
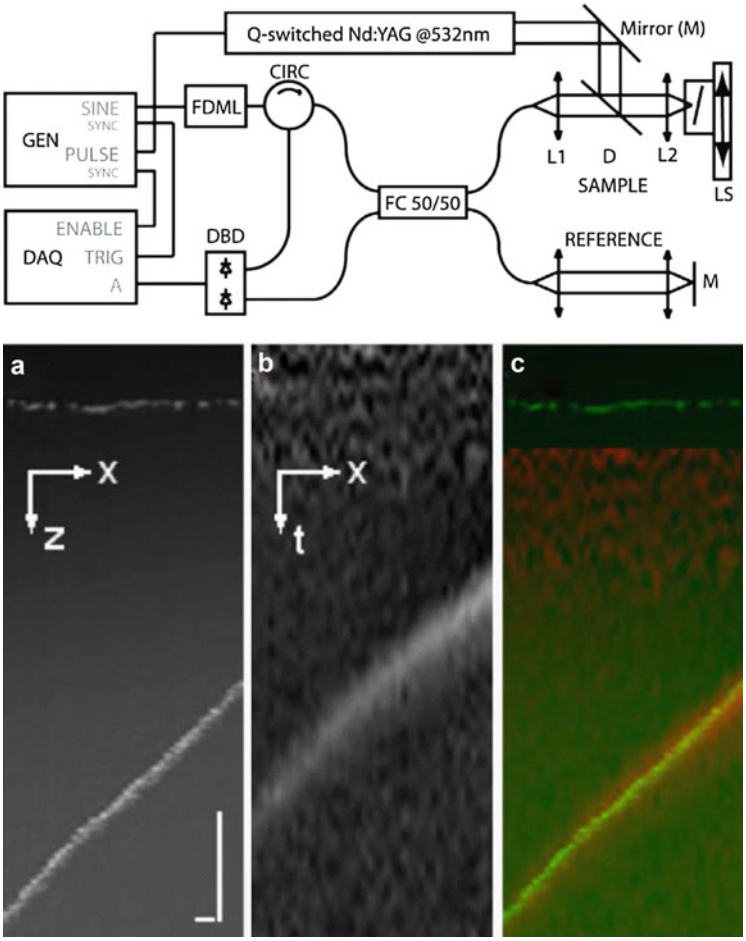

Fig. 24.19 FDML for contact less photoacoustic imaging [103]. *Top*: Setup for noncontact photoacoustic signal detection with an FDML-based OCT system. *Bottom*: (**a**) OCT contrast image, (**b**) photoacosutic contrast image, (**c**) combined contrast image of a phantom

24.6.5 FDML for Noncontact Photoacoustic Imaging

Another application that has been demonstrated by Blatter et al. [103] with an FDML laser makes use of the phase stability of FDML in combination with the high fringe frequency of the FDML OCT signal. The high fringe frequency and sweep speed of FDML-based OCT require high analog detection bandwidth and digital sampling rate. Because of this, the OCT system is capable of acquiring transients with nanosecond resolution making it sensitive to the transients which occur in photoacoustic imaging. Using an innovative analysis concept of the OCT fringe data, Blatter et al. could demonstrate the simultaneous detection of OCT and photoacoustic contrast in a phantom [103] (Fig. 24.19).

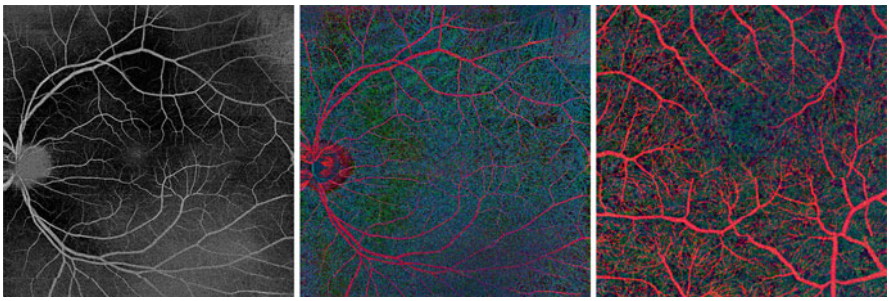

Fig. 24.20 Retinal ultrawide field microangiography with FDML [61]. *Left*: bw-contrasted wide field image. *Center*: Wide field image with color-coded depth. *Right*: Zoomed in view of foveal region

24.6.6 FDML for Functional Ultrawide Field Microangiography

The applications detailed above used the phase information mainly to acquire entirely new types of images with a contrast sensitive to contrast agent concentration or photoacoustic signal strength. However, the OCT phase information can also be used as a very powerful tool to add additional contrast to standard OCT images. Especially contrasting blood vessels appears to be a very important functional extension of OCT in the future. Microangiography using OCT has been demonstrated with different experimental setups that do not necessarily required FDML lasers [112]. However the increased imaging speed of FDML enables the acquisition of large fields of view at reasonable imaging time and without the need of mosaicing (Fig. 24.20).

24.7 Megahertz (MHz) and Multi-megahertz (Multi-MHz) OCT Using FDML

Imaging speed is one of the most important performance parameters in OCT. The 10× speed increase from ∼3 kHz A-scan rate of old time domain OCT systems to ∼30 kHz of spectral domain systems in 2003 triggered a paradigm shift in OCT imaging with respect to imaging protocols, averaging strategies, and data analysis approaches. A further 100× increase in imaging speed well into the megahertz (MHz) line rates can open many more entirely new fields of OCT applications. Live 3D surgical guidance, large area survey scans, functional OCT analysis, and many more are just a few applications where megahertz and multi-megahertz imaging speeds are mandatory. There have been a few demonstrations of concepts which are potentially capable of multi-MHz line rates [77–80]; however due to the challenging requirements of OCT, especially with respect to system sensitivity, it is not clear if such concepts can be used for biomedical OCT.

Table 24.6 Selected milestones in fast OCT with live 3D

	Year	Eff. line rate kHz	Vol. rate (Hz)	Data MS/s	Volume size depth x W x H	MV/s	Real-time visualization

Only two techniques have achieved multi-MHz 3D OCT imaging of biomedical samples in vivo: (a) spectral domain SD OCT systems using arrayed waveguide technology [108, 109] and (b) FDML lasers as the only swept source-based OCT [43, 85]. The combination of performance parameters makes FDML a unique source for ultrahigh-speed megahertz OCT. The high sweep speed at a wide sweep range and very good output power performance make FDML the system of choice for many of the most demanding OCT imaging applications. To date there have been very few demonstrations of OCT systems with multi-MHz line rates, not only because of the limited availability of fast FDML laser sources but also because the extreme data stream generated with such fast OCT systems. The most recent systems which are capable of live processing and live 3D display without time limitation have to handle sustained data rates of >2 Gbytes/s [113] (Table 24.6).

At these speeds not only the data stream itself but also the processing poses a problem. Whereas early high-speed OCT systems often used FGPA processing, the advent of software development environments for standard PC graphics boards (GPU) for massively parallel processing leads to a paradigm shift in how to handle the large amounts of data. Today the record in real-time processing and 3D display is at 26 volumes/s, 2.65 million A-scans/s and 1.38 billion voxels/s [107]. The processing includes data transfer to the first GPU, cubic spline interpolation, data resampling, zero padding, Fourier transformation, data cropping, projection to logarithmic scale, transfer to second GPU, 3D volume display (ray cast) [113]. At the heart of the OCT system, a 3.2 MHz FDML laser enables these multi-MHz OCT line rates. The technology of multi-MHz FDML will be discussed in the following paragraphs.

24.7.1 MHz OCT at 1,300 nm

The initial FDML implementations in 2006 achieved sweep rates of up to 370 kHz [27, 59, 62]. Due to the demand for higher imaging speeds, a further scaling of sweep rate was necessary. To push the FDML speed well into the MHz range,

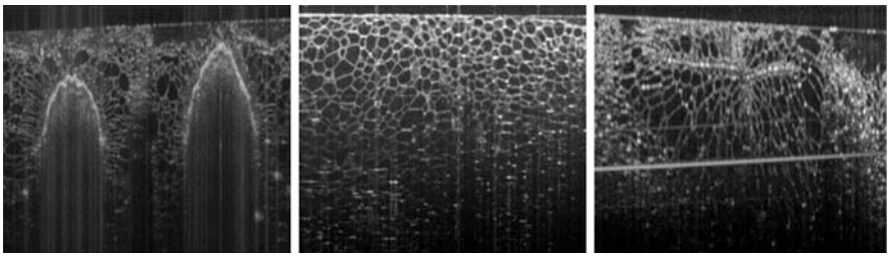

Fig. 24.21 MHz OCT imaging of low scattering samples [43]. MHz OCT images of Kiwi and cucumber 1 MHz (*left*), 2.6 MHz (*center*), and 5.2 MHz (*right*)

a combination of a fast FFP-TF drive frequency and extensive buffering has been applied. The laser design is described in detail in [43].

The most critical point in MHz OCT is the inevitable loss of image quality. On the one hand, the system sensitivity goes down, because at constant power levels on the sample, fewer photons are back reflected from the sample for each sweep, and thus the shot noise sensitivity limit drops. In theory, for many 1,300 nm imaging applications, this point should not be very critical, because the permitted power levels for various samples are often well above 10 mW enabling a sensitivity of ~100 dB even at multi-MHz imaging rates. In practice, it is increasingly difficult to really achieve this theoretical limit, because with the increase in sweep rate, also the OCT signal fringe frequencies are pushed well into the GHz range. For such wide electronic bandwidths, low noise electronics are difficult to implement, or fundamentally not possible. It turns out that the higher the OCT imaging speed, the lower noise the laser has to be to achieve shot noise-limited OCT detection [39]. So the most critical question is: "What OCT image quality can be achieved with multi-MHz FDML lasers?"

Figure 24.21 shows MHz OCT images of low scattering samples at 1 MHz, 2.6 MHz, and 5.2 MHz A-scan rate. Low scattering samples are good to assess the OCT system imaging performance with respect to artifacts, fixed pattern noise, ghost images, etc., because of the low signal levels in between the structures. It can be seen that at all these rates a reasonable image quality is possible. Only at 5.2 MHz the loss in resolution due to a narrower sweep bandwidth is noticeable.

Figure 24.22 shows MHz OCT images of highly scattering samples at A-scan rates of 1 MHz, 2.6 MHz, and 5.2 MHz. Highly scattering samples are good to assess the OCT dynamic range performance, because the high amount of total back reflected power generates high fringe signal levels. Because noise on fringe signals cannot be reduced by dual balanced detection schemes, highly scattering samples can reveal poor amplitude noise performance of the source. Again, it can be seen that at all these rates good overall image quality is possible, and the strong scattering does not generate extensive bands of background signal levels. Only at 5.2 MHz the increased speckle size due to the narrower sweep bandwidth is noticeable.

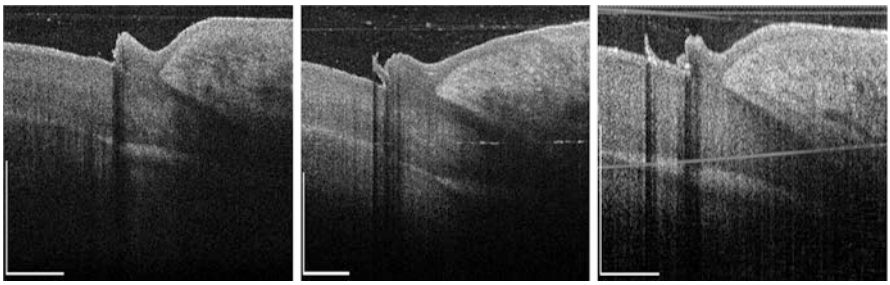

Fig. 24.22 MHz OCT imaging of highly scattering samples (nail bed) [43]. Direct comparison of imaging performance of 1 MHz (*left*), 2.6 MHz (*center*), and 5.2 MHz (*right*). The images show in vivo B-frames of human finger (nail bed). All three images are single non-averaged B-frames consisting of 1,250 A-scans each. The corresponding acquisition times were 1.3 ms, 480 μs, and 250 μs, respectively. Scale bars denote 1 mm in water

24.7.2 MHz OCT at 1,050 nm: Retinal Ultrawide Field OCT

The first multi-MHz FDML OCT imaging has been performed in the 1,300 nm region, because the typical 1,300 nm applications usually have higher permissible exposure levels on the sample. Much more challenging is in vivo retinal imaging, since there the typical OCT power levels are below 1.9 mW. This makes about 95 dB shot noise-limited sensitivity at 2 MHz axial scan rate. Another problem of 1,050 nm is specific to FDML, it is caused by the long fiber delay line. Whereas the linear GVD is zero at 1,320 nm for standard optical fiber, at 1,050 nm standard single mode fiber has about 40 ps/nm/km. Also the fiber and the optical components loss are higher, and active optical elements are less reliable and lower power.

In 2011, Klein et al. published the first swept source MHz 1,050 nm ultrawide field retinal OCT [45]. The high imaging speed allowed for the first time a single shot ultrawide field coverage of $\sim 70^\circ$ with dense isotropic sampling. Figure 24.23 (top) shows an OCT image acquired in 2012 with a newer 1.68 MHz system using a dispersion-compensated 1,050 nm FDML laser [85, 111]. A series of 3D OCT data sets consisting of 1,088 frames with 1,088 A-scans was acquired in 0.85 s each, i.e., a rate of 1.2 volumes/s sustained over 24 volumes. Despite the high speed, the quality is good, penetration well through the choroid is observed, and the long ranging depth without sensitivity roll off of the laser enables visualization of the entire nerve head structure. Figure 24.23 (bottom, left) shows a fundus projection, reconstructed from the 3D OCT data set. Because of the high sampling density in both directions, the quality approaches the quality of scanning laser ophthalmoscopic images, which enable a very accurate absolute registration of the scans for follow-up studies. Figure 24.23 (bottom, right) shows the additional advantage of ultrawide field OCT en face reconstruction over standard SLO, i.e., the depth resolved extraction of image contrast from different layers of the retina. The image shows a color-coded visualization.

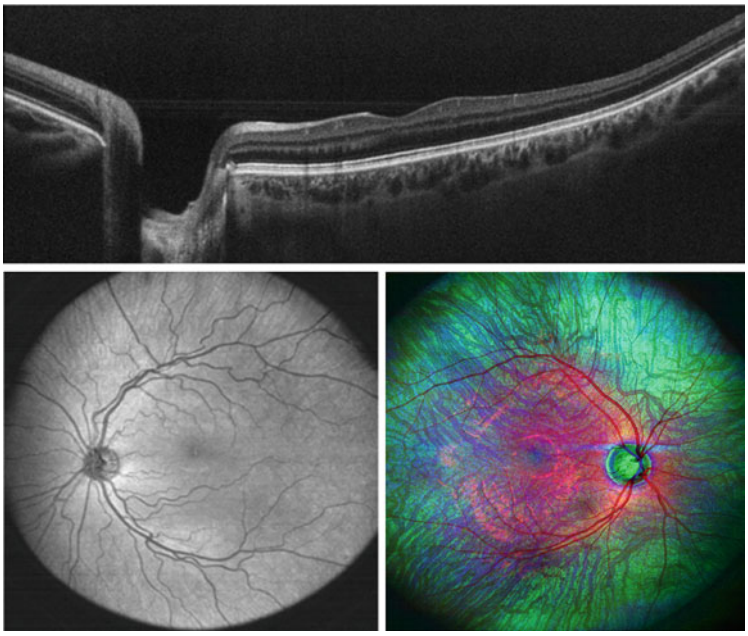

Fig. 24.23 Ultrawide field retinal MHz [45, 85, 111]. *Top*: Averaged cross section – 3D volumes consisting of 1,088 frames and 1,088 A-scans acquired in 0.85 s each or 1.2 volumes/s. *Bottom left*: High-definition reconstructed fundus view (1,900 × 1,900 data set). *Bottom right*: The densely sampled ultrawide field 3D data set enabled for the first time high-definition depth resolved en face projections and segmentations over a large part of the anterior pole

So in summary, FDML lasers have demonstrated the capability of OCT systems going well into the multi-MHz scan rate range. For many applications, the image quality is already sufficient. The results have triggered vibrant research efforts on other alternative laser designs, and currently several non-FDML lasers appear to be good candidates as the second multi-MHz OCT laser source. So it can be expected that in the future other swept sources also achieve MHz sweep rates which will make MHz and multi-MHz OCT applications more easily accessible for research groups.

24.8 Parallel Techniques: Multi-spot OCT Systems

24.8.1 The Problem of Low Sensitivity at MHz OCT Imaging Speed

The initial demonstrations of multi-MHz OCT have shown good image quality. However, especially at 1,050 nm, it should be considered that the data was acquired in a healthy volunteer. For routine imaging in clinical practice and in patients with cataract, the system sensitivity of the MHz OCT might not be sufficient.

Figure 24.24 shows a graph with the different values of shot noise-limited sensitivity for various MHz imaging speeds. It can be seen that with 1.4 mW on

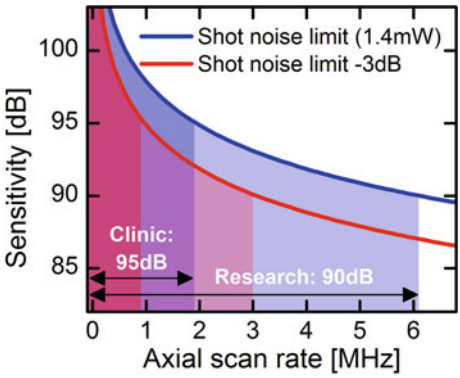

Fig. 24.24 Maximum possible MHz OCT speed for retinal imaging applications. The figure shows the theoretical shot noise limit and the sensitivity that can realistically be achieved (−3 dB) due to losses in the imaging setup. With a required sensitivity of more than 95 dB, this sets an upper OCT speed limit of ∼2 MHz line rate [85]

the sample, the imaging speed for clinical applications should not exceed 2 MHz. From a physical point of view, it could be argued that faster OCT imaging also leads to a lower amount of energy at each spot on the sample and that the power can be increased linearly. Indeed, the scanning operation is not considered in current OCT systems, so from a viewpoint of ANSI standards, more power could be applied in case the scanning operation is ensured. However, since in research very often multi-scan protocols are applied, where the OCT scans several times over the same sample spot, the situation would get very complex and the OCT system power would need to be changed depending on the imaging protocol. So it is preferred to find another solution.

24.8.2 Increasing the Sensitivity of MHz OCT I: Multi-spot OCT

The first solution is to apply several parallel OCT detection channels. The concept of multichannel OCT is used in the "multi-beam" OCT systems of Michelson Diagnostics, where four channels with different focusing increase the depth of field. However in this case, the total power on the sample is quadrupled at a single spot. Vitkin et al. [41] and Wieser et al. [43] demonstrated in 2010 a setup where the different spots are separated on the sample by a distance of several millimeters. Potsaid et al. [94] applied this concept to the human retina. Since this concept distributes the heat load on the sample caused by the OCT laser, more power can be applied. To distinguish this configuration from the four-beam incident on the same spot on the sample, the approach with separated spot is termed multi-spot OCT. Depending on the separation, each spot of the OCT system can have the same power as a single spot system. The ANSI standard usually defines a circular area over which the laser power has to be integrated to be considered in the exposure estimations.

Figure 24.25 shows the beam delivery optics for multi-spot detection. It should be noted here that multi-beam, multichannel, and multi-spot setups are usually more compatible with swept source OCT than with spectral domain systems. It is technically easier, cheaper, and more compact to use several photo-receivers and

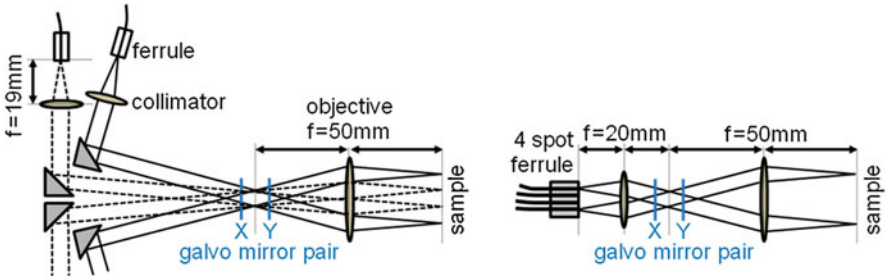

Fig. 24.25 Multi-spot beam delivery for multi-MHz OCT [43]. *Left*: Multi-beam setup with four individual collimators for reduced aberrations [43]. *Right*: More compact setup, but with increased lens aberrations [41]

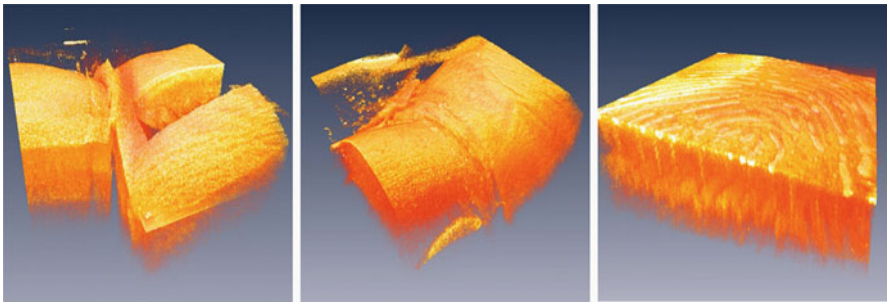

Fig. 24.26 Multi-spot MHz OCT images [43]. 4 × 1 MHz = 4 MHz (*left*), 4 × 2.6 MHz = 10.4 MHz (*center*), 4 × 5.2 = 20.8 MHz (*right*) – fastest 3D OCT to date

analog-to-digital converter channels than to build several spectrometers. Figure 24.26 shows 4-spot MHz OCT up to 20.8 million A-scans per second. With a rate of 4.5 billion voxels per second, this represents the fastest 3D OCT imaging to date. However, the data has not been processed and displayed live and in real time. The data was not streamed; only one volume could be acquired. But the data clearly shows the possibility of good image quality at 20 million OCT depth scans per second. A similar approach has been followed for retinal OCT imaging with MHz FDML lasers at 1,050 nm. In Ref. [85], Klein et al. investigated how well the different volumes from a multi-spot retinal OCT system can be aligned. The system ran at 2 × 3.35 = 6.7 MHz. Here the problem is non-reproducible aberrations caused by the lens of the human eye. For first investigations the system was operated at 2 × 800 μW, so half of the power is permissible for single spot. Figure 24.27 shows the results. It can be seen that both volumes can be fused very smoothly. However, the image quality of the individual spots exhibits very low signal levels. The combination of 3.35 MHz and 800 μW causes a sensitivity of only ~88 dB.

The concept of multi-beam approaches can significantly reduce the thermal stress on the sample and can increase the allowed power exposure levels according

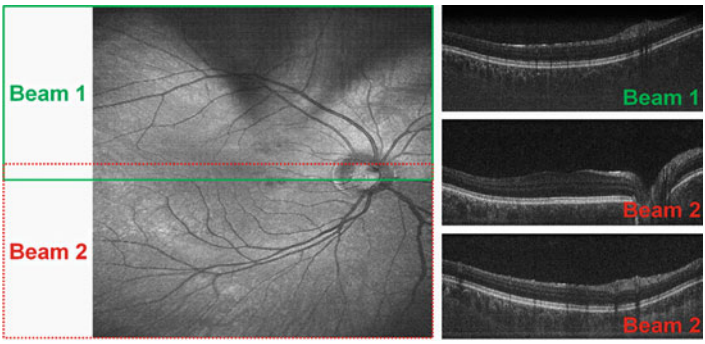

Fig. 24.27 6.7 MHz multi-spot OCT in human retina. Two volumes acquired with the different spots can be seamlessly fused. At 6.7 MHz A-scan rate, this is the fastest flying spot retinal 3D OCT to date [85]

to ANSI standard by splitting up the power to the different beams. However, as can be seen in Fig. 24.27 (left), an overlap region is required for numerical fine alignment and correction of potential image distortions caused by the lens aberrations. The overlap region is scanned twice which has to be considered calculating the power levels. A solution that can increase signal levels without increasing the total power will be presented in the next section.

24.8.3 Increasing the Sensitivity of MHz OCT II: Joint-Aperture OCT (JA-OCT)

A very recent technique in retinal MHz OCT is the so-called joint-aperture (JA) detection [111]. It is a multichannel OCT technique; however there is no multi-beam or multi-spot technique. JA-OCT is specifically tailored to ultrahigh-speed OCT systems. JA-OCT combines illumination from a standard active OCT channel with passive detection on a multitude of additional passive channels (Fig. 24.28, left). The active channel is equivalent to the single channel in a standard OCT system. However, no light is incident on the sample from the passive channels; they only collect light that is backscattered under an angle with respect to the beam from the active channel. This multiplexed approach combines the advantages of angle-resolved detection and does not sacrifice imaging speed. Additionally, the collection efficiency and thus the effective sensitivity of the OCT system are increased, and the quality of the OCT signal from the active beam is not compromised. As mentioned, both aspects are very important for ultrahigh-speed OCT systems, which already suffer from relatively low signal levels due to lower exposure time. Figure 24.28 (right) shows two possible layouts of a JA beam delivery system.

For JA-OCT the interferometer configuration is slightly different for the active and the passive channels. The layout of a JA-OCT system is shown in Fig. 24.29. The reference arms for the passive channels are Mach-Zehnder-type configurations,

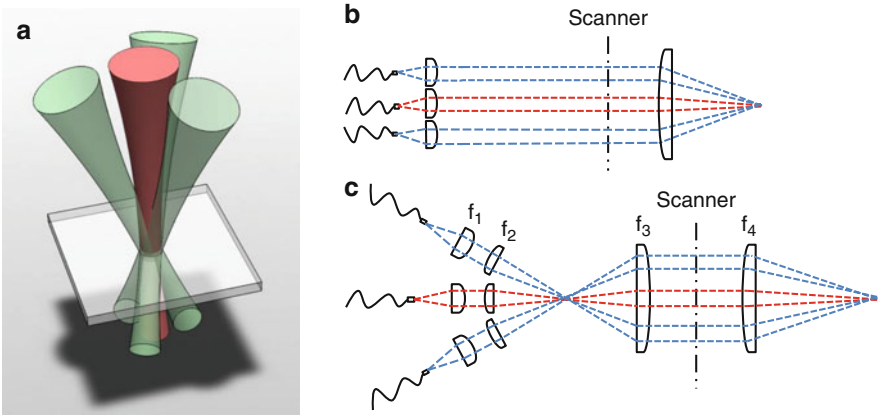

Fig. 24.28 Joint-aperture OCT [111]. *Left*: Concept of joint aperture. *Right*: Different implementations, without (**b**) and with (**c**) intermediate focus

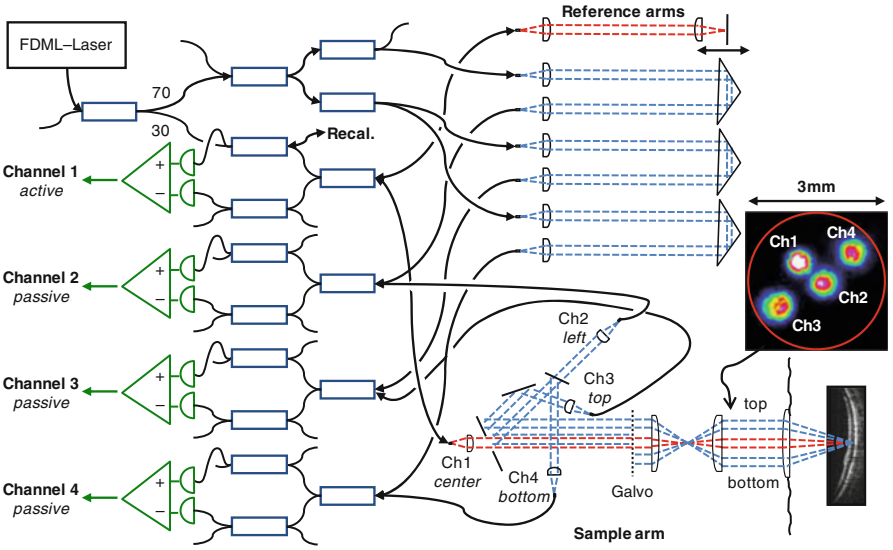

Fig. 24.29 JA-OCT interferometer [111]

and the one for the active channel a Michelson type. The beams, or in the case of the passive channels the beam paths, are combined via D-shaped mirrors and a mirror with a center hole. The losses due to clipping are several 10 %.

Figure 24.30 shows a comparison of image quality for standard OCT and JA-OCT at different levels of frame averaging. It can be seen that the image quality with respect to signal levels and especially with respect to speckle noise is significantly improved.

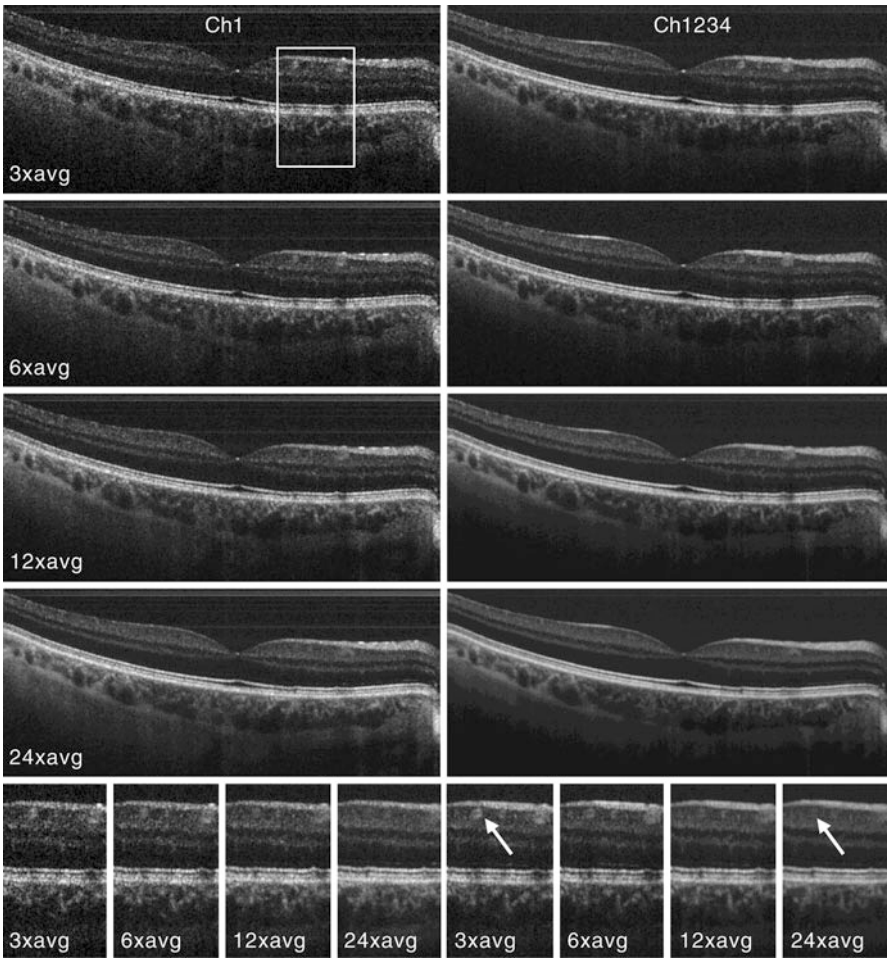

Fig. 24.30 Comparison of image quality of standard OCT and JA-OCT [113]. Averaging of adjacent frames in standard single-channel OCT (*left*) and JA-OCT (*right*). The image quality of the compounded JA-OCT images is always superior to single-channel imaging. *Bottom*: In the enlarged image sections, it can be clearly seen that averaging of frames spanning less than 100 μm distance already blurs out important image detail, such as the blood vessel indicated by the *arrow*. So the less averaging required in JA-OCT helps maintain image detail

24.9 Conclusion

So far, the main impact of FDML lasers has been the demonstration of OCT systems with dramatically higher imaging speed. The first versions have pushed the speed from several 10 KHz line rate which have been standard for the first FD-OCT systems to several 100 kHz, and later on FDML lasers have helped to break the barrier of 1 MHz line rate with swept sources. Besides the higher imaging speed, FDML lasers

have been proven useful for many different applications, where good phase stability, long coherence, low laser noise, or similar is required. Despite these many initial applications, only very few more applied or clinical studies using FDML have been published. The first reason is that commercial FDML lasers have only very recently become available. Also this may be attribute to the difficulty to build proper OCT systems that can handle the high imaging speed and with it the huge data rates generated by these multi-MHz OCT systems. It is interesting to see how the high-speed FDML results have triggered vibrant research efforts to realize non-FDML sources which can achieve similar performance. Currently in 2013 there are several promising candidates of swept laser sources with alternative technology. It can be expected that the availability of more than one swept laser technology for MHz OCT will spur research on applications to find out where MHz OCT imaging speeds are required. MHz imaging speeds may lead to even more applications of OCT as one of the most exciting optical imaging technologies in biomedical application today.

25.1 Signal Introduction: OCT Acquisition and Multiplexing

For time- or frequency-encoded OCT systems samples, sections are obtained by quickly acquiring voxels along the optical axis of the imaging system [1–5]. More precisely the data is acquired along cylindrical sections of the samples that have roughly the length of the depth of field and then by scanning the beam along the sample surface. Differently, full-field OCM (FFOCM) [6–9] produces "en face" images (i.e., of a plane layer parallel to the sample surface) without scanning the light beam. FFOCM detects the interferometric signal across a plane section of the sample at a given depth and a 2D slice is thus obtained directly. When using this geometry, we can understand the main advantage of FFOCM over the competing OCT approaches: it allows the use of medium to large numerical aperture microscope objectives with a high transverse resolution of about one micrometer. For this reason in our first paper, we called it full-field optical microscopy (FFOCM) [10] and other authors did the same

later [11], so we will continue here to use FFOCM because the microscopic resolution is more and more required for the various applications of this technique.

To record these images, the entire field is illuminated by a *spatially incoherent* source with low temporal coherence length (i.e., broadband) and is acquired on megapixel detectors such as CCD or CMOS cameras. The difference between FFOCM and OCM (see ▶ Chap. 26, "Assessment of Breast, Brain and Skin Pathological Tissue Using Full Field OCM" about OCM) is that OCM takes also "en face" images but uses a *single spatial mode optical source* (laser or SLD) that is focused by a microscope objective and scanned at the required depth [12, 13].

In the time-domain OCT approach, each voxel of the sample volume is scanned sequentially; a significant improvement has been achieved using spectroscopic or Fourier domain OCT that multiplexes the data by acquiring in parallel all the voxels along a line: typically a few hundred voxels are simultaneously acquired using a fast linear detector working in the kHz range. Typical values are of the order of megavoxels/s.

FFOCM allows millions of voxels acquisition in a few tens to thousand images/s range depending of the camera speed and the required signal-to-noise ratio. Here typical values are in the range of 100 megavoxels/s.

25.2 Full-Field Optical Coherence Microscopy

25.2.1 FFOCM: The Experimental Setup

In the case of full-field optical coherence microscopy, we combine an interferometer and a microscope. The experimental setup is shown schematically in Fig. 25.1.

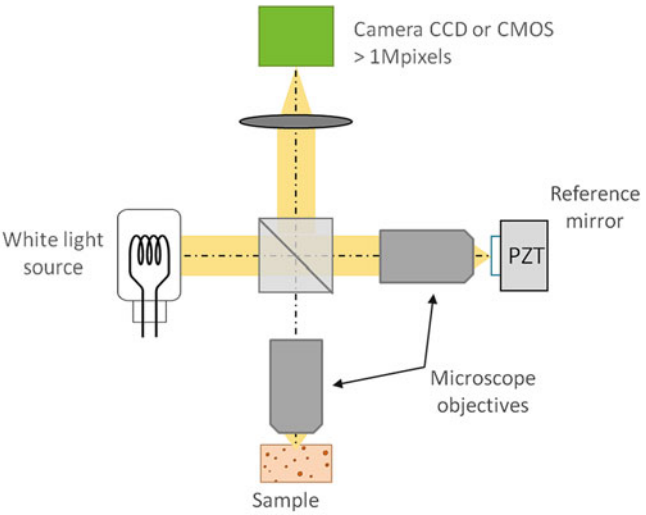

Fig. 25.1 Principle of the full-field OCM setup

This is a Michelson interferometer in the Linnik configuration where two identical microscope objectives are used in the object arm and in the reference arm.

Here we will describe the basic principles of the setup and the elementary signal processing.

The light source chosen for our system is a simple halogen lamp tungsten filament with a nominal power of 150 W that illuminates the interferometer via a Koehler illumination device that allows obtaining a homogeneous illumination of the sample. The emission spectrum of the source is very broad and can be modeled by that of a black body centered in the near infrared around 800 nm. This broadband incoherent source has a very short spatial and temporal coherence length leading to a sub-micrometer sectioning ability and avoiding cross talk.

The light beam emitted by the source is divided into the two arms of the interferometer through a broadband non-polarizing beamsplitter cube. The average power impinging the sample is of the order of 1 mW/mm^2.

The objectives that are mostly used for biomedical applications are immersion ones (oil or water) in order to reduce the surface reflection and to minimize the aberrations induced by the surface topographic irregularities. Routinely 10× water immersion objectives with a 0.3 numerical aperture (NA) are used but we have also used 20× (0.5 NA, water), 40× (0.8 NA, water), and 30× (1.05 NA, silicone oil) and a few more objectives working in air. The choice of two identical microscope objectives minimizes the path differences between the two arms and maximizes the overlap between the interfering wavefronts. The use of a sample immersion liquid (mostly buffer solutions) increases the duration of biological samples observation without damaging them under illumination.

Furthermore, using liquid immersion microscope objectives minimizes chromatic dispersion between the two arms when images are formed in depth.

25.2.1.1 Image Acquisition

The tomographic image intends to reveal the intensity reflected by a slice at a chosen depth; we call it $R_{obj}(x, y)$. The backscattered amplitude is calculated using the combination of two or four images obtained for two or for values of the phase ψ shifted by π or $\pi/2$, respectively. The recorded signal is given by

$$I(x,y,t) = \frac{I_0}{4}\left\{R_{inc}(x,y) + R_{ref}(x,y) + 2\sqrt{R_{obj}(x,y)R_{ref}(x,y)}\cos\left[\phi(x,y) + \psi\right]\right\}$$

where ϕ is the (unknown) phase difference between the reference signal and the object signal of the signal, ψ is the phase shift induced by the shift of the reference mirror, I_0 is the photon flux at the entrance of the interferometer, R_{ref} is the (rather uniform) reference mirror reflectivity, $R_{obj}(x, y)$ is the fraction of light reflected by the object that interferes with the reference beam, and $R_{inc}(x, y)$ is the fraction of light that does not interfere (light backscattered by the other slices of the sample, and the stray light of the interferometer). More precisely $R_{obj}(x, y)$ represents the reflectivity distribution of the sample structures contained in the coherence volume. $R_{obj}(x, y)$ thus corresponds to an en face tomographic image.

The two possible choices of two or four images need to be clarified:

- One can see easily that if R_{ref} is uniform over the field of view, four successive values of ψ (e.g., 0, π/2, π, 3π/2) allow to isolate the term $\sqrt{R_{obj}(x,y)R_{ref}(x,y)}$ that is proportional to $\sqrt{R_{obj}(x,y)}$ that is the amplitude of the backscattered signal intensity.
- OCT images always contain speckle because of the interference of the light backscattered by different tissue microstructures located inside the coherence volume. For this reason the amplitude and the phase of the recorded backscattered signals are random and we do not lose too much information by simply taking two images (instead of four) and rely on the absolute value of the real part of the complex signal (instead of the amplitude).

A software was developed to calculate and display the tomographic image in real time (at several tens of Hertz, depending on the camera frame rate and the computer speed).

By moving the sample step by step in the axial direction, one may acquire a stack of en face tomographic images. Once a three-dimensional data set is recorded, sections of arbitrary orientation can be extracted. Volume-rendering images can also be computed.

25.2.1.2 Full-Field OCM: Spatial Resolution and Sensitivity

As we mentioned earlier since conventional OCT produces axially oriented images, a depth of field equal to the axial extent of the images is required to avoid dynamic focusing as the coherence gate is scanned. Low-NA lenses are then used in order to obtain a large depth of field, which consequently limits the transverse resolution.

Full-field OCM produces en face tomographic images. In this configuration, microscope objectives with relatively high numerical aperture (NA) can be used. The transverse resolution of full-field OCM is that of a microscope, i.e., of the order of 1 μm.

Nevertheless as conventional OCT, full-field OCM has an axial resolution determined by the coherence length of the illumination source. In contrast to the spectrum of ultrashort femtosecond lasers, the spectrum of a thermal light source is very smooth. It does not contain spikes or emission lines that could cause side lobes in the coherence function and create artifacts in the images. In addition, the optical power is much more stable. The effective spectrum of the system is actually imposed above all by the spectral response of the detector. With our silicon-based CCD (e.g., DALSA), the effective spectrum is centered around $\lambda = 750$ nm, with width $\Delta\lambda = 300$ nm (FWHM). Using the usual formula that supposes a Gaussian shape spectrum:

$$\Delta z = \frac{2\ln 2}{n\pi}\left(\frac{\lambda^2}{\Delta\lambda}\right)$$

The theoretical axial resolution in a medium with refractive index $n = 1.33$ (water) is $\Delta z = 0.5$ μm. We have experimentally measured 0.7 μm as can be seen on Fig. 25.2.

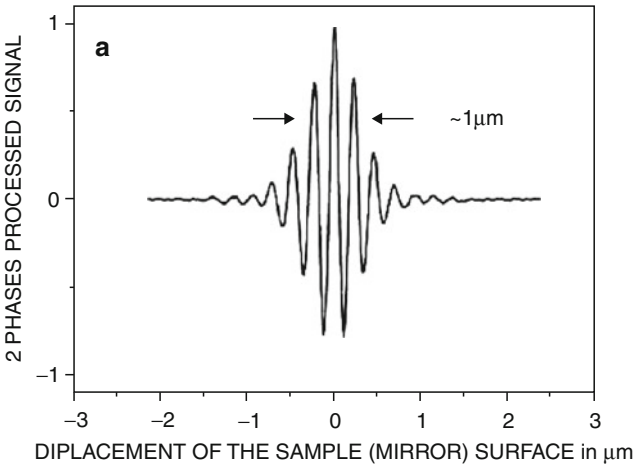

Fig. 25.2 Axial response of the Linnik interferometer (silicon camera, tungsten source)

If dispersion mismatch occurs in the two arms of the interferometer, the axial resolution is degraded. Since biological tissues are constituted mainly of water, the use of water immersion or silicone oil microscope objectives minimizes dispersion mismatch.

What Are the Parameters that Limit the FFOCM Sensitivity?

In general when using a standard tungsten halogen illuminators, we are not limited by the light level impinging the camera; indeed, we can work close to the saturation level for an optimum signal-to-noise ratio. More precisely the important parameter is the amount of electrons stored during the acquisition time. In order to get the maximum signal-to-noise ratio, one must optimize the following performances of the camera:

- The images close to the saturation level must be shot noise limited. The test for that is that the difference between two successive identical images must be much higher that the difference between two dark images (see Appendix).
- The full-well capacity W must be as high as possible (typically between 100,000 and 1,000,000 of charges for silicon cameras and around 1,000,000 for InGaAs cameras).
- Both for the signal-to-noise ratio and to be able to perform in vivo experiments, we need frame rate higher than $Fr = 150$ frames/s.
- The digitalization must be achieved with at least 10 bits in order to avoid sampling errors.
- The number N of pixels that we currently use today is one to four million for silicon cameras and 250,000–500,000 for InGaAs cameras.
- The camera must be equipped with an external trigger or at least an internal trigger in order to synchronize the image acquisition with the piezoelectric modulation of the path difference.

To summarize our overall quality factor Q for maximizing the signal-to-noise ratio, $\mathbf{Q} = \mathbf{W.Fr.N}$; it represents the amount of charges that can be stored during one second on the camera chip.

In order to increase the signal-to-noise ratio, the reference arm mirror must have a reflectivity that ensures a reference power equal or higher than all the incoherent light impinging the camera (light diffused by the sample that is function of the numerical aperture, or stray light of the setup).

As discussed in the Appendix, the images are mainly shot noise limited and one can show that a detection sensitivity of the order of 90 dB ($R_{\min} = 10^{-9}$) can be obtained by accumulating images during a full acquisition time of less than a second.

25.2.2 FFOCM: The LLTech Research Setup

In 2011, LLTech, an ESPCI ParisTech spin-off, has launched the first FFOCM system for clinical research applications (Fig. 25.3).

This system is based on the principle that we have described but it contains a number of improvements that are necessary in the framework of clinical research:

- It is a "plug-and-play" system, for instance, the zero path difference, which is often tricky to find in a Linnik configuration (1 μm position with 10 cm long arms!), is automatically positioned.
- The field of view that is required for pathology is typically of the order of 1″ (2.5 cm) in diameter whereas the standard field of view of the cameras using 10× objective is close to 1 mm. Stitching of elementary sub-images is then required to make such large images; because the transverse resolution is 1.4 μm (sampling 0.7 μm/pixel), it is possible to zoom in and out in these large images that are recorded in about 5 min.

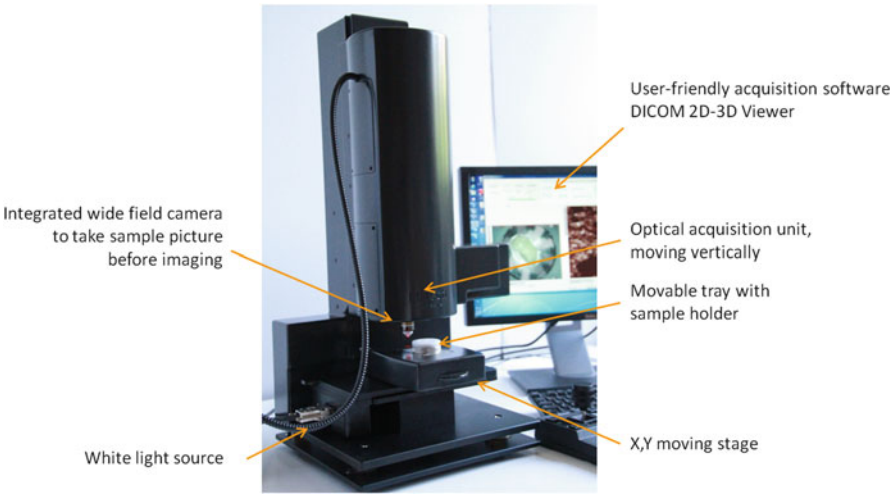

Fig. 25.3 Picture of the LLTech light CT scanner

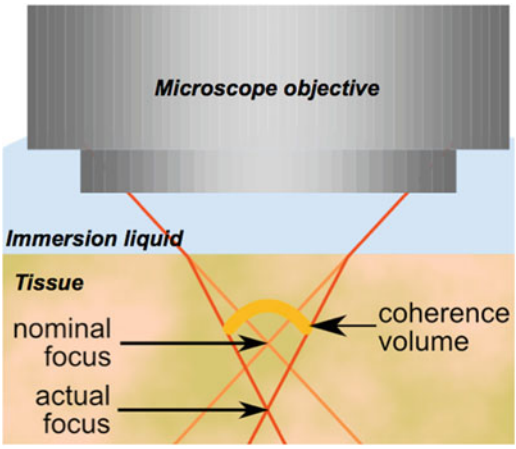

Fig. 25.4 The refractive index mismatch between the immersion liquid refractive index and the tissue refractive index induce a shift between the coherence volume and the focus (From Jonas Binding PhD defense, Paris 2012)

- For ex vivo experiments, the sample is placed in its sample holder and gently pressed against a transparent window. Incorporation of a liquid avoiding sample drying is ensured.
- When exploring a sample in depth, the following problem has to be solved: the refractive index of the tissue being generally different from the immersion liquid index, there is a shift between the focus and the zero path difference (coherence volume) as can be seen on Fig. 25.4 [14–16].

When this shift turns to be larger than the depth of field (e.g., 8 μm for 0.3 NA water immersion objectives), one can observe a reduction of the signal and a degradation of the image quality. The software that drives the system motors automatically compensates for this shift. For ex vivo or in vivo samples, at the end of the sample arm is the biological tissue to be imaged. It could be placed within a specific sample holder. Usually one explores either a large field of view obtained at a few depths or a stack of tomographic images of smaller lateral size.

Finally the LLTech system being designed to be placed in a research hospital environment, the images are available using DICOM data format that is a standard in medical imaging for handling, storing, printing, and transmitting information.

25.2.3 Improving the Available Depth Using InGaAs Cameras

In order to extend the capabilities of the full-field OCM technique and to improve the penetration, an infrared InGaAs FFOCM system has been developed [11, 17, 18]. Indeed in biological tissues there is a decrease in scattering coefficient with increasing wavelength.

For FFOCM tissue imaging systems, the camera detection sensitivity range is the limiting factor and silicon-based cameras are used to probe the 600–1,000 nm wavelength region. For wavelengths >1,000 nm, indium gallium arsenide (InGaAs) chips allow a detection range in the 900–1,700 nm band.

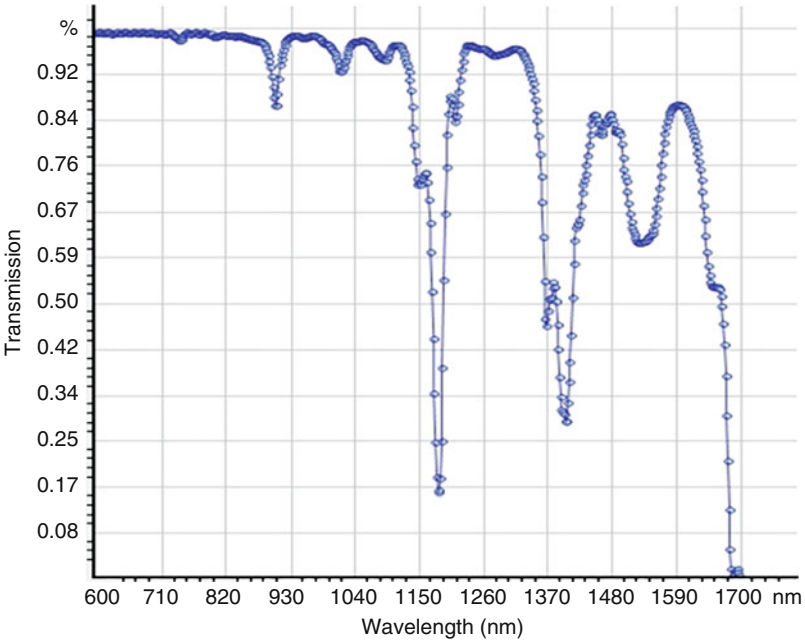

Fig. 25.5 Near-IR transmission of silicone oil (1 cm path)

Results presented here have been carried out using *silicone oil immersion* instead of water. This type of configuration has seemingly not been used in the past.

An infrared beamsplitter was used but microscope objectives were not optimized for this particular wavelength range: we only replaced Olympus 10× objectives by Zeiss 10× ones because their transmission is better above 1 µm. The InGaAs camera (Xeva-1.7-640c, Xenic, Leuven, Belgium) has been mounted onto the full-field OCT setup described on Fig. 25.1. This InGaAs camera full-well capacity (the largest charge that the camera can hold per pixel before saturation) is larger than two million e^- with and a frame rate of 25 Hz.

Water absorption spectrum is a major limitation when imaging at wavelengths higher than 1.25 µm (the working distance of the objective being about 3 mm, 6 mm of water has to be considered).

Silicone oil refractive index is about 1.41, which limits its usage to medium numerical aperture water immersion objectives (typically NA <0.35 unless spherical aberration would limit the transverse resolution). Nonetheless, it allows an almost full transmission from 0.9 up to 1.6 µm except for two absorption bands as shown on Fig. 25.5.

Indeed, the advantage of silicone oil can be appreciated by comparing the number of fringes observed on a mirror when measurements are performed in oil

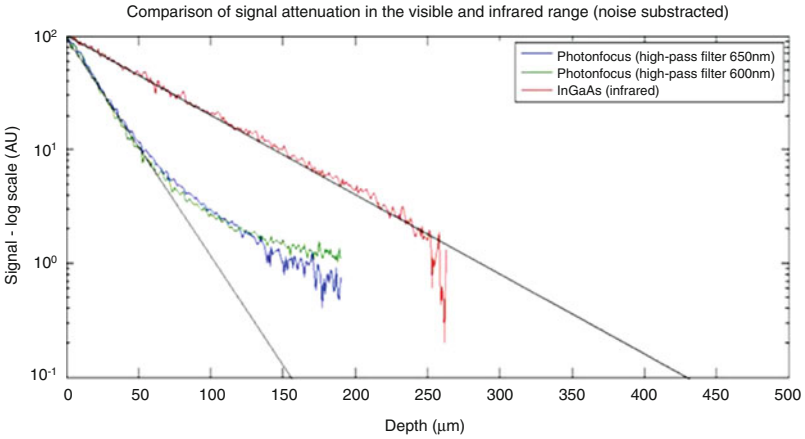

Fig. 25.6 Damping of the FFOCM signal (semilog scale) using a silicon camera (*red* and *green curves*) and InGaAs camera (*red curve*) [19]

immersion (about three periods, FWHM) for the near-infrared setup (InGaAs) in comparison to water immersion (about eight periods, FWHM).

In comparison to a configuration with silicone oil in the visible range (i.e., CMOS camera), the spectral bandwidth achieved by the InGaAs setup is significantly larger (i.e., $\sim$ 600 nm vs. 150–200 nm), but the central wavelength being about two times larger, the theoretical axial resolution is approximately similar to what we get using silicon cameras (around 1 μm). However, the gain lies in the effective spectrum achieved with silicone oil immersion and therefore a gain in penetration depth. The high absorption of water above 1,100 nm is thus drastically reduced by the oil immersion medium in both arms, allowing to fully benefit from the near-infrared part of the polychromatic light source. Recently, Dubois's group compared two similar FFOCM configurations (both silicon and InGaAs cameras) but within water as immersion medium showing limited or no gain in the near-infrared range [18].

As expected, a significant increase in photons' mean free path is observed with the InGaAs configuration (Fig. 25.6). The exponential attenuation shows an approximately threefold increase in penetration depth for the infrared system (red curve) in comparison to systems in the visible range (blue and green curves).

For this particular tissue (fibroadenoma), the multiple scattering shown by the departure from the exponential signal attenuation [7] is quasi absent from the infrared curve up to 250 μm in depth while it already occurs at around 70 μm for the two systems in the visible range. From this result, a power law expressing the wavelength dependence can be extracted. The broadness of both spectra require the use of each central spectrum resulting in a power law dependence scaling as λ^2 compatible with the Mie scattering regime. This result is confirmed by the direct image of this fibroadenoma breast tissue (Fig. 25.7).

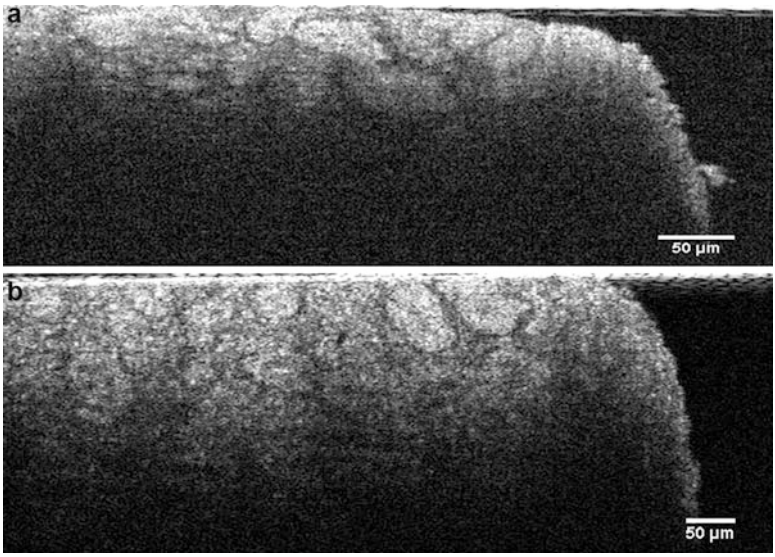

Fig. 25.7 Cross-sectional view of breast fibroadenoma imaged at (**a**) silicon camera, image depth: 200 µm (**b**) InGaAs camera image depth: 300 µm [19]

25.3 Clinical Research Applications of FFOCM

We have described in details the applications of FFOCM that have been performed in various hospitals in ▶ Chap. 26, "Assessment of Breast, Brain and Skin Pathological Tissue Using Full Field OCM" on clinical applications of full-field OCM. These studies include the breast (tumors and nodes), brain, and skin. Images of other organs can be found on http://www.lltechimaging.com/.

25.4 Nondestructive Evaluation and FFOCM: From Electro-optics to Art Materials

In these domains, the first range of applications deals with layered materials: one can control the thickness and the integrity of the various layers even if some of them scatter light (i.e., in solar cells) in a noncontact and nondestructive way. The very high sensitivity of FFOCM (90–100 dB) allows getting the scattering level map associated to a specific slice in a better way than usual scatterometers.

We also think that the submicron slicing ability of FFOCT matches the requirements of art materials. We have been able to reveal multiple layers even in highly scattering paints. As an example of layered and scattering materials, lacquers are easily imaged using FFOCT (Fig. 25.8).

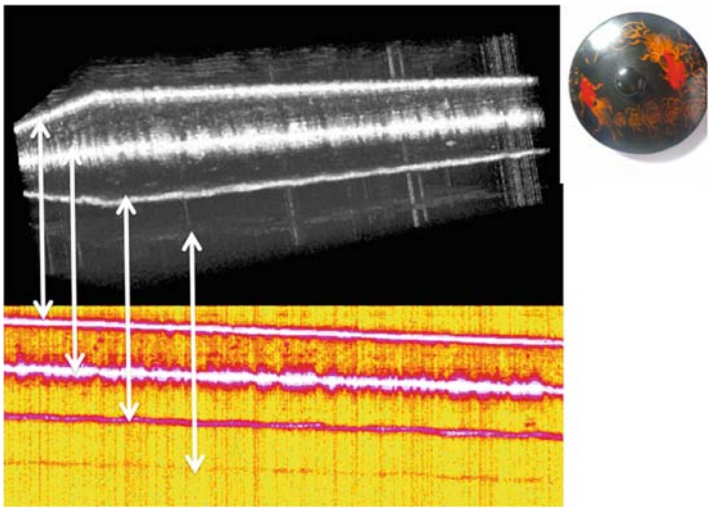

Fig. 25.8 3D FFOCM image of a Vietnamese lacquer and detail of a section (in *yellow*) [20]

25.5 Multimodal FFOCM: Fluorescence and Elasticity

Despite the good quality of the images, FFOCM provides a morphological contrast that could advantageously be completed by adding valuable complementary information.

As other OCT groups, we have worked in two directions in order to get new form of contrast.

25.5.1 FFOCM and Fluorescence Using Structured Illumination

One of the problems in cancer diagnosis is to be able to reveal the invasion of cancer cells and to identify these cells by the size of their nuclei. In FFOCM, the signals are dominated by the strong backscattering level of fibrous tissue that masks those of the nuclei that appear dark or are hidden under a strong background (see ▶ Chap. 26, "Assessment of Breast, Brain and Skin Pathological Tissue Using Full Field OCM").

As the sectioning cannot be obtained through the FFOCM signal, another method should be used to collect the fluorescence signal at the same depth that has been selected. Structured illumination is now a very popular approach to achieve fluorescence full-field sectioning with an axial resolution that is equivalent to what is achieved in confocal microscopy. Nevertheless, in order to get a sectioning of 1 μm, high numerical aperture must be used: we have chosen 1.05 NA silicone oil immersion objectives. Moreover, the camera dark noise must be reduced. The setup is represented on Fig. 25.9.

As an example, Fig. 25.10 shows the FFOCM image of a basal cell carcinoma where nuclei are not clearly visible and appear when using acridine orange as fluorophore.

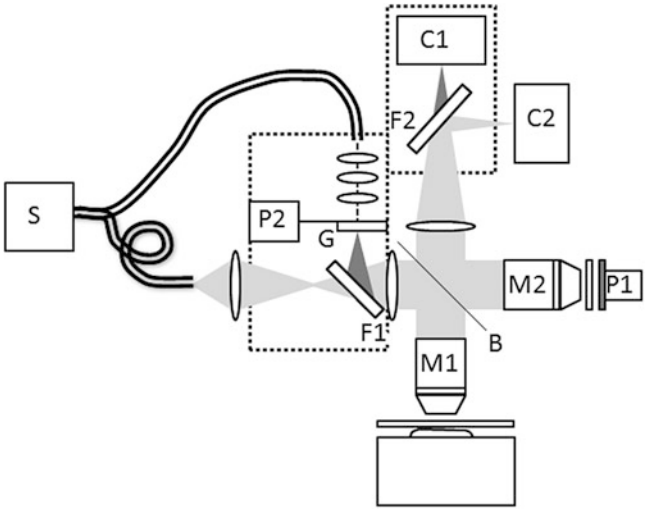

Fig. 25.9 Setup used for simultaneous recording of structured illumination and FFOCM. *S* Xenon Source, *C*1 Fluorescence camera, *C*2 FFOCT camera, *M*1, *M*2 microscope objectives, *P*1, *P*2 piezoelectric modulators, *F*1, *F*2 filters, *G* Ronchi grid, *B* beamsplitter [21]

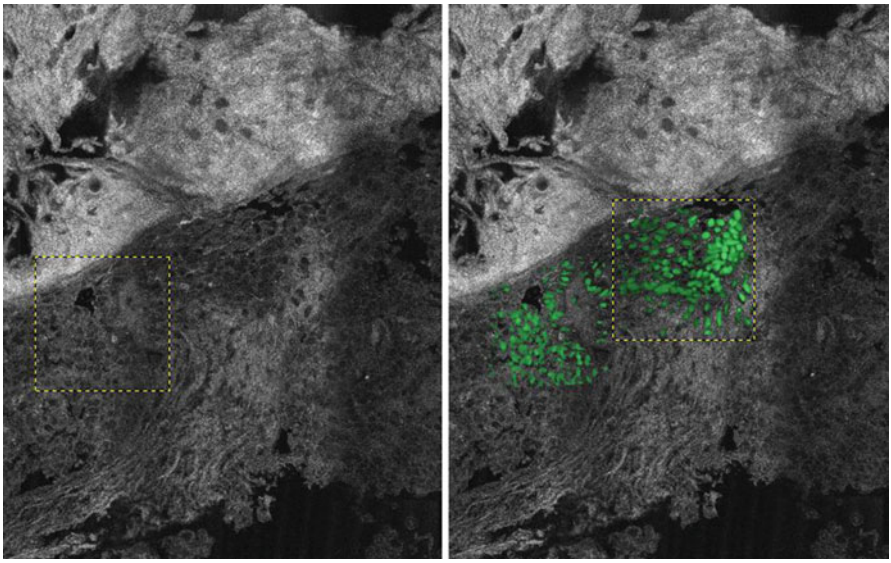

Fig. 25.10 Basal cell carcinoma (*BCC*). FFOCM image (*left*) and combined FFOCM/SIM image (*right*). The SIM image shows the increased density of nuclei due to cell proliferation. The upper part corresponds to the epidermis. The epidermis shows high contrast in FFOCT, compared to the BCC area, suggesting a significant refractive index change. FFOCM image size: 370 × 480 μm [21]

25.5.2 FFOCM Elasticity Map

Organ structures, tissues, and cells are characterized by their intrinsic mechanical properties. Moreover, the mechanical properties of cells are related to their structure and function: changes in those properties can reflect cellular healthy or pathological states. Adding this contrast to morphological images could be a powerful help for diagnosis. In this study, we add the elastographic contrast to FFOCM, and by combining it with elastography, one recreates a "virtual palpation" map at a micrometer scale.

We have used two static methods to add the elastographic contrast to FFOCM images. In the first method, we register a volumetric image before and after mechanical solicitation of the sample. From those two sets of images, we estimate the 2D and 3D strain maps inside the sample by using two different algorithms: one based on cross-correlations and one based on finite elements. We use this method not only with the custom LLTech setup but also with an endoscopic FFOCM setup (see below). In the second method, the sample is submitted to a low-amplitude periodical compression and using a phase-shifting modulation method derived from the one used earlier: so we are able to retrieve the local phase map modulation directly related to the local displacement. Those methods provide values of the local elastic properties along the compression axis. As an example, we have represented on Fig. 25.9 what we have obtained on a mouse ear that is a strongly heterogeneous sample in terms of their mechanical properties (Fig. 25.11).

25.6 Full-Field OCM for Endoscopy

All OCT systems have a limited maximum imaging depth in tissues of typically 1–2 mm due to absorption and scattering of light by the biological structures. For in situ and in vivo imaging of internal organs, a probe is thus required. The adaptation of the OCT technique into endoscopic setups [22, 23] allows the access to a variety of areas of the human body where high-resolution in-depth imaging is needed. Endoscopic OCT is now mainly used for intravascular imaging [24] where it is able to distinguish between different types of plaques. A second main domain of application is biopsy guidance with needlelike probes [25, 26]. However, the typical axial and transversal resolutions of such OCT systems lie between 5 and 30 μm, which is less than that of full-field OCM.

25.6.1 Principle: OCT Signal with Two Interferometers

A FFOCM system with probe has to address the problem of keeping the performances of FFOCM in a setup using a miniaturized, medically safe probe. Such systems with a probe rather use two coupled interferometers, as proposed in [27–29]. Indeed, integrating the probe as an arm of the Linnik interferometer could cause perturbations and damage the interference signal during in vivo use.

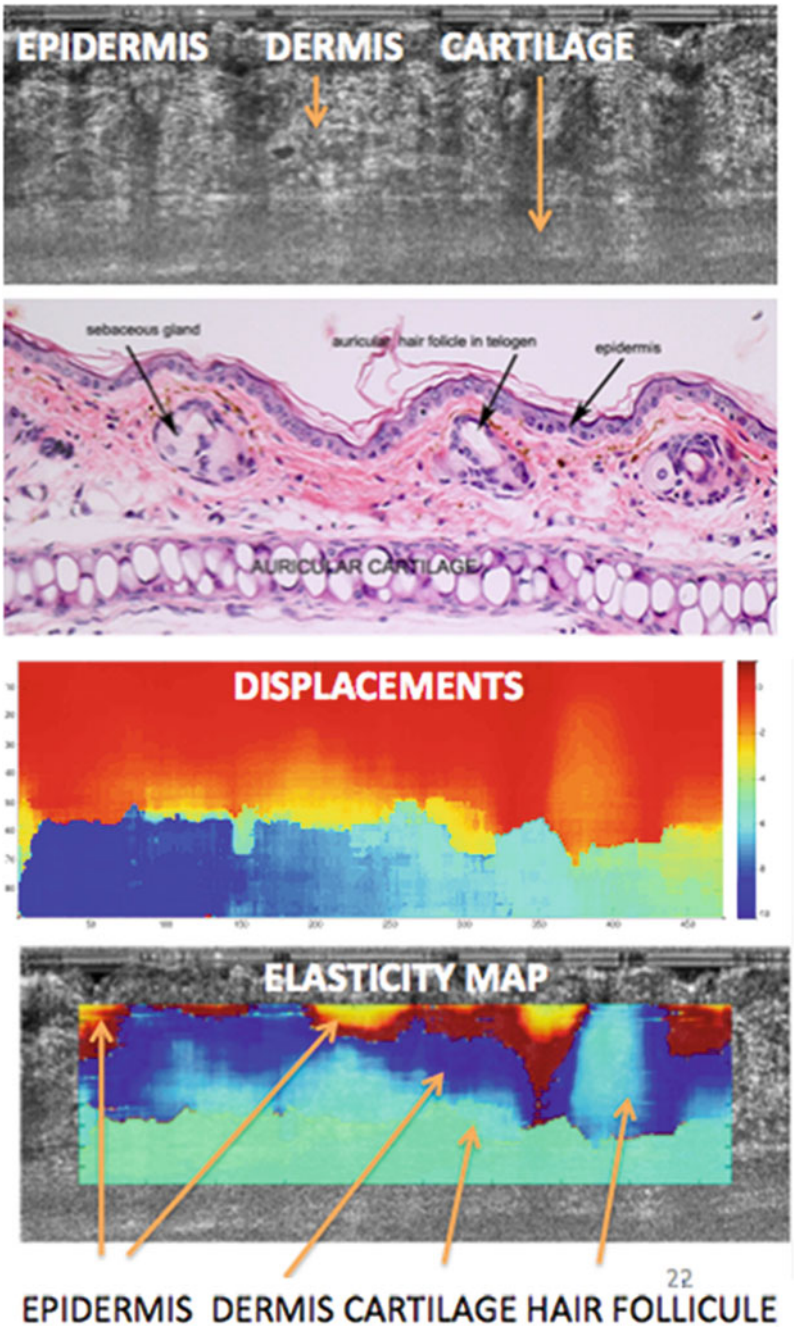

Fig. 25.11 FFOCM section of a mouse ear (*top left*), axial displacement map (*top right*) and elasticity map (*bottom right*) and typical H&E stain

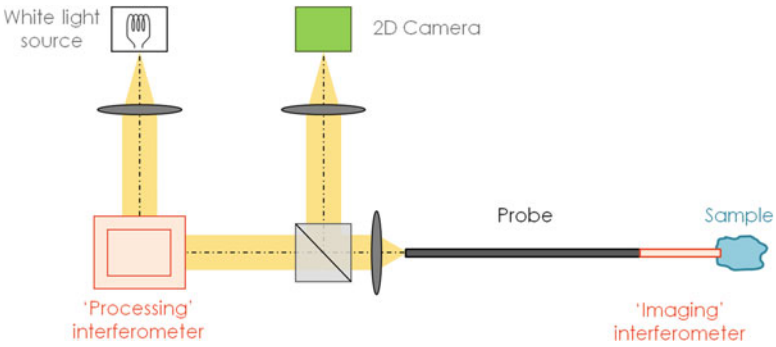

Fig. 25.12 Simplified principle of an endoscopic full-field OCM system with a common-path imaging interferometer

If the probe comprises an optical fiber or fiber bundle, bends and twists in the fibers will create differences between the states of polarization of light in the reference and object arms, thus distorting the signal. Moreover, it would also require to set identical probes in both arms of the Linnik interferometer, which would induce very large optical path lengths difficult to balance. On the contrary, in a system with two interferometers, the probe is not part of an interferometer arm and is only used to transport an image. It is thus entirely passive and insensitive to its environment. Such a system is to privilege for in situ imaging, where one needs a system able to image outer or inner parts of the body that are difficult to reach.

The main principle of endoscopic FFOCM systems is based on the coupling of two distinct interferometers: one is external to the probe, and one is placed at the distal end of the probe in contact with the tissue to image. The distal interferometer has to be kept simple for in situ imaging, for example, a common-path design is an adequate solution. It does not require any advanced miniaturized mechanical systems at the tip of the probe, which are likely to increase the diameter as well as the cost of the probe.

The principle of the system is described on Fig. 25.12 [30]. The broadband white light source is a Xenon arc lamp coupled to an optical fiber. This source spectrum is not as smooth as the one obtained with a thermal light source, e.g., a tungsten filament, but the luminance and the power level injected into the fiber are much higher. The use of a source with very low temporal coherence ensures a good axial resolution, whereas the spatial incoherence increases the sensitivity by decreasing cross-talk effects. It illuminates a Michelson-type processing interferometer, which modulates the spectrum at a frequency dependent on the path length difference. This spectrum is then injected into the probe to the distal imaging interferometer, which is common path: interferences occur between the reference beam reflected at the tip of the probe and light backscattered by structures at each depth within the tissue. The 2-D detector, a 1 megapixel camera such as a CCD or CMOS, detects the superposition of the modulated spectra coming from the processing interferometer and from the imaging interferometer. A maximum signal is detected only when both path length differences match, so that by setting the path length difference of the external interferometer, one

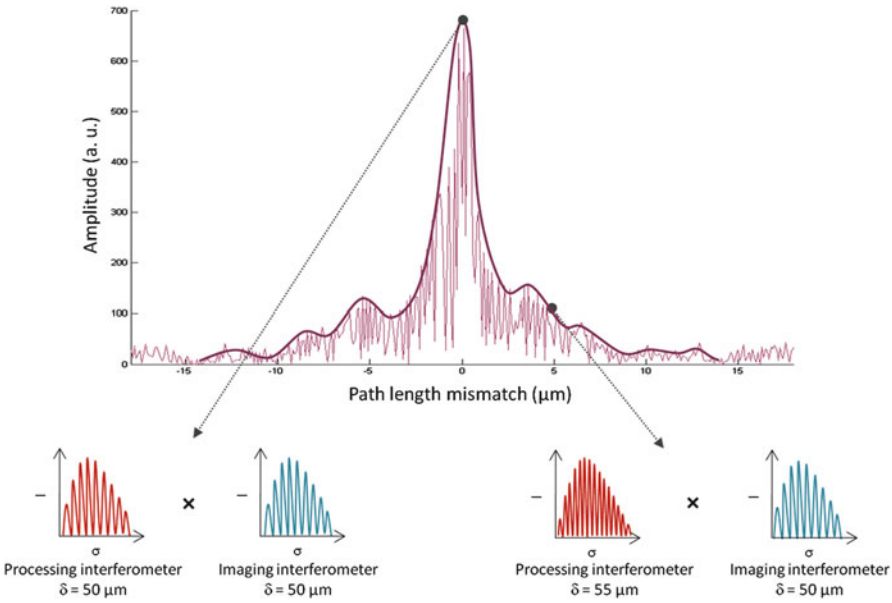

Fig. 25.13 Signal collected on one point of the 2-D detector showing interference fringes coming from a planar mirror placed at 25 μm ahead of the probe in air. The path length difference of the imaging interferometer is thus 50 μm. The path length difference of the processing interferometer is scanned from 30 to 70 μm using a step motor

sets the imaging depth within the sample. Furthermore, for extracting the interference signal from the background, we use a phase-shifting method with a piezoelectric modulation in the processing interferometer. A 3D image can be reconstructed by performing a one-dimensional depth scan using the processing interferometer.

Figure 25.13 shows, for example, the signal collected from a planar mirror as a function of the path length difference mismatch between both interferometers. The envelope of this signal gives an axial resolution of 1.8 μm.

Such a system can be used with different probes without changing the bulk setup to perform flexible or rigid endoscopy.

25.6.2 Flexible Endoscopy

A fiber bundle can be used as a flexible endoscope to transport a coherent image. Bundle as thin as 0.9 mm with as many as 30,000 optical fibers is available, which is suitable for biomedical applications. The use of a multimode fiber bundle degrades the image quality by the pixelation effect of the fibers and by additional artifacts. Indeed, cross talk resulting from coupling between adjacent cores in the bundle, and between propagation modes in one core, creates a ghost signal [31]. However, imaging of samples can still be achieved, as shown on Fig. 25.14. Transversal resolution is 4.9 μm and sensitivity is −70 dB.

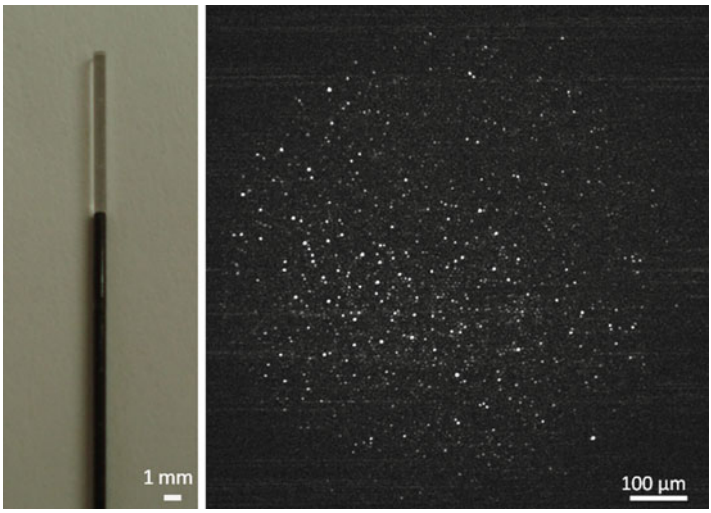

Fig. 25.14 Flexible probe composed of a fiber bundle and a graded refractive index (*GRIN*) lens (*left*). Image of a phantom (2 µm diameter TiO_2 beads embedded in a polyurethane matrix) (*right*)

25.6.3 Rigid Endoscopy

Graded refractive index (GRIN) lenses are thin lenses with a cylindrical shape that can be readily used as a rigid endoscope. For instance, two lenses can form a probe with a diameter of 2 mm and a length of 150 mm (GRINTECH, Germany), for a numerical aperture of 0.1. The transverse resolution is then 3.5 µm, for a sensitivity of −80 dB when averaging 20 images during about 1 s, which is enough to get signal from biological tissues. Figure 25.15 shows images taken with this probe on ex vivo samples.

The system can be used in vivo, as demonstrated on the skin (Fig. 25.16). The forward-viewing probe is applied in direct contact with the tissue and can image up to depths of 200 µm [30].

The rigid probe can also be used as a needlelike probe or be inserted inside a biopsy needle to image internal organs and perform biopsy guidance. Figure 25.17 shows examples on brain and kidney.

Appendix

FFOCM: Signals and Noises

(***The calculation is performed for a single pixel of the camera and the notations are indicated on the*** Fig. 25.18)

(a) Negligible incoherent and stray light level ($N_{\text{inch}} < \alpha N_0$)

Let a N_0 be the number of photoelectrons generated from the reference arm $\alpha N_0 \sim N_{\text{sat.}}$

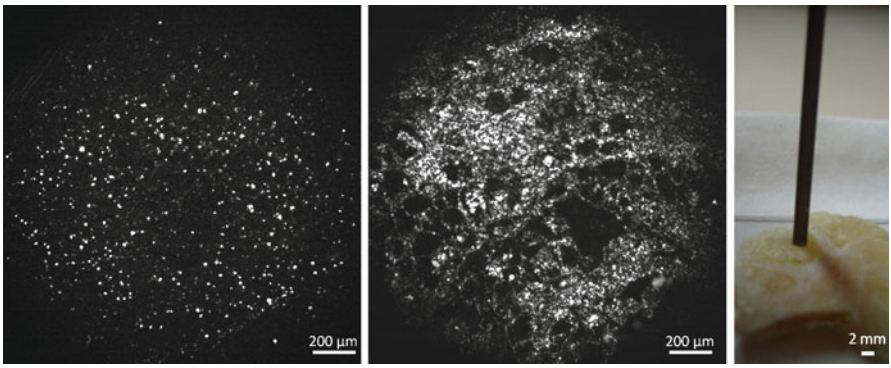

Fig. 25.15 Images of FFOCM with a rigid probe. *Left*: phantom. *Right*: ex vivo human breast sample

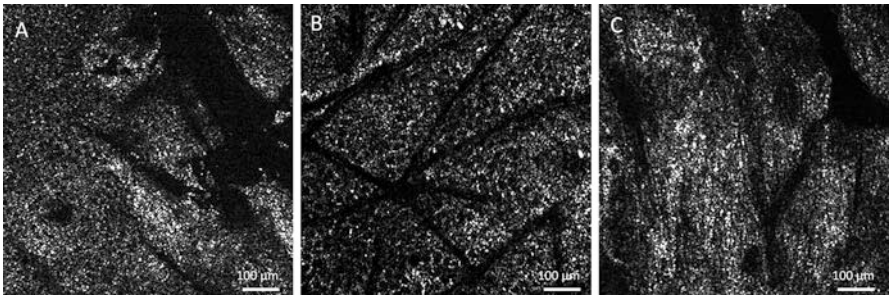

Fig. 25.16 Endoscopic FFOCM images on human skin in vivo, at depths of 30 µm under the surface, on the cheek (**a**), forearm (**b**), and mole (**c**). The epidermis shows epithelial cells

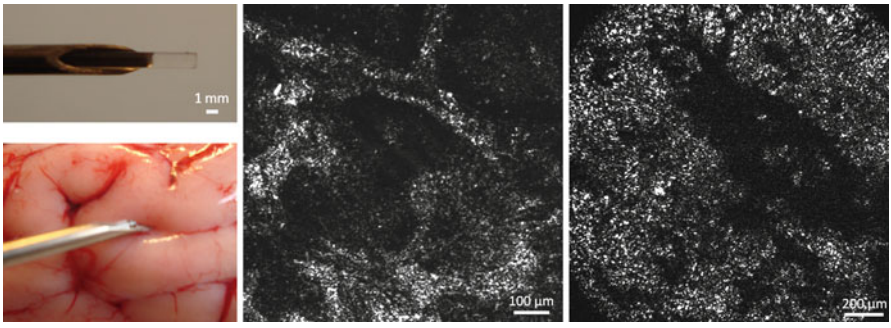

Fig. 25.17 Endoscopic FFOCM needlelike probe. Ex vivo images on human brain (*left*), and rat kidney (*right*) at depths of 20 µm ahead of the probe

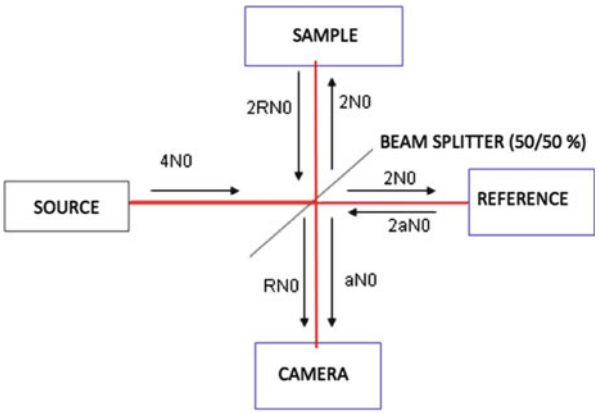

Fig. 25.18 Representation of the various light levels impinging the various parts of the interferometer

Let $R\,N_0$ be the number of photoelectrons generated from the object slice under examination ($R << \alpha$).

Let N_{inch} be the number of stray light- and incoherent light-induced photoelectrons ($N_{\text{inch}} << N_{\text{sat}}$).

For a π-shifted two-phase detection (+ or −),

$$I_+ = \alpha N_0 + RN_0 + N_{\text{inch}} + 2\sqrt{\alpha N_0 RN_0}\cos\varphi$$
$$I_- = \alpha N_0 + RN_0 + N_{\text{inch}} - 2\sqrt{\alpha N_0 RN_0}\cos\varphi$$

The measured signal is

$$\begin{aligned} S &= I_+ - I_- \\ &= 4\sqrt{\alpha N_0 RN_0}\cos\varphi \end{aligned}$$

We usually take its absolute value:

$$\begin{aligned} \langle|\cos\varphi|\rangle &= \left\langle\sqrt{\cos^2\varphi}\right\rangle \\ &= \left\langle\sqrt{\frac{1+\cos(2\varphi)}{2}}\right\rangle \\ &= 1/\sqrt{2} \end{aligned}$$

Please note that this is true for a random scattering sample and not for a mirror sample.

The signal is then

$$\begin{aligned} S &= 4\sqrt{\alpha N_0 RN_0/2} \\ &= 4\sqrt{N_{\text{sat}} RN_0/2} \end{aligned}$$

The shot noise being
$B = \sqrt{N_{\text{sat}}} = \sqrt{\alpha N_0}$ (the reference being the major signal)
The signal-to-noise ratio is

$$\begin{aligned} \text{S/B} &= 4\sqrt{RN_0/2} \\ &= 4\sqrt{RN_{\text{sat}}/2\alpha} \end{aligned}$$

The limit of detection (signal = noise) corresponds to $4\sqrt{R_{\min}N_{\text{sat}}/2\alpha} = 1$, so that

$$R_{\min} = \frac{\alpha}{8N_{\text{sat}}}$$

Typical numerical value
Using typical values of $\alpha = 0.16$ $N_{\text{sat}} = 200{,}000$ for silicon cameras, one gets
$R_{\min} = 10^{-7}$ or 70 dB for a two-image acquisition, 1 Mpixels, 75 processed images/s.
Averaging 100 images takes a few more than 1 s and leads to $\text{R}_{\min} = 10^{-9}$ or **90 dB**.

(b) Significant incoherent and stray light level ($N_{\text{inch}} =$ or $> \alpha N_0$)
We have then $\text{N}_{\text{sat}} = \alpha N_0 + N_{\text{inch}}$
The signal is

$$\begin{aligned} S &= 4\sqrt{\alpha N_0 RN_0/2} \\ &= 4\sqrt{(N_{\text{sat}} - N_{\text{inch}})RN_0/2} \end{aligned}$$

The shot noise is $B = \sqrt{N_{\text{sat}}}$
The signal-to-noise ratio is

$$\begin{aligned} \text{S/B} &= 4\sqrt{\frac{(N_{\text{sat}} - N_{\text{inch}})RN_0}{2N_{\text{sat}}}} \\ &= 4\sqrt{\frac{\alpha N_0 RN_0}{2N_{\text{sat}}}} \end{aligned}$$

The limit of detection (signal = noise) corresponds to $4\sqrt{\frac{(N\text{sat} - N_{\text{inch}})R_{\min}N_0}{2N_{\text{sat}}}} = 1$

$$R_{\min} = \frac{1}{8.(N_{\text{sat}} - N_{\text{inch}})} \cdot \frac{N_{\text{sat}}}{N_0}$$

$$R_{\min} = \frac{\alpha N_{\text{sat}}}{8.(N_{\text{sat}} - N_{\text{inch}})^2}$$

Assessment of Breast, Brain and Skin Pathological Tissue Using Full Field OCM

26

Eugénie Dalimier, Osnath Assayag, Fabrice Harms, and A. Claude Boccara

The experiments described here have been performed in hospitals under the guidance of doctors [1] using the LLTech setup described in this chapter. We acknowledge doctors' efforts in evaluating our technology. In this chapter we have intentionally limited the field of applications to medical pathology of the breast, brain, and skin. The reader interested in other organs or in animal studies may find a large number of 2D or 3D images in the atlas [2].

> Let us underline that the technique used here takes "en face images" with a camera (full field: FF) and mixes interferometry (OCT) and microscopy (M); in order to point out its unique ability to reveal details at micron and sub-micron scales we will call it FFOCM rather than FFOCT.

The aim of this chapter is to assess whether the images of the breast, brain, and skin tissue obtained by FFOCM contain sufficient detail to allow pathologists to make a diagnosis of cancer and other pathologies comparable to what was obtained by *conventional* histological techniques. More precisely, it is necessary to verify on FFOCM images if it is possible to differentiate a healthy area from a pathological area.

26.1 Breast Cancer

Breast cancer is the most common cancer in women and is still the second leading cause of cancer mortality in women; however, breast cancer mortality has declined steadily since 1990. This decrease is due to more effective treatments and more systematic screening for detecting the presence of tumor at different stages earlier. For this type of injury, surgery techniques called conservative that remove only the tumor (lumpectomy) are preferred to the removal of the full breast (mastectomy). One of the difficulties of the procedure is to perform the lumpectomy excision of the tumor and to ensure that the surgical margins are good. Resection margins are healthy when the entire tumor and some healthy tissue surrounding it are removed.

Histological examination performed during surgery is called intraoperative examination; it consists in histological sections obtained by freezing the sample during the procedure to better orient surgery. However, it has emerged in recent years in the case of very small tumors (smaller than 1 cm) that the latter could be inappropriate to establish a diagnosis [3] and that in the evaluation of margins, it provides an overall sensitivity of only 73 % [4]. Moreover, part of the sample that is lost during cutting and freezing introduces artifacts [5–9].

It therefore appears that the improvement of the evaluation in terms of sensitivity and specificity of excision margins during surgery using a rapid, easy-to-use method, independent of the operator, which does not damage the tissue and provides a spatial resolution sufficient to enable pathologists to diagnose should be of paramount interest. As we have seen in the other chapters of this book, OCT, requiring no contrast agent and allowing making "virtual sections" in the sample surface, therefore seems appropriate. Indeed, several studies using OCT for imaging breast tissue and lymph nodes have been published in recent years [10–15]. One of the first studies showed that benign and malignant lesions could be differentiated by the criteria of comparison with histology using the technique called "ultrahigh-resolution 3D OCT" [11]. Another study, using spectral OCT, evaluated the surgical margins after excision of a breast tumor using diagnostic criteria based on "large scatterers" rather than on the morphology of the tissue at a microscopic level [12]. The techniques used in these two studies have limited spatial resolutions: the first has a transverse resolution of 6 μm and an axial resolution of 3.5 μm and the second transverse resolution of 35 μm and an axial resolution of 6 μm. In this resolution range, the OCT images appear blurry compared to traditional histology slides. Indeed, the alternative optical technique should allow reproducing the conditions used for the analysis of histology slides, i.e., an image area of the order of cm^2 and transverse resolution close to 1 μm.

We described in the FFOCM chapter that FFOCM acquisition of en face images offers the best lateral and axial resolution. Indeed, FFOCM can operate without the necessary depth of field of other types of OCT (time domain, spectral, or Fourier domain, swept source). For these types of OCT, the available depth should be about the depth of field of the lens, requiring objectives of low numerical aperture, which limits the lateral resolution of these systems typically to 5–40 μm. FFOCM offers

an isotropic resolution in the micrometer or submicrometer range. At this resolution, the comparison of images with histology is good enough to distinguish the different structures within and different lesions. Moreover, the en face acquisition geometry provided by FFOCM is intrinsically similar to the geometry of histology slides preparation, which facilitates the pathologist's assessment and eventually eases the adoption of the technique.

26.1.1 Breast Structure

The breast was the first organ studied because large amount of material can be made available for preclinical testing, firstly, on one hand, because of the high incidence of breast cancer in the population and secondly, on the other hand, in the case of mastectomy, because much of the tissue taken is not involved directly in the diagnosis and could be used in the first phase of this study.

Each milk duct channel is lined with epithelium which is a thick envelope and can penetrate deep into the breast. Interlobular channels undergo expansion forming the lactiferous sinus before terminating by groups of intralobular channels terminal. Each group constitutes a form of ovoid mammary lobule. The lobules contain from 10 to 100 cells (or acini) that are rounded cavities that constitute the secretory mammary gland. The supporting tissue of the breast is consisting essentially of fibrous tissue and fat and contains numerous muscular bundles. The breast is richly vascularized through three arteries (axillary, internal thoracic, and intercostal). The lymphatic breast system is composed of lymph vessels whose role is to fight infections.

26.1.2 Experimental Procedure

The process of paraffin embedding tissue samples in order to obtain histology slides, so-called slices for HES stained with hematoxylin-eosin-safran, takes place within four main steps in total lasting 2–5 days. A preliminary stage of this work has been performed to ensure the safety of the imaging procedure; thus, within ten samples (five pathological and five healthy), parts of mastectomy set and stored in the pathology department of Tenon's Hospital in Paris were imaged by FFOCM. Standard tests were performed on these samples and the results were compared with those obtained on samples from the same breast but that have not been imaged.

For H&E, immunohistochemistry with the markers usually involved in the evaluation of tumors were tested: estrogen receptors and progesterone (Cerb B2 (Her2/neu), ki-67, E-Cadherin). In the case of samples from healthy portions, the signals of the markers, such as cytokeratin (CK 7, 14, 18, 5/6) and vimentin, were measured and are given the same values as those obtained on not imaged samples. Extraction of DNA and RNA of nucleic and ribonucleic acids has been carried out on samples imaged in FFOCM. No changes have been noticed.

26.1.3 Optimization of the Imaging Protocol for FFOCM-Histology Comparison

The first part of the work was to make possible the comparison of histology slices samples with the images obtained in FFOCM. Iterative sequences of FFOCM imaging and comparison with corresponding HES slices were made to determine the most effective imaging protocol. Tissue samples were all chosen by pathologists from mastectomies or lumpectomies. Fresh tissue samples were preferred in this study: we found that images have a better contrast and the procedure is close to clinical conditions. After macroscopic evaluation of the tumor, at least four samples were collected for each patient: one in the tumor zone, one on the edge of the tumor, and, in the case of mastectomy, two samples areas appearing healthy. The selection of these three types of samples is intended to allow the identification of the three regions of interest of the breast tissue: normal breast tissue, cancerous breast tissue, and the area between the normal part and the pathological one in order to allow the evaluation of surgical margins.

Once selected, the tissue sample is placed in a sample holder and immersed in buffer type mineralized PBS (phosphate-buffered saline) to prevent its drying. This solution also has a refractive index close to that of water and hence the biological tissues. The sample was gently pressed against the silica window of the sample holder in order to obtain an imaging surface as flat as possible and to reduce optical aberrations.

26.1.4 Comparing FFOCM and Histology

One of the main difficulties in comparing the two types of images comes from the difference in orientation of the sample in the sample holder and into the paraffin block. It is therefore difficult to observe the same slice using FFOCM and HES. Thus, in the first step FFOCM images of the sample at different depths (surface: 20 μmm, 40 μmm, 60 μmm, and 80 μmm) were systematically recorded and HES slices at equivalent depths achieved.

The acquisition and processing time for 1.4×1.4 cm^2 field of view is about 5 min. All images presented were taken using direct (not reversed) LUT; structures with a high backscattering level appear white. At the end of the imaging procedure, the samples are placed in a cassette; the anonymity of patients is provided in accordance with the rules ethics relating to studies on human tissue.

Once the histology slides corresponding to FFOCM images are performed, the working sessions with the pathologist are organized to compare the two types of images. For this purpose, the images are observed without digital zooming and compared with histological images at low magnification, and recognition of structures is done on the two types of support by progressive zoom in and out.

By successive comparison of a large number of images of healthy breast tissues and pathologic ones, it was possible to highlight in the FFOCM images characteristics of normal breast tissue and their modification in case of cancer.

These structures are the lobules, ducts, fibrous tissue, the blood vessels, and the adipose tissue which are represented in Fig. 26.1.

In general, the structures containing spans of collagen (fibrous tissue and muscle) return an important backscattered signal (white on the FFOCM images). Instead, the epithelial structures (lobules and ducts) backscatter less and appear gray. Lobules structures (A) appear as dark gray and rounded. Longitudinal sections of mammary channels (B) appear as dark gray elongated structures with epithelial membrane of variable thickness. Their clear gray level in the thick elastic surrounding membrane distinguishes these glands, tangentially sectioned by FFOCM (C). We can also note the presence of calcifications that appear very white. Blood vessels in tangential section (D) do not have the thick epithelial membrane of ducts but are also distinguished by the presence of a thin elastic membrane. Adipocytes (E) are not backscattering features and appear as black rounded structures that differ only by the presence of the membrane that is more diffusive and appears white. The honeycomb structure characterizing adipose tissue is very well reproduced on the FFOCM images. Normal fibrous tissue (G) has a grainy and moderately backscattering level. In an area of cancerous stroma, fibrous tissue appears very different; it is composed of fine highly backscattering structures that appear white. In scar area (F) fibrous tissue is made of thick and wide spans that induce a low level of backscattering.

During a routine histological examination of a mastectomy, the nipple was excised and analyzed for the presence of Paget disease.

The FFOCM image of a nipple is shown in Fig. 26.2 with the corresponding histological image. The elongated structures are milk ducts cut transversely (E), and one can recognize their white elastic membrane. Sebaceous glands (D and F) are rounded structures along the nipple; they correspond to rounded structures on histology and scored on GS (B). The outer edge of the nipple is a layer of skin where one recognizes the dermoepidermal border by its reticulated appearance (C).

When imaging pathological tissues:

- *Malignant tumors* can invade and destroy adjacent structures. A malignant tumor can spread through remote metastasis (cells detached from the original tumor to proliferate at a distance). Infiltrating cancer is when the proliferation of cancer cells exceeds specific limits histological and if metastatic cells spread to other organs by lymphatic channels.
- *Benign tumors* are localized tumors. If cancer cells are contained within well-defined limits, the structure is called carcinoma in situ. However, such a tumor can develop into malignancy, which may be fatal if not treated.

Tumors that develop from glandular epithelial structures are called adenocarcinoma: If the spread is within a lobule and without exceeding the limits, we speak of in situ lobular carcinoma (often benign). If the tumor develops from a milk duct, it is called ductal adenocarcinoma; this tumor is malignant in most cases. The presence of a tumor in the breast results in the case of invasive cancer is revealed by a change in the appearance of breast tissue and of a structure having a stellar or nodular shape.

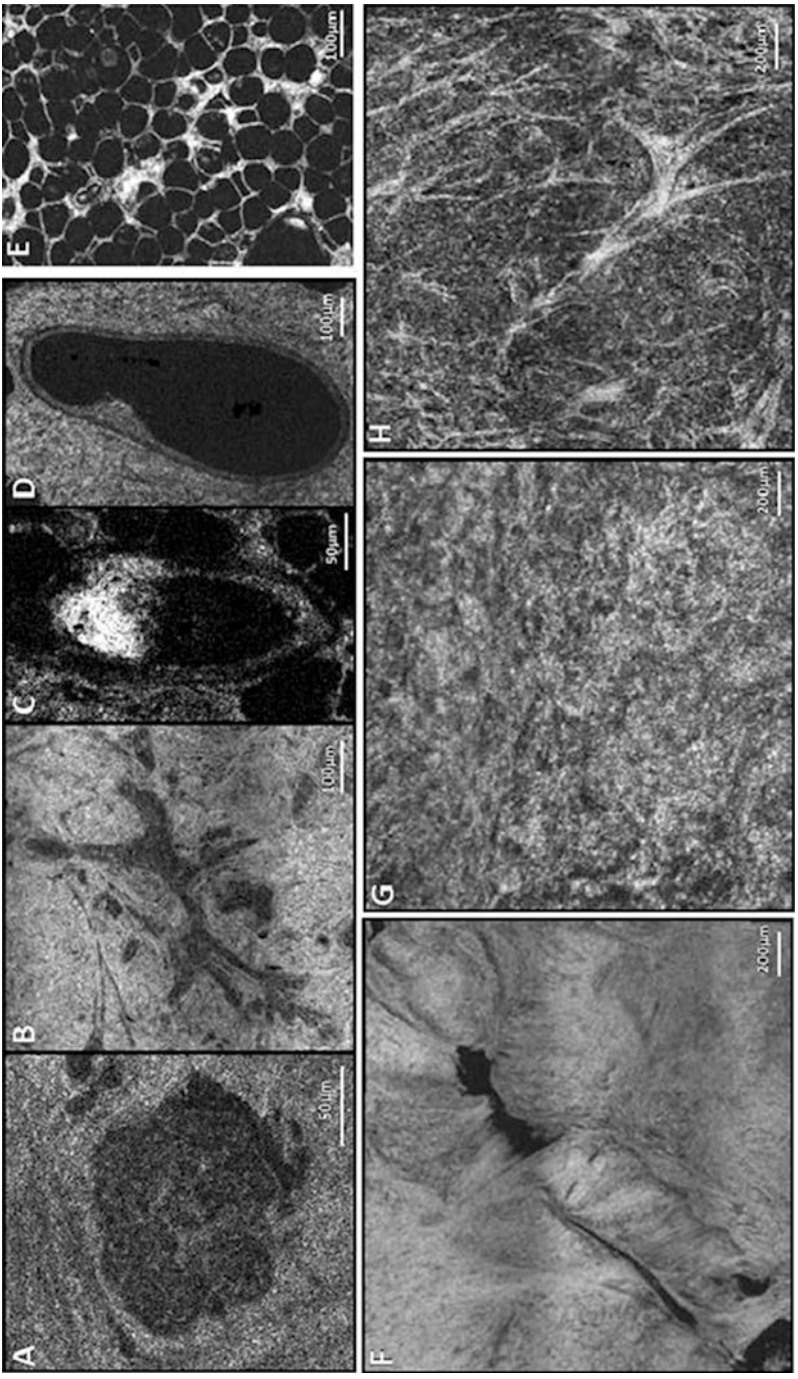

Fig. 26.1 Basic structures of breast tissue: lobule (**a**), milk duct (**b**), cutting cross milk duct with calcification (**c**), blood vessel (**d**), adipocytes (**e**), scar fibrous tissue (**f**), normal fibrous tissue (**g**), fibrous tissue surrounding carcinomatous cells in tumorous stroma (**h**)

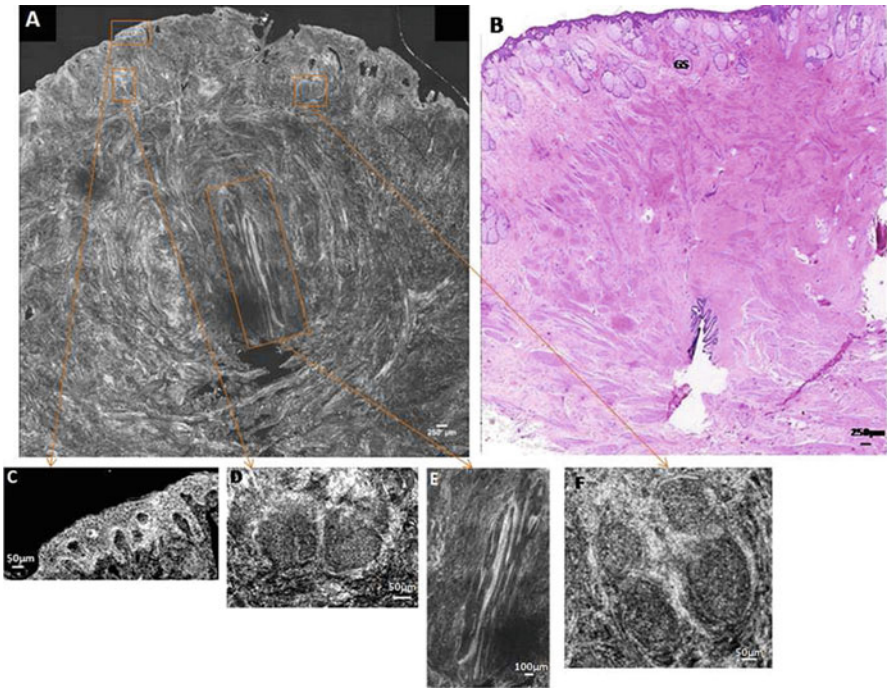

Fig. 26.2 Nipple: dermoepidermal junction of the outer skin layer (**c**), sebaceous glands (**d**) and (**f**), milk duct transected (**e**)

Examples of invasive cancers are represented in Figs. 26.3 and 26.4. Figure 26.3 is a tumor called stellar and Fig. 26.4 one nodular tumor. In both cases the fibrous and adipose tissue are separated; in the case of the stellar tumor, stroma tends to invade the adipose tissue (Fig. 26.3c). Fibrous tissue has a characteristic appearance of fine highly scattering spans (Fig. 26.3c, d), which is distinct from normal fibrous tissue (Fig. 26.4d). Adipocytes at the edge of the stroma (Fig. 26.3e) appear smaller and less rounded in form than in healthy tissue. In the case of nodular tumor, adipose tissue surrounds cancer cells that form a dense region of dark gray.

The difference in appearance of the fibrous web can be used to mark the margins of the tumor. A circular channel dilated with secretions in the lumen is visible in the center of the sample. These changes in appearance of the fibrous tissue and the shape of the adipocytes are highly visible on the images FFOCM, while it does not appear clearly on the histological images. These characteristics are used as criteria for classification of breast tissue by the FFOCM imaging technique.

There are also cases where invasive cancer and carcinoma in situ are simultaneously developed for a patient, as in the example of Fig. 26.5. Ductal carcinoma in situ is characterized by channels extended by the presence of cancer cells in the interior (D). Invasive ductal carcinoma components result in the presence of fine highly scattering

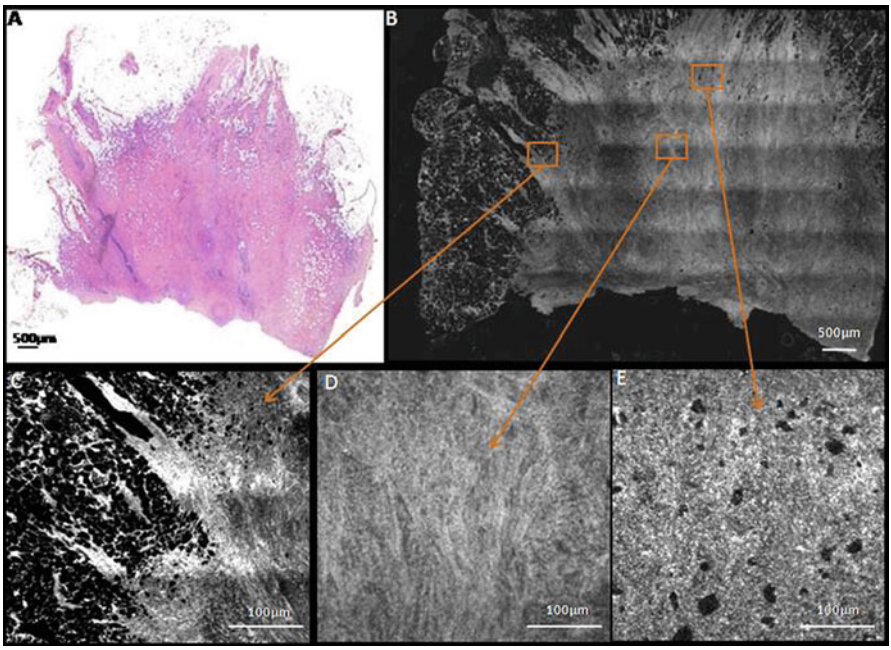

Fig. 26.3 Infiltrating carcinoma: stellar tumor (**a**, **b**). Invasion of adipose tissue (**c**), fibrous tissue tumor (**d**), small adipocytes, and deformed (**e**)

fibrous tissue (B) and foci of darker grey carcinoma cells (D). Ductal in situ components are recognisable by enlarged ducts and lobules filled with cancer cells.

A fibroadenoma is represented in Fig. 26.6. This lesion is characterized by the presence of dilated ducts called tubular easily recognizable in the FFOCM image (B).

Lobular carcinoma in situ is shown in Fig. 26.7, it is characterized by a proliferation of small cells widely dilated acini of lobules (C). This lesion is benign; however, in the example shown here, a milk duct (D) has at its center proliferation that is a sign of malignancy.

Upon an analysis based on FFOCM images, it is possible to start a classification breast tissue. This approach is described in detail in [16].

26.1.5 FFOCM and Lymph Nodes

In this section, we intend to discuss the usefulness of FFOCM as a tool for classification of lymph nodes in order to assess whether this imaging technique could help surgical ablation of lymph more efficiently. Surgical treatment of breast malignancy is based on the removal of the primary tumor and the axillary dissection that involves the removal of more than half of the lymph nodes in the armpit on the same side. This process of removal of lymph is still considered

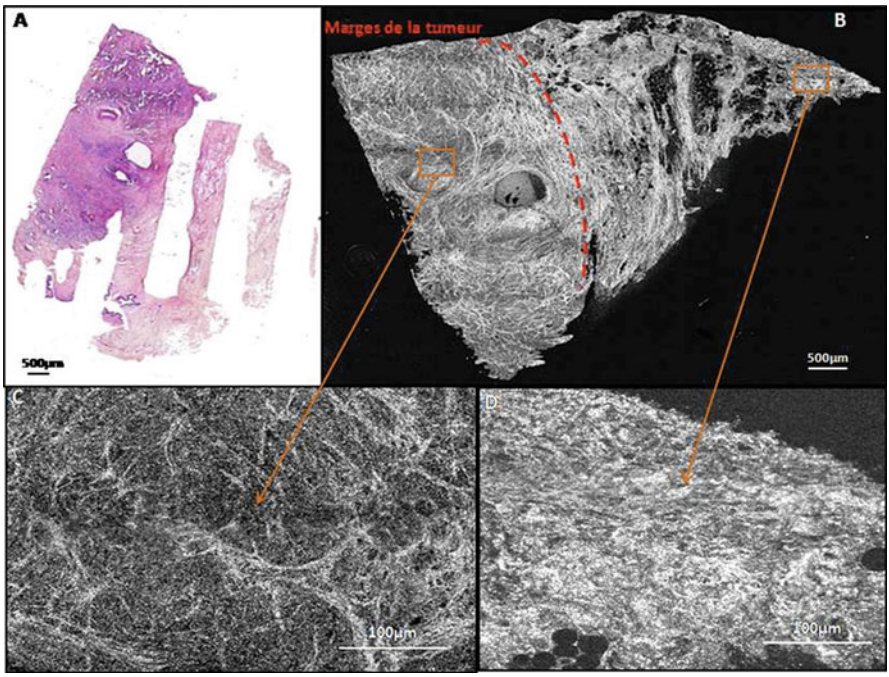

Fig. 26.4 Infiltrating carcinoma: tumor nodule (**a**, **b**). Fibrous tissue surrounding cancer cells (**c**), normal fibrous tissue (**d**)

as the standard even if it has several drawbacks. In fact, it often induces complications in the arm such as the decrease in the sensitivity of touch, pain in the upper arm on the operated side, a reduction in the function of the shoulder joint, or lymphedema of the arm in 80 % of cases [17]. In addition, it was shown for T1 tumors (tumor size less or equal to 2 cm) that the percentage of invaded axillary lymph nodes is 23 %, which means that 77 % of axillary dissection are unnecessary [18]. To limit the number of dissections, axillary sentinel node technique was introduced in 1998 [19]. The sentinel lymph node is a lymph node in the armpit. It is anatomically the closest to the breast tumor and, accordingly, will be the first node receiving lymphatic drainage from a tumor. If it is invaded, axillary dissection is performed; however if it appears not invaded, lymph nodes in the area are not removed.

The results of sentinel nodes analysis are used to determine the type of treatment to administer after surgery but are only available until several days after the operation, once achieving complete histology slides. It would be useful to the surgeon to have a quick picture of lymph to assess their invasion during the operation. It is in this spirit that FFOCM lymph nodes images have been made in order to estimate if this imaging technique is able to distinguish invaded lymph from healthy ganglions.

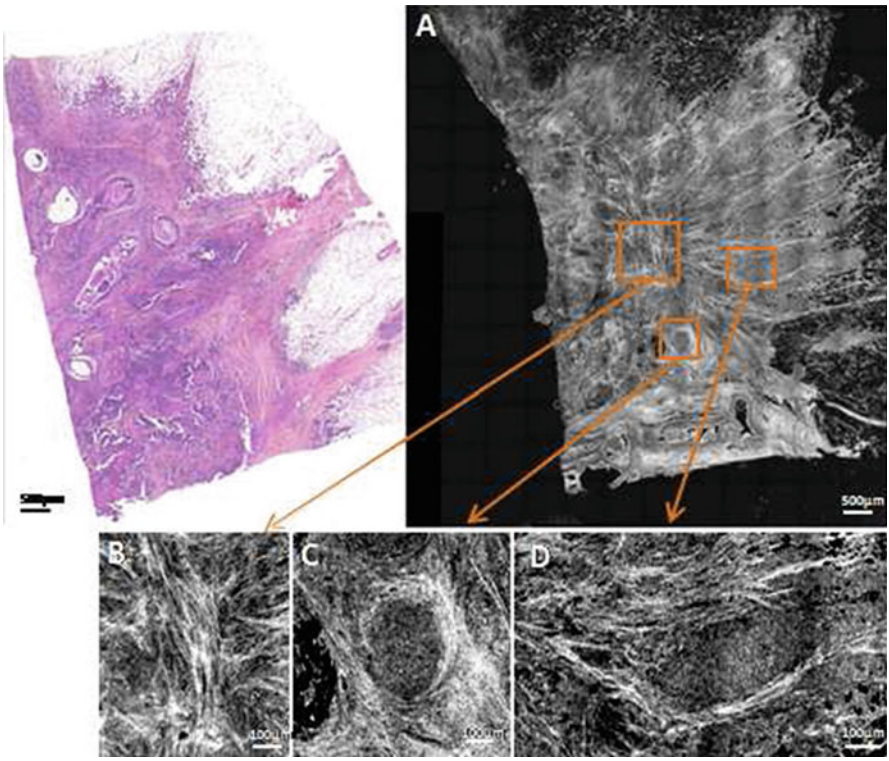

Fig. 26.5 Ductal adenocarcinoma with ductal in situ component: fibrous tissue finely spans highly diffusive (**c**), recognizable by its enlarged channel membrane elastic (**c**), fibrous tissue (*white*) surrounding cancer cells (*dark gray*) (**d**)

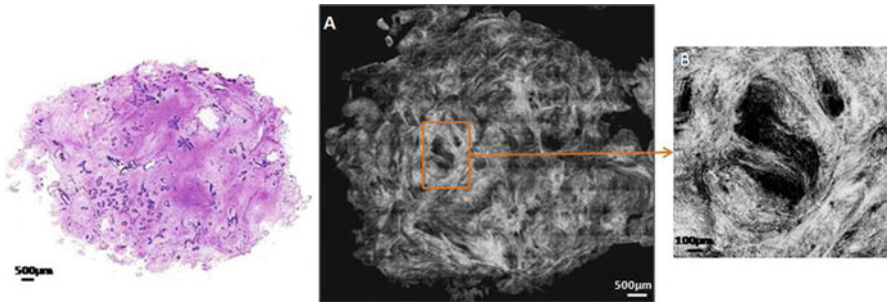

Fig. 26.6 Fibroadenoma (**a**) with characteristic enlarged channel (**b**)

An initial study using the elastic scattering spectroscopy (ESS) showed the usefulness of intraoperative analysis lymph nodes [20], but this study provides only macroscopic information and not microscopic architectures. Normal breast node tissues are seen in Fig. 26.8: one can see dense fibrous tissue and spans (D)

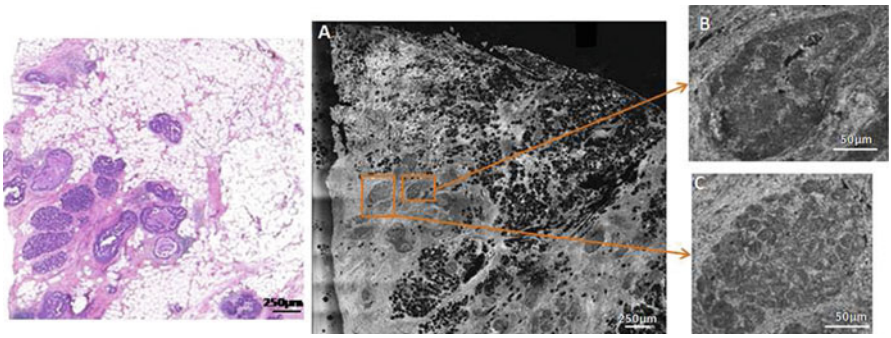

Fig. 26.7 Lobular carcinoma in situ (**a**) channel with expanded cellular proliferation in the center (**b**), with expanded lobule with visible acini (**c**)

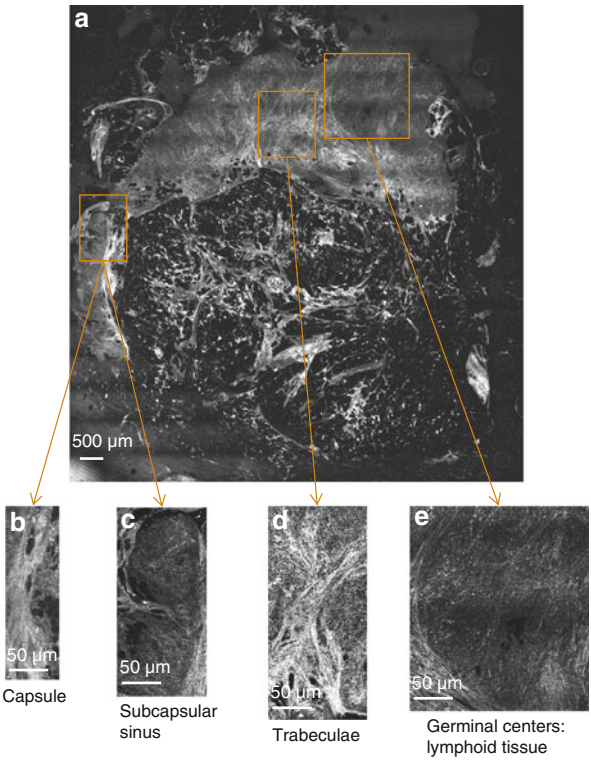

Fig. 26.8 Normal lymph node FFOCM images

that appear white. Subcapsular sinus (C) stands below the capsule, while terminal centers (E) appear as areas gray rounded.

The tumor lymph nodes are as recognizable in Fig. 26.9 as the structure of the ganglion is no longer respected and cell invasion within a zone lymphoid appears as

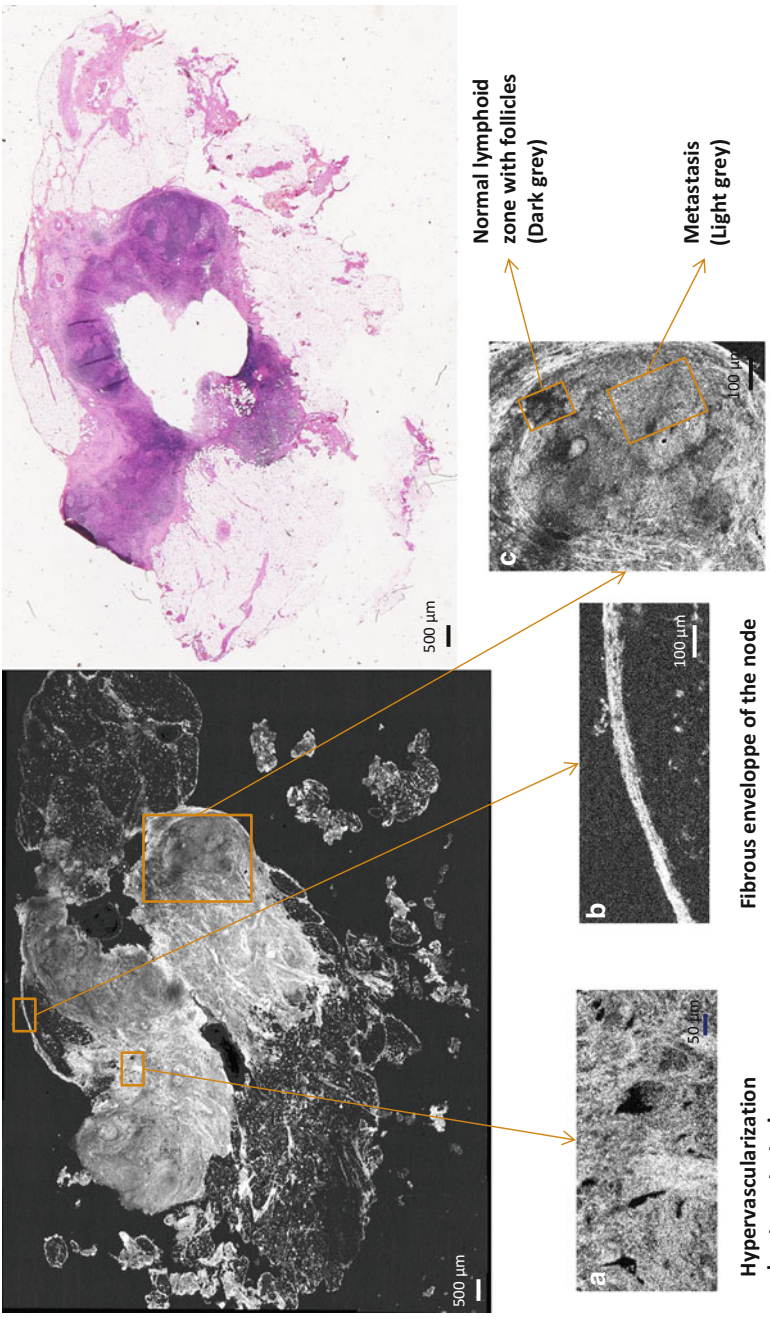

Fig. 26.9 Invaded lymph node FFOCM images

light gray areas. These zones correspond to purple regions on the HES slice that are clusters of cancer cells (C bottom); healthy lymphoid appears very dark gray (C top). Also, by zooming in the FFOCM image, we note the presence of many vessels reflecting hypervascularity characteristic of the presence of metastases (A).

26.2 FFOCM Study of Brain Tissue

26.2.1 Specificity of Brain Tissue Surgery

The encouraging results on breast tissue prompted us to test full-field OCT diagnostic of the brain where resection is difficult and risky. In this section we offer a preliminary phase of preclinical evaluation with FFOCM as an intraoperative tool of brain tumor surgery. Despite significant progress in the diagnosis and treatment of tumors, the survival rate for malignant tumors of the central nervous system (CNS) remains low [21]. Awake surgery technique, which was developed in the 1990s by Professor Mitchell Berger at UCSF, has improved the quality of resection of tumors located near the functional areas of the brain. This surgery intends to avoid language disorders or sensorimotor functions penalties. However, when removing a tumor, the neurosurgeon should be able to identify the nature of the tissue that is removed. Current tools for the identification of tissue include intraoperative MRI, the use of a surgical microscope, the fluorescence-guided resection, and finally extemporaneous histological analysis.

Intraoperative MRI provides low-resolution images of the surgical field and complete section of the brain that are sufficient for a rough estimate of the abnormal tissue excised but offers low acquisition resolution (ranging typically between 0.5 and 1 mm) and artifacts occur at the air-tissue interface. Using an operating microscope illuminated by a xenon lamp gives a clear vision of the operative field but is limited by the low capacity of discrimination of white light. Fluorescence-guided resection allows a more accurate assessment of the tumor region with the specific binding of fluorophores on cancer cells and therefore allows a better selection of pathological tissues than the white-light operating microscope. However, this technique requires the absorption of an exogenous fluorophore by the patient before the operation and is only sensitive to solid tumors with a low sensitivity to detect infiltration of the brain parenchyma by cancer cells.

The results that we will show in this section are, to the best of our knowledge, the only large images with a resolution sufficient to distinguish microstructural cerebral parenchyma. The first published study using OCT for the study of brain tissue was performed with a surgical probe OCT system [22]. This in vivo system has axial and lateral resolutions limited to 16 and 30 μm, respectively, and is focused on a single sample of excised brain. Nevertheless, it was possible to recognize a melanoma and an artery. Later, SD-OCT systems have been favored for their better resolution (4/8 μm, transverse/axial) allowing distinguishing areas of solid tumors, areas

invaded by the tumor and normal tissue [23] through the depth attenuation of signals. More recently, a study involving more patients with gliomas (9 in all) and using a TD-OCT system with 15 μm axial and transverse resolution was used to classify samples as malignant or benign with a good correlation with the histopathological diagnosis [24]. However, in this case too, the differentiation was based on the attenuation of the signal returned by the tumor zones relative to the healthy areas. The classification does not lead to the recognition of microscopic structures of the brain parenchyma in contrast to what we will show with FFOCM. A study published in 2005 showed images of brain microstructures using an ultrafast laser providing axial/lateral resolution of 1.3/3 μm, respectively. Thus, it was possible to differentiate malignant tissue from healthy tissue by the presence of blood vessels, microcalcifications, and cysts in the tumor tissue [25]. However, the images obtained are small (2×1 mm^2), and they have only been performed on fixed tissue and require a femtosecond laser whose cost is high and size is rather large limiting its implementation under clinical conditions.

Our imaging technique presented here and described in ▶ Chap. 25, "Time Domain Full Field Optical Coherence Tomography Microscopy" combines several advantages; their large sizes are comparable to those of samples embedded in paraffin for histological analysis, thus facilitating images analysis by physicians. The imaging system is compact, can be placed in the operating room, and provides a sufficient resolution (1 μm axial and lateral) for distinguishing brain tissue microstructures.

The histological and immunohistochemical analysis of excised tissues (from stereotactic biopsies or samples excised during surgery) is the only reliable method to analyze tissues and cellular level architectures. However, this method requires the use of paraffin and staining of tissue, which cannot be obtained during surgery. The extemporaneous examinations are poorly made during the surgical resection of a brain tissue tumor, as the brain parenchyma limit is very difficult to section and to color selectively.

For these reasons there exists a need for a rapid and reliable method that would bring information to neurosurgeons during the operation for guiding the surgical procedure. The objective of this preliminary study is to ensure that healthy and pathologic brain structures are recognizable through FFOCM images.

26.2.2 Nervous System Tumors

There are benign and malignant brain tumors. Neurons are postmitotic cells and cannot produce purely neuronal tumor. Glial cells, in contrast, can produce cancers called gliomas, which are primary most common brain tumors, although still rare in the world's population [21]. Some are benign gliomas such as astrocytoma, the most common, while others, such as glioblastoma, are malignant.

Among benign brain tumors, there are meningioma and papilloma choroid plexus. Microscopically, meningioma is composed of spans cells organizing themselves in vortex of concentric spheres.

26.2.3 Brain Tissue FFOCM Imaging

All images in this study were performed on brain tissue samples from the neurosurgery department of Pr. Devaux, Hospital Sainte-Anne. Agreement of the patients was obtained following the standard procedure for consent patients undergoing biopsy or surgery in this hospital. This study was conducted with samples of fresh tissue from the tumors surgically excised. Immediately after surgical ablation, the sample was sent to the pathology department. The total surface of the sample was imaged. Once imaged, the sample was immediately fixed in formalin-zinc. Then, the pathology department followed the standard histology process. Samples from diseased tissue were observed. For this study, 20 samples from 11 different patients were included. The results have been published in an article [26].

26.2.4 Cortex and Hippocampus

Samples of cortex and hippocampus were obtained from patients treated for surgery of epilepsy. On these samples containing no cancer cells, we have verified that it was possible to recognize different areas of brain parenchyma or morphologically. Indeed Fig. 26.10 shows a cross section of a brain parenchyma.

The gray and white matter differ significantly: in fact we recognize the cell body of neurons in the cortex and the beams leading to the axon white matter. The cell bodies of neurons appear as black dots with a triangular shape. Cortex does not contain myelin; it appears dark gray. Myelin fibers are strong backscatters [25, 27] and appear white in the images (C). Capillaries are distinguished by a thin collagen membrane which appears gray or white (D). It is important to note that on a single FFOCM image, these three types of structures appear (cell body, axon, vessels), whereas classical HES staining of myelin fibers do not appear clearly and it is necessary to make special staining of the paraffin block by Bodian-Luxol.

The hippocampus consists of two parts: Ammon's horn and the dentate gyrus consist of gray matter. It is a very complex structure folded upon itself and formed by a single layer of neurons. The hippocampus comprises a plurality of anatomical regions or fields named CA1, CA2, CA3, and CA4 (Ammon's horn 1, 2, 3, and 4). Regions of the hippocampus are recognizable in the FFOCM image (Fig. 26.11). More precisely there are CA1 field and stratum radiatum, CA4 field, the crack of the hippocampus, the dentate gyrus, the hippocampal alveus, and the furrow. Other structures appear by zooming in the FFOCM image: large pyramidal neurons of CA4 that are responsible for memory and granule neurons and smaller and more rounded neurons that form the granular layer of dentate gyrus are visible.

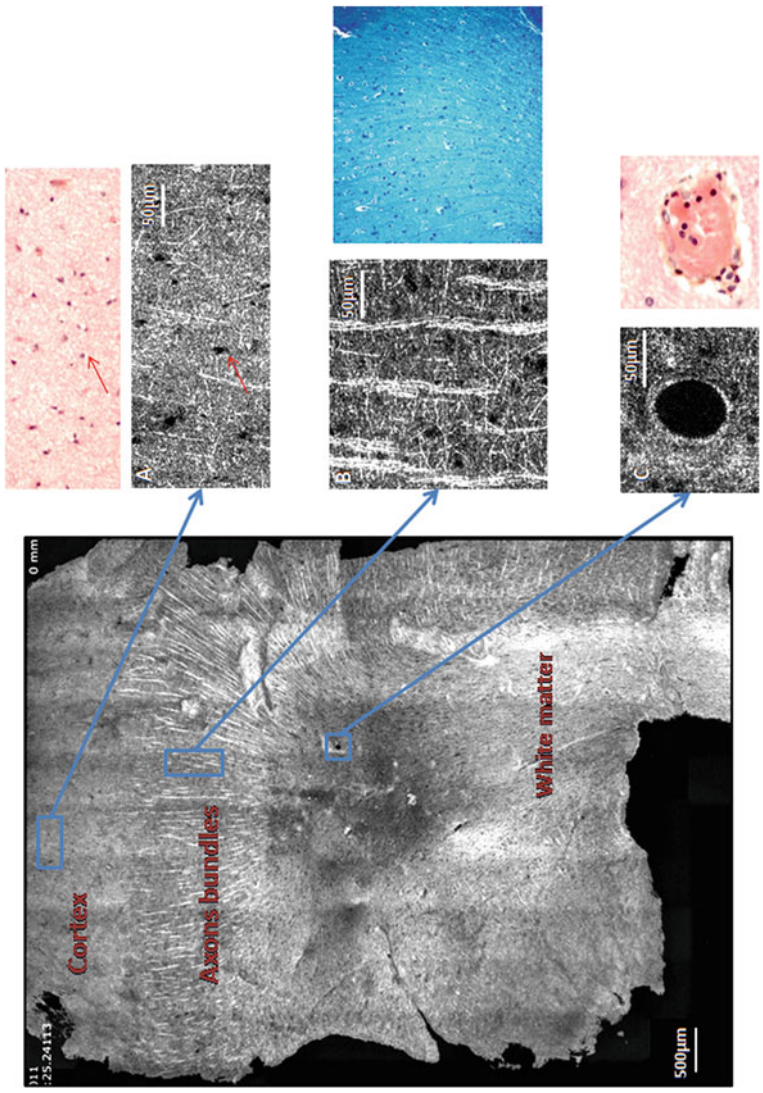

Fig. 26.10 FFOCM image of a sagittal section of the brain parenchyma: cell bodies neurons (**b**), myelin fibers (**c**), capillary (**d**)

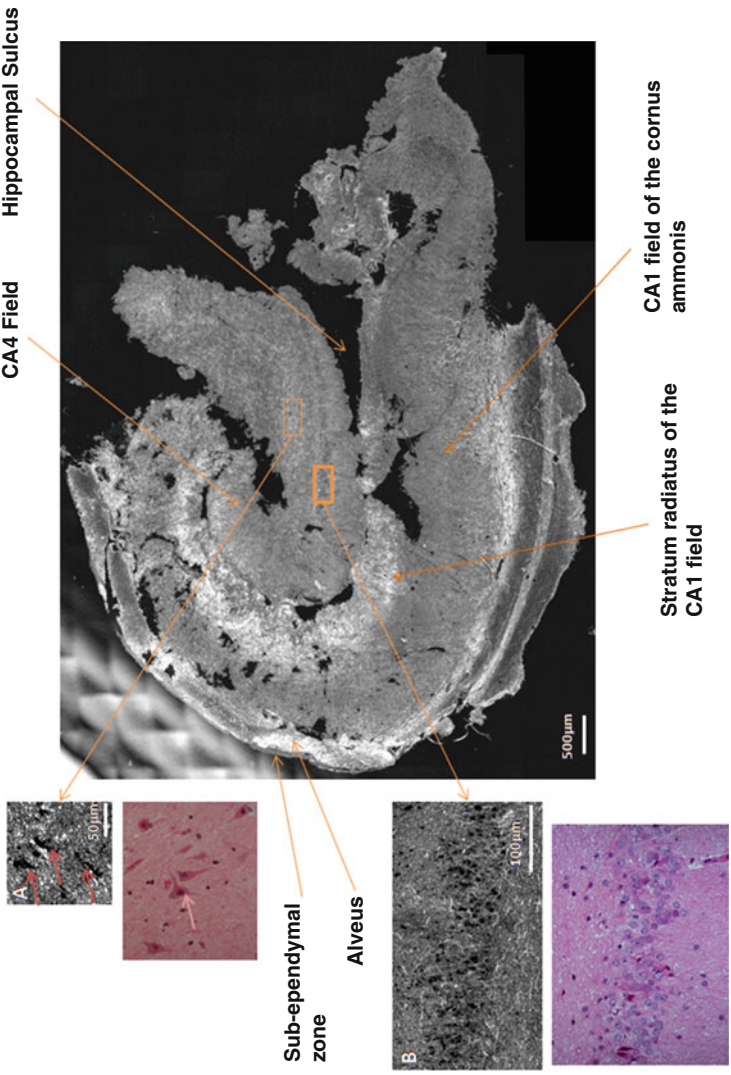

Fig. 26.11 FFOCM image a coronal section of hippocampus

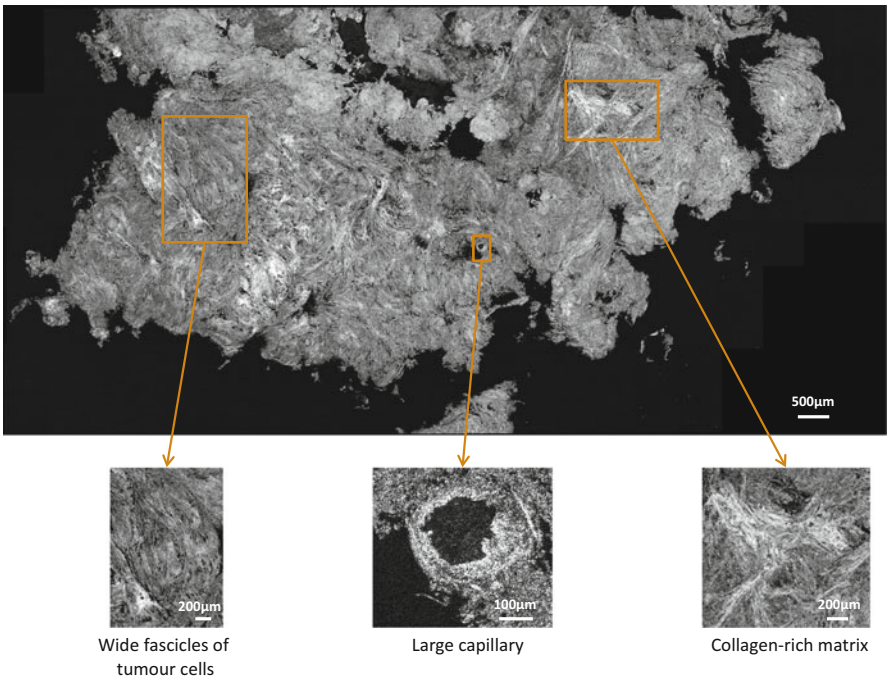

Fig. 26.12 FFOCM image a fibroblastic meningioma grade I

26.2.5 Meningiomas

Meningiomas are tumors developed at the expense of the meninges (grade I tumors) and three variants for each of grade II and grade III meningiomas. The most common subtypes are meningotheliomatous, transitional or mixed type, fibrous, and psammomatous. The stroma is often rich in collagen and reticulin and the tumor is often richly vascularized. An example of meningioma is shown in Fig. 26.12. The morphological characteristics of the tumor found in FFOCM image are large clusters of cancer cells (A), the matrix rich in collagen (C), and the presence of large capillaries surrounded by a white elastic membrane (B) characterizing tumor vasculature.

26.2.6 Choroidal Plexus Papilloma

Choroid plexus papillomas grow at the expense of the choroid plexus. The choroid plexus are papillary formations, which form the cerebrospinal fluid. They consist of connective tissue covered with epithelial cells forming papillae. These lesions have a very particular form of words in "cauliflower." This architecture is easily recognized as can be seen in Fig. 26.13. Papillae filled with blood differ significantly;

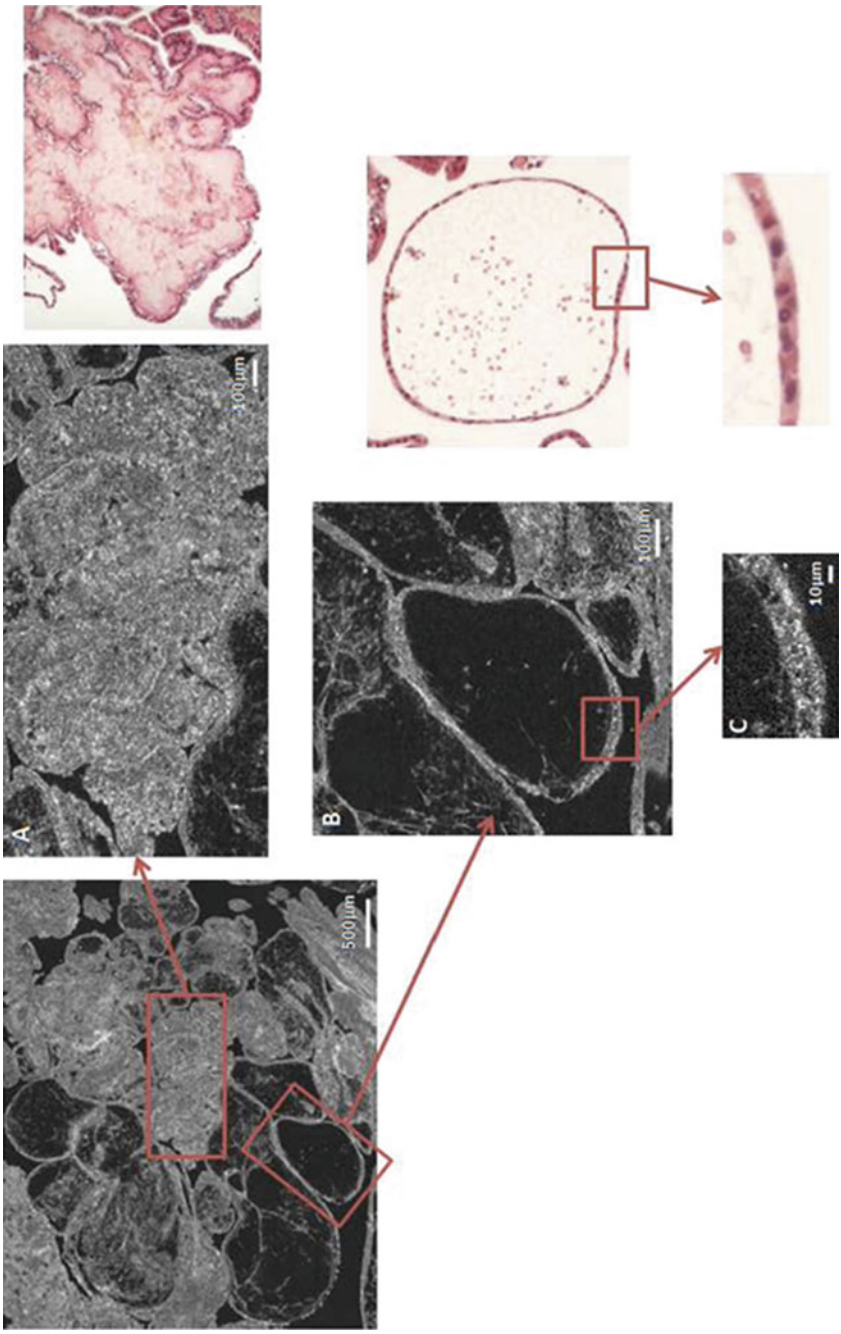

Fig. 26.13 Choroid plexus papillomas FFOCM and histology

by zooming in the image, we can acknowledge the good comparison with histology. Similarly, on a papilla, information at the cellular level is visible; there are the layers of epithelial cells that are connective tissue-like clusters.

26.3 Skin Tissue

26.3.1 FFOCM Study of Skin Tissue

The skin is the organ most readily accessible. Yet its clinical examination is limited nowadays to either the low-resolution, superficial analysis given by the dermatoscope or the high-resolution diagnostic allowed by histology, to the expense of an invasive and tedious procedure. This hampers the possibilities of an early diagnosis of skin cancer that could be decisive regarding the chance of cure of the patient. This is particularly critical as skin cancer is currently the most frequent cancer, with about 3.5 million new cases every day. As FFOCM can provide virtual sections of the tissue noninvasively and without the need for a contrast agent, it appears well suited for the analysis of skin pathological tissues. The usefulness of such a technique can also be highlighted for the analysis of margins in skin surgery. Basal cell carcinoma (BCC), the most frequent skin cancer, mostly affects facial areas; therefore, it is desired that excision surgeries remain as minimally invasive as possible. In that context, Mohs micrographic surgery is a commonly employed treatment for BCC. In Mohs protocol, excised tissue is examined during the surgery using frozen section histology as in breast surgery, as detailed above. An alternative technique such as FFOCM can prove preferable as it is simpler, noninvasive, occupying a small footprint, and operator independent.

Several studies have been published on the use of OCT imaging techniques on skin, and in particular to assess its capacity to discriminate cancerous tissue [28–34]. The results showed that the altered architecture of cancerous areas could be visualized and matched to the histological or light microscopy analysis. The OCT systems used however had a lower resolution (5–10 μm axial and transverse) than that allowed by FFOCM. It is therefore very relevant to examine the capacities offered by FFOCM on the analysis of skin pathological tissues.

26.3.1.1 Skin Structure

Skin is made of three separate layers. On top, the epidermis contains the stratum corneum, the stratum granulosum, the stratum spinosum, and the stratum basale that makes the junction with the dermis. The dermis mostly contains collagen and blood vessels, among which adnexal structures such as pilosebaceous structures or sweat glands can be found. Finally, adipocytes lay in the hypodermis.

26.3.1.2 Skin Tissue FFOCM Imaging

Skin tissues used for this study were obtained from the Hopitaux Universitaires de Genève, in collaboration with Dr Salomon and with informed consent from the patients. Fresh and formaldehyde fixed tissues were examined ex vivo, before being processed as histology slides.

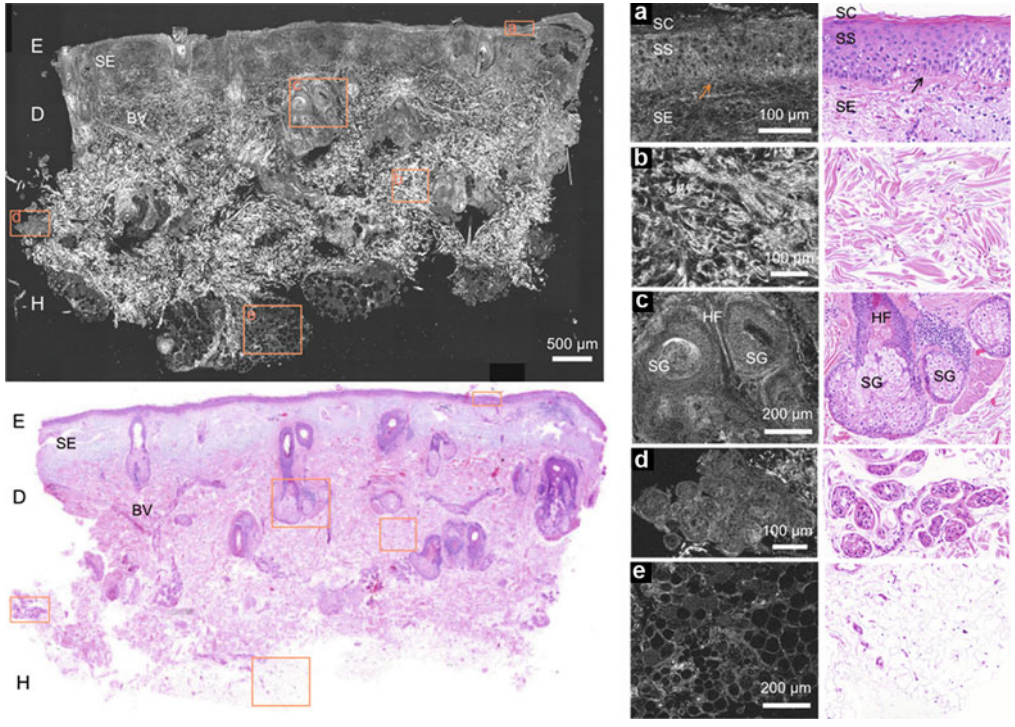

Fig. 26.14 FFOCM image of a normal aged skin and the corresponding histological slide. The three layers of the skin, epidermis (*E*), dermis (*D*), hypodermis (*H*), as well as a solar elastosis region (*SE*) and blood vessels (*BV*) are clearly distinguished. At high magnification, the stratum corneum (*SC*) can be differentiated from the stratum spinosum (*SS*) (inset 2**a**) and the enlargement of the nuclei from the basal layer (*arrows*) to the upper spinous layer is highly visible. The elastotic superficial dermis (SE in 2**a**) contrasts with the highly refractive collagen fibers of the dermis (2**b**). A pilosebaceous unit with hair follicle (HF) and sebaceous glands (SG) (2**c**), a sweat gland unit (2**d**) and adipocytes with their bright cell membranes (2**e**) are identified

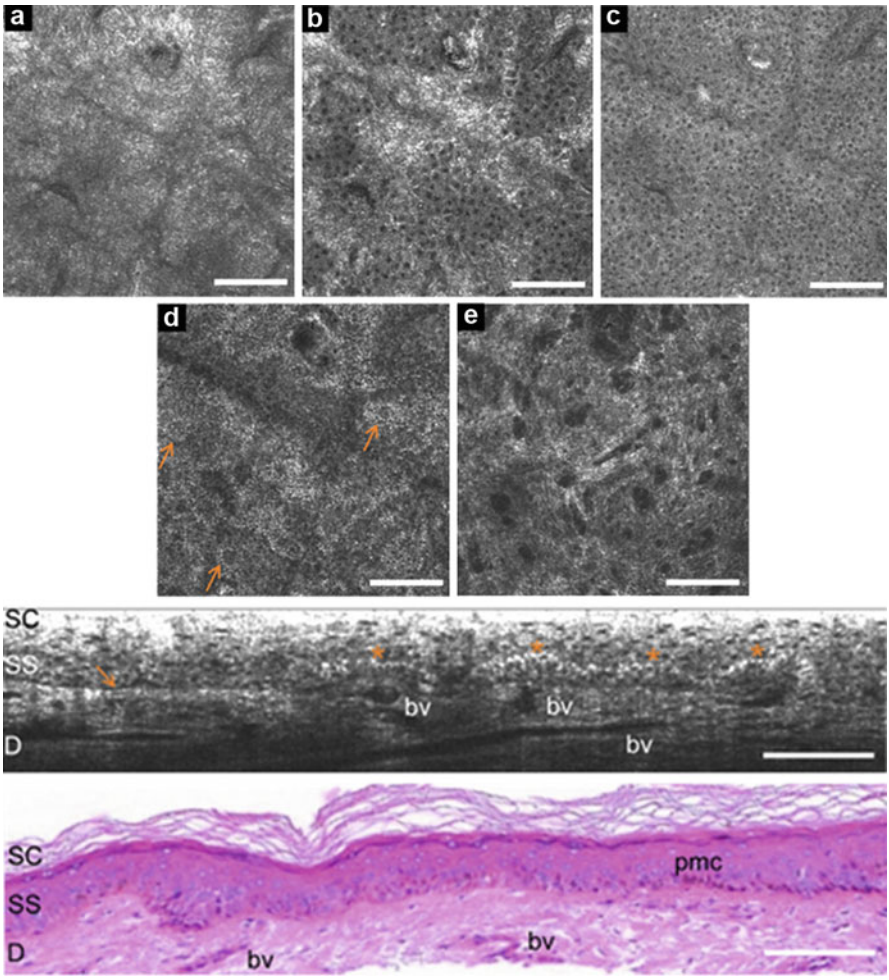

Fig. 26.15 *Left*, tangential images of skin fresh excision. (**a**) Stratum corneum (depth 10 μm); (**b**) stratum granulosum (depth 25 μm); (**c**) stratum spinosum (depth 35 μm); (**d**) stratum basale where *arrows* point at some papillaries (depth 60 μm); (**e**) dermis (depth 100 μm). Scale bar represents 200 μm. *Right*, vertical reconstruction and histological corresponding slide. Visible layers: stratum corneum (*S*), stratum spinosum (*SS*), dermis (*D*). The basement membrane (*arrow*) and melanin caps (stars) are visible. Blood vessels (*bv*) can also be identified. Scale bar is 100 μm

26.3.1.3 Normal Skin

As shown in Fig. 26.14, the main skin layers and structures can be easily identified and compared to histology in a vertical excision. Tangential imaging of the skin, allowing vertical reconstruction, is also possible as demonstrated in Fig. 26.15.

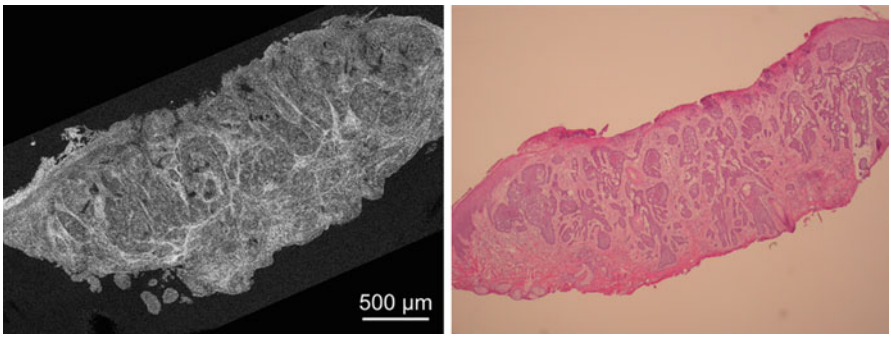

Fig. 26.16 Comparison of the FFOCM image of a vertical skin fresh excision with nodular basal cell carcinoma, with the corresponding histological slide

26.3.1.4 Cancerous Skin

An example of BCC lesion is shown in Fig. 26.16. The BCC nodules, surrounded by dense peritumoral stroma, are clearly distinguished from normal tissue, and this is confirmed by the histological slide. A closer analysis on another sample shows that the tumorous cell aggregations are visible on OCT images as black spots densely arranged (Fig. 26.17).

A more extensive description of the capacities of FFOCM in skin imaging for clinical and cosmetics applications is presented in publications [34, 35].

In conclusion, these studies, the first that we have conducted in a clinical hospital environment using FFOCM, open a critical door in the process of assisting and replacing cryogenic sections when many are impossible to perform cryogenic sections as intraoperative diagnostic tools. Although the contrast of the image is not able to provide the chemical or biological signature used by the pathologists, this nondestructive endogenous technique brings a large number of valuable informations dealing with the tumor malignancy, the margins, etc.

The expected field of application of FFOCM is clearly tissue selection and identification:

- Needle core biopsy in the operating room, where the aim is to validate the tissue sample "quality" for further chemical and biological analysis; studies have already started [36–39].
- Biobanking is another field where tissue selection is critical; a first trial using FFOCM is underway.
- Tissue selection in the grossing room could be performed in order to identify the optimal sample for further histology/immunohistochemistry.
- Intraoperative assessment of surgical margins in various organs such as the prostate, breast, etc. could be performed in order to optimize the resection process [37, 38].

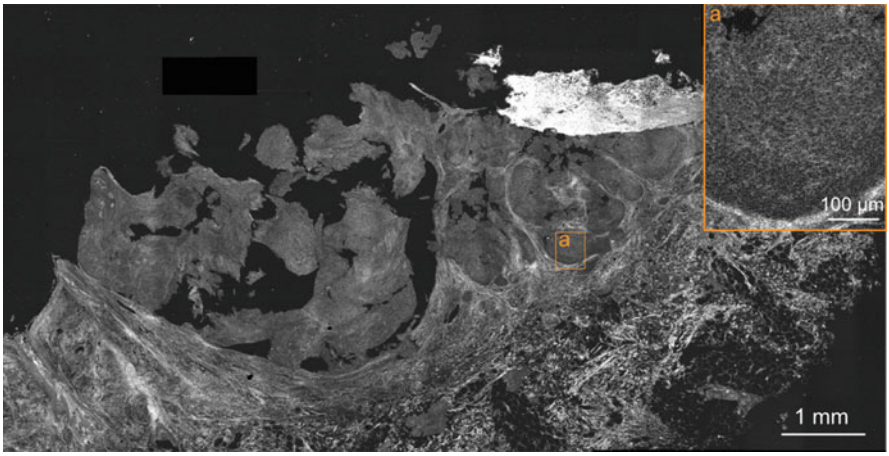

Fig. 26.17 Basal cell carcinoma in a skin vertical excision. Inset sows zoom of region *a*

Finally we hope that the endoscopic FFOCM approach described in ▶ Chap. 25, "Time Domain Full Field Optical Coherence Tomography Microscopy" will become a useful tool in the surgeon's hands for an in situ and in vivo diagnostic.

27.1 Introduction

Optical coherence tomography (OCT) images three-dimensional biological tissues with micrometer resolution. While time-domain OCT required axial scanning of the imaging plane or the specimen, Fourier-domain OCT enabled parallel detection of all depths, which allowed to increase the acquisition speed by several orders of magnitude. When increasing the numerical aperture (NA) for achieving microscopic resolution, the advantage of Fourier-domain over time-domain OCT is lost. The resolution and sensitivity of FD-OCT imaging is only optimal within the Rayleigh range. Both degrade outside of the focal region, which shrinks with the square of the NA. The sensitivity is lost due to the confocal gating as photons from out-of-focus layers do not even reach the detector.

In full-field swept-source OCT, a parallel illumination and detection and the abandoning of the confocal gating allowed to maintain sensitivity over larger measurement depths [1, 2].

In digital holography (DH) entire wave fields, including their phase and amplitude, are captured, and the image information is calculated from the interference pattern. This allows for numerical refocusing in order to obtain images of the specimen over a larger measurement depth than provided by the focal depth [3–5]. But DH does not provide tomographic imaging, as no cross-sectional images are obtained.

Finally, by combining digital holography and full-field swept-source OCT, tomographic images are obtained, with optimal sensitivity and resolution spanning regions much larger than the focal range. Using numerical algorithms, comparable to the ones first shown in interferometric synthetic aperture microscopy (ISAM, [6–10]) and inverse scattering for full-field OCT [8, 11], the depth of focus can be extended, and thus, a depth-independent resolution and sensitivity can be obtained.

The combination of digital holography with time-domain and Fourier-domain OCT was shown by several groups. Massatsch et al. [12] demonstrated the combination of time-domain OCT with digital holography. However, when using time-domain OCT, axial scanning is still required. First optical sectioning using digital holography with multiple wavelengths was shown by Kim in 1999 [13], but cumbersome and inefficient reconstruction algorithms were used, and imaging quality was not comparable to OCT. The limitations were mostly due to the small number of wavelengths used. Later work used OCT technology to obtain better images, but in the applied reconstruction algorithms, the focus was fixed to a single layer, and thus, the principal advantage of digital holography – virtual refocusing – was not used [14, 15]. An efficient reconstruction using simulated full-field OCT data was shown using inverse scattering techniques but not demonstrated experimentally [8, 11]. Finally, a consequent combination of digital holography with full-field swept-source OCT was shown in holoscopy [16–18, 23]. The extended depth of focus in terms of sensitivity and resolution compared to standard confocal scanning OCT was demonstrated, and images were shown that demonstrate an imaging quality comparable to full-field swept-source OCT.

27.1.1 Sensitivity Improvement of Holoscopy

In FD-OCT the imaging depth resulting in optimal images is limited to the focus region, which extends over two Rayleigh lengths z_R. The Rayleigh length at the Numerical Aperture (NA) is given by

$$z_R = \frac{\lambda}{\pi \mathrm{NA}^2},$$

with λ being the wavelength. Therefore, for the total measurement depth d, only a ratio of $2z_R/d$ of the B-scan shows optimal sensitivity and resolution. This motivates the definition of a photon efficiency of confocal OCT η_{confocal} by

$$\eta_{\mathrm{confocal}} = \frac{2z_R}{d} = \frac{2\lambda}{\pi d \mathrm{NA}^2}.$$

The photon efficiency for various measurement depths, ranging from 0.3 to 3 mm, at a central wavelength of 823.5 nm is shown in Fig. 27.1. The photon efficiency drops rapidly with increasing NA, and for microscopic NA around 1.0, it is several orders of magnitude smaller than the optimal value $\eta_{\mathrm{confocal}} = 1$.

