breccia residuals (Fig. 7.14). This dissolution occurred at a level some 400 m above the salt-encased storage level of the WIPP waste isolation facility is not considered a significant risk factor in terms of longterm site stability (Holt and Powers 2010). A heated scientific (and at times not so scientific!) debate of just how deep surface karst penetrates into the bedded halite of the Salado Formation in the vicinity of the WIPP site continues today (see Chap. 12 for detail of waste isolation in bedded and diapiric salt).

Further north, near the subcropping western edge of the North-west Permian Shelf is Bottomless Lakes State Park, located some 20 km southeast of Roswell. Encircling the lakes are the gypsum, halite and dolomitic redbeds of the Artesia Group and San Andres Formation. Away from the lakes are numerous other sinkholes and collapse dolines, most of which are circular, steep walled or vertical holes, 50–100 m across and 30–60 m deep, with the greatest density of features aligned along the eastern side of the Pecos River floodplain. Water in the various sinks that make up the Bottomless Lakes is crystal clear and generally brackish to saline (6,000–23,000 ppm), attesting to its passage through subsurface layers of gypsum and salt. Although the lakes are around 30 m deep, dark-green moss and algae coat the bottoms giving the impression of great depth and hence the name of the park (Lea Lake; Fig. 7.13c.) To the west, many of the playas in depressions near Amarillo in the High Plains of Texas have a similar genesis as solution depressions atop dissolving Permian salt, but most do not intersect the regional watertable and so do not hold permanent surface water (Paine 1994). Further south, near Carlsbad Caverns, there are other subsidence chimneys that form lakes

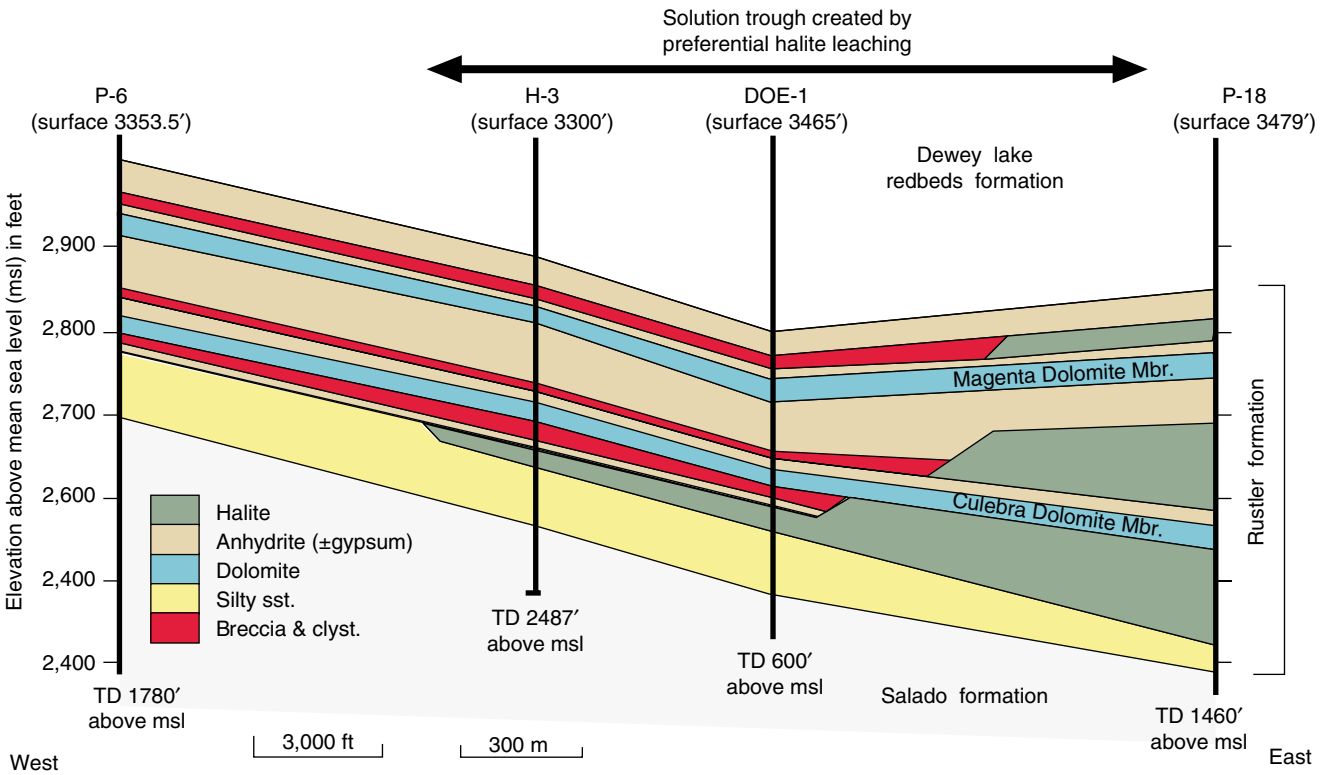

Fig. 7.14 Differential dissolution of halite in Rustler Formation in the vicinity of the WIPP site (see Fig. 7.12 for location). Note the anhydrite-gypsum and breccia residuals (as distinct from the bedded anhydrite). The solution trough lies some 400 m above the level of the salt-encased WIPP (waste isolation pilot plant) subsurface waste storage facility in the Salado Formation

where they intersect the watertable and are locally known as "Bottomless" (Fig. 7.13d).

Although much of the preceding discussion focused on salt dissolution influencing Tertiary to recent sediment pattern in West Texas, this is merely part of a longer acting set of dissolution-sedimentation interactions that have influenced sedimentation motifs as far back as the Triassic. For example, in the Texas Panhandle the extent and thickness of the late Triassic Dockum Group strata are best preserved in the central portions of a local syndepositional basin that was produced by dissolution of underlying Permian salt (Dickerson et al. 2014). This longterm influence of retreating salt mass edges over tens to hundreds of millions years is obvious in the sediments of various ages that surround many salt basins, worldwide.

Holbrook Anticline, Arizona

Subsidence driven by natural salt solution at depth generates regional-scale drape or monoclinal folding in strata atop the retreating salt edge. This is the corollary of the formation of a subsidence trough (Fig. 7.15a). The 70-km long dissolution front in the Permian Supai Salt of Arizona is defined by more than 500 sinkholes, fissures and subsiding depressions some 40–50 m across and 20–30 m deep (Neal 1995; Johnson 2005). Away from the main dissolution zone the northeasterly-dipping Schnebly Hill Formation (aka Supai Salt) is composed of up to 150 m of bedded halite, with local areas of sylvite along its northern extent (Fig. 7.15a). Atop the solution front there are a number of topographic depressions with playa lakes that in total cover some 300 km^2. Salt-dissolution induced features include areas known as; The Sinks, Dry Lake Valley, and the McCauley Sinks (Neal et al. 2001; Martinez et al. 1998). The Sinks region includes more than 20 steep-sided caprock sinkholes, with some that are more than 100 m across and up to 30 m deep (Fig. 7.15b). Regional expanses of Supai Salt removal produce a regional gravity depression, largely coincident with a surface topographic depression, where there is as much as 100 m of collapse and topographic displacement. The solution front is essentially coincident with the updip end of the Holbrook Anticline, a flexure defined by dip reversal in an otherwise northeasterly dipping succession (Fig. 7.15a).

Rather than orogenically driven, the Holbrook Anticline is a subsidence-induced monoclinal flexure created by the northeasterly migrating dissolution front (Fig. 7.15a, b). It may be the largest single solution-collapse fold structure in the world (Neal 1995). The reverse dip of the flexure directly overlies the salt-dissolution front and marks the location of

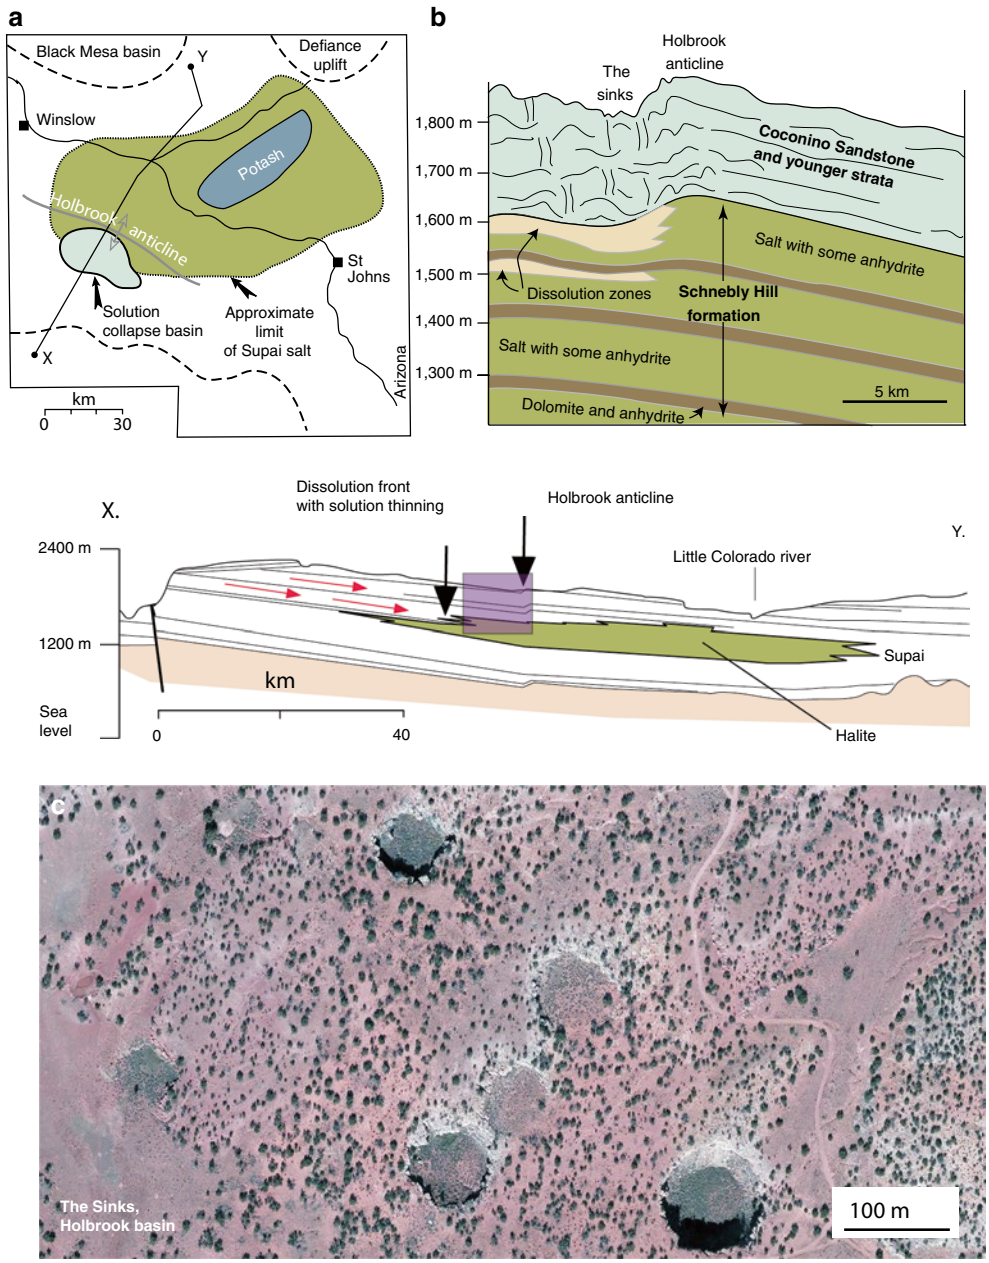

Fig. 7.15 Holbrook Anticline, Arizona. Shows distribution of dissolution features seen at the surface at various scales and their relationship to the underlying Permian Schnebly Hill (Supai) salt. (**a**) Map view (**b**) Cross sections show the Holbrook Anticline is a monocline flexure created by dissolution of the underlying Schnebly Hill Formation. (**c**) aerial view of the Sinks region (In part after Neal 1995; Johnson 2008a) McCauley Sinks region, Arizona (Bing® image mounted and scaled in MapInfo)

two major collapse depressions known as The Sinks and Dry Lake Valley, both occur where salt is within 300 m of the surface (Peirce 1981). Although it has periodically held surface water, reports of several hundred acre-feet of flood water in the Dry Lake Valley playa draining overnight supports the notion of active fissure and cavern formation related to salt removal at depth. Major surface drainage events took place in 1963, 1979, 1984 and 1995, with more than 50 new sinkholes forming in the valley during that period. The continuing rapid appearance of new sinkholes testifies to the ongoing nature of dissolution in the underlying evaporites. According to Neal (1995), dissolution front features began forming in the landscape in the Pliocene and continue to form today.

The caprock collapse sinkholes centre in the Coconino Sandstone bed that overlie the salt, which is located 200–300 m below the at-surface features. These caprock sinkholes define regions of focused breccia pipe development and discreet upward cavity migration (chimney stopping). The underlying salt is bedded and there are no indications of halokinesis anywhere in the basin. Sinkhole regions lie just ahead of a dissolution front that is migrating downdip, driven by the widespread dissolution of halite.

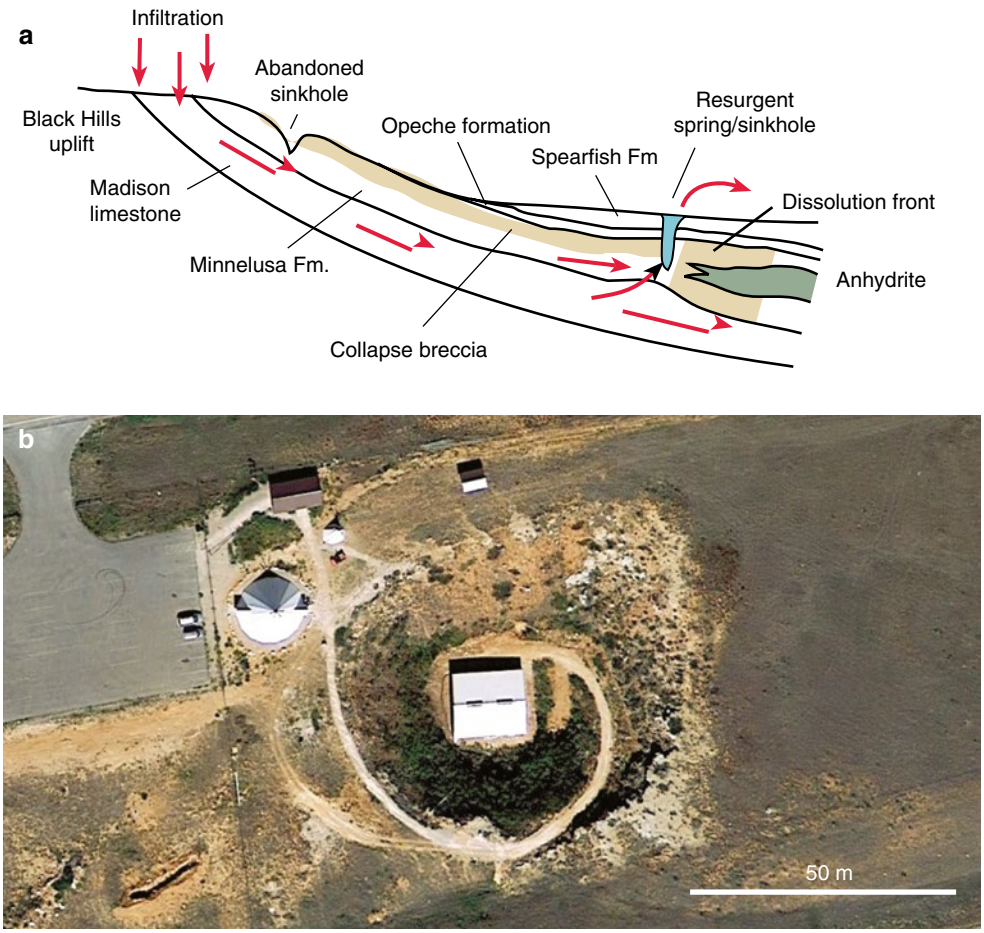

Fig. 7.16 Evaporite karst, South Dakota. (**a**) Minnelusa dissolution; as the Black Hills are slowly lowered by erosion, the anhydrite dissolution front in the subsurface Minnelusa moves downdip and radially away from the centre of the uplift. As the front expands the resurgent springs defining the outflow pipes dry up and new ones form down dip (After Epstein 2001). (**b**) Vore Buffalo Jump sinkhole, near Sundance, Wyoming (Image courtesy of Google Earth)

Other karst features attributed to evaporite dissolution in the Holbrook basin are; pull-apart fissures, graben sinks (downward dropped blocks), breccia pipes and plugs, and numerous small depressions with and without sinkholes (Neal et al. 1998, 2001). Interestingly, many of the "karst" features occur in sandstones, not limestones, such caprock collapse sinkholes can form wherever pervasive dissolution has removed the underlying salt, independent of caprock lithology (Fig. 7.5). The presence of the more than 500 karst features in the Holbrook basin, some of which formed in days, evokes practical karst hazard and infrastructure concerns, even in such a sparsely populated region (Martinez et al. 1998).

Black Hills, South Dakota

Another area of ongoing evaporite karstification is the Black Hills region of South Dakota (Fig. 7.16a; Epstein 2001; Rahn and Davis 1996). Substratal salt bed dissolution, centred on anhydrites in 4 beds, mostly in the Minnelusa Formation (Pennsylvanian – Permian), has produced breccia pipes and pinnacles, regional collapse breccias, sinkholes, and extensive disruption in the overburden of otherwise stratiform beds. Anhydrite removal in the Minnelusa probably dates back to the early Tertiary when the Black Hills were first uplifted and it continues today[4]. In the 1990s, houses in Rapid City, South Dakota, were damaged by the sudden development of collapse sinkholes, up to 10 m across, which formed in the brecciated outcrop zones of gypsum relic beds up to 9 m thick (Rahn and Davis 1996).

Evidence for recent natural collapse includes fresh scarps surrounding shallow depressions, steep-sided sinkholes more than 20 m deep, and sediment disruption and contamination in water wells and springs. Several sinkholes in the Spearfish Formation west of Spearfish, South Dakota, which today support fish hatcheries and are used for local agricultural water

[4]The Plains Indians that inhabited the area 300 years ago trapped and slaughtered thousands of buffalo as their primary food by stampeding the animals over the rim of a large steep-sided sinkhole near Sundance, Wyoming (the Vore Buffalo Jump; Fig. 7.16b).

The Mammoth Site in Hot Springs, South Dakota, is a salt dissolution sinkhole in the Spearfish Formation. There some 26,000 years ago, well before humans had migrated to north America, mammoths and other megafauna died after falling into what was then a steep sided water-filled sinkhole.

supply, probably originated as the surface expressions of stoping chimneys initiated some 150 m below in the salts of the Minnelusa Formation (Fig. 7.16a; Epstein 2001).

As the anhydrite dissolution front migrates further down dip and radially away from the centre of the Black Hills uplift, resurgent springs that once defined the active edge of the subsidence trough are overstepped. They dry up and new ones form further downdip. Abandoned sinkholes and breccia pipes, preserved in cross section on downcut canyon walls, attest to the former positions of the outward migrating artesian dissolution front (see also Fig. 7.72). The Spearfish Formation, mostly comprising redbed shale and siltstone, is regionally considered to be a confining layer to the active aquifer system. However, secondary fracture porosity develops locally via collapse/subsidence within the lower Spearfish Fm. as a consequence of cavity creation, via salt dissolution, in the Minnelusa Fm. (volume contraction fractures) or the hydration of anhydrite to gypsum (volume expansion fractures). Thus, updip of the anhydrite solution front, localised fracturing in the overlying lower Spearfish Formation makes a respectable aquifer, especially for a regional shale, and it yields potable water through both pumped wells and springs.

As well as the active karst centred on the Minnelusa Formation there is abundant evidence of multiple-cycle paleokarst in the same strata. Many active modern caves transect and expose these older paleokarst features in the cave walls (Palmer and Palmer 1995). The Kaskaskia paleokarst zone for example, is part of the Mississippian-Pennsylvanian unconformity in North America, is typified by ancient sinkholes, fissures, and dissolution caves at and near the top of the Kaskaskia Sequence (Madison Limestone and equivalents) and is covered by basal Absaroka siliciclastics (Chesterian to Morrowan). In the Black Hills, the Kaskaskia unconform-ity/paleokarst postdates earlier paleokarst features produced by sulphate-carbonate interactions. These include ancient cemented evaporite breccias, dissolution voids, saline bedrock alteration zones, and uranium mineralization in chimney stopes. Both the Kaskaskia paleokarst and earlier evaporite dissolution features are intersected by post-Laramide caves, which are part of the uplift hydrology that is still actively altering and dissolving shallow Minnelusa sulphates and limestone. Uranium deposits, aquifers, and petroleum reservoirs in the region are concentrated along both the paleokarst Kaskaskia horizon and earlier sulphate-related Minnelusa features. Each phase of karst modified and preferentially followed the zones of porosity and structural weakness left by earlier dissolution phases, producing an interrelated complex of modern and now-relict karst features.

Subsidence and Landscape in Diapiric Regions

When diapiric salt is actively flowing near the surface it typically elevates the landscape (Table 6.5). In continental settings this places highly soluble halite, and somewhat less soluble gypsum/ anhydrite caprocks, in the zone of active phreatic and vadose groundwater flow. This in turn creates dissolution caverns, cavern collapse fractures, slumping and landscape/gully retreat, typically focused in to the vicinity of subcropping salt dome crests. Sinkholes in such settings tend to form atop landscape highs, rather than in the intervening lows between the diapirs. Such diapir karst landforms dominate the Texas coast of the Gulf of Mexico, the Zagros/Hormuz region of the Middle East and parts of the drainage feeding the Ebro Basin of Spain.

Salt Valleys, Moab region. Utah

The salt valleys over the axis of the salt-cored anticlines in the Paradox fold and fault belt (Canyonlands, Utah and Colorado) are in large part created by subsidence of the anticline crests (See Fig. 6.83 for location). The resulting depressions that occupy the crestal positions of salt-cored anticlines may be 50 or more kilometres long, kilometres wide and several hundreds of metres deep. Traditionally, the collapse of the anticlinal salt crests was attributed to crestal dissolution of the salt walls (diapirs) that form the anticline cores (Fig. 7.17; Doelling 2001). Other workers, calling on scaled physical models and their own field observations, have proposed that the salt valleys are more the result of regional extension and that salt dissolution had only a minor

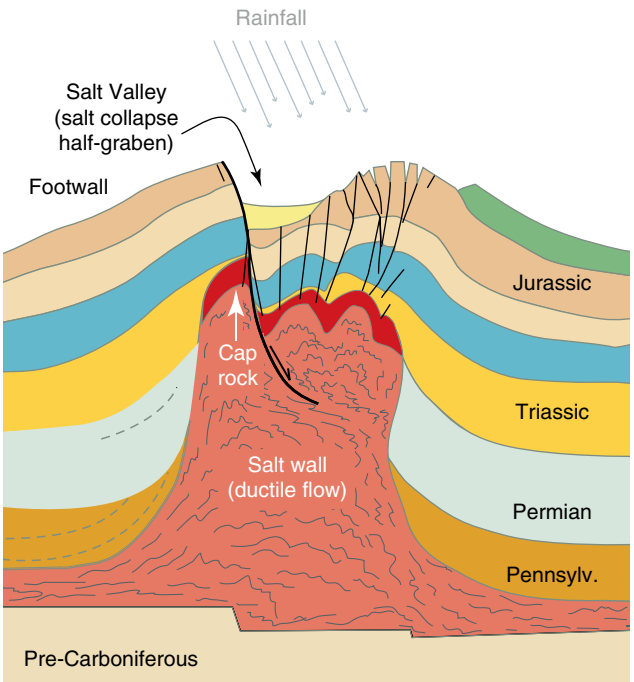

Fig. 7.17 Schematic illustrating typical crestal collapse structures and the formation of sediment-filled salt collapse grabens, as seen on the crest of many elongate salt walls in the Paradox Basin in southeast Utah. The collapse structure at the top of the salt wall is in part generated during salt dissolution by reactivation of a regional system of Tertiary joints, although most of the faulting is likely related to cataclastic deformation bands formed earlier and at greater depths (After Fossen 2010)

influence in the development of the axial depressions (Walsh and Schultz-Ela 2003). The problem as to the relative importance of karstic collapse versus diapir fall in extension is still not fully resolved. Neither school denies the existence of widespread salt karst across the region, only its relative import in forming the valley depressions.

Gutiérrez (2004) presents several arguments and lines of evidence that refute the tectonic extension model for the collapsed salt valleys and supports a salt-dissolution-driven subsidence interpretation. Field evidence against regional-extension diapir fall driving valley formation includes: (1) A thick cap rock is consistently present at the top of the salt walls; (2) The concentration of subsidence deformation structures is along the crest of the anticlines (salt walls), while extension would drain the base of the structure first; (3) Mapped deformational structures not consistent with the proposed NNE extension, especially the crestal synforms and NE–SW grabens; (4) Dissolution-induced subsidence structures controlled by ring faulting, reveal deep-seated dissolution penetrating the walls; (5) Large blocks of wall material have foundered several hundred meters into the salt wall; (6) Abundant evidence of recent and active dissolution subsidence; (7) The documented aseismic nature of the recently-active collapse faults. He concludes that, although underground salt dissolution seems to be the main cause for the generation of the salt valleys, this phenomenon may have been favoured by regional extension tectonics, which further enhanced the circulation of groundwater and salt dissolution.

Similar salt-dissolution geomorphic expressions to the Utah canyonlands typify outcrops in parts of the western Ogaden Basin, Ethiopia (Mége et al. 2013). There the uplift and incision of the Ogaden plateau is cut down to the base of the Gorrahei Formation, an upper Cretaceous evaporite formation. Debuttressing of this and the overlying sedimentary formations resulted in widespread and spectacular gravitational-spreading landforms across a minimum surface area of 15,000 km^2.

Five Islands, Gulf of Mexico

Five salt-dome crests, locally known as "the Five Islands," are located near the western boundary of the Mississippi River delta plain in coastal south Louisiana. The present landscape of the islands reflects a combination of salt-dome induced uplift and salt dissolution (Lock and Kupfer 2003; Autin 2002; Autin and McCulloh 1995). The islands, align in an approximately NW-SE trend, are named Jefferson Island (JI), Avery Island (AI), Weeks Island (WI), Cote Blanche Island (CBI) and Belle Isle (BI) (Fig. 7.18a). The five salt domes coring the islands have pierced, uplifted and shed sediment, while their surrounding flanks subsided and accumulated sediment. Each dome is nearly circular in plan, with maximum elevation ranging from approximately 52 m asl on Weeks Island to 23 m asl on Jefferson Island. Avery, Weeks, and Cote Blanche Islands are large mounds with small sinkhole ponds, whereas the crests of Jefferson Island and Belle Isle are marked by larger lacustrine collapse structures (Figs. 13.46 and 13.48). Each "island" landform is, surrounded by lowland Pleistocene terraces and/or Holocene delta plain marshes (Fig. 7.18a, b). Sediment cover on the mound is made up of the Late Wisconsin Peoria Loess covering alluvial deposits of the Prairie Complex. The Prairie Complex crops out parallel to the coast and consists of alluvial deposits of the Late Pleistocene Mississippi and Red Rivers.

On Weeks Island the high salt island landform has a base that is marked by a pronounced increase in topographic slope between 15 and 23 m MSL. A generally north-south trending ridge is mostly underlain by loess-covered sandy deposits of the Prairie Complex and so forms the "Devil's Backbone," which defines the highest part of the island (Fig. 7.18b). The middle (level) salt island landform occupies elevations of 8–23 m, and the low salt island landform occupies lower elevations down to sea level. Both landforms are underlain by mostly sandy, but locally loam-covered deposits of the Prairie Complex. The lowermost landscapes are tributary gully fills and perimeter colluvial aprons, still maintained by slow uplift of the salt core. Geomorphic evidence of ongoing salt-induced uplift on Weeks and the other islands includes; surface lineations, linear gullies, and excessively-steep land surface topography coincident with steep topography on spines that define the top of the underlying salt (Autin and McCulloh 1995).

Thus topographic features on all of the Five Islands were formed by a combination of; (i) rising diapiric salt spines, (ii) sediment reworking and development of a drainage network moving sediment away from uplifted areas, and (iii) subsidence creating sediment sinks (Autin 2002). Uplands are drained by small gullies that dissect the dome landscape and cut into the Peoria Loess. The gullies contain a graded wash fill that passes laterally and downdip into the aggrading colluvial aprons. Where the low salt island landform approaches sea level, the apron's fill in turn interfingers with finer grained aggrading sediment of the adjacent Holocene coastal marsh. Active dissolution of the salt crest creates sinkholes and water-filled ponds atop the salt and typify degradational dissolution zones on both the high and low salt island landscapes.

The boundary between aggradational and dissolutional components of the landscape may in part coincide with underlying anomalous zones of differential shear within the underlying salt indicated by shear zones, locally known as black salt (Fig. 6.14d; Kupfer 1976; Lock 2000). The problematic development of an active sinkhole on Weeks Island, first noticed in 1992, occurs in a position of sharp change in landform slope (transition from high island to gully fill). It lies atop the projected alignment of what is known as Shear Zone E in the underlying salt (Autin and McCulloh 1995) and its development along with karst dolines focused in black salt is discussed in detail in Chap. 13).

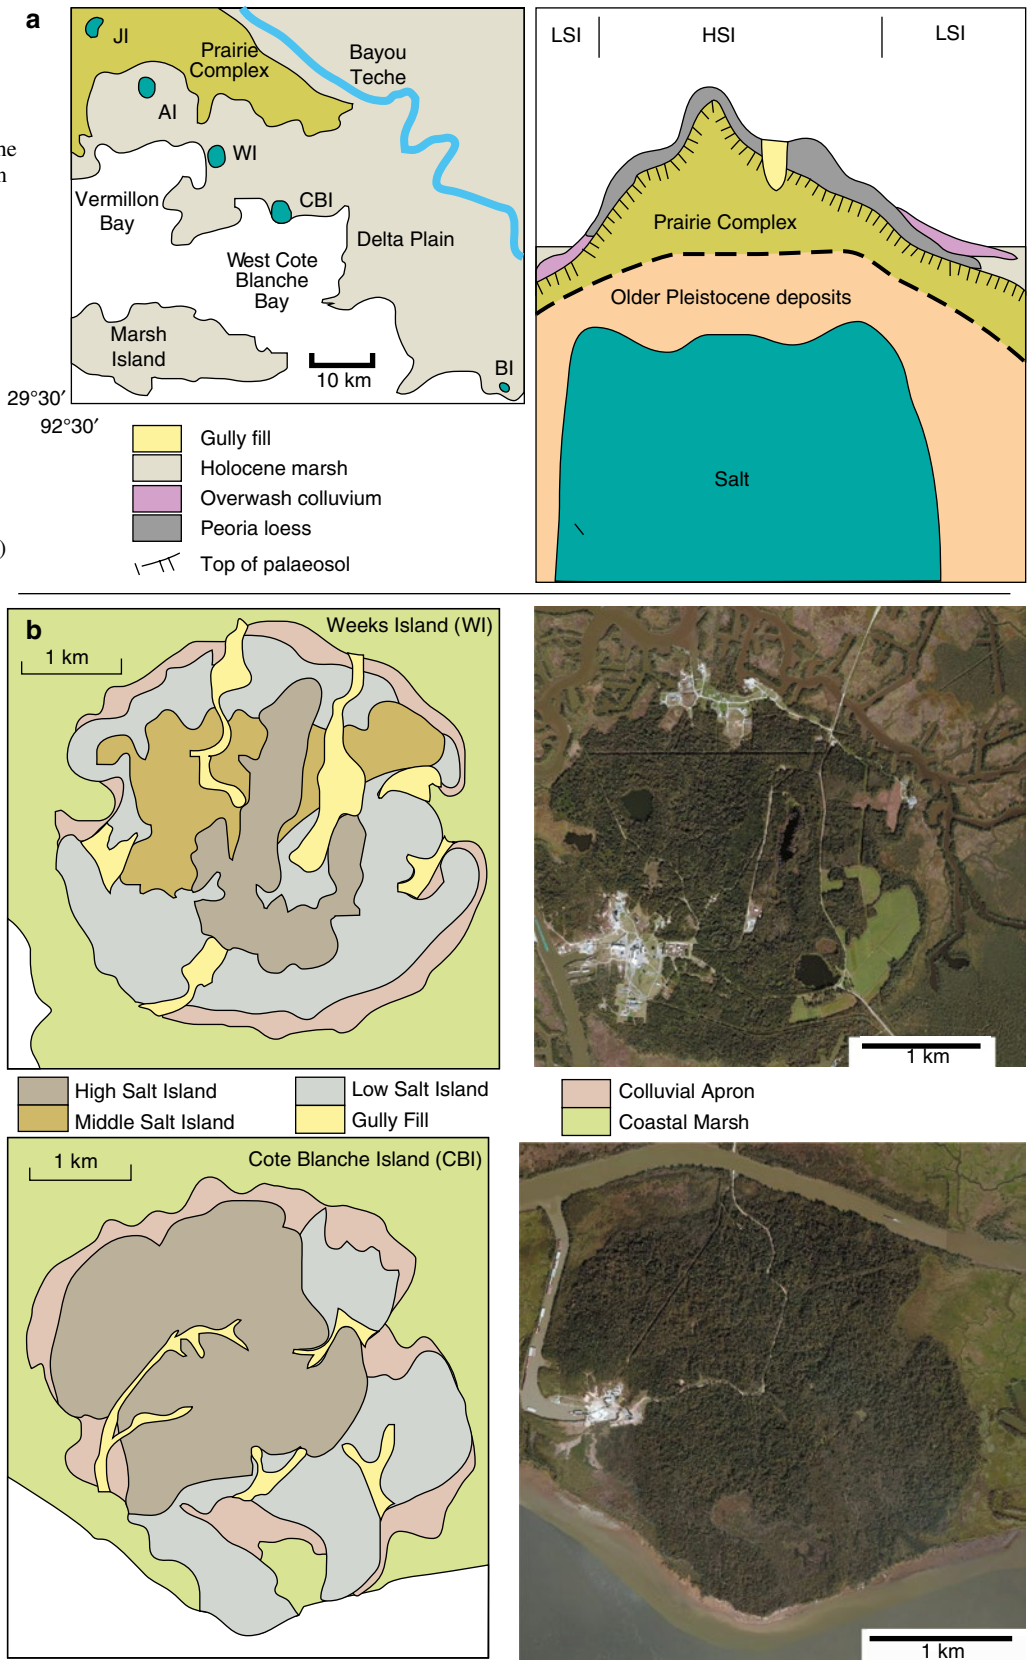

Fig. 7.18 Five Islands Domes, Gulf of Mexico. (**a**) The Five Islands of south Louisiana are aligned in a NW-SE direction along the western margin of the Mississippi River delta plain. The idealised salt dome cross section illustrates the relationship between salt island landform components and surficial stratigraphy. A palaeosol marks the top of the uplifted Prairie Complex across the islands. Beneath the high salt island landsurface (HSI) the Peoria Loess and local gully fill sediment veneer the Prairie Complex. Holocene marsh and overwash colluvium occur as veneer deposits beneath the low salt island (LSI) landsurface. (**b**) Geomorphic features of Weeks Island and Cote Blanche Island, the surface features of Weeks Island largely reflect the dissolution topography of the underlying salt, which includes the various solution ponds

Zagros/Hormuz Region, Arabian (Persian) Gulf

Active salt glaciers (namakiers) typify the foreland fold region of the Zagros-Hormuz province (Infracambrian-Cambrian salt), in a region made up of a number of E-W trending anticlinal mountain ridges and synclinal valleys and in the Qom region of central Iran (Miocene salt). Many islands and ridges further to the south also have squeezed Hormuz salt cores, but salt is no longer flowing at the surface (Fig. 6.85). More than 200 degraded namakiers and salt plugs (diapirs, domes) occur throughout the Arabian Gulf region, many are associated with hydrocarbon and metal sulphide shows (Kent 1979; Talbot and Jarvis 1984).

Salt flow at the surface in the region of Zagros namakiers of southeast Iran, such as the Konasariah extrusion, began in the Pliocene and continues today with average uplift rates ≈ 2 mm/year with the velocity of the salt flow decreasing away from the salt vent (Fig. 7.19a, b). Similar geomorphology also typifies actively extruding Miocene salt fountains in Central Iran, as in namakiers the vicinity of the holy city of Qom (Fig. 7.20; Warren 2008). In both regions, the upper portions of actively flowing namakiers retain few deeply penetrating caves beneath their sediment carapace due to ongoing salt replenishment.

Karst and karren features are most obvious away from the active vent, nearer the dissolving edges of active glaciers, especially in areas where the salt supply has slowed and the namakier edge is retreating to form steep slopes with little or no soil cover (Zone 4 in Figs. 7.19 and 7.20; Zarei et al. 2012). As a general rule, the upper portions of an actively flowing salt mound are covered by residual soils of the insoluble components (suffusion karst) that , which remained in place as the flowing salt is dissolved. Dolines below the surface of these soils enlarge and the soils thicken as the moving salt dissolves in its passage away from the vent. Ultimately, once the supply of mother salt is depleted the at-surface namakier dissolves to leave behind no more than a gypsum-encrusted surface (e.g. Kuh-e-Gach described in Warren 2008).

Iranian namakiers possess different diameters (1–15 km) and range in outline from conical to cigar shaped, with varying intensities of surface karst and rilling (Fig. 6.87). Salt plug landscapes can be divided in four types based on the intensity of supply versus dissolution (Bosak et al. 1999); active, passive, ruins of plugs and unbreached plug domes (Fig. 7.21). Active plugs are positive relief features with centrifugal drainage networks and the plug surface dominated by flowing halite with relatively minor development of karst. Small ephemeral features, including shallow caves, are

(**b**) Zone 4 features on the edge of the salt tongue showing relative loss of soil on steep dissolution edge of tongue, while the edge of the playa is supplied saline waters via dissolution of the salt tongue

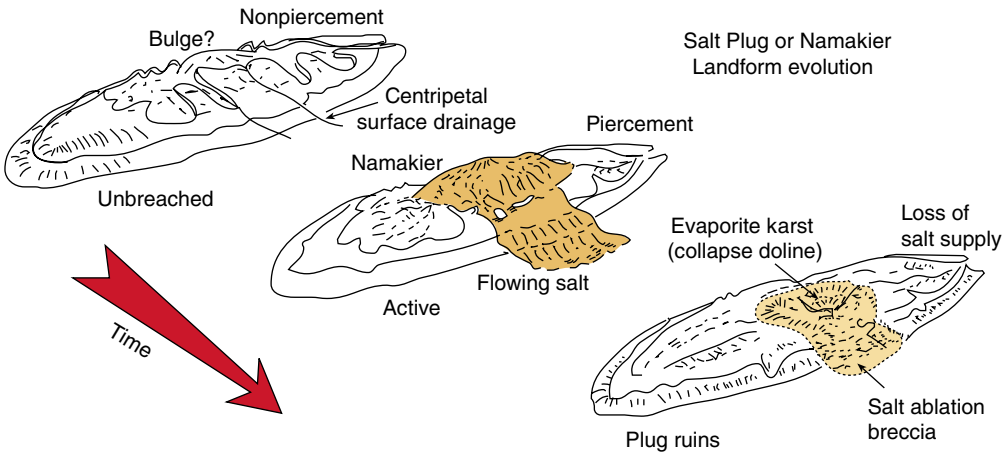

Fig. 7.21 Landform evolution in an area where salt is flowing at the surface in a salt glacier (namakier). Based on various salt plugs in the Zagros foreland belt near the Straits of Hormuz (e.g. Fig. 6.85)

typical of the salt glacier surface, but in an active namakier the salt is flowing too fast to preserve them for more than a few hundred to a few thousand years depending on the lateral extent and rate of extrusion of the diapir. Even so, these features are of interest as they illustrate karst forming on a mobile substrate (Bruthans et al. 2009; Filippi et al. 2011; Zarei et al. 2012). The karstic carapace atop the moving and dissolving namakier is dominated by soils, typically composed of a combination of dissolution residues, fluvial deposits and wind transported dust (loess). As the moving salt dissolves, dolines develop in the surface of these soils, they enlarge with time as the soils thicken.

Once a supply from the mother salt layer ceases, the namakier stops its outward expansion and begins to shrink to ultimately subside and disappear. This occurs over time scales of hundreds to thousands of years post flow, to leave behind a salt-ablation carapace. As the salt dissolves, soils that previously had accumulated about to namakier edge, now touch down over the whole extent of the former salt glacier. Ultimately, karstification and salt core collapse becomes so pervasive across the former namakier extent so that only the edges of the relict plug still show any positive relief (Fig. 7.21). Salt plug ruins are even more disturbed and indicate complete cessation of any surface salt flow. Overall, in the local Iranian landscape underlain by salt, inactive plugs tend to be negative landscape features (depressions). Exotic "Hormuz" blocks of various sizes are scattered as dissolution residues about the edges of the "ruined" depressions, but no salt outcrops (Fig. 6.86). Internally draining dendritic stream networks feed into the collapsed core of the ruined plug, creating a reversed drainage direction compared to that of an active plug.

To the south of the active onshore Zagros namakier province are numerous salt-cored islands in various stages of namakier dissolution, such as Hormuz, Das and Yas islands (Fig. 6.85). These once extrusive salt masses are now largely inactive with only minor at-surface evaporite residues present, mostly as gypcretes and caprock remnants. Highest parts

of the islands are typically covered by dissolution breccias that cap the salt core below. Salt beneath the breccia carapace is pervasively karstified and where relatively shallow, as at Hormuz Island, it is covered by suffusion karst and cross-cut by tube caves (Fig. 7.30). Active flow of the squeezed salt in the various island cores seems to have ceased sometime in the Miocene so that terrains of exotic blocks now outline much of the surface expression of former outcropping salt masses.

Salt Dissolution: Solution Breccias and Residues

Evaporite solution breccias (syn. evaporite collapse breccias) form whenever the removal of evaporite salts allows the intercalated or overlying rock to settle and become fragmented. Breccia horizons and a pile of finer-grained insolubles are the typical end result of complete subsurface dissolution of an evaporite. Frequently, especially in outcrop or about the buried edges of an evaporite bed, they are the only evidence of a former evaporite unit (McWhae 1953; Middleton 1961; Stanton 1966; Elliott and Warren 1989; Swennen et al. 1990). In evaporite paleokarst such breccias are one of the most reliable indictors of the former evaporites, even in situations where all soluble salts have been flushed.

The impervious internal make-up of a buried salt mass means it dissolves like a melting block of ice. That is, it shrinks via a series of retreating fronts, all moving from the edges inward and all defined by an expanding rind of insoluble residues. Retreat is most rapid along solution fronts in contact with large volumes of undersaturated pore water crossflow, as occurs along the upper side of shallow salt layers, atop shallow diapir crests, in zones near active faults that intersect bedded or halokinetic salt, or about the feather edge of subcropping inclined beds and allochthons. Pervasive and rapid dissolution creates cavities filling with collapse clasts derived from adjacent lithologies (collapse solution breccia). Slower dissolution rates create higher salinity pores forming residual rinds made up of less soluble salts (typically anhydrite or gypsum). As dissolution eats inward it can also create free-flowing residues of sand- to mud-sized insolubles, which in their turn infiltrate and sometimes fill spaces between breccia clasts. These fines, known as dissolution flour, are varying combinations of quartzo-feldspathic mud, microcrystalline dolomite and calcite rhombs, all previously dispersed through a now-dissolved salt mass.

Defining Evaporite Dissolution Breccia

Breccia is a nongenetic rock type that ranges across sedimentary, igneous and structural regimes. As a rock descriptor

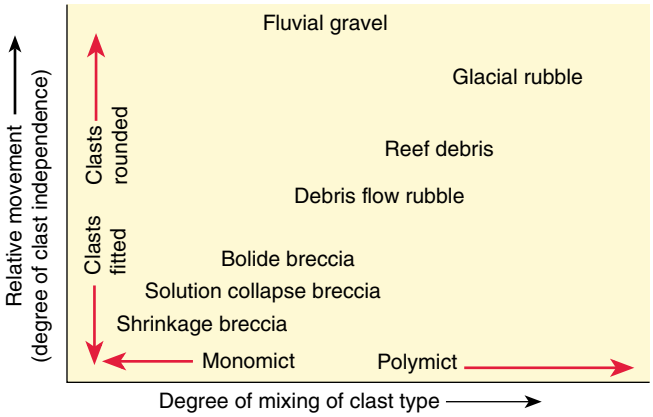

Fig. 7.22 Evaporite solution breccias classification (based on the degree of clast movement and mixing after von Engelhardt et al. 1977)

it needs a prefix to define its origin. Depositional breccias can be thought of as "proto-conglomerates" that is, deposits composed of clasts or eroded fragments not transported sufficient distances to become rounded and so become a conglomerate (Fig. 7.22). Nonevaporitic sedimentary breccias of this kind are commonplace. They form in glacial or alluvial outwash, can be an outcome of waves impacting reefs or sea cliffs, or can form in response to slope failure As a group, depositional breccias tends to indicate lateral rapid change in energy levels.

Some evaporite breccias are also depositional or "proto-conglomerates" composed of gypsum, anhydrite or halite clasts in an evaporite matrix, they are common in many large-scale ancient evaporite basins, perhaps even on Mars (Wezel and Baioni 2010). For example, evaporite depositional breccias laid down is slope settings typify portions of the Appenine and Sicilian Messinian (Manzi et al. 2005), and the Zechstein of Germany (Schlager and Bolz 1977). Reworking, gravity displaced downslope transport, and redeposition in relatively deep-water basin interior settings typify both cases, via a variety of gravity-flow processes, including slumping, massflowage, and turbidity current. Large volumes of reworked bottom-nucleated evaporite crystals, mostly gypsum clasts, accumulated in foot of slope positions due to intense erosional denudation of primary gypsum deposits, first precipitated in shallow, restricted platform basins (Fig. 5.60).

In contrast, evaporite-dissolution collapse breccias are diagenetic horizons, usually dominated by cm-metre angular collapse clasts in a mud-sand matrix of dissolution flour. Internally, they can appear similar to some depositional breccias. Commonly used sandstone and carbonate breccia classifications do not adequately address the variable character of solution collapse breccias as they emphasise depositional energy levels and the style and rate of surface sediment supply, not overburden and intrasalt collapse. Hence, we need to define a relevant breccia classification (Fig. 7.23), then we

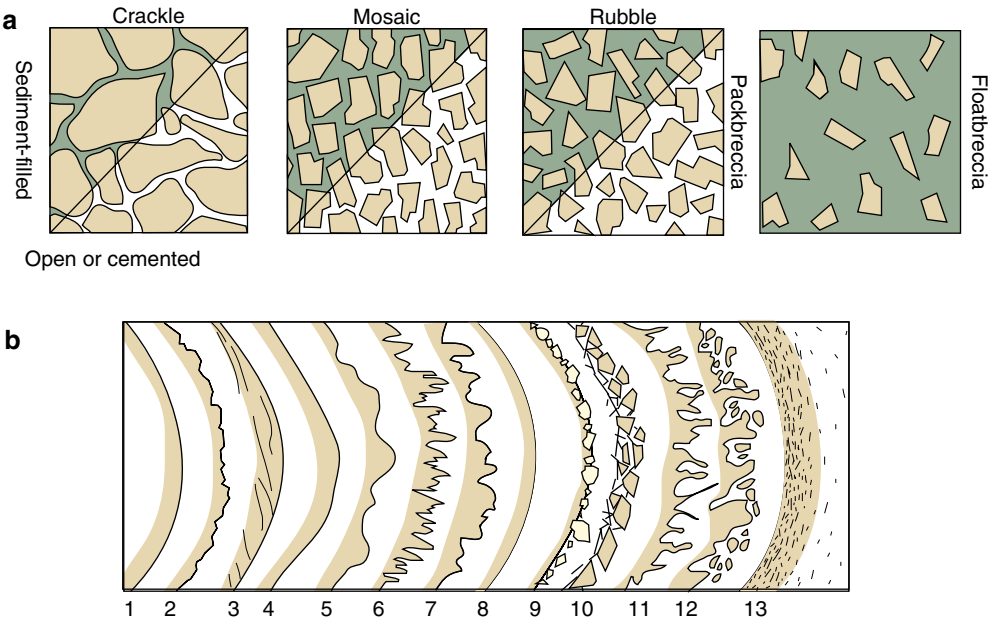

Fig. 7.23 Breccia description. (**a**) Nongenetic classification of breccias (After Stanton 1966; Morrow 1982). (**b**) Nature of clast contacts; *1* smooth, *2* slightly pitted, *3* striated, polished, *4* faceted, *5* solution rounded and pitted, *6* stylolitic, *7* ragged, *8* weathering rim or alteration rind, *9* microfragment armouring, *10* fragments in process of breaking out, *11* jagged, *12* crumbled, *13* diffuse, gradational (After Laznicka 1988)

can reliably discuss how evaporite solution breccias relate to sedimentary breccias.

Breccias are by definition composed of angular clasts, typically rock fragments of granule or pebble size and larger. Whenever classifying a breccia one should ask the following (Morrow 1982):

- Are clasts of a single lithic type (monomict/oligomict) or of widely variable types (polymict); are lithic types in clasts similar or different from the rocks bounding the breccia body; are clasts composed of durable rock fragments or of a mixture of hard and soft clasts?
- Are clasts closely fitted, loosely fitted, or spatially independent, i.e., crackle or mosaic- packbreccia or floatbreccia (Fig. 7.23a)?
- Do clast shapes and clast-to-clast contacts indicate either plasticity of clasts or brittle behaviour at the time of sedimentation? What is the nature of the clast edge (Fig. 7.23b)?
- Are spaces between clasts filled with cement or with detrital matrix; i.e. clast-support or matrix-support?
- Does a weathering rind or coat extend all around a clast, or is it developed only on one side, or is there no indication of weathering?
- What is the nature and style of clast size and size grading; evidence for bedding; imbrication or other spacial alignment of clasts?
- What is the overall size and shape of the breccia deposit; is there a sharp lower contact and/or sharp upper contact; is the breccia body discordant (trans-stratal) or concordant (interstratal) in relation to bounding rocks?

Packbreccias are clast supported, while floatbreccia clasts float in a finer matrix of granules, sand or mud. Distinction between crackle, mosaic and rubble breccia depends on whether the clasts are fitted, mildly disoriented or totally independent (Fig. 7.23a). Crackle denotes a fabric in which there is little relative displacement of fragments. Mosaic implies fragments are largely but not wholly displaced. Rubble breccias are completely disordered and no fragment boundaries match. Some packbreccias have particulate matrices, others are cemented by spar or silica, indicating clast support at the time of formation. Elements other than fabric, such as the size and shape of the breccia body, its stratigraphic setting, the depositional setting of adjacent sediments and lateral equivalents to the breccia provide evidence of origin. Intrastratal breccias indicate former bedded salts, while trans-stratal breccias characterise breccia chimneys and halokinetic dissolution breccias.

Evaporite solution or collapse breccias tend to form diagenetically as undersaturated pore waters flush a buried evaporite bed. Clasts in the resulting breccia can be derived from a lithology that once overlay the dissolving salt bed, or can come from thin stringers and beds that were once entrained in the now dissolved salt. Distance travelled by the clasts before being redeposited is negligible in many dissolution breccias, often only centimetres to a few metres. Timing of clast movement may be episodic or a single widespread instantaneous event. That is, clasts in an evaporite solution breccia may have moved into a cavity in concert, like a school of fish, or they may have gently sloughed and foundered a few at a time, with little breakage or change in orientation. The distance of movement is dependent on the size

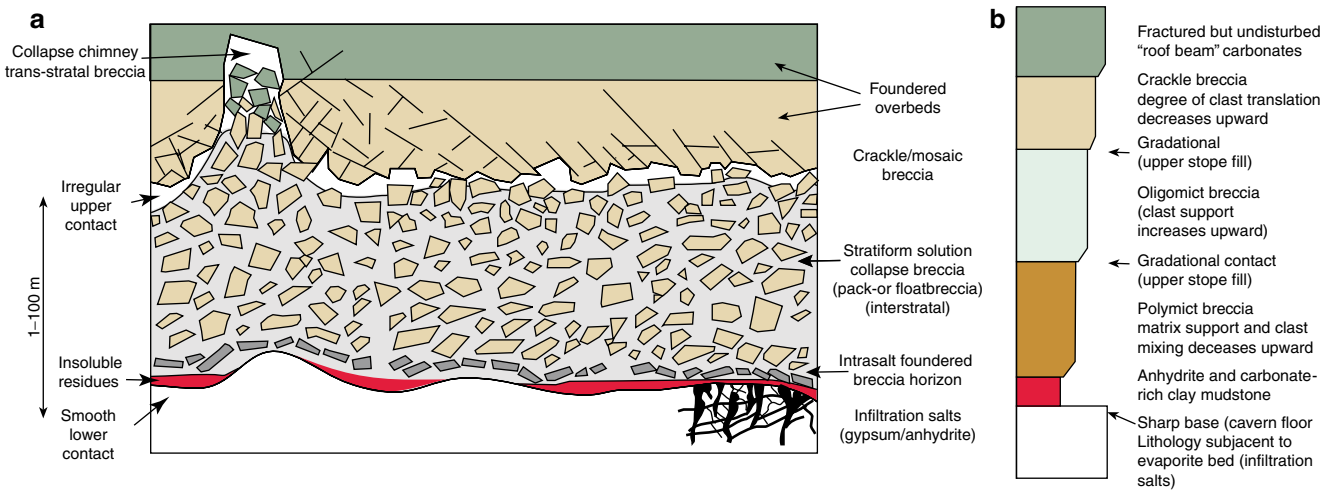

Fig. 7.24 Lithological distribution in an evaporite dissolution triggered collapse breccia. (**a**) lateral facies distribution. Left half of figure illustrates relationships in a trans-stratal chimney, right half in a stratiform solution collapse breccia. (**b**) Ideal vertical sequence of breccia cumulates in an evaporite solution breccia

and lateral extent of the solution cavity into which the clasts move and whether the clasts originally resided in thin interbeds within the dissolving evaporite or if they were part of a thick strong roof-spanning lithology that once overlay the dissolving salt bed. If the cavity is only a few millimetres to centimetres high, the overburden founders gradually and gently and so clast orientation and fitting is little disturbed by the process of dissolution, then crackle and mosaic breccias will be commonplace. If large local cavities develop, the collapse of the roof span is more likely to be catastrophic and the result to be dominated by disturbed rubble or packbreccias (Fig. 7.23a).

Bedded Solution-Collapse Breccias

Stanton (1966) in a benchmark paper on formation of evaporite dissolution breccias demonstrated solution, subsidence, and evaporite flowage act simultaneously during subsurface brecciation. The resulting evaporite solution breccia in the Upper Devonian Leduc Formation, Alberta Basin, Canada, is made up of cm-dm angular dolomite clasts in a matrix of dolomite mud or anhydrite. He concluded that, in the dissolution of interbedded halite-anhydrite-dolomite succession, an anhydrite-supported floatbreccia is a transitional stage to a dolomite clast-supported packbreccia. Angular fragments of the dolomite overburden and interburden in an anhydrite-supported breccia (floatbreccia) are loosely supported by solution-thinned, but still abundant, nodular anhydrite with folded and stretched textures indicating viscous flowage during dissolution. As breccia forms and flows, dolomite fragments are continuously broken and rebroken, while the supporting anhydrite matrix carries a high proportion of loose, whole or broken dolomite rhombs (silt-sand size crystals). Ultimately, a dolomite packbreccia forms by the complete solution of the anhydrite. It then consists of tightly packed dolomite fragments and clasts, within a matrix of sand-sized detrital rhombs and dolomite microspar cement.

At the bed scale, evaporite solution breccias typically have planar to slightly irregular, continuous lower contacts, often coated with insoluble residues (Fig. 7.24a). The footwall edge to a breccia is usually covered by a few centimetres of mud- to sand-sized insoluble residues. The thickness of a pure evaporite that dissolves to produce a thin layer of insoluble residues may be substantial. For example, the Hartlepool Anhydrite contains only 0.5–0.8 % insolubles (Smith 1972). Complete solution of a 100 m thick bed produces a layer of insolubles a mere 50–80 cm thick. In many breccia beds the insoluble residues now make up the matrix between clasts that were derived by the breakup of thin beds of carbonates or clastics. These are the fragmented remains of thin intrasalt beds that were once supported and interlayered by the now dissolved salt. This interval tends to be more polymictic than the upper, roof-derived, part of the breccia unit.

Insoluble residues typically consist of fragmented chert, detrital quartz, silt, clay and dolomite rhombs, which are later cemented by authigenic phases (typically calcite, dolomite or silica cements). Many evaporite beds originally entrain dispersed syndepositional silt-sized dolomite rhombs. When the encasing salts dissolve, a dissolution residue or matrix is left behind; it is dominated by solution-disaggregated dolomite crystal silts and sands and is sometimes called "chalky dolomite." A high degree of initial

intercrystalline porosity in the residue makes it an excellent potential aquifer for later mineralising solutions or hydrocarbons, especially when it forms at burial depths where much of the adjacent nonevaporite sediment is tight, having lost its porosity via mechanical and chemical compaction.

Siliciclastic and carbonate sand, bound by early evaporite cements (e.g. halite cements in aeolian, wadi, or oolite sands), can also be leached during burial diagenesis to create permeability in an otherwise tightly cemented sand. In extreme cases the result is disaggregated freeflowing subsurface sand, with depositional levels of permeability that remain until it is recemented by subsurface processes.

Sometimes, rocks in the footwall beneath the breccia bed are locally veined and cemented by infiltrations of satin spar and poikilotopic gypsum or anhydrite. Smith (1972) argues the fractures hosting such footwall stockworks were first created by the pressure of crystallisation of the evaporite itself; others envisage a more passive process of cement fill within pre-existing joints or fractures. In my own work I have found the joints are often the result of passive fill in joints and fractures created by the extensional stress in units above or below a dissolving salt unit. Because pure halite has often completely dissolved, its former presence is difficult to determine, especially in core or image logs, but these tell-tale fracture-fills remain in the log signature (especially in image logs) and indicate a much thicker former salt bed.

The basal zone of insoluble residues passes up into the main breccia body, an interval dominated by packbreccia or floatbreccia. Breccia fragments and clasts in the main breccia can be angular or solution-rounded (Fig. 7.24a). Almost all rubble texture in a breccia is generated by the collapse of overlying or interbedded lithologies into cavities created by dissolving salt beds. Where the original sequence was made up of interbedded salts and other lithologies, the resulting clast rubble typically collapses in sequential order, so that the rubble pile retains the crude stratigraphic order of the former intrasalt beds.

Clasts are composed of varying amounts of sandstone, dolomite, limestone, mudstone and chert fragments. The main breccia may be polymict or monomict, depending on the nature of the intrasalt beds and the overburden. Breccias can be clast- or matrix-supported (packbreccia versus floatbreccia) depending on the amount of residue entrained in the evaporitic interval prior to dissolution. Pure evaporites, interbedded with indurated dolomites and other nonevaporite strata, tend to produce clast-supported packbreccia fabrics. Evaporite sequences interbedded with, or underlying, nonconsolidated sediments, or evaporites with a high content of dispersed impurities, tend to produce matrix-supported floatbreccia fabrics.

Unlike its lower contact, the upper contact of the main breccia interval is typically gradational, progressing from rubble-breccia in the main body into mosaic, crackle then ultimately into unaltered overburden (Fig. 7.24b). A breccia begins to accumulate on the bottom of a growing cavern marking the contact of undersaturated pore waters and the salt. As the salt begins to dissolve, the insoluble clay-sized material that was present as impurities in the salt accumulates in thin layers on the floor of the cavern. Later in the dissolution process, and higher in the breccia sequence, angular to etched clasts of mixed intrasalt and roof rock form a polymictic breccia. Polymictic breccia passes upward into a monomict breccia made up of angular clasts of roof rock. Gradually, the overlying rock is not broken into clasts but is merely fractured and expanded to form crackle breccia. Crackle fractures, if they are not filled with cement, can provide excellent pathways for subsurface mineralising fluids and can act as reservoirs for oil and gas.

The contrast between a sharp lower contact and a gradational upper contact is one of the most reliable characteristics of a solution breccia, especially if coupled with pseudomorphs and satin-spars. It can be used both in outcrop and subsurface studies (core and image logs) to separate an evaporite solution breccia from a depositional breccia (protoconglomerate), which has evidence of syndepositional infiltration and depositional drape along its upper contact, and a tectonic breccia, which has cataclastic and typically symmetrical contacts related to fault or shear zones.

Where complete removal of less soluble evaporites has not yet occurred, evaporite salts, such as flow-textured laminar to nodular anhydrite, remain as part of the matrix within the main breccia interval. In cores through thick-bedded evaporites the upper bed contact is often defined by a zone of disturbance in the anhydrite textures. The typical fabric is very similar to soft sediment disturbance textures associated with rapid water escape in sands. The anhydrite just below the contact is typically made up of angular but contorted anhydrite blocks in a finer anhydrite matrix. Often, there are also highly distorted and folded blocks or fragments of dolomite and other disturbed intrasalt beds. I have seen these zones at the contacts of many thick anhydrite beds with the adjacent nonevaporite strata including; the San Andres and Seven Rivers formations of West Texas, the Khuff Formation in Abu Dhabi and Saudi Arabia, caprocks to Gulf of Mexico diapirs and Zechstein Formation anhydrites in NW Europe. These disturbed contacts define intervals of subsurface dissolution where the process of dissolution and brecciation is not complete. In many cases dissolution processes may no longer be active, as the adjacent nonevaporite beds no longer have sufficient permeability to transmit undersaturated fluids. They are a form of frozen dissolution breccia that define the early fluidisation stage, where the bed is dissolving from its edges inward like a melting block of ice.

Local reprecipitation of evaporites into the breccia matrix may also generate large poikilotopic crystals, which encase the dissolutional residues. Such cements are typically

coarse-grained anhydrites with a somewhat anhedral form and isotopic signatures indicative of elevated temperatures typical of the mesogenetic realm. Pseudomorphs of now-dissolved evaporite minerals and nodules, composed of calcite, silica or celestite, may also remain either in the matrix or within clasts. Cement may be a fine-grained crystalline precipitate of equidimen-sional calcite crystals, as described by Swennen et al. (1990) in the Belle Roche breccias in Belgium, or a sparry coarsely crystalline dolomite or calcite (burial spar). Coarse sparry or saddle dolomite is often associated with mesogenetic evaporite solution breccias in Mississippi-Valley-type deposits (Olson 1984; Warren and Kempton 1997). Isotopic and petrographic character in dolomite burial cements in evaporite solution breccias are often complex and multistage. For example, there are six burial-related stages of dolomite formation and two episodes of breccia formation preserved in the evaporite solution breccias of the Tripolis Unit, Mainalon Mountain, Greece (Papioanou and Carotsieris 1993; Karakitsios and Pomonipapaioannou 1998).

The lower Visean Belle Roche breccia (east Belgium) is a classic multistage evaporite dissolution collapse breccia (Fig. 7.25; Swennen et al. 1990). Its origin as a dissolution breccia is indicated by: (a) the sharp lower contact of the breccia and a gradual transition into the overlying strata,

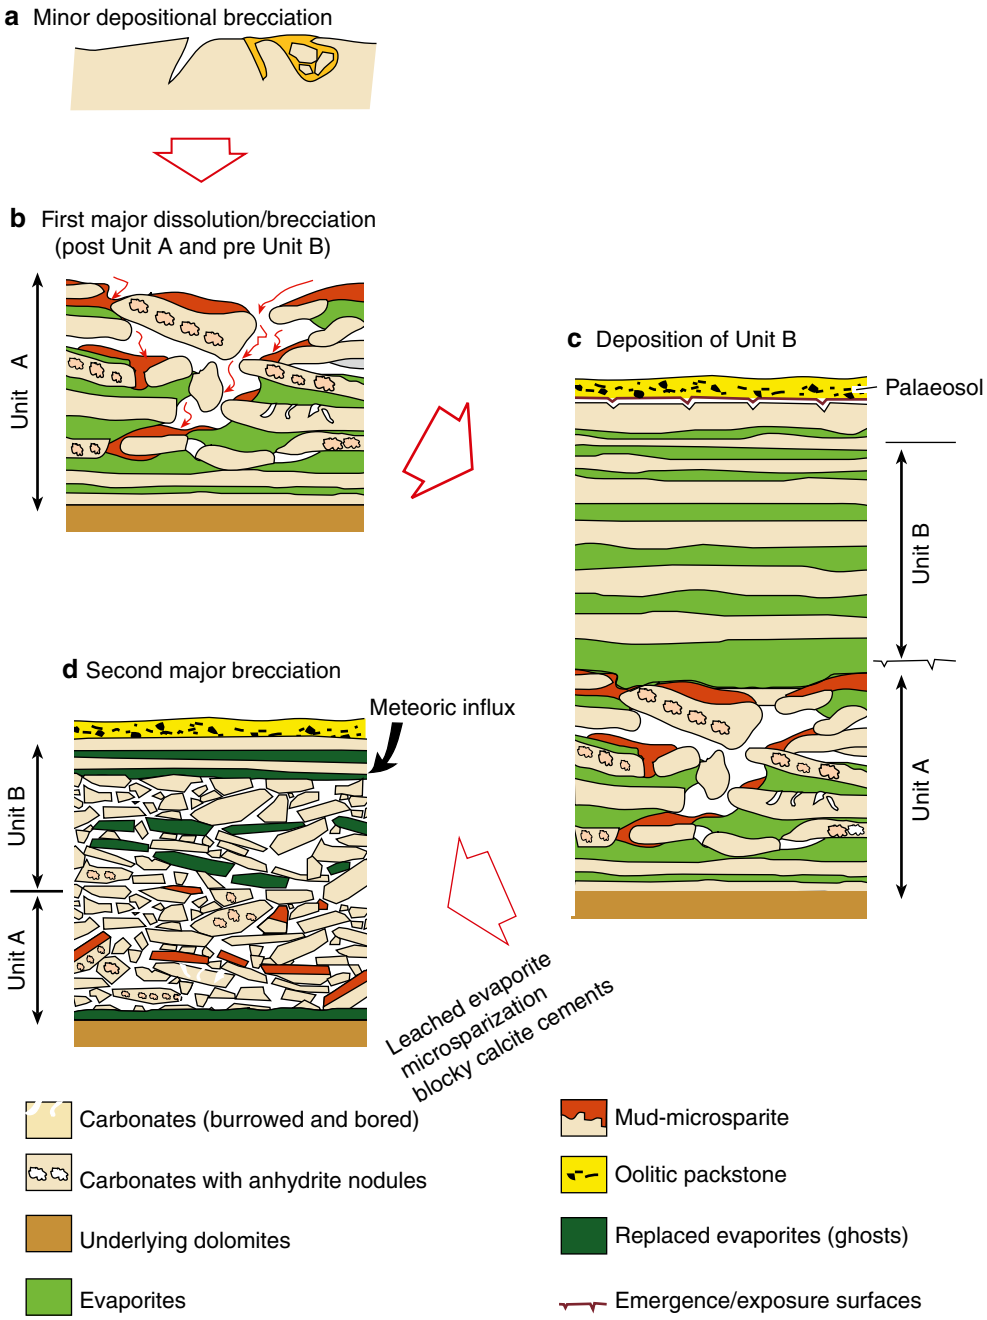

Fig. 7.25 Sequential brecciation episodes in the lower Visean Belle Roche breccia (After Swennen et al. 1990). (**a**) Minor syndepositional dissolution and fracture brecciation mainly related to shrinkage. (**b**) This occurred shortly after deposition of bedded evaporites of unit A and involved incompletely lithified clasts, infiltration of freeflowing mud with ooids. (**c**) Resumption of evaporitic sedimentation to deposit unit B with palaeosol cap. (**d**) Second major brecciation event driven by meteoric influx. It overprinted both unit B and unit A. The brecciation process was mostly foundering rather than cavern collapse, and so stratigraphic order was retained in the breccia stack. Foundering means the overlying beds parallel the general stratification

(b) the presence of semicontinuous clast layers within the breccia giving it a crude 'stratification', and (c) the existence of several types of evaporite pseudomorphs that are now composed of calcite, dolomite and silica. The majority of the sedimentary carbonates making up the breccia fragments show primary features indicating they were originally deposited under hypersaline subaqueous conditions and were interbedded with the now-dissolved evaporite beds. Similar evaporite solution breccias, with similar textures are found in similar age rocks in the Wexford basin, Ireland (Nagy et al. 2005).

Belle Roche breccia has a typical interlocking packbreccia fabric showing a subparallel clast alignment and crude internal layering that indicates foundering by gradual subsidence, rather than catastrophic collapse into a large cavity (Fig. 7.25b, c; Swennen et al. 1990). Multiple brecciation episodes are obvious in the lower breccia (Unit A), where brecciated and veined fragments occur within a microsparite (neomorphosed mud) matrix. There were at least two major brecciation episodes (Units A and B) driven by the successive dissolution of interlayered evaporite units. The second brecciation event related to infiltration of meteoric water and to the complete dissolution of any remaining evaporites (Fig. 7.25d). Meteoric infiltration was probably triggered by uplift related to an orogenic event at the end of the Visean (Sudetic orogenic phase).

Isotopically, three periods of brecciation are seen, the first of which took place early in the diagenetic history. The early breccia matrix consists of infiltrated marine sediments. The fragments and the sedimentary matrix subsequently neomorphosed and lithified in meteoric waters in the shallow burial environment. Multiple water-rock interactions in an open system caused an oxygen isotopic composition of the limestones in equilibrium with meteoric water. This $\delta^{18}O_{PDB}$ composition varies between 8.9 and 5.5‰ depending on the palaeogeographical position (Fig. 7.26). The early diagenetic interaction led also to a spread in the carbon isotopic composition, which ranges between an Early Visean marine ($\delta^{13}C_{PDB} \approx +1$‰) and a palaeosol ($\delta^{13}C_{PDB} \approx -3$‰) isotopic composition. Due to the localised migration of fluids along fractures in the subsurface, a second evaporite dissolution, collapse brecciation and cementation period occurred.

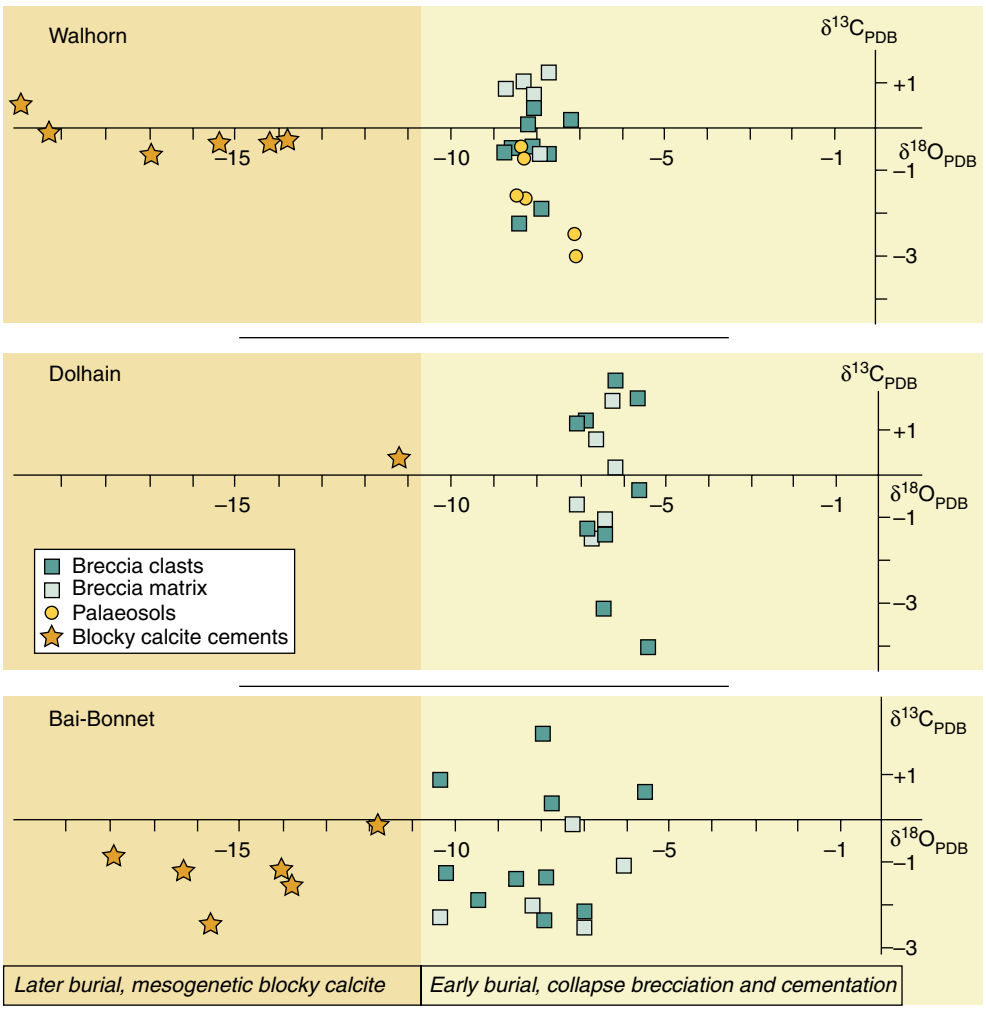

Fig. 7.26 Carbon and oxygen isotope values in Lower Visean limestone breccia components and paleosols at three different localities in Belgium: Walhorn, Dolhain, and Bai Bonnet. Plot shows there are two periods of cementation, (1) An earlier burial period tied to clast, matrix cement and paleosol signatures and, (2) A later warmer mesogenetic period when the blocky calcite cements formed (After Muchez et al. 1992)

During this period, breccia fragments and the early diagenetic matrix locally neomorphosed a second time. The oxygen isotopic composition of the limestone constituents became more negative due to ongoing interaction with increasingly warmer mesogenetic burial fluids. In time, and with further burial re-equilibration, the $\delta^{18}O$ composition of the breccia fragments and matrix moved toward the plot field of the dull orange-brown luminescent blocky calcite cements ($\delta^{18}O_{PDB} \approx -15$ to 20‰), filling the secondary cavities. A third period of brecciation and neomorphism caused the pervasive development of orange-yellow zoned and bright luminescent microsparites to sparites and of granular to blocky calcites with the most negative $\delta^{18}O$ values (Fig. 7.26).

Some of the breccias in this region were dolomitised relatively shallow in active-phreatic mixing zones, via processes facilitated by bacteria (Nielsen et al. 1997). Locally, high degrees of dolomite supersaturation were produced in anaerobic to dysaerobic zones during bacterial sulphate reduction. The sulphate came from the dissolving evaporites and organics from adjacent interbeds. The resulting dolomite precipitates show characteristic bacterial morphologies, such as spheroidal and dumb-bell shaped inclusion patterns, overgrown by dolomite cements with rhombohedral outlines. The dumbbell-shaped portions of the crystals are interpreted as bacterially-related precipitates based on; (1) textural similarities with documented bacteriogenic precipitates, (2) the presence of 'bacterial' microspheres and framboidal pyrite embedded within the dolomite, and (3) their general geological setting. Geochemical characteristics of the dolomites and associated minerals also support a bacterial origin. The bacteriogenic intervals show a ubiquity of framboidal pyrite, depleted in ^{34}S ($\delta^{34}S_{CDT} = -22.4$ to -25.5‰), testifying to a period of bacterial sulphate reduction. The isotopic composition of the spheroidal dolomites ($\delta^{13}C_{PDB} = -2.4$ to -3.2‰ and $\delta^{18}O_{PDB} = -3.8$ to -3.4‰) suggest a contribution from oxidized organic carbon produced during bacterial sulphate reduction. The ^{18}O depletion of the spheroidal dolomite crystals and their occurrence adjacent to, and within evaporite karst cavities suggests a possible mixing zone origin, with a contribution from meteoric waters. The rhombohedral cement-overgrowths have $\delta^{18}O_{PDB}$ values in the range 0 to +5.3‰, indicating precipitation from normal to slightly evaporated contemporaneous seawater. This dolomitisation event predates the onset of blocky calcite cementation in all localities.

In general, as a thick widespread evaporite bed dissolves, it does so more rapidly and pervasively in zones of greatest fluid access. This can be along a fault-bound edge, along a thinned feather edge, along an upper or lower contact, or along joints and fracture planes that cut the bed. As the salts dissolve, carbonate cements may precipitate as cement rinds within stratiform cavities, or along cross-cutting fracture planes. Alternating episodes of dissolving, fracturing and cementing will form veined fracture infills and fragments with clasts of cement within the disappearing bed. With further collapse, these cements may be rebrecciated and cemented numerous times into internally complex clasts and fragments. Ongoing repetition of this process can create clasts made up of nothing but multiple episodes of vein and cavity-fill cements. Some fracture and block-defining cements can remain, and, with the disappearance of the supporting evaporite, evolve to form an open lacework or cellular grid of cemented materials and residues called a boxwork[5] limestone. Such boxworks are especially obvious in nearsurface dissolution settings, as in rauhwacke terrains or phreatic zones of growing tepee structure crusts. Once a rock is more deeply buried and compressed, the boxwork either collapses or is only preserved as delicate laceworks encased within massive cements. For example, even after burial, local relics of boxwork texture can still be seen beneath the V's of the Permian tepees of West Texas and the Triassic tepees of Italy (Kendall and Warren 1987).

Flow of water through cavities during breccia collapse in the active phreatic zone can rework fine-grained matrix material. Localised cm-dm cavities can fill with waterlain laminae that are typically overprinted by water escape features, slumps and, less commonly, with ripples and cross-beds. If the cavity lies in the vadose zone, or if a deeper phreatic cavity contains biogenic or thermochemical gases, such as methane or H_2S, then the cavity may be ornamented with microstalactites, "snottites" and other speleothems. Calcitic vadose speleothems ornament cavities in dissolution breccias in the Kirschberg Evaporite breccia of central Texas (Warren et al. 1990), while pendulous sphalerite stalactites, precipitated in thermochemically-derived H_2S/methane-filled bathyphreatic[6] cavities, typify the evaporite-replacing breccia ores in the Cadjebut Pb-Zn mine, Australia (Warren and Kempton 1997). Cavities and flow paths associated with deeper evaporite dissolution events and the formation of MVT style mineralisation can also be associated with the formation of mesogenetic hydrothermal zebra dolomites (Diehl et al. 2010).

Breccia Extent

Evaporite solution breccia beds can be syndepositional, or form much later after millions of years and hundreds to thousands of metres of burial, halokinesis, and uplift. Breccia beds

[5]The term boxwork is nongenetic, it describes an aggregate with plates or septa which intersect at various angles leaving open boxlike spaces, which may be subsequently infilled or cemented.

[6]Bathyphreatic is used to describe the hydrologic zone typified by deep, near-stagnant waters, situated at depths well below the zone of active phreatic circulation.

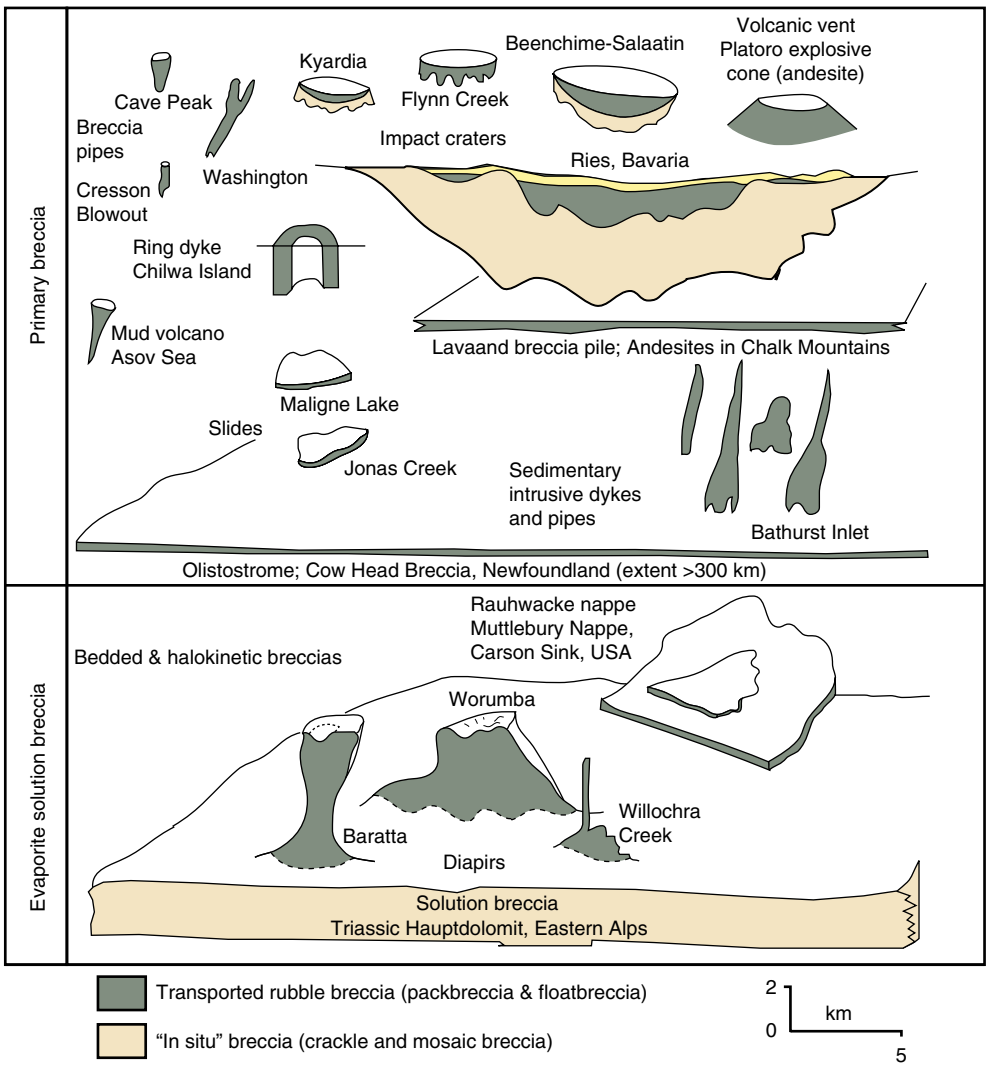

Fig. 7.27 Size and shape of various breccia bodies that occur in sedimentary successions (Modified in part after Laznicka 1988). Evaporite-related ("evaporites that were") geometries are illustrated in the lower part of the figure

tend to be widespread and stratabound, with geometries that indicate the distribution of the precursor evaporite (Fig. 7.27). If the precursor layer was part of a stacked cyclic sequence of platform evaporites interlayered with carbonates or siliciclastics, the breccias tend to stack into interstratal cyclic horizons. This is the most easily recognised style of evaporite solution breccia. If the precursor evaporite was part of a halokinetic or remobilised sequence then the solution breccia is trans-stratal and follows the distribution of former salt stems, salt welds, or thrust planes. Recognising this second type of collapse breccia is more difficult, especially in core.

Intensity of brecciation and the general geometry of the foundered strata in the breccia bed can vary widely from place to place, even within a single unit (e.g. Smith 1972). The geometry of collapse indicators is related to variations in:

(a) Inflow geometry of the solution front: water may enter along a fracture, fault, blanket aquifer, reef, diapir margin, etc. The timing of development of the solution front may in turn be related to episodes of seismic or tectonic instability (e.g. seismic pumping driving episodic basin dewatering, or periodic uplift or sea level lowering creating a gravity head to drive meteoric flow).
(b) Rate of evaporite solution: this is dependent on the rate of formation water crossflow and the saturation state of the cross-flow. This is in turn controlled by climate, tectonics, regional uplift, development of major unconformities, etc.
(c) Confining pressure: related to thickness of overburden at the time of collapse. This is in turn related to the age of collapse (burial/uplift timing).

Stratiform Breccias

The simplest and most general styles of interstratal collapse are typified by blanket aquifers and broad areas of gentle sagging and floundering, where diffuse undersaturated water flow over large areas has slowly removed bedded evaporites

Table 7.3 Features of an interstratal breccia created by foundering, which is the most common mechanism creating an evaporite solution breccia

Characteristic features of an interstratal dissolution breccia	Commonplace textures and features of the adjacent crackled matrix. Equivalents also occur in some recemented breccia fragments, details on their genesis given later.
Sharp lower contact and irregular upper contact to breccia bed. Oligomict clasts derived from overlying and intrasalt lithologies. Breccia body shows a crude stratification, with clasts of differing lithologies often stacked in original stratigraphic order. Depositional textures in some breccia fragments indicate hypersalinity during deposition. Zone of insoluble residues (silt, chalky dolomite, etc.) lies atop lower contact, and sometimes has infiltrated into fractures beneath. Evaporite cements in fractures beneath lower contact. Several types of evaporite pseudomorphs (nodules, radial textures, length slow chalcedony, etc.) are present in clasts or matrix and interclast cements.	Pseudomorphs of former crystals retaining shapes after bird-beak gypsum, axe-head anhydrite or halite hoppers, now filled or partially filled (moulds and casts) with calcite, chalcedony or quartz, baryte, celestite, strontianite. Thumbnail to fist-sized rounded moulds or vugs, in limestone or dolomite host, with irregular edges defining positions of former chicken-wire, nodular or spherical evaporite (cauliflower vugs). Vugs may be filled or partially filled with calcite, chalcedony or quartz, baryte, celestite, strontianite. Silica fill in vugs (geodes) is a varying combination of length-slow chalcedony (quartzine) and spherulites composed of lutecite. Euhedral crystals of authigenic limpid dolomite or quartz (some are double-terminated) in dolomites adjacent to breccia horizon. Minute rectangular relics of anhydrite in quartz or other minerals such as calcite (obvious in quartz because of contrasting moderate birefringence and the rectangular cleavage – but are very small). Coarsely recrystallized (sparry) limestone and dolomite, often porous, and without skeletal debris. Internally the sparry interval may be massive, laminated or contorted. Form by calcitisation or dedolomitisation when evaporite dissolved (especially common in association with telogenetic alteration). Net-textures, a small-scale relic of original bedded gypsum/anhydrite, typically with displaced impurities that outline edges of structures, typically relict patches in secondary, sparry limestone. Small contortions typically related to flow of insoluble residues and characterised by sedimentary structures that are slumped or fractured during subsurface movement in response to evaporite dissolution.

In part after West (1979)

(Table 7.3; Fig. 7.27; Hauptdolomit). The blanket aquifer can lie above, below, or even within the dissolving evaporite bed. Overburden brecciation in such gently foundering regions is minor, so fossils and sedimentary structures are mostly preserved in blocks with near-original orientations. Larger interbed and overburden clasts tend to be tabular, and only slightly separated or disorientated, i.e., dominated by mosaic to crackle breccias.

In areas of more focused dissolution where large caverns and solution planes have formed within the dissolving evaporite beds, the whole of an overlying sequence can be reduced by chimney stoping and doline collapse to a rubble breccia — a mass made up of completely disarticulated and rotated (commonly rectangular) blocks and fragments ranging from silt-size to blocks many metres across. In still other areas, foundered strata can be bound by sharp folds or dislocations that are in effect normal faults. Such areas of intense brecciation are often the end product of localised collapse and can grade laterally and vertically into almost unbrecciated equivalents. These dislocations can be sharp and clean, or associated with areas of intense diagenetic alteration, including calcitisation, silicification, dolomitisation and precipitation of ferroan carbonates. This latter group of intensely altered and replaced breccia intervals within a carbonate or sandstone host can be part of a larger group of fault-focused, often metalliferous, deposits with hydrologies driven by evaporite solution (Warren 2000b).

Hydrology and Texture

Salt beds that dissolve during early burial tend to create characteristic ductile breccia textures and soft sediment slumps in the overburden. These are features that can be used to distinguish syndepositional from later more brittle modes of mesogenetic collapse breccia formation related to subsurface or basinal waters or to even later uplift and re-entry into the active phreatic (telogenetic) zone (Fig. 1.9). Evaporites dissolving early in their burial cycle, even while subjacent strata are accumulating, tend to evolve into ridge and furrow dissolution geometries that influence thickness and depositional style in the lower parts of the overlying sediments. Overlying clastic beds are typically no more than partially lithified when the underlying evaporite dissolves and so are highly disturbed by ongoing soft-sediment textures, which are driven by collapse of their substrate. Such syndepositional collapse and accommodation creates widespread intrabed slumps, water escape textures and other soft sediment deformation features in the beds immediately above the dissolution horizon. Breccia clasts in such scenarios are typically contorted (early plastic deformation) and typically show rounded to crumbly edges.

In contrast, bed collapse after induration tends to create angular clasts and caprock collapse breccias dominated by structures indicative of more brittle collapse failure and sharp-edged angular clasts. This group includes trans-stratal joint and chimney stopes that may have tens to hundreds of metres of relief, as well as pervasive interstratal angular

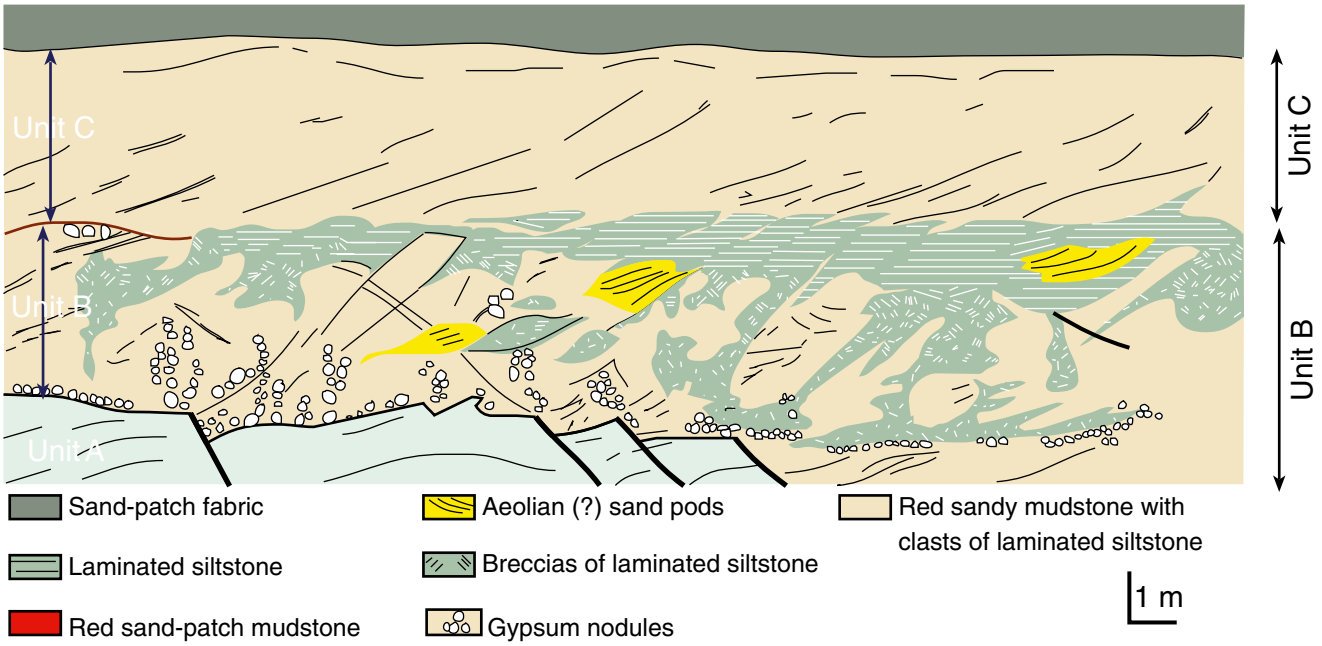

Fig. 7.28 Syndepositional collapse features related to dissolution of an underlying evaporite bed in the Lower Blomiden Formation (Late Triassic) near Blomiden, Nova Scotia. See text for discussion of units A–C (After Ackermann et al. 1995)

breccias derived from overlying strata, where the clasts show little or no evidence of internal deformation (Fig. 7.5). Stopes form in the rock above the growing salt cavities, as the roof collapses and accumulates in an aggrading cavern, maintained by ongoing dissolution of the salt. Fractures and faults form in the rock layers for some distance above and around stoped perimeters. Porosity and permeability created by this fracturing and faulting can provide pathways for late stage cements and can trap or transmit hydrocarbons and metalliferous fluids (Chaps. 10 and 15).

Early dissolution of a nearsurface evaporite tends to be a response to facies-controlled permeability corridors in the blanketing unconfined aquifers. Areas of preferential ingress into the evaporite bed are controlled by depositional permeabilities within the overburden (e.g. ingress beneath porous and permeable sand-rich fluvial channels versus less ingress beneath relatively impervious mud-rich floodplain sediments). In contrast, the hydrologies of later dissolutional systems tend to be more directional and focused by secondary permeability features. By then, the overlying and underlying beds are indurated and relatively impervious so that major zones of undersaturated infiltration or crossflow with the evaporite edges are controlled by joints, faults, fractures or reef crests, as well as regional tilting or sag. Undersaturated pore water arriving at the site of dissolution can be either from meteoric or basinal sources and enter from above or below the evaporite bed.

The feedback between early shallow salt dissolution and partially consolidated overlying sediment styles can be traced for over 35 km of the outcrop length in the Blomiden Formation (Late Triassic) of the Mesozoic Fundy rift basin of Nova Scotia (Ackermann et al. 1995). This unit exemplifies syn-dissolutional salt loss, which was induced by shallow groundwater freshening tied to fluvial sedimentation. Fluvial sands of variable thickness (unit C) lie atop a highly chaotic and slumped mudstone with evaporite nodules still visible in its lower parts (unit B; Fig. 7.28). The primary lamination in clasts in the chaotic mudstone unit preserves much of the evidence of syndepositional collapse of the evaporite substrate. It is characterized by highly disrupted bedding that is commonly cut by small (<0.5 m) domino-style synsedimentary normal faults. It also preserves evidence of downward movement of fines, of geopetal structures, of variable thicknesses related to local hollows after evaporite solution, and of irregular, partially faulted contacts with the overlying unit. Unit B is underlain by a normally faulted massive mudstone (unit A).

Although the thickness of the fluvial sandstone (unit C) is highly variable, the overlying flat-bedded mudstone exhibits only gentle regional dip, hence the bulk of the evaporite layer must have dissolved prior to the deposition of the flat bedded floodplain mudstones. Like unit B, the sands of unit C exhibit numerous soft sediment deformation features including; dewatering structures, convoluted bedding, kink bands, and convergent small-scale fault fans. The frequency and intensity of these features increases dramatically above low points in its base, showing unit C sands were laid down within local solution depressions or furrows that were still expanding as sediment was deposited. Unit B (the chaotic unit) is characterised by blocks of laminated claystone, which become increasingly disrupted and brecciated downward toward its base where locally abundant gypsum nodules are still preserved. Lenses and fissure fills of mudstone to coarse sandstone within the

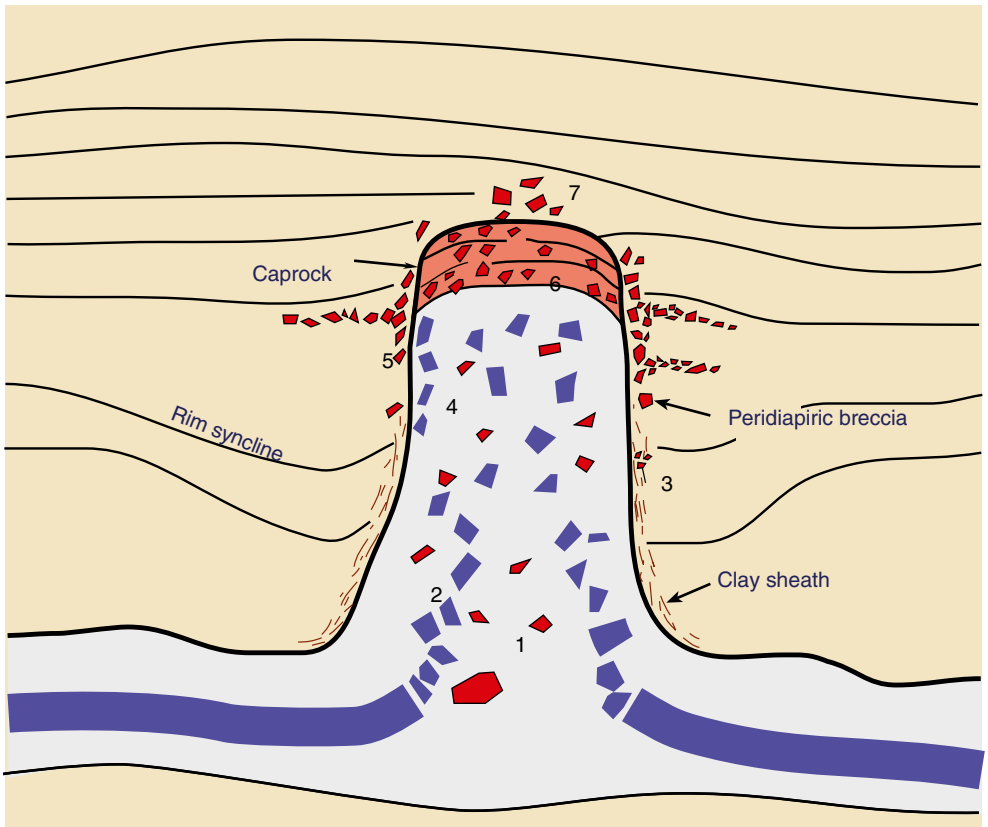

Fig. 7.29 Distribution of diapir associated breccias. (*1*) Slabs of anhydrite in granular halite; (*2*) Internal flowage breccia formed by dismemberment of competent internal beds; (3) Breccia pockets in "clay sheath"; (*4*) Transported flowage breccia of wallrock fragments incorporated into outer zones of stock; (*5*) Peridiapiric ablation breccia, extent is greater in zones of former salt glaciers; (*6*) Caprock breccia; (*7*) False caprock breccia, a dissolution breccia generated by salt collapse (After Laznicka 1988)

chaotic unit often entrain clasts of laminated mudstone originally derived from immediately overlying beds.

Both the chaotic unit and the overlying fluvial sands were deposited as an underlying evaporite layer underwent syndepositional subsidence and karst collapse. Groundwaters driving the dissolution were probably tied to the same river system that was depositing units B and C. The former presence of underlying evaporites is now solely indicated by residual gypsum nodules within the lower part of unit B (Fig. 7.28).

In contrast, breccias that form after induration of overlying strata tend to be combinations of interstratal and trans-stratal geometries with collapse breccia clasts that are made up of well-indurated angular blocks. Post-induration interstratal breccias tend to follow the lateral distribution of the evaporite bed from which they formed, while trans-stratal (transformational) breccias tend to cross cut the strata and form by a combination of chimney growth and overburden stoping (Fig. 7.29). Soft sediment deformation features are less pervasive in post-induration breccias and are typically restricted to intervals where insoluble residues accumulated in joint and fracture-defined fluid-filled cavities.

Post-induration interstratal breccia beds tend to have sharp flat bases and uneven, wavy to transitional blocky upper surfaces, as described earlier. If the dissolved evaporite was pure, with few intrasalt beds, the resulting rubble breccia unit is thin, but widespread. For example, a clean 100 m thick bed of salt may, when dissolved, leave behind a residue bed and rubble breccia that is no more than 0.5–2 m thick, but that residue may form a continuous marker horizon with a lateral extent of hundreds of kilometres. Core recovery from such intervals is often difficult. Even with good core recovery, recognising beds composed of little more than solution residues is difficult, they are easily mis- interpreted as unconformities, tectonites, or syndepositional intraclast breccias. Preserved evaporite indicators, such as "cauliflower" chert or calcite concretions, are one way to define the evaporite association of such breccias.

Spectacular breccia-filled trans-stratal solution chimneys focused on former positions of the Salina Group salts and influencing the overlying Detroit River Group distribution dominate Silurian outcrops in the Mackinac Straits area of Michigan and western Lake Erie (Carlson 1992; Black 1997). They are paleokarst features created by evaporite dissolution and joint-controlled stoping. There are three styles of breccia in the region: (1) megabreccia beds in which blocks up to several 100 m in size moved intact except for some minor tilting; (2) relatively thin intraformational or intrastratal breccia developed along the bedding planes both regionally and within layers in the megabreccia blocks; (3) thicker trans-stratal breccias extending vertically from a few feet to several 10s m and abutted by undisturbed bedded strata. The thickest trans-stratal breccias stope vertically up to 460 m and at one site the individual blocks have fallen 290 m.

Some solution caverns have recently been reactivated on a much smaller scale (Carlson 1992). But most of the intense evaporite karstification, chimney stoping and celestite replacement took place in the Late Silurian. Not all breccia chimneys reach the surface, and areas of this "blind" salt karst can only be located using geophysical techniques.

The evaporite dissolution features in the Mackinac Straits area of Michigan illustrate the multicyclic karstic signatures with multiple times of formation that typify the periphery of many evaporite dissolution zones of saline giants. At least three major evaporite dissolution events have created deep karst overprints in two zones along the northern Michigan Basin (Black 2012). Dissolution of outer margin Silurian evaporites resulted in the Mackinac Breccia during the early Devonian. Then rebound and exposure or a later, delayed brief basin rebound drove the development of surficial evaporate epikarst[7] in the middle Detroit River Group. This occurred before the next subsidence phase and renewed deposition of intracratonic sediments, which continued into Mesozoic. Hundreds of millions of years later, Pleistocene glaciation pumped fresh water into shallow Silurian and Devonian carbonate aquifers in the Michigan Basin and this in turn stressed various intracratonic beds via repeated glacial-induced loading and unloading. Buried early-Devonian paleokarst in the Detroit River Group focused the effects of hydrostatic pressure buildups along hydraulically open faults and fractures which first developed the ancient karst.

The current karsted zone in the Michigan Basin varies from totally removed evaporites and collapsed formations along the northern margin of the Detroit River Group subcrop, to an irregular still active evaporite dissolution front along the current salt edge, some 29–39 km further basinward. The last glacial retreat from the Lake Huron basin, approximately 10,000 years before present, opened and flooded the basin. The lake level dropped approximately 150 m in the Lake Huron basin to Lake Stanley stage at 10,000–7,500 ybp to approximately 58 m asl compared to the 177 m above sea level of present-day Lake Huron. This is likely the time when most of the visible collapse sinkholes in Northern Michigan formed. Some of these sink-holes have been identified beneath the waters of Lake Huron recently by subbottom profiling. Water venting from them, into the lake, has conductivity values ranging from 123 to 1,821 μS/cm, attributed to high levels of chloride and sulphate (Black 2012). A benthic ecosystem of anoxic chemosynthetic bacteria composed of biolaminites and filamentous bacteria grows in the vicinity of the vents. There are no known land springs from this system, which has an active swallow area of hundreds of square kilometres.

Diapiric Solution Breccias

Salt diapir (halokinetic) breccias are transtratal features that ultimately contain no salt, but outline a former diapir geometry. Diapiric solution breccias and their reworked debris aprons (salt ablation breccias) are forming today in and around at-surface salt diapirs in a number of areas worldwide, including the Arabian/Persian Gulf (Fig. 6.84; Table 7.4). Once the stem salt or its allochthon has dissolved, the only evidence of former flowing salt may be a few pseudomorphs after halite or calcium sulphate, either in the breccia clasts or in the interclast matrix. The breccia itself is typically an allochthonous assortment of angular clasts in a matrix made up of insoluble residues (sometimes called "rock flour"), which is typically dominated by finely crystalline carbonate, clay, sericite and chlorite. Classic examples, where little or no salt remains, outcrop extensively in the Mesozoic and Tertiary sediments of the La Popa Basin in Mexico, in the Neoproterozoic strata of the Flinders Ranges of South Australia, the Macdonnell Ranges of the Amadeus Basin of Central Australia, and in sediments caught up in the Damara Orogen and the Lufilian foldbelt of southern and central Africa (Table 7.4; Giles and Lawton 2002; Mount 1975; Lemon 1985; Kennedy 1993; Behr et al. 1983; Jackson et al. 2003). Some of the breccia blocks carried up from depth by flowing salt can be large (a kilometre or more across); they typically line up parallel to the salt stem edge or weld, or form a chaotic carapace at the exposed top of the former salt stem.

Diapiric breccias are always trans-stratal and clasts tend to be polymict associations of allochthonous fragments. Clasts of varying diameters are combinations of; (a) material that was once an intrasalt bed, (b) buoyed material that was plucked or was enclosed by flowing salt, and (c) material that was derived from the collapse of overburden as the active diapir deflated and dissolved (Fig. 7.29). The complex folding that accompanies salt flow means breccia bodies defining a former diapir are much less likely than bedded solution breccias to preserve original stratigraphic layering of any intrasalt beds.

Breakage and rotation of intrasalt beds begins once the encasing salt begins to move. Flowing salt can also pluck large blocks from strata adjacent to a salt wall or in contact with the flowing bed of the mother salt layer. Once caught up in flowing salt, the clasts are carried toward the surface to accumulate as breccia masses in stratigraphically higher regions of former salt, either in stems and feeders or spread out laterally across areas of former allochthons. Clasts often include metamorphic-grade minerals, such as magnesian-talc,

[7] Epikarst: pertains to the upper/outer layer of karstified rock in the unsaturated zone, immediately below the soil layer.

Exokarst: pertains to features found on a surface karst landscape, ranging in size from karren to dolines and subsidence bowls.

Endokarst: pertains to all features beneath the surface and hosted by a vertically layered karst system. It includes the full spectrum of underground voids and the dissolutional features present on the rock surfaces surrounding them. Klimchouk (2012) argues usage of the term endokarst should be expanded to include much hotter and deeper process sets that includes igneous and metamorphic fluids acting to create porosity at great depth.

Table 7.4 Areas of modern outcropping and subcropping diapiric salt karst

Modern at-surface diapiric salt karst	Age of mother salt	Reference
Cordillera de la Sal, Atacama Desert, Chile	Miocene salt	Fryer (2005)
Cardona diapir, Spain	Triassic salt	Lucha et al. (2008)
Vrancea Subcarpathian Hills, Romania	Miocene salt	Giurgiu (2005)
Mt. Sedom, Israel	Late Miocene-Pliocene, Sedom Fm	Frumkin (1998)
Zagros Mt. Diapirs, southern Iran	Infracambrian Hormuz Salt	Bruthans et al. (2010)
Qom diapirs, central Iran	Miocene, Lower Red Formation	Warren (2008)
Arabian/Persian Gulf, diapirs	Infracambrian Hormuz Salt	Kent (1970)

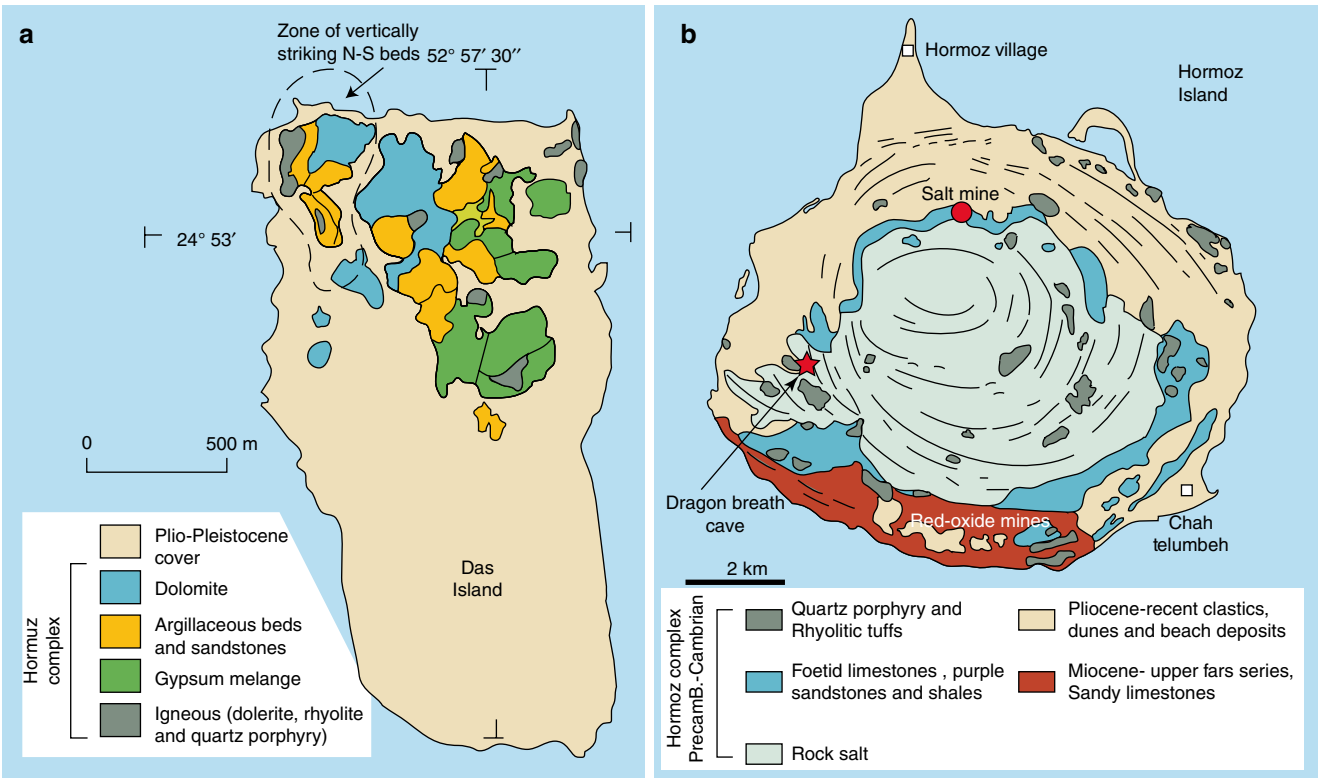

Fig. 7.30 Evaporite dissolution breccias on Gulf Islands cored by Hormuz Salt Series diapirs. (**a**) Das Island, showing chaotic nature of the Hormuz Complex that includes blocks of ferruginised and rafted material that are hundreds of metres across (After Kent 1987). Surficial geology is no longer visible in current satellite imagery due to construction of a refinery on the island. (**b**) Hormuz Island; still shows salt ridge cored curvilinear outcrop patterns due to shallow halokinetic salt subcrop and numerous blocks of Precambrian volcanics hundreds of metres across and carried to the surface by salt flow as is seen today in Qom salt fountain (After Hurford et al. 1984)

sodian-scapolite and dravite-uvite tourmaline, which likely indicate clasts were carried from depths where the metamorphic/diagenetic grade was higher than the current stratigraphic level of the breccia. Solution breccia emplacement in the Damara Orogen also encompasses processes of fluidisation and cataclasis within mobile evaporite units in thrust belts and welds. These breccias were actively forming at greenschist and higher metamorphic grades and so lie outside the sedimentary focus of this chapter (see Fig. 14.2).

Recognising the occurrence of higher temperature and metamorphic grade indicators is useful when a core or cuttings are recovered from a well that has intersected a breccia body and an attempt is made to distinguish interstratal breccias and transtratal chimneys from diapiric breccias and welds, as well as from associated allochthon debris aprons. Halokinetic breccias can also outline former thrust or glide planes after the dissolution of the original halite or calcium sulphate horizons that lubricated the thrust. Such thrust-weld breccias are termed rauhwacke and are discussed later in this chapter.

Diapiric dissolution breccias define areas above subcropping salt plugs in numerous islands in the Arabian Gulf, in what is one of the world's largest salt provinces and also one of its largest hydrocarbon provinces. Most of these diapir-cored Gulf Islands are plug ruins that have experienced little salt movement since being squeezed by the mid Miocene collision of the Arabian and Iranian plates. Today these regions of outcropping Hormuz Complex are heavily eroded and largely covered by Neogene shoal water carbonates and marine-cut platforms, as in Das and Hormuz islands (Fig. 7.30a, b).

These diapiric breccias are the outcrop expressions of what is locally called the Hormuz Complex or the Hormuz Salt Series, from the type section on Hormuz Island where the breccia is still actively forming (Fig. 7.30b). The breccia complex is a polygenetic assemblage of lithologies that includes both nonevaporite blocks carried along by salt flow and remnants of the supporting salt and gypsum/anhydrite matrix. The Hormuz Formation at the mother salt level was originally deposited as a basinwide evaporite near the Precambrian/Cambrian boundary and has since been mobilised numerous times into salt structures that intersect various levels of the overlying stratigraphy (Kent 1987; Talbot 1998). The range of clasts in the Hormuz Complex is diverse, but uniform over most of the Gulf islands. In none of the outcropping breccias are there any clasts derived from the cubic kilometres of indurated Palaeozoic and later sediment, through which the salt passed on its passage to the surface (Fig. 7.29; Kent 1970, 1987). One of the most characteristic raft lithologies is a black foetid finely laminated and bedded dolomite that is often coarsely recrystallised and shows evidence of deep burial diagenesis. It was deposited in the same hypersaline setting that was also responsible for the deposition of the thick salt beds that became the Hormuz Complex. Similar foetid dolomite blocks characterise megabreccias in regions of outcropping diapiric breccias of the Neoproterozoic Ara Formation in Oman (Peters et al. 2003). In the South Oman Salt basin these dolomites are still encased in salt and act as self-reservoired and self-sourced carbonate slivers sealed in salt (Fig. 10.67). Siliciclastic blocks composed of sandstones and siltstones are also widespread in the Arabian Gulf breccias, they are mostly reddish, grey or greenish grey and variably indurated. Throughout the region, both dolomites and siliciclastics can outcrop as spectacular rafted blocks up to several 100 m across (Fig. 7.30).

Igneous rocks are another important component of rafted megabreccia blocks in many diapiric breccias worldwide (Wilson 1975). In Gulf island breccias the igneous rafts tend to be dominated by acid tuffs (trachytes and rhyolites) along with acid intrusives and dolerites (Fig. 7.30; Kent 1970). On the Iranian mainland the igneous rafts in namakier residues are referred to as "greenstone" blocks, as they are dominated more by basalts and dolerites. Throughout the salt-cored Gulf islands and on the Iranian mainland, large volumes of red specular haematite characterise outcrops of the Hormuz Complex. Some rafts of silicified shale are crosscut by malachite-stained joints. On Hormuz Island the outermost ring of the salt plug itself is made up of haematitic tuffs, locally so rich in iron oxide that it is mined as a source of pigment (Fig. 7.30b; Kent 1987). The significance of Fe-rich phases in terms of ferroan chloride brine haloes and metal transport in halokinetic provinces is discussed further in Chap. 15 and in Warren (2000b, 2008). Salt-buoyed and salt-encased xenoliths exposed in salt mines in Five Islands region of Louisiana have been used in the salt-covered region of the Gulf of Mexico to determine the transitional nature of the subsalt igneous basement (Stern et al. 2011). Other than these xenoliths there are no other samples to study of the deep Jurassic basement.

Texturally near-identical Neoproterozoic diapiric megabreccias, breccias and breccia trains crop out in the Flinders Ranges of South Australia (Figs. 7.31 and 7.95b; Dalgarno and Johnson 1968). Many breccias in anticlinal cores of the Flinders ranges halokinetic terrane are still located at or near the level of the mother salt bed (Callanna Beds) with current outcrop patterns largely indicative of the positions of deeper basement faults (Backé et al. 2010). Today, they define the polytectonic remnants of former autochthonous salt pillows or glide planes and inversion structures, rather then true salt-cored diapirs. Some structures, such as the Oratunga and Wirrealpa diapirs, still preserve evidence of their earlier formative extension phase and show subcircular patterns of outcrop and breccia wings at allochthonous stratigraphic positions well above the level of the original mother salt bed. Almost all the transtratal breccias line up along major regional shears and faults (welds) surrounded by jostling depopods or minibasins, indicating that the mother salt bed was flowing as the basin was under extension. The salt was then remobilised during the inversion phase and the transition from haselgebirge to rauhwacke textures (Fig. 7.31a). Lemon (1985, 1988, 2000), Dyson (2004) and Rowan and Vendeville (2006) clearly illustrate synkinematic controls on sedimentary facies and thicknesses adjacent to many of these breccia masses in the Flinders Ranges (Fig. 7.31b, c).

Diapiric breccias in Flinders Ranges are heterogenous, with polymict clasts set in a strongly folded and disrupted matrix, dominated by weathered pale-grey siltstones and fine sandstones. Clasts are mixtures of dolomites with gypsum and anhydrite pseudomorphs, dolomitic sandstones, siltstones and sandstones with displacive halite casts along bedding planes, and angular igneous fragments of diabase and basic volcanics, including amygdaloidal basalts (Lemon 1985). The margins of many former diapirs in the Flinders Ranges are also characterised by numerous sub-economic copper shows in a haematitic matrix, much like the copper shows in the Gulf Islands.

Banded and aligned fabrics of clasts in the breccia masses of the Flinders Ranges diapirs indicate that shaping, disruption, mixing, and alignment of clasts occurred during salt-buoyed flow. Rafts showing coherent flow alignment can be blocks of megabreccia up to 500 m across (Fig. 7.31b, c). Long axis alignments of large raft blocks near the edge of a breccia mass are frequently near vertical and aligned subparallel to the diapir margin. Rafts nearer the centre of the breccia mass are more randomly distributed, a feature that indicates frictional alignment of large clasts near the diapir edge at the time salt was flowing or flow was collapsing.

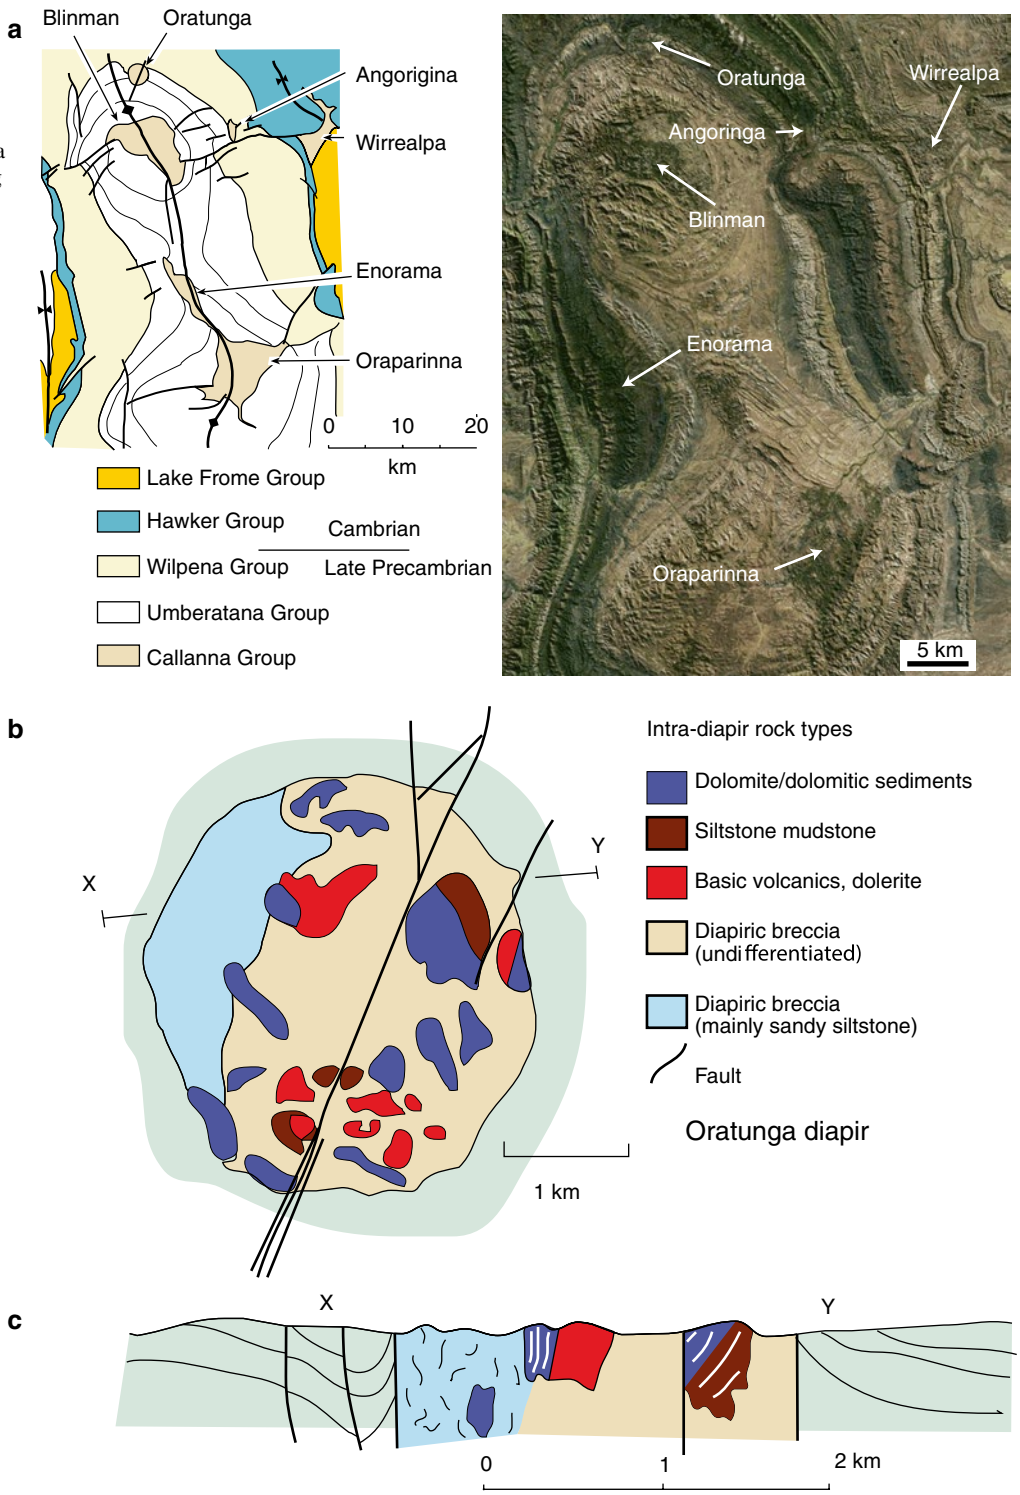

Fig. 7.31 Halokinetic breccias, Flinders Ranges, Australia. (**a**) Regional distribution of halokinetic breccia in the Callanna Formation. (**b**) Distribution of large megabreccia lithoclasts or rafts in outcropping breccia matrix that define the Oratunga Diapir. (**c**) East-west cross section of Oratunga Diapir (Modified from Lemon 1985)

There is similarity between the size and lithology of rafts found in Neogene diapir crests in the Arabian Gulf and those in breccia masses in the Flinders Ranges. Steeply dipping bedding in rafts located near the diapir edge is also a feature of both areas and suggests flow alignment (Fig. 7.30 and Fig. 7.31b).

Matrix minerals in the Flinders Range's breccias include: carbonate, chlorite, feldspars (both detrital and authigenic), haematite, magnesio-riebeckite, quartz, stilpnomelane, and talc. Mount (1975) interpreted them as zeolite facies minerals formed during breccia emplacement via reactions involving hypersaline fluids. Although all the at-surface breccias

lack preserved salts he argued conditions during breccia formation were aqueous, low pressure, and hypersaline. Mineral-forming reactions occurred in an oxidative low-grade metamorphic environment replete with CO_2 , with open system fluid throughput and low temperatures (150–300 °C). He concluded this palaeohydro-chemical system had strong affinities to natural hydrothermal and geothermal systems. It indicated a later deeper burial stage comparable to the current salt-filled diagenetic systems of the Iranian namakiers. The matrix minerals formed as solution flour at a time when most of the salt had already dissolved from the system and only the breccia bodies remained to outline the former salt geometry.

The late extension-stage geometries shown by the halokinetic breccias of the Flinders Ranges also means that where the crestal rather than the stem or feeder portions of the diapir breccia crop out they tend to show classic "falling diapir" geometries with suprasalt depopods, along with oversteepening related to subsequent compression and diapir squeezing (Fig. 6.80). Examples include the Wirrealpa and Oraparinna diapirs (Dyson 1998, 1999). The falling diapir stage is characterised by crestal collapse and the formation of fault-defined graben thicks in the overlying sediments (Fig. 6.93b). As the diapir was collapsing, the underlying salt was thinning and dissolving. This facilitated the growth-fault focused escape of formerly confined basinal fluids on to the seafloor. This mechanism explains the formation of large fault-fed baryte masses atop many former diapir crests, along with the various small copper shows found in association with the diapir breccia margins (Chap. 13; Warren 2000b).

Mount (1975) noted breccia/host rock contacts were invariably abrupt and coincided with planes of weakness in the host strata. The breccia edge – country rock contacts match across some diapir stems, despite synformational sculpting and quarrying by invading diapir material. Adjacent host strata were rarely brecciated against a diapir, illustrating again the passive nature of the intrusion. His observations help explain why material from overburden strata located adjacent to a rising salt stem is not broken into rafts and transported to the surface. Salt emplacement is predominantly a passive process driven by the flow of pressurised salt into pre-existing planes of entry. Where contact deformation has occurred, it usually predates diapirism and was due to glide plane faulting that then controlled subsequent breccia geometry. Mount (op. cit.) termed this style of contact 'permitted intrusion.' He argued it occurred under extension of the cover or overburden, perhaps induced by regional extension. Alteration of the host rock adjacent to contacts was absent but for minor dolomitisation and sideritisation in certain areas.

Instead of using models of forcible injection for diapir emplacement that prevailed in the 1960s and 1970s in the Flinders Ranges, Mount (op. cit.) used the outcrop geometries to stress the passive nature of salt flow into tensional structures. He concluded that "diapir" in terms of the then popular notion of active piercement, was not the most appropriate term to explain breccia emplacement in the Flinders Ranges. His understanding of the dominantly passive nature of the diapiric process preceded by almost two decades our current models of brittle overburden atop weak flowing salt. In 1975 he stated, "… The overburden was relatively brittle, its weight the prime driving force to the intrusions. Mobility of source material, rather than factors such as density, was paramount to diapirism. The mobility is explained by the former presence of saline evaporites in the interstices of the breccias."

Diapiric Versus Salt Ablation (Retreat) Breccias

Diapiric collapse breccias are classified as a type of evaporite solution breccias in the preceding discussion and are typically considered the result of subsurface dissolution of a diapiric feature that retains the outline of the original subsurface salt stem or allochthon. But this definition does not encompass the notion of breccias created by the leaching of an at-surface salt allochthon or namakier, nor does it include breccia created by the dissolution of salt-lubricated thrust sheets (rauhwacke; Table 7.5). When a namakier shrinks it does so via at-surface dissolution of the salt mass, much in the same way a glacier retreats as it melts (Fig. 7.21). Likewise, the outer edge of a salt glacier expands and contracts like the outer edge of an ice glacier. When the salt mass retreats it leaves behind a jumbled mass of material it once buoyed, which can include megabreccia blocks tens of metres across, as well as the insolubles of its carapace and insoluble intrasalt layers. These chaotic breccias are similar to a diapiric collapse breccia, but contain a much more polymict assemblage of clasts than an evaporite collapse breccia (after bedded salt) and often show evidence of mechanical reworking of portions of the breccia material by waves or currents. A separate term is probably needed to distinguish them from the more general term diapiric breccia; I call them salt ablation or salt-retreat breccias (Table 7.5).

Salt ablation breccias are forming today atop and peripheral to the dissolving edges of retreating namakiers in the Zagros of southwestern Iran (Fig. 7.32; Talbot and Jarvis 1984; Bosak et al. 1999). Wherever an active but shrinking salt tongue subcrops or lies beneath a dissolution-derived gypcrete carapace, the clasts accumulate by breakup of the soft overburden and by stacking of fragments and rafts formerly held within the now dissolved salt matrix. The resulting namakier breccia is composed of a coarse, unsorted, heterolithic (polymict) rubble supported by a fine-grained calcareous matrix dominated by solution flour. This material can be mixed with fluvial and alluvial material (note the fans

Table 7.5 Comparison of salient features for separating the main types of breccias created by dissolving evaporites

Feature of interest	Evaporite collapse breccia (stratiform after bedded salt)	Evaporite collapse breccia (transtratal after diapiric salt)	Salt ablation (retreat) breccia (stratiform after an at-surface allochthon)	Rauhwacke breccia (transtratal dissolution residues) from a salt-lubricated compressional thrust sheet(s)
Timing of brecciation	Subsurface	Subsurface	Can be at-surface or nearsurface	Subsurface and telogenetic
Overall shape of unit	Stratiform (sometimes with local chimneys) with passive base	Transtratal (includes salt and fault welds), shale sheath drag zone	Stratiform with disturbed lower contact (former gumbo)	Transtratal (regional extent) defines salt-influenced thrust wedge geometries
Diversity of breccia clasts	Upward transition from low-polymict to monomict (crackle)	Polymict from intrasalt layers and plucked subsurface material	Polymict intermixed with surface sediments (e.g. fluvial, alluvial, reef)	Polymict from intrasalt layers and plucked subsurface material
Metamorphic grade of clasts in breccia	Matches adjacent sediments	Higher than adjacent sediments	Higher than adjacent sediments	Higher than adjacent sediments (fluid focus and squeezing can create alteration halo)
Vertical stacking in the breccia mass	Broadly matches the original stratigraphic order, even in any stoped transtratal chimneys	Chaotic (salt flow churns clasts along diapir stem then via dissolution and welding)	Chaotic for salt-carried clasts, but more cover sediment toward its top (e.g. reef carapace on blocks)	Flow aligned in thrust sheet can become less ordered due to telogenetic collapse
Image logs and seismic	Discernible in image log but ambiguous, can be confused with stratiform conglomerate bed, etc. Typically mapped as an unconformity in seismic.	Discernible in image logs, but ambiguous, can be confused with tectonic breccia. Seismic geometries are characteristically transtratal.	Discernible in image logs, but ambiguous, can be confused with stratiform conglomerate. Seismic geometries (wings and tongues) are characteristic but difficult to resolve. Features are transitional or subcomponent of diapiric breccias.	Discernible in image log especially by consistent dips shown in parallel flow textures in structurally controlled laminar anhydrites preserved in subsurface thrust sheets
Examples	Cretaceous Kirschberg breccia (Zahm and Loucks 2011)	Flinders Ranges diapirs (Backé et al. 2010)	Zechstein of onshore Germany (Mohr et al. 2007)	Western margin of South Oman Salt Basin (pers. obs.)

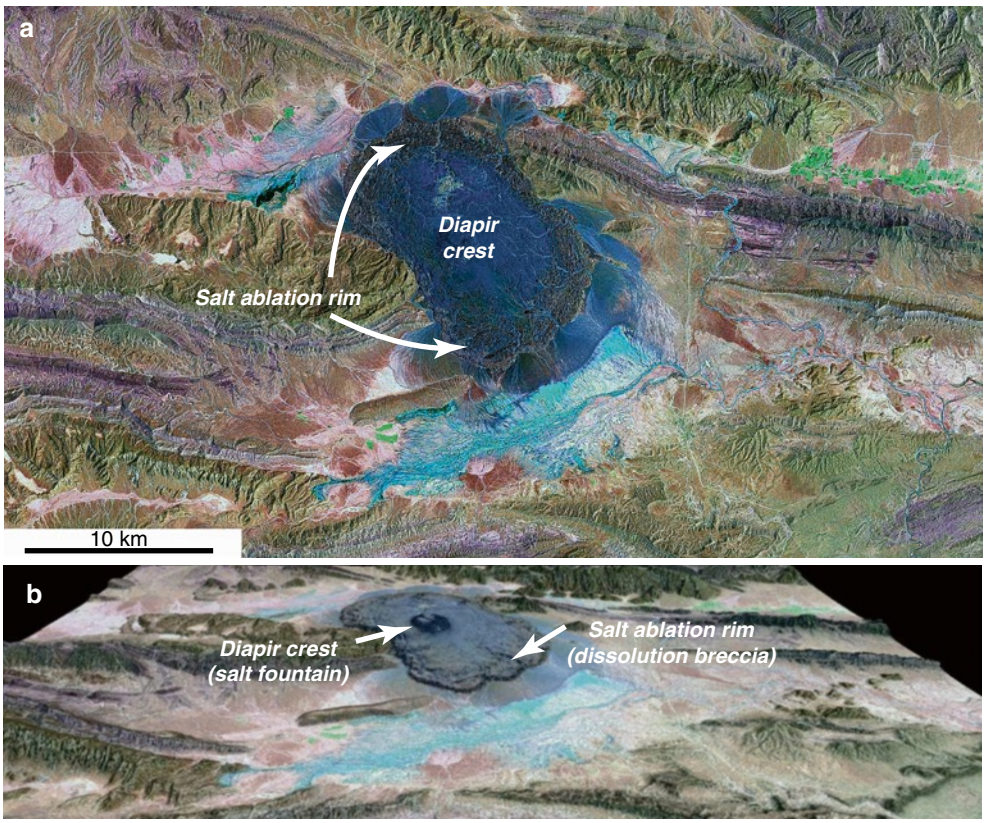

Fig. 7.32 East Mazyjan diapir, (Iran; 27.98 N, 54.91 E). showing the active salt fountain crestal region passing centripetally out to salt ablation rim with associated salt ablation breccias. (**a**) Plan view. (**b**) Lateral view using DEM overlay on Landsat image (After Warren 2008)

fed by alluvial streams that cross the ablation zone in Fig. 7.32a) or marine carbonate debris from times when the sea encroached on the salt tongue.

Ongoing dissolution of the namakier leaves behind a rubble moraine at the level of the former salt allochthon (Fig. 7.21). Thus, salt ablation breccias associated with salt cores of the various island diapirs of Arabian Gulf are jumbles of exotic material carried to the surface by upwelling salt, which is then combined with the disrupted remnants of the Neogene marine carbonate shoals and buildups that once covered earlier now-dissolved salt tongues (Hormuz Complex). The mixing of contemporary sediment (alluvial or marine) with salt-buoyed megabreccia blocks and insolubles in the salt, and the stratiform circum-stem or circum-weld nature of its occurrence, is what distinguishes a salt ablation breccia from a diapiric breccia formed by subsurface salt dissolution (Table 7.5).

Breaking out the age of the former cover sediments within buried salt ablation breccias is useful in attempting to time episodes of at-surface salt in Phanerozoic successions adjacent to former salt stems. Such a combination of marine, fluvial and cave sediments, along with karst phenomena including dissolution breccias was studied and dated in the Namakdan diapir on Qushm Island, using a combination of ^{14}C, U-series, and OSL methods (Bruthans et al. 2010) The Namakdan diapir hosts the world's longest salt cave (3 N Cave; 26.612 N, 55.508 E). The main factors influencing the diapir morphology are; sea-level oscillations, uplift rate of the diapir and its surroundings, and erosion. Although the diapir uplift rate has been constant for the last 50 kyr (≈4 mm/year at a distance 600 m from the diapir edge), the uplift rate decreases with the distance from the diapir centre. Drag-induced host rock deformation extends for ≈ 300 m from the outside edge of the diapir, and host rocks in this zone have an uplift rate of 0.4–0.6 mm/year, which is two to three times greater than the regional uplift rate. Based on known sea-level oscillations, radiometric dating, and geological evidence, the Namakdan diapir was repeatedly flooded by seawater between 130 and 80 kyr BP. At that time a submarine residuum, composed mainly of gypsum and dolomite, formed cap rock and its breccia on the water-covered parts of the diapir. After 80 kyr BP, surficial drainage network and karst development started. Blind valleys and their corresponding cave systems evolved continuously for 20–30 kyr (see later). Between 9 and 6 cal kyr BP the rate of sea-level rise exceeded the Namakdan diapir uplift rate by the factor of 3. As a consequence there was upward incision of cave streams and gravels filling blind valleys near the former seashore. Cave passages, accessible today on the Namakdan and Hormuz diapirs, started to form 3–6 cal kyr BP when sea level stabilized and downward stream incision began. Older cave levels are still preserved, but are mostly filled with sediments and salt precipitates (see later).

Belous et al. (1984) described reworked breccia trains (salt ablation breccias) composed of fragments of Devonian basalt and limestone at several stratigraphic levels in sediments surrounding the Late Palaeozoic Adamovsk salt stock in the southern Ukraine. They attributed breccia trains to lateral redeposition of salt-lifted blocks during periods of stock unroofing, possibly via a salt glacier mechanism. Similarly, drilling in 1991 in the Tapley Hill Formation on the flank of the Blinman Diapir (Flinders Ranges, South Australia) intersected an anhydrite-cemented breccia, with most clasts not derived from the enclosing shale (Cooper 1991). The intra-Tapley breccia is interpreted as a salt ablation breccia, it is a residue of a salt glacier once flowing across the Neoproterozoic seafloor under a relatively deep water mass. Recognition of numerous salt ablation breccia levels in circum-stem positions about the Pinda and Wirrealpa structures in the Flinders Ranges, South Australia, led Dyson (1998, 2004) to describe the precursors to the current breccia- defined outlines as "Christmas-tree" diapirs, a sedimentary origin that is somewhat different interpretation to that illustrated in Fig. 6.45.

Salt-Cored Thrust and Fold Breccias, Rauhwacke and Orogeny

Rauhwacke horizons are the weathered and leached remnants of what were once 'weak' salt-entraining tectonised layers (Jeanbourquin 1988, 1994; Warren 1999). Under stress, their evaporitic precursors acted as rheologic inhomogeneities providing surfaces of décollement during orogeny. Halite, or sometimes anhydrite/gypsum, are the main lubricants during the formation of stratiform tectonite or décollement layers. The inherent lack of strength of halite or anhydrite/gypsum under stress, when compared to other lithologies, focuses the greater part of the detachment, fold or thrust plane movement into the salt-entraining interval, which can also move salt into higher levels in the thrust sheet (Chap. 6).

Rauhwacke are evaporite solution breccias (Table 7.5) that define outcrops and subcrops of evaporite-lubricated thrust-planes and have been described from the Appalachians, Jura Mountains of Switzerland, the Atlas Mountains of Morocco, the Zagros and the Salt Range of Pakistan (Davis and Engelder 1985; Som-maruga 1999; Jadoon and Frisch 1997; Alavi 2007; Fudral et al. 2010). Jordan and Nuesch (1989) and Jordan et al. (1990) describe deformed flow-aligned anhydrite textures in décollement horizons preserved in tunnels intersecting the main Alpine thrust planes. Similar features occur in laminar anhydrites in thrust sheets along the western margin of the South Oman Salt Basin (pers. obs.). In both cases these features are typified in wells by consistent flow-annealed dips in the anhydrite (as seen in image logs) that contrast strongly with the highly fractured

patterns in the nonevaporite lithologies making up the footwall and hanging-wall lithologies.

These laminar anhydrites are deeper less-leached equivalents of near-surface zones where meteoric waters create rauhwacke from their evaporitic tectonite precursor. That is, rauhwacke units are the weathered outcrop expressions of evaporite-lubricated thrust planes, glide planes and detachment terranes within orogenic belts. In some older studies, the rauhwacke itself was considered to have facilitated thrusting. In other, seemingly conflicting studies, rauhwacke was considered to be obviously nontectonic as it could contain channel fill sediments, parallel lamination, cross-lamination, graded bedding, clastic dykes and other sedimentary structures. Now we know that much of this confusion was created by a lack of understanding of its evaporite genesis and poor definition of the term itself. An evaporite-lubricated thrust horizon or décollement is where the rauhwacke protolith forms. Subsequent weathering and mechanical reworking of the thrust horizon, first in subcrop and then outcrop, created rauhwacke layers with sedimentary structures. That is, rauhwacke is herein defined as an exhumation-driven post-thrusting evaporite dissolution/alteration overprint on a former salt-lubricated thrust or tectonic melange. Erosional unroofing to the level of the evaporite-facilitated thrust creates rauhwacke, which can then be reworked by fluvial and other surface processes. Rauhwacke is an evaporite dissolution overprint, it is not the cause of the thrust event.

Conceptually, rauhwacke as a process overlaps with those that create both salt fold and fault welds and in some situations may have once fed salt into what are now salt ablation breccias in other cases its precursor was a halite tectonite or salt lubricated thrust associated with halite mylonites and "haselgebirge" (Leitner et al. 2011). Rauhwacke typically forms a dissolution residue in the nearsurface and at outcrop as the more soluble evaporite components are leached from an unroofed thrust breccia, or deeper in the subsurface as the sheared evaporite and its surrounds are metasomatically converted to less soluble salts, such as calcite spar or dolomite. Halite is typically a major component at depths where translatent thrusting occurred, but was subsequently dissolved to leave behind deformed anhydrite at shallower depths. Rauhwacke breccias in outcrop are dominated by carbonate and clastic fragments in a cataclastic matrix. Boxwork and cellular honeycomb textures, so common in rauhwacke horizons, are the outcrop expressions of pervasive weathering of an evaporite precursor.

As well as the tectonite specific usage of rauhwacke, the term is sometimes still used interchangeably with the French terms cornieule or cargneule. In this broader sense of usage the term rauhwacke describes a porous or cavernous carbonate sedimentary rock (especially a cellular dolomite), with angular cavities filled with soft, friable, evaporitic residues that easily dissolves or falls out to leave a rough, corroded and fretted angular surface (e.g. Schreiber 1988; Fudral et al. 2010). This less specific usage is associated with widespread textures indicating preferred dissolution of dolomite or evaporite clasts leaving behind the surrounding calcite cement. Evaporite boxwork or cellular or honeycomb fabric, all nongenetic terms, and not rauhwacke should be the preferred descriptors when angular salt solution textures cannot be tied to décollement.

Surface-related karsting of different tectonised protoliths forms structurally and geometrically distinct types of rauhwacke in the Swiss Alps. Schaad (1995) identified two end members in rauhwacke outcrop in the region (Fig. 7.33a, b): (a) dolomite-bearing gypsum, and (b) gypsum-bearing dolomite. Dolomite-bearing-gypsum rauhwacke develops as karst-fill sediment within the thrust plane, and is typified by unstructured, often polymictic units, with geometries that reflect the shape of the precursor karst cavity. In contrast, gypsum-bearing dolomite rauhwacke makes up stratiform geometries that are dominated by dolomite breccias with crackle to mosaic textures. This form of rauhwacke is a solution-collapse breccia developed after the solution of widespread tectonised once halite-rich evaporite beds and salt masses. Sometimes, karstification of thrust plane evaporites is aided by synformational fluvial or fluvioglacial processes that are focused into valley depressions created by salt edge retreat, much in the same way as gently-dipping evaporite beds dissolve in the near subsurface. Pomoni-Papaioannou and Karakitsios (2002) recognise similar features to Schaad (*op. cit.*) in the rauhwacke horizons that define major evaporite (Carnian) lubricated thrusts in central western Crete and the Ionian zone of the Greek mainland (Fig. 7.33c). They go on to note that rauhwacke can be observed for more than 700 km along the outcropping base of the external nappes of the Hellenides.

Most of the deformation/lubrication in the precursor horizon to a rauhwacke breccia comes from the unique Newtonian flow properties of halite. But there is an under appreciated aspect of gypsum flow in a dissolution zone that may also contribute to the deformation in a rauhwacke horizon. Gypsum tends to deform more rapidly when bathed in increasingly saline solutions (de Meer and Spiers 1999). This means that where an exhumed anhydrite unit has converted to telogenetic gypsum, those parts of the gypsum subject to crossflow by increasingly saline brines are more susceptible to ongoing deformation.

As with all evaporite solution breccias, much information relevant to the rauhwacke protolith must be inferred rather than directly observed at outcrop. But in some relatively unleached thrust windows in the European Alps there are transitions between salt-cored tectonite protolith and rauhwacke that are still preserved as subcrop and even occasional outcrop. In the Austrian Alps, Spötl (1989a, b) describes

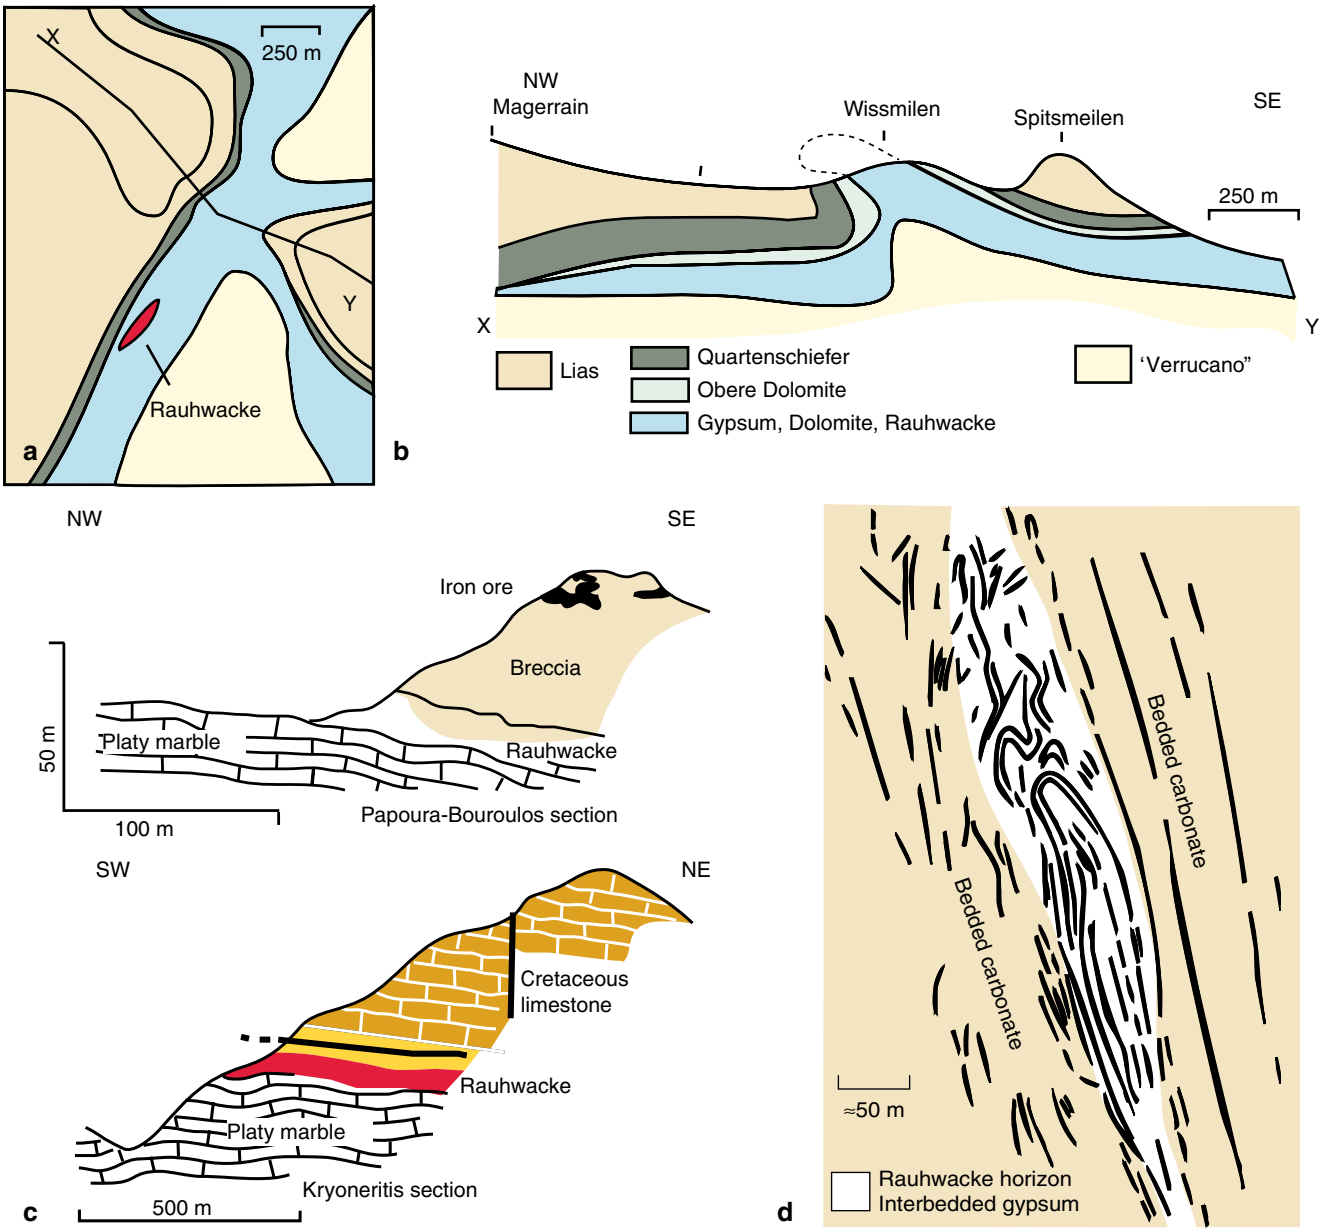

Fig. 7.33 Rauhwacke. (**a**) Plan view of rauhwacke developed atop subcropping gypsum (After anhydrite) in thrust décollement of the European Alps (From Schaad 1995). (**b**) Cross section X-Y, with position shown in 7.33a. (**c**) Geological sections in the Rodakino region, Crete showing development of rauhwacke along décollement, which was lubricated by Triassic evaporites (After Pomoni-Papaioannou and Karakitsios 2002). (**d**) Outcrop trace showing increase flow deformation in a rauhwacke layer (formerly halite-rich) in the Gillen Member of the Neoproterozoic Bitter Springs Formation, Amadeus Basin, central Australia (After Lindsay 1987)

tectonised evaporitic breccias that were created, and are still preserved, in the faults and thrusts of the Upper Permian-Lower Triassic Haselgebirge Formation. All these salty tectonic breccias, with 30–65 % halite, once flowed and fragmented during the Alpine Orogeny (Middle Cretaceous – Late Eocene) and are part of a giant regional tectonic melange created when Mesozoic salt was caught up in a continent-continent collision belt (Fig. 7.34; Schorn et al. 2013a, b). The Haselgebirge Fm. was also involved in tectonism well before the Alpine thrust event. The subduction or tectonism driving this salt-cored thrust melange was tied to the closure of the Meliata-Hallstatt ocean to the south of the Northern Calcareous Alps and may have preceded the main Alpine Orogeny by 50 million years (Spötl et al. 1998). Many of the Haselgebirge outcrops are sheared compressional remnants of earlier formed rift-stage salt walls and diapirs (Schorn and Neubauer 2014).

Haselgebirge Fm. breccias contain polymict clasts (from cm to several tens of metres in diameter) that in the subsurface are embedded in a halite matrix (Spötl et al. 1998;

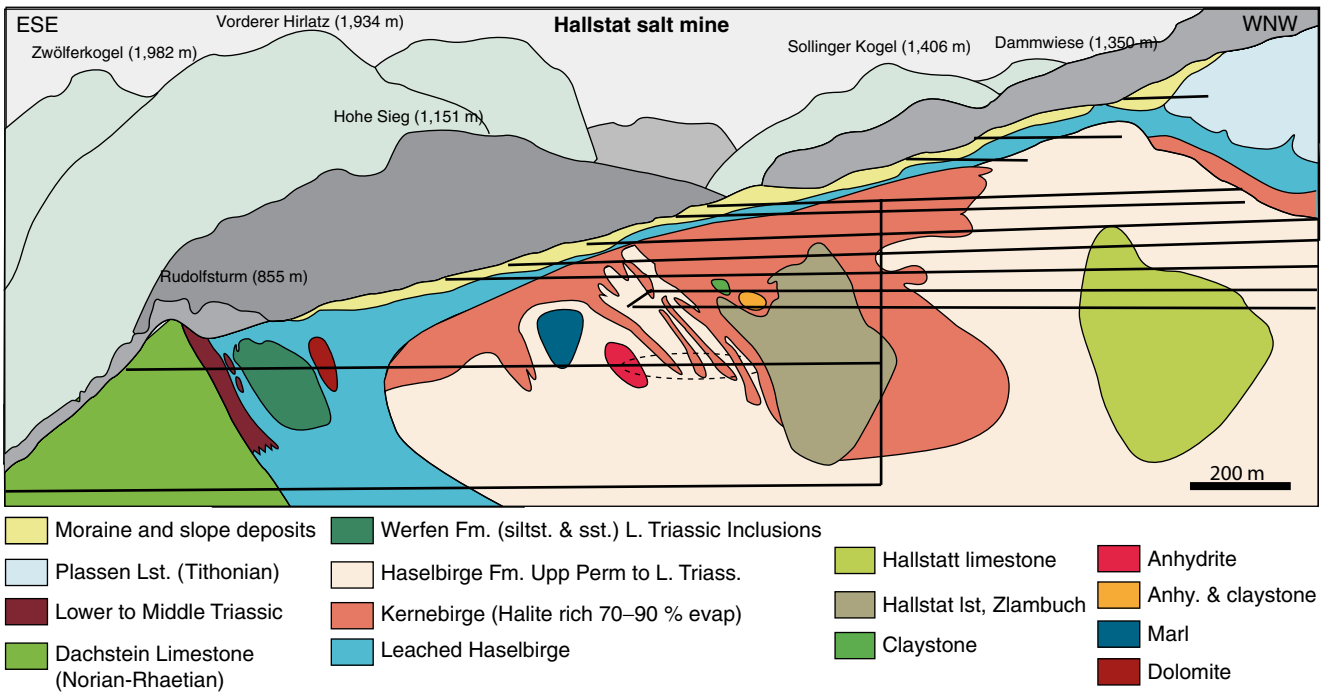

Fig. 7.34 Simplified ESE-WNW-trending profile through the Hallstatt salt mine area (After Schorn et al. 2013b)

Leitner et al. 2011). The breccia matrix contains varying amounts of clay and silt impurities[8] (normally in the range of 15–55 %) plus minor quantities of anhydrite. In addition to clasts form by the tectonic breakup of the initial intrasalt beds (shales, silts, sandstones, anhydrites, scarce pyroclastic rocks), while nappe transport drove huge blocks of faulted Mesozoic carbonates, marls and shales into the underlying visco-plastic (halokinetic) Haselgebirge Fm. Like their brecciated surrounds, these partially or completely isolated overburden blocks show evidence of severe strain that includes; internal fragmentation, stretching, translation and rotation. Overburden pressure seems to have controlled the degree of brecciation and slickensides within these detachments.

In the subsurface the tectonised "Haselgebirge" breccias sit within intervals of recrystallised halites and anhydrites, still preserving what at first sight appears to be mm-cm scale depositional lamination. Closer inspection of the layered halites and anhydrites defines preserved isoclinal noses and overfolds, along with flow aligned, pervasively recrystallised halite, clearly illustrating the tectonite origin of the laminae (Spötl 1989a; Leitner et al. 2011). Pervasive salt flow and recrystallisation means most relics of primary structures in the halite beds are destroyed or strongly deformed. Recognisable remnants of primary sedimentary features in the Haselgebirge Formation are preserved only within blocks and fragments composed of carbonate and anhydrite. For example, Leitner et al. (2013) describe partially-deformed syndepositional skeletal halites in a mudstone matrix in a clast that is now pseudomorphed by anhydrite and polyhalite. $^{40}Ar/^{39}Ar$ analyses date the polyhalite from within a number of deformed halite hoppers at 235–232 Ma (Middle Triassic), some 20–25 Ma after sedimentation. That is, the polyhalite replacement took place pre-deformation, fed by crossflowing brines at relatively shallow burial depths.

All the clast fragments and blocks were once more competent intrasalt beds, which have been progressively fragmented by tectonism and flowage to now constitute the majority of clasts in the Haselgebirge Fm. breccias. According to Leitner er al. (2011) the Haselgebirge in the Alps is a proto-cataclasite that originated by the interaction of recrystallisation of halite and the (hydro)fracturing of mudrock under tectonic deformation experiencing paleo-differential stresses ranging up to 2.5–4.5 MPa. The various breccias preserve evidence of their progressive tectonic evolution from limited ductile halite-encased deformation → brittle fracturing → boudinage → individual rotation of newly developed clasts → development of localised matrix-supported breccias (not laterally persistent) → laterally persistent matrix breccias with increasingly homogenous grain sizes (Spötl 1989a, Spötl et al. 1998; Leitner et al. 2011).

In the early stages of intrasalt bed breakup the clasts were angular. With ongoing clast deformation and rotation, the

[8]High levels of impurities meant Haselgebirge salt could not be exploited using conventional mining techniques. Instead the sinkwerk method was used. A sinkwerk is a chamber or sump in a salt mine filled with water to dissolve salt. The resulting brine is then pumped via pipelines to a saltworks for processing at the surface.

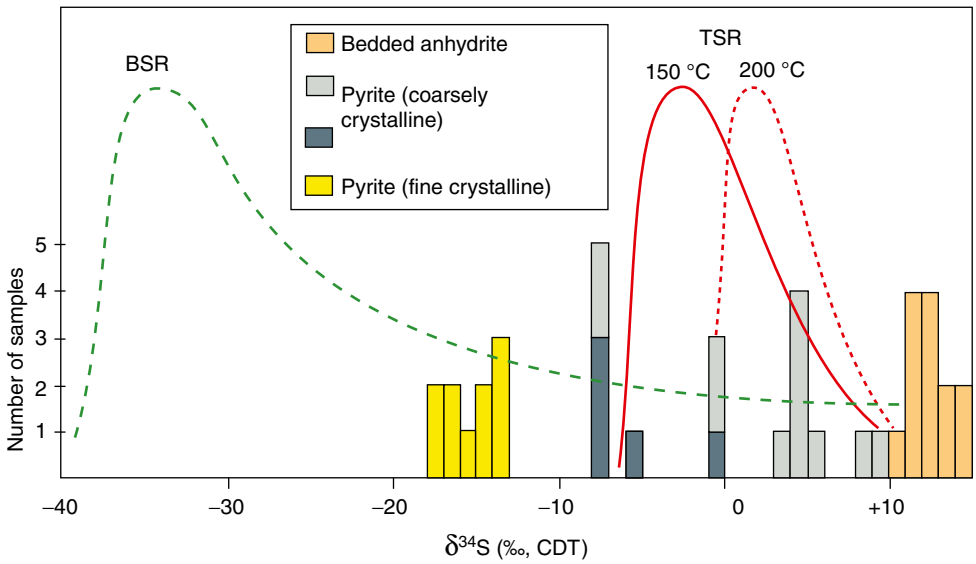

Fig. 7.35 Frequency distribution of sulphur isotope values for sulphates, sulphides and native sulphur from the Haselgebirge Fm. melange, Austria (After Spötl et al. 1998). Theoretical $\delta^{34}S$ distribution curves for pyrite produced during bacterial (BSR) and abiogenic thermal sulphate reduction (TSR) processes are shown. Note that pyrite $\delta^{34}S$ values are close to and within compositions expected for TSR

clasts become rounded and develop slickensided boundaries. The brecciation of the intrasalt beds reflects the different responses of anhydrite or carbonate to strain, when compared with halite. In response to shear stresses of much less than 1 MPa at geologically significant stain rates, halite typically flows and recrystallises via pressure solution (Fig. 6.4a). Due to their higher strength, shale, carbonate or anhydrite intrabeds respond in a brittle fashion and tend to brecciate, not flow, at the same strain rates.

The higher temperature origin of most of the diagenetic products in the Haselgebirge unit is clearly seen in the sulphur isotopic evolution of sulphate reduction products (Spötl et al. 1998) and the high temperatures indicated by recrystallised halite fabrics (Leitner et al. 2011). Sulphates in the Haselgebirge matrix largely preserve their Permian-early Triassic marine signatures and range in $\delta^{34}S$ from +9.8 to +13.8‰ (Fig. 7.35). Matrix dolomite alteration was driven by thermochemical sulphate reduction (TSR) and is indicated by the replacement of anhydrite by calcite + pyrite ± native sulphur and would have required temperatures in excess of 150 °C (see Chap. 9 for detail on TSR and BSR). Pyrite associated with TSR is coarsely crystalline and characterized by a small sulphur isotope fractionation relative to the precursor Permo-Triassic anhydrite.

Interestingly, the carbonates associated with TSR show low Fe/ Mn ratios reflecting rapid reaction of ferrous iron during sulphide precipitation. As a result, TSR-related dolomite and calcite typically show bright Mn(II)-activated cathodoluminescence. This is in marked contrast to the dull cathodoluminescence of many (ferroan) carbonate cements in many nonevaporitic deep-burial settings. In addition to carbonates and sulphides, authigenic silicate formation in the Haselgebirge was closely related to TSR (T > 150 °C), and included authigenic quartz, K-feldspar, albite and K-mica. Increasing illite crystallinity in the Haselgebirge also defines the sequence's entry into the anchizone (see Chap. 14 and Fig. 14.7 for further discussion of meta-evaporites and related clay transformations). Likewise, halite recrystallization temperatures of 110–150 °C are indicated by grain-size piezometry (Leitner et al. 2011).

Similarly, the rauhwacke that characterises outcrops of the Triassic Burano Evaporite Formation from the Secchia River Valley of Italy is intensely modified and tectonised as its evaporitic precursor was the main décollement horizon during the formation of the Northern Apennines chain (Lugli 2001). Inclusion temperatures of the various burial products clearly show a high temperature (greenschist) genesis (Fig. 7.36). Regionally, the Burano Formation is up to 2,200 m-thick and composed of metre-to decametre-scale interbeds of gypsum-anhydrite and dolostones with minor halite. The deposit has been affected by a complex array of postdepositional modifications, thermal events and large-scale evaporite dissolution, all acting to destroy an evidence of the environment of deposition. Carbonate clasts are composed of; massive and-or laminated dolomitic mudstones, wackestones, oolitic packstones and oolitic, peloidal, bioclastic grainstones. All can appear as mega-boudins within a calcium sulphate groundmass. The dolostones, (with a $\delta^{18}O = -5.7$ to -3.7‰; $\delta^{13}C = +1.3$ to $+3.0$‰; PDB) have been overprinted by sparry magnesite during Mg-metasomatic replacement ($\delta^{18}O = -14.0$ to -2.6 ‰; $\delta^{13}C = -2.6$ to $+1.4$ ‰; PDB) via orogenically-driven hydrothermal circulation (Lugli 2001; Lugli et al. 2002). Homogenization temperatures of fluid inclusions in hydrothermal magnesite range from 275 to 310 °C (Fig. 7.36a).

Anhydrites in the Burano are characterized by flow structures such as centimetre-scale pseudo-lamination composed of aligned prismatic crystals with transposed isoclinal folds

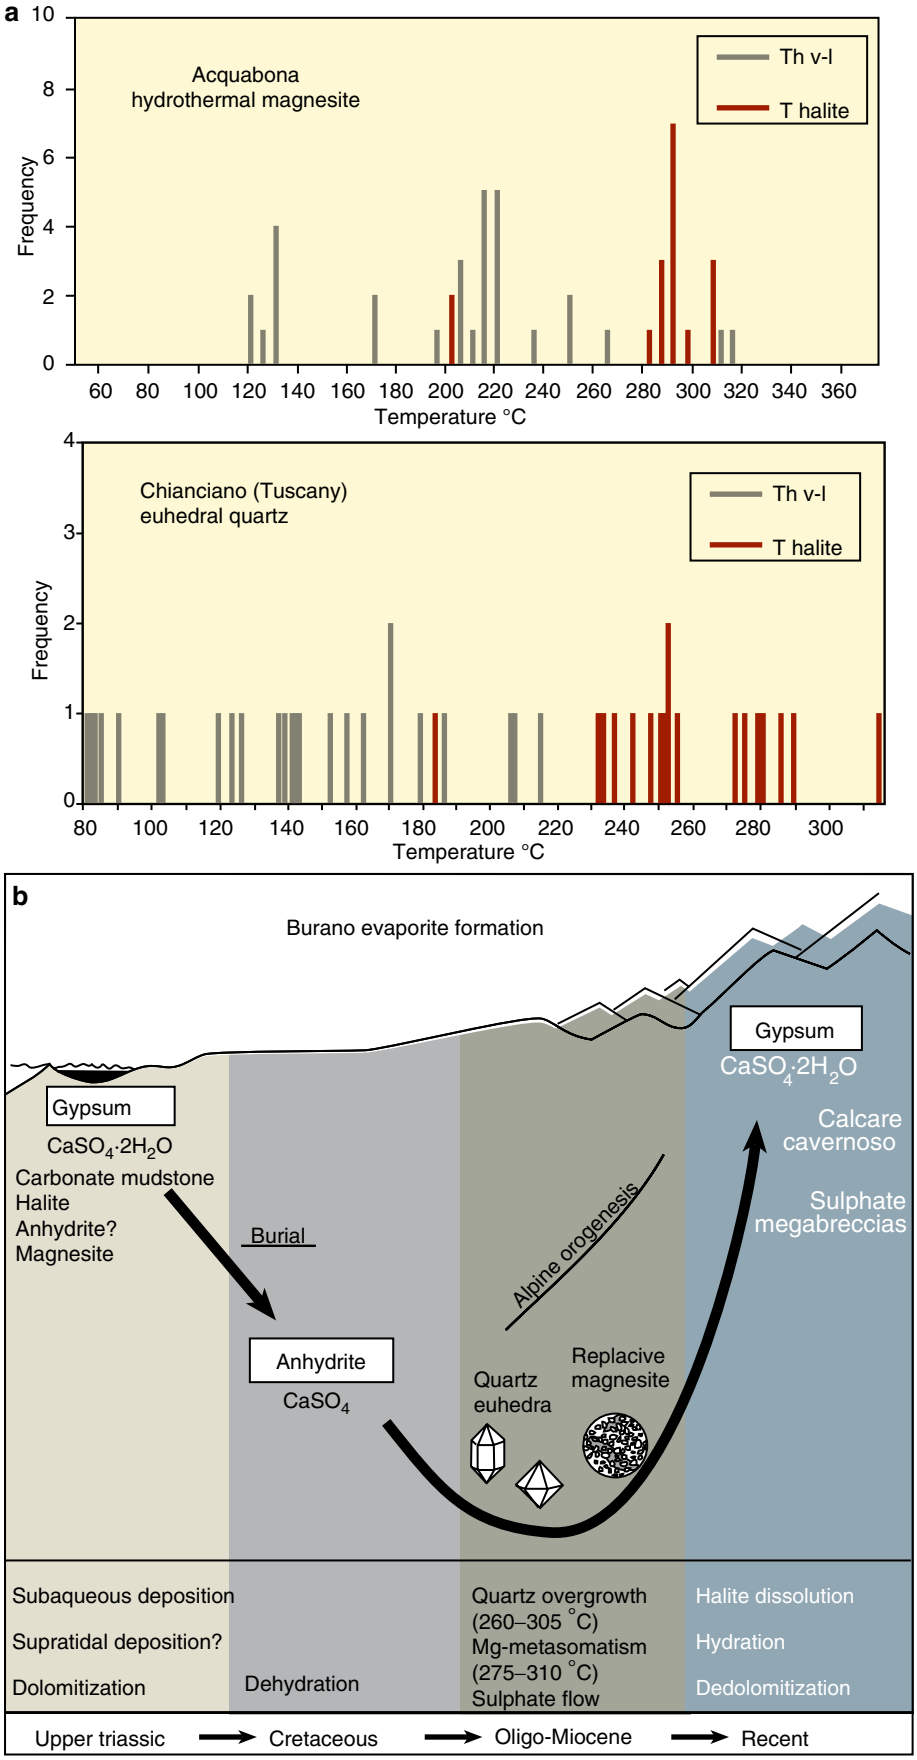

Fig. 7.36 Burano Evaporite Formation (After Lugli 2001), (**a**) Frequency histogram of fluid inclusion results from vapour to liquid homogenization temperatures (v-l) and halite melting temperatures (halite) in fracture-filling sparry magnesite from the Acquabona region and authigenic quartz euhedra from Chianociano region in Tuscany. (**b**) Reconstruction of the geologic history. Not to scale and adapted from the original gypsum-anhydrite-gypsum burial cycle of Murray (1964)

outlined by dolostones fragments. No primary textures remain. Homogenization temperatures of fluid inclusions in authigenic quartz incorporated into sulphate rocks range from 260 to 305 °C (in the Emilia area) and from 230 to 315 °C (in the Tuscany area; Fig. 7.36a). Outcropping and nearsurface gypsum is composed of xenotopic irregular cloudy crystals and, more rarely, by centimetre-scale idiotopic crystals showing the same structures as the anhydrite rocks. The gypsum is a late alteration product from anhydrite, formed during migration of sharp hydration fronts and meteoric flushing. Hydration is a two step process as indicated by the presence in the gypsum encasing corroded anhydrite micro-relics and by authigenic quartz crystals that still include anhydrite (Fig. 7.36b).

Evolution of Burano Evaporites during the Apennines tectogenesis was ongoing and tectonically driven by the processes of burial compression and exhumation (Fig. 7.36b; Lugli 2001). It can be divided into: (a) prevalent deposition of gypsum in the Upper Triassic; (b) gypsum dehydration at burial conditions to form anhydrite (Cretaceous?); (c) syntectonic flow of anhydrite rocks, brecciation of dolostones; syn-growth stage of quartz euhedra at deep burial conditions possibly related to the development of the Oligocene-Miocene greenschist facies of the Apuane metamorphic complex; (d) hydrothermal deposition of sparry magnesite and partial Mg-metasomatic replacement of dolostones by magnesite; (e) sub-surface dissolution of halite to form thick matrix-supported residual caprock-like anhydrite megabreccias; (f) complete regypsification of anhydrite at subsurface conditions; and (g) evaporite dissolution at surface exposure producing dolostone breccias with partial calcitisation and removal of most evaporite clasts ("calcare cavernoso" or rauhwacke).

Rauhwacke sheets (carbonate thrust breccias) also define outcrop of tectonic slices in nappe piles now dominated by pelitic rocks of Early Mesozoic age in the Carson Sink region of Nevada (Muttlebury and Lovelock Formations; Speed 1975; Speed and Clayton 1975). There the most extensive carbonate breccia nappe, the Muttlebury Nappe, extends over an area of 100 km^2 (Fig. 7.27). The outcropping rauhwacke sheets are interlayered and interlensed with non-brecciated marble slabs. The coarse grain size and granoblastic texture of the "marble" suggests an origin via metamorphic overprint of at least moderate grade. But the degree of apparent recrystallisation in the Muttlebury marble contrasts with a lack of recrystallisation and metamorphic alteration in the intercalated limestones and rauhwacke breccias. That is, the apparent metamorphic grade of these marbles is seemingly incompatible with that of the adjacent unmetamorphosed sedimentary carbonates and is best explained by emplacement along an evaporite-lubricated thrust. A nearby 30 m -thick gypsum klippe shows internal isoclinal folding due to strong translatent movement. Speed and Clayton (op. cit.) correlate it as a lateral equivalent to rauhwacke of the Muttlebury Nappe. Remnants of the same folding style are preserved in the matrix of some breccia beds in the rauhwacke of the Muttlebury Nappe.

Chert caught up in the granuloblastic calcite marbles, and interlayered with rauhwacke sheets of the Muttlebury Nappe, contains ubiquitous length-slow chalcedony, implying a possible evaporite precursor for the marbles. But the genesis of the marble is best resolved using their stable isotopic signatures (Fig. 7.37; Speed and Clayton 1975). Carbon and oxygen isotope ratios of calcites from various carbonate rocks in the Carson Sink, including the marbles, fall into two distinct trends. One has nearly constant $\delta^{13}C$ and variable $\delta^{18}O$

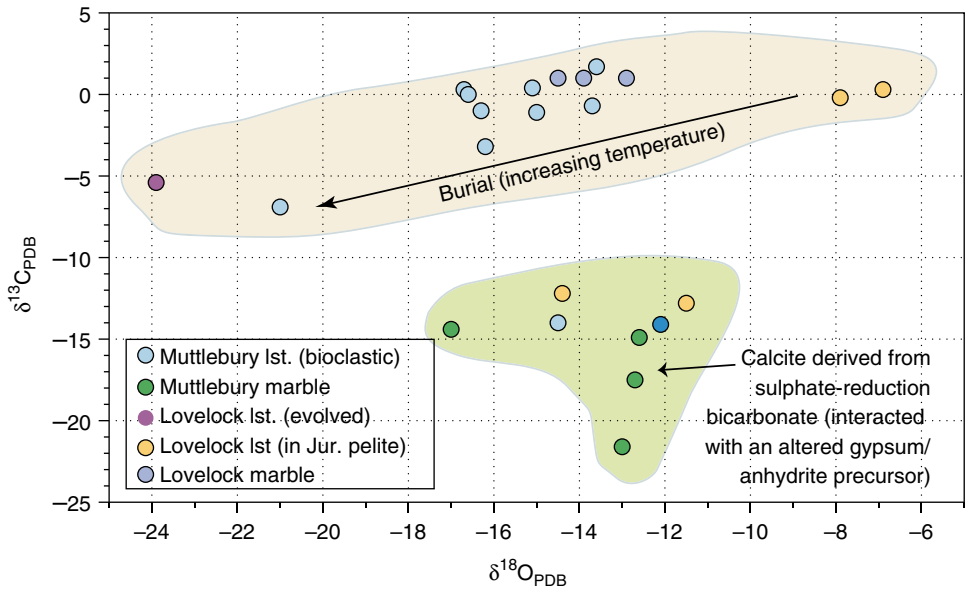

Fig. 7.37 Plot of $\delta\ ^{13}C_{PDB}$ versus $\delta\ ^{18}O_{PDB}$ for specimens from the Muttlebury and Lovelock Formations and from limestones in pelitic rocks below the Muttlebury Formation. C-O co-variance fields define two trends, burial and sulphate reduction – see text (Replotted from Speed and Clayton 1975)

related to rock-fluid re-equilibration under increasing burial temperatures; the other has nearly constant $\delta^{18}O$, and a $\delta^{13}C$ signature that varies between −7 and −25 ‰ (PDB). The first trend encompasses all the fine-grained carbonate rocks and calcarenites of the region, whereas the second encompasses all analyses of the problematic granuloblastic calcitic marbles. Speed and Clayton's (1975) interpretation of the isotopic trend of the Muttlebury Marble is that the marble's precursor was a coarse-grained gypsum or anhydrite-lubricated décollement caught up in active thrust and glide planes. When active it had acted much like the anhydrite-lubricated Alpine thrusts (Fig. 8.12).

These calcium sulphate-cored décollement sheets were subsequently calcitised bioepigenetically (perhaps during early telogenesis), with the sulphate-reducing bacteria utilising sulphate from the décollement plane and organic carbon from sources outside of the sulphate beds, perhaps the nearby euxinic limestones, or perhaps hydrocarbons percolating and focused by the now inactive thrust sheet (hence its $\delta^{13}C$ signature). Thus, Speed and Clayton argue the process of marble formation in the thrust nappe was similar to that now forming the calcitised sulphurous cap rocks of diapirs in the Gulf of Mexico.

In my opinion the rauhwacke breccias in the Muttlebury Formation, now interlayered with somewhat enigmatic bioepigenetic marbles, are altered intraformational tectonic breccias. The marbles, with their more negative carbon values, were created by meteoric/telogenetic dissolution of calcium sulphate remnants in previously salt-lubricated thrusts. Crossbedded calcarenites and quartz sands are water-reworked matrix components in the rauhwacke breccia, much like in the type area of rauhwacke in the Alps; they are mechanically reworked accumu-lations of insoluble residues and stringers that were originally disseminated through the antecedent sulphate beds.

Older but impressive examples of salt-lubricated thrust sheets and evaporite-hosted rauhwacke melange outcrop in Neoproterozoic sediments caught up in orogenic belts in the Katangan copper belt of Central Africa, and in outcrops in the Flinders Ranges of South Australia and the Amadeus Basin of Central Australia (Figs. 7.31 and 7.33d, respectively). The original evaporite matrix to the breccias has long since dissolved in these outcrops of former salt lubricated thrusts leaving behind a complex highly brecciated melange, sometimes entraining large megabreccia blocks that can be kilometres across. In subcrop of such sequences there can be numerous pseudomorphs after anhydrite preserved, as in the Mine Series associated with Cu mineralisation in the Katangan belt and its equivalents (Muchez et al. 2008; Kamona and Friedrich 2007).

Rauhwacke in many Proterozoic basins that have experienced regional compression occurs in close association with diapiric breccias that indicate an extensional halokinetic stage that preceded compression and thrusting. Even after the halite and anhydrite have dissolved, both the breccia blocks and the finer-grained matrix still retain a number of indicators of the former presence of widespread evaporites and include; (a) pseudomorphs of gypsum, anhydrite and halite crystals, (b) dolomite textures in breccia fragments that mimic anhydrite nodules, enterolithic folds, and chicken-wire textures, (c) doubly terminated euhedral quartz and length-slow quartz, (d) minor volumes of actual calcium sulphate (mostly regypsified at outcrop) as a pore filling cement, (e) hypersaline fluid inclusions in authigenic phases and (f) meta-evaporitic alteration haloes about the breccias bodies that indicate an evaporite source. Rauhwacke horizons are the structured remnants of much thicker salt masses (Fig. 7.38).

Melanges of dissolution residues in both Australia and Africa outline a combination of diapiric structures and subsequent thrust welds. The original salt in both areas was first precipitated in rifts, which evolved into passive margins, with both autochthonous diapirs and allochthonous salt tiers, and then into salt-lubricated thrust belts during subsequent orogenesis. The salt was sourced in the Callanna Group in the Flinders Ranges and the Roan Supergroup in the Katangan Copper belt (Lemon 1985; Jackson et al. 2003). The details of the diapiric breccias in the Flinders Ranges were discussed earlier (Fig. 7.31). Many workers in the Flinders Ranges focused on the diapiric nature of the breccias, although salt-lubricated thrust plane (inversion) rauhwacke breccias are widely visible in outcrop. Work by Jackson et al. (2003) and Backé et al. (2010) has clearly defined the intimate interrelationship between halokinesis, thrust plane development, inversion and salt in the Katangan and Adelaidean foldbelts. Classic diapiric geometries are outlined by the brecciated residuals of the Roan Supergroup, as in the Mukondo Diapir (Fig. 7.38b). Former salt-lubricated thrust planes are now outlined by rauhwacke breccia sheets in both the Katangan Copperbelt of Shaba (Democratic Republic of the Congo) and Zambia. These regions also contain the world's largest concentration of stratiform copper-cobalt ores, with their genesis largely focused by the interactions between metalliferous basinal brines and salt sheets (Warren 2000b; El Desouky et al. 2009).

During the Lufilian orogeny, the Katangan basin structure was radically transformed first by extrusion of allochthonous evaporites, then by orogenic shortening (Fig. 7.38c; Jackson et al. 2003; El Desouky et al. 2009). Salt tectonics began during deposition and gravity gliding of the Roan Supergroup between 1050 and 950 Ma. In mid-Roan time, salt walls and extrusions of evaporites began to be emplaced (former salt now outlined by breccias and gigabreccias – as in Flinders Ranges). In early Kundelungu time (940–850 Ma) the evaporitic diapirs enlarged. Lufilian deformation began by laterally squeezing diapirs to form salt welds between 850

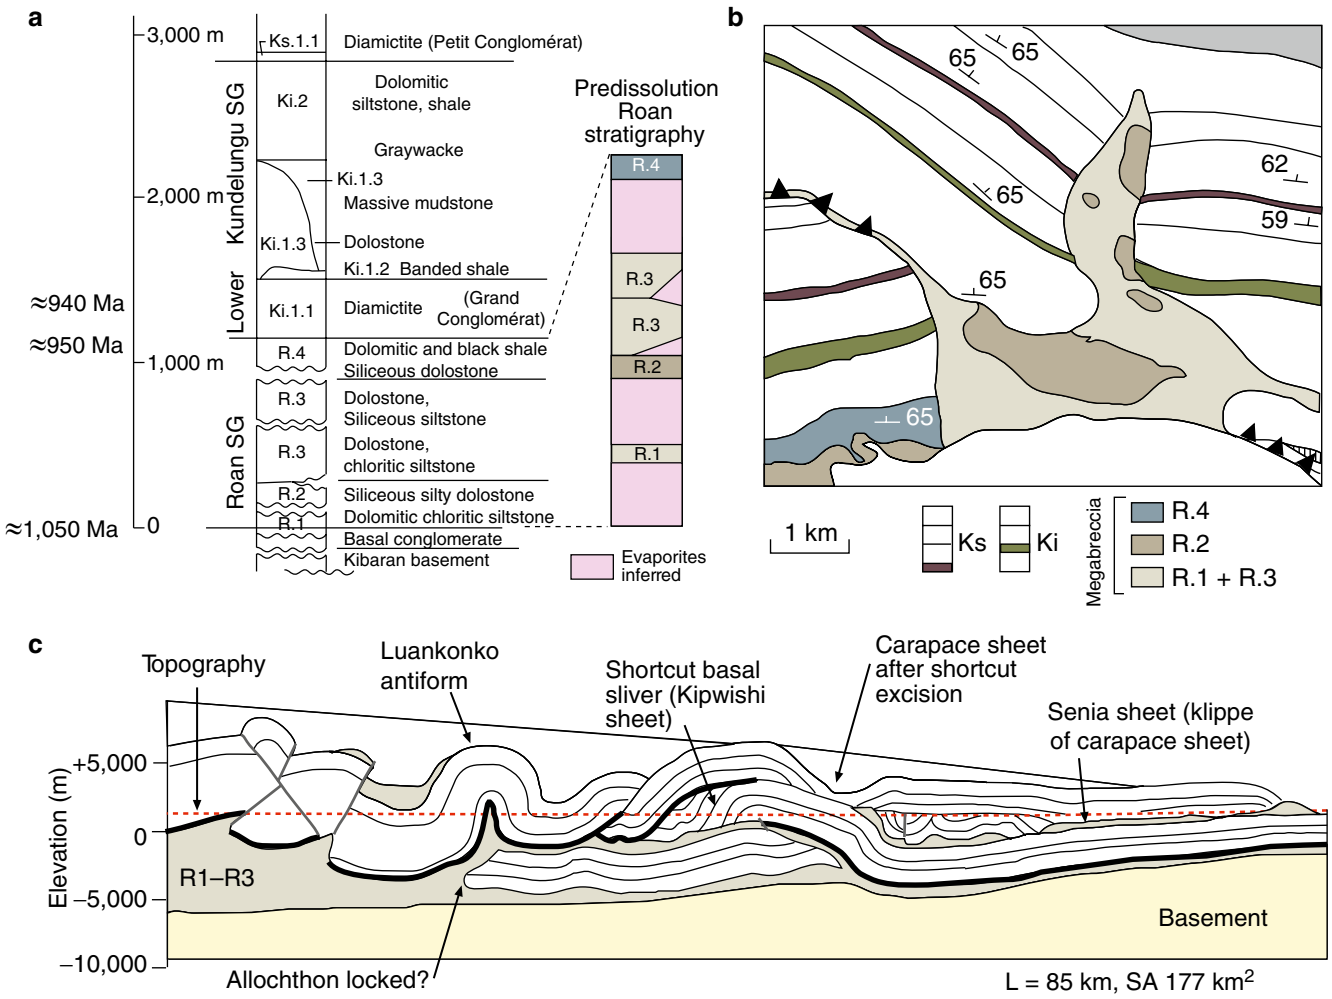

Fig. 7.38 Lufilian halokinetic breccia or rauhwacke (After Jackson et al. 2003). (**a**) Katangan stratigraphic column with a side column showing qualitatively restored evaporite thicknesses. Basal units below R.1 are based on the Zambian Copperbelt not the Katanga region. (**b**) Map of Mukondo Diapir, representing a down-plunge oblique section. In the diapir's northern apophysis, the Roan evaporite-gigabreccia passively pierced 2 km upward through accumulating Ki and Ks overburden in the southern limb of Mutaka Synform. This diapir appears to be rooted in autochthonous Roan. The separate Roan diapir in the extreme northeast is allochthonous. (**c**) Regional reconstruction of Katangan thrust section at the end of Lufilian time with no vertical exaggeration. The level of the modern topography indicated by dashed red line

and 650 Ma. Then, a large sheet of commingled Roan evaporite and carbonate-dominated sediments and ores was extruded northward by ≈65 km. Extrusion was fast enough to blanket a uniform pre-orogenic footwall unit without overriding any synorogenic deposits, much like the Salt Range in Pakistan today (Fig. 6.73). Continued shortening then emplaced large thrust sheets, lubricated by the pre-existing salt-sediment extrusive sheet. Restorations by Jackson et al. (2003) suggest that the Lufilian foreland in the Katangan area shortened from 193 to 85 km and that the depositional northern edge of the evaporite basin controlled the shape of the Outer Lufilian Arc.

Bed geometries in both the Flinders Ranges and the African copper belt show that a post salt-solution distinction between rauhwacke and diapiric breccias is difficult in core and, without sufficient outcrop analogs or seismic, can be near impossible. Lithologically, at the lower temperature end of the burial spectrum, the components of rauhwacke and diapiric breccia residuals are near identical. Our increased understanding of tiered allochthon emplacement of salt masses, and the time equivalence of early updip extension and downdip compression, makes such a distinction increasingly irrelevant at the lower temperature end of burial. When formed, updip extensional diapirs pass downdip into compressional toe-of-slope regions and both areas will become compressional (inverted) later in the Wilson Cycle (Fig. 5.32).

Rauhwacke and its precursor salt-lubricated thrust planes and alteration haloes tend to be dominantly interstratal stratiform surfaces defined by focused slippage, adjacent fault

plane brecciation and subsequent solution collapse. Such thrust planes often separate a brittle-faulted hanging wall from a less altered footwall succession (thin-skinned tectonics discussed in Chap. 6 and illustrated in Fig. 7.38c). Occasionally a rauhwacke breccia cuts up-section as a thrust ramp or riser. In contrast, diapiric solution breccias tend to be identified by largely trans-stratal geometries that outline the shape of the precursor salt diapir. But salt-lubricated allochthon sheets evolve into thrust planes, while former salt welds and diapirs can be reactivated to become the inverted base of salt-lubricated thrust sheets (see Fig. 6.75a). When diapirs, allochthons, depopods and detachment surfaces are part of the same salt-lubricated system, the two breccia styles merge and become near impossible to separate. Older 1950s vintage notions that salt diapirs indicated active halite intrusion and so were a separate tectonic style to thrusting, led to heated but possibly unnecessary argument in the 1960s and 70s on ways to separate diapirs from décollement in the Flinders Ranges outcrops (e.g. Burns et al. 1977). We now know they are part of the same salt-lubricated association with diapiric intervals and salt tiers often acting as a plane of weakness for subsequent thrusting as the basin passes from extension into compression (Wilson Cycle; Backé et al. 2010).

The presence of halite in the thrust melange that precedes the leaching of salt that creates rauhwacke is inherent to the definition. However, in some tectonised situations, the evaporite unit that is caught up in folded and tectonised intervals can be a buried unit made up of a combination of anhydrite and carbonate beds, with the anhydrite converting to gypsum at shallower depths. This is the situation that created folded tectonised carbonate breccias in the Lower Cretaceous Oncala Group of the Cameros Basin in Northern Spain (Quijada et al. 2014). These stratiform fold breccias were previously interpreted and sedimentary slump or collapse breccias. The breccias consist of angular carbonate mudstone fragments floating in a matrix of calcite and quartz crystals. The breccias are made up of variably folded and collapsed interbeds that are laterally associated to, and made up of, alternating layers of carbonate mudstone and calcite with numerous quartz pseudomorphs after gypsum, showing strong similarities to the breccia fragments and matrix. This suggests the now brecciated beds were originally composed of alternating carbonate mudstone and $CaSO_4$ layers.

Oncala breccias are associated with frequently polyharmonic deformation structures, with axial trends that are consistent with respect to the regional tectonic structure, indicating that they are related with the Alpine contractional deformation of this area of the Cameros Basin. In combination these features suggest that the carbonate breccias were formed by tectonic deformation of alternating layers of carbonate mudstone and calcium sulphate, which have very different rheological behaviours. As a result, during tectonic deformation, sulphate flowed and carbonate layers were broken and displaced, producing a breccia of carbonate fragments within a sulphate groundmass. Later, the sulphate groundmass was replaced by quartz and calcite, and the breccia acquired the composition we now see in outcrop.

Worldwide, where a concept of salt allochthon breccia versus rauhwacke, and former flowing salt beds, needs to be better defined is in the higher-temperature higher-pressure realm of metamorphism. Rauhwacke when used to define a type of breccia has inherent notions of a thrust sheet, inversion and an alteration halo about the salt-cored thrust plane. Fluids focused along the salt-cored thrust can penetrate, alter and even mineralise adjacent strata. Salts can survive as halite to burial temperatures in excess of 450 °C and as anhydrite to temperatures >900 °C (Chap. 14). Rauhwacke as a concept explaining near-fault alteration has been applied to salt-lubricated thrust residues and alteration/mineralisation haloes within this temperature range (greenschist to amphibolite facies). But notions of diapirs and salt welds are largely restricted to the sedimentological literature, yet diapirs and welds too must pass into the metamorphic realm. Published salt allochthon and weld models, based largely on seismic interpretations of sedimentary basins, have no such notion of alteration haloes, yet extensive contemporary ferroan carbonate haloes are seen in outcrop in Algeria, the Flinders Ranges and the McArthur Basin. Combining the two notions into a single model of structural evolution and mineralised fluid focusing will give increased exploration success in copper and base metal metamorphic/halokinetic terrains such as the Mt Isa-Cloncurry belt of Queensland, Australia and the Yunnan province of China (Chap. 15).

Partial Salt Dissolution: Residues of Less-Soluble Salts

Whenever a thick evaporite bed comes into contact with undersaturated waters it dissolves to leave behind a bed of insoluble residues. So far we have concentrated on characteristics of evaporite solution breccias with insoluble residues that no longer retain preserved salts. But there are intermediate stages in many subcropping and subsurface beds and diapirs in sedimentary basins, where less soluble salts remain after the more soluble salts have dissolved. The result is a cumulate laminar layer or breccia dominated by less soluble salts, typically anhydrite, that were originally dispersed through a now largely dissolved halite bed. At the same time as the beds dissolve, pore fluid salinity increases at the dissolution contact. As this water mixes with throughflowing waters in adjacent beds it can precipitate anhydrite or gypsum cements in nonevaporitic strata (burial and telogenetic salts).

If the dissolution is rapid and focused, overburden and intrasalt beds brecciate and fail via incremental crack-seal

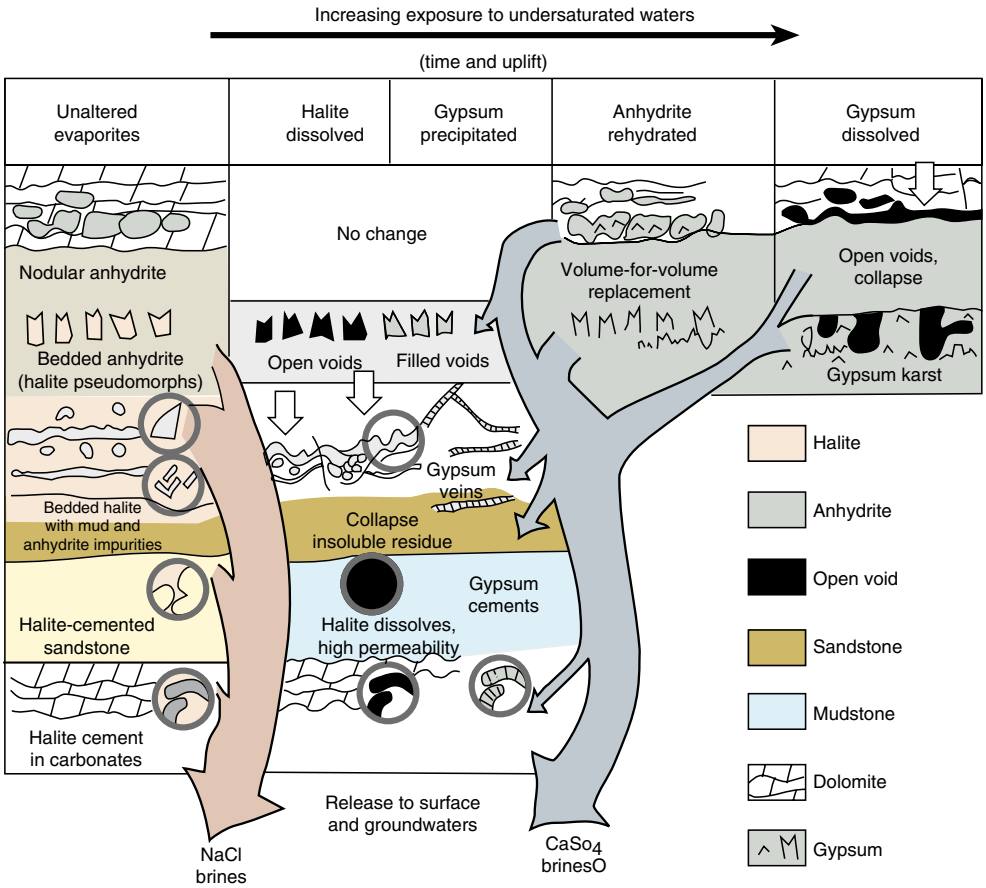

Fig. 7.39 Salt-dissolution processes related to ongoing exposure to undersaturated waters. Unaltered evaporite is shown on the left, initial alteration in contact with somewhat undersaturated water in the middle, and intense alteration after prolonged contact with undersaturated water is shown on the right. Degree of exposure to undersaturated water is largely related to uplift and time (After Hovorka 2000)

processes, with residual anhydrite or alabaster matrices surrounding the former intrasalt breccia blocks. If the dissolution is slower and subsidence or "let down" of the overburden gentler, then a residue bed of layered sulphates forms (Fig. 7.39). In this case the overburden span or roof tends to subside in parallel, with no more than minor crackle fracturing at the contact with the accreting laminar sulphate bed. If the subsiding overburden is a clay, then satin spar veins fed by high salinity brines coming off the dissolution front can infill any gravitational and hydraulic fractures forming brittle structures in response to collapse-induced extensional stress.

Less soluble salts tend to accrete at the boundary of the salt bed in contact with the undersaturated crossflow. If dissolution occurs at the top of a salt bed then accretion occurs along the base of the residue bed (youngs downward – as in anhydrite caprock atop a diapir). If it occurs along the underside of a thick salt unit, the less soluble salts accrete to the top of the bed (youngs upward – an "upside-down" caprock known as a basal anhydrite). It occurs at the margins of a salt structure then it is called a "lateral" caprock (Fig. 6.113). In all cases, the accretion of less soluble salts generally leads to a distinctive wavy-laminated fabric, either in anhydrite or in mud-sized residual material (that includes carbonates as well as clays). The wavy structure forms as small and disaggregated layers of insolubles are wrapped around larger clasts or nodules of anhydrite.

The mineralogy and thickness of the residue layer depends on the proportion of insolubles in the original evaporite bed and the salinity and chemical composition of the undersaturated waters. Relatively pure halite or potash units tend to produce thin layers of residual impurities. Anhydrite or mudstone insolubles hosted in the original intrasalt beds are typically first incorporated as bedding-parallel elongate clasts in the bed, often with minimal modification to their pre-collapse textures. Ultimately, with enough time, freshening and flushing, all the residual anhydrite dissolves and only nonevaporite clasts and fine-grained insolubles remain (typically muds and loose silt-sized dolomite rhombs).

Focused Rapid Dissolution – Evaporite Clasts

Differing solubilities between bittern, halite and $CaSO_4$ salts mean that breccias can be created by the rapid preferential dissolution of more soluble salts driving collapse that leaves behind less soluble salts in the matrix. Brecciated beds of

less soluble strata are typically composed of angular blocks of bedded gypsum/anhydrite, which fragment and settle as the supporting halite or bittern beds dissolve. These fractionated breccia beds are sometimes encased or underlain by halite, showing evidence of flow or slippage into chambers created by differential dissolution. Other times the breccias have characteristic smooth bases and more irregular tops. Sulphate-matrix collapse breccias typify parts of the subcropping margin of the Permian Castile Formation of the Delaware Basin in West Texas and New Mexico (Hovorka 2000), and the Middle Miocene (Badenian) gypsum of southern Poland and the Ukraine (Babel 1991) and the Permian Khuff Formation of Abu Dhabi and Saudi Arabia (pers. obs.).

Babel (op. cit.) describes preferential intra-evaporite dissolution processes in gypsum of the Middle Miocene (Badenian), southern Poland. Gypsum-clast breccias can form by the early diagenetic dissolution of halite beds within a thick laminated gypsum section. Sometimes the transformed interval is a single cm-thick bed and halite dissolution is interpreted to have occurred during a short freshening interval that only affected sediments just below the sediment-brine interface. Other times, the dissolution front was thicker, altering substantial thicknesses of halite to form crackle/rubble zones in bedded calcium sulphates that are tens of metres thick. Dissolution in some areas took place while parts of the gypsum beds were still water-saturated and soft, leading to complex soft-sediment deformation textures. Dissolution in other areas occurred after the gypsum was indurated and created classic collapse breccia intervals, with smooth bases and irregular crackled upper surfaces. Residual intervals within gypsum karst are typically defined by very fine-grained gypsum and clay horizons that routinely also define the base of a collapse interval. The brecciated intervals pass up or later-ally into faint or unlaminated gypsum alabaster (aka compact gypsum), often precipitated from telogenetic fluids tied to the rehydration of exhumed anhydrite.

Because partially-dissolved evaporite breccias define the edges of many buried evaporite units, and are typically associated with syn-dissolutional flowage of some of the remaining salt layers, they are easily confused with primary debris flows in the evaporite bed. This is especially so when the dissolving salt beds are adjacent to pinnacle reefs, which have acted as artesian aquifers during evaporite drawdown, as is the case with many of the inter-reef salt beds adjacent to the pinnacle reefs in the Silurian of the Michigan Basin (pers. obs.). Separating primary emplacement from a secondary dissolution origin can be difficult in brecciated and clast-rich beds and residues. Genesis is best resolved using oriented core, image logs and ties to detailed seismic mapping of salt collapse haloes above and around pinnacles.

Diffuse Dissolution -Markers and Residue Beds

Gypsum-anhydrite caprocks atop diapirs are widely recognised products of preferential salt dissolution. Less widely recognised stratiform equivalents to caprocks occur where undersaturated groundwaters flush the upper and lower contacts of stratiform or bedded halite. Such a set of processes affects halite beds in Maha Sarakham evaporites beneath the Khorat Plateau of NE Thailand (Fig. 7.40; Sessler 1990; Utha-aroon et al. 1995; Warren 1997) and the San Andres salts of the Palo Duro Basin of West Texas (Hovorka 2000; Gustavson et al. 1994). As any thick salt mass dissolves the mineralogy of the various residues typically depends on how long the evaporites were in contact with invading undersaturated waters and on the chemical make-up of the crossflowing waters; invading waters can be meteoric or basinal.

Gypsum has been reported as deep as 4,000 m in the oilfields of west Texas (Amadi et al. 2012), but most telogenetic rehydration probably occurs within a few hundred metres of the surface and much within the topmost few tens of metres (Ford and Williams 2007). Rehydration of buried anhydrite advances along reopening joints or new fractures, with the consequence that the hydration front can be highly irregular. It is common to find small patches of anhydrite surviving in gypsum cliffs where there has been rapid exposure. Quinlan (1978) argued that hydration involves dissolution with immediate reprecipitation.

In a relatively impervious rock, the slow hydration of anhydrite to gypsum and the related volume increase creates a swelling pressure of 295 kPa or 2.92 Atm (Azam 2007). Beyond a 200 m depth (≈bathyphreatic), hydration products are probably slowly dispersed in fluid crossflow with little expansion of rock volume (Gorbunova 1977) or via satin-spar precipitation in veins created by hydrofracturing or halite dissolution (Philipp 2008). Above that depth, mineral volume expansion of 30–67 % may occur, causing flow, folding and gypsum intrusion at depth, brittle fracture towards the surface, and recreation of some bulk porosity in the $CaSO_4$ unit. At the surface tightly folded or small-scale block-faulted topography may appear along with blisters, tents and tumuli (see earlier). Little or no groundwater flow occurs within the deeper telogenetic zones where anhydrite begins to rehydrate. As exhumation proceeds, overburden lessens, and the amount of halite that is preferentially dissolving increases. A thick exhuming evaporite mass tend to dissolve most along its upper surface where porosity and permeability is enhanced by ongoing undersaturated crossflows.

Gentle Dissolution at the Top

Uplift, or simply the cessation of evaporite deposition, allows undersaturated waters to come into contact with a salt bed. Undersaturated meteoric pore waters tend to pond atop the

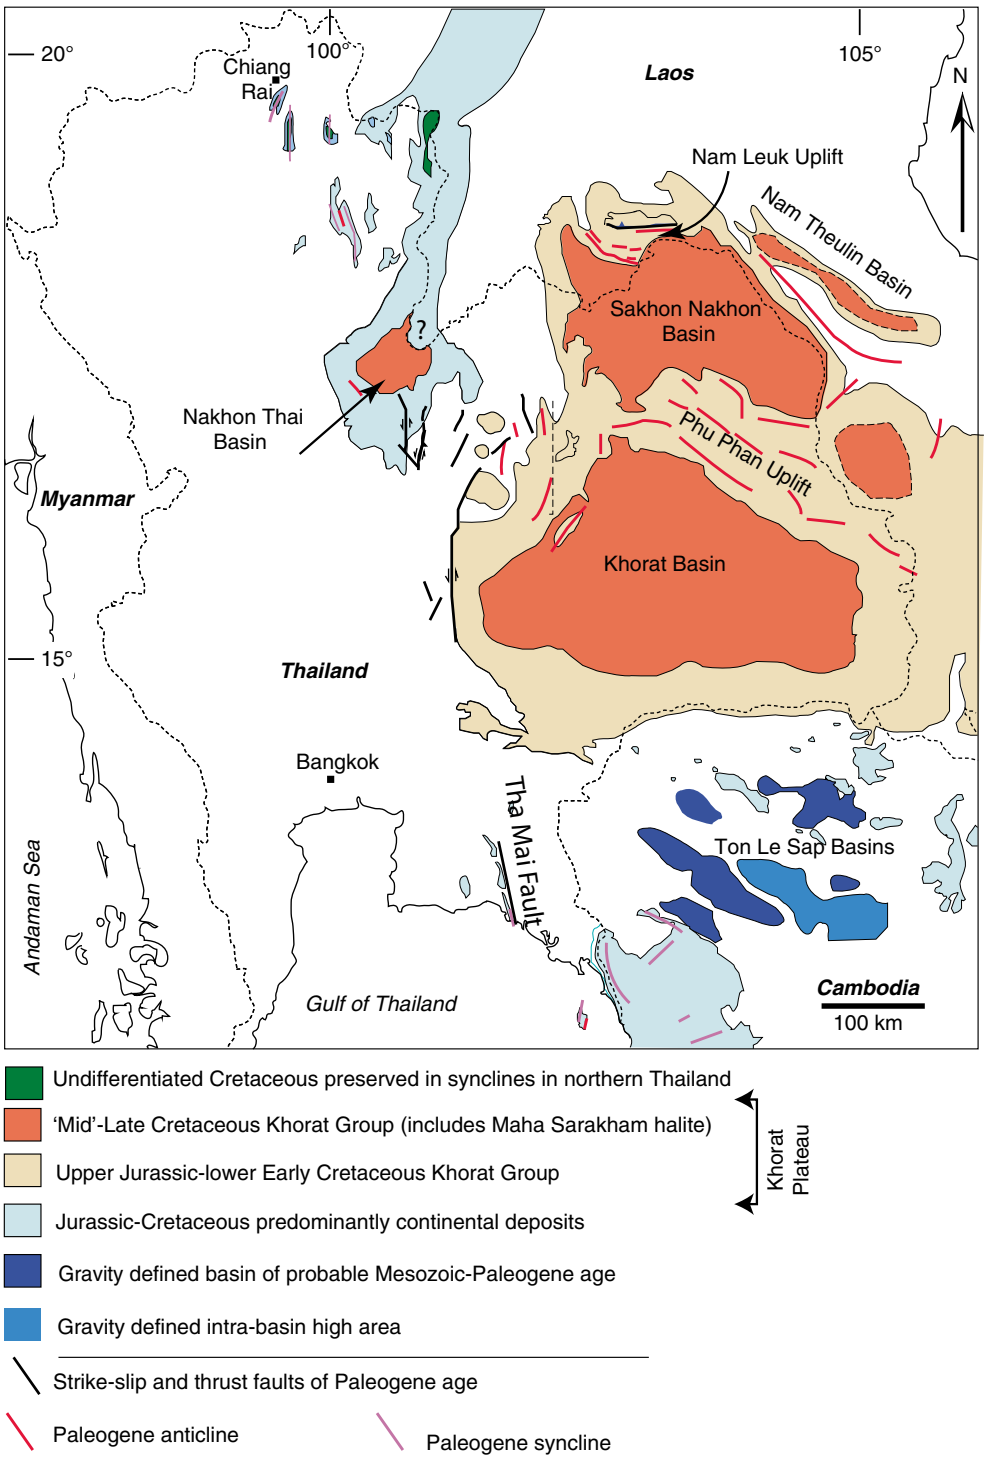

Fig. 7.40 General Geology of the Khorat Basin in Thailand and surrounds (After Morley 2012)

relatively impervious buried salt and so a shallowly-buried, or an exhuming, salt mass dissolves most from the upper salt mass contact down.

Maha Sarakham Salt, Thailand

Cretaceous Maha Sarakham sediments of NE Thailand are Albian-Cenomanian age and unconformably overlie continental deposits of the upper Jurassic to Aptian Khorat Group (Racey 2009; Morley 2012). Maha Sarakham sediments were deposited as a thick sequence (up to 1,000 m) of basin-wide evaporite interlayered with clays (Fig. 7.40). Beds tend to be stratiform about the basin edge and halokinetic in the thicker, deeply buried beds of the present centre (Fig. 7.41a). Three thick evaporite units (informally called

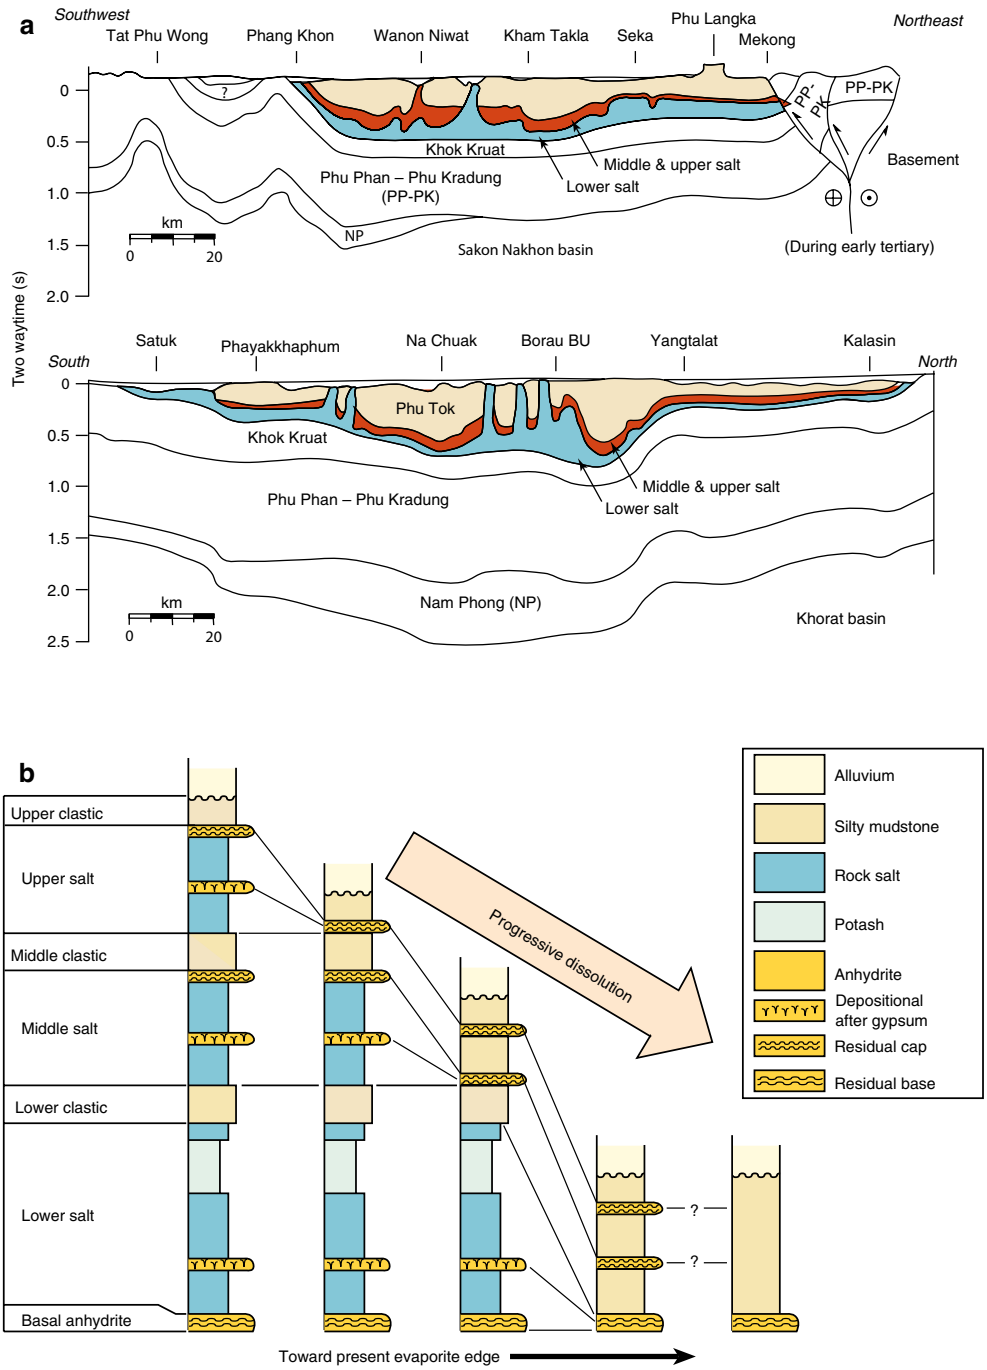

Fig. 7.41 (**a**) Regional subsurface structure of Maha Sarakham Formation showing preferential development of diapirs in lower salt toward the basin centre and dissolution toward structural edges of basin. (**b**) Progressive dissolution of halite and accretion of residual anhydrite beds toward the present basin edge (After Utha-aroon et al. 1995). See Fig. 11.37 for detailed stratigraphy related to potash occurrence

the Lower, Middle and Upper Salt), or their residual equivalents, are present throughout the basin (Fig. 7.41b). Evaporite minerals in the various beds include: sulphates, rock salt and potash minerals. Potash is found mostly in the upper part of the Lower Salt unit, but saltern halite is by far the most common salt and many beds preserve pristine chevron textures (Chap. 11). The salterns occasionally freshened so cm-scale gypsum nodules and beds with subaqueous textures (<1 m thick) were deposited in an otherwise dominantly halite succession, typical of Cretaceous marine evaporites (Fig. 7.42a). All the gypsum was converted to anhydrite during shallow burial and only returns to gypsum during exhumation and halite dissolution. The three main halite units that make up the Maha Sarakham Formation are laterally continuous and are traceable basin-wide. Nevertheless, ongoing interplays between salt dissolution and flowage have been active from the Cretaceous until today. Associated bed "sandwiching" means lithostratigraphic correlation from one place to another is not a straightforward exercise.

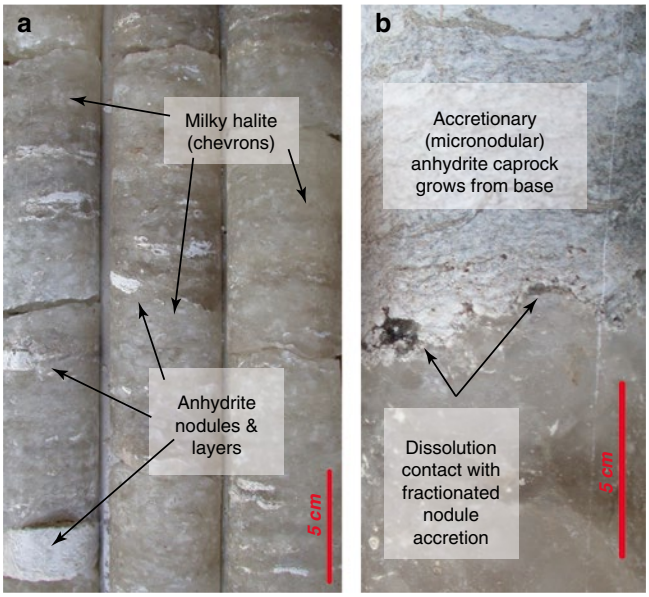

Fig. 7.42 Formation of the laminar bed of nodular anhydrite residues at the upper contact of the lower halite member of the Cretaceous Maha Sarakham Formation, NE Thailand. (**a**) General distribution of white-grey anhydrite nodules and layers dispersed in chevron halite in core. (**b**) Contact between dissolving halite and upper white-grey unit of dispersed anhydrite nodules and blebs. This laminar accretionary anhydrite bed defines the upper dissolution contact of the lower halite member. Some 2 m above this contact are the redbeds of the lower clastic member. The anhydrite unit preserves the shapes and sizes of the anhydrite blebs that were dispersed through the halite prior to its dissolution (as in Fig. 7.42a). These nodules and blebs are left behind to form a layered and accreting sulphate unit as halite is dissolved at the halite anhydrite contact (Scale bar is 5 cm long)

Thick clastic redbeds of mudstone separate each of the three main salt beds and are informally called the Upper, Middle and Lower Clastics (Fig. 7.41b). In core the clastic units are largely homogeneous clay beds, with locally laminated and stromatolitic horizons, infrequent nodular caliche horizons, occasional anhydrite nodules, root structures and mudcracks. Near their contact with adjacent salt beds there are beds of anhydrite residues overlain with clays hosting fractures and fissures filled with satinspar anhydrite and halite, indicating dissolution of a portion of the adjacent salt bed.

Depositionally, the lower halite in the Maha Sarakham is composed of chevron halite with dispersed cm-scale anhydrite nodules and stringers after gypsum (Fig. 7.42a). The earliest evidence for salt dissolution is cm-dm karst-pits filled by coarse recrystallised halite cement forming a syndepositional dissolution texture identical to that in the modern Qaidam Basin. Salt dissolution next occurred in shallow burial along bed boundaries where clastic units were in contact with bedded salts. Waters undersaturated with respect to halite, moved through adjacent redbed aquifers, initially as the clastics underwent deep weathering then as the buried clastics acted as conduits for compactional and basinal waters. This style of clastic-groundwater-driven dissolution left behind accreting residue textures at each major salt/clastic contact. Where the dissolving salt bed was composed mostly of clean halite all that now remains is a thin laminar residue of accreted insoluble clay residues. Due to the highly saline and anoxic nature of the brine leachate, the iron in these zones is reduced and where the salt bed is still actively dissolving the colour of the adjacent clastic has been altered from red to green.

In other regions of the basin, where the dissolving halite contained numerous anhydrite nodules, micronodules and stringers, the resulting dissolution residue is composed of stacked micronodular anhydrites that can be partially rehydrated to gypsum (Fig. 7.42b). These residual beds can occur along both the upper and lower dissolving bed contacts of all three salt units. At the contacts of the Upper and Middle Salt members the $CaSO_4$ residuals tend to be dm-m thick on the upper bed contact, but somewhat thinner on the under-side (cm-dm). On the underside of the Lower Salt member, the $CaSO_4$ residual is much thicker (≈1–2 m) and probably evidences a much greater volume of focused throughflushing driven by dewatering of the underlying Khorat Group sediments (see later basal anhydrite section).

Each $CaSO_4$ residual bed is made up of undulose thinly-layered to laminated light grey to off-white anhydrite/gypsum nodules and micronodules. Individual layers may be as thick as 2 cm (Fig. 7.42b). Lamina/layer orientation ranges from horizontal to vertical, with clays and organic matter defining the laminae and the nodule edges. Where a halite residual undergoes more localised dissolution the anhydrite beds are broken and brecciated, with interclast matrix infiltrating from the adjacent clastic member. Brecciated textures are most common in residues of the Upper Salt member as this unit is more effected by modern nearsurface meteoric leaching. If the Upper Salt member is still present in the stratigraphy it protects the Middle Salt member from surface driven dissolution.

Within the Middle Salt member is a basinwide dm-m-thick anhydrite marker bed. Complete dissolution of the halite encasing the marker bed of the Middle Salt member, and associated gentle foundering of the overlying middle clastic member, stacks the marker bed along with other anhydrite nodules and stringers in their original stratigraphic order (Utha-aroon et al. 1995). This gentle style of oriented solution-stacking of the intrasalt sulphate beds even preserves the subaqueous gypsum pseudomorphs of the anhydrite marker bed in their original growth position. Recognition of preferential dissolution occurring in a basin's stratigraphy allows a correlation across areas where halite beds have disappeared and only the anhydrite residuals remain (Fig. 7.42b). The final stage of salt dissolution occurs when the anhydrite residuals completely dissolve and brecciate to leave the three clastic members stacked one atop the other.

Where the Upper and Middle Salt members of subcropping Maha Sarakham Fm have completely dissolved, the present-day landsurface is defined by topographic depressions adjacent to a blind valley karst system atop a suprasalt high. Fluvial systems flow into this depression and feed subsurface waters to the dissolution front, which in turn focuses and stacks Quaternary fluvial channel sands. Outcropping and subcropping examples of this style of sequential halite dissolution define caprock outliers of the Maha Sarakham Formation in the Nam Theun syncline in central Lao (Fig. 7.10c). As about the edges of the much larger Khorat Plateau, Cretaceous halite along the syncline axis is retreating from the meteoric-flushed edges and top of the salt bed, leaving behind distorted and slumped remnants now patchily exposed in erosional banks along the river (pers. obs).

Some geomorphologists working in the salt solution terrains of NE Thailand have not recognised the effects of salt solution on the stacking pattern of fluvial systems. Instead, they have interpreted the thickened sections of Quaternary fluvial sediments as indicating a deepening of the river thalweg and have related it to Quaternary uplift and not dissolution downcutting. Effects of preferential dissolution along the edges of a bedded halite unit further emphasize the pitfalls of using simplistic notions of lateral correlation between thin marginward anhydrite and thick basin-centre halite (Fig. 5.38c).

Palo Duro Basin, West Texas

Hovorka (2000) has described the textures and effects of salt solution on the widespread Permian salt beds of West Texas (Fig. 7.43). She focused on the solution processes occurring beneath the High Plains of the Texas Panhandle, an area typified by landscape stability and the slow, longterm deposition of overburden. There the upper surface of the salt approximately parallels the hydrologic flow lines and so lies at a low angle to the land surface. In the Palo Duro Basin the top-of-salt lies at a depth of 250–300 m, approximately paralleling the low relief Southern High Plains. This salt dissolution surface regionally crosscuts Permian stratigraphy, so that in the northwest, the Seven Rivers Formation is the uppermost salt-bearing unit and overlying salts have been dissolved; while down hydrologic gradient to the southeast, the younger Salado halite is partly preserved.

Hovorka's examination of the residues left after regional low-angle salt dissolution in the Palo Duro Basin showed that salt dissolved and residues formed via incremental dissolution of the uppermost salt unit over a wide area. It was accompanied by passive stratiform subsidence of overlying strata (Fig. 7.43). Horizontal fractures in overlying strata indicate vertical extension, while syntaxial satin spar gypsum fillings show that the fracture opening occurred incrementally as underlying salt was dissolved (Gustavson et al. 1994). Typically, the creation of overburden voids atop most salt beds in West Texas does not lead to catastrophic collapse. Rather, stratiform beds of insoluble residues, perhaps associated with satin-spar veining in associated mudstones, are the best evidence that impure salt beds have been dissolved.

Diagnostic features of the regional low-angle crosscutting dissolution surface atop salt units in the Palo Duro Basin are: (1) Mixtures of insoluble components from the previously underlying halite with a wavy lamination in anhydritic intervals. This reflects the accretion of newly released insoluble components against existing insoluble residues. (2) Residual beds in positions that are laterally equivalent to preserved salt, (3) Anhydrite residual beds that stack one atop the other with little or no internal deformation, providing there were depositional sulphate beds in the original salt. (4) Syntaxial, horizontal, gypsum-filled fractures in overlying units. These are the same sets of features that define regional dissolution

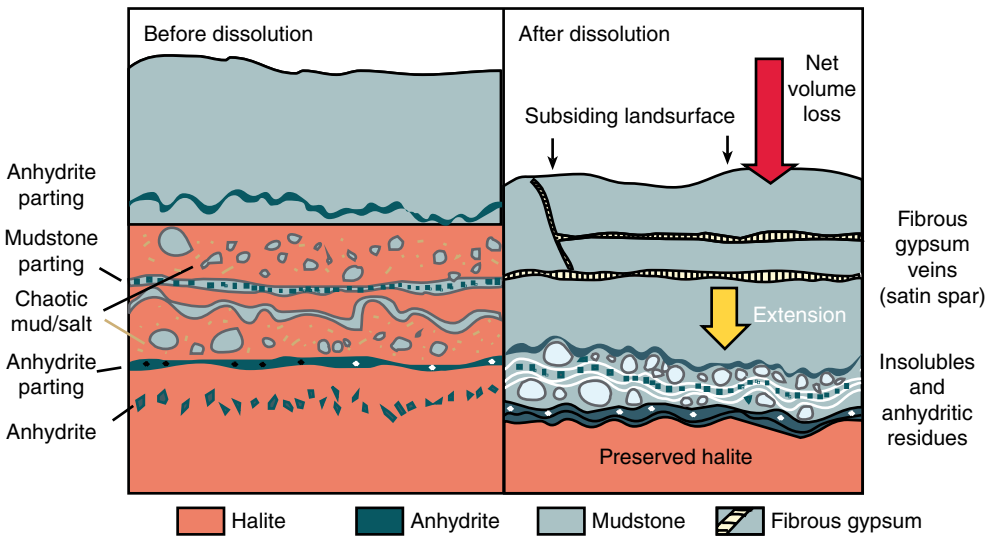

Fig. 7.43 Crossflow of undersaturated groundwater at the top of an impure halite bed creates an insoluble residue of anhydrite and mud under conditions of regional, low-angle salt dissolution and passive letdown of overlying strata, which fracture and are cemented by satin spar gypsum (After Hovorka 2000)

atop Cretaceous halite in the Maha Sarakham of Thailand (Utha-Aroon et al. 1995) and probably characterise all shallow low angle salt beds undergoing exhumation.

Dissolution from the Bottom

Undersaturated escaping basinal waters, or deeply circulating meteoric waters, can drive dissolution on the underside of a thick salt bed. In this situation the salt dissolves from the bottom up, and the residual wavy-layered anhydrite bed has a finite thickness controlled by its inherent crossflushing hydrology. To date this mode of preferential salt solution has only been documented in Maha Sarakham, probably because it is one of the few, if not the only, saline giant where both the upper side and the underside of the thick salt unit has been extensively cored and studied. However, similar near-constant thickness layers of anhydrite typify the base of many other saline giant basins, worldwide (Table 7.6).

Table 7.6 Various basins with possible dissolution-derived basal anhydrites

Basin	Age	Reference
South Pyrenean foredeep	Eocene	Rosell and Orti (1980)
Zechstein Basin	Permian	Peryt et al. (1993)

Basal Anhydrite, Thailand

Preferential dissolution of the underside of the Maha Sarakham Formation of NE Thailand is occurring where it is bathed in a crossflow of compactional and thermobaric waters (Warren 1997; El Tabakh et al. 1998a). The resulting basal anhydrite passes downward, via a thin cm-thick organic-rich residue layer, into underlying nonevaporite sediment made up of calcite-cemented fluvial sands and shales of the Khok Kruat Group. The basal anhydrite bed is characterised by a near constant basinwide thickness and consistent stratigraphic textures across the underside of large portions of the salt (Fig. 7.44). In many evaporite basins of the world, similar constant thickness beds are described as basal anhydrites, but are assigned a primary depositional origin.

To explain the subsurface processes that effect the underside of thick evaporite beds, the salts of the Khorat Plateau of Thailand are ideal. The region is unique in that the various salt layers of the Maha Sarakham Formation have been extensively and continuously cored from top to bottom and a simple gamma log suite run in the boreholes. This was done in the 1970s and 1980s in a World Bank funded exploration project for potash salts. The cores were double-sealed in plastic wrap and archived at a DMR core store in Udon Thani, where they are still available for study. Everywhere it was cored the underside of the thick Lower Salt of the Maha Sarakham Formation is typified by a thin, distinctive basal anhydrite bed composed of flattened mosaic nodules, with a bed thickness that is surprisingly consistent (Fig. 7.44). Work to date has clearly shown the basal anhydrite is a diagenetic unit created by ongoing salt dissolution. It is a pressure-welded nodular anhydrite unit that accreted in the subsurface as a buildup of insoluble residues on the underside of a basinwide dissolving halite sequence (Fig. 7.45a). The process was driven by the escape of undersaturated compactional and thermobaric waters. It is, in effect, an upside-down caprock (Fig. 7.45b).

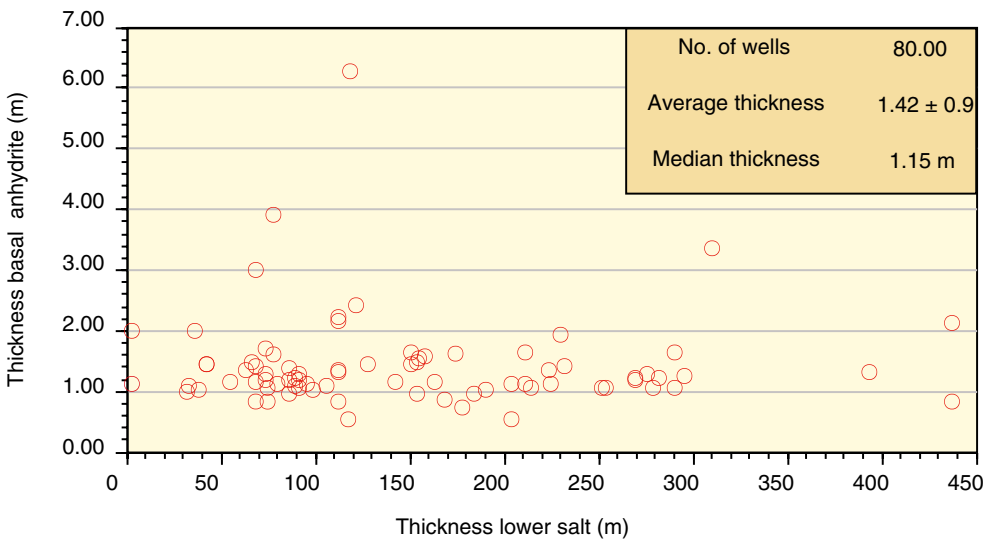

Fig. 7.44 Crossplot of thickness of the basal anhydrite unit versus thickness of the overlying "Lower Salt" in the Maha Sarakham Formation, Thailand

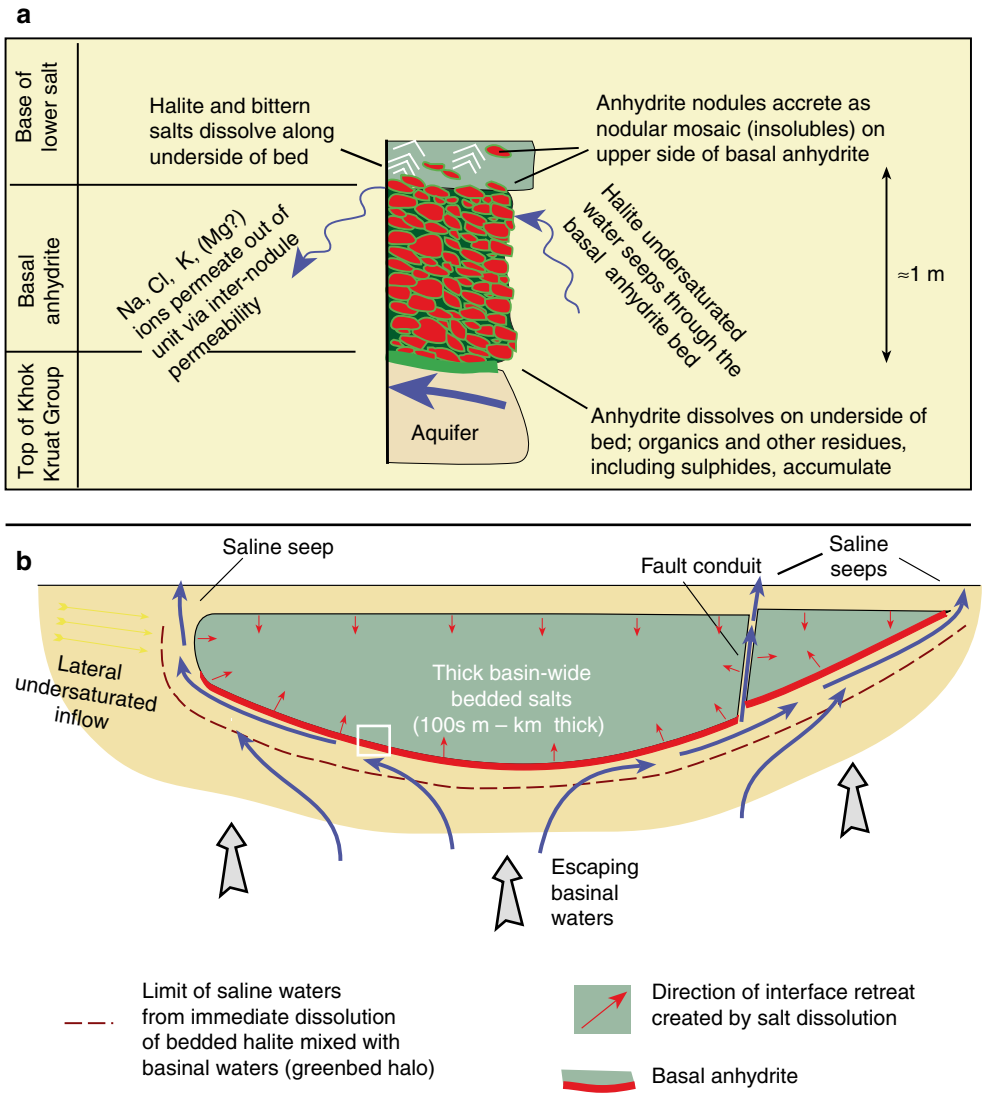

Fig. 7.45 Mode of formation of a diagenetic basal anhydrite. (**a**) Vertical profile through a dissolution-generated basal anhydrite. (**b**) Schematic *cross section with white box* showing relative position of vertical profile (Modified from Warren 1997)

Unlike depositional anhydrites within saline giant fills, which typically thicken into the lowstand platform wedge, the basal anhydrite of the Maha Sarakham has a near constant thickness across the entire basin that is independent of the thickness of the overlying Lower Salt (Fig. 7.44). There are a few wells where the anhydrite is thicker than 1–2 m, but there the anhydrite shows evidence of flow thickening and the wells are typically located at or near the dissolution edge of the Lower Salt where larger karst cavities can form and suprasalt and sub-salt sulphate residues can fold, fault and stack (Fig. 7.41b). The near constant thickness of the basal anhydrite across the Khorat and Sakon Nakhon basins reflects the intrinsic self-limiting permeability of a nodular anhydrite unit accreting beneath a salt overburden. Wherever upwelling basinal waters contact the underside of the Lower Salt unit it dissolves, leaving behind a nodular anhydrite residue. The nodular residue continues to accrete along its top by gathering anhydrite nodules via preferential solution of the salt host. These nodules were originally suspended within the now dissolving bedded halite. At the same time as new nodules are accreting along the upper side of the basal anhydrite, the anhydrite may be dissolving along its underside.

The overall dissolution process is driven by escaping compactional waters flushing the underbelly of the salt (Fig. 7.45b). If the basal anhydrite accretes to where it is more than a metre or two thick it starts to act as an aquitard for waters seeping through its internodular porosity. This slows water access to the halite contact. Thickness can increase until it reaches a point where undersaturated compactional waters can no longer flow through internodule permeability, to reach the halite-anhydrite dissolution front. Once undersaturated waters no longer access the halite dissolution front, anhydrite accretion slows and even shuts down along the upper side of the basal anhydrite unit. Even so, compacting undersaturated waters continue to flow along the underside of the basal anhydrite, where anhydrite dissolution occurs. Once sufficient anhydrite dissolves from its

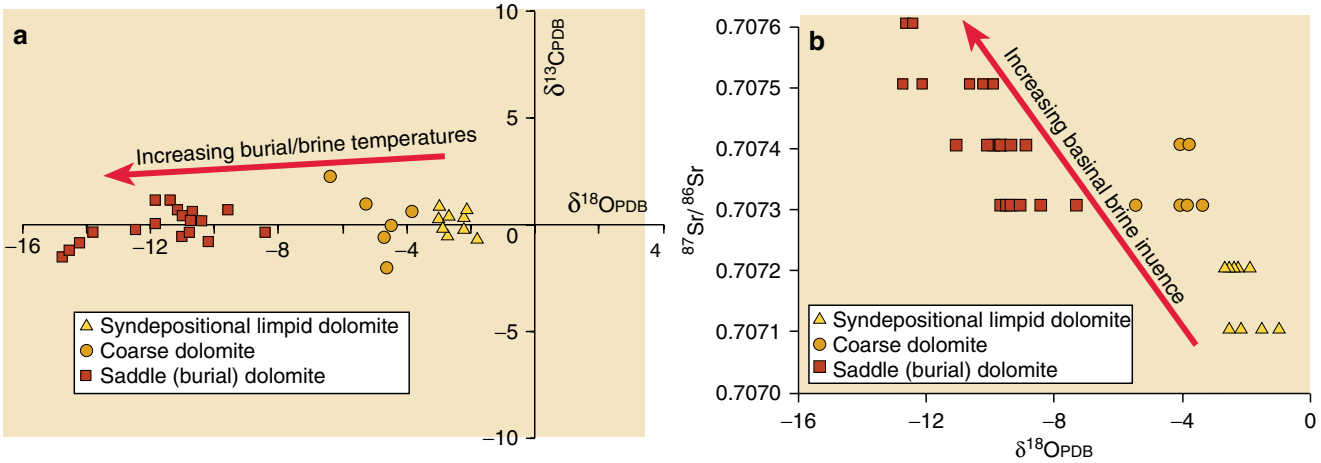

Fig. 7.46 Isotopic signatures in the three types of dolomite occurring in the basal anhydrite of the Maha Sarakham Fm. Thailand. (**a**) Crossplots of dolomite $\delta^{18}O$ and $\delta^{13}C$ isotopic values showing influence of increasing temperature related to ongoing burial. (**b**) Crossplot of $\delta^{18}O$ versus $^{87}Sr/^{86}$ Sr showing influence of ongoing basin brine evolution from limpid dolomite through coarse and saddle dolomite precipitates (After El Tabakh et al. 2003)

underside, undersaturated waters can again reach the halite and dissolve it anew. Basinwide near-constant thickness of the basal anhydrite reflects a buffering interaction between the rate of anhydrite nodule accretion or docking on its upper surface and the rate of anhydrite loss on its lower surface. In effect a basal anhydrite has a "half-life." The actual thickness is determined by the inherent transmissivity of the material between the nodules.

Coarse and saddle burial-stage calcian dolomite precipitates from brines flushing internodular zones in the basal anhydrite. Crystals continue to grow and re-equilbrate into higher temperature forms in response to ongoing burial. This is shown by the evolving carbon and oxygen isotope signatures, as well as $^{87}Sr/^{86}Sr$ ratios, which all define a burial trend from early limpid dolomite through coarsely crystalline dolomite through to saddle dolomite with precipitation signatures indicating increasingly higher temperature basinal fluids (Fig. 7.46a, b; El Tabakh et al. 2003; Warren 2000a).