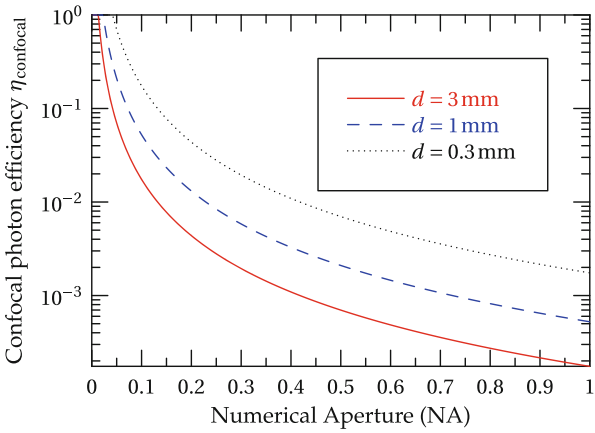

Fig. 27.1 Photon efficiency $\eta_{\text{confocal}} = 2z_R/d$ for a confocal FD-OCT. The photon efficiency describes the relative amount of backscattered photons that can be used for imaging with optimal diffraction limited resolution and sensitivity

In holoscopy all photons backscattered within the NA are detected and provide optimal resolution when refocused to the plane in which they were scattered. Holoscopy thus allows in principle an optimal photon efficiency of $\eta_{\text{holoscopy}} \approx 1$. It is therefore more efficient than FD-OCT and allows either to increase the sensitivity and imaging speed or to reduce the light intensity on the specimen.

27.2 Digital Holography

In digital holography, a wave field $O(x, y)$ of light scattered or reflected by the object is captured by recording the interference pattern of $O(x, y)$ with a well-known reference wave $R(x, y)$. The interference pattern $I(x, y)$ can be described by

$$\begin{aligned} I(x,y) &= \gamma |O(x,y) + R(x,y)|^2 \\ &= \gamma \Big(|O|^2(x,y) + |R|^2(x,y) + (O^* R)(x,y) + (O R^*)(x,y) \Big), \end{aligned}$$

where γ is a factor considering camera sensitivity and scaling between squared field strength and measured intensity values and x and y denote coordinates of the camera pixels. With a known reference wave $R(x, y)$, the wave field $O(x, y)$ can be computed by multiplying with $R/|R|^2$:

$$\left(\frac{R}{|R|^2} I \right)(x,y) = \gamma \left(\underbrace{\frac{R|O|^2}{|R^2|}(x,y) + R(x,y)}_{\text{Autocorrelation and DC term}} + \underbrace{\frac{O^* R^2}{|R|^2}(x,y)}_{\text{Conjugated signal}} + \underbrace{O(x,y)}_{\text{Signal term}} \right)$$

As in FD-OCT additional terms appear. Here, the autocorrelation term denotes the interference of the sample with itself. The DC term describes an offset to the entire

image, created by object and sample wave fields. The signal term is the wave field that was captured from the object, and the conjugated signal is proportional to the complex-conjugated object wave field.

In digital holography the reference illumination on the camera is in most cases applied under an angle to the object wave (off-axis holography), resulting in a separation of all three terms after a two-dimensional Fourier transform of the acquired interference pattern $I(x, y)$. In Fourier space the signal term can then be filtered, and disturbance of the non-signal terms can be minimized (see, e.g., [5]).

In FD-OCT similar terms arise in the spectral interference pattern, which disturb the final A-scan.

27.2.1 Propagation

Having obtained the object wave field $O(x, y)$ does in general not give any information about the structures of the object itself, as the object field from a deep volume cannot be focused onto the camera, i.e., for large parts of the sample volume, only an unfocused image is obtained. To solve this issue, one can propagate the wave field numerically by computing its diffraction pattern in the appropriate plane. One effective way to do this is the angular spectrum approach (see, e.g., [4, 5, 19]).

Using this approach the wave field $O(x, y)$ is first two-dimensionally Fourier transformed to obtain its angular spectrum, i.e., it is decomposed to plane waves propagating in different directions:

$$\tilde{O}\left(k_x, k_y\right) = \mathcal{F}[O(x,y)] = \int \mathrm{d}x\,\mathrm{d}y\;\; O(x,y)\mathrm{e}^{-\mathrm{i}\left(k_x x + k_y y\right)},$$

The original field $O(x, y)$ is then expressed as a superposition of plane waves $\exp(\mathrm{i}(k_x x + k_y y))$, each propagating in direction given by (k_x, k_y) and with amplitude $\tilde{O}\left(k_x, k_y\right)$

$$O(x,y) = \frac{1}{(2\pi)^2}\int \mathrm{d}k_x, k_y\;\; \tilde{O}\left(k_x, k_y\right)\mathrm{e}^{+\mathrm{i}\left(k_x x + k_y y\right)}.$$

Each plane wave

$$\tilde{O}\left(k_x, k_y\right)\mathrm{e}^{+\mathrm{i}\left(k_x x + k_y y\right)}$$

can be propagated in z-direction by multiplication with the phase factor

$$e^{+\mathrm{i}k_z z}, \;\text{ with }\; k_z = \sqrt{k^2 - k_x^2 - k_y^2}.$$

Thus, the propagation of the entire wave field $O(x, y)$ is achieved by propagating the plane waves it is composed of. Mathematically the propagation of the diffracted field from a known wave position can be described by an operator, called propagator $\mathcal{P}_{k,\,z}$.

The propagator is defined as

$$\mathcal{P}_{k,z}[O(x,y)] = \mathcal{F}^{-1}\left[\mathrm{e}^{+ik_z z}\mathcal{F}[O(x,y)]\right], \tag{27.1}$$

where k is the wavenumber and z denotes the propagation distance. The propagator yields results identical to the first Rayleigh-Sommerfeld diffraction integral [20].

27.3 Theory of Holoscopy

Holoscopy contains two critical steps: acquiring scattered object fields at multiple wavelengths by a camera and efficiently processing of the data to obtain tomographic images, which incorporates the reconstruction principles known from digital holography.

27.3.1 Basic Setups of Holoscopy

Setups that can be used for holoscopy are similar to the setups used in digital holography. Both techniques are based on the interference of a wave that is scattered or reflected by the sample and a well-known – usually spherical or plane – reference wave. The sample is illuminated with an extended, usually collimated, beam. The backscattered light is superimposed with the reference beam, and the resulting interference pattern is recorded. In contrast to digital holography, this is done in holoscopy for many wavenumbers using a swept-source laser and is thus comparable to swept-source OCT.

In general, no imaging optics are required for either technique, but the achievable lateral resolution is limited without using imaging optics. Digital holography and holoscopy can be used lensless or with microscope objectives to achieve high-resolution holoscopy. Schematic drawings of possible holoscopy setups are shown in Fig. 27.2a, b.

27.3.2 The Acquired Images

In holoscopy, the interference image $I(x, y, k)$, which is caused by a superposition of a reference wave field $R(x, y, k)$ and a sample wave field $O(x, y, k)$ on the camera, is dependent on the wavenumber k. We assume that the fields R and O have been acquired for the entire plane, i.e., for all (x, y). In practice this is never the case,

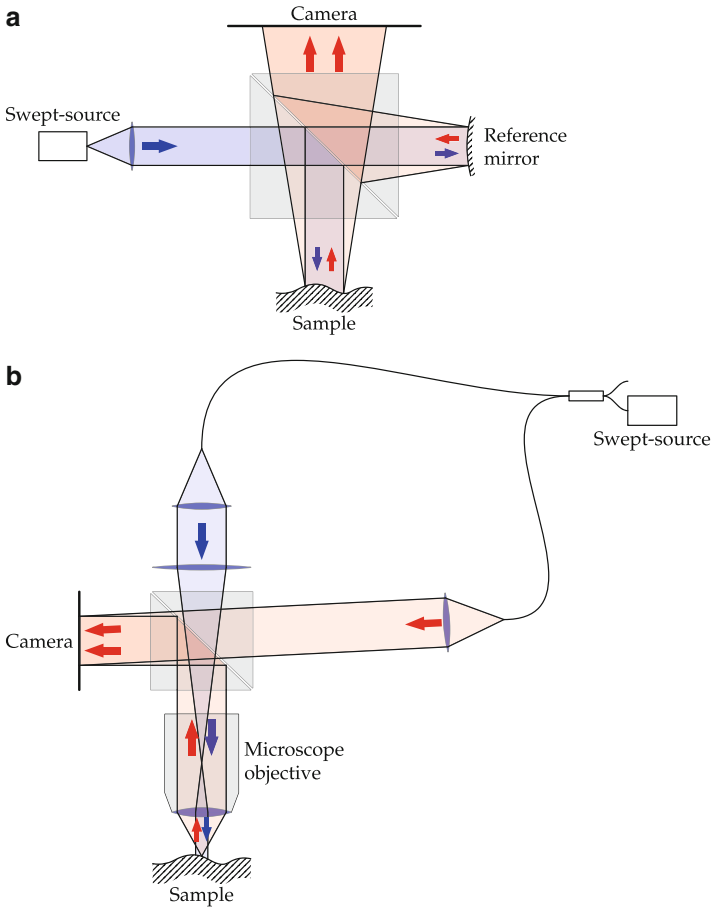

Fig. 27.2 (**a**) Schematic drawing of a lensless holoscopy setup. Coherent light of a known reference beam and light scattered from the sample are superimposed and digitized for many wavelengths. (**b**) Mach-Zehnder-type setup of a high-resolution holoscope

and limitations of the camera size will result in a limited resolution and/or lateral field of view. The only difference compared to digital holography (as shown in Sect. 27.2) is that the wavenumber k is now an additional variable as data are acquired for multiple wavenumbers. Additionally, it is assumed that the camera lies in the $z = z_0$ plane. The interference pattern in this plane is given by

$$\begin{aligned} I(x,y,k) &= \gamma |R(x,y,k) + O(x,y,k)|^2 \\ &= \gamma \Big(|R(x,y,k)|^2 + |O(x,y,k)|^2 + (R^* O)(x,y,k) + (R O^*)(x,y,k) \Big). \end{aligned} \tag{28.2}$$

The meaning of the terms is identical compared to the case of digital holography: the term $|R(x,y,k)|^2$ describes the absolute value of the reference field, which contributes mostly to the DC part of the recorded interference pattern. The term $|O(x,y,k)|^2$ describes the interference of the object wave with itself (autocorrelation). Finally, $2\mathrm{Re}(R^*O)(x, y, k)$ is the real cross-correlation term and contains the information of interest.

The reference wave is usually a plane or spherical wave, described by

$$R(x,y,k) = A_C(k)A_R \cdot \exp[i\boldsymbol{k} \cdot \boldsymbol{x} + i\phi_0(k)]|_{\boldsymbol{x}=(x,y,z_0)}, \tag{28.3}$$

where $\boldsymbol{k}$ is the wave vector, which defines wavelength and propagation direction of the wave, z_0 is the camera plane, $A_C(k)$ is the relative amplitude spectrum, and A_R describes the overall amplitude of the reference wave. $\phi_0(k)$ is the initial phase in the reference plane, in which the path length in the sample arm is the same as the one in the reference arm. In this plane, both reference and sample waves, have the same phase for all wavenumbers k. For on-axis imaging geometry, the reference wave is propagating perpendicular to the camera. To reduce spatial fringe frequencies on the camera, a spherical reference wave can be used similar to digital holography (see, e.g., [4]).

In case of the Michelson-type setup, as shown in Fig. 27.2a, the spherical wave can be created by subjecting a plane wave to a reference mirror with a given focal length f. In a Mach-Zehnder-type setup, a spherical wave can be created by focusing the light with a suitable lens. The following will describe the Michelson setup. Adjusting the formalism for a Mach-Zehnder-type setup is straightforward, as the introduction of a spherical reference wave in our computations is equivalent to introducing a numerical lens. Both lead to identical phase factor multiplications [19].

Let the distance from the reference mirror to the camera be denoted z_0. Then the reference field is given by

$$R(x,y,k) = A_C(k)A_R \cdot \mathrm{e}^{\mathrm{i}k\sqrt{x^2+y^2+(z_0+f)^2}-ikf+i\phi_0(k)}. \tag{27.4}$$

This describes a spherical wave originating at a distance f behind the reference plane (Fig. 27.3).

The fraction of light backscattered from the sample at a transversal position (x, y) at a distance z from the reference plane is given by the scattering potential $\eta(x, y, z)$, thereby neglecting any angular dependence of the backscattering. The collimated light enters the sample, moves a distance z to the scatterer, is backscattered, and then is propagated by a distance $z + z_0$ to the camera. Assuming the validity of the first-order Born approximation [21], which assumes single scattering and a constant incident wave field throughout the volume, the object field $O(x, y, k)$ and its angular spectrum $\tilde{O}_{xy}(k_x, k_y, k)$ in the camera plane are just a superposition of the fields generated by the backscattering in each depth, i.e.,

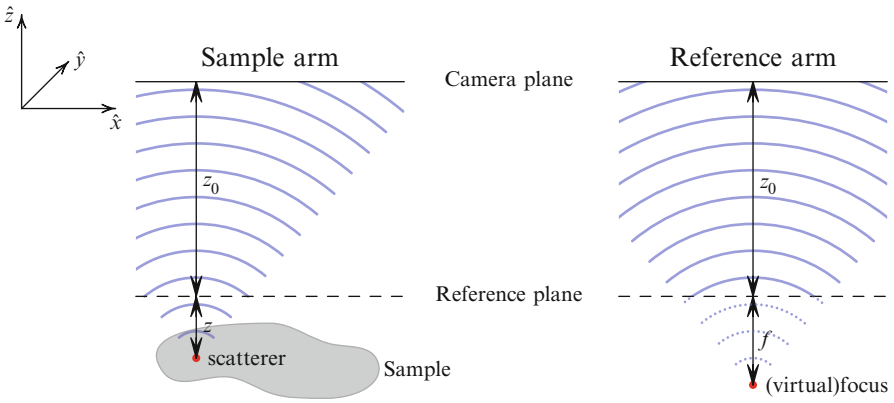

Fig. 27.3 Coordinate as used in the computation of the sample (*left*) and reference (*right*) wave field. The sample is made of several point scatterers whose fields are superimposed in the camera plane. In this case, the reference wave is a spherical wave with a (virtual) origin behind the reference plane. The configuration can be achieved by using a spherical reference mirror as shown in Fig. 27.2a

$$\begin{aligned} O(x,y,k) &= A_O A_C(k) \cdot \int \mathrm{d}z\, \mathcal{P}_{k,z_0+z}\left[\eta(x,y,z)\mathrm{e}^{\mathrm{i}kz}\mathrm{e}^{\mathrm{i}\phi_0(k)}\right], \\ \tilde{O}_{xy}\left(k_x,k_y,k\right) &= A_O A_C(k) \cdot \int \mathrm{d}z\, \mathrm{e}^{\mathrm{i}k_z(z+z_0)+\mathrm{i}kz} \cdot \mathrm{e}^{\mathrm{i}\phi_0(k)} \cdot \widetilde{\eta}_{xy}\left(k_x,k_y,z\right). \end{aligned} \tag{27.5}$$

The coordinate system as used for reference and object field is illustrated in Fig. 27.3.

27.3.3 The Phase-Corrected Propagator and Object and Reference Field

Propagating a wave field by the propagator $\mathcal{P}_{k,z}[\cdot]$ will change the overall phase of the field. In OCT, depth information is contained in the phase of the wave field, and thus, arbitrarily changing the phase will destroy this depth encoding. If a wave is propagated by a distance z by the propagator $\mathcal{P}_{k,z}[\cdot]$, its overall phase will change by $\mathrm{e}^{\mathrm{i}kz}$. For focusing of the object without changing the phase information, and thus without changing the depth encoding, the propagator needs to be adapted accordingly. This motivates the definition of a phase-corrected propagator

$$\mathcal{P}^0_{k,z}[\cdot] \equiv \mathrm{e}^{-\mathrm{i}kz}\mathcal{P}_{k,z}[\cdot].$$

The phase-corrected propagator is just a mathematical construct. Physical propagation of the wave field in free space will inevitably change the phase of the wave. Nevertheless, computations simplify significantly when introducing the phase-corrected propagator.

The reference as well as the object wave field, given by Eqs. 27.4 and 27.5, travel the same optical path length from the light source to the reference plane and have an identical time-dependent phase term $\phi_0(k)$, and common phase factors occur in reference and sample that need to be taken into account during reconstruction. In general, changing the overall phase of the two fields in exactly the same manner does not change the measurable quantity $I(x, y, k)$. For the following computations, it is therefore advantageous to redefine and simplify the phases of object and reference field, instead of using the previously obtained and physically motivated formulas, similar to the way the phase-corrected propagator replaces the propagator Eq. 27.1.

The phase-corrected reference wave field is therefore introduced by

$$\begin{aligned} R_0(x,y,k) &\equiv R(x,y,k)\cdot \mathrm{e}^{-\mathrm{i}\phi_0(k)}\cdot \mathrm{e}^{-\mathrm{i}kz_0} \\ &= A_R A_C(k)\mathrm{e}^{\mathrm{i}k\sqrt{x^2+y^2+(z_0+f)^2}-\mathrm{i}k(z_0+f)}. \end{aligned} \tag{27.6}$$

For $f \to 0$ the origin of the reference wave goes to the reference plane. Holograms of this kind are also referred to as Fourier holograms as they can be reconstructed in paraxial approximation by means of a simple Fourier transform (see, e.g., [4]).

The phase-corrected object wave field is accordingly defined by

$$\begin{aligned} O_0(x,y,k) &\equiv O(x,y,k)\cdot \mathrm{e}^{-\mathrm{i}\phi_0(k)}\cdot \mathrm{e}^{-\mathrm{i}kz_0} \\ &= A_O A_C(k)\int \mathrm{d}z\, \mathcal{P}^0_{k,\,z_0+z}\left[\eta(x,y,z)\mathrm{e}^{\mathrm{i}2kz}\right]. \end{aligned} \tag{27.7}$$

It is worthwhile to note the similarity to the standard FD-OCT cross-correlation term, except for the phase-corrected propagator $\mathcal{P}^0_{k,\,z_0+z}[\cdot]$. If the effect of the propagator can be reverted, images can be reconstructed similar to FD-OCT reconstruction by a Fourier transform. The effect of a propagator also arises in standard FD-OCT, but its influence is neglectable since FD-OCT works near the focal plane.

27.3.4 Obtaining the Phase-Corrected Object Wave Field

Interference of the phase-corrected object and reference wave gives the same intensity distribution as real physical waves:

$$I(x,y,k) = \gamma|R(x,y,k)+O(x,y,k)|^2 = \gamma|R_0(x,y,k)+O_0(x,y,k)|^2$$

and consequently also Eq. 27.2 still holds, if R and O are replaced by R_0 and O_0, respectively. Hence, the phase-corrected object wave field can be calculated from the acquired interference patterns.

27.3.4.1 On-Axis Geometry

The measured intensity $I(x, y, k)$ contains two conjugated parts $R_0^* O_0$ and $(R_0^* O_0)^*$, which are referred to as twin images in holography.

In FD-OCT the two conjugated terms cause the inability to distinguish negative from positive time delays and halve the effective measurement depth. They are usually separated by ensuring that all parts of the object are on one side of the reference plane. In this case, the complex signal is be obtained by removing all negative frequency components, i.e., by performing a Hilbert transform $\mathcal{H}_k[\cdot]$ with respect to the k-axis:

$$I^{\mathcal{H}}(x, y, k) = I(x, y, k) + \mathrm{i}\mathcal{H}_k[I(x, y, k)]. \tag{27.8}$$

$$\approx \gamma(R_0{}^* O_0)(x, y, k) + \gamma\Big(|O_0|^2(x, y, k) + \mathrm{i}\mathcal{H}_k\Big[|O_0|^2(x, y, k)\Big]\Big). \tag{27.9}$$

The phase-corrected object field can be approximately obtained by simply dividing the intensity Eq. 27.8 by the complex-conjugated phase-corrected reference field from Eq. 27.6:

$$O_0(x, y, k) \approx \frac{I^{\mathcal{H}}(x, y, k)}{\gamma R_0^*(x, y, k)} + \text{DC term} + \text{autocorrelation term}. \tag{27.10}$$

27.3.4.2 Off-Axis Geometry

In digital holography, off-axis reference illumination is commonly used to separate the twin images, the DC, and the autocorrelation term. This is also possible for holoscopy with a similar setup (Fig. 27.2b). The reference wave is not aligned perpendicular to the camera plane. This introduces a carrier frequency as illustrated in Fig. 27.4, which allows a separation of the terms after a two-dimensional Fourier transform.

With a suitable filter function $w(k_x, k_y)$, the object field can be isolated:

$$I_{\text{filtered}}(x, y, k) = \mathcal{F}_{xy}^{-1}\left[w\left(k_x, k_y\right)\mathcal{F}_{xy}[I(x, y, k)]\right].$$

The filter function $w(k_x, k_y)$ will act as computational aperture, and the lateral PSF in position space is determined by the filter function.

The resulting signal after this spatial filter can be approximated by the object wave field which can be determined approximately from the filtered intensity of the interference pattern by

$$O_0(x, y, k) = \frac{\gamma\left(R_0^* O_0\right)(x, y, k)}{\gamma R_0^*(x, y, k)} \approx \frac{I^{\text{filtered}}(x, y, k)}{\gamma R_0^*(x, y, k)}.$$

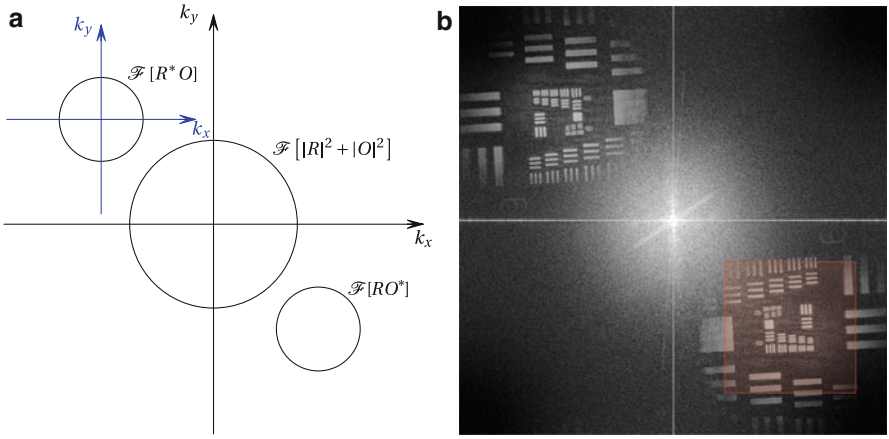

Fig. 27.4 (**a**) Off-axis separation of the different terms in frequency space. Suitable filtering and an inverse Fourier transform can isolate the appropriate wave field. The exact filter function is wavelength dependent, and thus, a suitable phase shift needs to be added to compensate for this effect. (**b**) Fourier transform of a hologram of a US Air Force (*USAF*) test chart acquired at 867.5 nm and the respective filtering window is shown

The autocorrelation object term $|O_0(x, y, t)|^2$ and the complex-conjugated wave field $O_0^*(x, y, k)$ are removed, which is not possible with the on-axis geometry. The autocorrelation terms add additional coherence noise, especially in the upper areas of the reconstructed volume. Filtering of the complex-conjugated signal resolves also the complex-conjugate ambiguity entirely similar to full-range OCT.

27.4 Reconstruction

27.4.1 Reconstruction Within One Rayleigh Length

To reconstruct the scatterer distribution of the specimen, the corrected object wave field $O_0(x, y, k)$ is propagated back for all wavenumbers to a common plane within the volume of interest by applying the phase-corrected propagator. The propagation reverts the effect of the phase-corrected propagator in Eq. 27.7 for the chosen reconstruction distance. The focus of the reconstruction lays in the chosen common plane of the volume. The data obtained after propagation are equivalent to measured full-field FD-OCT data. A Fourier transform along the k-axis is performed analogous to FD-OCT processing, to achieve the depth sectioning. The reconstructed volume will have diffraction limited resolution in the common propagation plane. The other planes will have degraded lateral resolution as observed with imaging optics.

With a distance z_P of the common plane to the reference plane, the reconstructed object is obtained by

$$\begin{aligned}\mathcal{P}^0_{k,\,-z_0-z_P}[O_0(x,y,k)] &= A_O A_C(k) \int \mathrm{d}z\, \mathcal{P}^0_{k,\,-z_0-z_P} \mathcal{P}^0_{k,\,z_0+z} \left[\eta(x,y,z)\mathrm{e}^{2\mathrm{i}kz}\right] \\ &= A_O A_C(k) \int \mathrm{d}z\, \mathcal{P}^0_{k,\,z-z_P} \left[\eta(x,y,z)\mathrm{e}^{2\mathrm{i}kz}\right],\end{aligned}$$

where the property $\mathcal{P}^0_{k,z_1}\mathcal{P}^0_{k,z_1}[\cdot] = \mathcal{P}_{,k,z_1+z_2}[\cdot]$ has been used to combine the operators. Performing a Fourier transform then gives the scattering potential:

$$\tilde{A}_C(z) * \eta_{z_P}(x,y,z) = \frac{1}{\pi A_O} \int \mathrm{d}k \exp(-\mathrm{i}2kz) \mathcal{P}^0_{k,\,-z_0-z_P}[O_0(x,y,k)], \tag{27.11}$$

where $*$ denotes the convolution operation with respect to the z-axis and $\tilde{A}_C(z)$ is the point spread function obtained by Fourier transforming the spectrum. Due to $\mathcal{P}^0_{k,0}[\cdot] = \mathrm{id}[\cdot]$ being the identity operator, the scattering potential is only reconstructed without aberrations for the layer $z = z_P$.

27.4.2 One-Step Reconstruction

27.4.2.1 Reconstruction in Free Space

For a complete depth-independent reconstruction of the volume data, single reconstructions for different reconstruction depths z_P as outlined in Sect. 27.4.1 are needed so that the propagator vanishes for all layers. In order to achieve this, one needs to set $z_P = z$ in Eq. 27.11 which gives

$$\tilde{A}_C(z) * \eta(x,y,z) = \frac{1}{\pi A_O} \int \mathrm{d}k\, \mathrm{e}^{-\mathrm{i}2kz} \mathcal{P}^0_{k,\,-z_0-z_P}[O_0(x,y,k)] \Big|_{z_P=z}.$$

For the angular spectrum, the respective equation reads

$$\tilde{A}_C(z) * \tilde{\eta}_{xy}(k_x,k_y,z) = \frac{1}{\pi A_O} \int \mathrm{d}k\, \mathrm{e}^{-\mathrm{i}2kz} \mathrm{e}^{-\mathrm{i}(k_z-k)(z_0+z_P)} \left[\tilde{O}_0(k_x,k_y,k)\right] \Big|_{z_P=z}.$$

The convolution operation $*$ only affects the z-axis and thus remains untouched from the change to the angular spectrum. Finally, setting effectively $z_P = z$ gives

$$= \frac{1}{\pi A_O} \int \mathrm{d}k\, \mathrm{e}^{-\mathrm{i}(k+k_z)z} \mathrm{e}^{-\mathrm{i}(k_z-k)z_0} \left[\tilde{O}_0(k_x,k_y,k)\right].$$

Going back to spatial space gives

$$\tilde{A}_C(z) * \eta(x,y,z) = \frac{1}{\pi A_O} \mathcal{F}_{xy}^{-1} \left[\int \mathrm{d}k \, \mathrm{e}^{-\mathrm{i}(k+k_z)z} \mathrm{e}^{-\mathrm{i}(k_z-k)z_0} \mathcal{F}_{xy}[O_0(x,y,k)] \right]. \quad (27.12)$$

With this transformation all layers are reconstructed with diffraction limited resolution. However, this relation is only valid if the applied free-space propagator is correct. Lenses in between sample and camera or a sample with refractive index larger than one ($n > 1$) need a different propagator.

27.4.2.2 Reconstruction in a Medium

In a medium with index of refraction n, the wavenumber k will be increased by a factor n. Assuming that entry and exit to the medium are parallel to the camera plane, the lateral components of $\boldsymbol{k}$ will remain unchanged, as they must not change abruptly when entering or leaving the medium (see, e.g., [21]). Therefore, for propagation in the medium, the wave vector needs to be changed according to

$$\boldsymbol{k}' = \begin{pmatrix} k_x \\ k_y \\ k_z' \end{pmatrix} = \begin{pmatrix} k_x \\ k_y \\ \sqrt{n^2k^2 - k_x^2 - k_y^2} \end{pmatrix},$$

and it follows

$$\|\boldsymbol{k}'\| = nk,$$

where $\boldsymbol{k}'$ denotes the wave vector in the medium. In the one-step reconstruction by Eq. 27.12, the kernel needs to be modified by replacing k and k_z by nk and k'_z, respectively. However, assuming that z_0 describes the propagation distance to focus the reference plane, which is in a medium not equal to the physical distance, the phase factor does not need to be modified. The reconstruction is then given by

$$\tilde{A}_C(z) * \widetilde{\eta}(k_x,k_y,z) = \frac{1}{\pi A_O} \times \int \mathrm{d}(nk) \underbrace{\exp\left(-\mathrm{i}\left(k_z' + nk\right)z\right)}_{\text{kernel}} \underbrace{\exp(-\mathrm{i}(k_z-k)z_0)}_{\text{phase}} \tilde{O}_0(k_x,k_y,k). \quad (27.13)$$

This integral transform with the modified kernel can also be calculated by a Fourier transform on non-equidistant data points (NFFT, [22]). By using $\sqrt{1-x^2} \approx 1 - x^2/2$

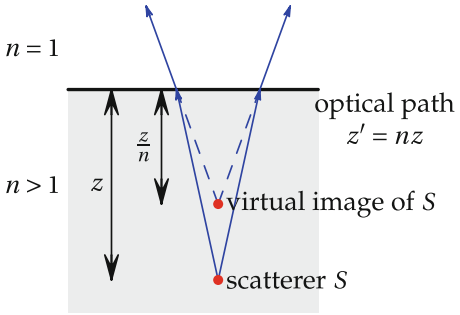

Fig. 27.5 After an optical interface to a medium with different index of refraction the apparent focus position of the virtual image is reduced by a factor 1/n whereas the optical path length is increased by a factor of n

a simplification is possible for low to moderate NA: in paraxial approximation the term for k_z can be expanded and rewritten to

$$\exp\left(+\mathrm{i}\left(k_z' + nk\right)z\right) \approx \exp\left(+\mathrm{i}\left(2nk + \frac{1}{n}\left(k_z - k\right)\right)z\right).$$

By introducing the optical path length $z' = nz$, the kernel is modified to

$$= \exp((+\mathrm{i}(2-\zeta)k + \zeta k_z)z'), \tag{27.14}$$

with

$$\zeta = \frac{1}{n^2}. \tag{27.15}$$

ζ describes the proportionality constant between imaging distance and optical path length as illustrated in Fig. 27.5. The complete reconstruction formula is then

$$\tilde{A}_C\left(z'\right) * \tilde{\eta}\left(k_x, k_y; z'\right) = \frac{1}{\pi A_O}\int \mathrm{d}k \underbrace{\mathrm{e}^{-\mathrm{i}((2-\zeta)k+\zeta k_z)z'}}_{\text{kernel}} \underbrace{\mathrm{e}^{-\mathrm{i}(k_z-k)z_0}}_{\text{phase}} \tilde{O}_0\left(k_x, k_y; k\right). \tag{27.16}$$

For $\zeta = 0$, Eq. 27.16 reduces to Eq. 27.11 with $z_P = 0$, i.e., the chosen reconstruction distance is the reference plane. For increasing n the parameter ζ tends to zero; thus, the higher the refractive index of the sample, the better the approximation by Eq. 27.11. In fact, for $\zeta < 0.5$ the reconstruction by Eq. 27.11 yields better results than the reconstruction by Eq. 27.12, which assumes free space. In case the paraxial approximation of Eq. 27.14 is not valid, the more general formula Eq. 27.13 needs to be used.

If n of the medium is not exactly known, an approximate solution of the reconstruction can be used for a fast experimental determination of ζ. By first

Fourier transforming the object waves $O_0(x, y; k)$ with respect to the k-axis, i.e., using FD-OCT depth discrimination on the unprocessed holograms and only afterwards performing holographic refocusing with the center wavenumber for at least two different depths, the focus positions and the optical path lengths of these layers can be determined. A linear regression of these points gives ζ and the reference propagation length z_0.

27.4.2.3 The Complete Reconstruction Integral

The reconstruction described by Eq. 27.16 can be evaluated by a variable substitution. Introducing

$$\kappa_\zeta(k_x, k_y; k) = (2-\zeta)k + \zeta k_z = (2-\zeta)k + \zeta\sqrt{k^2 - k_x^2 - k_y^2}$$

and substituting the integral variable simplifies the reconstruction integral to

$$\tilde{A}_C(z') * \tilde{\eta}(k_x, k_y; z') = \frac{1}{\pi A_O}\int \mathrm{d}\kappa_\zeta \frac{\mathrm{d}k}{\mathrm{d}\kappa_\zeta} \mathrm{e}^{-\mathrm{i}\kappa_\zeta z}\mathrm{e}^{-\mathrm{i}(k_z-k)z_0}\tilde{O}_0(k_x, k_y; k), \qquad (27.17)$$

where $\mathrm{d}k/\mathrm{d}\kappa_\zeta$ is neglectable and only results in a different weighting of frequencies in the dataset. As κ_ζ depends on the lateral frequencies k_x and k_y, evaluation of the integral in Eq. 27.17 requires an interpolation of the dataset in frequency space. In practice, the integration is performed over the range between a minimum and maximum of κ_ζ,

$$\kappa_{\zeta,\min} = 2k_{\min}$$
$$\kappa_{\zeta,\max} = (2-\zeta)k_{\max} + \zeta\sqrt{k_{\max}^2 - (k_x)_{\max}^2 - (k_y)_{\max}^2},$$

which are obtained from the minimum and maximum wavenumber ($k_{\min}$, $k_{\max}$) during the sweep and the NA of the setup (maximal k_x and k_y) as indicated in Fig. 27.6 and shown in more detail in [23]. For low to moderate NA this leads to a reduction of the axial frequency range and thus a loss in axial resolution, since samples below $\kappa_{\zeta,\min}$ and above $\kappa_{\zeta,\max}$ have to be discarded. For high NA imaging and high axial resolution the distortion in frequency space becomes too large for this reconstruction to be effective. Integrating from $\kappa_{\zeta,\min}$ to $\kappa_{\zeta,\max}$ will miss a large portion of the sampled data and sampling density in the κ_ζ, k_x and k_y space varies considerably, which makes interpolation imprecise. Suitable algorithms need to be developed and applied for high NA holoscopy.

27.4.3 Resolution

27.4.3.1 Axial Resolution

The axial resolution is determined by the sweep range of the swept-source laser and the spectral shape, after spectral apodization of the acquired signals. The resolution

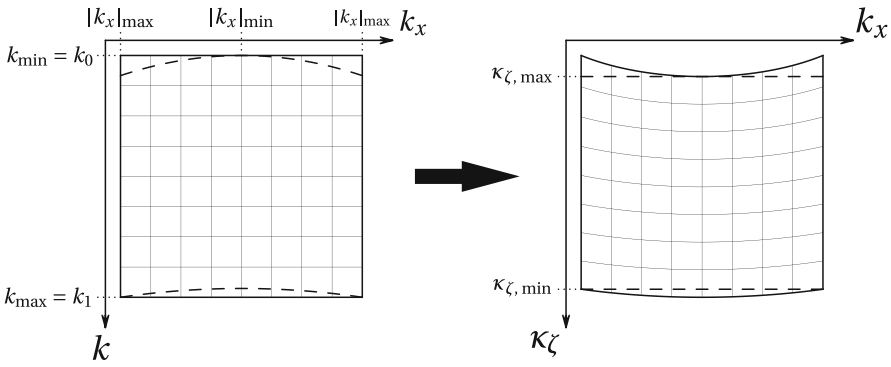

Fig. 27.6 Coordinate transformation that is required for the one-step reconstruction

will thus be approximately the OCT resolution using an identical light source [24]. However, applying the complete reconstruction, the interpolation variable κ_ζ is determining the axial resolution instead of the original wavenumber k. As some parts of the $\boldsymbol{k}$-space cannot be used for reconstruction, it will thus be slightly decreased. The discretization of the interpolated reconstruction integral yields the spacing of subsequent A-scan data points to

$$\Delta z = \frac{2\pi}{N\Delta\kappa_\zeta}.$$

Assuming a Hann-apodized spectrum, the axial resolution will thus be twice as large [25], resulting in

$$\sigma_z = \frac{4\pi}{\left|\kappa_{\zeta,\max} - \kappa_{\zeta,\min}\right|}.$$

27.4.3.2 Lateral Resolution

The lateral resolution is determined by the numerical aperture of the setup in analogy to classical imaging systems.

In lensless holoscopy the aperture is given by the sensor area. The NA can be computed from the distance of the camera to the sample (see also Fig. 27.7). However, distance cannot be decreased arbitrarily to increase NA, as interference fringe frequencies become higher and can no longer be resolved and physically the space between camera and sample needs to be sufficiently large to allow superposition with the reference wave.

For the setup using imaging optics (Fig. 27.2b), the resolution is determined by the circular aperture of the objective.

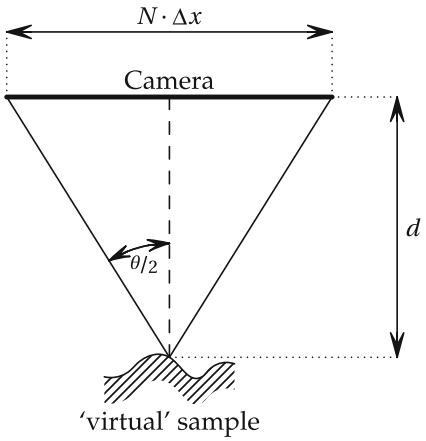

Fig. 27.7 Definition of the numerical aperture of a lensless holoscopy setup

27.4.4 Numerical Complexity and Execution Speed

For one focal volume the simple reconstruction by Eq. 27.11 requires the propagation of each acquired hologram to a certain depth. For a single propagation of an image array of size $N_X \times N_Y$, two 2D Fourier transforms of size $2N_X \times 2N_Y$ are required, if zero padding is applied to prevent circular convolution artifacts. One transform is needed to go from position space to Fourier space and one to go back. Consequently, for N holograms at different wavelengths, a total of $2N$ two-dimensional Fourier transforms of size $2N_X \times 2N_Y$ are required. For each lateral position, a one-dimensional Fourier transform of size N needs to be performed afterwards to gain depth information, i.e., additional $N_X \times N_Y$ Fourier transforms calculate the final data. In total, $2N$ Fourier transforms of $2N_X \times 2N_Y$ arrays plus $N_X \times N_Y$ one-dimensional Fourier transforms of N data points are needed for each focal volume. The overall time complexity C_{SL} of a simple reconstruction with a single focus layer is of the order of

$$C_{SL} \sim \mathcal{O}(8NN_XN_Y \cdot \log(4N_XN_Y) + NN_XN_Y \cdot \log N).$$

The one-step reconstruction of the complete volume by Eq. 27.16 reduces the computational complexity significantly. It also requires N two-dimensional Fourier transforms of size $2N_X \times 2N_Y$ to bring the images to Fourier space and $2N_X \times 2N_Y$ one-dimensional Fourier transforms of size N to gain depth information. For the complete volume, this is $4\times$ more than for the reconstruction of only one focal volume by propagation and Fourier transform, because the Fourier transform to get the depth information is performed on the spatial frequency spectrum and not in the position space of the refocused planes. Because of the Hermitian symmetry, i.e., the same information content in positive and negative frequencies,

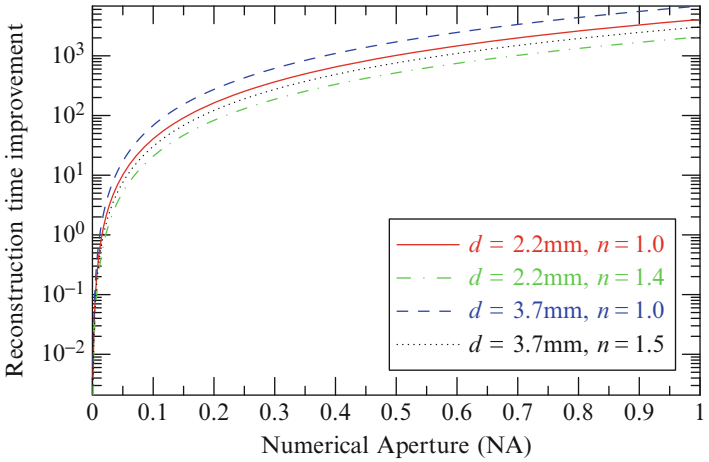

Fig. 27.8 Approximate increase of the reconstruction speed by using the one-step algorithm of Eq. 27.16 instead of sequentially applying Eq. 27.11 for multiple focal volumes. The increase of speed depends on measurement depth d and the refractive index n of the sample

the inverse transform from 2D Fourier space to position space only requires $N/2 + 1$ two-dimensional Fourier transforms of size $2N_X \times 2N_Y$, which is about half the amount required for the propagation and Fourier transform approach. The overall time complexity C_{FV} of the one-step reconstruction for the full volume can thus be written as

$$C_{FV} \sim \mathcal{O}(6NN_XN_Y \cdot \log(4N_XN_Y) + 4NN_XN_Y \cdot \log N).$$

On a quad-CPU Opteron 6150, a reconstruction of a dataset of 1,024 holograms with 1,024 × 1,024 pixel by Eq. 27.11 of one focal volume took about 22 s, whereas a reconstruction of the complete volume by Eqs. 27.12 or 27.16 took about 40 s, i.e., about twice the time required for the reconstruction of the focal volume. For the lensless setup with 0.05 NA shown in Fig. 27.2a, the confocal parameter (i.e., twice the Rayleigh length) was $2z_R = 220$ µm and the measurement depth of 3.7 mm was achieved (see Fig. 27.9). Thus, a data set would need 17 reconstructions of different focal volume for an overall diffraction limited resolution in air. Hence, the one-step reconstruction of the complete volume offered a speedup of about 8.5 times for this low NA setup. For the scattering sample in Fig. 27.9 with refractive index $n = 1.5$ this speedup is reduced by a factor $\zeta = 1/n^2 \approx 0.44$, because the focal range is increased by a factor n and the effective total measurement depth is the optical depth which is reduced by a factor $1/n$. The full reconstruction is still about three to four times faster in this case.

For the high NA measurements shown in Fig. 27.12 in the next chapter, the confocal parameter was reduced to about $2z_R = 30$ µm and the measurement depth

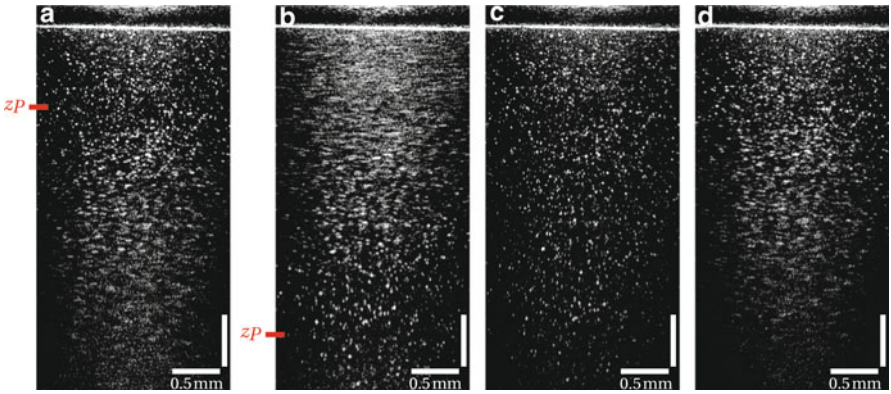

Fig. 27.9 B-scans from a reconstructed volume of a scattering phantom [26] consisting of multiple point scatterers. (**a**) and (**b**) result from reconstructions of the focal volume according to Eq. 27.11 at two different propagation depths z_P, which correspond to virtual numerical foci of the reconstruction. Outside the focal regions the lateral resolution is degraded. The confocal parameter was 220 µm. (**c**) One-step reconstruction of the complete volume by Eq. 27.16 with the correct refractive index $n = 1.5$ ($\zeta = 0.44$). No lateral resolution degradation is visible. The loss of intensity in depth is caused only by a sensitivity roll-off due to the limited instantaneous coherence length of the laser source. (**d**) One-step reconstruction of the complete volume by Eq. 27.12 without correcting for the increased index of refraction in the sample volume (i.e., $n = 1.0$ and thus $\zeta = 1$). Focus degradation is worse than in the reconstruction for a single focal volume. This is due to the fact that the former corresponds to $\zeta = 1$ and the latter to $\zeta = 0$. The correct value of $\zeta = 0.44$ is thus closer to the reconstruction of a single plane by Eq. 27.11

was about 2.2 mm. Therefore, in air about 70 reconstructions are required with Eq. 27.11. With a refractive index of about $n = 1.4$, the volume can be reconstructed about 15 times faster using the one-step reconstruction.

For higher lateral resolution, this factor will increase further. The actual gain of time for the reconstruction depends on the ratio of confocal parameter $2z_R$ to the measurement depth d of the system and the refractive index n of the sample. The expected improvements in reconstruction speed are shown in Fig. 27.8. At high NAs near unity, the one-step reconstruction is expected to be about three orders of magnitude faster.

27.5 Examples of Holoscopy

27.5.1 Lensless Holoscopy

Holoscopic imaging of a scattering sample which contains $300 - 800$ nm sized iron oxide nanoparticles embedded in polyurethane resin [26] demonstrated the effectiveness of the technique. The images shown in Fig. 27.9 were acquired at NA 0.05 using a Mikrotron EoSens CMOS camera and a Superlum Broadsweeper BS840 with a tuning range of 50 nm centered at 848.5 nm. It demonstrates the

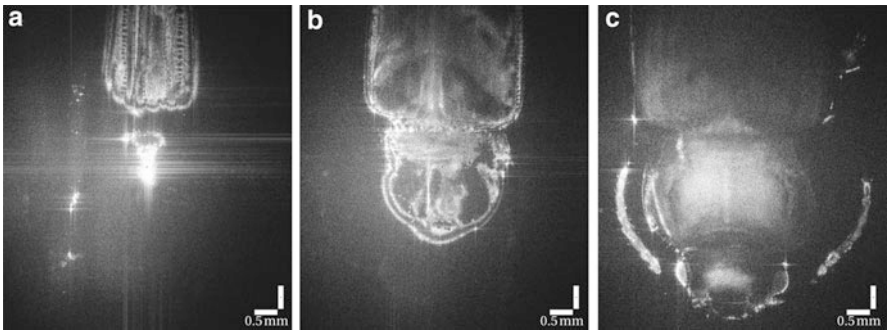

Fig. 27.10 En face tomographic images of a bug at three different layers. The image cube was acquired by holoscopy. For reconstruction the one-step algorithm described by Eq. 27.16 was used. Internal structures of the bug can clearly be seen

simple reconstruction according to Eq. 27.11, which propagates the object field from the camera plane to one depth in the sample first and then applies the axial Fourier transform. This gave high lateral resolution only in the focal range around the reconstruction depth z_P (Fig. 27.9a, b). Applied to the same dataset, the one-step reconstruction by Eq. 27.16 obtained a volume which images the nanoparticles sharply in all layers spanning a depth of more than 30 Rayleigh lengths (Fig. 27.9c). However, the index of refraction of the sample volume needs to be incorporated correctly. A one-step reconstruction of a complete volume when falsely assuming an index of refraction of air (see Eq. 27.12) reconstructed only a limited depth range correctly (Fig. 27.12d). In this phantom, having a refractive index of about $n = 1.5$, the simple reconstruction shows better results than the one-step reconstruction with $n = 1.0$, as the actual $\zeta = 1/n^2 = 0.44$ is closer to 0 than to 1.0.

Holoscopy has also been demonstrated for more complex biological structures. In Fig. 27.10 en face images of a bug at three different depths are shown. The image quality of structures from within the bug is degraded because of refraction on the outer shell, caused by its nonhomogeneous refractive index. The outer shell of the bug however is sharply imaged within all depth layers.

In vivo images of a fingertip have been acquired at an acquisition rate of about 7×10^6 A - scans/s, which is comparable to the fastest OCT measurements up to date. The results are shown in Fig. 27.11. Imaging quality is sufficient to clearly visualize the ducts of the sweat glands.

27.5.2 High-Resolution Holoscopy

The advantage of holoscopy becomes more significant for higher NA since the Rayleigh length drops quadratically with the NA. So far, holoscopy has been demonstrated with NA of up to 0.14 using a 5× Mitutoyo Plan-IR microscope

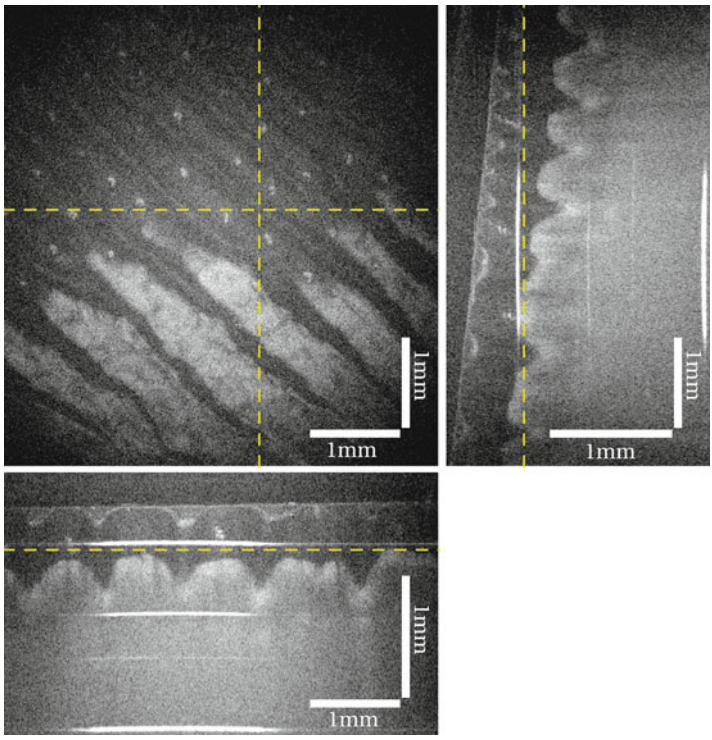

Fig. 27.11 Volumetric measurement of a fingertip acquired using holoscopy. The acquisition speed of 7, 000 frames/s corresponds to about 7×10^6A - scans/s

objective, a Basler ACE acA2040-180 km camera, and a Superlum Broadsweeper BS840-1 with a tuning range of 82 nm centered at 841 nm. A Mach-Zehnder Interferometer as shown Fig. 27.2b was used. B-scans from reconstructed volumes demonstrated that also for more complex structures at NA 0.14 a one-step reconstruction by Eq. 27.16 is possible while maintaining lateral resolution over the depth (Fig. 27.12). However, additional artifacts were introduced by reflections of the microscope objective.

27.5.3 Artifacts in Holoscopic Imaging

Due to the lack of a confocal gating, holoscopic imaging suffers from numerous artifacts, either because of additional light reaching the detector which cannot be filtered properly or because the reconstruction process is not capable to re-obtain the actual scattering structures. Some artifacts occur for both, confocal and scanning OCT, but effect the images differently. Other artifacts are restricted to either one of the two imaging technologies.

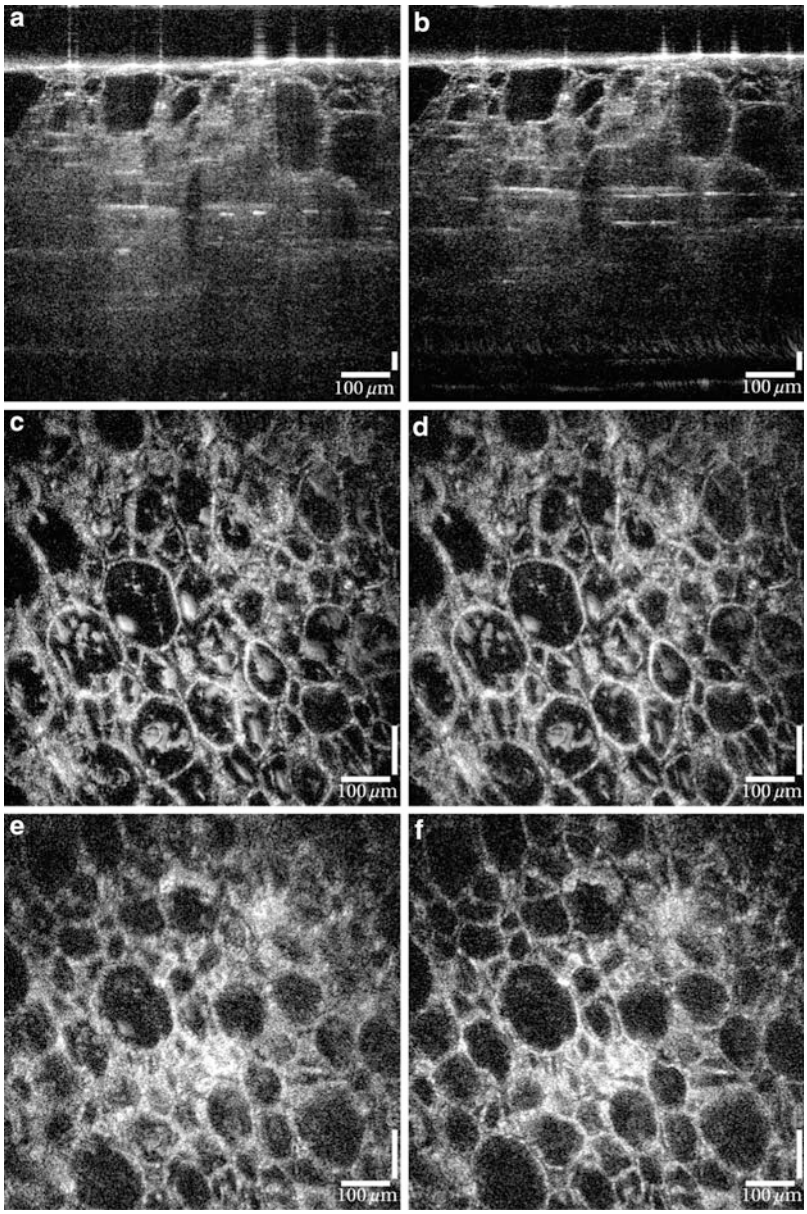

Fig. 27.12 Holoscopic images of a grape acquired at 0.14 NA using the Mach-Zehnder interferometer with additional microscope objective. Simple reconstruction by propagating the field to one focal plane (*left column*) is compared with the one-step reconstruction of the complete volume (*right column*). (**c**) En face image of the focal plane of the simple reconstruction. (**d**) En face image of the same plane in the one-step reconstruction. (**e**) En face image of the simple reconstruction in an optical distance of about 160 µm

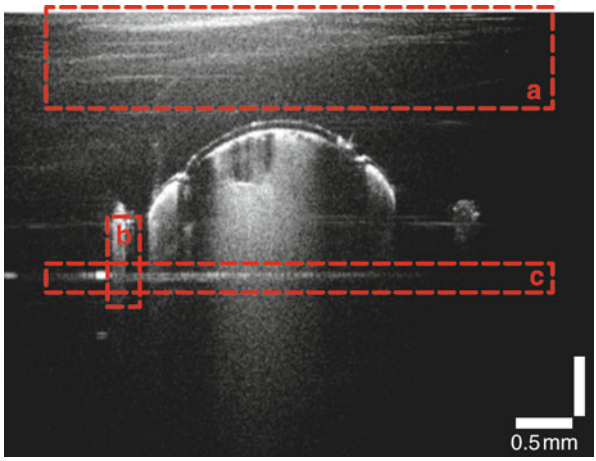

Fig. 27.13 B-scan of the bug shown in Fig. 27.10 with artifacts caused by holoscopic imaging. Autocorrelation terms create an increased noise floor in the upper part of the image (**a**). Multiple scattering of photons causes wrong depth assignment of the structures resulting in a bright shadow beneath strongly scattering surfaces (**b**). Reflecting or scattering parallel surface from within the setup causes horizontal lines in the B-scans (**c**)

27.5.3.1 Autocorrelation Artifacts

Interference of sample radiation originating from various depths within the sample (autocorrelation terms) causes additional signals in the tomographic data as shown in the area (*A*) of Fig. 27.13. In off-axis holoscopy (Fig. 27.2b), these artifacts can be filtered. Since the ratio between sample and reference light cannot be adjusted arbitrarily in on-axis, lensless holoscopy, autocorrelation artifacts can be quite dominant. The autocorrelated signals are not to be imaged sharply, making them appear mostly as an additional noise floor with speckles. This is in contrast to FD-OCT where the imaging structures are often clearly identified as twin images.

27.5.3.2 Multiple Scattering

Multiple scattering is a major problem in holoscopy. For the images shown, artifacts of multiply scattered photons are rather neglectable. In a single focus layer reconstruction as described in Sect. 27.4.1, the multiple scattered photons will in most scenarios be assigned to a higher depth, but their lateral origin will be correct. This can be seen in Fig. 27.13 in the area marked by (*B*) which shows a bug's antenna. Strongly scattering structures therefore appear to have a shadowlike vertical structure below them.

27.5.3.3 Horizontal Lines

In Fig. 27.13 a horizontal line (*C*) is shown, which originates from reflecting interfaces within the setup. To minimize these effects, parallel plates and surfaces perpendicular to the optical axis should be avoided, and the number of optical

Fig. 27.12 (continued) from the virtual focus shows deteriorated resolution (**f**) En-face image of a one-step reconstruction of the same layer. No degradation of the lateral resolution is observed. The confocal parameter was 28 µm. Remaining artifacts arose because of reflections from within the setup

components in the setup should be kept small. Tilting of optical components and using an off-axis holoscopy suppress these artifacts significantly.

27.6 Conclusion

Holoscopy enables an increased depth of focus in terms of uncompromised sensitivity and resolution. So far, measurements with an extension of the focal region by a factor of about 15 were demonstrated, without reaching the theoretical limit. The benefits of holoscopy become especially visible at high NA, as it allows to preserve the Fourier-domain SNR advantage even in this range.

Current implementations of holoscopy face many challenges: reduced image quality caused by artifacts, incoherent background and multiple scattered photons, and lack of cameras and suitable tunable light sources. If these problems are solved, higher sensitivity and acquisition speed will make holoscopy a clinically useful alternative to full-field time-domain OCT (see, e.g., [27–29]), extended focus optical coherence microscopy (OCM) [30, 31], and μOCT [32].

28.1 Introduction

Cellular imaging of human tissues remains an important advance for many clinical applications of optical coherence tomography (OCT). Current diagnosis and management of many human diseases, including cancers and various inflammatory and autoimmune conditions, depend upon biopsy and histopathologic analysis of cellular and subcellular features. Imaging cells with traditional OCT methods, however, has not been routinely possible due to the limited transverse resolution of such techniques.

The term optical coherence microscopy (OCM) refers to optical coherence tomography methods with high transverse spatial resolution. OCM techniques use higher numerical aperture focusing than conventional OCT and therefore typically generate *en face* rather than cross sectional images in order avoid the depth of field

limitation in the cross-sectional plane. Combining high transverse resolution with coherence-gated detection, OCM enables cellular imaging in human tissues without the use of extrinsic contrast agents. Coherence gating dramatically reduces detection of unwanted scattered light, improving image contrast and enabling imaging to greater depths than possible with confocal microscopy. This has made OCM a promising approach for cellular resolution imaging of human pathologies without the need for conventional tissue staining and histologic processing. Coherence gating in OCM also enables the use of lower numerical aperture focusing than required for classic confocal microscopy, which makes OCM a key technology to enable cellular level, internal body imaging in endoscopic applications. Beyond biological specimens, OCM techniques have also found application for imaging of novel materials, which require non-invasive, non-destructive high resolution microscopic analysis.

Two general approaches for OCM have been described. The point-scanning, or "flying spot," approach is based directly upon the principle of confocal microscopy where the scattering medium is illuminated at a single point, which is subsequently relay imaged to a pinhole point detector. The pinhole imposes a spatial gate on photons returning from the sample and serves to preferentially reject light from outside the focal plane. Two-dimensional *en face* images are created by raster scanning the point focus. Traditional fiber-optic OCT systems are inherently confocal and implement the point-scanning technique. As the transverse spot size is reduced in the OCM limit, the confocal axial response becomes comparable to the axial coherence gate and the combined confocal and coherence gating creates both important advantages and challenges. In contrast to point-scanning OCM systems, the second approach to OCM involves full-field illumination and detection. The full-field technique is similar to conventional white-light interference microscopy and produces *en face* images using parallel illumination and detection. Full-field OCM/OCT techniques typically use CCD based detection and have achieved impressive image quality. The full-field methods have the advantage of simplicity and highly parallel data acquisition, but because of their inherent sensitivity to motion, in vivo imaging is challenging. The full-field approaches are covered in detail in other chapters in this book.

This chapter focuses on point-scanning, confocal OCM implementations, and this approach to optical coherence microscopy is henceforth assumed. The chapter provides an overview of OCM image formation and discusses several of the challenges and advantages of the technique. In addition, system design approaches for high resolution OCM are covered, with a focus on enabling technological developments. Examples of cellular level imaging in human tissues are presented. The capability to visualize cellular structure promises to have important implications for many clinical applications, including optical biopsy and the detection of neoplastic changes.

28.2 Confocal Microscopy

Confocal microscopy was first proposed by Marvin Minsky in the late 1950s [1]. Imaging can be performed in reflectance or fluorescence modes, depending on

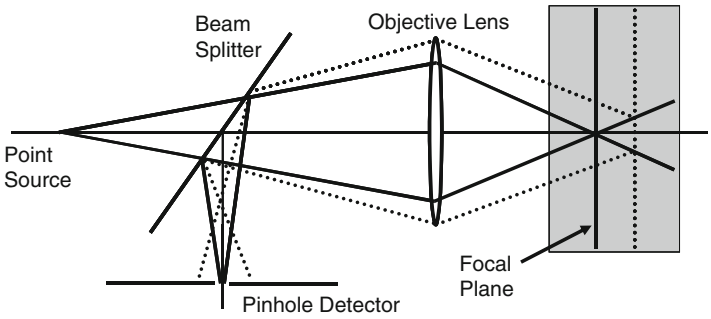

Fig. 28.1 Schematic illustrating the principle of reflectance confocal microscopy

the specific application. Figure 28.1 illustrates the basic principle of confocal microscopy in reflection geometry. A point source illuminates a sample plane through a focusing objective lens. The backscattered light from the focal plane is recollected by the objective lens and focused through a pinhole detector. Unwanted scattered light from outside the focal plane is also collected by the objective, but this light is defocused at the detector and is therefore rejected. The spatial discrimination against out of focus scattered light is known as confocal gating. The combination of focused illumination and spatially filtered detection reduces blurring, increases effective resolution, and improves contrast through improved signal to noise ratio [2]. The single point transverse resolution of a confocal microscope is typically defined as the width of the transverse point spread function. For a focused Gaussian beam, the transverse spot dx can be characterized by the $1/e^2$ radius of the transverse response [3], which is given as

$$dx = \frac{0.46\lambda}{NA} \tag{28.1}$$

The axial response of a confocal microscope to a perfectly reflecting plane at the focus under Gaussian beam assumptions can similarly be described as

$$dz = \frac{1.4n\lambda}{NA^2} \tag{28.2}$$

where dz represents the FWHM of the axial irradiance [4]. As shown, the transverse resolution varies inversely with the numerical aperture (NA) of the objective lens, while the axial resolution or axial sectioning capability of the confocal microscope varies inversely with the square of the NA. Hence, image quality in scattering objects requires the use of high magnification, high-NA objectives. With such high NA lenses, typically NA 0.7–1.2, confocal microscopy systems can achieve 3–5 um axial sectioning capability and better than 1 um transverse resolution [5].

To generate an image in two dimensions, several scanning approaches have been demonstrated, including sample scanning, objective scanning, and beam scanning [3]. The use of laser sources marked a major development in confocal microscopy [6, 7] and enabled high speed, high resolution point scanning systems at multiple wavelengths. Typically, the confocal scanning laser microscope (CLSM) samples an *en face* scan plane by rapidly raster scanning the beam on tissue.

Confocal laser scanning microscopy was demonstrated for in vivo cellular imaging of human tissues at visible wavelengths [4]. Advances in instrumentation and design led to the development of video-rate reflectance systems capable of reliable imaging in clinical applications [4, 8, 9]. These systems offer high power illumination and extension to deeper penetrating wavelengths in the near infrared. Operating at wavelengths of 800 nm and 1,064 nm, the systems provide transverse resolution of 0.5–1 um and axial sectioning capacity of 3–5 um. Confocal reflectance imaging of human skin [9–13], oral mucosa [14], and cervix [15] has demonstrated the capability to image normal and pathologic cellular features in vivo with impressive correlation of confocal images with histology. Commercial versions of the CLSM imaging system now offer new tools for clinical diagnostic applications in dermatology and other specialties where open access to tissue specimens is possible. In addition, endoscope compatible reflectance confocal microscopes are being developed [16, 17].

Using exogenous fluorescence dyes to provide contrast, fluorescence confocal endoscopy has been developed for clinical application in the gastrointestinal tract [4, 18–24]. Excellent in vivo image quality has generated excitement about this technology and has set a standard for reflectance-based endoscopic methods to match. Because excitation of fluorophores is typically performed with visible wavelengths, however, fluorescence confocal imaging has limited penetration depth. In addition, exogenous dyes can have toxicities, which may limit clinical applicability. Reflectance-based, endoscopic confocal or optical coherence microscopy methods that can provide comparable image quality at greater depths, but without the need for exogenous contrast, would therefore be an important advance.

28.3 High Transverse Resolution in Optical Coherence Tomography

Compared with confocal microscopy, conventional optical coherence tomography systems work in the opposite focusing limit. In OCT, the focal spot size is comparatively large because of the need to use relatively low NA lenses in order to preserve a sufficient depth of field for cross sectional imaging. As the NA of the OCT optics increases, the depth of field decreases and signal loss occurs at depths away from the focus. Figure 28.2 compares these focusing limits and their implications for OCT image formation. Images are acquired by setting the focus to a defined position in the tissue and detecting light from different depths by coherence gating, either in the time domain or in the frequency domain. In confocal

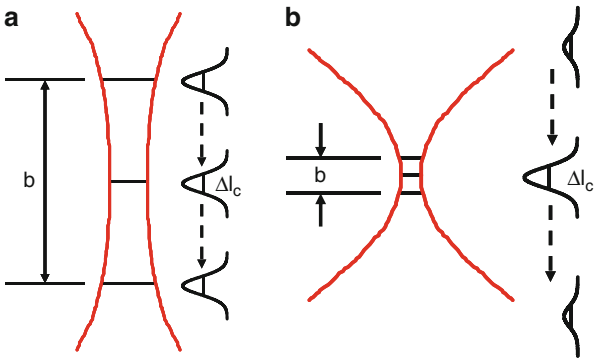

Fig. 28.2 Focusing limits for OCT imaging. Use of a low numerical aperture lens (**a**) preserves depth of field across the entire depth scan while a higher aperture lens (**b**) leads to restricted confocal parameter and signal loss at the edges of the depth scan. Confocal parameter, *b*; Coherence length l_c

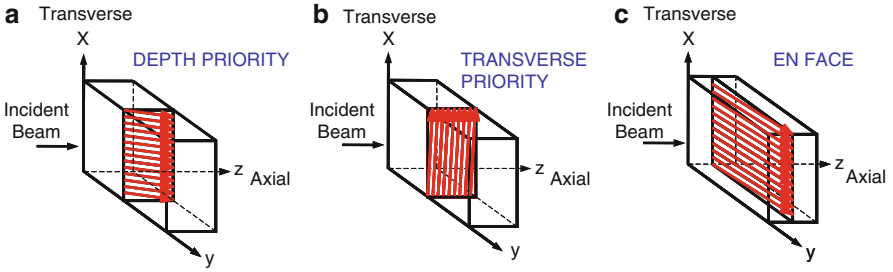

Fig. 28.3 Image scanning protocols for optical coherence tomography

microscopy, the goal is precisely to use high NA focusing to restrict the depth of field, such that light outside of the focal plane is rejected. *En face* images are then formed by rapidly raster scanning the beam.

Several solutions to overcome the depth of field restriction in OCT have been demonstrated in the literature. These methods can be classified into three types according to the image acquisition scan protocol, as illustrated in Fig. 28.3. Depth priority methods maintain the cross-sectional imaging plane of conventional OCT by rapidly acquiring along the depth axis while scanning the transverse beam position at the image frame rate. Transverse priority OCT techniques also scan a cross-sectional plane. In contrast, however, the transverse beam position is scanned to rapidly acquire the transverse axis, while varying the depth axis at the frame rate. The third option is to acquire an *en face* image plane analogous to confocal laser scanning microscopy.

28.3.1 Depth Priority Techniques

One strategy for maintaining high transverse resolution across the image using depth priority scanning is to coordinate the optical focus depth with the depth of the

coherence gate. This approach has been termed focus tracking in the literature and has been used by Schmitt et al. to generate high quality cross-sectional images of human skin with 3 um transverse resolution [25]. Coherence depth scanning was synchronized with focus depth scanning by mounting the reference reflector and the focusing objective on a single translation stage. The disadvantage of this setup is the relatively limited axial scan rates that can be achieved using mechanical translation of the objective. Image acquisition required nearly 30 s for 256 lines. Lexer et al. devised a different scheme for high speed focus tracking based on a novel microscope design that shifts the beam focus through the object without changing the reference path length [26]. Images were acquired of an in vitro human cornea specimen in approximately 1 s with 5 um transverse resolution. The ability to scan the focus without translating the optical path required careful choice of the microscope magnification, which limits overall design flexibility. Other groups have investigated fast focus adjustment using a variable focus micromachined mirror [27, 28] or liquid lens [4, 29, 30].

Typical focus tracking approaches are not readily compatible with high speed, Fourier domain detection OCT techniques. In Fourier domain OCT, backscattered or backreflected light is acquired from all depths simultaneously in the frequency or Fourier domain and axial scan information is subsequently reconstructed using a Fourier transform. Fourier domain OCT methods have been shown to have a significant speed and sensitivity advantage compared with time-domain OCT [31–33]. Two basic Fourier domain implementations have been demonstrated. Spectral/Fourier domain OCT uses a broadband light source and a spectrometer with a line scan camera in the detection arm. Swept source/Fourier domain OCT uses a frequency swept laser source and individual photodiode detectors. In either implementation, depth scanning of the coherence gate is not performed, and it is therefore impossible to perform classic focus-tracking to extend depth of field. The increases in speed and sensitivity, however, have made Fourier domain detection the method of choice for most OCT imaging applications, such as ophthalmology and intravascular imaging [4, 34–36]. Strategies for improving the transverse resolution that are compatible with both time and Fourier domain detection are therefore desirable.

One technique for improving transverse resolution that works for all OCT implementations has been termed C-mode scanning in analogy to ultrasound. This method was demonstrated for OCT by Drexler et al. using an ultrahigh resolution OCT system with 1 um axial $\times$ 3 um transverse resolution [37]. Figure 28.4 presents the concept of C-mode scanning. Multiple OCT images with high axial and transverse resolution were acquired with the focal position set at different depths. The individual images in Fig. 28.4a clearly demonstrate the limited depth of focus. These images were overlapped and fused in Fig. 28.4b to form a single image with extended depth of field. Cellular and subcellular structures in the Xenopus laevis tadpole are visualized. C-mode scanning and image fusion techniques have also been demonstrated for Fourier domain OCT [38, 39]. Like focus-tracking, C-mode scanning still requires translation of the focal position in depth, albeit at a much slower rate. The number of images required scales inversely with the desired transverse resolution. As the focal spot and depth

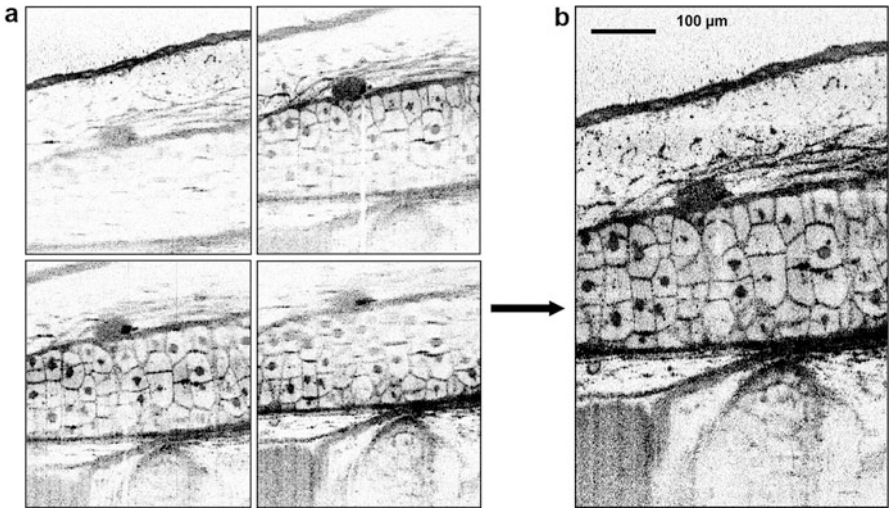

Fig. 28.4 C-mode scanning in optical coherence tomography. Acquisition of individual images with high transverse resolution but restricted depth of field can be reconstructed to form a single image with extended depth of field (Images are reproduced from Drexler et al. [37])

of field for an individual image is reduced, more images are required, which reduces the overall frame rate that can be achieved in the composite image. To address this limitation, Yang et al. developed a multi-focus fiber probe capable of simultaneously generating images at different depths in tissue [40]. In the initial demonstration, four simultaneous images were acquired while maintaining a spot diameter of 9–14 um.

Other techniques are being developed to increase the image depth of field without requiring focus translation or offset. Ding et al. proposed the use of an axicon lens in the OCT probe to generate a long focal volume [41]. In phantom imaging experiments, a 6 mm focusing depth range with 10 um transverse resolution was demonstrated. Axicons produce a cylindrical Bessel beam field distribution with an extended central lobe lying along the optical axis of the lens and are typically used in the form of refracting cone lenses. Unfortunately, there is a trade-off between signal intensity and focusing range since the axicon distributes the focal energy along the focusing range and the central lobe of the Bessel field carries only a fraction of the total power compared with a focused Gaussian beam. In double pass reflection geometry, the squared signal loss limits the utility for high sensitivity imaging in biological tissues. Leitgeb et al. has improved upon the initial axicon demonstration by using the improved sensitivity of spectral domain detection in combination with a modified confocal detection scheme [42]. Transverse resolution of $\sim$1.5 um was maintained over 200 um image range with a sensitivity of 105 dB. Liu et al. have used sample beam apodization as an alternative means to achieve longer depth of field while preserving lateral resolution. In a method they have termed micro-optical coherence tomography (µOCT), a custom designed microscope using beam

apodization is combined with a high speed, ultrahigh resolution spectral/Fourier domain OCT system to achieve resolution of 2 um × 2 um × 1 um with 16 kHz axial scan rate [43]. Striking cellular resolution images of human coronary arteries and human trachea ex vivo have been demonstrated [43, 44]. Techniques such as these are compelling for high speed, cross-sectional cellular imaging and will undoubtedly be the subject of further research and development.

Another approach for increasing transverse resolution without focus adjustment is the use of post-processing algorithms. Image processing is attractive for increasing resolution since the algorithms require minimal to no modifications to existing OCT setups and can be applied offline to large volumes of data. Advanced image processing approaches are enabled by the enhanced phase stability of Fourier domain OCT methods. Ralston et al. have introduced synthetic aperture inverse scattering methods for reducing transverse blurring in OCT images [45]. Depth of field and resolution improvement was demonstrated in scattering phantoms and selected human breast specimens [46]. Adie et al. subsequently showed that computational aberration correction can be combined with synthetic aperture techniques to further image enhancement [47]. The development of high speed processing strategies for real-time imaging [48] and further investigation of these methods in the high NA limit has promise for cellular imaging.

28.3.2 Transverse Priority and En Face Imaging

Transverse priority image acquisition requires rapid transverse scanning of the beam on tissue and slow depth scanning, as illustrated in Fig. 28.3b. Podoleanu et al. suggested transverse priority scanning for performing OCT imaging of the retina and skin [49]. As in C-mode scanning, transverse-priority acquisition enables a slow translation of the focus in tissue at the image frame rate. If focus-tracking is implemented to coordinate the depth scan and focus translation, then no image fusion is required and data collection is very efficient. Cobb et al. demonstrated continuous focus tracking to achieve in vitro OCT images of excised rabbit esophagus at 1 frame/s with transverse resolution of 10.5 um [50]. Transverse scanning was performed at 1.37 kHz using a miniaturized probe, and the reference path length was adjusted to compensate for index of refraction path length shifts produced by the air-tissue interface.

To date, *en face* imaging has proven to be the most robust approach for achieving fine enough transverse resolution for cellular imaging in scattering tissues. In the *en face* plane, the position of the coherence gate can be matched to the position of the optical focus while the beam is raster scanned in two transverse dimensions on the sample. In this manner, high speed focus tracking methods are not required and the image acquisition rate is limited only by the speed of the XY scanner. Furthermore, high NA can be used to achieve high axial and transverse resolutions, in the confocal limit. The implementation of *en face* optical coherence microscopy was first demonstrated by Izatt and colleagues [51], although it has a history in the development of confocal interference microscopes [52–56]. Izatt and others

demonstrated that broadband coherence gating can significantly enhance the imaging depth of conventional confocal microscopy [51, 57, 58]. Subsequently, Izatt et al. showed that *en face* OCM could generate high quality images of cellular features deep below the surface in human gastrointestinal tissues [59]. In vivo *en face* optical coherence tomography was implemented for imaging in the skin and retina, although systems were limited to relatively low transverse resolution and were not capable of visualizing cellular features [49, 60]. In comparison, the development of *en face* optical coherence microscopy for in vivo cellular imaging applications has been relatively slow. In part, this is related to the numerous exciting developments in OCT imaging, which have spread the efforts of researchers across many fronts. In addition, however, OCM technology development for cellular imaging presents unique challenges and requires additional complexity compared with other OCT methods. The remainder of this chapter is devoted to discussing the challenges and the advantages of *en face* OCM imaging and to describing progress toward in vivo cellular imaging applications.

28.3.3 *En Face* Imaging in the Time and Fourier Domain

En face OCM systems based on time domain and Fourier domain detection techniques have both been developed and will be detailed in this chapter. Given the dramatic speed advantages of Fourier domain versus time domain OCT for cross-sectional imaging, it is worth discussing the relative performance of the two approaches for *en face* imaging. For imaging in the *en face* plane, time domain detection approaches can actually have an advantage in terms of imaging speed compared with Fourier domain detection. This results from precisely the same property of Fourier domain detection that creates the sensitivity advantage for cross-sectional imaging. Using spectral/Fourier domain detection or swept-source/Fourier domain detection, signals from multiple depths are detected simultaneously. In order to acquire an *en face* image, an entire three-dimensional volume must effectively be acquired. This places a tremendous demand upon the Fourier-domain OCT system axial line rate and data processing capabilities in order to achieve high frame rates in the *en face* plane. For a typical image of 500 × 500 pixels, acquisition speeds of 8 frames/s require an axial scan rate of two million axial lines per second. This is beyond the specifications of standard spectral/Fourier domain or swept source/Fourier domain systems reported in the literature. For spectral/Fourier domain systems with line rate of 29 kHz [34], acquisition of a 500 × 500 scan volume would take over 8 s. Similarly, swept source/Fourier domain systems operating at 15–20 kHz [38, 61, 62] would require 12–17 s for the same volume.

By contrast, time domain OCT imaging systems acquire signals from only a single *en face* plane. Rather than scanning in depth to generate a Doppler frequency for detection, *en face* imaging systems use phase modulation in the reference arm to provide an external carrier [59]. The reference path is set to the focus depth such that only one depth is sampled at any given transverse position. Image acquisition rate is then determined by signal to noise constraints and by the

maximum speed of the XY scanners. In addition, the intrinsic sensitivity advantage of Fourier domain detection vanishes when only a single *en face* plane is of interest. For a given image acquisition time, the increase in line rate required for sampling a three-dimensional volume in Fourier domain detection cancels the sensitivity advantage compared with sampling a single *en face* plane in time domain.

There are, however, significant advantages to performing *en face* OCT and OCM imaging using Fourier domain detection. Sampling of an entire volume can be quite powerful. Within the depth of field allowed by the confocal parameter of the optics, arbitrary *en face* planes can be displayed from the volume or structures can be rendered in three dimensions. In addition, Fourier domain detection provides greatly increased phase stability compared with time domain detection. Choma et al. [63] and Joo et al. [64] demonstrated this property and implemented spectral/Fourier domain phase microscopy using common path interferometer designs. Other OCT/OCM methods including numerical dispersion compensation [65] and spectroscopic OCM [66] have also shown to have advantages in the spectral/Fourier domain.

Importantly, the volumetric nature of the Fourier domain data makes possible computational approaches for aberration correction and compensation of path length variations between reference and sample arm, which are critically important for fiber-optic microscope and endoscope configurations. In addition, the majority of commercial laser scanning confocal microscopes have a variation of the optical path length as the beam is scanned over the field of view. This delay variation with scanning is caused by optical designs which use paired galvanometer scan mirrors, where the mirrors are not located precisely at the telecentric scan planes. This has prevented the integration of OCM using time domain detection with widely available commercial microscopes, since it is difficult to match the coherence and confocal gates across the field of view as the beam is scanned. In addition, with fiber-optic sample arm probes, manipulation and stretching of the fiber leads to small path length changes that can degrade signal. Fourier domain OCM systems, which acquire a volumetric image around the zero path delay, can allow pixel-by-pixel optimization of path-delay variation over the field of view.

Ultrahigh imaging speeds for Fourier domain OCM are also becoming available, particularly for swept source/Fourier domain imaging. Axial line rates of up to 5.2 MHz have been demonstrated using Fourier-domain modelocked (FDML) lasers [67] and up to 1 MHz using vertical cavity surface emitting lasers (VCSEL) [68, 69]. As imaging speeds for *en face* Fourier domain OCM continue to improve, the advantages of these methods over time domain techniques will become more important for future in vivo imaging applications.

28.4 Combined Confocal and Coherence Gating in OCM

OCM utilizes high NA optics together with broadband light sources to reject unwanted scattered light using both confocal gating and coherence gating. To understand how these two mechanisms interact, consider the detected heterodyne signal in a typical time domain OCM system. An equivalent derivation can also be

shown for Fourier domain systems. In the time domain system, light from the low coherence light source is split between a reference arm and a sample arm. The reference and sample reflectivities are denoted R_r and R_s, respectively. A wavelength dependent phase delay ϕ (ω,t) can be imparted by a reference phase modulator. Light returning from the sample and the reference path interferes at a photodetector. Ignoring the transverse dependence of the interfering electric fields, the time averaged photocurrent at the detector can be written as [70]

$$i_D = \left\langle \frac{\eta e}{h\nu} \frac{|E_R + E_S|^2}{2\eta_f} \right\rangle \tag{28.3}$$

where η is the detector quantum efficiency, e is the electronic charge, $h\nu$ is the photon energy and η_f is the intrinsic impedance of the fiber core material. The detector response time is taken to be much longer than the coherence time for a low-coherence source but much shorter than the heterodyne signal beat oscillations. For a polychromatic, low-coherence source, the oscillating component of the heterodyne signal depends on the sum of the interference due to monochromatic plane waves and can be determined by integration of the cross-spectral interference term over the bandwidth of the light source. Ignoring the sample arm confocal response and assuming pure phase delay scanning from the reference arm modulator, the heterodyne photocurrent can then be written in terms of the optical frequency ω and center frequency ω_0 as

$$\begin{aligned} i_D(\Delta l) &\propto R_R R_S \left\{ F^{-1}[S_o(\omega)] \right\} \cos\left(\omega_o \Delta t_p\right) \\ &= R_R R_S G_o \left(\frac{2\Delta l}{v_g}\right) \cos\left[\frac{2\omega_o \Delta l}{v_p} + \phi(\omega_o, t)\right] \end{aligned} \tag{28.4}$$

where

$$v_p = \frac{2\Delta l}{\Delta \tau_p} \tag{28.5}$$

and

$$v_g = \frac{2\Delta l}{\Delta \tau_g} \tag{28.6}$$

describe the phase velocity v_p and group velocity v_g in terms of the phase delay $\Delta\tau_p$, group delay $\Delta\tau_g$, and the difference in path length $\Delta l = l_S - l_R$ between the sample and reference arms. The source power spectrum $S_o(\omega)$ is related to the autocorrelation $G_o(\Delta\tau_g)$ by the Fourier transform with respect to the group delay. The autocorrelation is a measure of the degree of temporal coherence of the source. Using the concept of the time-bandwidth product in Fourier transform theory, it is

clear that the width of the interference signal envelope decreases for larger bandwidth or shorter coherence length light sources. In the case of a Gaussian light source spectral distribution, the full width at half maximum (FWHM) of the interference signal in free space can be shown to relate to the center wavelength λ_0 and spectral bandwidth $\Delta\lambda$ as [70]

$$\Delta l_{FWHM} = \frac{2\ln 2}{\pi}\left(\frac{\lambda_0^2}{\Delta\lambda}\right) \tag{28.7}$$

This expression is typically used for the specification of the coherence gate or axial resolution of a low-coherence interferometry system.

Izatt et al. described the heterodyne signal in OCM by incorporating a sample reflection in confocal geometry [59]. The influence of the sample arm confocal microscope is determined by the convolution of the field reflectivity function $R_S(x, y, z)$ with the confocal impulse response $[h_I(x, y, z)]^2$. The appropriate confocal point spread function for a fiber-based microscope has been described by Gu et al. [71]. For an axially distributed reflectivity that is present in scattering media, the heterodyne signal can be written as an integral over the sample arm path length l_S. Replacing R_S in Eq. 28.4 with the confocal response and integrating over the sample path, the heterodyne current becomes

$$i_D(\Delta l) \propto \int_{-\infty}^{\infty} dl_S R_R \left[R_S(l_S) \otimes [h_I(l_S)]^2\right] G_o\left(\frac{2\Delta l}{v_g}\right) \cos\left[\frac{2\omega_o \Delta l}{v_p} + \phi(\omega_o, t)\right] \tag{28.8}$$

where the (x,y) dependence of R_s and h_I have been ignored for simplicity. The heterodyne component is the convolution of the sample arm confocal response with the carrier dependent source autocorrelation term. For a single scatterer at a depth location l_{s0} with reflectivity $R_s(l_{s0})$, the heterodyne current reduces to [59]

$$i_D(\Delta l) \propto R_R R_S(l_{S0}) \sqrt{I_C(l_{S0})} G_o\left(\frac{2(l_{S0} - l_R)}{v_g}\right) \cos\left[\frac{2\omega_o(l_{S0} - l_R)}{v_p} + \phi(\omega_o, t)\right] \tag{28.9}$$

where I_c represents the confocal intensity response and, by definition, $l_s = 0$ corresponds to the position of the focus.

From Eq. 28.9 it is evident that control of the positions and widths of the confocal and coherence gates are decoupled. The confocal gate width is determined by the NA of the focusing objective and its position is set by the focus position. For the coherence gate, the width is determined by the light source bandwidth, and, for fixed focus position, the depth location is set by the reference arm path length l_R. The maximum heterodyne signal occurs when the reference and sample arm path lengths match $l_{S0} = l_R$ such that the coherence and confocal gates overlap. The sensitivity of the heterodyne signal to the relative position of the gates scales with the NA of the objective lens. For high NA, the confocal parameter b as shown in

Fig. 28.2b is quite small and results in a small depth of field for imaging. When the reference path length is set to the microscope focus, $l_R = 0$, the heterodyne amplitude is subject to the multiplication of the coherence and confocal gate point spread functions.

28.5 Advantages of OCM

For imaging in scattering media, combined confocal and coherence gating can have advantages compared with confocal gating alone. Coherence and confocal gating reject unwanted out of focus scattered light using distinct mechanisms. The confocal gate rejects light based on spatial imaging constraints, while the coherence gate rejects photons based on the path length they travel in tissue. The multiplicative effect of the two gates can be stronger than either gate individually, achieving greater image contrast and image penetration in scattering tissue. Moreover, as Wang et al. point out, the typical Gaussian coherence gate has a functional response which is not only more effective than the confocal gate but also more effective than the exponential extinction of incident light in tissue [72]. Figure 28.5 compares measured point spread functions on a log scale from an early OCM demonstration [51]. At depths of several tens of micrometers from the focus, the coherence gate rejects scattered light with orders of magnitude better efficiency than the confocal

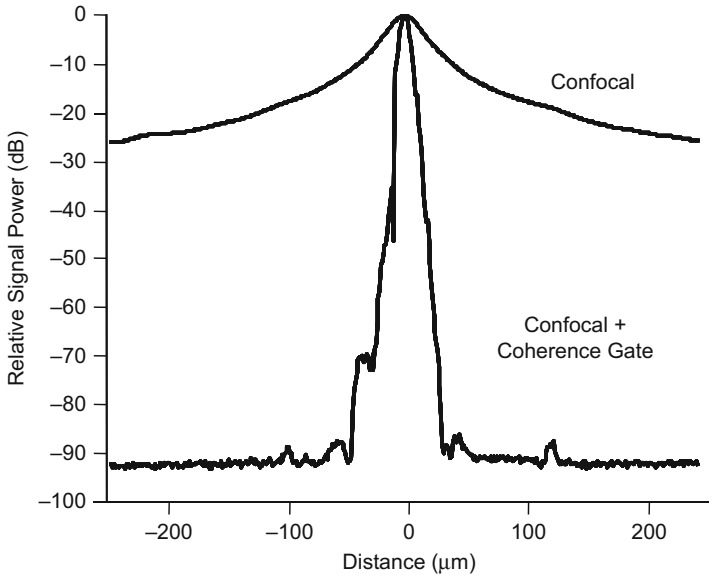

Fig. 28.5 Measured confocal and coherence-gated axial resolutions for a typical OCM imaging system. Data is presented on a log scale and demonstrates the improved rejection of out of focus scattered light using combined confocal and coherence-gating compared with confocal gating alone (Figure is reproduced from Izatt et al. [51])

gate alone. In addition, the confocal axial response is affected by aberrations when focusing into tissue, which causes broadening of the peak of the point spread function and increases the wings of the response [73]. Combined coherence and confocal gating can help to minimize reductions in contrast due to loss of confocal axial resolution.

Image penetration depth limits in confocal microscopy and their enhancement using coherence gating have been studied by several investigators [51, 58, 74–76]. Using single scattering theory, and signal to background noise considerations, Izatt et al. estimated the confocal penetration limit to be in the range of 5–8 mean free paths (MFP) [51]. Schmitt et al. used Monte Carlo simulations to investigate the role of multiple scattering and concluded that penetration depth is actually limited to the range of 2–4 MFP [75, 76]. Smithpeter et al. subsequently used experimental measurements to predict a similar penetration depth of about 3–4 MFP in amelanotic tissue [74]. Coherence gating has been shown to enhance image penetration by rejecting multiply scattered light, particularly from superficial depths. Based on the shot-noise quantum detection limit, initial estimates of imaging depth improvement were placed at 2–3 times compared with confocal gating alone [51]. As researchers became more aware of the sensitivity of coherence-gating methods to multiple scattering, these expectations were tempered. In highly scattering media, contrast in OCT and OCM images is limited by the ratio of single scattered to multiple scattered light, not by the quantum sensitivity limit [77]. Furthermore, the system sensitivity to multiple scattering is a function of both the optical properties of the tissue as well as the system design parameters, including the numerical aperture. Given these constraints, precise quantification of the image depth enhancement will depend upon the specifics of the application. Nonetheless, several initial studies in human tissues have demonstrated significant improvement using coherence gating. In one study, imaging of cellular features in colonic crypts was possible at depths of 500 um [59]. Another study imaging human oral mucosa demonstrated an average depth improvement of 33 % [78].

Since image quality is dependent upon both contrast and resolution, the question of resolution degradation in OCM images deep in scattering media is closely linked to the notion of imaging depth in OCM. Bizheva and Boas studied these questions using both simulation and experiment over a range of typical OCM parameters for scattering anisotropy and imaging NA [79]. Their results indicate relatively small changes in axial resolution at both low and high NA when imaging in media with low scattering anisotropy of 0.2. However, in media of high scattering anisotropy of 0.9, axial resolution degradation is quite rapid after 3–4 MFP. Moreover, degradation is more pronounced at lower NA compared with higher NA. With respect to transverse resolution, their results show no significant change up to seven MFP for either low or high anisotropy and some resolution degradation after seven MFP. Further studies such as these will be important to determine optimal parameters for deep cellular imaging in highly scattering tissues.

Combined coherence and confocal gating can have additional advantages beyond imaging depth improvement. One such advantage lies in the ability to use

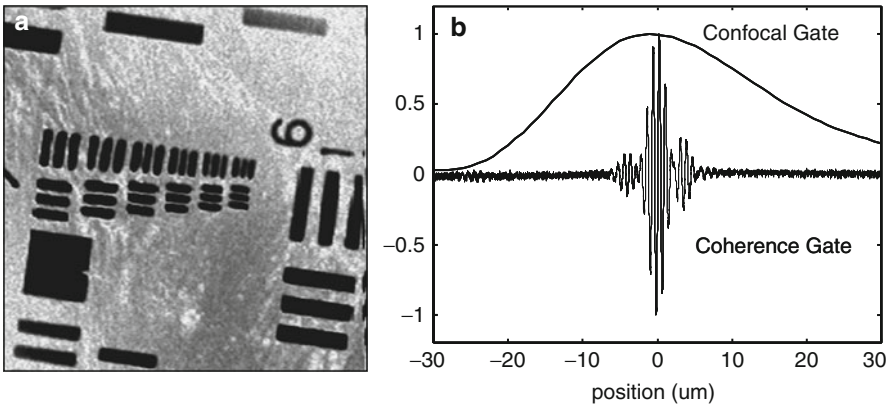

Fig. 28.6 Optical coherence microscopy using a femtosecond laser source. High transverse resolution of <2 um allows visualization of even the smallest elements of the USAF 1951 resolution target (**a**). This transverse resolution was achieved with a reduced numerical aperture compared with that typically used for confocal microscopy, resulting in a confocal axial resolution of only ~30 um. A short coherence gate of ~3 um was then used to compensate for the lower confocal resolution (Images reproduced from Aguirre et al. [80])

ultrahigh axial resolutions provided by very broad bandwidth light sources. Results from confocal microscopy in human skin demonstrate that achieving an axial resolution of <5 um is important for high contrast imaging of cellular features [4]. Such an optical slice axial thickness is similar to the conventional section thickness used in histopathology. Because the axial resolution depends inversely on the square of the NA ($1/NA^2$), achieving a 5 um axial resolution with confocal microscopy alone requires high NA objectives, typically in the range of 0.7–1.2 NA. Most OCM systems to date have operated in this limit, using the confocal axial section as the dominant gating method with the coherence gate acting mostly to reduce the background from out of focus scattered light.

The development of ultrahigh resolution OCT techniques opened the possibility of using the coherence gate rather than the confocal gate to set the optical section thickness [37]. Transverse resolution of 1–2 um can be maintained with much lower NA, since the transverse spot size only scales inversely with the NA ($1/NA$). This implies that OCM with ultrahigh axial coherence resolution can achieve high contrast cellular imaging with significantly reduced NA compared with confocal microscopy. Figure 28.6 demonstrates this operating limit. A confocal microscope with an axial resolution of ~30 um was combined with a broad bandwidth modelocked Ti:Al_2O_3 solid-state laser light source and an OCM system with a broadband phase modulator [80]. The coherence gate measures ~3 um and provides most of the optical sectioning power of this microscope. The effective NA of the microscope was only ~0.22. Figure 28.6a shows that high transverse resolution is still maintained. The smallest elements measuring 2.2 um in width on the USAF 1951 resolution target can be visualized. Figure 28.7 demonstrates that high contrast cellular images in human tissue can be achieved, despite the low

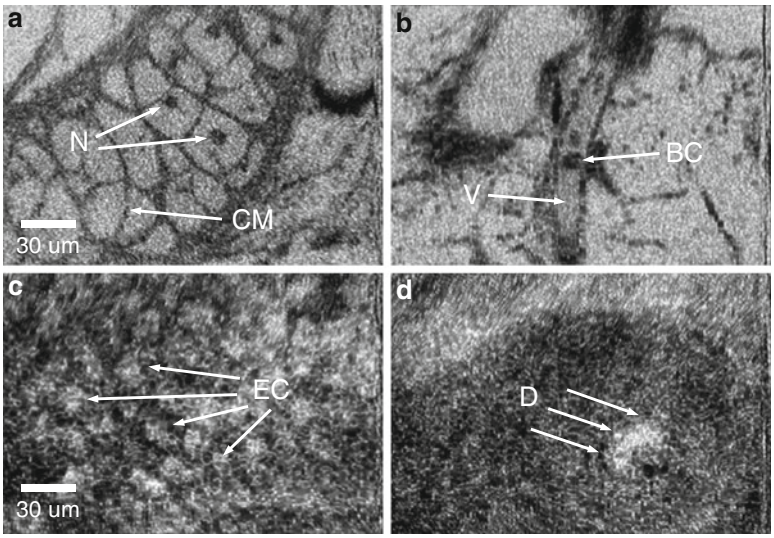

Fig. 28.7 In vivo cellular imaging with optical coherence microscopy. Images of Xenopus laevis tadpole (**a**, **b**) show cell membranes (*CM*), cell nuclei (*N*), and individual blood cells (*BC*) in a vessel (*V*). Epidermal cells (*EC*) and a duct (*D*) structure are also in images of human skin (**c**, **d**) (Images reproduced from Aguirre et al. [80])

confocal axial resolution. Figure 28.7a, b present images from the Xenopus laevis tadpole, a commonly used model organism in developmental biology specimens. Cell nuclei and membranes as well as small vessels and blood cells are visible. Figure 28.7c, d show images of human skin in vivo. Epidermal cells and the lumen of a sweat duct can be clearly identified.

The ability to image with reduced NA makes OCM an enabling technology for endoscopic imaging. Miniaturization of high NA objectives is a challenging optical design problem [81]. Using a broad bandwidth light source to provide ultrahigh axial coherence resolutions can reduce the numerical aperture requirement, therefore allowing smaller and simpler probe designs. Figure 28.8 further highlights this advantage. Confocal axial and transverse resolutions are plotted versus numerical aperture. OCM can achieve sufficient transverse resolutions in the range of 0.2–0.5 NA and lower, despite the rapid degradation of the axial resolution seen in confocal microscopy.

Figure 28.9 further illustrates the advantage of OCM for cellular imaging at lower numerical aperture compared to confocal microscopy. These images were acquired using a Fourier domain/swept source OCM system operating at 1.3 um center wavelength [82] and described in further detailed later in this chapter. Figure 28.9a, b demonstrate OCM images of colonic crypts and goblet cells taken with 10×/0.3 NA and 20×/0.4 NA lenses, respectively. For comparison, Fig. 28.9c, d are simulated confocal images generated from stacks of OCM images taken at the same magnifications and at the same tissue location. The image stacks have been summed over all depths, which simulates an effective axial resolution

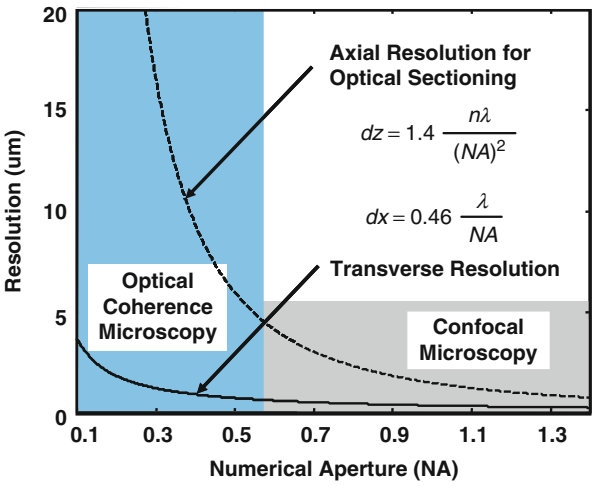

Fig. 28.8 Operating ranges for optical coherence microscopy compared with confocal microscopy

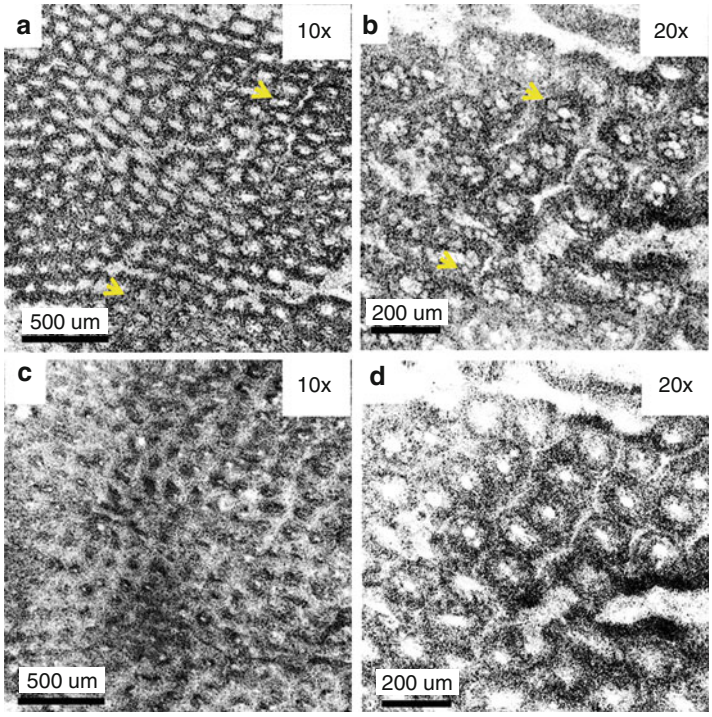

Fig. 28.9 Comparison of OCM and confocal images of human colon. OCM images at 10× (**a**) and 20× magnification (**b**) exhibit high contrast and high resolution compared to the confocal images at similar magnification 10× (**c**) and 20× (**d**). Confocal images were formed from summing over all depths in a volumetric OCM image acquired using Fourier domain OCM (Images reproduced from Ahsen et al. [82])

provided from only the confocal gate. Cellular features in the OCM images are clearly visible, however there is loss of resolution and contrast for cellular features in the simulated confocal images.

An added advantage of OCM using lower NA lenses with lower magnification is the ability to achieve larger fields of view, large depth of field and longer working distance compared with confocal microscopy. Improved field of view allows the user to survey larger regions of tissue and helps to provide context to the microscopic features visualized with OCM. Furthermore, the larger confocal axial resolution affords the possibility of acquiring multiple depth sections around the location of the focal plane. This may be useful for applications such as characterizing the three dimensional shape and size of cells in a particular tissue layer. This type of imaging cannot be performed with confocal microscopy without translating the focus.

28.6 Technology for OCM

Cellular imaging with OCM comes at the cost of increased system complexity compared with conventional OCT as well as confocal microscopy. System designs must incorporate the core features of a confocal microscope, including a two-axis scanner and reasonably high NA lens, in addition to the heterodyne interferometer and detection electronics necessary in OCT. To achieve ultrahigh coherence axial resolutions, very broadband light sources must be used. Furthermore, optical interferometer and microscope designs capable of supporting these large spectral bandwidths must be developed. For in vivo imaging, the imaging speed is also a critical parameter. Visualization of cellular and subcellular features requires sufficient speed to eliminate motion artifacts and transverse blurring. Based on work with confocal microscopy, a speed of ~8 frames per second is desirable, even with the use of contact tissue stabilization schemes [4]. This necessitates fast raster scanning and either high speed phase modulation methods in the time domain or ultrahigh speed axial rate systems in the Fourier domain. High speed imaging also requires high power light sources to overcome signal loss due to reduced pixel dwell times. At near-infrared wavelengths, permissible tissue exposures for high speed imaging are in the range of 10–20 mW. Including coupler loss and optical transmission loss, typical system throughput can be quite low, however, and this can substantially increase the light source output power requirements to obtain sufficient tissue illumination. Finally, an OCM system must have some mechanism to ensure overlap of the confocal and coherence gates in scattering tissue. This section reviews progress on technology for OCM that will enable high speed in vivo imaging.

28.6.1 Broadband Light Sources

Light source requirements for OCM essentially parallel the requirements for OCT. Near infrared wavelengths between 800 and 1,300 nm are desirable to take advantage of lower absorption and scattering in tissue compared with visible

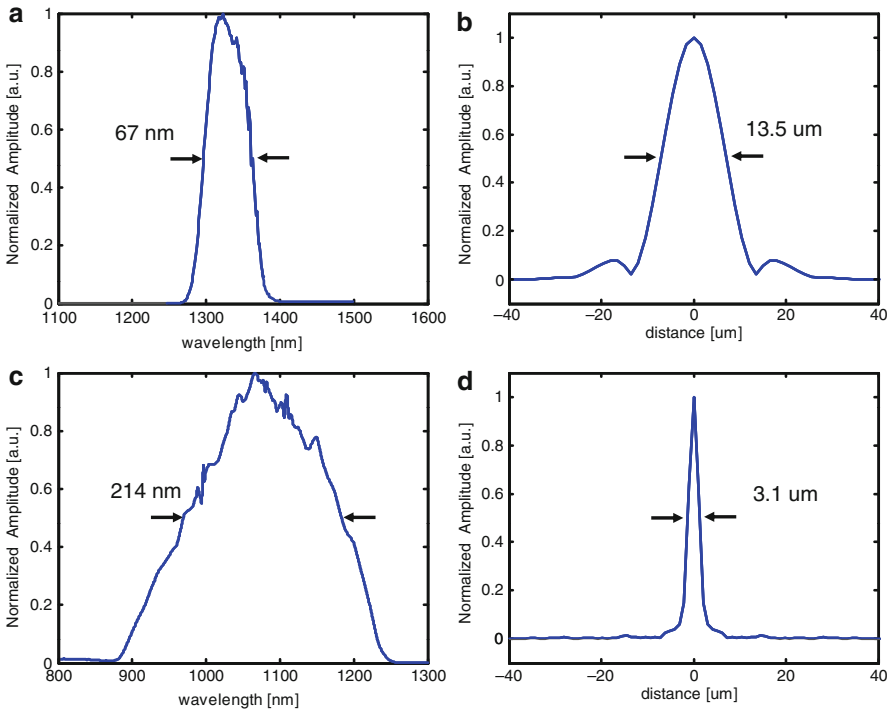

Fig. 28.10 Comparison of light sources for optical coherence microscopy. A typical superluminescent diode source provides a spectrum of around 70 nm (**a**), which corresponds to an axial resolution of about 14 um (**b**). State of the art femtosecond lasers and continuum generation can provide much broader spectra and higher axial resolution. Shown here are results achieved using a compact Nd:Glass oscillator. Spectral bandwidth (**c**) measures over 200 nm, corresponding to an axial resolution of about 3 um (**d**)

wavelengths. Within this range, the shorter wavelengths near 800 nm provide increased contrast and better resolution for a fixed optical bandwidth compared with the longer wavelengths near 1,300 nm. Nonetheless, the increased penetration depth at longer near infrared wavelengths is attractive for imaging below the surface in scattering tissues. For time-domain or spectral/Fourier domain implementations of OCM, broadband superluminescent diode light sources or modelocked femtosecond solid state lasers are utilized. Superluminescent diode light sources have typical bandwidths in the range of 40–80 nm and output powers between 1 and 20 mW. Figure 28.10a presents a measured spectrum from a typical superluminescent diode at 1,300 nm. The coherence gate can be computed from the autocorrelation of the spectrum and has a width of 13.5 um, as shown in Fig. 28.10b. Superluminescent diodes offer compact, stable, turnkey solutions and have been widely applied in clinical studies with OCT. Femtosecond lasers have enabled ultrahigh resolution OCT with coherence gates of less than 5 um. These systems offer superior performance in terms of bandwidth and output power compared with the SLD's, but they are typically expensive as well as complex to

build and operate. The use of supercontinuum generation in highly nonlinear fibers has enabled the application of commercially available femtosecond lasers for OCT. Such commercial laser sources can be made highly stable and compact, compared with research prototypes, which allows the development of portable systems for clinical investigations outside of the research laboratory. Figure 28.10c, d present the measured spectrum and the computed coherence gate for a laser light source of this type [83]. Using a compact Nd: Glass oscillator coupled into a Germanium-doped, high numerical aperture, nonlinear fiber, an optical spectrum of over 200 nm centered at 1,060 nm was generated using self phase modulation nonlinearity. This enables resolutions of $\sim$3 um in air. Moreover, the average power was $>$100 mW, enabling high speed imaging. The wavelength range around 1,060 nm is compelling for use in scattering tissues because it offers both increased penetration compared with the 800 nm region and improved resolution compared with 1,300 nm. Some studies suggest that this wavelength window is an optimum choice for ultrahigh resolution imaging [84], and continuous wave lasers around 1,060 nm have been extensively used for confocal imaging [4, 85]. Fully-integrated, turn-key supercontinuum generation systems utilizing photonic crystal fibers are also now available and have been used by several groups for optical coherence imaging [43, 86].

Swept source/Fourier domain OCM systems require wavelength swept laser sources with ultrahigh sweep speeds. As previously mentioned, recent novel laser designs to achieve high scan speeds include the Fourier domain modelocked (FDML) laser [67, 87] and the vertical cavity surface emitting laser (VCSEL) [68, 69]. Figure 28.11 demonstrates the characterization of a state of the art VCSEL laser used for OCM imaging [82]. The laser operates at 1,310 nm with 117 nm sweep bandwidth and sweeps at 280 kHz, providing a bidirectional axial scan rate of 560 kHz. Figure 28.11 shows the spectrum and characterization of this light source. The VCSEL is wavelength scanned using a microelectromechanical (MEMS) tunable cavity, and has the unique feature of a micron-scale cavity length allowing single mode lasing with an extremely narrow instantaneous linewidth, which supports a long coherence range for imaging. Figure 28.11d shows the minimal roll-off in image signal as a function of depth, consistent with long instantaneous coherence length during the sweep.

28.6.2 Time Domain Phase Modulation Schemes

For time domain OCM systems, broadband and high speed phase modulators are required. The basic goal is to provide a phase delay to the reference arm light, without imparting significant group delay that would cause the coherence gate to shift relative to the confocal gate. The first OCM system demonstrated by Izatt et al. used a piezo-electric fiber stretcher to dither the reference path length by a fraction of a wavelength [51]. A similar approach employs a piezo-electric stack to vibrate the reference mirror [59, 78, 88]. This method uses a relatively simple interferometer design that supports broad optical bandwidth but is limited to relatively slow modulation rates and therefore does not allow real-time imaging.

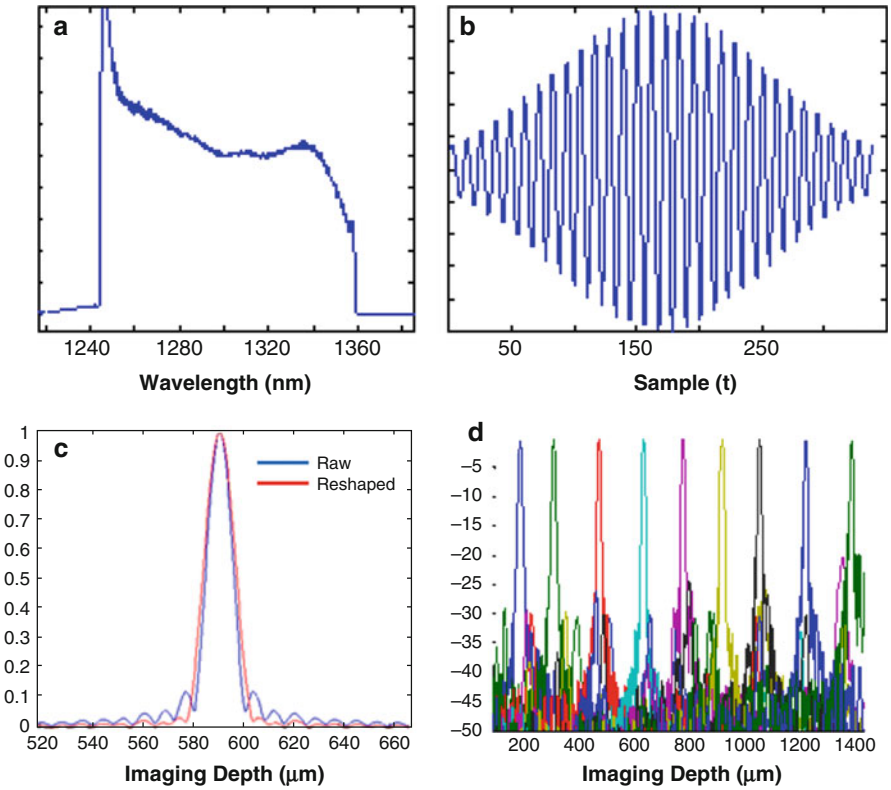

Fig. 28.11 Vertical cavity surface emitting laser (*VCSEL*) for high speed swept source OCM. (**a**) Spectrum of the VCSEL showing 117 nm tuning range. (**b**) Interferometric fringe signal after spectral reshaping and numerical dispersion compensation. (**c**) Axial point spread function after Fourier transformation of the raw acquired fringe data (*blue curve*) and the fringes after spectral reshaping (*red curve*). (**d**) Sensitivity fall-off of the VCSEL swept source as a function of depth showing no significant change in the sensitivity over the imaging range (Figure reproduced from Ahsen et al. [82])

An alternative approach to reference arm phase modulation involves the use of a rapid scanning optical delay line (RSOD) similar to those designed for OCT [89, 90]. The RSOD uses a grating and lens combination to perform an optical Fourier transform. A scanning mirror in the Fourier plane of the delay line imparts a wavelength dependent phase shift which, when passing back through the lens-grating combination, produces a group delay scan in the time domain. In addition, offsetting the optical beam from the scanning mirror center axis allows the generation of a phase delay scan, which adds a Doppler frequency shift to the heterodyne signal. Zvyagin et al. demonstrated that, with proper choice of grating, lens, and offset parameters, the RSOD can also be set to generate phase delay without group delay [91]. Aguirre et al. utilized this approach in an all-reflective configuration to construct a broadband optical phase modulator for OCM imaging [80].

The reflective design eliminates chromatic aberration encountered with lens geometries. Using resonant galvanometer scanners, RSOD modulators such as this are capable of producing modulation frequencies in the MHz range [90]. An OCM system utilizing an RSOD modulator has been used for in vivo cellular imaging at 4 frames per second, as shown previously in Fig. 28.7.

Acousto-optic (AO) and electro-optic (EO) modulators are excellent solutions for high speed modulation. Several investigators have used EO modulators in OCT to provide a highly phase stable Doppler shift at 1,300 nm wavelength [92–94]. Electro-optic modulators can be driven at very high modulation rates in the GHz range, well beyond what would be needed for even the fastest OCM system. Linear, broadband EO phase modulators are not widely available at wavelengths outside of the standard telecommunications band encompassing 1,300–1,500 nm. Moreover, typical $LiNbO_3$ crystals used in EO modulators are highly birefringent. For unpolarized superluminescent diode sources, this does not present a significant problem. However, with polarized broadband laser sources that have complex polarization evolution in the fiber, the polarization dependence of EO modulators can make them difficult to use and potentially necessitate polarization control or diversity approaches.

Acousto-optic modulators have also been applied for cross-sectional, transverse-priority and *en face* OCT imaging [50, 95, 96]. AO modulators are available at many wavelengths and provide a pure frequency shift rather than a phase modulation, but typical frequency shifts are in the tens of MHz range. To reduce the frequency shift to a lower value more suitable for OCT or OCM imaging, a modified approach can be used in which a pair of AO modulators is cascaded with opposite frequency shifts offset in magnitude by a small amount. For example, Xie et al. used AO modulators with frequencies of +55 MHz and −54 MHz giving a round-trip, double pass net frequency shift of 2 MHz [95]. This approach requires the added complexity of two separate modulators and drive electronics, but like the EO modulation schemes, it can provide a highly stable modulation. In addition, AO modulators are generally polarization insensitive.

Dispersion compensation is another important challenge in using either an EO or AO modulators with broadband OCT or OCM systems. The optical materials used in modulators introduce large amounts of dispersion in the reference arm that must be balanced or compensated in order to preserve the axial point spread function. This issue has been addressed primarily by using rapid scanning optical delay lines (RSODs) to remove second order dispersion [93, 97]. An RSOD alone, however, cannot remove higher order dispersion terms. One approach that enables compensation of high order dispersion is to place identical optical materials as are used in the reference arm modulator in the sample arm. Wiesauer et al. used this strategy to achieve <3 um axial resolution in a free-space *en face* OCT system [98]. However, this approach is undesirable for use in endoscopy or other applications using fiber-optic sample probes, since it would require free space coupling out of and into the fiber in order to introduce the dispersion compensation material. Chen et al. demonstrated a simple and elegant modification to the RSOD compensation technique which allows dispersion management up to third order by using a length

of single-mode optical fiber in the sample arm [99]. This technique was theoretically analyzed and experimentally demonstrated for EO as well as AO modulators and a resolution of ~2.8 um was achieved with an AO modulator at 800 nm wavelength. The same group subsequently developed a technique for optimization of the spectral throughput of AO modulators which supports more than 200 nm bandwidth at 800 nm [100]. With the development of suitably broadband dispersion compensation approaches, AO and EO modulators promise to be widely used for high speed in vivo OCM imaging in the future.

Two interesting approaches to *en face* imaging have been demonstrated which do not require modulators in the reference arm. The first approach makes use of the inherent modulation imparted by raster scanning the beam with a galvanometer mirror. In the case when the scan field in the sample arm is curved, a sampling function based on Newton rings can be used [101]. Alternately, an offset of the beam on the galvanometer scanner mirror can be used to produce a parallel fringe sampling function [102]. A second approach uses homodyne detection based on 3 × 3 optical couplers [103]. The homodyne method takes advantage of the inherent phase shifts between the ports of the coupler to obtain amplitude and phase information. Images of a *Xenopus* tadpole were demonstrated with sensitivity of ~90 dB and transverse resolution of 9.4 um. OCM schemes that do not require modulation can result in simpler system designs and are therefore promising for further study.

28.6.3 Microscope Scanner Designs

Microscope design principles for OCM imaging are similar to those for confocal microscopy in epi-reflection mode. The microscope consists of three basic subsystems: (1) an XY scanning apparatus, (2) collimation and relay optics, (3) a focusing objective. The XY scanner should ideally maintain the same optical path length to the focus across the entire scan field in order to ensure overlap of the confocal and coherence gates. The most direct way to do this is would be to mechanically scan the microscope and sample with respect to each other using translation stages. For high speed imaging, however, beam steering is the preferred method. Galvanometer mirror scanners have been widely used for OCM, because rotating polygon scanners typically used for video rate confocal microscopes [4] introduce an unwanted path length shift across the scan. Resonant scanning galvanometers can offer fast axis scan rates, as high as 10–15 kHz, which are sufficient for video rate imaging with high line density per image.

Collimation and relay optics are typically composed of multiple-element achromatic lenses designed and coated for use at near-infrared wavelengths. Focusing objectives are generally chosen to provide field flatness, which aids in reference path length matching across the field of view. Furthermore, water immersion lenses are often used for imaging in biological tissue to minimize aberrations from refractive index mismatch. However, high quality focusing objectives designed for the near infrared are not widely available, and therefore most systems

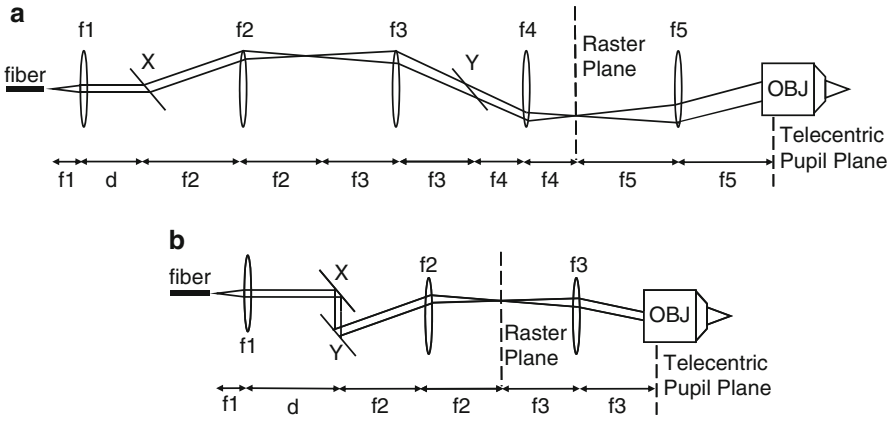

Fig. 28.12 Fiber-optic confocal microscope designs typically used for OCM. A true telecentric design (**a**) separates the transverse scanners and precisely images the points of angular scan on each axis to the telecentric plane of the objective. An approximate geometry (**b**) which uses a pair of closely spaced galvanometer scanners can also work well but introduces aberration

have used lenses designed for visible wavelengths. This leads to poor optical throughput as well as focusing aberrations. As near IR imaging methods, including multiphoton and harmonic microscopies as well as OCT, become more established, it can be expected that near IR objective lenses will become more readily available.

Figure 28.12 illustrates two examples of benchtop OCM microscope designs for use with galvanometer scanners and an infinity corrected objective lens. The design in Fig. 28.12a is a true telecentric design. The beam from the fiber is collimated and directed onto the center of the first galvanometer scanner. The center point of this galvanometer is then relay imaged to the center point of the second scanner by lenses f2 and f3. A final telescope, formed by lenses f4 and f5, then images the scanners to the telecentric pupil plane in the objective lens. This design offers true telecentricity in that the beam can be made to pivot on both axes about the telecentric plane and there is negligible path length delay variation with scanning. The disadvantage of this design is that it requires several lenses and a relatively large optical path. A second design, shown in Fig. 28.12b, uses a closely-spaced pair of galvanometers after the collimator. The center point between the mirrors is imaged by a single telescope to the telecentric pupil plane. This configuration can provide only approximate telecentricity, since neither of the pivoting mirrors can be exactly imaged to the correct pupil plane in the objective. The spacing between the galvanometers should be minimized to reduce the degree of scan induced path length delay that results. This design offers compactness, and is more amenable to use with handheld imaging devices.

The development of miniaturized microscopes for endoscopic confocal and OCM imaging is a critical enabling step necessary for widespread application of these techniques for human clinical imaging. Two separate challenges must be

overcome: design of small diameter, high NA objective lenses and development of miniaturized, fast two-axis scanners. These issues have been the topic of significant research efforts in recent years. Ideally, the device diameter would be a maximum of 3–4 mm in order to enable its use through the accessory ports of clinical endoscopes. As described above, OCM has the important advantage that it can image with lower NA compared with confocal microscopy, which facilitates the development the small diameter objective lenses required. Several approaches for developing compact endoscopic scanning devices have been investigated. Some groups are pursuing fiber imaging bundles for confocal [16, 19, 104–107] and optical coherence imaging [108]. Fused coherent fiber bundles consist of thousands of individual fibers which preserve spatial relationship between proximal and distal ends. Each fiber in the bundle serves as an image pixel, and scanning can be performed at the proximal end of the fiber bundle using conventional galvanometer scanners. Fiber bundles tend to have poor optical efficiency, however, and image pixelation as well as fiber cross talk can degrade resolution and contrast. In addition, phase differences between individual fiber paths can present problems for phase sensitive heterodyne detection methods.

Single-mode fiber scanners have much better optical efficiency, but require miniaturized scanners located at the distal tip of the fiber optic probe. Two-dimensional scanning of the input fiber tip has been used by several groups for endoscopy, confocal microscopy and multiphoton microscopy [109–112]. Piezo-electric devices typically require resonance drives to achieve sufficient deflection, which limits their ability to scan arbitrary XY scan patterns. Two axis resonant piezo scanners can scan a two dimensional plane using a Lissajous scan pattern [109] or a spiral scan pattern [113, 114]. The scanner from Wu et al. utilized a tubular four quadrant piezo actuator, and is particularly promising for endoscopy due to is small diameter of 2.4 mm and capability for rapid imaging at 3.3 frames/s [114]. Sawinski and colleagues developed a novel non-resonant piezolever fiber scanner (PLFS) capable of scanning arbitrary patterns with independent X and Y axes [115, 116]. This device was subsequently incorporated into an endoscope with a custom designed objective lens and demonstrated for cellular resolution OCM imaging [117]. Figure 28.13 shows a schematic and photo of the device with diameter of 8 mm used for imaging. Imaging was performed with 600 Hz drive on the fast axis and up to 4 Hz on slow axis to scan a raster pattern. Images of human colon ex vivo and human skin in vivo are demonstrated with <2 um transverse resolution and <4 um axial resolution.

Two-axis micro-electro-mechanical systems (MEMS) may also enable a wide range of fiber optic endoscope devices for OCT and OCM. Two-axis MEMS scanning mirrors have been demonstrated for confocal microscopy applications [118] and one and two axis scanners have been designed for optical coherence tomography applications [4, 119–127]. Figure 28.14 illustrates an example implementation of a two-axis MEMS scanning catheter used for 3D and *en face* ultrahigh resolution OCT imaging. The scanner, shown in the scanning electron micrograph in Fig. 28.14a, has a large 1 mm diameter mirror for high resolution imaging. It uses angular vertical comb (AVC) drive actuators on the mirror and on the outer gimbal

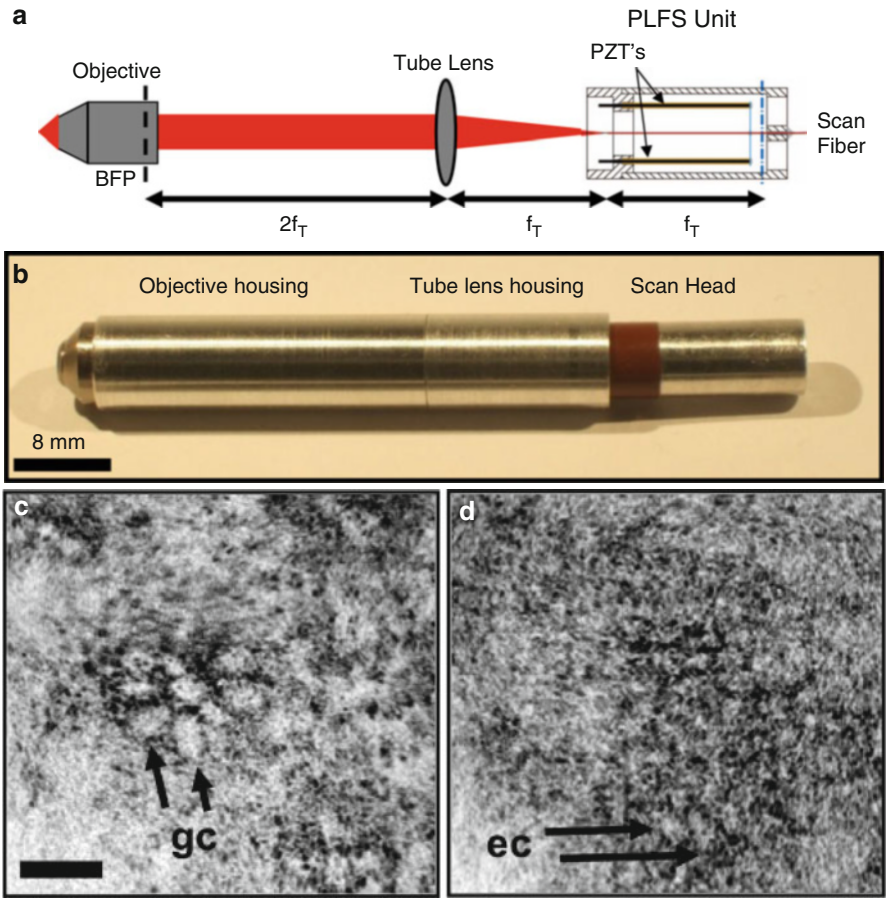

Fig. 28.13 Piezo-electric scanning endoscope for OCM imaging. (**a**) Endoscope design showing a non-resonant piezolever fiber scanner (*PLFS*) incorporated into a forward looking microscope configuration with a miniaturized objective lens. Piezoelectric benders *PZT's*, Tube lens focal length f_T, Back focal plane *BFP*. (**b**) Packaged endoscope design measuring 8 mm in diameter. (**c**, **d**) In vivo cellular images of human skin acquired with the endoscope. Scale bar, 50 um (Figure modified from Aguirre et al. [117])

to actuate in two dimensions over large angles of >8° with only ~50 V applied bias [123, 128]. The mirror and gimbal axes can achieve high resonance frequencies of over 1 kHz for high speed imaging. The mirror was incorporated into a small diameter catheter, as shown in Fig. 28.14b. The device consists of an outer aluminum housing with maximum diameter of ~5 mm. A fiber collimator delivers light to an achromatic objective lens (not visible in the schematic), which focuses the beam. The MEMS scanner is used in a post-objective scanning configuration with the focused beam reflected at 90° out of the device for side-view imaging. Figure 28.14c shows a three-dimensional rendering of hamster cheek pouch

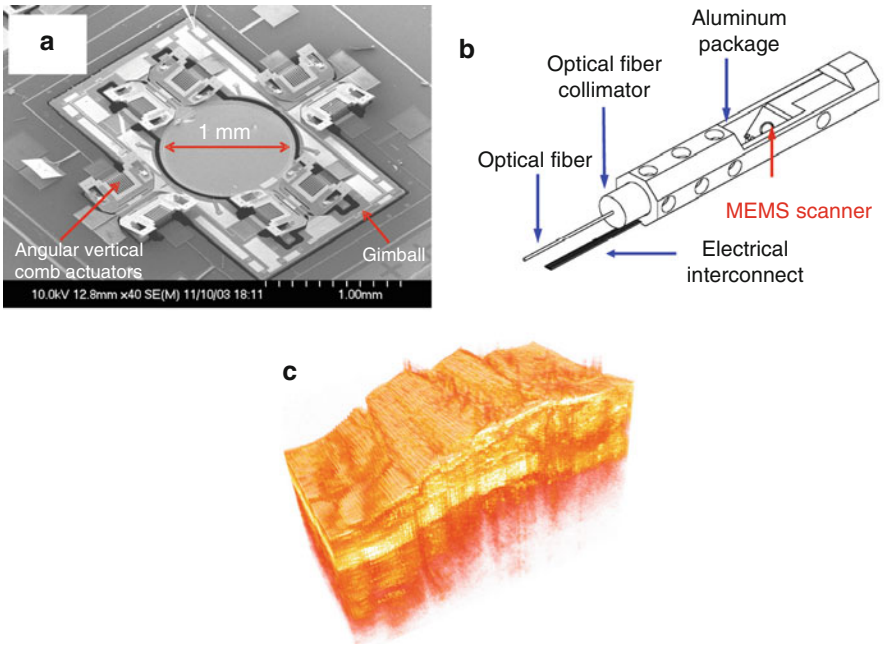

Fig. 28.14 Two-axis MEMS scanning catheter endoscope for three-dimensional and *en face* imaging. A large 1 mm diameter MEMS mirror (**a**) was integrated into a 5 mm diameter catheter package (**b**). Three-dimensional imaging was demonstrated in vitro of the hamster oral mucosa (Figure reproduced from Aguirre et al. [128])

acquired in vitro with the miniaturized catheter. While catheter designs such as this are continuing to advance, other challenges such as focus adjustment and tissue stabilization remain to be addressed. Therefore, in vivo endoscopic confocal and OCM imaging remains a difficult problem.

28.6.4 Controlling the Overlap of Coherence and Confocal Gating

OCM is critically sensitive to the overlap of the confocal and coherence gates determined by matching of the reference and sample arm optical path lengths. Focusing into a sample with a change in index of refraction leads to a reduction in heterodyne amplitude and loss of resolution because the confocal and coherence gates shift relative to each other. Optical path length (OPL) is defined as

$$OPL = nl \tag{28.10}$$

If the reference and sample refractive indices are matched, $n_S = n_R$, the reference arm OPL remains equal to the sample arm OPL as the focus is translated deeper into the sample. This does not hold true when the refractive index of the sample is

different from that of the reference arm. In this case, a physical thickness of δl over which $n_S \neq n_R$ produces an OPL mismatch of

$$\Delta L_{OPL} = (n_S - n_R)\delta l = \Delta n \delta l. \tag{28.11}$$

The index mismatch is particularly important when using dry objectives and can be minimized by the use of water immersion objectives. Given the variations in index of refraction in tissue [129], path length mismatch cannot be insured in general by matching the reference path to the microscope focus outside of tissue. Furthermore, fiber optic imaging probes such as catheters or handheld microscopes are subject to path length shifts between the reference and sample arms produced by stretching and bending of the optical fiber as the probe is positioned for in vivo imaging. The sensitivity to path length changes between the reference and sample arms is exacerbated when the confocal and coherence gates are both very small. Using broadband laser sources to provide ultrahigh coherence axial resolutions, as in Fig. 28.10, allows the confocal gate to be longer than in standard confocal microscopy. This helps to make the gate overlap less sensitive to index variations.

To ensure optimum image quality in highly scattering tissue, some form of overlap alignment between the confocal and coherence gates is desirable. This is most easily done by adjusting the reference arm path length. Schmitt et al. used a focus-tracking scanner with the reference mirror and the sample objective mounted on the same translation scanner [25]. As the objective was translated by a distance Δz toward the sample, the optical pathlength in the reference arm increased by an amount $2\Delta l$. Since focus tracking requires a change of $\Delta l = n^2 \Delta z$ and $n^2 \approx 2$ for biological tissues, this technique provided approximate overlap alignment of the confocal and coherence gates across the depth scan. This approach does not work for fiber optic systems with separate reference and sample paths. Most investigators have instead used manual adjustment of the reference path length with a translation stage. The position of the focus was determined using image intensity as the metric. For in vivo imaging applications, high speed adjustment is required. Aguirre et al. used a galvanometer scanner in the reference path to quickly scan depth and provide a depth profile of image intensity [117]. The focal position could then be determined and the DC offset to the depth scanner adjusted to ensure overlap of confocal and coherence gates. This method is essentially an autofocusing technique, analogous to the autofocus methods used in digital cameras. The ability to rapidly and automatically align overlap for OCM in tissue is important to ensure optimum image quality at different depths.

In the Fourier domain, minor path length mismatch between reference and sample arms can be computationally corrected. Fourier domain OCM images are extracted from a volumetric dataset, with each point in the *en face* image taken from an entire axial depth scan. If the confocal gate and depth of field of the microscope optics are sufficiently long, then the *en face* image can be optimized at each point by finding the point of maximal overlap of the confocal and coherence gates within each axial scan. Such corrections can also be applied to compensate for microscope path length delay scanning and focusing aberrations that limit performance in time domain interferometric microscopes. Graf et al. demonstrated methods for

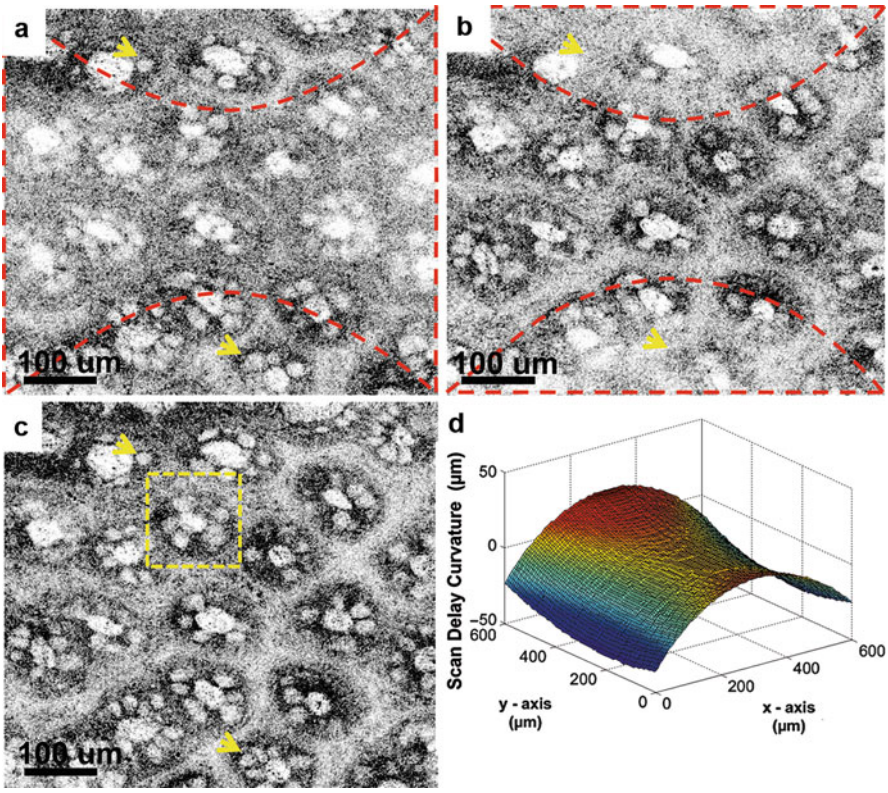

Fig. 28.15 Correction of optical path delay variation with scanning. (**a**, **b**) OCM images acquired at two distinct depths. (**c**) Corrected image after using volumetric Fourier domain OCM data set to optimize the image at every point along the field of view. (**d**) Plot of scan delay curvature measured from a coverslip (Figure reproduced from Ahsen et al. [82])

correction of coherence gate delay curvature from scanning induced path length variations [130]. Lee et al. [131] and Ahsen et al. [82] have also incorporated algorithms for removing scan delay curvature artifacts introduced by the beam scanners to enable *en face* image optimization in tissue. Figure 28.15 demonstrates this concept for correction of scan delay variation introduced by closely spaced galvanometer scanners, as shown in Fig. 28.15b. A calibration method was first used to extract the delay curvature of the scan and then applied to correct the individual axial scans and produce a delay flattened scan.

28.6.5 State of the Art High Speed OCM System Designs

High speed implementations of OCM for cellular imaging have been developed using both time and Fourier domain detection. Aguirre et al. developed an ultrahigh resolution time domain system at 1,060 nm for imaging at 5 Hz frame rate with

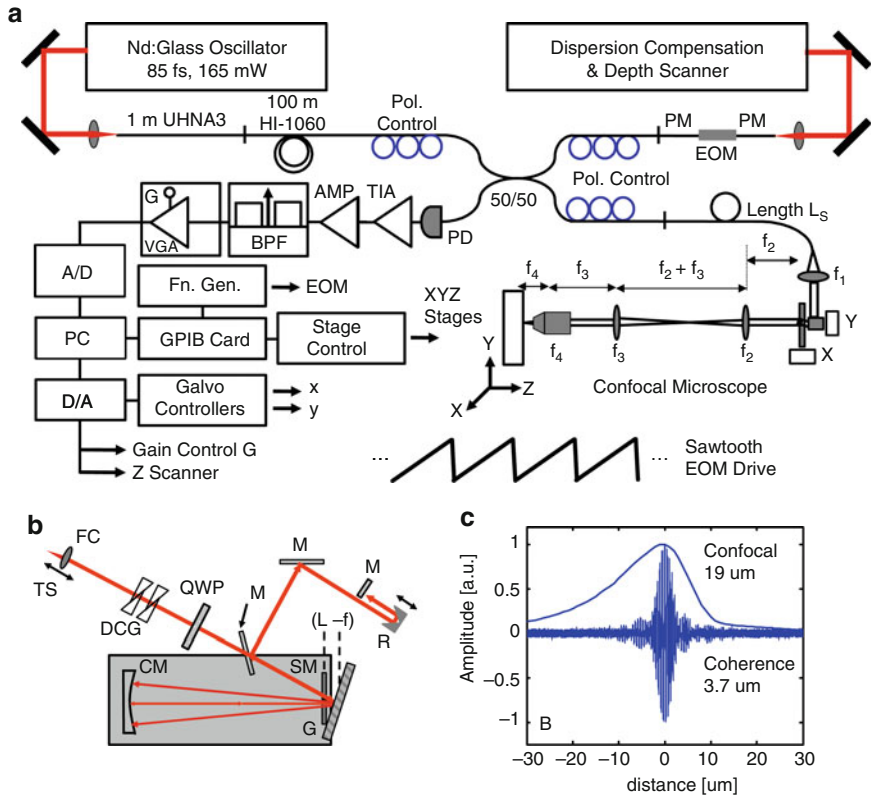

Fig. 28.16 High speed time domain OCM. (**a**) System diagram. The system operates at 1,060 nm center wavelength using a broadband electro-optic waveguide phase modulator. *TIA* transimpedance amplifier, *BPF* bandpass filter, *PD* photodiode, *VGA* variable-gain amplifier, *A/D* analog-to-digital converter, *PC* personal computer, *D/A* digital-to-analog converter, *PM* polarization- maintaining, *EOM* electro-optic modulator. (**b**) Schematic of the reference arm optical delay line used for dispersion compensation and path length scanning. *FC* fiber collimator, *DCG* dispersion compensating glass, *QWP* quarter waveplate, *M* mirror, *R* retroreflector, *CM* curved mirror, *SM* stationary mirror, *G* grating. (**c**) Axial resolution measurements demonstrating a coherence gate of 3.7 um and confocal gate of 19 um (Figure modified from Aguirre et al. [117])

resolutions of <4 um axial and <2 um transverse [117]. This system was demonstrated for in vivo imaging of human skin using a miniaturized endoscopic probe and has been subsequently used extensively for pathology laboratory studies of multiple tissue types [117, 132–135]. Figure 28.16 demonstrates the time domain system design and characterization.

A Nd:Glass femtosecond laser generating 85 fs pulses with >165 mW output power was spectrally broadened by self-phase modulation in a high NA optical fiber to generate >200 nm optical bandwidth centered at 1,060 nm, as shown previously in Fig. 28.10 [83]. A 50/50 fiber optic coupler divided the light between a reference arm and a sample arm, both of which also contained polarization controllers to achieve an

optimized interference point spread function. The reference arm used an electro-optic waveguide phase modulator designed for 1,060 nm center wavelength. After the modulator, reference-arm light passed into a grating optical delay line used for dispersion compensation. The delay line also contained a rapid-depth scanning galvanometer to adjust the coherence gate position. The optical delay line used for dispersion compensation and depth scanning is shown in Fig. 28.16b. The delay line was an all-reflective geometry modified from rapid scanning optical delay (RSOD) line configurations previously used for OCT and OCM [80]. The grating-lens delay was used here only to compensate dispersion, but not to generate group and phase delay, and an additional linear scanning galvanometer was used for depth scanning. In addition, a quarter-wave retarder compensated for wavelength dependent polarization properties of the source. Figure 28.16c demonstrates the measured confocal gate of 19 um and the coherence gate of 3.7 um. A fiber optic confocal microscope with achromatic lenses provided transverse optical resolution of <2 um. This system has been applied for in vivo imaging of human skin, and is readily compatible with endoscopic imaging devices. Figure 28.13 shown previously demonstrates results using this system together with a probe to perform in vivo imaging.

Imaging engines for high speed Fourier domain OCM systems are shown in Fig. 28.17a, b. Lee et al. demonstrated high speed spectral/Fourier domain OCM using a superluminescent diode light source and a fast, low noise charge coupled device (CCD) line scan camera capable of acquiring 210 kHz axial scan rate [131]. The SLD output of $\sim$100 nm bandwidth at 840 nm center wavelength was split between sample and reference arms by a 50/50 coupler and the interfering light was dispersed onto the CCD using a transmission holographic grating. The raw output signal from the CCD was processed using spline interpolation followed by numerical dispersion compensation and fast Fourier transformation (FFT) to reconstruct axial scans. Axial resolution measured 4.2 um and the total axial imaging range was 470 um.

Swept source/Fourier domain OCM was demonstrated by Huang and colleagues using a swept source configuration operating at 42 kHz axial scan rate with image resolution of 1.6 um transverse and 8 um axial [136]. Ahsen et al. extended these results using a high speed VCSEL MEMS tunable laser operating at 1,310 nm capable of 560 kHz axial scan rate, the characteristics of which are shown in Fig. 28.11 [82]. The imaging engine for ultrahigh speed swept source OCM is shown in Fig. 28.17b. An optical clocking method utilizing a Mach-Zehnder interferometer to generate a sampling frequency that drives a high speed data acquisition card allowed sampling of the interference fringes linearly in wavenumber, which eliminates the need for computational resampling and interpolation in post-processing. The system provided axial resolution of 8.1 um in tissue.

The microscopes used in both of the Fourier domain OCM systems (not shown) are inherently similar to the one used in the time domain system inf Fig. 28.16. The Fourier domain systems have an important advantage of allowing dispersion compensation using computational algorithms in post-processing. The lower phase stability and lack of direct access to the measured phase in the time domain makes numerical dispersion compensation much more difficult with time domain systems. As a result, interchange between objective lenses in a time domain system

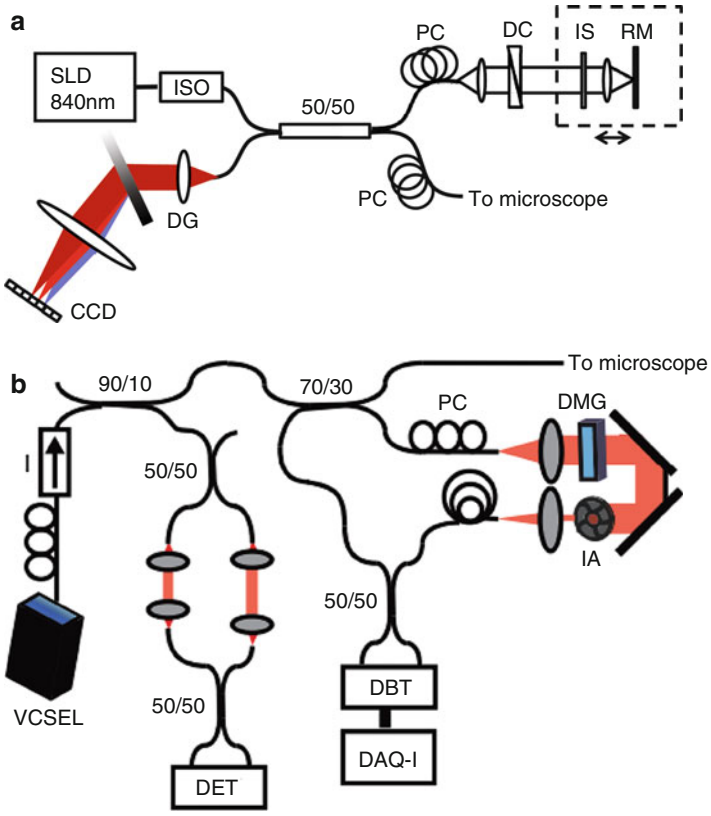

Fig. 28.17 High speed Fourier domain OCM system designs. (**a**) Spectral/Fourier domain OCM system. *PC* polarization controller, *DC* dispersion compensation, *IS* iris, *RM* reference mirror, *GS* galvanometer scanner pair, *OBJ* objectives, *S* sample, *DG* diffraction grating, *CCD* line scan camera, *ISO* isolator. [131] and **b** modified from Ahsen et al. [82])

requires manual adjustment of dispersion compensation in the system optics. With Fourier domain systems, however, seamless interchange between different objective lenses and imaging with variable magnification can be performed with subsequent computational dispersion compensation.

In a current era where Fourier domain OCT has nearly completely replaced time domain approaches for cross-sectional imaging, time domain methods remain relevant for high speed, ultrahigh resolution OCM. As Fourier domain OCM imaging speeds continue to increase, however, spectral and swept source OCM techniques will likely be the methods of choice for most future investigations. The ease of integration with Fourier domain OCT, as well as the ability to seamlessly switch sample arm optics while incorporating numerical dispersion compensation

and optimization algorithms to minimize optical path length variations, all contribute to systems that are both flexible and reliable for clinical use. Spectral domain OCM has the advantage of offering ultrahigh resolution through use of state of the art broadband laser sources. Swept source OCM, on the other hand, has not yet achieved the coherence gated axial resolution realized with time domain and spectral domain systems, but it has tremendous promise for continued improvement in imaging speeds.

28.7 Cellular Imaging Applications of OCM

As mentioned earlier, investigation of OCM imaging applications has generally lagged behind similar studies with OCT and confocal microscopy, in part because of the technical challenges. Early work developing technology has demonstrated imaging of plants [137], developmental biology specimens [80, 138], human skin [80], and human colonic mucosa [59]. Of the human imaging studies, to date, only imaging of human skin has been performed in vivo [117]. However, the promise of minimally invasive imaging at the cellular level in vivo will undoubtedly push these applications forward in the future as endoscopic microscopy imaging probes emerge. One of the most critical areas of investigation is likely to be early cancer detection. Excisional biopsy and histology are the time-tested gold standards for disease assessment at the tissue and cellular levels, and they continue to be the dominant method used for the diagnosis, staging, and management of many neoplasms. Biopsy and histology, however, can be subject to high false negative rates due to sampling errors, and can pose risks to the patient, such as bleeding, which also limit the ability to screen large areas. Optical imaging technology that provides real-time, high-resolution screening of vulnerable areas with resolution at or near that of histopathology could significantly improve clinicians' capabilities to identify malignancies at curable stages. The ability to visualize the histologic hallmarks of cancer at the tissue architectural and cellular levels, including alterations in glandular or stromal morphology, presence of abnormal mitoses and increased nuclear-to-cytoplasm ratio, in situ and in real time, without the need for tissue excision and processing, would be a major advance in cancer diagnostics.

Studies have now been published investigating OCM for imaging human malignant pathologies in multiple tissues, including the oral mucosa [78], gastrointestinal tract [132], thyroid [134], breast [133], and kidney [135]. Aguirre and colleagues developed a portable, high speed time domain OCM system (system diagram shown in Fig. 28.16) and performed ex vivo imaging of specimens in the hospital pathology laboratory. Imaging at the point of care allowed access to fresh tissue and to samples that could not otherwise be removed from the laboratory. Images were acquired in vitro with transverse resolution of <2 um and axial coherence gated resolution of <5 um over a field of view of up to 400 um square. Figures 28.18 and 28.19 present representative images of the gastrointestinal tract [132]. The image in Fig. 28.18a illustrates the characteristic pattern of squamous cells in the esophagus. Corresponding histology is shown in Fig. 28.18b. In the OCM images as well as

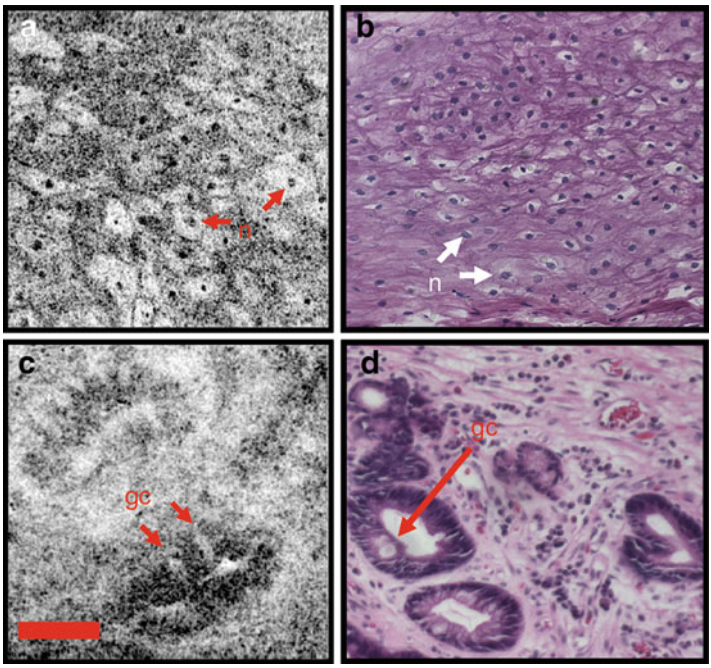

Fig. 28.18 OCM images and histology of normal squamous esophagus and Barrett's esophagus in vitro. Normal squamous mucosa (**a**, **b**) exhibits a characteristic pattern of squamous cells with centrally-located, highly scattering nuclei (*n*). Images of Barrett's epithelium exhibit the presence of intestinalized glands with hallmark barrel-shaped goblet cells (*gc*). Scale bar, 100 um, pertains to all images

histology, cell nuclei can be clearly differentiated from the surrounding cytoplasm and individual membranes which delineate cell boundaries. Figure 28.18c, d show example images of Barrett's esophagus. Barrett's esophagus is a condition in which chronic gastrointestinal reflux leads to a metaplastic change in the esophageal mucosa from the normal squamous architecture to a columnar architecture with similar features to gastric mucosa. The presence of Barrett's metaplasia is a predisposing risk factor for the development of dysplasia and adenocarcinoma of the esophagus. The hallmark histopathologic feature of Barrett's is the presence of barrel-shaped goblet cells. OCM identifies the glandular architecture of the Barrett's mucosa as well as the presence of goblet cells in the columnar epithelium.

Figure 28.19 shows a comparison of OCM images of normal and dysplastic colonic mucosa. The normal colonic mucosa shown in the OCM images and histology of Fig. 28.19a, b, respectively, exhibits a regular pattern of round crypts with numerous goblet cells and nuclei restricted to the basal aspect of the columnar epithelium. In contrast, Fig. 28.19c, d present images and histology from a tubular adenoma with low-grade dysplasia. Glands in the adenoma are larger and exhibit significant eccentricity compared with the small round crypts present in normal

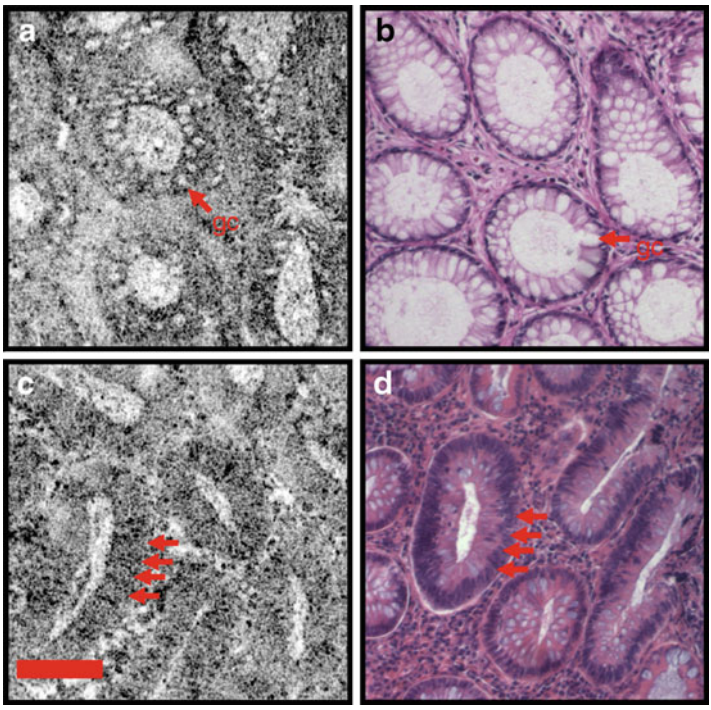

Fig. 28.19 OCM images and histology of normal and dysplastic colon in vitro. Normal colonic mucosa (**a**, **b**) shows the presence of round crypts with goblet cells (*gc*) and basally situated nuclei. Adenomatous dysplastic crypts (**c**, **d**) have increased eccentricity and exhibit characteristic cigar-shaped nuclei (*arrows*) in an epithelium which appears thickened. Scale bar, 100 um

mucosa. In addition, the adenomatous glands show the presence of cigar-shaped nuclei extending beyond the basal third of the columnar epithelium. OCM images correlate well with histology and demonstrate the ability to identify key histologic features of normal and pathologic tissues.

Figure 28.20 shows OCM imaging of malignant conditions of the breast [133]. The figure illustrates distinguishing features between carcinoma in situ and invasive carcinoma visualized with OCM. Lobular carcinoma in situ (LCIS), shown in A, and ductal carcinoma in situ (DCIS), shown in B, appear well circumscribed with a defined contour that is identifiable within the surrounding stroma. Invasive carcinoma, shown in C, destroys the normal stromal architecture with infiltration of tumor cells. The ability to aid in guiding core needle biopsy of breast lesions or in surgical resection margin assessment would be an important advance in the management of breast malignancies.

OCM achieves high resolution in three-dimensions for visualization of cellular and subcellular morphology. However, due to the high magnification of the objective lens, the field of view in OCM is generally restricted to the range of 500 um. From a clinical perspective, OCM is essentially a point-sampling technique and will

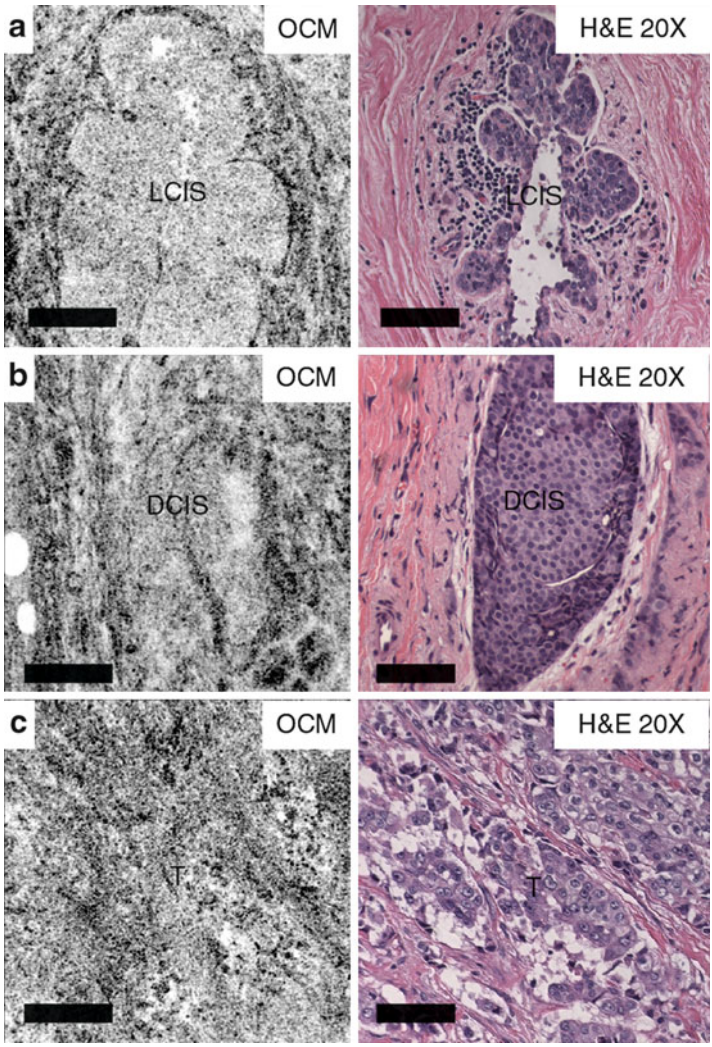

Fig. 28.20 OCM images and histology of neoplastic breast tissue in vitro. (**a**) Lobular carcinoma in situ, LCIS, and (**b**) ductal carcinoma in situ, DCIS, appear well circumscribed with a defined contour that is identifiable within the surrounding stroma. Invasive carcinoma (**c**) destroys the normal stromal architecture with infiltration of tumor cells, T Scale bars, 100 um (Images reproduced from Zhou et al. [133])

therefore suffer from sampling error in screening and diagnostic applications. One solution to this limitation involves the combination of OCM with conventional OCT imaging. Figure 28.21 presents an example data set to illustrate this point. The data was acquired with a combined OCT and OCM microscope with an adjustable objective lens magnification [117]. The microscope allowed precise registration of *en face* OCM images to OCT cross sectional image data. Figure 28.21a shows an

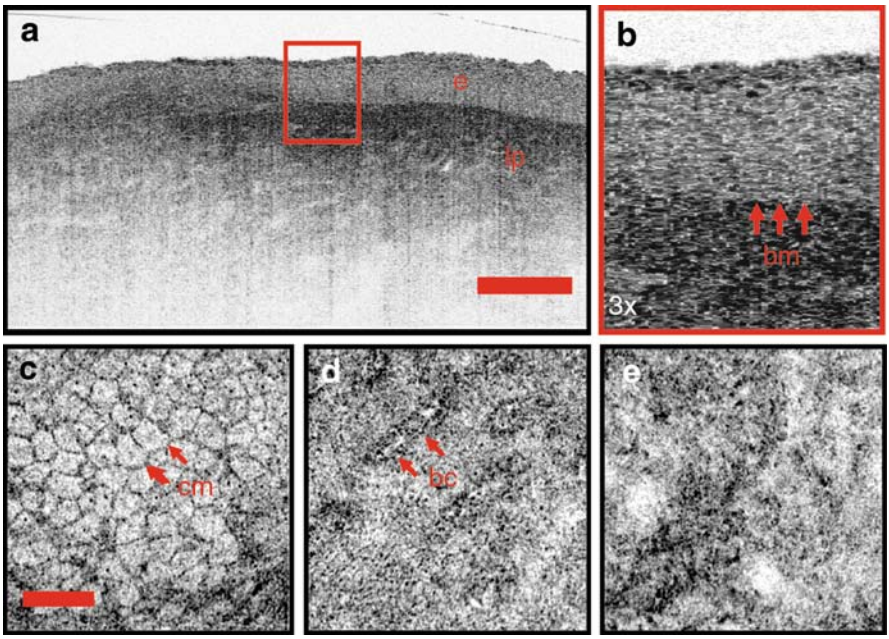

Fig. 28.21 Co-registered OCT and OCM imaging of normal cervix. Ultrahigh resolution OCT (**a**, **b**) clearly identifies the layers of the cervical mucosa and delineates the basement membrane (*bm*) separating the epithelium from the underlying lamina propria. OCM images at progressive depths identify cell membranes (*cm*) in the upper epithelium (**c**) as well as the rim of basal cells (*bc*) surrounding the ridges of lamina propria (**d**). OCM can image deep into the lamina propria, shown here by an image of the loose connective tissue at 400 um depth (**e**). Scale bars, (**a**) 500 um, (**c**) 100 um (Figure modified from Aguirre et al. [117])

ultrahigh resolution OCT image of squamous mucosa of the cervix. Transverse resolution was measured to be ~12 um with axial resolution of <3 um, and the field of view was 3 mm in length. OCT provides cross-sectional visualization of the epithelial layer thickness, with clear delineation of the basement membrane and underlying lamina propria. The lamina propria appears highly scattering compared with the stratified squamous epithelium. As shown by the 3× zoom view in Fig. 28.21b, OCT cannot clearly delineate cellular structure due to its limited transverse resolution. *En face* OCM images of the same region delineated by this zoom view allows cellular resolution with <2 um resolution over a restricted field of view. Figure 28.21c, d, e were obtained at imaging depths of 60 um, 150 um, and 400 um below the surface, respectively. The regular pattern of squamous cells is evident in Fig. 28.21c, while Fig. 28.21d shows the ridges of lamina propria projecting through the lower epithelial layers. A highly scattering rim of basal cells can be seen surrounding the islands of lamina propria. Figure 28.21e shows the disorganized loose connective tissue deep below the tissue surface.

The concept of imaging over multiple fields of view to allow visualization of tissue architecture at varying resolutions is a promising approach in clinical

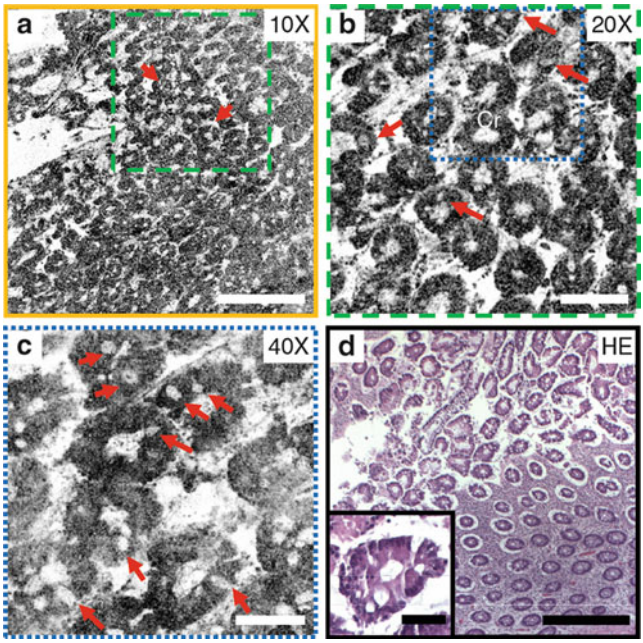

Fig. 28.22 Multi-scale OCM images of human colon, ex vivo. Coregistered images are acquired with (**a**) 10×, (**b**) 20×, and (**c**) 40× objectives. (**d**) Corresponding H&E histology image showing normal crypts in human colon. Scale bars: 10×: 500 um; 20×: 200 um; 40×: 100 um; HE: 500 um; Inlet: 50 um. Crypts, Cr. Goblet cells, *red arrows* (Images reproduced from Lee et al. [131])

applications such as endoscopic surveillance for dysplasia or resection of tumor margins. In these scenarios a clinically useful imaging solution should provide both high resolution to enable visualization of important architectural and cellular features as well as broad area coverage to avoid sampling error and excessive false negative rates. With high imaging speeds that are now available using OCT with Fourier domain detection techniques, it is becoming possible to survey large areas of tissue in vivo, which allows the user to identify areas of interest for closer inspection [139, 140]. OCM could then be used to look directly at cellular and glandular features in these focal regions. This mode of operation would be similar to the approach used by pathologists when viewing conventional histopathology slides. A lower magnification is first used to gain an appreciation for the overall tissue architecture including layers and glandular organization. Then a high magnification is used to investigate cellular features. Both views provide important information used for making a diagnosis. OCT and OCM can function as complementary imaging methods in an analogous way. OCT can survey large areas of tissue architectural morphology in a cross-sectional view, while OCM can provide high, cellular level resolution in an *en face* view.

Figure 28.22 shows a series of co-registered OCM images of human colon taken with varying magnifications using a spectral/Fourier domain OCM system to illustrate

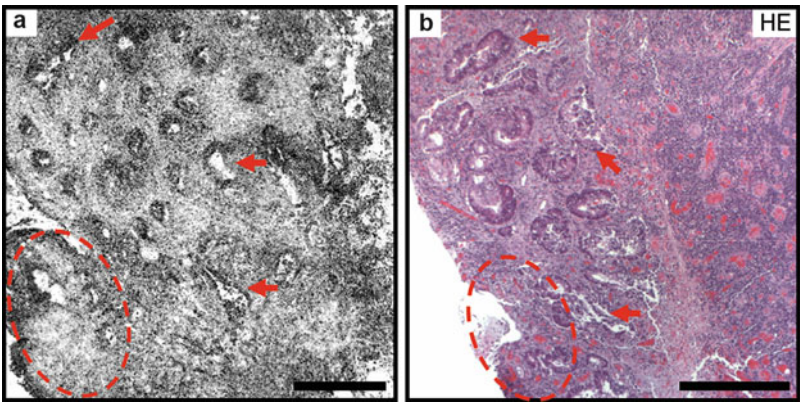

Fig. 28.23 Mosaicked OCM image of the human colon specimen with ulcerative colitis. (**a**) Nine individual 900 × 900 um images taken with a 20× objective are combined to create a mosaicked image with enhanced field of view of 2.1 × 2.1 mm^2. (**b**) Corresponding H&E histology image. Scale bars, 500 um. Crypts, *red arrows* (Images reproduced from Lee et al. [131])

this point [131], At lower magnification (10×) the organization of crypt structure can be appreciated, while use of higher magnification (20× and 40×) allows analysis of cellular features, including individual goblet cells. Miniaturized OCM imaging probes using zoom lens technology may in the future allow users to seamlessly change magnification and to flip between cross-sectional and *en face* views as needed to analyze tissue morphology in vivo during endoscopic or surgical procedures.

The field of view can also be extended in OCM utilizing mosaicking techniques, as has been done in confocal microscopy [141]. Figure 28.23 presents an example of mosaicking using OCM. Nine individual en face OCM images, each with 900 × 900 um field of view and acquired with a 20× objective lens, were assembled with an overlap ratio of 33 % to generate the mosaicked OCM image over a large imaging area (2.1 × 2.1 mm^2) [131]. Comparative histology is also shown. Compared to wide field acquisition of images at lower magnification, mosaicking approaches require longer acquisition time but can offer composite high definition images with both very high resolution and large field of view.

28.8 Summary and Future Prospects

This chapter has reviewed several important developments in optical coherence microscopy during the past 20–25 years. Techniques are progressing rapidly and new system designs and technology are becoming available for high-speed imaging. Miniaturized two-axis scanning devices are also being developed for endoscopic and laparoscopic applications. In addition, ex vivo tissue imaging studies are establishing the validity of OCM imaging in various organ systems. OCM undoubtedly represents an important advance in OCT imaging generally, but its ultimate clinical utility remains to be determined. OCM has several important advantages compared with confocal

microscopy, but the imaging technology is generally more complex. However, the development of high speed Fourier domain detection techniques is an important advance because it will enable OCM to be integrated with existing confocal scanning microscopes. The ability of OCM to provide variable magnifications and fields of view in microscopy, image tissue without the need for exogenous contrast, and integrate with endoscopic imaging devices, promises to provide powerful new approaches to make real-time, in situ, cellular-resolution optical biopsy a clinical reality.

OCM with Engineered Wavefront

29

Rainer A. Leitgeb, Theo Lasser, and Martin Villiger

29.1 Introduction

The promise of optical coherence microscopy (OCM) is to combine the high sensitivity and imaging speed of optical coherence tomography with the high spatial resolution of confocal microscopy, thereby providing cellular and subcellular resolution compatible with in vivo measurements. Thanks to the coherent amplification, OCT approaches the shot-noise limit. The resulting outstanding sensitivity is needed for imaging thick scattering tissues, such as skin, at depths up to 2 mm, and providing high acquisition speeds necessary for imaging large fields of view. This substantiated the hope to develop a diagnostic tool to perform optical biopsy, by measuring tissue in situ and in vivo and thereby overcoming the randomness and invasiveness of conventional tissue biopsies and histopathology [1]. To meet this goal it is important to significantly enhance resolution power, as many pathological features indicative of disease manifest on a subcellular scale. An isotropic resolution of approximately 1 μm would be highly desirable; ideally without compromising the acquisition speed, the sensitivity, or the imaging depth.

Much of the success of OCT resides on the decoupling of the lateral resolution from the axial resolution: the first is given by the numerical aperture (NA) of the

detection optics, whereas axial resolution is only defined by the spectral properties of the employed light source. Using the coherence gate rather than the confocal gate for depth sectioning proved extremely advantageous, as it replaced complex sample optics with sophisticated light sources. The central theorem is the Wiener-Khintchin theorem that states that the temporal coherence function can be expressed as Fourier transform of the spectral power density. As a consequence, axial resolution given by the width of the envelope of the temporal coherence function $\delta z = \Delta\tau c$ and spectral bandwidth $\Delta\lambda$ are inversely proportional: $\delta z \propto \lambda_c^2/\Delta\lambda$, with λ_c the central wavelength of the light source. Higher axial resolution requires light sources with larger bandwidths or shorter central wavelengths. Early efforts to increase resolution in OCT have focused on the axial direction, spurred by continuous advancements in light source technology. First implementations of ultrahigh-resolution OCT have been presented already in the framework of time domain OCT (TDOCT), employing femtosecond Ti:Sapphire lasers [2]. The main challenge was the dispersion management in order to avoid loss of axial resolution due to chromatically unbalanced optical path lengths between the interferometer arms. Besides spatially coherent laser sources, thermal sources exhibit very large bandwidths and have the additional advantage of being low cost. Due to their limited spatial coherence, they are incompatible with traditional, scanned focus OCT, but provide the ideal light source for full-field OCT. They offer excellent axial resolution, and the low spatial coherence acts as confocal gate, providing high lateral resolution and little cross talk. Up to now, some of the most impressive high-resolution OCM images have been demonstrated with this kind of full-field OCT [3]. On the other hand, ultrabroad bandwidth sources based on nonlinear spectral broadening in photonic crystal fibers offer not only high power spectral densities but also interesting wavelength bands outside the usual therapeutic window at 800 nm, both in the visible as well as at longer wavelength range around 1,300 nm [4, 5]. Their drawback, so far, is high spectrally dependent random intensity noise due to the nature of the light generation itself.

Improving the lateral resolution proved more challenging. For a conventionally focused beam, the lateral resolution and the confocal gate are directly linked. Whereas the lateral resolution scales linearly with 1/NA, the confocal gate scales quadratically with $1/NA^2$. For an improved lateral resolution, the confocal gate ultimately limits the available imaging range, or depth of field (DOF), for OCT imaging. Different strategies have been adapted to overcome the restrictions imposed on the DOF for OCM. In TDOCT one can apply dynamic focusing, a method that coordinates the reference arm scanning with scanning the focus position such that the confocal and the coherence gate always coincide [6]. This method is very powerful in combination with en face OCT. For en face OCT the scanning priority is in the transverse plane, whereas the axial direction is scanned slowly [7, 8]. The first en face OCM system, introducing the OCM terminology, has been demonstrated already in 1994 [9]. The coherence gate significantly enhances the imaging depth of conventional confocal microscopy, whereas the confocal gate suppresses multiply scattered out of focus light. Hence their combination seems to be ideal for revealing subsurface cellular details [10]. Dynamic focusing cannot directly be applied, however, in case of FDOCT. It is nevertheless possible to use

a C-mode technique by recording several tomograms focused at different depths and merge the in focus regions in post-processing [11]. A similar solution using axially displaced multifoci has been successfully integrated into a commercial system. Other strategies involve signal processing techniques for digitally refocusing the scattered field distribution, measured by the complex-valued OCT signal, to recover an extended DOF [13–15].

An alternative strategy is to specifically engineer an illumination and a detection beam that directly provide an extended DOF. Diffraction obviously embodies the limiting factor, but it is possible to significantly improve upon the situation with a conventional Gaussian-like focal volume. In principle, the illumination and detection beam can be independently tailored by defining appropriate wavefronts in the illumination and detection paths, respectively. An interesting example is to impose a conical wavefront onto a collimated Gaussian beam, which results in a Bessel-like beam [16]. Bessel-like beams have the extraordinary property of propagating over significant lengths without apparent diffraction. Airy beams are another example of such diffraction-less beams that have attracted a lot of attention and are currently extensively investigated. A Bessel-like beam consists of a central lobe, surrounded by a large number of concentric side lobes. The apparent defeat of the laws of diffraction can be understood by considering that all side lobes roughly carry the same amount of energy as the central lobe. Indeed, although the central lobe stands out in intensity, the energy is distributed over a relatively large area.

Ding et al. were the first to replace the conventional objective lens in front of the sample with an axicon lens [17], illuminating the sample with a Bessel pattern and defining an identical detection mode. Although the large optical bandwidth used in OCT can help to reduce the side lobes if refractive axicons are used, the resulting tomograms featured many such side lobes and suffered from the sensitivity critical double pass through the axicon. The coupling of light from a single scattering site into the detection fiber through the axicon is inherently inefficient and can readily induce a signal penalty of 20 dB. On the illumination side, the spread of the energy over the various side lobes can be partly compensated by increasing the source power.

Using identical paths for illumination and detection is very attractive, because it reduces system complexity and can be implemented into an endoscope. Fiber probes using micro-axicon lenses, or conically etched fiber tips, have been demonstrated [18, 19] but suffer from similar limitations. The helical scanning usually performed with endoscopes is well suited for such fiber probes. Using a conical sample lens in a bench-top configuration is more limiting, however, as it precludes normal beam scanning.

This can be helped with an additional relay system with integrated scanning mirrors. The axicon-type illumination results in an annular illumination in the back aperture of the sample lens. This offers an alternative view: A similar Bessel-like illumination pattern could be defined with a simple annular intensity mask, suffering from very little throughput. Using a pure phase mask, instead, illuminated with a collimated Gaussian beam, would provide far better transmission. Most flexibility for such a wavefront shaping is offered by Spatial Light Modulators (SLM). They are limited by the finite pixel width and cross talk between the elements. This drawback

is, however, outweighed by the attractive possibility to dynamically adapt the wavefront, e.g., compensating for additional sample-induced aberrations and achieve better imaging penetration. A simpler approach to shape the wavefront involves tailored phase masks. There exists already a multitude of designs for binary phase masks with different advantages for resolution and contrast. Probably, their most important advantage for biomedical imaging is the cheap and small footprint [20].

Systems with symmetric illumination and detection wavefronts offer interesting performance for both intensity [21] and phase masks [22] if only a moderate gain of DOF is attempted. For more significant extended DOFs, however, we found that decoupling the illumination and detection paths offers more flexibility and results in better performance [12]. Using an axicon for creating an annular illumination pattern in the back aperture of the sample objective provides an efficient way of illuminating the sample over an extended axial range. Decoupling the detection path avoids the critical double pass through the axicon. Defining instead a Gaussian detection mode with a lower NA provides an interesting compromise between axial imaging range, lateral resolution, and sensitivity. Importantly, the decoupled scheme allows for efficient scanning of the Bessel and the detection beam across the sample using appropriate relay optics and a 2D scanner with a single pivot point. Rapid scanning is indispensable for most in vivo applications to overcome respiratory and other movement artifacts. This extended focus scheme fully benefits from the parallel signal acquisition along depth characteristic of FDOCT without the time-consuming need to readjust the focus position.

Besides the benefits of an extended DOF, the combination of Bessel illumination with Gaussian detection also provides a very advantageous dark field effect. The imaging system is more sensitive to light scattered from small structures and suppresses specular reflections. This results in excellent contrast from many biological structures and enables the suppression of strong reflections that often limit the dynamic range. The Bessel beam further profits from a self-regeneration property that helps to look behind light shading obstacles. Extended focus configurations have been implemented for OCM at 800 nm central wavelength, but were also successfully applied at 1,300 nm for skin imaging.

The present chapter aims at providing an in-depth understanding of extended focus schemes and demonstrates interesting applications of Bessel-shaped illumination beams for optical coherence microscopy and tomography. As already alluded to, decoupled extended focus schemes feature specific characteristics that have particular advantages for imaging of biological tissue with Fourier domain OCM and OCT. We first introduce a theoretical framework to describe the OCM signal and understand the mechanism of the limited DOF using the formalism of the coherent transfer function (CTF). Implications on resolution, contrast, and sensitivity for specific realizations of the CTF are then discussed. In the subsequent section we demonstrate examples for high-resolution biomedical imaging with extended focus OCM and OCT. A unique feature of OCT and OCM as interferometric techniques is the availability of phase information. This enables important functional extensions such as the quantitative assessment of blood flow and

depth-resolved imaging of tissue microvasculature free of any contrast agent. Moreover, recent developments for contrast-enhanced OCM show great potential for adding structural and molecular specific contrast that is of paramount importance in biomedical imaging. The chapter concludes with a short outlook on future developments, in particular for contrast enhancement techniques, and applications of extended focus imaging as well as wavefront engineered OCM.

29.2 Theoretical Framework

Here we present a theoretical framework for image formation in OCT that encompasses both the coherence and the confocal gate. This framework enables to investigate the detrimental effect of the confocal gate on OCT and provides a toolset to devise possible remedies. This section follows closely the work [23].

Most imaging methods can be cast in a linear, shift invariant formalism, in which the final image is expressed as the convolution of the original object with the system response function, i.e., the point spread function (PSF). Whereas this view can be adopted for OCT in the case of low NA [24], the shift invariance in the axial direction is lost for a higher NA. Instead of reasoning in the spatial domain, looking at image formation in the spatial frequency domain provided interesting insights, both for OCT in general and the problem of extended depth of field in particular.

The object that is imaged can be described in terms of its susceptibility $\chi(\mathbf{r}) = \mathrm{n}(\mathbf{r})^2 - \mathrm{n}_0{}^2$. $\mathrm{n}(\mathbf{r})$ is the refractive index of the sample as function of the spatial coordinate $\mathbf{r}$, and n_0 is the average refractive index. Bold type indicates a vector quantity. Seeking an expression within the limits of the first-order Born approximation, both the incident and the scattered light propagate as if in a homogenous background with index n_0. Taking the inverse Fourier transform of this sample function, expressed in lateral coordinates $\boldsymbol{\rho} = [x, y]$ and z, and their corresponding spatial frequencies $\mathbf{q} = [q_\mathrm{x}, q_\mathrm{y}]$ and s, the OCT signal can be expressed as

$$\tilde{P}(\mathbf{q},k) \approx \underbrace{kA(k)}_{\text{source spectrum}} \int_s \underbrace{\mathrm{CTF}(\mathbf{q},s,k)}_{\text{filter function}} \underbrace{\tilde{\tilde{\boldsymbol{\chi}}}(\mathbf{q},s)}_{\text{object spectrum}} ds. \tag{29.1}$$

$\tilde{P}(\mathbf{q}, k)$ is one of the two complex conjugate terms of the interference signal, recorded as a function of wavenumber k in spectrometer-based or swept-source OCT, and lateral spatial frequency $\mathbf{q}$. $\mathbf{q}$ is obtained by inverse Fourier transformation of the signal along the lateral scanning position $\boldsymbol{\rho}$. The two tildes indicate the Fourier transformation along the lateral and the axial spatial coordinates. CTF($\mathbf{q}$, s, k) is the coherent transfer function of wavenumber k, depending on all spatial frequencies [25]. A(k) is the power spectral density of the light source, which is weighted by the wavenumber k, a remnant of the k^2 factor in the commonly used scattering potential $k^2\chi(\mathbf{r})$. The origin of the z coordinate is placed in the focal plane of the imaging optics, and the reference arm length is assumed matched to this position. An additional linear phase term would otherwise have to be added. The same formalism

obviously also holds for time domain OCT, except that $\tilde{P}(\mathbf{q}, k)$ does not directly correspond to any measured signal. Also, experimental limitations such as instantaneous coherence length, spectrometer resolution, or wavenumber linearization are ignored.

The CTF is defined through the illumination and the detection optics. Indeed, both parts play an equal role in OCT. The illumination optics defines the focal volume that scans over the sample. Part of this illumination light is scattered back by the sample susceptibility and then finally filtered by the detection optics that rejects any contribution that does not match the detection mode. The concept of the generalized aperture is convenient to express the illumination and detection modes, as it also holds for higher NA, and could be extended to vector notation [26]. The generalized aperture describes the electromagnetic field in the focal volume as the three-dimensional Fourier transformation of its plane wave decomposition. These components lie, by definition, on a spherical shell of radius k, and their angular distribution corresponds, within the limits of the Debye approximation, to the field distribution in the spherical output principle plane of the imaging objective with a radius corresponding to the focal length of this lens. And the radial distribution in this principle output plane corresponds, in turn, to the distribution in the flat input principle plane.

In spatial coordinates, the signal recorded for each wavenumber corresponds to the convolution in the lateral direction of the product of the illumination and the detection mode with the sample susceptibility, weighted by the power spectral density. No scanning in the axial direction is performed. The corresponding situation in the spatial frequency domain is the product of the sample spatial frequency spectrum (SSFS) with the convolution along all spatial frequencies of the illumination and detection modes, i.e., their generalized apertures, which defines the CTF. To take account of the absence of axial scanning, the integral along the axial spatial frequency s is taken to find expression (29.1). The integral along s is equivalent to a Fourier transformation back to the spatial domain, evaluated only at the position $z = 0$.

Hence, the CTF is defined as the convolution of the two spherical shells, m_{ill} and m_{det}, as represented in Fig. 29.1a:

$$\mathrm{CTF}(\mathbf{q}, s, k) = 1/2 \iint_{\mathbf{q}', s'} m_{\mathrm{ill}}(\mathbf{q}', s', k) m_{\mathrm{det}}(\mathbf{q} - \mathbf{q}', s - s', k) d\mathbf{q}' ds'. \tag{29.2}$$

The field distribution on the shells is entirely defined by the illumination and detection modes at the principle input plane of the sample objective. Panel (b) of Fig. 29.1 displays the resulting CTFs for three wavenumbers for a system with Gaussian illumination and detection modes, whose waists fill 70% of the aperture of the sample objective with NA = 0.5. Due to geometry, the CTF has an outer rim defined by a sphere of radius $2k$. For the Gaussian CTF, the transmission values are highest at this rim and then decay for smaller s. A change in wavenumber has the effect of scaling the CTF around the origin of the spatial frequencies with a scaling factor $2k$. Due to the limited bandwidth of the light sources used, usually limited to less than one

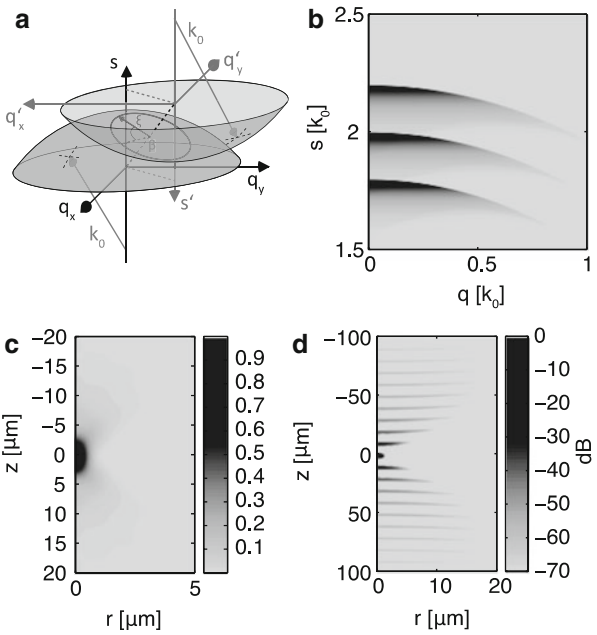

Fig. 29.1 (**a**) The convolution of the illumination and detection generalized apertures defines the CTF. (**b**) The CTF scales about the origin with the wavenumber. (**c**) The 3D FT of the CTF at a given wavenumber defines the corresponding focal volume. (**d**) Simulated tomogram of individual point-like scatterers aligned along the axial direction at 10 um intervals for a Gaussian illumination mode with an NA of 0.5

fifth of the central wavenumber, it is possible to ignore this scaling effect and simply assume that the CTF at a given wavenumber is a shifted copy of the CTF at the central wavenumber $\mathrm{CTF}(\mathbf{q}, s, k) \approx \mathrm{CTF}(\mathbf{q}, s, k_c) \bigotimes \boldsymbol{\delta}(s - 2(k - k_c))$. As usual, to reconstruct the tomogram, the inverse Fourier transformation from k to z is computed:

$$T(\mathbf{q}, z) \approx \int_k \tilde{P}(\mathbf{q}, k) \mathrm{e}^{i2kz} dk = \int_k kA(k) \mathrm{e}^{i2kz} \int_s \mathrm{CTF}(\mathbf{q}, s - 2(k - k_c), k_c) \widetilde{\widetilde{\boldsymbol{\chi}}}(\mathbf{q}, s) ds\, dk. \tag{29.3}$$

In this view, the tomogram can be pictured as the Fourier transform of the SSFS convolved with the central wavenumber CTF along s and weighted with the power spectral density of the employed light source. Panel (c) of Fig. 29.1 displays the focal volume corresponding to the central wavenumber's CTF. And panel (d) represents the tomogram of point-like scatterers, aligned along the axial direction at 10 μm intervals. This clearly illustrates the limited depth of field for a CTF with such a high NA. Only a single in focus scatterer appears clearly resolved. The signal of the out of focus scatterers drops rapidly in intensity and is blurred in the lateral direction. Although the coherence gating still works and clearly locates the signal at a single depth, this depth changes with the lateral scanning position.

Having revealed how the CTF impacts the final tomogram, it is possible to devise an ideal CTF: It should be separable along $\mathbf{q}$ and s, approach a Dirac function along the axial spatial frequency, and feature a smooth envelope along the lateral spatial frequencies. Along the axial spatial frequency, the CTF acts as the sampling

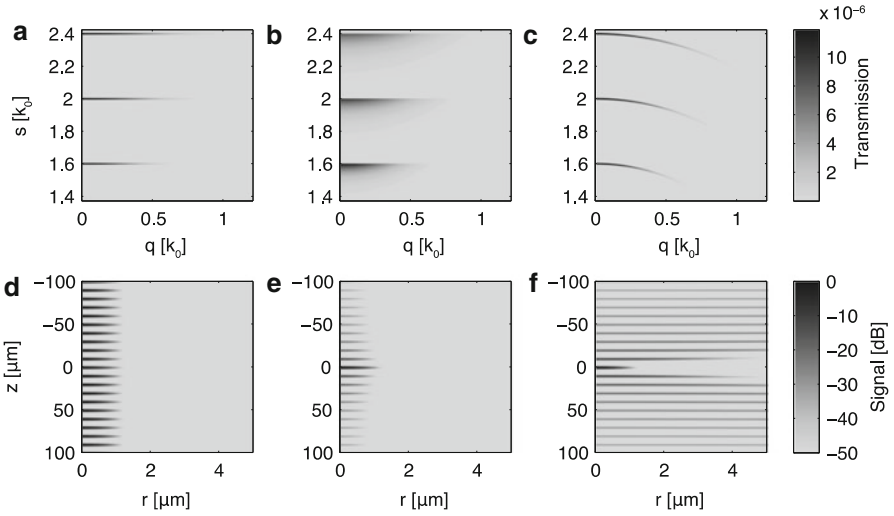

Fig. 29.2 (**a**) Hypothetical ideal CTF with very narrow support along s and no curvature. (**b**) Hypothetical CTF without curvature but finite support along s. (**c**) Hypothetical CTF with narrow support, but curvature. (**d**–**f**) Simulated tomograms of point-like scatterers resulting from the CTFs in (**a**–**c**)

function of the Fourier domain detection, mapping an axial spatial frequency to a specific wavenumber. The range of this mapping is imposed by the spectral bandwidth and defines the resulting axial resolution. In the lateral direction, the envelope of the CTF simply apodizes the higher lateral spatial frequencies, defining the lateral resolution.

This hypothetical situation of this idealized CTF is depicted in Fig. 29.2a, d and results in the expected ideal tomogram. A real CTF usually differs in two ways from this ideal CTF: Its width along *s* and the separability of the CTF along **q** and s. Most CTFs exhibit a curved shape, making the position of the window along *s* dependent on **q**. Figure 29.2b, e demonstrate the effect of a hypothetical CTF that still consists of two separable windows along **q** and *s*, but with an increased window width along *s*. Although the signal of the out of focus scatterers does not experience any blurring, their signal intensity drops rapidly with increasing out of focus distance. On the other hand, panels (c) and (f) show the effect of a very narrow window along *s*, but with a spherical curvature along **q**. In this case, defocused scatterers become extremely blurred. The integrated intensity over the blurs of the scatterers does not decrease with out of focus distance; it is simply spread over a larger area. The on axis signal, however, decreases at the same rate as in case of the previous CTF of Fig. 29.2b.

The defocusing mechanism can be understood by recognizing that the axial position of the scatterer location translates to a phase slope in the spatial frequency domain, for all but the in focus signals. Although the SSFS amplitude of a small scattering component can be assumed nearly constant over the spatial frequency range covered by the CTF, the curved shape of the CTF results in a sampling of

nonconstant axial spatial frequencies, and hence a spherical phase term, responsible for the observed blurring. ISAM [27] attempts to numerically compensate for this second effect by resampling the recorded signal in the spatial frequency domain.

If, instead of imaging individual scatterers, a tissue-like sample with many scatterers, spaced on a subresolution scale, were measured, a speckle pattern would result. In this case, the CTF of Fig. 29.2b would still result in a similar intensity decay as already observed for the single scatterers. The CTF of Fig. 29.2c, however, would result in constant signal intensity along depth. Although the resolution is lost, the signal energy is not. As is well known, speckle is resistant to defocusing.

This suggests the definition of two independent measures for the DOF: the first related to the width of the CTF along s, limiting the signal energy of out of focus structure, and the second related to the curvature of the CTF, resulting in a blurring of out of focus structure.

The CTFs depicted in Fig. 29.2 are hypothetical and cannot be engineered in practice. Certainly, a very low NA system approaches the ideal CTF, but limits the achievable lateral resolution. Striving for higher NA, the definition of the CTF as the convolution of the illumination and detection aperture severely constrains the solution space of realizable CTFs. With identical Gaussian-like illumination and detection modes, the curvature and the s-width of the CTF are directly linked and provide an identical definition of DOF. Using decoupled illumination and detection apertures provides more flexibility in engineering of a CTF, and the two criteria for the DOF will in general differ. Besides the two DOF criteria, it is also important to consider the third criterion of an ideal CTF: its lateral envelope, which should be wide and smooth to provide high lateral resolution without imaging artifacts.

29.3 Contrast and Contrast Enhancement

Imaging a scattering, semitransparent, three-dimensional object with a low coherent imaging system such as OCT and OCM is best described in terms of spatial frequencies and the concept of the CTF (see preceding section). Ignoring for the current discussion the limitations imposed on the depth of field and restricting the reasoning to the in focus region, Eq. 29.1 can be further simplified to

$$\tilde{P}(\mathbf{q},k) \approx kA(k)\mathrm{sCTF}(\mathbf{q})\tilde{\tilde{\boldsymbol{\chi}}}(\mathbf{q},s=2k), \tag{29.4}$$

where sCTF is in principle the envelope of the CTF along $\mathbf{q}$ or more precisely its projection along s:

$$\mathrm{sCTF}(\mathbf{q}) = \int \mathrm{CTF}(\mathbf{q},s,k)ds. \tag{29.5}$$

In this case, OCM imaging reduces to a linear, shift-invariant system and can be described in Fourier space as a filtering process. In the spatial frequency domain,

the sample or object spectrum is directly related to the image spectrum, simply weighted by this filter function.

Defined by the NA of the sample lens, the sCTF has an upper cutoff q_{cutoff}. The inverse Fourier transform of the sCTF defines the lateral PSF, and depending on the precise shape of the sCTF, the exact width of the PSF can vary.

In the axial direction, the resolution is entirely defined by the coherence length, i.e., the spectral span of the light source in the spatial frequency space. Along the axial direction, an OCM system always acts as a band-pass system, transmitting only the axial spatial frequencies in the band accessible by the light source, stretching from $s = 2k_{min}$ to $s = 2k_{max}$, where k_{min} and k_{max} are the minimum and maximum wavenumbers of the light source. Only object structure with axial spatial frequencies in that range can be imaged by OCM.

Besides spatial resolution, high contrast is of paramount importance for the visual impression of a tomogram. In terms of pure spatial frequencies, the contrast can be directly defined as the visibility of the image of a pure spatial frequency, i.e., a sinusoidal variation of the square of the refractive index along a defined direction, which is entirely defined through Eq. 29.4 by $kA(k)$ and sCTF($\mathbf{q}$).

More relevant in an experimental image is the contrast between various structures within the tissue. Figure 29.3a shows a schematic object spectrum, indicating different spatial frequency bands. The low frequency band is dominated by specular reflection (s-band). This contribution is caused by surface reflections, glass slides supporting cell samples, or other well-defined interfaces perpendicular to the optical axis. Such interfaces have a very broad axial spatial frequency spectrum (along s) mainly determined by the coherence length, but very low lateral spatial frequencies ($\mathbf{q}$).

The adjacent frequency band (tissue band) contains the macroscopic features of tissue morphology. The higher frequency (cell band) contains information of the subcellular structures. Figure 29.3b shows the sCTF of the instrumental counterpart. The diagram indicates several cases: First, the sCTF of a low NA imaging system, with a low cutoff frequency $q^{(1)}_{cutoff}$, i.e., a moderate lateral resolution; second, the sCTF of a higher NA OCM system with an increased cutoff frequency $q^{(2)}_{cutoff}$, i.e., an improved lateral resolution; and third, the sCTF of a dark field OCM system with an identical NA (when compared to the high NA OCM system), but suppressed lower spatial frequencies. This dfOCM system prevents the specular frequency band from being detected and privileges the structural bands.

Assuming two types of tissue, that both have similar spectra in the tissue band, but one of them has far more content in the cell band, would be imaged with varying contrasts with these three imaging systems. The low NA system would hardly be able to tell them apart. The higher NA system would provide sufficient contrast to distinguish the two, but only the dark field configuration would really allow a stronger differentiation of cell structures, i.e., resulting in a further contrast enhancement for all signal content in the cell band.

The integral contributions over different spectral bands are indicated by the boxes in Fig. 29.3a. A targeted selection of these contributions translates into an

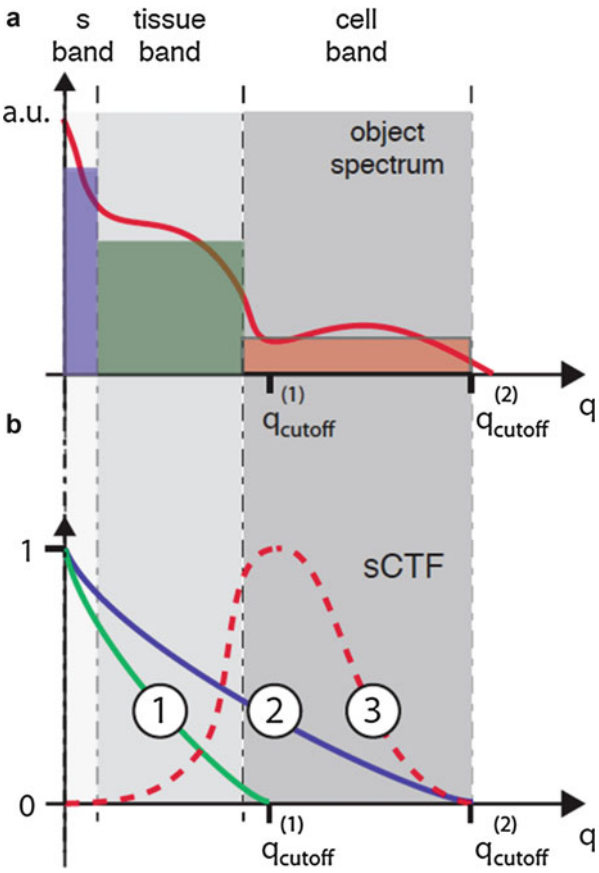

Fig. 29.3 (**a**) Object spectrum overlayed with the integral signal per k-band. (**b**) sCTF of a low NA OCM system (*1*), a high NA OCM system (*2*), and a dark field OCM (*3*) with identical NA as system (*2*)

intrinsic contrast enhancement, an important feature in OCM especially when aiming for structural and dynamic cell imaging.

The schematic and qualitative classification of the object spectrum into different frequency bands can be substantiated for instance with works by Schmitt et al. [28], who measured the power spectrum of index variations of biological tissue by analyzing light scattered by cell samples. The cell-associated index variations follow a power-law and show a fractal index structure within a particular band of spatial frequencies. These findings have been advanced in further studies [29, 30] indicating a fractal order for light scattering in cell clusters over a large span of spatial frequencies.

In OCM the generation of adequate contrast is as important as providing sufficient resolution when imaging small features of a specimen. Imaging almost transparent cells that only slightly differ from their surrounding in their refractive index, their absorbance, or the amount and polarization of the light they scatter increases the request for enhanced or specifically tailored contrast. This demand becomes even more challenging for the observation of dynamic cell processes.

Besides the contrast between different tissues or structure, the sensitivity Σ, the signal-to-noise ratio (SNR), and the dynamic range (DR) are important key factors. The SNR is given as a ratio between the signal and the sum of all noise contributions. The sensitivity is defined as the reciprocal of the smallest reflectivity that can be resolved. The SNR and the sensitivity are principally defined through the noise present in the system. The absolute value of the CTF has, however, likewise an influence. It acts as a filter that reduces the signal and, thus, can limit these characteristics. A sensitivity of 100 dB is typical for a well-designed OCM system which for a SNR = 1 corresponds to a minimum reflectivity of $R_{smin} = 10^{-10}$.

However the available dynamic range is limited well below the sensitivity of an OCM system.

In spectrometer-based FDOCT the signal contains a strong DC (reference) and weaker AC (interference) contribution. For a single line detector with N discretization levels and the DC part γ filling a major part of the quantum well capacity, only a minor part α of the full well capacity is available for the interference signal.

At the saturation level of the detector, the strongest possible signal α is given by $\alpha = \left(1 - \sqrt{\gamma}\right)^2$. Neglecting all noise contributions and an interference amplitude of $2\sqrt{\alpha\gamma}$, we obtain for the dynamic range DR

$$\mathrm{DR} = 2\sqrt{\gamma}(1 - \sqrt{\gamma})M \tag{29.6}$$

where the smallest interference contribution has been set to one discretization level $1/M$. For a typical setting with $\gamma = 0.75$ and $M = 2{,}048$ (11 bits), the resulting DR is typically 50 dB.

This argument is of paramount importance when detecting small signals next to very strong signals originating from specular reflection. To avoid the detection from saturating, the reference signal frequently has to be reduced at the cost of sensitivity. In dfOCM, the specular reflections are sufficiently suppressed to maximize system sensitivity and use the available dynamic range for detection of the small scattering signal of the sample (see Fig. 29.3c).

In swept-source systems, the commonly employed dual-balanced receivers improve the DR, but specular reflections maintain the capability to saturate the detection.

The issue of low frequency band suppression with dark field configuration is nicely demonstrated in Fig. 29.4a, b. Figure 29.4a is obtained with a standard OCT system and shows an en face intensity image of a USAF resolution test target. As expected, highly reflective lines appear bright, and low reflective areas are dark. Figure 29.4b on the other hand is obtained with a dark field OCT configuration (see Sect. 29.4.3). The resulting image is obviously a band-pass filtered version of the resolution test target pattern. Interestingly, the contrast of the small numbers labeling the test patterns, which presumably have a relatively broad frequency content, appears much enhanced in the dark field image.

Figure 29.4c, d demonstrates the effect of efficient exploitation of the system dynamic range for the structural signal, when using a dark field system. In this case the sample is skin, covered by a glass plate commonly applied for better stabilization. Again Fig. 29.4c is obtained with a standard OCT system. The strong reflex from the glass interface drives the camera load close to saturation, and only a small portion of

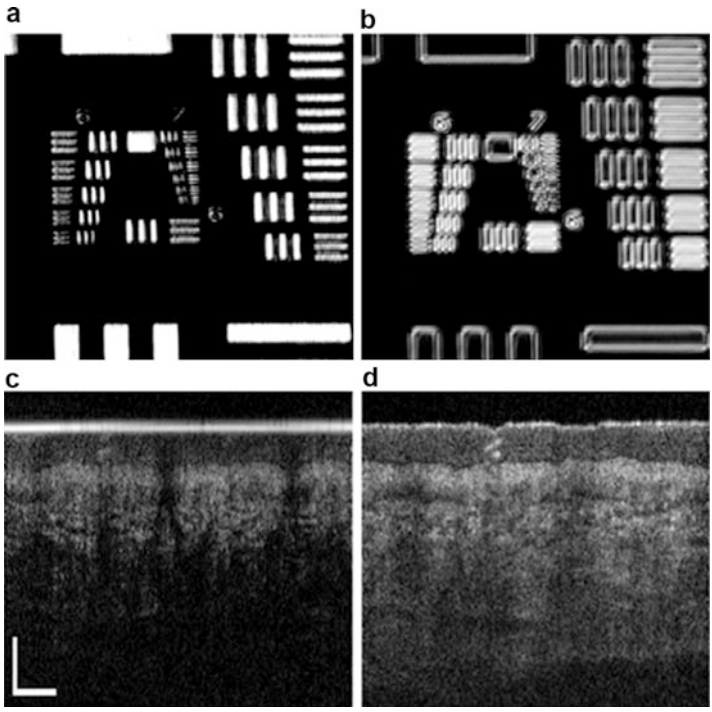

Fig. 29.4 (**a**–**b**) En face projections of a USAF resolution test target obtained with standard OCT and the xfOCT system, respectively, displaying the dark field effect. (**c**–**d**) Tomograms from skin with a glass plate on top. The glass surface is almost perpendicular to the optical axis, with the reference power adjusted to avoid saturation. Standard OCT in (**c**) is missing sensitivity due to the strong reflex from the glass interface. xfOCT in contrast does not suffer from the reflection and exhibits thus better sensitivity and depth penetration for the skin structures. Scale bar denotes 250 μm [57]

the dynamic range is left for the structure of interest, resulting in poor contrast. The situation is different for the dark field configuration as shown in Fig. 29.4d. The reflection is suppressed, and the full dynamic range is available for the actual structure, providing excellent contrast of various tissue structures. The imaging depths are likewise enhanced, due to the combined effect of the optimized sensitivity and the extended DOF that comes in hand with the dark field effect (see Sect. 29.4).

29.4 Extended Focus Optical Coherence Microscopy: Configurations and Applications

So far we presented a general theoretical framework to understand and investigate how specific illumination and detection modes define the CTF and influence the available DOF. Further, the meaning of contrast and specific regions of interest in the sample spatial frequency spectrum were discussed. As a reminder, the goal is to

design a system providing high spatial resolution in all three dimensions without compromising the parallel acquisition unique to Fourier Domain OCT. If speed is not a critical parameter, performing a confocal scan in all three dimensions will undoubtedly provide the best image quality. Here, instead, a compromise between image quality and imaging speed is pursued. The particular physics of Bessel beams makes this class of beams a strong candidate to help in such a compromise, and it is tempting to replace the conventional imaging lens with an axicon-like lens. The generalized aperture of the resulting focal spot is defined by a thin annulus. The CTF resulting from a symmetric system with identical illumination and detection modes is defined by the convolution of two such annuli. Indeed, this results in a narrow and flat CTF, approaching two of the three criteria of an ideal CTF. Unfortunately, the transmission values feature very strong variations. The CTF can be pictured as a ring of twice the diameter of the annulus of the generalized aperture and a strong, very narrow central peak, connected to the outer annulus with very low transmission values. In the tomogram, this results in very strong side lobes and a very poor imaging of edge-like structures. As discussed in the introduction, for a moderate gain of DOF, such a configuration does offer a valuable configuration with the benefit of simple physical implementation, as shown for instance by Liu et al. [21] and Lorenser et al. [22].

In the attempt of realizing a more substantial gain in DOF, decoupling of the illumination and detection aperture has shown better performance. A Bessel-like mode is still used to deliver the light into the sample and illuminate the sample with an axially extended light needle. The detection volume, however, is defined as a lower NA Gaussian mode. In the following, three specific implementations of this combination and their corresponding benefits for biological applications are discussed.

29.4.1 Extended Focus Optical Coherence Microscopy: xfOCM

This first realization of extended focus OCM (xfOCM) provided a near isotropic resolution of 1.3 μm in the lateral and 2 μm in the axial direction, over an axial range of 300 μm, corresponding to a more than tenfold increase in the DOF of a Gaussian system with identical lateral resolution. An axicon lens was used to generate a Bessel-like beam, which was relayed through a scanning system and finally projected into the sample space with a microscope objective of NA = 0.3. The decoupled detection was defined by the Gaussian-like fiber mode, relayed in a way to define an NA slightly below the illumination NA. The excellent axial resolution was achieved with an Ti:Sapphire laser centered at 800 nm. Figure 29.5 displays the schematic layout; details are provided in [12, 23].

The theoretical CTF corresponding to this configuration is shown in panel (b). For comparison, the CTF of a system with symmetric Gaussian-like illumination and detection resulting in a comparable lateral resolution is also depicted. The projections of these CTFs along s, i.e., their sCTFs, are plotted in the bottom part of the same figure. Due to the Gaussian detection, the CTF of the xfOCM

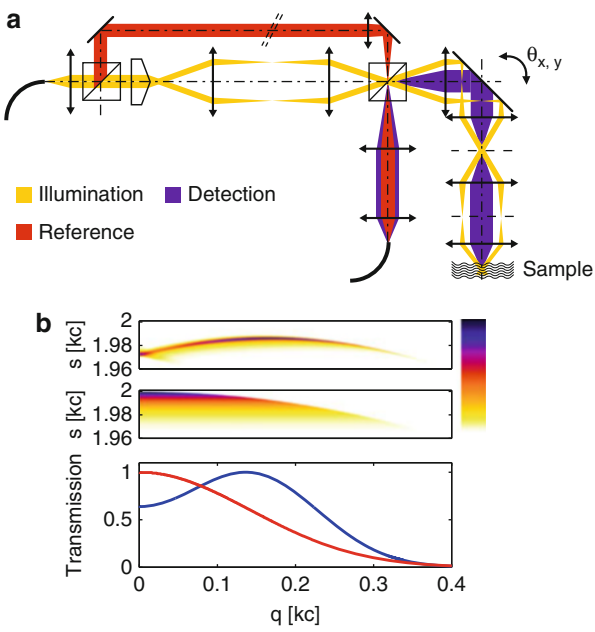

Fig. 29.5 (**a**) Schematic layout of the xfOCM, evidencing the decoupling of the illumination and the detection paths (not drawn to scale). (**b**) *Top*: CTF of the xfOCM configuration. *Middle*: CTF of a confocal Gaussian-like system with similar lateral resolution as the xfOCM. *Bottom*: Projections of the CTFs along *s*

configuration is curved along **q** and will eventually induce a defocusing for out of focus structure. Due to the Bessel-like illumination, the width of the CTF along *s* is very limited and provides a strong intensity signal over a significantly extended depth range. The Gaussian CTF, in contrast, features a much wider width along *s*, paired with a stronger curvature, resulting in a very short DOF.

The preferential selection of higher lateral spatial frequencies of the xfOCM scheme is clearly visible in the sCTF plots. The contrast is best for a spatial frequency range that is above the specular reflection band and contains valuable sample information.

Importantly, this configuration allowed efficient and rapid scanning of the extended focus beam over the sample. This is crucial to benefit from the advantage of the extended focus scheme and necessary for in vivo imaging to overcome movement artifacts.

29.4.1.1 Imaging of Langerhans Islets

We used this configuration for imaging of islets of Langerhans in mice [31, 32]. These agglomerations of insulin-producing beta cells are scattered throughout the pancreas and exhibit an excellent contrast when imaged with xfOCM. They are strongly vascularized and sense the blood glucose level to release, in response, insulin and achieve glucose homeostasis. Destruction of these islets due to an autoimmune attack results in type I diabetes. Using a mouse model of this type of diabetes, we were able to prove the capability of xfOCM to image islets down to a size corresponding to a cluster of only a few beta cells and perform quantitative analysis of their size distribution. Also, although access to the

pancreas involved surgery and is invasive, repeated imaging for longitudinal studies is possible. Analyzing the size distribution of islets during the onset of diabetes could help advance our understanding of this disease (Fig. 29.6).

29.4.1.2 Imaging of Cerebral Beta-Amyloidosis in Alzheimer's Disease

In a recent study, xfOCM has been applied in neuroscience to investigate Alzheimer's disease (AD) [33]. The pathology of AD is characterized by the accumulation of amyloid-β (Aβ) peptides in cerebral plaques and blood vessels. The APPPS1 mouse model of AD used in the study develops cerebral plaques consisting of human amyloid at the age of 2 months [34]. Three-dimensional xfOCM images of the AD brain structure clearly revealed Aβ plaques both ex vivo and in vivo without exogenous contrast agents, as shown in Fig. 29.7. By imaging brain samples simultaneously with xfOCM and confocal fluorescence, the structures observed with xfOCM were confirmed to be Aβ plaques. The image contrast was sufficient to allow segmentation of Aβ plaques and to analyze Aβ plaque volume in function of age, as well as other statistics. Furthermore, in vivo Aβ plaque formation was

monitored through a cranial window during a 1-month longitudinal study. To precisely re-localize the same region of brain tissue at several time points, image registration using the vascular network as a reference was employed.

29.4.2 Dark Field Optical Coherence Microscopy: dfOCM

A dark field configuration with its intrinsic contrast enhancement is particularly well suited for cell imaging. Analogous to xfOCM, the dfOCM illumination is based on a Bessel beam. To improve the annular illumination pattern in the back focal plane of the objective lens, it is filtered with a mask in a conjugate plane, blocking any light outside a thin annulus. Similarly, the light backscattered by the sample is filtered with a complementary mask, accepting only light within the non-overlapping inner portion of the ring illumination. This results in a strong suppression of specular reflection originating from flat interfaces, such as the microscope slide, i.e., contributions from low spatial frequency structures are eliminated to a large extent. In consequence, the sensitivity of dfOCM for very small intensities of backscattered light is highly improved. The overall interferometric setup of dfOCM [35] is very similar to xfOCM [12], and the major modifications are an increased numerical aperture of the objective lens ($NA_{eff} = 0.68$) ensuring an improved lateral resolution of <0.6 µm with a reduced DOF of approximately 45 µm. Figure 29.8 shows the illumination and detection modes at the sample objective and the amplitude masks positioned in planes conjugate to the Fourier plane of the objective. The corresponding sCTF defines a clear band-pass filter, centered on the cell frequency band and strongly suppressing the specular reflection band. Due to the high NA, the CTF features a significant curvature.

The resulting contrast enhancement is particularly interesting for the imaging of cells, subcellular structures, and dynamics of cell processes. The available DOF is sufficient for such samples and still provides the speed advantage of parallel imaging along depth inherent to detection in the Fourier domain.

For demonstrating the performance of dfOCM, Fig. 29.9 displays en face views and B-scans of individual cells of four different cell lines. The high sensitivity of

Dynamic range of *color bar*: 45 dB

dfOCM to weak scattering signals reveals distinct backscattering signal from these near-transparent objects. Significant differences between the various cell types are observed, pointing to fundamental differences in their internal organization. In this particular setting of the dfOCM imaging instrument, the specular reflections have been suppressed by more than 34 dB.

29.4.3 Extended Focus Optical Coherence Tomography xfOCT

The Bessel beam configuration has not only distinct advantages for microscopic imaging but can equally be applied to tissue imaging. In case of scattering tissue such as the skin, the optimal wavelength is 1,300 nm, where scattering becomes less prominent and water absorption has a local minimum. For this wavelength range the most promising OCT technology is based on wavelength-swept light sources. Recent developments of Fourier Domain Mode Locking (FDML) sources allowed for up to then unimaginable imaging speeds of several MHz A-scan rate [36]. High-speed tissue imaging is of particular importance for in vivo applications to keep motion artifacts small and measurement times short such as in endoscopy or for microcirculation imaging (see next section). Wavelength tuning sources are ideally launched

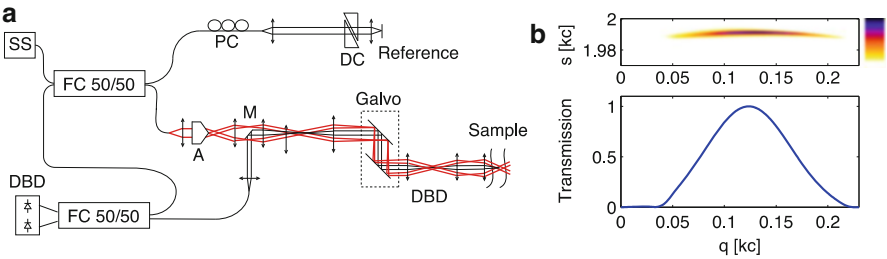

Fig. 29.10 (**a**) Optical setup of SS-OCT system employing a dark field xfOCM scheme via mirror *M*, A-axicon, *SS* swept source, *FC* fiber coupler, *PC* polarization control, *DC* dispersion compensating prisms, *DBD* dual balancing detector. (**b**) Theoretical spatial frequency picture for the configuration in [Blatter 2010] and CTF according to Eq. 29.2. Note the suppressed low frequency part for s(kc) characteristic for a dark field configuration

through single-mode fibers. A setup for extended focus imaging at 1,310 nm with swept-source (SS) OCT is depicted in Fig. 29.10 (lhs). Details can be found in Blatter et al. [37, 38]. The central element of this configuration is a small mirror M that serves both as spatial filter for the illumination Bessel mode through the axicon A, as well as central mirror for the Gaussian detection mode, basically exhibiting the filter characteristics of the masks in the dfOCM setup in Fig. 29.6 of the previous section. The images in the following are obtained with an FDML laser centered at 1,310 nm with a 140 nm full bandwidth, giving an axial resolution of 12 µm in air at 220 kHz A-scan rate. The lateral resolution can be evaluated from its $1/e^2$ lateral extent to be of ∼15 µm, constant over an axial distance of ∼500 µm. With such a configuration a sensitivity of better than 100 dB was achieved.

The setup has a detection NA of 0.06 and an effective illumination NA of 0.13. The calculated CTF is displayed in Fig. 29.10 (rhs). Due to the lower NA, the curvature in the CTF is reduced. But the dark field effect is obvious, with the characteristic suppression of the low spatial frequencies. This has been discussed in Sect. 29.3 and nicely demonstrated in Fig. 29.4.

Another important property of Bessel beams is the so-called self-healing effect. This is basically due to the conical illumination that manages to illuminate structures beneath obstacles, because they do not cast a clear shadow along the optical axis. This effect is clearly visible in case of skin hairs that produce shadows along the optical axis and reduce the signal from the underlying structure for standard OCT configurations (Fig. 29.11a, c). Almost no shadowing results for the xfOCT configuration (Fig. 29.11b, d). The spurious shadow is due to the decoupled Bessel beam illumination and axial Gaussian detection. Clearly the effect depends on the size of the obstacle and its position along the axis.

The performance for imaging of healthy human skin in vivo is well visible from Fig. 29.12a–c. Apart from pure structural imaging, OCT has also important functional imaging capabilities. The following section is dedicated to the advantages of xfOCT for label-free microvascular imaging.

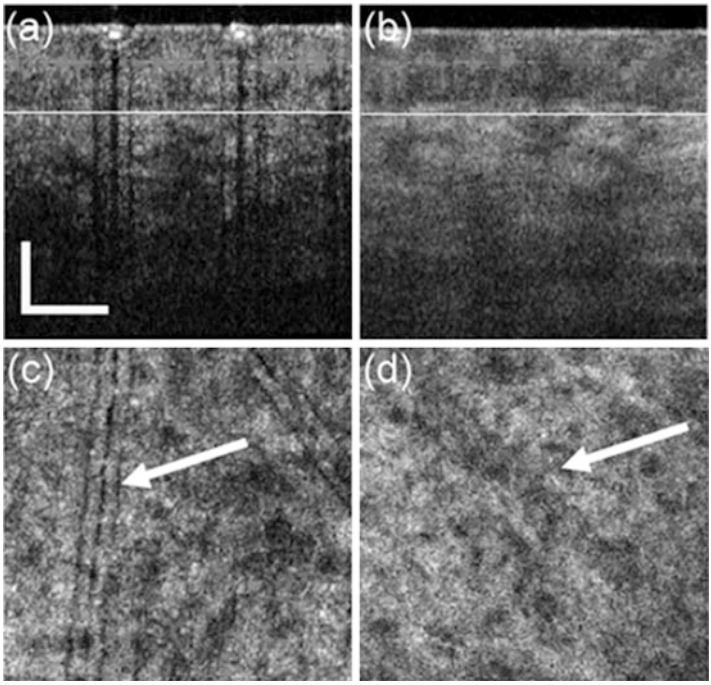

Fig. 29.11 Self-regeneration of Bessel beams: shadowing of skin hair along the depth. (**a**, **c**) Standard. (**b**, **d**) xf-configuration. (**a**, **b**) Tomograms. (**c**, **d**) En face projection views at depth indicated by the *white line* in the tomograms showing remaining shadowing in the standard OCT setup whereas only slight signal reduction is seen in xfOCT (*white arrows*). Tomograms are taken at different but close locations of the skin. Scale bar denotes 250 μm in every picture

29.4.4 Extended Focus Microcirculation Imaging

Since the first implementations of OCT, functional extensions of OCT have been extensively investigated [39–41]. They promise to compensate the intrinsically missing molecular contrast as provided, for example, by confocal fluorescence microscopy. A unique position among these techniques has Doppler OCT, as it allows not only to contrast blood flow in a fully noninvasive and label-free way but also to quantify flow within individual vessels in tissue. This is due to the fact that OCT is an interferometric technique with the possibility to track changes of the optical path length by fractions of the center wavelength.

Especially the availability of high-speed OCT technology based on Fourier domain detection boosted the development of highly sensitive optical angiography techniques. Clearly blood flow and tissue blood supply is a key information for understanding tissue health, as well as for effective treatment monitoring. Insight into capillary structure, its integrity, and perfusion would create new diagnostic capabilities in clinical practice and research.

(**e**) Shows preferentially flat vessel beds with larger vessels in the dermis [38]

In the following we review the implementation of intensity-based Doppler OCT on the dark field swept-source OCT platform operating at 1,300 nm center wavelength characterized in the previous section. We demonstrate examples for label-free high-resolution angiography in the human skin both healthy and diseased, including cases of nonmelanoma skin cancer.

The vascular contrasting method is based on calculating logarithmically scaled intensity differences between successive tomograms [42–47]. Ideally, the tomograms are taken at the same lateral position in order to keep speckle decorrelation signatures of static tissue low. Using the intensity information instead of the phase is easily implemented and better suited to high-speed FDML laser sources regarding trigger jitter between successive tomograms. An angiographic image P, contrasting flow against static tissue, is obtained by calculating the squared intensity difference between successive tomograms:

$$P(x, y_i, z) = \left(I(x, y_i, z) - I\left(x, y_{i+1}, z\right)\right)^2 \tag{29.7}$$

where $I(x, y, z) = 20 \cdot \log[|FFT\{I(x, y, k)\}|]$, x, y, z are the spatial pixel coordinates corresponding to fast and slow scanning and depth coordinate, respectively, and k is the wavenumber. Motion artifacts give rise to high intensity difference signatures; thus, a simple thresholding can help to exclude those images. This method is more robust against motion artifacts than a variance analysis over the full tomogram

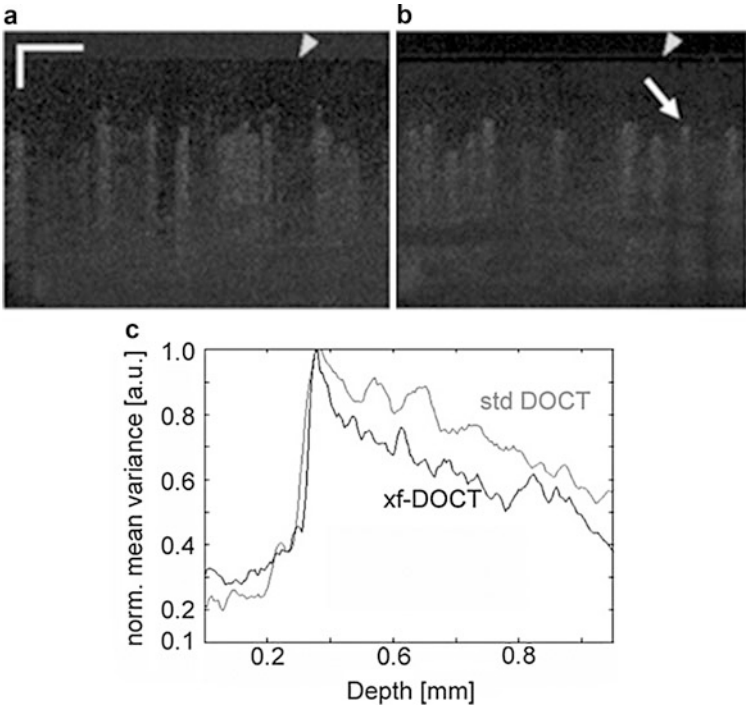

Fig. 29.13 Result of intensity difference tomograms. The static tissue appears *dark*, while motion is represented by *bright* values. Blood vessels are visible; however, their axial extend determination is limited by decorrelation. (**a**) Standard (*std*) DOCT mean intensity difference plot. (**b**) Extended focus (*xf*) DOCT. *Arrows* point at the skin surface in contact with a glass plate. *Long white arrow* points at vessel cross section. Scale bar denotes 250 μm. (**c**) Normalized mean depth profile through vessel showing a better defined vessel axial size and a steeper decrease of the signal with the xfDOCT scheme [37]

series acquired at the same position, since pictures with strong decorrelation are rejected. Furthermore, the difference is only calculated between successive tomograms, thus reducing the time interval over which correlation is required. This improves further the stability with respect to motion artifacts. Figure 29.12 below shows the vascular structure for healthy skin.

The en face images of Fig. 29.12d, e are obtained by adding the mean intensity difference values $P(x, y, z)$ (Eq. 29.7) along the axial extent indicated in Fig. 29.12a by the red bars. The visible small dots in Fig. 29.12d represent cross sections of small capillary loops in the uppermost skin layers, whereas deeper vasculature is characterized by flat vessel beds with increased vessel diameter (Fig. 29.12e).

Despite the high sensitivity to even capillary flow, such contrast methods have in common that they lead to axial signal decorrelation artifacts below blood vessels. They are due to multiple scattering as well as the refractive index change over time of intrinsically inhomogeneous blood. Figure 29.13 demonstrates this effect for an

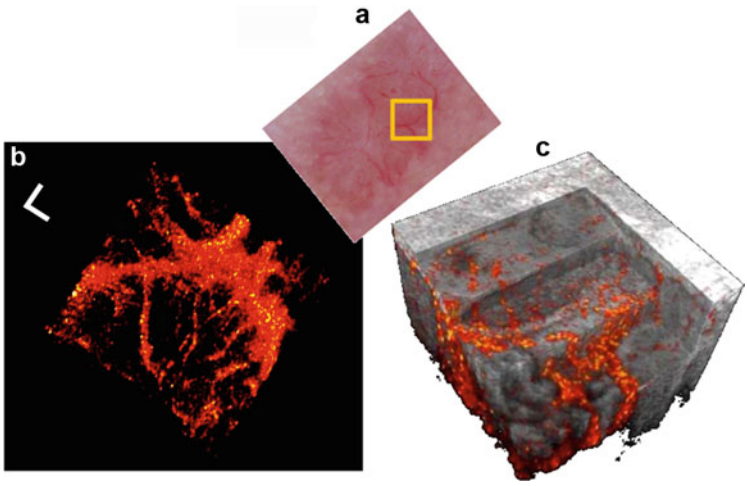

Fig. 29.14 BCC on the forehead. (**a**) Dermoscopy image with square indicating the OCT FOV. (**b**) Doppler OCT (DOCT) angiography using the xfOCT configuration. *Scale bars* indicate 250 μm. (**c**) Volume rendered overlay of microcirculation (*red*) on structural information (*gray scale*) [38]

intensity difference tomogram for a dark field xfOCT configuration as well as for a standard OCT configuration. The vessel tails are clearly visible in both cases.

However, by taking an average axial profile, it becomes visible that xfOCT suffers slightly less from these artifacts as shown in Fig. 29.13 (right). The extended focus curve exhibits an axially better defined vessel size and a steeper decrease of the variance signal. This can be attributed to the conical illumination of the Bessel beam illuminating structures below the vessel without actually crossing the vessel. Of course the effect is reduced by the standard axial Gaussian detection. It can be expected that the decorrelation tails would be better suppressed by configurations with Bessel illumination and detection (see above) at the expense of overall detection sensitivity.

Depth-resolved visualization of microvasculature is already a powerful tool for characterizing lesions [38, 48, 49]. Figure 29.14 shows the microvascular pattern of a basal cell carcinoma (BCC), a nonmelanoma skin cancer, assessed in vivo and in situ.

The standard tool in dermatology is the dermascope (Fig. 29.14a). It provides high contrast visual inspection and documentation, but is restricted to the surface alone. Deep structural and microvascular details are accessible through xfOCT as shown in Fig. 29.14b, c. Figure 29.14c shows a volume-rendered vascular contrast image together with the intensity information in gray scale that allows for better correlation between structure and vasculature. In combination with complementary optical methods for assessing metabolite concentrations or tissue oxygenation, the label-free microcirculation imaging modality could give unique insight into the metabolic demand of tissue.

29.5 Conclusion and Outlook

This work has given an overview of how beam engineering can enhance the imaging capabilities and performance of OCM by reviewing the current state of research. First, a theoretical description of image formation in OCM, based on the concept of the CTF, was presented. Next, implications of the CTF on image resolution and the depth of field, as well as the resulting contrast of biological tissue, were discussed. Engineering of a specific CTF can be aimed at extending the DOF or at achieving a dark field configuration to improve imaging contrast.

The various implementations of the described extended focus, and dark field modalities have demonstrated their potential in a wide range of applications, spanning from cell and small animal imaging to dermatology. The benefits in resolution, speed, and contrast enabled to address relevant questions in important research areas such as diabetes, Alzheimer's, or microcirculation. The extended focus concepts yield furthermore distinct advantages for mesoscopic resolution OCT and for its functional extension with Doppler OCT.

All the presented configurations rely on decoupling of the illumination from the detection aperture. While this is the fundamental concept that enabled the engineering of the reported CTFs, it adds significant system complexity and has limited its use to bench-top settings. The development of a fiber probe that achieves decoupling of the illumination and detection paths in an elegant and simple way would make the advantages of extended DOF and dark field accessible to an endoscopic setting. Clinical, catheter-based applications would greatly benefit from the gained resolution and contrast.

Although beam engineering can improve the contrast for imaging of biological samples, this signal is entirely defined by the structure, i.e., the refractive index, of the sample. The possibility to add contrast with molecular specificity remains a long-lasting goal and would expand the possibilities of OCM and open up new applications. In a recent effort, the high sensitivity of the dfOCM configuration to small backscattered signals was extended with a photothermal optical lock-in detection (poliOCM) [50]. The photothermal response [51, 52] provided a highly sensitive and specific extrinsic contrast mechanism. In poliOCM an external pump source modulated beyond 100 kHz induced time-varying changes of the refractive index in the close vicinity of strongly absorbing particles. Gold nanoparticles (AuNP) were used as small, point-like absorption centers, down to a size of only 6 nm. Tuning the pumping wavelength to the plasmon resonance of these AuNPs resulted in a strong local absorption and efficient heating of the AuNPs' immediate surroundings. AuNPs are interesting markers, as they offer good biocompatibility without any adverse bleaching, known from the widely used fluorescent labels. Modulating the reference signal with a phase variation locked to the pump modulation suppressed the signal from static structure, providing a selective image of the AuNPs. Turning off the reference arm modulation provided a conventional dfOCM tomogram. poliOCM still benefits from the parallel acquisition speed advantage and offers and interesting alternative to the much slower confocal microscopy,

especially for studies of cell dynamics, where both the biocompatibility of the probes and the imaging speed are crucial.

An alternative way to add the missing molecular contrast to OCM is to combine different imaging modalities with complementary contrast mechanisms into a multimodal platform. In case of thin samples, OCM can easily be combined with fluorescence and fluorescence lifetime microscopy. The most promising candidate for thick tissue imaging is photoacoustics (PA) as it combines high resolution with high absorption sensitivity [53]. A drawback of PA is the missing absorption contrast to the embedding tissue that would often be required for proper image interpretation. In that, it is fully complementary to the structural imaging provided by OCM. The combination of PA and OCM would therefore allow for more complete characterization of tissue structure and metabolism [46, 54–56]. In a recent work, an elegant combination of xfOCM and PA in a fully optical way using the same detection optics was shown [57, 58].

The framework of beam engineering presented in this chapter is limited to scalar expressions, ignoring the vectorial nature of light and the resulting polarization effects. Also, the aperture functions were assumed to be rotationally symmetric. Breaking this symmetry would offer additional parameters and offer more flexibility in designing a specific system CTF. Deformable mirrors and spatial light modulators, well known from adaptive optics, could provide a convenient toolset to explore more advanced beam engineering modalities. These wavefront manipulation devices were developed to correct for optical aberrations and help to recover a tightly focused spot, and more recently even to refocus light deep inside scattering samples, correcting for multiple scattering [59]. They could also serve to dynamically redefine the system CTF, test different regions of the sample spatial frequency spectrum, and vary the extension of the depth of field. This would enable to adapt contrast, resolution, and acquisition speed for the specific sample under investigation and would optimize the information content gained on the imaged tissue.

Holographic Optical Coherence Imaging 30

David D. Nolte, Kwan Jeong, John Turek, and Paul M. W. French

30.1 Introduction

Holographic optical coherence imaging (HOCI) is a wide-field imaging approach that acquires en face images from a fixed depth inside scattering media by using low-coherence off-axis holography as a coherence gate [1]. There are two forms of holographic recording in optical coherence imaging: (1) dynamic holography in photorefractive media and (2) digital holography on pixel-array detectors.

Photorefractive holographic OCI uses a holographic real-time film (most commonly a photorefractive quantum well structure [2]) to provide the coherent demodulation that extracts information-bearing light from the multiply scattered statistically incoherent background. The photorefractive effect responds to the gradient in intensity, rather than to direct intensity, and records low-coherence light interfering with a reference wave. The hologram is read out by diffracting a reconstruction beam into a video camera. The diffracted image is "background-free" because the nominally uniform background is not recorded. The real-time character of the holographic film makes it possible to interrogate tissue interactively by viewing on a video monitor without computed tomography or reconstruction.

The real-time character makes it adaptive and enables it to compensate mechanical motions in the optical system.

Digital holographic OCI uses a digital pixel array (either CCD or CMOS camera chip) placed at the recording plane, and the hologram is read out electronically to a computer. The speckle hologram is typically recorded on a Fourier plane, with interference fringes between the signal and reference modulated by the speckle envelope. The image is reconstructed using a fast Fourier transform (FFT) algorithm that generates an image and its phase conjugate. The pixel spacing of the array determines the smallest fringe spacing that can be supported by the Nyquist sampling theorem and hence sets the reconstruction spatial resolution.

This chapter gives an overview of the principles of holographic OCI. It begins with a description of off-axis holography as spatial heterodyne detection and continues with the origin and role of speckle in multichannel illumination of tissue. Image-domain holography (IDH) and Fourier-domain holography (FDH) are described. Holography in the Fourier domain has the capability for phase-contrast imaging that can acquire small sub-wavelength displacements despite long coherence length. The trade-offs between photorefractive and digital holography are discussed. The chief biological target is multicellular spheroids, specifically rat osteogenic sarcomas that are grown in vitro. After describing the physiological and optical properties of these spheroids, results from holographic OCI are presented using both photorefractive and digital holography.

30.2 Development and Applications of Holographic OCI

Holography is a wide-field 2-D coherent recording technique, making it an obvious choice as a coherence-gating method to image through turbid media [3]. It was with holography that Stetson first showed the principle of coherence gating for imaging through a fog-like medium [4]. In 1989 light-in-flight (LIF) holography was demonstrated, exploiting the finite coherence length of the light source to facilitate depth-resolved imaging of three-dimensional objects [5], including through optical diffusers. However, photographic film was used as the holographic recording medium, and each image acquisition had to be chemically developed before being reconstructed. Subsequent research has concentrated on using real-time methods to perform the holographic recording and reconstruction, focusing mainly on two techniques: “electronic” or “digital” holography [6, 7] and photorefractive holography [8]. These “off-axis holography” techniques are closely related to wide-field OCT, sharing many of the strengths and drawbacks. Perhaps the key advantage of the holographic approach is that the coherent detection is in the spatial domain, rather than the temporal, and so can provide a full-field sectioned image in “single-shot” acquisition, making it less sensitive to motion artifacts. Wide-field techniques may also employ sources of low spatial coherence, such as thermal sources [9] or LEDs [10], which provide short coherence lengths and reasonable average powers – usually with lower cost than the spatially coherent laser sources required for single-channel OCT. The chief drawback of wide-field coherence-gated

imaging is the lack of the strong spatial filter employed by conventional OCT systems and hence significant scattered backgrounds and speckle.

Photorefractive holography offers an opportunity to realize high-speed coherence-gated imaging *without* the scattered light background, and the dynamic range is not directly limited by the CCD camera but by the photorefractive material [11]. In 1993 Mamaev et al. [12] showed that a photorefractive crystal of strontium barium niobate (SBN) could be used to image through a suspension of milk in real time. This demonstrated the utility of photorefractive holography for coherence-gated imaging, albeit using narrowband c.w. radiation and imaging in transmission. In 1995 Hyde et al. demonstrated real-time 2-D/3-D imaging through a scattering solution of polystyrene spheres with both c.w. and ultrashort pulsed near-infrared radiation using rhodium-doped barium titanate (Rh-Ba:TiO_3) as the photorefractive recording medium [13]. This approach permitted a weak ballistic image to be recorded in the presence of an incoherent background 10^6 times higher [14], demonstrating that photorefractive holography is not sensitive to a uniform background of multiply scattered diffuse light. This reflects the *unique* behavior of photorefractive media that are sensitive, not to the incident intensity but to the *spatial derivative of the incident intensity distribution* – in contrast to all other wide-field imaging detectors.

A typical low-coherence photorefractive holography setup is nearly the same as for conventional or (image plane) digital holography except that the CCD in the holographic recording plane is replaced by a photorefractive medium. A holographic image formed by the coherent (ballistic) light is recorded and read out using a laser that may be at a different wavelength from the broadband source. Using Rh-Ba:TiO_3 as the photorefractive medium, wide-field 3-D imaging through scattering media of up to 16 MFP (round trip) thickness was demonstrated for the first time with sub-100 μm depth and transverse spatial resolution [13], albeit with a long ($\sim$300 s) integration time owing to the relatively slow response of Rh-Ba:TiO_3. To obtain both high-speed and near infrared sensitivity, the most promising candidates are semiconductor media and the highest sensitivities and fastest responses have been obtained from semi-insulating photorefractive MQW devices exploiting the transverse-field Franz Keldysh effect [15]. This approach permits rapid 3-D imaging through turbid media with NIR radiation and depth-resolved image acquisition with integration times shorter than 0.4 ms [16]. Thus, real-time 3-D imaging may be implemented with image acquisition direct to a videocassette recorder, without recourse to a digital frame grabber [17]. Using a high-speed CCD camera, photorefractive holography using PRQW devices realized depth-resolved imaging at 476 frames/s [18], By using a (spatially incoherent) LED source, PRQW holography provides sub-10 μm depth resolution [10] and speckle-free images through static turbid media including sandstone [19] and biological tissue [20]. The imaging depth range for OCI is approximately 0.7 mm [21] for imaging epithelial layers or 1 mm for tumor spheroids in reflection [22]. The axial resolution of OCI achieved 14 μm using short-coherence sources [23], and the lateral resolution is typically 10 μm [24] although this is determined solely by the optics and the magnification.

The first application of holographic OCI to living tissue was imaging into rat osteogenic tumor spheroids [22, 24]. The tumor spheroids are roughly spherical in

shape and have a differentiated structure with a 100–200 μm thick shell of proliferating cells surrounding a necrotic core. This tumor morphology was captured by holographic OCI as an average intensity dependence on radius [25]. Time-dependent changes in speckle intensities were also found to correlate with the metabolic health of the spheroids [26].

The early work on holographic OCI was performed using image-domain holograms for which the hologram plane was at or near the image plane of the imaging optics. Better performance was attained by using Fourier-domain holograms for which the hologram plane was at or near the Fourier plane of the imaging optics. This was especially important for reduction of light scattered to the CCD camera by imperfections in the holographic film. The Fourier-domain system [27] has a dynamic range approaching −100 dB. This system improvement enabled volumetric imaging of detail within mouse eye as well as tumor spheroids and demonstrated robust repeatability [28]. Phase-contrast imaging of tissue with sensitivity to surface topology down to 200 nm was also demonstrated in the Fourier system [29].

The direct capture of interference fringes on electronic pixel-array detectors had a long nascent period beginning with work by Joseph Goodman in the first decade after the invention of the laser [30, 31] and extending through the early 1990s [32–34]. The first use of digital holography (also called electronic holography) to image through living issue was by Emmet Leith's group in 1994 [35]. Progress in digital holography mirrored progress in CCD cameras, which became increasingly more powerful as well as inexpensive in the late 1990s, driven by consumer electronics markets. Breakthroughs in applications of digital holography had a cusp in the years 1994–1998 [36–40] after which many improvements and advances were made by many groups.

There was an early interest in low-coherence digital holography [33, 41] merged with full-field optical coherence tomography [9, 42–45] that employed in-line phase-shifting low-coherence interferometric imaging, which is the subject of several other chapters in this volume. Off-axis digital holography, on the other hand, employs spatial heterodyne detection on the pixel array without the need for phase shifting [46–49], which simplifies the image reconstruction, but with a trade-off in hologram resolution limited by the pixel pitch of the pixel-array detectors. The first application of low-coherence digital off-axis holography to living tissue was to multicellular tumor spheroids [50]. Living tissue exhibits highly dynamic speckle that is captured by the digital holography [51, 52] and has been used to derive a new form of functional imaging called motility contrast imaging (MCI) which is the topic of ▶ Chap. 37, "Motility Contrast Imaging and Tissue Dynamics Spectroscopy" in this volume.

30.3 System Architecture and Performance

30.3.1 Speckle Holography and Spatial Heterodyne

Speckle arises from the simultaneous illumination of an optically heterogeneous target by multiple optical modes. Fully developed speckle has a Poissonian intensity distribution for which the root variance of the intensity equals the mean intensity.

This speckle carries no structural information, but can contain statistical information related to the tissue. On the other hand, partially developed speckle with a mean intensity larger than the root-variance does carry partial structural information.

Whether speckle is fully or partially developed, it can remain coherent with respect to a reference wave. Holograms written between the speckle field and the reference wave are called speckle holograms. The basis of holographic OCI is the recording of speckle holograms, either from fully or partially developed speckle, in the presence of a statistically incoherent speckle background. In this sense, there are different types of speckle: (1) information-bearing speckle carrying statistical or structural information; (2) multiply scattered background speckle that is spatially and temporally coherent with the reference, but which represents channel cross talk and does not carry any spatial structural information from the target; and (3) statistically incoherent speckle that is outside the spatial or temporal envelopes of the reference. This last form of speckle does not generate holograms, while the first two do. Of these two, only the first carries explicit information about the target. The purpose of holographic OCI is to select only the information-bearing speckle, while attempting to suppress the noninformation-bearing (but still coherent) speckle by controlling spatial coherence and using statistical time averaging.

Off-axis speckle holograms consist of bright and dark spatial interference fringes within each speckle. The fringes define a spatial carrier wave that is modulated by the speckle envelope. Therefore, holography is based on spatial heterodyne detection that is the spatial analog to temporal heterodyne. The coherent field at the hologram recording plane is

$$E = E_s\left(\vec{r}\right)e^{i\vec{k}_s\cdot\vec{r}}e^{i\phi\left(\vec{r}\right)} + E_0 e^{i\vec{k}_0\cdot\vec{r}} \tag{30.1}$$

where $E_s\left(\vec{r}\right)$ is the speckle field amplitude that varies spatially and $\phi\left(\vec{r}\right)$ is the speckle phase that also varies spatially. The optic axis of the speckle field is defined by the direction of the scattered k-vector $\vec{k}_s$, although this vector also varies spatially. The reference field amplitude is E_0 and the k-vector of the reference is k_0. The coherent speckle hologram intensity is

$$I = |E|^2 = I_s\left(\vec{r}\right) + I_0 + 2\sqrt{I_s\left(\vec{r}\right)I_0}\cos\left(\vec{K}\cdot\vec{r} + \phi\left(\vec{r}\right)\right) \tag{30.2}$$

where the grating vector is $\vec{K} = \vec{k}_s - \vec{k}_0$ and the position vector $\vec{r}$ is in the hologram plane. The first term is the speckle intensity and the second term is the reference intensity. The third term is the coherent interference between the speckle and the reference fields, i. e., the hologram with interference fringes of fringe spacing Λ with $|K| = \frac{2\pi}{\Lambda}$. The hologram amplitude is modulated by the speckle intensity into regions of randomly distributed bright speckles, and the phase of each speckle is independent of each other. However, for off-axis hologram recording, the fringe orientation and spacing Λ are the same for every speckle. This is the spatial heterodyne term that allows coherent detection of depth-resolved scattered light.

30.3.2 Image-Domain Versus Spatial Fourier-Domain OCI

Holographic OCI was initially performed using image-domain OCI, in which a photorefractive film was located at or near the image plane of the imaging optics. However, dust and other imperfections on the device can produce highly localized scatter in the reconstructed images [25]. These background problems were almost eliminated by conversion of image-domain OCI to Fourier-domain OCI, in which the holographic film is located at the Fourier plane [27]. The key to this conversion is the recognition that diffuse targets such as tissue produce relatively uniform intensity distributions at the Fourier plane (unlike specular test charts that are commonly used for system alignment characterization) permitting uniform hologram recording in the photorefractive film.

The optical configurations for photorefactive holography are shown in Fig. 30.1 for both image-domain and Fourier-domain holography. In Fourier-domain photorefractive OCI, the background scattered from a defect on the holographic film is uniformly distributed at the CCD plane, while it forms a replica of the defect (strong background) in image-domain OCI. In Fourier-domain OCI, in addition to the removal of strong spot background, the total background in the images is reduced and hence the dynamic range is extended. The amount of scattered light that is collected depends on the square of the numerical aperture, where the numerical aperture is proportional to the diameter, D, of the imaging lens in image-domain OCI but size, L, of the imaging CCD chip in Fourier-domain OCI. The ratio of the total background collected in images in image-domain OCI to those for Fourier-domain OCI is $(D/L)^2$. Therefore, Fourier-domain holography enables OCI to become background free in practice, and the signal-to-background ratio in Fourier-domain OCI improved by over 30 dB relative to image-domain OCI and hence allowed the imaging of weaker or thicker objects.

The full optical system for both photorefractive holography and digital holography is shown in Fig. 30.2. The low-coherence light source is either a mode-locked titanium-sapphire laser (nominal 100 fsec) or a superluminescent diode operating near 840 nm. This is passed through a half-wave plate and a polarizing beam splitter (PBS) to create the signal and reference arms of the Mach-Zehnder interferometer. The intensity ratio of the signal to reference arms is typically 10:1. The signal beam passes through a beam expander and illuminates the biological sample through a second polarizing beam splitter and quarter-wave plate. The returned signal is relayed to an image plane and is then Fourier transformed by lens L4 to the holographic plane. When a PRQW device is at the hologram plane, a physical hologram is recorded and the reconstruction is achieved through diffraction of the reference beam and Fourier transformation by lens L6 to the image plane of a digital camera. Alternatively, the digital camera can be placed at the hologram plane and reconstructed numerically.

A specialized capability for photorefractive holography using photorefractive quantum well (PRQW) devices is in speckle reduction. This is achieved by controlling the spatial coherence using a diffuser plate in the beam expander of Fig. 30.2. The diffuser and the steering mirror are vibrated by a piezo-stack at

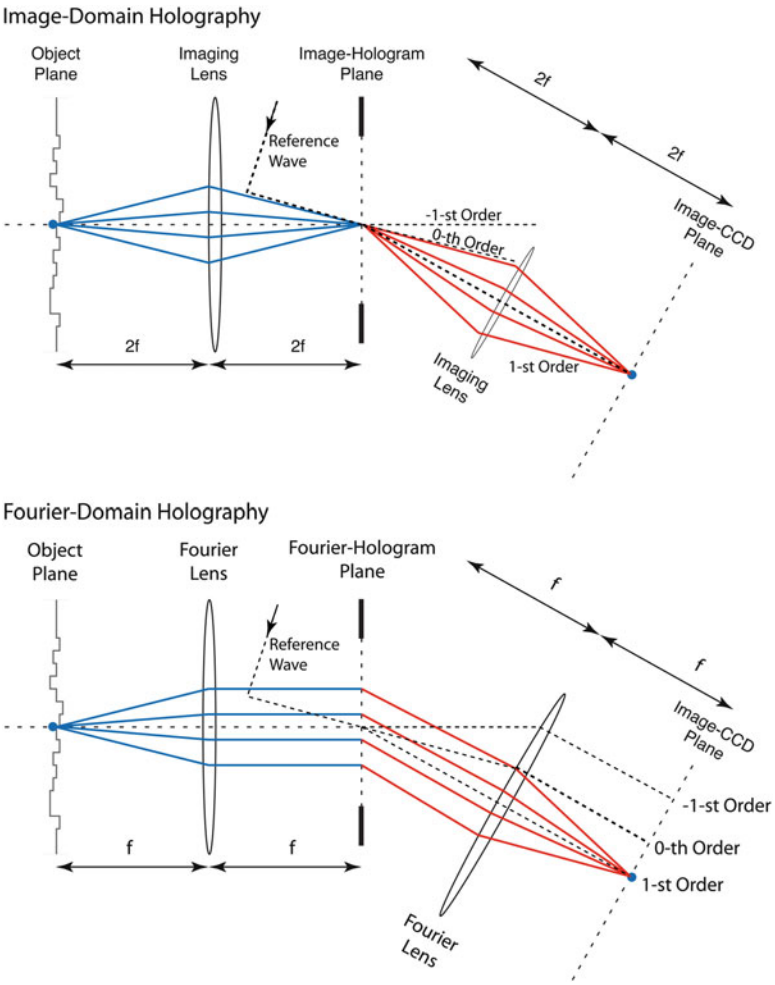

Fig. 30.1 Image-domain holography (*IDH*) vs. Fourier-domain holography (*IDH*). Image-domain holography places the holographic film at or near the image plane, while Fourier-domain holography places the holographic film at or near the Fourier plane (Note: FDH is based on spatial Fourier techniques and is not to be confused with spectral techniques)

a frequency near 100 Hz. The high-speed photorefractive device tracks the moving hologram fringes in real time, maintaining the diffraction that is the basis of the coherence gating, while the vibrating mirror and vibrating diffuser reduce speckle effects by time-averaging the holographic readout on the camera. These eliminate stray speckle and reduce channel cross talk [53]. Digital holography, on the other hand, cannot use these vibrating mirror or diffuser techniques because the fringes would wash out during the fringe motion. Therefore, photorefractive optical coherence imaging has the advantage of imaging internal structure over digital

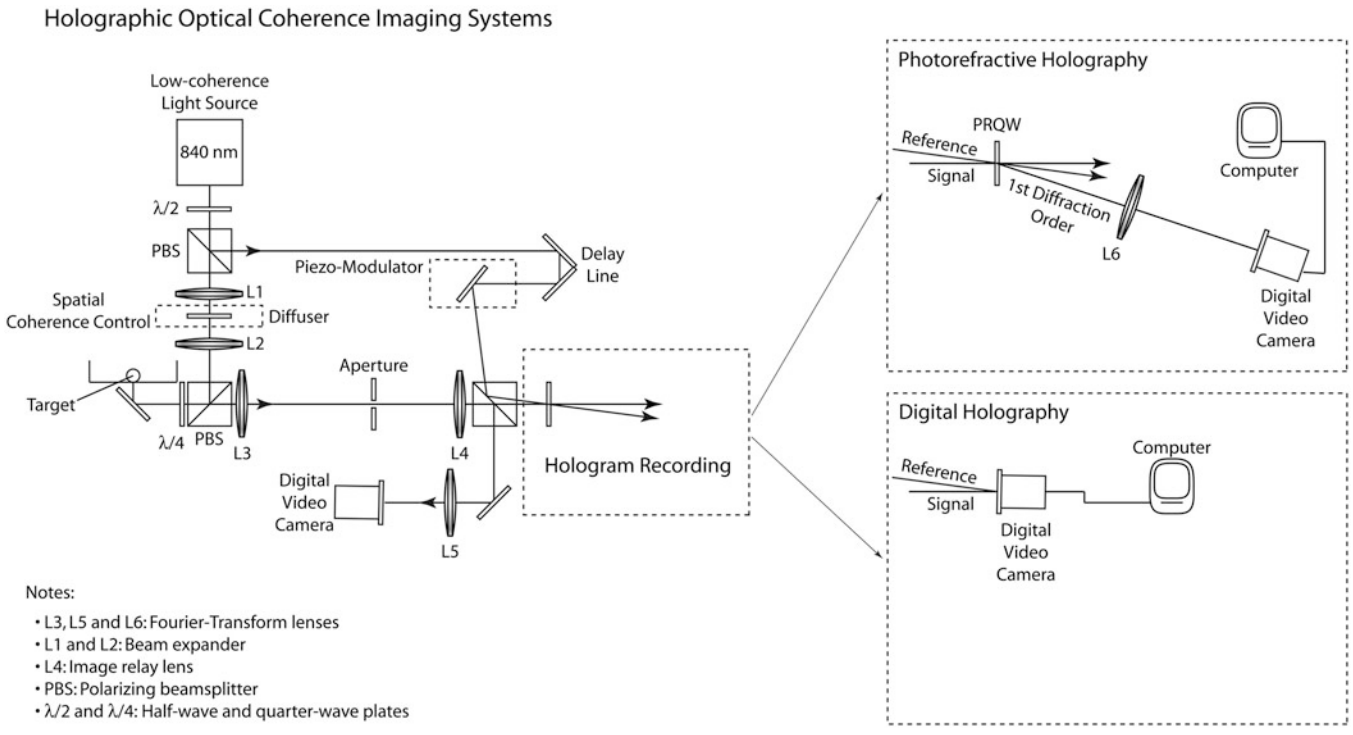

Fig. 30.2 Experimental schematic of the Fourier-domain holography system for photorefractive holography and digital holography. The holographic plane is at the Fourier plane of lens L4. The photorefractive quantum well (*PRQW*) records a physical hologram that is reconstructed by diffraction to a camera. Alternatively, a CCD chip records a digital hologram that is reconstructed by a FFT algorithm

holographic optical coherence imaging. Digital holography, on the other hand, has an advantage for dynamic speckle studies. Therefore, these two approaches to optical coherence imaging trade off between imaging structure and imaging dynamics.

30.3.3 Photorefractive Holography

Holographic OCI was initially developed using bulk photorefractive crystals and volume holograms [8], which were replaced with photorefractive semiconductor quantum well (PRQW) devices [16] because of their high sensitivity [2, 54]. These devices use molecular beam semiconductor growth processes to produce semiconductor structures that have enhanced optical properties based on quantum localization of electrons in very thin layers (7.5 nm). The enhanced optical properties make these devices sensitive dynamic holographic materials, with interferometric and imaging applications in laser-based ultrasound detection, femtosecond pulse processing, and interferometric bioassays, among others [16, 55–58].

Holographic OCI with PRQW devices uses the same short-coherence light sources as conventional OCT, including either pulsed laser sources or superluminescent diodes. For the PRQW devices, the probe wavelength of the source is at the absorption-edge wavelength of the semiconductor, which is typically $\lambda \approx 840$ nm.

The key performance parameters of the photorefractive quantum wells that are relevant for the OCI application are the minimum writing intensity, the fringe-spacing dependence, and the spectral bandwidth of the quantum well diffraction spectrum. The PRQW devices record fully developed holograms using intensities of only 10–20 $\mu W/cm^2$. The intensity dependence of wave mixing in a PRQW device is shown in Fig. 30.3a. The data are from two-wave mixing [15], showing fully developed gratings above 20 $\mu W/cm^2$. The fringe-spacing dependence is shown in Fig. 30.3b. The diffraction efficiency from four-wave mixing increases rapidly above a 5 μm fringe spacing. In speckle holography, a minimum of three fringes are needed per speckle to ensure a well-defined spatial carrier frequency. The 5 μm cutoff places a minimum speckle diameter at around 15 μm. Although speckle size is related to the lateral spatial resolution of the imaging optics, they are not identical, and in the case of Fourier-domain holography, they have an inverse relationship. The bandwidth of the diffraction spectrum is set by the inhomogeneous width of the quantum-confined excitons which is approximately 5 nm. Broader widths are possible through bandgap engineering, but Coulomb correlation effects prevent significantly broader bandwidths to be attained [59, 60].

30.3.4 Digital Holography

The discreteness of the pixels of a CCD or CMOS array sets limits on the resolution of off-axis digital holography. The interference fringes need to be well sampled by the

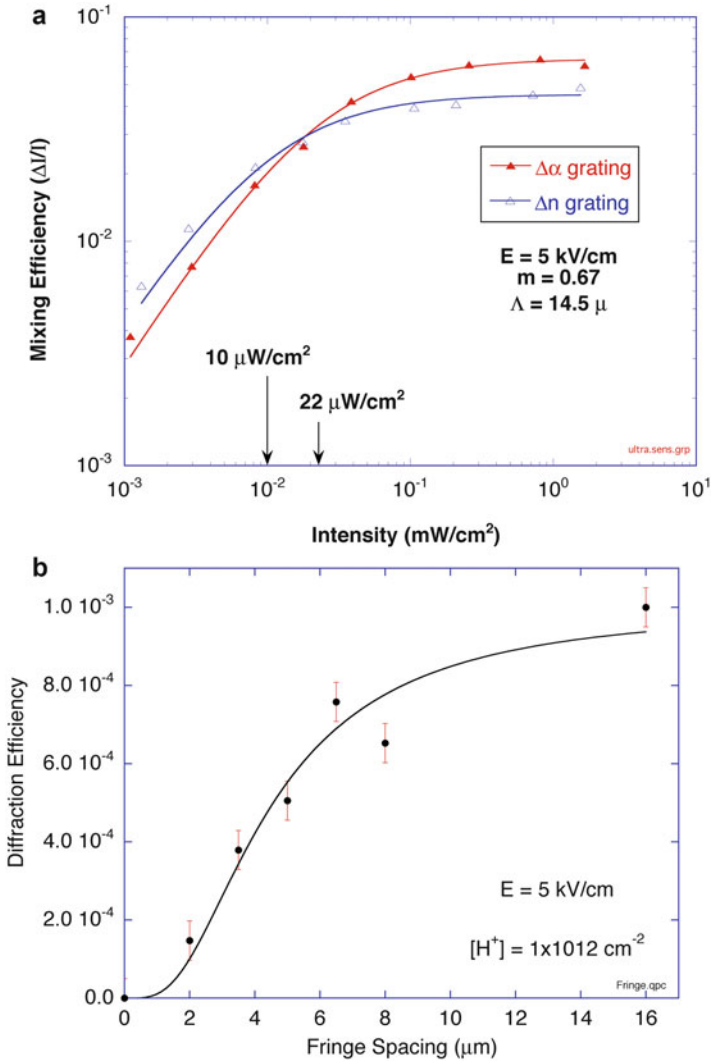

Fig. 30.3 Demonstration of the sensitivity of the holographic film in (**a**) shows a fully saturated holographic grating for an intensity of only 10–20 μW/cm^2. The fringe-spacing dependence in (**b**) shows a cutoff of 5 μm

discrete pixels, as shown in Fig. 30.4. Full resolution is predicted using Nyquist sampling theory, with two pixels per fringe spacing Λ and two fringes per speckle. However, a general rule of thumb for practical implementation is three pixels per fringe and three fringes per speckle. In other words, at the sensor plane, the condition

$$a_{speck} \approx 3\Lambda \approx 3\left(3\Delta x_{pix}\right) = 9\Delta x_{pix} \tag{30.3}$$

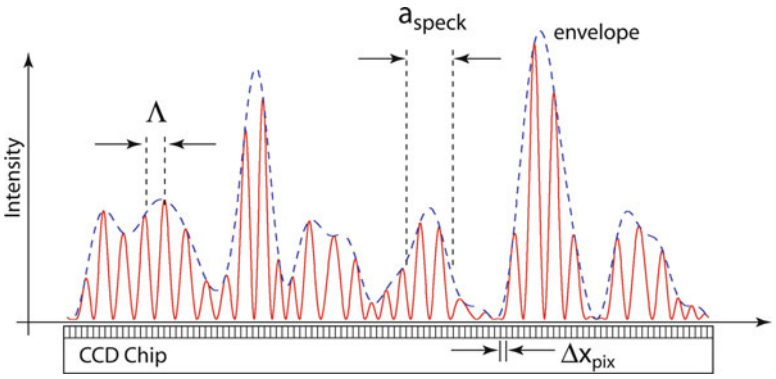

Fig. 30.4 Spatial variation of interference fringes and speckle envelope across a CCD chip. Optimum digital holography performance uses three interference fringes per speckle and three digital pixels per fringe

is nominal. These parameters are evaluated on the Fourier plane for Fourier-domain holography. The condition of the speckle size at the camera gives the magnification by lens L4 in Fig. 30.2 to be

$$M = \frac{9\Delta x_{pix}}{\frac{f_{Obj}\lambda}{D_{tum}}} \tag{30.4}$$

where f_{Obj} is the focal length of the objective lens and D_{tum} is the diameter of the tumor. The maximum angle that can be detected is set by the size of the CCD chip, placing a condition on the diameter of the camera detector area and the marginal aperture of the objective lens, through $D_{cam} = MD_{lens}$, giving another requirement for the magnification

$$M = \frac{D_{cam}}{D_{lens}} \tag{30.5}$$

Equating the two magnifications gives a resolution

$$\begin{aligned} \mathbb{R} &= 2\lambda \cdot f/\# \\ &= 18\Delta x_{pix}\frac{D_{tum}}{D_{cam}} \end{aligned} \tag{30.6}$$

where the resolution is independent of the characteristics of the objective lens.

30.4 Multicellular Tumor Spheroids

In vitro monitoring of tissue response to drugs is an area of strong interest to pharmaceutical companies [61]. Although the in vitro environment is artificial, the biochemistry, metabolism, and cell signaling response of cells grown as 3D constructs closely simulates in vivo tissue because three-dimensional cell cultures have active 3D intercellular signaling pathways that are often absent in 2D dish cultures. Therefore, in vitro experiments are a validated (and inexpensive) surrogate for in vivo response. The most common in vitro tissue cultures are multicellular spheroids. Multicellular spheroids of normal cells or neoplastic cells (tumor spheroids) are balls of cells that may be easily cultured up to 1 mm in size in vitro [62–67]. The spheroids can be used to simulate the optical properties of a variety of tissues such as the epidermis and various epithelial tissues and may be used to simulate the histological and metabolic features of small nodular tumors in the early avascular stages of growth [67]. Since the introduction of the concept of multicellular tumor spheroids in the early 70s [68], 3-D aggregates of permanent cell lines have offered a reliable model for systematic study of tumor response to therapy [65, 69].

Beyond a critical size (about 100 μm), most spheroids develop a necrotic core surrounded by a shell of viable, proliferating cells, with a thickness varying from 100 to 300 μm. The development of necrosis has been linked to deficiencies in the metabolites related to energy generation and transfer. The limiting factor for necrosis development is oxygen – the oxygen consumption and oxygen transport reflecting the status of the spheroid [63, 70]. Early work [71] launched the study of therapeutic strategies for cancer. The response to drug therapy was quantified from analysis of spheroid volume growth delay, increase in the necrotic area, and change in survival capacity. This work focused on hypoxia and its induction by chemical agents [72].

Tumor spheroids are cultured in a rotating bioreactor (Synthecon, Houston, TX) where they were maintained in suspension. The spheroids may be grown up to several mm in diameter and are thus large enough to simulate the thickness of different mammalian tissue (skin epidermis is 70–120 μm thick over most of the human body). An advantage to using this continuous culture model is that fresh spheroids of varying size are easily prepared on a daily basis. Overall, the tumor spheroids provide a reasonable tissue model that does not require special handling of animal subjects.

Electron microscopy sections of two types of tumor embedded in Toluidine-blue-stained epoxy resin and sectioned at 1 μm thickness are shown in Fig. 30.5. The tumors are nearly a millimeter in diameter, and each shares a common morphology. The outermost layers of the tumors have healthy, proliferating cells that form a shell from 100 to 200 μm thick. These cells are in close proximity to the nutrients and oxygen of the growth medium. This layer is structurally homogeneous and is optically homogeneous as well. Deeper inside the tumors, the cells become apoptotic because of nutrient deprivation and oxidative stress from the diffusion

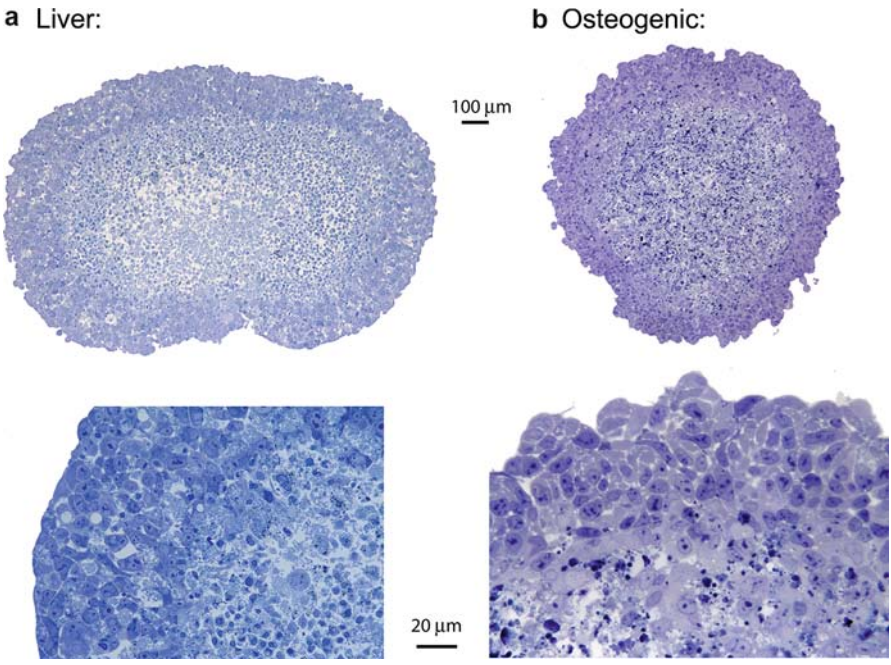

Fig. 30.5 Cross-sectional TEM micrographs of multicellular tumor spheroids consisting of (**a**) human liver and (**b**) rat osteogenic cells. The spheroids have an outer shell of healthy proliferating cells around a necrotic core. The higher magnifications at the *bottom* show the transitions from the shells to the cores

limitation of nutrients and oxygen into these avascular spheroids. The apoptotic cells give way, deeper in the tumor spheroids, to necrotic regions characterized by voids of extracellular debris or by microcalcifications, which are especially pronounced in the osteogenic spheroids. The core is structurally heterogeneous and is optically heterogeneous as well. Therefore the tumor spheroids have the general morphology of a healthy outer shell that tends to be homogeneous and a core of necrotic regions that are spatially heterogeneous.

Experimentally measured reduced scattering coefficients μ' of rat osteogenic tumor spheroids are on the order of 8 mm^{-1} to 15 mm^{-1}. There is a weak tumor size dependence to the extinction coefficient with decreasing extinction with increasing tumor size. The phase function for two tumors of slightly different diameter is shown in Fig. 30.6a. A tumor with a diameter of 416 μm is fit best with an anisotropy factor of $g = 0.9$, and a slightly larger tumor with a diameter of 484 μm is fit with a smaller factor of $g = 0.85$. Therefore, the rat osteogenic tumor spheroids are relatively translucent tumors with strong forward scattering. Maps of the optical densities of several tumors are shown in Fig. 30.6b, obtained using coherent heterodyne transmission interferometry.

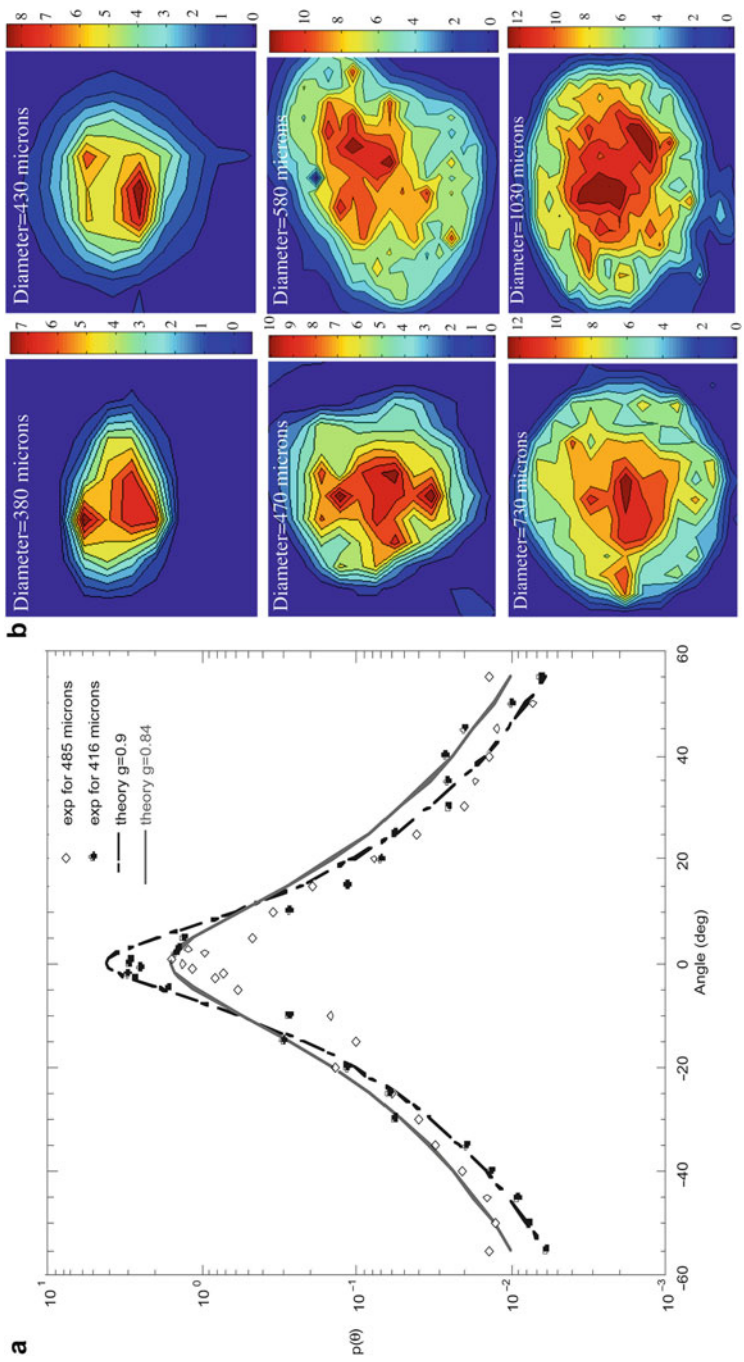

Fig. 30.6 Henyey-Greenstein phase function (**a**) and optical density maps (**b**). The HG functions were obtained using incoherent illumination in a forward-scattering arrangement. The optical densities were measured using coherent heterodyne detection of transmitted light

30.5 Photorefractive OCI of Tumor Spheroids

The principal acquisition mode for holographic imaging of tumor spheroids is called a "fly-through". In this mode, the reference mirror is stepped by 10 μm, several successive images are averaged on the CCD camera and downloaded to the computer, the mirror steps again, and the process reiterates. The raw data are stored in a volumetric data cube of en face sections at successive depths from the top of the tumor through the bottom of the tumor (that usually sits on the surface of a Petri dish). Selected en face (called XY) sections of a 400 μm diameter tumor are shown in (Fig. 30.7a) separated by 23 μm (approximately equal to the longitudinal coherence length). The top of the tumor is at frame 15, and the Petri dish appears in frame 66. The tissue gray scale is logarithmic in a range from −50 to −85 dB. Alternatively, the data cube can be viewed laterally, giving pseudo-B-scans (called YZ sections), shown in (Fig. 30.7b) for the same tumor on logarithmic scale. The Petri dish is at the bottom of each YZ section. The distance between the selected sections is 26 μm (approximately equal to the transverse optical resolution for this data). The reflected intensities are brightest in the necrotic core, with relatively weak reflections arising from the homogeneous healthy tissue shell.

The data for this tumor are visualized volumetrically in Fig. 30.8 for two selected threshold values of the isosurfaces. The left-hand figure has a low threshold and displays the full tumor volume with the Petri dish at the bottom. The right-hand figure has a high threshold to display only the brightest reflections from the tumor. The brightest features reside toward the center of the tumor, which is consistent with the necrotic core of the tumor spheroids. The necrotic core contains relatively large (10–20 μm) necrotic voids with extracellular debris as well as microcalcifications that are fairly pronounced in these osteogenic tumor spheroids. The heterogeneity of these internal structures are the likely source of the bright reflections that are localized internally to the tumor.

The dynamic range of holographic OCI is illustrated by selecting a set of A-scans from the volumetric data. These are shown in Fig. 30.9 on a logarithmic scale. The peak tissue reflectance is approximately −50 dB, and the noise floor is approximately −95 dB, providing a dynamic range through the tissue of 45 dB. The high reflection of the Petri dish is observed in these data at the depth of 400 μm. The initial rise of reflectance with increasing depth to about 150 μm, followed by a nearly linear (exponential) decrease with increasing depth, is consistent with an optically homogeneous healthy outer shell that produces weak reflectances, but with the strongest reflectances arising from the necrotic core. The absence of signal below the Petri dish is a signature of low channel cross talk. Multiply scattered light would appear to originate from greater depths. Therefore, if channel cross talk were significant in these tumors, a diffuse tail would have been present at depths below the Petri dish. This confirms the relatively low extinction and low multiple scattering of these osteogenic tumors.

A striking feature of the cross-section images in Fig. 30.7 is the speckled quality and the absence of specific structure. Fully developed speckle can arise

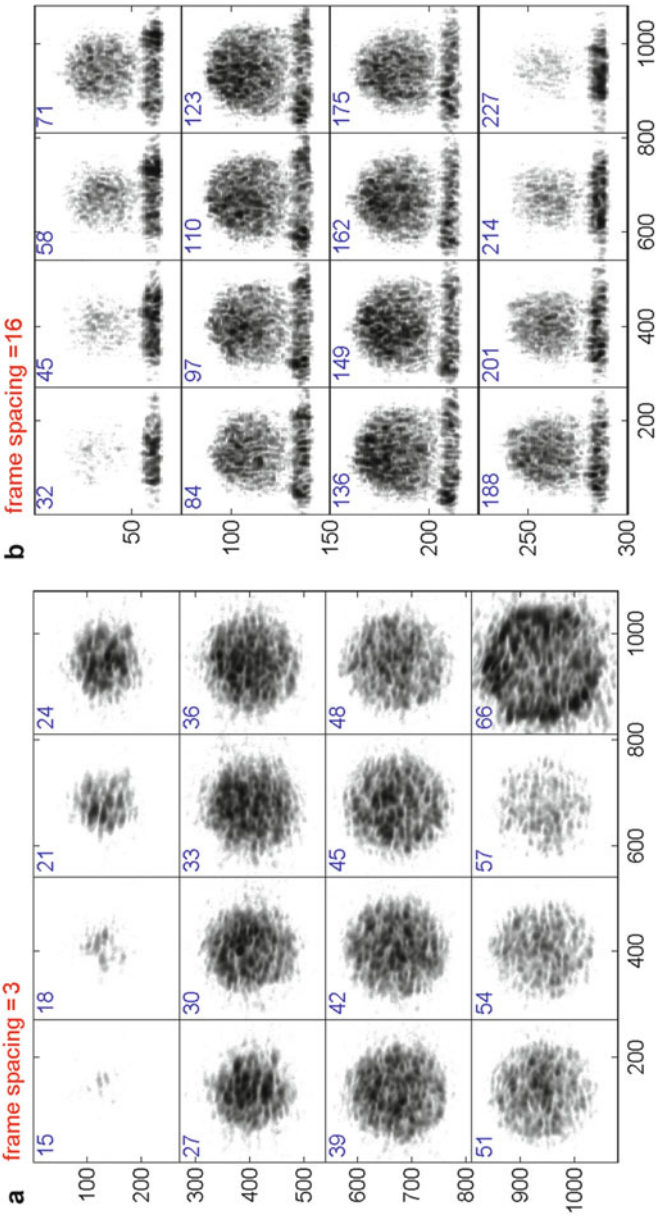

Fig. 30.7 Sections from a healthy rat tumor. Selected xy en face sections are shown in (**a**), and pseudo-B scans are shown in (**b**). The Petri dish reflection appears in frame 66 of the en face sections and at the *bottom* of the B-scan sections. The exposure time per frame was 0.5 s

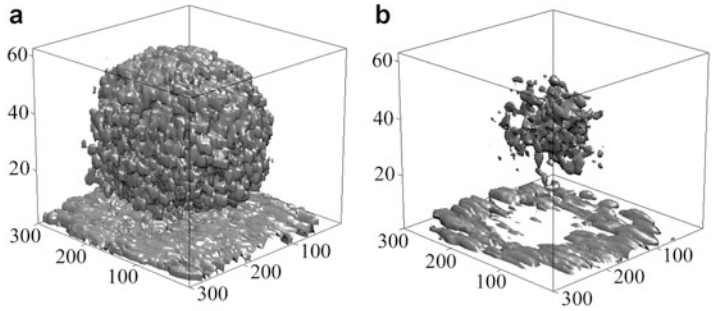

Fig. 30.8 Volumetric rendering of a tumor on a Petri dish. The image in (**a**) is the full isosurface, while in (**b**) a higher isosurface is shown. This illustrates the increasing intensity of reflections from the core of the tumor

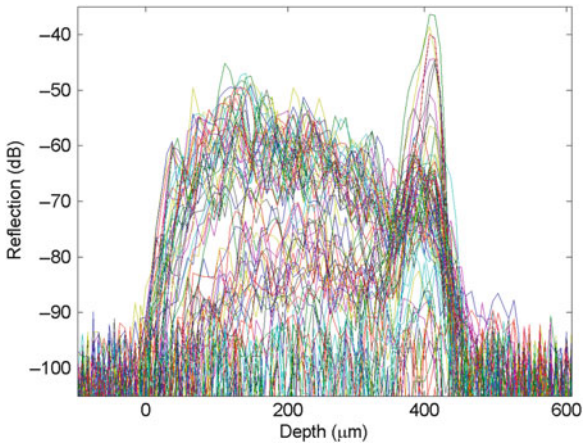

Fig. 30.9 Numerous A-scans of a tumor on a dB scale. The Petri reflection is at the *right*. The dynamic range of reflectivities from tissue is approximately 45 dB, showing the noise floor near −95 dB. The exposure time per frame was 2.5 msec

when the density of scatterers per modal volume is large, leading to a characteristic Poisson distribution of intensities with a speckle contrast of unity. Histograms of the intensity at several selected depths for a 560 μm diameter rat tumor are shown in Fig. 30.10. The histogram at a depth of 180 μm exhibits nearly perfect Poisson behavior, while the distributions from greater depths show a peak in the intensity probability. A fit of the 180 μm depth data to the Poisson distribution is shown in the inset of Fig. 30.10. The fit is good over two orders of magnitude and deviates only at the lowest intensities. Therefore, the intensity distribution at a depth of 180 μm shows fully developed speckle and hence no identifiable structure. On the other hand, the intensity distributions at deeper levels do show deviations, with well-defined maximum probabilities. This is indicative of specific structure, possibly arising from necrotic voids or microcalcifications within the core.

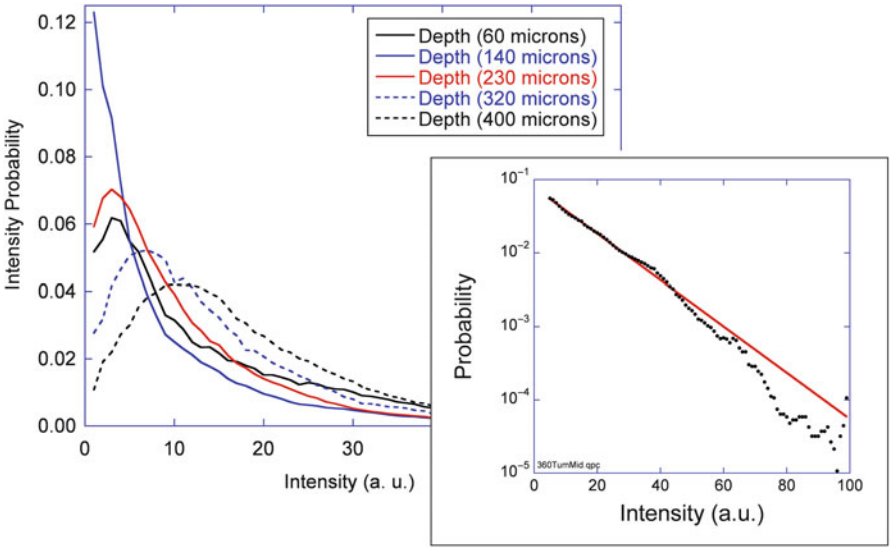

Fig. 30.10 Histograms of intensity distributions for increasing depth. The average intensity increases with depth. The inset is a log plot of the histogram from a depth of 180 μm, showing classic Poisson distribution behavior, signifying fully developed speckle from the healthy top shell of the tumor

30.6 Digital Holographic Optical Coherence Imaging

Digital holograms are captured on the Fourier plane with a small crossing angle between the optic axis of the signal arm and the reference beam. The acquisition exposure time is 10 msec. An example of a digital hologram of a tumor spheroid is shown in Fig. 30.11. The entire hologram is in Fig. 30.11a, and a magnification of a small area is shown in Fig. 30.11b with speckle modulating interference fringes. A line section is shown in Fig. 30.11c in which the interference fringes are difficult to distinguish from the speckle modulation. There is a high background, but these are outside the coherence envelope and do not generate periodic fringes. Because the holograms are acquired on the Fourier plane, a fast Fourier transform algorithm is sufficient to do the image reconstruction. A line section through the reconstruction is shown in Fig. 30.11d on a logarithmic scale. There is a DC spike and a zero-order ungated image at the center and two side bands that are the reconstructed coherence-gated images – a direct image and a phase conjugate.

Optical sections of a large millimeter diameter tumor spheroid are shown in Fig. 30.12 with a color scale in dB from −60 to −90 dB. Optical sections are taken every 10 μm, and only every eighth section is shown in the figure in steps of 80 μm. These data were taken with the illumination beam incident from the bottom of the transparent sample holder, and the coherence gate is moved successively higher into the spheroid. The midsection is around frame 64, showing high intensity

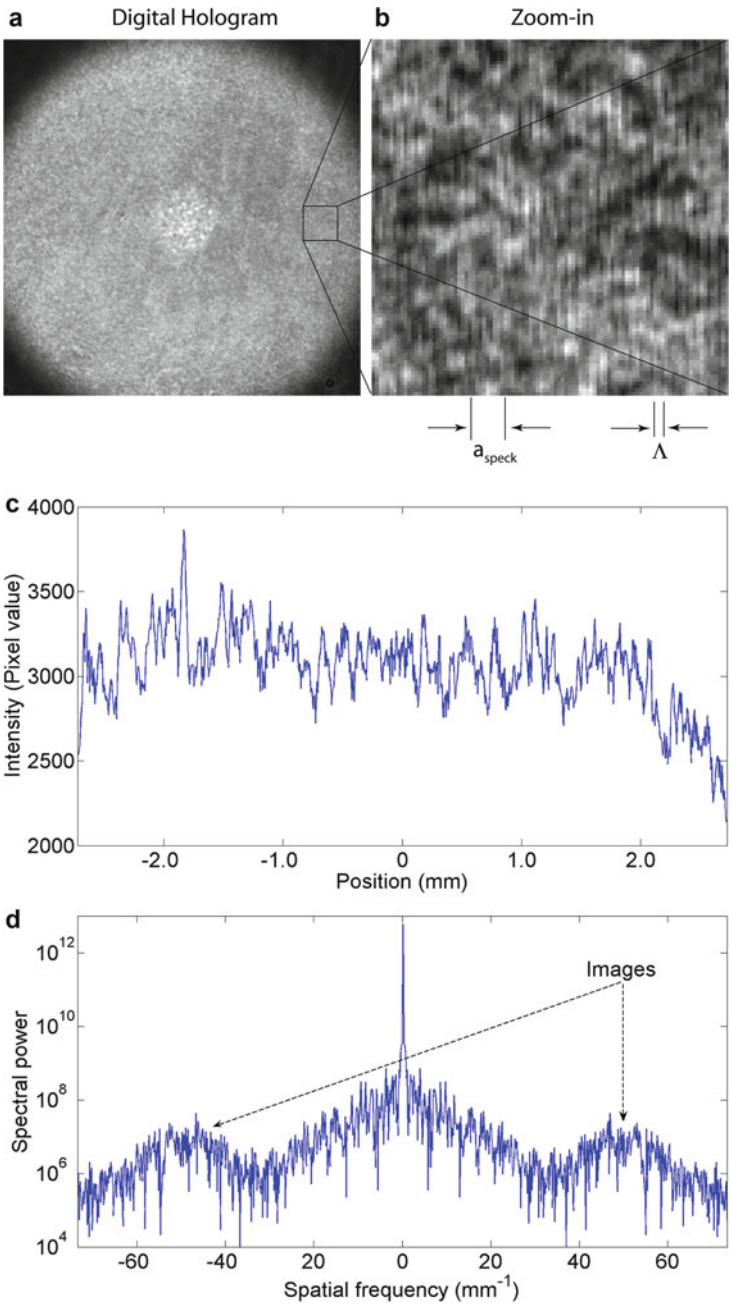

Fig. 30.11 (**a**) A full digital hologram. (**b**) a magnification of one region showing fringes modulated by speckle. (**c**) A line section through the hologram. (**d**) A line section through the Fourier reconstruction showing the image sidebands

reflectances from the core and relatively weaker reflectances from the proliferating shell that is more optical homogeneous. The data in Fig. 30.12 have a much finer speckle than the corresponding photorefractive data in Fig. 30.7. The broader applicability of digital holographic optical coherence imaging is demonstrated for a mouse eye in Fig. 30.13. The cornea, the iris, and the lens in the mouse eye are all discernable in the section that was extracted from a stack of en face sections [50].

Photorefractive and digital holography applied to optical coherence imaging are both en face coherence-gated formats. The relative advantages between photorefractive holography and digital holography trade off between biological structure and ease of use. The high-speed updating of photorefractive quantum wells allows the use of vibrating diffusers and reference mirrors to reduce spatial coherence (and hence reduce channel cross talk) and to time-average the reconstructed speckle (speckle reduction). Photorefractive holography also has the advantage that no computed reconstruction is needed. Digital holography, on the other hand, is simple and has become relatively inexpensive with improving performance of digital cameras at decreasing cost. However, typical frame speeds currently prevent the use of vibrating elements in the optical system, and digital holography of biological tissues is highly speckled. Although high-contrast speckle

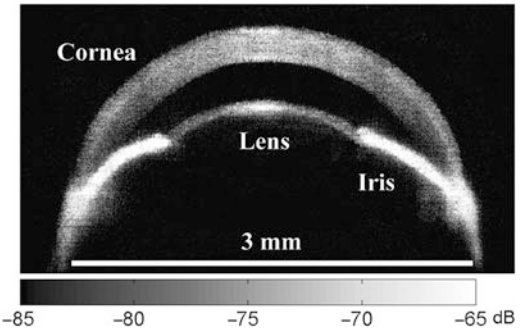

Fig. 30.13 Section of a mouse eye that is constructed from a stack of en face sections acquired with digital holography

carries little structural information of tissue, it does carry a high information content related to the dynamics within the tissue, leading to optical coherence imaging applications that use intracellular motions as a novel form of imaging contrast [51, 52, 73–75], which is the topic of ▶ Chap. 37, "Motility Contrast Imaging and Tissue Dynamics Spectroscopy" in this volume.

31.1 Introduction

The trade-off between transverse resolution and depth-of-field, and the mitigation of optical aberrations, are long-standing problems in optical imaging. The deleterious impact of these problems on three-dimensional tomography increases with numerical aperture (NA), and so they represent a significant impediment for real-time cellular resolution tomography over the typical imaging depths achieved with OCT. With optical coherence microscopy (OCM) [1], which utilizes higher-NA optics than OCT, the depth-of-field is severely reduced [1, 2], and it has been

postulated that aberrations play a major role in reducing the useful imaging depth in OCM [3]. Even at lower transverse resolution, both these phenomena produce artifacts that degrade the imaging of fine tissue structures. Early approaches to the limited depth-of-field problem in time-domain OCT utilized dynamic focusing [4]. In spectral-domain OCT, this focus-shifting approach to data acquisition leads to long acquisition times and large datasets [5]. Adaptive optics (AO) has been utilized to correct optical aberrations, in particular for retinal OCT [6–8], but in addition to requiring elaborate and expensive setups, the real-time optimization requirements at the time of imaging, and the correction of spatially varying effects of aberrations throughout an imaged volume, remain as significant challenges. This chapter presents computed imaging solutions for the reconstruction of sample structure when imaging with ideal and aberrated Gaussian beams. These post-acquisition methods are based on the ability of an OCT system to infer the complex scattered field and make use of a physics-based forward model to describe the "imaging operation" and thus connect the measured signal to the sample structure. Inversion of this forward model to recover the object structure is referred to as inverse scattering.

The complexity of the solution to the inverse scattering problem for OCT is increased by the fact that data acquisition is typically performed using 2D (rather than 3D) beam scanning. When 3D scanning of the point spread function is performed over the object volume,[1] such as in the case of OCT with dynamic focusing [4], a quantitative (band limited) reconstruction of the object can be obtained through straightforward 3D deconvolution. In practice, due to time constraints on data acquisition, only two-dimensional (transverse) beam scanning is performed, i.e., with the focus depth fixed. Consequently, the acquired three-dimensional signal can be written as a two-dimensional (transverse) convolution of the point spread function with the object structure, with a third dimension that is indexed by optical wavenumber.

Interferometric synthetic aperture microscopy (ISAM) [9–12] is a solution to the inverse scattering problem for OCT that utilizes Fourier-domain resampling of the signal. The ISAM Fourier resampling provides a band-pass filtered version of the 3D Fourier transform of the sample structure. This solution to the inverse scattering problem was called *ISAM* in recognition of the similarities between far-from-focus OCT and synthetic aperture radar (SAR).[2] Given these similarities, it is not surprising that object reconstruction in ISAM can be performed via the method of aperture synthesis in SAR.[3]

Computational adaptive optics (CAO) provides post-acquisition aberration correction through a connection between the aberrated forward model and the

[1] Similar to acquisition of a *z*-stack in confocal microscopy

[2] Both measure time of flight while sequentially illuminating the object over a range of angles (see Section 31.2.3 for further details relating an illumination wave vector to the wave vector of the collected scattering).

[3] The ISAM Fourier-domain resampling relationship is known in SAR as the Stolt mapping.

pupil function modified by hardware-based AO [13]. The presence of aberrations modifies the forward model utilized for ISAM reconstruction. In particular, certain aberrations require spatially dependent reconstruction, such as the depth-dependent artifacts introduced by spherical aberration [13]. The solution of this more general forward model requires additional computation for full-volume reconstructions. Computational AO can be utilized with OCT processing to correct aberrations near the optical focus, or it can be combined with ISAM to extend the aberration-corrected reconstruction far from focus.

This chapter is divided into two main parts: the first deals exclusively with ISAM (Sects. 31.2 and 31.3), and the second deals with CAO for OCT and ISAM (Sect. 31.4). In addition to summarizing key theoretical aspects and the experimental validation of these methods, the key ISAM resampling result is understood within the context of the Ewald sphere formalism used in diffraction tomography (Sect. 31.2.2). Furthermore, ISAM and CAO are compared to other related techniques (Sect. 31.5), such as numerical refocusing in digital holographic microscopy. This section also discusses the general applicability of these computed imaging methods to other system geometries, such as in holoscopy, that acquire interferometric data over a broad optical bandwidth. In the latter sections, the phase stability requirements and practical limitations are discussed (Sects. 31.6 and 31.7). Finally, a summary and outlook is presented discussing the impact that these computed imaging techniques hold for the future of broadband optical interferometric tomography.

31.2 ISAM Theory

31.2.1 Forward Model

This section provides a summary of the derivation of ISAM for the far-from-focus regime where the effects of defocus are most significant. This is derived for a standard OCT imaging geometry based on Cartesian beam scanning [9, 14]. The near-focus result is included in the final forward model at the end of this section without proof. The near-focus forward model contains relatively minor differences from the far-from-focus model, and the reader is referred to Ref. [15] for further details of the derivation. Although the treatment below is presented for scalar optical fields, the theoretical framework of ISAM is also valid for large numerical aperture setups where the vector nature of optical fields is significant [15].

We begin with the three-dimensional dispersion-corrected complex analytic signal, $S(x, y; k)$, acquired through two-dimensional transverse scanning of the incident focused beam along the x- and y-axes, with the third dimension indexed by optical wavenumber k. This signal can be written as a convolution of the (complex) system point-spread function (PSF), $h(x, y, z; k)$, with the scattering potential $\eta(x, y, z)$ [15, 16]

$$S(x, y; k) = \iiint h(x - x', y - y', z'; k)\eta(x', y', z')\ dx'dy'dz'. \tag{31.1}$$

Due to a double-pass (reflection imaging) geometry in OCT, the system PSF, $h(x, y, z; k) = \mu_r k^2 |P(k)|^2 g^2(-x, -y, z; k)$ [15], is defined in terms of a product of the complex incident and (identical) collection beam $\sqrt{\mu_r} k |P(k)| g(x, y, z; k)$. The optical power spectral density is denoted by $|P(k)|^2$ and μ_r determines the interferometric (power) splitting ratio. Without loss of generality, the axial coordinate origin $z = 0$ is set at the nominal (aberration-free) beam focus, with the z-axis oriented in the propagation direction of the incident beam. (The physical significance of the *transverse* coordinate inversion in the definition of $h(x, y, z; k)$ in terms of $g(-x, -y, z; k)$ is related to the 3D (vector) spatial frequency support of the instrument, $\mathbf{Q}_{\text{range}}$, such that $\mathbf{Q}_{\text{range}} \subseteq -2\mathbf{k}_{\text{range}}$, where $\mathbf{k}_{\text{range}}$ is the range of optical wave vector components of the focused beam. A coordinate inversion along the *axial* dimension can be found in Eqs. 31.6 and 31.9 below. The relationship between the incident optical wave vector $\mathbf{k}$ and the detected object spatial frequency $\mathbf{Q}$ is also discussed in Sect. 31.2.3.) By invoking the convolution theorem, we can write Eq. 31.1 in the transverse spatial frequency domain as

$$\tilde{S}(Q_x, Q_y; k) = \int \tilde{h}(Q_x, Q_y, z'; k) \; \tilde{\eta}(Q_x, Q_y, z') \; dz', \tag{31.2}$$

where the tilde (˜) denotes the two-dimensional (2D) transverse Fourier transform and $\tilde{h}(Q_x, Q_y, z; k)$ encodes the (depth-dependent) transverse band-pass response of the effective PSF.

In order to simplify Eq. 31.2, let us consider a plane wave decomposition of the focused optical beam [15, 17] and write

$$g(x, y, z; k) = \frac{-i}{2\pi} \iint \frac{G(Q_x, Q_y; k)}{k_z(Q_x, Q_y)} \exp\{i[Q_x x + Q_y y + k_z(Q_x, Q_y) z]\} \; dQ_x dQ_y, \tag{31.3}$$

where $G(Q_x, Q_y; k)$ is the pupil function of the beam (see Sect. 31.4.2 for further details). The integration limits are over the aperture of the objective lens, but since the optical field is taken to be zero outside this aperture, the limits of the integration can be extended to infinity, and the above equation can be equated with an inverse Fourier transform. The complex exponential term is written in terms of the optical wave vector $\mathbf{k} = (k_x, k_y, k_z)$ corresponding to each plane wave component, where $k_x = Q_x$, $k_y = Q_y$, and $k_z(Q_x, Q_y) = \sqrt{k^2 - Q_x^2 - Q_y^2}$. For an ideal Gaussian beam, $G(Q_x, Q_y; k)$ is a real Gaussian weighting. Computing the transverse Fourier transform of Eq. 31.3 results in

$$\tilde{g}(Q_x, Q_y, z; k) = -i2\pi \frac{G(Q_x, Q_y; k)}{k_z(Q_x, Q_y)} \exp[ik_z(Q_x, Q_y) z]. \tag{31.4}$$

The complex exponential term can be recognized as the angular spectrum propagator [18] that can be utilized to propagate the optical field by a given distance z.

Substitution of $z = 0$ provides the plane wave coefficients of the optical field at the beam focus. Notice the constant phase factor of $-i$ relating $\tilde{g}(Q_x, Q_y, 0; k)$, the angular spectrum at focus, to the pupil function $G(Q_x, Q_y; k)$. This can be attributed to the Gouy phase shift associated with a focused beam [19], which results in a $\pi/2$ phase retardation of the focused beam (relative to a plane wave) upon propagation from the objective lens to the beam focus.

Taking into account the double-pass detection geometry, we can make use of Eq. 31.4 and the convolution theorem to express the (transverse) transfer function of the system PSF in Eq. 31.2 as

$$\tilde{h}(-Q_x, -Q_y, z; k) = -4\pi^2 \mu_r k^2 |P(k)|^2 \iint \frac{G\left(Q'_x, Q'_y; k\right)}{k_z\left(Q'_x, Q'_y\right)} \frac{G\left(Q_x - Q'_x, Q_y - Q'_y; k\right)}{k_z\left(Q_x - Q'_x, Q_y - Q'_y\right)} \times \exp\left\{-i\left[k_z\left(Q'_x, Q'_y\right) + k_z\left(Q_x - Q'_x, Q_y - Q'_y\right)\right] z\right\} dQ'_x \, dQ'_y. \tag{31.5}$$

This form for $\tilde{h}(-Q_x, -Q_y, z; k)$ allows us to make an approximation for the far-from-focus case. When $|k_z|$ is large, the integrand in Eq. 31.5 rapidly oscillates due to the complex exponential term. The method of stationary phase [20] can be used to approximate the right-hand side of Eq. 31.5 at the stationary points of the oscillating phase. Using the stationary point at $(Q'_x, Q'_y) = (Q_x/2, Q_y/2)$ [15], the method of stationary phase gives

$$\tilde{h}(-Q_x, -Q_y, z; k) \approx \frac{i4\pi}{-z} \mu_r k |P(k)|^2 G^2\left(\frac{Q_x}{2}, \frac{Q_y}{2}; k\right) \exp\left[-i2k_z\left(\frac{Q_x}{2}, \frac{Q_y}{2}\right) z\right]. \tag{31.6}$$

Note that this expression, derived for large $|k_z|$, decouples the amplitude and phase contributions to the transverse transfer function of the system. A coordinate inversion over the axial and transverse dimensions is evident from inspection of the expressions for the system PSF and the optical beam (cf. Eqs. 31.6 and 31.4). Apart from a slowly varying factor of $-1/z$, which represents the signal decay with distance from focus, the characteristic depth dependence of the system PSF is captured by the complex exponential term. Most importantly, it is the *phase* variation across the transverse frequency bandwidth that is responsible for the apparent degradation of resolution with increasing distance from focus.

The usefulness of the far-from-focus approximation in Eq. 31.6 becomes apparent when substituted into the forward model in Eq. 31.2:

$$\tilde{S}_F(Q_x, Q_y; k) = H_F(-Q_x, -Q_y; k) \int \frac{\tilde{\eta}(Q_x, Q_y, z')}{-z'} \exp\left[-i2k_z\left(\frac{Q_x}{2}, \frac{Q_y}{2}\right) z'\right] dz'$$
$$\text{with} \qquad H_F(-Q_x, -Q_y; k) = i4\pi\mu_r k |P(k)|^2 G^2(Q_x/2, Q_y/2; k), \tag{31.7}$$

where $H_F(-Q_x, -Q_y; k)$ is the far-from-focus band-pass response of the instrument, and we have used the fact that $k_z(-Q_x/2, -Q_y/2) = k_z(Q_x/2, Q_y/2)$. Note that the forward model is now in the form of a Fourier transform with space and frequency variables of z' and $2k_z(Q_x/2, Q_y/2)$, respectively.

In order to provide a forward model applicable to both near- and far-from-focus regimes, we note that a separate near-focus approximation results in a forward model that has the same form as Eq. 31.7, but with a slightly different (near-focus) band-pass response $H_N(Q_x, Q_y; k)$ and without the $-1/z'$ attenuation factor in the integrand [15]. The main difference between $H_F(Q_x, Q_y; k)$ and $H_N(Q_x, Q_y; k)$ is a factor of i resulting from the Gouy phase shift and a slowly varying real (amplitude-only) function of the arguments Q_x, Q_y, and k (see Eqs. 42 and 43 in Ref. [15] for the full expressions). For utility in evaluation, an *attenuated scattering potential* can be defined as

$$\widetilde{\eta}'(Q_x, Q_y, z) = \rho(z)\widetilde{\eta}(Q_x, Q_y, z), \tag{31.8}$$

where $\rho(z) = -1/z$ when far from focus and $\rho(z) = 1$ when near focus, where the transition point between the two regimes occurs at one Rayleigh range [15]. This now allows us to write the forward model for both the near- and far-from-focus regimes in the frequency domain as

$$\begin{aligned} \tilde{S}(Q_x, Q_y; k) &= H(-Q_x, -Q_y; k)\widetilde{\widetilde{\eta}}'(Q_x, Q_y, Q_z), \\ \text{with} \quad Q_z &= -2k_z\left(\frac{Q_x}{2}, \frac{Q_y}{2}\right) = -2\sqrt{k^2 - (Q_x/2)^2 - (Q_y/2)^2}, \end{aligned} \tag{31.9}$$

where $\widetilde{\widetilde{\eta}}'(Q_x, Q_y, Q_z)$ is the 3D Fourier transform of the attenuated scattering potential. The instrument transfer function is then $H(Q_x, Q_y; k) = H_N(Q_x, Q_y; k)$ when within one Rayleigh range of the focus, and $H(Q_x, Q_y; k) = H_F(Q_x, Q_y; k)$ otherwise. Note that this reduces the many-to-one mapping in Eq. 31.2 to a one-to-one mapping between the Fourier (spatial frequency) domain of the object and the Fourier domain of the signal. Inherent in this mapping is the coordinate warping relating the Fourier coordinates of the object, (Q_x, Q_y, Q_z), to the Fourier coordinates of the signal, $(Q_x, Q_y; k)$. Also note that for an ideal Gaussian beam, the instrument transfer function is symmetrical, i.e., $H(-Q_x, -Q_y; k) = H(Q_x, Q_y; k)$. The functional form of the required coordinate warping $Q_z = -2k_z(Q_x/2, Q_y/2)$ was originally developed in the field of geophysics [12, 21] and is known as the Stolt mapping.

Before we discuss the inverse scattering procedure, it is worth pointing out the operator description of the forward model [22]:

$$\tilde{S}(Q_x, Q_y; k) = K\ \widetilde{\widetilde{\eta}}'(Q_x, Q_y, Q_z), \tag{31.10}$$

where the operator K maps from the vector space representation of the object to the vector space of the signal. The observed (discrete) signal will generally be noisy and band limited, resulting in an inverse problem that is ill-conditioned and possibly ill-posed. Since the inverse K^{-1} is not expected to exist, it is appropriate to compute the solution $\tilde{\tilde{\eta}}^{+}\left(Q_x, Q_y, Q_z\right)$ that minimizes $\left\|\tilde{S} - K\,\tilde{\tilde{\eta}}^{+}\right\|$, where $\| \bullet \|$ denotes the $l_2(\mathbb{R}^2)$ norm. This solution can be written as

$$\tilde{\tilde{\eta}}^{+} = (K^{*}K)^{-1}K^{*}S = K^{+}S, \tag{31.11}$$

where K^{+} is the pseudoinverse of K, K^{*} is the adjoint of K, $K^{*}K$ is the normal operator, and $(K^{*}K)^{-1}$ is the inverse of $K^{*}K$ restricted to the orthogonal complement to the null space. The operators K and K^{*} affect the coordinate transformation in Eq. 31.9, i.e., between the coordinate systems $(Q_x, Q_y; k) \leftrightarrow (Q_x, Q_y, Q_z)$, and the normal operator acts as a space-invariant filter.

31.2.2 Inverse Scattering Procedure

The following provides a procedure for inverting the signal model in Eq. 31.9. These steps include the full procedure to obtain a quantitatively accurate reconstruction of the scattering potential. In practice, however, it is common to omit steps 2 and 5 below since they do not produce a significant qualitative improvement to the reconstruction. In this problem the normal operator is approximately diagonal, and so it is useful to compute the *unfiltered* solution $\eta_A = K^{*}S$. The advantage of this approach using the adjoint operator is that stable solutions are obtained (without the need for regularization). The full pseudoinverse (with appropriate regularization) is more susceptible to noise, but results in a more localized PSF with reduced width. The required steps for ISAM (corresponding to the unfiltered solution η_A) are highlighted in bold:

1. **Take the transverse Fourier transform of the complex interferometric (phase stable) signal** $S(x, y; k)$**, to get the Fourier-domain data** $\tilde{S}\left(Q_x, Q_y; k\right)$.
2. Apply a linear filter, i.e., Fourier-domain multiplication of $\tilde{S}\left(Q_x, Q_y; k\right)$ and a transfer function, in order to compensate for the (ideal spatially invariant) transfer function of the instrument $H(Q_x, Q_y; k)$. In practice, the slowly varying effects of the instrument band-pass response obtained when imaging with an ideal Gaussian beam are usually ignored, i.e., $H(Q_x, Q_y; k)$ is set to unity.
3. **Remap the coordinate space of** $\tilde{S}\left(Q_x, Q_y; k\right)$ **according to the Stolt mapping in Eq. 31.9. This crucial step is the basis of the computational efficient reconstruction provided by ISAM and can be performed through resampling** k **to** Q_z**, i.e., by evaluating** $\tilde{S}\left(Q_x, Q_y; k\right)$ **at the desired values of** Q_z **using** $k = \frac{1}{2}\sqrt{Q_x^2 + Q_y^2 + Q_z^2}$. This resampling "rephases" the transverse spatial frequencies (for each given value of Q_z) to produce constructive

interference across the bandwidth simultaneously for all depths (see the ISAM resampling curve in Fig. 31.6).
4. **Take the inverse Fourier transform to recover $\rho(z)\eta(x, y, z)$, the attenuated scattering potential.**
5. A quantitatively accurate map of the scattering potential $\eta(x, y, z)$ can be computed by dividing by $\rho(z)$ to compensate for signal loss away from the focus. This step is commonly omitted or replaced with other depth normalization methods.

Note that it may also be necessary to add preprocessing steps to account for material dispersion and to compensate for phase instabilities in the instrument. See Sect. 31.6.1 for the requirements on phase stability.

31.2.3 Relationship to Diffraction Tomography

Similarities between the OCT forward model and diffraction tomography[4] have been recognized in the comprehensive review paper by Fercher et al. [23]. In this section, we will see how these commonalities can be used to determine the ISAM resampling relationship in Sect. 31.2.1, Eq. 31.9.

Figure 31.1 shows the geometry of a far-from-focus scattering event, where $\mathbf{k}_{in}$ and $\mathbf{k}_{out}$ are the wave vectors of the plane wave components of the incident and scattered field, respectively. Recall from Eq. 31.3 that an arbitrary field can be expressed as a superposition of plane wave components. These wave vectors satisfy the scattering vector relationship:

$$\mathbf{Q} = \mathbf{k}_{out} - \mathbf{k}_{in}, \tag{31.12}$$

where $\mathbf{Q}$ is the three-dimensional spatial frequency of the sample that is probed. This vector relationship is a consequence of momentum conservation. For a given $\mathbf{k}_{in}$, the (far-field) placement of the detector in diffraction tomography provides access to spatial frequencies that lie on a sphere with radius k, known as the *Ewald sphere of reflection* [24].

For an OCT system, the angular relationship between the incident and scattered wave vectors is governed by the specific imaging geometry. Consider scattering from the far-from-focus scatterer in Fig. 31.1, i.e., in the regime where the correction of defocus is required most. Figure 31.1c presents a simple geometrical optics argument describing why the angular detection range of scattering vectors is constrained to a narrow solid angle centered about the $-\mathbf{k}_{in}$ direction. This acceptance angular range of the OCT imaging geometry reduces with increasing distance from focus, so that in the far-from-focus limit,

$$\mathbf{k}_{out} = -\mathbf{k}_{in}. \tag{31.13}$$

[4]Through the basic theorem of diffraction tomography

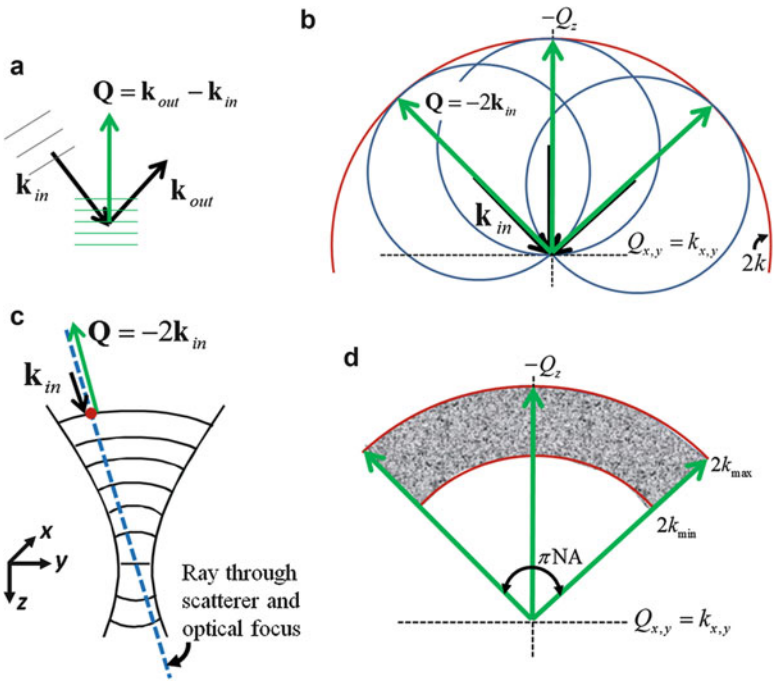

Fig. 31.1 Description of scattering in the far-from-focus regime using the Ewald sphere formalism utilized in diffraction tomography, and the resulting spatial frequency bandwidth of the instrument. (**a**) Scattering geometry showing the relationship between object spatial frequency Q (*green vector*) and the optical wave vectors k_{in} and k_{out} (*black vectors*) for the plane wave components of the incident and scattered fields, respectively. (**b**) Ewald spheres (*blue circles* with radius *k*) corresponding to three different incident wave vectors (*black vectors*), showing the spatial frequency coverage resulting from the detection of all scattering angles as well as the particular spatial frequency detected through the measurement of direct backscattering (*green vectors*). The spatial frequency coverage resulting from the measurement of direct backscattering is given by the limiting Ewald sphere (*red circle* with radius 2*k*). (**c**) Geometrical optics argument limiting the collection of scattered light from far-from-focus scatterers to direct backscattering. (**d**) Far-from-focus spatial frequency coverage of an OCT system. Note that although the bandwidth limits of the instrument are drawn as sharp cutoffs, the magnitude of the instrument transfer function is better approximated along each dimension by a Gaussian-shaped function

Consequently, as the beam is scanned transversally along the *x*- and *y*-axes during data acquisition, the angle of the effective illumination wave vector (which is perpendicular to the incident wavefront of the illumination beam) is scanned, resulting in the sequential acquisition of sample spatial frequencies from far-from-focus object structure. In contrast, for a scatterer at the optical focus, the full range of scattering angles is detected simultaneously.

The essential physics of the far-from-focus ISAM resampling result can thus be captured by substituting Eq. 31.13 into Eq. 31.12:

$$\mathbf{Q} = -2\mathbf{k}_{in}, \tag{31.14}$$

with $|\mathbf{Q}| = 4\pi/\lambda$. This implies that the sample spatial frequencies that are acquired by varying the angle of the illumination lie on a sphere of radius $2k$, known as the *Ewald limiting sphere* [24]. Note that Eq. 31.14 is equivalent to Eq. 2.10 in the paper by Fercher et al. [23]. However, rather than restricting the discussion to direct backscattering that is parallel to the z-axis (i.e., one-dimensional low-coherence interferometry (LCI), with $Q_z = -2k$ and $Q_x = Q_y = 0$), the ISAM result becomes accessible by considering the detection of backscattering corresponding to all illumination angles within the NA of the imaging system, i.e., where $\mathbf{k}_{in}$ spans over the solid angle of illumination. Maintaining this angular diversity in the incident (and antiparallel backscattered) wave vectors, calculation of the magnitude squared of the vectors in Eq. 31.14 yields $Q_x^2 + Q_y^2 + Q_z^2 = 4k^2$, which can be rearranged to give

$$Q_z = -2\sqrt{k^2 - (Q_x/2)^2 - (Q_y/2)^2}, \tag{31.15}$$

which is the ISAM coordinate mapping in Eq. 31.9. Note that the negative sign of the square root was chosen to be consistent with the direction of the backscattering vector $-\mathbf{k}_{in}$ (see Fig. 31.1c). The coordinate mapping in Eq. 31.15 which relates the frequency coordinate of the signal, k, to axial spatial frequency of the object, Q_z, is the basis of the key resampling step in Sect. 31.2.2 for reconstructing far-from-focus object structure with ISAM.

31.3 Experimental Demonstration and Validation

31.3.1 Resolution Phantom

Tissue phantoms consisting sub-resolution "point" scatterers provide a sample for the investigation of resolution in OCT and ISAM. Three-dimensional imaging was performed on a silicone tissue phantom laced with titanium dioxide scatterers, with mean diameter of 1 μm. Imaging was conducted using an 800 nm spectral-domain (SD)-OCT system with 100 nm bandwidth, at an $NA \sim 0.05$ (confocal parameter of 239 μm). Figure 31.2 shows a side-by-side visualization of the OCT and ISAM reconstructions obtained from the same raw dataset. The OCT dataset begins to show transverse blurring at a distance of 240 μm from focus, with increased blurring with distance from focus. In contrast, the ISAM reconstruction provides spatially invariant transverse resolution over a depth exceeding nine Rayleigh ranges. These results provided the first experimental demonstration that ISAM was able to correct defocus simultaneously for all depths.