The laminar underside of the basal anhydrite is made up of what remains once the anhydrite is dissolved, namely, an undulose cm-thick microlaminar organic-rich insoluble residue layer. It contains micronodules and fissure fills of metal sulphides (mostly pyrite and bornite) created by metal fixing and driven by thermochemical sulphate reduction (Warren 2000b). Overall this "upside-down" cap rock is very similar to a pressure solution mega-seam and its diagenetic mode of formation is not all that dissimilar except that the fluid flow is more one sided. This model, explaining laterally extensive, constant thickness basal anhydrites on the undersides of thick halites as a form of dissolution residue, has implications for other evaporite basins that possess basal anhydrite units with near constant thickness.

Caves in Evaporite Karst

At first sight, medium to large scale evaporite karst surface landforms, such as dolines, polje-like depressions, subsidence bowls and collapse dolines, appear near-identical to those found in and on carbonate karst. Likewise, all the smaller-scale intracavern features, both dissolutional (pipes and cavities) and constructive (speleothems), can be preserved as karst zones in and above an evaporite host, even when the formative hydrology becomes inactive and the system is buried (palaeokarst). But, as we shall see, the much higher rates of dissolution of halite and gypsum compared to limestone or dolomite means there are significant differences in rates of formation and cave geometries compared to carbonate caves in nonevaporitic hosts. One cannot simply take models of caves developed by studies of carbonate karst and use them to unreservedly interpret evaporite caves. Differences reflect the inherently higher solubility and flowability of the host salts at earth surface conditions and means most evaporite-hosted caves show peculiarities compared to carbonate karst.

The high solubility of evaporite beds atop deeply-circulating pressurised and jointed aquifers (confined hydrologies) means deep-phreatic chimneying is a common cave-forming mechanism in and atop buried salt beds (Fig. 7.6). When a stoping chimney cave breaches the watertable, it can lead to the rapid creation of numerous steep-sided water-filled collapse dolines. This in turn means high volumes of sediment can swallowed quickly, especially in suprasalt regions with strong roof spans covered by loose sediment. In such settings, large at-surface natural sinkholes can form in days or even hours[9].

[9]The Catholic Church in the early Middle Ages of Europe explained such rapidly formed sinkholes as being "Gateways to Hell," the result of the parishioners sinning a little to much, and/or not paying sufficient tithes to ameliorate the work of the Devil.

Most of the action in uplifting salt beds and masses begins well below the watertable. It takes place hundreds of metres below the surface at bathyphreatic depths where anhydrite is reconverting to gypsum and where caprocks and other dissolution residues are forming. Early dissolution is greatest at contacts between the salt bed and joints or fractures in adjacent aquifers. Thus patterns of jointing or fracturing control the extent and style of caves in a salt host and typically creates high-density maze caves. With halite, the only type of NaCl mass that makes it to the surface is in active or recently active diapirs and namakiers, and so becomes a host to accessible vadose caverns. Prior to its dissolution this cave-hosting diapiric halite is impervious, flowing and re-annealing. Hence, most of the karst action accessible for study in halite caves is vadose and tied to perched watertables, which is most obvious near the margins of namakier salt sheets, well away from locations of active salt fountains.

If phreatic caves ever do form nearer salt fountain domes, these early cavities are quickly closed by the pressurized salt flow needed to bring salt to surface and make it accessible to speleologists. Rather than being telogenetic features, many of the metre-scale blebs of finely-layered gravitationally-aligned laminar halite seen within diapirs intersected in deep salt mines, and floating in a matrix of flow foliated coarse-crystalline halite, are the result of mesogenetic salt precipitating in gas-filled open cavities within the diapir mass. These laminar cavity filling growth-aligned halite textures are not telogenetic. Neither are they salt clasts preserving primary (relict) depositional texture of the mother salt. They indicate the existence of former or present-day gas-filled (often CO_2) cavities, which are a hazard occasionally encountered during potash mining, for example in the diapirs of NE Germany (Hedlund 2012). Their presence and their ability to blow out mine walls clearly show that pressurized gas pockets and associated cavern fill textures are not uncommon mesogenetic features in flowing salt. But most of the shallow cavities and fill textures studied by speleologists in salt are telogenetic.

Cave-forming processes are either vadose or phreatic and many caves show textural evidence indicating transit from one realm to the other. At any one time the transition from vadose to phreatic landforms is tied to depth to watertable. This is seen in the gypsiferous cap karst to diapirs and allochthons of Triassic salt in the Betic Cordillera of Spain (Calaforra and Pulido-Bosch 1999). The crests of the salt structures are dominated by collapse dolines (vadose), this passes radially out into the belt of solution dolines occupied by seasonal saline lagoons and further out into rim of saline springs that form wherever the watertable intersects the landsurface (phreatic). Some caves pass from phreatic to vadose a number of times in response to watertable fluctuations tied to varying climate and tectonics.

Vadose processes characterise the uppermost part of a karst aquifer and have air in pores above any water surface or perched watertable. Water drainage is free-flowing under gravity; cave passages drain downslope and show strong gravitational orientations (numerous sub-vertical features). Because they form above the watertable, vadose cave walls are subject to surface seepage, evaporation and drying. Speleothems decorating the cave walls indicate varying combinations of gravity and airflow and include; stalactites, stalagmites, cave popcorn, helicites and flowstones.

Caves can form in a salt bed on its way down (syndepositional to early burial phreatic), on its way up (evaporite telogenesis begins at bathyphreatic depths) and at the bottom of the bed's burial history (mesogenetic gas-driven karst).

Gypsum Caves

Active caves beneath gypsum karst landforms first formed as deep phreatic maze caves and are characterised by dense passage networks with numerous contemporaneously closed loops, typically in bedded evaporites. Vadose cross sections of the same system can be quite large due to the high solubility and relative homogeneity of the host, especially if formed in a thick capstone. Heimkehle cave in the Zechstein anhydrites in the Harz Mountains of Germany has a overall passage length of more than 2 km, with large rooms up to 22 m high and 65 m wide. It was large enough to be used in World War II to house a factory manufacturing parts for JU88 aeroplanes. Other gypsum caves, some more than 150–200 km long, are well documented in Miocene gypsum hosts in west Ukraine (Table 7.7; Klimchouk 2000; Klimchouk and Andrejchuk 2003; Andrejchuk and Klimchouk 2004; Klimchouk 2007) and much of our current understanding of the gypsum karst process comes from this region.

Gypsum cave walls in the vadose realm are relatively undecorated compared to carbonate caves. But calcitic speleothems can form and are well documented, as are alabastrine flowstones and selenite rinds on cave walls, in northwest Texas (McGregor et al. 1963), in Alabaster Cave and others in the Blaine Gypsum in western Oklahoma (Johnson 1996; Bozeman and Bozeman 2002), and in quarries intersecting the gypsum karst system in the Kirschberg Evaporite member near Fredericksburg, Texas (Warren et al. 1990).

Phreatic Gypsum Caves

Phreatic caves in bedded evaporites atop artesian aquifers typically grow as upward stoping and branching blind flow loops caverns (phreatic cupolas) and chimneys, which can begin to grow deep below the watertable as bathyphreatic or hypogenic[10] karst. For example, deep artesian systems drive

[10]Cave origin can be epigenic (by shallow circulation of meteoric groundwater) or hypogenic (by rising groundwater or production of deep-seated solutional aggressiveness). Epigenic mazes form by diffuse infiltration through a permeable insoluble caprock or by floodwater supplied by sinking streams. Most hypogenic caves involve deep sources of aggressive waters and are instigated at bathyphreatic depths (Palmer 2011).

Table 7.7 Representative morphometry of gypsum maze caves that formed as confined aquifer phreatic systems, compared to Mammoth Cave (unconfined aquifer system) and Carlsbad and Lechuguilla caves (now both unconfined aquifer systems but first formed as sulphuric acid caves with gypsum precipitates)

cupola karst and blind chimney stopes in the Black Hills of Dakota (Fig. 7.16), the Elk Point Basin of Canada (Fig. 7.16) and the Optymistychna Cave, western Ukraine (Fig. 7.47). Deeper in a basin, where bathyphreatic caves are bathed by centripetal mesogenetic crossflows, water flow is slow and phreatic karst is influenced by the escape of H_2S- and CO_2 -rich basinal waters, not necessarily by confined meteoric head. Fluid flow at these greater depths is driven by pore water gradients that reflect potentiometric variations in temperature, organic maturation, pressure and salinity of basinal waters.

Passages in mesogenetic and telogenetic evaporite-hosted caves tend to first develop near fractures and joints in adjacent aquifers and then expand into maze cave networks. Once growing in the main evaporite mass, some phreatic maze passages can show internal upward-directed switchback gradients independent of jointing in adjacent aquifers. Cave orientations within the evaporite bed and away from the aquifer inflow level are tied to internal inhomogeneities in the host bed such as less soluble or more soluble intrasalt beds and changes in mineral proportions.

Phreatic tubes are the most common passage shape in smooth-walled blind-dissolution pockets and cupolas in bathyphreatic gypsum caves. Tube or channelway shapes range in cross section from near-circular (isotopic dissolution of soluble host) to elliptical tubes to canyon-shaped keyholes (Fig. 7.48; Klimchouk 1992, 1996). Ornamentation is minimal where undersaturated crossflow drives the rapid dissolutional breakdown of the cave wall and the resulting passages are smooth, with local scalloped dissolution irregularities. Dense intersecting maze cave networks first form in the early stages of exhumation at the contact between a tight but soluble gypsum/anhydrite unit and a less soluble carbonate or siliciclastic aquifer (Figs. 7.47 and 7.48). This less soluble bed is the supply conduit for groundwater crossflows that dissolve the edges of the initially impervious anhydrite/gypsum bed. The greatest rate of water supply to the dissolving gypsum contact is along joints and fractures in the adjacent aquifer bed (especially with limestone aquifers). Accordingly, the meshwork of caves penetrates the gypsum bed and tends to follow joint and fracture patterns of the adjacent aquifer.

More stagnant phreatic portions of telogenetic $CaSO_4$ cave systems can be saturated and so precipitate isopachous crusts and crystal rinds. Gypsum is the commonplace isopachous precipitate in voids in this setting, while anhydrite tends to dominate in cavities in the deeper mesogenetic realm (Garcia-Guinea et al. 2002). By the time phreatic maze caves are exhumed and enter a vadose setting, where they are accessible for speleological study, much of the earlier phreatic ornamentation has already been dissolved by the increasing undersaturated throughflow and cavern interconnection. This is associated with uplift into the more hydrologically-active phreatic realm, which always precedes entry into the vadose realm (Warren et al. 1990).

Some of the longest and most complex phreatic maze cave systems in the world are found in Miocene gypsum in west Ukraine. Optymistychna Cave, with more than 214 km of surveyed passages, is the world's longest gypsum cave and the second or third longest cave of any type (Table 7.7; Fig. 7.47; Klimchouk 2007). The world's longest cave, at

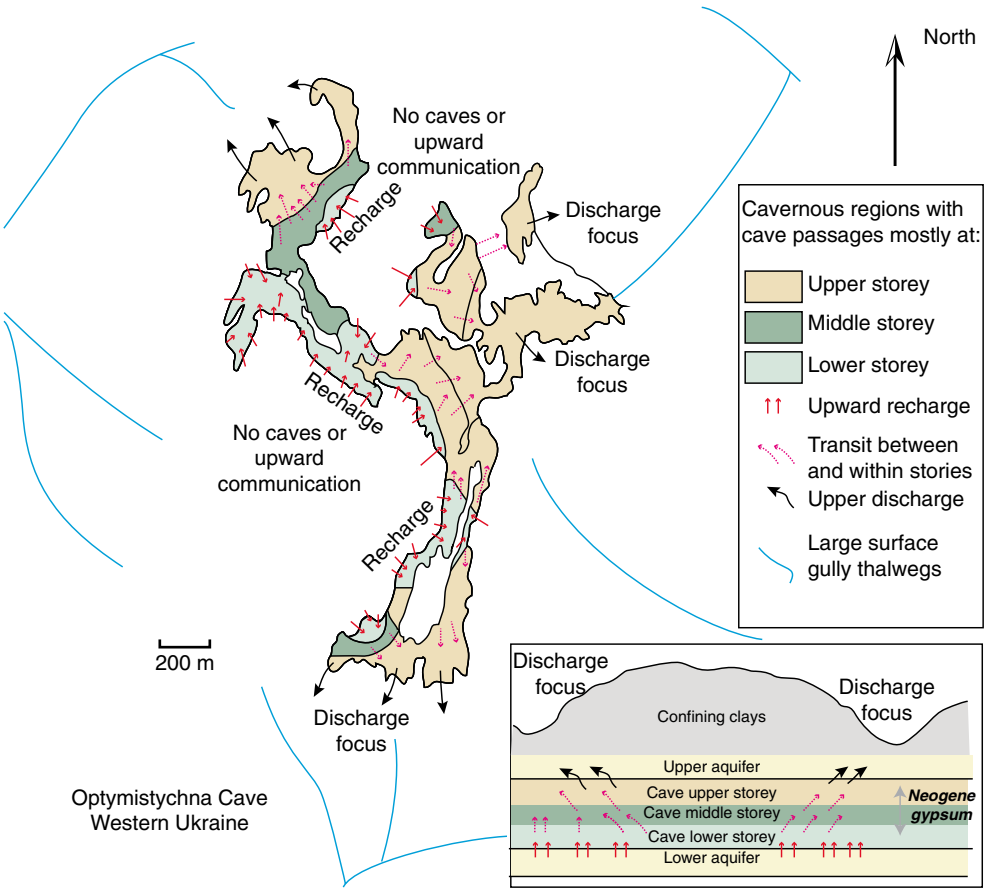

Fig. 7.47 Optymistychna Cave, western Ukraine, is part of a 214+ km long maze in a confined Neogene gypsum host, showing multi-story cave levels and the reconstruction of its recharge-discharge arrangement during the time of its formation. Inset diagrammatically shows the hydrostratigraphy and the stair-case effect of the recharge-discharge offsets. The relative thickness of the 18 m-thick gypsum bed (18 m) is exaggerated in the cross section (After Klimchouk 2007)

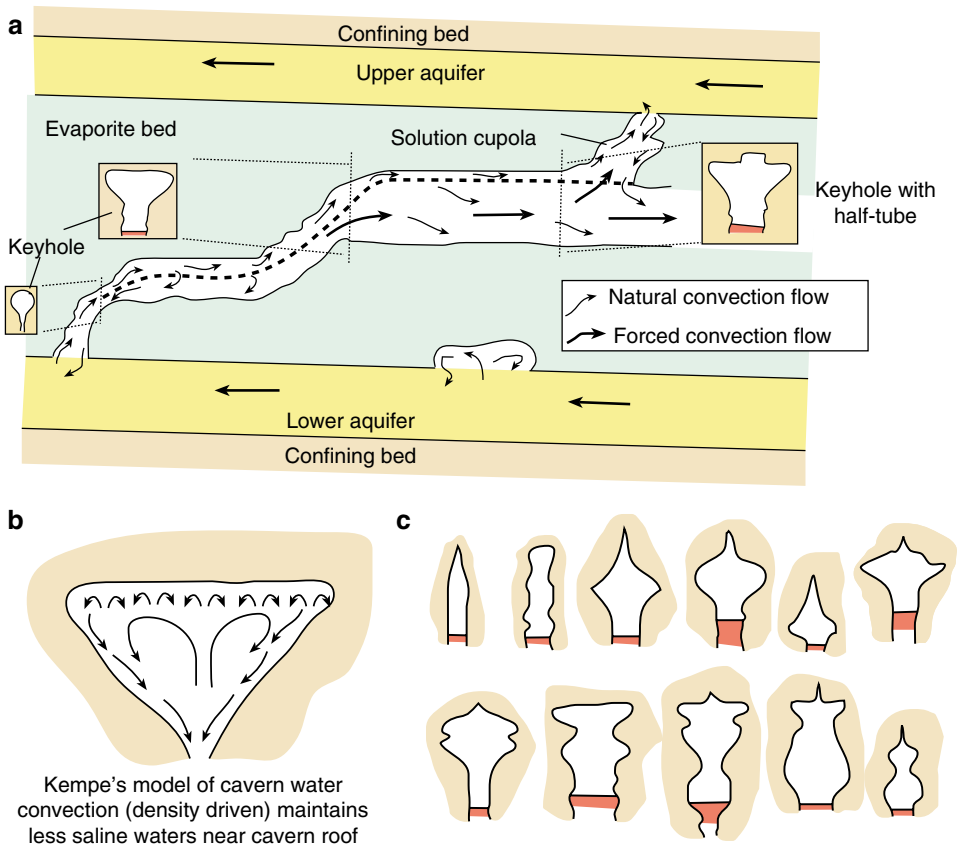

Fig. 7.48 Maze caves. (**a**) Formation of upward expanding dissolution cupolas by pressurized buoyant currents, such a system drives the formation of gypsum caves in the western Ukraine. The diagram shows the schematic relationship between lines of natural and forced convection flow on the mature stage of artesian speleogenesis, when conduit connection has already been established through the gypsum, but forced flow is slow due to the major constraint of the upper confining bed, see also Fig. 7.47. (**b**) Cross section of Kempe's (1972) model for phreatic tube cavern development via dissolution due to natural density convection, (**c**) examples of typical cross-sections from the gypsum caves of the western Ukraine showing varieties of notching or faceting effects from differing rates of lateral expansion (dissolution) (After Klimchouk 1992, 1996; Kempe 1972)

550 km, is the carbonate-hosted Mammoth Cave of Kentucky. The West Ukraine region contains the five longest known gypsum caves in the world, accounting for well over half of the total known length of known gypsum caves on Earth. By area and volume the world's largest gypsum caves are: Ozernaja (330,000 m^2 and 665,000 m^3; with 122 km of documented passages it is also the world's 10th longest), Zoloushka (305,000 m^2 and 712,000 m^3), followed by Optimisticheskaja Cave (260,000 m^2 and 520,000 m^3). They are all complex joint-controlled maze caves, formed under confined aquifer conditions that existed from the Pliocene to the Early Pleistocene (that is karstification on the way up – telogenesis or gypsum exhumation, initially focused on the underside of the bed). Their growth patterns indicate upward-transverse phreatic groundwater circulation, with ultimate cavern fusion across the gypsum bed. All these west Ukrainian caves were fed by artesian crossflow in sub-gypsum and supra-gypsum aquifers that were sourced in the Carpathian Mountains.

High rates of dissolution in phreatic gypsum caves, relative to rates of water crossflow, are indicated by bevelled, faceted and "keyhole" cross sections in the Ukrainian caves (Fig. 7.48a; Klimchouk 1996; Pfeiffer and Hahn 1976). Keyholes indicate density stratification and convectional circulation in cave-forming waters, with shapes sometimes complicated by lithological discontinuities in the gypsum bed (Fig. 7.48b; Kempe 1972). Convection in caves is most pronounced where sluggish artesian flow and low flow velocities dominate.

This was the case in the Pliocene to early Pleistocene history of the maze caves of the western Ukraine (Klimchouk and Andrejchuk 2003). At that time the deeply buried gypsum dissolved via upward growing but blind, phreatic cavities, with a reflux of somewhat denser "spent" waters sinking toward the base of the cave. Spent water was replaced by less dense inflow waters supplied from the lower aquifer. This set up a natural density-stratified convection, which maintained fresher (less dense) waters near the phreatic cave roof. Upward growing blind caves tend to expand more at their tops driving the transition from subcircular to keyhole caverns along the cave conduit. After dissolving gypsum and increasing in density, a portion of the "spent" cave water sank all the way back into the underlying aquifer where it once again joined the regional throughflow in the lower aquifer. Once a stoping cave breached the top aquifer water flow direction in the cave was controlled by temperature, pressure and density contrasts between aquifers on either side of the gypsum bed. It seems that post-breach most of the cave water continued to rise through the cave system into the overlying aquifer (Figs. 7.48a and 7.49) Similar keyhole and cupola morphologies are developed in low flow rate bathyphreatic sulphuric acid caves in carbonate hosts (e.g., early stages in the formation of the Carlsbad and Lechuguilla caverns; Fig. 7.62).

Formation of keyhole passages is not an exclusively phreatic phenomenon in density-stratified gypsum caves. Keyholes in the vadose portions of many telogenetic carbonate caves indicate the transition of the cave passage from phreatic, with circular cross sections, to vadose with

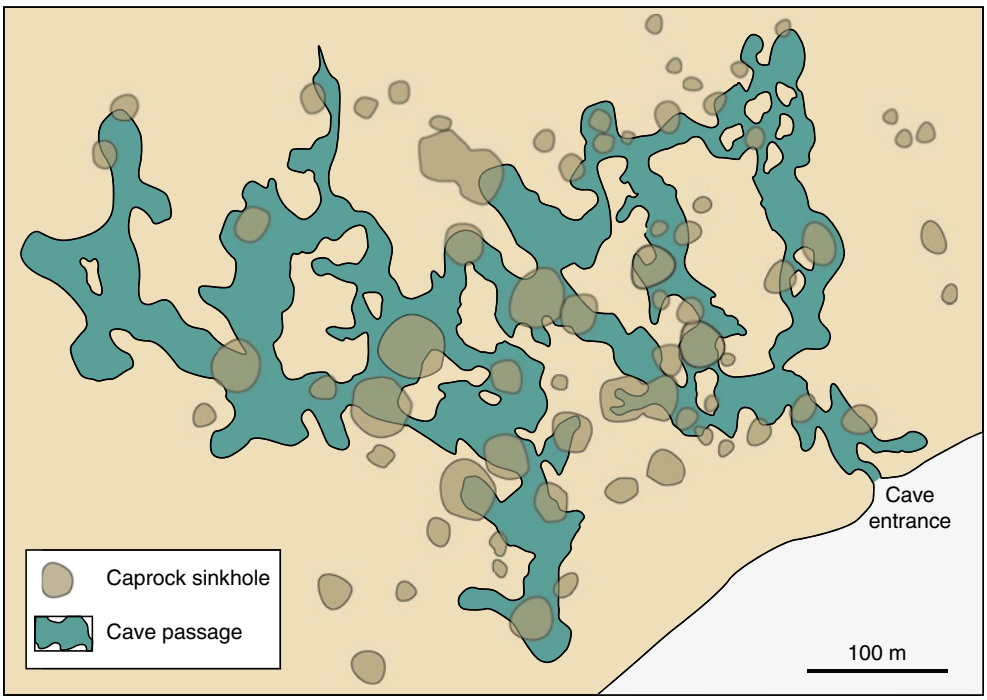

Fig. 7.49 Map illustrating the correlation between caprock sinkholes and vadose passages in Permian gypsum subcrop in the region of Kungur Caves in Russia (Waltham et al. 2005)

deepening drainage slots at the base of the passages (e.g. Calaforra and Pulido-Bosch 2003). Phreatic stoping, followed by vadose cavern enlargement, probably explains the close correlation between caprock sinkhole distribution and position of underlying vadose passages in Permian gypsum subcrop in the Kungur Cave region in the Russian Urals, where the caprock thickness is a little as 25 m (Fig. 7.49).

Vadose Gypsum Caves

A lowering of the watertable, either by uplift or climatic change tied to increasing local aridity, converts a former phreatic cave into a vadose cave. This is the recent history of the accessible portions of the gypsum maze caves worldwide, including documented examples in New Mexico, the western Ukraine and Saudi Arabia where the passage into the middle-upper Pleistocene marks the transition from phreatic to vadose in most of the accessible caves. It is characteristic also of the very recent history of some natural phreatic caves where watertables were artificially lowered to allow quarrying of gypsum (Klimchouk 2012).

Climate shifts or watertable fluctuations at the early end of the burial cycle can create alternating vadose-phreatic conditions in evaporite beds in the early stages of burial and so create an early watertable-associated karst level in the accumulating evaporites. That is, a gypsum bed hosting a vadose hydrology on its way down into burial, may pass through the watertable a number of times before its ultimate burial and passage into the mesogenetic realm. This is the case today in the captured recharge playas in central Australia (Fig. 2.63) and about the edges of some halite-filled salars in the Andes (Fig. 3.43) and many Canadian salt lakes (Last 1993a), where fluctuating hydrologic conditions alternate between vadose and phreatic. Similarly, Quaternary climate shifts have variably karstified the gypsiferous sediments of many Sinic playas. For example, Yauro and Cooper (1997) document Pleistocene lake basins in north-west China, such as in the Chaidamu Basin, where exposed gypsum beds evidence karst overprints that include: corroded flutes, fissures, small caves and associated collapse breccias and roof falls, followed by phreatic evaporite cement overprints. Watertable fluctuation is a hydrological overprint that is preserved as alternating ornamented surfaces in gypsum caves, disconformities and cave fills in many ancient lacustrine gypsum units.

Miocene Epikarst in the Madrid Basin, Spain

The Miocene sedimentary record of the Madrid Basin displays several examples of palaeokarstic surfaces sculpted within the gypsum bed at the same time that the overlying strata were deposited (Rodríguez-Aranda et al. 2002; Cañaveras et al. 1996; Sanz-Montero et al. 2006). The karst indicates a time of freshening (early burial karst) in the same lacustrine setting that was also depositing further gypsum atop the karst. One of the better documented of these palaeokarstic surfaces separates the Lower and Intermediate units at the boundary between what are two main lithostratigraphic units in the basin (Fig. 7.50). There epikarst formed in Aragonian lacustrine gypsum as it was covered by terrigenous deposits of the overlying Intermediate unit. Karst features include infiltrations of the overlying Aragonian marls into the gypsum of Lower unit for up to 5.5 m below the epikarst surface. The presence of a shallow, but fluctuating, watertable at the time of karstification, along with low hydraulic gradients in the evaporite basin, were the main factors controlling karst style.

Karstification was extensive and rapid, it took place in a relatively short time frame of several thousands of years (Fig. 7.50; Rodríguez-Aranda et al. 2002). Stage 1 of the karstification was the accumulation and bioturbation of a bed of lenticular gypsum in a moderately saline lake (Fig. 1.39). During periods when the lake dried out, plants colonised the poorly indurated and exposed gypsum ground (Stage 2). These halophytic plants contributed to the local transformation of primary gypsum to anhydrite through a dissolution–reprecipitation process, similar to that reported from vadose zones in supratidal sabkhas, salinas and losing playas. Stage 3 corresponds to the death and decay of plants, with the root holes behaving as preferential conduits for entry of meteoric water. Anhydrite, which had formed in the soil via respiring plant roots, was unstable and transformed to secondary gypsum. Continued vadose flushing of the initial conduits resulted in the formation of cylindrical and funnel-shaped pits that mimic, but do not strictly represent, root casts or rhizoconcretions (Stage 4). Both the vertical vadose conduits and gypsum caves only penetrated a few metres below the palaeokarst surface, suggesting the ongoing presence of a shallow, still saline watertable. The position of the watertable played a critical role throughout (stages 1–6) and limited the depth reached by both exokarst and endokarst features (Fig. 7.50). In addition, the formation of roughly planar, horizontal cavities was probably related to the top of the watertable, which also represented the maximum depth for root penetration (stage 4).

Formation of horizontal caves was constrained by stratification planes in the gypsum host rock. Conduits and caves were coeval with larger gypsum dolines, and all were partially to completely filled by varying combinations of clayey mudstone, carbonate and detrital gypsum (stage 5). Clays in the karst fill are mostly coarsely laminated, green mudstone beds, possibly reworked from mudflat and alluvial fan deposits that are laterally associated with the lacustrine gypsum (Rodríguez-Aranda 1995). Clay infiltration was probably tied to periodic floods of the karstified surface, with the caves and doline floors making depressions where waters ponded with a relatively high concentration of suspended fine-grained siliciclastic material and organic detritus.

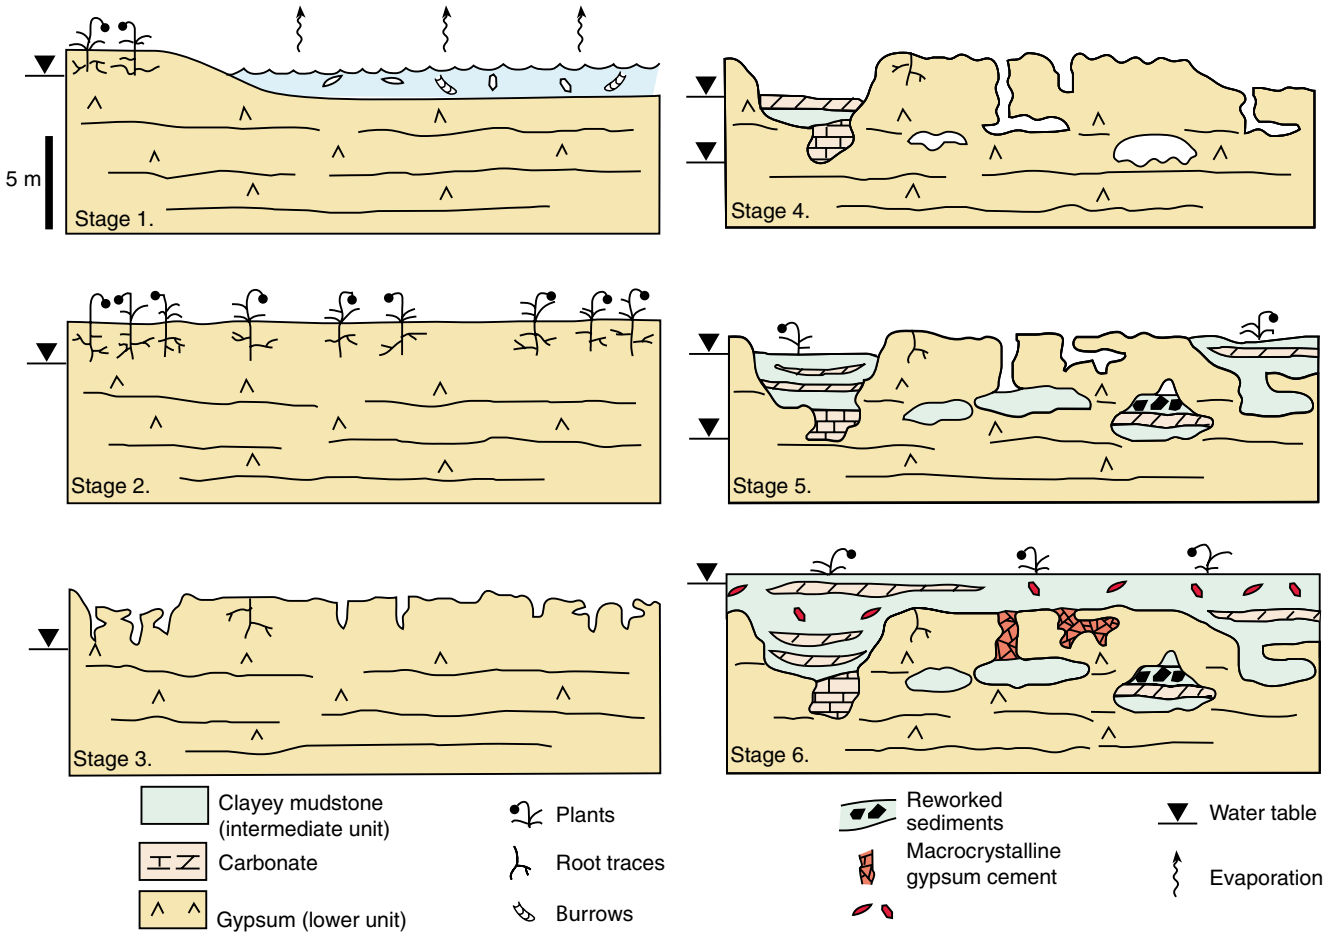

Fig. 7.50 Development of epikarstic surfaces and associated endokarst in the Miocene Gypsum of the Madrid Basin. See text for detail of the evolutionary stages (After Rodríguez-Aranda et al. 2002)

These mudstone fills in the gypsum caves are similar to the mud-filled cavities observed by Last (1993a) in modern saline lakes of the northern Great Plains of western Canada, and are consistent with the episodic clastic input patterns recognized in similar gypsum karst in the Sorbas Basin, SE Spain (Calaforra and Pulido-Bosch 1999, 2003).

Carbonate is present in the sedimentary fill of both dolines and gypsum caves. Carbonate in the dolines consists of massive to peloidal dolomicrite or nodules developed in laminated claystone, whereas carbonate in caves typically consists of calcite rafts and patches of reworked calcitised gypsum. The doline carbonates were probably deposited in shallow water that was episodically ponded in the karstic depressions. The carbonate nodules are probably pedogenic, arguing for punctuated deposition with times of subaerial exposure during the sedimentary fill of the dolines. Calcite rafts in clayey cave deposits suggest inputs of clastic sediment alternated with periods of standing water when calcite rafts precipitated at the air–water interface of pools in the caves (Taylor and Chafetz 2004). Sanz-Montero et al. (2006) argues that much of the dolomite replacing and mantling corroded gypsum crystals in the Madrid Basin is microbially facilitated.

Alluvial fine-grained sediments of the Intermediate unit then accumulated and filled any remaining irregularities in the epikarst surface, which was pocked by numerous doline depressions and unfilled cavities (pits and conduits) (Stage 6). Once dolines were entirely filled by fine-grained sediment and the adjacent epikarst surface was also covered, a sedimentary discontinuity was preserved between the top of the bedded gypsum and the overlying clay. Clay had by then accumulated in the various pits and conduits that were not filled in earlier stages of karstification.

Infill of the remaining cavities includes macrocrystalline gypsum cement meshworks or mosaics that are especially obvious in cavities with little or no earlier detrital fill (Stage 6). They indicate saline phreatic conditions where a rise in the watertable accompanied the deposition of the terrigenous sediments that now sealed the palaeokarstic surface. The same saline pore waters, perhaps derived by ongoing subsurface gypsum dissolution, also drove the precipitation of displacive gypsum crystals in some nearsurface clays.

Subsequent to this early paleokarst, somewhat younger paleokarst features overprint the same gypsum beds. They are driven by later uplift and telogenesis and typified by sagging and suffosion overprints at the lower boundaries of various Plio-Pleistocene terrace deposits in the Madrid Basin (Gutiérrez et al. 2008).

Modern Karst in Cretaceous Gypsum, Texas

At the other end of burial cycle are telogenetic vadose gypsum caves responding to recent uplift of buried anhydrite beds and the transition from phreatic maze caves to vadose caves with gypsum and calcite speleothems. Ornamented vadose gypsum caves, a late stage of this conversion, are today exposed within the workings of the Fredericksburg Gypsum Quarry in a 10-m (30 ft) thick gypsum bed. The gypsum is the nearsurface remnant of the Cretaceous Kirschberg Evaporite Member, which was exposed during the late Tertiary exhumation of the Edwards Plateau (Warren et al. 1990). Early stages of the uplift were typified by the rehydration of anhydrite back to gypsum and the formation of fibrous vein fills.

Complete telogenetic dissolution of the evaporite level is indicated by a widespread evaporite solution breccia, which constitutes one of the most permeable and most important aquifer intervals in the Edwards Plateau (Barker et al. 1994).

Relatively impervious nodular gypsum hosts most of the caves, with nodules showing varying overprint by coarser crystalline gypsum daisy textures. Much of the cave fill and ornamentation is made up of a more permeable alabastrine gypsum precipitate (Fig. 7.51a). Where a gypsum bed is completely dissolved by cave expansion all that remains of the former gypsum karst is a jumble of speleothem clasts beneath and within a dolomitic crackle breccia. Most of the larger blocks in the breccia were derived from the overlying Edwards Formation and are now encased in a residuum or matrix of silt- to sand-sized dolomite rhombs ("chalky"

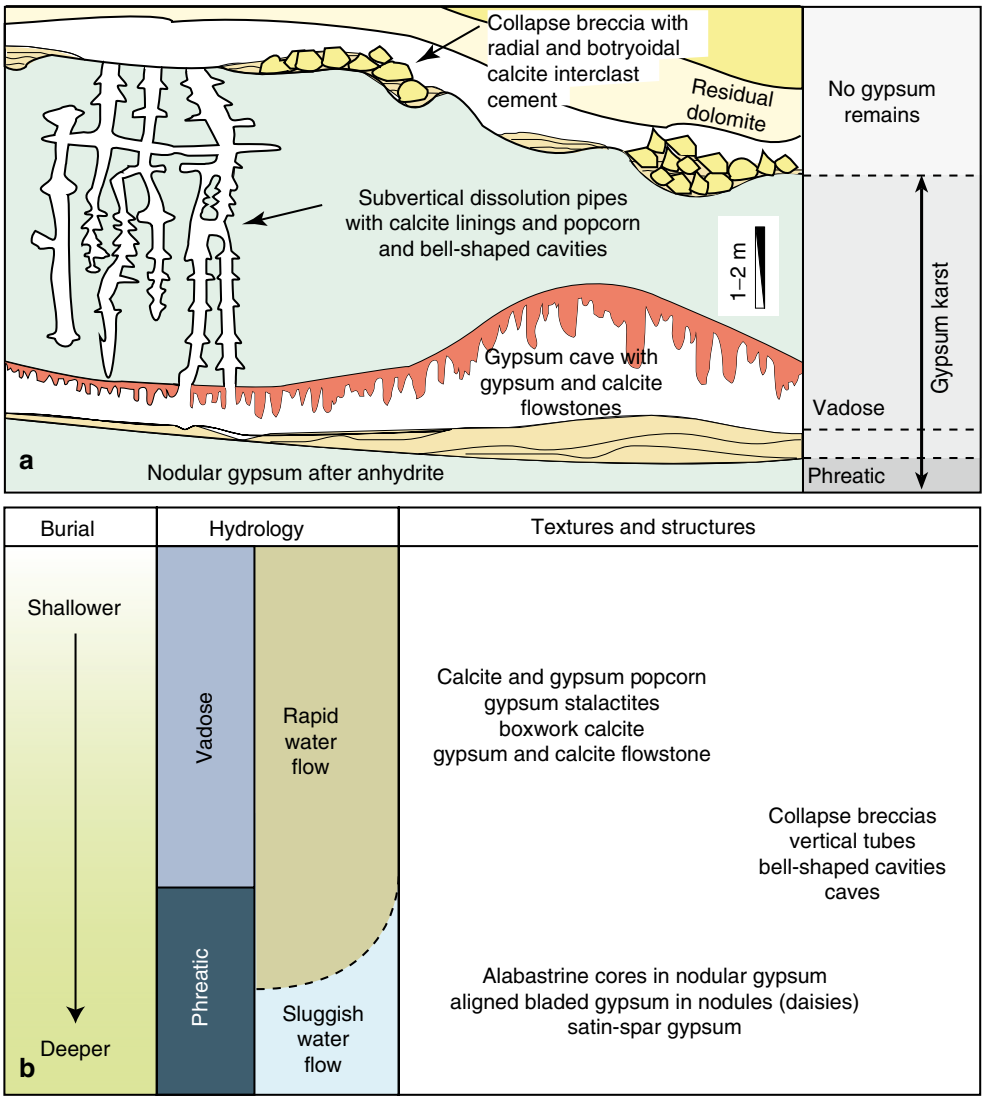

Fig. 7.51 Model karst and related calcite textures developed though sequential complete dissolution and retexturing of an uplifted gypsum bed – based on textures in the subcrop of the Fredericksburg Gypsum in central Texas. (**a**) Schematic cross section through the dissolving now vadose gypsum bed. (**b**) Textural evolution related to groundwater regime (Modified from Warren et al. 1990)

dolomite). The rhombs were originally floating in a matrix of gypsum/anhydrite and their equivalents can still be found as dispersed rhombs and layers in nearby, as yet undissolved, gypsum beds.

Friable alabastrine gypsum up to 10–20 cm thick, coats cave walls in zones of sluggish and perched groundwater crossflow. It is made up of silt-sand sized euhedral prisms with a delicate open "pack-of-cards" texture that could only be preserved in caverns experiencing very low rates of fluid cross flow. Gypsum is also locally reprecipitating as small stalactites and stalagmites in vadose cavities. Walls tend to be smooth and unornamented in other nearby caves with more active throughflow.

The following sequence of exhumation and karsting was listed by Warren et al. (1990) as indicative of a transition from deep phreatic to vadose hydrologies (Fig. 7.51b):

- *Formation of nodular "daisy-head" gypsum* As uplift raised this bed of nodular anhydrite into the zone of rehydration, replacement by gypsum was at first slow but pervasive, with near-stagnant phreatic fluids oozing into the calcium sulphate bed. At the microscale, stagnant deeper phreatic waters seeped into the nodular anhydrite bed. Flow was focused along inter-crystalline porosity films within the dolomite rims surrounding the calcium sulphate nodules or it was focused along thin-bedded dolomite stringers within the anhydrite bed. Millimetre to cm-sized, aligned gypsum crystals nucleated off these flow paths and grew inward toward the nodule core via dissolution and replacement of the anhydrite to form daisy-textured gypsum. The main mesoscale permeability entries into the gypsum bed were provided by fractures in the adjacent aquifers, which began to render a maze cave network.
- With further uplift there was a change to more active hydrologic conditions, which modified the rate of gypsum growth and fine gypsum crystallites that characterise alabaster came to be the dominant precipitate. Replacive gypsum grew more rapidly through the unit as a microcrystalline alabaster texture overprinted some of the nodules. The adjustment in gypsum texture as the unit was exhumed probably reflects more pronounced fluctuations in temperature and saturation tied to increased groundwater crossflow (Fig. 7.51b). This was probably related to greater access of undersaturated phreatic water to the unit as the dense network of joint-controlled maze caves permeated the gypsum and were fed from joints and fractures in the adjacent aquifer and possible increasing influence of unconfined waters atop the exhuming evaporite.
- *Karst structures and calcite/gypsum speleothems* As the gypsum bed passed into the zone of active phreatic flow and then vadose infiltration, the process of gravity-driven karstification began in earnest. Nodular and alabastrine gypsum now was subject to widespread dissolution. Phreatic groundwater entry was first along joint mazes, while vadose infiltration in the exhumed parts of the unit tended to expand former phreatic caves and to create new vertical pipes with scalloped edges indicating the downcutting process. Gypsum and calcite speleothems formed in caves and pipes within regions of less active vadose crossflow, mainly as cave popcorn, flowstone and alabastrine laceworks (Fig. 7.51a).
- *Brecciation and complete loss of gypsum* Complete dissolution of the gypsum bed produced zones of collapse breccia, with circumclast radial and botryoidal calcite cement (speleothems). Collapse occurred gradually over wide areas of contact between the bedded gypsum and adjacent strata so that the overlying beds tend to be lowered gently into broad folds. Regionally, the overburden stratification was little disrupted by widespread foundering associated with the complete flushing of gypsum. Regionally a residual zone of pulverulent dolomite rhombs ("chalky" dolomite) overlain by packbreccia now defines the cap to the dissolved gypsum bed. Where gypsum remains, some of this unconsolidated dolomite residuum is washed from the upper surface of the dissolving gypsum into karstholes and pipes that cut down into the gypsum to accumulate on the conduit floors with classic "vadose silt" textures.

There is abundant calcite precipitating as void fill in rubble breccia cavities and pipe linings, but there is no discernable conversion of the chalky dolomite to calcite (dedolomitisation) in this system. XRD shows chalky dolomite remains well ordered and near stoichiometric. The lack of dedolomitisation raises the question: Is dedolomitisation commonplace in evaporite beds on the way down in the burial cycle, when newly formed dolomite is more likely to be a less -ordered highly-metastable form of dolomite? The corollary is that it is less common in evaporite beds on the way up (see calcitisation of evaporites discussion later in this chapter)?

The end result of unroofing an ancient evaporite bed in this humid region of central Texas, where the karsted gypsum beds never outcrops, is a stratiform chalky calcitic/dolomitic residuum layer that underlies a gently folded and collapsed packbreccia bed (Warren et al. 1990). The former position of a regional decametre-thick $CaSO_4$ bed is now defined by cm-metre thick interstratal packbreccia characterised by brecciated and rebrecciated fragments of calcite popcorn, boxwork and botryoidal calcite, all intermixed with fragments of the overlying strata and the dolomite residuum. None of the original evaporite salt remains in the final breccia.

Zahm and Loucks (2011) have mapped this dissolution breccia and associated fracture patterns in outcrop, for more

than 100 km across the Comanche Shelf of central Texas (along Interstate Highway 10). They defined three consistent intervals across the outcrop and subcrop belt: (1) a characteristic substratal fracture/alteration interval beneath the evaporite zone; (2) an intrastratal interval containing the evaporites or fractured breccia residuals; and (3) a suprastratal interval overlying the evaporite level that typically shows deformation and fractures generated by collapse into the caverns created by evaporite dissolution. Deformation within the substratal interval is characterized by low-intensity opening-mode fractures with orientations that parallel pre-existing Palaeozoic structures, which unconformably subcrop below the zone of interest. Intrastratal deformation, which is characterized by both extensional and compressional structures and fractures, including normal and reverse faults and folding. Faults and fold axes within this zone also tend to parallel pre-existing structural trends. In addition, zones of extensive chaotic brecciation occur in localized areas. Finally, suprastratal deformation includes extensional and compressional faulting and zones of high intensity opening-mode and shear fracture zones. Clearly evaporite dissolution, independent of any external tectonic stress can create fractures. This and the associated creation of open fractures in overburden has important environmental implications wherever a fractured aquifer so created is proposed as a possible subsurface brine disposal level, as in fractured Devonian carbonates beneath the Cretaceous tar sand areas of Alberta (Chap. 10). Such systems must be shown to be sealed, with no collapse fracture-related connections to shallower aquifers.

Modern Gypsum Karst in Saudi Arabia

Similar telogenetic gypsum transformations, associated with gypsite/alabaster replacement, brecciation and karstification, are seen at Dahl Hit (*dahl* = *cave*) at Ain Hit in eastern Saudi Arabia (Fig. 7.52a, b). There the 72 m-thick type section of the Hith Formation outcrops in the roof and sides of a large collapse-prone doline mouth to a phreatic tube cave. In the subsurface the Hith Anhydrite is a major regional seal to the prolific reservoirs of the Arab Formation of Saudi Arabia and the western Emirates and it is typically more than 120 m thick in these oilfields (Chap. 10). The tubular cave mouth defines the lower part of the breached doline floor and leads down into a phreatic tube cave that has yet to be completely surveyed. The cave entrance is located at the Hith Anhydrite's contact with the limestones of the overlying Sulaiy Formation. The cave is steeply inclined (≈30°) and floored by a scree slope composed of packbreccia created by gypsum layer breakdown. Blocks in the packbreccia are jumbled combinations of collapsed carbonate overburden and transforming blocks of Hith Formation anhydrite. Larger blocks range up to 3–5 m across. Like most phreatic tube caves, the cave walls are smooth and unornamented with the floor covered by angular blocks of fallen roof. Much of the fine bottom sediment that covers the packbreccia on floor of the water-filled parts of the tube cave is composed of insolubles from dissolution of the Hith Anhydrite.

For centuries Hit Dahl at Ain Dit was a source of fresh water for the local population (*Ain* = *water spring*). But overpumping in the last few decades has led to a drastic drawdown of a potable water layer that once floated atop more saline phreatic water in the cave proper. The rapid lowering of the watertable destabilised the cave roof. Dahl Hith is now a dangerous cave to visit. On my last visit in 2005 a large section of the roof had just collapsed in the preceding days. Much of the interior of the cave fissure is now packed with freshly collapsed blocks making cave access much more difficult than in the past. Recently (2011), the watertable has risen by more than 25 m, unfortunately it seems this may be due to an influx of polluted water (possibly excessive agricultural runoff or sewage entering the groundwater) and the former clear waters are now at times clouded by bacterial blooms and scums, metabolising the high levels of phosphates and nitrates now in the system (<http://www.saudi-caves.com/sewage/index.html> last accessed June 10, 2014).

At outcrop scale (Fig. 7.52c) the retreating dissolution edge of the gently dipping Hith Fm. creates an obvious zone of bedding disturbance, megabrecciation, slumping and folding in the Sulaiy Formation. The current contact with the dissolved and monoclinally dipping Hith Formation (≈30–40°) at Hit Dahl is defined by large collapse features and rotated mega-blocks of overburden in the flexure zone atop the shallow subcrop edge of the anhydritic Hith. A megabrecciated zone defines overburden collapse along the subcropping monoclinal edge of the Hith in Saudi Arabia and it can be traced as an elongate at-surface expression of the Hith for more than 550 km along strike. Similar, also spectacular, collapse dolines and rotated mega-blocks characterise gypsum karst features in the subcrop belt of the Eocene Gachsaran Formation in the foreland foldbelt of Iran (Cucchi and Zini 2003).

Active collapse fractures, visible in plan view of the cave entrance and in the Hit cave wall, show the effects of solution-related extensional collapse on the meteoric conversion of grey anhydrite to white-buff alabastrine gypsum (Fig. 7.52a, d). Bedding parallel layering in the Hith is largely preserved on conversion to the fine alabaster crystals, which create an almost mimetic preservation of precursor texture. Thin extension fractures parallel to the main fracture/collapse allow the formation of thin alabaster streaks, which are clearly visible in the left third of the photo (Fig. 7.52d).

The nature of the anhydrite-to-gypsum conversion front at Dahl Hit varies from fracture parallel, as seen in Fig. 7.52d to bedding parallel, as seen in Fig. 7.52e. In the latter case the upper boundary of the residual anhydrite block shows a nodular replacement contact with the newly precipitated alabaster. In contrast, its lower contact shows a more feathered

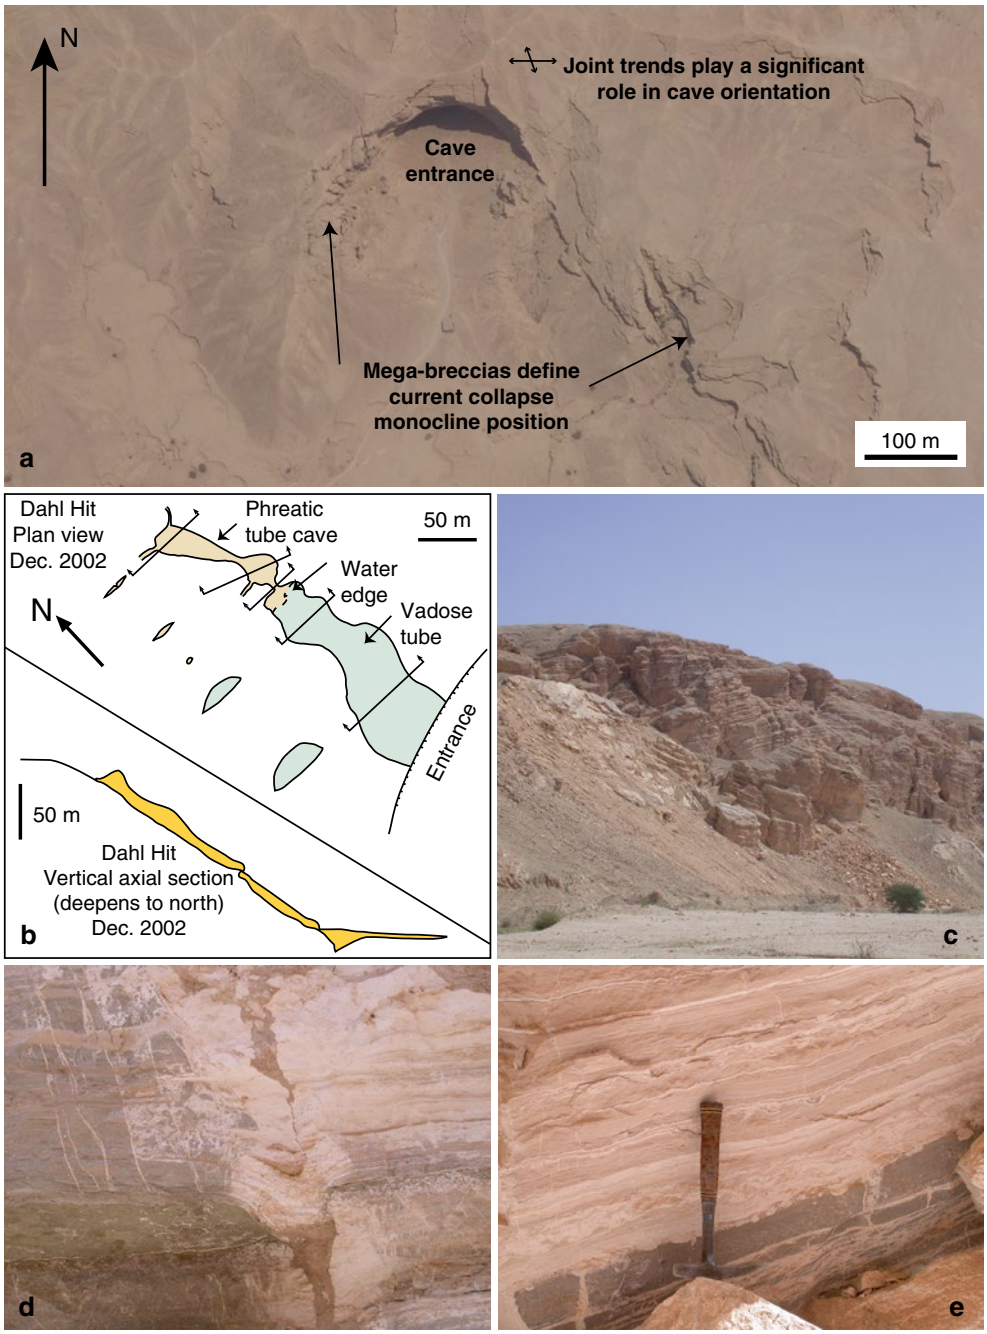

Fig. 7.52 Dahl Hit at Ain Hit in Saudi Arabia. (**a**) Plan view showing joint-set control on cave mouth. (**b**) Surveyed geometry of Dahl Hit (Replotted from Gregory et al. 2002). (**c**) Mega breccia along collapse monocline is an overburden disturbance created by the nearsurface conversion and dissolution of the underlying Hith anhydrite. Cliff ≈ 100 m. (**d**) Contact between alabastrine gypsum and anhydrite in the area of the cave entrance showing a v-shaped breccia- and clay filled cavity some 50 cm across. (**e**) Detail of the conversion front with buff alabastrine gypsum at top, grey remnant anhydrite below, upper conversion contact is nodular, lower transition is feathered, Bedding parallel white veins in the alabastrine gypsum are satin spar gypsum. Images **c** through **e** illustrate the effects of anhydrite conversion at the outcrop edge of the Jurassic Hith Fm. anhydrite at Hith Dahl

relationship. White bedding-parallel satin-spar has formed in small fractures in the anhydrite and parallels the main entry fractures creating the alabaster zone. Satinspar is the last gypsum phase to form and has also grown in bedding-parallel fractures as well steeper veins that crosscut some anhydrite-alabaster contacts. Veins were created by extension in response to the growth of void space. Most of the grey anhydrite is being replaced from the edges inward, but the alabaster, which is less consolidated and somewhat more permeable, can accommodate a much higher density of bedding parallel fractures. It is a largely inhomogeneous response to tension created by dissolution and contrasts with the more isotopic response seen in the satinspar growing in the Permian clays where the Khuff anhydrite subcrops.

The replacement sequence at Hit Dahl is laminated anhydrite passing directly into laminated alabaster. It may reflect the much lower rates of fluid rock interaction experienced by the Hith Fm. during uplift as compared to the more humid conversions occurring deeper and earlier in the uplift history at Fredericksburg, Texas. The greater disturbance in the overburden at Hit Dahl compared to Fredericksburg reflects the greater thickness and resulting locally steeper dip of the monoclinal defining the edge of the dissolving $CaSO_4$ bed and perhaps a greater strength in the roof span in Saudi.

Halite Caves

Because of its high solubility, halite does not make it into outcrop or shallow subcrop as easily as gypsum/anhydrite. Where halite is at the surface it tends to be in regions of Pleistocene halite deposition (salt on its way down) or in zones of active diapirism (salt coming up very quickly). Chabert and Courbon (1997) noted caves in ancient rock salt in several regions: Algeria (in diapirs, mostly as shafts and short caves up to 280 m long), Chile (diapirs, with caves 250–500 m long), Israel (in a diapir as tube caves several hundred metres in length), Romania (in diapirs, with caves up to several hundred metres long), Spain (in diapirs, with caves up to 650 m long), Tajikistan (several caves 300 to 2,500 m long and up to 120 m deep), and in the namakiers of Iran and the offshore island relicts where cavern lengths range from several hundred metres to kilometres (Table 7.7).

Halite in an active namakier rises and spreads rapidly, so any karst in an active salt diapir tends to be a feature associated with the immediate underside of a caprock. Karst processes cannot deeply penetrate while salt is flowing, even when the plug rises more than 300 m above the surrounds. So, more extensive halite hosted caves are best developed about the margins of a namakier where halite's susceptibility to rapid dissolution means the length of a cave developed below the caprock can be substantial. There is a report of a single salt halite cave (Cave 3 N) on Qeshm Island, Iran, with a passage length of more than 9 km (Bruthans et al. 2002). Once the rate of diapir rise has slowed or ceased the positive topography of the now inactive diapir controls the depth of development of doline collapse on the diapir itself. That is, deeper collapse dolines can now form in the more central topographically higher portions of a salt structure, once the rate of rise has slowed (e.g. Calaforra and Pulido-Bosch 1999).

The high solubility of halite means a halite cave system can form in a few hundred years rather than the thousands to tens of thousands of years needed to form carbonate karst (Bruthans et al. 2010). Not only is rate of cavern formation very fast (dissolution/downcutting of 20 mm/year), these rapidly forming karst features are hosted in and atop a flowing rock mass. This means some of our notions of karst process and cave stability, related to the rate and density of cavern expansion, need to be modified when dealing with halite karst. For example, unlike gypsum and carbonate karst, jointing is not significant in controlling cavern orientation in namakier karst.

Modern Halite Karst in the Dead Sea Depression

Halite caves occur in the Mt. Sedom diapir, where halokinetic Miocene salt is sporadically exposed beneath a weathering and fractured gypsiferous caprock (Fig. 7.53; Frumkin and Raz 2001; Frumkin and Ford 1995). Water enters the various caves in Sedom diapir through breaches in the caprock. Most of the caves in the higher parts of Mt. Sedom salt are vadose inlet caves; these are meandering steeply inclined tubes and canyon slots located within or immediately below the caprock. They form where salt solution quickly carves out near vertical slots and shafts (typically < 2 m wide and much deeper) that lead down from the surface, sometimes along pre-existing fractures and shears in the salt. Inlet caves in the central portions of the mountain can only be accessed through their sinks and appear to have no distinct outlet. All

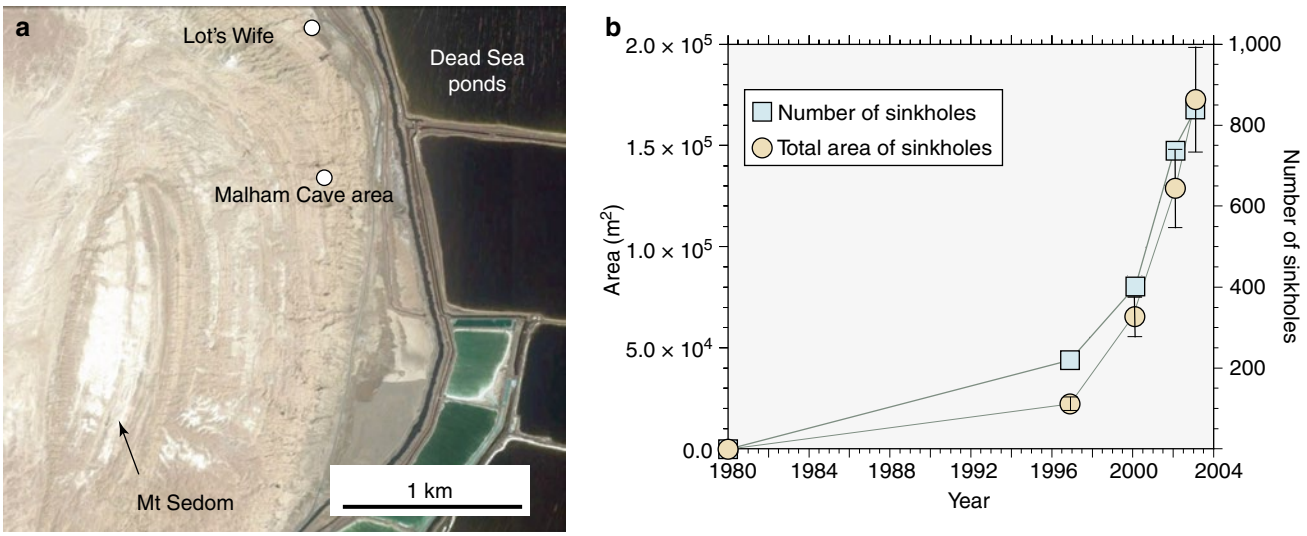

Fig. 7.53 Dead Sea karst. (**a**) Mount Sedom, Israel, showing typical anticlinal core and low elevation (Google Earth image). (**b**) Growth rate of sinkholes along the west coast of the Dead Sea, both in numbers and area coverage. The sinkhole development significantly accelerated since 1997; currently there are more than 1,000 sinkholes, and their numbers are increasing at a rate of 150–200 per year (After Yechieli et al. 2006)

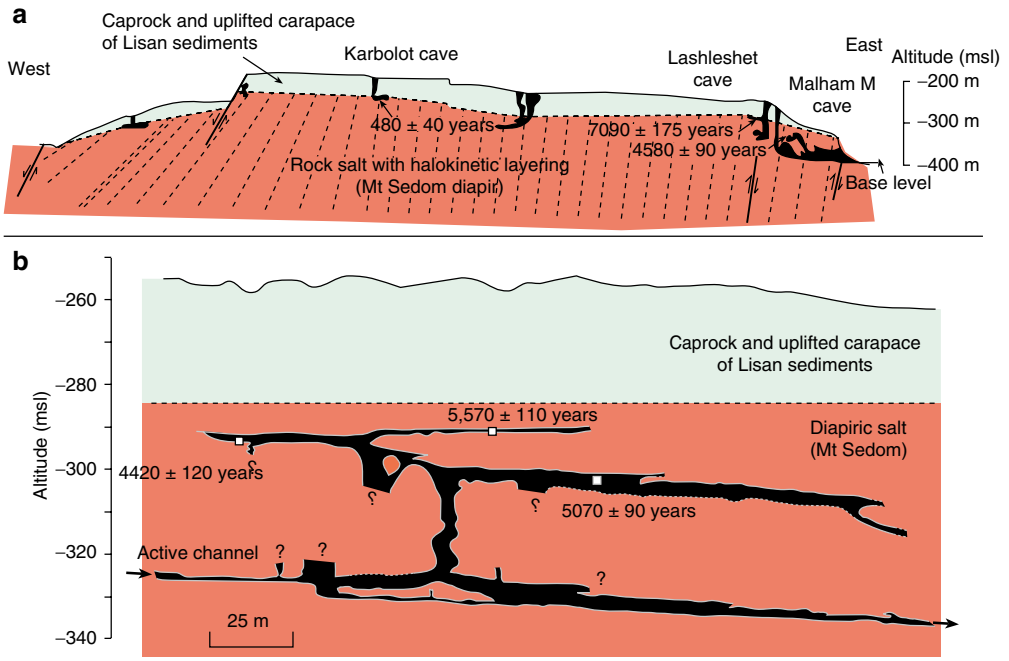

Fig. 7.54 Halite caves beneath the caprock carapace of Mt Sedom, Israel (After Frumkin 1996). (**a**) East-West cross section through the southern part of Mount Sedom, showing ages of upper levels of caves in ^{14}C yr B.P. Dashed lines indicate dip of salt layers within the diapir. Caves are coloured black. The oldest cave date comes from Lashleshet Cave, which lies at the top of the eastern escarpment, implying this was the earliest region on the Sedom uplift to experience vadose flushing. (**b**) Vertical section along part of Malham South Cave, showing several dated levels. The age of the uppermost level (5,570 ± 110 year B.P.) indicate the minimum exposure age of this site created by the halokinetic uplift of the landsurface (See Fig. 4.53 for location of Mt Sedom)

terminate several tens of metres above the regional watertable (e.g. Karbolot Cave; Frumkin 1994a, b, 1996).

The lower parts of inlet caves often contain steep silt and clay banks with surge marks that indicate occurrence of low energy water ponding, with variable residence times. Silt and clay sediments settling at the bottoms of inlet caves impede infiltration, extending the residence time of pond water (Frumkin 1994a, 1996). Three of the studied caves in northern Mount Sedom had perennial ponds throughout the period 1984–1995. The ponds are perched, without any lithologic control, tens of metres above the nearest potential outlet at the foot of the mountain (Fig. 7.55a). Water level in each pond differs from the others by tens of metres. All pond waters are highly concentrated, up to 324 g/l, with solutes consisting mainly of sodium and chlorine. Fresh inflow waters reach halite saturation within a few hours of reaching the pond. Both dissolution and precipitation features form the pond edges, and their equivalents can be seen on cave walls wherever ponds have dried out. Dissolution is indicated by horizontal notches, which connote density stratification in the ponds when aggressive fresh flood waters temporarily diluting the upper parts of the pond. Subsequent saturation of holomictic pond waters is indicated by the growth of cm-scale halite crystals on the bottom and sides of the ponds.

Towards the periphery of Mt Sedom, the inlet caves lead down to laterally expanding vadose cave levels that drain onto the Dead Sea plain. Sedom Cave, is the longest laterally expanding diapir cave, with an aggregate length between two subparallel conduits of 1.8 km. Malham Cave, another large perched and laterally expanding cave, lies a few hundred metres south of Sedom Cave (Fig. 7.54b; Frumkin 1996). It has an aggregate passage length of more than 5.5 km and reaches to some 194 m below the landsurface. There is an upper tier of largely inactive passages and a lower active channel level. ^{14}C dates on fossil wood in the upper cave level shows meteoric waters began to sculpt the upper cave more than 5,500 years ago. Ongoing uplift of Mt Sedom salt means the active channel level in Malham Cave is now downcut some 10–12 m lower than when it began. Malham Cave passages quickly developed an open outlet through which floodwater escaped directly to the Dead Sea floor, proving that during this period some 4,000 years ago rock salt had already risen above region hydrological base level at the Malham outlet point within the eastern escarpment (Fig. 7.54a). Lashelshet Cave, an inlet cave on the highest point on the diapir cross section, has an even older age of more than 7,000 years since cave initiation. Caves in the northern part of Mt Sedom did not begin to form until some 3,000 years later (Frumkin 1996).

Based on their study of the caves of Mt Sedom, Frumkin and Ford (1995) concluded cave passages develop in two main stages: (1) an early stage characterized by inlet caves with high downcutting rates into the rock salt bed, and steep passage gradients; (2) a mature laterally expanding stage characterized by lower downcutting rates and the establishment of a wider subhorizontal perched stream bed armoured with alluvial detritus. This style of cave tends to develop toward the periphery of the diapir mound. In the mature expanding stage downcutting rates are controlled by the uplift rate of the diapir and changes of the level of the Dead Sea.

Passages may aggrade to create wide flat bevelled passages and slots with thick sediment armoured bases (Frumkin 1998). A lack of a consistent phreatic level in the blind bottoms of perched water levels and the presence of the horizontal slots in the lower levels of Sedom Cave means dissolution in both types of caves is largely restricted to times of flooding and perched or backed up freshwater in the vadose zone. This explains the tapering passages of inlet caves and the widespread alternation of armouring and bevelling as well as formation of narrow horizontal meandering slots toward parts of the top of the meandering channel that is now Sedom Cave.

Mass balance calculations in the halite caves of Mt Sedom yield downcutting rates of 0.2 mm s^{-1} during peak flood conditions, this is about eight orders of magnitude higher than reported rates in any limestone cave stream (Frumkin and Ford 1995). However, floods have a low recurrence interval in the arid climate of Mount Sedom so that longterm mean downcutting rates are lower: an average rate of 8.8 mm/year was measured for the period 1986–1991, while Frumkin (2000) estimate the average regional vadose downcutting rate in the Mt Sedom karst region to be 20 mm/year. This is still at least three orders of magnitude higher than rates established for limestone caves and more than able to cope with the rate of supply of the diapiric salt.

The highly impervious nature of halite and its resupply in actively growing diapirs means that, unlike carbonate and gypsum caves, there is no real watertable level to define maximum cave development in a rising salt stem. Rather, the inlet caves are simple dissolution tubes where rainwater has accessed halite and sank until it was saturated and then dissolution stopped until the next flood. Toward the edge of the rising stem these inlet caves breached the edge of the salt mound and vented their perched groundwaters to the surrounding plain (Fig. 7.54; Sedom and Malham caves). This creates a downcutting and laterally expanding cave system, which is still some metres to tens of metres above the base level of the regional watertable in the surrounding plain. The expanding cave level is dominated by mostly horizontal growth, often with a sediment-armoured floor. It has numerous benches in the walls that probably reflect changes in the hydrological base level.

Dense anastomose cave networks that characterise gypsum caves are not found in the halite caves of Mt Sedom. This reflects the ability of diapiric halite to re-anneal and the fact that all exhumed halite that makes it to the surface is diapiric, not bedded. At-surface halite is not sandwiched between jointed aquifers above and below the dissolving layer. Rather it is a growing mound subject to dissolution at its top and sides.

Away from Mt Sedom, there are active collapse sinkholes and caverns forming in the alluvial fans and clastic aprons that overlie the bedded Quaternary lacustrine halite of the Dead Sea (salt on its way down in the burial cycle). In the sediments around the lakeshore the pace of collapse has accelerated in the last 60 years due to a drastic lowering of the circum-lake watertable and the associated lakeward migration of the saline-fresh water interface (Fig. 2.64). For example, a series of collapse dolines 2–15 m diameter and up to 7 m deep, appeared in 1990 in the New Zohar area. In January 2001 a large sinkhole, some 20 m deep and 30 m wide, cut though the asphalt surface of the main road along the western shore of the Dead Sea. It was opened by the passage of a busload of tourists on their way from Ein Gedi to the solarium. Existing tourist facilities, such as the Ein Gedi beachside parking, were shut down after the road was damaged and several buildings have since collapsed into sinkholes. Sinkholes have since developed in other areas about the Dead Sea Margin including Qalia, Ein Samar, Ein Gedi and Mineral Beach. The process began in the southern part of the Dead Sea coast and slowly spread northward along the Israeli coast and is more localized in the northern and southern parts on the Jordanian side and has increased as the sea level fell (Ezersky and Frumkin 2013; Arkin and Gilat 2000).

Three main types of sinkhole or doline fill have been recognized atop the dissolving Holocene salt beds of Sedom; (1) gravel holes in alluvial fans, (2) mud holes in the intervening bays of laminated clay deposits between fans, and (3) a combination of both types at the front of young alluvial fans where they overlap mud flats. Fossil, relict sinkholes have been observed in the wadi channels cutting into some old alluvial fans, showing this is a natural and ongoing process. While lake levels continue to fall (Fig. 4.45), the potential for subsidence hazards related to karst collapse is ongoing.

Sinkholes and related subsidence has been the focus of much geological study, but Closson et al. (2010) pointed out that an even more significant and ultimately damaging environmental effect of the ongoing water level lowering are hectametre and larger scale landslides along the retreating shorezone. In the 1990s, international builders created major tourist resorts and industrial plants along the Jordanian and Israeli shore while, during the same period, geological hazards triggered by the level lowering spread out. From the beginning of the year 2000, sinkholes, subsidence, landslides,

and river erosion damaged infrastructures more and more frequently: dykes, bridges, roads, houses, factories, pipes, crops, etc all suffered as a result. There is evidence of an older set of widespread ground collapses, sinkholes and caves that are tied to an earlier substantial fall in the Dead Sea water level some 4 ka. It may even be that the events described in Genesis 14 in the Christian Bible took place at the time of a substantially lowered sea level. The described battle, which occurred prior to the fall of Sodom and Gomorah, perhaps took place on the subaerially exposed flats of the Southern Basin of the Dead Sea. The "pits of slime" described in the fall perhaps were solution collapse sinkholes activated by the 4,000 ka fall in the Dead Sea water level (Frumkin and Elitzur 2002).

Modern Halite Karst in Crests of Diapiric Hormuz Salt (Precambrian) in the Arabian Gulf

Namakier outcrops in and about the Arabian Gulf range from structures actively extruding salt to those in ruins where salt has not flowed for tens of thousands of years (Fig. 7.21). Likewise the halite caves developed in the namakiers of Iran, or their offshore island counterparts, show a broad range of ages and styles of salt cave development tied to the time since cessation of salt flow (Filippi et al. 2011; Bruthans et al. 2010; Talbot et al. 2009).

Surfaces of actively flowing namakiers on the Iranian mainland are characterised by karren flutes and pinnacles, with numerous small-medium dolines, collapse structures, swallow holes and small caves at their base. Caves tend to be sediment-armoured meandering tube caves or subvertical canyon slots that are centred on joints in the salt beneath a thin suffusion mantle. In contrast, the halite caves in the diapiric cores of the many islands in the Arabian Gulf have a more mature bevelled meandering style with thicker sediment armouring on the cavern floor. Many of these caves breach the retreating edges of former namakiers and salt fountains.

Salt movement in the various diapiric cores of these islands is inactive or is greatly reduced compared to the Miocene when these structures were active namakiers. For example, Dragon Breath Cave on Hormuz Island is a linear meander tube cave fed by an ephemeral stream in a shallow valley filling with alluvium (Figs. 7.55 and 7.56; Bosak et al. 1999; Filippi et al. 2011). The surrounding landscape is classic salt karst with numerous depressions, blind valleys, ponors and subrosion sinks. Together they form a highly pockmarked centripetally-ringed topography, which outlines those central parts of the island underlain by shallow subcropping Hormuz salt. The cave itself is one of a number of tube caves exiting about the edge of the zone of diapiric salt. Hosted in steeply dipping diapiric salt, it is around 100 m long with its main passage created by a minor ephemeral stream. Its near flat roof, with an average inclination of 5.4 %, is a notable feature and reflects either joint-related dissolutional spalling of the roof or an earlier watertable slot related to backup of a freshened water body.

The current cave passage has cut down a metre or more into earlier cave floor sediments (sediment armour), which contain clasts up to 50 cm in diameter. The cave formed by initial ingress along a linear joint, which was then widened by salt dissolution, so allowing meandering of the stream trace within the salt. It is a cave system very similar to the mature stages of laterally expanding caves in Mt Sedom. The base level of the cave correlates with the surface of a widespread marine terrace, which is now uplifted some 20 m above sealevel and defines much of the periphery of Hormuz Island. The raising of the marine terrace is related to the ongoing raising of the island via salt flow.

Bruthans et al. (2000, 2010) show that the style of karst landform developed in dissolving diapiric salt in the Arabian Gulf Islands reflects the thickness of the carapace that caps the dissolving salt core. They distinguished four classes of diapir cap, each with a specific association of superficial and underground karst forms, namely: (1) outcropping salt, (2) thin capping (0.5–2 m), (3) capping with moderate thickness (5–30 m), (4) capping with greater thickness (more than 30 m). Cap thickness controls or reflects: (1) the density of recharge points, with high densities of recharge points in the thinner caps; (2) the amount of concentrated recharge which occurs at each recharge point, with suffusion karst characterising thinner caps; (3) the rate of lowering the ground surface atop the salt, with the faster rates of lowering occurring beneath thinner caps, and (4) the amount of load transported by underground flood-streams into cave systems. The volume of sediment load tends to be locally higher and focused beneath the thicker caps, especially where inflow streams abut the edges of a dissolving salt dome. The thickness of caps atop expanding halite caves does not appear to influence the shape or style of the cave developed within the salt mass; more important seems to be the thickness of cap in the recharge area of the cave and the type of recharge into the salt environment. That is, how much water is passing into the salt and is its flow ongoing or ephemeral?

Halite caves in the relatively mature salt stems of the various islands of the Arabian Gulf, unlike carbonate systems, can swallow and store huge volumes of clastic sediment, volumes that would clog the entrance to a carbonate system. The extreme solubility of halite enables the pace of dissolution/corrosion enlargement in a salt cave to keep pace with large amounts of sediment carried into the cave by external inflows. Stream sediments arriving at the cave entrance, including boulders, move inside and are trapped within the salt itself. Sediment is not dumped outside the cave entrance, which is the typical situation in blind valley river mouths at carbonate caves (Bruthans et al. 2000). For example, coarse-grained sediment fractions are carried hundreds of metres

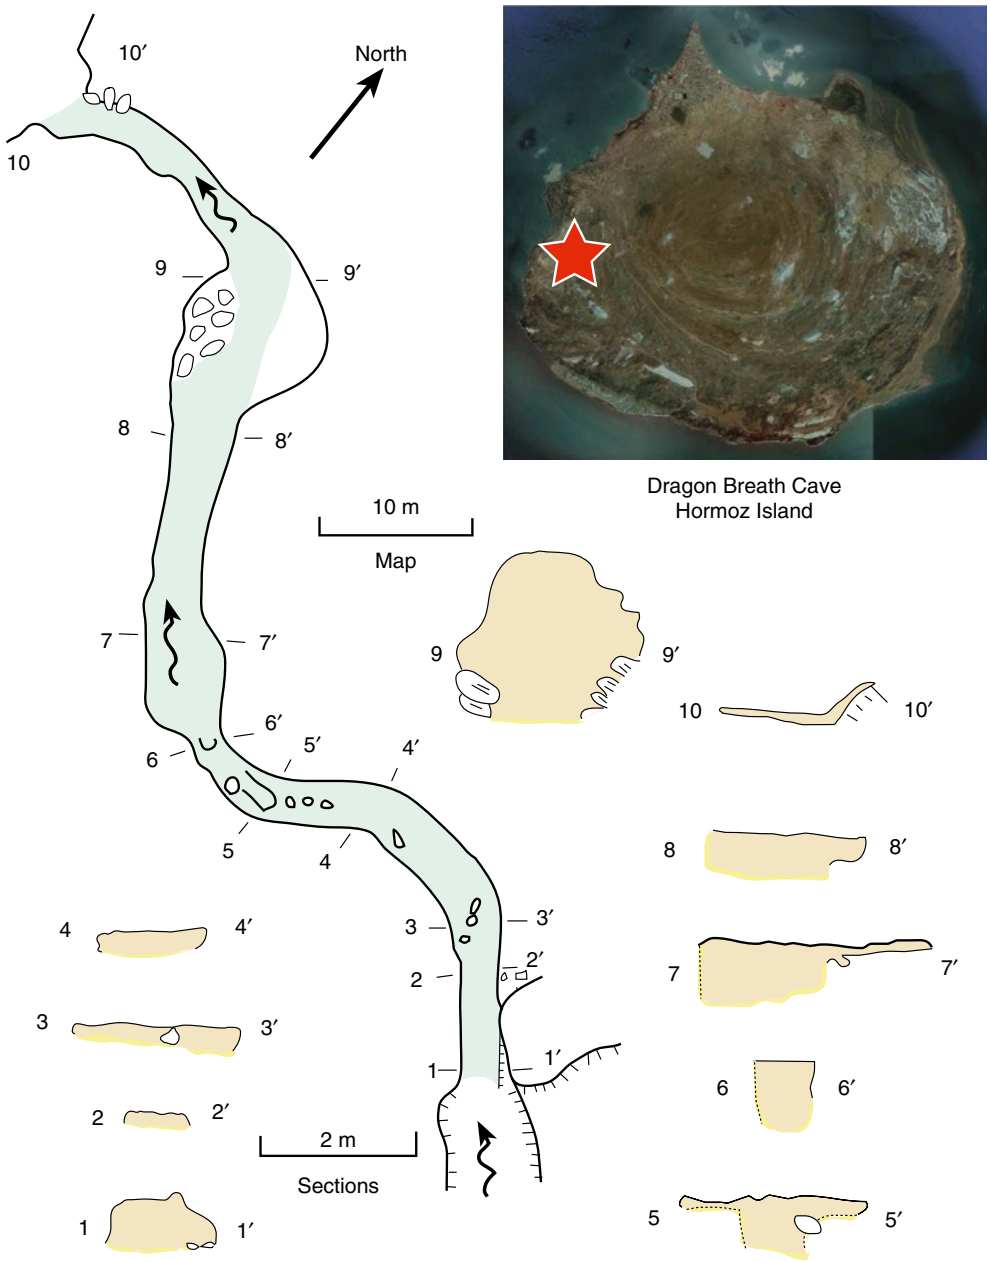

Fig. 7.55 Map of Dragon Breath Cave, a meandering karst cavity draining the edge of the inactive diapiric core of Hormuz Island, Arabian Gulf (After Bosak et al. 1999). Star marks cave position on insert, see Fig. 7.30b for location of cave in the island geology (Landsat image of island courtesy of NASA)

into the cave by two large intermittent streams entering the upper part of the Ponor Cave (Hormuz Island). The clasts in the resulting intra-cave alluvial fan conglomerates range from cobble of several centimetres up to 1 m diameter boulders, only sand-sized particles make it to the lower part of the same cave.

Caves capable of storing such coarse alluvium within the cavern itself are halite-specific with no equivalent in a carbonate karst terrain. There the boulder-size fraction in the cave itself is the result of roof fall and almost all stream-borne coarse alluvium is deposited outside the cave.

Cave walls in zones of less intense dissolution and stream crossflow are decorated with halite, gypsum and anhydrite speleothems. Anhydrite forms speleothems in preference to gypsum in those parts of the cave with very high salinity waters. Some of these speleothems can be quite large, up to a few metres long. Compared to the growth rates of calcite speleothems in carbonate caves the growth rates of evaporite speleothems are phenomenal. Halite stalactites, several metres long and curving into the direction of airflow, formed in the mouth of Dragon Breath cave in a few years rather than millennia needed for carbonate counterparts (Bosak et al. 1999). In August 1997, a network of numerous halite stalagmites and stalactites blocked the entrance to Dragon Breath Cave. In March 1998 there were no remains of the speleothem meshwork, while in

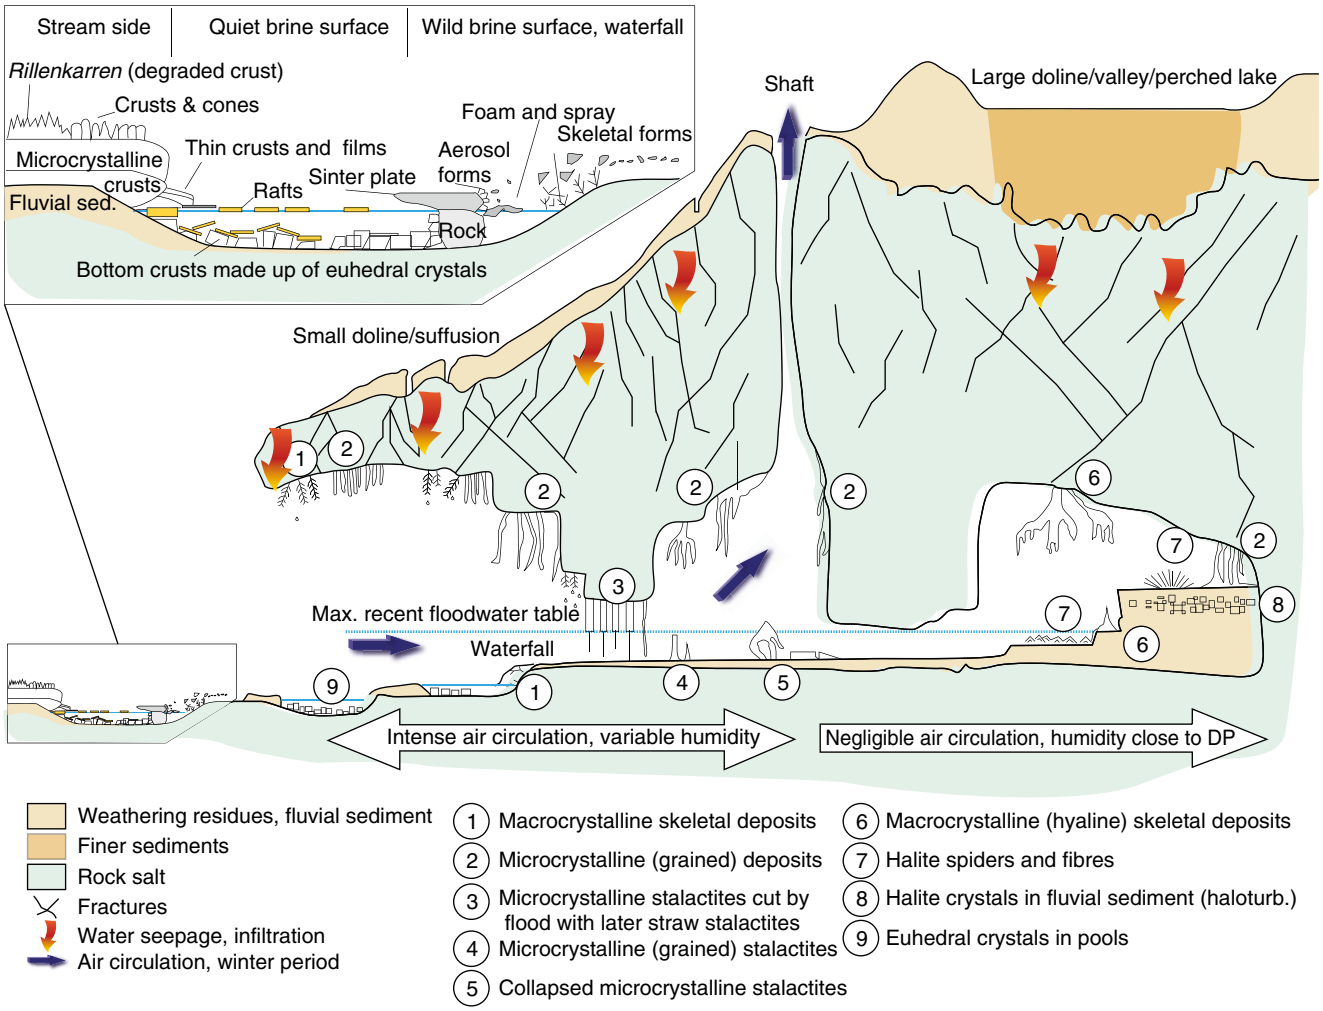

Fig. 7.56 Halokinetic salt cave ornamentation (inspired by the 3 N Cave, Namakdan) with various secondary halite deposits and the dependence of their occurrences on the environmental conditions (After Filippi et al. 2011)

February 1999, the stalagmites had reappeared (Bosak et al. 1999). Similar halite structures occur in the caverns of Mt Sedom and on the wet roofs of some salt mines.

In summary, karst deposits forming in namakiers encompass a range of mechanisms and textures (Fig. 7.56; Filippi et al. 2011): (i) via crystallization in/on streams and pools, (ii) from dripping, splashing and aerosol water, (iii) from evaporation of seepage and capillary water, and (iv) other types of evaporative deposits. The following examples of halite textures are distinguished in each of the above-mentioned groups: (i) euhedral crystals, floating rafts (raft cones), thin brine surface crusts and films; (ii) straw stalactites, macrocrystalline skeletal and hyaline deposits, aerosol deposits; (iii) microcrystalline forms (crusts, stalactites and stalagmites, helictites); (iv) macrocrystalline helictites, halite bottom fibres and spiders, crystals in fluvial sediments, euhedral halite crystals in rock salt, combined or transient forms and biologically induced deposits. The occurrence of particular forms depends strongly on the environment, especially on the type of brine occurrence (pool, drip, splashing brine, microscopic capillary brine, etc.), flow rate and its variation, atmospheric humidity, evaporation rate and, in some cases, on the air flow direction. Combined or transitional secondary deposits can be observed if the conditions changed during the deposition. Euhedral halite crystals originate solely below the brine surface of supersaturated streams and lakes. Macrocrystalline skeletal deposits occur at places with rich irregular dripping and splashing (i.e., waterfalls, places with strong dripping from the cave ceilings, etc.). Microcrystalline (fine grained) deposits are generated by evaporation of capillary brine at places where brine is not present in a macroscopically visible form. Straw stalactites form at places where dripping is concentrated in small spots and is sufficient to assure that the tip of the stalactite will not be overgrown by halite precipitates. If the tip is blocked by halite precipitates, the brine remaining in the straw will seep through the straw walls and helictites start to grow.

Macrocrystalline skeletal deposits and straw stalactites usually grow after a major rain event when dripping is strong, while microcrystalline speleothems are formed continuously during much longer periods and ultimately (usually) overgrow the other types of speleothems during dry periods. The rate of secondary halite deposition is much faster compared to carbonate karst. Some forms lengthen more than 0.5 m during the first year after a strong rain event; however, the age of speleothems is difficult to estimate, as they are often combinations of segments of various ages and growth periods alternate with long intervals of inactivity.

Evaporite Speleothems in Non-evaporite Karstified Host

Evaporite minerals can form speleothems in the drier parts of carbonate caves where airflow dries cave capillary waters to salinities appropriate for precipitation (Table 7.8). Gypsum, epsomite, and mirabilite are the usual sulphate minerals found in caves. By far the most representative of this group and perhaps the second most common cave mineral is gypsum (Onac 2005). It forms a huge variety of speleothem types ranging from the less spectacular white, soft moonmilk deposits composed of microcrystals, to curving clusters, to prismatic crystals up to 2 m long. It also forms the enormous and spectacular stalactites (the so-called chandeliers) exposed in Lechuguilla (New Mexico) and Cupp-Coutunn (Turkmenistan) caves. Two other common cave sulphates that usually occur as colourless white fibrous efflorescences on cave walls and sediments are mirabilite and epsomite. Both minerals are highly sensitive to variations in relative humidity and temperature.

Gypsum and epsomite speleothems are especially common in vadose caves in areas receiving less than 250 mm of rainfall per year. Even in the ever-wet climate of New Guinea, powdery gypsum crusts can coat carbonate substrates in caves like Selminum Tem and Atea Kanada in a region where the annual rainfall is more than 4,000 mm. But these are relatively minor portions of the total volume of cave decoration with the sulphate sourced in the weathering of pyritic impurities and are only found in parts of the cavern system subject to vigorous air circulation.

Table 7.8 Evaporite minerals and their mode of occurrence in cave speleothems

Mineral	Composition	Type of occurrence
Gypsum	$CaSO_4 \cdot 2H_2O$	Dripstone, wall crusts, flowers, bladed crystals, pore cement in cave soils
Halite	NaCl	Dripstone, wall crusts, flowers, pore cement in cave soils
Epsomite	$MgSO_4 \cdot 7H_2O$	Dripstone, flowers, pore cement in cave soils
Hexahydrite	$MgSO_4 \cdot 6H_2O$	Loose crusts on cave walls and floors
Mirabilite	$Na_2SO_4 \cdot 10H_2O$	Dripstone, flowers, loose tufts of crystals
Bloedite	$Na_2SO_4 \cdot MgSO_4 \cdot 4H_2O$	Loose crusts on cave walls and floors
Celestite	$SrSO_4$	Loose crusts on cave walls and floors
Baryte	$BaSO_4$	Loose crusts on cave walls and floors

The most common vadose evaporite speleothem is gypsum, which forms as relatively fine-grained granular crusts on the limestone wall of most arid-zone carbonate caves. It grows and accretes via uniform seepage and evaporation of brines escaping from the porous cave wall. This is an ongoing process whereby older crusts become detached, fall off and, if not dissolved by throughflowing waters, accumulate on the cave floor as new crusts continue to form on the walls. It is really a form of salt weathering that just happens to occur inside a cave. Gypsum also accumulates as granular layered rinds in many phreatic and bathyphreatic carbonate caves that were moulded by sulphuric acid speleogenesis in their early stages of formation (see later).

But the most noticed evaporite speleothems in carbonate karst are not various crusts and small prisms but the spectacularly curved gypsum and halite flowers (rarer epsomite and mirabilite) that protrude as lacy intertwined ribbons hanging from cavern ceilings and walls (Fig. 7.56; Filippi et al. 2011). These cave flowers (oulopholites) typically grow as curved radiating masses of very long (up to 50 cm), narrow crystals. New growth originates at the base of the crystal strings as saturated brines emerge from the cave wall, driven by capillary evaporation. Faster growth in the centre of a bundle of crystals creates the radiating or flower-like pattern. Often they grow from waters issuing from crevices and fractures in the cave wall and their growth contributes to parts of the cave wall breaking away or spalling (salt weathering). Changes in cave atmosphere and rates of capillary supply drive varying growth rates and hence the curvature of the crystals, much like the controls on helicites (twisted stalactites). Oulopholites are especially sensitive to seasonal changes in cave airflow. The growth of gypsum anemolites (wind-controlled oulopholites) in a cave in the Ukraine was found to vary with changes in cave humidity (Maltsev and Ford 1991). When air moves into this cave each summer, and cave humidity is 70–90 %, accretions of up to 7 mm form. In winter, the airflow reverses, the humidity rises and the same structures tend to dissolve.

Baryte and celestite (Table 7.8) are relatively insoluble in comparison to other cavern sulphates (Onac 2005). Celestite typically forms crystalline crusts on cave walls or as distinct blue needles atop gypsum crusts, while baryte has been documented as a cement in numerous cave soils. Only under special conditions does direct precipitation of these less soluble sulphates from meteoric waters take place in caves, rather both minerals occur in caves invaded by thermal

waters or hydrothermal solutions. Occurrences of celestite are known from Crystal Cave (Ohio), Lechuguilla Cave (New Mexico), Cango Cave (South Africa), and Valea Rea Cave (Romania). Baryte is known from caves in England, Italy, Hungary, France and Russia.

Sulphate speleothems are not restricted to evaporative crusts in caves in warmer climates, Harmon et al. (1983) reported at least three sulphate minerals (gypsum, epsomite, and mirabilite, the latter possibly cryogenic) in speleothems in Castleguard Cave in the Canadian Rockies, with the most spectacular forming large ice-clear stalactites of epsomite and mirabilite. Some 60 other sulphate salts have been described from caves (e.g., alunite, chalcanthite, halotrichite, jarosite, melanterite, etc.), these minerals are much less common than those listed in Table 7.8. Hill and Forti (1997) list ten sulphate salts as derived from normal vadose karst processes; many others come from the interaction of karst waters with ore bodies. White (1988) lists four possible sources of cave sulphate, divided into two distinct source groups;

- Carbonate bedrock source:
  (a) Dissolution in sulphate-bearing beds
  (b) Oxidation of pyrite in the bedrock
  (c) Weathering of anhydrite nodules
- Deep groundwater source:
  (a) Movement of deep H_2S waters into contact with phreatic karst waters to form sulphuric acid, which may dissolve calcite and deposit gypsum.
- To this list Hill and Forti (1997) add guano and weathering basalts.

As well as salt flowers in carbonate caves, halite is a rapidly growing vadose speleothem in its own right. Halite speleothems in carbonate caves form best in arid regions, where parent materials are leached from the regolith by circulating brackish groundwaters and redeposited under evaporative conditions in the cave environment. Lowry (1967) discussed halite speleothems from the carbonate caves beneath the Nullarbor, while Goede et al. (1992) notes the region has what may be the world's largest halite speleothems in a carbonate cave. Nullarbor's saline speleothems in Mullamullang Cave include the distinctive "coffee and cream" textures made up of a mixture of fine powdery and more coarsely crystalline magnesian calcite crusts, and varying levels of iron and manganese oxide, intermixed with fragments of halite and gypsum flowers.

Huge single evaporite crystals with geode-like textures can form in zones where saturated brine pools covers the cave floor or can rim a deep phreatic cavern. Where fluid chemistry fluctuations are minimal in these gypsum saturated phreatic waters, clear impurity-free gypsum blades can grow as single crystals up to a metre or more in length and decimetres in width (e.g. phreatic crystals in sulphuric acid caves in Lechuguilla caverns of New Mexico, the lmeria caverns in Spain and the Dnestrovsko-Pricernomorskij karst caves of the western Ukraine).

More unusual cave precipitates tied to gypsum include; alunite ($KAl_3(SO_4)\cdot 2(OH)_6$), and rare phosphate–sulphate sanjuanite $Al_2(PO_4)(SO_4)(OH)\cdot 9(H_2O)$ and rossiantonite ($Al_3(PO_4)(SO_4)\ 2(OH)_2(H_2O)_{14}$). All are secondary mineral deposits hosted in different quartz-sandstone caves in the Gran Sabana region, Venezuela (Sauro et al. 2014). The cavernous hosts to these gypsum and other sulphate speleothems encompass the 'tepuis' (table mountains) along the topographic edge of the Guyana Shield (Venezuela and Brazil) and formed in the Precambrian quartz-sandstones of the Roraima Supergroup. Due to the extended time scale required for speleogenesis in such hard and barely soluble quartz-sandstone lithologies, some of these caves are considered to be as old as 20–30 My. Deposition of sulphates in these caves is not linked to the quartz-sandstone host rock (Sauro et al. 2014). Rather, these mineral deposits originate from a long term external atmospheric sulphate source, with potential contributions of marine non-sea salt sulphates, terrestrial dimethyl sulphide and microbially reduced H_2S from the forests or peatbogs within the watershed. Air currents within the caves are the most plausible means of transport for aerosols, driving the evaporative accumulation of sulphates and other secondary minerals in specific locations. Moreover, the studied sulphate minerals often co-occur with silica speleothems of biological origin. Although this association would suggest a possible biogenic origin for the sulphates as well, direct evidence proving that microbes are involved in their formation is absent.

Hazards Tied to Evaporite Karst

Surface constructions and other anthropogenic activities atop or within evaporite karst is even more problematic than in carbonate terranes due to inherently higher rates of dissolution and stoping (Yilmaz et al. 2011; Cooper and Gutiérrez 2013). Unlike the relatively slow formation of limestone karst, gypsum/ halite karst develops on a human/engineering time-scale and can be enhanced by human activities. In 2006, the Nanjing Gypsum mine in China broke into a phreatic cavity in a region of gypsum karst, driving complete flooding of the mine in some 3 days. Associated groundwater drainage caused a sharp drop in the local piezometric level of up to 90 m in a well in nearby Huashu village. Resultant ground subsidence severely damaged nearby roads and buildings (Wang et al. 2008). In Ukraine, dewatering of gypsum karst to facilitate sulphur mining substantially increased the rate of gypsum dissolution and favoured the expansion of sinkholes within an area affected by the associated cones of depression (Sprynskyy et al. 2009). Overburden collapse into nearsur-

Table 7.9 Processes and mechanisms driving the creation of gypsum karst hazards, with examples

Action	Subsidence mechanisms	Examples
Removal of ground fluid	Loss of buoyant support for soil particles; compaction of sediment; possible failure of material bridging a void, thus, causing catastrophic collapse	Sinkholes overlying gypsum karst in Lithuania (Paukstys et al. 1999). Earthquakes beneath Hamburg, Germany (Dahm et al. 2011)
Shrinkage of organic or clay-rich materials	Consolidation of sediment; net loss of organic material	Shallow depressions from desiccated swelling clays (Biddle 1983; Driscoll 1983); subsidence of peat in subsidence hollows (Cooper 1998)
Hydrocompaction of sediments	Softening and yield of metastable interparticle bonds by the introduction of water	Building subsidence caused by compaction of gypsiferous silt in alluvial fan, e.g., Calatayud Spain (Gutiérrez and Cooper 2002) This effect is aggravated by broken water pipes in Calatayud and leaking septic tanks in Mosul, Iraq (Jassim et al. 1997)
Fluvial karstification of gypsum bedrock	Loss of mechanical support; syn- and post-sedimentary subsidence of alluvial deposits into depressions forming at the alluvium/gypsum contact	Subsidence depressions on alluvial flood plains, Calatayud Graben, Spain (Gutiérrez 1996), river valley 'subrosion' (Ford 1997)
Downwashing of unconsolidated sediments	Downward movement of sediments into existing voids or breccia pipes resulting in gradual growth of shallow depressions	Sinkholes in Lithuania (Paukstys et al. 1999); sinkholes in Ripon (Cooper 1986)
Gradual collapse of unconsolidated materials overlying gypsum karst	Sagging of materials overlying a void leading to concomitant lowering of the cover/gypsum interface, and growth of a surface depression	Sinkholes in West Ripon (Cooper 1998).; minor earthquakes beneath Hamburg, Germany (Dahm et al. 2011)
Catastrophic collapse of unconsolidated sediments into existing voids (may be preceded by a period of gradual subsidence)	Collapse that probably requires a triggering mechanism; travelling of a void upwards through unconsolidated sediment possibly accompanied by removal of sediment by rapid water flow through the void	Sinkholes in Ripon (Cooper 1986, 1998); sinkholes in China (Yaoru and Cooper 1997); sinkholes in glacial drift overlying gypsum karst, Nova Scotia (Martinez and Boehner 1997)
Catastrophic collapse of competent strata into voids (breccia pipe propagation)	Failure of material bridging void; development of sinkhole generally requires a triggering mechanism	Sinkholes in Ripon (Cooper 1986), New Mexico (Martinez et al. 1998), NW territories, Canada

After Lamont-Black et al. (2002)

face gypsum caves can create stoping chimneys, which break out at the surface as steep-sided dolines, often surrounded by broader subsidence hollows. Such swallow-holes, up to 20 m deep and 40 m wide, continue to appear suddenly in gypsum areas throughout the world.

Although halite is even more susceptible to dissolution, it typically is not an urban engineering problem; large numbers of people simply do not like to live in a climate that allows halite to make it to the surface. However, in the Dead Sea region the lowering of the water level encouraged karstic collapse in newly exposed mudflats and has damaged roads and other man-made structures (Frumkin et al. 2011). Catastrophic doline collapse atop poorly managed halite/potash mines and solution brinefields is an anthropogenically-induced or enhanced geohazard in developed regions and will be discussed in more detail in Chap. 13.

Gypsum karst is a documented natural hazard in many parts of Europe (Fig. 7.59) and similar areas of shallow subcropping gypsum are common in much of the rest of the world (Table 7.9). For example, areas surrounding the city of Zaragoza in northern Spain are affected, as is the town of Calatayud (Gutiérrez and Cooper 2002; Gutiérrez et al. 2008). Gypsum dissolution is responsible for subsidence and collapse in many urban areas around northern Paris, France (Toulemont 1984), in urban areas in and around Stuttgart and other towns peripheral to the Harz Mountains in Germany (Garleff et al. 1997), in Pasvalys and Birzai in Lithuania (Paukstys et al. 1999), in the Muttenz-Pratteln area in northwestern Switzerland (Zechner et al. 2011), in the Perm area of Russia (Trzhtsinsky 2002), in the Sivaz region of Turkey (Karacan and Yilmez, 1997), in the region centred on the city of Mosul in northern Iraq (Jassim et al. 1997) and in a number of areas of rapid urban development in eastern Saudi Arabia (Amin and Bankher 1997a, b). Large subsidence depressions caused by gypsum dissolution in China have opened up in the Taiyuan and Yangquan regions of Shanxi Coalfield and in the adjacent Hebei Coalfield.

Variation in the watertable level, induced by groundwater pumping, is another anthropogenic trigger for dolines surfacing. As the watertable declines it causes a loss of buoyant support to the ground, it also increases the flow gradient and water velocity, which facilitates higher rates of crossflow and deeper aquifer recharge in subsequent floods and so reduces the geomechanical strength of the cover and washes away roof span support. Dolines can also be associated with groundwater quality issues. Collapse dolines or sinkholes are frequently used as areas or sumps for uncontrolled dumping industrial and domestic waste. Because of the

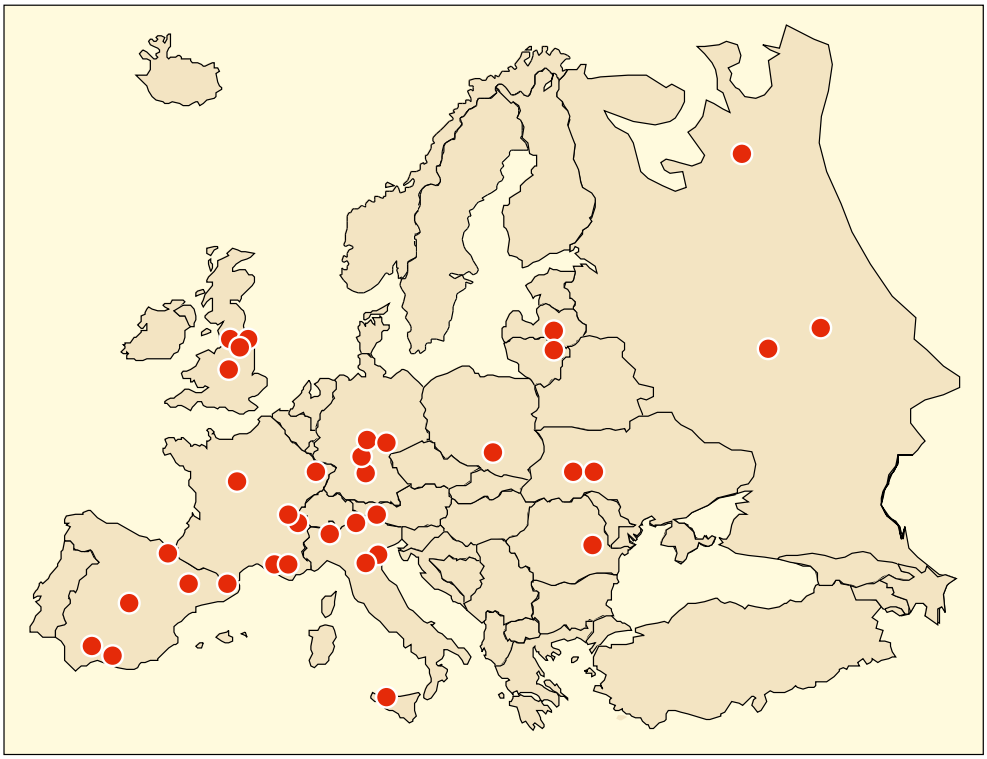

Fig. 7.57 Areas in Europe associated with the development of intervals subsidence and collapse tied to with gypsum karst

direct connection between them and the regional aquifer, uncontrolled dumping can cause rapid dispersion of chemical and bacterial pollutants in the groundwater. In the case of Riyadh region Saudi Arabia, a lake of near raw sewage has appeared in Hit Dahl (cave) and is likely related to the increased utilisation of desalinated water for sanitation and agriculture. In the Birzai region of Lithuania numerous sinkholes developed in Devonian gypsum subcrop are in direct connection across the regional hydrology. Accordingly, the amount of agricultural fertilizer use is limited in order to help protect groundwater quality.

One of the problems associated with rapid surfacing of evaporite collapse features is that any assignment of sinkhole cause will typically lead to an assignment of blame, especially where anthropogenic infrastructure has been damaged or destroyed by the collapse, or lives may have been lost. Areas of natural evaporite karst are typically areas of relatively shallow evaporites. Shallow evaporites makes such regions suitable for extraction via conventional or solution mining. When a collapse does occur in a mined area, one group (typically the miners) has a vested interest in arguing for natural collapse, the others, typically the lawyers and their litigants, will argue for an anthropogenic cause. The reality is typically a combination of natural process enhanced to varying degrees by human endeavours. In the examples in this section much of the driving process for the collapse is natural, while the cause of any unexpected karst-related disaster is typically geological ignorance combined with political/community intransigence. See Chap. 13 for a further discussion of karst and stope examples that include collapses and explosions where the anthropogenic drivers can dominate (Fig. 7.57).

Problems in the Ripon Area, UK

The town of Ripon, North Yorkshire, and town's surrounds experiences the worst ongoing gypsum-karst related subsidence in England (Cooper and Waltham 1999). Some 43 events of subsidence or collapse in the caprock over the Ripon gypsum have occurred over the last 160 years, within an area of 7 km^2 (Figs. 7.58 and 7.59). This gives a mean rate of one new sinkhole every 26 years in each square kilometre. Worldwide, the highest documented event rate occurs in Ukraine, in an area of thin and weak clay caprocks above interstratal gypsum karst, where new sinkholes appear at a rate of 0.01–3.0 per year per km^2. (Waltham et al. 2005). In the Ripon area, numerous sags and small collapses also typify surrounding farmlands. Subsidence features are typically 10–30 m in diameter, reach up to 20 m in depth and can appear at the surface in a matter of hours to days. To the east of the town, one collapse sinkhole in the Sherwood Sandstone is 80 m in diameter and 30 m deep, perhaps reflecting the stronger roof beam capacity of the Sherwood Sandstone.

Shallow subcropping Zechstein gypsum occurs in two subcropping bedded units in this area, one is in the Permian Edlington and the other is in the Roxby Formation

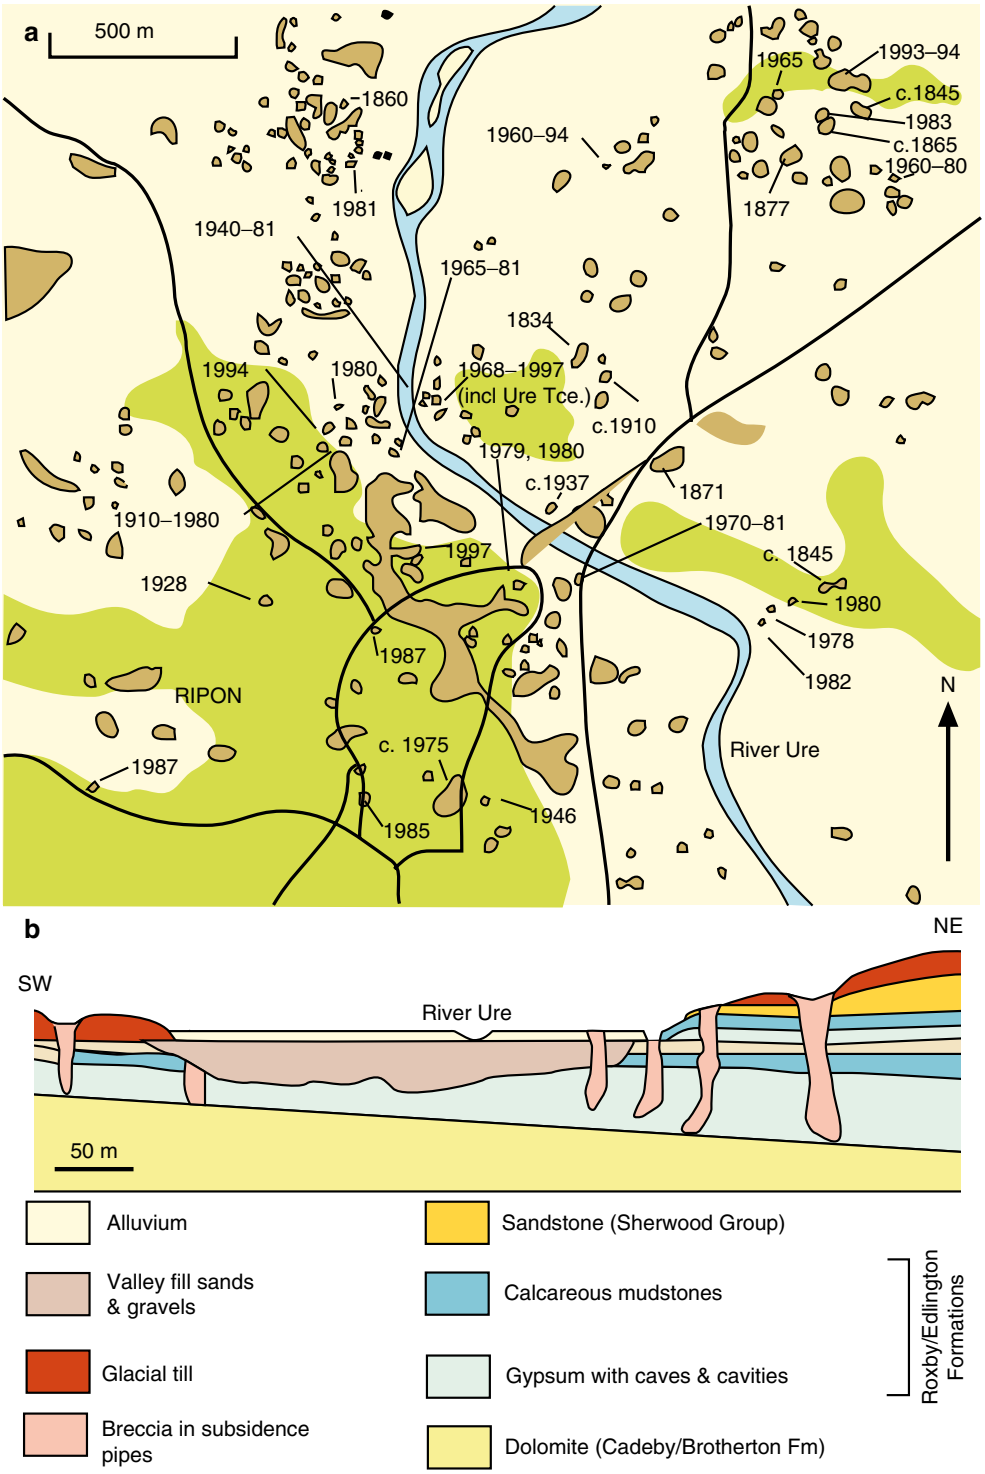

Fig. 7.58 Ripon karst (**a**) Surface distribution of karst features (*shaded brown*) and time of formation, where known, of subsidence features surfacing in and around the town of Ripon, United Kingdom. Urban areas are shaded green. (**b**) Idealised geological cross section (After Cooper and Waltham 1999; Jones and Cooper 2005)

(Fig. 7.58b). Together they form a subcrop belt about a kilometre wide, bound to the west by the base of the lowest gypsum unit (at the bottom of the Edlington Formation) and to the east by a downdip transition from gypsum to anhydrite in the upper gypsum-bearing unit of the Roxby Formation. The spatial distribution of subsidence features within this belt relates to joint azimuths in the Permian bedrock, with gypsum maze caves and subsidence patterns following the joint trends (Cooper, 986). Most of the subcropping gypsum is alabastrine in the area around Ripon, while farther to the east, where the unit is thicker and deeper, the calcium sulphate phase is still anhydrite.

Fluctuations in the watertable level tied to heavy rain or long drought are thought to be the most common triggering

Fig. 7.59 Catastrophic collapse in areas of Ripon gypsum subcrop, UK. (**a**) Subsidence crater caused by the dissolution of Permian gypsum in area known as Corkscrew Pits at Hutton Conyers, near Ripon. Looking N. These subsidence hollows formed after the dissolution of Permian gypsum. The water-filled hollow in the foreground is about 3 m in diameter and some 1.5 m deep. The farmer has been tipping waste in it for about 15 years, but it keeps subsiding. Behind it is another much larger hollow and to the right, part of three intersecting hollows called Corkscrew Pits are visible. (**b**) Collapse at the rear of a house in Ure Terrace in the village of Ripon, April 1997 (Photographs courtesy of British Geological Survey)

mechanism for subsidence. Many of the more catastrophic collapses occur after river flooding and periods of prolonged rain, which tend to wash away cavern roof span support. Subsidence is also aggravated by groundwater pumping; first, it lowers the watertable and second, it induces considerable crossflow of water in enlarged joints in the gypsum. When recharged by a later flood, the replacement water is undersaturated with respect to gypsum.

Thomson et al. (1996) recognised four hydrogeological flow units driving karst collapse in the Ripon area:

1. Quaternary gravels in the buried valley of the proto-River Ure
2. Sherwood Sandstone Group
3. Magnesian Limestone of the Brotherton Fm. and the overlying/adjacent gypsum of the Roxby Fm.
4. Magnesian limestone of the Cadeby Fm. plus the overlying/adjacent gypsum of the Edlington Fm.

Local hydrological base level within this stratigraphy is controlled by the River Ure, especially where the buried Pleistocene valley (proto-Ure) is filled by permeable sands and gravels, as these unconsolidated sediments, when located atop a breached roof beam, are suscepible to catastrophic stoping to base level (Fig. 7.58). In the area around Ripon the palaeovalley cuts down more than 30 m, reaching levels well into the Cadeby Formation, so providing the seepage connections or pathways between waters in all four units wherever they intersect the palaeovalley. There is considerable groundwater outflow along this route with artesian sulphate-rich springs issuing from Permian strata in contact with Quaternary gravels of the buried valley (Cooper 1986, 1995, 1998).

The potentiometric head comes from precipitation falling on the high ground of the Cadeby formation to the west and the Sherwood Sandstone to the east. Groundwater becomes largely confined beneath glacial till as it seeps toward the Ure Valley depression, but ultimately finds an exit into the modern river via the deeply incised sand and gravel-filled palaeovalley of the proto-Ure. Waters recharging the Ure depression pass through and enlarge joints and caverns in the gypsum units of the Edlington and Roxby Formations, so the highest density of subsidence features are found atop the sides of the palaeovalley. This region has the greatest volume of artesian discharge from aquifers immediately beneath the dissolving gypsum bed. Although created as an active karst valley, the apparent density of subsidence hollows is lower on the present Ure River flood-plain than the surrounding lands as floodplain depressions are constantly filled by overbank sediments (Figs. 7.58 and 7.59a).

Cooper (1998) defined 16 sinkhole variations in the gypsum subsidence belt at Ripon, all are types of entrenched[11],

[11] *Entrenched karst* occurs where the entire thickness of the soluble rock is entrenched along the sides of valleys but the insoluble cap spans most interfluves.

Subjacent karst occurs where the soluble rock is locally breached by erosion over a minor part of its thickness, karst features may be expressed at the surface as combinations of springs and collapse features. *Mantled karst* is wholly or partly covered by a relatively thin veneer of post-karst rock or sediment and is part of the contemporary landscape.

subjacent and mantled karst. Changes in karst style are caused by; the type of gypsum, the nature and thickness of the overlying deposits, presence or absence of consolidated layers overlying the gypsum and the size of voids/caverns within the gypsum.

To the west of Ripon, the gypsum of the Edlington Formation lies directly beneath glacial drift. These unconsolidated drift deposits and the loose residual marl atop the dissolving gypsum gradually subside into a pinnacle or suffusion (mantled) karst. But between Ripon town and the River Ure, the limestone of the Brotherton Formation overlies the Edlington Formation. There the karst develops as large open caverns beneath strong roof spans (entrenched karst). Ultimate collapse of the roof span creates rapid upward-stoping caverns in loosely consolidated sediment. Stopes break though to the surface as steep-sided collapse dolines or chimneys with sometimes catastrophic results. A similar entrenched situation is found east of the Ure River but there karstified gypsum units of both the Edlington and the Roxby formations are involved.

When a chimney breaks through, the associated surface collapse is very rapid[12]. A recently documented example of one such subsidence crater, which opened up in front of a house on Ure Bank terrace on 23rd and 24th April, 1997, is documented by Cooper (op. cit.) as follows (Fig. 7.59b).

> "…The hole grew in size and migrated towards the house, to measure 10 m in diameter and 5.5 m deep by the end of Thursday. Four garages have been destroyed by the subsidence. This collapse was the largest of one of a series that have affected this site for more than 30 years; and earlier collapse had demolished two garages on the same site and an 1856 Ordnance Survey map shows a pond on the same site. The hole is cylindrical but will ultimately fail to become a larger, but conical, depression. As it does so, it may cause collapse of the house, which is already damaged, and the adjacent road. The house and several nearby properties have been evacuated and the nearby road has been closed. The gas and other services, which run close to the hole, have also been disconnected in case of further collapse..."

Cooper (1998) found the sites of most severe subsidence in the Ripon area (including the house of Ure terrace; Fig. 7.59b) are located at the sides of the buried Ure Valley, an area where the water seeps from the gypsum into the river gravels. In 1999 the Ure Terrace sinkhole was filled using a long conveyor belt that was cantilevered over the hole so that no truck needed to back up close to the sinkhole opening. The hole was surcharged to a height of 0.5 m. The hole remains unstable, but the collapse of the fill is monitored to document fill performance and the fill is periodically topped up. After the sinkhole was filled, the road adjacent to the sinkhole was re-opened and the site of the sinkhole fenced. The severely damaged Field View house remains standing next to the sinkhole. The nearby Victorian Ure lodge was not directly damaged by the 1997 sinkhole, but its western corner fell within the council-designated damage zone, and was left unoccupied. It fell into disrepair and was subsequently demolished,

Problems with Miocene gypsum, Spain

Karstification has led to problems in areas of subcropping Miocene gypsum in the Ebro and Calatayud basins, northern Spain. Cliff sections and road cuts indicate the widespread nature of karstification in the gypsum outcrops and subcrops in Spain (Fig. 7.60a, b) Areas affected are defined by subsidence or collapse in Quaternary alluvial overburden and include; urban areas, communication routes, roads, railways, irrigation channels and agricultural fields (Soriano and Simon 1995; Elorza and Santolalla 1998; Guerrero et al. 2013). In the region there can be a reciprocal interaction between anthropic activities and sinkhole generation, whereby the ground disturbance engendered by human activity accelerates, enlarges and triggers the creation of new sinkholes. Subsidence is particularly harmful to linear constructions and buildings and numerous roads, motorways and railways have been damaged. Catastrophic collapse and rapid karst chimneying into roads and buildings can have potentially fatal consequences. For example, several buildings have been damaged around the towns of Casetas and Utebo. In the Portazgo industrial estate some factories had to be pulled down due to collapse-induced instability (Castañeda et al. 2009). A nearby gas explosion was attributed to the breakage of a gas pipe caused by subsidence. The local water supply is also disrupted by subsidence and pipe breakage so that 20,000 inhabitants periodically lose their water supply. The most striking example of subsidence affecting development comes from the recently built village of Puilatos, in the

[12] A. H. Cooper in a lecture to the general public argued that collapse dolines breaching the landscape between Ripon and Darlington were the inspiration for thn Alice in Wonderland (see also <http://www.bgs.ac.uk/caves/alice_in_wonderland.html> last accessed Jan 5, 2015).

In Chap. 1, Lewis Carroll wrote:

"...The rabbit-hole went straight on like a tunnel for some way, and then dipped suddenly down, so suddenly, that Alice had not a moment to think about stopping herself, before she found herself falling down what seemed a deep well. Either the well was very deep, or she fell very slowly, for she had plenty of time as she went down to look about her, and to wonder what would happen next..."

Charles Lutwidge Dodgson, who later adopted the Lewis Carroll pseudonym, was born in Cheshire and spent his early days at Croft, near Darlington. There, a trio of ponds called Hell's Kettles were believed by locals in the Dark Ages to be bottomless links to hell. The pits are now known to be gypsum collapse features only 22 ft deep but they may have inspired this passage from the Carroll's first chapter. In 1852 Carroll moved with his parents to Yorkshire when his father became Canon Dodgson of Ripon. Here, he first met Mary Badcock. Carroll, a keen mathematician, scientist and photographer, took pictures of Mary that were later adapted by Sir John Tenniel into illustrations in the first edition of Alice in Wonderland.

Fig. 7.60 Gypsum karst, Calatayud region, Spain. (**a**) View from the town of Cataluyud toward the retreating front of Miocene gypsum and the contact with the encroaching flood-plain of the Rio Jalón. (**b**) Mantled steep edge of a collapse doline exposed in a highway cut on the approach to Cataluyud. Bedded gypsum makes up the right half of the exposure, doline-fill alluvium the left, indicating why strong lateral contrasts in mechanical strength exist in the region

Gallego Valley. This was severely damaged by subsidence and abandoned before it could be occupied.

Collapse affects irrigation channels in the countryside with substantial economic losses (Elorza and Santolalla 1998). In 1996 a doline collapse surfaced and cut the important Canal Imperial at Gallur village. New dolines often form in close proximity to unlined irrigation canals. The ongoing supply of fresh irrigation waters to field crops can also encourage sinkhole generation in the fields. Though not directly visible, natural sinkholes also form in the submerged beds of river channels cutting regions of subcropping gypsum (Benito et al. 1998). On December 19th, 1971, a bus fell from a bridge into the Ebro River at Zaragoza, near where the so-called ‘San Lazaro well’ (a submerged gypsum sinkhole) is located. Ten people lost their lives in this accident, nine of them where never found. Locals suggested that bod-

ies were carried into the sinkhole and sank into the caverns fed by this losing stream. Karstification in the Zaragoza region is characterised by the preferential intrastatal dissolution of glauberite beds, which are more soluble than the gypsum interbeds, this leads to collapse and rotation of gypsum blocks and river capture (Guerrero et al. 2013).

Sometimes even well-intentioned attempts to remediate culturally significant buildings under threat of karst collapse can exacerbate collapse problems. Gutiérrez and Cooper (2002) cite examples from the city of Calatayud, Spain. Subsidence-induced differential loading across doline edges drives the tilting of the 25 m high tower of the San Pedro de los Francos church, which leans towards and overhangs the street by about 1.5 m. In places, the brickwork of the church indents the pre-existing tower fabric, which probably dates from the eleventh Century or the beginning of the twelfth Century. This indentation and the non-alignment of the church and the tower walls indicates that most of the tower tilting occurred prior to the construction of the church. In 1840, the upper 5 m of the tower was removed and the lower part buttressed for the safety of the Royal family, who visited the town and stayed in the palace opposite. On 3rd June 1931, San Pedro de los Francos church was declared a "Monument of Historical and Artistic value." Due to its ruinous condition, the church was closed to worship in 1979. Micropiling to improve the foundation was started in 1994, but this corrective measure was interrupted when only half of the building was underpinned. Very rapid differential settlement of the building took place in the following year, causing extensive damage and aggravating the subsidence problem. Colegiata de Santa María la Mayor was constructed between the thirteenth and eighteenth centuries, it has an outstanding Mudéjar (a 72 m high tower) and numerous Renaissance features; it is considered the foremost monument in the city of Cataluyud. As with the San Pedro de los Francos Church, recent micropiling work, applied to only one part of the cloister, has been followed by alarming differential movements that have drastically accelerated the deterioration of the building. Large blocks have fallen from the vault of the "Capitular Hall" and cracks up to 150 mm wide have opened in the brickwork of the back (NW) elevation, which has now been shored up for safety. The dated plaster telltales placed in these cracks to monitor the displacement demonstrate the high speed of the deformation produced by subsidence in recent years. On the afternoon of 10 September 1996, the fracture of a water supply pipe flooded the cloisters and the church with 100 mm of muddy water. Ten years earlier a similar breakage and flood had occurred. These breaks in the water pipes are most likely related to karst-induced subsidence. Once they occur, the massive input of water to the subsurface may trigger further destruction via enhanced dissolution, piping and hydrocollapse (Gutiérrez and Cooper 2002).

Gypsum Karst in Mosul, Iraq

A similar quandary of multiple areas of structural damage from gypsum-induced subsidence affects large parts or the historic section of the city of Mosul in northern Iraq (Jassim et al. 1997). The main part of its old quarter is over a century old and some buildings are a few hundred years old. Mosul lies on the northeastern flank of the Abu Saif anticline and near to its northern plunge (Fig. 7.61). It was built on the western bank of the Tigris River on a dip slope of Middle Miocene Fatha limestone that is directly underlain by bedded gypsum and green marl (equivalent to Lower Fars Formation). Houses in the old city were built on what seemed to be at the time a very sound rock foundation.

Water distribution in the city was done on mule back in the early part of last century and the estimated water consumption did not exceed 10 l per person per day (Jassim et al. 1997). Discharge from households was partly to surface drainage and partly to shallow and small septic tanks. The modern piped system of water distribution did not start until the 1940s, resulting in a sudden increase in water consumption (presently around 200 l per person per day) and it was not associated with a complementary sewer system. Increased water consumption meant larger and deeper septic tanks were dug at the perimeter of buildings (which never seemed to fill) resulting in a dramatic increase in water percolating downwards, water that was also more corrosive than previously due to the increased use of detergents and chlorination. This water passes through the permeable and fractured limestone to the underlying gypsum. On its way through the limestone it enlarges and creates new dissolution cavities, but eventually finds its way into the older gypsum karst maze, which is then further widened as water drains back into the Tigris. Caverns in the gypsum enlarge until the roof span collapses. Since the 1970s more and more buildings in the old city have fractured and many are subject to sudden collapse. The problem is further intensified due to the expansion of the city in the up-dip direction (west and south-west) including the construction of industrial, water-dependent centres with integrated drainage. Water seeping/draining from these newly developed up-dip areas eventually passes under the old city before discharging in the Tigris river. The process was slightly arrested in the 1980s by the completion of a drainage system for the city, but the degradation of the old city continues.

Coping: Man-made Structures Atop Salts

The towns of Ripon in the UK and Pasvales and Birzai in Lithuania house some 45,000 people, who currently live under the ongoing threat of catastrophic subsidence, caused by natural gypsum dissolution (Paukstys et al. 1999). Special measures for construction of houses, roads, bridges and railways are needed in these areas and should include:

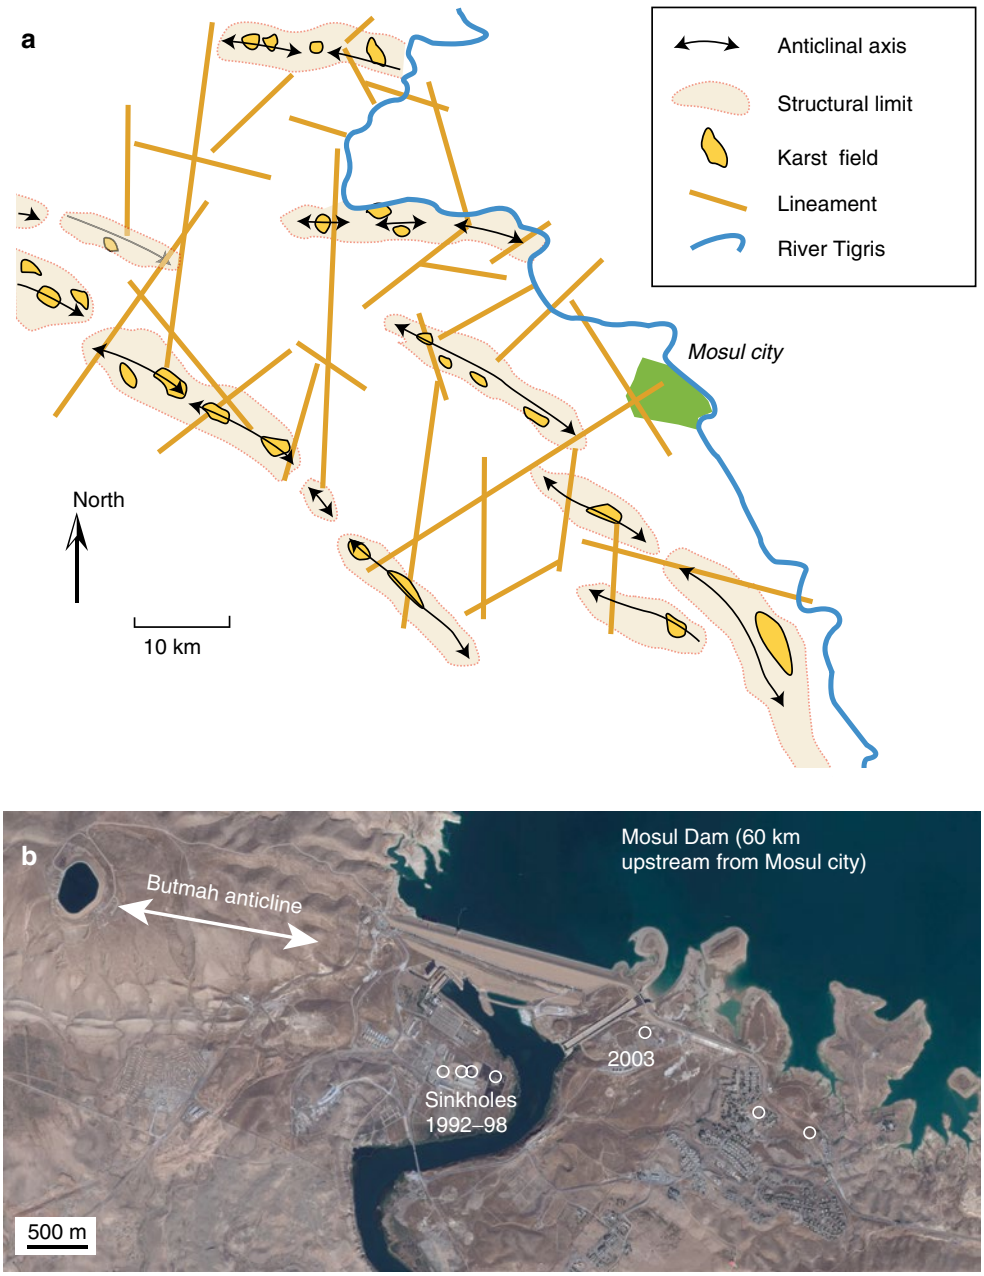

Fig. 7.61 Karst problems in Iraq. (**a**) Evaporite karst zones developed in anticlinal crests exposing a gypsiferous zone in Miocene lower Fars (Fat'ha) Formation (after Jassim et al. 1997). (**b**) Karst development in the foundation region of the Mosul Dam, Iraq. The white circles indicate at-surface karst features (Scaled and annotated Bing® Image)

incorporating several layers of high tensile heavy duty reinforced plastic mesh geotextile into road embankments and car parks; using sacrificial supports on bridges so that the loss of support of any one upright will not cause the deck to collapse; extending the foundations of bridge piers laterally to an amount that could span the normal size of collapses; and using ground monitoring systems to predict areas of imminent collapse (Cooper 1995, 1998).

Dams to store urban water supplies are costly structures and failure can lead to disaster, large scale mortality and financial liability (Cooper and Gutiérrez 2013). For example, at two and a half minutes before midnight on March 12, 1928 the St. Francis Dam (California) failed catastrophically and the resulting flood killed more than 400 people. The collapse of the St. Francis Dam is considered to be one of the worst American civil engineering disasters of the twenteenth century and remains the second-greatest loss of life in California's history, after the 1906 San Francisco earthquake and fire. The collapse was partly attributed to dissolution of gypsum veins beneath the dam foundations. The Quail Creek Dam, Utah, constructed in 1984 failed in 1989, the underlying cause being an unappreciated existence of, and consequent enlargement of, cavities in the gypsum strata beneath its foundations.

Unexpected water leakage from reservoirs, via ponors, sinkholes and karst conduits leads to costly inefficiency, or

even project abandonment. Unnaturally high hydraulic gradients, induced by newly impounded water, may flush out sediment that previously blocked karst conduits. It can also produce rapid dissolutional enlargement of discontinuities, which can quickly reach break-through dimensions with turbulent flow. These processes may significantly increase the hydraulic permeability in the region of the dam foundation, on an engineering time scale. Accordingly, numerous dams in regions of the USA underlain by shallow evaporites either have gypsum karst problems, or have encountered gypsum-related difficulties during construction (Johnson 2008b). Examples include; the San Fernando, Dry Canyon, Buena Vista, Olive Hills and Castaic dams in California; the Hondo, Macmillan and Avalon dams in New Mexico; Sandford Dam in Texas; Red Rock Dam in Iowa; Fontanelle Dam in Oklahoma; Horsetooth Dam and Carter Dam in Colorado and the Moses Saunders Tower Dam in New York State. Up to 13,000 tonnes of mainly gypsum and anhydrite were dissolved from beneath a dam in Iraq in only 6 months causing concerns about the dam stability (Fig. 7.61b). In China, leaking dams and reservoirs on gypsum include the Huoshipo Dam and others in the same area. The Bratsk Dam in eastern Siberia is leaking, and in Tajikistan the dam for the Nizhne-Kafirnigansk hydroelectric scheme was designed to cope with active gypsum dissolution occurring below the grout curtain. Gypsum karst in the foundation trenches of the Casa de Piedra Dam, Argentina and El Isiro Dam in Venezuela, caused difficult construction conditions and required design modifications.

Another illustration of the problems associated with water retaining structures and the ineptitude, or lack of oversight, by some city planners comes from the town of Spearfish, South Dakota (Davis and Rahn 1997). As discussed earlier in this chapter, the Triassic Spearfish Formation contains numerous gypsum beds in which evaporite-focused karst landforms are widely documented across its extent in the Black Hills of South Dakota (Fig. 7.16). The evaporite karst in the Spearfish Fm. has caused severe engineering problems for foundations and water retention facilities, including wastewater stabilization sites. One dramatic example of problems in water retention atop gypsum karst comes from the construction in the 1970s of now-abandoned sewage lagoons for the City of Spearfish.

Despite warnings from local ranchers, the Spearfish sewage lagoons were built in 1972 by city authorities on alluvium atop thick gypsum layers of Spearfish Formation. Ironically, at one point during lagoon construction, a scraper became stuck in a sinkhole and required four bulldozers to pull it out. Once filled with sewage, within a year the lagoons started leaking badly; the southern lagoon was abandoned after four years because of ongoing uncontrollable leaks, and the northern lagoon did not completely drain, but could not provide adequate retention time for effective sewage treatment. Attempts at repairs, including a bentonite liner, were ineffective, and poorly treated sewage discharged beneath the lagoon's berm into a nearby surface drainage. The lagoons were abandoned completely in 1980. This was after a US $27-million lawsuit was filed in 1979 by ranchers whose land and homes were affected by leaking wastewater. A mechanical wastewater treatment plant was constructed nearby on an outcrop of the non-evaporitic Sundance Formation. The engineering firm that designed the facility without completing a knowledgeable geological site survey was reorganised following the lawsuit.

Likewise, the development of Chamshir Dam atop Gascharan Formation outcrop and subcrop in Iran is likely to create ongoing infrastructure cost and water storage problems (Torabi-Kaveh et al. 2012). The site is located in southwest of Iran, on Zuhreh River, 20 km southeast of Gachsaran city. The area is partially covered by evaporite formations of the Fars Group, especially the Gachsaran Formation. The dam axis is located on limestone beds of Mishan Formation, but nearly two-thirds of the dam reservoir is in direct contact with the evaporitic Gachsaran Formation. Strata in the vicinity of the reservoir and dam site have been brecciated and intersected by several faults, such as the Dezh Soleyman thrust and the Chamshir fault zone, which all act in concert to create karst entryways, including local zones of suffusion karst. A wide variety of karstic features typify the region surrounding the dam site and include; karrens, dissolution dolines, karstic springs and cavities. These karst features will compromise the ability of Chamshir Dam to store water, and possibly even cause breaching of the dam, via solution channels and cavities which could allow significant water flow downstream of the dam reservoir. As possible and likely partial short term solutions, Torabi-Kaveh et al. (2012) recommend the construction of a cutoff wall and/or a clay blanket floor to the reservoir.

Clearly, difficulties in building hydraulic structures on soluble rocks are many, and dealing with them greatly increases project and maintenance costs. Gypsum dissolution at the Hessigheim Dam on the River Neckar in Germany has caused settlement problems in sinkholes nearby. Site investigation showed cavities up to several meters high and remedial grouting from 1986 to 1994 used 10,600 tonnes of cement. The expected life of the dam is only 30–40 years, with continuing grouting required to keep it serviceable.

Grouting costs in zones of evaporite karst can be very high and may approach 15 or 20 % of the dam cost, currently reaching US$ 100 million in some cases. In karstified limestones grouting is difficult, yet in gypsum it is even more difficult due to the rapid dissolution rate of the gypsum. Karst expansion in limestone occurs on the scale of hundreds of years, in gypsum it can be on the order of a decade or less. Grouting may also alter the underground flow routes, so translating and focusing the problems to other nearby areas.

In the Perm area of Russia, gypsum karst beneath the Karm hydroelectric power station dam has perhaps been successfully grouted, a least in the short term, using an oxaloaluminosilicate gel that hardens the grout, but also coats the gypsum, so slowing its dissolution. The Mont Cenis Dam, in the French Alps, is not itself affected by the dissolution of gypsum. However, the reservoir storage zone is leaking and photogrammetric study of the reservoir slopes showed ongoing doline activity over gypsum and subsidence in the adjacent land.

Probably the worst example tied to an evaporite karst hazard is the significant dam disaster waiting to happen that is the Mosul Dam in Iraq (Fig. 6.71b; Kelley et al. 2007; Sissakian et al. 2014). It is ranked as the fourth largest dam in the Middle East, as measured by reserve capacity, capturing snowmelt from Turkey, some 70 miles (110 km) north. Built under the despotic regime of Saddam Hussein, completed in 1984 the Mosul Dam (formerly known as Saddam Dam) is located on the Tigris river, some 50 km NW of Mosul.

The design of the dam was done by a consortium of European consultants (Sissakian et al. 2014), namely, Swiss Consultants group, comprising: Motor Columbus; Electrowatt; Suiselectra; Societe Generale pour l'Industrie. The construction was carried out by a German-Italian consortium of international contractors, GIMOD joint venture, comprising: Hochtief; Impregilo; Zublin; Tropp; Italstrade; Cogefar. The consultants for project design and construction supervision comprised a joint venture of the above listed Swiss Consultants Group and Energo-Projekt of Yugoslavia, known as MODACON.

As originally constructed the dam is 113 m in height, 3.4 km in length, 10 m wide in its crest and has a storage capacity of 11.1 billion cubic meters. It is an earth fill dam, constructed on evaporitic bedrock atop a karstified high created by an evaporite cored anticline in the Fat'ha Formation, which consists of gypsum beds alternating with marl and limestone (Fig. 7.61b). To the south this is same formation, with the same evaporite cored anticlinal association that created all the stability problems in the city of Mosul (Fig. 7.61a). The inappropriate nature of the Fat'ha Formation as a foundation for any significant engineering structure had been known for more than a half a century. Then again, absolute rulers do not need to heed scientific advice or knowledge. Or perhaps he didn't get it from a well-paid group of Swiss-based engineering consultants. As Kelley et al. (2007) put it so succinctly.... "The site was chosen for reasons other than geologic or engineering merit."

The likely catastrophic failure of Mosul Dam will drive the following scenario (Sissakian et al. 2014); "… (dam) failure would produce a flood wave crest about 20 m deep in the City of Mosul. It is estimated that the leading edge of the failure flood wave would arrive in Mosul about 3 h after failure of the dam, and the crest of the flood wave would arrive in Mosul about 9 h after failure of the dam. The total population of the City of Mosul is about three million, and it is estimated that about two million people are in locations within the city that would be inundated by a 20 m deep flood wave. The City of Baghdad is located about 350 km downstream of Mosul Dam, and the dam failure flood wave will arrive after 72 h in Baghdad and (by then) would be about 4 m deep."

The heavily karsted Fat'ha Formation is up to 352 m thick at the dam and has an upper and lower member. The lower member is dominated by carbonate in its lower part (locally called "chalky series") and is in turn underlain by an anhydrite bed known as the GBo. Gypsum beds typify its upper part, and the evaporite interval is capped by a limestone marker bed. The upper member, crops out as green and red claystone with gypsum relicts, around the Butmah Anticline. Thickness of individual gypsum beds below the dam foundations can attain 18 m; these upper member units are intensely karstified, even in foundation rocks, with cavities meters across documented during construction of the dam. Gypsum breccia layers are widespread within the Fatha Formation and have proven to be the most problematic rocks in the dam's foundation zone. The main breccia body contains fragments or clasts of limestone, dolomite, or larger pieces of insoluble rocks of collapsed material. The upper portion of the accumulation grades upward from rubble to crackle mosaic breccia and then a virtually unaffected competent overburden. Breccia also may form without the intermediate step of an open cavity, by partial dissolution and direct formation of rubble. As groundwater moves through the rubble, soluble minerals are carried away, leaving insoluble residues of chert fragments, quartz grains, silt, and clay in a mineral matrix. These processes result in geologic layers with lateral and vertical heterogeneity on scales of micro-meters to meters.

High permeability zones in actively karsting gypsum regions can form rapidly, days to weeks, and quickly become transtratal. So predicting or controlling breakout zones via grouting and infill can be problematic (Kelley et al. 2007; Sissakian et al. 2014). For example, four sinkholes formed between 1992 and 1998 approximately 800 m downstream in the maintenance area of the dam (Fig. 7.61b). The sinkholes appeared in a linear arrangement, approximately parallel to the dam axis. Another large sinkhole developed in February 2003, east of the emergency spillway when the pool elevation was at 325 m. The Mosul Dam staff filled the sinkhole the next day, with 1,200 m^3 of soil. Another sinkhole developed in July 2005 to the east of the saddle dam. Six borings were completed around the sinkhole and indicated that the sinkhole developed beneath overburden deposits and within layers of the Upper Marl Series. Another cause for concern at Mosul Dam in recent years is a potential slide area reported

upstream of the dam on the west bank. The slide is most likely related to the movement of beds of the Chalky Series over the underlying GBo (anhydritic) layer.

To "cope" with ongoing active karst growth beneath and around the Mosul Dam, a continuous grouting programme was planned, even during dam construction, and continues today, on a six days per week basis. It pumps tens of thousands of tons of concrete into expanding karst features each year (Sissakian et al. 2014). The dam was completed in June 1984, with a postulated operational life of 80 years. Due to insufficient grouting and sealing in and below the dam foundation, numerous karst features, as noted above, continue to enlarge in size and quantity, so causing serious problems for the ongoing stability of the dam. The increase in hydraulic gradient created by a wall of water behind the dam has accelerated the rate of karstification in the past 40 years. Since late 1980s, the status of the dam and its projected collapse sometime within the next few decades has created ongoing nervousness for the people of Mosul city and near surroundings. All reports on the dam since the mid 1980s have underlined the need for ongoing grouting and monitoring and effective planning of the broadcasting of a situation where collapse is imminent. For "Saddam's dam" the question is not if, but when, the dam will collapse. To alleviate the effects of the dam collapse, Iraqi authorities have started to build another "Badush Dam" south of Mosul Dam so that it can stop or reduce the effects of the first flood wave. However this new dam has a projected cost in excess of US$ ten billion and so lies beyond the financial reach of the current Iraqi government. Recently, problems related to the dam increased with the takeover of the region by the forces of ISIL[13].

Given the existing geologic knowledge base in the 1980s, in my opinion, one must question the seeming lack of understanding in a group of well paid consultant engineers as to the outcome of building such a major structure, atop what was known to be an active karstifying gypsum succession, sited in a location where failure will threaten multimillion populations in the downstream cities. The same formation that constituted the base to the Mosul dam was known at the time to be associated with ground stability problems atop similar gypsum-cored anticlines in the city of Mosul to the south. Even more concerning to the project rationale should have been the large karst cavities in highly soluble gypsum that were encountered a number of times during feasibility and construction of the dam foundations (Fig. 7.61a). Or, perhaps, as Lao Tzu observed many centuries ago, " …So the unwanting soul sees what's hidden, and the ever-wanting soul sees only what it wants."

Canals, like dams, that leak in gypsum karst areas can trigger subsidence, which can be severe enough to cause retainment failure. In Spain, the Imperial Canal in the Ebro valley, and several canals in the Cinca and Noguera Ribagorzana valleys, which irrigate parts of the Ebro basin, have on numerous occasions failed in this way. Similarly, canals in Syria have suffered from gypsum dissolution and collapse of soils into karstic cavities. Canals excavated in such ground may also alter the local groundwater flow (equivalent to losing streams) and so accelerate internal erosion, or the dissolution processes and associated collapse of cover materials. In the Lesina Lagoon, Italy, a canal was excavated to improve the water exchange between the sea and the lagoon. It was cut through loose sandy deposits and highly cavernous gypsum bedrock, but this created a new base level, so distorting the local groundwater flow. The canal has caused the rapid downward migration of the cover material into pre-existing groundwater conduits, producing a large number of sinkholes that now threaten an adjacent residential area. Pipelines constructed across karst areas are potential pollution sources and some may pose possible explosion hazards. The utilization of geomorphological maps depicting the karst and subsidence features allied with GIS and karst databases help with the grouting and management of these structures. In some circumstances below-ground leakage from water supply pipelines can trigger severe karstic collapse events. Where such hazards are identified, such as where a major oil and gas pipeline crosses the Sivas gypsum karst in Turkey, the maximum size of an anticipated collapse can be determined and the pipeline strength increased to cope with the possible problems.

Solving the Problem?

Throughout the world, be it in the UK, Spain, eastern Europe, or the Middle East, it is a fact that weathering of shallow gypsum forms rapidly expanding and stoping caverns, especially in areas of high water crossflow, roof beams and unconsolidated overburden and in areas of artificially confined fresh water. Rapid karst formative processes and mechanism will always be commonplace and widespread

[13] On August 7, 2014, the Islamic State of Iraq and the Levant (ISIL) movement captured the Mosul Dam complex from the Peshmerga. ISIL control of the dam created fears that its power supply could be restricted, or the water flows to downstream areas greatly inhibited. In a less likely scenario, there were worries the dam could be breached, causing widespread flooding and destruction downstream. On August 17, 2014, Peshmerga and the Iraqi Army launched a successful operation to retake control of the dam from ISIL militants. United States air strikes assisted the Kurdish and Iraqi military, damaging or destroying 19 vehicles belonging to ISIL, as well as a checkpoint near the dam.

Some estimates suggest that the dam would begin to crumble within weeks if grouting stopped, which explains why ISIL brought in their own engineers to keep the grouting process going. Any group trying to establish a new state needs control of water supplies and power-generation, so it was in the interests of ISIL to keep the dam intact. (It was not known at the time of recapture if they had planted explosive charges throughout the structure, just in case they needed a Doomsday option).

Table 7.10 Summary of possible changes in the karst system (natural or anthropogenic) that can accelerate of trigger karst development in evaporitic terrains

Type of change	Effects	(1) Natural processes. (2) Human activity
Increased water input to the ground (cover and bedrock).	Increasing percolation accelerates suffosion. Enhances rate of dissolution. Increases weight of sediment. May reduce mechanical strength of sediment.	(1) Rainfall, floods, snow melt, permafrost thaws. (2) Irrigation, leakages from utilities (pipes, canals ditches), water impoundment, runoff concentration (urbanisation, soakaways) or diversion, vegetation removal, poorly monitored drilling, unsealed wells, fluid injection, solution mining.
Watertable decline.	Increases effective weight of sediment (loss of buoyant support). Slow phreatic flow replaced by more rapid downward percolation favoring suffosion, especially when water-table is lowered below the rockhead. Suction effect	(1) Climate change, sea; level decline, entrenchment of drainage network, tectonic uplift. (2) Water abstraction, dewatering for mining operations, decline of lake water levels.
Impoundment of water.	May create very high hydraulic gradients favoring dissolution and internal erosion processes. Imposes a load.	(1) Natural lakes. (2) Reservoirs, lagoons.
Permafrost thawing.	Favors dissolution Significant reduction in strength of sediments	(1) Climate change. (2) Development, deforestation, water storage.
Static loads	Favors compaction and the failure of cavity roofs.	(1) Aggradation processes. (2) Engineered structures, dumping, heavy vehicles.
Dynamic loads.	Favors the failure of cavity roofs and may cause liquefaction-fluidisation processes involving a sharp drop in the mechanical strength of soils.	(1) Earthquakes, volcanic explosions. (2) Artificial vibration (blasting, explosions)
Thinning of sediments over voids	Reduces the mechanical strength of cavity roofs. May concentrate runoff and create a local base level for groundwater flows.	(1) Erosion processes. (2) Excavations.
Underground excavations.	Disturb groundwater flows. May intercept phreatic conduits. May weaken sediment over voids.	(1) Biogenic pipes. (2) Mining and tunnelling
Waterproofing of reservoir bottoms.	Trapped pressurised air in the vadose zone during rapid rises of watertable.	(2) Waterproofing blankets in reservoirs

After Gutierrez (2010)

(Table 7.10). Resultant karst-associated problems can be both natural and anthropogenically induced or enhanced. It is fact that natural solution in regions of subcropping evaporites is always rapid, and even more so in areas where it is encouraged by human activities, especially increased cycling of water via damming, groundwater pumping, burst pipes, septic systems, agricultural enhancement and uncontrolled storm and waste water runoffs to aquifers.

Typically, the best way to deal with a region of an evaporite karst hazard is to map the regional extent of the shallow evaporite solution front and avoid it (Table 7.11). In established areas with a karst problem the engineering solutions will need to be designed around hazards that will typically be characterised by short-term onsets and often tied to rapid ground stoping/subsidence events, followed by ground collapse. If man-made buildings of historical significance are to be restored and stabilized in such settings, perhaps it is better to wait until funds are sufficient to complete the job rather than attempt partial stabilization of the worst-affected portions of the feature. Significant infrastructure (including roads, canals and dams) should be designed to avoid such areas when possible or engineered to cope with and/or survive episodes of ground collapse. A piecemeal approach to dealing with evaporite karst can intensify and focus water crossflows rather than alleviate them. In the words of Nobel prizewinner, Shimon Peres; "If a problem has no solution, it may not be a problem, but a fact – not to be solved, but to be coped with over time."

Sulphuric Acid Speleogenesis

Historically, most carbonate karst networks have been interpreted as epigenic (surface-driven) responses to vadose/shallow-phreatic leaching of carbonate bedrock, in a hydrology driven by throughflowing fresh to brackish meteoric waters. Leaching and cavern/joint enlargement is seen as a response to waters enriched in carbonic acid. Carbonic acid is derived from CO_2 in the atmospheric and soil zones. Most vadose cave ornamentation is a response to CO_2 degassing at or above the watertable and precipitates are dominantly calcite, with lesser volumes of other carbonate minerals (aragonite, magnesite) and rare sulphates.

Yet, we have seen how gypsum maze caves do not fit neatly into this epigenetic meteoric/watertable dominated template for karst formation. Telogenetic gypsum karst in an evaporite basin starts deeper (hypogenic), typically in water crossflows driven by deep artesian circulation or escaping

Table 7.11 Problems and outcomes in some regions of gypsum subcrop

Problem	Effected regions/area	Outcomes/responses	Responses	Relevant references
Cities and towns in regions underlain by shallow evaporate (subcrop)	Paris (France), Dzerzhinksk (Russia), Zaragoza, Calatayud and the outskirts of Madrid (Spain), Birzai and Pasvalys (Lithuania), Ripon and Darlington (UK).	Building instability, problematic restorations	Documentation, probing, mapping, avoidance where possible	Cooper and Gutiérrez (2013), Tolmachev et al. (2003), Tolmachev and Leonenko (2011), Galve et al. (2009), Thierry et al. (2009), Gutiérrez et al. (2008), Waltham et al. (2005)
Dams, ponds, pipelines, canals and water wells in regions underlain by shallow evaporate (subcrop)	Various dams in USA and Middle East Sewage ponds, Spearfish (USA) Oil pipeline across Sivas region (Turkey)	Dam storage leakage and possible dam collapse (e.g. Mosul Dam, Iraq) Pipeline leakage and associated pollution – Poor quality water supply (e.g. Birzai Lithuania) Subsidence associated with water abstraction	Karst characterization and mapping in regions of intersection. Forward planning of infrastructure character and limitations, avoidance on placing infrastructure atop active evaporite karst. Monitoring is required and increased pipeline strength planned so as to allow drape without breakage. Avoidance where possible	Cooper and Gutiérrez (2013), Sissakian et al. (2014), Kelley et al. (2007), Torabi- Kaveh et al. (2012), Yilmaz et al. (2011), Johnson (2008b),
Roads and rail networks underlain by shallow evaporate (subcrop)	Highways in US, Europe, the Middle East and elsewhere	Road subsidence, collapse, loss of line of site below bridges and overpasses	Appropriate planning and highway construction techniques including strengthening road bases, grouting, as well as bridge pylons capable of integrity in situation of ground collapse. Avoidance where possible	Alberto et al. (2008), Cooper and Saunders (2002), Frumkin et al. (2011), Tolmachev et al. (1999)
Unexpected problems in salt related conventional mining, solution wells, salt storage caverns	Common to all is a combination of short-term profit, poor understanding of the geology, no monitoring of possible subsidence and ground collapse, poor contingency planning.	Rapid formation of at-surface collapse dolines, loss of infrastructure, and sometimes loss of life (minimal compare to above ground storage problems and explosions)	Monitoring, technical understanding and forward planning. Better training and appropriate qualifications of all involved personnel	See Chap. 13 for full discussion, documentation and recommendations (Tables 13.6, 13.7, 13.8, and 13.9)

In part after Cooper and Gutiérrez (2013)

Table 7.12 Active and inactive sulphuric cavern systems, not all are related to evaporite dissolution, but all accumulate gypsum

basinal fluids. In the last two decades the importance of similar hypogene leaching of carbonates has been recognised in systems driven by the ascent, mixing and cooling of H_2S- and CO_2 -rich basinal brines. Examples are now documented in what were once considered classic regions of meteoric leaching (Table 7.12; Davis 1980; Egemeier 1981). Caverns can form in carbonate hosts well below the watertable where there is frequently a calcium sulphate association in the

deeper parts of the hydrology, both in basinal generation of H_2S and in the typical early byproducts of cavern creation.

Bathyphreatic caves are still classified by some carbonate sedimentologists as a form of hydrothermal karst with an implication of hot hydrothermal waters. There certainly are some bathyphreatic caves developed as carbonate karst that do have an association with hot circulating waters, especially those caves forming host cavities to some MVT deposits (Warren and Kempton 1997). But many sulphuric acid groundwaters that form caves and cavern gypsum, such as those of the Carlsbad system, were probably not all that hot. The term hypogene (formed at depth) is more appropriate than hydrothermal (waters with elevated temperature) in classifying caves formed by cooling and mixing of hydrocarbon-rich basinal waters, which have encountered deeply buried beds of sulphate evaporites on their way to the surface. Significant hypogenic karst collapse features typify the Konya Closed Basin of central Turkey, where they are known as obruks[14].

Hypogene caves in carbonate hosts can contain substantial volumes of gypsum precipitated as cavern fills and limestone replacements at scales ranging from microcrystalline crusts on the cave wall to cavern-filling accumulations of phreatic gypsum crystals deposited either as pelagic laminites or as spectacular crystal-clear prisms that can be metres long and wide (Buck et al. 1994). The accumulation of large volumes of cave-fill gypsum, independent of the climate at the landsurface, does not fit well with older notions of surface-driven meteoric circulation and arid cave atmospheres for gypsum speleothems. Hypogene caverns and their gypsum fills can develop wherever oxygenation of rising H_2S-laden hypogene waters occurs, this typically first occurs at bathyphreatic depths, and can be hundreds of metres below the meteoric watertable.

Early stages of hypogenic caves display no relationship to meteoric recharge conduits in their overburden as this is typically an epigenic overprint formed during later uplift. Hypogenic cave passages typically follow ramiform, network, or spongiform patterns (Palmer 2011; Klimchouk 2012a). Time and ongoing exhumation brings a hypogene cave closer to the land surface and moves it out of its formative bathyphreatic hydrology. By the time hypogene caves are accessible to speleologists the evidence of the formative hydrology is largely overprinted by classic meteoric-driven karst textures and precipitates.

H_2S needed to drive hypogene cavern formation is carried by escaping basinal waters that have experienced biochemical or thermochemical reduction of sulphate evaporites and petroleum. Less commonly, they are derived by groundwater oxidation of pyrite, or they entrain volcanogenic thermal waters. As anoxic, H_2S-enriched basinal waters rise along fractures in a limestone host, it cools and mixes with the underside of a layer of meteoric pore water, which typically is oxygenated. As sulphide-rich waters mix and become oxidized, the most aggressive byproduct of their oxidation is sulphuric acid, which can be biologically-mediated by sulphur-oxidising bacteria (Chap. 9). This aggressive water leaches and dissolves the surrounding carbonate aquifer, so that hypogene caverns tend to have large chambers with narrow connections and deep shafts along fracture or joint avenues where the sulphide-rich waters rose (inverted tear-drops). As the acid is spent the concentrations of calcium and sulphate in the cave waters can build to gypsum saturation and the resulting gypsum ornamentation can be spectacular.

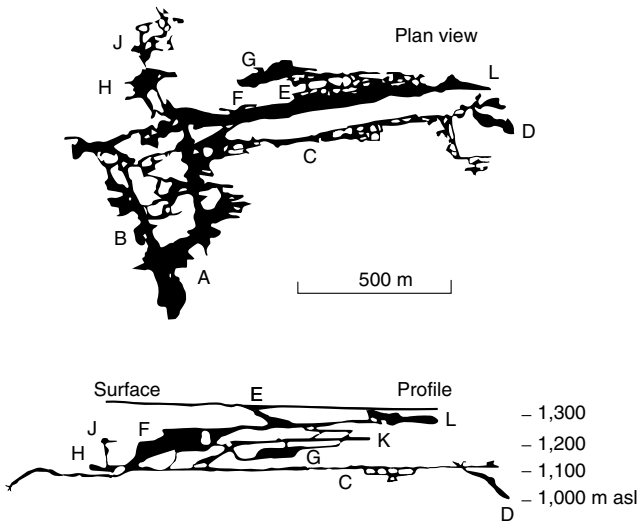

Fig. 7.62 Carlsbad caverns, New Mexico. Map and profile view showing multi-tiered extent across 300 m depth (After Klimchouk 2007)

The best-documented example of sulphuric acid speleogenesis in the western literature is the Carlsbad-Lechuguilla cavern system in Permian reefal limestones of the Guadalupe Mountains, USA (Figs. 7.62 and 7.63a; Hill 1990, 1995; Palmer and Palmer 2000; Klimchouk 2007; Stafford et al. 2008a, b). Although meteoric processes now form calcitic speleothems in these caves, the early host caverns were etched bathyphreatically by sulphuric acid and walls were free of calcite speleothems. Sulphuric acid caverns created by mixing of H_2S waters with oxygenated phreatic waters began to form in the Carlsbad system some 10–12 Ma and as much as 200 m below the watertable. Remnant blocks of laminar pelagic gypsum, a widespread byproduct of sulphuric acid leaching, still cover the floor of the now largely inactive and exhumed Carlsbad Cavern (*pers. obs.*).

[14]Obruk is an internationally recognized Turkish geomorphic term, describing hypogenic collapse dolines, which crop out in the currently semiarid and almost flat land of Konya Closed Basin in central Turkey. These megadolines, with surface diameters and depths reaching several hundreds of meters, are still surfacing with an estimated temporal frequency of once per 5–10 years (Bayari et al. 2009).

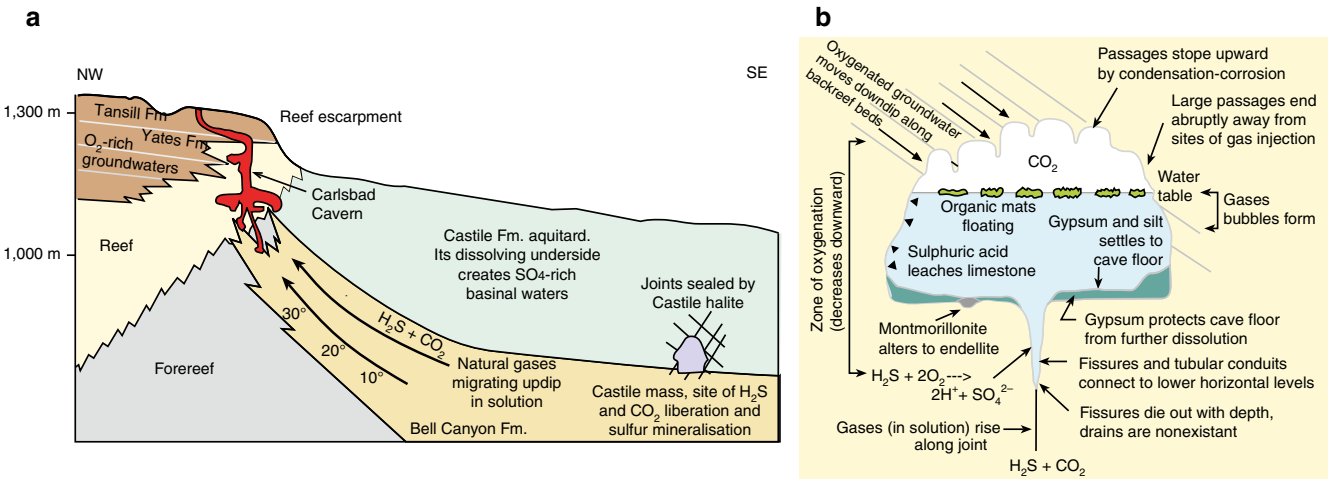

Fig. 7.63 Sulphuric acid speleogenesis. (**a**) Schematic section of Delaware Basin. Escape of natural gas from hydrocarbon kitchen in the basin centre is focused along the dissolving underside of the laminated anhydrite of the Castile Formation. It reacts thermochemically with the sulphate ions to produce H_2S, CO_2 and calcite replacement of the anhydrite (this forms the characteristic Castiles when later exhumed). H_2S and CO_2 continue their focused escape through the Bell Canyon Formation toward the basin margin where they enter limestones of the Capitan and Goat Seep Reefs. There the gases mix with oxygenated groundwater, hydrogen sulphide in solution and dissolved oxygen combine to form sulphuric acid, which then leaches the host limestone, especially along the more permeable joints and fissures. (**b**) Hydrogen sulphide reacts with dissolved oxygen to form sulphuric acid which leaches a cavern. The sulphuric acid is neutralised by the limestone so that caverns tend to terminate abruptly away from zones of gas injection. Oxygenation and hence the acidic reaction die out with depth so that large rooms do not extend far below the horizontal extent of the cavern. With successive lowering of base level, driven by uplift and climatic change, new horizontal levels became connected with older horizontal levels by spring shafts and joint chimneys (After Hill 1990; Forti et al. 2002). The gas-filled cavern top and an associated watertable is only present during the more mature stages of exhumation. The process of mixing of H_2S-rich and meteoric waters that creates the hypogene cavern is a totally phreatic system and is largely unrelated to the presence or absence of a watertable

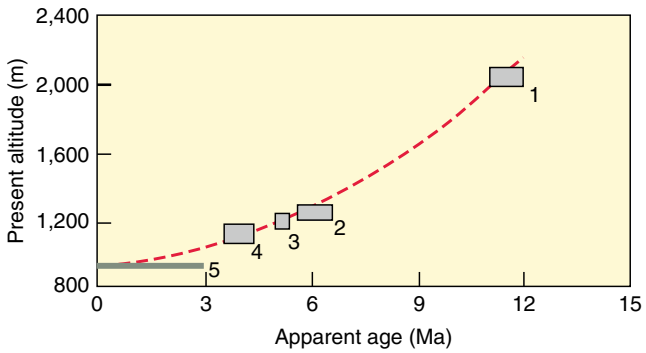

Fig. 7.64 Age versus elevation for several cave levels in the Guadalupe Mountains (After Polyak et al. 1998). *1* Cottonwood Cave and Virgin Cave; *2* Endless Cave and Glacier Bay (Lechuguilla Cave); *3* Lake Lebarge (Lechuguilla Cave); *4* New Mexico Room, Big Room, and Green Clay Room (Carlsbad Cavern); *5* present watertable

$^{40}Ar/^{39}Ar$ dating of fine-grained alunites that were formed during hypogene leaching, and still present in residual clays, show that the "Big Room" level of Carlsbad Cavern formed 3.9–4.0 Ma, while the upper level of Lechuguilla Cave formed 5.7–6.0 Ma (Fig. 7.64). Other older and now more elevated hypogene caves in the Guadalupe Mountains formed at various times from 6.0 to 11.3 Ma (Polyak et al. 1998). Alunite ages increase with, and are strongly correlative to, cave elevation, indicating an 1,100-m decline in the watertable tied to ongoing Neogene uplift and tilting (Fig. 7.64).

The cavern forming process is driven by chemical changes in oil- and gas- rich basinal waters moving up dip from the evaporite-sealed Delaware Basin (Fig. 7.63a). Rising waters derive much of their sulphate content by dissolution of the underside of Castile anhydrite and this also drives karst/pipe formation within the Castile Formation (Stafford et al. 2008a). Some of the sulphate undergoes thermogenic and biogenic sulphate reduction to form H_2S and CO_2, with bacteriogenic "Castile" calcite precipitated as a sulphate-reduction byproduct along the contact between the underlying aquifer and the Castile Fm. Sulphate-H_2S enriched basinal waters then enters the Capitan and Goat Seep strata via crosscutting joints, typically along local aquifers created by the steeply dipping forereef beds, or via lenses of the sandy equivalents to Bell Canyon siliciclastics.

Rising basinal waters carry large volumes of H_2S, CO_2 and methane in solution. As it rises the waters depressurize and release the various dissolved phases as gas bubbles (degasses). By the time the water comes to within a few metres of the watertable it has released almost all of its gas as bubbles (Fig. 7.65; Palmer and Palmer 2000). We shall focus on the H_2S because of its role in precipitating hypogene gypsum fills, but released CO_2 and methane released as gas bubbles from ascending brines also play a role in hypogene caves. Like H_2S, they can create chemosynthetic ecosystems in the deep phreatic, systems which function independent of energy input from the surface (Chap. 9).

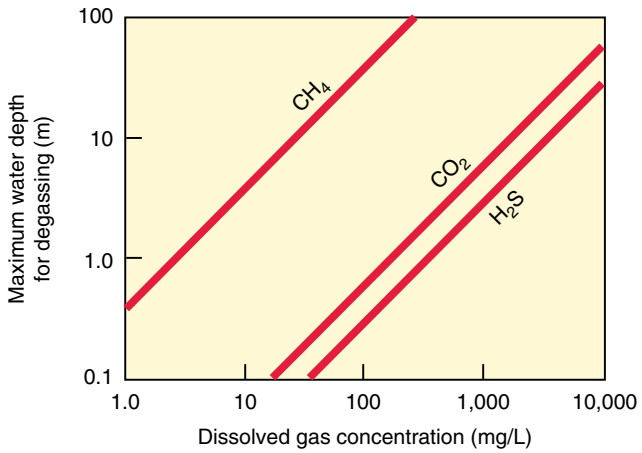

Fig. 7.65 Maximum depth at which degassing of H_2S, CO_2, and CH_4 can take place below the unconfined watertable. Partial degassing occurs at depths well below the respective lines, but no degassing will occur above the line (After Palmer and Palmer 2000)

On arrival in the shallower phreatic levels of the basin, the H_2S reacts with oxygenated groundwater to form sulphuric acid:

$$H_2S + 2O_2 \rightarrow HSO_4^- + H^+$$

Once formed, the sulphuric acid immediately attacked the limestone host and etched out the early outlines of the various Carlsbad caverns via the reaction:

$$HSO_4^- + H^+ + CaCO_3 + 2H_2O \rightarrow Ca^{2+} + SO_4^{2-} + 3H_2O + CO_2$$

This adds further sulphate to the already sulphate-enriched cave waters. If the dissolving carbonate host is dolomitic, then significant magnesium is also added to the cave water. Expanding horizontal benches in such hypogene phreatic caverns indicate intervals of most intense phreatic mixing between H_2S and SO_4 saturated basinal waters. They are located in the lower portion of the oxygenated active phreatic system and may not necessarily be tied the presence of a watertable.

Sulphuric acid caves have sponge-like(spongiform) edges and no calcitic speleothems ornament the growing cavity. Cave walls tend to end abruptly in the horizontal plane as the acidity of the cave waters is quickly quenched away from fissures supplying H_2S. Likewise, since the level of dissolved oxygen in cavern waters decreases with depth, the fissure passages and pits tend to terminate vertically via a rapid narrowing downward channelway This forms an inverted "tear drop" cavern, a shape less seen in epigenic carbonate karst (Fig. 7.63b).

Ongoing leaching means calcium and sulphate levels continue to build in cavern waters, which are already near or at gypsum saturation from earlier leaching of the Castile Formation. Gypsum starts to precipitate in the cave water column and on the cave walls. Fine laminated and layered pelagic gypsum builds up beneath the water-covered parts of the cave floor, typically atop endellitic silts. Huge centripetal splays (metres long and decimetres wide) of ice-clear prismatic gypsum precipitate in stable phreatic portions of the cavern system. Alabaster crusts can coat vadose areas of the cave walls, often in association with the growth of acidophilic archaea and sulphur-oxidising bacteria.

Smectitic clays, released by the leaching of the carbonate bedrock settle through the quiescent cave waters, along with the gypsum crystallites forming in the supersaturated cave waters, to form a pelagic ("rain-from-heaven") unit of laminated gypsum and silt on the cave floor (Fig. 7.63b). Acidic cave waters convert some of the accumulating smectite to endellite ($Al_2Si_2O_5$ $(OH)_4 \cdot 2H_2O$), a brightly coloured clay indicative of acidic conditions in hypogene caves. Two other low-pH, sulphuric-acid indicator minerals, alunite and natroalunite, also occur in association with the endellite (Cunningham and Takahashi 1992; Hill 1995). The same sulphuric acid environment facilitates the formation of secondary late-stage, uranium-vanadium minerals tyuyamunite and metatyuyamunite at redox boundaries in the caves and their presence helps explain elevated levels of radon that typify the modern cave air in the various Carlsbad caverns (Hill 1995).

Even though further uplift has drained the waters from today's caverns, relicts of the gypsum spar and blocks of layered granular pelagic gypsum remain. Such blocks are sporadically scattered over the deeper parts of the floor of the "Big Room" in Carlsbad Cavern as remnants of a former gypsum layer that was up to 10 m thick. Internally, the blocks and rinds of the pelagic units show a laminated or microfolded fabric indicative of it subaqueous origin (pers. obs). In Lechuguilla Cave, phreatic spar gypsum ornamentation forms "chandeliers" or "ferro di lancia" accumulations of ice-clear gypsum crystals, which now, with subsequent watertable lowering, protrude from the exposed and accessible areas of the cave.

Even more widespread and spectacular examples of gypsum chandeliers line the Cupp-Coutum and other now inactive hypogene sulphuric acid caves of Kugitangtau Ridge, Turkmenistan (Maltsev and Malishevsky 1990). The phreatic calcium sulphate textures record a phase of hypogene activity within a pre-existing karstic groundwater conduit system (Bottrell et al. 2001). Hypogene fluids entered the caves through fault zones and deposited sulphate, sulphide and carbonate minerals under phreatic conditions. Locally, intense alteration of limestone wall rocks also occurred at this stage. Elsewhere in the region, similar faults contain economic quantities of galena and elemental sulphur mineralization. Comparisons between the Pb and S isotope compositions of minerals found in cave and ore deposits confirm the link between economic mineralization and hydrothermal activity at Cupp-Coutunn. The predominance of sulphate mineralization in Cupp-Coutunn implies that the fluids were

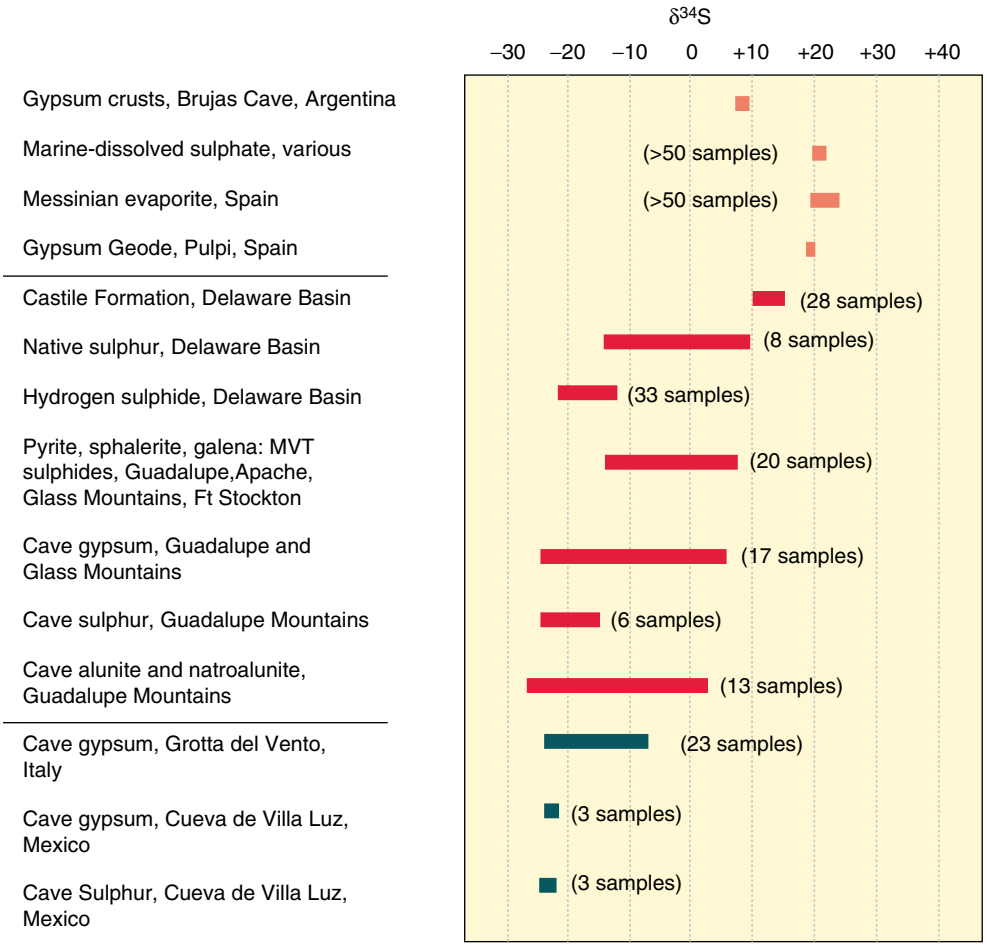

Fig. 7.66 Range of sulphur isotope values for various H_2S associated cave deposits in the USA, Italy and Mexico (After Hill 2000; Hose et al. 2000; Polyak and Guven 1996; Galdenzi and Maruoka 2003; Garcia-Guinea et al. 2002; Sancho et al. 2004). Cave gypsum and sulphur in the Delaware Basin are significantly enriched in the light isotopes compared to the Castile Formation. Their isotopically light composition within the basin (H_2S gas, native sulphur) and in the reef (sulphides and sulphur/gypsum cave deposits) reflect bacterial sulphate reduction where sulphate solutions mixed with hydrocarbons to produce isotopically light hydrogen sulphide. Similar products from sulphuric acid caves in Italy and Mexico also plot in the negative sulphur range and are clearly not indicative of a meteoric or marine source

more oxidized in the higher permeability zone associated with the karst aquifer.

Following the hypogene phase, speleothemic minerals were precipitated under vadose conditions (Bottrell et al. 2001). Speleothemic sulphates show a bimodal sulphur isotope distribution. One group has compositions similar to the hydrothermal sulphates, whilst the second group is characterized by higher $\delta^{34}S$ values (Fig. 7.66). This latter group may either record the effects of microbial sulphate reduction, or reflect the introduction of sulphate-rich groundwater generated by the dissolution of overlying evaporites. Oxygen isotope compositions show that calcite speleothems were precipitated from nonthermal groundwater of meteoric origin. Carbonate speleothems are relatively enriched in ^{13}C compared to most cave deposits, but can be explained by normal speleothem-forming processes under thin, arid-zone soils dominated by C_4 vegetation. However, the presence of sulphate speleothems, with isotopic compositions indicative of the oxidation of hydrothermal/hypogene sulphide, implies that CO_2 derived by reaction of limestone with sulphuric acid ('condensation corrosion') contributed to the formation of ^{13}C-enriched speleothem deposits.

Blocks composed of white, fine-grained, pelagic (phreatic) gypsum cover large floor areas (over 1,000 m^3) of the upper cave level of the Grotta Grande del Vento, Italy (Galdenzi 1990; Galdenzi and Maruoka 2003). In this case the gypsum does not form the spectacular "ferro di lancia" found in New Mexico and Turkmenistan, although there are some coarsely crystalline aligned prisms that are interpreted to have grown in the cave mud. Today's gypsum textures on the walls of the Frasassi caves are much less diverse and more localised than when sulphate precipitation was at its peak in the hypogene phreatic caverns of the early Pleistocene (Galdenzi and Maruoka 2003; Tisato et al. 2012). What makes Grotto Grande so interesting is that the process of gypsum formation is still active in some accessible parts of the cave where H_2S-rich waters mix with oxygenated ground waters. Hollow vaterite spherules have been precipitated in the laboratory from bacterial cultures collected from such caves in Italy and Spain (Sanchez-Moral et al. 2003).

Native sulphur can be found in sulphidic caverns of New Mexico either admixed with gypsum in the remnant pelagic blocks or as canary-yellow sulphur crystal coats on the undersides of dipping beds of the forereef or the siliciclastic

Bell Canyon Formation. $\delta^{34}S$ values are as low as −25.8‰ (CDT) in this cave sulphur. Similar values in the cave gypsum (−25.6‰) and the endellite, indicate that they too are end products of microbial reduction reactions metabolising escaping hydrocarbons. Their isotopic signatures are not products of meteoric diagenesis (Fig. 7.66; Hill 1990).

Throughout the various caves of the Guadalupe Mountains, sulphur isotope results have been crucial in defining its hypogenic speleogenesis (Fig. 7.66; Hill 1990, 2000). Cave gypsum with such negative values could not have been derived directly from Castile anhydrite beds, without bacterial mediation (mostly by anoxic sulphate reducers at depth, then sulphate oxidisers near the watertable). Thus, inorganic models based on local brine pooling and saturation (Bretz 1952) or the inorganic cooling of basinal water (Queen et al. 1979) are not directly applicable to Carlsbad precipitates. Such inorganic models are more relevant to the ice-clear 8 m long, 1 m wide, gypsum crystals filling giant geodes in a Triassic limestone host at Pulpí in SE Spain (Garcia-Guinea et al. 2002) and to gypsum crusts in Brujas Cave, Argentina (Sancho et al. 2004).

The average isotopic composition of marine-fed Castile gypsum/anhydrite is +10.3‰. If the cave gypsum had precipitated directly from cooling Castile brines, then gypsum in the cave fill should have a similar signature to the Castile Formation; clearly, it does not (Fig. 7.66). Sulphur isotope data also discount sulphate derivation from a pyrite precursor, as proposed by Jagnow et al. (2000). Metal sulphide values in the Guadalupe Mountain samples (mostly pyrites) range from $\delta\ ^{34}S = -9.3$ to +12.6‰ (mean = −2.2‰ for 20 samples; Fig. 7.66). As there is no significant isotopic fractionation involved in the subsurface leaching of sulphides (less than 1‰), it must be concluded that the isotopically lighter signatures of cave floor gypsum and sulphur (mean $\delta^{34}S = -16.8$‰ for 22 samples) are not derived from a pyrite source. Instead, the consistent isotopically light signature in the cave precipitates support a model of bacterial sulphate reduction acting on Castile Formation sulphate (and hydrocarbons) and ultimately creating sulphuric acid leading to caves with gypsum as a widespread precipitate.

Sulphuric acid speleogenesis is no longer active in the accessible portions of the New Mexico or Turkmenistan caves. But sulphuric acid driven cave expansion is occurring today in the Cueva de Villa Luz in Mexico (Hose and Pisarowicz 1999; Hose et al. 2000), Grotta Grande del Vento in Italy (Galdenzi 1990) and the Movile Cave in Romania (Sarbu et al. 1994). In all three examples, the cave water and cave atmosphere is enriched in hydrogen sulphide and the biochemical action is centred around the watertable (Table 7.13).

Oxidation of sulphide-rich waters seeping from the cave walls and the associated precipitation of fine-grained gypsum is largely microbially driven (Fig. 7.67). It is localised to seepages at or near the watertable and the precipitation

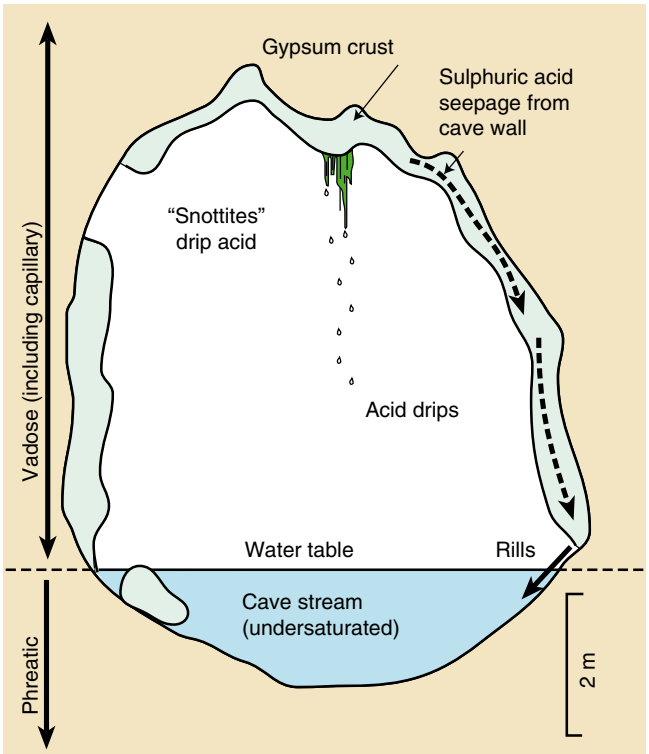

Fig. 7.67 Mechanisms for cave enlargement. *1*. Conversion of limestone to gypsum crust by sulphuric acid, dissolved by the cave stream and by infiltrating freshwater. *2*. Drips of sulphuric acid from the gypsum wall crust and snottites corrode limestone below. Microbial activity enhances the oxidation reactions that produce the acid. *3*. Sulphuric acid seeps through the gypsum crust and dissolves the limestone at the base. Solutional rills are common (after Hose et al. 2000)

chemistry is facilitated by sulphur-oxidising bacteria. Near identical microbial mat communities float at the air/water interface in the active sulphuric waters of Movile Cave, Romania, and coat the cave walls (forming snottites) in Cueva de Villa Luz, Mexico. In all, the process set today is mostly vadose and tied to the changing chemical conditions across the watertable interface. Textures in vadose wall gyp-

sum are not the same, nor as widespread as the relict phreatic pelagics and gypsum spars we see in palaeohypogene caves in New Mexico and Turkmenistan.

Measured H_2S levels in the cave atmosphere of Cueva[15] de Villa Luz reach 210 ppm, while SO_2 typically exceeds 35 ppm, conditions which require researchers to use masks and breathers. These gases, plus oxygen from the cave air, are absorbed by water films that gather on the cave walls, via infiltration and condensation. Sulphur-oxidizing bacterial colonies in water films on cave walls and floating on cave waters facilitate the conversion of the abundant hydrogen sulphide to sulphuric acid. Microbes probably also facilitate the conversion of carbon dioxide to carbonic acid. Low pH waters (0.0–3.0, with a mean of 1.4) drip from microbial veils on the cave walls onto the limestone floor. Such wall growths look like delicate stalactites made of phlegm, locally dubbed "snottites" (Fig. 7.67). As the acid drips, it forms rillen and incised channels in wet limestone walls adjacent to the main cave stream. On the cavern slopes, above main stream level, the sulphuric acid reacts with the surrounding limestone to produce a pasty plastering composed of microcrystalline (alabastrine) gypsum and microbes, with surface pH values between 0.5–3.0.

Cueva de Villa Luz is fed by more than 25 groundwater springs, with a combined flow of 200–300 l/s. Inlet water chemistry defines two categories: (a) those with high H_2S content (300–500 mg/l), mean $P_{CO2} = 0.03–0.1$ atm, and no measurable O_2; and (b) those with less than 0.1 mg/l H_2S, mean $P_{CO2} = 0.02$ atm, and modest O_2 contents up to 4.3 mg/l. Both water types have a similar source, as shown by their dissolved solid content. However the oxygenated water has been exposed to aerated conditions upstream from the cave inlets so that much of the original H_2S has been largely lost via outgassing and oxidation to sulphate, increasing the sulphate concentration in the waters by about 4 %. Modelling of the cave water chemistry shows that it can be produced by dissolution of sulphate, carbonate, and chloride minerals, which are present deeper in the basin (Hose et al. 2000).

Two cave-enlarging mechanisms were identified in the Cueva de Villa Luz (Fig. 7.67; Hose et al. 2000): (1) Sulphuric acid from oxidation of hydrogen sulphide prior to its exit into the cave, which converts subaerial limestone surfaces to gypsum and is aided by the activities of sulphur-oxidising bacteria. Most of this gypsum ends up falling into the cave stream where it is redissolved and lost via the stream exiting the system. (2) Strongly acidic droplets, formed on microbial filaments, which dissolves limestone as it drips onto the cave floor. Possible sources of H_2S in the Cueva de Villa Luz system are the evaporites of the Villahermosa petroleum basin, which is less than 50 km downdip and to the northwest, or the hydrothermal system of the El Chichon volcano located some 50 km to the west. Depletion of ^{34}S values for sulphur stabilized from H_2S in the cave atmosphere (−11.7‰), along with the hydrochemistry of the spring waters, favour an evaporite – sulphate reduction origin over a volcanogenic source.

In part, so much more gypsum occurs in the caverns at Carlsbad, compared to the amount of gypsum accumulating on cave walls in other active sulphuric acid caves of today, simply because there was so much more dissolved gypsum entering the cave system along the edges of a dissolving evaporite bed. When it was active, the Carlsbad system was located in the outflow zone of a large regionally draining basin, with escaping waters focused into the growing cave system by the dissolving under-side of the bedded basinwide anhydrite of the Permian Castile Fm. Likewise the gypsum-rich Turkmenistan caverns are tied to nearby dissolving Miocene evaporites.

But there is another key difference when comparing gypsum precipitation processes at Carlsbad to modern sulphuric acid caves, such as Cueva de Villa Luz. Gypsum textures in now inactive hypogene karst fills of Carlsbad and similar systems elsewhere indicate significant volumes of phreatic gypsum accumulated within expanding caves, situated as much as 100–200 m below the meteoric watertable. In contrast in all the accessible parts of the active sulphuric acid caves of Mexico, Italy and Romania, the documented gypsum precipitation is a microbially-mediated vadose seepage process, where H_2S rich waters condense and seep down vadose cave walls. It leads to unique lithoautotrophic systems centred on the sulphate oxidisers in the vadose zone at or immediately above the watertable.

So, how relevant are these modern biogenic gypsum products compared to the much more spectacular and voluminous gypsum precipitates forming in inaccessible blind and deep hypogene caverns, some tens to hundreds of metres below the watertable? We can access the results of this bathyphreatic hydrology only as relicts that have survived exhumation into the vadose realm, as in the deeper levels of Carlsbad Caverns. In terms of models of gypsum precipitation and the relative contribution of sulphur-oxidising microbes to gypsum formation in hypogene karst systems, we have the same scale and process-comparison problems that plague all studies of ancient evaporite deposition. What we have available to develop analogues in modern sulphuric caves, such as Cueva de Villa Luz, is from vadose cave regions that are accessible and measurable, but how reliably can we generalise our conclusions on what forms hypogene gypsum using only these models of vadose cave wall products.

Studies of process in active sulphuric acid caves is restricted to parts of a cave system where people can crawl, sweat, swim and sample. These accessible parts are probably not the parts of a brine-flushed carbonate cavern system where most gypsum precipitates and accumulates. To interpret processes for hypogene gypsum we must use the textures

[15] Translates as "Cave of the Lighted House." The cave has at least 24 natural skylights, mostly vertical shafts and is lined with dissolution features such as natural bridges, boneyards, and rillenkarren walls.

and extent of the bathyphreatic gypsum itself. Even if such places were accessible in some yet to be discovered part of an active hypogene cave system, the elevated levels of H_2S would make it extremely toxic to generalist lifeforms like us. Some carbonate workers would argue that H_2S-related karstification of marine carbonates, with significant hypogene gypsum as a byproduct is not a widespread diagenetic process. They argue that the bulk of published karstification studies in the literature support this contention.

To this I would argue that the literature on carbonate karst reflects a sampling bias. That is, most studies of modern karst process are done in caves that are accessible for study. By definition, these caves are near to and connected to the landsurface and so are in locations where meteoric karst predominates. Most H_2S-related karstification takes place at greater depths in basins where buried $CaSO_4$ is dissolving and so supplying H_2S via TSR or BSR. In Chap. 9 we shall see that H_2S (sour gas) is a significant fluid component in most carbonate-evaporite basins and that much of this H_2S is produced by thermochemical sulphate reduction. Evaporite-associated examples from the Gulf of Mexico, the eastern US and Canadian shelf, the Mediterranean and the Middle East will be discussed.

H_2S can also be a significant component in fluids hosted in normal marine shelf sediments flushed by altered marine brines. For example, fluids collected during the drilling of the southern Australian continental margin (Leg 182 of the Ocean Drilling Program), show unusually high salinities (to 106‰) in nonevaporitic Miocene to Pleistocene carbonate and siliciclastic sediments (Swart et al. 2000). High contents of H_2S (to 15 %), CH_4 (to 50 %), and CO_2 (to 70 %) were encountered at three drill sites and are associated with H_2S dominated clathrates. Outside of deep seafloor brine lakes, these levels of H_2S are some of the highest yet reported during the history of either the Deep Sea Drilling Project or the Ocean Drilling Program. The high concentrations of H_2S, necessary for the formation of hydrates under these conditions, were provided by the abundant SO_4 tied to the high salinities of the pore fluids, and the associated high concentrations of organic material. One hypothesis for the origin of these fluids is that they were formed by evaporation of brines on the adjacent continental shelf during previous lowstands of sea level. They then sank into the underlying sediments (brine reflux) where their residuals remain today.

High solubility of evaporites underlines the importance of hypogenic rather than epigenic processes during the onset of evaporite karst. Recognition of solubility at depths measured in hundreds of metres has significance implications for storage of hazardous wastes in evaporite beds accessible from the surface. Historically, most karst-specific studies of the WIPP area in west Texas addressed the karst hazard issue utilizing epigenic karst concepts (Bachman 1990; Hill 2003; Lorentz 2006; Powers et al. 2006). This can confuse interpretations of observed permeability features when dealing with hypogenic karst.

Identification of a hypogenic origin for many caves in the Rustler and Seven River Formations (Stafford et al. 2008a, b) and interpretation of regional karst development in the context of hypogenic speleogenesis calls underlines a hazard for the WIPP site in terms of the longterm stability of intrasalt permeabilities. Another historical example of possible concern in the framework of epigene versus hypogene effects would the Neckar nuclear power plant in Germany. It is situated in the Neckar River valley above a multi-aquifer system containing a sulphate bed undergoing dissolution. Ground deformations recorded in the immediate vicinity of the plant and a major 60 m-deep collapse occurred in 1964 a few kilometres away (Klimchouk 2007). Also of possible concern is the Rovensky nuclear power plant in Ukraine, where old and recent collapse and subsidence features were recorded in the immediate vicinity of the plant and induced by hypogenic karst in the confined Cretaceous chalk aquifer, a part of the Volyno-Podol'sky artesian basin.

Mineralised Hypogene Breccias

As they form, or after they form, hypogenic and mesogenetic evaporite solution breccias can act as permeable foci for base metal, sulphur, and hydrocarbon accumulations. Where the dissolving bed contains sulphate evaporites, it can act also as a source of sulphur to base metal sulphide precipitates and so become a locus for ore deposition (Warren 2000b). This is clearly seen in the ores of the now depleted Cadjebut Mine on the Devonian Lennard Shelf, West Australia (Warren and Kempton 1997). Other evaporite associated Pb-Zn deposits, tied to evaporite precursors, are discussed in Chap. 15.

The Cadjebut zinc mine (now abandoned) is situated at the southern margin of the Emanuel Range and is hosted by platform carbonates of probable Givetian age near the base of the Pillara Limestone (Fig. 7.68). The orebody lies approximately 500 m to the north of the Cadjebut Fault and trends subparallel to it over a strike length of 3 km. Surface expression of the orebody is the "No Way Gossan," which crops out 100 m to the west of the mine portal. The orebody is roughly linear in shape, trending toward the northwest and dipping with the host dolomite at 5–10° to the northeast.

Cadjebut Mine had pre-mining reserves of 3.8 million tonnes of 17 % combined zinc and lead. Ore grade mineralization (Zn-Pb) occurs as two stratabound lenses, referred to as "lens 1" and "lens 2" (Fig. 7.69), ranging in thickness from 4 to 6 m. The width of the orebody varies from 50 to 150 m, as defined by a cut off grade of 7 % lead-zinc, and is flanked to the north and south by hypogene alteration haloes of marcasite, calcite and baryte (Tompkins et al. 1994a, b). The contact between ore grade mineralization (>7 % Zn + Pb) and the alteration halo is usually abrupt over a distance of a few metres. In section, the ore-bearing lenses are stacked vertically above one another and separated by about 5–6 m of barren or weakly mineralized dolostone (Fig. 7.69). In

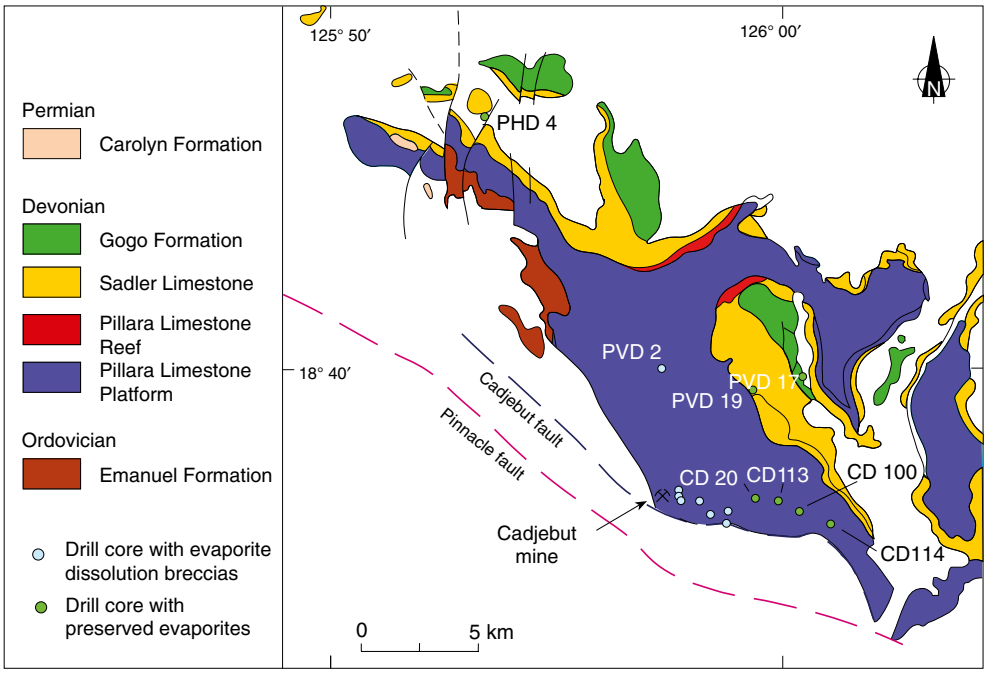

Fig. 7.68 Regional mine geology showing Cadjebut evaporites and mineralisation, also shows selected cored wells with and without evaporites (After Warren and Kempton 1997)

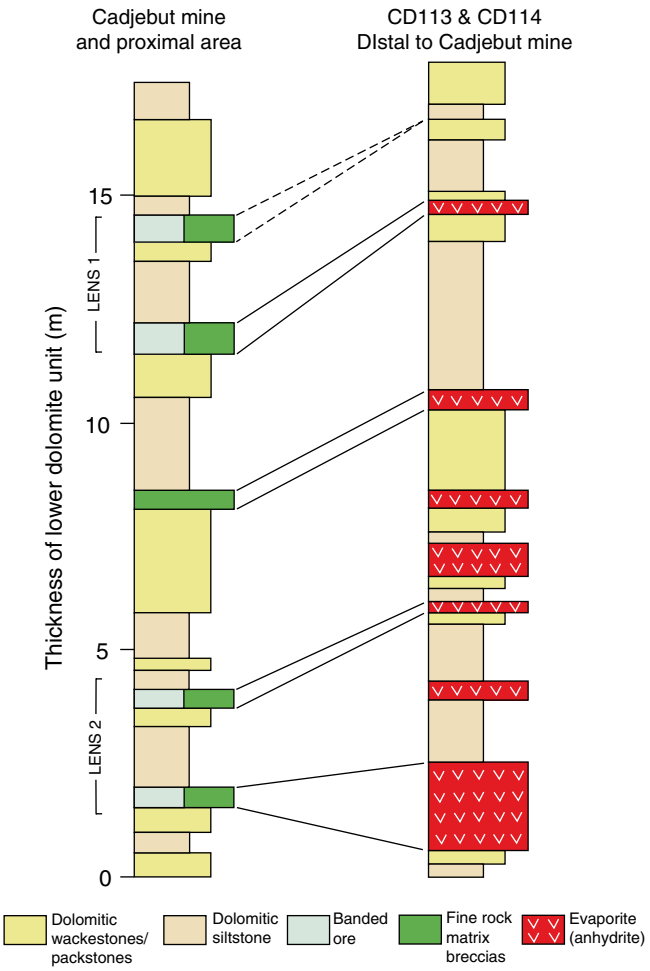

Fig. 7.69 Cadjebut mine area geology, showing lateral correlation passage from ore lense to solution breccia to equivalent evaporite bed in more distal positions from mine. See Fig. 7.68 for locations (After Warren and Kempton 1997)

plan view, both ore lenses have a broad sinusoidal shape and display the same geometrical congruence.

Two dominant ore types are present (Fig. 7.70): (a) stratiform, rhythmically banded zinc-rich ore; and (b) stratiform to stratabound, lead-rich breccia-hosted cavity-fill ore. The rhythmically banded ore occurs as four stratiform horizons, two throughout lens 2 and two in the northern part of lens 1. Rhythmically banded baryte and/or rhythmically banded marcasite form a halo around the orebody and are associated with the rhythmically banded zinc-rich ore.

There is a one-to-one correlation of sulphide-mineralised horizons in the Cadjebut Mine with evaporite dissolution breccia horizons in the immediate area around the mine, and with remnant bedded anhydrite units away from the mine (Fig. 7.69). Calcium sulphate beds were the precursor lithology to the sulphide ore lenses at Cadjebut. The stratabound linear nature of the Cadjebut deposit reflects a time when upwelling metalliferous basinal fluids interacted with bedded stratiform nodular anhydrite beds and trapped hydrocarbons to precipitate lead and zinc sulphides. Current structure in the mine region still preserves a gentle drape anticline, which Warren and Kempton (1997) interpret as a partial artifact of the mineralisation structure, enhanced by the sequential loss of the surrounding evaporites, after ore had locally replaced a bedded anhydrite precursor. The linear nature of the anticlinal structure indicates some form focusing of ore fluids and hydrocarbons, either atop an active underlying fault, or within a pre-existing anticlinal trap, perhaps created as a rollover drape on the edge of a evaporite-dissolving front (e.g. Fig. 7.71a). Hydrocarbon residues (bitumens) are still present in the ore zones.

The rate of evaporite dissolution versus the rate of supply of mineralising fluid controlled the large scale textures

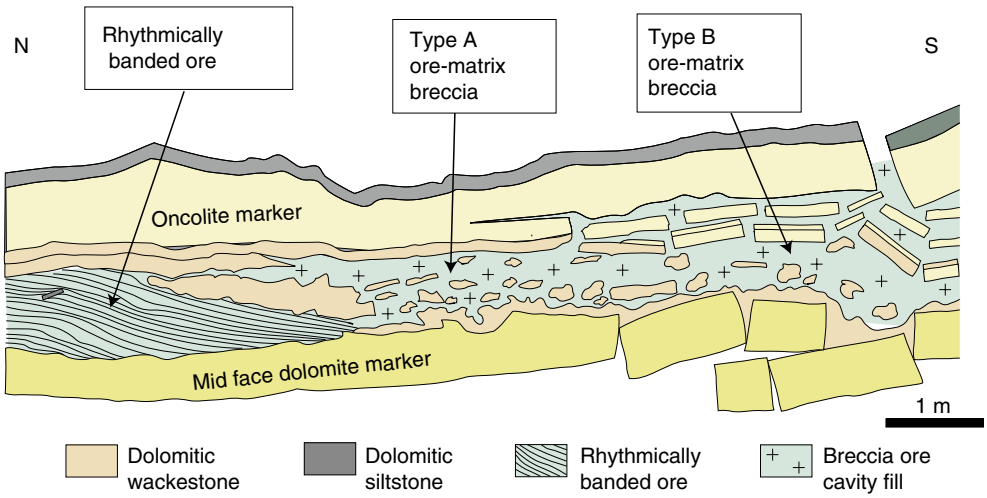

Fig. 7.70 Ore types in the Cadjebut Mine based on mapped mine panels (After Warren and Kempton 1997)

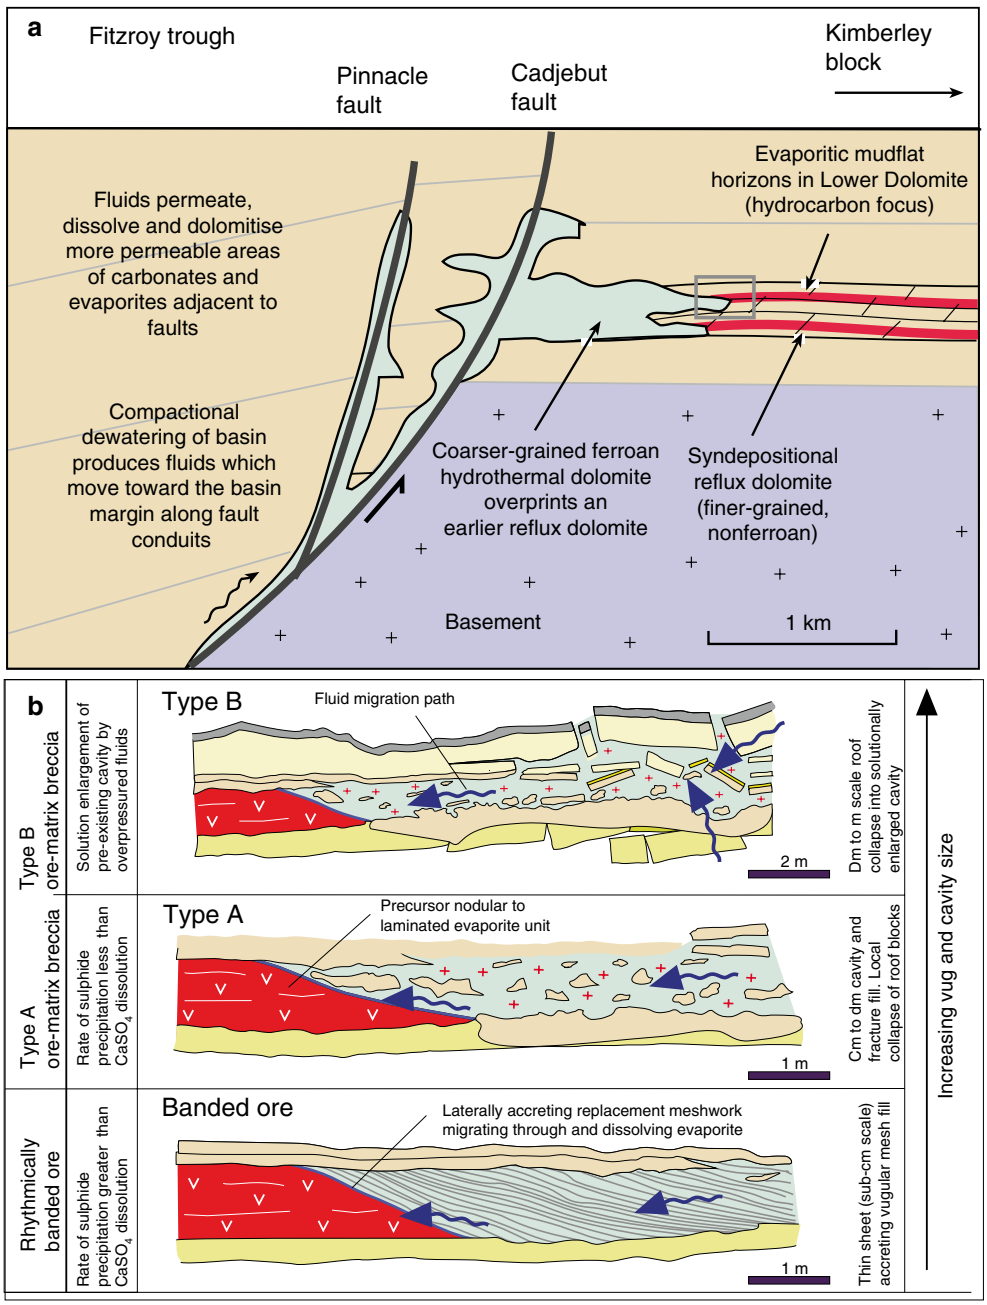

Fig. 7.71 Cadjebut MVT ore, NW Australia. (**a**) Schematic cross section showing the relationship between basinal fluids moving up along regional extensional faults to act as sources for burial dolomite in the platform carbonates, and the focusing/replacement effect of sulphate beds in the evaporitic mudflat sediments of the Lower Dolomite (rectangle indicates zone of sulphide mineralisation. (**b**) Schematic showing controls on ore texture reflect an interplay between rate of supply of metalliferous fluid and the rate of evaporite dissolution (After Warren and Kempton 1997)

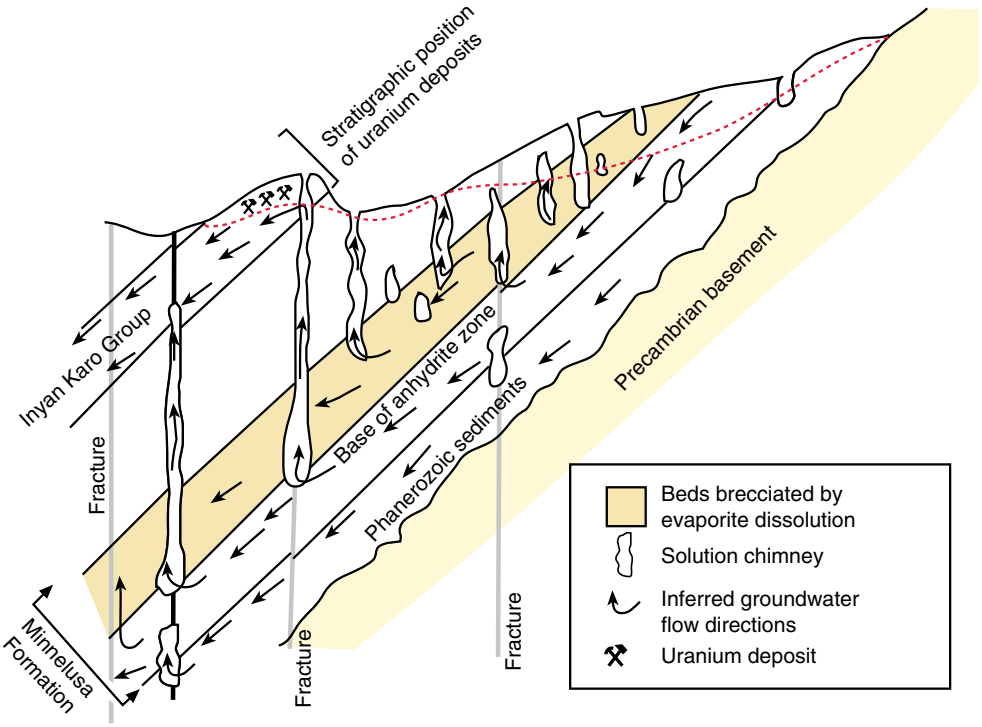

Fig. 7.72 Infiltrated uranium mineralisation in the Cretaceous Inyan Kara Group sand-stones, southern Black Hills (South Dakota). Solution collapse chimneys and breccias in the Late Palaeozoic Minnelusa Formation transport uraniferous groundwaters to precipitation sites (Modified from Gott et al. 1974)

within the Pb-Zn ores (Warren and Kempton 1997). Lead-zinc mineralisation in the Cadjebut Mine occurs as three distinct ore types (Fig. 7.71b):

- Stratiform rhythmically-banded zinc-rich ore,
- Stratiform Type A ore-matrix breccia ore, and
- Crosscutting Type B ore matrix breccia ore.

The rhythmically-banded ore formed under conditions where the potential for sulphide precipitation exceeded the rate of evaporite dissolution. This occurred in cm-sized laminar dissolution meshworks that ate their way into the anhydrite beds (Fig. 7.71b). Millimetre-laminated colloform to pendulous microstalactitic sphalerites were the dominant precipitates. Type A ore matrix breccia formed in irregular cm-dm stratabound cavities. These formed at times when the rate of sulphide precipitation was slower than the rate of sulphate dissolution. Such hypogene cavities were not sufficiently large to instigate catastrophic roof collapse. Type B ore-matrix breccia ores formed in dm-metre sized crosscutting cavities, fractures and veins. Cavern space was sufficiently large to allow the single-event roof span collapse and rotation of metre-sized roof blocks into the caverns. Type B ore-matrix breccias are lead-rich compared to the banded ore and are interpreted by Tompkins et al. (1994a, b) to postdate the formation of banded ore. All the Cadjebut ore textures were created from sulphate supplied by the dissolving evaporites across mm-dm-sized replacement fronts or meshworks under deep bathyphreatic and likely overpressured gassy conditions (Warren and Kempton 1997).

Evaporite solution breccias can also focus the deep-meteoric confined flow of radiogenic hypogene groundwaters and so control the distribution of economic uranium deposits. For example, in the uranium district of southern Black Hills, South Dakota, Gott et al. (1974) showed how an extensive blanket of collapse breccia and trans-stratal breccia chimney fills were produced by the dissolution of gypsum and anhydrite beds in the upper part of the Late Palaeozoic Minnelusa Formation (Fig. 7.72). Up to 83 m of evaporites were removed and numerous breccia chimneys were created that extend up to 430 m vertically into Cretaceous continental sandstones of the Inyan Kara Group (Fig. 7.72). The chimney fill consists of downward displaced sandstone blocks that were later cemented by calcite.

As breccia pipes stoped toward the surface, Gott et al. (1974) argue that this phreatic chimneys created a plumbing system through which artesian oxidised waters leached and transported uranium from deeply buried uraniferous sands and granites up into the Cretaceous section (Fig. 7.16a). There they encountered organic-entraining Cretaceous sands and so precipitated carnotite-dominated infiltrations along redox mixing interfaces in water-filled cavities.

Filled Vugs and Nodules

Replaced nodules and characteristic vug shapes are some of the most used indicators for the former presence of evaporites in both the core and outcrop (Table 7.2). They typically define former crystal clusters and nodules of gypsum,

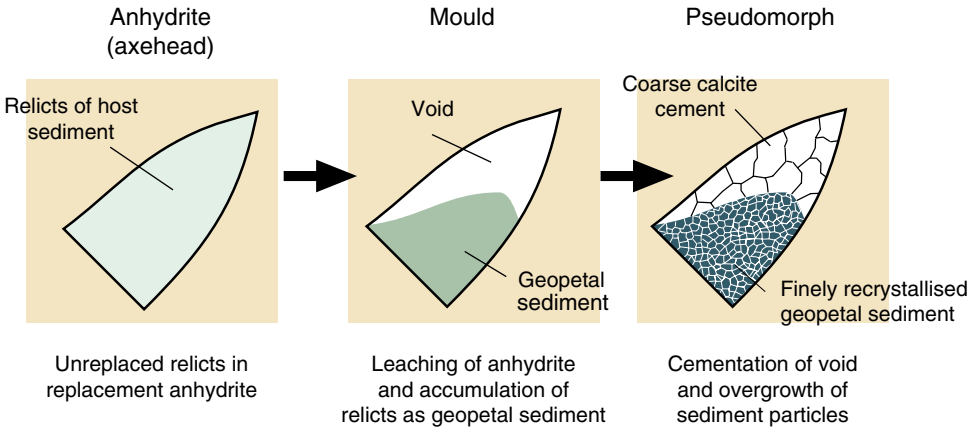

Fig. 7.73 Replacement of axe-head anhydrite by carbonate spar showing how void shape needs to be preserved for reliable genetic interpretation. The fill is also a geopetal

anhydrite or halite in a matrix composed of mud or silt. Unlike the interiors of halite or anhydrite beds, buried evaporite nodules in a non-evaporite matrix are not isolated from the ongoing effects of crossflowing nearsurface and basinal waters. Whenever an undersaturated pore fluid flushes the matrix, it also dissolves or replaces the salts. So, the burial evolution of an evaporite crystal cluster on its way down is typified by leaching of the soluble salt and its replacement by the pseudomorphing mineral phase, typically a carbonate spar or silica, with internal layering that preserves the thermal and chemical history of the cross-flowing pore waters.

Resultant replaced crystals and vug fills are composed of varying combinations of silica, calcite, dolomite, celestite, baryte and strontianite. Internal textures and nodule fabrics can be spectacular and include; linings and splays of silicified and calcitised evaporite crystallites, evaporite moulds and residues, calcitised evaporitic dolomites (dedolomites), cross-cutting drusy dissolution veins and solution enlargement fabrics, with late stage hydrothermal precipitates often infilling the last porosity. Despite the diagenetic complexity, most nodules and vugs mimic the shape of the evaporite parent and this typically leads to recognition of the evaporite connection. When mineralised and exhumed, the vug-fill can weather out of the softer matrix to create dispersed surfaces of nodules or clustered piles, leading to colourful descriptions of such outcrops as "Mendip potato stones" and "Bristol diamonds."

An open vug in a rock indicates that something has dissolved, while a nodule composed of chert or calcite indicates that something has been replaced or filled. Deciding whether or not that something had an evaporite forebear is frequently dependent on shape and texture. Smooth walled nodules, especially ones now composed of chert or baryte, are a commonplace diagenetic replacement in normal marine sediment and need not indicate an evaporite precursor. A reliable evaporite indication of a syndepositional $CaSO_4$ nodule only comes if the rugose irregular surface texture and the shape of the precursor anhydrite nodule or layer remains. In other words, nodules with surfaces of irregular ridges and vugs, textured like the flowerets of a cauliflower, likely indicate an evaporite antecedent. Such nodules are usually described as "cauliflower" textured (e.g. cauliflower chert or cauliflower vug). If Magadi-style silicate gels were the nodule's parents, then nodule surface should show remnant crocodile-skin texture. Without this, or if only smooth walled nodules shaped like cucumbers and melons are present then a thin section of the nodule, especially of its outer portion is needed as this is where small relict crystallites or replaced lath outlines indicative of former salts may still be visible.

Similarly, if single coarse-grained crystals or crystal clusters (desert roses) were either dissolved or replaced and now constitute open or filled moulds, then the original crystal shape should be clearly discernable in order to reliably proclaim its parenthood (Fig. 7.73). If lenticular gypsum was replaced, it should have the bird-beak shape of its precursor, while lenticular anhydrite replacements may be axe-head or barrel shaped (Figs. 1.29 and 1.45). If displacive halite clusters were replaced there should be evidence of cubes and hoppers on the outside of the vug or nodule.

Preservation of the shapes of evaporite crystals with similar outlines creates difficulties when trying to separate silicified replacements of beds of growth-aligned gypsum from beds of nahcolite/trona. Yet it is the separation of these pseudomorphs that is the fulcrum to arguments such as the nature of early Archaean seawater. Both gypsum and trona have a monoclinic bladed form and both can form nodules or grasslike beds of growth-aligned prisms. Once the actual salt has gone, defining original salt mineralogy and separating crystals with similar shapes using partly altered pseudomorphs can be very difficult.

Silicified Evaporites

Silicified anhydrite nodules and $CaSO_4$ crystals are widely reported and reliably documented in sediments as old as Early Archaean and as young as Holocene (Table 7.14).[16]

[16]Quartzine is a form of chalcedony composed of fibres having a positive crystallographic elongation parallel to the c axis.

Table 7.14 Selected examples of silicified evaporites

Occurrence and age of host	Comments	Reference
Silica precipitates in Holocene alkaline lakes along the Coorong coastal plain, South Australia. Type area for "Coorong style" chert.	Direct precipitation (?bacterially mediated) of opal-cristobalite in small mm-scale vugs in and on the surface of tepee-overprinted strandzone magnesite/dolomite crusts around the edge of Milne Lake and probably in crusts in other lakes accumulating evaporitic lacustrine dolomite, magnesite, hydromagnesite, aragonite and gypsum.	Peterson and Von der Borch (1965)
Nodules and polygons of chert in diatomaceous beds of the late Pleistocene High Magadi beds, Lake Magadi, Africa. Type area for "Magadi-style" chert.	Chert in nodules and polygons is a weathering product of sodium silicate gels. Conversion involves shrinkage and induration. It creates a characteristic "crocodile-skin" texture on the surface of newly formed chert. This texture is associated with soft sediment deformation in the surrounds and sodium carbonate salts in adjacent sediments.	Eugster (1967), Jones et al. (1967), Hay (1968)
Pleistocene nodules in saline mudflats, Lake Olduvai, Africa.	Magadi-style chert nodules (crocodile-skin) formed by replacement of a sodium silicate (magadiite) precursor.	Hay and Kayser (2001)
Double-terminated euhedral quartz in Pleistocene sabkha dolomite, offshore Al Jabyl, Saudi Arabia (Pleistocene "Herikimer diamonds").	Megaquartz as individual crystals and clusters of crystals and overgrowths on detrital quartz. Individual crystals up to 1 mm long, many with shallow dolomite mould impressions on their crystal faces, some partly, or completely, engulf dolomite rhombohedra.	Chafetz and Zhang (1998)
Gypsum-rich silica nodules, Moghra Formation, Miocene, Northwest Qattara depression, Western Desert, Egypt	Nodules occur in two shale horizons, consist mainly of quartz and are composed of gypsum-free matrix and gypsum-rich megacrystalline quartz. The matrix consists of microflamboyant quartz (less than 36 μm in diameter) and chalcedony. The megacrystalline quartz occurs as lenticular and prismatic forms (length: 90–250 μm; width: 30–90 μm). Structure of the silica nodules begins with quartzine in its outer rim, then gypsum-free microcrystalline quartz in the middle part and ends with gypsum-rich lenticular to prismatic megaquartz in the nodule center.	Khoriby (2005)
Chert nodules in gypsiferous limestones of the Kef Eddour Member (Ypressian-Priabonian- Eocene) near Metlaoui and Sehib (Tunisia)	Silica with $\delta^{18}O$ values from +25 to +28.6 ‰ (SMOW)]replaced the outer parts of anhydrite nodules at pH < 9. In contrast, pore-fluid pH values > 9 in the innermost parts of the anhydrite nodules prevented silica precipitation. This chemical barrier is preserved in the microquartz rims left after dissolution of the remaining anhydrite.	Henchiri and Slim-S'Himi (2006)
Quartz geodes and nodular chert in Campanian (Cret.) marly clays and calcarenites, Basque-Cantabrian Basin, Northern Spain.	Silica replacement of cauliflower geodes and chert as spherulitic fibrous quartz (quartzine-lutecite). There are small anhydrite laths included in some of the megaquartz crystal fills.	Gomez-Allday et al. (2002)
Quartz geodes and chert hosted in Triassic red mudstones, Bristol district of the UK.	Silica replacement in open voids after cauliflower textured anhydrite. Loose euhedral double-terminated quarts crystals aggregating on bottom of some geodes after the $CaSO_4$ is dissolved and are called "Bristol Diamonds."	Tucker (1976a)
Nodules developed in a single layer in Bundsandstein (Triassic) redbeds, Iberian Range, Central Spain.	Cauliflower shaped chert nodules and geodes, some are filled with concentric layers of quartz and carbonate, others are still open and partially filled and fractured. Relict anhydrite textures and rare laths, bacteria played a role in dolomitisation of some nodules.	Alonso-Zarza et al. (2002)
Chert nodules in Triassic of North Carolina, USA.	Cauliflower chert with relict anhydrite.	Wheeler and Textoris (1978)
Nodules and crystals in Lower Purbeck Beds, (Jurassic) Dorset, UK.	Silica replacement of individual and clustered gypsum bird-beaks and enterolithic anhydrite nodules (with small relics of anhydrite preserved).	West (1964, 1973)
Discrete horizons, scattered nodules in layers and individual replaced crystals in Seven Rivers, Yates and Tansill formations, Guadalupe Mountains, (Permian) Delaware Basin, USA.	Cauliflower nodule and geodes. Nodules, bird-beak gypsum, axehead anhydrite were all replaced by silica and calcite spar. Initial replacement by black megaquartz (with anhydrite, dolomite, water and hydrocarbon inclusions). This was followed by blocky calcite spar fill of voids created by late-stage dissolution of remaining anhydrite (telogenetic).	Ulmer-Scholle et al. (1993)
Thin layers of chert nodules in fluvio-lacustrine muds sandwiched in acidic volcanics of the Lower Permian Bolzano Volcanic Complex, Northern Italy.	Magadi-style chert showing soft-sediment deformation and shrinkage cracks (crocodile-skin), imply a sodium silicate parentage. Transformation to quartz and concomitant (re)crystallization created a variety of silica textures, dominated by microflamboyant quartz.	Krainer and Spötl (1998)
Fist-sized nodules and geodes in layers and dispersed zones in Fort Payne Fm., Warsaw Limestone, St Louis Limestone (Mississippian) of south-central Kentucky and Tennessee, USA.	Concludes that megaquartz characterized by strong undulose, radial extinction, the existence of anhydrite laths included in megaquartz crystals with 'cubic' appearance terminations, the growth of spherulitic, fibrous-radial quartz aggregates (quartzine-lutecite), and crusts of zebraic chalcedony are all evidence of silica replacing anhydrite nodules.	Milliken (1979)

Occurrence and age of host	Comments	Reference
Fist-sized nodules and layers in Fort Payne Fm. and Warsaw Limestone, (Mississippian) near Woodbury, Tennessee, USA.	Silica replacement of anhydrite to form cauliflower cherts with outlines reminiscent of the nodules in the Abu Dhabi sabkha. Soft sediment deformation in the surrounding matrix argues silicification took place prior to complete induration of matrix. Silica was derived from sponge spicules.	Chowns and Elkins (1974)
Silicified nodules and clasts representing anhydrite pseudomorphs in Mississippian Wexford Fm., Ireland.	Evaporites indicators mostly as chert nodules and clasts representing pseudomorphs of former now silicified gypsum within the breccia unit and also as distinct anhydrite/gypsum beds, over 2 m thick, within the breccia and as rare gypsum veins.	Nagy et al. (2005)
Silicified anhydrite nodules, Pimenta Bueno Formation, Siluro-Devonian in the Parecis Basin, central Brazil.	The playa-lake deposits show early diagenetic dolomitisation of lime mud, precipitation of anhydrite nodules and extensive silicification. Theses anhydrite nodules were replaced by gypsum and chalcedony during telodiagenesis.	Goldberg et al. (2011)
Pseudomorphs after anhydrite in the Mines Subgroup (Neoproterozoic), in the Katangan Copperbelt, Democratic Republic of Congo.	Silicified anhydrite defines oval, round and cauliflower-shaped nodules, or in lenses that may be wedge-shaped, or as laths. There are two main types of siliceous replacement and cementation. Type 1: dolomite precipitated first and was replaced by Cu–Co sulphides and authigenic quartz. Relicts of anhydrite and halite are still present. Type 2, authigenic quartz and sulphides precipitated prior to dolomite and the crystals are free growing	Muchez et al. (2008)
Palaeoproterozoic chert nodules in the Bartle Member (2.2 Ga) of the Killara Formation, Yerrida Group, Yerrida Basin of Western Australia	Association indicates an evaporitic-pyroclastic-thermal-spring environment associated with rifting at about 2.2 Ga. The chert member contains silica pseudomorphs after evaporite minerals that in places enclose relict isolated crystals and aggregates of crystals of gypsum and anhydrite. The evaporite minerals are associated with minerals such as baryte and analcime	Pirajno and Grey (2002)

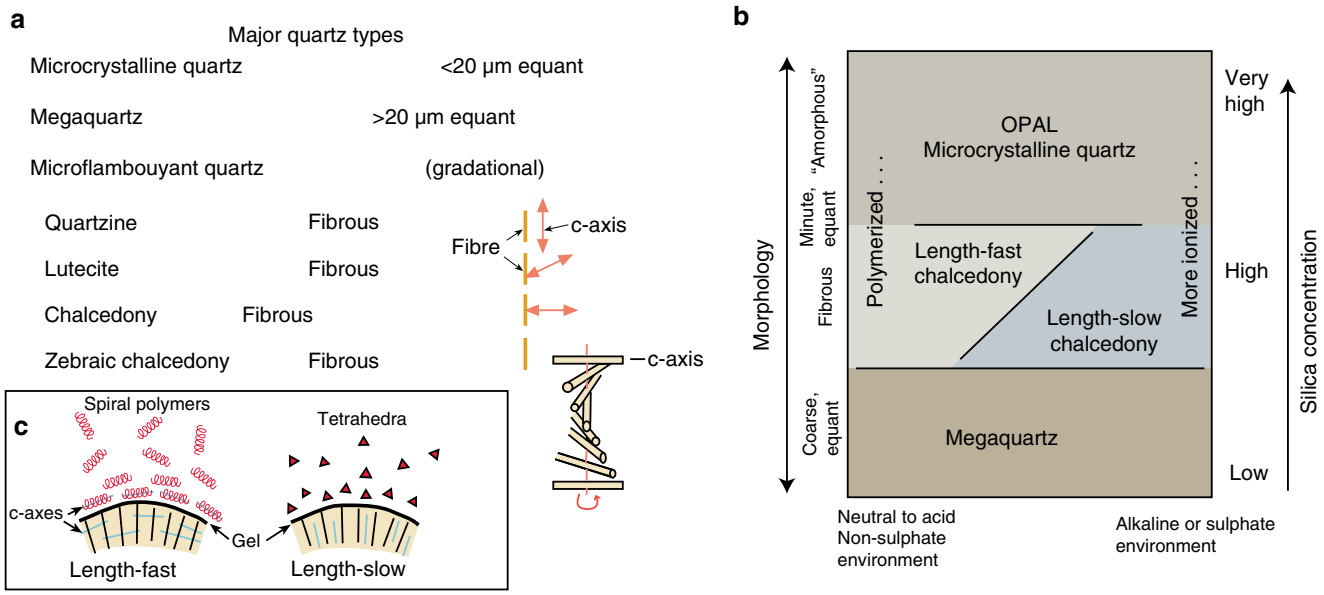

Fig. 7.74 Chalcedony as an indicator of vanished evaporites. (**a**) Major quartz types based on crystal size and orientation of chalcedony fibres with respect to c-axis (After Milliken 1979). (**b**) Style of chalcedony precipitate is controlled by the degree of polymerization, which in term reflects environment of precipitation. (**c**) Crystallite orientation (single tetrahedra versus spiral polymers) with respect to growth surface controls formation of length slow versus length fast crystals – see text (**b** and **c** after Folk and Pittman 1971)

Quartzine and lutecite[17] (aka length-slow chalcedony) typically infill or replace nodules that preserve characteristic cauliflower shapes of the antecedent anhydrite/gypsum nodule (Fig. 7.74a; Arbey 1980; Hesse 1989). According to Folk and Pittman (1971), rates of nucleation and crystallization are the main controls on crystal size and variety of silica precipitating in a void in a dissolving nodule. Rates in turn depend on the level of silica saturation or its concentration in the mother brine (Fig. 7.74b, c). According to Keene (1983), precipitation of length-slow quartz is favoured in waters with high SO_4 and Mg levels.

[17]Lutecite is a form of chalcedony characterised by fibres that are seemingly elongated about 30 °C to the c axis.

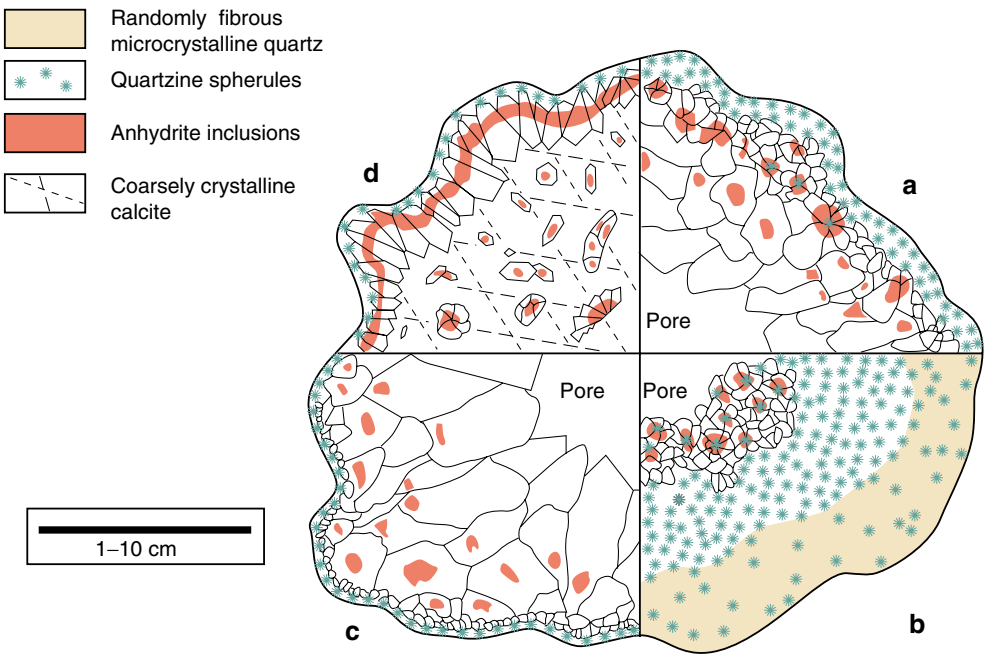

Fig. 7.75 Texture in silicified-calcitized anhydrite nodules. (**a**) Most common style of nodule with thin rim of spherulitic quartzine followed inward by megaquartz characterised by increasing crystal size and with frequent anhydrite inclusions. (**b**) Nodule with a large proportion of fibrous quartz. Thick rim of spherulitic quartz passes inward to strongly undulose megaquartz. Some of the megaquartz has anhydritic nuclei. (**c**) Nodule with a thin rim of spherulitic quartzine passing inward to a large proportion of megaquartz. (**d**) Nodule with megaquartz rim and an interior filled with calcite. Calcite may have filled a cavity or replaced earlier silica. Late stage cavity-fill calcite is often defined by a thin rim of authigenic baryte or sulphide, prior to precipitation (Modified from Milliken 1979)

High (alkaline) pH levels in the mother solution tend to ionize dissolved silica. Neutral or low pH levels favour silica crystallites made up of combined $Si(OH)_4$ groups. These tend to polymerise into spiral chains at lower pH and higher concentrations. At high concentrations and high pH the silica precipitates possess a fibrous chalcedonic form reflecting their rapid rates of precipitation. High pH at the precipitation site means silica crystallites also tends to be present in solution as single ionized tetrahedra that attach themselves one by one to the growing surface, so creating fibres of quartz with the c axes oriented parallel to the long axis of the growing fibres (length-slow). Under low pH or in non-sulphate settings the silica is polymerized into spiral silica chains that attach tangentially to the growth surface of the silica gel, with their c-axes parallel to the growing crystal surface and perpendicular to the eventual direction of the fibres (Fig. 7.74c; length-fast; Folk and Pittman 1971).

Milliken (1979) summarised the typical petrographic and hand specimen scale features of silica that replaced $CaSO_4$ nodules in Mississippian sediments of southern Kentucky and northern Tennessee (Fig. 7.75). Such nodules typically have knobbly irregular cauliflower-like surfaces, while diagnostic internal textures include: (1) length-slow chalcedony after lathlike evaporites, especially anhydrite; (2) quartzine; and (3) small amounts of lutecite associated either with megaquartz that shows strong undulose extinction, or with euhedral megaquartz (Chowns and Elkins 1974). The megaquartz often encloses small blebs of residual anhydrite.

Many buried calcium sulphate nodules are silicified in a multistage process that involves both replacement and void filling (West 1964; Chowns and Elkins 1974). The process commences about the margins of a nodule (stage 1) with a volume for volume replacement of anhydrite by microcrystalline quartz. It normally ends with the growth of euhedral drusy quartz crystals into a central vug (stage 2 and 3). This mode of replacement exemplifies textural changes as seen from the edge toward the centre of the geode in texture style A in Fig. 7.75. However, as noted by Milliken (1979) this edge inward evolution of the geode or nodule fill is typified by a variety of textural styles, which she denoted a styles A through D.

Stage 1 chalcedony or quartzine mimics or pseudomorphs the felted lath textures of the precursor anhydrite in the outer portion of the nodules in all styles. Anhydite pseudomorphs occur as radiating or decussate aggregates with a distinctive flow-like pattern indicating a felted anhydrite precursor. Identical decussate and flow textures occur in laths that make up sabkha anhydrite nodules and define their explosive mode of growth (Fig. 1.45). As well as silicified lath microtextures, outlines of larger crystals that predated anhydritisation and silicification may be preserved by the nodule margin, these crystal outlines vary from prismatic to bladed. Many silicified nodules still retain the knobbly cauliflower outline of its

precursor anhydrite, other nodule edges preserve the interfacial outlines of gypsum or trona or borate precursors.