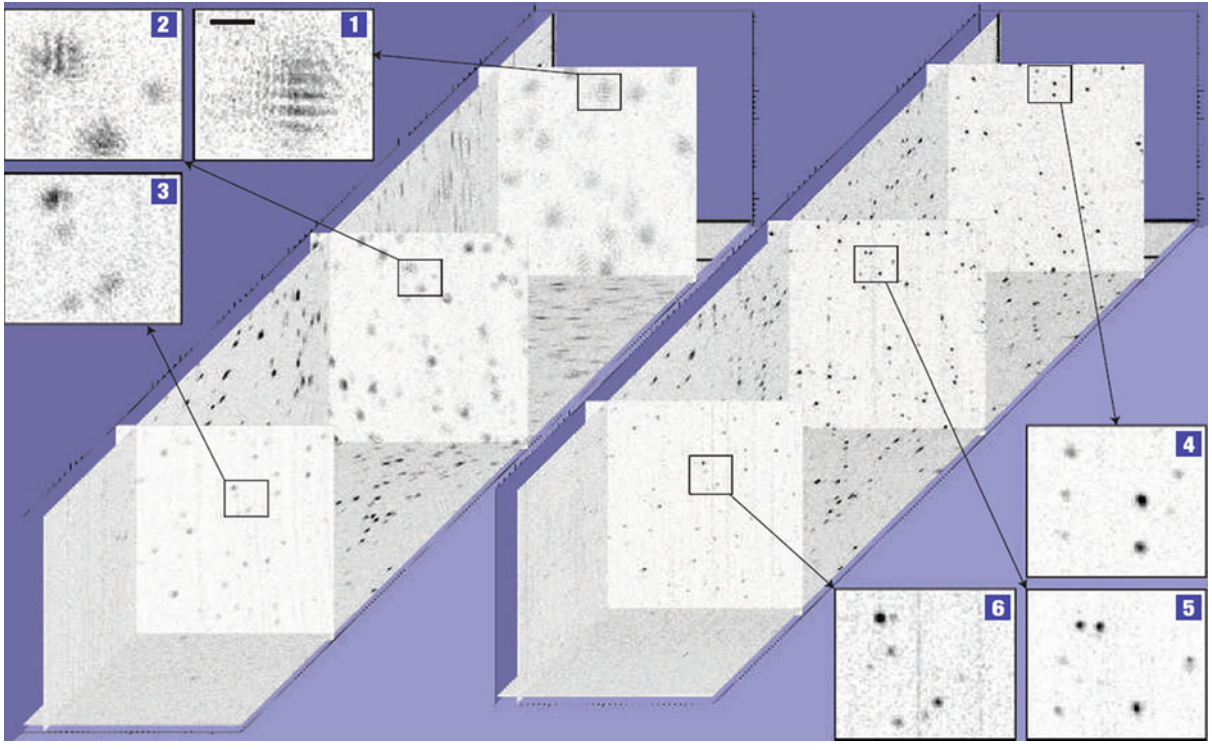

Fig. 31.2 Three-dimensional OCT (left) and ISAM (right) images of a silicone phantom containing titanium dioxide microparticles. The three en face planes in each dataset correspond to (*1*) $z = 1{,}100$ μm, (*2*) $z = 475$ μm, and (*3*) $z = -240$ μm, where $z = 0$ μm is the focal plane. The images were generated from a single 3D dataset acquired using an 800 nm SD-OCT system at an imaging NA of 0.05 (From [9])

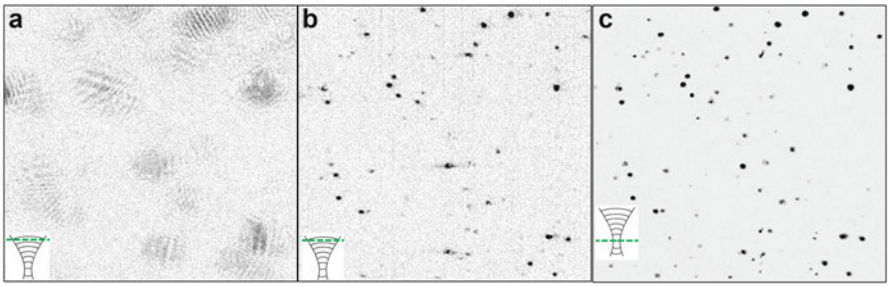

Fig. 31.3 Cross-validation of ISAM and in-focus OCT in a silicone phantom containing titanium dioxide microparticles. (**a**) En face OCT from 3.75 Rayleigh ranges above the focus and (**b**) the same en face plane extracted from the 3D ISAM reconstruction. (**c**) In-focus OCT obtained by shifting the beam focus to the same depth as in (**a**) and (**b**). The inset in the *lower left* of each panel shows the relative depths of the displayed en face planes with respect to the beam focus. The two datasets were acquired using an 800 nm OCT system with an $NA \sim 0.05$ (Adapted from [25])

31.3.2 Cross-Validation with OCT

It is obvious from Sect. 31.3.1 that ISAM provides significant improvements in resolution in the far-from-focus regime. But does three-dimensional ISAM accurately reconstruct the object structure? This question was addressed by comparing specific en face planes extracted from 3D ISAM reconstructions to in-focus OCT images of the same plane. In a sparse tissue phantom (see Fig. 31.3), the resolution and scatterer positions in an en face ISAM image are in excellent agreement to in-focus OCT of the same plane, demonstrating that ISAM provides an accurate reconstruction of the object. It should be noted that the signal-to-noise ratio (SNR) of the in-focus OCT is higher. This can be attributed to the increased light collection efficiency at the focal plane of the optical system, due to the $1/|z|$ depth dependence in the forward model describing the away-from-focus signal (see Eqs. 31.8 and 31.9). The improved signal collection at focus is the reason to place the object near the focus. In practice, the focus is positioned at approximately 50–75 % of the maximum imaging depth in a given sample.

For biomedical imaging applications it is important to confirm the reconstruction accuracy of ISAM in biological tissue. Figure 31.4 presents results of rat mammary tissue, once again comparing a specific en face plane extracted from 3D ISAM reconstructions to the in-focus OCT image of the same plane. Close agreement between structural features of tissue is seen between the far-from-focus ISAM reconstruction and the in-focus OCT. As with the phantom results, the in-focus OCT demonstrates higher SNR, resulting in better definition of structural features with weak signals. Additionally, since the acquisition rate was relatively low (0.6 frames/s), uncorrected phase instabilities may also result in degraded definition of weak signals. Sections 31.6 and 31.7 discuss the relevant data acquisition requirements, limitations of ISAM, and practical methods to address these limitations.

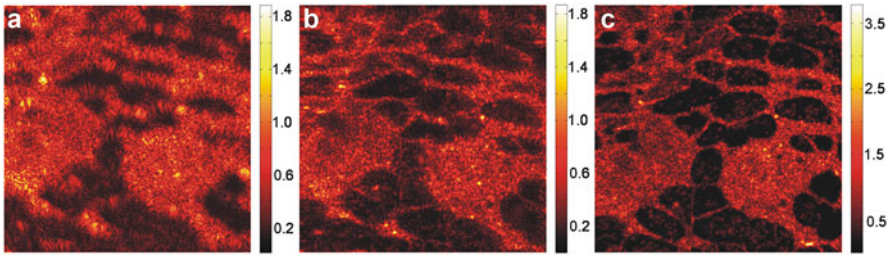

Fig. 31.4 Cross-validation of ISAM and in-focus OCT in rat mammary tissue. (**a**) En face OCT from eight Rayleigh ranges above the focus and (**b**) the same en face plane extracted from the 3D ISAM reconstruction. (**c**) In-focus OCT obtained by shifting the beam focus to the same depth as in (**a**) and (**b**). The datasets were acquired using an 800 nm OCT system with $NA \sim 0.1$ (From [25])

31.3.3 Validation of ISAM with Histology

Histological analysis is the gold standard for diagnosing the pathological status of tissue. Thus, in order to test the accuracy of reconstruction in tissue, ISAM of resected human breast tissue was performed and compared to histology. Imaging was performed using an OCT system with 800 nm central wavelength and 100 nm bandwidth, with a focused beam numerical aperture of 0.05. Figure 31.5 shows a volumetric ISAM rendering and selected en face sections from near- and far-from-focus regions. The en face ISAM sections clearly provide improved resolution compared to OCT, over an extended depth-of-field. Tissue structure reconstructed by ISAM shows a close correspondence to histology, demonstrating that ISAM provides anatomically accurate reconstructions of biological tissue. This suggests that ISAM could be applied for high-resolution "optical biopsy" over a large imaging depth, as compared to OCM.

31.4 Computational Adaptive Optics

31.4.1 Aberrated Forward Model

The forward model in Eq. 31.9, which forms the basis of ISAM, is essentially space invariant. Apart from a gradual depth-dependent amplitude variation (the main contribution being the $1/z$ signal decay with distance from focus), and a gradual through-focus variation of the (Gouy) phase, the transfer function of the instrument, $H(Q_x, Q_y; k)$,[5] is space invariant. Spatially invariant resolution has been clearly demonstrated for ISAM reconstructions of data acquired with (near ideal) Gaussian

[5]The minus signs on the coordinates (Q_x, Q_y) have been dropped, since, for an ideal Gaussian beam, the instrument transfer function $H(-Q_x, -Q_y; k) = H(Q_x, Q_y; k)$. For the aberration correction filter in Section 31.4.2, Hermitian symmetry applies, i.e., $H_{AC}(Q_x, Q_y; k) = H^*_{AC}(-Q_x, -Q_y; k)$.

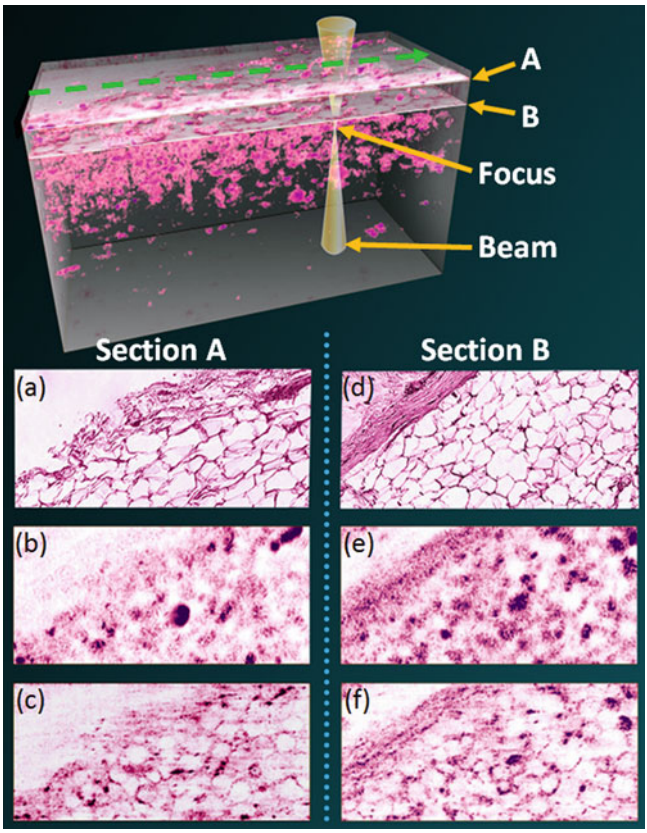

Fig. 31.5 Three-dimensional ISAM of resected human breast tissue compared with histology. En face images are shown for depths located at 643 μm (Section A) and 591 μm (Section B) above the focal plane. (**a**, **d**) Histological sections show comparable features with respect to the (**b**, **e**) OCT data and (**c**, **f**) the ISAM reconstructions. The ISAM reconstructions resolve features in the tissue which are not decipherable from the OCT data. To acquire this 3D dataset, the beam was raster scanned in the geometry shown at the *top* (*dashed green arrow*) (Adapted from [9])

beams [9, 15, 16, 25]. However, for an aberrated Gaussian beam, the ISAM reconstruction can produce a spatially varying point spread function, as seen, for example, by the asymmetry about the focus that is introduced by spherical aberration [13].

The effect of aberrations can be incorporated through a generalization of the forward model in Eq. 31.9. This approach considers the impact of aberrations as an extra (space-variant) filtering step in the forward model. In the general case, the effect of aberrations can have a dependence on all three spatial coordinates. This coupling between the space and frequency domains leads to an aberrated forward model that is defined in a piecewise manner over the spatial domain. This three-dimensional space-dependent imaging operation was considered by Frieden, who

introduced the concept of an *isotome* [26], or volume of stationarity $V(x_0, y_0, z_0)$ centered at position (x_0, y_0, z_0). The term isotome is a generalization of the term *isoplanatic patch* used in astronomical adaptive optics to denote the angular range over which a wavefront correction with hardware-based adaptive optics is valid [27]. The *isotomic volume* is then the region of space over which the 3D imaging operation can be considered space invariant. When restricted to one such isotome, the aberrated forward model can be written as

$$\tilde{S}_A(Q_x, Q_y; k)\big|_{V(x_0, y_0, z_0)} = H_A(Q_x, Q_y, x_0, y_0, z_0; k) H(Q_x, Q_y; k) \widetilde{\widetilde{\eta}}'(Q_x, Q_y, Q_z), \tag{31.16}$$

where $H_A(Q_x, Q_y, x, y, z; k)$ represents the extra (space-dependent) filtering step and $\widetilde{\widetilde{\eta}}'(Q_x, Q_y, Q_z)$ is the axial Fourier transform of the modified scattering potential defined in Eq. 31.8. In the general case, a different forward model of the signal may be required to describe the signal at different spatial locations.

In practice, space invariance in the transverse dimension is achieved over a relatively wide field of view, and Eq. 31.16 can be written for a slab volume geometry, $V(z_0)$, centered at depth z_0 as

$$\tilde{S}_A(Q_x, Q_y; k)\big|_{V(z_0)} = H_A(Q_x, Q_y, z_0; k) H(Q_x, Q_y; k) \widetilde{\widetilde{\eta}}'(Q_x, Q_y, Q_z). \tag{31.17}$$

For the special case when the effects of particular aberrations are space invariant, $V(x_0, y_0, z_0)$ is equal to the complete volume acquired, and Eq. 31.16 reduces to

$$\tilde{S}_A(Q_x, Q_y; k) = H_A(Q_x, Q_y; k) H(Q_x, Q_y; k) \widetilde{\widetilde{\eta}}'(Q_x, Q_y, Q_z), \tag{31.18}$$

where $H_A(Q_x, Q_y; k)$ is an additional filtering step in the ISAM forward model of Eq. 31.9. When imaging with an ideal Gaussian beam, the instrument transfer function, $H(Q_x, Q_y; k)$, is slowly varying and can be ignored in practice. However, the phase distortions that aberrations induce across the bandwidth of the signal cannot be ignored since they can result in severe broadening of the point spread function or modify its functional form (i.e., to exhibit non-Gaussian structure).

31.4.2 The Computed Pupil and Hardware-Based AO

Computational adaptive optics is based on the Fourier optics result connecting the objective lens pupil function that is physically modified by hardware-based AO systems to the Fourier transform of the complex optical field at the nominal (aberration-free) focus. The objective lens pupil function, $P(x, y)$, describes the

deviation of the aberrated optical wavefront from an ideal spherical wavefront. It is related to the focal-plane transverse frequency response of the illumination beam according to [18]

$$\tilde{g}\left(Q_x, Q_y, 0; k\right) = P\left(\frac{-2\pi z_f Q_x}{k}, \frac{-2\pi z_f Q_y}{k}\right), \tag{31.19}$$

where z_f is the (object-side) focal length of the objective lens and the coordinate change $(x, y) = (-2\pi z_f Q_x/k, -2\pi z_f Q_y/k)$ provides the mapping between transverse spatial frequency and the spatial coordinates of the objective lens pupil. As done in Ref. [18], a prefactor of $2\pi A z_f/k$ in the right-hand side of Eq. 31.19 has been set to unity. The pupil phase aberration, Φ_g, is included in the generalized pupil function [18]

$$P(x, y) = P_{\text{ideal}}(x, y)\exp\left[ik\Phi_g(x, y)\right], \tag{31.20}$$

where $P_{\text{ideal}}(x, y)$ for a typical OCT system is a real Gaussian envelope. Since the ideal beam focus is the impulse response of the (single-pass) imaging system, $\tilde{g}\left(Q_x, Q_y, 0; k\right)$ can be regarded as the (transverse) amplitude transfer function [18]. Making use of Eqs. 31.4 and 31.19, the transverse Fourier domain of the aberrated OCT PSF may be written in terms of the objective lens pupil function as

$$\tilde{g}\left(Q_x, Q_y, z; k\right) = i2\pi P\left(\frac{-2\pi z_f Q_x}{k}, \frac{-2\pi z_f Q_y}{k}\right)\exp\left[ik_z\left(Q_x, Q_y\right)z\right], \tag{31.21}$$

where the phase of the pupil function, Φ_g (x, y), can conveniently be expressed as a sum of Zernike polynomials [14, 28], as is commonly done to represent aberrations in optical systems.[6]

Due to the double-pass (epi-illumination) imaging geometry, the OCT PSF is related to the square of the optical beam [15, 16]. A *computed pupil* is defined here as the convolution of the pupil functions (see Eq. 31.5) that are physical modified by hardware-based AO. Note that this definition of the computed pupil uses the exact expression for the PSF, i.e., before the asymptotic approximations made by ISAM. This is important since the convolution operation (of phase-only pupil functions) can produce depth-dependent amplitude and phase structure in the transverse Fourier domain that is not preserved after the asymptotic approximations, such as that far-from-focus approximation in Eq. 31.6. In particular, depth-dependent amplitude structure in the transverse Fourier domain of the PSF, $\tilde{h}_A\left(Q_x, Q_y, z; k\right)$, was found to contribute to the asymmetry about the beam focus when imaging with a beam that has spherical aberration [13].

[6]Since the Zernike polynomials are defined on a unit circle, *normalized* spatial coordinates are employed.

Aberrations of the computed pupil are described by an aberration filter, $H_A(Q_x, Q_y; k)$, which are calculated as the deviation of the computed pupil function from its ideal functional form:

$$H_A(Q_x, Q_y, z_0; k) = \frac{\tilde{h}_A(Q_x, Q_y, z_0; k)\tilde{h}^*(Q_x, Q_y, z_0; k)}{\left|\tilde{h}(Q_x, Q_y, z_0; k)\right|^2 + \alpha} = \frac{\left[\tilde{g}_A(Q_x, Q_y, z_0; k) \bigotimes_{\|} \tilde{g}_A(Q_x, Q_y, z_0; k)\right]\left[\tilde{g}(Q_x, Q_y, z_0; k) \bigotimes_{\|} \tilde{g}(Q_x, Q_y, z_0; k)\right]^*}{\left|\tilde{g}(Q_x, Q_y, z_0; k) \bigotimes_{\|} \tilde{g}(Q_x, Q_y, z_0; k)\right|^2 + \alpha}, \tag{31.22}$$

where $\bigotimes_{\|}$ denotes a convolution over the transverse spatial frequency coordinates, the asterisk $(*)$ denotes the complex conjugate, α is a regularization constant, and the transverse Fourier transform of the aberrated optical field, $\tilde{g}_A(Q_x, Q_y, z_0; k)$, can be evaluated using Eqs. 31.20 and 31.21. Intuitively, this definition provides the deviation of the actual phase fronts of the OCT PSF from the ideal (unaberrated) phase fronts. In addition, it should be noted that due to the Fourier-domain amplitude structure that can result from the convolution operation mentioned in the paragraph above, in general $\left|\tilde{h}_A(Q_x, Q_y, -z; k)\right| \neq \left|\tilde{h}(Q_x, Q_y, -z; k)\right|$. An aberration correction filter can be calculated by inverting the effects of $H_A(Q_x, Q_y, z_0; k)$. Although this calls for a (potentially space-variant) regularized inverse, this step can be approximated through the use of a simpler phase-only aberration correction filter [14]:

$$H_{\mathrm{AC}}(Q_x, Q_y; k) = \exp\left[-ik\Phi_h\left(-2\pi z_f Q_x/k, -2\pi z_f Q_y/k\right)\right], \tag{31.23}$$

where the PSF phase aberration $\Phi_h(x, y)$, defined here in the spatial coordinate system of the objective lens pupil, can be calculated from a convolution of the pupil functions as

$$\Phi_h\left(\frac{-2\pi z_f Q_x}{k}, \frac{-2\pi z_f Q_y}{k}\right) = \arg\left\{\left[P\left(\frac{-2\pi z_f Q_x}{k}, \frac{-2\pi z_f Q_y}{k}\right) \otimes_{\|} P\left(\frac{-2\pi z_f Q_x}{k}, \frac{-2\pi z_f Q_y}{k}\right)\right]\right\}. \tag{31.24}$$

Equations 31.23 and 31.24 thus provide the connection between the objective lens pupil function $P(x, y)$, the phase of which is physically modified in hardware AO, and the filtering operation used to correct aberration effects at the nominal focal plane of an OCT tomogram. For correction of the depth-dependent aberration effects implied in Eqs. 31.17 and 31.22, see the space-variant aberration correction steps shown in Fig. 31.6.

The aberration correction filter $H_{\mathrm{AC}}(Q_x, Q_y; k)$ is based on the concept of a generalized 3D pupil [29] and so can correct both monochromatic and chromatic aberration [15, 30]. Correcting chromatic aberration is relevant to broadband

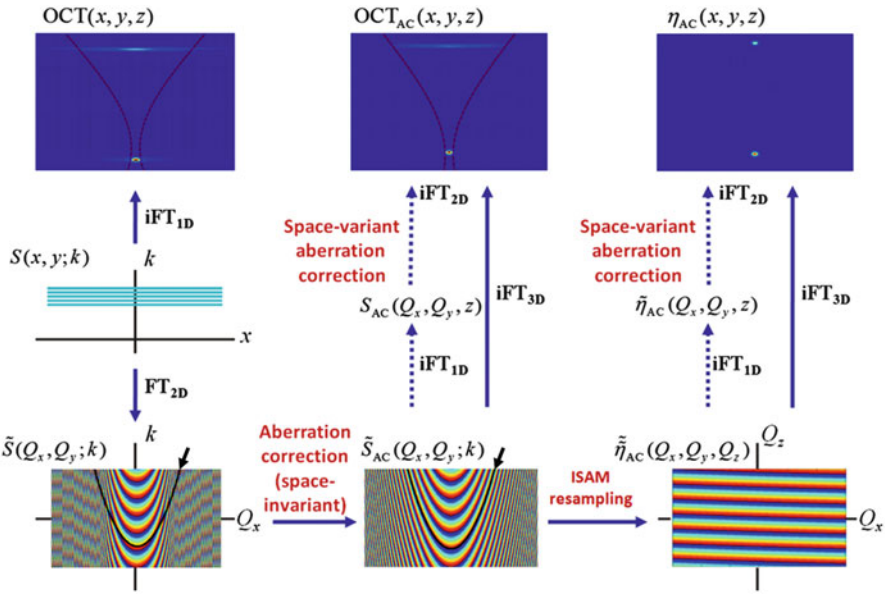

Fig. 31.6 Overview of CAO processing for OCT or ISAM. *Bolded blue arrows* denote processing steps for space-invariant aberration correction, while the *dashed blue arrows* indicate the steps enabling space-variant aberration correction (i.e., at specific en face depths). See the text for definition of the variables. The *dashed red curves* in the $\mathrm{OCT}(x, y, z)$ and $\mathrm{OCT}_{\mathrm{AC}}(x, y, z)$ images represent one transverse scan position of the incident optical beam with respect to the two-scatterer sample. Frequency domain images in the bottom row represent the phase profiles associated with the out-of-focus scatterer, with an ISAM resampling curve (corresponding to a fixed value of Q_z) superimposed in *black* and highlighted by *black arrows* (From [14])

imaging systems since it manifests both as longitudinal (along the z-axis) and transverse blurring. In the absence of chromatic aberration, the k-dependence of the 3D aberration correction filter is a simple scaling of the monochromatic aberration function. The presence of chromatic aberration however results in more complex 3D pupil phase functions. This filtering operation which corrects chromatic aberration is a generalization of numerical dispersion correction in OCT [31, 32]. Numerical dispersion correction in OCT is a one-dimensional correction applied independently to each A-scan, whereas chromatic aberration also has a dependence on the transverse pupil coordinate [30].

31.4.3 Computational AO for Broadband Interferometric Tomography

This section provides an overview of how CAO can be utilized. The reference to *broadband interferometric tomography* is intended to indicate the general applicability of CAO for correcting aberrations in the numerous imaging

geometries and system designs that acquire interferometric data over a broad optical bandwidth, for the purposes of tomography, such as spectral-domain OCT, swept-source OCT, full-field OCT, and holoscopy [33]. In particular, the connection between aberrations of the objective lens pupil (the phase of which is physically adjusted using AO hardware) and deviations from the ideal instrument response in the Fourier domain of the tomogram is generally applicable to broadband interferometric data. The main requirement of phase stability is discussed in Sect. 31.6.1.

Figure 31.6 presents an overview of how CAO can be combined with OCT to correct aberrations near the optical focus, or how it can be combined with ISAM to extend the aberration-corrected reconstruction far from focus. ISAM is based on the fact that defocus in the spatial domain manifests as a coordinate warping in the Fourier domain of the signal. This result, governed by the physics of data acquisition, relates the 3D FT of the complex OCT tomogram to the 3D FT of the object structure through the Stolt mapping. Reconstruction via ISAM resampling (see black curve superimposed in the Fourier domain corresponding to a given value of Q_z) corrects defocus by restoring constructive interference across the transverse bandwidth for all depths simultaneously.

Aberrations disrupt the ideal phase behavior in the Fourier domain, and the ISAM resampling does not result in constructive interference across the transverse bandwidth (see ISAM resampling curve in the bottom left image of Fig. 31.6). The effects of the aberrations can be deconvolved using the aberration correction filter, to restore the expected phase profile across the transverse band (see ISAM resampling curve in the central image at the bottom row of Fig. 31.6). The aberration correction filter $H_{\mathrm{AC}}(Q_x, Q_y; k)$ in Eq. 31.24 provides a space-invariant correction throughout the volume. In general, the effects of aberrations will be depth-dependent and can be corrected using the space-invariant aberration correction pathways in Fig. 31.6, by making use of two-dimensional aberration correction filters $H_{\mathrm{AC}}(Q_x, Q_y; z_0)$ at a given depth of z_0. This can be accounted for in computational AO by performing separate corrections for the space-invariant and space-variant effects.

31.4.4 Resolution Phantom Results

Figure 31.7 shows volumetric data from a silicone phantom laced with titanium dioxide microparticles. The 3D dataset was acquired with a highly astigmatic beam. Astigmatism was generated with a plano-convex cylindrical lens, of focal length f = 1,000 mm, positioned between the collimator and galvanometers of the sample arm. The nominal aberration-free optics in the sample arm had an $NA \sim 0.1$. Because of this astigmatism, the microparticles do not look like points in the OCT volume, but demonstrate two orthogonal and axially separated line foci, with the plane-of-least-confusion between them. The computed pupil correction was calculated from Eqs. 31.23 and 31.24, i.e., as the convolution of astigmatic pupil functions. The phase aberration of the pupil function, Φ_{g}, was expressed as a linear

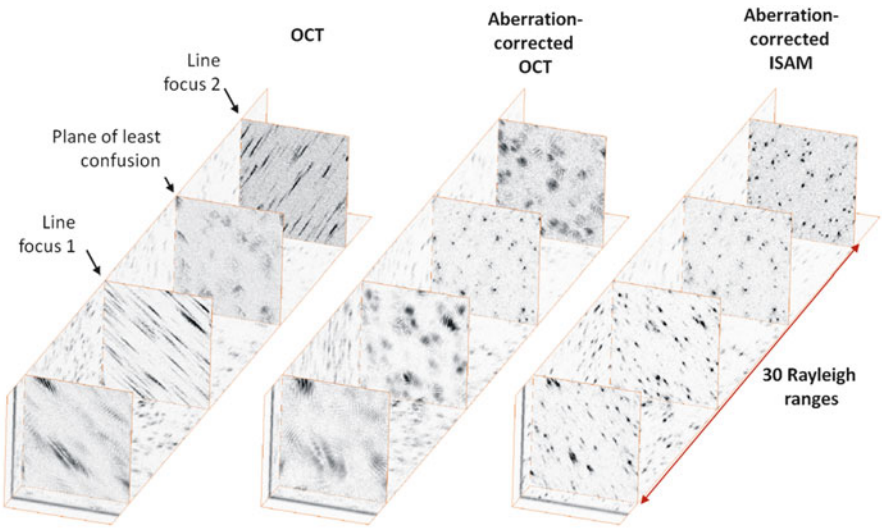

Fig. 31.7 Computational aberration correction of astigmatism in a silicone phantom containing titanium-dioxide microparticles. These renderings were generated from a single 3D dataset that was acquired with a highly astigmatic illumination beam. The OCT reconstruction highlights the plane-of-least-confusion and the two en face (x-y) planes with the best line foci, located 300 μm above and 300 μm below it. The aberration-corrected OCT and aberration-corrected ISAM reconstructions show en face planes corresponding to the same depths as the OCT rendering. Dimensions of the rendered 3D dataset are 256 × 256 × 1,230 μm ($x \times y \times z$), where the units of the z-axis denote optical path length (Adapted from [14])

combination of the Zernike polynomials Z_5 and Z_6 describing astigmatism at 45° and 0°, respectively [28]. Notice that, after the correction of astigmatism, the plane-of-least-confusion is restored as the focal plane, and the planes previously showing line symmetry now show circular symmetry. The subsequent application of ISAM reconstructs the entire volume with focal-plane resolution over a depth range greater than 30 Rayleigh ranges (see Sect. 31.4.7 for quantitative analysis of the resolution).

31.4.5 Tissue Results

Figure 31.8 shows CAO for 3D imaging of highly scattering muscle tissue. The dataset was collected with a 1,330 nm SD-OCT system, but with an astigmatic beam ($NA = 0.09$, defined at the $1/e^2$ level). Astigmatism, a common aberration in retinal or catheter-based OCT, was emulated through the insertion of cylindrical lenses in an otherwise standard OCT sample arm design. The effects of the astigmatism on the reconstruction were found in practice to be well corrected using a single (space-invariant) aberration correction filter. This data provides evidence that the condition of space invariance can be satisfied when imaging in highly scattering tissue and therefore for the validity of the signal model approximations in Eqs. 31.17 and 31.18.

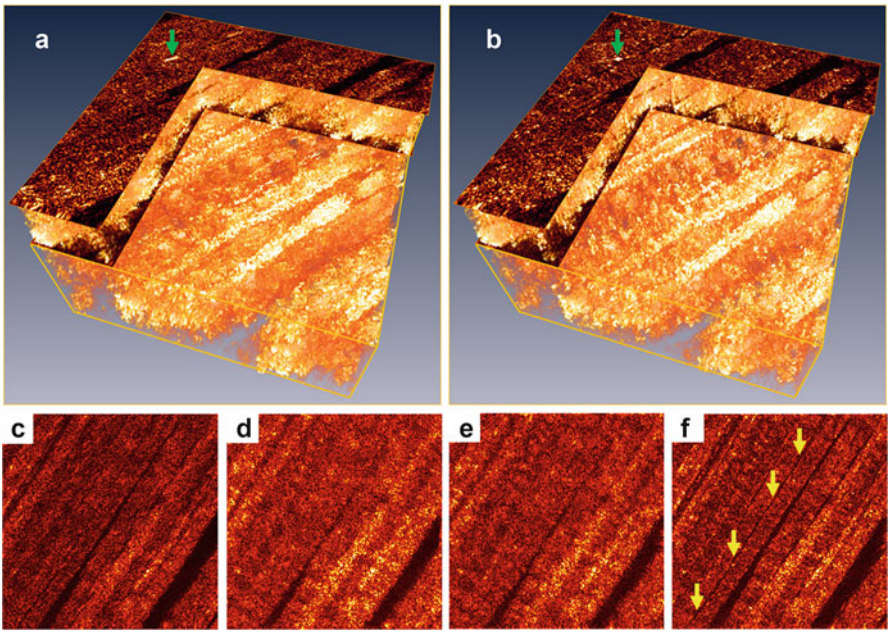

Fig. 31.8 Three-dimensional reconstructions of a rabbit muscle tissue dataset that was acquired with an astigmatic optical system. (**a**) OCT processing and (**b**) CAO-ISAM reconstruction of the complete volume. The displayed volumes span 1 × 1 × 1 mm (optical depth). An en face plane extracted from 110 μm below the tissue surface is shown for (**c**) OCT, (**d**) CAO-OCT, (**e**) ISAM, and (**f**) CAO-ISAM. The *green arrow* in (**a**) shows that the long axis of the astigmatic point spread function is aligned approximately parallel to the muscle fiber bundles, and the *yellow arrows* in (**f**) highlight previously unresolved fine tissue structure that is clearly resolved after CAO-ISAM. The midpoint between the axially separated astigmatic line foci is 600 μm below the tissue surface

31.4.6 Methods to Optimize the Aberration Correction

In hardware-based AO there are generally two methods to optimize the pupil correction. The first is the use of so-called guide-stars [27]. Since in astronomical imaging distant stars present as point sources of light, they have been used in astronomical AO for wavefront sensing.[7] Natural guide-stars are stars that are present near the region of interest [27]. However, when no suitable star is present, an artificial guide-star can be generated by focusing a high-power laser in the upper atmosphere [34]. In AO-OCT the guide-star can be generated by the focused imaging beam itself [6, 8] or by a separate static beam that is focused into the sample [7, 35]. The aberration correction in optical microscopy can also be optimized through the use of image metrics such as the peak amplitude of signals, or the

[7] A point source of light generates approximately planar wave fronts far from the source.

spatial frequency content of images. Since this method does not require the use of a wavefront sensor, it is known as sensor-less AO [36–38].

Image metrics have been utilized in CAO to guide the aberration correction in tissue phantoms while using Zernike polynomials to correct the pupil aberrations [14]. A drawback with this approach is that when high-order aberrations are present, the correction requires a large number of Zernike polynomials, potentially requiring computationally expensive optimization. In addition, it has been shown that the more general (non-Zernike) correction using the segmented pupil approach is preferred when imaging in biological samples [39].

Guide-star-based CAO has also been demonstrated in silicone resolution phantoms and in scattering biological tissue by making use of point-like scatterers as guide-stars [30]. By isolating the signal from a guide-star, aberrations of the computed pupil[8] can be detected. The guide-star signal can be isolated via windowing in the spatial domain, and the phase component of the computed pupil aberration can be digitally conjugated in the Fourier domain of the tomogram. Ideally, the window should be large enough to capture all the aberrated signal of the PSF; however, if it is too large, the signal from neighboring scatterers will be included, and the quality of the pupil measurement will be compromised. In a sample with many scatterers, this motivates an iterative approach and the use of a window size sufficient to capture the majority of the aberration-free signal. With each iteration the size of the aberrated PSF reduces, thus bringing more of the PSF signal within the window and resulting in the correction of increasingly higher-order aberrations. The guide-star-based correction is valid over an isotome (or isotomic volume), which is the volumetric extension of the term isoplanatic patch in astronomical AO.

31.4.7 Advantageous Use of Aberrated Optics

In order to determine the effectiveness of CAO and ISAM, it is worth quantifying the depth-dependent resolution and signal-to-noise ratio. Figure 31.9 presents quantitative analysis of these parameters for the data presented in Fig. 31.7, acquired with an astigmatic imaging beam. Notice that the resolution of aberration-corrected OCT exhibits Gaussian-like behavior, whereas aberration-corrected ISAM shows spatially invariant resolution equivalent to that at the aberration-corrected focus. For comparison, the ISAM resolution for imaging with a standard Gaussian beam (i.e., without the cylindrical lens) is seen to be similar to that of ISAM with the astigmatic optical system.

Figure 31.9b shows the depth-dependent signal-to-noise ratio (after ISAM), comparing imaging with the astigmatic system to that of a standard Gaussian beam. The astigmatic system is seen to have a flatter depth-dependent SNR. The

[8] Aberrations of the computed pupil correspond to deviations from the ideal (complex) PSF, $h(x, y, z_f)$, in the objective lens pupil plane, i.e., at depth $z = -z_f$.

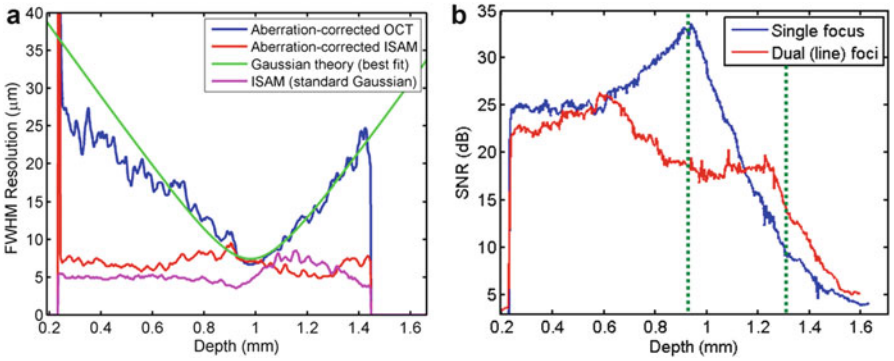

Fig. 31.9 Depth-dependent resolution and signal-to-noise ratio when imaging with an astigmatic beam. Analysis of a 3D dataset of a silicone tissue phantom containing titanium dioxide microparticles, showing (**a**) depth-dependent resolution (along the *x*-axis) vs. depth for the aberration-corrected OCT and ISAM and (**b**) signal-to-noise ratio after ISAM reconstruction, comparing the cylindrical lens setup producing two axially separated line foci to a standard single-focus setup (Figure generated from data presented in [14])

SNR at the focal plane is reduced, but deep in the sample where SNR is low, the signal is boosted. The flatter depth-dependent response can be attributed to preferential light collection from the two axially separated confocal gates.

These results suggest an interesting prospect for high-resolution optical tomography. Since CAO can circumvent the resolution penalty associated with optical aberrations, then it can actually be preferable, from a signal collection perspective, to image with an aberrated optical system. Specifically, the advantage of this CAO signal collection scheme is that it reduces the dynamic range between all imaging planes. A lower dynamic range allows for a system to achieve relatively uniform SNR for all depths. Lower dynamic range can be especially beneficial when measuring with a photodetector having a single integration time for light from multiple acquisition depths. In this integrated approach to interferometric optical tomography, traditional optical hardware and computational techniques play synergistic roles.

31.5 Comparison to Related Techniques and Acquisition Geometries

CAO and ISAM as described above take advantage of the fact that the data available are coherent. That is, the measurement provides a means to infer the complex optical field at the detector. This is important as the fundamental laws of physics describe the behaviors of fields, but do not uniquely determine the behavior of intensities. While intensities may always be computed from fields, the converse is not generally true. Access to the fields not only allows us to do in

post-processing many things normally done with physical optical elements, but also things impossible with physical optical elements, for example, the reconstructions in ISAM with in-principle unlimited depth-of-field. Below some related techniques are discussed.

31.5.1 Holographic Reconstruction and Aberration Correction

Digital holography provides access to the complex optical field in the plane of measurement. This allows for the calculation of the field that would have been measured in any other plane separated from the measurement plane by free-space. Moreover, it allows the calculation of the field that would result from the insertion of additional optical elements such as lenses, all accomplished in post-processing [40, 41]. For example, the field may be refocused to bring into focus planes that were defocused at the expense of defocusing planes that had been in-focus. Without further information to section the sample in three dimensions, the signals from the in-focus plane and the out-of-focus planes appear in superposition in the resultant image (traditional digital holography does not employ low-coherence depth discrimination). However, the focal plane can be thus scanned through the object and, under certain assumptions about the sample,[9] can numerically provide an extended depth of focus [42].

Holoscopy is a broadband digital holographic technique that utilizes a swept laser source to record multiple holograms over a broad optical bandwidth [33]. Three-dimensional object structure is encoded in the 3D data (which can be written as a function of two transverse dimensions and wavenumber), much as in wide-field OCT. Here the data are sufficient to distinguish the signals arising from different planes in the sample, and so numerical refocusing can bring into focus the structure of the sample in one plane without corruption of the image by superposed defocused images from other planes. In 3D tomographic imaging, holographic refocusing can be described as the numerical analog of a z-stack, such as in confocal microscopy, where the focus is physically translated through the sample. Spatially invariant resolution can be achieved in holoscopy by synthesizing a z-stack reconstruction by combining separate sequentially numerically focused planes.

It has been recognized that a SD-OCT system can be thought of as a system for digital holographic tomography [43]. Spectral-domain OCT instrumentation, however, combines this aspect of (broadband) holography with the advantages of confocal-type transverse beam scanning to obtain high-quality tomographic images of scattering biological tissue [1, 44]. The use of confocal beam scanning makes OCT well suited to imaging in scattering biological tissues because of its ability to

[9]Holographic reconstructions of solid 3D objects are possible from a 2D holographic dataset since the surface (or *boundary*) of a 3D object is 2D. A 3D dataset is required for 3D reconstruction of the internal structure of scattering samples such as biological tissue.

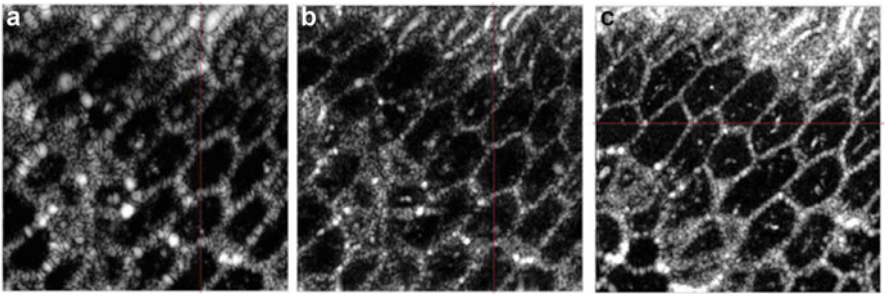

Fig. 31.10 Numerical refocusing of OCT data from an onion. (**a**) En face plane from outside the focal region. (**b**) The same en face after numerical refocusing. (**c**) A representative plane from the focal region (Figure adapted from [47])

reduce cross talk (which is present with spatially coherent full-field illumination) and reject out-of-focus multiple scattering.

The connection between broadband/swept-source holography and SD-OCT is highlighted in [43], the only difference being that SD-OCT data is acquired via point beam scanning over two spatial dimensions. Thus, just as in digital holography and holoscopy, numerical refocusing can be applied to OCT data [45–48], and the focus of the acquired dataset can then be freely adjusted in post-processing. Figure 31.10 shows an onion sample being brought into focus numerically. In Fig. 31.10a, an en face plane outside the focal region suffers from defocus; Fig. 31.10b shows the same en face after numerical refocusing. The optimal reconstruction was determined using entropy as an image metric. Finally, Fig. 31.10c shows a representative en face plane from the focal region.

It should be stressed that ISAM is not a refocusing technique. Rather, it is a reconstruction technique that is an implementation of the solution of the inverse scattering problem for OCT and directly computes sample structure, not the data that would be collected with a different optical system. It may be easily misinterpreted as a method with extended depth-of-field or infinite focal depth. In fact, the notion of a focus has little to do with the reconstruction except as the size of the focal spot pertains to the spatial bandwidth of the system. Nonetheless, for the end user, the main practical difference between ISAM and numerical refocusing techniques in digital holography is that ISAM provides a simultaneous reconstruction at all depths within the tomogram and is thus significantly more efficient (faster). With numerical focusing, a given shift of the focus (corresponding to a given propagation distance) produces optimal resolution at only a single plane, whereas the ISAM resampling step removes defocus for all depths without the need for multiple numerical focus-shifting operations.

Numerical correction of optical aberrations has also been demonstrated in digital holography [41, 49–52]. Compensation of spherical aberration and astigmatism has been shown for imaging in thin biological samples such as a single cell [49]. However, the benefits of numerical aberration correction have not been demonstrated for

holographic tomography in scattering tissue. This is likely due to cross talk problems, occurring with full-field illumination using spatially coherent illumination [53], that impede progress toward high-quality digital holographic tomography of tissue. Although the majority of the work on holographic aberration correction was performed using monochromatic laser sources, numerical correction of aberrations has also been demonstrated in nonbiological samples at a small number of discrete wavelengths [54, 55] and for broadband holography [56].

31.5.2 Full-Field and Rotational Imaging Geometries

The full-field swept-source imaging geometry is of interest for its potential for rapid data acquisition, where interferometric data is acquired in parallel from the entire sample volume while the illumination wavelength is scanned. An additional benefit is that full-field detection does not result in signal decay with distance from focus inherent to imaging with beam-scanning OCT systems. The solution of the inverse scattering problem via Fourier space resampling has been described for full-field ISAM (FF-ISAM) using swept-source illumination and demonstrated through simulations [57]. This theoretical work has also been extended to the use of optical sources for partially (spatially) coherent illumination [53].

Although the methods of FF-ISAM had been explored theoretically, until recently its experimental implementation remained open. Mimicking the techniques of digital holography, holoscopy was initially performed using numerical refocusing where several independent refocusing steps were applied, and for each step, a small volume of data which was deemed in-focus was extracted.

In order to improve the efficiency of numerical refocusing in holoscopy, a Fourier-domain coordinate warping very similar to FF-ISAM was derived and demonstrated experimentally [58]. By utilizing coordinate warping rather than refocusing, the computational complexity of the reconstruction was significantly reduced, and the full reconstruction can be performed in a single computationally efficient step. Figure 31.11 demonstrates holoscopy on a grape using an effective NA of 0.14. Digital refocusing is computationally expensive, and thus for practical considerations, each en face plane was not individually brought into focus. Instead, $\sim$15 virtual focal planes were used throughout the tomogram, and regions around each virtual focus were chosen to approximate the local neighbourhood, but each refocused volume still suffers from residual defocus (Fig. 31.11c). With the one-step reconstruction, every plane is brought into focus simultaneously, providing a higher-quality reconstruction than refocusing (Fig. 31.11f). With increasing NA, the depth of focus decreases, meaning that for the numerical refocusing method, many more virtual foci are required. In contrast, using a Fourier-domain coordinate warping similar to ISAM, the reconstruction requires the same computation regardless of the NA or depth of focus. Figure 31.12 shows the time improvement of the one-step coordinate warping scheme over numerical refocusing. It shows that at high NAs, the one-step reconstruction can be up to three orders of magnitude faster than 3D object reconstruction via digital refocusing.

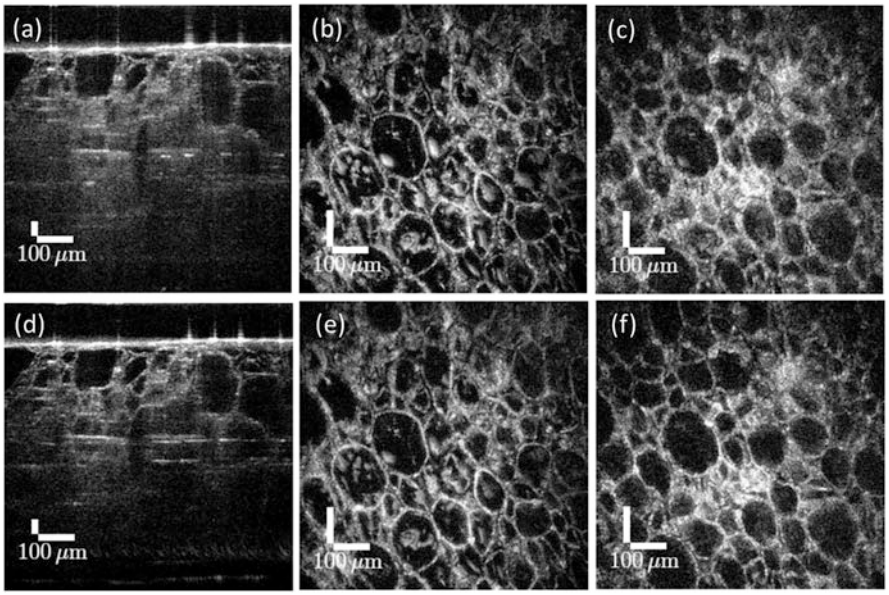

Fig. 31.11 Holographic reconstruction of a grape comparing refocusing to the one-step reconstruction. (**a**) Cross section from the refocused volume. (**b**) En face plane at the virtual focus. (**c**) En face plane 160 μm above the virtual focus. Since each plane is not separately brought into focus, defocus is still visible away from each virtual focus. (**d**) Cross section from the one-step reconstruction. (**e**) En face plane at same location as (**b**). (**f**) En face plane at same location as (**c**). The section does not suffer from defocus since the one-step reconstruction simultaneously brings every plane into focus. The NA was 0.14 (confocal parameter of 28 μm) (Figure adapted from [58])

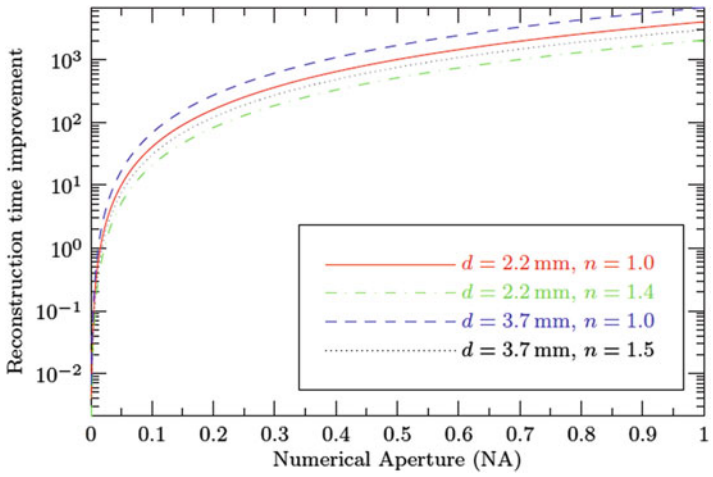

Fig. 31.12 Speed increase of the one-step Fourier-domain coordinate warping over numerical refocusing. The speed of a numerical refocusing reconstruction depends on the depth of focus in the sample and thus depends on both NA and refractive index (From [58])

Another important geometry is the catheter-based or rotational imaging geometry, used for gastrointestinal and cardiovascular OCT applications. The inverse problem for this imaging geometry has been investigated in theory and simulations, where the inversion utilizes the Radon transform and the projection-slice theorem to convert between the polar and Cartesian representation of the Fourier-domain signals [16]. Further work is needed to experimentally demonstrate ISAM and to incorporate CAO, especially since the optical systems utilizing this imaging geometry are known to suffer from astigmatism [59–61].

31.5.3 Fourier Migration Techniques in Other Imaging Fields

The Fourier resampling method in ISAM is similar to the well-known migration-by-Fourier-transform technique introduced by Stolt in 1978 in the field of geophysics [21, 62]. Researchers in many other branches of imaging have adopted a similar approach.

In ultrasound imaging, 3D phase shift migration is a method for implementing a synthetic aperture focusing technique (SAFT) [63]. While the technique can be performed in the time domain with a delay-and-sum approach, the Fourier-domain implementation allows for fast and efficient reconstructions. SAFT originates from a method developed in the 1970s and 1980s from ultrasonic nondestructive testing (NDT) called synthetic aperture imaging (SAI). Some authors have framed the SAFT methods in the context of computed tomography, diffraction tomography, and holography [64, 65]. Others have characterized the transverse and longitudinal resolutions in SAFT [66].

While synthetic aperture radar (SAR) has been developing since the 1960s, the digital processing algorithms were developed later. In the 1980s, a full computer-aided tomographic formulation of spotlight-mode SAR related these algorithms to those developed for medical x-ray computed tomography [67]. Subsequently, a method called the range migration algorithm (RMA) based on the seismic migration theory was developed first for strip map radar and then spotlight-mode radar systems [68–70]. The RMA method utilizes the Stolt transform in the processing chain [71].

31.6 Phase Stability Considerations

31.6.1 Phase Stability Requirements for ISAM and CAO

The ISAM forward model requires that several things are specified or assumed such as a Gaussian beam profile, focus location, and sampling spacing (both transverse and axial) that are necessary. As discussed above, deviations from a Gaussian beam can be taken into account by use of CAO, and the location of the focus can, in principle, be determined through an iterative approach using image metrics to optimize the reconstruction quality [47]. Even if these two assumptions are not completely satisfied or are not fully taken into account, reasonable reconstructions are still

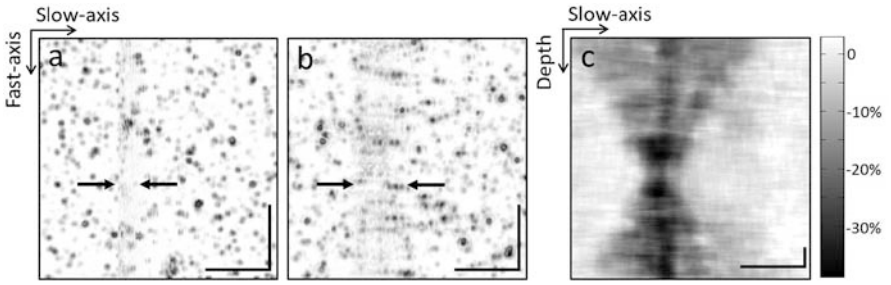

Fig. 31.13 Depth-dependent phase stability requirements. A silicone tissue phantom with sub-resolution titanium dioxide microparticles is used to investigate an ISAM reconstruction following a localized disturbance (a tap to the mounting stage) during image acquisition. (**a**) An en face plane near the optical focus. The effect of the disturbance remains localized (width along the slow axis is approximated by *black arrows*). (**b**) An en face plane 135 μm above optical focus. The blurring due to the localized disturbance now has a larger lateral extent (width along the slow axis is approximated by *black arrows*). (**c**) An image-based representation of the percent change in SNR comparing reconstructions obtained with and without the disturbance. The region which experiences a drop in SNR traces out the optical beam profile and demonstrates the depth-dependent local interrogation time. Scale bar represents 100 μm (Adapted from [74])

possible and may be sufficient for the end application. Ensuring a known relationship between A-scans, though, proves to be more difficult and warrants specific consideration when designing a high-resolution ISAM/CAO system. Often referred to as "phase stability" [72, 73] because of the scale to which it is required (often measured in radians), this term encapsulates many factors such as galvanometer jitter (in 1D or 2D point scanning techniques), wavelength variability (in swept-source techniques), sample and system motion, and environmental vibrations (especially in non-common-path interferometry) which can contribute to the degradation of reconstruction quality in computed imaging techniques such as ISAM and CAO.

As a guideline, a system can be considered locally phase stable if the measurements do not deviate by more than $\lambda/4$ over the specified "local interrogation time." The local interrogation time is defined as the time over which a small region or point in 3D space is probed by the imaging beam [74]. Notice that stability over the local interrogation time will have different implications for different OCT imaging geometries or systems such as swept source, spectral domain, time domain, full field, etc. In a spectral-domain point-scanned geometry, the stability requirements vary as a function of depth (see depiction of beam profile scanning in Fig. 31.13). This is because the local interrogation time will vary depending on the magnitude of the correction desired and thus should be directly proportional to the shape of the blurred or aberrated PSF. In Fig. 31.13, the depth-dependent stability requirement is demonstrated experimentally with an SD-OCT system with central wavelength at 1,330 nm and a bandwidth of 105 nm. Using a silicone-based tissue phantom with sub-resolution TiO_2 scatterers, Fig. 31.13a demonstrates that near the focus, a localized disturbance (in this case a tap to the mounting stage) affects the ISAM reconstruction over a small lateral range. Data collected further from

the focus (135 μm above), as shown in Fig. 31.13b, reveals that the local disturbance affects an extended lateral range. By measuring the local SNR across the slow axis, the region affected by the disturbance (manifested as a drop in SNR when compared to a non-perturbed reconstruction) traces out the imaging beam profile, shown in Fig. 31.13c. This means that when an ISAM reconstruction in a spectral-domain, point-scanned OCT system many Rayleigh ranges from the focus is desired (or if strong aberrations are to be corrected with CAO), local stability over a larger area (longer interrogation time) is required. Interestingly, this also suggests that the stability requirements can also be different for each scanning axis in the presence of an asymmetric PSF, such as is the case with astigmatism.

31.6.2 Obtaining Phase-Stable Data

When designing a high-resolution ISAM/CAO system, both the hardware and software play important roles in obtaining and processing phase-stable data. Phase stability is affected by several major factors: galvanometer jitter, swept-source variability, sample and system (beam-delivery instrument) motion, and environmental vibrations. Discussed here are hardware considerations and post-processing techniques which, together, can overcome these factors to provide the best possible ISAM and CAO reconstructions.

31.6.2.1 Hardware Methods

Dual galvanometer mirrors are typically used in OCT for lateral beam scanning in a raster pattern. The physical construction and mechanical operation of galvanometers make them inherently subject to imperfections and noise. Assuming precise synchronization between mirror scanning and acquisition hardware, the scanned beam pattern for each frame can be divided into two parts, one which is repeatable and common to all frames and the other which represents noise and varies randomly for each frame. Although not required, the repeatable portion is typically made as linear as possible. The second term (the noise) should be made minimal by choice of low-jitter galvanometers. This design choice will also present trade-offs between speed, accuracy, and jitter. In catheter/endoscopic setups [16, 72], a cylindrical coordinate system is used, and thus instead, smooth and reliable motor rotation and pullback methods need to be considered.

In swept-source systems, extra phase instability is associated with the difficulty of repeatedly linearizing the acquired spectrum in wavenumber (though groups have successfully performed other phase-sensitive imaging modalities like Doppler OCT with swept-source systems [75]). Hardware triggers using fiber Bragg gratings have been used to generate a reliable trigger indicating a reference around which the acquired spectrum can be linearized in wavenumber [76].

Sample and beam-delivery system motion likely presents the greatest challenge to computed imaging techniques such as ISAM and CAO. Without the possibility for in vivo use, clinical applications may be very limited. Sample and system

motion can be addressed with hardware in two major ways. First, if possible, the sample movement can be restricted by use of sample-specific mounting stages. However, in many cases (such as when imaging the human eye), either contact with the sample is not possible or motion is involuntary and inevitable. Second, by scanning faster or imaging a smaller region, it may be possible to retain phase stability. For a spectral-domain system, this means a faster line-scan camera which can reach speeds faster than 90,000 A-scans/second [30, 77]. For a swept-source system, speeds are typically limited by the swept laser source, which can achieve MHz rates [78, 79]. However, because of the physical motion of swept-source elements (e.g., scanning Fabry-Perot filters or rotating polygon mirrors), faster scanning may also be associated with greater mechanical (and therefore phase) instability. Faster scanning, in general, results in shorter exposure times and thus can result in a trade-off between imaging sensitivity and speed.

Finally, environmental factors can lead to instability in the acquired data. In many OCT/ISAM/CAO setups, separate paths are used for the sample and reference arms. Therefore, any slight change to one arm and not the other such as fiber bending, air currents, or mechanical vibrations that modulate the optical path difference will affect the phase stability. Optical path difference fluctuations are a special case of phase instability where, as opposed to sample motion or galvanometer jitter, the effect is entirely in the axial dimension. To mitigate this effect, a common-path setup can be used where both the sample and reference beams overlap (and thus are subject to the same environmental factors) for nearly their entire propagation distance. In the next section, an alternative software or hardware/software combination, which can be used to address this issue, is discussed.

31.6.2.2 Software Methods

For a non-common-path system, a phase reference can be used to remove any optical path difference fluctuations throughout the full 3D dataset. Previously, a coverslip has been used to provide a clean, flat surface along which there should be little phase fluctuations [73, 80]. Mathematically, the phase fluctuations of the acquired data are written as a function of the wavenumber and expanded to the first two terms using a Taylor series expansion around the central wavenumber, k_0:

$$\phi'(x,y;k) = \phi'(x,y;k_0) + (k-k_0)\frac{\partial\phi'}{\partial k}\bigg|_{k=k_0} + \ldots \tag{31.25}$$

By performing a linear fit along the unwrapped phase, the $\phi'(x, y; k_0)$ and $\frac{\partial\phi'}{\partial k}\Big|_{k=k_0}$ can be determined and applied to the acquired data, $S(x, y, k)$, as $S'(x,y;k) = S(x,y;k)e^{-i\phi'(x,y;k)}$. Figure 31.14 shows an experimental validation of this method. Three-dimensional imaging was performed over 800 × 800 μm (transverse) ×2,000 μm (axial) at 4 B-mode frames/s, on a system with 800 nm central wavelength and 100 nm bandwidth and a sample arm NA of 0.05. First, in

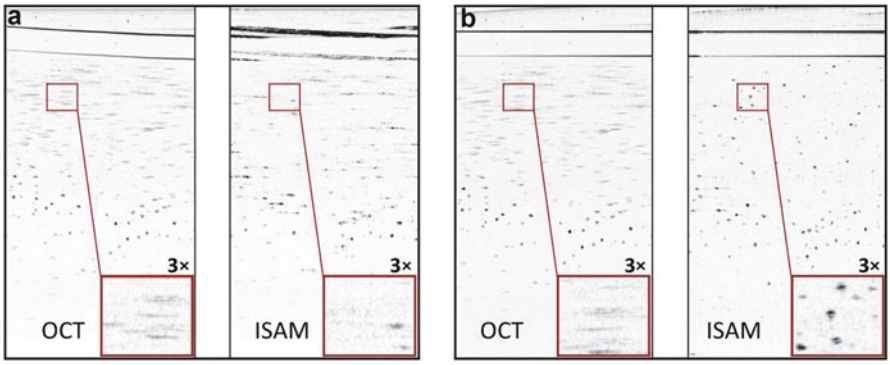

Fig. 31.14 Silicone-based tissue phantom demonstrating the use of phase correction. (**a**) Far from focus, even after ISAM has been applied, point scatterers still remain blurred and are not well resolved. (**b**) After using a coverslip for phase correction, full constructive interference is recovered and point scatterers are well defined. The images shown were extracted from a 3D dataset. Phase correction was applied to the entire 3D dataset and the cross-sectional frames shown are oriented along the slow-scanning axis. Image dimensions are 800 μm (transverse) ×2,000 μm (depth) (From [81])

Fig. 31.14a, ISAM was performed without phase correction. Far from focus, full constructive interference was not obtained. After phase correction using a surface coverslip as a phase reference (Fig. 31.14b), the sub-resolution scatterers are fully revealed along the entire imaging depth.

With the addition of a fiber stretcher (or similar phase modulator) to induce a desired optical path change, axial phase disturbances have also been corrected using an iterative "phase equalization" method [48]. For more generalized phase correction, both axial and transverse movements need to be compensated. Post-acquisition, cross-correlation algorithms have previously been utilized in various averaging techniques [82] and have also been shown to correct for transverse motion or instabilities between acquired frames [14].

Common to many of these techniques, though, is a required high spatial overlap between A-scans. Ensuring a large oversampling factor, though, either greatly reduces the acquired field of view or increases the acquisition time (thus making the data inherently more susceptible to phase noise). Care should be taken to balance all the benefits and drawbacks of each method.

31.7 Practical Limitations and Opportunities

The phase stability requirements outlined in Sect. 31.6.1 can determine the reconstruction quality of dynamic samples or of static samples measured at slower acquisition rates. The first case presents the more serious limitation. Sample or system motion on the order of the interrogation time can disrupt the expected phase

relationship during the sequential or multiplexed acquisition of transverse spatial frequencies in the away-from-focus regime (see Fig. 31.13). For a given set of scanning parameters (A-scan rate, transverse sampling period, and range), the imaging NA and overall depth of reconstruction cannot be chosen arbitrarily. There is a trade-off between the imaging NA and the absolute distance from focus that can be reconstructed without degradation resulting from phase instabilities. This is because at a given distance from focus, the interrogation time is directly proportional to the synthetic aperture length, which in turn is proportional to the imaging NA. For the measurement of dynamic samples, this places an upper bound on the imaging NA for a given set of scanning parameters. An increase of the imaging speed (A-scan rate) by a factor β will reduce the interrogation time by a factor of $1/\beta$ and thereby increase the upper bound on NA by a factor β. Preliminary work suggests that with the recent developments in high-speed acquisition, in vivo ISAM and CAO are feasible.

The reduction in signal collection with increasing distance from focus becomes a serious problem for cellular resolution tomographic reconstruction over the typical imaging depth ranges in OCT. This is a natural consequence of the reduction in the width of the axial confocal gate with increasing NA, and for a given NA, it limits the overall depth range of the reconstruction. The decay of signal strength with distance away from focus has a $1/|z|$ dependence [15], resulting in an increase of the required dynamic range of the instrument as imaging NA and distance from focus increase. For example, at 1 mm away from the focus with an imaging NA of 0.4, the signal collection relative to the focus is attenuated by five orders of magnitude (see Fig. 6 in [15]). Therefore, in order to image the highest scattering signals at the focus as well as weak scattering signals at a depth of 1 mm (assuming a 40 dB dynamic range of signals from typical tissues), the dynamic range of the instrument is required to be on the order of 90 dB. If the NA is reduced to 0.05, the dynamic range requirement reduces to 70 dB (see Fig. 6 in [15]). One method to equalize the signal collection vs. depth is to acquire multiple datasets, each with a different focus depth (these datasets may be separated by many Rayleigh ranges from each other). This solution comes at the expense of increased acquisition time, which could lead to motion artifacts between volumetric datasets. Another method is to strategically position the focus deep within the sample to enhance the collection of weak signals from greater depths within the sample. This solution also counteracts the exponential attenuation that the incident light already experiences with increasing depth into the sample, effectively reducing the required dynamic range. Finally, exploiting synergistic roles between aberrated optics and computational methods (see Sect. 31.4.7) can also reduce the dynamic range requirements without affecting the imaging NA or resolution.

Multiple scattering and/or sample-induced aberrations are the major limiting factors on imaging depth in OCT. In OCM, which can achieve cellular transverse resolution through the use of higher-NA optics, it is thought that aberrations represent a more severe limitation to imaging depth than that imposed by multiple scattering [3]. The assumption of single scattering, i.e., the first Born approximation, is used to linearize the inverse scattering problem [24]. When this assumption breaks down,

the accuracy of both ISAM and OCT is degraded, leading to an imaging depth that is limited by the collection of multiple scattering [23, 83, 84]. Although ISAM and CAO share the multiple scattering limitation with OCT/OCM, recent work in hardware-based wavefront control suggests that pupil corrections based on generalized segmented pupil approaches can utilize the turbidity of the medium to provide sub-diffraction resolution [85–87] and enable improved focusing deep into tissue [88]. The phase conjugation of wavefront aberrations, shown to be equivalent to a time reversal operation [89], has been demonstrated for imaging or focusing in optics and ultrasonics [89–93]. These approaches to hardware-based wavefront control provide promising future areas of investigation for CAO.

Finally, a limitation that is not obvious at an imaging NA below about 0.2 is that of vignetting. Scatterers near the edge of the transverse field of view are probed by a truncated synthetic aperture, which results in a reduction of signal amplitude and an attenuation of high lateral spatial frequency components. This problem becomes apparent further away from focus and nearer to the edge of the lateral field of view. Vignetting can be addressed by increasing the transverse field of view by half the maximum synthetic aperture length (this should be done for the synthetic aperture length at the maximum distance from focus that is desired in the reconstruction).

31.8 Summary and Future Outlook

ISAM and CAO enable computational reconstruction of sparse and highly scattering samples in broadband optical interferometric tomography. ISAM is a solution to the inverse scattering problem that utilizes Fourier space resampling to reconstruct areas typically regarded as out of focus in OCT, overcoming the perceived trade-off between transverse resolution and depth of focus. CAO provides post-acquisition correction of optical aberrations for OCT imaging near the optical focus or for far-from-focus ISAM reconstructions. The underlying theory behind ISAM was connected to the principles of diffraction tomography. In particular, ISAM resampling is now understood from the Ewald sphere description of the process of optical scattering and signal detection in OCT. A general signal model was also presented for the case where severe optical aberrations can restrict the volumes of stationarity (or space invariance) in 3D tomography. Approximations were presented for specific situations where 2D or 3D space invariance holds, since these situations can readily be (approximately) achieved in practice. Methods for the optimization of aberrations in CAO, based on previous approaches in hardware wavefront control that utilized guide-stars or image metrics, were presented.

Results in tissue phantoms demonstrated the correction of astigmatism with CAO and the correction of defocus with ISAM over a depth range spanning tens of Rayleigh ranges. Cross-validation of ISAM with OCT in phantoms and biological tissue demonstrated that ISAM can provide similar resolution as “in-focus” OCT. The anatomical reconstruction accuracy of ISAM was validated in human breast tissue through a comparison with the corresponding histology. The validity of space-invariant approximations was demonstrated with CAO and ISAM

reconstructions of tissue phantoms and biological tissue. Related work by other groups in OCT and holography was highlighted, and experimental results were presented to demonstrate the phase stability requirements of ISAM and CAO.

The combination of ultrahigh axial resolution [94] with ISAM and CAO presents an opportunity for unprecedented 3D visualization of tissue. Traditional diagnosis of neoplastic changes is based on cellular features such as atypia of cell nuclei, accelerated rate of growth, and local invasion. This motivates the pursuit of isotropic cellular-level resolution over a large depth-of-field. The development of high-NA instrumentation to achieve this presents both challenges and opportunities for ISAM and CAO.

Imaging applications where high isotropic resolution over a large depth-of-field could add significant value include optical biopsy, image-guided surgery, and the study of tumorigenesis. One of the important capabilities for clinical applications of ISAM and CAO is the ability to perform real-time tomography in vivo. Current work is aimed at real-time in vivo ISAM and parallelization of 3D ISAM algorithms using GPU-based hardware architectures. In addition to the enhanced diagnostic value of high isotropic resolution, real-time 3D reconstruction of cellular-scale tissue structure could translate the diagnostic functions currently available in the pathology lab toward real-time point-of-care scenarios. Isotropic cellular resolution could also provide valuable insights on the fundamental question of how tumors grow and spread, both in cell cultures and scaffolds in vitro, as well as in animal models in vivo. In contrast to histopathology, where tissue excision provides a "snapshot" of tissue, ISAM with CAO could be used to monitor tumor development in three dimensions within the same animal.

The impact of computational methods in high-resolution optical tomography is expanding. The work reported in this chapter provides evidence that optical imaging science is moving toward an integrated approach where optical hardware and computation play synergistic roles. An interesting possibility with CAO and ISAM is that imaging systems can now be designed to optimize signal collection over an extended volume rather than minimizing aberrations at a given depth. The computed pupil in CAO provides the flexibility of a large number of independent segments, allowing the correction of large phase gradients without the limiting requirement of having to determine the phase correction at the time of imaging.

Future work will investigate CAO for correcting space-variant and sample-induced aberrations and the potential advantages of using a computed pupil for phase conjugation (time reversal) imaging deep into turbid media. These investigations will be able to quantify the dimensions of isotomic volumes in tissue and help to understand the relative impact of multiple scattering and aberrations on imaging depth in high-resolution tomography. The pursuit of isotropic cellular resolution over the depth ranges typically achieved in OCT is a challenging and open area for the application of ISAM and CAO. An application area that could significantly benefit from CAO is retinal OCT (e.g., the imaging of rods/cones). Further work is also needed to enable ISAM and CAO for catheter- and needle-based OCT applications, e.g., for the computational correction of astigmatism typically encountered with these imaging geometries. Ultimately, studies on the improvement of sensitivity and

specificity to diagnose diseases, and/or the ability to longitudinally track disease progression, will determine the role of ISAM and CAO in biomedicine.

Acknowledgments We thank all our colleagues for their contributions to the research presented in this chapter. by the composition and organization of the structural components of tissue, including elastin, collagen, and the extracellular matrix and cytoskeletons of cells, as well as its fluid content [1]. Tissue pathologies are accompanied by changes in one or more of these factors, which often leads to a palpable disease state.

Despite its utility, palpation is limited by its subjectivity, low spatial resolution, and poor sensitivity. Over the last 20 years, a diagnostic imaging technique known as elastography has emerged that addresses these issues. In elastography, images (elastograms) are generated based on a tissue's mechanical properties [2]. A range of different approaches has been adopted, generally sharing three key steps.

1. A mechanical load is applied to a tissue.
2. Tissue displacement in response to the load is determined.
3. A mechanical property of tissue is estimated from the measured displacement.

Initially, elastography was developed using ultrasound [3] or magnetic resonance imaging (MRI) [4] as the underlying imaging modalities. A number of pathologies have been targeted, most notably, breast cancer [5], liver fibrosis [6], and prostate cancer [7]. Clinical results have demonstrated improved diagnostic capabilities. For example, in a multicenter study of ultrasound elastography in breast cancer involving more than 750 patients, improved specificity (89.5 %) and positive predictive value (86.6 %) compared with standard ultrasound (76.1 % and 77.2 %) were reported [8]. Both ultrasound and magnetic resonance elastography are commercially available, including from Echosens, General Electric, Hitachi, Philips, Siemens, Supersonic, Toshiba, and Ultrasonix.

The use of optical coherence tomography (OCT) as the underlying imaging modality in elastography, known as optical coherence elastography (OCE), was first demonstrated by Schmitt in 1998 [9]. Closely related optical elastography techniques based on laser speckle imaging [10, 11], ultrasound-modulated optical tomography [12, 13], and digital holography [14, 15] have also been demonstrated. OCE has a number of distinctive aspects in comparison to ultrasound and magnetic resonance elastography or OCT, including.

Spatial resolution: OCE has the potential to provide a spatial resolution of 1–10 μm, much higher than for (clinical) ultrasound and MR elastography. Such resolution provides information on length scales not previously studied, with the potential to resolve mechanical heterogeneity in diseases such as cancer.

Acquisition speed: OCE provides for 2D image acquisition rates exceeding 1 kHz – generally much higher than for ultrasound or magnetic resonance elastography. Such high speed promises 3D in vivo application without motion artifact.

Sensitivity: Sub-nanometer (possibly tens of picometer) displacement sensitivity enables the measurement of smaller changes in mechanical properties than other forms of elastography. This sensitivity has the potential to better differentiate subtle changes, e.g., between benign and malignant tumors.

Contrast: The Young's modulus of soft tissue varies from Pa to MPa, whereas the scattering coefficient of such tissues (largely determining contrast in OCT) is typically in the range 2–20 mm^{-1}. Thus, there is an apparent advantage in the dynamic range of mechanical over optical contrast.

Imaging penetration: OCE penetrates only millimeters from the probe, which is much less than for ultrasound and MR elastography. This limitation is overcome by exploiting fiber optics in endoscopic and interstitial probes, which expands the applications of OCE, e.g., to the assessment of atherosclerotic plaques in coronary arteries.

The landscape of OCE is rapidly changing. OCT technology has matured to the point that sub-nanometer displacement sensitivity and rapid image acquisition speeds are enabling, for the first time, the generation of high-resolution, high-contrast elastograms. Commercial and clinical successes in ultrasound and magnetic resonance elastography promise to pave the way for OCE. Current research efforts are focusing on the key advances needed to enable clinical OCE, i.e., quantitative and repeatable measurements, practical imaging probes integrated with loading mechanisms, and convincing demonstrations of contrast in pathological tissue.

In this chapter, we review the basic principles and development of OCE. We begin by describing the mechanical principles of tissue deformation. We then describe how deformation has been measured and review OCE techniques proposed so far. We discuss the development of imaging probes and the fidelity of contrast in elastograms before presenting an outlook for OCE. Throughout, we touch on applications of OCE, which are in their infancy.

32.2 Tissue Deformation

Fundamentally, elastography is a method for mapping the mechanical properties of tissue from a set of displacement measurements. First, let us consider the physical principles that govern tissue deformation. We use the conventional quantities defined in continuum mechanics to link tissue displacement, deformation, load, and elasticity [16]. We describe the load applied to tissue and the resulting deformation using stress and strain tensors. A constitutive equation is then used to define the elasticity by relating these tensors. In this analysis, we describe tissue as a linearly elastic solid, allowing us to derive a number of elastic properties that characterize its mechanical behavior, including those properties that most closely describe the variations in stiffness that are sensed by manual palpation. It should be recognized that the assumption of linear elasticity is generally not valid for the majority of soft tissues, which are more accurately described as nonlinear viscoelastic materials [1]. However, in elastography, these assumptions are often made to simplify the analysis. Similar analyses have been used to describe tissue deformation in ultrasound and magnetic resonance elastography [17, 18].

32.2.1 Stress Tensor

The application of a mechanical load results in stress acting throughout a tissue. To analyze the stress, we consider a volume, subject to an arbitrary number of external forces, $\mathbf{F}_m$, as illustrated in Fig. 32.1a. These external forces give rise to internal forces distributed throughout the volume. To define the corresponding

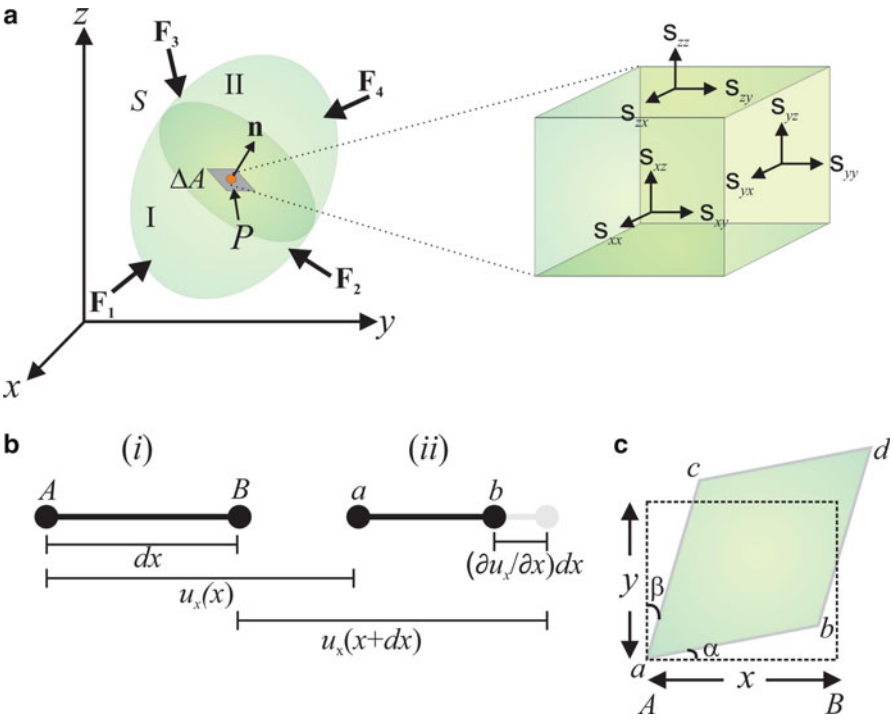

Fig. 32.1 (**a**) Stress components acting at the point *P* located within a deformable body under load. (**b**) Normal strain along the *x*-axis of the cube in (*a*) *(i)* before and *(ii)* after compressive deformation. The *gray line* in *(ii)* represents the initial length. (**c**) Shear strain: *xy*-plane of the cube in (*a*) after shear deformation. The *dashed rectangle* represents the *xy*-plane before deformation

stress, we divide the volume into two portions (I and II), using the plane *S* which passes through an arbitrary point, *P*, with unit normal vector, **n**. Considering I, we assume this portion is in equilibrium under the action of the external forces $\mathbf{F}_1$ and $\mathbf{F}_2$ and the internal forces distributed over the plane *S* representing the actions of II on I. To obtain the stress acting in the small area ΔA in the plane *S* containing *P*, we assume that the forces acting in this area can be reduced to a resultant force $\Delta\mathbf{F}$, where the limiting direction of $\Delta\mathbf{F}$ is perpendicular to *S*. The stress vector, $\boldsymbol{\sigma}_\mathbf{n}$, acting at this point is defined as

$$\boldsymbol{\sigma}_\mathbf{n} = \lim_{\Delta A \to 0} \frac{\Delta \mathbf{F}}{\Delta A}. \tag{32.1}$$

The S.I. unit of stress is the Pascal, equivalent to Nm^{-2}. Equation 32.1 defines the particular case where the direction of the resultant force, $\Delta\mathbf{F}$, is also the direction of the stress vector. More generally, the direction of the stress vector is inclined to ΔA and is described by two components: a normal stress perpendicular

to ΔA and a shear stress acting in the plane of ΔA. Consider the infinitesimal cubic element located at the point P, shown in Fig. 32.1a, with faces parallel to the coordinate axes. Each component of stress acting on the cube is highlighted in Fig. 32.1a. Two subscripts are used for each component. The first indicates the direction of the normal to the plane and the second indicates the direction of the stress component. The total stress acting on the cube is described by a second-order tensor:

$$\boldsymbol{\sigma} = \begin{bmatrix} \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{xz} & \sigma_{yz} & \sigma_{zz} \end{bmatrix}. \tag{32.2}$$

32.2.2 Strain Tensor

The strain tensor describes each component of the deformation resulting from an applied load. Consider the x-axis of the infinitesimal cube presented in Fig. 32.1a. In Fig. 32.1b, this axis is shown (*i*) before and (*ii*) after compressive deformation. The component u_x describes the displacement at the point A. The initial length along the x-axis, $|AB|$, is given by dx. After deformation, this length ($|ab|$ in Fig. 32.1b) is given by $dx + \frac{\partial u_x}{\partial x} dx$. The normal strain is defined as the unit elongation/contraction:

$$\varepsilon_{xx} = \frac{|ab| - |AB|}{|AB|} = \frac{\partial u_x}{\partial x}. \tag{32.3}$$

The same analysis holds for the normal strain in the y- and z-axes, ε_{yy} and ε_{zz}, defined as $\frac{\partial u_y}{\partial y}$ and $\frac{\partial u_z}{\partial z}$, respectively. In OCE, the strain defined in Eq. 32.3 is often referred to as the local strain [19]. As the strain is a ratio of lengths, it is dimensionless. By convention, tensile strains are positive and compressive strains are negative. Following this convention, the quantity $\frac{\partial u_x}{\partial x} \partial x$ in Fig. 32.1b is negative, and therefore, the compressive strain ε_{xx} is also negative. Analogously to stress, the strain has both normal and shear components. The xy-plane of the cube in Fig. 32.1a is illustrated in Fig. 32.1c. After deformation, the area $dxdy$ takes the form of a parallelogram in the general case. The shear strain is defined as the change in angle between two axes that were originally orthogonal. From Fig. 32.1c, the shear strain, ε_{xy}, is given by $\alpha + \beta$. For small displacement gradients, we have $\alpha = \frac{\partial u_y}{\partial x}$ and $\beta = \frac{\partial u_x}{\partial y}$, where u_y is the displacement along the y-axis at the point A, allowing the shear strain, ε_{xy}, to be defined as $\frac{\partial u_y}{\partial x} + \frac{\partial u_x}{\partial y}$. By interchanging x and y and u_x and u_y, it can be demonstrated that $\varepsilon_{xy} = \varepsilon_{yx}$. Shear strain components in the xz and yz planes can be defined in a similar manner. The infinitesimal strain tensor describing each component of strain can then be expressed as

$$\varepsilon = \begin{bmatrix} \varepsilon_{xx} & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{yx} & \varepsilon_{yy} & \varepsilon_{yz} \\ \varepsilon_{zx} & \varepsilon_{zy} & \varepsilon_{zz} \end{bmatrix}$$

$$= \begin{bmatrix} \dfrac{\partial u_x}{\partial x} & 0.5\left(\dfrac{\partial u_x}{\partial y} + \dfrac{\partial u_y}{\partial x}\right) & 0.5\left(\dfrac{\partial u_x}{\partial z} + \dfrac{\partial u_z}{\partial x}\right) \\ 0.5\left(\dfrac{\partial u_y}{\partial x} + \dfrac{\partial u_x}{\partial y}\right) & \dfrac{\partial u_y}{\partial y} & 0.5\left(\dfrac{\partial u_y}{\partial z} + \dfrac{\partial u_z}{\partial y}\right) \\ 0.5\left(\dfrac{\partial u_z}{\partial x} + \dfrac{\partial u_x}{\partial z}\right) & 0.5\left(\dfrac{\partial u_z}{\partial y} + \dfrac{\partial u_y}{\partial z}\right) & \dfrac{\partial u_z}{\partial z} \end{bmatrix}, \tag{32.4}$$

where the shear components are scaled by 0.5, as $\varepsilon_{xy} = \varepsilon_{yx}$, $\varepsilon_{xz} = \varepsilon_{zx}$, and $\varepsilon_{yz} = \varepsilon_{zy}$. It should also be noted that in dynamic elastography techniques, the strain rate is often measured. Strain rate is defined as the rate of change of strain with time [1] and is easily obtained from the expressions defined in Eq. 32.4.

32.2.3 Constitutive Equation for a Linearly Elastic Solid

Having defined the load applied to tissue using the stress tensor and the resulting deformation using the strain tensor, a constitutive equation relating the two is used to define tissue elasticity. In elastography, the most commonly used constitutive equation is that of a linearly elastic (or Hookean) solid in which the relationship between stress and strain is linear and strain is independent of the rate at which the load is applied. The constitutive equation for a linearly elastic solid is

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl}, \tag{32.5}$$

where i, j, k, and l define each tensor component. As σ and ε are second-order tensors, C is a fourth-order tensor, consisting of 81 elastic constants, referred to as the elasticity tensor. To simplify the analysis, it is frequently assumed that the elasticity is isotropic, i.e., elasticity can be described without reference to direction. This imposes maximum symmetry on the tensor, reducing the 81 elastic constants to two and resulting in the isotropic linear elastic constitutive equation, defined as

$$\sigma_{ij} = \lambda\varepsilon_{kk}\delta_{\mathrm{ij}} + 2\mu\varepsilon_{ij}, \tag{32.6}$$

where λ and μ are the elastic constants, also known as the Lamé constants, and δ_{ij} is the Kronecker delta (equal to 1 if $i = j$ and 0 otherwise). As ε is dimensionless, the unit for λ and μ is that of stress, i.e., the Pascal. It should be noted that constitutive equations that more accurately model the nonlinear viscoelastic response of soft

tissue to loading have also been proposed [20]. However, their complexity has restricted their use in OCE.

32.2.4 Elastic Properties

A number of descriptors may be derived from the Lamé constants for a material's elastic properties. In this section, we define these descriptors, namely, Young's modulus, shear modulus, bulk modulus, and Poisson's ratio and describe their relevance to OCE.

Young's modulus, E, characterizes the elasticity of a material subjected to uniaxial stress, i.e., only one normal stress component in Eq. 32.2 is nonzero. Uniaxial stress is generally a good approximation for the loads applied in OCE. For a load acting along z, E is defined as $\sigma_{zz}/\varepsilon_{zz}$, i.e., the ratio of normal (axial) stress to normal (axial) strain. In terms of the Lamé constants, it is expressed as $\frac{\mu(3\lambda+2\mu)}{(\lambda+\mu)}$. E has the same unit as stress, i.e., the Pascal.

Shear modulus, G, is the ratio of shear stress to shear strain, e.g., $\sigma_{xz}/\varepsilon_{xz}$. It is equal to the Lamé constant, μ, and its unit is the Pascal.

Bulk modulus, K, is defined as the ratio of hydrostatic pressure, σ, to unit volume change, $\Delta v/v$. Hydrostatic pressure describes the situation when all shear stress components are zero and the normal stress components are equal, i.e., $\sigma_{xx} = \sigma_{yy} = \sigma_{zz}$. K is a measure of the compressibility of a material and defined as $\lambda + \frac{2}{3}\mu$, and its unit is the Pascal. Its unit of measurement is the Pascal.

Poisson's ratio, ν, is defined as the ratio of the normal strain along the axis of stress to the normal strain in each orthogonal axis. In compression, it is the ratio of elongation per unit breadth to contraction per unit length, e.g., $-\varepsilon_{xx}/\varepsilon_{zz}$, where the negative sign results from the division of a tensile normal strain, ε_{xx}, by a compressive normal strain, ε_{zz}. It is defined in terms of the Lamé constants as $\frac{\lambda}{2(\lambda+\mu)}$. As it is a ratio of two strains, it is dimensionless.

The Lamé constants, Young's modulus, shear modulus, bulk modulus, and Poisson's ratio are related. Only two of these parameters are independent for an isotropic, linearly elastic material, and thus, measurement of any two determines the other parameters. For soft tissue, the high water content results in the near conservation of volume upon compression. As a result, the bulk modulus of soft tissue has been reported to vary by less than 15 % from that of water [17]. The incompressibility of soft tissue also results in a Poisson's ratio of very close to but not exceeding 0.5. As these properties do not vary significantly for soft tissues, the goal of most OCE techniques is to estimate Young's modulus or shear modulus, which has a much larger dynamic range. These moduli also correspond most closely to what is sensed by manual palpation of the tissue. In soft tissue, it is readily shown that $E \approx 3G$, under the assumption that $\nu \approx 0.5$ [16]. Therefore, Young's modulus is the most common single property used to characterize tissue elasticity and the most commonly probed property in OCE. The value of Young's

modulus of soft tissues extends from tens of Pascals, in very soft tissues such as adipose [21], to hundreds of kPa to MPa, as in hard tumors [22].

32.2.5 Equations of Motion

In some OCE techniques, as well as in some ultrasound and magnetic resonance elastography techniques, a dynamic (sinusoidal) load is applied to the sample. In this case, inertia must be taken into account. The constitutive equation of motion for a linearly elastic solid is given by Navier's equation as [16]

$$\rho_0 \frac{\partial^2 \mathbf{u}}{\partial t^2} = (\lambda + \mu)\nabla(\nabla \cdot \mathbf{u}) + \mu \nabla^2 \mathbf{u}, \tag{32.7}$$

where ρ is the density of the tissue and $\mathbf{u}$ is the displacement vector. Transverse and longitudinal waves can propagate independently in the material: S (shear) waves and P (pressure) waves, respectively. For shear wave propagation, there is no volume change in the material. The dilatation term ($\nabla \cdot \mathbf{u}$) is therefore zero and Eq. 32.7 becomes

$$\nabla^2 \mathbf{u} = \frac{1}{c_s^2}(\lambda + \mu)\nabla(\nabla \cdot \mathbf{u}) + \mu \nabla^2 \mathbf{u}, \tag{32.8}$$

where c_s, the shear wave speed, is defined as $\sqrt{\mu/\rho}$. Pressure waves are irrotational, i.e., $\nabla \times \mathbf{u} = 0$, allowing $\mathbf{u}$ to be written in terms of a potential, ψ, such that $\mathbf{u} = \nabla\psi$. The wave equation then becomes

$$\nabla^2(\nabla\psi) = \frac{1}{c_p^2}(\lambda + \mu)\nabla(\nabla \cdot \mathbf{u}) + \mu \nabla^2 \mathbf{u}, \tag{32.9}$$

where the P-wave speed, c_p, is defined as $\sqrt{\frac{\lambda+2\mu}{\rho}}$.

For soft tissues, the pressure wave speed, typically several thousand m/s, is orders of magnitude faster than the shear wave speed, typically several m/s [18]. The focus in dynamic OCE to date has mainly been to measure elasticity from the shear wave properties [23–26]. There are several reasons for this: firstly, as the P-wave speed depends on variations of the bulk modulus, it has a much lower dynamic range in tissue than S-waves; secondly, the high speed of P-waves makes their detection challenging.

An advantage of dynamic OCE is that it should enable the complex dynamic mechanical response of a sample to be measured, providing information about both its elastic and viscoelastic properties. OCE techniques that have been used to measure viscoelastic properties of tissue are discussed in more detail in Sect. 32.4.4. Dynamic OCE is also potentially more suitable for in vivo measurements, as it enables loading in a frequency range not affected by sample motion, e.g., due to breathing.

32.3 Measuring Displacement in OCE

The accuracy and dynamic range of the displacement measured in response to a load has a major impact on elastogram quality. In this section, we describe three techniques to measure the displacement: speckle tracking, phase-sensitive detection, and use of the Doppler spectrum.

32.3.1 Speckle Tracking

Speckle is the phenomenon of fine-scale, apparently random, fluctuating light and dark intensity present in all coherent imaging systems. In OCT, it is generated by the summation of the multiple backscattered optical wavefields arising from the sub-resolution sample scatterers. The wavefields may be represented as a summation of complex phasors, which determines the intensity and phase of the detected signal. A detailed analysis of OCT speckle can be found elsewhere [27].

Speckle tracking may be considered to be a sub-branch of the much broader field of speckle metrology, developed since the late 1960s [28, 29]. The utility of speckle for tracking motion in OCE arises because each speckle realization, far from being random, is dependent upon the precise location of backscatterers within the sample. As the backscatterers translate, within a certain range, so does the speckle pattern associated with them. Under the assumption that the relative positions of sub-resolution scatterers remain fixed while they translate, any variation of the speckle pattern between successive acquisitions, or equivalently, of its second-order temporal statistics, can be used to measure sample motion. This is shown in Fig. 32.2, in which a small portion of an OCT speckle pattern acquired from a homogeneously scattering phantom under compressive load (applied from above) is shown in false color. The pattern is shown for four increments in load, increasing from Fig. 32.2a–d. Translation of a single bright speckle is highlighted by a black outline in each figure part. Evident in Fig. 32.2 is the gradual decorrelation of the speckle pattern with load, a major limitation of the technique. This decorrelation is caused by the reorganization of the positions of the sub-resolution scatterers due to loading. It limits the maximum measurable displacement to considerably less than the OCT resolution.

The speckle shift is typically evaluated by calculating the cross-correlation of a portion of B-scans acquired at two time points during compression [9]. Consider a point scatterer embedded in a transparent medium at position (x, z). When the sample is placed under load, the scatterer is displaced to a new location, $(x + \Delta x, z + \Delta z)$. The normalized cross-correlation between the OCT signal before, $I_1(x, z)$, and after loading, $I_2(x, z)$, within a predefined window of dimensions $X \times Z$, is given by

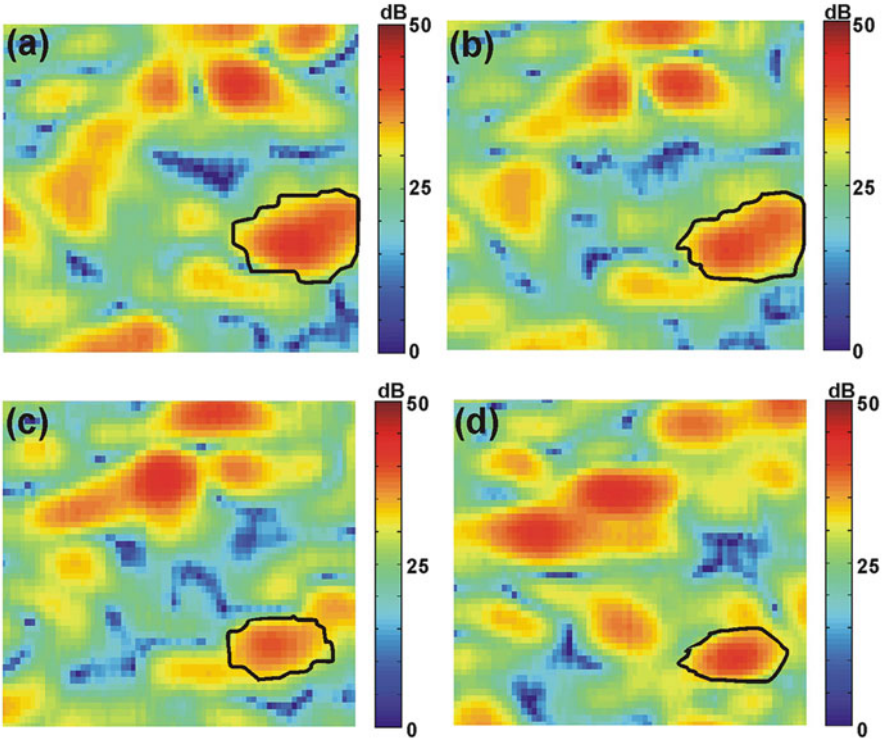

Fig. 32.2 Speckle pattern of a silicone phantom (logarithmic intensity scale) under increasing compressive load (applied from above) from (**a**–**d**). Image dimensions 50 × 50 μm. *Black outline* highlights the evolution of an individual speckle

$$\rho(x',z') = \frac{\int_{-Z/2}^{Z/2}\int_{-X/2}^{X/2} I_1(x,z)I_2(x-x',z-z')dxdz}{\sqrt{\int_{-Z/2}^{Z/2}\int_{-X/2}^{X/2} I_1^2(x,z)dxdz \int_{-Z/2}^{Z/2}\int_{-X/2}^{X/2} I_2^2(x-x',z-z')dxdz}}. \quad (32.10)$$

The relative displacement, between the acquisition of $I_1(x, z)$ and $I_2(x, z)$, in the x and z directions can then be determined from

$$\Delta u_x = \max[(\rho(x',z'))] \text{ for } z' = 0, -X/2 \le x' \le X/2, \quad (32.11)$$

and

$$\Delta u_z = \max[(\rho(x',z'))] \text{ for } x' = 0, -Z/2 \le z' \le Z/2. \quad (32.12)$$

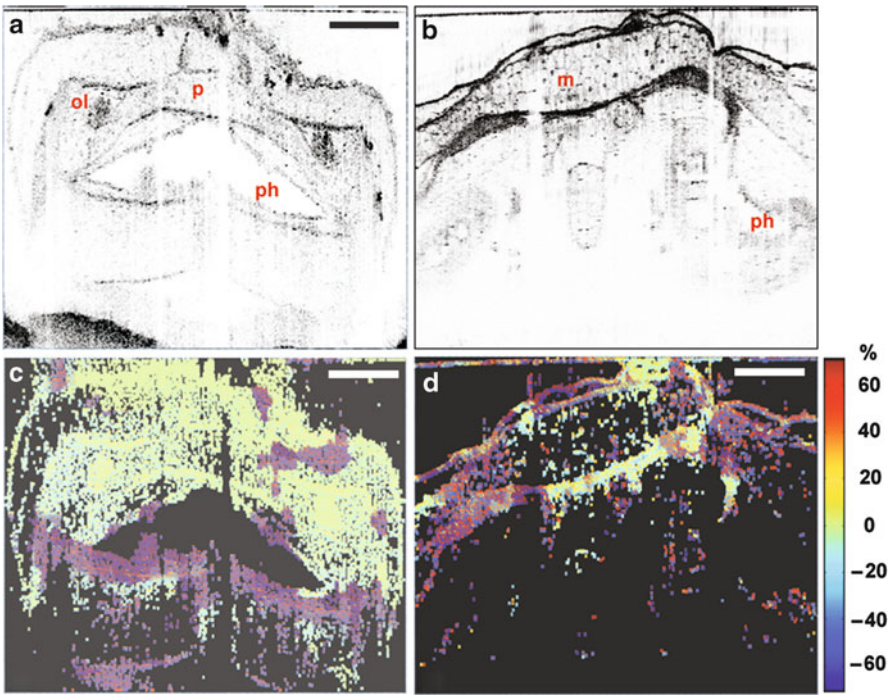

Fig. 32.3 OCT images and strain maps of a *Xenopus laevis* tadpole at different life cycle stages. (**a**, **c**) Representative structural OCT and OCE relative (local) strain maps, respectively, for stage 42 (3 -day-old). (**b**, **d**) Representative structural OCT and OCE relative (local) strain maps for Stage 50 (15 -day-old). Scale bar = 300 μm (adapted from [34])

From Eqs. 32.10–32.12, ρ is maximum for $x' = \Delta x$ and $z' = \Delta z$, respectively. Correlation-based speckle tracking was used in early OCE research [9, 30–34] and has been commonly used in ultrasound elastography [3]. Early examples of OCE elastograms obtained using correlation-based speckle tracking, along with the corresponding OCT images, acquired from a *Xenopus laevis* tadpole at different stages of development are shown in Fig. 32.3.

The minimum measurable displacement obtainable with speckle tracking is determined by the spatial sampling in the underlying OCT system, assuming an adequate OCT SNR. For cross-correlation techniques that use a central difference approach to evaluate Eq. 32.10, this corresponds to 0.5 pixels [10]. Displacements as small as 0.1 pixels can be measured using parametric techniques, such as the maximum likelihood estimator [11, 35]. However, these estimators result in intolerably large errors for displacements >0.8 pixels.

The maximum measurable displacement using the cross-correlation method is set by speckle decorrelation, as mentioned, which depends on the sample elasticity as well as on the size range, density, and arrangement of the sub-resolution scatterers. In a study on a silicone phantom containing titanium dioxide particles,

the maximum displacement was reported to be ~0.5 times the resolution of the OCT system [35]. Low OCT SNR also results in decorrelation between successive B-scans [35], reducing the accuracy of displacement measurements with increasing depth in the sample.

The above limits imply a severely limited dynamic range for speckle tracking. Consider an OCT system with spatial resolution of 10 × 10 × 10 μm and spatial sampling such that the axial pixel size is 3 μm and the lateral pixel size is 1 μm. Use of a smaller pixel size either imposes restrictions on the field of view (for fixed pixel count) or increases in the acquisition time (for more pixels). Using cross-correlation, minimum and maximum measurable displacements of ~1.5 and ~5 μm (from the example in [36]), respectively, might be reasonably expected and correspond to a dynamic range of ~3.3, with the same range applying to the measurable elasticity in OCE.

An additional limitation is that the displacement is calculated within a predefined window ($X \times Z$ in Eq. 32.10). The window sets the imaging spatial resolution of each displacement measurement, lowering it relative to the OCT image resolution, typically by a factor of 5–10 [9, 31].

An important further consideration when using speckle tracking is the avoidance of decorrelation caused by changes in the tissue configuration not related to its elastic properties, such as bulk motion, Brownian motion, or blood flow. This implies an acquisition speed high enough to ensure the speckles remain correlated between successive scans.

An advantage of speckle tracking is that motion can be tracked in more than one spatial dimension. Speckle tracking in OCE has been performed in only one or two dimensions, but 3D tracking has been proposed in ultrasound [37]. 3D tracking would provide the opportunity to measure shear strain in addition to normal strain (see Eq. 32.4) and to remove the otherwise necessary assumption of isotropic mechanical behavior. This may provide additional OCE contrast in anisotropic tissues, such as skin and muscle, as has already been demonstrated in ultrasound [38] and magnetic resonance elastography [39]. Indeed, 3D information is routinely obtained in magnetic resonance elastography.

32.3.2 Phase-Sensitive Detection

Speckle tracking utilizes changes in the *intensity* of an OCT image with loading. In Fourier-domain (FD) OCT, after performing a Fourier transform on the detected spectral fringes, the depth-resolved complex signal is obtained. This provides the opportunity to analyze the *phase* of the detected signal. OCT phase is generally random in soft tissue; however, it is temporally invariant if the sample is stationary. If a sample is subjected to mechanical loading, its axial displacement, Δu_z, between two A-scans, acquired from the same lateral position, results in a phase shift, $\Delta\phi$ [40]. The displacement, Δu_z, along the axis of the incident beam is defined as

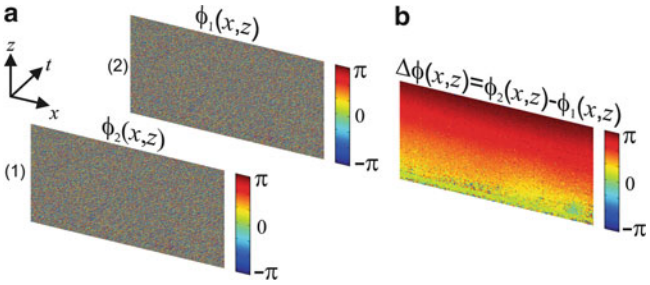

Fig. 32.4 Schematic illustration of phase-sensitive detection with experimental data from a mechanically homogeneous silicone phantom. (**a**) The phase of OCT B-scans acquired at the same lateral position before (*1*) and after (*2*) sample loading. (**b**) Phase difference between the B-scans shown in (**a**). As the load was applied from the *top*, the phase difference is maximum in this position, reducing to near zero at large depths

$$\Delta u_z(z,t) = \frac{\Delta\phi(z,t)\lambda}{4\pi n}, \tag{32.13}$$

where λ is the mean wavelength of the source and n is the average refractive index along the beam path. The phase difference is calculated either between two successive A-scans in a B-scan (requiring high lateral sampling density) [40] or between two A-scans acquired in the same lateral position in successive B-scans [41]: the latter is illustrated in Fig. 32.4 with experimental data acquired from a uniformly scattering silicone phantom. Phase-sensitive detection was initially developed for Doppler flow velocity measurement in OCT [42]. Indeed, the phase-sensitive technique is based on the Doppler shift; thus, unlike speckle tracking, only the axial component of the displacement can be detected. If we assume that the maximum measurable displacement is set by the maximum unambiguous phase difference, i.e., 2π, then this corresponds to half the source center wavelength (in the sample medium). The minimum measurable displacement, $\sigma_{\Delta u_z}$, is determined by the phase sensitivity of the OCT system [43], which, in the shot-noise limited regime, is related to the OCT signal-to-noise ratio (SNR) and is approximated as

$$\sigma_{\Delta\phi} = \frac{1}{\sqrt{SNR}}, \quad SNR >> 1. \tag{32.14}$$

Park et al., in their work on flow imaging [44], demonstrated good agreement between Eq. 32.14 and experimental results for OCT SNR >30 dB. It is important to emphasize, however, that this approximation is only valid for large OCT SNR.

Another source of phase noise is introduced under the successive A-scans scenario if the temporally displaced beams are not precisely overlapped in space. The phase noise introduced due to lateral beam motion, Δx, between successive A-scans is given by [44]

$$\sigma_{\Delta x} = \sqrt{\frac{4}{3}\left\{1 - \exp\left[-2\left(\frac{\Delta x}{w}\right)^2\right]\right\}}, \tag{32.15}$$

where w is the $1/e^2$ beam width at the focus. In practice, to minimize phase noise due to scanning, dense sampling is performed along the axis used to calculate the phase difference. As an example, consider a typical OCT system with a $1/e^2$ beam width of 25 μm at the focus. Acquiring A-scans in 1 μm lateral steps ensures that the phase noise due to scanning is <0.05 rad, within a factor of 5 of the limiting phase noise for OCT SNR = 40 dB. A further source of phase noise, σ_{mech}, is introduced by mechanical instabilities in the system, such as jitter in the scanning mirrors. Combining Eqs. 32.14 and 32.15 and including mechanical instabilities, considering each of these processes to be additive and Gaussian, the total phase noise, σ_{Tot}, is given by

$$\sigma_{Tot} = \sqrt{\sigma_{\Delta\phi}^2 + \sigma_{\Delta x}^2 + \sigma_{mech}^2}. \tag{32.16}$$

To minimize σ_{Tot}, both $\sigma_{\Delta\phi}$ and σ_{mech} must be negligible and the OCT SNR must be maximized (see Eq. 32.14). Under these conditions, displacement sensitivity of ~20 pm has been reported [45]. The minimization of σ_{mech} has been discussed in detail in relation to optical coherence microscopy (see ▶ Chap. 28, "Optical Coherence Microscopy" for more details). Techniques employed to minimize σ_{mech} include the use of a common-path interferometer and a reference reflector within the sample arm. In practice, $\sigma_{\Delta\phi}$ is often appreciable due to the requirement to laterally scan across the sample, such that typical displacement sensitivities lie in the range 0.1–1 nm.

A key advantage of phase-sensitive detection over speckle tracking is its larger dynamic range. If we consider the phase difference between two A-scans acquired using an OCT system with mean wavelength of 1300 nm and minimum OCT SNR of 30 dB, the displacement dynamic range in air is >60, almost 20-fold larger than that achievable using the cross-correlation method for speckle tracking described in Sect. 32.3.1.

A major limitation is imposed by phase wrapping, one which invalidates the assumption of a linear relationship between phase difference and displacement (Eq. 32.13). Phase jumps of 2π not only occur when the desired phase difference is close to the 2π limit but also arise due to noise when the OCT SNR is low. In the case of dynamic loading, phase wrapping due to noise can be mitigated by faster acquisition. An alternative means of mitigation is intensity thresholding and weighting, which gives preference to the phase difference estimated from pixels with high SNR. On the other hand, robust algorithms to correctly unwrap phase may enable significant increases in the dynamic range of phase-sensitive OCE, e.g., successfully unwrapping one such event would lead to a 3 dB improvement in dynamic range. However, it must be emphasized that all phase-unwrapping algorithms break down in the presence of high noise.

Phase-sensitive detection possesses several advantages over speckle tracking, including the larger dynamic range, lower computational complexity, and higher displacement sensitivity. Also, the spatial resolution of displacement measurements is matched to that of the underlying OCT system: the displacement is not estimated in an $X \times Z$ window, as is the case in speckle tracking.

The above discussion has not explicitly considered determining the displacement by phase measurement under dynamic mechanical loading. Liang et al. [46] developed a technique to measure displacement under dynamic loading using phase-sensitive detection. The vibration amplitude is calculated from the displacement and used to estimate the strain rate. A related technique has also been presented for measuring vibration within the ear [45]. In the next section, we consider a recently introduced improvement over these phase-sensitive methods for detecting vibration amplitude.

32.3.3 Doppler Spectrum

A major limitation of phase-sensitive detection is the large drop-off in accuracy with decreasing SNR (Eq. 32.14). Recently, with the goal of reducing this drop-off, a new technique has been proposed for extracting the displacement from the measured intensity under dynamic mechanical loading. Joint spectral- and time-domain optical coherence elastography (STdOCE) improves vibration amplitude measurement in dynamic OCE [47] by adapting the technique previously proposed for Doppler flow imaging [48]. STdOCE provides more accurate vibration amplitude measurements than the phase-sensitive technique in the case of low OCT SNR ($<$20 dB), thereby extending the depth range of accurate dynamic OCE measurements.

Dynamic loading results in an amplitude spectrum of frequency tones described by Bessel functions of the first kind. In STdOCE, a Fourier transform is performed in the time domain, i.e., across multiple A-scans. If the A-scan rate is much higher than the loading rate, the result is a Doppler spectrum containing frequency tones, which can be used to extract the vibration amplitude at each depth in the sample.

STdOCE is closely related to a previously reported dynamic OCE technique based solely on time-domain (TD) OCT [19, 49]. The bandwidth of the frequency tones in TD-OCT increases with both the bandwidth of the source and the A-scan velocity, which causes them to overlap in frequency and restricts measurements to only the first few tones. This limits the accuracy and requires the use of a very slow A-scan acquisition rate ($\sim$1 Hz). Nonetheless, this technique was capable of being used to demonstrate the first in vivo dynamic OCE measurements [49].

In STdOCE, the increased number of tones in the Doppler spectrum provided by spectral-domain (SD) OCT allows a signal processing technique proposed in ultrasound elastography to be employed [50], in which the vibration amplitude is determined from the variance or spectral spread of frequency tones in the Doppler spectrum. Figure 32.5 shows the data acquisition and processing procedure for

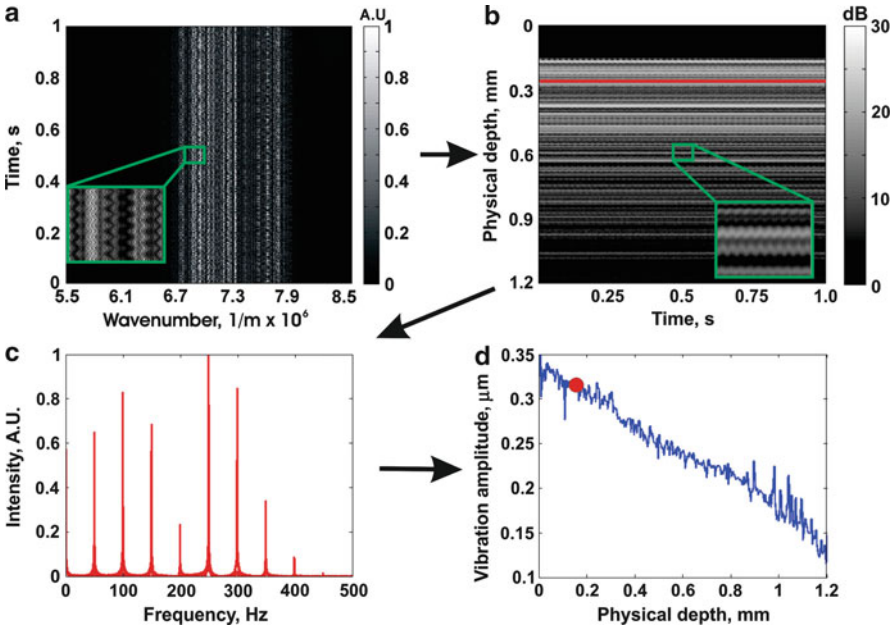

Fig. 32.5 Data processing procedure for STdOCE: (**a**) 2,000 spectral interferograms; (**b**) A-scans obtained after Fourier transform in *k*-space; (**c**) Doppler spectrum after Fourier transform in time, performed at depth indicated by the *red line* in (**b**); and (**d**) vibration amplitude (peak) calculated using the spectral spread algorithm. The *red dot* in (**d**) corresponds to the vibration amplitude calculated from the Doppler spectrum in (**c**) (reproduced from [47])

STdOCE. In Fig. 32.5a, 2,000 successive spectral interferograms acquired from the same lateral position in a homogeneous phantom are shown. In Fig. 32.5b, the corresponding depth-resolved A-scans, after Fourier transformation in *k*-space, are shown. In Fig. 32.5c, the Doppler spectrum obtained after performing a second Fourier transform in the time domain at the depth indicated by the red line in Fig. 32.5b is shown, with nine overtones in evidence. Having calculated the Doppler spectrum, the spectral spread algorithm is used to calculate the vibration amplitude. The vibration amplitude calculated from the spectrum in Fig. 32.5c is indicated by the red dot in Fig. 32.5d. This procedure is repeated for each depth in the sample, allowing a vibration amplitude plot (blue line in Fig. 32.5d) to be generated.

Figure 32.6 demonstrates the superiority of STdOCE over a representative technique for phase-sensitive detection [45]. In Fig. 32.6a, a structural OCT image of a soft phantom containing a stiff inclusion is shown. The inclusion is located in the center of the image and is indicated by the labeled arrow. Below the inclusion, a shadow artifact, corresponding to a region of low OCT SNR, is also labeled. A plot of the OCT SNR, at the lateral position indicated by the vertical red arrow in Fig. 32.6a, is shown in Fig. 32.6d. Vibration amplitude images generated using STdOCE and phase-sensitive OCE are shown in Fig. 32.6b, f, respectively. In both

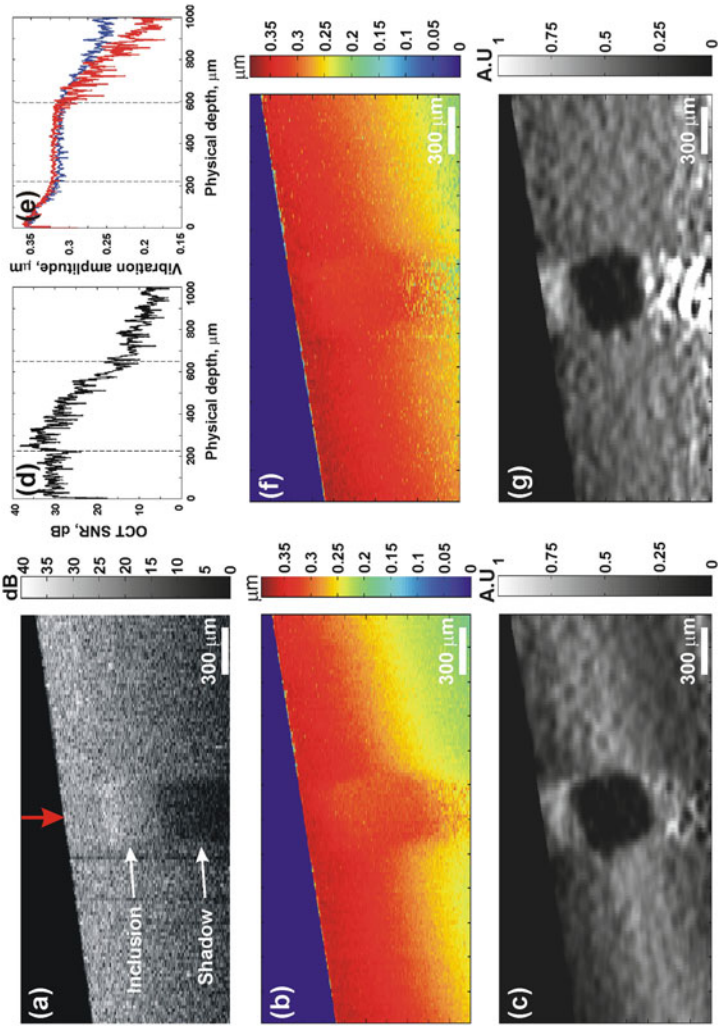

Fig. 32.6 Soft phantom containing a stiff inclusion: (**a**) OCT structural image; (**b**) vibration amplitude image; (**c**) elastogram for STdOCE; (**d**) OCT A-scan; (**e**) vibration amplitude plots for STdOCE (*blue*) and phase-sensitive OCE (*red*) at the lateral position indicated by the *red arrow* in (**a**), where the *dashed lines* in (**d**) and (**e**) indicate the boundaries between the soft bulk and hard inclusion; (**f**) vibration amplitude image; and (**g**) elastogram for phase-sensitive OCE [47]

Table 33.1 Comparison of different methods to measure displacement in OCE

	Minimum displacement	Maximum displacement	Axial resolution	Lateral resolution	Dimension of elasticity measured	Minimum data required
Speckle tracking	~0.1 × pixel size	~0.5 × OCT resolution	5–10 × OCT resolution	5–10 × OCT resolution	1D, 2D, 3D	2 A-scans
Phase-sensitive	~20 pm	~0.5 × source wavelength	OCT resolution	OCT resolution	1D	2 A-scans
Doppler spectrum	~10 nm	~0.5 × OCT axial resolution	OCT resolution	OCT resolution	1D	>10 A-scans

images, the stiff inclusions are denoted by the lower rate of change in vibration amplitude with depth, i.e., lower strain. Vibration amplitude plots generated using both techniques, at the lateral position indicated by the red arrow in Fig. 32.6a, are shown in Fig. 32.6e. Both plots match well until a depth of ~600 μm. At depths >600 μm, the decrease in vibration amplitude is higher for the phase-sensitive technique (red). This is caused by an underestimation of the vibration amplitude in the low OCT SNR region below the inclusion. In comparison, the decrease in vibration amplitude with depth measured with STdOCE below the inclusion is the same as that above the inclusion, as expected for these mechanically uniform regions. The strain elastograms corresponding to Figs. 32.6b and f are shown in Figs. 32.6c and g, respectively. The artificially high strain in the phase-sensitive elastogram (Fig. 32.6g) is clearly visible below the inclusion. As the elastogram is used as a surrogate for elasticity, this leads to errors in the interpretation of elastograms.

In this section, we described the two main techniques used to measure the displacement in OCE: the technique used in early OCE papers, speckle tracking, and the most commonly used technique in recent papers, phase-sensitive OCE. A recent improvement on phase-sensitive OCE that applies to dynamic displacement, STdOCE, based on the analysis of the Doppler spectrum, was also described. As discussed, each technique has its advantages and disadvantages, and these are summarized in the table below. It is expected that phase-sensitive techniques will continue to be prominent, as they enjoy a significantly larger dynamic range than speckle tracking and require the acquisition of much less data than STdOCE (Table 32.1).

32.4 OCE Techniques

In this section, we consider the wide variety of techniques that have been used to estimate elasticity from the measured displacement, as categorized by the nature and dynamics of the loading mechanism. We divide OCE techniques into five categories: compression, surface acoustic wave, acoustic radiation force, magnetomotive, and spectroscopic.

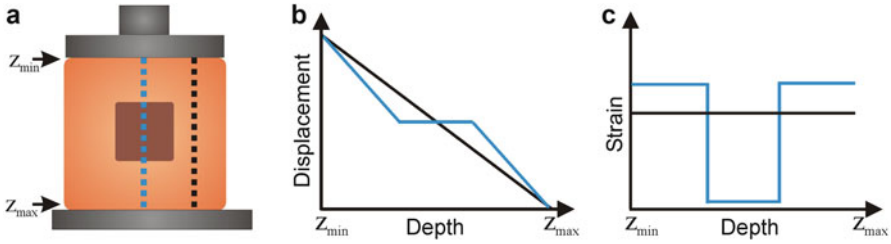

Fig. 32.7 (**a**) Illustration of an external load applied to a tissue sample, (**b**) tissue displacement versus depth for the positions indicated by the *blue* and *black lines* in (**a**), and (**c**) corresponding strain versus depth

32.4.1 Compression

In compression OCE, a step load is introduced externally to a sample between acquisitions (of either A-scans or B-scans) and the strain is estimated from the change in measured displacement with depth. This technique was used by Schmitt et al. in the first demonstration of OCE [9]. Compression elastography is the most straightforward to implement and is also the most mature in ultrasound elastography [3, 5]. In compression OCE, a number of assumptions are commonly made: (1) the stress is uniformly distributed throughout the sample, allowing the strain to be used as a surrogate for elasticity; (2) the sample is linearly elastic; and (3) it compresses uniaxially. These assumptions are also made in a number of dynamic OCE techniques [19, 49, 51], with one notable exception [52]. The adequacy and appropriateness of these assumptions is discussed in detail in Sect. 33.6.

The basic principle of compression OCE is illustrated in Fig. 32.7. A soft material containing a stiff inclusion, resting on a rigid, immovable surface, is subjected to a step load by an external compression plate. The displacement versus depth introduced at the positions indicated by the black and blue lines in Fig. 32.7a is shown in Fig. 32.7b. The displacement in the homogeneous region of the sample (black line) decreases linearly to zero at z_{max}, i.e., the sample undergoes uniform compression. The displacement through the center of the sample (blue curve) shows a local deviation in the displacement in the region corresponding to the stiff inclusion. Assuming the inclusion has a Young's modulus much larger than the background material, it can be considered to displace as a bulk, i.e., the displacement at each position in the inclusion is equal.

In Fig. 32.7b, the presence of the inclusion can be readily distinguished from the displacement. However, the difference in slope would be less visible if the stiffness of the inclusion approached that of the bulk medium. Furthermore, displacement alone cannot be used to quantify stiffness, as the displacement at a given depth in the sample is also dependent on the distance from the load. To overcome these issues, the uniaxial local strain, i.e., $\partial u_z/\partial z$ in the strain tensor (Eq. 32.4), may be plotted. The local strain corresponding to the displacement plots in Fig. 32.7b is plotted in Fig. 32.7c. The homogeneous region (black line) undergoes constant strain versus depth, whereas the hard inclusion undergoes a locally reduced strain

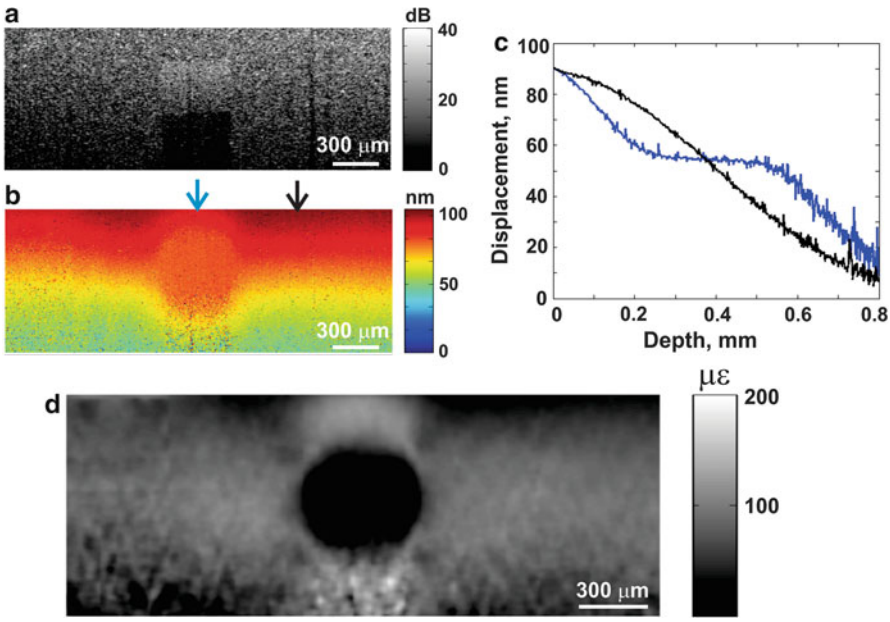

Fig. 32.8 (**a**) OCT image of a soft phantom containing a stiff inclusion, (**b**) displacement map generated for a load similar to that shown in Fig. 32.7a, (**c**) displacement plots corresponding to the positions indicated by the *blue* and *black* arrows in (**b**), and (**d**) elastogram generated from the displacement map in (**b**)

(zero strain in the ideal case of bulk motion of the inclusion shown here). It should also be noted that because the total change in displacement from z_{max} to z_{min} is the same in both regions, the strain above and below the inclusion is higher than that in the homogeneous region.

Experimental phase-sensitive compression OCE results from a phantom similar to the sample illustrated in Fig. 32.7, i.e., a stiff inclusion embedded in a soft surrounding material, are presented in Fig. 32.8. In Fig. 32.8a, the OCT image is shown. The inclusion is visible in the center of this image. The displacement map calculated from the phase difference between B-scans is shown in Fig. 32.8b and the displacement plots, similar to those illustrated in Fig. 32.7b, are presented in Fig. 32.8c at the lateral positions indicated by the arrows in Fig. 32.8b. In Fig. 32.8d, the corresponding strain image is presented. Each pixel in this image corresponds to the local strain estimated at that spatial location. The local strain is presented in $\mu\varepsilon$, signifying microstrain. As expected, the stiff inclusion has lower strain than the surrounding soft material. The strain is estimated as the change in displacement, Δu_z, over a depth increment, Δz, which, in turn, defines the strain axial resolution [53]. This estimation results in an inherent loss of spatial (axial) resolution in compression OCE. For the results shown in Fig. 32.8d, Δz was 75 μm, while the axial resolution of the OCT system was ~8 μm. Although it is a qualitative measurement of elasticity (in the sense that local strain cannot be

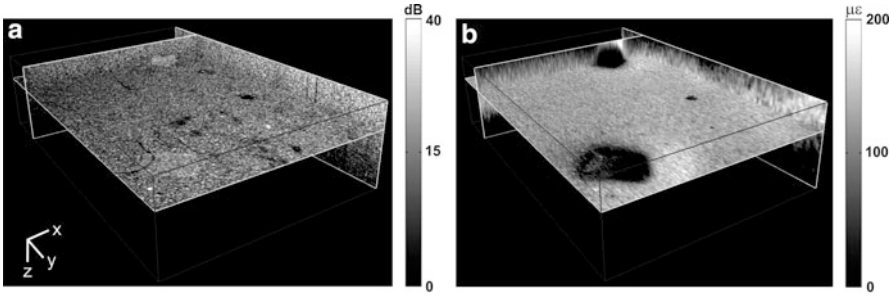

Fig. 32.9 3D-OCT (**a**, **b**) compression 3D-OCE images of the same soft phantom with two stiff inclusions visible, showing enhanced mechanical over scattering contrast for the chosen values of scattering strength and stiffness. Scale bars represent 200 μm

used to determine modulus because the local stress is not known), we define the strain image as an elastogram.

The two major factors in determining the strain measurement accuracy are the displacement measured from the OCT data and the method used to calculate strain from the measured displacement. The techniques used to measure displacement were discussed in detail in Sect. 32.3. Four estimation methods have been used to determine strain in compression OCE: finite difference, ordinary least squares, weighted least squares, and Gaussian smoothed weighted least squares (GS-WLS) [53]. In order to compare these methods, strain imaging parameters have been defined. The strain sensitivity, S_ε, is defined as the standard deviation of the strain estimate, σ_ε, and the strain SNR, SNR_ε, is defined as the ratio of the mean to the standard deviation of the strain estimate, $\mu_\varepsilon/\sigma_\varepsilon$. The GS-WLS method has been shown to provide an improvement in both sensitivity and SNR of 3 dB compared with weighted least squares, 7 dB compared with ordinary least squares, and 12 dB compared with finite difference. For all methods, strain spatial resolutions <40 μm did not provide accurate strain estimation [53].

3D visualizations of an OCT image and the corresponding elastogram, generated using GS-WLS strain estimation, are presented in Fig. 32.9. The sample is a soft silicone phantom containing two stiff inclusions. The elastogram axial resolution is 75 μm, and the lateral resolution is 10 μm. The inclusions are more readily visible in the elastogram than in the OCT image, demonstrating the potential of compression OCE to provide additional contrast in comparison with OCT. The subject of strain contrast in compression OCE will be discussed in greater detail in Sect. 32.6.

32.4.2 Surface Acoustic Wave

In recent years, a number of OCE techniques based on the measurement of the velocity of waves propagating along the sample surface have emerged [14, 15, 25, 54–57]. The shear modulus can be extracted from this velocity measurement using

inverse methods. Proposed techniques have used phase-sensitive detection in SD-OCT [54, 55], swept-source OCT [25, 57], and digital holography [14, 15]. In this subsection, we focus on the technique employing holographic detection.

Digital holographic imaging (DHI) is in many ways similar to OCT, as it is an interferometric technique that provides both the amplitude and phase of light scattered from an object. As such, it is similarly sensitive to tissue displacements, on the order of a fraction of the light wavelength. The primary difference is that DHI typically uses a long-coherence length light source that does not provide depth-resolved imaging. At the same time, DHI more naturally provides tissue surface displacement imaging over wide areas, ranging from imaging of vibrations on an eardrum [58], to induced vibrations over the whole human body [59]. Because DHI provides such comprehensive surface displacement data, it is helpful to look toward other areas of science where surface data have been employed for elasticity measurements. In fact, nondestructive testing has been widely employed to analyze the integrity of structural materials, where inversion of vibration data to produce a quantitative elastogram is treated as a boundary value problem [60, 61]. On a much larger scale, seismology is concerned with the analysis of the earth's surface movements (e.g., from earthquakes), which has been used to produce maps of the stiffness within the interior of the earth [62].

In seismology, the depth-dependent stiffness of, e.g., layers of rock, is often found by analysis of Rayleigh waves (also known as surface acoustic waves or SAWs) [63]. The ability to depth-resolve elasticity using SAWs is due to two key features of the waves: (1) SAWs propagate laterally with a penetration depth proportional to their wavelength and, thus, are only "sensitive" to materials within this characteristic depth, and (2) the wave velocity depends upon the material's Young's modulus E within this sensitive region (which we will define as our sensitivity kernel) according to $c_R \approx \frac{0.87+1.12\nu}{1+\nu}\sqrt{\frac{E}{2\rho(1+\nu)}}$, where ν is Poisson's ratio and ρ is mass density (both of which vary only slightly in tissue). As illustrated in Fig. 32.10, we can therefore measure SAW velocity versus frequency and use this to infer the depth-dependent elasticity. A stiff surface layer with an underlying soft layer will appear as a positive dispersion in the SAWs (i.e., wave speed increasing with frequency) because higher frequency waves "feel" only the stiffer surface material, resulting in higher velocity. Conversely, a soft surface layer with stiff underlying layer is negatively dispersed.

By using an appropriate model for the sensitivity kernel of the SAWs, one can construct a linear system relating a measurement of the SAW velocity dispersion, $c_R(f)$, to the 1D depth-dependent Young's modulus of the sample, $E(z)$. This inverse method was first demonstrated in soft materials using a single-point optical vibrometer scanned away from a point source actuator [64, 65]. It was subsequently translated to DHI, where depth-resolved elasticity was measured in 2-layer phantoms up to 55 mm deep (Fig. 32.10 panels e, f) [15]. The advantage of using DHI to perform SAW elastography is the capability for real-time imaging of SAWs across the entire tissue surface, extending the 1D measurement of E into three dimensions. Importantly, this could have applications in performing whole-breast elastography,

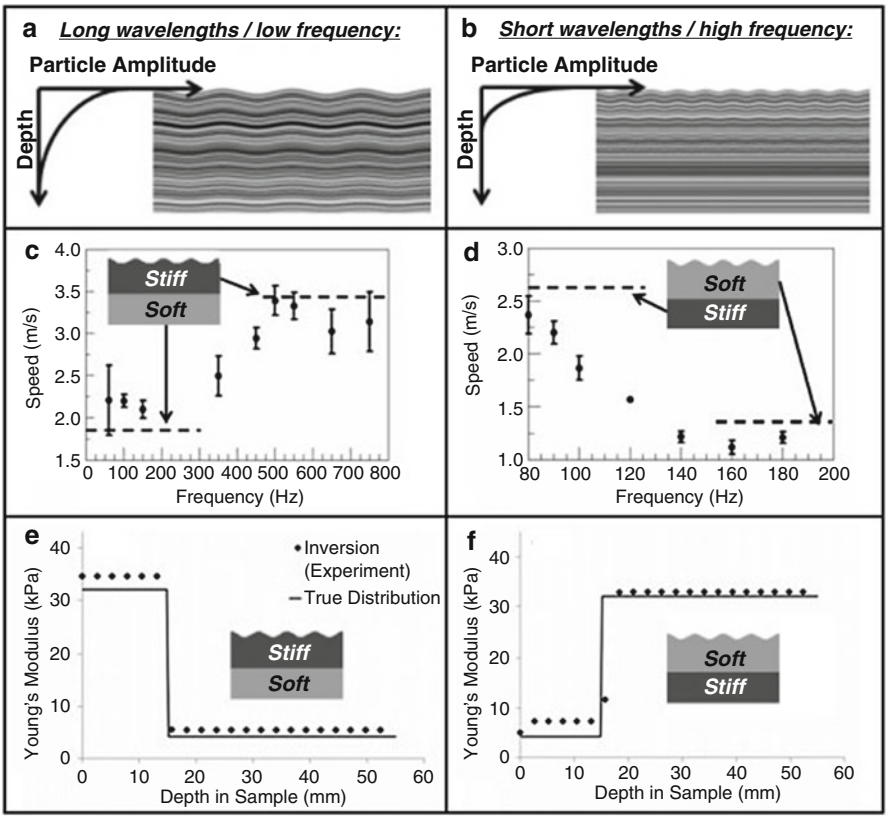

Fig. 32.10 Relationship between velocity dispersion of SAWs and depth-dependent stiffness. (**a**, **b**) Schematic illustration of SAWs versus depth showing how frequency affects the depth of penetration. (**c**, **d**) SAW velocity dispersion curves obtained using DHI in 2-layer tissue phantoms (data reprinted from [14]). (**e**, **f**) Reconstructed elastic depth profile in 2-layer phantoms is consistent with the actual phantom stiffness (Data reprinted from [15])

as a quantitative method to replace manual palpation currently used in breast cancer screening. In materials of similar elasticity as the human breast, SAW frequency sweeps from 20 to 600 Hz would be expected to provide elastograms over depths from nominally 5–50 mm. Currently, it has been qualitatively shown that DHI can detect perturbations in SAWs propagating over a 5 mm tumor-like inclusion embedded 9 mm deep in a breast tissue phantom [15] and that SAWs on real tissues appear well behaved when visualized with DHI (Fig. 32.11).

The visualization of SAWs using DHI deserves some attention here. There are several standard techniques employed in DHI for dynamic displacement measurement, which typically include off-axis holography and either Fourier transformation or spatial phase-shifting of the resulting fringe pattern [66, 67]. Interestingly, SAW elastography only requires measurement of the SAW phase velocity under a condition of a priori knowledge of the SAW frequency. Using this advantage, a method was recently

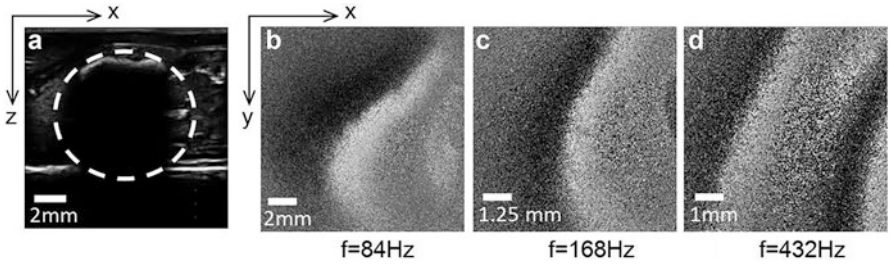

Fig. 32.11 Imaging SAWs in chicken thigh. (**a**) B-mode ultrasound showing the depth position of the thigh bone (*dashed circle*). (**b**–**d**) Corresponding DHI phase maps of SAWs propagating on the surface as a function of frequency. While low-frequency SAWs are strongly perturbed by the presence of the bone, well-behaved SAWs at high frequencies suggest that the softer tissue above the bone is relatively elastically homogeneous (Reprinted from [15])

developed to extract SAW phase (modulo π) using an on-axis DHI system without any phase modulation [14]. This method circumvents the limitation to the maximum spatial frequency of fringes imposed by off-axis holography, with the trade-off that one cannot readily extract the amplitude of the SAWs (only the phase). Example SAW phase maps obtained from chicken tissue are displayed in Fig. 32.11, revealing apparent wave "crests" corresponding to where the SAW phase wraps from π back to zero, which is a very intuitive way of visualizing the SAW wave fronts.

In summary, DHI-based elastography is a promising method for quantitative elastography that exploits the depth-penetrating property of SAWs to provide elastography several centimeters into tissues. Importantly, it is not limited by the shallow depth penetration of light but trades off overall spatial resolution. While standard elastography requires 3+1D (spatial+temporal) data collection, SAW-based elastography requires only 2+1D (spatial+frequency) data collection with the use of an appropriate model for SAWs to solve the boundary value problem. Future emphasis in this area will be on extending the current quantitative 1D elastography method to 3D.

32.4.3 Acoustic Radiation Force

In acoustic radiation force impulse (ARFI) imaging, a focused ultrasound pulse creates a localized mechanical load within a sample and the resulting deformation is measured using imaging techniques. Its initial development was based on ultrasound detection [68], with continuing clinical and commercial interest [69, 70]. More recently, OCT-based ARFI has been proposed, allowing smaller displacements to be measured with improved spatial resolution [23, 26, 71, 72].

Consider an acoustic wave, propagating in tissue generated using an ultrasound transducer. A unidirectional force is applied to absorbing or reflecting targets in the propagation path of the acoustic wave. This force results from a transfer of momentum from the acoustic wave to the tissue. Under the assumption of plane

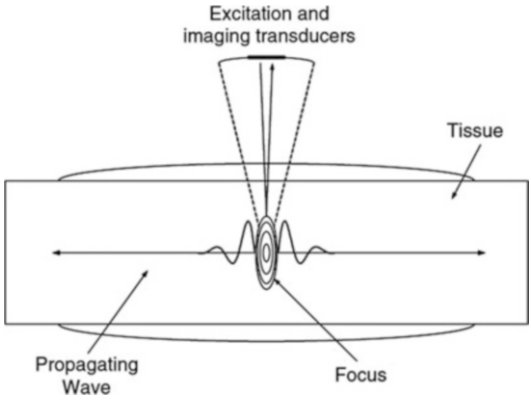

Fig. 32.12 Illustration of shear wave propagation caused by a focused ultrasound pulse (Reproduced from [2])

wave propagation, the acoustic body force (i.e., force per unit volume) applied to tissue at a given location due to local absorption is given by $F = \frac{2\alpha I}{c}$, where F has units of kg/(s^{2}cm^2), c is the speed of sound (m/s) in the tissue, α is the tissue absorption coefficient (m^{-1}), and I is the average intensity of the acoustic beam (W/cm^2) at the given location.

On-off modulation of the acoustic wave results in a corresponding on-off modulation of the local force and, hence, displacement, which can be measured directly or through the generation of an accompanying shear wave propagating in the direction perpendicular to the direction of the focused ultrasound beam, as illustrated in Fig. 32.12. The goal in ARFI imaging has primarily been to measure the sub-surface shear wave speed, c_s, which is directly related to the sample's shear modulus, μ, by $c_s = \sqrt{\mu/\rho}$, where ρ is the density of the tissue. Both speckle tracking [71] and phase-sensitive detection [23, 26] have been used to measure the shear wave speed in ARF-OCE. Axial displacement has also been measured in an ARF-OCE technique [72].

A related ARFI technique known as transient optoelastography has also been proposed [12, 73]. This technique is based on ultrasound-modulated optical tomography (UMOT) [13]. Detection of variations in laser speckle patterns recorded on the surface of a sample due to acoustic stimulation at depths up to several centimeters is possible, providing information from much greater depths than possible using OCE. However, the spatial resolution is determined by that of the ultrasound beam and is, therefore, much lower than that of OCE.

In all ARFI techniques, it should be considered that the high-intensity acoustic pulses used can be potentially harmful and above the safe limits set by, e.g., the U.S. Food and Drug Administration (FDA) [68]. However, this may prove not to be a major concern in ARF-OCE, as much smaller tissue displacements are required than when using ultrasound detection. Another noteworthy issue is the use of water or gel to couple the transducer and sample required to achieve acoustic impedance matching. Furthermore, same-side optical imaging and acoustic loading requires use of an annular or off-axis acoustic transducer.

32.4.4 Magnetomotive

Magnetomotive OCE (MM-OCE) utilizes an external magnetic field to induce magnetomotion within a sample of interest and OCT to detect displacements within the sample on the order of tens to hundreds of nanometers. Magnetomotion can be produced via internal excitation through the use of magnetic nanoparticles (MNPs) distributed within the sample [74–76], through a magnetic implant embedded in a sample [77], or via external excitation, e.g., through the use of a metallic slab transducer placed in contact with the sample [78]. MM-OCE can perform optical rheology of viscoelastic materials by measuring the dynamic response of a sample, either to a step excitation [74] or to a frequency sweep [75, 78]. The natural resonant frequencies of the sample can be connected to elastic and viscous moduli through an appropriate mechanical model.

The use of step excitation for optical rheology of tissue phantoms is shown in Fig. 32.13. These measurements were carried out in silicone phantoms doped with titanium dioxide particles to provide optical scattering and iron oxide MNPs to provide internal magnetomotive forces. Motion-mode (M-mode) measurements show an under-damped response to the (broadband) step excitation, where the dominant relaxation frequency is the natural resonance of the sample. The Young's modulus of the samples was varied over a range from 0.4 to 140 kPa, as calibrated using a commercial indentation instrument. The resonant frequency of the sample showed a linear dependence versus the square root of the Young's modulus, which is consistent with the behavior of a Voigt model, as previously adopted to model the mechanical response of bulk tissue [52].

Magnetomotive resonant acoustic spectroscopy (MRAS) is another magnetomotive technique to measure tissue elasticity [75]. MRAS utilizes a frequency sweep to measure the natural resonant frequencies of tissue-mimicking phantoms and biological samples. This approach provides improved signal-to-noise ratio compared to the step excitation, due to the increased measurement time of the sweep. Experiments in tissue-mimicking phantoms confirmed that the longitudinal vibration modes (natural resonant frequencies of the sample) depended on both sample viscoelastic properties as well as the geometrical dimensions (cylinder aspect ratio). For known sample geometry, Young's modulus and the viscous damping coefficient of the samples were determined by fitting the data to a viscoelastic mechanical model. In this model, Young's modulus was proportional to the square of the resonant frequency, while the viscous damping coefficient was proportional to the Lorentzian-shaped linewidth (related to the quality factor Q) of the resonant peak.

With biological tissue, where the geometry of the sample is not well controlled, MRAS has shown the ability to track relative changes in Young's modulus of the sample. Figure 32.14a shows measurements of the complex mechanical spectrum of rat liver undergoing formalin fixation. The increase in the resonant frequency with time can be seen in both the amplitude and phase of the mechanical response. Over a period of 147 min, the resonant frequency of the tissue undergoing fixation increased by a factor of 2, which suggests an increase in Young's modulus by a factor of 4.

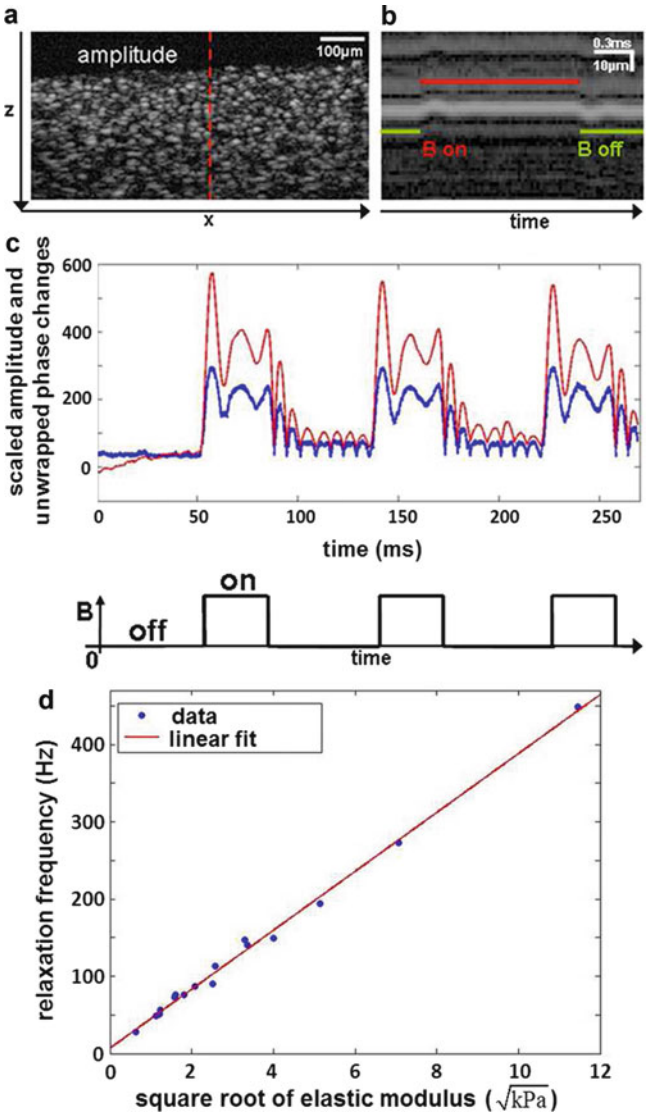

Fig. 32.13 Optical rheology of tissue phantoms based on a step magnetic excitation. (**a**) Cross-sectional OCT image. (**b**) M-mode image at the transverse position denoted by the *dashed red line* in (**a**). (**c**) Average scatterer response showing the amplitude (*blue*) and phase (*red*) characteristics of the magnetomotion from the excitation profile shown directly below (**c**). (**d**) The natural resonance frequency of phantoms of varying stiffness (adapted from [74])

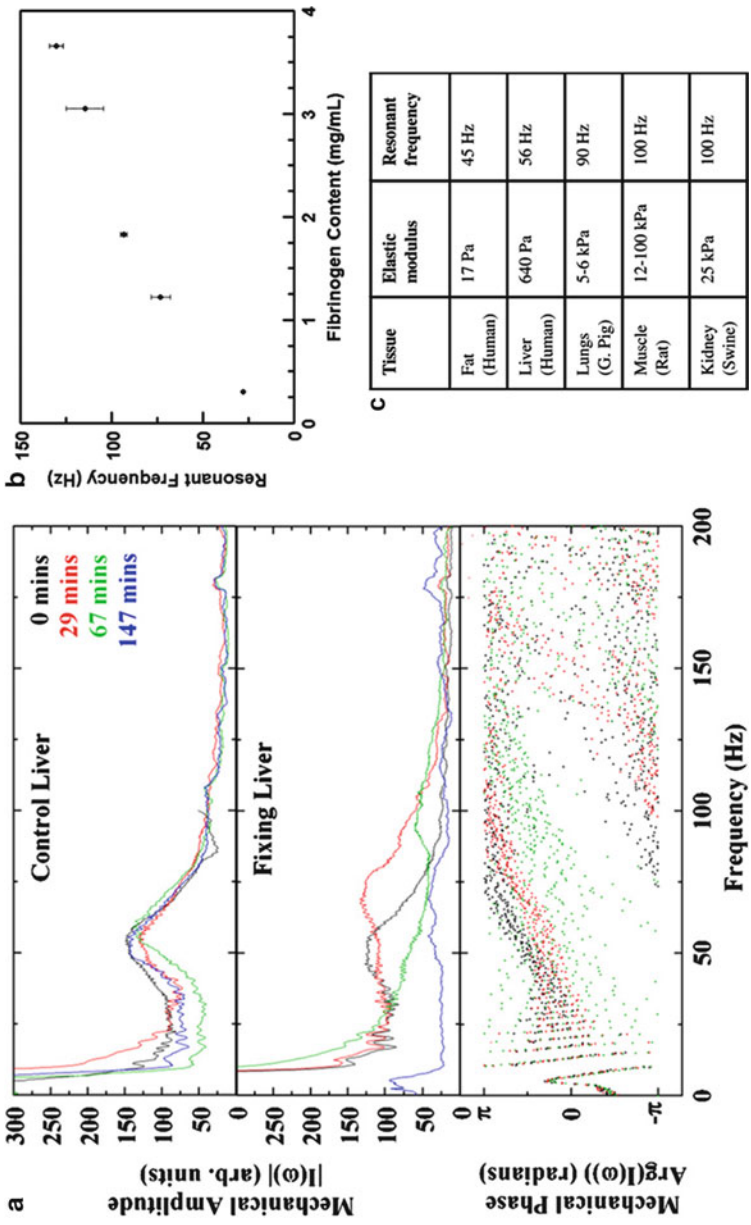
MRAS was utilized in a subsequent study to evaluate the dependence of the resonant frequency of fibrin clots vs. fibrinogen concentration [78]. The viscoelastic properties of fibrin networks are important in bleeding and clotting disorders. Clots were formed with controlled geometry in custom-printed rectangular wells, and in



Tissue	Elastic modulus	Resonant frequency
Fat (Human)	17 Pa	45 Hz
Liver (Human)	640 Pa	56 Hz
Lungs (G. Pig)	5-6 kPa	90 Hz
Muscle (Rat)	12-100 kPa	100 Hz
Kidney (Swine)	25 kPa	100 Hz

Fig. 32.14 MRAS of biological samples. (**a**) Longitudinal tracking of rat liver tissue undergoing formalin fixation ex vivo (from [75]), (**b**) resonant frequency of fibrin clots prepared in custom-printed rectangular wells (From [78]), and (**c**) table of natural resonant frequencies for different tissues (From [79]). Magnetomotion was produced via internal iron-oxide MNPs in (**a**) and (**c**), but with an external microtransducer in (**b**)

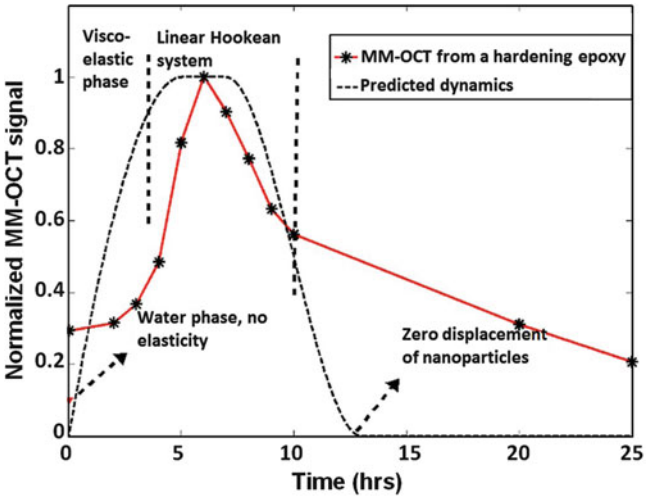


Fig. 32.15 Magnetomotive response of an epoxy sample undergoing transition from a viscous liquid state to a rigid solid (Adapted from [79])

this study an external microtransducer was used in order to avoid embedding the clots with MNP nanotransducers. Figure 32.14b presents results from M-mode measurements, showing that the resonant frequency increases monotonically with fibrinogen concentration. The Young's modulus is proportional to the square of the resonant frequency. Figure 32.14c presents measurements of the natural vibration frequencies for different types of tissues [79].

The magnetomotion facilitated by MNPs has been investigated in a wide range of viscoelastic conditions [79], experimentally simulated through the hardening process of epoxy from a viscous liquid to its final hardened state (see Fig. 32.15). The epoxy had a characteristic setting time of 12 h at a temperature of 90 °C. The low initial MM-OCT signal shows that initially the MNPs are not bound within the viscous fluid and so experience virtually no elastic restoring forces. Since the direction of the magnetic gradient force is the same regardless of polarity of the magnetic field [75], the oscillating magnetic field simply results in unidirectional displacements in addition to the Brownian motion of the particles in the liquid. Since the signal processing detects only sinusoidal motion, the liquid phase regime does not generate an appreciable MM-OCT signal. As the epoxy sets, it enters the regime of a linear Hookean system, where the MNPs that are now bound to the matrix experience elastic restoring forces. Finally, as the epoxy hardens the MNPs become tightly bound to the medium (which now has a significantly increased elastic constant), and the magnetomotion tends to zero. Ongoing work with a dual coil setup will enable bipolar forces on the magnetic particles, to extend the regime of applicability of MM-OCE to highly viscous samples [80].

Further work on MM-OCE will investigate the contributions of tissue geometry to the complex mechanical spectra and the extraction of quantitative mechanical properties. Finite element modeling, discussed in detail in Sect. 32.6, can simulate

deformation due to magnetomotive forces in irregularly shaped samples and help disentangle the impact of biomechanical heterogeneity on the bulk natural vibration modes of the sample. Extending these M-mode MM-OCE measurements to perform B-mode (or volumetric) imaging has the potential to provide spatially localized information on the mechanical properties of heterogeneous samples.

32.4.5 Spectroscopic

Mechanical spectroscopic imaging of tissue was first reported in landmark papers on ultrasound-stimulated vibro-acoustography [81, 82]. Vibro-acoustography utilizes the radiation force of focused ultrasound (see Sect. 32.4.3) within tissue to excite sinusoidal motion in the kHz regime and a sensitive hydrophone to detect the amplitude and phase of the resulting acoustic emission. Instead of pulsed ultrasound considered in Sect. 32.4.3, local excitation in the kHz regime was achieved through the use of two confocal ultrasonic transducers (each operating at ~3 MHz) to generate at their difference frequency a kHz oscillation of the ultrasonic energy density at the overlap of the foci. These overlapped foci were raster scanned within the sample to record an image of the object motion. Mechanical spectroscopy was performed by tuning the difference (beat) frequency between the transducers. Vibro-acoustic spectrography of human iliac arteries ex vivo demonstrated clear differences between stiffer calcified regions and nearby normal regions of the artery, at an excitation frequency of 6 kHz. These differences were observed in both the (mechanical) amplitude and phase images [81].

Motivated by the success of ultrasound vibro-acoustography [83–86], mechanical spectroscopic imaging has also been developed for OCE [87]. Utilizing a spectral-domain OCT platform for phase-sensitive B-mode imaging during external mechanical excitation [32, 46], 2D B-mode images were recorded over a wide range of excitation frequencies (20–1,000 Hz). Signal processing steps were developed to extract the (spatially localized) complex mechanical displacement. Figure 32.16 shows spectroscopic OCE in rat mammary tissue consisting of tumor adjacent to adipose. Peaks in the mechanical spectra at 83 and 385 Hz were attributed to adipose and tumor regions of the tissue, respectively. Contrast between mechanically distinct regions of the tissue can be seen in both the amplitude and mechanical phase response images corresponding to 83 Hz excitation. In particular, the mechanical phase image highlighted an oval region of the sample, with a mechanical phase shift of $+\pi$ that is characteristic behavior above resonance. The distinction of this region from its surroundings was seen over a wide frequency range (25–83 Hz, and at 125 and 167 Hz), suggesting a relatively low resonant frequency. Appearing as oval-shaped structures in the histology image, this feature was attributed as a fluid-dense follicle or vacuole.

Spectroscopic OCE is at an early stage of development and several areas require further investigation. As discussed in Sect. 32.4.4, the impact of tissue geometry,

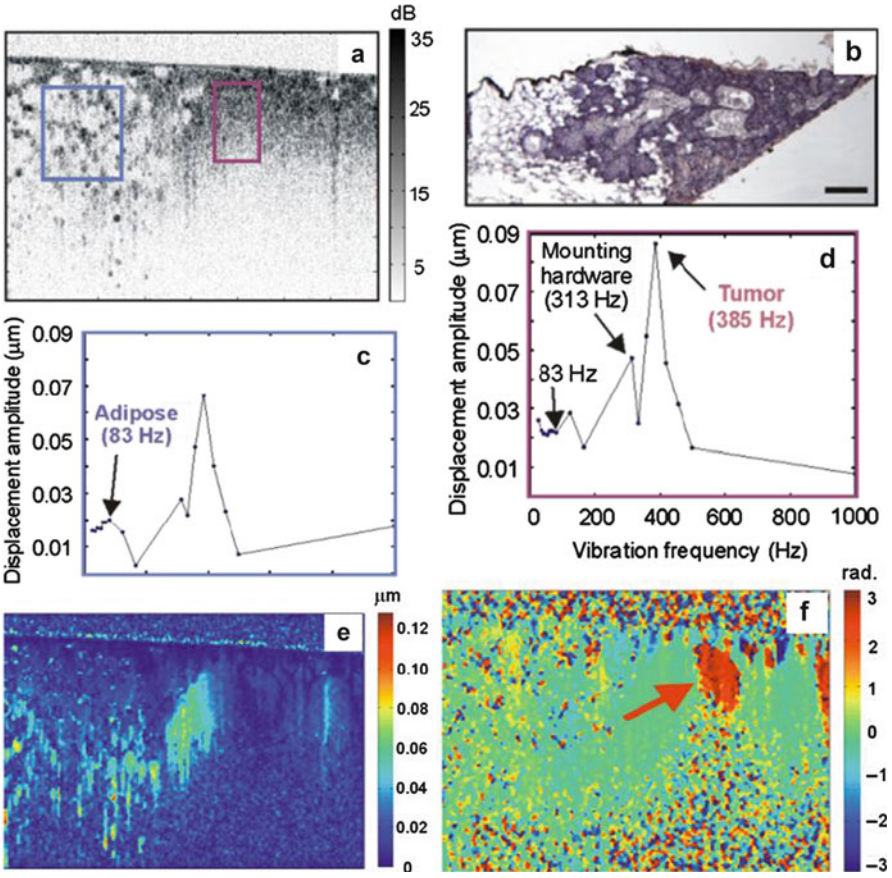

Fig. 32.16 Spectroscopic OCE of rat mammary tumor adjacent to adipose tissue. (**a**) B-mode OCT image, (**b**) corresponding nearby histology, (**c**) mechanical amplitude spectrum for adipose (spatial average over *blue box* in (**a**)), (**d**) mechanical amplitude spectrum for tumor (spatial average over *magenta box* in (**a**)), (**e**) displacement amplitude image at excitation frequency of 83 Hz, and (**f**) displacement phase image at excitation frequency of 83 Hz (Adapted from [87])

heterogeneity, and the natural vibration modes of the mechanical mounting hardware on the complex mechanical response measured in the sample needs to be determined. Further work on theoretical modeling and simulation (see Sect. 32.6) could provide a method to invert the complex displacement maps in order to extract the elastic and viscous properties of the sample. These simulations could also investigate the role of mechanical coupling on the spatial resolution of the inversion process. ARF-OCE (see Sect. 32.4.3) is a promising approach to address potential resolution limitations with external (bulk) mechanical excitation [23]. Further work is required to adapt ARF-OCE for B-mode or volumetric spectroscopic imaging. Finally, it would be interesting to extend the excitation frequency range into the kHz regime (as in ultrasound-stimulated vibro-acoustography). Ultimately, the

success of spectroscopic OCE will depend on characterizing the appropriate frequency ranges (or specific excitation frequencies) that maximize contrast between regions of tissue with distinct biomechanical properties.

32.5 Implementation

Translation of OCE techniques to clinical use requires further development of practical probes that enable simultaneous loading and imaging of tissue. This section reviews initial efforts to implement OCE in vivo, using probes suitable for superficial tissues such as skin and catheter-based and needle-based probes suitable for use within the body.

32.5.1 Imaging Superficial Tissues

Most initial OCE studies performed imaging and loading of small samples from opposite sides [40, 49, 52]. While this configuration may be sufficient for imaging small ex vivo tissue samples or phantoms, imaging and loading from the same side are essential for in vivo imaging. In the first OCE paper [9], loading and imaging were performed from the same side using an annular piezoelectric actuator, but an A-scan rate of 11 Hz and decorrelation of speckle due to sample movement limited the in vivo capabilities of this setup. A same-side OCE setup was later proposed using a similar design [19], as shown in Fig. 32.17. An annular piezoelectric transducer is fixed to an imaging window and coupled directly to the sample, enabling simultaneous, concentric actuation and imaging of the tissue. This ring

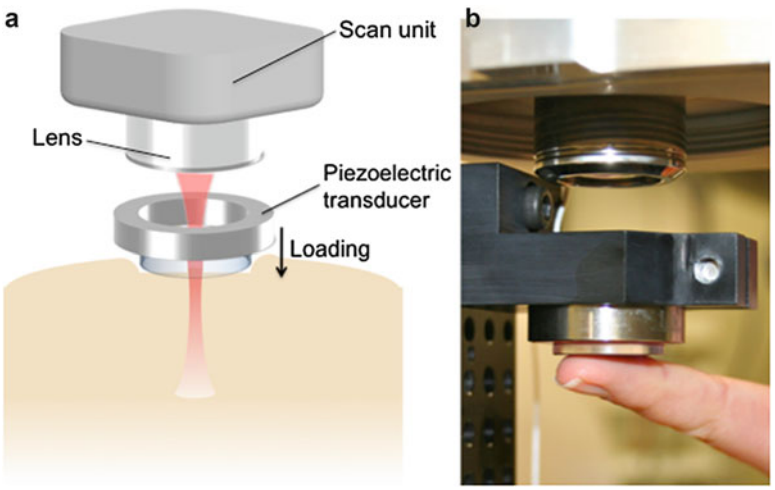

Fig. 32.17 Ring actuator design for in vivo OCE of superficial tissues. (**a**) Probe schematic and (**b**) photograph of implementation for skin imaging

actuator design can be used to apply pico- to microscale displacements to tissue over a wide range of frequencies and has been used in compression and spectroscopic OCE studies [51, 87], including the first in vivo 3D OCE measurements, which used human skin as the target tissue [51].

To perform ARF-OCE or SAW-OCE requires either an impulse load or vibrational load applied to the tissue. Implementation of these dynamic loading techniques requires careful synchronization of the actuation and imaging, but they have the practical advantage that the tissue loading may be performed adjacent to the imaging, eliminating the need to combine actuation and imaging capabilities into a single device. SAW-OCE on skin in vivo has been achieved using a mechanical shaker coupled directly to the tissue [54]. The mechanical shaker employed a piezoelectric element to introduce an impulse load to the tissue, and the resulting surface waves were measured by the adjacent OCT probe. For applications where direct contact of the probe with tissue is not desirable, such as imaging of the cornea, a noncontact implementation of SAW-OCE has also been proposed using a remote laser pulse to generate surface waves [88].

Other loading techniques for superficial tissues have included an air puff system for measuring the elastic response of the cornea [89, 90] as well as an annular suction device which applies a suction force concentric with the OCT imaging to measure elasticity of skin in tension [32].

32.5.2 Catheter-Based OCE

Implementation of OCE using miniaturized, fiber-based probes for endoscopic and intravascular imaging presents new challenges for developing loading schemes that can be deployed in such confined spaces. One natural approach to overcoming this issue is to use physiological deformation of the tissue as the "loading" mechanism. This is especially suitable for tissues that undergo regular changes in luminal pressure, such as airways and blood vessels. This concept has been used for measurement of the elastic properties of the airway wall using anatomical OCT (*a*OCT), a long-range OCT technique for profiling of hollow organs [91]. Here, changes in airway dimensions versus pressure were measured in patients with and without obstructive lung diseases to investigate the correspondence of airway wall compliance with pathology.

Luminal pressure changes have also been proposed as a loading technique for performing intravascular OCE [92, 93]. Although physiological deformation of tissue is convenient to measure, quantitative measurement of mechanical properties requires controlled loading of the tissue. An OCT imaging catheter that achieves this has been proposed for applying acoustic radiation force at localized points deep in the body [94]. A catheter design incorporating a piezoelectric ultrasound transducer into the distal probe head has the advantage that direct contact with the tissue is not required, as the acoustic radiation force may be focused to induce a tissue "push" at a desired distance from the probe. Such a probe design, shown in Fig. 32.18, has been realized for combined OCT and ultrasound structural imaging

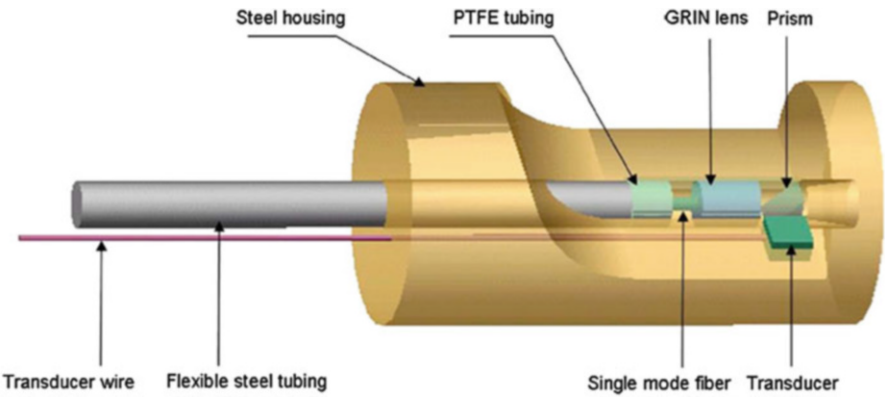

Fig. 32.18 Schematic of combined ultrasound and OCT probe that may be suitable for performing catheter-based ARF-OCE. *PTFE* polytetrafluoroethylene, *GRIN* graded-index (Adapted from [94])

of arteries [94], but not yet been used to perform elastographic measurements. Another proposed technique for catheter-based OCE incorporates a small palpation device in the distal end of the probe, which may consist of a controlled liquid jet or mechanical indenter for compressing adjacent tissues [95]. Despite the several proposed embodiments of catheter-based OCE, results acquired using such a probe have yet to be reported.

32.5.3 Needle-Based OCE

The recent development of three-dimensional OCT needle probes has allowed imaging deep within solid tissues, extending potential OCT applications to include, e.g., biopsy and surgical guidance and monitoring of interstitial procedures [96, 97]. When needles are inserted into soft tissue, the needle exerts a force on the tissue ahead of the tip, as well as a shear force on the surrounding tissue due to friction. Measurement of this needle-induced deformation has been used to perform the first needle-based OCE measurements [98]. These measurements used a forward-facing probe design and phase-sensitive displacement measurement to capture 1D deformation ahead of the needle during insertion. The deformation caused by a flat end-faced needle, such as the one employed in these studies, can be approximated as compression of a column of tissue ahead of the needle [99]. Therefore, changes in the displacement with depth, i.e., the strain, indicate changes in mechanical properties.

Results from needle insertion into excised pig airway wall, consisting of layers of varying stiffness, are shown in Fig. 32.19. The displacement plot shows three distinct slopes, indicating the locations of tissue boundaries, as well as providing a measure of their relative stiffness. The displacement curve is in agreement with the corresponding histology acquired along the path of needle insertion, which shows layers of mucosa, submucosa, and smooth muscle.

(**a**) Photograph of OCE needle probe insertion into sample; (**b**) measured tissue displacement ahead of the *needle tip* shows changes in slope at the positions of the *red stars*, indicating different tissue types; and (**c**) corresponding histology validates the presence of three tissue types (Reproduced from [98])

32.6 Fidelity of OCE: Comparison to Models of Tissue Deformation

In this section, we discuss artifacts that can arise in OCE and limit the accuracy with which elastograms represent the underlying elastic properties of tissue. We present initial efforts to use modeling of tissue deformation to investigate the impact of parameters such as tissue geometry and boundary conditions on the resulting contrast in elastograms. We also review initial efforts in OCE to produce more reliable, quantitative elastograms by approaching elasticity reconstruction as an inverse problem.

32.6.1 Limitations on the Mechanical Fidelity of Elastograms

In OCE, constructing a map of elasticity from measured displacements requires some assumptions to be made about the tissue, such that its observed behavior and mechanical properties may be linked through a mathematical model. The most common of these assumptions, which underlie image formation in compression, ARF, and SAW techniques described in Sect. 32.4, are (1) tissue is linear elastic, which allows stress and strain to be related linearly through elastic constants, and (2) tissue is isotropic (properties are direction independent), which reduces the fourth-order elasticity tensor to two elastic constants for describing the mechanical behavior of tissue (as described in Sect. 32.2.3). Magnetomotive and spectroscopic techniques (Sects. 32.4.4 and 32.4.5) have employed a more advanced model of tissue behavior, accounting for viscoelastic properties, but image formation and quantitative measurements in these techniques rely on assumptions about the tissue geometry and mechanical coupling of tissue regions.

Use of such assumptions simplifies the characterization of tissue, facilitates the development of OCE methods, and may in some cases prove sufficient for producing clinically useful images. However, tissue behavior in general is much more complex, exhibiting varying degrees of nonlinearity, viscoelasticity, poroelasticity,

anisotropy, and geometric complexity. When simple assumptions break down in the presence of such complexities, the resulting elastograms contain mechanical artifacts, limiting their fidelity to the underlying tissue properties and, ultimately, their potential clinical utility.

For OCE to advance toward clinical implementation, it is necessary to test the validity of assumptions employed in the various techniques, understand where they break down, and quantify the impact of artifacts on image contrast and reliability. Such quantitative assessment requires comparison of the measured tissue deformation in OCE to that predicted by mechanical models. Discrepancies between the two will highlight sources of mechanical artifacts and allow their effects on image contrast to be assessed. In addition to serving as an investigative tool, modeling of tissue deformation may also be used as part of an iterative elasticity reconstruction process to produce quantitative elastograms.

Accurate modeling of tissue deformation involves solving for complex geometries and heterogeneous elasticity fields, and therefore, numerical methods are preferred over analytical methods for accurate representation of tissue deformation. The predominant numerical method for modeling tissue deformation is the finite element method (FEM). In FEM, the tissue geometry is divided into a mesh of individual elements, and the governing equations of motion are solved for each element. FEM has been used in OCE to validate new methods for estimating velocity and strain [30], to validate new loading techniques for generating elastographic contrast [77, 100], and to estimate stress and strain fields in artery walls under luminal pressure [92], but has not yet been used to evaluate the limitations of mechanical artifacts on image contrast. Such investigations have been performed extensively in ultrasound elastography [101–104]. However, the impact of mechanical artifacts on image contrast in OCE will differ from those in ultrasound elastography due to different limits on measurable displacement and an increased sensitivity to boundary conditions, as images are generally limited to the first few millimeters of tissue. In the next section, we report on early efforts in using FEM to investigate sources of mechanical artifacts and evaluate their effects on image contrast for the particular case of compression elastography.

32.6.2 Modeling of Compression OCE

In compression elastography, strain is measured and used to represent elasticity. Interpreting strain elastograms as one-to-one representations of modulus assumes a uniform stress distribution within the sample. This assumption is invalid for samples with heterogeneous mechanical properties or when stress concentrations arise at tissue boundaries. Stress distribution beyond the sample surface cannot be measured directly, but FEM allows us to simulate the stress distribution for a given sample and investigate sources of its nonuniformity. In the case study described here, FEM is employed to simulate sample deformation in compression OCE of tissue-mimicking phantoms. The effect of feature geometry and boundary

conditions on mechanical artifacts and the resulting image contrast are investigated in both FEM and experiments.

Careful fabrication of phantoms with known geometry and mechanical properties was essential for input to the model and fair comparison of the simulated and measured sample deformation. Silicone was used, as its optical and mechanical properties can be controlled over a wide range, and it can be readily molded into complex shapes [105]. Two types of phantoms were fabricated: mechanically homogeneous phantoms and phantoms comprising a hard inclusion (Young's modulus 450 MPa) in soft bulk (Young's modulus 23 kPa). The mechanical behavior of the silicones was measured independently using compression tests, providing stress-strain curves for each material from which moduli were estimated. Compression OCE was performed using a ring actuator setup as described previously [51]. A phase-sensitive technique [40] was used to measure sample displacement, and weighted least squares (WLS) strain estimation [53] was used to generate elastograms.

A linear elastic, axisymmetric 3D model was employed, and the phantom geometry and material behavior from the compression tests were used as inputs to the simulations. FEM produced simulations of sample displacement and strain fields, which were compared to that produced experimentally for validation. Once agreement was obtained between the measured and simulated displacements and strain, the simulated stress distributions could also be analyzed to aid interpretation of mechanical artifacts in the elastograms. Two prevalent sources of stress nonuniformity in the compression experiments are discussed here: friction and stress concentrations at feature boundaries.

Friction: For a homogeneous sample undergoing uniaxial compression, the strain and stress are expected to be uniform throughout the sample. For nearly incompressible materials such as soft tissues, axial compression is coupled to lateral expansion in order to conserve volume, as discussed in Sect. 32.2.4. If friction is present between the sample and the compressor, this restricts lateral motion of the sample at the boundary, resulting in lower strain, and, as a result, a region of apparently higher stiffness in the elastogram. To demonstrate the effect of friction on the resulting elastogram, two OCE measurements of a 0.8 mm thick, homogeneous silicone phantom were acquired with different boundary conditions. The results are shown in Fig. 32.20. In the first experiment, a lubricant was applied at both surfaces to allow slipping of the sample boundary against the compression plate. In the second, no lubricant was used on either surface. In the resulting elastograms shown in Fig. 32.20, the lubricated case shows a homogeneous strain field, as expected, while in the non-lubricated case, the effect of friction manifests as two bands of low strain at the top and bottom surfaces. These experiments were also simulated with FEM, using the two extreme boundary conditions of frictionless and no-slip at the surface, respectively. The representative plots (taken from the center of the sample) of displacement versus depth in Fig. 32.20 show good agreement between the measured and simulated displacements. This example demonstrates the importance of considering boundary conditions both when acquiring and interpreting elastograms in compression OCE.

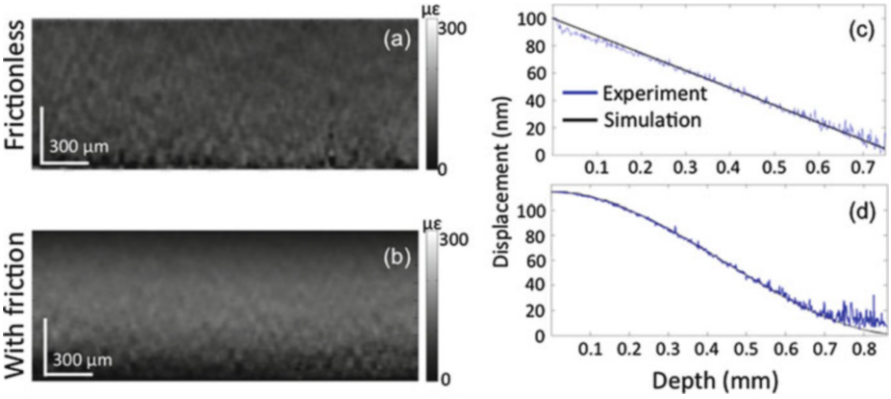

Fig. 32.20 (**a**, **b**) Experimental strain elastograms and (**c**, **d**) comparison of measured and simulated displacement plots for the cases of (**a**) and (**c**) frictionless and (**b**) and (**d**) no-slip conditions at the boundaries

Stress Concentrations at Feature Boundaries: When a lesion of higher stiffness than that of the background is present, this creates a region of low strain in the elastogram, as expected. However, stress concentrations also arise above, below, and at the sides of the lesion, resulting in regions of higher strain at these locations. Thus, the assumption of stress uniformity does not hold for this geometry; if the strain image were interpreted directly as elasticity, the regions of higher strain about the inclusion would erroneously be interpreted as regions of low stiffness. The magnitude of this artifact increases for increasing modulus contrast between the lesion and the background material and also depends on the position in depth of the lesion. To demonstrate the presence of these artifacts and the nonuniform stress field for the case of a stiff lesion, compression OCE was performed on a soft phantom with a hard inclusion embedded. The resulting experimental elastogram, simulated strain, and simulated stress fields are shown in Fig. 32.21. The experimental and simulated strain both show the regions of higher and lower strain around the inclusion, and the simulated stress field allows analysis of where the stress uniformity assumption fails.

Although a linear elastic FEM was employed in this initial study, the silicone materials used exhibit nonlinear behavior, as do many tissues. This results in a nonlinear relationship between the strain introduced to the sample and the resulting strain contrast; i.e., the elastogram contrast changes as a function of stress on the sample. This was observed to cause discrepancies between the model, for which a single modulus value was assigned to each material, and the experiments, in which the effective stiffness of each material varied depending on the applied stress. Although tissue may be assumed to behave linearly at strains <0.1 [22], remaining in this linear regime is not always feasible when performing elastography of tissue, as large local deformations are common in the body; e.g., arteries undergo physiological strains of up to 0.2 [93]. This highlights a need to employ more advanced models of tissue to enable more accurate construction of elastograms.

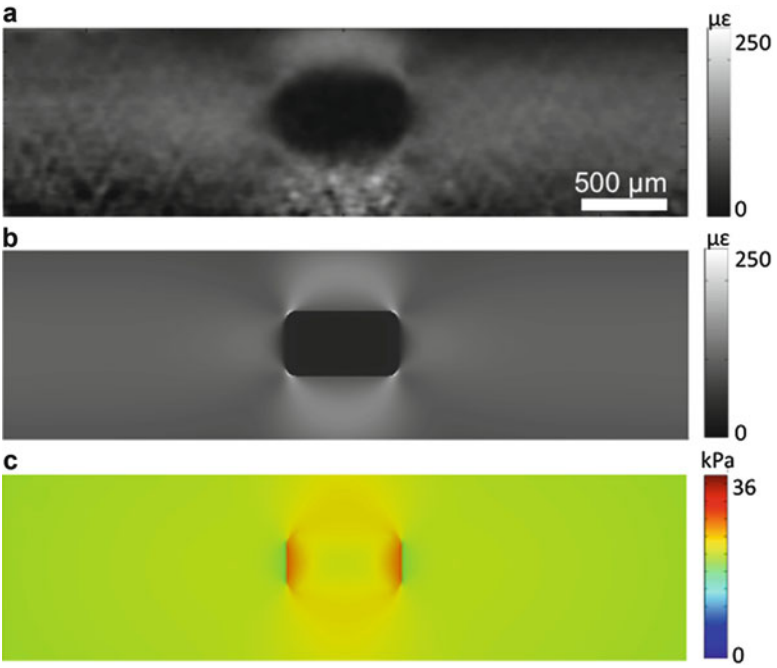

Fig. 32.21 (**a**) Measured strain, (**b**) simulated strain, and (**c**) simulated stress of a phantom comprising a stiff inclusion in soft bulk, demonstrating regions of high strain due to stress concentrations about the inclusion

32.6.3 Model-Based Elastography: Inverse Methods for Quantitative Elastograms

As seen in the preceding example of compression elastography, elastograms constructed based on simplified models of tissue deformation do not always accurately represent tissue elasticity. In ultrasound and magnetic resonance elastography, several techniques have aimed to produce quantitative, reliable elastograms by approaching elastography as an inverse problem [106]. The forward problem in elastography can be formulated as follows: given a distribution of mechanical properties and boundary conditions, calculate the displacements resulting from an applied load, as described in Sect. 32.6.2. The inverse problem for elastography, then, attempts to calculate the distribution of mechanical properties from a distribution of measured displacements. Reconstructing elasticity images using inverse methods has been an active area of research in ultrasound and magnetic resonance elastography for several years [106], but only a few studies in OCE have begun to approach this problem. The earliest of these studies were toward the application of OCE for assessment of atherosclerotic plaque vulnerability [93, 107, 108]. These studies proposed an iterative approach to solving the inverse problem using FEM, in which the mechanical parameters in the model are optimized to produce the best match to

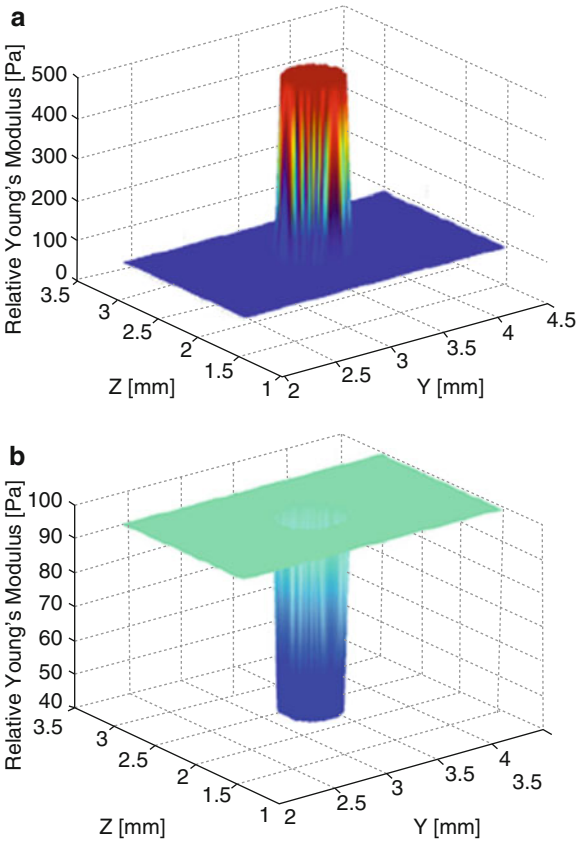

Fig. 32.22 Estimated distribution of elasticity for (**a**) a hard inclusion in a soft bulk, simulating a calcified nodule in an artery wall, and (**b**) a soft inclusion in a stiffer bulk, simulating a lipid pool in an artery wall, as determined by an iterative solution to the inverse problem using simulated OCE data as an input to a finite element model of tissue (Modified from [108])

the measured displacements using OCT. Images of the resulting elasticity distributions for a hard and soft inclusion embedded in a bulk material of constant stiffness are shown in Fig. 32.22. These studies showed promising results in simulations of OCT-derived displacements of tissue, but would be very computationally intensive to implement and may be prone to error in the presence of experimental system noise.

Quantitative, model-based OCE has also been achieved by measuring sample response to a mechanical waveform, then fitting the measured response to an analytical model for motion in a viscoelastic material [52]. Although it provides quantitative maps of Young's modulus, this method requires solving the wave equation for each pixel, a computationally intensive and slow process. More recent studies have moved toward quantification of Young's modulus by implementing transient loading techniques in which the shear modulus may be extracted directly from the velocity of shear waves in the sample [23, 26, 56]. However, these quantitative techniques come at a loss of resolution, as they assume tissue homogeneity for the length over which shear wave speed is calculated [56, 57]. This assumption may not be suitable for imaging organs with heterogeneous, complex structures, such as the breast.

32.7 Outlook

Since its first demonstration in 1998, over 200 papers on OCE and related techniques have been published, accumulating over 500 citations in 2012 alone. As the technical development of OCT reaches maturity, the scope and capacity for the development of OCE is increasing. Indeed, over the last 2 years, the number of groups publishing in OCE has doubled. Comparison of the published literature suggests that OCE is at a similar stage of development to that of ultrasound elastography in the late 1990s, and thus, continued rapid development is expected in the coming years. In the following, we predict the key developments needed to enable the technique to flourish.

Imaging Probes: The majority of OCE results have been demonstrated on excised tissue when in vivo imaging is the intended application. However, the clinical applicability of many current implementations is limited. A key requirement is the development of probes incorporating both imaging optics and loading mechanisms. In recent years, as discussed in Sect. 32.5, this has been recognized, and an increasing number of OCE probe implementations have been proposed [19, 72, 98, 109]. This is a key enabling technology required for clinical OCE imaging, and substantial further work is required.

Displacement Measurement: Measurement of mechanical properties over a large range and with high sensitivity is ultimately limited by the measurable displacement. Using cross-correlation in speckle tracking, the dynamic range of measurable strain is limited to $\sim$3.3. In phase-sensitive compression OCE, the measurable displacement range enables a strain dynamic range of $>$60 and the minimum measurable displacement in phase-sensitive detection is in the sub-nanometer range [45]. In both speckle tracking and phase-sensitive methods, there is significant scope for improvement. In speckle tracking, there is a scope for parametric algorithms to provide sub-pixel displacement sensitivity, and in phase-sensitive methods, phase unwrapping algorithms will enable maximum displacements beyond the 2π limit.

Elastogram Fidelity: Contrast in elastograms depends not only on the true elastic contrast within the tissue being probed but also on the accuracy of the employed mechanical model of tissue behavior. As illustrated in Sect. 32.6 for the particular case of compression OCE, erroneous assumptions about tissue mechanics, such as the assumption of uniform stress distribution, result in significant artifacts in elastograms, degrading their fidelity to the true underlying elastic properties. This and other common assumptions, such as that of linear elastic tissue behavior or tissue homogeneity over the acoustic wavelength in wave-based techniques, allow for straightforward estimation of the distribution of elastic properties and may in many cases prove sufficient for providing clinically useful contrast. However, the validity of employed assumptions must be assessed for each technique and proposed application. Finite element modeling is expected to remain an essential tool for validating the contrast generated using various OCE techniques and for analyzing how variables such as geometry, heterogeneity, boundary conditions, and loading rate impact on contrast.

Applications: Until now, the reported results of applying OCE to tissue have largely served to demonstrate a particular technique or implementation. In so doing,

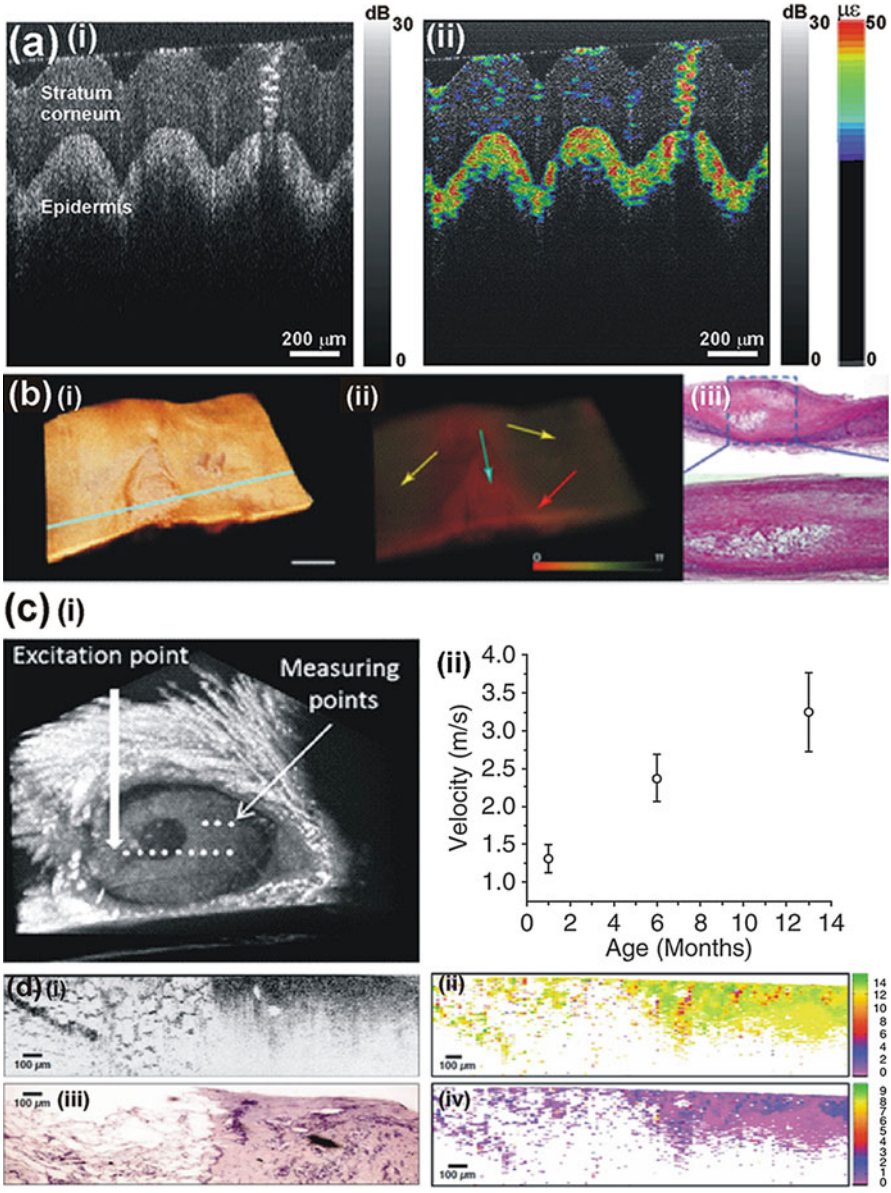

Fig. 32.23 Example images from potential OCE clinical applications. (**a**) Dermatology, (Adapted from [51]), (**b**) cardiology [72], (**c**) ophthalmology [57], and (**d**) breast cancer [52]

such reports have highlighted a number of potential applications, including in dermatology (Fig. 32.23a) [11, 19, 24, 32, 51], cardiology (Fig. 32.23b) [30, 31, 72, 92, 107, 108, 110], ophthalmology (Fig. 32.23c) [57, 89, 90, 111], and breast cancer (Fig. 32.23d) [15, 52, 112]. As well as human in vivo applications, there is

opportunity for clinical ex vivo applications, e.g., as an intraoperative tumor margin assessment in freshly resected tumor masses and as a tool in studying animal models of disease.

Although various applications show promise or appear attractive, there is a need to *prove* the ability of OCE to provide additional contrast (particularly over standard OCT) through baseline ex vivo studies, co-registered with histology, of diseased and non-diseased tissue. To date, there have been no reports focused on the systematic application of OCE to multiple cases of a particular pathology. As discussed above, enabling such studies also depends on the further development of imaging probes.

OCE is undoubtedly at an early stage of development, especially when compared with the closely related fields of ultrasound and magnetic resonance elastography. The recent increase in activity in the field and the acceleration of progress suggest there is good cause to expect future clinical applications of this emerging technique.

Note: Since submitting this manuscript in April 2013, many works in this field, including our own, have been published. For a more recent review, see B. F. Polarization Sensitive Optical Coherence Tomography

33

B. Hyle Park and Johannes F. de Boer

Keywords
Polarization sensitive OCT • PS-OCT • Jones vector • Mueller matrix • Stokes parameter • Poincaré sphere

Optical coherence tomography (OCT) is an interferometric technique capable of noninvasive high-resolution cross-sectional imaging by measuring the intensity of light reflected from within tissue [1]. This results in a noncontact imaging modality that provides images similar in scale and geometry to histology. Just as different stains can be used to enhance the contrast in histology, various extensions of OCT allow for visualization of features not readily apparent in traditional OCT. For example, optical Doppler tomography [2] can enable depth-resolved imaging of flow by observing differences in phase between successive depth scans [3–5]. This chapter will focus on polarization-sensitive OCT (PS-OCT), which utilizes depth-dependent changes in the polarization state of detected light to determine the light-polarization changing properties of a sample [6–11]. These properties, including birefringence, dichroism, and optic axis orientation, can be determined directly by studying the depth evolution of Stokes parameters [7–10, 12–16] or indirectly by using the changing reflected polarization states to first determine Jones or Mueller matrices [11, 17–21]. PS-OCT has been used in a wide variety of applications, including correlating burn depth with a decrease in birefringence [14], measuring the birefringence of the retinal nerve fiber layer [22, 23], and monitoring the onset and progression of caries lesions [24].

33.1 Theory

Waves can generally be categorized as either longitudinal or transverse. Sound traveling through air is a classic example of a longitudinal wave. In this case, the wave propagates by compression and rarefaction of air. These local oscillations are constrained to occur in the same direction as the wave itself. A longitudinal wave traveling in a particular direction can be characterized completely by its amplitude, frequency, and phase (for propagation through a given medium). The same cannot be said for transverse waves. In contrast to longitudinal waves, local oscillations for transverse waves are oriented perpendicular to the direction of wave propagation. The three parameters that completely describe a longitudinal wave are not adequate for a transverse wave, while the amplitude, frequency, and phase of two transverse waves might be identical, they can differ by the direction of their local oscillations. For monochromatic light propagation in the z-direction, the electric field component can oscillate in the x-direction, y-direction, or any arbitrary combination of the two. This extra degree of freedom is described by its state of polarization.

Following the notation of Bohren and Huffman [25], consider a homogeneous monochromatic electromagnetic wave propagating in the z-direction with angular frequency $\omega = 2\pi c/\lambda$ and wave number $k = \omega N/c$, where $N = n + i\kappa$ represents the complex refractive index and λ and c are the wavelength and the speed of light, respectively, *in vacuo*. This wave can be described by its complex electric field $\mathbf{E}_C(z, t)$, given by

$$\mathbf{E}_C(z,t) = \mathbf{E}\, e^{i(kz-\omega t)} \tag{33.1}$$

where $\mathbf{E} = \mathbf{A} + i\mathbf{B}$ represents a vector of complex amplitude that lies in the xy-plane. In a particular plane, say $z = 0$ for convenience, the tip of the electric field traces out a curve known as the vibrational ellipse, given by

$$\mathbf{E}_{vib}(t) = \mathrm{Re}\{\mathbf{E}_C(z=0,t)\} = \mathbf{A}\cos\omega t + \mathbf{B}\sin\omega t \tag{33.2}$$

If the real vector $\mathbf{A} = 0$ (or $\mathbf{B} = 0$), the vibrational ellipse collapses to a straight line and the wave is said to be linearly polarized along the direction of $\mathbf{B}$ (or $\mathbf{A}$). If $|\mathbf{A}| = |\mathbf{B}|$ and $\mathbf{A} \cdot \mathbf{B} = 0$, the vibrational ellipse is a circle and the wave is said to be circularly polarized. In general, a monochromatic wave of the form in Eq. 33.2 is elliptically polarized (Fig. 33.1).

The effect of light propagation through a material with a complex index of refraction, $N = n + i\kappa$, can be seen through expansion of Eq. 33.1 to yield

$$\mathbf{E}_C(z,t) = \mathbf{E}\, e^{-(\omega\kappa/c)z}\, e^{i((\omega n/c)z-\omega t)} \tag{33.3}$$

It can be inferred that the imaginary part of the complex refractive index, κ, determines the attenuation of the wave as it propagates through the medium and that the real part, n, determines the phase velocity. There are a wide variety of media in which the index of refraction is independent of the polarization state of light.

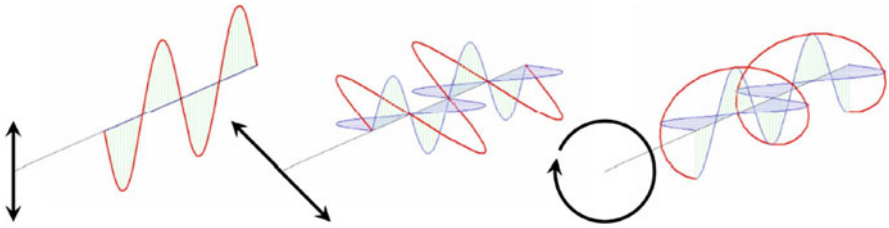

Fig. 33.1 Vibrational ellipses (from *left* to *right*) for vertically linear polarized light, linear polarized light oriented at 45° with respect to the vertical and horizontal orientations, and circularly polarized light

In these cases, light can propagate with no change of its polarization state. However, there are also many materials for which this is not the case. The goal of PS-OCT is to ascertain these light-polarization changing properties of a sample.

A material is said to be birefringent if the real part of its refractive index is polarization state dependent. Calcite is a classic example of a crystal with uniaxial birefringence; the difference in the real part of the refractive index of calcite causes light traveling through it to decompose into two beams that travel at different speeds. The orientation of this decomposition depends on that of the crystal and will be along and orthogonal to the material optic axis. Assuming a difference in refractive index of Δn, the two beams will experience a phase retardation, η, given by

$$\eta = \frac{2\pi \Delta n x}{\lambda} \tag{33.4}$$

where x is the distance traveled through the birefringent material. This phase retardation leads to an alteration of the resultant polarization state of the wave. Organized linear structures can exhibit form birefringence. This includes a variety of biological tissues, such as tendon, muscle, nerve, bone, cartilage, and teeth.

A difference in the imaginary portion of the refractive index leads to a differential attenuation of polarization states. Materials exhibiting this quality are termed dichroic. The differential attenuation experienced by light traveling through a dichroic material can be quantified by an amount of diattenuation, d, given by the ratio [26, 27]

$$d = \frac{P_1^2 - P_2^2}{P_1^2 + P_2^2} \tag{33.5}$$

where P_1 and P_2 are the electric field amplitude attenuation ratios for light polarized along and orthogonal to the optic axis of the material. These amplitude attenuation ratios, P_i, can be derived directly from the corresponding imaginary portion of refractive index, κ_i, according to the relation

$$P_i = e^{-2\pi \kappa_i x/\lambda} \tag{33.6}$$

where x is the distance traveled through the dichroic material. It should be noted that, unlike phase retardation, neither the amplitude attenuation ratios nor diattenuation scale linearly with the distance traveled through the tissue. While similar measures such as biattenuance [28, 29], defined simply as the difference in the imaginary portions of the refractive index of a dichroic material, have been recently introduced, diattenuation remains the more commonly used measure of differential attenuation.

33.1.1 Jones Formalism I

The Jones formalism provides a convenient mathematical description of polarized light and polarization effects [30]. In this section, an introduction to this calculus will be followed by its application to a simplified analysis of early PS-OCT systems.

33.1.1.1 Jones Vectors

In the previous discussion of vibrational ellipses, the complex vector **E** was described in terms of its real and imaginary parts, **A** and **B**. A somewhat more useful decomposition can be done in terms of a pair of orthonormal basis vectors to yield

$$\mathbf{E} = E_{\parallel}\hat{\mathbf{e}}_{\parallel} + E_{\perp}\hat{\mathbf{e}}_{\perp}E_{\parallel} = a_{\parallel}e^{-i\delta_{\parallel}}E_{\perp} = a_{\perp}e^{-i\delta_{\perp}} \tag{33.7}$$

where $\hat{\mathbf{e}}_{\parallel}$ and $\hat{\mathbf{e}}_{\perp}$ are unit vectors along the horizontal and vertical, respectively. In this case, the vibrational ellipse can be reformulated as

$$\mathbf{E}_{vib}(t) = a_{\parallel}\cos\left(\omega t + \delta_{\parallel}\right)\hat{\mathbf{e}}_{\parallel} + a_{\perp}\cos\left(\omega t + \delta_{\perp}\right)\hat{\mathbf{e}}_{\perp}. \tag{33.8}$$

The overall irradiance, or intensity, of the beam of light then can be expressed as the scalar quantity

$$I = a_{\parallel}^2 + a_{\perp}^2 \tag{33.9}$$

It is worth noting that while the overall irradiance of a beam is not dependent on its polarization state, it is possible to measure irradiance along a particular orientation (e.g., the intensity of a beam in the horizontal direction).

Linear polarization states occur for phase differences $\Delta\delta = \delta_{\parallel} - \delta_{\perp} = m\,\pi$, where $m \in \mathbb{Z}$, as the vibrational ellipse collapses to a line described by

$$\mathbf{E}_{vib}(t) = \left(a_{\parallel}\hat{\mathbf{e}}_{\parallel} + (-1)^m a_{\perp}\hat{\mathbf{e}}_{\perp}\right)\cos\left(\omega t + \delta_{\parallel}\right). \tag{33.10}$$

The orientation of the linear polarization state depends on the ratio of amplitudes $a_{\parallel}$ and $a_{\perp}$. The polarization state of light is horizontal or vertical when $a_{\perp} = 0$ or

$a_{\parallel} = 0$, respectively, and oriented at $\pm 45^{\circ}$ if $|a_{\parallel}| = |a_{\perp}|$. An orientation angle θ can then be defined according to the relations:

$$\begin{aligned} a_{\parallel} &= a\cos\theta \qquad a_{\perp} = a\sin\theta \\ a &= \sqrt{a_{\parallel}^2 + a_{\perp}^2} \quad \theta = \tan^{-1}\frac{a_{\parallel}}{a_{\perp}} \end{aligned} \tag{33.11}$$

where α can be thought of as an overall amplitude of the electric field and $\Delta\delta = 0$.

Circular polarization states are obtained when $|a_{\parallel}| = |a_{\perp}|$ and $\Delta\delta = \frac{\pi}{2} + n\pi$, which is evident through the form of the resultant vibrational ellipse:

$$\mathbf{E}_{vib}(t) = a_{\parallel}\big(\cos\left(\omega t + \delta_{\parallel}\right)\hat{\mathbf{e}}_{\parallel} \pm \sin\left(\omega t + \delta_{\parallel}\right)\hat{\mathbf{e}}_{\parallel}\big). \tag{33.12}$$

This describes a circle, the handedness (left or right circular) of which is determined by the sign between the orthogonal components. Circular polarization states differ only in their phase difference compared to linearly polarized light at 45°, and so the phase difference $\Delta\delta$ between orthogonal electric field components reflects the ratio between circular and linear components of the polarization state.

The electric field decomposition in Eq. 33.7 can be rewritten as a complex 2-vector such that

$$\mathbf{E} = \begin{bmatrix} E_{\parallel} \\ E_{\perp} \end{bmatrix} = \begin{bmatrix} a_{\parallel}e^{-i\delta_{\parallel}} \\ a_{\perp}e^{-i\delta_{\perp}} \end{bmatrix} = a\,e^{-i\delta_{\parallel}} \begin{bmatrix} \cos\theta \\ e^{i\,\Delta\delta}\sin\theta \end{bmatrix}. \tag{33.13}$$

While the time-invariant electric field vector $\mathbf{E}$, also known as a Jones vector, does depend on the amplitude and exact phase of the electric field components, it should be noted that the polarization state itself is completely determined by the orientation angle θ and the phase difference $\Delta\delta$.

33.1.1.2 Jones Matrices

Just as two vectors of length n can be related using a matrix of dimension $n \times n$, two polarization states can be related using a complex 2×2 matrix known as a Jones matrix. The polarization properties of any non-depolarizing optical system can be described using a Jones matrix. The transmitted polarization state $\mathbf{E}'$ as a result of an optical system represented by a Jones matrix $\mathbf{J}$ acting on an incident polarization state $\mathbf{E}$ can be determined by

$$\mathbf{E}' = \begin{bmatrix} E'_{\parallel} \\ E'_{\perp} \end{bmatrix} = \begin{bmatrix} J_{11} & J_{12} \\ J_{21} & J_{22} \end{bmatrix} \begin{bmatrix} E_{\parallel} \\ E_{\perp} \end{bmatrix} = \mathbf{J}\,\mathbf{E}. \tag{33.14}$$

Subsequent transmission of $\mathbf{E}'$ through an optical system $\mathbf{J}'$ results in a polarization state $\mathbf{E}'' = \mathbf{J}'\ \mathbf{E}' = \mathbf{J}'(\mathbf{J}\ \mathbf{E}) = \mathbf{J}'\mathbf{J}\ \mathbf{E}$. As a result, the combined polarization effect of a cascade of optical elements, $\mathbf{J}_1, \mathbf{J}_2, \cdots, \mathbf{J}_n$, can be described by the product $\mathbf{J} = \mathbf{J}_n \cdots \mathbf{J}_2\mathbf{J}_1$.

The Jones matrix for a birefringent material that induces a phase retardation η between electric field components parallel and orthogonal to a polarization state characterized by an orientation angle θ and a circularity related to ϕ is given by [31]

$$\mathbf{J}_b = \begin{bmatrix} e^{i\eta/2}C_\theta^2 + e^{-i\eta/2}S_\theta^2 & \left(e^{i\eta/2} - e^{-i\eta/2}\right)C_\theta S_\theta e^{-i\phi} \\ \left(e^{i\eta/2} - e^{-i\eta/2}\right)C_\theta S_\theta e^{i\phi} & e^{i\eta/2}S_\theta^2 + e^{-i\eta/2}C_\theta^2 \end{bmatrix}, \tag{33.15}$$

where $C_\theta = \cos\,\theta$ and $S_\theta = \sin\,\theta$. The Jones matrix of a dichroic material with attenuation ratios of P_1 and P_2 for electric field components parallel and orthogonal, respectively, to a polarization state given by an orientation angle Θ and a circularity Φ has the form [31]

$$\mathbf{J}_d = \begin{bmatrix} P_1C_\Theta^2 + P_2S_\Theta^2 & (P_1 - P_2)C_\Theta S_\Theta e^{-i\Phi} \\ (P_1 - P_2)C_\Theta S_\Theta e^{i\Phi} & P_1S_\Theta^2 + P_2C_\Theta^2 \end{bmatrix}. \tag{33.16}$$

33.1.1.3 Early Bulk-Optic PS-OCT Systems

Prior to 1992, the emphasis in OCT was the reconstruction of two-dimensional maps of tissue reflectivity while neglecting the polarization state of light. Hee et al. then presented an OCT system able to measure the changes in the polarization state of light reflected from a sample [6]. Using an incoherent detection technique, they demonstrated birefringence-sensitive ranging in a wave plate, an electro-optic modulator, and calf coronary artery. In 1997, the first two-dimensional images of birefringence were presented using a similar system, and the effect of laser-induced thermal damage on tissue birefringence in bovine tendon was demonstrated [7], followed in 1998 by a demonstration of the birefringence in porcine myocardium [8]. In 1999, phase-sensitive detection was implemented to determine the phase relation between the interference fringes in orthogonal polarization channels, which allowed for calculation of the Stokes parameters (Sect. 33.1.2.1) of the reflected light with a single measurement. Hitzenberger et al. used the phase relation in 2001 to determine the optic axis orientation of a birefringent sample [12].

The underlying theory behind extraction of the reflectivity and birefringence of a sample using these three bulk-optic PS-OCT systems will be discussed in the context of the Michelson interferometer presented by Hee et al. [6]. A schematic diagram of this early bulk-optic system is shown in Fig. 33.2. Collimated light with a short coherence length passes through a polarizer (Pol) to select a pure linear horizontal input state and is split into reference and sample arms by a polarization-insensitive beam splitter (BS). Light in the reference arm passes through a zero-order quarter-wave plate (QWP) oriented at 22.5°. Light in the sample arm passes through a QWP oriented at 45° and through focusing optics, producing circularly polarized light incident on the sample. Reflected light from the sample, in an arbitrary (elliptical) polarization state determined by the optical properties of the sample, returns through the focusing optics and the QWP. After recombination with light from the reference arm, the light in the detector arm is split into its horizontal

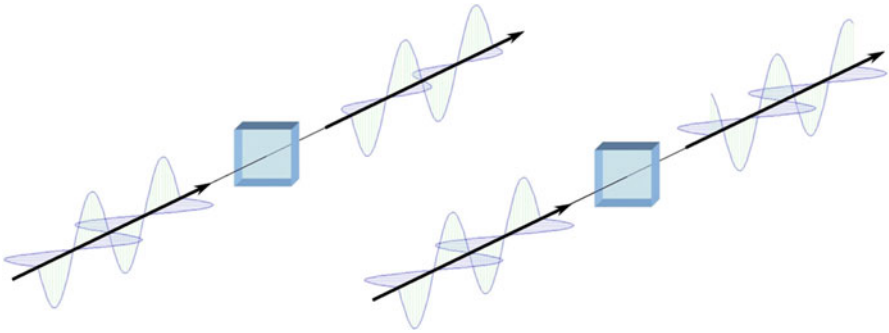

Fig. 33.2 Illustration of diattenuation (*left*) and birefringence (*right*). For diattenuation, the horizontal electric field component is attenuated more than the vertical component. The birefringent material on the right creates a phase delay between the horizontal and vertical electric field components

and vertical components by a polarizing beam splitter (PBS) and detected separately (Fig. 33.3).

The intensity detected in each polarization channel can be described by a two-dimensional intensity vector **I**, where the two components describe the horizontal and vertical polarized intensities. The intensities at the detectors are given by

$$\langle \mathbf{I}(\Delta z) \rangle = \left\langle \begin{bmatrix} E_{r\|} E_{r\|}^* \\ E_{r\perp} E_{r\perp}^* \end{bmatrix} \right\rangle + \left\langle \begin{bmatrix} E_{s\|} E_{s\|}^* \\ E_{s\perp} E_{s\perp}^* \end{bmatrix} \right\rangle + \left\langle \begin{bmatrix} E_{r\|} E_{s\|}^* \\ E_{r\perp} E_{s\perp}^* \end{bmatrix} \right\rangle + \left\langle \begin{bmatrix} E_{s\|} E_{r\|}^* \\ E_{s\perp} E_{r\perp}^* \end{bmatrix} \right\rangle, \tag{33.17}$$

where $\mathbf{E}_r = \begin{bmatrix} E_{r\|}, & E_{r\perp} \end{bmatrix}^T$ and $\mathbf{E}_s = \begin{bmatrix} E_{s\|}, & E_{s\perp} \end{bmatrix}^T$ are the Jones vector representations of light returning from the reference and sample arms, respectively, $*$ represents the complex conjugate, T is the transpose operation, and the angular brackets ($\langle \cdots \rangle$) denote time averaging. The last two terms of Eq. 33.17 correspond to the interference between reference and sample arm light.

The polarizer in the source arm allows for full transmission of only horizontally polarized light and can therefore be parameterized with attenuation ratios $P_1 = 1$ and $P_2 = 0$ along and orthogonal to an orientation $\theta = 0$. After the polarizer, horizontally polarized source light is described by the Jones vector

$$\mathbf{E}(z) = E(z) \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \tag{33.18}$$

where $E(z) = \int \tilde{e}(k) e^{-ikz} dk$ represents the integrated overall complex electric field amplitude of field amplitudes $\tilde{e}(k)$. From the Wiener–Khintchine theorem, it follows that

$$\langle \tilde{e}^*(k) \tilde{e}(k') \rangle = S(k) \delta(k - k'), \tag{33.19}$$

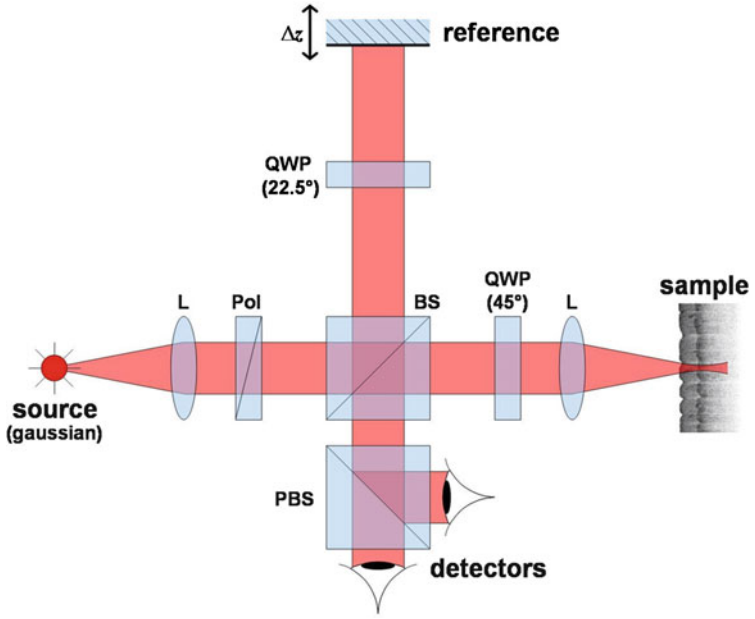

Fig. 33.3 Schematic of the bulk-optic PS-OCT system. The output of a source with a Gaussian spectrum is linearly polarized and split using a nonpolarizing beam splitter into sample and reference arms. The reference arm is composed of a quarter-wave plate (*QWP*) oriented at 22.5° and a mirror. The sample arm uses a QWP at 45° and a lens to focus light onto a sample. The reflected light from both arms is recombined and the resulting interference pattern is split using a polarizing beam splitter (*PBS*) onto two separate detectors. Individual axial scans are generated by translation of the reference arm mirror, and images are formed by combining axial scans for different lateral positions of the beam on the sample

which defines $\tilde{e}(k)$ in terms of the source power spectral density $S(k)$. The beam splitter divides the incident light by amplitude evenly between the sample and reference arms of the interferometer such that the Jones vectors describing the light entering each arm is given by

$$\mathbf{E}_{si}(z) = \mathbf{E}_{ri}(z) = \frac{E(z)}{\sqrt{2}}\begin{bmatrix}1\\0\end{bmatrix}. \tag{33.20}$$

The polarization state of light reflected from the reference arm can be calculated by multiplying $\mathbf{E}_{ri}$ (z) by the Jones matrices of the optical elements in the reference optical path. A QWP aligned at 22.5° can be characterized by $\mathbf{J}_b$ with $\eta = \pi/2$, $\eta = \pi/8$, and $\phi = 0$, and so the reflection reference polarization state is given by

$$\mathbf{E}_r(z_r) = \mathbf{J}_b\left(\frac{\pi}{2}, \frac{\pi}{8}, 0\right)\mathbf{J}_b\left(\frac{\pi}{2}, \frac{\pi}{8}, 0\right)\mathbf{E}_{ri} = \frac{1}{2}E(2z_r)\begin{bmatrix}1\\1\end{bmatrix}, \tag{33.21}$$

where z_r is the single-pass length of the reference arm. The horizontal and vertical components of the electric field have equal amplitude and phase. The polarization state of light returning from the sample arm can be computed similarly. In this case, the orientation of the QWP is $\theta = \frac{\pi}{4}$. Dichroism can generally be neglected for biological tissue, and the round-trip nature of light propagation in OCT cancels the effect of any circular birefringence. The measurable Jones matrix for a biological sample can then be modeled as a linearly birefringent material and can be written in the form $\mathbf{J}_S = \sqrt{R(z)}e^{i2kz\overline{n}}\mathbf{J}_b(2kz\Delta n, \alpha, 0)$, with $R(z)$ and $kz\overline{n}$ representing the scalar reflectivity and average phase delay of a wave propagating to some depth z, $\overline{n}$, and Δn representing the average and difference of the refractive indices along the parallel and orthogonal to the orientation of the material, α. The Jones vector of the light reflected from the sample arm is then given by

$$\begin{aligned}\mathbf{E}_s(z_s + z) &= \mathbf{J}_b(\tfrac{\pi}{2}, \tfrac{\pi}{4}, 0)\mathbf{J}_S\mathbf{J}_b(\tfrac{\pi}{2}, \tfrac{\pi}{4}, 0) \\ &\propto \sqrt{R(z)}\int \tilde{e}(k)e^{-2ik(z_s+z\overline{n})}\begin{bmatrix} e^{2i\alpha}\sin(kz\Delta n) \\ \cos(kz\Delta n)\end{bmatrix}dk\end{aligned} \tag{33.22}$$

where z_s is the optical length of the arm up to the sample surface. Using the Wiener–Khintchine theorem, the interference terms in the horizontally and vertically polarized channels are

$$\begin{aligned}A_H(z,\Delta z) &= E^*_{rx}E_{sx} + E_{rx}E^*_{sx} \propto \sqrt{R(z)}\int \sin(kz\Delta n)\cos(2k\Delta z + 2\alpha)S(k)dk \\ A_V(z,\Delta z) &= E^*_{ry}E_{sy} + E_{ry}E^*_{sy} \propto \sqrt{R(z)}\int \cos(kz\Delta n)\cos(2k\Delta z)S(k)dk\end{aligned} \tag{33.23}$$

with z the depth in the tissue and $\Delta z = z_r - s_s - z\overline{n}$ the optical path length difference between sample and reference arms. A Gaussian power spectral density is assumed for the source

$$S(k) \propto \exp\left(-\left(\frac{k-k_0}{\kappa}\right)^2\right) \tag{33.24}$$

with a full width at half maximum (FWHM) spectral bandwidth given by $\kappa 2\sqrt{\ln 2}$. The integration over k in Eq. 33.23 can be performed analytically and, in the approximation $\kappa z\Delta n \ll 1$, simplifies to

$$\begin{aligned}A_H(z,\Delta z) &\propto \sqrt{R(z)}\sin(k_0 z\Delta n)\cos(2k_0\Delta z + 2\alpha)e^{-(\Delta z/\Delta l)^2} \\ A_V(z,\Delta z) &\propto \sqrt{R(z)}\cos(k_0 z\Delta n)\cos(2k_0\Delta z)e^{-(\Delta z/\Delta l)^2}\end{aligned} \tag{33.25}$$

with the FWHM of the interference fringe envelope given by $\Delta l 2\sqrt{\ln 2}$ where

$$\Delta l = \frac{1}{\kappa} = \frac{\lambda_0^2\sqrt{\ln 2}}{\pi\Delta\lambda} \tag{33.26}$$

and $\Delta\lambda$ is the spectral FWHM of the source in wavelength.

Demodulation of the signals eliminates the $\cos(2k_0\Delta z)$ terms in Eq. 33.25 to yield intensities in the horizontal and vertical polarization channels proportional to

$$\begin{aligned} I_H(z) &= |A_H(z)|^2 \propto R(z)\sin^2(k_0 z\Delta n) \\ I_V(z) &= |A_V(z)|^2 \propto R(z)\cos^2(k_0 z\Delta n) \end{aligned} \tag{33.27}$$

The total reflected intensity and phase retardation as functions of depth are given by

$$\begin{aligned} I_T(z) &= I_H(z) + I_V(z) \propto R(z) \\ \eta(z) &= \tan^{-1}\left(\sqrt{\frac{I_V(z)}{I_H(z)}}\right) = k_0 z\Delta n \end{aligned} \tag{33.28}$$

Examination of Eq. 33.25 reveals that $A_H(z, \Delta z)$ and $A_V(z, \Delta z)$ differ in phase by 2α. Hitzenberger et al. [12] took advantage of this fact by using phase-sensitive detection to then additionally extract the sample optic axis orientation.

33.1.2 Mueller–Stokes Formalism

There are two weaknesses of the Jones formalism: the inability to describe partially polarized light and the inability to describe the processes that lead to depolarization. These shortcomings are addressed by Stokes parameters and Mueller matrices [25], which are quantities based on irradiance, a measure of the energy per unit area and time of a light beam. If two or more quasi-monochromatic beams propagating in the same directions are superposed incoherently, that is to say, there is no fixed relationship among the phases of the separate beams; the total irradiance is merely the sum of the individual beam irradiances. This property of irradiance makes it particularly attractive as a basis for an alternative way to describe polarization phenomena.

33.1.2.1 Stokes Parameters

Following the treatment in Bohren and Huffman [25], consider the following experimental setup to determine a set of irradiance measurements by which a polarization state can be completely characterized: a monochromatic beam, a set of perfect polarizers, and a detector capable of measuring irradiances regardless of polarization state. The simplest measurement is the overall irradiance of the beam. With no polarizer, the irradiance of the beam, ignoring the factor $k/2\omega\mu_0$, is given by $E_\parallel E_\parallel^* + E_\perp E_\perp^*$. The simplest polarization characterization is to use horizontal and vertical linear polarizers to determine the difference in the irradiances of the horizontally and vertically polarized components of the beam given by $E_\parallel E_\parallel^* - E_\perp E_\perp^*$. While these measurements immediately reveal the fraction of the overall beam irradiance due to horizontally and vertically polarized light, it reveals nothing regarding the phase between these elements. This can be overcome using linear polarizers oriented at +45° and −45° to measure $E_+E_+^* - E_-E_-^*$, where

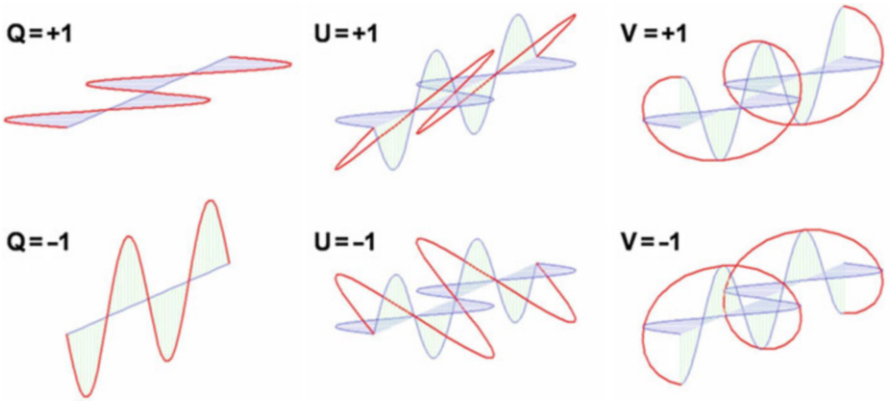

Fig. 33.4 Electric field components for various polarization states corresponding to the different Stokes parameters

$E_+ = \frac{\sqrt{2}}{2}\left(E_\parallel + E_\perp\right)$ and $E_- = \frac{\sqrt{2}}{2}\left(E_\parallel - E_\perp\right)$ are the complex electric field component amplitudes in a basis spanned by light at +45° and –45° as defined by $\hat{\mathbf{e}}_+ = \frac{\sqrt{2}}{2}\left(\hat{\mathbf{e}}_\parallel + \hat{\mathbf{e}}_\perp\right)$ and $\hat{\mathbf{e}}_- = \frac{\sqrt{2}}{2}\left(\hat{\mathbf{e}}_\parallel - \hat{\mathbf{e}}_\perp\right)$. Between these measurements, any completely linearly polarized beam can be fully characterized; however, light with any circularity cannot be characterized. Using circular polarizers to measure $E_R E_R^* - E_L E_L^*$ then rounds out the characterization, where $E_R = \frac{\sqrt{2}}{2}\left(E_\parallel - iE_\perp\right)$ and $E_L = \frac{\sqrt{2}}{2}\left(E_\parallel + iE_\perp\right)$ are the complex electric field component amplitudes in a basis spanned by right and left circularly polarized light as defined by $\hat{\mathbf{e}}_R = \frac{\sqrt{2}}{2}\left(\hat{\mathbf{e}}_\parallel + i\hat{\mathbf{e}}_\perp\right)$ and $\hat{\mathbf{e}}_L = \frac{\sqrt{2}}{2}\left(\hat{\mathbf{e}}_\parallel - i\hat{\mathbf{e}}_\perp\right)$. These measurements can be summarized as follows:

$$\begin{aligned} I_m &= E_\parallel E_\parallel^* + E_\perp E_\perp^* \\ Q_m &= E_\parallel E_\parallel^* - E_\perp E_\perp^* \\ U_m &= E_+ E_+^* - E_- E_-^* = E_\parallel E_\perp^* + E_\perp E_\parallel^* \\ V_m &= E_R E_R^* - E_L E_L^* = i\left(E_\parallel E_\perp^* - E_\perp E_\parallel^*\right) \end{aligned} \tag{33.29}$$

The polarization state of any monochromatic beam can be described using these four parameters (Fig. 33.4).

The Stokes parameters can be used to describe a nearly monochromatic, or quasi-monochromatic, beam by simply taking time averages over an interval long compared with the period, such that

$$\begin{aligned} I &= \left\langle E_\parallel E_\parallel^* + E_\perp E_\perp^* \right\rangle \\ Q &= \left\langle E_\parallel E_\parallel^* - E_\perp E_\perp^* \right\rangle \\ U &= \left\langle E_\parallel E_\perp^* + E_\perp E_\parallel^* \right\rangle \\ V &= \left\langle i\left(E_\parallel E_\perp^* - E_\perp E_\parallel^*\right) \right\rangle \end{aligned} \tag{33.30}$$

These quantities can be described by the notation s_j, where $s_0 = I$, $s_1 = Q$, $s_2 = U$, and $s_3 = V$. Algebraic manipulation of the Stokes parameters leads to $I^2 = Q^2 + U^2 + V^2 + 4(\langle a_{\|}^2\rangle\langle a_{\perp}^2\rangle - \langle a_{\|}a_{\perp}e^{i\delta}\rangle\langle a_{\|}a_{\perp}e^{-i\delta}\rangle) \geq Q^2 + U^2 + V^2$. Equality holds if the light is purely polarized; if the light is unpolarized, $Q = U = V = 0$. The degree of polarization P can now be defined by

$$P = \sqrt{\frac{Q^2 + U^2 + V^2}{I^2}} \tag{33.31}$$

The degree of polarization of a beam of light can range from unity for purely polarized light to zero for unpolarized light.

Determination of Stokes Parameters in PS-OCT

The most direct method for measuring the Stokes parameters for light in a PS-OCT system is with a complete set of irradiance measurements (e.g., $E_{\|}E_{\|}^*$, $E_{\perp}E_{\perp}^*$, $E_{+}E_{+}^*$, etc.). This can be implemented with a set of polarizers and wave plates in the detection arm of an OCT interferometer. However, characterization of a polarization state would then require a multitude of measurements from any particular region of tissue. While sufficient for determining the polarization properties of a crystalline sample, this can be problematic for biological samples, especially for in vivo and clinical settings. Motion artifacts and other time constraints dictate that practical implementation of PS-OCT uses a minimum of measurements from any single location.

In 1999, de Boer et al. demonstrated a PS-OCT system that used phase-sensitive detection to determine the phase relation between the interference fringes in orthogonal polarization channels, which allowed for calculation of the Stokes parameters of the reflected light with a single measurement [10]. It is evident from Eq. 33.30 that all four Stokes parameters can be derived from phase-sensitive measurement of $E_{\|}$ and $E_{\perp}$ for light returning from a sample (as opposed to their corresponding irradiances). Using a system similar to that illustrated in Fig. 33.3, de Boer et al. utilized phase-sensitive detection of the interference fringe intensity for each polarization component to determine the complete Stokes parameters of light in a single measurement according to the relation [10]

$$s_j(z_s) = \frac{(8\pi)^2 \int \left|\tilde{\mathbf{I}}(z_s, 2k)\right| dk}{P_0} \int \frac{\tilde{\mathbf{I}}^*(z_s, 2k)\sigma_j \tilde{\mathbf{I}}(z_s, 2k)}{\left|\tilde{\mathbf{I}}(z_s, 2k)\right|} dk, \tag{33.32}$$

where $\tilde{\mathbf{I}}(z_s, 2k)$ is a complex 2-vector representation of the components for positive k of the Fourier transform of the measured interference fringe intensities, σ_0 is the 2×2 identity matrix, and σ_1, σ_2, and σ_3 are the Pauli spin matrices.

It should be noted that an interferometric gating technique such as OCT measures only the light reflected from the sample arm that does interfere with the

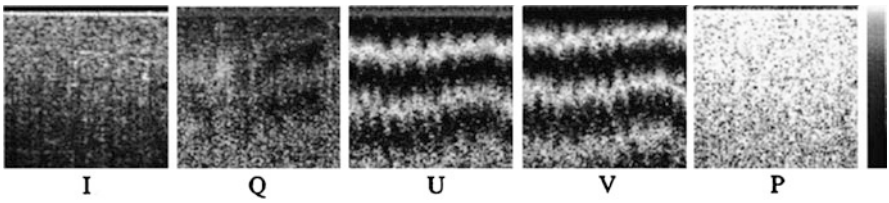

Fig. 33.5 PS-OCT images of ex vivo rodent muscle, 1 × 1 mm, pixel size 10 × 10 μm. From *left* to *right*: the Stokes parameters (**I**); normalized parameters (**Q**, **U**, **V**) in the sample frame for right circularly polarized incident light; and the degree of polarization (**P**). The *gray scale* to the right gives the magnitude of the signal, 35 dB range for I, from 1 (*white*) to –1 (*black*) for **Q**, **U**, and **V**, and from 1 (*white*) to 0 (*black*) for **P** (Reprinted from Fig. 2 of Ref. [10] with permission of the Optical Society of America)

reference arm light. On first inspection, this suggests that the degree of polarization will always be unity, since only the coherent part of the reflected light is detected [17]. A closer inspection of Eq. 33.32 reveals that the Stokes parameters of each spectral component of the source are determined with a spectral resolution inversely proportional to the interval over which the Fourier transform was taken. Integration over the wave number k sums the Stokes parameters of each spectral component with a weight proportional to the power spectral density $S(k)$. The larger the Δz interval and the higher the resolution in k-space, the more Stokes parameters of incoherently superposed beams are summed. When the Stokes parameters of reflected light do not vary over the source spectrum (the polarization state does not vary), the Stokes parameters add without changing the degree of polarization. However, when the Stokes parameters vary over the source spectrum, the sum of Stokes parameters over the spectral necessarily leads to an overall degree of polarization less than unity.

Rodent muscle was mounted in a chamber filled with saline solution and covered with a thin glass lip so that the muscle was not dehydrated during measurements. Figure 33.5 shows images of the four Stokes parameters in the sample frame for right circularly polarized incident light. Several periods of S_2 and S_3, cycling back and forth between 1 and -1, can be observed in the muscle.

33.1.2.2 Mueller Matrices

The Stokes parameters can be written as a real 4-vector $\mathbf{S} = [I, \quad Q, \quad U, \quad V]^T$, where $I, Q, U, V \in \mathbb{R}$. This allows for characterization of an optical system with a real 4×4 matrix $\mathbf{M}$, known as a Mueller matrix, that relates an incident Stokes vector $\mathbf{S}$ to a transmitted Stokes vector $\mathbf{S}'$ such that

$$\mathbf{S}' = \begin{bmatrix} I' \\ Q' \\ U' \\ V' \end{bmatrix} = \begin{bmatrix} M_{11} & M_{12} & M_{13} & M_{14} \\ M_{21} & M_{22} & M_{23} & M_{24} \\ M_{31} & M_{32} & M_{33} & M_{34} \\ M_{41} & M_{42} & M_{43} & M_{44} \end{bmatrix} \begin{bmatrix} I \\ Q \\ U \\ V \end{bmatrix} = \mathbf{MS} \tag{33.33}$$

Since Stokes vectors can be used to describe depolarized and partially polarized light, Mueller matrices have the advantage over Jones matrices of being able to describe depolarization effects.

Vector and matrix quantities in the Jones formalism can be converted into Stokes parameters and Mueller matrices using the relations [25]

$$\begin{aligned}\mathbf{S} &= \langle \mathbf{U}(\mathbf{E} \bigotimes \mathbf{E}^*)\rangle \\ \mathbf{M} &= \mathbf{U}(\mathbf{J} \bigotimes \mathbf{J}^*)\mathbf{U}^{-1} \\ \mathbf{U} &= \begin{bmatrix} 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & -1 \\ 0 & 1 & 1 & 0 \\ 0 & i & -i & 0 \end{bmatrix}\end{aligned} \tag{33.34}$$

where $\otimes$ represents the Kronecker tensor product. The Mueller matrix for a partial polarizer (a dichroic material) $\mathbf{M}_P$ can be formed from Eq. 33.16 to yield

$$\mathbf{M}_P = \begin{bmatrix} q_1 & q_2 C_{2\theta} & q_2 S_{2\theta} C_\phi & q_2 S_{2\theta} S_\phi \\ q_2 C_{2\theta} & q_3 + (q_1 - q_3) C_{2\theta}^2 & (q_1 - q_3) C_{2\theta} S_{2\theta} C_\phi & (q_1 - q_3) C_{2\theta} S_{2\theta} S_\phi \\ q_2 S_{2\theta} C_\phi & (q_1 - q_3) C_{2\theta} S_{2\theta} C_\phi & q_3 + (q_1 - q_3) S_{2\theta}^2 C_\phi^2 & (q_1 - q_3) S_{2\theta}^2 C_\phi S_\phi \\ q_2 S_{2\theta} S_\phi & (q_1 - q_3) C_{2\theta} S_{2\theta} S_\phi & (q_1 - q_3) S_{2\theta}^2 C_\phi S_\phi & q_3 + (q_1 - q_3) S_{2\theta}^2 S_\phi^2 \end{bmatrix}, \tag{33.35}$$

where $q_1 = \frac{1}{2}\left(P_1^2 + P_2^2\right)$, $q_1 = \frac{1}{2}\left(P_1^2 - P_2^2\right)$, and $q_3 = P_1 P_2$. The Mueller matrix for a retarder (a birefringent material) $\mathbf{M}_R$ is given by

$$\mathbf{M}_b = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & C_\eta + \left(1 - C_\eta\right) C_{2\Theta}^2 & -S_\eta S_{2\Theta} S_\Phi + \left(1 - C_\eta\right) C_{2\Theta} S_{2\Theta} C_\Phi & S_\eta S_{2\Theta} C_\Phi + \left(1 - C_\eta\right) C_{2\Theta} S_{2\Theta} S_\Phi \\ 0 & S_\eta S_{2\Theta} S_\Phi + \left(1 - C_\eta\right) C_{2\Theta} S_{2\Theta} C_\Phi & C_\eta + \left(1 - C_\eta\right) S_{2\Theta}^2 C_\Phi^2 & -S_\eta C_{2\Theta} + \left(1 - C_\eta\right) S_{2\Theta}^2 C_\Phi S_\Phi \\ 0 & -S_\eta S_{2\Theta} C_\Phi + \left(1 - C_\eta\right) C_{2\Theta} S_{2\Theta} S_\Phi & S_\eta C_{2\Theta} + \left(1 - C_\eta\right) S_{2\Theta}^2 C_\Phi S_\Phi & C_\eta + \left(1 - C_\eta\right) S_{2\Theta}^2 S_\Phi^2 \end{bmatrix} \tag{33.36}$$

Mueller Matrix Determination in PS-OCT

Yao et al. [11] and Jiao et al. [17] have presented a method by which the full Mueller matrix of a biological sample can be obtained. Their systems used variable wave plates and polarizers to sequentially obtain the four irradiance measurements $I_H = \langle E_\parallel E_\parallel^* \rangle$, $I_V = \langle E_\perp E_\perp^* \rangle$, $I_P = \langle E_+ E_+^* \rangle$, and $I_R = \langle E_R E_R^* \rangle$. Since the overall intensity of light has the property $I = \langle E_\parallel E_\parallel^* \rangle + \langle E_\perp E_\perp^* \rangle = \langle E_+ E_+^* \rangle + \langle E_- E_-^* \rangle = \langle E_R E_R^* \rangle + \langle E_L E_L^* \rangle$, the Stokes parameters will be given by

$$\mathbf{S} = \begin{bmatrix} I_H + I_V \\ I_H - I_V \\ 2I_P - (I_H + I_V) \\ 2I_R - (I_H + I_V) \end{bmatrix} \tag{33.37}$$

Acquisition of the reflected Stokes parameters for incident polarization states characterized by $\hat{\mathbf{e}}_{\parallel}$, $\hat{\mathbf{e}}_{\perp}$, $\hat{\mathbf{e}}_{+}$, and $\hat{\mathbf{e}}_R$ then yields sufficient information to completely determine the Mueller matrix of a sample. One disadvantage is that determination of a Mueller matrix requires a relatively large number of sequential measurements from any location in a sample. More importantly, this mathematically complete characterization can be difficult to interpret; decomposition of a given Mueller matrix [26, 27, 31] to yield useful parameterization of polarization effects can be difficult to obtain.

A number of subsequent publications have also determined the Mueller matrix for a sample using faster systems with a more traditional two-channel detection scheme similar to that shown in Fig. 33.3 [19, 20, 32]. However, these studies compared the Jones vectors for light incident on and reflected back from a sample to first determine the sample Jones matrix, which is used to derive a corresponding Mueller matrix. The coherent detection of OCT and the nature of Jones vectors necessarily dictates that the degree of polarization be unity. Unless these calculations are performed in a wavelength-dependent manner, any resultant Mueller matrices can be used to only determine the non-depolarizing polarization properties of a sample, negating any potential advantage of the otherwise difficult-to-interpret Mueller matrix.

33.1.2.3 Poincaré Sphere

The Poincaré sphere is a three-dimensional representation of polarization states that allows for a more intuitive depiction of polarization phenomena. The Q-, U-, and V-components of the Stokes parameters are sufficient to describe the polarization state of light. For a partially polarized beam, the I-Stokes parameter additionally provides only the degree of polarization. In the case of a fully polarized beam, $I^2 = Q^2 + U^2 + V^2$. Thus, an explicit parameter to describe only the intensity of a beam is unnecessary, and the Stokes parameters can be expressed as a real 3-vector of the form

$$\vec{S} = \begin{bmatrix} Q \\ U \\ V \end{bmatrix} \tag{33.38}$$

Such vectors can be pictured in a three-dimensional space known as a Poincaré sphere [33]. In the conventional Poincaré sphere notation, the direction of a polarization state is described by a vector $\vec{S} = [q, \quad u, \quad v]^T$, where $q = Q/I$, $u = U/I$, and $v = V/I$. The radius of the sphere itself is unity, and the magnitude of a polarization state vector is defined by its degree of polarization. However, in discussions of purely polarized light, a modified Poincaré sphere can be more

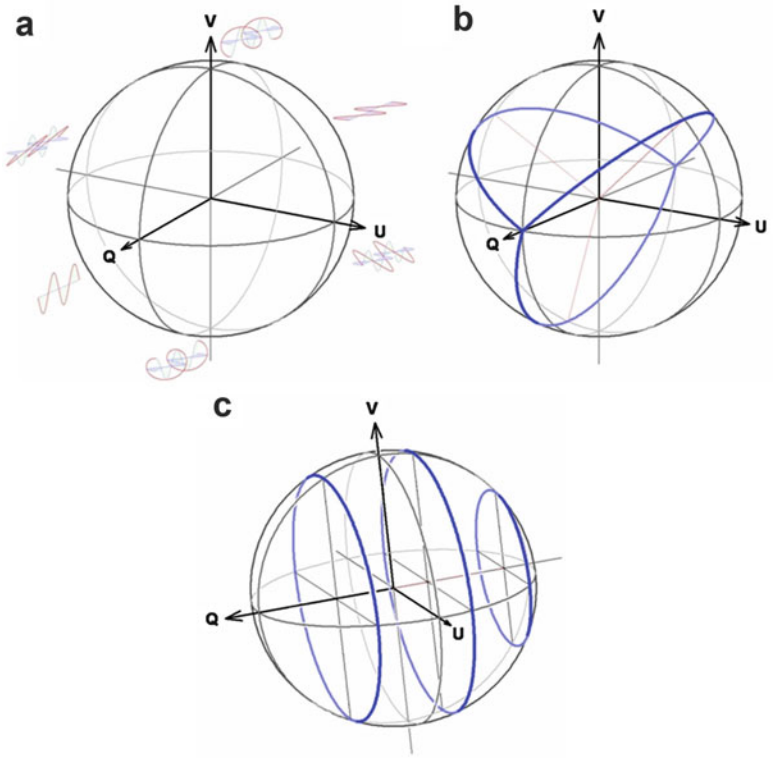

Fig. 33.6 (**a**) The Poincaré sphere with illustrations of the electric field representations of the major axes. (**b**, **c**) Poincaré spheres showing arcs of equal phase difference and equal amplitude ratio, respectively, between orthogonal electric field components

useful, where the Q-, U-, and V-parameters map to the x-, y-, and z-coordinates of a three-dimensional space. The radius of the sphere will be defined by I, and the degree of polarization will be ignored. It should be noted that the degree of polarization of light detected with optical coherence tomography can be less than unity [34]. The Poincaré sphere representation provides a convenient framework for visualizing polarization phenomenon by using the Q-, U-, and V-parameters as the x-, y-, and z-coordinates of a three-dimensional space (Fig. 33.6).

Polarization states with equal amplitude ratios and equal phase differences between orthogonal electric field components follow well-defined arcs in a Poincaré sphere representation. Using the definitions in Eq. 33.7, the Stokes 3-vector simplifies to

$$\vec{S} = \begin{bmatrix} a_{\parallel}^2 - a_{\perp}^2 \\ 2a_{\parallel}a_{\perp}C_{\Delta\delta} \\ 2a_{\parallel}a_{\perp}S_{\Delta\delta} \end{bmatrix} = \left(a_{\parallel}^2 + a_{\perp}^2\right) \begin{bmatrix} C_{\alpha} \\ S_{\alpha}C_{\Delta\delta} \\ S_{\alpha}S_{\Delta\delta} \end{bmatrix} \tag{33.39}$$

where α is governed by the amplitude ratio such that $C_\alpha = (a_\parallel^2 - a_\perp^2)/(a_\parallel^2 + a_\perp^2)$ and $S_\alpha = 2a_\parallel a_\perp/(a_\parallel^2 + a_\perp^2)$. It becomes evident that polarization states of equal amplitude ratio and equal phase difference between orthogonal electric field components trace latitude and longitude lines, respectively, where the Q -axis of the Poincaré sphere is treated as the pole.

The Jones matrices describing diattenuation and birefringence both fit the general form

$$\mathbf{J} = \begin{bmatrix} XC_\theta^2 + YS_\theta^2 & (X-Y)C_\theta S_\theta e^{-i\phi} \\ (X-Y)C_\theta S_\theta e^{i\phi} & XS_\theta^2 + YC_\theta^2 \end{bmatrix} \tag{33.40}$$

where X and Y are parameters defining the magnitude of polarization effects about an optic axis defined by θ and ϕ. For diattenuation, the general parameters take the form $X = P_1$ and $Y = P_2$, and in the case of birefringence, $X = e^{i\eta/2}$ and $Y = e^{-i\eta/2}$. For simultaneous birefringence and diattenuation about a common axis, $X = P_1 e^{i\eta/2}$ and $Y = P_2 e^{-i\eta/2}$. The transmitted state $\mathbf{S}' = [I', \quad Q', \quad U', \quad V']^T$ is the product of the equivalent Mueller matrix $\mathbf{M}$ and the incident polarization state $\mathbf{S} = [I, \quad Q, \quad U, \quad V]^T$. If no depolarization takes place, all such transformations can be completely described by the lower-right 3 × 3 sub-matrix of $\mathbf{M}$. This reduction of the Mueller matrix allows for examination of the 3-vector equivalents of the transmitted and incident states, $\vec{S}'$ and $\vec{S}$, in terms of polarization parameters X and Y and optic axis $\vec{A} = [C_{2\theta}, \quad S_{2\theta}C_\phi, \quad S_{2\theta}S_\phi]^T$, yielding the relation [35]

$$\vec{S}' = \frac{1}{2}\left((X^*Y + XY^*)\vec{S} + i(X^*Y - XY^*)\left(\vec{S} \times \vec{A}\right) + \left((X^*X + YY^*)I + (X-Y)(X^* - Y^*)\left(\vec{S}\cdot\vec{A}\right)\right)\vec{A}\right) \tag{33.41}$$

This expression allows for visualization of polarization effects in the Poincaré sphere.

For diattenuation, Eq. 33.41 simplifies to

$$\vec{S}' = q_3\vec{S} + \left(q_2 I + (q_1 - q_3)\left(\vec{S}\cdot\vec{A}\right)\right)\vec{A}. \tag{33.42}$$

Since this expression is a linear sum of $\vec{S}$ and $\vec{A}$, $\vec{S}'$ must be coplanar with $\vec{S}$ and $\vec{A}$. Furthermore, for $d = 1$, $q_1 = q_2 = \frac{1}{2}$ and $q_3 = 0$, and $\vec{S}' = \frac{1}{2}\left(I + \vec{S}\cdot\vec{A}\right)\vec{A}$. Since $\left|\vec{S}\cdot\vec{A}\right| \le I$, the transmitted polarization state is not only parallel to $\vec{A}$ but must be in the same direction as well. On the other extreme, if $d = -1$, then $q_1 = \frac{1}{2}$, $q_2 = -\frac{1}{2}$, and $q_3 = 0$, resulting in a transmitted polarization state $\vec{S}' = -\frac{1}{2}\left(I - \vec{S}\cdot\vec{A}\right)\vec{A}$. In this case, the transmitted polarization state is parallel to $\vec{A}$ but lies in the opposite direction. Thus, positive diattenuation can be visualized as a "pulling" of the polarization toward the optic axis, and a negative diattenuation value implies a "pushing away," as illustrated in Fig. 33.7a.

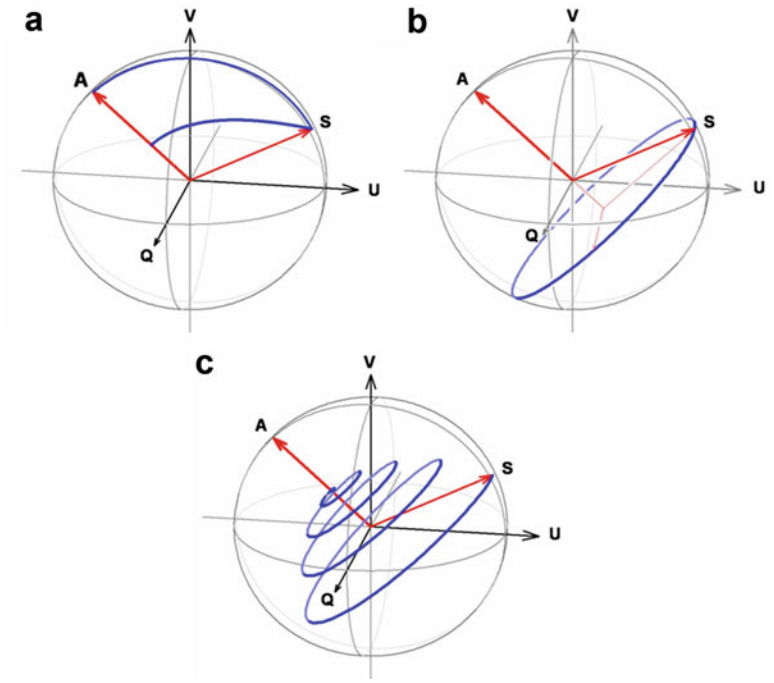

Fig. 33.7 Poincaré sphere representations of the effects of (**a**) diattenuation, (**b**) birefringence, and (**c**) the combined effect about a common optic axis A on a polarization state S. The "pulling" effect of diattenuation is evident from the trace (*inner arc*) of the transmitted polarization state as diattenuation increases (the normalized trace along the surface of the sphere is also shown). Birefringence is equivalent to a rotation in the Poincaré sphere. The combined effect has the appearance of a spiral

In the case of birefringence,

$$\vec{S'} = \left(\vec{S}\cdot\vec{A}\right)\vec{A} + C_\eta\left(\vec{S} - \left(\vec{S}\cdot\vec{A}\right)\vec{A}\right) + S_\eta\left(\vec{S}\times\vec{A}\right) \tag{33.43}$$

The first portion, $\left|\left(\vec{S}\cdot\vec{A}\right)\vec{A}\right| = \left|\vec{S}\right|\cos\theta_{\vec{S},\vec{A}}$, is the portion of $\vec{S}$ that lies along $\vec{A}$. Examination of the other vector components show that $\left|\vec{S} - \left(\vec{S}\cdot\vec{A}\right)\vec{A}\right| = \left|\vec{S}\times\vec{A}\right| = \left|\vec{S}\right|\sin\theta_{\vec{S},\vec{A}}$ and $\left(\vec{S} - \left(\vec{S}\cdot\vec{A}\right)\vec{A}\right) \perp \left(\vec{S}\times\vec{A}\right)$, which represent a decomposition of $\vec{S}$ along orthogonal directions in the plane perpendicular to $\vec{A}$. Thus, birefringence represents a rotation of $\vec{S}$ about the optic axis $\vec{A}$ in a Poincaré sphere representation.

The more general equation for the combined effect about a common optic axis is given by

$$\vec{S'} = q_3 C_\eta \vec{S} + q_3 S_\eta\left(\vec{S}\times\vec{A}\right) + \left(q_2 I + \left(q_1 - q_3 C_\eta\right)\left(\vec{S}\cdot\vec{A}\right)\right)\vec{A} \tag{33.44}$$

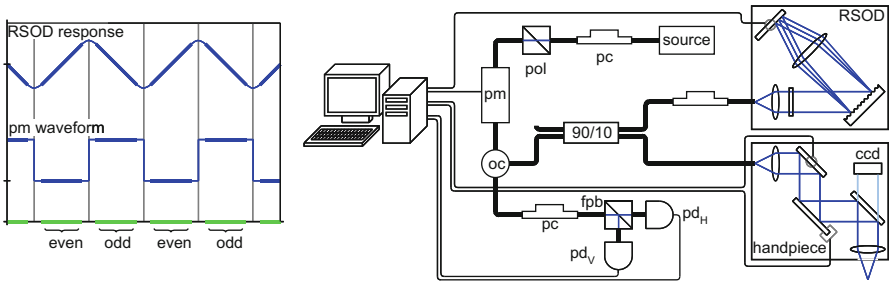

Fig. 33.8 Diagram of a fiber-based PS-OCT system and driving waveforms. The RSOD and phase modulator are driven by a rounded sawtooth and a step function, respectively, both at approximately 1 kHz. A phase delay is introduced such that the RSOD galvo response is in phase with the polarization modulator. The system processes the central 80 % of the positive and negative sloping regions of the RSOD response, yielding even and odd A-lines. (*pol* polarizer, *pc* passive polarization controller, *pm* electro-optic polarization modulator, *oc* optical circulator, *RSOD* rapid scanning optical delay line, *fpb* fiber polarizing beam splitter, *pd* fiber-pigtailed photodiodes, *ccd* charge-coupled device camera) (Reprinted from Fig. 1 of Ref. [37] with permission of the Optical Society of America)

Although direct analysis of this vector equation is more complicated, the combined trace on a Poincaré sphere is of a simultaneous pulling in toward and a rotation about the optic axis. It is worth noting that vector expressions for polarization effects have been formulated in a differential geometry as well [36].

Stokes Vector-Based Analysis for Fiber-Based PS-OCT

The previous PS-OCT systems were air-spaced interferometers that used bulk optical components that permitted precise control over the polarization state of light in the sample and reference arms. The incident polarization state does not vary and can be controlled so that it is circular. This insures insensitivity to the direction of the optic axis of the sample, which, for birefringent materials, must be constrained to the *QU*-plane in a Poincaré sphere representation. In this case, the change in the polarization state can be completely determined from the difference between the known incident polarization state and that reflected or backscattered from a particular point in the scan. Fiber-based interferometers offer distinct advantages in terms of system alignment and handling but pose design problems owing to polarization changes induced in optical fibers. To understand the problem posed by fiber-based PS-OCT [13–15], consider the schematic of a fiber-based PS-OCT drawn in Fig. 33.8. Assuming lossless transmission through optical fiber, diattenuation can be ignored; the main polarization effect of optical fiber in a system is birefringence. Since the amount and orientation of fiber birefringence in the system is an unknown quantity, it is clear that determination of sample polarization properties becomes quite complicated: the incident polarization state is no longer known and that the overall direction of the optic axis (from the combination of sample and fibers) is no longer constrained to the *QU*-plane.

Further, even if the birefringence in the fiber could be completely characterized at all times, it is entirely possible that the polarization state incident on the sample becomes aligned parallel or orthogonal to the optic axis of the sample. In this case, the incident polarization state remains unchanged upon reflection from the sample, and thus the amount or orientation of any sample polarization properties cannot be determined by examination of the reflected polarization state. It becomes clear that fiber-based PS-OCT must overcome two main difficulties: being able to compensate for an unknown amount of fiber birefringence to extract sample polarization properties only and to avoid the problem of the incident polarization state being aligned with or orthogonal to the optic axis of the sample.

Both these problems are solved by using multiple incident polarization states and by comparison of reflected light from the surface to that from some depth. The detected polarization state in a fiber-based PS-OCT system reflects the overall birefringence of both the sample and the fiber of the system. The fiber birefringence affects the polarization state reflected from the surface of the sample in the same way it affects light returning from some depth below the surface. Since orthogonality between states is preserved in a lossless system, the difference between these polarization states is due to the sample only. Comparison of at least two incident polarizations can be used to insure that polarization states will return information regarding the sample polarization properties, even if a polarization state becomes aligned parallel to the optic axis of the sample.

The optimal choice of two incident polarization states is dependent on the acquisition scheme. In earlier systems, the incident polarization state alternated during acquisition of successive depth profiles. The fact that these depth profiles were acquired separately makes it difficult to determine the absolute phase relationship between reflected polarization states. The optimal choice for recovery of tissue birefringence in this case is incident states that are perpendicular in a Poincaré sphere representation [13–15, 21, 22, 37].

Simultaneous acquisition of two polarization states, e.g., by modulating the polarization state within a single A-line (depth profile) in TD-OCT [38], SD-OCT [39], or swept-source OCT [40, 41], allows determination of the absolute phase relationship between reflected polarization states, which changes the optimal choice of the incident polarization states. In these cases, the optimal choice for incident polarization states becomes two states separated by 180° in a Poincaré sphere representation due to the fact that the phase relationship between reflected polarization states is available [42]. A brief rationale for this is given later at the end of Sect. 33.1.3 of this chapter.

The following discussion makes no assumption regarding the phase relationship between the two reflected polarization state depth profiles. The incident polarization state will be toggled between two different states in adjacent depth profiles such that all even A-lines have the same incident polarization state perpendicular to the incident state in a Poincare sphere representation of all odd A-lines. Let the intensity and polarization state of light at the sample surface be denoted by the scalar quantity I_j and normalized polarization 3-vector $\vec{I}_j = \left[Q_j, \quad U_j, \quad V_j \right]^T$,

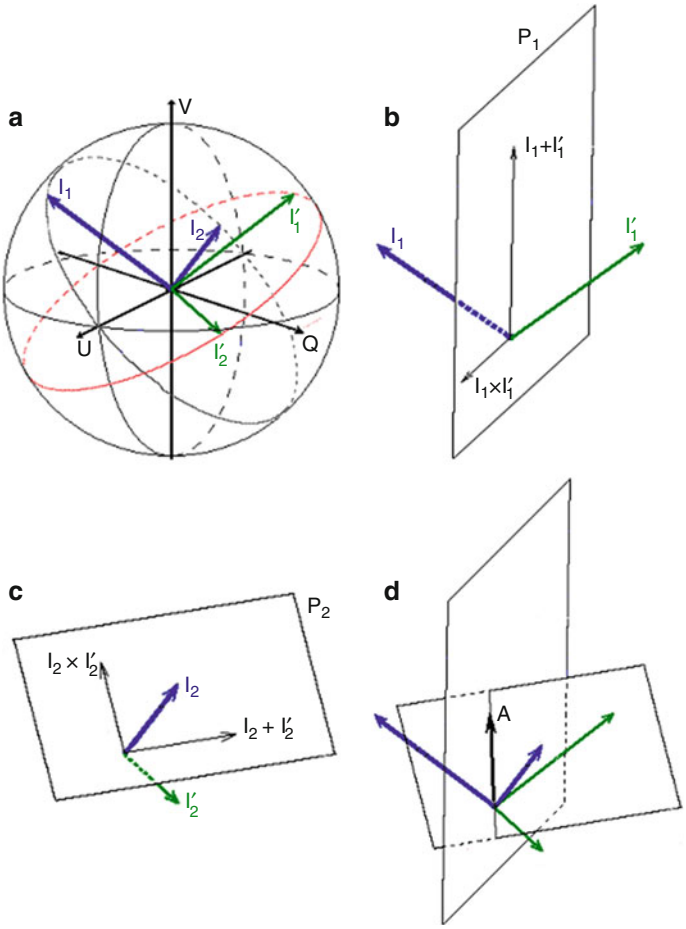

Fig. 33.9 Birefringence calculation illustrating (**a**) the surface states, I_1 and I_2, in *blue* and the reflected states, I'_1 and I'_2, in *green*, (**b**, **c**) the planes P_1 and P_2 that span all possible rotation axes, and (**d**) the intersection of the planes resulting in determination of the optic axis (Reprinted from Fig. 2 of Ref. [14] with permission from the International Society of Optical Engineering)

where $j = 1$ indicates even A-lines and $j = 2$ off A-lines. The sample polarization properties at a depth z computed from an adjacent pair of A-lines may then be calculated in the following way (Fig. 33.9). Let the intensity and polarization state at depth z be represented by I'_j and $\vec{I'}_j$, respectively. The plane P_j containing all possible axes that can rotate the surface polarization state, $\vec{I}_j$, to the normalized reflected polarization state at a depth z, $\vec{I'}_j$, is spanned by their sum and cross products. The intersection of the two planes P_1 and P_2 determines a single axis of rotation $\vec{A}$ capable of rotating both sets of polarization states simultaneously. The relative optic axis of the sample is then given by

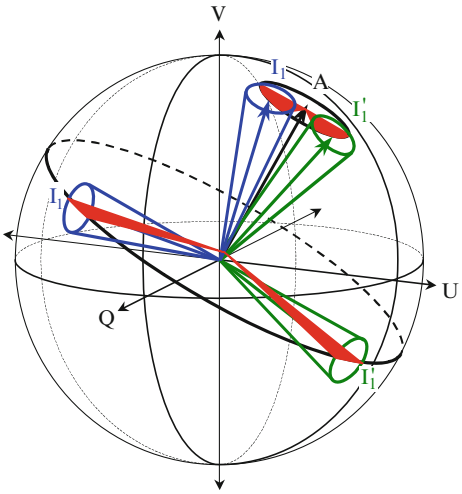

Fig. 33.10 Effect of noise on the calculated rotation angle. For a given optic axis $\vec{A}$, two pairs of $\vec{I}_1$ and $\vec{I'}_1$ are shown, one with large $\theta\vec{A}, \vec{I}_1$ and the other with small $\theta\vec{A}, \vec{I}_1$. The *cones* represent the uncertainty in orientation of the polarization states due to noise. The *red* areas show the variation in rotation angle θ_1 due to the uncertainty introduced by noise, demonstrating the increased uncertainty involved in determining θ_1 when the polarization state of incident light is closely aligned with the optic axis (Reprinted from Fig. 5 of Ref. [37] with permission of the Optical Society of America)

$$\vec{A} \parallel \left(\left(\vec{I'}_1 + \vec{I}_1\right) \times \left(\vec{I'}_1 \times \vec{I}_1\right)\right) \times \left(\left(\vec{I'}_2 + \vec{I}_2\right) \times \left(\vec{I'}_2 \times \vec{I}_2\right)\right)$$
$$\parallel \left(\vec{I'}_1 - \vec{I}_1\right) \times \left(\vec{I'}_2 - \vec{I}_2\right) \tag{33.45}$$

The final step in the analysis is determining the degree of phase retardation over this optic axis. θ_1 may be defined as the degree of rotation about $\vec{A}$ that takes $\vec{I}_1$ to $\vec{I'}_1$, and θ_2 is defined analogously. The expectation is that the two rotation angles are equal; however, in practice they differ slightly due to noise. The overall phase retardation is taken as the intensity-weighted average of the two angles. However, the effect of noise on the value of θ_j ($j = 1, 2$) increases as the angle between the rotation axis $\vec{A}$ and either Stokes states $\vec{I}_1$ or $\vec{I'}_1$ decreases. This may be illustrated by defining $\theta\vec{A}, \vec{I}_j$ and $\theta\vec{A}, \vec{I}_j$ as the angles between $\vec{A}$ and $\vec{I}_j$ and $\vec{I'}_j$, respectively, where $\sin\theta\vec{A}, \vec{I}_j = \left|\vec{A} \times \vec{I}_j\right| / \left(\left|\vec{A}\right|\left|\vec{I}_j\right|\right)$ and $\sin\theta\vec{A}, \vec{I}'_j = \left|\vec{A} \times \vec{I}'_j\right| / \left(\left|\vec{A}\right|\left|\vec{I}'_j\right|\right)$. In the absence of noise, the rotation angle required to rotate both incident polarization states to the reflected polarization states at depth z will be identical, such that $\theta\vec{A}, \vec{I}_j = \theta\vec{A}, \vec{I}'_j$. As illustrated in Fig. 33.10, the effect of noise on the polarization state of detected light can be modeled in the Poincaré sphere by adding a randomly

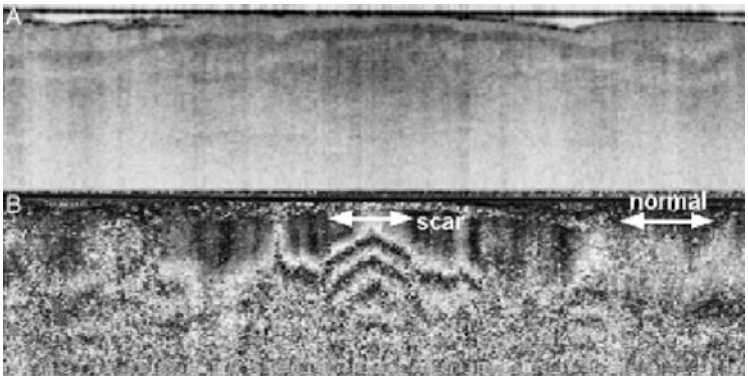

Fig. 33.11 PS-OCT images of scar tissue in vivo. Structural (**a**) and polarization-sensitive (**b**) images from a region of scar tissue on the hand, 5 mm wide by 1.2 mm deep. Labeled *arrows* in (**b**) indicate clinically determined regions of scar tissue and adjacent normal skin (Reprinted from Fig. 4 of Ref. [72] with permission of the Society of Investigative Dermatology)

oriented vector of a length proportional to the magnitude of the noise to the polarization state of the light. Since cross products are linear, $\vec{A} \times \left(\vec{I} + \vec{N}\right) = \vec{A} \times \vec{I} + \vec{A} \times \vec{N}$. As $\theta\vec{A}, \vec{I}_j$ decreases, the contribution to θ_j due to the signal decreases while that due to noise is unchanged. This means the calculated rotation angle θ_j becomes more susceptible to noise for small $\theta\vec{A}, \vec{I}_j$. To account for this, we additionally weight the calculated angles by the product of the sines of the angles between the axis of rotation and the polarization states. The degree of phase retardation is then given by

$$\theta = \frac{\left(I_1 I_1' \sin\theta\vec{A}, \vec{I}_1 \sin\theta\vec{A}, \vec{I}_1'\right)\theta_1 + \left(I_2 I_2' \sin\theta\vec{A}, \vec{I}_2 \sin\theta\vec{A}, \vec{I}_2'\right)\theta_2}{\left(I_1 I_1' \sin\theta\vec{A}, \vec{I}_1 \sin\theta\vec{A}, \vec{I}_1'\right) + \left(I_2 I_2' \sin\theta\vec{A}, \vec{I}_2 \sin\theta\vec{A}, \vec{I}_2'\right)} \tag{33.46}$$

These values can be encoded on a gray scale with black and white representing rotation of 0 and π radians, respectively, as shown in the images of scar tissue in vivo displayed in Fig. 33.11.

33.1.3 Jones Formalism II

As birefringence seems to be the primary polarization property exhibited by biological tissue, most PS-OCT analysis methods concentrate on determination of phase retardation. Schoenenberger et al. [43] analyzed system errors introduced by the extinction ratio of polarizing optics and chromatic dependence of wave retarders and errors due to dichroism. System errors can be kept small by careful

design of the system with achromatic elements but can never be completely eliminated. In principle, dichroism is a more serious problem when interpreting results as solely due to birefringence. However, Mueller matrix ellipsometry measurements have shown that the error due to dichroism in the eye is relatively small [44, 45], and earlier PS-OCT work shows that dichroism is of minor importance in rodent muscle [10]. Despite this, a method for simultaneous determination of sample birefringence and dichroism is desirable, especially one that can be applied to systems with the unrestricted use of optical fiber and fiber components.

The non-depolarizing polarization properties of an optical system can be completely described by its complex Jones matrix, $\mathbf{J}$, which transforms an incident polarization state described by a complex electric field vector, $\mathbf{E} = [H, \quad V]^T$, to a transmitted state, $\mathbf{E}' = [H', \quad V']^T$, and can be decomposed in the form $\mathbf{J} = \mathbf{J}_R\mathbf{J}_P = \mathbf{J}_{P'}\mathbf{J}_{R'}$ [31]. Birefringence, described by $\mathbf{J}_R$, can be parameterized by three variables: a degree of phase retardation η about an axis defined by two angles, γ and δ. Diattenuation, described by $\mathbf{J}_P$, is defined as $d = (P_1^2 - P_2^2)/(P_1^2 + P_2^2)$ and can be parameterized by four variables, where P_1 and P_2 are the attenuation coefficients parallel and orthogonal, respectively, to an axis defined by angles Γ and Δ. These seven independent parameters, along with an overall common phase $e^{i\Psi}$, account for all four complex elements of a general Jones matrix $\mathbf{J}$. Assuming that birefringence and diattenuation arise from the same fibrous structures in biological tissue and thus share a common axis ($\delta = \Delta$ and $Y = \Gamma$) [19], the number of independent parameters is reduced by two. An incident and reflected polarization state yield three relations involving the two orthogonal amplitudes and the relative phase between them [10]. Therefore, it is possible to use the six relationships defined by two unique pairs of incident and reflected polarization states to exactly solve for the Jones matrix of a sample.

In general terms, a PS-OCT system sends polarized light from a broadband source into the sample and reference arms of an interferometer, and reflected light from both arms is recombined and detected. Define $\mathbf{J}_{in}$ as the Jones matrix representing the optical path from the polarized light source to the sample surface, $\mathbf{J}_{out}$ as that going from the sample surface to the detectors, and $\mathbf{J}_S$ as the round-trip Jones matrix for light propagation through a sample [21]. This nomenclature can be applied to all PS-OCT systems, ranging from bulk-optic systems [6, 7, 9–12] to those with fibers placed such that they are traversed in a round-trip manner [20] to time-domain [13, 15] (Fig. 33.12) and spectral-domain [16] PS-OCT systems with the unrestricted use of optical fiber and non-diattenuating fiber components, and even for retinal systems [22], where the polarization effects of the cornea can be included in $\mathbf{J}_{in}$ and $\mathbf{J}_{out}$. The electric field of light reflected from the sample surface, $\mathbf{E}$, can be expressed as $\mathbf{E} = e^{i\psi}\mathbf{J}_{out}\mathbf{J}_{in}\mathbf{E}_{source}$, where Ψ represents a common phase and $\mathbf{E}_{source}$ represents the electric field of light coming from the polarized source. Likewise, the electric field of light reflected from some depth within the tissue may be described by $\mathbf{E}' = e^{i\psi'}\mathbf{J}_{out}\mathbf{J}_S\mathbf{J}_{in}\mathbf{E}_{source}$. These two measurable polarization states

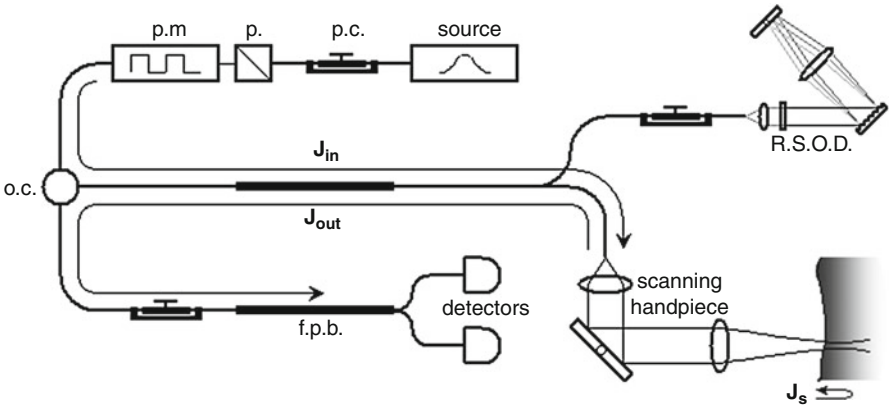

Fig. 33.12 Schematic of the fiber-based PS-OCT system (*p.c.* polarization controller, *p* polarizer, *pm* polarization modulator, *oc* optical circulator, *RSOD* rapid scanning optical delay, *fpb* fiber polarizing beam splitter). Jin, Jout, and JS are the Jones matrix representations for the one-way optical path from the polarization modulator to the scanning handpiece, the one-way optical path back from the scanning handpiece to the detectors, and the round-trip path through some depth in the sample, respectively (Reprinted from Fig. 1 of Ref. [21] with permission of the Optical Society of America)

can be related to each other such that $\mathbf{E}' = e^{i\Delta\psi}\mathbf{J}_T\mathbf{E}$, where $\mathbf{J}_T = \mathbf{J}_{out}\mathbf{J}_S\mathbf{J}_{out}^{-1}$ and $\Delta\psi = \psi' - \psi$.

If the optical system representing $\mathbf{J}_{out}$ is non-diattenuating, $\mathbf{J}_{out}$ can be treated as a unitary matrix with unit determinant after separating out a common attenuation factor. $\mathbf{J}_S$ can be decomposed into a diagonal matrix $\mathbf{J}_C = \begin{bmatrix} P_1 e^{i\eta/2}, & 0; & 0, & P_2 e^{-i\eta/2} \end{bmatrix}$, containing complete information regarding the amount of sample diattenuation and phase retardation, surrounded by unitary matrices $\mathbf{J}_A$ with unit determinant that define the sample optic axis. $\mathbf{J}_T$ can be reformed such that $\mathbf{J}_T = \mathbf{J}_{out}\mathbf{J}_S\mathbf{J}_{out}^{-1} = \mathbf{J}_{out}(\mathbf{J}_A\mathbf{J}_C\mathbf{J}_A^{-1})\mathbf{J}_{out}^{-1} = \mathbf{J}_U\mathbf{J}_C\mathbf{J}_U^{-1}$, where $\mathbf{J}_U = \mathbf{J}_{out}\mathbf{J}_A$. Since unitary matrices with unit determinant form the special unitary group SU(2) [46], $\mathbf{J}_U$ must also be a unitary matrix with unit determinant by closure and can be expressed in the form

$$\mathbf{J}_U = e^{i\beta}\begin{bmatrix} C_\theta e^{i(\phi-\varphi)} & -S_\theta e^{i(\phi+\varphi)} \\ S_\theta e^{-i(\phi+\varphi)} & C_\theta e^{-i(\phi-\varphi)} \end{bmatrix} \tag{33.47}$$

An alternative formulation for $\mathbf{J}_T$ can be obtained by combining information from two unique incident polarization states: $\begin{bmatrix} H_1', & H_2'; & V_1', & V_2' \end{bmatrix} = e^{i\Delta\psi_1}\mathbf{J}_T\begin{bmatrix} H_1, & e^{i\alpha}H_2; & V_1, & e^{i\alpha}V_2 \end{bmatrix}$, where $\alpha = \Delta\psi_2 - \Delta\psi_1$. The polarization properties of interest can be obtained by equating the two expressions for $\mathbf{J}_T$ to yield

$$e^{i\Delta\psi_1}\begin{bmatrix} P_1 e^{i\eta/2} & 0 \\ 0 & P_2 e^{-i\eta/2} \end{bmatrix} = \begin{bmatrix} C_\theta & S_\theta \\ -S_\theta & C_\theta \end{bmatrix}\begin{bmatrix} e^{-i\phi} & 0 \\ 0 & e^{i\phi} \end{bmatrix}\begin{bmatrix} H_1' & H_2' \\ V_1' & V_2' \end{bmatrix} \begin{bmatrix} H_1 & e^{i\alpha}H_2 \\ V_1 & e^{i\alpha}V_2 \end{bmatrix}^{-1}\begin{bmatrix} e^{i\phi} & 0 \\ 0 & e^{-i\phi} \end{bmatrix}\begin{bmatrix} C_\theta & -S_\theta \\ S_\theta & C_\theta \end{bmatrix} \tag{33.48}$$

In principle, parameters θ, ϕ, and α can be solved for with the condition that the off-diagonal elements of the matrix product on the right-hand side of Eq. 33.48 are equal to zero. In practice, real solution cannot always be found, as measurement noise can induce nonphysical transformations between incident and transmitted polarization states. To account for this, Eq. 33.48 can be solved by optimizing parameters θ, ϕ, and α to minimize the sum of the magnitudes of the off-diagonal elements. In principle, this can be achieved using two unique incident polarization states to probe the same volume of a sample. However, when two orthogonal incident polarization states are used [20], birefringence cannot be retrieved under all circumstances [47]. A better choice is to use two incident polarization states perpendicular in a Poincaré sphere representation to guarantee that polarization information can always be extracted [13–16, 22, 37]. The degree of phase retardation can easily be extracted through the phase difference of the resulting diagonal elements and the diattenuation by their magnitudes. It should be noted that these phase retardation values range from $-\pi$ to π and can therefore be unwrapped to yield overall phase retardations in excess of 2π.

As a control measurement, a series of OCT intensity images with varying single linear incident polarization states were acquired from chicken tendon and muscle tissue. The orientations for which the reflected polarization states from within the tissue varied minimally as a function of depth were chosen as those where the incident state was aligned parallel or orthogonal to the sample optic axis. The corresponding intensity profiles described attenuation parameters P_1 and P_2, from which depth-resolved control diattenuation plots were derived. PS-OCT scans were then acquired of the same tissue regions. After correcting for slight imbalances between the gains for the two orthogonal detectors, depth-resolved plots of both diattenuation and phase retardation were calculated. The resulting single-pass diattenuation plots are shown in Fig. 33.13. Numerical simulation revealed that the average angular displacement of a polarization state on the Poincaré sphere for a small diattenuation d is approximately (40d)°. Given that the a standard deviation of the order of 5° for individual polarization states reflected from the surface was found, the control and PS-OCT-derived diattenuation per unit depth of chicken muscle, 0.0380 ± 0.0036/mm versus 0.0622 ± 0.0533/mm, and tendon, 0.5027 ± 0.0353/mm versus 0.3915 ± 0.0365/mm, were within reasonable agreement. These diattenuation values correspond to angular displacement on the order of 1.5 − 2.5°/mm and 15 − 20°/mm for muscle and tendon, respectively. The slopes of the respective phase retardation plots, 179.7°/mm and 1,184.4°/mm for tendon, are well within expected parameters. The angular displacement of the Stokes vectors as a result of diattenuation are negligible compared with those due to birefringence in both cases, implying that for these samples, birefringence can be

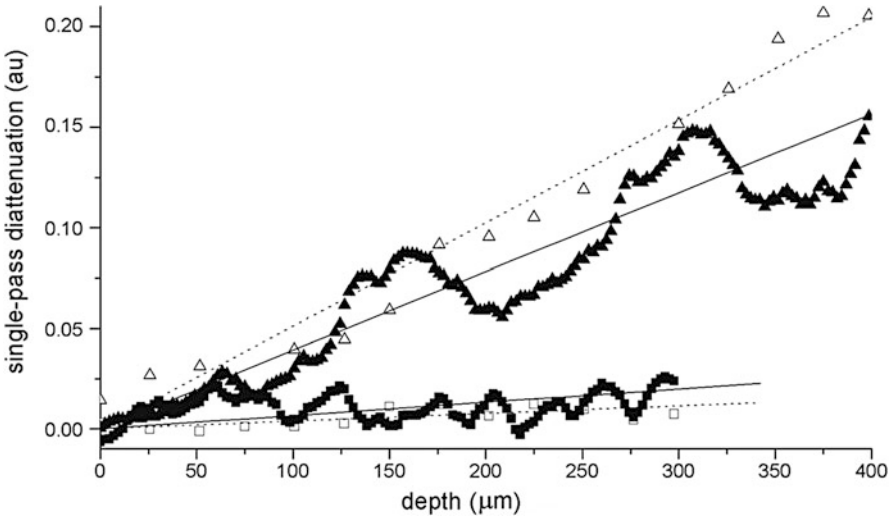

Fig. 33.13 Single-pass diattenuation as a function of depth. The open *triangles* and *squares* represent control diattenuation values of chicken tendon and muscle, respectively, calculated from comparison of the reflectivity profiles for linear incident polarization states along and orthogonal to the fiber direction. The *solid triangles* and *squares* are diattenuation values derived from PS-OCT images acquired from the same tissues. Linear least-squares fits are shown for all plots (Reprinted from Fig. 3 of Ref. [21] with permission of the Optical Society of America)

determined with accuracy even ignoring diattenuation. This was confirmed by applying the Stokes vector-based analysis presented in Sect. 33.1.2.3, which yielded similar slopes of 211.9°/mm and for muscle and tendon, respectively.

A relative optic axis can be derived from ϕ and θ, given in Stokes parameter form by $\mathbf{A} = [\,1, \quad C_{2\phi}C_{2\theta}, \quad C_{2\phi}S_{2\theta}, \quad S_{2\phi}\,]^T$. However, determination of this relative optic axis in a fiber-based system has a fundamental ambiguity. All members of the SU(2) group can be mapped to rotations in SO(3), and so $\mathbf{J}_{out}$, $\mathbf{J}_A$, and $\mathbf{J}_U$ all represent rotations in a Poincaré sphere representation. This means that $\mathbf{J}_C$, $\mathbf{J}_S$, and $\mathbf{J}_T$ are related by unitary transforms and are equivalent except for their respective coordinate systems. Therefore, the amount of phase retardation and diattenuation in $\mathbf{J}_C$, $\mathbf{J}_S$, and $\mathbf{J}_T$ is the same. The three matrices differ only in their eigenvectors and their optic axis equivalents in a well-defined manner dictated by $\mathbf{J}_{out}$. In other words, the optic axis of $\mathbf{J}_T$ is the product of the sample optic axis defined by $\mathbf{J}_A$ and the fiber transformations represented by $\mathbf{J}_{out}$.

Due to the round-trip nature of detected light propagation in tissue, the circular components of birefringence and diattenuation in the sample cancel. Only the linear components of these properties can be measured using PS-OCT. In mathematical terms, the optic axes of $\mathbf{J}_S$, defined by its eigenvectors, can represent only linear birefringence and diattenuation; the V-component (describing circular polarization effects) of the equivalent Stokes vector must equal zero. Therefore, all possible

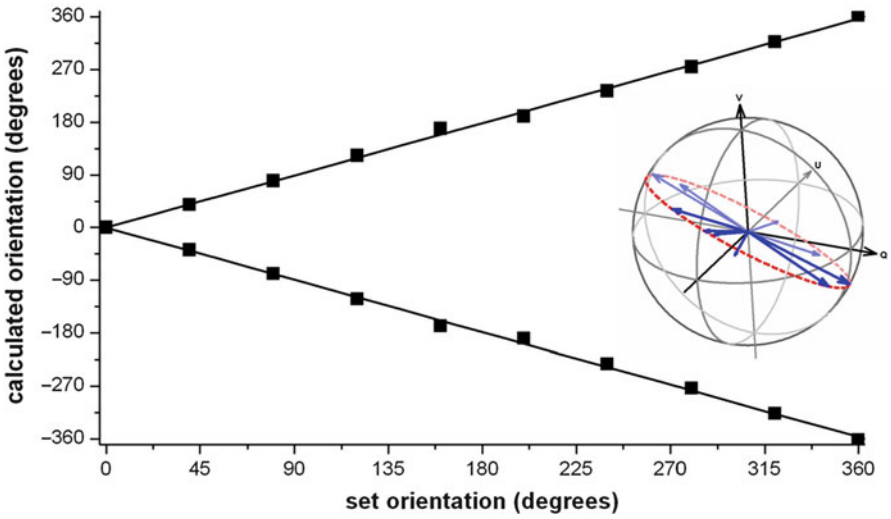

Fig. 33.14 Calculated optic axis orientation as a function of set orientation relative to 0° (*squares*, measured orientation; *lines*, linear fit to the data). As a result of the π-ambiguity (see text), the measured orientation can have both a positive and a negative slope with equal likelihood. Inset, Poincaré sphere representation of the calculated optic axes (*arrows*) for various set orientations of the tissue sample optic axis. The plane (*dashed circle*) in which these optic axes lie was determined by least-squares fitting (Reprinted from Fig. 1 of Ref. [48] with permission from the Optical Society of America)

optic axes for $\mathbf{J}_S$ lie on the QU-plane of a Poincaré sphere. Since $\mathbf{J}_T$ and $\mathbf{J}_S$ differ only by an overall rotation of their coordinate systems, the plane of all possible optic axes for $\mathbf{J}_T$ can be rotated off the QU-plane to some arbitrary plane passing through the origin. The optic axes of $\mathbf{J}_T$ can then have circular components that are entirely due to rotations of the coordinate system arising from system fiber. To verify this analysis, PS-OCT images were taken of a chicken muscle sample, its surface oriented orthogonal to the incident beam and rotated in 40° increments to span a full 360°. Details of the fiber-based PS-OCT system, capable of imaging at 2,048 depth scans per second, were presented by Pierce et al. [15]. It should be noted that the sample itself was rotated and that the fibers in the system were left untouched. Two different analysis methods, the vector-based method and the Jones matrix-based method, were used to analyze the data, providing nearly identical results. The resulting optic axes, along with a plane determined by least-squares fitting, are shown in the inset of Fig. 33.14. The rotation away from the QU-plane is evident, as is the coplanarity of the calculated optic axes.

One method of determining optic axis orientation is to simply determine the orientation as an angle on this tilted plane, as shown in Fig. 33.14. The resulting orientations, relative to that at 0°, are plotted as a function of the set orientation and show that the relative optic axis orientation can be recovered accurately. A second method is to rotate the calculated plane of optic axes back down onto the QU-plane

of the Poincaré sphere. The change in coordinate system due to optical fibers in the system can be decomposed into two parts: a rotation within the plane of possible measured optic axes and a tilting of the plane about some arbitrary axis in the QU-plane. The rotation within the plane causes an overall offset in the calculated orientation that has been discussed in previous publications [14, 20, 47, 48] and implies that only relative orientation angles, not absolute angles, can be determined from a fiber-based PS-OCT system. The tilting of the plane leads to what can be termed a π-ambiguity, or an indeterminacy in the sign of the orientation angle [48].

One proposed method to compensate for this tilting uses the reflection from the surface of a sample to determine the rotation needed to tilt the plane back onto the QU-plane by solving $\mathbf{E} = e^{i\psi}\mathbf{J}_{in}^{T}\mathbf{J}_{in}\mathbf{E}_{source}$, where $\mathbf{J}_{in}$ represents the sample arm fiber only [20]. Four possible solutions to $\mathbf{J}_{in}$ can be found that map to two unique rotations in SO(3) corresponding to common phase factors Ψ differing by π. In geometrical terms, this is the equivalent of the fact that there are two ways to rotate the plane of measured optic axes onto the QU-plane of the Poincaré sphere (faceup and facedown). This results in an ambiguity in the sign of the orientation angle. In other words, as the set optic axis orientation of a sample rotates in one direction, the measured optic axis orientation, depending on the correction chosen, could move in either direction. Thus, the sign of the orientation angle cannot be determined explicitly, only the absolute value, or magnitude, of change from one location to the next. The slope of Fig. 33.14, relating the calculated orientation to the set orientation for a set of data where the same correction could be used throughout, could be positive or negative with equal validity. This π-ambiguity is inherent to all fiber-based PS-OCT systems and implies that although the relative optic axis within an image can be determined, the direction of change in optic axis orientation cannot be compared from image to image absolutely without a priori knowledge.

The case where the information for the two polarization states are acquired simultaneously will now be briefly examined. In this situation, there is no ambiguity in phase between the reflected polarization states, and so $\alpha = \Delta\psi_2 - \Delta\psi_1 = 0$. The polarization properties of a sample can now be *analytically* determined by a simple diagonalization of the right-hand side of Eq. 33.48. The significance of knowledge of the absolute phase relation between the reflected states can also be appreciated by examination of the problem when an incident polarization state is aligned with or orthogonal to the optic axis of a sample. While the Stokes vector for a reflected polarization state might not differ from the incident state, the complex electric field will become shifted by $e^{i\eta/2}$ or $e^{-i\eta/2}$ if it is aligned with or orthogonal to the optic axis, respectively. The amount of birefringence can now be determined in this situation by examination of the overall phase shift between the incident and reflected complex electric fields. Therefore, simultaneous acquisition of the two reflected polarization states makes it possible to *always* recover birefringence using any two unique incident polarization states. In this case, the optimal choice for the two incident polarization states is given when they are separated by 180° in a Poincaré sphere representation, as this is ideal for determination of diattenuation.

33.2 Applications

PS-OCT has been applied to a wide variety of clinical problems, including in vivo examination of the polarization properties of the retinal nerve fiber layer [10, 22, 23, 49–55], the detection and monitoring of caries lesion progression and treatment [24, 56–63], and examination of articular cartilage for detection of osteoarthritis [64–71]. Rather than detail these myriad studies, this section will concentrate on dermatological and ophthalmic studies for illustrative purposes.

33.2.1 Dermatology

OCT and its variants have been applied to a wide variety of dermatological problems [72]. One of the first clinical applications of PS-OCT in particular was for the assessment of burn depth. Burns are classified by depth into first-, second-, and third-degree injuries. First-degree burns cause redness and pain (e.g., sunburn). Second-degree burns are marked by blisters (e.g., scald by hot liquid). In third-degree burns, both the epidermis and dermis are destroyed and the underlying tissue may also be damaged. A second-degree burn will heal if given proper care. However, a third-degree burn will not heal and requires a skin graft. Making the distinction between the two is difficult; a burn surgeon will often observe the injury over the course of several days before making an educated guess regarding burn depth [73]. Initial studies [14] have indicated the potential for PS-OCT to solve this problem by taking advantage of the fact that skin contains collagen, a birefringent material [7, 9]. At temperatures between 56 °C and 65 °C, collagen begins to denature and lose its birefringence [8, 74]. It should be expected that normal and burned skin differ in their natural collagen content and leads to a reduction in the ability of burned skin to alter the polarization state of light that has passed through and been reflected back from some depth.

The computationally efficient Stokes vector method [14–16, 37] described in Sect. 33.1.2.3 was used to correlate birefringence derived from data acquired with a fiber-based PS-OCT instrument [13] versus burn depth as determined by histological analysis for 22 burn sites in a rat model [14]. Figure 33.15 shows examples of normal, unburned rat skin and skin burned for 30 s at 75 °C, respectively. Figure 33.15a and e are histological sections, and comparison between the two highlights the damage to the adnexal structures, the contrast in H&E staining color, and the presence of hyalinization that are associated with thermal injury. Normal skin in Fig. 33.15a has a fairly uniform density of collagen fibers through the dermis that is not visible in the upper regions of Fig. 33.15e due to collagen coagulation. The effects of thermal injury are also readily apparent in the PS-OCT scans. In the burned tissue, the darker region extends to a visibly greater depth than in normal skin, indicating a lesser degree of birefringence in that tissue. This difference is quantified in the phase retardation plots. The degree of phase retardation depends on two factors: distance through the tissue that the light has traveled and the density of natural collagen. The variation with distance is evident in the first 300–500 μm in

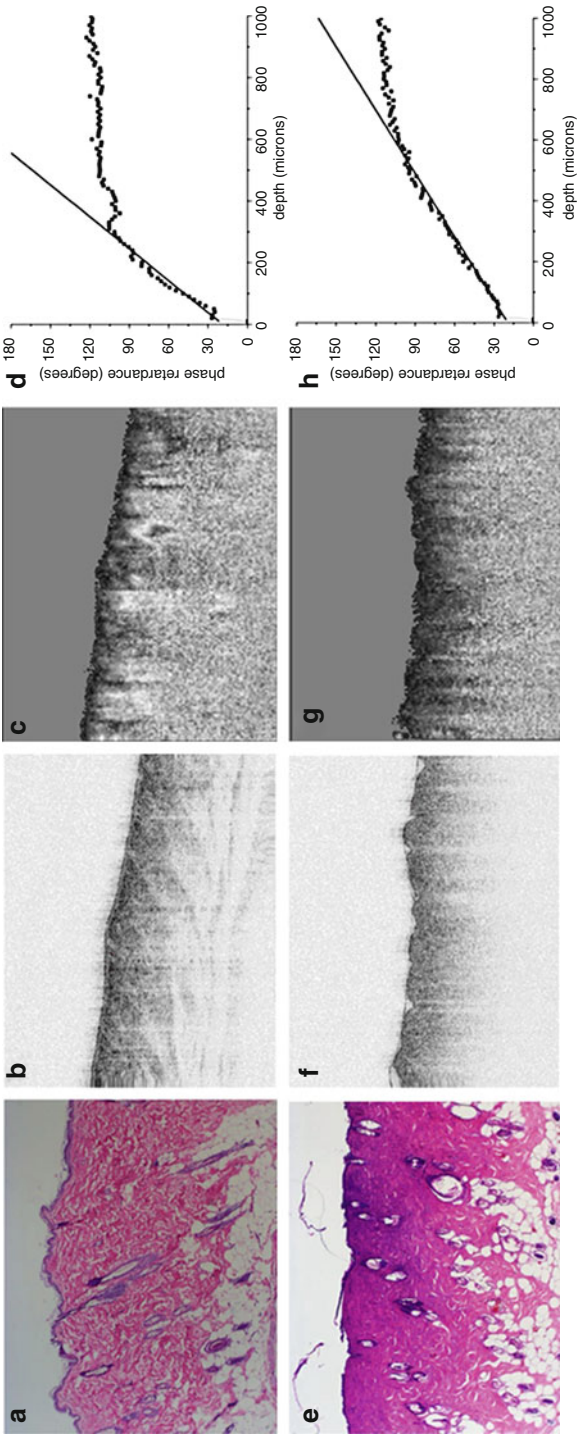

Fig. 33.15 Normal and burned rat skin, respectively, (**a**, **e**) histology, (**b**, **f**) OCT image, (**c**, **g**) phase retardation image, and (**d**, **h**) plot of phase retardance versus depth. The thermal injury was for 30 s at 75 °C. The dimensions of the histological images and phase maps are 3.2 mm by 2 mm, and depths in the graphs are measured from the tissue surface. The absence of speckle above the sample surface is due to the fact that calculation of the phase map was only performed below the surface (Reprinted from Figs. 3 and 4 of Ref. [14] with permission of the International Society for Optical Engineering)

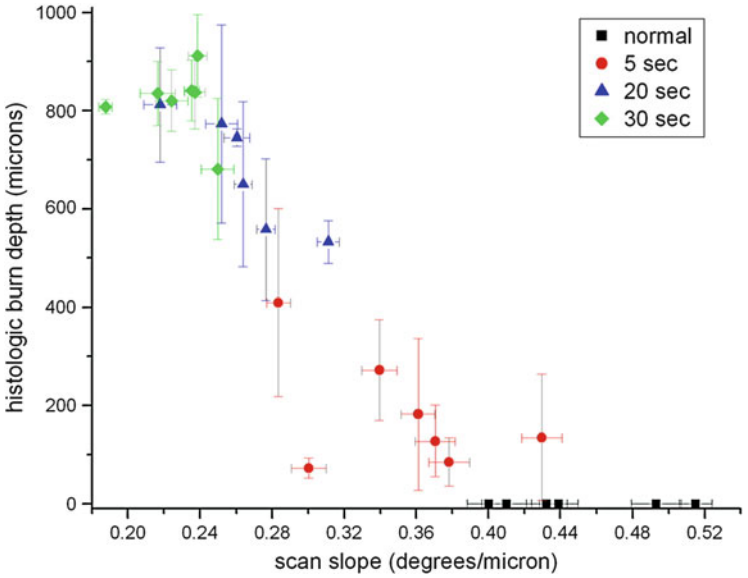

Fig. 33.16 Overall graph of burn depth determined by histological analysis as a function of phase retardation from PS-OCT by burn duration. The A-lines in an image are averaged to generate a graph of degree of phase retardation versus depth into the tissue. The slopes of the roughly linear portions of these graphs are determined by least-squares fitting and the slope and error reported as a measure of phase retardation (scan slope)

depth in the PS-OCT scans; as the depth increases, the degree of phase retardation increases. After this initial depth, the graphs asymptotically approach approximately 115°, which can be attributed to depolarization due to scattering as confirmed by Monte Carlo simulation of the phase retardation measured by randomized polarization states returning from tissue.

Figure 33.16 summarizes the results of the 22 burn sites grouped as normal skin and in three exposure durations of 5, 20, and 30 s at 75 °C. The thermal injury results in skin with lowered fractions of natural collagen. Comparing areas burned for 5 and 30 s, respectively, light that that has traveled a certain depth in the less burned skin will be retarded more than light traveling through the same depth in the tissue with more collagen denaturation. This correlation is clear in Fig. 33.16, where the degree of phase retardation per unit depth decreases with increasing burn depth.

While similar studies in animals have been performed that demonstrate a similar correlation between PS-OCT-derived birefringence and histologically determined burn depth [32, 75], such animal studies are far from the only clinical application of PS-OCT in dermatology. A good deal of work has been done toward establishing baselines for the polarization properties of normal human skin as PS-OCT technology has progressed [13, 72, 76–78]. This work has helped pave the way toward

assessment of burns in humans [79], identification and delineation of basal cell carcinoma [80] and dermal photoaging [81].

33.2.2 Ophthalmology

Ophthalmological application of OCT has arguably driven a great deal of its development and probably represents the most researched clinical application of the technology to date. PS-OCT in particular has been used to measure the birefringence of the human retinal nerve fiber layer in vivo [6, 22, 23, 50–52] for potential early detection of glaucoma, the world's second leading cause of blindness.

Glaucoma causes damage to the retinal ganglion cells, resulting in a thinning of the retinal nerve fiber layer (RNFL). In addition, nerve fiber layer tissue loss may be preceded by changes in birefringence as ganglion cells become necrotic and axons in the RNFL are replaced by a less organized and amorphous tissue composed of glial cells. When glaucoma is detected at an early stage, further loss of vision can be prevented by treatment. The visual field test is the current standard method of detecting loss of peripheral vision in glaucoma. However, measurements show that up to 40 % of nerves are irreversibly damaged before loss of peripheral vision can be clinically detected. PS-OCT has the potential to detect changes to the RNFL at an earlier time point through changes in its birefringence and thickness.

Ophthalmic studies can be performed using systems similar to that used by Cense et al. [22], in which a slit lamp has been adapted for use with PS-OCT. Figure 33.17 is a typical example of a structural-intensity time-domain OCT image of the retina in the left eye of a healthy volunteer obtained with a circular scan with a radius of 2.1 mm around the optic nerve head (ONH). The image measures 13.3 mm wide and 0.9 mm deep and is shown at an expanded aspect ratio in depth for clarity. Structural layers such as the RNFL, the interface between the inner and outer segments of the photoreceptors, and the retinal pigmented epithelium can be seen.

The addition of polarization sensitivity allows for localized quantitative assessment of the thickness and birefringence of the RNFL. Figure 33.18 shows two examples of combined thickness and birefringence measurements, one of a region temporal to the ONH and the other of a region superior to the ONH. The depth of the RNFL can be determined by a decrease in backscattered intensity from the RNFL to the inner plexiform layer. The birefringence of the RNFL can then be estimated from a linear least-squares fit of the measured double-pass phase retardation through the determined depth. Two main observations can be drawn from such graphs: the retinal layers directly below the RNFL are minimally birefringent and that the thickness and birefringence of the RNFL are not constant. These observations can also be seen in Fig. 33.19, which overlays the thickness and birefringence determined as in Fig. 33.18 on a circular scan across the ONH. The plots indicate that the RNFL is thickest and most birefringent superiorly and inferiorly to the ONH.

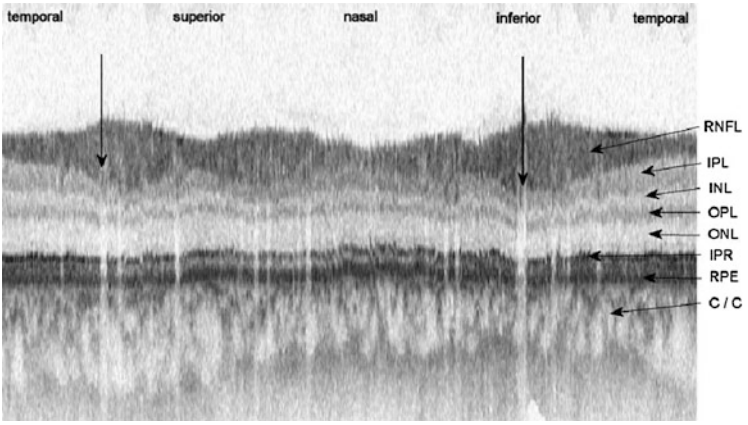

Fig. 33.17 A realigned OCT intensity image created with a 2.1-mm radius circular scan around the ONH. The dynamic range of the image is 36 dB. *Black* pixels represent strong reflections. The image measures 13.3 mm wide and 0.9 mm deep. Visible structures: retinal nerve fiber layer (*RNFL*), inner plexiform layer (*IPL*), inner nuclear layer (*INL*), outer plexiform layer (*OPL*), outer nuclear layer (*ONL*), interface between the inner and outer segments of the photoreceptor layer (*IPR*), retinal pigmented epithelium (*RPE*), and choriocapillaris and choroid (*C/C*). *Vertical arrows*: locations of the two largest blood vessels. Other smaller blood vessels appear as vertical white areas in the image (Reprinted from Fig. 3 of Ref. [23] with permission from the Association for Research in Vision and Ophthalmology)

En-face maps of RNFL thickness and birefringence can be generated from data obtained with recently developed spectral-domain ophthalmic PS-OCT systems [82]. A three-dimensional volume ($4.24 \times 5.29 \times 1.57$ mm^3) of the retina of a normal volunteer (right eye) was scanned at a rate of 29 fps with 1,000 A-lines/frame and contains 190 frames (B-scans) acquired in 6.5 s. The integrated reflectance, birefringence, and retinal nerve fiber layer (RNFL) thickness maps are shown in Fig. 33.20, confirming previous findings that the RNFL birefringence is not uniform across the retina. Superior, nasal, inferior, and temporal areas of the retina around the ONH are indicated by the letters S, N, I, and T. The integrated reflectance map, obtained by simply integrating the logarithmic depth profiles, illustrates the blood vessel structure around the ONH. The RNFL thickness map is scaled in microns (color bar on the top of the image) indicating an RNFL thickness of up to 200 mm. The central dark-blue area corresponds to the position of the ONH that was excluded from both the thickness and the birefringence maps. A typical bow-tie pattern can be seen for the distribution of the RNFL thickness around the ONH, showing a thicker RNFL superior and inferior to the ONH. The birefringence map illustrates a variation of the birefringence values between 0 and 5.16×10^{-4}, and it clearly demonstrates that the RNFL birefringence is not uniform across the retina; it is smaller nasally and temporally and larger superiorly and inferiorly to the ONH.

Given that measurements of the thickness and birefringence of the RNFL can be acquired with the speed and accuracy demonstrated, further research into changes

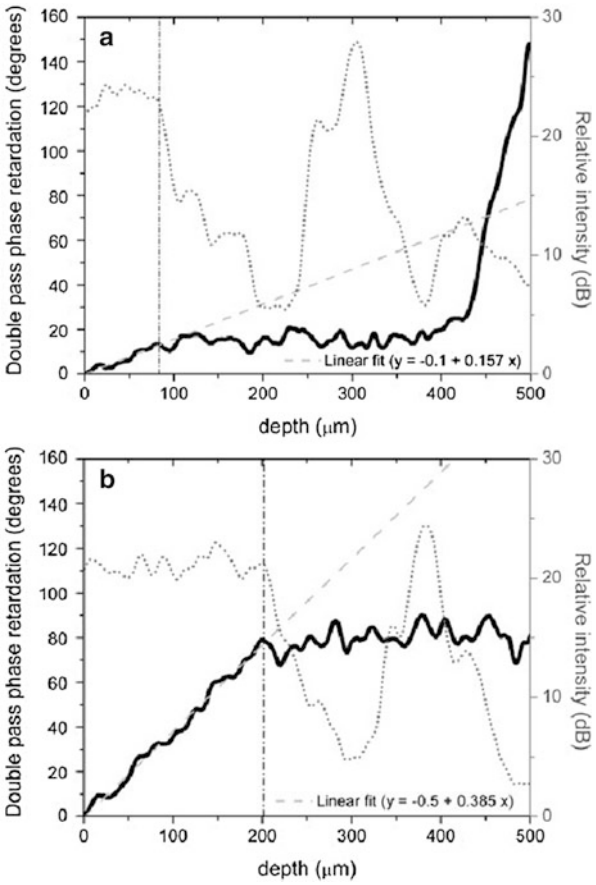

Fig. 33.18 Thickness (*dotted line*) and birefringence (*solid line*) plots of an area temporal (**a**) and superior (**b**) to the ONH. DPPR data belonging to the RNFL is fit with a least-square linear fit. The slope in the equation represents the DPPR/UD or birefringence. The *vertical line* indicates the boundary of the RNFL, as determined from the intensity and DPPR data. In (**a**), the increase in DPPR at a depth beyond 450 μm is caused either by a relatively low signal-to-noise ratio or by the presence of a highly birefringent material – for instance, collagen in the sclera (Reprinted from Fig. 2 of Ref. [23] with permission of the Association for Research in Vision and Ophthalmology)

in these parameters with glaucoma can be performed. Experiments – for instance, a longitudinal study with PS-OCT on patients at high risk for development of glaucoma – will either confirm of reject the hypothesis. In addition, PS-OCT can enhance the specificity in determining RNFL thickness in structural OCT images by using changes in tissue birefringence to determine the border between the RNFL and the ganglion cell layer.

33.3 Future Directions

33.3.1 Fourier-Domain OCT

In traditional or time-domain OCT (TD-OCT), a depth profile is obtained by scanning the length of the reference arm of an interferometer [1]. Alternatively, depth information can be retrieved by detecting the interference signal as a function

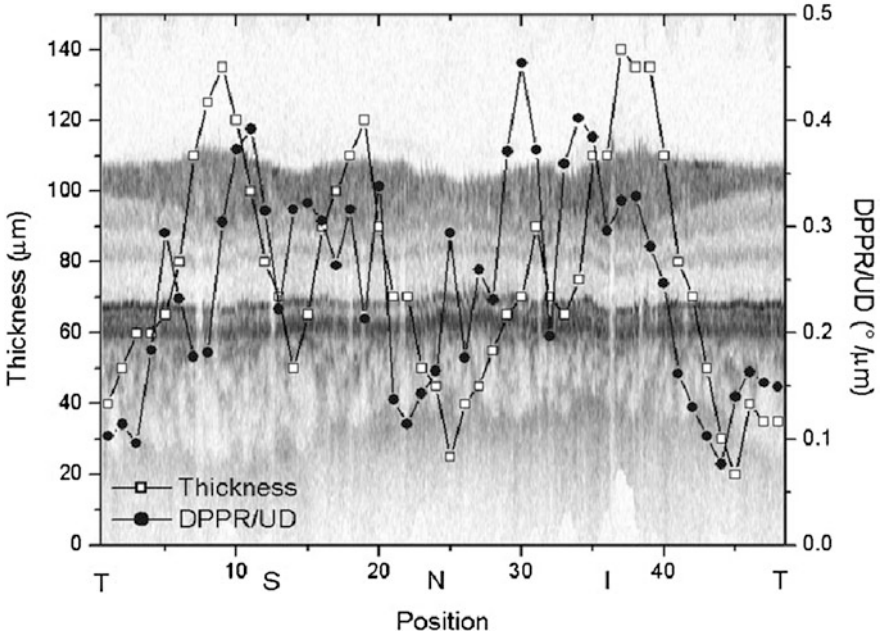

Fig. 33.19 A typical example of combined RNFL thickness and birefringence measurements along a circular scan around the ONH. The intensity image is plotted in the background. The RNFL is relatively thicker superiorly (*S*) and inferiorly (*I*). A similar development can be seen in the birefringence plot. The birefringence is relatively higher in the thicker areas, whereas it is lower in the thinner temporal (*T*) and nasal (*N*) areas (Reprinted from Fig. 4 of Ref. [23] with permission from the Association for Research in Vision and Ophthalmology)

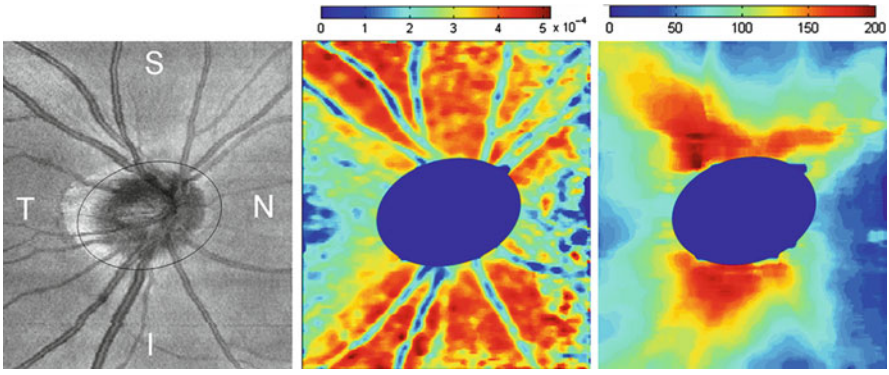

Fig. 33.20 OCT scan (4.24 × 5.29 mm^2) of the retina of a normal volunteer, centered on the ONH. (**a**) An integrated reflectance map showing a normal temporal crescent (*white* area temporal to the ONH), (**b**) birefringence map, and (**c**) RNFL thickness map (*color bar* scaled in microns). The *circle* on the *left* indicates the excluded area in the birefringence and thickness maps as corresponding to ONH. (*S* superior, *N* nasal, *I* inferior, *T* temporal) (Reprinted from Fig. 8 of Ref. [82] with permission of the International Society for Optical Engineering)

of wavelength. In spectral-domain OCT (SD-OCT), this is achieved with a broadband source and a spectrometer in the detector arm [83–85]. Optical frequency domain imaging (OFDI) uses a swept source and point detectors to acquire the same information [86]. The main advantage of these schemes, collectively known as Fourier-domain OCT, is a marked increase in sensitivity [87–91] that can be translated into increased imaging speed. SD-OCT [16, 39, 52, 76] and OFDI [92] systems with polarization sensitivity have been reported.

In both paradigms, the recorded interference signal can be converted into a depth profile by Fourier transform, which relates physical distance with wave number k. A proper depth profile is only obtained after remapping the interference signal evenly in k-space [85], requiring accurate assessment of the wavelength corresponding to each spectral element of the recorded signal. This accuracy becomes even more important with polarization-sensitive measurements. Even a slight mismatch of the wavelength mapping between the two analysis channels can give rise to an artificial appearance of birefringence [16]. While this is typically not the case with OFDI, alignment and calibration of polarization-sensitive SD-OCT systems to remove this artifact is critical for accuracy and has been reported by several groups [16, 39, 52, 82].

Since TD-OCT does not suffer from any such artifact, direct comparison of TD- and SD-OCT results can be used to verify the accuracy of the remapping procedure and removal of birefringence artifacts. Using a polarization-sensitive SD-OCT system [16], images were taken of a chicken muscle sample, its surface oriented orthogonal to the axis of the incident beam and rotated in 20° increments about this axis, spanning a full 360°. Data from orientations with signal saturation were ignored. The same sample was then imaged with the same geometry with a TD-OCT system capable of imaging at 2,048 depth scans per second [15, 37]. A more computationally intensive Jones matrix-based analysis capable of providing unwrappable phase retardations (in excess of 360°) was used to analyze both sets of data [21]. The data from the Jones matrix-based approach is displayed. Representative data acquired with both systems are displayed in Fig. 33.21. Average double-pass phase retardation slopes of $0.919 \pm 0.031°$/mm and $0.885 \pm 0.069°$/mm for time domain and spectral domain, respectively, are in excellent agreement. The resulting optic axes, along with a plane determined by least-squares fitting, as well as their corresponding orientation angles on that plane, are shown in Fig. 33.22. The calculated orientation shows good agreement with the set orientation angle of the tissue sample. These results demonstrate the accuracy of the system to determine sample polarization properties, such as phase retardation and optic axis orientation.

33.3.2 Noise Analysis

Assessment of its accuracy has developed as PS-OCT has evolved. In its earliest conception, Everett et al. [9] gave an analysis of the systematic error in the phase retardation due to background noise for the amplitude-based PS-OCT detection

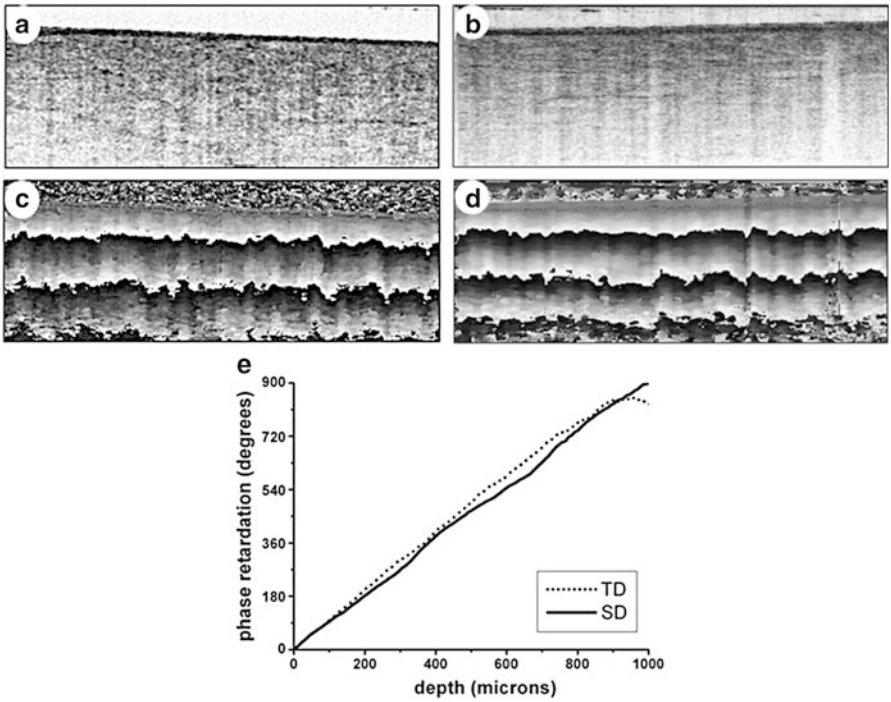

Fig. 33.21 Representative TD- and SD-OCT images of the same chicken breast muscle sample. The width of the images was 4.0 mm, and the depth was 1.2 and 1.4 mm for the TD- and SD-OCT images, respectively. Each set of images (TD,SD) are composed of an intensity image (**a**, **c**) and phase retardation image (**b**, **d**). The unwrapped phase retardation profiles were averaged over the full width of the image (**e**). Intensity images are gray-scaled encoded over the dynamic range of the image, and phase retardation images are gray-scaled from *black* to *white*, representing phase retardations from $-\pi$ to π radians, respectively (Reprinted from Fig. 8 of Ref. [16] with permission of the Optical Society of America)

scheme. They showed that for phase retardations close to 0° or 90°, the background noise on the detectors introduces a significant and systematic error. However, determination of the Stokes parameters of reflected light [10] reduces this error by calculating the Stokes parameters Q, U, and V based on the amplitude *and* phase relation between interference fringes [34]. The remaining variance in the computed Stokes vectors of reflected light (excluding polarization effects) can largely be attributed to a combination of multiple scattering, shot noise (in an optimized system), and speckle.

Multiple scattering will scramble the polarization mainly in a random manner. This offers some means to distinguish it from polarization effects. However, an optic axis that varies with depth will give changes in the polarization state that can make it difficult to distinguish from the random manner of multiple scattering. While a number of studies have demonstrated an ability to determine localized

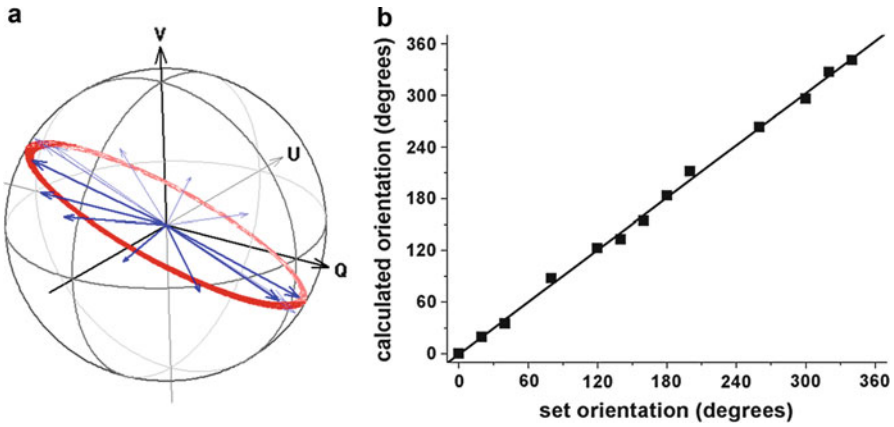

Fig. 33.22 (**a**) Optic axis orientation in a Poincaré sphere representation of the calculated optic axes (*arrows*) for various set orientations of the tissue sample optic axis. The plane (*dotted circle*) in which these optic axes lie was determined by least-squares fitting. (**b**) Calculated optic axis orientation as a function of set orientation relative to 0°. *Squares*: Measured orientation. *Line*: Linear fit to the data (Reprinted from Fig. 9 of Ref. [16] with permission of the Optical Society of America)

sample polarization properties, including depth-resolved changes in optic axis orientation [28, 93, 94], more research is necessary to truly solve this complex problem.