Stage 2 microquartz and quartz fill can assume euhedral faces as they grow into voids created by the dissolution of the nodule. At the same time the quartz may continue to engulf and pseudomorph small areas of residual anhydrite or other less common evaporite salts (e.g. styles A, C, D). Quartz crystals precipitated at this stage are commonly zoned, with more anhydrite inclusions found within the inner zone of the pseudomorph. Some quartz crystals are doubly terminated and probably grew via the support of a dissolving meshwork of anhydrite (Friedman and Shukla, 1980). With the final dissolution of the supporting mesh these quartz crystals sometimes dropped to the floor of the void to create a geopetal indicator. For example, such highly birefringent anhydrite spots define cauliflower nodules in 2.2 Ga sediments in the Yerrida Basin, Australia (El Tabakh et al. 1999a).

Stage 3, the final stage of the void fill is typified by the precipitation of coarse drusy euhedral quartz with no included anhydrite. This coarse quartz resembles coarse vein quartz.

Sometimes the processes of void fill may be arrested to leave a hollow core in the silica-lined geode (styles A, B, C). The void may be filled by a different burial stage cement such as baryte, sparry carbonate (e.g. ferroan dolomite or calcite), or even metal sulphides. This is the case with the large (up to 1 m diameter) silicified cauliflower-shaped anhydrite nodules of Proterozoic Malapunyah Formation of the McArthur Basin in Northern Australia where baryte, then metal sulphides and then sparry calcite typify the latter stages of void fill (pers. obs.). Similar fracture-filling baryte characterises the later diagenetic stages of silicified and calcitised anhydrite nodules in the Triassic Bundsandstein redbeds of the Iberian Range of central Spain (Fig. 7.84; Alonso-Zarza et al. 2002). Such geodes are typically excellent indicators of burial cement stratigraphy in a mudstone matrix that otherwise preserves few indicators of the evolving pore fluid chemistry.

Cauliflower chert may retain no evidence of former anhydrite lathes mimicked in chalcedony, but can be completely filled by various styles of coarser-grained megaquartz. The resulting nodules still retain the outline of the precursor evaporite nodule (Fig. 7.75). Work on diagenetic timing of numerous silicified $CaSO_4$ nodules (e.g. Milliken 1979; Geeslin and Chafetz 1982; Gao and Land 1991; Ulmer-Scholle and Scholle 1994) shows that most silica replacement begins with shallow burial, either in the zone of active phreatic flow or in the upper portion of the zone of compactional flow (probably at depths of less than 500–1,000 m). Early silica replacement in the zone of active phreatic flow is indicated by a lack of compressional flattening of the nodule, by the preservation of delicate surface ornamentation and the preservation of compactional drapes around replaced nodules. If replacement of an anhydrite nodule occurs later in the burial cycle, many anhydrite nodules have by then become flattened or sluggy and no longer retain a rugose surface. The result can be a series of "cucumbers" rather than "cauliflowers."

Milliken's (1979) isotopic evidence implies much silica replacement in the nodules she studied was relatively early in the burial cycle at temperatures that were <40 °C. Silica was supplied by throughflushing pore fluids with compositions ranging from seawater to mixed meteoric-seawater. Of course, nodule replacement by silica or calcite does not have to happen on the way down in the burial cycle, it may also happen during uplift back into the telogenetic realm, where the strata have once again entered the zone of active phreatic flow.

Historically, there were no documented examples of the process of evaporite replacement by quartz in Quaternary sediments. Now, autochthonous, doubly-terminated, euhedral megaquartz crystals have been observed infilling voids in a gypsum- and anhydrite-bearing Pleistocene sabkha dolomite sequence in the Arabian Gulf, as well as forming overgrowths on detrital quartz grains (Chafetz and Zhang 1998). These siliceous sabkha precipitates are forming within metres of the present sediment surface with a silica source that is probably recycled biogenic material. Individual quartz crystals attain lengths of 1 mm. Many quartz crystals faces preserve impressions of dolomite rhombs or they partly, or completely, engulf dolomite rhombohedra. This process of replacement is early burial, to see the full suite of silica replacement textures and the variations in timing of the replacement means one must study ancient evaporite sequences.

Overall, the texture of silica infill or replacement in a nodule is dependent on the rate of sulphate dissolution, timing of silica precipitation and rate of silica supply. Some nodules are dominated by the early *lit par lit* replacement textures (styles A and C in Fig. 7.75), others have textures indicating silica cements growing into an open phreatic void left after the complete dissolution of the $CaSO_4$. Such nodules may still retain a hollow centre where the anhydrite once resided (Fig. 7.76). When a silica-filled geode did not start to accumulate silica until after all the $CaSO_4$ dissolved, the main evidence for an evaporite precursor comes from the shape of the replaced nodule and its stratigraphic position within the evaporitic depositional sequence, e.g. beneath an erosional surface that defines the top of the capillary zone.

Not all the anhydrite nodules, now replaced by silica, were syndepositional. Maliva (1987) showed that nodular anhydrite parent, now indicated by quartz geodes in the Sanders Group of Indiana, first precipitated in the subsurface, while its surrounding matrix of normal marine Sanders Group sediment was still unlithified (Fig. 7.77). Anhydrite nodules formed in the subsurface during early burial as hypersaline reflux brines sank into the normal marine

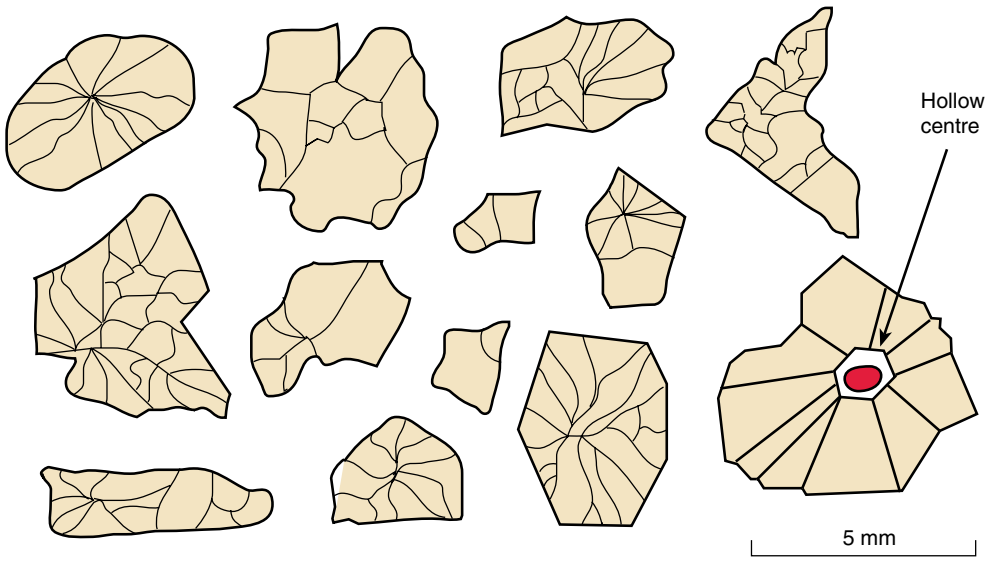

Fig. 7.76 Sketches showing various shapes of the quartz nodules and internal arrangements of megaquartz crystals from replaced anhydrite nodules in the Mesoproterozoic Wollogorang Formation of northern Australia and the Neoproterozoic Gaissa Sandstone/Porsanger Dolomite of Finnmark, Arctic Norway (In part modified from Tucker 1976b)

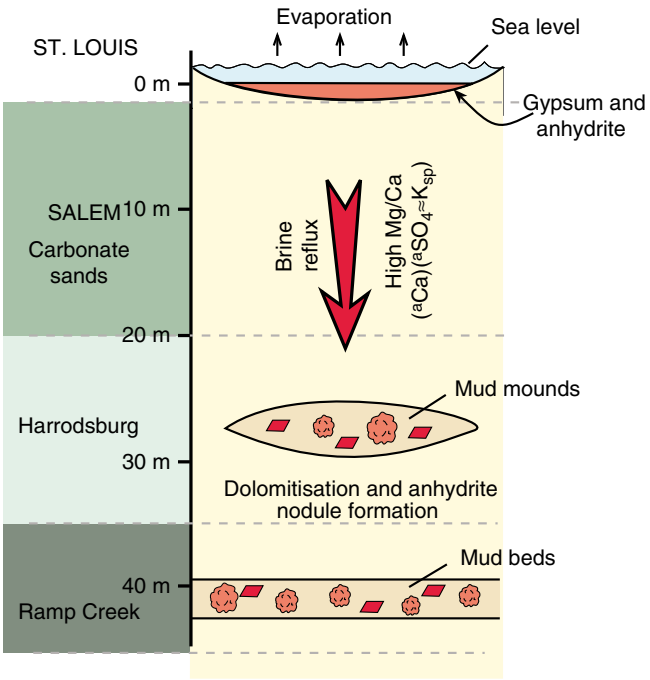

Fig. 7.77 Precipitation of anhydrite and gypsum during St. Louis Limestone deposition formed a dense magnesium- and sulphate-rich brine that percolated downward and seaward through the then unlithified sands of the Salem Limestone. Dolomitisation of carbonate mud mounds and beds in the Harrodsburg and Ramp Creek Formations released calcium causing pore waters to become supersaturated with respect to anhydrite, resulting in the precipitation of anhydrite nodules that were later silicified (After Maliva 1987)

limestones of the Ramp Creek and Harrodsburg Formations. Silica subsequently replaced the anhydrite. These geodes are almost invariably associated with the development of reflux dolomite.

Similarly, not all silica-replacing anhydrite in a particular region need come from the same source or be emplaced by the same set of processes. Silicified nodules within middle-upper Campanian (Cretaceous) carbonate sediments from the Lafio and Tubilla del Agua sections of the Basque-Cantabrian Basin, northern Spain preserve cauliflower morphologies, together with anhydrite laths enclosed in megaquartz crystals and spherulitic fibrous quartz (quartzine-lutecite). All this shows that they formed by ongoing silica replacement of nodular anhydrite (Fig. 7.78; Gómez-Alday et al. 2002). Anhydrite nodules at Lafio were produced by the percolation of saline marine brines, during a period corresponding to a depositional hiatus. They have $\delta^{34}S$ and $\delta^{18}0$ mean values of +18.8 and +13.6‰ respectively, consistent with Upper Cretaceous seawater sulphate values. Higher $\delta^{34}S$ and $\delta^{18}0$ (mean values of +21.2 and 21.8‰ characterise nodules in the Tubilla del Agua section and are interpreted as indicating a partial bacterial sulphate reduction process in a more restricted marine environment (Fig. 7.78a). Later calcite replacement and precipitation of geode-filling calcite in the siliceous nodules occurred in both sections, with $\delta^{13}C$ and $\delta^{18}0$ values indicating the participation of meteoric waters in both regions (Fig. 7.78b). Synsedimentary activity of the Penacerrada diapir (Kueper salt – Triassic), which lies close to the Lafio section, played a significant role in driving the local shallowing of the basin and in the formation of the silica in the nodules. In contrast, eustatic shallowing of the inner marine series in the Tubilla del Agua section led to the generation of morphologically similar quartz geodes, but from waters not influenced by brines derived from the groundwater halo of a diapir.

The chemistry that controls the precipitation of silica as it replaces calcium sulphate in early diagenesis is not well understood. Is it a response to biogenic or abiogenic changes in pH and alkalinity? When opal cristobalite was observed filling mm-scale fenestral vugs in strandzone crusts in a Holocene dolomite/magnesite lake in the Coorong it was

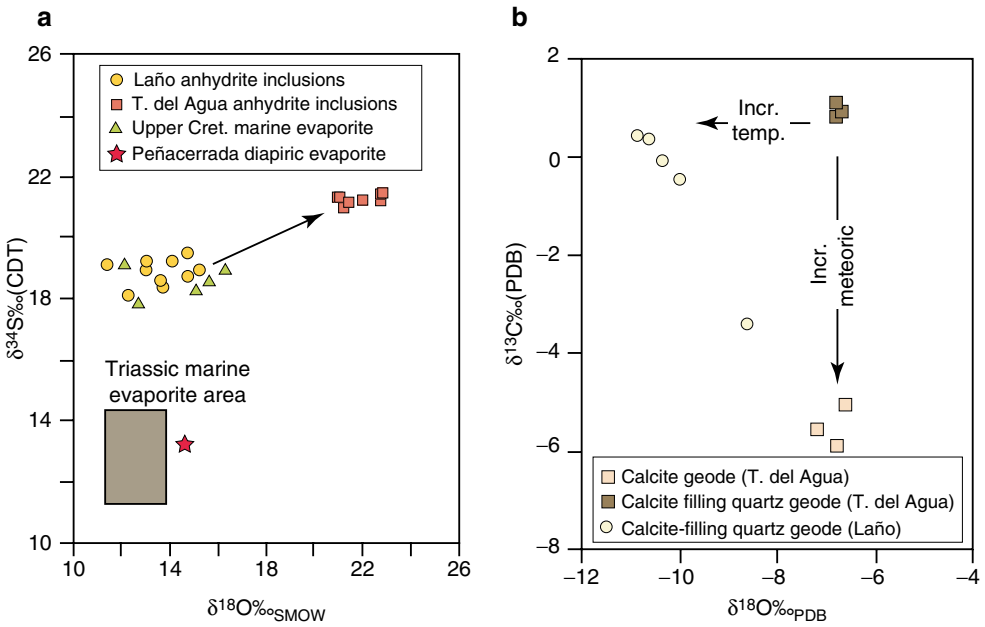

Fig. 7.78 (**a**) Plot of oxygen versus sulphur isotope composition of the Laño and Tubilla del Agua anhydrite inclusions together with other Triassic and Upper Cretaceous evaporite values from Spain. (**b**) Oxygen versus carbon isotope composition of the Laño and Tubilla del Agua calcites. The Tubilla del Agua values define a vertical meteoric calcite line where the lighter ^{13}C values indicate the vadose zone while the higher values denote a phreatic zone. More negative ^{18}O values from the Laño section indicate an increase in temperature of the pore-waters

considered an inorganic precipitate (Peterson and Von der Borch 1965). It formed where the pH of surface waters fluctuated between 10.2 and 8.5, and the seasonal fall in pH was considered to drive inorganic precipitation of silica dissolved in the schizohaline lake waters. The Coorong region came to be considered the type area for inorganic evaporitic precipitation of chert and a style of chert formation known as "Coorong-style." In the last decade sulphate-reducing bacteria have been shown to form dolomite in hypersaline coastal salinas in Brazil (Chap. 4) and some have applied similar notions to interpret the Coorong lake carbonates, that is, both regions are typified by bacterially mediated precipitates (Rosen et al. 1988; Wright 1999). The notion that silica precipitation in "Coorong-style" cherts is also microbially mediated is a distinct possibility.

Birnbaum and Wireman (1985) argued that bacterial degradation of organic matter must be important in forming silica precipitates in most evaporites. They demonstrated, through experiment, the strong influence of bacterial sulphate reduction on silica solubility. The ability of sulphate-reducing bacteria to remove silica from solution is related to local changes in pH and to hydrogen bonding within amorphous silica, followed by polymerization to higher weight molecules. During silica replacement of sulphate evaporites at relatively shallow burial depths, the pore fluid becomes depleted in dissolved sulphate as it is reduced to H_2S by the action of anaerobic sulphate-reducing bacteria, which metabolise sulphate from an anhydrite or gypsum substrate. Where this selective dissolution of the sulphate occurs in the presence of amorphous silica the reaction is accompanied by the precipitation of silica. Hence the microscale mimicry of the lath outlines in the outer parts of many replaced nodules. According to Birnbaum and Wireman it reflects bacterially-mediated silica replacement of nodules in relatively shallow burial settings where bacteria flourish.

Abiological processes, including thermochemical sulphate reduction are more important at greater burial depths where bacteria no longer survive. Providing matrix permeability is retained, silica replacement can continue into the thermobaric stage and can even persist into exhumation. Replacement under a thermobaric regime is frequently indicated by the preservation of hydrocarbon inclusions in the infilling silica cement.

Not all silicified nodules in evaporitic lacustrine sequences are replacements of $CaSO_4$ nodules, some form by transformation of sodium silicate gels. In the saline alkali lakes of the African rift valley, magadiite ($NaSi_7O_{13}(OH)_3{\cdot}3H_2O$) is a common sodium silicate associated with volcanogenic sediments (Eugster 1969). It forms beds and nodules in sediments outcropping about the margins of many of the trona-containing lakes in the East African Rift, including Lake Magadi and Lake Natron. Other sodium silicates such as kenyaite and Na-Al silicate gels and zeolites are also present locally in the African rift lakes.

Magadiite nodules in Lake Magadi weather into cherts called Magadi-style cherts with a characteristic reticulate or "crocodile-skin" surface created by shrinkage during the transformation from sodium silicate gel to chert nodule. When buried, Magadiite rich layers in the diatomaceous host sediment pass along strike into outcrop and into beds of crocodile skin chert (Fig. 4.42). Conversion of magadiite to bedded and nodular chert is thought to take place close to the sediment surface and be related either to the mobilisation and flushing of sodium by dilute waters in these shallow

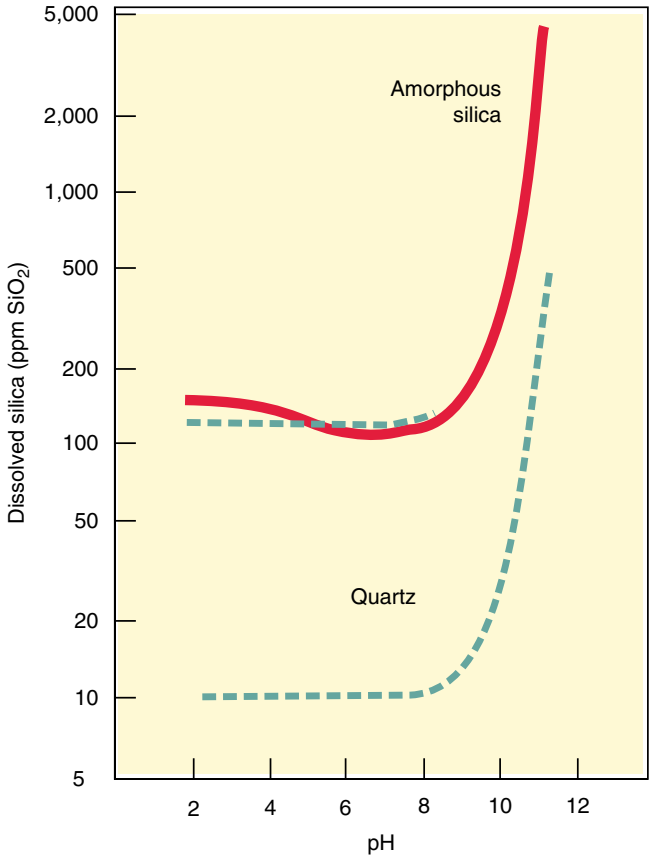

Fig. 7.79 Silica solubility curves at 25 °C. *Solid line* shows experimentally determined variation in solubility of amorphous silica with respect to pH. *Dashed lines* bracket the quartz solubility field (After Krauskopf 1967 – see also Fig. 4.41b)

environments or to spontaneous conversion to chert in deeper brine-saturated zones. Eugster et al. (1967) proposed that magadiite is precipitated by diluting silica-rich, sodium carbonate brines with fresher waters. Mixing lowers the pH, and although the pH change may have been as little as 0.5, a decrease in pH from 10.3 to 9.8 lowers amorphous silica saturation by more than 500 ppm (Fig. 7.79). Silica solubility changes very little when pH varies below a maximum of 8. Highly alkaline sodium carbonate waters containing abundant SiO_2 readily form in the Magadi rift valley via weathering and rapid subsurface hydrolysis of labile volcanic materials. Given the hydrogeochemistry needed for highly alkaline brines, evaporite minerals likely to be found in association with Magadi-style cherts are the sodium carbonates (trona, gaylussite or pirssonite; searlesite); gypsum is not present (Fig. 2.19; Hardie and Eugster 1970).

Surdam et al. (1972) listed the following textures as indicators of Magadi-style cherts that have evolved from a sodium silicate gel: (1) Preservation of the soft-sediment deformation features of the putty-like magadiite, such as enterolithic folding, lobate nodular protrusions, casts of mudcracks and trona crystals, and extrusion forms; (2) Contraction features, such as reticulate cracks and polygonal ridges on the surface of the chert, reflect the loss of volume in the transition (crocodile-skin chert; Fig. 4.42). In Phanerozoic strata an ability to separate cauliflower cherts (after gypsum/anhydrite nodules) from crocodile-skin cherts (associated with silicate gels in trona/natron soda lakes) is considered important in defining marine-fed versus continental hydrologies. However, it has yet to be shown that any of these textures are unique to magadiite-chert transitions.

Ancient Magadi-style chert nodules crop out in lacustrine rocks of the Middle Devonian (Middle Old Red Sandstone) Orcadian Basin, Scotland (Parnell 1986) and the fluviolacustrine sediments of the Permian Balzano volcanic complex in Italy (Krainer and Spötl 1998). The Scottish cherts are replacive nodules within organic-rich laminates and are the deposits of a stratified alkaline lake. Nodules exhibit soft sediment deformation features including sediment injection along shrinkage fractures within the nodules and preserved stellate quartz pseudomorphs after an evaporite mineral, possibly trona. Nodules were nucleated about vertical cracks in the host sediment and show polygonal or parallel aligned patterns. Thus the precipitation of the magadiite precursor must have occurred from nearsurface alkaline groundwaters flushing through partially consolidated sediments.

The Italian cherts form thin layers within a fluviolacustrine succession sandwiched between acidic volcanic rocks of the Lower Permian Balzano Volcanic Complex in northern Italy. These cherts are interpreted as analogs to Magadi-style abiogenic chert (Krainer and Spötl 1998). They show soft-sediment deformation features, shrinkage cracks, and well-preserved palynomorphs that document early diagenetic silica precipitation, volume loss by dehydration, and consolidation prior to mechanical compaction of the enclosing sediment. Similar chert layers were also noted in Triassic playa deposits of North Carolina replacing evaporite siliceous gels in 60 cm-thick siliceous beds intercalated with 20 cm-thick limestone tufa beds (Wheeler and Textoris 1978).

But evaporite-associated chert can probably accumulate in any number of highly alkaline settings, with or without trona extend all the way back to the Archaean (Pirajno and Grey 2002). White magadiite veins constitute rectilinear polygons (1–3 m across) in modern playa sediments in Alkali Lake, Oregon, and in adjacent muds associated with alkali salts and brines (Rooney et al. 1969). The same beds do not host substantial volumes of sodium bicarbonate salts. Jones et al. (1967) noted up to 2,700 ppm of dissolved silica in the present-day brines from Alkali Lake playa. Such values represent a substantial supersaturation with respect to amorphous silica, even at the playa's current pH levels, which are near 10.5 (Fig. 7.79). This level of supersaturation, in the absence of extensive trona suggests that these lacustrine sodium silicates precipitated directly from a hypersaline

silica-saturated solution without the need for a sodium silicate precursor. The debate as to how, where and when crocodile-skin chert can precipitate continues, as yet unresolved.

In thin section, Schubel and Simonson (1990) showed that chert with a magadiite precursor has a characteristic rectilinear or grid-work orientation of quartz crystals, visible in thin section. The texture seems to be inherited, a pseudomorph after the original spherulitic magadiite structure, which shows similar extinction patterns due to presence of 10–20 μm spherical aggregates of plate-like crystals. This microscale pseudomorphing implies a direct volume-for-volume replacement of magadiite by chert. Unfortunately the level of detailed preservation needed to make such distinctions is not usually preserved in older cherts where megaquartz dominates the fill. It is useful in separating cherts from magadiite precursors versus chert from other hypersaline associations in Neogene strata, and perhaps in a few examples it can be utilised in rocks from as far back as the Mesozoic.

As mentioned earlier, Folk and Pittman (1971) and Folk and Siedlecka (1974) concluded that length-slow chalcedony (lutecite) in chert nodules is a useful indicator of the former presence of evaporites (both anhydrite or magadiite precursors). But the occasional presence of length-slow chalcedony in nonevaporitic regimes, such as in turbidites and basalts, has shed suspicion on its absolute reliability. Heaney (1995) further refined the significance of lutecite by showing that in the early stages of its diagenetic evolution it is largely composed of a form of silica called moganite. Moganite is a polymorph of SiO_2 that is microcrystalline, fibrous and optically length-slow. Water content is ≈2 %, slightly higher than chalcedony and lower than opal (6–10 %). It is abundant in, but not restricted to, cherts formed in evaporitic environments. Nonevaporitic silica precipitates typically contain between 5 and 15 wt% moganite, whereas undeniably evaporitic specimens contain between 20 and 75 wt% moganite. No chert from nonevaporitic settings has been found to contain more than 25 wt% moganite. Consequently, enhanced moganite concentration (>20 wt%) in microcrystalline silica is a valuable indicator for vanished evaporites. Heaney noted a frequent association of moganite with "Magadi-style" crocodile-skin chert and suggested that moganite is a diagenetic alteration product of the hydrous Na-silicate magadiite. Unfortunately moganite is a metastable phase and all samples analysed by Heaney that are older than Cretaceous contain little or no moganite.

The transformation of magadiite to moganite must occur over hundreds to thousands of years in alkaline lake systems, whereas the inversion of metastable moganite to quartz probably requires tens of millions of years. But the moganite-evaporite association is broader than magadiite in soda lake cherts as moganite is forming as an authigenic phase in inland playas of central Australia and these Na-Cl brine systems never contained trona, magadiite or volcaniclastics (English 2001). The source of silica is a deeply weathered granitic terrain soaked in stagnant brines.

When dealing with chert nodules, lutecite is only a reliable evaporite indicator when it occurs in suitable host lithologies, is stacked into appropriate vertical sequences and occurs in association with other indicators of "the evaporite that was." The only undeniable single indicator that a chert has an evaporitic parentage is when relicts of the precursor salt still remain within the nodule.

Calcitisation and Dedolomitisation

Calcitisation and dedolomitisation are two often-associated diagenetic processes affecting both evaporite salts (anhydrite/gypsum) and evaporitic dolomites. Calcitisation of evaporites refers to the replacement of an evaporite bed by calcite or limestone. Dedolomitisation refers to the conversion of a dolomite to a limestone. Calcium sulphate evaporites are calcitised in two settings; the meteoric, via groundwater flushing and spar fill of the resulting voids, and in the deeper subsurface, via sulphate reduction (both bacterial and thermochemical). Waters in deeper burial settings situated below the active phreatic tend toward anoxia and in addition to H_2S can carry organics as suspended or dissolved hydrocarbons.

As well as replacement, the flushing of bedded evaporites by surface-derived, low-sulphate meteoric waters also brings on evaporite rehydration, dissolution. Calcite cements typify the nearsurface, while anhydrite conversion, via slow hydration, characterises the deeper near stagnant portions of the same meteoric flow system. Replacement is often bioepigenetic in shallower settings and thermochemical in even deeper and hotter settings. Thus the products of calcitisation tend to have diagnostic isotopic signatures.

Calcitisation of Evaporites

Like silicification, replacement of evaporite crystals and nodules typically by calcite, can occur at any time in the burial cycle from eogenesis through mesogenesis and into telogenesis; whenever the throughflushing waters are undersaturated with respect to the evaporite salts and supersaturated with respect to $CaCO_3$ (Table 7.15). The process is generally known as "evaporite calcitisation' and mainly involves substitution of calcite for gypsum or anhydrite and, to a lesser degree, of glauberite or thenardite. Evaporite calcitisation is most common during the meteoric/eogenetic alteration of evaporite units.

In South Australia, hollow aragonite (micrite rind) pseudomorphs after Holocene gypsum grow in the shallow subsurface about edges of coastal salinas in areas of active marine phreatic flushing (von der Borch et al. 1977; Warren 1982a). Similar early pseudomorphs after bottom-nucleated gypsum have been recognised in the Lower Carboniferous of the Vesder region, Belgium (Fig. 7.25; Swennen et al. 1981). There the process was under the influence of sulphate-reducing

Table 7.15 Selected examples of calcitisation and dedolomitisation in evaporitic settings

Occurrence and age	Comments	Reference
Gypsum replacement in sub-tepee limestones in Holocene carbonate, Marion Lake, Australia.	Aragonite skins formed on dissolving gypsum prisms in the boxwork limestone forming where a prism of less saline marine seepage water interacts with the outer edge of the Holocene gypsum fill. This an excellent example of a gypsum-shaped crystal void in the midst of its creation.	Warren (1982a)
Calcitised gypsum beds in Miocene-Pliocene sediments, Calatayud Basin, northern Spain.	Early calcitisation of lacustrine evaporite (gypsum, anhydrite) and/or magnesium carbonate (dolomite, magnesite) deposits driven by the encroachment of meteoric waters either at the contact of these deposits with overlying freshwater or where percolating freshwater enters at very shallow burial depth. Calcitisation occurs during the interaction between magnesite and Ca-enriched waters derived from the dissolution of gypsum or glauberite.	Sanz-Rubio et al. (2001), Cañaveras et al. (1998)
Calcitised beds in Tertiary lacustrine dolomites, Madrid basin, central Spain.	Mineralogy of bedded carbonates is now dominated by calcite and the limestones contain moulds of gypsum. Occurrences of calcitised dolomite textures in these facies suggests the influence of fresher water during expanding lacustrine cycles or further subsurface interactions with less saline groundwater.	Calvo et al. (1995)
"Gypsum-ghost" limestones adjacent to selenite lithofacies in the Miocene of northern Carpathian Foredeep, Poland.	Mass-balance chemistry shows a deficit of calcium and sulphur contents in the limestones compared to the composition of the selenitic gypsum and implies that the gypsum-ghost limestones system was open to mass transfer and cannot be related to simple and regionally extended replacement of solid sulphate rocks by limestones plus native sulphur; it is a transitional facies.	Gasiewicz (2000)
Calcitised Danian dolocretes in lacustrine beds, Provence Basin, France.	Dolocretes deposited around the palaeolake or playa margin subsequently leached and calcitised. Dolomite rhombs can be hollow. Fabric-destructive calcitisation attributed to drop in the lake level, when the upper part of the dolocrete was subjected to vadose flushing, whereas the fabric-preserving calcitisation (poikiliotopic) resulted from rise in lake level.	Colson and Cojan (1996)
Marbles in the Muttlebury Nappe, Jurassic Lovelock Formation, West Humboldt Range, Nevada.	Outcropping rauhwacke sheets are interlayered and interlensed with non-breccia marble slabs. The marble slabs are calcitised anhydrites from the original décollement of the thrust. They were produced bioepigenetically by the action of sulphate-reducing bacteria on the $CaSO_4$ antecedent.	Speed (1974, 1975)
Calcitisation of the Permian Raisby/ Cadeby Formation, UK.	Groundwater flushing converts nodular calcium sulphate into spar-filled cauliflower-shaped geodes. Fill is multistage telogenetic and with a consistent unroofing history outlined in zoned calcite linings of the geode fills.	Lee and Harwood 1989; Lee, 1990
"Castiles" or calcitised evaporites within the Ochoan (Lopingian) Permian rocks of the western Delaware Basin	Bacterial calcitisation of sulphate evaporites if the Castile Fm to form the characteristic "limestone buttes" via bacterial sulphate reduction and near-surface, methane seeps driven by hypogene waters escaping from the basin. Additional calcitized evaporites occur in the carbonate facies on the margins of the Delaware Basin where anhydrite nodules have been replaced by calcite spar as gravity-driven meteoric waters passed downdip flowing eastward through the Capitan backreef sediments.	Kirkland and Evans (1976), Scholle et al. (1992), Stafford et al. (2008a, b)
Calcitisation of Permian Karstryggen Formation, Central East Greenland.	Groundwater driven karstification on "the way down" created spar filled vugs after nodular anhydrite and was often associated with the precipitation of celestite.	Scholle et al. (1990, 1993)
Calcitised anhydrite in Poplar and Ratcliffe beds in association with Watrous Formation, Mississippian, Williston Basin, USA.	Anhydrite calcitisation occurred only after the Watrous unconformity was shallowly buried by redbeds, and replacement probably involved sulphate-reducing bacteria. Replacement calcite contains pseudomorphs and relicts of anhydrite, and pseudomorphs of secondary gypsum, indicating calcitisation occurred only after original Mississippian gypsum was altered to anhydrite.	Kendall (2001)
Dedolomites in the Mississippian Madison Group of Wyoming and Utah.	Two types of fracture-related dedolomites, one precedes and one postdates regional dolomitisation. The early dedolomite occurred as active groundwaters flushed anhydritic sequences during shallow burial. The later post-stylolitisation fracture-associated dedolomite records chemistries and isotopic signatures of deep tectonic-vein mineralisation.	Budai et al. (1984)
Calcitised anhydrite, Winnipegosis Formation, Middle Devonian, Saskatchewan.	Calcitisation of organic layers and anhydrite section occurred before compaction and was driven by the activities of sulphate reducing bacteria. It preserves characteristic structures of antecedent (lamination, nodular outlines).	Shearman and Fuller (1969), Fu et al. (2008)
Calcite-filled pseudomorphs in the Cambrian Parakeelya Alkali member of the Observatory Hill Formation, Australia.	Calcite pseudomorphs after trona and shortite occur in the perennial lake and saline mudflat facies of this alkaline playa. Cauliflower-shaped vugs are more commonplace in overlying marine section. Fills are composed of poikilotopic calcite with dull luminescent cores and alternating dull and semiluminescent rims. Replacement occurred deep and in association with thermochemical sulphate reduction.	Southgate et al. (1989), White and Youngs (1980)

Table 7.15 (continued)

Occurrence and age	Comments	Reference
Calcitised sulphate evaporites in the Palaeoproterozoic Tulomozero Formation carbonates of the Onega basin	(a) Calcite pseudomorphs of inclusion-containing nodules, swallow-tail twinned crystals and evaporite dissolution breccias. Euhedral crystals with swallowtail twinning indicate gypsum was an initial early diagenetic phase, and not solely the result of anhydrite hydration following burial. (b) Displacive crystalline carbonates, interpreted as calcitised (and in places dolomitised?) calcium sulphates which had entirely displaced and/or encapsulated their host silts. (c) Quartz nodules with minor residual components of anhydrite, dolomite and hematite	Brasier et al. (2011)

bacteria and the precipitates in zones of dissolved crystals are now composed of sparry calcite. Later in the burial history, compaction- or thermobaric-derived mesogenetic waters can leach $CaSO_4$ or other salts from the system to create characteristic voids that are then filled by burial-stage calcite. Examples of this deeper end in the burial spectrum include spectacular Au-enriched silica-rimmed dolomitic nodules after anhydrite in the Triassic redbeds of Spain (Bustillo et al. 1999; Alonso-Zarza et al. 2002). Even further along the burial cycle calcitisation can occur during exhumation and uplift during gypsum speleogenesis driven by hypogene waters, as occurred during formation of the castiles of west Texas (Stafford et al. 2008a).

Thus calcite replacement of calcium sulphate salts is not depth specific and can be driven by various hydrological processes (Pierre and Rouchy 1988):

1. Sulphate dissolution during flushing by bicarbonate-rich waters derived from:
   - dissolved atmospheric CO_2,
   - oxidation of organic compounds (marine or terrestrial),
   - thermal decarboxylation of organic matter.
2. Bacterial sulphate reduction in organic-rich or hydrocarbon-flushed sediments. Sulphate reduction may also be later and deeper where it is abiotic and thermochemically induced (Chap. 9).

Calcitisation of evaporite nodules is most widely documented where meteoric waters react with an evaporite bed in the active phreatic zone and not in the deep subsurface (Table 7.15). Meteoric flushing can occur soon after an evaporite unit is deposited (early mesogenetic replacement "on the way down") or it can occur after deeply buried evaporite units are uplifted move back toward the zone of active meteoric throughflow (telogenetic/hypogene or "on the way back up"). And, as we have already seen, the replacement process can continue "while at the bottom" in the mesogenetic setting and wherever epithermal fluids flush calcium sulphate nodules. This can be as part of an active volcanogenic system (Bustillo et al. 1999) or even in association with the cycling of seawater through hydrothermal anhydrite in mid ocean ridges (Chap. 16). In hydrologically-mature sedimentary basins, uplift-related meteoric flow is typically forced by head-driven circulation from high-elevation recharge areas (Fig. 8.17), which can drive calcitisation and replacement to depths of more than a thousand metres.

Late-stage calcite replacement of evaporite nodules postdates silicification in the Tosi Chert, Wyoming (Ulmer-Scholle and Scholle 1994). It was thermochemically driven and was associated with hydrocarbon migration. Similar pseudomorphic replacement by calcite or dolomite of euhedral trona and shortite crystals occurs in the saline facies of the Cambrian Lake Parakeelya Member, South Australia. It was mesogenetic and took place during burial diagenesis as basinal brines flushed the system at temperatures of up to 110 °C. The catabaric dissolution and removal of the sodium carbonate salts took place either coincident with or following the generation of hydrocarbons (Southgate et al. 1989).

One of the best documented examples of calcitised evaporites forming long after deposition and burial of the primary salt beds ("on the way back up") comes from the onshore Permian Raisby Formation of the UK. There, alteration processes related to relatively recent re-entry from the hypogene into the zone of active meteoric flushing, can be studied both in outcrop and in core. The Raisby Formation (formerly the Lower Magnesian Limestone) is the first major carbonate unit deposited in the English Zechstein series and outcrops as escarpments and coastal cliffs along the NW coast of the UK (Fig. 7.80). It is overlain by the Ford Formation (formerly Middle Magnesian Limestone), a classic wedge-shaped carbonate shelf succession, which today crops out in a north-south belt up to 5 km wide. It is interpreted as a barrier reef/shoal sequence with backreef and lagoonal facies composed of white to buff, soft, bedded oolitic and fine grained dolomite. The reef faces is buff to brown hard massive to rubbly reef dolomite and associated talus, passing up into algal-laminated dolomite with oncoliths. Bryozoa, crinoids, brachiopods, bivalves and gastropods are abundant, except near the top of the buildups where stromatolitic and encrusting algae dominate and define the transition into more hypersaline conditions. Its slope and

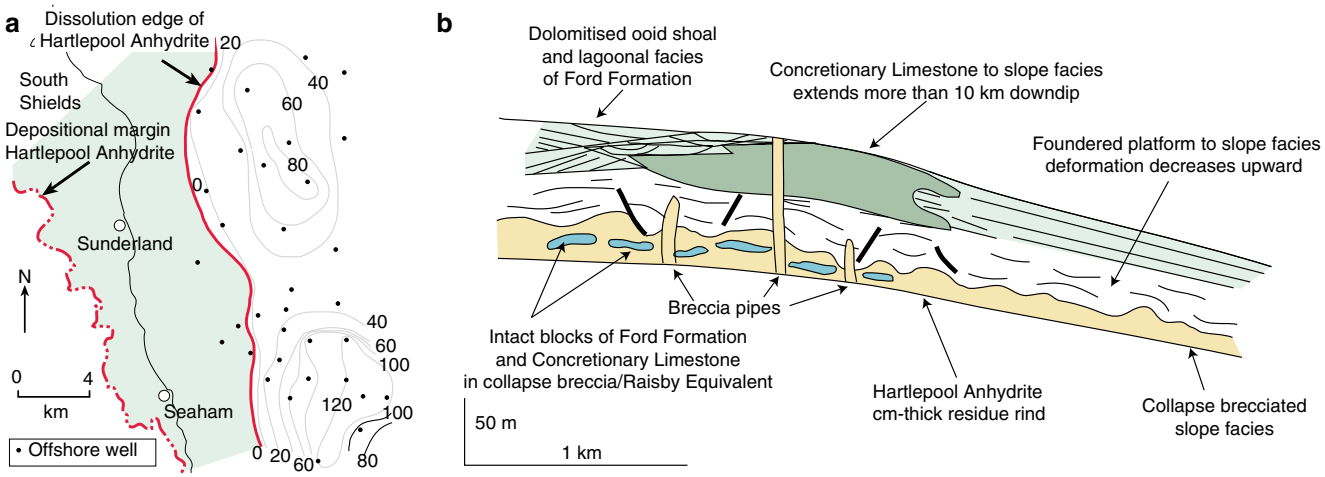

Fig. 7.80 Evaporite dissolution in the Permian Zechstein on the NW coast of England. (**a**) Extent of the dissolution zone of the Hartlepool Anhydrite from offshore anhydrite to onshore dissolution residue. Hartlepool isopachs in metres. (**b**) Facies patterns in the Raisby and related formations that make up the Zechstein unit formerly known as Magnesian Limestone. The cross section shows the relationship to dissolution residues of the Hartlepool Anhydrite seen in coastal outcrops where the anhydrite has dissolved

basin facies today consist of seaward dipping buff fine-grained dolomite. Offshore to the Raisby Formation lies the Hartlepool Anhydrite (Fig. 7.80a). Onshore the former position of the Hartlepool Anhydrite is defined by a regionally extensive dissolution residue at the base of the Raisby (Fig. 7.80b).

Outcropping Raisby dolomites contain nodular cavities, pores and pseudomorphic voids, which are lined or filled by calcite spar. Deep borehole cores sampling the Raisby Formation may still retain nodules and euhedral crystals of gypsum and anhydrite that are near-identical in size and shape to the cavities and pseudomorphs now seen in outcrop. This indicates that calcium sulphate nodules were once abundant in the subcropping Raisby Formation, but almost all the original salts have since been removed by crossflows of meteoric groundwaters.

Thus calcitisation of evaporite nodules is still active in appropriate zones of groundwater flushing along much of the coastal zone of NW England (Figs. 7.80 and 7.81; Lee and Harwood 1989; Lee 1994, 1995). Much earlier in the burial history of the Raisby Formation, primary Permian gypsum was replaced by anhydrite nodules. Later, coarser replacive burial anhydrite formed, postdating both pressure-solution and any further dehydration of any residual primary gypsum. During further mesogenetic burial, some of the anhydrite in the nodules was replaced by catabaric baryte, dolomite and sphalerite. Upon uplift of the Raisby Formation during the Tertiary, any remaining nodular anhydrite was telogenetically rehydrated to porphyroblastic gypsum. With further exhumation the gypsum was then dissolved by meteoric groundwaters and multiple stages of meteoric calcite cement

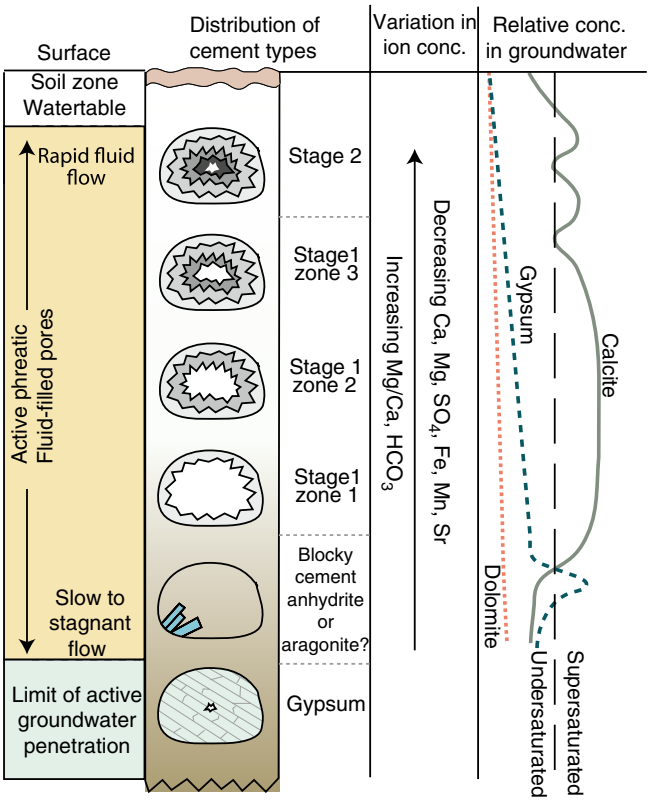

Fig. 7.81 Nodule evolution in the Raisby Formation, UK. *Vertical axis* indicates distance from the land surface, but may also indicate evolution through time of any one cavity. The lowermost cavity is filled with gypsum derived by rehydration of buried anhydrite. Contact with meteoric water causes dissolution of gypsum followed by local anhydrite pore cement that is then replaced by calcite. Succeeding calcite fill of cavities indicates increasing oxygenation and activity of groundwater system (After Lee and Harwood 1989)

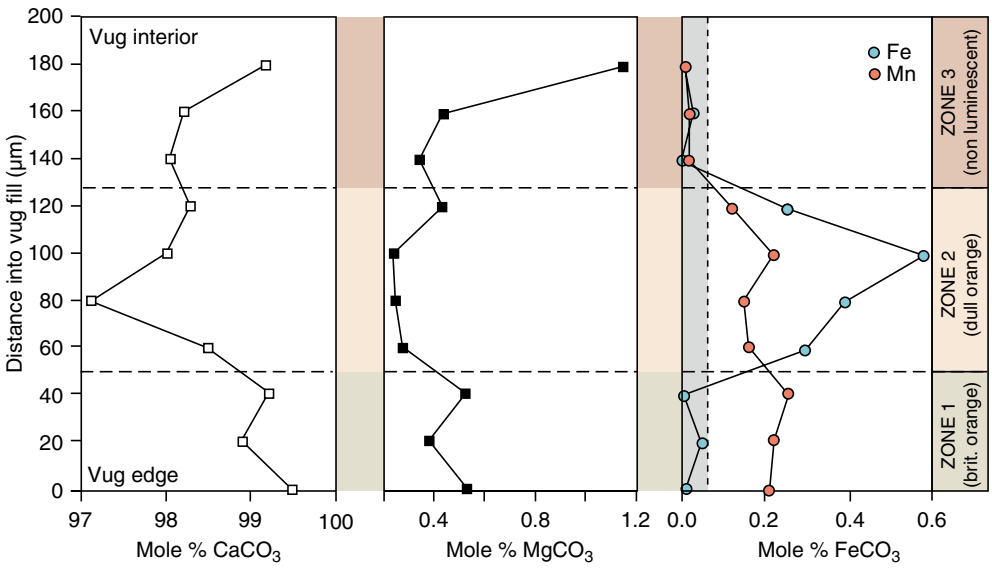

Fig. 7.82 Microprobe traverse through a Stage 1 cement crystal growing inward from the nodule wall showing distinct geochemical differences between Zone 1 (*bright orange*), Zone 2 (*dull orange*) and zone 3 (*nonluminescent*). *Shaded areas* indicate values are below reliable detection limits (After Lee and Harwood 1989)

precipitated within the voids (Fig. 7.81). All meteoric phreatic waters in this part of the UK are currently undersaturated with respect to dolomite and saturated with respect to calcite. Thus the calcite void fills in the Raisby Formation are made up of clear, inclusion-free, non-ferroan, low-magnesian telogenetic calcite.

There is an enigmatic episode of what was interpreted by Lee and Harwood (1989) as a widespread, but minor nearsurface anhydrite cement. It precipitated after regional exhumation had rehydrated all the buried anhydrite to gypsum and the gypsum had dissolved to form voids (Fig. 7.81). This early blocky crystal phase predated calcite void fills. It is encased in zone 1 calcite and is now replaced by calcite. Its blocky rectilinear prism termination precludes either a gypsum or a baryte precursor. The process and the mechanism which could have created an anhydrite-saturated pore water in the voids after gypsum leaching, in what must have been a shallow unroofing setting, is not well understood. Lee and Harwood (op. cit.) argue that if it is a calcite pseudomorph of anhydrite it perhaps indicates a short-term increase in salinity of nearsurface pore waters brought on by widespread meteoric dissolution of large volumes of subjacent halite (see also Handford and Moore, 1976).

The succeeding calcite infill of the leached gypsum nodules occurred in two phreatic (isopachous) stages; Stage 1 crystals are circumvoid equant, while stage 2 crystals are coarser, circumvoid and columnar (Fig. 7.81). Under cathodoluminescence the stage 2 columnar crystals are nonluminescent and alternate with internal sediment layers. Stage 1 crystals show three geochemically distinct cathodoluminescence zones probably related to increasing oxygenation of the crossflowing pore waters (Fig. 7.82). The successive zonation reflects increasing groundwater flow in the phreatic zone as the exhumed rocks approach the landsurface. Stage 1 – zone 1 (bright orange) cement has high Mn and low Fe and Mg values. Stage 1 – zone 2 (dull orange-luminescent) has relatively high Fe and Mn and low Mg values. Stage 1 – zone 3 (nonluminescent) has negligible Mn and little Fe in the calcite. Stage 2 cements have much higher Mg levels than stage 1, while the orange luminescing cements (zones 1 and 2) contain much higher levels of Sr than zone 3 or stage 2 cements (Fig. 7.82). This geochemical and cathodoluminescent zonation in calcitised nodule in the Raisby Formation is typical of increasing oxygenation in the pore fluids. It tracks the telogenetic passage of the uplifted strata from stagnant hypogene into an increasingly oxygenated and active groundwater system. But what of the early blocky calcite that Lee and Harwood (op. cit.) interpreted as post-gypsification anhydrite?

The process of meteoric calcitisation of $CaSO_4$ nodules is complicated in some parts of the Zechstein subcrop in central Germany by the presence of neoformed aragonite growing in anhydrite/gypsum vugs (Peckmann et al. 1999). It may be this calcite replacement of aragonite prisms that gives the unusual blocky crystal outlines that were interpreted as an unusual post-gypsification anhydrite in the preceding discussion of the Raisby Formation. Similar misinterpretations of blocky elongate calcite prisms as pseudomorphs after gypsum, not as aragonite cementstone replacements, have complicated the evaporite history of the Proterozoic McArthur Basin in northern Australia (Warren 1999; Chap. 8). Low $\delta^{13}C$ values (−10‰ PDB) of the aragonite inclusions growing in the Zechstein gypsum nodules indicate that some of its carbon is derived from organic matter that has been oxidized by bacterial sulphate reduction. The residual aragonite inclusions bear rhomb-shaped crystals of calcite that replace former dolomite. Elevated Mg/Ca ratios due to this dedolomitisation may have promoted the precipitation of aragonite instead of calcite during gypsification. This aragonite

has precipitated in the near-surface meteoric–vadose zone in recent times, it is a telogenetic precipitate. Aragonite crystals display a platy habit, while SEM analyses show that two types of micro-rods are associated with these plates (Peckmann et al. 1999). The mineralized micro-rods are interpreted to be fossilized bacteria. Aragonite inclusions, most of which contain organic-rich aggregations, yield a distinctive biomarker pattern. High concentrations of specific unsaturated fatty acids are clearly indicative of newly produced organic matter and reflect the presence of a discrete microbial community being associated with the formation of the aragonite. At one locality the aragonite is accompanied by native sulphur and the formation of sulphur was mediated by H_2S-oxidizing bacteria. This is corroborated by the presence of densely packed curved aragonite rods representing permineralized bacterial cells on and within the sulphur.

So far, most of our discussion has emphasised the importance of bicarbonate-rich deep meteoric circulation in calcitising exhumed calcium sulphate beds. But is this always so? The work of Peckmann et al. (1999) shows that aragonite can be a local product of bacterial sulphate reduction acting on gypsum nodules during exhumation of diapir crests. Kendall (2001) argues that biogenic sulphate reduction can be a more widespread process in shallow burial and that bacterial metabolism can calcitise widespread evaporite beds beneath unconformities, independent of active meteoric circulation. He cites beds of anhydrite nodules that are locally replaced by calcite, pyrite and celestite beneath an unconformity atop Mississippian anhydrites of Saskatchewan (Fig. 7.83a). Triassic clastics (Watrous Formation) immediately above the unconformity are green (reducing), rather than red (oxidising), and there is a regionally developed subunconformity alteration zone, where carbonates are dolomitised, and porosity is filled with anhydrite.

The unconformity lacks karstic features (unlike equivalent age surfaces in the USA), and probably formed in a hyperarid climate. Mississippian anhydrites near the unconformity are not preferentially dissolved, nor were they extensively hydrated. Anhydrite calcitisation probably involved sulphate-reducing bacteria and occurred only after the unconformity was shallowly buried by redbeds. Hydrogen sulphide, generated by bacteria in saline brines reduced redbed pigments to form the green halo. Replacement calcite contains pseudomorphs and relicts of anhydrite, and pseudomorphs of secondary gypsum. These indicate calcitisation occurred only after original Mississippian gypsum was altered to anhydrite and this, in turn, was partially converted back to secondary gypsum beneath the unconformity.

Replacement occurred concurrently with the formation elsewhere of a dolomitised zone beneath the unconformity. Sulphur isotopic ratios of replacement pyrite are depleted relative to Mississippian sulphate values, consistent with the activities of sulphate-reducing bacteria. $\delta^{34}S$ values for Mississippian Tilston and overlying Frobisher Evaporite anhydrites cluster around +18 to +19 ‰, comparable with Mississippian sulphate evaporite values worldwide. Values from the much younger replacement anhydrite porphyroblasts, and one value from anhydrite in the dolomitised zone are similar. Sulphides, associated with replacement calcite from the Filmore area, have $\delta^{34}S$ values that are depleted (by up to 19 ‰) relative to the Mississippian sulphates. Whole-rock analyses of Mississippian (Alida and Tilston Beds) limestones exhibit a narrow range of $\delta^{13}C$ ratios of +1.5 to +2.2 ‰, averaging +1.8 ‰, but have a wider range in $\delta^{18}O$ −1.2 to −6.4 ‰, averaging −3.86‰ (Fig. 7.83b). Carbon and oxygen are both depleted compared with estimated Mississippian marine carbonate values; almost certainly due to the addition of later diagenetic cements (Kendall 2001).

Mississippian dolomites have heavier $\delta^{13}C$ values (+2.6 to +3.6 ‰) and appear to be less altered. Their $\delta^{18}O$ ratios, however, are more varied. Two populations are present: one has preserved Mississippian compositions or is slightly depleted (−2 to −3‰ $\delta^{18}O$), but most are heavier – clustering around values of +0.9‰ $\delta^{18}O$, possibly reflecting precipitation from evaporated Mississippian seawater (Fig. 7.83b). A single analysis of dolomite from the dolomitised zone has a markedly different composition from the early diagenetic Mississippian dolomites. Replacement calcites have a narrower range of isotopic compositions, averaging −3.9 $\delta^{18}O$ and +1.5 $\delta^{13}C$. These averages are almost the same as those calculated for whole-rock analyses of the Mississippian limestones (−3.9 $\delta^{18}O$ and +1.8 $\delta^{13}C$). But the carbon isotopic ratios of replacive calcites, do not support this interpretation, rather they are identical to those of Mississippian limestones (Fig. 7.83b).

Kendall (2001) argues simple replacement of sulphate by pore-water bicarbonate (in equilibrium with host limestones) is unlikely because protons generated during the reaction should have created acidic conditions in which calcite would have dissolved. He notes a full explanation of the calcitisation remains elusive, but may involve replacement occurring in an active arid-zone groundwater system and/or bacterial sulphate reduction occurring upstream of the site of calcitisation.

Bustillo et al. (1999) describes some unusual mineralized and silicified carbonate-rich nodules hosted in Lower Triassic red mudstones in Central Spain (Fig. 7.84). From their borders to their centres, the nodules (geodes) display a characteristic zonation of; (a) a millimetric carbonate crust, (b) a quartz rim, (c) massive dolomite centres, (d) gold-bearing iron-rich infills (haematite laths and goethite with up to 7,000 ppm of gold) and (e) uplift related calcite cements that

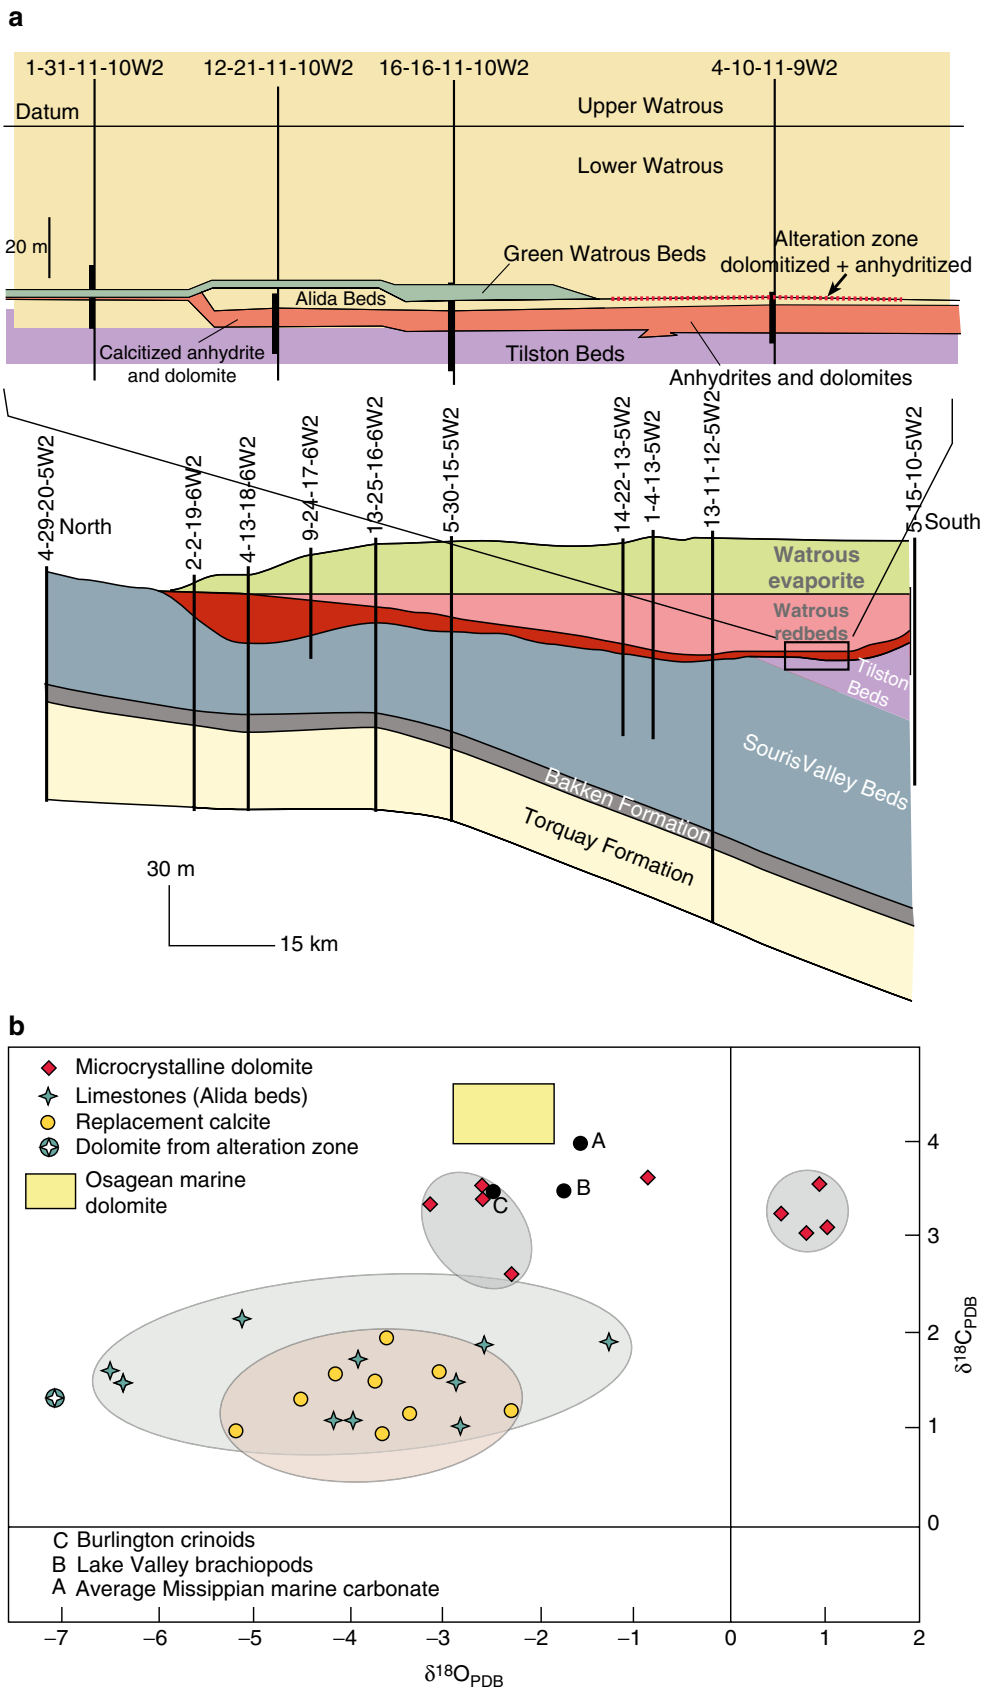

Fig. 7.83 Bacterial calcitisation, Saskatchewan (After Kendall 2001). (**a**) Diagrammatic section showing the regional unconformity, the northwards disappearance of older Triassic, Permian, Pennsylvanian and late Mississippian strata, and the northwards overstep of the Watrous by Jurassic deposits. Inset shows anhydrite (or calcitised anhydrite) and dolomite constitute the Tilston Evaporite. Most of Tilston Beds and overlying Alida Beds are limestones. Note the very thin calcitised anhydrite zone at the base of the Tilston Anhydrite (*arrowed*), and a dolomitised zone beneath the unconformity in the 4-10-11-9 W2 well. (**b**) Carbon-oxygen isotopic ratio cross-plot of calcites that have replaced anhydrite, host rock dolomites, and limestones of overlying Alida Beds. Note overlap of limestone and replacement calcites, and their clear distinction from dolomite values

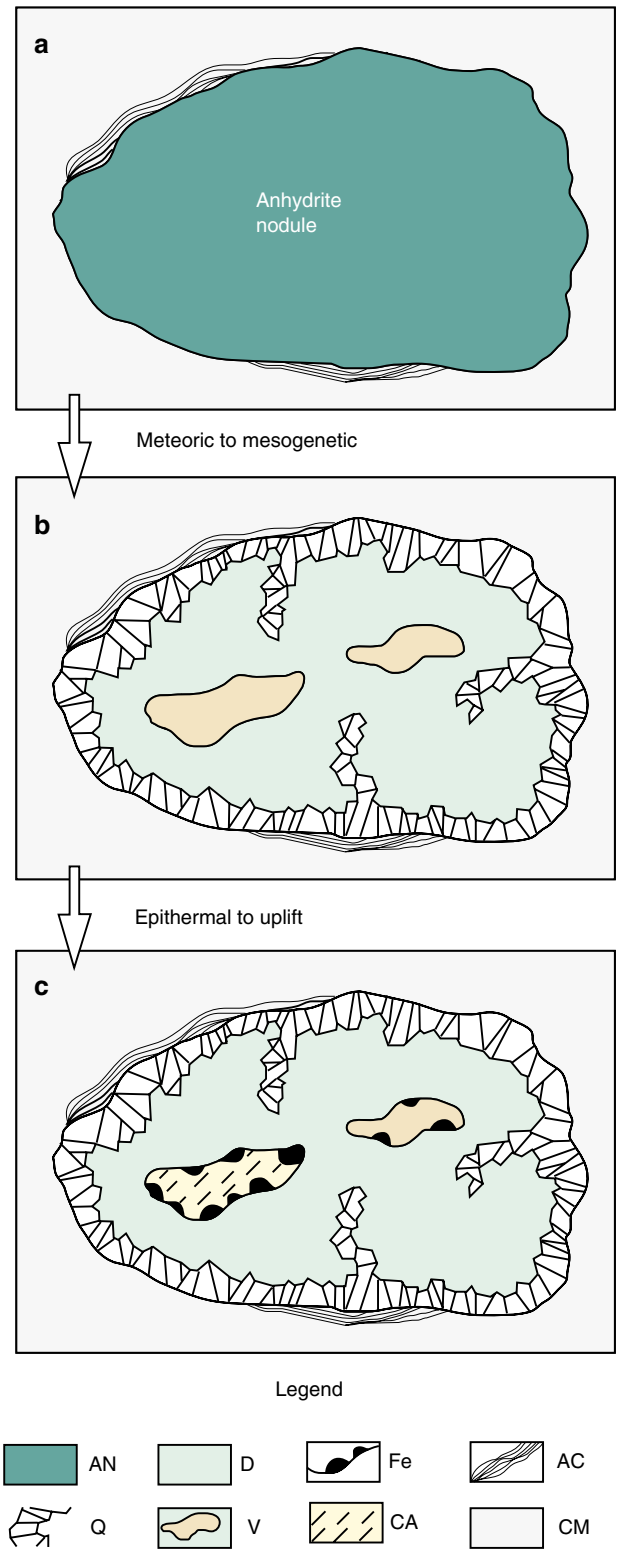

Fig. 7.84 Model of the Tordelrabano geodes, Spain (After Bustillo et al. 1999). Abbreviations: *AN* anhydrite, *D* dolomite, *Fe* oxides and hydroxides of iron, *AC* carbonate crust, *Q* quartz, *V* voids, *CA* calcite, *CM* mudstones. (**a**) Anhydrite nodules form in mudstones from early hypersaline fluids. Later, a crust (probably edaphic) forms around the anhydrite nodule. (**b**) Replacement of the anhydrite by dolomite and quartz from continental groundwaters. Voids form by dissolution of anhydrite or dolomite. (**c**) Filling of the voids by hydrothermal minerals (gold-bearing hematite–goethite). Subsequent precipitation of telogenetic calcite sometimes seal the central hollow. Textural evidence indicates that the geodes were originally nodular anhydrite, subsequently replaced by quartz and dolomite. The resultant porosity from this replacement ("on the way down"), or porosity created by later dissolution, has been filled by epithermal gold-bearing iron-oxide hydroxides, romanechite and calcite.

$\delta^{13}C$ values indicate the participation of meteoric waters in an early burial environment, which was characterized by both a sub-desert climate and a temperate-tropical climate. Oxygen signatures reflect very variable temperatures for all minerals, with the exception of late stage calcite, which was precipitated at <38 °C ("on the way up"). Iron-oxide temperature values in the gold rich cores can reach 85 °C (epithermal). The mineralogical assemblages denote a multistage history to the nodules characterised by early silica, then dolomite infill of a dissolving nodule (early diagenetic replacement "on the way down") followed by the epithermal[18] activity. This mineralization is linked to the Late Hercynian, calc-alkaline volcanism of Central Spain (the Hiendelaencina mining district). Once again, the evaporite replacement process is ongoing, not early versus late, but occurred throughout the burial cycle.

Dedolomitisation (Calcitisation) of Dolomite Matrix

One of the first reports of the alteration of dolomite to calcite was by the Swiss geologist on Morlot (1847) based on solution experiments and field studies in Styria. He coined the term dedolomite and suggested that groundwater leaching of pre-existing evaporite deposits, containing gypsum or anhydrite, would be enriched with calcium and sulphate, creating fluids driving calcitisation of former dolomites. Dedolomitisation of dolomite matrix is frequently associated with calcitisation of entrained evaporite nodules. Dedolomitisation describes the conversion of a dolomite back to a limestone by the growth of calcite rhombs within the dolomite matrix.

$$MgCa(CO_3)_2 + CaSO_4 \cdot 2H_2O \rightarrow 2CaCO_3 + Mg^{2+} + SO_4^{2-} + 2H_2O$$

This process can continue until the dolomite is completely converted to a limestone, or it may be arrested when the calcitisation of the matrix is no more than partial. Dedolomitisation has long been interpreted as a product of evaporite diagenesis and is typically ascribed to telogenetic calcium-rich groundwaters derived from a nearby dissolving gypsum/anhydrite or glauberite unit (Lucia 1961; Warrak 1974; Lee 1994). An evaporite association is the emphasis of the dedolomitisation discussion in this section; but dedolomitisation can also occur under the influence of calcium-rich basinal waters (mesogenetic), where the elevated levels of calcium are independent of evaporite dissolution. For

[18] Epithermal, said of a hydrothermal mineral deposit located within 1 km of the Earth's surface and precipitated in a temperature range of 50–200 °C, mainly occurs in veins.

example, Land and Prezbindowski (1981) documented dedolomitisation from hot, calcium-rich brines moving up into a dolomite reservoir in the Cretaceous Edwards Group of the Gulf Coast. They attributed the high calcium content of these brines to the authigenic albitisation of plagioclase in down-dip sandstones.

Texturally, calcitised dolomites (dedolomites) are identifiable if one or more of the following features are present in the limestone (Armenteros 2010 and references therein): (1) large rhombs, isolated or contiguous, comprising an equicrystalline mosaic of anhedral calcite; (2) preservation of the outlines of primary rhombic crystal dolomites that are either filled with sparite or are empty; (3) preservation of limpid rims and internal remains of the original dolomite rhomb outlines within a pervasive calcite cement; (4) preservation of the cloudy cores and clear rims of an earlier dolomite mosaic, later replaced by calcite (typically visible using CL microscopy); (5) rhombs with calcitised cores and/or calcitised zones; and (6) dedolomitised/calcitised rhombs with obliteration of the original crystalline structure. The presence of dolomite crystals with leached centres in a dedolomite indicates that the original dolomite nucleus probably contained inclusions of low-Mg calcite precipitated rapidly or fluid-filled microcavities. The preservation of cloudy cores and clear rims indicates most likely the replacement by a thin-film solution front without creation of substantial void space.

The textural variability of the dedolomitization/calcitization process is mainly controlled by the texture of the precursor rock. Where the micrite matrix is pervasively dolomitised, the reaction took place primarily through dissolution/precipitation; conversely, where significant amounts of micritic matrix remain, the reaction proceeded through mole per mole (mimic) replacement. In that case the transformation of dolomite to calcite took place across a submicron- thick solution film between the original dolomite host and the authigenic calcite, just as it does during neomorphism of aragonite and-or high-Mg calcite. In other cases, there is little textural preservation of the finer details of the precursor, calcite simply seems to fill the voids generated by earlier dissolution of dolomite (Armenteros 2010).

Thus, replacement can be either pseudomorphic or non-pseudomorphic. In the dolomites of the upper Muschelkalk of Prades (Catalonia, Spain), dedolomitisation took place through both processes simultaneously: non-pesudomorphosic calcite after dolomite is associated with wall fractures, and pseudomorphic replacement typifies the bulk rock (Ayora 1999). A non-pseudomorphic dedolomitisation reaction may produce a change in porosity because the molar volume of dolomite (65.365 $cm^3\ mol^{-1}$) is less than two times the molar volume of calcite (36.934 $cm^3\ mol^{-1}$) (Ayora 1999).

Evaporite-derived dedolomites are often associated with evaporite dissolution breccias, which indicate the now dissolved bed that supplied the excess calcium needed to dedolomitise (Lee 1994; Fu et al. 2008). Dedolomite under this scenario forms via the reaction of calcium sulphate-rich solutions with a pre-existing dolomite to produce calcite with magnesium sulphate as a possible byproduct. The latter is rarely preserved, as it is highly soluble, and either remains as dissolved ions in the escaping waters or is quickly redissolved and flushed by through-flowing groundwaters (Shearman et al. 1961). The $CaSO_4$ dissolution process is often driven by meteoric flushing of nearsurface oxidising waters and former ferroan dolomites are preferentially replaced. The resulting calcitised dolomites are outlined by intervals stained red with iron oxides and hydroxides.

With uplift-related (telogenetic) dedolomites the distribution of dedolomite can reflect variations in the regional hydrology. This can be seen in the dedolomites of the Lower Cretaceous Edwards Group in the Balcones fault zone area of south-central Texas (Ellis 1985, 1986). The Edwards Group consists of 120–180 m of porous limestone and dolomite that accumulated on the Comanche shelf in shallow-water subtidal, intertidal, and supratidal marine environments. During early burial diagenesis, carbonate mud neomorphosed to calcitic micrite, aragonite and Mg-calcitic allochems were altered to calcite or were leached, and evaporites formed in tidal-flat sediments. Each of these phases had a characteristic stable isotope signature (Fig. 7.85) Dolomite is widespread and formed in environments ranging from hypersaline to fresh-water as shown by the two isotope clusters in the Edwards dolomite.

Late Tertiary faulting along the Balcones fault zone, tied to Jurassic salt withdrawal, initiated a circulating, fresh-water aquifer system to the west and north of a fairly distinct "bad-water line," which roughly parallels the Balcones fault zone. To the south of the bad-water line, interstitial fluids remained relatively stagnant and contain over 1,000 mg/l dissolved solids. Because of the differences in the chemistry of the interstitial fluids, post-faulting diagenesis in the two zones has been very different. Water in the bad-water zone can be saturated with respect to calcite, dolomite, gypsum, celestite, strontianite, and fluorite, whereas water in the fresh-water zone is saturated only with respect to calcite. Due to the change in water chemistry, rocks in the fresh-water zone have been extensively recrystallised to coarse microspar and pseudospar, extensive dedolomitization has occurred, and late sparry calcite cements have precipitated. This created a suite of covariant isotope trends and clusters with the dedolomite showing a distinctive set of carbon and oxygen values relate to soil water influences (Fig. 7.85). In contrast, rocks in the bad-water zone retain fabrics associated with pre-Miocene diagenesis and there is little or no evidence of widespread dedolomite. The importance of meteoric diagenesis in the formation of dedolomite in shallow, subsurface telogenetic environments is illustrated by the

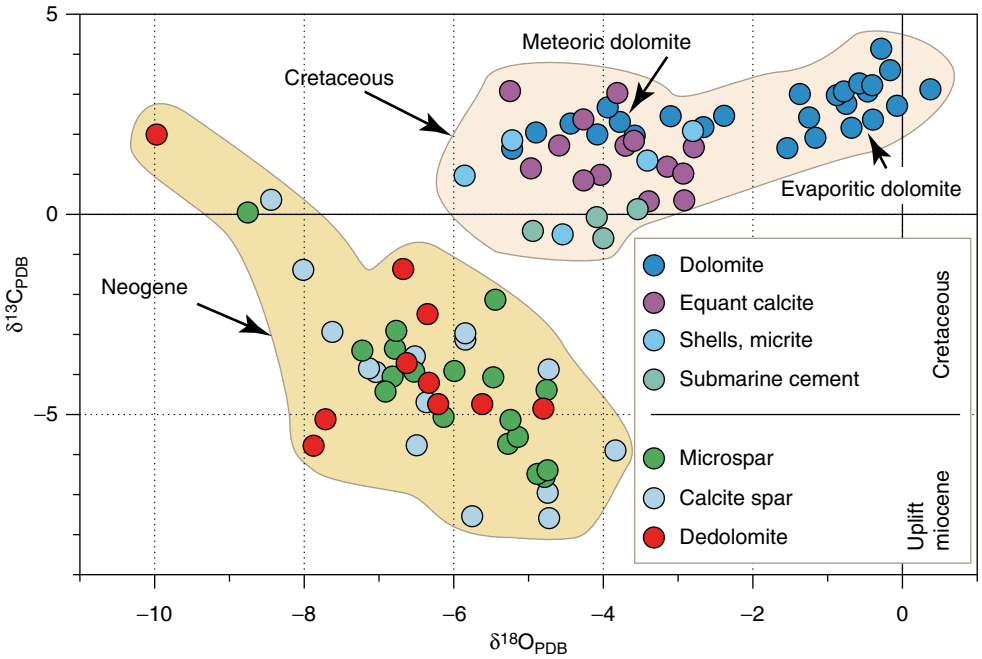

Fig. 7.85 Crossplot of $\delta\ ^{18}O_{PDB}$ and $\delta\ ^{13}C_{PDB}$ of selected samples taken from the Edwards Group, Balcones fault zone, central Texas, showing two clusters related to Cretaceous diagenetic overprints and Neogene telogenesis including dedolomite formed by $CaSO_4$ dissolution tied to uplift of the Edwards Plateau (Replotted from data in Ellis 1985)

fact that the Edwards Group had a stable mineralogy of calcite and dolomite before the circulation of fresh water began and drove the precipitation of meteoric spar, microspar and dedolomite. Isotopic values for the dedolomites follow a similar trend to those of the microspars and pseudospars. As with the microspars and pseudospars formed by entry of telogenetic water, it can be shown that dedolomites are in isotopic equilibrium with Edwards water on a regional scale, which supports the contention that the dedolomites are forming from present-day formation-water (Ellis 1985).

Also, carbonates in both the fresh-water and bad-water zones were deposited in similar environments and underwent the same diagenetic history until the establishment of the fresh-water zone in the Miocene. If dedolomite was related to subaerial exposure prior to the Miocene, it would have formed in both zones since erosion surfaces are found in both zones. Furthermore, dedolomite occurs throughout the entire 100- to 200-m thickness of the fresh-water zone in the cores studied. It is not concentrated in a few zones as would be expected if it formed during subaerial exposure (Ellis 1985). Clearly, in spite of the "stable" mineralogy related to mesogenetic stabilisation of the Edwards dolomites, considerable additional diagenesis occurred in the superimposed Neogene fresh-water zone, and dedolomitisation probably continues to occur today.

Dedolomites such as those of the Edwards Plateau, created by meteoric flushing of calcium-sulphate evaporite salts, typically occur beneath exposure surfaces, dissolution breccias or unconformities. Well-exposed and studied examples of dedolomites, associated with meteoric karstification of a shallowly buried sulphate system, typify Miocene lacustrine sequences of the Madrid Basin in central Spain and the Calatayud Basin of NE Spain (Cañaveras et al. 1996; Arenas et al. 1999; Sanz-Rubio et al. 2001). A variety of calcite spar mosaic fabrics, initiated by dedolomitisation and calcitisation of magnesites, formed in association with well-defined solution collapse breccias (Fig. 7.86). Dominant dedolomite textures are made up of sutured calcites and radial-fibrous calcites, the latter consisting of pseudospherulite mosaics and fibrous crusts. Other subordinate dedolomite fabrics consist of micro- to mesocrystalline mosaics of rhombic, occasionally zoned calcites, as well as reworked pseudospherulite crystals.

The diagenetic carbonate zone (DCZ) that hosts these textures in the Madrid basin overlies and grades laterally into lacustrine dolomite (lower dolomite unit – LDU) and evaporites (evaporitic unit – EU), and in turn is capped by a palaeokarst or exposure surface (Figs. 7.86a; Cañaveras et al. 1996). The boundary between the DCZ and the LDU is transitional and is defined by grading in the $\%MgCO_3$ profile (Fig. 7.86b). Mg values range from 0.1 to 1.2 % in the dedolomites of the DCZ and micrites of upper limestone unit (ULU) and from 8 to 14 % in the underlying dolomites of the LDU.

Geochemical evidence indicates dedolomitisation occurred in the shallow subsurface in early burial (<40 m depth) via the throughflushing of oxidizing meteoric-derived ground waters (Cañaveras et al. 1996). $\delta^{18}O$ values of the dedolomites in the DCZ average −6.7‰ and range from −6.1 to −7‰, while $\delta^{13}C$ averages −8.2‰ and ranges from −7.4 to −9.2‰. The $\delta^{18}O$ values in the LDU average −0.3‰ while $\delta^{13}C$ averages −6.1‰. Isotope values in the ULU

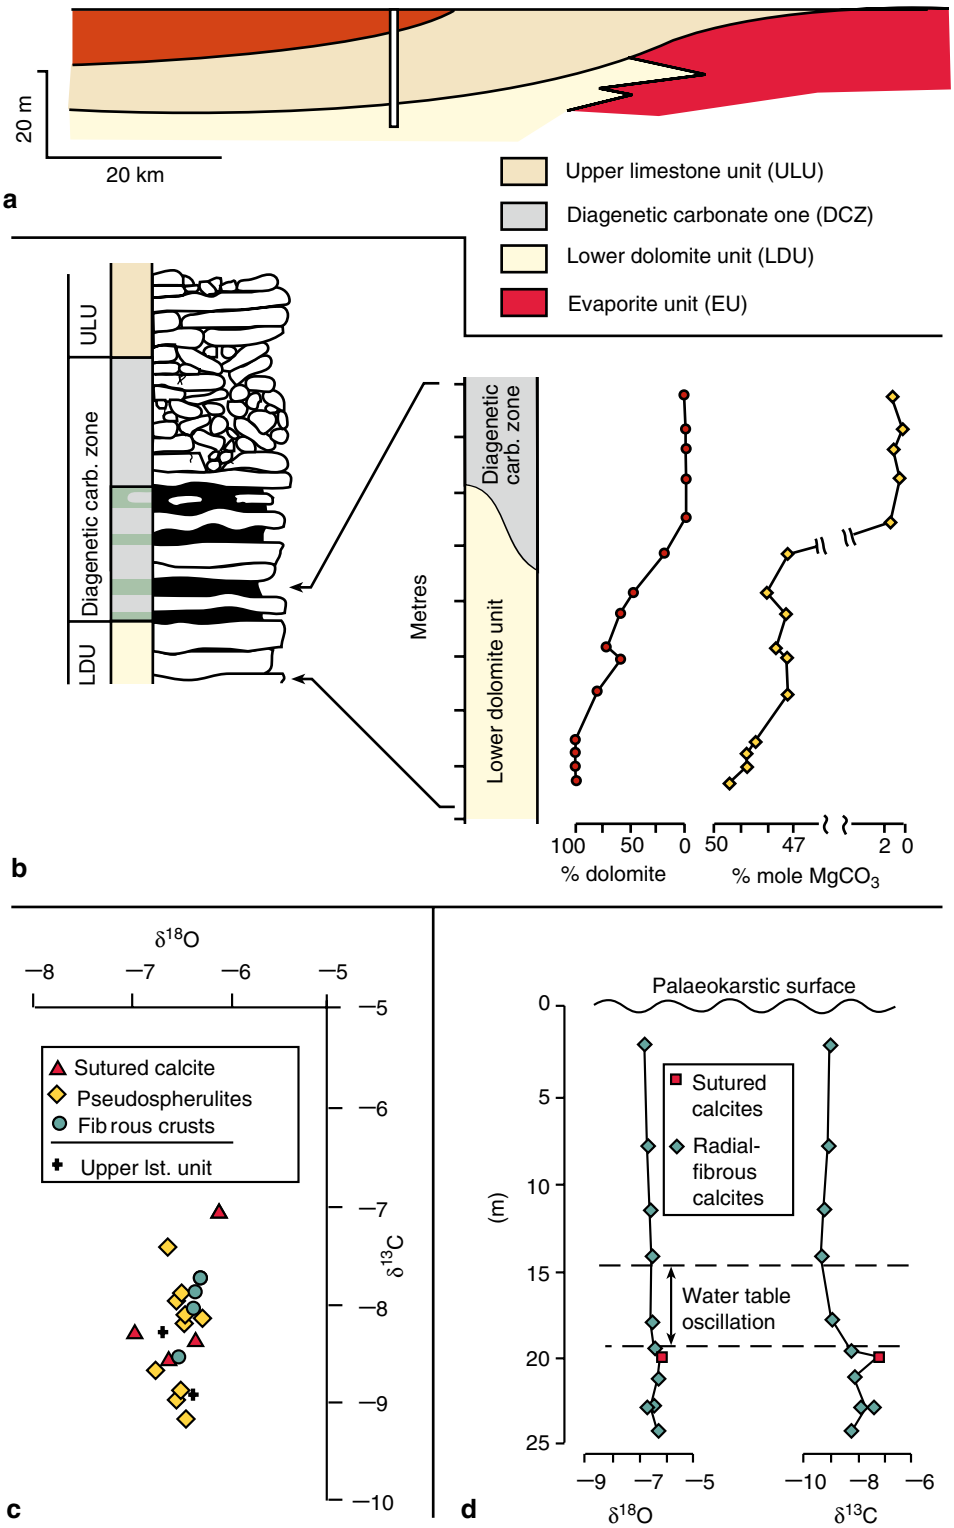

Fig. 7.86 Dedolomite in the Madrid Basin, Spain. (**a**) Distribution of the main subunits in Middle to Upper Miocene lacustrine units of the Madrid Basin, central Spain. (**b**) Shows the position of the solution collapse breccia in controlling the dedolomites and the nature of the contact between the lower dolomite unit (*LDU*) and the dedolomites of the diagenetic carbonate zone. (**c**) Oxygen-carbon crossplot of different types of calcite that make up the dedolomite. (**d**) Vertical trends in $\delta^{18}O$ and $\delta^{13}C$ in section of the Diagenetic Carbonate Zone (*DCZ*). The zone of carbon depletion between 15 and 20 m below the palaeokarst surface corresponds to a trend of more constant $\delta^{18}O$ values above this interval and more variable values below. These observations are consistent with the preservation of a palaeowatertable within the DCZ (After Cañaveras et al. 1996)

range from −6.4 to −6.8‰ in $\delta^{18}O$ and from −8.2 to −8.9‰ in $\delta^{13}C$ (Fig. 7.86c). The values of the dedolomites are consistent with precipitation from meteoric waters and give precipitation temperatures of 8–12 °C. Vertical trends in $\delta^{18}O$ and $\delta^{13}C$ can be used to define the average position of the watertable in the DCZ at the time the dedolomites were forming (Fig. 7.86d). This too supports a palaeokarst model characterized by an irregular shallow watertable and a narrow vadose zone (Cañaveras et al. 1996). The diagenetic system behaved as an open system for nearly all trace elements

analysed; but in the shallower zone (vadose zone) the system was partially closed with respect to strontium. The dedolomitisation was driven by two combined hydrographical patterns: authigenic recharge through limestone aquifers and allogenic recharge from adjacent mountains (Fig. 8.17).

Meteoric water influx at the margins of some shallow carbonate/evaporite lakes may be responsible for calcitization of the dolocrete and dolomitic muds fringing the lakes. Moreover, the calcitization, which occurs during early diagenesis due to drops in lake level, may either preserve or destroy the original dolomite fabric.

Dedolomites can also be formed via evaporite dissolution in the deeper subsurface mesogenetic realm where dissolution-derived basinal brines are escaping into the basin margin. Budai et al. (1984) suggested a subsurface setting for burial dedolomites of the Mississippian Madison Group of Wyoming and Utah. Two stages of fracture-related dedolomite are present, one that precedes and one that postdates regional dolomitisation. The early dedolomite occurred as active groundwaters flushed evaporitic sequences during shallow burial (on the way down in the burial cycle). The later post-stylolitisation fracture-associated dedolomite records chemistries and isotopic signatures of deep burial and tectonic-vein mineralisation. Associated with this late dedolomite are calcitised anhydrite nodules and stylolite-bitumen-related dedolomites that also indicate burial-related episodes of dedolomitisation. This episode of dedolomitisation took place during hydrocarbon maturation as basinal brines were moving through the Madison reservoir. Then hot Ca-enriched brines were able to dissolve anhydrite and dolomite, while at the same time precipitating calcite along stylolitised seams and within anhydrite nodules.

Celestite as an Evaporite Indicator?

Celestite ($SrSO_4$) occurs as crystals, nodules and cements in many bedded carbonates, particularly karstified limestones, but also in dolomitic and marly hosts (Hanor, 2000). Evaporite-associated celestite may replace or pseudomorph individual evaporite crystals, or it may be isopachous and passively fill fissures, vugs and nodular cavities created by the dissolution of an evaporite precursor, or it may form interclast cements within dissolution breccias. Internal textures preserved within a celestite nodule replacing an evaporite or an intergranular aggregate depend on the ratio of rock to fluid interaction and the timing of flushing.

Celestite, in association with baryte and strontianite can form massive intervals in diapir caprocks and haloes about the dissolving edges of salt allochthons. Caprock occurrences were discussed in the previous chapter and will not be discussed here. $SrSO_4$ in a bedded evaporitic carbonate host forms either as a primary precipitate from brines (Wood and Shaw 1976) or, more usually, by the diagenetic interaction of gypsum or anhydrite with groundwater-borne Sr-rich waters (Table 7.16). In this case the dissolution of a calcium-sulphate-containing bed supplies the SO_4, which then combines with Sr to precipitate as celestite, typically in zones of mixing between hypersaline and meteoric waters. West (1964, 1965, 1973, 1979) discusses the evaporite-celestite association in detail and the interested reader is referred to these benchmarks. Scholle et al. (1990) is recommended for a more general summary of celestite occurrence in sediments worldwide.

The Coahuila and the Burrros-Picachos platform sediments in Mexico is one of the largest exploited celestite regions in the world (Table 7.16; Dill et al. 2009 and references therein). Other significant evaporite/hydrothermal celestite deposits are located in Cretaceous evaporitic hosts in the Neuquen basin, Argentina, and in Northern Tunisia. In Europe, Spain is the leading strontium producer with its main output coming from the Montevives and Escuzar deposits, Granada. Both these celestite deposits are hosted in lower Miocene evaporitic sections of the Granada basin, which is an intermontane depocentre lying on the boundary between the internal and external zones of the Betic Cordillera. The primary mineralization is located in what is interpreted as a lower marine evaporitic unit, some 90 m thick. In Montevives the celestite replaces calcite in two stromatolitic limestone layers with ore thickness varying between 0.2 and 1 m an average grade of 86 %. The replacement of stromatolitic calcite and the infilling of fissures and cavities by celestite seem to be synsedimentary in the Montevives deposit, induced by salinity changes due to the mixture of sulphate salt waters and fresh waters during late Miocene times. In contrast, the Escuzar deposit is somewhat later and obviously karst related. Boulders of mineralized limestone with strontium, celestite and dolomite fill karst caverns in a gypsum host within the lower evaporite unit.

Similar, but not exploited, celestite-bearing beds of Lower Messinian age, and intercalated with clay and gypsum, also typify other basins of the Betic Cordillera. To the east, there are numerous celestite shows tied to $CaSO_4$ occurrences near Copaceni, Romania of Badenian age and near Cifteagil, Turkey. Various types of celestite occurrences hosted by Tertiary evaporite deposits and molasse-type volcanogenic sediments are found in the Sivas Basin, in east-central Anatolia, Turkey. Celestite deposits occur also as a fringe to Messinian gypsum beds at the southeastern edge of the Troodos ophiolite complex, near Maroni, Cyprus. They are part of a Neogene celestite occurrence (mostly Miocene hosts) that constitute a belt of calcareous-evaporitic sediment, that extends from the Iberian Peninsula, through the Mediterranean area, into the Arabian Gulf (Dill et al. 2005). Further eastward, and stratigraphically equivalent to Neogene Mediterranean sequences, are gypsum–strontium deposits

In part after Scholle et al. (1990), Hanor (2004)

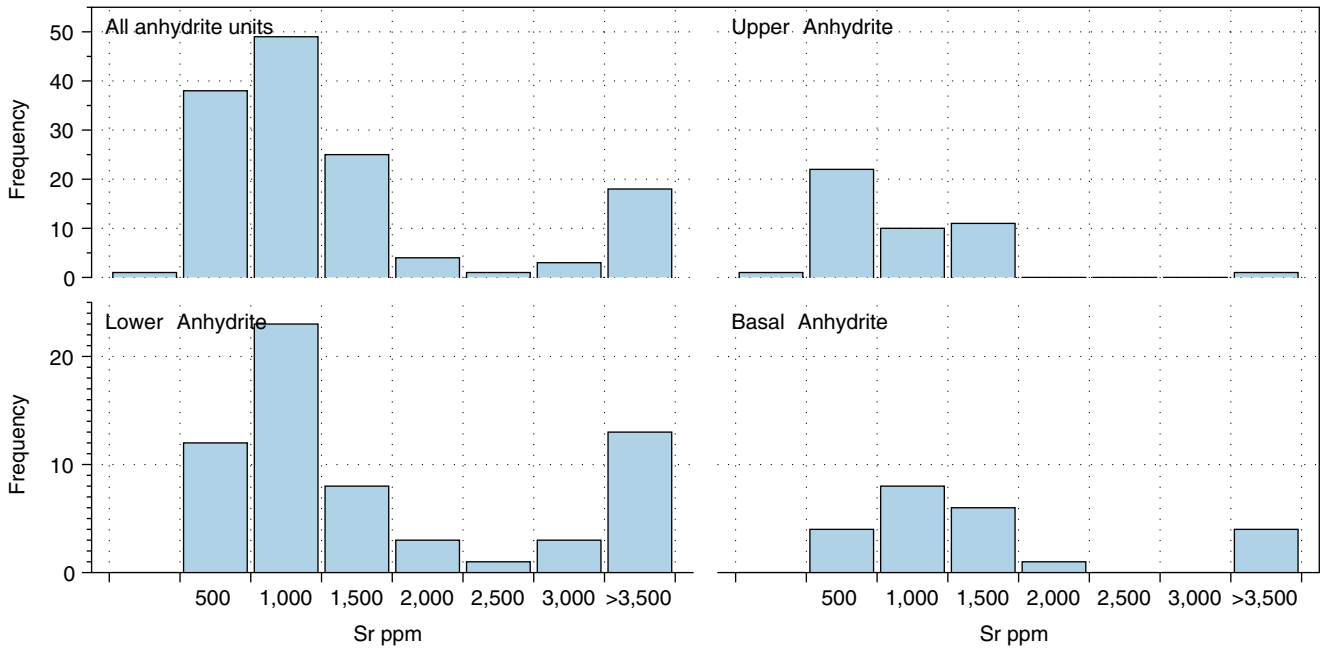

Fig. 7.87 Histograms showing strontium content of the main anhydrite units (*upper, lower and basal*) and a total frequency plot for the Polish Zechstein (Replotted from Hryniv and Peryt 2010)

that occur parallel to the Trucial Coast of the Arabian Gulf in Qatar and, to a lesser extent, the United Arab Emirates (Dill et al. 2005, 2009).

A number of papers over the past two decades have tied minor celestite occurrences with microbial microenvironments, often in saline settings with abundant gypsum (Sanz-Montero et al. 2009; Ziegenbalg et al. 2010). Experiments carried out by Schultze-Lam and Beveridge (1994) documented the epicellular precipitation of celestite on unicellular cyanobacteria. Douglas (2002) also found that celestite formed in the exopolymers surrounding purple sulphur bacteria in microbial mats from a Bahamian hypersaline pond. Gypsum-hosted endoliths in Death Valley, California (Douglas and Yang 2002) showed that organisms were able to precipitate Sr-rich minerals, such as celestite and carbonates, within a layered plexi. Each mineral type was segregated into a restricted chemical zone together with a specific microbe that helped to create the chemical conditions present at that particular depth in the community (Douglas 2005). In addition, Taberner et al. (2002) interpreted celestite as a byproduct of sulphate reducing bacteria in Eocene reefs and basinal sediments of NE Spain.

Strontium occupies calcium sites in the gypsum or anhydrite lattice, where it can be enriched ten times over the Sr content in enclosing dolostones (Carlson 1983). Strontium levels are around 2,000 ppm in marine gypsum and up to 5,000 ppm in anhydrite of marine origin (Stewart 1968). A study of strontium levels in the various anhydrites of the Zechstein series in northern Poland shows variations between units and a marked bimodal occurrence set (Fig. 7.87; Hryniv and Peryt 2010). Particular anhydrite levels differ, especially in the frequency of samples showing elevated Sr content. The greatest variation is seen in the Lower Anhydrite. This agrees with sedimentological observations indicating that the greatest differentiation of depositional environments occurred during the deposition of the Lower Anhydrite unit in Poland. It seems Sr content is a good indicator of brine concentration during primary gypsum precipitation and it seems that subsequent gypsum–anhydrite transformation does not affect the parent strontium distribution. The histograms of Sr content in the Basal Anhydrite indicate a slightly higher brine concentration than during Lower Anhydrite deposition, and the latter in turn was higher than brine concentration during the Upper Anhydrite sedimentation. The consistent elevated grouping seen across all three units and also clearly seen in the total frequency plot is indicative of samples and textures altered by diagenetic solutions with much of the Sr possibly coming from a source external to the host anhydrite. In general it seems that primary gypsum has somewhat elevated Sr contents compared to anhydrite (Table 7.17)

In this context it is notable that anomalously high concentrations of Sr occur within secondary gypsum samples in the Miocene (Badenian) gypsum of southern Poland, not in primary-textured gypsum (Kasprzyk 2003). This suggests localised primary gypsum leaching as the source or, alternatively, a supply of Sr form circulating pore fluids sourced by an anhydrite to gypsum phase change. Either interpretation

is supported by the petrography, which shows that replacive celestite is common in the secondary gypsum, whereas no discrete Sr mineral phase is seen within the anhydrite.

Such leaching of gypsum/anhydrite can create Sr-rich waters, as can the early dissolution of aragonite, which has enriched levels on Sr in the lattice when compared to calcite (Rodríguez-Aranda et al. 2005). Worldwide, most evaporite-associated regions of elevated strontium occur about basin margins rather than in the basin centre. This underline the importance of exposure/karstification in locally increasing Sr levels. Celestite volumes tend to build to ore grade levels in evaporite areas with a volcanic/volcaniclastic or magmatic association, such as the Coahuila and the Burrros-Picachos platform sediments (Dill et al. 2009). Such regions offer the possibility of brine leaching and enhancement Sr levels in hydrothermal-epithermal waters.

Documented sources of strontium-rich waters capable of precipitating celestite include:

1. Marine-derived brines (Frazier 1975; Baker and Bloomer 1988)
2. Waters formed during the conversion of aragonite to calcite (Nickless et al. 1975)
3. Waters formed during the dolomitisation of limestones (Wood and Shaw 1976)
4. Waters formed during the conversion of gypsum to anhydrite (Kushnir 1982; Orti et al. 1998)
5. Waters formed during the dissolution of subaerially exposed gypsum (Taberner et al. 2002)
6. Resurgent basinal waters that have leached Sr from feldspars and clays in arkosic redbeds (Scholle et al. 1990)
7. Red bed successions prograding atop a carbonate evaporite system and carrying a progradational meteoric hydrology that leaches Sr from the redbeds (Taberner et al. 2002) or from volcaniclastics
8. Shallow subunconformity waters with elevated Sr from bacterially-mediated calcitisation of anhydrites (Kendall 2001).

West (op. cit.) notes that sedimentary celestite has, in most cases, formed by direct replacement of gypsum or anhydrite; it tends to remain, even when exposed at the surface as it is much less soluble than either of those minerals. West's papers on celestite occurrences and controls in the Jurassic Purbeck evaporites of the United Kingdom remain as highlights in competent scientific documentation of field relationships and observation-based interpretation of process. He concludes that celestite formed by the selective removal of strontium from groundwater by reacting with dissolving beds and nodules of calcium sulphate.

Groundwaters containing a large proportion of calcium ions and a small proportion of strontium ions most commonly exist where limestones occur in proximity to the site of precipitation, likely facilitated by microbes. Celestite is less common where sandstones are the aquifers adjacent to a gypsum bed. The groundwater may be ascending or descending as it reaches the $CaSO_4$. Celestite beds of appreciable thickness are thus formed in Purbeck strata at the upper and lower boundaries of gypsum or anhydrite beds in contact with these groundwaters. Purbeck celestite replaced both nodular anhydrite and bird-beak gypsum roses (West 1964). Ongoing flushing by bicarbonate-rich groundwaters locally converted celestite to calciostrontianite (Salter and West 1966).

Carlson (1987) documented groundwater-driven replacement of calcium sulphate salts by celestite in Silurian carbonates of northwestern Ohio. Associated textures indicate evaporite dissolution and karstification. Celestites occur along the western margin of the Ohio (Cayugan) basin within the Greenfield Dolomite and undifferentiated Salina dolostones. The celestite replacements are more durable than the original evaporite salts, which have long since vanished from the outcropping carbonate. Replacement styles include: lenticular and prismatic crystals, replaced cauliflower nodules of anhydrite and laminar celestite beds replacing laminated evaporites. Remnants of the replaced material can be preserved as euhedral, deeply embayed outlines or within internally zoned growth bands that entrain inclusions of dolostone and anhydrite. Poikilo-topically enclosed remnants of anhydrite in celestite prisms with lenticular outlines show simultaneous extinction in thin section, possibly indicating that at the time of celestite replacement the gypsum was a single crystal and not a felted anhydrite mat. Alternatively, these lenticular crystals may be after axe-head anhydrite, implying a possibly later origin for at least some of the $CaSO_4$ than argued by Carlson. Other nodular and laminar celestite pseudomorphs display relict chickenwire and enterolithic structures indicating a primary anhydrite parentage.

Early, almost syndepositional, replacement of $CaSO_4$ nodules by celestite occurred in both the vadose and the active phreatic zone of the evaporitic Silurian Steinsfjord Formation of the Oslo Region, Norway (Fig. 7.88; Olaussen 1981). Marl and carbonate host sediments were deposited in supratidal, intertidal, and restricted subtidal environments. Celestite occurs in two distinct textural associations within these peritidal sediments: (1) as aggregates of tiny celestite crystals in nodular dolomicrites of the high intertidal facies, or (2) as anhedral or euhedral prismatic crystals infilling intrapores and interpores in the low intertidal to subtidal facies. Celestite is thought to have precipitated from SO_4 -enriched porewaters via the solution of calcium sulphate. Solution occurred early during evaporitic mudflat progradation as it was flushed by land derived meteoric waters (Fig. 7.88). Released sulphate then reacted with strontium generated by an aragonite to dolomicrite transformation within the high intertidal and an aragonite to calcite transformation in the low intertidal-subtidal.

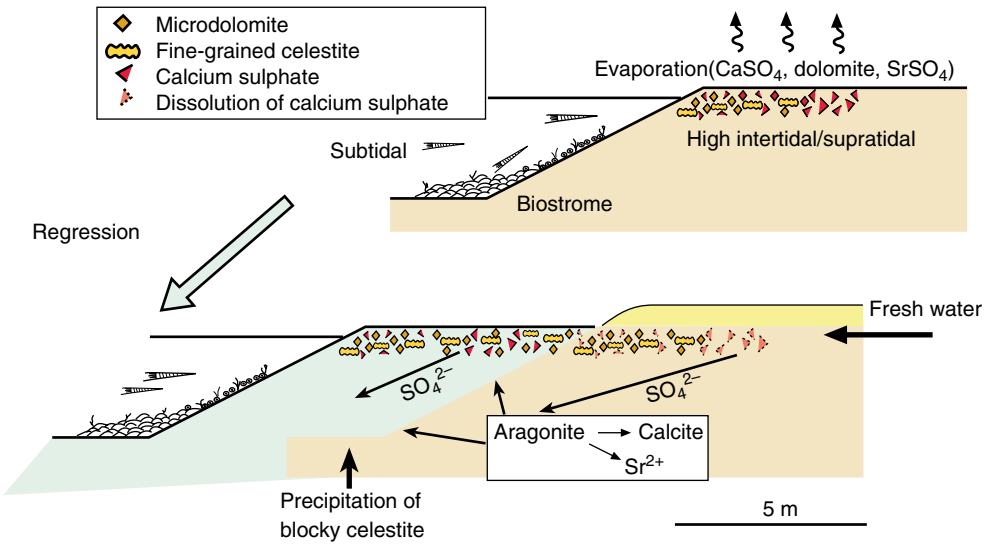

Fig. 7.88 Formation of early celestite replacement in the Brattstad Member of the Steinsfjord Formation, Norway. Strontium is derived from freshwater leaching of anhydrite and aragonite (After Olaussen 1981)

A similar progradational hydrology is documented in fracture-filling cements at La Tossa reef near Igualada, NE Spain, but in this case it was driven by a meteoric hydrology that continued to focus Sr flow well after the time of gypsum accumulation (Taberner et al. 2002). Fissure cements in other Eocene reefs along the same basin margin, such as Calders reef, tend to be dominated by baryte with only minor celestite. All reefs in the basin grew atop delta-lobe sandstones and prodelta marls, which at La Tossa, but not Calders reef, are overlain by Upper Eocene evaporites and hypersaline carbonates (Fig. 7.89a). Stable isotopic analyses of all reef carbonates indicate meteoric recharge was responsible for aragonite stabilization and calcite cementation.

Celestite precipitation at La Tossa began as reef stabilization occurred in early burial. Strontium needed for celestite precipitation was partly derived in situ from dissolution of aragonite corals in the reef and more basinal counterparts. However, $^{87}Sr/^{86}Sr$ data also suggest that Sr at La Tossa was also derived from dissolution of the overlying nearby calcium sulphate evaporites (Fig. 7.89b; Taberner et al. 2002). As the reef became lithified and stabilized, early burial fluid flow was increasingly focused in fractures and the cavities that linked them. The amount of residual strontium released from aragonite dissolution and recrystallization, along with gypsum dissolution, would have built up to supersaturated levels in the remaining interstitial fluids in the fractures.

^{18}O isotopic data suggest that local meteoric waters at La Tossa (a celestite-rich area) were enriched in Sr compared with those responsible for stabilization in other reefs in the area where fracture-filling cements are richer in baryte, with lesser celestite (Fig. 7.89b). At Calders, as in the La Tossa reef, meteoric cementation was completed before sulphate (baryte and minor celestite) cements precipitated in fractures and dissolution cavities. Calders reef is directly overlain by fluviodeltaic facies, related to the progradation of the St Llorenc del Munt fan-delta and so were susceptible to groundwater invasion immediately after deposition (Fig. 7.89a). Baryte may have formed in preference to celestite as a result of more efficient flushing of Sr from Calders reef before sulphate authigenesis.

Relatively low $\delta^{34}S$ and $\delta^{34}S$ enrichment ratios show that celestite at La Tossa reef formed from residual sulphate in pore waters after bacterial sulphate reduction. Taken together they also imply that there was a prior episode of sulphate recycling at La Tossa. Meteoric water reaching the La Tossa reef and nearby basinal areas was most probably charged with SO_4 from the dissolution of nearby younger Upper Eocene marine evaporites. This sulphate-rich groundwater, combined with organic matter present in the sediments, fuelled bacterial sulphate reduction in the meteoric palaeoaquifer. Strontium isotopes show a clear separation between the reef celestites and the subsequent evaporite phase (Fig. 7.89c). A progressive build-up of SO_4 and Sr concentrations occurred, it became relatively more important in time and drove ongoing celestite precipitation as more and more evaporites were dissolved.

In the other reefs (Calders Reef) a similar ongoing post stabilization source for Sr from dissolving gypsum was not present and so the volumes of celestite cement in their fractures are less. Furthermore, meteoric recharge at La Tossa post-dated the 34 Ma (Upper Eocene) time of evaporite deposition. Reef complexes in other parts of the same basin (e.g. Calders Reef) were stabilized by direct contact with waters from the deltaic wedge well before the time of any evaporite formation.

One of the most impressive examples of celestite precipitated in an active phreatic hydrology at a gypsum-limestone boundary is the evaporite-solution breccia-associated celestite mineralization in the Upper Permian successions in the Karstryggen Formation, central East Greenland (Fig. 7.90; Scholle et al. 1990). With an area of 80 km^2 and a potential resource of 25–50 tonnes at a grade of 50–60 % and local

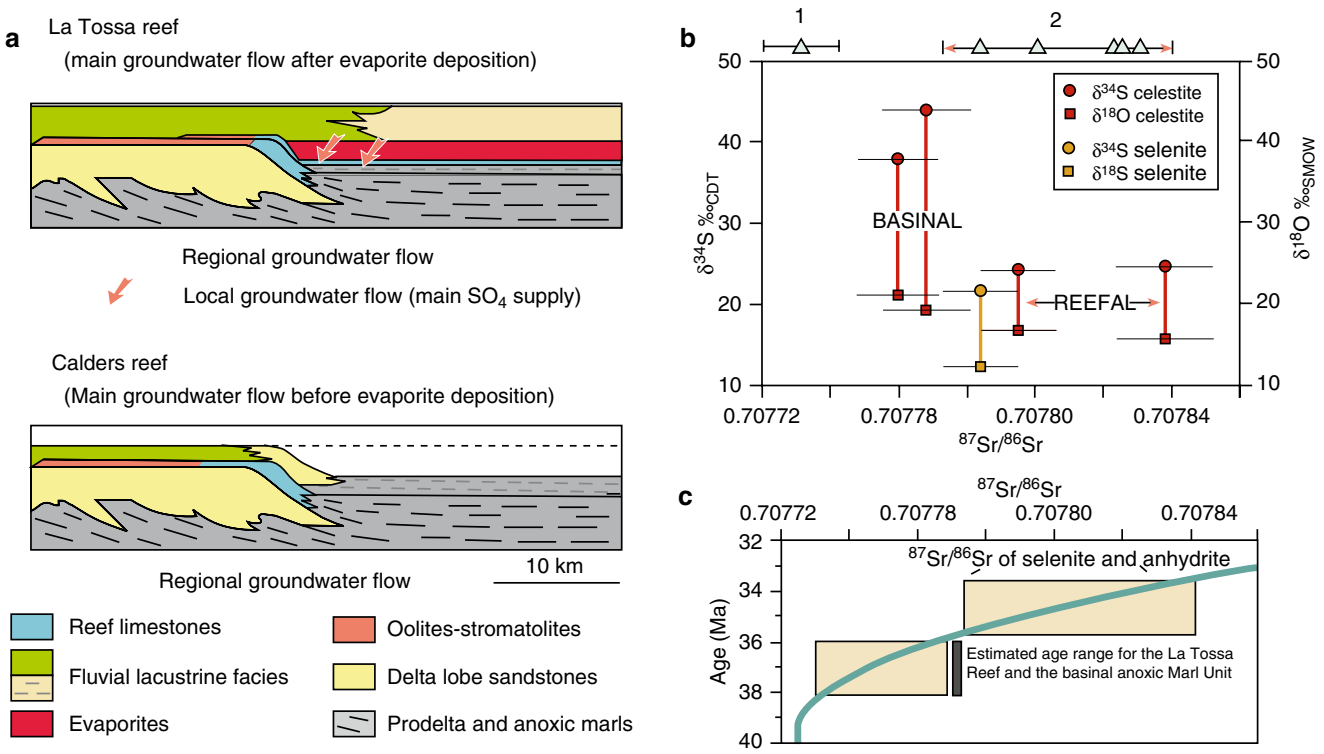

Fig. 7.89 Celestite in the Eocene La Tossa and Calders reefs, Spain (After Taberner et al. 2002). (**a**) Early diagenetic palaeohydrology determined for the basin margin La Tossa reef at Igualada, compared with the interpreted flow system at Calders reef. Arrows indicate the direction of fluid flow. The reef at Calders was flushed by lateral groundwater flow before evaporite deposition, whereas the major meteoric influence at La Tossa, Igualada, occurred after evaporite deposition and featured a local ongoing meteoric flow system that leached SO_4 and Sr from basinal evaporites. (**b**) Combined $\delta^{34}S$ and $^{87}Sr/^{86}Sr$ and δ^{18} O — $^{87}Sr/^{86}$ Sr cross-plot for celestite samples filling cavities in La Tossa reef and basinal sections. Isotopic ratios for the marginal selenitic gypsum are also plotted. The strontium isotopic composition are plotted as open triangles for stage 2 (meteoric-stabilisation) calcite cement from the reef (*1*) and the range of $^{87}Sr/^{86}Sr$ values for the Upper Eocene Lower Anhydrite Unit and selenitic gypsum (*2*). Celestite cements in reef fractures show $\delta^{34}S$, $\delta^{18}O$ and $^{87}Sr/^{86}$ Sr ranges that are closer to those of the Upper Eocene evaporites, whereas those celestites that depart from these values are from the basinal samples and later stage calcite cements in the reef. (**c**) Temporal variation in marine $^{87}Sr/^{86}Sr$ values. Except for near the inflection point, the errors in age estimates are incorporated in the thickness of the line. The measured $^{87}Sr/^{86}$ Sr values from the evaporites give an age of 34 ± 0.9 Ma for their formation. The age of the reef is constrained by the stratigraphic relationships with the evaporites and by comparison with outcropping reefs from the eastern margin of the basin

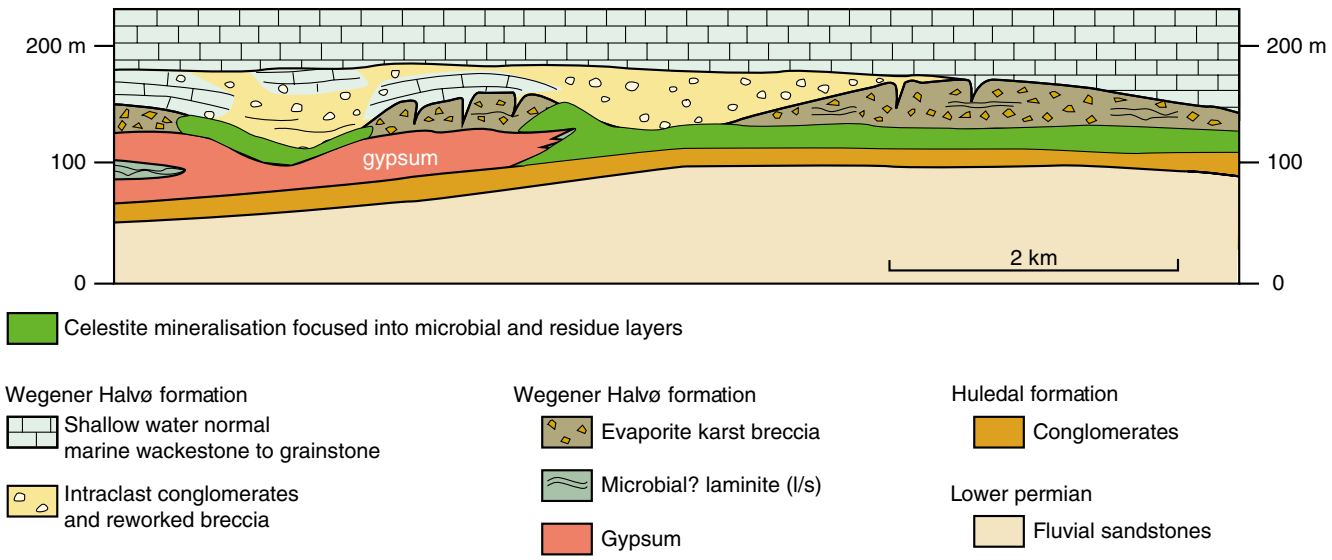

Fig. 7.90 Simplified east-west cross section in the Redval area Greenland showing the close lateral association between the calcium sulphate unit and the celestite mineralisation (After Scholle et al. 1990)

high-grade zones of more than 90 % celestite it constitutes one of the world's largest strontium deposits. It formed during replacement of the margins of a pre-existing gypsum (anhydrite) bed that had precipitated in one of several small structurally-controlled evaporite basins along the edge of a larger marine embayment. Celestite replaces both carbonate and evaporite minerals, as well as forming a passive void infill in pre-existing karst. There is a strong lateral association between the dissolutional edge of the saltern gypsum layer and the zone of celestite replacement. The timing of celestite emplacement at the boundary of the gypsum is not well constrained. The sulphate came from the dissolution of calcium sulphate, while the isotopic values indicate the strontium-rich waters came from the deep meteoric or compactional flushing of underlying red beds.

Not all evaporite-hosted celestite requires flushing of the edge of a sulphate bed by meteoric hydrologies. Celestite precipitating waters can also come from mixing of waters sourced in the burial dewatering of hydrated salts. Paleokarst cavities in the Lower Werra Anhydrite (Zechstein) of northern Poland are usually filled by bluish semitransparent anhydrite and more rarely by celestite, polyhalite, halite, and carbonate (Hryniv and Peryt 2003). In small karst cavities (a few centimetres across), rims of rod-like anhydrite crystals arranged in narrow bundles line the fissures, with the inner part of the cavity filled by a mosaic aggregate of short prismatic crystals of anhydrite and celestite, as well as coarse irregular anhydrite. Celestite crystals and fan-shaped aggregates, as well as spherulites of anhydrite, are rare in the smaller cavities and fissures. In bigger cavities (some ten centimetres across), multiple zones of fibrous anhydrite are arranged in different directions in the middle part of the cavity fill. The innermost parts of the larger karst cavities still remain as hollow in some cases, with the cavity walls encrusted by coarse, well-developed crystals of anhydrite and celestite.

Karst cavities in the Lower Werra Anhydrite developed in the subsurface by dissolution of $CaSO_4$ strata in halite-rich intervals flushed by gypsum dehydration waters. During gypsum dehydration, dissolution of halite increased the sodium chloride content of the solution and thus the solubility of calcium sulphate (Fig. 2.18b). Dissolved calcium sulphate was leached by diffusion and/or downward flow in the interstitial spaces, and the minerals in karst cavities precipitated from the same solutions as solutions became oversaturated. The work of Hryniv and Peryt (2003) shows that karst in sulphate deposits can develop non-telogenetically during ongoing burial and dewatering in a system without uplift and/or near-surface meteoric flushing.

So far, we have considered celestite as tied to direct dissolution of former bedded and nodular calcium sulphates, typically with nodular and enterolithic textures that indicate the evaporite association. But there are also laterally extensive stratiform and layered celestine deposits that are sufficiently rich in strontium to be mineable and hosted in epeiric carbonates. De Brodtkorb et al. (1982, 1997) described such an economic celestite-baryte deposit in Early Cretaceous strata from the extra-Andean region of Neuquen, west central Argentina. The ores are located in the sub-Andean Mesozoic belt and show a conspicuous stratabound character with an aerial extent that closely relates to the presence of regionally extensive platform sulphates. Isotopic $^{87}Sr/^{86}Sr$ data confirm an evaporitic origin for this celestite (Table 7.16). Host sediments were deposited during the transition to an epicontinental marine shelf environment from an earlier saltern. The celestite is always hosted in saline and hypersaline facies, as these beds were the source of the sulphate. Celestite forms as either syngenetic nodular beds with texture similar to those described earlier, or as more epigenetic stratabound ores composed of "in situ" celestite with texture showing stalactite growth and cavity infilling in its carbonate host, possibly as replacements of bedded saltern sulphates. There are also epigenetic vein-type ores. Open fill textures are interpreted as burial phreatic, precipitated by mesogenetic Sr-enriched solutions dripping into gas filled dissolution cavities in a previously karstified (?bathyphreatic) sulphate evaporite and carbonate host. Some have argued these enigmatic stratiform ores are primary seawater-derived precipitates, others see there origin as mesogenetic replacements of bedded calcium sulphate salterns.

Many stratiform celestites, including the Argentinian ores, have crystals encasing inclusions of solid hydrocarbons and textures showing they precipitated in association with saddle dolomite, burial anhydrite and metal sulphides. Hanor (2004) documents the worldwide association of such stratiform sediment-hosted celestite with epeiric carbonate platforms (Table 7.17). He notes their association with bedded platform sulphates and also points out that the largest known sedimentary celestine occurrences, each with several million metric tons of $SrSO_4$, cannot be readily explained as primary precipitates or nearsurface meteoric replacements of nodular sulphate evaporites. The largest deposits, as in South America and Greenland, tend to occur as epigenetic replacements in carbonate and evaporite hosts within epeiric platforms that range in age from Silurian to early Pliocene. There is variable evidence of associated hydrothermal activity in these deposits, and Sr isotopes typically have a more radiogenic signature than the prevailing seawater of the time (Table 7.17). Hanor argues the key to explaining the origin of these massive sediment-hosted celestites lies in determining why celestite is the replacement phase in these deposits and not baryte ($BaSO_4$), which is orders of magnitude less soluble.

Hanor (op. cit.) concludes that stratiform celestite hosted in epicontinental platforms did not form syndepositionally from Sr-enriched brines created by the evaporation of seawater. Sr is removed from concentrating marine brine during

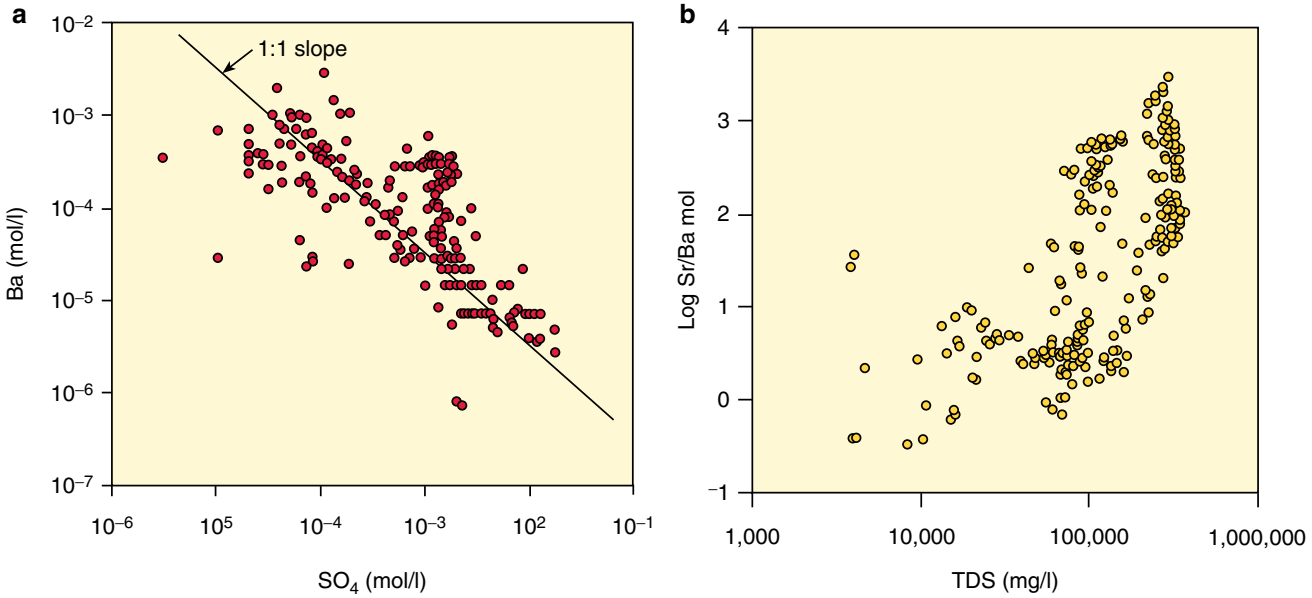

Fig. 7.91 Ba in subsurface basinal brines (After Hanor 2004). (**a**) Variation in dissolved Ba versus dissolved sulphate in basinal brines. (**b**) Variation in Sr/Ba ratio versus the salinity of basinal brines (See Fig. 8.40 for Sr trend)

the halite stage of evaporation as a dispersed sulphate phase and not as precipitated as bedded celestite. The association of large stratiform celestine deposits with marine platform carbonate–evaporite sequences most likely reflects, at least in part, the significant difference in the geochemical behaviour of Sr and Ba during mesogenetic diagenesis.

Concentrations of Sr in subsurface sedimentary fluids are buffered by silicate–carbonate mineral assemblages. Concentration of Sr in solution in modern subsurface waters increases significantly with increasing salinity (Fig. 8.40). The concentration of Ba, in contrast, is controlled by equilibrium with the baryte solid phase and is inversely related to the concentration of dissolved sulphate in subsurface fluids (Fig. 7.91a; Hanor 2004). Basinal fluids having the highest Sr/Ba ratios are also the most saline and have moderately high levels of sulphate (Fig. 7.91b). Thus hypersaline mesogenetic brines flushing through a carbonate platform will be more likely to be saturated with celestine than baryte. The precursors to such waters were produced in hypersaline pans and salterns by the evaporation of seawater. As these brines reflux into underlying or laterally adjacent sediments, they leach substantial amounts of Sr as they attempt to achieve chemical equilibrium with their host sediments. In contrast barium concentrations in subsurface reflux brines are kept relatively low by the presence of dissolved sulphate. Precipitation of widespread mesogenetic celestine occurs where these diagenetically altered reflux fluids come into contact with beds containing calcium sulphate minerals and/or sulphate-rich waters. Thus Hanor argues, the stratiform celestite ores of the world are not recrystallised primary precipitates or derived in meteoric mixing zones. They are the result of deeply circulating (hypogene) hypersaline brines moving through an anhydritic epeiric platform under a hydrological drive that is tied to platform restriction and creation of dense reflux brine. The elevated Sr does not come from the parent connate water, but from rock-fluid (brine) interactions with buried platform carbonates and sulphates. Hydrocarbons are often mobile in the same sediments at the same time.

Not all celestite – calcium sulphate associations are hosted in sediments. An unusual late-stage celestite is intimately associated with hydrothermal $CaSO_4$ (now gypsum) in the Asaka gypsum mine (Koriyama City, Japan). Celestite occurs on the sides of fibrous (satinspar) gypsum crystals and veins in the mine area. The satinspar indicates telogenetic alteration. The celestite is interpreted by Matsubara et al. (1992) as a hydration product of strontian anhydrite (SrO up to 0.94 wt %), which occurs in the same area. The hydration is very late, associated with uplift and meteorically-driven conversion of strontian anhydrite to gypsum, where the $SrSO_4$ molecule remains intact during the conversion and eventually crystallises as celestite. Chapter 16 discusses the worldwide occurrence of hydrothermal anhydrites and their association with high-temperature sulphide mineralisation.

Fluorite as an Indicator?

Fluorite (CaF_2) and baryte ($BaSO_4$) are not uncommon as hydrothermal phases in mineralised sedimentary carbonates especially in MVT (Mississippi Valley Type) settings. Compared to sediment-hosted celestite, the range of mesogenetic associations

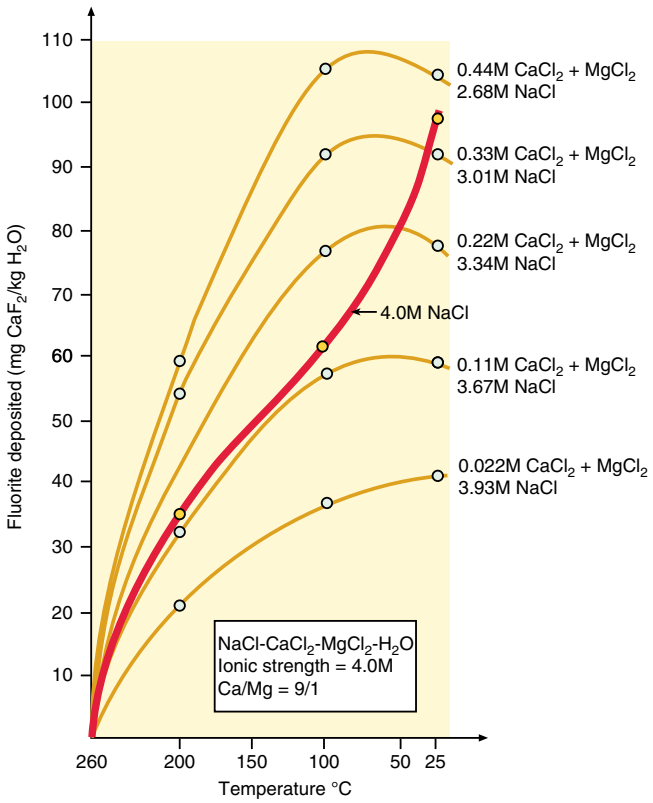

Fig. 7.92 Quantity of fluorite precipitated by cooling of $NaCl \pm CaCl_2 \pm MgCl_2 \pm H_2O$ solutions with Ca/Mg ratio of 9:1 and an ionic strength of 4 M from 260° to 25 °C (After Richardson and Holland 1979)

is more cosmopolitan and their appearance in a carbonate platform host typically reflects the carbonate's high susceptibility to replacement, especially when flushed by somewhat acidic, cooling hydrothermal and basinal fluids.

According to Richardson and Holland (1979), the solubility of fluorite in NaCl solutions increases with increasing temperature at all ionic strengths up to about 100 °C (Fig. 7.92). At NaCl concentrations above 1.0 M, the solubility of fluorite increases continuously above 100 °C, and it increases also with increasing $CaCl_2$ and $MgCl_2$ concentrations in the NaCl-dominant solutions. According to Munoz et al. 1999, this means that most nonmagmatic fluorite-carrying basinal waters in a sedimentary basin are derived in part from interactions with dissolving evaporites. The interaction allows such hydrothermally circulated waters (high salinity and $CaCl_2$ -bearing) to attain the elevated levels of dissolved fluorine required to precipitate significant volumes of fluorite during subsequent brine cooling. Elevated salinities in the subsurface can come from evaporite dissolution or from brine reflux. Much of the nonmagmatic fluorite dissolved in these saline brines is sourced by subsurface flushing of organic-rich black shales.

For example, fluorite is a minor late stage mesogenetic cement in Devonian carbonates in the Keg River Formation, Canada (Aulstead and Spencer 1985). The fluorite was carried to the site of precipitation by rising and cooling basinal brines that had flushed deeply buried bedded evaporites and organic laminites. Similar late-stage fluorite cements in voids and fractures have precipitated from structurally-focused basinal brine flows in the Jurassic reefal carbonates in Zaghouan Province in north-eastern Tunisia, in the Smackover Formation of the Gulf of Mexico, in the Upper Permian Karstryggen Formation of Greenland and in many other buried and faulted carbonate platforms subject to metal sulphide and saddle dolomite emplacement (Souissi et al. 1997). All these fluorites precipitated from highly saline brines sourced in deep halokinetic settings where mesogenetic salt dissolution dominates.

Likewise, the isotopic signatures of authigenic fluorites in a number of European fluorspar deposits show the supplying hydrothermal waters were sourced in, or carried by, brines from dissolving or tectonically juxtaposed evaporites. Examples include vein fluorites (Pb-Zn-F) associated with the Permian Haselgebirge evaporites in the Austrian Alps (Götzinger and Grum 1992), massive fluorites in veins that crosscut Cambro-Ordovician clastics in the southwestern Massif of Albigeois, France (Munoz et al. 1999) and in Toarcian shales atop the main unconformity atop the French Massif Central (Fig. 7.93a; Boiron et al. 2010). The latter is the most important fluorite district in France is thought to have formed during Mesozoic times (150 Ma, Bonhomme et al. 1987) during a third stage of extensional tectonics occurring much after the main rifting of the Atlantic ocean, and before the Gascogne gulf rifting, considered as Aptian-Albian.

Munoz et al. (1999) proposed a model of continental brine circulation (salinity: 20–26 wt% eq. NaCl, Ca–(Mg)–Na brines and T_h between 85 and 170 °C), penetrating deeply into the basement, with the formation of ores along faults where the fluorite deposited as a consequence of temperature drop.

Although, the main ores precipitate from saline waters with $\delta^{18}O$ around 0–3.2‰ and δD in the range of −15 to +63‰, Munoz et al. considered that isotopic features were indicative of meteoric waters that underwent an isotopic shift by interaction with host rocks. This was the main argument in favour of the continental origin of the saline brines the precipitated the fluorite. Boiron et al. (2010) noted that more recent paleogeographic reconstructions and fission track data tend to indicate that the French Massif Central was in great part covered by the sea during Lias and Dogger times making a continental/meteoric brine source less likely and argue for a more likely marine/evaporitic basinal brine source (Fig. 7.93a).

Likewise the largest fluorite and celestite province in the world is derived from hypersaline basinal waters and occurs with the borders of the Cretaceous carbonate-evaporite

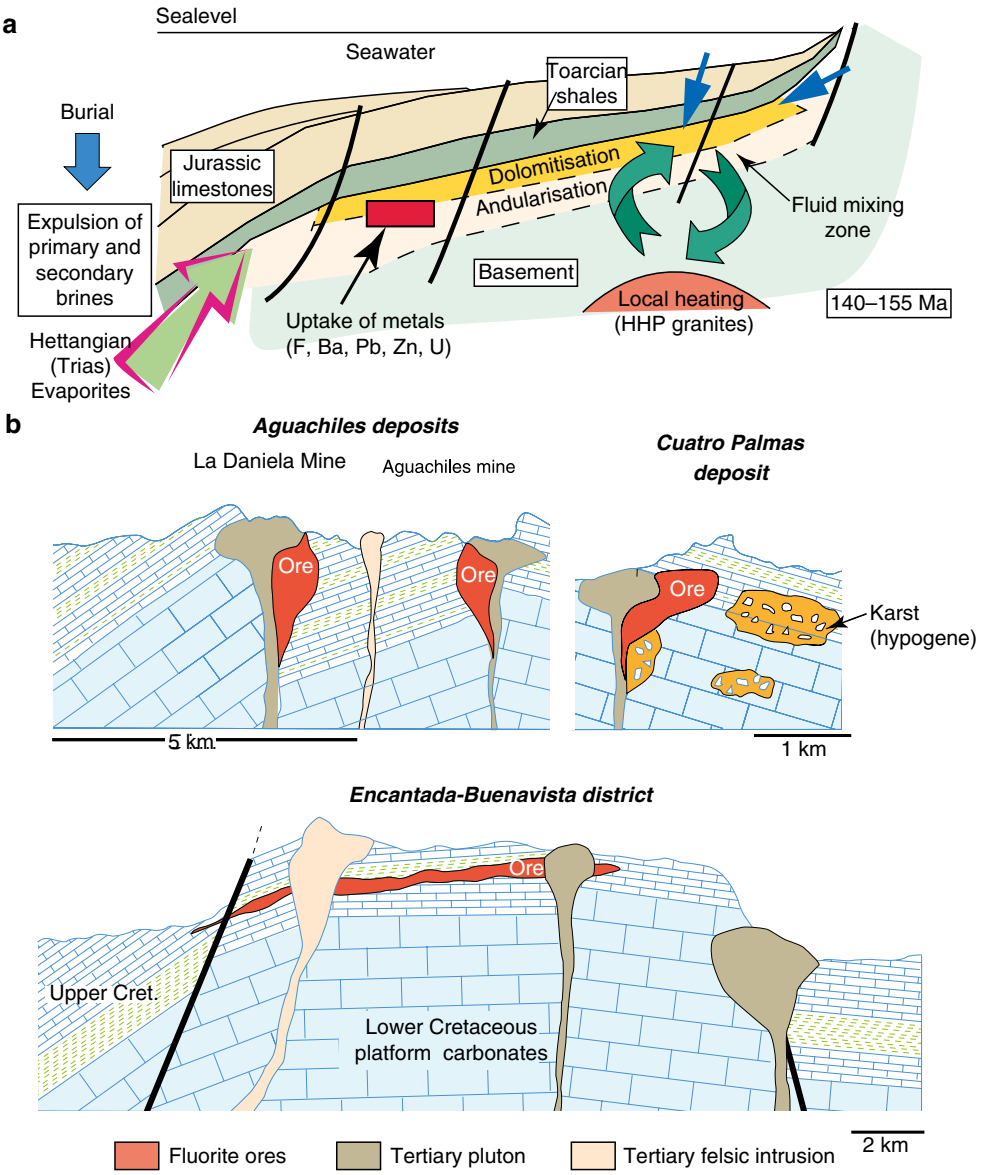

Fig. 7.93 Fluorite at the scale of basinal fluid escape. (**a**) Schematic of fluid circulation in the north-western part of the French Massif Central at the unconformity between the basement and sedimentary cover, showing the upward evaporitic brine migration below the Toarcian shales and associated mixing in fault zones (After Boiron et al. 2010). (**b**) Schematic cross sections of three different types of fluorite mineralization and emplacement; Aguachiles = unconformable fluorite lenses; Cuatro Palmas = Cave-filling fluorite; Encantada-Buenavista = fluorite mantos (After González-Partida et al. 2003)

platforms of Mexico (González-Partida et al. 2003). The various deposits define the border of the Morelos platform (La Azul deposit), the border of San Luis Valles platform (El Refugio deposit, El Realito deposit and Las Cuevas deposit), the border of Tamaulipas platform (numerous prospects, minor celestite and baryte deposits), along with that Zaragoza deposit, El Tule deposit, Sto. Domingo deposit, El Triangulo deposit, Aguachiles deposit, Cuatro Palmas deposit, Boquillas deposit, Pico Etereo deposit, and La Encantada–Buenavista deposit (Fig. 7.93b). Brines related to the various fluorite orebodies had a genetic relationship to the hypersaline basinal brines moving up dip from the Jurassic petroleum basins located west of the fluorite bodies. These brines have strong similarities to reported fluids from Mississippi Valley type deposits and the fluorite province is less than 80 km from the San Vicente MVT Pb-Zn district (Chap. 15). The fluorine-rich fluids were created in part by mesogenetic evaporite dissolution and migrated toward the platform margins during the mid-Tertiary (30–32 Ma) collision event along extensional faulted zones created during basin-and-range style tectonism. Mixing of two different salinity brines was responsible for precipitation and mineralization. Heat from magmas, related to the tectonic extension, caused decrepitation and changes in the shape of fluid inclusions near the fluorite contact zones but were not necessarily integral to the ore precipitation (González-Partida et al. 2003).

There is also a halokinetic/hydrocarbon/thrust fluid link to crosscutting fluorite veins in Jurassic carbonates of the Koh-i-Maran, Baluchistan in the North Kirthar Range, Pakistan (Guilhaumou et al. 2000) and the halokinetic Triassic evaporites of Tunisia (Dill et al. 2014). Clearly, the dissolution of deeply buried halite (both bedded and diapiric)

can supply the saline chloride brine needed to act as a fluoride and metal carrier in nonmagmatic sedimentary systems (see Chap. 15 and Warren 2000b).

As well as these broad-scale metallogenic basin-margin associations, fluorite also forms a widespread, but volumetrically minor, early diagenetic and even syndepositional authigenic mineral phase in some evaporitic matrices, where its precipitation may even be related to solar concentration of a surface brine. For example, fluorite has precipitated as ooids and pellets in a 40 cm thick tuff bed in the Gila Conglomerate of New Mexico (Sheppard and Mumpton 1984). It also forms microscopic near-spherical grains in lacustrine tuffaceous zeolitised Pliocene mudstones in Oregon. There overall fluorite content is around 5 % but is <16 % in the zeolitic tuff and is attributed to diagenesis of sediments in an alkaline lake independent of hydrothermal activity (Sheppard and Gude 1968). Fluorite also occurs as sparse isotropic euhedral cubes (50–200 μm diameter) within primary gypsum nodules at depths of 235–240 m below the present land surface in Eocene carbonate mudstones of Florida. Celestite also occurs in the same sediment. Cook et al. (1985) argued that the Florida fluorite was syndepositional with the precipitation of gypsum in the capillary zone of an Eocene sabkha mudflat. If so, it was ultimately derived by the evaporative concentration of normal seawater. Additional fluoride in the parent pore waters may have been derived by fluvial transport of salts weathered from Appalachian volcanics.

Cook et al.'s conclusion is perhaps supported by the work of Kazakov and Sokolova (1950) who documented sedimentary fluorite in various marine carbonates/evaporites in Russia in hosts that range in age from Cambrian to Cretaceous. In related laboratory experiments they observed that fluorite can precipitate from seawater brines concentrated three to four times by volume, especially if an additional (fluvial of volcanogenic) source of dissolved fluoride was available in the depositional setting.

In a similar fashion, Sheppard and Mumpton (1984) explain the primary precipitation of early diagenetic fluorite using the analogy of high fluoride alkaline lakes in the East African Rift, such as Lake Magadi, Lake Natron and Lake Manyara (Table 4.4). Subsequent to Surdam and Eugster's (1976) documentation of fluorite as a common authigenic phase in Pleistocene sediments of the Magadi Basin, Icole et al. (1990) documented stromatolitic layers that are mainly composed of fluorite rather than calcium carbonate in lower Pleistocene lacustrine beds along the western edge of Lake Natron, Tanzania. Without doubt these are early rather than later burial diagenetic precipitates. Moreover, Pleistocene fluorite is replaced by dolomite in the uppermost parts of some of the stromatolite layers, but this replacement still preserves the original sedimentary texture. Fluorite is also reported in sediments of Lake Bogoria, Kenya, in an interval that also contains sodium silicate gels (magadiite; Renaut et al. 2002). There is even a palaeobiological response to the high levels of fluorine in saline lake waters in the rift valley. Many fossil fish, preserved in the Plio-Pleistocene phosphoritic lacustrine sediments of Lake Manyara, are hyperostitic (enlarged and fused bone structures), a biological response to elevated fluorine levels in the lake waters (Schlüter and Kohring 2002).

The elevated fluoride concentrations in saline waters of the East African rift are linked to a number of sources and processes. Regionally these high values are in large part related to the development of saline (concentrated) groundwaters that have earlier flushed and leached hyper-alkaline volcanic rocks of the rift zone, including nepheline and carbonatite magmas and associated ash deposits (Chap. 16). These igneous sources can accumulate large concentrations of fluoride from melts and their epithermal volatile fractions. Hence, saline water sumps in the rift zone can accumulate fluoride directly as a result of weathering of these rocks, as well as further concentrating contributions from high-fluoride geothermal/hydrothermal solutions. The fine-grained and friable ashes surrounding most of the saline lakes are likely to be particularly reactive. Weathering of the silicate minerals in the lavas and ashes by silicate hydrolysis reactions produces Na-HCO_3 -rich groundwaters, which are relatively depleted in Ca and Mg. Hence, high concentrations of fluoride can occur as the solubility of fluorite (CaF_2) is not a limiting factor in the saline lakes (Edmunds and Smedley 2013; Ayenew 2008). Jones et al. (1977) reported extremely high fluoride concentrations (up to 2,170 mg/l) in saline groundwaters from boreholes in Magadi lake sediments.

Crocker (1979) proposed that granular blockspar (fluorite) ore in the Proterozoic Transvaal Supergroup of South Africa indicates primary synsedimentary endogenic fluorite mineralisation and is a time-specific precipitative stage tied to Precambrian dolomite evaporite facies. Rouchy et al. (1987) documented an association between fluorite, native sulphur and Visean (Carboniferous) evaporites. In an earlier paper, Amieux (1980) showed fluorite was a characteristic diagenetic stage in the black shale to evaporite transitional facies within the Ludian (Lower Oligocene) sediments of the Mormoiron Basin, Vaucluse, southeastern France. There the major fluorite precipitation phase postdates major dolomitisation and gypsification but precedes celestite and silicification. Likewise strontianite, celestite and fluorite formed lenses during the Middle Muschelkalk and layers in the Central European basin, when it was sealed off and subject to extensive evaporation (Dill et al. 2009). There, fluorine is considered an indicator for an intermediate levels of evaporation and is intimately bound to the dolomite–sulphate facies.

But, fluorite is not solely sourced or carried in evaporite brines, nor deposited only in a saline sedimentary host. That

is just the focus of fluorite discussion in this chapter. Fluorite can be found in fissure veins and stockworks in granitic rocks, greisens, pegmatitic carbonatites, metamorphics, and igneous rocks that include volcanic sublimates (Hodge 1986). These are not necessarily tied to an evaporite source nor an interaction with an evaporite-derived brine. Nor are some of the vein and stratified (manto) fluorite deposits that are associated worldwide with areas of rifting and faulting, where fluoride-rich hydrothermal fluids may migrate up from the lower crust or mantle to replace carbonate hosts (Van Alstine 1976).

Baryte as an Indicator?

Baryte is typically a diagenetic or secondary phase (replacement or pore fill cement) formed by the mixing of fluids; one containing barium (Ba^{2+}) and another containing sulphate (SO_4^{2-}), such that supersaturation is achieved upon mixing. Thus baryte in the sedimentary realm occurs in a wide variety of settings ranging from lakes and soils to cold seeps and vents on the deep open ocean floor to restricted epicontinental seaways (Johnson et al. 2009; Griffith and Paytan 2012). Baryte, like fluorite, is also a widespread hydrothermal precipitate or replacement. Increasingly, microbes are seen as playing a significant role in the precipitation of near-surface baryte, often with gypsum and dolomite as a co-precipitates (García-del-Cura et al. 2014; Sanz-Montero et al. 2009; Bonny and Jones 2008).

Because its geochemistry is similar to the major rock-forming cation, K+, the primary source for sedimentary baryte is via leaching of K-minerals, such as K-feldspars and K-micas. Baryte's occurrence is not specific to evaporitic sequences, but it is a commonplace replacement/cement in evaporitic hosts. This is especially true in those parts of a basin where evaporite-focused fluid flow brings together hot Ba-rich basinal brines (Cl-rich waters flushing and leaching arkoses (alkali feldspars and micas), redbeds, volcanics and volcaniclastics) and sulphate-rich waters from dissolving sulphate evaporites (anhydrite beds and nodules, halokinetic basal anhydrites, allochthon décollements, dissolution residues and diapir caprocks).

Economically, baryte's occurrence is mostly as gangue in various hydrothermal beds and veins entraining metalliferous ores, especially in halokinetic settings (Chap. 15). Baryte also forms stratiform layers, veins, nodules and cavity fills in sulphate-rich sediments, especially in the early Archaean, and is also a commonplace precipitate in black smokers and volcanic-hosted massive sulphide (VHMS) deposits (Chap. 16). In such cases, much of the sulphate is nonevaporitic, it comes to the precipitation site either as sulphide in solution which is oxidised to sulphate at the site of deposition or as sulphate ions carried by hydrothermally circulated seawater (Shikazono et al. 2012). Baryte is also a widespread modern precipitate in deepwater cold seeps, mud volcanoes, springs and brine lakes on the supra-allochthon floor of the Gulf of Mexico (Fu et al. 1994) and their Neogene caprock counterparts (Saunders and Thomas 1996). In the following section we focus on baryte with an obvious evaporite association.

Baryte can directly replace sedimentary gypsum or anhydrite throughout a rock layers diagenetic history. At 25 °C and 1 bar, the value of the equilibrium constant, K, for the replacement reaction:

$$CaSO_4 + Ba^{2+} \Leftrightarrow BaSO_4 + Ca^{2+}$$

as calculated from Gibb's Free Energy values, and assuming pure solids is:

$$K = 10^{5.5} = a_{Ca^{2+}} / a_{Ba^{2+}}$$

Thus, it is thermodynamically feasible for baryte to replace calcium sulphate at earth surface temperatures whenever the activity ratio of ($a_{Ca^{2+}}/a_{Ba^{2+}}$) is less than $10^{5.5}$, a condition met in many subsurface waters (Mossman and Brown 1986). At more elevated temperatures the limiting activity ratio is even less due to the retrograde solubility of anhydrite.

Loosely arranged platy crystals of baryte form pseudomorphs after lenticular gypsum in Quaternary arid soils from central Australia (Sullivan and Koppi 1993). In older sedimentary deposits, evaporitic baryte typically replaces nodular forms with irregular and coalesced outlines reminiscent of anhydrite or gypsum, or forms stratiform layers. In several such cases, isotopic analysis indicates the sulphate in the nodules and layers was remobilised from a calcium sulphate precursor such as; caprock sulphate (von Gehlen et al. 1962), sedimentary gypsum (Kesler et al. 1988; Parafiniuk 1989), or anhydrite-rich evaporites (Mossman and Brown 1986; Frimmel and Papesch 1990).

Stratiform baryte is often found as a late stage precipitate in association with pervasive ferroan carbonate haloes in the alteration zones around growth faults and salt welds in halokinetic provinces. These haloes tend to define zones where escaping Ba-rich hypersaline basinal waters are flowing out of the basin via halokinetically-focused fault conduits, often feeding stromatolitic baryte seeps on the seafloor (Warren 1999, 2000b). In ancient counterparts where the seepage conduits can outcrop (as in the Neoproterozoic sediments in the Adelaide fold belt) it is clear that the ascending iron- and barium-rich fluids interacted with sulphate present in anhydrite or gypsum nodules/beds, other times with sulphate beds or dissolution residues or with seawater sulphate. Modern examples of salt focused brine outflow in halokinetic provinces tend to occur in relatively deepwater muddy hosts. This is where the most active salt allochthon flow occurs, as on the continental slope and rise of the Gulf of Mexico or the tectonic high of the Mediterranean ridges (Castellini et al.

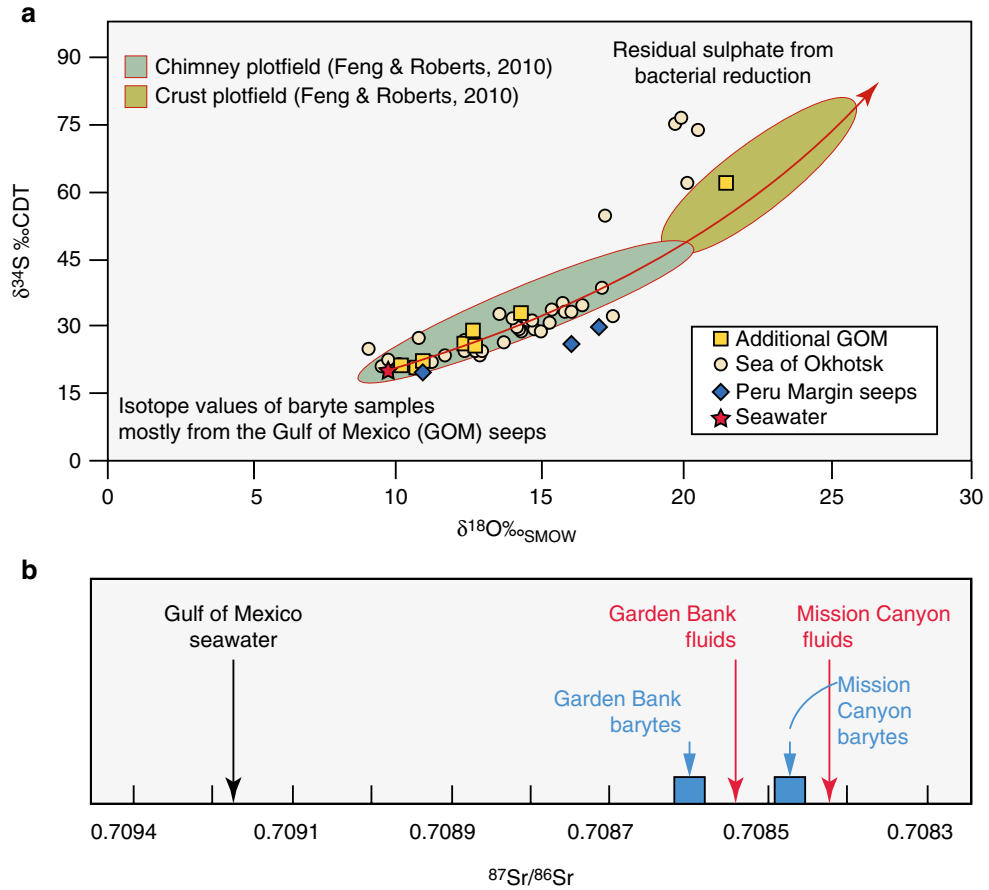

Fig. 7.94 Gulf of Mexico, cold seep baryte chemistry. (**a**) Plot-fields from sulphur and oxygen isotopic compositions of baryte samples from hydrocarbon seeps of the Gulf of Mexico (*green ellipses*, after Feng and Roberts 2010). Aquilina et al. (1997) interpreted their data (*blue diamond*) from the non-salt-allochthon Peruvian seep margin as having equilibrated at temperatures higher than 100 °C. Cooler temperatures are suggested from more recent investigations at hydrocarbon seeps in the Gulf of Mexico (*orange squares*, Fu, 1998 and *green plotfields*, Feng and Roberts 2014) and Derugin Basin, Sea of Okhotsk (*brown circles*; Greinert et al. (2004)). The data from the Gulf of Mexico baryte data show two trending covariant lines with slopes between 2.5 (chimneys) and 4.0 (crusts), The elevated sulphate values can be assumed to be residual sulphate which was isotopically changed during microbial sulphate reduction. (**b**) $^{87}Sr/^{86}Sr$ values for Gulf of Mexico seawater, seep fluids, and barytes (After Feng and Roberts 2010)

2006). Because brine lakes are commonplace in such settings, it can precipitates baryte layers in association with organic- and pyrite-rich laminites under the influence of sulphate reducing bacteria (Chap. 9).

The volume of cold-seep baryte in halokinetic salt basins in particular, and beneath continental margins in general, was under appreciated prior to the increase in deep seafloor surveying over the last few decades. Much of this new information in terms of the 3-dimensional aspects of seep position came from seismic data cubes collected as petroleum exploration moved into the increasingly deeper water offshore drilling realm. The northern Gulf of Mexico continental slope is now known for an extensive number of salt-edge focused hydrocarbon seeps, along with co-associated authigenic carbonate and baryte seeps. Baryte occurrences and volumes in the Gulf of Mexico region are now known to be more substantial than once thought (Feng and Roberts 2010). Seafloor observations and samples acquired at numerous sites atop various autochthonous and allochthonous salt sheets in the Gulf of Mexico indicate that baryte occurs on the seafloor as widespread chimneys, cones, crusts, irregular mound-like buildups up to meters high and as a material disseminated in seafloor sediment hosts (Fig. 9.58). Many of these features are focused atop faults and Jurassic salt edges.

Barytes exposed at the GOM seafloor usually have a porous fabric and are typically covered by dark-brown manganese rich coatings. Samples of baryte may also contain minor amounts of magnesium-calcite, pyrite, and detrital silicates. On a $\delta^{34}S_{Baryte}$ versus $\delta^{18}O_{Baryte}$ diagram, samples show linear or concave-upward trends that project down toward the isotopic composition of seawater sulphate (red arrow in Fig. 7.94a). Covariant isotope trend suggests that baryte is formed from seawater sulphate that has been isotopically modified to varying degrees by microbial sulphate reduction processes. Variations in sulphur and oxygen isotopes occur within individual study sites but there are

common trends across multiple sites(Feng and Roberts 2010). The variations primarily reflect local controls on the flux of barium rich seep fluids, e.g., rate changes in bacterial sulphate reduction and different possible electron donors in a closed or semi-closed pore-fluid system.

Historically, the origin of the fluid precipitating cold seep baryte has been the subject of some debate. Some argue for a local seawater source, others for a more distal subsurface fluid origin. Strontium isotope data in the Gulf of Mexico suggest a brine source that is likely deeper, rather than derivation from ambient or shallowly circulating seawater (Fig. 7.94b; Feng and Roberts 2010). Clearly, less ^{87}Sr is seen the GOM pore fluids than in contemporaneous GOM seawater, suggesting these saline pore fluids have been modified by inputs from less radiogenic sources, such as more deeply buried marine sediments or oceanic crust. A deep-seated source for the barium is further indicated by the $^{87}Sr/^{86}Sr$ ratios of barytes precipitating from the escaping pore fluids. It seems Sr isotopes vary over a narrow range regardless of location within the Gulf of Mexico. The $^{87}Sr/^{86}Sr$ ratios of seafloor barytes collected from the Garden Banks and Mission Canyon areas are consistently slightly lower than their respective ambient saline pore fluids (Fig. 7.94b). Based on this slight, but consistent, difference across both areas, Feng and Roberts (2010) concluded that the Sr in GOM baryte seeps mainly originated from hypersaline fluids that had flushed and leached more deeply buried sediments, with a small portion of Sr coming from ambient seawater ($^{87}Sr/^{86}Sr = 0.70917$).

Baryte in cores from the Walton-Magnet Cove baryte mine region, Nova Scotia, show a wide variety of massive stratiform to nodular textures frequently intermixed with siderite. Siderite forms a prebaryte, presulphide envelope to the deposit (Fig. 7.95a; Savard et al. 1998). Isolated light coloured baryte nodules, typically hosted in a Carboniferous matrix of ferroan dolomite, show complete gradations from chickenwire to enterolithic and are interpreted as a direct replacement of precursor nodular anhydrite hosted in intertidal and supratidal platform carbonates (Mossman and Brown 1986). The mine itself exploited a lenticular to stratiform mass of baryte, not nodules, and preserved liquid hydrocarbons in the ore zone (Fig. 7.95a; Boyle 1962). Unfortunately the Magnet Cove Baryte Mine ceased operations some 40 years ago and the mine pit and shaft workings are now flooded. Boyle described the structure of the deposit as "exceedingly complex." The region is marked by two major sets of faults oriented east-west and northwest-southeast. At the now abandoned Walton deposit the dominant feature is an east-west fault zone in the footwall of the baryte mass that joins a northwest fault that lies close to the hanging wall of the baryte mass.

Much of the baryte ore in the Magnet Cove deposit is associated with the Pembroke Formation (Fig. 7.95a). Regionally the Pembroke Formation is a complex multi-origin breccia intimately associated with halokinesis and base metal mineralisation and regionally it is tied to former salt and thrust welds (Waldron et al. 2010; Lavoie et al. 1998). Faults in the Magnet[19] Cove Mine are pre-ore and constitute brecciated intervals over several metres wide. Post-ore movement also brecciated the baryte and metal sulphides. The age of the faulting is probably post-Triassic. The ore-hosting sequence is the outcropping remnant of a halokinetic and allochthonous evaporite zone at the top of the Horton Group and it lies along the regional salt weld of the Ainslie Detachment. The likelihood of halokinetically focused extensional faults carrying Ba-rich basinal fluids into sulphate-rich horizons was not considered in the published literature on the Magnet Cove mine. But all the work on the mine geology, and its mineralogy, was published before notions of salt allochthons, rauhwacke and burial anhydrite existed.

Halokinetic fault-focused salt welds define the position of the massive baryte deposit in the Neoproterozoic Oraparinna diapir and other baryte occurrences associated with halokinetic structures in the Flinders Ranges of South Australia (pers.obs.). The similarities between Magnet Cove and Oraparinna in both structural style and position atop a halokinetic breccia are obvious (Fig. 7.95b). Unlike Magnet Cove, the baryte occurrence in the Oraparinna diapir was recognised as a halokinetic association (Dalgarno and Johnson 1968). The ore at Oraparinna occurs in 1–2 m wide extensional fracture fills. Like Magnet Cove, the detailed evolution of the Oraparinna diapir is yet to be fully documented in the light of modern ideas of salt allochthons and salt-cored thrusts. Suprasalt minibasins can be seen to separate the various diapir outcrops throughout the Flinders Ranges and clearly illustrate the evolution of an active extensional diapiric province into a subsequent compressional regime. As in Magnet Cove, a geological map of the structure shows a distribution of facies that reflect the strong influence of diapiric and subsequent thrust breccia (rauhwacke) on the adjacent facies and faults (Fig. 7.95b). Salt flow and passive diapirism controlled both the position of a collapse graben atop the Oraparinna diapir during its "falling diapir" stage and focused the subsequent compression of the same succession. What is yet to be studied in the Oraparinna Baryte Mine is the timing of baryte emplacement relative to salt dissolution and faulting in this succession.

[19] In 1955 Magnet Cove Barium Corporation, a subsidiary of Dresser Industries Inc., Dallas, Texas, purchased the property from Canadian Industrial Minerals Limited. Diamond drilling in 1956–57 discovered a lead-zinc-copper-silver ore body below the baryte deposit and sulphide production began in 1961. In 1967 Magnet Cove Barium Corporation became Dresser Minerals, which operated the mine until it closed in 1978. The Walton Mine produced baryte for 38 years. Most of the baryte was shipped to United States and Caribbean destinations where it was used as a weighting agent in drilling fluids with smaller amounts shipped to the Middle East for the same purpose.

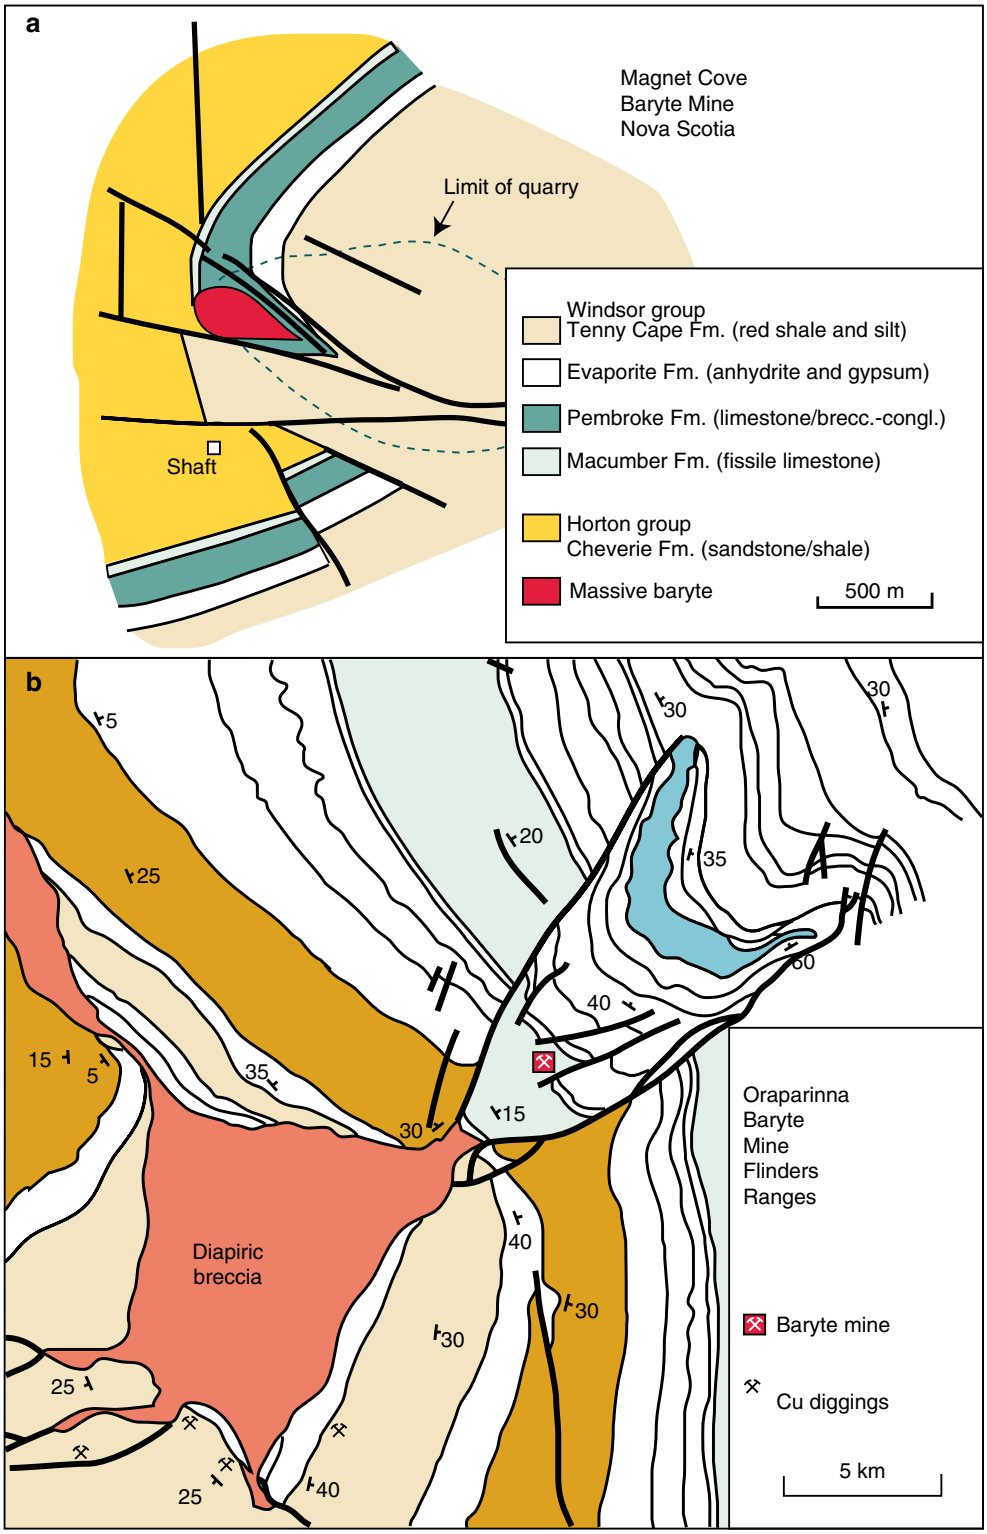

Fig. 7.95 Massive and vein-fill baryte deposited via halokinetic focusing. (**a**) Geology of the Carboniferous halokinetic section in the vicinity of the Walton-Magnet Cove Baryte Mine (aka Walton Mine), Nova Scotia (After Boyle 1962). A baryte mine and lead-zinc-silver-copper deposit. During its operation it was Canada's largest baryte mine and one of the largest baryte deposits in the world. See Fig. 15.46a for location. (**b**) Oraparinna Baryte Mine located in the compressed zone of an original falling diapir (Neoproterozoic Oraparinna Diapir) Flinders Ranges, South Australia (Redrafted from regional geological map of Dalgarno and Johnson 1966; see Fig. 7.31 for regional setting of the Oraparinna Diapir)

A well-documented younger analogue for baryte emplacement about salt structures is the fracture fill atop the Machar diapir in the North Sea (Fig. 10.56). Many individual fractures host multiple generations of carbonate, baryte and fluorite growth (Doran et al. 2004). Fluid-inclusions in the fracture-fills show maximum salinities (22 wt% NaCl eq.), suggesting that fluids had dissolved salt from the diapir during their ascent. Maximum fluid-inclusion temperatures (150 °C) from wells spanning the crest and flank of the Machar structure, are much hotter than expected for present

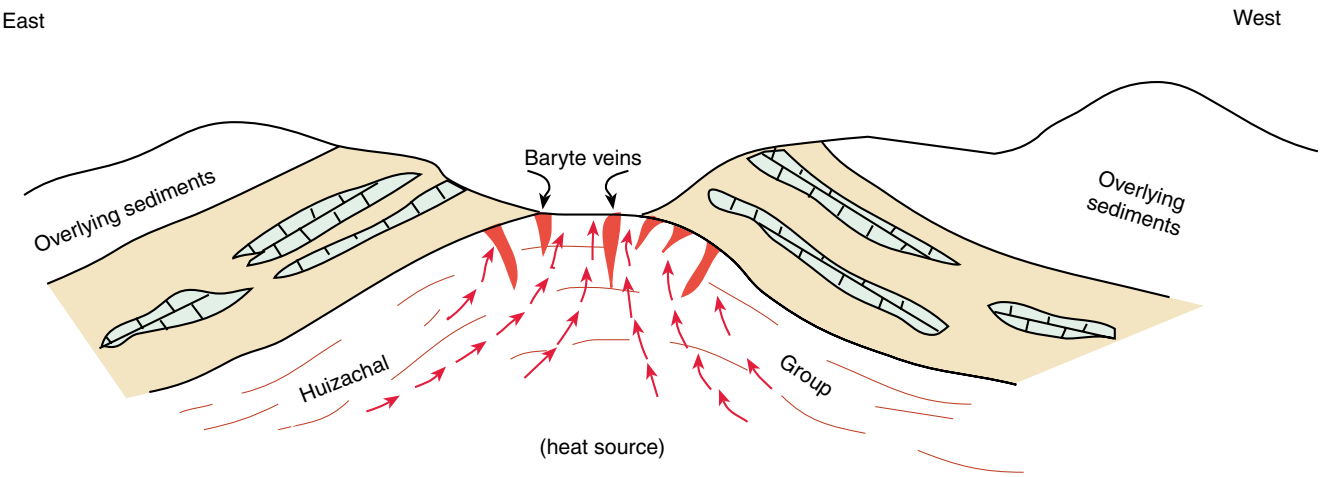

Fig. 7.96 Highly schematic E-W cross section through the Galeana district showing localisation of baryte veins at the contact with the Huizachal red beds, directly beneath the Olvido gypsum (*brown*). Baryte formed as ascending Ba-rich waters ponded beneath the gypsiferous residues (caprocks to allochthonous salt) of the Olvido Fm. (Modified from Kesler et al. 1988)

depths of 1,900–2,800 m. Carbon isotope signatures of the fracture-filling calcites range from +2 to +7 $^{13}C_{PDB}$ ‰ and exceed those of tightly constrained chalk matrix 0 to +3 $^{13}C_{PDB}$ ‰. Thus at least some of the carbon was derived externally to the chalk. Oxygen isotopes from fracture filling calcites (16–25 $^{18}O_{smow}$ ‰) are depleted relative to chalk matrix values (24 to 29 $^{18}O_{smow}$ ‰). The combined data sets indicate that fracture-filling material could not have formed from local chalk matrix pore-fluids. The likely explanation is pulsed expulsion of hot saline and hydrocarbon-bearing fluids from geopressured sandstones in the adjacent rim syncline that are then cemented on cooling into fractures at shallow depths.

A similar set of hypogene chloride-rich waters flowing along faults probably controlled the formation of mined willemite (Zn-oxide ore) in Cambrian ooid grainstones and archeocyathid mounds in the vicinity of the Beltana diapir in the Flinders Ranges, situated some 80 km northwest of the Oraparinna diapir (Groves et al. 2003). There the ore was first emplaced during a series of Cambro-Ordovician compressional events that reactivated salt diapirs and salt flows, which were first emplaced during Neoproterozoic extension and loading.

Yet another halokinetically focused baryte association is documented in the Galeana Baryte District of Mexico. Gypsum residues of the evaporitic Olvido[20] Formation (Upper Jurassic) form an anticlinal trap, seal and sulphate source to barium carried by basinal waters which had flushed the underlying redbeds of the Huizachal Group. Baryte occurs mostly as monomineralic veins and lenses in a limestone matrix along this contact (Fig. 7.96; Kesler et al. 1988; Conklin 1974). Halites and anhydrites of the halokinetic Olvido Formation created the seal and the faulted structures that focused ore precipitates. Regionally, the Olvido Formation defines the salt-cored Sabinas foldbelt, which is made up of a number of salt allochthon tiers and salt-cored detachments. This foldbelt is now in compression and thrust welds are common, in part in response to the Laramide orogeny. But when Ba-rich fluids were migrating it may well have been in its earlier stage of halokinetic extension (as was likely the case in the Oraparinna diapir). The spectacular salt allochthons of the La Popa basin, detailed in Chap. 6, are part of the same Sabinas foldbelt and were also created by the flowing salt of the Olvido Formation. There is an ongoing debate as to the ultimate origin of the barium now precipitated in the various vein fills. Kesler et al. (1988) argue it was sourced by Tertiary volcanism and that baryte mineralization occurred during the early Oligocene when magmatic activity in the Altiplano mobilized barium from the La Boca Formation, and barium-rich fluids reacted with gypsum of the Minas Viejas (Olvido) Formation. In contrast, Kroeger and Stinnesbeck (2003) conclude it was sourced in Jurassic volcanism and tied precipitation in extension veins synchronous with to Oxfordian carbonatite emplacement. In my opinion, a basinal brine, migrating toward the basin margins is an additional possibility. In terms of ore distribution, the differentiation of barium origins is largely academic. Ore control is clearly structural and related to mechanical strength contrasts, which were controlled by evaporite distribution and halokinetic style at the time of emplacement.

[20] Kroeger and Stinnesbeck (2003), established that the terms Minas Viejas and Olvido Fms. are synonyms for the same stratigraphic unit. Its outcrop distribution is now broken up by the effects of dissolution, tectonism and halokinesis, but originally it was deposited as single basinwide succession.

The Galeana barium district now lies at the western margin of the Sierra Madre Oriental in southern Nuevo Leon, Mexico, and it has been one of the leading $BaSO_4$ producers for the country. Ore-grade baryte fills reactivated steeply dipping (50–88° NW) fractures striking N40–50°E and, to a lesser extent, steeply dipping (60–85° SW) fractures striking N60–80°W, all formed at the crest of the San Marcos anticline (Fig. 7.96). Massive baryte veins also carry up to 10 wt% $SrSO_4$. Baryte likely formed when ascending barium-rich basinal brines ponded beneath, and partially dissolved, the relatively impervious halites of the Olvido Formation to create the anhydrite precursors to the gypsiferous residues that now define the outcrop of the Olvido Formation in the Galeana district. After baryte precipitated subsalt, the anticlinal crest was erosionally breached and so exposed mineable baryte at the surface.

Baryte is a widespread authigenic phase in bedded sandstones of the Salt Wash Member in the Late Jurassic Morrison Formation on the Colorado Plateau (Breit et al. 1990). There it forms as intergranular cements, poikilotopic cements, euhedral crystals and replacements of detrital grains. Areas that contain abundant baryte in the sandstone host coincide with the extent of evaporites in the underlying halokinetic Pennsylvanian Hermosa Formation. A genetic link between the baryte and the dissolving evaporite is reinforced by similar ranges in sulphur isotope data in both the gypsum and the baryte (Fig. 7.97a showing strong overlap in the $\delta^{34}S$ range from +8‰ to +14‰). Sulphate, derived from the dissolving evaporites, is thought to have risen along faults into the Morrison Formation; a process perhaps aided by halokinetic focusing (Fig. 10.87).

Evidence of a fault conduit for the Ba-rich waters is further supported by $^{87}Sr/^{86}Sr$ ratios in the baryte cements, which tend to decrease with increasing distance from the supplying fault from 0.7103 to 0.7084 (Fig. 7.97b; Breit et al. 1990). This trend reflects the mixing of radiogenic strontium from waters ascending the faults ($^{87}Sr/^{86}Sr = 0.7100$), with strontium in waters derived by dissolution of early diagenetic carbonate cements in the sands ($^{87}Sr/^{86}Sr = 0.7080$). As the $^{87}Sr/^{86}Sr$ values along the faults exceed those in the underlying Hermosa anhydrite (0.7085) it is thought that radiogenic strontium was also added to the ascending waters by reactions between the rising brine and the arkosic horizons that intersect the fault conduit. These same arkosic sands are also a source of the copper in ores in similar structural settings in the nearby Lisbon Valley (Chap. 15). A similar isotopic argument is used to show an evaporitic sulphate association for mesogenetic baryte mineralisation in the orefields of the northern Pennines (Crowley et al. 1997) and the Ain Allega and El Guiba halokinetic deposits in Tunisia (Abidi et al. 2012).

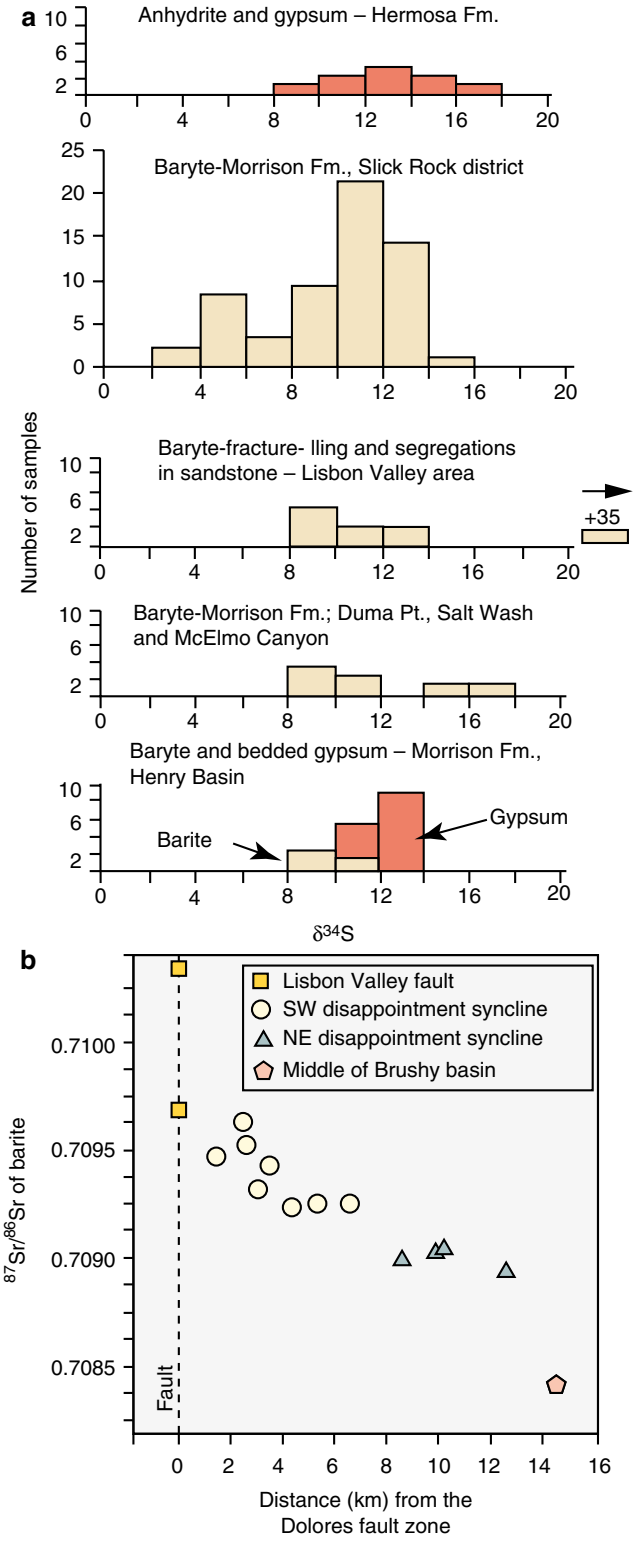

Fig. 7.97 Baryte in the Morrison Fm., Colorado Plateau. (**a**) $\delta^{34}S$ values (CDT) of baryte and gypsum in various regions in the Colorado Plateau. (**b**) $^{87}S/^{86}Sr$ of baryte versus distance from the Dolores fault zone in the Slide Rock district (After Breit et al. 1990)

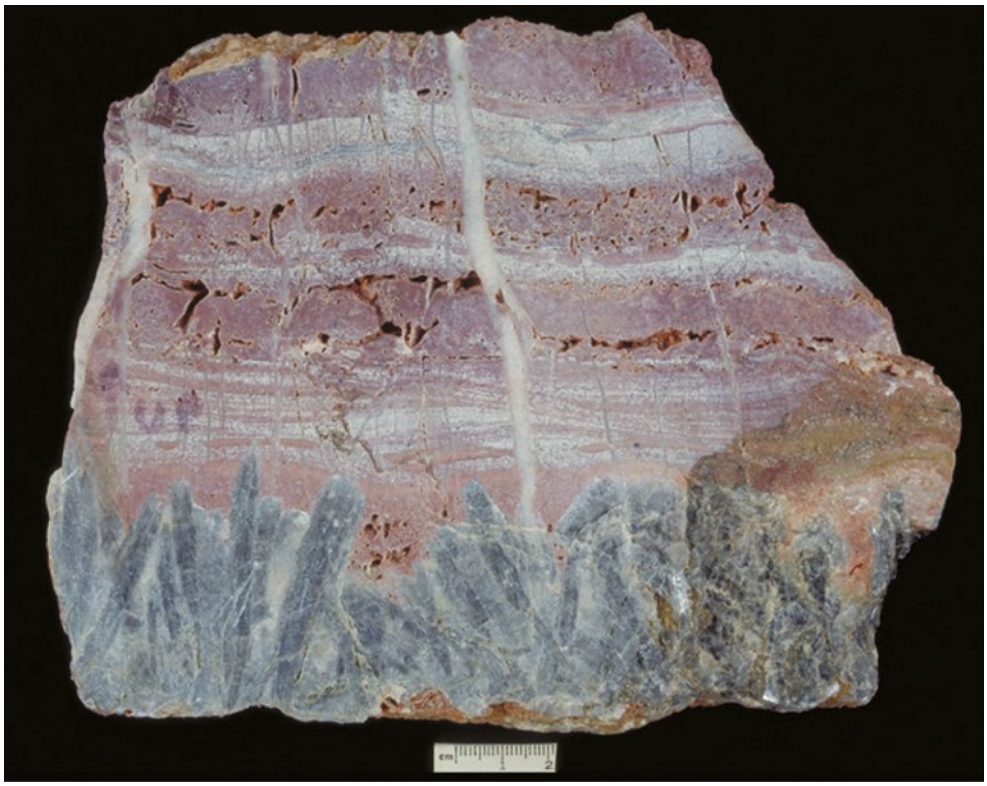

Fig. 7.98 Lower third of this slabbed specimen is composed of growth-aligned baryte (is it a possible replacement of bottom-nucleated evaporite; or, is it a primary baryte precipitate, associated in some areas with silicified marine-derived nahcolite evaporites?). The growth-aligned layer is overlain by current-rippled and silicified volcaniclastic sands. Sample collected from the early Archaean 3.45 Ga Warrawoona Fm. near North Pole, Western Australia

Local concretions of baryte precipitates in sandstones can create rosettes known as "sand rosettes" or "desert roses," where the baryte acts as a poikilitic cement that encases sand grains. Such baryte is thought to have been precipitated by reactions between soluble sulphate (usually from nearby dissolved gypsum or anhydrite) and basinal waters carrying $BaCl_2$. Baryte spar is a commonplace burial cement in reservoir sandstones where two basinal brines mix. The hydrodynamics of such deep mixing is often driven by tectonics, for example, the inversion tectonics of the North Sea (later in this chapter). Oxidised pyrite can also act as a source of sulphate in subsurface waters, especially in the vicinity of dewatering organic-rich shales.

A more enigmatic but significant baryte-evaporite associations is found in early Archaean metasediments. Some of these beds constitute the oldest sediments in the world, namely the ≈3.46 Ga Warrawoona Megasequence at North Pole, Western Australia, with equivalents in South Africa. Both areas are characterised by baryte beds with obvious growth-aligned textures (Fig. 7.98). Interpretations are that the baryte either pseudomorphs bottom nucleated subaqueous evaporite or that it represents a primary seafloor precipitate. The proponents of both interpretation can be involved in ongoing heated discussion that has significant implications for models of the earth's early atmosphere (e.g. Bose et al. 2012; Shen et al. 2009 and Runnegar et al. 2001). The various arguments as they relate to evaporite evidence of atmospheric evolution, were discussed in Chap. 2. Baryte, tied to evaporitic precursors, can also be preserved within meta-evaporite sequences (Chap. 14).

Authigenic Anhydrite as a Burial Salt

As we have seen, some forms of silica, calcite, dolomite, celestite, fluorite and baryte can be precipitates that mimic the outline of their evaporite precursor. They form in the positions of former evaporites either syndepositionally, mesogenetically and telogenetically, wherever waters of appropriate chemistry can cool, heat, mix or change redox state. We shall now see that some evaporite salts, especially anhydrite spar, can also precipitate mesogenetically via fluid mixing over wide areas. This can create substantial quantities of cements in the subsurface that are not directly related to the former position of a primary evaporite mass. Such precipitation takes slowly in relatively stable mixing zones, so crystals tend to be coarse and poikilotopic or replacive, often co-associated with late diagenetic calcite, saddle dolomite,

hydrocarbons and metal sulphides. Precipitative conditions are typically anoxic and thermochemical sulphate reduction is likely in these sulphate-rich settings (Table 7.18). Calcium and sulphate are typically carried to the precipitation site in chlorine-rich saline basinal brines, generated by the dissolution of evaporites, and capable of precipitating their dissolved load at chemical interfaces. This may be in strata adjacent to the dissolving evaporite bed or some distance away in fluid mixing zones related to fluid trapping and sometimes as mixing haloes along fluid escape conduits such as faults and fractures (Table 7.18).

Morphologically near-identical coarse poikilotopic anhydrite cements can also form during early syndepositional brine reflux within brine-saturated pores beneath an accumulating evaporite (Purvis 1989; Luczaj and Goldstein 2000). These syndepositional reflux salts are true evaporites in that they formed in a hydrology driven by solar evaporation. In contrast, burial salts that form in brines generated by the subsurface dissolution of salt beds are not "true" evaporites as they are not directly precipitated by processes driven by solar evaporation, nor do they replace the volume occupied by primary and secondary evaporite salts (Fig. 1.9). They are, in reality, evaporite transformation salts or burial salts. Distinguishing early reflux evaporite cement spar from later burial anhydrite spar can require detailed petrographic and isotopic study, especially in the absence of saddle dolomite or metal sulphides.

Anhydrite is a late stage burial salt in quartzose Rotliegende reservoir sands in Leman Field, North Sea and throughout regions of deeply buried Rotliegende Formation

Table 7.18 Selected examples of sparry burial anhydrite

Occurrence and age of host	Burial anhydrite fabric and subsurface temperature at time of precipitation	Reference
Yacoraite Fm. (Upper Cretaceous), Argentina.	Sparry anhydrite cement, containing hydrocarbon inclusions and brine, fills intergranular, mouldic and vuggy porosity in a carbonate host. Indicates anhydrite precipitated at 121–137 °C from 17 % equiv. wt. NaCl brine ($NaCl–MgCl_2$ –Na_2 SO_4 –$NaHCO_3$ –$NaCO_3$ basinal brine).	Cesaretti et al. (2000)
Maha Sarakham Fm. (Upper Cretaceous), NE Thailand.	Coarsely crystalline saddle dolomite rhombs float within a matrix of coarse, recrystallized anhydrite spar in the Basal Anhydrite. Isotopes indicate dolomite precipitated at temperatures ≈ 72–123 °C.	El Tabakh et al. (2003)
Smackover Fm. sandstones, (Upper Jurassic), Gulf of Mexico.	Anhydrite both as poikilotopic spar masses in which detrital grains are replaced and as smaller patches that have replaced single detrital grains. Precipitation temperatures >100 °C. Anhydrite is a relatively late cement and postdates all other volumetrically significant authigenic phases in the sandstones, including K-feldspar, dolomite, quartz, and most calcite cements.	Dworkin and Land (1994)
Smackover Fm. dolomites, (Upper Jurassic), Gulf of Mexico.	Anhydrite spar partially replaced allochems and prebitumen calcite cements in mesogenetic pores. Solid bitumen precipitated where hydrocarbons were present. Emplaced in temperature range 100–150 °C.	Heydari (1997, 2000)
Khuff Fm. (Upper Permian-Lower Triassic), Abu Dhabi, UAE and Saudi Arabia.	Burial stage poikilotopic crystals fill pore spaces between the detrital carbonate components. Crystals are typically 500 mm in length but locally may reach up to 3 mm.	Worden et al. (1995, 2000), Ehrenberg et al. (2007), Al Eid and Al Tawil (2009)
Kurrachine Dolomite, Trias-sic, Syria	Following fracturing and mesogenetic leaching by sulphate-bearing warm fluids, significant vuggy porosity was created, but was subsequently occluded by anhydrite burial cements made up of coarse mosaic anhydrite spar and occasional poikilotopic spar.	Hips and Árgyelán (2007)
Prider Fm. (Lower Permian) Kansas, USA.	Burial stage poikilotopic anhydrite cement replaces echinoderm fragments, parts of oncolites, some dolomite spar, and some stylolite seams. Precipitation occurred in the range 65–90 °C, with a few samples possibly up to 150 °C.	Luczaj and Goldstein (2000)
Rotliegende Fm. (Lower Permian), onshore and offshore NW Europe.	Poikilotopic sparry anhydrite enclosing sand grains. Distribution shows a strong fault/ fracture control. Precipitation temperatures in the range 120–140 °C.	Duguid and Underhill, (2010), Gauthier et al. (2000), Sullivan et al. (1994)
Swan Hills Fm. (Middle to Upper Devonian), Canada.	Coarse bladed crystals of sparry anhydrite enclosing dolomite clasts and possibly related to faults. Fluid inclusions in the anhydrite show crystals formed from basinal fluids at temperatures in excess of 90 °C. Machel (2013) documents the wider occurrence of burial anhydrite in Devonian carbonates in the Alberta Basin, than previously noted.	Duggan et al. (2001), Machel (2013)

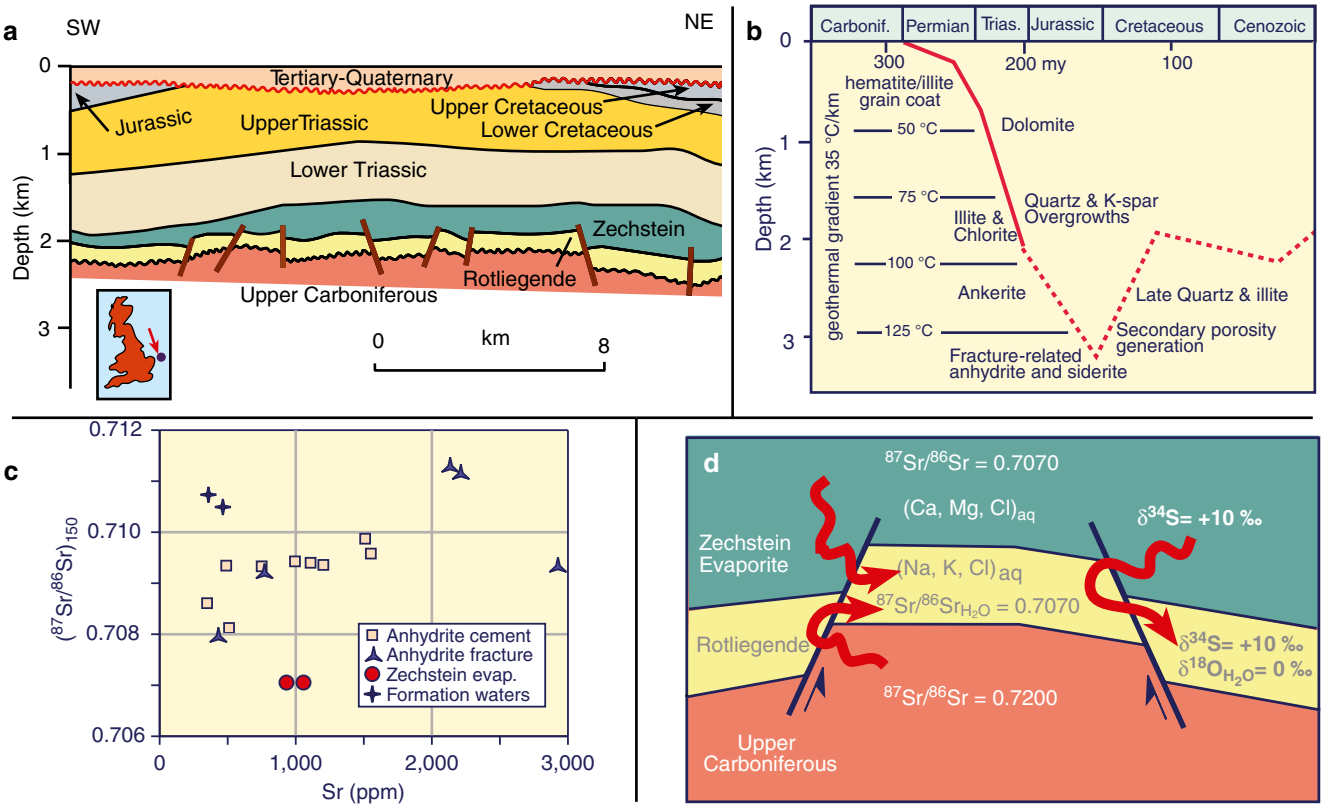

Fig. 7.99 Late stage anhydrite in Leman Field, North Sea. (**a**) Location of the Leman gas field and regional geological cross section. (**b**) Subsidence history of Rotliegende reservoir sandstone showing time and temperature of anhydrite precipitation postdates other diagenetic events and precedes secondary porosity formation. (**c**) Strontium isotopic ratios and composition of various anhydrite burial salts compared with formation waters and Zechstein salts. There is a general trend of increasing isotopic ratio with increasing Sr content. (**d**) Schematic section showing major sources of sulphur, strontium and carbon along with their migration from above and below the Rotliegende and subsequent mixing that precipitated anhydrite cements and fracture fill (Modified form Sullivan et al. 1994)

(Fig. 7.99a; Sullivan et al. 1994; Gauthier et al. 2000). Poikilotopic anhydrite spar in Leman field is best developed along coarser-grained sand laminae, suggesting their inherent higher permeabilities influenced sites of precipitation. The same sparry anhydrite cement also encloses late authigenic ankerite, ferroan dolomite and pressure-solved cemented grains, showing its deep burial origin. Anhydrite tends to be best developed in and near fractures forming cements zones up to 0.5 cm wide and 0.5 m long in Leman core. Crystals in fractures are bladed, coarsely crystalline and tend to grow subparallel to the fracture walls. Cemented coarse-grained laminae and anhydrite-filled fractures frequently intersect suggesting both styles represent the same generation of anhydrite cement.

Timing is best resolved using Sr and O isotopic analysis of the anhydrite cements. Oxygen isotope compositions indicate precipitation temperatures between 120 and 140 °C in waters with a $\delta^{18}O$ composition similar to the present day formation waters (≈0‰ SMOW; standard mean ocean water). These are the maximum inferred burial temperatures for the Rotliegende sandstone in Leman Field. Such temperatures occurred during the Late Jurassic-Early Cretaceous, at the start of basin inversion with maximum burial depths of 3.5–4 km (Fig. 7.99b). When corrected for their 150 Ma precipitation age, the Sr isotope ratios in the various anhydrite burial cements, and their Sr contents, are highly variable. ($^{87}Sr/^{86}Sr$) ratios range from 0.70797 to 0.71129 and Sr contents from 351 to 2,952 ppm (Fig. 7.99c). Fracture-filling anhydrite spar also traverses this entire strontium range, implying an origin from the same fluid. There is also a general trend of increasing Sr ratio with increasing Sr content of the anhydrite burial salts.

According to Sullivan et al. (1994) the late stage anhydrite indicates an unusual, short-lived event that juxtaposed the Zechstein evaporites and sandstones. The resulting geometry facilitated cross-formational fluid flow via fractures that were tectonically induced by inversion. At that time pore fluids were squeezed from the overlying Zechstein evaporites and underlying Carboniferous mudstones into the lower pressures of the Rotliegende regional aquifer (Fig. 7.99d). Mixing of the two waters precipitated dolomite and anhydrite cement, which in turn produced a Na-K-Cl

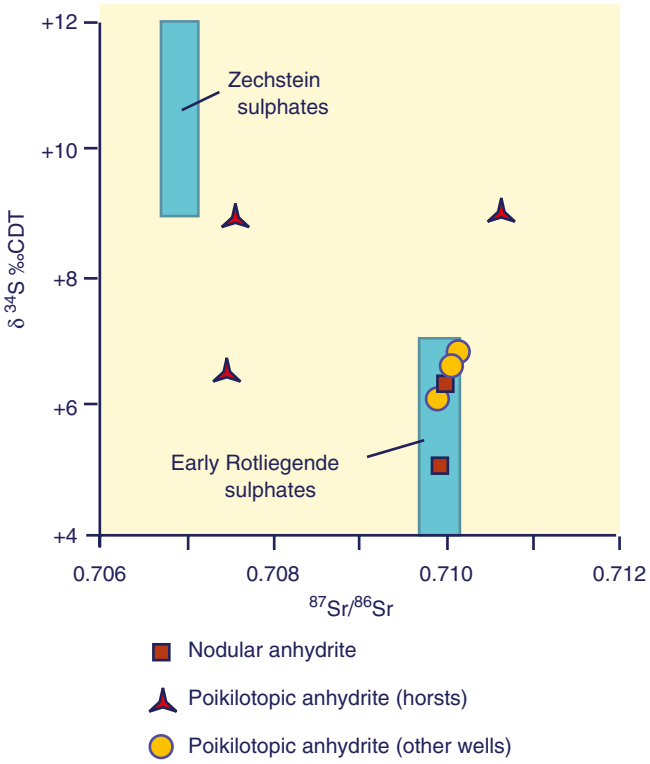

Fig. 7.100 Plot of sulphur versus strontium isotopic ratios for coarse anhydrite cements from the German Rotliegende. It clearly shows the affinity of anhydrite cements in horst blocks for Zechstein sources rather than an early Rotliegende signature (After Gaupp et al. 1993)

formation water. This pore water was lower in Ca + Mg than the overlying Zechstein, which in turn supplied most of the sulphate and some of the Sr to the anhydrite cements. Like the isotopic evidence, the chemical evidence shows the burial anhydrite precipitated from extremely saline formation waters derived by deep subsurface mixing of Zechstein evaporite brines and deeply circulating meteoric waters. Even today, the Zechstein brines in the Leman Field are extremely saline (165,530–238,531 mg/l), with cation/ chloride ratios indicating ongoing mixing of Zechstein marine evaporite brines with fossil meteoric water.

Onshore in northern Germany the Rotliegende gas reservoirs also contain coarse authigenic poikilotopic anhydrite cements, particularly in the vicinity of faults. Cross-formational flow of Zechstein fluids and fault-related fluid flow was responsible for this anhydrite, especially during times of mixing tied to fault activity (Gaupp et al. 1993; Gauthier et al. 2000). This is clearly seen in the isotopically distinct values of burial anhydrite within horst blocks compared to samples with similar authigenic and nodular anhydrite styles, but from wells outside of the horsts (Fig. 7.100). Anhydrite cements in sands atop horst blocks show affinities to Zechstein sulphates. In contrast, anhydrites in the other wells, where uplift has not juxtaposed Rotliegende sands to Zechstein fluids, retain an isotopic signature typical of early Rotliegende time. Once again, this observation underlines the importance of active faulting in facilitating brine mixing, which then precipitates authigenic minerals in the deep burial setting.

Late stage anhydrite and halite cements also characterise deeper burial cements in the aeolian and fluvial feldspathic sandstones of the Upper Jurassic Norphlet Formation and other Smackover sandstones of the Gulf Coast (McBride et al. 1987; Dworkin and Land 1994). Coarsely crystalline anhydrite, along with quartz and ferroan dolomite, precipitated as intergranular cements. Anhydrite averages 3 % by volume (maximum 21 %) in Norphlet wells in Mississippi and 1.3 % in Alabama. It occurs as scattered sparry crystals, in spherical and poikilotopic patches up to several centimetres across and can completely cement some sand laminae. All the anhydrite cements are patchily distributed in the Norphlet reservoirs and, as in the Rotliegende, tend to be better developed in the coarser sand laminae.

Oxygen isotopic values from the anhydrite averages 15.6 ‰ (SMOW). According to Dworkin and Land (1994) this burial anhydrite precipitated in near oxygen (and strontium) isotopic equilibrium with ambient burial fluids at temperatures of between 90 °C and 100 °C at depths ≈ 2.3 km (Fig. 7.101a). Authigenic halite cements, along with late stage carbonates, followed at temperatures up to 120 °C (<3 km burial). Subsequent dissolution of the cements, along with some labile detrital grains, created secondary porosity that makes up at least half of the economic porosity in the Norphlet tight gas sand reservoirs in this region. Potassium-rich brines, generated by dissolution of nearby bitterns, tended to stabilise K feldspar in the Norphlet so that authigenic K-spar can even coat quartz grains, as well as its more commonplace occurrence as overgrowths on detrital K-spar grain substrata.

Dworkin and Land (1994) argue that the expected isotopic composition and trace-element concentration of a marine brine-reflux-derived anhydrite cement in Smackover Formation quartzose sands should be: $\delta^{34}S_{CDT} = +16‰$, $\delta^{18}O_{SMOW} = +14‰$, $^{87}Sr/^{86}Sr = 0.7069$, Sr = 1,500–2,500 ppm, Ba < 20 ppm, and Mg > 200 ppm (indicated by the brown box in Fig. 7.101b). When geochemical analyses of Smackover anhydrite cements are compared with the predicted composition, it is apparent that most of the coarsely crystalline anhydrite is not a marine reflux cement. Rather, two groupings or generations of anhydrite cement can be distinguished using a strontium isotope to strontium content crossplot (Fig. 7.101b). An early cement, that may have been derived from slightly modified Late Jurassic seawater (possibly via reflux), is characterised by its Jurassic isotopic signature and high strontium content (>3,200 ppm). A second group of cements, that represent the bulk of coarsely crystalline cements in the Smackover sandstones, has a depleted strontium content (<3,000 ppm) and an elevated isotopic ratio. It may have

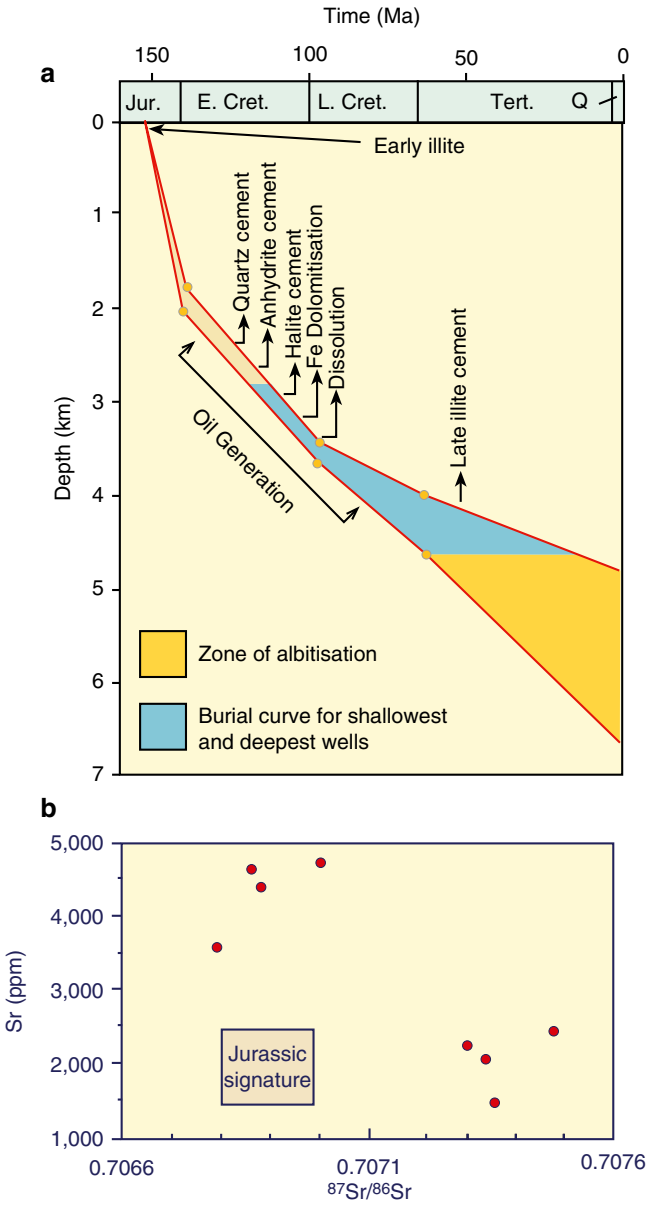

Fig. 7.101 Norphlet Formation (After Dworkin and Land 1994, 1996). (**a**) Burial evolution and diagenetic history. (**b**) Sr isotope signatures

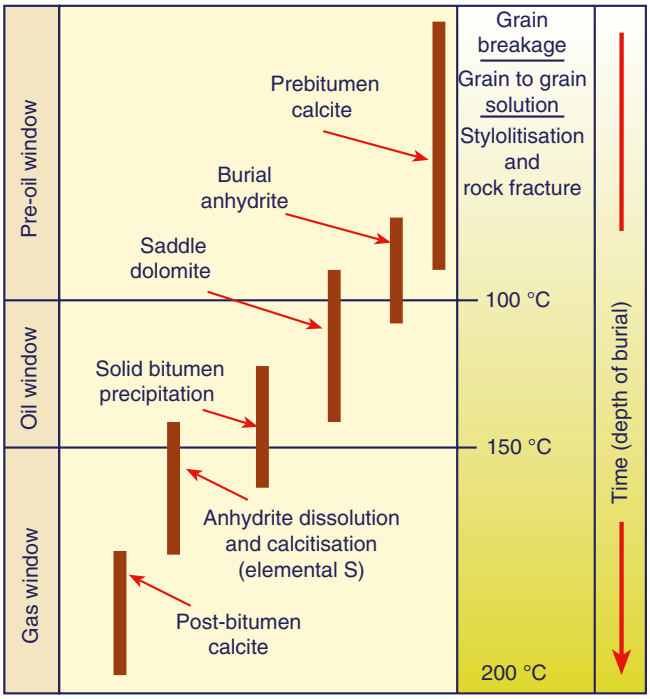

Fig. 7.102 General paragenetic sequence for the Smackover Formation in the northern Gulf of Mexico showing approximate temperature range of various events (After Heydari and Moore 1989; Heydari 1997)

precipitated later in the burial history or may represent burial recrystallisation of the first cement. It probably formed at slightly higher temperatures, which would have maintained relatively low strontium concentrations, and in the presence of pore fluids that had radiogenic Sr isotopic compositions. Such radiogenic pore fluids were probably derived from waters that were involved in the burial dissolution of feldspars.

As well as in Smackover sandstones, dissolution-derived sulphate-rich basinal brines also precipitate anhydrite burial salts in Smackover carbonates of the Gulf of Mexico (Fig. 7.102; Heydari and Moore 1989; Heydari 1997). Precipitates are made up of orthorhombic laths and blades that form spars replacing both allochem grains and calcite cements. The anhydrite spar and the calcite spar formed prior to reaching the oil window and are post stylolitisation. The arrival of liquid hydrocarbons and the precipitation of solid bitumens temporarily retarded further precipitation of calcite, anhydrite and dolomite burial cements. Later, the anhydrite was dissolved and replaced by a more finely crystalline calcite spar and elemental sulphur via thermochemical sulphate reduction processes. This occurred at the higher temperatures that typify the gas window.

Dissolution-derived late burial anhydrite is also widespread in the Lower Cretaceous carbonates of the Pearsall and Lower Glen Rose Formations, South Texas (Woronick and Land 1985). As in the Smackover, the anhydrite spar formed late, after the development of saddle dolomite cements. It crystallised mostly as bladed to fibrous anhydrite laths some 0.1–6.0 mm in length. Much of this anhydrite fills pre-existing intergranular pore space in the carbonates, but it can also replace fossils, matrix material and earlier calcite cements. Once formed, it was subject to corrosion and replacement by calcite. $\delta^{18}O_{SMOW}$ values for the anhydrite range from 19.5 to 22.9‰, values that are much more enriched than the Cretaceous seawater sulphate (+15‰). Woronick and Land (1985) interpret these enriched values as proof that none of the subsurface anhydrite in the Pearsall and the Glen Rose (including some associated nodular anhydrite) was precipitated directly from Cretaceous seawater.

They argue that even the nodular anhydrite (previously used as a sabkha indicator) was not primary but had recrystallised in the subsurface. This is supported by $\delta^{34}S_{CDT}$ values of the anhydrite and the modern Edwards Formation brines, which lie between 20 and 26‰. Directly precipitated Cretaceous marine evaporites should have $\delta^{34}S_{CDT}$ values of less than +16‰ (Fig. 2.35a).

They envision a basinward flowing deep meteoric aquifer, driven by hydrostatic flow, that was essentially saturated with respect to calcite, dolomite and $CaSO_4$. Periodically the meteoric waters mixed with upwelling hotter basinal fluids that were derived from more deeply buried and dissolving Jurassic salts. These basinal fluids contained abundant carbon dioxide, calcium, strontium (radiogenic) and barium, together with small amounts of lead, zinc and hydrocarbons. Mixing of the two waters caused the precipitation of burial anhydrite, as well as other burial cements, including saddle dolomite and metal sulphides.

Other carbonate platform sequences that entrain burial anhydrite cements derived from evaporite dissolution and upflow of sulphate-enriched basinal waters include (Table 7.18); the Devonian Keg River and Swan Hill formations of Alberta (Aulstead and Spencer 1985; Duggan et al. 2001) and carbon-ate reservoirs in the Middle Ordovician Trenton Group, SW Ontario (Middleton et al. 1993; Haeri-Ardakani et al. 2013).

All these examples of sparry burial anhydrite demonstrate an obvious association between advanced dolomitisation of platform carbonates and the precipitation of later diagenetic poikiloptopic and replacive anhydrite spar. This process, also called anhydritization by Kendall and Walters (1978), is widely observed, and has significantly reduced porosity in potential reservoir dolomites in the Devonian of Canada, the Permian Khuff of the Saudi Arabia and the Emirates, the Zechstein of NW Europe, the Jurassic of the Gulf of Mexico and the Arab cycles of the Middle East (see Chap. 10). As yet, it has attracted the interest of relatively few researchers and documentation is sparse. As a process it should characterise burial diagenesis in most deeply buried sulphate evaporite systems.

However, not all burial or sparry anhydrite or subsurface gypsum is associated with alteration of "true" evaporites. Anhydrite is a retrograde salt, so intergranular and replacive anhydrite cement precipitates in ocean crust or other volcanogenic settings when unmodified connate seawater is heated above 150 °C (Blount and Dickson 1969, 1973; Chap. 16). This is a widespread process in hydrothermal circulation cells in midoceanic ridges and is probably also active in the deeper portions of many sedimentary basins.

In shallower burial settings, aqueous sulphides can also be oxidised to sulphates, which then precipitate as an authigenic $CaSO_4$ phase. This often happens in surface regions of pyrite oxidation and mixing such as in mine wastes, lake bottoms and in seep positions on the seafloor, especially when microbially facilitated. Pyrite oxidation has formed 1.5–4 mm-sized euhedral tabular to lenticular gypsum crystals in sediments atop Mound Perseverance, a modern giant cold-water coral mound in the Porcupine Basin, located some 50 km west of the Irish coast (Pirlet et al. 2010) Non-evaporitic gypsum is also found as a gossan precipitate worldwide and in glacio-lacustrine deltaic sequences in tributary valleys of the Cuyahoga River, Ohio (Bain 1990). Crystals in the various tributary valley deltas display two styles of diagenetic gypsum related to the host sediment: (a) euhedral, translucent tabular crystals up to 4 cm across in pliable prodelta mud, or (b) bladed, dovetail poikilotopic gypsum sand crystals and rosettes up to 8 cm across growing within grain-supported delta-front sand. All these gypsums formed diagenetically as a result of oxidation of sulphides by calcium-rich, oxidizing porewaters mixing with more reduced waters where pyrite (the sulphur source) is present. In the Ohio examples, oxidizing, calcium bicarbonate rich water moves through delta-front and delta-top sands and migrates into and out of pyritic prodelta muds. As a result of this migration, pyrite is oxidized to form iron oxides and iron hydroxides, colouring the sediment yellow to red. At the same time, sulphides are converted to sulphates, which react with the calcium-rich water, resulting in the precipitation of gypsum. But such oxidative sulphate sources for $CaSO_4$ are relatively uncommon in the deep subsurface where pore waters are typically anoxic and reducing and interfaces with oxidising waters are not common.

Enigmatic Outlines in Pseudomorphs

This chapter discusses how evaporites can be replaced by various minerals at any time in their burial and uplift history. So far, I have focused on the more commonplace evaporites — namely, gypsum, anhydrite and halite morphologies — that are pseudo-morphed by silica, calcite, dolomite, baryte and celestite. These three evaporite salts constitute more than 90–95 % of modern and ancient precipitates, but there are also carbonate or silica pseudomorphs preserving the outlines of other evaporite salts, such as trona, gaylussite, pirssonite, glauberite, thenardite and other less common precipitates. Figure 7.103 illustrates some of the idealised and a few of the more typical shapes of these somewhat less common salts. If their euhedral forms are well preserved by their carbonate or siliceous replacements, they can be recognised still.

But all evaporites are soluble, so the preservation of a crystal form is often accompanied by enlargement or partial collapse of the void during the replacement process. This complicates the process of recognition and is, for example, the main reason why Archaean baryte at North Pole is still variably interpreted as a gypsum or nahcolite association.

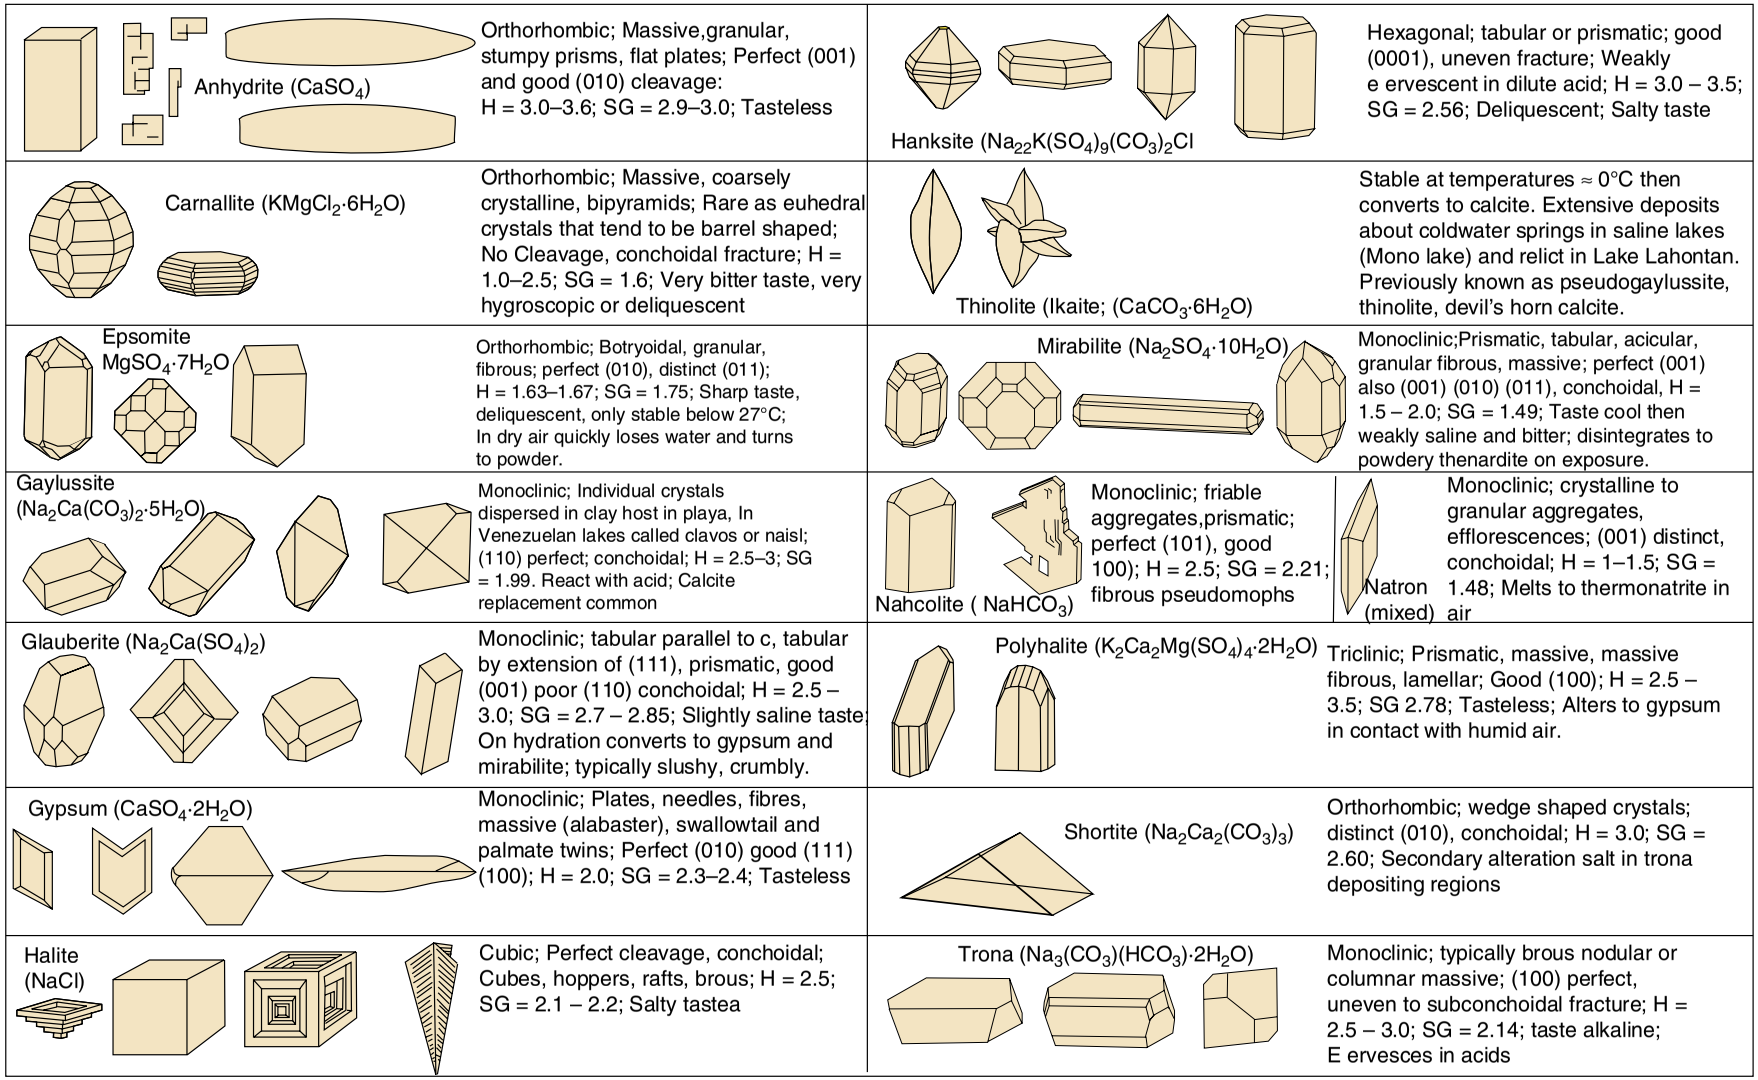

Fig. 7.103 Characteristic shapes of some of the various depositional evaporate salts and their physical properties

Table 7.19 Evaporite minerals susceptible to replacement by calcite and likely to show lozenge or discoidal outlines

Mineral	Formula	Crystal habit	Brine type
Gaylussite[a]	$Na_2\ Ca(CO_3)_2{\cdot}5H_2\ O$	Often elongated; also flattened wedged-shaped.	Na—CO_3 —Cl
Glauberite[a,b]	$Na_2\ Ca(SO_4)_2$	Tabular, prismatic, dipyramidal, and may be rounded or step-like.	(Mg) Na—SO_4 —Cl
Gypsum[b]	$CaSO_4{\cdot}2H_2\ O$	Thin to thick tabular; elongate; step-wise depressions or rough; acicular; prismatic with nearly equant cross section. Lenticular crystals with rounded or irregular terminations. Warped or curved irregular surfaces, long prismatic crystals occur bent into irregular or hoop-shaped forms.	(Mg) Na—SO_4 —Cl
Ikaite	$CaCO_3{\cdot}6H_2\ O$	Distinct asymmetry with a tendency toward a sigmoidal shape when viewed from the side and square-prismatic in overall shape that taper to the ends; strongly ribbed normal to the length.	Na—CO_3 —SO_4 —Cl
Mirabilite[b]	$Na_2\ SO_4{\cdot}6H_2\ O$	Short prismatic to acicular crystals.	Na—CO_3 —SO_4 —Cl and (Mg) Na—SO_4 —Cl
Pirssonite[a]	$Na_2\ Ca(CO_3)_2{\cdot}2H_2\ O$	Short prismatic; also tabular or pyramidal.	(Mg) Na—CO_3 —Cl
Thenardite[b]	$Na_2\ SO_4$	Dipyramid; tabular; rarely prismatic.	Na—CO_3 —SO_4 —Cl and (Mg) Na—SO_4 —Cl

After Finkelstein et al. (1999)
[a]Indicates likely diagenetic mineral
[b]Indicates a depositional association

Sodium carbonate salts are more likely to alter to calcite with burial as they already contain elevated levels of bicarbonate ions when they are deposited (Table 7.19; Southgate et al. 1989; Finkelstein et al. 1999). When preserved as isolated replacement crystals in a mudstone matrix, their calcitic pseudomorphs have easily confused or misinterpreted as gypsum, baryte of other lenticular forms.

Misidentifying a pseudomorph can lead to significant differences in the interpretation of depositional setting. In the case of the Upper Oligocene Creede Formation, southwestern Colorado, the interpretation of lenticular calcite in lacustrine laminites, as either ikaite or gypsum, is one of the pivotal pieces of evidence in defining the lacustrine depositional setting as deep, cold, fresh, and profundal versus shallower, periodically meromictic and hypersaline (Larsen and Crossey 1996 vs Finkelstein et al. 1999).

Because ikaite is only stable at near freezing temperatures, it is typically converted to thinolitic calcite (syn. jarrowites, devil's horn calcites, glendonites). Internally, ikaite pseudomorphs may preserve a characteristic granular structure made up of sand-sized, rounded to rhombic, calcite grains set in a matrix of sparry and spherulitic cements (Shearman et al. 1989; Shearman and Smith 1985). But the shape of a thinolitic calcite is easily confused with the outlines of other evaporite salts that have no implication of degassing in CO_2-saturated coldwater spring seeps.

Likewise, the recognition of ikaite in Neoproterozoic glacial sediments interlayered with pisolites and ooids can be used to imply that the high supersaturation of Precambrian seawater meant that coated grains were possible cold water precipitates. They were not exclusively tropical precipitates, unlike pisolites and ooids in today's oceans and inferred for similar coated grain textures throughout the Phanerozoic (James et al. 2005). Alternatively the interlayering of glendonites and coated grains can be used to support a "freeze or fry" climate model tied to "Snowball Earth."

For years, before ikaite was shown to be a cold water precipitate, not an evaporite, many crystals described as ikaite were considered named in a way that could be used interchangeably with the mineral gaylussite, or ikaite was described as pseudo-gaylussite. In terms of depositional setting, ikaite and gaylussite are not coprecipitates, but from older literature associations one could easily think they were.

Separating ikaite/gypsum/gaylussite is not the only difficult choice when attempting to identify the precursor to a fuzzy-edged angular outline, now filled by a later mineral phase. Other problem pseudomorph associations include baryte/ siderite/gypsum; acicular aragonite/gypsum; pyrite/ halite and even anhydrite/gypsum. The difficulty in deciding on the likely precursor of a possible pseudomorph, when the replacement process can destroy to varying degrees the original outline, emphasises the need to look at all sources of evidence when interpreting any ancient succession now leached of the original salts or the daughter products.

Summary

Evaporites are soluble in most subsurface situations. Even preserved evaporite beds show varying degrees of dissolution about their edges. The longer an evaporite bed remains in the subsurface the more likely it is to dissolve. Preservation or loss it is not a question of whether an evaporite will

dissolve in the subsurface, but when. This is why there are few preserved beds of evaporite salts older than Neoproterozoic. As thick evaporite units dissolve they leave behind characteristic breccias and other textures and replacements that allow the recognition of former extensive salt beds. The breccias can be interstratal beds or trans-stratal chimneys, distinguishing the two forms differentiates between blanket or more focused inflows. Dissolution can be driven by basinal fluids escaping from below or by fluids infiltrating from above. Salt units may not dissolve until they have flowed into diapirs and welds (halokinetic breccias) or have acted as décollement surfaces in fold and thrust belts (rauhwacke). All evaporite salt units will ultimately dissolve, many disappear in the diagenetic realm while others may be preserved until they attain metamorphic grades or interact with a magmatic body.

Hypersaline Fluid Evolution During Burial and Uplift

8

Basin-Scale Burial Hydrology

In Chap. 2 we discussed the hydrology of evaporite depositional and early diagenetic (eogenetic) settings, in this chapter we consider diagenetic evolution in subsequent hydrological stages in a sedimentary system containing thick salt, that is, rock-fluid interactions in an evaporite-entraining sequence experiencing ongoing burial, followed by possible uplift (mesogenesis followed by telogenesis. Thick, buried and dissolving evaporites influence subsurface hydrology and formation water chemistries throughout the burial cycle, as they interact with regional and local thermal and pressure regimes. Remobilization of salt and introduction of brine-carried carried components, notably dolomite and anhydrite, can have a significant impacts on reservoir quality, e.g. the Simonette oil field, Swan-Hills Formation (Devonian) Alberta, where late anhydrite and burial dolomite represent up to 50 % of the rock volume (Duggan et al. 2001). Evaporites that enter the metamorphic realm can have an extensive influence consequent rock type and distribution, well after the primary sedimentary and diagenetic salts are long gone (Chap. 14).

Flushing by basinal pore waters drives diagenetic alteration, recrystallisation and dissolution of evaporites within four hydrotectonic realms, namely (Fig. 8.1; Table 8.1):

1. Passive-margin burial,
2. Pull-apart burial,
3. Collision margin burial, and
4. Post-orogenic burial.

All four can be inter-related by the Wilson Cycle. Throughout their burial history, salt beds and allochthons act as foci for escaping basinal and tectonic fluids. Subsurface breaching of a stratiform salt aquitard, either in response to dissolution or to halokinesis, typically focuses crossflows of basinal fluid. Fluid may rise or sink through a breach, depending on the local temperature and pressure regime. Fluids flowing through a breach will mix with extrinsic basinal or meteoric fluids with differing chemistries and physical properties, so facilitating precipitation of authigenic phases at or near a salt breach (burial salts and metal sulphides).

The salt-floored passive margin burial realm is characterized by updip extensional tectonics, differential loading, growth faulting, relatively slow and steady subsidence and, in most salt-floored passive margins, by salt flow (Fig. 8.1a). Compressional tectonics is commonplace in downdip positions in the same salt-floored continental margins. The Mesozoic and Tertiary evolution of the Gulf of Mexico and Atlantic-margin basins are typical examples of this salt-lubricated hydrologic style (Fig. 6.1). Down to a depth of a kilometre or so, the shallower parts of this realm are typified by active to stagnant phreatic circulation. Below is the zone of compactional flow, which entrains both horizontal (average rates of 6 cm/year) and vertical flow regimes (average rates of 0.15 cm/year). Deeper still, or in zones of thermal anomalies around growing salt structures and shale diapirs, is the zone of thermohaline flow.[1]

Away from local thermal anomalies, temperatures increase steadily with depth according to regional geothermal gradients, which range from 15 to 30 °C/km in most passive margins. Nonevaporitic sediments shallower than 2–3 km depth are typically hydrostatically pressured, while deeper strata, especially thick impervious shales in rapidly accumulating depocentres such as suprasalt minibasins, tend to be geopressured. A transition to overpressuring can occur at much shallower depths (≈1 km or less) where evaporites, not shales, are the predominant basin aquitard (e.g. Jowett et al. 1993). This reflects very rapid rates of basinwide evaporite sedimentation and a complete loss of intrasalt porosity at shallow depths within these basinwide units.

Pull-apart or transform burial is characterised by extensional tectonics and rapid subsidence, along with high

[1]Thermohaline flow involves, or is dependent upon, density contrasts, which are related to the conjoint effects of temperature and salinity variations.

Table 8.1 (continued)

	Location and age of brine source	Role of salt	Reference
Post Orogenic burial	Ebro Basin, Spain, Triassic	Dissolution of buried evaporites caught up in the hydrology of compressional belt supplied much of the ionic content (& meganodules) to active evaporite systems in the Miocene outflow zones in adjacent foreland depressions	Salvany et al. (1994), Sánchez et al. (1999), Ortí et al. (2012)
	San Andres Formation, West Texas, Permian	Modern, deeply circulating Na–Cl brines in arkosic sandstone aquifers acquired their high salinity through the dissolution of halite and so displaced Permian age reflux brines and drove local gypsification of anhydrite (1,829 m)	Bein and Dutton (1993), Stueber et al. (1998), Amadi et al. (2012)
	Alberta Basin, Canada, Devonian	Two brine system; a 'heavy brine' that is a residual Middle Devonian evaporitic brine and a 'light brine' that probably originated from dilution of 'heavy brine' by deeply-circulating meteoric fluids in post-Laramide time.	Michael et al. (2003), Gupta et al. (2012)

sedimentation rates in the basin depocentre (Fig. 8.1b; Table 8.1). Pull-apart basins are an integral part of intraplate and interplate strikeslip fault zones in both rift and collision settings and tend to form at bends or sidesteps in the main strike-slip fault system (Fig. 5.32). Hence, in many salt tectonic provinces, such as the Zagros fold and thrust belt, there is a kinetic and mechanical relationship between releasing bends of strike-slip faults and the positions of salt diapirs (Fig. 6.90; Koyi et al. 2008).

When located in arid zones, sediment fill in a rapidly subsiding pull-apart basin can entrain thick salt beds, which subsequently become halokinetic. Such salt masses typify modern pull-aparts, such as the Dead Sea basin in the Middle East and Salar de Antofalla in NW Argentina (Stanislavsky and Gvirtzman 1999; Kraemer et al. 1999). Rapid burial, so typical of this setting, quickly moves thick salt sequences into the subsurface, while contemporaneous salt dissolution can move large volumes of dense hypersaline brines into adjacent aquifers. High rates of subsidence and sediment fill, along with consequent overpressuring, means porosity in associated nonevaporitic sediments can be maintained to much greater depths compared to similar lithologies in a typical passive margin deposit.

The collision margin burial realm is characterized by compressional tectonics, thrust faulting, extensive fracturing of strata and episodic movements of basinal fluids, typically in response to tectonic loading (Fig. 8.1c). Hot (100° to >250 °C), saline and highly pressured fluids are driven laterally out of the collision zone, via porous and permeable horizons, typically toward the craton or continental interior and vertically along faults and fractures (Oliver 1986). Such systems tend to characterise foreland basins, which in arid regions can become areas of interior drainage that quickly fill with various salts, as in seen in the widespread Miocene marine evaporites of the Zagros/Arabian Gulf region or the lacustrine trona deposits of the Eocene Green River Formation in the USA.

Buried evaporite beds caught up in a compressional suture are likely to be pressurized and remobilised, while cross-flows of less saline basinal fluids, as they are squeezed out of the non-evaporite sediments in the collision zone, can drive evaporite dissolution further toward the basin edge. The resulting chloride-rich brines may in turn become metal carriers. Compression-driven hydrologies can precipitate widespread burial dolomites and PbZn deposits, both within the orogenic belts and in the adjacent continental interior. The similarity between geochemistry of fluid inclusions in sphalerite in strata-bound sulphide deposits and that of oil field brines in the U. S. Gulf Coast sedimentary basin led Sverjensky (1986) to conclude that oil field brines can readily evolve into ore-forming solutions (Chap. 15).

The post-orogenic burial setting is characterized by a lack of intense tectonic activity, the dominance of topographically driven flow, telogenesis, and by relatively high fluid flow rates, which in zones of deep artesian circulation range from 1 m/year to 30 m/year (Fig. 8.1d). Flow is driven by elevation gradients created during uplift in the preceding orogenic phase. Postorogenic fluid flow takes over once the main phase of tectonic collision ends. This hydrologic style drives the dissolution of many buried salt units in continental interiors, encompasses the generation of Na-Cl brines, and gypsification of anhydrite (at depths that exceed 1,800 m), as is occurring today in the Permian and Michigan basins of the USA, the European Alps and the High Atlas.

Steep topographic gradients about basin edges of all three basin stages can create topographically-driven nearsurface fluid flow rates as high as 20 m/year in aquifers in the high relief portions of the basin (rift rim, transform edge, and

orogenic uplift zones). These are much higher rates compared to flow in low relief topographic settings such as passive margins and intracratonic sags, where nearsurface regional flow rates are typically ≈ 1 m/year, with local thermal- and density-driven flow rates up to 10 m/year. Fracturing and karstification in any aquifer system creates higher local flow rates that can be orders of magnitude greater than that measured in the matrix.

Gradients within shallow aquifers beneath the more central parts of a basin's depocentre are less than in the steep-sided tectonically active margins, but can still be of the order of metres per year. Deeper aquifers in all basins have much slower flow rates (compared to nearsurface rates) and are typically measured in metres per year or less. Free convection cells driven by the buoyancy forces associated with temperature and salinity fields about salt allochthons have flow rates in typical temperature and density drive convection cells ≈ 1 m/year, depending on thickness of the aquifer, fluid-density gradient, and regional permeability (Hanor 1987). Flow rates in deep aquifers within the cores of orogenic belts are typically ≈ cm/year and dissipate quickly when stress is alleviated (Garven 1995). Regional flow rates generated by compaction in a mud-rich sedimentary basin are typically much less than a cm/year, with locally or temporally higher rates during fault or microfracture venting of overpressured zones.

The presence of a subsurface evaporite unit, as it flows and dissolves, creates brine and density inhomogeneities that facilitate active and long term brine mixing interfaces and much higher local rates of subsurface fluid flow. For example, flow rates within descending brine plumes beneath thick buried and dissolving Miocene salt masses in the Dead Sea region are as high as 10 m/year (Stanislavsky and Gvirtzman 1999). These rates approach those in aquifers in the margins of a high relief basin. Flow gradients tend to be highly variable throughout all sedimentary basins containing flowing and dissolving salt.

The various tectonic process and the associated flow-drivers can co-exist in any salt floored basin, long after the original tectonic setting that deposited and buried the salt has passed (Fig. 8.2). In the salt floored Sverdrup Basin of the Canadian Archipelago the source of high salinity subsurface waters is clearly dissolving salt structures (Fig. 8.2) but the pore fluid movements are also influenced by the generation of biogenic and thermogenic gas, independent of salt dissolution and its Mesozoic sediment hydrology (Grasby et al. 2012). The Sverdrup Basin shows a general increase in average salinity values with depth, but at any given depth in the Sverdrup Basin there tends to be a much higher degree of variability at a particular depth than in other less tectonically mature salt-floored basins such as the Gulf of Mexico (Fig. 8.3a). Fresh to brackish to saline waters are observed in each Sverdrup sequence down to the 4 km limit of data availability (as studied by Grasby et al. 2012 and references therein). The Mesozoic section of the Sverdrup Basin was deposited in an open marine to freshwater siliciclastic system. Sedimentary basins of this nature that lack evaporite deposits typically do not have brines present (e.g. Mahakam basin, Indonesia; San Joaquin basin, California; Pattani basin, Thailand; Beaufort Basin, Alaska). In such basins where seawater evaporation wasn't significant, or secondary dissolution of evaporite beds was not prevalent, formation water salinities seldom exceed that of seawater itself (Fig. 15.3).

While the average salinity range for some formations in the Sverdrup Basin are near that of seawater, others greatly exceed seawater salinity (over 200 g/L) (Fig. 8.3a).

While evaporite units were not deposited in the Mesozoic section studied here, thick deposits of halite and gypsum are present in the underlying Late Carboniferous (Bashkirian) Otto Fiord Formation (Fig. 8.2b). These evaporite units form salt diapirs, which penetrate the Mesozoic sequence, and are exposed at the surface in many parts of the basin, as well as forming salt-cored anticlines (Fig. 8.2a). High salinity Na–Cl dominated spring systems, found on both Axel Heiberg and northern Ellesmere islands are also shown to derive salinity from sub-surface halite dissolution, whereby active modern hydrogeological systems are bringing freshwater into the subsurface and dissolving buried salt deposits.

Brines in the Sverdrup Basin are Na–Cl dominated and show a 1:1 NaCl ratio, consistent with halite dissolution driving brine generation. The spatial variation of TDS shows that the highest salinity brines in the basin are found in the region where there is a high occurrence of salt cored uplift and surface expression of diapirs (Fig. 8.2a), similar to diapirs that locally generate brines in other basins such as the Gulf of Mexico and Zechstein basins. As a result, while waters of the Sverdrup Basin are in general similar to the salinity of seawater, high salinity brines are formed locally due to halite dissolution in areas where salt diapirs have pierced major aquifer units and thermohaline mixing dominates.

Large regional aquifers (e.g. Heiberg and Isachsen formations) show the widest range of salinities and have averages much higher than seawater, whereas less regional, or shaly, systems (e.g. Roche Point, Bjorne formations) have a lower range of salinity and averages close to seawater (Fig. 8.3b). But in the vicinity of salt piercement these otherwise lower salinity range aquifers host hypersaline pore fluids. According to Grasby et al. (2012) this is similar to other basins where there appears to be a lithologic control on salt dissolution, such as the Gulf of Mexico and Tarim basins (see later). The high permeability of regional sand aquifers allows for faster generation of brines through density-driven circulation as well as being more prone to topographically and compaction-driven fresh water influx, especially about the basin margins.