Since calculation of any sample polarization properties is dependent on determination of the polarization state of light measured with PS-OCT, the accuracy of these polarization properties is highly dependent on the accuracy of polarization state determination. One such fundamental limitation in a shot noise-limited system arises from errors in phase determination as a function of the signal-to-noise ratio (SNR) of a measurement [16, 95]. To quantify this effect, 1,024 consecutive depth profiles at a single point on a glass slide were obtained at different SNRs using a variable neutral density filter in the sample arm of a spectral-domain PS-OCT system [16]. The polarization state reflected from the surface of the slide was determined, and the average angular deviation of these polarization states from their mean, as illustrated in the inset of Fig. 33.23, was calculated. The resulting data, plotted as a function of SNR in Fig. 33.23, demonstrate a decreasing average angular standard deviation with increasing SNR. The theoretical curve was generated based on a simple additive noise model. The standard deviation of a complex electric field can be estimated from the vector sum of a random complex vector to a complex electric field vector, where the relative length of the two vectors is determined by SNR [16]. This can be translated into an angular standard deviation, $\Delta\theta$, in a Poincaré sphere representation of a measured polarization states such that $\Delta\theta = \sqrt{2/SNR}$. It should be noted that this relation takes into account amplitude variations between orthogonal electric field components. The experimental results

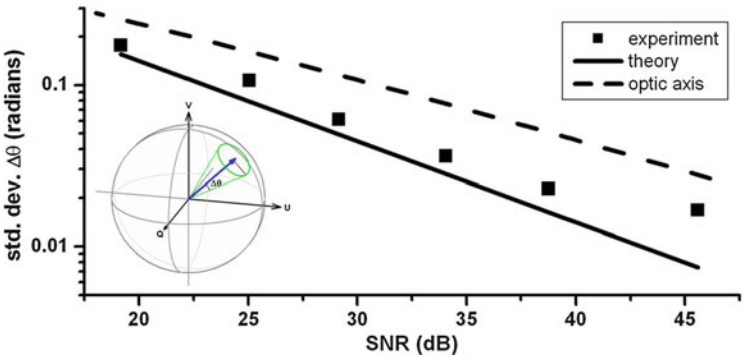

Fig. 33.23 Angular standard deviation in the Poincaré sphere, $\Delta\theta$, as a function of signal-to-noise ratio on a log–log scale for polarization state (*squares*, standard deviation over 1,024 measurements; *solid line*, theoretical curve; see text) and optic axis determination (*dashed line*, simulated prediction; see text). Inset, Poincaré sphere illustrating a probability distribution as indicated by a cone defined by the standard deviation, $\Delta\theta$ (Reprinted from Fig. 2 of Ref. [48] with permission of the Optical Society of America)

show good agreement with predicted theory, except at 45 dB, where the combined power of the sample and reference arms was outside the shot noise-limited range of the system. Clearly, this relation will affect the accuracy of any resulting sample polarization properties. To calculate the effect on optic axis determination accuracy, numerical simulations were performed for a range of SNR values. Figure 33.23 shows the resulting prediction of the mean angular standard deviations for optic axis determination as a function of SNR.

Speckle introduces noise on the Stokes parameters by the large fluctuations in the interference fringes that could be uncorrelated in the orthogonal detection channels. Kemp et al. have introduced quantifications of this effect in the notions of polarimetric speckle noise [96], or the standard deviation of a polarization state on the Poincaré sphere, and polarimetric signal-to-noise ratio [29], which estimates the ability of PS-OCT to estimate polarization parameters in the presence of polarimetric speckle noise. A great deal of work has been done with various speckle reduction techniques in OCT [97–108], the application of which reduces this noise as does averaging the Stokes parameters over distances larger than the coherence length. Speckle remains one of the principle problems in the development of OCT.

33.3.3 Other Developments

PS-OCT continues to develop and find application in ever expanding ways. For example, Ugryumova et al. have developed a system that uses variable incident angles to determine the three-dimensional sample optic axis [109]. Among the other recent applications of PS-OCT are studies of endoscopic OCT [110], examination

of collagen content in coronary plaque [111–115], and even detection of ultrastructural changes in murine muscle during exercise [116]. These novel fields of research show that, just as the field has evolved and grown since its inception, PS-OCT continues to advance rapidly and find application in clinical medicine and biological research.

Acknowledgements This research was supported in part by funding from the National Institutes of Health (1R24 EY12877, R01 EY014975, and RR19768, K99/R00 EB007241), the Department of Defense (F4-9820-01-1-0014), the Center for Integration of Medicine and Innovative Technology, and a gift from Dr. and Mrs. J.S. Chen to the Optical Diagnostics Program at the Wellman Center for Photomedicine. The authors would like to thank a number of graduate students and postdoctoral research fellows that have contributed to the results presented in this chapter: Mark Pierce, PhD, Barry Cense, PhD, and Mircea Mujat, PhD. We would also like to acknowledge the contributions of Dr. Teresa Chen, MD, of the Massachusetts Ear and Eye Infirmary.

Polarization sensitive OCT • Birefringence • Depolarization • Retina • Glaucoma • Age related macular degeneration

34.1 Introduction

Since its first introduction more than two decades ago [1], optical coherence tomography (OCT) has revolutionized retinal diagnostics [2]. Especially the paradigm shift from the early time domain instruments to spectral domain (SD) technology [3–5] was paramount for the enormous progress and success of OCT in recent years. The massively parallel approach of SD OCT provides a huge sensitivity advantage [6–8] and enabled improvements of imaging speeds by several orders of magnitude. While presently available commercial retinal OCT scanners can operate at speeds of several tens of kA-lines/s, speeds in the multi-100 kHz range and even beyond a MHz have been reported recently [9–12].

Despite their great success, all these intensity-based OCT systems still have a considerable drawback: they cannot directly differentiate between different tissues. Especially in ocular diseases where retinal layers are damaged, distorted, displaced, disrupted, or vanished, it is often very difficult to identify specific layers based just on backscattered intensity. This, however, is mandatory for correct diagnosis, monitoring, and follow-up. To overcome this and other limitations, additional information beyond signal intensity is required. One method to gain such additional information is to exploit the light's polarization state. This can be achieved by polarization-sensitive (PS) OCT [13, 14], the topic of this chapter.

PS-OCT measures, in addition to intensity, the polarization state of light and draws advantage from the fact that some tissues can change the polarization state of the probing light beam. Different mechanisms of light-tissue interaction can change the polarization state: birefringence, diattenuation, and depolarization. While diattenuation is regarded to be negligible in biologic tissue [15–17], the other two interaction mechanisms were demonstrated in various ocular tissues: e.g., birefringence was found in the corneal stroma [18, 19], the sclera [20, 21], ocular muscles and tendons [21], trabecular meshwork [20], the retinal nerve fiber layer (RNFL) [22, 23], Henle's fiber layer [24, 25], and scar tissue [26]. Depolarization was demonstrated in melanin-containing tissue like the retinal pigment epithelium (RPE) [25, 27, 28], the iris pigment epithelium [29], choroidal nevi and melanoma [30], but also in accumulations of pigment-loaded macrophage and – to a smaller amount – in the choroid [28, 31].

There is now already a large body of literature on PS-OCT in general and on applications of PS-OCT for ocular imaging. Reviews on these topics can be found, e.g., in [32, 33]. In this chapter, we will provide an overview of polarization changing light-tissue interactions found in the eye, of the theoretic and technical principles used in our own work (which forms the basis of the results reported here); a description of the use of PS-OCT to segment retinal layers and lesions based on their intrinsic, tissue-specific contrast; and various applications of PS-OCT to image healthy and diseased human retina. We would like to point out that this chapter does not contain a comprehensive description of all aspects and methods of PS-OCT. More information on other aspects and variants of this interesting functional extension of OCT can be found in ▶ Chaps. 33, "Polarization Sensitive Optical Coherence Tomography" and ▶ 35, "Jones Matrix Based Polarization Sensitive Optical Coherence Tomography" of this book.

34.2 Polarization Changing Light-Tissue Interactions

As mentioned above, three different light-tissue interactions may alter the polarization state of the incident light: birefringence, depolarization, and diattenuation. While the latter can be neglected in biological tissue [15, 16], the former two interaction types allow accessing tissue-specific properties. In order to describe changes in the polarization state, Jones or Mueller formalism may be used. Jones matrix formalism [34], which is limited to fully polarized light, is already sufficient for most scenarios in OCT because OCT is a coherent imaging technique. Therefore, only fully polarized light components from the sample may interfere with the light from the reference arm and will contribute to the OCT signal. Nevertheless, the more general formulation of Mueller calculus [35] which includes the description of partially polarized (or even depolarized) light is frequently used for the description of PS-OCT [36, 37].

Birefringence is caused by anisotropy of the material or tissue. In this case the refractive index is dependent on the polarization state of light and the direction of light propagation. We want to emphasize that our description presented here refers to linear materials where the polarization vector is linearly proportional to the

electric field [38]. In tissue this differing refractive index can be caused by a compounding of at least two different rather homogeneous dielectric materials. However, in order to observe a net birefringence, these materials have to be arranged in an organized manner which is then referred to as form birefringence [38]. This type of birefringence is typically found in tissue where fibrils of one refractive index are surrounded by material of a slightly different index, as is observed, for example, in the retinal nerve fiber layer [22] or Henle's fiber layer [24]. The propagation of light through a birefringent medium causes a time delay between two orthogonal polarization states (one state is parallel to the slow birefringent axis; the other state is parallel to the fast axis of the sample). This delay is equivalent to a phase retardation. The phase retardation remains unambiguous as long as the accumulated phase retardation remains below the wavelength period of the light. In the case of larger phase retardations, delays corresponding to multiples of the wavelength cannot be distinguished leading to a banding structure in the images. These banding structures may already be observed in the intensity images of "standard" OCT instruments and may cause misinterpretations of the underlying tissue. The second light-tissue interaction affecting the polarization state of light is scattering. Multiple scattering is known to depolarize the incident polarization state of light as even small changes of the polarization state arising from a single scattering event accumulate [39]. However, the dominating signal in retinal OCT originates from single scattered light. In this case the preservation of the incident polarization state depends on the size and shape of the scattering particle as well as on the direction and polarization state of the incident light [32, 40].

34.3 Principles of PS-OCT

Several different variants of PS-OCT have been reported in literature. They differ by the used basic OCT technique (time or spectral domain), by optical technology used (bulk or fiber optic), by interferometer arrangement, by incident polarization states, and by the number of measurements required per sample location. Furthermore, they differ by the calculus used to extract polarization parameters (Jones or Mueller calculus). Based on the different complexities of the used methods, the number of accessible polarization parameters varies, ranging from simple retardation measurements to fully characterized Jones and Mueller matrices. A comprehensive description of all these methods and techniques is beyond the scope of this chapter. Instead, we will restrict our description to methods used in our own work that provide access to those parameters that seem of greatest relevance for retinal imaging: parameters that characterize birefringent and depolarizing tissues.

34.3.1 Basic Setup

Figure 34.1 shows a generic sketch of a basic PS-OCT instrument of the type used in our own work. It is based on the original concept first reported by Hee et al. [13]

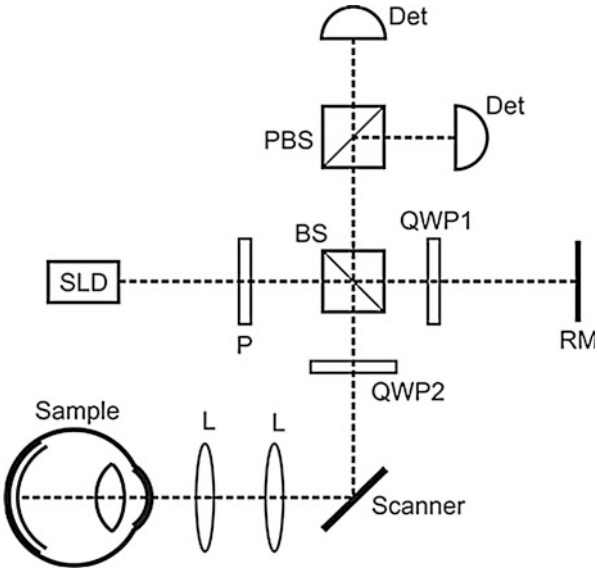

Fig. 34.1 Sketch of basic PS-OCT setup. *BS* beam splitter, *Det* detector, *P* polarizer, *PBS* polarizing beam splitter, *QWP* quarter wave plate, *RM* reference mirror, *SLD* super luminescent diode

in a time domain version. However, different variants and extensions of this instrument, bulk and fiber optic, time domain, and spectral domain, were later reported and used for various applications.

A broadband super luminescent diode (SLD) emits a light beam that is vertically polarized before it illuminates a Michelson interferometer. At the non-polarizing beam splitter BS, the light is split in a reference and a sample beam. The reference beam traverses a quarter wave plate QWP1 oriented at 22.5° to the vertical. After reflection at the reference mirror and back propagation through QWP1, the light is linearly polarized at 45° to the horizontal, providing equal reference power in both orthogonal polarization channels. The sample beam traverses QWP2 oriented at 45°, providing circularly polarized light to the sample. This ensures that the measured retardation of a birefringent sample is independent of its optic axis orientation. An x-y scanner and a scanning optics are used to scan the sample beam over the sample (eye/retina). After backscattering at the sample and back propagation through QWP2, the sample beam is usually in an elliptical polarization state that carries the information on the sample's polarization characteristics. This elliptical polarization state is to be measured and analyzed.

Sample and reference beams are recombined at the interferometer beam splitter BS where they interfere. In the detection arm of the interferometer, a polarizing beam splitter PBS splits the interfering beam into two orthogonal polarization states that are measured separately by two detectors, one for the horizontal and one for the vertical polarization state. The detectors convert the light intensity into electric signals that are amplified and recorded by frame grabbers or a data acquisition board and stored in a computer.

From the interferometric signals acquired in the two channels, information on various parameters can be derived. As we will show in Sect. 34.3.2, some basic information (reflectivity, retardation) can be obtained from the amplitude of the signals while other parameters (Stokes vectors, axis orientation) require also phase information. While the access to phase information with time domain systems required either computationally extensive methods like analytic signal continuation by a Hilbert transform [41] or more complicated experimental methods like signal demodulation [29], SD OCT methods directly provide a complex valued signal by Fourier transform of the real-valued spectral intensity data. From these complex valued signals, amplitude and phase information can readily be retrieved.

34.3.2 Calculation of Polarization States and Polarization Parameters

To illustrate how the birefringent properties of a sample can be characterized by a PS-OCT system as depicted in Fig. 34.1, we will now calculate the evolution of the polarization states of the beams within the interferometer. We will use the Jones formalism [34] which is best suited for calculation of polarization states of fully polarized beams and assume that the sample is a homogenous linear retarder. The calculation follows a similar path as used in our previous work [41, 42].

The beam incident on the Michelson interferometer, after passing the polarizer, is in a linear, vertical polarization state. Its Jones vector can be written as:

$$\tilde{\boldsymbol{E}} = \tilde{E}\begin{pmatrix} 0 \\ 1 \end{pmatrix}. \tag{34.1}$$

$\tilde{\boldsymbol{E}}$ is the electric field vector, with $\tilde{E} = E_0 \exp(i\omega t)$ the scalar electric field, E_0 the field amplitude, ω the angular frequency, and t the time. The upper and lower components of the vector in Eq. 34.1 correspond to the horizontal and vertical components of the electric field vector, respectively. For the sake of simplicity, we ignore the oscillating term $\exp(i\omega t)$ and set $E_0 = 1$ in the following.

The Jones vector of a beam after passing an optical element can be found by multiplying the Jones vector of the incident beam by the Jones matrix corresponding to the optical element. The Jones matrix is a 2×2 matrix consisting of – usually complex – elements. If more than one optical element is traversed, the input Jones vector has to be multiplied by the Jones matrices of all elements, in the order they are transmitted by the beam.

The beam described by Eq. 34.1 enters the Michelson interferometer where it is split by a non-polarizing beam splitter into a reference and a sample beam of equal field amplitudes. The reference beam passes both, the beam splitter and the quarter wave plate QWP1, twice. The effect of the beam splitter is simply to reduce the intensity of the reference beam by a factor of 2 at every pass, leading to a total intensity reduction of a factor of 4, equivalent to a reduction in field amplitude by

a factor of 2. The Jones matrix of a general retarder of retardation δ and fast axis orientation θ is [43]:

$$\mathbf{M}(\delta,\theta) = \begin{bmatrix} \cos^2(\theta) + \sin^2(\theta)\cdot\exp(-i\delta) & \cos(\theta)\cdot\sin(\theta)\cdot(1-\exp(-i\delta)) \\ \cos(\theta)\cdot\sin(\theta)\cdot(1-\exp(-i\delta)) & \cos^2(\theta)\cdot\exp(-i\delta) + \sin^2(\theta) \end{bmatrix}. \tag{34.2}$$

For QWP1, $\delta = \pi/2$ and $\theta = 3\pi/8$. The Jones vector of the reference beam, after double passing QWP1 (and the beam splitter) is:

$$\mathbf{E}_r(z_r) = \frac{1}{2}\mathbf{M}_{QWP1}\cdot\mathbf{M}_{QWP1}\cdot\begin{pmatrix}0\\1\end{pmatrix} = \frac{1}{2\sqrt{2}}\begin{pmatrix}1\\1\end{pmatrix}\cdot\exp(-i2k_0z_r), \tag{34.3}$$

where z_r is the (optical) length of the reference arm and k_0 the center wave vector of the source emission spectrum. This is a linearly polarized beam with its polarization axis oriented at 45°. It provides equal reference intensity for both, the horizontal and the vertical polarization component, which are separated by the polarizing beam splitter PBS of the detection unit. Furthermore, no phase shift occurs between the two polarization components (this would cause at least one of the vector components to have an imaginary part). Therefore, the reference beam influences neither the intensity ratio nor the phase of the interference signals recorded in the two detection channels.

The sample beam passes the beam splitter QWP2 and the sample (reflectivity: R) twice each. Again, the effect of the beam splitter is simply to reduce the field amplitude by a factor of 2. QWP2 has retardation and axis values of $\delta = \pi/2$ and $\theta = \pi/4$, respectively. Assuming that the polarizing properties of the sample can be described by a homogenous retarder (Jones matrix $\mathbf{M}_{sample}$, retardation δ_s(z), fast axis orientation θ_s (constant with depth)), the Jones vector of the sample beam, after exiting the interferometer towards the detection arm, is [41, 44]:

$$\begin{aligned}\mathbf{E}_s(z) &= \frac{1}{2}\mathbf{M}_{QWP2}\cdot\mathbf{M}_{sample}(\delta_s(z),\theta_s)\cdot\sqrt{R(z)}\cdot\mathbf{M}_{sample}(\delta_s(z),\theta_s)\cdot\mathbf{M}_{QWP2}\cdot\begin{pmatrix}0\\1\end{pmatrix} \\ &= \frac{\sqrt{R(z)}}{2}\cdot\begin{pmatrix}\cos(\delta_s(z))\exp(-i\delta_s(z))\\ \sin(\delta_s(z))\exp(i(\pi-\delta_s(z)-2\theta_s))\end{pmatrix}\cdot\exp(-i2k_0z\overline{n}),\end{aligned} \tag{34.4}$$

where z is the geometrical distance from the interferometer beam splitter to a sample reflection site, $\overline{n}$ is the mean refractive index of ordinary and extraordinary beam, and $\delta_s(z) = \Delta n\cdot z\cdot k_0$ (Δn is the refractive index difference between ordinary and extraordinary beam; for simplicity, no air gap has been assumed between beam splitter and sample surface).

After recombination at the beam splitter BS, reference and sample beams interfere. The recombined beams travel towards the polarization-sensitive detection unit where they are split by polarizing beam splitter PBS into horizontal and vertical polarization components. The interference terms $A_{H,V}$ at the detectors, corresponding to the horizontal and vertical polarization channels, respectively, are:

$$A_{H,V}(z,\Delta z) = A_{0;H,V}(z,\Delta z)\cdot \cos\left[\Phi_{H,V}(\Delta z)\right] \tag{34.5}$$

with

$$A_{0;H}(z,\Delta z) = \frac{\sqrt{R(z)}}{2\sqrt{2}}\cdot \cos\left[\delta_s(z)\right]\cdot\left|\gamma(\Delta z)\right| \tag{34.6a}$$

$$A_{0;V}(z,\Delta z) = \frac{\sqrt{R(z)}}{2\sqrt{2}}\cdot \sin\left[\delta_s(z)\right]\cdot\left|\gamma(\Delta z)\right| \tag{34.6b}$$

and

$$\Phi_H(\Delta z) = 2k_0\Delta z \tag{34.7a}$$

$$\Phi_V(\Delta z) = 2k_0\Delta z + \pi - 2\theta_s, \tag{34.7b}$$

where $A_{0;H,V}$ describe the envelopes of the interferometric signals caused by a single reflective site in the sample, $\Phi_{H,V}$ are the corresponding phase functions of the interferometric fringes, $\Delta z = z_r - z\cdot\overline{n}$ is the optical path length difference between reference and sample arms, and $|\gamma(\Delta z)|$ is the modulus of the complex degree of coherence of the interfering beams which describes the width of the interferometric signal (the axial point spread function). In Eqs. 34.7a and 34.7b an unimportant common phase term has been omitted.

The terms $\cos(\delta_s(z))$ and $\sin(\delta_s(z))$ in Eqs. 34.6a and 34.6b oscillate slowly with depth z, if a sample with constant birefringence Δn is assumed, giving rise to intensity oscillations in the horizontal and vertical polarization channels which are $\pi/2$ out of phase. The cosine term in Eq. 34.5 oscillates rapidly with path difference Δz and describes the fringes of the interferometric signals, as typically observed in time domain OCT. The fringes of the horizontal and vertical components have a phase difference of $\pi - 2\theta_s$.

34.3.2.1 Quantification of Birefringence-Related Parameters

To calculate sample reflectivity $R(z)$ and retardation $\delta_s(z)$, we only need the envelopes of the interferometric signals $A_{0;H,V}$. For simplicity, we assume

a coherence function of infinitesimal width (i.e., a nonzero amplitude only for $\Delta z = 0$) and can therefore omit the Δz dependence in the following equations:

$$R(z) \propto A_{0;H}(z)^2 + A_{0;V}(z)^2 \tag{34.8}$$

$$\delta_s(z) = \arctan\left(\frac{A_{0;V}(z)}{A_{0;H}(z)}\right). \tag{34.9}$$

A closer look at the phase terms $\Phi_{H,V}$ (Eqs. 34.7a and 34.7b) reveals that the information on the optic axis orientation θ_s of the sample is encoded entirely in the phase difference $\Delta\Phi = \Phi_H - \Phi_V$ of the two signals:

$$\theta_s = (\pi - \Delta\Phi)/2 \tag{34.10}$$

The unambiguous ranges of retardation and axis orientation, as provided by Eqs. 34.9 and 34.10, are 90° and 180°, respectively.

In time domain PS-OCT, amplitude and phase information can be retrieved, e.g., by lock-in demodulation [29] or by analytic continuation of the fully recorded fringe signals by a Hilbert transform [41]. In spectral domain PS-OCT, the inverse Fourier transform of the real-valued spectral interference signals directly yields complex valued signals of the form:

$$FT^{-1}\{I_{H,V}(k)\} \rightarrow A_{0;H,V}(z)\exp\left[i\Phi_{H,V}\right], \tag{34.11}$$

with $I_{H,V}(k)$ being the intensity as a function of wave number k in the horizontal and vertical polarization channel, respectively. For simplicity, the DC, autocorrelation, and mirror terms were omitted in Eq. 34.11. From these signals, amplitude and phase values can be directly taken and inserted into the corresponding parameters of Eqs. 34.8, 34.9, and 34.10 (it should be mentioned that the absolute phase values $\Phi_{H,V}$ in Eq. 34.11 have no physical relevance; however, their difference provides the sample axis orientation via. Eq. 34.10).

As an example for imaging a birefringent structure in the human eye, Fig. 34.2 shows a circumpapillary scan recorded with a SD PS-OCT system in a healthy volunteer [45]. In this area, the RNFL forms rather thick bundles in the quadrants superior and inferior to the optic nerve head which are birefringent. Figure 34.2a shows a generic fundus photo illustrating the measured area: the scan was recorded approximately along the circular white line. Figure 34.2b shows the cross-sectional reflectivity (intensity) image. The increased thickness of the superior and inferior RNFL bundles is clearly visible. Figure 34.2c shows the retardation image, where the increased retardation caused by these nerve fiber bundles is clearly observed (color change from blue to green). Figure 34.3d shows the axis

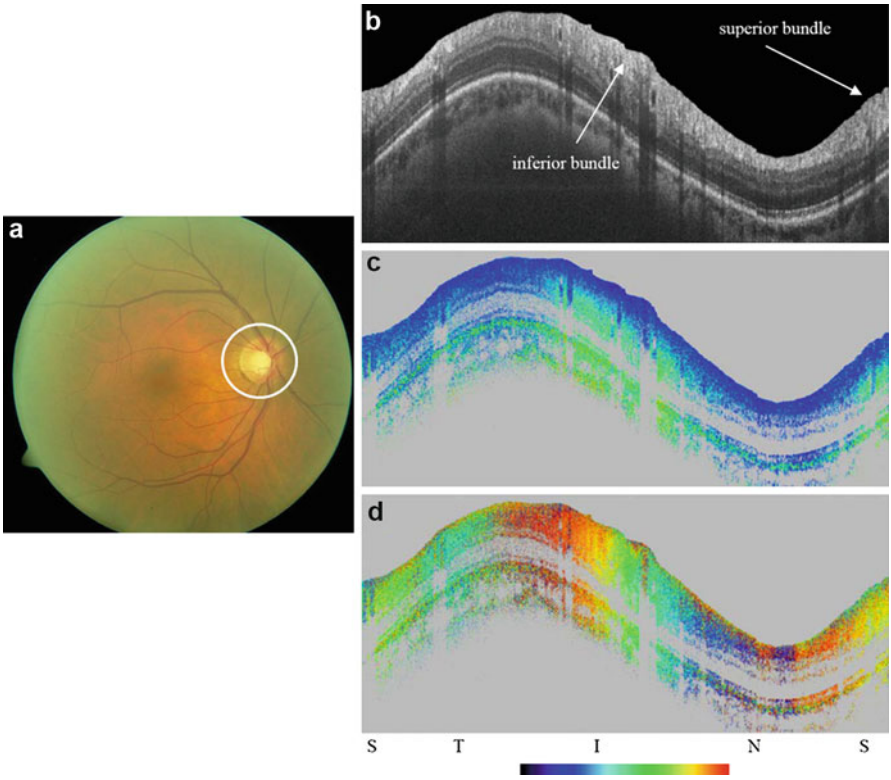

Fig. 34.2 Circumpapillary PS-OCT scan from healthy human retina. (**a**) Generic fundus photo illustrating scan geometry; the *white circle* indicates the approximate position of the scan line. orientation image, where the two full color oscillations from left to right indicate the radial orientation of the nerve fibers (360° rotation of axis orientation).

34.3.2.2 Quantification of Depolarization

Since OCT is based on a coherent detection method, the degree of polarization (DOP) known from classical polarization optics cannot be directly measured. The light corresponding to a single speckle is always fully polarized, i.e., its DOP = 1 [37]. However, PS-OCT can obtain information on depolarization by analyzing the local distribution of polarization states among neighboring speckles. In case of a depolarizing tissue, polarization states of adjacent speckles will be uncorrelated, i.e., the polarization states vary randomly, while in other tissues

(polarization maintaining or birefringent), the relation will be well defined. Therefore, depolarization is manifested by a scrambling of polarization states in PS-OCT images. To quantify this effect, we introduced a new parameter, the degree of polarization uniformity (DOPU), that has a strong formal relationship to DOP [28]. To quantify DOPU, we first calculate the Stokes vector $\boldsymbol{S}$ for each pixel in the PS-OCT image:

$$\mathbf{S} = \begin{pmatrix} I \\ Q \\ U \\ V \end{pmatrix} = \begin{pmatrix} {A_{0;H}}^2 + {A_{0;V}}^2 \\ {A_{0;H}}^2 - {A_{0;V}}^2 \\ 2A_{0;H}A_{0;V}\cos\Delta\Phi \\ 2A_{0;H}A_{0;V}\sin\Delta\Phi \end{pmatrix}, \tag{34.12}$$

where I, Q, U, V denote the four Stokes vector elements. Then we average Stokes vectors over adjacent pixels by calculating the mean value of each Stokes vector element within a rectangular evaluation window (kernel) and derive DOPU:

$$\mathrm{DOPU} = \sqrt{Q_m^2 + U_m^2 + V_m^2}, \tag{34.13}$$

where the indices m indicate mean Stokes vector elements. DOPU can be regarded as a spatially averaged DOP and is closely related to the apparent degree of polarization obtained by temporal averaging [37] and to the quantity $\overline{\zeta}$ that was used to describe the local correlation of polarization states for detection of multiple scattered light by OCT [46].

In case of a polarization preserving or birefringent tissue, the value of DOPU should be close to 1; in case of a depolarizing layer, DOPU is lower than 1. In a typical application, the use of DOPU to segment the depolarizing RPE in PS-OCT images of the retina, a threshold value of $\mathrm{DOPU_{thr}} = 0.7 - 0.8$ is used. All image areas where $\mathrm{DOPU} < \mathrm{DOPU_{thr}}$ are classified as depolarizing.

Figure 34.3 shows an example of imaging a depolarizing structure in the human retina, obtained by a high-resolution SD PS-OCT system [45]. Figure 34.3a shows a cross-sectional reflectivity image (B-scan) through the fovea of a healthy human eye. In the posterior retina, four boundaries are marked: the external limiting membrane (ELM), the boundary between inner and outer photoreceptor segments (IS/OS), the end tips of the photo receptors (ETPR), and the RPE. Figure 34.3b, c show a zoom-in of retardation and axis orientation data into the posterior three of these layers. While the top two boundaries show rather constant color values (indicative of low retardation and constant axis orientation in this area of the retina), the bottom layer shows a striking difference: the color values are scrambled, i.e., more or less random. The DOPU image (Fig. 34.3d) demonstrates this difference even better: while the IS/OS and the ETPR show DOPU values close to 1 (red color), the RPE is strongly depolarizing (green to blue colors, $\mathrm{DOPU} < 0.7$).

[45] by permission of the Optical Society of America)

34.3.3 Spectral Domain and Fiber-Optic Implementations

Several variants of the basic setup described in Sect. 34.3.1 have been reported. While the initial work was based on time domain technology in various forms [13, 14, 29, 41], spectral domain variants gained more attraction after the discovery of their huge sensitivity advantage. Bulk optic [21, 47] and fiber-optic [45] setups were reported, employing either a two-channel spectrometer with a single line scan camera [21] or two separate spectrometers, each equipped with its own camera [47]. Spectrometer-based SD PS-OCT systems require either a nearly perfect pixel-to-pixel correspondence of the spectrometers recording the two channels (otherwise, depth-dependent artifacts of mainly the axis orientation can occur [47]) or an additional post-processing step that corrects for the spectral mismatch (this is mandatory for single camera systems [21]). These spectrometer type systems typically operate in the 840 nm wavelength regime.

A related variant is based on swept source (SS) technology which is preferred at the longer wavelength centered around 1,050 nm. This technique has the advantage of improved imaging depth beyond the RPE, down to the choroid and sclera [48–51], however, is presently more expensive. Different versions of PS-OCT at this wavelength have been reported for retinal imaging, employing single [52] and multiple [53] input polarization states.

Bulk optic PS-OCT setups have the advantage that the optical components used are very stable with respect to their polarization properties. Once aligned, they can

be used without recalibration over extended periods of time. However, for commercial instruments, fiber-optic systems are preferred since they can be quite robust and need little optical alignment. The use of normal single-mode (SM) fibers (that are commonly used for intensity-based OCT), however, causes a problem for PS-OCT: the fiber is birefringent, and the exact amount of birefringence varies with environmental influences like bending and temperature. Therefore, it is neither easily possible to achieve a constant polarization state (e.g., circular) at the sample nor to maintain the polarization state of the light beam passing the fiber. Therefore, SM fiber-based PS-OCT systems usually require to probe the sample with more than one polarization state and retrieve the sample's polarizing properties by differential measurements and elaborate algorithms that compensate for possible changes of the light's polarization state within the fiber [54].

A solution to this problem is the use of polarization-maintaining (PM) fibers [45, 55, 56]. PM fiber-based PS-OCT systems can employ the same principles as described in Sect. 34.3.2. The amplitudes of the two orthogonal light components are well preserved throughout the PM fibers, enabling a direct calculation of sample reflectivity and retardation. However, due to the different propagation velocities of the two orthogonal modes in the PM fiber, the phase relation between the modes is lost, destroying the original elliptic polarization state backscattered from the sample. The phase difference, however, is needed to calculate axis orientation and Stokes vector. To solve this problem, the lengths of the PM fibers in the sample and reference arms have to be carefully matched. In this case, the phase differences in the two arms cancel each other. A remaining phase difference caused, e.g., by imperfect fiber length matching can be compensated in a post-processing step [45]. This method provides correct relative axis orientations; to obtain the absolute axis orientation, a calibration measurement is needed.

As an example of a state-of-the-art PS-OCT retinal scanner, Fig. 34.4 shows a sketch of one of our newest instruments. More than 200 patients with various diseases have been imaged with this device and several of the images presented in this chapter were recorded with the system. It is a PM fiber-based SD PS-OCT instrument employing a two-channel spectrometer with a single camera. An SLD emits a light beam centered at ~840 nm whose polarization state is matched by a polarization controller (paddle) PC to the orientation transmitted by the PM fiber polarizer. A 90:10 splitter directs 10 % of the beam to the sample and 90 % to the reference mirror. After passing the QWP, the sample light is in a circular polarization state and raster scanned via the galvanometer scanner and a telescope (lenses L1 and L2) over the retina. In the reference arm, a QWP ensures equal reference power in both polarization states, as described above. After recombination at the 90:10 splitter (90 % of the sample beam power is transmitted into the detection arm), the beams interfere and are guided to the polarizing beam splitter which separates the horizontal and the vertical state. The two polarization states are spectrally dispersed by a diffraction grating and imaged adjacent to each other onto a high-speed CMOS line scan camera (Basler sprint, 4,096 pixels).

[57] by permission of the Optical Society of America)

The camera is operated at a line rate of 70 kHz. With a light power of 730 μW at the cornea, a maximum sensitivity of 98 dB is obtained, with a roll-off of 8 dB over an imaging depth of 1.8 mm. The axial resolution is 7.8 μm in air or ∼5.7 μm in tissue (assuming a group index of ∼1.38). The maximum scan field size of the instrument is 40° × 40°. Various scan patterns, ranging from 512(x) × 125(y) up to 1,024 × 250 A-scans, are available. More details on the instrument can be found in ref. [57].

The processing of data acquired with this system comprises the following steps: the two adjacent spectra provided by the camera are separated and numerically resampled to achieve a pixel-to-pixel correspondence (this step is equivalent to squeezing/compressing one spectrum until it fits the width of the other one). Afterwards, standard post-processing steps (subtraction of the mean spectrum, rescaling from wavelength to wavenumber space, inverse Fourier transform) are performed. Then, amplitude and phase difference data are calculated, from which retardation, axis orientation, Stokes vectors, and DOPU values are obtained as described in detail above. Since the birefringence-related data of retinal structures are obtained by a measurement through the birefringent cornea, the influence of the cornea has to be compensated for. This is performed by retrieving the polarization state at the retinal surface (which corresponds to the influence exerted by the cornea) and subsequently compensating the polarization state distortions caused by the cornea by a software-based algorithm [58].

34.4 Applications of PS-OCT to Retinal Imaging

34.4.1 Imaging of the Macular Region

The macula represents the most precious location on the retina because it contains the fovea, which represents, in the healthy eye, the spot with the best vision. A variety of different diseases (e.g., age-related macula degeneration (AMD) and diabetic retinopathy (DR)) may alter the normal structure in the macular region, and in recent years, OCT has become an indispensable clinical tool for an accurate determination of these changes.

PS-OCT provides additional contrast that is not accessible with standard OCT. Figure 34.5 shows imaging examples obtained in a healthy volunteer recorded at 840 nm with a large field of view scan [57]. Within the DOPU images (e, j), the RPE can be easily outlined because it contains particles (e.g., pigments) that scramble the polarization state of the backscattered light. Birefringence introduced by Henle's fiber layer causes an increased retardation in the macula area (c.f. increased retardation at the junction between inner and outer segments of photoreceptors (IS/OS) and end tips of photoreceptors (ETPR) indicated by arrows in Fig. 34.5c, h). Note that because of the orientation of the fibers in Henle's fiber layer, no increase in retardation can be observed in the fovea centralis (c.f. dark blue color at the IS/OS junction). The instrument operates at an imaging speed of 70 kHz. This high speed enables, in order to reduce speckle noise and enhance the signal to noise ratio, recording and averaging of several B-scans at the same location resulting in high-quality scans shown in Fig. 34.5g–j.

In order to illustrate the similarities between different wavelength regions, Fig. 34.6 shows averaged PS-OCT images recorded at 1,040 nm with a swept source system [52]. Essentially the same polarization characteristics as with the 840 nm system can be observed within the anterior layers, the photoreceptor layers, and the RPE. However, the longer wavelength region provides a better penetration into choroid and sclera. The sclera is known to be highly birefringent which can directly be observed in Fig. 34.6b by the strong increase of retardation within this layer. This specific characteristic of the sclera can be used in order to segment the posterior boundary of the choroid based on PS-OCT data [59, 60].

If we take a closer look at the DOPU image recorded at the longer wavelength, we will observe lower DOPU values in the choroid than in the anterior retinal layers. These lower values are probably caused by pigments embedded within the choroid leading to a random polarization state for part of the backscattered light. Nevertheless, the images clearly show that the interaction between light and RPE scrambles (depolarizes) only the backscattered light while the polarization state of the transmitted light is preserved. While the basic polarization effects observed in the two wavelength regimes are qualitatively similar, a thorough quantitative comparison between the wavelengths is still missing.

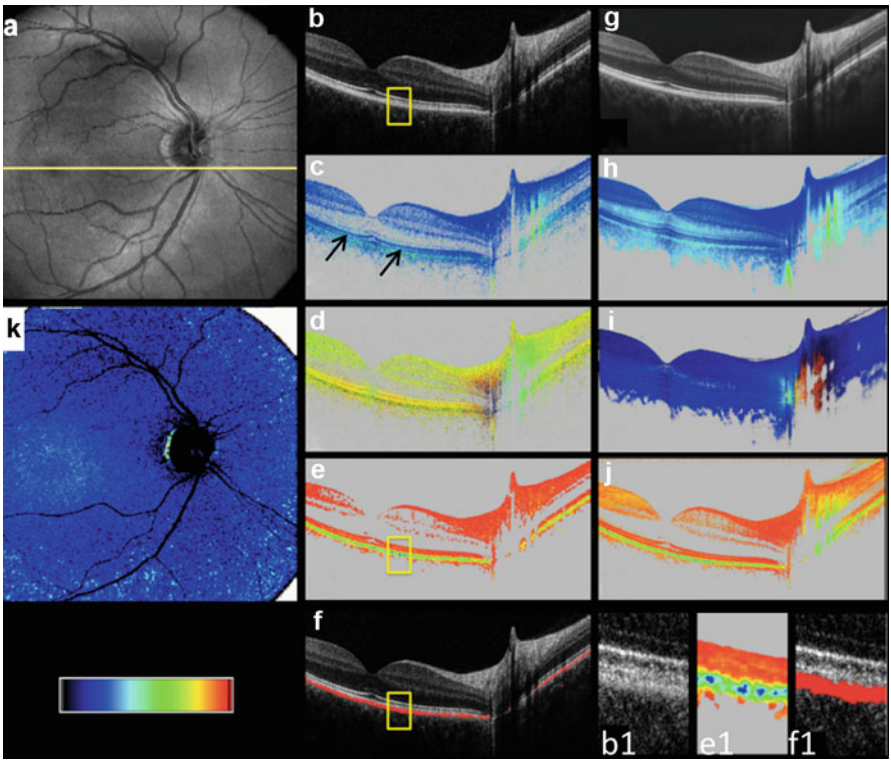

Fig. 34.5 PS-OCT measurement results recorded from a healthy human volunteer (scan angle: 40 × 40°, 1,024 × 250 A-scans). 34.4.1.1 Age-Related Macular Degeneration

In order to quantify changes caused by retinal diseases, accurate and automated segmentation algorithms are needed. While this is difficult to achieve when relying solely on the data provided by standard OCT intensity images, PS-OCT offers complementary information. As pointed out in the previous chapter, the OCT signal from the RPE is in a random polarization state. This effect is clearly visible in the DOPU images (c.f. Figs. 34.5e, j and 34.6d), and within these images, the location

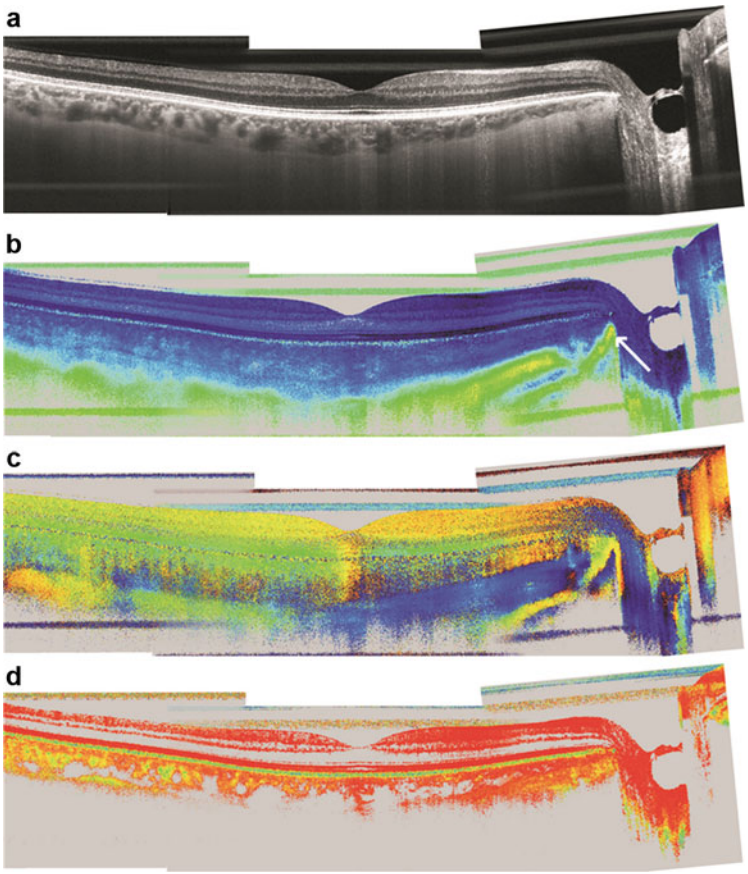

Fig. 34.6 Averaged PS-OCT images recorded at 1,040 nm with a swept source system. (**a**) Intensity, (**b**) phase retardation (*arrow* indicates the location of the sclera rim), (**c**) axis orientation, (**d**) DOPU (Same color scale as in Fig. 34.5) (Reproduced from Torzicky et al. [52] by permission of the American Academy of Optometry)

of the RPE can be determined quite easily because, in the healthy eye, other anterior retinal layers do not contain depolarizing tissue. In order to segment this layer automatically, the introduction of a simple threshold is already sufficient [28]. The segmented RPE can then be used as a backbone for other segmentation procedures.

The integrity of the RPE is of specific interest in AMD patients because it plays a fundamental role in the metabolism of the overlying photoreceptors. Currently, AMD can be regarded as the leading cause of blindness in the developed world [61]. Hence, improved diagnosis or a better treatment control is of social importance.

One of the first clinical indicators of this disease are drusen. In OCT drusen can be recognized by localized elevations of the normal RPE structure and represent

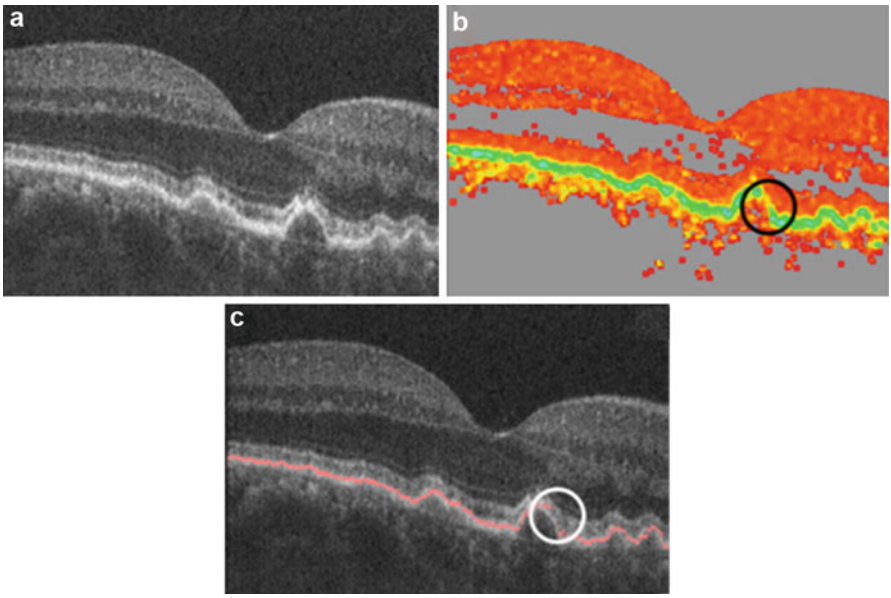

Fig. 34.7 B-scan images of a patient with drusen. (**a**) Intensity image, (**b**) DOPU image showing a small atrophic area (indicated by the *circle*) within the pigment epithelium, (**c**) segmented RPE overlaid to the intensity image (Reproduced from Ahlers et al. [63] by permission from the Association for Research in Vision and Ophthalmology)

a major risk factor for further disease progression. The evolution of the disease not only depends on several drusen parameters as size, area, and volume but also on the type of drusen [62]. Figure 34.7 shows exemplary PS-OCT B-scans recorded from a drusen patient [63]. Within the DOPU image (c.f. Fig. 34.7b), the localized elevation of the RPE can be clearly observed. In the intensity image, the RPE appears continuous; however the DOPU image shows a small focal skip lesion indicating a possible local destruction of this layer. Figure 34.7c shows the segmented RPE (thresholded DOPU image) overlaid to the intensity image. Together with an algorithm that searches for the "normal" RPE location (equivalent to the position of Bruch's membrane), [31] the drusen area and volume can be quantified. The reproducibility of drusen area and volume measurements using PS-OCT data showed a variability of only $\sim$7 % [31]. Motion artifacts occurring during the volume scan mainly account for this residual variability which therefore can be further reduced using, e.g., active eye tracking. Schlanitz et al. compared the automated drusen segmentation using PS-OCT with manual segmentation by expert readers and found excellent agreement between both methods [64].

Besides the segmentation capabilities, PS-OCT is able to provide additional information on the drusen and the underlying tissue which might be of importance in order to judge on the further development of these structures. Of specific interest is the continuity of the RPE throughout the druse which is regarded as an important indicator of a starting transition into the next stage of the disease

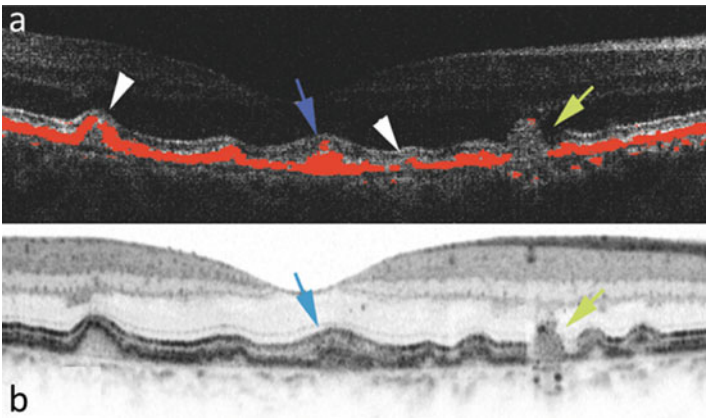

Fig. 34.8 Different appearance of drusen in PS-OCT data. (**a**) Segmented depolarizing tissue overlaid to the intensity image; (**b**) averaged intensity B-scan of a commercially available instrument. The *blue arrows* indicate a druse filled with depolarizing material; the *yellow arrows* indicate a drusenoid structure with complete absence of RPE. The *white arrowheads* indicate small atrophic lesions (Reproduced from Schlanitz et al. [64] by permission from the Association for Research in Vision and Ophthalmology)

(e.g., geographic atrophy). Figure 34.8 shows a comparison of segmented PS-OCT data with an intensity image recorded with a commercial instrument. From the information provided by the intensity image (c.f. Fig. 34.8b), only the disruption at the druse at the right hand of the image can be detected. On the other hand, the segmentation provided by PS-OCT (c.f. Fig. 34.8a) shows in addition discontinuities of the RPE roughly in the center of the image and on the druse at the left-hand side of the image. Moreover, PS-OCT can differentiate material underneath drusen: the center druse is filled with depolarizing material while the druse on the left-hand side of the image does not contain depolarizing material. However, the causes and the consequences of this difference with respect to the further development of the druse need further investigations.

As the disease progresses, atrophic zones may develop. These zones may already be visible in the en face intensity projection of OCT data (c.f. Fig. 34.9a). However, the en face map generated by a summation of depolarizing pixels along the A-scan direction using PS-OCT DOPU data shows increased contrast of the atrophic zone in comparison to the surrounding region (cf. Fig. 34.9b). Note that the contrast provided by PS-OCT has a similar appearance as that of autofluorescence (AF) imaging (c.f. Fig. 34.9c). In order to automatically segment the atrophic zones, the depth information provided by OCT is used in order to exclude image pixels that contribute to the en face map from other depths (e.g., from the choroid) than that of the "normal" location of the RPE [31]. After this exclusion a simple thresholding algorithm can be applied to segment the atrophic zones and to measure the corresponding area. Although the measured area is again influenced by motion artifacts, the variability of this measurement is only ~9 % [31].

(**b**) Depolarizing material thickness map (color scale 0–160 μm). (**c**) Autofluorescence image for comparison. (**d**) Intensity B-scan, (**e**) RPE segmentation B-scan, and (**f**) DOPU image (Reproduced from Zotter et al. [57] by permission of the Optical Society of America)

The neovascular form of AMD (nAMD) is in general associated with severe loss of visual acuity. Recent developments in therapy aim to prohibit vascular growth in order to reduce leakages into the neurosensory retina and in order to restore the retinal structure. Although the retinal thickness approaches normal values, visual acuity does not necessarily improve. Figure 34.10 shows an example of PS-OCT data recorded in nAMD. The elevation of the RPE and subretinal fluid are clearly observable. Although the RPE appears continuous in the intensity image, the DOPU image shows an atrophic area on the right-hand side of the lesion. The development of previously undetected RPE atrophies in nAMD might be responsible for the poor correlation between retinal thickness and visual acuity [63]. In the late stage of AMD fibrotic scars are frequently observed. The organized structure of collagen fibrils in these scars leads to form birefringence that can be detected using PS-OCT [26] as is shown in Fig. 34.11. The retardation image (c.f. Fig. 34.11b) clearly shows strong birefringence in the scar area. The information provided by the axis orientation (c.f. Fig. 34.11c) may be used in order to determine the fibril orientation. A quantitative analysis of the birefringence may be used as an indicator for the underlying consistency of these scars.

34.4.1.2 Other Diseases Affecting the Macula

The capability of PS-OCT to detect depolarizing tissue makes this technology well suited for any disease associated with pigmentation changes. One example is Stargardt's disease which affects, similar to GA, the RPE [65]. Figure 34.12 shows an example of PS-OCT measurements in comparison with AF imaging [57].

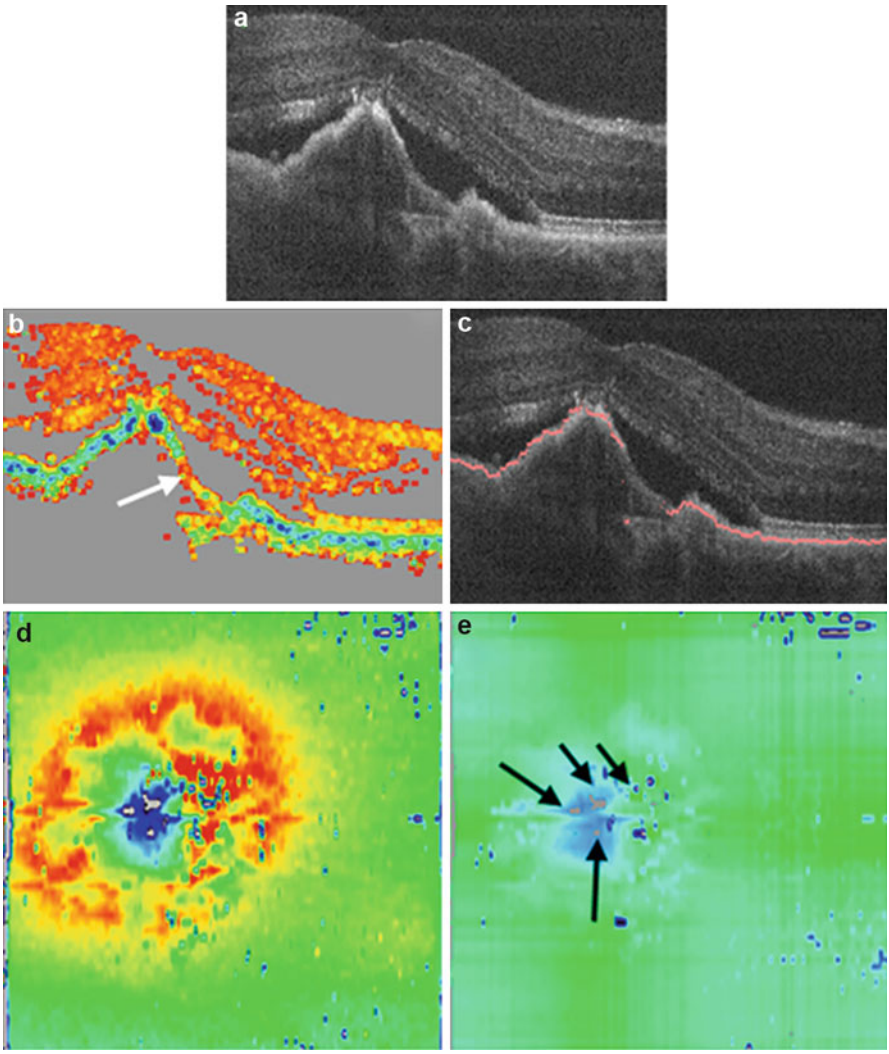

Fig. 34.10 PS-OCT images of a patient with nAMD. (**a**) Intensity image; (**b**) DOPU image (*white arrow* points to local RPE atrophy); (**c**) segmented depolarizing tissue overlaid to the intensity image; (**d**) retinal thickness map (Bruch's membrane to inner limiting membrane); (**e**) retinal thickness map (RPE to inner limiting membrane. Zones of RPE atrophy are displayed as gray pixels in (**d**) and are in addition marked with *arrows* in (**e**) (Reproduced from Ahlers et al. [63] by permission from the Association for Research in Vision and Ophthalmology)

Interestingly, the en face depolarizing tissue thickness map (Fig. 34.12b) shows more depolarizing tissue within the lesion than outside. This is contrary to the observation in most of the GA patients. The corresponding PS-OCT B-scans (Fig. 34.12e, f) show that the depolarization originates from the choroid. In contrast,

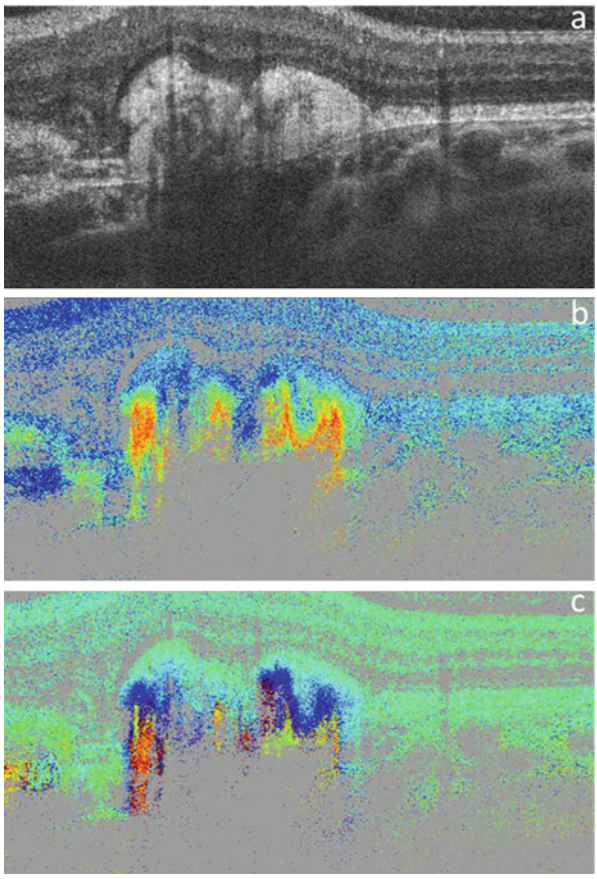

Fig. 34.11 PS-OCT images of a patient with fibrosis in the end stage of nAMD. (**a**) Intensity B-scan; (**b**) retardation image; (**c**) axis orientation image (Reproduced from Michels et al. [26] by permission from the British Journal of Ophthalmology)

the AF image (c.f. Fig. 34.12c) shows hypo-fluorescence within the atrophic lesion indicating that the structures within the choroid that give rise to depolarization are not fluorescent.

Idiopathic juxtafoveal telangiectasia (IJT), a disease that is associated with changes in the pigmentation, represents another example where PS-OCT is able to provide additional, clinically relevant information [66]. Here PS-OCT can be used in order to differentiate between morphological changes and to automatically segment deposits within the inner retina. The latter PS-OCT capability is of great interest in diabetic retinopathy [67]. The detection and quantification of deposits or hard exudates as a result of macula edema may be very valuable for monitoring disease progression and treatment control.

34.4.1.3 Retinal Pigmentation

One question remains on the origin of the depolarizing effect within the RPE. The RPE cells consist of regular constituents like cell nuclei and other organelles and

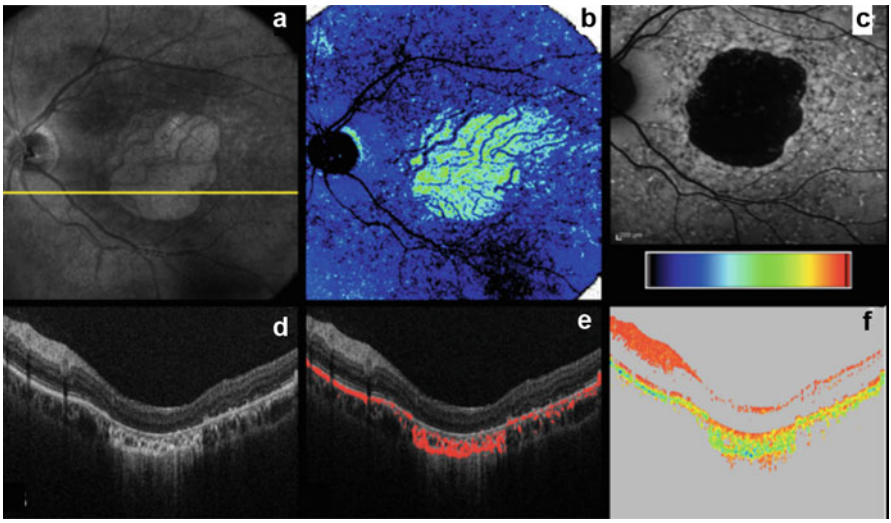

Fig. 34.12 PS-OCT images of a patient with Stargardt's disease (pathologic mutations in the ABCA4 gene). (**a**) Pseudo SLO image; *yellow line* indicates the position of the corresponding B-scan. (**b**) Depolarizing material thickness map (color scale 0–160 μm). (**c**) Autofluorescence image for comparison. (**d**) Intensity B-scan at the position of the *yellow line* in (**a**). (**e**) Segmented depolarizing material overlaid to intensity B-scan. (**f**) DOPU image (Reproduced from Zotter et al. [57] by permission of the Optical Society of America)

additionally contain pigments as melanin and lipofuscin. Pigments are large nonspherical particles that may cause depolarization [40]. A first PS-OCT study investigated the amount of depolarization caused by melanin as a function of melanin concentration in phantoms [68]. This study found a logarithmic decrease of DOPU values with melanin concentration and represents a first evidence that melanin is one cause of depolarization introduced by the RPE. Furthermore, this dependence allows estimating the melanin concentration within the RPE based on the measured DOPU value. In the healthy eye, the DOPU value measured in the RPE is lowest within the macula region and increases with eccentricity from the fovea [69]. A similar behavior can be found for the melanin concentration (using, e.g., autofluorescence imaging) which is further evidence that the depolarization in the healthy eye is mainly caused by melanin.

In order to test this assumption, patients with ocular albinism were imaged. This disease results in a significant decrease of retinal melanin. Depending on the amount of residual pigments present in the RPE, we expect to observe less depolarization in these patients. Figure 34.13 shows an example of PS-OCT measurements in a patient with ocular albinism [57]. The DOPU image (c.f. Fig. 34.13d) clearly shows the expected low depolarization (higher DOPU values as compared to the healthy eye, cf. Fig. 34.5e) at the level of the RPE. It is noticeable that the RPE does not appear as diffuse layer within the intensity image, as observed in normal eyes. In addition to the three bright layers (IS/OS, ETPR, RPE) that are normally

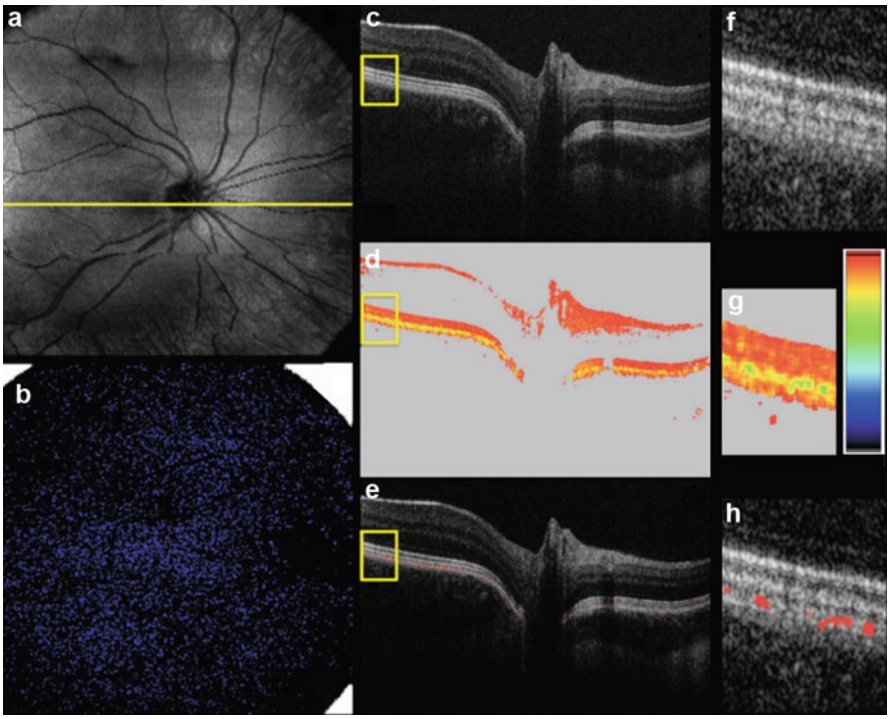

Fig. 34.13 PS-OCT images of a patient with albinism. (**a**) Pseudo SLO image; *yellow line* indicates the position of the corresponding B-scan. The *yellow boxes* in (**c**–**e**) mark the position of the enlarged areas of (**f**–**h**) (Reproduced from Zotter et al. [57] by permission of the Optical Society of America)

visible in the OCT intensity images, a fourth layer can be observed (the bottom layer is split into two layers; c.f. enlargements in the B-scans of Fig. 34.13f–h) [57, 68]. This additional bottommost layer might be associated with Bruch's membrane that is otherwise obscured by the diffusive broadening of the RPE, probably caused by multiple scattering in this layer.

34.4.2 Imaging in the Nerve Head and Peripheral Regions

The main tissue of interest for PS-OCT imaging in the region of the optic nerve head (ONH) is the birefringent RNFL. This layer is damaged by glaucoma, one of the leading causes of blindness in the world. A thinning of the RNFL can be observed before visual field loss is detected [70, 71]. Untreated, this thinning leads to irreversible vision loss and finally to blindness. An early detection of RNFL thinning is therefore imperative to prevent further progression of glaucoma.

Based on these considerations, scanning laser polarimetry (SLP) [22, 72] has been introduced as a tool to measure the RNFL thickness via its birefringence: if a constant RNFL birefringence is assumed, the retardation observed between two orthogonally polarized components of a sampling laser beam is directly proportional to the thickness of the RNFL. SLP is based on a confocal scanning laser ophthalmoscope with an integrated ellipsometer; it measures the retardation in the area of the ONH and calculates RNFL thickness maps that can be used for glaucoma diagnosis.

However, SLP has some shortcomings which are essentially caused by the fact that it is a 2-D imaging technique: since no depth information is available, the total birefringence of the ocular fundus is integrated in depth. This causes artifacts in subjects where the beam penetrates deeper, down to the birefringent sclera [73]. These artifacts are known as atypical GDx scans and occur in a considerable subset of healthy and glaucomatous eyes [74–77]. In these cases, a reliable diagnosis is not warranted. Furthermore, a constant birefringence is assumed to convert retardation into RNFL thickness maps. Since birefringence of the RNFL varies around the ONH [23], these thickness maps are distorted.

Since PS-OCT provides 3-D information, it can solve these problems. PS-OCT provides retardation and thickness information simultaneously and therefore also enables a direct measurement of tissue birefringence. This is illustrated in Fig. 34.14 [78]. A 3-D PS-OCT data set was recorded with the instrument shown in Fig. 34.4. The data set covers an area of 27°(x) × 24°(y), centered at the ONH. Figure 34.14a shows a pseudo SLO en face projection of reflectivity data. The horizontal yellow line indicates the position of the extracted B-scan shown in Fig. 34.14b (intensity), c (retardation). The topmost, brightly reflecting layer of Fig. 34.14b is the RNFL; its birefringence is revealed by the color change from blue to green in the retardation image (Fig. 34.14c) (best seen in the area around the thickest RNFL bundle, i.e., around the vertical yellow line). Figure 34.14d shows the reflectivity image with superimposed segmentation lines: the red lines show the boundaries of the RNFL (found by an intensity-based algorithm); the layers between the green lines correspond to the photoreceptors. These lines are obtained by first segmenting the RPE based on its depolarization and then generating a band of fixed width anterior to the RPE [78]. The vertical yellow lines in Fig. 34.14b, c correspond to the location of the extracted A-scan values plotted in Fig. 34.14e. This graph shows the extracted intensity (black dots) and retardation (red dots) values along a single A-scan. One can clearly see that, within the RNFL, the retardation linearly increases with depth due to the birefringence of the RNFL. The birefringence within the RNFL along this A-scan is obtained by fitting a straight line (black) to the red points located within the RNFL (marked by short red lines on the x-axis).

From the data presented in Fig. 34.14, three different types of quantitative en face maps can be generated: (i) RNFL retardation maps, retardation data are taken from within the band between the green segmentation lines of Fig. 34.14d (the photoreceptor layers provide the strongest signals and therefore the least noisy retardation data; since there are no birefringent layers between the RNFL and the photoreceptors around the ONH area, the retardation measured at the

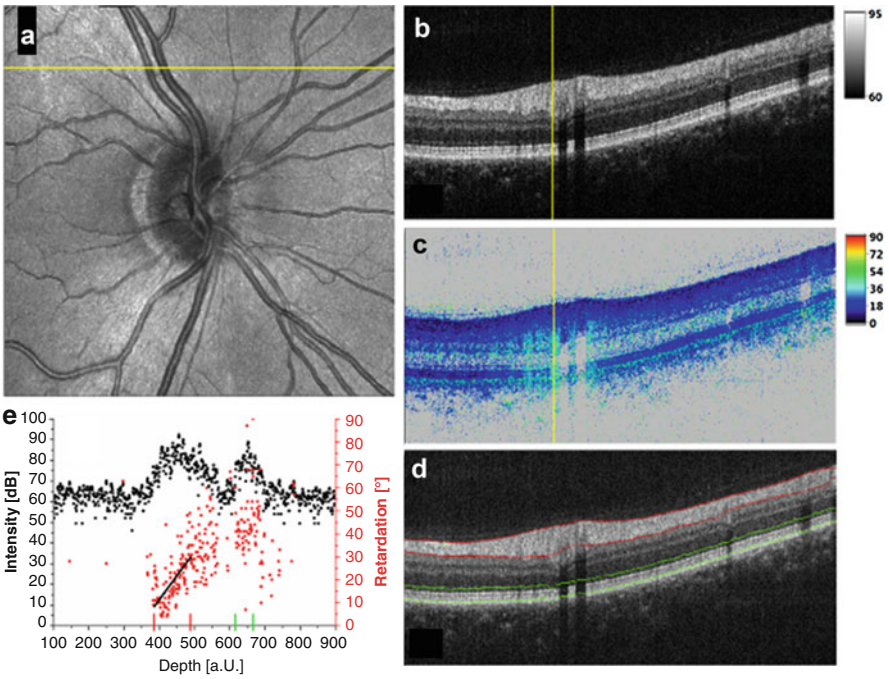

Fig. 34.14 3-D PS-OCT scan (scan angle 27 × 24°, sampling 1,024 × 250 A-scans). (**a**) Pseudo SLO en face image. *Yellow line* indicates the position of the B-scans shown in (**b**)–(**d**). (**b**) Exemplary reflectivity B-scan (log scale). *Yellow line* indicates the position of the extracted A-scan values presented in (**e**). (**c**) Corresponding retardation B-scan. Areas below a certain intensity threshold are displayed in gray (color scale: deg). (**d**) Intensity B-scan overlaid with segmented anterior and posterior boundary of the RNFL (*red lines*) and window indicating the area from which retardation is derived (between *green lines*). (**e**) Extracted intensity (*black dots*) and retardation (*red dots*) values for a single A-scan marked as *yellow line* in (**b**) and (**c**). Segmented RNFL is marked by red lines on the x-axis. Window indicating the area from which retardation is derived is marked by *green lines* on the x-axis. Linear regression fit of the retardation values within the RNFL is indicated by a *solid black line* (Reproduced from Zotter et al. [78] by permission of the Association for Research in Vision and Ophthalmology)

photoreceptors is equal to that at the posterior side of the RNFL); (ii) RNFL thickness maps (showing the vertical distance between the red segmentation lines depicted in Fig. 34.14d); and (iii) RNFL birefringence maps (depicting the slope of the retardation vs. depth linear fit of Fig. 34.14e as a function of x-y position of the recorded A-scan).

Figure 34.15 shows examples of the three quantitative en face maps [78]. The maps are averages from five data sets recorded in the same healthy eye. Figure 34.15a is a retardation map, showing the typical retardation pattern known from SLP: strong retardation along the superior and inferior RNFL bundles and low retardation on the temporal and nasal side. The RNFL thickness map of Fig. 34.15b shows a similar distribution (it is somewhat smoothed because some areal

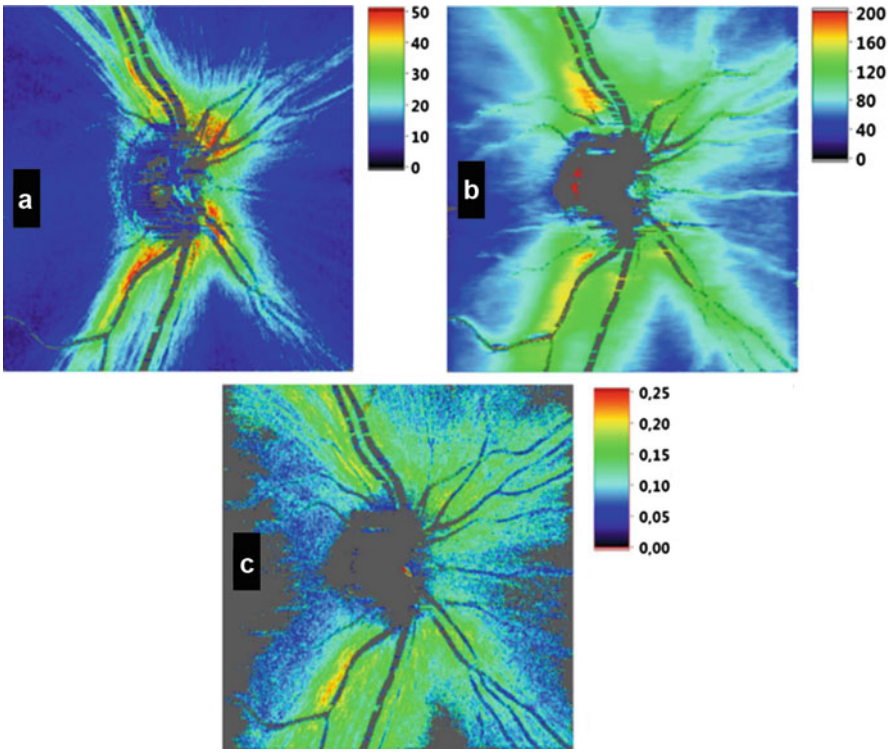

Fig. 34.15 Averaged 2-D en face maps calculated from five 3-D PS-OCT data sets recorded in the optic nerve head area of a healthy human eye. (**a**) RNFL retardation map (color scale: deg). (**b**) RNFL thickness map (color scale: μm). (**c**) RNFL birefringence map (color scale: deg/μm) (Reproduced from Zotter et al. [78] by permission of the Association for Research in Vision and Ophthalmology)

averaging is performed prior to calculating the thickness map). Finally, the birefringence map of Fig. 34.15c shows that the birefringence of the RNFL is not uniform. Especially on the nasal and temporal side, a lower birefringence is observed.

Figure 34.16 shows a comparison of retardation maps obtained by PS-OCT (Fig. 34.16a) and SLP (Fig. 34.16b) in the same eye. The SLP image was obtained by a commercial instrument (GDx VCC, Carl Zeiss Meditec). While the general patterns are in good agreement, the PS-OCT map shows a much better resolution, revealing thin nerve fiber bundles that are not resolved by the SLP instrument.

Figure 34.17 summarizes results obtained in ten healthy eyes. These TSNIT curves show the circumpapillary (azimuthal) distribution of RNFL retardation (Fig. 34.17a), thickness (Fig. 34.17b), and birefringence (Fig. 34.17c), measured along a circle around the ONH, starting at the temporal (T) position and going over the superior (S), the nasal (N), the inferior (I), and back to the temporal (T) position.

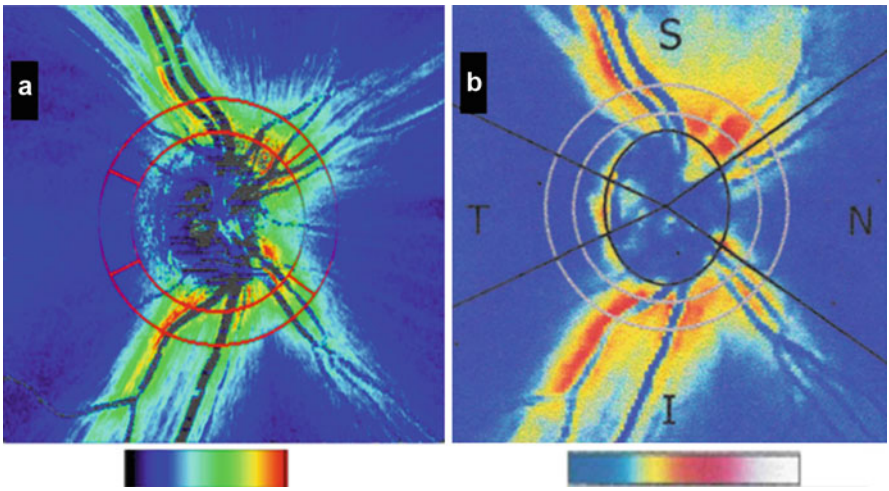

Fig. 34.16 Comparison between PS-OCT and SLP recorded within the same eye. (**a**) Averaged retardation map from Fig. 34.6a (color scale: 0–50°). *Red lines* indicate the region for the circumpapillary evaluation. (**b**) GDx VCC en face retardation map (color scale: 0–61°) (Reproduced from Zotter et al. [78] by permission of the Association for Research in Vision and Ophthalmology)

The data are taken from within the area marked by two red circles in Fig. 34.16a. The black curves show the mean values found for the ten eyes; the red curves indicate the position of mean ± standard deviation. For glaucoma diagnostics by SLP, deviations from a similar retardation standard curve (taken from a normative database) are analyzed. Since PS-OCT provides three different types of TSNIT curves, improved sensitivity and specificity can be expected.

Figure 34.18 shows a comparison of wide-field (40 × 40°) retardation maps obtained in a healthy (Fig. 34.18a) and a glaucomatous eye (Fig. 34.18b). The glaucomatous eye clearly shows a nerve fiber bundle defect in the superior hemisphere.

Apart from glaucoma diagnostics by analyzing RNFL birefringence in the ONH area, other applications of PS-OCT in the peripheral retina are conceivable, though not yet explored in greater detail. An example of a possible application is imaging of choroidal nevi and melanoma based on the depolarization caused by the melanin they contain. The contrast mechanism is similar to that reported for the RPE contrast in Sect. 34.3.2.2. Figure 34.19 shows an example of a 3-D data set obtained from an eye with a choroidal nevus [30]. Figure 34.19a–c show intensity, retardation, and DOPU images, respectively (each image contains sub-images of volume rendering, transverse scan, and horizontal and vertical B-scan). Figure 34.19d, e show different aspects of a volume-rendered DOPU data set, clearly visualizing the extension of the nevus (blue-green color). Figure 34.19f shows a corresponding color fundus photo. A limitation of these PS-OCT images is that the strong scattering and absorption of the melanin prevents the measurement of total thickness of the pigmented tumors; PS-OCT at 1,050 nm might overcome that limitation.

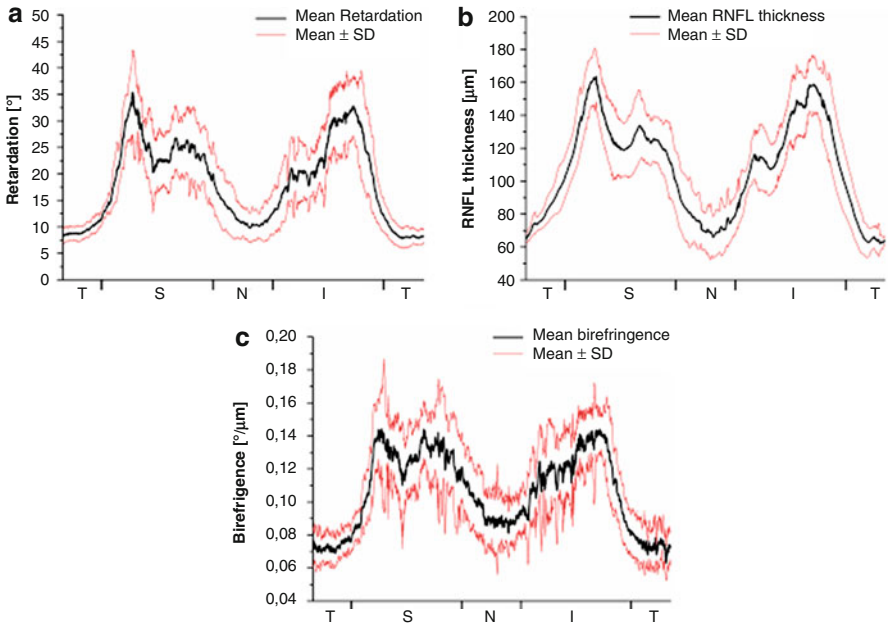

Fig. 34.17 Averaged RNFL retardation (**a**), thickness (**b**), and birefringence (**c**) circumpapillary plots ± standard deviation calculated from the measurement results of ten healthy eyes. The respective quantity is plotted as a function of the azimuth angle around the optic nerve head. The area from which the data of the circumpapillary plots are taken is indicated by two red rings in Fig. 34.16 (Reproduced from Zotter et al. [78] by permission of the Association for Research in Vision and Ophthalmology)

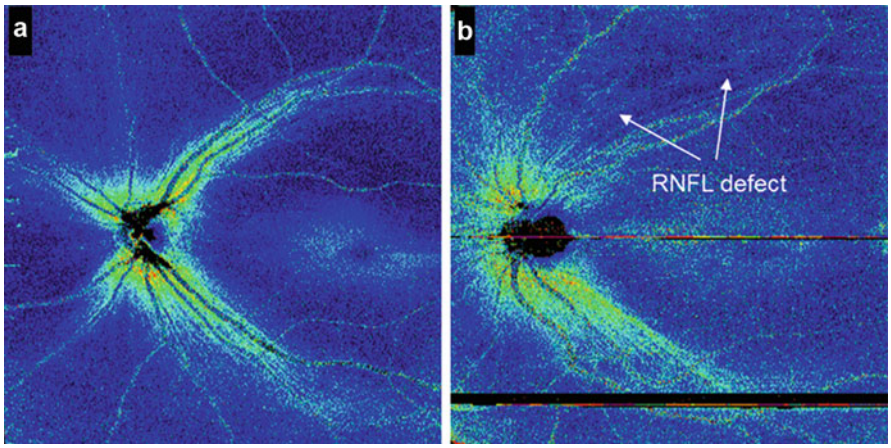

Fig. 34.18 Wide-field (40 × 40°) RNFL retardation maps obtained by PS-OCT in a healthy eye (**a**) and in a glaucomatous eye (**b**) (Reproduced from Zotter et al. [57] by permission of the Optical Society of America)

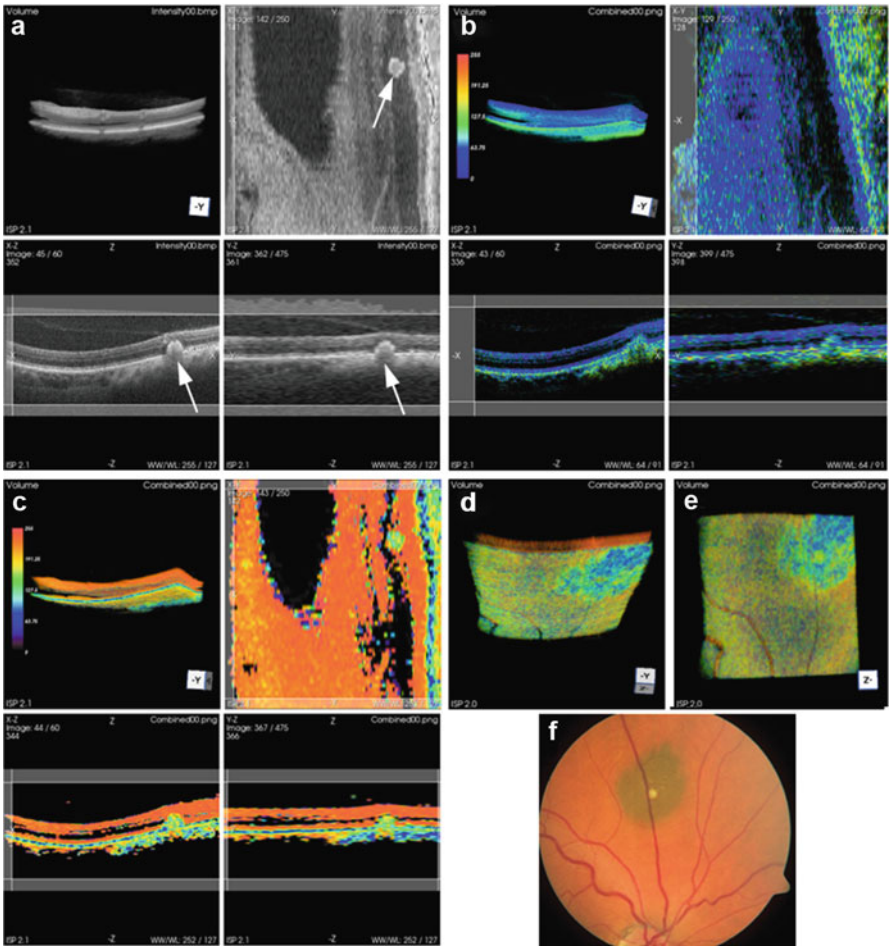

Fig. 34.19 3-D PS-OCT data set of the retina of a patient with a choroidal nevus. (**a**) Reflectivity; (**b**) retardation (color bar: 0 = 0°, 255 = 90°); (**c**) DOPU (color bar: 0 = 0, 255 = 1). Sub-figure arrangement: *top left*, volume rendering; *top right*, en face section; *bottom left*, horizontal B-scan; *bottom right*, vertical B-scan. (**d, e**) Additional views of the volume-rendered DOPU data set: (**d**) inclined upwards and (**e**) upwards. For better comparison with the fundus photo (**f**), these reverse-direction images are mirrored. Image size of OCT images: ~14.25°(x) × 15°(y) × 1.5 mm (z, in air) (Reproduced from Götzinger et al. [30] by permission of the Optical Society of America)

34.5 Conclusions

PS-OCT is a functional extension of OCT that provides intrinsic, tissue-specific contrast and thereby overcomes some of the limitations of conventional, intensity-based OCT. The eye contains several tissues that can change the light's polarization state. Therefore, PS-OCT has several applications in ocular imaging. Presently, the

most promising applications are glaucoma diagnostics via the birefringence of the RNFL and the automated segmentation of the RPE and of lesions that are associated with changes of the RPE, as found, e.g., in age-related macular degeneration.

Since PS-OCT is an extension of standard OCT techniques, essentially all new developments made for intensity-based OCT can be transferred to PS-OCT. Therefore, we expect that improvements in light source and camera technology that recently have led to ultrahigh-speed OCT systems will also further improve the imaging speed of PS-OCT. Furthermore, the integration of retinal trackers that are already available in some commercial OCT scanners will lead to motion-artifact free PS-OCT images that should further improve the precision of quantitative PS-OCT imaging.

Polarization sensitive OCT • PS-OCT • Jones matrix • Birefringence • Retardation • Diattenuation • Optic-axis

35.1 Introduction

Polarization-sensitive optical coherence tomography (PS-OCT) is an extension of OCT and is capable of measuring the polarization properties of biological tissues, such as phase retardation, diattenuation, and optic-axis orientation. It is known that several types of biological tissues possess microscopic fibrous structures including collagen fibers and nerve fibers. Since these microscopic structures are smaller than the resolution of OCT, standard OCT is not capable of assessing them. However, these microscopic structures are known to possess birefringence, and PS-OCT is capable of assessing these microscopic tissue properties by measuring its polarization property.

PS-OCT has been applied to several biological and clinical investigations such as the examination of burn depth of skin [1–5], corneal integrity [6, 7], retinal disorders including macular diseases [8–10], glaucoma surgery [11], quantification of the retinal nerve fiber layer [12–14] and choroidal thickness [15, 16], assessments of caries [17–19], and cardiovascular plaques [20, 21].

PS-OCT modalities are classified into several subtypes. One of the most widely utilized methods is the circular polarization-based method, which was first demonstrated by Hee et al. [22] and later widely investigated by Hitzenberger and his

associates [6, 8, 23]. In this chapter, this method is denoted as the Hee-Hitzenberger method. The Hee-Hitzenberger method determines the phase retardation and the optic-axis orientation of a sample by using a circularly polarized probe beam. Since this method uses only the intensity of OCT and does not use its phase to determine the phase retardation, this method is robust and stable. On the other hand, since the probe beam should be circularly polarized, the interferometer should be a bulk interferometer or built with a polarization-maintaining fiber. Another property of this method is its insensitivity to diattenuation. Although no particular utility was found for a diattenuation measurement of biological tissues, this limitation should be noted to understand the differences among several PS-OCT methods.

Stokes parameter-based PS-OCT has also been widely investigated [24]. This method is capable of determining the phase retardation and optic-axis orientation of a sample. As with the Hee-Hitzenberger method, the Stokes method is also not capable of measuring the diattenuation of a sample. One of the advantages of this method against Hee-Hitzenberger method is its ability to be implemented with a single-mode fiber, which is widely utilized for OCT [25–27]. The optic-axis orientation measured by this method is an absolute orientation if the system is implemented with a bulk interferometer and is a relative axis orientation if it is implemented with a flexible single-mode fiber. One drawback of this method is its requirement for an active optical device that alters the polarization state of a probe beam, typically an electro-optic modulator.

Mueller matrix-based PS-OCT has also been demonstrated [28, 29]. This method determines the Mueller matrix of a sample, and hence, it provides all of the polarization properties of the sample including the phase retardation, axis orientation, and the diattenuation except depolarization. The depolarization cannot be measured because of a fundamental limitation of a coherent imaging modality such as OCT [30]. Mueller matrix PS-OCT uses only the intensity signal of OCT, and hence, it could be robust in principle. However, this method requires relatively large numbers of measurements, and hence, the measurement time is relatively long. This long measurement time would deteriorate the polarization measurement accuracy of an in vivo measurement.

Among several subtypes of PS-OCT, Jones matrix-based PS-OCT, or Jones matrix OCT in short, is a method that determines the polarization properties of a sample by measuring the double-pass Jones matrix of a sample or its similar matrix [31–34]. This method can be implemented both with a bulk interferometer or a single-mode fiber-based interferometer. With the bulk interferometer, this method can provide a round-trip Jones matrix of the sample. On the other hand, with the single-mode fiber interferometer, a similar matrix of the round-trip Jones matrix of the sample is obtained. From the round-trip Jones matrix or its similar matrix, the phase retardation, the diattenuation, and the relative optic-axis orientation are obtained.

This chapter is dedicated to describing the principles and implementations of Jones matrix OCT.

35.2 General Principle

The objective of Jones matrix OCT is to obtain the tomographies of the round-trip phase retardation, diattenuation, relative optic-axis orientation, and backscattering intensity of a sample. To obtain these polarization parameters, Jones matrix OCT first determines the Jones matrix or its similar matrix at each location in the sample. Since a matrix and its similar matrix have the same eigenvalues, the phase retardation, namely, the phase difference between two eigenvalues, and the diattenuation, namely, the contrast of the squared power of the eigenvalues, are determined from the similar matrix. The axis orientation is determined as the directions of the eigenvectors of the round-trip Jones matrix of the sample. Since a matrix and its similar matrix do not always possess the same eigenvectors, the absolute axis orientation is not obtained from the similar matrix. However, Jones matrix OCT still provides a relative axis orientation from the similar matrix. The backscattering tomography can be obtained by several means from the Jones matrix as described later in this chapter.

35.2.1 Basic Principle of Jones Matrix Measurement

Although various implementations of the Jones matrix OCT exist, almost all of them share a similar concept. Namely, Jones matrix OCT determines a Jones matrix by measuring Jones vectors of two backscattered probe beams $\vec{E}_{out}^{(1)}(x,y,z)$ and $\vec{E}_{out}^{(2)}(x,y,z)$, which correspond to two different incident polarization states, $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$, where x, y is the transversal position and z is the position in depth. The Jones vectors of $\vec{E}_{out}^{(1)}(x,y,z)$ and $\vec{E}_{out}^{(2)}(x,y,z)$ are measured by a polarization-diversity OCT detection scheme, by which two OCT images of two orthogonal polarization components, typically the horizontal and vertical components, are obtained. One of the OCTs represents the first entry of the Jones vector, and the other represents the second entry. The details of the polarization-diversity detection are described in Sect. 35.3.2. Owing to the three-dimensional resolution of OCT, $\vec{E}_{out}^{(1)}(x,y,z)$ and $\vec{E}_{out}^{(2)}(x,y,z)$ are spatially resolved, that is, they are functions of space, while the incident polarization states $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$ are constants.

By denoting a Jones matrix of interest as $\mathbf{J}(x, y, z)$, the Jones vectors of incident and backscattered light are associated as

$$\begin{cases} \vec{E}_{out}^{(1)}(x,y,z) &= \mathbf{J}(x,y,z)\vec{E}_{in}^{(1)} \\ \vec{E}_{out}^{(2)}(x,y,z) &= \mathbf{J}(x,y,z)\vec{E}_{in}^{(2)} \end{cases}. \tag{35.1}$$

This set of equations corresponds to two measurements of OCT with different incident polarization states. By calculating $\vec{E}_{out}^{(1)}(x,y,z)\,[1 \quad 0\,] + \vec{E}_{out}^{(2)}(x,y,z)\,[0 \quad 1\,]$, these two equations are unified as

$$\mathbf{E}_{out}(x,y,z) = \mathbf{J}(x,y,z)\mathbf{E}_{in} \tag{35.2}$$

where $\mathbf{E}_{out}(x, y, z)$ and $\mathbf{E}_{in}$ are the Jones vector matrices of $\mathbf{E}_{out}(x,y,z) \equiv \left[\vec{E}^{(1)}_{out}(x,y,z) \quad \vec{E}^{(2)}_{out}(x,y,z)\right]$ and $\mathbf{E}_{in} \equiv \left[\vec{E}^{(1)}_{in} \quad \vec{E}^{(2)}_{in}\right]$. By using Eq. 35.2, the spatially resolved Jones matrix, i.e., Jones matrix tomography, is obtained from the measured Jones vectors matrix $\mathbf{E}_{out}(x, y, z)$ and predefined Jones vectors matrix $\mathbf{E}_{in}$ as

$$\mathbf{J}(x,y,z) = \mathbf{E}_{out}(x,y,z)\mathbf{E}_{in}^{-1} \ . \tag{35.3}$$

Since this equation contains the inverse matrix of $\mathbf{E}_{in}$, $\mathbf{E}_{in}$ should be a non-singular matrix. In other words, the two incident light beams should not be parallel, namely, $\vec{E}^{(1)}_{in} \neq \zeta \vec{E}^{(2)}_{in}$, where ζ is an arbitrary complex constant.

As represented by Eq. 35.3, the basic principle of Jones matrix OCT is very simple. However, there are still fundamental issues such as the effect of birefringence of the OCT system and the determination of $\mathbf{E}_{in}$. The following section describes an extended principle of Jones matrix OCT by which the system birefringence is canceled. In addition, the extended principle enables a determination of $\mathbf{J}(x, y, z)$ without any knowledge of $\mathbf{E}_{in}$.

35.2.2 Extended Principle of Jones Matrix Optical Coherence Tomography

The Jones vectors of incident and backscattered light in the previous section had been defined at just before and after the sample. However, in general, the optical components utilized in OCT have specific polarization properties. In particular, optical fiber, which is commonly utilized in an OCT interferometer, has birefringence, and this fiber birefringence is altered by several factors including mechanical stress and temperature. Hence, especially with single-mode fiber-based Jones matrix OCT, it is rarely possible to determine the Jones vector of the real incident light to the sample and also to measure the Jones vector of the backscattered light.

To first mathematically describe this issue and then provide its solution, we introduce a modified model of the Jones matrix measurement. Figure 35.1 shows a simplified schematic Jones matrix measurement by Jones matrix OCT. $\mathbf{J}_{in}$ and $\mathbf{J}_{out}$ represent Jones matrices of illumination and collection optics that may include the optical fiber, and $\mathbf{J}_s(x, y, z)$ is a single-trip Jones matrix of a sample. Note that, in this scheme, $\vec{E}^{(1)}_{in}$, $\vec{E}^{(2)}_{in}$ and $\vec{E}^{(1)}_{out}(x,y,z)$, $\vec{E}^{(2)}_{out}(x,y,z)$ are the Jones vectors of the light incident to and output from the system, respectively, not to and from the sample. The incident point can be arbitrarily defined and does not affect the final measurement results except for axis orientation as discussed later in this section. The output polarization is typically defined as that at a detection unit.

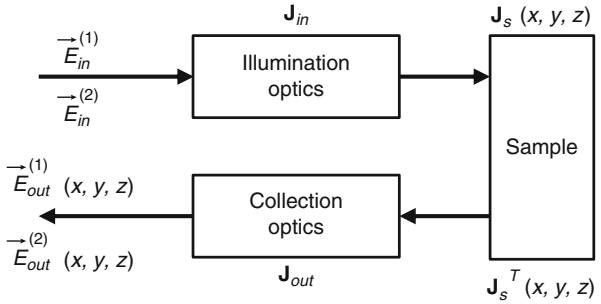

Fig. 35.1 A conceptual scheme of polarization properties of Jones matrix OCT. $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$ are the Jones vectors of the incident light to the OCT system, $\vec{E}_{out}^{(1)}$ and $\vec{E}_{out}^{(2)}$ are the those of output light from the system, $\mathbf{J}_{in}$ and $\mathbf{J}_{out}$ are Jones matrices of illumination and detection optics, and $\mathbf{J}_s$ is a single-trip Jones matrix of the sample

In this scheme, the entire Jones matrix of the system and the sample becomes

$$\mathbf{J}_{all}(x, y, z) = \mathbf{J}_{out}\,\mathbf{J}_s^T(x, y, z)\mathbf{J}_s(x, y, z)\mathbf{J}_{in} \tag{35.4}$$

where $\mathbf{J}_s^T\,\mathbf{J}_s$ is a round-trip Jones matrix of the sample [32]. According to the similar discussion with Sect. 35.2.1, $\mathbf{J}_{all}, \mathbf{E}_{in} \equiv \left[\vec{E}_{in}^{(1)} \quad \vec{E}_{in}^{(2)}\right]$ and $\mathbf{E}_{out} \equiv \left[\vec{E}_{out}^{(1)} \quad \vec{E}_{out}^{(2)}\right]$ are associated as

$$\mathbf{J}_{all}(x, y, z) = \mathbf{E}_{out}(x, y, z)\mathbf{E}_{in}^{-1}. \tag{35.5}$$

Note that the output Jones vector matrix $\mathbf{E}_{out}(x, y, z)$ can be measured and the incident polarization state $\mathbf{E}_{in}$ is arbitrarily selected.

The objective of the Jones matrix OCT measurement is to determine the phase retardation, diattenuation, and optic-axis orientation of the round-trip Jones matrix of the sample $\mathbf{J}_s^T(x, y, z)\ \mathbf{J}_s\ (x, y, z)$. For this purpose, $\mathbf{J}_s^T(x, y, z)\ \mathbf{J}_s\ (x, y, z)$ or its similar matrix should be obtained. This similar matrix at a position of (x, y, z) can be obtained by using $\mathbf{J}_{all}\ (x, y, z)$ and $\mathbf{J}_{all}\ (x, y, z_{surf})$ where z_{surf} is the position of the surface of the sample [33]. According to Eq. 35.4, the product of $\mathbf{J}_{all}\ (x, y, z)$ and the inverse of $\mathbf{J}_{all}\ (x, y, z_{surf})$ is expressed as

$$\mathbf{J}_{all}(z)\mathbf{J}_{all}\left(z_{surf}\right)^{-1} = \mathbf{J}_{out}\,\mathbf{J}_s^T(z)\mathbf{J}_s(z)\mathbf{J}_{in}\,\mathbf{J}_{in}^{-1}\mathbf{J}_s^T\left(z_{surf}\right)^{-1}\mathbf{J}_s\left(z_{surf}\right)\mathbf{J}_{out}^{-1} \tag{35.6}$$

where the variables of x and y are omitted for simplicity. By using the fact that $\mathbf{J}_s\ (z_{surf})$ is a unit matrix, Eq. 35.6 is simplified to be

$$\mathbf{J}_{all}(z)\mathbf{J}_{all}\left(z_{surf}\right)^{-1} = \mathbf{J}_{out}\,\mathbf{J}_s^T(z)\mathbf{J}_s(z)\mathbf{J}_{out}^{-1}. \tag{35.7}$$

On the other hand, by using the relationship of Eq. 35.5, the same product of $\mathbf{J}_{all}(z)\mathbf{J}_{all}(z_{surf})^{-1}$ is also expressed as

$$\begin{aligned}\mathbf{J}_{all}(z)\mathbf{J}_{all}\left(z_{surf}\right)^{-1} &= \mathbf{E}_{out}(z)\mathbf{E}_{in}^{-1}\mathbf{E}_{in}\mathbf{E}_{out}^{-1}\left(z_{surf}\right) \\ &= \mathbf{E}_{out}(z)\mathbf{E}_{out}{}^{-1}\left(z_{surf}\right).\end{aligned} \tag{35.8}$$

By combining Eqs. 35.7 and 35.8, the key equation of Jones matrix OCT

$$\mathbf{J}_{out}\,\mathbf{J}_{s}^{T}(z)\mathbf{J}_{s}(z)\mathbf{J}_{out}^{-1} = \mathbf{E}_{out}(z)\mathbf{E}_{out}^{-1}\left(z_{surf}\right) \tag{35.9}$$

is obtained. The left-hand side is a similar matrix of the round-trip Jones matrix of the sample, while the right-hand side consists of only measurable values.

In general, a matrix and its similar matrix possess the same eigenvalues. Therefore, the eigenvalues of the matrix obtained by Eq. 35.9 provide the round-trip phase retardation and the diattenuation of the sample. It is also noteworthy that this equation does not consist of $\mathbf{E}_{in}$. It indicates the selection of two polarization states of the two incident light beams $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$ is arbitrary as far as $\mathbf{E}_{in}$ is a non-singular matrix (see also Sect. 35.2.1).

35.2.3 Phase Retardation, Diattenuation, and Relative Optic-Axis Orientation

After determining the similar matrix of the round-trip Jones matrix by using Eq. 35.9, its eigenvalues and eigenvectors are obtained through one of the general numerical eigenvalue algorithms, for instance, which are described in Ref. 33. Such eigenvalue algorithms [35] are frequently available in standard programming libraries/languages for numerical computation, such as LAPACK (for Fortran 90 and C), MATLAB, and LabVIEW. The eigenvalues can also be obtained by the following equation

$$\lambda_{1,2} = \frac{T}{2} \pm \sqrt{\frac{T^2}{4} - D} \tag{35.10}$$

where T and D are the trace and the determinant of the similar matrix, respectively.

The phase retardation, diattenuation, and relative optic-axis orientation are then determined by these eigenvalues and eigenvectors as described in the following subsections.

35.2.3.1 Phase Retardation

The phase retardation δ is determined by the phase difference between two eigenvalues as

$$\delta \equiv \mathrm{Arg}[\lambda_1/\lambda_2] = \arctan\left[\frac{\mathrm{Im}(\lambda_1/\lambda_2)}{\mathrm{Re}(\lambda_1/\lambda_2)}\right]. \tag{35.11}$$

Although it is omitted for simplicity, δ, λ_1, and λ_2 are the functions of (x, y, z), such that a tomography of double-path phase retardation is obtained. In addition, the phase retardation measured at a particular position in the sample is affected by its anterior tissue. Thus, this phase retardation is a cumulative double-path phase retardation from the surface of the sample to the depth position being measured.

It should be noted that the selection of λ_1 and λ_2 from the two numerically obtained eigenvalues is arbitrary; the phase-retardation value has an ambiguity of π rad. For practical Jones matrix OCT, the phase retardation is aliased into a 0 to π rad range as

$$\delta' \equiv \begin{cases} \delta & : \quad 0 \le \delta < \pi \\ 2\pi - \delta & : \quad \pi \le \delta < 2\pi. \end{cases} \tag{35.12}$$

where δ' is the aliased double-path phase retardation.

35.2.3.2 Diattenuation

The diattenuation d is defined as the contrast of the amplitudes of the eigenvectors as

$$d \equiv \frac{\left||\lambda_1|^2 - |\lambda_2|^2\right|}{|\lambda_1|^2 + |\lambda_2|^2}. \tag{35.13}$$

Since λ_1 and λ_2 are the functions of (x, y, z), d is also a function of (x, y, z) and represents the tomography of diattenuation.

35.2.3.3 Relative Optic-Axis Orientation

The relative optic-axis orientation is defined as the direction of an eigenvector, which is a Jones vector of a characteristic polarization state of the similar matrix, on the equatorial plane of the Poincaré sphere. It should be noted that this eigenvector is not an eigenvector of the round-trip Jones matrix of the sample but that of the similar matrix. Hence, the optic-axis orientation obtained by this method is not identical to that of the sample but only a relative axis orientation.

Although this relative axis orientation is not a direct property of the sample, it would provide useful information to the extent that $\mathbf{J}_{out}$ is constant. In addition, a calibration technique of Jones matrix OCT that enables the absolute optic-axis orientation has recently been presented [36].

35.2.3.4 Degree of Polarization Uniformity

In addition to the abovementioned fundamental polarization properties, Jones matrix tomography can also be utilized to obtain the secondary polarization property of the sample, the so-called degree of polarization uniformity (DOPU) [37, 38]. DOPU measurement by PS-OCT was independently proposed by

Lee et al. [37] and Götzinger et al. [38]. DOPU is known to be associated with melanin concentration in the sample [39] and has been utilized for the segmentation of the retinal pigment epithelium [38].

DOPU is defined by spatially averaged Stokes parameters of the backscattered probe beam as

$$\mathrm{DOPU} = \sqrt{\overline{Q}^2 + \overline{U}^2 + \overline{V}^2} \tag{35.14}$$

where $\overline{Q}$, $\overline{U}$, and $\overline{V}$ are the normalized Stokes parameters defined as

$$\left(\overline{Q}, \overline{U}, \overline{V}\right) = \left(\sum_i \frac{Q_i}{I_i}, \sum_i \frac{U_i}{I_i}, \sum_i \frac{V_i}{I_i}\right). \tag{35.15}$$

$[I_i\ Q_i\ U_i\ V_i]^T$ is a Stokes vector of the ith pixel in a spatial kernel of the averaging. Since OCT is a coherence imaging modality, it is not possible to measure the degree of polarization [30]. However, DOPU is regarded as a spatial analogy of the degree of polarization.

Although DOPU is defined from the Stokes parameters, Jones matrix OCT can also provide DOPU from the Jones matrix by assuming a virtual incident beam and its resulting virtual output Stokes vector. For example, by assuming the incident polarization state of $[1\ 0]^T$, the virtual Stokes parameters are defined as

$$\begin{bmatrix} I \\ Q \\ U \\ V \end{bmatrix} \equiv \begin{bmatrix} |J_{11}|^2 + |J_{12}|^2 \\ |J_{11}|^2 - |J_{12}|^2 \\ J_{11}J_{12}^* + J_{11}^* J_{12} \\ i\left(J_{11}J_{12}^* - J_{11}^* J_{12}\right) \end{bmatrix} \tag{35.16}$$

where J_{11} and J_{12} are the upper-left and lower-left entries of the similar matrix $\mathbf{J}_{all}(z)\mathbf{J}_{all}(z_{surf})^{-1} = \mathbf{E}_{out}(z)\mathbf{E}_{out}^{-1}(z_{surf})$.

The DOPU is also directly calculated from $\mathbf{E}_{out}(z)$ by substituting $J_{11} = E_{out,11}$ and $J_{12} = E_{out,12}$ into Eq. 35.16, where $E_{out,11}$ and $E_{out,12}$ are the upper-left and lower-left entries of the Jones vector matrix $\mathbf{E}_{out}(z)$, respectively. Note that, in this case, the assumed virtual incident polarization state is $\mathbf{E}_{out}\left(z_{surf}\right)[1 \quad 0]^T$.

35.3 Implementation Theory

As we discussed in Sect. 35.2, Jones matrix OCT relies on two incident polarization states and Jones vector measurement of the backscattered beam. The former is realized by one of the polarization multiplexing mechanisms, and the latter is typically realized by a polarization-diversity detection scheme. This section is dedicated to providing a brief review of these methods.

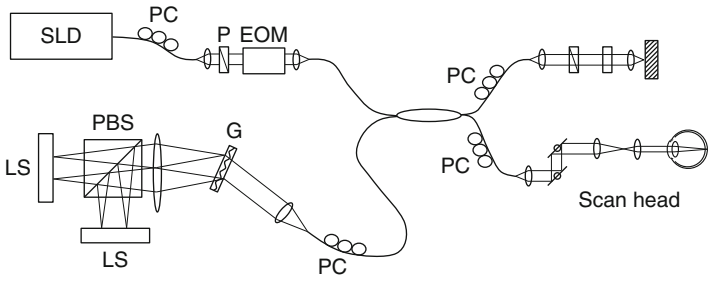

Fig. 35.2 Example of the optical scheme for polarization modulation along the transversal scan. *SLD* is a superluminescent diode light source, *PCs* are polarization controllers, *LPs* are linear polarizers, *ND* is neutral density filter, and *EOM* is an electro-optic modulator. This modulation scheme is particularly suitable for the SD-OCT scheme, and this example is equipped with a polarization-diversity spectrometer consisting of a grating (*G*), a polarization beam splitter (*PBS*), and two line scan CCD cameras

35.3.1 Multiplexing of Incident Polarization States

As is evident from Eq. 35.1, Jones matrix OCT relies on two incident polarization states. These two polarization states are multiplexed by several means in Jones matrix OCT measurement including time-division multiplexing [33], polarization modulation along the transversal scan (mainly for spectral domain (SD-)OCT) [40] or along the wavelength scan (only for swept-source (SS-)OCT) [41], frequency shifting [42], and time delay-based multiplexing [43, 44].

35.3.1.1 Time-Division Multiplexing

In the time-division multiplexing scheme, two polarization states of the incident beam are sequentially switched for A-line by A-line [33]. This method is the most straightforward implementation of incident polarization multiplexing.

35.3.1.2 Polarization Modulation Along the Transverse Scan

In this multiplexing scheme, the phase of a polarization component of incident light is modulated by a sinusoidal function along the transversal scanning direction. By this modulation, two incident beams with two polarization states are multiplexed such that one is modulated in phase and the other is not. After OCT detection, these two multiplexed components are demultiplexed by spatial frequency filtering based on a numerical Fourier transform along the transversal direction [40].

The modulation is typically performed by an electro-optic (EO) modulator as shown in Fig. 35.2. The EO modulator is configured to modulate the relative phase of the polarization component of a probe beam that oriented to one of the axes of the modulator (so denoted as EO-modulation axis) in respect to the phase of the OCT reference beam, while the relative phase of the polarization component oriented to the other EO axis (EO-non-modulation axis) is not modulated. The frequency of the modulation is defined in respect to the A-line frequency of the OCT detection so that it is several fractions of the A-line frequency. An example of the modulation

frequency was 9.23 kHz, which is one-third of the A-line frequency of 27.7 kHz [40]. Consequently, the modulation frequency of this method is around ten few kHz.

With the phase modulation depth of 2.405 rad, the theoretical modulation efficiency in the EO-modulation axis, which is the ratio of the total optical power of the modulated beam including those of high-order harmonics over non-modulated optical power in the EO-modulation axis, is 100 %. Under this condition, the polarization states of the non-modulated incident beam, which would be $\vec{E}_{in}^{(1)}$, and the modulated incident beam $\vec{E}_{in}^{(2)}$ are orthogonal to each other, and the maximum robustness of phase-retardation measurement is obtained [45].

Because of several kinds of turbulences, such as temperature drift, and imperfection of the EO modulator, the accurate modulation depth of 2.405 rad is hard to achieve in practice. Under non-ideal modulation conditions, $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$ are no longer orthogonal to each other. However, it is noteworthy that the extended principle of Jones matrix OCT also holds its validity for this non-ideal case because it does not rely on the orthogonality of the incident polarization states.

35.3.1.3 Polarization Modulation Along the Wavelength Scan

This scheme is a variation of the abovementioned polarization modulation method and is specifically applicable to SS-OCT. The phase modulation is performed by an EO modulator with a similar optical scheme to that in Fig. 35.2 but along the wavelength scan. Similar to the modulation along the transversal scan, the two incident polarization states are demultiplexed by frequency filtering but based on a numerical Fourier transform along the wavelength scan [41].

This scheme requires a typical modulation frequency of one-third or slightly less than half of the sampling frequency of wavelength sampling. A typical modulation frequency is 33.3 MHz [41] or 40 MHz [46] for a sampling frequency of 100 MHz. Therefore, the modulation frequency of this scheme is around a few 10 MHz and is higher than that of modulation along the transversal scan by a magnitude greater than 1,000. This high-frequency operation requires a resonant EO modulator [41] or a wave guide-based miniature EO modulator [7]. These EO modulators could be a potential limitation of the implementation of this method. On the other hand, similar to the transversal modulation scheme, the incident polarization states are not necessarily orthogonal. This fact relaxes the requirement for the implementation.

An advantage of this method over the transversal modulation is that $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$ are simultaneously obtained at exactly the same location in the sample. In the transversal modulation scheme, the probe locations on the sample corresponding to the two incident polarizations are slightly displaced to each other because the EO modulator alters the incident polarization state for each A-line. This small displacement results in a structural decorrelation between two OCT signals associated with the two incident polarization states, and it finally degrades the sensitivity of the Jones matrix measurement. This issue raises an additional requirement of the transversal modulation scheme, i.e., the A-lines should be dense enough in space so that the separation between adjacent A-lines is less than a fraction of the transversal optical resolution. The wide-range and high-speed measurements are in contradiction to each other with the transversal modulation scheme.

On the other hand, in the wavelength scan-oriented modulation scheme, the OCT signals associated with two incident polarization states are obtained at exactly the same time and location. Hence, the structural decorrelation does not occur. This property makes the wavelength-oriented modulation scheme suitable for high-speed wide-range measurements.

35.3.1.4 Shifting Frequency-Based Multiplexing

This scheme is for SS-OCT and has recently been demonstrated by Kim et al. [42]. In this scheme, the frequencies of the two incident beams with orthogonal polarization states are frequency shifted by two frequency shifter with different shifting frequency (20 MHz and 40 MHz). Namely, two incident polarization states are multiplexed in its frequency. This multiplexed incident beams would have different carrier frequency after interference with a reference beam, and these beams are demultiplexed by numerical Fourier transform.

To avoid unwanted interference, this scheme is equipped with an unpolarizer, which is a polarization-dependent delay unit generating a path length difference more than the instantaneous coherence length of the light source between the two polarization states.

35.3.1.5 Delay-Based Incident Polarization Multiplexing

If the coherence length of a light source in SS-OCT or the spectral resolution of a spectrometer in SD-OCT is high and hence the depth measurement range of the OCT is sufficiently long, the two incident polarizations can also be multiplexed at two different depths.

This polarization-dependent spectral delay can be implemented, for example, by two PBSs and two Dove prisms as depicted in Fig. 35.3a [43] or by the combination of a PBS and two quarter-wavelength plates (QWPs) as depicted in Fig. 35.3b [44]. Since the OCT images associated with two incident polarization states appear at different depths as depicted in Fig. 35.3c, it can be easily demultiplexed by cropping specific portions of the OCT images.

The relatively low extinction ratio of the reflection beam of PBS and the wavelength dependency of QWP would degrade the orthogonality of two incident polarization states. However, this issue is negligible because of a reason similar to that with the polarization modulation-based multiplexing methods, i.e., the orthogonality of the two incident polarization states is not required.

Since this scheme does not require any active optical components, such as an EO modulator, it is stable, and the sequential control of this type of Jones matrix OCT would be simpler than of those using polarization modulation schemes.

35.3.2 OCT-Based Jones Vector Detection

In Jones matrix OCT, the Jones vector of the backscattered probe beam after the collection optics, i.e., $\vec{E}_{out}^{(1)}$ and $\vec{E}_{out}^{(2)}$ of Fig. 35.1, is measured by a polarization-diversity detection unit. In the polarization-diversity detection unit, two orthogonal

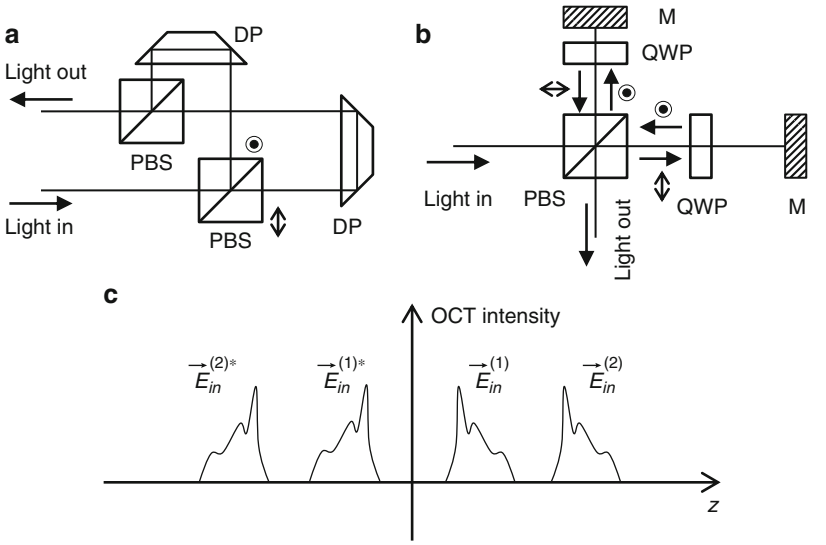

Fig. 35.3 (**a**, **b**) The optical schemes for delay-based input polarization multiplexing. *PBSs* are polarizing beam splitters, *DPs* are Dove prisms, *QWPs* are quarter-wavelength plates, and Ms are flat mirrors. (**c**) A schematic figure of demultiplexing two incident polarization components. The OCT images associated with two incident polarization states appear at different depths

polarization components, typically horizontal and vertical, of the probe and reference beams are split by a PBS or a Wollaston prism and detected by two detectors, except for some sophisticated polarization-diversity detection units that use a single detector. In this section, some examples of polarization-diversity detection units and the principle of OCT-based Jones vector measurement are presented.

35.3.2.1 Implementation Examples of Polarization-Diversity Detection Unit

A polarization-diversity spectrometer is a detection unit specifically utilized for SD-OCT. Although there are some variations, all of them split two orthogonal polarization components after combining the reference and probe beams in an interferometer.

Figure 35.4a is a straightforward implementation of a polarization-diversity spectrometer, which was originally developed for a Hee-Hitzenberger-type PS-OCT [23]. In this scheme, the probe and reference beams are combined in an OCT interferometer and then introduced into the polarization-diversity spectrometer unit. In this spectrometer unit, the horizontal and vertical polarization components of the beams are split by a fiber PBS and detected by two independent spectrometers. This polarization-diversity spectrometer is a straightforward implementation and is hence easy to design. On the other hand, it requires two whole spectrometers and thus results in double the implementation cost. In addition, it is sometimes difficult to obtain a fiber PBS with sufficient quality for some wavelength bands.

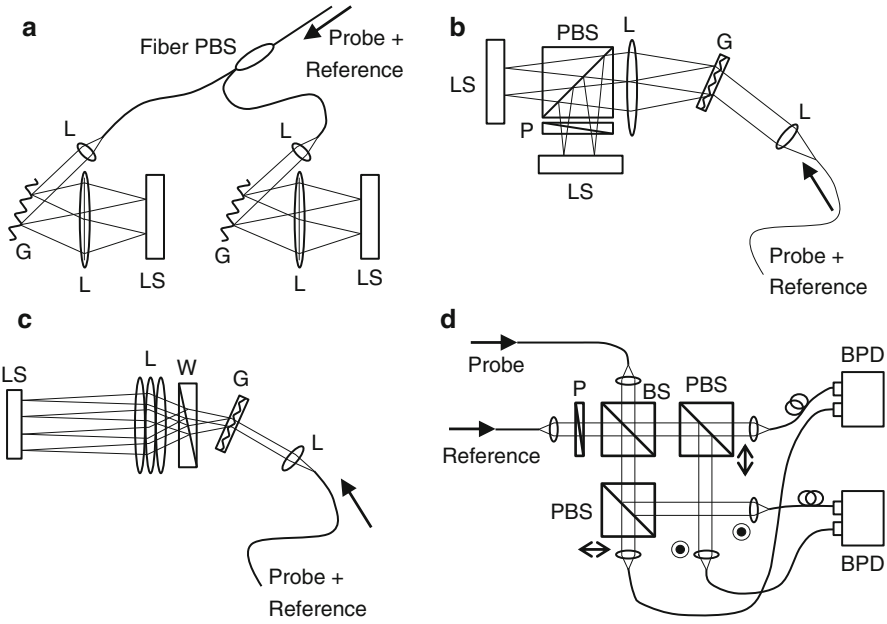

Fig. 35.4 Examples of polarization-diversity spectrometers (**a**–**c**) and polarization-diversity balanced detection unit (**d**). *L* lenses, *G* grating, *LS* line sensors grating, *PBS* polarizing beam splitter, *P* polarizer, *W* Wollaston prism, *BS* non-polarizing beam splitter, and *BPD* balanced photodetector

Figure 35.4b is a polarization-diversity spectrometer using only one diffraction grating [26, 40]. The vertical and horizontal polarization components are resolved into its spectral components by a single diffraction grating and then split into two polarization components by a PBS. Two polarization components are then detected by two line sensors.

The purity of polarization of a reflected beam by PBS is relatively low. To improve the purity and the accuracy of Jones vector measurement, a polarizer after reflection, a so-called cleanup polarizer, can be utilized. However, as discussed in Sect. 35.5.2, this relatively low purity of polarization and its resulting polarization cross talk would have no significant effect on the final result. As a result, the cleanup polarizer is optional.

This PS spectrometer is relatively easy to design, but it sometimes requires a large PBS to cover the whole area of the line sensors.

Figure 35.4c shows one of the sophisticated designs of polarization-diversity spectrometer using only one line sensor that was originally developed for Stokes parameter-based PS-OCT [27] and Hee-Hitzenberger method [47]. In this scheme, two polarization components are displaced relative to each other by a Wollaston prism, and two spectra corresponding to the two polarization components illuminate different areas of a single line sensor. This scheme requires fewer optical

components than the other schemes and can be compact. On the other hand, it requires more careful optical design to suppress aberrations to in turn obtain high spectral resolutions for both of the polarization components.

Figure 35.4d shows a balanced polarization-diversity detection unit for SS-OCT [41, 48]. The probe and reference beams are introduced into this detection unit through two independent fiber ports. Two beams are combined by a non-polarized beam splitter (BS) and then decomposed into its polarization components by two PBSs. Each of polarization components is then detected by two balanced photodetectors. Similar to the configuration shown in Fig. 35.4b, the purity of the polarization can be improved using cleanup polarizers, although this is optional. The polarizer at the input port of the reference beam is to balance the optical powers of the reference beam between two detection channels.

35.3.2.2 Principle of OCT-Based Jones Vector Measurement

To determine the Jones vector of the backscattered probe beam, the amplitudes and the relative phase of the electric fields of the horizontal and vertical polarization components should be measured. In Jones matrix OCT, this complex measurement is achieved by using an interferometric detection scheme through the polarization-diversity detection unit.

By annotating the Jones vectors of the backscattered probe beam and the reference beam at the polarization-diversity detection unit as $\vec{E}_{out}$ and $\vec{E}_{ref}$, the interference signal becomes

$$\left\|\vec{E}_{out}+\vec{E}_{ref}\right\|^2=\left\|\vec{E}_{out}\right\|^2+\left\|\vec{E}_{ref}\right\|^2+\vec{E}_{out}\circ\vec{E}^*_{ref}+\vec{E}^*_{out}\circ\vec{E}_{ref} \tag{35.17}$$

where $\|\|^2$ and $\circ$ denote the absolute-square and multiplication operations for each entry of the vector, respectively. The polarization-diversity OCT signal corresponds to the third term of the right-hand side of this equation:

$$\vec{E}_{out}\circ\vec{E}^*_{ref}=\begin{bmatrix}E^{(H)}_{out}E^{(H)^*}_{ref}\\E^{(V)}_{out}E^{(V)^*}_{ref}\end{bmatrix} \tag{35.18}$$

where the superscripts of (H) and (V) denote the horizontal and vertical components of the Jones vectors, respectively. The horizontal and vertical components of Eq. 35.17 are detected by two detectors, and the component described by Eq. 35.18 is selected through OCT image reconstruction. By configuring the optical setup to $E^{(H)}_{ref}=E^{(V)}_{ref}$, i.e., make the reference beam linear with 45° polarization, the polarization-diversity OCT signal becomes

$$\vec{E}_{out}\circ\vec{E}^*_{ref}\propto\begin{bmatrix}E^{(H)}_{out}\\E^{(V)}_{out}\end{bmatrix} \tag{35.19}$$

and the Jones vector of the backscattered probe beam is given.

In a practical optical setup, it is hard to accurately achieve the abovementioned condition of $E_{ref}^{(H)} = E_{ref}^{(V)}$. However, this condition is not required in practice as will be discussed in Sect. 35.5.1.

35.4 Implementation Examples

35.4.1 Schematics

To conclude the presentation of the principle and implementation of Jones matrix OCT, an example of one of the Jones matrix OCT systems is described in this section. The system is a swept-source Jones matrix OCT using the delay-based polarization multiplexing unit, which is similar to the systems described by Lim et al. [43] and Baumann et al. [44].

The schematic of the Jones matrix OCT is depicted in Fig. 35.5. The light source is a wavelength-scanning laser with a center wavelength of 1.06 μm, a scan range of 120 nm, and a −3-dB bandwidth of 100 nm (AXSUN Technologies Inc., NJ, USA). The scanning frequency of the light source is 100 kHz, and it results in an A-line rate of the Jones matrix OCT of 100,000 A-lines/s. The probe arm consists of a delay-based polarization multiplexer. This multiplexer gives a different delay to $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$, so OCT signals corresponding to these incident polarization states

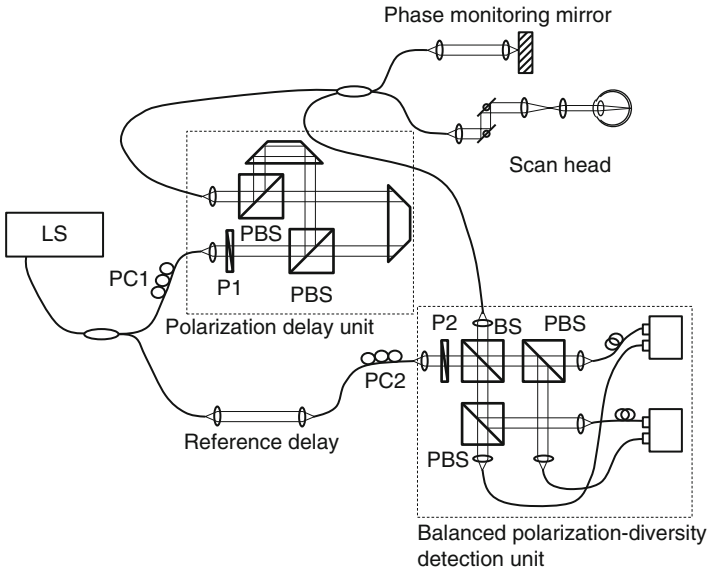

Fig. 35.5 Example of an optical scheme of Jones matrix OCT, which is based on a delay-based polarization multiplexer and a balanced polarization-diversity detection unit. *PC* polarization controller, *P* polarizer, and *PBS* polarizing beam splitter, *BS* non-polarizing beam splitter

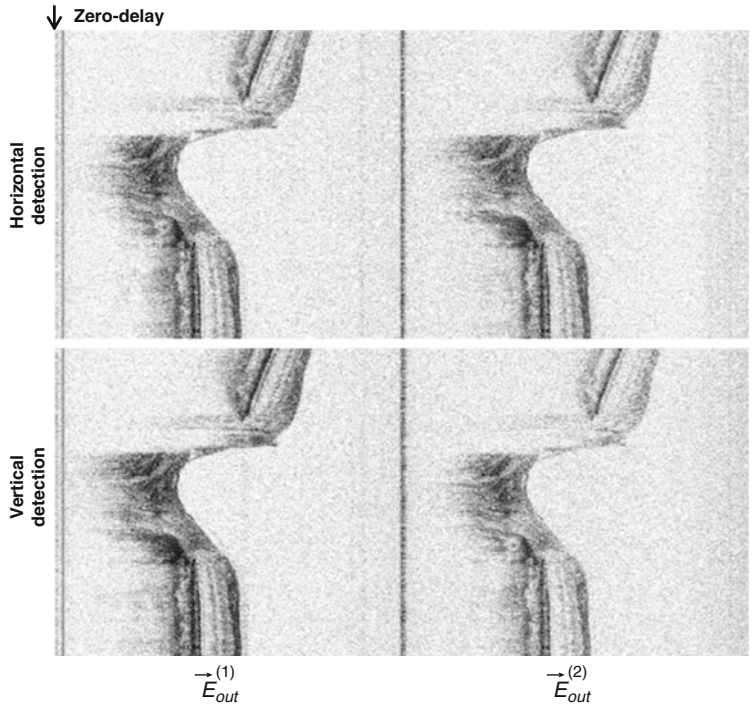

Fig. 35.6 Raw OCT images measured by the PD detection unit. The *upper image* is of horizontal detector, and the *lower image* is of vertical detector. Each image consists of two OCT images which correspond to the first and the second incident polarization states

appear at different depths in the OCT image. Since $\vec{E}_{in}^{(1)}$ and $\vec{E}_{in}^{(2)}$ signals appear at different depths, these two signals have different phase offsets. However, this difference in phase offset does not affect the Jones matrix measurement owing to the properties of Eqs. 35.8 and 35.9.

The OCT signals are detected by a balanced polarization-diversity detection unit that consists of a BS, two PBSs, and two InGaAs balanced photodetectors (350 MHz, PDB430C, Thorlabs Inc., NJ, USA).

The detected signals are digitized by a data acquisition board (DAQ, ATS9350, Alazar Tech, QC, Canada) with a sampling speed of 500 MHz after passing a high-pass filter (1.5 MHz Chebyshev) and a low-pass (250 MHz Chebyshev) filter.

Two of the spectra detected by two detection channels of the DAQ are resampled into the k-domain and Fourier transformed to obtain depth-resolved OCT signals. As shown in Fig. 35.6, each OCT image corresponding to each detection channel is composed of two OCT cross sections at two different depths that correspond to the two incident polarization states. Since each of the two detection channels provides two OCT signals, four OCT signals are acquired simultaneously. These four OCTs are the entries of the output Jones vector matrix $\mathbf{E}_{out}(x, y, z)$ discussed in Sect. 35.2.2.

In this particular implementation, the spectral sampling spacing after the rescaling was 0.402 cm^{-1}, and it results in a depth measurement range of 2.94 mm for a single incident polarization state. The depth resolution was 8.5 μm in air.

A phase monitoring mirror is utilized to stabilize the phase of the SS-OCT signal, which is particularly important to phase-sensitive OCT detection such as Doppler OCT [49, 50, 51].

The surface of the sample is segmented and $\mathbf{E}_{out}$ at the sample surface is obtained at each transversal position. This $\mathbf{E}_{out}$ is then averaged over x or (x, y) by complex Jones matrix averaging methods (described in Sect. 35.5.4) to have a single constant $\mathbf{E}_{out}(z_{surf})$. This $\mathbf{E}_{out}(z_{surf})$ is then utilized with Eqs. 35.9 to obtain a similar matrix to the round-trip Jones matrix of the sample. Finally, the methods described in Sect. 35.2.3 provide a phase-retardation image and a DOPU image.

The intensity OCT can be created by several means such as averaging squared intensities of the entries of the Jones matrix. In this particular example, the maximum intensity composite of all entries of the similar matrix is utilized as the intensity OCT.

35.4.2 Polarization Alignment

This Jones matrix OCT uses three polarization controllers (PCs) and two polarizers (POLs) that should be aligned properly.

POL1 and PC1 are used to balance the powers of the two incident polarization states. Since, in principle, the incident polarization states including its power and phase offset do not affect the polarization measurement as suggested by Eq. 35.8, the alignment of PC1 and POL1 fundamentally does not affect the Jones matrix measurement. However, under a constant amount of probe light power, equal signal-to-noise ratios (SNRs) of the OCT signals of the two polarization states would provide the robustness for phase-retardation measurement [45]. Hence, one possible optimal alignment of POL1 and PC1 is to have the same signal levels of two OCT signals associated with two incident polarization states that are obtained with a non-birefringent sample, such as a mirror. For this alignment, the OCT signals of each polarization states appearing at different depths are monitored; the orientation of POL1 is properly aligned to have an equal signal power to the two signals. Then, PC1 is aligned to have the maximum OCT signal strength, i.e., the maximum probe power. Once this alignment is done, realignment is not requires as far as the fiber birefringence between the light source and the delay-based polarization multiplexing unit is stable. Hence, frequent alignment is not required for POL1 and PC1.

POL2 and PC2 are to have optimal balance between the horizontal and vertical polarization components of the reference beam for the horizontal and vertical detection channels. POL2 is aligned to have the identical optical power to the transmitted and reflected light of PBS by monitoring the optical power with an optical power meter. PC2 is then aligned to optimize the reference power by which the sensitivity of OCT is maximized. The alignment of POL2 is associated with the condition of $E_{ref}^{(H)} = E_{ref}^{(V)}$, which was utilized to derive Eq. 35.19. In addition, as

will be discussed in Sect. 35.5.1, this condition is loosened for practical measurements (see Sect. 35.5.1), and hence, the required accuracy of this alignment is relatively low. The realignment of POL2 and PC2 is not required as far as the output power of the light source and the fiber birefringence of the source arm and the reference arm are stable.

PC3 is then aligned to have roughly equal OCT signals for two incident polarization states. PC3 only alters the birefringence of the collection path, $\mathbf{J}_{out}$, without harming its unitarity. As suggested by Eq. 35.9, $\mathbf{J}_{out}$ and hence PC3 have no fundamental influence to determine the polarization properties of the sample. However, when the noise property of phase-retardation measurements was taken into account, equally distributed OCT signals for two incident polarization states would provide high robustness for phase-retardation measurements [45]. The signal ratio between the two incident polarization states is not only affected by $\mathbf{J}_{out}$ but also by the birefringence of the optic media located before the sample, such as the cornea for retinal measurements, and the birefringence of the optic media varies among subjects. It is therefore recommended to realign PC3 for each measurement session.

35.4.3 In Vivo Measurement of the Posterior Eye

Examples of in vivo polarization-sensitive measurement of the human optic nerve head are shown in Fig. 35.7. The intensity image (Fig. 35.7a) is created as the maximum intensity composite of four entries of $\mathbf{E}_{out}$. The pore structure of a lamina cribrosa is visible at the deep region as indicated by an arrow.

Figure 35.7b is a tomography of double-path cumulative phase retardation. Rapid alteration of the phase retardation along the depth is observed at the myopic conus as indicated by a circle. This rapid alteration is an indicator of strong birefringence.

Figure 35.7c is a DOPU image, which was calculated from $\mathbf{E}_{out}$ by assuming the virtual incident beam of $\mathbf{E}_{out}\left(z_{surf}\right)\left[\begin{array}{cc}1 & 0\end{array}\right]^{T}$. Namely, the DOPU image is obtained only from the left two images of Fig. 35.6. In this image, moderately low DOPU value (yellow to green) is observed at the retinal pigment epithelium and lower part of the choroid. It would indicate the existence of melanin at these regions [39].

35.5 Advanced Issues

35.5.1 The Effect of Phase and Amplitude Unbalance of the Reference Beam

In the practical implementation of Jones OCT, it is sometimes hard to exactly balance the phase and amplitude of two reference beams for polarization-diversity detection. As indicated by Eq. 35.18, the unbalance between the reference beams will result in a failure to obtain accurate measurements of the Jones vector of the probe beam. And hence in the previous section, it had been assumed to be balanced as $E_{ref}^{(H)} = E_{ref}^{(V)}$.

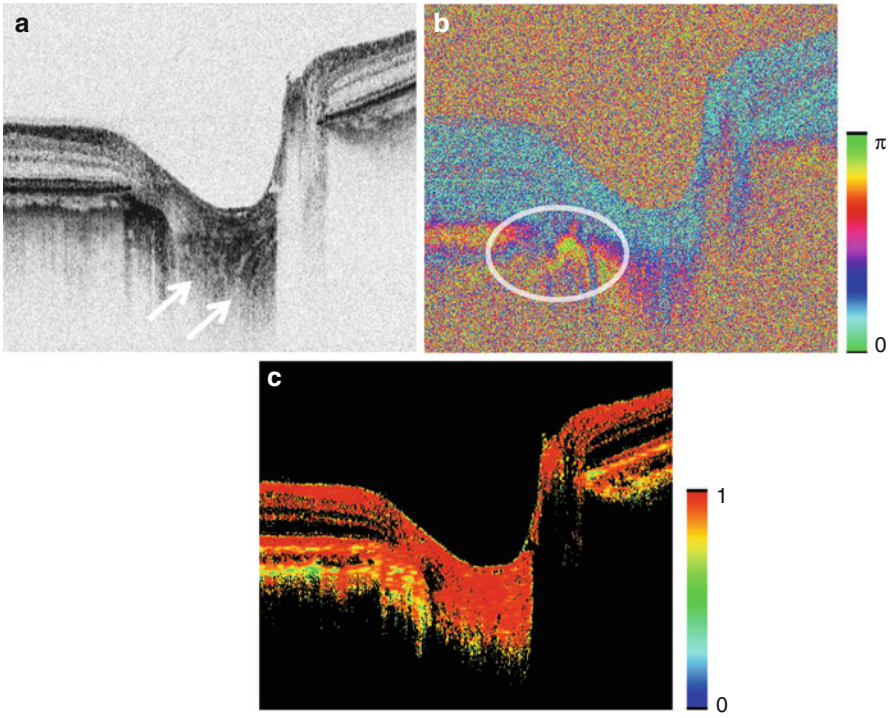

Fig. 35.7 Examples of tomography of an in vivo human optic nerve head. (**a**) Intensity images created as a maximum intensity composite of four elements of $\mathbf{E}_{out}$, (**b**) phase-retardation image, and (**c**) DOPU image

However, in practice, the extended principle of Jones matrix OCT, described in Sect. 35.2.2, provides correct polarization properties of the sample even without this condition of $E_{ref}^{(H)} = E_{ref}^{(V)}$. The detailed reason for this robustness is described below.

By using a complex constant $\eta \equiv E_{ref}^{(V)*}/E_{ref}^{(H)*}$, the measured Jones vector described by Eq. 35.18 becomes

$$\vec{E}_{out} \circ \vec{E}_{ref}^{*} = E_{ref}^{(H)^*} \begin{bmatrix} E_{out}^{(H)} \\ \eta E_{out}^{(V)} \end{bmatrix}. \tag{35.20}$$

The reference unbalanced Jones vector matrix obtained by this reference unbalanced measurement is

$$\mathbf{E}'_{out} = E_{ref}^{(H)^*} \begin{bmatrix} E_{out}^{(1)\,(H)} & E_{out}^{(2)\,(H)} \\ \eta E_{out}^{(1)\,(V)} & \eta E_{out}^{(2)\,(V)} \end{bmatrix} \tag{35.21}$$

where the superscripts of (35.1) and (35.2), respectively, indicate the first and second incident polarization states. By ignoring the global constant $E_{ref}^{(H)*}$ and by decomposing $\mathbf{E}'_{out}$ into a correct Jones vector matrix of the backscattered probe $\mathbf{E}_{out}$ and a matrix representing the reference unbalance $\boldsymbol{\eta}$, Eq. 35.21 becomes

$$\mathbf{E}'_{out} = \boldsymbol{\eta}\mathbf{E}_{out} \tag{35.22}$$

with

$$\begin{aligned} \boldsymbol{\eta} &= \begin{bmatrix} 1 & 0 \\ 0 & \eta \end{bmatrix} \\ \mathbf{E}_{out} &= \begin{bmatrix} E_{out}^{(1)(H)} & E_{out}^{(2)(H)} \\ E_{out}^{(1)(V)} & E_{out}^{(2)(V)} \end{bmatrix} = \begin{bmatrix} \vec{E}_{out}^{(1)} & \vec{E}_{out}^{(2)} \end{bmatrix}. \end{aligned} \tag{35.23}$$

This $\mathbf{E}'_{out}$ is a Jones vector matrix measured by a polarization-diversity detection unit with an unbalanced reference beam, while $\mathbf{E}_{out}$ is that measured with an accurately adjusted reference beam, which is identical to that of Sect. 35.2.2.

It should be recalled that since $\mathbf{E}_{out}$ and $\mathbf{E}'_{out}$ are obtained through OCT measurement, they are in practice the functions of space. By denoting $\mathbf{E}'_{out}(z)$ as a Jones vector matrix measured at a particular point of interest and $\mathbf{E}'_{out}(z_{surf})$ as measured at the surface of the sample, a similar calculation with Eq. 35.9 is defined as

$$\mathbf{E}'_{out}(z)\,\mathbf{E}'^{-1}_{out}(z_{surf}) = \boldsymbol{\eta}\mathbf{E}_{out}(z)\mathbf{E}^{-1}_{out}(z_{surf})\boldsymbol{\eta}^{-1} = \boldsymbol{\eta}\mathbf{J}_{out}\mathbf{J}_s^T(z)\mathbf{J}_s(z)\mathbf{J}^{-1}_{out}\boldsymbol{\eta}^{-1}. \tag{35.24}$$

As evidently shown in this equation, $\mathbf{E}'_{out}(z)\,\mathbf{E}'^{-1}_{out}(z_{surf})$ is a similar matrix of the round-trip Jones matrix of the sample. Hence, the principle described in Sect. 35.2.2 provides correct polarization properties of the sample by also using $\mathbf{E}'_{out}$ as an alternative to $\mathbf{E}_{out}$.

35.5.2 Polarization Cross Talk in the Polarization-Diversity Detection Unit

Some of the polarization-diversity detection units use PBS to split the horizontal and vertical polarization components. In general, the polarization purity of a reflection beam of PBS is low. This low purity would result in cross talk between two polarization detection channels.

One of the solutions to this issue is to use a cleanup polarizer as described in Sect. 35.3.2. However, a cleanup polarizer is only optionally required because of the intrinsic robustness of Jones matrix OCT to the polarization cross talk.

By using cross-talk coefficients of χ_1 and χ_2, the measured Jones vector matrix $\mathbf{E}''_{out}$ is expressed as

$$\mathbf{E}''_{out} = \begin{bmatrix} E^{(1)(H)}_{out} + \chi_1 E^{(1)(V)}_{out} & E^{(2)(H)}_{out} + \chi_1 E^{(2)(V)}_{out} \\ E^{(1)(V)}_{out} + \chi_2 E^{(1)(H)}_{out} & E^{(2)(V)}_{out} + \chi_2 E^{(2)(H)}_{out} \end{bmatrix}. \tag{35.25}$$

By considering that $\mathbf{E}''_{out}$ is actually a function of space and by using a matrix representation of the cross-talk coefficients of $\boldsymbol{\chi} = [\,1 \quad \chi_1;\, \chi_2 \quad 1\,]$, Eq. 35.25 is rewritten as

$$\mathbf{E}''_{out}(z) = \boldsymbol{\chi}\mathbf{E}_{out}(z) \tag{35.26}$$

where $\mathbf{E}_{out}(z)$ is an ideal Jones vector matrix of the backscattered probe beam identical to those in Sects. 35.2.2 and 35.5.1. By using $\mathbf{E}''_{out}(z)$ and $\mathbf{E}''_{out}(z_{surf})$, a similar calculation with Eq. 35.9 becomes

Evidently, $\mathbf{E}''_{out}(z)\,\mathbf{E}''^{-1}_{out}(z_{surf})$ is also a similar matrix to the round-trip Jones matrix of the sample $\mathbf{J}^T_s(z)\mathbf{J}_s$. Thus, the Jones matrix OCT method provides the correct polarization parameters of the sample even with the polarization cross talk of the polarization-diversity detection unit.

35.5.3 Unbalance in the OCT Signals of Two Incident Polarization States

The evenness of amplitudes and phases of OCT signals between two incident polarization states is corrupted for several reasons. For example, in a delay-based multiplexing scheme, depth-dependent signal decay and phase offset of OCT results in uneven amplitude and phase, respectively. Jones matrix OCT also has intrinsic robustness to this unevenness between OCTs of two incident polarization states.

By considering this unevenness, a measured Jones vector matrix becomes

$$\mathbf{E}'''_{out} = \begin{bmatrix} E^{(1)(H)}_{out} & \alpha E^{(2)(H)}_{out} \\ E^{(1)(V)}_{out} & \alpha E^{(2)(H)}_{out} \end{bmatrix} \tag{35.27}$$

where α is a complex constant representing the unauthorized difference in magnification of amplitude and the phase between OCTs of two incident polarization states. By using a matrix $\boldsymbol{\alpha} \equiv [\,1 \quad 0;\, 0 \quad \alpha\,]$ and an ideal Jones vector matrix of the backscattered probe beam $\mathbf{E}_{out}(z)$, $\mathbf{E}'''_{out}$ is decomposed as

$$\mathbf{E}'''_{out} = \mathbf{E}_{out}\boldsymbol{\alpha}. \tag{35.28}$$

By using $\mathbf{E}'''_{out}(z)$ and $\mathbf{E}'''_{out}(z_{surf})$, a similar calculation with Eq. 35.9 provides

$$\mathbf{E}'''_{out}(z)\mathbf{E}'''^{-1}_{out}(z_{surf}) = \mathbf{E}_{out}(z)\boldsymbol{\alpha}\boldsymbol{\alpha}^{-1}\mathbf{E}^{-1}_{out}(z_{surf}) = \mathbf{E}_{out}(z)\mathbf{E}^{-1}_{out}(z_{surf}). \tag{35.29}$$

As evidently seen in this equation, unevenness between OCTs of two incident polarization states is canceled and does not affect the final results.

By combining the discussions in Sects. 35.5.1 through 35.5.3, practically measured Jones matrix vector would be expressed as $\hat{\mathbf{E}}_{out}(z) = \boldsymbol{\chi}\boldsymbol{\eta}\mathbf{E}_{out}(z)\boldsymbol{\alpha}$, and Eq. 35.9 is altered to

$$\hat{\mathbf{E}}_{out}(z)\hat{\mathbf{E}}^{-1}_{out}(z_{surf}) = \boldsymbol{\chi}\boldsymbol{\eta}\mathbf{J}_{out}\mathbf{J}^{T}_{s}(z)\mathbf{J}_{s}(z)\mathbf{J}^{-1}_{out}\boldsymbol{\eta}^{-1}\boldsymbol{\chi}^{-1}. \tag{35.30}$$

This matrix is still similar to the round-trip Jones matrix of the sample. Hence, cross talk in a polarization-diversity detection unit, unbalance of the reference beams, and unevenness of OCTs of two incident polarization states do not affect the final result.

35.5.4 Jones Matrix/Jones Vector Matrix Averaging

Jones matrix OCT relies on the measured value of $\mathbf{E}_{out}(z_{surf})$. Since the error of phase-retardation measurement is severely affected by the SNR of $\mathbf{E}_{out}(z_{surf})$ [45], it would be good to enhance the SNR by averaging several $\mathbf{E}_{out}(z_{surf})$ obtained at several transversal positions. However, $\mathbf{E}_{out}(z_{surf})$ obtained at each transversal position have random global phase due to the interference among scatters in a coherence volume. So simple complex averaging of $\mathbf{E}_{out}(z_{surf})$ is not be utilized because it cancels not only the noise but also the OCT signal.

A solution for this issue is Jones matrix/Jones vector matrix averaging method [7]. In this matrix averaging method, at first, a relative global phase of two complex 2×2 matrices is conjectured as

$$\Delta\varphi^{(2,1)} \equiv \mathrm{Arg}\left[\sum_{i=1}^{2}\sum_{j=1}^{2}\frac{1}{\left|M^{(1)}_{i,j}\right|^{-1} + \left|M^{(2)}_{i,j}\right|^{-1}}\exp i\left(\varphi^{(2)}_{i,j} - \varphi^{(1)}_{\mathrm{i,j}}\right)\right] \tag{35.31}$$

where the complex matrices $\mathbf{M}^{(1)}$ and $\mathbf{M}^{(2)}$ are

$$\mathbf{M}^{(1),(2)} = \begin{bmatrix} \left|M^{(1),(2)}_{1,1}\right|\exp\left(i\varphi^{(1),(2)}_{1,1}\right) & \left|M^{(1),(2)}_{1,2}\right|\exp\left(i\varphi^{(1),(2)}_{1,2}\right) \\ \left|M^{(1),(2)}_{2,1}\right|\exp\left(i\varphi^{(1),(2)}_{2,1}\right) & \left|M^{(1),(2)}_{2,2}\right|\exp\left(i\varphi^{(1),(2)}_{2,2}\right) \end{bmatrix} \tag{35.32}$$

and $\Delta\varphi^{(2,1)}$ is the relative global phase of $\mathbf{M}^{(2)}$ respect to $\mathbf{M}^{(1)}$.

The Jones matrix/Jones vector matrix averaging is then defined as complex averaging of complex matrices in which the global phase of each matrix is defined by Eq. 35.32 in respect to a particular reference matrix and canceled out before performing the complex averaging.

The utility of this matrix averaging is not only limited to the averaging $\mathbf{E}_{out}(z_{surf})$. The signal-to-noise ratio of the measured Jones matrix of the sample can also be enhanced by averaging several Jones matrices measured at a small region of interest, i.e., averaging kernel.

35.6 Conclusion

The principle and implementation of Jones matrix OCT was presented in this chapter, and the high intrinsic robustness of this technique was discussed. Owing to this robustness, the requirement for calibration of Jones matrix measurement is very low. Thus, Jones matrix OCT would provide a robust and stable platform to determine the polarization properties of biological samples.

This chapter was organized to provide an insight into and comprehensive overview of Jones matrix OCT, and hence, a more detailed description of practical implementations would be not enough. To better understand the implementation details of Jones matrix OCT, the reader is encouraged to explore the literature, for example, Refs. [7, 31, 39–43, 45, 46, 50]. This chapter hopefully provides the reader with the foundation necessary to achieve a deep understanding of Jones matrix OCT presented in these individual research articles.

36.1 Introduction

Optical coherence tomography provides cross-sectional images of tissues at micrometer scale resolution up to several millimeters deep. Within these volumes information on the physiological function of tissues can be derived, such as flow and perfusion as discussed in ▶ Chap. 21, "Swept Light Sources". Assessment of nanoscale organization of tissue, assessed through elastic light scattering properties, is demonstrated in ▶ Chap. 27, "Digital Holoscopy" and will be elaborated below. Given the large optical bandwidths involved in low coherence interferometry (LCI), the development of spectroscopic LCI modalities seems almost straightforward. In this chapter, the combination of spatial and spectroscopic information from these low-coherent signals is discussed. With spectroscopic OCT (SOCT) [1–9] and low-coherence spectroscopy (LCS) [10–13], localized absorption and/or (back)scattering spectra of tissue can be measured. The spectroscopic content of the

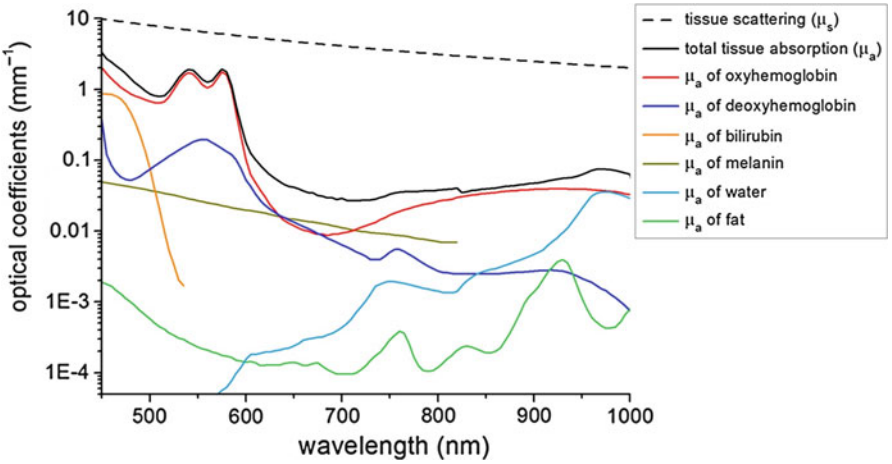

Fig. 36.1 Absorption spectra of common chromophores in human tissue, total tissue absorption, and tissue scattering for biologically normal concentrations (Data obtained from Ref [44]). Scattering is assumed to follow power-law dependence on wavelength $\mu_s = a\lambda^{-b}$

SOCT signal can be used for contrast enhancement, but our focus will be on quantification of depth-resolved spectra to retrieve the concentration of tissue chromophores (e.g., hemoglobin and bilirubin) and characterize tissue light scattering. One promising application is measurement of hemoglobin and bilirubin levels to monitor anemia and jaundice in neonates, which is currently only possible by frequent, invasive heel pricks [14]. Figure 36.1 shows the absorption spectra of the most common chromophores in tissue, as well as the general trend of wavelength-dependent scattering.

Roughly, the scattering coefficient μ_s shows an inverse power-law dependence on wavelength $\mu_s = a\lambda^{-b}$, from which the parameters (a,b) depend on the size distribution, concentration, and relative refractive index of the scattering volume elements (e.g., cell membranes, collagen fibers, mitochondria). A light scattering experiment thus provides information on the structural organization of the probed tissue. A demonstration of this paradigm was given by Van der Meer et al. [15] by determining the attenuation coefficient μ_{LCI} (see Sect. 36.2.2, Eq. 36.8) averaged over the bandwidth of an 800 nm OCT system, of cells forced into apoptosis and necrosis. Both apoptosis, programmed cell death, and necrosis, accidental cell death, are processes that are known to follow a cascade of morphological changes at the (sub)cellular level. The experiment shown in Fig. 36.2 demonstrates that, even though OCT does not have sufficient resolution-to directly image processes at the subcellular level, it is still sensitive to the associated morphological changes through changes in light scattering.

A major application of spectroscopic LCI is the quantification of spatially localized hemoglobin concentration and oxygen saturation which, combined with local perfusion measurements, can have significant impact on cancer care.

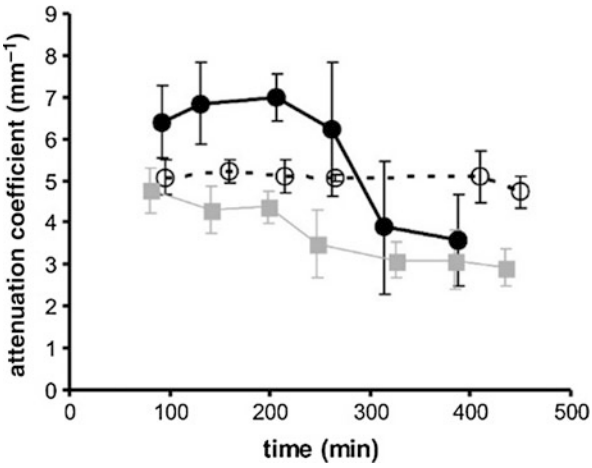

Fig. 36.2 The measured attenuation coefficient for 800 nm light in pelleted human fibroblasts, as a function of time. Time was measured in minutes from the point that the cells forced into necrosis (*filled squares*) or apoptosis (*filled dots*). Untreated control cells show no change in scattering (*open circles*)

A tumor's local oxygen status, specifically hypoxia, is considered one of the "hallmarks of cancer" predicting progression and response to therapy. The potential of spectroscopic LCI may be further enhanced by quantification of changes in tissue morphology during disease progression based on spectrally resolved scattering properties. The potential of this method is illustrated in Fig. 36.3, showing in panel A and B in vivo obtained volume rendering resp. individual B-scans of vulvar intraepithelial neoplasia (VIN), a precursor of cancer. Panel C sketches how the signal decay with depth is quantified though the attenuation coefficient μ_{LCI}, a procedure that is detailed in Sect. 36.2.2. Panel D indicates the potential of discriminating between normal and premalignant tissue using μ_{LCI} [16]. Similar results were obtained discriminating between normal kidney tissue and kidney cancer [17, 18].

Despite this application potential, clinical studies have been reported where the measurement of only one parameter (e.g., the value of μ_{LCI} averaged over the bandwidth of an OCT system) was not sufficient to differentiate between different grades (pathologists' assessment of tumor aggressiveness) of urothelial carcinoma of the bladder [19]. As we discuss in the next sections, spectroscopic LCI provides the possibility of retrieval of not only $\mu_{LCI}(\lambda)$ but also of backscattering coefficients $\mu_b(\lambda)$ which shows large sensitivity to morphology.