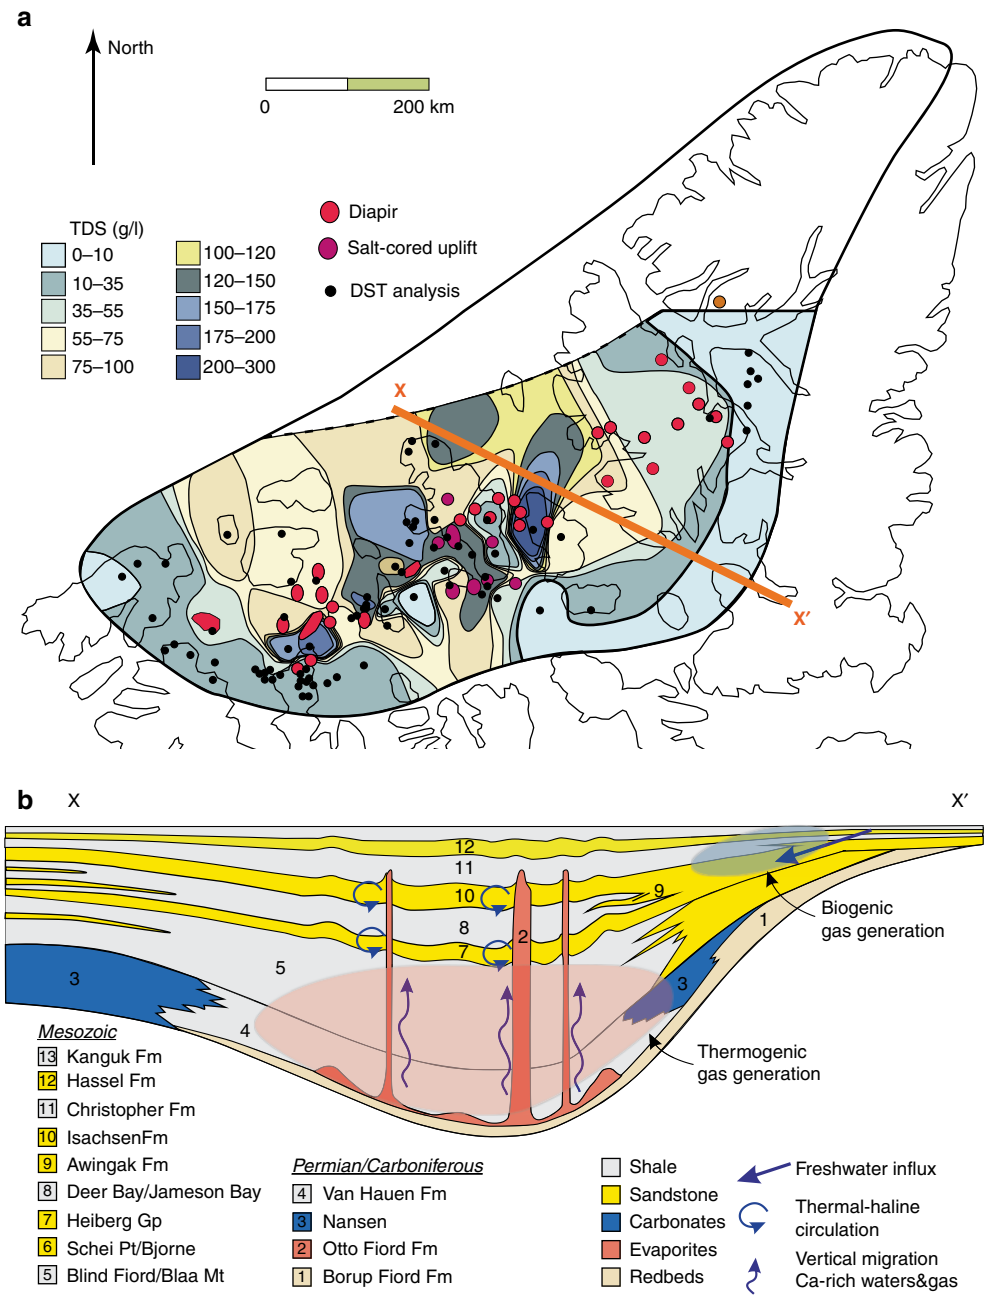

Fig. 8.2 Salt and salinity in the Sverdrup basin. (**a**) Spatial variability of TDS in the Sverdrup Basin along with locations of salt-cored anticlines and surface exposed diapirs. (**b**) Cross section in the Sverdrup Basin (see (**a**) for location) showing simplified stratigraphy and sandstone aquifers, along with major salt related and catagenic fluid flow processes thought to affect formation waters in the basin (After Grasby et al. 2012)

Thus, while formation waters in the Sverdrup Basin are in general consistent with a seawater origin, there is high variability in formation water geochemistry. Local anomalies of very high salinity waters are associated with salt piercement structures and salt dissolution driving thermohaline circulation (Fig. 8.2a). Dissolution of halite from the diapir edges formed localised brines with over an order of magnitude higher TDS concentration than average for the basin (Fig. 8.3b). In contrast, fresh water influx lowered salinities along the basin margins. This fresh water influx also appears to have initiated generation of biogenic gas by lowering TDS and concentrations of SO_4 below inhibitory levels and depressing the local temperature field that would normally inhibit methanogenesis. At the same time catagenesis is associated with the vertical migration of Ca-Na-HCO_3 enriched basinal brines. Mixing interfaces between these various waters drives more intense diagenetic alteration in these zones.

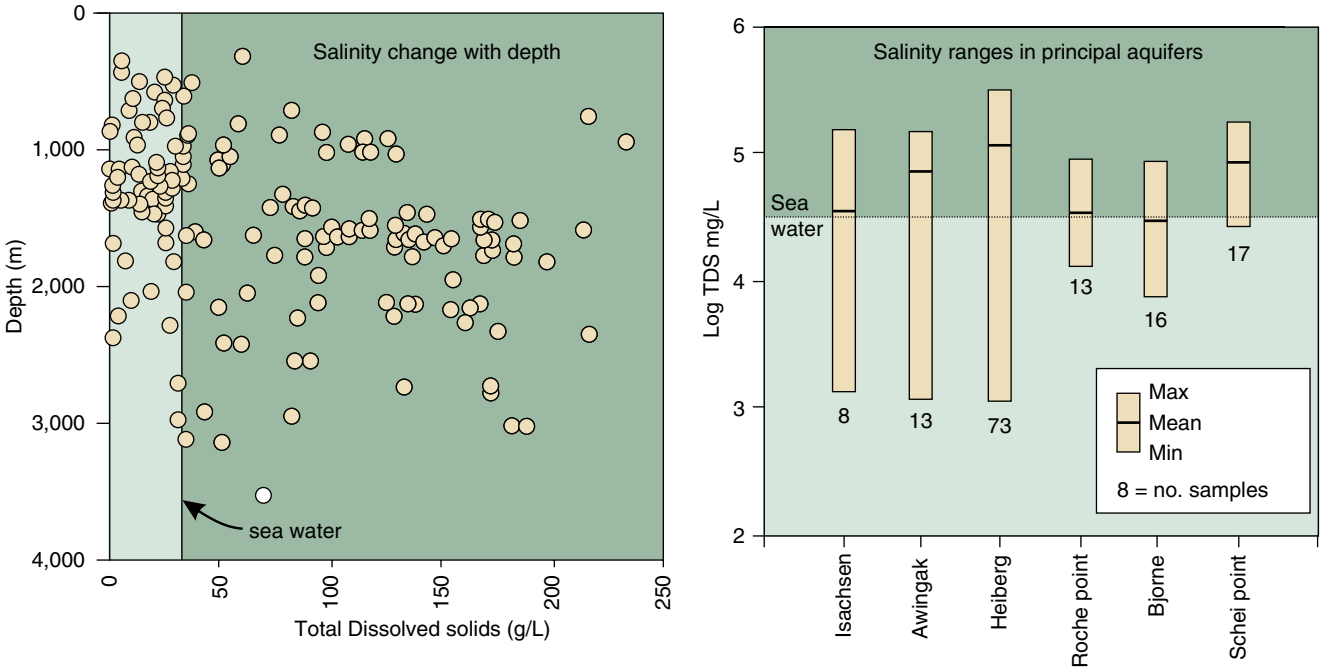

Fig. 8.3 Pore fluid salinity in various wells in the Sverdrup Basin, Canada. (**a**) Plot of total dissolved solids vs. sample depth for all formations, (**b**) plot showing mean average and range of total dissolved solids (TDS) for key sandstone aquifer units Seawater salinity is defined by the contact between light (fresh-brackish) and dark (hypersaline) *green* shading (After Grasby et al. 2012)

Fluids in Subsiding Basins

The zones of compactional and thermobaric/thermohaline flow lie beneath the zone of active phreatic circulation. The zone of active phreatic flow is typically tied to topography, surface-related processes, such as brine reflux and the position of the shoreline (see Chap. 2). The compactional and thermohaline zones, rather than the active phreatic zone, dominate the greater part of any sediment pile accumulating within an extensional zone in a passive margin, or in the subsiding foreland depression fill of a compressional regime or in the rapidly subsiding parts of pull-apart basins. As well local cementation, these same fluids can drive the formation of exotic or "out of sequence" cements (Neilson and Oxtoby 2008).

Compactional Fluids

The compactional regime is characterised by the upward and outward expulsion of pore waters formerly trapped within the compacting sediment pile. If fluid cannot freely escape, the compacting sediment may become overpressured. Compactional waters include connate[2] waters, waters modified by brine-rock interactions, and meteoric waters originally buried within shale, sand or carbonate aquifers. Compactional or consolidation-related flow is a typical response to basin subsidence and ongoing sedimentary loading, which drives out interstitial fluids from compressible and hydraulically conductive buried strata. As it needs overburden loading to drive it, compactional fluid flow is characteristic of the mechanical dewatering stages of the basin's burial history and it dominates the early subsiding and filling stages of a sedimentary basin. Compactional loading of more mature sediment piles can be reactivated in regions of thrust sheet stacking, which can renew brine expulsion from the buried matrix (Fig. 8.1c; Garven 1995). In this case it is the loading of the thrust sheets and the lateral compression of the basin that drives further fluid expulsion. It is a process that is quickly alleviated once thrust stacking ceases (Bitzer et al. 1998).

Compactional flow as an early-burial fluid migration mechanism is typical of young rapidly subsiding nonevaporitic

[2]Connate waters are subsurface waters with chemistries near-identical to those of waters, which were present in the pores at the time of deposition (Hanor 1994a). The term connate comes from the Latin (*connatus* = born with). Connate properties of subsurface brines include connate isotopic properties, connate Br/Cl ratios and other ionic proportions. Very few subsurface waters are truly connate because ongoing subsurface chemical alteration and diagenesis (water-rock interaction) influences the chemical make-up of most entombed waters. Some authors use the term connate interchangeably with the more general term subsurface water, but to avoid confusion its use should be preserved for those waters and brines that are truly connate (Hanor 1994a). Hence, most basinal brines are not connate, this is especially obvious in subsurface regions where thick evaporites are dissolving creating high salinity Na-Cl dominated brines.

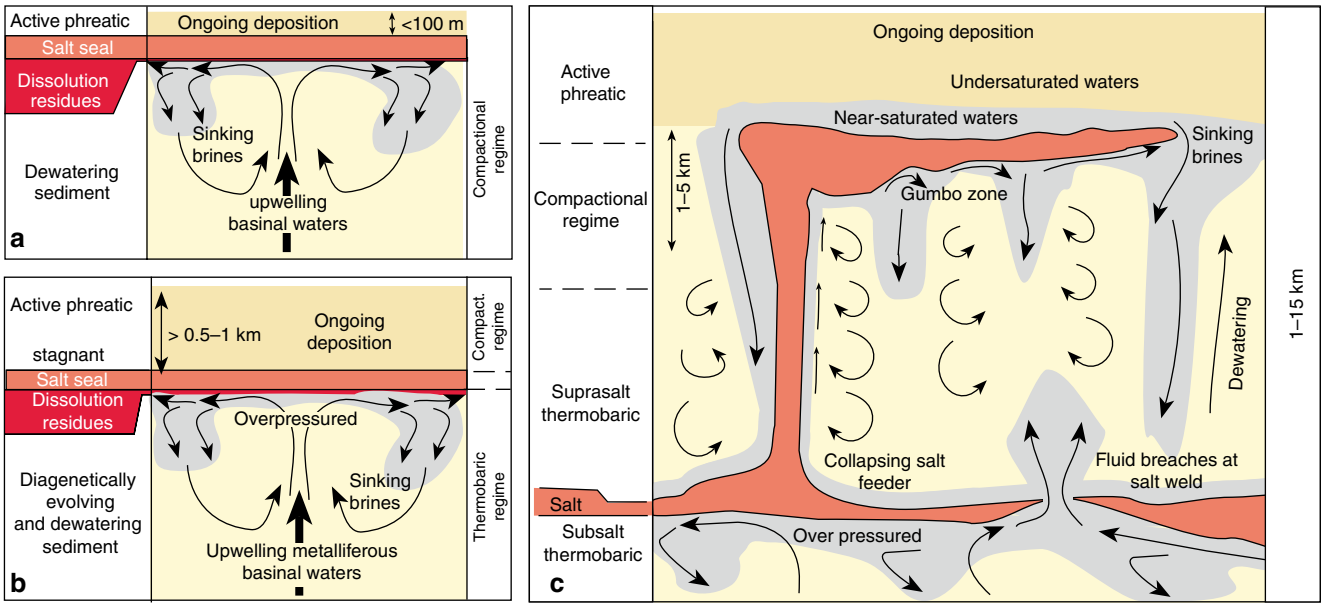

Fig. 8.4 Brine flow regimes. (**a**) Compactional regime. (**b**) Thermobaric regime. (**c**) Flow regimes in diapiric province, also shows potential region for escape of hydrocarbon bearing or possibly metalliferous fluids at breach zones in flowing salt bed (salt welds, growth faults, fault welds, etc.)

basins, where it dominates mud-rich sections deeper than 1,000–2,000 m (e.g. many Tertiary basins in SE Asia). Sediment ages in these basins typically range up to a few tens of millions of years. Differences in pressure heads between adjacent areas are the main driving force to fluid flow and the systems are often compartmentalised by growth faults and mud diapirs. Most expelled fluid tends to move upward through still porous overlying strata during the earliest stages of compaction (Magara 1986). Then, in the later stages of compaction, as interbedded clays become relatively impermeable, the principal direction of fluid migration becomes stratigraphic and is controlled by interbedded permeable beds of less compacted and variably cemented sandstones and carbonates.

In contrast, a subsiding basin succession entraining a widespread evaporite bed always contains a highly effective aquitard/aquiclude, almost as soon the salt is deposited. If water-saturated sediments are compacting beneath a thick rapidly accumulating unit of basinwide evaporites, its underside deflects the otherwise upward flow of escaping compactional waters (Fig. 8.4a). Rising compactional water is initially undersaturated with respect to the evaporite salt but the salt's edges quickly becomes a zone of salt dissolution and accreting insoluble residues (Chap. 7). Water flows obliquely along the underbelly of the dissolving evaporite bed until it reaches a breach in the salt or the edge of the bed. There fluid flow may once again become strongly vertical. As a general rule of thumb, thick evaporite units in a subsiding basin will focus and pond upward-escaping compactional waters and restrict regions of brine escape to areas atop fractures, growth faults, dissolution-induced breaches, or dissolution edges of the evaporite unit. Halokinesis, through its inherent thickening and thinning of bedded salt, may help focus fluid escape via welds into breached salt withdrawal basins, typically situated between growing salt anticlines, allochthon sheets and diapirs (Fig. 8.4c).

Thermobaric-Thermohaline Fluids

Thermobaric fluid[3] flow occurs in the deeper parts of a sedimentary basin where the temperatures and pressures are greater and is intimately related to compactional flow in its uppermost parts (Fig. 8.4b, c). By definition, it is a zone of widespread diagenetic alteration where significant volumes of "new" pore waters are released by dehydration of clay minerals and catagenesis or the dehydration of hydrated evaporite minerals, such as gypsum to anhydrite or carnallite to sylvite. Fluids in the thermobaric/thermohaline regime move in response to pressure/density gradients generated by the related phase changes, such as the generation of hydrocarbons, or the release of mineral-bound water, or ongoing lithostatic loading (Fig. 8.5). Density contrasts created by salinity or temperature gradients beneath or adjacent to a

[3]Thermobaric is typically considered to indicate a higher-pressure, higher-temperature pore fluid and is contrasted by some authors with thermohaline waters indicating higher-temperature higher-salinity fluids. Sometimes the terms are considered interchangeable and some authors use them in place of the term hydrothermal, others consider them separate definitions. Usage of all three terms in the literature can be poorly constrained. Using a general term such as "subsurface waters" with an appropriate discriminator as a prefix, such as; hypersaline, pressured, heated, etc., may be more apt.

dissolving salt bed can drive laterally extensive subsalt convective flow cells made up of thermobaric/thermohaline pore waters. Chemical changes in the sediment matrix mean thermobaric/thermohaline waters frequently contain methane, carbon dioxide and hydrogen sulphide derived from the thermal alteration of organic matter, as well as metals leached from basinal shales and volcaniclastics (Aquilina et al. 2011). Interfaces associated with mixing of varying thermobaric and thermohaline water masses are regularly focused into fault damage zones where permeabilities are periodically elevated (Table 8.2).

Low permeabilities of deeply buried sediment between or below impervious evaporite beds mean typical regional rates of fluid flow in intra or subsalt beds are slow (mm-dm/year) except in zones of seismic pumping and faulting (Table 8.2; Shaker 2008). As in compactional zone hydrologies, it is in the interval adjacent to a salt bed where overpressure tends to develop best and long-term flow rates are elevated, regularly aided by processes such as natural hydrofracturing. Rates of fluid flow and the rate of creation of mixing zone interfaces can be enhanced by the formation of temperature anomalies in the buried sediment, which are tied to the higher conductivity of salt.

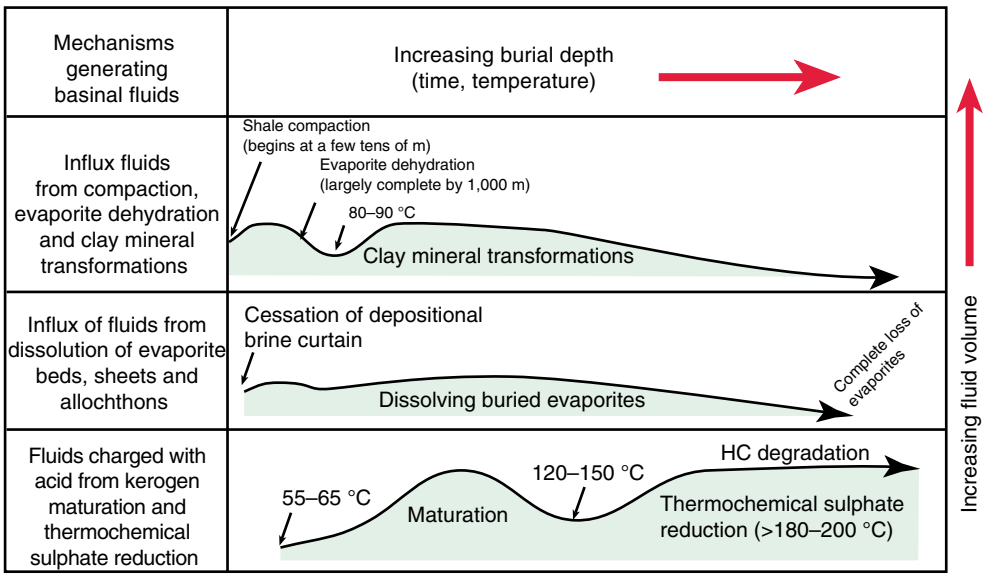

Fig. 8.5 Mechanisms that release thermobaric waters into a basin with thick buried evaporites. Increasing burial releases fluids (brines, acids or gases) as indicated by the shaded portions of each row. The fluids would interact and when undersaturated with respect to the salt mass may have increased the rate of salt dissolution. (No vertical scale is implied)

Table 8.2 Selected examples of mesogenetic hypersaline subsurface flow-focused diagenetic alteration.

Occurrence, host age and reference	Hydrothermal aspect	Comment
Pb-Zn-Ba ore, Jebel Hamra, Central Tunisia; Cretaceous – Upper Aptian; (Bejaoui et al. 2013)	Pb-Z-Ba mineralization is spatially and possibly genetically related to E-W trending fractures, which acted as conduits and/or depositional sites for circulating hydrothermal fluids. Fluid inclusion and sulphur isotope data suggest the contribution of evaporite-derived basinal brines in ore formation.	Mineralization occurs as stratiform lenses, and breccia- and paleokarst-fillings. Ore reserves are around 0.5 Mt and grades are 7 % Zn and 3 % Pb. Sulphide mineralization occurs as local replacement of dolomitised and silicified carbonate strata. Combined field, sedimentological, mineralogical, isotopic and geochemical data of the Lower Cretaceous mineralization in Jebel Hamra is compatible with Mississippi-Valley-type mineralization.
Dolomites in Albenza Formation, Alps, Northern Italy Jurassic (Ronchi et al. 2011)	An increase in the precipitation temperature (up to 130 °C) and a decrease in diagenetic fluid salinity (from marine to brackish) are observed from the first pervasive replacement dolomite to the dolomite cement phases. Dolomitization was limited to palaeohighs or faulted platform margins in the Early Jurassic carbonates. The pervasive replacement phase is interpreted based on a 'compaction model'; the formation fluids expelled from compacting basinal carbonates were funnelled along faults into permeable palaeohighs.	Petrographic analyses showed a first, pervasive, replacement dolomitisation phase (D1) followed by volumetrically less important dolomite cement precipitation phases (D2, D3 and D4). The $\delta^{18}O_{PDB}$ values fall between −8.2 and 0.1‰, with the more depleted samples belonging to dolomite cement-rich dolostones; the $\delta^{13}C_{PDB}$ ranges from 2.6 to 3.7 %. Analysis of trace elements showed different Fe and Mn contents in the sub-surface and outcropping dolostones, and a higher Fe in the younger dolomite cements. Dolomite cements precipitated according to the 'tectonic squeegee' dolomitisation model

(continued)

Table 8.2 (continued)

Occurrence, host age and reference	Hydrothermal aspect	Comment
Hydrothermal dolomite, Reinecke field, West Texas; Upper Pennsylvanian Lower Permian; (Saller and Dickson 2011)	Fine to coarsely crystalline dolomite with undulose extinction that formed diagenetically late and constitutes ≈25 % reservoir matrix. These dolomites overgrow stylolites, indicating precipitation during deep burial. Low $\delta^{18}O$ values, consistent with primary fluid inclusions, indicate dolomite precipitation or recrystallization at 92–118 °C.	Two types of dolomite; (a) stratiform, replaced micrite-rich facies, and is interpreted as early dolomite that recrystallized in hydrothermal brines. (b) crosscuts stratigraphy and depositional facies with vertically continuous morphologies that trend NW-SE. This dolomite forming in hydrothermal brines derived from latest Permian-aged highly evaporated seawater brines that descended deep into the basin because of their greater density and then ascended because of heating and thermal convection.
Jean Marie Member (Redknife Fm.) July Lake Area, NE British Columbia, Canada Devonian (Upper) (Wendte et al. 2009)	Pure dolostones occur as metre-thick bodies, at the very top of the Jean Marie in only a few wells. Dolomite also occurs as a selective replacement of internal sediment infilling fractures. This mode of occurrence, as well as the patchy distribution of pure dolostones at the very top of the Jean Marie, suggests that matrix replacement dolomites formed from fluids that were delivered from flow through a vertical, or near-vertical, fault-conduit system, rather than from fluids that were delivered from flow laterally through matrix pores in a stratal-controlled system	Later mineral phases, including (in paragenetic order) saddle dolomite cement, sphalerite, dickite and baryte, are also interpreted as part of the fault/fracture controlled system of diagenesis. The homogenization temperatures of saddle dolomite range from 80 °C to 163 °C and those of sphalerite and baryte, collectively, from 55 °C to 126 °C, with a broad range of calculated salinities for all these phases ranging from approximately 9.0–27.0 wt% $NaCl + CaCl_2$ equivalent. The wide range of salinities for these phases is interpreted to be from the mixing of evaporative brines with less saline formation waters away from the fault/fracture conduits. Hydrothermal diagenesis possibly starting as early as latest Devonian and continuing into the early Mississippian, at burial depths no deeper than approximately 900 m
Trenton-Black River dolomites, Mohawk Valley, New York State, USA; Silurian; (Slater and Smith 2012)	Linear dolomite bodies occur in outcrop suggest that host carbonates have undergone significant fault-related hydrothermal alteration. Dolomite occurs in the Lower Ordovician Tribes Hill Formation, which is regionally a Lower Ordovician shaly limestone with patchy dolomitisation	The outcrop has an en echelon fault, fracture, and fold pattern. Most of the dolomitisation occurs in fault-bounded synclines or sags flanked by anticlines. The dolomite structures are highly localized, occurring around faults, and are absent away from the faults and fractures. Area serves as a scaled analog for the Trenton–Black River hydrothermal dolomite reservoirs of eastern United States
Bitumens in Ara Group salts, South Oman Salt Basin Cambrian-Precambrian Boundary (545 Ma (Schoenherr et al. 2007a, b, c)	Vitrinite reflectance shows highly heterogeneous maximum paleo-temperatures. Paleo-temperatures of 380 °C were obtained from coke-like solid reservoir bitumen, which most likely formed from thermal cracking of oil. This process is related to hydrothermal fluids, deriving from deeper pre-salt strata, which entered the intra-salt carbonate stringers during times of basement tectonic activity via hydrofractures	Solid reservoir bitumens from the Ara Group indicate a polyphase hydrothermal evolution. Salt diapirs encase isolated, partly highly overpressured carbonate bodies (intra-salt "stringers") which represent a predominantly self-charging hydrocarbon system. A large number of stringer cores show that reservoir quality is decreased by the presence of solid reservoir bitumen. High maturities ("pyrobitumens") occur in close vicinity to the fractures and precipitation of "migrabitumens" with increasing distance to the hydrothermal source
Sparry magnesites and dolostones of the Ibor Group, Western Spain; Ediacarian 635–542 Ma); (Herrero et al. 2011)	D_1 is a relatively early dolomite replacement of fine grained peritidal limestones. Coarser crystal size of D_2, which shows similar geochemical features as D_1, formed by dolomitisation of coarser grained limestones. The replacement of D_1 and D_2 by M_1 and M_2 advanced along stylolites, fractures and bedding planes fed by hydrothermal fluids, co-associated presence of talc and forsterite. D_3, a coarse dolomite, completely destroyed any previous texture and D_4 (dolomite cement) post-dates magnesite formation.	Dolostones (D_1–D_4) and magnesites (M_1–M_2) formed by hydrothermal replacement of primary peritidal limestones. Oxygen and carbon isotopes of D_1–D_4 overlap with $\delta^{18}O_{SMOW}$ values ranging from −15.12 to −13.12 ‰ and $\delta^{13}C_{PDB}$ from −0.13 to +3.21 ‰. Sr isotope values for D_1 and D_2 range from 0.7028 to 0.7091. Magnesites (M_1 and M_2) show oxygen values higher than −12.77 ‰, and $\delta^{13}C_{PDB}$ values show the same variability as for the dolomites. D_3 and D_4 oxygen isotope values are between −11.76 and −11.09 ‰, and the carbon isotope values range are similar to the other diagenetic phases. Sr isotope values for the magnesites and late dolomites (D_3 and D_4) are 0.7095–0.7104, being higher than those of the D_1 and D_2 dolomites

Fluid density tends to increase in thermobaric/thermohaline waters in contact with the dissolving edges of salt units and the direction of regional brine flow is typically focused by the salt edge (Fig. 8.4). These brines have locally anomalous chemistries and can drive diagenetic alteration when mixed with cooler less-dense brines derived from adjacent sediments. For example, the Slave Point, Sulphur Point and Keg River formations of Northeast British Columbia contain numerous gas fields, particularly along the preferentially dolomitised reefal shelf edge margin (Morrow et al. 2002). The typical reservoir facies is a coarse-crystalline white dolomite known as the Presqu'ile Dolomite. It follows the shelf edge within the Slave Point Group, but coarse-crystalline dolomite is also regionally extensive within underlying strata. The dolomite is made up of two geochemically distinct but related phases, both precipitated from thermobaric waters, along with exotic cements such as anhydrite and celestite (Fig. 8.6a; Neilson and Oxtoby 2008).

The organic-rich Klua Shale, the Otter Park Shale, and marlstones equivalent to the Sulphur Point and Slave Point formations are aquicludes that blocked the upward and lateral flow of warm dolomitising brines derived from dissolution of buried evaporites (Fig. 8.6b). Presqu'ile dolomitisation along the Slave Point shelf edge is interrupted in places where the Klua Shale extends shelfward underneath the Slave Point Formation. The Watt Mountain shale was also a regional aquiclude that prevented upward circulation of dolomitising fluids in areas behind the Slave Point shelf edge. The flow of dolomitising NaCl-$CaCl_2$-$MgCl_2$-H_2O brine solutions began early in the shallow subsurface perhaps even as their brine source (Slave Point evaporite) was still being deposited. This precipitated dolomite cements (type 1) at temperatures >50 °C, during northwestward-directed shallow subsurface brine reflux from the Elk Point evaporite basin. This was followed by later upward-directed subsurface convective flow of NaCl-$CaCl_2$-$MgCl_2$-H_2O and NaCl-$MgCl_2$-H_2O brines, generated by the ongoing burial dissolution of evaporites, mixing with less saline thermobaric waters escaping from nearby shale and so precipitating later dolomite cements (type 2). These type 2 dolomites are much less voluminous than type 1 and precipitated at temperatures ≈ 130 °C during the Late Devonian-Carboniferous. Later lower salinity brines that precipitated late calcite cements and some latest type 2 dolomite may have interacted with connate fluids of marine origin or, less likely, with meteoric fluids (Morrow et al. 2002; Wendte et al. 2009).

The importance of a buried, slowly dissolving, salt mass in focusing thermobaric fluid flow throughout much of a basin's burial history was also illustrated by Wolfgramm and Mumm (2000). They used fluid inclusion analyses to reconstruct the spatial and temporal variation of fluid composition and thermal properties within sediments beneath the Zechstein salt in northeast Germany. Precipitates from early thermobaric fluids, migrating in the deeper parts of the basin, were characterised by complex salinities, with sulphur contents that increased toward the contact with the Zechstein. This suggests a partial exchange with the overlying evaporites. Inclusions of coexisting fluids dominated by NaCl,

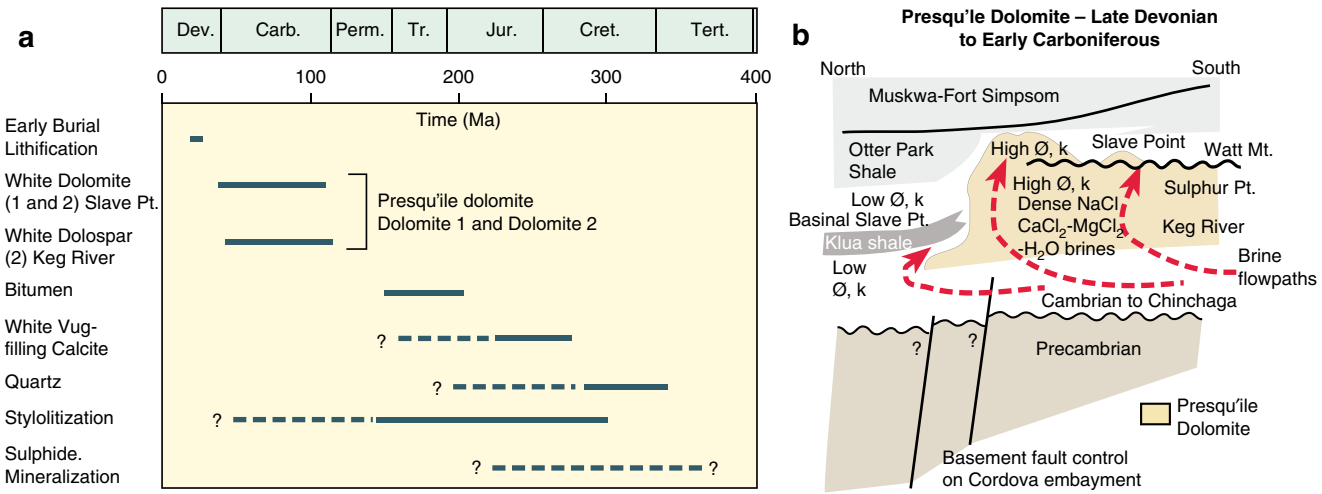

Fig. 8.6 (**a**) Chart of diagenetic events for the Keg River to Slave Point strata. Presqu'ile dolomitisation (dolomite 1 and dolomite 2) precedes the thermal maturation of organic material and the emplacement of reservoir bitumen. Calcite cementation coincides approximately with the onset of gas generation followed by minor quartz and sulphide (sphalerite and galena) cementation. (**b**) Schematic reconstruction of time of dominant Presqu'ile dolomitisation around the Cordova embayment. Dense residual Elk Point brines flowed downdip and northwestward by gravity displacement of less dense subsurface fluids. This flow was confined beneath the Watt Mountain Formation shale. The absence of this confining layer allowed upward flow of brines into the overlying porous Slave Point Formation, where downdip brine flow may have been deflected upward against the low permeability basin fill of shaly units of the Cordova embayment. Initially, dolomitisation occurred at temperatures below 50 °C, but an increase in basal heat flow and ongoing burial caused dolomite precipitation to continue at 130 °C (After Morrow et al. 2002)

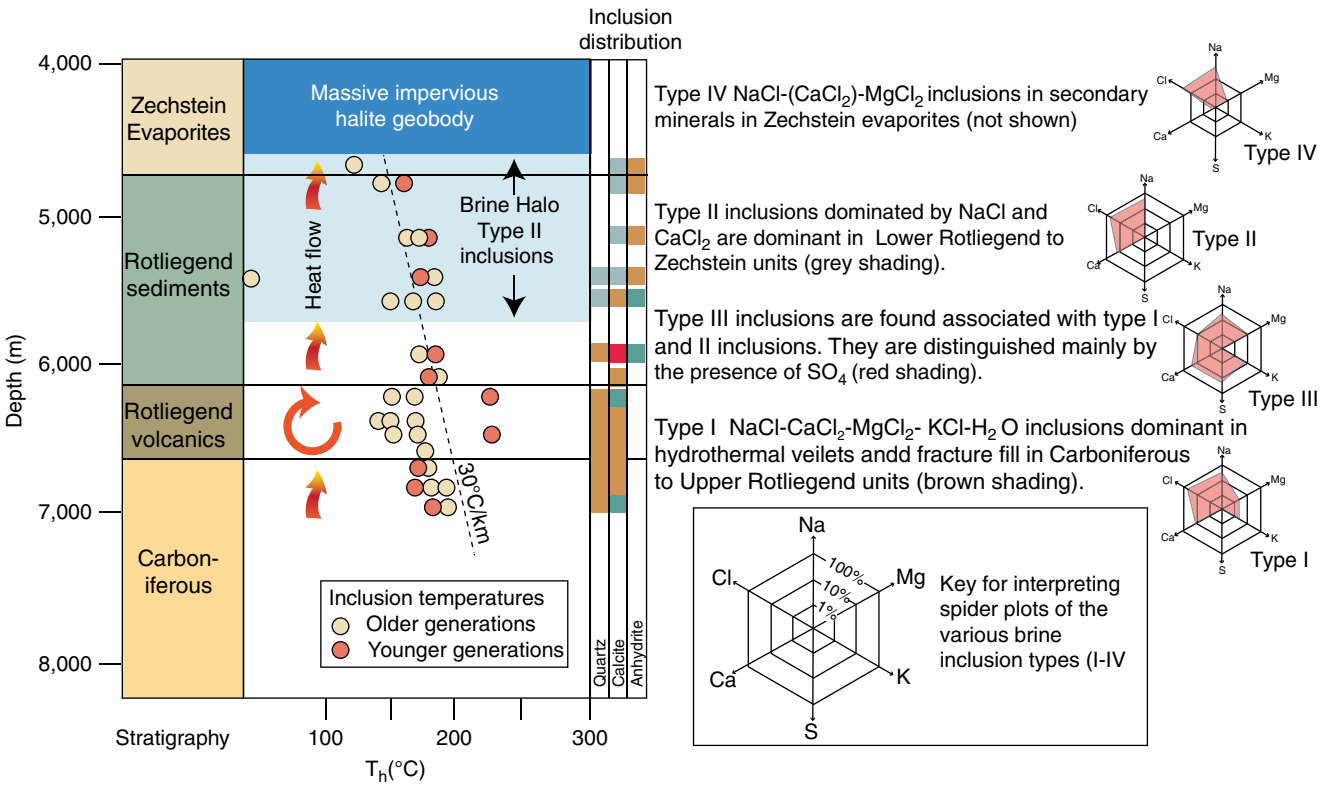

Fig. 8.7 Inclusion homogenisation temperature (T_h) versus depth in the Parchim 1/68 well, NE German Zechstein Basin. Plot is based on measurements of inclusions with varying chemistries (Type I–IV) collected from authigenic cement phases (quartz, calcite, anhydrite) Plot distribution shows the strong influence of salt dissolution brines on authigenic/pore water chemistry across a zone several hundreds of metres thick below the dissolving Zechstein salt mass (Adapted from Wolfgramm and Mumm 2000)

$CaCl_2$ and KCl are largely restricted to authigenic minerals in the Upper Carboniferous sediments and Rotliegend volcanics located in juxtaposition to the overlying evaporites. Younger, secondary fluid inclusions, sometimes containing gas phases, show increasing temperatures related to further burial. Thermal properties of all fluid inclusions indicate steep thermal gradients below the base of the Zechstein and Rotliegend sediments with type II fluids indicating an ongoing plume of brine sourced in the dissolution of Zechstein salts (Fig. 8.7). This documents convective or advective heat and associated focused subsalt fluid flow in the deeper thermobaric parts of the basin. Throughout its burial history the Zechstein salt mass acts as the seal and upper focus to a widespread convective brine system until its continuity is broken by salt withdrawal and thinning.

Deep Flow in Pull-Apart Basins

Another variation on this compaction/thermobaric theme is the evolving hydrology created by rapid subsidence and fluctuating tectonics that typify transtensional basins or pull-apart basins. The best-documented example of hydrological evolution associated with a salt mass in such a setting is the Dead Sea (Stanislavsky and Gvirtzman 1999; Katz and Starinsky 2009). Deep saline pores brine in the Dead Sea region are in part a residual product of intensively evaporated seawater that seeped into the depression back in the Miocene to accumulate as a widespread marine-fed basinwide halite. In places in the Dead Sea depression (e.g. Mt Sedom and surrounds), this halite is still near the surface, kept there by ongoing salt flow (Fig. 8.8a). Dissolution of buried Miocene salt and the associated migration of residual brine today drives zones of dolomitisation within the adjacent Cretaceous carbonate aquifers. This dissolutional brine occurs in deep wells located more than a 100 km from the Dead Sea depression. The feasibility of such longterm lateral migration of brine from Dead Sea evaporites over the past 3-6 Ma, was verified by palaeohydrologic modelling (Stanislavsky and Gvirtzman (1999).

Their results show that two basin-scale ground-water systems coexist in the present Dead Sea rift valley, one atop the other but with opposite flow directions (Fig. 8.7b, c). The upper system is a topography-driven flow of meteoric water fed from the surrounding highlands, which flows eastward into the rift via shallow aquifers (<1 km deep). The second system is a density-driven migration of the Dead Sea brine moving in the opposite direction (westward) through deep

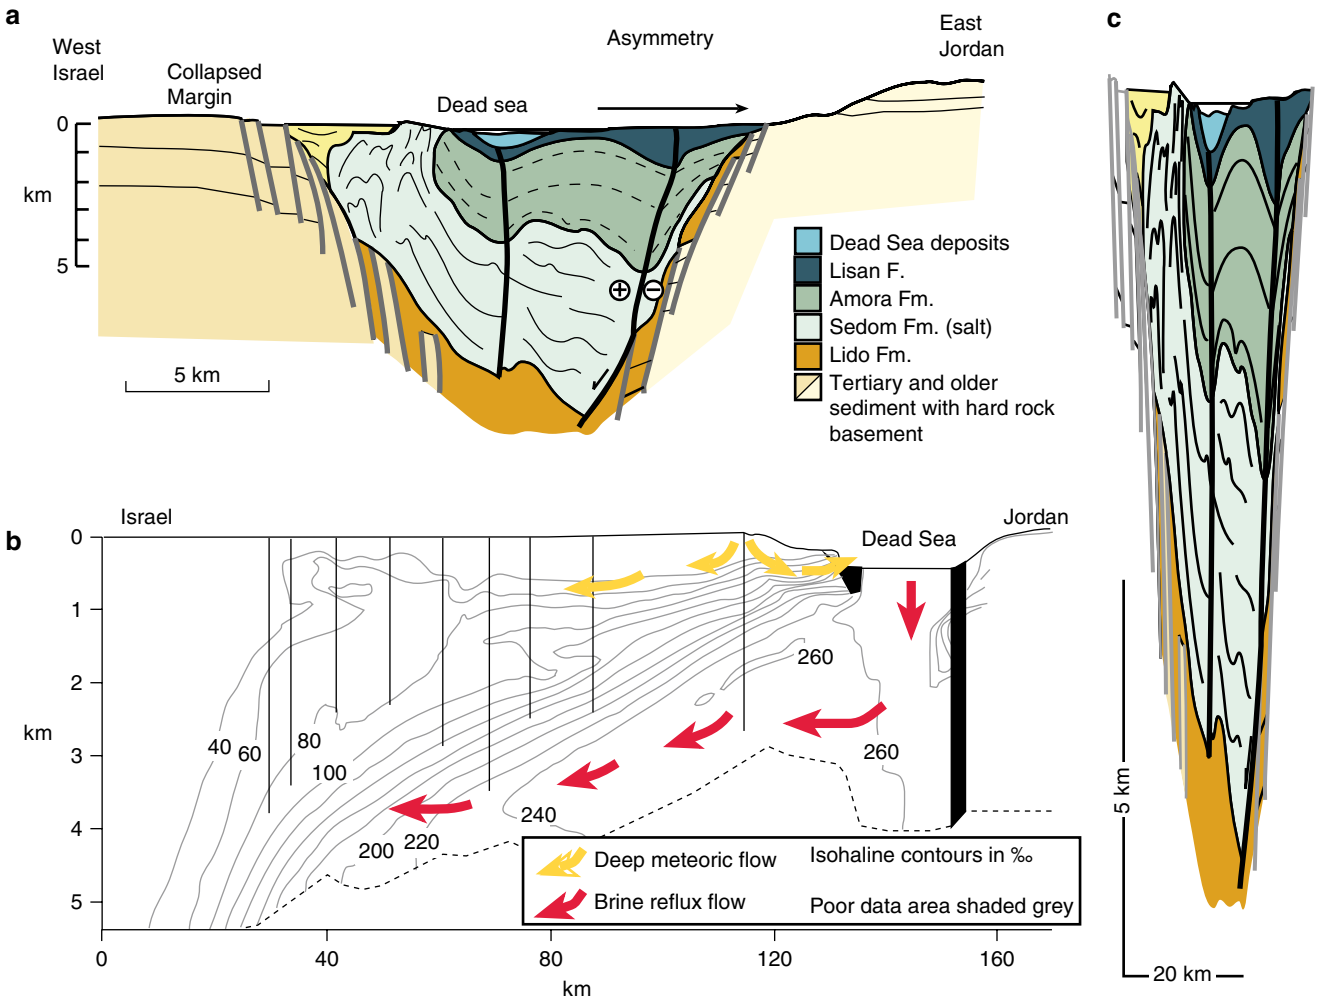

Fig. 8.8 (**a**) Dead Sea cross section showing asymmetric nature of fill. Shallow hard rock basement (aquiclude) occurs to the west of the basin fill (After Zak and Freund 1980). (**b**) Present deep westerly brine flow driven by dissolution of deeply buried Miocene salt (brine curtain: After Stanislavsky and Gvirtzman 1999). (**c**) Schematic geology based on 8.8a (which is a same scale section) stretched to match the same proportions as the vertically exaggerated scale of Fig. 8.5b so as to better demonstrate the importance of dissolving Miocene salt in driving deep brine flow

Jurassic and Triassic aquifers (up to 4–5 km deep). This deep flow is maintained by ongoing dissolution of the thick halokinetic Miocene evaporites.

The longterm configuration of these flow systems has been modified by the hydrological evolution of the Dead Sea depression (Katz and Starinsky 2009). There was an earlier (1.5–2.0 Ma) pervasive westward intrusion of brine into adjacent somewhat shallower (1–2 km) aquifers. The total mass of salt that entered the Cretaceous Judea and Kurnub aquifers at that time was 1.9×10^{11} and 3.9×10^{10} kg of salt per 1 m width slice of cross section (Stanislavsky and Gvirtzman 1999). Subsequent subsidence meant more than 80 % of that earlier shallow outward-directed brine pulse seeped back into the Dead Sea depression. In contrast, for more than 2 Ma, deep highly-saline dissolution-derived density-driven brines have been flowing westward toward the Mediterranean from the Dead Sea Basin. They have displaced older pore waters in deeply buried (2–4 km) Jurassic and Triassic aquifers across a lateral distance of more than 150 km. Clearly, this is a region where ongoing brine flushing of adjacent deep aquifers is driven by ongoing salt dissolution.

Flow in and Adjacent to Collision Belts

Compactional and thermobaric flow regimes are active as long as sediments are accumulating within areas of subsidence. With the cessation of sedimentation/subsidence, or with tectonic uplift, compaction driven flow decreases and ultimately ceases and most overpressure dissipates. When a mature basin, which is characterised by hydrological equilibrium in its sediment pile, then undergoes collision, overthrusting and basin inversion, a whole new set of

disequilibrium processes are set up and can drive renewed deep-fluid migration (Fig. 8.1c). Reverse faults and thrust welds in stacked thrust sheets in growing overthrust belts can focus fluid escape, while the thrust sheet loading acts as a huge press. Compression drives thermobaric waters out of the deeper parts of the compressing basin into the shallower basin margins, with periodic fault release sucking fluid into the fault ("squeegee" mode).

Some authors have explained MVT sulphides as forming in the basin margin zones of compressional terranes where these escaping chloride-rich metalliferous "squeegee" waters mix with topographically driven meteoric waters (Oliver 1986). This process was thought capable of precipitating sulphides in passive margin carbonate platforms located hundreds of kilometres in front of the active thrust belt. Subsequent modelling of fluid flow and heat transport in compacting and dewatering thrust belt by Deming et al. (1990) showed flow velocities created by the "squeegee" effect are in the order of centimetres per year and thermal anomalies of the order of 5 °C, neither are sufficient to make significant contributions to mass and energy transfer. Likewise, Bethke and Marshak (1990) argued that rates of fluid expulsion in convergent margins are far too low to produce efficient advective heat transport. Most models assume thrust systems that are hosted in otherwise laterally homogenous aquifers. Actual measurements, based on texture and time-aware samples for isotope determinations in fold and thrust belts, rather than generalised assumptions in computer modelling, shows orogenic thrust-focused flow is a reality, in both evaporitic and non evaporitic compressive belts (Warren et al. 2014).

The inherent assumption in this modelling of chemical equilibrium between porewater and the enclosing rock in a sedimentary basin is perhaps justified by the inherently low flow rates associated with long term widely dispersed leakage (homogenous drainage) of compactional fluids in nonevaporitic mineralogically stable sediments. But assumptions of homogeneity of fluid flow are weaker in areas when episodic and focused dewatering (seismic pumping) is occurring in association with a mass of compressed impermeable sediment, especially if it contains a salt mass. Flow velocities about the edges of any compressed but impervious salt mass can be locally high in relation to reaction rates. Drilling in compressional terranes in the Middle East and the Gulf of Mexico shows overpressure beneath sealing salt sheets periodically approach lithostatic (Shaker 2008). Vein textures and inclusion studies show hydrofracturing tends to occur preferentially and numerous times in zones of sediment adjacent to salt lubricated décollement. As fluid is sucked into these near-salt zones during fault release (typically along the base of the décollement) it doesn't come from the salt (it is impervious) but from the adjacent sediment. Then as compression takes over once more we have a system where the pore fluids drawn into the region of contact with the salt are renewed in an undersaturated state with respect to the salt mass and so are capable of dissolving salt as they are squeezed out ("squeegee" mode) along the underside of the salt mass. This gives a mechanism that drives the ongoing creation of chloride-rich waters capable of constant renewal and of carrying hydrocarbons and metals. The redox front across this interface and breach points in the salt are both capable of focusing base and precious metal precipitation (Warren 2000b).

Hence, inversion-related thrust faulting, which juxtaposes potential aquifers against pressured and dissolving evaporite beds, can mobilise focused thermobaric brine escape from deep aquifer systems. It can move hydrocarbons and metals, while at the same time precipitate late-stage authigenic evaporite cements. This is clearly seen in the authigenic sulphate cements in the Rotliegend Formation in Leman Field in the Southern Permian Basin of the North Sea (Fig. 7.99; Gaupp et al. 1993; Sullivan et al. 1994). Coarse-grained burial-stage poikilotopic anhydrite cements increase in abundance in the vicinity of faults cutting the Rotliegend sands. Isotopic data show this late stage anhydrite precipitated at maximum burial of 3.5–4 km during the Late Jurassic- Early Cretaceous, that is, at the start of basin inversion. The data indicate an unusual, short-lived catastrophic event of cross-formational fluid flow along fractures and reactivated faults induced by basin inversion. Late stage magnesite and dolomite cements may also be related to influx of the same subsurface brines.

Remobilization of basinal brine during inversion typically occurs during a compressional event many millions of years after first burial (Wilson Cycle) and may revitalise the formation and migration of hydrocarbons. For example, rising saline chloride-rich formation waters in Mesozoic hydrocarbon traps in the Timor Sea, Northern Australia are sourced in more deeply buried Palaeozoic evaporites (Figs. 8.9 and 8.10; O'Brien et al. 1999; Lisk et al. 2000; Rollet et al. 2006). Some 5.5 Ma there was a transient fluid flow event, driven by Mio-Pliocene inversion, and associated far-field fault reactivation, ultimately driven by the collision of the Australian plate with SE Asia. It had a major impact on the seal integrity of numerous fault dependent hydrocarbon traps in the Timor Sea and allowed hot (90–130 °C), highly saline (>200,000 ppm) brines from deep Palaeozoic evaporite-derived brines to migrate up the reactivated faults to chemically and thermally overprint the reservoir and other shallower intervals Fig. 8.9). Apatite fission track data suggest that this regional episode of fluid migration was short and lasted for between 10,000 and 100,000 years. It resulted in the development of a prominent, localised Late Tertiary heating 'spike', that if ignored can significantly affect the accuracy of modelled thermal histories in the region.

Upon entering a shallow clastic aquifer system (centred on the Eocene Grebe Formation), microbial oxidation of

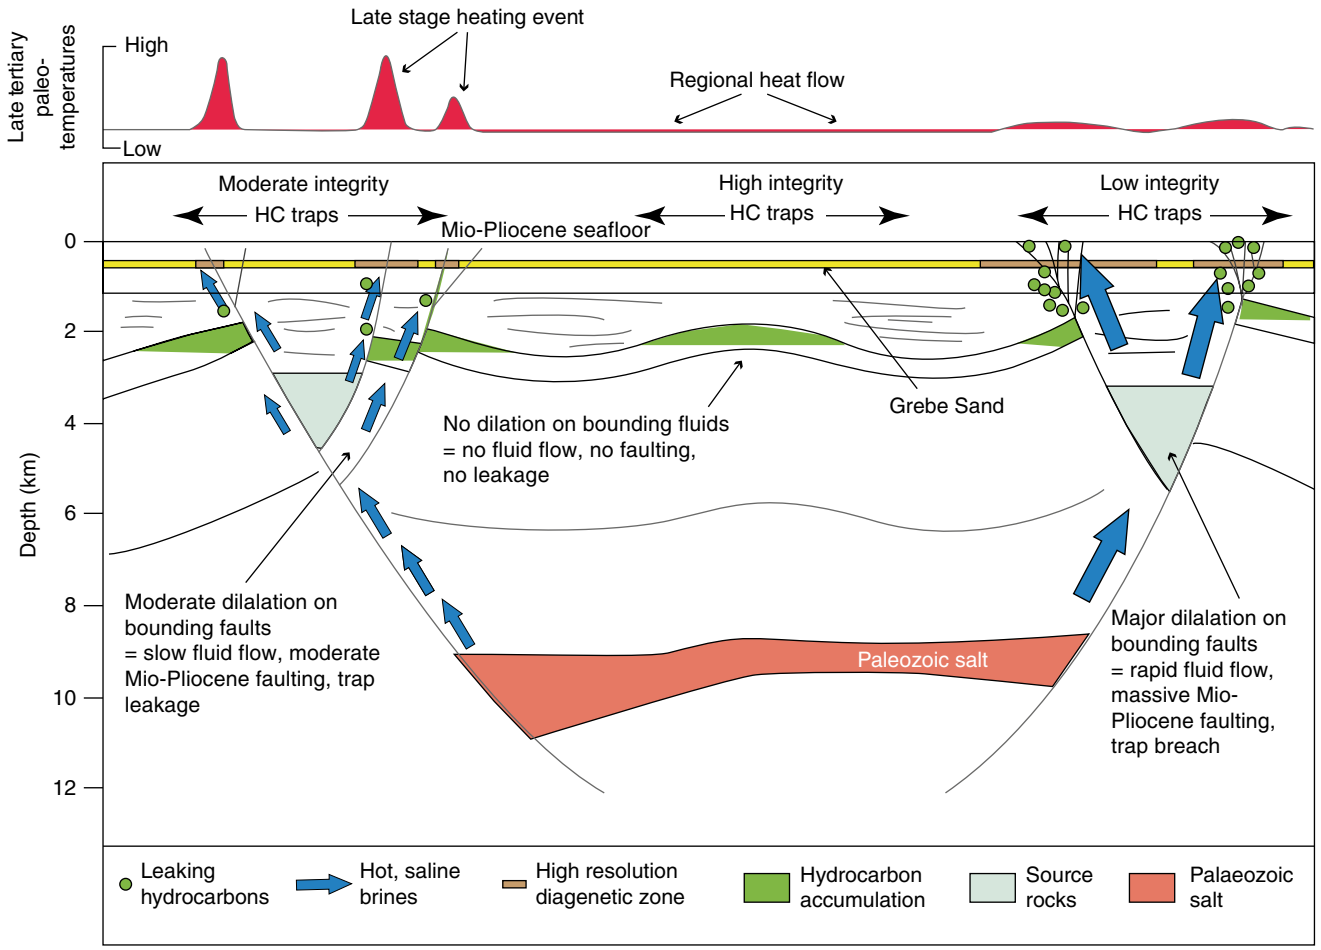

Fig. 8.9 Schematic representation of the latest Miocene/Early Pliocene fluid flow event in the Timor Sea (After O'Brien et al. 1999)

the hydrocarbons liberated CO_2 which, in turn, resulted in significant and very isotopically light carbonate cementation that creates a negative displacement in the $\delta^{13}C$ signature in intervals where it is pervasive as in the East Swan 2 well (Fig. 8.10). This cementation event produces sufficient acoustic impedance with the surrounding uncemented sands that it allows these hydrocarbon-related diagenetic zones (HRDZs) to be mapped seismically. Since both the size and acoustic response of the HRDZs are directly proportional to the amount of hydrocarbons that have leaked from the fault traps, their presence or absence provides a powerful indicator, predrill, of both trap integrity and the likely thermal regime that the traps have experienced.

There are three categories of traps: (1) high, (2) moderate, and (3) low integrity traps (Fig. 8.9). These have characteristic hydrocarbon fill-spill, fluid flow and thermal histories. In moderate and light intensity traps, dilatation was moderate to intense respectively, and allowed hot, highly saline brines from dissolving Palaeozoic evaporites to migrate up the reactivated faults and so chemically and thermally overprint the reservoir and shallower intervals with "thermal spike" cements. Leaky fault segments over partially breached traps typically only extended for 200–1,000 m, whereas over the breached traps, leaky segments extended for 3,000–5,000 m. Regions of high integrity traps are largely unreactivated and hence the conduits for brine migration from depth were absent. Consequently, these trap regions are the most representative of the thermal histories of the source rock depocentres.

Another example of fault -evaporite fluid/matrix cement interaction in a collisional setting and its influence on fractures and related fluid flow is seen in the fractured Oligocene carbonate lacustrine reservoirs of the western Qaidam Basin, China (Fig. 8.11; Zeng et al. 2012). Most fractures in the various carbonate reservoirs are small and related to steeply dipping faults, bedding-plane slip faults, terranes and so probably not directly related to crossflows of warmer salt dissolution and subvertical opening-mode fractures. Other fractures are diagenetic in origin. Fracture occurrence and abundance patterns are controlled largely by lithology, bed thickness, and proximity to larger faults.

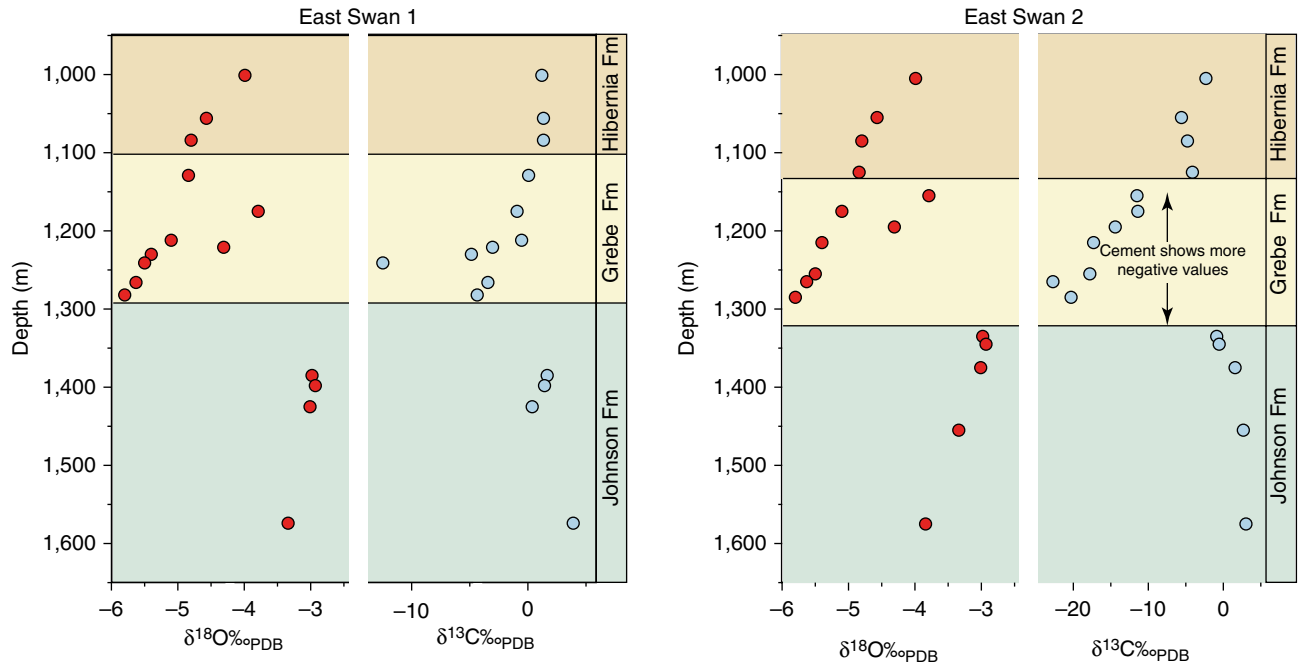

Fig. 8.10 Stable isotope measurements for authigenic calcite cements in the East Swan-1 and -2 wells in the Timor Sea, offshore NW Australia (Replotted from Table 2 in O'Brien et al. 1999)

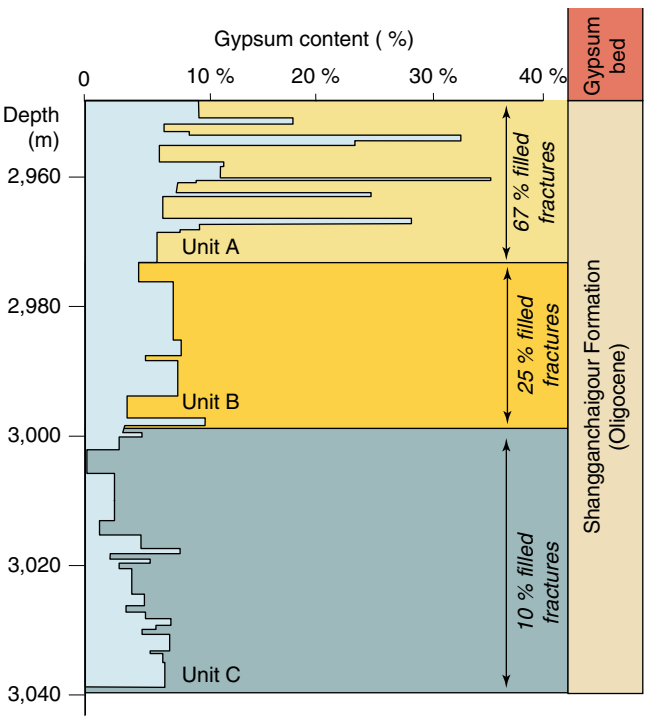

Fig. 8.11 Relationship between the gypsum content and the proportion of all-filled fractures in core in a well in the Oligocene Shangganchaigou Nanyishan field, NW Qaidam (After Zeng et al. 2012). The gypsum beds lie above *unit A*. In unit A, 67 % of the fractures are filled; in *unit B*, 25 %; in *unit C*, < 10 %. N = 150

Non-economic fractures are generally filled with calcite, gypsum, or glauberite ($Na_2\,Ca[SO_4]_2$). The amount of fracture-filling determines the effectiveness of fractures as fluid conduits and hence the distribution of high-quality reservoirs. Open fractures provide the main pathways for fluid flow; open fractures are parallel to and occur near faults, and many do not coincide with the present-day direction of the maximum horizontal compressive stress. The main control on those cements that degrade the fracture flow properties is proximity to evaporite beds in the lacustrine stratigraphy (Fig. 8.11). Once again this is an example of how highly saline evaporite precipitating fluids occur in a cementation halo, in this case adjacent to a rotated and deformed $CaSO_4$ bed.

As well as upward directed fluid flow and elevated pressures associated with collision, effects of thrusting can drive salt-derived fluids downward into lithologies where they would not otherwise be present, such as when evaporitic basinal fluids become syntectonic fluids in igneous basement caught up in a fold and thrust belt. For example, deep basinal brines, derived from dissolving Triassic evaporites, were driven, via fractures and shears, into hard rock basement (phyllites and gneisses) of the Pyrenees during the Alpine orogeny (Fig. 8.12; Travé et al. 2007; McCaig et al. 2000).

Detailed inclusion work by McCaig et al. (2000) suggest that the fluid history of the Pyrenees evolved through stages: (1) Upper Triassic evaporite formation with sinking of reflux

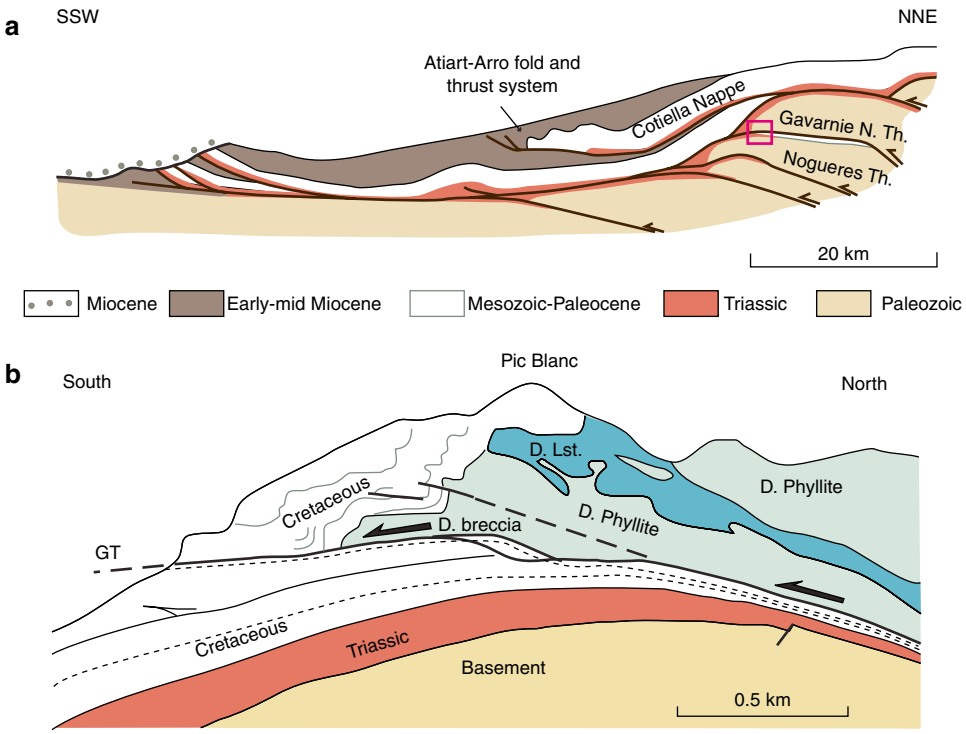

Fig. 8.12 Pyrenees thrust belt, Spain. (**a**) Regional schematic showing relation of various thrusts to evaporite décollement, *red rectangle* indicates approximate position of (**b**) (After Travé et al. 2007). (**b**) Detailed cross-section through the Plan de Larri in the central-western Pyrenees centred on the Gavarnie Thrust (*GT*; After McCaig et al. 2000). D. phyll. is mostly low grade Devonian phyllite; D. lst is mostly low grade Devonian carbonate; the Triassic section is Upper Triassic shales, carbonates and evaporites; D. breccia is a Late Cretaceous breccia weld (rauhwacke) that in outcrop is composed mostly of Devonian clasts; Cretaceous is mostly Upper Cretaceous carbonates

brines into underlying redbeds and fractured basement rocks; (2) Circulation of brines with formation of Pb-Zn deposits along faults at some time between the Triassic and the Upper Cretaceous; (3) Renewed extension with erosion of Triassic rocks in many areas and further drawing down of Triassic brines into the basement; (4) Deposition of Upper Cretaceous and Palaeocene carbonates containing connate waters of marine origin: (5) Formation of the Pyrenean thrust belt with overpressuring and expulsion of the brines along shear zones and faults including fractured basement, and; (6) Creation of topography with a high-level circulation system in the Mesozoic thrust sheets driven largely by topography. At the southern margin of the Axial Zone there was limited mixing of the deeper, overpressured brines with these more dilute, hydrostatically pressured fluids. An important point noted by McCaig et al. is that because of their density, hypersaline brines are difficult to expel from the upper crust, and may be involved in a succession of alteration and mineralisation events in the same general area over hundreds of millions of years.

Although the décollement to the Pyrenean thrust is in a Triassic salt layer, isotopically much of the cement signature in outcrop studies of the various thrusts indicate a thermal separation in oxygen values in early and later cements. This is also seen in backthrust thrust terranes and so probably not directly related to crossflows of warmer salt dissolution waters. For example, in the El Guix and L'Escala features, the thrust-related vein and fracture C-O plotfields consistently have more negative oxygen values compared to matrix limestones indicative of warmer fluids or greater burial the thrusts (Fig. 8.13). In the Atiart feature a separation is much less clear, perhaps arguing for a more pervasive meteoric overprint and less tectonic cement maturity there (for more detailed discussion see Warren et al. (2014) on the use of C-O isotopes in interpreting burial stages and permeability evolution in thrust terranes). Travé et al. (2007), conclude the fluid precipitating the calcite veins in the upper mineralised backthrust (as sampled in Atiart Arro outcrops) was consistent with a meteoric origin for the source waters. In contrast, the fluids precipitating calcite veins in the other thrust -related fractures such as the salt core-El Guix thrust, was consistent with a warmer formation water origin. However, presence of Na in all the fractures of the backthrust Ariart array, including the upper mineralised backthrust (meteoric dominated) indicates that these fractures also served as a pathway for a hypogene fluid in contact with underlying evaporites.

Worldwide, it is likely that dense salt-dissolution-derived brines, sourced deep in the basin by ongoing salt solution, are involved in a number of alteration and mineralisation events in the same general area of the basin. But they probably move in short-lived diagenetic pulses or events

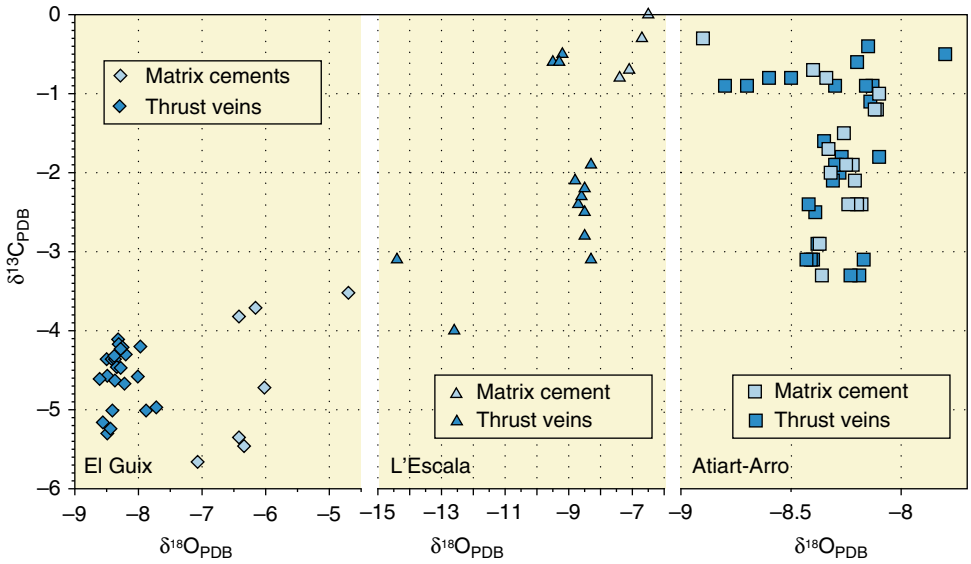

Fig. 8.13 $\delta^{18}O$ versus $\delta^{13}C$ of calcite cements in the veins and host rocks from three different thrusts in the Pyrenees (Travé et al. 2007)

(≈10^5–10^6 years), which are likely spread over hundreds of millions of years. Such fluid movements occur as flow events in reactivated parts of the basin as it experiences the various stages of the Wilson tectonic cycle (i.e. rift, collision and post-collision; Fig. 5.32). Even after a salt bed passes into the metamorphic realm it, and its brine halo, can continue to act as a source of Na and Cl. In that case the participating sodium and chlorine ions come not from halite (gone by 450–500 °C) but from compressed scapolite cages and other meta-evaporitic daughter phases, e.g., the Mt Isa-Cloncurry region of Australia (Chap. 14).

Flow in Post-orogenic Hydrologically-Mature Basins

After inversion or uplift, evaporite beds re-enter the zone of deep meteoric (artesian) circulation and active phreatic flow (telogenesis). Meteoric fluids enter via infiltrating rainfall and groundwater as strata are increasingly flushed by meteoric waters (Fig. 8.1d). Gravitational pore-brine sinking, driven by topographic gradients and recharge along the uplifted margin of the basin, is the most important mechanism driving fluid migration. This gravity-driven circulation is sometimes termed centripetal flow, as it encompasses flow into the basin centre from the surrounding highland areas. It is antithetic to centrifugal flow, which characterises the compactional, thermobaric and compressional regimes that tend to move water in the opposite direction, from the basin centre toward the basin edges.

Three conditions must be met to allow topography driven flow: (1) the basin needs to be partially elevated above sea-level/brine level, (2) the flow system requires ongoing water replenishment via infiltrating rainfall and groundwater in the uplands regions, and (3) aquifers must have sufficient permeability at depth to allow the entry of waters into the deep subsurface. An exception to the general requirement of a meteoric feed and suprasealevel hydrologies is a subsealevel foreland basin or saline giant undergoing evaporative drawdown, such as the Mediterranean in the Late Miocene (Messinian), where seawater was the major gravitationally driven groundwater feed.

Another exception to the general assumption that centripetal flow is driven by a potentiometric head that is always supplied by the uplift, may occur in glacial times. Today the Williston Basin in Manitoba has a hydrology controlled by recharge in the Rocky Mountains, but in Pleistocene glacial meltwater periods this may have not been true. The km-scale thickness of the continental ice sheet and consequent loading over subglacial lakes may have provided sufficient hydrologic head to reverse the regional-scale flow system of evaporite-dissolution derived basinal brines in the Williston Basin (Grasby and Betcher 2000). Similarly, in the Michigan basin, the meltwaters of the retreating icesheet moved dilute waters (<20 g/1 TDS) some 110 km laterally into the Devonian carbonate aquifers, significantly depressing freshwater-saline water mixing zones (McIntosh et al. 2011).

More typically, salt dissolution in the post-orogenic continental realm feeds brine into adjacent deeply-circulating confined aquifers beneath and atop thick well-preserved evaporite intervals. For example, over the last 5–10 Ma, subsurface Na–Cl brines in various subsalt sandstone aquifers along the edges of the Anadarko, Midland and Palo Duro Basins have acquired their high salinity through the dissolution of Permian halite by deep meteoric circulation of groundwaters. These basins make up the northern portion of the Permian Basin of West Texas and Oklahoma (Fig. 8.14; Bein and Dutton 1993).

System	Series	Group/ formation	General lithology	Hydrogeological unit
Tertiary		Ogallala	Fluvial and lacustrine clastics	Upper Aquifer System
Cretaceous		Fredericksburg	Limestone sandstone	
		Paluxy		
Triassic		Dockum	Fluvio-deltaic and lacustrine clastics

Precambrian			Igneous, metamorphic	Basement aquiclude

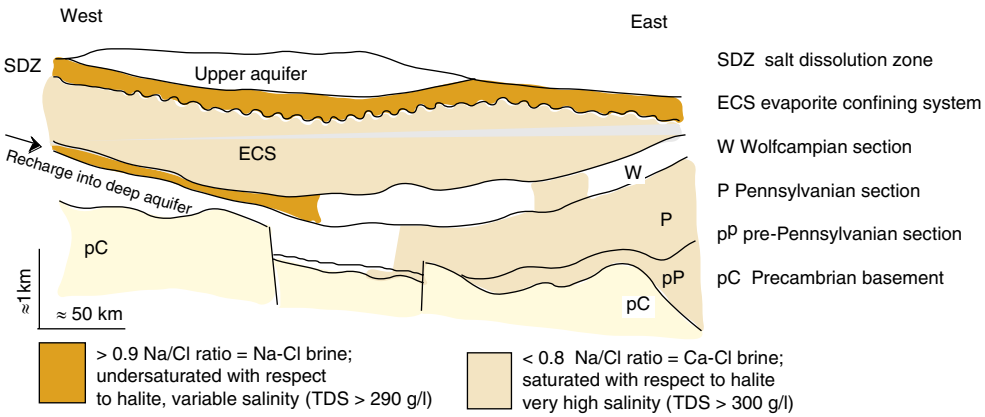

Fig. 8.14 Na/Cl molal ratios define subsurface hydrology in Permian Basin, West Texas and Oklahoma. The relict Ca-Cl brines are held in place by the low permeabilities of the evaporite confining zone, while Na-Cl brines derived by halite dissolution are to be found in the salt dissolution zone (*SDZ*) and the Wolfcampian section (*W*) of the deep basin aquifer (After Bein and Dutton 1993). The *upper part of the figure* shows the relevant stratigraphy of the region, *centred* on the Central Basin Platform and the occurrence of the major hydrogeologic units within this stratigraphic framework (After Stueber et al. 1998)

Topographically driven, initially fresh, meteoric water moved into the western half of the deep-basin brine aquifer through nearsurface salt dissolution zones and then downward as Na–Cl brines seeped along the various deep aquifers to depths of thousands of metres (SDZ = salt dissolution zone in Fig. 8.14). Above the deep aquifer are Ca–Cl basinal brines that are relict Permian mixtures of descending evaporitic brines and connate Permian and Pennsylvanian seawaters. Little or no Neogene meteoric Na–Cl brine has penetrated this Ca–Cl brine zone, which is hosted by the evaporite confining system (ECS). The lack of ingress reflects the extremely low permeability of deeply buried halite and intrasalt shale, anhydrite- or halitecemented strata that dominate the ECS ("block of ice" analogue). Ages of the Ca–Cl brine in the ECS, based on ^{4}He and ^{40}Ar analyses of carbonates in the central part of the deep aquifer, range from 100 to 300 Ma (Zaikowski et al. 1987), making it a true "fossil" groundwater. This is the same salt where viable halobacteria have been cultured from brine inclusions preserved in its chevron halite (Vreeland et al. 2000).

To the south of the Palo Duro Basin, in the carbonate platform of the eastern Central Basin platform in West Texas, halite beds occur only in Upper Permian (upper Guadalupian and Ochoan) strata in the Permian Basin. As in the Palo Duro Basin, late stage uplift has influenced pore water composition of some of the original reflux brines in the more permeable subsalt beds. Extremely saline evaporated seawater apparently descended into adjacent Palaeozoic carbonates during halite deposition in the Late Permian, mixing with and displacing marine formation waters by buoyancy-driven convective flow (brine reflux; Stueber et al. 1998). These modified evaporitic brines were the dominant fluids in the Palaeozoic carbonates until the late Tertiary, when topographically-driven meteoric water began to flow into deeper Palaeozoic strata from outcrops and nearsurface aquifers in southeastern New Mexico in association with tectonic uplift that began at 5–10 Ma.

Meteoric water dissolved halite and anhydrite from Permian evaporites near the basin margin and seeped eastward along the regional hydraulic gradient, while mixing with and displacing modified evaporitic brine in the deeper parts. These meteoric waters, driven topographically, have now migrated large distances to displace saline waters deep and drive biodegradation in a basin characterised by numerous oil reservoirs with solution-gas drives.

The original dense brine that sank from Salado and Rustler evaporites into the underlying carbonates of the Central Basin Platform during the Late Permian may not have been of uniform composition, making it more difficult to separate it chemically from brines influenced by connate water or any subsequent deeply circulating meteoric waters (Fig. 8.15) That is, initial brine composition was not solely of a composition that resulted from 23-fold concentration of seawater (Stueber et al. 1998). Multiple depositional cycles in Salado evaporites, as described by Lowenstein (1987a), represent periodic invasions of seawater into the Salado basin, followed by progressive drawdown and concentration of brine. Therefore, the degree of seawater concentration reached during each cycle probably varied, and the projection of the data trend plotted to a 23-fold concentration in the upper panel of Fig. 8.15 is an oversimplification (Stueber et al. 1998).

The dense reflux brines that began to sink into underlying carbonates during the Late Permian probably had a range of initial compositions along the seawater evaporation trajectory and lay somewhere to the right of the halite precipitation point (Fig. 8.15a). The range of Br concentrations above 450 mg/l observed in formation waters from the 365 m (1,200 ft) thick Pennsylvanian–Wolfcampian carbonate section in the Central Basin Platform below the Salado and Rustler evaporites is largely a relic of this inhomogeneity.

The present locations of the most saline formation-water compositions below the seawater evaporation trajectory in the Permian of West Texas probably indicate relict evaporitic brines mixed with seawater when they entered the carbonate strata, much like the mixing that has been documented for the Messinian drawdown and is occurring today in the Dead Sea depression. As the brine mixed with phreatic seawater, each evaporitic brine composition along the seawater evaporation trajectory to the right of halite saturation would have been displaced along a line essentially parallel to the portion of the seawater evaporation trajectory prior to halite precipitation (Fig. 8.15a, b). When the range of data points representing formation waters with present Br levels greater than 450 mg/l is projected along such lines back to the seawater evaporation trajectory to the right of halite saturation, a range of seawater evaporitic concentration between 11 and 16.5-fold is indicated for the more saline waters. The concentration dissolution trends are also clearly seen in the Cl/Br and Na/Br crossplot, while the $\delta^{18}O$ – Br crossplot clearly shows the effect of meteoric mixing (dilution) on both these values (Fig. 8.15b, c, respectively).

Thus, modified evaporitic connate brines were the dominant precipitative fluids for cements and replacement in the Palaeozoic carbonates of the Central Basin Platform and the Palo Duro Basin until the late Tertiary, when meteoric water began to flow into deeper Palaeozoic strata from outcrops and nearsurface aquifers in southeastern New Mexico, in association with tectonic uplift that began at 5–10 Ma. Neogene meteoric water dissolved halite and anhydrite from Permian evaporites near the basin margin and sank eastward along the regional hydraulic gradient, mixing with and displacing the modified evaporitic brine in deeper hydrogeologic systems of the Devonian and San Andres aquifers. The mixing curve is indicated by the dashed line, lowered Br values and the negative $\delta^{18}O$ signatures (Fig. 8.15a, c). These

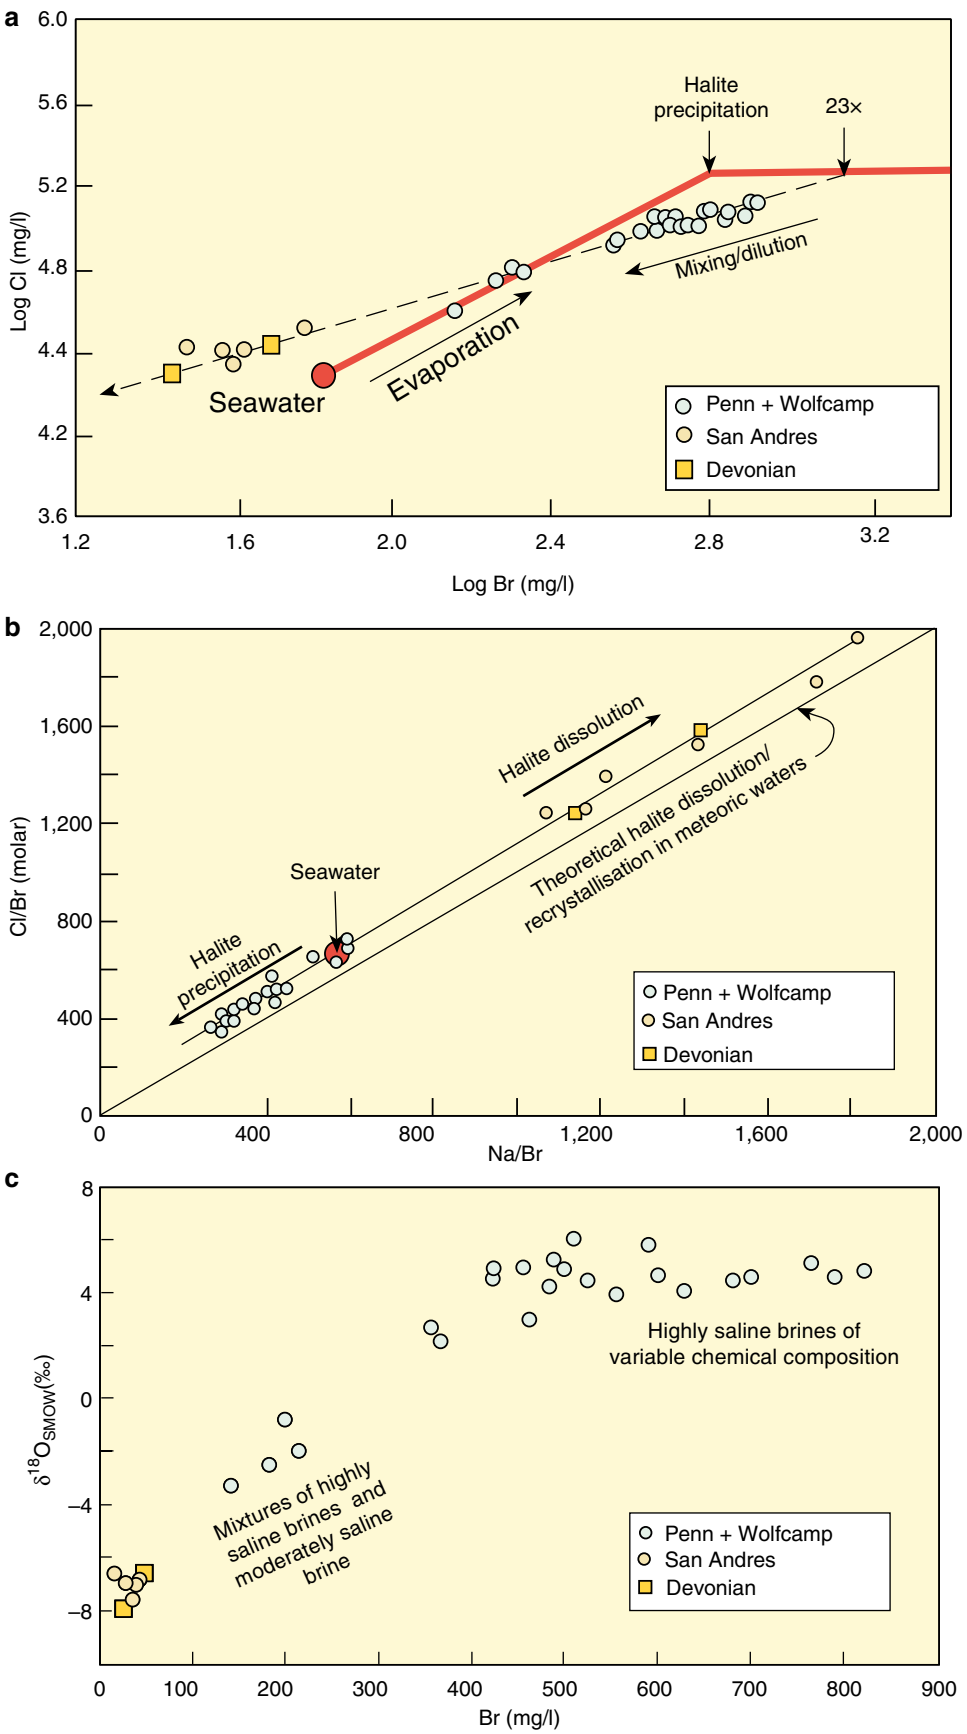

Fig. 8.15 Chemical character of 32 formation-water samples from carbonate reservoirs in the Southwest Andrews area (After Stueber et al. 1998). (**a**) Log Cl versus log Br. Seawater evaporation trajectory is from Carpenter (1978). *SW* seawater composition. Halite precipitation = 450 mg/l = 2.65 Log Br (mg/l). *Dashed line* marks the likely mixing trend among the brines. (**b**) Cl/Br vs. Na/Br molar ratios in formation waters relative to the compositional trend formed by seawater evaporated past halite precipitation and seawater that has dissolved halite. Regression line drawn through data points has $r^2 = 0.99$. The range of theoretical compositions that result from dissolution and recrystallisation of halite in fresh water is also shown. (**c**) Oxygen isotope composition plotted against Br concentration

late Cainozoic meteoric fluids probably are responsible for widespread biodegradation of oil in the San Andres/Grayburg interval in the Andrews oilfield area. More regionally such deep meteorically driven dissolution of gypsum/anhydrite beds supplied sulphate-ions for the bacterial production of reduced sulphur with the organics supplied by trapped and upwelling hydrocarbons. This reduced sulphur was then oxidised to form economic accumulations of natural sulphur in West Texas (Chap. 12; Hentz and Henry 1989; Lee and Williams 2000).

The Alberta Basin, Canada, is another area of post orogenic fluid circulation where evaporite-derived subsurface waters currently interact with less saline deeply circulated meteoric waters within artesian aquifers (Fig. 8.16a;

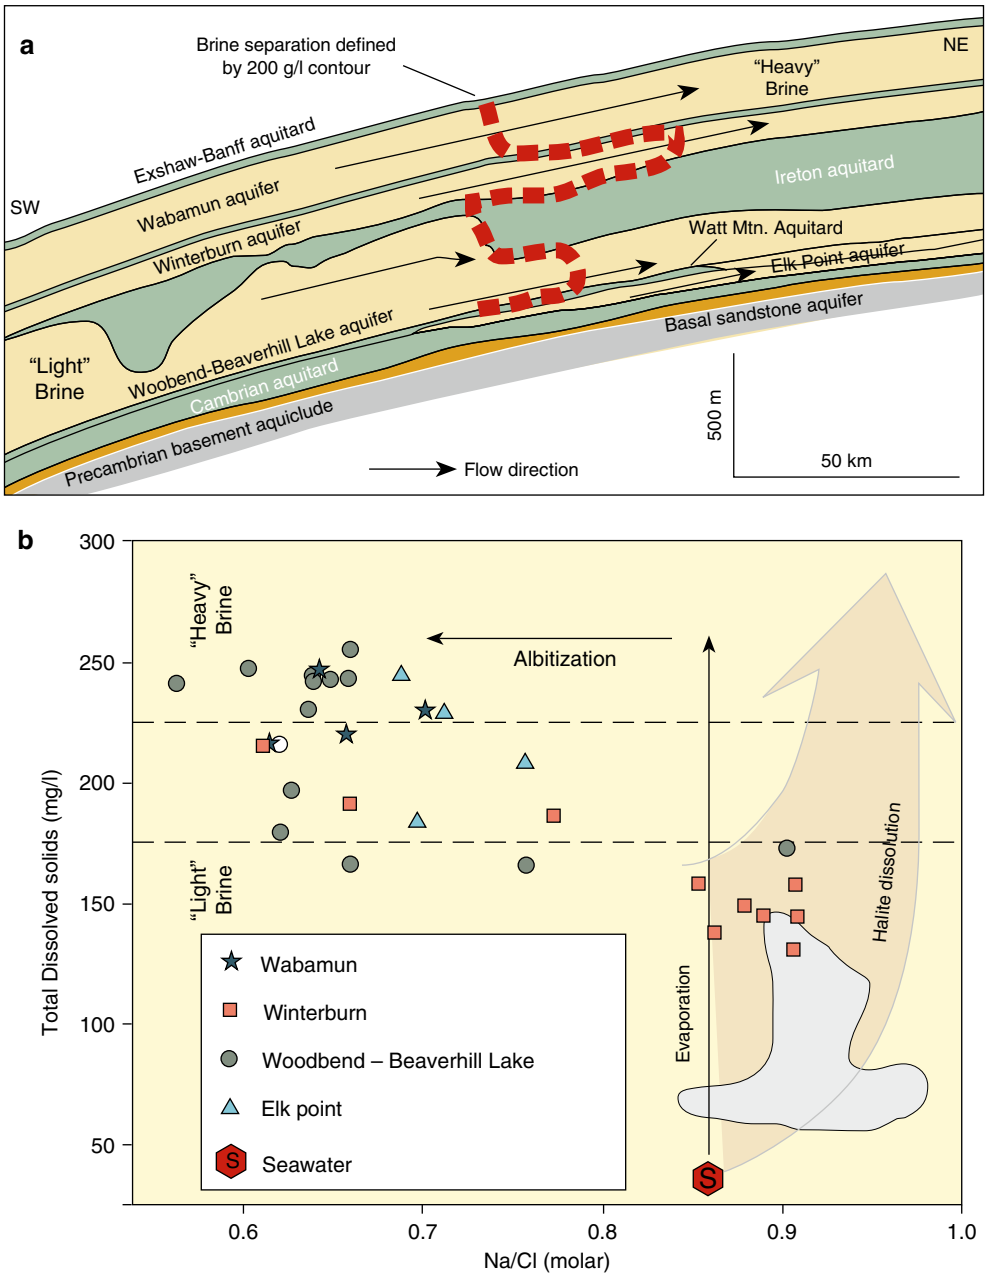

Fig. 8.16 Basinal fluids in Devonian of Alberta Basin (After Michael et al. 2003). (**a**) Hydrogeological cross-section perpendicular to the deformation front to the west showing conceptually the differential advancement of the less saline formation water displacement front against a high-saline connate brine reservoired in the Cambrian–Devonian hydrostratigraphic group. (**b**) Distribution of Na/Cl ratios versus salinity in Devonian formation waters showing some processes that may have influenced the brines. The grey plot field shows the distribution of hydrochemical measurements for Mississippian strata where halite dissolution driven by deep meteoric circulation controls much of the hydrochemistry of the deep aquifer

Michael et al. 2003; Gupta et al. 2012). Regionally, the Devonian succession contains two brines types (a 'light brine' with TDS <200 g/l and a 'heavy brine' with TDS >200 g/l), and both brines are pressurized by the potentiometric head supplied by the Rocky Mountains to the west, with the dominant artesian flow indicated by arrows in Fig. 8.16a.

The subsurface interface between the two brine types is typically lobate and controlled by permeability variations in the host aquifer, as evidenced by concurrent, steep changes in hydraulic head, and salinities (Fig. 8.16a). Hydraulic heads in the lower two aquifers (Elk Point and Woodbend–Beaverhill Lake), range from 625 to 750 m, whereas heads in the upper two aquifers (Winterburn and Wabamun) range from 500 to 800 m. This implies that the Ireton is an effective aquitard between the lower two and the upper two aquifers. According to Michael et al. (2003) the geological and hydrogeochemical data suggest the following processes determined the present composition of the 'light' and 'heavy' brines: original seawater, evaporation of brines beyond gypsum onset but below halite saturation, dolomitisation, clay dehydration, gypsum dewatering, thermochemical sulphate reduction, and halite dissolution. As in the San Andres Fm., the two brines can be separated by Na/Cl proportions; lighter brines show values >0.9 indicative of derivation from halite dissolution, while heavy brines tend to show values <0.7 reflecting a more relict marine-derived signature (Fig. 8.16b).

An influx of meteoric (from the south) and metamorphic (from the west) waters is recognized only in the 'light brine.' Albitisation (sodic replacement) is unequivocally identified only in aquifers hosting the "heavy brine." The "heavy brine" is likely a residual Middle Devonian evaporitic brine from the Williston Basin of the Elk Point Basin, or it may have originated by partial dissolution of thick, laterally extensive Middle Devonian evaporite deposits to the east. The "light brine" probably originated from dilution of 'heavy brine' by deeply circulating meteoric fluids in post-Laramide times, similar to the dilution seen in the San Andres aquifer.

This notion of a early pore brine remaining in place for extensive periods of time and preserving its connate character for hundreds of millions of years is testament to the long term low permeability of evaporite beds. Utilising present-day profiles of isotopes, solutes, and helium in porewaters recovered from 860 m of Cambrian to Devonian strata on the eastern flank of the Michigan Basin, Clark et al. (2013) argue for such long term pore brine immobility. Their focus was on a 240-m-thick, halite-mineralized, Ordovician shale and carbonate aquiclude sampled some 400–800 m below the modern landsurface. It sits unconformably on Precambrian basement and hosts Br-enriched, post-dolomitic brines (5.8 molal Cl), which they interpret as originating via reflux from Silurian seawater-derived brines that were precipitating the overlying Salina salts. Authigenic helium has been accumulating in this salt-sealed aquiclude for more than 260 Ma and is isolated from underlying allochthonous, ^{3}He-enriched helium that originated from the rifted Precambrian base of the Michigan Basin and the Canadian Shield. This Palaeozoic age and consequent immobility of the pore fluids in this Ordovician aquiclude strengthen the safety case for a deep longterm waste repository in the region.

So far, we have discussed brine styles and long term stability in the deeply buried stable portions of post-orogenic aquifers. But, when buried evaporites are caught up in the hydrology and stress fields of compressional tectonic belts they can be subject to syn- and post-orogenic deep meteoric flow. Their dissolution can supply much of the ionic content to actively accumulating evaporite systems in hydrologic outflow zones in an adjacent foreland depression. This was the case in the Miocene saline lakes of the Ebro Basin of NE Spain (Sánchez et al. 1999; Salvany et al. 1994). The current saline lakes in the same area (such as Lake Banyoles and Salada Mediania) are considered to be karstic relics of a more active saline hydrology that was set up during the Early and Middle Miocene, via intense compressional deformation and associated high relief in the basin margin.

Evaporite sedimentation at that time took place under a gravity-fed continental brine hydrology not connected to the sea (Sánchez et al. 1999). The sedimentation around the margins of the Ebro Basin was detrital, originating from alluvial systems that surrounded large saline mudstone plains (Fig. 8.17). These plains were linked to extensive saline and carbonate lakes in lacustrine systems that in their central depressions were dominated by playa depressions up to 100 km long and 30–50 km wide.

Three concentric hydrologically controlled and segregated subenvironments characterised the lacustrine depression: (1) central lake areas dominated by gypsum and halite pans; (2) intermediate lake areas with pervasive laminated gypsum and anhydrite as well as diagenetic glauberite, and (3) marginal lake areas with nodular diagenetic anhydrite, which gradually passed into distal alluvial plains (Fig. 12.27). In some marginal lake areas that were isolated from the central lacustrine systems there were small evaporitic lakes up to a few kilometres across. There local deposits of carbonate, gypsum and anhydrite precipitated from moderately concentrated brines, along with abundant diagenetic chert (Salvany et al. 1994).

Evaporitic successions in the central gypsum-halite lake area attain thicknesses of more than 200 m and almost all of it was derived from evaporation of deeply circulated meteoric waters that had dissolved Mesozoic evaporites and carbonates in folded basement in the adjacent Iberian Highlands (Fig. 8.17). Most of the carbonate-rich marginal lakes corresponded to zones of the first diffuse emergence of this deeply-circulated groundwater. Waters then fractionated as they moved toward the lowest parts of the lake depression. Since the Miocene the groundwater hydrology has evolved

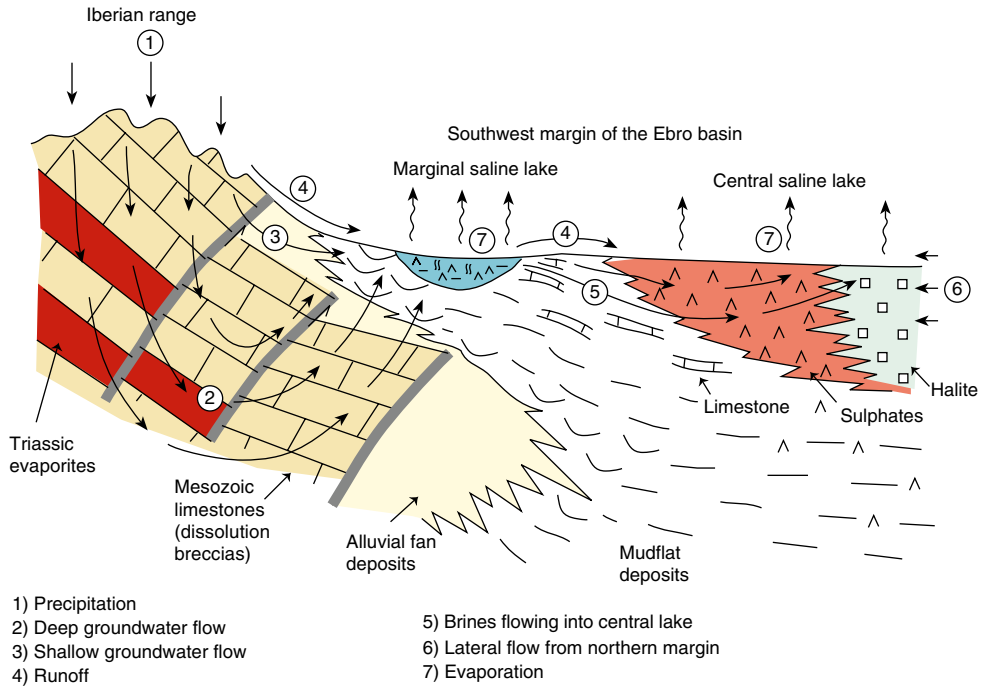

Fig. 8.17 Palaeohydrologic pattern of the compressional (thrust) margin of the Miocene Ebro Basin, Spain (After Salvany et al. 1994). The Miocene lacustrine evaporites in the Ebro Basin are ultimately derived from the deep meteoric leaching of Triassic evaporites in the Iberian Range along the southern margin of the basin. Ongoing surface and nearsurface evaporative fractionation of shallow brines divided the Miocene chemical sediments into a series of bioturbated carbonate-rich gypsum lakes and a more central gypsum-halite-rich lake system

and matured to that of today where focused springs, rather than diffuse resurgence zones, define zones of initial groundwater outflow (Sánchez et al. 1999). Anhydrite meganodules, forming diagenetically in zones of hypogene crossflow into Miocene gypsum, are another consequence of this saline crossflow of brines from dissolving Triassic evaporites (Fig. 1.56; Ortí et al. 2012)

In summary, dissolving subsurface evaporites contribute to basinal pore salinities, chemistries and can drive fluid flow and mineral alteration at all stages of burial and uplift, and continue to do so as long as salt and permeability live on in the sediment pile.

Alteration, Pressure Cells and Salinity-Driven Convection

All water-bearing sediments compact and alter within the zones of compaction and thermobaric waters, as various connate or subsurface waters escape from the sediment pile. Pore waters issuing from compacting sands, shales and limestones are typically not halite-saturated, so salt masses tend to dissolve wherever fluids from dewatering sediment piles come into contact with salt beds or allochthons.

Evans and Nunn (1989) and Ranganathan and Hanor (1988) analysed salinity-driven convection in permeable sands near salt structures in the Gulf Coast. Sarkar et al. (1995) modelled salinity-driven free convection in less permeable shale-dominated media beneath a dissolving salt sheet or allochthon. Morton and Land (1987), Land (1991), and McKenna and Sharp (1997) noted salinity inversions in the south Texas portion of the Gulf of Mexico basin, where more saline pore waters (including brines >100,000 ppm total dissolved solids) overlie less saline waters (≈20,000 ppm). Strong buoyancy gradients exist where such inversions occur, as the shallower pore waters are both cooler and more saline than deeper pore waters. Most of these hydrologies are maintained by the rise of brine along fractures and faults from basinal depths where deeply buried salt is actively flowing and dissolving. Convective return of brine occurs in areas away from the supplying structure (Sharp et al. 2001).

Haloes, Convection and Saltout

Over time, the ongoing dissolution of the edges of a salt bed, allochthon or salt wall sets up a dense subsurface brine halo. As it builds, the halo becomes so saline and dense that it starts to drive free convection. Saline pore waters slowly sink beneath the underbelly of the dissolving salt bed or allochthon, or spread laterally atop the upper side of a salt bed or edge of a diapir. Pore water from the salt underbelly sinks to depths where it reheats, flows laterally and then rises to

return once more to the underside of the evaporite bed to complete the convection cell (Figs. 8.4b and 8.18). Such density-driven convective circulation is an important mechanism of depositing and remobilising pervasive secondary salts (burial salts) in subsalt beds that were originally nonevaporitic. It also creates basal "caprock" residues along the underside of the bed or allochthon and lateral caprocks on the margins of a salt structure (Fig. 6.113).

Buried evaporite beds in contact with adjacent aquifers become sites of phreatic salt flushing as soon as the solar-driven active phreatic brine reflux hydrology starts to dissipate. Hence, burial dissolution of salt from its edges inward begins as soon as the bed enters the zone of compactional water flow (Chap. 7). This explains why the upper and lower contacts of many thick ancient evaporite beds are not depositional contacts. Rather they are zones characterised by dissolution residues, recrystallisation and pressure solution textures. For the same reason, well preserved primary and syndepositional textures in bedded evaporites are rarely found at the contacts with adjacent non-evaporite lithologies. Depositional fabrics are best preserved internally within an evaporite bed, away from the edges where basinal fluids are eating into and altering the original evaporite textures. Diagenetic waters continue to dissolve or "melt" evaporite contacts until the evaporite dissolves or all effective permeability is lost in the adjacent beds.

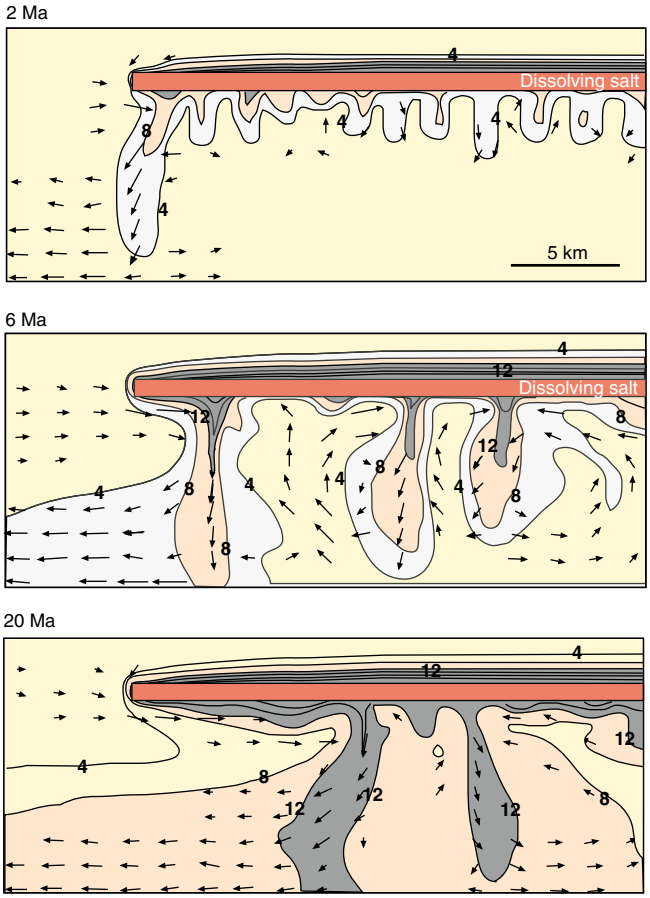

Fig. 8.18 Modelled temporal evolution of brine plumes associated with ongoing dissolution of a salt sheet in a shale matrix at times of 2, 6 and 20 Ma (After Sarkar et al. 1995). Contours of plumes are given in terms of salinity difference: calculated as pore water salinity minus seawater salinity (3.5 %). Numbers are in wt%. The leftmost plume, best developed in earlier stages, is mostly fed by a brine cascade focused by ongoing dissolution of the salt edge. Without halokinesis this would be a retreating bed feather-edge. Vertical exaggeration is 2×

The modelling of plumes beneath salt beds and subhorizontal allochthonous salt sheets, such as occur in the Gulf of Mexico, shows free convection has the potential to be a significant mechanism in both salt dissolution and mass transport, even if the sediments beneath the salt have permeabilities as low as 0.01 md (Fig. 8.18; Sarkar et al. 1995). In such low permeability sediment it will take some 10 Ma for the subsalt convection to develop to full strength. Once active, an average of 3–5 m of salt is dissolved off the underbelly every million years, with a maximum darcy flux of 3 mm year^{-1}. Measured matrix permeabilities of overpressured shales immediately beneath allochthonous salt (the gumbo zone) are much higher than 0.01 md and so the actual flow and dissolution rates are much higher.

Chloride-rich density-derived convective flow cells are an inherent part of the hydrology beneath all dissolving evaporite seals. They continue to repeatedly cycle subsalt pore water through the underlying sediment column until subsalt permeability is shut down by compaction and thermobaric cementation. It can move volatile-entraining chloride-rich brines through base metal and organic-containing shales and cupriferous redbeds beneath buried salt beds and sheets. Wherever such waters break out from beneath the salt seal into suitably prepared ground, the associated cooling and brine mixing can precipitate metal sulphides or facilitate the focused escape of liquid and gaseous hydrocarbons (Warren 2000b). Breaches typically occur via growth faults, salt welds or via seismic pumping along thrusts and thrust welds; all these features centrifugally drain basinal pore waters from beneath a salt bed or allochthon sheet. Simultaneously, the escape can drive other diagenetic reactions such as secondary porosity formation (via brine mixing and changes in pCO_2) or the precipitation of authigenic burial cements.

Where halite dissolution is occurring along the flank of a salt stock or diapir (shale sheath), the resulting dense pore fluids move into adjacent upturned permeable beds (Fig. 8.4c). Any cavity created by local dissolution of the salt stem is quickly filled, either by salt flow from the stem, or, if dissolution is rapid enough, by the collapse of sedimentary beds against the stem to form "downthrown" slivers and blocks (Chap. 6). As dissolution of the salt stem proceeds, the resulting high salinity (high density) pore brines can spall off a sinking brine halo that is maintained by ongoing dissolution. Such high salinity pore waters tend to sink away from

the stem down the more porous extensional portions of adjacent steeply dipping beds. Unlike the self-limiting rate of salt loss associated with the undersides of subhorizontal salt geometries, steeply dipping beds about a salt stem create a plumbing system with a tendency to self drain and so facilitate further dissolution of the stem and the set up of conditions suitable for the "salt-out" of rising hydrocarbons.

The evolution of such a suprasaltself draining, self-convecting fluid system has been modelled by Wilson and Ruppel (2007). They conclude that thermohaline suprasalt convection associated with salt domes can drive significant fluid flow, mass and heat transport in suprasalt positions in halokinetic continental margins, especially if halite dissolution is considered part of the suprasalt modelling. Likewise, they found suprasalt faults cause significant, but highly localized, increases in flow rates, typically tied to seafloor seeps and discharge zones. Transient models that include halite dissolution show an evolution of flow during brine formation from early salt-driven convection to later geothermal convection, with characteristics of the latter controlled by and interplay between seafloor relief and evolving salt geometry (Fig. 8.19). Their modelling shows suprasalt dissolution atop a salt structure creates hypersaline haloes more than a few hundred metres to a kilometre thick in time frames of 100,000–250,000 years after creation of the structure (Fig. 8.19).

Predicted fluid flow rates are around a few millimetres per year or less for homogeneous sediments with a permeability of a millidarcy, comparable to compaction-driven flow rates. Sediment permeabilities likely fall below 1 md at depth in the Gulf of Mexico salt province basin, but such thermohaline convection can still drive pervasive mass transport across the seafloor, affecting sediment diagenesis in shallow sediments (Fig. 8.19). They conclude that in more permeable settings, such flow drives water circulation of fluid cells with differing temperatures and so can influence methane hydrate stability, the positions of seafloor chemosynthetic communities, and the longevity of fluid seeps. Across a time frame of a million years, one of the most significant effects of the dissolution of the upper portion of the salt is the increasingly thicker halo of hypersaline brines in the overlying sediment mass (note there is no significant additional sedimentation that would drive ongoing salt flow via differential loading in their simple model.

However, it does show that active suprasalt fluid circulation in convective cells is driven by thermohaline processes,

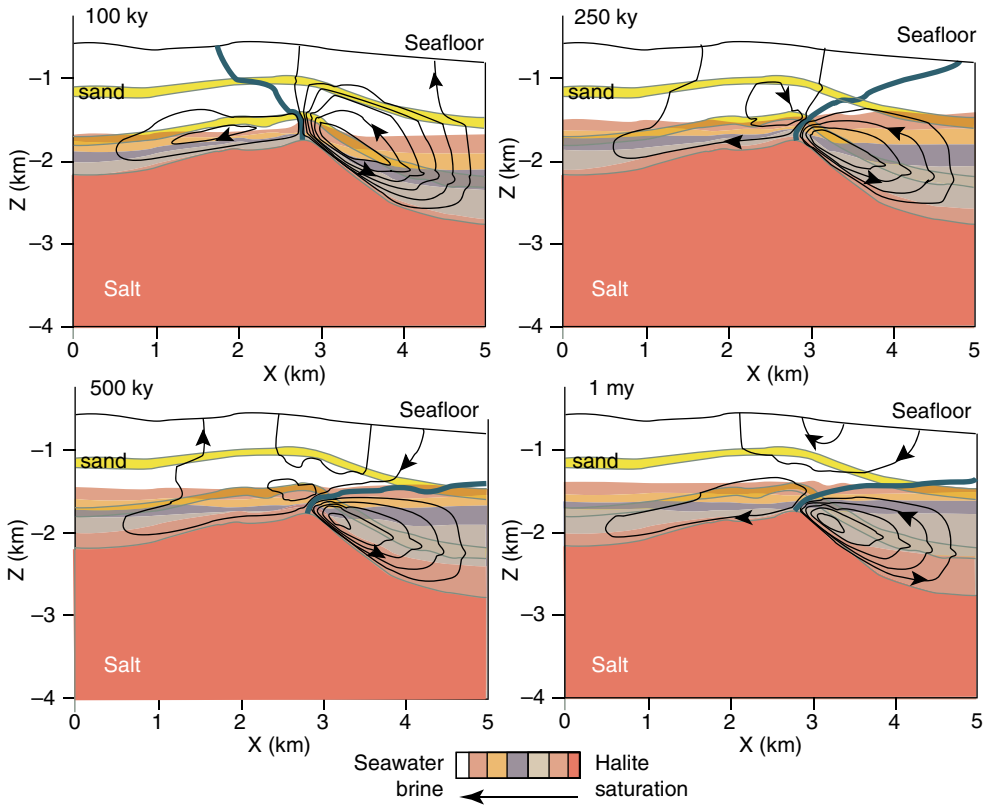

Fig. 8.19 Stream function and salinity distribution for the fully-coupled transient case, with two permeable suprasalt sand layers (*yellow*) included in the modelled muddy sediments. *Black lines* indicate convective flow direction, shading denotes normalized salinity, with white corresponding to salinity close to that of seawater and *pink* representing salt saturation. *Thick dark green line* indicates flow divide between clockwise and counterclockwise convective flow cells. (*A*) 100 kyr. (*B*) 250 kyr. (*C*) 500 kyr. (*D*) 1 Ma (After Wilson and Ruppel 2007)

tied to salt dissolution in the sediment mass atop the salt. It also illustrates that pore salinities increase in the lower part of the sediment column atop a dissolving salt structure. This set of inherent and related fluid flow processes can enhance hydrocarbon foci so define hydrodynamic suprasalt trap configurations and saltouts.

Hydrocarbons rising through suprasalt and subsalt brine haloes are less soluble than if in fresher pore waters. Price (1976, 1981) noted that at standard temperature and pressure (STP) the solubilities of n-pentane and methyl-cyclohexane decreased from 40 ppm in fresh water to 3 ppm in water with a salinity of 300,000 ppm. This means hydrocarbons dissolved in less saline basinal waters tend to "salt out," or exsolve, in the vicinity of brine plumes adjacent to a salt stock or along the underside of a salt bed or allochthon. "Salting out" is a direct result of the increase in the salinity of the carrier fluid as the salt body halo is approached (Fig. 8.20).

The accumulation of oil and gas along the underside of a salt seal, or adjacent to a salt stock, drastically slows the rate of salt dissolution. Halite is near insoluble when in direct contact with exsolved hydrocarbons rather than pore waters. Such conditions help explain why hydrocarbon legs adjacent to a salt stem have a propensity to stack one atop the other, with the hypersaline halo hydrology of the stem acting as highly efficient top and lateral seals. Of all the various evaporite traps, stacked salt-stem focused and sealed, steeply-inclined reservoir beds are among the most highly productive regions in the world in terms of barrels of oil equivalent (BOE) per unit area (Halbouty 1979).

Large-scale vertical migration of subsurface waters and crude oils, via shears and fractures against salt structures, was noted in the Louisiana Gulf Coast by Hanor and Sassen (1990). They concluded that the vertical upward flux of brine and hydrocarbons in this system followed extensional fault and fracture permeability in sediments adjacent to the salt and did not otherwise move vertically through shales sandwiched between the various sand reservoirs. In the immediate region about the salt stem they found that higher salinities were localised in the same areas where hydrocarbon production occurred over and around the salt domes. This implies dissolution of salt is driven by the same warm fluids rising from geopressured intervals and carrying with them buoyant hydrocarbons into shallower depths. Thus, most of the vertical fluid transport out of the deeper levels in a halokinetic basin is focused into the zone of structural disturbance adjacent to diapir stems.

Put simply, salt stems, beds and allochthons create temperature, salinity and fracture discontinuities that induce local thermohaline fluid flow. As long as sediments adjacent to a subsiding/ flowing stratiform salt bed or allochthon can maintain some degree of permeability, much of the more interesting subsurface hydrology occurs in and around brine haloes, centred about intervals or masses of slowly dissolving salt. Ongoing thermohaline-driven dissolution, alteration and flow near the edge of the bed or stem, and extending into adjacent beds, creates chemical and pressure gradients that exert significant influence of the style and patterns of subsurface fluid flow. This in turn exerts a strong influence on the location and style of various hydrocarbon and metal accumulations (see Chaps. 10 and 15).

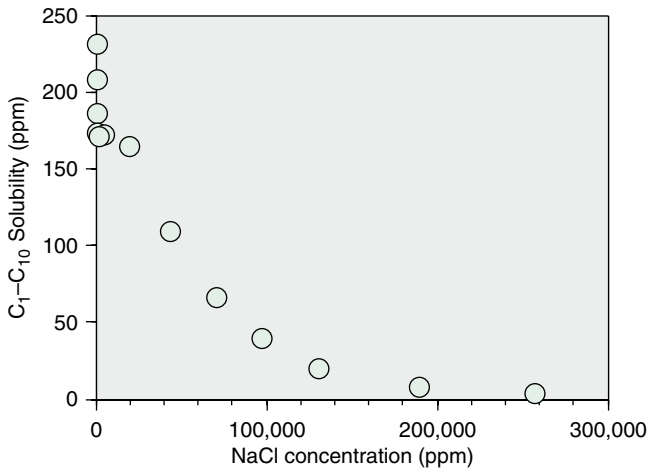

Fig. 8.20 Aqueous solubility of a C_4–C_{10} petroleum distillation fraction as a function of NaCl concentration at a near constant temperature (≈ 195 °C) and pressure (765 bars) (Replotted from data in Table 4 of Price (1981))

Evaporites as Pressure Seals

Abnormal formation pressure is any pressure that exceeds or falls below the normal pressure to be expected at a given depth, it is sometimes described as disequilibrium compaction. A formation can only be abnormally pressured if the following conditions are met; (1) there must be porosity, as the formation must have the means of storing a pressurized fluid, (2) there must be a horizontal and vertical seal. An abnormally pressured zone will be unable to retain its pressure differential if it is adjacent to a permeable boundary.

The various terms and parameters use to describe a subsurface pressure regime are illustrated in Fig. 8.21a (After Shaker 2008). Normal or hydrostatic pressure is the pressure exerted by a column of fluid extending down to the depth of interest, for a typical porewater column it increases at a rate around 0.465 psi per foot of depth (≈10.5 kPa/m). Hence, the normal pressure expected at 10,000 ft is 4,650 psi; abnormal pressure at this depth would be higher or lower than 4,650 psi (32 MPa). In reality, a hydrostatic pressure gradient will vary slightly, depending on the salinity of the pore fluid and the presence or absence of a salt seal (Table 8.3). For fresh water the gradient is 0.43 psi/ft (9.8 kPa/m) and for a salt-saturated solution it is 0.53 psi/ft

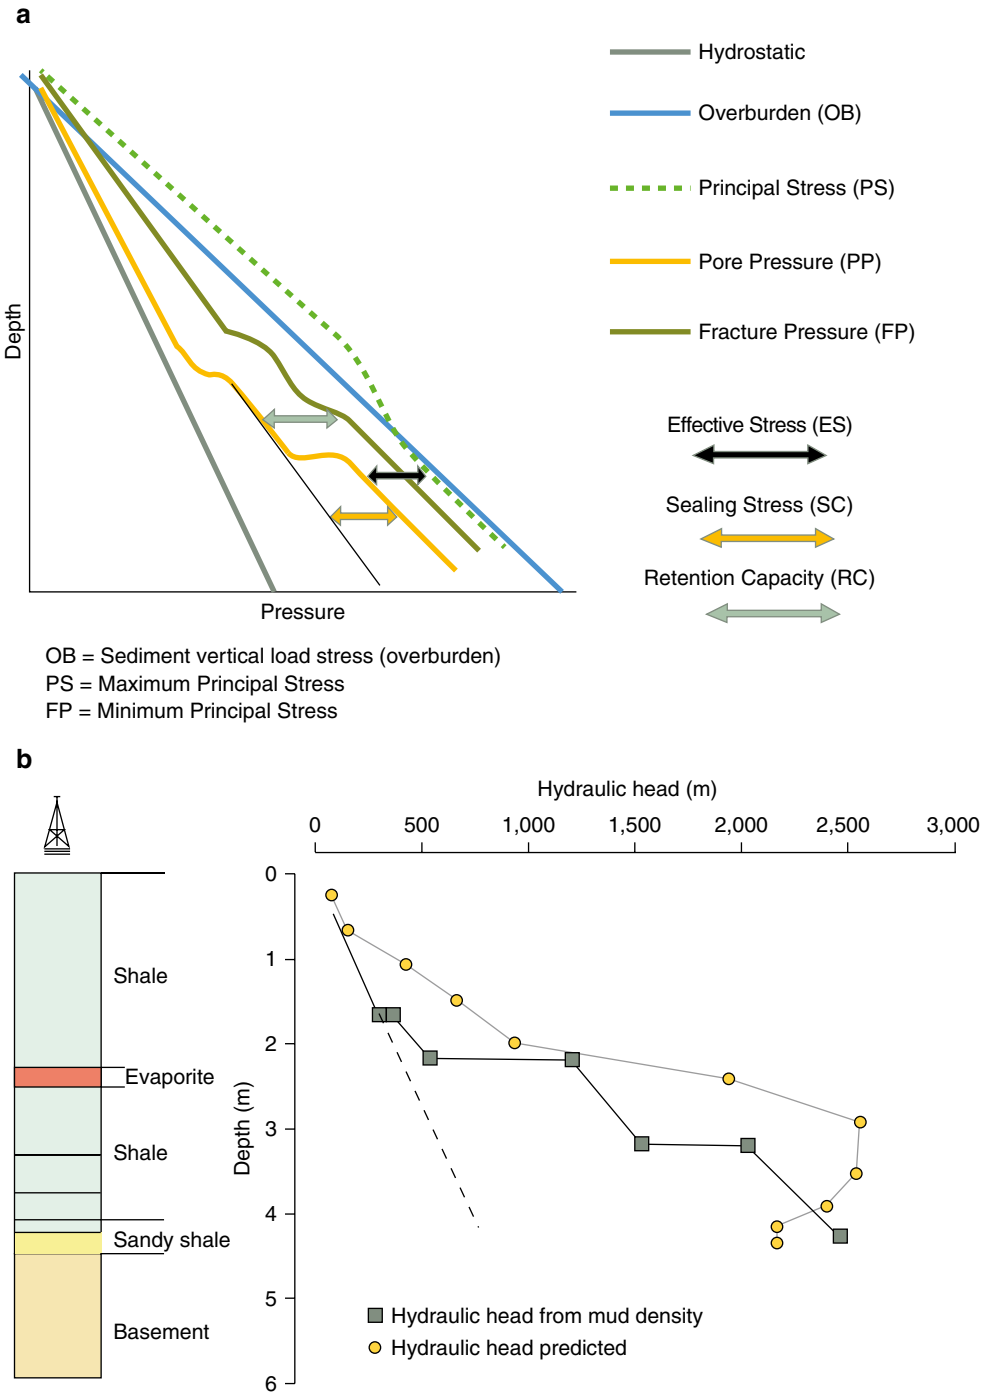

Fig. 8.21 Overpressure. (**a**) Illustration of pressure related terms (After Shaker 2008). (**b**) beneath Messinian evaporites in the Gulf of Lions in the Mediterranean, as indicated by mud densities in the offshore well drilled at kilometre 155 and by predictive modelling (After Burrus and Audebert 1990)

(11.9 kPa/m). Overburden pressure, also called lithostatic pressure, confining pressure or vertical stress, is the pressure or stress imposed on a layer of rock at a particular depth by the weight of overlying material. It is transferred via point-to-point grain contacts and so is related to the density of the overlying rock column. Effective stress is the difference between external stresses acting on the rock matrix (overburden pressure) and pore pressure. Fracture pressure in drilling is the magnitude of the pore pressure at which mud circulation is lost. The retention capacity is defined as the least principal stress minus the pore pressure.

Stress fields, in particular the maximum (PS) and minimum (FP) principal stresses, determine the actual pressure envelopes in a subsurface sediment column (Shaker 2008). Principal stress dictates the progress (transgression and regression) of the pore pressure (PP), with fracture pressure (FP) representing the breaching limit (Fig. 8.21a). These

Table 8.3 Pressure gradients of various fluid columns, including brines of different salinities

Fluid type	Density (g/cc)	API (degrees)	Salinity (g/l)	Gradient (kPa/m)
Brine	1.250	−18	374	12.25
	1.20	−14	398	11.76
	1.115	−8	222	11.27
	1.125	−6	182	11.02
	1.100	−3	147	10.78
	1.075	0	108	10.54
	1.050	3	71	10.29
Seawater	1.025	7	35	9.99
Freshwater	1.000	10	0	9.80
Heavy oil	0.950	18		9.31
Light oil	0.850	35		8.33
Distillates	0.650	88		6.37
Deep gas	0.500			4.90
Shallow gas	0.300			2.94

relationships can be stated in a simple equation, as defined by Terzaghi (1943):

$$PP = PS - ES \text{ or } PP = PS - \left(PS - PP\right)$$

Therefore, principal stress is the driving mechanism of a pore pressure build up. Sealing capacity (SC) is expressed by the transgression of the excess pressure in a specific subsurface pressure compartment, whereas retention capacity (RC) represents the maximum capability of trapping in a specific hydrocarbon column, When hydrocarbons are present then buoyancy pressure is part of the pressure regime. In a confined reservoir it is created by the density difference between hydrocarbons present and water, it is equal to the water gradient minus the hydrocarbon gradient, multiplied by the height of the hydrocarbon column.

About 80 % of the abnormally pressured basins of the world appear to be controlled by low permeability seals (Hunt 1990). Most intervals of abnormal pressure can be related to faults, thick shales, extensive salt seals, or various combinations. Typically pressure gradients are classified as:

- Underpressured (subnormal): <0.465 psi/ft
- Normally pressured: 0.465–0.65 psi/ft
- Moderately overpressured: 0.65–0.8 psi/ft
- Highly overpressured: 0.8–0.9 psi/ft
- Extremely highly overpressured: >0.9 psi/ft

Overpressured cells are the most common type of abnormal pressure and are characterised by fluid-supported pressures (typically geopressured[4] rather than hydropressured). Underpressured cells are matrix-supported pressure seals and are not as common as overpressured cells. Underpressure may be the result of the depletion of a reservoir of some or all of its producible fluids, or can form by surface exposure of the permeable bed at a topographic depth greater than interval where the pressure is being measured or where it is penetrated by the drill bit, or forms by the uplift of a fully enclosed and compacted formation. Both underpressured and overpressured cells are sealed or isolated from their surrounds, otherwise pressure gradients would quickly return to normal. Evaporites play important roles in such isolations due to their inherent low permeabilities. A salt unit does not generate overpressure as it lacks porosity, but due to its exceptional seal capacity can hold back substantially pressurized fluid columns.

Possible causes of abnormal pressuring in sediment pore waters held back by the evaporite seal are numerous and can overlap in the same sequence. They include:

1. *Epeirogenic Movements:*
   (a) Compactional disequilibrium during subsidence associated with rapid deposition (geopressured). Porosity reduction beneath a rapidly accumulating mass of sediment is inhibited by the difficulty in expelling pore fluids from relatively impervious sediment. As water is not very compressible, most of the overlying sediment's weight is then borne by the pore water, rather than the matrix so creating high fluid pressures in the undercompacted unit. Thus the creation of overpressures by compaction disequilib-

[4]Geopressures (a form of overpressure [pore fluid pressure exceeds hydrostatic]) are found in units of rock in which the free flow of fluids has been effectively prevented by either the in-situ formation of an impermeable barrier bed, or the appropriate placement of such a barrier through tectonic activities such as: folding, faulting, or diapiric action of shale or salt. A hydro-pressured zone is an overpressured sequence where hydraulic communication to the surface is maintained and the excessive pressure is due to the weight of the overlying fluids (measured as topographic head in confined artesian waters).

1 psi/ft = 22.5 kPa/m = 0.0225 MPa/m = 22.5 MPa/km.

1 MPa = 145.038 psi.

rium typically requires high sedimentation rates (or erosion rates for underpressure) and a permeability seal or aquitard.

(b) Uplift and topographic recharge (artesian) means that in areas of recharge (high elevation and descending flow) the fluid pressures are below hydrostatic. In areas of discharge (low elevation and ascending flow) the fluid pressures are above hydrostatic (hydropressured). If a seal is present adjacent to the artesian aquifer, then overpressure or underpressure can develop.

2. *Hydrocarbon Generation:*
Maturation of trapped organic matter generating fluids that cannot easily escape to the surface. Thermal maturation of kerogen in hydrocarbon source rocks is associated with marked increases in the volume of pore fluid and thus can also lead to overpressure generation. That is higher density kerogen is replaced by lower-density oil and gas, which requires more volume for the same mass. This is true of the generation of both oil and gas from kerogen, although the latter process is more important in terms of changes in the volume of pore fluids. The driving maturation process can be biogenic as well as the more typical thermogenic.
3. *Mineral conversion:*
Volume changes in reactions involving clay mineral transformation with the associated release of fluid. For example, under high pressure and temperature, structural water is expelled from smectite (montmorillonite) as it converts to illite. Transformation of gypsum to anhydrite (or carnallite to sylvite) can occur fairly early on in the burial process and in the case of gypsum creates up to 38 % free water in pore spaces. If the transforming unit is encased in salt then drainage is restricted and an increase in pore pressure can result especially if the pressurised unit is carried along by halokinesis. But in nonencased beds, the transformation tends to occur at shallow depths where it is usually possible for most of the expelled water to escape.
4. *Aquathermal Pressuring:*
Water expands with temperature more than mineral grains do. Thus, as sediments are heated with burial, the expansion of water generates fluid pressure. This effect is much smaller than compaction disequilibrium and requires a near perfect pressure seal to be effective.
5. *Buoyancy Forces:*
Created by density differences between reservoir fluids. Hydrocarbon column heights can result in substantial overpressure at the top of reservoir compartments, especially when appreciable amounts of buoyant gas are present.
6. *Tectonic Stresses:*
Compressive and dilational regional stresses create pressure cells. For example, if large-scale tectonic stresses change over geologically short periods of time, the driving tectonic compression can generate pore pressure in a fashion analogous to compaction disequilibrium. Deglaciation in regions of former thick ice sheets can also drive pore pressure changes
7. *Osmotic Pressures:*
Created by salinity contrasts across semipermeable membranes (shales and clays) with associated water flow to equalize brine concentrations as long as salinity contrast is maintained by ongoing saline recharge.

Other than this list of possible general causes for abnormal pressures, our discussion will now consider only intervals of abnormal pressure where evaporites have played a role in the creation or retention of anomalous geopressure or hydropressure. The evaporite unit typically does this by acting as a highly effective permeability barrier. For a more general discussion on overpressuring, its causes and effects, the reader is referred to Hunt's excellent paper or subsequent review papers by Yu and Lerche (1996); Converse et al. (2000); Swarbrick et al. 2002 and Gutierrez et al. 2006.

Salt-Maintained Overpressure

Salts (especially halite) are second only to clathrates in ability to form an effective seal to circulating pore waters and hydrocarbons, including methane. Like clathrates, evaporite layers can generate overpressures at very shallow burial depths, unlike clathrates they do not dissolve in response to rising temperature. Evaporites create the highest and sharpest depth-related pressure differentials known in sedimentary basins in both overpressured and underpressured settings (Fertl 1976). Salt-sealed overpressured intervals can be as shallow as a few hundred metres below the surface or deeper than 6,000 m.

Unlike thick shales, evaporites better fit Hunt's (1990) definition of a true pressure seal, which he defined as an impermeable rock with zero transmissivity maintained over long periods of geologic time. Very little subsalt fluid can escape through a salt mass, which until breached tends to hold back all the compactional and thermohaline waters, gases or liquid hydrocarbons rising from below. In contrast, shale seals consistently leak all these fluids to varying degrees. In consequence, fluid pressures can rise rapidly in porous sediments encased within or beneath a rapidly aggrading salt seal, even at relatively shallow depths. Likewise, pore pressures tend to rise in geopressured, finedgrained, poorly-drained muddy sediments accumulating in a rapidly-subsiding salt withdrawal basin (minibasin). Hence, both subsalt and suprasalt associations can quickly become overpressured (Fig. 8.21b; Burrus and Audebert 1990; Yassir and Bell 1994; Lerche and Petersen 1995).

Early onset of subsalt overpressure, and consequent slowing of subsalt fluid escape means that brine-saturated shales and silts below the contact with the salt can remain unconsolidated or semiconsolidated (hence porous and overpressured) to much greater depths and ages than would compacting shales without an evaporite cover. This is the case in many Permian shale beds beneath Zechstein evaporite pressure seals in northern Germany. Despite their Permian age, subsalt Zechstein shales tend to retain fresh, highly porous and plastic physical properties, so that when intersected by the drill bit they are prone to severe heaving, especially below depths of 1-2 km (Thomeer and Bottema 1961; Williamson et al. 1997). Drilling through sharp pressure boundaries into these shales in order to test underlying Rotliegend sands can be a problem, as can drilling on the way through porous rafts of Permian anhydrite or overpressured dolomite "floaters" suspended in halokinetic Zechstein salt (Finnie 2001; Strozyk et al. 2012).

Similar heaving shales beneath thick salt beds and allochthons are encountered regularly in the Gulf of Mexico, Russia, the Middle East, Asia and North Africa (Fertl 1976). Overpressured rafts ("stringers") of porous Neoproterozoic platform carbonate and basinal silicilyte, suspended in halokinetic halite, are widespread in the South Oman Salt basin (Kukla et al. 2011b). Internally, when drilled a salt seal appears normally pressured, but its lack of permeability means it can be holding back a substantial fluid column and the well can transition into lithostatic pressures, even though the drill bit has only breached the lower salt contact by a few centimetres. Casing set in halokinetic salt can be subject to longterm intrasalt creep and this too can create longterm well stability problems (Chap. 13).

Some of the highest measured bottom-hole pressures (formation pressures) in the world, and some of the highest wellhead flow pressures (measured while wells are in production), are found in subsalt reservoirs. These high pore pressures can occur not just in compressed subsalt muds of Tertiary age, but also in evaporite-sealed fractured and vuggy carbonates that are not particularly young. For example, in the gas and condensate fields of the Central Mississippi salt basin, highly overpressured intervals occur in deeply buried dolomitic Jurassic Smackover Formation reservoirs. Down to depths of 3,600 m the fluid pressure gradients approximate hydrostatic (0.465 psi/ft or 10.5 kPa m^{-1}). By 6,000 m a powerfully overpressured zone subsalt zone is entered and the gradient increases to 1.0 psi/ft or 20.35 kPa m^{-1}. This approximates the lithostatic (overburden) stress for that depth. There salt rollers in Jurassic Louann Salt are associated with deeply buried growth faults, which cut the overlying Smackover carbonate reservoirs. Faults sole above the Smackover within an anhydrite seal (typically Haynesville Fm. and equivalents) and so fail to leak fluids from the intervals below the anhydrite seal, allowing pressures to build (North 1985).

Another example of an overpressured basin in older strata lies beneath the Permian salt seal of the Tengiz oilfield in the Precaspian basin of western Kazakhstan. The structure traps some 25×10^9 bbl of oil in an upper Palaeozoic carbonate platform (Fig. 8.22a; Anissimov et al. 2000; Collins et al. 2006). The field is part of the giant Palaeozoic carbonate platform in the Primorsky Bend on the northeast Caspian Coast. The reservoir is made up of Upper Devonian to middle Carboniferous carbonates that are variably overlain by a 150–200 m thick shale and then sealed by thick Permian halite. This halite enables overpressuring with pressure gradients beneath the seal of $\approx$20 kPa m^{-1}, values similar to those in the Smackover and once again approaching lithostatic. Gradients in the nearby water-filled Karaton structure are slightly less due to pressure loss through a breach in the evaporite seal (Fig. 8.22b).

Likewise, the Permian salts of the Zechstein Group form seals to overpressured gas reservoirs in eolian Rotliegend sands of the southern North Sea (Fertl 1976). In the Groningen gas field in the Netherlands, one of the world's largest gas fields ($\approx$100 tcf), the gas reservoir is only slightly overpressured (0.5 psi/ft or 11.3 kPa m^{-1}). But formation pressures in Rotliegend sands below Zechstein salt in northern Germany are much higher ($\approx$0.9 psi/ft or 20.5 kPa m^{-1}), and in some areas in the Main Zechstein dolomite (Hauptdolomit) once again approach lithostatic (1.0 psi/ft or 22.6 kPa m^{-1}).

The Buntsandstein in the Lower Saxony basin, Germany, is another interesting overpressured and hydrofractured example related to Permian Zechstein salt. But in this case the overpressure developed in a Triassic redbed sandstone situated above the halokinetic Zechstein salt, but below the bedded Triassic Röt halite (Nollet et al. 2005). Two generations of vein cements occur in the sandstone. The first generation formed as carbonate cements in fractures developed in weakly consolidated rocks, without any significant increase in fracture permeability. Veins were filled syntectonically by fibrous calcite and blocky to elongate-blocky quartz. The stable isotopic signatures ($\delta^{18}O$ and $\delta^{13}C$) of this vein fill indicates that the calcite veins precipitated from saline connate waters at temperatures of 55–122 °C (Fig. 8.23a).

The second vein generation, composed of blocky anhydrite spar, crosscuts these earlier calcite veins and was syntectonically (halokinetically) precipitated in open fractures. Fluid inclusions indicate that these anhydrite veins precipitated from hypersaline brines at a minimum temperature of 150 °C (Fig. 8.23b, c). Based on $\delta^{34}S$ measurements, the source of the sulphate is seen to be hypersaline fluids migrating from underlying halokinetic Zechstein evaporites. Macro- and microstructures indicate all veins were formed during subsidence (not later diapir squeezing) and that the anhydrite veins formed under conditions of overpressure,

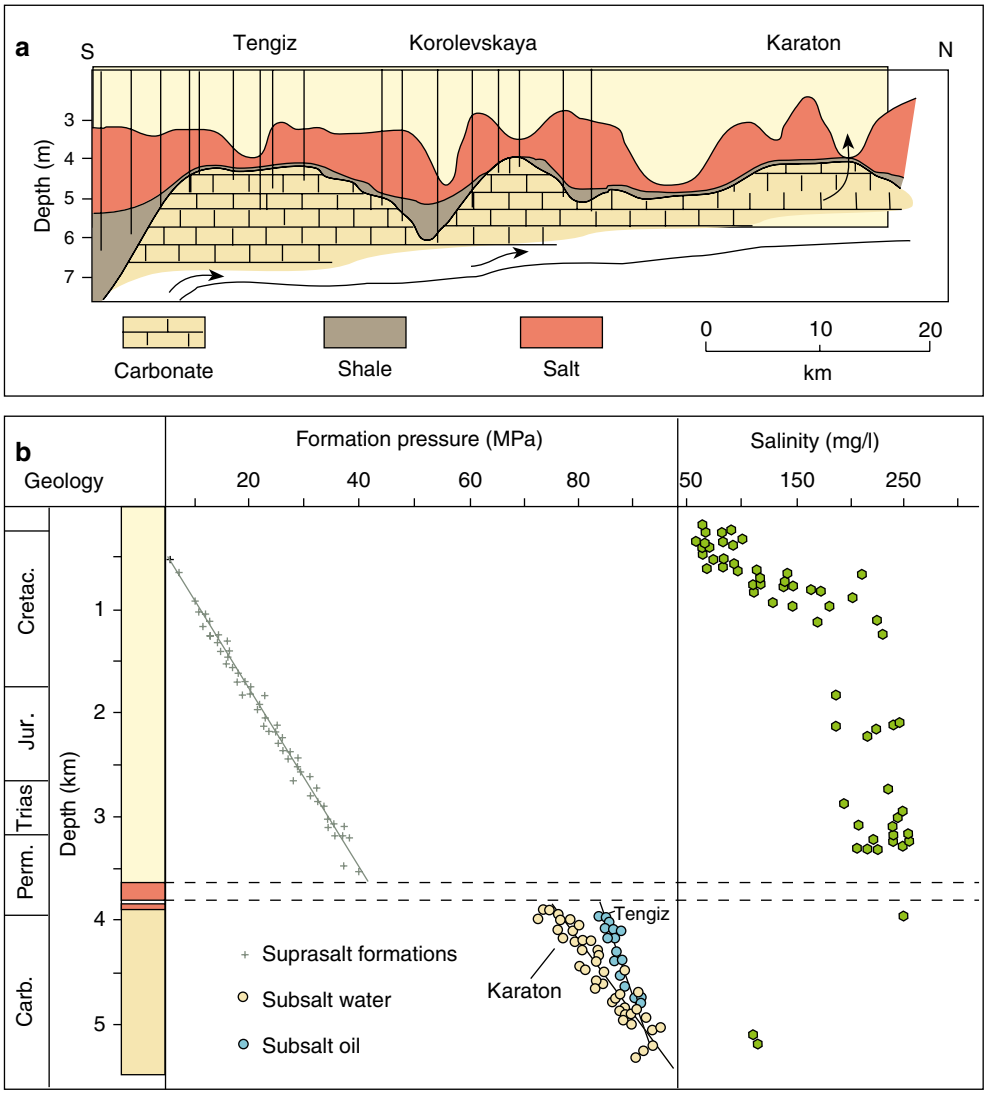

Fig. 8.22 Tengiz oil field, Kazakhstan. (**a**) East west cross section showing how the evaporite seals the oil in a number of carbonate buildup traps. When the salt is breached at the Karaton structure the oil has escaped and the structure is water filled. (**b**) Measured pressure plotted against depth, clearly shows the base of the evaporite is the top of the overpressure (After Anissimov et al. 2000)

generated by hydraulic inflation, rather than non-equilibrium compaction beneath seals. The latter is more typical of salt sealed overpressure or geopressure. Large volumes of $CaSO_4$ -enriched fluids formed as gypsum dehydrated (under significant pressure) in the underlying Zechstein unit and was released into the Buntsandstein during progressive burial and hydrofracturing.

One of the most impressive examples of the ability of an evaporite seal to generate and maintain an overpressured subsalt cell comes from the Alborz discovery in Central Iran (Gretener 1982; Mostofi and Gansser 1957). Five other earlier wells had failed to reach target due to drilling difficulties due to "an extremely troublesome evaporite section that continually menaced drilling and caused numerous sidetrack operations." The discovery well (Alborz 5) had drilled through some 2,296 m of middle to late Tertiary clastics and some 381 m of Oligo-Miocene salt. On its way to the blowout point it had penetrated normally to slightly overpressured salt (halokinetic) and then penetrated some 5 cm into the fractured subsalt Qom Limestone (Oligo-Miocene). On August 26, 1956, the entire drill string and mud column were blown back out the hole. At that time the mud pressure was 55 MPa (8,000 psi) at a reservoir depth of 2,700 m (8,800 ft), a pressure depth ratio of 20.5 kPa/m or 0.91 psi/ft (a lithostatic value!). In 82 days, the well released five million barrels of oil and a large but unknown quantity of gas before it self-bridged and the flow died on November 18, 1956. The temperature of the oil at the surface was measured at 115 °C and at the time of the blowout the mud column density was 2.07×10^3 kg/m^3 (129 lb/ft^3).

Some of the oldest documented occurrences of preserved overpressure, associated with producible hydrocarbons, come from blocks of Neoproterozoic silicilyte (Al Shamou or Athel), encased within the halokinetic Ara Salt of Oman. Initial fluid pressures within fractured slivers of the Athel Silicilyte in the South Oman Salt Basin can be as high as 19.8 kPa m^{-1} (Amthor et al. 1998). This, and other older (preTertiary) examples of salt-sealed overpressure clearly

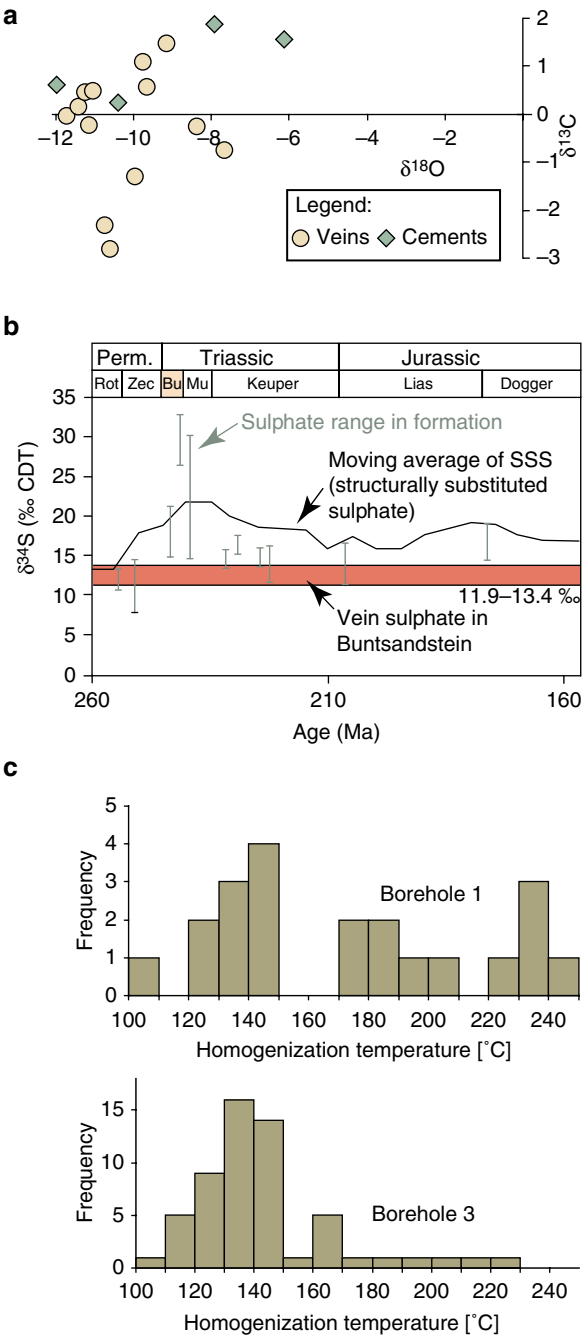

Fig. 8.23 Anhydrite in the Buntsandstein (After Nollet et al. 2005). (**a**) Carbon isotopic signature ($\delta^{13}C$) plotted against oxygen isotopic signature ($\delta^{18}O$) for the calcite veins and cements in borehole 1–4. Veins and cement values show strong overlap indicating that they precipitated from the same or related fluids. (**b**) Sulphur isotopic signature during Permian to Jurassic time compared with results of veins in the Buntsandstein. The data correlate with Zechstein sulphur isotopes, which suggests that the anhydrite layers in the Zechstein are the source rock for the anhydrite veins in the Buntsandstein (*Rot* Rotliegend, *Zec* Zechstein, *Bu* Buntsandstein, *Mu* Muschelkalk). (**c**) Homogenization temperatures of fluid inclusions in anhydrite veins represented in a histogram for samples from the two analysed boreholes. The wide range in homogenization temperature (from inclusions in the same sample) suggests that the primary inclusions in the vein crystals are re-equilibrated during further basin evolution. This means that only the lower values of T_h represent the minimum temperature of vein formation

illustrate the ability of evaporites to maintain seal integrity over time frames of 250–500 Ma and atop pressure fields approaching those that induce hydrofracturing. In contrast, most compacting and subsiding shaly sediments, with permeabilities ranging from 10^{-4} to 10^{-8} darcies, are thought to be too permeable, by several orders of magnitude, to preserve overpressures for time frames longer than 200–250 Ma (Lee and Williams 2000).

If hydrofracturing occurs, with associated pressure release, growth-pulsed fibrous cements of halite, gypsum and carbonate may precipitate in new fracture nets immediately beneath the evaporite seal. But in systems where the evaporites are subsequently dissolved only carbonate vein fills and their fracture nets will remain as brittle sediment indicators beneath a layer of dissolution breccia or insoluble residues.

Salt's impervious nature and its ability to flow, while intrasalt beds fracture, leads to additional interesting pressure scenarios wherever stringers[5] and rafts are caught up in masses of halokinetic salt. Fracturing of intrasalt beds and their encasement in flowing salt is an inherent mechanism in almost all autochthonous and allochthonous salt masses. It creates un-expected pressure rises when drilling through thick sequences of salt. Porous blocks or stringers intersected while drilling halokinetic salt can be isolated or clustered (Fig. 8.24a). Common practice is to bleed them down, since they typically have limited extent within the salt mass. At the well site the observed rate of depletion should give some idea of how long the process may take. In the worst case scenario one raft will "blow-out" into another in a cluster leaving the rig operator to wait until equilibrium is re-established. Generally, no pressure transitions are observed prior to drilling into a stringer, reflecting their isolated nature and sharp boundaries with the salt. The isolated stringer typically occurs in boudinaged or folded clusters remnants of what were once intrasalt beds. Beds were broken into folded or boudined clusters in zones of extension and compression within the flowing salt mass (Fig. 8.24b).

In the Zechstein, for example, the Z3 bioclastic layer of dolomite, Plattendolomit, is deposited on top of the Z2 Stassfurt halite (Fig. 5.64). A $CaSO_4$ layer was precipitated as gypsum, followed by the Z3 evaporites and the Leine halite (Finnie 2001). Water from the gypsum was expelled as the sulphate dewatered and transformed into anhydrite. The overlying halite did not permit the upward movement of this water and so it was forced into the adjacent porous platy

[5]The terms raft and floater are sometimes used to specify layered, competent blocks of non-salt lithologies of varying sizes now encased in halokinetic salt. The terms raft and floater imply buoyancy, but carbonate, dolomite dolerite and anhydrite have a higher density than halite and are expected to sink under the influence of gravity over geological timescales (Van Gent et al. 2011). The term stringer may be more appropriate than raft or floater.

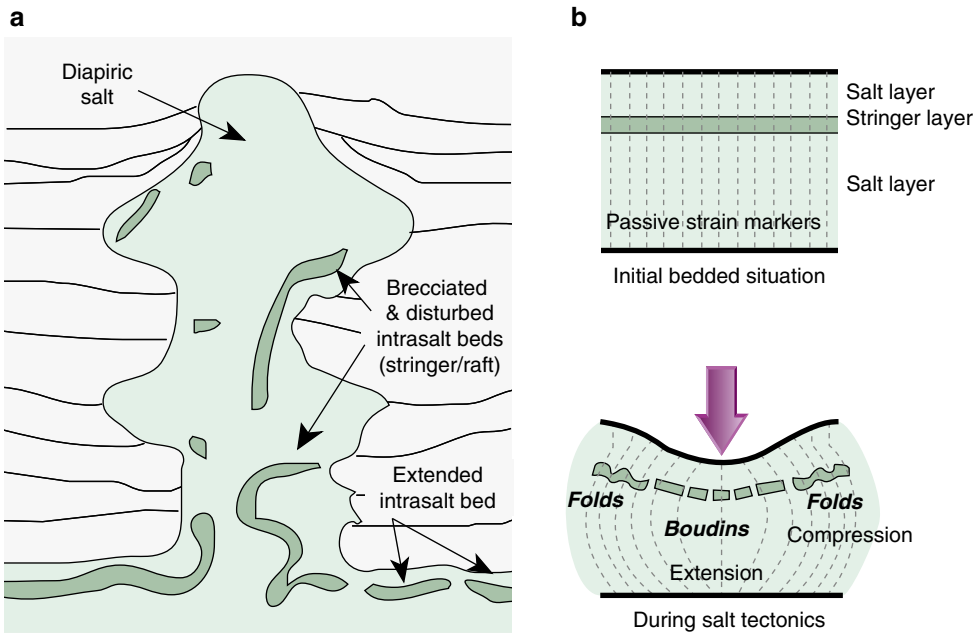

Fig. 8.24 Pressurised stringers and rafts. (**a**) Likely distribution style of isolated overpressured blocks of deformed and fractured intrasalt beds (*shaded green*) in a diapir or salt wall (Based in part on modeling of Koyi 2001). (**b**) Model explaining origin of folded and boudin style stringers in deforming salt (After van Gent et al. 2011)

dolomites. The Plattendolomit already contained fluid and so excess fluid was accommodated in part by pressure-driven leaching. When the Zechstein's most mobile salt layer, the Z2 Stassfurt halite, began to move, it carried with it the overlying Platten/Hauptanhydrite, which buckled and deformed much more brittlely than the surrounding halite. Eventually these intrasalt beds fractured into discrete stringers and were carried along encased by the flowing Stassfurt salt as it pierced the base of the Z3 (Fig. 8.24). Stringers floating in the salt become overpressured by either; (i) being uplifted to shallower depths where they continue to hold their deeper pressures because of the surrounding impermeable salt, or (ii) overpressures are generated in the raft by the folding and squeezing nature of almost all subsurface salt creep in the inverted structures of the North Sea (van Gent et al. 2011).

Source rock maturation within the stringer carbonate can also contribute to the overpressure. Intrasalt stringers or floaters tend to de-pressurise when these overpressured porous rock masses come into contact with minibasin sediments at the edge of the salt mass, or with any other permeable units at the upper or lower edges of the encasing and flowing/dissolving salt mass.

This is most clearly seen in the black-salt encased Late Neoproterozoic to early Cambrian intra-salt Ara (stringer) reservoirs of the South Oman Salt Basin (Fig. 8.25; Kukla et al. 2011b). These carbonate bodies are isolated in salt and frequently contain low-permeability dolomites and are characterized by high initial hydrocarbon production rates due to hard overpressures.[6] But not all stringers are overpressured and a temporal relationship defined by increasingly overpressured reservoirs within stratigraphically younger units is observed. There are two distinctly independent pressure trends in the stringers; one is hydrostatic to slightly-above hydrostatic, and the other is overpressured from 17 to 22 kPa m^{-1}, almost at lithostatic pressures (Fig. 8.25a).

The black staining of the halite is caused by intragranular microcracks and grain boundaries filled with solid bitumen formed by the alteration of oil (Fig. 8.26a–c). The same samples show evidence for crystal plastic deformation and dynamic recrystallization. Subgrain-size piezometry indicates a maximum differential paleostress of less than 2 MPa. Under such low shear stress, laboratory-calibrated dilatancy criteria indicate that oil can only enter the rock salt at near-zero effective stresses, where fluid pressures are very close to lithostatic. In Schoenherr et al's (2007b) model, the oil pressure in the carbonate stringer reservoirs reservoir increases until it is equal to the fluid pressure in the low but interconnected porosity of the Ara Salt, plus the capillary entry pressure (Fig. 8.27). When this condition is met, oil is expelled into the rock salt, which dilates and increases its permeability by many orders of magnitude. Sealing capacity is lost, and

[6]The term hard overpressure is an often misunderstood term, dating back to Loucks et al. (1979), who recognized three pressure regimes that they defined in terms of pressure-depth gradients:

(a) Normal pressure (0.465 psi/ft, 8.9 PPG equivalent mud weight, 1.07 kg/l),

(b) Soft overpressure (0.465 to 0.700 psi/ft, 13.5 PPG equivalent mud weight, 1.62 kg/l), and

(c) Hard overpressure (> 0.700 psi/ft, 13.5 PPG equivalent mud weight, 1.62 kg/l)

The term hard overpressure is also mis-used without reference to pressure gradient to describe narrow transition zones (as often typifies overpressure transitions in the immediate vicinity of a salt seal).

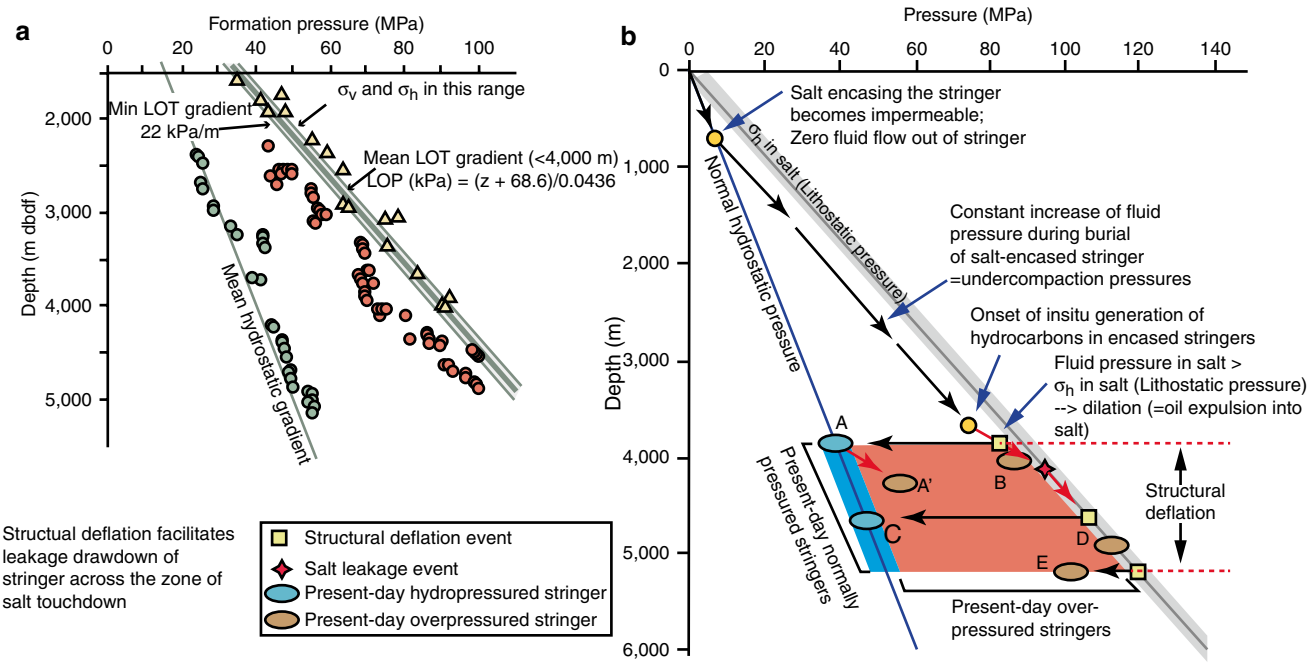

Fig. 8.25 Overpressure in the carbonate stringers of the South Oman Salt Basin (After Kukla et al. 2011a, b). (**a**) Measured formation pressures in the Ara carbonates (*circles*) versus depth. The plot shows two different pressure populations: one at near-hydrostatic pressures, with a mean pore-pressure coefficient $\lambda = 0.49$ (*green circles*), and one at near-lithostatic pressures, with a mean pore-pressure coefficient $\lambda = 0.87$ (*red circles*). *Brown triangles* are leakoff test (LOT) data, and z is depth in metres. The *thick grey band* represents the range of differential stress difference ($\sigma_1 - \sigma_3$ [maximum principal stress – minimum]) in rock salt as derived from integrated density logs and subgrain size piezometry. tvdbdf = true vertical depth below derrick floor. (**b**) Schematic illustrating mechanisms of overpressure generation and pressure deflation in the Ara Stringers through the burial process (see text for detail)

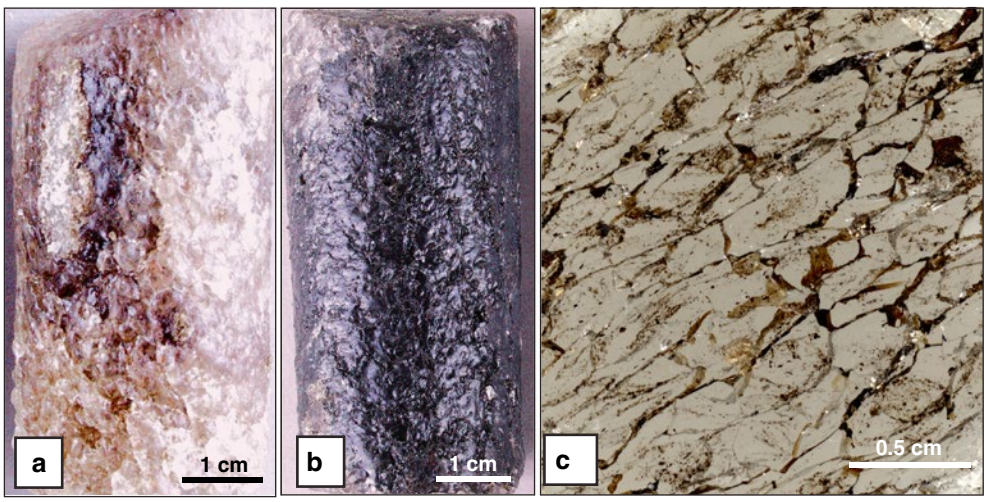

Fig. 8.26 Hydrocarbon-impregnated halite ("black halite") from the Ara Salt, South Oman Salt basin. (**a**) Lightly impregnated salt core, (**b**) Heavily impregnated zone in salt core, this is classic Omani "black salt". (**c**) Photomicrograph of naturally-impregnated salt showing interconnected polyhedral porosity outlined by the darker hydrocarbons (All images courtesy of Janos Urai; see Schoenherr et al. (2007b) for full detail on creation of black salt polyhedral porosity)

fluid flow will continue until the fluid pressure drops below the minimal principal stress, at which point rock salt will reseal to maintain the fluid pressure at lithostatic values.

Inclusion studies in the halite indicate ambient temperatures at the time of entry were in excess of 90 °C, implying hydrocarbons could move into polyhedral interconnected tubes in the halite. These conduits were created in response to changes in the polyhedral angle in the halite in response to elevated temperatures (Lewis and Holness 1996).

Hydrocarbon-stained "black salt" can extend up to 100 m from the pressurised supplying stringer into the Ara salt (Fig. 8.26). It indicates a burial-mesogenetic pressure regime and is not the same process set as seen in the telogenetic "black salt" regions of the onshore Gulf of Mexico. The latter are created by dissolution, meteoric water entry, and clastic contamination, as in the crests of nearsurface diapirs such as Weeks Island (Fig. 13.48). An Ara stringer enclosed by oil-stained salt but now below the lithostatic gradient likely indicates a later deflation event that caused either complete

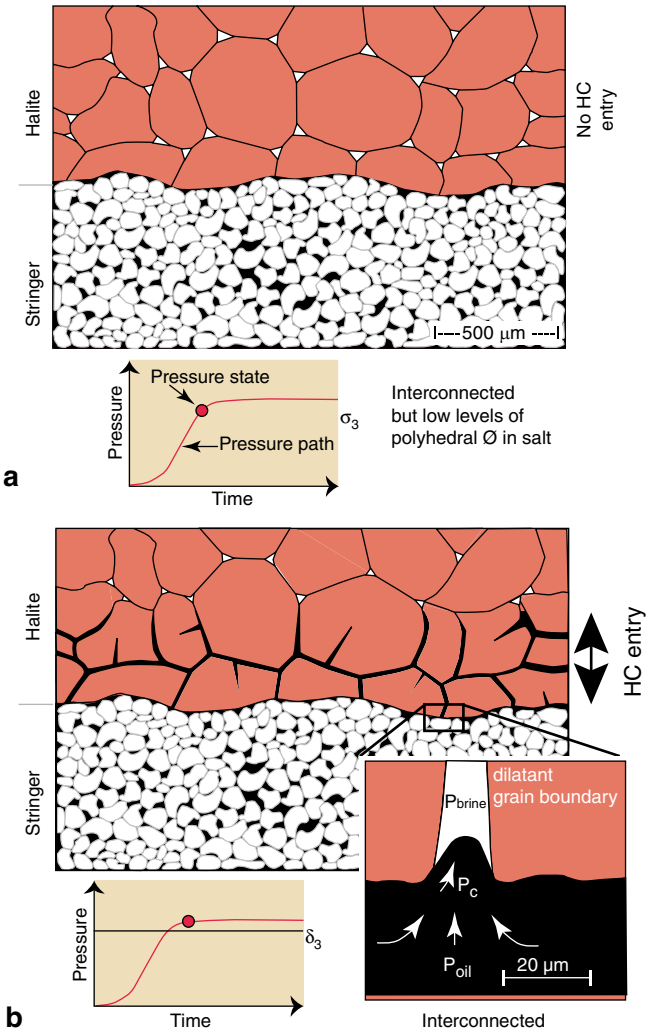

Fig. 8.27 Entry of pressurised hydrocarbons (*HC*) into polyhedral salt pores. (**a**) Schematic cross section in (a) shows the interface of stringer reservoir and Ara Salt. Halite has an interconnected but low porosity represented by the triangular white spaces between the salt crystals (cut perpendicular to the triple junction tubes – thermal response in salt). The *red dot* in the schematic pressure-versus-time diagram indicates that the oil pressure (P_{oil}) is equal to σ_3 in the Ara Salt. (**b**) Because of overpressure buildup, P_{oil} in the stringer exceeds the minimum principal stress (σ_3) of the salt by the capillary entry pressure (P_c), allowing the entry of oil into the triple junction tubes of the salt, leading to a diffuse dilation of the Ara Salt by grain boundary opening and intracrystalline microcracking (After Schoenherr et al. 2007b)

(C) or partial (E) loss of overpressures. Alternatively, stringers showing overpressure, but below the lithostatic gradient (E), might be explained by regional cooling or some other hitherto unexplained mechanism (Fig. 8.25b; Kukla et al. 2011a, b).

Structural, petrophysical and seismic data analysis suggests that overpressure generation in the Ara is driven initially by fast burial of the stringers in salt, with a subsequent significant contribution to the overpressure from thermal fluid effects and kerogen conversion of organic-rich laminites within the stringer bodies. If the overpressured stringers come in contact with a siliciclastic minibasin, they will deflate and return to hydrostatic pressures (A) in Fig. 8.25b. When the connection between the minibasin and the stringers is lost, they can regain overpressures because of further oil generation and burial (A'). If hydrocarbon generation in undeflated stringers stops relatively early, the fluid pressures do not reach lithostatic pressures (B). If hydrocarbon generation continues, the fluid pressures exceed the lithostatic pressure (red star), leading to dilation and oil expulsion into the rock salt to what is locally known as "black salt" (D and E).

As well as these examples of overpressure associated with older evaporites, overpressure readily develops in salt-sculpted Tertiary basins. For example, overpressure occurs in salt shear (gumbo) transitions beneath some, but not all, shallow salt allochthons in Green and Mahogany canyon regions in the Gulf of Mexico (Fig. 5.71; Beckman 1999: Shaker 2008). Where salt allochthons are climbing the stratigraphy, subsalt sealing and associated overpressure can occur beneath the salt mass at shallower levels than is observed in overpressured shale basins.

In terms of extension and compression regimes within a single allochthon tongue, Shaker (2008) noted that in extensional regions in halokinetic basins the magnitude and direction of the principal stresses are controlled by sediment load, salt thickness, and salt emplacement-displacement history. Therefore, the maximum principal stress is not necessarily represented by the vertical weight of the overburden, as is usually assumed in quiescent terranes. Salt buoyancy usually acts upward and has the tendency to accelerate and decelerate the principal stress above and below the salt, respectively. A distinctive shift of the pore pressure envelopes and normal compaction trends takes place across the salt body in several wells drilled trough salt below minibasins in the Mississippi Canyon, Green Canyon, and Garden Banks areas of the Gulf of Mexico. A lower pore pressure gradient has been observed below the salt and a higher gradient above the salt barrier. On the salt-rooted minibasin scale, a high-gradient was also observed in areas where the salt was emplaced and a lower gradient where the salt withdrew (Shaker and Smith 2002). On the other hand, in the compressional portion of a salt allochthon system, lateral stress generated by the salt movement piling up salt at the foot of the slope acts as the maximum principal stress, whereas the load of sediment represents the minimum stress.

Extreme overpressuring is commonplace in subsalt settings in the Gulf of Mexico at depths of 3,000–4,000 m and it variability creates drilling problems, as evidenced in the BP Horizon spill and explosion on April 20, 2010. Gas generated at greater depths in these regions can be trapped under the salt seal at pressures approaching lithostatic. It means drilling under the allochthonous salt on the Gulf Coast slope can intersect undercompacted sediments that are moderately

Table 8.4 Typical mud weights used to drill overpressured sub-allochthon intervals in the Gulf of Mexico

After O'Brien and Lerche (1994)

to extremely overpressured and friable (Hunt et al. 1998). The influence of highly effective Jurassic salt seals on pressure gradients in the Neogene stratigraphy of the Gulf of Mexico is seen in the increased mud weights typically required for safe drilling, once an evaporite allochthon is breached by the drill (Table 8.4). Most wells intersecting salt allochthons in the deepwater realm of the Gulf of Mexico are overpressured at some depth below the base of salt with mud weights controlling pressures ranging from 14 to 17.5 ppg.

For example, in the offshore Mahogany area, salts sheets are encountered below 2,300 m (7,500 ft) subseafloor with an average thickness of 1,150 m (3,800 ft; Walton and Urband 1997). The interval of disturbed sediments (gumbo), first sealed below the salt as the allochthon sheet rolled into place across the seafloor, now extends 300–500 m (1,000–1,500 ft) below the salt base. Formation temperature at the salt base is around 75 °C (170 °F). Rotary sidewall cores collected from the salt show it is very dense and competent. Fracture gradient checks performed in and below the salt mass by pump-in leak-off tests, approach 0.988 psi/ft (19 ppg). The fracture pressure is only 0.5 ppg higher than the pore pressure in those wells. Yet in other subsalt wells the underlying disturbed sediments cannot support a mud column of 16.9 ppg (0.879 psi/ft gradient). Pore pressure gradient decreases as drilling progresses below the salt, until the sediments became more competent and less affected by the influence of early sealing beneath the salt allochthon trap.

But subsalt pressures in allochthon basins are very unpredictable, as it is not the salt itself that generates abnormal pressure (it lacks porosity). The overpressure comes from the inability of basinal fluid to move through the salt mass or to drain freely from thick underlying shales. For adjacent sediment to be abnormally pressured, fluid must be generated by compactional or thermobaric/catabaric processes in the sediments beneath the salt. The salt mass itself is only the barrier to this escaping fluid. So, where sediments immediately below a salt mass are not carrying overpressured fluids, the contact with the salt is not overpressured. In fact, lower than regional pressure gradients are found below some salt allochthons, as well as the more typical higher pressures. For example, a few subsalt wells in the Mississippi Canyon region have mud[7] weights indicating much lower subsalt pressures (11–12.5 ppg mud weights).

Such lowered pressures may indicate zones of rapid salt solution and creation of pore space via dissolutional collapse. Nor can overpressure be correlated to the thickness of the overburden atop a salt allochthon. The only generalisation is that, if abnormal pressures are present immediately beneath or adjacent to a salt mass, the pressure boundary will typically be sharp and correspond to the contact with the salt mass.

Thick shale-rich suprasalt successions in the withdrawal sinks (minibasins) of some more deeply buried salt units are also overpressured (Fig. 6.47). Shale-sealed sands sometimes show evidence of permeability connections through shale gouge zones about salt masses. Shaker (2004) argues that at the scale of salt-rooted minibasins, higher pressure gradients tend to occur in areas where the salt was present, while lower gradients tend to occur in areas where the salt has been withdrawn into adjacent allochthons. But this is a dynamic situation in which seal rupture (often along growth faults in the edges of minibasins and atop a zone of thinned salt) is followed by a cycle of fluid movement, a pressure drop, resealing, and renewed pressure buildup from the continuous generation of thermogenic gas. It creates dynamic pressure regimes where overpressuring beneath salt allochthons can occur a number of times in the minibasin history and is sometimes called seismic valving or pumping (McBride et al. 1998a, b).

Seismic valving defines a fluid system where the build-up of fluid overpressure within an aquifer, juxtaposed against a fault, temporarily attains lithostatic pressure and so drives the periodic release of fluids that move out depressurise the aquifer. It contrasts with the seismic pumping mechanism in

[7]Drilling mud weights (pounds per gallon or ppg) are sometimes used to estimate pore pressure in permeable formations as they tend to take in drilling mud if the mud pressure is significantly in excess of the pore pressure and produce fluids into the well if the converse is true.

which faulting, driven by externally imposed stresses, controls periodic fluid movements along the fault (Sibson 1981, 2003). The two processes can be closely interrelated in time and space

Conceptually, the close interrelationship between the terms seismic pumping and seismic valving is best explained using the analogy of a hand-driven water pump that is being used to raise water from a water well. As the handle of the pump lifts the piston it creates a low-pressure region that draws in water across a one-way valve into the pump cavity (seismic pumping). Then as the action of the handle is reversed it compresses the water beneath the piston forcing water out of the pump faucet (seismic valving). Likewise, fluid flow in an extensional regime is related to cycles of dilatancy and fault release in the region of the fault. Extensional dilatancy in the fault and its vicinity draws in pore waters (and hydrocarbons) from its surrounds. This is followed by an episode of fault release, whereby overburden loading now compresses and drives water up along the fault into higher levels. Hence, with salt-induced seismicity active in a normal fault or growth fault, the episode of fault release drives fluid up along the steeply dipping fault.

Seismic pumping and valving of fluid flow is also possible in a reverse fault or thrust scenario. Once again the time of fault release is the time when fluid is sucked into the fault plane ("squeegee mode" mentioned earlier). But the low angle of the thrust means it does not easily drain up the fault to the surface but remains under subsequent compression to act as a fracture propagator, as evidenced in multistage fracture filling mineralisation associated with the thrust. This is especially so in sediment beneath salt-lubricated (and sealed) thrusts.

Active growth fault zones at the edge of a salt-cored minibasin and typically soling into salt welds have created fluid conduits supplying the numerous shallower reservoirs in Eugene Island and Ship Shoal areas (Farley 2005). One such fault was intersected in South Addition Block 330, offshore Louisiana and was sampled at a depth of 2,460 m by the extended "Pathfinder" well (Fig. 8.28; Anderson et al. 1994b). Oil and gas in this region is being produced from Neogene reservoirs as young as 400,000 years old and the field is located beneath numerous active seafloor seeps. Eugene Island is one of the largest Pleistocene oil fields in the world and is surrounded mostly by gas-dominated fields in the south additions of offshore Louisiana. More than 600 million BBL of oil equivalent has been produced from this field since its discovery in 1971 (Fig. 8.28a, b). Sediments filling the minibasin consist of alternating sequences of sands and shales that are likely floored by deepwater turbidites from the ancestral Mississippi River delta. The studied fault sits atop a breached salt allochthon and defines the edge of a classic salt-floored Gulf Coast minibasin.

In spite of the removal of what was once an underlying salt allochthon via earlier salt evacuation, deeper sediments are still geopressured. The pressure buildup reflects ongoing rapid deposition of thick deepwater shale above the evacuating salt allochthon. Rapid mud deposition produced permeabilities in the lower part of the minibasin fill that were too low for the compacting pore fluids to escape. Oil and gas still seeps from silty shales, adjacent to the fault zone, which has been naturally fractured. Coring revealed that fracturing extends at least 100 m from the growth fault into the shales of the upthrown block. Hydrocarbons in the fault zone are geochemically identical to those sampled from producing reservoirs located within sands that abut shallower splays of the same fault zone system (Fig. 8.28b, c). Hydrocarbons did not flow from the growth fault at economically viable rates during drillstem tests. Analysis of fluid pressures shows that the main 'A' fault is currently a profound lateral permeability barrier, with an 1,800 psi water pressure differential across it. Even so, Anderson et al. (op cit.) noted that the larger the drawdown pressures applied across perforated intervals, the lower the permeabilities of the fault zone. Flowable hydrocarbons are present and must be partially supporting the matrix. The balance between tectonic stresses and pore pressures, within the relatively tight zone defined by the growth fault, was found to be such that with an increase in pressure of 500 psi or so, large volumes of fluid could be transmitted from depth, suggesting a method that may allow production from such deep zones in the future.

Pressure data in Block 330 supports the notion of periodic fluid flow in the fault being driven by a combination of "seismic valving" and "seismic pumping" within salt-floored extensional basins. Based on their studies of the Eugene Island growth fault, Anderson et al. (1994a, b) and Losh et al. (1999, 2002) concluded that hydrocarbon migration associated with the fault was episodic. It was driven by pressure increases deep within the geopressured turbidites of the subsalt play, which rose until stresses reopened fractures in the various fault zones that connected with the upper reservoir chambers (seismic valving). At that time, large volumes of hydrocarbons were released rapidly as transient bursts towards the surface. With each pressure release, the faults closed back up. Losh et al. (1999) modelled coupled heat and mass flux in the A6ST well and concluded that the palaeothermal anomaly in the fault zone was short-lived, having a duration of less than 150 years. The anomaly could have been produced by a 2×10^6 m^3 pulse of fluid ascending the fault at an actual velocity of over 1 km/year (darcy flux of 330 m/year) from 3 km deeper in the basin. Simple Darcy law computation indicates transient fault permeability on the order of 110 md during this flow.

Pulsing of fluid up weld-floored growth faults is probably the norm in this style of trap. Put another way, with added pressure, fluid (including oil and gas) is expelled up the fault

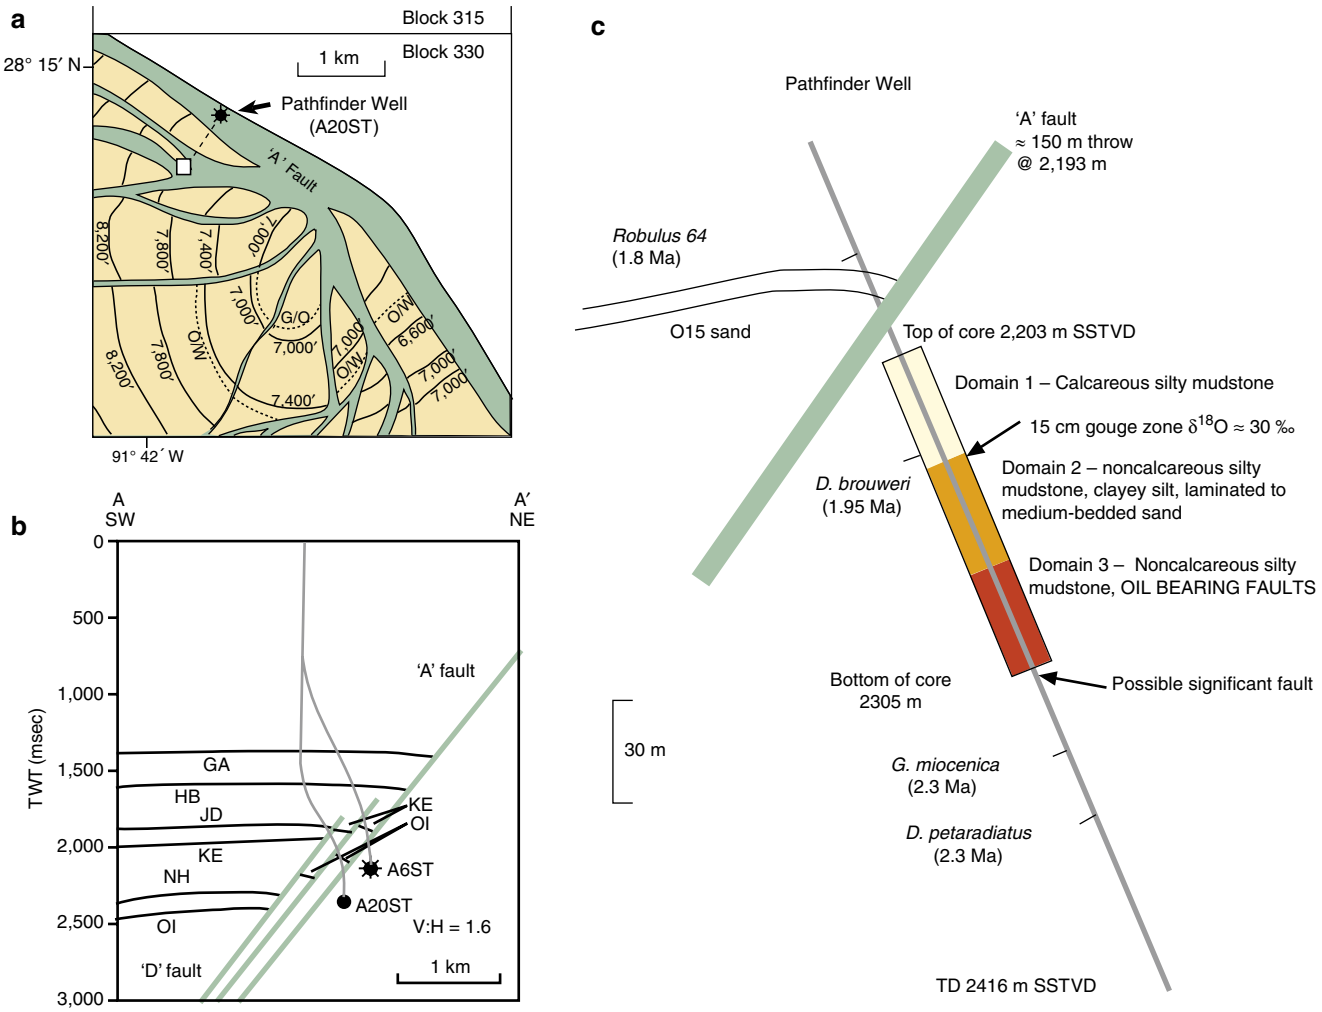

Fig. 8.28 Growth fault characteristics, Block 330 Eugene Island, Louisiana. (**a**) Structure contour map of O1 sand, showing position of the Pathfinder well. (**b**) Southwest-northeast cross section AA' showing Pathfinder (A20ST) and A6ST well trajectories, the 'A' fault, subsidiary structures and selected sand tops. Depth in milliseconds two-way travel time (TWTT); 1 ms approximately corresponds to 1 m depth in this section. (**c**) Summary cross section of core from Pathfinder well showing core location relative to 'A' Fault zone and biostratigraphic markers. *SSTVD* subsea true vertical depth (After Anderson et al. 1994b)

zone, but then the very act of releasing the fluids drops the pressure and the fault becomes tight once more. Over and over, the cycle repeats. A pulse of high-pressure fluid ascending the fault lowers effective stress in the fault zone sufficiently to produce a significant transient increase in fault permeability. If the fluid is in an area of the fault adjacent to downthrown, relatively low pressure reservoir sands, so the fluid will discharge into them. Permeability in and adjacent to the fault then decreases, such that fluid cannot re-enter the fault zone and escape from the reservoir.

On the broader scale, salt's ability to deform with its accumulating overburden into growth fault-defined minibasins means pressure cells in suprasalt sediments not only show episodic changes in a high-gradient vertical pressure transition, they can also be subject to rapid lateral changes in pressure. Many lateral seals in this situation are subvertical and tend to follow fault trends with their geopressured tops sometimes defined by high temperature carbonate cements. Using a 3D model of fluid flow history in the Eugene Island area, Anderson et al. (1991) concluded that many convective heat flow anomalies at the surface indicated the upward movement of hot subsurface fluids along various salt-floored growth faults. Many of the larger fluid compartments in this laterally restricted system consist of a series of smaller compartments, each with a single top seal and several side seals, which are active growth faults (Gordon and Flemings 1998). Similar episodic salt movement of various fault-defined pressure cells within the Jurassic Smackover Formation, atop the Louann Salt of the Mississippi Salt Basin, US Gulf Coast, has created a meshwork of large fluid compartments. Adjacent internal pressures range from normal (hydrostatic) in one compartment to 70 MPa (10,000 psi) above normal on the other side of the fault.

Controlling Unpredicted Pressure Changes

Drilling through salt can be rapid and predictable if there are few interlayered nonsalt beds. Typical rates of penetration (ROP) in salt masses are 15–40 m/h, meaning that a km section can usually be drilled in 2 or 3 days with a PDC (polycrystalline diamond cutter) bit. ROP is important because speed minimizes hole closure from creep. Salt is essentially impermeable, so the effect of drilling fluid density (mud weight-MW) on ROP is small. MW management and increased weights can be used to control closure rate, while sustaining reasonable penetration rates. However, high MW carries risks of lost circulation in unexpected non-salt zones (Dusseault et al. 2004).

Massive salt does not present as many drilling problems as fractured shales within and adjacent to the salt, but there are other challenges in drilling salt such as washout, rapid borehole closure, mud weight control issues, and casing placement decisions. Of these, the most problematic are subsalt overpressured or pressured reversion regions and the prediction of pressure regimes encountered during the penetration of extensive rubble or sheared zones (gumbo), which are common underneath salt tongues and sometimes within and lateral to diapirs. In such zones it may be difficult to decide where salt ends and nonsalt sediments start. Not knowing where these contacts are can be problematic as principal stresses are perpendicular and parallel to any plane without shear stress. Thus the orientation of principal stresses is likely to be affected by the presence of weak salt bodies or nearby severely overpressured formations (Fredrich et al. 2003).

Overpressures beneath evaporites are more of a problem to predict than pressures encountered when drilling thick variably pressured shales (e.g. Zilberman et al. 2001; Merrell et al. 2014). Most current overpressure control methods, which use slightly overbalance methods of mudweight to minimise formation damage, were first developed in shale sequences, where there is typically a well-defined transition over tens to hundreds of metres into the zone of overpressure. Transitions are often identifiable by changes in resistivity, density and sonic signatures in MWD (measurement while drilling) logs. Close monitoring of bottom hole pressure and the recognition of this transition zone allows the drilling engineer to set casing, if needed, and to increase mud weight before entering the zone of overpressure. Evaporite seals can be much thinner (down to 3 m), with sharp pressure transitions at their lower boundaries across a few cm. A sharp dissolutional contact along the underside of almost all thick evaporites and the inherent ability of a salt mass to support high fluid overpressure beneath intervals as little as 3–4 m thick means there may be little, if any, development of a pressure transition zone. Highly pressured sediments can be entered immediately below the base of the evaporite, whereas pressures appear normal as the evaporite is drilled (e.g. Alborz 5 blowout).

If a basal anhydrite (upside-down caprock; see Chap. 7) has developed on the underside of a halite mass, there may be a slowing of the drill penetration rate immediately prior to entry into the overpressured interval. However floating anhydrite or dolomite rafts in diapiric halite also slow drill penetration rates. In one situation pressure tends to bleed off with time; in the other the well may be susceptible to a major high fluid volume blowout.

Low strength casing set in a thick halokinetic salt mass, which tends to heave over time, will deform and can even shear during the active life of the well (Merrell et al. 2014). Likewise, "drilling on" through heaving and often geopressured shales beneath a salt allochthon (gumbo) is a challenge for the drilling engineer, further compounded by the possibility of encountering heaving intrasalt "shales" or overpressured intrasalt anhydrite and dolomite rafts on the way to the lower contact (e.g. Seymour et al. 1993; Zilberman et al. 2001). A lack of consolidation/induration in muddy Neogene sediments about a salt allochthon means it can be quite difficult to attain a tight cement seal behind casing in such weak and friable overpressurred lithologies. It is highly possible that a lack of consolidation behind cemented casing was a contributing factor to the blowout and spill that was the BP Horizon.[8] Macondo disaster, which occurred in the Gulf of Mexico on April 20, 2010. It was also a contributing factor in the subsequent technical difficulties experience when trying to re-establish control (kill the well) once the blowout had occurred.

Important factors controlling subsalt pressure distribution below both primary beds and allochthons are:

- Lateral extent and thickness of the salt body (Fig. 8.29a; diameter of drainage collection)
- Presence of areas of halokinetically thinned, or faulted or discontinuous salt (Fig. 8.29b; leakage)
- Depth of salt burial, salt buried at shallower depths (>1–2 km) may not have developed widespread overpressured intervals in the underlying sediments (with allochthons this is typically due to a lack of lateral or updip seal)

[8]Deepwater Horizon oil spill is also referred to as the BP oil spill, the BP oil disaster, the Gulf of Mexico oil spill, and the Macondo blowout. At approximately 9:45 pm CDT, on 20 April 2010, highpressure methane gas from the well expanded into the drilling riser and rose into the drilling rig, where it ignited and exploded, engulfing the platform. At the time, 126 crew members were on board The disaster claimed the lives of 11 rig personnel whose bodies were never found. The explosion and fire was followed by the sinking of the Deepwater Horizon oil rig and consequent loss of well control. Oil flowed onto the deep seafloor for 87 days, until the well was capped and flow greatly reduced on 15 July 2010. After several failed efforts to contain the flow, the well was declared sealed on 19 September 2010. The total discharge from the Macondo spill is estimated at 4.9 million barrels (210 million US gal; 780,000 m^3). The U.S. government's September 2011 report pointed to defective cement in the well as the main cause of the blowout (Graham et al. 2011).

- Rate of burial, slow burial may have allowed overpressure to dissipate in the subsalt beds
- Presence of a widespread sand-rich section underlying the salt may facilitate drainage and loss of pressure. More laterally restricted sand-rich sections under the salt can form both an excellent trap and reservoir for hydrocarbons (Fig. 8.29c)
- Presence of a shale sheath or gouge about a salt structure. Suprasalt sands that connect to this gouge may be overpressured but tend to be in pressure connection. Intervening sands that are unconnected to the gouge can be independently overpressured (Fig. 8.29c).

Likely variations in formation pressure on entering and exiting an evaporite unit mean mud weights are often designed specific to the geology being drilled. For example when seeking a target in the Najmah Formation, which lies below the Gotnia Salt and its Hith Anhydrite cap, the following procedure is followed (Al-Saeedi et al. 2013; Fig. 8.29d). Hith formation in a 12¼" well section is opened with

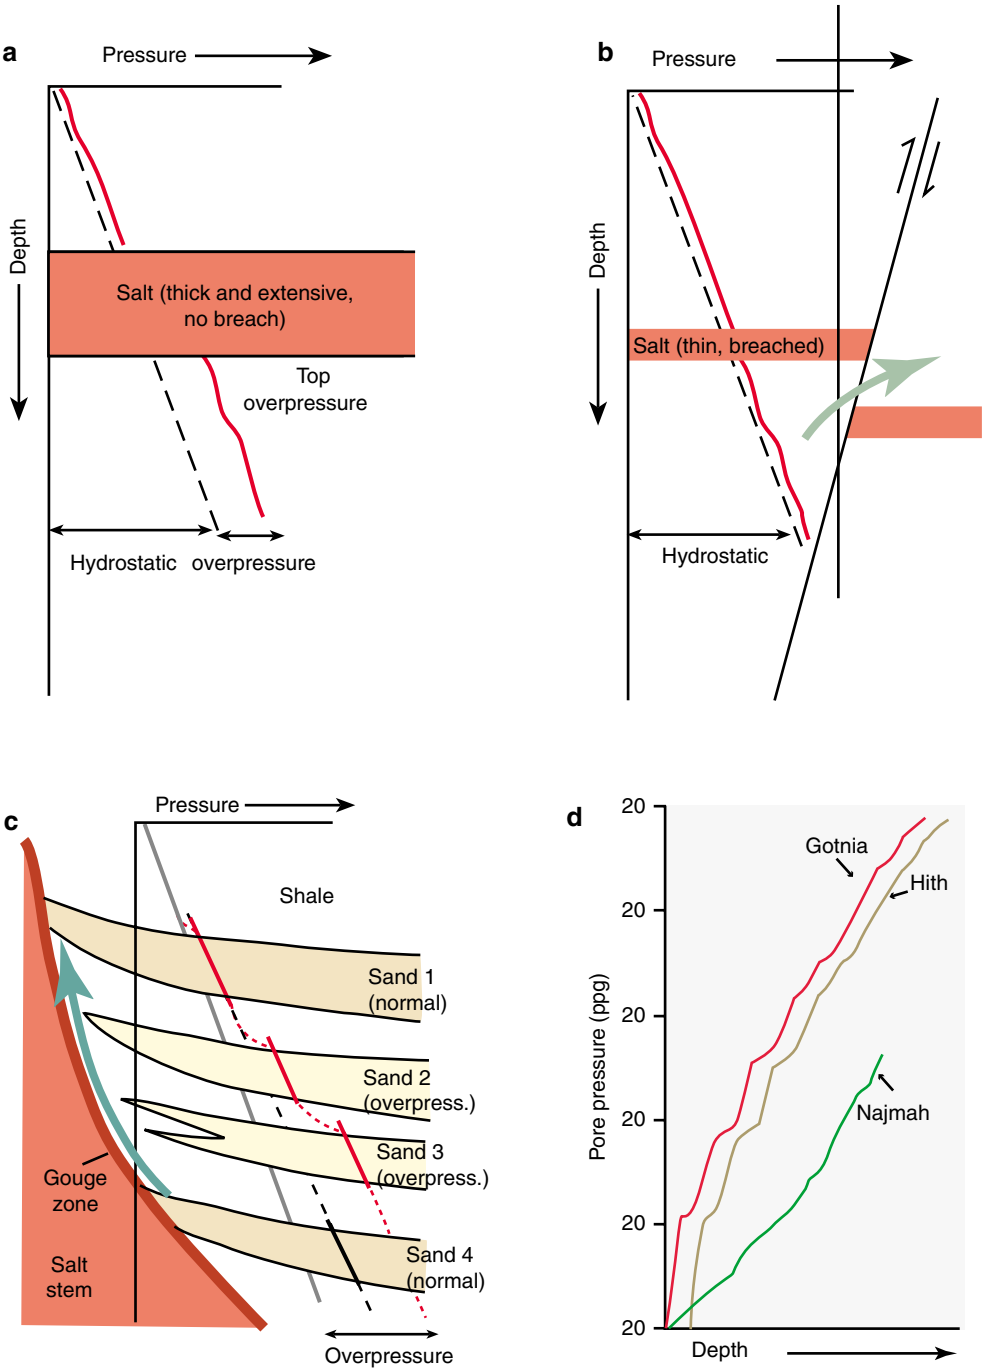

Fig. 8.29 Pressure profiles of various evaporite profiles. (**a**) Overpressure beneath a thick laterally extensive salt bed or allochthon. (**b**) Normally pressured beneath a thin discontinuous (faulted) salt layer. (**c**) Overpressure in suprasalt sands encased in shale. Sands which are in contact with the shale gouge tend to be in pressure connection, while those which are not are independently pressured (in part After Shaker 2004). (**d**) Mudweights utilised to drill Gotnia salts and underlying Najmah reservoir in northern Kuwait (After Al-Saeedi et al. 2013)

18.5 ppg mud. Formation integrity tests are carried out, up to 21 ppg, prior to opening the Gotnia formation. This ensures supra-Hith wellbore integrity if increased mudweights are required later. Then, prior to entering Gotnia first salt, mud weight is increased to 19.3 ppg. In the Raudhatain wells of North Kuwait the Gotnia salt is opened with 19.5 ppg mud weights. Significant offset well data from the previous wells in the area is taken into consideration in setting mud weights. Currently, the applied overbalance pressure over the Gotnia formation is limited to 0.7 ppg. Salt drilling is done with a controlled rate of penetration of 25–30 ft/h, even though salt can be drilled much more rapidly. Flow checks are done at every drilling break and bottoms up are circulated at the top of every salt-anhydrite layer in the Gotnia to confirm the thickness. This also ensures that the connection gases from the previous connection have been circulated out of the well prior to making the next connection. This is done in order to minimize the impact of head reduction (H_2S is a possible hazard in this geology). If the gas units are ±50, then the mud weight is increased prior to drilling further.

To minimise the possibility of blowouts, contingency plans are in place prior to drilling each Gotnia well. Two large volume mud plants have been established in North Kuwait specifically tied to drilling Gotnia penetrating wells. Prior to any well entering Gotnia Formation salts, it is standard practice that 2,000 bbls of 20-ppg kill mud are stored on the rig and, while drilling the Gotnia section, 400 MT of baryte is maintained on location 1,500 bbls of kill mud is kept ready in the mud plant with proper logistics support to transport this mud to the rig site in any emergency. Any kick taken on well bore with the mud weights above 19.8 ppg is controlled by bull[9] heading the gain back into the formation. This is done on the basis of experience gained from the previous wells to control the large volume of kick, protect the casing and to avoid the risk of taking H_2S gas in the well bore.

To counter the mud losses, 200 bbls of an 80 ppb LCM pill is prepared and kept ready prior to entering the Gotnia layers. Only in rare cases are MWD tools used in this Gotnia section (Al-Saeedi et al. 2013). When they are, the concentration of LCM pills does not exceed 45 ppb, due to the limitation of the downhole tools. At the first sign of losses, this pill is pumped into the well bore and it is allowed to soak for 2 h. In case of complete losses, pills are tried up to two times to control the losses. If there is no sign of healing with maximum of two pills, drillable plugs are set and cement plugs pumped to cure the losses. According to Al Saeedi et al., these practices have greatly helped in avoiding more days spent on mud-loss control situations.

Drilling Mud Chemistry in Salt Systems

Although drilling salt may appear to be simple, salt behaviour can be complex especially if the mud chemistry allows substantial amount of salt to pass into solution. Drilling fluids saturated with drill cuttings from mixed mineralogy salt formations can have a particularly complex chemistry, which can be difficult to understand and control. It means there can be drilling mud related problems, typically related to varying combinations in and around the well bore of saline precipitates, salt flows and salt dissolution, namely:

- Dissolution of salt resulting in hole enlargement (subsaturation).
- Temperature fluctuations driving unwanted combinations and precipitates.
- Deformation of salt, reducing the hole diameter and leading to stuck pipe.
- Degradation of well control – resulting from unexpected inflows of hydrocarbons, CO_2, H_2S or brine liquids and lost circulation.
- Recrystallization of salt and other intramud and intrafiltrate precipitates, stripping the emulsifiers and wetting agents from standard oil- and synthetic- base muds, resulting in water wet solids in the mud stream and a degradation of mud properties.

Halite-anhydrite lithologies, even when bedded as across much of the Arabian Peninsula, are complicated systems to drill, especially if the target subsalt reservoir is a fractured carbonate with matrix storage. In this case there is the possibility of exiting the salt into a system that maybe normally pressured or highly overpressured. If the mud weight is weighted to deal with overpressure but the reservoir is normally or even underpressured the chances of mud-induced formation damage are high.

One of two approaches is used with water-based fluids if they are chosen for drilling evaporites: (1) Use of a saturated salt system or, (2) Use of a slightly undersaturated system to encourage hole enlargement, which keeps salt deformation from engendering stuck pipe. The undersaturated option is sometimes difficult to manage, depending on the actual conditions, can easily lead to excessive hole enlargement, which may cause further complications in obtaining a collapse – resistant, tightly bonded and cemented casing. Water-based drilling fluids should be designed to be compatible with the

[9]Bull heading is the most common method of a contingency well kill. If there is a sudden need to kill a well quickly, without the time for rigging up for circulation, the more blunt instrument of bullheading may be used. This involves simply pumping the kill fluid directly down the well bore, forcing the well bore fluids back into the reservoir. However, it can be limited by the burst-pressure capabilities of the tubing or casing, and can risk damaging the reservoir by forcing undesired materials into it. The principal advantage is that it can be done with little advanced planning.

salt to be drilled. This can be difficult for mixed solutions, like halite-carnallite, where non-standard oilfield salt additives, like magnesium chloride, would be required, and may not be readily available. It is important to have the mud system completely saturated when the salt is first penetrated to prevent excessive hole enlargement in the top of the salt. Once the salt is being drilled, the system will stay mostly saturated due to some level of formation dissolution.

In some areas, the use of undersaturated salt systems has been perfected so that the rate of salt dissolution is matched to the rate of salt creep. One difficulty with this approach is that for long salt sections, the rate of intrasalt creep can vary internally, and the mud in the annulus can saturate at the bit (from salt cuttings), then it can not dissolve more salt as it circulates up the annulus. This method is best used in areas where the salt section is short and where it is a common practice on existing offset wells.

Al Saeedi et al. (2013) concluded that, when using water-based mud to drill salt-anhydrite in environmentally sensitive areas, saturated salt systems should be utilized in order to avoid excessive hole enlargement. Although the drilling fluid is saturated at surface temperatures, in down hole conditions, due to high temperatures, the solubility of salt increases slightly, providing conditions promoting salt dissolution, resulting in hole washouts. The selection of the type of salt additive for a salt saturated mud system is another important aspect of bore hole conditioning, depending on the type of salt in the formation. In case of soluble bitterns in the formation, like potassium and magnesium salts, magnesium chloride may be needed in the mud system to saturate the system, but it is not a commonly available oil field chemical. Using regular mud additives, like sodium chloride or calcium chloride, still tends to dissolve some magnesium salts, resulting in unwanted hole enlargement, adding an additional mix of Na, Ca and Cl into the drill mud can create unwanted precipitates

The presence of anhydrite in a formation also influences the type of mud selected for drilling calcium sulphate units (Al-Saeedi et al. 2013). When $CaSO_4$ is dissolved in water, it forms Ca^{2+} and SO_4^{2-} ions, of which calcium creates more harm in a water base mud. Anhydrite drilling with a water-base mud causes aggregation and flocculation due to calcium sulphate passing into solution, resulting in thickening of the mud. Calcium sulphate also increases apparent viscosity, gel strengths and yield point in the mud. Partially-soluble calcium also increases hardness in the filtrate and the likelihood of scale. Also, evaporite minerals like anhydrite tend to percolate readily into water base muds. Though these problems can be overcome by using effective thinners and soda ash, there is a limited space for error in these sensitive formations and these factors have determinable effects. In contrast, using and oil-base mud to drill salt-anhydrite interfaces, gives a lower water content in the mud system. This reduces the amount of salt dissolution and hole enlargement to a greater extent. From the early days, the Gotnia Formation in Kuwait was drilled with a high oil/water ratio oil-based mud to better preserve the hole gauge.

Oil- or synthetic base muds can also be used to drill salt sections. The oil-wetting ability and lower water contents reduce salt dissolution and control hole enlargement, but salts will still dissolve into the water phase, keeping it saturated. There are several reactions that can occur due to the excess lime concentration and high chlorides. The reactions can be unpredictable and vary depending on salt composition and temperature. These systems can be formulated with a variety of salts in the water phase as an alternative of calcium chloride. Sodium-chloride and magnesium chloride internal phase systems have been used successfully.

Although oil-based systems are preferred for drilling salt, so that a gauge hole can be preserved, salt dissolution products can be more detrimental to inverted emulsion muds than to water base muds. The most damaging aspects are recrystallization of salt and magnesium hydroxide precipitation. Both reactions produce extremely fine particles with a tremendous surface area. This can lead to a rapid depletion of emulsifiers and oil-wetting agents. Consumption of the emulsifiers and wetting agents can result in water-wetting of solids.

Salt-Generated Underpressure

Most naturally underpressured cells are created by a combination of uplift and erosion or by glacial rebound. Abnormal pressures in an underpressured interval are less than would be expected if a normal hydrostatic gradient was present. Underpressure occurs when the confining pressure on a subsurface sediment compartment is reduced and, providing the matrix is flexible, this allows the compartment to relax and expand. If little or no fluid can enter the compartment, then existing pore fluids in the expanded compartment must fill a somewhat larger space and so the pressure drops. An analogy is often made to what happens when a water-soaked sponge is held in a bucket of water. Overpressure is the situation in the water-filled pores of the sponge when the sponge is squeezed, while underpressure is analogous to when the squeezed sponge is released and water is drawn back into the pores of the sponge.

Reduction of lithostatic load in natural situations is most often related to uplift and erosion of a low permeability sediment pile (like shales and claystones). This typically instigates an elastic dilation of rock-pore volumes and so induces underpressuring drawing in fluids from adjacent strata (e.g. lenticular sands). Rather than tectonic uplift, in regions of former ice sheets, fluid underpressuring is often tied to a rapid load reduction via melting of the former glacier and

associated isostatic rebound. Anthropogenically-induced underpressure is regularly associated with hydrocarbon extraction. In all underpressured situation where an evaporite is present it acts as an aquitard or aquiclude preventing easy entry of water as load is released.

A not uncommon effect of underpressuring in some depleting oil fields is the creation of a cone of subsidence, as has happened on the seafloor atop Ekofisk field in the North Sea. Ekofisk is a supra diapir field that was discovered in 1969. Four wells were placed on production within 18 months of the discovery and consistently produced at rates of up to 40,000 bbl/day (Van den Bark and Thomas 1980). Full production began in 1971, by 1984, the seabed atop the salt-cored structure had subsided some 3 m, prompting a major project to jack up the offshore platforms. It was decided that water-injection pressure maintenance should be used to arrest the reservoir pressure decline and so minimize future seabed subsidence. Void fluid replacement equivalent to extracted volume was achieved in 1993, but subsidence continued. Additional laboratory studies found that water injection had induced shear in the chalk. Shear failure and water-weakening of the rock matrix was driving additional deformation of the chalk, even under conditions of near-constant or decreasing stress levels. Despite ongoing void-replacement waterflooding, seabed subsidence continued until 1998, when the subsidence rates slowed dramatically. It seemed the water-weakening effect was expended and the reservoir pressure had once again increased (Agarwal et al. 2000).

One of the most striking examples of salt-associated underpressuring comes from the Keyes Field in the Oklahoma Panhandle. It produced gas from a depth of 1,460 m (4,790 ft) for more than 50 years with a pressure-depth gradient shown in Fig. 8.30 (Hunt 1990; Powley 1980). Keyes Field is located in an area of the Amarillo Uplift that rose by around 1,500 m (4,920 ft) during the Laramide orogeny and later cooled. Fluid pressures above the Keyes gas sand and down to the Blaine Anhydrite show a normal gradient of 44.5 psi/100 ft. Below the Blaine there are two anomalous pressure cells. The upper anomalous cell extends from the base of the Blaine Anhydrite to the top of the Wellington Salt seal (at a depth of 853 m or 2,800 ft). Fluid pressure at its top (≈1,000 ft or 305 m depth) starts at zero and increases down to the top of the Wellington Salt. The gradient in this upper cell is 44 psi/100 ft. The lower cell extends from the base of the Wellington Salt to the top of the Precambrian basement. Beneath the Wellington Salt pressures once again start around zero, then increase along a gradient of 0.465 psi/ ft (10.5 kPa/m). Overall the Keyes Field is underpressured by some 9 Mpa (1,300 psi) for its current depth. Lithologies at the base of each of the pressure cells support the full weight of the overburden. That both evaporite beds are acting as highly effective seals to their respective pressure regimes is indicated by the fact that fluid pressures start again at zero in the zone immediately beneath each evaporite. In terms of hydrocarbon components, underpressured compartments are important in that they indicate isolation of rocks in the underpressured cell, prior to extraction this isolation has prevented water washing and biodegradation of accumulated oils at depths where these processes would otherwise be important influences on oil quality.

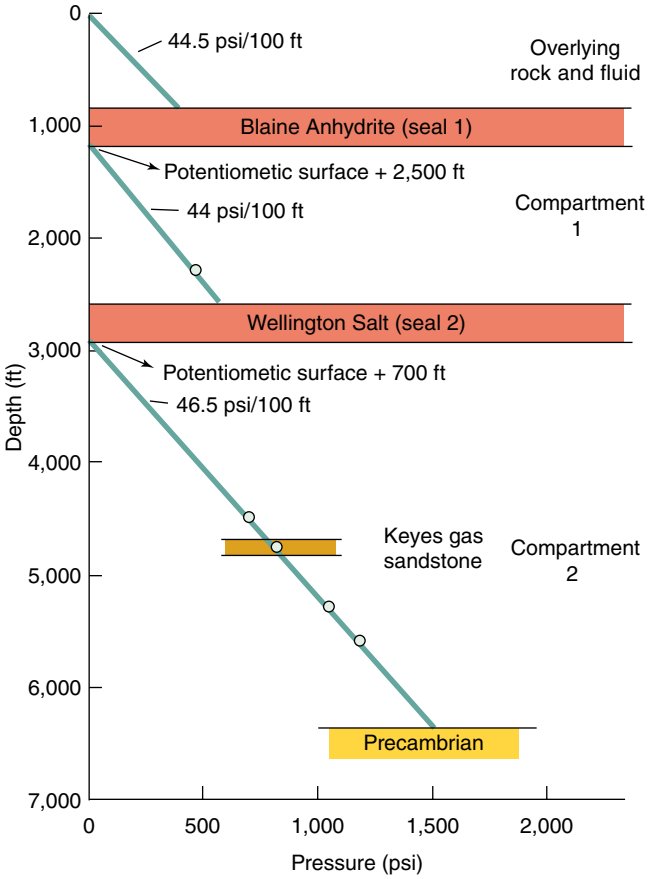

Fig. 8.30 Pressure-depth gradient for the Keyes gas field, Cimarron and Texas counties, Oklahoma. Underpressured intervals are due to uplift and the maintenance of isolated pressure cells across evaporite aquicludes (After Hunt 1990; Powley 1980)

Temperature Anomalies and Brine Flow

Thermal anomalies associated with buried salt have been known since the 1930s (Hawtof 1930) and can have significant influence on the maturation state of source rocks for hydrocarbons. Such anomalies relate to halite's higher thermal conductivity compared to most rock types (Fig. 8.31a). Thermal differentials drive basin fluid circulation, especially thermohaline circulation in sediments adjacent to an interval of halokinetic salt. At room temperature the thermal conductivity of salt is typically three times that of adjacent

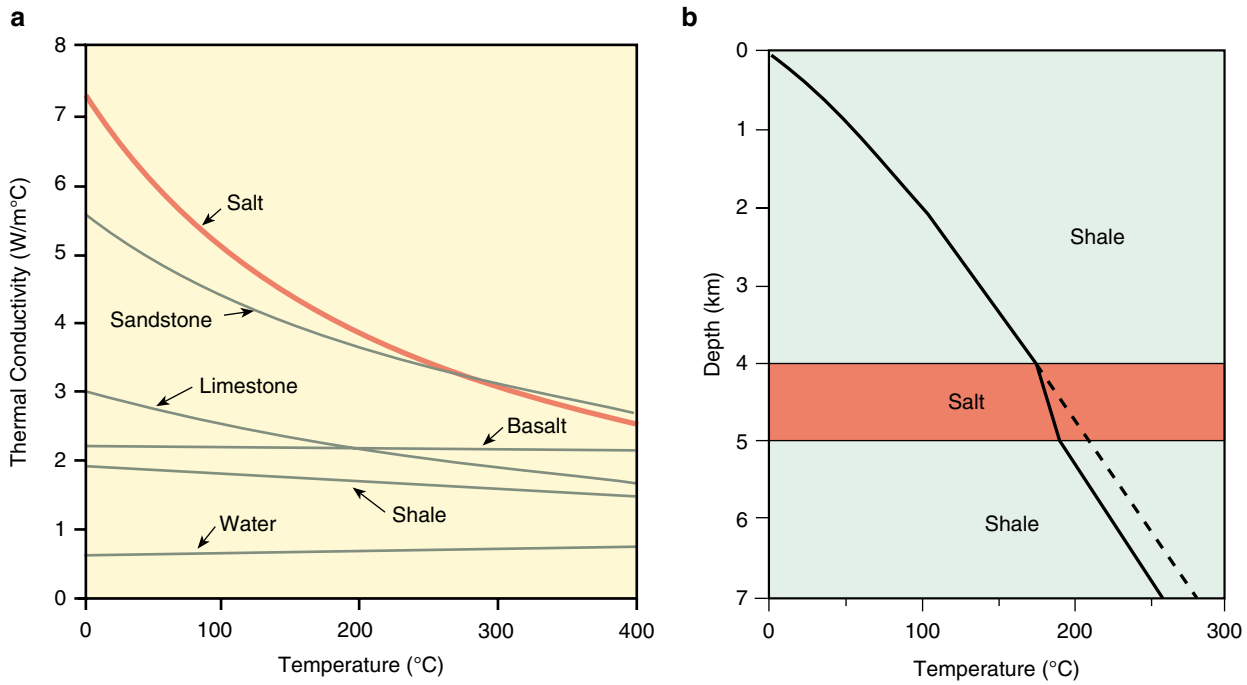

Fig. 8.31 Thermal properties of salt. (**a**) Thermal conductivity of various rock grain types (zero-porosity lithologies) and water as a function of temperature. (**b**) Vertical steady-state temperature gradient for a shale section with salt (*solid line*) and without salt (*dashed line*). The temperature plot (**a**) was used to construct the steady state profiles of Figs. 8.32 and 8.33 (After Mello et al. 1995)

shales. At 150 °C its thermal conductivity is about two thirds of its 25 °C value and still more than twice that of an adjacent now-compacted shale. Thus a salt bed or salt structure, with its much higher conductivity, exerts a strong influence on the thermal depth profile in an evaporite-entraining basin (Fig. 8.31b; Yu et al. 1992; Petersen and Lerche 1995; Mello et al. 1995).

When conductive salt remains as a bed, it raises the temperature gradient in sediments atop the salt bed, lowers the temperature gradient in the salt layer and makes beds below the salt layer cooler than they would be if the salt was not present. For example, with a 1 km-thick salt bed encased in shale, sediments below the salt are 20 °C cooler than they would be if salt were not present (Fig. 8.32a). According to Mello et al. (1995) the cooling effect is proportional to the thickness of the salt layer. All subsalt sediments are subject to non-transient cooling effects that last as long as the salt remains. Such temperature differences obviously affect organic maturation in sediments above and below the salt layer.

If the salt bed has flowed and a salt diapir is present, but with its crest buried well below the sediment surface, the conductive spine of salt sets up a thermal dipole with a positive anomaly atop the spine and a negative anomaly at its base (Fig. 8.32b). Sediments atop the spine are hotter than they would be without the salt, while sediments below the structure are cooler. Elevated vitrinite reflectance values above buried salt structures have been recognised in the oil industry for many years. However, the cooling effects on beds below a salt bed, diapir or sheet were largely ignored until the work of Mello et al. (1995).

If the diapir crest is at the sedimentation surface, as it is during the passive salt diapir stage, the structure acts as a thermal monopole. The salt spine acts as a sink that channels or drains heat to the surface (Fig. 8.32c). In this situation, temperatures around and beneath the salt spine and its source layer are less than would exist in a basin without salt. The amplitude of the negative anomaly locally reaches −85 °C and its cooling effect extends out for more than three times the diameter of the salt spine (Mello et al. 1995).

The contrast in thermal regimes where a thermal dipole is created when the salt crest is deeply buried versus a monopole where the crest is at the surface raises the question, how close to the surface need a diapir crest be before it starts to act as a heat sink rather than a heat source? Modelling by Mello et al. (1995) suggests the following rule of thumb; the maximum negative anomaly amplitude is reduced 10–15 °C for every 250 m of increase in the depth to the top of the salt spine (assuming a shale-rich host). The amount of heat drained from a basin is thus sensitive to the depth to the top of a salt structure and the length of time for which the salt remains at or near the surface before the structure is buried. Basins characterised by syndepositional salt flow and the maintenance of salt spines near the surface will produce the coldest situation with respect to subsalt sediments. This mechanism may help explain why many oil-prolific salt basins still produce large amounts of hydrocarbons today,

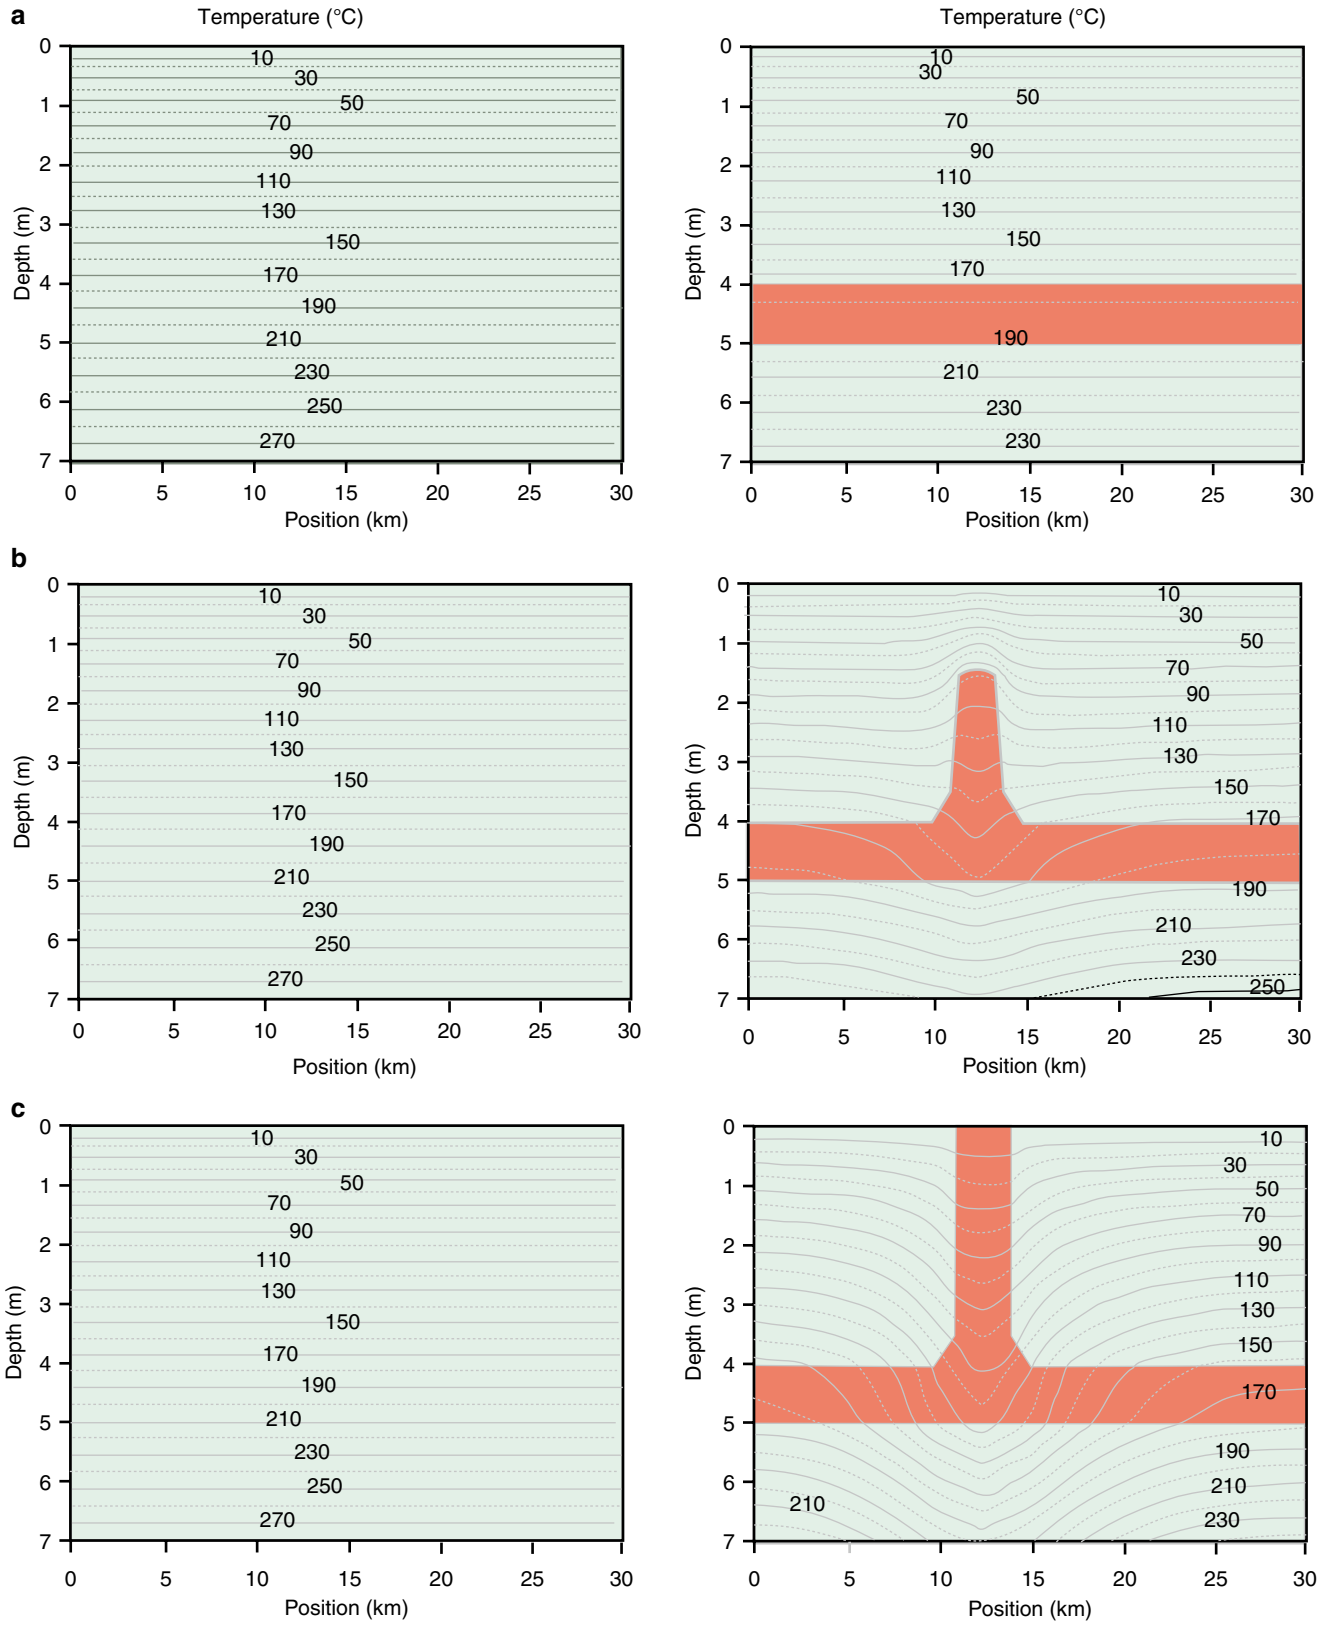

Fig. 8.32 Model of steady-state temperature distribution for a shale section containing salt with varying geometries (shown on *right hand side*) versus the same shale section with no salt (*left hand side*). All calculations use shale and salt thermal properties and gradients given in Fig. 8.31. (**a**) Salt layer, note that sediments below the salt layer are 20 °C cooler than in a shale section with no salt. (**b**) Salt diapir that is connected to its source layer and is not in contact with the surface. Notice the elevated temperatures atop the salt spine and the reduced temperatures beneath the spine – a thermal dipole. (**c**) Salt diapir that is connected to its source layer and is also at the sediment surface. The salt spine acts as a highly efficient heat drain that collects and channels heat from around and beneath the spine and delivers it to the surface. In this situation there is no heating associated with the spine, only cooling – a thermal monopole (After Mello et al. 1995)

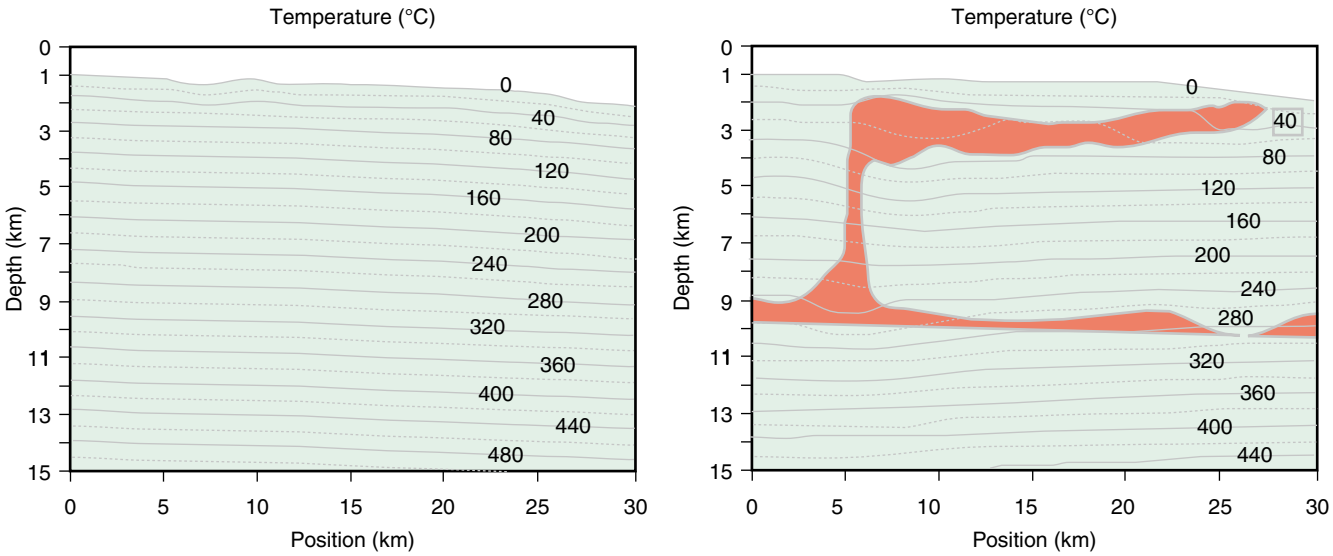

Fig. 8.33 Model of steady state temperature distribution created by the emplacement of an allochthonous salt sheet (*right hand side*) versus profile in a shale section with no salt (*left side*). Three major negative anomalies are associated with this geometry: a zone of cooling beneath the sheet; a negative or cooling anomaly associated with the dome, which feeds the sheet; and a zone of cooling beneath the lower sheet (After Mello et al. 1995)

when some thermal calculations, which do not account for salt effects, suggest that most of the known source rocks in the basin should be overmature (Mello et al. 1995).

Of course, simple salt spines, as modelled in Fig. 8.32b, c, are regularly part of a much more voluminous allochthonous salt complex, where salt sheets form layers or tiered canopies at a number of different stratigraphic levels. Figure 8.33 presents a thermal model for such a system based on structures in the Gulf of Mexico. The salt sheet is modelled as a steady-state regime in a shale host; it lies within 500 m of the sediment-water interface and still connected with the mother salt bed. It should generate three negative thermal anomalies (Mello et al. 1995):

- a negative thermal anomaly beneath the salt source layer (mother bed);
- a thermal anomaly associated with the salt stem that feeds the allochthonous salt sheet;
- a thermal anomaly below the salt tongue itself.

There are also some positive anomalies above the salt dome and its tongues, but these are small (<15 °C) compared with the magnitude of the negative thermal anomalies. The minimum anomaly with the greatest magnitude is ≈−82 °C located directly beneath the salt dome (Fig. 8.33; position 5 km, depth 10 km). The salt source layer or mother bed contributes only −10 °C of the thermal anomaly in the deepest parts of the section. Constructive interference between the salt sheet and the feeding salt spine creates a local thermal anomaly of −55 °C at the inside inflection point of the two structures (Fig. 8.33; position 7.5 km and depth 4.5 km).

Application of salt related thermal anomalies to lateral variations in source rock maturation and fluid flow in NW Europe is discussed in Magri et al. (2008), in the Triassic of the Jeanne d'Arc basin, offshore Newfoundland, Canada by Baur et al. (2010), and the effects of evaporites in the Paradox Basin, Utah by Rasmussen and Rasmussen (2009). But understanding and predicting thermal anomalies tied to salt distribution is useful in more than source rock maturation studies. Subsurface changes in temperature drive a variety of subsurface physical phenomena, which include oil viscosity, thermal expansion properties of lithologies and the magnitude of chemical and mineral solubilities, which also tied to salt mineralogy and the distribution of top and lateral caprocks. In combination, they drive lateral variations in thermohaline flow patterns in salt basins.

Fluid Flow in Halokinetic Basins

Most subsurface heat transfer in a sedimentary basin is via fluid flow. So, the distribution of thermal anomalies around salt structures by definition also indicates brine flow patterns. Accordingly, flow is enhanced by density plumes created during salt dissolution.

Suprasalt Fluid Flow and Alteration

Like dissolution from the underbelly of a salt layer, dissolution atop and adjacent to a salt spines creates free convecting density plumes in adjacent minibasin sediments.

Thermal drive created by thermal anomalies interacts with density plume drive to speed up flow rates in fluids convecting adjacent to the salt spine. If the crest of a diapir has risen to where it lies once again in the active phreatic flow regime, intense dissolution-and caprock formation generates brine plumes. Both top and lateral caprock scenarios generate plumes of dense chloride-rich brine, carried most readily by adjacent sand aquifers (Hanor and Mercer 2010; Steen et al. 2011; McCammon and Hanor 2012).

Using a dense network of well log data collected in the vicinity of the Bay St. Elaine salt dome in SE Louisiana, Cassidy and Ranganathan (1992) calculated salinity profiles in various strata surrounding the now buried dome crest (Fig. 8.34). Salinities range from approximately 4–12 wt%, with most isosalinity lines sloping away from the salt dome. On the southwestern side of the dome (cross sections OA and OC), salinities are 2–4 wt% higher at a given depth than on opposite sides of the dome, possibly reflecting a greater rate of salt dissolution and enhanced

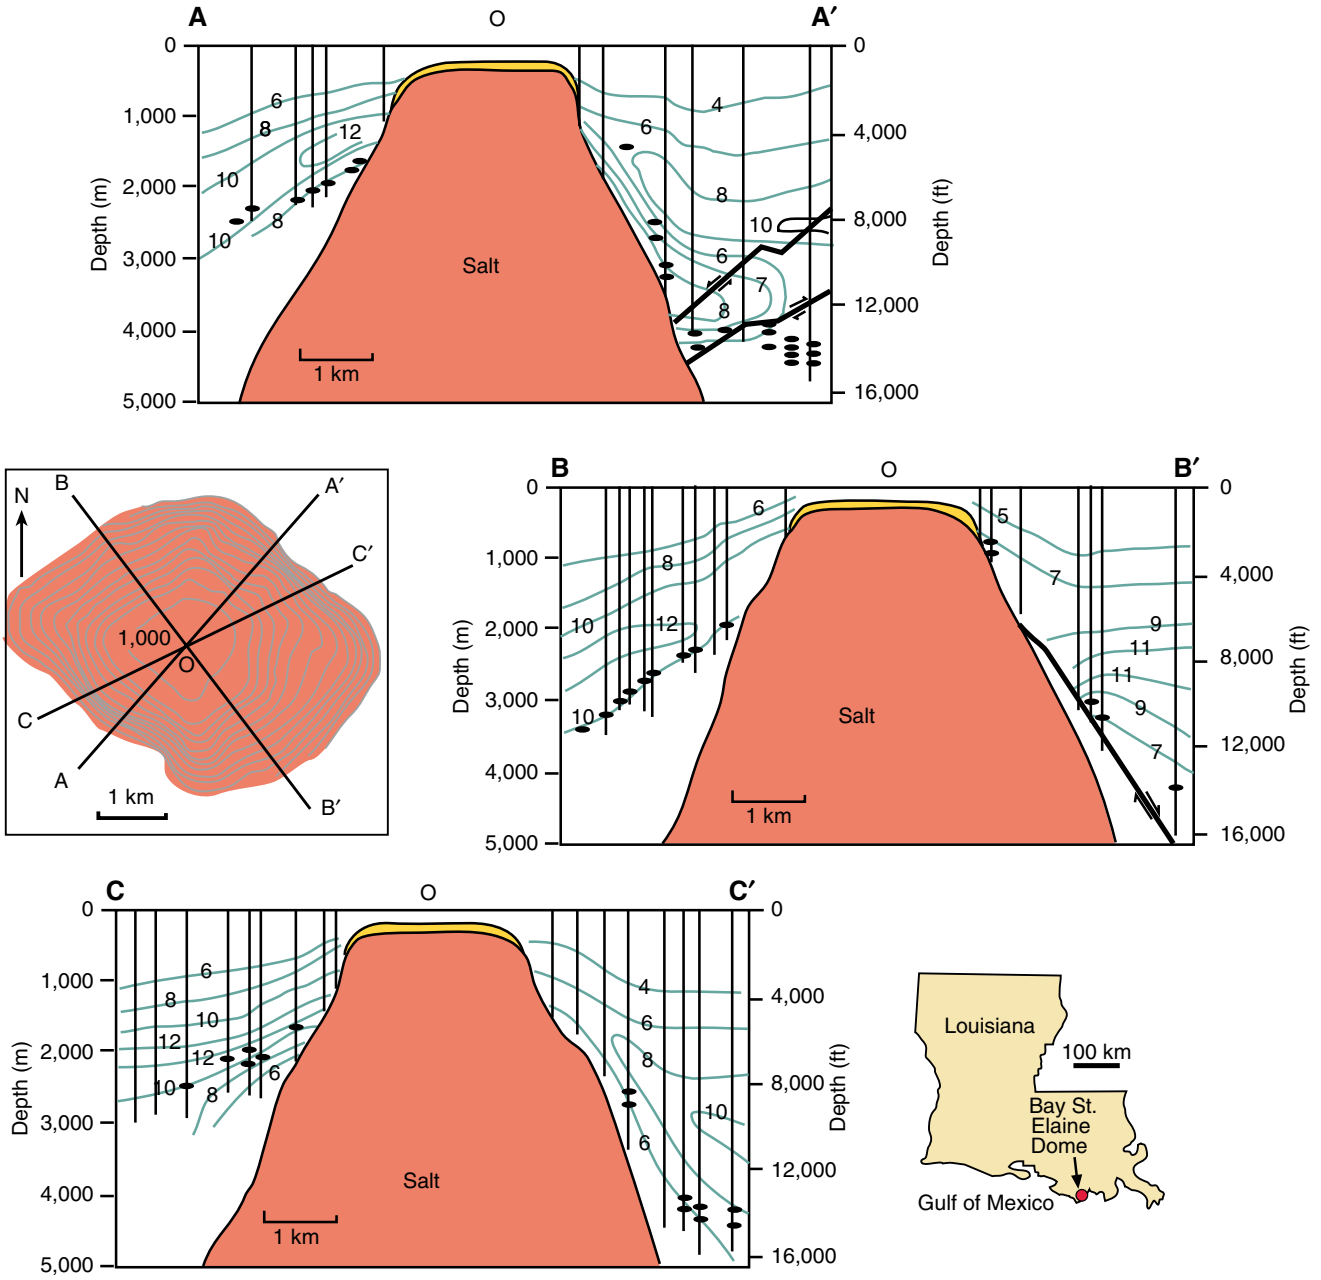

Fig. 8.34 Cross sections of pore water salinity (wt%) about the Bay St. Elaine salt dome, Louisiana (depth contours on plan view are 1,000 ft). Sections OA' and OC' show lobes or plumes of relatively fresh subsurface waters (<6 wt%) adjacent to the NE flank of the dome. *Black ellipses* on wells show intersected hydrocarbon zones (After Cassidy and Ranganathan 1992)

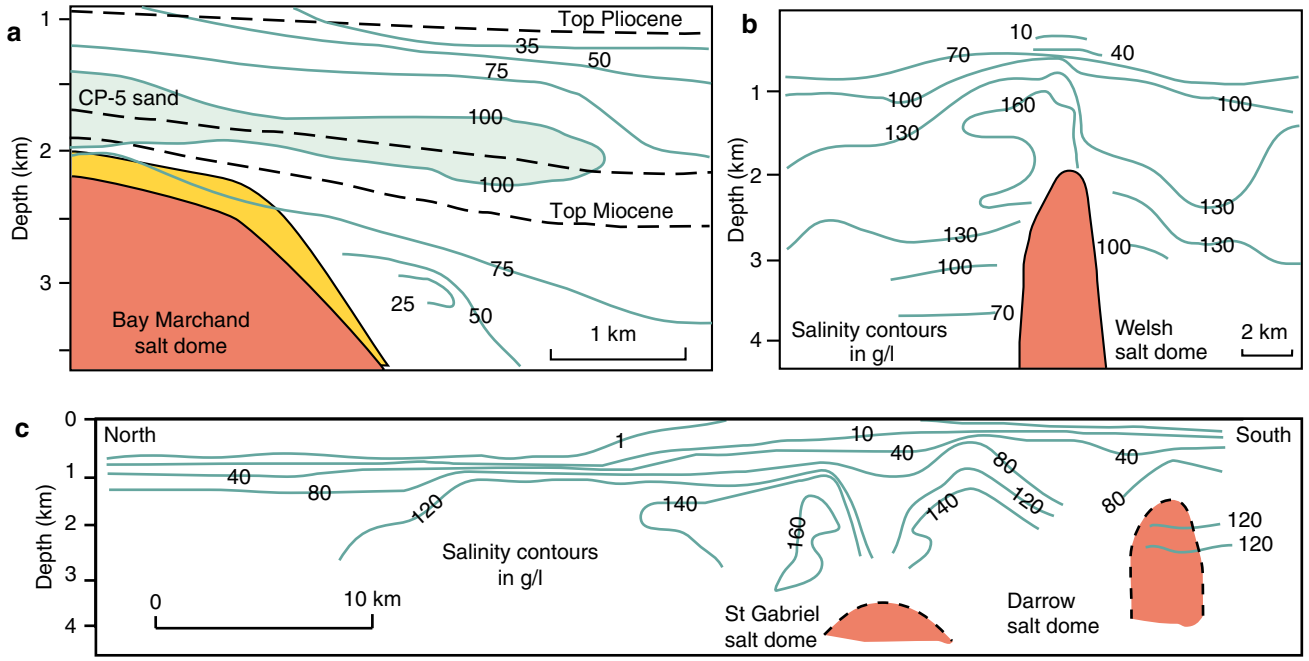

Fig. 8.35 Cross section of salinities in the vicinity of several diapirs in the of the Louisiana Gulf Coast showing the various shallow salinity plumes (g/l) generated by subsurface brine dispersion away from the dissolving crests of the salt domes. (**a**) East west section on the southwest flank of the Bay Marchand Dome. The cross hatched axis of the high salinity plume corresponds to the CP-5 Sand (After Bruno and Hanor 2003). (**b**) Welsh dome section where a regional high salinity layer (<130 g/l) sits atop a zone of overpressure, with higher salinity in the vicinity of the dissolving salt crest (After Bruno and Hanor 2003). (**c**) Salinity fields mapped around the St. Gabriel dome where saline waters occur near to, but not atop, the dome crest. Darrow dome data are limited but appear to follow the regional pattern of high salinity water near dome crest (After Bennett and Hanor 1987)

fluid transfer of heat. Lowest salinities occur on the northeastern side (cross sections OA' and OC', Fig. 8.34). On all sides of the dome, salinities increase with depth from the shallowest sands to a surface that roughly coincides with the top of overpressured sediments. Within the overpressured section, salinities decrease as depth increases, to levels on some flanks that are one-half the maximum value found in the hydrostatically pressured zones. For example, the saltiest waters in cross section OC have a salinity of 12 wt% and occur just above the shale sheath. Within the shale sheath, salinities of interstitial waters are as low as 6 wt%. Similarly, in section OC', the saltiest waters have a salinity of more than 10 wt% at a depth of 3 km. In hydrostatically pressured sections on the southwestern flank (cross sections OA and OC) and the northwestern flank (cross section OB), salinities are greatest near the dome and decrease away from the dome. In the overpressured section as well as in the shallower parts of sections OA' and OC', salinities are lowest adjacent to the dome, and increase away from the dome, perhaps reflecting a salt-stem-focused resupply of freshened compactional waters from below. Salinity contours are deflected downward near the fault on the southeastern side of the dome (cross section OB'), but seem unaffected by the faults on the northeastern side (cross section OA').

In a hydrostatically pressured section, one would expect elevated salinities near the salt dome, assuming that the dome is the major source of dissolved salt (Hanor et al. 1986). However, the observed salinity distribution (Fig. 8.34) in the vicinity of the Bay St. Elaine dome cannot be explained merely by radial diffusion of salt as it is dissolved from the dome into a static downwelling fluid column. With radial diffusion,[10] the salt concentration should be highest near the dome and decrease away from the dome. A common observation in the subsurface waters of the Gulf Coast is that salinities of interstitial waters in the overpressured suprasalt section are actually lower than salinities of waters at the base of the hydrostatically pressured section (Fig. 8.35; Hanor et al. 1986). However, the lobe of relatively fresh water (salinity of less than 6 wt%) next to the dome in cross sections OA' and OC' (Fig. 8.34) dips too steeply to be explained merely by the slope of the overpressured section near the dome.

[10]Diffusion is the movement of ions from areas of high concentration to low concentration and follows Fick's first and second laws. Diffusion is a slow process even in liquids and even slower in a porous medium in muddy sediments because ions can migrate only through the pores and the rate depends on pore throat size.

Cassidy and Ranganathan (1992), argue that the observed salinity pattern at Bay St. Elaine indicates fresher overpressured pore waters are now escaping upward in a halo around the diapir, especially on the northeastern flank of the dome (cross sections OA' and OC'), where the areas of highest salinity are separated from the dome by relatively fresh (salinity of less than 6 wt%) pore waters. The low salinity of waters immediately adjacent to the northeastern flank of the dome also may reflect a greater degree of insulation of the salt dome from dissolution on this flank. They note an alternate explanation is that the compactional pore waters may be upwelling at a slight distance away from the salt-sediment contact, thereby retaining their low salinities as they ascend. The presence of faults on the northeastern side (cross section OA') does not appear to affect the salinity contours. There are not enough control points under the fault in section OB' to evaluate the sealing versus nonsealing nature of the fault.

The salinity field documented about the Bay St. Elaine dome is in striking contrast to the salinity fields mapped around the Bay Marchand and Welsh domes (Fig. 8.35a, b). There, much saltier waters occur next to the domes in sands feeding an adjacent brine plume. The plume extends as a brine layer sourced in regions near the dome tops down to the zone of freshened and geopressured waters at some depth below (Bennett and Hanor 1987; Hanor 1994a, b). Bay Marchand dome is part of a deep-seated allochthonous salt ridge that also includes the Caillou Island and Timbalier salt domes (Figs. 8.35a, 10.53). Something like 7.2×10^{11} kg of solid NaCl must have been dissolved to account for the elevated salinities around the Bay Marchand dome (Bruno and Hanor 2003). This mass is equivalent to something 0.3 km^3 or a 300 m reduction in the height of the current dome. This is a lower limit to the total volume of salt dissolved from the dome as it is based on dissolved ions creating the pore content only of the current system. Most likely, there were earlier pore volumes from dissolved salt that are now flushed from the system. In Welsh dome, the zone of highest salinities occurs atop the crest of the dome and not in a sinking plume off to the side of the dome (Fig. 8.35b). Bennett and Hanor (1987) calculated that in this system the volume of brine in the current porosity corresponds to dissolution of at least 2 km of salt from the structure. A lack of a crestal collapse graben over this structure implies salt is still being replenished in the diapir stem. The salinity pattern above Welsh Dome cannot be explained by downwelling of salt dissolution-derived brines. Rather, the upward transport of dense high-salinity brines to levels well above the salt crest is perhaps indicative of episodic expulsion of saline fluids rising along the dome edge.

The salinity halo about St Gabriel dome is characterised by a crestal zone that is fresher than the more saline brine layers/plumes on either side of the dome crest (Fig. 8.35c). It is yet another brine distribution pattern in this region of the Gulf Coast and may reflect a situation of fresher upwelling geopressured waters, which are locally displacing a more saline brine layer created by dome crest dissolution.

Clearly, salt is still dissolving from the crests of shallowly buried salt structures in the Gulf Coast, this is especially so where there is a well-developed brine plume indicating solute transport directed away from the salt (Bay Marchand and Darrow domes). Clearly also, there are nearby domes in the same region where this brine is locally displaced by salt stem-focused upwellings of subsurface waters. These waters may be more saline (Welsh Dome) or less saline (Bay Marchand and St Gabriel). The interactions are complex and there is no simple single model to explain the variety of pore salinity fields. They vary according to differences in the rates of crestal salt dissolution versus rates of stem-focused upwelling and are tied to the laterally varying mechanics of compaction flow and salt withdrawal, fluid buoyancy effects, and different suprasalt permeability fields (Cassidy and Ranganathan 1992).

Density inversion created by the nearsurface dissolution of a diapir crest, in conjunction with a thermal drive and overpressured shales, is sufficient to drive large-scale suprasalt convective cells in the Gulf of Mexico with flow rates of metres per year (Hanor 1994a). This is two to three orders of magnitude faster than the mm/year rates that are typical of the thermobaric zone in nonevaporitic basins. Similar elevated flow rates typify the dissolving crests of many structures in the North Sea diapir fields (Williams and Ranganathan 1994).

Circumsalt fluid flow drives diagenetic alteration in sediments adjacent to a salt stem. This is demonstrated by zones of calcitic alteration on the west flank of the West Hackberry Dome, Louisiana Gulf Coast (Fig. 8.36a; McManus and Hanor 1993). Drilling has defined some 5×10^{10} kg of authigenic calcite-pyrite cement in Miocene sands adjacent to the salt spine at depths of 1.4–2.1 km, across a 1.5×1.5 km area. The Sr, C and S isotopic compositions of the cements show Ca and S were derived from dissolution of the salt-dome anhydrite cap and that carbonate was derived both by thermochemical oxidation of methane and by sulphate reduction, possibly at temperatures as low as 70 °C. Constraints on the maximum aqueous concentrations of Ca, which can be released by dissolving diapiric salt, require that more than 5×10^9 m^3 of aqueous fluid, equivalent to a fluid volume/pore volume ratio of >250:1, were involved in destroying salt, transporting Ca and SO_4, and precipitating these cements. Thus, the presence of such cements about a salt structure requires a dynamic subsurface mass-transport regime involving either large volumes of throughflushing fluid or fluids that are extensively recirculated.

An equivalent to this subsurface calcite/pyrite cement halo outcrops in a quarry in the Eocene Carrizo Sandstone adjacent to the Butler salt dome, east Texas (Fig. 8.36b;

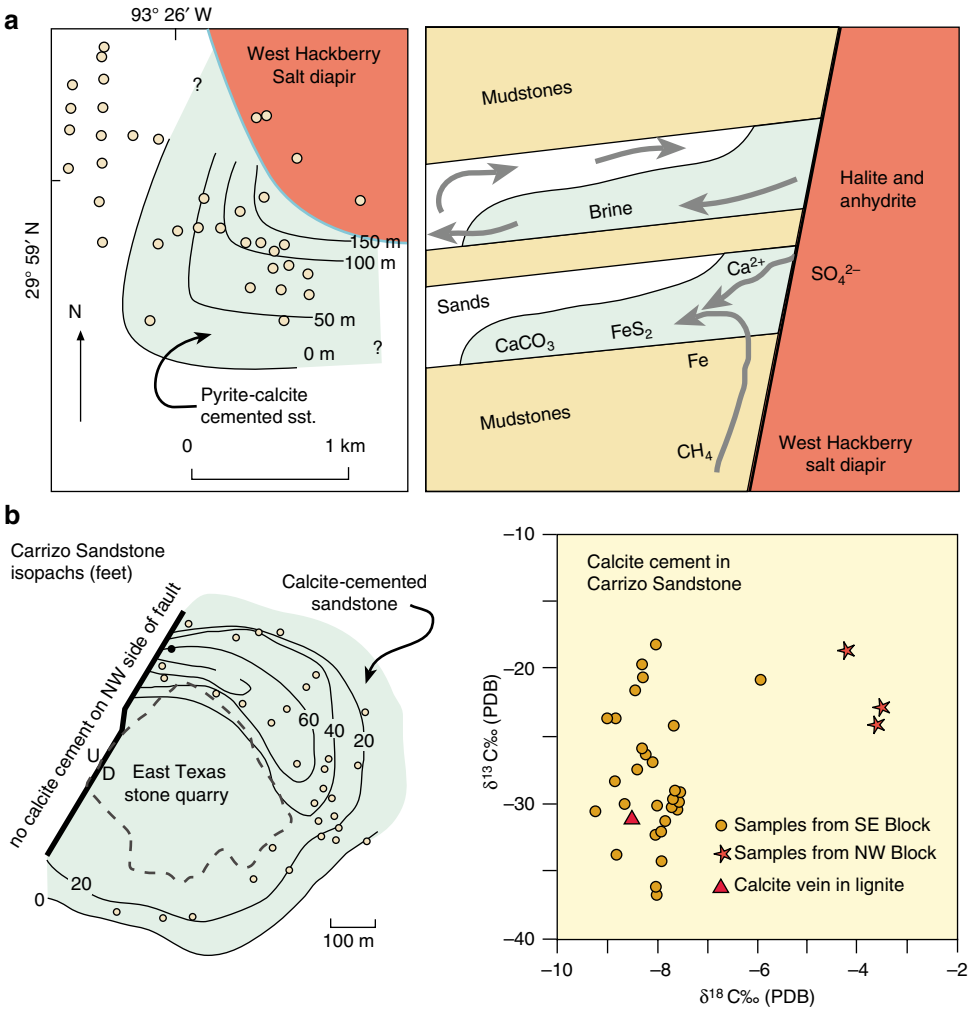

Fig. 8.36 Pyrite and calcite cements in diapir edge sands. (**a**) West Hackberry Dome, Louisiana showing cumulative thickness in metres of cemented sands, *brown dots* show borehole control. Model schematic shows hydrological circulation at the time of cementation. Dense brines with Ca and SO_4 derived from dissolution of salt stock flow down basal parts of sand beds. Upward flow of less dense fluid above brine plume. Thermogenic methane migrates up side of dome. Thermal reduction of S and oxidation of C results in precipitation of calcite and iron sulphides (After McManus and Hanor 1993). (**b**) Isopach map of the cemented zone in the subcropping Carrizo Sandstone based on drill information (*small brown dots*). The NE-trending fault forms the northwestern boundary of the cemented zone. The detailed thickness of the cemented zone within the quarry is unknown but probably was 40 ± 20 ft. Also shown are the carbon and oxygen isotope compositions of calcite cements in the Carrizo Sandstone cores (Enos and Kyle 2002)

Enos and Kyle 2002). The Carrizo is a fine- to medium-grained quartzarenite to sublitharenite with up to 42–50 % cement, principally poikilotopic calcite with local pyrite. Shallow drill holes in the surrounds of the quarry shows cemented zone is delimited by a steeply dipping normal fault, which is radial to the northeast part of dome crest. Cements extend southeast of the fault as a lenticular body some 750 m across and thickest near the fault where it is more than 25 m thick. Pyrite concretions are found on both northwest and southeast sides of the fault, as well as along the fault plane, whereas the calcite cement is present only to the southeast of the fault. $\delta^{13}C$ values for the calcite (–19 to –37 %) suggest bicarbonate was supplied mainly by bacterial oxidation of methane, whereas $\delta^{18}O$ data for calcite (–6 to –9 %) indicate meteoric water was involved in supplying diagenetic fluid. $^{87}Sr/^{86}Sr$ values for calcite (~0.7073) are within the range for Middle Jurassic seawater, suggesting that dissolution of anhydrite from the Louann Salt provided the Ca. Pyrite is more ^{34}S-rich ($\delta^{34}S$ range of 10–16 %) than typical sulphides in Gulf Coast salt dome cap rocks and is interpreted to represent H_2S supplied from deep sour gas reservoirs.

Early H_2S supply from deep sour gas reservoirs was channelled upward along the flank of the nearby Butler Dome and outward along the radial fault, resulting in early pyrite precipitation along the fault zone and in adjacent sediments. Early pyrite cements along the fault may have formed a barrier to subsequent fluid circulation, blocking the northwestward movement of both Ca-rich waters from the dome and

deep natural gas moving along the fault, thus confining calcite precipitation to the southeast of the fault. Bacterial oxidation of this thermogenic gas resulted in calcite precipitation, although mixing with shallow ground water bicarbonate may account for the broader range in $\delta^{13}C$ values in the calcite cement. Enos and Kyle (2002) propose that this type of cementation occurs in similar settings associated with circumsalt hydrocarbon leakage to shallow levels and may represent a previously unrecognized self-sealing type of hydrocarbon trap.

Rapid upward advection[11] of hot brines along the flanks salt domes in the Northern Gulf of Mexico Basin and in the Danish Central Trough seems to require an adjacent and deeper overpressured shale or mudstone succession to focus flow up the sides of the salt structure (Williams and Ranganathan 1994). The upward passage influences pore fluid chemistry interfaces, especially redox fronts, near the stem. This creates higher temperature gassy fluid haloes with interfaces that can precipitate metal sulphides and other diagenetic minerals. Inclusions in some of these diagenetic precipitates indicate temperatures were some 40–80 °C above the ambient temperature of the laterally adjacent sediment. Williams and Ranganathan (1994) conclude that thermal perturbations in excess of 60 °C can be repeatedly produced near the margins and crests of salt domes via focused dewatering of thick strongly overpressured minibasin intervals around the dome.

Dewatering can be triggered and stopped by cyclically pulsing the permeability at the salt stem sediment interface (analogous to seismic valving). Modelling shows the upwelling thermal plumes about the dome crest will dissipate within 100,000 years from the cessation of dewatering (Williams and Ranganathan 1994). Stratigraphically shallow and gravitationally unstable brine plumes from salt dissolution, once formed, will also dissipate once the salt has dissolved, but fade more slowly by sinking and mixing on a 1 Ma. time frame.

Burial Dewatering of Hydrated Salts

So far we have focused on subsurface hydrologies in halite-rich shale-dominated basins undergoing various styles of salt flow and dissolution. Halite is the dominant mineral in most thick basinwide evaporite successions, but in some basins anhydrite, not halite, is the dominant salt. In such settings there can be interesting subsurface hydrological effects tied to dewatering of the gypsum precursor to the anhydrite. Conversion occurs whenever a thick gypsum bed is buried and passes into the thermobaric zone. As the burial temperature rises above 60 °C, bedded gypsum alters and dewaters to nodular or laminar anhydrite, with an accompanying 39 % decrease in rock volume. Potentially, at around a kilometre of burial, this can generate a pressure kick that is significantly in excess of hydrostatic. The conversion of gypsum to anhydrite also defines the depth below which calcium sulphate stylolites cannot form and anhydrites may flow (Fig. 1.57).

Conversion depth influences early organic maturation and rock strength (Jowett et al. 1993). Because gypsum dehydration occurs during shallow burial, it is unlikely to be responsible for overpressures that occur at greater depths, where the primary role of the evaporite in the pressure system is as a pressure seal to underlying compacting fine-grained sediments or as a facilitator, via its evacuation, to the rapid accumulation of thick piles of geopressured sediment.

Conversion to anhydrite is accompanied by a four- to sixfold increase in thermal conductivity (gypsum ≈ 0.8 W/m·K; anhydrite ≈ 5.6 W/m·K) and the consumption of heat. At 25 °C the transformation of gypsum to anhydrite releases 4 kcal/mol. In a hydrologically-open compacting sediment pile, gypsum conversion is typically complete by 800–1,000 m of burial, corresponding to a total pressure of ≈250–300 atm (25–30 MPa). Transformation may occur at much shallower depths if the pore fluids are saline, or may not be complete until greater depths if the overlying unit is overpressured (Fig. 8.37; Jowett et al. 1993; Testa and Lugli 2000). When modelling organic maturation in an ancient calcium sulphate basin, via thermal modelling and backstripping techniques, it is important to know the depth at which the gypsum to anhydrite conversion occurred.

In a simple sensitivity test, using a basal heat flow of 2×10^{-6} cal/cm^2/s or 2 HFU's, Jowett et al. (1993) calculated the thermal gradient through bedded anhydrite is 18 °C/km, while through gypsum it is 63 °C/km. With such large differences in thermal gradient, using the wrong lithology over a particular burial depth range can create large errors in organic maturation modelling. For example, assuming 500 m of anhydrite instead of 800 m of decomposing gypsum will produce a 42 °C discrepancy at the base of the evaporite unit (Fig. 8.37a versus b). Such an error significantly effects thermal maturation, so that a source beneath the anhydrite would not reach the oil window, while that beneath the gypsum would.

[11] Advection is a general term used to describe transport of fluids, solids and heat through porous media. It requires permeability to move pore fluids so that ion transport is related to the average linear velocity of water in the pores, which is equal to Darcy velocity divided by effective porosity. In the vicinity of a dissolving salt bed it is associated with dispersion, which describes movement within groundwater as ions or contaminants spread out by mechanical mixing and diffusion. For example, a slug of brine into fresh porewaters mixes with the fresh as it moves away from the dissolution front. The brine covers a larger area as its concentration declines.

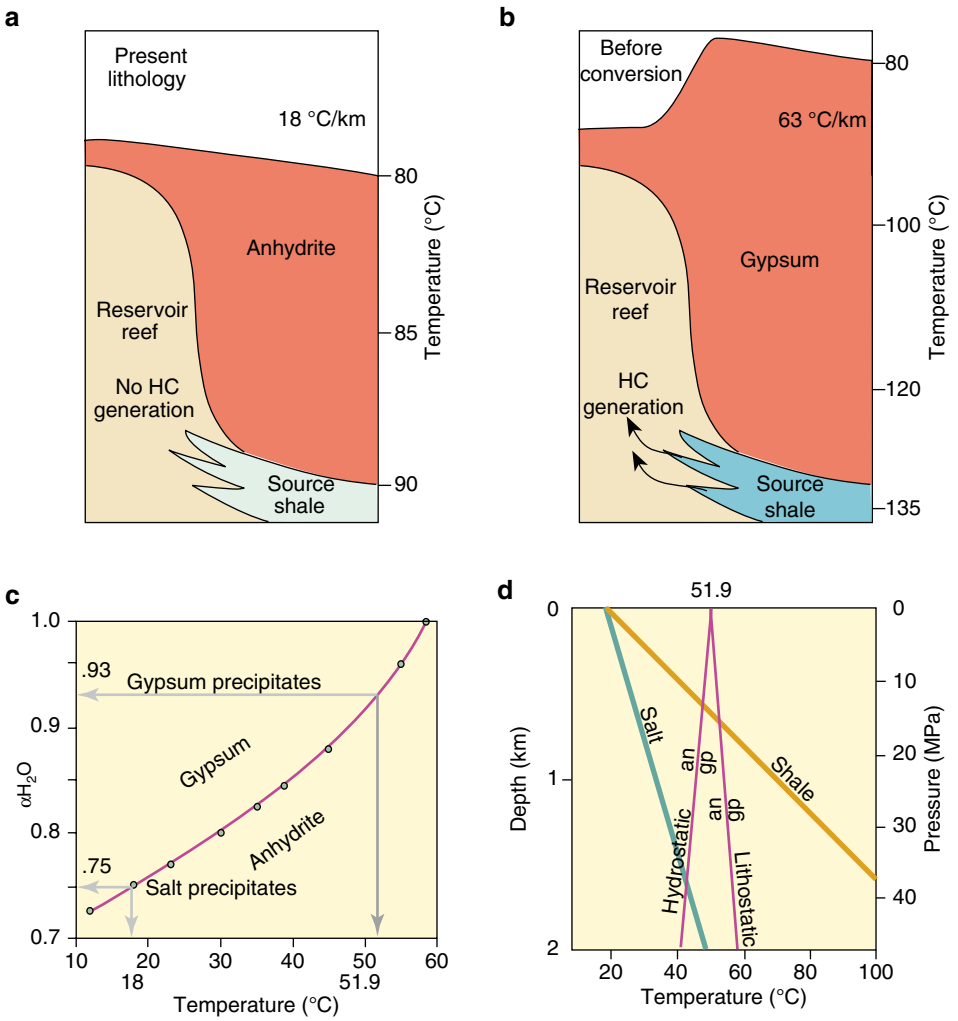

Fig. 8.37 Gypsum to anhydrite conversion (After Jowett et al. 1993). (**a**) In an evaporite basin containing 500 m of anhydrite, the calculated palaeothermal temperature implies the underlying source would not reach the "oil window." (**b**) If the conversion to anhydrite is later, so that the basin can be decompacted prior to gypsum converting to anhydrite, then the low thermal conductivity of the gypsum increases the geothermal gradient and the source rocks do reach the "oil window." (**c**) The laboratory relationship between the activity of water and the temperature of the gypsum to anhydrite conversion (After Hardie 1967). (**d**) Depth relationship for the temperature of the gypsum-anhydrite conversion below a shale insulator and a shale conductor. Conversion of gypsum to anhydrite occurs where the temperature line intersects the geothermal gradient in the overlying rock. Hence the conversion depth is much greater beneath halite (conductor) than beneath shale (insulator) (After MacDonald 1953; Hardie 1967; Hanshaw and Bredehoeft 1968)

The temperature, and hence the depth at which the transformation occurs depends on the activity (salinity) of the pore waters where the transformation is taking place. Transformation to anhydrite occurs at progressively higher temperatures as the activity of water (α_{H2O}) increases. When pore fluids have a α_{H2O} of 0.93 (equivalent to precipitation of gypsum from seawater) the transformation takes place at 52 °C (Fig. 8.28c; Hardie 1967). When the water is at halite saturation with a α_{H2O} of 0.75 the transformation occurs at 18 °C. The α_{H2O} in pore waters in ancient evaporites is indicated by the associated lithologies. If a thick anhydrite bed (deposited as gypsum) is associated with normal siliciclastics (shales and sandstones), the α_{H2O} of the burial fluids at the time of transformation was ≈0.93 and occurred at a temperature ≈50 °C. If the anhydrite retains evidence of coeval halite, or early diagenetic halite cement, then the temperature was around 20 °C at the time of transformation and so occurred at much shallow depths, perhaps within metres of the surface (Hovorka 1992).

When gypsum converts to anhydrite, the molar volume of the solid phase decreases by $\Delta V_s = -28.37$ cm^3/mol of anhydrite formed, corresponding to a volume decrease of some 39 % (Zen 1965; Hanshaw and Bredehoeft 1968). But the released fluid means there is a corresponding increase in molar volume of pore fluid of ΔV_f –36 cm^3 for the 2 mol of water created by the conversion. Because pressures on the fluid (P_f) and pressures on the solid (P_s)

are different, the molar entropy change (S) and the molar volume change (ΔV) are related by the equation (Hanshaw and Bredehoeft 1968):

$$dP_s / dT = S / \left(\Delta V_s + V_f dP_f / dP_s\right)$$

The measured entropy change is $\Delta S = -135.84 + 65.17 \log_{10} T - 0.043\ T$ (Hardie 1967), where T is the temperature in degrees Kelvin.

In a hydrostatically pressured system with free drainage allowing escape of the conversion water (e.g. gypsum with intercalated sand beds or porous carbonates) the overburden pressure is taken up only in the solid phases, so favouring the denser solid phase (anhydrite). In this situation, $dP_f/dP_s = \rho_f/\rho_s \approx 0.4$, and the slope on a dP_s/dT on a P–T plot is negative. That is, the conversion temperature decreases with depth and gypsum converts at shallower depths (Fig. 8.37d). If, on the other hand, the water from the conversion cannot freely escape from the decomposing gypsum, pore fluids may become geopressured (e.g. escaping pore fluids from a buried gypsum bed sealed beneath a thick widespread salt unit and intercalated with tight shales or lime mudstones). Overburden pressure is then taken up in both the solid and fluid phases. In this case P_f can approach P_s, dP_f/dP_s approaches unity, and the slope of dP/dT becomes positive (Hanshaw and Bredehoeft 1968). Then the conversion temperature increases with depth and for a given geothermal gradient the conversion of gypsum to anhydrite occurs at progressively greater depths. Hanshaw and Bredehoeft (1968) calculated the lithostatic conditions created by the conversion can only be maintained for a "geologic instant," even when the confining beds have hydraulic conductivities as low as 10^{-10} cm/s ($\approx 10^{-3}$ md as in a tight shale).

Most natural systems lay somewhere between the hydrostatic and the lithostatic curves, the dominance of one over the other is difficult to quantify, it can only be estimated by looking at the nature and thickness of the overburden and the intercalated lithologies within the converting calcium sulphate bed. If the water of hydration cannot drain freely from the dewatering gypsum, the bed converts to a quicksand-like consistency, typically indicated by thick nodular sequences of enterolithic folds with crestal fold vergences that may be oriented in the direction of minimum stress (Warren 1991). Escaping conversion water ultimately seeps into adjacent strata and escapes the unit. This escaping water of crystallisation can help lubricate nearby growth faults and other relatively shallow slippage features, including nappes.

Based on the ubiquitous presence of flow-aligned anhydrite textures in décollement sutures in the European Alps and elsewhere (e.g. Jordan and Nuesch 1989; Jordan et al. 1990) it seems that a common effect of sulphate dehydration is an initial decrease in the intrinsic strength of the $CaSO_4$ unit and an enhanced ability to act as a lubricant. Laboratory testing of mechanical strength during the dehydration of gypsum to bassanite ($CaSO_4.1/2H_2O$) under closed drainage supports these observations (Fig. 8.38). There is a large decrease in differential stress under undrained conditions at temperatures ≈ 110 °C, indicating high pore pressures induced by gypsum dehydration (Heard and Rubey 1966; Murrell and Ismail 1976). Thus a non-draining dehydrating gypsum bed can act as a zone of weakness or décollement at the base of a thick salt or shale succession. However, in the low temperatures of the laboratory the reaction product is bassanite not anhydrite; a mineral that, like dolomite, is very difficult to manufacture under the kinetic restraints of the laboratory, but is abundant in the real world.

Building on earlier work, but now using varying degrees of pore fluid drainage, the experiments of Olgaard et al. (1995) and Ko et al. (1995) clearly show that under well drained conditions the weakening of the gypsum tends to occur in the early stages of the dehydration reaction (Fig. 8.38). Their experiments were run at varying temperatures (23–150 °C), at confining pressures that mimic free to limited drainage (0.1–200 MPa), and at strain rates $0\ 7 \times 10^{-7}$ to $6 \times 10^{-5}\ s^{-1}$. As more porosity was created by ongoing dehydration there followed a rapid decrease in pore pressure. The experimental peak in pore pressure corresponded to an observed weakening and embrittlement in the gypsum. Under drained conditions this weakening occurred in the first 1 % of the reaction.

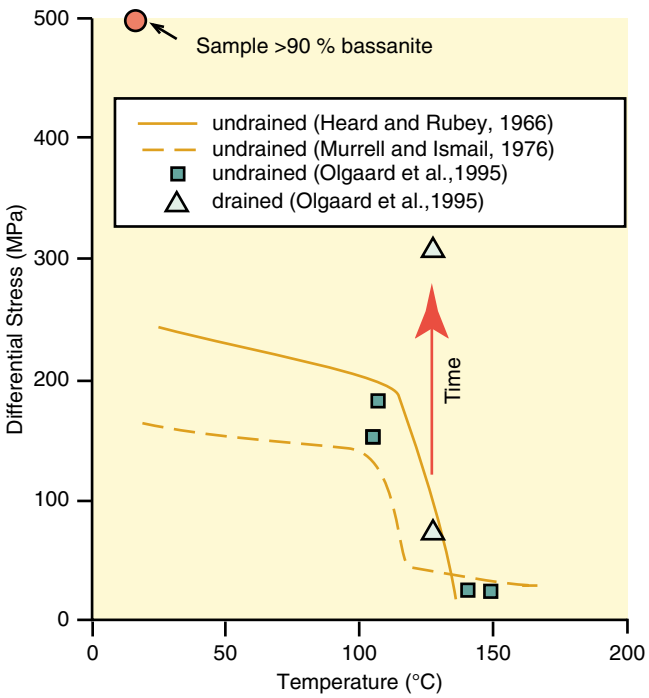

Fig. 8.38 Plot showing differential strength of dehydrating gypsum decreases above 110 °C in undrained conditions where the water of crystallisation cannot freely escape. Under drained conditions there is an initial decrease in differential strength followed by an increase. This is shown by samples at either end of time *arrow* (After Ko et al. 1995)

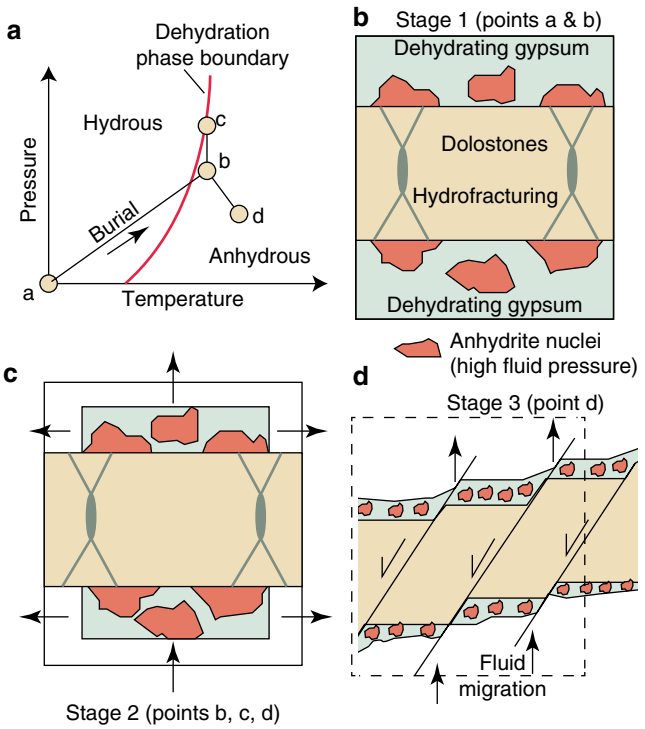

Fig. 8.39 Gypsum dewatering and faulting (After de Paola et al. (2007). (**a**) During burial (increasing pressure and temperature), gypsum dehydration reactivation begins beyond the dehydration phase boundary (indicated by *point b*). At this stage a pressure increase (*point c*) can stop the reaction until further thermal energy is input into the system (further burial) or a pressure decrease (*point d*) can drive the state of the rock further into the anhydrous phase stability field. (**b**) Gypsum dehydration reaction increases fluid pressures, trapped at the gypsum-dolostones interface, promoting hydrofracturing and faulting within the brittle dolostone layers. The permeability increases within the dolostone layers and causes fluid discharge. (**c**) Negative volume change, following fluid expulsion within the dehydrated rocks, which causes vertical thinning and isotropic horizontal extension. (**d**) The superposition of brittle cyclic fracture openings and slip along faults within the dolostones as well as ductile deformation (flowage and boudinage within the gypsum-anhydrite rocks) favour fault-linkage and upward propagation of the fault system within the Triassic Evaporite unit

Ultimate strength was recovered within 3 % of the reaction and ultimately exceeds that of pure gypsum. They concluded that, unless the surrounding rocks had very low permeabilities, the pore pressures during real world dehydration could only equal or exceed lithostatic pressures during the earliest stage of the gypsum dehydration reaction.

Microstructural observations of Ko et al. (1995, 1997) showed that the initial stage of loss of water of crystallisation creates isolated areas of dehydrated gypsum surrounded by new fluid-filled porosity. Excess pore pressures develop as long as this porosity is not interconnected or fluid is produced faster than it can escape through any newly forming interconnected porosity. Under slow fluid leakage conditions an excess pore pressure first develops, which leads to weakening; but this is followed by strengthening (shown by time arrow in Fig. 8.38). The drainage evolution of the various mosaics or networks of dehydrated gypsum within the converting gypsum unit control the timing of the development of minimum strength and maximum pore pressure. While the dewatered regions are isolated, a pore pressure can build up, which, as it becomes more pervasive, weakens the gypsum. But, as the locally dehydrated intervals start to fuse with each other, pore fluids can now flow from one area to another and ultimately escape into the adjacent non-calcium sulphate surrounds. This strengthening of the dewatering gypsum over time marks an internal transition from undrained to drained behaviour.

One of the limitations to this experimental work is that it was conducted using a gypsum sample held in a confining pressure sleeve, such that, once the pore meshwork was connected, the dewatering fluid could "flow away." This relatively easy egress may not reflect the subsurface reality of an anhydrite bed sandwiched between or within an impervious possibly halokinetic halite mass. Such was the case with $CaSO_4$ -filled fractures in the Buntsandstein, where the gypsum-anhydrite conversion was likely later and deeper in the burial cycle (Fig. 8.23; Nollet et al. 2005).

Dewatering gypsum will create characteristic faulting patterns in the various intrasalt and suprasalt beds. These dewatering (burial) related faults exhibit a diverse range of strikes, and can develop under conditions where the regional tectonic stress field is weak or absent (e.g. polygonal faults). De Paola et al. (2007) document a complex system of synsedimentary faults in the Umbria-Marche Apennines (Italy), they are geometrically similar to polygonal fault systems and developed during an early Jurassic extensional episode. This particular fault pattern was created during relatively early burial via gypsum dewatering. It differs from many extensional fault systems in that it lacks the aligned structures that are developed within a classical bimodal conjugate. "Andersonian"[12] set of faults. Rather, faulting is primarily controlled by the development of volumetric instability in Triassic evaporites due to burial dehydration (anhydritisation). Once again, these less predictable structural alignments reinforce a general notion that even shallow-buried evaporites (not just halites but also dewatering gypsums) tend to be "squishy" or fluid-like in their responses to stress (as emphasised in Chap. 6). Adjacent non-evaporite beds tend to behave more competently-brittlely when subject to gravitationally derived stress

The lithological architecture of the Triassic Evaporites (Burano Fm.), comprising interbedded Ca-sulphate layers and dolostones, played a fundamental role in controlling the

[12] Andersonian theory of faulting relates the principal stress axes to faulting and assumes no shearing stress can act at the Earth's surface (air-rock interface). Thus, in terms of the principal stress axes, σ_1 bisects the acute angle between the conjugate shear fractures. σ_2 is defined by the intersection of a pair of conjugate shear fractures, while σ_3 bisects the obtuse angle between the conjugate shear fractures.

deformation processes. Cyclic fluid overpressure build-up/release and the coexistence of brittle and brittle-ductile flow processes led to horizontal isotropic and non-planar extensional strain fields within the dehydrating rock mass, which favoured the development of complex deformation patterns.

During burial (increasing pressure and temperature) and weak gravitationally driven extension, gypsum dehydration reactivation begins beyond the dehydration phase boundary (point B to the right of red line in Fig. 8.30a; De Paola et al. 2007). At this stage, increased pressure (Fig. 8.30a, point C) can stop the reaction until further thermal energy is input into the system (further burial) or there is a decrease in pressure (Fig. 8.30a, point D), which can drive the state of the calcium sulphate bed further into the anhydrous phase stable field. In the initial phases of gypsum dehydration (Fig. 8.30a, point B), increasing fluid pressures, especially in areas adjacent to gypsum-dolostones interfaces, causes patchy mechanical weakening (strength reduction and embrittlement tied to fluid loss in conversion to anhydrite) and so promotes hydrofracturing and faulting within the dolostone layers tied to zones or patches of anhydrite formation in the gypsum (Fig. 8.30b; Stage 1). Brittle deformation within the dolostone units causes an increase in crack porosity and permeability, favouring local fluid pressure reductions, thus driving the state of the gypsum-bearing rocks further into the stability field of the anhydrous assemblage (toward point D in Fig. 8.30a).

Fracture opening and slip along extending faults within the brittle dolostones allow large volumes of fluids to be drained from the dehydrating gypsum layers, via interconnected fracture networks running along pathways of cataclastic fault planes (Fig. 8.30b). Fluid drainage into the fracturing dolomites results in volume contraction of the dehydrating calcium sulphate rocks that is accommodated by vertical thinning and horizontal isotropic extension (Fig. 8.30c, stage 2). Horizontal isotropic extension, counteracting the horizontal shortening, prevents the space compatibility problems arising via volume reduction during dehydration (Fig. 8.30c; as explained in Cartwright and Dewhurst 1998). This state of non-plane strain is accommodated within the composite gypsum-dolostones sequence by mixed deformation processes: flow and boudinage within the ductile gypsum-bearing rocks, and brittle hydrofracturing and faulting within the dolomitic rocks (Fig. 8.30d). Repeated fault reactivation, under transiently increasing fluid pressure conditions, favours fault-linkage and upward propagation of the fault system within the Triassic Evaporites and into the overlying carbonates of the Calcare Massiccio formation (Fig. 8.30d, stage 3). With further reaction, the increase in porosity and permeability makes drainage more efficient and the pulse of excess pore pressure decreases rapidly (Fig. 8.38; Olgaard et al. 1995; Ko et al. 1997).

Thus De Paola et al. (2007) have developed a mechanical model showing that the studied fault patterns developed under a stress field consistent with almost homogeneous stress intensities within the horizontal plane, tending to create polygonal failure patterns. Local relatively-early gypsum dehydration induced strain fields and transient fluid pressure conditions that were dominant over weak regional extensional tectonics. Their findings are relevant to many other areas where complex faulting patterns—including polygonal faults—occur in association with dewatering (pressurised) evaporite or clay-rich sedimentary sequences (Morley et al. 2014).

As well as acting as a lubricant, escaping water of crystallisation can act as a catalyst in dissolution-reprecipitation reactions within saline units subjacent to the dewatering salts such as gypsum, carnallite and polyhalite. So, as buried gypsum dewaters to anhydrite the escaping water is saturated with respect to $CaSO_4$ but undersaturated with respect to other evaporite minerals, possibly including any nearby carbonates (Sass and Ben-Yaakov 1977) and any halite or bittern salts. As such water seeps through the surrounding rocks it can leach minerals to create secondary porosity or bring about mineralogical transformations. Throughflow of such waters has dissolved marine carbonate grains to form anhydrite-filled moulds during Permian brine reflux in the shallow subsurface of the Palo Duro Basin, Texas (Bein and Land 1982).

With complete dewatering, a gypsum bed that is 100 m thick will convert to a 62 m anhydrite bed (Borchert and Muir 1964; p. 133). This releases a total of 48.6 m^3 of water per square metre of cross-sectional area. At 30 °C this volume of $CaSO_4$ -saturated water can dissolve 8.1 m^3 of halite or 54 m^3 of carnallite or convert 81 m^3 of carnallite to sylvite:

$$KMgCl_3 \cdot 6H_2O + 4H_2O \rightarrow KCl + Mg^{2+} + 2Cl^- + 10H_2O$$

Similar fluid rock interactions in the subsurface obviously influence many of the minerals and burial cements we now see in evaporites and adjacent beds. As well as basinal fluids evolved from dissolving evaporites, fluids from dewatering evaporites (especially gypsum and the hydrated bittern salts, such as carnallite) may also exert a substantial influence on the diagenetic and metallogenic evolution of the sediment pile (Chaps. 15 and 16).

Brine-Rock Burial Evolution

Approximately 20 % by volume of most sedimentary basins is made up of pore water of varying salinity, temperature, pressure and ionic proportions. Most fluids stored in the deeper parts of these basins are highly-saline brines and

mostly calcium chloride waters with major cations present in the proportion Na > Ca > Mg (Collins 1975). More than 70 % of oil field waters are either saline (10,000–50,000 mg/l) or brines (>50,000 mg/l). More than 50 % of the world's basinal waters are more saline than seawater (>35,000 mg/l). All formation waters (aka subsurface or basinal waters) in a sedimentary basin originate from meteoric, marine, or hydrothermal sources, or a combination (Moldovanyi and Walter 1992). Mechanisms proposed to account for elevated salinities of subsurface waters compared to most nonevaporitic surface waters include; membrane filtration or reverse chemical osmosis (reviewed by Graf 1982), expulsion of evaporatively concentrated (connate) seawater (Rittenhouse 1967; Carpenter 1978; Stoessell and Moore 1983), halite and potash salt dissolution (e.g., Land and Prezbindowski 1981; Hanor 1988), and meteoric water-rock interactions in sediments over thermal anomalies or in tectonically active areas (Hardie 1990). Most of these alternatives can be rejected as significant factors in hypersaline brine formation (Land et al. 1988; Hanor 1994a, b). It is now generally accepted that subsurface brines more saline than 100,000–120,000 mg/l are mostly related to evaporites via their depositional brine aprons or their subsequent dissolution haloes. Significant modifications to the connate fluid chemistry must occur during burial diagenesis in response to changing solution-mineral equilibria with increasing temperatures.

Several workers have suggested that ionic compositions in all basinal pore water indicate mixtures in varying proportions of (a) brines associated with evaporite residues, (b) head-driven deeply circulating meteoric inflows and (c) compaction waters (Kharaka et al. 1985; Egeberg and Aagaard 1989; Moldowan et al. 1994; Land 1995a, b). For much of the ensuing discussion we concentrate on subsurface brine chemistries associated with connate brines or evaporite dissolution.

Brine Chemistry at Depth

Hanor (1994a, b) studied the chemistry of basinal waters worldwide and divided them into three groups; (a) Na-HCO_3 and Na-acetate waters, typically with TDS <10,000 mg/l, (b) Cl-dominated halite undersaturated waters with salinities between 10,000 and 250,000–300,000 mg/l, these waters include Na-Cl waters and Na-Ca-Cl at higher salinities and, (c) Cl-dominated halite-saturated waters, with salinities typically in excess of 300,000 mg/l. Major cation concentrations show a systematic trend with increasing concentration. Ca and K become increasingly dominant, while Na and pH decrease with increasing brine concentration, especially above 300,000 mg/l (Fig. 8.40). In moderately saline waters, the monovalent cations Na and K have 1:1 slopes when plotted against TDS, while the divalent cations Mg, Ca and Sr show 2:1 slopes. The pH of moderately saline waters lies in the range 7–9, while high salinity brines are in the range 3–4. Most highly concentrated basinal brines are acidic; this has important implications for the leaching and transport of

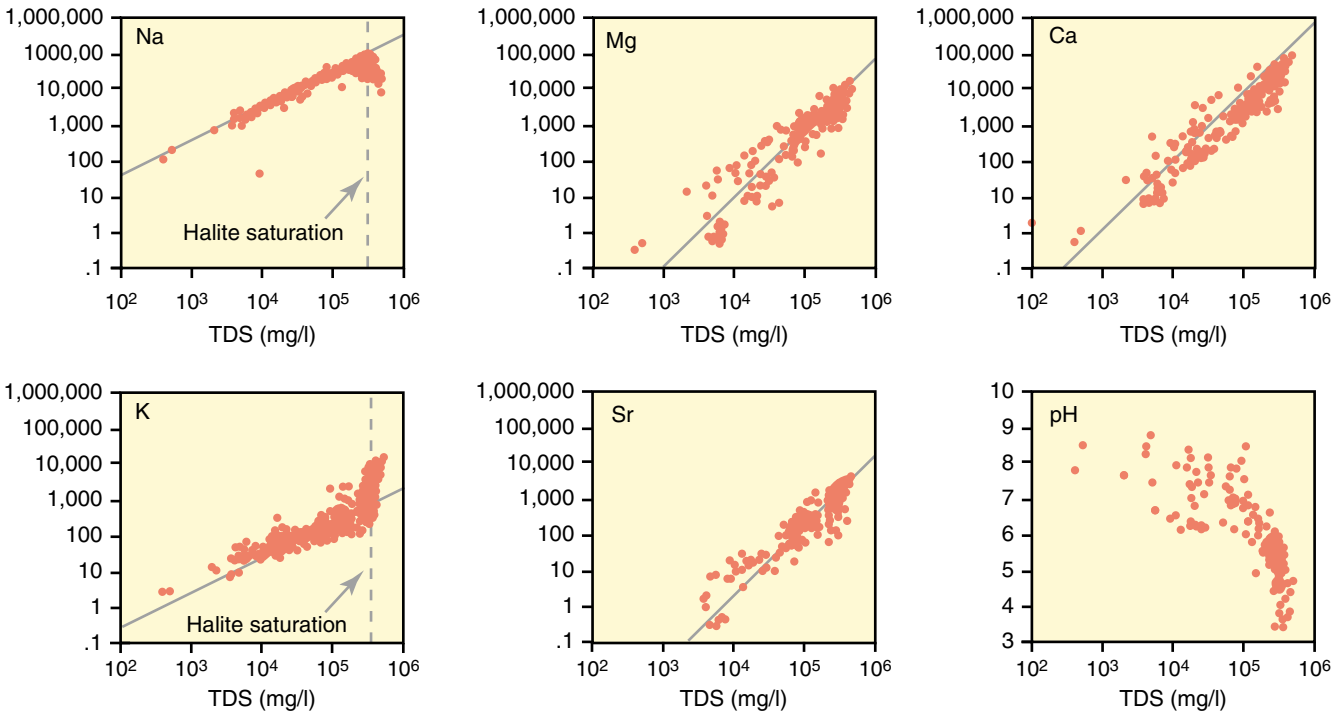

Fig. 8.40 Scatter plots of the covariance of log Na, Mg, Ca, K, Sr and pH with log TDS (total dissolved solids) for typical saline basinal waters worldwide (After Hanor 1994a). Note the 1:1 slopes for Na and K and the 2:1 slopes for the divalent cations. All values, except for pH, are in mg/l

metals in the relatively low temperature range (<200 °C) that typifies sedimentary basins (Warren 2000b).

Well-defined ionic trends with increasing salinity seen in Fig. 8.40 led Hanor (1988, 1994a, b) to suggest that the chemistry of most deep subsurface brine in salt-entraining basins is controlled by the subsurface dissolution of halite and the subsequent buffering of pore water compositions via interactions with multiphase silicate-carbonate mineral assemblages. Dissolution of halite produces a progressively more NaCl-dominated fluid without any systematic increase in K, Ca, Mg and Sr ions, which are supplied by fluid interactions with the adjacent silicate-carbonate assemblages. Such water-rock interactions explain the Na–Ca–Cl brines so common in subsurface brines. These proportions cannot be explained by a simple evaporitic concentration of seawater beyond gypsum saturation and the retention of connate reflux waters. Marine brines precipitating halite contain little or no Ca^{2+} as it has been depleted by $CaCO_3$ and gypsum/anhydrite precipitation (Fig. 2.12). Volumetrically important subsurface reactions capable of modifying connate brines towards higher Ca/(Na + Ca) values include dissolution of anhydrite, albitisation of plagioclase feldspars, and dolomitisation of limestones (Land 1987). Potassium (as well as Ba and perhaps Sr) can come from albitisation or illitisation of K-feldspar, especially in redbed and volcaniclastic sequences.

In terms of anions, the inherently high solubility of dissolving evaporites means they typically supply unbuffered components into pore waters, the most obvious being chlorine and bromine (Ranganathan 1991). Other than halite cement, there is no source of chlorine in nonevaporitic lithologies (except minor hydroxl-bearing minerals such as mica or apatite). Hence, average chlorine content in nonevaporite basins worldwide is only 48,640 mg/l (Br = 155 mg/l), while the average for basins entraining buried salt or their dissolution breccias is 118,392 mg/l (Br = 1,583 mg/l; Worden 1996). Palaeozoic basin brines also show higher average chlorine contents than Mesozoic basins, which are in turn higher than Tertiary basins (Worden 1996). The difference probably reflects the longer time for more pervasive evaporite solution and circulation in the older basins. Worden (1996), like Hanor, concluded that in an evaporite-entraining basin the dissolution of halite is the major control on the chlorine content of subsurface waters.

If dissolution of thick buried salt explains the elevated salinity of deeply buried highly saline basinal brines, then any sediment undergoing burial will ultimately come into contact with these brines. It will experience water-rock diagenetic interactions tied to basinal fluids derived from this dissolving evaporite and these interactions will continue into the later deeper stages of the rock's burial history. The tie of basinal brine chemistry to buried dissolving salt is clearly seen in the pore water chemistry of the deeply buried Permian Gharif Formation in the Ghaba Salt Basin of Oman (Hartmann et al. 2000). The degree of diagenetic overprint varies, depending on burial history. Sandstone at shallow depth (>2,600 m) shows intense dissolution of aluminosilicate and carbonate minerals, combined with minor kaolinite precipitation and compaction, whereas deeply buried sandstone (>2,600 m) is highly compacted and tightly cemented by quartz, carbonate, and sulphate minerals.

The Lower Gharif in the Ghaba Basin consists of coastal-plain siliciclastic rocks passing upward into the marine bioclastic– oolitic Haushi limestone. The Middle Gharif is characterized by fluvial cross-bedded sandstone interbedded with red–brown, mottled siltstones and mudstones containing calcrete and root traces. The top part consists of alluvial-plain mudstone with less calcrete. None of the three formations entrain evaporites. The cementation history in these Gharif sands illustrates what is a typical depth-related set of burial cement stratigraphies for many sedimentary basins.

Eight carbonate cement phases were differentiated in the sands of the Gharif Fm. by Hartmann et al. (2000). In general, the sequence is: calcrete/dolocrete, calcite I/dolomite I and calcite II as consecutive eogenetic phases all predating early quartz I, this is followed by burial diagenetic dolomite II and calcite III/Fe-dolomite/ankerite. Calcrete and dolocrete are present in fluvial sandstone of the Middle and Upper Gharif. Trace amounts of calcite I and dolomite I overgrow reworked caliche nodules. Pore-occluding, poikilitic, brightly luminescent calcite II is present in shallow wells and in the Huqf–Haushi outcrops. Later-formed, patchy poikilitic, brightly luminescent calcite III is restricted to samples from depths of <2,600 m. Dolomite II is present in some wells as small, red-luminescent rhombohedra. Fe-dolomite/ankerite occurs in various amounts (0–27 ‰) as intergranular rhombohedra that fill pores and corrode earlier quartz I and feldspar overgrowths.

Caliche carbonates have $\delta^{18}O$ and $\delta^{13}C$ values from −0.3 to −0.7 and −1.8 to −2.2 ‰, respectively (Fig. 8.41a). Pristine shell material and "whole-rock" shallow-marine Haushi limestone (Lower Gharif) show $\delta^{13}C$ values between 0.5 and 5 ‰ and $\delta^{18}O$ values ranging from −1.6 to −2.6 ‰. The stable-isotope composition of early calcite II ranges from −7 to −10 ‰ and from −19 to −23 ‰ for $\delta^{18}O$ and $\delta^{13}C$, respectively. Calcite III, which formed after calcite II, has $\delta^{18}O$ values of −4 to −9 ‰ and $\delta^{13}C$ values of −2 to −14 ‰. Fe-dolomite/ankerite has $\delta^{18}O$ values ranging from −4 to −9.5 ‰ and $\delta^{13}C$ values of −3 to −11 ‰ (Fig. 8.41a). All these isotopic values of the various cements in these sandstones are consistent with ongoing burial diagenesis in an environment characterised by increasing temperature in the presence of hydrocarbons. The calcite II cements formed from meteoric waters that infiltrated the Gharif sands during the late Triassic Early Jurassic. This was followed by burial and the entry of high salinity pore water from dissolution of

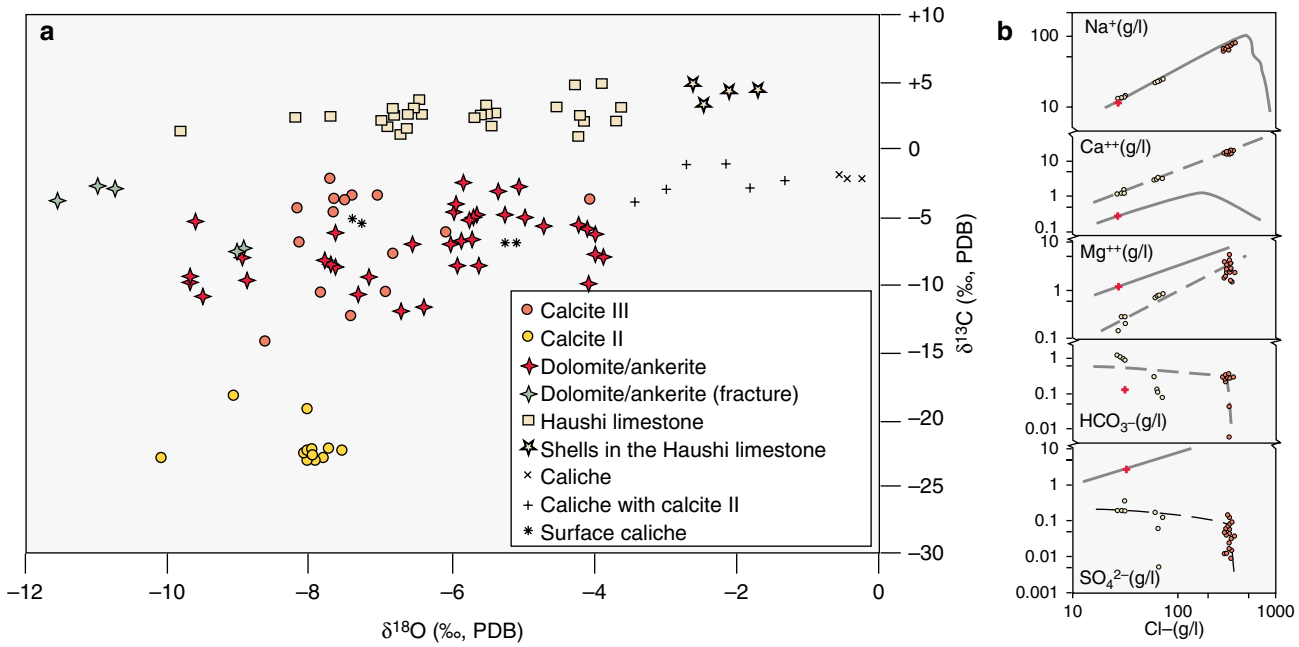

Fig. 8.41 Hydrological signature of the Permian Gharif Formation, Oman. (**a**) Stable isotope signatures of Gharif Formation minerals – see text for explanation of trends. (**b**) Variation in dissolved cations and anions as a function of dissolved chloride in Gharif Formation pore waters. *Light brown circles* represent low-salinity brines influenced by meteoric waters. *Light red circles* indicate highly saline brine samples derived from subsurface dissolution of the Ara Fm. salt. *Dashed lines* represent the present trends between dissolved ions and chloride. *Solid lines* are the seawater evaporation dilution lines from Carpenter (1978). *Crosses* represent the seawater concentration for each dissolved ion (After Hartmann et al. 2000)

the Ara salt. During this time of deeper burial and more saline pore waters the Fe-dolomite and ankerite cements precipitated.

The current pore waters in the Gharif are Na–Cl brines with various amounts of Ca, Mg, SO_4, and HCO_3 (Fig. 8.41b; Hartmann et al. 2000). Dissolved Na increases with increasing Cl along the seawater evaporation–dilution curve (Carpenter 1978), confirming dissolving halite as the main ion source to the present saline brines. Values for Mg and Ca also increase, but values for Mg are depleted and those of Ca are enriched relative to the seawater evaporation–dilution curves, imply ongoing rock-fluid interactions. In addition, all brines are depleted in sulphate, but mostly enriched in bicarbonate compared to seawater, perhaps reflecting sulphate reduction processes (Fig. 8.41b).

With time and burial the carbonate minerals precipitating from the evolving pore waters of the Gharif Fm. in the Ghaba Salt Basin evolved from depositional pore waters of low salinity (<50 g/l) with $\delta^{18}O_{SMOW}$ values of −0.5 to −1.5 ‰ in the more marine Lower Gharif to 2 ‰ in the arid fluvial Middle and Upper Gharif (Fig. 8.41b). During subsequent shallow burial (Late Triassic to Early Jurassic), the pore water in the Gharif members changed to high-salinity brines (≈180 g/l) with $\delta^{18}O_{SMOW}$ values of −4 to −7 ‰. The current highly saline, deep-burial pore water with a heavy $\delta^{18}O$ signature (0.5–5 ‰) is the result of rockwater interactions in what is a rock-dominated system. Thus present porewater compositions in the deeper parts of the basin, as indicated by both isotopic and ionic compositions, mainly reflect interaction with pore fluids derived by deeper subsurface dissolution of underlying Neoproterozoic Ara Group evaporites. This process is coupled to the precipitation of late diagenetic carbonates and sulphates. Subsequent recharge of isotopically light surface water was driven by inversion along the uplifted southeastern basin margin and was driven by obduction of the Oman Mountains in the Late Cretaceous and the creation of the Huqf-Haushi Arch (Figs. 10.8b and 10.67a).

Ceriani et al. (2002) documented a similar post-rift burial infiltration of saline brines in non-evaporitic sediments deposited in an evaporite-floored aborted rift. They studied the evolution of quartz overgrowths and burial dolomite cements in the Upper Sarir Sandstone (Lower Cretaceous) in Abu Attifel oilfield in the Sirt Basin, Libya. Fluid inclusions along the grain-overgrowth boundary of early quartz overgrowths yield homogenization temperatures from 130 to 141 °C and salinities between seawater and freshwater. Aqueous fluid inclusions in later quartz overgrowths have homogenization temperatures from 114° to 129 °C and salinities between 18 and 21 wt% NaCl equivalent. Fluid inclusions in adjacent dolomite burial cements have variable homogenization temperatures (120–141 °C) and high salinities (20–22 wt% NaCl equivalent).

This cooling trend in homogenization temperatures of fluid inclusions, tied to increasingly saline pore waters, is the result of quartz cements first forming in a bath of hot, low-salinity, connate fluids at a burial depth around 2.5 km. These hot fluids were flowing through the Sarir sands, driven by the increased heat flow related to regional rifting of the Sirt Basin. Later quartz overgrowths and burial dolomite cements precipitated during a time of regional cooling tied to the end of the rifting. Authigenesis occurred at a depth of around 3.8 km and was driven by the cooling of pore fluids concurrent with the invasion of dense saline fluids from subadjacent areas of salt deposition and brine reflux. The most likely brine source was a reflux plume from a thick section of Eocene evaporites, although dissolution of subadjacent Cretaceous salts cannot be entirely ruled out (Ceriani et al. 2002). A similar evaporite-associated reflux model was used to explain cool pore brines associated with U-rich dolomitisation and subsequent anhydrite precipitation and replacement in the lower Krider Member of the Nolans Limestone in the Hugoton Embayment in Kansas (Luczaj and Goldstein 2000).

Worldwide, the ionic proportions in a subsurface saline brine can reflect either the original make-up of the waters in the pores at the time of deposition (such as connate waters in inclusions in chevron halite in the Permian Nippewalla Group; Fig. 2.42), or the effects on ongoing subsurface fluid flow and rock reactions changing the original depositional proportions (as in the salt-dissolution-derived Na-Cl waters of the Gharif Formation).

With evaporite-associated subsurface waters there is still considerable debate about the role of residual evaporated seawater (=connate brine) in the chemistry of basinal brine versus dissolving buried evaporites (Moldovanyi and Walter 1992). In part, the debate centres on the ability of thick evaporite sections to store connate brine from the time of deposition due to the early creation of evaporite seals by early porosity loss. Most halite-dominated sequences are tight by 100–500 m burial. A "connate" versus "water-rock interaction" argument is made more difficult by requisite hydrology needed to precipitate and preserve a thick, near monomineralic, evaporite sequence. Significant volumes of salts can only accumulate where ongoing brine reflux drives the associated flux of considerable volumes of brine into the adjacent underlying sediments where it disperses into the regional flow system (as in the Sarir Sandstone).

This is the concept of brine disposal, brine leakage, brine reflux or the brine curtain as enumerated by Holser (1979), Sanford and Wood (1991), Rosen (1994) and Warren (1999), respectively. It is summarised in Chaps. 2 and 5. The drawdown hydrology that typified the depositional hydrology of most ancient evaporite settings means that substantial volumes of relatively unmodified but dense pulses of concentrated seawater (=connate) or continental brines can be drawn into and stored in sediments about and beneath the evaporite bed and its brine curtain (Fig. 2.75). This refluxed connate brine could be stored in subadjacent continental strata (e.g. fluvial or eolian sediments) as well as in a marine host and can be released later during burial diagenesis and compactional flushing. The question becomes not whether connate pore waters were present beneath and within a thick evaporite bed, but when were these waters flushed from the system and how much water rock interaction took place during and after that flushing.

One reason for confusion between connate and dissolution derived subsurface waters is that some older studies did not distinguish between brine samples collected from porous beds encased within an evaporite sequence and those pore waters collected in adjacent more permeable sediments located above and below an evaporite bed. When this distinction is made, those brines collected within sediments with relict pore fluids encased by a bedded salt unit (with chevrons) are typically found to be connate brines, while those outside the evaporite succession are more likely to reflect chemistries related to salt dissolution and ongoing water rock interaction. For example brines within an evaporite aquitard and a nearby deep brine aquifer in the Palo Duro Basin of West Texas have $\delta^{37}Cl$ values of −0.4 to 0.0 ‰ (Fig. 2.41b; Eastoe et al. 1999). They were not generated by dissolution of halite.

Another possible confusion in terms of a meteoric versus dissolution origin of diagenetic cements in carbonates in evaporite-entraining basins lies in the possible misinterpretation of oxygen isotope signatures of some burial cements precipitated from hypersaline pore waters. The work of Dickson et al. (2001) on carbonates of the Central Basin Platform West Texas underlines this dilemma. Pennsylvanian to Lower Permian cyclic platform carbonates from the Southwest Andrews area of West Texas are now 3 km below the landsurface. Isolated samples of brachiopod shell, zones of calcite cement, and saddle dolomite from limestone cores of the Southwest Andrews oilfields were analysed isotopically in order to determine if: (1) diagenesis was dominated by early, meteoric processes, as suggested by earlier bulk rock isotope studies, (2) whether significant burial diagenesis occurred in hypersaline waters, and (3) whether most burial cements are allochthonous or internally derived.

Bulk isotopic analyses of the limestones show systematic variation in $\delta^{13}C$ and $\delta^{18}O$ that historically have been interpreted according to a geochemical model tied to length of subaerial exposure and stratigraphic position (Fig. 8.42; Dickson et al. 2001). Chemically zoned calcite cements show four growth stages. Stage 1 and 2 cements have average $\delta^{13}C$ values of −4.6 ‰ and average $\delta^{18}O$ of −5.0 ‰, and most are thought to have precipitated early during subaerial exposure, while bathed in meteoric waters. A few stage 1 cements with average $\delta^{13}C$ values of −4.7 ‰ and $\delta^{18}O$ of −1.4 ‰ apparently precipitated below the sediment surface from modified seawater in a sulphate reduction zone.

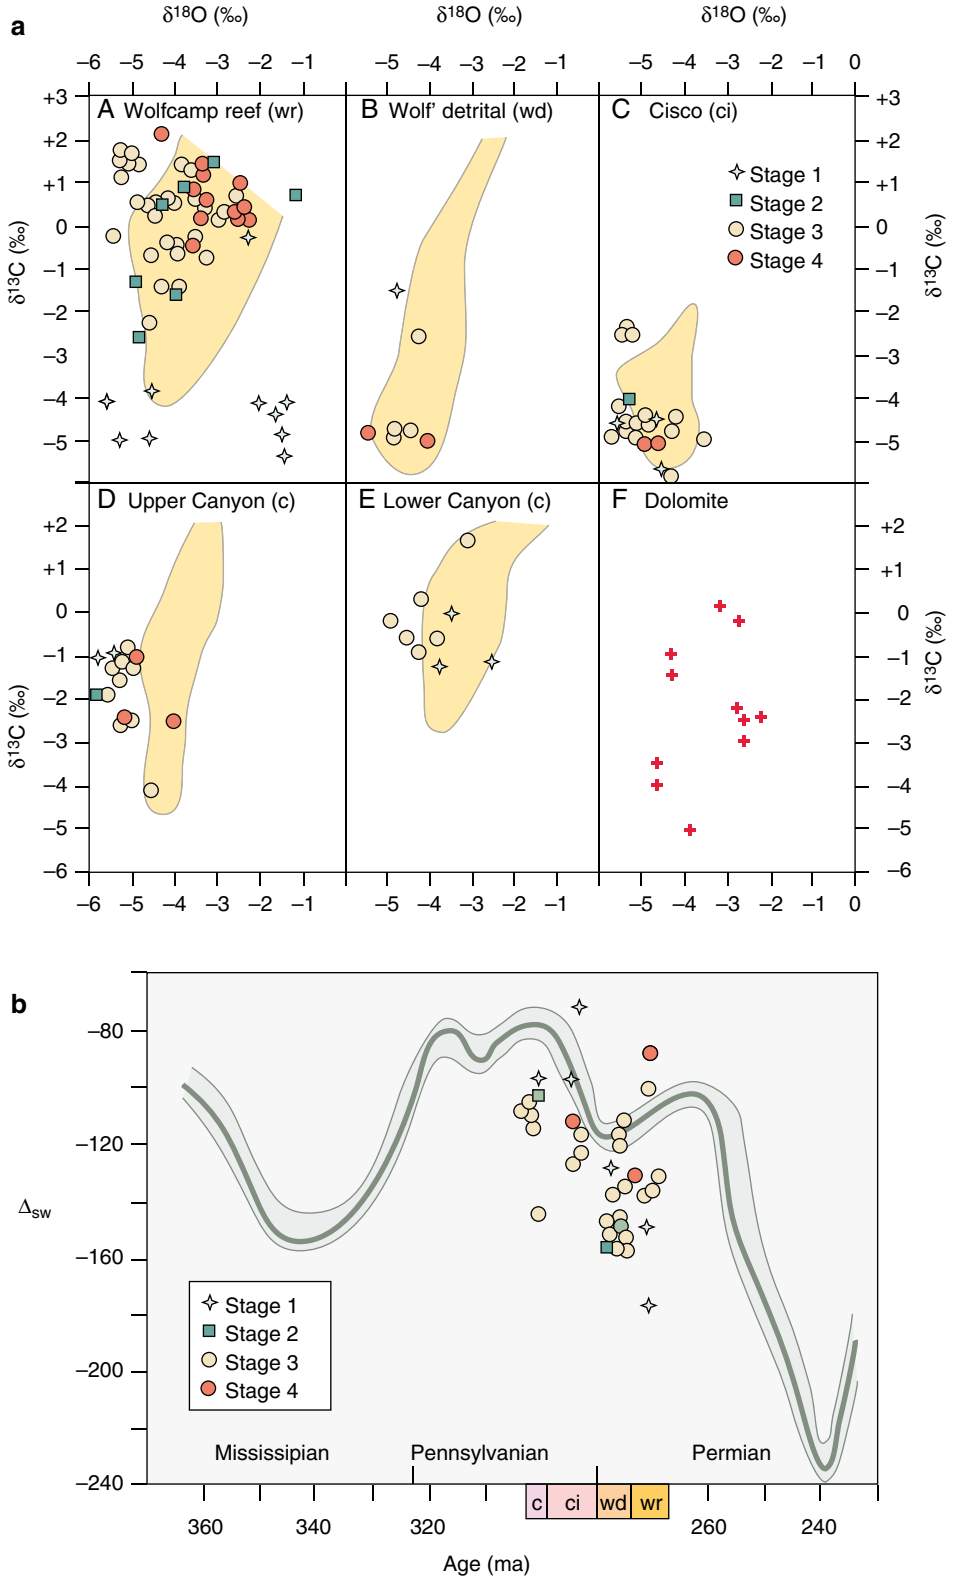

Fig. 8.42 Isotopes from the Palaeozoic carbonate platform of the southwest Andrews area, West Texas (After Dickson et al. 2001). (**a**) Carbon–oxygen isotope scatter-plots (A–E) of calcite cement crystals from Wells V7, X1, and Parker "B" 12. The cements are zoned and are grouped into four stages, stage 1 being the oldest and stage 4 being the youngest. Plots are listed by stratigraphic occurrence (*a*) Wolfcampian reef, (*b*) Wolfcampian detrital, (*c*) Cisco, (*d*) Upper Canyon, and (*e*) Lower Canyon intervals, while (F) is a carbon–oxygen isotope scatter plot of data from individual crystals of saddle dolomite in all stratigraphic intervals, except the Wolfcampian detrital. (**b**) $^{87}Sr/^{86}Sr$ data from selected separated cement stages (1–4) of the same calcite crystals as in (**a**) plotted on the late Palaeozoic seawater strontium isotope curve and its 76 % confidence band (*grey*; curve from Denison et al. 1998). Δ_{SW} is defined as:

$$\Delta_{SW} = \left({}^{87}Sr/{}^{86}Sr_{unknown} - {}^{87}Sr/{}^{86}Sr_{modern\,seawater} \right) \times 10^5$$

But stage 3 and 4 calcite cements precipitated later, thin sections show they are postcompaction and now make up to 25 % of the total rock volume. They have $\delta^{13}C$ values (−0.2 to −4.4 ‰) that vary according to stratigraphic position, and are similar to bulk rock samples of the host limestone. Their $\delta^{13}C$ values indicate these later cements are locally derived via dissolution of adjacent strata. $\delta^{18}O$ values of stage 3 and 4 cements (−5.5 to −3.5 ‰) are isotopically indistinguishable from the stage 1 and 2 cements precipitated from meteoric water (Fig. 8.42a). The expected decrease in $\delta^{18}O$ expected from elevated temperatures during burial (the present formation temperature is ≈55 °C) has been negated by their precipitation from late Permian hypersaline brine with $\delta^{18}O$ values of +5 ‰. These stage 3 and 4 cements are composed of sparry calcites and saddle dolomites with $^{87}Sr/^{86}Sr$ values that are lower than $^{87}Sr/^{86}Sr$ values for contemporaneous Permian marine carbonate (≈0.70830; (Fig. 8.42b). This indicates incorporation of Sr with low $^{87}Sr/^{86}Sr$ values (0.70672–0.70682), which were derived from the same late Permian hypersaline brines. Entry into normal marine carbonates was driven by ongoing brine reflux during the deposition of the overlying Permian evaporites.

Dickson et al. (2001) went on to conclude that the buried platform carbonates of Southwest Andrews area have several diagenetic features, all driven by the creation of a reflux curtain, which are probably more common as diagenetic overprints in ancient evaporite-associated limestones than previously recognized. They note: (1) Burial cements have $\delta^{18}O$ values similar to meteoric cements yet they were precipitated from later hypersaline pore waters with $\delta^{18}O$ values some 5 ‰ greater than contemporary seawater. (2) Deep-burial cements have $\delta^{13}C$ values similar to the bulk rock because carbon was derived from pressure dissolution of nearby carbonate. (3) Bulk-rock isotope values are characteristic of marine limestones subjected to meteoric diagenesis, yet they have suffered substantial deep burial diagenesis under the influence of hypersaline waters.

The chemical and isotopic compositions of highly saline water in evaporite-entraining basins complicate simple notions of meteoric versus normal-marine burial diagenesis, especially in intervals close to the dissolving evaporites. Most pore waters are not simply derived during the congruent dissolution of halite beds, nor are they only connate brines (Land 1995a; Levet et al. 2002). Na and Cl dominate the ionic composition of most sedimentary brines, even in basins that lack preserved evaporites, with the next most abundant cation being Ca and the next most abundant anion Br. This is not the ionic hierarchy of seawater, where the next most abundant cation is Mg and the next most abundant anion is SO_4, hence most subsurface waters in a sedimentary basin are no longer connate outside of sediments/ brine inclusions encased in salt that preserve primary chevrons.

Today, the three mostly commonly offered explanations for the formation of Na-Ca-Cl basinal brines are (Land 1995b): (1) preservation of seawater-derived brines that have precipitated halite (raises the Br/Cl ratio) as well as participated in dolomitisation and $CaSO_4$ precipitation (exchanges Mg for Ca and removes calcium sulphate from the brine), (2) subsurface halite dissolution accompanied by salt recrystallisation (partitions bromide into the brine) in association with the dissolution of detrital anorthite (component of detrital plagioclase) - this mechanism may include the deep circulation of meteoric water or escaping compactional waters from thick shale sequences, and (3) reverse osmosis (shale membrane filtration) driven by pressure resulting from compaction, whereby water molecules, uncharged species and small and univalent cations preferentially pass through the shale, so creating calcium, chloride and bromine rich residual brines.

Some or all of the mechanisms may be acting concurrently in most sedimentary basins either as time sequential overprints on the same strata or in different areas and depths in the same basin (Demir and Seyler 1999). It means that when compared with water stored in the same strata, but from other areas of the basin, subsurface formation waters may show differences in salinity, element content and/or isotopic composition on a local scale of hundreds of meters or across kilometres. Therefore, using geochemical information obtained from one regional part of the basin for the reconstruction or modelling of the fluid evolution in the entire sedimentary basin can be highly problematic (Lüders et al. 2010).

Effects and Indications of Water-Salt Interactions

This chapter has shown that dense subsurface waters derived from dissolving evaporites, tend to move through permeable sediments or along permeable conduits such as faults and fractures. They drive various diagenetic processes and flow is typically maintained by density gradients (indicated by thermal or salinity changes). Ongoing diagenesis (or rock-fluid interaction) in nonevaporitic strata also means ionic concentrations of most basin waters are buffered and controlled by the solubility of minerals in the sediment. The low solubility of the common cement minerals such as calcite and quartz means large fluxes of pore waters through nonevaporite lithologies are required to move and precipitate significant volumes of such cements (Bjørlykke and Gran 1994). In contrast, in the temperature range of sedimentary basins, little water flows through the interior of a salt bed or allochthon. But inherently high solubility means that when the edges of a dissolving evaporite unit are flushed by basinal water crossflows, the dissolving salt contributes large

volumes of ions to adjacent more permeable sediments. Even so, most basin brines, even in intervals adjacent to the dissolving evaporite, have salinities well below halite saturation (350–400 g/l). A possible exception is the Michigan Basin where some of the higher salinity basinal brines are clearly halite-buffered (Wilson and Long 1993).

Solution of buried evaporites explains why: (a) salinities increase in a systematic almost linear fashion with depth in sedimentary basins with bedded evaporites near the base of the sequence (Dickey 1979); (b) salinity around active salt stems/domes indicates the advective flow of waters up along the stem and then horizontally into overlying beds (Hanor 1988; Bray and Hanor 1990); (c) pore waters in sediments adjacent to a dissolving halite-dominated section lack sulphate, while evaporite sections with a greater proportion of gypsum/anhydrite can generate sulphate waters (Pluta and Zuber 1995); (d) in halokinetic provinces such as the central graben of the North Sea the salinity of the pore waters correlates better with the inverse distance to the nearest evaporite mass than it does to burial depth (Gran et al. 1992); and (e) why there is no significant increases in salinity with depth in the northern North Sea (59–62°N), which is an area with no known evaporites (Bjørlykke and Gran 1994).

The total volume of salts in the world's oceans is about 2.2×10^7 km^3 and there is about the same amount of Cl in the world's sedimentary basins (salts and porewaters) as there is Cl in the modern ocean (Borchert and Muir 1964). This means that of all the major sediment types, evaporites have the shortest mass half ages estimated to be $\approx2\times10^8$ years (Garrels and Mackenzie 1981). Hence, there are no significant potash or thick halite deposits preserved that are older than Neoproterozoic (Warren 2000c, 2010). Evaporite dissolution throughout burial and metamorphism and the associated discharge of Na-Cl rich brines into the basin's subsurface waters, and ultimately to the ocean, explains much of the short mass residence time for chloride. For the same reasons, the residence time for Cl in the world's oceans is the longest of any element and is of the same order ($\approx2.2\times10^8$ years) as halite's mass half-life (Land 1995a).

Hence, the chlorinity of the Precambrian oceans could not be more than around 50 % different from today. It also means that when large ancient basinwide salt basins rapidly accumulated their salts via drawdown, they could have substantially altered oceanic salinity. For example, the Permian Zechstein evaporites of northwest Europe, with a volume of 2.4×10^6 km^3, is equivalent to some 10 % of the volume of the current oceanic reservoir.

High concentrations of the ions from dissolution of buried salts typically indicate effective diffusive or advective transport of the ions from the salt-sediment contact and concentrations usually decrease further away from salt beds or domes. Steep gradients or abrupt changes in subsurface salinity, rather than gradual changes, typically indicate limited advective mixing of pore water across a permeability barrier (Bjørlykke and Gran 1994). Near a subsurface evaporite unit the chemical composition of the pore water concentrations are high and can approach equilibrium with the major evaporite minerals (typically halite or anhydrite). Burial cements can precipitate in pores in this zone when saturation is reached. The precipitation of evaporitic burial cements is even more likely when subsurface waters of differing salinities and compositions are mixed (Chap. 2; Sullivan et al. 1994).

Subsurface halite-dominated sequences dissolve in two ways; by incongruent[13] or congruent dissolution. Incongruent dissolution occurs typically at low water rock ratios, whereby the halite recrystallises as more soluble components are lost to adjacent pore fluids. For example, when halite recrystallises in the presence of waters with a bromine content less than that of the original salt-precipitating (connate) water, it will become bromine depleted. At the same time the pore waters become relatively enriched in bromine, supplied by the rupture and dispersion of bromine-enriched connate fluid inclusions during the recrystallisation process. Congruent dissolution is the total or bulk dissolution of salt via through-flushing basinal brines. It forms subsurface Na-Cl brines with high chlorine contents and higher Br/Cl ratios compared to nonevaporitic subsurface waters (Worden 1996).

Congruent dissolution of potassium-rich bittern salts is an even more effective means of creating-Br enriched hypersaline waters as minerals like sylvite entrain order-of-magnitude higher levels of bromine compared to sedimentary halite. Congruent or incongruent dissolution of K-salts leads to waters that are bromine-enriched relative to evaporated seawater (e.g. Fig. 2.33). Hanor (1994a) proposed that K-salt dissolution explained the bromine enrichment seen in many basinal brines in sedimentary basins with buried evaporites.

Incongruent dissolution is used to explain the bromine depletion of recrystallised Jurassic halite remaining in diapir crests in the Gulf of Mexico (Stoessell and Carpenter 1986) and is thought to be an important process in regions of salt flow and deformation worldwide (Land et al. 1995, 1988). In the Champion-Klepac #1 well in the Gulf of Mexico, sylvite occurs atop a thick halokinetic halite succession at the top of the diapiric Jurassic Louann Salt (Fig. 8.43; Land et al. 1995; Land 1995a, b). The well recovered some 150 m of salt, which is underlain by more than another kilometre of salt. The bittern sequence lacks $MgSO_4$ salts, giving a mineralogy that, according to Hardie (1990), is a prime candidate for a

[13] Incongruent dissolution of a mineral occurs via decomposition or reaction in the presence of a liquid, converting one solid phase into another solid, e.g. the conversion of orthoclase to kaolinite or carnallite to sylvite. It may not involve porosity creation.

Congruent dissolution describes the transition from a solid substance to a liquid of the same composition. By definition it involves a stage of porosity creation.

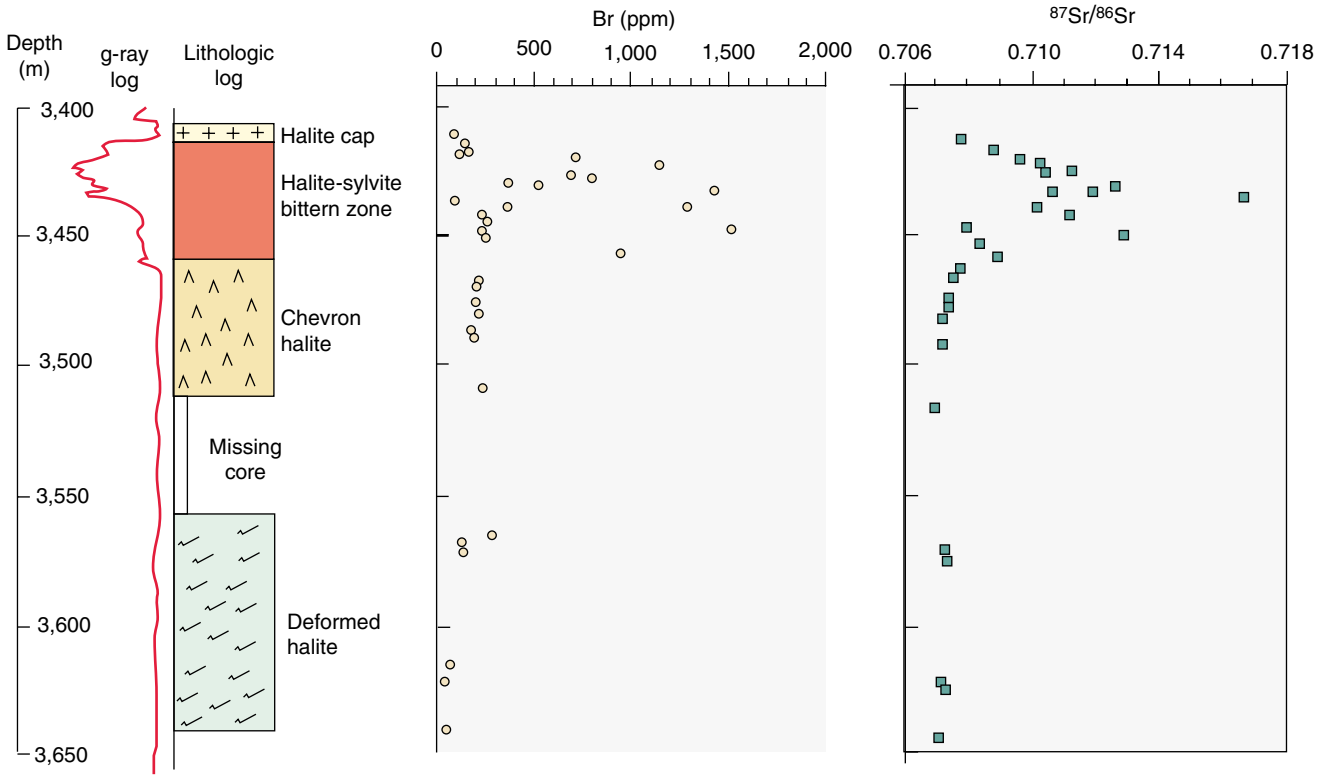

Fig. 8.43 Gamma-ray log, lithologic log, Br concentration and $^{87}Sr/^{86}Sr$ ratio in whole rock samples from the cored interval through the Louann Salt in the Champion-Klepac #1 well (After Land et al. 1995). The well was drilled to a total depth of 4,800 m. Based on the monotonous gamma log, pure halite, at least 1,050 m thick, underlies the cored interval

nonmarine, possibly hydrothermal, brine source, or perhaps indicates evaporation of a Jurassic seawater with ionic proportions different from today (Fig. 2.45).

Alternatively, Land et al. (op. cit.) argue the sylvite is the result of incongruent halite -bittern solution. The present bittern zone, encased in recrystallised halite, is interpreted to be a diagenetically modified "fractionated residue" created during the dissolution of more soluble marine bittern phases, such as carnallite, that were once present along with the sylvite. Sylvite is less soluble in halite-saturated subsurface waters than other bittern salts, which were primary coprecipitates (kieserite, epsomite, carnallite, etc; see Figs. 2.15 and 2.16). Incongruent formation of recrystallised halite and the associated accumulation of the sylvite residue supplied Mg, Br and SO_4 to the escaping pore brines.

Bromine values from deformed halite lower in the Klepac core can be used to argue that incongruent halite dissolution and recrystallisation during halokinesis can supply bromine to escaping pore fluids. Br values in the primary halite chevron-dominated succession beneath the bittern succession are uniform and centred around 200 ppm (range 170–234 ppm). This fits into the range of typical marine values (Holser 1979). Values in the deformed salt are much lower, averaging 110 ppm and decreasing to values of 29–60 ppm in the lower portions of the core. Did the bromine escape during incongruent recrystallisation of the flowing salt, or was the halite reworked and recrystallised at the time of deposition? Resolution hinges on an improved understanding of how flowing salt recrystallises (Fig. 6.5). Over a time frame of millions of years can the outer portions of a thick flowing salt periodically pressurise and leak fluid, or is the flow mechanism purely one of localised halite recrystallisation, pressure solution and edge dissolution within a relatively closed hydrology? At the present time we simply do not have the answer.

Crustal Cycling of Brines?

Cratonic or shield brines, which are ubiquitous hypersaline waters in open faults and fractures at depths >1 km in Precambrian rocks around the world, are among the most enigmatic of all crustal fluids with respect to their age and origin (Bottomley et al. 2002). Not only do shield brines have very high salinities (up to 300 g/l), which are comparable to sedimentary formation brines in evaporite-floored basins, their chemical compositions are of the Ca-Cl type and their O and H isotopic compositions plot well above the global meteoric water line in $\delta^{18}O$ versus $\delta^{2}H$ plot space (i.e., they are depleted in ^{18}O or enriched in ^{2}H relative to meteoric water). Arguments for both in situ water-rock interactions (Frape et al. 1984), and ancient, concentrated marine sources have been presented to explain their compositions and

widespread occurrences (Bottomley et al. 1994, 1999) and to model per descendum flow paths for some types of shield-hosted ore deposits (e.g. Mernagh et al. 1994).

Bromine elevation in a pore water in a sedimentary host is readily explained by the subsurface dissolution of the more saline evaporite salts, but saline Na-Ca-Cl type groundwaters and brines also occur in deep mines over extensive areas of the Canadian Precambrian Shield. These waters have elevated Br/Cl ratios which imply the chlorinity of these waters was derived from the deep infiltration of residual evaporitic brines, perhaps as remnants of the great marine/hypersaline apron that typify strata of the Palaeozoic era in this region (Bottomley et al. 1994, 1999). Boron concentrations in these waters are generally low ($<\approx 2$ mg/l) relative to seawater or to Alberta Basin Devonian formation waters. However, the $^{11}B/^{10}B$ ratios of these waters are significantly greater than the average value for continental crustal rocks. Moreover, Bottomley et al. argue that the boron isotopic ratios generally trend to higher values with increasing chlorinity, which supports the conclusion from the Br-Cl relationship that most of the chloride in these shield brines is of marine origin, rather than a product of water/basement rock interactions. In a subsequent paper Bottomley et al. (2002) used ^{129}I measurement to determine the minimum age of brines in basement fractures in the Con gold mine in Yellowknife (Northwest Territories), and found the brines are at least Cretaceous and probably Devonian. He concludes a Pleistocene age and cryogenic origin is impossible.

Seawater freezing was proposed by Herut et al. (1990) and Starinsky and Katz (2003) as an alternative explanation for the saline chemistry of Canadian Shield brines (Fig. 8.44). Based on minerals present in salt lakes in Antarctica such as Lake Bonney and Vanda Lake, we know that seawater freezing can form various sodium and magnesium salts and high salinity brines. Thick beds of mirabilite occur on the McMurdo Ice Shelf. From experiment, we know that when seawater freezes at −1.9 °C, a small amount of calcium carbonate is the first salt to drop out, usually as aragonite. Next, sodium sulphate

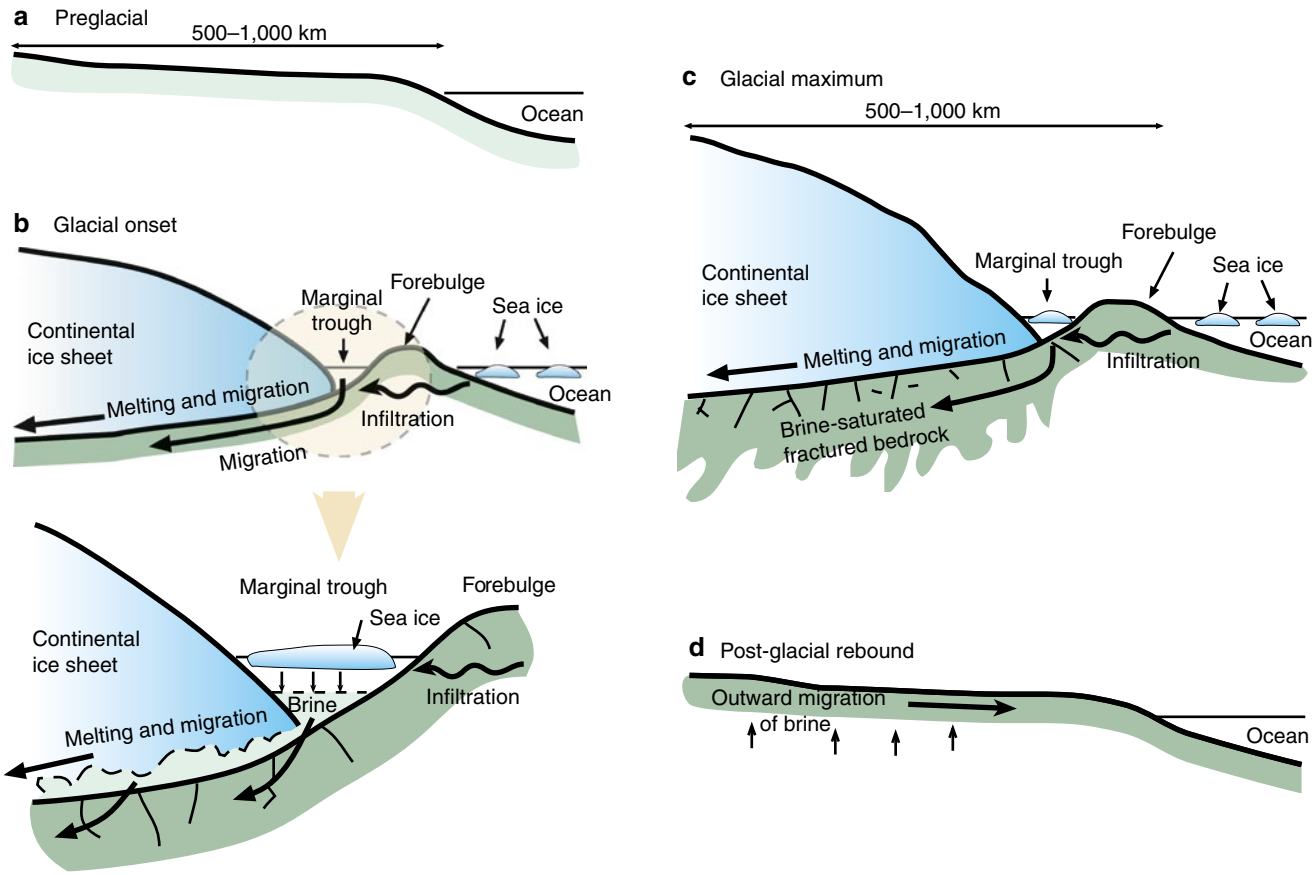

Fig. 8.44 Isostatic and hydrological evolution of a marine-cryogenic basin: (**a**) Continent-ocean boundary before the onset of a glacial cycle. (**b**) An ice sheet develops on the continent, depressing the crust underneath and forming a forebulge along the coast. Seawater infiltrates into the marginal trough between the ice edge and the forebulge and sea ice crystallizes on its surface. The resultant brine sinks to the bottom and infiltrates the underlying sediments and rocks via cracks and shear zones and by non-equilibrium melting of the ice sheet base. Then, it migrates inland, along the inclined ice-rock contact, towards the centre of the depression. Loss of brine from the trench is compensated by fresh seawater flow through the forebulge. (**c**) During the glacial maximum the basement rocks below the ice sheet become saturated with brine. (**d**) Increased melt water head developing during glacial decline, accompanied by postglacial lithospheric rebound, drive the brines outwards from the centre of the glaciostatic depression to their present sites (After Starinsky and Katz 2003)

precipitates as mirabilite at −8.2 °C, sodium chloride as hydrohalite ($NaCl{\cdot}2H_2O$) at −22.9 °C, and then sylvite + $MgCl_2{\cdot}12H_2O$ at −36° (Nelson and Thompson 1954). At −54 °C this cryogenic sequence of salts ultimately produces a calcium chloride brine slurry that precipitates antarcticite ($CaCl_2{\cdot}6H_2O$). One of the few places in the world where this mineral occurs naturally is in a brine lake known as the Don Juan Pond in the Dry Valleys (Wright Valley) of Antarctica, where the TDS of the bottom brine can exceed 500 kg/m^3 (Torii and Ossaka 1965).

Up to the point of halite precipitation, seawater freezing has the same effect on chlorine-bromine relationships in residual brines as solar-driven evaporation. So, seawater freezing beneath thick ice sheets may be an important process controlling the composition of formation waters seeping into fractures and cracks in sub-glacial hard rock sequences. However, recent work on the origin of the various salts in Antarctic salt lakes has shown that, while the mirabilite in Lake Bonney and Vanda Lake are derived by seawater freezing, the antarcticite in Don Juan Pond may not be. Rather, it formed by freezing of a resurgent brine that was created by water-rock interactions in a deeply circulated groundwater moving through fractures within a granite host (Takamatsu et al. 1998).

The influence of glaciation in driving cryogenic brines into fractures below the icesheet is now well documented in polar shield regions. In temperate regions that were covered by glacial ice in the Late Pleistocene periodic ice sheet loading can also influence the direction and volume of deep meteoric or hypogene waters in a sedimentary basin. In a study of brine springs discharging from Devonian carbonates of the Western Canada Sedimentary Basin, Grasby and Chen (2005) concluded that spring waters possessed a distinct water chemistry, compared to subsurface brines in laterally equivalent units deeper in the basin (Fig. 8.45).

Deep-basin brines on the Devonian strata in the Western Canadian Sedimentary Basin have Na/Cl molar ratios typically <0.8, which is related to water-rock interaction buffering Na. In contrast, brine springs have Na/Cl molar ratios close to one, which is again indicative of halite dissolution, as are their Br/ Cl ratios but they are different proportions to the deep subsurface brines, with the southern Saskatchewan brines occupying an intermediate position (Fig. 8.45a). Grasby and Chen (2005) documented a progressive shift in Na/Cl molar ratios and Br/Cl ratios from deep-basin (connate) brines with an altered seawater signature, to waters near the edge of the basin with a signature of dissolved evaporites (Fig. 8.45b). This trend indicates that the model for cryogenic ice-forced formation of shield brines, as documented by Starinsky and Katz (2003), does not directly apply to the pore waters of the WCSB.

But, stable isotope data suggest that the waters discharging in the brine springs originated as Pleistocene meltwater. These waters are interpreted to originate as an influx of sub-glacial meltwater driven by ice-load as it induced a reversal of the basin-scale artesian flow system (Fig. 8.46). Esker distribution shows a notable relationship between shield and

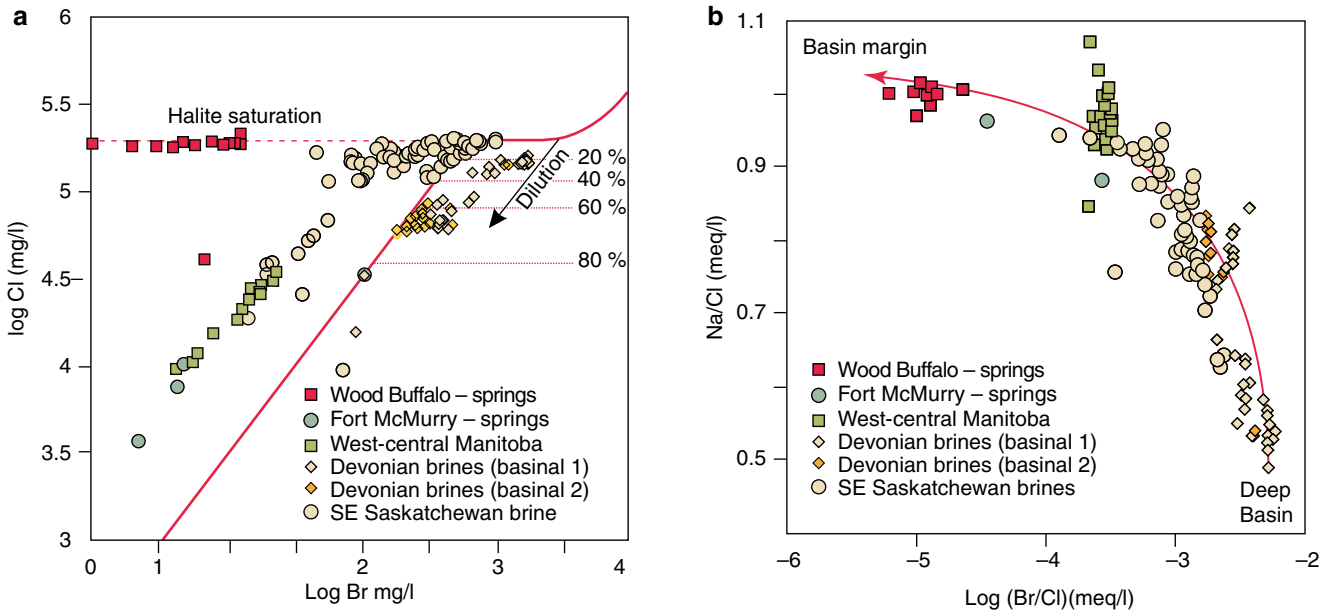

Fig. 8.45 Brine chemistry in West Canadian Sedimentary Basin. Fig. 8.46 Glacial-induced flow reversal in the West Canada Sedimentary Basin. (**a**) Regional map of till thickness – *orange line* indicates cross section position illustrated in **b**. (**b**) Schematic sections showing evolution of basin hydrodynamics for the past 50 Ma. with Devonian evaporite extent shown in *red*. (*1*) Initial onset of topography-driven basin-scale fluid flux in response to tectonic rebound of the western margin of the basin at end Laramide time, (*2*) Diminished flow due to Tertiary erosion lowering the topographic gradient across the basin leading to quasi-stationary hydrologic equilibrium, (*3*) Loading tied to Pleistocene continental glaciation reverses the topographic gradient across the basin and thus the direction of fluid flow, leading to significant subglacial meltwater recharge along the carbonate outcrop belts in NE Alberta and central Manitoba and increased salt dissolution in the relatively shallow (hypogene) subsurface, (*4*) In response to off-loading of the melting ice sheet, the hydrodynamic system of the basin shows a transient response trying to re-establish a new hydrologic equilibrium. This reversal drives a discharge of glacial meltwaters that have now obtained a high salinity from dissolution of salt beds, this still drives the observed modern-day spring outflow system on the basin margin (After Grasby and Chen 2005)

sedimentary rocks and the dissolution front of the Prairie evaporites (Fig. 8.46a). An integrated sedimentary basin/ice sheet model supports the interpretation that high permeability carbonate units acted as preferential subglacial drains that in turn affected esker development. The fluid flow history of the Western Canada Sedimentary Basin is characterized by back-and-forth pore-fluid movement through geological time, in response to changing boundary conditions (Fig. 8.46b). Grasby and Chen (2005) conclude that the brines discharging from the northern and eastern edge of the WCSB are not related to deep-basin brines, rather they were once fresh glacial waters that came in contact with, and dissolved, subcropping evaporite units on the northeastern margin of the basin and subsequently mixed with deeper basin brines. If so, then the modern-day flow systems and brine chemistries, driven by glacial loading and unloading, may not be indicative of historic (pre-glaciation) movements of economic fluids through the basin.

In warm pore fluids at the other end of the temperature and sedimentary-burial spectrum, there is the possible creation of hot hypersaline brines in a fractured hard-rock basement host beneath the evaporite basin, via infiltration of connate waters. This leads to an interesting quandary; have hypersaline basinal brines entered and influenced the chemistry of the hard rock basement that lies beneath most evaporite-floored sedimentary basins (such as the Gulf of Mexico), or are these waters juvenile residuals from magmatic or metamorphic fractionations (Markl and Bucher 1998)? Land (1995b) argues for the former. Using quantified mass volume and element residence times he concludes that as the porosity of rocks is reduced during burial, discharge of saline formation waters contributes to crustal chloride cycling. During deep burial, corrosive saline formation waters dissolve metastable detrital minerals derived from crustal/basement rocks and transfer incompatible elements such as Li and B from the igneous crust to the sedimentary crust. Likewise, albitisation transfers Ca from the crustal silicate (igneous) mineral reservoir to the crustal carbonate and aqueous (sedimentary) reservoirs. Metamorphism, and then melting of albite-enriched rocks, accounts for the elevated sodium contents of igneous rocks relative to sedimentary rocks. In this way average sediments have become enriched through time in Ca, Cl, Br, S, Li, and B, and depleted in Na relative to average igneous crust.

In support of the ability of evaporite brines to enter and so influence basement chemistry during metamorphism and overpressuring, McCaig et al. (2000) documented evaporite-derived Na-Cl brines in inclusions in the northern end of the Alpine shear zone, Europe (Figs. 8.12 and 8.47a, b). The brines occur where the regional shear cuts the Neouvielle granodiorite in the Hercynian Axial Zone and also to the south in several localities in the footwall and hangingwall of the Gavarnie Thrust on the southern margin of the Axial Zone. Inclusion fluids generally decrease in salinity from 27 to 35 % at the northern end of the transect to 7–22 % on the southern margin of the Axial Zone. The evaporitic origin is seen in the Cl-Br-Na systematics of the fluid inclusions, which show chemistries consistent with a change from halite to halite + sylvite precipitation with progressive evaporation. The fluids in the basement shear zones are interpreted to have essentially the same evaporitic origin as those still contained in nearby Triassic sediments. Brine inclusions in the sediments have Cl/Br ratios lower than seawater indicating relict signatures derived by marine evaporation and halite precipitation in the upper Triassic. It is possible that final concentration of brines in the Neouvielle Massif also involved retrograde hydration reactions via removal of water by precipitation of hydrous minerals.

The somewhat lower salinities seen at the southern margin of the Axial Zone are interpreted by McCaig et al. to reflect mixing of evaporite-derived brines with a higher level fluid (connate or meteoric water) circulating within the Mesozoic carbonates of the higher thrust sheets. At one locality where Triassic evaporites are still present, high Cl/Br ratios at relatively low salinities are present in inclusions within the underlying Triassic redbeds, but low Cl/Br ratios at higher salinities are seen lower in the sequence. This is consistent with dissolution of halite by a dilute fluid, but with limited penetration downwards.

In a related paper, Travé et al. (2000) demonstrate the involvement of evaporite-related fluids in sediments atop the evaporite-lubricated thrust of the Al Guix anticline in the Pyrenees of NE Spain (Fig. 8.47). The El Guix anticline is the southernmost structure of the south-Pyrenean fold-and-thrust belt. Compressional activity in the area represents the latest stages of Alpine compressional tectonics and overprints the Upper Eocene-Oligocene fluvio-lacustrine deposits that overlie halokinetic Triassic evaporites. Based on a detailed structure of the timing and chemistry of various microfracture cements Travé et al. (2000, 2007), conclude that the Pyrenean fold-and-thrust belt and its deformed southern foreland basin were hydrologically compartmentalised, both in time and space (Fig. 8.13). During the early Eocene, when the thrust front affected soft-sediment in the Ainsa basin, medium-scale fluid flow cells dominated the thrust faults. Fluids in the basin were largely formation fluids derived from Eocene marine waters with a minor meteoric influence. During the middle Eocene; coeval with the Gavarnie thrust emplacement, the thrust fault was dominated by medium scale fluid flow system and a fluid that was basically a hypersaline Sr-rich brine stored within Triassic redbeds. No evidence was found of any significant input of either surface or metamorphic fluids during this time. During the same period, the thrust faults in the crystalline basement of the central Pyrenees were dominated by a large scale fluid flow mainly derived from the underlying silicate rocks as a

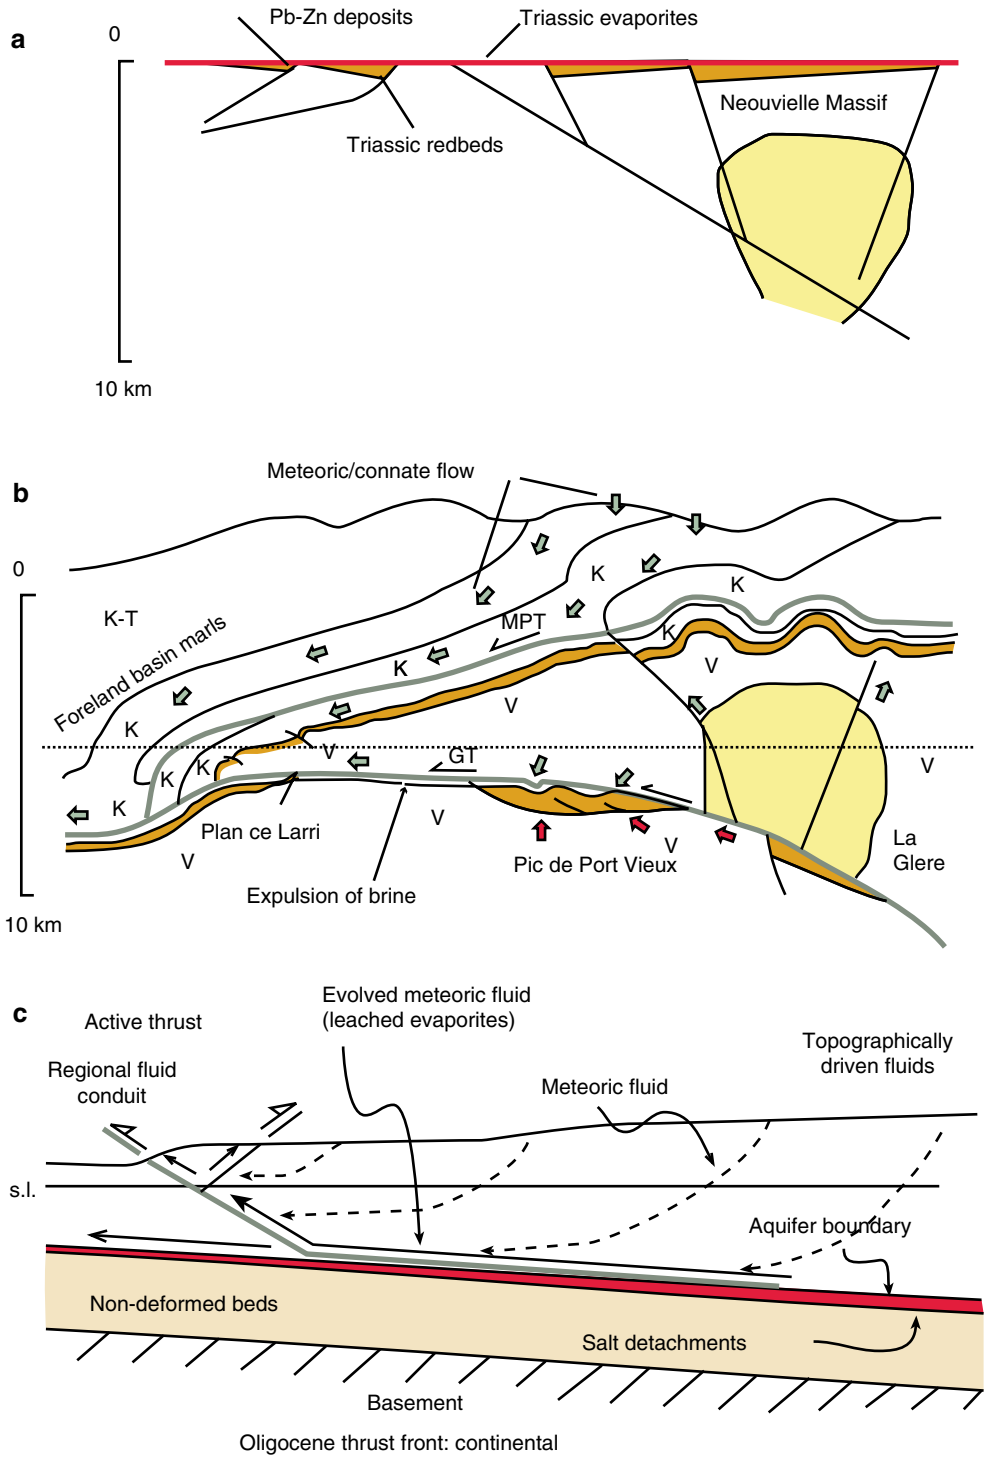

Fig. 8.47 Model for fluid evolution and mixing in the Pyrenees. (**a**) Situation at the end of the Triassic: Brines from marine-fed Triassic evaporites sink and displace older formation waters in the underlying redbeds and fractured basement rocks. Pb-Zn deposits formed along normal faults sometime between the Triassic and the middle Cretaceous, due to circulation of metalliferous basinal brines, probably due to density convection. (**b**) Situation during Eocene thrusting. Section above the present exposure level is conjectural (above *dashed line*). Detail of part of section below thrust line is given in Fig. 8.7. *Arrows* show inferred directions of fluid flow. Note local movement of fluid into the Pic de Port Vieux culmination driven by dilatancy. *V* Variscan basement (Silurian and Devonian phyllites, Cambro-Ordovician schists and late granitoids). *K* Cretaceous to Palaeocene carbonates, *K-T* Tertiary marls and flysch of the foreland basin, locally interthrusted with Cretaceous carbonates, *GT* Gavarnie Thrust, *MPT* Mont Perdu Thrust (**a**, **b** After McCaig et al. 2000; Horizontal and vertical scales are equal, but there is no precise correspondence between the two diagrams). (**c**) Fluid flow in the El Guix anticline during the Oligocene when deeply circulating and evolved meteoric waters mixed with evaporitic waters from Triassic evaporites that also created the décollement for the thrust plane (After Travé et al. 2000)

result of metamorphic devolatilisation reactions. During the Oligocene, the most external part of the fold-and-thrust belt developed on top of a salt detachment horizon (Fig. 8.47c). Then the thrust front affected mostly cemented continental materials of late Eocene-Oligocene age and the thrusts were conduits for meteoric fluids and also for evolved meteoric fluids migrating a short distance upwards after being in contact with the underlying evaporitic beds focused by the décollement.

Thus, the fluid history in the Pyrenean collision zone evolved through a series of stages in time and space, linked also to economic accumulations of base metals Travé et al. (2007): (1) Upper Triassic evaporite formation with sinking of brines into underlying redbeds and fractured basement rocks; (2) Circulation of brines with formation of Pb-Zn deposits along faults at some time between the Triassic and the Upper Cretaceous; (3) Renewed extension with erosion of Triassic rocks in many areas and further draw down of Triassic brines into the basement; (4) Deposition of Upper Cretaceous and Palaeocene-Eocene carbonates containing connate waters of marine origin: (5) Formation of the Pyrenean thrust belt with overpressuring and expulsion of the brines along shear zones and faults; (6) Creation of topography with a high-level circulation system in the Mesozoic thrust sheets driven largely by topography (McCaig et al. 2000). At the southern margin of the Axial Zone there was limited mixing of the deeper, overpressured brines from evaporitic sediments with more dilute, hydrostatically pressured fluids (Travé et al. 2000).

A similar interaction between hydrothermal ($\approx$200 °C) fluid circulation, associated with the cooling of a granite mass, and hypersaline fluid circulation driven by sinking of dense hypersaline brines, derived in Triassic evaporitic rifts of the Western Approaches, is important in controlling the fracture-related low temperature base metal and uranium accumulations of South Cornwall (Gleeson et al. 2001).

It seems that the role of evaporite basin brines extends well beyond the limit of sediments within a sedimentary basin. We shall pursue this topic further in a discussion of meta-evaporites in Chap. 14 and in various metal accumulations in Chaps. 15 and 16. For now, to complete this section, let us consider the observations of Yardley (2013) in a recent review paper on the role of basinal brines in crustal processes.

He noted the following;.... “In recent times, the role of basinal brines in giving rise to mineralisation and metasomatism in underlying basement has been recognised in a number of areas. Dolomite veins in Caledonian metamorphic rocks of SW Scotland have been linked to penetration of post-orogenic basinal brines by Parnell et al. (2000a), while Holness (2003) has found widespread evidence of fluid penetration into crystalline rocks during exhumation. In the Cloncurry district of Queensland, widespread growth of actinolite and albite (i.e. sodic-calcic metasomatism) has affected basement crystalline rocks as they cooled through greenschist facies conditions under an extensional regime (De Jong and Williams 1995). Subsequent isotope studies implicate a major contribution from the infiltration of basinal fluids (Kendrick et al. 2008). Infiltration of both formation brines and associated hydrocarbons into Precambrian basement rocks has been recognised on the western flanks of the Oslo Graben by Munz et al. (1995, 2002) and Gleeson et al. (2003), and is associated with quartz veins and albitisation. Boiron et al. (2010) have documented a range of examples of ore deposits linked to brines moving between basin and basement, and cite Precambrian unconformity-type U deposits as an important example. Basement rocks beneath sedimentary basins fracture and extend during basinal development, and since the cooled basement rocks are essentially fluid absent at this stage (Yardley 2009), fluid from the overlying basement is readily drawn down. This will be particularly effective if the basal formations in the basin are overpressured.”

Clearly the influence of evaporite-derived subsurface waters extends beyond the sedimentary realm into the metamorphic and igneous realms (Chaps. 14 and 16, respectively).

Halotolerant Life in Feast or Famine: Organic Sources of Hydrocarbons and Fixers of Metals

9

Introduction

A hydrocarbon source rock is generally considered to be a fine-grained rock that, during its burial and heating, generates and releases enough fluids to form commercial accumulations of oil or gas (Fig. 9.1a). Back in 1981, Kirkland and Evans made the observation that some 50 % of the world's oil sequestered in carbonate reservoirs may be associated with mesohaline micritic source rocks. Heresy or not, the notion that much of the oil in carbonate reservoirs, sealed by evaporite salts, may have been sourced in earlier less saline, but still related, evaporitic (mesohaline) conditions, is worthy of consideration. The association between mesohaline waters, the accumulation of organic-rich sediments and the evolution of the resulting evaporitic carbonates into source rocks has been noted by many, including: Woolnough (1937), Sloss (1953), Moody (1959), Dembicki et al. (1976), Oehler et al. (1979), Malek-Aslani (1980), Kirkland and Evans (1981), Jones (1984), Hite et al. (1984), Eugster (1985), Sonnenfeld (1985), Ten Haven et al. (1985), Warren (1986), Evans and Kirkland (1988), Busson (1991), Edgell (1991), Beydoun (1993), Benali et al. (1995), Billo (1996), Aizenshtat et al. (1998), Carroll (1998), Schreiber et al. (2001), Love et al. (2007), Schnyder et al. (2009), Warren (2011), Comer (2012).

As long ago as the middle of last century, Weeks (1958, 1961) emphasised the importance of evaporites as caprocks to major hydrocarbon accumulations. He also pointed out that many of the cycles of deposition that involve organic-rich carbonate marls or muds also end with evaporites. Many of these authors noted an association with Type I-II hydrogen-prone kerogens in evaporitic source rocks and related this to the ability of halotolerant photosynthetic algae and cyanobacteria to flourish in mesohaline waters. Such kerogens tend to be oil-prone rather than gas prone and typified by long-chain hydrocarbons (Fig. 9.1b).

Much of the organic matter preserved in evaporitic carbonates, and the resulting source rocks, originated as planktonic blooms (pelagic "rain from heaven") or from the benthic biomass ("in situ" accumulations). Such organics typically settled out as seriate pulses of organic matter (often pelleted) that sank to the bottom of a layered brine column. Each pulse was tied to a short period when surface brines were diluted and halotolerant producers (mostly cyanobacteria and algae) flourished in the freshened lit zone. That is to say, the laminated mesohaline mudstones that constitute evaporitic source rocks reflect biological responses to conditions of "feast or famine" in variably layered bodies of brine. Warren (1986, 2011) referred to the schizohaline salinity cycles of saline settings as repetitive episodes of "life or death."

Organic matter buried in organic-rich sediment undergoes numerous compositional changes before it becomes a source rock, at first dictated by microbial agencies and then by thermal stress (Horsfield and Rullkotter 1994). This continuum of processes is called thermal maturation. Based on vitrinite reflectance (R_o) measurements of macerals, a maturing source rock can be divided into three consecutive stages: eogenesis (diagenesis)[1] ($R_o < 0.5$ %); catagenesis (0.5 % $< R_o <$ 2.0 %); and metagenesis (2.0 % $< R_o <$ 4.0 %), with the oil generation window typically in the R_o range 0.5–1.3 % (≈65–150 °C: Table 9.1). Reflectivity is measured by shining a beam of monochromatic light (with a wavelength of 546 nm) on to a polished surface of the vitrinite macerals and measuring the percentage of the light reflected with a photometer. Put simply, it measures the degree of darkening (roasting?) of the organics associated with heating of the rock during burial and is not really a direct indication of oil maturation.

[1]The term *diagenesis*, as used by petroleum geochemists, describes processes of organic modification or alteration in the presence of pore waters where circulation is driven by surface processes. This usage is much more restrictive than the sedimentological use of the term which encompasses all alteration or modification from the time of sediment deposition until the onset of metamorphism. In order to minimise any possible confusion, the term *eogenesis* is preferred by some workers, but this is a different meaning to eogenetic as used by Choquette and Pray (1970).

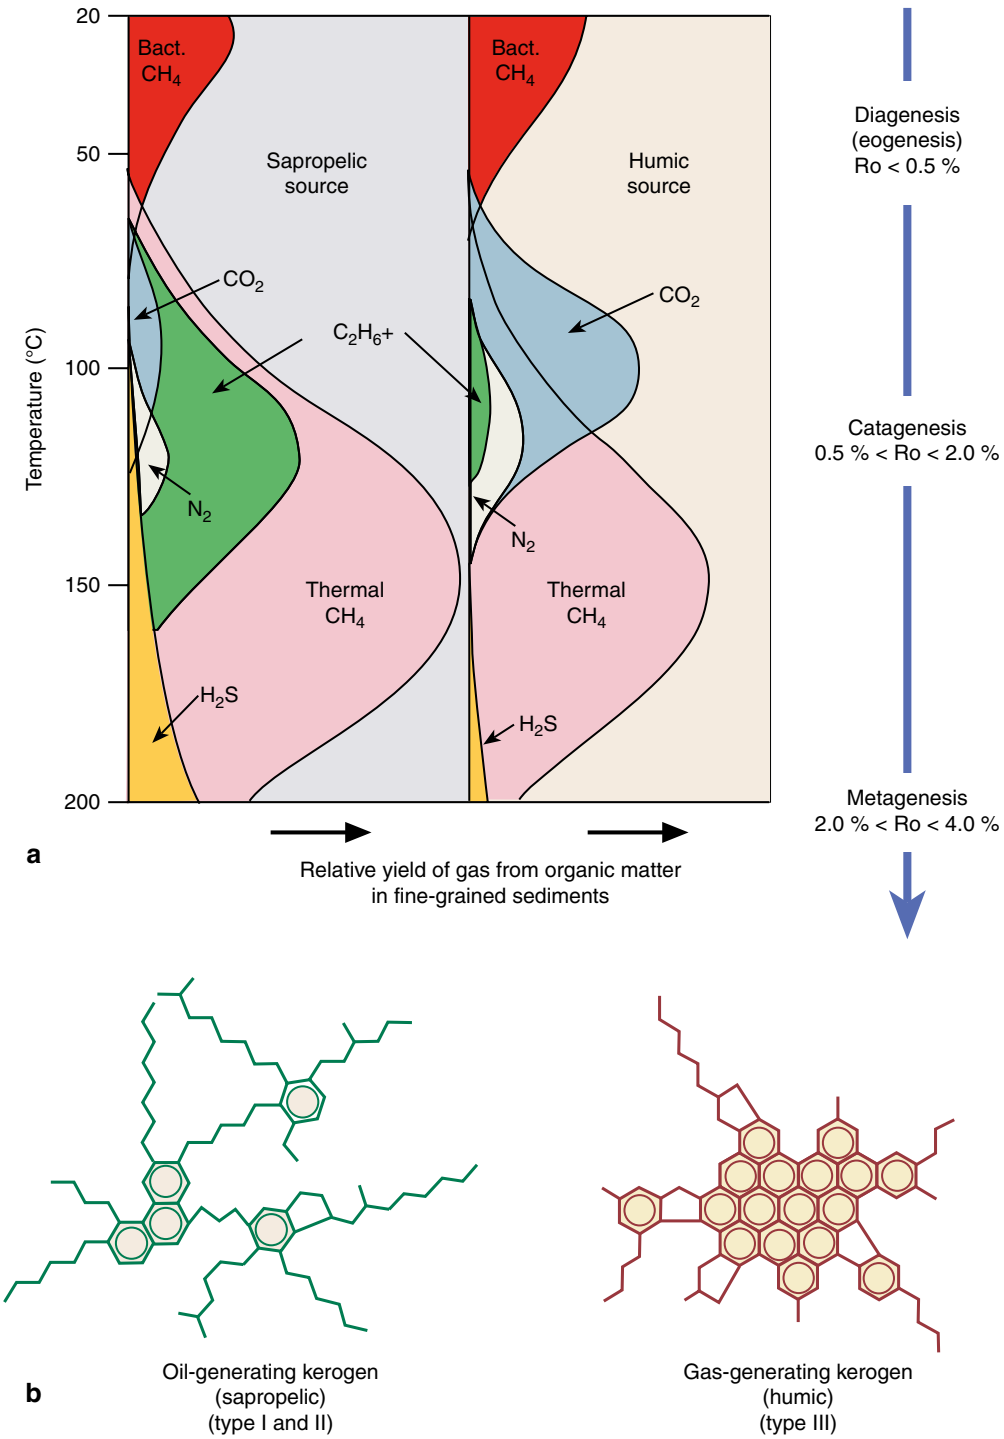

Fig. 9.1 Organics and source rocks. (**a**) Relative volumes of gases and liquids derived from a sapropelic and a humic source rock (After Hunt 1996). Evaporitic source rocks tend to be sapropelic and contain less iron as a reductant so they are also likely to generate more H_2S. (**b**) Molecular structure of typical oil-generating (sapropelic) and gas-generating (humic) organic matter showing the greater preponderance of long-chain hydrocarbons in the sapropelic material (After Hunt 1996)

Macerals are recognizable remains of different types of organic matter that can be differentiated under the microscope by their morphologies. As originally defined, macerals are the microscopic organic components of coal and consist of an irregular mixture of different chemical compounds, which are analogous to minerals in inorganic rocks, but differ from minerals in that they have no fixed chemical composition and lack a definite crystalline structure (Fig. 9.2). Macerals change progressively both chemically and physically during ongoing burial and heating; as the rank of macerals (coaly material) advances or the maturity of the organics increases. Macerals in any sediment can be classified into four major groups: vitrinite, inertinite, alginite and exinite (Fig. 9.2a). Liptinites broadly encompass the alginites

Table 9.1 The generation defined oil and gas window approximately related to some common maturity parameters

Parameters (oil and gas)	Temperature (°C)	Vitrinite reflectance (R_0%)	Transformation ratio[a] (0–1)	Spore colour index (1–10)	Rock Eval (T_{max} – °C)
Oil maturation					
Early mature	80–115	0.5–0.7	0.05–0.15	4.0–5.0	432–442
Mid mature	115–145	0.7–1.0	0.15–0.65	5.0–7.0	442–455
Late mature	145–165	1.0 to >1.3	0.65–0.95	7.0–9.0	455–465
Post mature	>165	>1.3	>0.95	>9.0	>465
Gas maturation					
Early mature	115–145	0.7–1.0	0.05–0.45	5.0–7.0	455–465
Mid mature	145–220	1.0–2.2	0.45–0.85	7.0–9.0	465–525
Late mature	>220	2.2 to >3.0	0.85–0.95	10	525–575
Post mature	??	>3.0	>0.95	10	>575

After Cornford 2005
Figure 9.1 also shows relationship between maturation, R_o and temperature
[a]Transformation ratio (LLNL) of Type II kerogen for oil maturation, and Type III kerogen for gas maturation

and exinites. Vitrinite is derived mostly from woody plant tissue and includes the macerals collinite and telinite, most coals have a high percentages of vitrinite macerals (Fig. 9.2b). The inertinite group comprises fusinite, micrinite, sclerotinite, and semi-fusinite, which are all rich in carbon but poor sources of volatiles. The exinite/alginite (liptinite) macerals, characterized by high hydrogen content (and hence excellent liquid hydrocarbon-generating potential), include alginite, cutinite, resinite, and sporinite (Fig. 9.2b). Alginites are commonplace macerals in evaporitic settings, while vitrinites are rare, reflecting a lack of higher plants in most hypersaline settings. A lack of vitrinite and poor calibrations to alginite maturation indices can lead to poor correlations between actual source rock maturity and that indicated by vitrinite-based estimates in evaporitic source rocks.

This is the case for the Type II source rocks in the Hanifa-Hadriya interval in Saudi Arabia (Ayres et al. 1982), which contains little or no vitrinite. Reflectance measurements determined from a few phytoclasts in such mesohaline source rocks may be unreliable and other geochemical evidence, such as thermal alteration indices (TAI) or biomarker maturity parameters, should always support R_o measurements of maturity in such sediments (Table 9.1). Significant proportions of oil-prone macerals or bitumens, as are common in many mesohaline source rocks, tend to retard the normal progression of vitrinite reflectance with maturity (Price and Barker 1985).

Transformation of organic matter to liquid and gaseous hydrocarbons is the result of thermal cracking of kerogen[2]. Kerogen is the major global precursor of petroleum and its formation, mostly via biologically-induced alteration of plant and animal detritus, its formation is complete by the end of eogenesis. Around 90 % of the organic material in a source rock at the onset of catagenesis is dispersed kerogen, consisting of a range of residual materials with basic molecular structures that are dominated by stacked sheets of aromatic hydrocarbon rings, in which atoms of sulphur, oxygen, and nitrogen also occur. Attached to the ends of the rings are various hydrocarbon compounds, including normal paraffin chains (Fig. 9.1b). Mild heating of kerogen over long periods of time results in the cracking of the kerogen molecules and the release of the attached paraffin chains.

Further heating, perhaps assisted by the catalytic effect of clay mineral transformation and evaporite dewatering in the source rock matrix, may then produce soluble bitumen compounds, followed by the various saturated and unsaturated hydrocarbons, asphaltenes, and others of the thousands of hydrocarbon compounds that make up crude oil mixtures. Thus kerogen cracking is induced by burial and heating and it releases micropetroleum (a mixture of liquid and gaseous hydrocarbon products that are soluble in organic solvents) into the pore system of the source rock. The maturity and evolution of the kerogen is paralleled and indicated by increasing maceral (vitrinite) maturity (Table 9.1). Once released into the pores of the source rock, micropetroleum migrates toward the surface via secondary migration pathways and along the way a portion of this material can be trapped in a variety of reservoirs of varying quality.

The nature of the organic precursors to kerogen exerts a strong influence on kerogen structure and bulk composition, and hence on subsequent oil- and gas-generating characteristics. Source rock kerogens enriched in long chain hydrogens (aliphatics or parafins) tend to be oil-prone type I sapropelic source rocks and are associated with algal, bacterial and archaeal precursors (indicated by C_2H_6+ in Fig. 9.1a). Kerogens that are strongly depleted in long-chain hydrogens are typically type III humic (vitrinitic) source rocks, associated with organics sourced

[2]Kerogen is the solid organic assemblage in a rock that is insoluble in organic solvents and encompasses numerous macerals.

Oil-Prone (cracking to condensate and gas)	*Liptinite*	*Algal amorphous*	*Sapropel*	*Type I (Type (IS)*	Pure algal Includes bacterial biomass.
Light oil condensate-prone	*Exinite*	*Herbaceous*		*Type II (Type (IIS)*	Cuticle gives waxy oil.
Gas-prone	*Vitrinite*	*"Woody"*	*Humic*	*Type III*	Type II can be a mix of I, III and IV. Amorphous vitrinite & oil-impregnated fluorescent vitrinite exist.
Dead carbon	*Inertinite*	*"Coaly"*	*Not recognised*	*Type IV or IIIB*	Minor gas potential from semi-fusinite.

Fig. 9.2 Kerogen (After Cornford 2005) (**a**) Simplified classification of organic matter in sedimentary rock. Bitumen is extracted from ground rock using organic solvents and consists of hydrocarbons and non-hydrocarbons. Treatment of the extracted residue with hydrochloric (HCl) and hydrofluoric (HF) acids removes most carbonate and silicate minerals, respectively and leaves behind the kerogen. This kerogen residue consists of various macerals that can be identified by organic petrography. (**b**) Approximate equivalence of terms used to describe kerogen using different techniques for its study

from higher plants (Figs. 9.1a and 9.2b). They are gas prone and the gaseous products are dominated by methane (dry gas), sometimes with associated hydrogen sulphide or nitrogen. Like hydrocarbons, hydrogen sulphide is generated both biochemically and thermochemically.

Obviously, not all source rocks are evaporitic. Organic matter accumulating in mesohaline sediment is derived from the activities of the halotolerant[3] and halophilic biomass, mostly algae, bacteria and archaea. Kerogen derived from burial of this organic matter will be composed of their somewhat altered remains, as will the expelled hydrocarbons. Sapropelic organic matter is created by decomposition and polymerization of high-lipid organic materials (with aliphatic long-chain hydrocarbons), which are commonplace in algal and bacterial sediments deposited under anaerobic conditions. Hence, sapropelic organic matter tends to be associated with oil-prone Type I or Type II proto-kerogens (Figs. 9.1b and 9.2b). Humic organic matter tends to contain less long chain hydrocarbons and so constitutes a large proportion of the more gas-prone source rocks found in coaly sediments and in dispersed terrestrial organics deposited in prodelta settings. It is mostly associated with Type III protokerogens.

Unoxidised evaporitic organic matter tend to be hydrogen-rich and oil-prone; its sapropelic kerogens (Type I or Type I-II) contain higher proportions of long chain hydrocarbons from cyanobacterial, archaeal and bacterial precursors.

[3]Halotolerant organisms can tolerate high salt concentrations but grow better at somewhat lower salinities. Halophilic organisms grow best at very high salt concentrations and can be killed by lower salinities. *Haloxene* organisms cannot tolerate high concentrations of salts.

Higher plant material, which is the source of much of the humic component in nonevaporitic kerogen simply does not accumulate in large volumes in an evaporitic source rock; higher plants need fresh water and do not flourish in hypersaline waters.

The remainder of this chapter summarises and classifies evaporitic source rocks, looks at controls on organic enrichment in saline environments, and at the styles of hydrocarbon generation and metal-fixing associated with organic-prone mesohaline evaporites in the diagenetic realm. The following chapter looks at how evaporites form the seals and traps to reservoirs that store the generated hydrocarbons.

Evaporitic Source Rocks

Mass balance calculation of oil in the global petroleum system shows that 40 % of the world's generated oil is lost to the surface, 58 % is dispersed in the subsurface as oil, gas and pyrobitumens located somewhere between source and reservoir, while 2 % is to be found in pooled accumulations suitable for exploitation (Hunt 1996). Estimated reserve volumes, plus ultimate undiscovered resources, for conventional oil and gas are about the same, each is about 2×10^{12} BOE (barrels of oil equivalent) or 3.2×10^{11} m^3.

A plot of Phanerozoic source rocks shows that more than 90 % of the world's discovered original reserves of oil and gas comes from six intervals of geological history, covering only 35 % of Phanerozoic time (Fig. 9.3a; Klemme and Ulmishek 1991). The six intervals are (Fig. 9.3b): (1) Silurian, which generated 9 % of the world's recoverable reserves, (2) the Upper Devonian (Tournisian), 8 %; (3) Pennsylvanian-Lower Permian 8 %; (4) the Upper Jurassic, 25 %; (5) the Middle Cretaceous, 29 %; and (6) the Oligo-Miocene, 12.5 %. More than 78 % of the world's oil and gas is sourced in sediments deposited in restricted or silled anoxic systems located in intrashelf basins on platforms, or in restricted areas formed by circular and linear sags. Four of the six stratigraphic intervals occurred in worldwide first-order sealevel highs (transgressions) associated with greenhouse climatic conditions and the deposition of mostly sapropelic organic matter. The other two, Pennsylvanian-Lower Permian and the Oligo-Miocene, which source 20.5 %

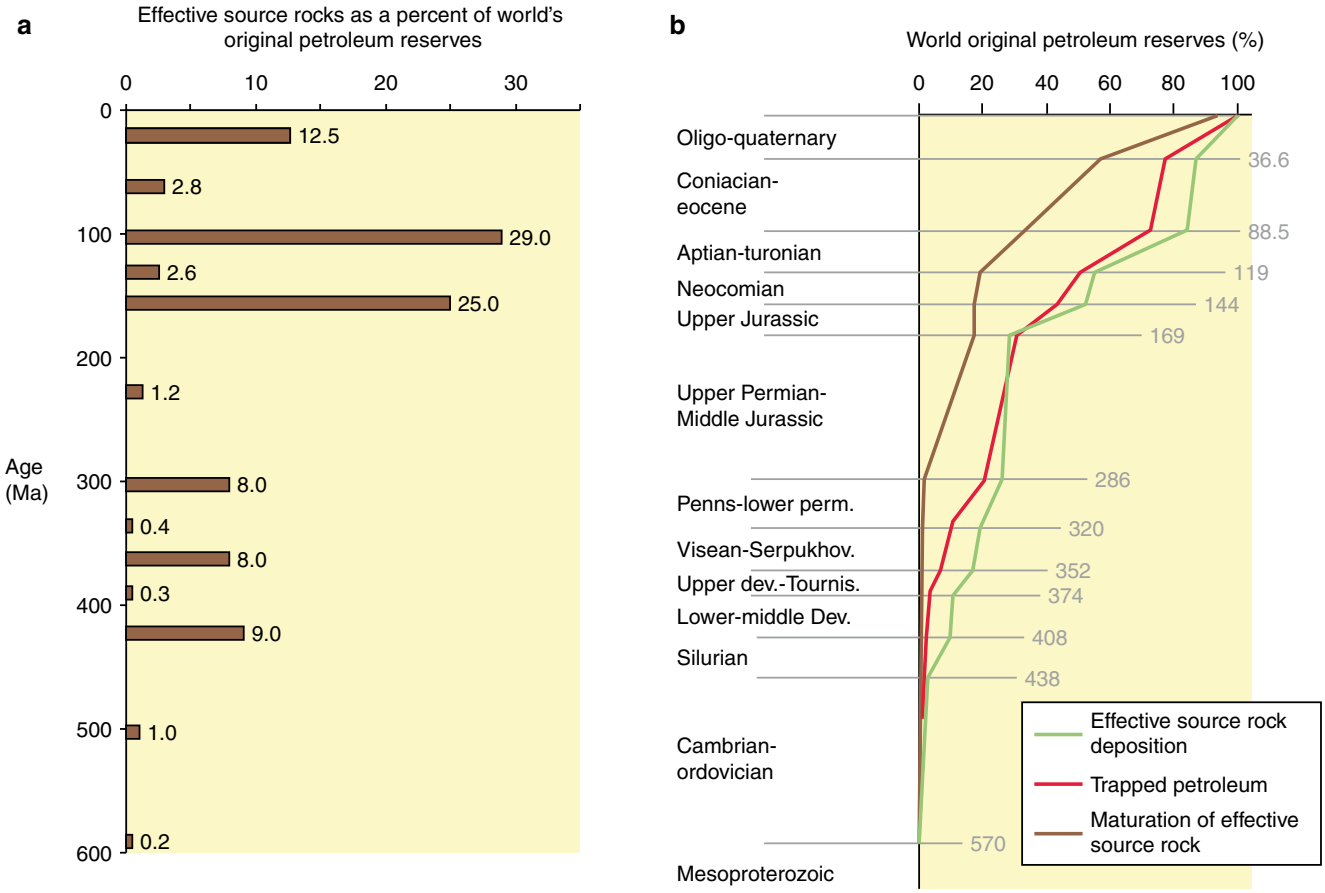

Fig. 9.3 Source rocks across time. (**a**) Time distribution of effective source rocks as a percentage of the world's original petroleum reserve generated by these rocks. (**b**) Cumulative plot of effective source rock deposition, maturation and trapped petroleum as a percentage of the world's original petroleum reserves (After Klemme and Ulmishek 1991)

of the world's oil and gas, occurred during times of lowered sea level (regressions) and deposited mostly type III kerogens (Hunt 1996). These were times of polar glaciation (icehouse climate mode). Something like two-thirds of the world's oil was generated in Tethyan basins in a system that covers less than a fifth of the world's land area and continental shelves. The efficiency of the Tethyan petroleum system, centred on the countries of the Middle East was facilitated by the deposition of widespread seals, such as the saltern anhydrites of the highly-effective Hith and Khuff formations and the basinwide halites of the Fars/Gachsaran (Chap. 10). As well, these strata experienced gentle structuration of reservoir beneath the evaporite seal via draping, sometimes in association with flow and dissolution of Infracambrian Hormuz salt, or folding of a Gachsaran Formation seal caught up in the foreland fold and thrust belt along the Zagros collision zone.

A common theme to most source rocks, both evaporitic and nonevaporitic, is that they require anoxic conditions to accumulate and preserve their organics. This in turn requires some way of restricting the influx of oxygenated waters to the depositional site and is usually accomplished by thermal or density stratification of a water body, typically in a setting where plankton flourish periodically in the upper water mass. This is why so many subaqueous evaporitic settings are also settings where organics tend to accumulate. By definition, evaporites require restricted inflow conditions to accumulate, they are also typically areas of density-stratified waters with high salinities in the lower denser more saline water mass. Levels of dissolved gases are negligible to non-existent in the lower brine body as it does not easily exchange with the atmosphere, so encouraging long-term bottom anoxia.

This does not mean all of the world's source rocks were deposited in evaporitic settings, only that the restricted conditions that favour the accumulation of evaporites are similar to conditions that favour the accumulation of some types of organic-rich bottom sediments, especially in the interval that precedes deposition of actual salts. In arid climates any minor changes in inflow conditions, such as hydrographic isolation from the ocean, can easily force a transition from one into the other. Hence the common association of source rocks with layered basin waters typical of the early mesohaline phase and the onset of evaporitic sedimentation in many lacustrine/epeiric settings (Table 9.2). In the marine realm, the same need for tectonic or eustatic restriction to create a basin suitable for source rock accumulation (intrashelf, circular or linear sag) also explains why, if further restriction and hydrographic isolation from the ocean ensues, the same region is easily covered by a sequence of salts (Fig. 5.32).

Worldwide, studies of ancient evaporitic basins have shown that organic-rich mesohaline sediments can accumulate beneath ephemeral surface brines, in salterns, or in basin and slope settings in both marine and continental settings (Kirkland and Evans 1981; Oehler 1984; Warren 1986; Evans and Kirkland 1988; Rouchy 1988; Busson 1992). The most prolific accumulations of organics in ancient evaporitic sediments tend to have been deposited as laminated micritic carbonates beneath density-stratified moderately-saline (mesohaline) anoxic water columns of varying brine depth.

There are three, possibly four, major mesohaline density-stratified settings where organic-rich laminites (source rocks) accumulate in saline settings that are also associated with, or evolve into, evaporite deposits (Fig. 9.4; Table 9.2):

1. Basin-centre lows in marine-fed evaporitic drawdown basins (basinwide salts).
2. Mesohaline intrashelf lows atop epeiric evaporitic platforms.
3. Saline-bottomed lows in perennial underfilled saline lacustrine basins.
4. Closed seafloor depressions in halokinetic deepwater marine slope and rise terrains.

Basin Setting 1: There are two depositional styles for basin-centre or basinwide mesohaline source rocks; (a) Basin-centre drawdown laminites intercalated and often sealed by basinwide salts, (b) Basin-centre laminites where the basin margin is a shallow, restricted, at times evaporitic, platform surrounding a slightly mesohaline deepwater starved-basin centre with bottom waters that were never drawndown or concentrated to where basinwide salts precipitated. Matrices in setting 1b basin-centre laminites range from fine-grained limestones through marls to siliciclastic muds.

In source setting 1a the basin is largely isolated from a surface marine connection and high levels of organics accumulate as radiogenic "black shales" (typically carbonate laminites), which are intercalated with, and overlain by, thick basinwide evaporite salts (typically halite-dominated). These laminites accumulate on the bottom of mesohaline density-stratified stagnant brine pools in topographically closed parts of the basin floor during the early stages of hydrographic isolation and drawdown. Inactive, typically subaerial, shelf margin reefs and pinnacles typically lie updip or encircle the basin-centre lows (Chap. 5). Subsequent encasement of these platform buildups and other potential reservoirs by "fill and spill" evaporites means these basins easily become highly focused hydrocarbon flow systems. Hydrocarbons accumulate in the reefs or shelf margin shoal reservoirs beneath basinwide evaporite seals. Such systems typify the marine-fed Silurian reef/Salina Salt association in the Michigan Basin, USA (Gardner and Bray 1984), the Devonian Rainbow Reef reservoirs of the Black Creek/Muskeg Basin of Alberta (Clark and Philp 1989) and Messinian marls of the Lorca Basin, Spain (Russell et al. 1997).

Table 9.2 Selected evaporitic source rocks

Formation/group, locality and age	Basin style	Characteristics and depositional setting	Reference
Messinian carbonates Lorca Basin, Spain, Late Miocene	1a Basinwide evaporite, marginal basin	Organic-rich laminated mudstones deposited in pre-evaporitic mesohaline marginal basins with density- and salinity-stratified brine columns. The basin underwent sporadic phases of circulatory restriction with marked production and preservation of organic matter, culminating in evaporative sedimentation (latest Miocene). As the water in this basin evolved toward evaporative conditions, a number of organic-rich depositional phases (>25 wt% TOC) occurred. During the early parts of these phases, the upper water was nutrient rich and comparatively normal marine, and the bottom water was anoxic and more saline. This was followed by rising salinities in the surface waters, holomixis and short phases of evaporite formation. Biomarkers in authigenic carbonates were synthesized by extremophilic (thermophilic and/or halophilic) bacteria.	Benali et al. (1995), Russell et al. (1997), Rouchy et al. (1998), Baudrand et al. (2010), Dela Pierre et al. (2012)
Gessoso-Solfifera Formation, Sicily, Late Miocene (Messinian)	1a Basinwide evaporite, marginal basin	Biomarker compositions from immature organic sulphur-rich marl samples from 10 of the 14 evaporite cycles in an Italian Messinian evaporitic basin (Vena del Gesso) indicate large variations in the composition of species in the water column (e.g., dinoflagellates, diatoms and other algae, cyanobacteria, methanogens, green sulphur bacteria and bacterivorous ciliates) and in contributions from the continent (i.e., land plants) within each marl bed and between marl beds. The marl beds were deposited within a stratified lagoon where anoxic conditions extended into the photic zone for much of the time	Damste et al. (1995), Keely et al. (1995)
Organic-rich marls, Gulf of Suez, Middle to Late Miocene	3 Rift basin, Continental to transitional marine	Inclusion studies show evaporitic environment of deposition (reducing conditions and high salinities), favoured oil generating kerogen. The oil produced from syn-rift (Miocene) reservoir rocks is a naphthenic, non-waxy crude with API gravity ranging from 27.9 to 34.9° and sulphur content between 0.88 and 0.98 wt%. These type B oils are distinguished from clastic sourced oils by a predominance of gammacerane and relatively low oleanane concentrations, suggesting that they were generated from mature marine carbonate source rocks, inferred to occur within the Upper Cretaceous Brown Limestone and Middle Eocene Thebes Formation. High sulphur oils are typically indicative of carbonate-evaporite source rocks	Kholief and Barakat (1986), Katz (1995a, b), Rouchy et al. (1995a, b), Cole et al. (1995), Dolson et al. (2001), Bakr and Wilkes (2002), Younes and Philp (2005)
Alcanar Formation (Casablanca Beds), Tarragona Basin, Middle Miocene, Offshore Spain	3 Rift, transitional	Hypersaline organic-rich carbonate marl/mudstone source rock, (gammeracene in Amposta oil). All source rocks subject to rapid maturation during rapid Pliocene burial.	Barbé et al. (1988, 1990)
Bresse and Valence salt basins, France, Paleogene	3 Rift basin, Continental to transitional marine	Organic matter is mostly immature and occurs in intercalated non-halite beds. Type III kerogen is tied to terrigenous deposition. Type I kerogen is abundant in mesohaline evaporitic laminites of Valence basin. Type II is more abundant in Bresse basin. Organics accumulated beneath a perennially stratified brine column of up to tens of metres. Syndepositional dissolution of halite may have aided the accumulation of significant amounts of oil-prone organic matter in non-soluble brecciated residues.	Curial et al. (1990)
Bituminous Limestone, Carmague Basin, France, Oligocene	3 Continent-continent collision sag	Continuous Neogene subsidence so saline lacustrine source-rocks are within oil or gas window. Sulphur- rich crude geochemistry in Gallician and Ste Cecile wells suggest confined lagoonal-saline lacustrine bituminous limestone source.	Connan and Dessort (1987), Mascle and Vially (1999)
Salt IV Formation, Mulhouse Salt Basin, Europe, Lower Oligocene	3 Rift basin, Continental to transitional marine	Biomarker assemblages are dominated by acyclic isoprenoids, especially phytane ($0.13 < Pr/Ph < 0.52$), n -alkanes with specific distribution patterns, and steranes. Large differences in distributions indicate changes in palaeoenvironment. The largest changes are in desmethyl- and methylsterane distributions and are probably linked to occasional reconnection of the stratified evaporite basin to the sea, leading to a dinoflagellate bloom in the upper waters of a density-stratified brine column.	Damste et al. (1993), Hofmann et al. (1993a, b), Hollander et al. (1993), Keely et al. (1993)

Table 9.2 (continued)

Formation/group, locality and age	Basin style	Characteristics and depositional setting	Reference
Qom Fm., Qom Basin, Iran, Oligo?-Miocene	Rift or foreland (poorly constrained)	Laminated micritic carbonates below salt of Upper Red Formation, in a compressional basin, related to Zagros collision belt.	Shakeri et al. (2007), Morley et al. (2009)
Eocene Qianjiang and Lower Eocene-Paleocene Xingouzhui Formation of Jiangling-Dangyang area, Jianghan Basin of northwest China, Eocene-Paleocene	3 Foreland flexure basins, mountain-front fault depressions	Anoxic evaporitic lacustrine source rocks generated most of the crude oils. High salinity and low Eh enhanced preservation of oil-prone organic matter and facilitated incorporation of sulphur. Anoxia and the unusual presence of abundant sulphate as gypsum resulted in microbial reduction of sulphate to sulphide and incorporation of this sulphur into the kerogen. Biomarkers show that source rock in the Sha 13 well (1,322 m) was deposited under more saline, lower Eh conditions than the Ling 80 well (1,808 m), although both are from the Qianjiang Formation. Sha 13 sample is more organic-rich (6.62 vs. 1.27 wt% TOC), has a higher hydrogen index (794 vs. 501 mg HC/g TOC) and faster reaction kinetics. Kerogen from the Sha 13 sample is Type I because it has a high hydrogen index and an atomic S/C ratio (0.074).	Jiang and Fowler (1986), Huang and Shao (1993), Peters et al. (1996), Grice et al. (1998), Ritts et al. (1999), Hanson et al. (2001)
Green River Formation, Uinta Basin, Wyoming and Utah, Eocene	3 Foreland flexure basin from Laramide orogeny	Laminated organic mudstones and oil shales deposited in deeper anoxic bottom waters of a perennial saline and density-stratified alkaline lake. Gilsonite and tabbyite bitumens are associated with Parachute Creek Member, deposited during a major expansion and freshening of ancient Lake Uinta. Compound specific isotopic analyses of b-carotene and phytane ($\delta^{13}C = -32.6$ to $-32.1‰$) from these bitumens reflect input from primary photosynthetic producers such as cyanobacteria. Sterane $\delta^{13}C$ values (− 34.5 to −29.2‰) reflect contributions from lacustrine algae, while extremely depleted $\delta^{13}C$ values for methylhopanes (−58.1 to −61.5‰) suggest input from methanotrophic bacteria. Variations in the $\delta^{13}C$ values of the a-b-hopanes (−51.4 to 37.7‰) imply additional input from other bacterial sources. The wurtzilite bitumen generated from the saline facies of the Green River Formation was deposited during a later regression of Lake Uinta. Compound specific isotopic analyses of phytane ($\delta^{13}C = -30.1‰$) and steranes ($\delta^{13}C = -29.6$ to −26.7‰) from this bitumen indicate continued input from primary producers and eukaryotes. The higher relative concentrations of gammacerane ($\delta^{13}C = -26.9‰$) indicate increasing input from aerobic species. Slight enrichment in $\delta^{13}C$ in the wurtzilite extract (and several biomarkers) suggests sulphate-reducing bacteria outcompeted methanogens, thereby, eliminating the influence of methanotrophs in this later saline stage of deposition.	Ruble et al. (1994), Katz (1995)
Shahejie Formation, Shengli Oil Province, Bohai Bay Basin, East China, Eocene	3 Continental half-graben, Palaeogene rift with Neogene subsidence	Source rock is mainly the lower part of the Third Member (Es 3) of Eocene Shahejie Formation and is a lacustrine organic-rich dark mudstone/oil shale with good quality Type I-II kerogen at the oil-generative stage at Ro = 0.4–0.8 %. First Member (Es 1) of Oligocene portion of Shahejie Formation has excellent oil potential in the nearby Gunan Basin but is immature in the Fulin Basin. Oil and rock samples from both basins can be grouped into three major biomarker families. First family shows low Pr/Ph (<1), a high gammacerane index (>0.3) and notable beta-carotene, typical of carbonate-evaporite environments. It exists in Es 1 rocks and the related oils and is early mature [β β/(β β + α α) = 0.2–0.3], and [S/(R + S) = 0.10–0.20]. Second family shows high Pr/Ph (>1), a low gammacerane index (<0.2) and abundant 4-methyl steranes, indicative of freshwater lacustrine conditions like those in Es 3. It shows higher maturation [β β/(β β + α α) = 0.30–0.50] and [S/(R + S) = 0.35–0.55] and notable diasteranes. Third family is transitional, has source and maturity ratios between the above families, and occurs in the Es3 unit samples from the basin interior.	Chen et al. (1996), Jin et al. (2010), Wang et al. (2010)

Organic shales, Interior Basin and N'Komi rift, Cretaceous	3 Continental rift	Kissenda and Melania Shale members deposited as mesohaline lacustrine muds beneath stratified brine column, pre Aptian Salt	Kuo (1994)
Bucomazi Formation, Cabinda, offshore Angola, Cretaceous	3 Rift basin, continental to transitional marine	The Lower Congo hydrocarbon habitat is dominated by the Pre-Salt Bucomazi petroleum system. These lacustrine, often super-rich, laminated evaporitic sediments reveal considerable organofacies variations between their early lacustrine basin fill and later sheet drape development with three major depositional regimes reflecting salinity and water depth control. ^{13}C depleted basal sediments, showing strong gammacerane/4-methyl sterane signatures, were segregated by a major isotopic excursion. This event represents the transition from an early saline playa lake to a deeper water salinity-stratified mesohaline lake supporting a high level of bottom anoxia. For the intermediate sediments, sterane and tricyclic diterpane abundances, plus sterane/hopane ratios, had marine connotations and can be interpreted as the result of intermittent marine incursions. Foreshadowing irreversible oceanic ingression, a resurgence of gammacerane abundance in the uppermost sediments typified littoral-shallow marine depositional conditions.	McHague (1990), Burwood (1999), Burwood et al. (1992, 1995), Burwood and Mycke (1996), Schoellkopf and Patterson (2000), Farrimond et al. (2004), Hartwig et al. (2012)
Lagoa Feia Formation, Campos Basin, Brazil, Early Cretaceous	3 Rift basin, continental to transitional marine	Rift-stage lacustrine sediments are the source rock of all petroleum so far discovered in the Campos Basin, the most prolific oil province in Brazil. These organic-rich shales were deposited in anoxic brackish to saline lakes. Petroleum migration pathways involve direct contact between source and reservoir rocks within the rift sequence. Later migration to the marine sequence reservoirs is related to windows in the halokinetic salt layer connected to growth faults and unconformities.	Trindade et al. (1995), Mello and Maxwell (1991), Beglinger et al. (2012)
Organic rich evaporitic mudstones, Durlston and Lulworth Fms, (Purbeck LS. Group), Dorset Coast UK, Earliest Cretaceous	3 Coastal synrift lagoons and lakes at edge of carbonate platform	Total organic carbon (TOC) of up to 8.5 wt% and high hydrogen index (HI) values (up to 956 mgHC/gTOC) and biomarkers point to a Type I OM, generally considered as derived from algal-bacterial biomass. Similarities to coastal lagoons of southern Australia (Marion Lake and Coorong regions). Interpreted as responses to a period of enhanced primary productivity within salinity -stratified coastal lagoonal/lacustrine settings at times of low sea level. Biomarkers support upward freshening and presence of *Botrycoccus*	Riboulleau et al. (2007), Schnyder et al. (2009)
Neuquen Basin, Argentina Jurassic-Cretaceous (Upper Valanginian-Lower Barremian)	2 Backarc-Foreland Basins	Agrio Fm., La Manga Fm. deposited in epeiric intrashelf basin sags, transgression typically atop evaporitic/eolian continental cycles. Throughout the Jurassic and Cretaceous periods, depositional patterns were related to waxing and waning of a narrow seaway that was connected to the Pacific realm through gaps in the magmatic arc. Widespread anoxia (temp/salinity) and Type II organic matter preservation occurred in the context of peak transgressions during the Toarcian, Oxfordian, Tithonian, late Valanginian and Hauterivian. A protracted history of regular subsidence and moderate heat flow at a back-arc position, together with the presence of widespread evaporite seals, has resulted in regional zonation of the stacked hydrocarbon occurrences. Halokinesis in Huitrin Fm (Permian)	Uliana and Legarreta (1993), Carozzi et al. (1993), Urien and Zambrano (1994), Lazo et al. (2005), Tyson et al. (2005)
Kimmeridgian Shale, North Sea, Jurassic	1b Evap-carb platform surrounding sediment-starved deep marine basin centre generated by ongoing Permian-Mesozoic rifting	Seawater flowed southwards from Boreal Ocean into Tethyan Ocean but evaporation in the shallow waters of the archipelago of islands and shoals created waters of increased salinity and in some cases local strong brines and evaporites, which sank and flowed as saline bottom currents (from 34 to 42‰) into deeper water. Areas of ponded deeper mesohaline water were commonplace in the more rapidly subsiding grabens, separated by sills, denser waters accumulated until they were able to spill over the sills. In this way more saline waters migrated along the sea bottom depressions, their paths being determined by local tectonic features, but mostly in a north to south direction. A stable water stratification ensued, the halocline being at about 50 m water depth and periods of widespread increased salinity are marked by "hot" shales.	Cooper et al. (1995), Miller (1990)

Malm Zeta, East Bavarian carbonate platform (Solnhofen), Germany (Malm)	1b Marine platform (sub wave-base)	Evaporitic platforms in an arid zone carbonate archipelago with anoxic mesohaline base to water column with density and thermally stratified bottoms in inter-reef depressions (Lagerstatten assemblages)	Schwark et al. (1998)
Shelf margin laminites in salinity-stratified intrashelf lows across the Arabian Gulf region from Syria, NW Iraq, Iran through the Arabian Gulf to central Oman (e.g., Diyab, Tuwaiq and Hanifa Formations), Upper Jurassic (Oxfordian-Kimmeridgean), also Middle Triassic Kurra Chine Dolomite in Syria and Cretaceous (Valanginian) Garau Formation in Iran	2 Density- stratified intrashelf basins surrounded by evaporitic platform. Some lows are possibly tied to salt withdrawal	Organic-rich laminated mudstones and wackestones deposited in pre-salt intrashelf, mesohaline basins on a gently downwarped epeiric platform. Intrashelf basins that retain organics all have a density and salinity stratified water column with mesohaline bottom carbonates. These basins source more than 90 % of the hydrocarbons in the Middle East. They are argillaceous dolomitic limestones that feed the most prolific petroleum system in the world and underlie the world's richest reservoir: the Arab D in the Arab Formation. One of the most prolific source units is the Hanifa Fm. in the Arabian Basin of Saudi Arabia. In the deeper parts of the intrashelf Arabian Basin (waters ≈ 30 m deep) the Hanifa is composed of laminite muds and marls, while in the surrounding shelf it is dominated by grainstones and packstones. Within the Hanifa laminites there are discrete but minor primary laminae of anhydrite (originally gypsum), as well as early diagenetic anhydrite nodules, both indicators of occasional hypersalinity. There are also laminae of fibrous calcite, which some authors have interpreted as another indicator of hypersalinity. The Hanifa is a widespread and prolific source, it can entrain more than 30 m of laminites; total organic carbon exceeds 1 %, with some sections having more than 5 %. The kerogen is predominantly hydrogen rich, the generated oils have a high sulphur content, a Pr/Py <1, and a predominance of even-numbered normal alkanes.	Ayres et al. (1982), Palacas (1984), Kirkland and Evans (1981), Evans and Kirkland (1988), Droste (1990), Beydoun (1993), Carrigan et al. (1995), Whittle and Alsharhan (1996), Fox and Ahlbrandt (2001), Ibrahim et al. (2002), Goff (2005), Abboud et al. (2005), Rabbani and Kamali (2005)
Upper Hamanlei (Antalo) Limestone Fm. Blue Nile (Abay) Basin, Ethiopia, Jurassic (Oxfordian-Kimmeridgean)	3 Intracratonic postrift? flexure sag basin	Lacustrine, schizohaline black shales/mudstones of the Upper Hamanlei (Antalo) Limestone Fm deposited in a continental intracratonic rift sag basin. These lacustrine source rocks sit atop sulphate-rich mudflat sediments of Middle Hamanlei (Gohatsion) sediments which created density stratified bottom waters via their dissolution.	Wolela (2007)
Smackover trend of Mississippi, Alabama and Sunniland of Florida, northeastern Gulf of Mexico, Upper Jurassic	2 Shallow restricted-circulation salinity stratified intrashelf basin on a broad carbonate platform	Oil and gas in this trend are generated from algal-rich light-brown to black laminated lime mudstones (argillaceous content <6 %) of the Lower Smackover Formation. Deposition occurred in intraplatform depressions surrounded by a broad carbonate platform. Bottom waters were stratified with slightly saline waters supplied from the broad platform surrounds and the shoaling carbonate system was sealed by the sulphate evaporites of the Buckner Anhydrite.	Oehler (1984)
Cifuentes Fm., Cuban Basin, offshore Cuba, Upper Jurassic (Tithonian)	2 Marine-fed rift graben, rift to drift transition	Transition to incipient ocean/passive margin carbonate platform. Marine hypersaline elevated sulphur source, similar to Sunniland oil source in Florida	Grimalt et al. (1991), Campos et al. (1996), Magnier et al. (2004)
Ionian/Adriatic basins, Offshore western Greece and onshore Albania, Upper Jurassic (Toarcian to Tithonian)	1a Synrift to postrift sag	A mesohaline stratified column in shallow restricted sub-basins in Triassic Ionian evaporitic basins. Lack of detailed stratigraphy in subsurface evaporites of Ionian zone means precise position of the shale source horizons is poorly defined but this evaporitic succession is more than 200 m thick with local mesohaline carbonate mudstones with TOC of 0.6–11.2 wt% (average 2.2 wt%).	Zappaterra (1994), Cota and Baric (1998), Rigakis and Karakitsios (1998), Karakitsios and Rigakis (2007)
Tithonian marls, Sureste Basin, Middle Jurassic	2 Platform	Massive calcareous black shales and dark grey, clayey laminated mudstones, averaging 220 m thickness, deposited under anoxic density-stratified conditions on a marine carbonate shelf	SantamarÌa-Orozco et al. (1998)

Todilto Formation, Toldilto Basin, USA, Middle Jurassic	3 Foreland flexural basin (lacustrine?)	The Limestone Member of the Todilto Fm. is a widespread carbonate laminite up to 3 m thick, overlain in the subsurface by up to 30 m of $CaSO_4$ known as the Gypsum Member, although it is mostly anhydrite. The Limestone Member is the source rock for 6 known hydrocarbon accumulations in the sands of the underlying Entrada Fm, while it and the overlying $CaSO_4$ are the seal. The quantity of TOC is low (≈1 %) for such a thin source rock and it has some unusual characteristics compared to most evaporitic source rocks. Laminite couplets are 0.15 mm thick yet are laterally continuous for up to 3.7 km and form widespread cohesive "sheets", which invariably contain remnants of vascular plants. The Todilto is probably lacustrine with a marine seep hydrology, similar in hydrology to the coastal salinas of southern Australia. The organics reflect the growth of a healthy conifer cover in its surrounds and its waters were density-stratified lacustrine, probably fed via a marine seepage inflow and periodic seasonal runoff. This maintained a density-stratified brine column, first at carbonate saturation during deposition of the Limestone Member, then at gypsum saturation during the deposition of the Gypsum Member.	Vincelette and Chittum (1981), Evans and Kirkland (1988)
Offshore east coast of USA, Middle to Lower Jurassic	2 Rift	Epeiric carbonate platform margin with local deeper-water anoxia in part related to anoxic slightly saline marine bottom	Sassen and Post (2008)
Dagorda Fm, Coimba Fm, Benha Fm., Lusitanian Basin, Offshore Portugal, Lower Jurassic	1b Rift to post rift sag	Laminated organic-rich mudstones, deposited in density-stratified waters in a post-rift thermal subsidence sag depression. Setting similar to Kimmeridgian shale in North Sea?	Kassler (1979), Uphoff (2005)
Posidonia Shale Beds, Mittelplate Oil field, Germany, Central European Basin, Lower Jurassic	2 or 4 Euxinic rim syncline depressions	Epeiric shelf seaway (Taorcian), with evaporitic platform highs possibly underlain by Zechstein salt structures, that is, restricted anoxic sea floor depressions in topography created by halokinetic Zechstein Salt	Littke (1993)
Manari Fm, Pirara Fm, Takutu Basin, Guyana, Early Jurassic (Taorcian?)	3 Rift, Lacustrine	Laminated grey brown micritic shale with Type I/II kerogen. Deposited at 2 degrees N palaeolatitude in an intracratonic Jurassic rift valley	Webster (2004)
Carnian "Kueper" Basin, NW Jordan	2a Intracratonic (postrift sag basin)	Organic-rich shales are common, especially as part of evaporite–carbonate cycles. Black shales from RH-1 well (850–1,380 m) are slightly carbonaceous, non to slightly calcareous with amorphous organic matter and some miospores and plant tissue. (rapidly subsiding intraplate epeiric basin, possibly depositionally analogous to Purbeck Group on Dorset coast)	Dill et al. (2012), Makhlouf and El-Haddad (2006)
Organic mudstones intercalated with evaporites, Mandawa Basin, Tanzania, Triassic	3 Rift basin, continental to transitional marine	Total organic carbon (TOC) values range from 1.23 to 7.41 % (wt) of kerogen Type II/III. The evaporite (hypersaline) influence is indicated by the presence of C-24-tetracyclic terpanes, gammacerane and C-35- homohopanes. The relative abundance of tricyclic terpanes (C-19-C-28 +) with respect to pentacyclic terpanes (C-27-C-35,) seem to change with depth, whereby the tricyclic/hopanes ratio apparently increases with depth. The mixed organic input from marine and terrestrial precursors are indicated by mixed abundances of C-27-, C-28-, C-29- steranes.	Kagya (1996)
Morondava Basin, Madagascar, Liassic	3 Rift to drift	Andafia Fm (Jurassic) and more local Sakamena Fm (Permo Triassic) Fm. Towards the end of the rift period, restricted marine conditions resulted in the deposition of Liassic evaporites in Madagascar, Tanzania, Kenya, Ethiopia and Somalia. Geochemical work by the EARHS identified an outstanding regional source-rock in association with these evaporites in Madagascar and Tanzania	Rayer and Slind (1999)
Irati Formation, Parana Basin, Brazil, Upper Permian (Artinskian)	3 Intracratonic sag	Irati Formation (upper Assistencia member) deposited in an intracratonic, schizohaline lacustrine depression as a bituminous shale (made up of black laminated mudstones with TOC up to 16.3 %)	De Araújo et al. (2005), Santos et al. (2009)

Oil Shales, Junggar Basin, NW China, Upper Permian	3 Controversial, with tectonic interpretations ranging from foreland flexure to regional transtensional basin	Junggar Basin is one of the largest oil-producing basins in China, its Upper Permian oil shales are among the thickest and richest lacustrine source rocks in the world. Together the Jingjingzigou, Lucaogou, and Hongyanchi Formations of the southern Junggar Basin comprise over 1,000 m of organic-rich lacustrine facies. They record an evolution from relatively shallow, evaporative lakes to freshwater lakes with fluvial systems. Jingjingzigou Formation was deposited in a perennial saline lake characterized by low TOC and HI, and biomarker features (such as abundant β-carotene) consistent with a specialized saline or hypersaline biota. Biomarker distributions in Jingjingzigou Formation extracts most closely resemble oils from the giant Karamay oilfield. Overlying Lucaogou Formation represents one of the richest and thickest lacustrine source rock intervals in the world, yet it contradicts conventional lacustrine source rock models in at least two important aspects. First, deposition occurred at middle palaeolatitudes (39–43° N) rather than in the tropics. Second, limited nutrient supply in a drainage basin dominated by intermediate volcanic rocks appears to have caused low to moderate primary productivities. Stable salinity stratification and low inorganic sedimentation rates in a deep lake nonetheless resulted in deposits with up to 20 % TOC and HI near 800. Overlying Hongyanchi Formation has 1–5 % TOC but low HI, and was deposited in freshwater oxic to sub-oxic lakes.	Carroll (1998), Carroll et al. (1992), Tang et al. (1997)
Ravnefjeld Formation, East Greenland, Upper Permian	3 Rift basin, continental to transitional marine	The Ravnefjeld Formation is subdivided into five units that can be traced throughout the Upper Permian depositional basin. Two of the units are laminated and organic rich, and were deposited under anoxic conditions. They are considered good to excellent source rocks for liquid hydrocarbons with initial average TOC (total organic carbon) values between 4 and 5 % and HI (hydrogen index) between 300 and 400. The cumulative source rock thickness is between 15 and 20 m. The source rocks are separated and enclosed by three units of bioturbated siltstone with a TOC of less than 0.5 % and an HI of less than 100. These siltstones were deposited under relatively oxic conditions. The organic geochemistry of the source rocks is typical for marine source rocks with some features normally associated with carbonate/evaporite rift environments [low Pr/Ph (pristane/phytane), low CPI (carbon preference index), distribution of tricyclic and pentacyclic terpanes]. The establishment of anoxic conditions and subsequent source rock deposition was controlled by eustatic sea level changes.	Christiansen et al. (1993)
Ucayali Basin, Middle-Late Permian	3 Foreland basin	Ene Fm., passing from marine carbonate (Copacabana Fm) up into evaporitic continental/volcanics	Mathalone and Montoya (1995)
Fish River Subgroup, Nama Group, Nama Basin, Namibia, Early Permian, (Artinskian)	3 Rift	Organics form Permian saline Lake hosted in calcite vein fill in sub-unconformity Cambrian host. Saline lacustrine indicated by abundant gammacerane, β-carotene and 3b-methylhopanes while 24-isopropyl cholestanes and dinosteroids not detectable. Saline lacustrine equivalent to Irati Fm (Perm.) in Brazil	Gierlowski-Kordesch and Kelts (1994), Summons et al. (2008)
Phosphoria Formation, Little Sheep Creek, Montana, Permian	1b Foreland flexure basin	Correlations between biomarker indicators of anoxia and salinity suggest that anoxia was in part the result of a chemocline separating normal marine waters above from more saline bottom waters. Anoxia and salinity in the bottom waters increased with time making conditions in the basin progressively more hostile to benthic organisms.	Dahl et al. (1993)
Kupferschiefer Formation, NW Europe, Permian	1a Rift basin, restricted marine	Thin, widespread organic-rich laminated mudstone deposited in shallow mesohaline marginal sea-lakes with waters which were <100 m deep and mostly 10–30 m deep. Surface exchange with Zechstein ocean was restricted by palaeohighs.	Bechtel and Puttmann (1997), Slowakiewicz and Mikolajewski (2009)

Sub salt-allochthon oil seeps, Windsor Group, Nova Scotia, Canada, Carboniferous	3 Rift basin, continental to transitional marine	The oil seeps are either associated with upper Horton Group (Ainslie Formation) or basal Windsor Group (Macumber Formation) sediments. The biomarker distributions of the samples are similar to Stoney Creek oils and their lacustrine carbonate source rock (Albert Shale) of the Moncton Sub-basin, New Brunswick, as are oils from seeps in the Pugwash Salt mine.	Fowler et al. (1993)
Black shales in the Paradox Member of the Hermosa Formation, Paradox Basin, USA, Carboniferous (Pennsylvanian)	1a Foreland flexural basin	Organic-rich black shales (informally known as the Cane Creek, Chimney Rock, Gothic shales) form a carbonate laminite basal sequence to a number of salting-upward evaporite cycles in the Paradox Member. Mineralogically the shales are between 30 and 50 % calcite or dolomite with clays and quartz sand forming the remainder of the matrix. TOC values of 5 % of hydrogen-prone organics in the black shales are usual, with values of 10 % not uncommon and the highest values more than 20 %. The organics are mixtures of halotolerant debris and marine-style organics formed when surface waters were at marine salinities, as well as occasional terrestrial organics washed into the basin from the surrounding hinterland.	Evans and Kirkland (1988), Hite et al. (1984)
Anhydritic lacustrine beds, East Shetland Platform, North Sea, Middle Devonian	3 Rift basin, restricted marine	The UKCS well 9/16–3 drilled on the western flank of the Beryl Embayment indicates local development of hypersaline environments equivalent to the Achanarras/Sandwick fish bed. Shows close affinity with contemporaneous Middle Devonian source rocks of the Inner Moray Firth and crude oil in Beatrice oil field.	Duncan and Buxton (1995)
Muskeg Formation and Lower Keg River Member, Alberta, Devonian Canada	1a Rift basin, restricted marine	Laminated organic-rich bituminous mudstones deposited in pre-evaporitic density stratified water columns. Vertical migration from the Muskeg formation to the Muskeg Reservoirs may have occurred through local fracturing of anhydrites driven by the dissolution of Black Creek halite.	Clark and Philp (1989), Stasiuk (1994)
Pricaspian Basin, Kazakhstan, Devonian and Permian evaporites	1a Rift to foreland at onset continent-continent collision	Izembet (Zilair) Formation and equivalents, as well as Carboniferous black shales. Deposited as hypersaline carbonate source rock (black shales) contemporaneous with Devonian depositional shelf reservoirs and Kungurian (foreland) base salt in Karachaganak, Zhanazhol oils and Astrakhansk condensate (Precaspian basin)	Chakhmakhchev and Suzuki (1995), Ulmishek (2001a), Gürgey (2002)
Devonian oils, Appalachian Basin	1a Epeiric intracratonic margin passing into foreland basin	Hydrocarbon coats on mesogenetic quartz cements in Ohio portion of Appalachian basins (foreland basin) show some hypersaline source affinities, similar to Michigan Basin.	Obermajer et al. (1998), Dix and Robinson (2003)
Laminated evaporitic, A-1 mudstones, Michigan Basin, Silurian	1a Rift basin, restricted marine	Biomarker characteristics indicate a carbonate/evaporite source rock deposited under hypersaline conditions in a strongly reducing environment. The source rocks occur in the basin centre in organic-rich laminites of the inter-reef A-1 Salina Formation, a mesohaline carbonate deposited beneath a density stratified brine column.	Gardner and Bray (1984), Obermajer et al. (1998), Obermajer et al. (2000)
Oils, Tarim Basin, Tabei Uplift, NE China, Cambro-Ordovician	1b Platform, intracratonic sag	Evaporitic source rock (limestone and dolomite interbedded with mudstone and sulphates) in central and northern parts of basin (also Ordovician). Biomarkers indicate some source rocks (Tabei) come from diaromatic carotenoids of photosynthetic sulphur bacteria	Liu et al. (2003), Sun et al. (2003)
Chandler Formation, Amadeus Basin, Australia, Lower Cambrian	1a Foreland flexure	Thin bituminous pre-evaporitic carbonate mudstone deposited subaqueously in a restricted basin immediately prior to the deposition of the thick halites of the Chandler Formation.	Bradshaw (1988)

Formation/group, locality and age	Basin style	Characteristics and depositional setting	Reference
"Q" oil associated with Ara Salt, south Oman Salt Basin, Oman Neoproterozoic-Early Cambrian	1 Rift then collision	The Q oil family is highly unusual and distinct from the more prevalent Huqf oil family by having an extraordinarily high C27/C29 sterane ratio and $\delta^{13}C$ values near −30‰. Tends in the patterns of norsteranes in south Oman carbonate stringer oils suggest the Q oil source originates from one of the upper units of the Ara carbonate and evaporite sequence likely a siliciclastic source rock lying stratigraphically above the A6 carbonates The high relative abundances of 24-isopropylcholestanes in Q oils likely originate from demosponges and the 17-methylpentatriacontane, which is so abundant in Q oils, is a biomarker for early arthropods that inhabited the salt basins of Oman at the very beginning of the Cambrian Period.	Grosjean et al. (2012)
Hormuz Series, Arabian Gulf and counterparts in India and Pakistan, Neoproterozoic to Early Cambrian	1 Rift basins, restricted marine	Almost all the Persian Gulf and large areas of southern Iran and northeastern Arabia are underlain by a thick sequence of sediments, known as the Hormuz Series. It is made up of interbedded salt, anhydrite, dolomite, shale and sandstone. It is not only the cause of many salt-dome-related oil and gas fields but is also considered to have been a major source rock for hydrocarbons in Ordovician, Devonian, Carboniferous, Permian and perhaps younger reservoirs. These oils have characteristic biomarkers and highly depleted carbon isotopes signatures indicative of their prokaryotic precursor.	Alam and Ahmed (2008), Amthor (2000), Edgell (1991), Grantham et al. (1988); Peters et al. (1995), Quadri and Quadri (2003), Schoenherr et al. (2007a, b, c, 2009)
Browne Fm, B1, B2 and B4 members, Officer Basin, Neoproterozoic (780–800 Ma)	1a Postrift sag	Organic rich, laminated dolomites interlayered with evaporites, kerogens are now mostly overmature	Apak et al. (2002), Ghori (2002), Craig et al. (2013)

See Fig. 9.7 for location

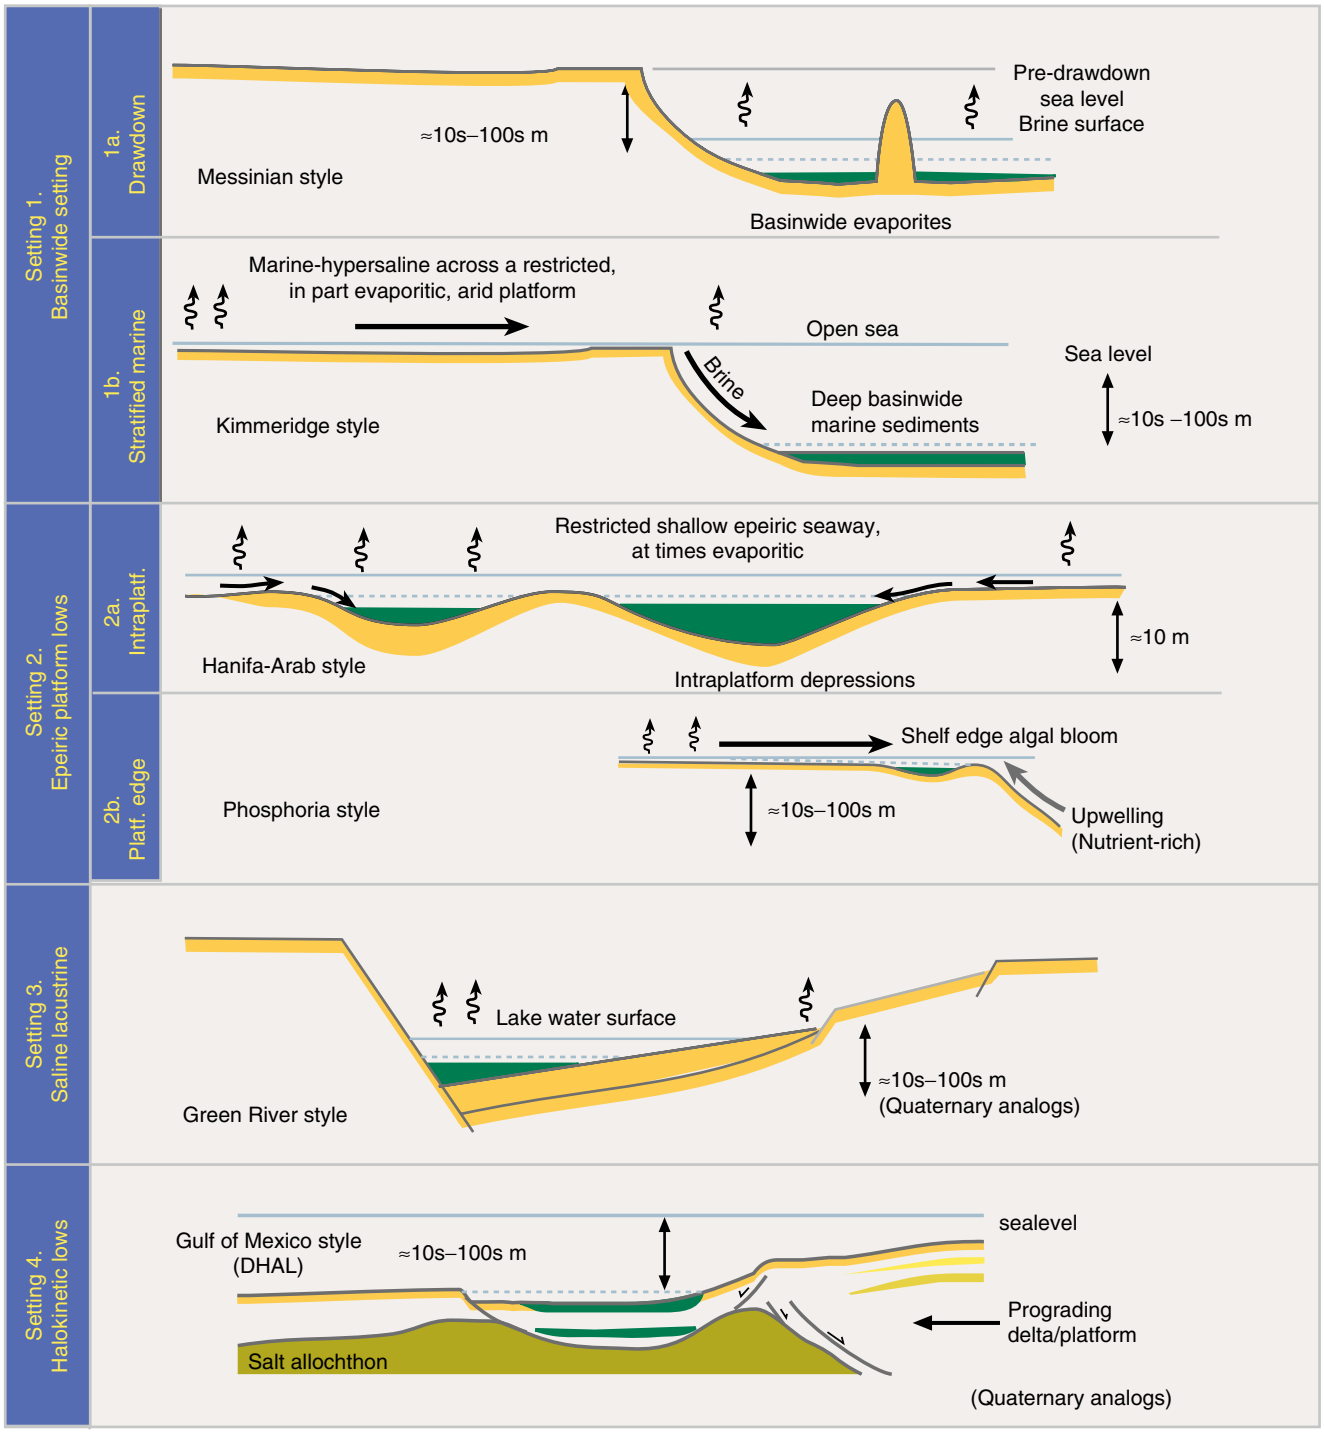

Fig. 9.4 Dominant depositional styles for evaporitic source rocks (*shaded green*). All the water bodies show evidence of salinity-related density stratification (indicated by *dashed line*), this is also reflected in an associated heliothermic stratification. (*DHAL* Deepsea hypersaline anoxic lake)

Expulsion efficiencies suffer from encasement and widespread salt plugging of the potential source rocks in many evaporite-rich setting 1a basins. This tends to retain volatiles in the source beds until the whole system becomes overmature. For example, in the Gibson Dome No, 1 well, in the Paradox Basin almost all of the black shales intercalated in the halite cycles in the Paradox Member are mature enough to have generated oil (Hite et al. 1984). But the hydrocarbons have been largely retained in this mature source rock, reflecting the highly efficient sealing effects of the intercalated evaporite beds and salt cements (mostly halite). Only where the black shales are intercalated or in contact with porous

carbonates have the hydrocarbons escaped. The source potential of these shales is very high; the "Gothic shale" is capable of generating almost 5,000 barrels per acre. But that potential is never more than partially realised. Paradox "shales" are responsible for an accumulative production of a little more than 400 million barrels of oil and about 1 TCF of gas in the Paradox Basin in fields such as Ismay and Aneth (Peterson and Hite 1969).

This problem of evaporite plugging plagues many basinal source rocks where the basin centre evolved to accumulate basinwide evaporites and is one of the main reasons for the dearth of large onshore oilfields beneath bedded salt or within intrasalt carbonates in the Zechstein basin of NW Europe. Organic-rich source intervals such as the Stinkdolomit, Stinkkalk, and Stinkscheifer are widespread, but the associated oil accumulations are never more than localised and small scale. Setting 1a sediments can be characterised by very rich organic source beds but the intercalated seals prevent most of the volatiles from ever escaping into a reservoir. In the South Oman Salt basin this source-seal association characterises earliest Cambrian intrasalt source rocks that supply hydrocarbons to intrasalt carbonate stringer reservoirs (Grosjean et al. 2009). In even older examples, where formerly thick salt has been leached and basin temperatures extended beyond the oil window into the greenschist metamorphic realm, such episodes of later burial dissolution of salt facilitates contact of formerly encased organics with basinal waters carrying Cu, Pb and Zn. The newly released volatiles and kerogens in these systems can play an important role as reductants and metal fixers, as in the Mesoproterozoic Pb-Zn laminates in McArthur Basin, NW Australia, that, (Warren 2000b).

Basin Setting 1b: Basin-centre mesohaline accumulations in this setting are much more efficient petroleum producers than style 1a as they lack intercalated beds of basinwide halite or anhydrite, which otherwise plug and cement source intervals. Style 1b source rocks develop where dense mesohaline bottom waters pond in the deeper parts of deep density-stratified restricted-marine basins. Slightly elevated bottom brine salinities are maintained by a series of dense brine underflows, fed from nearby shoalwater evaporitic platforms (Fig. 9.4). A deepwater "marine" centre typifies such basins, along with widespread evaporitic and shoal water carbonate sediments in the surrounding platforms and shelves. Setting 1b basins are best thought of as stunted or underdeveloped basinwide evaporite systems. Development of the basinwide evaporite hydrology was suspended prior to the basin centre drawdown reaching the state of complete hydrographic isolation, which is needed for widespread salt precipitation. Evaporitic conditions (mostly bedded anhydrites) dominated on isolated platform depressions about the basin margin. Typical examples of this style of association are Kimmeridge shales of the North Sea (Miller 1990; Cooper et al. 1995), organic-rich laminites of the Cherry Canyon Formation in the Permian Delaware Basin of West Texas (Jones 1984), the Devonian Woodford Shale in the US midcontinent (Comer 2012) and possibly some of the Devonian laminites of the Alberta Basin (Clark and Philp 1989).

In this setting, waters in the deepwater basin centre remain starved of sediment and density-stratified, with the upper less saline part of the water column typified by normal marine water maintained through surface connections to the open ocean. The little sediment matrix that does accumulate in the basin centre settles into an anoxic thermally/density stratified bottom so that the sediment matrix of the source laminites is dominated by a planktonic or nektonic biota and a more or less constant elevated organic content. Carbonate banks or reefs in the surrounding platform grade landward through lagoonal and evaporitic platform facies in to terrestrial clastics. At times of slightly lowered sea level these epeiric platforms can go evaporitic and so deposit widespread platform salts (Chap. 5). Such basins show a centrifugal salinity gradient where the highest salinity areas are in the surrounding shallow evaporite platforms, which supply dense saline waters that trickle and seep basinward to pond in seafloor lows at the anoxic base of a density stratified water column.

With setting 1b, the formation of evaporites and saline waters about the basin edge is not typically followed by the deposition of basin-centre evaporites. At the time the deepwater organic laminites are accumulating, the deep basin centre waters lie at the bottom of the thick density-stratified water column in a semi-enclosed seaway. Bottom brines may be no more than 3–5‰ more saline than the normal marine waters. For example, at the time the Purbeck evaporites were accumulating on the adjacent platform, the anoxic bottom waters in the marine basin centre, atop the accumulating Kimmeridge shales, had salinities around 42‰, temperatures ≈30 °C and densities ≈1.0270. The overlying near normal marine waters had salinities of 34–39‰, surface temperatures of 26 °C in the south and as low as 6 °C further north in the region of the Boreal Ocean inflow and densities around 1.0267 (Miller 1990).

Basin Setting 2: Upper Jurassic source rocks of the Middle East are well studied examples of the epeiric shelf or marine evaporitic platform settings and typify style 2 source rocks, which are deposited within local somewhat deeper, density-stratified mesohaline intrashelf lows (Fig. 9.5; Table 9.2; Ayres et al. 1982; Evans and Kirkland 1988; Droste 1990; *pers obs*.). In the Tethyan of the Middle East this style of source rock feeds a petroleum system that is probably the most efficient in the world. It evolved from Upper Jurassic source rock accumulators (typically with TOC's ≈1 % and occasionally up to 6–10 %) into evaporitic mudflats sealing the mostly bioclastic reservoirs of the

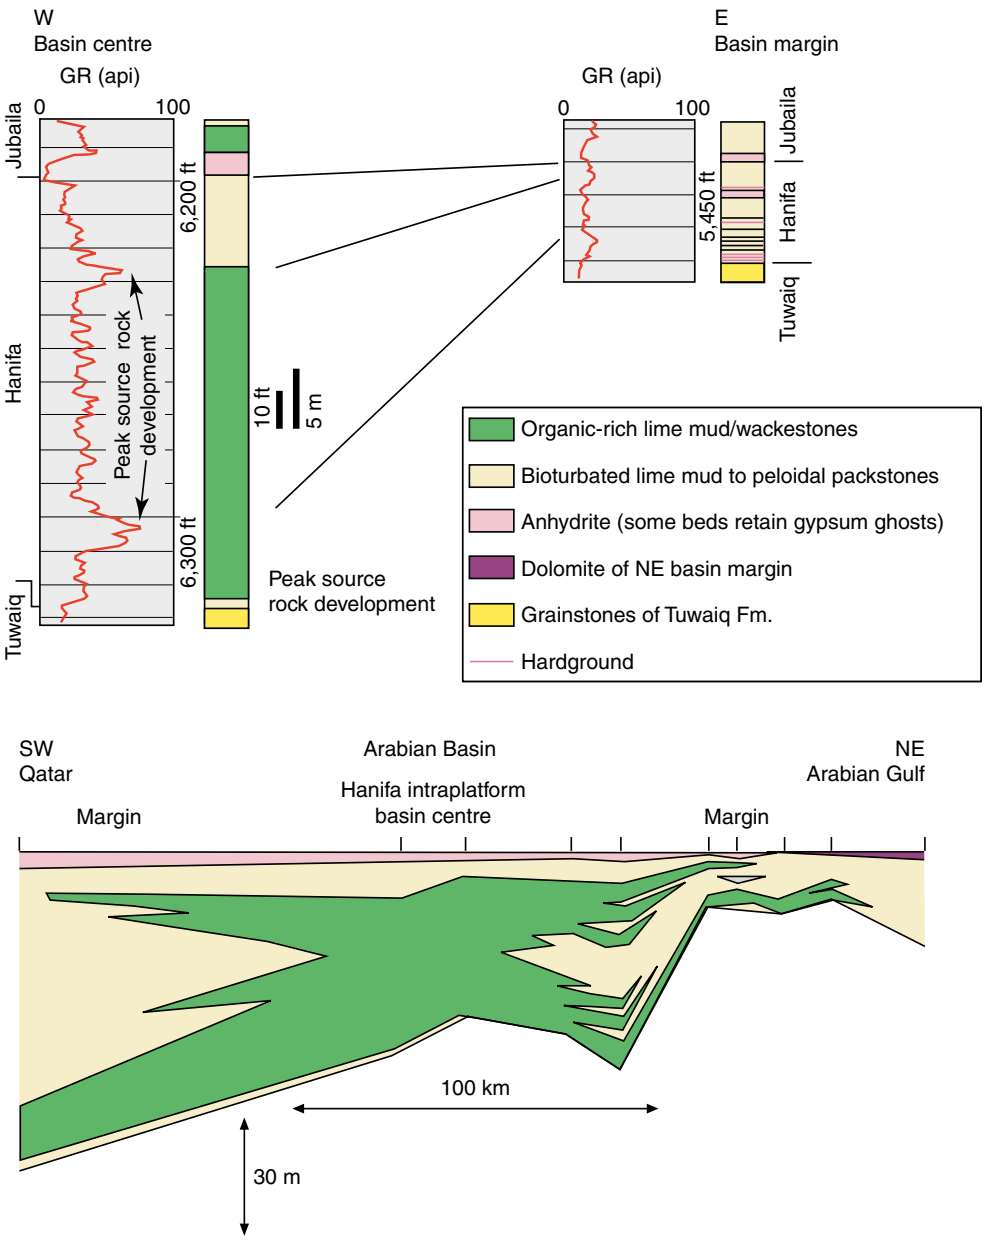

Fig. 9.5 Characteristics of the Hanifa Formation, Saudi Arabia, a setting 2 intraplatform basin source rock that was deposited beneath relatively shallow and anoxic mesohaline bottom waters in a slight depression on the shelf and was surrounded by epeiric evaporitic sedimentation, as indicated by the presence of anhydrite in the Hanifa Fm (After Droste 1990). Peaks in the organic content of these carbonate mudstones are indicated by peaks in the gamma curve. Cross section is redrafted from Carrigan et al. 1995

carbonate platform of the Arab cycles, beneath the regional Hith Anhydrite seal, which was deposited on a saltern-covered platform (Fig. 10.8). The laminite source rocks in the various intrashelf depressions were deposited at times of widespread epeiric carbonate deposition and stagnant oceanic circulation.

It was a time when much of the Arabian platform was covered by a warm shallow greenhouse sea precipitating varying combinations of carbonates and evaporites. Denser warmer waters, generated by evaporation of epeiric waters and water of the surrounding evaporitic mudflats, were concentrated to where they were somewhat more saline than normal seawater. Dense brines then trickled and seeped over the shallow seafloor into the lower parts of restricted intrashelf basins, to create density-stratified water bottoms that were not more than tens of metres deep and no more than 10–30‰ more saline than seawater (Ayres et al. 1982). Ongoing mixing and dilution of the bottom-hugging brines during their passage to the lows meant the basal water mass in the intrashelf lows, although saline, rarely attained gypsum saturation (mostly mesohaline anoxic brines). The overlying column was usually near normal marine salinity. Salt withdrawal and dissolution of salt diapirs and allochthons, sourced in the Precambrian Hormuz salt, perhaps helped create the intrashelf depressions and may also have played a role in generating a portion of the bottom brines. As for the source rocks of the style 1b Kimmeridge Clays where

halokinesis and salt solution of Zechstein mother salt played a role in generating local briny anoxic bottoms, so too in the Jurassic of the Middle Eas (Clark et al. 1999).

Thus, one of the most prolific intrashelf source rocks in the Middle East, the Hanifa Formation, was deposited in the intrashelf Arabian Basin of Saudi Arabia (Figs. 9.5 and 10.14; Droste 1990). It sources most of the hydrocarbons reservoired in the Arab cycles of Saudi Arabia and is regionally sealed by the Hith Anhydrite. The organic-rich portion of the Hanifa, deposited in the "deeper" parts of the intrashelf basin (waters ≈ 30 m deep), is composed of laminite muds and marls, while in the surrounding Arabian shelf it is dominated by grainstones and packstones. All Hanifa facies can be locally overprinted with later anhydritic burial and reflux cements and later diagenetic dolomites. As the various depressions filled with laminites they shallowed to where the stratification was lost and the sediment became an open marine packstone-wackestone, equivalent to sediments deposited over the rest of the Arabian Platform.

Later episodes of hydrographic isolation of the platform, via buildup of a transgressive platform rim and a slight fall in sea level, then drove deposition of anhydritic saltern or mudflat caps of the various Arab cycles A-D and ultimately the deposition of the regional Hith Anhydrite seal (Fig. 10.14). Within parts of the Hanifa laminites there are discrete laminae and thin beds of primary anhydrite, as well as early diagenetic anhydrite nodules, both indicators of periodic hypersalinity. Likewise, the restricted evaporitic caps to some of the source cycles in basin margins to the Hanifa Formation in the Arabian Basin can locally preserve aligned gypsum ghosts, indicating a subaqueous gypsum precursor in the shallower parts of the epeiric seaway (Fig. 9.5). Similar, but volumetrically less prolific, intrashelf source rocks characterise parts of the Lower Smackover Formation (Upper Jurassic) of the northeastern Gulf of Mexico, as in the Mississippi Interior Salt Basin (Oehler 1984), and parts of the Cretaceous Sunniland Formation of Florida (Palacas et al. 1984).

A variation on this density-stratified mesohaline epeiric platform-depression style of source rock accumulation is the phosphate and organic-rich sediment of the Phosphoria Formation in the USA (Stephens and Carroll 1998). This laminated unit sources much of the oil in Wyoming and was deposited in shelf edge depressions of the Phosphoria Sea adjacent to an area of marine upwelling. The nutrient- rich waters facilitated algal blooms near and atop the shelf edge, while bottom-hugging brines, seeping seaward from the evaporitic hinterland, ponded in stagnant shelf edge depressions. Overlap of the two systems created local anoxic shelf-edge mesohaline depressions with anoxic bottom waters that preserved a rain of organics detritus from the overlying algal blooms (Fig. 9.4). This system requires an epeiric evaporitic hinterland to supply bottom-hugging brines and, like the saltern-sealed Jurassic intrashelf depressions of the Middle East, has no modern counterpart.

Basin setting 3: These source rocks accumulated in sediment-starved or underfilled saline lakes in arid climates. The laminites typically accumulated in the early continental stage of infill in an opening rift, prior to its opening into a marine-fed marginal evaporite basin, or in the restricted lacustrine stage of a foreland flexure in a collision belt (Figs. 5.32 and 9.5). Modern underfilled saline rift lakes have some of the highest rates of organic productivity known and can accumulate high levels of organics within carbonate laminites. Some of these lacustrine laminites accumulate beneath deep density-stratified water columns, while others accumulate as "moat facies" or microbial mudflats about lake margins (Fig. 9.6; Table 9.2). The likelihood of numerous water level changes during the life of a saline lake especially effect laminites deposited in shoal water moats and margin mudflats and so can lower their preservation potential (Bohacs et al. 2000). Most oil-prone style 3 lacustrine source rocks were deposited at the bottom of perennial salinity-stratified hydrologies, with water column depths measured in metres to tens of metres, not as subaerially exposed algal mudflats. Examples include the Wilkins Peak Member of the Eocene Green River Formation, USA, the Lagoa Feia Formation of the Alagoas portion of the Campos Basin in Brazil, the Bucomazi Formation in offshore West Africa and the Jingjingzigou Formation in the Junggar Basin, China (Table 9.2).

The desiccation needed to form underfilled lacustrine succession typically means that saline lacustrine phases have lesser aerial extents compared to times of freshwater deposition. But this does not necessarily mean the evaporitic lacustrine source rocks are less prolific than their freshwater counterparts. Within the Green River Formation there are two associations (fresh and saline) of lacustrine organic laminites exemplified by the Luman Tongue and the Laney Member (Fig. 9.6a; Horsfield et al. 1994). The Luman Tongue consists of organic-rich mudstones deposited as profundal sediments at a time when lake waters were relatively fresh. Proximal organic-poor sediments, as well as coals and thin sandstones, were deposited in the lake plain. The highest levels of TOC in the Luman Tongue are found in lake margin deposits, which contain a mixture of alginite and vitrinite, but they have a low hydrogen index and a low petroleum generation potential (Fig. 9.6b, c). In fact, the petroleum generation potential of these freshwater deposits is no more than moderate.

In contrast, the organic percentages of the carbonate laminites of the Laney Shale are much higher (6–22 %) and they are hydrogen prone. The most organic-rich samples were deposited in the lowest parts of the lake and are composed mostly of alginite with relatively minor contributions from higher plants. The much higher petroleum potential of the

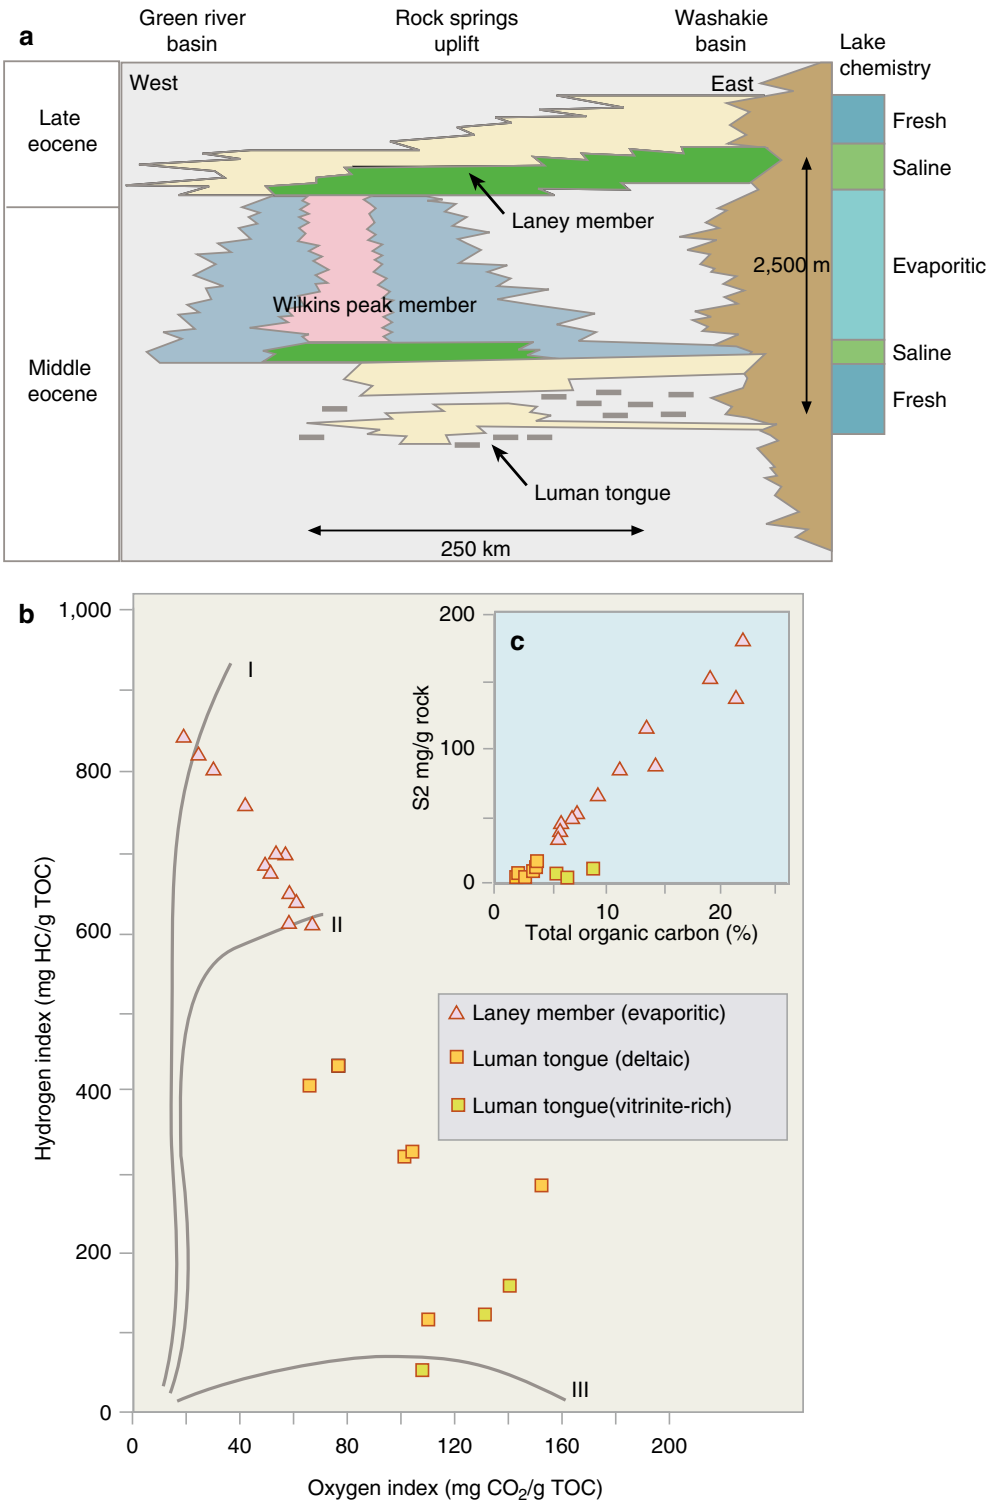

Fig. 9.6 Kerogen character of Laney Member and Luman Tongue of the Eocene Green River Formation, USA. (**a**) Schematic E-W cross section showing lateral extents and thicknesses of various lacustrine units (After Bohacs et al. 2000). (**b**) Hydrogen and oxygen indices. (**c**) Pyrolysis yields of hydrocarbon-equivalents (mg/g rock) plotted against organic carbon percentages (**b**, **c**: After Horsfield et al. 1994)

Laney shale reflects the marked density stratification of Lake Gosiute waters at the time the Laney was accumulating. At that time bottom anoxia was stabilised by the perennial highly saline bottom waters (Fischer and Roberts 1991). The vertical transition from saline lacustrine Jingjingzigou Formation to the highly prolific brackish oil shales of the lacustrine Lucaogou Formation in the Permian Junggar Basin of NW China may represent a similar dissolution-induced transition in the lake water column and help explain the lakes unusual latitude (Table 9.2; Carroll 1998).

Fig. 9.7 Worldwide distribution of evaporite-related source rocks named with respect to hosting basins (Replotted from Salt-Work GIS database version 1.7 see Table 9.2 for bibliographic details)

Basin Setting 4: is an increasingly documented open-ocean evaporite-associated source rock setting where density-stratified saline bottom brines and organic-enriched laminites accumulate in brine-bottomed depressions atop and adjacent to shallow and dissolving salt allochthons (Fig. 9.4). With burial these laminites may act as source rocks, but unlike the restricted settings of the preceding three styles, deposition typically occurs beneath open marine water atop continental slope and rise sediments. The laminites accumulate on the floor of deep brine pools that form on or near the margins of actively flowing and dissolving shallow salt allochthons. This association is discussed in detail later in this chapter and it is also a significant setting for the formation of base metal-hosting laminites as in Tunisia and the Red Sea (Warren 2000b). As yet it is not a widely documented environment for hydrocarbon source rocks, but it may in part explain the higher than expected source potential of many prodelta and slope muds in the passive margin fill of evaporite-floored halokinetic rifts.

Source rocks of settings 1a, 2 and 3 are typified by the accumulation of mm-scale layers of oil-prone organics typically in a matrix of fine carbonates. Setting 1b typically contains higher levels of siliciclastic fines and in many cases is a basinal marl or occasionally a laminated siliciclastic carbonate shale. The matrix of setting 4 laminites tends to be composed of whatever detrital sediment is accumulating atop the salt allochthon. In many situations, such as the Gulf of Mexico and the Mediterranean allochthon terranes, this matrix is a siliciclastic mud/clay laid down at the distal ends of prodelta wedges. In others, such as the Jurassic and Cretaceous of the Arabian Gulf and the Triassic of Tunisia, the matrix was carbonate mud.

The presence of mesohaline and marine carbonate muds, rather than aluminosilicate clays, in the matrix of many organic-rich evaporitic source rocks can change maturity and migration parameters. Mesohaline carbonate source rocks are susceptible to early generation of bitumens and volatiles compared with terrigenous shales. The proportion of bitumens (extractables) in the organics of carbonate source rock is high compared to that of shales as most mesohaline carbonates are largely isolated from high levels of terrigenous influx and the associated load of "spent" or oxidised organic matter (Warren 1986). For the same reason much of the early asphaltic product in a mesohaline carbonate laminite begins to migrate early in the burial history, whereas similar materials are held longer in the lattice of aluminosilicate clays (Warren 1986; Cordell 1992). Espitalie et al. (1980) showed that carbonate source rocks are likely to provide larger volumes of hydrocarbons for pooling than analogous terrigenous shales for the same levels of TOC. Geochemical analyses show that heavy oils from carbonate source rocks can form at marginally mature stages and at lower temperatures than required for oil generation from terrigenous shales, although much of the key data is ambiguous (Jones 1984).

Evaporitic source rocks deposited from mesohaline waters are a reality (Fig. 9.7; Table 9.2). No matter what the evaporitic depositional setting (Fig. 9.4), like non-evaporitic source rocks, they are typified by the common overriding

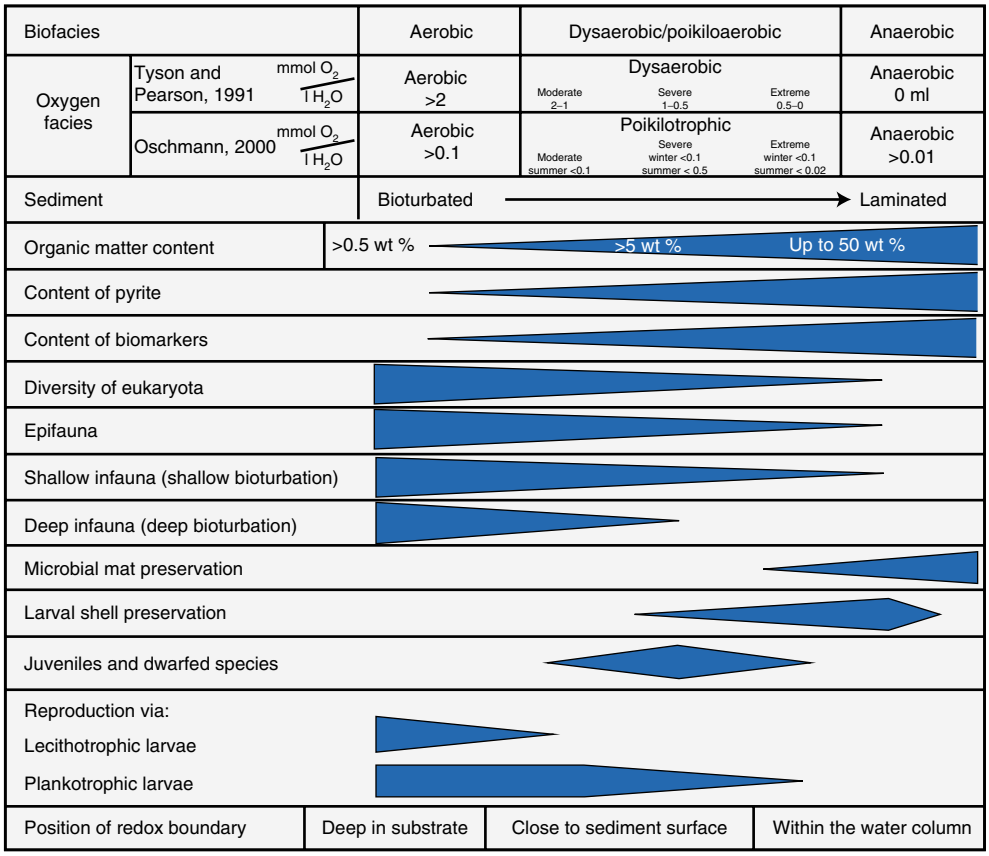

Fig. 9.8 Comparison of typical features of anaerobic, dysaerobic and aerobic sediments in evaporitic and nonevaporitic settings (After Oschmann 2011)

characteristics of anoxia and lamination. Preserved lamina in most source rocks indicates microbial binding coupled with a lack of effective grazers and burrowers (Fig. 9.8). So let us now look to the modern, and at relevant processes in biomarkers to see why this is so and how saline source rocks differ from non-saline source rocks.

Halobiota: Adaptations and Bio Markers

As long ago as 1826 during his voyage on the Beagle, Charles Darwin described biological aspects of the production of solar salt from an inland lake some 23 km from El Carmen, Patagonia. Although unfamiliar with bacteria (after all, Louis Pasteur was only a 4 year-old child at the time), he recognised that there was a "putrefying life-form" in the mud; that algae caused a green colour on the lake; that flamingoes fed on the brine shrimp and worms; and that other "infusorial animalcula" were part of the salt producing system. Yet in 1957, in his classic book on evaporites, Lotze made the statement: "Nicht das Leben, sondern der Tod beherrscht die Salzbildungsstätten" (Not life, but death rules the locales of salt deposition). Likewise, the name of the Dead Sea in the Middle East comes from the time of the Roman occupation when it was given the Latin name *Mortuum Mare* for its perceived lifelessness[4].

For many geologists, saline environments are seen as biotal deserts, largely devoid of biological activity and hence little source rock potential. Like Sir Charles Darwin, we now know that this is not the case. Rather, many modern saline water bodies are sites of periodic but intense organic activity, where numerous highly specialized algal, bacterial and archaeal species infrequently flourish and die back (cycles of feast or famine). Occasionally, they can leave behind substantial volumes of oil-prone organic residues in laminated bottom sediments, especially in mesohaline carbonates, which on burial can evolve into prolific source rocks. Even in modern saline settings, where evaporite depositional settings are not as diverse or widespread, conditions are such that mesohaline carbonates can preserve high levels of total organic carbon (TOC; Fig. 9.9).

[4]The Dead Sea described in Pliny the Elder's *Natural History* as being free of life.

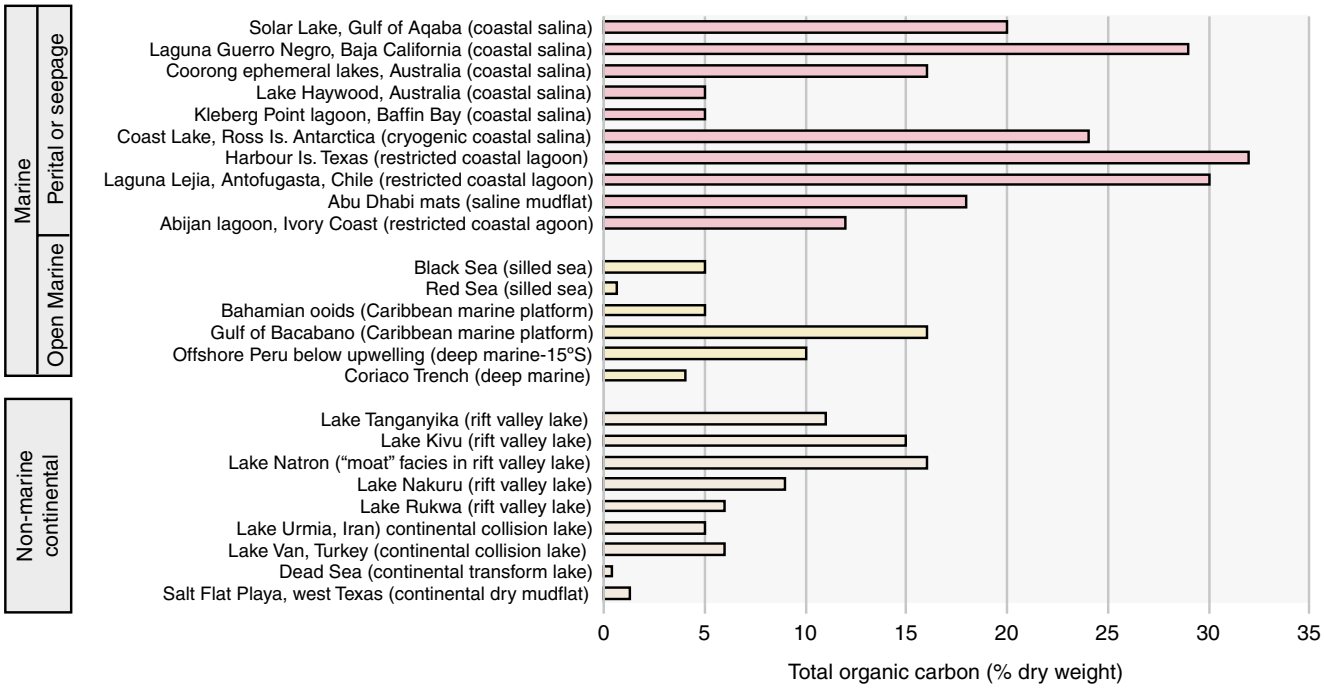

Fig. 9.9 Total organic carbon (TOC as dry wt. percent) in various modern saline settings (Compiled from various sources listed in this chapter and Warren 1986)

Metabolic Pathways in Producers and Consumers

Before we discuss how halotolerant and halophilic biomass accumulates in saline environments, we need to review some basic biology and biochemistry. Our understanding of the taxonomy and biogeochemistry of the prokaryota, the cyanobacteria, bacteria and archaea, which dominate the biota of many hypersaline waters, has undergone quantum change in the past few decades. In the late 1970s, Professor Carl Woese proposed, on the basis of ribosomal RNA affiliations (gene mapping), that life be divided into three domains instead of two, namely: Eukarya, Eubacteria, and Archaebacteria (Woese and Fox 1977; Woese 1993). He later decided that the domain Archaebacteria was a misnomer, and shortened it to Archaea while assigning Archaebacteria as a life kingdom name (Table 9.3). He did the same for domain Eubacteria, shortening it to Bacteria and designated the other prokaryote kingdom as Eubacteria (Woese et al. 1990). This reclassification recognises 3 domains and 6 kingdoms making up the entirety of life on Planet Earth (Table 9.3; Fig. 9.10a).

DNA base -pair studies (16S rRNA gene sequencing) show that species of the domain Archaea are as different from species of Bacteria as from *Homo sapiens* (Fig. 9.10a, b). But Woese's notion of three domains of life, proposed more than 40 years ago, did not take the biological world by storm. Before the advent and take-up of hybridization and genome mapping techniques as a basis for classifying all life, the inferred evolutionary relationships among microbes were contradictory and very messy. Microbial species and interspecies relationships were not easily established on the basis of intricacies of differences in cellular structure, which are often minimal, or by staining, or by the fossil record. None of these approaches when applied to microbes are species-, or even phyla-, specific. For example, based on their morphology, the archaeal *Halobacteriaceae* can be grouped with the bacterial gram-negative rods (a gram positive or gram negative description indicates whether or not the microbial cell wall reacts with Gram's stain). The advent of gene-based classifications threw classic morphological and stain-based microbial groupings into disarray. All the dust has yet to settle from this cladistic confrontation between morphology and gene-mapped subdivisions between and within the microbial and eukaryotal realms (Roger and Simpson 2009). For example, the term halobacteria is now mostly used colloquially to describe the halophilic archaea, while commonly used metabolic terms, like sulphate-reducer and sulphur-oxidizer, are polyphyletic (Table 9.3).

The initial chagrin of those botanists and zoologists versed in classic ecological and cladistic techniques to Woese's laboratory-based tripartite domains is understandable; after all, in his nonanthropocentric regime large

Table 9.3 Life chart showing its domains and kingdoms and some of the relevant parameters and phyla/families

Domain	Bacteria	Archaea	Eukarya			
Kingdom	Eu-bacteria	Archaea-bacteria	Protista	Fungi	Plantae	Animalia
Cell type	Prokaryote	Prokaryote	Eukaryote	Eukaryote	Eukaryote	Eukaryote
Cellular style	Unicellular (with no cell nucleus)	Unicellular (with no cell nucleus)	Unicellular and multicellular	Unicellular and multicellular	Multicellular	Multicellular
Metabolic style	Autotroph and heterotroph	Autotroph and heterotroph	Autotroph and heterotroph	Heterotroph	Autotroph	Heterotroph
Typical environmental conditions	Moist	Extreme (typically anoxic = anaerobic)	Moist	Moist	Moist	Moist to dry
Examples (mostly at phyla level)	Cyanobacteria, Proteobacteria, Chlorobiaccae, Flexibacteria, Spirochaetes, Bacteriacea	Euryarchaeota (halophiles and methanogens), Crenarchaeota (sulpho-archaea), Nanoarchaeota, Korarchaeota	Red, green and brown algae, amoebas, dinoflagellates, sporozoa, ciliates, zoo-flagellates, slime moulds, water moulds	Sac fungi, club fungi, black moulds	Angiosperms, gymnosperms, horsetails, ferns, mosses, bryophytes	Sponges, Cnidarians, flatworms, roundworms, rotifers, mollusks, annelids, echinoderms, arthropods, vertebrates

See also Table 9.4 and Fig. 9.9

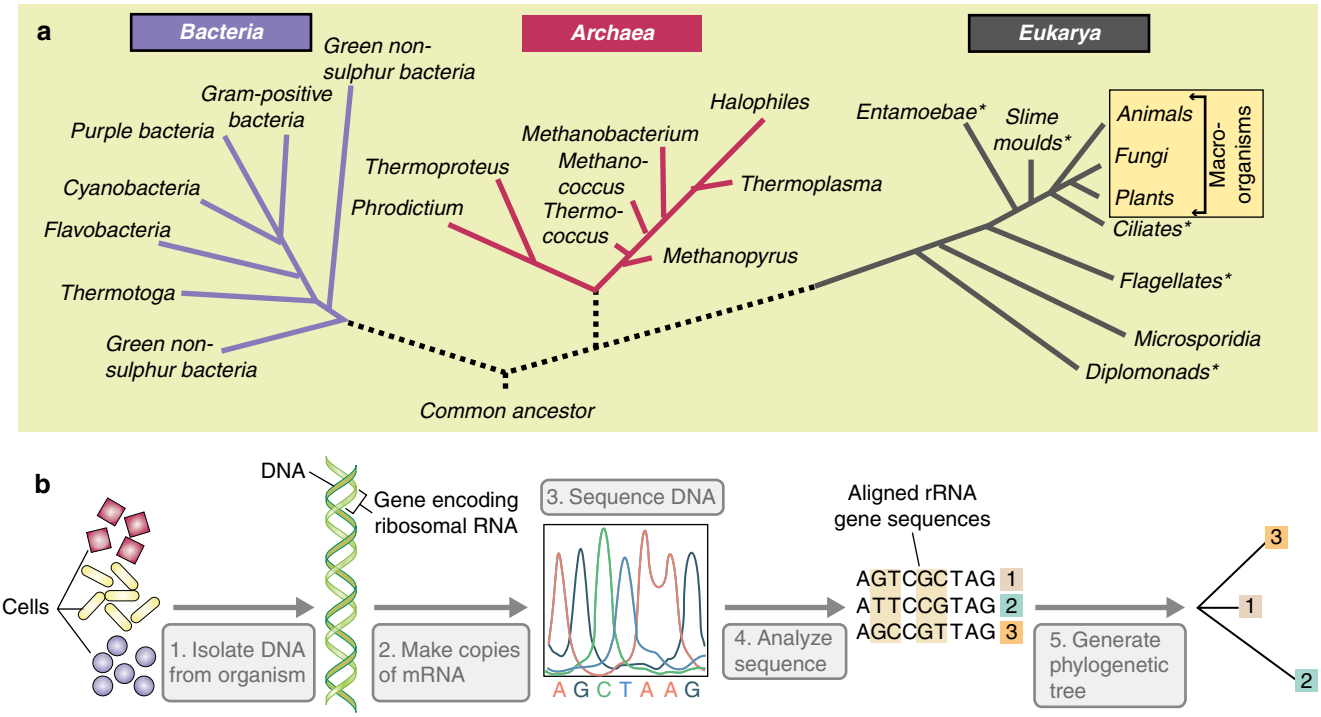

Fig. 9.10 Life domains mapped by gene splicing. (**a**) Tripartite classification of the domain of life based on genetic differences (as proposed by Woese et al. 1990). The *asterisk* (*) in the Eukarya domain indicates the denoted group belongs to the Protista. (**b**) The technique used in defining ribosomal RNA gene phylogenies. *1*. DNA is extracted from cells. *2*. Copies of the gene encoding rRNA are made by the polymerase chain reaction. *3*, *4*. The gene is sequenced and the sequence aligned with sequences from other organisms. A computer algorithm makes pair-wise comparisons at each base and generates a phylogenetic tree, *5*, that can be used to depict evolutionary relationships and affinities (See Madigan et al. 2015 for details of technique)

portions of the classic realms of botany and zoology are relegated to a few twigs on the outermost branches of the Eukaryan limb (Fig. 9.10). Even today some books and articles today still refer to archaea as types of bacteria and illustrations of the domains of life are focused on the Eukarya. Many macrobiologists still feel Woese's system

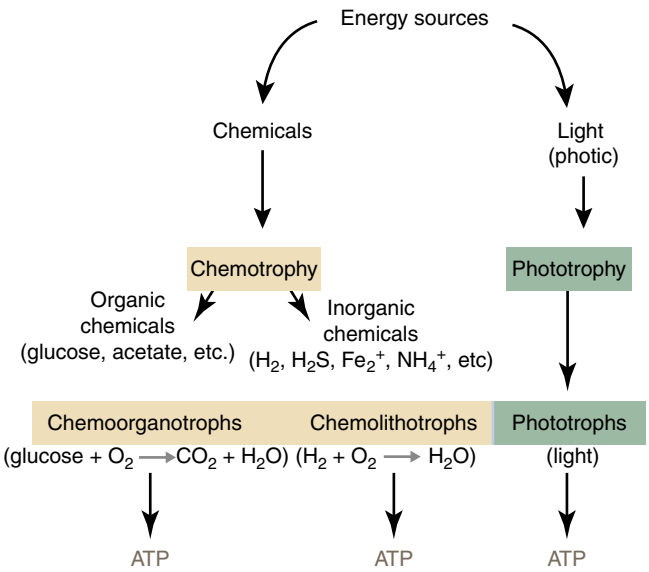

Fig. 9.11 Energy and carbon flows in a framework of metabolic energy conservation in the microbial realm

gives too much prominence to the microbial in terms of the world's biomass. In this Woese's detractors may be wrong. Estimates of the subsurface intraterrestial prokaryotic biomass, aka subsurface lithoautotrophic microbial ecosystem (SLiME), place it as high as 100 trillion tonnes (1×10^{14} to 1×10^{18} g of carbon; Pedersen 2000; Fredrickson and Onstott 1996). As such, if it could be stacked above ground, this amount of "gray goo" would cover the earth with a biological layer some 15 m thick. Since the surface biosphere mass is approximately 4.6×10^{17} g of carbon, the biomass of the rock-bound subsurface microbial biosphere may well exceed that of the surface biosphere. Woese's tripartite conclusions, with various modifications, are slowly moving into the general biological literature (Roger and Simpson 2009).

Cyanobacteria, formerly known as blue-green algae, are now placed in the bacterial kingdom as cells lack a membrane -bound nucleus. And yet, like many other prokaryotes, but they are not totally comfortable in their new cladistic home. Unlike any other bacteria, cyanobacteria photosynthesise aerobically. Instead of the bacteriochlorophyll pigments found in purple and green bacteria, cyanobacteria contain chlorophyll-a, as do all eukaryotic phototrophs, and produce free oxygen as a photosynthetic byproduct, as do all plants (Fig. 9.11). Yet cyanobacteria lack the organized chloroplasts of eukaryotes and have their photosynthetic apparatus distributed peripherally in thylakoids within the cellular cytoplasm. Cyanobacteria are a significant component to modern laminated mat communities in many saline settings. These biolaminites are still called "algal mats" by some geologists, who are not aware of the cladistic rehousing of the former "blue green algae, and they still refer to ancient counterparts as "cryptalgalaminites" – a more appropriate designation is microbialite or for finely layered forms as laminar microbialite or stromatolites (Chap. 1).

Light Dwellers and Pigmentation

Where light penetrates a water mass, photosynthesizers can live. Photosynthesizing autotrophic[5] cyanobacteria (prokaryotes) and algae (eukaryotes) are the dominant primary producers in modern mesohaline waters, along with lower and varying inputs from the higher plants and photosynthesizing bacteria. When nutrients are available, halotolerant alga and cyanobacteria constitute the bulk of the planktonic biomass in the upper layer of a stratified brine column and construct the upper parts of microbial mats in oxygenated settings wherever light penetrates to the sediment surface. And so, all three domains of photosynthetic life are represented in saline environments, although most higher plants only survive at the lower end of the mesohaline range.

The loss of various colour spectra as white light penetrates deeper into a brine column or sediment has led to the evolution of colour-adapted layered photosynthetic communities utilising a ranges of colour-specific pigments. In a clear well-lit brine body, reds and yellows are lost within a few metres of the brine surface, wavelengths in the blue colour spectra can penetrate up to 100 m, depending on water turbidity (Fig. 9.12).

[5] *Autotrophs* (literally "self feeders") are organisms capable of producing organic compounds from simple inorganic compounds (producers not consumers). Autotrophs use carbon dioxide (CO_2) as a sole source of carbon for growth and obtain their energy from light (photosynthetic autotrophs or photoautotrophs) or from the oxidation of inorganic compounds (chemosynthetic autotrophs or chemoautotrophs) (Fig. 9.11).

Photoautotrophs use light as a source of energy and CO_2 as a source of carbon (oxygenic photosynthesis).

Chemoautotrophs use endogenous light-independent reactions to obtain energy, these reactions involve inorganic molecules and an electron donor other than water and do not release oxygen.

Lithoautotrophs depend upon inorganic compounds as electron donors for energy production.

Heterotrophs (literally "feeders on others") use organic molecules synthesized outside their body as a source of energy and carbon (consumers, detritovores, decomposers). They are *saprophytes*, obtaining their nutrients from dead organic matter. Most *chemotroph*s are autotrophic, but some are heterotrophs (*chemoheterotrophs*), which use inorganic oxidation for energy but use organic matter for carbon as well as supplemental energy. Photosynthetic bacteria have the biochemistry for either anoxygenic photosynthesis (non O_2-producing) or oxygenic photosynthesis (O_2-producing). Most photosynthetic bacteria are autotrophs that fix CO_2 (photoautotrophs), but some rely on organic matter for their carbon (photoheterotrophs). Adaptive prokaryotes switch their modes of metabolism depending on environmental conditions (Peters et al. 2005).

Although the cyanobacteria are prokaryotal, like eukaryotic algae and higher plants, they are photoautotrophs that produce oxygen and so they live in oxic settings where light, nutrients and CO_2 are available. The typical aerobic photosynthetic reaction is

$$CO_2 + 2H_2O = CH_2O + H_2O + O_2$$

That is, carbon dioxide and water react in the presence of chlorophyll and sunlight to form carbohydrate plus water plus oxygen (Fig. 9.12a).

All aerobic photosynthesising organisms that split water molecules and generate oxygen, contain varying proportions of the pigments chlorophyll- α, phycobilin and β-carotenes. Chlorophyll-α is a green pigment that absorbs red and blue-violet light (680 nm), hence the green colour of photosynthesising cyanobacteria and plants. It is made up of molecules that contain a porphyrin 'head' and a phytol 'tail' (Fig. 9.13a, b). The polar (water-soluble) head is made up of a tetrapyrrole ring and a magnesium ion complexed to the nitrogen atoms of the ring, its phytol tail typically extends into the lipid layer of the thylakoid membrane. Chlorophyll-β is a closely related molecule and occurs only in green algae and plants, while chlorophyll-c is found only in the photosynthetic members of the Chromista supergroup. This is a polyphyletic grouping within the Protist Kingdom – it includes diatoms, kelp and coccoliths, as well as dinoflagellates, which are alveolates along with the foraminifera (Table 9.3).

Phycobilisome[6] pigments are water-soluble proteins that occur only in the cyanobacteria and red alga (rhodophytes). Phycobilin absorbs light in the blue-green, yellow, and orange regions of the spectrum compared to chlorophyll, which absorbs light in the blue and red regions (Fig. 9.13b). Its presence allows communities to photosynthesise into deeper waters and sediment depths, where only the longer wavelengths penetrate (blue-green spectrum). Phycobilin molecules are linear tetrapyrroles and are structurally related to chlorophyll-α, but lack the phytol side chain and the magnesium ion (see biomarker discussion later in this chapter). They must pass their absorbed photic energy to chlorophyll and so occur in chlorophyll-rich oxygen-evolving photic reaction centres called chloroplasts. Cyanobacterial chloroplasts make up an extensive, intracellular system of flattened, membranous sacs, called thylakoids, the outer surfaces of which are studded with regular arrays of phycobilisome granules.

Carotenes are accessory water-insoluble pigments in most oxygenic photosynthesizers and are directly attached to cellular membranes. They are orange-red or yellow in colour and absorb the blue-violet and blue-green wavelengths missed by chlorophyll (Fig. 9.13b). Structurally they are isoprenoids (terpenes) and are what give autumn leaves their colour when deciduous plants re-absorb chlorophyll in preparation for winter. In the hypersaline realm, carotene pigments from algae like *Dunaliella sp*. and some archaea are what give the characteristic red or pink colours to brines whenever they are blooming (Oren 2009).

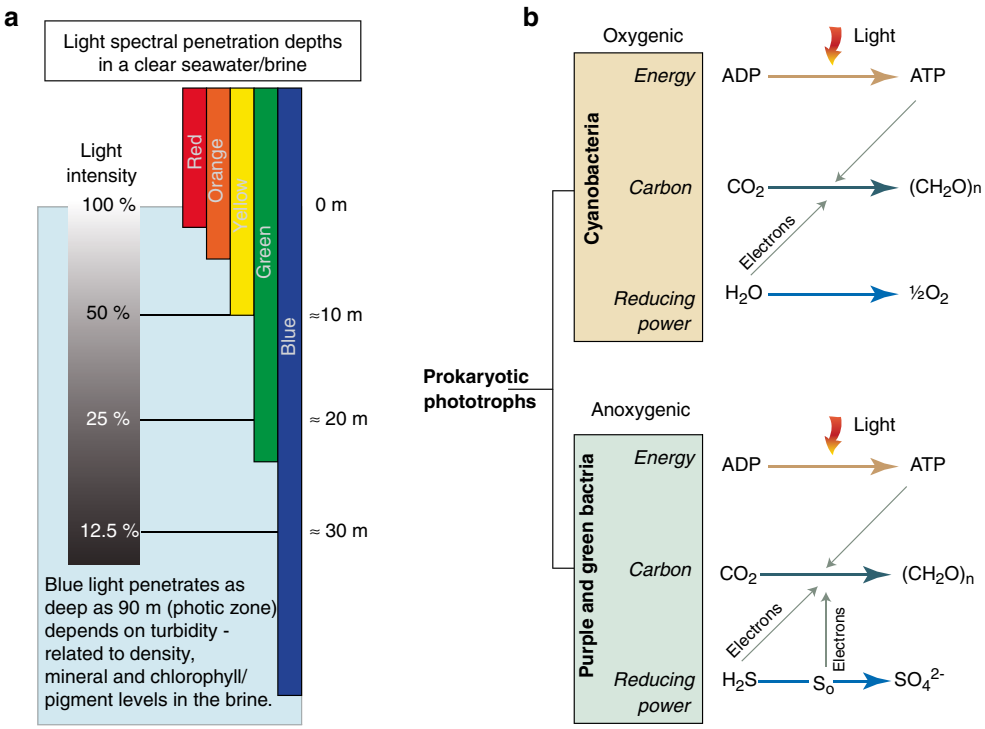
In contrast to the cyanobacteria, all other photosynthetic bacteria in saline waters are [5]chemoautotrophs and flourish in anoxic conditions (Fig. 9.12b). Anoxygenic photosynthesis, which can be found in purple bacteria, green sulphur bacteria, green non-sulphur bacteria, and heliobacteria, differs from oxygenic photosynthesis in that it requires only one photosystem and, since no splitting of water occurs, no oxygen is produced (Fig. 9.12b). The green and purple sulphur bacteria take their hydrogen atoms from biologically or volcanogenically produced H_2S and generate sulphur as a waste product (hence their names; Table 9.4). In contrast, the purple and green nonsulphur bacteria use electrons from organic substrates or hydrogen gas, not a sulphur source (Table 9.4).

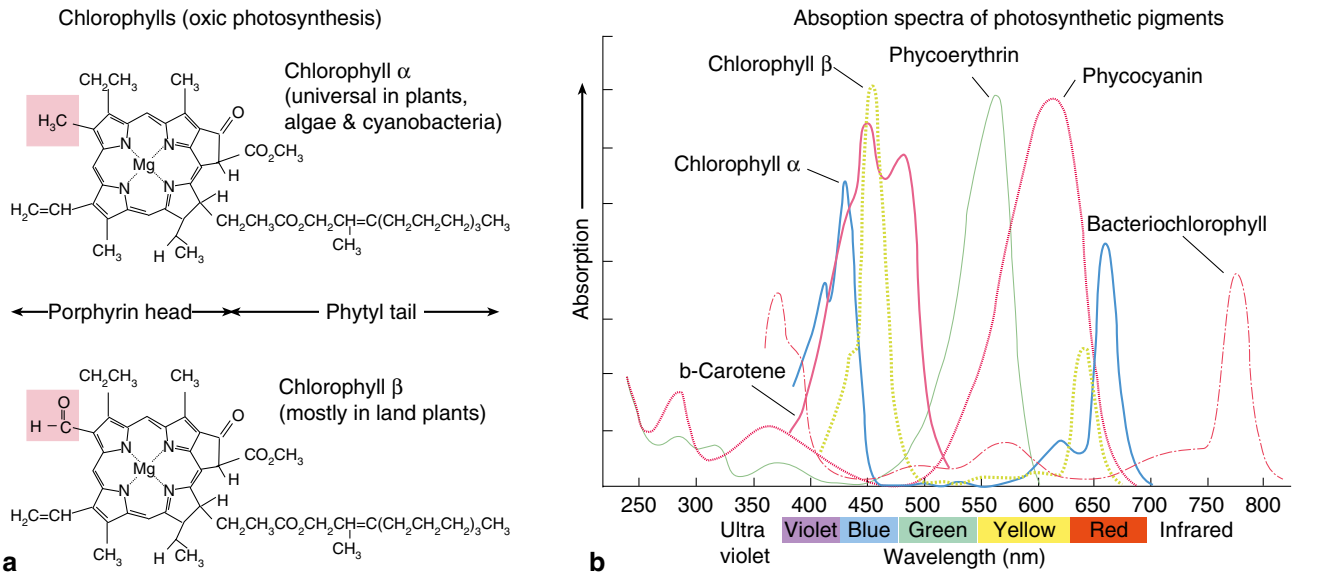
[6]Pink to purple colours that typify many hypersaline water bodies comes from concentrations of mostly carotenoid pigments present in the cytoplasm of various halophilic microorganisms. Most haloarchaea are red due to a high content of C-50 carotenoids of the bacterioruberin series in the cell membrane (Fig. 9.13). Photosynthetic cyanobacteria and eukaryotes (e.g., unicellular green algae of the genus *Dunaliella*) contribute to the pigmentation of the hypersaline waters thanks to the presence of chlorophylls and C-40 carotenoids (mostly all-*trans*- and *9-cis*- β-carotene). Chloroplasts in *D. salina* and *D. parva* accumulate large quantities of this β-carotene at their peripheries in the form of droplets (plastoglobuli) and so blooms appear brown-red, not green like most other alga and cyanobacteria. The carotene seems to act as photoprotective 'sun-screen' to protect chlorophyll integrity and shield cellular DNA from the high levels of irradiance that characterizes the normal habitat of halophilic *Dunaliella*. It may also act as a 'carbon sink' to store excess carbon produced during photosynthesis under conditions where growth is nutrient-limited but photosynthetic carbon fixation must continue.