This chapter starts with outlining the theory of spectroscopic LCI, describing methods to quantitatively obtain localized spectra. This includes computational and instrumental considerations such as proper correction for point spread functions of the LCI equipment. We then discuss the retrievable optical property spectra, e.g., absorption and scattering spectra that can be derived from these measurements and their interpretation in terms of physiologically relevant tissue characteristics. We conclude by presenting clinical examples of spectroscopic LCI.

(**c**) The decay of the OCT signal versus depth in a region of interest selected from the images of panel (**a**) or (**b**) is determined by fitting a mathematical model of the OCT signal to this data (after careful calibration of the system). (**d**) Results demonstrating the capability of differentiating between normal and VIN tissues by the attenuation coefficient μ_{LCI} [16]

36.2 Theory

The general form of the detected LCI interferogram is written as:

$$i_D = |E_s + E_R|^2 = |E_s|^2 + |E_R|^2 + 2\{E_s E_R^* \cos(k2d)\} \tag{36.1}$$

where E_S and E_R are the fields returning from sample and reference arm, respectively, with wave number $k = 2\pi/\lambda$ with λ the wavelength. Further, $2d$ is the optical path length difference so that d is the assigned depth location in the tissue. Wave number k and optical path length difference $2d$ form the fundamental Fourier pair in LCI data analysis. Classic time domain detection receives all wavelengths at once, while modulating $2d$ using a moving reference arm (effectively integrating Eq. 36.1 over k), whereas in Fourier domain OCT, the signal is obtained as function of k, integrating over $2d$. The goal of spectroscopic LCI modalities is to obtain information in k and d domains simultaneously, with high resolution in both domains.

Both 2d-domain and k-domain descriptions of the OCT signal i_D are equivalent and are related by Fourier transformation:

$$i_D(2d) = |\Im\{i_D(k)\}| \tag{36.2}$$

where $\mathfrak{I}$ denotes the Fourier transform. Since the wave number k is directly related to wavelength λ, wavelength dependent spectra $i_D(\lambda)$ can be obtained from the backscattered LCI signal. We drop the factor "2" going onward and use the concepts "spatial domain" and "depth domain" interchangeably.

36.2.1 Localized Spectroscopic Information

Time-frequency analysis – Due to wavelength-dependent scattering and absorption by the different structures in tissue, the spectral content of the OCT signal changes with depth. Therefore direct application of the Fourier transform on either spatial or spectral domain detected signal Eq. 36.2 is not appropriate to obtain localized spectroscopic information because the depth resp. wave number varying information will be lost. Instead, spectral analysis methods, conventionally called time-frequency (TF) [20] analysis must be used (or, for the present context, depth-wavelength analysis). In most studies, the preferred method has been to use short-time Fourier transforms (STFT):

$$STFT(k, d; w) = \int_{-\infty}^{\infty} i_D(d')w(d - d'; \Delta d)e^{-ikd'}d(d') \tag{36.3}$$

where w is an analysis window confined in space around d with spatial width Δd, for example, a Gaussian function. The multiplication with a relatively short window effectively suppresses the signal outside the analysis point $d \pm \Delta d$. Physically, the STFT can be considered as the result of passing a signal through an array of band-pass filters with linearly increasing center frequency and constant bandwidth which is inversely proportional to Δd. Thus, there is an inherent trade-off between spectral and spatial resolution. A window with short spatial width Δd will localize the signal well in space but will have reduced k-resolution; conversely a signal with long width will be less well localized in space with the benefit of increased spectral resolution. For a Gaussian window, a spatial domain width Δd will yield a spectral resolution of $\Delta k = 1/(2\Delta d)$.

The wavelet transform was introduced to partially overcome this trade-off by adjusting the window size to the frequency being considered. The basic difference between the wavelet transform and the STFT is that the duration and the bandwidth of the wavelet are both changed (while shape remains the same). Physically, the wavelet transform can also be seen as an array of band-pass filters with constant relative bandwidth with respect to the center frequency. In contrast with the STFT, which uses a single analysis window, the wavelet transform uses short windows at high frequencies and long windows at low frequencies. Again, there is a trade-off between time and frequency resolutions. However, these resolutions depend on frequency: the frequency (resp. time) resolution becomes poorer (resp. better) with increasing analysis frequency.

The wavelet transform projects a signal on a family of functions deduced from a (complex) window function w, the "mother wavelet," by translations and dilations:

$$WT(\kappa, d; w) = \int_{-\infty}^{\infty} i_D(d') w\left(\frac{d - d'}{\kappa}\right) d(d') \tag{36.4}$$

The variable κ is the scale factor, dilating ($|\kappa| > 1$) or compressing ($|\kappa| < 1$) the wavelet w. When mother wavelets are used that are well localized around a wave number k_0, then a time-frequency interpretation is possible through $k = k_0/\kappa$.

Bilinear TF distributions do not suffer from the resolution trade-off between both domains. The most important member of this class is the Wigner distribution:

$$WD(k, d) = \int i_D(d + d') i_D{}^*(d - d') \exp(ikd') d(d') \tag{36.5}$$

The Wigner distribution is the Fourier transform of an autocorrelation measure of the signal $i_D(d)$. Whereas in conventional autocorrelation computations, the result is a function of lag only, here the functional dependence on d is maintained. In concordance with the Wiener-Khinchine theorem, the straightforward interpretation of the WD is as a localized power spectral density of the detector signal.

The drawback of the WD lies in its quadratic nature: whereas the STFT of two signals X and Y yields $STFT_x(k, d) + STFT_y(k, d)$, the WD will contain interference terms, e.g., $WD_{x+y}(k, d) = WD_x(k, d) + WD_y(k, d) + 2\mathrm{Re}[WD_{x,y}(k, d)]$. Even though the interference term contains information on the separation of X and Y (e.g., in space), when it overlaps with the signal terms, interpretation of the WD becomes challenging. In practice (like with the STFT), the signal is analyzed using a window w. This pseudo-WD effectively smoothens the time-frequency distribution, suppressing the interference terms. However, a short smoothing window will be narrow in time and wide in frequency, leading to a good time resolution but bad frequency resolution and vice versa. It is possible to add a degree of freedom by considering a separable smoothing function $\Pi(k, d) = w_1(k, \Delta k) w_2(d, \Delta d)$ that allows independent control in both time and frequency of the smoothing applied to the WVD; Δk and Δd denote the width of the window functions in the spectral and spatial domain, respectively. The STFT compromise between time and frequency resolution is now replaced by a compromise between the joint time-frequency resolution and the level of suppression of the interference terms. Robles et al. showed that the pseudo-WD can also be obtained by STFT analysis using two k-domain window sizes $\Delta k_1 >> \Delta k_2$. The result $STFT_1(k, d) \times STFT_2(k, d)$ is mathematically equivalent to a pseudo-WD with window widths of $W_1(k, \Delta k = k_2/2)$ in the spectral domain and window $W_2(d, \Delta d = 1/(2\ k_1))$ in the spatial domain. As for the WD, any remaining interference terms may carry information, for example, on average spatial scatterer separation [7–9].

Xu et al. [21] also define a third class of time-frequency distributions, based on the presumed known spectral profiles of the laser source and the sample. This allows for fitting the obtained OCT signal to this model equation, thereby retrieving the sought spectral properties. In practice, there may exist an optimal time-frequency analysis depending on the application. For example, the STFT is completely free of artifacts such as introduced by the quadratic analysis of the energy distributions. The poor depth resolution resulting from the requirement of a high spectral resolution may not be a problem at all when analyzing relatively large tissue structures, where a spatially averaged spectrum over the entire tissue structure is required. For example, a spectral resolution of 6 nm in LCS corresponds to a depth resolution of 22 μm, which is sufficient to measure hemoglobin concentrations from optical property spectra in distinct regions of the epidermis and the dermis [12] (see Sect. 36.3.2).

Hardware-based approaches and considerations – For proper quantification of local spectra, signal attenuating factors caused by the LCI system need to be accounted for. The two dominating factors are the confocal point spread function (e.g., loss of sensitivity away from the focal region) and the sensitivity roll-off in depth for spectral domain LCI, caused by the finite resolution of the spectrometer (or the finite instantaneous bandwidth of the swept source).

Confocal point spread function – The confocal point spread function (PSF) for a single-mode fiber-based OCT system was derived in [22] and validated experimentally in [23]. It can be directly imaged using OCT on a highly diluted (e.g., negligible scattering) sample.

An example of this procedure is shown in Fig. 36.4 for LCS, in a weakly scattering medium (0.038 vol.% of ø198 polystyrene spheres, $\mu_s << 1\ \mathrm{mm}^{-1}$). The PSF is then given by

$$T\left(d_{focus} - d\right) = \frac{\alpha}{\left(\frac{d_{focus}-d}{2Z_R}\right)^2 + 1} \tag{36.6}$$

where α is a scaling factor, d_{focus} is the geometrical position of the focus in the sample, and Z_R is the Rayleigh length of the system (Fig. 36.4b). From Z_R, the beam waist can be computed as $\omega = (Z_R\lambda/2\pi)^{1/2}$, and from that the NA can be derived, using $NA = \sin(\theta) \approx \sin(\lambda/(\pi\ \omega))$. In the preceding definitions, $Z_R\ \omega$ and NA are defined in the medium, e.g., $Z_R = nZ_0$ where Z_0 is the Rayleigh length of the system measured in air and n is the refractive index. Clearly, the PSF is therefore wavelength dependent. When possible the calibration should be performed wavelength resolved (Fig. 36.4).

The confocal PSF can also be exploited to optimize the trade-off between spatial and spectral resolution by restricting the spatial extent of the collected data region. Xu et al. used high-numerical-aperture optics, geometrically restricting the spatial extent of the signal while using long analysis windows to extract high-resolution spectral information [24].

Sensitivity roll-off – SOCT suffers, when using spectral domain detection (▶ Chaps. 5, "Spectral/Fourier Domain Optical Coherence Tomography", ▶ 6, "Complex and Coherence-Noise Free Fourier Domain Optical Coherence

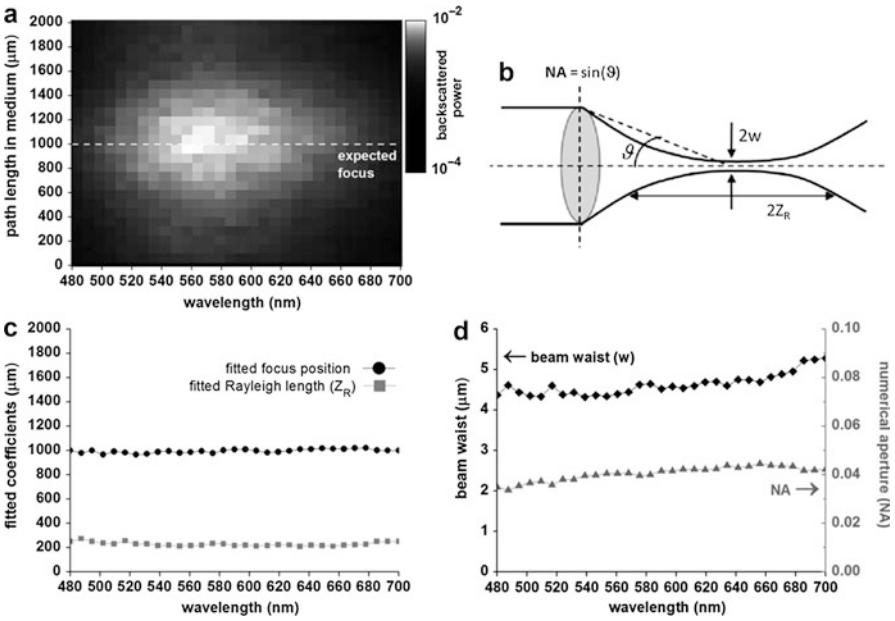

Fig. 36.4 (**a**) Point spread function measurement (*PSF*) on a weakly scattering sample of ø198 spheres (0.038 vol.%), (**b**) schematic illustration of focus geometry, (**c**) fitted focus position (d_{focus}) and Rayleigh length (Z_R) on the measured PSF, (**d**) calculated beam waist (ω) and numerical aperture (*NA*). The parameters Z_R, ω, and NA are defined within the medium ($n = 1.35$)

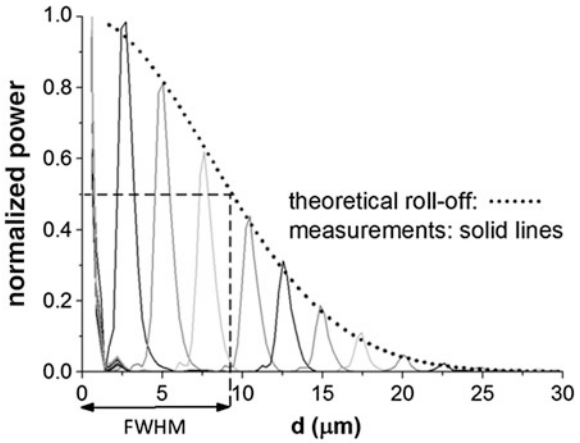

Fig. 36.5 Theoretical and measured sensitivity roll-off of a spectral domain LCS setup using an Ocean Optics USB4000 spectrometer

Tomography", and ▶ 7, "Optical Frequency Domain Imaging"), from the inherent loss of sensitivity with depth due to the finite resolution of the detecting spectrometer (or the finite instantaneous bandwidth/sampling time in swept-source implementations). This causes unwanted signal attenuation that can, similarly to the confocal PSF correction, be accounted for in post-processing.

Here too, the effect can be turned to advantage by limiting the spatial extent of the collected data. Figure 36.5 shows the theoretical and measured roll-off of an LCS system based on a commercially available Ocean Optics USB4000 spectrometer. The "low" spectral resolution of 8 nm of this device results in roll-off function with full width at half maximum of FWHM ~10 μm, so that meaningful interference signals are only collected in a window of approximately 20 μm around the equivalent position of the reference arm in the sample. Details of spectral domain LCS can be found in [13].

36.2.2 Quantitative Determination of Optical Properties

Retrievable properties using spectroscopic low-coherence interferometry – In general, all methods described above result in a wavelength-resolved power spectrum $\boldsymbol{S}$ acquired within a depth window Δd around a depth d in the sample. We will indicate all wavelength-dependent parameters in the remainder of this chapter by a bold-faced character. The following theory assumes validity of the 1st Born approximation, e.g., the illuminating field is much stronger than the scattered field. Under this assumption, the LCI signal is formed by single backscattering, so that the amplitude of $\boldsymbol{S}(d)$ decreases exponentially with measurement depth and the attenuation coefficient $\boldsymbol{\mu_{LCI}}$ of the sample. Hence, we can describe $\boldsymbol{S}(d)$ using Beer's law:

$$\boldsymbol{S}(d) = \boldsymbol{\zeta} \cdot \boldsymbol{\mu}_{b,NA} e^{-\boldsymbol{\mu}_{LCI} 2d} \tag{36.7}$$

The factor 2 in Eq. 36.7 accounts for round-trip attenuation to and from depth d. We note that if the amplitude $\mathbf{E}(d)$ of the LCI signal is considered, rather than backscattered power, this factor drops from Beer's law since $\mathbf{E}(d)$ is proportional to the square root of $\boldsymbol{S}(d)$. We also assume that the influence of the PSF and sensitivity roll-off have been accounted for in preprocessing. The LCI-attenuation coefficient $\boldsymbol{\mu_{LCI}}$ is given by

$$\boldsymbol{\mu_{LCI}} = \boldsymbol{\mu_t} \equiv \boldsymbol{\mu_s} + \boldsymbol{\mu_a} \tag{36.8}$$

with $\boldsymbol{\mu_t}$ the attenuation coefficient, defined as the sum of the scattering coefficient $\boldsymbol{\mu_s}$ and the absorption coefficient $\boldsymbol{\mu_a}$. The latter 3 parameters are formally defined in textbooks, e.g. [25], and are discussed in more detail below. We introduce the LCI-attenuation coefficient $\boldsymbol{\mu_{LCI}}$ (the experimental outcome) because in practice, even when correction for PSF and roll-off is not (optimally) performed, and/or when the first Born approximation does not hold, a single exponential decay model Eq. 36.7 is often suitable for fitting the OCT system [23]. In these cases, the simple relation of Eq. 36.8 breaks down, i.e., $\boldsymbol{\mu_{LCI}} \neq \boldsymbol{\mu_t}$. However, the $\boldsymbol{\mu_a}$ can still be retrieved because absorption takes place *along the photon's path* (regardless of its trajectory), but values for "$\boldsymbol{\mu_s}$" should be interpreted with caution in this case.

The parameters $\boldsymbol{\zeta}$ and $\boldsymbol{\mu_{b,\ NA}}$ determine the amplitude of $\boldsymbol{S}(d)$ at $d = 0$. The system-dependent parameters are defined by $\boldsymbol{\zeta} = \boldsymbol{S_0}\cdot\boldsymbol{T}\cdot 2\Delta d$, with $\boldsymbol{S_0}$ the source power spectrum incident on the sample and $\boldsymbol{T}$ the axial point spread function Eq. 36.6. The backscattering coefficient $\boldsymbol{\mu_{b,\ NA}}$ is a sample-dependent parameter, which is defined as the product of the scattering coefficient $\boldsymbol{\mu_s}$ and the scattering phase function $\boldsymbol{p}(\theta)$, integrated over the numerical aperture ($\boldsymbol{NA}$) of the detection optics:

$$\boldsymbol{\mu_{b,NA}} = \boldsymbol{\mu_s}\cdot 2\pi\int_{\pi-\boldsymbol{NA}}^{\pi}\boldsymbol{p}(\theta)\sin\theta\, d\theta \tag{36.9}$$

To quantitatively determine the $\boldsymbol{\mu_{b,\ NA}}$ of the sample using Eq. 36.8, knowledge of $\boldsymbol{\zeta}$ is required. A method to determine $\boldsymbol{\zeta}$ is by a separate calibration measurement on a sample with a known $\boldsymbol{\mu_{b,\ NA}}$, e.g., using Mie theory on well-defined scattering particles [11].

To determine $\boldsymbol{\mu_{LCI}}$ the same calibration measurement may be used, although it is not always necessary since $\boldsymbol{\mu_{LCI}}$ can be obtained directly from the slope of the exponential decay between two or more chosen depths d (according to Eq. 36.7, see also Fig. 36.3c). As a consequence, $\boldsymbol{\mu_{LCI}}$ can be determined in any depth region of interest. The sample's attenuation is composed of the losses due to both scattering and absorption. When correcting $\boldsymbol{S}(d)$ for the attenuation, also the $\boldsymbol{\mu_{b,\ NA}}$ can be determined at any depth of interest.

Interpretation of measured properties – The absorption coefficient $\boldsymbol{\mu_a}$ is directly related to the individual absorption spectra and concentrations of chromophores (e.g., water, hemoglobin, bilirubin) present in the probed volume. The diagnostic value of $\boldsymbol{\mu_s}$ measurements depends on its relation to tissue morphology and organization. Ideally, tissue classification based on $\boldsymbol{\mu_s}$ would be highly correlated with classification by the pathologist based on microscopic evaluation. The classic approach is to model tissue as an ensemble of spherical scatterers with an effective size to match the experiment. The scattering cross section $\boldsymbol{\sigma_s}$ and phase function $\boldsymbol{p}(\theta)$ are then obtained, e.g., by Mie theory [25]. The scattering coefficient follows from

$$\boldsymbol{\mu_s} = \frac{f_v}{V}\boldsymbol{\sigma_s}\left[2\pi\int_0^{\pi}\boldsymbol{S_{P-Y}}(f_v,\theta)\boldsymbol{p}(\theta)\sin\theta\, d\theta\right] \tag{36.10}$$

where f_v is the volume fraction of the particles with volume V and $\boldsymbol{S_{P\text{-}Y}}$ is the Percus-Yevick structure factor [26] accounting for interparticle correlations at high volume fractions (but still assuming validity of the 1st Born approximation). The term between square brackets evaluates to unity for low concentrations and decreases with increasing f_v. The expression for $\boldsymbol{\mu_{b,\ NA}}$ is analogous to Eqs. 36.9 and 36.10. This approach is attractive because model systems consisting of well-defined particle sizes and size distributions can be readily constructed for system calibration and evaluation of measurement accuracy. The drawback is that all complexity of tissue scattering is reduced to a single effective scatterer, which makes it tempting to interpret scattering data only in terms of tissue structures of approximately equal size.

Alternatively, we start with the work of Fercher (▶ Chap. 4, "Inverse Scattering and Aperture Synthesis in OCT") where the scattering potential $\boldsymbol{m}'(r)^2$-1 is introduced, with $\boldsymbol{m}'$ is the relative complex refractive index at location $\boldsymbol{r}$ in the sample (with respect to the average refractive index $\boldsymbol{m_0}$). The scattering coefficient is obtained as

$$\boldsymbol{\mu_s} = \frac{1}{dV}\int_{4\pi}\left|\Im_r\left\{\boldsymbol{m}'(r)^2 - 1\right\}\right|^2 d\Omega \tag{36.11}$$

For example, the scattering coefficient of a volume element dV is obtained by integrating the squared magnitude of the Fourier transform of the scattering potential over solid angle. By a form of the Gladstone-Dale relation, the scattering potential is related to the spatial distribution of mass density ρ(r) [27]:

$$\boldsymbol{m}'(r)^2 - 1 = \frac{2\boldsymbol{\alpha}}{\boldsymbol{m}_0}\rho(r) \tag{36.12}$$

where $\boldsymbol{\alpha}$ is a tissue-specific proportionality factor. Equations 36.11 and 36.12 form the desired link between tissue scattering and architecture. However, the spatial mass density cannot be resolved from a scattering measurement directly. It is therefore more appropriate to evaluate the statistics of the spatial refractive index/mass density fluctuation by means of their correlation functions. For the case of spectroscopic OCT, Yi and Backman [28] used a Whittle-Matern refractive index correlation function $\boldsymbol{C_m}(r)$ to arrive at the following approximate expression for the scattering coefficient:

$$\boldsymbol{\mu_s} \approx 2\left[\boldsymbol{\sigma_m^2}\right]\sqrt{\pi}\Gamma\left(1 - \frac{b}{2}\right)\boldsymbol{k}^2\boldsymbol{l}_{corr,\,m} \tag{36.13}$$

where $\Gamma(\cdot)$ is the gamma function, $\boldsymbol{\sigma_m^2}$ is the variance of the refractive index fluctuation, b is a power law coefficient (see Sect. 36.2.3) assumed <2, and $\boldsymbol{l_{corr,m}}$ is the correlation length of the refractive index fluctuation. Interpretation of tissue scattering in terms of the (statistics of) mass density distribution is attractive because it directly relates to the assessment of tissue slices by a pathologist. The drawback is the difficulty in creating samples with well-controlled and verifiable $\boldsymbol{\sigma_m^2}$, b, and $\boldsymbol{l_{corr,m}}$ for calibration and validation experiments.

36.2.3 Separation of μ_s and μ_a

To quantitatively measure the scattering and absorption coefficient spectra of the sample, their individual contributions to the measured $\boldsymbol{\mu_{LCI}}$ need to be separated (Eq. 36.8). Several methods have been described to achieve this, which will be discussed in this section.

Least squares fitting [12, 29] – This method models the scattering dependence on wavelength with a power law: $\boldsymbol{\mu_s} = a{\cdot}\lambda^{-b}$, with scaling factor a and scatter power b.

The absorption coefficient spectrum is modeled as the sum of the absorption spectra $\boldsymbol{\mu_{a,\,i}}$ of all present chromophores i with contribution c_i: $\boldsymbol{\mu_a} = \sum_i (c_i \cdot \boldsymbol{\mu_{a,\,i}})$. Next, least squares fitting of the model $\boldsymbol{\mu_t} = a \cdot \lambda^{-b} + \sum_i (c_i \cdot \boldsymbol{\mu_{a,\,i}})$ to the measured $\boldsymbol{\mu_t}$ with fit parameters a, b, and c_i results in the individual contributions of $\boldsymbol{\mu_s}$ and $\boldsymbol{\mu_a}$ (scattering is modeled by inverse power-law dependence on wavelength $\mu_s = a \cdot \lambda^{-b}$). In addition, this method directly provides the concentrations c_i of the present chromophores. A restriction of this method is that all present chromophores and their literature absorption spectra need to be known. A similar approach was developed by Xu et al. in Ref [29].

Calibration measurement [11, 24, 30] – The $\boldsymbol{\mu_a}$ of a scattering sample can be obtained by subtracting the $\boldsymbol{\mu_s}$ of that sample from the measured $\boldsymbol{\mu_t}$, if this $\boldsymbol{\mu_s}$ is known from a separate calibration measurement without absorption but with equal $\boldsymbol{\mu_s}$. This is a straightforward method for in vitro experiments, but for in vivo experiments, it requires the assumption that tissue scattering is equal for absorbing and non-absorbing tissue regions, which is likely to induce errors in the $\boldsymbol{\mu_a}$ determination.

Kramers-Kronig (KK) relations [31–33] – For certain applications, it may be feasible to separate scattering and absorption based on the physical ties between the real and imaginary part of the complex refractive index $\boldsymbol{m}$ as a function of frequency $\boldsymbol{\omega} = c \times \mathbf{k}$ where c is the speed of light: $\boldsymbol{m(\omega)} = \boldsymbol{n(\omega)} + i\boldsymbol{\kappa(\omega)}$. By the principle of causality, $\boldsymbol{n(\omega)}$ and $\boldsymbol{\kappa(\omega)}$ are related through the Kramers-Kronig relations,

$$\boldsymbol{n(\omega)} - 1 = \frac{2}{\pi} P \int_0^\infty \frac{\omega' \boldsymbol{\kappa(\omega')}}{(\omega^2 - \omega'^2)} d\boldsymbol{\omega'} \tag{36.14}$$

and the inverse transform given by

$$\boldsymbol{\kappa(\omega)} = \frac{2\omega}{\pi} P \int_0^\infty \frac{\boldsymbol{n(\omega')} - 1}{(\omega^2 - \omega'^2)} d\omega' \tag{36.15}$$

where P denotes the Cauchy principal value of the integral. The imaginary part of the refractive index is related to the absorption coefficient through

$$\boldsymbol{\kappa(\omega)} = \frac{c\boldsymbol{\mu_a}(\omega)}{2\omega} \tag{36.16}$$

Robles et al. used the KK relations to separate the contributions of $\boldsymbol{\mu_a}$ and $\boldsymbol{\mu_s}$, from $\boldsymbol{\mu_t}$ [33]. Their method relies on the determination of the $\boldsymbol{\mu_a}$ from the real part $\boldsymbol{n(\omega)}$ of the refractive index Eqs. 36.15 and 36.16, which is obtained from the nonlinear dispersion phase term of the low-coherent interferometric signal. Subsequently, the $\boldsymbol{\mu_a}$ is subtracted from the measured $\boldsymbol{\mu_t}$ to determine $\boldsymbol{\mu_s}$. Currently, this method has only been applied in vitro.

36.2.4 Accuracy of SOCT and LCS

The accuracy of the optical property spectra determination in SOCT and LCS is limited by:

1. The size and number of averages in the investigated region of interest (ROI): the size (in depth) determines the depth/spectral resolution, depending on the analysis method chosen as discussed above in Sect. 36.2.1. The number of lateral averages is of importance since a single (S)OCT measurement essentially returns a speckle pattern, with standard deviation to intensity ratio of 0.52 (for fully developed speckle). This value reduces with the square root of the number of independent A-scans in the averaging, which can either be performed spatially (increasing the ROI width) or temporally (increasing the measurement time).
2. Sample homogeneity in the ROI: clearly, if volumes with different spectral signatures are present in the ROI, e.g., a vessel and a substantial surrounding region, the fidelity of the localized spectra assigned to the vessel is reduced.
3. The optical density ($\boldsymbol{OD} = \boldsymbol{\mu_t} \times \mathrm{d}$) of the tissue covering the ROI: because it directly influences the optical power available for local signal formation.
4. The localized sensitivity of the system, which for SOCT is determined by the sensitivity roll-off in depth and the decrease in sensitivity away from the focus determined by the confocal point spread function.

The accuracy of SOCT to quantify spatially localized absorption profiles of chromophores embedded in weakly scattering media with a single measurement over the full spectral bandwidth of the light source was investigated Hermann et al. [34]. The precision of the method as a function of the chromophore absorption, the sample thickness, and the different parameters related to the measurement procedure were evaluated both theoretically and experimentally in single and multilayered phantoms (Fig. 36.6). It was demonstrated that in weakly scattering media, SOCT is able to extract $\boldsymbol{\mu_a}$ as small as 0.5 mm^{-1} from 450 μm thick phantoms with a precision of ~2 % in the central and ~8 % at the edges of the used wavelength region. As expected, in phantoms with the same absorption properties and thickness ~180 μm, the precision of SOCT decreases to >10 % in the central wavelength region. Similar results were obtained for LCS absorption measurements [10]. However, when measuring in large ROIs, the accuracy may be improved to <0.5 mm^{-1} by spatial averaging.

The limitation in the accuracy of the $\boldsymbol{\mu_a}$ determination directly influences the accuracy of chromophore concentration measurements by SOCT and LCS. When measuring in the NIR wavelength region around 800 nm, the absorption coefficient of most tissue chromophores is relatively low compared to tissue scattering (Fig. 36.1). As a consequence, it is challenging to use the method for the accurate quantification of absorption in the presence of scattering. In addition, the spectral features of the tissue chromophores are only moderately distinct, which hampers the distinction between, e.g., oxyhemoglobin and deoxyhemoglobin by SOCT (Fig. 36.7). Current applications of SOCT and LCS therefore focus on the visible wavelength region, where absorption is substantially higher and the chromophores

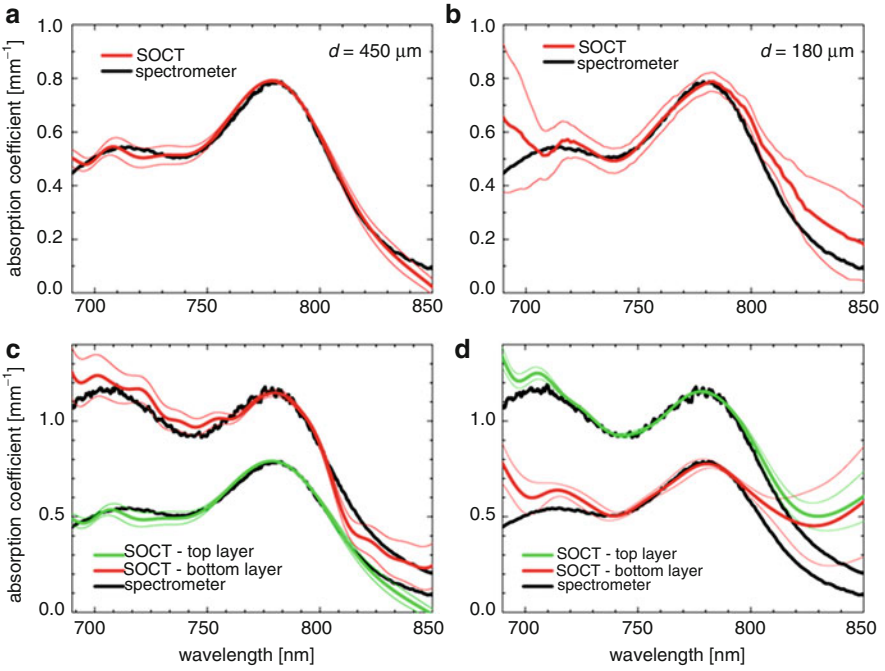

Fig. 36.6 Absorption profiles of measured from 450 µm- (**a**) and 180 µm thick (**b**) single-layered as well as double-layered (**c**, **d**) gel phantoms doped with indocyanine green using SOCT (*red* and *green lines*) and control measurements with a spectrometer (*black lines*). (**c**) Low absorption layer on top (∼490 µm) and high absorption layer below (∼530 µm). (**d**) High absorption layer (∼560 µm) on top of a low absorption layer (∼510 µm). *Thin red lines* indicate the standard deviation for 200 SOCT measurements [34]

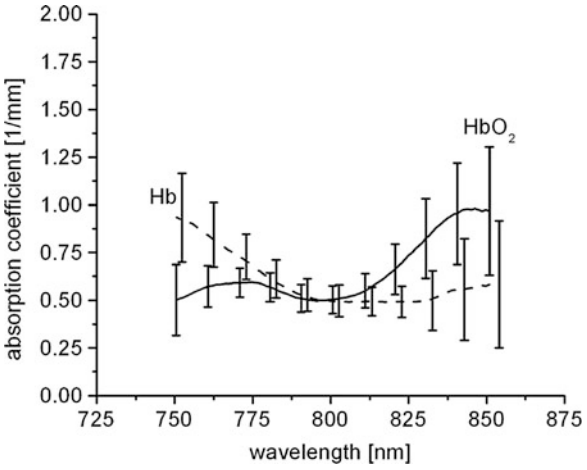

Fig. 36.7 Absorption spectra of hemoglobin (*dashed line*) and oxygenated (*solid line*) hemoglobin measured by spectroscopic optical coherence tomography. Spectral resolution was 1 nm. The *plotted lines* are the average of 1,000 absorption spectra; the *error bars* correspond to the standard deviation (not all error bars are plotted for clarity) [5]

exhibit more distinct absorption features. In this wavelength region, an accuracy of 0.5 mm^{-1} for the determination of $\boldsymbol{\mu_a}$ will be sufficient to, e.g., measure a 6 % oxygenation change or a 2 % change in hemoglobin concentration for whole blood. The imaging depth in the visible wavelength range is lower than for the NIR due to higher tissue scattering and absorption, but is at least 0.5 mm in adult human skin.

36.3 Applications

36.3.1 Contrast Enhancement

The spectroscopic content of the OCT signal can be used to enhance contrast in the OCT image, based on either endogenous or exogenous contrast agents. This application does not require quantitative determination of optical property spectra with high spectral resolution, but can rely on approaches that ensure good depth resolution such as shifting of the spectral center of gravity [4, 35, 36], spectral triangulation [37], and spectral autocorrelation analysis [38]. For SOCT systems that operate in the NIR, the outcome of the spectral analysis is commonly mapped to a false color scale, which is combined with the high-resolution OCT image that shows the spatial distribution of the contrast agent. When operating in the visible wavelength range, the spectral information can be mapped to a color scale that "matches" our visual perception, as was shown by Robles et al. for endogenous contrast agents in Fig. 36.8 [9] and by Li et al. for exogenous contrast agents [30] using the dual window method described in Sect. 36.2.1. The lower panels of Fig. 36.8 quantifying optical spectra within the true-color image are discussed in Sect. 36.3.2.

A relatively unexplored application is OCT speckle reduction using "frequency compounding," e.g., by averaging OCT images obtained at different wavelength bands [39–41]. Averaging N different realizations of the speckle patterns (e.g., OCT images) improves the speckle contrast by $\sqrt{N}$.

36.3.2 Localized Measurements of Optical Properties

Supported by the structural tissue information of an OCT image, SOCT and LCS offer the possibility to accurately and simultaneously quantify a unique set of optical wavelength-resolved properties ($\boldsymbol{\mu_t}$, $\boldsymbol{\mu_a}$, $\boldsymbol{\mu_s}$, and $\boldsymbol{\mu_{b,\,NA}}$) and, derived from that, tissue chromophore concentrations within a very confined and controllable tissue volume of choice. As a consequence, SOCT and LCS can solve several methodological problems related to conventional reflectance spectroscopy, e.g., assumptions on photon path lengths, probing volume, and homogeneity of the investigated tissue. This offers new opportunities for tissue diagnostic applications. This section describes the current applications of SOCT and LCS for localized measurements of optical properties.

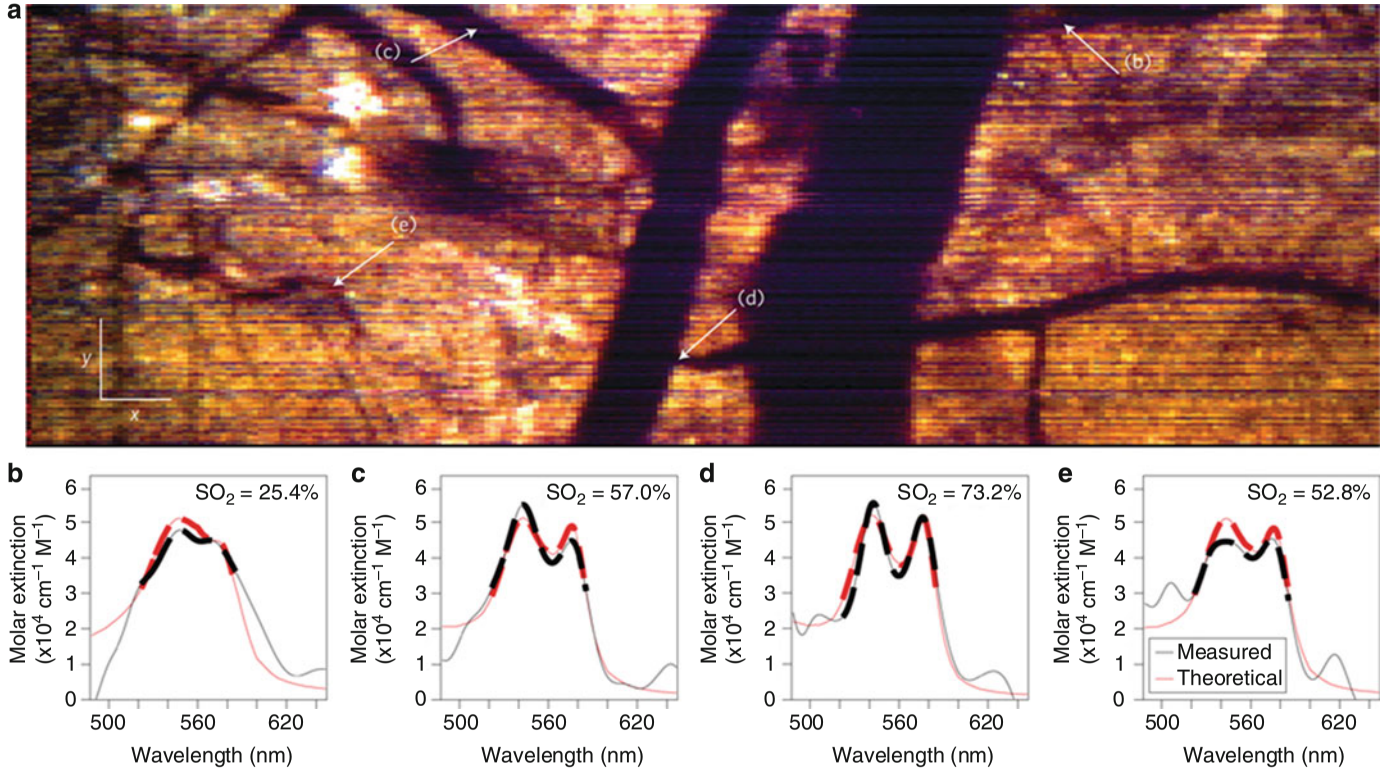

Fig. 36.8 (**a**) En face true-color OCT image with *arrows* indicating points where the spectra in panels (**b**–**e**) are quantified. *White x* and *y scale bars*, 100 μm. (**b**–**e**) Spectral profiles from points (**b**–**e**) in (**a**) measured spectral profiles (*black*) are superposed with the theoretical hemoglobin molar extinction coefficients (*red*). The *dashed* portion of the curves outlines the region used to determine SO_2 levels. All spectra were selected from depths immediately below each corresponding vessel [9]

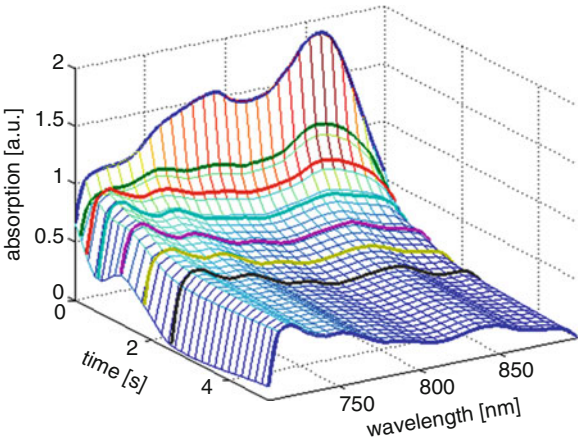

Fig. 36.9 Time evolution of spectral absorption for a non-scattering, absorbing ICG phantom. Photobleaching caused by the measurement light leads to time-dependent changes of the absorption profile. *Thick lines* indicate measured time points [42]

Absorption-based applications – The first absorption coefficient spectra measurements by SOCT were performed in vitro on homogeneous media in the absence of scattering, among others described in [2, 5, 7, 8]. Using the methods discussed in Sect. 36.2.3, these experiments were followed by in vitro validation studies on absorbing turbid media in homogeneous configurations for SOCT and LCS [11, 13, 33] and also in layered configurations for weakly scattering and absorbing media for SOCT [29, 34, 42]. The high acquisition speed of frequency domain OCT enables dynamic spectroscopic measurements. Figure 36.9 shows the absorption dynamics of indocyanine green (ICG) in a non-scattering phantom in the near-infrared wavelength region measured with LCS [42]. The bleaching effect of the light incident on the sample leads to a temporal change of its absorption characteristic.

The full potential of low-coherent interferometry techniques to do both *quantitative* and *localized* measurements of optical property measurements for applications in tissue has been shown using layered, more densely scattering and absorbing media [12].

The absorption coefficient spectrum of tissue is composed of the relative contributions of the present tissue chromophores. Hence, decomposition of the measured $\boldsymbol{\mu_a}$ by SOCT and LCS results in the individual chromophore concentrations.

A particularly interesting tissue chromophore is hemoglobin, since its absolute concentration is related to clinical parameters such as the blood content of the investigated tissue volume and the hematocrit of whole blood. In addition, the ratio between oxyhemoglobin and deoxyhemoglobin provides the oxygen saturation of the investigated tissue volume, which is related to the oxygen supply and consumption of the tissue. The first localized in vivo measurements of hemoglobin concentrations and oxygen saturations were performed by LCS in combination with least squares fitting, which are shown in Fig. 36.10 and are described in Ref [12]. Figure 36.10 shows that the total hemoglobin concentration differs substantially between a vessel poor (3.0 ± 0.5 g/L, region 2) and a vessel rich region (7.8 ± 1.2 g/L, region 3) in the human

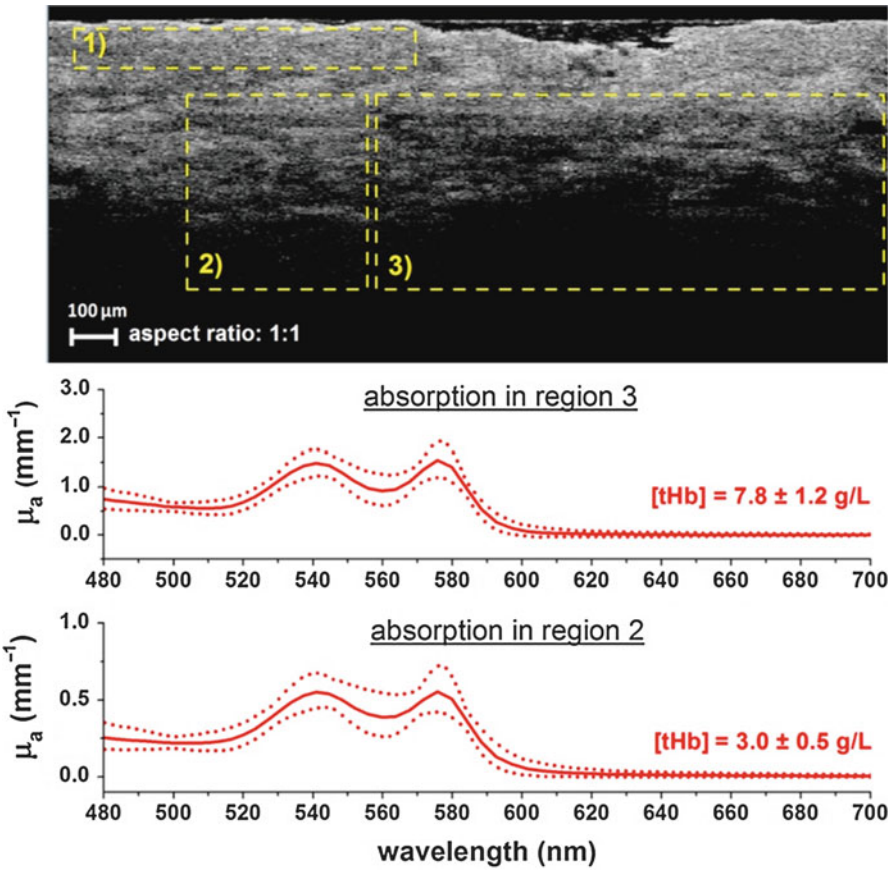

Fig. 36.10 In vivo LCS measurement on the skin of the palmar side of a human finger joint, supported by an OCT B-scan. The absorption spectra (*solid lines*) and their confidence intervals (*dotted lines*) are shown for the selected regions 2 and 3 in the dermis. From the absorption spectra, the total hemoglobin concentration [tHb] and oxygen saturation were determined. The attenuation spectrum in the epidermal region 1 did not exhibit any absorption features, as is expected from the absence of blood vessels in this skin layer (data not shown) [12]

dermis of the finger, corresponding to normal dermal blood volume fractions of 2 % and 5 %, respectively. Due to error propagation in the ratio of oxy- and deoxyhemoglobin, the oxygen saturation was determined with less accuracy, accounting for 81 ± 34 % and 100 ± 31 % for regions 2 and 3, respectively. Tissue attenuation in the epidermal layer (region 1) only exhibited the contribution of scattering (not shown), which agrees with the expected absence of blood vessels in this skin layer. Localized measurements of tissue oxygen saturation were also shown in a mouse model by Robles et al. using METRICS OCT (lower panels of Fig. 36.8) [9].

Although currently not yet investigated, other tissue chromophores have potential to be quantified by SOCT and LCS as well, depending on the investigated wavelength region (Fig. 36.1). As addressed in Ref [14], a valuable application of LCS and/or SOCT would be the noninvasive determination of bilirubin concentrations inside blood vessels for jaundiced neonates.

Scattering-based applications – The possibility to combine elastic scattering spectroscopy with OCT is discussed in ▶ Chap. 27, "Digital Holoscopy" and was explored in numerical simulations in [43]. This section focuses on the scattering property measurements that can be obtained using the theory described in Sect. 36.2.2, which result in scattering $\boldsymbol{\mu_s}$ and backscattering $\boldsymbol{\mu_{b,\ NA}}$ coefficient spectra. This offers the unique possibility for a combination of simultaneous, quantitative, and spectrally resolved measurements of $\boldsymbol{\mu_s}$ and $\boldsymbol{\mu_{b,\ NA}}$ [11]. This combination of optical properties is characteristic for particle or tissue type and therefore offers new opportunities for tissue and/or particle characterization studies. For these studies, the measurement of both $\boldsymbol{\mu_s}$ and $\boldsymbol{\mu_{b,\ NA}}$ may assist in better differentiation, because low contrast in $\boldsymbol{\mu_s}$ can be accompanied by high contrast in $\boldsymbol{\mu_{b,\ NA}}$. The latter is illustrated in Fig. 36.11 for LCS measurements on polystyrene spheres of various sizes (Ø 409, 602, 799, and 1,004 nm). Whereas the $\boldsymbol{\mu_s}$ spectra are similar for all spheres at these concentrations, the $\boldsymbol{\mu_{b,\ NA}}$ spectra differ substantially both in absolute value and in spectral features, i.e., sphere size-dependent oscillations as a function of wavelength. Note that the measurements (dots) agree well with the expected values (solid lines) from Mie calculations. Another encouraging result is that, although the $\boldsymbol{\mu_s}$ spectra are similar, LCS succeeds in distinguishing the samples based on subtle differences in scatter power b. Further demonstrating the potential of this method, Yi et al. [28] extracted scatter power and correlation length of the refractive index (e.g., analysis based on Eq. 36.13).

Figure 36.12 shows that accurate agreement with Mie calculations is obtained also for a wider range of sphere concentrations and sizes, i.e., more densely scattering media. For clarity reasons, only the values at $\lambda = 700$ nm have been displayed. This suggests the absence of the influence of multiple scattering and/or dependent scattering (presence of a large non-unity structure factor $\boldsymbol{S}(\theta)$) on the LCS signal for these measurements. If present, these effects will result in an underestimation of $\boldsymbol{\mu_s}$ and an overestimation of $\boldsymbol{\mu_{b,\ NA}}$ (Sect. 36.2.2). These effects have been observed for densely scattering media at shorter wavelengths [11]. Hence, the quantitative interpretation of scattering property measurements on tissue should be made with caution, although the absolute measured value of $\boldsymbol{\mu_s}$ and $\boldsymbol{\mu_{b,\ NA}}$ can still contain tissue-specific information. We repeat that multiple and/or dependent scattering does not affect the absolute measurement of $\boldsymbol{\mu_a}$, since absorption always takes place along the (known) photon path in LCS and SOCT. Although the spectra in Figs. 36.11 and 36.12 were measured in the absence of absorption, quantitative $\boldsymbol{\mu_s}$ spectra agreeing with Mie calculations have also been measured in the presence of absorption by both time domain and spectral domain LCS [13].

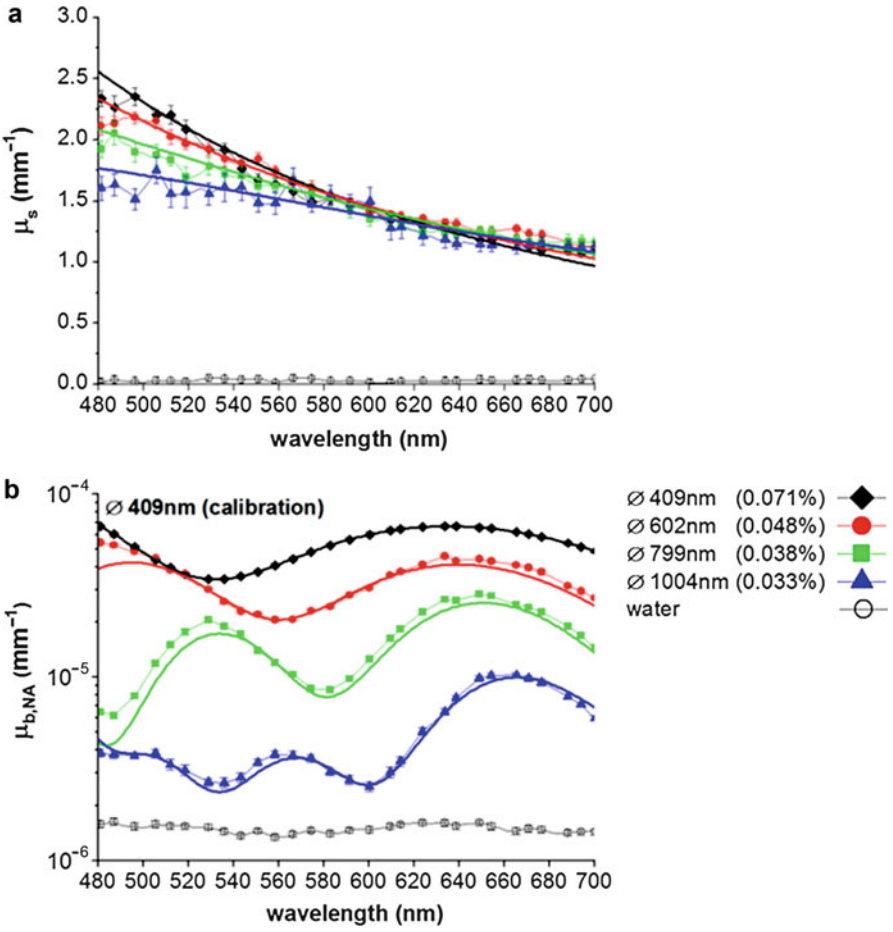

Fig. 36.11 LCS (*dots*) and Mie (*thick solid lines*) results for (**a**) scattering coefficients $\boldsymbol{\mu_s}$, and (**b**) backscattering coefficients $\boldsymbol{\mu_{b,NA}}$ for four aqueous suspensions of different sized polystyrene spheres, and water. *Error bars*, representing the 95 % confidence intervals of the fitted values, may fall behind data points. The $\boldsymbol{\mu_{b,NA}}$ were calibrated using the 409 nm sample and the procedure described in Sect. 36.2.2 [11]

36.4 Recent advances in the field of Spectroscopic Low-Coherence Interferometry

Since the acceptance for publication of this chapter in 2012, some interesting advances have been made in the field of Spectroscopic Low-Coherence Interferometry. For the completeness of this chapter, these advances will be briefly described here. The application of in vivo oximetry by SOCT has been demonstrated and validated in individual vessels of the retina and the skin [45, 46]. Although the probing depth for most applications of SOCT and LCS is limited to

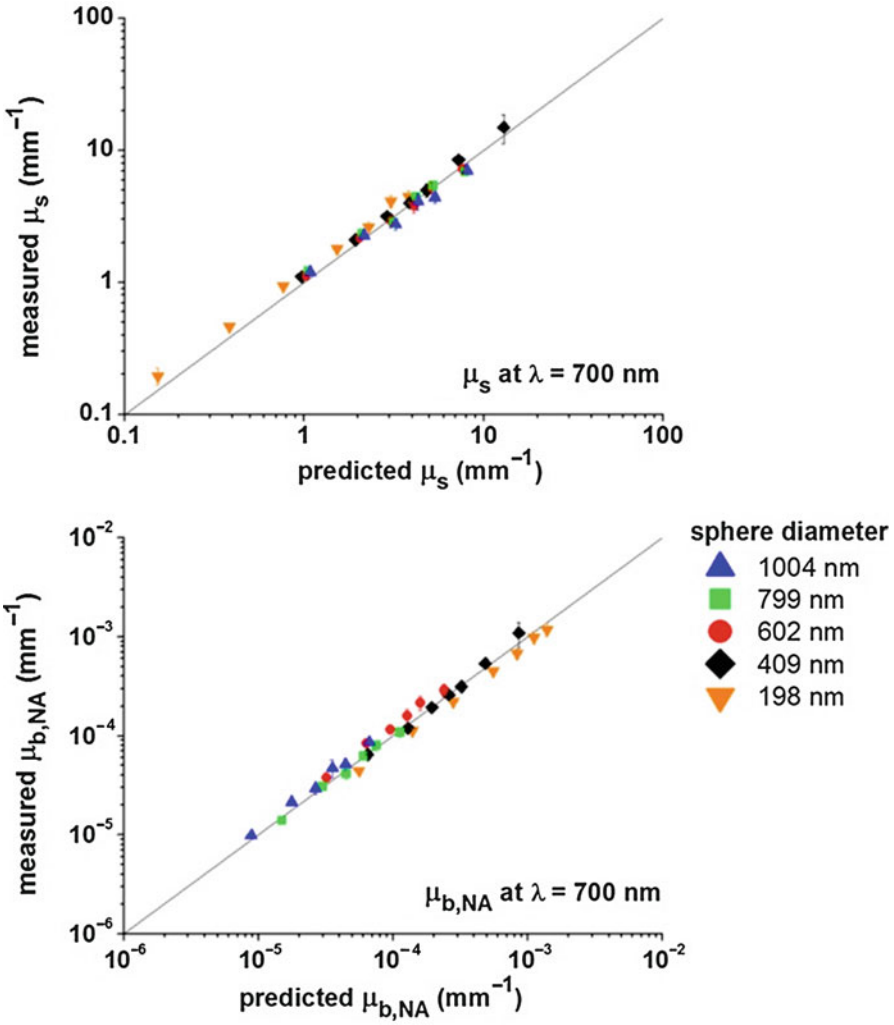

Fig. 36.12 Measured (LCS) versus predicted (Mie theory) values of $\boldsymbol{\mu_s}$ and $\boldsymbol{\mu_{b,NA}}$ for different-sized polystyrene spheres and various concentrations. For clarity reasons, only the values at $\lambda = 700$ nm have been displayed

$\sim$1 mm in tissue due to the analysis of single scattered photons, the probing depth can be increased considerably by also analyzing multiple scattered photons – at the expense of spatial resolution. Refs [47, 48] show how to retrieve spatially resolved spectroscopic information from larger depths using this principle. A more comprehensive and validated comparison of the time-frequency analysis methods for SOCT and LCS described in this chapter is described in Refs [49–51]. Other analysis methods for the visualization of spectroscopic information in SOCT images are compared in Ref [52].

36.5 Conclusion

Spectroscopic low-coherence interferometry groups modalities that quantify spatially resolved spectral properties. The best known to date are spectroscopic OCT and low-coherence spectroscopy. Spatially resolved measurement of absorption spectra allows retrieval of local chromophore concentrations such as (oxy)hemoglobin and bilirubin which has various potential applications ranging from determination of oxygen saturation in small tissue (tumor) volumes to monitoring jaundice in neonates while preventing invasive heal pricks. Similarly, the spectra of scattering properties such as the scattering coefficient and backscattering coefficient hold a wealth of information on tissue organization. The potential of this method is yet to be explored, but "non-spectroscopic" results (e.g., averaged over the LCI systems wavelength bandwidth) are promising.

This chapter starts by describing time-frequency (or "depth-wavelength") analysis to obtain localized spectra from LCI data. We discuss the most common form, short-time Fourier transform, and its inherent trade-off between spatial and spectral resolution. We proceed to discuss methods to meet that challenge, based on the wavelet transform and on the pseudo-Wigner distribution. Intriguingly, a convenient way to perform the latter analysis is through dual-window STFT analysis.

Signal decay with depth caused by instrumental factors can both be a problem and an asset. In the former case, we present calibration methods to account for the axial confocal point spread function and the sensitivity roll-off in depth. In the latter case, these effects are maximized, e.g., by using very large NA optics and/or spectrometers with spectral resolution in the order over several nanometers, thus highly localizing the detected interference signal in the spatial domain while leaving room for sufficient spectral resolution.

We proceed to describe the LCI signal in terms of depth-resolved absorption and (back)scattering coefficients and discuss approaches to separate the contributions of absorption and scattering to the total signal attenuation. We briefly touch on the possible diagnostic significance of scattering measurements by seeking direct theoretical relations between light scattering properties and (statistical) descriptors of tissue organization.

After discussing the spectroscopic accuracy of spectroscopic OCT and low-coherence interferometry, we discuss clinical and experimental applications: in vivo measurements of local hemoglobin concentrations and oxygen saturation are discussed as well as in vitro validation of quantitative measurements of scattering and backscattering spectra.

Concluding, low-coherence interferometry continues to have significant diagnostic potential as it not only allows high-resolution volumetric imaging but also provides localized measurement of parameters describing the physiological status. As other chapters in this book demonstrate, measurement of flow and perfusion has spectacularly improved in recent years. In this chapter, we highlighted the opportunities and challenges of localized spectroscopy within these tissue volumes.

37.1 Introduction: Biological Relevance of Intracellular Motion

Motion is the defining physiological characteristic of living matter. If we are interested in how things *function*, then the way they *move* is most informative. Motion provides an endogenous and functional suite of biomarkers that are sensitive to subtle changes that occur under applied pharmacological doses or cellular stresses. This chapter reviews the application of biodynamic imaging to measure cellular dynamics in three-dimensional tissue culture for drug screening applications. Nanoscale and microscale motions are detected through statistical fluctuations in dynamic speckle across an ensemble of cells within each resolution voxel. Tissue dynamics spectroscopy generates drug-response spectrograms that serve as phenotypic fingerprints of drug action and can differentiate responses from heterogeneous regions of tumor tissue.

Motion occurs across broad spatial and temporal scales. At one extreme, molecules executing Brownian diffusion cross nanometers in microseconds. At the other extreme, metastatic crawling cells cross microns in hours. Spanning these scales, different functional processes take place: molecular diffusion, molecular

polymerization or depolymerization of the cytoskeleton, segregation of enzymes into vesicles, exocytosis and endocytosis, shepherding of vesicles by molecular motors, active transport of mitochondria, cytoskeletal forces pushing and pulling on the nucleus, undulations of the cell membrane, push and pull at cell-to-cell adhesions, deformation of the cell, cell division, and ultimately to movement of individual cells through tissue. All of these very different types of cellular dynamics are active and useful indicators of the functioning behavior of cells in tissue.

Imaging motion in three-dimensional tissue is simpler than imaging structure or performing molecular imaging in 3D, because motion modulates coherent light through phase modulation that is detected by interferometry [1]. Anytime light scatters from a displacing object, the phase of the light is modified. If the light has coherence, then the motion-induced phase shifts of one light path interfere with the phase shifts of other light paths. Even light that is multiply scattered in tissue carries a record of the different types of motions that the light encounters. By measuring the fluctuating phase of light scattered from living tissue, different types of motion across different space and time scales can be measured.

This article reviews the principles of low-coherence dynamic imaging of three-dimensional tissue that uses low-coherence digital holography to spatially isolate optical signals that return from specific depths inside tissue, as in optical coherence tomography (OCT) [2–5]. Digital holographic optical coherence imaging is ideally suited to dynamic imaging because of the well-developed speckle and high signal-to-noise of dynamic speckle. For drug screening in three-dimensional tissues, tissue dynamics spectroscopy (TDS) produces drug-response spectrograms that serve as fingerprints of tissue responding to different applied drugs [6, 7]. These drug-response fingerprints capture the phenotypic similarities and differences among different drugs and cell types and can be used to build a phenotypic database that can serve as a dynamic classifier of new compounds.

37.2 Dynamic Light Scattering from Cells and Tissue

Dynamic light scattering is a characterization tool for remotely extracting dynamic information, such as internal displacements, diffusivities, and velocities [8, 9], from inside media. In the dilute limit, in which light is scattered once, dynamic light scattering is called quasi-elastic light scattering (QELS) [10]. In biological applications, QELS is useful for optically thin systems, such as cell monolayer cultures, and it provides information on diffusion and directed motion in the cytosol [11, 12], nucleus [13], and undulations of the plasma membrane [14–18]. However, as the optical thickness of a sample increases beyond one optical transport length, multiple scattering becomes significant, and the diffusive character of light begins to dominate [19–21]. In this multiple scattering limit, diffusing-wave spectroscopy (DWS) [22] and diffuse correlation spectroscopy (DCS) [23–25] continue to carry motional signatures from inside tissue in the field and intensity fluctuations of the scattered light.

Dynamic light scattering (DLS) is a fundamental process by which light scattered from displacing scatterers experiences phase shifts related to the

magnitude and direction of displacement [8]. Living tissue is a dense collection of scatterers that are executing many different types of motion, leading to a rich collection of phase shifts. For the slow motions inside a cell (microns per second and slower), the phase drift associated with displacements is equivalent to an ultra-low-frequency (ULF) Doppler shift in the light frequency. The Doppler frequency offsets are too small to measure directly, but by using interferometry (such as digital holography), the phase modulation is measured as a heterodyne intensity fluctuation signal. The fluctuating intensities of the backscattered speckle contain the motional information of the scatterers.

Fluctuation analysis begins with the autocorrelation function of the intensity fluctuations. The autocorrelation is defined by

$$A_I(\tau) = \langle I(0)I(\tau)\rangle = V_I F(\tau) + \langle I\rangle^2 \tag{37.1}$$

where the intensity variance is $V_I = (\langle I^2\rangle - \langle I\rangle^2)$, and the delay-dependent function $F(\tau)$ is a decorrelation function that has contributions from many different dynamic processes in the cells and tissue. In the case of single scattering (QELS), it can be defined as a sum of independent exponential decorrelations as [26]

$$F(\tau) = \sum_n f_n \exp\left(-q^2 \Delta x_n^2(\tau)\right) \tag{37.2}$$

where $\Delta x_n^2(\tau)$ is the mean-squared displacement (MSD) of moving scatterers inside the cells and tissue [8] and $q = 2\,k$ is the backscattering vector where $k = 2\pi/\lambda$. The index n represents the n-th process or n-th set of cellular constituents that contribute to the mean-squared displacement, and f_n is the fractional contribution of the n-th process to the total variance. The high-content information of dynamic imaging originates from the summation over the different types of processes. If these processes have widely distributed characteristic times, then their contributions can be separated and isolated, enabling their quantification as they are affected by applied drugs.

Typical time scales for scattering are related to the scattering vector and to the motion of the scatterer. For particles diffusing with a diffusion coefficient D, or drifting with a drift velocity v, the characteristic decorrelation times are

$$\tfrac{1}{\tau}\big|_{Diff} = q^2 D \qquad \tfrac{1}{\tau}\big|_{drift} = qv \tag{37.3}$$

respectively, where the expression for drift is also equal to the Doppler frequency shift. Motions in living cells are not fast. Even molecules executing Brownian motion are hindered by the crowded molecular constituents of the cytoplasm [27]. Therefore, characteristic decorrelation times for light scattered from tissue range from many milliseconds to as slow as hundreds of seconds. This time frame is easily accessible with frame rates of common digital cameras.

When there are many processes that have characteristic times that are similar, the decorrelation function of Eq. 37.2 becomes difficult to separate into

isolated contributions. It is then more convenient to work in the frequency domain by taking the Fourier transform of the dynamic imaging decorrelation function in Eq. 37.1. The mean-squared displacement of processes in biological systems is rarely by simple diffusion and commonly displays the signature of anomalous diffusion. Deviation from free diffusion is described phenomenologically through the relation

$$\Delta r^2 = D^* \left(\frac{t}{t_0} \right)^{\beta} \tag{37.4}$$

where D^* is a time-independent coefficient and t_0 is a characteristic time. The exponent for normal Fickian diffusion is $\beta = 1$. If $\beta < 1$, the diffusion is called subdiffusive, while if $\beta > 1$, the diffusion is called superdiffusive. Superdiffusive behavior occurs if there is persistent and correlated motion of the particle, as in the active transport of organelles. On the other hand, subdiffusive behavior is the most commonly encountered case when motion is constrained or impeded in some way, such as diffusion of molecules through the crowded cytosol.

Even in the presence of multiple scattering, dynamic light scattering information can still be extracted [28, 29] using diffusing wave spectroscopy (DWS) [30, 31] and an equivalent formulation of multi-scattering dynamic light scattering called diffuse correlation spectroscopy (DCS) [23, 25, 32, 33]. For multiple scattering in thick tissue, the effective squared scattering vector is

$$q_{eff}^2 = 4k^2 \left[1 + \frac{z}{l_s}(1 - g) \right] \tag{37.5}$$

where g is the anisotropy factor (typically $g \approx 0.9$ in tissue), z is the coherence-gated depth in the tissue, and l_s is the mean-free scattering length of a photon (typically $l_s \approx 20$ μm). Multiple scattering causes the effective squared scattering vector to increase linearly with depth from the value set by single backscattering. This has the effect of "speeding up" the light fluctuations from increasing depths.

In biological applications, DCS has been used to monitor tissue response to burns [34], brain activity [35], blood flow [24, 25] and tissue structure [36]. DCS uses high-coherence laser sources and measures the temporal diffusing field autocorrelation function. The primary uses have been for macroscopic measurements of blood flow, which has been validated through comparisons with Doppler flowmetry and ultrasound [37–39]. A technique related to DCS, but that more directly uses speckle imaging, is speckle contrast imaging (SCI) [24]. This technique is used primarily for imaging of vasculature in vivo because the fast motions of blood cells blur the speckle contrast in images acquired with a long exposure time [40].

Optical coherence tomography (OCT) forms images by scanning and rastering. Speckle in OCT has long been considered an unwanted side effect of the coherent imaging, and many approaches have been explored to reduce speckle [41–43]. However, speckle decorrelation also can be studied in OCT data to provide similar

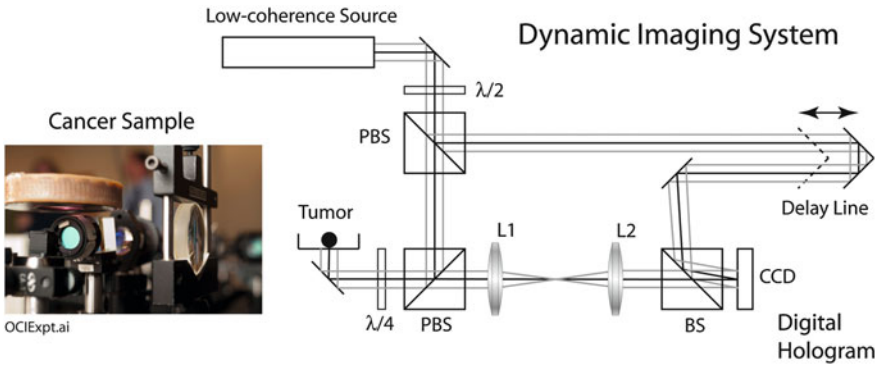

Fig. 37.1 Biodynamic imaging experimental setup that uses off-axis digital holography to capture dynamic speckle from a living tissue sample

information as provided by DCS. This has been used to measure intracellular rheology [12] and diffusion [44] and to find dynamic signatures of apoptosis [45] and motion of mucosa [46]. OCT is used in a Doppler mode for blood flow detection [47, 48]. Motility contrast imaging (MCI) is a related tissue-scale functional imaging technique that uses subcellular motion as the imaging contrast [49–51]. Motility contrast imaging of live tissue is based on two principles: dynamic light scattering from the motions of the constituents of living cells and coherence-gated depth resolution [52] that isolates the motional signals from specific depths.

37.3 Motility Contrast Imaging of Living Tissue

In biodynamic imaging, the coherence gate is formed by a low-coherence light source detected by digital holography on a CCD camera chip [53] (see ▶ Chap. 31, "Interferometric Synthetic Aperture Microscopy (ISAM)"). Light scattered from a selected depth is recorded in the digital hologram. When dynamic light scattering and coherence gating are combined, intracellular motion can be measured volumetrically up to 1 mm deep inside tissue with a spatial resolution of tens of microns. The basic optical configuration for an optical coherence imaging (OCI) system is shown in Fig. 37.1. Low-coherence light is split at a beam splitter into a signal arm that illuminates the sample and a reference arm that has a variable-delay retroreflector. Light scattered from the sample intersects with the reference beam at the plane of the CCD electronic chip [54] with a small crossing angle of about two degrees. The selected depth is defined by the path length from the beam splitter to the CCD plane. The low-coherence light source is either a 100 fsec Ti:sapphire laser or a Superlum superluminescent diode, both operating at a center wavelength of 840 nm. The hologram is recorded on the CCD chip and is "read-out" by a digital Fourier transform algorithm, which is stored as a layer in a volumetric data set.

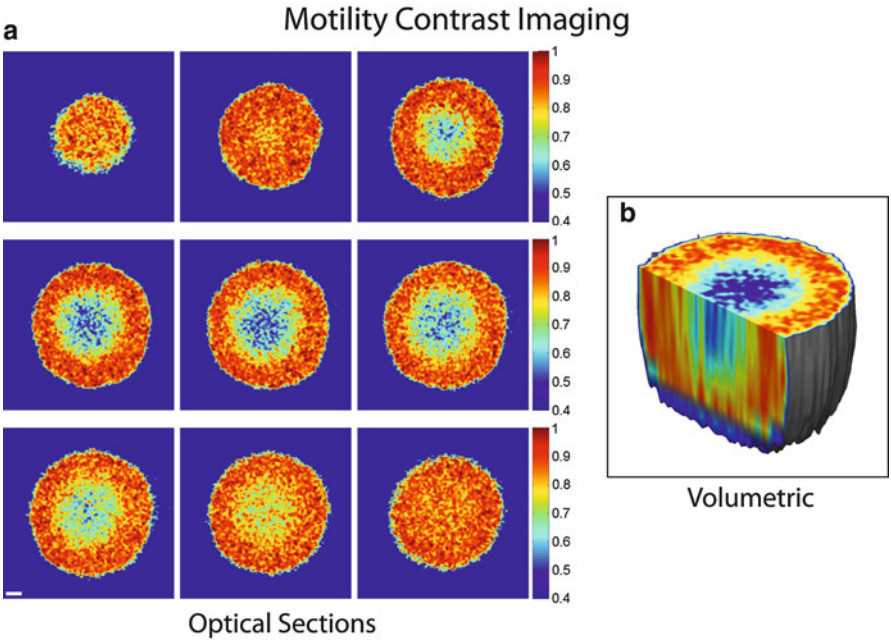

Fig. 37.2 (**a**) False-color motility contrast image of an 800 μm-diameter tumor spheroid, showing the proliferating shell (*red*) and the necrotic core (*blue*). (**b**) Volumetric motility contrast image

A motility metric captures the general activity level of a living sample. The simplest motility metric is the normalized standard deviation (NSD) of fluctuating time-dependent speckle, which is also the temporal contrast

$$NSD = \sqrt{\frac{\langle I^2 \rangle - \langle I \rangle^2}{\langle I \rangle^2}} = \frac{\sqrt{V_I}}{\langle I \rangle} \tag{37.6}$$

The NSD(x,y,z) motility metric is volumetric, with depth defined by the digital holographic coherence gate and the (x, y) coordinates of the image defined by reconstruction. An example of motility contrast imaging of a three-dimensional multicellular tumor spheroid is shown in Fig. 37.2 [50]. The spheroid is approximately 0.8 mm in diameter. The data are color coded according to the motility metric, with red signifying a high degree of motion and blue signifying a low degree of motion. For a spheroid of this size, the core is hypoxic and necrotic. The 200 μm thick proliferating shell is clearly discernible surrounding the less active core. The proliferating shell has high motility (red), and the necrotic core has low motility (blue).

Biodynamic imaging is a general imaging technique because it is responsive to intracellular motions, which occur in all living samples. Therefore, there are many

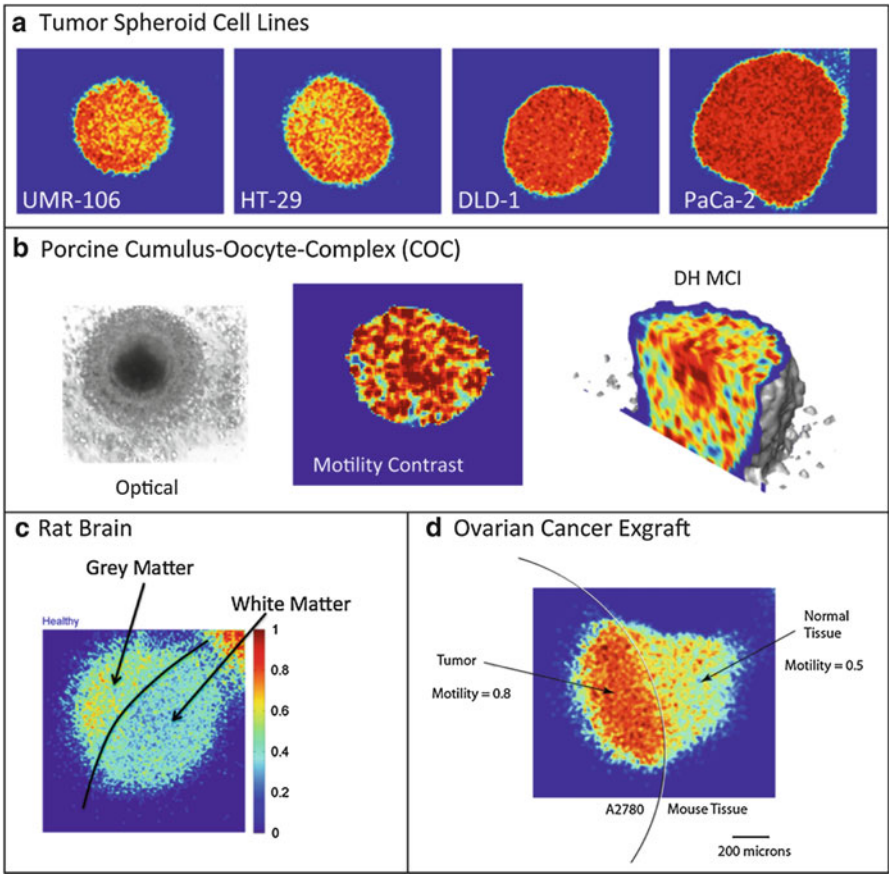

Fig. 37.3 Motility contrast images of (**a**) multicellular tumor spheroids derived from several different cell lines, (**b**) porcine cumulus-oocyte complexes, (**c**) *white* and *gray* matter of excised rat brain, and (**d**) cancer and normal tissue in a mouse ovarian cancer exgraft

potential applications for this new form of dynamic and functional imaging. Several of these are illustrated in Fig. 37.3. In (Fig. 37.3a) MCI is used to measure the activity of tissues from different cell lines, showing increasing activity from UMR-106 (rat osteogenic sarcoma), HT-29, and DLD-1 (human adenocarcinomas) to PaCa-2 (human pancreatic). A possible application in artificial reproductive technologies would be viability assessment of eggs and embryos prior to implantation in in vitro fertilization clinics. The motility activity of the central oocyte inside a cumulus-oocyte-complex (COC) is shown in Fig. 37.3b. MCI has been applied to tissue ex vivo as well, extending applications beyond purely in vitro culture. For instance, Fig. 37.3c shows the motility contrast between excised rat brain gray and white matter. Gray matter contains the cell bodies and is more dynamically active, while white matter consists primarily of axons. Figure 37.3d

shows the margin between normal tissue and cancerous tissue in a mouse exgraft in which the cancerous tissue is more dynamically active than the normal tissue.

37.4 Tissue Dynamics Spectroscopy and Drug-Response Spectrogram Fingerprints

The information received from coherence-gated light scattered from tissue relates to the many different types of motion that occur within cells across broad frequency ranges. It is possible to extend motility contrast imaging to tissue dynamics spectroscopy (TDS) by performing fluctuation spectroscopy to separate these motion contributions into partially overlapping frequency bands related to the different types of motion [55]. Tissue dynamics spectroscopy provides a label-free and noninvasive probe of cellular function and provides a functional assessment of drug candidates as a unique and new form of phenotypic profiling [7].

The Fourier transform of Eq. 37.1 under conditions of anomalous diffusion takes the form

$$S(\omega) = FT(A_I(\tau)) = \frac{V_I}{\pi}\sum_n \left[\frac{4}{(3-\beta_n)}\frac{f_n\omega_n^{\beta_n}}{\left(\omega_n^{1+\beta_n}+\omega^{1+\beta_n}\right)}\right] \tag{37.7}$$

where β_n is an anomalous diffusion exponent that is usually in the range $\beta_n \approx 0.7$–1.3.

Equation 37.7 retains the summation over the different dynamic processes taking place inside living tissue, and each process has a characteristic frequency ω_n given by $\omega_n = \sqrt[\beta]{q^2 D_n^*/t_n}$. Because most motions in living cells are stochastic, even if they are actively driven by molecular motors consuming ATP, they can be described in terms of an effective (active) diffusion coefficient D_n^* that describes different types of motion, such as vesicle or nucleus motion.

An example of a fluctuation power spectrum from a tumor spheroid grown from the DLD-1 adenocarcinoma cell line is shown in Fig. 37.4. The baseline spectrum shows a knee frequency around 0.1 Hz with a slope around $\beta \approx 1$. Two hours after 50 μM valinomycin is applied (a mitochondrial decoupler), the knee has shifted to 0.03 Hz with a smaller slope $\beta < 1$. Nine hours after the dose is applied, the spectrum has no clear knee frequency, and the slope is noticeably subdiffusive. Valinomycin reduces the mitochondrial membrane polarization (MMP) and suppresses the generation of ATP, thus significantly slowing the cellular metabolism. The shift of the spectrum to lower frequencies reflects this reduced metabolic activity, and the more subdiffusive slope may reflect a broader range of motional contributions.

The power spectrum of Eq. 37.7 changes as a function of time through the shift in the parameters $\Delta\omega_n(t)$, $\Delta f_n(t)$, and $\Delta\beta_n(t)$. The changes can be small, which suggests the use of a differential spectral response defined by

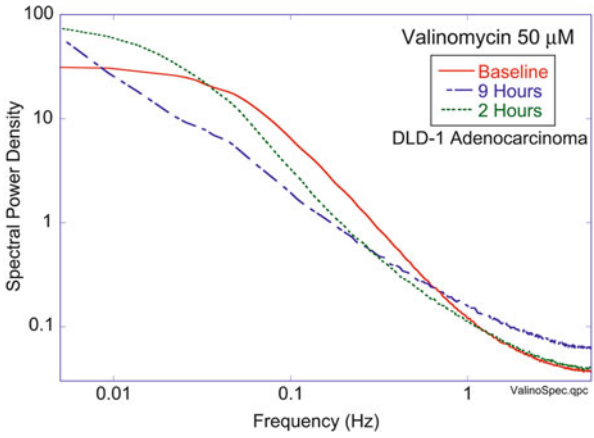

Fig. 37.4 Power spectrum of DLD-1 adenocarcinoma tumor spheroid responding to 50 µM valinomycin. The spectra 2 h and 9 h after the dosing is compared to the baseline spectrum. The spectrum has three orders of magnitude of dynamic range and spans three decades of frequency from 0.005 to 5 Hz

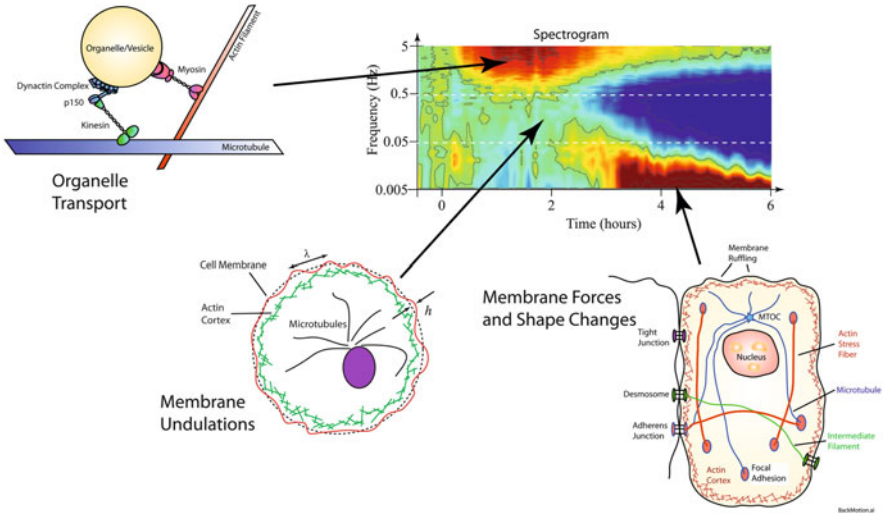

Fig. 37.5 The origin of spectroscopic motional signatures in a tissue-response spectrogram. The highest frequencies (around 5 Hz) relate to organelle transport, the mid-frequencies (around 0.5–0.05 Hz) to membrane undulations, and the lowest frequencies (around 0.005 Hz) to membrane forces and shape changes

$$D(\omega,t) = \frac{S(\omega,t) - S(\omega,0)}{S(\omega,0)} \tag{37.8}$$

This relative differential spectrogram captures the changes in spectral content as a function of time after a dose or a condition is applied. Tissue contains a wide range of characteristic frequencies producing complicated differential spectrograms.

An example of a tissue-response spectrogram is shown in Fig. 37.5 for pH 9 applied to rat UMR-106 osteogenic sarcoma tumor spheroids. The two-dimensional

representation of the differential response is presented as relative frequency content change as a function of time. The treatment is applied at $t = 0$, and the tumor spheroids are monitored over 6 h. The times preceding the treatment show the system baseline. The spectrogram shows an initially high-frequency enhancement that decays over several hours. There is a sudden enhancement of low frequencies around 3 h after the change in pH.

The mechanistic interpretation of the tissue-response spectrogram is facilitated by considering the backscattering frequencies from dynamic intracellular processes. The general relationship for single backscattering under heterodyne (holographic) detection is $q^2D = \omega_D$ for diffusion, and $qv = \omega_d$ for directed transport, where D is the diffusion coefficient, and v is a directed speed. The ranges in the parameters for directed transport and diffusion, respectively, are $0.006 < v < 2$ μm/s and $4 \times 10^{-4} < D < 0.1$ μm^2/s, set by the lowest and highest frequencies of 0.005–5 Hz. These are well within the range of intracellular motion in which molecular motors move organelles at speeds of microns per second [13, 56–59], although diffusion of very small organelles, as well as molecular diffusion, is too fast to be resolved by a frame rate of 10 fps. Membrane undulations are a common feature of cellular motions, leading to the phenomenon of flicker [60–64], and the characteristic frequency for light scattering from membrane undulations is in the range around 0.01–0.1 Hz [58, 61, 65]. The very low frequencies below 0.01 Hz relate to cellular rheology and the response of the cells to their local force environment, possibly including blebbing or the release of apoptotic bodies.

37.5 Phenotypic Profiling Based on Drug-Response Spectrograms

Cellular systems are highly complex, with high redundancy and dense cross talk among signaling pathways [66]. Biochemical target-based high-content screening can isolate single mechanisms in important pathways, but often fails to capture integrated system-wide responses. Phenotypic profiling, on the other hand, presents a systems-biology approach that has more biological relevance by capturing multimodal influence of therapeutics [67]. Ironically, phenotypic profiling is anachronistic, harking back to the days before genomics provided isolated targets. Nonetheless, it remains today one of the most successful approaches for the discovery of new drugs [68].

Most phenotypic profiling continues to be performed on two-dimensional culture, even though two-dimensional monolayer culture on flat hard surfaces does not respond to applied drugs in the same way as cells in their natural three-dimensional environment. This is in part because genomic profiles are different in primary monolayer cultures [69–71]. Several studies have tracked the expression of genes associated with cell survival, proliferation, differentiation, and resistance to therapy that are expressed differently in 2D cultures relative to three-dimensional culture. For example, three-dimensional culture display expression profiles more like those from tumor tissues than when grown in 2D [72–77].

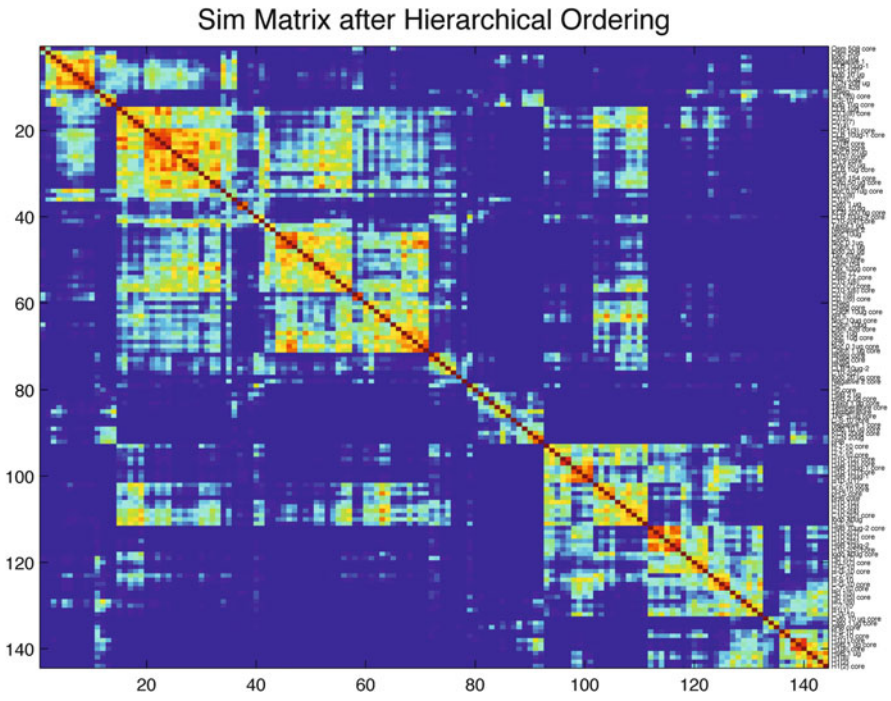

Fig. 37.6 A clustered similarity matrix among 144 different drugs, doses, and cell lines. The nearly block-diagonal structure after hierarchical ordering shows the quasi-orthogonality among the different groups of drug response

In addition, the three-dimensional environment of 3D culture presents different pharmacokinetics than 2D monolayer culture and produces differences in cancer drug sensitivities [78–81].

A drug-response spectrogram acts like a fingerprint, showing a distinct pattern in response to an applied drug or condition that is unique for that drug and cell line. To apply bioinformatic algorithms to the drug-response spectrograms, it is first necessary to convert the two-dimensional data format of the drug-response spectrograms into a quantitative feature vector [82]. Feature recognition and extraction is not a unique process, but a simple approach defines frequency response ranges across multiple time frames. The resulting feature vectors are N-dimensional representations of the specific response of the tissue cell line to the drug and dose. A similarity matrix is constructed from the correlation coefficients among the many pairs of feature vectors for different drugs and cell lines. A similarity matrix for 144 different drugs, doses, and cell lines is shown in Fig. 37.6 after unsupervised hierarchical clustering [83]. The drugs consist of nocodazole, colchicine, taxol, cytochalasin D, iodoacetate, TNF, cycloheximide, KCN, changes in pH and osmolarity, and several RAF inhibitors. The cell lines are UMR-106 rat osteogenic sarcoma as well as human HT-29 and DLD-1 adenocarcinomas. The clustering algorithm orders the tissue-response spectrograms of the different drugs and cell lines into groups based

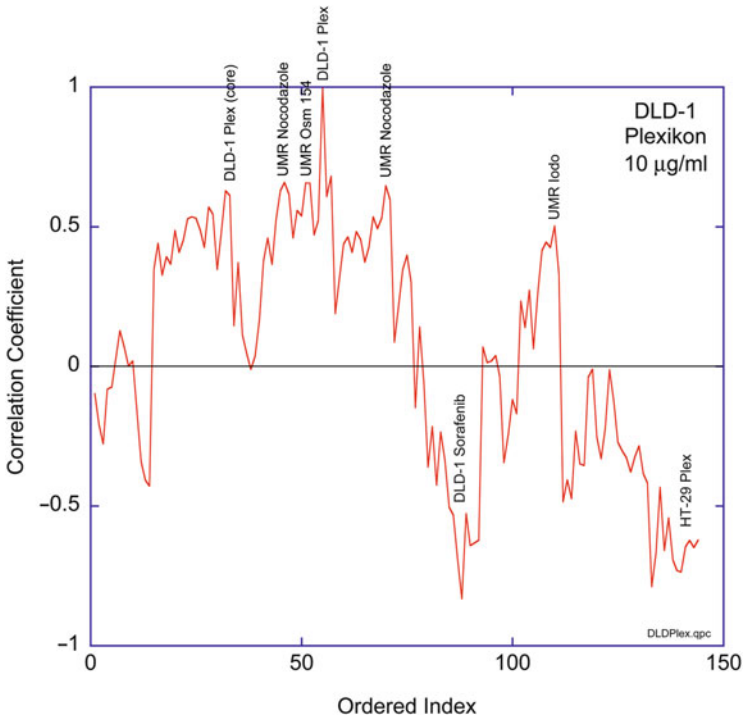

Fig. 37.7 Correlation graph as the cross-section of Fig. 37.6 centered on the response of DLD-1 shell to the PLX-4032 RAF inhibitor. The response of the related HT-29 adenocarcinoma (with a KRAS mutation) is anticorrelated to the same RAF inhibitor

on the similarity of their response. The similarity matrix shows strong block-diagonal structure, indicating that groups with high similarity have little overlap with other groups. By comparing a feature vector with in the groupings, it is possible to assign physiological attributes to the different groups. For instance, on the right of the similarity matrix, the groups are assigned enhanced or suppressed properties such as membrane motions, mechanical responses, and effective temperatures. This quasi-orthogonality among the groups provides the basis of a phenotypic classification scheme in which a new lead compound of unknown mechanism may be compared against a reference compound library of dynamic tissue response spectrograms that have known mechanisms of action.

An example of a correlation comparison is shown in the graph in Fig. 37.7 for the RAF inhibitor PLX-4032 at 10 µg/ml applied against the DLD-1 adenocarcinoma cell line that has a BRAF mutation. The graph is the cross section of the similarity matrix in Fig. 37.6 centered on the DLD-1 PLX-4032 response in the shell of the tumor spheroid. The same RAF inhibitor applied against the similar HT-29 cell line leads to an anticorrelation (shown on the far right of the graph). The HT-29 cell line has a KRAS mutation that the DLD-1 cell line does not share. There is also a strong anticorrelation between DLD-1 spheroids treated with Plexikon compared with

sorafenib, which is another RAF inhibitor that has a different mechanism of action. This is just an illustrative sample, showing the potential for phenotypic comparisons among different cell types and different applied drugs.

37.6 Future Directions in Biodynamic Imaging

Using intracellular motion as suite of functional biomarkers is a new concept that is in its infancy. In this review, dynamic light scattering imaging and spectroscopy were described in the context of applications to drug discovery. Drugs have a wide range of mechanisms of action which can be partially matched by the wide range of different types of cellular motions that may be affected by specific drugs. Metabolic activity of cells is clearly observed in the dynamic light scattering, and hence the effect of drugs on cell metabolism, and in particular cellular toxicity, is a prime target for dynamic imaging. Cell proliferation is another sensitive measure of the effect of a drug, and dynamic imaging is well suited to interrogate cellular proliferation and to monitor how proliferation is affected by applied drugs.

An attractive application for dynamic imaging is in the field of personalized medicine. Cancers are heterogeneous both genetically and phenotypically. Choosing the correct therapy for a patient is often a long process of trial and error, and sometimes a prescribed chemotherapy has no benefit, while carrying severe side effects. By applying dynamic imaging to heterogeneous biopsies from a cancer patient, there is an opportunity to apply combinations and sequences of drugs to the tumor samples to find which are most effective for treating that specific patient. This approach would go far beyond the current paradigm of only a small number of therapies applied to broad populations of patients, many of whom fail to respond.

Going beyond drug screening, the ubiquity of motion in all living tissue suggests that the generality of this approach is broad. For instance, there is significant motion involved in developmental biology, as stem cells differentiate into cells of different identities and move through morphogenic fields in the developing embryo. Metastatic cancer cells move by amoeboid crawling motions through tissue across millimeters. Mitosis and cytokinesis are large-amplitude and energetic processes with relatively high speeds, but with low probability per cell per time. Pixel-based interrogation of light scattered from proliferating tissue is likely to uncover distinct frequency signatures of these processes. Neurological processes in the brain involve high synaptic activity with the emission and absorption of synaptic vesicles, and action potentials are energetic processes that require active cellular metabolism to sustain membrane depolarization. In the arena of artificial reproductive technologies, the assessment of viable oocytes and developing embryos is essential for effective in vitro fertilization. These examples illustrate just some of the many possible applications of dynamic imaging.

Elastic Scattering Spectroscopy and Optical Coherence Tomography

38

Adam Wax, Michael Giacomelli, and Francisco Robles

38.1 Introduction

Elastically scattered light contains information about the scattering medium with which it has interacted. The elastic scattering process can be interpreted as a change in the momentum of light due to its interaction with a scattering object. By analyzing this change in momentum, structural information such as the size, shape, and organization of scattering objects can be recovered. Recently, light-scattering techniques have been developed for examining biological cells and tissues both in the laboratory and the clinic. These techniques are broadly termed elastic scattering spectroscopy (ESS).

In order to implement an effective ESS method for probing cells and tissues, it is important to isolate the component of returned light which has undergone a single scattering process. This is complicated by the fact that only a small fraction of light exits the scattering medium after a single scattering event. The majority of the returned light exits the tissue having undergone multiple interactions with various scattering components, creating an overall background of diffuse light. ESS methods aim to distinguish the singly scattered light from the diffusive background, often relying on polarization gating or modeling. As an alternative approach, the

use of coherence gating, which is responsible for depth resolution in optical coherence tomography (OCT), offers a powerful method for suppressing the detection of diffuse light.

In this chapter, the development of cell and tissue analysis methods based on the combination of ESS and OCT is discussed. Background information consisting of an overview of the advantages of ESS is presented first. This is followed by a survey of ESS schemes which employ coherence gating to isolate photons which have scattered once. Finally, a review of recent experimental results which use combinations of ESS and OCT methods is presented, including basic validation experiments, studies of in vitro cells, preclinical studies of animal and human tissues, and ultimately an in vivo clinical study.

38.2 Elastic Scattering Spectroscopy

Many clinical and laboratory studies seek to determine the structure of cells and biological tissues. The most widespread approach is based on traditional pathology analysis, which relies on examining histological slides of fixed and stained specimens using a light microscope. While histopathology is the current gold standard for clinical diagnosis of disease, it limits the knowledge of cell structure by the artifacts it introduces in preparing tissue samples for study. Tissue processing requires fixation, sectioning, and often the addition of exogenous staining agents which alter the structure of the cells in nontrivial ways. In addition, this approach can only reveal a snapshot of the evolution of an individual cell and must rely on statistical studies of large ensembles of cells to assess their development in time. ESS methods offer the opportunity to study living cells in situ by providing a noninvasive means of measuring cellular structure without the need for exogenous contrast agents. In addition, since light scattering does not perturb the structure or function of cells, ESS techniques permit studies of the development, formation, and function of cellular structures through examination of the properties of the *same* cells at extended intervals.

In this section, the two basic approaches for deducing structure based on light scattering are discussed. In one approach, the wavelength dependence of scattered light is examined for a fixed angular collection. In the other, the wavelength is fixed and the angular dependence of the scattered intensity is examined. Both approaches recover structural information by assessing the change in the momentum of light due to elastic scattering but are implemented differently. For each approach, the section below will present a brief overview of its theoretical basis, the experimental schemes used to implement it, and clinical and laboratory results obtained using light-scattering techniques for measuring cellular structure and organization.

38.2.1 ESS Using Spectral Analysis

Light incident on a scattering particle can be used to deduce its structure by examining the wavelength dependence of the scattered light [1]. Spectral ESS

approaches have been developed as biomedical diagnostic methods for identifying diseased tissue by probing cellular structure. One complication in application of spectral ESS is that in general, single scattering events cannot be directly measured in biological tissue [2]. Three basic approaches have been implemented to overcome this challenge. The first is to use an analytic method to model coarse features of the measured spectrum which are then removed, leaving the residual for analysis. The second approach is polarization gating, which can be employed to discriminate low-order scattering from the diffusive background. These approaches were used in experiments with various models of living tissues as well as ex vivo and in vivo human tissues [3, 4]. Analysis of these data can be accomplished using Mie theory or Fourier transform-based analysis, where periodic variations in spectral ESS signals are related to spatial correlations over specific length scales. The Fourier transform-based method for analyzing periodic variations in spectral ESS signals has been used to measure the size distribution of cell nuclei in clinical studies [5–7] but was later found to be vulnerable to corruption by absorption features [8]. As an alternative, coherence gating, the depth sectioning method employed in OCT, can also be employed to detect singly scattered light for ESS analysis. This approach avoids the limitations of the other approaches, including avoiding the influence of absorption due to hemoglobin in underlying layers. The combination of spectral ESS and OCT is discussed further below.

38.2.2 ESS Using Angular Features

Another ESS method which can be used to determine the structure of a scattering object is analysis of the angular distribution of scattered light. Angular ESS methods rely on deducing scatterer size by measuring the differential cross section or a portion of it. This approach obtains similar information to that obtained with spectral ESS methods but possesses its own considerations for implementation. Both approaches examine the momentum transferred to the light during elastic scattering and both must isolate the contribution of single scattering for analysis. However, angular ESS methods are not vulnerable to the effects of absorption, which does not vary appreciably with scattering angle. In order to determine structure by analysis of angular ESS signals, a theoretical basis of the angular dependence of scattering is needed.

A straightforward approach is to use the Born approximation to relate the scattered field with fluctuations in density and in turn the dielectric properties in the sample. Spatial correlations in the density of the sample can be obtained through Fourier transform of the measured angular distribution within the small angle approximation [9]:

$$\mathcal{I}\left[\left|E\left(\vec{\theta}\right)\right|^2\right] \propto \left\langle \partial\rho\left(\vec{r}_\perp{}'\right)\partial\rho\left(\vec{r}_\perp{}' + r\hat{\theta}\right)\right\rangle \equiv \Gamma_\rho(r). \tag{39.1}$$

In this expression, the mean squared field, E, as a function of scattering angle, θ, is related to the two-point density correlation function, $\Gamma_\rho(r)$, of the sample as a function of separation, r, along the direction given by the scattering angle θ.

An alternative to analytic approaches is to numerically solve Maxwell's equations for a range of scattering geometries and then compare a measured distribution to a database of simulated values. Frequently, Mie theory has been used because it can rapidly produce exact scattering solutions for spherical scatterers and approximately correct solutions for nearly spherical scatterers. Surprisingly, even moderately aspherical objects such as the nuclei of many types of cells can show relatively good agreement with Mie theory [10], allowing application to a variety of biological scatterers.

A more sophisticated approach to modeling scattering is to use the T-matrix method, also referred to as the extended boundary condition method (EBCM), a generalization of Mie theory to arbitrarily shaped objects that reduces to Mie theory in the spherical case [11]. Because most cell nuclei are approximately spheroidal rather than spherical, the T-matrix is a more widely applicable alternative to Mie theory that can provide more accurate solutions. Furthermore, the T-matrix method enables simulation of the effects of parameters beyond the size and refractive index of cell nuclei, including the extent to which scatterers are elongated (aspect ratio) and the orientation of scatterers [12, 13].

Unfortunately, generating comprehensive databases of T-matrix solutions is computationally challenging, both because nonspherical solutions are more computationally complex and because the range of biologically interesting geometries is much larger than in Mie theory [14]. This disadvantage is partially offset by the availability of very efficient FORTRAN codes that implement recent advances in T-matrix modeling [15].

Experimentally, detection of angular ESS signals has been demonstrated with Fourier plane imaging. In this approach, the detection element is located in a Fourier transform conjugate plane [16] to the scattering sample such that the spatial distribution of light in the Fourier plane corresponds to light scattered at a particular angle by the sample. Thus, a spatially selective detection scheme such as an aperture can be used to detect light scattered over a range of angles. In one implementation of an angular ESS scheme, the input slit of an imaging spectrograph was placed in a Fourier plane of scattering samples, enabling both spectral and angular scattering to be observed simultaneously [17]. This approach, termed elastic light-scattering fingerprinting, was used to study early carcinogenesis events in ex vivo rat colon [18]. In another implementation, angular ESS information has been obtained using Fourier plane imaging in a microscopy scheme [19]. This method has been applied to study scattering changes associated with apoptosis [20]. A third approach uses holographic methods to record angular scattering due to localized particles [21]. These approaches offer the advantages that scattering data are collected in parallel rather than serially; they are compatible with broadband light sources and permit detection of light scattered near the backscattering direction which is important for probing the structure of larger structures, such as cell nuclei.

38.3 Angle-Resolved Low-Coherence Interferometry: Combining ESS and OCT for Detecting Precancerous Cells

Angle-resolved low-coherence interferometry (a/LCI) has been developed as an angular ESS method for probing the structure and organization of cells and their components. The a/LCI technique is unique among angular ESS approaches in that it uses coherence gating, the mechanism employed in optical coherence tomography (OCT) to achieve depth resolution, in order to isolate the component of returned light due to single scattered photons. While a/LCI and OCT share the ability to selectively probe subsurface layers, conventional OCT implementations lack the resolution and contrast to quantitatively assess changes in subcellular features. In contrast, because a/LCI uses elastic scattering spectroscopy to assess structure, it can detect changes in subcellular structure. Early efforts to combine the ESS and OCT methods sought to perform a/LCI using a Michelson interferometer [9, 22, 23] to measure depth-resolved scattered fields as a function of scattering angle. In a/LCI, the transverse component of the momentum transfer associated with the light-scattering process is detected by using Fourier plane imaging concepts with interferometry where the reference field is tailored to select specific transverse momenta, i.e., angles of propagation for detection. This section presents the optical design and evolution of a/LCI schemes and the theoretical basis which permits structural information to be extracted from the scattering distributions.

38.3.1 Optical Design of a/LCI Systems

There have been three implementations of a/LCI systems for detecting the angle-resolved scattering distribution using low-coherence interferometry. These include the Michelson interferometer-based a/LCI prototype; a second-generation a/LCI system based on a Mach–Zehnder interferometer, which records depth-resolved data in the time domain; and, the most recent, clinical a/LCI implementation based on spectral-domain interferometry. The primary driving force behind the evolution of a/LCI systems has been to improve the speed of data acquisition while also providing low-noise, high-fidelity measurements, to enable clinical application to detecting dysplasia in human epithelial tissues based on measuring the size of cell nuclei.

The first a/LCI systems used time-domain interferometry in Michelson geometry similar to time-domain OCT. Depth scanning was accomplished by translating the sample [23] or reference [22] arms, while measurement of the angular distribution was accomplished by translating a lens perpendicular to the beam pass to scan the angular distribution across a photodiode. However, this approach suffered from limited sensitivity due to the use of a kHz Doppler shift to separate the interferometric signal from the DC background. Combined with the very low intensity per angle of typical scattered fields, these systems required long scan times of greater than 30 min to acquire sufficiently high sensitivity measurements.

Following the demonstration of time-domain a/LCI, an improved implementation based on a Mach–Zehnder interferometer (MZI) was developed to address these limitations [24, 25]. The MZI implementation improved sensitivity by separating the collection optics from the angle scanning optics and introducing acousto-optic modulators with balanced heterodyne detection. The resulting system demonstrated higher angular resolution and sensitivity combined with faster scan times of less than 5 min and enabled a number cellular [26] and ex vivo tissue studies [27].

Recent advances in OCT have shown that improvements in signal-to-noise and reductions in data acquisition time are possible by recording the depth scan in the Fourier (or spectral) domain [28–30]. These advances were leveraged to implement Fourier-domain a/LCI [31]. In this approach, measurement is again performed using a Mach–Zehnder interferometer, but the reference arm is fixed and a spectrometer is used to read out a spectral interferogram as in Fourier-domain OCT. Furthermore, by using an imaging spectrometer, angle scanning optics are obviated by rapid parallel detection along the spatial channel of the spectrometer.

By combining the Fourier-domain a/LCI scheme with a coherent fiber bundle, angle-resolved measurements can be performed endoscopically, enabling in vivo applications. Figure 38.1a depicts an endoscopic a/LCI system using a coherent fiber bundle [32]. The system again consists of a Mach–Zehnder interferometer, now implemented using fiber-optic components to minimize space. Light from a superluminescent diode (SLD) is divided into a sample (90 %) and reference (10 %)

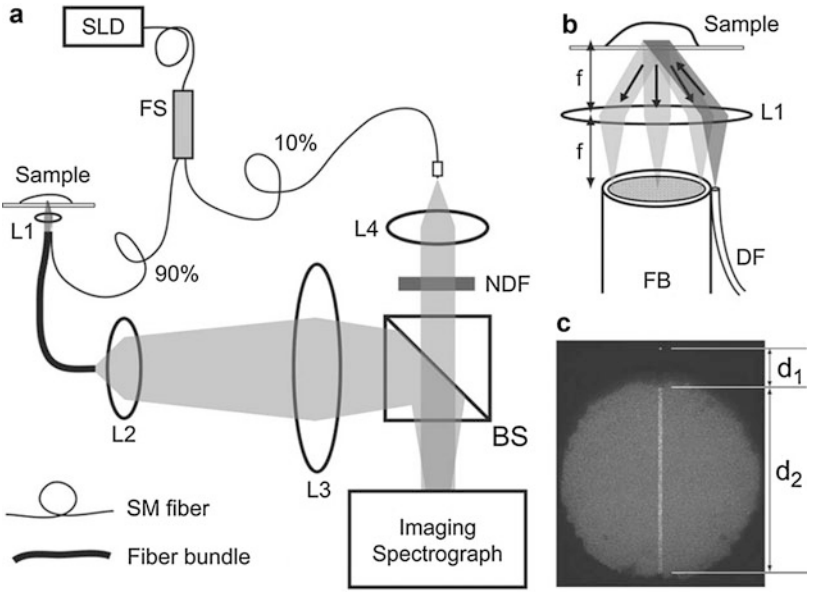

Fig. 38.1 Fiber-based Fourier-domain a/LCI system taken from [32]. (**a**) Diagram of the endoscopic interferometer. (**b**) Detailed view of the sample optics. (**c**) Photograph of the fiber bundle face

arms by a fiber splitter (FS). The sample arm light is delivered by a polarization-maintaining delivery fiber (DF) and grin lens L1 onto the sample (Fig. 38.1b). The use of a separate delivery fiber is essential because it ensures the illumination angle and polarization state are precisely controlled, an essential feature for accurately determining cell morphology [33].

Light scattered from the tissue surface is collected by lens L1 and relayed to the distal face of the fiber bundle. By positioning the face of the fiber bundle in the Fourier plane of L1, each channel of the bundle receives light scattered at a particular angle. The light relayed by the bundle is imaged onto the entrance slit of an imaging spectrometer along with the overlapped reference field. The imaging spectrometer slit is positioned along the center of the fiber bundle (Fig. 38.1c) with approximately 130 fibers imaged onto the slit in order to capture a comparable angular range as used in previous a/LCI systems. By carefully determining the magnification so that individual fibers are adequately sampled, cross talk between adjacent angular channels can be minimized. Although the fibers are not single mode, coherence gating effectively rejects any contribution from higher-order modes which experience a much greater optical path length [34].

An alternative collection method to using a coherent fiber bundle is to use a single-mode optical fiber combined with mechanical scanning to obtain scattering measurements. This approach was implemented in the fiber-optic interferometric two-dimensional scattering (FITS) system to perform polarization-resolved one- or two-dimensional scattering measurements by translating a single-mode fiber across the back focal plane of a collection lens [35]. Polarization selectivity is obtained using a novel hybrid Michelson–Sagnac hybrid interferometer implemented in fiber. By mixing the scattered field and reference field inside of an optical fiber, the polarization state of the detected field can be precisely measured. Furthermore, as the reference and sample arms propagate along common single-mode fibers, the system is relatively insensitive to dispersion, even in very long fiber probes. Although the FITS system forgoes the sensitivity advantage of parallel detection, it was the first a/LCI system capable of 2D measurement of scattered fields.

38.3.2 Processing a/LCI Distributions to Obtain Structural Information

As discussed above, a/LCI signals must be processed and then analyzed in order to determine structural features from measurements of angle-resolved scattering. In frequency-domain a/LCI, light at each scattering angle is detected as a function of wavelength such that the detected signal can be related to the signal and reference fields (E_s, E_r) by [36]

$$I(\lambda_m, \theta_n) = \left\langle |E_r(\lambda_m, \theta_n)|^2 \right\rangle + \left\langle |E_s(\lambda_m, \theta_n)|^2 \right\rangle + 2\mathrm{Re}\left\langle E_s(\lambda_m, \theta_n) E_r^*(\lambda_m, \theta_n) \cos(\phi) \right\rangle, \tag{38.2}$$

where ϕ is the phase difference between the two fields, the indices (m, n) correspond to a particular pixel, and $\langle\rangle$ denotes a temporal average.

In order to process the raw pixel data to produce depth-resolved scattering measurements, the data are processed as described in [37], in a process similar to Fourier-domain processing of OCT signals. First, the average intensities of the sample and reference beams are measured independently and then subtracted from I. Second, at each scattering angle, the spectrum in wavelength (λ) is converted into a linear function of wavenumber (using $k = 2\pi/\lambda$), using a cubic spline interpolation. At this point, any chromatic dispersion in the system is corrected numerically using empirical parameters. Finally, at each scattering angle, the spectrum as a function of wavenumber is 1D Fourier transformed to generate a signal which is a function of optical path length (or depth in the sample).

This processed signal is analyzed to determine structural information, typically the size of cell nuclei in a tissue sample. First, the angular distribution is divided by the normalized reference field, which varies smoothly from 0.5 to 1, to produce a signal that is linear in the scattered field. The scaled data are then squared to yield scattered intensity versus angle and path length. These data are further processed to remove high-frequency noise by binning the angular data. The angular data for a particular depth (optical path length) are then compared to database of theoretical predictions which have been calculated previously. Chi-squared values are calculated as the mean square difference between the data and each theoretical prediction for a range of scatterer diameters. The minimum chi-squared value is determined by searching through all values generated and the corresponding size is reported as the best fit. The uncertainty in these measurements is given as the change in structure diameters where the minimum chi-squared value is doubled.

Although this procedure is generally applicable, additional steps must be taken for the specific case of analyzing scattering due to cell nuclei. As discussed in detail in [33], accurate size determination can be complicated by other structures if the angular data are compared directly to the predictions of Mie theory. First, one must consider that Mie theory predicts scattering by a homogenous dielectric sphere while, for most cells, the nucleus is not a sphere but rather a spheroid. In addition, the presence of inhomogeneities in and around the nucleus can also complicate interpretation of the angular-scattering distribution.

The a/LCI analysis algorithm for extracting nuclear size information from cells and tissues consists of four steps. First, data from a particular region of interest are selected, usually corresponding to a particular tissue layer. The data are then filtered to remove high-frequency oscillations, as described above. Since the angular distribution is Fourier transform related to the two-point correlation function (Eq. 38.1), removing these oscillations over fine angular scales corresponds to suppressing scattering arising from long correlation distances. Physically, this step removes the contribution to angular scattering arising from coherent scattering by neighboring cell nuclei which are necessarily spaced at distances greater than the cell size. This effect was examined in a previous study [38] which systematically varied cell spacing to demonstrate that this process permitted accurate size determinations in the presence of coherent scattering by adjacent cell nuclei.

An additional filtering step is then implemented, which uses a second-order polynomial to remove the background trend from the processed data. This step is important to enable fitting using chi-squared minimization and serves to isolate the oscillatory component of the angular scattering due to diffraction, as described in [39]. The final step of the analysis is to compare the processed angular distribution to theoretical distributions which have also had their background trend removed. For determining the size of cell nuclei, a database of calculated distributions will include a Gaussian distribution of scatterer sizes, characterized by a mean diameter (d) and a standard deviation (δd) in the size parameter, a range of refractive indices of the nuclei ($n_{nucleus}$), and a range of refractive indices of the cytoplasm ($n_{cytoplasm}$).

As a final note, when fitting data for cell nuclei, whether in isolated cells or from tissue, criteria that establish a unique fit are needed. The a/LCI processing typically employs two checks, including a comparison with scattering that is constant versus angle and demanding that the chi-squared value for the best fit is at least 10 % greater than the next best value to ensure a unique fit.

Processing of a/LCI data can be readily generalized to two-dimensional, solid angle-resolved fields resulting in more accurate measurement of size and shape. In this case, the database of theoretical scattering solutions is constructed with scattered field intensities recorded over two dimensions. The scattering simulations and the 2D measurement coordinates are coregistered by comparing measurements from known scattering samples to the simulated values. During this step, effects such as field curvature can be removed if present. After coregistration, low-pass filtering is implemented similar to the 1D process by using a 2D filter kernel and second-order polynomial subtraction. The processed measurement data is then compared on an angle per angle basis to generate a χ^2 error value for each database entry. As in the 1D case, the simulation with the lowest χ^2 value indicates the scattering geometry.

38.4 Applications of a/LCI

A number of studies have employed a/LCI to investigate structure through depth-resolved angular-scattering measurements. These include validation experiments with polystyrene microspheres and in vitro cells which have served to demonstrate various aspects and capabilities of the technique. Further experiments have applied a/LCI to examine the nuclear morphology of epithelial cells in tissues drawn from animal models of carcinogenesis. Finally, a clinical implementation of a/LCI has been developed which introduces an endoscopic fiber-optic probe that is compatible with standard endoscopes. This section concludes with ex vivo and in vivo studies which apply the new fiber probe to detect precancerous changes in human epithelial tissues.

38.4.1 a/LCI Validation Experiments

Validation of the a/LCI approach was first achieved by measuring the scattering distribution of polystyrene microspheres [22]. Upon realizing Fourier-domain a/LCI,

it became much easier to acquire scattering data and a study was undertaken to demonstrate the capability of the system across a range of clinically relevant-sized polystyrene microspheres of sizes 6.0, 8.0, 9.7, 12.0, and 15.0 μm [37]. The results showed that a/LCI-determined mean diameter agreed very well with the corresponding NIST traceable mean diameters, producing an r^2 value of 0.9997.

While polystyrene microspheres are suitable targets for developing light-scattering systems, measurement of cell nuclear morphology is a more challenging target due to the lower refractive index compared to the surrounding medium. The first application of a/LCI to measurement of nuclear morphology was accomplished using monolayers of cultured HT29 epithelial cells [9], a line of human tumor cells. This study demonstrated sub-wavelength precision and accuracy by comparing the light-scattering results to quantitative image analysis (QIA). This first application also developed the signal-processing methods to account for the nonspherical and inhomogeneous nature of cell nuclei. Significantly, this work identified a power law correlation function that described the residual light-scattering signal once the nuclear contribution was removed. A more comprehensive study of scattering by in vitro cells was completed by Pyhtila et al. [33], which explored the role of polarization in analyzing light-scattering signals from cell nuclei. A comprehensive list of a/LCI nuclear morphology data for in vitro cells can be found in *Biomedical Applications of Light Scattering* [40].

The first use of the T-matrix method for assessing the size of cell nuclei using with a/LCI was demonstrated using cultured MCF-7 breast cancer cells [12]. In these experiments, 37 a/LCI measurements were taken with 48 angles per measurement from six cell monolayers prepared on coverslips. Cells were then imaged using DAPI fluorescence and QIA to determine nuclear diameter. Analysis was enabled by a T-matrix database that contained simulated scattering for nuclei from 7.5 to 12.5 μ diameter in increments of 40 nm, spheroidal aspect ratio from 0.56 to 1 (prolate to spherical) in increments of 0.01, background index of refraction 1.35 and 1.36, and scatterer index of refraction 1.42 and 1.43, all with a 10 % standard deviation normal size distribution. Both methods provided nearly identical answers, with QIA yielding an EVD of 9.52 μm (95 % standard error = 0.44 μm) and an aspect ratio of 0.70 ± 0.026 and a/LCI with T-matrix determining an EVD of 9.51 ± 0.34 μm with an aspect ratio of 0.69 ± 0.032 determined. These results confirmed the ability of a/LCI to measure both the size and shape of living cell nuclei with extremely high accuracy.

Following the demonstration of T-matrix-based analysis in a/LCI, the technique was generalized to 2D using and the FITS system to analyze scattering from stretched polystyrene microspheres [41]. In these experiments, small numbers of microspheres were mixed into transparent plastic, heated beyond their melting point, and then allowed to cool under tension. The resulting phantoms had a nearly perfect spheroidal geometry of known size and shape. A database was prepared using the T-matrix method to simulate the complex polarization state of the 2D angle-resolved fields over 360° of azimuth angle and 30° of polar angle (corresponding to the range achieved in 1D a/LCI). In total, 10,250 unique scatterer geometries were simulated with equal volume diameters ranging from 8 to 18 μm in

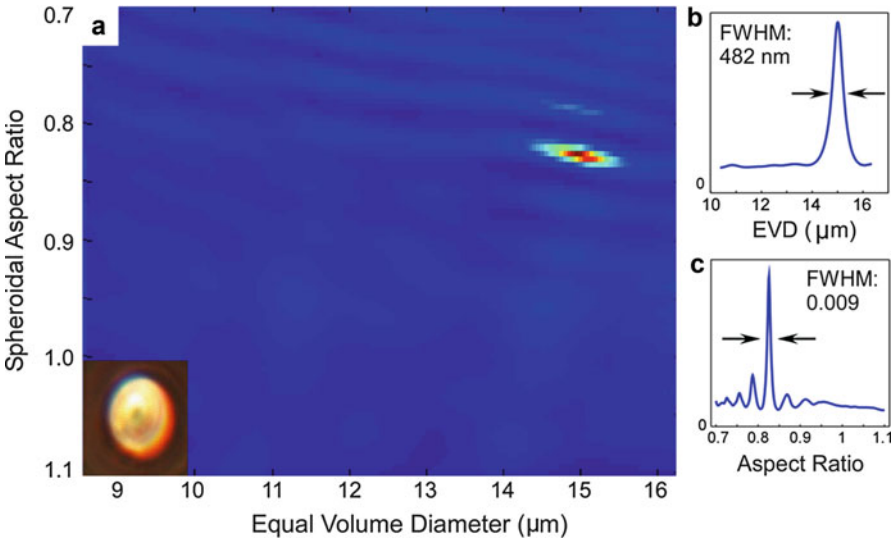

Fig. 38.2 (**a**) χ^2 error plotted against equal volume diameter and aspect ratio for a single 0.82 (determined by QIA) 15 μm stretched microsphere (see inset). (**b**) Plot of χ^2 compared to diameter. (**c**) χ^2 error compared to aspect ratio (Adapted from [41])

80 nm increments and aspect ratios between 0.7 (prolate spheroidal) and 1.1 (oblate spheroidal) in steps of 0.005 [42].

Individual stretched microspheres were selected and scanned using the FITS system and then analyzed using a T-matrix database. Measurements were presented for three representative samples of microspheres with a diameter of 15.02 μm +/− 80 nm prior to stretching [43]. In the spherical geometry, a/LCI measured an equal volume diameter (EVD) of 15.00 ± 0.24 μm and an aspect ratio of 0.995 ± 0.04. For a slightly stretched (QIA aspect ratio = 0.93) spheroid, a/LCI measured an EVD of 14.95 ± 0.33 μm and an aspect ratio of 0.925 ± 0.01. Finally, for a moderately stretched (QIA aspect ratio = 0.82) spheroid, an a/LCI measured an EVD of 15.00 ± 0.24 μm and an aspect ratio of 0.825 ± 0.005 (Fig. 38.2). This analysis demonstrated that 2D a/LCI size and shape determinations are unique even over very large parameter spaces.

38.4.2 Application of a/LCI in Cell Biology

The ability of a/LCI to noninvasively measure changes in cell nuclei with wavelength accuracy has been applied to measurement of cell dynamics in several experiments. In the first of these, subtle changes in the volume of cell nuclei with changes in osmolarity were measured with Mie theory [44]. This study also showed that changes in cell nucleus shape due to a substrate texture could be measured with a/LCI but required multiple measurements with different orientations of the sample.

With the development of T-matrix-based fitting for the measurement of both size and shape, a/LCI was extended to measure deformation of cell nuclei in response to nanopatterned substrates within a single measurement [13]. These results demonstrated that real-time quantitative measurement of changes in live cells in response to environmental stimuli was possible without the use of exogenous contrast agents.

The improved accuracy enabled by T-matrix-based fitting was subsequently used to investigate the onset of apoptosis in breast cancer [45]. In these experiments, cells were treated with one of two chemotherapeutic agents at levels sufficient to initiate apoptosis. Treated cells were then measured at regular intervals with a/LCI and the size and shape determined with T-matrix-based processing. The T-matrix fit was then subtracted from the angular-scattering data and Fourier transformed to obtain a residual signal correlation function. While the size and shape data did not appreciably change due to treatment, analysis of the residual signal using a fractal dimension formalism did produce statistically significant results, showing a dramatic change 3 h after treatment with paclitaxel (Fig. 38.3a) and doxorubicin (Fig. 38.3b). Subsequently, time courses demonstrated a statistically significant change after just 90 min (Fig. 38.3c), demonstrating that angle-resolved light scattering can detect pre-apoptotic changes in nuclear organization.

38.4.3 Application of a/LCI to Detecting Precancerous Lesions in Animal Tissues

The first application of a/LCI to assessing structure within tissues was in quantitative studies of the nuclear morphometry of epithelial cells in a rat model of esophageal carcinogenesis [46, 47]. Changes in the size and texture of cell nuclei due to neoplastic transformation were observed in situ via quantitative measurements of basal epithelial cell nuclei, approximately 50–100 μm beneath the tissue surface. In the first study, a/LCI measurements, made on freshly excised tissue samples without using exogenous contrast agents or tissue fixation, were compared to traditional histopathological images to establish a correlation with the degree of neoplastic transformation [47]. The grading criteria from this initial study were then used to detect neoplastic transformation in a prospective study [46].

The rat esophagus studies focus on two morphological parameters: the mean nuclear size and the fractal dimension. The a/LCI measurements of these parameters from the first study are presented graphically in Fig. 38.4. The measurements are grouped by histological classification: normal epithelium, low-grade dysplasia (LGD), high-grade dysplasia (HGD), epithelium with vacuolated cells, or epithelium with apoptotic cells. The latter two classifications were seen in tissues treated with prospective chemopreventive agents. The observations of vacuolization and apoptosis using a/LCI are important findings as it illustrates a potential application of the technique for assessing the efficacy of chemopreventive agents or the toxic effects of chemicals on tissue health.

In this first study [47], the mean nuclear size was found to be a powerful indicator of neoplastic progression, resulting in 80 % sensitivity and 100 %

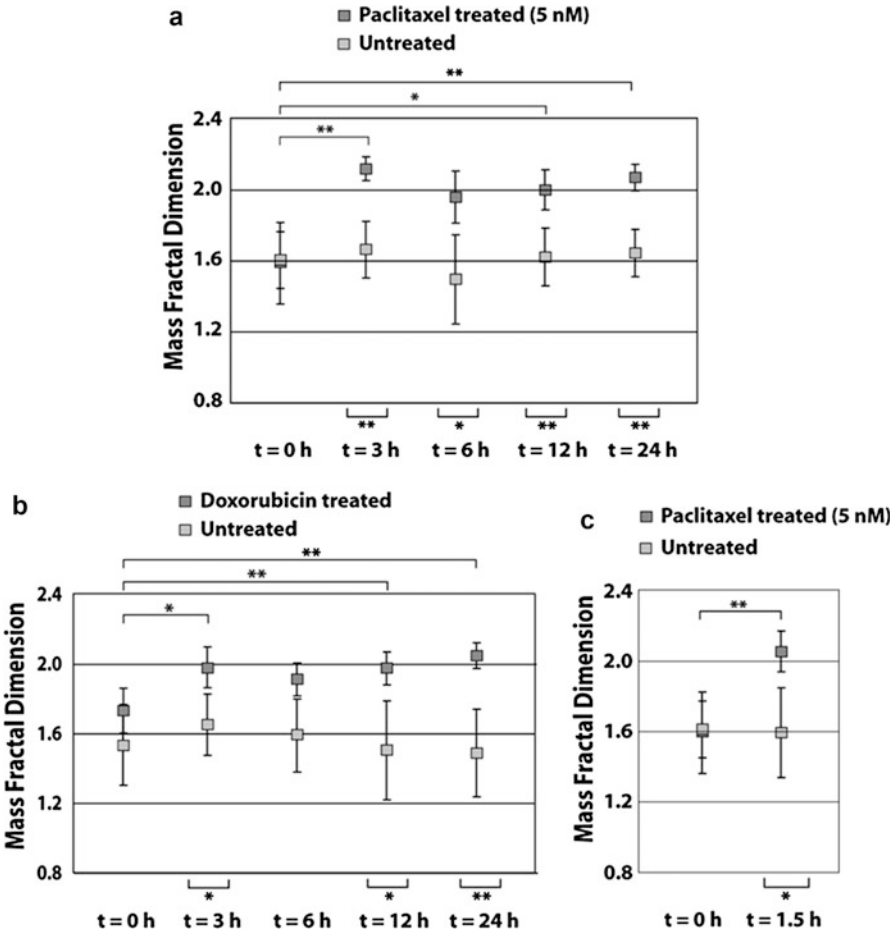

Fig. 38.3 a/LCI T-matrix-measured fractal dimension of chemotherapy-treated cells. (**a**) Fractal dimension after 0, 3, 6, 12, and 24 h after paclitaxel treatment demonstrating a rapid increase in fractal dimension following the initiation of apoptosis. (**b**) Previous results repeated for doxorubicin. (**c**) Paclitaxel treatment after 90 min (Taken from [45])

specificity in distinguishing normal from dysplastic tissues. In addition, apoptotic cells could be easily distinguished via nuclear size distribution. The fractal dimension measurements did not improve the diagnostic capability of a/LCI for classifying neoplasia, but fractal dimension measurements were later found to offer utility in assessing therapy [45].

In a second prospective study of the rat esophagus carcinogenesis model [46], the tissue classifications established in the initial study were used to grade tissue samples. Freshly excised esophageal tissues were examined using a/LCI at time points of 8, 12, and 20 weeks following treatment with N-nitrosomethylbenzylamine (NMBA). The degree of neoplastic transformation

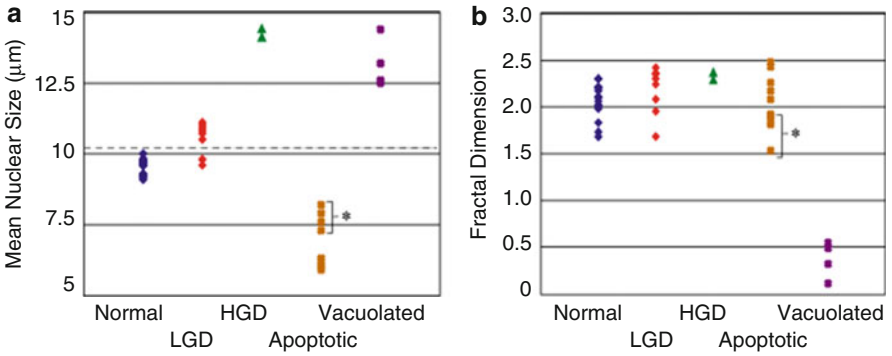

Fig. 38.4 (**a**) Average cell nuclei size from intact excised rat esophagus tissues as determined with a/LCI. The *dashed line* represents a decision line between normal and dysplastic cells. (**b**) Fractal dimensions of subcellular components measured using a/LCI. There is a significant difference ($p < 0.05$) between normal and dysplastic (LGD+HGD) populations (From Ref [47])

was assessed by measuring the average diameter of the cell nuclei in the basal layer and comparing to the grading criteria established previously. This prospective study showed that a/LCI successfully identified 58 of 60 normal tissue sites (97 % specificity) and 20 of 22 dysplastic tissue sites (91 % sensitivity) upon comparison to traditional histopathology. In addition, this study further reinforced the use of a/LCI for assessing the efficacy of chemopreventive agents, by comparing the modulation in incidence of neoplastic change due to addition of difluoromethylornithine (DFMO) to the diet of the animals. The a/LCI data showed no difference in incidence at 8 weeks but that DFMO was effective in reducing the incidence of dysplasia at 12 and 20 weeks post-NMBA treatment. Traditional tumor metrology measurements confirmed the observation of modulation in incidence at 20 weeks but could not detect it at earlier times, suggesting that a/LCI can provide greater sensitivity than traditional methods.

38.4.4 Application of a/LCI to Human Tissues

The first demonstration of the clinical utility of a/LCI was shown with measurements on ex vivo human tissue samples from three patients with dysplastic Barrett's esophagus (BE) who underwent esophagogastrectomies [48]. The tissue was opened longitudinally and data was taken within 2 h of resection. These studies showed a high sensitivity and specificity for distinguishing dysplastic BE tissue from healthy columnar tissue (Fig. 38.5), as would be found in the gastric epithelium. No non-dysplastic BE tissue was encountered. A follow-up study was conducted using the first portable a/LCI system in the pathology clinic, enabling data to be taken within 1 h of resection [36]. This study employed a handheld optical probe, allowing precise selection of the location for each data point and enabling better coregistration. Three types of tissue from a single specimen were probed.

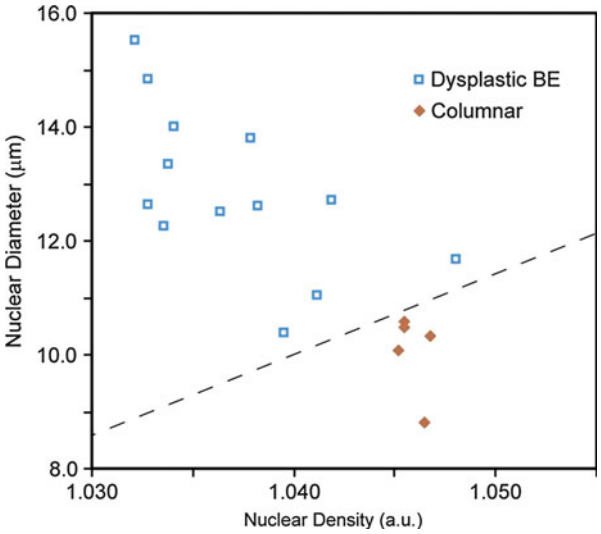

Fig. 38.5 Scatter plot of pathological tissue classification versus mean nuclear diameter and mean relative refractive index over superficial 150 μm of tissue. *Dashed line* indicates potential decision line for identifying dysplastic tissue in Barrett's esophagus (From [48], with permission)

Data were acquired from normal squamous tissue from the esophagus, from the normal-appearing gastric tissue from the stomach, and from Barrett's tissue in the esophagus which appeared normal but was later classified as low-grade dysplasia in the pathology report. As with the previous ex vivo study, no non-dysplastic BE tissue was observed. These data showed good sensitivity (100 %; 6/6) for the superficial 150 μm of the epithelium using a similar decision line used in the previous study; however, the specificity was lower (56 %; 5/9). When the analysis was extended to include a deeper segment of tissue, which contained the basal layer, there was again excellent sensitivity (100 %; 6/6) but also improved specificity (78 %; 7/9). This result indicated that the deep basal layer might provide the greatest insight into the disease state of the tissue as measured by a/LCI.

Upon completion of the clinical a/LCI system, the first-in-man pilot study was conducted [49]. This study included 46 patients undergoing routine upper endoscopy for BE at two endoscopy centers. The study design compared a/LCI data from three to six tissue sites per patient with a coregistered standard biopsy for each. Upon pathological classification of these biopsies, the a/LCI measurements were correlated with the disease state to evaluate the diagnostic ability of a/LCI.

In total, this study included 172 coregistered optical and physical biopsies. For analysis, these biopsies were classified as either "dysplastic" ($n = 13$) or "non-dysplastic" ($n = 159$) according to their pathological state. For dysplastic tissues, a statistically significant ($P < 0.001$) increase in nuclear diameter in the deep epithelial layer (200–300 μm beneath the tissue surface) was observed compared with non-dysplastic tissues, consistent with previous a/LCI studies. To evaluate the diagnostic capacity of a/LCI-measured nuclear size in the basal layer, a receiver-operating characteristic (ROC) was developed. This metric showed good overall performance, producing an area under the curve (AUC) of 0.91, and identified an

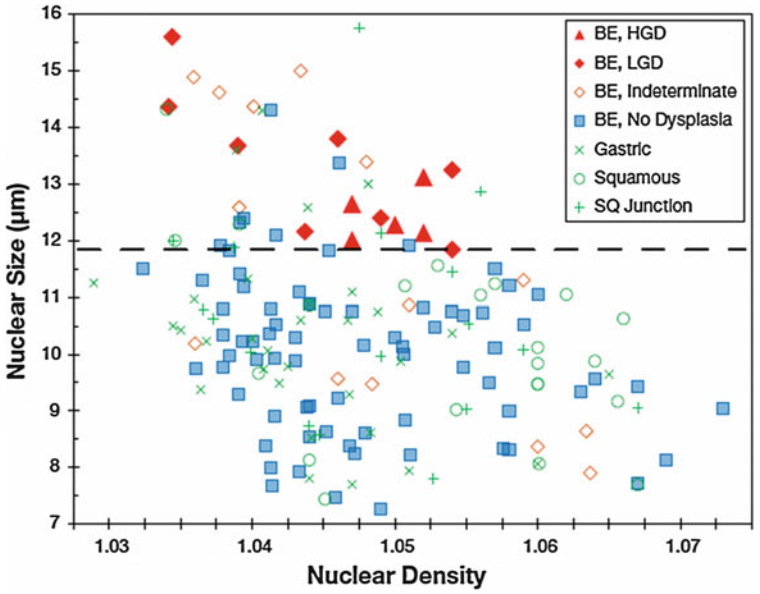

Fig. 38.6 Scatter plot of optical biopsies from pilot a/LCI in vivo clinical study. Data points are colored according to pathological diagnosis. *Dashed black line* indicates optimal decision line (Taken from [49])

optimal decision line at 11.91 μm for the classification of dysplasia. This decision line (Fig. 38.6) yielded a sensitivity of 100 % (13/13), a specificity of 84 % (134/159), an overall accuracy of 86 % (147/172), and positive and negative predictive values of 34 % (13/38) and 100 % (134/134), respectively. This pilot in vivo study represented a significant step in the development of an a/LCI-based clinical diagnostic of dysplasia in the esophagus and provides proof-of-concept for future trials.

The most recent application of a/LCI in a clinical study used the approach to evaluate dysplasia in colonic epithelium [50]. In this study, tissues from 27 patients undergoing partial colonic resection surgery were examined with the a/LCI technique in the pathology lab. As in previous studies, a/LCI measurements of nuclear morphology were compared to traditional histopathology. The results showed a statistically significant correlation ($P < 0.0001$) between increased nuclear size in the basal layer of the epithelium, at a depth of 200–300 μm beneath the tissue surface, and the presence of dysplasia. In addition, the nuclear density, a metric that compares the refractive index of the cell nuclei to the surrounding cytoplasm, showed a statistically significant *decrease* with the presence of dysplasia. Combining these two metrics, an ROC analysis was conducted, producing an AUC of 0.91, and used to construct a decision line (Fig. 38.7). By using this decision line, which

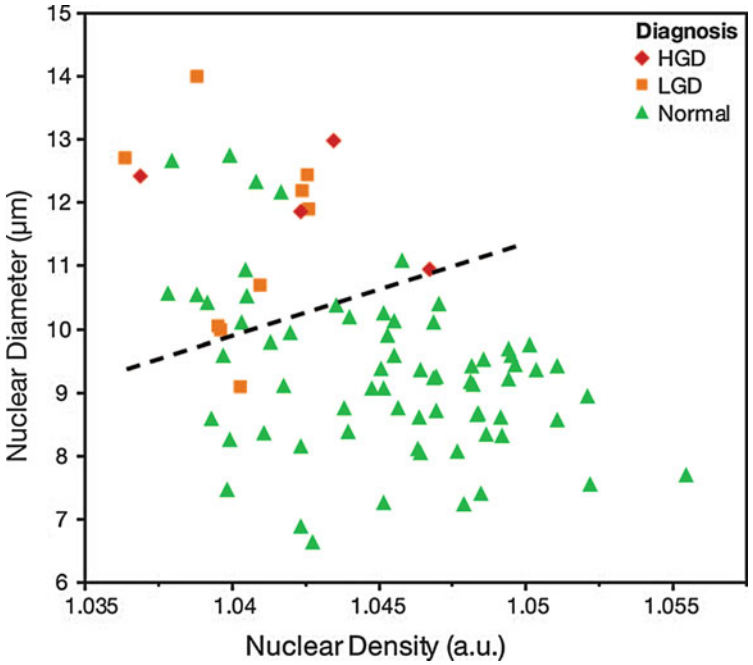

Fig. 38.7 Scatter plot showing a/LCI measurements of nuclear size (micrometer) and nuclear density for the depth segment 200–300 μm beneath the surface of colonic epithelium sorted by pathological diagnosis. The *dashed black line* was determined using an ROC analysis, providing an ideal decision line for the prediction of dysplasia [50]

is nearly identical to that previously determined by Pyhtila et al. [48] (see Fig. 38.4 above), a sensitivity of 92.9 % (13/14), a specificity of 83.6 % (56/67), and an overall accuracy of 85.2 % (69/81) are achieved. The corresponding negative predictive value of 98.2 % (56/57) is comparable to that found in previous a/LCI studies. This preliminary demonstration of applicability of a/LCI to evaluating colonic epithelium serves as motivation to pursue in vivo clinical studies in this organ site.

The use of a/LCI to evaluate dysplasia in BE and other sites was considered in a recent review article that compared the technique to the capabilities of other developing advanced imaging modalities including OCT [51]. It was identified that not only is discrimination of dysplasia important but that other factors such as ease of use, reliability, and cost, particularly related to the economics of surveillance, must be considered. Thus, while several technologies have demonstrated proof of principle, there is a need for data that substantiates improved clinical outcomes. Further work with a/LCI is underway via commercial development by Oncoscope, Inc. (Durham, NC) to establish improved outcomes compared to standard of care as well as to gain regulatory approval.

38.5 Combination of Spectral ESS and OCT Methods

Recently, there has been increased interest in using spatially resolved spectroscopic methods, such as spectroscopic OCT (SOCT), to detect spectral features for ESS [52]. In SOCT, depth-resolved spectral profiles are obtained by processing LCI signals using a window filter [53], which results in decreased axial resolution but provides some information regarding the spatially resolved, spectral dependence of the scattered light. Fourier-domain low-coherence interferometry (fLCI) uses SOCT methods to obtain structural information by analyzing the spectral modulation of white light due to elastic scattering. The fLCI approach has advanced significantly in the past few years by incorporating a novel processing scheme that avoids the resolution trade-off between depth resolution and spectral features, named the dual-window (DW) processing method. This section describes the fLCI technique and the DW method, along with application to probing morphological features for early cancer diagnosis. Results from phantoms and ex vivo tissue studies are reviewed.

38.5.1 Fourier-Domain Low-Coherence Interferometry and Dual-Window Method

The general principle behind fLCI is illustrated in Fig. 38.8a. Light scattered from a spherical object with diameter d, such as a microsphere or cell nucleus, will contain two components that interact with each another, one originating from the front surface and another from the back surface. This interaction produces periodic oscillations in the spectrum with a frequency given by the optical path length difference of the two components, and is related to the diameter of the object by $2 \cdot n \cdot d$, where n is the refractive index (RI) of the object. It is important to understand that these local oscillations are found in the vicinity of the scatterer, and hence, fLCI necessitates high spectral *and* spatial resolution.

To obtain the local oscillations via fLCI, a parallel frequency-domain OCT (pfdOCT) system is used (Fig. 38.8b). The light source consists of a xenon arc lamp (250W Thermo Oriel), which provides a spectral bandwidth ($\sim$250 nm) wide enough to observe the spectral ESS features of interest. This source, however, presents some challenges due to its low spatial coherence. Thus, the pfdOCT system is designed to minimize the detrimental effects of the thermal light source by using a 4f interferometer [56] and by collimating the light onto the sample, which reduces the number of spatial modes illuminating each diffraction-limited spot [57].

To obtain depth-resolved spectroscopic information and gain access to the local oscillations, the DW method is used [58]. This method consists of processing each interferogram using two short-time Fourier transforms (STFTs) and then multiplying the results. Each STFT involves sweeping a window across the interferometric data while simultaneously taking a FT at each step. This process yields a map,

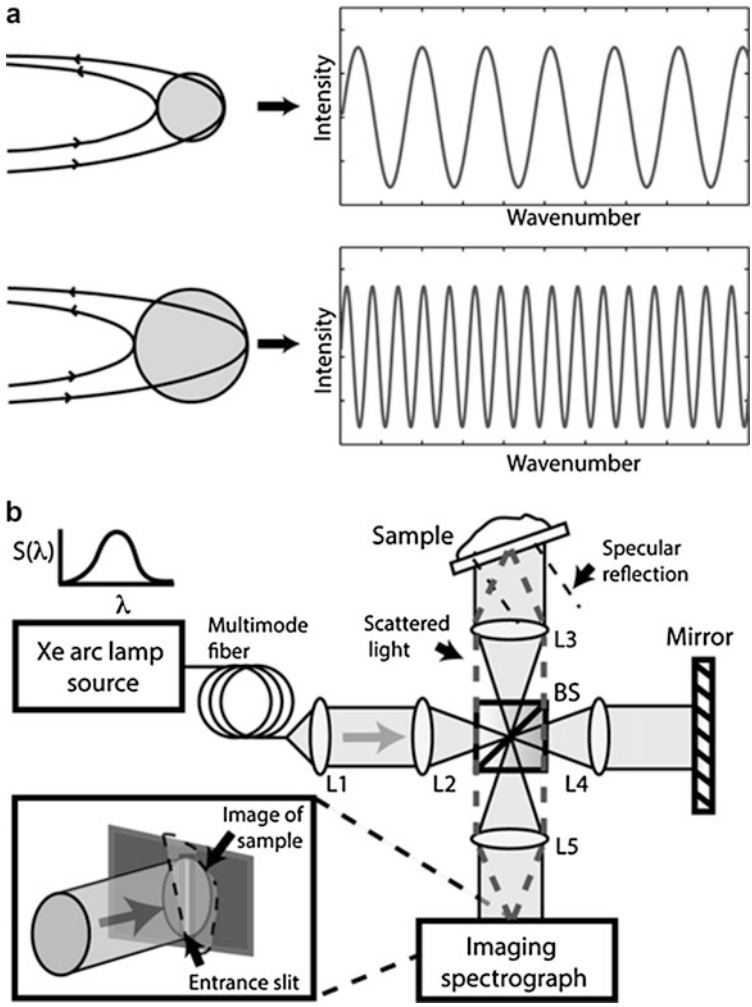

Fig. 38.8 (**a**) General principle of fLCI: scattering from a spheroidal object produces periodic spectral oscillations, proportional to the diameter (Taken from [54]). (**b**) pdfOCT system consists of a modified 4f Michelson interferometer geometry (Taken from [55])

known as a time–frequency distribution (TFD), which describes the localized backscattered spectra. Note, however, that the windowing process in STFTs introduces an inherent trade-off between the spectral and spatial resolutions, and while this method is routinely applied in SOCT, it is inadequate for fLCI. The DW method, on the other hand, utilizes the high spectral resolution of a STFT using a narrow window, and the high spatial resolution of a STFT using a wide window to avoid the deleterious effects of the time–frequency trade-off. Mathematically, this may be described as

$$DW(k,z) = STFT_1(k,z) \cdot STFT_2^*(k,z) = \iint 4E_S^*(k_1)E_s(k_2) \cdot \cos(k_1 \cdot d)\cos(k_2 \cdot d) \cdot e^{\frac{(k_1-k)^2}{2a^2}} \cdot e^{\frac{(k_2-k)^2}{2b^2}} \cdot e^{-(k_1-k_2)^2} dk_1 dk_2, \quad (38.3)$$

where d is the path length difference and a and b are independent parameters that set the widths of the windows.

While implementation of the DW method is relatively simple, the use of two STFTs has significant implications on the resulting TFDs. Specifically, the DW TFD may be considered a bilinear distribution, which, in general, provides a representation of the time–frequency space that does not suffer from the resolution trade-off. In fact, when a is small compared to b, the DW TFD simplifies to

$$DW(k,z) = 4b\sqrt{\pi}\iint Ws(\Omega,\zeta) \cdot e^{-2\frac{(\Omega-k)^2}{b^2}} \cdot e^{-2(d+\zeta+z)^2 a^2} \cdot \cos(2\Omega \cdot d) d\Omega d\zeta, \quad (38.4)$$

where $\Omega = (k_1 + k_2)/2$ and $q = k_1 - k_2$ represent a change in the coordinate system, $W_S(\Omega, \zeta)$ is the Wigner distribution of the sample filed, and ζ is the conjugate space of Ω. The Wigner distribution is a bilinear distribution that has been extensively studied [59]. Equation 38.4 shows that the DW method is equivalent to probing the Wigner TFD of the sample field with two orthogonal windows that independently tune the spatial and spectral resolutions. Thus, like the Wigner distribution, the DW also avoids the trade-off that hinders STFTs. If, however, the windows are chosen inadequately, for example, using a narrow window with a width of a single pixel and a wide window that spans the full spectral range, undesirable artifacts associated with other types of bilinear distributions will pollute the results [59].

38.5.2 Experimental Results

38.5.2.1 Phantom Studies

The capabilities of fLCI were first demonstrated using a 2-dimensional phantom consisting of polystyrene microspheres (1.55 μm mean diameter, 3 % variance) attached to a glass coverslip [52]. The results from this work showed that the size of scatterers could in fact be determined with sub-wavelength accuracy ($d = 1.65$ +/− 0.33 μm). Later, fLCI was shown to be capable of sizing cell nuclei in vitro (T84 epithelial cells in a monolayer), further confirming the methods' ability to evaluate this important biomarker [60]. In a subsequent study, a more complex, 3-dimensional, scattering phantom was considered to assess the potential of quantifying nuclear morphology in tissue. The phantom in Ref [61] consisted of two layers containing polystyrene beads (with RI $n_b = 1.59$) of different sizes suspended in a mixture of agar (2 % by weight) and water, with RI $n_a = 1.35$.

Data were acquired with the pfdOCT system and processed with the DW method. Representative processed spectra from two microspheres, one from the front layer

and another from the back layer (blue solid lines in Figs. 38.9a, b), show two important features: The low-frequency spectral oscillations (dotted green line) represent the scattering cross section of the microspheres as a function of wavenumber and are theoretically described by Mie theory ($\sigma(k)$, red dashed line) [1]. This spectrally dependent backscattering behavior has been analyzed previously by various groups using light-scattering spectroscopy (LSS) [4], confocal light absorption and scattering spectroscopy [62], and also SOCT [63]; however, analysis of these features is highly sensitive to the RI of the medium and scatterer, which need to be known a priori. The other important feature of the DW processed spectrum is the high-frequency, local oscillations (i.e., the fLCI measurement). After subtracting the low-frequency component, a FT of the local oscillations reveals a correlation function with a peak corresponding to the diameter of the microspheres (Fig. 38.9c, d). Note that this measurement is independent of the RI of the medium.

Results from the entire phantom are shown in Fig. 38.9e, where the fLCI results (color) are overlaid with the OCT image. Here, the top layer shows scatterers with a yellow hue corresponding to an average size of 3.82 +/−0.67 μm, and the bottom layer shows a red/purple hue corresponding to an average size of 6.55+/−0.47 μm. Both measurements are in good agreement with the expected size (4.00 ± 0.033 μm and 6.98 ± 0.055 μm, respectively) and with the results from the low-frequency component (LSS measurement). These results demonstrated that fLCI can determine the size of scatterers with sub-wavelength accuracy in thick, turbid samples, such as intact tissue.

38.5.2.2 Animal Studies

The ability of fLCI to detect structural changes associated with neoplastic transformation was tested using two animal models. The first study employed a hamster cheek pouch carcinogenesis model where neoplastic (precancerous) changes are induced by topical treatment with 7,12-dimethylbenz[a]anthracene (DMBA). In this study, each tissue sample was harvested and examined using a pfdOCT system with a white light source [57]. The data were analyzed using the DW method and the local oscillations were examined to determine the average nuclear size in the basal layer of the epithelium. Based on these results, the tissues treated with DMBA showed an increased average nucleus size that was significantly ($p < 0.0001$) greater than that seen for the untreated animals. In this small proof-of-principle study, complete separation between the treated and untreated samples was realized with a simple, nuclear size-based decision line.

The second fLCI study employed the azoxymethane (AOM) rat carcinogenesis model [64], a well-characterized and well-established model for colon cancer research and drug development [65]. The progression of this model is similar to that seen in humans and is a good surrogate for human colon cancer development. In this study, tissues from 40 animals were analyzed with 30 receiving AOM treatment and the remainder serving as an untreated control. Tissues were examined at 4, 8, and 12 weeks after the AOM dosing using the pfdOCT system and the fLCI measurements were compared to the observed number of aberrant crypt foci (ACF), preneoplastic lesions that are biomarkers of neoplastic transformation in this model [66].

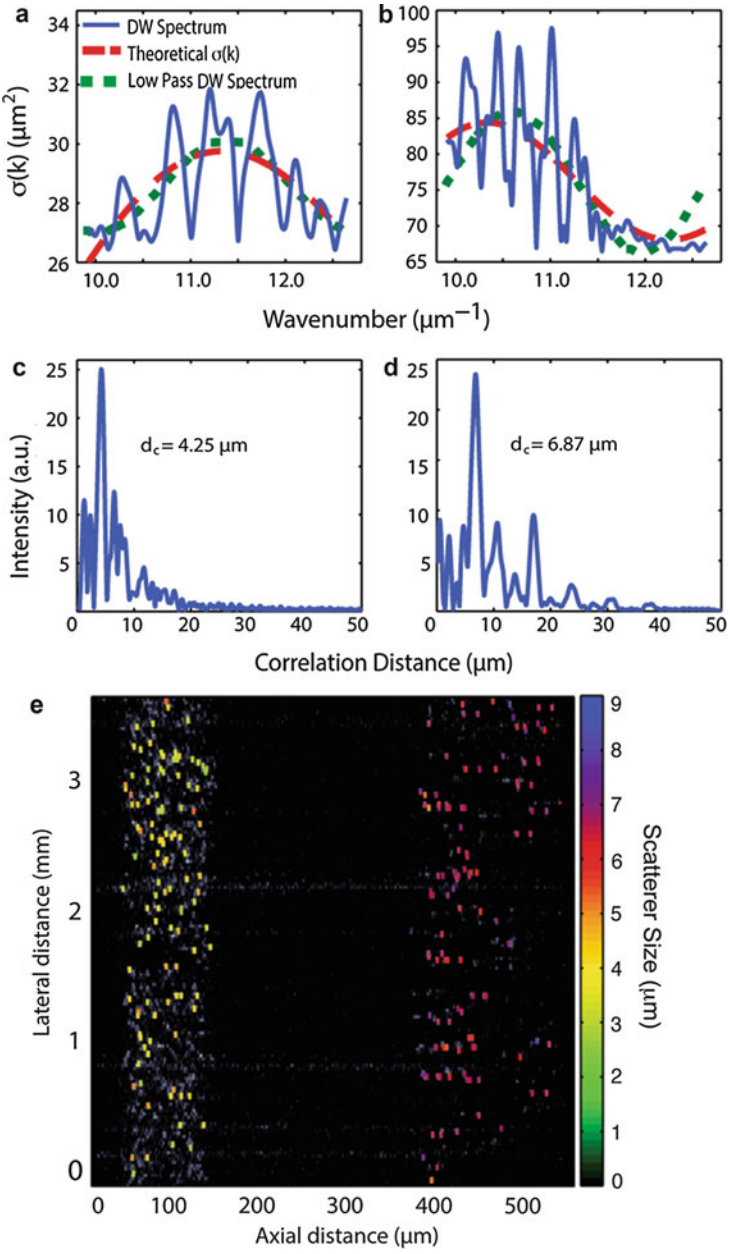

Fig. 38.9 (**a**, **b**) Representative depth-resolved spectra from the front layer and back layer, respectively, of the scattering phantom with microspheres of 4.00 ± 0.033 μm and 6.98 ± 0.055 μm in diameter in each layer. (**c**, **d**) Correlation function from (**a**) and (**b**), respectively, with a peak corresponding to the diameter of the scatterer. (**e**) Functional fLCI map, with the color indicating the scatterer size, overlaid with the OCT image of the phantom (Adapted from [61])

Again, data were acquired with the pfdOCT system and the depth-resolved spectra were generated using the DW method. For this study, a lateral resolution of 10 μm and an axial resolution of ~1.1 μm were achieved, a RI of $n = 1.38$ was used to convert the optical path length to physical axial distance in tissue, and a constant nuclear RI of $n_n = 1.395$ was used for the fLCI analysis [67]. For the generation of the DW TFDs, the window standard deviations used were $a = 0.029\ \mu m^{-1}$ and $b = 0.804\ \mu m^{-1}$, resulting in TFDs with an axial resolution of 3.45 μm and spectral resolution of 1.66 nm. Three different tissue sections were analyzed based on their depth from the tissue surface: surface section 0–25 μm, midsection 22.5–47.5 μm, and low section 37.5–62.5 μm. Here, the OCT images were used to contour the surface of the tissue to permit consistent analysis of the same depth in tissue.