Chlorophylls absorb red and blue wavelengths much more strongly than they absorb green wavelengths, so chlorophyll-bearing cyanobacteria and most photosynthesizing plants appear green. In contrast, the carotenoids and phycobiliproteins strongly absorb green wavelength, so microbes and algae with large amounts of carotenoid pigments appear yellow to brown, those with large amounts of phycocyanin appear blue, and those with large amounts of phycoerythrin appear red.

Pigment levels can indicate the stratification of the microbial community in any photoresponsive biomass in a brine column. Red wavelengths (long wavelengths) in white light are absorbed in the first few metres of a brine column or the uppermost millimetre or two of a microbial mat (chlorophyll utilizers flourish). The blue and green wavelengths (shorter) reach deeper into the brine column.

Halophilic archaea were first investigated microbiologically as a common cause for spoilage of salted fish, with their carotene imparting a characteristic red colour. None of the halophilic archaea have been proved to cause disease, so their effects on salted foodstuffs are largely aesthetic. Haloarchaeal spoilage explains the red colour and the foul smell in "red herring." The phrase "throw in a red herring" means to mislead. Spoiled salted fish were once used by poachers to distract hunting hounds. Poachers would interpose themselves between the prey and the hunting party and drag a sack of red herring across the trail to mislead the dog pack, which would follow the scent trail left by the red herring and not the prey. This would give the poachers the opportunity to bag the prey.





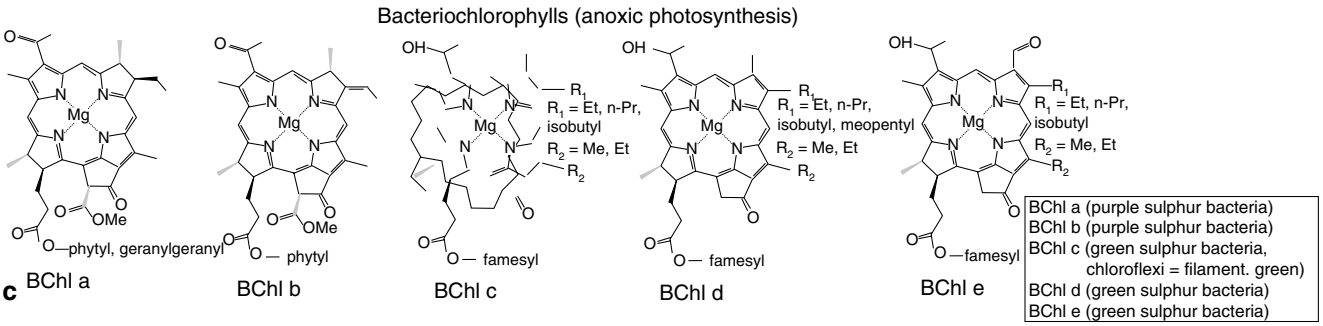


Fig. 9.12 Light penetration and photosynthesis. (**a**) Spectral attenuation of the spectra in sunlight penetrating a brine varies with depth showing different wavelengths penetrate to different depths. (**b**) Prokaryotic photosynthetic pathways and products – cyanobacterial pathway is oxic, bacterial pathway is anoxic

(**b**) Absorption spectra of the Chlorophylls, β-carotene and phycobilisomes (phycoerythrin) is dominant in *blue-green* coloured cyanobacteria and phycocyanin in red coloured cyanobacteria. (**c**) Bacteriochlorophyll structures

Table 9.4 Summary of metabolic styles of prokaryotes focusing on Archaea and Bacteria

Phylum or family			Informal Group	Dominant metabolic pathways and lifestyles
Prokaryotes	Halo-adapted Bacteria	Cyanobacteria	Cyanobacteria (T, L)	Aerobic oxygenic photolithotrophs with chlorophyll-a plus phycobiliproteins for light gathering; they use hydrogen by splitting water as electron source and generate oxygen; use the Calvin cycle to generate carbohydrates; some heterocystous cyanobacteria (*Anabena*, *Nostoc*) form heterocysts, which facilitate nitrogen-fixation.
		Proteobacteria	Purple sulphur bacteria (T, L)	Anaerobic obligate photoautotroph (use H_2S, not water) and may form sulphur granules. Contain bacteriochlorophyll a or b. Divided into two families, the *Chromatiaceae* and *Ectothiorhodospiraceae*, which respectively produce internal and external sulphur granules Group includes many sulphur-reducers (e.g., *Pseudomonas*) and some sulphate-reducers (e.g., *Desulphovibrio*). Many species are halophilic or alkaliphilic and are common in saline settings with abundant sulphate reducers (produce the H_2S they require), eg. in meromictic saline lakes..
			Purple non-sulphur bacteria (T, L)	Oxygen-tolerant anaerobic facultative photoautotroph. Most can grow as photoheterotrophs, photoautotrophs or chemoheterotrophs – switching pathways depending on: intensity of anaerobiosis, availability of carbon source (CO_2 for autotrophic growth, organic compounds for heterotrophic growth), and availability of light (needed for phototrophic growth). Originally thought that these bacteria could not utilise H_2S as an electron donor, hence "non-sulphur" in their group name. Sulphide can be used if present at low levels. Higher concentrations of H_2S (in which the purple and green sulphur bacteria thrive) are toxic.
	Archaea	Chlorobiaccae	Green sulphur bacteria (T, L)	Anaerobic obligate photoautotroph (use H_2S sulphide ions, sulphur, hydrogen or ferrous iron as an electron donor, not water). Sulphur deposited extracellularly can be further utilised. Contain chlorophyll a and bacteriochlorophyll c, d or e. Some species can survive in extreme low-light conditions.
		Flexibacteria	Green non-sulphur bacteria (L)	Anaerobic thermophilic photoheterotroph in sulphide-rich zones, but are capable of autotrophy. Remove hydrogen in simple organic molecules (such as ethanol, lactic acid of pyruvic acid) or hydrogen gas substrate. Can grow lithotrophically or organotrophically under appropriate conditions, or as thermophilic aerobic organotrophs.
		Spirochaetes	Spirochaetes (L)	Free-living (flagellate) mostly obligate anaerobic chemoheterotrophs, some species can live in saline waters, like Mono Lake. Constitutes a broad association other species are symbiotic, parasitic. Also aerobic, microaerophilic, facultatively aerobic, or anaerobic organotrophic species. Can catabolize carbohydrates, amino acids or lipids.
		Bacteriacea	Flavobacteria (L)	Anaerobic organotrophs, e.g., halocline dwellers in Urania Basin. *Bacteroides* ferments sugars to acetate and succinate, whereas *Flavobacteria* ferments glucose (almost exclusively). Chemoautotroph, parasite. *Psychroflexus tropicus* is an obligate halophilic species growing in a hypersaline lake in Hawaii.
		Euryarchaeota	Halophile (L)	Aerobic photoautotroph, chemoautotrophs that require very high salinities (1.5–5.5 M, prefer 3–4 M) and complex nutrients for growth. CO_2 fixed via Calvin cycle. Anaerobic respiration used by some *Halobacterium* species with nitrate, sulphur, thiosulphate as terminal electron acceptors. Includes *Halobacterium*; *Halobaculum*; *Natrosobacterium*; *Natrialba*; *Natrosomonas*; *Natrarococcus*; *Haloarcula*; *Halococcus*; *Haloferax*; *Halorubrum.*
			Methanogen (T)	Strictly anaerobic chemoautotrophs; *Methanopyrus* is an extreme thermophile; some can fix nitrogen. Lithotrophs generate methane using hydrogen and carbon dioxide (*Methanobacterium*, *Methanothermus*, *Methanococcus*, *Methanogenium*, *Methanoplanus*). Organotrophs – generate methane from methyl groups of formate, methanol (*Methanosphaera*, *Methanosarcina*, *Methanococcoides*) or acetate.
		Crenarchaeota (sulpho-archaea)	Thermophile (T)	Range of obligate anaerobic chemotrophs, some aerobes that require temperatures above 50 °C for growth (sometimes higher than 70 °C, highest temperature 115 °C) and use sulphur as electron acceptor (except *Sulpholobales*, which uses oxygen or ferric iron, grows in Italian sulphur springs at 80 °C and in a pH of 2–4, dies if pH >7). Organotrophs oxidize organic compounds for energy (oxygen or sulphur serves as final electron acceptor). Lithotrophs – can also grow organotrophically using sulphur as an electron acceptor.
			Acidophile (T)	Acidophilic thermophilic aerobic chemoautotroph, organotroph. For example, *Sulpholobales* (*see above*)
		Nanoarchaeota	Symbiont on *Ignoccus* (T)	Phylum currently has only one representative, *Nanoarchaeum equitans* hosted on hot vent archaeal community in Iceland. Its cell is only 400 μm long.,
		Korarchaeota	New group of extreme thermophile (T)	Only described from 16S rRNA gene sequence which show it does not belong to the main archaea groups of Euryarchaeota and Crenarchaeota (if it is a real phylum then it is the closest to life's universal ancestor in the earliest Archaean ≈3.7 Ga).

T thermophilic, *L* can construct laminated microbial communities

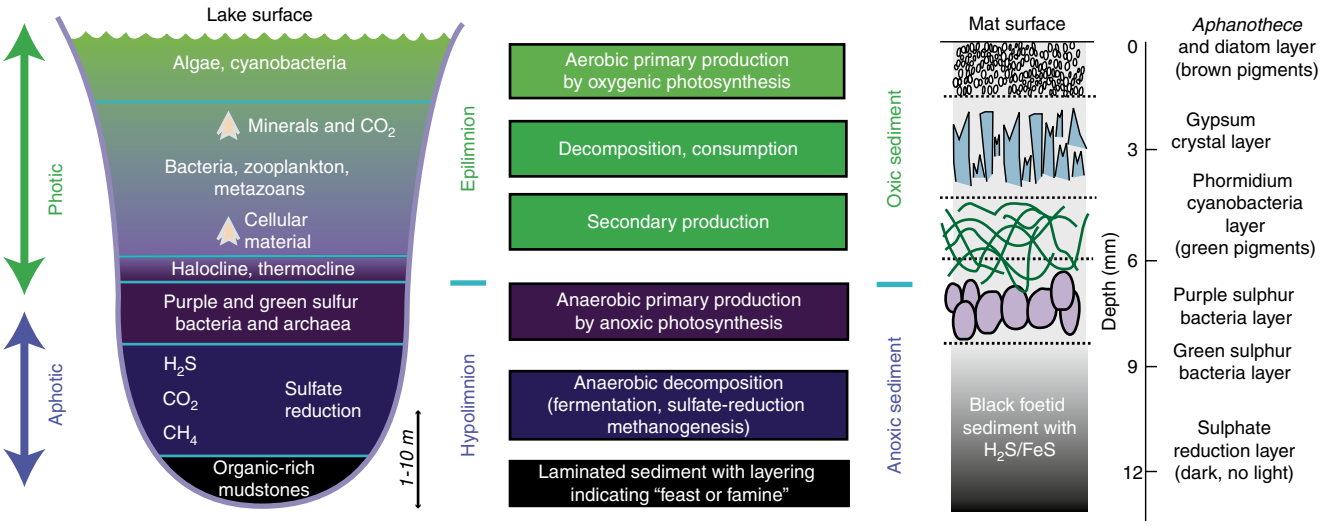

Fig. 9.14 Salinity (temperature) layering in a brine lake water column and a microbial mat show similar metabolic stacking of the halobiota (not to same scale) with anoxic waters below the halocline and oxic waters above in the water column. The same oxic to anoxic transition with depth occurs in a halotolerant microbial mat. This oxic/anoxic salinity/density related layering in the brine column of the lake, and the pore fluids of the mat, controls the distribution of the microbial communities and so stacks their metabolic requirements, pathways and products (including biomarkers)

They utilize a single type of photosynthetic reaction centre with a different photosynthetic pigment (bacteriochlorophyll) to the cyanobacteria and higher plants. Phycobilins and chlorophylls, characteristic of the cyanobacteria, are not found in these chemoautotrophs. Various forms of bacteriochlorophyll absorb light of longer, less energy-rich wavelengths compared to chlorophyll and phycobilins of the cyanobacteria (Fig. 9.13b, c). Green bacteria pigments are dominated by bacteriochlorophyll c (740 nm); d (725 nm), or e (714 nm), while purple bacteria pigments utilise longer wavelength light, via bacteriochlorophyll a (800–890 nm) or bacteriochlorophyll b (1,015 nm). Hence, purple bacteria typically live deeper in the photic zone[7] or in a microbial mat than green bacteria or cyanobacteria.

Green sulphur bacteria (Chlorobiaceae) and purple sulphur bacteria (Chromatiaceae) typically oxidise H_2S via anoxic photosynthesis and produce native sulphur or sulphate byproducts, some species can also use inorganic elemental sulphur, sulphide, or thiosulphate as the electron donor during anaerobic photosyntheis. Their metabolism means Chlorobiaceae and Chromatiaceae inhabit a zone in the chemocline of stratified water masses where sulphidic conditions occur in a light-penetrated zone (photic zone euxinia; Fig. 9.14).

The following simplified equation typifies anoxygenic photosynthesis in purple or green sulphur bacteria:

$$CO_2 + 2H_2S = CH_2O + H_2O + 2S$$

That is, carbon dioxide and hydrogen sulphide react in the presence of bacteriochlorophyll and sunlight to form a carbohydrate (such as glucose) as well as water and sulphur. Many purple and green sulphur bacteria store elemental sulphur as a reserve material that can be further oxidized to SO_4 by using it as a photosynthetic electron donor. Some of the green sulphur bacteria are probably the most energetically efficient of all phototrophic organisms; they can live photosynthetically in environments where light intensities that are less than 0.01 % of typical daylight. Green sulphur bacteria have been found living near a black smoker off the coast of Mexico at a depth of 2,500 m. At this depth, the bacterium, designated GSB1, lives off the dim glow of the nearby thermal vent. Other purple sulphur bacteria live at a depth of 100 m in the Black Sea.

Non-photosynthesizers and Layering

All the groups we have discussed to date are primary producers that are light-dependent and, along with halotolerant photosynthetic eukaryotes, make up the base of the food chain in most modern hypersaline ecosystems. But there are other classes of green and purple sulphur microbes that are [5]lithotrophs and chemotrophs, they can metabolise sulphur independent of a light source (they are chemoautotrophs not photoautotrophs). In many saline microbial communities these non-sulphur bacteria regularly inhabit unlit layers beneath the lit-community layers above, where the aerobic cyanobacteria and anaerobic purple and green sulphur bacteria (photosynthesizers) thrive, while a community of sulphate

[7]The *euphotic* (photic) zone describes the upper part of a water mass exposed to sufficient sunlight for photosynthesis to occur. Below is the aphotic zone. The lit zone can extend down to a few cm in a turbid water body, or as much as 200 m in clear waters (Fig. 9.12).

reducers and fermenters live below. This metabolic layering is seen in both microbial mats and stratified brine columns (Fig. 9.14). In addition, these lithotrophic microbes can be a significant biomass component in deep seafloor seep communities and in cavern waters formed by the action of sulphuric acid where gypsum is a byproduct.

Lithotrophic sulphur-oxidisers in saline waters do not require light to metabolise and include both bacteria (e.g., *Thiobacillus sp*.) and archaea (e.g., *Sulpholobus sp*.). Other lithotrophs in saline waters use substances such as nitrate and reduce it to nitrite (e.g., strains of *Nitrobacter sp*.). *Sulpholobus* is an archaeal hot spring dweller and transforms H_2S to elemental sulphur, it flourishes at temperatures in excess of 90 °C and can live in environments where pH hovers around 1, such as the gypsum wall coats and "snottites" in sulphuric acid caves (Fig. 7.67). *Thiobacillus sp*. are widespread in marine and hypersaline settings, where they oxidize thiosulphate and elemental sulphur to sulphate. For example, a unicellular halophilic, chemoautotrophic sulphur oxidizing bacterium, *Thiobacillus halophilus*, was described in a hypersaline salt lake in western Australian where it grows in waters with salinities of up to 240‰ (Wood and Kelly 1991). In the last few years, as a result of genetic typing, many of the sulphur-oxidizing bacteria originally classified under the genera *Thiobacillus* have been reclassified into the α, ß, and γ subclasses of the Proteobacteria. It probably means there is a broader range of sulphur-oxidising forms in hypersaline environments than current species listings suggest. It also means and that the current informal separation of sulphur-oxidisers into the purple and green bacterial groups is likely polyphyletic and certainly still confused (Table 9.4). Much of the sulphide this group metabolises is biogenic, a byproduct of nearby sulphate reducers, except perhaps around brine springs, cold seeps and hot hydrothermal vents, where it can be thermogenic.

Archaea, which make up life's third domain, are mostly extremophiles thriving in highly stressed conditions, including the extremely saline (Kates et al. 1993; Turich and Freeman 2011). Archaea are further subdivided into two kingdoms: (1) the Crenarchaeota; of which all members presently isolated are either thermophiles that metabolise sulphur (via sulphur oxidation, respiration and reduction) or are pscyhrophiles (cold-dwelling), and (2) the Euryarchaeota; a diverse group, which includes the halophilic Halobacteriaceae, some thermophiles and all methanogens (Table 9.4). Some sulphur-oxidizing archaea are also acidophiles that can grow at a pH approaching zero, others are hyperthermophiles growing at temperatures of up to 115 °C about vents on the deep seafloor.

Archaea and bacteria that require extreme salinities to metabolise are called halophiles, those that can tolerate salinities in excess of 25 % are termed hyperhalophiles, most modern hyperhalophiles are archaea. Many aerobic halophilic archaea (order Halobacteriales) are moderate thermophiles with growth optima at temperatures between 35 and 50 °C and sometimes even higher. This may be an adaption to the high temperatures that typify stratified waters in heliothermic salt lakes worldwide. One of the most impressive extremophiles is *Halobacterium lacusprofundi*, it is both a halophile and a psychrophile and thrives in microbial mats in the supersaline (≈350‰) cold bottom waters (<0 to 11.7 °C) of meromictic Deep Lake in Antarctica (Franzmann et al. 1988). The lake lies in a small isolated depression in the Vestfold Hills, with a brine surface that is some 50 m below sea level. Its perennial waters are thermally and chemically stratified, while its bottom water mass is too saline to freeze. Bottom water temperatures fluctuate between +10 and −15 °C, remaining below 0 °C for 8 months of the year. The microbial diversity in Deep Lake is extremely low and is dominated by haloarchaea, with apparently low numbers of *Dunaliella sp*. and bacteria (of the beta- and gamma-proteobacteria) also present in the bottom sediment (Cavicchioli 2006).

Halophilic archaea in hypersaline depositional settings typically function as heterotrophs (decomposers), with the ability to facultatively photosynthesise whenever conditions are suitable. Other archaea are anaerobic chemoautotrophs that are sulphur dependent and can flourish in the dark (Table 9.4). They thrive in the vicinity of hydrothermal/volcanogenic vents in saline lacustrine rifts or in marine hydrothermal brine springs atop salt allochthons or in the basal waters of density-stratified brine lakes and seaways. They also inhabit subsurface hypersaline brines that characterize bathyphreatic/hypogene hydrologies atop dissolving sulphate caps of salt allochthons. Sulphur-dependent archaea resemble ancestral prokaryotes, as do modern methanogenic archaea, and in the early Archaean their ancestors were the dominant life forms (Fig. 9.15).

All methanogens are obligate anaerobic archaea and today thrive in three habitats; (a) bodies of anaerobic mesohaline to fresh water (e.g., the warm anoxic bottom brines of Solar Lake), (b) haloes about anoxic brine springs and, (c) the anaerobic digestive tracts of ruminants and some molluscs. So, all biogenic methane passed into the atmosphere comes from symbionts in the guts of animals, as well as from decomposers in salterns, swamps, marshes, paddy fields, dumps and sewage works. The world's biogenic methane is due to the work of a few dozen species of methanogenic archaea. They are a little modified cosmopolitan group of strict anaerobes, with a clear ancestral line extending back to the early Archaean (Margulis and Dolan 2002). Methanogens are able to grow at temperatures between 4 and 100 °C, at pH values from 3 to 9, and at salinities ranging from hypersaline to freshwater. Despite this huge taxonomic diversity, the substrates that can be used by methanogens are rather limited – hydrogen, acetate, formate,

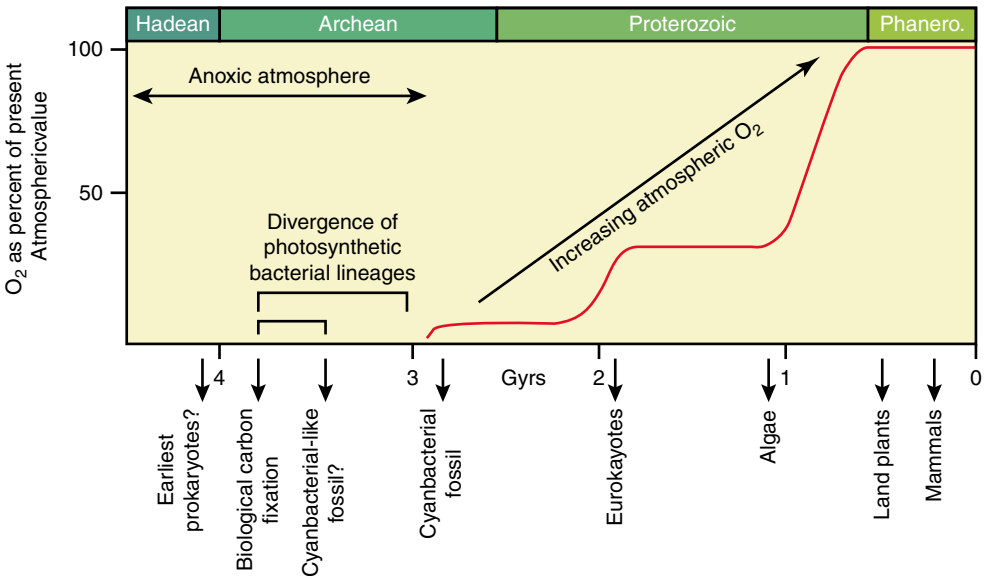

Fig. 9.15 Evolution of photosynthetic metabolism across geological time (In part after Xiong and Bauer 2002)

some alcohols, and methylated compounds (Schubert 2011). The most important of these are hydrogen and acetate, which give rise to two different kinds of methanogenesis: (1) the fermentation of acetate to CO_2 and CH_4 and (2) the reduction of CO_2 with H_2. More than 70 % of today's methanogens use the latter pathway.

Halophilic bacteria as a group is more biochemically divergent than the halophilic archaea and capable of using a range of aerobic and anaerobic metabolic styles (Table 9.4). Some halophilic purple and green nonsulphur bacteria are chemoautotrophic halophiles that can function independent of a light source, while other halotolerant and halophilic bacteria (including cyanobacteria) are oxygenic photoautotrophs (oxidisers). Within the anaerobic halophilic bacteria of the order Haloanaerobiales there are several moderately thermophilic representatives. *Halothermothrix orenii*, the first truly thermophilic halophile discovered, was isolated from Chott El Guettar, a warm saline lake in Tunisia. It grows optimally at 60 °C and up to 68 °C at salt concentrations as high as 200‰ (Cayol et al. 1994). The halophilic *Acetohalobium arabaticum* strain Z-7492 has a temperature optimum of 55 °C (Kevbrin et al. 1997). Under suitably stressed conditions many halophilic bacteria become heterotrophic, utilising either anaerobic or aerobic respiration pathways.

By evolving the ability to symbiogenetically split water as a hydrogen source some 2.5 billion years ago, and so excrete oxygen, the prokaryotic cyanobacteria ultimately enabled the eukaryotic lineages to flourish and displace anaerobic bacteria and archaea as the middle to late Precambrian world's primary producers (Fig. 9.15; Margulis and Dolan 2002). By the Mesoproterozoic this had allowed eukaryotic photosynthesis to develop and ultimately led to the evolution of the higher plants. As oxygen became more plentiful in the ocean and the atmosphere, it was increasingly difficult for anaerobes to flourish in most surface waters. Some retreated to the inhospitable and typically anaerobic environments where they still flourish today, others acquired aerobic bacteria as endosymbionts and today thrive in the aerobic/dysaerobic conditions that typify the hypersaline bottom waters of many density-stratified brine bodies.

Many halotolerant and halophilic bacteria and archaea living in hypersaline surface waters are heterotrophs and usually feed on the remains of other organisms. Heterotrophic metabolism shows variation in the terminal electron acceptor. In aerobic respiration it is oxygen and the breakdown product is CO_2, in anaerobic respiration it may be sulphate or nitrate and the breakdown product is H_2S or nitrite (Table 9.4). In all life forms, including [5]heterotrophs, energy is obtained from high-energy electrons using cyclic or non-cyclic electron transport schemes during which the energy is transferred into and stored as adenosine triphosphate (ATP), while low energy electrons are released by the end reaction. Adenosine triphosphate (ATP) is the basis of all life as it is the energy-carrying molecule found in the cells of all living things. ATP captures chemical energy obtained from the breakdown of food molecules and releases it to fuel other cellular processes.

Exceptions to this general metabolic scheme are the fermenters, like the methanogens, are groups where energy is stored in the form of proton-motive force (PMF), as well as in ATP. Fermentation may be the only metabolic mechanism in halotolerant and halophilic species that inhabit the lowermost living parts of a microbial mat or flourish in the vicinity of the halocline in layered brine column communities, while it may be an emergency system in others (Table 9.4). Fermentation always occurs under anaerobic conditions when there is no electron acceptor. It breaks down an organic compound, such as a sugar or amino acid, into smaller

organic molecules that then accept the electrons released during the breakdown of the energy source. As glucose is broken down to lactic acid, each molecule of glucose yields only two molecules of ATP, and considerable quantities of glucose must be degraded to provide sufficient energy for microbial growth. Only a relatively small output of energy is obtained per glucose molecule consumed, as the organic molecule is only partially oxidized. Hence, the presence of fermentative halotolerant bacteria and archaea and their less efficient metabolisms, rather than oxic decomposers, facilitates preservation of larger quantities of organic end products (proto-kerogens).

Methanogenesis and sulphate reduction are two terminal anaerobic biomineralization pathways in hypersaline systems that convert low molecular-weight products of other bacterial processes (degradation of polymers, fermentation) into CO_2 and methane (Teske et al. 2003). Sulphate-reducing bacteria are physiologically and phylogenetically highly diverse compared to the methanogens and range across a number of bacterial groups. Sulphate-reduction is also found in some archaea such as the genus *Archaeoglobus* of the archaeal phylum *Euryarchaeota*. These various sulphate-reducers constitute a phenotypic group, extending across the Bacteria and Archea, and capable of oxidizing a wide variety of low-molecular weight compounds (short-chain fatty acids, alcohols, alkanes, aromatic compounds, acetate) to CO_2. When biochemical conditions are anoxic and suitable for growth, the environmental range of sulphate-reducers is limited only by sulphate availability. When sulphate is depleted, methanogenic archaea become the dominant anaerobic microbial population. Autotrophic methanogens (all archaea) utilize hydrogen as an energy source for the reduction of CO_2 to methane; specialized genera of methanogens are also capable of inter- and intramolecular disproportionation of C_1 and C_2 carbon compounds (methanol, methylamines, acetate) to methane and CO_2.

Where methane and sulphate coexist in any anoxic environment (for example, at the interface of sulphate-reducing and methanogenic sediment layers, or at methane seeps and vents beneath marine or hypersaline waters), sulphate-dependent anaerobic methane oxidation takes place, whereby methane of biogenic origin is oxidized to CO_2 with sulphate as the terminal electron acceptor (Teske et al. 2003).

The varying metabolic pathways of the microbial communities inhabiting a layered brine column create an interdependent layered microbial ecosystem that reflects the varying degrees of light penetration, oxygenation and anoxia within a variably layered brine body (Fig. 9.14). A similar layered pore fluid community (greater anoxia with depth) also characterises microbial mats. In a brine column, oxygenic photosynthesizers (mostly alga and cyanobacteria) characterize the upper well-lit oxic portions of the brine column (Fig. 9.14). Below this community of producers, the remainder of the photic zone is characterised by downward decreasing light levels and the increasing dominance of oxygenic decomposers (bacteria, zooplankton and metazoans) over producers, with secondary production occurring in the microbial community (green and purple sulphur bacteria) that floats atop the halocline. If light penetrates to anoxic waters below the halocline, anoxic photosynthesizers flourish there (sulphur-oxidising phototropic bacteria and archaea). As light levels fall away in the anoxic waters below, the biota is increasingly dominated by the anaerobic decomposers (sulphate-reducers, methanogens and fermenters). If light does not reach the halocline, specialised forms of chemosynthetic green and purple sulphur oxidizers (not photoautotrophs – e.g., some flavobacteria) occupy the narrow interface at the halocline created by the contact between oxic and anoxic waters. In schizohaline settings subject to periodic freshening of the surface waters, the associated bloom of halotolerant producers (alga and cyanobacteria) in the upper water column can swamp the ability of the various decomposers to degrade all the organic matter before it reaches the bottom and so laminated organic-rich and hydrogen-prone mesohaline carbonates can then accumulate on the bottom.

In the same way, a microbially layered gypsum crust or a carbonate mud shows prominent coloured bands due to the presence of different types of brightly pigmented photosynthetic prokaryotes. This vertical colour zonation seen in all growing microbial communities in saline sediments is related to the same vertical zonation in light wavelengths that is seen in a brine column (Fig. 9.14). Typically, the upper layer of the microbially bound sediment pile is orange-brown, due to the presence of unicellular cyanobacteria (*Halothece*-type). This layer may be a few millimetres to a few centimetres thick depending on the intensity of light penetration. Below, is a brightly green layer is with mainly filamentous (*Phormidium*-type) cyanobacteria. Below is a purple-red layer of photosynthetic purple sulphur bacteria, and below that is a black, sulphide-containing layer (Ionescu et al. 2007).

As the potency of sunlight is only slightly attenuated by any overlying shallow brine sheets, the upper layer of a microbially-bound sediment (microbialite) experiences high light intensities. Accordingly, unicellular cyanobacteria in the uppermost brown layer are characterized by low chlorophyll contents and high carotenoid pigment content, as well as large quantities of mycosporine-like amino acids that provide protection against harmful ultraviolet radiation (Ionescu et al. 2007). The underlying layer of green-coloured cyanobacteria experiences light intensities approximately two orders of magnitude lower than at the microbialite surface. This green layer contains high concentrations of chlorophyll -α and phycocyanin, and lower concentrations of carotenoid pigments (Fig. 9.13b). The underlying red-purple layer, is

situated below the oxic/anoxic boundary, typically contains both *Chromatium* or *Halochro-matium* and *Ectothiorhodospira–Halorhodospira*-like purple bacteria. These anaerobic genera utilise the remaining infrared light, which was not absorbed by the communities above, as an energy source. Sulphide, produced by bacterial sulphate reduction in the lowermost black layer, seeps up into this zone where it serves as the electron donor for their photosynthesis. Also below this layer along with the sulphate reducers are the anaerobic fermenters and methanogens.

Salinity Tolerance

Photosynthesis is the only significant means by which new organic matter is synthesized on Earth. It is the ultimate source of biomass in almost all ecosystems, including hypersaline settings, and accounts for most organic matter buried in sediments and rocks, including biomarkers (Fig. 9.16; Peters et al. 2005a, b). Since the Archaean, almost all organic matter has been produced by photosynthetic fixation of carbon from CO_2 in a process set known as primary productivity (Fig. 9.15).

Photosynthesis can occur with (aerobic), or without (anaerobic) oxygen as a by-product. Respiration and other processes (such as sulphate reduction, methanogenesis and fermentation) result in the near complete oxidation of organic matter and its recycling back to the atmosphere as CO_2. Across Earth history, around 0.1 % of the carbon biomass (via primary productivity) was preserved in sediments and so was then available for petroleum generation (Tissot and Welte 1984). In the following discussion the various biological components of the carbon cycle will now be used to discuss adaptations and niche extent in the halobiota living under hypersaline conditions.

Progressive brine concentration leads to sequential blooms of diverse macro and microbial species adapted to different ranges of salinity (Figs. 9.17 and 9.18). As modern surface brine is concentrated from 60‰ to around 200‰, dense eukaryotic algal and cyanobacterial populations appear, grazed by ostracodes, brine shrimp and brine fly larvae (Fig. 9.17a, b). Halotolerant protists are also found feeding in this salinity range, along with yeasts and other fungi. Halotolerant microbial mats cover the bottom of many hypersaline ponds and shallow lakes at this stage. In anoxic waters in this salinity range there are a variety of sulphur-oxidizing, sulphate-reducing, homoacetogenic, methanogenic and heterotrophic bacteria and archaea flourishing at the base of stratified brine columns or in the lower parts of meso-haline microbial mats. Increasing osmotic stress and loss of appropriate habitat as a water body shrinks with ongoing desiccation means much of the macroscopic stenohaline[8] benthic fauna dies off or dies back to refugia about springs and seeps (Fig. 9.17c).

From about 240‰ to more than 320‰, halophilic archaea and bacteria come to dominate (Ghai et al. 2011). As ever more elevated salinities are attained, most other biological activity first slows and then ceases. At the elevated salinities where halophiles and hyperhalophiles flourish, a few eukaryotes, such as brine shrimp, and a handful of algae, including various *Dunaliella sp*. (a naked unicellular biflagellate green alga), are the only other living forms that the halophilic microbes encounter (Fig. 9.18a, b).

Primary Producers (Photosynthesizers)

Primary production is the synthesis of new organic material from inorganic molecules such as H_2O and CO_2 under aerobic or anaerobic conditions. It is dominated by the process of photosynthesis, which uses sunlight to synthesise organic molecules such as sugars, although chemosynthesis, which can occur in the dark, represents a small fraction of primary production. In reverse order of importance, organisms responsible for primary production in hypersaline conditions, include higher plants, algae and some bacteria (including cyanobacteria).

Higher Plants

A variety of obligate and facultative halophytic higher plants (angiosperms) can survive in moderate-to-high salinity conditions that surround saline pans and lakes. Many such terrestrial halophytes must survive long periods of drought and live where vadose soils completely desiccate, such plants are called xero-halophytes. Xero-halophyte adaptations include, deep and extensive roots, high levels of water storage (cacti), highly reduced leaf areas sometimes reduced to spines and scales, fine hairs on the leaf surface, sunken stoma and stoma that only open at night and permanently rolled leaves or leaves with a propensity to roll in drought and so reduce their surface area. They can have leaves with salt bladders that can excrete salt with the evaporation water (e.g., saltbush genera such as *Atriplex*, *Halimione*, *Rhagodia* and *Chenopodium*), so that over time the leaf can be covered by extruded salt crystals. Most xero-halophytes cannot survive in water-logged saline conditions where roots are subject to long term low oxygen conditions. There the halophytic succulents tend to dominate and constitute a group generally known as the samphires, they include genera such as *Salicornia Arthrocnemum*, *Halocnemum and Halosarcia*. These succulents are capable of surviving on the landward edges of saline mudflats and pans where they can be continually immersed in saline waters for weeks to months.

Then there are the hydro-halophytes that grow in settings subject year-round to partial or complete submersion in brine. Modern hydro-halophytes are most common along the lower salinity edges of mesohaline waters (e.g., mangroves

[8] Stenohaline describes the salinity tolerance of an organism that cannot cope with a wide range of salinity.

Euryhaline is the opposite of stenohaline and describes organisms able to adapt to a wide range of salinities.

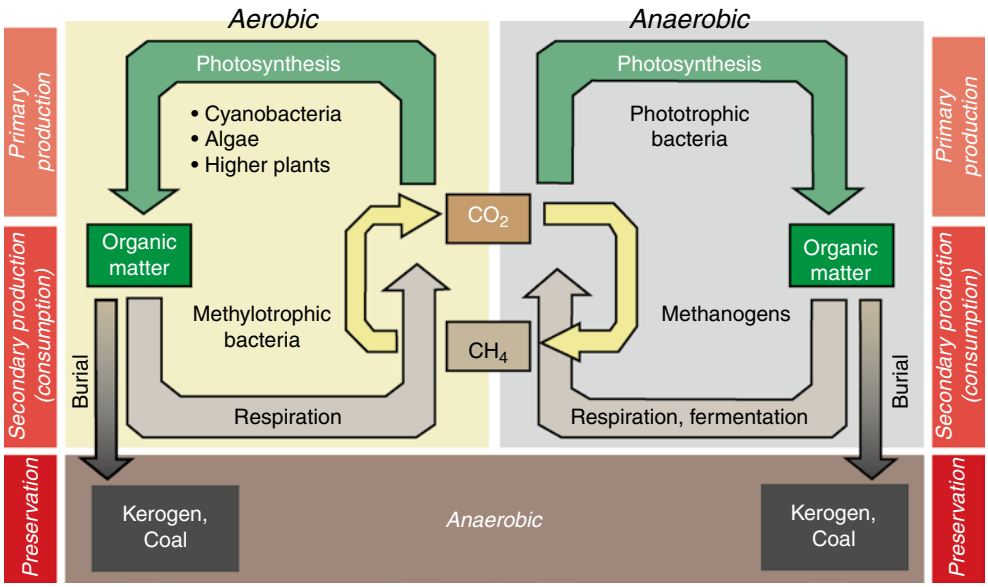

Fig. 9.16 Carbon fixation and cycling. New organic matter is produced by photosynthetic fixation of carbon from CO_2 (primary productivity). This can occur with (aerobic), or without (anaerobic) oxygen as a by-product of photosynthesis. Respiration and other processes (such as sulphate reduction, methanogenesis and fermentation) result in the near complete oxidation of this organic matter back to CO_2

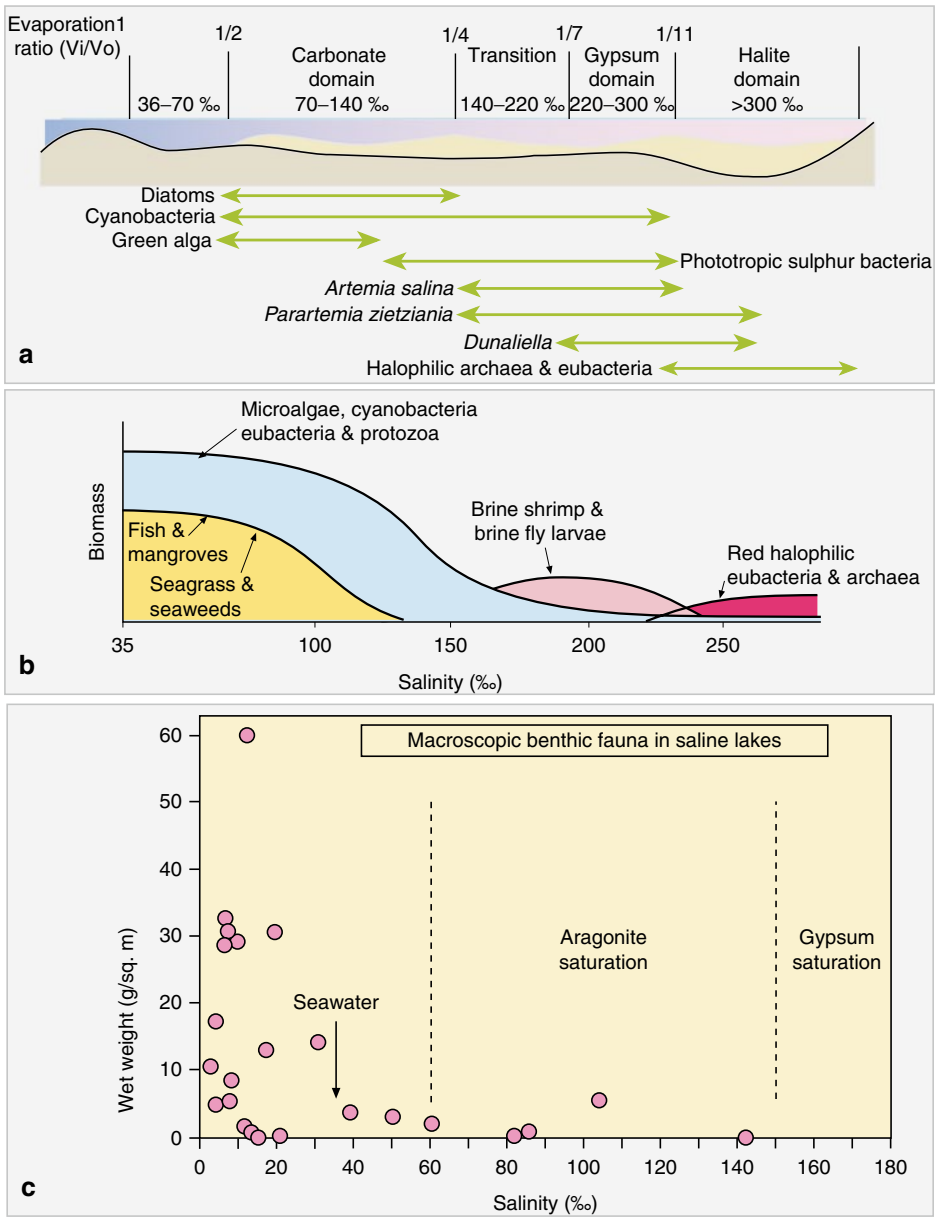

Fig. 9.17 Salinity tolerances. (**a**) Typical salinity ranges of the halotolerant biota where V_i is the volume of inflow to the basin and V_o is the volume of outflow (includes evaporation and reflux; after Barbé et al. 1990). (**b**) Typical salinity ranges and biomass proportions of the biota in modern marine saltwork ponds. (**c**) Standing crop (g/m^2) of the macroscopic benthic fauna in selected athalassic (nonmarine) saline lakes of the world (After Hammer 1986)

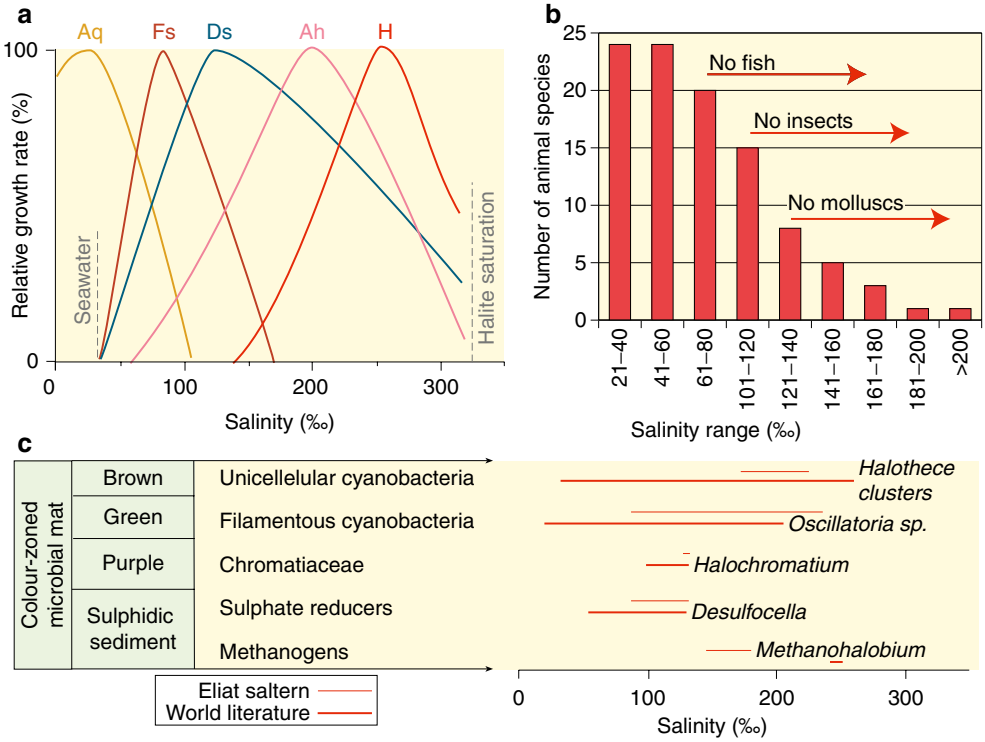

Fig. 9.18 Salinity tolerances. (**a**) Optimal ranges of selected halotolerant and halophilic micro-organisms. *Agmenellum quadraplicatum* (*Aq*) is a slightly halotolerant cyanobacterium, *Fabrea salina* (*Fs*) is a moderately halophilic protist, *Dunaliella salina* (*Ds*) is a halophilic green alga, *Aphanothece halophytica* (*Ah*) is an extremely halophilic filamentous cyanobacterium, and *Halobacterium sp*. (*H*) is an extremely halophilic archaea (After DasSarma and Arora 2001). (**b**) Decrease in variety of animal species in saline lakes of southeastern Australia (After Bayly and Williams 1973). (**c**) Range of observed optimum salinities for phototrophs in various microbial layers and for the sulphate-reducing bacteria and methanogenic bacteria in microbial crusts. It plots the ranges for a mat from a gypsum saltern in Eliat, Israel and compares values to those in the worldwide literature (Plotted from data listed in Table 2 in Sørensen et al. (2004))

on the landward side of Khor al Bazam in Abu Dhabi) but cannot flourish in environments where longterm salinity is greater than 5–10‰ above seawater. For example, mangrove seedlings cannot survive immersion for more than 48 h in mesohaline salinities of 60‰. Salt in adult mangroves is preferentially stored in the bark and in old leaves and is dispersed back into the environment when the leaves or bark are shed.

One of the more interesting mangrove occurrences in a saline setting is the healthy mangrove population (*Avicennia marina*) lining the seawater spring ponds in the hydrographically isolated Lake Macleod, Australia. The mangrove stands occupy an area around 22.5 ha and survive in and about perennial seawater seeps, regions where the escaping seawater has travelled more than 18 km underground via a calcarenite dune aquifer. The trees can reach 5 m height but many are stunted by the inherent elevated salinities (Ellison and Simmonds 2003).

Continually submersed halophytic angiosperms are largely restricted to saline-tolerant varieties of seagrass. All marine seagrasses die back once bottom salinities exceed 60–70‰. For example, four species of *Halophila sp*. collected in Redfish Bay, Texas, were able to grow in tanks with salinities of up to 74‰, without chlorophyll levels being affected, but only for a relatively short period of time (McMillan and Moseley 1967). In more continental settings the subaqueous angiosperm with the highest salinity tolerance is *Ruppia sp*. (aka duckweed or widgeon-grass), with an occurrence range of 0.6–390 g/l TDS (seawater salinity ≈31–34 g/l TDS = total dissolved solids). It thrives in normal marine waters, but also in the schizohaline coastal lakes in the Coorong region of southern Australia and near marine spring outflow zones in Lake Macleod, Western Australia. Perennial *Ruppia sp*. communities in the Coorong Lakes occupy deeper (up to metres deep), well lit permanent water bottoms with salinities of 12–50 g/l. Annual or seasonal communities inhabit shallow lake bottoms, characterised by less permanent waters with seasonal surface water salinities up to 230 g/l prior to complete lake desiccation (Brock 1982a, b). In ephemeral lakes in Western Australia, Geddes et al. (1981) found healthy *Ruppia sp*. growing in waters of 4–78 g/l TDS, but at 82–142 g/l, only drupelets (fruits) were present. *Ruppia* taxa are opportunist plants that die back to root mats when salinities rise or the saline lake dries out.

They quickly return to a growth phase once surface waters return to suitable salinities. An ability to quickly revitalise is why *Ruppia* species fluorish in shallow waters ponds in front of delta sediment prisms in Cuenca de Pozuelos, a high altitude saline playa in North-west Argentina (McGlue et al. 2012).

Preservation potential of organics from continental xerohalophytes is low, as organic matter in desert soils is typically oxidised and degraded. Organic remains of halophytes growing in submersed or brine saturated soils are more likely to be preserved. Kenig et al. (1990) found that, along with intertidal microbial mats, the other major contributors to organic matter preserved in the modern supratidal sediments of the Abu Dhabi sabkha were derived from mangroves (especially cuticle from *Avicennia sp*.) and lagoonal seagrasses (especially *Halodule sp*.).

Charophytes (stonewarts) are another group of opportunistic submersed mostly freshwater plants that includes halotolerant species, which can flourish in lower salinity regions of a saline lake or lakewide at times of brine freshening (Fig. 9.17a; Soulié-Marsche 2008; Burne et al. 1980). They are not known to occur in marine waters. The general outline of the complete plant, somewhat resembles an aquatic horsetail due to the whorls of branchlets arising from a "stem." They are photosynthesizers, thought to show strong affinities to green alga, although some taxonomists link them more closely to bryophytes and are thought to be ancestral associates of some of the first land plants. Their fossil record extends back to the Silurian, but the whole living plant is rarely fossilised, what is typically preserved are calcified female fructifications, termed gyrogonites, which display a characteristic and unique spiralled structure. These "oogonia" are a major contributor to the numerous calcispheres found in ancient saline mudstones and lunettes.

Lamprothamnium papulosum is the most common charophyte in the saline lakes of Australia. Studies of this species in saline lakes in the Coorong region, Australia, show it can be part of a healthy bottom community at 70‰, although it does not generally successfully germinate or grow above 53‰ (Burne et al. 1980). This is two to three times the typical salinity association documented for modern charophyte occurrences in brackish lakes in the northern Hemisphere.

Charophyte remains are not uncommon fossils in ephemeral saline lakes and sabkhas worldwide as they regenerate readily in freshened waters, even after considerable periods of desiccation. However, germination and growth require a transient period of suitably freshened water cover. Charophytes in saline lakes are opportunist species that dieback or retreat to "seep" refugia in harsh times. Widespread oogonia horizons in evaporitic sediments indicate episodes of freshening, as in the carbonate lakes of the Coorong and the coastal gypsum salinas in the "Chain of Lakes" at the southern end of Yorke Peninsula, South Australia and the sabkhas of North Africa (Soulié-Marsche 2008; Burne et al. 1980). *Lamprothamnium williamsii* is abundant in 65 ka coxiellid beds in Lake Eyre where it presence indicates a more humid period in the lake's hydrology (García and Chivas 2004). Likewise, sediment layers with the remains of *Lamprothamnium papulosum* in Fuente de Piedra, southern Spain, indicate times of freshening in a saline lake with a flora typically dominated by *Dunaliella sp*. (Garcia and Niell 1993).

Alga and Cyanobacteria

Rather than higher plants, halotolerant green algae and cyanobacteria, are the dominant primary organic producers in moderately hypersaline (mesohaline to penesaline; 60–200‰) settings. With elevated salinities restricting the grazers, green algal densities in a surface brine layer can be more than 10^5 ml^{-1}. Mesohaline algae are mostly obligately aerobic, photosynthetic, unicellular microorganisms. Green algae of the genus *Dunaliella*, e.g., *Dunaliella salina*, *D. parva*, and *D. viridis*, are ubiquitous in modern brine lakes, such as Great Salt Lake, Hutt Lagoon and the Dead Sea, where they constitute the base of the food chain for the halotolerant fauna (Fig. 9.18a; DasSarma and Arora 2001). Most species of green algae are moderate halophiles, with only a few extreme halophiles, e.g., *Dunaliella salina*, *Dunaliella viridis* and *Asteromonas gracilis*. For example, salinity contrasts in Great Salt Lake, Utah, seem to control cyanobacterial distributions and their associated pigmentation controls red-green brine colouration (Roney et al. 2009). Cyanobacterial distributions and pigments influence brine colour and the distribution of water colours in Great Salt Lake can be used to map salinity. *Aphanothece halophytica* proliferates in the highly saline pink waters of the northern arm (27 % salinity), while *Nodularia spumigena* fluorishes in the green waters of the less saline south (6–10 %) (Fig. 9.18a). Anthropogenic ponds at Hutt lagoon show a similar set of seasonal biogenic brine colours (Fig. 9.19).

The halophilic *Dunaliella parva* (a flagellate alga of the Chlorophyceae) is the sole primary producer in Dead Sea brines, with several species of hetrotrophic haloarchaea dependent on its periodic blooms. *Dunaliella sp*. can survive in marginward refugia, even when the upper and low water layers in the Dead Sea are NaCl-saturated. *Dunaliella salina* is one of the most environmentally tolerant eukaryotic organisms known and can cope with a salinity range from seawater to NaCl saturation, and a temperature range from <0 °C to >38 °C (Oren 2005). *Dunaliella* in the Dead Sea is capable of growing rapidly under hypersaline conditions, and this may be responsible for producing isotopically heavy $\delta^{13}C$. The consumption of this isotopically heavy glycerol by *Halobacteriales*, which feed on the *Dunaliella* blooms would in turn lead to a ^{13}C enrichment of the total biomass (Grice et al. 1998).

Fig. 9.19 β-Carotene manufacturing plant on the saltflats of Hutt Lagoon, Western Australia (Image mounted and scaled in MapInfo®, using a Bing® image base)

Halophilic *Dunaliella sp*. can contain high levels of β-carotene and pigment levels tend to increase with increasing salinity. It means that blooms in hypersaline pans can be harvested and processed to manufacture β-carotene. *Dunaliella salina* contains more than ten times the levels of β-carotene compared to other halophilic Dunaliella species and at higher salinities cells can contain as much as 10–14 % β-carotene dry weight, so it is the preferred commercial species (Moulton and Burford 1990). Two of the largest β-carotene producers in the world are Western Biotechnology Ltd. (Perth, Western Australia) and Betatene Ltd. (now Cognis Nutrition and Health, Melbourne, Victoria), both began operations in 1986 in Australia and now supply more than 90 % of the world's needs. Both operators grow the algae in large and shallow (approx. 20 cm deep) wind-stirred ponds constructed either on the bed of the hypersaline coastal salina known as Hutt Lagoon, or formed by artificially expanding and isolating a lagoon flat (Fig. 9.19).

Each of the artificial production ponds atop the surface of Hutt Lagoon is 5 ha in area and was constructed using earthen berms. The Hutt Lagoon production plant has a total current pond area of 50 ha and there are also smaller ponds for research purposes. Ponds used by Betatene Ltd. at Whyalla in coastal South Australia are even larger. High salinity is maintained in the shallow pond waters using a combination of wind-driven mixing, solar evaporation and seawater pumped into the ponds. Uncontrolled episodes of freshening (rainfall) can lower pond salinities. This can favour the growth of the less carotenogenic species (*D. viridis*, *D. minuta and D. parva*) as well as allowing grazing protozoa such as the ciliate *Fabrea salina* and the amoeba *Heteroamoeba sp*. to invade the pond. Such invasions can rapidly decimate algal production.

Along with *Dunaliella sp*., numerous species of cyanobacteria flourish at the elevated salinities where the activities of metazoan grazers are severely limited. Typically they construct laminated microbial mats and stromatolites in water-covered mesohaline areas and peripheral strandzone mudflats (Fig. 1.10). Various cyanobacterial species constitute the upper parts of these microbial "high rises" with species dominance in the layer changing according to their tolerances to salinity and light (Figs. 9.14). *Microcoleus chthonoplastes* is a cosmopolitan mat former and is the dominant filamentous blue-green in flat laminated mats in Guerrero Negro in Baja California Sur, Mexico, in Solar Lake in the Sinai and in Deep Lake in South Australia. In Guerrero Negro it grows best in brine-covered pans with a salinity range of 60–95‰. *M. chthonoplastes* tends not to do as well beneath pan waters with longterm salinities above 100‰. In Solar Lake it flourishes beneath waters with an annual salinity range of 45–180‰ and it still manages to photosynthesise, although not all that well, at salinities approaching 300‰. *Arthrospira subsalsa*, another filamentous cyanobacterial form, flourishes in mats worldwide at salinities of up to 150–180‰. At higher salinities and higher light intensities the nonfilamentous unicellular and coccoid cyanobacterial species come to dominate. The halophylic unicellular *Aphanothece halophytica* dominates mat surfaces in Guerrero Negro in pans with surface salinities up to 200‰. In Sabkha Gavish in the Sinai it occurs across an even broader salinity range of 250–330‰. Why the same cyanobacterial species seems to have different salinity ranges in different parts of the world is not clear. It may reflect a response to differing temperature regimes or to different rates of change in salinity of the waters atop the growing mats.

Recently, Davila et al. (2013) have documented a halophilic cyanobacterial community that lives as endoliths in

subaerially exposed halite nodules in the hyperarid Atacama Desert. They photosynthesise occasionally and utilise hypersaline pore brines created by deliquescence of halite at times of slightly increased atmospheric humidity, independent of rainfall events.

Diatoms (halotolerant bacillariophytal algae with siliceous tests) are another commonplace primary producer in mesohaline and lower penesaline environments (Fig. 9.17a). Their buoyant cells, often augmented by chitin threads or colonial adaptions, enable them to keep within the photic zone better than many other algae. They flourish at times of freshened lake waters or in perennial seepage and dissolution ponds (posas) about the edges of some salars, where they become a major component in some lacustrine stromatolites (Fig. 1.11b, c). Several benthic diatom species are conspicuous in building stromatolites, for example, *Mastogloia sp*., *Nitzschia sp*., *Amphora sp*., *Diploneis sp*. They function in a manner analogous to that of cyanobacteria in that they produce extracellular gel, are motile, phototropic, can trap and bind sediment, and produce surface irregularities of the mat (Winsborough et al. 1994).

Some varieties of benthic diatoms can live in lake brines with longterm salinities around 120‰, while the upper limit for diatom growth is around 180‰ (Clavero et al. 2000; Cook and Coleman 2007). The most halotolerant diatom taxa in the saltern ponds of Guerrero Negro are *Amphora subacutiuscula*, *Nitzschia fusiformis* (both *Amphora* taxa), and *Entomoneis sp*.; all grow well in salinities ranging from 5 to 150‰. Three strains of the diatom *Pleurosigma strigosum* were unable to grow in salinities of less than 50‰ and so are true halophilic alga. A similar assemblage of *Amphora sp*., along with *Cocconeis sp*. and *Nitzschia sp. d*ominate the high salinity (150‰) saltern ponds near Dry Creek, Adelaide, Australia (Cook and Coleman 2007).

Anoxic Sulphur-Oxidising Bacterial Photosynthesizers

Sulphur oxidation as a general biogenic process involves the oxidation of various reduced sulphur compounds, such as H_2S, inorganic sulphur (S^0), and thiosulphate ($S_2O_3^{2-}$), to form sulphate (SO_4). It occurs within the sulphur cycle in both oxygenic and anoxic environments (Fig. 9.20a). In this section we shall concentrate on photosynthetic sulphur oxidisers (anoxic primary producers), not the chemolithic sulphur oxidisers, which inhabit oxic settings. These anoxic photosynthesizers are colloquially known as the purple sulphur bacteria and green sulphur bacteria. In a microbial community, both groups occupy the anaerobic photosynthetic niche between the chemolithotophic aerobic sulphur-oxidising bacteria above and aerobic heterotrophs below. Purple sulphur bacteria tend to be metabolically more versatile than green sulphur bacteria, but both predominantly utilize the sulphide and sulphur in waters rising from below, as their electron source (Fig. 9.20a). In both microbial mats and stratified water bodies, the purple sulphur bacteria typically inhabit the lit brine layer immediately above green sulphur bacteria, both groups occupy a light-penetrated zone that is located directly beneath the oxic-anoxic interface.

Anoxygenic halotolerant to halophilic sulphur-oxidising photobacteria are a prolific group of primary producers and can create dense biolaminae in a variety of a sulphide-rich lit environments. Halophilic phototrophic sulphur-oxidising bacteria are typically filamentous CO_2 -fixers (both green and purple sulphur bacteria) utilising sulphide or H_2S, not water, as an electron donor for their photosynthesis (Table 9.4; Fig. 9.12b). They grow in hypersaline niches where light reaches into anoxic, sulphide-H_2S containing water columns or in microbially-bound anoxic pore waters a few millimetres below the surface of a mat. These anaerobes obtain their energy from light, especially from near-infrared radiation (800–900 nm), a part of the light spectrum that is not absorbed by the chlorophyll pigments in the cyanobacterial layers above.

Sulphide, produced by sulphate reduction in the layers below, serves as electron donor in the oxidation process. Different sulphur oxidising bacterial species thrive in different salinities, ranging from seawater to halite precipitating (Fig. 9.20b). As they use H_2S as the electron donor and produce various oxidised sulphur metabolites, the final product of this metabolic pathway is sulphate or sulphur and yellow sulphur nodules in modern mats can indicate their presence (Fig. 9.20a).

Typical sulphur-oxidising primary producers in mesohaline waters and microbial mats include; *Chromatium salexigens*, *Thiocapsa halophila*, and *Rhodospirillum salinarum*, with optimal growth in these species between 60 and 110‰ (Fig. 9.20b; Caumette 1993; Ollivier et al. 1994). Phylogenetic studies in the last two decades have moved fully halophilic sulphur oxidising species, once classified as *Ectothiorhodospira sp*., into a new genera the *Halorhodospira*; that is, *Ectothiorhodospira* is now considered the basonym for the halophilic bacterial grouping *Halorhodospira*. In highly alkaline soda lakes where Dunaliella is absent, anoxygenic phototrophic purple bacteria of the genera *Ectothiorhodospira* and *Halorhodospira* predominate and, instead of *Dunaliella sp*., form the base of the food chain utilised by haloarchea.

For example, shallow brines of the small soda lakes in the Wadi Natrun can be coloured an intense purple-red, due to the development of the purple sulphur oxidising bacteria *Halorhodospira halophila*. In contrast, *Halorhodospira abdelmalekii*, and *Halorhodospira halochloris* show green pigmentation in pure cultures, while pigmentation in *Halorhodospira halophila* is always purple-red. Small natural brine puddles in hypersaline locations may show separate development of green- and red-coloured species of

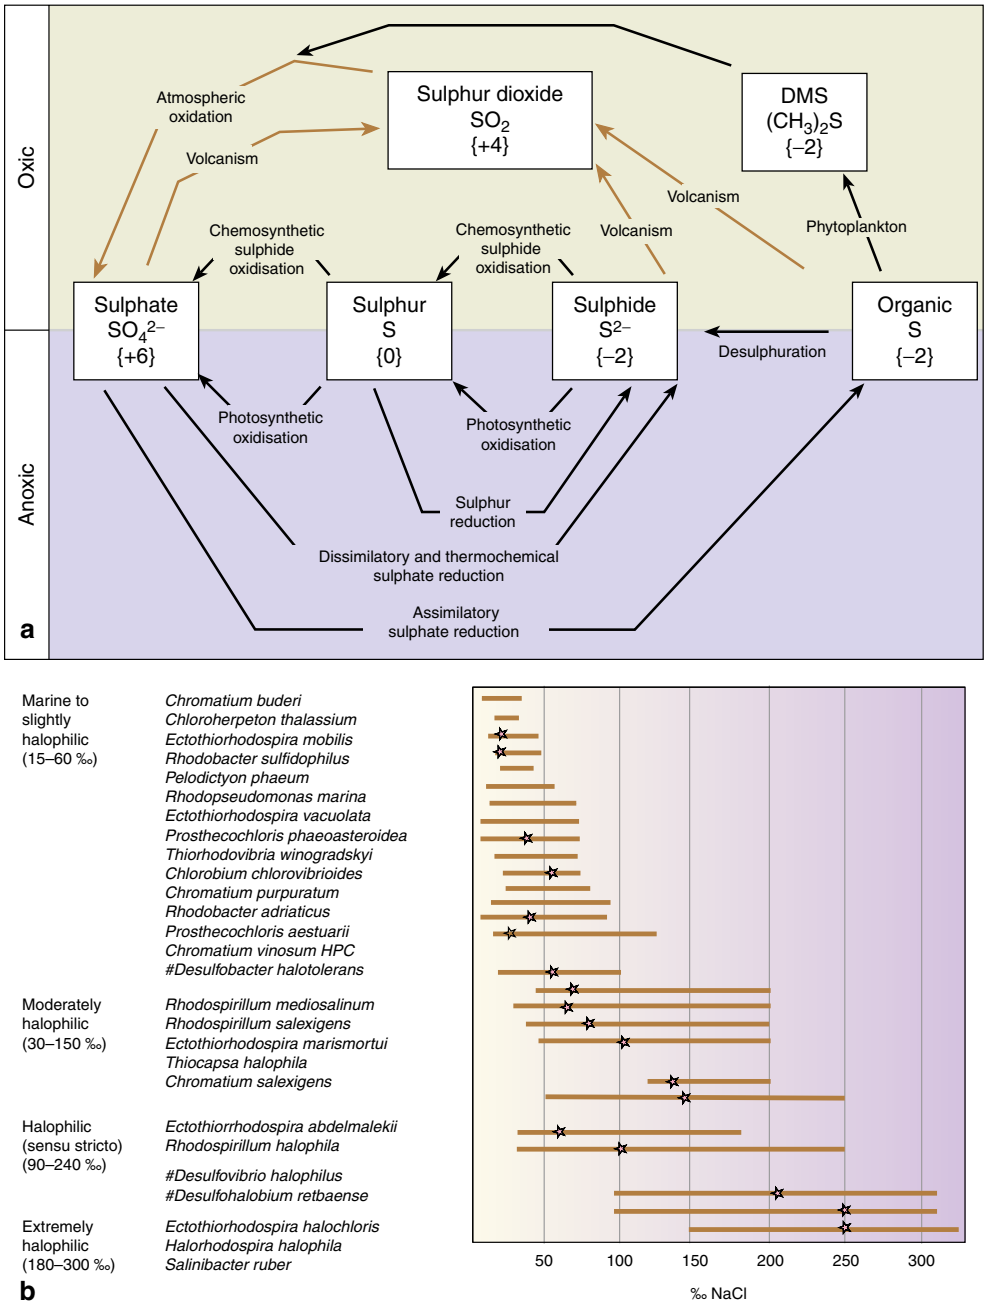

Fig. 9.20 Sulphur cycle and salinity tolerance. (**a**) Summary of the sulphur cycle showing the two types of microbially-mediated sulphur oxidation photosynthetic versus chemosynthetic (oxidation states of sulphur are shown in parentheses). Microbial pathways shown by solid lines; brown lines show geological processes involving sedimentary organic-sulphur, calcium sulphate (gypsum/anhydrite) and Fe-sulphide (pyrite). (**b**) Salinity tolerances in phototrophic halophilic bacteria including the sulphur oxidisers and the sulphate-reducers (#). *Star* on bar indicates the salinity for optimal growth (In part after Caumette 1993; Ollivier et al. 1994)

Halorhodospira, while top layers of the sediments of Wadi Natrun lakes (Egypt) show separate layers of the green-coloured and the red-coloured *Halorhodospira sp*. (Imhoff 1988); Imhoff et al. 1979).

Halorhodospira abdelmalekii, *Halorhodospira halochloris*, and in particular *Halorhodospira halophila* are among the most halophilic phototrophic bacteria known and confirm the observation that bacteria are capable of inhabiting the same highly saline environment as halophilic archea. Isolates of *Halorhodospira halophila* from soda lakes in the Wadi Natrun have salt optima of 250‰ total salts and can survive in halite-saturated solutions (Fig. 9.20b). The moderate halophile *Ectothiorhodospira marismortui* is a strict anaerobe found in the hypersaline growths about sulphur springs in the Dead Sea. Seep waters at the time of this purple sulphur oxidising bacteria was collected had a pH around 5.2, a salinity ≈170‰ and a temperature of 40 °C. Isolates of this species grew poorly at a pH of 5.5 but thrived in the neutral pH range between 7 and 8 (Oren 2005, 2009).

Bacterial Chemosynthesizers

The habitat range of the halobiota described so far exists in, or near, an environment that is lit and the community layering is controlled by whether the setting is oxic or anoxic. But

there is also a range of halotolerant and halophilic bacterial chemotrophs (mostly thiotrophic[9]) that can flourish in environments where light no longer penetrates. They fix CO_2 as cellular material using chemical compounds without the need for light and often occupy trophic levels also occupied by the decomposers and fermenters. There are separate phyla of sulphur-oxidizing and sulphur- reducing chemotrophic bacteria but as in much of the field of microbial cladistics, an agreed classification is still a matter of intense debate.

Bacterial Sulphur-Oxidizers

Sulphur-oxidizing chemosynthesizers (non-photosynthesizers) include halotolerant variants, such as the filamentous *Beggiatoa* (*qv*), *Thiothrix*, *and Thioploca*. They are anaerobes, they use sulphur as an electron donor and oxidize it by adding oxygen in seawater and lower-end hypersaline brine settings. The final product of the reaction is sulphate. This group does not require light, only sulphide, and is often found at the interface between oxic and sulphidic environments in microbial mats in saline lagoons and on the deep seafloor near brine lake edges or in the vicinity of hydrothermal and sulphidic seeps.

Beggiatoa sp. dominate the white mats and bacterial meadows typical of the chemosynthetic communities covering the deep sea floor near brine seeps and hydrothermal vents. These sites are typically on water bottoms well below the depth of light penetration. Unlike most bacteria, *Beggiatoa* and its mats in these settings can be recognized by eye, by recognising its typical stringy morphology. It is a filamentous bacterium, which is motile via gliding and stores elemental sulphur inside the filaments, giving filaments and mats a shinning white appearance. Filaments can be several millimeters to centimetres long and are formed by long rows of cells with diameters between 1 and 200 μm. Such white *Beggiatoa* mats typically occupy the zone between the oxygenated water column and underlying anoxic sediment, they inhabit the narrow chemical interface where the O_2 and sulphide diffusion gradients meet (Gilhooly et al. 2007).

In saline lakes, such as Guerrero Negro, Mexico, the *Beggiatoa* community of the hypersaline microbial mats of occupies the sulphide-oxic interface, typically located a few millimetres below the mat surface in daylight hours. At night its biosignature disappears from the mat community, suggesting it may have exited into the overlying water column as it tracks a rising sulphide-oxygen boundary (Jesse et al. 2009).

In addition to oxygen, the larger-diameter *Beggiatoa* species (>4–10 μm diam. filaments) can also use internally-stored nitrate in the oxidation of sulphides. The nitrate can act as an alternative electron acceptor for sulphide oxidation. Nitrogen utilisation increases the rate of sulphide oxidation in oxygenated waters and also allows these nitrate storers to survive periods of anoxia. Other chemotrophic sulphur bacteria live as symbiotic sulphur-oxidising bacteria in animal tissues of invertebrates in the same un-lit brine pool communities as *Beggiatoa* (Levin 2005). These brine-controlled chemosynthetic cold-seep communities, situated atop salt allochthons, are discussed later.

Bacterial Sulphate-Reducers

Dissimilatory[10] sulphate reduction induces large ^{34}S isotope fractionations and can produce sulphide depleted in ^{34}S by 4–49‰ compared to the sulphate precursor. When iron is present pyrite is typically precipitated, when no iron is present, as in a limestone host, then biogenic calcite is the precititate as in many salt allochthon caprocks. In general, the rate-limiting step in sulphate reduction is the breaking of the first S-O bond, namely the reduction of sulphate to sulphite (Fig. 9.20a). Dissimilatory sulphate reduction can occur up to quite high salt concentrations and black, foetid sulphide-containing sediments form the bottom to modern coastal salinas and salt works, well into the penesaline salinity range (Oren 2001).

There are more than 120 species of sulphate-reducing prokaryotes, belonging to four bacterial and two archaeal phyla. Amongst the sulphate reducing bacteria, the most salt-tolerant is the halophilic *Desulphohalobium retbaense*. Isolated from Lake Retba in Senegal, it is capable of growing at NaCl concentrations of up to 250‰ (Ollivier et al. 1994). Two other sulphate-reducing halophilic isolates are *Desulphovibrio halophilus* and *Desulphovibrio oxyclinae*, which can tolerate NaCl concentrations of up to 180–225‰ (Fig. 9.17b; Caumette 1993; Krekeler et al. 1998). Another isolate, similar to *Desulphovibrio halophilus* has been collected in brine pool samples from the allochthon-associated deep-water brine lakes on the floor of the Red Sea. There it grows at salinities up to 240‰, but only slowly. *Archaeoglobus* and *Sulphobus* are two known archaeal sulphate reducers, both are thermophiles and live in active hydrothermal regions.

[9]Thiotrophic describes an organism that oxidizes sulphur compounds as a major part of its metabolism. Purple and green sulphur bacteria are generally not called thiotrophic because they gain energy by photosynthesis and are thus classified as phototrophic, even though sulphide is required for this process.

[10]Dissimilatory sulphate reducers release large amounts of hydrogen sulphide (H_2S and HS) to the ambient environment, as products of their energy metabolism and so cause the characteristic smell of rotten eggs in the host sediment. The process is carried out by a heterogeneous group of bacteria and archaea that occur in anoxic environments with temperatures up to 105 °C.

Assimilatory sulphate reduction is conducted by some bacteria in order to synthesize sulphur-containing cell components. It is another form of intracellular sulphate reduction, it is a metabolic process set that reduces sulphate to typically produce sulphide groups attached to amino acids, which are assimilated as useful components into the cell.

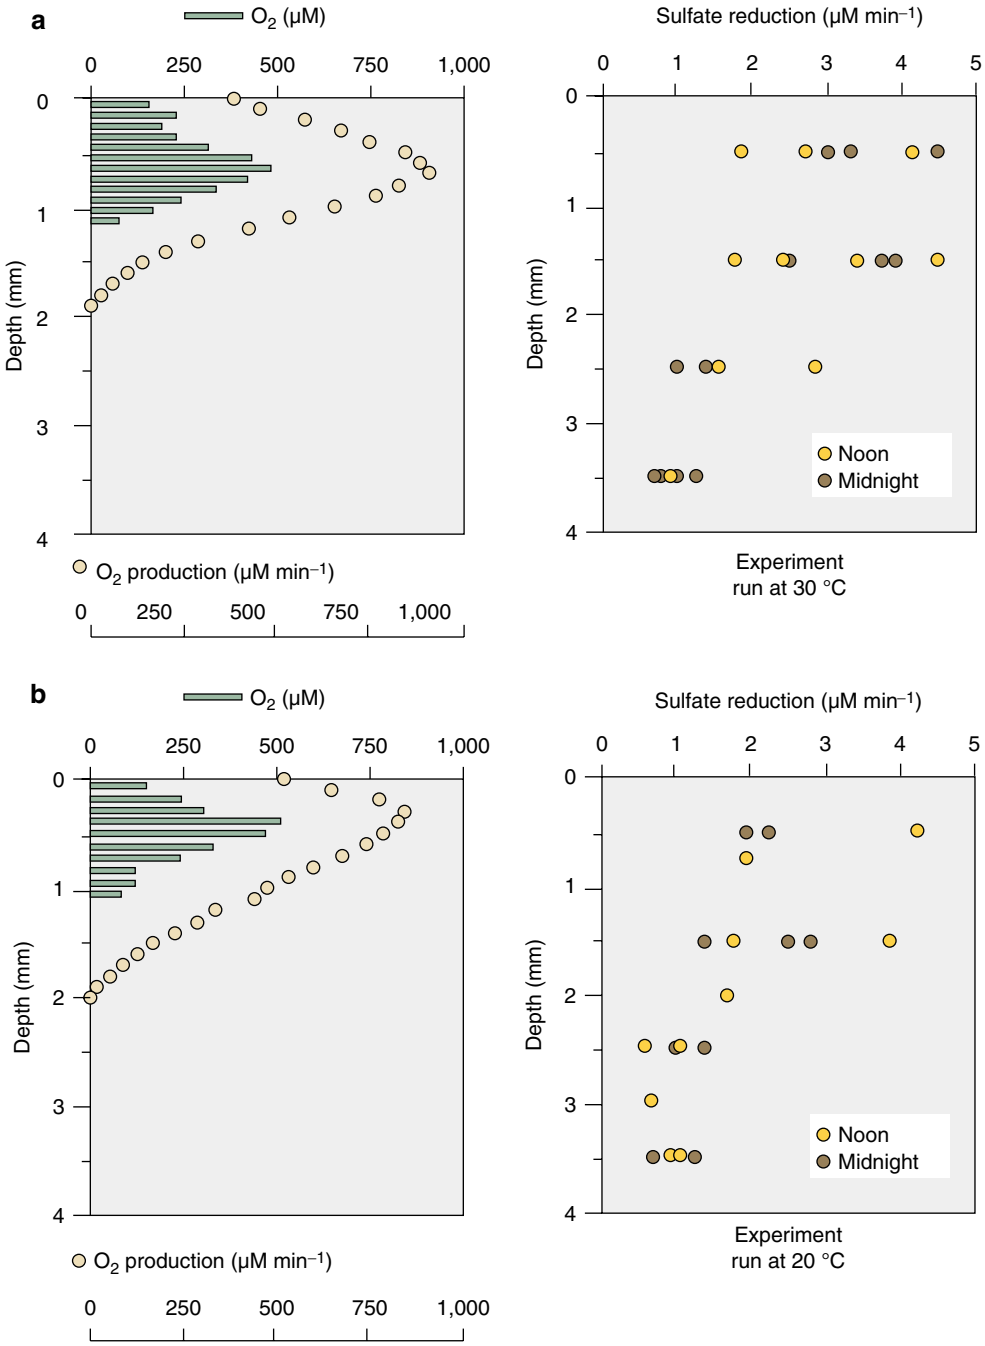

Fig. 9.21 Depth related distribution of dissolved oxygen and oxygen production rate measured at noon (*left hand figures*) plotted against sulphate reduction rate (*right hand figures*) sulphate reduction measurements were made at noon and midnight. Experiment in (**a**) was run at 30 °C and (**b**) at 20 °C. In both cases the sulphate reducers extend well into the oxic portions of the microbial mats (After Canfield and Des Marais 1991)

As we saw in the previous section in any microbial mat the zone of photosynthetic oxygen synthesis overlaps with a zone of sulphide production by sulphate reduction and the two can be separated by a zone of oxygen-dependent microbial sulphide oxidation (inhabited by the purple and green sulphur oxidising bacteria). These metabolic activities create steep, opposing gradients of oxygen and sulphide, which fluctuate with the rhythm of day and night (Canfield and Des Marais 1991). Historically it was assumed sulphate-reducing bacteria were obligate anaerobes, but in cyanobacterial mats from the saline evaporation ponds in Baja California, Mexico, this may not be so. *Desulphobacter* and *Desulphobacterium* are always restricted to the greater depths in the mats, which are anoxic. However, the *Desulphococcus* and *Desulphovibrio* groups are predominant in the upper part of the layered microbial community and thriving in the lower part of the photo-oxic zone (Fig. 9.21; Risatti et al. 1994), where they are able to deal with temporal exposures to oxygen concentrations as high as 1.5 mM (Sigalevich and Cohen 2000).

Most halophilic and halotolerant sulphate-reducing bacteria are incomplete oxidisers that grow on lactate and produce acetate. Dissimilatory sulphate reduction provides relatively little energy, and therefore the need for sulphate reducers to spend a substantial part of their available energy budget for the production of organic osmotic solutes may set the upper limit to the salt concentration at which these bacteria can grow (Oren 2001 and later discussion in this chapter). Oxidation of lactate to acetate and CO_2 yields much more energy. Recently, the first halophilic acetate-oxidizing sulphate-reducing bacterium was isolated: *Desulphobacter halotolerans* was collected from the hypersaline bottom sediments of Great Salt Lake, Utah. It has a rather restricted salinity range, being unable to grow above 13 % NaCl (Brandt and Ingvorsen 1997). Even so, it possesses the highest NaCl tolerance reported for any member of the genus *Desulphobacter*.

No viable bacterial sulphate-reducing communities have been collected at the more extreme salinities, where halite precipitates, although when radioactive tracers are used to define rates of sulphate reduction it is obvious that sulphate reduction does occur at elevated salinities approaching halite saturation. In modern coastal salt pans northeast of Capetown, South Africa, the rate of dissimilatory sulphate reduction increased up to salinities of 272–311‰, beyond that, toward halite saturated salinities, the rate of isotope uptake decreased (Porter et al. 2007). Some sulphate reducers may also be alkalophiles; for example, *Desulphonatronovibrio hydrogenovorans* is a H_2 -utilising sulphate-reducing bacterium isolated from the trona beds of Lake Magadi, it functions optimally at pH 9.5 and 3 % w/v NaCl.

Halobiotal Heterotrophs (Consumers)

Secondary production describes the generation of biomass by heterotrophic (consumer) organisms in an ecosystem. It is associated with the transfer of organic material between various trophic levels, and represents the quantity of new tissue created through the use of assimilated food (Fig. 9.16). Secondary production is typically defined as including all biomass generated by heterotrophs. Organisms responsible for secondary production in hypersaline sediments include a few animals (vertebrates and invertebrates), protists, fungi and many species of bacteria and archaea (Figs. 9.17 and 9.18).

Vertebrates

Marine fish species can survive and even flourish in perennial seawater spring pools and seeps that line the edges of coastal salinas. For example, Timms (2009) found healthy populations of the Port Lincoln Hardyhead (*Leptatherina presbyteroides*) in a number of marine spring pools about the edges of coastal salinas of South Australia. Likewise Logan (1987) noted the estuarine Yellowtail Trumpeter (*Amniataba caudavittata*) and the Few-ray Hardyhead (*Craterocephalus pauciradiata*) living in seawater seep pools about the edges of Lake Macleod. At times of salina-wide freshening these fish species, along with marine forams and diatom in the refugia, as well as other halotolerant species spread out into other parts of the salina, dying back to the spring-seep refugia when the lakes dry out once more. But none of these species have evolved to survive at elevated salinities much beyond that of seawater (>35–40‰).

The highest natural brine salinities at which viable fish populations have been observed, living in a permanent brine lake, are around 60–90‰. For example, the white-lipped or alkaline tilapid fish (*Oreochromis alcalica*) lives in such mesohaline waters in African rift lakes and even flourishes at 36–40 °C and in pH ≈ 10.5 within thermal spring and moat brines about the edges of Lake Natron and Lake Magadi. Desert pupfish in the Sonoran Desert can survive for short periods in waters of drying pans that are as saline as 100–140‰ (Helfman et al. 1997, p.313). Unlike desert pupfish, tilapids are one of the few higher organisms that can tolerate perennial hypersalinity (DasSarma and Arora 2001). Rates of survival among the tilapia are dependent on the rate of salinity rise, with maximum hypersalinity tolerance occurring when elevated salinities are attained gradually (Gonzalez 2012). In the lab, black-chinned tilapia (*Sarotherodon melanotheron*) populations survived well, up to around 120‰ when the salinity was raised 2–8‰/day.

All fish living in saline settings tend to inhabit perennial waters centred on spring refugia and expand into broader niches at times when an upper fresher oxygenated layer typifies the upper portion of the brine column. But this can be a hazardous environment in a saline setting, especially if the upper oxygenated water mass has an anoxic underbelly. Stratified water masses are subject to instability either via dessication and salinisation, or equally destructive wind-induced holomixis. In the modern Salton Sea there is a strong correlation between winds that overturn the stratified lake waters and significant fish and barnacle kills due to inimical waters (low oxygen, high H_2S and ammonia) rising into the upper water column (Marti-Cardona et al. 2008). Following death, fish carcasses float to the lake surface and deposit and accumulate along the Salton shore, which retains wave washed sediments that are rich in disarticulated fish and single bone and scale elements, along with a significant component of barnacle shells.

Malenda et al. (2012) argue similar mass kills of Triassic fish species took place during deposition of the saline lacustrine Lockatong Formation in the northeast USA. High wind events caused overturning of the lake waters, either depleting oxygen levels or toxically poisoning the fish with upwelling H_2S and ammonia-rich brines. After death, bacterial

decomposition bloated the fish by generated gas in tissues causing the fish carcasses to float. The decomposing fish carcasses were driven shoreward by wind and wave action and deposited on the shoreline and were possibly scavenged by phytosaur populations the Mesozoic equivalent to today's flocks of gulls in the Salton Sea.

As well as leaving traces or their avian presence as tracks and nest mounds preserved in the rock record (Scott et al. 2009, 2012), many modern birds in saline lakes also feed on organic-rich detrital lake rims. Others feed on the periodic planktonic blooms that occur at times of lake water freshening. One of the most spectacular examples of avian exploitation of the halotolerant plankton is the pink flamingo (lesser flamingo) population of African rift lakes. Stilts, gulls and pelicans are other opportunist avians that feed on halobiotal blooms that occur in periodically freshened salinelakes and their remains and trace.

The influence of flamingo grazing on organic matter and type is documented in Laguna de Pozuelos (Fig. 9.22; McGlue et al. 2012; Ferrero et al. 2004). The climate of the basin is cold and semiarid (Köppen BSk adjacent to ET) showing an annual temperatures average below 9 °C near lake and it is markedly seasonal, with a rainy season in summer (between December and March) and a dry season throughout the rest of the year. Average annual rainfall is about 350 mm making it one of the most humid intermontane depressions in the region.

The lake supports a rich diatom flora (estimated density of the diatoms suspended in the water is 4×10^3 cell l^{-1} and 2×10^3 cells g^{-1} of those in the sediment) consisting mainly

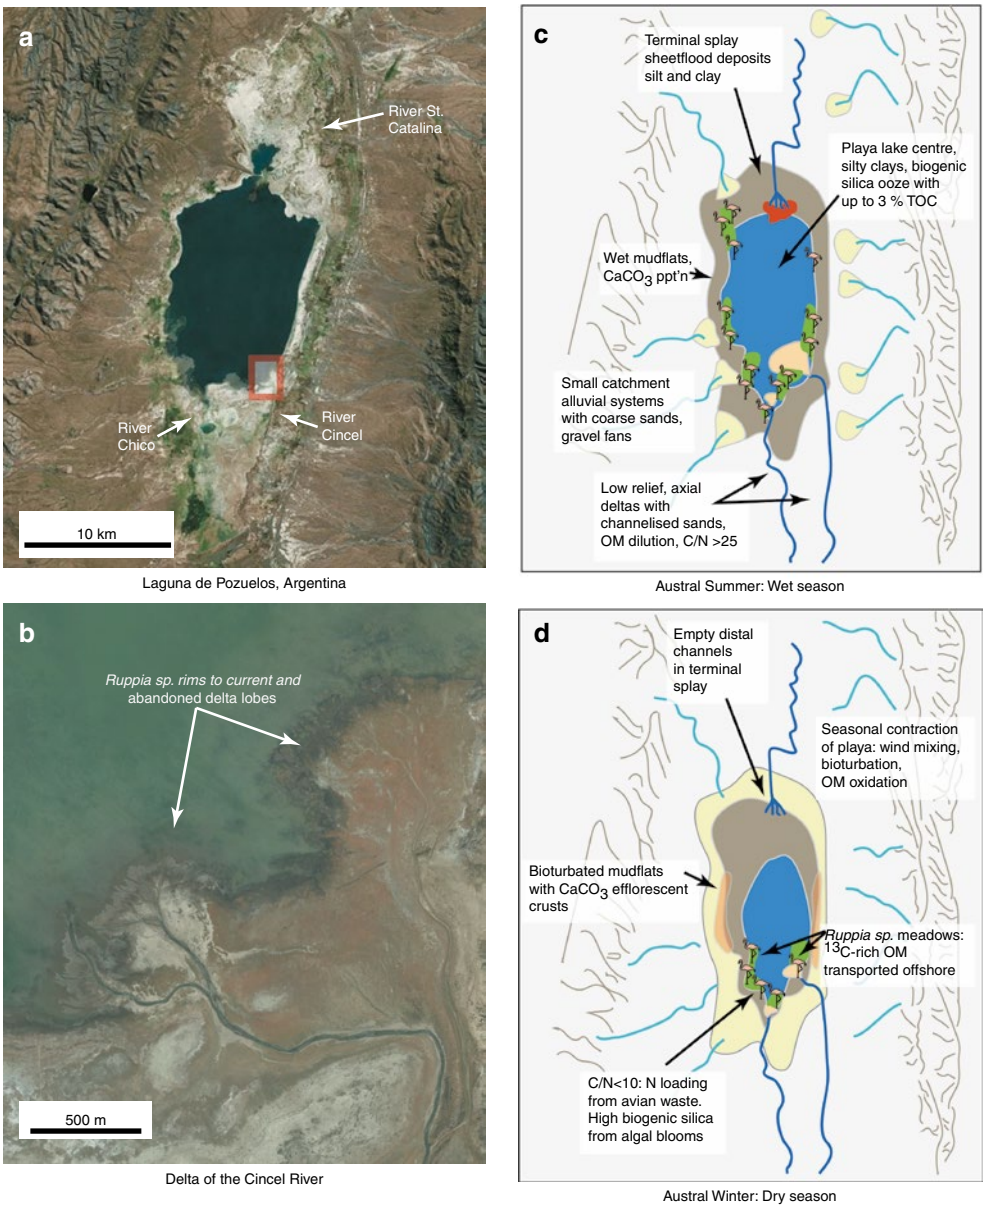

Fig. 9.22 Laguna de Pozuelos, Argentina. (**a**) The laguna is an intermontane location and is seasonally fed from snowmelt mostly by three rivers (Chico, Cincel and St Catalina) and a series of bajada inflows. (**b**) Detailed view of the delta lobes at the mouth of the Cincel River. Ruppia sp. meadows rim the strandzones of both the active and inactive delta lobes. (**c**) Wet season (austral summer) when river inflow is active (*dark blue* for main inflows) and flamingo population is spread across the lake edge feeding on duckweed. (**d**) Dry season (austral winter) when lake levels are low, flamingoes an their duck weed food-source are confined to southern margins of seasonal changes in flamingo distribution indicated by pink flamingo symbol (In part after McGlue et al. 2012)

of *Cocconeis placentula*, *Nitzschia perspicua*, *Nitzschia hungarica*, *Navicula minuta* and *Navicula perminuta*, which are indicators of moderate alkaline (pH = 8.0–8.5) waters. The abundance of *Nitzschia sp*. Indicates waters masses with elevated mesohaline salinity, at least in dry periods. Zooplankton shows an average annual density of 220 individuals l^{-1}, the predominant invertebrate fauna consists of copepods (*Beckella sp*., *Attheyella sp*.), Cladocera (*Daphnia sp.*) and rotifers (*Hexarthra sp.*). This planktonic microfauna supports an extraordinarily numerous colony of flamingos that graze by filtering the waters. In summer the flamingo colony increases extraordinarily in size with as many as 25,000 flamingoes (made up of 4 species) in the shallows of the lake feeding on the halotolerant plankton (mostly diatoms) that flourishes in the lower salinity upper water mass that has spread over much of lake (Fig. 9.22c). The extent of the perennial lake waters varies from less than a few square kilometres when dry, and the basin is experiencing a few drought years, to more than 150 km^2 when water full.

Silty clays and diatom ooze are the dominant playa-lake centre facies, with concentrations of total organic carbon commonly exceeding 3 wt% in this sub-environment (Fig. 9.22c). Elemental and stable isotopic analyses point to a mixed organic matter composition in the playa-lake centre, with substantial contributions from algae and transported aquatic macrophytes. Bulk sediment and organic mass accumulation rates in the southern playa-lake centre approach 0.22 g cm^{-2} $year^{-1}$ and 2.89 mg cm^{-2} $year^{-1}$, respectively, indicating moderately rapid deposition with negligible deflation over historic time. Playa margin facies contain higher percentages of fragmented biogenic carbonate (ostracods and charophytes) and inorganically precipitated aragonite crusts due to seasonal pumping and evaporation of ground water with much of the precipitation occurring in the dry season (Fig. 9.22d). Organic matter accumulation is limited along these heavily bioturbated wet and dry mud flats. Fluvial–lacustrine transitional environments, which are key waterbird habitats (Fig. 9.22b), are either silty terminal splay (northern axis) or sandy deltas (southern axis) containing highly oxidized and partially allochthonous organic matter. Organic matter accumulation is limited along heavily bioturbated wet and dry mud flats. Fluvial–lacustrine transitional environments, which are the key flamingo habitats (Fig. 9.22b), they are either silty terminal splay (northern axis) or sandy delta (southern axis) deposits that contain highly oxidized and partially allochthonous organic matter.

TOC values tend to be elevated in the perennially subaqueous laguna centre and are consistently more than 3 wt%, whereas samples from the southern deltas and playa margins typically exhibit TOC values < 1.5 wt% (Fig. 9.22). Laguna bottom samples typically contain low total nitrogen levels with C:N (carbon:nitrogen) values ranging from 2 to 79, with a mean of ≈ 22 (McGlue et al. 2012). Samples collected from mud flats north-west of the main Río Santa Catalina channel and within the mouth of the Río Cincel delta exhibit low total nitrogen, leading to C:N values >30. Most of the laguna sediments have C:N values <20, which is typical for lakes with mixtures of algal and higher plant matter. An exception to this pattern is observed near the Río Chico delta, where values of total nitrogen substantially increases and C:N values fall to <5.

Flamingo activity is high year round in this locale, probably due to the availability of nutrients for the phytoplankton and favourable shallow water depths allowing the birds to filter feed across large parts of the delta. Seasonal foraging probably impacts both the carbon and nitrogen cycles across other similar microhabitats in the laguna and leads to period input of organics with elevated $\delta^{13}C$ values. Avian waste products, especially urea, are rich in organic nitrogen and ammonia, which likely explains the higher nitrogen levels in the sediments in regions of year round flamingo filter-feeding. Local eutrophication from these waste products probably drives phytoplankton blooms, as evidenced by elevated concentrations of biogenic silica in the distal Río Chico environment (from diatoms, especially *Cocconeis placentula*, *Nitzschia hungarica* and *Navicula sp*.). A similar set of avian-induced eutrophication processes is seen in many of the east African rift lakes where flamingo populations build to phenomenal numbers as they feed on halotolerant plankton blooms in mesohaline lake waters. Likewise the mesohaline waters of Great Salt Lake, Utah, act a food stop for over million migrating birds made up of some 250 different bird species (Aldrich and Paul 2002). These birds feed mostly on large populations of brine shrimp, *Artemia salina*, and the brine flies, *Ephydra ripara*, which flourish in both arms of the lake.

Throughout the Neogene in African rift lakes, hippopotami (*Hippopotamus amphibius*) are probably the largest vertebrates capable of leaving traces of its presence in semi-arid to arid alkaline lake-margin sediments. This is especially so in regions of muddy organic-rich sediments near brackish lake margin springs, as in the saline-alkaline mudflats rimming the crater lake of the Ngorongoro Crater, Tanzania (Deocampo 2002). There the organic content of muds that infill hippopotami trackways or furrows leading to the spring is as high as 17 % TOC versus organic contents around 6–7 % in mudflat sediments adjacent to the trackways. A population of some 15–20 hippopotami are known to inhabit Lake Nakuru, feeding on grassy meadows along the lake shore at night and spending their days defecating, while immersed in the mesohaline lake waters (Matagi 2004).

Invertebrates (Ingesters, Grazers and Pelletizers)

Large numbers of a relatively few species of halotolerant invertebrates can survive, graze and produce pellets in low to moderately mesohaline environments. This can be seen in the broad range of salinities tolerated by a number of

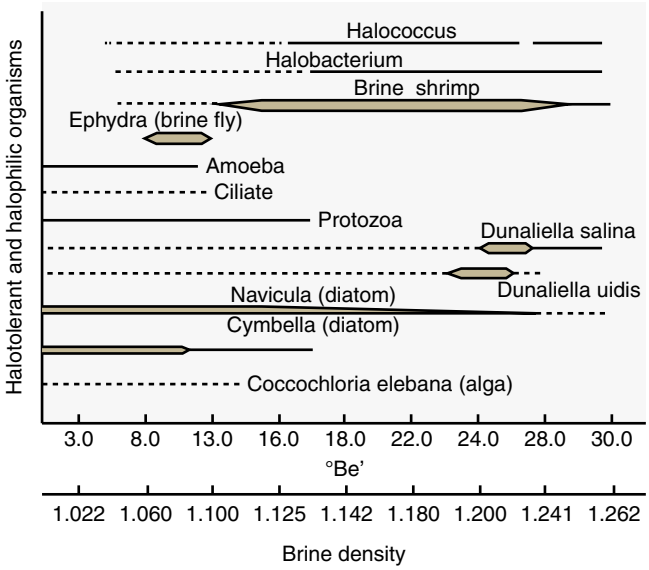

Fig. 9.23 Salinity ranges of halotolerant and halophilic organisms in the mirabilite-accumulating Barkol Lake, China (After Dongyan et al. 1998)

well-adapted species in marine and continental saline settings (Fig. 9.17a). The salinity ranges in the mirabilite-precipitating waters of Lake Barkol, China, are a good example of such biological adaptation (Fig. 9.23) The lake has a salt content of 215–338 g/l, a pH of 7.2–7.81, a δD and $\delta^{18}O$ range of −23.7 to +2.4‰ and −11.13 to +4.53 %, respectively. Brine shrimp (*Artemia salina*), an invertebrate heterotroph, in the lake can ingest, graze and defecate across a broad salinity range and this is typical of brine shrimp in saline settings worldwide.

As in the oceans, faecal pellets of the zooplankton (invertebrates) in stratified brine lakes and salterns (e.g., brine shrimp in Fig. 9.23) are very important in rapidly moving planktonic organic matter to the water bottom. That is, pelletisation is a biogenic mechanism that quickly moves suspended planktonic algal and bacterial debris from it original site, where it is floating in an oxygenated freshened upper water layer, into a sediment layer beneath hypersaline anoxic bottom brines. There, the anaerobic decomposers are far less efficient destroyers of long chain hydrocarbons than their aerobic counterparts. Cosmopolitan examples of pellet producers that feed on alga and bacteria during times of freshening and feast in saline settings include; copepods, brine shrimp, ostracodes and halotolerant molluscs such as *Fragum erugatum*.

Fragum erugatum thrives beneath the mesohaline bottom waters of Shark Bay, Australia where it can survive salinities in Hamelin Pool of up to 70‰, but flourishes at salinities around 50–55‰. In the well-lit low nutrient mesohaline bottoms where it filter feeds and defecates, its metabolic efficiency is greatly enhanced by the rich xooanthellate flora that symbiotically populate its mantle (Berry and Playford 2002). During intense storms (hurricanes or cyclones) the remains of this almost monospecific benthic community have been washed into laterally accreting beach ridges that now define the edge of Hamelin Pool.

A more unusual saline symbiosis in a marine invertebrate association is found in mollusc biostromes adjacent to hypersaline waters of brine lakes that occurs on the deep dark sea bottom, atop salt allochthons in the Gulf of Mexico. There, even though these molluscs cannot tolerate elevated salinities, biostromes of chemosynthetic molluscs rim the halocline-defined edge of methane-and H_2S saturated brine lakes, situated atop salt allochthons. Biostromes are dominated by *Calyptogena* clams, along with serpulid worms, sea anemones, galatheid crabs (stone crabs like *Paralomis sp.*), swimming holothurians and amphipods (Macdonald et al. 1990). The worms and molluscs are chemotrophs with symbiotic chemosynthetic microbes (including purple-oxidising bacteria and methanogenic archea) that inhabiting their flesh/gills and thrive on the H_2S and methane escaping across the halocline.

On land, insects flourishing about the edges of hypersaline lakes include halotolerant brine flies, such as *Ephydra hians* and *E. gracillis*. Their eggs hatch, and their larvae feed and pupate in microbial mats and berms of organic scum about the strandlines of most modern saline lakes (Fig. 9.17b). Both the larvae and the adult flies are scraper-gatherers feeding on the cyanobacteria and diatoms in benthic mats. Brine-fly larva of various species are well adapted to saline conditions as they burrow and ingest microbial mat materials. Adults are grazers and form thick flying and feeding "carpets" around the edges of salt lakes. *Ephydrella marshalli* larvae collected from subaqueous benthic mats about the edges of commercial salt works/lagoons on Port Phillip Bay, Victoria, have survived several days immersed in hypersaline sodium chloride media at ≈200‰ (up to 5850 mOsm/l; Marshall et al. 1995). Likewise larvae of dolichopodid brine fly *Hydrophorus plumbeus* collected in Mono Lake[11] survived immersion for a week in NaCl brine with a salinity as high as ≈190‰ (5,600 mOsm/l; Herbst and Bradley 1988). Adult flies have extra long body hairs that enable them to encase themselves in an air bubble and so walk about on the underside of the water surface of a brine lake. They do this to

[11] The term mono, used in the name Mono Lake, California, is likely a Yokut Indian word for naturally salted brine-fly pupae, a local delicacy before European settlement. However the Yokut people lived 200 miles north of Mono Lake, they harvested brine flu in Owens Lake, not Mono Lake. Prior to European settlement a small group of people (≈200 persons) calling themselves Kutzadika'a inhabited the Mono Lake region. The name Kutzadika'a, roughly translated, means "fly eaters" and Kutsavi was the Kutzadika'a term for brine fly, not Mono. Numbering around 200 individuals, the Kutzadika'a spent most of the year in the Mono Basin following an annual cycle of food gathering that seasonally focused on brine fly.

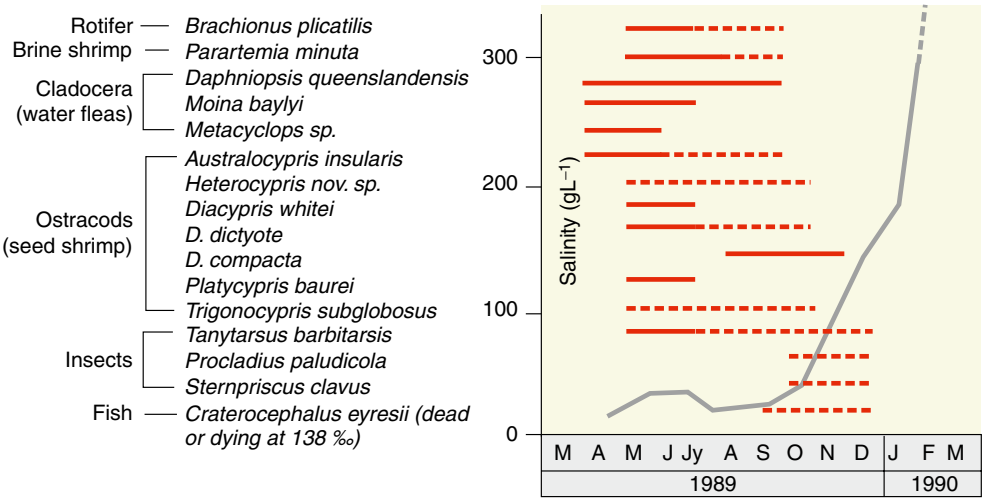

Fig. 9.24 Salinity related occurrences of major macrofauna during the 1989 flooding of Lake Torrens, Australia (After Williams et al. 1998)

gain access to richer food sources and to lay eggs. Brine flies evolved at the start of the Cenozoic and since then, through larval burrowing have restricted the preservation of lacustrine microbiolites, while also creating a diagnostic trace fossil assemblage in saline lacustrine settings (Eggermont and Verschuren, 2006).

Adults and larvae of staphilinid salt beetles also inhabit saline settings. In the Sinai and Tunisian sabkhat as well the Solar Lake cyanobacterial margins, adults of the salt beetle *Bledius carpa* excavate chambered burrows to depths of 10–12 cm in which they store and feed on lumps of cyanobacterial mat (Gerdes et al. 2008). When the mat surface is flooded the beetles can survive for weeks in their submerged burrows.

The contribution of insects to the surface biomass can be high in evaporitic settings, mostly as chitin. But, in terms of their preservation potential as fossils, the remains of most flies and insects, and their carapaces, rank low unless encased in saline concretions (Park and Downing 2001). Then the three dimensional preservation of insect soft tissues is possible via replacement with silica-based minerals as well as calcite, celestite, apatite, and gypsum. But the more usual evidence of arthropods and other invertebrates living in saline settings is via mineralization of faecal pellets and the preservation of burrow traces.

Halotolerant pellet-producing planktonic crustaceans include; ostracodes such as *Cypridistorosa*, *Paracyprideinae sp.*, *Dia-cypris compacta*, and *Reticypris herbsti*, copepods such as *Nitocra lacustris* and *Robertsonia salsa*, and brine shrimp such as *Artemia salina*, *Parartemia zietzianis* and other related species. Halotolerant ostracode remains are a common component of mesohaline sediments, dense populations spread out from refugia and flourish at times of freshened surface water layers (Fig. 9.24). For example, *Platycypris baueri* has the broadest salinity range of any ostracode found in Australia, it is able to survive at salinities ranging from 5 to 195‰, but is much more abundant in the middle of this salinity range and does best in waters with salinities above 70‰ (De Deckker 1981). Yet, it was not present in this upper salinity range during the 1989 flood of Lake Torrens, Australia, when it occurred only at much lower salinities (Fig. 9.24; Williams et al. 1998). The species diversity plot in Lake Torrens shows a typical saline pan biotal response to strandline retreat. This allows the halotolerant terrestrial insect population to follow the retreating strandline to scavenge and feed on the decomposing victims of the increasing salinity in the retreating brine sheet. Thus they are found scurrying about the edges of highly saline water sheets but do not actually inhabit the water.

Brine shrimp (*Artemia sp.*), another cosmopolitan pellet producer in saline settings, survive across a wide range of salinities from 25 to 340‰, with their optimal range around 60–100‰ (Post and Youssef 1977; Torrentera and Dodson 2004). *Artemia salin*a inhabits various mesohaline coastal salinas, atop calcarenite aquifers in the Yucatan, Mexico. These marine-fed North Coast hypersaline pools and salterns show a range of extreme alkalinity, salinity and temperature conditions, as well as hypoxia and in some instances, total desiccation (Fig. 9.25). Weather is characterized by three seasons: rain from the end of June to October, cold storms from October–November to March, and the dry season from March to June. The four locations, Celestun, Chuburna, Xtampu and Las Coloradas salinas, exhibit a similar range in water temperature, nitrites, and phosphates, but at a single time can differ in salinity, oxygen content, water depth, nitrates, ammonia, silicates, carbonates, sulphates, and pH, much like the coastal salinas of the Coorong and Brazil (Fig. 9.25).

The dominant multicellular organism and pelletiser in all these hypersaline ecosystems is *Artemia*. Brine shrimp abundance and population dynamics were significantly correlated

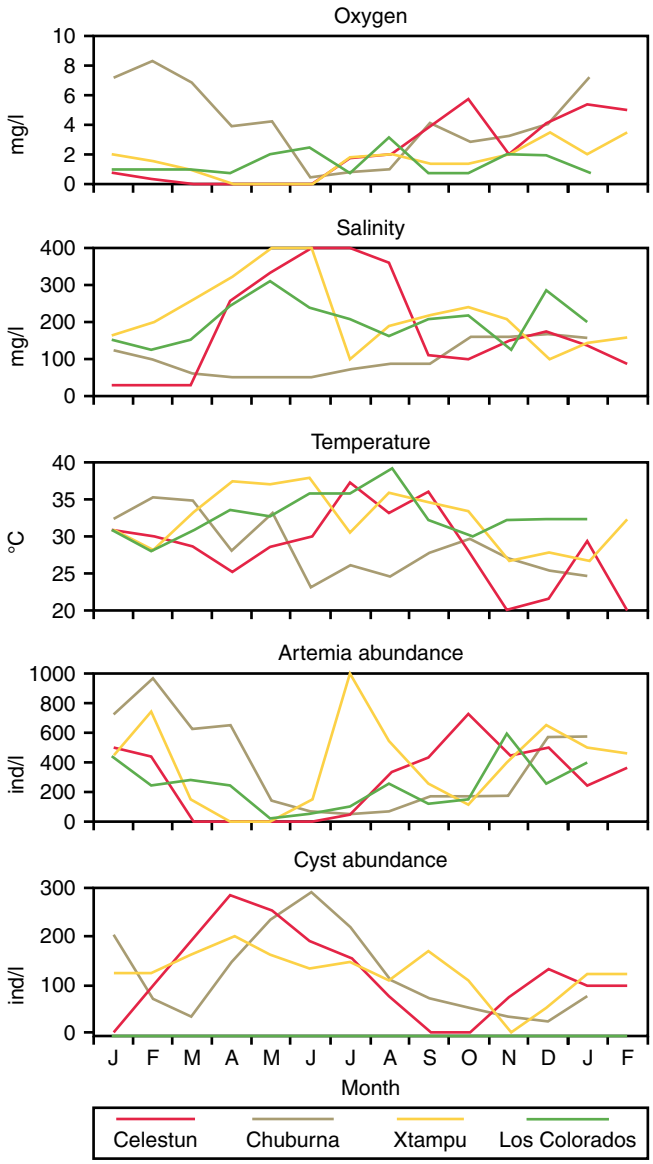

Fig. 9.25 Monthly variations in dissolved oxygen, salinity, temperature, and relative abundance of Artemia individuals and cysts in the Yucatan hypersaline habitats for Celestun, Chuburna, Xtampu and Las Coloradas mesosaline waters (After Torrentera et al. 2004)

with specific environmental conditions, most often water temperature, salinity, and oxygen concentration. Elevated temperature, salinity and low oxygen levels were consistently detrimental to levels of brine shrimp across all settings and encouraged cyst formation. The different schedules of *Artemia* numbers and cyst production at each location suggests hydrological and hence habitat partitioning among the brine shrimp populations (Torrentera and Dodson 2004). Interestingly, large flocks of flamingoes, along with other costal birds including herons and pelicans, inhabit all these saline waters and, along with *Artemia spp*., feed on the planktonic blooms.

Parthenogenetic variants of various *Artemia* species as well as bisexual forms, flourish in marine and continental saline waters worldwide (Triantaphyllidis et al. 1998). Brine shrimp are well adapted to the fluctuating oxygen and salinity levels that characterize mesohaline ecosystems. When conditions become too harsh then the adults respond by producing encysted eggs, which are often found in amongst the pellets in modern evaporitic sediments. Encysted *Artemia* eggs, with their natural cyst coat of glycerol and trehalose can hatch after 4 years of anoxic storage in a laboratory, something that the eggs of most arthropod species cannot achieve (Wharton 2002). Geddes (1975a, b, c) argued increased osmotic stress is the dominant limit on the upper salinity tolerance of adult Australian brine shrimp (*Parartemia zietzianis*) and this is probably also true for most, if not all, *Artemia sp*. in hypersaline waters (Geddes 1981). Halotolerant ostracodes and brine shrimp feed on plankton living in the upper water mass of density-stratified brine columns but can also ingest benthic mats wherever a less saline water mass intersects the lake margin or when bottom waters salinities are suitably lowered (De Deckker 1981; De Deckker and Geddes 1980).

Historically, based on studies in the Northern Hemisphere, centred on Great Salt Lake, brine shrimp have long been considered to be obligate planktonic filter feeders. Any grazing of benthic mats was assumed to take place by accident when the organisms' constant random swimming knocked pieces from the mats into the brine column where it was ingested. But observation of the feeding habits of austral brine shrimp, feeding on microbial scum in the subaqueous gypsum domes of Lake Inneston, South Australia (pers obs.) and on the benthic mats of Lake Haywood in Western Australia (Savage and Knott 1998), show brine shrimp are capable bottom feeders that choose to feed on benthic mats in shallow hypersaline lakes. They will alter their normal planktonic feeding pattern to do so. The animals roll over so their ventral surface faces the benthic mat and their phyllopods continue to beat although all forward motion has ceased. The phyllopods brush the mat, releasing diatoms and cyanobacterial cells, along with crystallites, which are then ingested by the shrimp (Savage and Knott 1998). Both ostracodes and brine shrimp can produce large amounts of pelleted carbonate detritus, which can be a common component of many ancient evaporitic laminites and source rocks (Finkelstein et al. 1999).

Halotolerant gastropods, another pellet producer, follow a benthic lifestyle that allows them to graze on halotolerant algae and plants. Modern examples, such as *Coxiellada sp*., flourish during short periods of freshening in saline environments and are quite common in saline lakes in central Australia and the schizohaline lakes of the Coorong region and the maar lakes in Victoria, Australia. These coxiellids withstand lake desiccation and high salinities (up to 124 ‰) by sealing its aperture with mucous along the edge of its

operculum (De Deckker 1982). Nevertheless, it cannot survive in lakes that remain dry for several years and requires a relatively high frequency of flooding to survive. Low beach ridges, composed almost exclusively of dead coxiellid tests, define the strandzones and berms of many Australian salt lakes. Isolated tests of immature coxiellid gastropods can be found in penesaline sediments well away from the freshened lake margin (e.g., in the somewhat deeper water lacustrine clays of Lake Eyre and some Coorong Lakes). They may have been deposited there as a result of juveniles of the species travelling and grazing upside down along the underside of water-air interface, held there by surface tension forces. As the feeding gastropods grow they become too heavy and lose contact with the air-brine interface. They sink through the salinity-layered water column, only to osmotically desiccate and die in the anoxic hypersaline bottom waters. Complete shells are incorporated in the bottom laminites to give some characteristic biometrics in a biocoenosis of these lacustrine sediments (mostly diminutive adults and very few juveniles).

Marine cerithid gastropods are also halotolerant and can survive in salinites of 80–90‰. The cerithid *Pirenella conica* is typical of these euryhaline snails and is found grazing biolaminites and sandy beaches in the intertidal zones of saline lagoons and sabkhas of the Middle East from Israel to the Emirates and the Red Sea (Taraschewski and Paperna 1981; Jones et al. 1978). These pelletising cerithids are what restricts the seaward extent of the cynaobacterial mats in the lagoons of the Abu Dhabi and Saudi sabkhat.

Some marine foraminifera are commonplace epibionts on marine seagrasses and so where seagrasses can live and survive, so can some species of foram. This is evidenced by the rich benthic foraminiferal biota living on seagrass banks in Shark Bay, Western Australia where mesohaline salinities ranging from 40 to 56‰ and occasionally up to 70‰, yet even at this level of salinity stress a few porcelaneous taxa still grow and survive (Davies 1970). The large benthic foram *Marginopera vertebralis* is one of the Shark Bay inhabitants; Pleistocene tests of this species, with elevated carbon and oxygen isotope values, have been interpreted as indictors of hypersaline waters along the semiarid southern Australian shelf during Pleistocene sea level lows (Rivers et al. 2009). One of the most impressive modern halotolerant forams is *Peneroplis planatus*. In Khor al Bazam, Abu Dhabi, it is epiphytic on seagrass in lagoon waters with a salinity of 42‰ and on seaweed growing in the same mesohaline lagoon in salinities ranging up to 70‰ (Murray 1970).

The ability of some marine foram species to survive across a range of salinities has led to some interesting death assemblages in continental lacustrine sediments of inland Australia. Viable marine foraminifera were documented in waters in a number of Australian salt lakes by Cann and De Deckker (1981). Some species can encyst and survive fluctuating salinities and periods of desiccation in both coastal and inland salt lakes, whereas others can only be found in permanent waters. Forams in continental settings generally prefer salinities and/or chemistries of lakes that approach that of seawater, optimum growth and the appearance of new generations typically occur at these thalassohaline values.

Two such species that flourish during short periods of flooding in the inland Australian salt lakes, such as Lake Eyre, are *Ammonia beccarii* and *Elphidium crispum. A. beccarii* requires water chemistries and salinities similar to seawater, i.e., with sodium and chloride as dominant ions. Although this species can survive a broad range of salinities (from 7 to 67‰), it grows and reproduces most successfully at salinities between 20 and 40‰ (Cann and De Deckker 1981; De Deckker 1982). Encysted forms of *A. beccarii* cannot survive summer droughts in modern coastal salinas and require permanent surface waters in order to persist. *E. crispum* is a marine foram species that thrives in ephemeral saline lakes of the Coorong without needing avian replenishment after a drought. It can survive summer evaporative episodes by encysting in numbers necessary for widespread re-establishment in the following winter freshening. The salinity range of this species is as yet unknown, although it is thought to survive at relatively high salinities (De Deckker 1982).

Encysted forms of both species are carried hundreds of kilometres inland on the feet and feathers of coastal sea birds, which flock every few years to newly flooded inland salt lakes, such as Lake Eyre, in order to nest and feed (a time of "feast" in mesohaline lake waters). If surface water salinities are suitable the forams bloom. Later, as salinities in these inland lakes increase once more, the foram population dies back and tests are deposited in a lacustrine sediment matrix (Ludbrook 1965). In the Dead Sea Rift, similar avian-transported A*mmonia beccarii tepida* fossils typify marl and sandstone beds in lacustrine evaporitic sediments, which have accumulated at times of freshening of upper lake waters across the past 2 million years (Almogi-Labin et al. 1995). Occurrences of *Ammonia beccarii* in mesohaline lacustrine sediments of the Pliocene Bouse Formation, southwest USA, are assigned a similar avian transport genesis (Spencer et al. 2013). Even more ancient counterparts, preserving evidence of this opportunistic lifestyle, could create a palaeontological dilemma.

Halotolerant protists, like the forams just discussed, lack a cell wall, can be planktonic or benthic and typically ingest algae and bacteria. Protists are unicellular eukaryotes that were once classified as single-celled animals under the general term protozoa, but as some are not animals this term is now obsolete. Protists are phylogenetically grouped in the Eukaryota at the same level (Kingdom) as animals, plants and fungi. Protists encompass groups such as the rotifers, forams, radiolaria and alga, the term is sometimes described as the

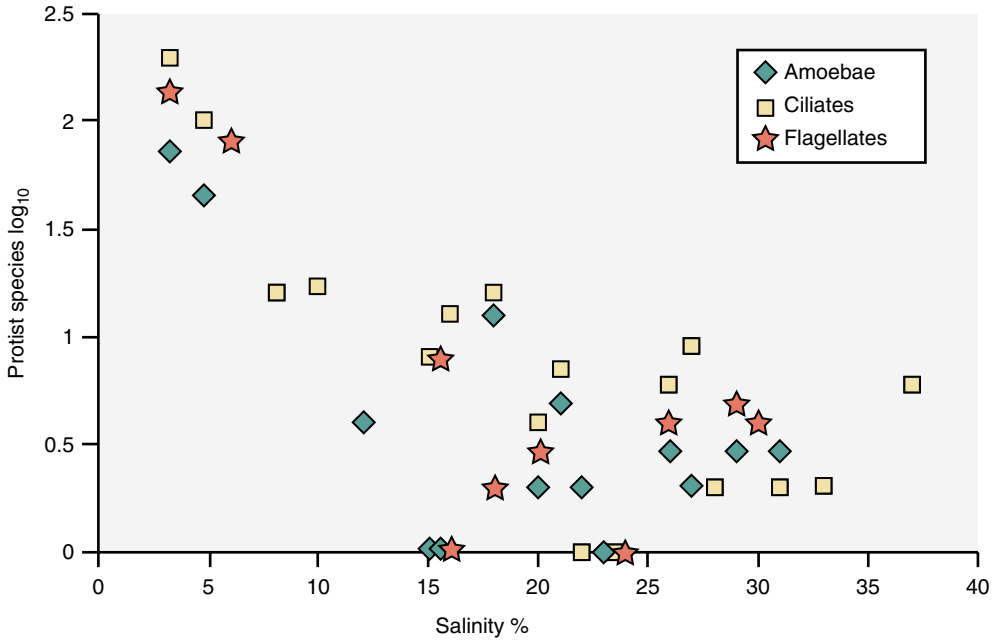

Fig. 9.26 Number of documented protist species in various saline settings across a range of salinities (After Hauer and Rogerson 2005)

polyphyletic "grab-bag for all eukaryotes that are not animals, plants or fungi" (Simpson and Roger 2004). Identified protist species living in hypersaline waters include the moderate halophile ciliate *Fabrea salina*, it has been collected from Hutt Lagoon in coastal West Australia, where it feeds on populations of *Dunaliella salina* (Fig. 9.19). In the coastal salinas of Sfax, Tunisia *Fabrea salina* is the main competitor heterotroph to the brine shrimp, *Artemia salina* (Elloumi et al. 2006). Another well-adapted protist is the extreme halophile *Porodon utahensis* from the Great Salt Lake, Utah (DasSarma and Arora 2001). Salt-tolerant rotifers (aka wheel animalcules) include species such as *Brachionus angularis* and *Keratella quadrata*. There is also a highly adapted set of protists inhabiting the halocline in the various deepsea brine lakes on the seafloor of the eastern Mediterranean (Edgcomb et al. 2009). Like the invertebrates and vertebrates, the number of viable generalist protist species decreases with increasing salinity and only more specialised species flourish at elevated salinities (Fig. 9.26; Hauer and Rogerson 2005).

Fungi, mostly yeasts (unicellular fungi), are another significant component of a saline salt lake biomass, like *Hortaea werneckii*, a black yeast that occurs in its highest numbers in waters at salinities indicating the onset of halite saturation and yet it can also live in fresh water and on us. In the latter case it causes a rare superficial and non-invasive skin infection *Tinea niger* with typical symptoms being non-scaly, smooth, black-brown painless spots, usually on the palm of the hands and the soles of the feet. It is a truly halotolerant species (Gunde-Cimerman et al. 2000; Gostincar et al. 2011).

Such fungi are chemoheterotrophic eukaryotes that grow best in aerobic saline conditions on carbohydrate substrates at moderate temperatures and in acidic to neutral pH brines. For example, a saprophytic hyphomycete (a minute fungi), *Cladosporium glycolicum*, was found in the Great Salt Lake Utah, growing on submerged wood panels at a salinity exceeding 260‰ it has also been isolated from brines in the Dead Sea. *Debaromyces hansenii* is another halotolerant yeast that when isolated from seawater can grow aerobically in salinities up to 250‰ and is capable of assimilating hydrocarbons, it has commercial significance as a biocontrol in the wine and chees industries, as do other salt-adapted fungi (Gunde-Cimerman et al. 2005, 2009; Gostincar et al. 2011). *H. werneckii* is polymorphic and is heavily melanised (black) with thick cell walls and it adapts its shape and lifestyle according to ambient salinity. At the highest salinities it exhibits an isodiametric type of thallus expansion, resulting in highly resistant meristematic cell clumps with endogenous conidiation (asexual spores). At lower salinities it grows as yeast cell clumps or as hyphae (filaments), depending on the substrate.

Extremophiles (Mostly Archaea)

The term extremophile is used to describe a group of organisms that from an anthropocentric viewpoint, "live in the borderlands of physiological possibilities" and utilises a number of specialised biochemical pathways (Table 9.5). This life group has evolved to flourish in extremes that can be defined in terms of temperature, salinity, acidity/alkalinity aridity, oxygen levels, pressure, radiation and various combination (Table 9.6; Seckbach 2005). We shall focus our attention on extremophiles that are well adapted to evaporitic environments (Fig. 9.27).

Table 9.5 Examples of the biochemical metabolic pathways utilised by archaea

Biochemical pathway reaction	Biochemical pathway reaction
Hydrogen oxidation	$2H_2 + O_2 \rightarrow 2H_2O$
Sulphur reduction	$H_2 + S^0 \rightarrow H_2S$
Sulphide oxidation	$4H_2S + 2O_2 \rightarrow 4H_2SO_4$
Sulphur oxidation	$2S^0 + 3O_2 + 2H_2O \rightarrow 2H_2SO_4$
Nitrate reduction	$H_2 + NO_3 \rightarrow NO_2 + H_2O$
Iron reduction	$H_2 + 2Fe^{3+} \rightarrow 2Fe^{2+} + 2H^+$
Methanogenesis (autotrophic)	$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$
Methanogenesis (heterotrophic)	$4CH_3OH \rightarrow 3CH_4 + CO_2 + H_2O$
Methanogenesis ("acetoclastic," heterotrophic)	$4CH_2COO^- + H_2O \rightarrow 3CH_4 + HCO_3^-$
Aerobic respiration	Organic compound $+ O_2 \rightarrow 2H_2O + CO_2$

Table 9.6 Extremophile characteristics

Environmental parameter	Type	Location and conditions	Examples
Salinity	Halophiles	Salt lakes, sabkhas and salterns (neutral and alkaline pH) up to and including halite saturation. Adaptation to cope with extreme osmotic pressure (salt in/out and glycerol)	Cyanobacteria, brine shrimp, diatoms, flagellates, *Dunaliella*, *Halobacteriaceae* (see text for detailed discussion)
pH	Acidophile	pH >5 and as low as 0–1 in some hydrothermal springs	*Acidithiobacillus sp*., *Picrophilus oshimae*, *Cyanidium caldarium*, *Dunaliella acidophila*, some fungi – *Trichosporon cerebriae*
	Alkaliphile	pH >9 in some African rift lakes	*Natronobacterium*, *Natrialba sp*., *Bacillus alcalophilus*, *Halomonas sp*., *Chromohalobacter sp*., *Arthrospira sp*.,
Temperature	Psychrophiles	−20 °C to >15 °C	*Psychrobacter*, *Polaromonas*, cyanobacteria, sea-ice diatoms and icy green algae, some insects.
	Thermophiles	45–80 °C	*Alicyclobacillus sp*.
	Hyperthermophiles	80–114 °C	*Aquifex*, *Thermotoga Cyanidium caldarium*, *Sulpholobus*, *Methanothermus*, *Pyrolobus fumarii* (alive at 114 °C) *Methanopyrus kandleri* (alive at 122 °C), prokaryotes such as *Mastigocladus*,
Hydrostatic pressure	Barophiles Piezophiles	Weight lovers Pressure lovers	Prokaryotic strain MT41 can tolerate pressures of more than 100 MPa
Radiation	Ultraviolet and ionizing	High level of radiation	Cyanobacteria, desert plants, archaeon *Thermococcus gammatolerans* and bacterium *Deinococcus radiodurans*
Thriving in organic solvents and under various atmospheres	CO_2 gas	Thriving in pure gas	*Cyanodiaceae* (grown in pure CO_2)
	Organic toxic solutions	Solutions with damaging agents	
Gravity	Hypergravity	>1 earth gravity	Such microorganisms not known on Earth (may be a significant factor in extraterrestrial environments)
	Hypogravity	<1 earth gravity	
Desiccation	Xerophiles	Anhydrobiotic conditions, low water activity	Prokaryotes, extreme halophiles on endoliths, fungi and lichens. Anhydrobiotic states in bacteria, yeast, fungi, plants, and animals such as nematodes and brine shrimp

After Seckbach 2005

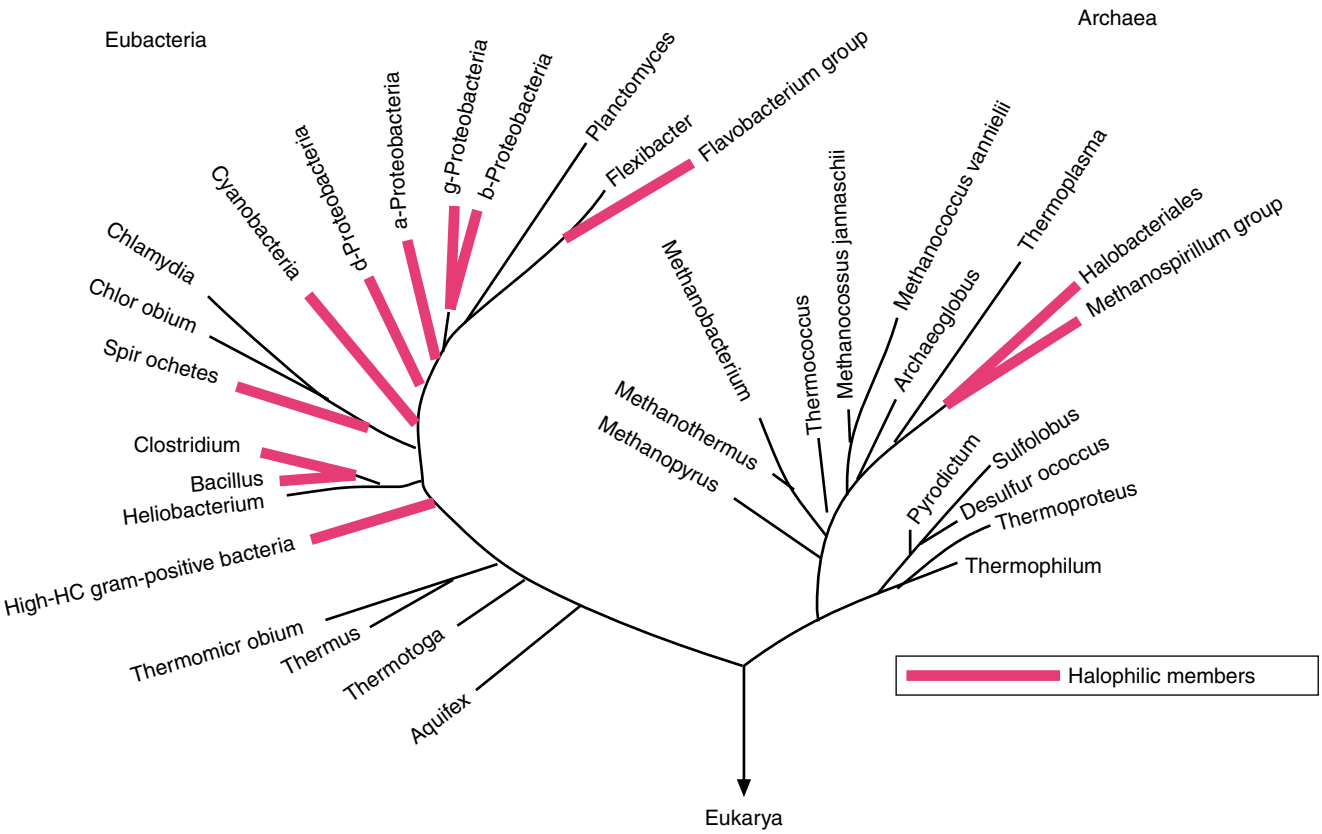

Fig. 9.27 Phylogenetic tree of the Bacteria and the Archaea, based on 16S rRNA sequencing comparisons, Bold lines indicate branches containing representatives able to grow at or near optimal rates at NaCl concentrations exceeding 15 % (After Ventosa et al. 1998)

As surface water salinities rise above 200–240‰, rates of oxygenic photosynthesis in algae and cyanobacteria slow and ultimately cease. Halophilic bacteria and archaea come to dominate, many as decomposers and fermenters (Fig. 9.17). Of the halophilic bacteria, two groups are well represented in elevated salinity ranges; the fermentative bacteria belonging to the family Haloanaerobiaceae and the halophilic members of the autotrophic sulphur-oxidizing bacteria of the family Ectothiorodhospiraceae. Both families were discussed earlier in this chapter. As the name suggests, the group loosely called halobacteria[12] flourish in supersaline waters, most halobacteria are not bacteria but archaea, which constitute the family Halobacteriacea. In taxonomy, the Halobacteriaceae are a family of the Halobacteriales in the domain Archaea.

One species of halophilic bacteria is worthy of special mention is *Salinibacter ruber* as, unlike most other Bacteria, it can flourish in the range of extreme salinities that until recently were considered to be the exclusive province of the Archaea. It constitutes a new genus and species, first isolated from brines found in saltern crystallizer ponds in Alicante and Mallorca, Spain (Oren 2002). *Salinibacter* is a motile rod, pigmented red (probably by a carotenoid) with an absorption maximum at 482 nm and a shoulder at 506–510 nm. Because of the red pigmentation, colonies of this bacteria in superhaline waters have probably been overlooked in the past. Historically, red colonies growing at salinities in excess of 250 g/1 have been widely considered to be archaeal. But this bacterial organism is no less halophilic than the archaeal halophiles: no growth was obtained below 100 g/1 NaCl, and for optimal growth concentrations between 150 and 230 g/1 are required. The physiological properties of *Salinibacter* are unusual for most bacteria: the organism apparently uses KCl to provide osmotic balance, while lacking high concentrations of organic osmotic solutes. Thus, its physiology resembles that of the halophilic Archaea more than that of other aerobes within the domain

[12]The term halobacteria (as opposed to the family *Halobacteriacea*, which exclusively encompasses the halophilic archaea) is a terminological carry-over from the old two-part morphology-based classification of life (see earlier discussion of Woese and his influence on microbial nomenclature and classification). When trying to make sense of the taxomic complexities that typify the microbial realms one should always remember that in contrast to eukaryotic nomenclature, there is no such thing as an official classification of prokaryotes. It remains a matter of scientific judgment and general agreement. The closest approximation to an "official" classification of prokaryotes would be one that is widely accepted by the community of microbiologists. The debate continues.

Table 9.7 Metabolic associations of some of the main halophilic archaeal genera

Metabolic process	Energy source	Carbon source	e- donor	e- acceptor	Conditions	Occurrence	Cultured representatives
Aerobic respiration	Organic matter (sugars, amino acids, glycerol…)	Organic matter	Organic matter	O_2	Moderate to extreme salinities (from 7 to 370 ‰)	Salt lakes	Haloarcula, Haloferax, Halorubrum, Natrinema
Anaerobic respiration		Organic matter		Nitrate, DMSO, organic acids	High pH	Soda lakes	Halobacterium, Haloarcula, Haloferax
Fermentation	Sugars, amino acids	Organic matter		Organic matter	Oxic, anoxic	Hypersaline Antarctic lakes	Halobacterium
Nonphotosynthetic photo heterorophy	Light	Organic matter	Organic matter	–		Solar salterns	Halobacterium

After Likens 2010

Bacteria. It tends to fluorish in lakes with elevated salinities and is a co-inhabitant with halophilic archea in many modern salt lakes (Boutaiba et al. 2011).

We shall now concentrate on salinity ranges of halophilic archaea known as haloarchaea. Haloarchaea require salinities in excess of 100‰ to live, and most achieve optimal growth at higher salinities, typically in the range 200–250‰. Haloarchea can survive in salinities approaching halite saturation (350–370‰). All known extremely halophilic archaea stain gram negative, do not form resting stages or spores and reproduce by binary fission or budding (Table 9.7). Cell diameters range from 0.1 to 15 μm and the length of a filament can be up to 200 μm (Oren 2002) They are morphologically diverse and cell shapes include spheres, spiral, rods, lobed, plate-shaped, irregular-shaped or pleomorphic variations. One of the more unusually-shaped Haloarchaea is the "Square Haloarchaeon of Walsby" or *Haloquadratum walsbyi*, which is square and thin in shape, giving it a morphology much like a postage stamp. Haloarchea may exist as single cells, as aggregates, or form filaments. Most Haloarchaea are considered pleomorphic, able to take on a range of shapes-even within a single species, they can extrude biofilms and can exchange their DNA at the genera level. This set of characteristics makes identification by any microscopic means difficult, so gene-sequencing techniques are used for species identification.

As of 2014, the family Halobacteriaceae currently possesses about 40 recognised genera and 144 species, with new genera and species being added every year (http://www.bacterio.net). Main taxonomic criteria for the identification and recognition are the sequence of the 16S rRNA genes and the composition of their characteristic membrane polar lipids, which are unique to the group and are composed of ether-linked phosphoglycerides (Fendrihan et al. 2006; Stan-Lotter 2011). Some of the more currently accepted haloarchaeal genera are as follows: *Haloarcula* (10 species); *Halobacterium* (*16 species*); *Halobaculum* (2 species); *Halococcus* (8 species); *Haloferax* (11 species); *Halorubrum* (25 species), *Haloterrigena* (9 species); *Natrialba* (6 species); *Natronobacterium* (6 species); *Natronococcus* (4 species); *Natronomonas* (2 species).

Cosmopolitan haloarchaea genera are *Halobacterium*, *Haloferax*, and *Halococcus* (Table 9.7). Haloarchaeans tend to prefer somewhat acidic to near neutral pH brines and so are commonplace in marine-fed brines, seeps, sea-bottom brine lakes and continental salt lakes. Some Archaea flourish in caprock brines, along with the sulphate-reducing bacteria and are also resident in sulphuric acid caves. *Halococcus sp*. are strict aerobes, their name reflects their coccoid cell shapes; they form pairs, tetrads, sarcinae or irregular clusters. Cells produce several orange or red carotenoid and retinal pigments needed to better cope with high levels of ultraviolet light that characterise supersaline brine sheets in arid settings. *Haloferax* prefers high Mg waters and is a major constituent in the halophilic biota of the Dead Sea. The pleomorphic *Haloarcula* typically grows with square and triangular shapes, with straight edges, sharp corners, and is very flat. In its square form it has a shape that is very similar in appearance to the interstices and brine vacuoles in a mass of halite crystallites.

Interestingly, highly saline microbial communities are dominated by extremely halophilic archaeal cells with square-shaped morphologies, they are likely pleomorphic genera and account for up to 75 % of total prokaryotes beyond 350 g/l (Likens 2010). Densities in these brines can be as high as 10^8 haloarchaeal cells per ml. These highly angular shapes are unusual for a lifeform and only possible because internal salt concentrations are as high as they are outside the cell (see cellular adaptations). It mean there is little or no net osmotic pressure on the cell wall, allowing it to adapt such high surface-area shapes. Similar shapes are not possible for organisms with 'normal' ionic strengths in the cell interior. Their cell shapes show surfaces and outlines that are indicative of "minimization of surface energy," whereby curved edges and spheroid outlines dominate.

Of the recognized genera of haloarchaea, two have representatives that live only in high pH soda lakes, such as Wadi Natrun and Lake Magadi, they are; *Natronobacterium* and *Natronococcu*s. They grow in highly alkaline trona-rich brines (pH 9–11) with very low levels of Mg (<0.024 g/l) and show optimal growth around 200‰. This group of Archaea is not found in marine-fed salterns or less alkaline continental systems (Grant et al. 1999). How *Natronobacterium* and *Natronococcu*s, and also the alkaliphile bacterium *Bacillus alcalophilus*, survive in soda lakes with these extreme chemistries is a problem not yet well understood (or at least it is a problem for us, trying to understand how they get can away with it). At such elevated pH levels any protons (H^+) pumped to the outside of a cell by electron transport or rhodopsin membranes, are sucked up by the hydroxyl ions and gone forever. Even though the resulting electric potential is still there, it can't be harvested by an ATPase-based metabolism, unless it can recycle protons from outside the cell (see next section).

How alkaliphiles get around this problem is not known, and it is probably the issue that limits the upper pH range of life. Proposed and partially documented high-pH coping mechanisms in alkaliphiles include; (i) buffering cell cytoplasm using polyamines rich in amino acids with positively charged side groups (lysine, arginine, and histidine), (ii) introducing acidic compounds to protect the cell from the alkaline environment (e.g., teichoic acid, acidic amino acids, and uronic acids), (iii) Na^+-ion channels actively driving the transfer of protons into the cell, (iv) synthesis of specific enzymes resistant to high pH.

Methanogenic archaea, as the name implies, produce methane as a byproduct of their autotrophic metabolism. Methanogens are all Archaea and constitute the strictest anaerobic grouping known. In saline settings, most methanogens do best in anoxic waters with salinities less than 150‰. No other group of living things breathe methane and so their metabolic enzymes are unique (as are the related biomarkers). Several, mostly moderate halophilic, methanogens have been identified in saline ecosystems and include *Methanohalophilus halophilus* from a microbial mat in Shark Bay, *M. mahii* fromsediments of the Great Salt Lake, and *M. portucalensis* from a coastal saltwork sediments in Portugal (Horikoshi et al. 2011). The slight halophile *Methanosalsus zhilinac* is also an alkaliphile and a slight thermophile. The extremely halophilic methanogen, *Methanohalobium evestigatum* comes from a salt lake in the Crimea; it has an NaCl optimum of 260‰ and is also a thermophile with a temperature optimum of 50 °C. Worldwide these and other methanogens form the base level in chemosynthetic foodchains in salt lakes and are common contributors to the chemosynthetic biota of deep-sea brine pools atop salt allochthons in the Gulf of Mexico (Fig. 9.58).

Methanogenesis oxidizes hydrogen using metabolic mechanisms that are not sufficiently efficient to rip out all the hydrogen from the carbon chains. As a biochemical process it occupies a terminal position in the degradation of carbohydrates in the reaction cycle of hypersaline ecosystems. Methanogenic Archaea in hypersaline environments utilise noncompetitive organic substrates such as methanol, methylated amines, and dimethyl sulphide, which originated largely from the breakdown of osmoregulator amines (osmolytes). Methanogens do not utilise carbon dioxide, acetate and hydrogen, which are the substrate for the sulphate-reducing bacteria living nearby. The reason for this metabolic restraint is the greater effectiveness of sulphate-reducing bacteria, which are out-competing methanogens for hydrogen and acetate (i.e., methanogens eat the leftovers).

Cellular Adaptations to Hypersalinity

Halotolerant and halophilic species have developed special biochemical mechanisms to cope with the tendency for cells to desiccate in the high osmotic pressures of mesohaline and hypersaline waters namely; slime, osmolytes, halo-adapted membranes and specialized proteins. Halotolerant cyanobacteria constitute a significant component of the upper layers in microbial (algal) mats in modern sabkhas and shallow brine lakes where they are subject to both periodic desiccation and hypersalinity. Such microbial mats show a worldwide recurrence of a few well-adapted cosmopolitan cyanobacterial species in the upper stories of a microbial mat; *Microcoleus chthonoplastes*, *Lyngbya sp*., *Entophysalis sp*., and *Synecococcus sp*. All are slimy; they are embedded in matrices of extracellular polymeric mucous that stores large amounts of water. It protects the cell from osmotic stress and acts as a buffer against extreme temperatures and ultraviolet rays (Gerdes et al. 2000a).

Other halotolerants and all halophiles adapt to osmotic stress at the intracellular level. *Dunaliella parva*, a halotolerant unicellular green alga that flourishes in mesohaline waters (optimum = 120‰, survival 20–340‰), distributes glycerol throughout its cytoplasm to increase the total solute concentration in the cell and so better cope with the high osmotic pressure induced by its high salinity surrounds. Glycerol is an osmotically active substance (osmolyte) that takes up space in the cellular fluids. It lowers the relative water content of the cell and so raises the internal osmotic pressure. Cytoplasmic concentration of glycerol in *Dunaliella parva* can reach 7 mol/l and can constitute over 50 % of the dry weight of cells growing in salinities ≈280‰. *Dunaliella* is the main primary producer in the Dead Sea brines and produces isotopically heavy ^{13}C products. The consumption of this isotopically heavy glycerol by Halobacteriales (main heterotroph in Dead Sea) in turn leads to ^{13}C enrichment of

their biomass (Grice et al. 1998). Glycerol is used as an osmolyte in other halotolerant and halophilic algae, as well as by yeasts, fungi and brine shrimp. Halotolerant and halophilic prokaryotes also use a variety of other sugars, sugar alcohols, amino acids and compounds derived from them (such as glycine betaine and ectoine) as osmolytes, leading to characteristic biomarker assemblages in ancient saline sediments (Turich and Freeman 2011).

Halophilic archaea have two main intracellular defence mechanisms to cope with the extreme osmotic gradients induced by hypersaline to supersaline conditions. One is a modification of the plasma (cell) membrane; the other is an adaptation of the protein structure itself. Unlike most life, the plasma membrane of halophilic archaea is dominated by rhodopsins and the cell membrane does not actively exclude salts, so the overall internal salt concentration in haloarchaeal cytoplasm is high. But the cell membrane is selective, it tends to exclude sodium, while actively pumping potassium into the cell against a thousand-fold concentration gradient. The total ionic strength remains the same on both sides of the plasma membrane, but the ratios of specific ions differ inside and outside the cell wall. Potassium is the dominant cation within the cell. Many cell functions require potassium, but would be disrupted by high levels of sodium. Cells of halophilic archaea can contain up to 4 mol/l of potassium chloride, which is eight times its concentration in seawater. Anaerobic fermentative halophilic bacteria of the order Haloanaerobiales use a similar "high potassium in the cell" strategy.

Rhodopsins (bacteriorhodopsins) constitute much of the protein in the purple patches in the cell membranes of photo-active haloarchaea. Patches contain 25 % lipids and 75 % protein, all of which is bacteriorhodopsin (Fig. 9.28a). Bacteriorhodopsin structure is arranged in groups of 3 protein molecules surrounded by a lipid with a few more lipids in the centre of the molecular cluster. These light-sensitive purple pigments convert light energy into chemical energy (proton pump) and so power the cell's ion pump (Fig. 9.28b). Thus, the purple membrane is a site of photosynthesis, but not the chlorophyll-based photosynthesis of cyanobacteria and eukaryotes. Purple membranes obtain energy from light but, unlike chlorophyll, do not use light to generate reducing power and cannot fix CO_2. Haloarchaea with purple membranes are still mostly heterotrophic but can function as facultative autotrophs in low oxygen conditions where they supplement their metabolic power with photosynthesis via the purple membrane patches. Almost all of this extra energy is used to pump potassium across the cell membrane and so maintain the cellular ionic balance (Fig. 9.28b).

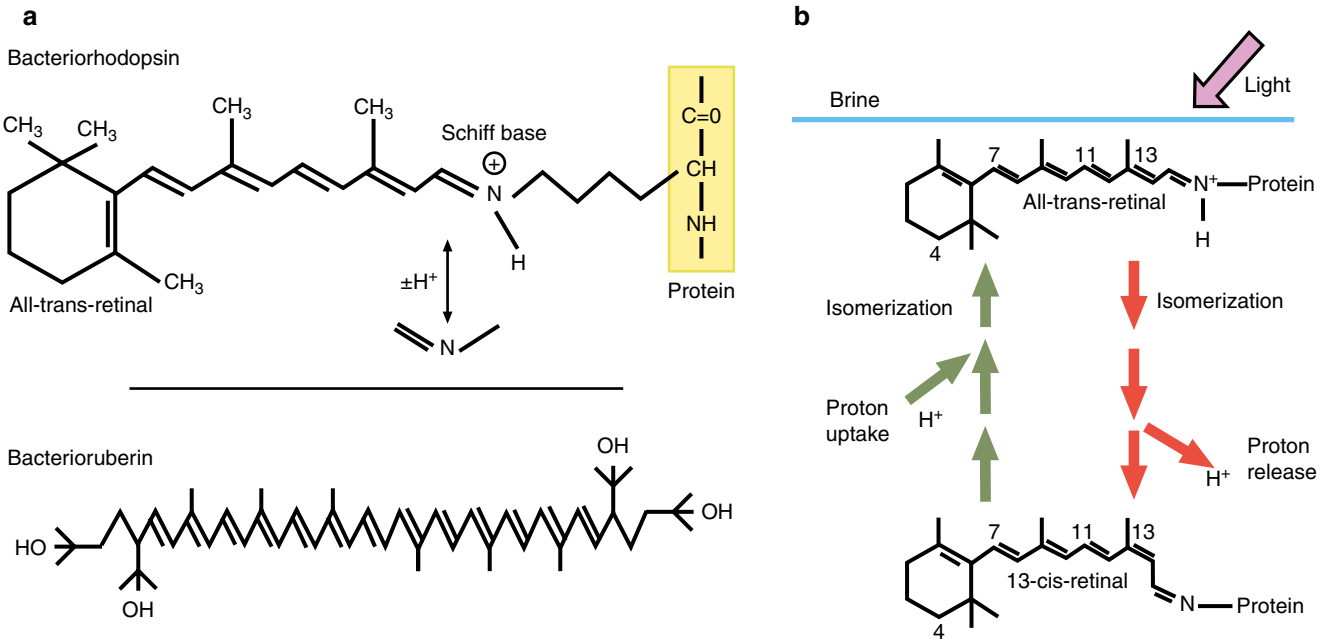

Fig. 9.28 Fischer projections of bacteriorhodopsin, bacterioruberin and the proton pump (MW = approximately 25,000), (**a**) Molecular structure emphasising retinal. Overall, bacteriorhodopsin is a protein that has 7 alpha-helical segments each spanning the halobacterial cell membrane. It contains one molecule of retinal per protein molecule which is bound via a Schiff base to the side chain -NH_2 group of a lysine residue. The Schiff base lysine is located 40 amino acids from the N-terminus and is near the outside of the membrane in the second helical segment. Interaction of retinal with the protein causes a large red shift, and hence light absorption is at 560–570 nm. The pigment looks purple when bound to the protein. Also shown is the structure of bacterioruberin. (**b**) Photon pumping; light rapidly changes the "straight" all-trans form of retinal in bacteriorhodopsin into the "bent" 13-cis form of retinal, with a concomitant release of a proton outside the cell membrane. The 13-cis form spontaneously returns to the all-trans form in a light-independent reaction, with the concomitant uptake of a proton from within the cell

As an example of the adaptive chemistry of this halophilic lifestyle, consider the archaea *Halobacterium halobium*. Its cell carries a combination of orange-red carotenoids: mostly β-carotene (C-40) and bacterioruberins (C-50). It is an aerobe facultative anaerobe. When oxygen levels fall, as often happens in hypersaline water bodies, but light still penetrates the brine, anaerobic photophosphorylation takes place in the cell membrane in the absence of chlorophylls and redox carriers. Waters and sediments where *H. halobium* flourishes then take on a blue or purple tint, as in the Dead Sea. In the past, prior to gene sequencing studies, bacteriorhodopsin's characteristic purple colour led to many haloarchaea in their photoactive stage being described as a separate species of purple bacteria. In the same brines but with higher oxygen levels, the main cellular metabolism of *H. halobium* is heterotrophic, not photoautotrophic. Cells in the heterotrophic mode are mostly coloured by carotenoids and now waters where it is thriving appear red, not blue-purple. This is its more normal respiratory metabolic mode in hypersaline waters, where it depends on b and c cytochromes as well as cytochrome oxidase to create ATP via the breakdown of glycerol and the other cellular contents from the now dead algae (especially *Dunaliella*) and cyanobacteria. This cytochrome-mediated pathway is not a particularly effective metabolic pathway for decomposers living at lower salinities. But in hypersaline waters these more efficient metabolic pathways cannot function. So, these highly salt-adapted halophilic cells can respire and produce ATP using their red membranes (carotenoids), under little or no stress from any other competing life forms, even if brines maintain relatively high levels of oxygen. The adaptive chemistry of *H. halobium* means it acts as a decomposer in oxygenated water, and as an anaerobic phototroph in dysaerobic to anoxic, but lit, hypersaline waters. There it can survive, although at lower metabolic rates, by using its purple membrane patches (bacteriorhodopsin) to pump protons across the cell membrane (Oesterhelt and Marwan 1993; Kates et al. 1993). Interestingly, the same species can colour the waters it inhabits either red or purple in response to changing oxygen levels.

Bacteriorhodopsin in the purple membrane of haloarchaea is best described as a two-dimensional oriented crystal containing the pigment molecule retinal. When bacteriorhodopsin captures a photon with its retinal "antenna" this induces isomerization of the retinal, which then becomes detached from the protein, triggering conformational changes in the protein itself (Fig. 9.23b). This eventually leads to a bleaching and the pumping of a photon across the cell membrane. Bacteriorhodopsin has an orderly orientation or "sidedness" in the plasma membrane, such that when it releases hydrogen/Na^+ ions in an illumination and bleaching cycle, the hydrogen ions are expelled only at the outer side of the membrane (ion pump). Conversely when bacteriorhodopsin regains its colour the necessary hydrogen can only approach from the inside of the membrane. Thus a cycle of bleaching and recovery sets up a hydrogen ion pump, which in turns sets up an energy gradient that drives ATP synthesis.

What is so impressive about bacteriorhodopsin is its extreme durability and stability. It survives intact at temperatures up to 140 °C and can reliably run through a photocycle more than 10 million times. There are a large number of intermediates in the bacteriorhodopsin reaction cycle, each of which can be addressed by light of a specific wavelength. This has led many to proclaim its potential in the development of biomolecular computers and biological solar cells. Synthetic bacteriorhodopsin is a working biostable optical switch, it can be fabricated in a monolayer by self-assembly and reliably store data with 10,000 molecules per bit. In the early 1970s it was extensively studied in the former Soviet Union as a way to counteract the West's dominance in semiconductors, some of this research is still classified as a state secret in Russia today.

Some halophilic archaeal strains, including *Halobacterium salinarium*, contain another rhodopsin pigment in their purple membrane called halorhodopsin. It acts as a Cl- pump, once again generating energy in highly saline conditions. It is usually present in the cell membrane in much smaller amounts than bacteriorhodopsin, but contains the same retinal pigment. It too absorbs light, which it converts to an ion gradient. However instead of pumping protons out, like bacteriorhodopsin, it pumps chloride ions inwards, which helps maintain osmotic balance in highly saline conditions. Since chloride ions have a negative charge, moving chloride inwards is equivalent in terms of energy to moving a proton outwards. Thus halorhodopsin generates a chloride ion gradient, which also supplies energy to the cell.

All this membrane adaptation merely shifts the osmotic balance problem from the cellular to the molecular level. Ions within the cell's cytoplasm still compete with proteins and other biomolecules for that universal solvent, water. In order to cope with high osmotic stress at the molecular level, halophilic archaeal proteins have evolved to maintain a high negative charge on the protein surface. This attracts water molecules and envelops the protein in a protective shroud of bound water.

For example, in the Dead Sea halophilic archaea (*Haloarcula marismortui*) the proteins of its metabolic enzyme (malate dehydrogenase) and its electron transfer protein (ferredoxin) are both wrapped in coats of acidic amino-acid sidechains, both of which carry a negative charge in neutral media. This predominance of charged amino acids on the surface of enzymes and ribosomes stabilizes the hydration shell of various cytoplasm molecules in high salinity intracellular surroundings, even when the extracellular brines are well into the halite saturation field. High-density surface charge binds water molecules to the

protein surface much more effectively than any mesophile protein. Hence, *Haloarcula* proteins do not dehydrate or unfold (denature) even when exposed to extremely high salinities. But, high levels of shielding cations (mostly potassium) are lost via osmosis in low salinity environments and an excess of negatively charged ions then destabilizes the molecular structure by ionic repulsion and the proteins lyse or disintergrate. Any species using a "salt in cytoplasm" strategy has an innate restriction to highly saline environments (obligate halophiles). Ironically, the intracellular acids that unfold normal proteins, counteract this tendency in the halophiles.

In summary, bioadaptations at the cellular level to highly saline conditions can be divided into two groups of responses (Oren 2001):

(a) **The "high-salt-in" option**. Accumulation of salts in the cytoplasm at concentrations equal to or higher than those of the outside medium. Generally, KCl is used as the main intracellular salt. Aerobic halophilic archaea (family *Halobacteriaceae*) utilise this strategy, as do fermenting bacteria, bacterial acetogenic anaerobes (*Haloanaerobium*, *Halobacteroides*, *Sporohalobacter*, *Acetohalobium*), and some sulphate reducers. This strategy is relatively inexpensive energetically, but requires far-reaching adaptations by the intracellular enzymatic machinery to the presence of high salt concentrations. Cells utilising this strategy show limited adaptability to changing salt concentrations (obligate halophiles) and have achieved success only after a long and complex evolutionary history.

(b) **The "low-salt-in" option**. Exclusion of salts from the cytoplasm and the accumulation of organic osmotic 'compatible' solutes (osmolytes) to provide osmotic balance. This strategy is used by halophilic and halotolerant eukaryal microorganisms, by most salt-requiring and salt tolerant bacteria, and also by halophilic methanogenic archaea. This strategy is energetically expensive; the energetic cost depends on the type of organic solute synthesized. No major modification of the intracellular machinery is needed in comparison to non-halophiles, and in most cases cells can rapidly adapt to changes in salinity, as exemplified by *Dunaliella salina*.

As Oren (2001) clearly illustrates, organisms living in increasingly high salinity environments have to devote increasing large proportions of their bioenergetic budgets to osmoregulation, either to synthesize organic solutes or to activate and maintain ionic pumps. This creates a natural salinity-related control over various metabolic pathways, their energy efficiencies and hence their biomarker distributions in the resulting sediments. The following metabolic styles function best at high salinities (Fig. 9.29):

1. Those processes that use light as an energy source (and are generally not energy-limited).
2. Heterotrophs (bacteria as well as archaea) that perform aerobic respiration, denitrification, and other dissimilatory processes that yield large amounts of ATP.
3. All types of metabolism performed by organisms that use the 'high-salt-in' strategy, even if the efficiency and amount of ATP obtained in their dissimilatory metabolism is low.

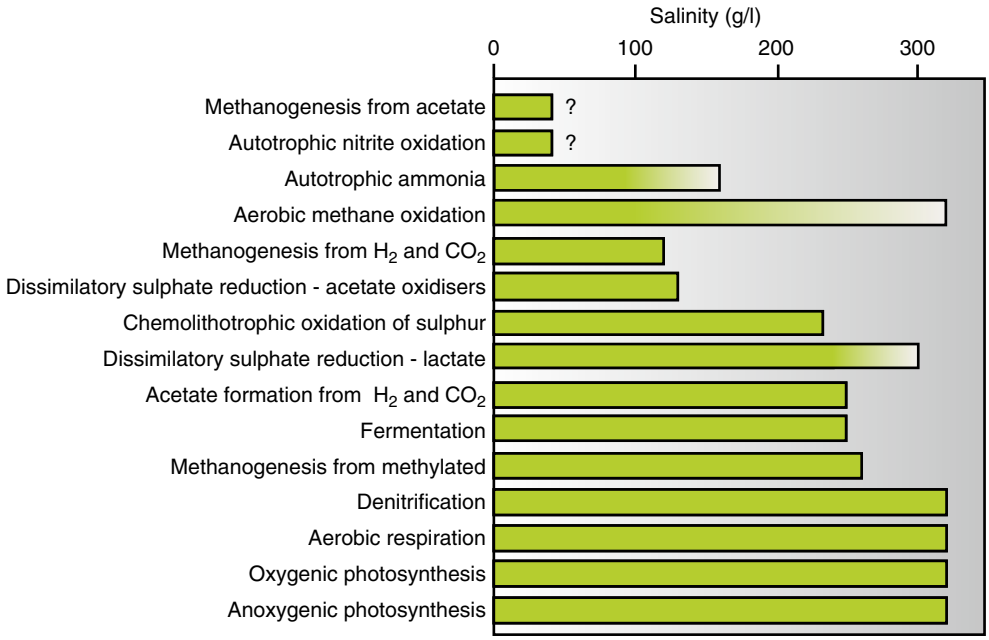

Fig. 9.29 Approximate upper salinity limits of selected microbial metabolic pathways (After Oren 2001 and references therein). Values presented are based on laboratory studies of pure cultures (*green bars*) and on activity measurements of natural communities in hypersaline environments (*white bar ends*)

Growth of phototrophic microorganisms in hypersaline surface waters is generally limited by the availability of inorganic nutrients and not by lack of light energy (Oren 2001). Accordingly, both oxygenic (*Dunaliella sp*., cyanobacteria) and anoxygenic phototrophs (*Halorhodospira*, *Thiohalocapsa*, *Halochromatium*), all produce organic solutes for osmotic stabilization. They may be found up to very high salt concentrations and in several cases can survive well into the halite saturation field. However, in the case of chemolithotrophs and anaerobic heterotrophs the amount of energy generated in the course of their dissimilatory metabolism is often insufficient to supply the demands of cell growth, osmotic adaptation, and life maintenance. Longterm growth and survival in hypersaline environments is not possible in such species. The 'high-salt-in' strategy is preferable for strongly energy-limited organisms (haloarchaea and fermentative halophilic bacteria) as it is energetically much less costly than the production of organic osmotic solutes. Clearly, salinity controls the various metabolic styles at the cellular level (Fig. 9.29; Oren 2001). Biomarker distributions indicative of the various metabolic pathways will likewise become salinity-related indicators in the rock record.

Life in a Layered Microbial Mat?

The laminated sediments (biolaminites or microbiolites) that typify many evaporitic carbonates and described by sedimentologists using the general, and perhaps somewhat dated, terms algal mats and cryptalgalaminites are in effect microbial "high rises," as are many living stromatolites (Chap. 1). They, and their entrained biomarkers, indicate the activities of an ecologically and phototopically layered microbial community (Ionescu et al. 2007). As a mat surface accretes, its organic constituents are buried. The biochemical make-up of the initial halobiota, which flourished in the hypersaline conditions at or above the mat surface, is altered by the metabolic activities of various decomposers flourishing below.

In order to investigate early or syndepositional changes in the dominant organic constituents and the main diagenetic processes, Grimalt et al. (1992) studied organic profiles in cross sections through two different cyanobacterial mats in a modern marine-fed salina in southern Europe. Changes in lipid composition were compared to the vertical distributions of the various microbial populations. Vertical distributions in the lipid patterns were defined using enrichment cultures from typical species of cyanobacteria, diatoms, purple bacteria, sulphatereducers and methanogens obtained from the layered mats.

Cyanobacteria *Phormidium valderianum* and *Microcoleus chthonoplastes* were the dominant primary producers in the sampled mats, they occurred almost as monocultures in the upper 6 mm of the mats (Fig. 9.30a). Worldwide, these and other cosmopolitan filamentous cyanobacterial photosynthesizers are the most obvious organisms in most mesohaline algal mats and surficial gypsum crusts (Canfield et al. 2004). Their chlorophyll creates a green layer a few mm thick beneath a sticky or slimy mucosal surface. As layers of these mucilaginous sheathed cyanobacteria aggrade via periodic growth spurts, it creates biolamination and the mineralised counterparts constitutes the layered and clotted textures seen in modern and ancient microbial structures, such as stromatolotites and bacteriogenic mud mounds (Chap. 1).

Below the cyanobacteria is a layer of aerobic to dysaerobic heterotorphs (bacteria and archaea), which in the presence of oxygen break down the organic materials produced by the living cyanobacteria (mostly abandoned algal sheaths and slime; Figs. 9.30 and 9.31). But because oxygen is only produced by photosynthesis, these organisms can only perform this process during daylight. The next layer below is dominated by chemolithotrophic sulphur bacteria, these are lifeforms that use the redox energy contained in the biochemical gradient between reduced sulphur compounds produced by sulphate reducers (below) and oxygen produced by the cyanobacteria (above). Utilising this redox gradient these purple sulphur bacteria synthesize organic matter and create the characteristic purple-orange layer seen below the green layer in an aggrading microbial mat. As they can only metabolise in a suitable redox gradient, they need to locate themselves exactly within this gradient, so they are typically the most motile forms in a microbial mat. The redox gradient lies deeper in the mat community during the day due to oxygen production by the cyanobacteria, but it rises and can even reach the mat surface in the dark of night (Fig. 9.30b). Below the chemolithotrophs are the phototrophic green sulphur bacteria. They are anaerobic photosynthesizers that fix sugars by utilising the infrared portion of the light spectrum as they convert sulphide to sulphate. Infrared radiation penetrates deeper into microbial sediment than the visible light used by the cyanobacteria, with depth of penetration aided by transparent gypsum crystals.

Below are the sulphate reducers, fermenters, and methanogens (Fig. 9.30b). Fermenters are relatively inefficient decomposers and do not completely break down the organics but break them into alcohols, lactates and other compounds exploited by other decomposers. During the day the sulphate reducers metabolise organics deep in the microbial mat via anaerobic respiration utilising a variety of chemicals including manganese, nitrate, sulphate and even CO_2. At night they rise somewhat with redox gradient and at times of prolonged bottom brine anoxia and brine column turbidity can even reach the mat surface or enter the lower parts of a density stratified brine column (Fig. 9.31; Des Marais 2003). They are very important decomposers in most mesohaline microbial mats and give the lower parts of a mat its characteristic "rotten egg" smell. Generally sulphate reducers consume up to a third of the organic carbon present at this depth in a typical mesohaline microbial mat.

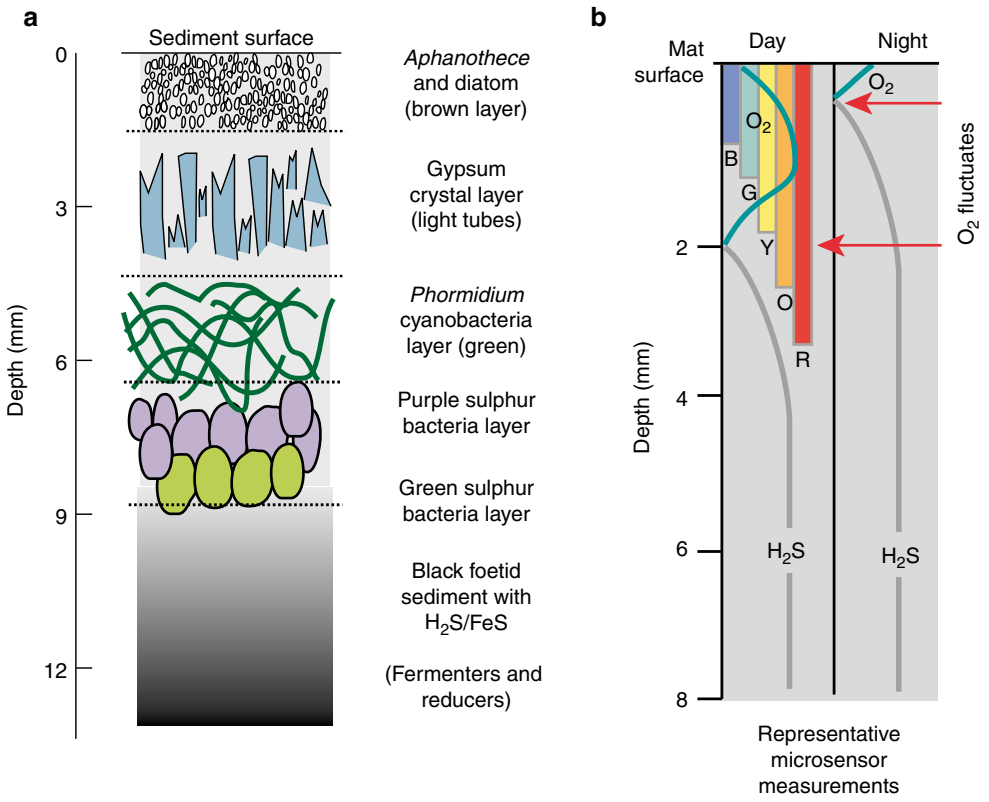

Fig. 9.30 Community and light layering in a microbial mat. (**a**) Typical microbial community in an evaporitic laminite in a modern coastal salina with salinity in the range 130–200‰ (After Caumette 1993). (**b**) Schematic of vertical gradients of O_2 and H_2S during the day and at night. The vertical bars at upper left represent the relative depths of penetration of blue (*B*), green (*G*), yellow (*Y*), orange (*O*), and red (*R*) light. Profile is for a filamentous micritic mat. Profiles in filamentous and unicellular mats are qualitatively similar, although the depth scale (mm) of such profiles tends to be greater for unicellular mats. It will also be deeper in mats growing in an around clear crystals such as gypsum or halite, which act as light tubes (After Des Marais 2003)

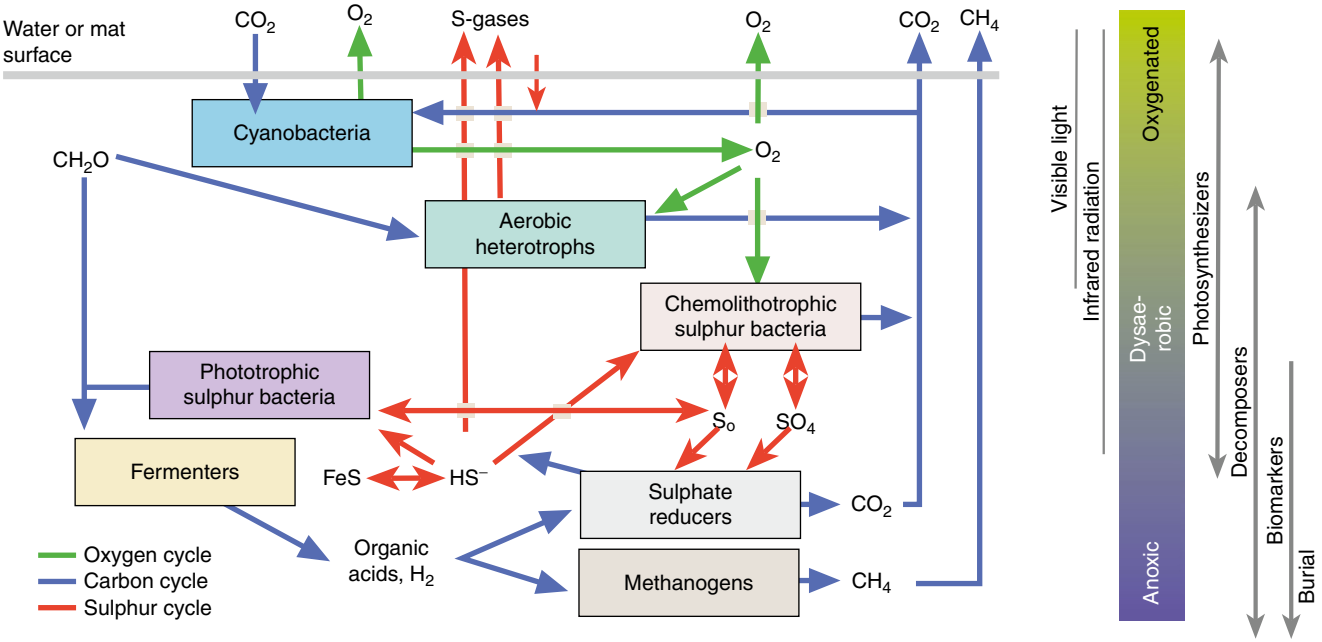

Fig. 9.31 Inter-relationships between microbes and the oxygen, carbon and sulphur cycles in the uppermost 5–10 mm of a microbial mat. The oxic-anoxic transition shifts lower in the mat in the daytime and higher in the mat at night (photosynthesis has stopped)

Deeper still in the mat are the methanogens (Fig. 9.31). All are anaerobes and utilise simple compounds created by the fermenters, such as CO_2 and hydrogen, along with organic components such as methanol, acetic acid, formic acid and methylamines to produce methane (Table 9.6). The methanogenetic metabolic pathway produces little biochemical energy and is usually the "last resort" community and makes up the lowermost living layer in the microbial high-rise.

Grimalt et al. (1992) found that the uppermost layers, dominated by cyanobacteria, typically leave no more than minor traces in the solvent-extractable lipids (biomarkers) in buried mat sediments.

Rather, the predominant fatty acid distributions in the lower parts of a mesohaline mat sediment parallel the compositions observed in the enrichment cultures of purple bacteria and appear to be mixed with acids characteristic of heterotrophic bacteria, including purple bacteria and sulphate-reducers. In other words, the organic signatures, even as the mats are accumulating a few millimetres above, are those of the decomposers not the primary producers. This implies that many biomarkers used to typify organic production in hypersaline settings typically do not come from organics of the primary producers but from the products of the decomposer community.

Anaerobic decomposers flourish within the sediment at the base of benthic mat communities or within the brine column at the halocline of a density stratified brine body. Defining where halotolerant and halophilic decomposers lived in ancient microbialites is not possible from their organic signatures alone; it requires a sedimentological interpretation of the sediment matrix, which is usually a laminite. But, as discussed in Chap. 1, evaporitic laminites and biolaminites are subaqueous sediments with near identical textures beneath stratified and unstratified brines across water depths ranging from less than a metre deep to hundreds of metres.

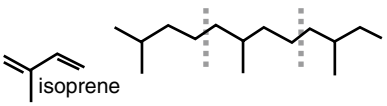
Biomarkers and Microbial Responses to Changing Salinities

Salinity-controlled transitions between a halotolerant and halophilic biota can been seen, indirectly in their organic residues and subsequent biomarkers. Biomarkers can be thought of as molecular or chemical fossils with a basic carbon skeleton derived from once-living organisms. Biomarkers are found in all modern sediments, as well as in petroleum and rock extracts and can provide information about species diversity, depositional environment, thermal maturity, migration pathways and hydrocarbon alteration (Table 9.8; Brocks and Summons 2003; Peters et al. 2005).

Commonly accepted environmental generalisations based on biomarker distributions include the notion that variation in the ratio between the isoprenoids[13] pristane and phytane indicates oxidising versus reducing conditions (this assumes pristane and phytane are both breakdown products of chlorophyll). In an oxidising environment the cleavage of the phytol side chain of chlorophyll is followed by decarboxylation to produce phytane (Fig. 9.32a). In a reducing environment the sidechain cleavage of chlorophyll is followed by its reduction to ultimately produce pristane. Low pristane/phytane ratios are thought to indicate reducing conditions, while higher values (>1) indicate oxidising conditions (Table 9.8). But Philp and Lewis (1987) have shown that the chemistry of chlorophyll breakdown is much more complicated in many natural systems and that variations in the ratio may also indicate varying inputs from the archaea, which contain much higher levels of phytane chains than bacteria. Values of pristane/phytane less than 0.5 may indicate hypersaline conditions where archaea dominated and ^{13}C values can be elevated (Grice et al. 1998).

Differences in the distribution of n-alkanes are also thought to indicate depositional differences in the organic contributors. Waxes in higher plants have significant concentrations of the long chain $C_{22–36}$ alkanes[14] with a pronounced odd/even distribution, such organics tend to be relatively rare in evaporitic source rocks, unless surface waters were freshened by periodic runoff from the land. Much of this terrestrial

[13] 9.6 Isoprenoids are a major class of nonsaponifiable lipids that occur in plants, animals, and bacteria and are characterized by chains of modular groups of five carbon atoms in which the typical pattern has four of the carbon atoms in a linear chain and a single carbon attached at the carbon one position removed from the end of the chain. The term isoprenoid is derived from the name of the five-carbon, doubly unsaturated branched hydrocarbon isoprene, which could in principle be the simplest monomeric chemical precursor for this class of compounds.



Isoprenoids are also known as terpenes. Terpenes are usually grouped according to the number of isoprene (C_5H_8) units in the molecule: monoterpenes ($C_{10}H_{16}$) contain two such units; sesquiterpenes ($C_{15}H_{24}$), three; diterpenes ($C_{20}H_{32}$), four; triterpenes ($C_{30}H_{48}$), six; and tetraterpenes ($C_{40}H_{64}$), eight. The carotenoid pigments are the best known tetraterpenes in the geological realm.

[14] Aliphatic hydrocarbons are any chemical compound belonging to the organic class in which the atoms are not linked together to form a ring. They are divided into three main groups according to the types of bonds they contain: alkanes, alkenes, and alkynes. Alkanes (n-alkanes) have only single bonds and a continuous chain structure, alkenes contain a carbon-carbon double bond, and alkynes contain a carbon-carbon triple bond. Aromatic hydrocarbons are classified as either arenes, which contain a benzene ring as a structural unit, or non-benzenoid aromatic hydrocarbons, which are characterized by special stability but which lack a benzene ring as a structural unit.

Table 9.8 Depositional significance of selected biomarkers

Setting	Biomarker/indicator	Detail
Hypersaline	Gammacerane	High relative to C31 hopanes in oils derived from sources deposited under hypersaline depositional conditions. High values indicate stratified water column during source deposition (Sinninghe Damste et al. 1995).
	Pristane/phytane	Very low values (<0.5) in oils derived from source rocks deposited under hypersaline conditions, indicates contribution of phytane from halophilic bacteria/archaea (ten Haven et al. 1987, 1988).
	Acyclic isoprenoids	Acyclic isoprenoid hydrocarbons are the predominant components in the organic matter extracted from sedimentary cores and oils of various hypersaline settings (Wang 1998). For example, the dominant hydrocarbons in Miocene/Pliocene sediments from the Dead Sea Basin, Israel, are regular isoprenoids with 19–25 carbon atoms (Grice et al. 1998)
	Low diasteranes	Oils from the hypersaline sources typically have very low amounts of diasteranes, which commonly suggests a source rock that has low content of catalytic clays, consistent with carbonate or evaporite source rocks (Mello and Maxwell 1991; Peters and Moldowan 1993). The amount of diasteranes in oils also decreases in highly reducing noncarbonate environments with increasing salinity (Philp and Lewis 1987).
	Elevated acidic amino acid content in fossil DNA	Strong linear correlation ($R^2 = 0.97$) between the salinity of an environment and the ratio of acidic to basic amino acids encoded by inhabitants of modern Dead Sea suggest it might be preservable in fossil DNA or fossil amino acids, serving as a proxy for the salinity of an ancient environment. (Rhodes et al. 2010)
	Other biomarkers	Predominance of even n-alkanes within C20–C30 range (especially mid-chain alkanes), presence of β-carotene and γ-carotene, dominance of the C27 steranes (Malinski et al. 2009).
	Organic sulphur compounds	There is a high abundance of organic sulphur compounds (thiolanes, thianes, thiophenes and benzothiophenes) in many anoxic hypersaline settings (Wang 1998). The distributions of the C-20 isoprenoid thiophenes in combination with those of the methylated 2-methyl-2-(4,8,12-trimethyltridecyl) chromans can be used to discriminate non-hypersaline from hypersaline paleoenvironments (Sinninghe Damste et al. 1989)
	Carbon isotopes	Depleted ^{13}C values (−20 to −30‰) are consistent with typical saline lake environments and reflect depletion of CO_2 by photosynthetic organisms (Peters et al. 1996).
	n-heneicosadiene	There is a predominance of n-heneicosadiene in the top layer of the gelatinous mat, which grows in the most extreme salinities of the various Abu Dhabi microbial mat communities. Its source is not yet known, but is considered to be an aerobe favoring the extreme conditions where it is found (Scherf and Rullkötter 2009)
	Novel McDGs	Novel non-isoprenoid macrocyclic glycerol diethers (McDGs) that contain a C32 diabolic acid-derived alkyl moiety (i.e., 15,16-dimethyltriacontane), with some components bearing additional methyl branching at C-7 and/or C-24. These McGDs are suggested to have been synthesized by some extremophilic (thermophilic and/or halophilic) bacteria (Baudrand et al. 2010)
	Archaeol/(Archaeol + Caldarchaeol) *100	Relative amounts of acyclic diether and tetraether membrane lipids synthesized by Archaea correlate with salinity from 0 to 250 practical salinity units (psu) in modern and ancient hypersaline settings. Reflects fact that because Archaea survive and thrive over a broad salinity range, well beyond that of haptophyte algae and other halotolerant plankton (Turich and Freeman 2011).
Anoxic	C35 homohopanes	High relative to total hopanes in oils derived from source rocks deposited under anoxic conditions (Peters and Moldowan 1993). Abundance of C35 homohopanes in oils (relative to C31–C34 homopanes) is correlated with source rock hydrogen index (Dahl et al. 1994).
	Pristane/phytane	>1.0 can indicate anoxic conditions, but the ratio is affected by many other factors.
	Isorenieratane and derivatives	Presence in oil indicates anoxic photic zone during source rock deposition, these compounds are biomarkers for green sulphur bacteria (Summons and Powell 1987).
	V/(V + Ni) Porphyrins	High = reducing conditions (Lewan 1984).
	Fossil okenane	Interpreted as a biomarker for planktonic purple sulphur bacteria of the family Chromatiaceae in the 1.64 Ga Barney Creek Fm. As such okenane is strictly a biomarker for anoxic and sulphidic conditions in the presence of light (photic zone euxinia) and indicates an anoxic/oxic transition in the photic zone (typically 12–25 m below water surface (Brocks and Schaeffer 2008). Also common in Lake Mahoney bottom sediments.
	28,30-bisnorhopane	High in a number of reducing environments (Schoell et al. 1992; Moldowan et al. 1994).
Lacustrine	Botryococcane	Presence = lacustrine source. Absence = meaningless (e.g., Moldowan et al. 1985).
	β-Carotene	Presence = lacustrine source. Absence = meaningless (Jiang and Fowler 1986).
	Sterane/Hopanes	Low in oils derived from lacustrine source rocks. (Moldowan et al. 1985)
	C26/C25 tricyclic terpanes	>1 in many lacustrine-shale-sourced oils (Zumberge 1987; Sajnovic et al. 2008)
	Tetracyclic polyprenoids	High in oils from freshwater lacustrine sources (Holba et al. 2000).

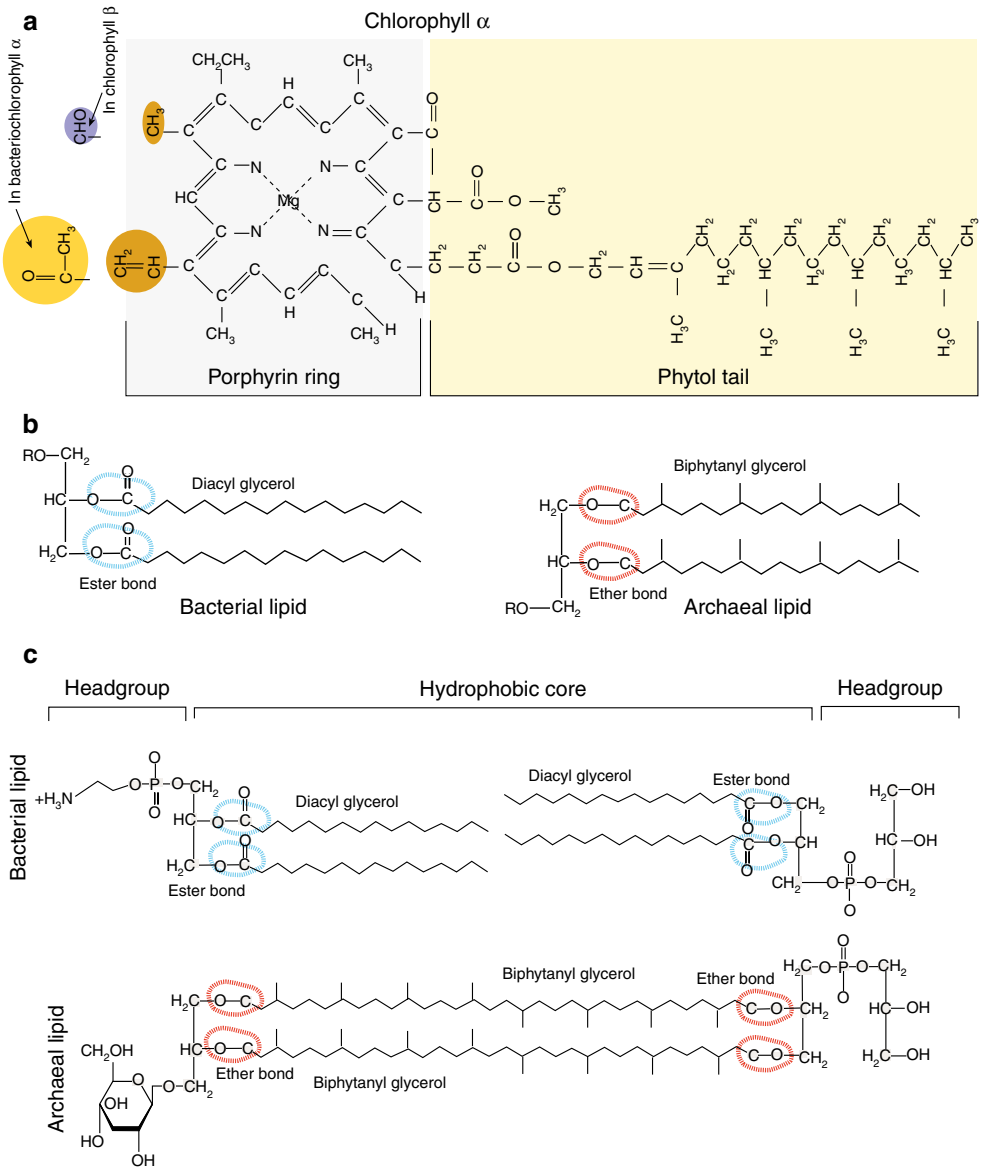


Fig. 9.32 Various molecular structures. (**a**) Chlorophyll a structure showing porphyrin ring and phytol tail. Alternate structures from bacteriochlorophyll a and chlorophyll *b*. (**b**) Phosphatidylanolamine forms a bi-layer lipid in bacterial cells. The acyl chain is usually, but not always straight. Some bacterial lipids have a methyl branch of a cyclohexal group at the end of the acyl chain, other lipids have one or more unsaturated bonds and the connection of glycerol to the acyl chain is via an ester linkage. (**c**) Lipids are monolayers in Archaea and the phytanyl chain contains isoprenoid-like branches. An ether linkage connects the phytanyl chain. Archaeal membranes also contain bilayer-forming diether lipids

organic material is oxidized and biodegraded before it makes it to the final site of deposition on the brine pool floor. In contrast a high algal input is characterised by n-alkanes in the $C_{16–18}$ region.

At its simplest, much of the utility of biomarkers in saline environments comes from salinity-related differences in contribution to organic matter of the general categories of primary producers (autotrophs), namely prokaryotes (cyanobacteria and bacteria) and eukaryotes (higher plants, algae) and archaea. Most triterpanes are associated with prokaryotic sources, whereas steranes tend to be produced by eukaryotes. Thus, the triterpane/sterane ratio can be a rough measure of the prokaryote/eukaryote contribution to the organic material. As salinity increases, the less salinity-tolerant eukaryotic organisms (mostly green algae) give way to more halotolerant bacteria and cyanobacteria (tricyclic and hopane producers) with a corresponding increase in the triterpane/sterane ratio (e.g., Summons et al. 1999). Thus high alkalinity/salinity settings are characterised by tricyclics (C_{20}-C_{24}; m/z 191), β-carotene ($C_{40}H_{56}$ compound; m/z 125) and gammacerane (C_{30} triterpane; m/z 191), all with prokaryote sources. Hence, high levels of gammacerane and β-carotene in ancient organic signatures are typically associated with nonmarine highly saline environments (Peters and Moldowan 1993; Peters et al. 2005).

Lipids, entrained as organic residues in modern evaporitic carbonates and gypsums from modern saline pans (mesohaline and lower penesaline waters), are mostly derived from heterotrophic bacteria acting on cyanobacteria and green algae (Figs. 9.17 and 9.18). The resulting n-alkane distributions show a high predominance of n-docosane. In the modern evaporitic carbonate domain (mesohaline), the C_{20}

highly-branched isoprenoid olephines, tetrahymanol (from bactiverous ciliates) and large amounts of phytol are precursors to most lipids found in buried evaporitic sediments. In contrast, the main lipid contributors to organics preserved in modern halites and bittern beds are the extremely halophilic archaea and their organic signatures are enriched in the isoprenoids, especially phytane (Table 9.8; Barbé et al. 1990; Wang 1998).

Likewise, Waples et al. (1974) and ten Haven et al. (1986), noted that Tertiary sediments deposited in many saline evaporitic lagoons retain high concentrations of regular C_{25} isoprenoids. They related it to the activities of the photolithotrophic *Chlo-robiaceae sp*., an anaerobic green sulphur bacteria, known to flourish at the halocline of modern saline lakes. It is thought to have flourished in similar stratified settings in ancient mesohaline to hypersaline seaways. Its biochemistry leads to the preservation of a series of 1-alkyl-2,3,6-trimethyl benzenes, thought to be derived from the breakdown of its aromatic carotenoids in sulphate- and sulphide-rich brines (Summons and Powell 1987). Ten Haven et al. (1988) went on to propose that there are a number of biomarkers indicating likely hypersalinity at the time of deposition including; short sidechain steranes, 5α(H), 14β(H), 17β(H) pregnanes and homopregnanes, as well as high gammacerane indices (gammacerane/C_{30} hopane). Gammacerane is a pentacyclic C_{30} triterpane thought to be a diagenetic alteration product of tetrahymenol (Table 9.8). The principal source of tetrahymenol is bactiverous ciliates, such as protists like *Tetrahymena*. Thus the presence of tetrahymenol is not restricted to any particular environment but the presence of tetrahymenol (and its daughter gammacerane) in large amounts suggests the presence of a stratified water column and possibly hypersalinity in the depositional setting (Table 9.8; Sinninghe Damste et al. 1995; Peters et al. 2005, p.576).

For Archaea, the cell membrane itself, due to its high thermal stability, is a good candidate for a biomarker. Archaeal cytoplasmic membranes do not contain the same lipids that prokaryotes and eukaryotes do. Instead, their membranes are formed from isoprene chains (ether lipids) made up from C_5 isoprenoid units (as for the side chains of ubiquinone) rather than C_2 units (ester lipids) in the normal fatty acids of the non-archaea (Fig. 9.32b). Halophilic Archaea do not have fatty acids, rather the cell wall is constructed of lipids, mainly of glycerol, connected to phytanyl chains some twenty carbons in length by ether bonds to form phytanylic diether. Typically these are organized in bilayers that make up the cell wall. In the case of archaea living in extreme conditions, two glycerol molecules can be connected to a double chain of phytanol to create a tetraether structure of forty carbons (Fig. 9.32c). Phytane-rich isoprene derivatives indicative of ancient archaea have been found in Mesozoic and Palaeozoic evaporitic sediments, and more generally in older Precambrian sediments (Hahn and Haug 1986). Interestingly, their chemical traces have even been tentatively identified in sediments from the Isua district of west Greenland, the oldest known sediments on Earth, some 3.8 billion years old. Biomarker evidence for green and purple sulphur bacteria is found in Palaeoproterozoic marine sediments from northern Australia in the form of a new carotenoid biomarker – okenane (Brocks et al. 2005).

Bacterioruberin constitutes the purple patches in the archaeal cell wall and we have already discussed its stability with respect to high temperatures in the living environment. It may well constitute an excellent as yet unrecognised biomarker for haloarchaea in ancient evaporitic sediments that were precipitated in moderate to extreme salinities (Brocks and Summons 2003). The likely fossil equivalent of bacterioruberin is perhydro-bacterioruberin, but it has yet to be discovered in geological samples. However, it is worth bearing in mind that some high-molecular weight biomarkers may have escaped detection because they are difficult to analyse using conventional GC-MS methods.

Do Biomarkers Indicate Hypersalinity?

Work in modern hypersaline systems clearly shows that archaea and bacteria can both flourish as heterotrophs in upper penesaline and supersaline waters at salinities higher than 200–250‰ and that cyanobacteria and some green algae can still survive and grow at these salinities (Caumette 1993; Ollivier et al. 1994). Hence, respective biomarker signatures in ancient counterparts will not be mutually exclusive and none of the biomarker indicators listed in Table 9.8 are exclusive indications of hypersalinity.

Also, some of the widely used biomarker-derived maturity indicators for low maturity oils, such as low levels of diasteranes, T_s/T_m ratios <1, somewhat low homohopane and sterane isomerization values, all historically derived from studies in ancient marine settings, are not as reliable when applied to relatively young saline-lacustrine oils, such as those sourced from hypersaline Oligocene laminites in the northern Qaidam Basin, China (Hanson et al. 2001). These sediments and their outcrop equivalents have vitrinite reflectance values in the range 0.68–1.0, all within the oil window (Fig. 9.1). The discrepancy between mature indications coming from vitrinite studies and the immature indications derived from various sterane isomerization ratios in these young hypersaline-sourced oils are perhaps explained by a lack of time for various sterane equilibria to develop. Some of these hypersaline oils come from hydrogen-rich type I lacustrine source sediments in the Qaidam Basin fill that may be as little as 3 million years old. But some other so-called maturity indicators, such as the low levels of diasterane probably are better tied to deposition of the source organics in

noncarbonate shales accumulating in hypersaline waters (Philp et al. 1991).

The fluctuating salinities that controls life in the depositional setting of all modern and ancient evaporites means that there is no simple single biomarker indicator for hypersalinity in any ancient sediment. For example, the 2-methyl hopanoids[15] are thought to indicate a cyanobacterial association (Table 9.8) and cyanobacteria are commonplace in mesohaline waters. But the presence of cyanobacteria and hence 2-methyl hopanoids are not limited to this setting. Likewise, the pentacyclic triterpenoid gammacerane is present in trace amounts in almost all bitumens and oils, but tend to be more abundant in sediments that were deposited under a stratified water column. This is a hydrological condition that is typical of, but not exclusive to, hypersaline lacustrine settings (Sinninghe Damste et al. 1995). A similar argument can be made for low pristane/phytane ratios that are used as indictors of both reducing conditions (assumes a chlorophyll precursor) and halophilia (assumes an archaeal precursor).

All biomarker signatures are indirect and somewhat ambiguous indicators of hypersalinity via assumptions of the relative make-up the original primary producers. In addition, all traces of biomarkers from the primary producers preserved in ancient strata have been overprinted by the effects of syndepositional decomposers, as well as subsequent mixing from various sources during catagenesis. The overprinting effects of the decomposers in microbial laminites are clearly seen when molecular characteristics of modern hypersaline sediment from the Ejinur salt lake (northern China) are compared to Tertiary (Eocene) core samples from Qianjiang Formation (hypersaline lacustrine) of Jianghan Basin, central eastern China (Fig. 9.33a; Wang et al. 1998b). N-alkanoic acids in saline sediments from both areas (Ejinur and Jianghan) show a pronounced even-over-odd predominance (EOP) and a bimodal distribution. In the lower molecular weight range, the C_{16} and C_{18} components are prominent, with the former dominant. For higher homologues (greater than or equal to C_{20}), docosanoic (C_{22}) and tetracosanoic (C_{24}) acids dominate the n-alkanoic acid homologues in the Jianghan and Ejinur samples, respectively. Alkanoic acids with an isoprenoid skeleton are more abundant in Jianghan samples, including C_{20}, C_{21}, C_{24}, C_{25} and C_{30} homologues, with a C_{25} component (3,7,11,15,19-pentamethyleicosanoic acid) most pronounced in the lower part of the Qianjiang Fm. The carbon skeletons of these isoprenoid acids in both units are attributed to archaeal decomposers.

Iso and *anteiso* branched carboxylic acids are prevalent in both the Ejinur samples and in the upper portion of the Qiangiang Formation. They derive from bacteria, probably sulphate-reducing bacteria, and their abundance clearly shows once again the importance of bacterial decomposers, along with haloarchaea, to the biochemical signature of organic matter in modern and ancient saline lake sediments. The presence of hopanoid acids and a 3-carboxy steroidal acid further attest to contributions from bacterial and eukaryotic sources, respectively. The occurrence of particular carboxylic acids in the Jianghan samples illustrate these compounds, indicators of halotolerant and halophilic decomposers, can survive as biomarkers in hypersaline source rocks.

Across a broader time and geographic scale, acyclic isoprenoid hydrocarbons are the dominant components in organic matter extracted from sedimentary cores and oils sampling various hypersaline settings in China; the results encompass the Tertiary Janghan salt lake basin, the Cretaceous Taian salt lake basin, and the Triassic, Permian and Cambrian Yangtze evaporitic marine platforms (Wang 1998). Inland saline lake basins in China such as Jianghan and Songpu are characterized by a tremendous predominance of phytane (C_{20}), which ranges up to 15 % of the total extract. The evaporitic marine sediments are also unique in retaining a complete series of super-long-chain acyclic isoprenoids, up to C_{40} (Fig. 9.33a). These isoprenoids in the marine evaporites possess head-to-head, tail-to-tail or regular linkages that indicate significant contribution from various archaea to the biomarker signature, i.e., a mixed archaeal contribution from halophiles, methanogens and acidothermophiles. Based on the split in distribution and composition of isoprenoids between the inland salt lakes and the evaporitic marine platform settings, Wang (1998) concluded that the archaeal biota in modern and Cenozoic inland salt lake sediments of China are likely dominated by halophilic archaea, while the halobiotal signatures of Mesozoic and Palaeozoic evaporitic marine sediments were predominantly those of methanogens and acido-thermophiles. He also found that the concentration of the various chlorine salts in the sediments is more directly proportional to the abundance of phytane than to sulphate, once again indicating the dominance of halophilic archaea in waters at the halite precipitation stage. He also noted that reduced species of sulphur, sulphide and organic sulphur compounds in the anoxic brines played a key role in the preservation and formation of the abundant phytane in these inland salt lake basins.

A predominance of degraded green algal and cyanobacterial biomarkers in mesohaline settings can be recognised in biomarkers preserved in even older, but organically

[15] Hopanoids are a group of compounds (triterpenoids) produced by prokaryotic organisms, and the diagenetic alteration products of these compounds (found in oils, rock extracts and sediment extracts). Just as steroids (steranes) are a useful group of biomarkers for identifying input from various eukaryotic organisms (e.g., plants and animals), an analogous group of compounds, hopanoids, are a useful group of biomarkers for identifying input from various bacteria. Hopanoids serve the same function in bacteria as sterols do in eukaryotes: they act as cell wall rigidifiers. In petroleum and its source rocks, hopanoid biomarkers exist as a subset of a group of compounds called triterpanes (isoprenoids).

(**b**) Structure and properties of representative bacteriochlorophylls, maleimides and porphyrins from source rocks in the northern and southern Zechstein basins, offshore NW Europe (After Pancost et al. 2002). Compare with primary structures shown in Fig. 9.28. (**c**) Relationship between pristane/phytane and the methyltrimethyltridecylchhroman (MTTC) ratio in Jurassic Malm carbonates of eastern Bavaria (After Schwark et al. 1998). The MTTC ratio is defined as 5,7,8-trimethylchroman/total MTTCs. (**d**) Variations in pristane/phytane ratio and the gammacerane index for oils from lacustrine source rocks in Angola (*Inset* shows gammacerane structure). Independent biomarker evidence suggests a marine source for the point that lies off the shaded trend (After Peters et al. 2005)

immature, evaporitic source rocks. The degree of methylation of 2-methyl-2-trimethyl-tridecylchromans (MTTCs) and the abundance of maleimides and bacteriochlorophylls implies a euhaline to mesohaline (≥30–40‰) marine-fed setting for the accumulation and preservation of organics during Kupferschiefer sedimentation in the Permian of NW Europe (Fig. 9.33b; Bechtel and Puttmann 1997; Pancost et al. 2002). These biomarkers are thought to be derived from green/purple sulphur bacteria (decomposers) within organic-rich laminites and suggest that the bottom waters were saturated with H_2S at the time of deposition. Maximum water depths were probably less than 100 m (it was a stratified

mesohaline drawdown basin at the onset of Zechstein salinity; see Chap. 5). Decomposers probably lived near the brine boundary between the photic zone and the anoxic (euxinic) bottom water at typical water depths of 10–30 m below the water surface, as in modern marine-fed density-stratified systems, much like in Lake Mahoney today (Fig. 9.45). Primary production in the upper water mesohaline column was dominated by photosynthetic cyanobacteria or green algae, while sulphate reduction in the bottom sediment was tied to the availability of abundant sulphate and organic detritus from the overlying water column.

Methanogenesis was also active during Kupferschiefer deposition. This is reflected in the light carbon isotopic composition of organic matter that had originated via recycling of CO_2 generated by methane-oxidizing bacteria in the water column (Bechtel and Puttmann 1997). Saccate pollen is the only morphologically preserved body fossil in organic matter within this laminated Kupferschiefer sediment, all other traces of cellular/microbial morphologies/fossils are gone. Euxinic conditions were confirmed by Pancost et al. (2002) over a much larger area of Kupferschiefer deposition than studied by Bechtel and Puttmann. They concluded that almost all of the Kupferschiefer seaway was subject to periods of photic zone euxinia and stratification during the early mesohaline history of the Zechstein Sea.

By themselves, high pristane/phytane ratios, high amounts of gammacerane, and MTTC ratios are not totally reliable indicators of hypersalinity. More reliable determinations can be made when two or more of these biomarkers are crossplotted and the resulting output shows a consistent trend. Figure 9.33c plots pristane/phytane ratio against the MTTC ratio in the Jurassic Malm Zeta laminites of eastern Bavaria in SW Germany (Schwark et al. 1998). The output shows a covariant decrease in the two measures, lipids from phototropic organisms and show ^{13}C values consistent with the heterotrophic metabolism of which is interpreted as indicating a trend from normal marine to mesohaline deposition.

A similar covariant trend can be seen in saline lacustrine source rocks when the pristane/phytane ratio is crossplotted against the gammacerane index in Mesozoic source rocks from the offshore of west Africa (Peters et al. 2005). Figure 9.33d plots variations in pristane/phytane (a redox and archaeal indicator) and gammacerane index (an indicator of salinity stratification in saline waters) for oils from a set of lacustrine source rocks. Increasing salinity in the depositional setting explains the covariant trend in the plot, whereby higher salinity was accompanied by density stratification and associated reduced oxygen levels in bottom waters. Independent biomarker evidence suggests a marine source for the point that plots off the shaded salinity trend in this figure (after Peters et al. 2005).

Although the levels of entrained organics are very low, similar covariant trends in pristane/phytane and gammacerane occur in $C_{21–25}$ isoprenoids, along with relatively heavy $\delta^{13}C$ signatures, in biomarkers extracted from the Miocene halites of the halokinetic Sedom Formation in Israel. They are enriched by 7‰ compared to lipids from photropic organisms and show ^{13}C values consistent with the heterotrophic metabolism of Halobacteriales. It indicates a predominance of halophilic archaea possibly consuming the remnants of *Dunaliella*-like bloom, when the salt was deposited in a CO_2 -limited system (Grice et al. 1998; Schouten et al. 2001).

A recent development in biological indicators during salinity progression comes from the work of Turich and Freeman (2011). In a wide-ranging study of archaeal biomarkers they found a distinct evolution in archaeol molecules related to increasing salinities in hypersaline waters. They found the relative amounts of acyclic diether and tetraether membrane lipids synthesized by Archaea correlate with salinity from 0 to 250 practical salinity units (psu) in modern settings (Fig. 9.34) They then examined the preservation of the lipid biomarker-salinity relationship in ancient sedimentary organic matter mostly using samples from two sequences of marls and diatomites deposited just prior to the Messinian Salinity Crisis in the Mediterranean. The archaeol ratio-based salinity estimates were consistent with expected absolute salinity, as well as the amplitude of isotope variations leading up to the Messinian Salinity Crisis. Their lipid biomarker approach to salinity reconstruction complements existing paleosalinity proxies, as listed in Table 9.8, because: (i) Archaea survive and thrive over a broad salinity range from 7 to 340‰, which is well beyond that of haptophyte algae and other plankton, which define much of the microfossil record in mesohaline settings, and (ii) it provides finer salinity resolution for the wide range of salinities broadly defined as hypersaline using existing biomarkers. Using their proxy, there is the potential to provide novel insights into salinity variation within desiccating basins in climatically sensitive seas (e.g., Dead Sea, Permian Delaware Basin), evolution of brines, timing of onset of hypersaline conditions and evaporite deposition, as they have done for the Messinian (Fig. 9.35).

In addition to the signature from their particulate organics, modern brines can also contain large amounts of dissolved organic matter (DOM), with levels that increase with increasing salinity (Hite and Anders 1991). This liquified organic is often entrained within brine inclusions in halite and other salt crystals and is not picked up in standard TOC determinations. Levels of volatile fatty acid (VFA), especially acetic acid, are also high in these saline brines and possibly reflect a higher bacterial contribution (Jørgensen et al. 2008). The relative contribution of DOM to the source potential is poorly understood in subsurface evaporitic systems where crossflowing basinal brines are dissolving buried halite and may also have significance in the survival of Archaean "proto-life" (Pasteris et al. 2006).

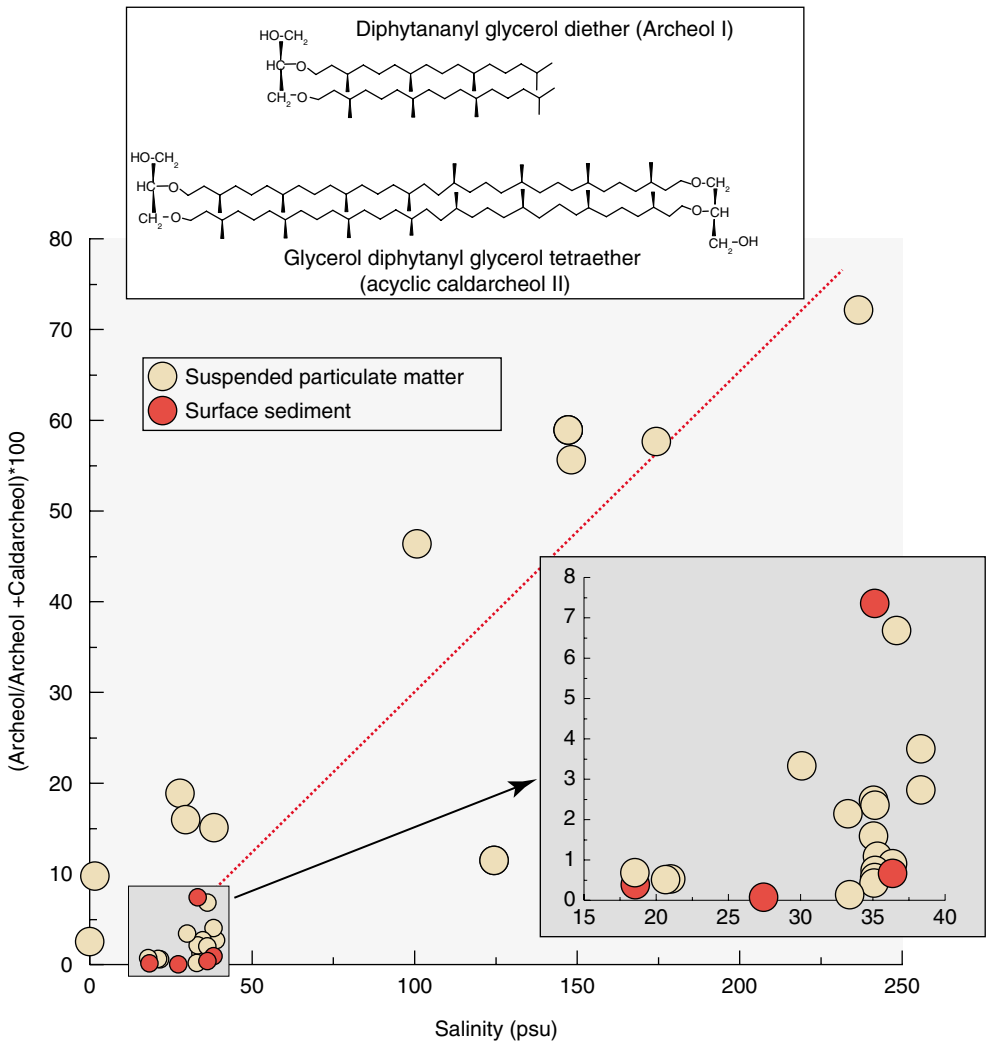

Fig. 9.34 Salinity and relative abundance of archaeol to caldarchaeol from modern suspended particulate matter in marine and marine derived waters plotted against salinity. *Brown circles* in the plot indicate suspended particles, while *red circles* indicating samples with some terrestrial influence. *Upper inset* shows Fischer projections of the utilised biomarkers; diphytanyl glycerol diether (archaeol, I) and glycerol dibiphytanyl glycerol tetraethers (acyclic caldarchaeol, II) as synthesized by Archaea (After Turich and Freeman 2011)

Organic Enrichment

The amount of organic matter preserved in an evaporitic sediment with the potential to become a source rock is a function of three factors, as expressed in the equation (Bohacs et al. 2000; Katz 2005):

$$Organic\ Enrichment = (P - De)/(Di)$$

where P is production, De is destruction and Di is dilution.

Maximum enrichment occurs when production is maximised and destruction and dilution are minimised. Production at mesohaline salinities is mostly via photosynthetic fixation of CO_2. It includes autochthonous organic matter, formed at or near the site of accumulation and derived from algae, bacteria and aquatic plants, as well as allochthonous organic matter carried in during floods (Bohacs et al. 2000). Katz (1990) showed that varying levels of solar input and water chemistry/stratification exert the largest effects on overall primary production in mesohaline settings. Initial destruction of organic matter is mostly a function of the efficiency of the various scavengers and grazers, which is generally a function of the availability of oxygen (Demaison and Moore 1980). In increasingly saline settings, bacteria then archaea dominate the scavenger/decomposer population, while the health of the metazoan grazers is largely inhibited by higher salinities. Dilution by an influx of minerals to a possible area of organic enrichment can limit levels of organic enrichment by decreasing the proportion of organic matter relative to inorganic matrix. The source of dilution can be detrital or evaporite precipitates.

Dissolved gas levels and temperature changes associated with heliothermal bottoms can create extreme levels of environmental stress in communities also attempting to cope with hypersalinity. For example, oxygen is supplied to any water body via exchange with the atmosphere and as a byproduct of photosynthesis of the biota living in the waters. In well-oxygenated water columns most of the organics produced by primary production are destroyed by microbial respiration and the conversion of organic matter back to CO_2. Much of the improved preservation potential, associated with "higher than marine" bottom salinities in mesohaline to hypersaline settings on biotal diversity, reflects the effect of increasingly low levels of dissolved oxygen in the bottom and pore waters. Oxygen levels in natural brines tend to decrease with increasing salinity (Fig. 9.36a). If not enhanced by the activities of bottom -living aerobic photosynthesizers, natural bottom brines will be dysaerobic to anaerobic by the time salinities reach halite saturation (Kinsman 1973; Warren 1986).

Dissolved CO_2 shows a similar depletion in nutrient-poor waters characterised by little no biological activity (Fig. 9.36b). Dissolved CO_2 levels in marine-fed modern salt

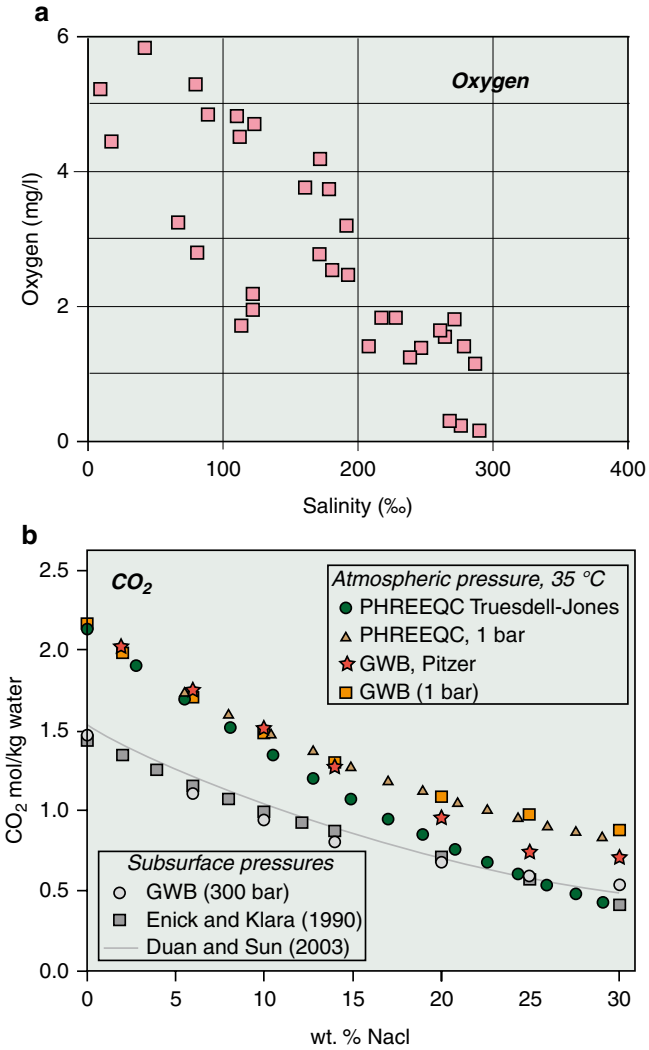

Fig. 9.36 Solubility of oxygen and CO_2 in brine. (**a**) Oxygen in natural brines (Replotted from Warren 1986), (**b**) CO_2 from various modelled brines (After Allen et al. 2005)

pans decrease to around 50 % of the original value as the brine concentration increases from 1.5 to 4 times that of seawater (Lazar and Erez 1992). CO_2 concentration in brine is also pH dependent; CO_2 content approaches zero in a marine brine at a pH of 8.5–9.0, which is the alkalinity of a brine with a salinity around 70‰ (Moberg et al. 1932). Likewise, measurements of CO_2 in the Dead Sea in 1992 showed its solubility was about 20 % of seawater (Barkan et al. 2001). Primary producers, such as algae and cyanobacteria, which are dependent on CO_2 for photosynthesis will suffer shortages at higher salinities.

The bottom-dwelling halobiota can also suffer increased thermal stress in increasingly hypersaline stratified water bodies, due to the tendency for the water mass to become heliothermal. This is because specific heat of any brine decreases as the salinity increases (Kaufmann 1960). For

example, when the salinity of the surface waters of the Dead Sea increased from 210‰ in the 1940s to 275‰ in the early 1980s, the specific heat decreased from 3,085 J/kgK to 2,985 J/kgK (Niemi et al. 1997; p. 127). Specific heat is the amount of heat needed to raise one gram of a substance by 1 °C. For a given amount of heat input, a unit volume of hypersaline water will show a greater increase in temperature than a less saline water. Given the same degree of insolation, it means density-stratified water columns generally are heliothermic, with bottom brines tending to be warmer than fresher surface waters. The resulting greater increase in temperature in a hypersaline bottom water compared to a less saline water can detrimentally effect thermally-intolerant benthic species. The temperature differences can be substantial, with surface waters at ambient atmospheric (≈30 °C) while bottom waters approach temperatures of 60 °C in some density-stratified perennial desert lakes such as Solar Lake[16] in the Sinai (Fig. 2.48).

An interesting association of halophilic microbes can be found in the heliothermal lakes of the Vestfold Hills in Antarctica (Gibson 1999; Cavicchioli 2006). The region is largely snow and ice-free and is thus classified as an Antarctic oasis. It contains a great variety of mesohaline lake systems with over 300 lakes and ponds including what is possibly the largest concentration of meromictic (stratified-heliothermal) lakes in the world. There are 37 permanently stratified water bodies, including six marine basins and seven seasonally isolated marine basins. The stratified basins also have great variety of hydrological styles, ranging in salinity from 4 to 235 g l^{-1}, in temperature from −14 to 24 °C, in depth from 5 to 110 m, in area from 3.6 to 146 ha and surface level from 30 m below to 29 m above sea level.

Three of hypersaline lakes, Organic Lake, Ekho Lake and Deep Lake, have been studied in some detail (Bowman et al. 2000). Like many of the other brine-filled depressions, these lakes are subsealevel relics of an earlier marine embayment, isolated from the ocean by isostatic uplift some 6 ka, but still receiving salt input via marine aerosols (Gibson 1999). Organic Lake is a shallow meromictic brine lake with waters as much as 7.5 m deep and an oxycline at 4–5 m. Its surface waters are moderately saline (8 g/l) and their temperature fluctuates between −14 and +15 °C. Bottom waters are perennially saline with a TDS of 210 g/l and a near constant temperature of −7 °C. Nearby Ekho Lake is 42 m deep, meromictic and heliothermally heated with bottom waters maintaining a year-round temperature of 15–16 °C. Salinities range from 14 g/l at the surface down to 160–180 g/l on the lake bottom, which is permanently anoxic below an oxycline at 12–20 m.

[16]Israelis living in desert kibbutz communities construct artificial black plastic line pans in the desert, fill them with stratified waters and plumb household water pipes through the bottom brine in the pans to create a domestic water heater.

The most hypersaline lake is Deep Lake. Its waters are up to 36 m deep, but unlike the other two lakes it is holomictic and aerobic all the way down to the sediment-water interface. Although salinities are around 320 g/l, its water temperatures can be as low as −18 °C due to a lack of brine stratification and associated heliothermy. The biota in holomictic Deep Lake is almost 100 % haloarchaeal and it is home to that very robust microbe *Halobacterium lacusprofundi*, (Franzmann et al. 1988; see earlier). The biotal make up of the two meromictic lakes (Organic and Ekho lakes) is more complex with varying combinations of the Proteobacteria and Cytophagales. Ekho Lake also contains a number of the Haloanaerobiales, perhaps reflecting its warmer year-round bottom temperatures, a biotal result of heliothermic heating in this frigid region's cryogenic hydrology.

But the dominant biomass control in most mesohaline to hypersaline environments, at least for most multicellular life, is not dissolved gas or even temperature in the ambient environment, but the increase in osmotic pressure that comes with increasing salinity. At a concentration of 300‰, sodium chloride brine exerts an osmotic pressure on a cell of more than 100 atm (Bass-Becking 1928; Reed et al. 1984). Cells of species that typically inhabit marine or brackish waters quickly desiccate in such brines, leading to rapid death (e.g., Geddes 1975b), hence the adaptations at the cellular level that typify halotolerant and halophilic organisms.

The tendency of bottom waters in many deeper hypersaline water masses to become anoxic, hotter, and osmotically pressured, has helped create many ancient lagerstaette associations (fossil "death communities"), with inherent excellent preservation of fine details in the entrained fossil forms. For example, the widely known Cretaceous Solnhofen micritic plattenkalk of Bavaria preserves the feathers of the bird-like dinosaur *Archaeopteryx* and many "death-dance" trackways of finely preserved marine crustaceans that once wandered into the hypersaline and anoxic bottom water layers of the Solnhofen lagoon. Similarly, the communities of chemosynthetic mussels, which inhabit nutrient-rich deep dark bottoms about the edges of modern anoxic brine lakes atop dissolving salt allochthons, can suffer mass extermination when sediment slumps occur and mollusc biostromes, carried along by the slump, end up in the anoxic H_2S-rich, death-dealing hypersaline waters of the brine lake (MacDonald 1992).

High pore water salinities, extreme osmotic stress, a propensity for anoxia in the stratified bottom waters, anoxic pore brines and high bottom temperatures all tend to exclude aerobic burrowing and grazing animals from evaporitic bottom sediments. This minimises a biota that would otherwise oxidise and destroy microbial debris in similar sediments deposited beneath less saline waters.

Biological Responses to Variably Layered Brines: Cycles of "Feast or Famine"

Brines in modern evaporitic depressions are typically layered, with denser more saline waters supporting an ephemeral mass of less dense inflow water. The bottom layer in a perennial brine system tends to be more stable compared to the upper and its physical condition changes little until stratification is lost via mixing of the two water masses. Once mixing occurs the waters in the lake can completely evaporate. Conditions in the floating less dense upper layer are both ephemeral and variable, with wide fluctuations in salinity before desiccation or mixing. When salinities are lowered, this upper layer periodically supports a widespread planktonic bloom (feast). Then, as ongoing evaporation concentrates the upper layer, conditions become increasing less suitable for life (famine) and a mass die-off occurs, first of the haloxene species, then the halotolerants, then the halophiles. The bloom and the following dieback creates a pulse of organic matter that can swamp the abilities of the anaerobic decomposers in the lower water column to strip it of its hydrogen. Organics can then reach the sediment interface with their long-chain alkanes still largely intact. In conditions where light penetrates to the bottom of the brine column, even when the waters atop the sediment surface are oxygenated, the halotolerant primary producers can be sufficiently productive and the underlying anoxic decomposers sufficiently inefficient that substantial volumes of hydrogen-rich microbial matter can be retained into burial.

When surface water salinities are suitable, evaporite basins have some of the highest measured rates of organic productivity in the world (Fig. 9.37; Warren 1986). When biodiversity is low and salinity is high, a proliferation of well-adapted species can generate productivity levels that are much higher than those observed in most nonevaporitic settings. These saline systems are indicative of general principles seen in all stressed ecosystems, namely, as the harshness or abiotic stress in a system increases the biotic stress decreases on a few well-adapted species (less predators and grazers). The total biodiversity (number of species) decreases, while at the same time the biomass (total mass of organisms in the system) initially increases (Garcia and Niell 1993). Ultimately, it too declines as conditions become unsuitable for any life (inset in Figs. 9.37).

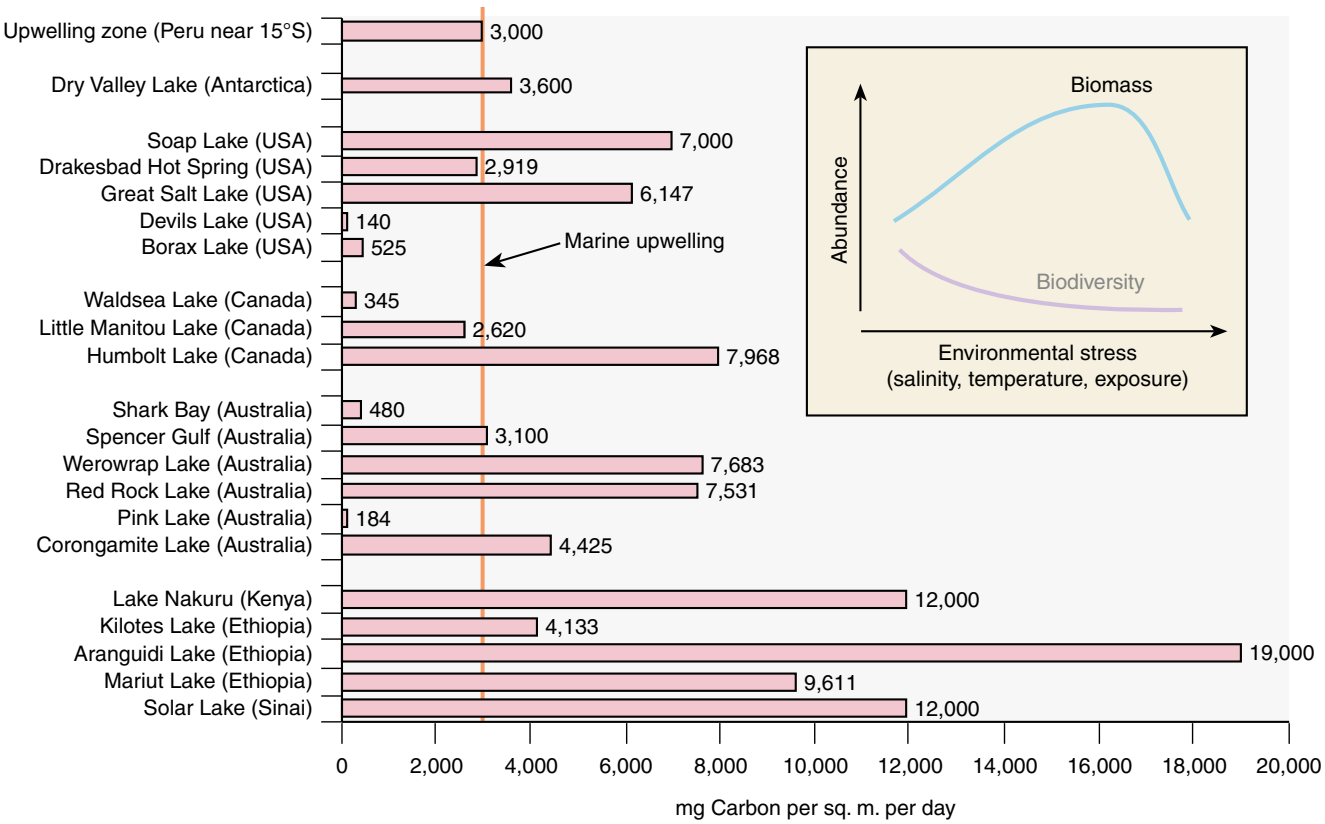

Fig. 9.37 Organic productivity (maxima) in various saline ecosystems. Typical marine upwelling zone ≈250–500 mg C/m²day (the solid line is world marine maxima based on an upwelling zone, offshore Peru); tropical shoal water seagrass banks ≈500–1,200 mg C/m²day; open marine waters are less than 100 mg C/m²day and average 20 mg C/m²day and coastal waters 40–50 mg C/m²day. But, preservation is more important than production rate in terms of source potential (Compiled from sources listed in Warren (1986) and this chapter)

Salinity Change Influences Organic Productivity: A Flamingo Connection in East African Saline Lakes

One of the most visually impressive indications of periodic but very high levels of organic productivity in a well adapted biota in a salinity-stressed layered water body resides in the "flamingo connection." Flamingos (*Aves*, *Phoenicopteridae*) represent an ancient lineage of long-legged, microphagous, colonial wading birds. Although often misperceived as tropical species, flamingo distribution is more closely tied to the great deserts of the world and to hypersaline lake sites, than it is to equatorial regions (Bildstein et al. 1993). Flamingoes are filter feeders that thrive on the dense halotolerant cyanobacterial blooms in the mesohaline shallows of saline lakes around the world. This creates a connection between flamingoes, mesohaline planktonic blooms and saline lakes, first noted in the geological literature for the east African rift lakes by Kirkland and Evans (1981) and well documented in Lake Nakuru by Vareschi (1982). Sedimentary textures and structures associated with flamingoes, where they dominate the macrofauna in some modern saline lakes, are described by Scott et al. (2009, 2012). Ancient avian counterparts can leave a characteristic set of trackways and trace fossils that can be used to refine mid-late Tertiary lacustrine depositional models (Melchor et al. 2012).

Two species of flamingo flock in huge numbers in the East African rift lakes, namely, the greater and the lesser flamingo (*Phoenicoptus ruber roseus* and *P. minor* respectively), the lesser flamingo has spectacular pink-red[17] colouration in their feathers. These bright pink waders feed and breed in mesohaline rift lakes where cyanobacterial blooms can be so dense that a secchi disc disappears within a few centimetres of the lake's water surface (Warren 1986). Lake Natron, where trona is the dominant evaporite, is a major breeding ground for flamingoes in East Africa and is the only regular breeding site for the lesser flamingo in Africa (Simmons 1995). Lesser flamingoes build nesting platforms on the trona pavement in the more central parts of the lake. These spectacular birds not only feed in saline waters, they can choose to nest on evaporite pavements!

Worldwide, only six sites are used for breeding by the lesser flamingos: Lake Natron (Tanzania), Etosha Pan (Namibia), Makgadikgadi-Pan (Botswana), Kamfers Dam (South Africa), as well as two pans in the "Little Rann of Kachchh" (India). Recent estimates of lesser flamingos at the main distribution areas are as follows: 1.5–2.5 million in eastern Africa; 390,000 in northwestern India; 55,000–65,000 in southwestern Africa; and 15,000–25,000 in western Africa. The highest population densities occur in Kenya (1.5 million) and Tanzania (600,000) (Childress et al. 2008). Lesser flamingoes are well adapted to the harsh conditions associated with living and breeding in hypersaline alkaline conditions. Worldwide, they follow an itinerant lifestyle, ranging across their distribution areas in search of saline water bodies with appropriate cyanobacterial blooms. In the east African rift the flocks can travel up to 200 km a day between feeding and breeding sites, which are generally at geographically separate locations (Fig. 9.38a).

Lake Natron has the highest concentration of breeding flamingoes in any lake in East Africa. Both the greater and the lesser flamingo are found there, with the lesser flamingo outnumbering the greater by a hundred to one. Lesser flamingoes bred at Lake Natron in 9 out of 14 years from 1954 to 1967. But while Lake Natron is an essential breeding site, it is not a focal feeding site for flamingoes.

Major feeding sites in the Africa rift valley are Lakes Nakuru and Bogoria (formerly Lake Hannington) in Kenya and entrain waters that are mesohaline with an abundance of halotolerant cyanobacteria, dominated by *Arthrospira* (Figs. 9.39 and 9.40). Lake Nakuru is a mesohaline soda lake with a pH ≈ 10.5 and a typical annual salinity range of 15–45 ‰, nearby lake Bogoria is somewhat larger, also an alkaline soda lake, with somewhat higher salinities. The Lake Nakuru depression measures some 6.5 km by 10 km, with a water covered area of some 5–45 km^2 experiencing an annual pan evaporation rate of 1,500 mm beneath a Cfb Köppen climate (Fig. 9.38b; Vareschi 1982; Krienitz and Kotut 2010). It contains a eutrophic bottom water mass in the lake centre, with thermally stratified water column that can be up to 4.5 m deep. The Lake Bogoria' water mass is up to 4 km wide, some 17 km long with thermally stratified eutrophic waters up to 10 m deep. It lies beneath a Cfb climate with a pan evaporation of 2,600 mm. It is fed by a combination of rainfall (≈760 mm/year) and numerous (>200) hydrothermal springs about the lake edge (Fig. 9.38c).

Water depths in both lakes vary from year to year, in large part depending on the vagaries of annual runoff/inflow. The higher level of hydrothermal inflow in Bogoria's hydrology, along with its somewhat steeper hydrographic profile, means the lake area and water depth varies less from year to year compared to Nakuru (Fig. 9.38d). Lakes Nakuru and Bogoria, which at peak breeding times can support lesser flamingo populations in excess of 1.5 million birds, have surface areas that are less than half those of lakes Natron and Magadi, which in turn have small areas compared to most ancient lacustrine evaporites and yet Nakuru and Bogoria are two of the most productive ecosystems in the world. What makes both lakes so productive are dense populations of halotolerant cyanobacteria, especially *Arthrospira sp*., which flourish and periodically reach peak growth in their waters.

To utilise dense cyanobacterial populations, which flourish in mesohaline lakes worldwide, flamingo beaks have

[17] An aviator once described Lake Nakuru as "a crucible of pink and crimson fire," with a million flamingos painting an astonishing band of colour that burst into pieces as the birds took flight.

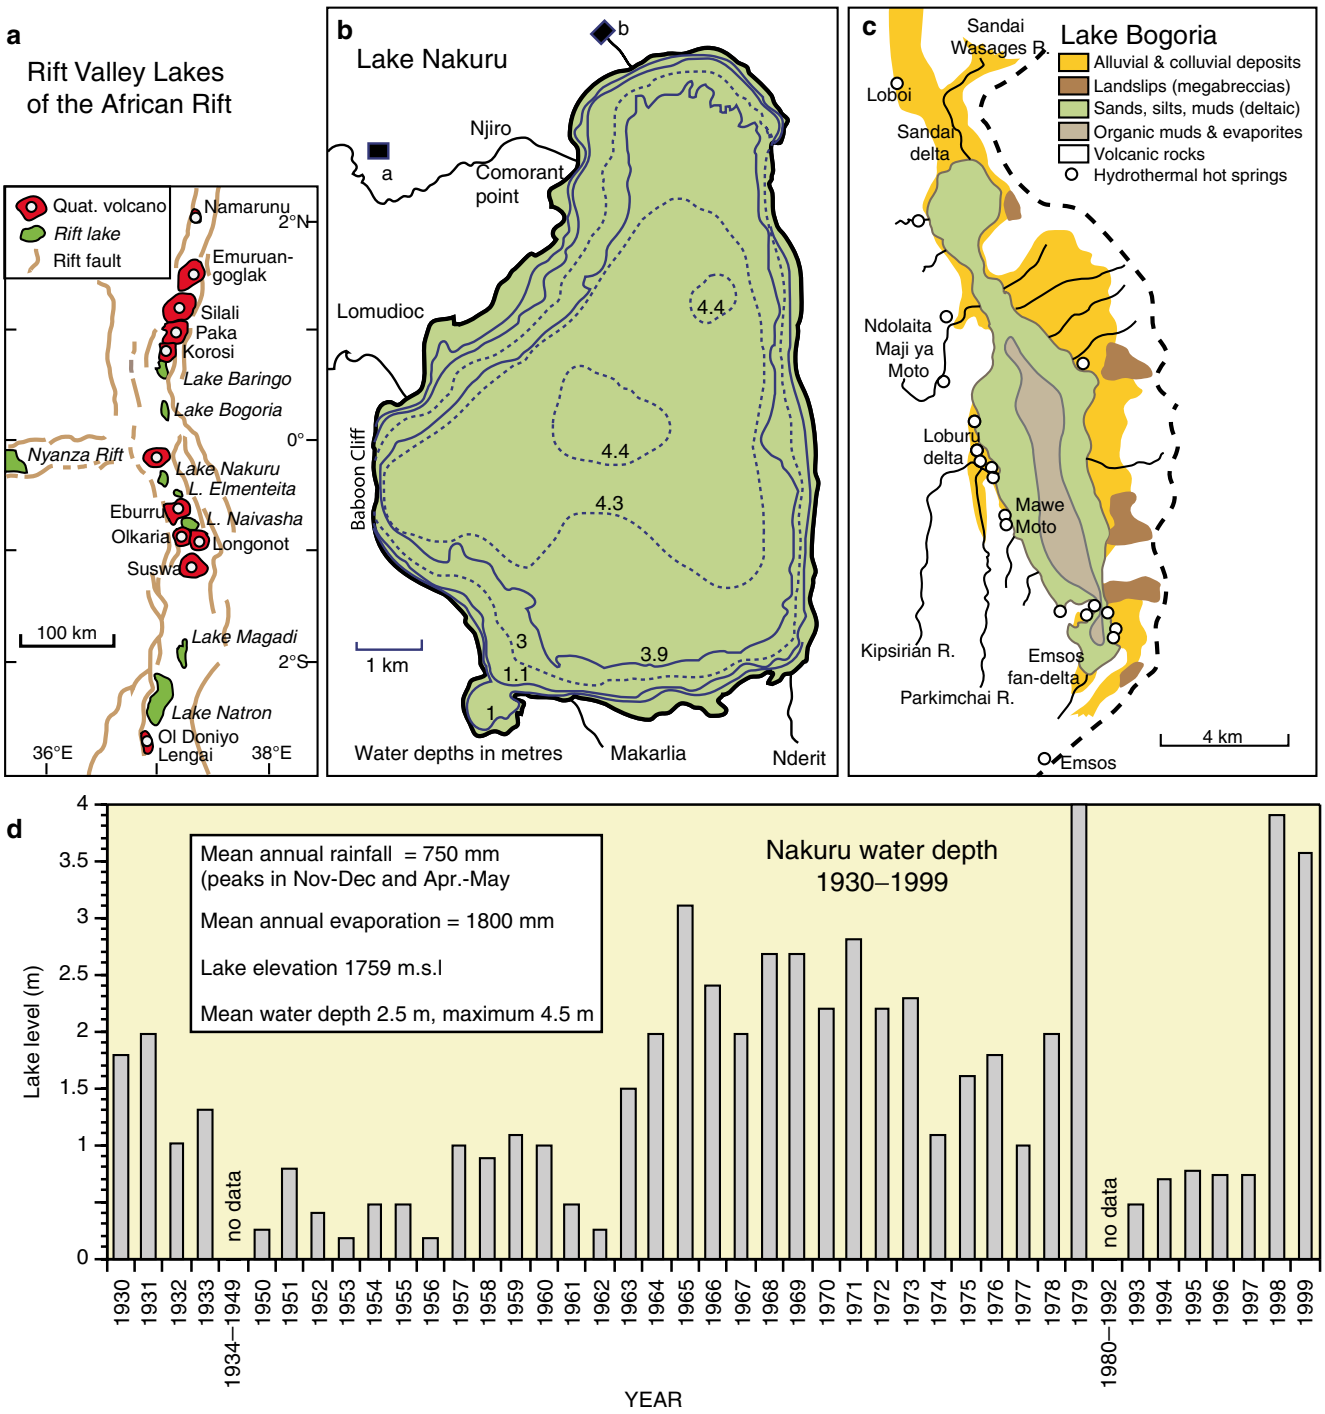

Fig. 9.38 African rift valley (**a**) Location of lakes and Quaternary volcanoes in the African rift valley centred on Lake Nakuru and Lake Bogoria. (**b**) Lake Nakuru bathymetry (Dec 1979) and subsequent strandzone changes. Solid isopleths are actual shorelines at different lake levels over a 20 year period; from outer to inner are December 1979, January 1969, January 1967 and January 1961. Dashed isopleths are based on soundings taken in December, 1971. Two sewage plants are located at *a* and *b* (After Vareschi 1978) (**c**) Surface geology of Lake Bogoria (After McCall 2010). (**d**) Lake levels in Lake Nakuru from 1930 to 1999. Data are not sufficiently detailed to record times of complete lake drying or drought and there are also substantial times when no data were collected/published (1934–1949 and 1978–1992)

evolved into highly efficient plankton-extraction apparati unlike that possessed by any other bird group on earth; the affinity is more to the baleen of whales (Bildstein et al. 1993). A flamingo beak houses a high volume water-filtering system made up of a piston-like tongue and hair-like structures called lamellae made up of rows of fringed platelets that line the inside of the mandible. In the lesser flamingo, the lamellae fibres have the appropriated spacing for capturing coiled filaments of *Arthrospira*. Lamellar spacings are wider in the beaks of the greater flamingo than those in

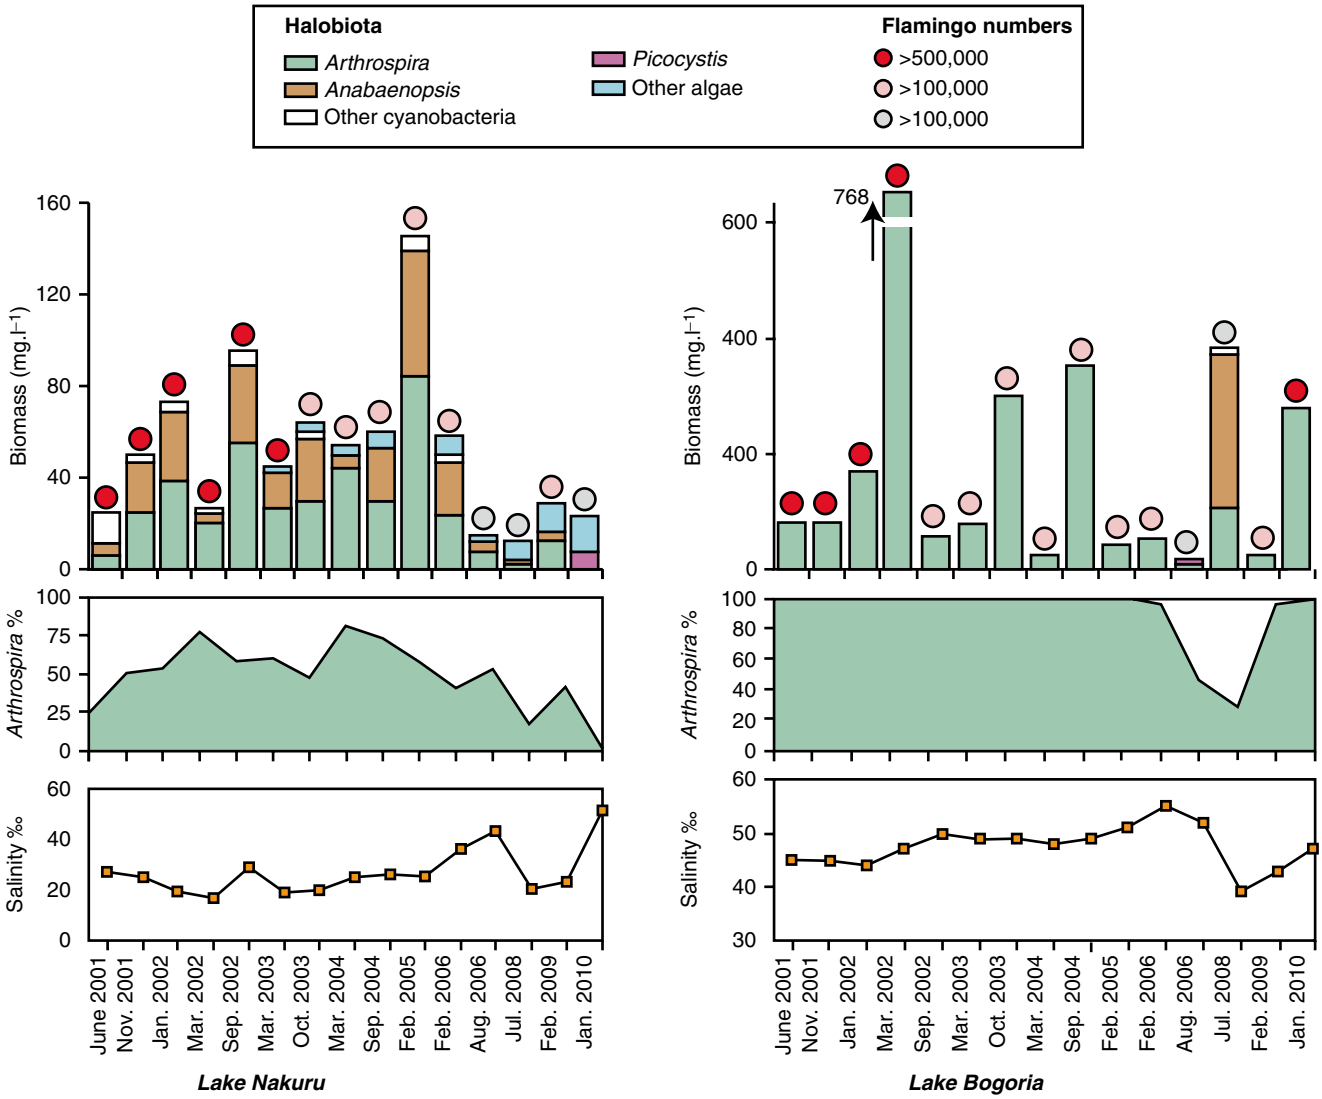

Fig. 9.39 Changes in total phytoplankton biomass, biomass contribution of the dominant phytoplankton species, number of flamingos, percentage contribution of *Arthrospira* to total phytoplankton biomass, and salinity in Lake Nakuru and Lake Bogoria in the African rift valley for the period 2001–2010. Note that the time scales are irregular but the same for the two lake while vertical scales differ in magnitude for some of the measured parameters (After Krienitz and Kotut 2010)

the beaks of the lesser flamingo so these larger-sized birds are more generalist feeders of lake zooplankton. Thus, in any mesohaline lake where the two bird species feed and coexist, they do not compete for the same food source.

By swinging their upside-down heads from side to side just below the water surface and using the piston-like tongue to swish water through their lamella-lined beaks, flamingoes siphon the lake plankton into their gullets at phenomenal rates. Lesser flamingoes can filter as many as 20 beakfulls of plankton-rich water a second. This means some individuals filter upwards of 20,000 l of water per day. How the birds manage to do so in brackish to mesohaline waters, while maintaining their osmotic integrity, remains a mystery. When the rift lakes are typified by dense cyanobacterial blooms, each adult bird ingests around 72 g dry weight of *Arthrospira* per day (Vareschi 1978). This means the Nakuru flock is able to ingest 50–94 % of the daily primary production in the lake (about 60–80 t). Rates of planktonic renewal in these rift lakes is obviously extremely high. Rates of biomass production by *Arthrospira* can be spectacular. Vonshak (1997) reported doubling times of 11–20 h of *Arthrospira* in a culture growing under mesohaline conditions at 35 °C.

Flamingoes are mostly nocturnal feeders and will feed for up to 12–13 h in a 24 h period. As mentioned, the preferred planktonic food of the lesser flamingo is the cyanobacterium *Arthrospira platensis* (formerly *Spirulina platensis*), which is typically the main phytoplankton component in Lake Nakuru and Lake Bogoria waters (Fig. 9.39). Unfortunately,

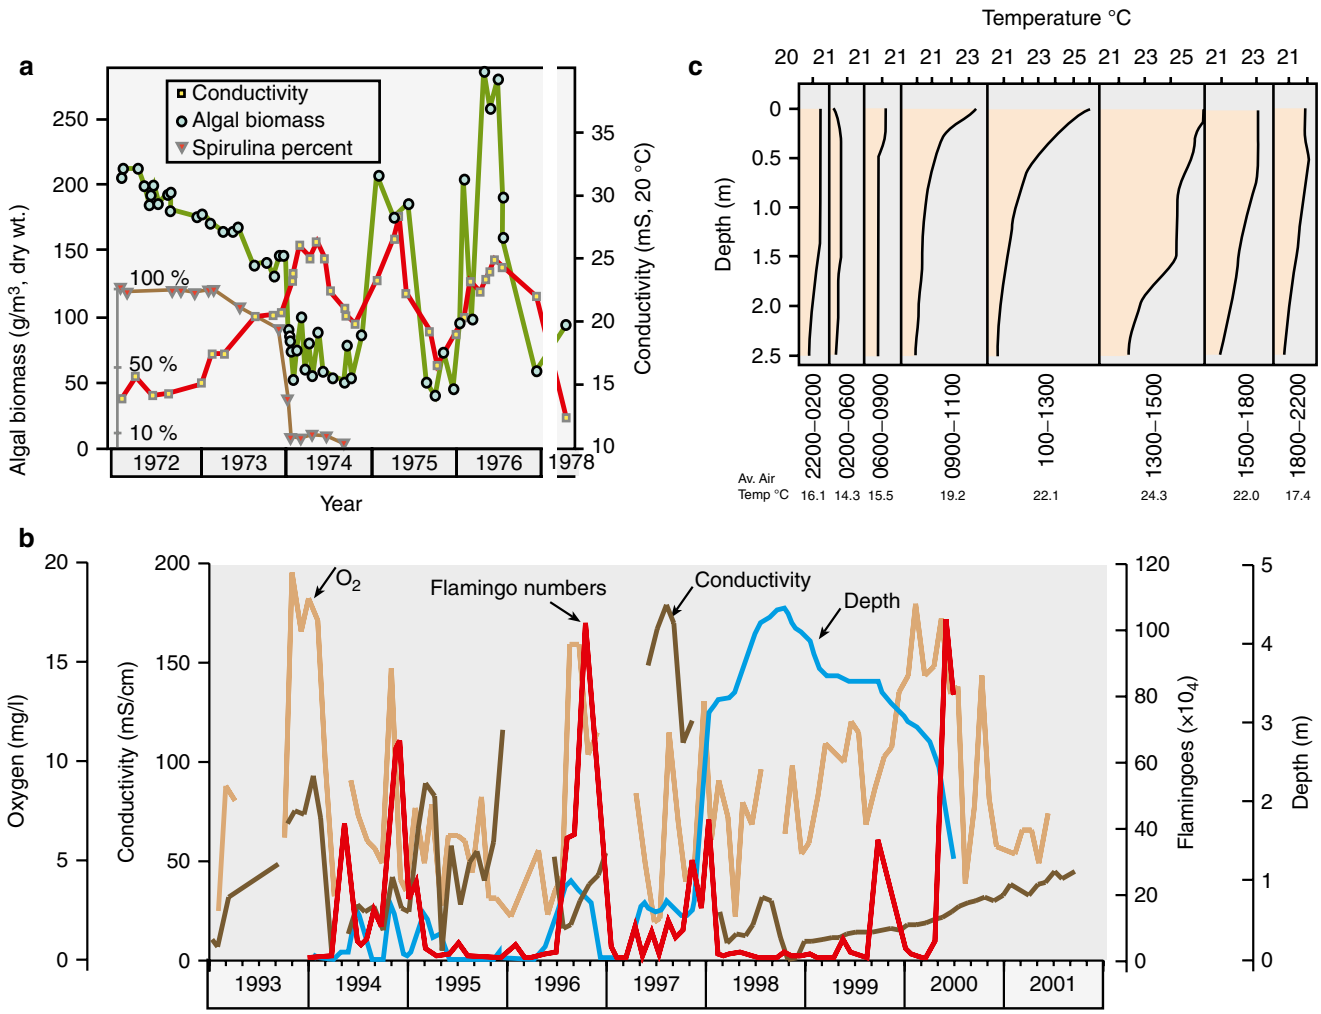

Fig. 9.40 Lake Nakuru. (**a**) Trends of algal biomass and conductivity of lake water during 1972–1978. The percent contribution of *Arthrospira platensis* to the total algal biomass is also shown. (**b**) Monitored water depths, conductivities, oxygen levels and flamingo numbers at Lake Nakuru for the period 1993 to mid 2001. Water depth and flamingo data only available from 1994 to mid 2000. Data is digitised and replotted to a common time scale from data in an online progress report by Odada et al. 2006 discussing conditions in the Lake Nakuru area (http://www.worldlakes.org last accessed Sept 24, 2012) (**c**) Mean water temperature profiles at different times of day from 1972 to 1973 (**a**, **c**: After Vareschi 1982)

the dense populations of *Arthrospira* function best at a preferred range of temperature and salinity, meaning acme populations tend to collapse irregularly and unpredictably in both Lake Nakuru and Bogoria, leading to highly-stressed malnourished flocks of flamingoes subject to mass dieback (Fig. 9.39; Vareschi 1978; Krienitz and Kotut 2010).

Arthrospira has high levels of the red pigment phycoerythrin and so when ingested in large volumes it accumulates in flamingo feathers to give the birds their world famous colouration, hence the "flamingo connection." Once digested, the carotenoid pigment dissolves in fats, which are then deposited in the growing feathers. The same effect is seen when shrimp change colour during cooking due to carotenoid alteration. The amount of pigment laid down in the feathers depends on the quantity of pigment in the flamingo's diet. Lesser flamingoes, with beak design maximised to feed on *Arthrospira* have a more intense pink colour in their feathers than greater flamingoes. The latter species sits higher in the Lake Nakuru food chain and so gets the slight pink tinge in its feather colour, mostly second-hand from the lake zooplankton, which also feed on *Arthrospira*.

As well as possessing very high levels of phycoerythrin in its cytoplasm, *Arthrospira* is also unusual among the cyanobacteria in its unusually high protein content (some ten times that of soya). This, and the high growth rate of this species, explains why Nakuru and Bogoria acme populations can support such spectacular population levels of flamingoes. A lack of cellulose in the *Arthrospira* cell wall means it is a source of plant protein readily absorbed by the gut, making it a potentially harvestable human food source in saline water

bodies in regions of desertification. In Lake Chad, and in some saline lakes in Mexico, *Arthrospira* accumulates as a lake edge scum that has been harvested for millennia by the local people (including the ancient Aztecs) and used to make nutritious biscuits.

When *Arthrospira* stocks are low in the rift lakes, the lesser flamingo can consume benthic diatoms. However, net primary productivity of benthic diatoms in East African soda lakes is one to two orders of magnitude less than that of *Arthrospira*, and the carrying capacity of the habitat with diatoms is lower by the same order (Tuite 2000). This lower productivity is seen in the peak 25,000 bird population, which are diatom feeders, in Laguna de Pozuelos in Argentina (Fig. 9.22; area ≈100–130 km^2, more than three times that of Nakuru, yet the peak flamingo numbers are two orders of magnitude lower).

In Lake Nakuru, *Arthrospira* and other lake plankton are also consumed by one species of introduced tilapid fish and one species of copepod and a crustacean. Rotifers, waterboatmen, and midge larvae also flourish in the mesohaline waters of Lake Nakuru. The mouth-breeding tilapid *Sarotherodon alcalicum grahami* was introduced to the lake in the 1950s to control the mosquito problem and fish-feeding birds (such as pelicans) have flourished ever since (Vareschi 1978). During times of nonoptimum water conditions, when either freshening or somewhat elevated hypersalinity lessens the number of *Arthrospira*, the tilapids can displace the flamingoes as the primary consumers of planktonic algae.

In 1972 Lake Nakuru waters held a surface biomass of 270 g/m^3 and an average biomass of 194 g/m^3 but, as in most hypersaline ecosystems, Nakuru's organic production rate varies drastically from year to year as water conditions fluctuate (Fig. 9.40a; Vareschi 1978, 1979). *Arthrospira* was in a long-lasting bloom in 1971–1973, and accounted for 80–100 % of the copious phytoplankton biomass in those years. In 1974, however, *Arthrospira* almost disappeared from the lake and was replaced by much smaller-diameter planktonic species, such as coccoid cyanobacteria that dealt better with elevated salinities. This transfer in primary producer make-up in the lake waters made the flamingoes less efficient feeders. When the relatively large filaments of *Arthrospira* dominate the lake plankton, a flamingo's beak filters between 64 and 86 % of the plankton held in each mouthful of lake water (Vareschi 1978). When the much smaller coccoids come to dominate the filters are much less efficient feeding mechanism. The change in plankton species was also tied to a serious reduction in algal biomass (and protein availability), which in 1974 was down to 71 g/m^3 in surface waters and averaged 137 g/m^3 in the total water mass. As a result the flamingo numbers feeding in the lake declined from 1 million to several thousands and the flamingoes moved to other lakes, like Bogoria, where *Arthrospira* were flourishing (Vareschi 1978).

The lower salinity limit for an *Arthrospira* bloom is ≈5‰ and it does better when salinity is more than 20‰. The species dominance of *Arthrospira* and its higher biomass in somewhat more saline lake waters is clearly seen in the near unispecific year-round biomass of nearby Lake Bogoria (salinity 40–50‰). Its surface salinity is higher year round than Lake Nakuru (salinity ≈ 30‰) and the somewhat fresher waters of Lake Elmenteita (salinity ≈ 20‰; Fig. 9.38a). Because of this, Lake Bogoria is a more reliable food source for feeding flamingoes compared to either Nakuru or Elmenteita. Birds tend to migrate there to feed when conditions for *Arthrospira* growth are not ideal in other nearby alkaline lakes (too fresh or too saline). This was the case in 1999 when high rainfall and dilution of lake waters caused the *Arthrospira* levels to fall in both Nakuru and Elmenteita. It was also true in late 2012 when Nakuru water levels were at near historic highs and the waters too fresh to support a healthy *Arthrospira* population.

The driving mechanism for the abrupt change in biomass in Lake Nakuru in the period 1972–1974 was not clearly defined. It was thought to be related to increased salinity and lowering of lake levels, driving the growth of coccoid species other than *Arthrospira sp*. that were better adapted to higher salinity, but offering less protein to the feeding birds (Fig. 9.40a; Vareschi 1978). There is also the simple fact that, in a lake with no surface outflow, ever more saline waters cover ever-smaller areas on the lake floor. There have been times in the last 70 years when most of Lake Nakuru has dried up and pools of saline water only a few tens of centimetres deep remained. This was the case in 1962 and most recently the case in 2008 (Fig. 9.38d).

After the lake level lows of the 1960s, during the mid to late 1970s and in the 1980s the Nakuru hydrology returned to more typical inherent oscillations in water level and salinity (schizohalinity). The flamingo populations in Nakuru returned to impressive numbers but followed the vagaries of *Arthrospira* blooms. Since the early 1990s more reliable long-term data sets on physical lake condition and flamingo numbers have been compiled (Figs. 9.39 and 9.40b). In that time frame, in 1993, 1995 1998, 2008 and 2012, the flamingo populations feeding in Lake Nakuru were once again at very low levels and the remaining bird populations were stressed and subject to mass dieback.

In 1998, unlike 1974, the stress on the flamingo population was related to lake freshening driving the decrease in *Arthrospira* biomass, not increased salinity and desiccation. In the preceding bountiful year (1996), the *Arthrospira*-dominated biomass had bloomed at times when salinities were favourable and died back at times of elevated salinities and lake desiccation, as in 1974. By 2000 formerly low salinities had once again increased making surface waters suitable for another widespread *Arthrospira* bloom and the associated return of high numbers of feeding flamingoes, which continued until 2007 (Fig. 9.40c).

Freshening favours a cyanobacterial assemblage dominated by picoplanktic chlorophytes (*Picocyctis salinarum*) and the nostocalean *Anabaenopsis*, the latter creates slimy masses that clog the flamingo's feeding apparatus. The combination drives much of the flamingo population to starvation (Krienitz and Kotut 2010). With freshening, comes also the possibility of the growth of strains that produce toxins (such as *Anabaenopsis* or *Microcystis*), possibly not in the feeding areas, which tend to remain too saline for *Microcyctis*, but in the spring waters where the flamingoes fly in order to bathe and cleanse their feathers (Kotut and Krienitz 2011).

It seems that breeding flamingoes come to Lake Nakuru to feed in large numbers when there is water in the lake with appropriate salinity and nutrient levels to facilitate an *Arthrospira* bloom. In some years when heavy rains occur, lake levels rise significantly and the lake waters, although perennial, stay in the lower salinity tolerance range for *Arthrospira platensis*, keeping cyanobacterial numbers and protein levels at the lower end of the spectrum, as in the El Niño period between October 1997 to April 1998. Once lake levels start to fall, salinities and rates of salinity change return to higher levels, then water conditions once again become appropriate for an *Arthrospira* bloom. But environmental stress on the flamingoes also comes with further elevated salinities and desiccation moving lake hydrochemistry into salinities at the upper end of *Arthrospira* tolerance.

One of the reasons Lake Nakuru is suitable for phenomenal cyanobacterial and algal growth at times of *Arthospira* bloom is the maintenance of suitable temperatures and oxygenation in the upper water mass, where the photosynthetic *Arthrospira* thrive. Nakuru develops a daily thermocline in the upper 1.5 m of the water column that dissipates each day in the late afternoon via wind mixing. Overturn recycles nutrients (derived from decomposition of bird and other droppings, including those of resident hippopotami) back to the oxygenated lit surface waters to facilitate an ongoing bloom the next day (Fig. 9.40c).

Numbers of flamingoes feeding in Lake Nakuru and Lake Bogoria are used in popular press as indicators of the environmental health of the lakes. Thousands of birds died in Lake Nakuru in 1995 and more than 30,000 birds may have died in Lake Bogoria in the first half of 1999. The most dramatic die-offs in the last decade were at Lake Nakuru in August 2006, when some 30,000 died, and Lake Bogoria in July 2008, when 30,000 birds died Some environmentalists have argued in the popular press that mass die-offs and their perception of lowered numbers of flamingoes in Lake Nakuru and Lake Bogoria in the 1990s were indicators of uncontrolled forest clearance, an uncontrolled increase in sewerage encouraging eutrophication, and increase in heavy metals from increasing industrial pollutants in the lake, along with general stress on the bird population from tourists and the drastic increase in local human population centred on the town of Nakuru (third largest in Kenya). Numbers of people in the town, which is the main city in the rift valley, have grown by an average of 10 % every decade for the past 30 years.

But like much environmental doomsday argument, it is more based on opinionated[18] prediction than on scientific fact. When numbers of feeding flamingoes in Lake Nakuru are compiled across last two decades it is obvious that flamingo numbers oscillate widely, but it is also obvious that the peak numbers in 2000s are equivalent to the peak numbers in 1990s. A notion of longterm fall in numbers of feeding flamingoes in the lake is not based on scientific reality.

Likewise, when studies were done on the cause of the mass dieoff in Lake Bogoria in 1999, it was found to have a natural not an anthropogenic cause (Krienitz et al. 2003; Ballot 2004). The flamingoes had ingested the remains of toxic cyanobacteria that constitute part of the population of the microbial mats that had bloomed to form a floor to the fresh water thermal spring areas about the lake edge. There the mats are dominated by thermally tolerant species; *Phormidium tere-briformis, Oscillatoria willei, Arthrospira subsalsa* and *Synechococcus bigranulatus*. The influence of cyanotoxins in the deaths of the birds is reflected in autopsies which revealed: (a), the presence of hot spring cyanobacterial cells and cell fragments (especially Oscillatoria willei), and high concentrations of the cyanobacterial hepato- and neurotoxins in flamingo stomach contents and faecal pellets; (b), observations of neurological signs of bird poisoning – birds died with classic indications of neurotoxin poisoning – the ophistotonus behaviour (neck snapped back like a snake) of the flamingoes in the dying phase, and the convulsed position of the extremities and neck at the time of death. Cyanobacterial toxins in stomach contents, intestine and faecal pellets were 0.196 g g^{-1} fresh weight (FW) for the microcystins and 4.34 g g^{-1} FW for anatoxin-a. Intoxication with cyanobacterial toxins probably occurred via uptake of detached cyanobacterial cells when birds come daily to the springs to drink and wash their feathers after an overnight feeding session in the saline waters of the lake proper.

When heavy metal studies were undertaken in Nakuru lake sediments, the amount of heavy metals (Cd, Cr, Cu, Hg, Ni, Pb, Zn) were found to be in the typical range of metals in

[18] Aka a "Chicken Little" or "the sky is falling" attitude to the world: such reportage, so popular in much of the world's newsprint and in the religious extremes, be it reporting environmental Armageddon, the "end of peak oil," or the coming of the next prophet, sells more newspapers and gets more zealous believers than any "good news" stories or fact-based analysis and discussion. In the prevailing zeitgeist, being a skeptic and advocating testing of all hypotheses (the basis for scientific endeavour) is considered a negative position; The questions; Leading questions, so common with the popular press, like; "When did you last beat you wife?" and "Are you a climate skeptic?" and your ability to reply without prejudicing popular perceptions is key. Otherwise when you answer either question with statement like "I don't beat my wife" or "The proposition that climate change since the start of the Industrial Age ties mostly to anthropogenic causes, is still equivocal," typically puts you in the same place in the minds of the true believers Prejudice be it green, left wing, right wing, religious or otherwise will always color the perceptions of such a listener.

sediments in lakes worldwide. The exception is Cd, which is elevated and can perhaps be ascribed to anthropogenic activity (Svengren 2002). All other metals are present at low levels, especially if one considers that Lake Nakuru lies within a labile catchment where the bedrock is an active volcanogenic-magmatic terrane.

Rise and fall of lake levels, drastic changes in salinity, a periodically stressed biota, and a lack of predictability in water character are endemic to life in saline ecosystems (cycles of "feast or famine"). Natural variations controls the number of feeding flamingoes in Nakuru and Bogoria. Oscillations in one or more of these factors are not necessarily anthropogenically induced. In general, sufficient base-line scientific data in these schizohaline ecosystems is not yet available and so accurate determinations of the relative import of increased human activity versus natural environmental stresses on longterm bird numbers are not possible.

Nearby Lake Magadi is also characterised by seasonal freshening, high productivity levels and bright red waters. In this case the colour comes from haloalkaliphilic archaea, not cyanobacteria. Archaeal species belonging to the genera *Natronococcus*, *Natronobacterium*, *Natrialba*, *Halorubrum*, *Natronorubrum and Natronomonas*, all occur in soda brines of Lake Magadi. Lake centre brines where this biota flourishes is at trona/halite saturation with a pH up to 12. Stratified moat waters around the trona platform edge are less chemically extreme and moat bottom sediments preserve elevated levels of organics (≈6–8 %). Lake Magadi also harbours a varied anaerobic bacterial community in the moat waters, including cellulolytic, proteolytic, saccharolytic, and homoacetogenic bacteria (Shiba and Horikoshi 1988; Zhilina and Zavarzin 1994; Zhilina et al. 1996). When the homoacetogen *Natroniella acetigena* was isolated from this environment its pH growth optimum was found to be 9.8–10.0, and it continued to grow in waters with pH up to 10.7 (Zhilina et al. 1996).

Regionally, salinities in the east African rift valley lakes range from around 30–50‰ total salts (w/v) in the more northerly lakes in the rift (Fig. 9.32a; Bogoria, Nakuru, Elmenteita, and Sonachi) to trona and halite saturation (>200‰) in lakes to the south (Lakes Magadi and Natron). Yet across this salinity range a combination of high ambient temperature, high light intensity and a continuous resupply of CO_2, makes some of these soda lakes amongst the highest in the world in terms of their seasonal planktonic biomass (Grant et al. 1999) and also places them among the world's most productive ecosystems (Fig. 9.37; Melack and Kilham 1974). Organic production is periodic, and pulses of organic product periodically swamp the ability of the decomposers and so accumulate as laminites in the lake centres.

As we have seen, the less alkaline lakes are dominated by periodic blooms of cyanobacteria, while the hypersaline lakes, such as Magadi, can on occasion support blooms of cyanobacteria, archaea and alkaphilic phototrophic bacteria (Jones et al. 1998). Halotolerant and halophilic biota living in the variably saline and layered water columns constitute small-scale "feast or famine" ecosystems, which at times of "feast" are far more productive than either tropical seagrass meadows or zones of marine upwelling (Fig. 9.37).

The "flamingo connection" supports a general observation that short periods of enhanced organic productivity are followed by episodes of lessened productivity in various schizohaline lake waters worldwide. It reflects the general principle that increased environmental stress favours the survival of a few well-adapted and specialised halotolerant species adapted to the feast and famine life-cycle that exists in most saline depressions. This same general principal of schizohaline ecosystems can be clearly seen in the decrease in invertebrate species (grazers and predators) with increasing salinity in the carbonate lakes of the Coorong of Southern Australia, where only brine shrimp remain alive in waters with salinities in excess of 200‰ (Fig. 9.41).

"Feast or Famine" in the Dead Sea

Effects of occasional freshening on biomass in stratified brine columns that are supersaline, not mesohaline, is clearly seen in the present "feast or famine" productivity cycle of the Dead Sea (Figs. 9.42 and 9.43; Oren and Gurevich 1995; Oren et al. 1995; Oren 2005). *Dunaliella sp*., a unicellular green alga variously described in the past as *Dunaliella parva* or *Dunaliella viridis*, is the sole primary producer in the Dead Sea waters. Then there are several types of halophilic archaea of the family Halobacteriaceae (prokaryotes) which consume organic compounds produced by the algae.

Two distinct periods of organic productivity (feast) have been documented since the Dead Sea became holomictic in 1979 (Oren 1993, 1999). The first mass developments of *Dunaliella sp*. (up to 8,800 cells/ml) began in the summer of 1980 following a dilution of the saline upper water layers by the heavy winter rains of 1979–1980 (Fig. 9.42a, b). The rains drove a rapid rise of 1.5 m in lake level and an increase in the level of phosphates in the lake's surface waters (Fig. 9.42c). This bloom was quickly followed by a blossoming in the numbers of red halophilic archaea (2×10^7 cells/ml), *Dunaliella* numbers then declined rapidly following the complete remixing of the water column and the associated increase in salinity of the upper water mass. By the end of 1982 *Dunaliella* had disappeared from the main surface water mass. Archaeal numbers underwent a slower decline.

During the period 1983–1991 the lake was holomictic, halite-saturated and no *Dunaliella* blooms were observed. Viable halophilic and halotolerant archaea were probably present in refugia about the lake edge during this period, but in very low numbers. Then heavy rains and floods of the winter of 1991–1992 raised the lake level by 2 m and drove a new episode of meromictic stratification as the upper five metres of the water column was diluted to 70 % of its normal

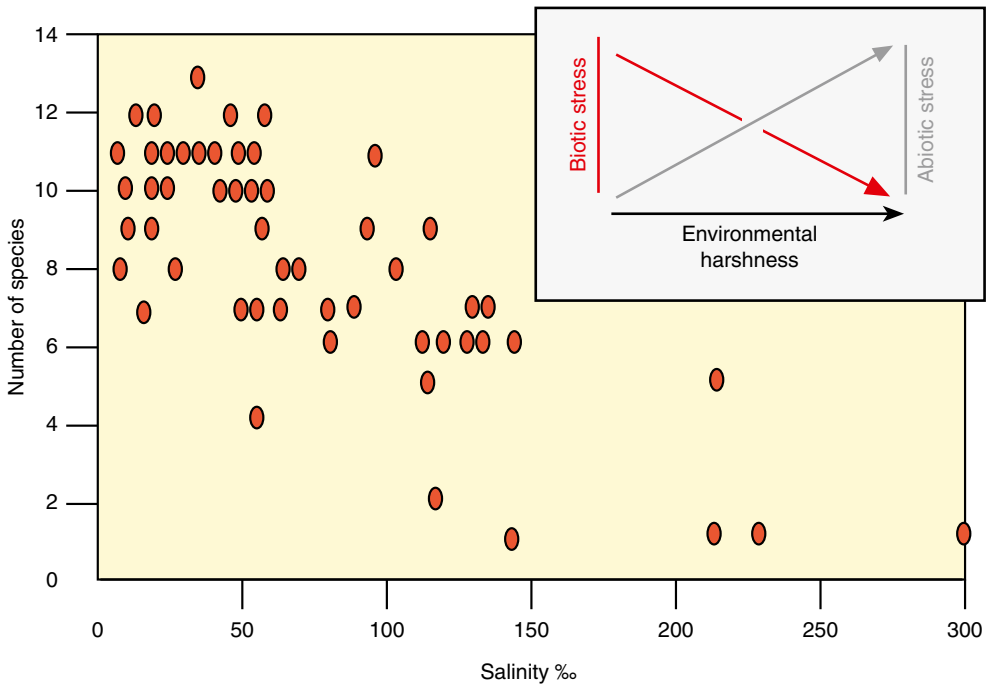

Fig. 9.41 Effect of increasing salinity on metazoan species diversity in the saline lakes of the Coorong region, South Australia (After De Deckker and Geddes 1980)

surface salinity (Fig. 9.42). High densities of *Dunaliella* reappeared in this upper less saline water layer (up to 3×10^4 cells/ml) at the beginning of May 1992, rapidly declining to less than 40 cells/ml at the end of July 1992 (Fig. 9.43). An associated bloom of heterotrophic haloarchaea (3×10^7 cells/ml) continued past July and continued to impart a reddish colour to the surface and nearsurface waters.

Much of the archaeal community was still present at the end of 1993 but the amount of carotenoid pigment per cell had decreased two- to three-fold between June 1992 and August 1993 (Oren and Gurevich 1995). A remnant of the 1992 *Dunaliella* bloom maintained itself at the lower end of the pycnocline at depths between 7 and 13 m (September 1992—August 1993), perhaps chasing nutrients rather than light. Its photosynthetic activity was low, and very little stimulation of archaeal growth and activity was associated with this algal community (Fig. 9.43). It seems that once stratification ends and the new holomictic period begins, the remaining Archaeal community, which was largely restricted to the upper water layers above the halocline, spreads out more evenly over the entire upper water column until it too dies out. No substantial algal and archaeal blooms have developed in the Dead Sea since the winter floods of 1992–1993 until mid 2015.

Colouration of the Dead Sea waters from the initial algal bloom allowed Oren and Ben Yosef (1997) to use Landsat images, collected in May 1991 and in April and June 1992, to plot the development of the *Dunaliella sp*. bloom. In contrast, the carotenoids of the subsequent archaeal bloom did not produce a recognizable spectral signal in the images. The April 1992 image obtained at the time of the onset of the algal bloom, prior to its lakewide spread, suggests it originated in shallow areas near the shore of the lake, where light penetrated to the bottom of the brine column. It was probably instigated by resting cells that had survived in near surface sediment of the shallow lake margin and were reinvigorated by the combination of lowered salinities and light.

The ultimate decline of the lakewide bloom of halophilic archaea in the Dead Sea appears to be related to viral infection (Oren et al. 1997). For example, in October 1994, during the decline of the halophilic archaeal population in the upper 20 m of the Dead Sea water column, there were between 0.9 and 7.3×10^7 virus-like particles per ml of brine. Virus-like particles outnumbered archaea by a factor of 0.9–9.5 (averaging 4.4). Water samples collected during 1995 contained low numbers of both archaea and virus-like particles (1.9–2.6×10^6 and 0.8–4.6×10^7 ml^{-1}, respectively in April 1995), with viral numbers sharply declining afterwards (less than 10^4 ml^{-1} in November 1995 January 1996). Oren et al. (*op cit*.) suggest that viruses play a major role in the decline of halophilic archaeal communities in many other hypersaline environments where protists and metazoa are absent.

Enhancement in organic productivity levels (feast) by well adapted, highly productive halotolerants during times of freshening in hypersaline settings is also seen in marine-margin mudflats For example, a study of benthic mats in Storr's Lake

in the Bahamas showed that a reduction in brine salinity from 90 to 45‰ significantly enhanced CO_2 and N_2 fixation rates, but additions of inorganic nutrients and dissolved organic carbons (DOC) did not show any significantly enhanced rates compared with the salinity controls (Pinckney et al. 1995). That is, dissolved organic carbon/dissolved organic nitrogen uptake in the mats was not influenced over the entire range of salinities (45–90‰) seen in this study of mesohaline growth. Rather, abiotic (osmotic) stress, induced by hypersaline conditions in these Bahamian lagoons, created lower productivity in the saline-tolerant (haloxene) microbial mats, even when nutrient levels were high. When the osmotic stress on the biota was relieved by a lowering of salinity, mats underwent enhanced primary production and nitrogen fixation. Changing nutrient levels were far less significant than changing salinity levels as controls on mat productivity. Salinity-induced stress in these halotolerant microbial mats outweighs nutrient levels, which are the typical limiting factor regulating phototrophic growth in normal marine and brackish waters.

Feast or Famine in the Messinian Lorca Basin, Mediterranean

"Feast or famine" cycles, as just noted in the African rift lakes and the Dead Sea, suggest that periodic freshening of surface waters in stratified brine bodies (usually by meteoric water or seawater influx) tend to facilitate the accumulation on an anoxic stratified bottom of organic-rich pulses of organic matter, dominated by halotolerant remnants. The notion that subsequent accumulation of a thick salt seal atop mesohaline source rocks, once the basin was cut off from a surface marine connection, helps explain the intimate association between evaporites and underlying or interbedded hydrocarbon seen in the many occurrences listed in Table 9.2.

For example, organic-rich evaporitic marls were deposited beneath stratified brines in the Lorca Basin, located within the tectonically evolving Betic Cordillera of southeastern Spain. It was a rapidly subsiding basin in an open-marine setting during much of the Miocene (Benali et al. 1995). By the Upper Miocene (Messinian) the basin was becoming more restricted and accumulating thick diatomite-bearing sediments (Tripoli Unit), which are overlain by the Main Messinian Evaporite series. This evolution from marls to gypsum/halite beds records the onset of the "salinity crisis" throughout the Mediterranean region (Fig. 5.50a). Restriction by the time of the deposition of the Tripoli Unit in the Lorca Basin led to intercalations of thin precursor evaporitic layers, mostly subaqueous and sabkha Ca-sulphates, with diatomites (Fig. 9.44; Rouchy et al. 1998). Prior to the main salinity crisis, the alternation of evaporites and diatomite cycles indicates periodic restriction and the development of mesohaline conditions, followed each time by an episode of marine reflooding.

Fig. 9.44 Lorca Basin, Spain, showing organic character of normal marine, mesohaline and evaporitic Messinian sediments with the richest organic contents in the mesohaline transition into evaporite deposits (After Benali et al. 1995)

Schizohalinity drove both the varying levels of primary production in surface waters and the preservation of organic matter in the hypersaline bottom sediments, finally culminating in widespread evaporative sedimentation in the latest Miocene. As basin waters evolved toward perennial hydrographic isolation and holomixis there were unusual evaporative conditions that heralded the main salinity crisis. These were a number of salinity stratified mesohaline surface floods when the resulting anoxic bottoms accumulated oil shales with up to 25 % TOC (Fig. 9.44; expanded section). When oil shales were accumulating, the system was meromictic; upper water mass was nutrient-rich and mesohaline with near normal marine salinities, while the bottom waters were anoxic and somewhat more saline than surface waters (Benali et al. 1995). Later in the basin history, when mixed gypsum marls and clastic gypsum sequences were accumulating, the oil-prone quality of any potential kerogen in the basin was diluted by rapid deposition of gypsum precipitates and an influx of oxidised organic detritus.

The formation of organo-sulphur compounds, replacement of sulphates by carbonates and the high levels of elemental sulphur are other byproducts of early diagenetic/microbial processes occurring in the Lorca oil shale. The high abundance of phytane, 2,3-dimethyl-5-(2,6,10-trimethylundecyl)-thiophene, mid-chain C_{20} isoprenoid thiophenes and bithiophenes and bis-O-phytanyl and O-phytanyl-O-sesterterpanyl glycerol ethers indicates that the organic matter in these sediments was deposited under anoxic hypersaline conditions (Table 9.8; Russell et al. 1997). Isopranyl glycerol ethers occur in sulphur-bound macromolecular matter, which contrasts with the low concentrations of these compounds as free lipids. However, the distribution of these isopranyl glycerols is paralleled by the occurrence of free phytanic acid in both the oil shales and intercalated laminated carbonates and by 3,7,11,15,19-pentamethyleicosanoic acid in the laminated carbonates. A high level of input from bacterial decomposers is indicated by 2-hydroxytetracosanoic acid, noctadec-11-enoic acid, hopanoic acids and the distributions of iso- and anteiso-C_{15} and C_{17} homologues and minor amounts of iso-C_{16} and anteiso-C14. These branched fatty acids are characteristic of sulphate-reducing bacteria, which would have inhabited the anoxic bottom brine. The relative proportions of the iso- and anteiso-compounds in the total fatty acid distributions are tied to the proportion of reduced sulphur in the sediments.

As in Lake Nakuru and the Dead Sea, cyanobacterial and halotolerant algal blooms in freshened surface waters created these organic-rich Messinian carbonates. Blooms of halotolerant species, followed by die back, drove cycles of "feast or famine" in the Lorca oil shales.

The Where and When of Productivity

Most biological studies in freshwater lakes and in the oceans have found that the highest levels of organic productivity (primary productivity) occur annually within the zone of maximum light penetration in the upper few metres of the water column. long-term salinity stratification or meromixis in the perennial waters of an evaporite basin, can change the locus of maximum organic productivity, especially in situations where the required nutrients lie at or below the halocline. Haloarchaea in the Dead Sea can survive by facultative photosynthesis long after their primary food source has died back (Fig. 9.43). But is there a more general layering of the halobiota in stratified brines where the chemical interface created by the coming and going of the halocline allows life to flourish via chemosynthesis, not photosynthesis? If so, then bacterial productivity in upper fresher waters of a layered brine column may come to rely on nutrients supplied from permanently saline and anoxic bottom waters.

Mahoney Lake is a small (19.8 ha), up to 15 m-deep meromictic oligotrophic mesohaline lake in British Columbia, Canada. The lake originated as a glacial kettle after the retreat of the Wisconsin ice sheet some 13,000 years ago. A halocline separates a variably oxygenated mixolimnion[19] from a permanently anoxic sulphidic monimolimnion at a depth of around 6 m in the lake brine column (Fig. 9.45a). Total dissolved solids vary from 10,000 mg/l near surface to 85,000 mg/l near bottom, with rapid changes across the halocline. It has been a saline meromictic/holomictic system for the last 9,000 years, with some meromictic episodes lasting as long as 1,100 years. The oldest sediment layers that contain okenone (a purple sulphur bacteria biomarker) are 11,000 years old, okenone likely also indicates times of brine stratification in the lake waters (Fig. 9.45b; Overmann et al. 1993, 1996). The high salt content of the bottom waters in this small endorheic basin is thought to be derived by weathering of alkali-rich Tertiary-age rocks of the Marron Formation. Heterotrophic bacterial production in the lower mixolimnion at times exceeds concomitant primary production in the upper waters of the same mixolimnion by a factor of 7 (Fig. 9.45c). In this highly productive sulphidic interval lives an extremely dense population of the phototrophic purple sulphur bacteria *Lamprocystis purpurea* (aka *Amoebobacter purpureus*, which is present year round as a layer or "bacterial plate" centred on the lake halocline (Klepac-Ceraj et al. 2012). The Mahoney Lake halocline harbours the densest population of phototrophic sulphur bacteria ever reported in a natural body of water. It is sufficiently abundant to form the base of a food chain, where it constitutes 70 % of the diet of planktonic copepods living in the upper water mass.

Each year, following ice melt, a layer of freshened water enters the lake, renewing a well-defined uppermost oxygenated layer (mixolimnion), which disappears within a few months. For example, the stability of the mixolimnion declined sharply between May and July 1993, in parallel with the disappearance of the low-salinity uppermost surface water layer, the warming of the lower waters of the mixolimnion, and the resulting loss in density stratification (Fig. 9.45c; Overmann et al. 1996). This allowed mixing across the perennial halocline and the release of nutrients into the lower parts of the mixolimnion. For most of an annual cycle any bacterial growth in the lower mixolimnion is limited by the supply of inorganic phosphorus or nitrogen, which can come from above or below. In Mahoney Lake, liberation of phosphorus from upwelling of the remains of purple sulphur bacteria in the lower waters, and degradation of allochthonous dissolved organic carbon floating at the halocline, act as a carbon source for the bacteria and so render heterotrophic bacterial production largely independent of photosynthetic phytoplankton cycle in the overlying waters of the uppermost mixolimnion.

That is, the *L. purpurea* layer acts as a 'nutrient cap,' limiting the upwelling of nutrients, it also acts as a shading sheet, so beneath it there is little light penetration (Overmann et al. 1996). Enrichment cultures from the bacterial plate suggests it contains very few *Chlorobiaceae* (green sulphur bacteria). Lake sediments are correspondingly rich in the pigment okenone, a biomarker for *Chromatiaceae*, and they lack isorenieratene, a biomarker for *Chlorobiaceae* (purple sulphur bacteria – Table 9.8). Analogously, okenone diagenetic products in sediments and sedimentary rocks are diagnostic of ancient, highly euxinic systems with penetration of sulphide only to

[19] Jargon of lacustrine stratification

Mixolimnion: the upper, low density, freely circulating water layer of a meromictic lake.

Monimolimnion: the deep, usually salty, layer of a meromictic lake typically it is a perennially stagnant or noncirculating water mass.

Meromixis: a condition in a lake (meromictic lake) where the bottom noncirculating water mass is adiabatically isolated from the upper water mass.

Holomixis: a condition in a lake describing complete overturn and mixing of the lake water mass.

Hypoliminion: is the lowermost water mass in a lake, characterised by a generally uniform temperature (or density) profile.

Eutrophic lake: a lake characterised by an abundance of nutrients and a seasonal deficiency of oxygen in the hypolimnion. Waters are usually shallow and sediments are organic-rich laminites.

Oligotrophic lake: a lake characterised by a deficiency in nutrients. The bottom sediments typically contain low levels of organics and the water column is deep.

Monomictic Lake: A lake which undergoes one period of complete mixing during the year separated by one period of thermal stratification.

Both were measured simultaneously during incubation around solar noon (After Overmann et al. 1993, 1996)

shallow depths within the photic zone (see Table 9.2; the 1.7 Ga Barney Shale in Northern Australia).

The nature of the sulphidic microbial community that resides in the aphotic hypolimnion and/or in the lake sediments is poorly known, and it is unclear whether the sulphate reducers that supply sulphide for phototrophy live only within, or also below, the plate of purple sulphur bacteria centred on the halocline. Klepac-Ceraj et al. (2012), profiled distributions of 16S rRNA genes and suggest that microbial diversity is greatest in the hypolimnion (down to 8 m) and in the bottom sediments. They found biotal diversity is lowest in the photosynthetic plate (>7 m). Shallower depths (5–7 m) are rich in Actinobacteria, Alphaproteobacteria, and Gammaproteobacteria, while deeper depths (up to 8 m, bottom sediments) are rich in Crenarchaeota, Natronoanaerobium, and Verrucomicrobia. The heterogeneous distribution of Deltaproteobacteria and Epsilonproteobacteria between 7 and 8 m is consistent with metabolisms involving sulphur intermediates in the halocline, with sulphate reduction in the hypolimnion (Fig. 9.45a).

Similar purple bacterial layers cap the haloclines of brine lakes on the deep seafloor of the Urania Basin in the Mediterranean Sea. The bacterial community utilises sulphur compounds crossing the brine interface from anoxic waters below and thrives many thousands of metres below the photic zone (Sass et al. 2001). Sulphur-oxidising bacterial communities, independent of light penetration, probably occur atop marine suprasalt brine-lake haloclines worldwide.

The effect of salinity stratification on productivity in many saline lakes does not follow the predictable annual cycle seen in saline Lake Mahoney and in most freshwater temperate dimictic lakes (dimictic = seasonally mixed). This lack of annual cyclicity in the organic production is clearly seen in the timing of meromictic stages of the Dead Sea (Fig. 9.43).

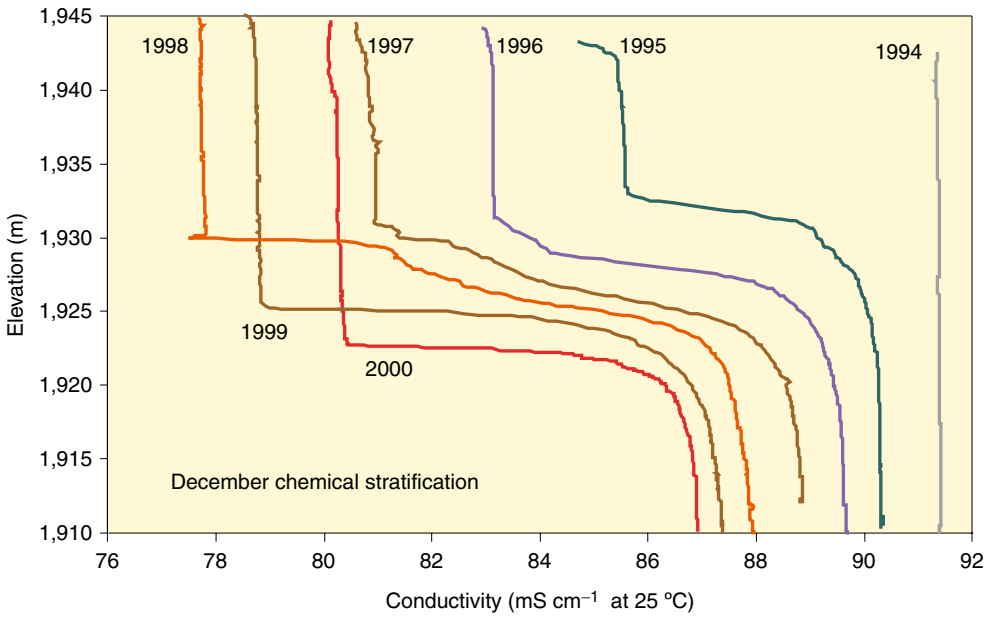

Fig. 9.46 Mono Lake, California, conductivity profiles in December for the years 1994–2000 (Figure was redrafted from a database downloaded from http://www.monobasinresearch.org/data/, last accessed Jan. 15, 2013)

Multiple years of stratification without breakdown (meromixis) is also characteristic of Mono Lake, California where photosynthetic activity was measured in its hypersaline and stratified waters during an 8-year period from 1982 to 1990 (Jellison and Melack 1993). Exceptionally large volumes of freshwater runoff in 1982 and 1983 led to a 2.6-m rise in surface elevation of Mono Lake and the onset of a new period of meromixis in the lake (Fig. 4.23). In 1984 chemical stratification accounted for a density difference of $1.2–1.5 \times 10^{-2}$ g/cc between the 2 and 28 m water depths. At the same time the midsummer density difference between 2 and 28 m depths that was due to temperature was approximately 0.5×10^{-2} g/cc. Salinities ranged from 77 to 98 g/l across the interface and sodium, chloride, sulphate, and carbonate were the major ions in both the upper and lower water mass.

This 8-year time frame in Mono Lake spans the onset (1983), persistence (1984–1987), and breakdown of meromixis (1988). Following the onset of meromixis, the algal biomass in the lake each spring and autumn decreased from 1984 to 1986: annual primary photosynthetic production was reduced from 269 to 462 gC m^{-2} $years^{-1}$ (1984–1986) compared to nonmeromictic conditions of 499–641 gCm^{-2} $years^{-1}$ (1989 and 1990). A gradual increase in photosynthetic production then occurred, even before meromixis ended, because of increased vertical flux of ammonium from the anoxic saline bottom, due to deeper mixing and the buildup of ammonium in the monimolimnion. Annual primary production in the lake was greatest in 1988 (1,064 gCm^{-2} $years^{-1}$) when the weakening of chemical stratification and eventual breakdown of meromixis in November of that year allowed a large upward influx of ammonium (source of nitrogen) into the photic zone.

Another transition from monomixis to meromixis occurred in Mono Lake from 1994 to 1995 (Fig. 9.46; Melack and Jellison 1998). During the preceding monomictic conditions in 1993 and 1994, the lake had thermally stratified in March and had mixed to the bottom by each December. During meromictic conditions in 1995, 1996 and 1997, the absence of holomixis during winter once again resulted in persistent anoxic conditions beneath the chemocline, the accumulation of ammonium in the monimolimnion, its depletion in the mixolimnion, and low mixolimnetic chlorophyll concentrations in the spring and autumn. The meromictic state continued until mixing in 2003 and was preceded by a trend of year-to-year deepening of the chemocline, which indicates increasing liability to mixing in a meromictic lake. The same deepening of the halocline marks the transition to holomixis in the Dead Sea (Fig. 4.43).

The TOC content of a core through the laminites of Mono Lake, sampling the last 300 years, shows an overall tendency toward increasing TOC content in the period 1700–1800, then a consistent trend hovering around 6 % but with wider variations in TOC in the last 60 years, since the diversion of the inflow to the Los Angeles water supply in 1941 (Fig. 9.47; Benson et al. 2003). The highest values of TOC in the core occur in this time frame, 14 % around 1970, as do some of the lowest, e.g., around 4 % in 1943 and 1980. Clearly, the perennially anoxic saline bottom waters of the lake, with a pulse of productivity (a time of feast) in those years when the lake transitions from meromictic to holomictic, have facilitated the preservation of organics at levels that in ancient counterparts would characterise a source rock. Whether the fluctuations in TOC levels in the bottom sediments reflect varying intensities in algal blooms or some other factor related to the volume of organics reaching the bottom is not yet defined.

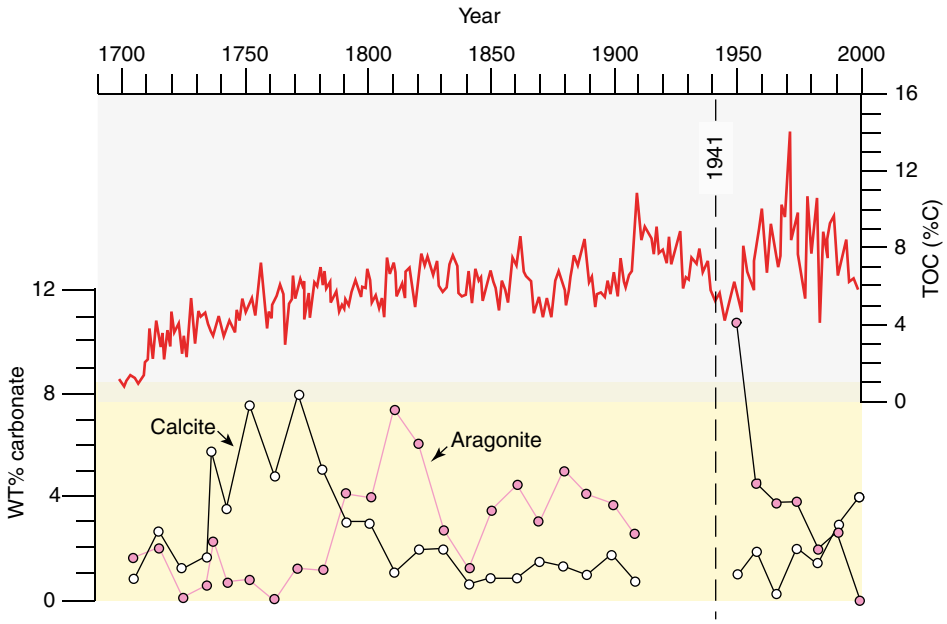

Fig. 9.47 TOC and carbonate proportions in a core through Mono Lake laminites deposited in the last 300 years (After Benson et al. 2003)

Predicting Preservation of Benthic Organics

Predicting how organic productivity in surface waters relates to organic preservation under a variable layered brine column is difficult. It is commonly assumed in source rock modelling that saline waters at the base of a stratified saline water column are anoxic and will always favour the preservation of organic matter product by plankton (Demaison and Moore 1980). The effectiveness of stratified brines in the preservation of pelagic organic matter originally produced in photic and oxygenated water is especially obvious when comparing open marine and density-stratified hypersaline environments. Estimates for the preservation efficiency of primary organic matter in the modern shallow open-marine oxygenated bottoms centre around 0.1 % (Menzel and Ryther 1970), while on the floor of the anoxic Black Sea it is about 4 % (Deuser 1971). In contrast, preservation efficiency beneath density-stratified hypersaline lakes and epeiric seaways subject to times of feast or famine can be as high as 85 % (Hite and Anders 1991). This vast improvement in preservation in part reflects the "salting effect" of a perennial dysaerobic to anoxic saline bottom brine layer and the periodic proliferation of a photosynthetic biomass in a freshened upper brine body. Plankton that is blooming in a stratified brine column is liable to mass mortality as ongoing evaporation increases nearsurface salinities to intolerable levels ("feast or famine"). Schizohaline surface waters means most organic-rich evaporitic mesohaline sediments are deposited as laminites, facilitated by repetitive "life and death cycles" in the halobiota (Warren 1986).

Yet mesohaline to moderately penesaline bottom waters of some density-stratified shallow modern brine lakes are oxygenated, not anoxic. Bottom microbial mat communities below such waters are dominated by halotolerant oxygen-producing photosynthesising benthic cyanobacteria. These benthic primary producers create and maintain elevated oxygen levels in the well-lit bottom waters immediately above the mat and are the hypersaline equivalents of marine seagrasses. But, benthic microbial mats tend to be anoxic no more than a few millimetres below such photosynthesising surface layers of microbes (Fig. 9.30). Burial via mat aggradation tends to quickly move newly created cyanobacterial organics into an anoxic regime, where organic preservation is much more likely. An association of permanent bottom hypersalinity and anoxia a few mm below the sediment brine interface, tends to prevent burrowers from entering the bottom sediment in a mesohaline bottom covered by microbial mats. Burrowing is a major mechanism for maintaining oxygenation in normal marine sediment, where it tends to prevent substantial accumulations of organic matter in marine water covered bottom sediments.

Lake Hayward, Australia is meromictic and a good case in point; it is a shallow perennial hypersaline coastal salina filled by brines less than 2 m deep. Photosynthesis via its benthic microbial mat community, is normally sufficient to supersaturate the bottom with dissolved oxygen, even during periods of brine column stratification, yet bottom sediments contain 5–7 % TOC (Burke and Knott 1997). Laminated microbial mats in the permanently submersed mesohaline centre of the lake are dominated by photosynthesising cyanobacteria *Cyanothece sp*., while *Microcoleus sp*. are dominant in the biolaminites of the lake's seasonally desiccated strandzone. In daylight the oxygen saturation can be as high as 270 % in the uppermost photosynthesising mat and the immediately overlying bottom waters (Burke 1995).

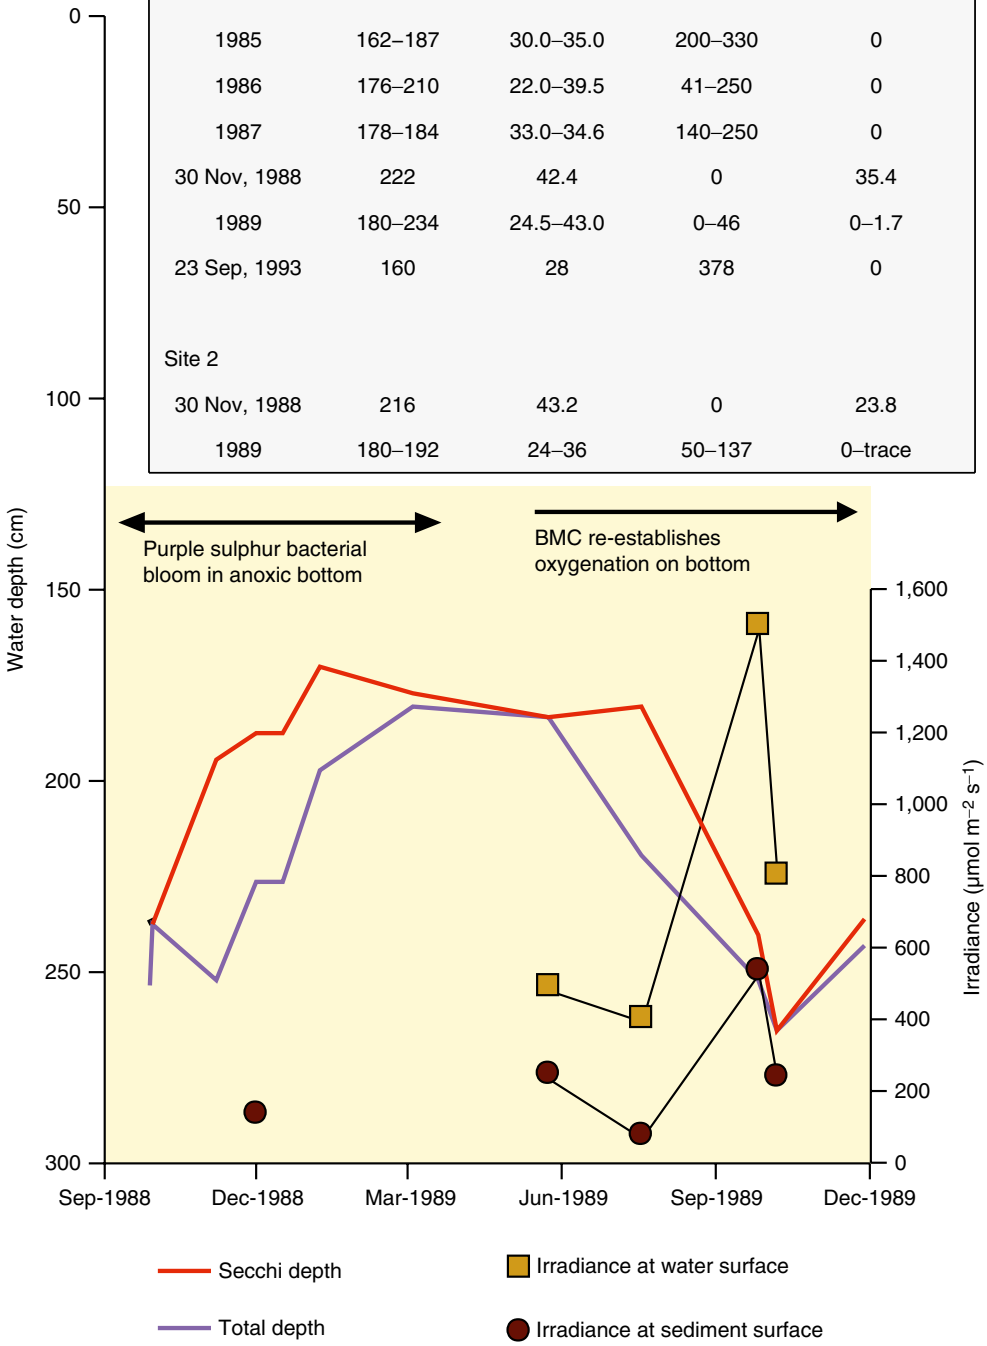

Fig. 9.48 Effect of gypsum precipitation on benthic microbial communities and oxygenation in Lake Hayward, West Australia (Compiled from data in Burke and Knott 1997)

However, after an unusually dry year in 1987, the lake salinity in the upper waters increased to 260 g/l and gypsum precipitated in upper portions of the lake water column (Fig. 9.48; Burke and Knott 1997). Turbidity generated by gypsum crystallisation in the brine mass was sufficient to obscure the benthos completely, despite the shallowness of the lake (secchi curve in Fig. 9.48). As a result, the amount of benthic oxygenic photosynthesis was greatly reduced and benthic mats began to decay. During brine stratification in the following winter (1988), bottom waters became anoxic and supported a healthy population of purple sulphur-oxidising bacteria.

However, during the next few years, after each subsequent brine column overturn, healthy cyanobacterial mats were

reestablished and they were able to again supersaturate the bottom waters with oxygen year round. It seems that the development of a healthy microbial benthic mat community in Lake Hayward prevents periodic bottom anoxia, whereas nearby meromictic lakes, that do not contain a healthy halotolerant microbial benthos, tend to annual anoxia during stratification. The lake illustrates a general principle that healthy halotolerant microbial mat functions as a strong homeostatic mechanism in allowing longterm stability of elevated oxygen levels in bottom waters of the shallow brine lake, but an increase in salinity can make the bottom anoxic.

Gypsum precipitation in the brine column is not the only cause of brine column turbidity and bottom anoxia in shallow waters. Planktonic blooms (a time of feast) can also substantially reduce light penetration to the bottom of a shallow brine lake (Horsfield et al. 1994). If the bloom is intense it can prevent benthic cyanobacteria from photosynthesising. The shaded part of system eutrophies as decomposing planktonic remains rain down through the now dark brine column. Decomposition in the upper portions of the column uses up all the oxygen in the water column. The oxic-anoxic interface rises from the sediment into the brine column, killing off any oxygen-requiring benthic species. Such hypertrophication overwhelms the delivery of oxygen to the bottom by the photosynthetic benthos and facilitates higher levels of organic delivery to bottom sediments than occurs with the benthic mats. This eutrophic and slimy bottom style of deposition naturally characterises the central portions of Solar Lake, Egypt (Fig. 4.12). It may explain why the TOC of its bottom sediments, accumulating beneath pore waters that are perennially anoxic, are elevated compared with microbially-bound bottom sediments of Lake Hayward (15–20 % versus 5–6 %).

In a study of eutrophication in modern saltfields Javor (2000) found that in shallow gypsum and the pre-gypsum ponds there was an interesting inverse relationship between the level of nutrients (nitrates and phosphates) in the brine column and the development of microbial mats on the water covered pan floor. In a high nutrient brine system (eutrophic or well-nourished) the algae and bacteria flourished as planktonic forms and the biomass buildup in the upper parts of the brine column tended to shade the sediment surface so that there was little or no development of a microbial mat and bottom waters were dysaerobic to anoxic. In a low nutrient (oligotrophic) system there was little or no planktonic development of algae or bacteria and microbial mats tended to flourish on the perennial pond floor. She found benthic mats in low nutrient systems formed from salinities of 50,000 ppm to gypsum saturation. At lower salinities benthic mats were destroyed by the feeding activities of invertebrates and fish.

Most benthic microbial mats beneath hypersaline waters depend, in large part, on nutrients recycled by the bacterial decomposers that make up the underside of the living part of the mat. Even if nitrogen and phosphorus levels in the overlying brines are low, there may be sufficient nutrient recycling within the mats to allow the bottom mats to continue to grow. Javor (*op. cit.*) found that once a gypsum crust becomes well established over the floor of a crystalliser pond there was little recycling of nutrients from beneath the crust. From this point downstream in the crystalliser pans, nitrate and phosphate nutrients concentrated by evaporation were recycled into the biomass living in the brine column and not within the benthic mat. In oligotrophic gypsum ponds the gypsum crust is stable and the bottom waters are oxygenated. In eutrophic gypsum ponds at the same salinities the bottom waters become anoxic and sulphate-reducing bacteria flourish. In these systems the gypsum dissolves and the bottom is typically covered by a black slimy organic-rich mud, containing no more than a few embayed and dissolved gypsum remnants, much like the central facies in Solar Lake. If portions of this slimy bottom become suspended and are flushed into the next stage of the crystalliser brine stream they create a problem in the final product known as "black spot." Brine shrimp are often added to the mesohaline ponds of a saltworks to control planktic blooms and so minimise "black spot."

That organic enrichment occurs naturally in the mesohaline carbonate stage and not in subsequent gypsum or halite layers is clearly seen in the evaporitic marls and salts of the Oligocene Mulhouse Basin (Fig. 9.49; Hofmann et al. 1993b). This deposit is one of a few ancient evaporitic settings where organic chemistry has been studied in a detailed fashion, rather than as generalisations from spot samples. Organic matter occurs mostly in finely laminated carbonate marls (varves), which can contain up to 7 % TOC, anhydrite beds contain 0.08–0.78 % TOC, halite beds 0.01–0.25 % TOC and the potash beds <0.1 % TOC. The marls are characterized by thin, continuous bedding-parallel laminae that are not disturbed by any bioturbation.

Layering is interpreted as seasonal varves with the clay and carbonate forming alternate sheets in the couplet (see inset in Fig. 9.49). In spring and summer the increased temperature in surface waters favoured precipitation of micritic carbonate, in autumn and winter the phytoplankton died back and rainfall/runoff transported clastic debris into the basin. On the basis that the laminar couplets in these mesohaline carbonates are varves, Hofmann et al. (1993b) were able to plot the relationship between sedimentation rate and TOC content in the marls (Fig. 9.49). Marls deposited during times of low sedimentation rate tend to be organic-rich, while marls deposited at times of higher sedimentation tend to contain lower amounts of organics. They concluded that the even-lower levels of organics typifying the more saline salt beds (anhydrite and halite) indicate even more dilution, due to inherently higher sedimentation rates.

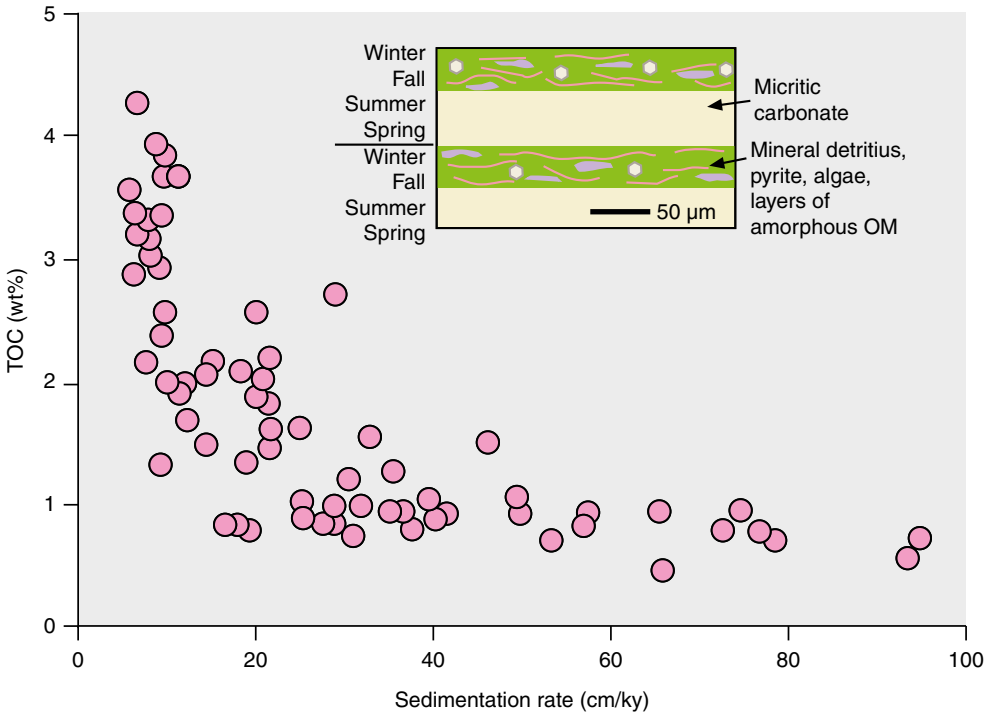

Fig. 9.49 Sedimentation rate versus percent of total organic carbon content (*TOC*) in laminite marls from the Oligocene evaporites of the Mulhouse Basin, Europe. *Inset* shows the scale and mineral/organic distribution in the laminae (varve couplets) of the sampled intervals (After Hofmann et al. 1993b)

Proximity of organic-rich mesohaline laminites to ancient bedded evaporites has lead some geologists to postulate that bedded salts are potentially also organic-rich sediments with the same level of source potential as mesohaline carbonates. This is not borne out by TOC analysis of evaporitic salts in the Mulhouse Basin. Likewise, worldwide measurements of total organic matter levels in ancient $CaSO_4$ and NaCl lithologies tend to be normal or depleted (Katz et al. 1987). Mesohaline carbonates, not higher salinity salts, are the source rocks to many ancient evaporite-associated reservoirs (Fig. 9.4). But, levels of dissolved organic matter and volatile fatty acids rise in increasingly saline brines and may be considered potential mobile or liquid sources if caught up in intercrystalline interstices and inclusions (Hite and Anders 1991). Levels of DOM and VFA may be high in such penesaline salts and could be released in the subsurface when halite beds are dissolved by crossflows of surface brines. But in general the typically low levels of solid organic matter in bedded halite reflects the higher depositional rates of evaporitic salts when compared with evaporitic carbonates (dilution effect). Under the same rate of supply of detrital organics, the higher rate of halite accumulation dilutes the associated organic content compared to carbonate sequences.

Whatever the finer controls on accumulation levels, observations of organic accumulations in modern and ancient mesohaline saline systems show that peaks or pulses in primary production ("feasts") in density-stratified brine lakes are controlled by two factors; (1) the occasional presence of an ephemeral less saline surface water mass, and (2) a periodic supply of nutrients (nitrate/ammonia and phosphate), possibly from a combination of inflow/runoff and leakage from the lower hypersaline water mass. The biota contributing the organic pulse, which ultimately reach the bottom sediments to form organic-rich laminae, are largely dependent on the timing of photosynthetic activity. Modern saline lakes with a well defined annual freshening of surface waters will deposit varved evaporitic carbonates (e.g., Lake Tanganyika with up to 7–11 % TOC in deep bottom laminites; Cohen 1989), while other brine lakes and seaways, with less predictable stratification, may form similar carbonate laminites, but the organic layering may not be annual (Dead Sea, Mono Lake analogs).

Populations of purple-sulphur oxidising bacteria define the position of the oxic-anoxic interface in hypersaline settings. They reside a few millimetres below the mat surface beneath shallow brines with healthy cyanobacterial mats on the bottom. In deeper brines they reside at the halocline. Shading of a healthy cyanobacterial mat, either by planktonic blooms or mineral saturation in the brine column, allows the oxic-anoxic interface to rise from within the mat into the brine column and bring with it its healthy population of purple bacteria. If organic debris from a planktonic bloom settles to the sediment surface at this time there is less likelihood it will be broken down by fermenters and decomposers before it is buried. Hence, elevated TOC levels from times of planktonic feasting are more likely to be preserved.

Life, Brine Seeps and Dissolving Salts

There is an association between chemosynthetic communities, saline anoxic bottom brines, biogenic limestone crusts organic-enriched laminites, metal sulphides and salt allochthons in some modern marine slope and rise settings (Warren 2000b). Historically, a relatively deep open marine setting was not considered an area where hypersaline bottom brines facilitated the accumulation of organic and metal sulphide-rich mesohaline sediments. Yet it is in seafloor settings where shallow salt allochthons are actively flowing and dissolving and, as such, is a zone of potential mesohaline source rocks (Fig. 9.4). So far, most of the scientific work on this topic is focused on the biogenic process sets visible in the brine seeps and mud volcanoes that typify parts of the seafloor underlain by flowing and dissolving salt.

As a rising allochthonous salt sheet reaches a position just beneath the seafloor it is dissolving from its edges inward, while at the same time it is releasing and focusing chloride-rich brines into its surrounds (Fig. 9.50a; Sassen et al. 2004). The brines are generally carrying varying combinations of liquid hydrocarbons and thermogenic methane from mature source rocks, as well biogenic methane and thermogenic liquids and gases from sediments caught up in rapidly subsiding sediments atop salt floored minibasins, and H_2S from thermochemical and biochemical reactions in lateral and crestal caprocks. Gassy and hydrocarbon-liquid bearing brines move along the salt edge, and associated faults, to feed seeps and vents to the seafloor.

Such brine-issuing vents are well documented in the 200–1000 m depths of the Gulf of Mexico and even deeper such as the 1,920 m-deep seafloor on top of Green Knoll, an isolated salt diapir rising seaward of the Sigsbee Escarpment in the northern Gulf of Mexico (Fig. 9.50a). There methane- and chloride-rich vent brines are supplied in part by congruent seawater dissolution of the underlying Louann salt, and in part by hydrocarbon-rich basinal waters escaping from deeper within the salt sealed sediment column (Table 9.9; Aharon et al. 1992). In the Gulf of Mexico, typically the venting Na-Cl brines are up to seven times saltier than ambient seawater and the geometry of their subsurface passage to the seafloor largely reflects breaks in the continuity of allochthonous salt sheets that underlie much of the continental slope (Thrasher et al. 1996; Sassen et al. 2004).

Venting of hydrocarbon-rich (methane) hypersaline anoxic brines onto the seafloor, both by lateral flow and by diffusion upward through the underlying clastic sediments, gives rise to characteristic seafloor seeps, with methane hydrates and methane-saturated anoxic brine lakes, ranging in diameter from 1 m to 20 km, and surrounded by a rim of bacterially-formed calcite-cemented crusts (Collett et al. 2009). The seeps are inhabited by methane-oxidising archaea. Their metabolic processes, in combination with bacterial sulphate reduction give rise to the characteristic set of seep carbonates that precipitate as nodules and sheets in the vicinity of the vent sites (Fu Chen et al. 2007). Likewise, only specialised microbes (extremophiles) inhabit the bottom waters and sediments of the brine lakes and mud volcanoes, while spectacular chemosynthetic mollusc-tube worm biostromes grow in normal marine waters about the brine lake and mud chimney edges. Venting hypersaline brines can either seep and dissipate via mixing with oxygenated marine bottom waters on the open ocean floor to form spectacularly red braided channel-ways or can seep into closed depressions on the seafloor to form lakes of density-stratified anoxic bottom brine. It is here on the floor of these brine pools, especially in Precambrian counterparts to modern examples of the brine deeps of the Red Sea that organic- and sulphide-enriched laminites accumulate (Chap. 15).

Geological and Hydrological Features

Venting anoxic Fe-carrying chloride brines create seafloor redbeds at sites were brines move onto the ocean floor but do not pond in seafloor depressions (brine lakes). Brine redbeds are loosely consolidated red-orange iron-oxide deposits, with surfaces characterised by anastomose and braided patterns created by brines trickling as thin brine sheets disperse as sheets over the seafloor (Aharon et al. 1992; Sassen et al. 2004). Redbed clays are coated by red iron-oxides, and can also contain sand-sized crystals of authigenic euhedral dolomite and botryoidal hematite. Similar iron-oxide deposits (redbeds) define the oxygenic edges of the Red Sea brine pools including the Atlantis II deep. The ferrous iron of the redbeds was originally extracted in its ferric form during the flushing of buried sediment by dissolution derived anoxic pore waters in the peridiapiric and salt sheet surrounds (Hanor 1994a). Once vented onto the oxygenated seafloor, the dissolved iron precipitates as hematite and other ferrous hydroxides. In this dispersed seepage setting scenario the seafloor surface itself constitutes a redox front between the escaping reduced basin brines and oxygenated marine waters.

Figure 9.51a, b shows clearly that red iron oxides are stable in the oxygenated conditions that typify the open seafloor (see also Sheu and Presley 1986a, b). In contrast, in the more reduced conditions in highly saline subsurface waters and bottom waters of brine pools, precipitated iron phases are dominated by pyrite, siderite and other ferroan carbonates. The pH does not vary widely in such reduced saline settings (Fig. 9.51b), and the relationship between pyrite and siderite becomes clearer when activities of dissolved sulphur or dissolved bicarbonate are plotted against Eh. Pyrite is the stable

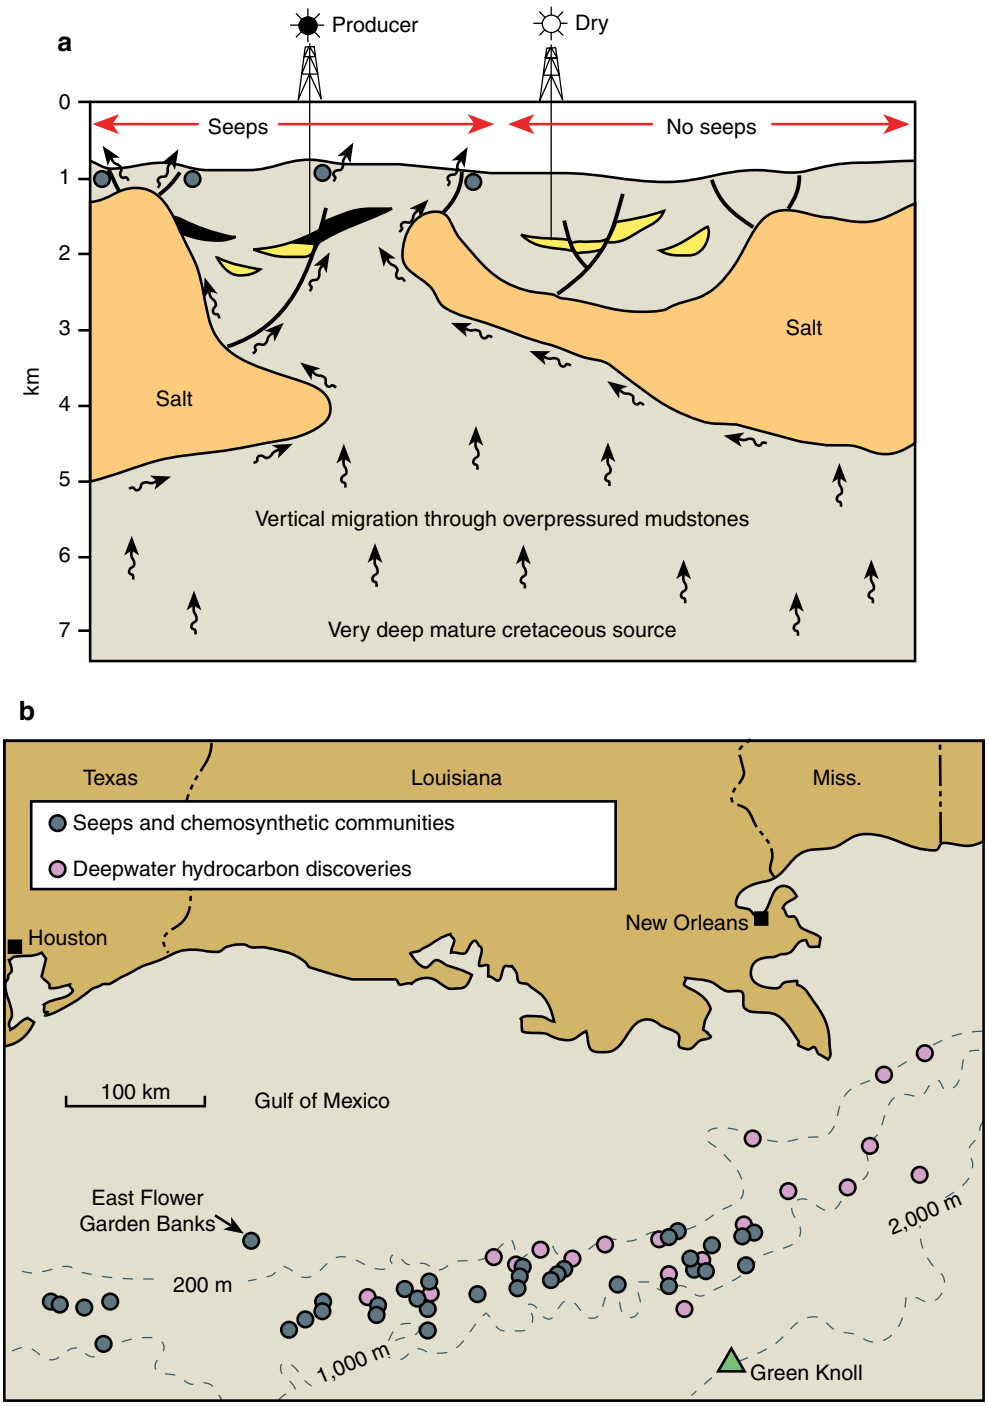

Fig. 9.50 Brine seeps. (**a**) Model of hydrocarbon migration and seepage in the deepwater Gulf of Mexico. Seepage indicates a change in the salt continuity in an intrasalt basin, but it does not indicate the presence of an effective migration pathway to a specific hydrocarbon trap. (**b**) General association of seeps, chemosynthetic communities and hydrocarbon discoveries in the deepwater Gulf of Mexico (After Thrasher et al. 1996)

phase in anoxic conditions where levels of dissolved sulphide are high (Fig. 9.51c), while siderite and other ferroan carbonates are the stable phases under anoxic conditions where the activities of dissolved sulphide are very low and bicarbonate activities are high (Fig. 9.51d).

On its way to the surface the same brine chemistry precipitates the pyrite and ferroan carbonate cements in peridiapiric sands as around the Hackberry dome and in the Carrizo sand outcrop (Fig. 8.36). It also explains the formation of iron silicates, such as chamosite and berthierine (the Fe_3O_4 silicates in Fig. 9.51c, d), in anoxic environments where the activities of both sulphide and bicarbonate are very low. This siliceous Fe-phase chemistry has important implications in terms of the reduction state of Archaean and Proterozoic seawater chemistry and the precipitation of banded iron ores (Chap. 2).

Dense anoxic brines pond in stratified hypersaline lakes on the modern deep seafloor wherever vented brines can seep into closed depressions. Such seafloor lakes typify deep seafloors atop shallowly-buried salt masses around the world and are now called deepsea hypersaline anoxic lakes (DHALS). The venting and ponded bottom brines create water column brine interfaces with the overlying seawater

and host well-adapted chemosynthetic communities. These brine-filled lows tend to form via local subsidence atop dissolving shallow allochthonous salt sheets or atop areas of salt withdrawal as underlying salt is withdrawn into adjacent growing salt structures (growth-fault and rim syncline depressions). The redox interface in such seafloor pools is located at the halocline and so is some metres to tens of metres above the seafloor.

For example, the Orca Basin in the Gulf of Mexico is a brinefilled minibasin at a depth of 2,400 m, some 600 m below the surrounding seafloor with an area more than 120 km^2 (Fig. 9.52a). Its bottom is covered by a 200 m

column of highly saline (259‰) anoxic brine, which is more than a degree warmer than the overlying seawater column (Fig. 9.52b). The pool is stable and has undergone no discernable change since it was first discovered in the 1970s. It is a closed dissolution depression fed by brines seeping from a nearby subsurface salt allochthon (Addy and Behrens 1980). A large portion of the particulate matter settling into the basin is trapped at the salinity interface between the two water bodies. Trefry et al. (1984) noted that the particulate content was 20–60 µg/l above 2,100 m and 200–400 µg/l in the brine column below 2,250 m. In the transition zone, the particulate content was up to 880 µg/l and contained up to 60 % organic matter.

A core from the bottom of the Orca brine pool captured laminated black organic-enriched pyritic mud from the seafloor to 485 cm depth and entrains three intralaminite turbidite beds of grey mud with a total thickness of 70 cm (Fig. 9.52c; Addy and Behrens 1980). This is underlain by grey mud from 485 cm to the bottom of the core at 1,079 cm. The laminated black mud was deposited in a highly anoxic saline environment, while grey mud deposition took place in a more oxic setting. The major black-grey boundary at 485 cm depth has been radiocarbon dated at 7,900 ± 170 years and represents the time when escaping brine began to pond in the Orca Basin depression. Within the dark anoxic laminates of the Orca Basin there are occasional mm- to cm-thick red layers where the iron minerals are dominated by hematite and other iron hydroxides and not by pyrite. These layers represent episodes of enhanced mixing across the normally stable oxic-anoxic halocline and indicate the short-term destruction of bottom brine stratification. When the plot of leachable iron is plotted it is obvious that the pore brines in the black mud intervals can store iron in its soluble ferric (3+) form, a reflection of the anoxia typifying these black mud pore brines.

Similar suprasalt brine pools, with microbial distributions tied to density layering in the brine column, typify the salt-floored compressive deep seafloor atop the accretionary complex of the Mediterranean Ridge. There, sheets of Miocene evaporites have been folded and thrust to shallow depths below the deep seafloor. The consequent dissolution of Messinian evaporites created saline brine pools, such as the Bannock, Tyro, Discovery, L'Atalante, and Urania brine lakes and basins (Westbrook and Reston 2002; Cita 2006). The Discovery, L'Atalante, and Urania brine lakes constitute what is sometimes referred to as the "anoxic lake region" of the Mediterranean Ridge. The "anoxic lake region" and the brine lakes of the Tyro Basin lie on the growing front of the Hellenic side of the accretionary wedge, while Bannock Basin is located atop the toe of the accretionary complex. Brine lakes on the Hellenic side of the ridge are a response to sediment deformation with a strong diapiric component. Fluids are driven out of the compacting pre-Messinian sediments, as it is overridden by the growing Messinian salt wedges (Figs. 5.49 and 5.53). Rising fluids dissolve and breach the evaporite cover wherever it is thin, leading to the escape of hypersaline fluids both ahead of the deformation front and through the pre-Messinian wedge. In contrast, the brine lakes of the Bannock Basin are a result of a seamount as it was dragged into the accretionary complex by the subducting African plate. The disturbance created a reinvigorated hydrology as it ploughed through evaporites of the accretionary complex and allowed hypersaline fluids to escape to the seafloor (Fig. 9.53).

Life, Fe and Sulphur in Seafloor Brine Lakes

The various brine lakes on the deep-sea floor of the Mediterranean, occur thousands of metres below the photic zone, within depressions that entrain bottom waters up to ten times as saline as Mediterranean seawater. In the Bannock Basin the various brine-filled depressions or sub-basins create a closed outer moat around a central seafloor mound that is 10 km across (Fig. 9.53a). The chemical composition of the Tyro Basin bottom brine is related to the dissolution of the underlying halite-dominated evaporites, while the chemical composition of the Bannock Basin (Libeccio Basin in the Bannock area) implies derivation from dissolving bittern salts (de Lange et al. 1990). In the "anoxic lakes region", sodium chloride is predominantly sourced in the L'Atalante and Urania lakes, but L'Atalante is much richer in potassium chloride than the other lakes. The Discovery basin brine is almost exclusively the product of dissolution of magnesium chloride (bischofite) salts. It has a density of 1,330 kg/m^3, which makes it the densest naturally occurring brine yet discovered in the marine environment (Wallmann et al. 2002). Its concentration profile in sediment beneath the brine lake shows the age of this lake is between 700 and 2,000 years. The high concentration of magnesium chloride drives dissolution of biogenic calcium carbonate, but facilitates excellent preservation of siliceous microfossils and organic matter. In basin bottom muds there are large euhedral crystals of gypsum, up to 10 cm across, precipitating from these brines (Cita 2006).

Biomarker associations of the organics accumulating in these brine lakes define two depositional styles: typical marine and hypersaline (Burkova et al. 2000). Algal and bacterial biomarkers typical of saline environments were found in layers 0.60–0.75 m below the sediment surface in the Tyro Lake Basin, as well as normal marine indicators derived from pelagic fallout ("rain from heaven"). Saline indicators include; regular C-25 isoprenoids, squalane, lycopane, isolycopane, tetraterpenoid and tetrapyrrolic pigments, monoalkylcyclohexanes, tricyclic diterpanes, steranes, hopanes, bio- and geohopanes. According to Burkova et al. (2000), the saline organic signatures come from microbial mat layers, redeposited from a Messinian source into the sapropels of

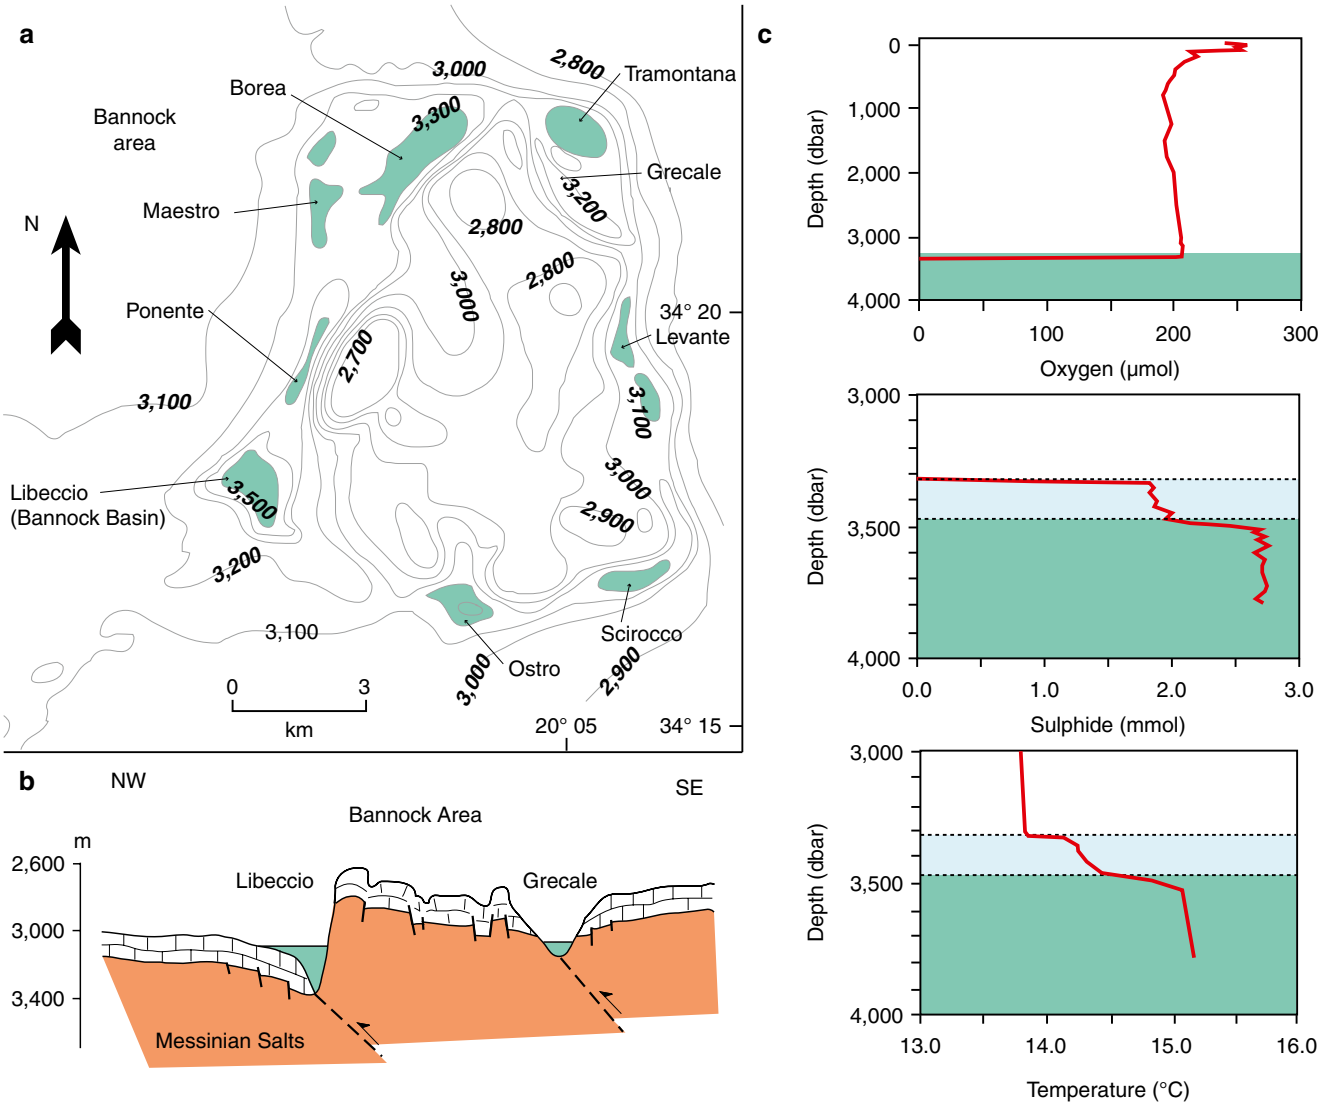

Fig. 9.53 Brine pools (DHALS) in the Bannock Basin, Mediterranean Ridge. (**a**) Bathymetry of Bannock area, seafloor contours in metres (After Camerlenghi 1990). (**c**) Water column and brine column characteristics (oxygen, sulphide and temperature profiles; replotted from data tables in Bregant et al. 1990)

the modern depression. Alternatively, they may indicate the activities of a chemoautotrophic community, which flourishes at the halocline or around active brine vents. As in the Orca Basin, the organic content of the bottom sediments of the Mediterranean brine pools is much higher than is found in typical deep seafloor sediment (Fig. 9.54a).

Anoxic hypersaline brines in Mediterranean brine lakes are highly sulphidic and among the most sulphidic bodies of water in the marine realm, with H_2S concentrations consistently greater than 2–3 mmol (Fig. 9.53c; Table 9.10; Henneke et al. 1997). The brine body below the Urania chemocline is more than 100 m thick and contains up to 11 mM hydrogen sulphide, making it the most sulphidic water body in the known marine realm. In combination with the sulphide are very high levels of methane both in and below the halocline (≈5.56 mM; Borin et al. 2009). In contrast, there is little to no H_2S in the anoxic bottom brine of the Orca Basin (Table 9.10). There the iron concentration is 2 ppm, a value more than 1,000 times higher than in the overlying Gulf of Mexico seawater. Such high levels of reducible iron in the Orca Basin are thought to explain the lack of H_2S in the bottom brine and a preponderance of framboidal pyrite and extractable iron in the bottom sediments (Sheu 1987). Both the Orca Basin, and the brine pools on the floor of the Mediterranean, show sulphate levels that can be more than twice that of the overlying seawater.

Pyritic sulphur is the main phase of inorganic reduced sulphur in the Tyro and Bannock basins, where it makes up

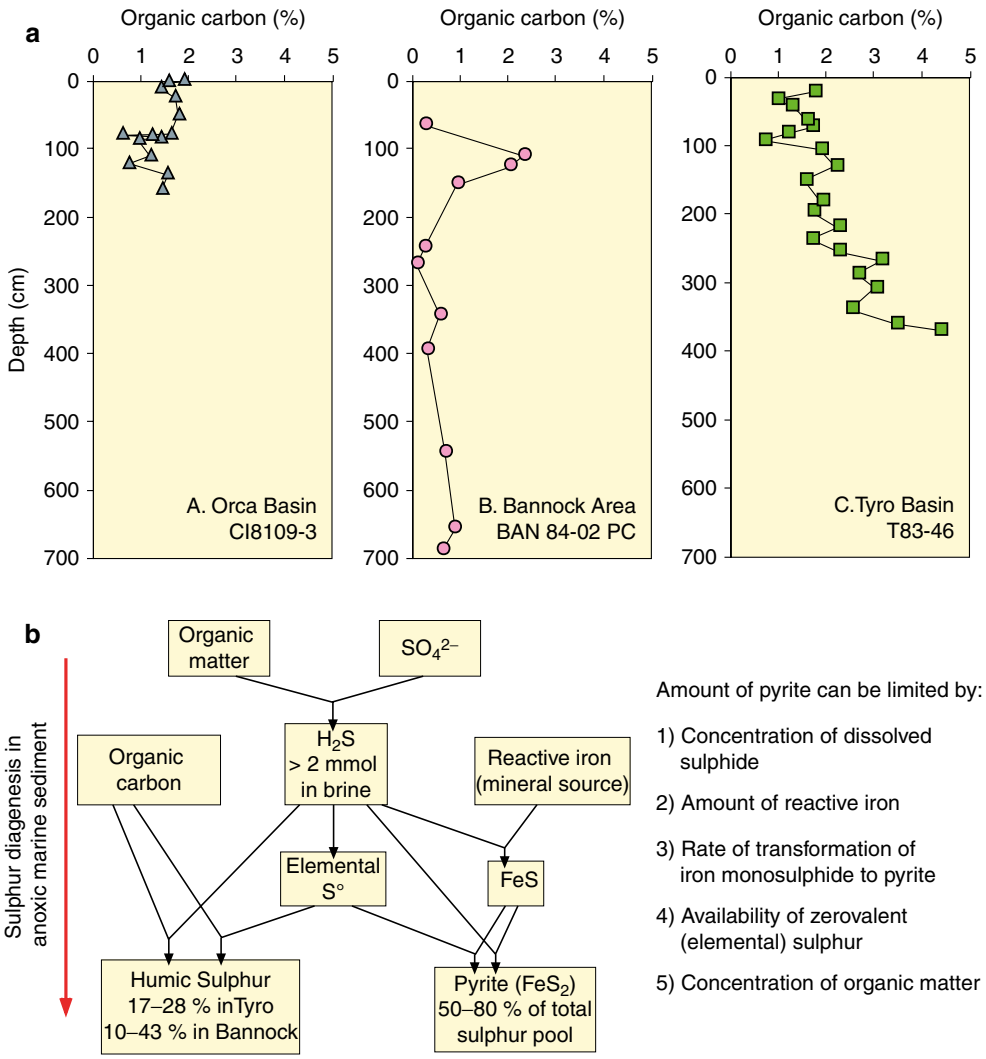

Fig. 9.54 Organic characteristics of brine pool bottom sediment. (**a**) Total organic carbon as % dry weight versus depth (Plotted from Tyro and Orca data in Table 1 of Sheu 1987, and Bannock data from Henneke et al. 1997). (**b**) Modes of occurrence of sulphur in brine pool bottom sediments (After Henneke et al. 1997)

Table 9.10 Chemical make-up of various salt allochthon-associated brine pools compared to oxygenated seawater from the Mediterranean

Region of brine occurrence	Salinity (‰)	pH	O_2 (µM)	H_2S (mM)	SO_4 (mM)	Ca (mM)	Cl (mM)	PO_4 (µM)	NH_4 (µM)
Urania Basin (Mediterranean)	200	6.8	0	8.6–11	85	34	2,830	41.2	ND

Seawater (Mediterranean)	39	8.2	200	0	31	11	660	0.2	0.2

After Sass et al. 2001

50–80 % of the total sulphur pool. It is also present at the same levels in cores from the two basins, that is, around 250 µmol per gram dry weight (Henneke et al. 1997). Humic sulphur accounts for 17–28 % of the total sulphur pool in the Tyro Basin and for 10–43 % in the Bannock Basin (Fig. 9.54b). Sulphur isotope data show negative $\delta^{34}S$ values for both pyritic sulphur, with $\delta^{34}S = -19$ to $-39‰$; and for humic sulphur, with $\delta^{34}S = -15$ to $-30‰$; indicating that both pyritic and humic sulphur originated from microbially produced H_2S within the brine column.

Marine sediment fills in all the active brine lakes of the Mediterranean Ridge range in age from Holocene to Late Pleistocene and are typically made up of turbidites interlayered with laminated intervals composed of alternating green gelatinous muds and grey reduced oozes. Usually, the density of the bottom brine layer in the Bannock region is high enough to support a layer of finely dispersed organic debris, allowing substantial bacterial mats to float at the seawater-brine interface (halocline) and so form suspended deep mid-water bacterial mats (Erba 1991). While the organics

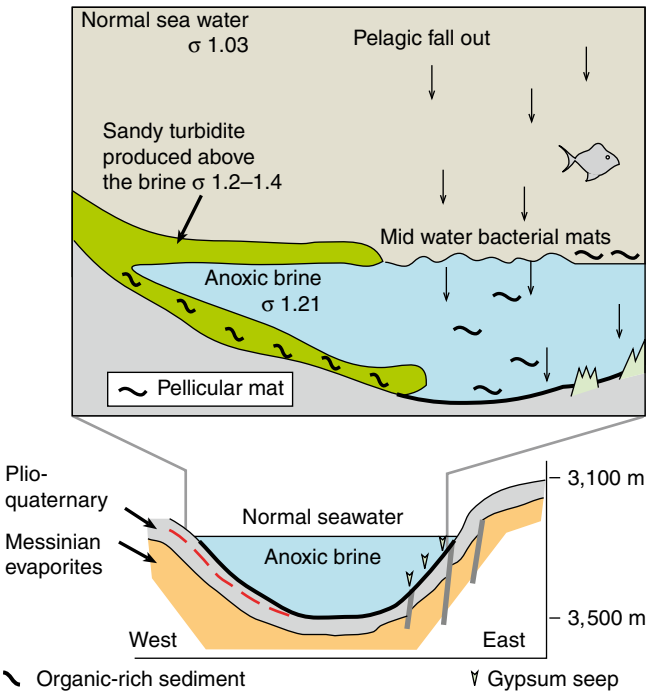

Fig. 9.55 Formation and sedimentation model for pellicles in Mediterranean seafloor brine lakes. Bacterial (pellicular) mats grow mid-water at the interface between normal seawater and anoxic brine and trap biogenic and inorganic particles. When pelagic sedimentation prevails, pellicles sink to the basin floor after load increases to breach levels at the halocline interface (*right side*). Occasional turbidity currents and sediment slumping disrupts the interface and transports fragments of pellicles to the basin bottom in coarser sandier layers (After Erba 1991)

float on the oxic side of the halocline they are subject to oxidation and biodegradation (Fig. 9.55). Owing to the high density of the bottom brines, moving this floating organic material to the floor of density-stratified brine pools appears at first to be a difficult proposition. Bottom sediments in the Urania Basin for example contain very little particulate organic matter (>1 % TOC). Yet, organic contents in the anoxic bottom muds beneath Tyro and Orca basins can be as high as 4–5 % organic carbon (Fig. 9.54a). The propensity for organics to remain suspended at the halocline can be overcome when mineral crystals, such as pyrite, precipitate at the interface via diffusive brine mixing in combination with bacterial sulphate reduction. Newly formed crystals attach to organic matter floating at the halocline to create a combined density that carries the suspended pellicular organics to the pool floor. In such a brine pool scenario, the redox front that fixes pyritic sulphur occurs at the halocline, and not at its more typical marine position located at or below the sediment-seawater interface. The metal sulphide crystals then sink, carrying organic matter coats to form characteristic metal and organic rich laminites on the floor of the anoxic brine lake.

So, organic debris first formed at the halocline can then accumulated as pellicle layers within the pyritic bottom muds (laminites). Pellicular debris is also carried to the bottom during the emplacement of turbidites when the halocline is disturbed by turbid overflow (Fig. 9.55; Erba 1991). Hence, pellicular layers are typically aligned parallel to lamination, or are folded parallel to the sandy bases of the turbidite flows, or line up parallel to deformed layers within slumped sediment layers. Individual pellicle layers are 0.5–3 mm thick and dark greenish-grey in colour. Similar pellicular layers cover the surface of, or are locked within, recent gypsum crystals recovered from bottom sediments of the Bannock area. This gypsum is growing today on the bottom of the Bannock Basin, atop areas about the brine pool margin that are directly underlain by dissolving Miocene evaporites (Corselli and Aghib 1987; Cita 2006). Other than the Dead Sea, it is one of the few modern examples of a deepwater evaporite, but its seepage-fed genesis means it is a poor analogue for deepwater basinwide salt units.

The community of bacteria and archaea flourishing at the halocline in sulphidic marine brine pools on the deep Mediterrannean floor is quite diverse, largely independent of primary production in the euphotic zone, with the number of identified unique halobacteria and haloarchea species expanding every year (Albuquerque et al. 2012). Bottom brine in the Urania brine lake has a salinity of 162‰ and the chemocline of the brine lake is some 3,490 m below the ocean surface, so only a very small amount of phytoplanktonic organic carbon ever reaches the 20 m thick chemocline. Yet the oxic waters of the upper part of the chemocline support a rich bacterial and archaeal assemblage in and below the interface between the hypersaline brine and the overlying seawater, much like the chemosynthetic bacterial community associated with the halocline in Lake Mahoney (Sass et al. 2001; Borin et al. 2009).

Sulphide concentration in Urania Basin increases from 0 to 10 mM within a vertical interval of 5 m across the interface (Fig. 9.56a). Within the halocline, the total bacterial cell counts and the exoenzyme activities are elevated and biogenic activity continues below the halocline. Bacterial sulphate reduction rates measured in this layer are ≈14 nmol SO_4 cm^{-3} day^{-1} and are among the highest in the marine realm. They correspond to the zone of maximum bacterial activity in the chemocline (Fig. 9.56b). Particulate organic content is 15 times greater than that in the overlying normal marine waters. A similar focus of microbial occurrence (bacterial and archaeal) is seen at the halocline in l'Atalante Basin and is probably typical of all chemocline layers in the various Bannock brine lakes (Yakimov et al. 2007).

Employing 11 cultivation methods, Sass et al. (2001) isolated a total of 70 bacterial strains from the chemocline in the Urania Basin (Fig. 9.56a). These strains were identified as the flavobacteria, *Alteromonas macleodii*, and *Halomonas aquamarina*. All 70 strains could grow chemo-organoheterotrophically under oxic conditions. Twenty-one of the isolates could grow both chemo-organotrophically and chemo-lithotrophically (decomposers and fermenters). While the most probable numbers in most cases ranged

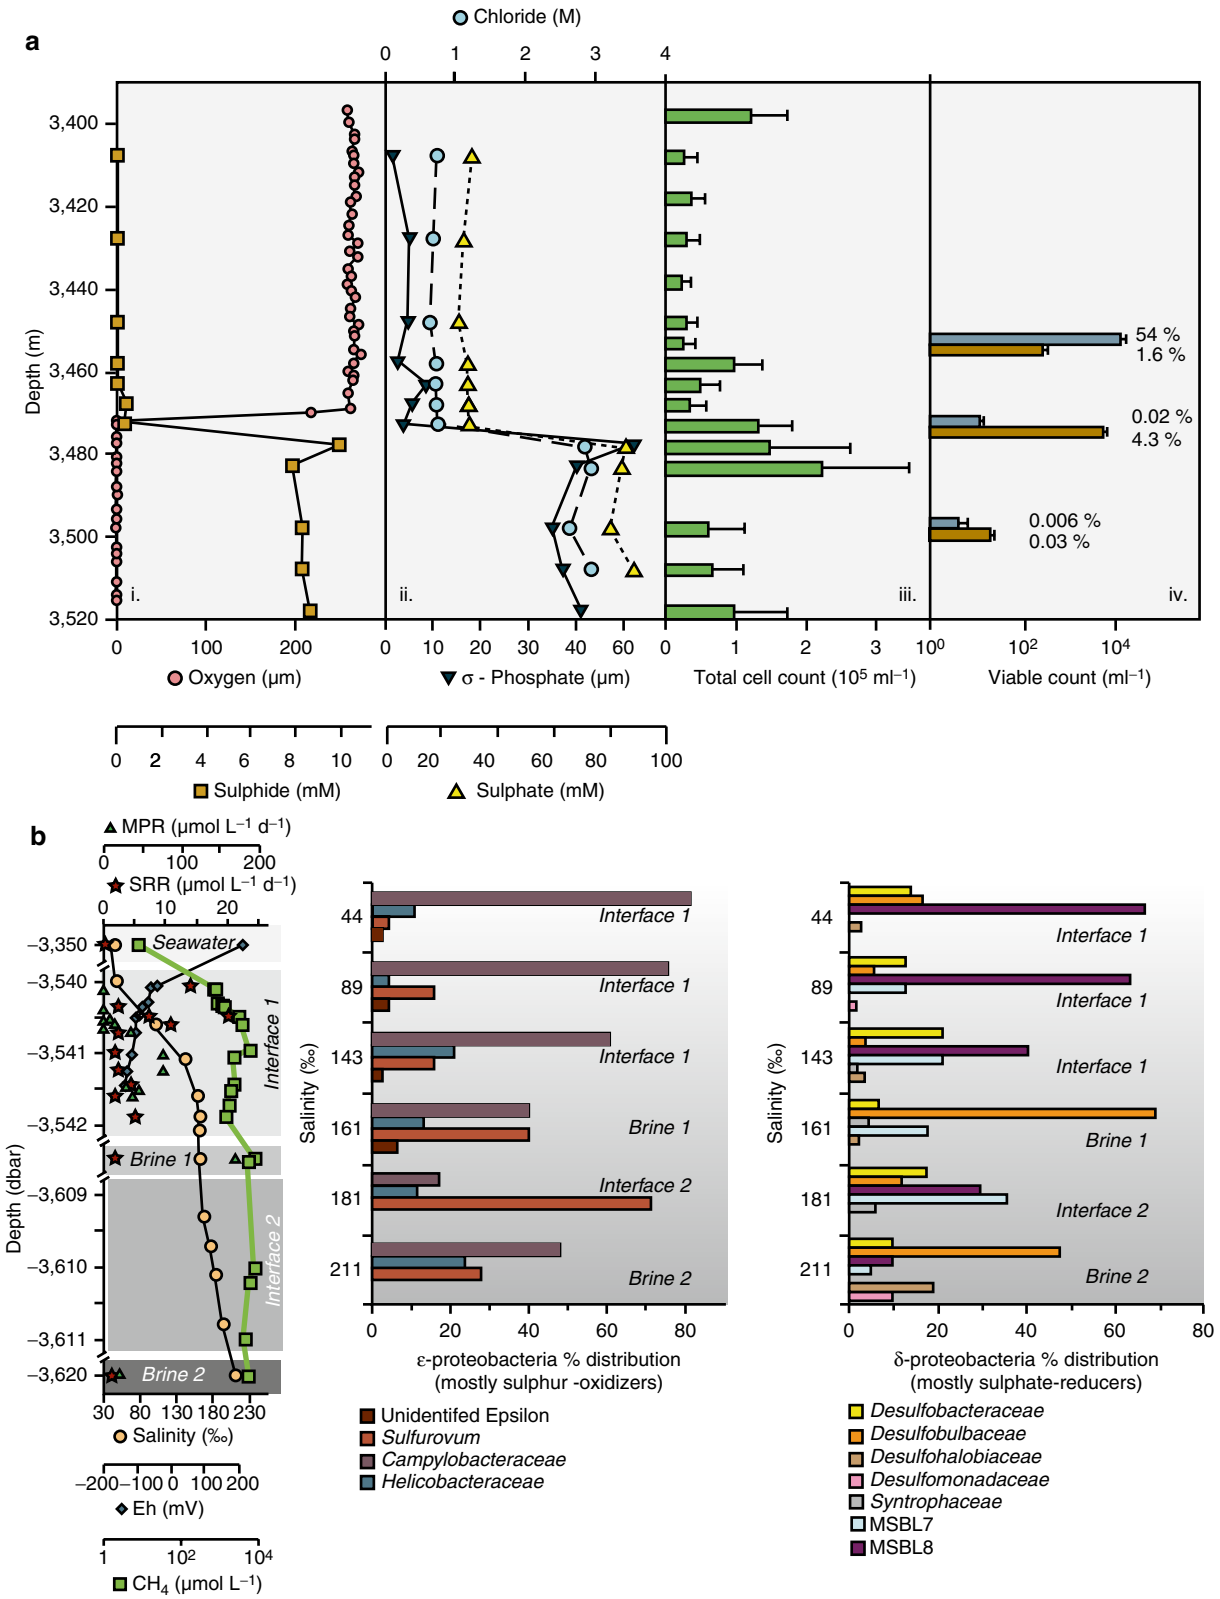

Fig. 9.56 Urania Basin, Mediterranean Ridge. (**a**) Physicochemical parameters, total cell counts, and MPN across the oxicanoxic boundary of the Urania Basin, Mediterranean Ridge (After Sass et al. 2001). (*i*) Oxygen and sulphide concentrations; (*ii*) Sulphate, orthophosphate and chloride concentrations; (*iii*) Total cell counts; (*iv*) Viable cell counts in anoxic media containing the amino acid mixture (*solid bars*) and in oxic media containing thiosulphate (*cross-hatched bars*). The percentages are relative to the total cell count and the error bars indicate standard deviation. (**b**) Relative distribution of sequences belonging to the ε-and δ-Proteobacteria (mostly sulphate reducers) are stratified across the halocline and below in the water column of the Urania basin (After Borin et al. 2009). The methane production (MPR) rate is an order of magnitude higher than the rate of sulphate production rate (SPR) over much of the halocline, as are relative levels of methane versus H_2S. Note that the depth scale on the salinity-Eh profile is not continuous but focused into salinity-controlled zones that tie to the microbial samples

between 0.006 and 4.3 % of the total cell counts, an unusually high value of 54 % was determined above the chemocline with media containing amino acids as the carbon and energy source.

Subsequent detailed work focused on the various layers that make up the Urania halocline showed the high sulphide levels in and below the halocline, make it a mecca for bacterial sulphate reducers, as do high levels of methane for the methanogens (Fig. 9.56b; Borin et al. 2009). Microbial abundance showed a rapid increase by 2 orders of magnitude from 3.9×10^4 cells mL^{-1} in the deep oxic seawater immediately above the basin, up to 4.3×10^6 cells mL^{-1} in the first half of interface 1. Although less pronounced than in the first chemocline, a second increase in microbial counts occurred in interface 2. Deceleration of falling particulate organic matter from the highly productive interface 1, is probably responsible for stimulating microbial growth and hence cell numbers in interface 2. That is, compared to the overlying seawater column, bacterial cell numbers increased up to a hundred-fold in interface 1 and up to ten-fold in interface 2. This is a consequence of elevated nutrient availability, with higher numbers in the upper interface where redox gradient was steeper. Bacterial and archaeal communities, analysed by DNA fingerprinting, 16S rRNA gene libraries, activity measurements, and cultivation, were highly stratified within the various layers of the chemocline and metabolically more active along the various chemocline layers, compared with normal seawater above, or the uniformly hypersaline brines below.

Detailed analysis of 16S rRNA gene sequences revealed that in both chemocline interfaces the ε- and δ-Proteobacteria were abundant, predominantly as sulphate reducers and sulphur oxidizers, respectively (Fig. 9.56b). The only archaea in the first 50 cm of interface 1 were Crenarchaeota, which consist of organisms having sulphur-based metabolism, and hence could play a role in sulphur cycling in the upper interface. In the deepest layers of the basin below the halocline, MSBL1, putatively responsible for methanogenesis, dominated among archaea (Fig. 9.57). The work of Borin et al. (2009) illustrate that a well adapted and complex microbial community is thriving in the Urania basin's extreme chemistry, The elevated biomass centred on the halocline is driven largely by sulphur cycling and methanogenesis.

Similar detailed studies of interface-controlled chemosynthetic communities in other Mediterranean DHALs have been documented in Lake Thetis (Ferrer et al. 2012; Oliveri et al. 2013) and Lake Medee (Yakimov et al. 2013). Medee Lake is the largest known DHAL on the Mediterranean seafloor and has two unique features: a complex geobiochemical stratification and an absence of chemolithoautotrophic Epsilon-proteobacteria, which usually play the primary role in dark bicarbonate assimilation in DHALs interfaces worldwide. Presumably, because of these features, Medee is less productive and exhibits reduced diversity of autochthonous prokaryotes in its interior brine layers. Indeed, the brine community almost exclusively consists of the members of euryarchaeal and bacterial KB1 candidate divisions which are ubiquitous in the DHAL biota worldwide. In Medee, as elsewhere, they are thriving on small organic molecules produced by a combination of degraded marine plankton and moderate halophiles living in the overlying stratified brine column.

In another DHAL, the Kebrit Deep on the deep floor of the Red Sea, a similar assemblage of halophilic archaea and bacteria flourish in hypersaline waters below the chemocline (Fig. 9.57). Kebrit Deep (24°44'N, 36°17'E) measures 1 by 2.5 km, with a maximum depth of 1,549 m and is one of the smallest salt allochthon-associated brinepools of the Red Sea. It is located near the site of the well-known metalliferous Atlantis II deep (Fig. 15.14). The Kebrit Deep is filled by an 84 m thick, anaerobic, slightly acidic brine lake (pH approximately 5.5) with a salinity of 260‰ and a temperature of 23.3 °C (Antunes et al. 2011). The brine has a high gas content that is made up largely of CO_2, H_2S, small amounts of N_2, methane and ethane, with remarkably high quantities of H_2S (12–14 mg S l^{-1}; Hartmann et al. 1998). The presence of sulphur is self-evident by the strong, characteristic odour present in brine samples, and hence the name of basin (Kebrit is the Arabic word for sulphur). Like the Atlantis II deep there are impregnated massive sulphides accumulations on the floor of Kebrit Deep. Kebrit samples are porous and fragile, and consist mainly of pyrite and sphalerite. Prior to gene sequencing studies, sulphur isotope values provided strong evidence for biogenic sulphate reduction being involved in sulphide-forming processes in Kebrit Deep. They are linked to bacterial methane oxidation and sulphate reduction centred on the brine-seawater interface (see Chap. 15 for metallogenic details).

Most of the archaeal sequences in Kebrit Deep cluster within the *Thermoplasmatales* (Marine group II, Marine Benthic group D, and the KTK-4A cluster) among the *Euryarchaeota*, while the remaining sequences do not show high similarity to any of the known phylogenetic groups (Fig. 9.57). One of these sequences was shown to cluster with the later described SA2 group, while another (accession number AJ133624) clusters together with two gene sequences from L'Atalante Basin waters, defining a novel deeply-branching phylogenetic lineage within the Crenarchaeota.

Gene sequencing studies on water samples from the brine–seawater interface in the Kebrit deep retrieved sequences from the KB1 group, as well as *Clostridiales* (mostly *Halanaerobium*), *Spirochetes* (ST12-K34/MSBL2 cluster), *Epsilonproteobacteria* and *Actinobacteria*, but no archaeal sequences were detected in these interface samples (Antunes et al. 2011). Under strictly anaerobic culture conditions, novel halophiles were isolated from samples of these

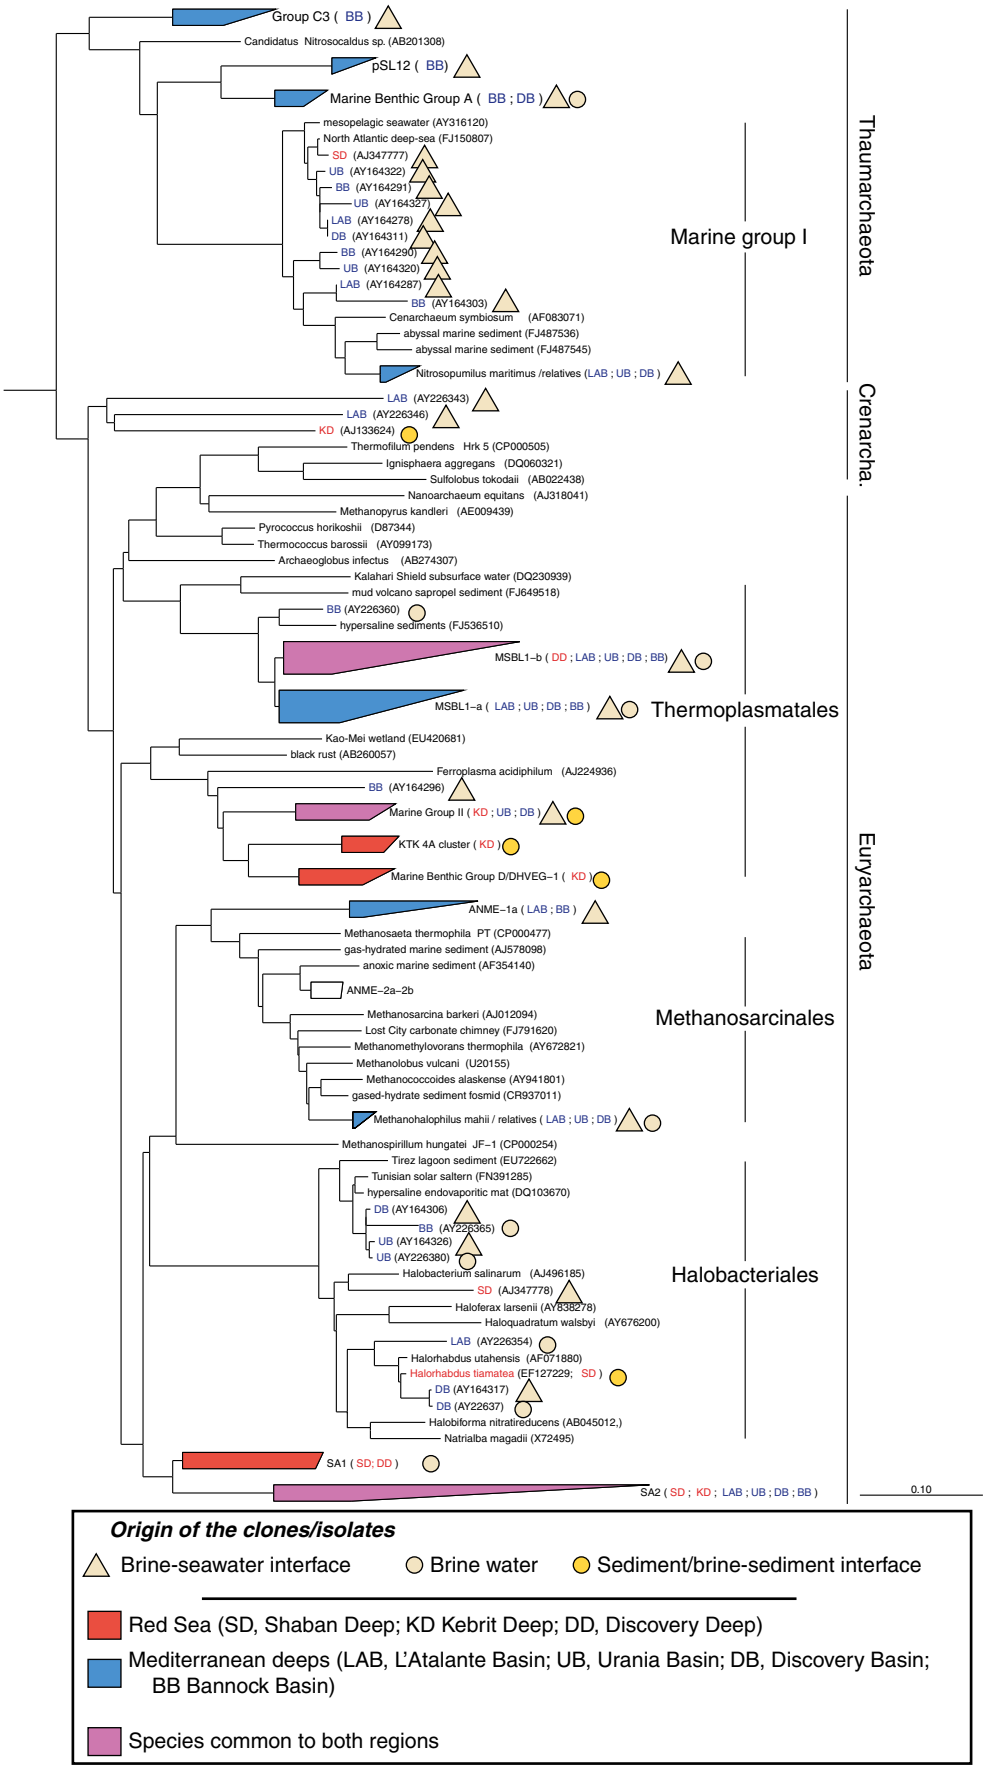

Fig. 9.57 Major lineages of Archaea as identified via gene splicing techniques in samples of deep-sea brines from the Red Sea, in *red*, the Mediterranean Sea, in *blue* and those that occur in both brines, in *purple* (After Antunes et al. 2011)

waters and belong to the halophilic genus *Halanaerobium*. They are the first representatives of the genus obtained from deep-sea, anaerobic brine pools (Eder et al. 2001). Within the genus *Halanaerobium*, they represent new species that grow chemo-organotrophically at NaCl concentrations ranging from 5 to 34 %. They contribute significantly to the anaerobic degradation of organic matter, which formed at the brine-seawater interface and is slowly settling into the bottom brine. Similarities in the make up of the Archaeal population, tied to similar metabolic process sets at the brine interface across various deep seafloor brine lakes in the Gulf of Mexico, the Mediterranean and the Red Sea is illustrated in Fig. 9.57.

Neither Tyro nor Bannock Basin bottom sediments show a significant correlation between pyritic sulphur and the organic carbon in the bottom sediments, suggesting predominantly syngenetic pyrite evolution in bottom sediments of these brine lakes (Henneke et al. 1997). That is, both pyritic and humic sulphur preserved in the bottom sediments formed either in the lower water column or at the sediment-brine interface, not in the sediment itself. Ongoing diagenetic processes within the bottom sediments only form an additional 5 % of the total pyrite. Van der Sloot et al. (1990) clearly showed that metal sulphides, as well as organics and other minerals, precipitate at the brine-seawater interface in the Tyro Basin, as they do in the Orca Basin. They found extremely high concentrations of Co (0.015 %), Cu (1.35 %) and Zn (0.28 %) in suspended matter at the halocline. These high particulate Co, Cu and Zn concentrations correspond to sharp increases in dissolved sulphide across the interface (a redox front), and indicate precipitation of metal sulphides at the interface. Humic sulphur in the bottom sediments correlates with the pyritic sulphur distribution and is related to the amount of gelatinous pellicle derived from bacterial mats growing at the halocline between oxic seawater and bottom brine (Erba 1991; Henneke et al. 1997).

Additionally, the degree of pyritisation in the sediments (DOP ≈ 0.62) indicates that present-day pyrite formation is limited by the reactivity of Fe in the Bannock and Tyro basins and not by the availability of organic matter, the latter being the process that limits pyrite formation in most normal marine settings (Fig. 9.54b). The degree of pyritisation (DOP) is defined as [(pyritic iron)/(pyritic iron + reactive iron)]. Raiswell et al. (1988) showed that DOP in ancient sediments can distinguish anoxic from normal marine sediments. Anoxic sediments show DOP values between 0.55 and 0.93, while normal marine sediments have DOP values less than 0.42. The DOP levels in the Bannock and Tyro basins confirm observations made in ancient anoxic sediments. Thus, although the Tyro and Bannock basin brines differ in their major element chemistry, reflecting a different salt source, their reduced sulphur species chemistry appears to be similar, but is significantly different from normal marine systems and capable of precipitating metal sulphides above the sediment surface.

Pools of hypersaline, anoxic brines, underlain by laminated pyritic organic-rich sediments, are far more widespread in halokinetic terrains than just in the Orca, and Mediterranean Ridge basins. For example, similar brine seeps and pools have now been documented atop and adjacent to numerous salt allochthons along much of the continental slope of the Gulf of Mexico. In the Green Canyon area, wherever shallow allochthonous salt sheets are dissolving just beneath the seafloor, organic-enriched pyritic sediments are also commonplace (Fig. 9.54a, b; Reilly et al. 1996). Similar cool-seep systems are active today along the foot of the Florida Escarpment and the Blake Ridge, where they are focused and in part fed by subadjacent dissolving salt allochthons (Paull et al. 1992).

Rim Life, CH_4 and H_2S in Seafloor Brine Lakes

On the deep dark seafloor, a light-independent chemosynthetic seep biota grows and flourishes in salt sheet focused regions of both hydrocarbon (methane) and H_2S outflow (Fig. 9.58a). Escape of nutritive methane and H_2S into brine-filled pockmark pools and minibasin salt lakes supports symbiont-containing mussel, clam and tubeworm communities, which can construct dense biostromes around the pool rims, especially in regions of the rim edge stabilised by the precipitation of biogenic carbonate cements. They are common atop salt-allochthon floored basins, where edges of salt allochthons focus the upward escape of gaseous and liquid hydrocarbons.

Where sea bottom temperatures are suitably low, methane hydrates (clathrates) form atop focused outflow zones and oil seeps are common at the sea surface above vent clathrates (Dalthorp and Naehr 2011). Gas hydrate or clathrate is an ice-like crystalline mineral in which hydrocarbon and non-hydrocarbon gases are frozen within rigid molecular cages of water. They can be thought of gaseous permafrost. Their occurrence is not just tied to the cold temperature portion of the deep seafloor; clathrates are the dominant seals to large gas reservoirs in the permafrost regions of Siberia. Methane hydrates are commonplace associations where methane, which can be thermogenically or biogenically sourced, occurs just below the deep cold seafloor. In much of world it accumulates in many seafloor regions independent of any underlying evaporite occurrence (Thakur and Rajput 2011). Evaporite edges just tend to focus the outflow zones (Fig. 9.58).

Clathrate formation on the seafloor requires bottom temperatures not encountered until the seafloor bottom lies beneath a water column 450–500 m deep. Beneath the clathrate-covered seafloor, temperature increases with depth

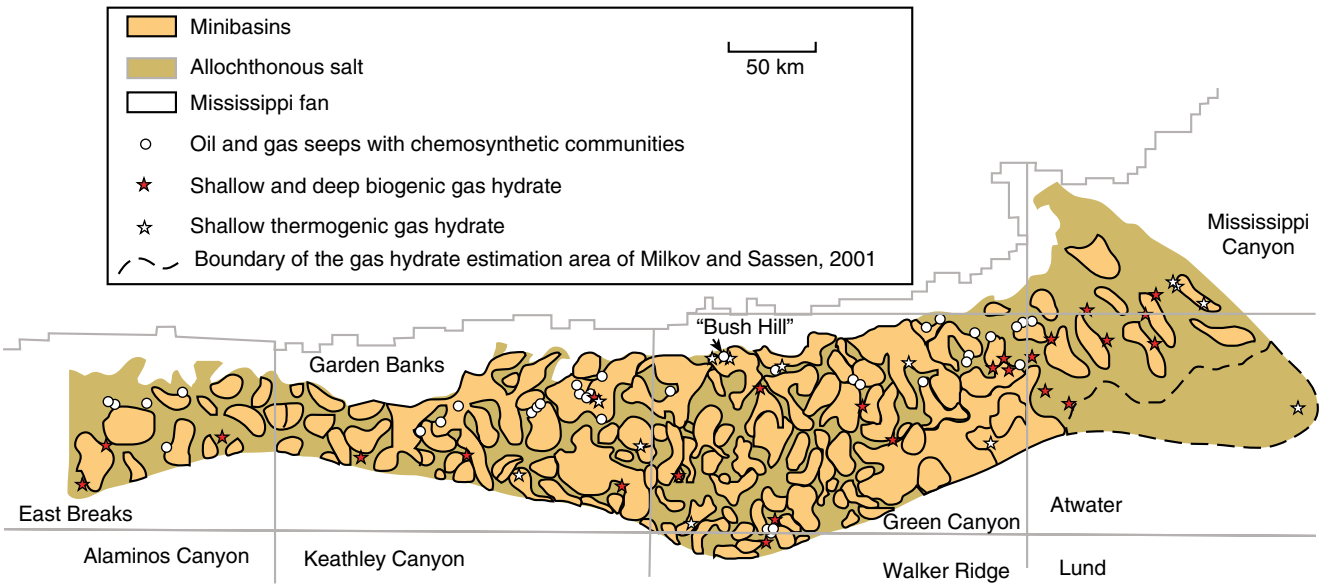

Fig. 9.58 Seeps in the northern Gulf of Mexico showing selected occurrences of seeps and methane hydrates, some with well developed chemosynthetic communities (After Milkov and Sassen 2001)

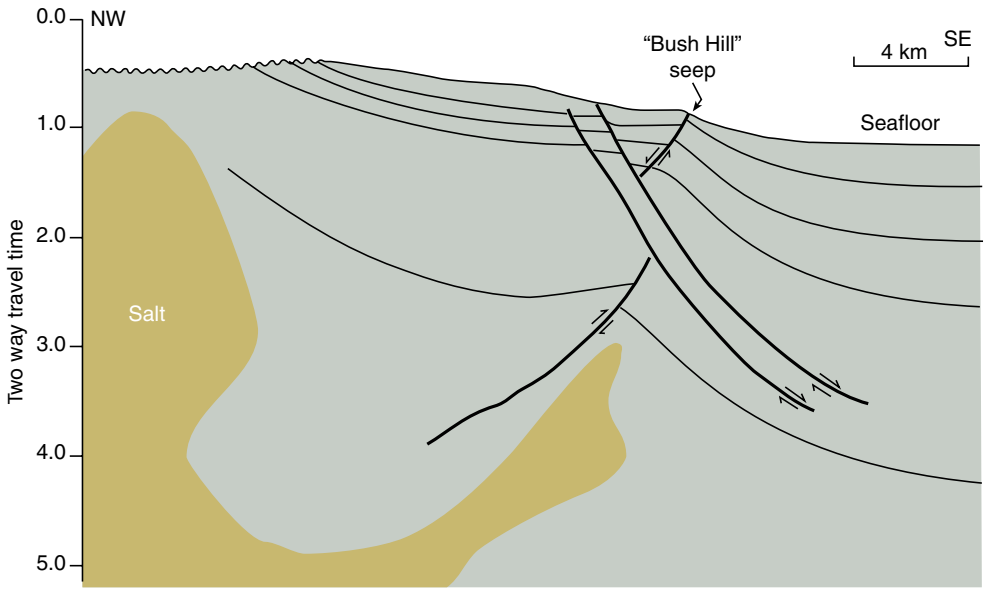

Fig. 9.59 Interpretation of seismic line showing strong structural control on location of the chemosynthetic seep at "Bush Hill" (After Reilly et al. 1996)

and this limits the depth at which gas hydrates will occur, so below most clathrate layers an accumulation of free gas is likely. Clathrates, seeps and brine pools are not unique to, but are often very obvious about, salt allochthon edges where salt flow induces extensional faulting and funnels a focused rise of methane, degraded oil and H_2S to the cold seafloor (Chap. 6). Hence, breaks in the lateral extent of the various salt sheets act as a focusing mechanism for escaping thermogenic and biogenic methane and other gases and fluids (Fig. 9.58; MacDonald et al. 2000, 2003). Rapid burial of organic-entraining sediments in supra-allochthon minibasins encourages the creation of biogenic methane that sources much of the gas escaping to the seafloor away from salt-edge focused seeps. Hence, in the salt allochthon province of the northern Gulf of Mexico there is a definite association between brine pool chemosynthetic communities, thicker gas hydrates and the edges of minibasins (Fig. 9.59; Reilly et al. 1996; Milkov and Sassen 2001).

In all these setting clathrates are a food source for various methanogenic microbes and so there are various multicellular lifeforms dependent on these microbes. One obvious dependency is seen in the eco-niche occupied by a small 2–4 cm-long highly specialised polychaete called *Hesiocaeca methanicola*. It was recently discovered (in 1997) flourishing

in regions of methane hydrate atop the deep seafloor in the Gulf of Mexico (Fisher et al. 2000). These "ice worms" inhabit indentations ("burrows") in blocks and layers of methane clathrate and glean or harvest biofilms of the methanotropic bacteria that are metabolising methane on the block surface. In turn, the ice worm supplies oxygen to the methanotropes and via its movement appears to contribute to the dissolution of hydrates. Mature ice worms can survive in an anoxic environment for up to 96 h.

The mussel-tubeworm dominated seep biota in the Gulf of Mexico is dependent on chemosynthesising microbes as a food source. This community is the coldwater equivalent to chemosynthetic hydrothermal communities flourishing in the vicinity of black smoker vents (MacDonald 1992; MacDonald et al. 2003). In both settings it is methane and sulphide, not light, that provides the energy source for the bacteria and archaea that make up the base of the food chain. Methanotropic bacteria live symbiotically on a seep mussel's gills, taking in methane and convert it to nutrients that nourish the mussels. Seep mussels and clams (*Bathymodiolus childressi*, *Calyptogena ponderosa and Vesicomya cordata*) continually waft methane-rich water through their gills to help their chemo-autotrophic bacterial symbionts grow and periodically harvest some of the excess growth. Their lifestyle means that seep mussels need to live near a supply of dissolved gas, they can inhabit isolated seep outflows on the deep seafloor where gas is bubbling out, including the edges of mud volcano pools, but do best about the more stable and quiescent edges of methane-saturated brine pools and lakes. There they grow as a fringe to the brine pool, and exist about the pool rim wherever they can keep their siphons above the halocline. They construct a biogenic edge (biostrome) to the brine pool atop and within sediments generally cemented by methanogenic calcite. Such rims typically extends some 5–10 m behind the pool edge (Smith et al. 2000). The inner edge of the mussel biostrome is elevated only a few centimetres from the surface of the pool and is distinguishable by an abundance of smaller individuals, present in high densities. At the outer edge of the mussel biostrome, there is a high frequency of disarticulated shells and low densities of still living larger individuals.

Also living atop seafloor seeps and about some brine pools are knots and clusters of chemosynthetic polychaete tubeworms (*Lamellibrachia luymesi* and *Seepiophila jonesi*). These tubeworms (aka seep beard-worms) can be up to 2.5 m log and possess a microbe-dependent metabolism evolved to exploit the abundant H_2S and methane associated with the hydrocarbon-rich brine seeps (Fig. 9.59). They grow as rims and clumps atop H_2S seeps, as at Bush Hill on the floor of the Gulf of Mexico (Fig. 9.59; Reilly et al. 1996; McMullin et al. 2010). Tubeworm "bushes" in cold seep regions of the Gulf of Mexico are typically rooted in the H_2S-rich muds. Growing individual tubes actively extend down into the H_2S-rich mud as well as up into the O_2-rich water column giving the cluster a morphology similar to a tree or shrub. Their "roots" extend into the earth, while "branches" extend above. Continuing the plant analogy, it seems that tubeworm shrubs absorb H_2S through their "roots" and O_2 through their "branches" (Freytag et al. 2001; Bergquist et al. 2003). As a group, seep tubeworms are related to the giant rift tubeworm (*Riftia pachptila*), which inhabits active hydrothermal seeps in active seafloor rifts.

Via a specialised haemoglobin molecule, vestimentiferan tubeworms in the Gulf of Mexico provide H_2S and O_2 as nutrients to sulphur-oxidising bacteria living symbiotically in trophosome structures, which extend for up to 75 % of the length of each tubeworm. Unlike hydrothermal tubeworms such as *Riftia pachptila* that grow to lengths of more than 2 m in less than 2 years, *Lamellibrachia luymesi* grow very slowly for most of their lives. It takes from 170 to 250 years to grow to 2 m in length, making them perhaps the longest living known invertebrate species (Bergquist et al. 2000). With five or six species currently known to flourish there, the brine-fed cold seeps of the Gulf of Mexico host the highest biodiversity of vestimentiferan siboglinid tubeworms worldwide.

Interestingly, when the fast growing giant hydrothermal tubeworms (*Riftia pachptila*) were first collected from the vicinity of black smokers in the 1977, figuring out what they lived on in deep dark waters was mystifying: especially as adults had no mouths, guts, or anuses! They were first thought to be absorbing tiny food particles through their skin. The function of the trophosome was unknown but thought to be related to dealing with toxicity not feeding, after all these structures were lined with sulphur crystals. It is now known that the sulphur-oxidising bacteria, which inhabit the trophosome cells of these specialised siboglinids, use H_2S to produce nutrients in the form of organic carbon for the tubeworms to metabolise. Elemental sulphur is the common metabolic intermediate or food source of the sulphur-oxidising bacteria that live symbiotically in rift and cold seep tubeworms.

There is a time-based evolution in the biotal make-up of chemosynthetic communities in the Gulf of Mexico (Glover et al. 2010 and references therein). The earliest stage of a cold seep is characterised by a high seepage rate and the release of large amounts of biogenic and thermogenic methane, H_2S and oil (Sassen et al. 1994). As authigenic carbonates with characteristic negative $\delta^{13}C$ values precipitate as a metabolic byproduct of microbial methanogenesis, they provide a necessary stable substrate for the settlement of larval vestimentiferans and seep mussels. These seep communities begin with mussel (*Bathymodiolus childressi*) beds containing high biomass communities of low diversity and high endemicity. Individual mussels live for 100–150 years, whereas mussel beds may persist for even longer periods,

with growth rates of mussels largely controlled by methane concentrations (Nix et al. 1995).

The next successional stage consists of vestimentiferan tubeworm aggregations dominated by *Lamellibrachia luymesi* and *Seepiophila jonesi*. Young tubeworm aggregations often overlap in time with, and normally persist past the stage of mussel beds. These tubeworm aggregations and their associated faunas go through a series of successional stages over a period of hundreds of years. Declines in seepage rates result from ongoing carbonate precipitation occluding pores and so forming aquitards, as well as the influence of *L. luymesi* on the local biogeochemistry as it extracts ever larger volumes of H_2S. In older tubeworm aggregations, biomass, density, and number of species per square meter, decline in response to reduced sulphide concentrations.

Once seep habitat space becomes available, more of the nonendemic background species, such as amphipods, chitons, and limpets, can colonise the mussel and tubeworm aggregations. Due to the lowering concentrations of sulphide and methane, the free-living microbial primary productivity is reduced. The number of associated taxa is positively correlated with the size of the tubeworm-generated habitat, so diversity in this stage remains fairly high although the proportion of endemic species is smaller in the older aggregations. This final stage may last for centuries, as vestimentiferan tubeworms can live for over 400 years (Cordes et al. 2009).

Even as seepage of hydrocarbons declines in a particular seep site, the authigenic carbonate layers of relict seeps can still provide a stable seafloor substrate for marine filter feeders, such as cold-water corals. The scleractinians *Lophelia pertusa* and *Madrepora oculata*, several gorgonian, anthipatharian, and bamboo coral species form extensive reef structures atop now inactive seeps on the upper slope of the Gulf of Mexico (Schroeder et al. 2005). The corals obtain their food supply from the water column and are not dependent on chemosynthetic microbes. The coral communities also harbour distinct associated assemblages, consisting mainly of the general background fauna, but also contain a few species exclusively associated with the corals and a few species that are common to both coral and seep habitats.

Although individual tubeworms and molluscs in chemosynthetic brine pool communities may live for more than 300–400 years, vagaries in the rate of brine and nutrient supply to the seafloor mean many mussel and tubeworm colonies are overwhelmed by a rising halocline and so die in a shorter space of time. Their partially decomposed remains can spread out as part of the organic-rich debris atop the halocline, along with bacterial, algal and faecal residues, where it is acted upon by a rich community of aerobic and anaerobic decomposers. If the organic matter is mineralised or attaches to other interface precipitates such as pyrite, it sinks to the anoxic brine pool bottom, where it is largely preserved and protected from further biodegradation.

The inherently unstable nature of the seafloor in the vicinity of active salt allochthons and brine lakes means it is subject to slumping, especially in the vicinity of brine fed mud volcanoes. In such settings, parts of the carbonate-rich biostrome rim are periodically killed "en masse" as sediment about a brine pool edge collapses, slumps and slides into anoxic pool waters, carrying with it the chemosynthetic community. As well as further elevating levels of preserved organics in the brine pool bottom sediments, this process also creates potential fossil lagerstaette (see later discussion of Burgess Shale). Death of seep communities, even if it survives such catastrophic events, ultimately comes when the supply of seep gases and liquid hydrocarbons is cut off to any single seep.

Hardgrounds, Settings and Stable Isotopes

Associated with the brine-pool communities, and helping form an initial stable seafloor substrate for the colonising seep invertebrates, are calcite-cemented biogenic crusts. These cemented hardgrounds precipitate as a microbial byproduct wherever methane and H_2S are bubbling up in and around brine pool edges and gases are being metabolised by chemosynthetic archea and bacteria (Canet et al. 2006; Fu Chen et al. 2007; Feng et al. 2009). The resulting biogenic calcite crusts have $\delta^{13}C_{PDB}$ values ranging to as low as −53‰, which is characteristic of methanogenic carbon (Fig. 9.60a). Seep sediments retain a group of unsaturated 2,6,10,15,19-pentamethylicosane (PMI_{Δ}) compounds, also produced by methane-oxidizing archaea, with $\delta^{13}C_{PDB}$ values ranging from −107.2 to −115.5‰. In combination the isotope values, textures and biomarkers indicate a combination of bacterially catalysed methane oxidation and sulphate reduction plexi in the crusts.

Fabrics of the two flat sides of methanogenic calcite crusts crust are texturally distinct. The "top" side is composed entirely of microcrystalline calcite, while the bottom is composed entirely of "wormy" carbonate cement that is interpreted as a random, low fidelity replacement of bacteria. Microcrystalline calcite is coated by "wormy" carbonate cement in the interior of the thick crust, and dispersed pyrite framboids appear to be indicators of collaborating colonies of methane-oxidizing archaea and sulphate-reducing bacteria. Fu Chen et al. (2007) propose that the "wormy" carbonate texture, particularly with microcrystalline calcite and pyrite framboids present, is a likely indicator of biologically controlled fabrics produced during methane oxidation and sulphate reduction.

Hypersaline brines and entrained gases escaping and pooling on the Gulf of Mexico seafloor do so either into quiescent brine lakes and pools or as mud chimneys and volcanoes (Fig. 9.61; Joye et al. 2009). Both environments are

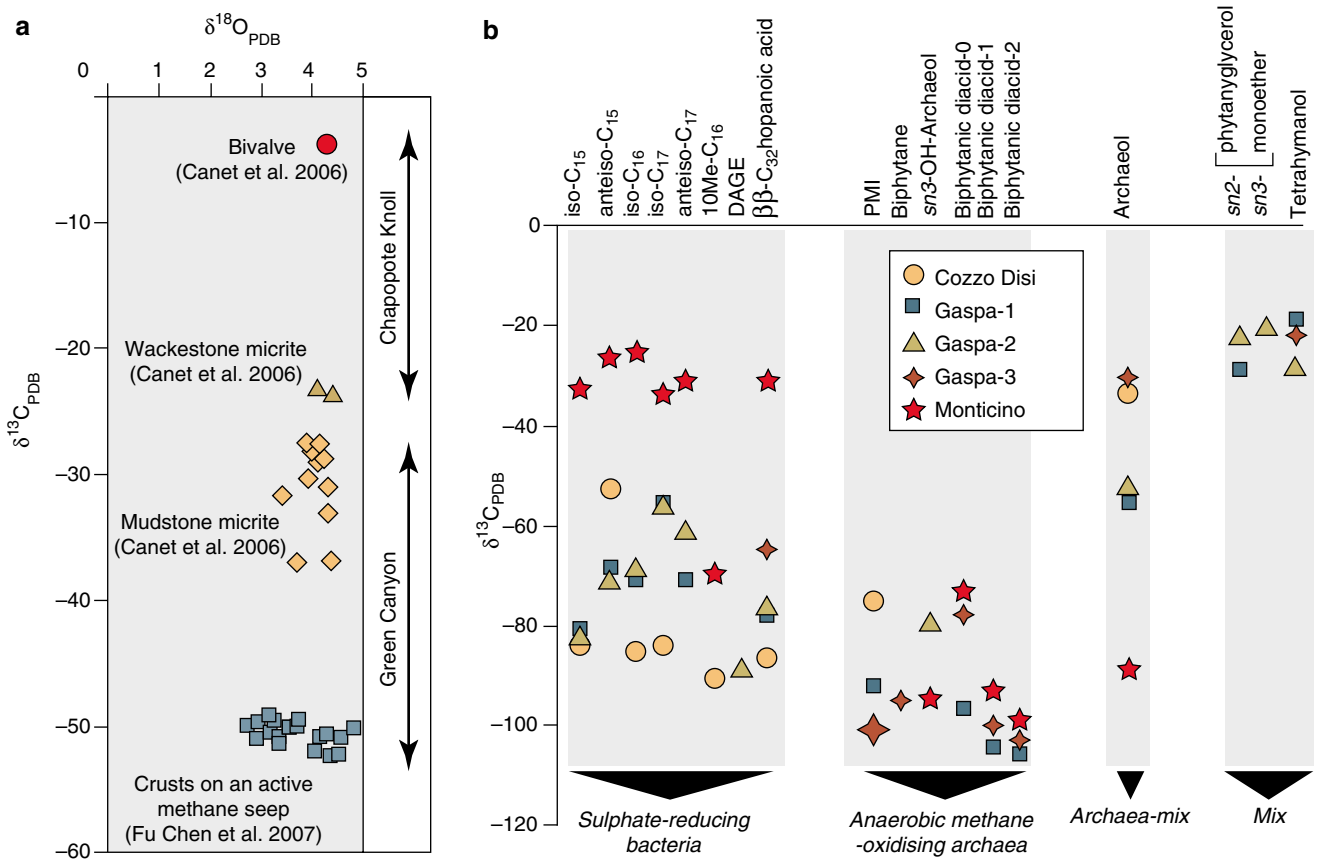

Fig. 9.60 Isotope characteristics of cemented crusts and Messinian carbonates. (**a**) Carbonate-cemented seep crusts at methanogenic brine seep sites in the Gulf of Mexico (Data replotted from Canet et al. 2006; Fu Chen et al. 2007). (**b**) Carbon isotopic composition of selected molecular fossils in authigenic seep carbonates in Messinian sediments from locations in Sicily and the Northern Apennines (After Ziegenbalg et al. 2012). The plot illustrates a shift toward less negative $\delta^{13}C$ values of biomarkers from anaerobic methanotrophic archaea (ANME) to markers from sulphate-reducing bacteria (SRB), archaeol (archaea-mix), and other water column-derived compounds (others). The wide span of $\delta^{13}C$ -archaeol values reflects a mixture from ANME-sourced archaeol and archaeol derived from other, non-methanotrophic archaea. Note that SRB lipids from Monticino cluster at less negative $\delta^{13}C$ values (*red stars*)

anoxic and hypersaline, brine pools are typified by low fluid-flow rates and waters free of suspended sediment, while flow rates in mud volcano chimneys are more vigorous and the waters tend to be more turbulent and carry more suspended load. The sharp salinity transition between hypersaline brine and seawater typifies the water column in both settings, and a higher suspended particle load underscores the more rapid fluid-flow regime of the mud volcano (Fig. 9.61a, f). Brines in both are mildly sulphidic; concentrations of dissolved inorganic carbon are elevated relative to seawater. Microbial abundance is 100 times higher in brines than in the overlying seawater (Fig. 9.61a, f), showing that brine-derived substrates produce high microbial biomass. The brines are gas charged; the dominant dissolved alkane is methane (94–99.9 %) with a stable carbon isotopic composition, ^{13}C, of −62‰.

The brines form via halite dissolution and contain no sulphate. Seawater sulphate diffuses into the brine, and concentrations decrease with depth, reflecting a combination of microbial consumption through sulphate reduction (both sites) and upward advection of sulphate-free brine in a mud volcano (Fig. 9.61b, g). The hydrogen profile in the mud volcano brine is fairly uniform (hundreds of nanomolar), reflecting the potential importance of autotrophic acetogenesis and/or hydrogeno-trophic methanogenesis. In the brine pool, however, hydrogen concentration increases to micromolar levels between ≈25 and 100 cm depth and remains high (≈μ6 M) to 180 cm, promoting acetogenesis. Such high hydrogen concentrations indicate active fermentation and substantial inputs of labile organic matter. Concentrations of dissolved organic carbon (DOC) increases with depth (Fig. 9.61b, g), suggesting a deep-subsurface DOC source (thermogenic?). In the brine pool, extra labile DOC, probably coming from the surrounding chemosynthetic community can further stimulate fermentation (Joye et al. 2009).

Rates of acetate production and levels of sulphate reduction are much higher in brine pools, whereas the mud volcano supports much higher rates of methane production

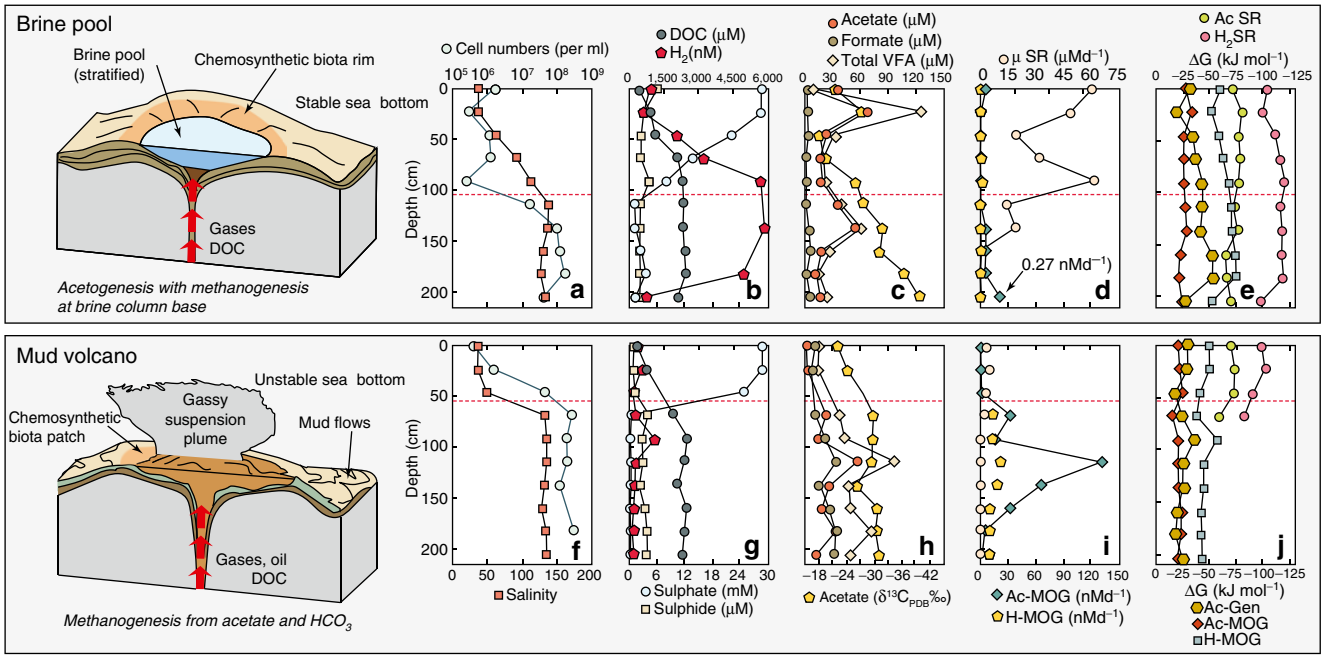

Fig. 9.61 Depth profiles of microbial abundance, geochemistry, activity and energetics in the brine pool halocline. Charting of the profiles as (**a**–**j**) as vertical comparison for brine pool (as **a**–**e**) and mud volcano (**f**–**j**). *Red dashed line* indicates position of the halocline. Microbial abundance (cell count and salinity as **a**, **f**); Hydrogen (H_2), Sulphate (SO_4), Hydrogen sulphide (H_2S) and DOC concentration as (**b**, **g**); VFA concentration and the acetate carbon ^{13}C as (**c**, **h**); Rates of microbial processes for methanogenesis as (**d**, **i**), the rate scale for profile D is 100 times lower than the scale for (**i**); and the Gibbs free energy ΔG yield as (**e**, **j**). Abbreviations; *SR* sulphate reduction, *Ac-MOG* acetate-based methanogenesis, *H-MOG* hydrogen-based methanogenesis, *Ac-SR* acetate-based sulphate reduction, *H-SR* hydrogen-based sulphate reduction, *Ac-Gen* acetatogenesis (After Joye et al. 2009)

(Fig. 9.61d, i). Joye et al. (2009) found no evidence of anaerobic oxidation of methane (AOM), despite high methane fluxes in both settings. It suggests both these systems are leaking methane into the overlying water column. Joye et al. conclude that the contrasting halo-adapted microbial community compositions and metabolisms are linked to differences in dissolved-organic-matter input from the deep subsurface and different fluid advection rates between the two settings.

Ancient Saline Seeps

Isotope character of ancient methanogenic seep carbonates and cements in the Messinian 'Gessoso Solfifera' Formation in Sicily, at Cozzo Disi and Contrada Gaspa, as well as in the northern Apennines from the Monticino locality, were studied by Ziegenbalg et al. 2012 (Fig. 9.60b). Historically, these authigenic carbonates (that include the native sulphur deposits of the Cosi Disi mine) were thought to be a result of microbial degradation of organic compounds in a sulphide-rich evaporitic setting and probably related to bacterial sulphate reduction. But, prior to the Ziegenbalg et al. study, organic indicators of actual mechanisms were not well documented (Fig. 9.60b). $\delta^{13}C_{PDB}$ values are as low as −49‰ and reflect incorporation of carbon derived from the oxidation of methane, which was suggested in earlier isotopic studies to have been linked to bacterial sulphate reduction.

Molecular fossils extracted from the limestones reveal that methane was indeed oxidized in an anaerobic process by archaea and sulphate-reducing bacteria. The observed biomarker patterns resemble those of methane-seep carbonates, such as those in the brine pools on the deep sea floor of the modern Gulf of Mexico. The latter form as a consequence of the anaerobic oxidation of methane (AOM). Supporting this interpretation, AOM-specific, ^{13}C-depleted archaeal biomarkers were identified in the Messinian carbonates, such as tail-to-tail linked pentamethylicosane (PMI; $\delta^{13}C$ −101 to −75‰), as well as compounds derived from sulphate-reducing bacteria (iso- and anteiso-fatty acids; $\delta^{13}C$ as low as −85‰).

Although the biomarker results clearly point to anaerobic oxidation of methane in the formation of the Italian crusts, the compound inventory also reveals distinct differences to patterns found at marine methane-seeps in modern settings (Fig. 9.60b). For example, sn3-hydroxyarchaeol is in some samples the only hydroxyarchaeol present, something usually not found at seeps. Archaeol is less depleted in ^{13}C than PMI at most sites (^{13}C; −55 to −30‰), pointing to the co-occurrence of methanogenic or halophilic archaea with

(**b**) Stable isotope plot showing distinctive plotfield of each of the 3 seep carbonates (After Natalicchio et al. 2013)

archaea involved in AOM. In addition; (1) The presence of calcite pseudomorphs after lenticular gypsum, (2) ^{18}O-enrichment in carbonates, and (3) the biomarkers O-phytanyl-O-sesterterpanyl glycerolether (extended archaeol), tetrahymanol, and possibly phytanylglycerol monoethers as well as non-isoprenoidal macrocyclic glycerol diethers, confirm that carbonate formation took place under evaporitic conditions in the overlying brine columns (Fig. 9.62a). AOM has previously been shown to be inhibited in some brine pools on the modern seafloor, but the work of Ziegenbalg et al. 2012 demonstrate that AOM functions in solar-driven hypersaline environments as well as on the deep sea floor.

The formation of seep carbonates at first beneath a hypersaline sea, during precipitation of the Messinian evaporites of Italy, was confirmed in a geological study of rock textures and stable isotope signatures in transported limestone blocks in Messinian mass transport complexes in the Tertiary Piedmont Basin, NW Italy (Fig. 9.62; Natalicchio et al. 2013). Seep carbonates are preserved as blocks within a chaotic unit emplaced during drawdown tied to the Messinian salinity crisis (Fig. 9.62a, b). All these carbonates show characteristic negative $\delta^{13}C_{PDB}$ values (from −27 to −15‰), defining a stable isotope plot field that overlaps seep micrites in the modern Gulf of Mexico. It indicates the involvement of hydrocarbon-rich fluids in the genesis of the Italian seep carbonates (Fig. 9.62c compared with 9.60a). Three types of carbonates are recognised: (i) vuggy carbonates; (ii) *Lucina* carbonates; and (iii) tubeworm carbonates (Fig. 9.62a, b).

Vuggy carbonates blocks are characterised by carbonate pseudomorphs after gypsum and probably formed during the first stage of the salinity crisis. They are the product of a complex diagenesis, influenced by both hypersalinity and cross seepage of hydrocarbon-rich fluids. These rocks lack chemosymbiotic biotal assemblages, reflecting their

formation under extreme environmental conditions of the Messinan salinity crisis, inhospitable for most metazoans. In contrast, *Lucina* and tubeworm carbonates are characterised by chemosymbiotic macrofauna, represented respectively by *Lucina* bivalves and putative vestimentiferan tubeworms. These carbonates indicate the escape of brines into lower salinity likely-normal marine waters in the overlying deep-water column.

The latter biotal assemblage has not been widely documented in ancient seep carbonates and prior to the work of Natalicchio et al. (2013) had not been reported from the Messinian sediments of the Piedmont Basin. Both *Lucina* and tubeworm carbonates are interpreted as the product of hydrocarbon seepage during the second stage of the salinity crisis related to the gravity-induced collapse and mass transport of olistostrome blocks from earlier formed gypsum saltern (Fig. 9.62b; see Chap. 5, especially Fig. 5.53 associated text for discussion of relevant literature). These two types of seep carbonates formed under less severe conditions than the vuggy carbonates, allowing the survival of seep-dwelling metazoans. During this second stage of the Messinian Salinity Crisis, the seafloor was probably characterised by an irregular topography and a thin bottom layer of dense anoxic brines, produced by the dissolution of evaporites, dominantly gypsum.

It seems that the Miocene vestimentiferan worms were able to thrive on carbonate cemented seep that were morphologic highs, with the posterior part of worm tubes located just below the oxic–anoxic interface, but the anterior part projecting into oxic water, as in the Gulf of Mexico today. On the adjacent *Lucina* seeps, not only were *Lucina* bivalves oxygen-dependent, but many specimens reveal boreholes in their shells, reflecting drilling predation by an oxygen-dependent set of marine borers (Taylor and Glover 2009). Unlike the tubeworms, the infaunal *Lucina* bivalves were only able to live at seeps positions with an overlying oxic water column, much like *Bathymodiolus childressi* in modern Gulf of Mexico brine lakes and seeps. Subsequent and ongoing gravity-driven transport brecciated the various seep-limestone blocks, so that currently they outcrop at various stratigraphic levels in the Messinian transport complex (lower right of Fig. 9.62a).

Outcropping in the Canadian Northwest Territories are Cretaceous counterparts to Gulf of Mexico methanogenic brine-seeps (Savard et al. 1996). Ancient methane-rich mud mounds grew atop growth faults activated by salt diapirism in the Sverdrup Basin. Crusts still preserve relic splays and isopachous layers of fine, acicular aragonite, and large botryoids of low-magnesium calcite, showing spectacular entanglement of former fibrous calcite and aragonite cements, as occurs in seep crusts today in parts of the Gulf of Mexico. These ancient hardgrounds also show the characteristic ^{13}C depleted values of methanogenic cements.

A similar set of brine-pool seafloor-seep deposits typify even older, locally-cemented and fossil-rich lenses of Cambrian carbonates hosted in the basinal Burgess Shale, near the Cathedral escarpment in British Columbia (Fig. 6.93; Johnston et al. 2009). The Middle Cambrian Burgess Shale Formation, is remarkable for its preservation of non-biomineralized fossils. It is exposed in an outcrop belt that extends some 60 km from the type area around Field, British Columbia, to a mountain known as The Monarch on the eastern edge of Kootenay National Park. World famous Cambrian soft-body fossils assemblages (including forms such as *Hallucigenia* a precursor to the velvet worms) are known from several localities in the Burgess Shale. For more than three decades, the Burgess Shale fossil assemblages have been interpreted as a "normal fore-reef faunal complex." This unusual soft tissue biotal assemblage is used to illustrate the Cambrian explosion and the associated plethora of soft-bodied Cambrian life forms, that are long since extinct (Collins et al. 1983).

These sites invariably occur in close proximity (≈50 m according to Johnston et al. 2009) to the Cathedral Escarpment, a steeply dipping surface marking the headwall of the gravity-collapsed margin of the platformal carbonates of the Cathedral Formation, against which the Burgess Shale accumulated. The trend of the Cathedral Escarpment coincides with a fault-controlled, linear, palaeotopographic feature known as the Kicking Horse Rim. Faults along this structure were probably important conduits for dolomitizing and mineralizing brines rising from deeper saline strata along the platform margin during the Middle Cambrian, even as the Burgess Shales were accumulating (Powell et al. 2006). The altered strata that precipitated from the fault-focused magnesian brines have now been metamorphosed to lower greenschist facies and currently host clinochlore and minor double-terminated quartz euhedra. Based upon the bulk-rock composition, the protolith of these seep-related magnesian-rich strata is inferred to have been composed of Mg smectite, with lesser kaolinite, and minor brucite.

Epiphyton-rich carbonate megablocks occur within the basinal strata adjacent to the Cathedral escarpment. Previously these blocks were interpreted as olistoliths and were thought to have spalled off the Cathedral Escarpment. However, the biota and texture in these "blocks" are unlike the peritidal strata that comprising the adjacent Cathedral platform margin. More likely they are part of local deep-water carbonate mud mound chemosynthetic seep association that grew in the basin near the faulted Escarpment face (Johnston et al. 2009). Evidence for early brines crossflows and surface brine lakes on the deep seafloor includes the aforementioned lenses of dark, magnesium-rich clinochlore (>30 wt% MgO vs ≈2 % in background shales) within the Burgess Shale. The clinochlore distribution defines an alteration halo best developed in proximity to the escarpment wall.

These clinochlores are interpreted as precipitates from seafloor brine seeps, analogous to those currently forming at the foot of the Florida Escarpment and on the distal shelf and slope of the northern Gulf of Mexico. Similar magnesian brucite/brunnerite alteration haloes about brine-fed faults occur along faults that sole out in rauhwacke levels in Neoproterozoic outcrops in the Flinders Ranges and the Mesoproterozoic carbonates of the Mcarthur Basin, Australia (Chaps. 7 and 15).

Like modern brine seeps focused along the base of the Florida escarpment, fault-fed brines likely formed standing pools on the Cambrian deep seafloor along the foot of the Cathedral fault escarpment. There Cambrian brine lakes hosted abundant chemosynthetic organisms in a narrow biotal fringe around brine pool peripheries, but not within the highly saline and anoxic waters of the brine pools (Fig. 9.63). Sponges, priapulid worms, hyoliths, linguliform brachiopods and trilobites predominate in this fringe facies. Shales only a few metres basinward from the pools are interpreted as hemipelagic muds, nearly barren of animal fossils. Increased biologic productivity localized at the seeps would account for the patchy distribution of fossils in the Burgess Shale in a narrow zone close to the Escarpment. The discovery of brine seep deposits and associated fringing communities at this well known Burgess Shale locality shows that at least some assemblages in the Burgess Shale were preserved within their habitat and were part of a deep seafloor community supported by chemosynthesis. Instability on the brine pool margins, as we see in the Gulf of Mexico seafloor today, probably aided rapid pickling in waters of the brine lake and facilitated the preservation of soft tissue in a Cambrian lagerstaette.

If the evaporite and saline chemosynthetic indicators that made up of various brine pool/seep systems are not recognised in ancient counterparts, then, once the underlying or adjacent allochthonous salt sheets have dissolved or moved on, the evaporite hydrology that focused the accumulation of organic-rich pyritic brine pool sediments will become an enigma (Warren 2000b). In the Phanerozoic, any remaining organic constituents will be made up primarily of marine plankton, a benthic marine biota and bacteria from a normal marine setting. Sediments above and below the pyritic pellicular laminites and possible lagerstaette are also made up of normal marine deepwater deposits. There will be little geochemical evidence to show that these organic-rich pyritic sediments were preserved in a hypersaline deep marine environment.

Evidence of the significance of flowing evaporites in creating such a sequence will only come from sedimentological and structural analysis of core or outcrop from below and adjacent to the laminites, and the recognition of halokinetic breccias, salt welds, chemosynthetic biostromes and marine-cemented hardgrounds within a deeper water marine sediment matrix.

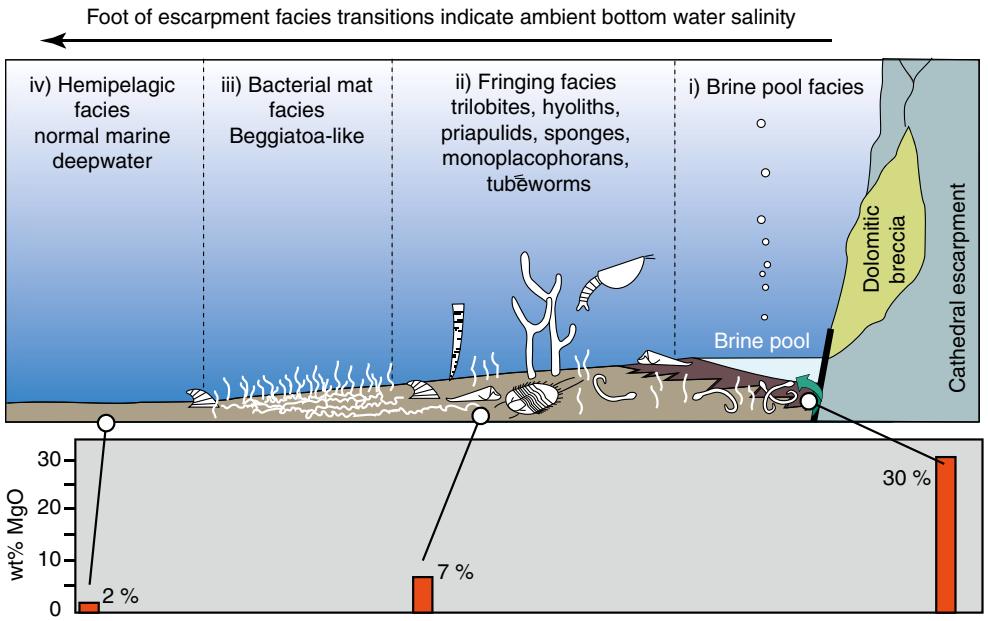

Fig. 9.63 Salinity-related facies transitions in the Burgess Shale brine pools at Monarch Assiniboine and located at the foot of the Cathedral Escarpment, British Columbia: (*i*) brine pool facies; (*ii*) fringing fauna facies: examples of fauna shown include trilobites, hyoliths, priapulids, monoplacophorans, sponges, and pogonophoran (?) worm tube Byronia. White filaments mark inferred presence of sulphur-oxidizing bacteria like modern *Beggiatoa*; (*iii*) bacterial mat facies with rare fauna; (*iv*) hemipelagic facies. To right is Cathedral Escarpment with it characteristic dolomitized breccia; brines rising along the fault scarp indicated by green arrow. Lower part of figure plots typical MgO values for facies (*i*), (*ii*) and (*iv*) of 30, 7 and 2 wt%, respectively (After Johnston et al. 2009)

Life in the Saline Subsurface

It is becoming increasingly obvious that chemolithotrophic microbial communities influence diagenesis to depths well below the eogenetic realm (Fry et al. 2008; Reith 2011; Parkes et al. 2011). Some microbial members of the seep communities have chemolithotrophic metabolisms that can continue to be active in H_2S and methane-rich pore waters into biozones possibly extending a kilometre or two below the surface. Some predict the extent of viable chemolithotropes, possibly utilising hydrogen, could be deep as 15 km (Hazen and Schiffries 2013). But such extreme biozone depths are not yet sampled and beyond 500 m depth no reliable cultures have been recovered (due to possible sample contamination problems, related to nonsterile drilling fluids or access to samples by contaminated mine waters).

As any organic matter in evaporitic sediments is buried it becomes hotter and this, along with increasing pressure, will ultimately kill off most of the chemosynthetic biota. Pore water can also be anomalously heated locally by intrusions and crossflows of fault-focused hydrothermal fluids. Organics, both conventional source rock precursors and chemolithotrophic debris, are altered in a number of ways in the subsurface burial environment, mostly tied to rates of temperature increase and the presence or absence of oxygen and other gases in the pore fluids (Fig. 9.64).

Subsurface interfaces (mixing zones) between hypersaline water, typically with reducing dysaerobic to anaerobic chemistries, and less saline waters, typically with more oxidised and oxygenated chemistries, create redox fronts in aquifers adjacent to subsurface evaporites. In hypogene and outcropping aquifers the interface is often defined by a colour transition from green (reduced) to red (oxidising) forms of iron in the sediment matrix. Less saline waters tend to dissolve evaporites and create secondary porosity (mostly vuggy and collapse fracture), while at the same time chloride or sulphate rich ions pass into solution.

Sulphur occurs in variety of oxidation states in the subsurface with the three oxidation states of −2 (sulphide and reduced organic sulphur), 0 (elemental sulphur) and +6 (sulphate) being the most significant. Where the sulphate in solution interacts with the organics in the vicinity of the redox interface, H_2S is generated via sulphate reduction, either biogenic or thermochemical. H_2S in solution creates acids that can dissolve adjacent carbonate matrix, and then reprecipitate the bicarbonate as deep phreatic blocky calcite cements, along with pyrite and other metals on the reducing side of the redox interface (Fig. 9.64). Much of the H_2S that is found in elevated amounts in an evaporitic basin is bacterially or thermochemically generated via sulphate reduction from sulphate carried by brine and derived from dissolving sulphate beds. Additional H_2S in an evaporite basin can be generated from local magmatic and biogenic sources.

Any association of dissolved sulphate and hydrocarbons (or organic matter) is thermodynamically unstable in all diagenetic settings and the chemical response is sulphate reduction (Machel 2001). Sulphate reduction

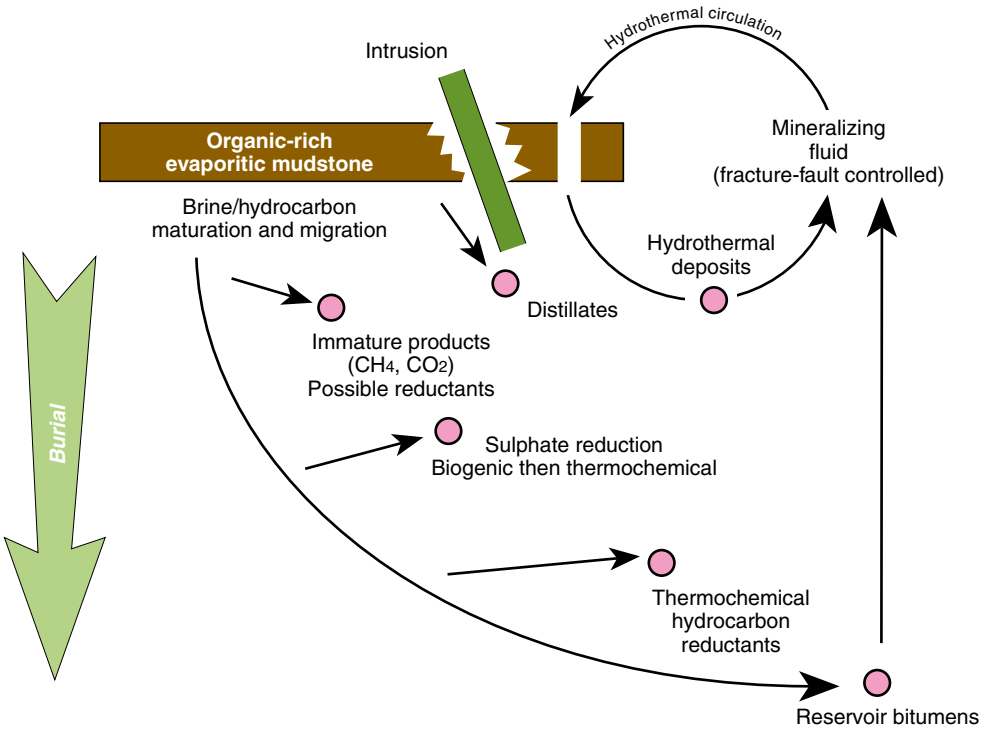

Fig. 9.64 The role of organic-rich evaporitic mudstones in burial diagenesis. The mudstones can act as a source of hydrocarbons and as a reductant for metals

reactions can be bacterially mediated through the activities of sulphate-reducing bacteria (bacterial sulphate reduction-BSR) or inorganically mediated under conditions of increased temperature and pressure (thermochemical sulphate reduction – TSR). Both scenarios require the presence of organic matter, or its more evolved subsurface equivalent in the form of hydrocarbons (oil or gas), and result in similar but not identical carbonate cements, mostly blocky calcite or occasional mesogenetic dolomite. The bacterially-mediated sulphate reduction system operates at lower burial temperatures <110 °C, mostly <60–80 °C, in a temperature range equivalent to vitrinite reflectances R_o of 0.2–0.3. Thermochemical sulphate reduction processes require temperatures of more 120 °C and R_o values ranging from 1.0 to 4.0 (Fig. 9.65). Both these processes, BSR and TSR are very important in the realms of economic geology as the H_2S produced can react with metal-bearing fluids to precipitate metalliferous sulphides (Fig. 9.64; and ore deposits as discussed in Chaps. 15 and 16).

Bacterial Sulphate Reduction (BSR)

BSR takes place in surface and nearsurface environments where sulphate-reducing bacteria utilise dissolved sulphate and organics/hydrocarbons to produce H_2S (Fig. 9.65a, c; Trudinger et al. 1985; Machel 1987, 2001; Hill 1995; Riciputi et al. 1996; Aref 1998b). So far we have discussed bacterial sulphate reducers in the context of stratified brine columns, where they flourish in anoxic cool waters beneath the halocline, or in benthic cyanobacterial mats where they occupy the low anoxic portions of the mat. In this section we will look at the nature of BSR in the extended subsurface, where bacteria inhabit warmer fluids in pores and fractures, either in sediments entering the burial environment or in sediments undergoing telogenesis as they are uplifted and re-enter cooler nearsurface settings. When the term bacterial sulphate reducer is used it now known to be used phylogenetically as there are both bacterial and archaeal members of the grouping (220 species of 60 genera), some of whom inhabit bottom brines and oilfield waters with salinities in excess of 200 ‰.

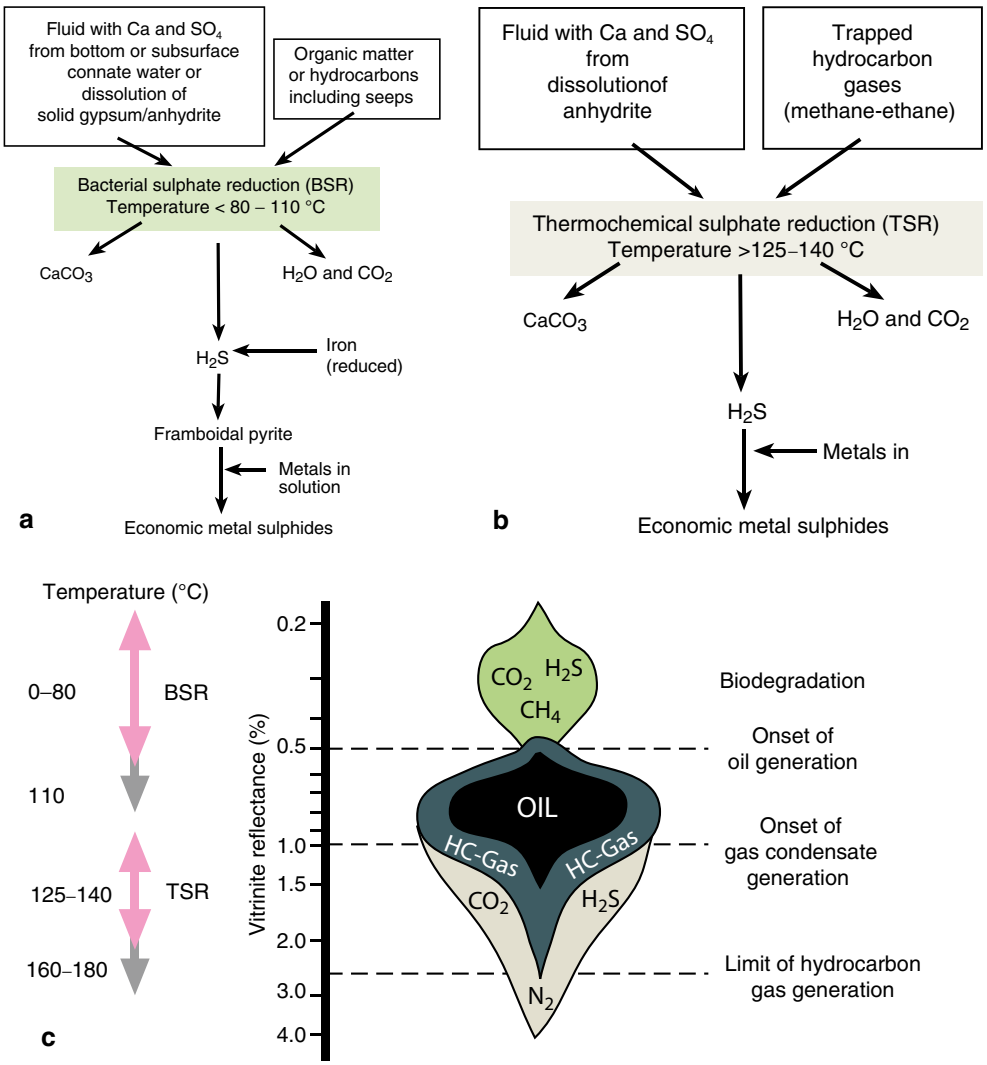

Fig. 9.65 Chemical pathways and thermal regimes associated with sulphate reduction. (**a**) Bacterial sulphate reduction – BSR. (**b**) Thermochemical sulphate reduction – TSR. (**c**) Thermal regime and hydrocarbon generation stages tied to characteristic values of vitrinite reflectance (In part after Machel 2001; Warren 2000b) Note that there is a lack of biogenically produced pyrite framboids during thermochemical sulphate reduction

Bacterial sulphate reduction occurs at temperatures typically <80 °C, although hyperthermophilic archaeal sulphate-reducers (*Archaeoglobus* sp.) can grow around hydrothermal vents on the deep ocean floor at temperatures up to 114 °C. In regions with normal geothermal gradients the temperature range <60–80 °C corresponds to burial depths from the surface down to 2,000–2,500 m. Tentative identifications of sulphate reducers, active in formation waters of sandstone reservoirs in the Samotlor high-temperature oil reservoir (Western Siberia, Russia) and collected from depths of 2,500 m, were documented by Bonch-Osmolovskaya et al. (2003). BSR processes and bacterial sulphate reducers are widespread in many anoxic saline subsurface sediments and not directly related to evaporite beds. But the discussion in this section concentrates on those types of sulphate reduction that are commonplace in regions of dissolving evaporites and associated saline pore waters. Such systems tend to form bioepigenetic limestones and cements with textures and isotopic signatures typically indicating an evaporite precursor or association.

Bacterial sulphate reduction is usually expressed by the equation;

$$Ca^{2+} + 2SO_4^{\ 2} + 2CH_4 + 2H^+ \rightarrow 2H_2S + CaCO_3 + 3H_2O + CO_2$$

It is the metabolic process set used by a group of prokaryotes to obtain energy by oxidizing organic compounds or molecular hydrogen (H_2) while reducing sulphate (SO_4^{2-}) to hydrogen sulphide (H_2S). In a sense, these organisms "breathe" sulphate rather than oxygen, in a form of anaerobic respiration used for the last 3.5 billion years. At pH < 6–7 the produced H_2S is undissociated; at pH > 6–7, H_2S dissociates so that H_2S —> $H^+ + HS^-$ (Hill 1995). In this equation, SO_4 indicates dissolved sulphate, which is derived either from shallow phreatic refluxing brine/seawater or from dissolving sulphate evaporites such as gypsum, glauberite, or anhydrite. $CaCO_3$ represents bioepigenetic limestone products, which typically precipitate as cements or replacements of precursor evaporite sulphates. CH_4 represents a host of possible organic compounds or hydrocarbons, mostly organic acids and other products of aerobic or fermentative biodegradation.

The initial S–O bond rupture during the BSR commonly involves a kinetic fractionation of about −15 to −30‰ in the $\delta^{34}S$ values depending on the specific types of bacteria involved and their growth rates (Table 9.11). Subsequent sulphur isotope fractionation can be even larger, if intermediate compounds, such as thiosulphate or polysulphides, are produced. Bacterial reduction of these compounds involves additional negative fractionations, and disproportioning of enrichment of the resulting sulphide in ^{32}S. In this way, composite negative sulphur fractionations of up to −65‰ can be obtained during BSR (Machel et al. 1995).

Table 9.11 Summary of sulphur isotope fractionations of inorganic compounds

Isotope fractionation	Process	$\delta^{34}S_{CDT}$ (‰)
SO_4^{2-} --> S^{2-}	Bacterial sulphate reduction (BSR)	−15 to −65‰
	Thermochemical sulphate reduction (TSR)	−20‰ at 100 °C
		−15‰ at 150 °C
		−10‰ at 200 °C
Maturation		< −2‰
S^2 --> S^o	Oxygen	−5 to −7.5‰
	Sulphate	±0 to −3‰
	Hydrocarbons	?
	Anaerobic bacteria	±0 to +2‰
	Aerobic bacteria	±0 to −18‰
S^o --> SO_4^{2-}		±0‰

After Machel et al. 1995

There are two well established genera of sulphate-reducing bacteria, *Desulphovibrio* and *Desulphotomaculum*, they seem to be quite unrelated to each other and their relation to other bacterial groups is also obscure. Members of the better known genus, *Desulphovibrio*, are mesophilic (prefer a moderate temperature range) and can be moderately halophilic (Fig. 9.19b); at the present time the genus is thought to contain seven species. *Desulphotomaculum* species are somewhat more difficult to isolate and purify. They are characterised by spore formation and are sometimes thermophilic; only one moderately halophilic strain has been reported in the five recognised *Desulphotomaculum* species (Postgate 1984).

Mesophilic isolates of the genus *Desulphovibrio* will typically not grow above 45 °C. Thermophilic isolates of the *Desulphotomaculum* genus have been grown at temperatures as high as 70 °C – the most common species of thermophile being *Desulphotomaculum nigrificans*. However, Rozanova and Khudyakova (1974) isolated an apparent *Desulphovibrio sp*. having a maximum growth temperature of 85 °C, while Zobell (1957) claimed that he had isolated viable sulphate-reducing bacteria from an oil-bearing reservoir where growth was occurring at 104 °C under a pressure of 1,000 atm. Both these higher temperature reports were not biologically documented under absolutely sterile collection conditions. The upper temperature limit for subsurface biogenic sulphate reduction is usually considered to be 80–85 °C (Trudinger et al. 1985), a reasonable estimate for documented sulphate reducers in most evaporitic and shallow subsurface settings. It means the most vigorous bacteriogenic reduction (>50 °C) typically extends from any nutrient-rich brine column oxic-anoxic interface down to redox fronts at burial depths of a kilometre or so.

Under suitably pressurized deep-sea seep conditions, and perhaps some subsurface conditions, biogenic sulphate

reduction can extend into higher temperature regions. Work in the anhydritic deep-sea hydrothermal vent sediments of the Guaymas Basin in the Gulf of California has revealed biologically mediated sulphate reduction by hyperthermophilic Archaea at temperatures up to 110 °C, with an optimal rate at 103–106 °C (Huber et al. 1989; Jørgensen et al. 1992). But such hyperthermophilic sulphate reducers are not recovered from formation brines of most subsurface hydrocarbon-rich settings, otherwise sweet (non H_2S) oils would be a rare style of oil occurrence at temperatures less than 110 °C (Machel 2001).

Bacterial sulphate reduction in evaporitic settings typically occurs near an aerobic/anaerobic interface. It may be a density interface in a layered brine column, it may be at the aerobic-anaerobic interface just below the sediment surface, it may be at an oil/water contact at greater depths, or it may be a subsurface diffusion or mixing zone, focused by faults, fractures and bedding boundaries. Although most geologists think of the BSR communities as anaerobes, work on microbial mats has shown some members of the phylogenetic SRB can, in fact, tolerate and even respire oxygen (Baumgartner et al. 2006). Investigations of modern microbial mat systems have demonstrated that some members of the SRB are both abundant and active in the oxic zones of microbial mats (Fig. 9.20).

Additionally, SRB have been found to be highly active in the lithified zones of microbial mats, suggesting a connection between sulphate reduction and mat lithification. For example, much of the micrite precipitated as syndepositional cement in marine stromatolite laminae in metre-high structures in tidal channels of Lee Stocking Island in the Bahamas, are a byproduct of bacterial sulphate reduction. This BSR-induced precipitation occurs within millimetres of normally oxygenated seawater (Visscher et al. 2000). Likewise BSR controls the precipitation of microbial carbonate in mm-layered mats in a modern hypersaline lake on Eleuthera Island in the Bahamas and primary dolomites in Brazilian coastal salinas (Dupraz et al. 2004, 2009).

At broader subsurface scales, anoxic interfaces suitable for BSR tend to form near the dissolving margins (top or bottom) of shallow salt beds and allochthons, or within diapir caps, or near fractures and other breaches in dissolving calcium sulphate beds. These are all sulphate-rich environments where focused crossflow and mixing occurs between reduced basinal waters and more oxic waters. Wherever hydrocarbons are involved, most sulphate-reducers cannot directly digest long chain n-alkanes (paraffins) as nutrients. Instead, they depend on metabolic residues of hydrocarbon biodegradation, such as the various organic acids produced by aerobic biodegradation of oil (Davis and Kirkland 1970; Machel 1987, 1995; Lock et al. 2004). Thus, sulphate reducers in the deeper subsurface have been historically thought of anaerobes, which depend on aerobic bacteria to create suitably biodegraded hydrocarbon substrates. Sulphate-reducing bacteria then oxidize the biodegraded hydrocarbons to HCO_3 and bitumen residues, while simultaneously reducing the dissolved sulphate to H_2S. Where methane is the main carbon source, all the methane is oxidized into HCO_3, and no bitumen residue forms (Machel 1989). Production of H_2S favours the precipitation of carbonate cement or the replacement of dissolving sulphates by calcite. H_2S may escape into the atmosphere or come into contact with dissolved oxygen in an aquifer or a diffusion zone, where it is oxidized into elemental sulphur, as in most shallow sulphur deposits (Chap. 11; Berner 1980).

Sulphate-reducing bacteria are responsible for the laminar vuggy bioepigenetic limestones that make up the caprocks of the Gulf Coast and Zechstein diapirs, the Castile Formation mounds in the Gypsum Plain, Culberson County, West Texas, the Messinian Gessoso Solfifera of Sicily, as well as numerous other calcitic limestones that replace sulphate evaporites worldwide (Kyle and Posey 1991; Peckmann et al. 1999). Subsequent weathering of the encasing gypsum means indurated and less soluble calcitic buttes tend form irregular steep-sided hillocks, as in the Castiles rising 3–30 m above the Gypsum Plain of West Texas (Kirkland and Evans 1980; Stafford et al. 2008a, b). Castile calcite masses did not precipitate at the surface, they originally formed hypogenically, some hundreds of metres below the surface (Fig. 7.63a).

The bacterial/hydrocarbon association of these bioepigenetic limestones is evidenced by their negative $\delta^{13}C$ and $\delta^{34}S$ signatures (Fig. 9.66a, b). Carbon in calcite making up a Castile is sourced by the breakdown of organic matter or hydrocarbons and does not come from dissolution of marine limestone (Fig. 9.66c lists typical $\delta^{13}C$ values from various organic sources). Sulphate-replacing calcites formed by BSR are typically ^{13}C depleted, and this isotopic signature, along with their more negative sulphur isotope signature (compared to marine sulphates), is used to characterise BSR-induced calcites worldwide (Figs. 9.66 and 9.70).

Widespread bioepigenetic limestone buttes or castiles today outcrop in areas of exhumed Miocene evaporites along the margin of the Red Sea (Aref 1998b; Pierre and Rouchy 1988). There, carbonate masses are vuggy and form irregularly stratiform limestones within or adjacent to capping beds of sulphate evaporites. As in the Castiles of West Texas and the diapir caprocks of the Gulf Coast, the vuggy Red Sea buttes are stained by hydrocarbon residues and smell of hydrocarbons when broken with a hammer. Associated natural sulphur (S_2) is usually yellow, but may be brown to black due to bitumen staining. The carbonate masses replacing the gypsum or anhydrite are made up of varying amounts of aragonite, calcite, or dolomite. $\delta^{13}C_{PDB}$ mean values for carbonate minerals typical of organic-derived signatures and

ranging from −3.3 to −31.3‰ (Fig. 9.66a). There is some overlap, but most are heavier than the $\delta^{13}C$ values of nearby crude oils (−28.1 to −29.3‰). Oxygen values from the Red Sea castiles define two groups. One is clustered around 0‰ and is dominated by aragonitic mineralogies with lesser calcite and is thought to indicate BSR replacement of gypsum that occurred soon after deposition. The other group is mostly calcite and dolomite, its $\delta^{18}O_{PDB}$ values range from −6 to −11‰ and is interpreted as a later meteoric-influenced BSR, occurring during halokinetic uplift and telogenetic flushing of rising diaper caps by fresher groundwaters. This stage is likely akin to that forming the patchy BSR limestones in meteoric-overprinted caprocks atop coastal plain diapirs in the Gulf of Mexico.

The activities of the BSR biota metabolising hydrocarbons and gypsum in the Red Sea buttes is characterised by a presence of a community of sulphate-reducing bacteria thriving on carbon substrates contained in petroleum. Specifically, a set of nonisoprenoidal macrocyclic glycerol diethers (McGDs), tentatively ascribe to sulphate-reducing bacteria, have a stable carbon isotope composition close to that of petroleum n-alkanes associated with the resulting carbonates (Aloisi et al. 2013). The presence of archaeol that is ^{13}C-enriched, relative to bacterial lipids, suggests that Archaea are present but either indirectly involved or not involved in the transformation of petroleum-derived carbon. The lipid biomarker pattern is distinct from those observed in settings where sulphate reduction is coupled to the

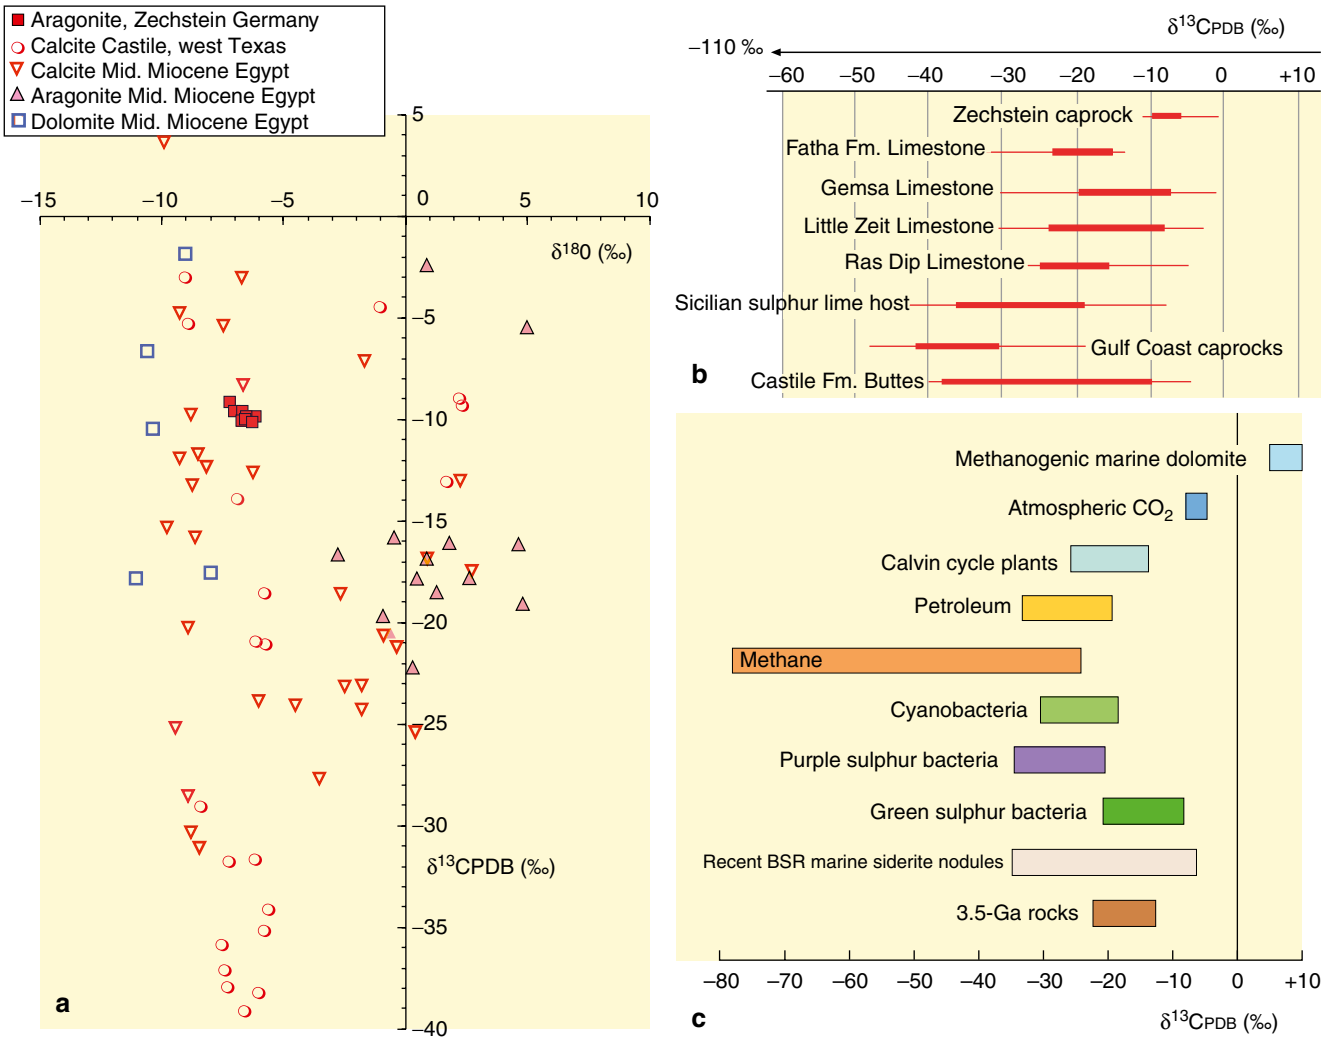

Fig. 9.66 Stable isotope signatures of bacterial calcite. (**a**) Outcropping samples from calcite buttes of the Castile Formation, Delaware Basin, West Texas, various Middle Miocene outcrops along the Red Sea coast and aragonite inclusions in gypsum of Zechstein, Germany. (**b**) Bioepigenetic carbonates from Miocene of Gulf of Suez, caprocks in the Gulf of Mexico, sulphur deposits of Sicily and Castile Fm. buttes in West Texas. Thin line indicates range, thick line plots standard deviation about mean (Both figures replotted from data in Aref 1998b; Jassim et al. 1999; Kirkland and Evans 1976; Peckmann et al. 1999; Pierre and Rouchy 1988 and references therein). (**c**) Typical $\delta^{13}C$ ranges of various microbial and higher plant materials and products

anaerobic oxidation of methane. The results suggest that petroleum migration has triggered the microbial transformation of gypsum into carbonates in the Gulf of Suez, independent of archaeal metabolism.

In the 1st Eocene reservoir interval of the giant Wafra field, Partitioned Zone, Saudi Arabia and Kuwait, is replete with bacterial sulphate reduction calcite cements and associated oil biodegradation (Wani and Al-Kabli 2007). The bacteriogenic cements occur mostly in vugs left by anhydrite dissolution and have covariant plot fields that overlap those of similar BSR cements in the Castiles of West Texas (Fig. 9.67a, b compare with Fig. 9.66a; Saller et al. 2014). Such calcites in Wafra field formed late in the diagenetic evolution, in a zone of mixing between rising oilfield brines and sluggish descending meteoric waters (Fig. 9.67b, c). Brine flows in both directions and is focused by the under-

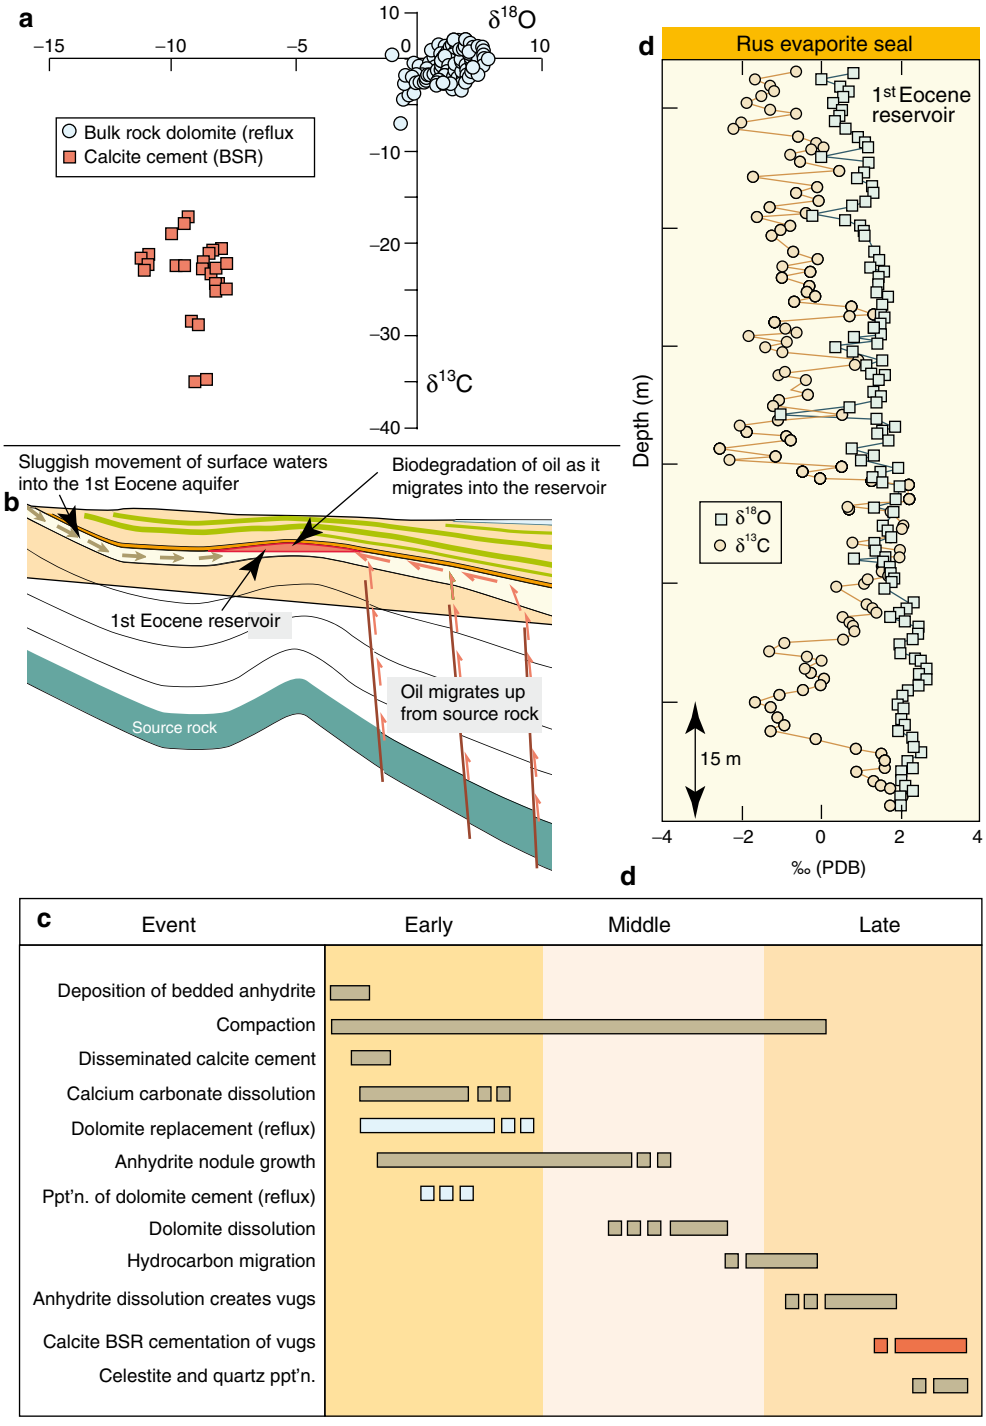

Fig. 9.67 BSR cements and oil biodegradation in the giant Wafra Field, Partitioned Zone, Saudi Arabia and Kuwait. (**a**) Stable isotopic analyses of bulk dolomite samples (dominantly co-variant reflux dolomite signatures) and calcite cements lining vugs showing dominantly BSR signatures. (**b**) Schematic model for biodegradation of oil as it migrates into the First Eocene reservoir. (**c**) Relative timing of various diagenetic events in the First Eocene reservoir, with *red-blue shading* as in (**a**). (**d**) Plot of stable isotopic compositions versus depth for bulk dolomite samples in a representative well. The general vertical trends are interpreted as secular changes in seawater during the late Paleocene and early Eocene. Some covariant spikes of $\delta^{13}C$ and $\delta^{18}O$ could be related to contamination by small amounts of calcite with very low $\delta^{13}C$ and $\delta^{18}O$ values (After Saller et al. 2014)

side of the regional Rus evaporite seal. As a consequence of the biodegradation, which is tied to an episode of leaching of anhydrite nodules and cements, heavy oil is currently extracted from very porous vuggy dolomites at depths of ≈300–400 m within the Paleocene-Eocene Umm Er Radhuma Formation.

Porosity in the dolomites in the vuggy intervals is typically 30–50 %, associated permeability ranges from 100 to 2,000 md, with the reservoir characteristics determined largely by diagenesis (Fig. 9.67c). Early diagenesis was dominated by reflux dolomitization, dissolution associated with dolomitization, and precipitation of sulphates. The highest permeabilities now occur in subtidal facies. Low-permeability typifies tidal flat facies and the combination or the two depositional associations now layers the reservoir response. Heavy oil preferentially fills high-permeability dolomites of the subtidal facies; whereas, low-permeability, tidal-flat facies are typically filled with water because their pore throats were too small to allow entry of viscous oil.

Late-stage diagenesis is dominated by bacterial sulphate reduction (BSR), which drove dissolution of prior sulphate nodules, calcite cementation, sulphur precipitation, and biodegradation of oil. BSR is indicated by very low $\delta^{13}C_{PDB}$ compositions of calcite cements (−17.1 to −34.9 ‰), which require an organic carbon source, probably oil (Fig. 9.67a). The oxygen isotopic compositions of the calcites support precipitation from formation waters similar to those in the current reservoir (Fig. 9.67d). BSR probably started during initial oil emplacement and continues to the present. BSR intensity is heterogenous, resulting in produced oils with gravities of 14–21° API. Even heavier oils remain in the reservoir, they did not flow during primary production. Secondary and tertiary recovery approaches are planned for the field. Primary production was likely greatest in areas and intervals with lighter, less viscous oil and perhaps less intense BSR.

Microbial creation of stratiform bioepigenetic limestone is a widespread but under-recognised process at the dissolving edges of many gypsum/anhydrite masses interacting with escaping hydrocarbons. It typifies near surface seeps in the Fergana and Amudarya depressions of central Asia and the Mesopotamian depression in Iraq (Jassim et al. 1999). Bedded examples of coarsely crystalline gypsum replaced by texturally similar bioepigenetic calcite characterise contacts of some Upper Miocene gypsum outcrops in the Lorca Basin (Rouchy et al. 1998). Likewise the Ratynsky Limestone, with its characteristic light carbon signature and sulphur association, is a bioepigenetic limestone bed that defines the top of outcropping and subcropping artesian gypsum karst in the western Ukraine (Andrejchuk and Klimchouk 2001).

Thermochemical Sulphate Reduction (TSR)

During thermochemical sulphate reduction, H_2S is produced as sulphate is inorganically reduced, via inorganic reactions with hydrocarbons, at temperatures typically in excess of 140 °C, which is too hot for any known life (Fig. 9.65b, c; Worden et al. 1995; Heydari 1997; Machel 2001). Reactive hydrocarbons caught up in the TSR reaction are mostly branched and n-alkanes, with lesser cyclic and mono-aromatic species in the gasoline range. Historically, the efficiency of thermochemical sulphate reduction in producing H_2S was inferred from experimental evidence or from levels of sour gas (H_2S-entrained) in deep oil and gas wells, rather than direct observation of subsurface processes (Trudinger et al. 1985; North 1990). In the past three decades this has now changed with the direct documentation of TSR-produced H_2S (sour gas) in natural gas reservoirs in the Permian Khuff Formation of Abu Dhabi (Worden et al. 1995, 1996; Worden and Smalley 1996) and identification of oil markers that, in association with sulphur isotopes ($\delta^{34}S$), can identify oils that have experienced TSR (Amrani et al. 2012).

In sour Khuff reservoirs hotter than 140 °C, anhydrite has been partially replaced by TSR calcite, and hydrocarbon gases have been partially or fully replaced by H_2S. That is, anhydrite and hydrocarbons have reacted to produce calcite and H_2S.

Worldwide, the lowest temperature at which TSR occurs may be lower than the 140 °C seen in the Khuff Fm. Machel (1998) suggests that the onset of TSR occurs in a range from 100 to 145 °C depending on variations in chemical kinetics, which will differ from basin to basin. If so, then one can expect TSR-derived H_2S to form at shallower depths than the 4,000 m suggested by the work of Worden et al. (1995) or Heydari (1997).

Carbon and elemental sulphur isotope data from the gases and minerals in the Khuff Fm. show that the dominant general reaction is (Worden et al. 1995, 1996; Worden and Smalley 1996; Heydari 1997):

$$CaSO_4 + CH_4 \rightarrow CaCO_3 + H_2S + H_2O$$

Gas chemistry and isotope data also show that C_2+ gases react preferentially with anhydrite via reactions like:

$$2CaSO_4 + C_2H_6 \rightarrow 2CaCO_3 + H_2S + S^o + 2H_2O$$

Sulphur is generated by this reaction and is locally present, but is also consumed by the reaction:

$$4S^o + CH_4 + 2H_2O \rightarrow CO_2 + 4H_2S$$

The frequently quoted and experimentally observed reaction between anhydrite and H_2S with CO_2 to produce calcite and sulphur:

$$CaSO_4 + 3H_2S + CO_2 \rightarrow CaCO_3 + 4S + 3H_2O$$

has been shown, by gas chemistry, calcite $\delta^{13}C$ and sulphur $\delta^{34}S$ data, to be insignificant in the Khuff Formation.

Rather, a direct reaction between hydrocarbons and anhydrite occurs in solution. It takes place within residual pore waters that are initially dominated by carbonate dissolved out of the marine carbonate matrix. The first-formed replacive calcite thus contains carbon that was derived principally from a marine dolomite matrix with a $\delta^{13}C$ signature of 0 to +4‰. Continuing reaction leads to the progressive domination of pores water derived by TSR carbonate, with a minimum $\delta^{13}C$ of about –30‰ (Fig. 9.68a). The spread of carbon isotope values in the replacive TSR calcite shows that in the earliest stages of TSR the ambient formation water was dominated by bicarbonate derived from dissolution of the matrix dolomite. As TSR commenced, the first-formed aqueous carbonate species plus the newly dissolved calcium from the dissolving anhydrite led to supersaturation with respect to calcite. However, this calcite was initially dominated by the dolomite-derived carbonate and thus inherited the dolomite's heavier carbon isotope signature. As TSR proceeded, the methane-derived carbonate came to dominate, leading to ever more negative $\delta^{13}C$ and $\delta^{18}O$ values in the resulting calcite (Fig. 9.68a).

When petrographically determined amounts of replacive calcite in the Khuff Formation are plotted as a function of depth (Fig. 9.68b) it shows that TSR starts around 4,300 m depth (corresponding to a present-day temperature of 140 °C) for all of the anhydrite types apart from the coarsest (poikilotopic variety), which shows signs of reaction only below 4,500 m. This implies that availability of sulphate from anhydrite is the rate-limiting step during the earlier stages of reaction when anhydrite is replaced *in situ* by calcite on the very edges of anhydrite nodules and crystals (Worden et al. 2000). Later, as TSR proceeds, and the thickening calcite rind begins to isolate the anhydrite from the dissolved methane, the reaction becomes transport controlled. TSR ceases once calcite has effectively armour-plated (totally isolated) the remaining anhydrite. Finely crystalline anhydrite underwent more extensive and more rapid TSR than coarser anhydrite crystals because these had a greater ratio of surface area to volume, allowing more and faster dissolution and requiring more calcite to isolate them from methane. Localized loss of H_2S occurs in the Khuff reservoir by reaction with indigenous Fe-bearing clays. Consequently, Khuff reservoirs with a relatively high siliciclastic content have less H_2S than would be expected from the advanced state of anhydrite replacement with calcite in these units.

Thermochemical sulphate reduction produces substantial volumes of very low salinity subsurface water in the vicinity of the reaction zone. Locally, the salinity of formation water in evaporite lithologies undergoing TSR is, therefore, not necessarily high. In the Khuff reservoir the water salinity and isotope data show that the original formation water was locally diluted between four and five times by water from TSR (Worden et al. 1996). A typical Khuff gas reservoir rock volume calculation suggests that initial formation water volumes can only be increased by

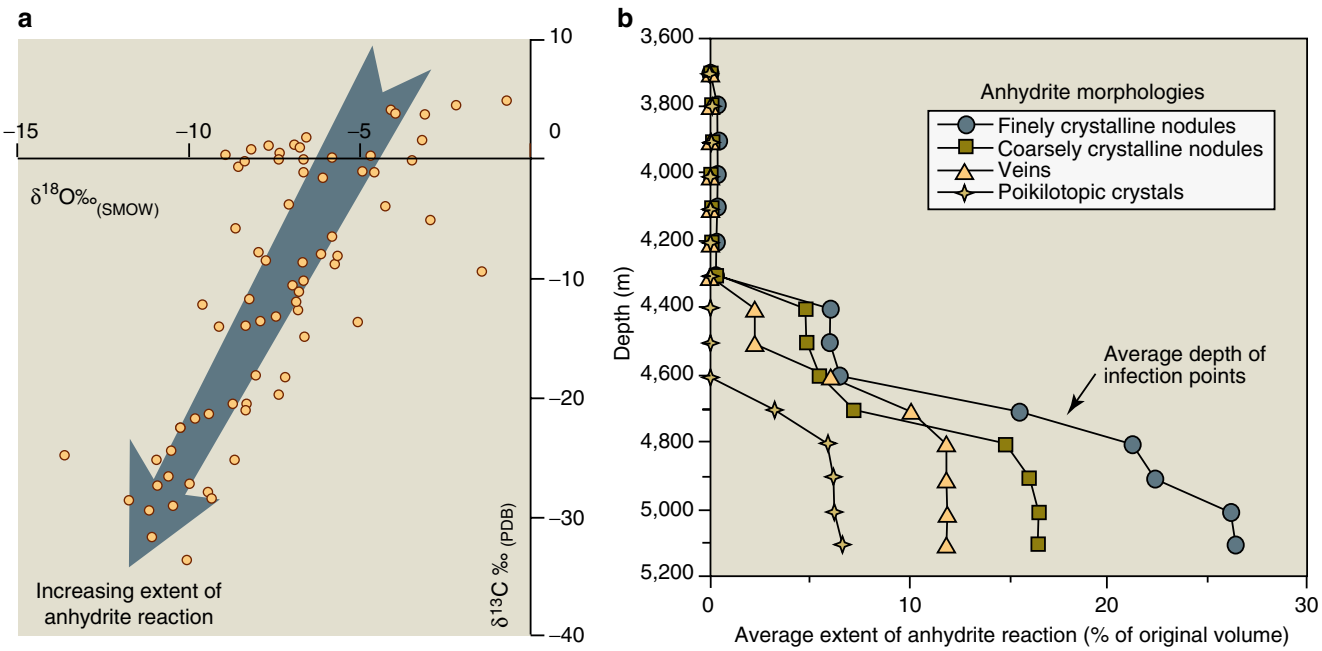

Fig. 9.68 Thermochemical sulphate reduction in the Permian Khuff Fm., UAE. (**a**) Stable isotopes of thermochemical calcite. *Arrow* shows trend of increasing calcite reaction. (**b**) Depth versus the average extent of anhydrite replacement by calcite for the different types of anhydrite. Anhydrites with smaller crystal sizes are more reactive at any given burial depth (After Worden et al. 2000)

about three times as a result of TSR. The extreme local dilution shown by the water salinity and $\delta^{18}O$ data in the Khuff must, therefore, reflect transiently imperfect mixing between TSR water and original formation water. Dissipation of this water into surrounding lithologies may aid further dissolution of adjacent evaporites. TSR is believed to cause the dilution of formation waters by up to 50 % locally and up to 30 % on a reservoir scale (Worden et al. 1996; Yang et al. 2001). On the other hand, there might be other reactions involved in TSR, some of them consuming water, so that the amount of water produced is probably highly variable and, according to Machel (2001), negligible at a regional scale.

Anhydrite dissolution and calcitisation in the Jurassic Smackover Formation in Mississippi, USA, does not occur below temperatures of 140–150 °C, suggesting that, as in the Khuff, it is a thermochemical process (Fig. 9.69a). Thus, gas window diagenesis in deeply buried dolomitised Smackover reservoirs is largely driven by thermochemical sulphate reduction. Reaction of sulphate with H_2S generates S° that, in turn, reacts with CH_4 to form more H_2S in a self-reinforcing cycle (Heydari 1997, 2000). Closed-system diagenesis prevents the escape of H_2S and, with sulphate abundantly available (Buckner Anhydrite), but without Fe^{2+} to remove H_2S by pyrite precipitation, the reaction tends to continue until all hydrocarbons are consumed. TSR-generated CO_2 results in precipitation of post-bitumen calcite with negative $\delta^{13}C$ compositions.

Concentration of H_2S in Mississippi Smackover reservoirs varies consistently with temperature (Fig. 9.69b; Heydari 1997). Reservoirs studied are of the same age (150 Ma), similar lithology (clean oolitic limestone), and bounded by impermeable layers (Buckner anhydrite above and lime mudstones below). Heydari (1997) found that concentration of H_2S is very low in reservoirs that have experienced temperatures of 120 °C or less for more than 50 m.y. This suggests TSR has not yet occurred, and therefore it is not a time-dependent process and not necessarily kinetically or rate driven. High H_2S concentrations occur in reservoirs with temperatures in excess of 140 °C and levels tend to increase with temperature, so suggesting TSR is occurring and is ongoing. If so, it is a temperature-dependent process (thermodynamically-driven).

Amrani et al. (2012) defined a set of organo-geochemical criteria for produced oils, which can be used to define the degree of TSR alteration of Smackover oils. Oils that experience TSR exhibit significant ^{34}S enrichment in the benzothiophenes (BTs) compared to dibenzothiophenes (DBTs), while in unaltered oils both compounds have similar isotopic compositions. The $\delta^{34}S$ values of BTs are close to those of sulphate-bearing evaporites of the Smackover Fm., whereas the $\delta^{34}S$ values of DBTs are spread over a wider range and gradually approach those of the BTs (Table 9.12; Fig. 9.70). They propose that BTs can be a sensitive tracer for the intensity of TSR alteration of an oil or condensate as they form readily under TSR conditions, with large ^{34}S enrichments

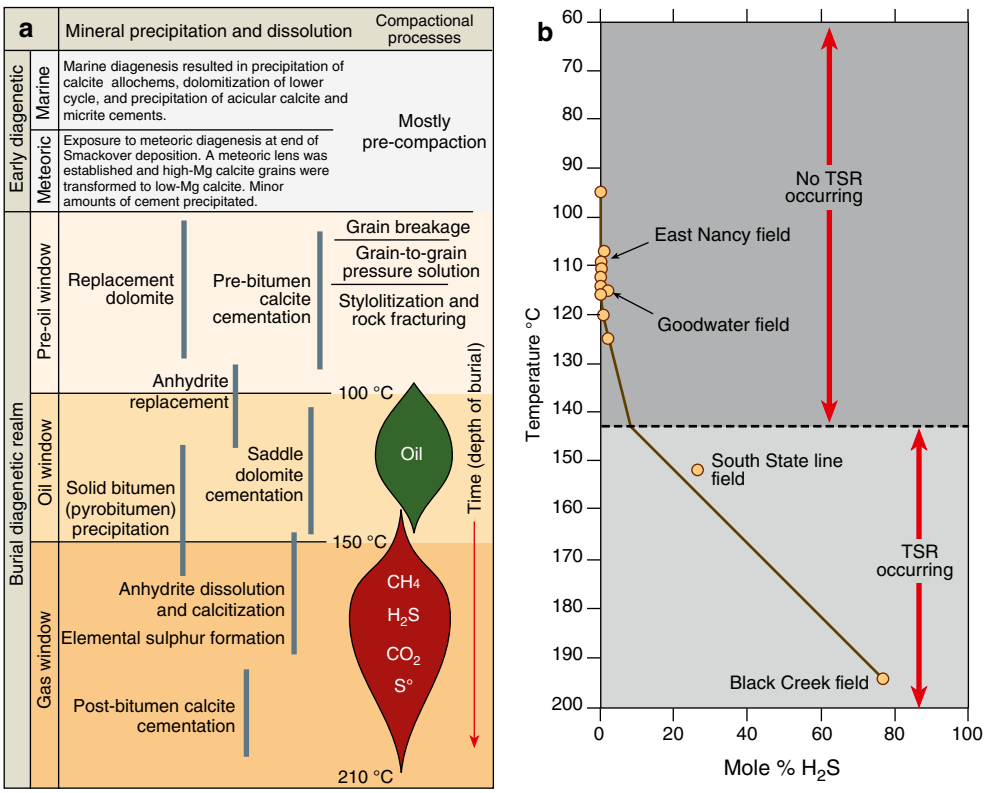

Fig. 9.69 Thermochemical sulphate reduction in the Smackover Formation, Gulf of Mexico. [a]DBT content refer to dibenzothiophene and its alkylated groups including methyl-, dimethyl- and trimethyl-dibenzothiophenes
[b]Thiadiam content stands for thiadiamondoids including thiaadamantanes (trimethyl- and tetramethyl-thiaadamantanes), thiadiamantanes (thiadiamantane, methyl-, dimethyl- and trimethyl-thiadiamantanes) and thiatriamantanes (thiatriamantane, methyl-, dimethyl- and trimethyl-thiatriamantanes)

relative to the bulk oil. In contrast, DBTs exhibit relatively small changes in $\delta^{34}S$, preserving their original $\delta^{34}S$ values longer than do BTs because of their greater thermal stability and slow rate of formation. If this relationship holds in other oil basins then a comparison of the $\delta^{34}S$ values of BT and DBT can be used to detect TSR alteration from the very early stages up to highly altered oils (Table 9.12; Fig. 9.70).

Sour (H_2S-entrained) natural gas, associated with thermochemical sulphate reduction, typifies dolomite reservoirs in the Lower Triassic Feixianguan Formation, Northeast Sichuan Basin, China (Jiang et al. 2014). The sulphate comes from dissolution of the abundant Triassic saltern anhydrites, which also act as seals across oilfields of the region. Reservoirs were initially filled with oil, later replaced by gas during burial to 7,000 m followed by uplift to about 4,000 m. A plot of carbon and oxygen stable isotope clearly breaks out the host matrix limestones and dolomites from the various burial cements. Isotope plots, broken out by timing and texture, defines three separate C-O plot fields, related to pre-TSR, TSR and post TSR calcite cements (Fig. 9.71a). The TSR plot field, with its negative carbon isotope values, overlaps with the TSR plot fields seen in other already discussed examples (e.g., Fig. 9.68).

Pre-TSR diagenesis (in time order), included host neomorphism and recrytallisation of the host dominated by eodiagenetic dolomitization via brine reflux, fracture-related calcite cementation, baryte, quartz, celestite, and fluorite mineralization and a dolomite recrystallization stage at burial temperatures up to 130 °C (Fig. 9.71b). TSR followed, and resulted in anhydrite replacement by TSR-calcite, petroleum destruction, formation of sulphur-rich pyrobitumen and elemental sulphur and generation of large volumes of H_2S, CO_2. Diagenesis during TSR can be subdivided into oil-stage TSR and gas-stage TSR with oil-stage TSR defined by the presence of primary oil and bitumen inclusions in the TSR-calcite.

Based on aqueous inclusion homogenization temperatures, oilstage-TSR commenced at a temperature of 116 °C with a mode between 130 and 140 °C (Fig. 9.71b). Gas-stage TSR started at a temperature of 135 °C and continued to maximum burial temperatures of about 220 °C. Trace amounts of pyrite, baryte, quartz and celestite grew during

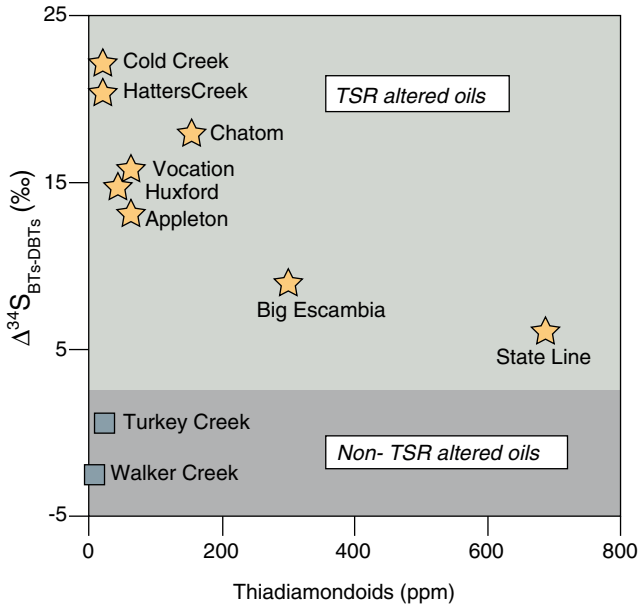

Fig. 9.70 ^{34}S fractionation between BTs and DBTs isomers (Δ^{34}SBTs-ΔBTs) as a function of total thiadiamondoid concentration (Table 9.11), which includes thiaadamantanes (trimethyl- and tetramethyl-thiaadamantanes), thiadiamantanes (thiadiamantane, methyl-, dimethyl- and trimethyl-thiadiamantanes) and thiatri-amantanes (thiatriamantane, methyl-, dimethyl- and trimethyl-thiatriamantanes). The plotted $\delta^{34}S$ values for alkylated BTs and DBTs are the numerical averages of all measured isomers (After Amrani et al. 2012)

TSR. Post-TSR diagenesis was dominated by fracture-related calcite precipitation as well as celestite and sparry anhydrite crystallization. Formation water salinity increased from depositional values (3.5 wt%) up to 24 wt% during pre-TSR dolomite recrystallization, probably due to an influx of evaporite-dissolution associated water from the overlying Jialingjiang Formation. Later pre-TSR baryte, quartz, celestite, and fluorite mineralization was associated with a transient decrease in water salinity (Fig. 9.71c) During TSR, formation water salinity decreased from 26 wt% to as low as 4 wt%, as a result of fresh water being produced by TSR reactions (Jiang et al. 2014).

The Sichuan example illustrates that, if anhydrite and methane remain in reservoirs reaching 140 °C and above, thermochemical sulphate reduction can continue into the low temperature end of the metamorphic realm (>200 °C). Alonso-Azcarate et al. (2001) documented vein deposits containing native sulphur, gypsum, quartz and rare sphalerite in the very low-grade greenschist metasediments in Cervera del Rio Alhama of the Mesozoic Cameros Basin, NE Spain. In outcrop the veins are hosted by lacustrine evaporites, which now comprise alternations of dolomite and recrystallised gypsum layers, the latter was anhydrite during metamorphism and converted to gypsum during telogenesis. Fluid inclusion homogenization temperatures and quartz-sulphate oxygen isotope geothermometry indicate formation of the veins around 225 °C. Fluid inclusions contain sulphur along with a gas phase comprising H_2S, N_2, CO_2 and minor CH_4. These are all reactants and products of sulphur generation via thermochemical sulphate reduction (TSR) in the anchizone. The conversion utilised organic matter, followed by a partial re-oxidation of some H_2S via SO_4 to then produce sulphur. These TSR reactions differ from those observed in most petroleum-related sour gas settings in that there is no evidence for secondary carbonate precipitation during TSR and in that significant S isotopic fractionation exists between sulphate (around +20‰) and reduced products (sulphur is around – 11‰).

H_2S, Natural Gas and Metallogeny

Clearly, at lower temperatures H_2S (sour gas) is bacterially produced from organic matter by BSR, and nonbiogenically by TSR at higher temperatures (Fig. 9.65a, b). In deep evaporite sealed oil and gas provinces, the proportion of bacteriogenic H_2S that becomes one of the many constituents of the trapped natural gas in a reservoir is negligible compared to H_2S produced by TSR (Hunt 1996). However, further updip, the proportion of bacteriogenically-produced H_2S can be much higher and in the near surface caprocks, hypogene caves and sea bottom brine lakes can exert major control on the precipitation of metal sulphides (Chaps. 15 and 16). Isotopically, there is significant overlap in the sulphur signal between BSR and TSR as there tends to be only minor fractionation of the precursor S-isotope signature during TSR, although, in general, bacterially formed H_2S tends to show more negative sulphur isotope values (Fig. 9.72).

H_2S is one of the deadliest[20] gases produced naturally in large amounts. At nearsurface conditions it is almost three times as soluble as CO_2 and more than 70 times as soluble as methane. Its critical temperature of 100.4 °C is also much higher than that of CO_2. Above this temperature all

[20] Small amounts of hydrogen sulphide occur in crude petroleum, but natural gas can contain up to 90 %. At very low concentrations of less than 10–100 ppm it smells like rotten eggs and there is a common misapprehension that its foul odour is a warning. At 100 ppm the gas kills the sense of smell in 3–15 min and will cause you to cough or your eyes to water. Over 100 ppm your eyes and throat may begin to sting. At 200 ppm, your eyes and throat will begin to burn and you will get headaches. Only 600 ppm, or 0.06 of 1 % will cause death, if you are not treated very quickly. Over 1,000 ppm causes respiratory paralysis and a sudden agonizing death from asphyxiation.

H_2S is heavier than air, invisible, highly explosive and can destroy steel and rubber seals very quickly. Modern drill rig floors are all fitted with gas sniffer warning systems.

Hydrogen sulphide is considered a broad-spectrum poison, meaning that it can poison several different systems in the body, although the nervous system is most affected. The toxicity of H_2S is comparable with that of hydrogen cyanide or carbon monoxide. It forms a complex bond with iron in the mitochondrial cytochrome enzymes, thus preventing cellular respiration.

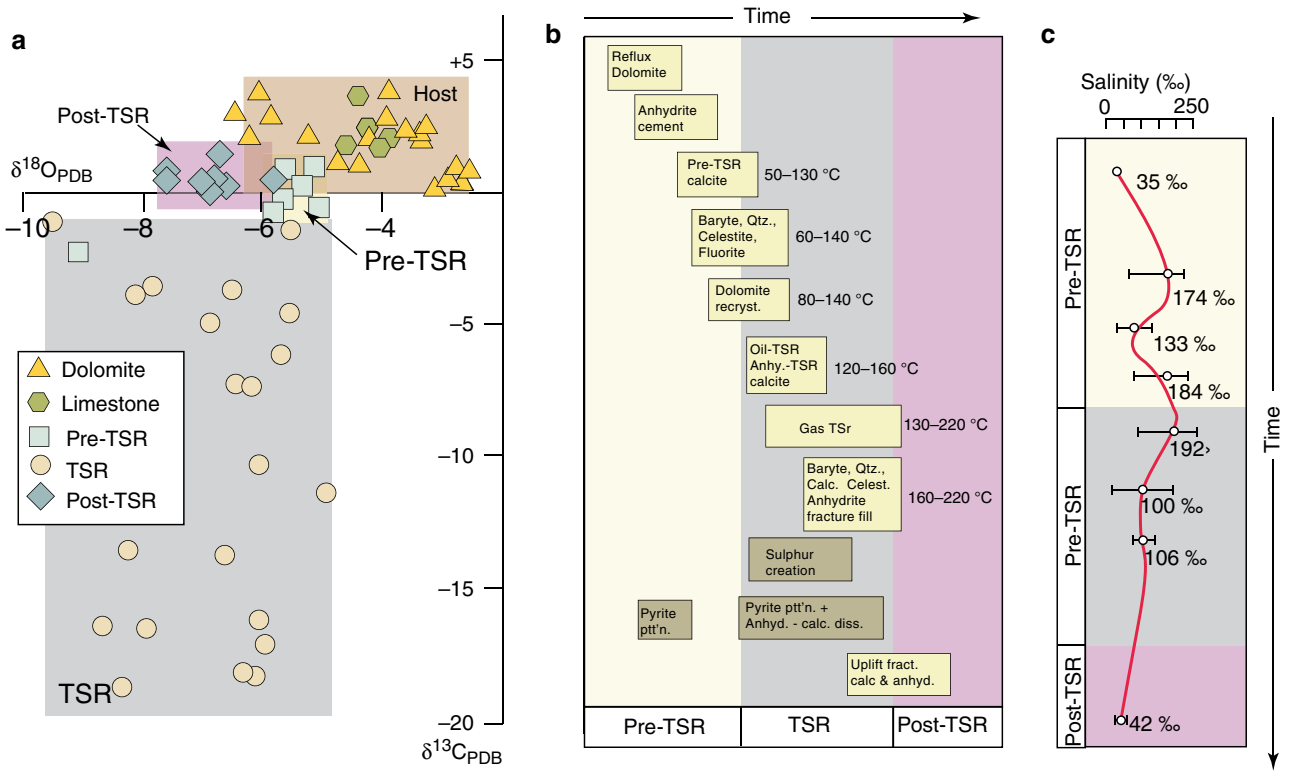

Fig. 9.71 Thermochemical sulphate reduction (TSR) in Jialingjiang Formation, NE Sichuan Basin, China. Fig. 9.72 Typical ranges of naturally occurring sulphur isotopes under thermochemical and bacterial sulphate reduction (After Emery and Robinson 1993)

undissolved H_2S is in the gas phase. Large quantities of both CO_2 and H_2S gas are thermochemically generated at temperatures greater than 120–140 °C in mature to overmature source rocks. Peak generation for methane is around 140 °C, while H_2S has not yet reached its peak generation at temperatures of 170 °C (Figs. 9.65c). H_2S forms best at temperatures beyond where petroleum geochemists have already lost interest, but its genesis is of great importance in the formation of base and precious metal deposits (Warren 2000b).

Because of its high reactivity, it is difficult for H_2S to migrate from its source to a distant reservoir (Hunt 1996). Away from direct contact with deeply buried reactive and dissolving anhydrites, H_2S in most oil and gas reservoirs is largely the product of sulphate reduction from sulphate ions in solution or the thermal decomposition of sulphur-containing oil. Interestingly, all the natural gas reservoirs with high thermochemical H_2S contents, listed in Table 9.13, are interbedded with anhydrites, or have anhydrite above or below the reservoir horizon. At its critical temperature of 104 °C and a pressure of 14 MPa (2,000 psi), H_2S is forty times more soluble in water than at surface conditions.

Wherever H_2S in solution comes into contact with metalliferous chloride brine it is likely to be involved in a number of metal sulphide forming reactions (Chap. 15). Sulphide products range from the cool shallow biogenic precipitation of syngenetic framboidal pyrite at seafloor brine-lake interfaces to the formation of hot, subsurface hydrothermal

Table 9.13 Regions of natural gas deposits with high H_2S contents. In all these, the deposit is stored in a carbonate reservoir that is interbedded with anhydrite, or there is an anhydrite unit above or below the deposit

Region	Reservoir age	Lithology	Depth (m)	% H_2S in total gas
South Texas, USA	Upper Jurassic (Smackover)	Limestone	5,793–6,098	98

After Hunt 1996

sulphides, which often also involve dissolution and alteration of the adjacent carbonate rock matrix. For example, in a Mississippi Valley type (MVT) scenario, a metal sulphide phase typically coprecipitates with hydrothermal or saddle dolomite in bathyphreatic or vuggy porosity at temperatures in the range of 60–180 °C (Hill 1995):

$$H_2S + CO_2 + MeCl^+ + Mg^{2+} + 2CaCO^3 + H_2O = MeS + Ca^{2+} + CaMg(CO_3)^2 + HCO_3^- + Cl^- + 3H^+$$

The formation of metal sulphide from hydrogen sulphide generated by TSR can be expressed in the general reaction;

$$H_2S + Me^{2+} = MeS + 2H^+$$

Such reactions create acid, which in turn is capable of forming secondary porosity in a deeply buried limestone host. It is why bathyphreatic vuggy porosity with sphalerite stalactites are found in many MVT ore deposits, such as Cadjebut in Western Australia where these metalliferous dripstones formed in methane-rich bathyphreatic vugs and pores (Warren and Kempton 1997).

When considering the association of sulphate evaporites with mineralization and developing exploration paradigms it is important to realise that it is not the sulphate evaporites that are directly responsible for the precipitation of metal sulphides during bacterial and thermochemical sulphate reduction (Warren 2000b). Rather, evaporite dissolution or reaction places sulphate/sulphide in a fluid medium so that it can then react with liquid or gaseous hydrocarbons. It is this sulphate-entraining solution that is reduced in the presence of organic matter or hydrocarbons to form H_2S. And it is the H_2S in solution that then precipitates the metal sulphides at or near a redox interface, which is a zone where slightly more oxidised metalliferous chloride brines can interact with a H_2S buildup on the reduced side of the interface.

Thus, ore textures in areas where sulphate evaporites are dissolving and metal sulphides are precipitating are most likely to be open space or porosity-fill textures. Ore textures and the degree of layering will depend on a number of factors including: the size of the dissolution front (interpore versus laminar versus vug versus solution-collapse cavern), the rate of fluid crossflow at the interface, the degree of stability of the redox interface, and the distance the sulphate ion travels before it is reduced (Warren and Kempton 1997). Precipitation of the metal sulphides may occur directly across from a dissolving sulphate bed or nodule, where it is producing H_2S on the other side of a fluid-filled reaction interface. Or it may occur after H_2S, derived from TSR, has seeped and migrated into a closed structure (aka prepared ground) located elsewhere in the sedimentary succession.

When H_2S accumulates at an interface where oxygen is also present and large volumes of metalliferous brines are absent, it can form accumulations of native sulphur, rather than metal sulphides, via the reactions:

$$2H_2S + O_2 = 2S° + 2H_2O\,(pH < 6-7)$$
$$HS^- + O_2 + H^+ = S° + H_2O\,(pH > 6-7\text{ to }9)$$

Elemental sulphur can form and persist near a redox interface where Eh ≈ –0.2 to +0.2. This is thought to be the mechanism that generated the economic evaporite-associated sulphur deposits in hydrocarbon leakage haloes within the Gulf of Mexico diapir caprocks and the stratiform sulphur deposits of Culberson Co. West Texas (Fig. 12.69). The presence of abundant free sulphur (S°) in peridiapiric Pb-Zn deposits such as Bou Grine is used by some workers to argue that in such situations the supply of metals to a sulphate/sulphide reduced environment was the reaction-limiting step (Bechtel et al. 1996).

Sulphur sourced from TSR in the deep subsurface may not all be consumed by the reaction of methane and water, especially where metalliferous fluids are not present in sufficient quantities to form metal sulphides. However, as sulphur melts at temperatures between 113 and 120 °C, any such sulphur formed during TSR (requires temperature >140 °C) will be molten. Such sulphur occurrences typically occur in deep stratigraphic zones dominated by carbonate and calcium sulphate lithologies (Hunt 1996). For example, molten sulphur was recovered from a depth of 6,098 m (20,000 ft) in the Jurassic Smackover carbonate-evaporite sequence in southern Mississippi on the US Gulf Coast. It was also recovered from the Cambro-Ordovician Arbuckle limestone-dolomite at a depth of 9,586 m (31,441 ft) in the Bertha-Rogers well in the Anadarko Basin, Oklahoma. Wells in the Permian Zechstein dolomites in western Germany have recovered molten sulphur from depths between 3,000 and 4,300 m (10,000–14,000 ft).

Elemental sulphur reacts with H_2S to form polysulphides, which are powerful oxidants that quickly convert any saturated hydrocarbons to thiopenes, thiols and sulphides (Hunt 1996). This reactivity means that all the hydrocarbons from pentane, through butane, propane, ethane and finally methane are oxidised to CO_2 at elevated temperatures in the presence of H_2S. Hence, it is no surprise that whenever molten sulphur is recovered, no appreciable amounts of methane or the higher hydrocarbons are present.

Criteria used to distinguish BSR from TSR metal sulphide outcomes include textural features and sulphur isotopic compositions (Pirajno 2009). With BSR, pyrite framboids (the equidimensional, raspberry-shaped spheroids found in many diverse environments, both modern ancient; Rickard 1970) are typical. For TSR, pyrite tends to be euhedral or a replacement of other minerals and is often associated with coarse calcite spar. Finely disseminated stratabound pyrite associated with kerogen is likely to have formed by BSR. The most reliable indicator for biogenic (BSR) sulphide is the sulphur isotopic composition of resulting minerals (Fig. 9.72). Fractionation of sulphur isotopes during dissimilatory sulphate reduction produces sulphides that are depleted in ^{34}S. Thus, strongly negative fractionations, ranging from −15 to −65 ‰ characterise BSR, whereas for TSR negative fractionations are smaller and temperature dependent with values around −20‰ at 100 °C, −15‰ at 150 °C and 10‰ at 200 °C and tending to decrease further with increasing temperature (Table 9.11; Machel et al. 1995). TSR sulphur isotope values show a much stronger overlap with typical marine sulphide values, especially at temperatures above 150 °C.

Hydrothermal Cracking in Saline Rift Lakes

Not all the hydrocarbons found in evaporitic sediments have necessarily evolved from millions of years of gentle kerogen burial into basin depths where temperatures exceed 60 °C in the sediment layers. In some evaporitic situations the heating and evolution of entrained organics is much more rapid, driven by the near surface circulation of hydrothermal waters typically tied to magmatic injections in igneous sills and dykes. Such magmatic heating of organic matter can be commonplace in evaporite accumulating areas where the evaporite depression was tectonically induced, as in many rift settings. Hence, hydrothermal hydrocarbons may be an integral part of source rock evolution of the early brackish to mesohaline lacustrine fill of evaporite-sealed rift successions, with organics typically first accumulating on the bottom of density/salinity stratified lakes (Tiercelin et al. 1993).

One such example is the oil now seeping onto the lake floor off Cape Kalamba in Lake Tanganyika at the south end of the Ubwari Peninsula (Tiercelin et al. 1989; Simoneit et al. 2000). The area lies at the intersection of faults controlling the morphology of the northern basin of the Tanganyika Rift. Oil samples collected at the surface of the lake 3–4 km offshore from Cape Kalamba lack typical suites of polynuclear aromatic hydrocarbons. This indicates an origin via hydrothermal alteration of immature biomass in the organicrich mesohaline sediments of the lake bottom. Based on the constituents of the modern bottom sediments, the prime producers were diatoms and cyanobacteria, which constitute most of the 6 % TOC that is found in sediments on the modern deep lake floor. Compositions of the oils and nearby tar balls demonstrate a <200 °C temperature during formation/generation, similar to the fluid temperatures identified at the Pemba hydrothermal site some 150 km north of Cape Kalamba (Table 9.14). generation seems to have occurred in the lake depression slightly before 25 Ka, during a drier climatic environment when the lake level was lower than today. Hydrothermal smokers or chimneys also occur on the subaqueous floor of the Lake Tanganyika (Barrat et al. 2000). It may well be that the deposition of any future overlying evaporite seal in this underfilled lacustrine situation may focus the flow of micro-petroleum into more appropriate landward sands, but ancient economic lacustrine counterparts of this style of hydrothermal oil have yet to be documented.

Not all hydrothermally-cracked oil is found in lacustrine rift-valley fills. Equally impressive in terms of hydrocarbon volumes and origins are the oils forming in the hydrothermally-flushed deepwater sediments on floor of the Guaymas Basin in the Gulf of California (Fig. 9.73a). The area, known to be actively producing hydrothermal hydrocarbons, measures some 3×9 km, with a thickness greater than 120 m, given a 2 % TOC and a 50 % expulsion efficiency, at least 30 MMbbl of oil could be generated from this region (Simoneit 1991). Radiocarbon dates show this oil forms in association with thermochemical sulphate reduction in less than 5,000 years (Didyk and Simoneit 1989; Peter and Scott 1991a, b). But unlike the rift association of east Africa, the anhydrite in this hydrocarbon system is largely hydrothermal and is created by the convective heating of seawater (retrograde solubility).

Leg 64 of the DSDP intersected sills and hydrothermal alteration at depth in all holes drilled in the basin. Thermogenic hydrocarbon gases, H_2S and CO_2 were seen at all sites, as were thermally altered lipids (bitumens) in positions close to, or below the sills (Simoneit et al. 1984). A number of hydrothermal mounds rise 20–30 m above the southern Guaymas Trough floor, below waters some 2,000 m deep. Most are actively discharging vent fluids at temperatures up to 315 °C and bottom pressures of 200 bars. Samples collected from the mounds are strained and cemented with petroleum bitumens and smell strongly of "diesel."

Muddy sediments and hydrothermal fluids of the Guaymas Basin are enriched in organics derived from diatomaceous oozes and microbial detritus. The basin hinterland is desert, so levels of terrigenous detrital organics are low. Buried diatom-rich sediments contain up to 3–4 % oil-prone TOC and average around 2 % TOC, which is cracked by the circulating hydrothermal fluids to generate thermally derived hydrocarbons. In general the n-alkanes range from C_{12} to C_{35} with a maxima at C_{19}, C_{22}, and a strong odd-to-even carbon-number predominance $>C_{24}$ (CPI in range 1–2), while pristane and phytane are about equal (Pr/Ph = 1.06; Fig. 9.73b, Simoneit 1991). Petroleum is carried as droplets entrained in the venting hydrothermal fluid or as a bulk phase. It also occurs in pore spaces and cavities in the chimneys and mounds and in hydrocarbon-bearing inclusions within amorphous silica and anhydrite. Thermal stress causes rapid maturation and petroleum expulsion in sediments exposed to temperatures of more than 50 °C. The "oil window" migrates upwards in the sediment column as the magmatic heat front rises (Simoneit 1991).

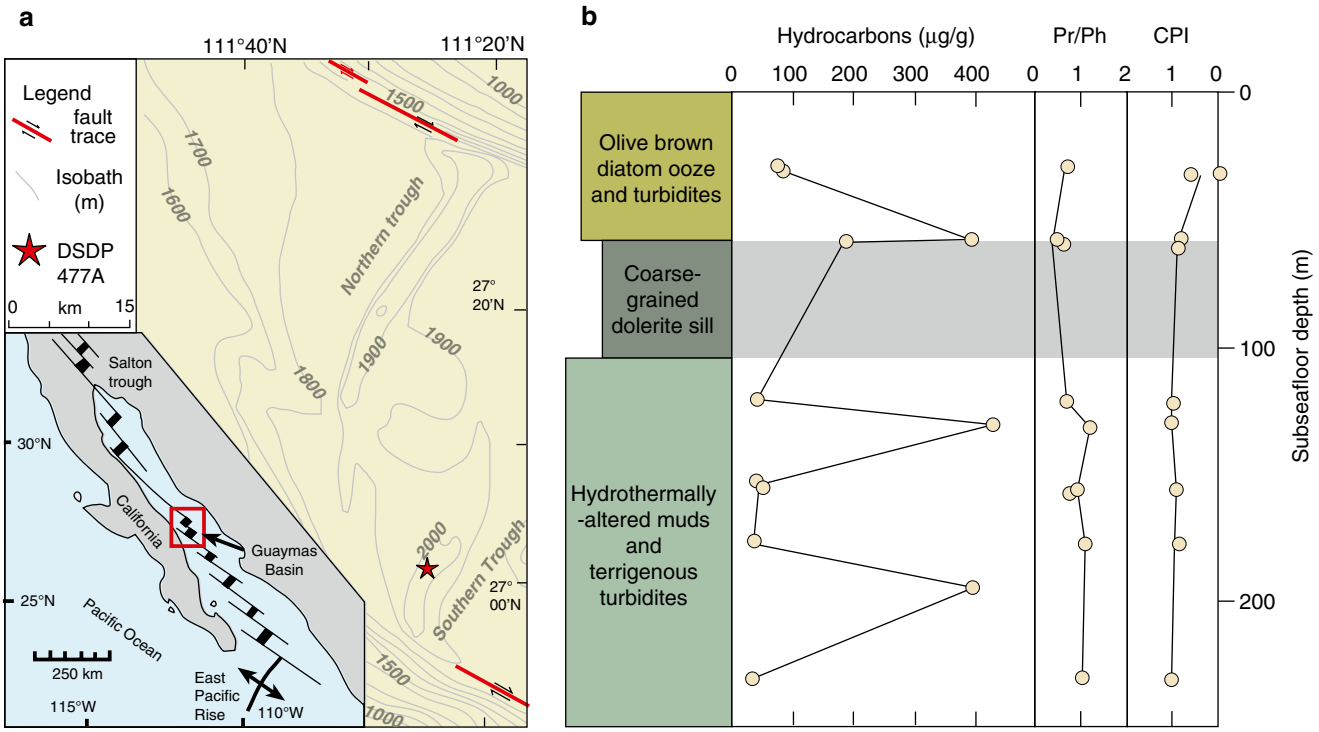

Fig. 9.73 Guaymas Basin. (**a**) Location of DSDP drill hole 477A. (**b**) Lithologic column, hydrogen concentration, pristane to phytane ratio (*Pr/Ph*) and carbon preference index (*CPI*) in DSDP hole 477A (After Simoneit 1991)

Hydrothermal oil generation processes in the Guaymas sediment column differ significantly from the conventionally accepted scenario for petroleum formation in sedimentary basins, where organic matter input, subsidence, geothermal maturation, oil generation, and oil migration are discrete and successive steps that occur over a long period of geological time and a thermal history related to regional sediment burial (Simoneit 1994). Rather, in hydrothermal petroleum formation several of the steps of oil generation occur simultaneously and can complete the organic matter maturation to oil-generating processes in geological time measured in thousands, not millions or tens of millions, of years (Table 9.14).

Another area of hydrothermal petroleum is the Davis-Schrimpf seep field in the onshore Salton Sea, Southern California (Fig. 9.74a; Svensen et al. 2007; Mazzini et al. 2011). This is the onshore extension of the same ridge system that defines the Guaymas Basin more than 500 km to the south. As in the Guaymas Basin, saline water-, mud-, gas-, and petroleum bearing seeps are part of the geothermal system in the Salton Sea. Seeps in the Davis-Schrimpf seep field (≈14,000 m^2) show considerable variations in water temperature, pH, density, and solute content. Water-rich springs tend to be hypersaline, have low densities compared to gryphon outflows (<1.4 g/cm^3), while Cl contents areas high as 45,000 ppm, and temperatures range between 15 and 34 °C. In contrast nearby gryphons expel denser water-mud mixtures (to 1.7 g/cm^3), have lower salinities (3,600–5,200 ppm Cl), and temperatures range between 23 and 63 °C. The main driver for this seep system is CO_2 (>98 vol% of expelled gas). Halogen geochemistry of the waters shows 2 trends indicates that mixing of slightly deeper and shallow pore waters occurs and it seems that near-surface dissolution of halite may overprint the original fluid compositions, so creating the trend dichotomy (Fig. 9.74b).

δD and $\delta^{18}O$ increase proportionally, with salinity and isotopic composition of the waters indicate a dominantly meteoric origin, modified by surface evaporation, with little or no evidence of deep fossil or magmatic components (Mazzini et al. 2011). Very high Cl/Br (>3,000) measured at many seep water pools suggests that increased salinities result from dissolution/recycling of halite crusts near the seep sites. Carbon isotopic analyses conducted by Svensen et al. (2007) suggest that hydrocarbon seep gases have a thermogenic origin. Their

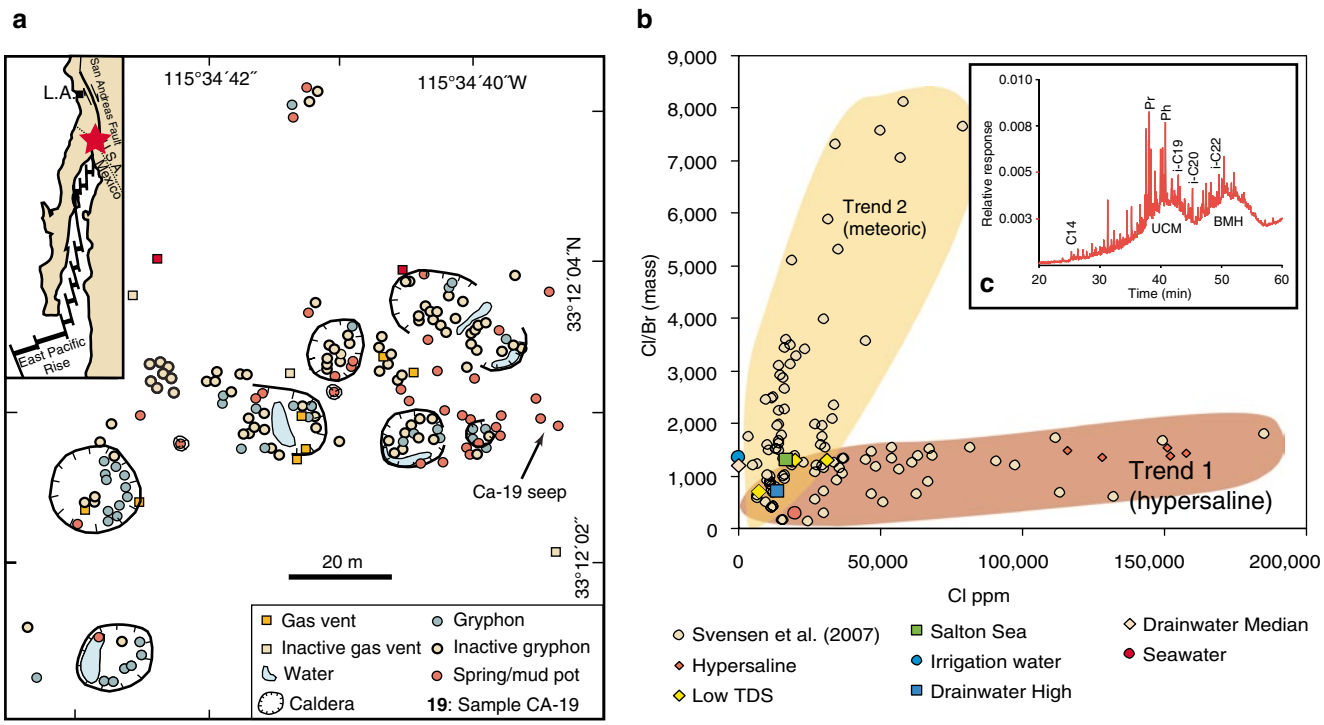

Fig. 9.74 Brines and hydrothermal oil in the Salton Sea, Southern California (After Svensen et al. 2007 and references therein). (**a**) Davis-Schrimpf seep field is characterized by clusters of gryphons, local subsidence structures, and calderas. Generally, gryphon mud towers are as high as 3 m with a central conduit, where mud and water chambers are located below ground level. Mud pots and springs are open circular depressions as much as 30–50 cm below ground level, but may occasionally form positive structures to a few tens of centimeters high. (**b**) Analyses of gryphon and spring water collected from Davis-Schrimpf field show a wide range in Cl and Br contents as do other seep an subsurface waters collected in the region. Compositions of waters define two trends in Cl–Br space related to salinity and origin of the waters. (**c**) Organic geochemistry of CA-19 seep fluid. Gas chromatography shows occurrence of homologous series of normal alkanes (n-Cxx) and isoalkanes (i-Cxx). Presence of unresolved complex mixture (UCM) and high concentrations of Pr and Ph suggests influence of biodegradation. Biomarker hump (BMH) is typical for source rocks with low to moderate maturity

hypothesis of hydrocarbon generation via hydrothermal cracking is supported by the presence of petroleum in a water-dominated spring, composed of 53 % saturated compounds, 35 % aromatics, and 12 % polar compounds (Fig. 9.74c).

At various seafloor and onshore spreading axes, hydrothermal systems, active under a cooler sedimentary cover, generate petroleum from the generally immature organic matter in the sediments (e.g., Guaymas Basin, Escanaba Trough, Salton Sea, etc.). The alteration reactions are primarily reductive and to a lesser extent oxidative, and are generally associated with the emplacement of hydrothermal anhydrite and baryte (Table 9.15). The process occurs in heated systems with high water to rock ratios, where the interplay of high temperature water, carbon dioxide and methane under pressure represents the effective and efficient thermal driving force for reactions and solvent for product extraction and migration. Migration of hydrothermal petroleum can occur as a bulk phase, or in emulsion and solution.

Table 9.15 Overview of hydrothermal processes affecting organic matter alteration

Hydrothermal petroleum generation		
Alteration reactions (importance)	Compound type	
(a) Reduction (primary)	Aliphatic hydrocarbons	
(b) Oxidation (minor)	PAH, alkones	
(c) Synthesis (trace)	Thioheterocyclic compounds	
Hydrothermal petroleum migration		
Source of organic matter	Products	Relative concentration
(a) Marine (Guaymas Basin)	Gas (CH_4-C_{10})	High
	Oil (C_8--C_{40+})	Intermediate
	Asphalt (>C_{40})	Minor
(b) Terrigenous (Middle Valley)	Gas (CH_4-C_{10})	Trace
	Oil (C_8--C_{40+})	High
	Asphalt (>C_{40})	Intermediate
Hydrothermal fluids as solvents		
Fluid	Relative importance state:	Effect:
(a) Water	Dominant/ near-critical	Enhanced oil solubility
(b) Methane	Minor/supercritical	Complete oil solubility
(c) Carbon dioxide	Minor/supercritical	Complete oil solubility
Hydrothermal petroleum migration		
(a) Effective in systems with high water to rock ratios (unlike conventional sedimentary basins)		
(b) Migration styles		
Bulk phase (trapped in filled veins and voids)		
Emulsion (trapped in fluid inclusions)		
Solution (precipitated as wax crystals in chimneys and fluid conduits)		

After Simoneit 1994

Hydrothermal oils and the associated deep seafloor circulation in the Guaymas basin have been used as a modern analogue to explain the hydrocarbon-entraining Proterozoic ore systems in the McArthur Basin, Australia (Chen et al. 2003) and Besshi-type ore deposits (Chap. 16). Polycyclic aromatic hydrocarbons in ore and mudstones within the McArthur River ore deposit show compound distribution patterns similar to those of hydrothermally generated petroleum in the Guaymas Basin, both are significantly different from those found in conventional oil accumulations. The polycyclic aromatic hydrocarbon abundances and their isomer distributions result from a temperature gradient between the source of mineralizing fluids and the sediments, indicating an active hydrothermal system fringed the McArthur ore system during ore precipitation within partially-lithified seafloor sediments.

Although the evidence is clear for hydrothermally-cracked hydrocarbons migrating through sediments at active spreading centres, the inherent association with active faulting and tectonism in modern ocean spreading centres means most hydrocarbon product is lost to the overlying seawater column through a lack of appropriate longterm traps and seals (Kvenvolden and Simoneit 1990). Perhaps such systems are more likely to trap oils in areas where there is a fortuitous association between hydrothermal circulation and downdip end of salt allochthons flowing basinward across a deep seafloor in a salt floored rift, as in some parts of the Red Sea troughs and in the Proterozoic McArthur succession (Chap. 15).

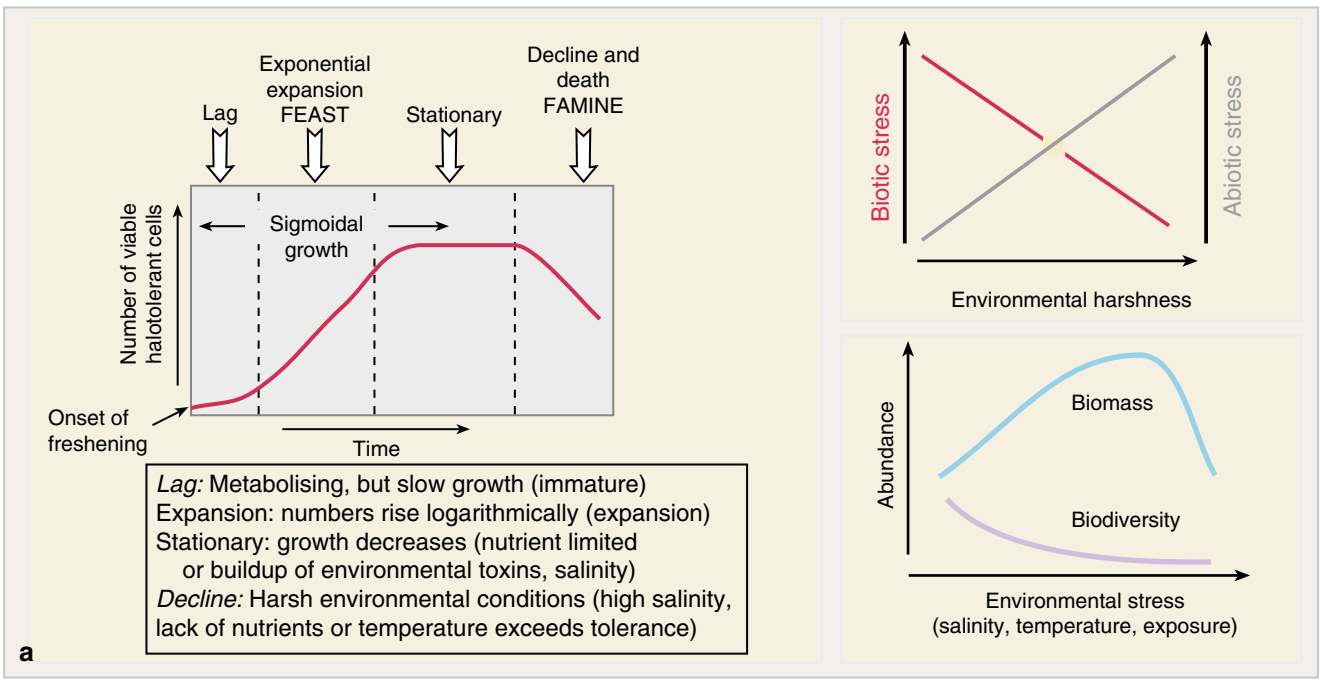
There is an even older example in this hydrothermally-cracked oil spectrum. It is indicated by oil remnants in a 3.2 Ga Early Archaean deep-sea volcanogenic massive sulphide deposit in northwest Australia (Rasmussen and Buick 2000). Archaean seawater lacked sufficient sulphate or Ca to form anhydrite, so oil was preserved in fluid inclusions within hydrothermal baryte, and as pyrobitumens intergrown with polymetallic sulphides. Petrographic textures show that the oil was emplaced and thermally altered (cooked) before latestage sulphide mineralization. Its presence implies subseafloor hydrothermal petroleum generation was active during the Early Archaean, possibly providing an energy and carbon source for a subsurface microbiota that was metabolizing hydrothermal sulphur species.

Summary

Evaporites and associated brines play a significant role in the deposition, accumulation and subsurface evolution of both the organic matter and its hydrocarbon products as well as related metal sulphide accumulation, throughout eogenesis, mesogenesis, telogenesis and metamorphism.

Organic matter in modern hypersaline systems tends to accumulate in bottom sediments beneath density-stratified saline water and sediment columns in evaporitic settings where upper portions of layered hydrologies are subject to oscillations in salinity and brine level. Organic matter is not produced at a constant rate in such systems, rather, it is produced as pulses by a halotolerant community in response to relatively short times when less stressful conditions occur in the upper part of the layered hydrology (Fig. 9.75). This happens when an upper less-saline water mass forms on top of nutrient-rich brines or within wet mudflats when waters in and on top of the uppermost few millimetres of any microbial mat freshen.

The resulting bloom (a time of "feasting") by halotolerant algae and cyanobacteria is a time characterized by very high levels of organic productivity (Fig. 9.75a). In mesohaline waters where light penetrates to the bottom, the organic-producing layer is generally the upper algal and bacterial



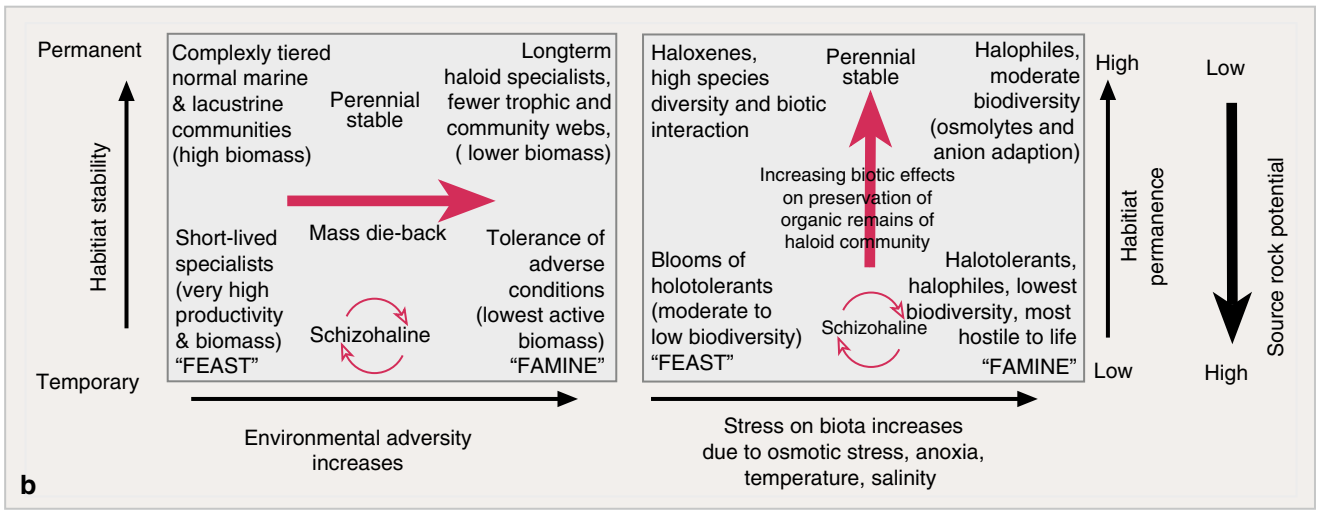


Fig. 9.75 Life in saline systems. (**a**) General ecological principles in stressed saline ecosystems. Sigmoidal growth curve of life moving into a newly created niche (as is created by a freshening event setting up a layered brine). As environmental harshness increases due to abiogenic stress factors (such as increasing salinity, osmotic stress and temperature) the level of biogenic stress (predation or grazing) decreases allowing a few well adapted species to flourish leading to a decrease in biodiversity and a short-term increase in biomass. (**b**) Schematic summary ("halomancy") of the interrelationships between habitat stability, environmental stress or adversity, biodegradation, anoxia and source rock potential in an evaporite basin, showing why schizohaline environmentally stressed mesohaline systems tend favour the accumulation of organic matter in bottom sediments

portion of benthic laminated microbialites (typically characterized by elevated numbers of cyanobacteria). In stratified brine columns, the typical producers are the planktonic algal or cyanobacterial community inhabiting the upper freshened water mass. Halotolerant autotrophic microbial communities, living off the remains of this plankton, float mid-water at the halocline of the density stratified brine columns. Similar aerobic decomposers can also constitute bottom-layer communities in zones of oxygenated oligotrophic waters.

Short pulses of extremely high organic productivity during times of freshened mesohaline surface waters in-turn create a high volume of organic detritus settling through the water column and/or construction of benthic microbial mats. Then, with the end of the freshening event, the ongoing intensely arid climate that characterizes evaporitic depressions means that salinities, temperatures and osmotic stresses increase rapidly in the previously freshened water mass. This leads to a time of mass die-off, in the once flourishing mesohaline community ("famine;" Fig. 9.75). First, these increasingly salty waters can no longer support haloxene forms. Then halotolerant life dies back and finally, by the halite precipitation stage, only a few halophilic archaea and bacteria remain in the brine column (typically acting as heterotrophs and fermenters). Repeated pulses of organic matter created during a freshening event in a stratified brine column thus create laminated bottom sediment.

Hydrogen-rich algal and eubacterial debris is best preserved within sediments where pore waters are anoxic and remain so until the resulting kerogen is sufficiently buried for it to generate liquid and gaseous hydrocarbons (Demaison and Moore 1980). Thus the preservation of organics with long-chain hydrocarbons intact is most likely in settings characterized by long-term anoxia (typically inhabited by less efficient decomposers). This tends to occur beneath stratified eutrophic saline brine columns with a permanent anoxic mesohaline bottom water mass and a transiently freshened upper water mass. Preservation is also possible in benthic mats in shallow oligotrophic systems with permanently hypersaline pore waters, but the propensity for periodic bottom oxygenation means preservation potential of oil-prone mats is less likely in this setting, as is also the case in mats of the strandzone.

Increasing rates of mineral precipitation at higher salinities means levels of hydrogen-prone organics are highest in sediments deposited in schizohaline waters that remain in the mesohaline field. Once ambient salinities pass into the penesaline and supersaline, the proportion of organics in the sediment becomes insignificant as it is rapidly diluted by large volumes of gypsum and halite (or trona and glauberite in some continental penesaline/supersaline waters).

Feast and famine cycles are a biotal response to environmental salinity conditions that at first are eminently suitable and then increasingly adverse to life. It reflects the typical biological response to rapid niche creation and expansion as the freshened water layer sets up in the evaporitic depression, and is known as the sigmoidal growth response (Fig. 9.75a). Freshening of surface waters creates a vacant ecological niche into which microbial life rapidly expands, flourishes and then once more dies back as drying or brine concentration shrinks suitable niche space.

Long-term stability in any ecosystem leads to domination by "specialist" species that are well adapted, diverse and efficient in terms of energy flow-nutrient utilisation (Fig. 9.75b). This biodiverse community takes up and recycles carbon very efficiently through the system and the potential for large volumes of carbon passing into the burial realm is low and hence source potential is also low (a good analogy in the marine realm is the ecosystem that typifies a stable tropical coralgal reef).

In contrast, a schizohaline system is one defined by high habitat instability, its lack of habitat permanence encourages opportunistic lifestyles (cycles of "famine or feast"). Opportunist species expand rapidly into any suitable niche space, but then just as quickly die back or encyst as conditions become adverse. Such systems are characterised by high biomass pulses and relatively low species diversity, leading to pulses of organics accumulating in the evaporitic depression, with the remains likely to be buried and "pickled" beneath anoxic bottom brines and pore waters, giving such systems a higher source rock potential (Fig. 9.75b).

Some hypersaline settings are intermediates in that their waters are constantly hypersaline, stressful to most life, but suitable to a few well-adapted species. These regions are usually populated by a few very specialized species (e.g., "high-salt-in" halophiles) that can survive and flourish in conditions where most life dies. They photosynthesise and metabolize successfully in these hypersaline conditions (for example, by living near haloclines), but do so at rates that are much slower than the growth rates attained by halotolerant "opportunists" at times of "feast." The long-term cycling of organic materials means bottom sediment layers tend to have lower levels of entrained organics preserved compared to the schizohaline-mesohaline.

There are four main geological association where feast and famine conditions during deposition encourage the preservation of elevated levels of hydrogen-prone organic matter, namely; mesohaline platforms and basinwide settings, especially in the early mesohaline stages of salt precipitation. These evaporites source rock association have no modern day counterparts, whereas the mesohaline lacustrine and deep seafloor stratified brine lake associations for source rocks.

Once the enhanced levels of organics stored in an evaporitic host enter the burial realm, other aspects of the evaporite association can further aid in preservation of evaporitic protokerogens. Shallowly buried sediments and their pores

beneath hypersaline depositional settings are generally filled by anoxic high-salinity pore fluids. This is especially so in a reflux curtain, which tends to slow or prevent the entry of less dense fresher waters. The latter tend to carry communities of the more efficient oxygenic decomposers. Dense, highly-saline reflux curtains below salt beds can persist for tens of millions of years and last to depths that are well into the catagenic realm. This prevents or slows entry of oxidising waters from above or below, other than in local fault or salt wedge edge-focused regions in the basin hydrology. However if the organics are encased in salt, this can slow or prevent the release of catagenic fluids and the evolving organics can remain until the temperatures of thermochemical sulphate reduction and then metamorphosis are reached. If the kerogens remain encased in salt, the lack of any effective permeability can be a negative in terms of hydrocarbon transfer and storage, but a positive in the creation of chloride-rich metal sulphide carriers as fluids are released when halite ultimately dissolves at uppermost diagenetic or lower end metamorphic realm and beyond.

Hydrocarbons and Evaporites

10

Introduction

Even though evaporites constitute less than 2 % of the world's sedimentary rocks, one-half of the world's largest oilfields are sealed by evaporites, the other half are sealed by shales (Fig. 10.1; Grunau 1987). Kirkland and Evans (1981) argued that evaporites overlie or seal carbonates containing an estimated 50 % of the world's known total petroleum reserve. Of the world's 25 largest gas fields, 9 are sealed by evaporites and 16 by shales and hydrates. Sixteen are capped by Mesozoic seals, 7 by Palaeozoic seals, and only two by Tertiary seals. Fourteen are in the 1,000–2,000 m seal-depth interval, nine in the 2,000–3,000 m interval; and two in the 0–1,000 m interval. As one would expect, more gas fields than oilfields are sealed by Palaeozoic caprocks, and more oilfields than gas fields are sealed by Tertiary caprocks. Surprisingly, the seal depth intervals for the 25 largest oil and gas fields do not differ significantly. However, Grunau argues many "supergiant"[1] gas accumulations below depths of 3,000 m and have either not yet been discovered, or have not yet been put in production (e.g. much of the Khuff-hosted gas in North Dome in the Middle East).

The exemplary ability of evaporites to act as seals holding back large hydrocarbon columns is clearly seen in the Middle East, where Ghawar, the world's largest oil field, is sealed by bedded evaporites of the Arab Formation and the overlying Hith Anhydrite seal Fig. 10.1a). This seal holds back an estimated remaining reserve of more than 100–200 billion barrels. Evaporites also seal Safaniya the world's largest offshore field, also in Saudi Arabia, with estimated reserves of more than 25–30 billion barrels of oil and 5 billion cubic feet of natural gas. Likewise evaporites are the seal to North Field in offshore Qatar, the world's largest single gas field (non-associated gas) with more than 500 tcf of reserves (Fig. 10.1b; Alsharhan and Nairn 1997). This gas is reservoired and sealed in the evaporitic dolomites of the Permian Khuff Formation and recent announcements by the Qatari Government have documented more than 900 tcf of certified non-associated gas in the structure.

According to Klemme (1983) all the supergiant gas fields in the world are overlain directly, or somewhat directly, by laterally extensive evaporite beds or by permafrost carapaces with their attendant gas hydrates. Most of the giant Russian gas fields (largely in Siberia) have hydrate seals, while those of the Middle East are mostly sealed by evaporites. In 53 % of the gas fields that have a net recovery of 3.5 tcf or more, evaporites are either associated with the reservoirs or form the trap (Billo 1996). Evaporite seals play a significant role in facilitating Suadi Arabia's position as the world's dominant producer of crude oil (Fig. 10.2).

All of the giant gas fields in thrust belts have an evaporite seal (Downey 1984) reflecting salt's ability to maintain seal integrity as it deforms, while underlying sediments fracture into salt-sealed reservoirs. Chengzao and Qiming (2008) conclude that high-quality regional salt cap rocks are essential for the formation of the super-rich, abnormally pressured, giant gas fields, such as Kela-2 in the Tarim basin, while buried anticlines under the overthrust décollement zone are favourable gas habitats. Deforming shallow salt allochthons in the Gulf of Mexico and elsewhere, not only control the seafloor topography focusing deposition of nearby sand and carbonate buildups, but later can flow over these deposits to create the seal (Fig. 6.66). Halokinesis creates both suprasalt and subsalt traps. The presence of an impervious salt bed or allochthon also helps maintain higher than expected porosities and pressures in underlying reservoirs (Fig. 8.22).

In the gently-folded belt in front of the main Zagros deformed zone in Iran and Iraq an intimate association exists between sediment deposition, salt flow and the creation of salt-sealed reservoirs. This foreland basin is an area

[1] A giant oil field contains more than 0.5×10^9 barrels of expected ultimate recoverable oil, while a supergiant contains more than 5×10^9 barrels (Fitzgerald 1980). The equivalent separation between giant and supergiant gas fields is 0.5×10^9 and 5×10^9 BOE, respectively.

BOE is barrels of oil equivalent on a BTU basis; 1 barrel of oil = 5.61 ft^3, so the respective cutoffs for giant and super giant gas fields are 3 and 30 tcf (trillion cubic feet).

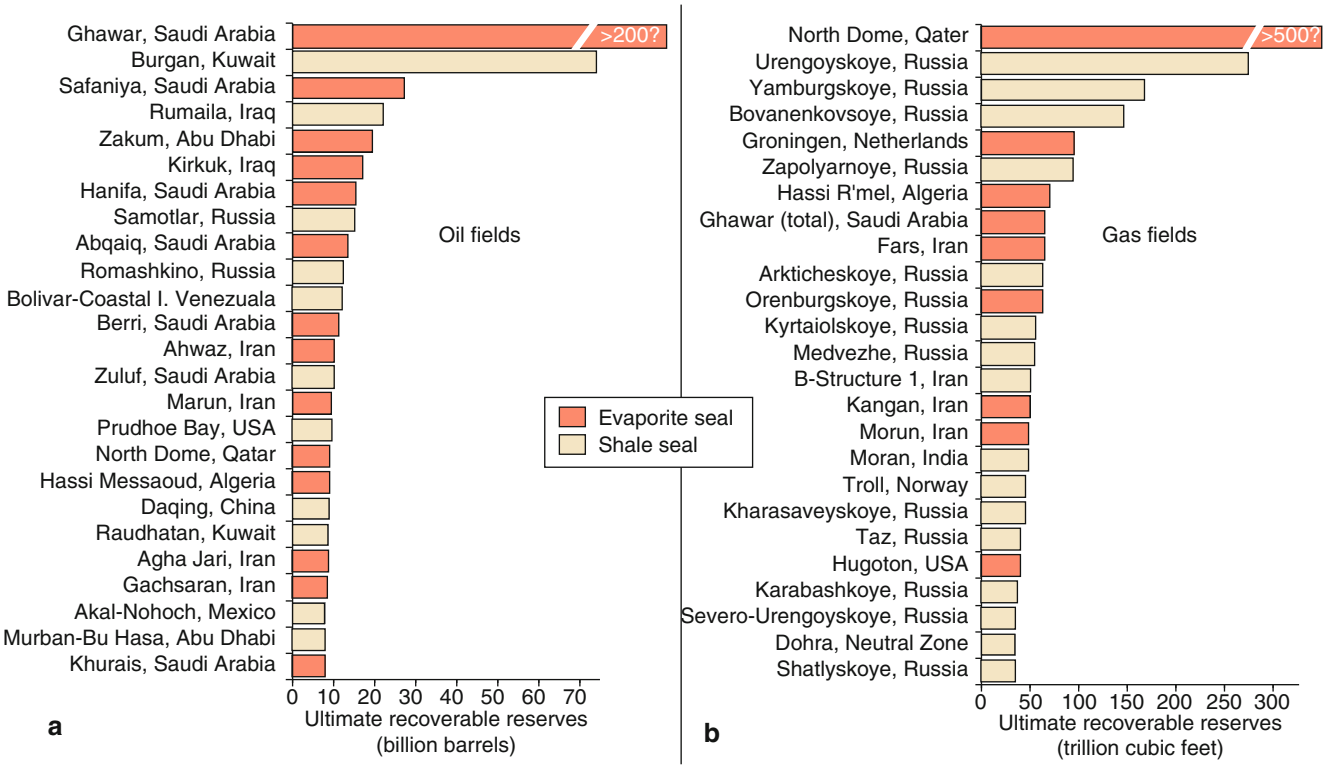

Fig. 10.1 Seal type and ultimate recoverable reserves in 25 of the world's largest oil (**a**) and gas (**b**) fields (In part after Grunau 1987)

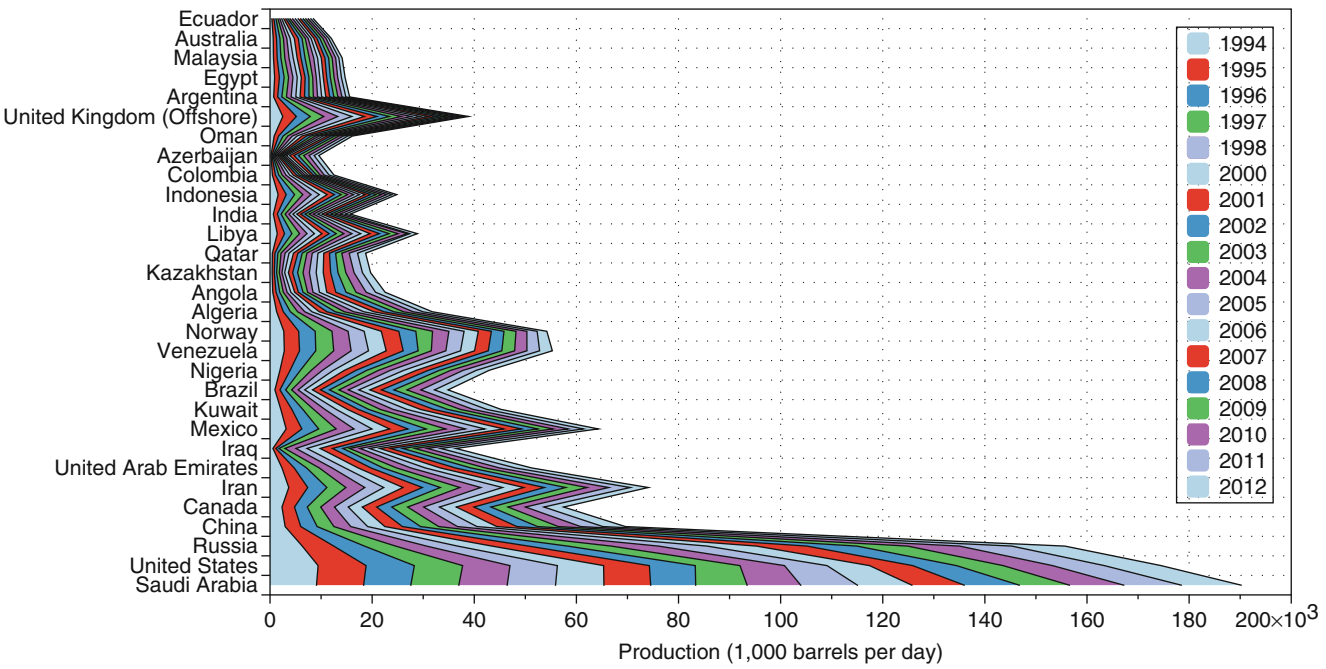

Fig. 10.2 Annual crude oil production from top 20 producing countries, cumulative area plot, ranked by 2012 production (Data downloaded and replotted from U.S. Energy Administration website <http://www.eia.gov> last accessed September 10, 2013)

undergoing compression and syndepositional folding, where crests are still growing at the surface (growth folds) and so controlling the distribution and structuration of both reservoir and seal. The same collision system also created the restriction that allowed the Fars-Gasharan seal to precipitate. It is an area with a great deal of potential for future evaporite-associated discoveries, as evidenced by the 1999 discovery of the Azadegan oil field, near Ahwaz in the Zagros Foldbelt of southern Iran. As announcedby NIOC (National Iranian Oil Company) in September 1999, the structure holds a possible 24–26 billion barrels of oil in place over an area of more than 520 km^2, with something like 5–6 billion barrels of recoverable oil. If the size of the projected field is confirmed by ongoing drilling, it will become one of the world's supergiant fields. To put this level of reserves into some perspective, 26 billion barrels of oil in place is more than the total known reserves in China.

The International Energy Agency (IEA) has predicted that unconventional oil, which includes bitumen, heavy oil, and tight oil, will contribute only 13 % of the global supply and unconventional gas consisting of tight gas, shale gas, and coalbed methane, 26 % of the global gas supply by 2035. Conventional petroleum supply will come largely from the remaining reserves and reserve growth from both discovered and undiscovered giant fields. Today, most of the larger simpler more readily and predictably exploited siliciclastic reservoirs have been found (Fig. 10.3). There is the exception of deepwater realm settings, targeting turbidite and other deepwater sands sealed by muds. But, in many frontier regions for such deepwater sands, such as the Gulf of Mexico, offshore Brazil, Angola and Namibia, salt plays a role either as seals or the creation of suprasalt trap configurations. Oil and gas exploration in circum-Atlantic Aptian basins is increasingly focused on carbonate and lacustrine reservoir systems, these too are settings where evaporite seals and brine-derived diagenetic fluids are more common.

The importance of the evaporite-hydrocarbon association is clearly seen in a compilation of giant oil and gas discoveries across the period 2000–2012 (Fig. 10.3; Bai and Xu 2014). Of the 120 giant oil and gas fields discovered in that period some 54.6 % were hosted in marine carbonates and 12 % in lacustrine carbonates, meaning less than a third of new giant discoveries were in siliciclastic reservoirs (Fig. 10.3a). Some 56 % of these oil and gas giants had an evaporite seal, with 82 % of the marine carbonates having an evaporite seal and 91 % of the lacustrine carbonates having an evaporite seal (Fig. 10.3b, c). Clearly, carbonate reservoirs with evaporite seals constitute the majority of the giant oil and gas discoveries in the period 2000–2012, and the proportions of this association are likely to increase in conventional discoveries across the next decades.

Of the 120 oil and gas giants discovered in the period 2000–2012, one is a megagiant field with a recoverable reserve of 50 Bboe or more and 6 are supergiant fields with recoverable reserves of 5 Bboe or more. The seven largest fields are: Galkynysh (aka Yolotan or Osman) gas field in the Ama-Darya basin of Turkmenistan with an original[2] 2P reserve of 67.1 Bboe, making it likely the second largest known gas field in the world; Kashagan oil field (18.1 Bboe) in the North Caspian basin; Kish 2 gas field in the Arabian basin (Iran): Lula (previously known as[3] Tupi), Franco and Libra oil fields in the Santos basin of offshore Brazil; and Sulige gas field (5.7 Bboe) in the Ordos basin, China. In this listing, the geology of Galynysh is not yet reliably published, of the remaining 6, only Sulige does not have an evaporite association (Saltworks® data base, version 1.6). In this scenario, evaporites studies can only become more important in both exploration and development in the years to come.

Predicting the position and quality of potential reservoirs in evaporite terranes is difficult without integrating notions of feedback between deposition, diagenesis and structural evolution. Therein lies the difficulty in placing evaporite-associated reservoirs and traps in classic terms of structural, stratigraphic and diagenetic traps. When classifying a field with an evaporite trap, the fact that salt is so mobile, so soluble, and so diagenetically active, separates it from other trap styles in a petroleum system. It means that a salt unit, by its comings and goings, plays ongoing and multiple roles in generating reservoirs and traps from the time of deposition through diagenesis to structuring. Tying the resulting oil and gas field to a static and categoric breakdown is near impossible as salt-induced structuring, diagenesis and deposition are often penecontemporaneous and in a state of intimate feedback with adjustments contuing throughout the mesogenetic and telogenetic realms.

Over the years, I have come to regard conventional pigeonholes for salt-associated traps (such as depositional, diagenetic, structural) as next to useless in predicting likely positions of hydrocarbons in evaporitic provinces. Rather, as a salt unit is typically the most obvious feature on a seismic section, especially in carbonate terrains, I use a much simpler classification of; "Where's the salt?" At their simplest, evaporite-associated reservoirs all occur adjacent to either bedded or halokinetic salt, or their solution residues (Table 10.1; Fig. 10.4). With bedded or halokinetic salt or solution breccias, there are three possible positions of potential reservoir, namely; subsalt, intrasalt and suprasalt. Within

[2] 1P reserves = proven reserves (both proved developed reserves + proved undeveloped reserves).

2P reserves = 1P (proven reserves) + probable reserves; hence proved AND probable.

3P reserves = the sum of 2P (proven reserves + probable reserves) + possible reserves; hence, all 3Ps are proven AND probable AND possible.

[3] Name changed to honour former Brazilian President, Luiz Inacio Lula da Silva.

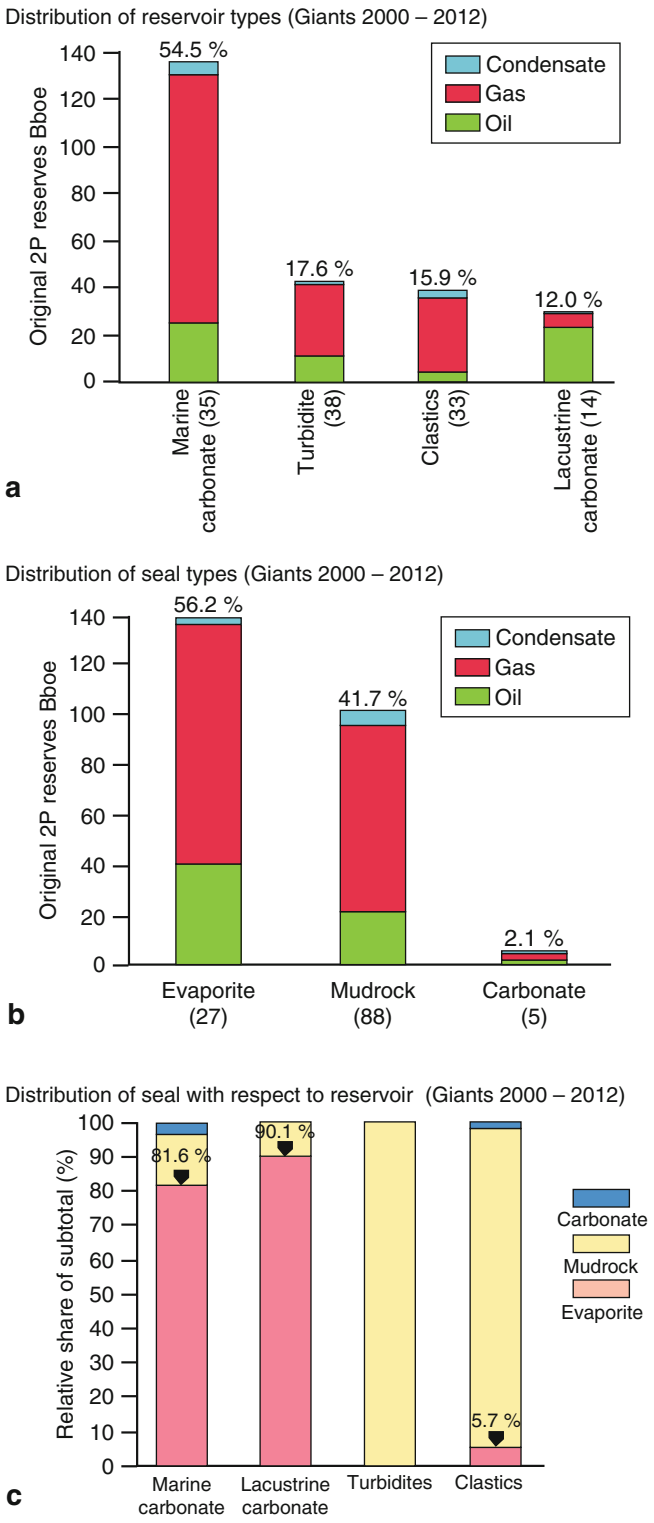

Fig. 10.3 Evaporite seals to giant fields discovered in the period 2000–2012. (**a**) Dominant reservoirs for oil and hydrocarbon type. (**b**) Seal mineralogy. (**c**) Relations of reservoir to seal mineralogy (After Bai and Xu 2014)

Table 10.1 Role of evaporites in creating hydrocarbon reservoirs and traps

		Effect of evaporite on nearby reservoir		Effect of seal itself	
		Depositional	Subsurface/diagenetic	Depositional	Subsurface/diagenetic
Bedded salt	Suprasalt	Presence of brine, either from salt dissolution or deposition of nearby salt can prevent accumulation of carbonates or siliciclastics containing a normal marine biota.	Solution of bedded salt creates collapse sinks and fronts that can enhance deposition of porous sediments or encourage collapse fracturing in overlying beds	Not applicable	Dissolution of salt creates a dense brine plume that aids in the formation of hydrodynamic traps
	Intrasalt		Solution of surrounding salt creates fractured and brecciated intrasalt beds that can stack into porous solution breccias	Not applicable	Permeable intervals are encased in bedded salt
Halokinetic	Subsalt	Evaporite bed acts as a source of Mg-rich brine that improves permeability of underlying or adjacent bed (creation of mouldic porosity and brine reflux dolomite)		Evaporite bed acts as top seal and/or lateral seal to reservoir (well documented)	Evaporite bed acts as a source of saturated brine for cement plugging of underlying or adjacent unit
	Suprasalt	Shallow halokinetic salt focuses the deposition of porous sediment around areas of uplifted seafloor or land surface. Can also influence the formation of slumps and CCD-related sedimentation	Dissolution of the upper salt surface creates a caprock reservoir	Salt flows carries blocks of anhydrite/dolomite and allochthon dissolution creates salt ablation (retreat) breccias	Passage of salt allochthon creates adjacent zones of alteration/cementation that may continue to act as a barrier to fluid flow even when the salt is no longer present (weld)
	Intrasalt	Not applicable	Salt flow can break up, fracture and rotate organic-rich intrasalt beds, allowing them to become self-sourcing reservoirs encased in a halokinetic salt seal	Brecciation of intrasalt bed leads to overpressured blocks within the salt mass	Salt flow allows salt unit to maintain seal integrity
	Subsalt	Not applicable	Brine plume created on the underside of a dissolving salt allochthon can alter underlying beds, which in some situations (e.g. fluid breakthrough) can enhance permeability of underlying beds via dolomitisation/fracturing	Salt allochthon acts as top seal or lateral seal to reservoir sands (well documented). The ability of salt to maintain seal integrity under both extension and compression is significant	Passage of salt allochthon creates adjacent zones of alteration/cementation that may continue to act as a barrier to fluid flow even when the salt is no longer present (weld)

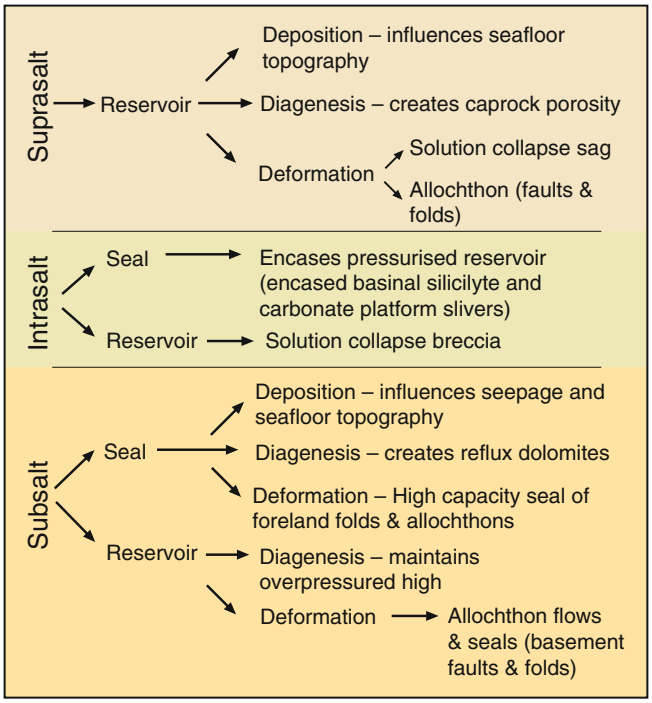

Fig. 10.4 Classification of evaporite seals and associated reservoirs relative to the salt body position and the dominant mechanisms

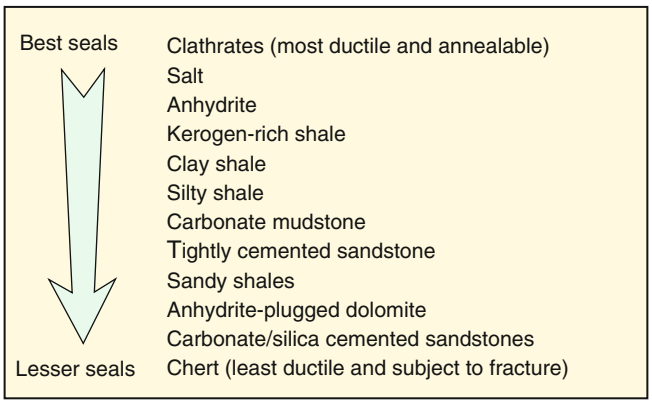

Fig. 10.5 Differing ability to form a seal is related to a rock's inherent ductility in the subsurface (In part after Downey 1984)

a single hydrocarbon fairway there may be reservoirs sitting in more than one position. Where I can, I further classify each reservoir in terms of the relative roles of deposition, diagenesis and structure as controls on the position of the targeted hydrocarbon accumulations.

Understanding and predicting lateral continuity of both bedded and halokinetic salt seals is an important exploration and development tool. Think about this, when a seal bed with a vertical permeability of 10^{-8} darcies is a mile long on each side and is cut by a single fracture 6 μm wide, then the drainage through that single fracture is equivalent to the total fluid flux through the square mile of seal. Downey (1984) calculated that a single fracture 25 μm wide atop a 150 m oil column would leak oil at rate of more than 150 million barrels per million years. Halite is such an excellent seal as it tends to flow rather than fracture. When is does fracture in the subsurface the crack quickly reanneals and sutures via pressure-solution recrystallisation (Chap. 6).

Continuity of ancient saltern and mudflat seals and their ability to resist fracturing via reannealing means salt beds can gather and constrain subsalt hydrocarbons over large drainage areas. In suprasalt traps, the role of salt in creating reservoirs and traps ranges from stratigraphic seal, through diagenetic trap, to a creator of structural traps (anticlinal

[halokinetic], fault and drape traps). The key factor in assessing the capacity of any seal, including salt, is timing of any microfracturing or fracturing relative to hydrocarbon emplacement in an underlying or adjacent potential reservoir. In other words, does any loss of seal capacity precede or postdate possible storage of hydrocarbons in the reservoir? We shall soon examine a number of examples from various bedded and halokinetic reservoir associations. First, we need to consider why salt units are excellent longterm seals; it's a discussion where salt's inability to maintain ongoing penetrative fractures cannot be overestimated.

Seal Capacity of Evaporites

In Chap. 9 we saw that there is a depositional association between evaporites and some types of organic-rich oil-prone source rocks. In Chap. 6 we saw how flowing salt created structures capable of trapping substantial volumes of hydrocarbons. But, of the various reasons for the evaporite-hydrocarbon association (source, trap and seal), the most commonly cited is the efficiency of evaporite layers in holding back substantial hydrocarbon columns for lengthy periods of time, even as adjacent nonevaporite strata fracture and leak. Using a worldwide database of 350 giant oilfields, MacGregor (1996) showed oil pools are dynamic short-lived phenomena, with a median age of 35 Ma. A third of them show evidence for post-entrapment destructive processes, particularly erosion, fault leakage, gas flushing and biodegradation. Biodegradation began in many cases prior to complete filling of the trap. Re-entrapment of oil released from spilling or breached traps was common to all regions. He found the main controls on oilfield preservation to be post-entrapment tectonism and seal type, with temperature and hydrodynamic regimes being secondary factors. He concluded the potential for giant oilfields is greatest in tectonically quiescent basins with evaporite seals. As areas with the best development of this association he cites as the Middle East centred on Saudi Arabia/UAE and the Permian Basin of the southwest USA. Billo (1996) noted a similar association when discussing the same areas.

So Why Do Evaporites Seal?

In terms of seal capacity and resistance to fracturing, the most effective sedimentary seals are gas hydrates, followed by evaporites, then shales (Fig. 10.5; Downey 1984). To seal an economic accumulation of hydrocarbons, any sealing surface or lithology needs to be laterally continuous, maintain a constancy of properties over large areas, be relatively ductile, and be widespread over a sedimentary basin. A fundamental requirement for any effective seal is that the minimum[4] displacement pressure of the lithologic unit comprising the sealing surface be greater than the buoyancy pressure of the hydrocarbon column in the subjacent accumulation. Hence, the size of the pore throats and the density of entrained hydrocarbons and water are of great importance in determining whether or not a particular lithology can act as a seal. Density/buoyancy differences between oil and gas means there are fields, such as some evaporite-cemented San Andres Formation mudstones in the Permian Basin of Texas, where dolomitic mudstones act as a seal to liquid hydrocarbons, yet flow gas.

Any lithology can be a seal, but other than[5] clathrates, evaporites are the most effective regardless of hydrocarbon type and structural setting (Fig. 10.5). Unlike the low temperatures requirements for a clathrate seal, evaporite seals, with their extremely high[6] entry pressures, ductility, very low permeabilities and large lateral extents, can maintain seal integrity over wide areas, even when exposed to a wide range of subsurface temperature and pressure conditions. A typical shale seal has a permeability $\approx 10^{-1}$ to 10^{-5} md, with rare values as low as 10^{-8} md (Fig. 10.6a). Quantitative measurement of evaporite permeability is beyond the capacity of standard instruments used in the oil industry and is mostly a topic of study for engineers working with waste storage caverns (see Chap. 13). Their work shows the permeability of halite is a nanodarcy or less, that is, undamaged subsurface salt has measured[7] permeabilities that are less than 10^{-21} m^2 (10^{-6} md) with some of the tighter halite permeabilities $\approx 10^{-7}$ to 10^{-9} md and typical massive anhydrites $\approx 10^{-5}$ md (Beauheim and Roberts 2002). Pore pressures in such halites typically approach lithostatic (Ehgartner et al. 1998).

Measures of salt permeability or brine permeation are typically described through Darcy's law (Bérest et al. 2011).

[4]Entry pressure is the minimum capillary pressure required to force oil or gas from one water-filled pore to the next.

[5]Gas or methane hydrates (more precisely called clathrates) are the solid form of mostly methane trapped in a crystalline framework of ice and are only found in low temperature seafloor or permafrost conditions. They seal onshore supergiant fields of west Siberia and Timan-Pechora basins of Russia and occur also as solid bacterial-associated products in the deep seafloor, where temperatures are low and water depths exceed 500 m. Seafloor clathrates are thought to contain more than 20 quadrillion cubic metres of methane. In oil equivalents this is around 15 trillion m^3 (116 trillion barrels), more than 30 times the likely volume of oil and gas reserves (Hunt 1996).

[6]Synonymous with minimum displacement pressure.

[7]In most oilfield applications the millidarcy (md), which is 0.001 darcies, is used as a measure of permeability. Permeability is fundamentally a L^2 unit. In SI it is expressed in μm^2, which is 10^{-12} m^2. In conventional metric use it is expressed in m^2 (metres squared) or cm^2. The conversion between oilfield and SI units is 1 darcy = 9.869×10^{-13} m^2. In practical terms, 1 md and 1 μm^2 are essentially equivalent, while in terms of hydraulic conductivity, 1 darcy = 10^{-5} m/s.

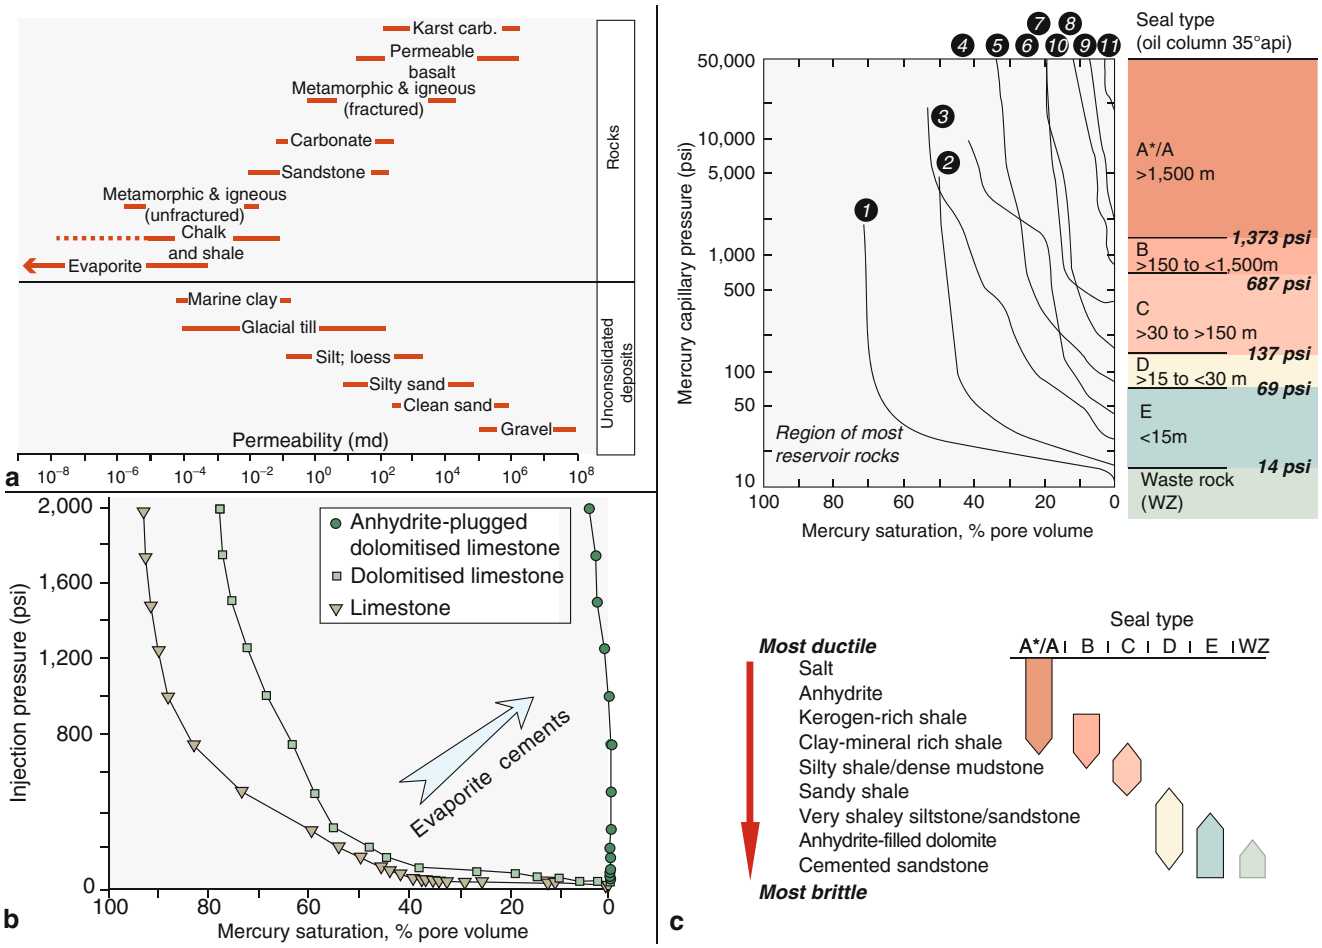

Fig. 10.6 Seals. (**a**) Relative ranking of permeability of various lithologies (In part after Beauheim and Roberts 2002) (**b**) Hg-injection curves from representative lithologies in a sequence undergoing reflux dolomitisation and overdolomitisation (From Warren 1992). (**c**) Seal classification (A-E) based on air-mercury pressure curves for typical seal lithologies, denoted 1–9 (After Sneider et al. 1997 and Sneider 1995)

However, some authors believe that undisturbed rock salt is both liquid-tight and gas-tight in its primary state, and that the origin of the non-zero permeability measured during laboratory tests is likely due to damage that occurred during test sampling and preparation, or to undetected tiny leaks from the testing equipment. For these authors, the permeability observed in the vicinity of a well bore or a salt storage cavern (Chap. 13) is a secondary permeability, i.e., induced by the stress changes generated via drilling and cavern creation. According to Bérest et al. (2011) these differing views may also be explained, in part, by differences in salt compositions and crystal character. Bedded salt formations can contain a significant amount of insolubles (clay, anhydrite), which might be more permeable than the salt itself.

In terms of oil and gas seals, little or no leakage will take place through a laterally continuous evaporite seal when the reservoired hydrocarbon is oil. Even when the reservoired hydrocarbon is methane, little or no loss occurs, even by diffusion (Ehgartner et al. 1998). The much greater efficiency of evaporite seals is clearly seen in the total hydrocarbon volumes held back by the two lithologies. Total worldwide shale sediment volume in the crust is more that an order of magnitude greater than that of evaporites, yet the split between reservoired hydrocarbons below a shale or an evaporite seal is roughly 50:50 (Grunau 1987). Likewise, typical volumes of salt-sealed giant fields discovered in the last decade are much larger than that in mudrock-sealed systems (Fig. 10.3b).

Typical bedded evaporites, especially beds composed of monomineralic assemblages such as massive nodular anhydrite or massive halite, have measured entry pressures in excess of 3,000 psi. Most impure evaporite beds have entry pressures greater than 1,000 psi, as do many evaporite-plugged reflux dolomites (Figs. 10.6b and 10.7). Contrast this with most shales, which tend to be water-bearing (mostly bound and structural water) and have typical entry pressures between 900 and 1,500 psi (Fig. 10.6c; Sneider 1995, Sneider et al. 1997). Although such shales are respectable seals, over time shale allows substantial diffusive leakage of methane and even liquid hydrocarbons via inherent microporosity, less so if the shales are organic-rich. Even ignoring salts abil-

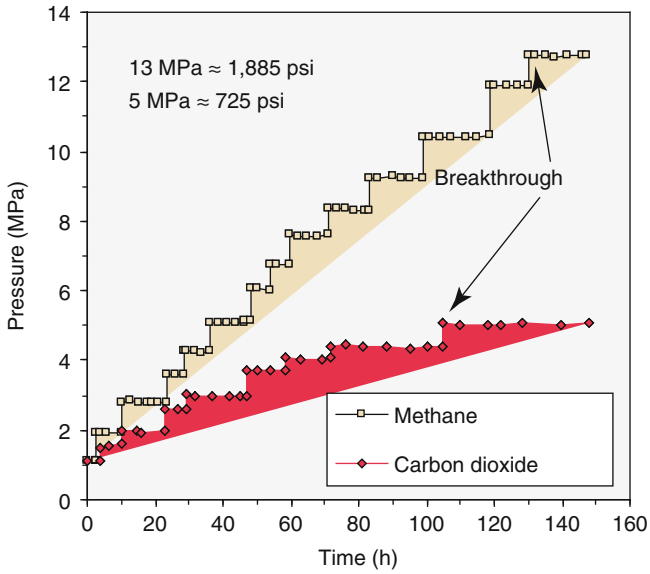

Fig. 10.7 Comparison of laboratory-measured breakthrough pressures between CH_4/brine system and CO_2/brine system for Midale anhydrite seal-rock (After Li et al. 2005)

ity to reanneal under stress, an evaporite seal has much lower intrinsic permeability that helps maintains its integrity. With permeabilities of 10^{-7} md, a hydraulic gradient of 0.01, and a porosity of 0.01, a brine would take somewhere between 3 and 30 million years to flow 1 m into an unfractured halite seal, while anhydrite, which has permeability some 100 times higher, a brine would take between 30,000 and 300,000 years to flow 1 m into the seal (Beauheim and Roberts 2002). Evaporites are excellent longterm seals to substantial hydrocarbon columns.

With the exception of clathrates, thick halites and some anhydrites, almost all fine-grained subsurface rocks will at some time in their burial history be subject to microfracturing and leakage. Otherwise, organic-rich mudstones and shales could not act as source rocks and there would be no primary migration of hydrocarbons. In contrast, rather than fracturing, most salt seals tend to lose their seal integrity either through dissolution windows or through salt-flow-induced breaches, which are defined by areas of overburden touchdown and focused subsalt leakage. Thick salt beds experience brittle fracture only at very shallow nearsurface and typically vadose conditions, such as Salar Grande in South America (Fig. 3.51).

Halite's very high ductility and its ability to flow, reanneal and re-establish lattice bonding by solution creep when subject to stress give it a low susceptibility to fracturing (Fig. 6.5b). The ability of a halite unit to maintain seal integrity, and so prevent the escape of hydrocarbons, reflects a combination of an ability to flow and reanneal under stress, and the small size of molecular interspace in its ionically-bonded NaCl lattice. Massive bedded halite units contain few, if any, interconnected pore throats. The distance between NaCl lattice units is 2.8×10^{-10} m, while the smallest molecular diameter of a hydrocarbon molecule (methane) is 3.8×10^{-10} m. The most common way that hydrocarbons migrate through an unfractured undissolved halite bed is if the halite contains impurities that render it locally porous and make it brittle during deformation.

Whether buried halite beds that enclose organic intrabeds can release volatiles during catagenesis is still a matter of some discussion among organic geochemists. The longterm lack of fracture or pore throats in buried salt beds is why organic-rich intrasalt carbonate or shale laminites tend to be inefficient source rocks in style 1a source rocks (Fig. 9.4). Likewise, possible flushing and maturation effects are poorly understood in subsurface situations where encased organic-rich beds are in contact with hydrated salts converting to their anhydrous equivalents (such as gypsum to anhydrite or carnallite to sylvite, mirabilite to thenardite). Loss of water of crystallisation has the potential to allow organic-rich fluids to escape as the hydrated salts transform to their anhydrous forms. Typically, such burial transformations occur in the first kilometre of burial and may only allow immature hydrocarbons to escape into adjacent more porous sediments (Hite and Anders 1991). There they must be stored, mature and remigrate in later burial if they are to act as source rocks (Warren 1986). Many intrasalt organic-rich beds survive well into the metamorphic realm and evolve into graphitic quartzites and marbles encased in meta-evaporitic albitites and scapolites.

As a general rule, even as a halite bed fractures, its inherent lack of strength and the consequent ability to flow means any microscale intercrystalline fractures quickly reanneal by a combination of flow and pressure-solution induced recrystallisation. Current consensus is that some thin impurity-rich salt beds, interlayered with carrier beds, do leak small amounts of volatiles, but much less efficiently than thicker organic-rich mudstones and shales; whereas organics encased in thicker salt beds probably cannot leak from the unit until the enclosing salt dissolves or natural hyrofracturing occurs (as in the Ara Salt of Oman, Fig. 8.27). Evaporite beds and allochthons constitute some of the strongest longterm subsurface barriers to the vertical migration of hydrocarbons in a sedimentary basin both as a seal to hydrocarbons and in CO_2 sequestration.

Of possible concern in the latter situation is where measured seal capacity values and breakthrough pressures, obtained in the hydrocarbon field development stage, are then applied without re-evaluation in a CO_2 sequestration evaluation/study. This is especially so when potential CO^2 sequestration barriers are anhydritic carbonate seals, especially with elevated impurity levels (Li et al. 2005). In Midale evaporite seals (Mississippian-age anhydrites and dolomitic anhydrites) in Weyburn Field, southeastern Saskatchewan,

the gas breakthrough pressure was found to be nearly proportional to the interfacial tension of the gas/brine system. Hence, the breakthrough pressure in this CO_2/brine system (sequestered CO_2) is significantly reduced compared with that of the original CH_4/brine system (original gas field), due to the much lower interfacial tension of the former fluid (Fig. 10.7). That being the case, if the pressure during or after CO_2 injection is the same or higher than the original hydrocarbon reservoir pressure (pre-hydrocarbon depletion), then a seal rock that held back the original gas in a gas reservoir or an oil reservoir with a gas cap, may not be tight enough to seal injected/sequestered CO_2. Breakthrough pressure of seal rocks for a given reservoir should be re-evaluated whenever a depleted hydrocarbon field is chosen as a possible CO_2 storage site.

Environments Favouring Seal Continuity

When assessing any hydrocarbon accumulation the top, lateral and bottom seals must be identified and evaluated. Theoretically, the thickness of a seal does not contribute to seal capacity: a clay shale (4–10 μm particle size) with an entry pressure of 600 psi is theoretically capable of sealing a 900 m oil column. In reality, it is unlikely a shale bed only a few cm thick is a laterally continuous, unbroken, unbreached unit, capable of maintaining stable lithic character over a sizeable area. A thin evaporite perhaps could be, but a thicker seal provides many layers of contingent sealing beds and so gives a larger probability of a sealing surface being continuous over an entire prospect. Evaporite seals more than 30 m thick are considered excellent, while shale seals more than 50 m thick and evaporite seals more than 10 m thick are typically considered adequate.

Seal continuity rather than measured seal capacity is likely the most important factor in assessing seal quality. In the laboratory, one can measure the displacement or entry pressure necessary to force a given hydrocarbon mixture through a rock sample under given conditions of temperature and pressure. However, there are many difficulties in extrapolating quantitative data from a capillary pressure test on a 4–8 inch (10–20 cm) diameter core into a reliable prediction of the seal character across the entire sealing surface. A simple domal closure of 2,950 ha (6,400 acres) provides a ratio between a typical seal sample (4 inch diameter whole core) and the area of top seal of 1 to 3.5 billion. Average values of seal properties measured from core without a reliable geological model for the reservoir are next to useless in quantifying seal integrity. What is needed is knowledge of the likeliest weakest points in the seal across the structure of interest. It's the difference between guarantees that you will on average survive if you swim in these shark- and stinger-infested waters, versus you are advised not to swim in this lagoon. Most of us prefer the second option, it's the same when investing tens to hundreds of millions of dollars in developing an oil or gas field.

Saltern and deepwater evaporite beds make excellent seals because the density-stratified hydrology of their depositional setting guarantees there was little lateral variation in depositional rock properties over large areas of the salt-covered basin floor (Chaps. 2 and 5). Evaporite-plugged mudflat units also make effective seals, as do platform carbonates plugged by evaporite cements precipitated from dense reflux brines. But high levels of entrained impurities, less predictable depositional topography and lateral variations in early diagenetic fluid flux rates mean that, compared to saltern and basinwide-style seals, these dirtier seal types are more subject to problems with lateral continuity, as well as showing a higher propensity for stress fracture and failure.

Deposition of saltern anhydrite atop the various Arab cycle carbonate reservoir sands of Saudi Arabia and the Emirates not only formed the highly effective Hith seal (Fig. 10.8a), but aided in the preservation of underlying reservoir porosity and permeability by preventing later entry from above of meteoric waters capable of precipitating eogenetic intra-reservoir carbonate cements.

Once dissolution starts to thin a previously effective seal, it begins to leak. Even the Hith Anhydrite can leak once it is less than 10 m thick, as can be seen by the migration of Jurassic-sourced oil in Cretaceous reservoirs along the edge of the Hith Anhydrite (Fig. 10.8a; Hawas and Takezaki 1995). In my opinion, this leakage in the thinned Hith can be tied to increasing proportions of dolomite residues near the dissolutional feather edge of the Hith and a consequent propensity for brittle responses near this edge, with local faulting tied to collapse fracturing. There would be little loss of seal capacity in an anhydrite bed as thin as 10 m if it remained as relatively pure nodular anhydrite.

Leakage is obvious in Al Rayyan Field, Qatar, where the upper Arab anhydrite, the intra "C" anhydrite, and the intra "D" anhydrite of the Arab Formation do not form effective

Fig. 10.8 Evaporites as seal and a control of charge distribution. (**a**) Hith Anhydrite isopach showing thickening from the UAE west into Saudi Arabia and some of the main fields producing from Jurassic reservoirs in this region (In part after Alsharhan and Kendall 1994). Note the lack of Jurassic reservoirs to the east of the Hith erosional edge showing the effectiveness of the saltern evaporite in holding back substantial oil and gas columns sourced in Hanifa mudstones (see Fig. 9.4). (**b**) Distribution and timing of charge in the oil and gas fields along the highly productive eastern margin of the South Oman Salt Basin is controlled by the retreating dissolution edge of the Neoproterozoic Ara Salt and the underlying Huqf Fm. source rock, which became mature in the Cretaceous. seals; only the Hith acts as a regional seal for the field (Brown and Loucks 2001; Clark et al. 2003). The intra "C" and intra "D" beds are interpreted as depositionally discontinuous with relatively high dolomite contents. This reflects original shoalwater carbonate deposition in the cycle capstones, which were deposited as thinned, and perhaps pinched-out, evaporitic mudflats onlapping the carbonate shoal reservoir. Likewise, the intra "C" sabkha unit, with its higher fraction of intercalated porous dolomite intrabeds, promotes seal failure via fracturing and faulting. The discontinuous salina deposits in the intra "D" anhydrite also lack sufficient lateral continuity to form an effective seal over the structure. Brown and Loucks (op. cit.) found that the major cause of seal failure in the thin, upper anhydrite is fault offset, whereby fault throw exceeds seal thickness. The high fraction of brittle dolomite in these anhydrite intrabeds results in wider seal damage zones, allowing greater potential for along-fault leakage. In contrast, where fault throw in the field does not exceed the thickness of the Hith, nor the thickness of the middle, and lower anhydrites in the Arab cycles in the field, the evaporites capping the various intra-Arab cycles remain as intact seals. Faults intersecting these beds also cause less structural (brittle fracture) damage due to the higher anhydrite fractions of the beds, so that along-fault leakage from connected intrasalt beds is minimal.

Hydrocarbon migration and trapping in the south Oman salt basin, with its subsalt Neoproterozoic Huqf source rock, is strongly controlled by the continuity of the Neoproterozoic Ara Salt. In the centre of the basin, where thick Ara salt is still present, there is an additional substantial volume of bituminous oil still trapped in intrasalt organic-rich Ara carbonate and siliceous stringers of the salt-sealed Athel silicilyte (Schoenherr et al. 2007b; Ramseyer et al. 2013). In the updip peripheral syncline along the east flank, salt dissolution controls structural style and trap formation (Heward 1990), with retreat of the salt edge the main factor in charge timing (Fig. 10.8b; Terken et al. 2001). Traps in Palaeozoic clastics in the eastern basin margin were initially formed by halokinetic structuring in the Paleozoic, and subsequently filled by salt dissolution breaches driving dissolution drape and oil emplacement. The subsalt Neoproterozoic Hufq source rock began to generate oil in the middle of the Cretaceous and the retreat of the salt's dissolution edge can be mapped in the successive fillings of the various fields that define the productive eastern margin of the basin. As the result of the westward retreat of the dissolving salt edge through time, traps get progressively younger toward the basin centre (Fig. 10.8b).

Salt dissolution has today removed most of the salt along the east flank of the south Oman salt basin, and its timely removal is largely responsible for the present-day hydrocarbon-filled structures. Oil accumulations mimic a negative image of the salt structures first formed during the earlier halokinetic stage as early salt withdrawal basins then became inverted into oil bearing turtle structures. Anticlines resulted from drape of strata over Haima and Al Khalata turtle structures and drape over deeper laterally discontinuous siliceous and carbonate stringers floating in the Ara Salt. Where salt dissolution occurred, formerly salt-encased stringers leaked and became the grounded remnants that now form chaotic solution residue horizons both in outcrop and in the subsurface (Terken et al. 2001; Peters et al. 2003).

Wherever marine carbonate reservoir sands are sealed by salterns or basinwide salt beds, the width of the subeconomic transition zone from economic reservoir into an overlying depositional seal is typically narrow and sharp. Such seals are created as basin isolation drives rapid platform or basinwide drawdown (e.g. anhydrites capping the Arab cycles in Ghawar or Salina Fm. salt seals of the Michigan Basin). The narrow transition reflects a rapid onset of hydrographic isolation, which typifies many marine-fed saltern and basinwide evaporite settings (Chap. 5: a corollary of Walther's Law). However, reflux brines associated with evaporite deposition can complicate the poroperm transition across the depositional contact as they drive formation of salt cements, which can plug porous carbonates in the zone below the evaporites. Likewise, a continuous depositional transition from reservoir to seal generates an uneconomic hydrocarbon-filled gradational depositional passage into a seal. Such gradational transitions from reservoir to seal characterise many nonevaporite sealed stratigraphic traps, such as reef-grainstone shoals drowned beneath onlapping lagoonal shales, or point bar sands buried beneath floodplain muds.

Gradational contacts tend to show subeconomic transitions from reservoir to seal both vertically and laterally. Much of the hydrocarbon can lie in partially salt-plugged porous dolomites that are "not quite reservoir, hardly seal" (Fig. 10.6b). Compared to pure-evaporite seals beneath many allochthonous salt bodies, both salt-plugged and shale-sealed intervals are much more prone to longterm leakage and the creation of thicker transition zones from reservoir to seal. Understanding and predicting the distribution of salt plugging is a significant problem in reliably modelling reserves and production estimates in evaporite-sealed reservoirs worldwide.

The transition from a potential dipping reservoir sand into a near vertical diapir stem or a subhorizontal salt allochthon tends to create sharp effective lateral and top seals. This is due to the passive mode of salt emplacement, which creates a sharp rather than a transitional boundary. Syndepositional stacking of reservoir sands against a passive diapir stem seal in the Gulf of Mexico has created some of the most productive acreage anywhere in the world (in terms of recovered bbl/acre; Halbouty 1979). Sharp contacts also create potentially hazardous sharp transitions into zones of high overpressure (see Chap. 8).

Reservoirs and Traps

At its simplest, evaporite-associated reservoirs occur adjacent to either bedded or halokinetic seals (or their solution residues) in subsalt, intrasalt or suprasalt positions (Table 10.1). Bedded salt seals are further subdivided into lacustrine, platform or basinwide settings, while halokinetic salt seals are either autochthonous or allochthonous.

Bedded Salt Seals

The main function of bedded evaporites in the evaporite hydrocarbon association is as a seal to subsalt accumulations of oil and gas (Table 10.2). In some cases, high levels of primary intergranular porosity in grain-dominated limestones are preserved beneath a salt seal (e.g. Jurassic Arab cycles on the Arabian Peninsula) or intercrystalline porosity fashions a variably dolomitised subsalt limestone reservoir (e.g. San Andres reservoirs on the Central Basin Platform fields of West Texas). Impermeable evaporite beds and salt-plugged dolomites capping various upward-shoaling platform cycles, effectively seal off underlying porous carbonates from later surface-driven influxes of freshwater or other suprasalt diagenetic fluids. Evaporite horizons, or any pervasively-plugged adjacent diagenetic haloes, are not potential reservoirs, unless a bed dissolves into a solution breccia, or intergranular salt cements are leached from previously salt-plugged sands or dolomites.

During evaporite deposition there is usually an associated hydrological system of basinward flushing dense brines (reflux). This occurs in the early stages of salt deposition and shallow burial (<100–200 m burial) prior to the loss of intrasalt and subsalt permeability, especially where a gypsum saltern is accumulating atop a marine platform carbonate. Circulation is driven by gravitational instability, set up by an updip dense brine plume or brine curtain below accumulating evaporites (Fig. 2.81).

At its periphery this refluxing plume mixes with and displaces less dense subsurface and connate waters to create or enhance the reservoir properties of adjacent subsalt limestones via reflux dolomitisation. As dense Mg-rich brines seep downdip from the platform saltern or mudflat they create intervals of porous dolomites in more distal zones, located seaward of overdolomitised evaporite-plugged areas. In some cases the most extensively dolomitised carbonates in these more distal zones are high-energy, shallow water grainstones and packstones. These were the sediments with the higher permeabilities at the time of dolomitisation. However, in areas of pervasive syndepositional marine cementation, some originally porous carbonates may have already lost much of their intergranular permeability via overgrowths of isopachous rim cements. In this situation the less cemented platform mudstones act as aquifers to the refluxing brines and so are preferentially dolomitised. Likewise, in more restricted portions of an epeiric carbonate platform where the only sediment beneath a salt seal is lagoonal mud, it is dolomitised and sometimes converted into a reservoir with intercrystalline permeability (e.g. the Levelland-Slaughter trend in the San Andres Fm, West Texas and New Mexico). In some muddy platform carbonates, only the pelletal and sandy burrow fills retain sufficient permeability to be dolomitised, while their muddier surrounds are not (e.g. Red River Dolomite of North Dakota). Whatever the setting, the rule of thumb is that refluxing brines will preferentially dolomitise whatever carbonate facies is capable of acting as an aquifer at the time of reflux.

The economic significance of reflux dolomite was first noted in the 1960s in the various evaporite-associated Permian dolomite reservoirs of West Texas (Adams and Rhodes 1960). Reflux dolomitisation also controls porosity/permeability distribution in the finer-grained parts of some Jurassic Arab Formation reservoirs in Saudi Arabia, as well as the Permian Khuff Formation in the Arabian Gulf, the Smackover Formation carbonates of the Gulf of Mexico, the Upper Permian Changxing Formation and the Lower Triassic Feixianguan Formation, NE Sichuan Basin, China, and many other oil and gas fields across the globe where dolomites occur beneath an evaporite seal (Sun 1995; Warren 2000a; Jiang et al. 2013). Yet, in other depositionally similar evaporitic settings, some of the mesohaline laminites that underlie bedded salts are not dolomitised, typically because they were evaporite-cemented in the strandzone prior to the onset of reflux flushing. They were too tight to transmit the volumes of Mg-rich brine needed for dolomitisation. Likewise, dolomites immediately below a saltern or mudflat brine source tend to be overdolomitised and/or evaporite-plugged, there the aquifer limestones were located in the zone of most intense flushing by salt-supersaturated brines (Fig. 10.9). Syndepositional permeability in units deposited immediately after a transition into widespread evaporite deposition and the condition of subsalt aquifers, controls the type and extent of the brine reflux alteration halo. So, porosity evolution in subsalt sediments can vary widely, according to the ambient hydrology.

Worldwide, Phanerozoic dolomite reservoirs are defined by four syndepositional associations (Sun 1995; Warren 2000a): (1) evaporitic mudflats in a carbonate platform, most often a ramp profile (roughly equivalent to peritidal-dominated carbonate of Sun 1995), (2) saltern-sealed platform carbonates with mudflat development over palaeotopographic highs – this system typically develops across an epeiric platform behind a rimmed shoal profile (roughly equivalent to subtidal carbonate associated with evaporitic tidal flat/lagoon of Sun 1995), (3) basinwide evaporite seal (subtidal carbonate associated with basinal

Table 10.2 Some of the many Palaeozoic platform reservoirs and fields sealed by bedded evaporites

Field or area	Reservoir and age	Reservoir	Trap type	Seal	Reference
Gulf of Suez	Rudeis and Belayim Middle Miocene	Cyclic shallow ramp lagoonal carbonates deposited within a restricted embayment	Dolomites created by brine reflux	Massive basinwide evaporites	Orszag-Sperber et al. (1998), Sun and Esteban (1994)
Mesopotamian Platform	Euphrates-Jeribe Early Miocene	Locally dolomitised and packstones, with red algae, mollusks and benthic foraminifers	Reflux dolomites, skeletal buildups and biostromes	Saltern and mudflat evaporite cap	Buchbinder (1996), Sun and Esteban (1994)
Oolitic to siliciclastic ramp reservoirs, offshore Angola	Pinda Group (Albian)	Littoral sandstones with interparticle porosity to various types of dolomitised marine shelf to shoreline carbonates with mouldic, vuggy, and intercrystalline porosity	Late Cretaceous segmentation of the reservoir series by salt tectonic gravitational gliding into halokinetic "turtleback" and rafts	Evaporitic mudflats/shales	Eichenseer et al. (1999)
Sunniland Field, Southern Florida	Sunniland limestone, Early Cretaceous	Dolomitised bank margin grainstones and mudstones	Low relief anticlinal trap, possibly halokinetic	Massive saltern anhydrite	Halley (1985), Loucks and Crump (1985)
Walker Creek Field, Chatom Field, and Mt Vernon Field, Gulf of Mexico Basin, Arkansas, USA	Smackover Formation, Jurassic (Oxfordian)	Oolitic-pisolitic dolomitised limestone retaining varying levels of primary intergranular porosity and calcite cement	Up-dip and down-dip depositional pinchout of oolitic grainstone bars, modified by halokinetic faulting (underlying Louann Salt)	Saltern and mudflat (Buckner Anhydrite)	Chimene (1991), Feazel (1985), Druckman and Moore (1985)
Appleton Field, Gulf of Mexico Basin, Alabama, USA	Smackover Formation, Jurassic (Oxfordian)	Dolomitised algal peloid ooid grainstone with intercrystalline and vuggy porosity	Combination structuralstratigraphic trap Up-dip and down-dip depositional pinchout of oolitic grainstone bars on high of crystalline basement	Saltern and mudflat (Buckner Anhydrite)	Haywick et al. (2000), Petta and Rapp (1990)
Ghawar, Qatif, Uthmaniya and other Arab Fm. fields in Saudi Arabia	Arab Formation, Late Jurassic (Tithonian and Kimmeridgian)	Partially dolomitised skeletal, peloidal and oolitic grainstone (Arab D), peloidal/oolitic/skeletal grainstone (Arab C)	Low amplitude anticlines related to basement faulting and possible halokinesis of Hormuz Salt	Nodular anhydrites and tight mudstones of Arab cycles and the overlying Hith Anhydrite	Cantrell et al. (2001), Saner and Sahin (1999, 2000), Meyer et al. (1996), Wilson (1985)
Feixianguan sour gas fields in the Sichuan Basin, China	Lower Triassic Feixianguan Formation and lesser production from Upper Permian reefalcarbonates	Dolomitised oolitic shoals and reef carbonates	Low angle drape structure and bedded $CaSO_4$ intralayers	Anhydrite cements and nodules are present in the ooidreplaced dolomites	Jiang et al. (2013, 2014)
McElroy Field, Central Basin Platform, Texas, USA	Grayburg Formation, Permian (Lower Guadalupian)	Dolomitised shelf carbonates ranging from mudstones to fusulinid wackestones	N-S trending asymmetrical anticline with steeper eastern limb. Permeability pinches out to west due to increasing evaporite plugging (anhydrite and gypsum)	Evaporites and siltstones of the Queen Formation; Anhydrite plugged porosity is heterogeneous.	Harris and Walker (1990)
Ghawar, Qatif, Uthmaniya and other Khuff Fm. fields in Saudi Arabia	Khuff Formation (Members A-C), Permian	Dolomitised and leached peloidal grainstones, wackestones and mudstones, variable anhydrite cements	Low amplitude anticlines related to basement faulting and possible halokinesis of Hormuz Salt	Saltern cap and varying development of evaporitic mudflats	Al-Jallal (1995), Dasgupta et al. (2002)
Reeves Field, Midland Basin and Levelland-Slaughter trend, Northern Platform, Permian Basin, Texas USA	San Andres Formation, Permian	Dolomitised skeletal wackestones and mudstones	Stratigraphic with structural assist via draping over former shelf edge	Strandline anhydrites of the San Andres Formation	Chuber and Pusey (1985)

Pecos Slope Field, Permian Basin, New Mexico, USA	Abo Formation, Permian (Leonardian)	Fluvial sandstone	Tectonically fractured stratigraphic wedge-out of fluvial clastics	Anhydrite of the Yeso Formation	Bentz (1992)
Tarchaly, Rybaki, Sulecin' Barnowko--Buszewo fields, west Poland and Thuringian basin fields, East Germany	Zechstein main dolomite; Early Permian	Dolomitised oolitic/pisolitic grainstones and mudstones	Shelf margin buildup beneath evaporite seal, structurally assisted	Zechstein anhydrite cap (basinwide)	Depowski and Peryt (1985), Peryt and Dyjaczynski (1991), Gorski et al. (1999), Karnin et al. (1996)
Aneth Field, Paradox Basin, Utah	Hermosa Formation (one main reservoir, several semi-isolated intervals), Pennsylvanian	Leached and recrystallized oolitic limestone and dolomitised mudstone	Dolomitised carbonate mound	Evaporitic organic-rich dolomitic shale	Peterson (1992)
Lisbon Field, Utah, USA	Leadville Formation; Mississippian	Dolomitised (sucrosic) and karstified platform carbonates (wackstone-packstone)	Faulted anticline beneath supra-unconformity halokinetic evaporites of the Paradox Basin	Paradox Salt (basinwide)	Miller (1985)
Stanley Field, Williston Basin, North Dakota, USA	Mission Canyon Formation; Mississippian	Pisolitic-oolitic limestone with local skeletal marine grainstone. Fenestral porosity with primary interparticle and intraparticle	Updip facies change to fractured evaporitic mudflats and porous grainstones from downdip wackestone and mudstone	Massive platform anhydrite of the Rival Member top seal	Beach and Giffin (1992)
Elkhorn Ranch Field, Williston Basin, North Dakota, USA	Mission Canyon Formation; Mississippian	Dolomitised skeletal mudstones and wackestones	Hydrodynamic trap where structure assists in localising accumulation, but trap stratigraphic passage is into an anhydrite seal	Massive platform anhydrite top seal of the Mission Canyon Formation	DeMis (1992)
Glenburn Field, Williston Basin, North Dakota, USA	Mission Canyon Formation; Mississippian	Pisolitic limestone exhibiting subaerial exposure and vadose diagenesis with porosity pinchouts via evaporite plugs	Solution collapse anticline in underlying Devonian Salt	Massive saltern anhydrite and ferruginous shale caps, structurally assisted (anticlinal)	Borchert et al. (1990), Gerhard (1985)
Little Knife Field, Williston Basin, North Dakota, USA	Red River, Duperow, Mission Canyon; Ordovician, Devonian, Mississippian	Dolomitised shallow shelf to evaporitic mudflat carbonates	Combination anticlinal nose and porosity pinchout	Massive Mission Canyon platform anhydrite top seal, lateral change to nonporous carbonates	Wittstrom (1990), Lindsay and Kendall (1985)
A and E pools, Rainbow Field, Canada	Keg River Formation, Rainbow Member, Middle Devonian (Givetian)	Dolomitised limestone and limestone	Pinnacle reef enclosed in evaporites and bituminous carbonates	Muskeg Member evaporites	Schmidt et al. (1985)
Pinnacle reef fields, Michigan Basin, SE Michigan USA	Guelph Formation and equivalents; Middle Silurian	Dolomitised and karstified pinnacle reefs	Pinnacle reef enclosed in evaporites and bituminous carbonates	Salina Group evaporites	Gill (1985), Obermajer et al. (2000)
Medicine Pole Hills Field, Killdeer Field, Pennel Field, Williston Basin, North Dakota, USA	Guelph Formation and equivalents; Middle Silurian	Sucrosic dolomites of evaporitic mudflats (intercrystalline and vugular porosity)	Combinations of anticlinal noses and porosity pinchout, preferential dolomitisation at top of anticline and evaporite karst	Red River Anhydrite	Fischer et al. (1990), Clement (1985), Montgomery (1997)

evaporites of Sun 1995), and (4) nonevaporitic carbonate sequences associated with topographic highs/unconformities: platform-margin buildups or burial related fault/fracture controls. Three of the four worldwide dolomite-hydrocarbon associations show an intimate association with evaporites. Brine reflux is the dominant process in dolomite creation in all three, although it can be overprinted by later burial dolomites. The process of mixing-zone dolomitization typically considered part of process set (4) has received enough criticism in recent years to suggest that it no longer be considered viable for making large amounts of dolomite. In its place Li et al. (2013) propose a somewhat more specific model, which still requires fluid mixing whereby an ascending flow of freshwater mixes with evaporated seawater about the edge of a saline basin, leading to extensive dolomitization (e.g. Fig. 5.39).

Dolomite reservoirs created by brine reflux can be subdivided using the dominant depositional style of the evaporite capstone, namely, platform and basinwide (Fig. 5.9). In platform evaporite-sealed dolomite associations, the evaporite seal is typically ≈5–10 m thick (although it can be 20–30 m thick) and is usually dominated by saltern or mudflat anhydrite interlayered with shoaling platform carbonates. This evaporite cap can be further subdivided into evaporitic mudflat or saltern-dominated. Basinwide seals to carbonate reservoirs tend to be thick (>100 m), halite-prone in the basin centre and to cap carbonate buildups about the basin edge. Such buildups typically grew prior to the saline giant stage. Ongoing or longterm regional reflux beneath accumulating evaporites in both platform and basin settings can "overdolomitise" the reservoir and encourage evaporite plugging leading to occlusion of effective porosity (Warren 2000a for summary). In platform settings such porosity-depleted overdolomitised zones tend to be most common in regions of restricted carbonate deposition beneath leaky evaporitic mudflats (these are the typical caps to Sun's peritidal association). These sediments tend to accumulate in the more updip evaporite-dominated portions of a carbonate platform, where underlying carbonates have been flushed for extended periods by hypersaline brines. With basinwide-sealed associations, a later burial overprint and pervasive intra-reservoir karst/fracturing events seem to be needed to create and maintain economic porosity levels.

"Peritidal" Muddy Carbonates with Evaporitic Mudflat Seals

Evaporitic mudflats dominate the ephemeral water portions of an evaporite basin. As discussed in Chap. 5, the use of a tidal nomenclature is not appropriate in a highly restricted to hydrographically isolated epeiric setting where saltern evaporites are accumulating. Strandzone rather than the intertidal and supratidal in the peritidal is more appropriate, but peritidal terms are used in the following discussion to conform to historic subdivisions. Strandzones can create dolomite-forming hydrologies within stacking muddy epeiric platform carbonates whereby highly saline Mg-rich brines, sourced in the mudflats, seep into adjacent restricted lagoonal marine carbonates (Fig. 10.9). Without subsequent fracturing, leaching and other diagenetic enhancements to their permeability, such fine-grained mimetic syndepositional dolomites constitute no more than a few economic reservoirs. Those intervals that do constitute reservoir tend to be low permeability systems, which are patchily distributed in a host formation that is extensively plugged with variable levels of evaporite cement. Enhancements to this generally low and patchy permeability can occur if karst, fracturing or burial leaching subsequently modify the host lithology. Early diagenetic permeability tends to increase where the dolomitised marine mudflat was located further out on the platform and away from areas of most intense dolomitisation and evaporite plugging.

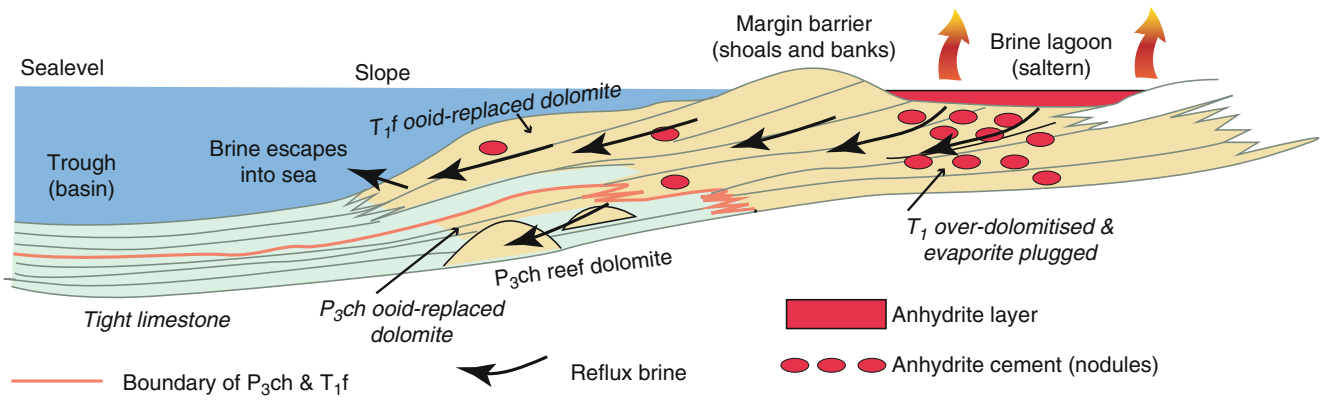

Fig. 10.9 Model of reservoir creation via saltern brine reflux, based on dolomite distribution in the Upper Permian Changxing Formation (P_3ch) and the Lower Triassic Feixianguan Formation (T_1f), NE Sichuan Basin, China (After Jiang et al. 2013)

Ordovician Red River Fm., Williston Basin, USA and Canada

The Red River Formation was deposited in an epeiric seaway that occupied the Williston Basin in the Middle to late Ordovician. The Williston Basin is located on the southern edge of the Canadian Shield, straddling the US-Canadian border and centred on Saskatchewan and North Dakota (Fig. 10.10). The Williston Basin was an intracratonic sag basin in the middle of the Laurentian craton. The Late Ordovician succession comprising Red River strata (Fig. 10.10a) exhibits a series of large-scale cycles of limestone, dolomite and anhydrite units deposited across a broad, shallow, low-relief epeiric sea (El Taki and Pratt 2010). The Lake Alma anhydrite unit (Unit "A") is present over the entire study area, whereas the Coronach anhydrite (Unit "B") occurs only in the southern and southwestern portion of Saskatchewan and adjacent USA, and the youngest anhydrite (Unit "C") is only present in North Dakota (Fig. 10.10c).

The basin itself is circular, about 800 km across, and is filled with up to 4,600 m of Phanerozoic sediments. The Palaeozoic

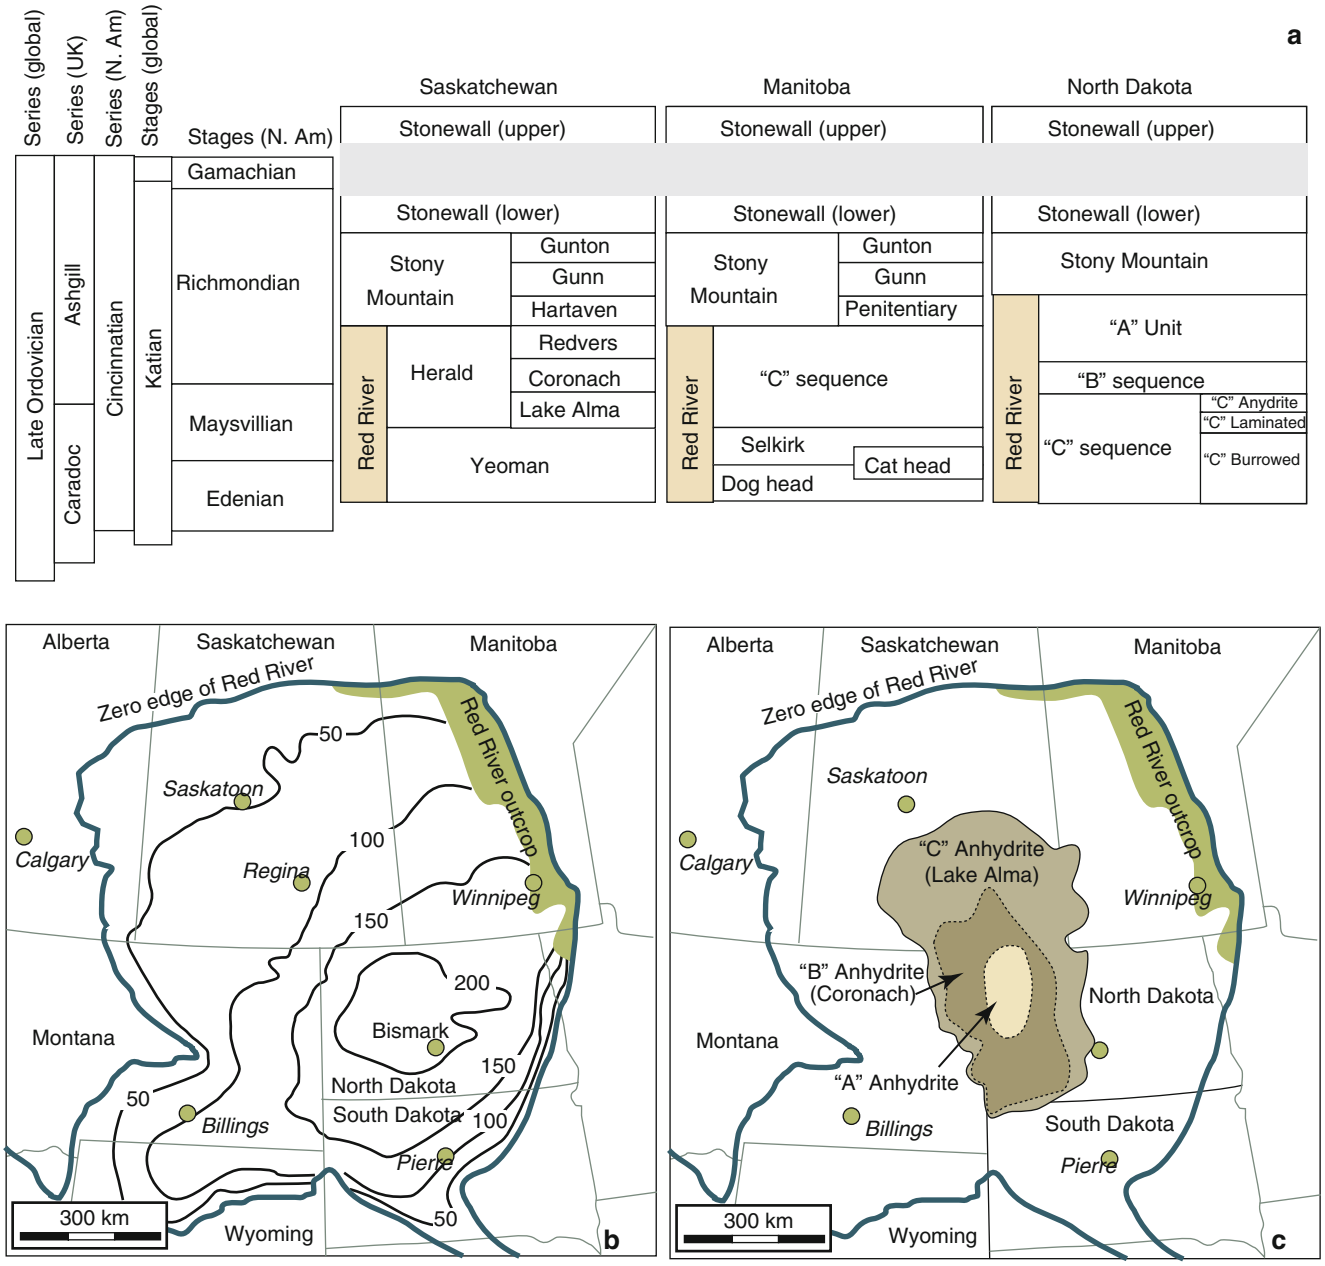

Fig. 10.10 Red River Formation in the Williston Basin. (**a**) Lithostratigraphic nomenclature of the Red River, Stony Mountain and Stonewall strata in Saskatchewan, Manitoba and North Dakota. (**b**) Isopach map of Red River strata showing the depocentre near Bismarck, North Dakota. (**c**) Distribution of the three successive anhydrite units (A-C) in Red River strata (After El Taki and Pratt 2010)

succession is predominantly carbonate and up to 2 km thick. It is overlain by a Mesozoic succession of mainly fine terrigenous clastic rocks up to 1.5 km thick and a Tertiary succession of mostly coarse terrigenous clastics that is less than a kilometre thick. The maximum thickness of the Red River Fm. occurs in the basin centre close to Bismarck, North Dakota, and where it is slightly more than 200 m thick (Figs. 10.10b and 10.11; Pu and Qing 2003). Like most intracratonic sag basins, the Williston Basin preserves sediments deposited across substantial stretches of geological time.

During the Cambrian and Ordovician there was first a phase of tension in the basin, likely related to rifting along the margins of Laurentia, as Rodinia continued its rifting trajectory, which was followed by far-field compression driven by the Taconic Orogeny (Allen et al. 2010; Middle Ordovician to early Silurian). Sedimentation was broadly affected by local as well as regional fault systems, which were later reactivated at various times. Accordingly, dolomudstones and anhydrites of the Lake Alma and Coronach members host a variety of synsedimentary deformation features —seismites— induced by earthquakes generated by movements of these faults, while the low-energy, subaqueous environmental setting was conducive to their preservation (El Taki and Pratt 2010). Within the basin are several major epeirogenic structures of which, in terms of controlling hydrocarbon distribution, the Cedar Creek anticline and Nesson anticline are the most prominent. Both anticlines have long episodic histories of responding to farfield tectonic movement. Elsewhere in the basin, the subsurface dissolution of Palaeozoic evaporites resulted in collapse and inversion structures in post-Middle Devonian strata, such as the Birdbear structure in Canada (McTavish and Vigrass 1987).

Red River strata in North and South Dakota consist of three carbonate-evaporite depositional sequences known as the A, B and C cycles (Fig. 10.10a, b; Pu and Qing 2003). Each sequence starts with a burrowed, normal-marine mudstone to wackestone and packstone at the base, followed by a laminated mudstone representing more restricted mesohaline deposition, which in turn is overlain by a bedded to enterolithic evaporative mudflat anhydrite which can be traced over much of the basin. Similar evaporite capped cycles typify the Lake Alma and Conanach formations in Canada.

Industry terminology in the oil fields of the USA informally defines these evaporites as capstones to the "A," "B," and "C" cycles. Some workers also distinguish a lower "D" zone that lacks an anhydrite cap (Fig. 10.11b). In ascending order, a typical Red River cycle consists of: (1) locally dolomitised burrowed carbonate mudstones and skeletal wackestones that define a "Burrowed Member," which is around 9 m thick in the B zone and up to 90 m thick in the C zone; (2) irregularly laminated carbonate mudstones that constitute a 3–12 m-thick "Laminated Member;" and (3) an impure 3–6 m capping anhydrite showing nodular-mosaic, nodular, or enterolithic textures (Fig. 10.11c). All members thin toward the edge of the basin where the anhydrites disappear completely.

Subtidal lithologies in each cycle are classic Zone X sediments composed of partially dolomitised burrowed biomicrite wackestones with fragments of echinoids, brachiopods, bryozoans, trilobites, molluscs, ostracods, and gastropods, and lesser amounts of solitary corals and stromatoporoids (Fig. 5.19). These subtidal dolomitic units are poorly bedded and heavily bioturbated and were laid down in a quiet-water epeiric platform setting.

The Red River Formation is 90–180 m thick in Cabin Creek Field on the Cedar Creek anticline in Montana, on the southwest side of the Williston Basin. Its lower part is a tight bioturbated marine limestone (Ruzyla and Friedman 1985). The average depth to pay across Cabin Creek Field is 2,750 m, with a 15.2 m net pay thickness, a productive area of 30.5 km^2 (7,620 acres), and an estimated 224 million barrels of oil in place. Here, and throughout much of the Williston Basin, economic porosity is largely restricted to bioturbated and partially dolomitized platform limestones and in many subsurface situations the burrows have controlled the intensity and style of dolomite (Gingras et al. 2004).

The overlying strandline (intertidal?) portions of a cycle are dolomitic biomicrite wackestones, deposited under somewhat more energetic bottom conditions (Zone Y). These deposits are still muddy but contain graded beds, crossbeds, ripple marks, imbricate shell lags and conglomerates. They also contain allochems characteristic of strandlines, such as oncolites, ooids, intraclasts, and peloids. The overlying anhydritic sediments in each cycle (Zone Z) include wavy-laminated micritic dolomites and organic-rich mudstones, along with evidence of completely restricted and at times subaerial conditions in the form of desiccation cracks, erosion surfaces, intraclast breccias, solution collapse breccias, and nodular anhydrites. This capstone in the vicinity of the Cabin Creek anticline was deposited on the platform in a mudflat mosaic of sabkhas and salinas. Offstructure, wireline signature shows the thickness and purity of nodular anhydrite in the seal bed increases, indicating a greater propensity for subaqueous deposition.

Evaporitic strandzone sediments in the reservoir interval in Cabin Creek Field show evidence of subsequent leaching; they contain empty gypsum and anhydrite moulds, corroded anhydrite crystals and solution collapse breccias. Early micritic dolomites of the supratidal are mimetic, typically laminated, but these units tend to be overdolomitised and salt plugged, so are relatively poor quality reservoirs. Upper contacts of the evaporite-cemented dolomite intervals are typically sharp, often erosional and pass abruptly up into the limestones of the next cycle suggesting exposure prior to the passage into the next cycle. This style of transition also

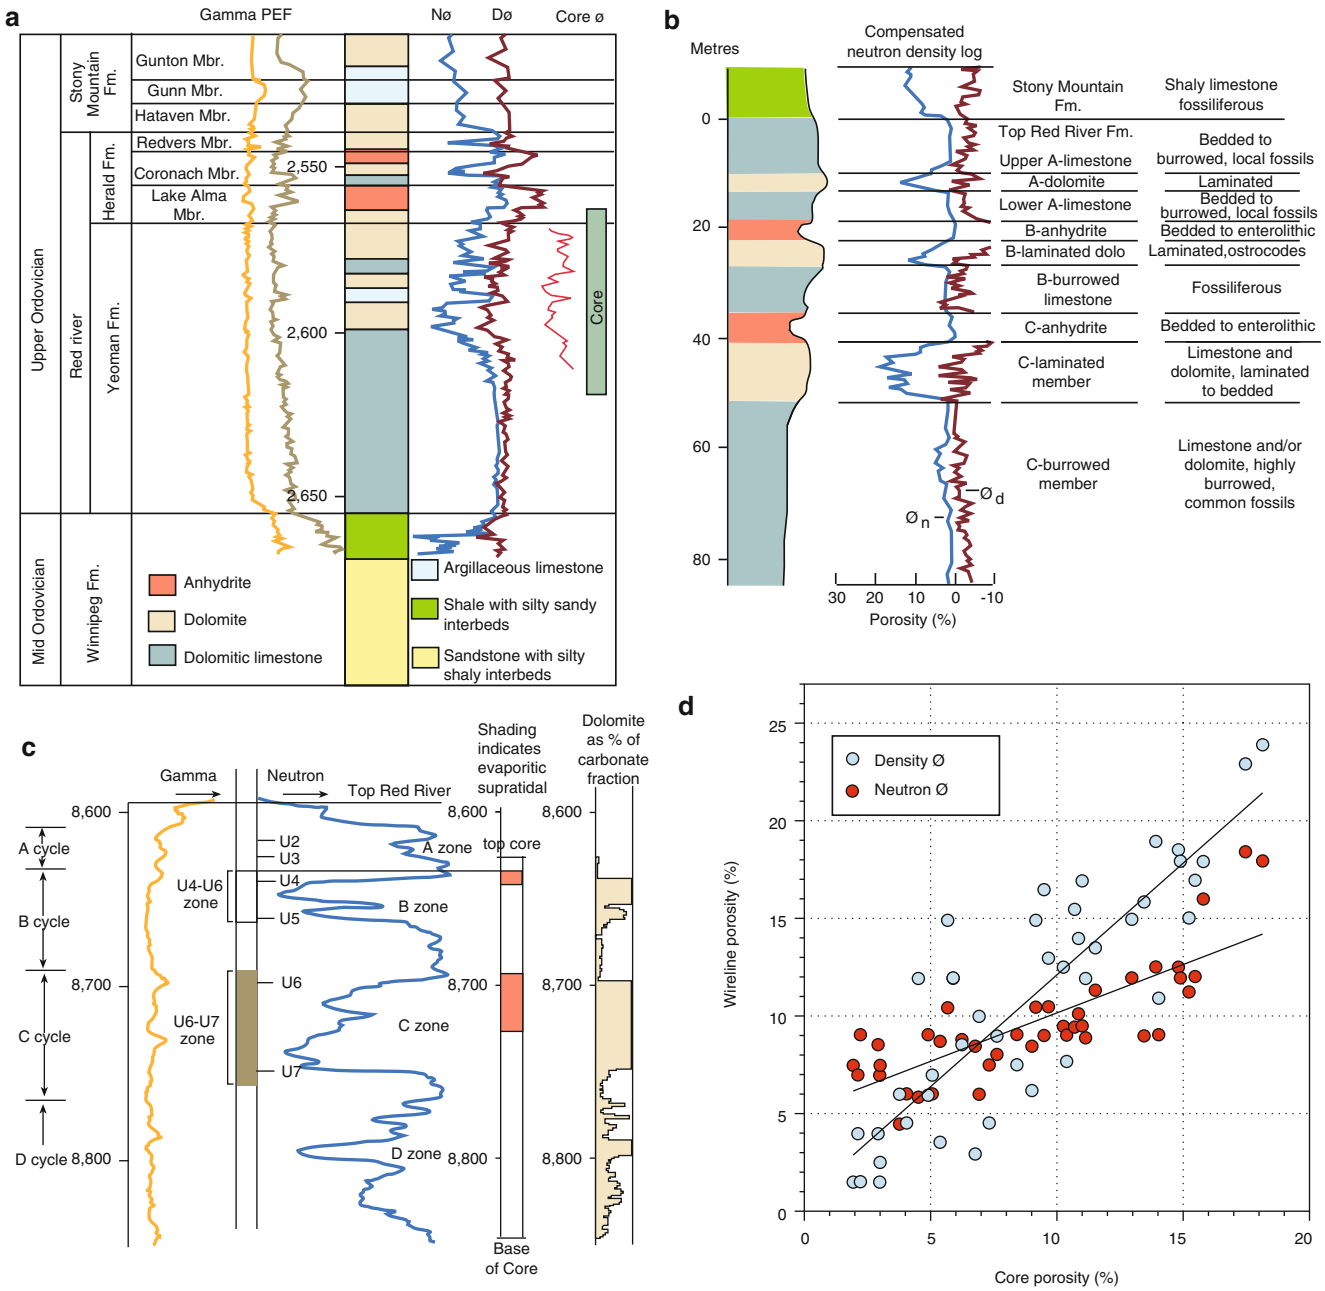

Fig. 10.11 Evaporitic mudflat (peritidal) style of deposition in the Ordovician Red River Dolomite, North Americas. (**a**) Red River stratigraphy with wireline data from well 7-3-7-11 W2 in Midale area, Saskatchewan (After Pu and Qing 2003). (**b**) Typical section showing detailed sedimentary character of the main cycles (After Longman et al. 1983). (**c**) Core section in the Cabin Creek Field, shows the close relationship between dolomite occurrence and evaporite beds (After Clement 1985) (**d**) Relationship between core porosity, neutron log and density log porosity in well 14-16-7-11 W2 in Midale area Saskatchewan (After Pu and Qing 2003)

characterises sediments inmodern evaporite mudflats and sabkhas. In contrast, the bases of the various dolomite intervals are transitional and conformable with the underlying marine limestone interval, this pattern is typical of a brine transition driven by an early reflux hydrology.

As in Cabin Creek Field, Red River dolomite throughout the rest of the Williston Basin is mostly of two types; (a) a mimetic evaporitic-mudflat reflux mesohaline dolomite, which is primary and precipitated penecontemporaneously as wavy-laminated or peloidal mudstones intercalated with the strandline (supratidal) carbonates; and (b) an associated, perhaps slightly later, somewhat coarser-grained brine-reflux dolomite, which dolomitised underlying portions of the intertidal and subtidal sediments immediately below and downdip of the micritic mudflat dolomite (Pu and Qing 2003; Clement 1985; Longman et al. 1983).

The proportion of dolomite decreases downward from the base of each evaporitic mudflat (supratidal) unit due to the sinking and mixing of dense hypersaline waters, which originated in the strandzone (supratidal?). Brine reflux dolomites selectively replace skeletal fragments and burrows of the marine carbonate platform. Within productive areas, dolomitised limestones consistently show improved porosity and permeability compared to nearby undolomitised limestones (Fig. 10.11c).

Red River reservoirs throughout much of the Williston Basin are not hosted in mesohaline mudflats, but in porous dolomitised marine lenses, typically some 27–43 m below the "C" Anhydrite Member and its equivalents. Permeable lenses vary in thickness from less than 3 m up to 60 m thick and are up to 1.5 km across (Fig. 10.12). The lateral extent of these porous lenses and the possible interconnections between them is poorly understood because most producing fields are small and consist of only a few wells. Most cored reservoir intervals are dominated by *Thalassinoides-like* burrow networks, with individual dolomitised burrows 1–2 mm to >1 cm across within a less dolomitised matrix. Reservoir porosities are typically less than 15 % and permeabilities less than 30 md, with most wells showing a poor to moderate relationship between porosity and permeability (Fig. 10.13). Porosity development seems to be related to the degree of dolomitisation, with some porosity enhancement of partially dolomitised intervals occurring during later burial by partial dissolution of residual calcite matrix. The initial formation of dolomite may well have been bacterially mediated and focused along organic-rich linings of the burrows (Gingras et al. 2004). The mechanism was perhaps similar to that of the sulphate-reducing bacteria forming modern dolomites in the mesohaline salinas of Brazil (Fig. 4.17). Dolomite-lined burrow meshworks then acted as a focus for subsequent dolomitisation.

There is general agreement that dolomites of the mottled Red River C member are genetically related to Mg-rich brines seeping through restricted marine muddy carbonates. These dense hypersaline basin waters were depleted of their calcium and sulphate, either through attendant deposition of aragonite and gypsum, or perhaps by ongoing bacterial sulphate reduction. What is not agreed is whether the dolomitising brines were descending or ascending at the time of widespread dolomitisation. Longman et al. (1983) argued that brine migration was localised by "holes" in the anhydrite mudflat seal (Fig. 10.12a). Fracturing, minor faulting, or early expulsion of subsurface waters from the carbonate host probably formed the "holes." When the descending Mg-rich hypersaline brines first entered the underlying carbonate sediments beneath the "holes" they were oversaturated and precipitated cryptocrystalline dolomite (overdolomitisation), but as they migrated away from the holes they lost their potency and produced rhombs floating in a dissolving calcitic matrix. This calcite may have been precipitated as an early diagenetic phase or left as unreplaced vestiges of original calcite (or aragonite subsequently altered to calcite) during dolomitisation.

Perkins (1991) agreed with the brine reflux model for the widespread mimetic dolomite fabric but went on to argue that following further burial, limestones tended to chemically compact through pressure solution, whereas late stage fractures were localized in the more brittle dolomitised portions of the Red River Formation. These fractures served as conduits for late stage leaching fluids, possibly associated with hydrocarbon generation, which locally enhanced porosity in dolomite intervals adjacent to active fractures through the removal of associated calcite. On the scale of individual burrows, late-stage leaching is reflected in "overly porous" dolomite haloes around cemented burrow centres and highly porous dolomite seams along stylolitic contacts.

Kendall (1983) also agrees with a brine reflux model but argues that once the gypsum cap was deposited (prior to its burial conversion to anhydrite) it was an aquifer not an aquitard and that the brine flux could just as easily been upward and focused via brine resurgence through more permeable intervals in the gypsum bed. He goes on to suggest that the control on the dolomite intensity was a series of megapolygonal sutures, much like the resurgence of saline groundwaters seen atop giant polygonal cracks in Pleistocene playas (Fig. 2.59).

The complexity of dolomite-reservoir to seal interrelationships in the Red River Dolomite is symptomatic of similar relationships in many other mudflat-associated dolomite reservoirs (Warren 2000a). The dolomitisation process is ongoing from deposition through burial and uplift. Likewise, the burial evolution of the adjacent evaporite seal is also ongoing from first deposition until complete subsurface dissolution. The evaporitic interval can act as both as a source of fluids, as in reflux dolomites and dissolving salt beds, or as a focus to fluid access as when rising basinal fluids pool and spread beneath a laterally extensive evaporite seal, or where a breached salt bed or allochthon facilitates the ingress of fluids either from below or above the breach. Generally, dolomite reservoirs contain multiple styles of dolomite created at different times in the hydrological evolution of the adjacent evaporite seal (Warren 2000a).

Platform Carbonates with Bedded Saltern Seals

Porosity in saltern-sealed carbonates typically occurs as multiple zones within stacked shallowing-upward evaporitic cycles that pass into mudflats near the basin edge or intrabasin highs (Warren 2000a). The saltern evaporite platform reservoir grouping in part corresponds to the "subtidal carbonate associated with evaporitic tidal flat/lagoon" grouping of Sun (1995). Each economic zone is formed by porous, partially to completely dolomitised subtidal limestones. Reservoirs

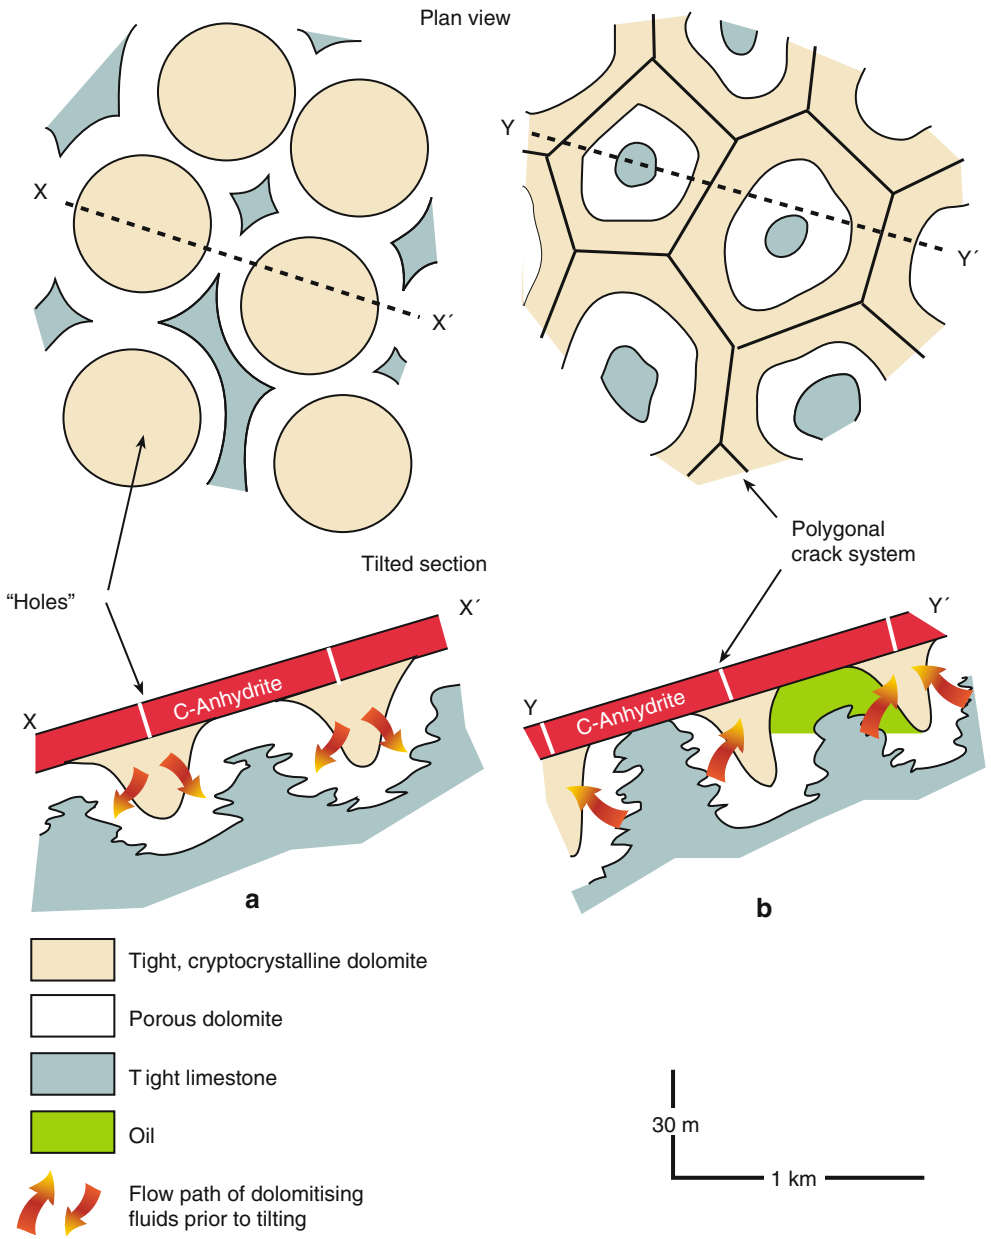

Fig. 10.12 Models explaining the occurrence of patchy diagenetic dolomite that characterises much of the reservoir in the various fields in the Red River Formation. (**a**) The descending hole model of Longman et al. 1983. (**b**) The ascending megapolygon model of Kendall (1983). See text for discussion

are typically capped by tight, dominantly saltern evaporites, with local highs indicated by seal transitions from saltern into evaporitic mudflat. Reservoir quality in the subtidal carbonate is related to depositional facies and varying intensities of diagenetic overprint.

Reflux dolomitisation is a common permeability enhancing mechanism beneath many leaky pans and saltern seas (as in the reef-rimmed Permian Basin of West Texas). But retention of relict primary porosity in epeiric limestones beneath tight sub-saltern units, rather then intensity of reflux dolomitisation near the platform edge, is a significant control on reservoir quality in the Middle East (as evidenced by the many saltern-sealed interior mounds and shoals making up the main Arab D reservoirs across the Arabian Peninsula; Fig. 10.14). In both settings, better quality reservoirs tend to occur in higher energy, grain-dominated limestones (oolitic/peloidal/pisolitic packstones) or dolostones, but quality reservoirs can also form in lower-energy lagoonal dolo-mudstone/wackestone with an overprint of coarsely crystalline dolomite.

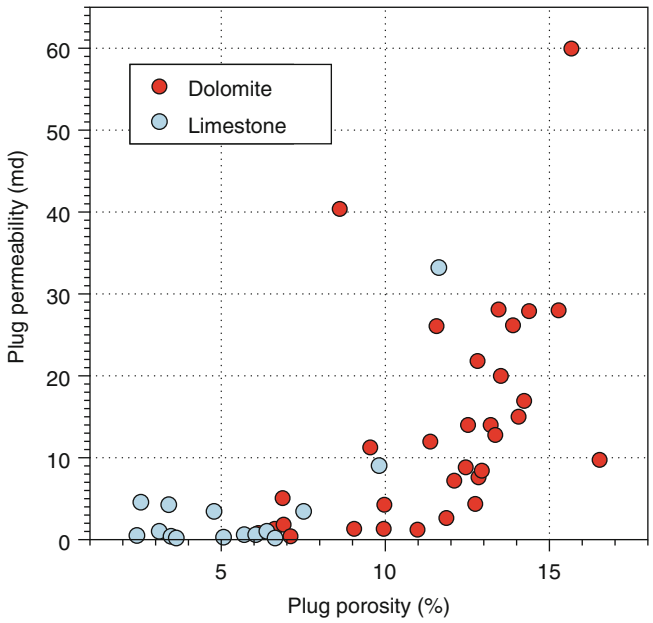

Fig. 10.13 Cross plot of core porosity and permeability in the Red River Formation in well 3-8-1-11 W2, Midale Field, Saskatchewan. Clearly shows the improvement in porosity and permeability associated with dolomitisation (Replotted from Pu and Qing 2003)

Finely crystalline, mud-dominated mimetic dolomites typically form a thin cap beneath a saltern seal or stacks in updip evaporitic mudflat positions, where they lie nearer the brine source. Such mudflat dolomites are typically low permeability sediments that require further diagenetic enhancement to attain reservoir quality (see previous section).

Jurassic Arab Formation, Arabian Gulf

The Late Jurassic (late Kimmeridgian) Arab Formation within and around the Arabian Gulf hosts some of the most prolific oil fields in the world, including Ghawar and Safaniya fields (Ehrenberg et al. 2007; Lindsay et al. 2006; Pollastro 2003; Lucia et al. 2001; Sahin and Saner 2001; Meyer et al. 2000; Cantrell et al. 2001; Beydoun 1998; Alsharhan and Kendall 1994; Wilson 1985). This prolific petroleum system includes several regional organic-rich source rocks, stacked reservoirs and multiple seals (Al-Husseini 1997). Jurassic strata were deposited across a broad platform (Murris 1980) that is sometimes characterized as "layer cake." Chronostratigraphic correlation from outcrops to wells, well to well, and from country to country, defines a late Jurassic regional anhydritic sealed carbonate platform encompassing

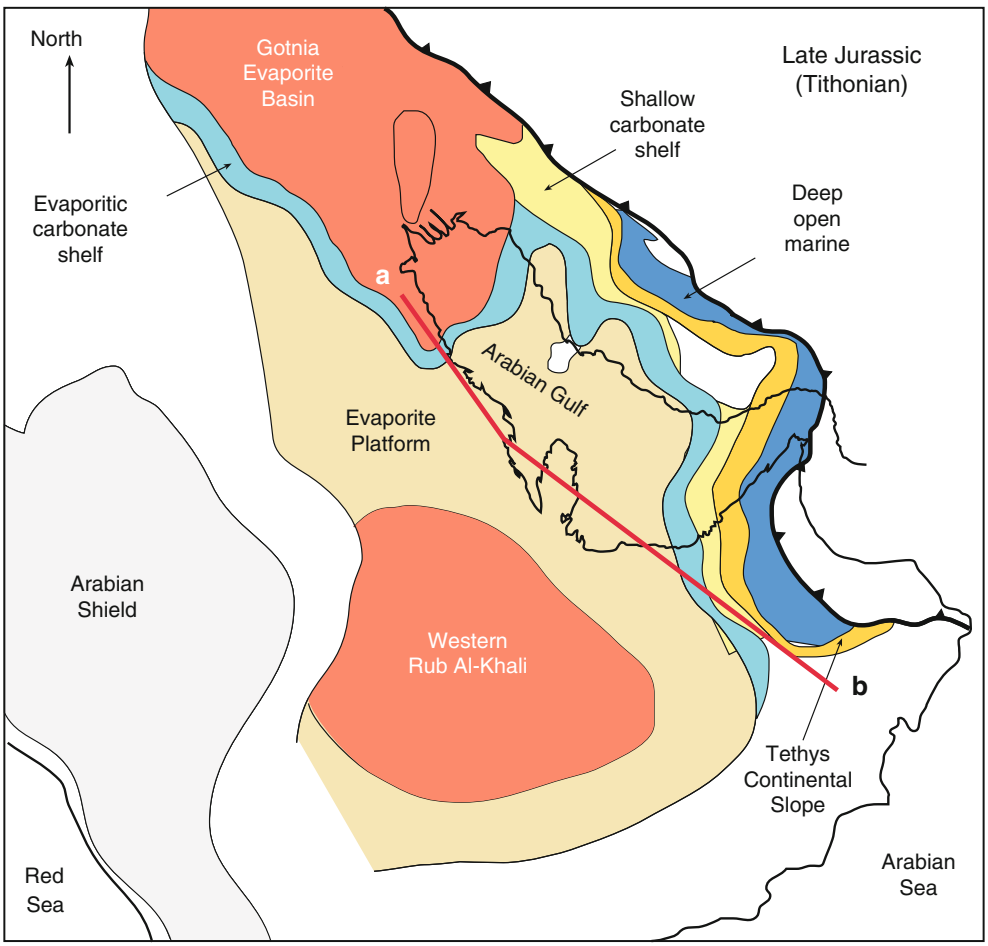

Fig. 10.14 Late Jurassic Tithonian palaeogeography of the Arabian Gulf (After Al-Husseini 1997). Deposition of the four carbonate-anhydrite cycles of the Arab Formation and the overlying Hith Anhydrite constitute the dominant regional reservoirs and caprocks. The western Rub' Al-Khali and Gotnia basins were inland salterns characterised by halite rather than platform-wide anhydrite, which is the dominant evaporite salt in the Arab and Hith formations

large intrashelf basins with grainier rims. At times of hydrographic isolation, the platform evolved into a widespread saltern that with further isolation was characterized by halite-filled depressions known as the Gotnia and Rub Al-Khali salt basins (Fig. 10.14; Al-Husseini 1997).

The proposed regional stratigraphic framework for the Jurassic, as defined by Al-Husseini (1997), is as follows; (1) Upper Triassic-? Lower Jurassic continental clastics (Minjur Formation and equivalents) and the subsequent pre-Toarcian unconformity indicating regional erosion and non-deposition over the Arabian platform. (2) A Toarcian sequence (Marrat Formation and equivalents) providing a basal Jurassic regional datum, except in Oman. (3) Late Toarcian and Aalenian corresponding to a substantial sea-level lowstand and a regional depositional hiatus. (4) The Middle Jurassic Dhruma Formation corresponding to four different sequences with a major intervening hiatus. The Upper Dhruma Member, together with the Tuwaiq Mountain Member, forms the topmost sequence (Fig. 10.15). The correlation between the Dhruma, Tuwaiq Mountain, Hanifa and Jubaila formations, to their equivalents in other Arabian Gulf countries, still requires clearer definition. (5) The Arab and Hith Anhydrite formations are Tithonian, based on their sequence assignment, while the Sulaiy Formation is mostly Berriasian and straddles the Jurassic Cretaceous boundary.

The four Tithonian Arab Formation carbonates (A-D members) were deposited as transgressive to early highstand deposits, while the Tithonian Arab, Gotnia and Hith anhydrites are perhaps late highstand deposits which overstep inland salterns (Gotnia and western Rub' Al-Khali basins). Each carbonate and overlying anhydrite cap in the four Arab cycles (Arab A-D) are interpreted as complete third-order cycles by Al-Husseini (1997). The equivalents to the Kimmeridgian Jubaila Formation and Tithonian Arab carbonates are absent because of non-deposition in Kuwait. The Tithonian Hith Anhydrite provides a regional stratigraphic datum in the Arabian Peninsula, except in Oman and the eastern United Arab Emirates (UAE). There the Arab and Hith Anhydrite formations are absent as they have been eroded or were never deposited, so the former eastern and southeastern extent of the Hith is not well understood.

The main reservoirs within this prolific petroleum system are oolitic-peloidal grainstones and dolomitised limestones, within a regionally extensive, mostly muddy, carbonate platform that is now called the Arab Formation. The Arab Formation is typically divided into four cycles (A through D from base to top); all cycles can produce, but the Arab D is the most productive over much of the Gulf. Each cycle shoals up from a more marine base to restricted-marine, variably dolomitised, limestone to mudflat dolomites and evaporites. The lower portion of the Arab D is typically a bioclastic lime mudstone or wackestone with normal marine fossils. Away from topographic highs, local organic-rich mudstones were deposited in intrashelf basins and are lithologically identical to similar intrabasinal successions in the underlying Diyab Formation. The lower Arab D is overlain by a middle unit of clean washed calcarenite, largely composed of sorted and rounded skeletal particles and ooids (grainstone-packstone), and an upper variably developed thin dolomitic mudflat sequence, which grades across a metre or two of anhydrite-plugged carbonate into massive to nodular anhydrites of the Arab D capstone. This anhydrite was deposited within a regional sulphate saltern/pan with local, but still widespread, evaporite mudflats atop local highs. Evaporitic mudflats also encircled the depositional edges of the basin. Microfossil and macrofossil content in the marine portion of the Arab D is a useful discriminant of water depth and restriction (Fig. 10.16; Wyn Hughes 1996; Lindsay et al. 2006).

For example, Al-Awwad and Collins (2013) show that locally the reservoir lithofacies in Khurais Field, Saudi Arabia, are made up of: couplets of (1) lime mud and (2) intraclastic lithofacies representing basinal turbidites; (3) pelletal lithofacies representing lower shoreface sands and silts; (4) stromatoporoid lithofacies representing a reef; (5) *Cladocoropsis* and (6) dasyclad lithofacies representing a lagoon; (7) peloidal and (8) oolitic lithofacies representing shore-attached sand sheets; (9) cryptomicrobial lithofacies representing supratidal flats; (10) anhydrites representing sabkha followed by salina deposits; and (11) stratigraphically reoccurring dolomite (Fig. 10.16). These are arranged in two, partially preserved, third-order sequences, the upper of which represents the Arab-D Member and the lower of which represents the upper Jubaila Formation. Within these sequences lie six fourth-order high frequency sequences, composed of fifth-order parasequences and parasequence-scale cycles. The preserved upward shallowing trend of the Arab-D reservoir is manifested laterally by a regional eastward thickening interpreted to be the result of an eastward progradation across the shallow Late Jurassic epeiric shelf and into the relatively deep Arabian intrashelf basin.

Regionally, atop the anhydrite-capped marine-dominated limestone and dolomite of the Arab D are the more restricted cyclic carbonates-anhydrites of the Arab A-C. These sediments in the United Arab Emirates show depositional relationships that correspond to the outline of the current and possibly the late Jurassic edge of the evaporite basin, although exact detail has been obscured by edge dissolution and erosion (Fig. 10.17). Wireline signatures in the anhydrite caps to the various A-C cycles in oil fields in both Saudi Arabia and eastern Abu Dhabi indicate evaporite mudflats made up of mosaics of sabkhas, ephemeral brine pans and salinas (personal observation) and are very similar to signatures in shoal water portions of the Arab D capstone. As in the Arab D cap, the proportion of subaqueous anhydrite increases in the capstone away from the crests of many fields, showing that many current highs were also highs in the Jurassic. Unbreached anhydrite caps in all Arab D cycles are highly effective seals, for example, the anhydritic cap to the Arab D holds back a 400 m-oil column in Ghawar Field,

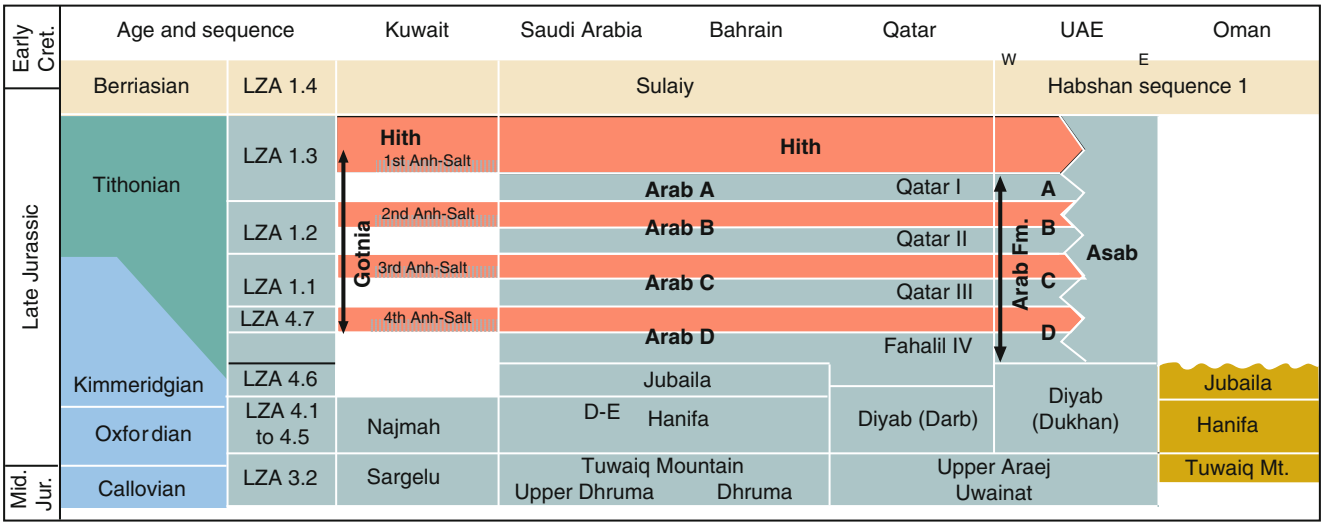

Fig. 10.15 Stratigraphy of the Late Jurassic sediments of the southern Arabian Gulf (After Al-Husseini 1997)

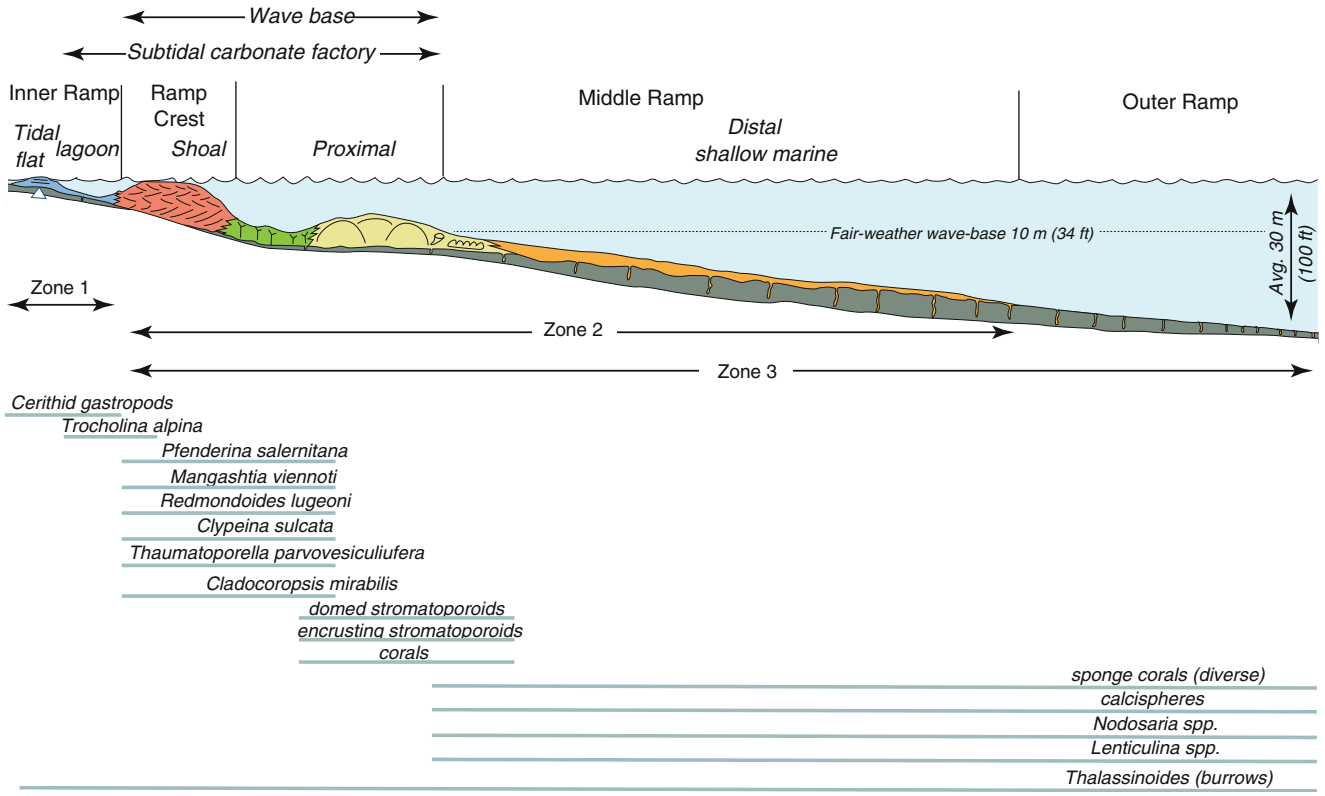

Fig. 10.16 Palaeoenvironmental distribution across zones 1–3 of various biotic elements within the carbonate stage of the Arab-D reservoir, based on Ghawar but applicable to other Jurassic reservoirs in Saudi Arabia (After Lindsay et al. 2006). The schematic reconstruction does not include the evaporitic saltern stage. This model depicts deposition of one ideal carbonate cycle from the inner ramp, ramp-crest shoal, proximal, and distal middle ramp to outer ramp. *Grey coloured* unit is a transgressive mud-rich deposit that forms the base of a cycle capped by a firmground that developed during maximum flooding and was extensively burrowed by *Thalassinoides*. Subsequent units tend to shoal upward and are progradational or regressive. *Orange coloured* unit is distal middle-ramp debris-flow deposits of rudstone and floatstone. *Brown fill* indicates proximal middle-ramp biostromes and mounds of stromatoporoids and corals. *Green* with fork shapes is proximal middle-ramp *Cladocoropsis* banks deposited in sheltered areas between and upslope of biostromes and mounds. *Red* is the cross-bedded ramp-crest grainstone shoal. *Blue* is inner-ramp lagoon intertidal islands. Those facies and rock types that are abundant in each reservoir zone are *underlined* by the titles and associated *arrows* showing depositional extents of zone 1, zone 2, and zone 3. Distribution of common to abundant faunal and floral elements (both laterally at any one time and stratigraphically through the reservoir zones) is shown by *grey bars*

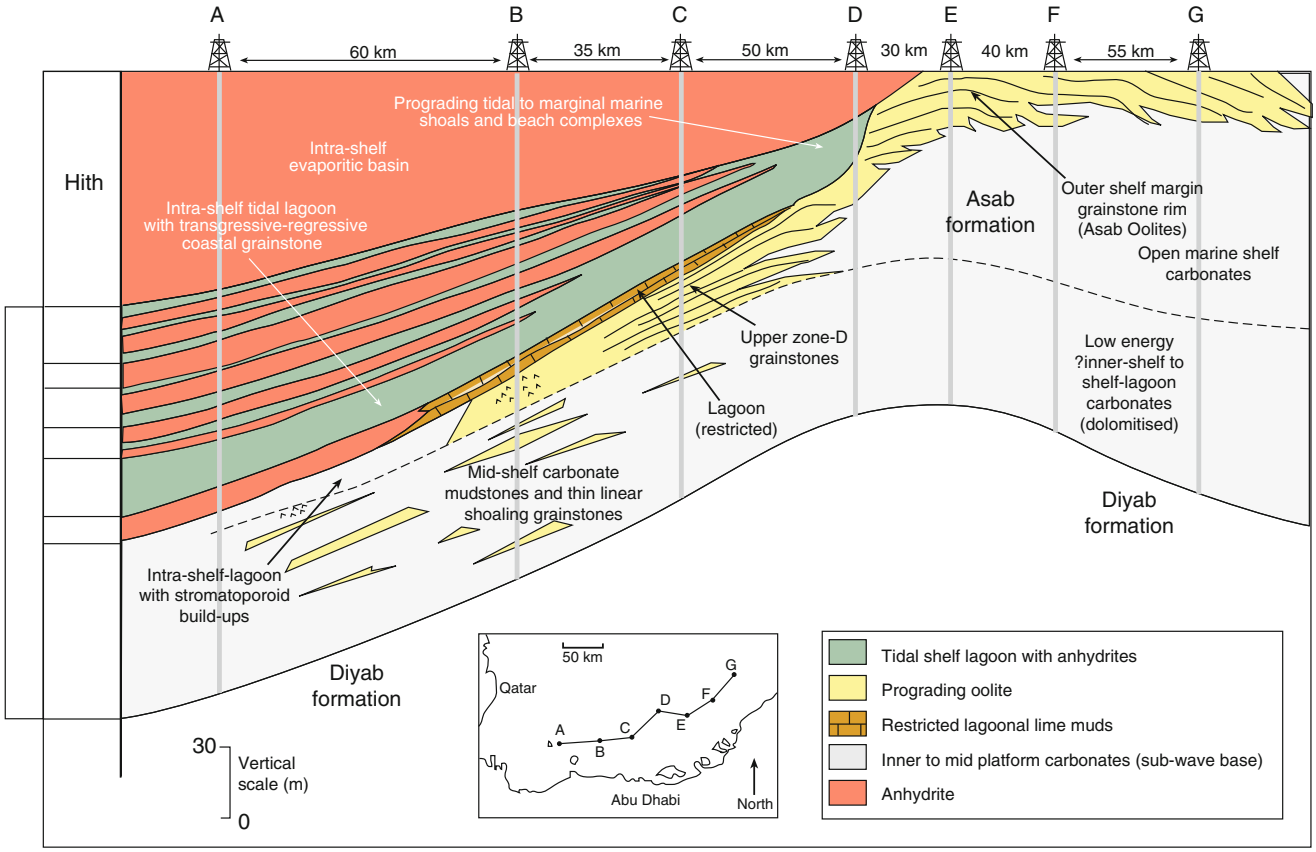

Fig. 10.17 Schematic east-west cross-section of the Arab and Hith formations, offshore Abu Dhabi. Note: Datum is possibly affected by erosion and evaporite dissolution with the amount of truncation increasing to the east. Facies relationships between wells are schematic (After Al Silwadi et al. 1996)

Saudi Arabia. Wireline signatures in the crest of the field indicate a mosaic of salinas and sabkhas.

The Asab Formation in the eastern United Arab Emirates is laterally equivalent (although not necessarily time equivalent) to the Arab Formation (Fig. 10.17). Definitions of Arab-A,-B, and -C vary from field to field across the Gulf and do not necessarily represent the same chronostratigraphic unit. The combined Arab-ABC is defined by Grötsch et al. (2003) as a lithostratigraphic unit composed of high-frequency dolomite-anhydrite shallowing-upward cycles capped by the massive Lower and Upper Hith Anhydrite. The top of the underlying Arab-D reservoir in the eastern UAE is typically picked at the top of a clean gamma-ray trend, which is usually an oolitic and bioclastic grainstone section. Its top typically coincides with the first occurrence of a gamma kick, indicative of a black marker limestone that commonly contains pyrite. However, in my opinion, this marker is not always a depositional unit and may be a dissolution residue created by fluid crossflow along the underside of the anhydrite sealing the Arab D. Although a useful correlative marker of the reservoir top, it probably does not represent a time-line.

If we assume the Arab D is the base of the section throughout the Arabian Peninsula, then the difficulty in breaking out three separate cycles (Arab A-C cycles) atop the Arab D reflects the high degree of textural similarity of all restricted and dolomitised evaporite-capped shoaling cycles. The inherent lack of an entrained time-significant fossil assemblage and the vagaries of syndepositional evaporite dissolution in all evaporitic mudflats makes detailed well-to-well correlation at the level of the Arab A-C very difficult. There are more than three anhydrite beds in the A-C interval (Fig. 10.17). Short but significant episodes of subaerial exposure and freshening characterised the brine sheets depositing these marine-fed mudflat cycles. Intraformational evaporite dissolution residues, sometimes show high gamma kicks and without reference to core can be easily misinterpreted as maximum flooding surfaces.

Capping the cycles of the Arab Formation is a thick regional unit of subaqueous saltern anhydrite, the Hith Anhydrite, which extends over much of the Arabian Gulf region. In Saudi Arabia and the eastern UAE, it holds back almost all of the oil and gas sourced in Jurassic mudstones. It is only at the edge of the Hith in the central and western UAE

that Jurassic sourced oil is found as widespread accumulations in the overlying Cretaceous succession (Fig. 10.8a).

Deposition of the various widespread anhydrite caps in the Arab Formation across the Arabian Plate indicate higher order sealevel falls, within what was a second order sequence accumulating during the late Kimmeridgian. For much of this time, when evaporites were not accumulating, open-marine to restricted-marine epeiric carbonates were the dominant sediments (Fig. 10.17; Sharland et al. 2001; Al-Saad and Sadooni 2001). During the preceding Hanifa and Jubaila time (middle Oxfordian and early Kimmeridgian, respectively), local organic-rich intrashelf basins deposited starved-basin sequences of laminated organic-rich dark-coloured marls and mudstones (Fig. 9.5; Ayres et al. 1982).

Prior to hydrographic isolation that marked the end of the Arab D, oolite/peloidal shoals and patchy coral-algal stromatoporoid banks were deposited as local higher energy shoals across the muddy epeiric platform that typified marine stages of Arab Formation deposition across the Arabian Peninsula (Fig. 10.16). Regionally, similar but more laterally continuous Kimmeridgian equivalents to these higher energy marine carbonates lined the epeiric platform margin. This band of shelf-edge shoals was a hydrodynamic barrier that periodically restricted free surface exchange between Arabian Platform waters and deeper open-marine (Tethyan) waters to the east and facilitated deposition of the various anhydrite capstones (Fig. 10.14). This shoal-rimmed margin thus separated a muddy interior epeiric platform, with its intrashelf depressions, from the deeper open-water marine slope carbonates. Edges of the various intrashelf basins of the epeiric shelf behind the main shelf margin shoal were ramp-style progressions around somewhat deep (≈30 m) intrashelf basins (Sharland et al. 2001). Much of the regional platform-margin shoal rim was destroyed during later continental collision.

Regionally, much of the reservoir quality in the undolomitised or poorly dolomitised limestone reservoirs in the Arab D can be directly tied to partially-preserved primary porosity in grainstone (ooid, skeletal and peloid) shoals and local reefal (stromatoporoid) debris aprons in the epeiric interior seaway. In many parts of the platform interior (e.g. the offshore UAE) the shoaling of the Jurassic seafloor and the formation of seafloor shoals in the Arab Formation was facilitated by salt structures sourced in the Precambrian Hormuz salt.

After deposition of the Arab D, ongoing higher order eustatic changes formed the numerous parasequences that make up the widespread A-C cycles of the Arab Formation in the epeiric shelf interior. Eustatic fluctuations drove periodic marine flooding episodes on the platform, followed by filling of accommodation space, hydrographic isolation and capping by evaporites and exposure surfaces. With each transgression another more open marine platform unit defined the base of a cycle and was deposited as marine to mesohaline, skeletal-poor peloid wackestones/mudstones. Local shoaling on the epeiric platform led to progressively higher bottom energies culminating in thin local buildups of ooid and peloid grainstones that are now producing intervals in the Arab ABC.

Progressive platform restriction followed, via a combination of active carbonate aggradation and high order falls in relative sealevel (3rd to 5th order), which periodically exposed the shelf margin within an environment of net evaporation across the arid platform. This drove numerous brining-upward depositional cycles in the Arab ABC, with most, but not all culminating in the deposition of mudflat gypsum. Gypsum beds were porous at the time the various Arab ABC sulphates were deposited and brine reflux drove the formation of mimetic dolomites in the immediately underlying limestones. Dolomitisation is less pervasive, but still significant, in terms of reservoir quality in the underlying Arab D (Fig. 10.19). Thus syndepositional reflux dolomitisation occurred many times during the accumulation of evaporite caps to the various muddier units of the Arab Fm. and each probably indicates platform restriction related to higher order sealevel falls or local halokinetically- or basement fault-induced seafloor uplift. Some evaporite beds associated with these higher-order relative sealevel falls were leached by a subsequent rise in sealevel, so that all that remains of some of these higher order evaporite deposits are nodules cementing carbonate remnants in thin dolomites, along with widespread cm-scale dissolution surfaces and residues, often associated with gamma peaks in the wireline log (pers. obs.).

Any model explaining reflux dolomitisation on the Arabian Shelf as only occurring during the deposition of the four major cycle caps in the Arab Formation is too simplistic, as is the notion that the reservoir sediments of the Arab D cycle are the same as those of the subsequent A-C cycles. Given that the Arab D is the dominant producer throughout the Arabian Peninsula, we shall now focus on the detail of its reservoir characteristics and any relationship to diagenesis, perhaps tied to reflux and vertical crossflows that were focused by its evaporite seal.

The best-documented and regionally largest accumulation of hydrocarbons in the Arabian Peninsula occurs in Ghawar Field in Saudi Arabia (Fig. 10.18). It not only stores hydrocarbons in the Jurassic section, but also entrains rich gas reserves in the underlying Permian Khuff Formation and with more than 150–200 billion barrels of ultimate recoverable oil is the world's largest single oil-filled structure. Even so, it is approaching the 50 % recovered mark.

Production began in Ghawar field in 1951 and reached a peak of 5.7 million barrels per day in 1981. This is the highest sustained oil production rate achieved by any single oil field in world history. At the time that this record was achieved, the southern areas of Hawiyah and Haradh had not

yet been fully developed. Production was restrained after 1981 for market reasons, but Ghawar remains the world's most important oil field. Its daily production of 30–31° API oil exceeds 5 million barrels per day, which is more than half of Saudi Arabia's cumulative oil production. Ultimate recoverable resource estimates for Ghawar range from 66 to 150 Gb, with some estimates exceeding 200 Gb. By 2005, Ghawar's cumulative production was some 61 Gb, if an assumption of around 150 Gb is used and assuming that the production was near constant at around 5 Mbpd for 2006 and 2007, then produced share of ultimate recoverable resource by end of 2007 was 43 % (Höök et al. 2009). This is in line with the 48 % of Ghawar reserves produced as stated by Saudi-Aramco.

The following discussion will only deal with the geology of the Jurassic section in Ghawar. Detailed studies of various aspects of Ghawar and its outcrop equivalents in Saudi Arabia have been published by Lindsay et al. (2006), Cantrell et al. (2001), Cantrell and Hagerty (1999, 2003), Stenger et al. (2003), Lucia et al. (2001), Meyer et al. (1996, 2000), Saner and Sahin (1999), Douglas et al. (1996), Wyn Hughes (1996), Powers (1962). The following section is a summary of aspects of this work, along with some comments of my own.

Ghawar Field, Saudi Arabia

The Arab-D carbonate reservoir of the Upper Jurassic Arab Formation in the onshore Ghawar Field was discovered in 1948. Following further separate discoveries in culminations along the structure's main axis, five production areas were quickly identified as parts of a single giant Ghawar oil field (Stenger et al. 2003). From north to south Ghawar is made up of Ain Dar, Shedgum, Uthmaniyah, Hawiyah and Haradh (Fig. 10.18a). At the Arab-D level, the field is a NNE-trending composite anticline, 230 km long and about 30 km wide, with a productive area of more than 693,000 acres in a single, pressure-continuous reservoir.

Within the Jurassic section, the Ghawar produces from the evaporite-sealed Arab D, with the reservoir section extending down into mudstones of the uppermost Jubaila Formation. Production layering is typically broken out into 4 zones with the main production intervals broken into further finer subdivisions (Fig. 10.19). Limestones of Zone 1 and 2 typically constitute the best quality Arab D reservoirs (Fig. 10.18b). Arab-C, Hanifa and Fadhili oil reservoirs are also present in parts of the field, but the Arab-D reservoir accounts for nearly all of the oil reserves and production.

Across the field the Arab-D reservoir is comprised of a series of stacked shallow water, platformal carbonate sediments deposited as a cleaning-up and a shallowing-up carbonate succession stacked into metre-scale cycles or parasequences. The bulk of the reservoir is comprised of limestone, though some dolomite is present. Anhydrite is present in the reservoir as cement, but typically in minor amounts (Table 10.3). The cleanest and most porous rocks – hence the most favourable in terms of production – are situated in the grainier upper portion of the reservoir (Zone 2) Interparticle porosity predominates in the various reservoirs,

After Cantrell and Hagerty (2003). See also Fig. 10.16

though locally, other porosity types are important; for example, mouldic and intercrystalline porosity in dolomitised portions of the reservoir. Each of the major upward-shoaling cycles that make up the Arab D was initiated in deeper subtidal water that shoaled to near sea-level. The proportion of skeletal grainstones and packstones, along with ooid grainstones, increase within each cycle and within the Arab D overall. The top of the Arab-D carbonate is characterized by a thinner unit of dolomitised carbonate mudstone (Zone 1), capped by an evaporite seal.

By far the most abundant reservoir rock texture in the Arab-D is packstone; likewise, the most abundant reservoir lithofacies is skeletal-oolitic (SO; Tables 10.3 and 10.4; Cantrell and Hagerty 2003). The other significant lithofacies in the Ghawar reservoir are; *Cladocoropsis* (a characteristic finger-shaped and sized stromatoporoid) lithofacies (CLADO), stromatoporoid-red algae-coral lithofacies (SRAC), bivalve-coated grain-intraclast lithofacies (BCGI), micritic lithofacies (MIC) and dolomite lithofacies (DOLO), all of which are described in detail by Mitchell et al. (1988). Similar, if not identical, lithofacies make up Arab D reservoirs in other fields in Saudi Arabia and the western United Arab Emirates (e.g., Al-Awwad and Collins 2013). In a detailed petrographic and petrophysical characterisation of the Ghawar Arab D reservoir Cantrell and Hagerty (2003) defined seven related limestone reservoir rock types based on the values of: (1) the amount of cement, (2) the amount of matrix (lime mud), (3) the grain sorting/grain packing, (4) the dominant pore type, and (5) the size of the largest moulds (Tables 10.4 and 10.5; Fig. 10.20).

At the broadest scale of reservoir classification the Arab D reservoirs are either limestone or dolomite (Table 10.5) In terms of porosity and permeability in the limestones, the amount of matrix is the most important of these five parameters and breaks down into three reservoir types (1-III). Cantrell and Hagerty (op cit.) break our two broad families, A and B in each of the three reservoir types (Table 10.5). Family, A, is relatively coarse-grained and poorly sorted rock with relatively large moulds. Family, B, is a generally fine to medium-grained, well-sorted rock with few or small moulds. Together this constitute 6 families of reservoir rock in the Arab D. Reservoir rock type IV is a seventh limestone family in Ghawar. Type IV limestones contains more than 10 % cement, this modifies pore size distribution enough to warrant a separate limestone reservoir family (Fig. 10.20). Each of the seven limestone types is characterized by distinctive porosity-permeability relationships (Fig. 10.20). Similar matrix-lean limestone reservoir characterise better quality reservoirs in Abqiq Field in Saudi Arabia and the Jurassic Arab Formation reservoirs of Qatar (Figs. 10.21 and 10.22, respectively).

Dolomites in Ghawar constitute reservoir rock type V and are further subdivided according to their dolomite crystal texture, although stratigraphic position and porosity can also

Table 10.4 Interrelationships between texture, lithofacies and modes of occurrence in Arab D reservoir in Ghawar Field, Saudi Arabia

	Lithofacies

be effective pointers in their classification (Table 10.5; Fig. 10.23a; Cantrell and Hagerty 2003). The four dolomite textures are: fabric preserving (Vfp), sucrosic (Vs), intermediate (Vi) and mosaic (Vm). The mimetic Vfp dolomite is only found in Zone 1 of the Arab-D (immediately below the anhydrite cap) where it is the major dolomite type. Sucrosic (Vs) dolomite occurs in dolomites with more than 12 % porosity, Vm less than 5 % and Vi between 5 and 12 %. Vfp dolomites have pore systems similar to their precursor limestone, but the pore systems of the other dolomite types are unique.

Powers (1962) and Lucia et al. (2001) concluded that once an interval in the Ghawar Field of Saudi Arabia is dolomitised, its reservoir quality is tied to the proportion of dolomite and dolomite crystal size (Fig. 10.23b, c). In general, when dolomites are compared to limestones in the Arab D they show lower porosities (Fig. 10.22). This is clearly seen in wireline-based porosity histograms of Zone 1 in the Arab D from Abqaiq Field, a supergiant field with 17 billion barrels of proven reserves, in eastern Saudi Arabia (Fig. 10.19; Sahin and Saner 2001). In part, this decrease in porosity with dolomitisation is a reflection of the originally lower precursor porosity in muddier transitional sediments that typically underlie a mudflat or saltern seal (mimetically dolomitised Zone 1 carbonates – Vfp).

Anhydrite-derived, corrected porosity in wireline-defined anhydrites in Zone 1 is greater than zero in Abqaiq Field, eastern Saudi Arabia (Fig. 10.21a; Sahin and Saner 2001). This value comes not from the actual anhydrite beds, which are tight, but from the thin dolomite stringers that are intercalated within the anhydrite; they sit at the limits of vertical resolution of the wireline tool in such finely layered sequences. Controls on the Arab D reservoir are similar to those in Ghawar, with limestone matrix type rather than dolomitisation as the prime control (Fig. 10.21b). Once the proportion of dolomite in a muddy succession attains 80–90 %, the reservoir character substantially improves compared to its muddy limestone precursor (Fig. 10.23b).

In many fields the dolomitisation process is most pervasive in lime mudstones below an evaporite unit or its former solution residues (e.g. Zone 1 in Ghawar). The reason why dolomites can form excellent reservoirs in tight mud-rich lime precursors in many mudstone of the Arab cycles (and the Permian Khuff of Saudi Arabia, Permian and Triassic dolomites in the Sichuan Basin of China and San Andres of West Texas) is the development of intercrystalline porosity. Hence, within the muddier facies of Ghawar there is a significant tie of reservoir quality to dolomite percent and crystal size, as in the coarsely crystalline sucrosic intervals in the dolomitised interval of Ghawar. Crystal size in the dolomites is related to reservoir quality with coarser crystals defining the higher porosity/permeability intervals, probably reflecting a propensity for larger pore throats and remnant dissolution voids in the more coarsely crystalline dolomites (Fig. 10.23c). Locally such coarsely crystalline dolomite can create high permeability "super-k" layers (Meyer et al. 2000).

But dolomites in the Arab Formation in Saudi Arabia are not from a single generation of reflux dolomite, nor are the dolomitised units laterally homogenous. When dolomite is subdivided by texture and stratigraphy (not porosity as was done in Table 10.5; Fig. 10.24; Cantrell et al. 2001) then five types of dolomite occur in the Arab D reservoir in Ghawar Field, namely:

1. Finely crystalline, non fabric preserving (NFP) dolomite in Zone 3 (lower Arab D) with considerable preserved calcite, low oxygen isotope values and generally poor reservoir quality. Dolomite is typically associated with hiatal surfaces.
2. Medium crystalline NFP dolomite with elevated oxygen isotope values and very poor reservoir quality in Zone 2 (upper Arab D). Occurs essentially as dolomite beds with little or no reservoir quality.
3. Medium to coarsely crystalline (NFP) dolomite with low oxygen isotope values and very good reservoir quality in Zone 2. Petrographically it is similar to medium-crystalline NFP dolomite but shows a lighter isotopic signature. It is an important reservoir component as it occurs in 'super k' intervals (Meyer et al. 2000).

   It is characterised by a high degree of intercrystalline porosity and locally retains leached mouldic porosity (typically after *Cladocoropsis*).
4. Finely crystalline fabric preserving (FP) dolomite in Zone 1 (uppermost Arab D) with elevated oxygen isotope values and generally fair to poor reservoir properties. It is minor in terms of overall reservoir volume in the Arab D and also occurs in association within and below the overlying C-D anhydrite transition. Typically it forms layers or thin sheetlike beds in Zone 1. Reservoir quality typically reflects the characteristics of the overprinted limestone facies, most of which were relatively mud free and partially cemented mudlean packstones.
5. Rare locally occurring saddle dolomite (not sampled in the Cantrell et al. 2001 study).

Overall, dolomite comprises around 14 % of the Arab D in Ghawar, with the highest proportion in Zone 1 below the anhydrite cap (Figs. 10.25 and 10.26; Cantrell et al. 2001). Zones 2B and 3A have less dolomite, but it is still a significant fraction of the reservoir matrix. Dolomite is a relatively insignificant contributor to reservoir matrix in Zones 3B and 2A. Within each reservoir zone much of the total dolomite percentage in a well comes from individual layers, which are intercalated with limestones. Laterally many of these dolomite layers can vary greatly in the proportion of dolomite (e.g. Zone 2B). On a Ghawar-wide basis dolomite increases

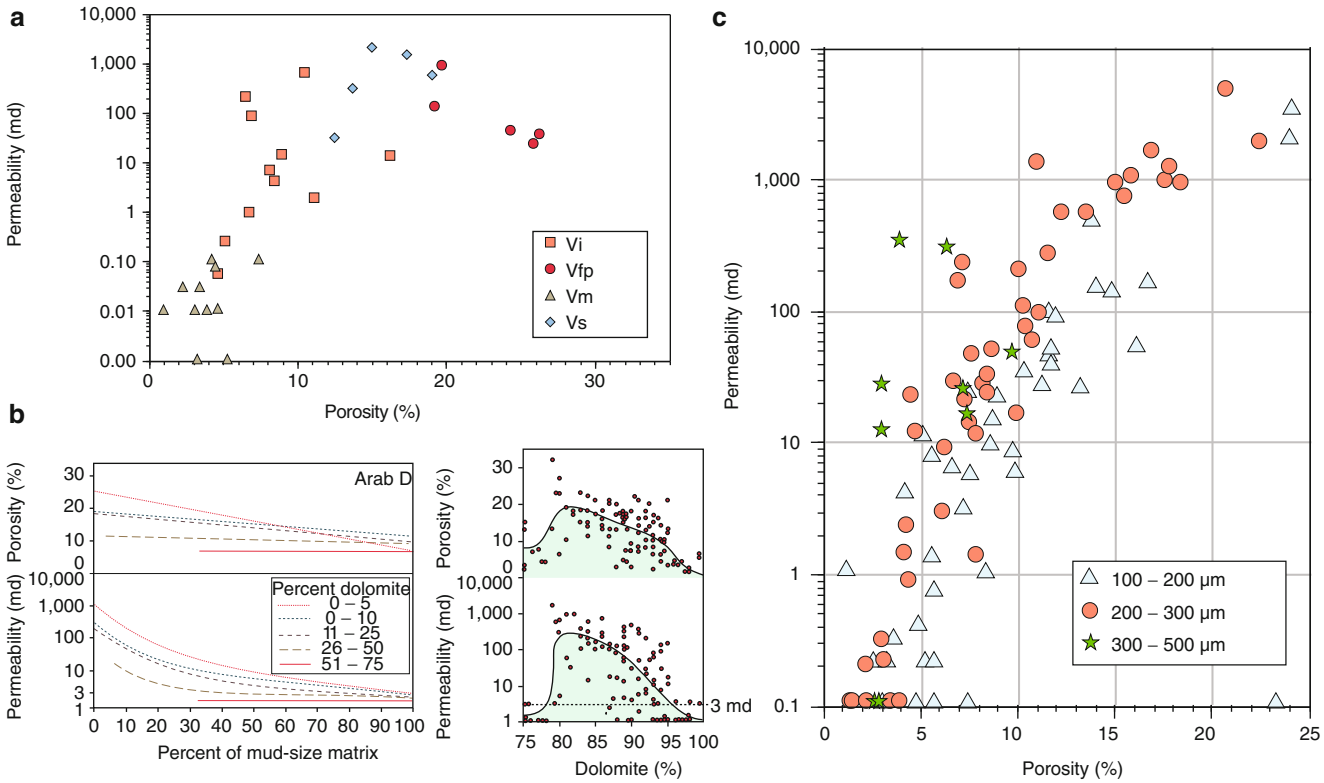

Fig. 10.23 Reservoir properties of dolomites in the Arab D, Ghawar Field, Saudi Arabia. (**a**) Textural-petrophysical classification of dolomite reservoirs (After Cantrell and Hagerty 2003). (**b**) Effect of mud size and dolomite percentage on porosity and permeability in the Arab D in Ghawar Field. There is a drastic increase in permeability when the dolomite proportion is between 80 and 90 % (After Powers 1962). (**c**) Interparticle porosity permeability crossplot for dolomites of various crystal sizes (After Lucia et al. 2001)

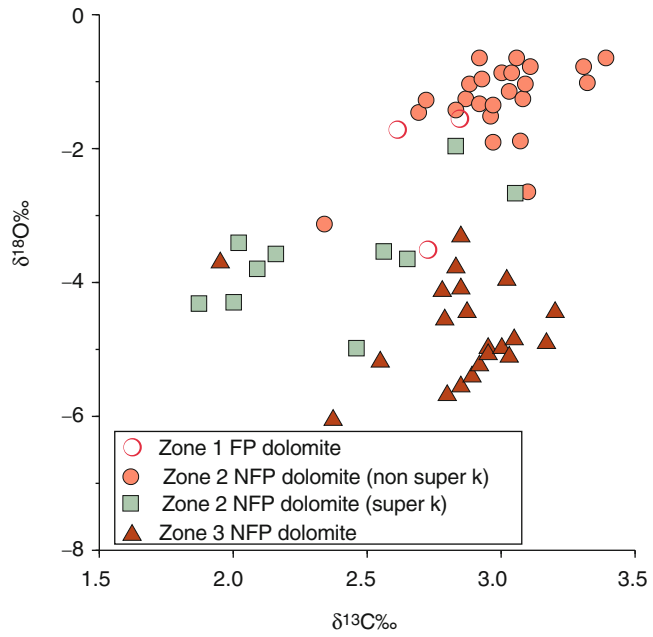

Fig. 10.24 Isotopic compositions of dolomites in Arab D, Ghawar Field, Saudi Arabia, based on textures (After Cantrell et al. 2001)

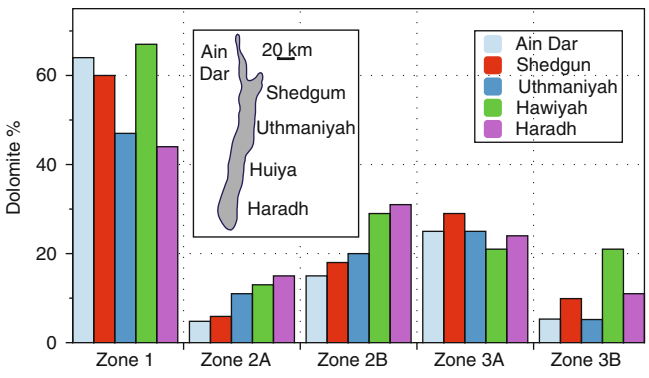

ZONE	Dolomite (%)	Dolomite thickness (m)	Zone thickness (m)
1	55.3	1.4	2.5
2A	10.1	1.5	14.5
2B	24.8	5.2	21.0
3A	21.8	4.1	18.8
3B	10.5	1.7	16.0
Total Arab D	13.9	9.9	71.3

Fig. 10.25 Block diagram shows average percent dolomite in different Arab D reservoir zones for each field area of Ghawar Field, Saudi Arabia. The table summarises dolomite percent for all Arab D in Ghawar Field (Data re-charted from Cantrell et al. 2001)

systematically from north to south in Zones 2A and 2B, but zone 3A displays an inverse trend by generally decreasing from north to south (Cantrell et al. 2001).

When Cantrell et al. (2001) mapped dolomite distribution over Ghawar Field they identified a series of parallel linear trends of high dolomite content that extended for tens of kilometres along northeasterly trends (Fig. 10.26). These trends are especially obvious in Zone 2B but are also discernable in Zones 2A and 3A. Locally the trends connect areas of pervasive dolomitisation, where much of the section (virtually 100 % of Zones 1, 2A, 2B and 3A) is replaced by dolomite. There may also be some saddle dolomite in these same areas, but it is rare. Northeast trends are present, but less obvious, in southern Ghawar. The trends suggest some structural control to the dolomite distribution and, according to Cantrell et al. (2001), indicate diagenetic patterns that are responses to a series of underlying fractures or faults. These structural features facilitated movement of dolomitising fluids into the reservoir.

As for the dolomites in the Red River Formation discussed previously, what is not clear in Ghawar is whether the dolomitising fluids (other than zone 1 dolomites) were ascending or descending when they drove the dolomitising process. Similar fault- and fracture-controlled distributions of dolomite have been documented by Warren and Kempton (1997) in metalliferous evaporite-sealed Devonian carbonates of the platform margin of Canning Basin, Australia and by Hurley and Budros (1990) in the Silurian Scipio Albion Trend in Michigan. Dolomite's propensity for ongoing alteration and replacement in Ghawar, and its proximity to a fluid-focusing evaporite layer (first as a fluid source and then as a seal) throughout its burial history, means the origin of the Ghawar dolomites is probably not a simple unidirectional fluid flow story (Warren 2000a). Fractures in the host carbonates may have been conduits for descending reflux fluids early in the burial history, but may have then acted as conduits for upwelling fluids later in the field's burial history. During this upwelling stage, various unbreached evaporite seals acted to pond and store escaping basinal fluids. Such flow reversals would overprint early-formed dolomites with later burial signatures.

Partially preserved primary pore spaces in the Arab D limestones throughout the region typically remain as well-defined relicts in evaporite-sealed banks of weakly dolomitised coral-stromatoporoid reefs and skel-ooid grainstones and grain dominant packstones. These build-ups and shoals are also characterised by leached moulds of stromatoporoid and coral branches and other aragonite allochems. Yet, once the overlying evaporite cap was deposited, there is little evidence of subsequent meteoric diagenesis or karst, and little or no evidence of later pervasive diagenesis and calcite cementation. Much of the leaching in the reservoir seems to have been early and perhaps was an integral part of the same reflux hydrology that was dolomitising portions of the Arab Formation adjacent to evaporite beds. Considering their age (≈150 Ma) and relatively deep current burial (1,200–3,000 m), this preservation of widespread primary void skeletal moulds in any limestone is unusual. Wilson (1985) argued the early emplacement of the evaporite capstones atop limestone buildups and the subsequent deposition of the Hith Anhydrite was what preserved economic porosity levels into the burial realm. Burial beneath saltern and mudflat sediment in an environment that was consistently arid and hot meant that once all the gypsum had converted to tight nodular anhydrite beds within the first few hundreds of metres of burial, the resulting seals slowed fluid flow and largely prevented further influx of suprasalt subsurface waters, which would otherwise drive pervasive shallow subsurface cementation in most of the carbonate.

The relatively pristine relict porosity in the reservoir limestones, with solution-mouldic and variably-dolomitised overprints that characterises the Arab D in Ghawar, is a reservoir style that is part of a wider association seen in many evaporite-sealed limestone and dolomite reservoirs worldwide. Such reservoirs tend to show widespread leaching of aragonite allochems without associated karst surfaces or meteoric calcite cements. High Mg-calcite allochems (red algae, echinoids, crinoids) in the same sequence are relatively unaltered or mimetically replaced by dolomite. The process driving this precompaction leaching was not entry of meteoric waters, but flushing and brine mixing driven by early burial through flushing of hypersaline marine brines (Sun 1992). As well as the enhancing porosity in the Arab cycles, such evaporite-associated reflux waters have enhanced porosity levels in formerly aragonitic sediments of the Permian San Andres Fm. of West Texas, and the Miocene carbonates of the Middle East and SE Spain.

Slaughter-Levelland Trend, West Texas and New Mexic

Another region of variably dolomitised limestone forming high volume evaporite-sealed reservoirs within an epeiric carbonate platform is the Slaughter-Levelland trend of New Mexico and Texas (Fig. 10.27a). There the main play is in the Permian San Andres Formation with the occurrence of better quality reservoir defined by the transition from platform carbonates in the south into updip massive anhydrites and halites in the north. The lower member of the San Andres contains two evaporite-sealed intervals (P_1 and P_2) that form the main reservoirs (Fig. 10.27b). The producing style is a stratigraphic-diagenetic trap defined by updip pinchout (to the north) from a porous dolomite into nonporous evaporite-plugged dolomite beneath regionally extensive evaporite seals. Production from most dolomite reservoirs in the trend is slow but constant.

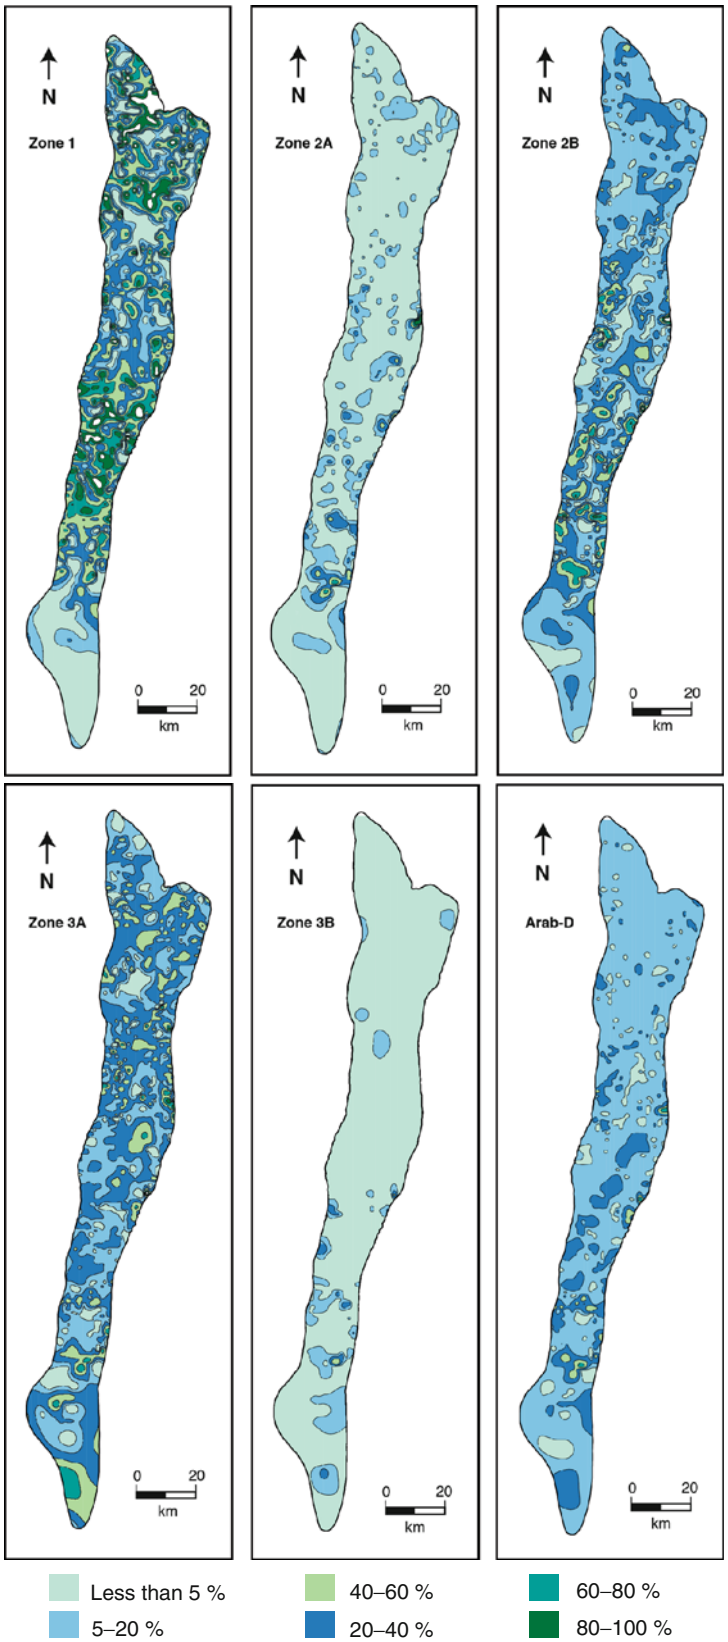

Fig. 10.26 Map of the percent dolomite in the various reservoir zones of the Arab D in Ghawar Field, Saudi Arabia (After Cantrell et al. 2001). Clearly shows a linear fracture-related distribution Zone 2 and in the total plot for the Arab D (*right hand side* of figure)

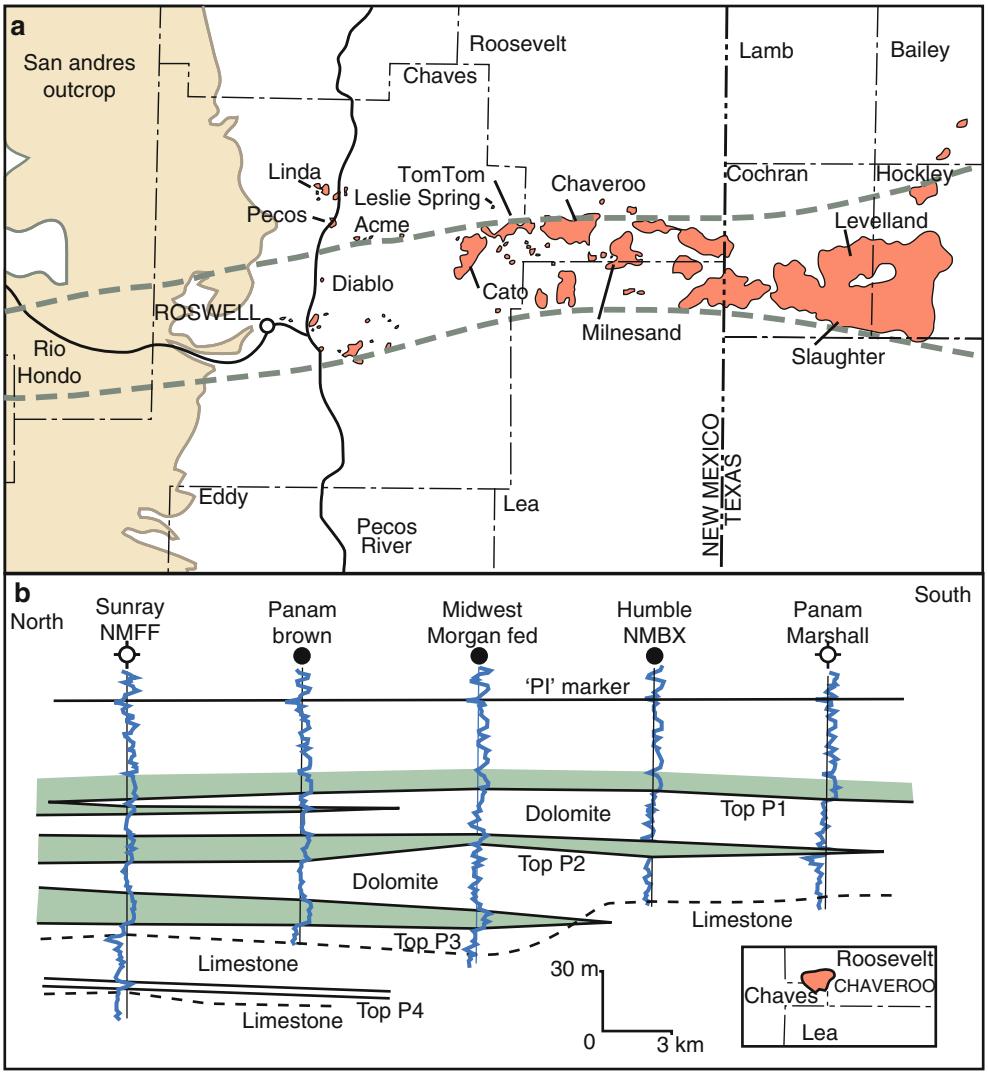

Fig. 10.27 San Andres Formation in the Levelland-Slaughter trend near Roswell, New Mexico (After Elliott and Warren 1989; Warren 1991). (**a**) North-south section through Chaves and Roosevelt counties in the vicinity of Chaveroo Field. (**b**) Map of the Levelland-Slaughter trend and its equivalents in the San Andres outcrop belt west of Roswell

Cleaning-upward cycles in the lower member can be divided into 5 lithofacies groupings (P_1 to P_5) stacked into shoaling upward successions, with each cycle being 15–50 m thick (Elliott and Warren 1989). Shaly carbonate mudstones define the base of each cycle; they are the initial low-energy deeper water deposits formed atop a flooding surface. These laminar mudstones are overlain by more massive biomicritic packstones and wackestones (≈10 m thick) containing brachiopods, bryozoa, crinoids, molluscs, and cephalopods, sometimes forming what may be local low relief bioherms with phylloid algal debris. These various mudstones were deposited on an open marine shelf, initially below wave base and under low-energy conditions.

Next come the dolomitised intervals (typical matrix porosities 10–12 %; permeabilities 20–30 md), which constitute the main reservoir in the trend (Fig. 10.28a). It is by far the most variable carbonate unit and in places retains remnants of primary texture, giving three variably dolomitised subtypes:

1. Wispy laminated to microstylolitised biomicrites, intramicrites, and peloidal micrites and packstones that entrain poorly preserved open marine faunas. Skeletal material is typically preserved as moulds, which near to the anhydrite cap are filled or partially filled with anhydrite cement. This is the most common reservoir unit in the Slaughter-Levelland trend.

2. Oolitic peloid-foram grainstones, which were deposited as localized shoals (uncommon unit in the Slaughter-Levelland trend).
3. Inter- to supratidal mudstones with fenestra, pisolites, biolaminites, and possible desiccation cracks (uncommon unit in the Slaughter-Levelland trend).

Next comes a massive to laminar anhydrite unit that historically was interpreted as a sabkha deposit (Ward et al. 1986). It is metres-thick in the Slaughter-Levelland trend and is made up of a dm-scale interbedded nodular anhydrite and laminated anhydrite. Some cores immediately to the north of the field preserve vertically aligned anhydrite nodules (gypsum "ghosts"), which pass downward into laminated and bedded nodular mosaic anhydrite (Fig. 10.28b). The alignment, the lamination, the purity, the thickness of the units, and the fact that it is laterally equivalent to subaqueous platform gypsum to the north implies that in the Levelland–Slaughter area this unit was laid down near the depositional edge of a saltern (Elliott and Warren 1989). In the Palo Duro Basin, situated further to the north of the Slaughter-Levelland trend, the equivalent to the various saltern anhydrite caps are overlain by saline-pan halites.

To the west of Roswell the outcrop, equivalents to the anhydrite seals are dissolution breccias, which can be used as a regional mapping datum in the vicinity of the Rio Hondo outcrops (Elliott and Warren 1989). Lateral facies changes can be seen in each outcropping cycle, showing the carbonate intervals were deposited as facies mosaics on an extensive relatively low energy muddy carbonate marine platform, with each cycle separated by evaporites.

The mosaic distribution of the reservoir carbonates and a lack of grainstone and shoreline/strandline shoals, either in outcrop or the subsurface, led Elliott and Warren (1989) and Warren (1991) to revise the reservoir model for San Andres deposition the Levelland-Slaughter Trend. In contrast to previous models that saw the reservoirs in the Slaughter Levelland trend as sabkha-sealed depositional pinchouts, they argued sabkhas are a relatively minor component in the widespread subaqueous saltern seal. Rather than a stratigraphic control the reservoir dolomites were created by brine reflux through relatively muddy epeiric platform carbonates via brines fed from updip salterns (Fig. 10.29; Warren 1991).

This saltern edge model of San Andres deposition offers a different exploration strategy for the San Andres reservoirs on the Northwestern Shelf of the Permian Basin and elsewhere (Warren 1991). Generally, saltern-associated reservoirs do not form by updip pinchout of marine grainstones and mudstones into stacked sabkhas. Rather, the reservoir trend marks the transition from an updip, evaporite-plugged, partially-dolomitised subtidal–intertidal section into a dolomitised, subtidal–intertidal sequence characterized by intercrystalline and relict interparticle porosity. Unlike areas closer to the source of the reflux brines and beneath the saltern proper, these regions are not pervasively plugged with evaporite cements. This dolomitised zone passes down-dip into more tightly-cemented open marine subtidal limestones. Updip plugging was driven by episodes of widespread evaporite deposition and the associated sluggish reflux of supersaturated brine into the underlying newly forming dolomites. The downdip subtidal–intertidal section saw some evaporitic plugging, but it did not suffer the longterm massive influx of evaporite cements experienced further updip. Its more marine-marginal position allowed the porosity to remain open and magnesium-rich solutions associated with brine reflux to enter the carbonates to evolve into more coarsely crystalline dolomites. The Levelland-Slaughter reservoir trend is not a palaeoshoreline, nor is it a stratigraphic pinchout trap. It is a diagenetic front and trap with the best reservoir quality defined by the zone immediately downdip of the thinning edge of the San Andres saltern (Warren 1991).

Dolomitised Limestones, Central Basin Platform, West Texas

The same diagenetic control to reflux dolomite intensity seen at the regional scale in the Levelland Slaughter trend is also true at the oil field scale on the Central Basin Platform to the south. Saller and Henderson (1998) noted similar variations in reflux-related "dolomite intensity" controlling reservoir properties in the evaporite-sealed North Riley Field at the northern margin of the Central Basin platform and in South Cowden Field on the east-central margin of the Central Basin platform, Texas (Fig. 10.30a). The main reservoir units in North Riley Field are permeable dolomites of the Leonardian (Permian) Clear Fork Formation, while dolomites of the Grayburg Formation (Guadalupian, Permian) are the main reservoir in South Cowden Field. Replacive dolomitisation and the creation of intercrystalline porosity in both fields was driven largely by the reflux of evaporatively concentrated seawater circulating shortly after deposition of the original limestone matrix.

Ongoing reflux-driven evaporite plugging means porosities and permeabilities are lower in platform-interior dolomites and higher in dolomites near the platform margins in both fields (Fig. 10.30b). Reservoir porosity and permeability are not strictly facies dependent in either field. As in the Slaughter-Levelland trend, Saller and Henderson (*op cit.*) found the distribution of porosity and permeability is largely the result of location within the diagenetic dolomitising system and to a lesser extent reflects the original depositional permeability of the limestones.

Due to inherently higher brine densities beneath an evaporite-depositing lagoon or saltern, the dense saline dolomitising brines, generated by evaporative concentration of seawater in restricted evaporitic mudflats and salterns, percolated downward and seeped basinward

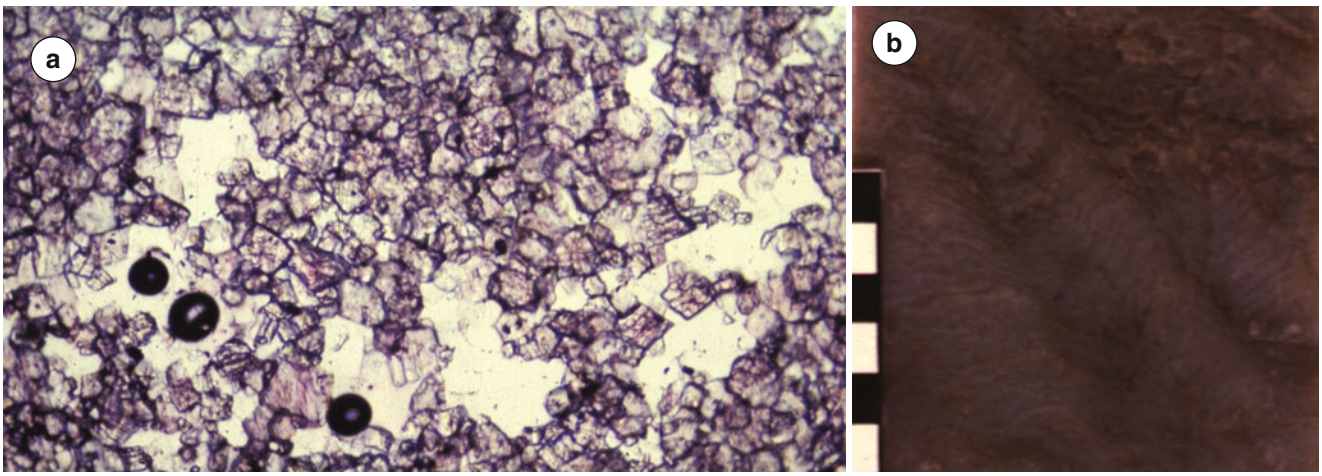

Fig. 10.28 Lithofacies of the San Andres Formation. (**a**) Dolomitised pel-mouldic wackestone/packstone showing angular highly altered pelloidal outlines, moulds can be plugged by anhydrite (image is about 2 mm wide). (**b**) Elongate nodules of anhydrite typical of the seal facies showing remnant subaqueous gypsum ghosts with internal swallowtail-V's still visible (scale bar in cm)

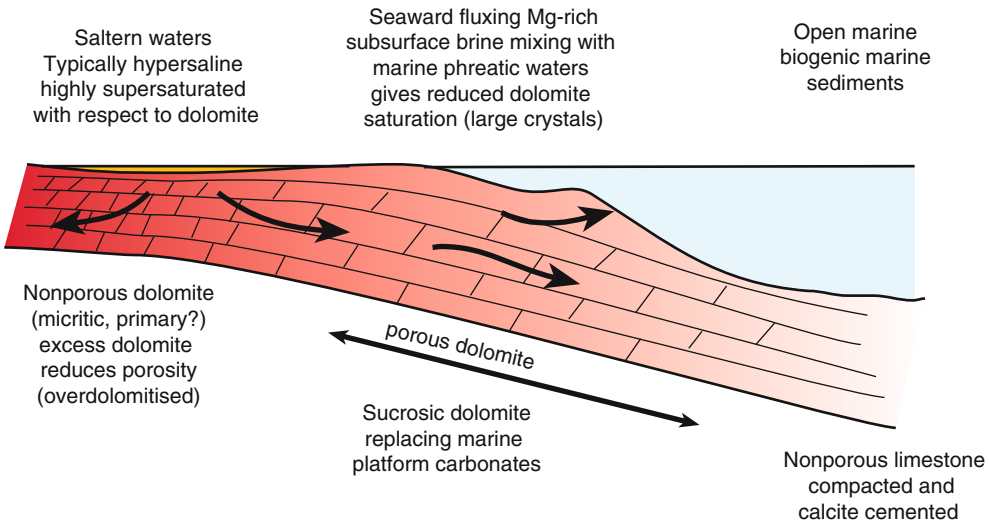

Fig. 10.29 Reflux brines drive dolomitisation in marine carbonates some distance downdip from intervals of more restricted shoreward carbonate that tend to be overdolomitised and evaporite plugged (After Saller and Henderson 1998 and Elliott and Warren 1989, see also Fig. 10.9)

(refluxed) through the sediments. Refluxing brines, supersaturated with respect to dolomite and calcium sulphate, precipitated large quantities of dolomite and anhydrite cement in the proximal parts of the reflux system. This lowered dolomite saturation in waters flowing into distal portions of the reflux system. Lower dolomite saturations resulted in less dolomite, fewer nuclei and larger crystals (not overdolomitised) along with more intercrystalline porosity and permeability retention in distal parts of the system (Fig. 10.29). Many platform-interior wells in both fields are structurally higher than wells near the platform margin, yet structurally lower wells near the platform margin are more porous and permeable, and have produced three to ten times more oil than the platform-interior wells (Saller and Henderson 1998).

Reservoirs in the Jurassic Smackover Fm., Gulf of Mexico

More than 1 billion barrels-equivalent of oil and gas has been discovered in the Smackover of the northeastern Gulf Coast Basin (Prather 1992a, b). The majority of these hydrocarbons are found in a few large fields such as Jay, Big Escambia Creek, Blackjack Creek, Chunchula, and Hatter's Pond, and the fields in the Mobile Bay complex. Except for the fields in the Mobile Bay complex, which have Norphlet Sand reservoirs, the Smackover Formation is the primary hydrocarbon reservoir in the large fields and many smaller fields, such as Vocation, Barnett, Uriah, and Appleton. Like the Arab D in the Middle East, the richness of Smackover hydrocarbon system in the region is a result of the co-occurrence of microlaminated lime mudstone source rocks, dolostone reservoir

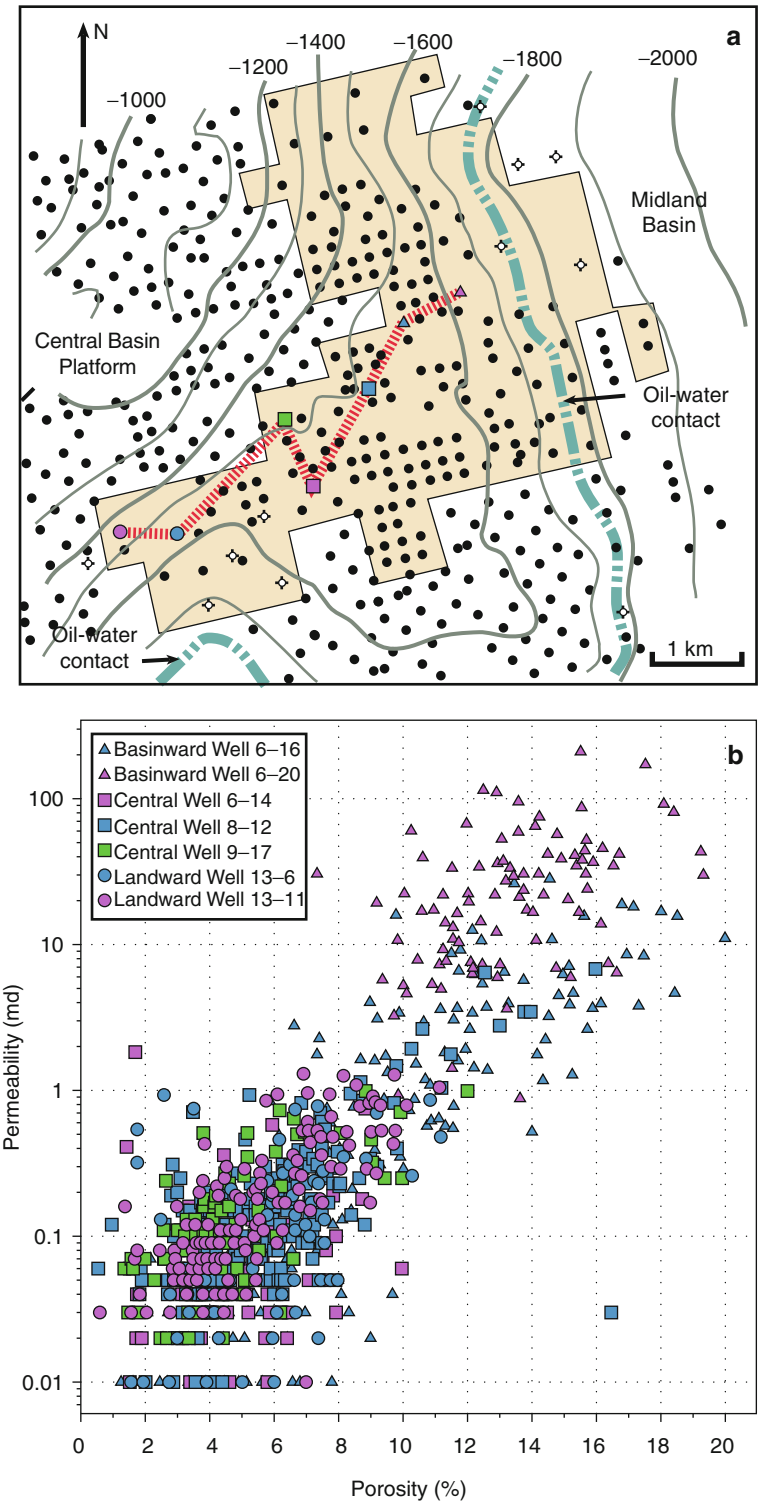

Fig. 10.30 South Cowden Field, West Texas (After Saller and Henderson 1998). (**a**) Well transect runs from the overdolomitised evaporite-plugged platform (○) to a dolomitised transitional zone (□) to the more basinward partially dolomitised platform wells with minor evaporite plugging (△) (**b**) porosity permeability from all measured plugs in wells along the transect. Increase in reservoir quality corresponds to a decrease in evaporite plugging and an increase in dolomite crystal size along the downdip reflux pathway (as shown in Fig. 10.29)

rocks, and an evaporite cap, all within an overall shoaling depositional package (Moore 1984; Heydari 1997).

The Smackover Formation forms a subsurface arc about the Gulf of Mexico and was deposited in a transgressive-regressive event during Upper Jurassic (Oxfordian) time (Fig. 10.31a). It is underlain by the siliciclastic eolian-wadi Norphlet Formation in more marginward areas and by the Louann Salt Formation further out in the Basin. The Smackover, and the overlying Buckner Anhydrite Member of the Haynesville Formation, were deposited in three depositional stages that correspond to periods dominated by marine transgression, aggradation,

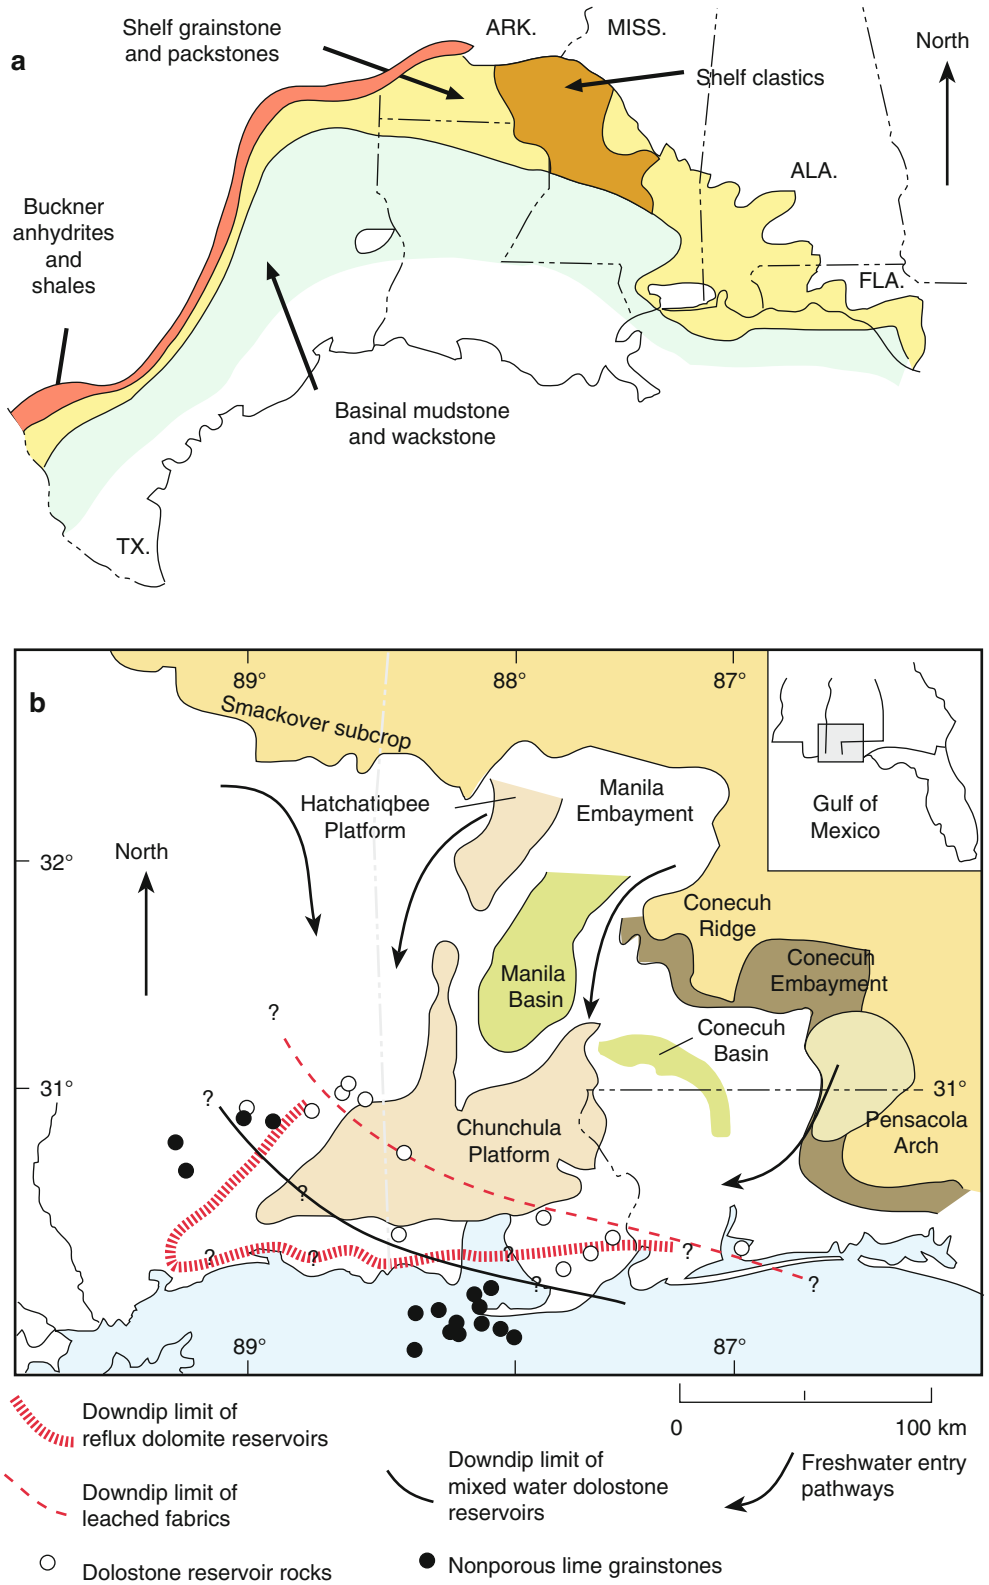

Fig. 10.31 Smackover Formation, Northern Gulf of Mexico. (**a**) Generalised map of Smackover distribution along the coast of the United States (After Melas and Friedman 1992). (**b**) The downdip limit of reflux and shallow burial mixed water zones occurs between dolostone reservoir rocks and nonporous lime grainstones (After Prather 1992a)

and ultimately progradation. The Buckner Evaporite and its equivalents, which form the seal to the various upper Smackover fields was interpreted as sabkha until the mid 80s (Lowenstein 1987a). But in the 90s its interpretation changed to an evaporitic mudflat, a mosaic of sabkhas and salinas passing up and laterally into a saltern (Mann 1988, 1990; Mann and Kopaska 1992; Prather 1992a, b; Benson et al. 1996).

The Smackover is a combination of platform dolomites, shelf-margin oolitic and peloidal grainstones, and slope and basin limestones. It can be subdivided into three informal units, the lower, middle, and upper Smackover (also known as Smackover C, B and A, respectively). Each unit was deposited in a different depositional setting on a gently shoaling carbonate ramp. Lower Smackover deposition accompanied a rapid sea level rise that inundated most palaeohighs in the basin to produce a depositional system that was first transgressive and then aggradational in nature (Benson et al. 1996; Prather 1992a, b). Most sediment in the lower Smackover is basinal and consists of laminated dark brown to black mudstone, alternating with laminae of pyritic siliciclastic silt or sand. Locally it is organic rich and has acted as a source rock for the hydrocarbons accumulated in the overlying Smackover sands (Heydari 2000). Lamina style in the lower Smackover changes upward from very thin parallel laminae near the base to thicker irregular laminae higher in the section. Algal patch reefs grew in lower Smackover time around the periphery of some palaeohighs, driven by the rising sea.

The middle Smackover is composed of sediments deposited on a low-energy, open-marine platform, laid down as sedimentation caught up with relative subsidence. Short-term sea level fluctuations produced numerous shallowing-upward packages (parasequences) in the middle Smackover. Two lithofacies are typical of the middle Smackover: a wispy-laminated, crustacean-pellet carbonate mudstone containing a sparse pelagic fauna and a densely burrowed skeletal-pellet wackestone containing a benthic fauna. Tidal flat, lagoon, and shoal complexes formed in topographically higher parts of the northern Gulf, while sub-wavebase sediments were deposited in deeper waters and away from salt structure-induced seafloor shoals.

The upper Smackover consists of several grain-supported lithofacies deposited in shoal settings ranging from strandzone (tidal) bars and channels to beaches, islands, and algal-stromatoporoid reefs. Burrowed pellet and oncolite packstones and algal-stromatoporoid boundstones formed as moderate-energy outer shoals, and sequences of crossbedded mixed allochem, oolite, and oolitic grainstones comprised the current-reworked inner shoals. During upper Smackover deposition, sea level was relatively stable allowing the Smackover to aggrade and prograde. Upper Smackover deposits are peritidal or strandzone dominated. Short-term sea level fluctuations produced shallowing upward packages capped by exposure surfaces in crestal locations and deposited widespread syndepositional isopachous marine cements of aragonite (now calcite).

During lower Buckner deposition, evaporitic mudflats form over the crests of the palaeohighs and pass off-structure and landward into salterns. Short-term sea level fluctuations produced a series of higher-order shallowing-upward evaporitic mudflat cycles behind the main oolite shoal. Development of subaqueous gypsum increased during ongoing restriction of the northern Conecuh Embayment and ultimately led to widespread deposition of the subaqueous saltern evaporite seal that defines the upper Buckner Anhydrite. This unit seals most Smackover reservoirs.

Dolomitised upper Smackover facies constitute the most productive reservoirs. In fact, dolomitisation and leaching are critical to the preservation of economic levels of porosity throughout the Smackover in the northern Gulf of Mexico (Fig. 10.32). Historically, a minimum of 4 % porosity and 0.1 md permeability in Smackover carbonates is considered to be reservoir grade (Becher and Moore 1976). Economic Smackover porosity is of three main types:

1. Partially preserved primary interparticle porosity
2. Leached mouldic porosity
3. Intercrystalline porosity within coarsely crystalline dolomites

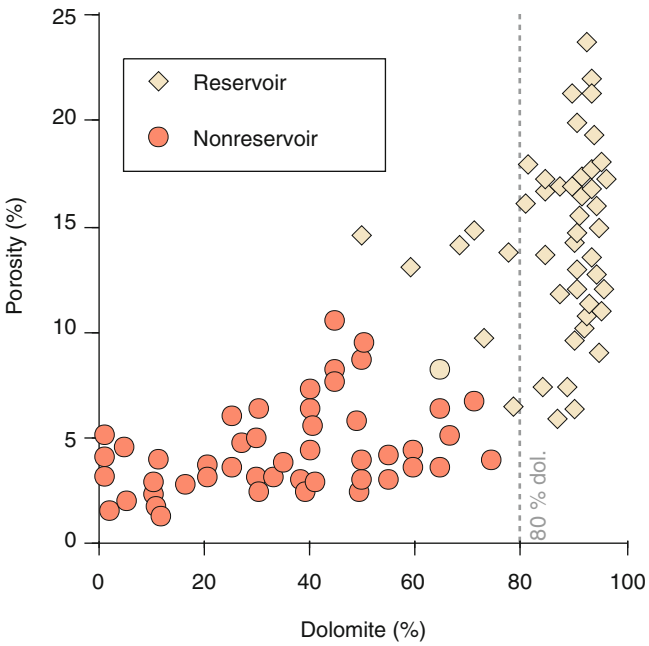

Fig. 10.32 Relationship between porosity and the degree of dolomitisation in Jay Field, Conecuh Embayment. The lower Smackover facies in the field shows low porosity and are relatively less dolomitised compared to the upper Smackover grainstones, which have high porosity and are extensively dolomitised (Data from point count data and are replotted from Melas and Friedman 1992)

Most reservoirs are found in: (a) grainstone shoals, (b) fractured and dolomitised sediments of the inner-shelf and, (c) algal stromatoporoid buildups (Mancini et al. 2000). The best reservoirs in Arkansas, Louisiana and eastern Mississippi are in dolomitised intervals that preserve incompletely cemented interparticle and mouldic porosity (Fig. 10.31a). The updip Smackover close to the palaeoshoreline in this region often contains leached mouldic porosity due to mixed-water flushing. In east Texas, Alabama, and Florida, the precipitation of dolomite with intercrystalline porosity has enhanced the reservoir potential of the Smackover grainstones.

Dolomitization is usually required to form a reservoir in innershelf Smackover sediments and enhances the reservoir character in the grainier shoal sediments. A rule of thumb in the region is that a minimum of 80 % dolomite is necessary for consistently good reservoir quality (Fig. 10.32), but rocks that are 100 % dolomite, or dolomites with pervasive evaporite cements, are not good reservoirs. Individual reservoirs can be as thick as 10 m, with porosities as high as 26 %, and matrix permeabilities as great as 6.5 md. Although enhanced reservoir quality is often related to reflux dolomitisation, the distribution of dolomite, like that of the interparticle porosity and the mouldic porosity, is in large part inherited from porosity trends in the original depositional setting.

Geochemical and petrographic data suggest that calcite/aragonite alteration and dolomitisation took place in: (1) phreatic seawater-seepage, (2) brine reflux, (3) nearsurface mixed-water, (4) shallow-burial mixed-water, and (5) deeper burial environments. These settings overlapped in time and space to form a "platform-scale" dolostone composed of a complex mixture of dolomites and authigenic cements (Prather 1992a). Of the five, the brine reflux and the deeper burial settings can be thought of as end members of a diagenetic spectrum creating dolomites. They are also the most easily separable of the five using isotopic signatures (Fig. 10.33a). The other three form a related but overlapping group of subsurface alteration features. Texturally, without isotopic data and with the exception of early isopachous rim cements, it is very difficult to assign origins to the various replacements and cements that typify the Smackover reservoirs.

Brine reflux dolomitisation of the upper Smackover was largely driven by movement of hypersaline brines created by deposition of the overlying Buckner Anhydrite member of the Haynesville Formation. Flushing by dense brine explains the distribution of early dolomite in southeastern Alabama and western Florida (Barrett 1986; Saller and Moore 1986; Worrall and Warren 1986). Such beds constitute thin zones within the upper 5–7 m of the Smackover throughout the Conecuh Embayment and show enrichment in $\delta^{18}O$, which is indicative of precipitation from evaporated brines. Replacement of precursor marine cements by dolomites rich in ^{18}O places this phase of dolomitisation early in the paragenetic sequence, consistent with a reflux origin parallel to the basin strandline or palaeoshoreline. Thicker zones (5–15 m) of isotopically-enriched reflux dolomite occur locally around the Conecuh Ridge, Pensacola Arch, and over the Chunchula Platform (Fig. 10.31b). Time-slice lithofacies maps show that these thicker dolomite zones correspond to the locations of coastal evaporitic mudflats, which were first established on palaeotopographic highs within a pericontinental setting (Prather 1992a). These zones show aggradational geometries produced during an early regressive phase of Smackover/Haynesville deposition. Thicker zones of enriched dolostone probably formed in these areas because of the ongoing aggradation of the reflux dolostone host through time.

Thin zones of enriched dolostones similar to those over most of the Conecuh embayment also occur sporadically around the flanks of the Chunchula Platform, Manila Basin rim, and the flanks of the Hatchatiqbee Platform (Fig. 10.31b). The downdip limit of thin reflux dolostones tentatively, inferred from very limited well control, appears to parallel depositional strike. Thinness or absence of enriched dolomite zones updip of this line may be associated with rapid progradation of the shoreface/coastal-sabkha couplet resulting in rapid lateral shifting of reflux zones, which prevented aggradation of reflux zones and allowed little time for refluxing brines to circulate deeper into the upper Smackover grainstones.

Brine reflux was driven by Buckner deposition and was tied to regional drawdown hydrology in the region behind the oolite shoals. Drawdown driving the reflux also influenced porosity evolution in the adjacent Smackover shoals that formed the isolating sill. For example, the drop in relative sea level in the Conecuh Embayment during the Oxfordian (Prather 1992b) exposed thick submarine oolite sand bars of the upper Smackover on the southern flank of the Conecuh Basin. It created a subaerial sill, which separated the Conecuh Basin from the Gulf, as more than 100 m of Buckner salts were laid down as a saltern within the isolated intraplatform sag. The sill today consists of a thick (18–55 m) lower unit of medium to finely crystalline sucrosic dolostone and oolite dolograinstone overlain by a thinner upper unit of finely crystalline oolite dolograinstone. $\delta^{18}O$ analysis indicated that the dolostone in the sill is composed of three populations of dolomite. Two populations of dolomite depleted in ^{18}O occur in the lower sill (Fig. 10.33b, groups II and III). A third population found in the upper part of the sill is relatively enriched in ^{18}O (Fig. 10.33b, group I). The contact between the upper and lower units is gradational over about 1 m and has no apparent relationship to stratal boundaries. This contact was first noted by Vinet (1982) in wells from Jay, Blackjack Creek, and Big Escambia Creek fields, and was subsequently located in more wells by Prather (1986).

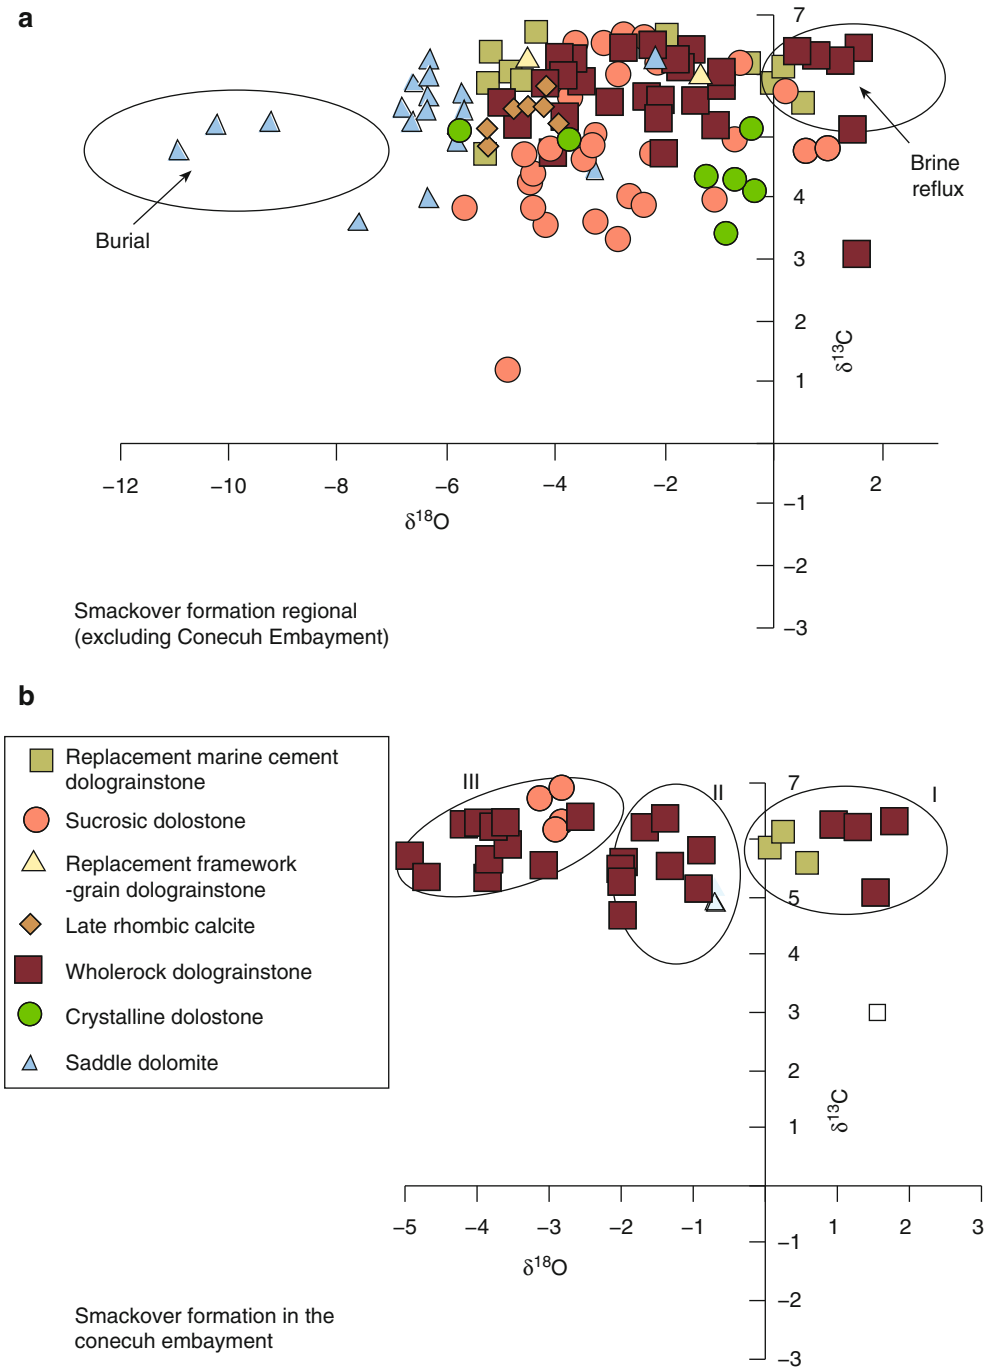

Fig. 10.33 Stable isotopic signatures of the Smackover Formation, Northern Gulf of Mexico (After Prather 1992a). (**a**) Plot of $\delta^{18}O$ and $\delta^{13}C$ of dolomites from the Northern Gulf of Mexico, excluding the Conecuh Embayment and deeper burial dolomites. (**b**) Plot of $\delta^{18}O$ and $\delta^{13}C$ of dolomites from Conecuh Embayment

The association of a relatively abrupt localized geochemical and lithologic discontinuity within rocks beneath a sill that was subaerial during a sea level lowstand suggests the discontinuity may represent a fossil watertable (Prather 1992a). If this is the case, the following events must have taken place: (1) partial dolomitisation of the lower unit as seawater seeped through the sill to recharge the saltern brines in the Conecuh Basin, (2) complete dolomitisation of the upper unit by reflux processes as the upper sill was buried during aggradation and progradation of Buckner evaporites (fill and spill sedimentation of the basin), and (3) continued burial dolomitisation of the lower unit by ^{18}O-depleted dolomitising fluids. Each of these events gave rise to each of the three isotopic groups of dolomite from

the sill: (1) seawater seepage dolomite with $\delta^{18}O$ values of −0.6 to −1.9‰, (2) reflux dolomite with $\delta^{18}O$ values of 2.0–1.0‰, and (3) later burial dolomites with $\delta^{18}O$ values of −2.6 to −4.6 ‰ (Fig. 10.33b).