A representative OCT image of an AOM-treated rat tissue sample is shown in Fig. 38.10a, where the dotted line delineates an averaged region from the mid depth

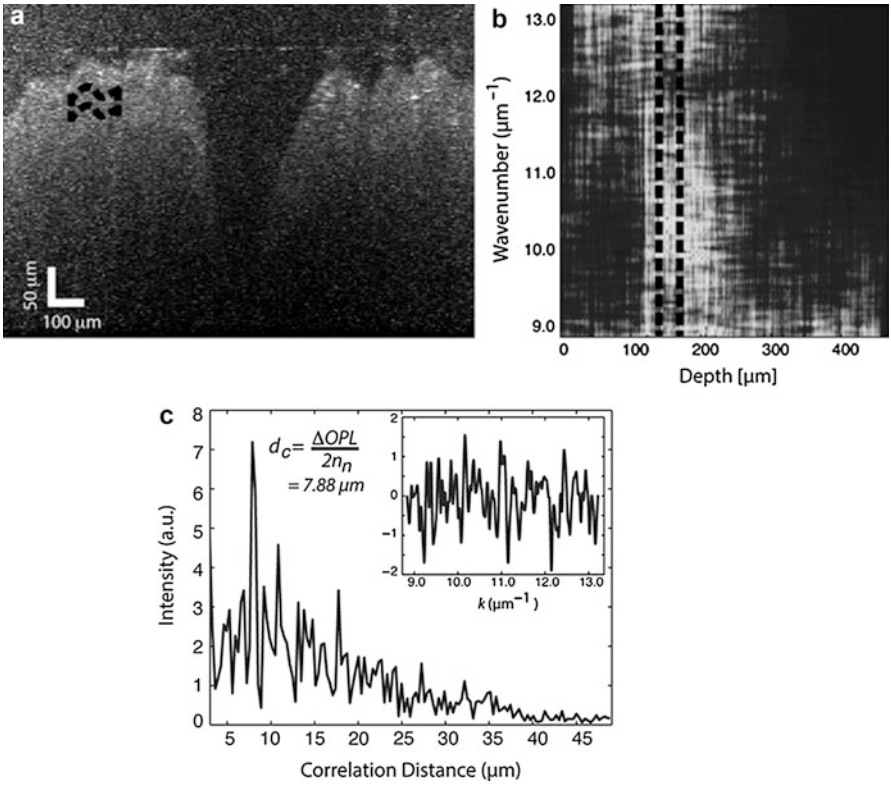

Fig. 38.10 (**a**) pfdOCT image of an ex vivo, AOM-treated rat colon sample. (**b**) DW TFD of average region (after alignment and averaging laterally), (**c**) Correlation plot from the averaged region in the dotted region of (**a**) where the peak reveals the average nuclear diameter (7.88 μm). Inset shows the average local oscillations from the region between the *dotted lines* in (**b**) (Adapted from [64])

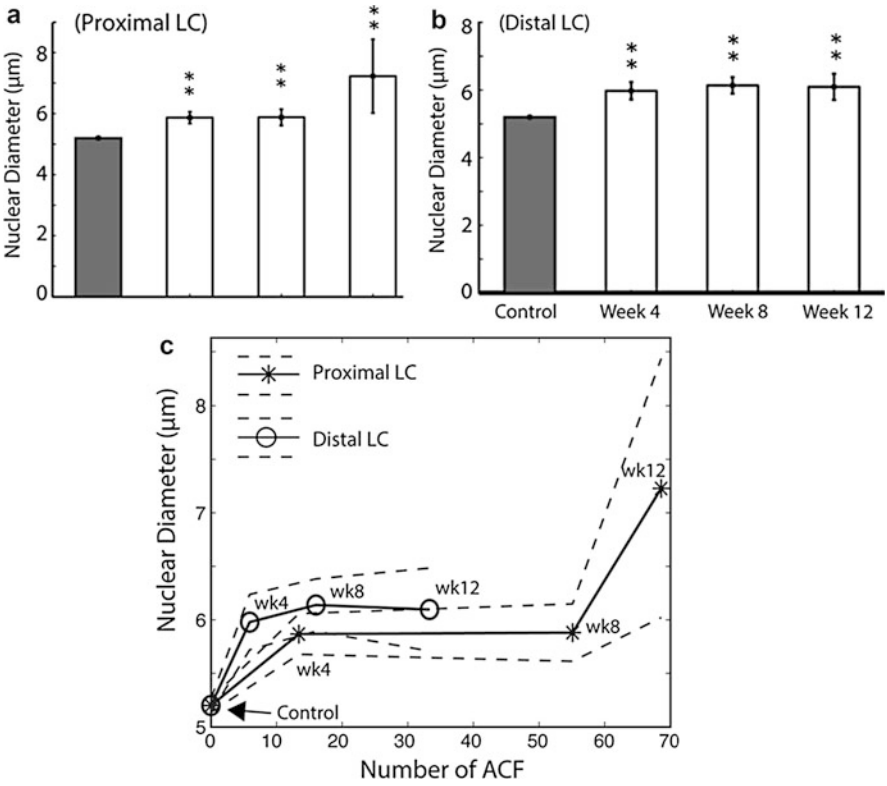

Fig. 38.11 Results by colon length segments. Highly statistical differences (*p value* $<10^{-4}$ **) were observed between the control group and treated groups for the proximal LC (**a**) and distal LC (**b**). (**c**) Plots of the measured cell nuclear diameter as a function of the number of ACF. For clarity, the time of measurement is noted next to each point (*wk* week) (Taken from [64])

section. The corresponding DW TFD (after alignment and averaging laterally) is shown in Fig. 38.10b, c showing the average correlation function for that section (corresponding local oscillations are shown in the inset).

The nuclear diameters of the treated groups were found to be significantly different from the control group (*p-values* $<10^{-4}$ **) for all time points and for both the proximal and distal sections of the left colon (LC). Further, a close inspection of the results (Fig. 38.11) revealed a plateau region in the increase of the nuclear diameter, for both the distal and proximal LC, that is initially independent of the number of ACF. This behavior strongly suggests that the field effect of carcinogenesis, which ubiquitously affects the tissue, can also be observed by measuring changes in nuclear morphology. The data also show that once the number of ACF increased to the maximum value observed in this study (∼70), the measured increase of the nuclear diameter was specific to the region manifesting more advanced neoplastic development, supporting the hypothesis that fLCI can locate more aggressive cancerous development.

Other groups have used OCT and spectral ESS features for imaging and tissue analysis. For example, Adler et al. have used a similar approach that analyzes the local oscillations near zero frequency (a method known as spectral autocorrelation) to provide functional contrast of scatterers [68]. Bosschaart et al. have used low-coherence spectroscopy to assess wavelength dependence of scattering coefficients [69], building on previous work by Faber et al. [70]. Recently, Tay et al. have optimized the spectral autocorrelation approach by using the dual-window method and have shown promising results using ex vivo human palatine tonsil samples [71].

This section has demonstrated the capabilities of fLCI for assessing structure in strongly scattering media by using a combination of spectral ESS and low-coherence interferometry. The results summarized here also demonstrate the ability of fLCI to quantitatively distinguish between tissues that are normal and those that exhibit early precancerous development, including signs of the field effect of carcinogenesis. Further development of this approach could lead to a modality for in vivo, noninvasive clinical screening.

38.6 Conclusions

The combination of ESS and OCT methods can provide unique methods for probing the properties of scattering samples. The depth resolution achieved via coherence gating in OCT can be exploited to obtain scattering signals for ESS analysis. Information for analyzing the structure of scattering objects can be obtained by observing the wavelength or angular dependence of elastic scattering. However, the component of light which has been scattered a single time is most useful. The desired signal can be isolated from the diffuse background due to multiply scattered light using coherence gating in a similar manner as in OCT.

In this chapter, methods for combining angular and spectral ESS methods with the depth resolution of coherence gating have been presented. The a/LCI technique examines angular-scattering distributions to assess structure while using coherence gating to obtain depth resolution, similar to the method used in OCT. As a complimentary method, fLCI has been developed as a synthesis of spectral ESS and spectroscopic OCT methods. This new method has been applied to detect nuclear morphology in animal models and is expected to be further developed for clinical applications.

By combining ESS and OCT methods, a/LCI can provide a viable means for detecting nuclear morphology in situ which cannot be accomplished by current OCT technology, which lacks the ability to observe subcellular features in all but the most advanced research systems. Nuclear morphology measurements can serve as biomarkers of disease progression, particularly as indicators of precancerous tissue states. The key difference between a/LCI and OCT is that the beam input to the sample is collimated rather than focused. In OCT, a focused beam, typically a few microns across, is used to obtain lateral resolution. However, a focused beam necessarily contains a broad angular distribution. When this broad angular distribution is incident on a scattering particle, the angular-scattering pattern from the particle is convolved with the angular distribution of the incident light.

The convolution process serves to smooth out the features in the measured angular distribution. In a/LCI, the incident light is a pencil beam (~0.5 mm diameter), with a very narrow angular distribution determined by the diffraction angle of the collimated beam (angular resolution = 1–2 mrad). This narrow angular resolution permits accurate measurement of the scattered angular distribution.

The a/LCI technique has been applied to study nuclear morphology in cultured cells as well as intact tissue specimens. After validation experiments with in vitro cells and animal tissues, the a/LCI technique has been advanced to study human epithelial tissues, including an in vivo study of the approach for detecting precancerous lesions in the esophageal epithelium.

Nonlinear Interferometric Vibrational Imaging (NIVI) with Novel Optical Sources

39

Stephen A. Boppart, Matthew D. King, Yuan Liu, Haohua Tu, and Martin Gruebele

39.1 Introduction

Optical imaging is essential in medicine and in fundamental studies of biological systems. Although many existing imaging modalities can supply valuable information, not all are capable of label-free imaging with high-contrast and molecular specificity. The application of molecular or nanoparticle contrast agent may adversely influence the biological system under investigation. These substances also present ongoing concerns over toxicity or particle clearance, which must be properly addressed before their approval for in vivo human imaging. Hence there is an increasing appreciation for label-free imaging techniques. It is of primary importance to develop imaging techniques that can indiscriminately identify and quantify biochemical compositions to high degrees of sensitivity and specificity through only the intrinsic optical response of endogenous molecular species.

Multiphoton coherent Raman scattering techniques, such as coherent anti-Stokes Raman scattering (CARS) and stimulated Raman scattering (SRS), have drawn considerable attention due to many distinct advantages over other imaging modalities [1–3]. Raman scattering processes provide chemical contrast during imaging of materials by exploiting the vibrational "fingerprints" of the molecules contained within the sample. In addition to its label-free imaging capabilities, there are many

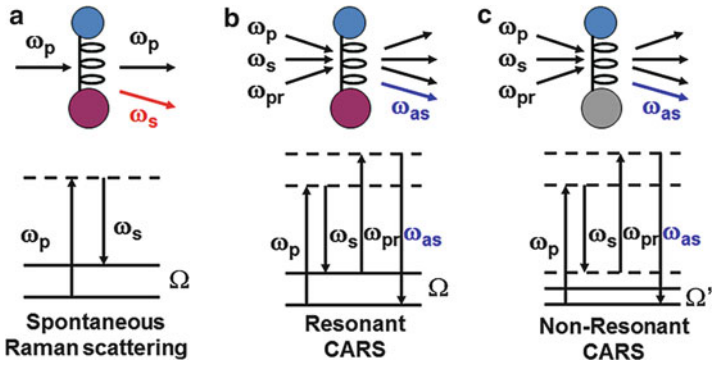

Fig. 39.1 Comparison of (**a**) spontaneous Raman scattering, (**b**) resonant CARS, and (**c**) nonresonant CARS. Optical frequencies of pump, probe, Stokes, and anti-Stokes photons are related by $\omega_{as} = \omega_p - \omega_s + \omega_{pr}$

other notable advantages to CARS imaging. The blue shifting of the generated signal makes it easily separable from the excitation sources and the strong fluorescence background emission of biological samples. In addition, the phase matching requirements of the nonlinear CARS process permit high-resolution three-dimensional imaging [4, 5]. The CARS process is also a much more efficient process than spontaneous Raman scattering, allowing for high-speed image acquisition [6, 7].

In CARS excitation, Raman-active molecular vibrations are coherently driven to generate a strong anti-Stokes Raman signal. The wave-mixing process requires a pump, Stokes, and probe excitation fields to produce the higher-frequency anti-Stokes signal (Fig. 39.1). The pump frequency at ω_p and the Stokes frequency at ω_s induce a vibrational coherence when $\omega_p - \omega_s$ coincides with a molecular vibrational frequency, Ω_R. The subsequent probe frequency at ω_{pr} generates the anti-Stokes signal at $\omega_{as} = \omega_{pr} + \omega_p - \omega_s = \omega_{pr} + \Omega_R$. Under these conditions, there is significant enhancement in the resonant CARS signal. When $\omega_p - \omega_s$ is of resonance, the electronic response of the material produces a nonresonant CARS signal. By isolating the resonant contribution to the collected CARS signal, detailed molecular information can be obtained.

Conventional CARS imaging uses narrowband nanosecond or picosecond sources with frequencies tuned to selectively excite a single Raman resonance. However, this approach is limited in that the obtainable spectral information is not sufficient to discriminate between different biomolecules, or to determine their relative concentrations in unknown samples containing molecules with overlapping Raman bands. These limitations can be overcome by using a broadband Stokes pulse to cover a larger bandwidth of vibrational excitations in what is referred to as multiplex CARS [8–12]. The additional structural information made available by multiplex methods allows for quantitative molecular imaging of unknown samples. However, one disadvantage of multiplex CARS comes with the higher peak field intensities of the ultrafast broadband laser sources compared to narrowband sources, leading to a large nonresonant contribution to

the overall signal due to the increased electronic response. The nonresonant CARS often dominates the collected signal and can easily mask any low-intensity resonant spectral features. The interference between the resonant and nonresonant signals poses additional problems as this leads to distortion of the retrieved Raman line shapes, which makes it difficult to measure molecular concentrations quantitatively. The presence of this undesirable nonresonant contribution has led to a variety of approaches aimed at suppressing the background signal in order to make multiplex CARS methods feasible for sensitive biomedical imaging applications [13].

The most widely used approach to suppress nonresonant CARS signal is the introduction of a local oscillator, or reference beam, for phase-sensitive interferometric detection [5, 6, 14–24]. Spectral interferometry acts to simultaneously enhance the resonant signal while eliminating the nonresonant contribution. Many variations in interferometric detection schemes have been introduced, including time-resolved interferometry [14], vibrational phase-contrast [17, 18], phase-cycling [19], and spectral-domain heterodyne CARS [6, 24]. While there are advantages to each approach, there are also significant disadvantages that can limit their applicability for quantitative high-speed imaging techniques. Time-resolved methods, such as Fourier-transform CARS [14, 15], rely on temporal scanning of the excitation pulses in order to retrieve spectral information. Likewise, phase-cycling schemes require scanning of the excitation phase to obtain the Raman spectrum [19, 20]. These methods are largely devised to overcome the constraints to spectral resolution resulting from the implementation of broadband excitation sources, but conversely impose limitations on imaging speed due to the temporal- or phase-scanning requirements. Phase-contrast CARS does not suffer these limitations and can provide much faster acquisition rates using a single-beam experimental setup [17]. However, this technique is restricted by the associated difficulties with quantitative spectral reconstruction. The most promising methods use heterodyne interferometry in a spectral-domain OCT-like scheme, which combines imaging speed, chemical sensitivity, and high spectral resolution [6, 24]. In such methods, the sensitivity increase comes from the interference of the generated CARS signal with a stable local oscillator, resulting in a possible sensitivity gain up to 1,000-fold [19]. The amplification occurs for both the resonant CARS signal and the nonresonant background, followed by the computational recovery of the phase-sensitive resonant contribution.

Nonlinear interferometric vibrational imaging (NIVI) [21] takes advantage of the speed and sensitivity of the spectral-domain detection while eliminating the dominant nonresonant background, allowing for quantitative reconstruction of Raman line shapes. This method differs from other heterodyne schemes in that spectral inteferometry enables full characterization of the CARS signal field. In the time domain, the resonant and nonresonant contributions can then be separated easily [25–27]. NIVI employs a two-pulse excitation scheme with a transform-limited Stokes pulse and a time-delayed chirped broadband pulse to probe the resonant CARS vibrational excitations. The high-resolution Raman spectrum can then be computationally reconstructed from the interferogram generated from

the spectral-domain interference of the CARS signal with a reference pulse [21, 28]. This results in the amplification of the resonant component and provides quantitative molecular detection with reliable reconstruction of the Raman spectrum.

The important attributes of NIVI over other interferometric CARS-based techniques are that it simultaneously implements heterodyne amplification [29, 30], time-resolved resonant signal isolation [25], and spectral-domain interferometric field reconstruction [21]. The technique has been demonstrated in the quantitative analysis of lipid samples [31] and with molecular imaging of biological samples, including skin domains [32] and rat mammary tumor margins [33]. NIVI was capable of differentiating normal and tumor tissues with >99 % confidence and of detecting the molecular tumor margin within 100 μm. It was shown that the NIVI spectra of biomolecules are equivalent to the corresponding Raman spectra and can be acquired up to 1,000 times faster than with spontaneous Raman microscopy, at comparable signal-to-noise ratios [31, 34]. In the following sections, the theory, experimental setup, and demonstrated results of NIVI are covered in detail. Also discussed are the future directions for extending the imaging capacity of this technique into the Raman fingerprint region (500–1,800 cm^{-1}) using ultrabroadband fiber continuum sources.

39.2 Theory

Conventional multiplex CARS measurements utilize a narrowband pump/probe pulse and a broadband Stokes pulse. However, methods using broadband pulses originating from a single femtosecond source have been devised by implementing a positively chirped pump/probe pulse [21, 28]. In doing so, the probe field is able to interact with the resonant coherent excitation over the extended vibrational time decay, whereas the nonresonant contribution due to the instantaneous electronic response only occurs for the duration of the transform-limited Stokes pulse. NIVI takes advantage of this increase in resonant CARS signal produced by the chirped excitation pulse and recovers the complex Raman spectra through an interferometric detection scheme. The resulting CARS signal has an identical chirp as the excitation pulse, and by measuring the cross-correlation of the signal with a known reference signal, the time-resolved resonant contribution can be extracted. By this method, an accurate Raman spectrum can be retrieved while eliminating the dominant nonresonant signal.

CARS is a wave-mixing process that involves the interaction of three photons to generate a fourth anti-Stokes photon at higher frequency than the incident photons. The CARS process using two broadband pulses, E_p and E_s, corresponding to the pump/probe and Stokes pulses, respectively, can be described in the frequency domain by the equations

$$A(\Omega) = \chi^{(3)}(\Omega) \int_0^\infty E_p(\omega + \Omega) E_s(\omega)^* d\omega \tag{39.1}$$

$$P^{(3)}(\omega) = \int_0^\infty A(\Omega) E_P(\omega - \Omega)^* d\Omega \tag{39.2}$$

where $A(\Omega)$ is the Raman transition amplitude, $\chi^{(3)}$ is the third-order nonlinear susceptibility of the material, $P^{(3)}$ is the third-order hyperpolarizability, and Ω is the resonant molecular vibrational frequency. The two equations give the two-step time evolution of a CARS process involving many possible simultaneous Raman-active vibrations. By Eq. 39.1, a molecule is put into a coherent vibrationally excited state by the pump frequency ω_p and Stokes frequency ω_s that are separated by the vibrational frequency $\Omega = \omega_p - \omega_s$. Using a broadband Stokes pulse enables the simultaneous excitation of vibrational modes over a wide range of frequencies. The generation of anti-Stokes radiation is described by Eq. 39.2, in which the molecule is stimulated from the coherently excited vibrational state by the probe frequency ω_1 to produce the higher energy photon at $\omega_{AS} = \omega_p + \Omega = 2\omega_p - \omega_s$. For broadband excitation, the anti-Stokes signal must be summed over all probe frequencies. The Raman response of the sample is contained in the nonlinear susceptibility, $\chi^{(3)}(\Omega)$ which contains resonant and nonresonant contributions, $\chi^{(3)}(\Omega) = \chi^{(3)}_{NR} + \chi^{(3)}_R(\Omega)$.

For CARS using a chirped pump/probe pulse, the spectrum can be expressed by the equation

$$E_p(\omega) = E_0 \exp\left[-i(\omega - \omega_0)^2/2\alpha\right] \tag{39.3}$$

where α is the chirp rate of the pulse. From the stationary phase approximation for a small α, the time-domain signal can be written as

$$E_p(t) = \alpha^{-1/2} E_0(\alpha t + \omega_0) \exp[i(\alpha t/2 + \omega_0)t]. \tag{39.4}$$

The Stokes pulse spectrum $E_S(\omega)$ is transform limited and centered about $t = 0$ such that $E_S(\omega)$ is real. Because of this, the instantaneous frequency of the pump/probe pulse at $t = 0$ is ω_0, which can be approximated as a δ function. With these representations of the pump/probe and Stokes pulses, the nonlinear polarizability expressed in Eq. 39.2 can be approximated as

$$P^{(3)}(\Omega) = \chi^{(3)}(\Omega) \int_0^\infty \alpha^{-1/2} E_0(\omega_0) \delta(\omega + \Omega - \omega_0) E_s(\omega)^* d\omega \tag{39.5}$$

$$= \chi^{(3)}(\Omega) \alpha^{-1/2} E_0(\omega_0) E_s(\omega_0 + \Omega).$$

The anti-Stokes pulse in the time domain $E_{AS}(t)$ can be calculated by Eq. 39.2, yielding

$$E_{AS} = \alpha^{-1/2} E_0(\alpha t + \omega_0) \exp[i(\alpha t/2 + \omega_0)t] \frac{1}{2\pi} \int_0^\infty d\Omega \chi^{(3)}(\Omega) E_s(\omega_0 - \Omega) E_0(\omega_0) \exp(i\Omega t). \tag{39.6}$$

The chirp of the probe can be removed by multiplying the anti-Stokes pulse by the conjugate phase $\exp[-i(\alpha t/2 + \omega_0)t]$. Then, the inverse Fourier transform of this product produces $\chi^{(3)}(\Omega)$, weighted by the Stokes spectrum, which is the estimation of the Raman spectrum.

NIVI is implemented experimentally by reconstructing the complex CARS field from the interferometric cross-correlation of the anti-Stokes and reference fields, retrieving amplitude and phase information of the anti-Stokes field. The interferogram is generated by mixing the CARS field with a transform-limited reference pulse. The measured interferogram, $I(\omega)$, is described by the equation

$$I(\omega) = |E_{AS}(\omega)|^2 + \left|E_{ref}(\omega)\right|^2 + 2\mathrm{Re}\left[E_{AS}(\omega)E_{ref}(\omega)^* \exp(-i\omega\tau)\right] \tag{39.7}$$

where $E_{AS}(\omega)$ and $E_{ref}(\omega)$ are the anti-Stokes and reference fields, respectively, and τ is the time delay between the two pulses (Fig. 39.2a). The spectral interferogram contains DC components from the CARS and reference fields and the phase-sensitive cross-term that contains the NIVI signal. The DC reference term can be removed by the subtraction of the known reference spectrum. The remaining terms can be separated in the time domain, wherein the DC component of the CARS field can be rejected, leaving only the phase-sensitive components (Fig. 39.2b). Substituting $\chi(\omega) = E_{AS}(\omega)E_{ref}(\omega)^*$ and taking the inverse Fourier transform of $I(\omega)$ yields

$$FT^{-1}(I(\omega)) = FT^{-1}(\mathrm{DC}) + \chi(t-\tau) + \chi(-t-\tau). \tag{39.8}$$

The first term is a slowly varying DC component symmetric about $t = 0$, while the last two terms are time reversed from each other. As it is known that there is no CARS signal prior to the vibrational coherence induced by the Stokes pulse, the time origin can be shifted to be the center of the Stokes pulse, thereby isolating the $\chi(t - \tau)$ term (Fig. 39.2c). The Fourier transform of the remaining term results in $\chi(\omega) = \chi^{(3)}(\omega)^* E_s(\omega - \Omega)E_{ref}(\omega)^*$. The nonresonant CARS signal is real and can be rejected by discarding the real part of $\chi^{(3)}$. The NIVI spectrum is represented by the imaginary part of $\chi^{(3)}$ and is analogous to the spontaneous Raman spectrum (Fig. 39.2d).

39.3 Instrumentation

The experimental NIVI setup is shown in Fig. 39.3. A mode-locked Ti:Sa oscillator (Coherent, MIRA, 82 MHz) is used to seed a regenerative amplifier (Coherent, RegA-9000). The 380-mW, 82-MHz Ti:Sa output is amplified to 1.1 W at a 250-kHz repetition rate, resulting in microjoule pulse energies. The amplifier output is split through a 90:10 beam splitter, sending 90 % of the light to pump an optical parametric amplifier (Coherent, OPA-9450), which generates the Stokes pulse at 1,060 nm and the reference pulse at 655 nm, corresponding to the idler and signal pulses generated from the OPA, respectively. The remaining 10 % of the amplifier output is used as the probe beam. The probe pulses are linearly chirped to ~6 ps by passing the beam through an 85-cm bar of BK7 glass. A delay line is

placed in the beam path to control the temporal delay of the probe and, therefore, the instantaneous pump wavelength. The probe and Stokes beams are recombined using a dichroic mirror and delivered to the sample in a collinear geometry. The wavelengths of the pump and Stokes pulses were tuned to target the spectral range of 2,800−3,000 cm^{-1}, corresponding to the C−H stretching vibrational region. The power of the excitation pulses varied depending on the application, i.e., higher powers are needed for imaging of biological samples, which are highly scattering and contain low concentrations of the specific target molecules.

The probe and Stokes pulses were focused onto the sample with parallel polarization using a high-NA objective. Tight focusing of these excitation beams relaxes the phase matching conditions required for four-wave-mixing processes [2]. The nonlinear interaction of the excitation fields produces the CARS signal at a higher frequency than the incident radiation. The forward-generated CARS signal is collected by a second objective. A high-pass filter is used to remove the excitation wavelengths, transmitting only the blue-shifted CARS signal. The CARS and reference beams were combined at a 50:50 cube beam splitter for collinear detection by spectral interferometry which requires precise spatial and temporal overlap. The combined beams were spatially filtered at a 30-μm pinhole to improve beam

and interference quality. They were subsequently dispersed by a grating (1,200 grooves/mm), and the spectral interferogram was acquired on a 2,048-pixel line camera (DALSA P2) at a 1-kHz line rate. The implementation of spectral interferometry allows for a significant increase in image acquisition speed, signal-to-noise ratio, and signal stability.

39.4 Quantitative Analysis of Lipids

The quantitative capabilities of NIVI for bioanalytical and biomedical imaging applications were demonstrated by measuring the relative degree of unsaturation of different lipid samples [31]. NIVI was shown to be comparable to spontaneous Raman scattering in the ability to distinguish subtle vibrational spectral features, however, with data collection approximately 200 times faster for comparable signal-to-noise ratio. The interferometric technique allows for the spectra to be reconstructed with the same $\chi^{(3)}$ line shape as Raman spectroscopy, without the nonresonant line shape distortions typically obtained from CARS measurements. Quantitative measurements are straightforward because the NIVI signal is linear in analyte concentration. Combining the spectral quality of spontaneous Raman and the high speed of CARS imaging techniques provides a powerful tool for quantitative label-free biomedical imaging.

The comparison of NIVI and spontaneous Raman spectra for six various lipid samples in the spectral range (2,700−3,050 cm^{-1}) containing the C−H stretching vibrational bands is shown in Fig. 39.4. In this spectral region, there is significant overlap of methyl, methylene, and =CH− stretching bands, which makes spectral analysis quite challenging. The presence of unsaturated C=C bonds within the lipids is evident in the intensity of the small spectral feature centered at 3,010 cm^{-1}. The relative intensity of this peak with those of the saturated C−H stretching modes at 2,856 and 2,885 cm^{-1} provides quantitative information as to the degree of unsaturation. A singular value decomposition algorithm to extract the principal spectral components was applied to assess the accuracy of NIVI with Raman spectroscopy. The number of C=C double bonds per unit volume ($N_{C=C}$/mL) was determined for each measurement (Fig. 39.4b). Both spectroscopic techniques produced excellent linear fits when plotted against data obtained from a standard chemical assay, verifying the quantifiable information content of the NIVI spectra.

39.5 Biological Imaging with NIVI

In addition to the chemical bonding probed in lipid samples, other biological compounds, such as proteins and nucleic acids, contain characteristic bonding motifs that produce unique spectral structures that can be used to identify and quantify the presence of such molecules in complex media by NIVI. The ability to evaluate relative molecular concentrations from the spectral profile in the C−H stretching region and to use this information to map the molecular composition

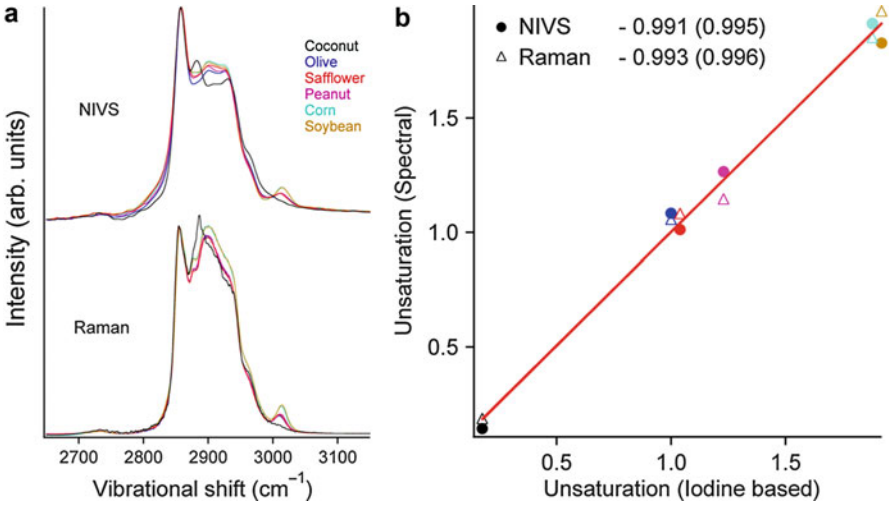

Fig. 39.4 (**a**) Comparison of polarized NIVI and isotropic Raman spectra of various cooking oils. Relative variations are expected due to the polarization sensitivity of NIVI and Raman depolarization ratios of different vibrational mode symmetries. (**b**) Relative $N_{C=C}$/mL derived from NIVI and Raman spectra plotted against unsaturation data obtained from an iodine assay. The slopes of the linear fits are listed with the correlation coefficients in parentheses (Figure adapted from [31] and reproduced with permission)

of complex biological tissues was demonstrated in the imaging of ex vivo porcine skin (Fig. 39.5) [32]. It was shown that the probed C−H spectral region was adequate to distinguish the stratum corneum, epidermis, dermal stroma, and the collagen and adipose domains of the subcutaneous tissue.

Distinct spectroscopic domains arising from the relative lipid and protein concentrations provide the contrast in the images. Evident in the spontaneous Raman spectra in Fig. 39.5c, three primary vibrational bands could be used to decompose the broadband NIVI spectra. The dermis and epidermis show higher concentrations of CH_3 symmetric stretches, and the stratum corneum exhibits comparable amplitudes of the CH_2 and CH_3 symmetric stretching modes. The higher signal of the CH_2 band results from the higher relative concentrations of lipids in the stratum corneum compared with the dermis and epidermis. An image showing the resonant CARS signal over the entire probed bandwidth is provided in Fig. 39.5a. The color-coded molecular map resulting from the molecular-specific decomposition is shown in Fig. 39.5b. A NIVI composite image can be generated by modulation of the molecular map by the intensity map (Fig. 39.5d). Each color in the composite image represents a molecular vibration appropriate for tissue identification and allows for the spatial differentiation of the prevalent molecular species. Comparison of the NIVI composite image with a corresponding H&E-stained tissue section shows that the individual skin domains can be clearly discriminated. However, the NIVI image contains the added benefit of molecule-specific information made available in an instantaneous label-free manner without the need for histological staining

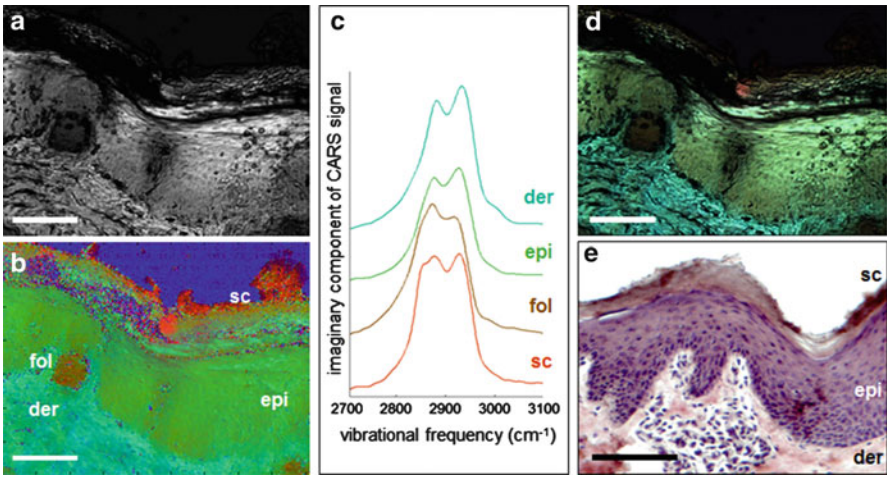

Fig. 39.5 Molecular imaging of cutaneous tissue. (**a**) Intensity image (total integrated spectral power). (**b**) NIVI composite showing discrimination of stratum corneum (*sc*), epidermis (*epi*), dermis (*der*), and hair follicle (*fol*). (**c**) NIVI spectra for each domain in (**b**), as obtained by cluster analysis: each spectrum is the result of averaging the spectra of the members of most prevalent cluster in regions of 20 × 20 pixels^2 within each domain. The scale bar is 100 μm in every image (Adapted from [32], with permission)

procedures. Such advantages make NIVI a promising diagnostic technique for quantitative histological and cytological measurements.

The combination of quantitative chemical accuracy and fast image acquisition speed provides reliable tissue characterization suitable for differentiating normal and cancerous tissues. To translate this technique into a robust approach for the reliable distinction of pathologic tissue states, several key factors were addressed. It has been demonstrated that the NIVI signal is linear to the biochemical composition, which permits proper analysis of the tissue composition. In addition, rapid imaging of histological sections, resected tissue specimens, and in situ tissue is permitted by the millisecond spectral acquisition. Lastly, the reduction of complex spectral information to a simple visual code allows for a clear and accurate diagnosis.

We have used NIVI to study mammary tissues from a carcinogen-induced rat mammary tumor model [33]. Earlier Raman studies revealed that the ratio between relative fat and collagen concentrations was the key diagnostic parameter between normal and malignant tumor tissues [35, 36]. Normal tissues rich in lipids exhibit Raman signatures corresponding to $C-H_2$ and $C=C-H$ stretches observed at approximately 2,850 and 3,020 cm^{-1}. These bonding motifs are not as abundant in protein chemical structures, and the Raman signal is therefore decreased as the fat-to-protein ratio is reduced. Figure 39.6 shows the comparison of the NIVI spectra for normal and tumor tissues, as well as those for the reference spectra of collagen (protein) and methyl oleate (lipid). The differences in the Raman spectral

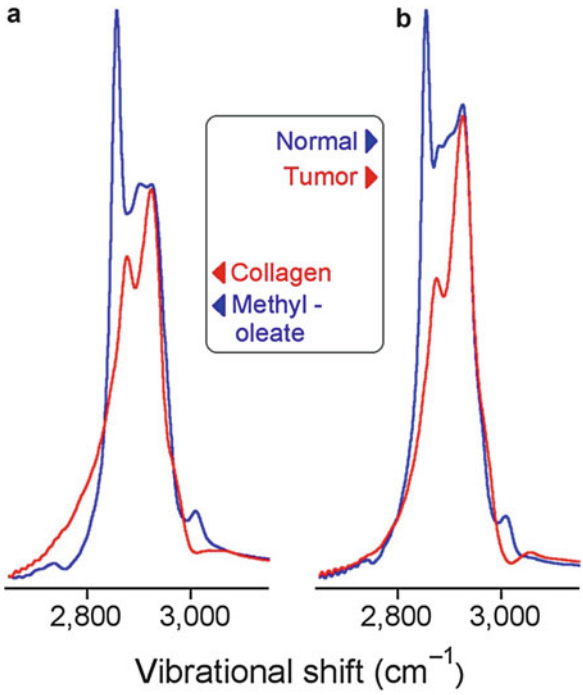

Fig. 39.6 Comparison of NIVI spectra for (**a**) reference spectra of collagen and methyl oleate, and (**b**) normal versus tumor tissues (Adapted from [33] and used with permission)

profiles are evident, and from these NIVI spectra, normal and tumor tissues can easily be accurately distinguished.

The NIVI spectra acquired from different tissue pathologies are sufficient for classifications to be made by comparing the relative intensities of C−H peaks arising from lipids and proteins. Figure 39.7 shows a number of NIVI images of normal and tumor tissues that were differentiated in this manner. The determination of major spectral components can be achieved through a variety of multivariate statistical techniques. The diagnostic algorithm developed in these studies combined principle component analysis (PCA) with logistic regression and reduces the spectral decomposition to only the most significant chemical components contributing to the acquired spectra. For the analysis, the spectra were digitized at 1,000 frequency data points in the range of 2,420–3,320 cm^{-1}. A singular value decomposition (SVD) algorithm was then used to extract the principal components of this data matrix. The three most significant principal components account for >99 % of the variance in the data. The segregation of the normal and tumor spectra is apparent in the two-dimensional subspace of the principal components C_2 and C_3, as shown in Fig. 39.7. A logistic regression could then be used to draw a decision line between the normal and tumor tissues. Figure 39.8 also shows the 99 % confidence intervals for the normal and tumor categories, based on a student's *t* test on the sample set. Images that contained both normal and tumor tissues lie near the decision line from the logistic regression. However, through visual inspection of these images, the normal and tumor tissues can be spatially resolved to less than 100 μm.

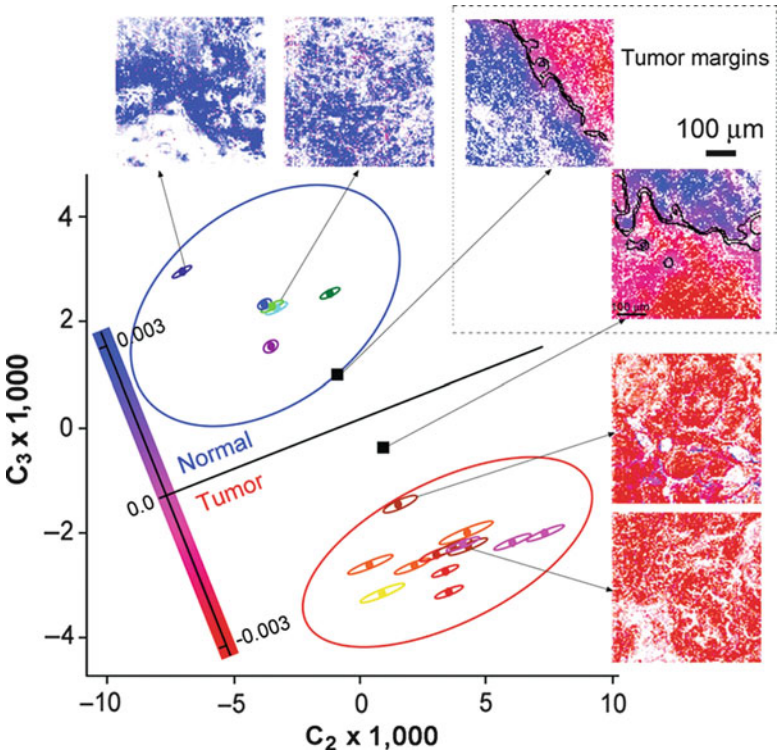

Fig. 39.7 Two-dimensional subspace showing clear differentiation between normal and tumor tissues based on SVD coefficients C_2 and C_3 of the spectral basis functions. Automated tumor margin identification is represented as *black curves* overlaid on the top-right NIVI images. The two boundaries of the margin demarcate normal and tumor domains at greater than the 99 % confidence interval. Tumor margins are readily resolved to 100 μm (Adapted from [33] with permission)

Automated detection of tumor margins can be achieved at the 100-μm scale (Fig. 39.7). The tumor margins were detected in less than a few seconds at the 99 % confidence interval. The images for margin detection again show the optimum linear combination of the spectral coefficients C_2 and C_3. A clean margin (1–2 pixels wide) demarcating the tumor and normal domains can be obtained, with the double band representing the 99 % confidence ellipses near the decision line. The margins are depicted in the upper-right images in Fig. 39.7.

39.6 NIVI with Novel Optical Sources

Although NIVI has been demonstrated as a high-performance multiplex CARS technique, three critical limitations largely limit its clinical translation. First, the inevitable alignment drift between the two collinear incident beams forbids

long-term imaging. Second, the cost and complexity of the amplified ultrafast laser system prohibit widespread application. Third, the narrow acquisition range of Raman frequency (2,700–3,100 cm^{-1}) is insufficient to differentiate biomolecules, which are more distinguishable in the fingerprint region (500–1,800 cm^{-1}). All these limitations can be overcome by integrating the advanced features of coherently controlled single-beam multiplex CARS into the current NIVI instrumentation, using a coherent fiber continuum source [37] based on a regular femtosecond (~100 fs) laser oscillator, rather than the broadband (<20 fs) solid-state laser employed in a typical single-beam multiplex CARS. The single-beam NIVI might be treated as if the spectral gaps among Stokes beam, pump/probe beam, and reference beam would disappear, so that the Stokes, pump, probe, and reference photons could be supplied by one broadband beam (pulse). Because the new features of single-beam setup, coherent control, and fiber continuum source are compatible with the key features of NIVI (i.e., heterodyne signal amplification and field reconstruction, time-resolved resonant signal isolation, and high spectral-resolution broadband interferometry) [16, 38, 39], all advantages of NIVI can be retained.

Due to broad bandwidth, the single-beam NIVI relies on precise shaping of the excitation pulses by a pixelated 4-*f* pulse shaper [40] to maximally stimulate molecular vibration signals that can be interferometrically detected. The importance of pulse shaping in imaging can be appreciated by comparing the performance of two-pulse shapers in two-photon excitation fluorescence microscopy (TPEF) and second-harmonic generation (SHG) microscopy, two nonlinear optical imaging techniques similar to NIVI. The pixelated pulse shaper significantly outperforms the common prism pair-based pulse shaper in resolving the microstructure of biological tissues (Fig. 39.8a). For largely the same reason, the pixelated pulse shaper-incorporated NIVI outperforms regular multiplex CARS (with prism pair-based pulse shaping or no pulse shaping) in resolving the Raman spectrum of biomolecules. The operation of the pixelated pulse shaper had been notoriously difficult until the invention of the multiphoton intrapulse interference phase scan (MIIPS) (see reviews in [41, 42]). MIIPS is a computerized procedure performed in the pixelated pulse shaper that automates the pulse measurement and shaping at targeted sample location and is therefore considered as a highly enabling technology in the ultrafast laser industry. Assuming automatic pulse shaping by MIIPS, we have proposed a "matched filter" pulse shaping method to selectively image a target molecule by NIVI [43]. Figure 39.8b demonstrates that specifically shaped pulses can selectively excite DNA over RNA, even though the two have very similar Raman spectra. This capability will be useful if a biomarker molecule can be identified for a particular human cancer.

In single-beam NIVI, the coherent fiber continuum [44] (Fig. 39.8c) is preferred over the broadband (<20 fs) solid-state laser because of several noticeable advantages: (1) environmental stability of passive extracavity spectral broadening compared to active intracavity broadband mode locking, (2) the absence of a trade-off between broad bandwidth and stable operation, and (3) intrinsic compatibility with alignment-free fiber-based components. Fiber continuum sources have been employed to perform single-frequency CARS [45] and multiplex CARS [46].

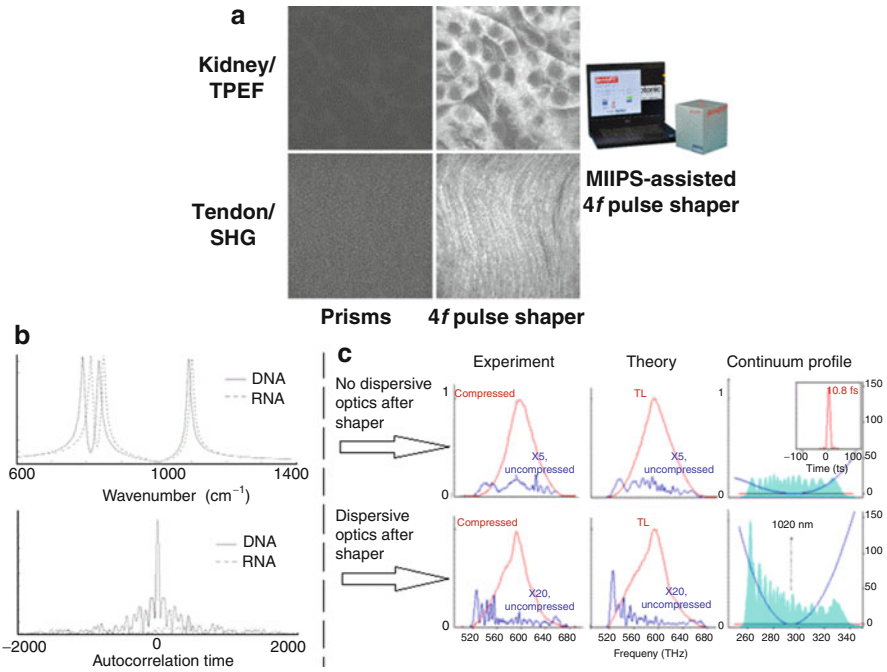

Fig. 39.8 (**a**) TPEF images of stained mouse kidney and SHG images of rat tendon using 12-fs laser pulses shaped by a prism pair, or an MIIPS-assisted pixelated 4-*f* pulse shaper. (**b**) *Top*: Raman spectra of phosphodiester modes of DNA (*solid line*) and RNA (*dashed line*). *Bottom*: time-domain autocorrelation signals for the pulse designed to selectively excite DNA. The signal from RNA (*dashed line*) is negligible in comparison to that from DNA (*solid line*) (Adapted with permission from [43]). (**c**) Adaptive pulse shaping and compression by MIIPS-assisted pixelated 4-*f* pulse shaper with or without dispersive optics after the shaper, as indicated by the agreement of SHG results between experiment and theory (Adapted with permission from [44])

Unfortunately, few known fiber continuum sources have sufficient coherence, bandwidth, or power for coherent control. We have developed an Yb laser-pumped fiber continuum [44, 47, 48], with broad bandwidth (880–1,180 nm), high average power (361 mW), and excellent coherence (Fig. 39.9a, b). These properties represent a significant improvement over the existing coherently controllable fiber continuum sources [38, 39] and have the potential for many future improvements [49, 50]. For the first time, both the spectrum and the spectral phase (i.e., full optical field) of fiber continuum can be simultaneously predicted with high accuracy (Fig. 39.9b). This degree of predictability and controllability allows us to compress and arbitrarily shape the fiber continuum using an MIIPS-assisted 4-*f* pulse shaper (Fig. 39.9c) [48] and to conduct multimodal multiphoton imaging on biological samples. Also, MIIPS adaptively compensates for the transmission optics and microscope objective after the shaper (Fig. 39.8c) [51], implying that the free-space NIVI optics can be fiber coupled externally.

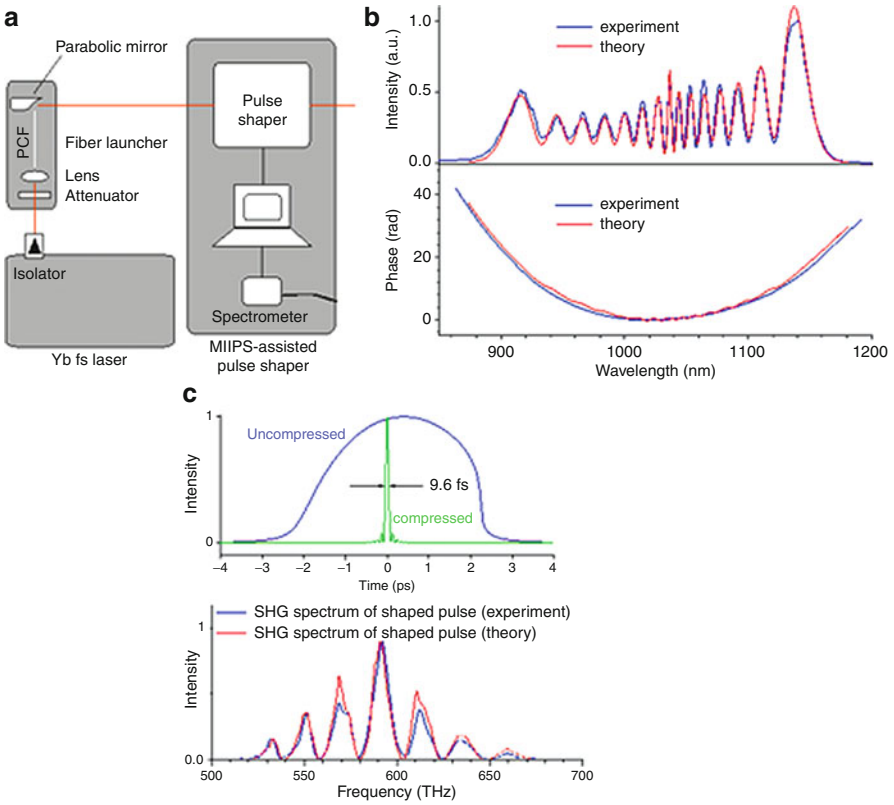

Fig. 39.9 (**a**) Schematic of fiber continuum source incorporating an MIIPS-assisted 4-*f* pulse shaper (Adapted with permission from [44]). (**b**) Comparison of the spectrum (*top panel*) and phase (*low panel*) of the fiber continuum between the experiment based on MIIPS-assisted 4-*f* pulse shaper (*blue curves*) and the theory based on generalized nonlinear Schrödinger equation (*red curves*) (Adapted with permission from [47, 48]). (**c**) *Top*: compression of fiber continuum pulse to transform-limited width of 9.6 fs by MIIPS-assisted 4-*f* pulse shaper. *Bottom*: comparison of the second-harmonic generation spectrum of a specifically shaped pulse of the fiber continuum (Adapted with permission from [48])

These preliminary results suggest the possibility for replacing the existing free-space lab NIVI system with a fiber-based clinical NIVI system. The key for this clinical translation is to replace the bulky amplified Ti:sapphire laser system or the solid-state laser-based fiber continuum source with a compact monolithic fiber continuum laser. The confinement of light to optical fibers eliminates the need for precise alignment of mirrors and other bulk-optical elements, making the optical system resistant to mechanical and thermal disturbances. In the future, the newly designed system will likely have reduced size, cost, complexity, and environmental instability, allowing NIVI to be performed by clinical personnel just as standard spectral-domain OCT is used by clinical personnel today.

39.7 Conclusions

We have described the theory, instrumentation, and demonstrated experimental results for imaging and spectroscopy with the technique of nonlinear interferometric vibrational imaging (NIVI). High-resolution Raman spectra were obtained using spectral interferometry to isolate resonant CARS signals generated from material samples and highly scattering biological tissues. The quantitative capacity of NIVI was demonstrated by the accurate determination of the degree of saturation in lipid samples. NIVI was also successfully used to map molecular constituents in skin domains and to differentiate between normal and tumor tissues in a rat mammary tumor model. Spectral-domain detection has been demonstrated, which allows for significant increases in image acquisition speed, signal-to-noise ratio, and signal stability.

In the future, increasing the spectral range into the Raman fingerprint region by increasing the Stokes bandwidth is expected to further enhance the sensitivity of NIVI for differentiating normal from tumor tissue, as well as permit detailed investigations into local biochemical compositions and dynamics. Novel application of supercontinuum sources will not only broaden the applicability of NIVI but will also advance the instrumentation towards compact all-fiber-based systems. The intrinsically complicated beam geometry of the NIVI instrument described in this chapter can be considerably simplified using compressible coherent continuum sources suitable for single-beam CARS excitation. NIVI, through continuing development as a highly sensitive and promising new real-time imaging modality, will be capable of addressing a greater range of fundamental biological studies and diagnostic clinical challenges.

Acknowledgments We thank all of our former colleagues, students, and researchers who have contributed to the development and application of this technology. Animals used for this research were handled and cared for under a protocol approved by the Institutional Animal Care and Use Committee (IACUC) at the University of Illinois at Urbana-Champaign. Since its inception, NIVI was supported in parts by grants for the US National Institutes of Health (NIH) and the US National Aeronautics and Space Administration (NASA). Ongoing research is being supported in part by an NIH Academic-Industry Partnership grant (R01 CA166309, S.A.B.). Additional information can be found at http://biophotonics.illinois.edu.

40.1 Introduction

40.1.1 Phase Contrast Microscopy

Microscopy is an important imaging tool in modern clinical medicine and basic biomedical research. Although microscopy is centuries old, cutting-edge research in techniques such as confocal microscopy, fluorescence microscopy, and quantitative phase microscopy continues at a rapid pace. The retrieval of phase information from microscopic samples has a long history [1] initiated by the development of the phase contrast microscope. Phase contrast microscopy is routinely employed for live visualization of cells since it enhances subcellular contrast. This technique exploits the fact that optically thin samples such as cells diffract light secondary to local variations in optical index. A phase plate and matching phase annulus added to the light train of a standard compound microscope can be used to interfere

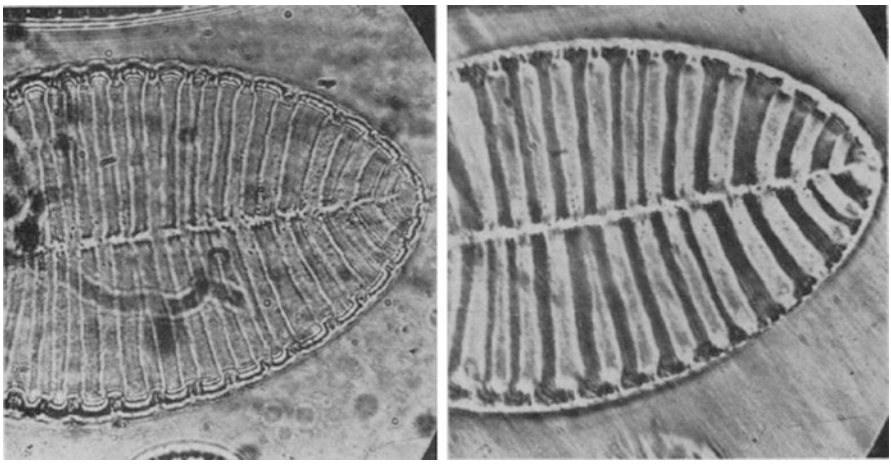

Fig. 40.1 Phase contrast microscopy. Brightfield (*left*) and phase contrast (*right*) images of a diatom. These are the oldest phase contrast micrographs from Zernike and were taken in 1932 (Figure from Zernike [1])

diffracted and undiffracted light. The degree of interference is manifest in the amplitude of the detected image. In this way, even unstained cells become distinguishable from their surroundings (Fig. 40.1). Frits Zernike was awarded the Nobel Prize for Physics in 1953 for this development.

Phase contrast microscopy has had an immeasurable impact by allowing the user to qualitatively visualize small, subcellular variations in optical index. Quantitative phase microscopy seeks to build upon the principles of Zernike to extract information relating to optical index, birefringence, motion, and flow. In addition to highlighting subcellular detail in unstained cells, quantitative phase techniques can measure small cell motions, small changes in cell index, and cytoplasmic flow.

Because of its sensitivity to phase and its ability to reliably quantify and track changes in coherent wavefronts, interferometry has recently gained momentum as a technique for the implementation of quantitative phase microscopy. This chapter seeks to review several of these interferometric techniques, with an emphasis on broadband interferometric techniques which exploit the principles of OCT. Both the underlying theory as well biological applications are discussed. Although this chapter gives particular focus to biologically relevant applications, the methods are readily extendable for other, nonbiological applications.

40.1.2 Definition of Interferometric Phase

When discussing coherent wavefields, it is usual to represent the wavefield as a complex function $\Psi(\mathbf{r}) = \sqrt{\mathrm{I}(\mathbf{r})}\exp(j\varphi(\mathbf{r}))$, where $\mathbf{r}$ is a vector representing three-dimensional position, $\mathrm{I}(\mathbf{r})$ is the intensity of the wave, and $\varphi(\mathbf{r})$ the phase of the field [2]. This representation is convenient for several reasons. The surfaces of constant

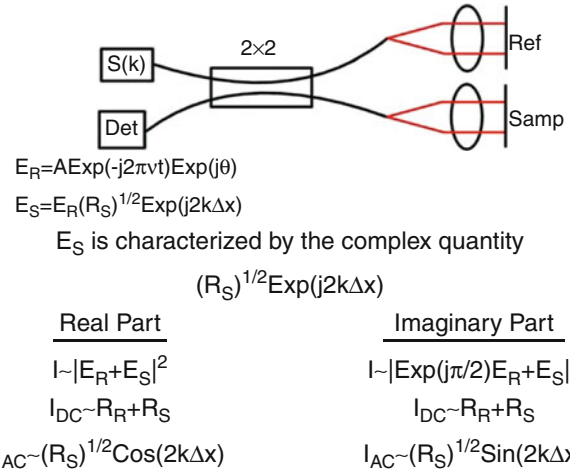

Fig. 40.2 Definition of the complex interferometric signal illustrated in a 2 × 2 50/50 Michelson topology. S(k) represents a monochromatic source. The free-space path length difference between the reference and sample arms is Δx. At the detector the reference electric field is characterized by an amplitude A which incorporates the reference arm reflectivity R_R and the double-pass attenuation in the 2 × 2, a time-varying component (v, optical frequency), and a phase θ which incorporates the initial phase of the light out of the source and phase accumulated in the interferometer. The sample field is an attenuated and phase-shifted version of the reference field. It is attenuated by the square root of the sample reflectivity and phase shifted by twice the product of the path length difference Δx between the reference and sample reflectors and the optical wavenumber k. When mixed at a square-law detector, the real (cosinusoidal) part of the complex interferometric electric field is measured. One method to gain access to the imaginary (sinusoidal) part of the field is to phase shift the reference field by π/2 rad with respect to the sample field

$\varphi(\mathbf{r})$ represent wavefronts, while $\nabla\varphi(\mathbf{r})$ describes the free-space propagation direction [2]. This definition decouples temporal and spatial variation in the field: the time-varying wavefunction is given by $\exp(j2\pi\nu t)\Psi(\mathbf{r})$, where ν is the frequency of the field. If $\Psi(\mathbf{r})$ is a one-dimensional wave propagating in a medium of uniform index n, $\varphi(\mathbf{r})$ can be represented as $\varphi(x) = nkx + \varphi_o$, where k is the free-space wavenumber ($2\pi/\lambda$; λ = free-space wavelength), x is the spatial coordinate in the direction of propagation, and φ_o is the initial or reference phase of the field. φ_o is analogous to a reference electrical potential insofar as both phase and potential are relative measurements.

Interferometry is a powerful, although by no means the only [2], technique for retrieving the phase of coherent wavefields. The interferometric signal is complex in nature and can be related to the linear difference between the sample and reference arm phase functions $\varphi_S(x)$ and $\varphi_R(x)$. If both arms are free space (i.e., $n = 1$), then $\varphi_S(x) - \varphi_R(x)$ reduces to $2k\Delta x$, where Δx is the free-space path length difference between the two arms (Fig. 40.2). One insight that can be drawn from this representation is that small displacements of the sample reflector can be monitored by holding the reference arm fixed and measuring the phase of the interferometric signal versus time. This is a powerful technique limited by the stability of the reference reflector.

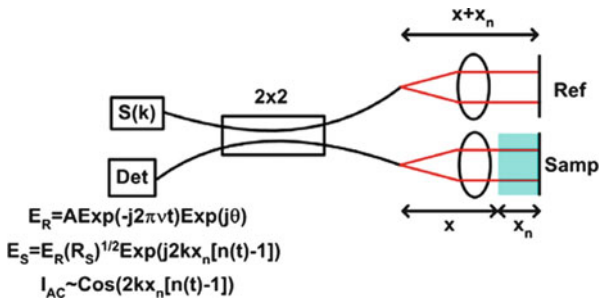

Fig. 40.3 Relationship of interferometric phase to changes in optical index

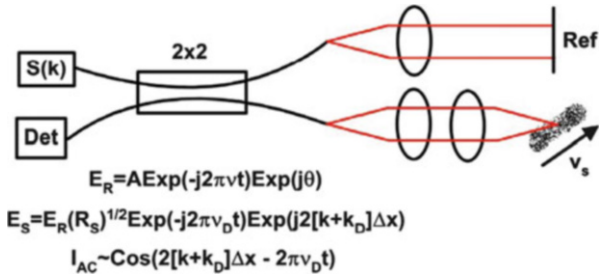

Fig. 40.4 Interferometric phase and scatterer-induced Doppler shift

The phase of the interferometric signal is sensitive to changes in optical index as well. Consider the setup in Fig. 40.3. The free-space path length of both arms are identical, but the sample arm has two compartments: one free-space compartment of path length x and another compartment of length x_n with a time-varying index n(t). The interferometric phase $\varphi_S(x) - \varphi_R(x)$ is now related to the index by $2kx_n$[n(t)−1]. Since the index of an aqueous solution is proportional to its osmolarity, this suggests a method for monitoring changes in solution osmolarity by tracking the interferometric phase.

Just as changes in index and in path length can be monitored by measuring interferometric phase, changes in sample arm wavenumber can likewise be monitored. The sample field frequency can be changed by reflection from a moving reflector or scatterer. This is the familiar Doppler shift that leads the field frequency v and wavenumber k to be changed by the quantities v_D and k_D, respectively (Fig. 40.4). Time variations in phase manifest in the beat term exp(−j2π$v_D t$). It should be noted that the effect of displacement, changing index, and Doppler shifting is inseparable. For example, if the sample reflector in Fig. 40.4 were moving as the index was changing, it would be impossible to establish the relative contribution of each term to the phase measurement.

40.2 Review of Prior Techniques

40.2.1 Monochromatic Interferometric Techniques

Monochromatic phase-sensitive interferometric techniques in cell biology predate their broadband counterparts by approximately half a decade. These monochromatic techniques are not able to perform depth sectioning and effectively integrate phase content along the optical axis. Nonetheless, their ability to measure cell volumes has yielded impressive results.

The maintenance of cell volume and osmolarity are basic homeostatic functions. As such, there is a keen interest in developing techniques that can quantify the response of various epithelial and endothelial cell types to osmotic and/or pharmacologic challenge. Monochromatic interferometry is an attractive candidate for measuring changes in cell volume because the phase of an optical field that is reflected from (or transmitted through) a cell responds linearly to changes in the thickness or optical index of that cell.

This principle was elegantly demonstrated by Farinas and Verkman in 1996 [3]. They performed full-field and single-point monochromatic Mach-Zehnder interferometry in which the reference optical field was mixed with a sample beam transmitted through a single-layer epithelial cell layer (Fig. 40.5). Since the interferometer was monochromatic, this technique is unable to coherently gate phase information at the cell-perfusate interface from that at other interfaces. Farinas and Verkman cleverly circumvented this problem by placing cells in a perfused flow chamber (Fig. 40.5). If it is assumed that the cell acts as a perfect osmometer (i.e., the product of cell volume and cell osmolarity is constant), it then follows that cell expansion (contraction) results from the influx (outflux) of free water into (out of) the cell, leading to a commensurate decrease (increase) in cell osmolarity. Given that the optical index is proportional to osmolarity, and since cell osmolarity is inversely proportional to cell volume per the perfect osmometer assumption, changes in interferometric phase shift are unambiguously related to changes in cell volume. This relationship is qualified with the assumption that the cell thickness scales linearly with cell volume.

The major drawback to this technique was in the retrieval of the interferometric phase data. The setup in Fig. 40.5 is a homodyne detection system insofar as both the reference and sample arm phase velocities are zero. As such, both non-interferometric and interferometric information reside at baseband, precluding the use of various hardware and software time-domain phase-sensitive retrieval techniques. Farinas and Verkman used a nontraditional technique that involved taking the inverse cosine of the data after it was normalized to have values ranging from -1 to $+1$. Normalization was aided by fringes generated from a spatial phase gradient placed in the reference arm. This inverse cosine operation yields the interferometric phase, but the sensitivity of this technique is limited by the accuracy of the normalization process. As interferometric images were acquired by the use of a CCD camera, imaging speed matched that of the camera frame acquisition rate ($\sim$1 s).

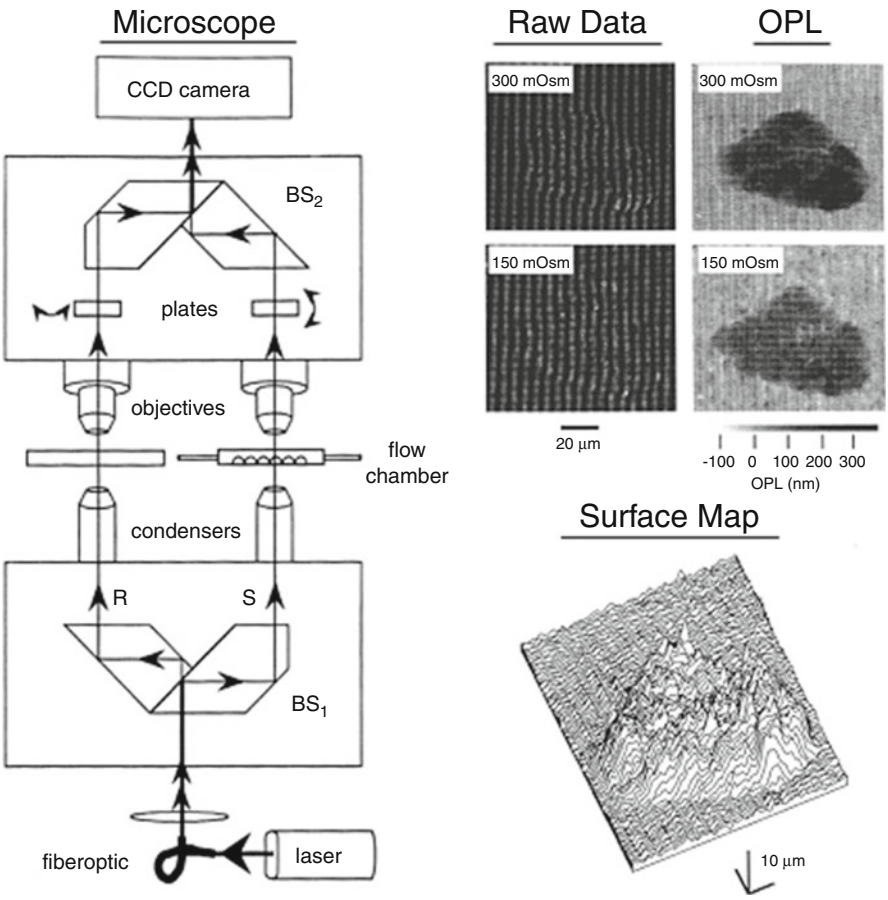

Fig. 40.5 Full-field Mach-Zehnder cell volume interferometer (Images are from Farinas and Verkman [3])

As expected, cells swell in response to a decrease in perfusate tonicity (Fig. 40.5). Since changes in optical index are small compared to the concurrent changes in path length, the change in phase never exceeded 2π. Since zero phase can be defined at the perfusate-coverslip interface, this technique avoids the commonly encountered 2π ambiguity problem that renders phase measurements relative as opposed to absolute.

The approach used by Farinas and Verkman was revisited in 2005 by M. Feld and colleagues [4, 5]. The setup uses a tilted reference arm to generate spatially varying fringes. Two other advances were introduced. First, Hilbert transformation was used to more directly retrieve the complex spatial interferometric signal. Second, a high-speed CCD camera which acquired 480×640 pixel images at a 291 Hz frame rate was used. The imaging speed of these systems is compatible with many cell dynamic applications (Fig. 40.6). Nonetheless, the monochromatic sources used prevent depth-selective isolation of the sample behavior.

Rightmost panel of images is the time-varying deformation of a red blood cell recorded using a high-speed version of the technique. (**a**–**b**) Are from Ikeda et al. [4] and (**c**–**f**) are from Popescu et al. [5]

40.2.2 Broadband Time-Domain Techniques

The use of phase-sensitive detection to extract nonpolarization-based functional information from the interferometric OCT signal was first demonstrated with color Doppler OCT [6, 7]. In CD-OCT, depth-resolved flow information is extracted from the complex-valued signal through a variety of time-frequency analyses. One conceptually straightforward analysis is to calculate the instantaneous Doppler frequency as the derivative of the phase with respect to time. This definition of Doppler shift provides an intuitive understanding of the relationships among phase, Doppler frequency, particle position, and particle velocity. The Doppler frequency (i.e., the derivative of phase with respect to time) is proportional to particle velocity (i.e., derivative of position with respect to time). The phase, which can be viewed as the integral of Doppler frequency, is proportional to the particle position, which is the integral of the particle velocity. Defining phase and position in terms of the integral of Doppler frequency and particle velocity, respectively, has the mathematical convenience of equating the unknown constant of integration with the unknown zero-phase point that generally renders phase, and consequently position, measurements relative as opposed to absolute.

It was in this framework that Yang et al. developed a phase-referenced interferometry (PRI) technique for the measurement of changes in cell diameter in response to an osmotic challenge (Fig. 40.7) [8]. This technique has two advantages over that of Farinas and Verkman [3]. First, because PRI employs a broadband light source,

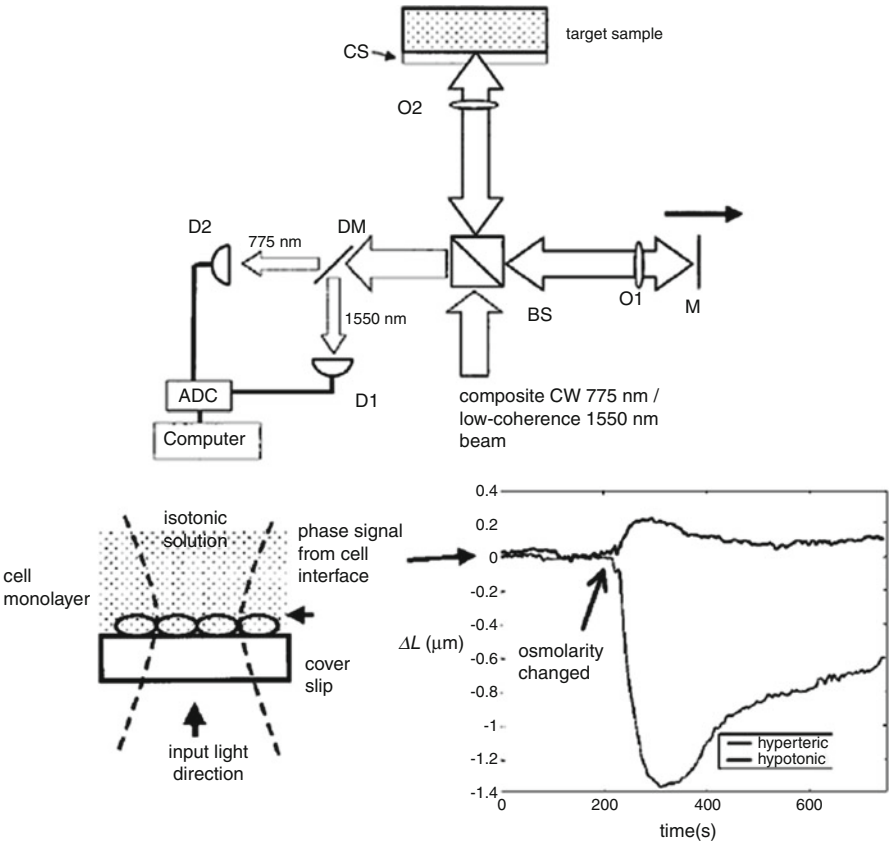

Fig. 40.7 Phase-referenced interferometry (Figures are from Yang et al. [8]

it is able to section via coherence gating signal from interfaces of interest (e.g., cell-perfusate interface) and reject signal from others. Second, since PRI uses a scanning delay line, the interferometric signal was encoded with a characteristic heterodyne beat frequency which allowed for the straightforward extraction of phase by Hilbert transformation of the data. PRI uses a CW source that is harmonically related to the broadband source center wavelength to measure and correct for interferometer jitter introduced by the scanning delay line. This correction was not required in Farinas and Verkman's full-field setup because data was acquired at a single point in time as opposed to over the course of several seconds. One disadvantage of this setup is that it acquires data pointwise and not in a full-field, parallel manner.

Yang et al. measured the average change in cell thickness of a few cells in response to a moderate hypo- and hypertonic challenge (Fig. 40.7). The reported system sensitivity was 3.6 nm, and the temporal resolution was several hertz. The cells underwent a two-step response to alterations in perfusate tonicity. Upon an increase (decrease) in tonicity, the cells contracted (swelled) for ~100 s. After this initial response, the cells gradually swelled (contracted) towards a new steady-state thickness.

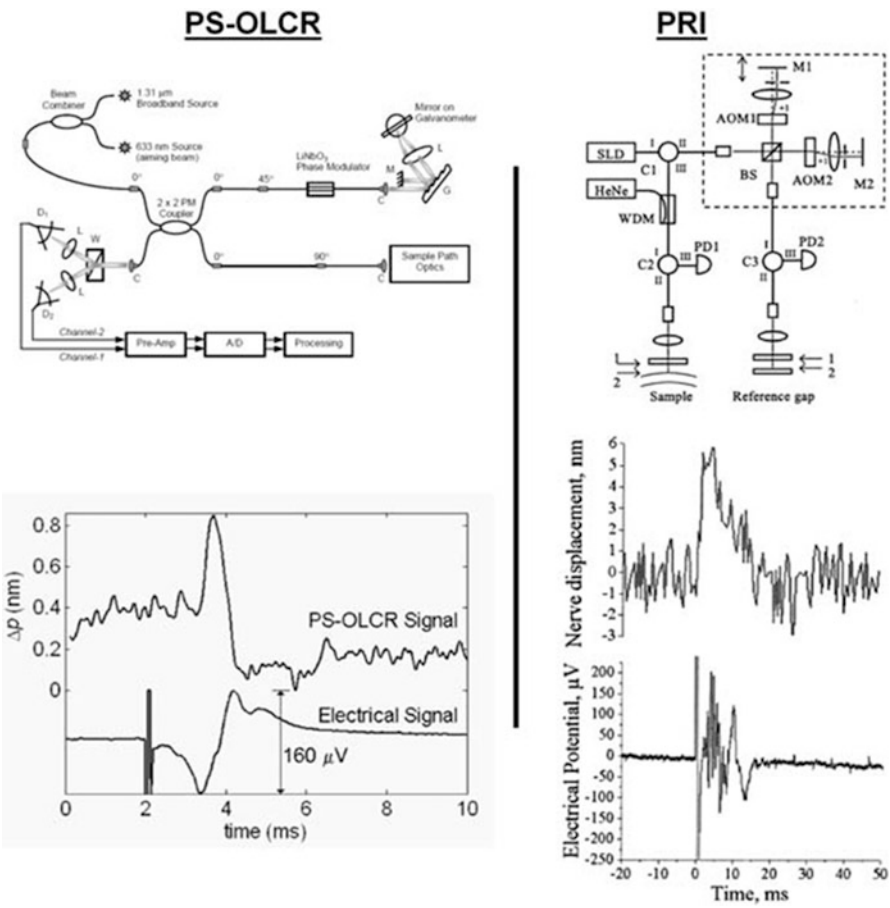

Fig. 40.8 Broadband, time-domain interferometer designs for detection of nanoscale neuronal activity associated with action potential generation. PS- OLCR figures from Akkin et al. [14] (PRI images from Fang-Yen et al. [13])

It is a well-established phenomenon that electrical action potentials in a neuron are associated with temporally correlated changes in neuron thickness, birefringence, and optical scattering [9–12]. Fang-Yen et al. [13] employed an improved heterodyne version of the phase-referenced interferometer to visualize such changes in neuron thickness. Rather than using a continuous-wave reference source, this setup employed an additional Michelson interferometer as a phase reference (Fig. 40.8). Phase differences taken between the interrogated sample and a passive reference gap mitigated the effects of phase noise introduced by the added interferometer.

Akkin et al. [14] employed polarization-sensitive optical low-coherence reflectometry (PS-OLCR) to detect action potential-related nerve swelling. The PS-OLCR system (Fig. 40.8) uses two decorrelated polarization channels within

a single-mode fiber. Optical path length changes were measured with respect to a selected depth along the optical axis. Longitudinal separation of orthogonal polarization components was achieved by placement of birefringent wedges in path of the sample illuminating light. In the detection arm, the optical phase associated with each polarization was separately detected and determined with the Hilbert transform. The differential phase mitigated common mode noise and provided the relative phase, and therefore path length, change between the two spatially separated polarization channels. Results obtained for electrical stimulation of a crayfish nerve bundle demonstrate subnanometer resolution capabilities of this system (Fig. 40.8).

40.3 Theoretical Limits to Phase Stability in Interferometry

OCT was first demonstrated by Huang et al. in 1991 [15]. Two key insights from this first demonstration were (1) the use of time-domain (TD) low-coherence interferometry techniques developed in telecommunications [16] to obtain depth-reflectivity profiles in biological tissue and (2) the use of laterally scanning sample arm optics to generate two-dimensional optical reflectivity profiles of tissue. It was quickly realized that phase-based information could be extracted from the interferometric OCT signal [6, 7, 17] and that this information could be used to characterize biological tissue.

There are two types of phase information which have been extracted from interferometric OCT signals. The first type is polarization-based phase, which describes the differential propagation of orthogonal polarization states in biological tissue. This technique is not the focus of this chapter and is discussed extensively elsewhere in this book. The second type of phase information is discussed in Sect. 40.1.1 and is referred to here as interferometric phase. This interferometric phase is sensitive to sample motion, Doppler shift, and changes in optical index. For example, in TDOCT, in the absence of sample arm motion and interferometer jitter, the real interferometric phase is proportional to $\cos(2k_o[x_R - x_S])$, where k_o is the source center wavenumber, x_R is the linearly swept reference arm path length, and x_S is the location of a sample reflector of interest. In the setting of sample motion δx, the signal is proportional to $\cos(2k_o[\Delta x - x_o + \delta x])$. If the interferometric phase is measured over successive scans, the relative (but not absolute) position of a reflector can be tracked.

In the early 2000s, it was demonstrated that spectral domain OCT techniques have a substantial amplitude sensitivity advantage over their time-domain techniques [18–20]. This prompted a shift in technology development for amplitude and phase imaging using OCT. With respect to phase imaging, the interferometric phase information is available in the native spectral domain (spectrally but not spatially resolved) or in the time domain (spatially but not spectrally resolved). Data processing to obtain displacement and Doppler data is substantially similar for both TD and SD-OCT. From a practical perspective, SD-OCT holds an advantage over TD-OCT in measuring interferometric phase since SD-OCT systems employ

few, if any, moving parts. Additionally, in SD-OCT a common path or coaxial interferometer topology can be employed [21, 22]. This approach has the advantage of forcing virtually all phase noise to be common mode between the reference and sample optical fields. From a theoretical perspective, the phase stability of SD-OCT holds an intrinsic advantage over TD-OCT. This advantage comes from the fact that phase stability is a straightforward function of amplitude stability. This relationship is explored in this section, in the context of SD-OCT. Experimental results that exploit the phase stability of spectral domain techniques are presented later in the chapter.

40.3.1 Phase and Doppler Sensitivity of Spectral Domain OCT

The complete spectral domain photocurrent in SD-OCT may be written as [18]

$$i(k) = \frac{1}{2}\rho S(k)\delta k\left[R_R + \sum_n R_n + 2\sqrt{R_r}\sum_n \sqrt{R_n}\cos\left(2k[\Delta x_n + \delta x_n]\right)\right]. \quad (40.1)$$

Here, S(k) is the source power spectral density, k is wavenumber (radians per meter), δk is the spectral channel bandwidth, ρ is the detector responsivity, R_R is the reference arm reflectivity, and R_n is the reflectivity of the nth sample reflector. The quantity $\Delta x_n + \delta x_n$ is the position of the nth reflector. Δx_n is an integer multiple of the discrete sampling interval in the x-domain, given by $m\pi/\Delta k$, where Δk is the total optical bandwidth interrogated and m is any positive or negative integer. δx_n accounts for subresolution deviations in reflector position away from $m\pi/\Delta k$. δx_n is an important quantity because it primarily manifests in the phase of $i(k)$. Note that n and m are distinct and separate variables: n indexes discrete reflectors in the sample, while m indexes elements in the one-dimensional x-domain A-scan array.

In swept-source OCT, $i(k)$ is directly measured, whereas in spectrometer- based Fourier domain OCT, $i(k)$ is integrated over the A-scan acquisition time in a charge-coupled device (CCD) or similar charge-accumulation detector. In either case, after Fourier transformation of the k-domain signal, the complex-valued x-domain signal and shot noise is given by, respectively,

$$I_{\text{signal}}(2\Delta x_n) = \frac{\rho S_o\sqrt{R_R R_n}}{2ef_{\text{ascan}}}E(2\delta x_n)\exp(jk_o 2\delta x_n). \quad (40.2)$$

$$I_{\text{noise}}(2\Delta x_n) = \sqrt{\frac{\rho S_o R_R}{ef_{\text{ascan}}}}\exp(j\phi_{\text{rand}}). \quad (40.3)$$

Here, E(·) is the unity-amplitude x-domain autocorrelation function, S_o is the total sample illumination power (i.e., $\int S(k)dk$), k_o is the source center wavenumber, and ϕ_{rand} is the random phase of the shot noise. f_{ascan} is the rate, in Hz, at which A-scans were acquired. In situations where the detector integration time is less than

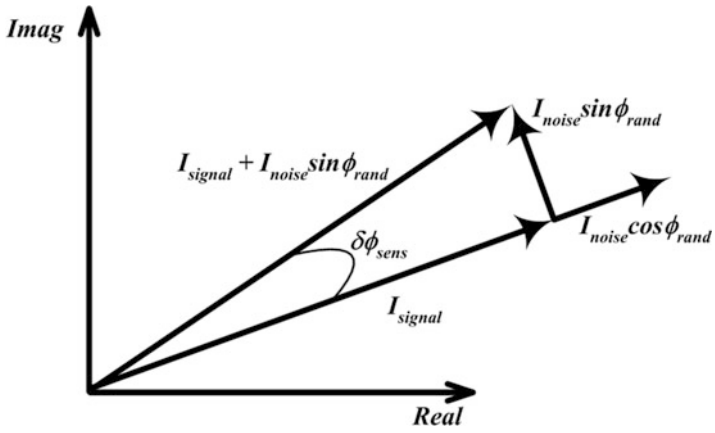

Fig. 40.9 Phase stability of spectral domain phase microscopy. In the x-domain, the signal and noise are complex-valued signals that add in a vectoral manner. If the phase of the noise is defined to be zero when I_{noise} is parallel to I_{signal}, then the error in the phase of I_{signal} is given by the component of I_{noise} that is perpendicular to I_{signal} (i.e., $I_{\text{noise}}sin_{\phi\text{rand}}$). The average rotation of I_{signal} caused by $I_{\text{noise}}sin_{\phi\text{rand}}$ taken over all ϕ_{rand} defines the phase stability

the interval between acquired A-scans, f_{ascan} is the numerical inverse of the integration time. It is assumed that $R_R >> R_n$. The amplitude signal-to-noise ratio of the nth reflector is given by the square of the ratio of the amplitudes of Eqs. 40.2 and 40.3. The shot noise-limited phase stability of the nth reflector signal is limited by the phase angle $\delta\phi_{\text{sens}}$ between $I_{\text{signal}}(2\Delta x_n)$ and $I(2\Delta x_n) = I_{\text{signal}}(2\Delta x_n) + I_{\text{noise}}(2\Delta x_n)$. The issue can be generally approached by considering the average value of the phase angle between $I_{\text{signal}}(2\Delta x_n)$ and $I(2\Delta x_n)$ over all values of ϕ_{rand}. This is given by (Fig. 40.9)

$$\delta\phi_{\text{sens}} = \frac{2}{\pi}\int_0^{\pi/2} \tan^{-1}\left(\frac{|I_{\text{noise}}|}{|I_{\text{signal}}|}\sin\phi_{\text{rand}}\right) d\phi_{\text{rand}}. \tag{40.4}$$

Equation 40.4 is derived in part from the representation of signal and noise in Fig. 40.9. At any particular instant, the signal vector (I_{signal}) and the noise vector (I_{noise}) have a random angular orientation with respect to each other. Since the phase of *Isignal* is not random, the phase of I_{noise} (i.e. ϕ_{rand}) can be conveniently defined with respect to I_{signal}. I_{noise} can be decomposed into components that are parallel ($I_{\text{noise}}\cos\phi_{\text{rand}}$) and orthogonal ($I_{\text{noise}}\sin\phi_{\text{rand}}$) to the signal vector. The parallel component contributes to amplitude sensitivity, while the orthogonal component contributes to the phase sensitivity. The phase noise of I_{signal} is defined by the magnitude of the rotation of I_{signal} by $I_{\text{noise}}\sin\phi_{\text{rand}}$. The phase noise also defines the phase sensitivity ($\delta\phi_{\text{sens}}$) since the smallest observable change in the phase of the signal vector is determined by the phase noise. In other words, an observable change in the signal phase must be larger than the phase noise.

If $|I_{noise}| \ll |I_{signal}|$, which is the usual case, then I_{signal}, $I_{noise}\sin\phi_{rand}$, and $I_{signal} + I_{noise}\sin\varphi_{rand}$ form a right triangle, and $\delta\phi_{sens}$ is the angle opposite $I_{noise}\sin\phi_{rand}$. $\delta\phi_{sens}$ is defined by the argument of the integral in Eq. 40.4, while the integral itself takes the average value of $\delta\phi_{sens}$ over all possible random values of ϕ_{rand}. This integral assumes that ϕ_{rand} has a uniform distribution. If it is assumed that $|I_{noise}| \ll |I_{signal}|$, then the arctangent function can be approximated by the value of its argument. The integral in Eq. 40.4 then simplifies to the mean value of the sine function over a quarter period, yielding

$$\delta\phi_{sens} = \frac{2}{\pi}\sqrt{\frac{1}{SNR(S_o, R_n, f_{ascan})}}. \tag{40.5}$$

where SNR(S_o, R_n, f_{ascan}) is the signal-to-noise ratio of the nth reflector.

Because the phase of $I(2\Delta x_n)$ is proportional to δx_n, displacements in a sample reflector can be tracked over time by tracking the phase over time. This is the basic principle of spectral domain phase microscopy (SDPM). SDPM may be extended to velocimetry measurements by noting that the instantaneous velocity of a reflector is given by the difference of δxn or two successive A-scans divided by the temporal sampling interval, which is equivalent to defining the instantaneous Doppler shift as the derivative of the phase with respect to time. This gives

$$v(t) = \frac{\lambda_o}{2\cos\theta} f_{dopp} = \frac{\lambda_o}{4\pi\cos\theta} f_{ascan}\left(\angle I(2\Delta x_n, t) - \angle I\left(2\Delta x_n, t - f_{ascan}^{-1}\right)\right) \tag{40.6}$$

Here, $\angle$ is the phase operator, λ_o is the source center wavelength, f_{dopp} is Doppler frequency shift, and θ is the Doppler angle between the optical axis and the direction of motion. The phase error in $v(t)$ is $\sqrt{2}$ times higher than the phase error in $\angle I(2\Delta x_n, t_o)$. The factor of $\sqrt{2}$ arises because velocity is proportional to the numerical difference between two successive phase measurements. As such, the uncertainty in difference (i.e., velocity) must be larger than the individual data points in the difference (i.e., phase). We assume that the summation of N random data points with identical standard deviations (or errors) has an error that is $N^{1/2}$ times larger than the error of each data point. The velocity sensitivity is thus (Fig. 40.10).

$$v_{sens} = \frac{\lambda_o}{2\sqrt{2}\pi\cos\theta}\delta\phi_{sens} f_{ascan} \frac{\lambda_o f_{ascan}}{\sqrt{2}\pi^2\cos\theta\sqrt{SNR(S_o, R_n, f_{ascan})}} \tag{40.7}$$

Equation 40.7 is consistent with the Cramer-Rao lower bound for a model-based velocity estimator [23], which has been previously verified in time-domain OCT [23]. In Doppler OCT imaging, it has been suggested that the minimum observable Doppler shift is related to the inverse of the observation period, which yields a velocity sensitivity of $\lambda_o f_{ascan}/2$ [24, 25]. The basis for this Fourier-limited assumption is that at least one cycle of the Doppler-induced electronic beat frequency must be

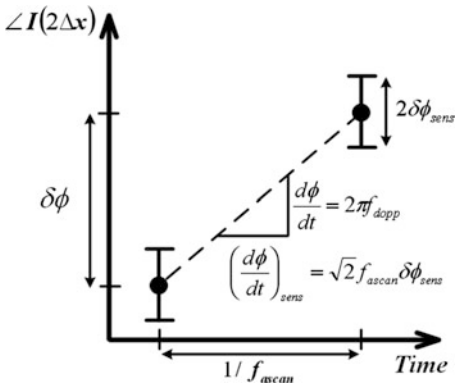

Fig. 40.10 Velocity sensitivity of Doppler flow imaging. dϕ/dt is experimentally calculated by taking the numerical derivative of the phase with respect to time. f_{dopp}, Doppler frequency shift

sampled in order to detect the motion of a reflector. If we define instantaneous Doppler shift (or velocity) as being the derivative of the phase (or position), it is clear the Fourier limit is overly restrictive. For example, if a reflector is moving at a constant velocity, the phase of the interferometric signal increases linearly over time. The accuracy of the phase difference between two sequential points, which is directly proportional to the instantaneous Doppler shift, is limited only by the phase noise on each individual point (Fig. 40.10). In this light, there is no clear need to sample an entire fringe of the Doppler-induced electronic beat frequency in the detector photocurrent.

40.4 SDPM Imaging Systems: Design, Characterization, and Validation

Spectral domain phase microscopy (SDPM) is being vigorously developed by several research groups for two main reasons. First, as discussed in Sect. 40.2, interferometry is a powerful technique for quantitative phase microscopy. Second, as discussed in Sect. 40.3, SD-OCT offers practical and theoretical advantages over TD-OCT in terms of phase stability. In this section, we describe several different SDPM topologies. We start with a detailed system characterization and validation of SDPM systems built by our group at Duke University. This discussion builds on the theoretical description of Sect. 40.3. The section closes with a discussion of more advanced topologies.

Figure 40.11 shows two spectral domain detection systems adapted to two types of sample arm optics. Both the swept-source and Fourier domain setup were adapted to tabletop imaging optics on a floated optical table, while the Fourier domain setup was additionally adapted to a Zeiss Axiovert 200 inverted microscope for the simultaneous acquisition of SDPM data and real-time video microscopy.

The insets to Fig. 40.11 illustrate experimental measurements from a clean glass coverslip for displacement sensitivity of 53 pm for the Fourier domain system (with ~9 μW incident on the coverslip) and 780 pm for the swept-source system (with ~3 mW incident on the coverslip). Despite these exquisite sensitivities, the experimental values are significantly higher (by a factor of 6 and 7×10^4,

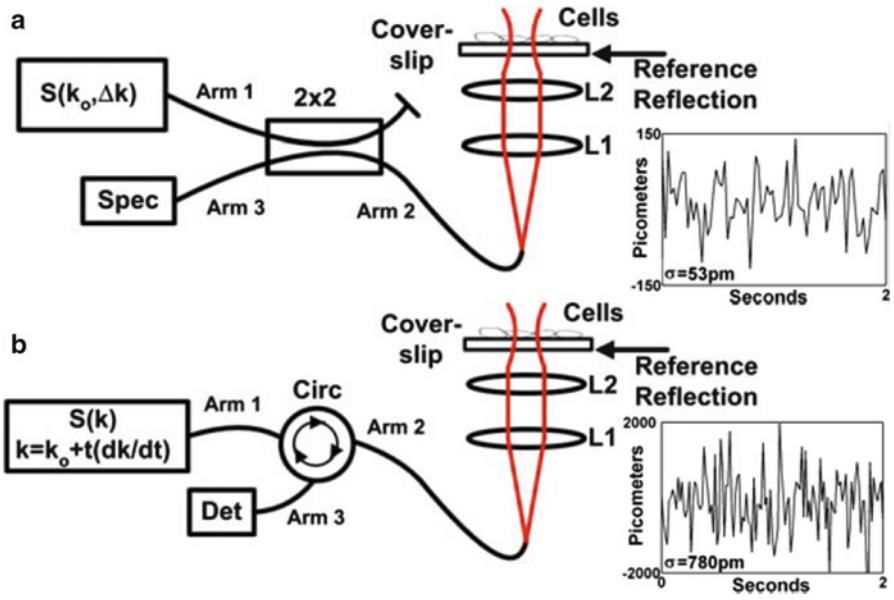

Fig. 40.11 Common-path spectral domain interferometers (**a**) Fourier domain SDPM interferometer. The source is a ~5 mW SLD with a center wavelength and 3 dB bandwidth of 830 nm and 45 nm, respectively. The spectrometer (Spec) has 25 ms readout rate and a 5 ms integration time. (**b**) Swept-source SDPM interferometer. The narrow linewidth source is swept through a 130 nm bandwidth over 5 ms with a center wavelength of 1,310 nm and an average power of ~3 mW (Micron Optics, Inc. [18]). The insets show the displacement signals recorded from a clean coverslip. The standard deviation of this signal defines the displacement stability at a particular sample reflectivity and sample illumination power. With ~3 mW incident on the coverslip, the swept-source displacement stability was 780 pm. With ~9 μW incident on the coverslip, the Fourier domain displacement stability was 53 pm (Figure is from Choma et al. [22])

respectively, for Fourier domain and swept-source interferometers) than theoretically predicted by Eq. 40.7.

The lower displacement sensitivity exhibited by the swept-source system is likely due to variability in the starting sweep wavelength. In other words, the first wavelength emitted by the swept source at the start of the wavelength sweep varies on the order of 780 pm sweep-to-sweep. This is an important design specification to consider given the increased interest in swept laser sources for spectral domain OCT. Possible limitations in the Fourier domain system include the presence of 1/f contamination in the sub-kilohertz bandwidth signal and any mechanical jitter in the sample arm optics which was not mitigated by the common path topology.

Equation 40.7 implies that the magnitude of the displacement stability noise floor is related to the square root of the reciprocal of the detector integration time. This is in contrast to amplitude sensitivity, which is a linear function of detector integration time. To test this model, we measured as a function of spectrometer integration time the displacement stability of the Fourier domain interferogram generated by a clean coverslip. Equation 40.7 predicts that the slope of $\log(\delta x_{\text{sens}})$

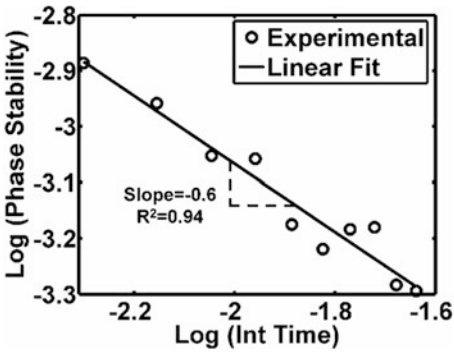

Fig. 40.12 Power (inverse square root) relationship between phase stability and detector integration time (Figure is from Choma et al. [22])

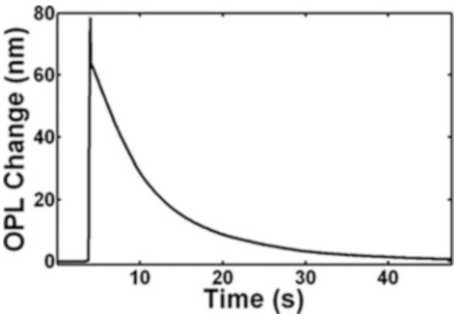

Fig. 40.13 Thermal expansion and contraction of a glass coverslip. The upswing corresponds to the application of a flame to the coverslip, and the downswing corresponds to cooling down to room temperature. The inset highlights the expansion of the coverslip

versus $\log(\Delta t)$ is -0.5. The experimental line has a slope of -0.6, which is consistent with the theory (Fig. 40.12).

Equation 40.7 predicts that the velocity sensitivity in spectral domain Doppler imaging is limited by phase stability. To test this prediction, we used SDPM to measure the velocity of thermal expansion of an uncoated glass coverslip transiently heated by a butane flame. The change in the optical path length (OPL) of the coverslip during heating and cooling was tracked by recording the phase of the x-domain interference signal at a depth corresponding to the thickness of the coverslip.

The rapid expansion and slow contraction of the coverslip is shown in Fig. 40.13. The baseline phase stability of the interference signal immediately before placing the flame near the coverslip was 0.4 mrad (18 pm). The phase stability is defined as the standard deviation of the x-domain interference phase at the depth corresponding to the coverslip thickness. The instantaneous velocity of expansion and contraction was calculated by numerically differentiating the OPL on sequential successive A-scans and multiplying that quantity by the line rate.

Figure 40.14 shows the instantaneously calculated velocity while the coverslip cooled off after flame removal. The yellow curve is a smoothed estimate of the actual velocity generated by low-pass filtering the phase data before calculation of

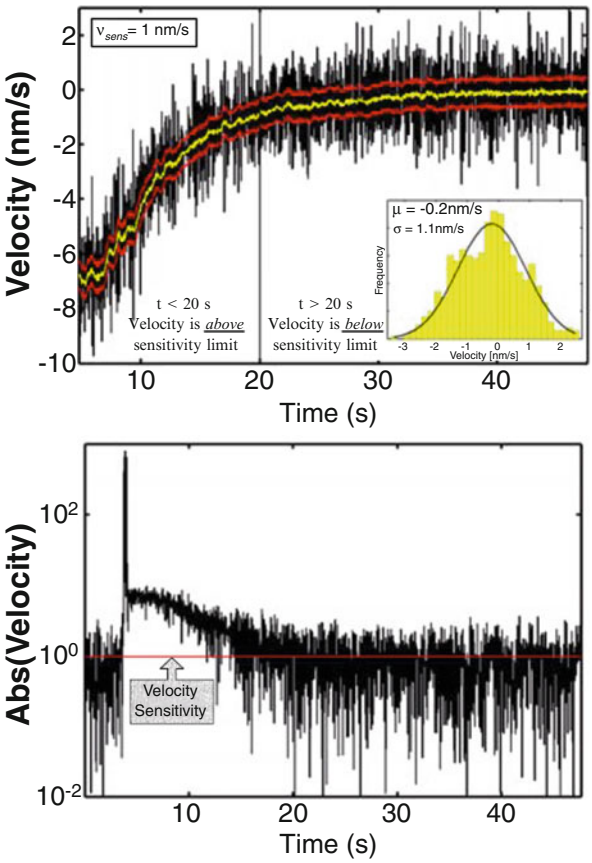

Fig. 40.14 Velocity sensitivity of SDPM. *Top*: Velocity of thermal contraction of glass coverslip ($t = 4.8$–48 s). The *black curve* is generated by taking the numerical derivative of the data in Fig. 40.13. The *yellow* line is the velocity estimated by low-pass filtering the raw data in *black*. The *red lines* are the velocity estimate plus/minus one-half of the predicted velocity sensitivity of 1 nm/s. The inset shows a histogram (*yellow bars*) of the velocity values measured for $t > 20$ s. The mean (μ) and standard deviation (σ) of the measured data are shown. The black curve is a Gaussian distribution with the measured μ and σ. *Bottom*: Absolute value of the velocity of expansion and contraction calculated from Fig. 40.13 and plotted on a log scale (From Choma et al. [26])

the Doppler shift. The red curves represent the estimated velocity plus/minus half of the velocity sensitivity calculated using Eq. 40.7. The black vertical line at $t = 20$ s represents the approximate time at which the magnitude of the velocity fell below the sensitivity of 1 nm/s. The inset to Fig. 40.14 (top) shows a histogram of the measured velocity values for $t > 20$ s. This data distribution, which is approximately Gaussian, has a standard deviation of 1.1 nm/s, consistent with the predicted velocity sensitivity of 1 nm/s.

Figure 40.14 (top) illustrates two points. First, the experimental velocity data were bound by a range defined by the actual velocity (estimated by low-pass filtering the velocity data) and the predicted velocity. This supports Eq. 40.7 as a valid expression for the noise and uncertainty in a Doppler calculation given a level of phase stability. Second, it demonstrates that the magnitude of the velocity must be greater than the velocity sensitivity in order to be resolved from zero velocity. In other words, when the velocity magnitude is equal to the velocity sensitivity, the "velocity signal-to-noise ratio" is unity, rendering the velocity measurement indistinguishable from zero velocity. Figure 40.14 (bottom) shows the absolute value of the expansion and contraction velocity on a log scale.

The predicted velocity sensitivity is shown as a horizontal red line. This figure draws an analogy with amplitude sensitivity for OCT in that the level of the "height" of the noise floor on a log plot is determined by the measurement sensitivity.

Phase-sensitive spectral domain interferometry has also been extended to collect multidimensional data. Towards this end, two distinct techniques have been demonstrated. Joo et al. [27] demonstrated a technique which they termed spectral domain optical coherence phase microscopy (SDOCPM) in which raster scanning was employed to acquire two-dimensional en face phase images of samples (Fig. 40.15). This system had a line scan rate of 29 kHz and a free-space axial resolution of $\sim$8 mm. Unwrapping the phase along transverse axes for a given axial depth yielded very sensitive information about the spatial dependence of the optical path length generated by the sample.

An alternate approach to full-field phase imaging builds on full-field parallel setups demonstrated for OCT [29, 30], and optical coherence microscopy [31] Sarunic et al. [28] demonstrated full-field SDPM images using a swept-source interferometer topology (Fig. 40.15). Interferograms acquired over the duration of the source sweep were collected simultaneously for all spatial positions during the integration time of a two-dimensional CCD camera. Phases unwrapped in space mapped out the surfaces of the samples of interest. Imaging speed for this particular demonstration was limited by the minimum integration time and duty cycle rate of the CCD used.

40.4.1 Applications in Cell Biology

The reductionist drive to describe living organisms in terms of complex interactions of basic building blocks and functional units (e.g., molecules, organelles, cells, tissues, organs) has been greatly facilitated by numerous imaging modalities (e.g., optical microscopy, ultrasound, magnetic resonance imaging). Elucidating in vivo structure and function in the cellular and subcellular regimes is a critical component of this drive. In these regimes, optical techniques hold great promise owing to their speed, spatial resolution, and nondestructive nature. In this section, several demonstrations of SDPM in cell biology are shown. It is hoped that these results motivate the development of SDPM as an important imaging tool in the cellular and subcellular regimes.

40.4.2 Characterizing Cardiomyocyte Contractility

The ability of SDPM systems to characterize dynamic cellular events was demonstrated on spontaneously beating 2-day-old isolated chick embryo cardiomyocytes (Fig. 40.16). A detailed description of the isolation and culture method can be found elsewhere [32]. Briefly, after decapitation of the embryo, the heart was removed, the atria and great vessels were trimmed away, and the ventricles were cleaned of connective tissue. Ventricular cardiomyocytes were dissociated by digestion of the

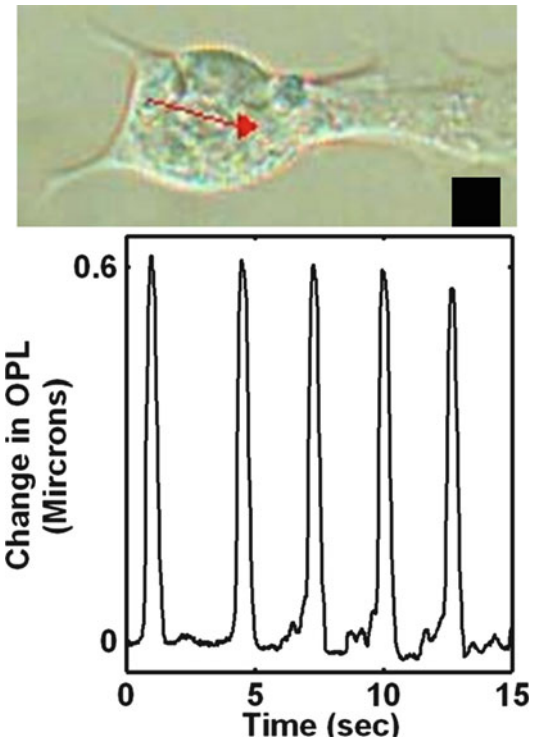

Fig. 40.16 Embryonic cardiomyocyte dynamics measured using SDPM. *Top*: Photomicrograph of an isolated ventricular cardiomyocyte from a 2-day-old chick embryo. The tip of the *red arrow* denoted the location of the SDPM beam. The *black box* is 10 × 10 μm. *Bottom*: Change in thickness of spontaneously beating cardiomyocyte measured using SDPM (Figure is from Choma et al. [22])

ventricle with DNAse and collagenase at 37 °C. Cells were cultured in DeHaan's 21,212 medium on glass coverslips and used within 24 h of enzymatic dissociation. During SDPM experiments, the cells were maintained at 37 °C using a heated microscope stage. At 37 °C the ventricular cardiomyocytes spontaneously beat via electromechanical coupling.

Using SDPM, we measured changes in cell thickness associated with cardiomyocyte contraction (Fig. 40.16). The cardiomyocyte depicted was spontaneously beating at ∼0.3 Hz. The dynamics of contraction were well represented in the SDPM trace.

40.4.3 Characterizing Cytoplasmic Flow in an Individual Cell

Cytoplasmic flow is central to a variety of cellular processes, including the development of neuronal polarity [33], cell migration [34], a-p axis formation in embryos [35], and amoeboid motion [36–47]. For in vivo Doppler imaging of cytoplasmic flow in *Amoeba proteus* [26], cellular measurements, an SDPM setup was relayed into a Zeiss Axiovert 200 using a documentation port as illustrated in Fig. 40.17. Simultaneous acquisition of SDPM and visible light microscopy video was achieved by placement of an 80/20 beamsplitter in the microscope optical path.

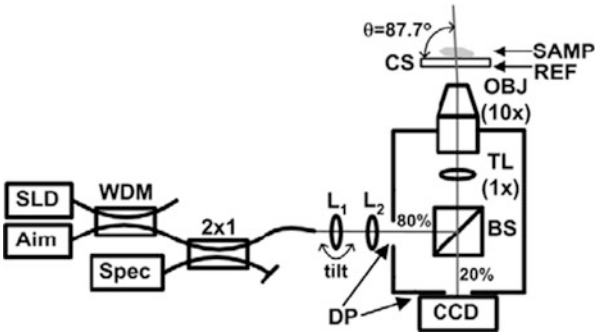

Fig. 40.17 SDPM setup adapted to Zeiss Axiovert 200 inverted microscope with simultaneous acquisition of SDPM and video light microscopy. A 635 nm aiming beam (*Aim*) is combined with an 840 nm superluminescent diode (*SLD*) (50 nm FWHM bandwidth) with a wavelength division multiplexing (*WDM*) fiber coupler. The combined light enters a 2 × 1 50/50 fiber coupler whose output fiber core is imaged via lenses (*L*) one and two onto a documentation port (*DP*) of the microscope with a magnification of $L_2/L_1 = 22$. The image formed at the documentation port is then relayed onto the sample (*SAMP*) with magnification of 1/10. The sample also is imaged onto a documentation port CCD. *CS* coverslip, *OBJ* microscope objective, *REF* reference reflection, *Spec* spectrometer, *TL* tube lens (From Choma et al. [26])

There was thus real-time display of video and A-scan data. The SDPM spot size (1/e diameter) on the sample was estimated from the magnification factor of the coupler fiber core being imaged onto the sample. This factor was (L2/L1) × (TL/OBJ), giving a calculated spot size of 12 μm and a calculated depth of focus of 1 mm. (L_n, nth lens, TL, tube lens, OBJ, objective lens; see Fig. 40.17 for more detail). The ration OBJ/TL is specified by the manufacturer as the effective or net magnification of a sample object onto the documentation port. The reflection from an uncoated coverslip surface proximal to the SDPM interferometer acted as the reference reflection.

Several amoebas (species *Amoeba proteus*) were placed on the other coverslip surface in a springwater solution. Since cytoplasmic streaming in these cells is nominally parallel to the coverslip surface, lens 1 (L1) was tilted to make a Doppler angle of $\theta = 87.7°$ between the SDPM light and the streaming. This Doppler angle represents a compromise between recoupling efficiency of the reference beam (highest at 90°) and optimal Doppler angle (optimal at 0°). The angle was verified through image analysis of the position of the aiming beam on the video image taken at calibrated displacements of the objective lens along the optical axis. With respect to recoupling efficiency of the reference beam, it should be noted that standard OCT sensitivity expressions here and in the literature are typically independent of reference arm power provided that (a) reference power is much greater than sample power and (b) the system operates in the shot noise limit.

A visible light microscopic image selected from a video recording of an extruding *A. proteus* is in Fig. 40.18. SDPM data were recorded from the location marked with the white triangle. This location was identified with a 635 nm aiming bean that was turned off after the acquisition window was marked with the triangle. The aiming

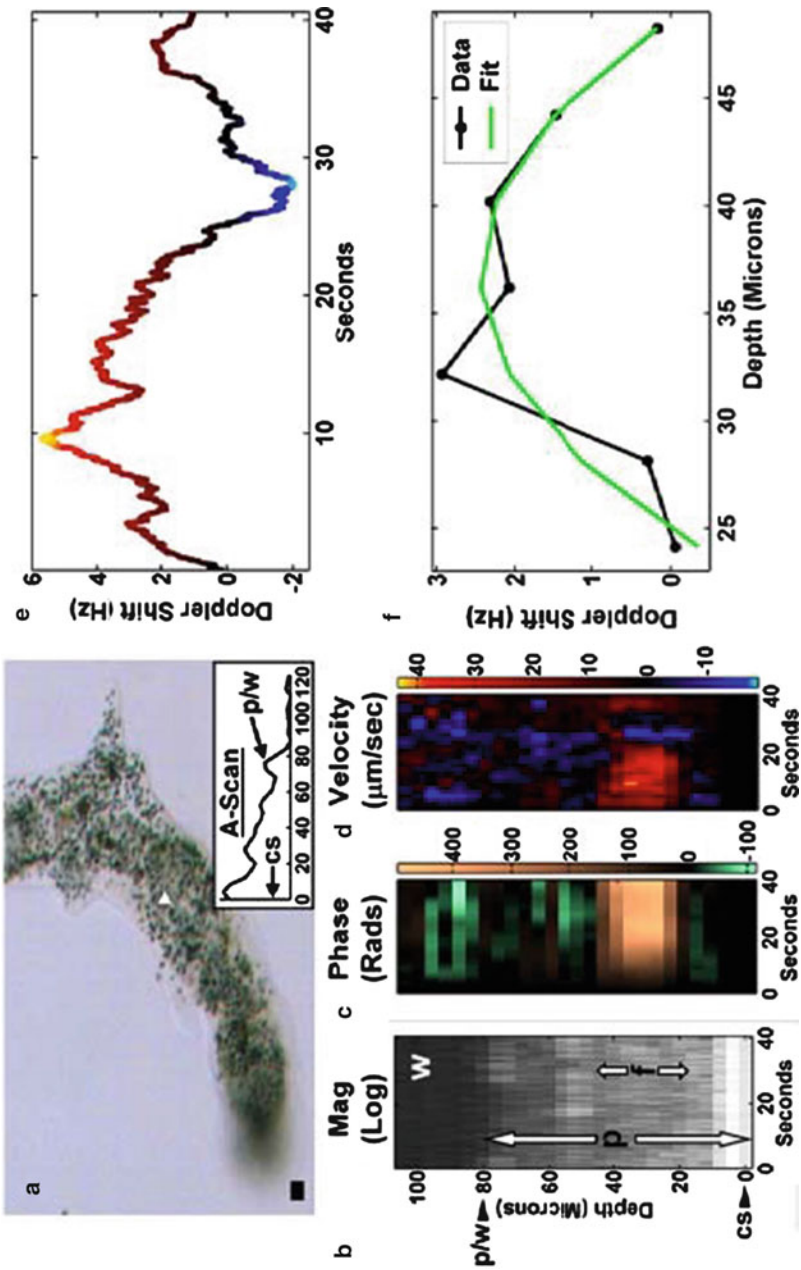

Fig. 40.18 (continued)

beam was turned off to avoid contamination of the data by photophobic reflex in A. proteus. M-mode recordings (repeated recordings at a given spatial location) of magnitude, phase, and derived Doppler images are in Fig. 40.18b–d. M-mode images have a vertical axis with units of depth, horizontal axis with units of time, and image intensity proportional to the measurement of interest (e.g., reflectivity, velocity). Between $t = 18-20$ s, several drops of a 50 mM $CaCl_2$ solution were added to the springwater solution. This triggered a slowdown and subsequent reversal in the cytoplasmic flow. The flow reversal is manifest as a decrease in accumulated phase (Fig. 40.18c) and as a change in the sign of the Doppler shift (Fig. 40.18d–e). The flow reversed again at t $\approx$ 35 s. Overall, measured flow rates were consistent with previously reported values for *A. proteus* [48].

Low-pass filtering of the Doppler data was performed to mitigate the influence of SNR variations due to speckle on the calculation of Doppler shift. Since speckle is multiplicative noise imposed on $I(2\Delta x)$ (i.e., $I = I_{\text{speckle}} \times [I_{\text{signal}} + I_{\text{noise}}]$), SNR($S_o$,$R_n$,$f_{\text{ascan}}$) is modulated by this multiplicative noise as well. Additionally, the "nulls" of the speckle pattern have a phase SNR of zero since there is zero signal. These nulls give the false impression that there is zero flow in an otherwise flowing sample. Likewise, SNR is maximum at the "peaks" of the speckle pattern, and the Doppler shift at these peaks presumably will most accurately represent the sample flow velocity. The Doppler data in Fig. 40.18 were low-pass filtered with a moving average filter with a time constant (or width) of 3,459 ms. This relatively longer time constant was chosen to emphasize changes in flow over the course of a few seconds. Figure 40.19 shows the Doppler shift recorded at a depth of 36 μm that was low-pass filtered with time constants ranging from 0 to 3,459 ms. The Doppler data is clearly interpretable with little to no filtering.

Visual inspection of the extruding *A. proteus* pseudopod on light microscopy indicates that the cytoplasm flows within a channel delineated on either side by non-flowing cytoplasm (the so-called gel, in contrast to the flowing "sol"). The gel has high viscosity and acts as a stationary conduit, while the sol, which has much lower viscosity, flows within that conduit. Flow is generated by active (i.e., ATP-dependent) cytoskeletal and cytoplasmic processes. In the absence of turbulence, which would be difficult to generate owing to the viscosity of

Fig. 40.18 Cytoplasmic flow in Amoeba proteus. (**a**) Photomicrograph of *A. proteus* pseudopod (*p*). The *white triangle* marks location of data collection, and *black box* in *lower left* is 10 × 10 μm. The inset to (**a**) shows an A-scan of the pseudopod (*abscissa* has units of depth in micrometers; ordinate has units of reflectivity in dB). The coverslip (*cs*) on which the pseudopod sits is located at zero displacement. The pseudopod/water (p/w) interface is clearly identified near 80 μm by a reflectivity peak followed by the decreased reflectivity of water. (**b**) M-mode magnitude image of *Amoeba proteus* pseudopod. (**c**, **d**) are M-mode phase and Doppler image, respectively. The *arrows* marked with "f" in **b** demarcate the flowing portion of the cytoplasm as determined from the phase and Doppler data in **c** and **d**, respectively. (**e**) Doppler shift versus time at a depth of 36 μm. (**f**) Doppler shift versus depth at $t = 20$ s. The *green line* is a least-squares parabolic fit of the flow profile ($R^2 = 80$ %) (From Choma et al. [26])

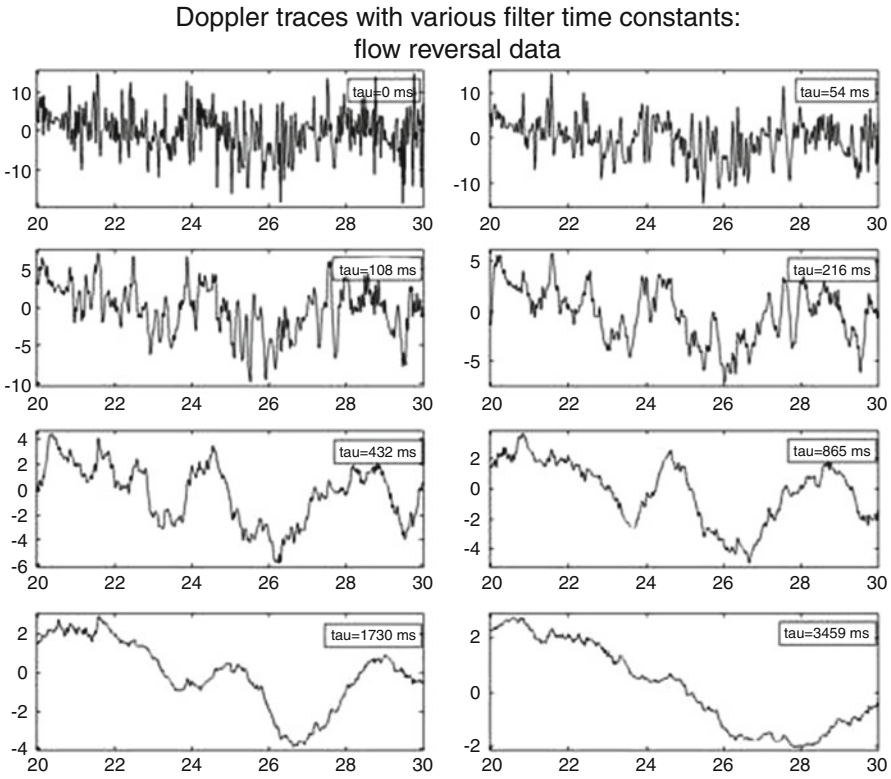

Fig. 40.19 Filtering of Doppler SDPM data Doppler shift versus time at a depth of 36 μm after processing with moving-average filters of various time constants (tau). Data points corresponding to flow reversal that occurs between 20 and 30 s are shown. *Abscissa* has units of time in seconds; ordinate, Doppler shift in Hz (From Choma et al. [26])

cytoplasm, the amplitude of the flow is expected to follow a parabolic profile as a function of depth. Figure 40.18f, which shows the Doppler frequency as a function of depth at $t = 20$ s, supports this laminar flow hypothesis. This measured flow profile matches that of an ideal parabolic flow profile with an R^2 value of 80 %. The laminar flow profile also is suggested from the plot of the flow-induced Doppler shift against both depth and time in a 3-D surface plot (Fig. 40.20).

Depth-resolved Doppler SDPM has been extended to obtain cross sections of *A. proteus* flow. Phase for all depths is unwrapped in time and in space, resulting in movies of cytoplasmic flow in a single cell. Representative frames from one such movie are shown in Fig. 40.21. There is the suggestion of antiparallel channels of flow within the pseudopod. Given the angle ambiguity presented by Doppler imaging, further investigation is needed to elucidate the origin of oppositely signed Doppler shifts from within the pseudopod.

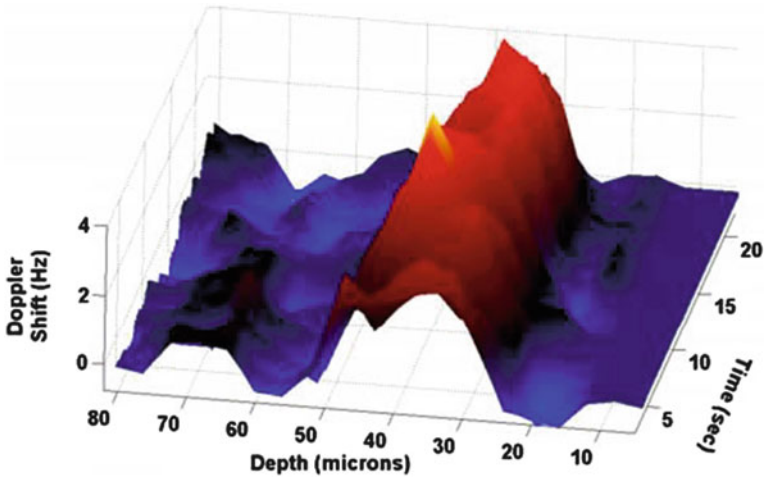

Fig. 40.20 Surface plot of flow-induced Doppler shift as a function of time and depth. Laminar (parabolic) cytoplasmic flow is suggested (From Choma et al. [26])

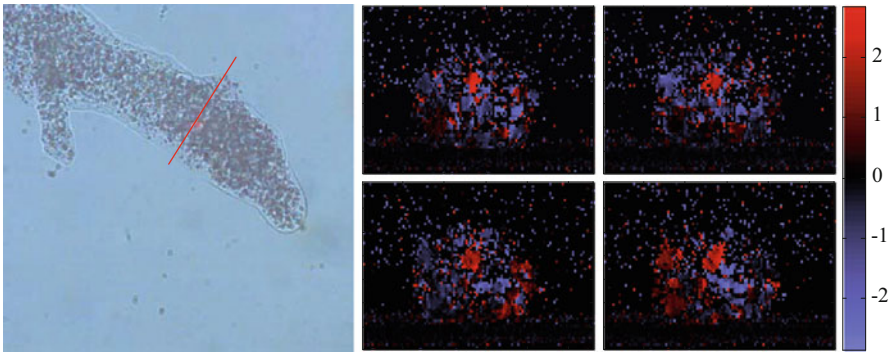

Fig. 40.21 Detection of cytoplasmic flow across the lateral plane of *A. proteus*. *Left*: CCD image of Amoeba cell with *line* denoting lateral acquisition plane. *Right*: Snapshots of time-sequential (Frames 13–16) B-mode phase difference images for flowing pseudopodium taken at 13.3 Hz. Flow direction is out of the page, and the lateral scan range is 153 mm. *Color bar* indicates mapping for phase differences (radians)

40.4.4 Characterizing Mechanical Properties of the Cytoskeleton Using Magnetic Tweezers and SDPM

Widespread interest in cellular motility, particularly as relates to cancer metastasis, has motivated extensive study of the mechanical properties of the cytoskeleton. The structural components of the cytoskeleton are responsible for coordinating cellular transport, locomotion, as well as internal signal transduction and gene expression.

Std. Dev.	0.35 μm	1.86 μm

Fig. 40.23 Mechanical deformation of cancer cells measured with SDPM. Average vertical displacement and recovery profile for untreated MCF-7 human breast cancer cell (*black line*) as well as those treated with cytochalasin D (*gray line*). A statistically significant ($p < 0.05$) increase in cell displacement was seen after 30 min of treatment. McDowell et al. [49]

Given the extraordinary sensitivity of SDPM systems to morphological changes in cellular samples, McDowell et al. [49] used this system to investigate the rheological properties of cancer cells, demonstrating the versatility of the SDPM technique and its ability to be complement standard methods practiced in well-established fields like cell biology.

McDowell et al. designed a calibrated magnetic trap to study the viscoelastic response of breast cancer cells to applied forces. Ferromagnetic beads attached to the cell surface served as handles with which the trap could pull on the cell; SDPM was used to measure the resulting change in cell thickness in the vertical direction (Fig. 40.22), distinguishing this experiment from previous works that probed lateral morphological changes in cells [50–53]. It was hypothesized that the magnitude of the cell thickness change related to the viscous properties of the cell. The quantitative data acquired with SDPM permitted fitting measured deformation to various proposed viscoelastic models. Fitting to these models allows for the extraction of quantitative constants that could be used to compare across cells in various experimental conditions. It was demonstrated that cells treated with cytochalasin D (an agent that depolymerizes actin, an important cytoskeletal component) have statistically significant different rheological properties than untreated cells (Fig. 40.23).

Fig. 40.22 (continued) (**b**). Photomicrograph of magnetic bead adherent to an MCF-7 human breast cancer cell (**c**). The SDPM system outputs a complex-valued M-scan, providing depth information over time (**d**). The magnitude of the M-scan gives a series of A-scans or depth profiles. The phase of the M-scan carries information about small changes in reflector position over time, seen in the plots on the *right*. Common-used models of cytoskeletal mechanics (**e**)

40.4.5 Whole-Cell Imaging Using SDPM

As previously discussed, SDPM has been extended to multidimensional imaging using raster scanning or full-field imaging. Representative images of cells obtained with these techniques are shown in Fig. 40.24. In both images, the source bandwidth was not adequate to obtain depth-indexed information. Since optical path length is an integrative term that accumulates in depth, the phase content at the furthermost reflective surface of the sample is comparable to the quantitative information obtained from the monochromatic techniques discussed earlier.

40.5 Conclusion

Over the past decade, quantitative phase imaging has made significant advances. These advances retain the original advantage of qualitative phase microscopy first described by Zernike (i.e., enhanced contrast) and augment this seminal technique with information regarding subcellular function and motion. These quantitative techniques were first demonstrated with monochromatic interferometry. These techniques can now image cellular dynamics at rates in excess of video rate. In parallel, phase-sensitive OCT techniques have been refined to detect cellular dynamics. Spectral domain phase microscopy (SDPM) is a functional extension of OCT which grew out of the increased phase stability available in SDOCT systems. SDPM allows for the depth-dependent measurement of cellular motions and dynamics with sensitivities in the picometer to nanometer regimes. This sensitivity has a lower limit defined by the image signal-to-noise ratio. In this chapter several initial demonstrations of the ability of SDPM to quantify cellular morphology and subcellular dynamics have been shown.

There are several technical advances to be made in SDPM over the next several years. The use of ultrabroadband sources with potentially hundreds of nanometers

of bandwidth will allow for better localization of phase information within cells. This will be important for the imaging of eukaryotic cells, which have nominal thicknesses of ~1–10 μm. It also will be important to push SDPM line rates into the hundreds of kilohertz regime. Several different cell types, most notable neurons and myocytes, have dynamics in the kHz regime. Detailed volumetric imaging of these cell types will require line rates at a considerable multiple of the detection bandwidth required for the detection of electrical action potentials.

Multimodal imaging that incorporates SDPM promises to be a powerful tool. From an OCT perspective, simultaneous acquisition of phase, polarization, and spectroscopic data in a depth-indexed manner can yield a tremendous amount of data about dynamic cell function. This data can be augmented with the simultaneous acquisition of molecular- or ion-specific fluorescent microscopic information. With this data in hand, the whole-cell and intracellular dynamics of several different key processes, ranging from excitation-contraction coupling to cell migration, can be studied with remarkable detail.

41.1 Introduction

Optical coherence tomography (OCT) is a recently developed imaging modality based on coherence-domain optical technology [1–4]. OCT uses coherence gating of backscattered light for tomographic imaging of tissue structure. Variations in tissue scattering due to inhomogeneities in the optical index of refraction provide imaging contrast. However, in many instances and especially during early stages of disease, the change in tissue scattering properties between normal and diseased tissue is small and difficult to measure. One of the great challenges for extending clinical applications of OCT is to find more contrast mechanisms that can provide physiological information in addition to morphological structure. A number of extensions of OCT capabilities for functional imaging of tissue physiology have been developed. Doppler OCT, also named optical Doppler tomography (ODT), combines the Doppler principle with OCT to obtain high-resolution tomographic images of tissue structure and blood flow simultaneously [5–13]. Spectroscopic OCT combines spectroscopic analysis with

OCT to obtain depth-resolved tissue absorption spectra [14, 15]. Polarization-sensitive OCT (PS-OCT) combines polarization-sensitive detection with OCT to determine tissue birefringence [16–20]. Second harmonic optical coherence tomography combines second harmonic generation with coherence gating to obtain images with molecular contrast [21]. These functional extensions of OCT provide clinically important information on tissue physiology, such as tissue blood perfusion, oxygen saturation, hemodynamics, and structural remodeling. Each provides several potential clinical applications, such as vasoactive drug screening, tissue viability and burn depth determination, tumor angiogenesis studies and cancer diagnosis, bleeding ulcer management, and ocular pathology evaluation [10, 11, 19, 22–24]. This chapter reviews the principle and clinical applications of Doppler OCT.

Noninvasive techniques for imaging in vivo blood flow are of great value for biomedical research and clinical diagnostics [25] where many diseases have a vascular etiology or component. In dermatology, for example, the superficial dermal plexus alone is particularly affected by the presence of disease (e.g., psoriasis, eczema, scleroderma), malformation (e.g., port-wine stain, hemangioma, telangiectasia), or trauma (e.g., irritation, wound, burn). In these situations, it would be most advantageous to the clinician if blood flow and structural features could be isolated and probed at user-specified discrete spatial locations in either the superficial or deep dermis. In ophthalmology, many ophthalmic diseases may involve disturbances in ocular blood flow, including diabetic retinopathy, low tension glaucoma, anterior ischemic optic neuritis, and macular degeneration. For example, in diabetic retinopathy, retinal blood flow is reduced and the normal autoregulatory capacity is deficient. Ocular hemodynamics is altered in patients with glaucoma, and severe loss of visual function has been associated with reduced macular blood flow. Simultaneous imaging of tissue structure and blood flow could provide critical information for early diagnosis of ocular diseases. Finally, three-dimensional mapping of microcirculation may also provide important information for the diagnosis and management of cancers.

Doppler OCT combines the Doppler principle with OCT to obtain high-resolution tomographic images of static and moving constituents simultaneously in highly scattering biological tissues [5–7]. The first use of coherence gating to measure localized flow velocity was reported in 1991 where the one-dimensional velocity profile of the flow of particles in a duct was measured [26]. In 1997, the first two-dimensional in vivo Doppler OCT imaging was reported using the spectrogram method [5–7]. The spectrogram method uses a short time fast Fourier transformation (STFFT) or wavelet transformation to determine the power spectrum of the measured fringe signal [5–8, 10, 11]. Although spectrogram methods allow simultaneous imaging of in vivo tissue structure and flow velocity, the velocity sensitivity is limited for high-speed imaging. It was not until 2000 when phase-resolved D-OCT (PR-D-OCT) was developed that Doppler OCT was applied for imaging vasculature in clinical studies [12, 22, 27]. Phase-resolved D-OCT uses the phase change between sequential A-line scans for velocity image reconstruction [12, 27–29]. Phase-resolved D-OCT decouples spatial resolution and velocity sensitivity in flow images and increases imaging speed by more than two orders of magnitude without compromising spatial resolution and velocity sensitivity [12, 28].

The significant increase in scanning speed and velocity sensitivity makes it possible to image in vivo tissue microcirculation in human skin [12, 22, 28]. A real-time PR-D-OCT system that uses polarization optics to perform Hilbert transformation was demonstrated [29]. A number of real-time, PR-D-OCT systems using hardware and software implementations of a high-speed processor have also been reported [30, 31]. Phase-resolved D-OCT was first demonstrated with time domain OCT systems [12, 22, 27]. Recently, the development of Fourier-domain OCT (FD-OCT) has significantly increased imaging speed and sensitivity [32–34]. Combination of FD-OCT with the phase-resolved method has been demonstrated by a number of groups [35–39]. Because the dynamic range of the phase-resolved Doppler OCT depends on the speed of the line scans, Fourier-domain Doppler OCT has an advantage over the time-domain method in terms of imaging speed and velocity dynamic range.

One of the limitations in using the Doppler shift to study blood flow is that the Doppler shift is only sensitive to the flow velocity parallel to the probing beam. However, in many biological cases where flow direction is not known, Doppler shift measurement alone is not enough to fully quantify the flow. Furthermore, there are many clinical applications, such as ocular blood flow, where vessels are in the plane perpendicular to the probing beam. A method to measure transverse flow velocity using the bandwidth (standard deviation) of the Doppler spectrum was reported in 2002 [13]. The advantage of this technique is that a single measurement of the Doppler spectrum will provide both transverse and longitudinal flow velocities [22, 27, 28, 40–43].

Recently, several groups have successfully extended a number of similar methods for mapping blood vessel networks. Ren et al. demonstrated a power Doppler angiography method by using a band-pass-filtered intensity image for imaging the moving scatterer in tissue [44]. Barton et al. proposed a method based on the speckle of conventional amplitude optical coherence tomography images [45]. Mariampillai et al. used speckle variance in a small 3D volume to image blood vessels [46]. The logarithmic intensity variance and differential logarithmic intensity variance for mapping vasculatures were also demonstrated [47]. Yasuno et al. used the intensity threshold binarization-based method for retinal and choroidal blood vessel imaging [48–50]. Jonathan et al. used a two-dimensional correlation map based on OCT intensity images for blood vessel extraction [51]. Jia et al. developed a split-spectrum amplitude-decorrelation angiography method [52]. Wang et al. proposed a method called optical microangiography to separate the static and moving signals with a modified Hilbert transform that remove low frequency static signals [53–55]. Liu et al. have demonstrated an intensity-based method that used an algorithm derived from a modified Doppler variance algorithm [43].

Owing to its exceptionally high spatial resolution and velocity sensitivity, Doppler OCT has a number of applications in biomedical research and clinical medicine. Several clinical applications of Doppler OCT have been demonstrated in our laboratory, such as screening vasoactive drugs, monitoring changes in image tissue morphology and hemodynamics following pharmacological intervention and photodynamic therapy, evaluating the efficacy of laser treatment in port wine stain patients, assessing the depth of burn wounds, and mapping cortical hemodynamics for brain

research [10–12, 22, 27, 28, 40, 41, 56, 57]. In addition, applications of Doppler OCT in ophthalmology [35, 36, 40, 43, 54, 56, 58–62] and in the gastrointestinal tract [63, 64] were demonstrated. Furthermore, the high resolution and high sensitivity of Fourier-domain D-OCT has enabled this technique to become a powerful tool for imaging and quantifying vascular hemodynamics for brain research and tumor angiogenesis studies [41, 65–67]. Recently, optical coherence elastography (OCE) that uses phase-resolved D-OCT to evaluate elastic properties of tissue was reported [68]. Phase-resolved D-OCT has also been extended to other applications where nm resolution of the phase-resolved method is required, for example, photothermal imaging [69] and extraction of photoacoustic signal [70].

41.2 Principles of Doppler OCT

Doppler OCT combines the Doppler principle with OCT to obtain high-resolution tomographic images of static and moving constituents in high scattering media. When light backscattered from a moving particle interferes with the reference beam, a Doppler frequency shift f_D occurs in the interference fringe:

$$f_D = \frac{1}{2\pi}(\mathbf{k}_s - \mathbf{k}_i) \bullet \mathbf{v}, \tag{41.1}$$

where $\mathbf{k}_i$ and $\mathbf{k}_s$ are wave vectors of incoming and scattered light, respectively, and $\mathbf{v}$ is the velocity vector of the moving particle (Fig. 41.1). Since Doppler OCT measures the backscattered light, assuming the angle between flow and sampling beam is θ, the Doppler shift equation is simplified to

$$f_D = \frac{2V \cos\theta}{\lambda_0}, \tag{41.2}$$

where λ_0 is the vacuum center wavelength of the light source.

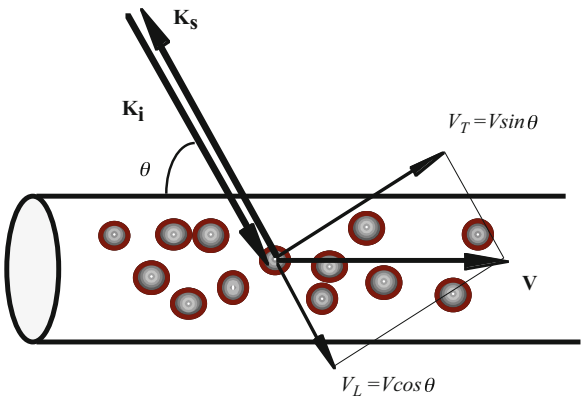

Fig. 41.1 Schematic of flow direction and probe beam angle

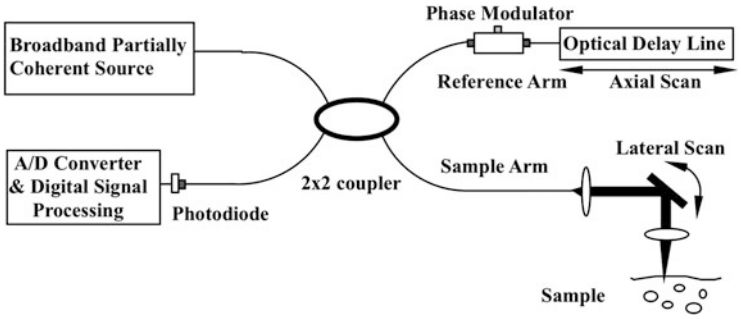

Fig. 41.2 Schematic of OCT system consisting of a fiber-based Michelson interferometer with a partially coherent light source

The optical system of Doppler OCT is similar to that of OCT. The primary difference is in signal processing. Figure 41.2 illustrates a Doppler OCT instrument that uses a fiber-optic Michelson interferometer with a broadband light as a source. Light from a broadband partially coherent source is coupled into a fiber interferometer by a 2×2 fiber coupler and then split equally into reference and sample arms of the interferometer. Light backscattered from the turbid sample is coupled back into the fiber and forms interference fringes with the light reflected from the reference arm. A rapid-scanning optical delay line is used for group delay and axial scanning. Because this delay line can decouple the group delay from the phase delay, an electro-optical phase modulator is introduced to produce a stable carrier frequency. The interference fringe intensity signal is amplified, band pass filtered, and digitized with a high-speed analog-to-digital converter. The signal processing is carried out at the same time as data is transferred to the computer, and real-time display can be accomplished by use of a digital signal processing board.

To understand the signal processing of Doppler OCT, let us look at the fringe signal due to the moving particles. If we denote $U(t)$ as a complex-valued analytic signal of a stochastic process representing the field amplitude emitted by a low coherent light source and $\overline{U}(v)$ as the corresponding spectral amplitude at optical frequency v, the amplitude of a partially coherent source light coupled into the interferometer at time t is written as a harmonic superposition

$$U(t) = \int_0^\infty \overline{U}(v) e^{2\pi i v t} dv. \tag{41.3}$$

Because the stochastic process of a partially coherent light source is stationary, the cross-spectral density of $\overline{U}(v)$ satisfies

$$\left\langle \overline{U}^*(v) \overline{U}(v') \right\rangle = S_o(v) \delta(v - v'), \tag{41.4}$$

where $S_o(v)$ is the source power spectral density and $\delta(v - v')$ is the Dirac delta function. Assuming that light couples equally into the reference arm and sample

arm with spectral amplitude of $\overline{U}_o(\nu)$, the light coupled back to the detector from the reference, $\overline{U}_r(\nu)$, and sample, $\overline{U}_s(\nu)$, are

$$\overline{U}_r(\nu) = e^{2\pi i\nu(2L_r+L_d)/c}K_r(\nu)e^{i\alpha_r(\nu)}\overline{U}_o(\nu) \tag{41.5}$$

and

$$\overline{U}_s(\nu) = e^{2\pi i\nu(2L_s+L_d)/c}K_s(\nu)e^{i\alpha_s(\nu)}\overline{U}_o(\nu), \tag{41.6}$$

where L_r and L_s are the optical pathlengths from the beam splitter to the reference mirror and sample, respectively; L_d is the optical pathlength from the beam splitter to the detector; and $K_r(\nu)e^{i\alpha r(\nu)}$ and $K_s(\nu)e^{i\alpha s(\nu)}$ are the amplitude reflection coefficients of light backscattered from the reference mirror and turbid sample, respectively.

The total power detected at the interferometer output is given by a time-average of the squared light amplitude

$$P_d(\tau) = \left\langle |U_s(t) + U_r(t+\tau)|^2 \right\rangle, \tag{41.7}$$

where τ is the time delay between light traveled in the sample and reference arms. Combining harmonic expansions for $U_s(t)$ and $U_r(t)$ and applying Eq. 41.4 when calculating the time-average, total power detected is a sum of three terms representing reference I_r, sample I_s, and the interference fringe intensity $\Gamma_{ODT}(\tau)$,

$$P_d(\tau) = \int_0^\infty (P_r(\nu) + P_s(\nu) + P_{ODT}(\nu))d\nu = I_r + I_s + \Gamma_{ODT}(\tau), \tag{41.8}$$

with

$$P_r(\nu) = S_o(\nu)|K_r(\nu)|^2, \tag{41.9}$$

$$P_s(\nu) = S_o(\nu)|K_s(\nu)|^2, \tag{41.10}$$

$$P_{ODT}(\nu) = 2S_o(\nu)K_r(\nu)K_s(\nu)\cos\left[2\pi\nu(\Delta_d/c + \tau) + \alpha_s(\nu) - \alpha_r(\nu)\right], \tag{41.11}$$

$$I_r = \int_0^\infty P_r(\nu)d\nu, \tag{41.12}$$

$$I_s = \int_0^\infty P_s(\nu)d\nu, \tag{41.13}$$

and

$$\Gamma_{ODT}(\tau) = \int_0^\infty P_{ODT}(v)dv. \tag{41.14}$$

When there is a moving particle, light scattered from a moving particle is equivalent to a moving phase front; therefore, Δ_d in Eq. 41.11 can be written as

$$\Delta_d = \Delta + 2\overline{n}V_z t, \tag{41.15}$$

where Δ is the optical pathlength difference between light in the sample and reference arms, V_z is the velocity of a moving particle parallel to the probe beam, and $\overline{n}$ is the refractive index of flow media.

To simplify the computation, we assume α_s and α_r are constants over the source spectrum and can be neglected. The spectral domain fringe signal, $P_{ODT}(v)$, is simplified to

$$P_{ODT}(v) = 2S_o(v)K_r(v)K_s(v)\cos\left[2\pi v((\Delta + 2\overline{n}V_z t)/c + \tau)\right]. \tag{41.16}$$

The corresponding time domain signal, $\Gamma_{ODT}(\tau)$, is given by

$$\Gamma_{ODT}(\tau) = 2\int_0^\infty S_o(v)K_r(v)K_s(v)\cos\left[2\pi v((\Delta + 2\overline{n}V_z t)/c + \tau)\right]dv. \tag{41.17}$$

A comparison of Eqs. 41.16 and 41.17 shows that there is a Fourier transformation relation between spectral domain and time domain signals. Consequently, there are two methods to acquire the Doppler OCT signal: the time-domain method and the Fourier-domain method.

In the time-domain method, a delay line is incorporated in the reference arm to generate a delay. A spectrogram analysis or phase-resolved algorithm is then used to determine the Doppler frequency shift. In the Fourier-domain method, the reference mirror is fixed, and there is no depth scan (τ = constant). The Fourier-domain fringe signal, $P_{ODT}(v)$, is obtained either by a spectrometer at the detection arm or by a frequency sweeping light source. The time domain signal, $\Gamma_{ODT}(\tau)$, is determined from the Fourier-domain signal by a Fourier transformation.

41.2.1 Phase-Resolved Doppler OCT Method

The first two-dimensional in vivo Doppler OCT imaging was reported using the spectrogram method [6, 7]. Researchers used the spectrogram method based on either short time fast Fourier transformation (STFFT) or wavelet transformation to determine the power spectrum of the measured fringe signal [5–7, 11, 71]. Although spectrogram methods allow simultaneous imaging of in vivo tissue structure and

flow velocity, the velocity sensitivity is limited for high-speed imaging. When STFFT or wavelet transformation is used to calculate flow velocity, the resolution is determined by the window size of the Fourier transformation for each pixel. The minimum detectable Doppler frequency shift, f_D, varies inversely with the STFFT window size. Because pixel acquisition time is proportional to the STFFT window size, the image frame rate is limited by velocity resolution. Furthermore, spatial resolution is also proportional to the STFFT window size. Therefore, a large STFFT window size increases velocity resolution while decreasing imaging speed and spatial resolution. This coupling between velocity sensitivity, spatial resolution, and imaging speed prevents the spectrogram method from achieving simultaneously both high imaging speed and high velocity sensitivity which are essential for measuring flow in small blood vessels where flow velocity is low.

Phase-resolved Doppler OCT overcomes the compromise between velocity sensitivity and imaging speed by using the phase change between sequential scans to construct flow velocity images [12]. The phase information of the fringe signal can be determined from the complex analytical signal $\widetilde{\Gamma}(t)$, which is determined through analytic continuation of the measured interference fringe function, $\Gamma(t)$, using a Hilbert transformation [10]:

$$\widetilde{\Gamma}(t) = \Gamma(t) + \frac{i}{\pi} P \int_{-\infty}^{\infty} \frac{\Gamma(\tau)}{\tau - t} d\tau = A(t) e^{i\phi(t)}, \tag{41.18}$$

where P denotes the Cauchy principle value, i is the complex number, and $A(t)$ and $\phi(t)$ are amplitude and phase term of $\widetilde{\Gamma}(t)$, respectively. Because the interference signal $\Gamma(t)$ is quasi-monochromatic, the complex analytical signal can be determined by

$$\widetilde{\Gamma}(t) = 2 \int_0^{+\infty} \int_0^{+\tau} \Gamma(t') \exp(-2\pi i v t') dt' \exp(2\pi i v t) dv, \tag{41.19}$$

where τ is the time duration of the fringe signal in each axial scan.

The Doppler frequency shift f_n at n'th pixel in the axial direction is determined from the average phase shift between sequential A-scans. This can be accomplished by calculating the phase change of sequential scans from the individual analytical fringe signal:

$$f_n = \frac{\Delta\phi}{2\pi T} = \frac{1}{2\pi T} \sum_{m=(n-1)M}^{nM} \sum_{j=1}^{N} \left[\tan^{-1}\left(\frac{\mathrm{Im}\widetilde{\Gamma}_{j+1}(t_m)}{\mathrm{Re}\widetilde{\Gamma}_{j+1}(t_m)} \right) - \tan^{-1}\left(\frac{\mathrm{Im}\widetilde{\Gamma}_{j}(t_m)}{\mathrm{Re}\widetilde{\Gamma}_{j}(t_m)} \right) \right]. \tag{41.20}$$

Alternatively, the phase change can also be calculated by the cross-correlation method:

$$f_n = \frac{1}{2\pi T}\tan^{-1}\left(\frac{\mathrm{Im}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\widetilde{\Gamma}_j(t_m)\cdot\widetilde{\Gamma}^*_{j+1}(t_m)\right]}{\mathrm{Re}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\widetilde{\Gamma}_j(t_m)\cdot\widetilde{\Gamma}^*_{j+1}(t_m)\right]}\right), \tag{41.21}$$

where $\widetilde{\Gamma}_j(t_m)$ and $\widetilde{\Gamma}^*_j(t_m)$ are the complex signals at axial time t_m corresponding to the j'th A-scan and its respective conjugate, $\widetilde{\Gamma}_{j+1}(t_m)$ and $\widetilde{\Gamma}^*_{j+1}(t_m)$ are the complex signals at axial time t_m corresponding to the next A-scan and its respective conjugate, M is an even number that denotes the window size in the axial direction for each pixel, N is the number of sequential scans used to calculate the cross correlation, and T is the time duration between A-scans. Because T is much longer than the pixel time window within each scan used in the spectrogram method, high velocity sensitivity can be achieved.

In addition to the local velocity information, the standard deviation of the Doppler spectrum gives the variance of local velocity and can be determined from the measured analytical fringe signal:

$$\sigma^2 = \frac{\int_{-\infty}^{\infty}(f-f_D)^2P(f)df}{\int_{-\infty}^{\infty}P(f)df} = \frac{1}{(2\pi T)^2}\left(1-\frac{\left|\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\widetilde{\Gamma}_j(t_m)\cdot\widetilde{\Gamma}^*_{j+1}(t_m)\right|}{\frac{1}{2}\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\left[\widetilde{\Gamma}_j(t_m)\cdot\widetilde{\Gamma}^*_j(t_m)+\widetilde{\Gamma}_{j+1}(t_m)\cdot\widetilde{\Gamma}^*_{j+1}(t_m)\right]}\right), \tag{41.22}$$

where $P(f)$ is the Doppler power spectrum and f_D is the centroid value of the Doppler frequency shift. The σ value depends on the flow velocity distribution. Variations in flow velocity will broaden the Doppler frequency spectrum and result in a large σ value. Thus, the Doppler variance image can be an indicator of flow variations and can be used to study flow turbulences. In addition, Doppler variance imaging can also be used to map microvasculature because it is less sensitive to the random direction and the pulsatile nature of blood flow in small vessels [22, 28]. Finally, standard deviation imaging can also be used to determine the transverse flow velocity [13].

Phase-resolved Doppler OCT decouples spatial resolution and velocity sensitivity in flow images and increases imaging speed by more than two orders of magnitude without compromising spatial resolution and velocity sensitivity. In addition, because two sequential A-line scans are compared at the same location, speckle modulations in the fringe signals cancel each other and, therefore, will not affect the phase difference calculation. Consequently, the phase-resolved method reduces the speckle noise in the velocity image.

41.2.2 Fourier-Domain Phase-Resolved Doppler OCT Method

Compared with conventional time domain OCT, which is based on a scanning optical delay line, Fourier-domain OCT measures interference fringes in the spectral domain to reconstruct a tomographic image. Modulation of the interference fringe intensity in the spectral domain is used to determine the locations of all scattering objects along the beam propagation direction by a Fourier transformation. Two methods have been developed to employ the Fourier-domain technique: a spectrometer based system that uses a high-speed line-scan camera [72, 73] and a swept laser source-based system that uses a single detector [74–78]. Fourier-domain phase-resolved Doppler OCT combines Fourier-domain OCT with the phase-resolved method and has the advantage of high-sensitivity, fast imaging speed, and large velocity dynamic range [35–39].

A schematic diagram of a swept source-based Fourier-domain Doppler OCT system is shown in Fig. 41.3. The output light from the swept light source is split into reference and sample arms by a 1 × 2 coupler. Two circulators were used in both reference and sample arms to redirect the back-reflected light to a 2 × 2 fiber coupler (50/50 split ratio) for balanced detection. In the reference arm, an EO phase modulator was used to generate a stable carrier frequency for elimination of the Fourier transform generated mirror image and low frequency autocorrelation noise [76].

The complex analytical depth-encoded signal was converted from the detected time fringe signal by the digital approach shown in the following block diagram [38] (Fig. 41.4), where FFT denotes the fast Fourier transform, FFT^{-1} denotes the inverse fast Fourier transform, and H(f) is the Heaviside function given by

$$H(f) = \begin{cases} 0 & f < 0 \\ 1 & f \geq 0 \end{cases}. \tag{41.23}$$

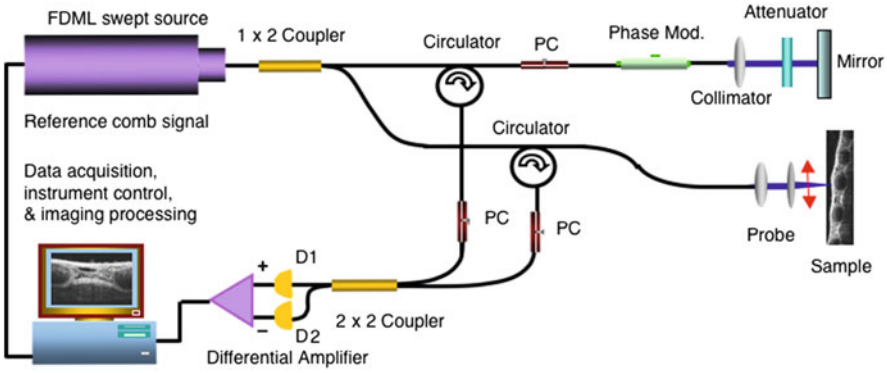

Fig. 41.3 Schematic of a swept source-based Fourier-domain Doppler OCT system

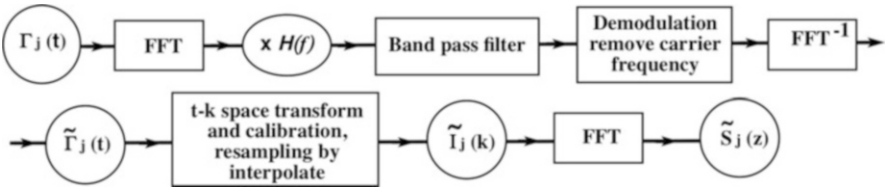

Fig. 41.4 Signal processing diagram for processing Doppler signals in swept source-based Fourier-domain Doppler OCT (From [38])

The time fringe signal $\Gamma(t)$ acquired with wavelength scanning is firstly transformed from time to frequency space by FFT. Multiplication of $H(f)$ selects the positive term of the Fourier transformed signal. The signal is then band-pass filtered to remove the low frequency and DC noises. The subsequent demodulation step shifts the center frequency of the filtered interference term from the carrier frequency to zero. The frequency fringe signal is then converted back to time space by inverse FFT. To cancel the distortion originating from nonlinearities in the wave number function $k(t)$, the data are numerically remapped from uniform time to uniform wave number space based on the function of $k(t)$, which is determined by the spectra calibration process provided by calibration comb signals generated from a fiber Fabry-Perot interferometer. Dispersion calibration is also performed at this step by adding a wave number-dependent phase term. The last FFT performed in k space retrieves the complex depth-encoded fringe signal $\tilde{S}(z) = A(z)e^{i\phi(z)}$, which contains both the amplitude $A(z)$ and phase $\phi(z)$ terms.

Using the phase-resolved method, the Doppler frequency shift and Doppler variance can be determined from the depth-encoded complex fringe signal $\tilde{S}(z)$ [38]:

$$f_n = \frac{1}{2\pi T}\tan^{-1}\left(\frac{\mathrm{Im}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{S}_j(z_m)\cdot\tilde{S}_{j+1}^{*}(z_m)\right]}{\mathrm{Re}\left[\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{S}_j(z_m)\cdot\tilde{S}_{j+1}^{*}(z_m)\right]}\right) \tag{41.24}$$

and

$$\sigma^2 = \frac{1}{(2\pi T)^2}\left(1 - \frac{\left|\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\tilde{S}_j(z_m)\cdot\tilde{S}_{j+1}^{*}(z_m)\right|}{\frac{1}{2}\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\left[\tilde{S}_j(z_m)\cdot\tilde{S}_j^{*}(z_m) + \tilde{S}_{j+1}(z_m)\cdot\tilde{S}_{j+1}^{*}(z_m)\right]}\right). \tag{41.25}$$

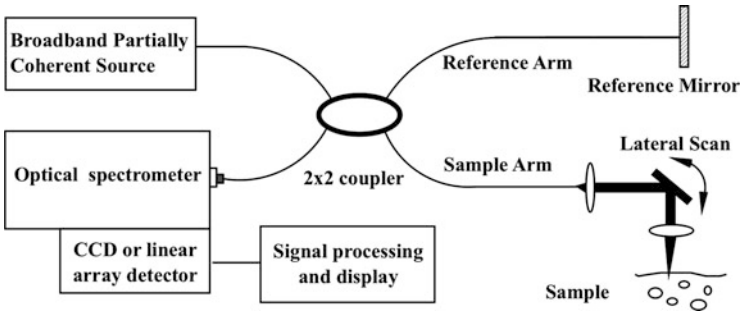

Fig. 41.5 Schematic of a spectrometer based Fourier-domain Doppler OCT system

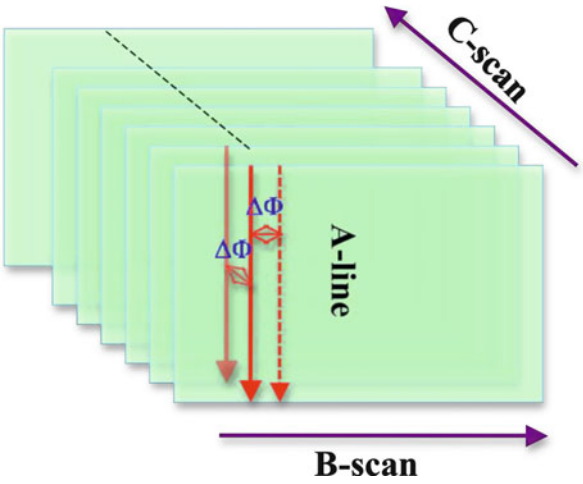

Fig. 41.6 Schematic signal processing diagram for the phase-resolved D-OCT system

A spectrometer based Fourier-domain Doppler OCT is shown in Fig. 41.5 [37]. The signal from the Michelson interferometer is directly coupled to a spectrometer that records the spectral fringe pattern, $P_{Doppler\ OCT}(\nu)$. The temporal interference fringe can be calculated by a Fourier transformation of the spectral fringe pattern (Eq. 41.17). The Doppler shift and variance can then be determined using phase-resolved Doppler OCT algorithms (Eqs. 41.21 and 41.22).

Phase-resolved D-OCT using cross-correlation between A-lines decouple velocity sensitivity, spatial resolution, and imaging speed. The development of FD-OCT greatly increased imaging speed, which enables cross-correlation not only between sequential A-lines in B-scan but also sequential A-lines in C-scan (Fig. 41.6) [12, 79]. For sequential A-lines in B-scan, T is the inter-A-line time. For sequential A-lines in C-scan, T is the inter-frame time. Therefore, a large velocity dynamical range can be achieved since the T can be increased by several orders of magnitude, which makes it possible to image and quantify flow in the capillary level [79].

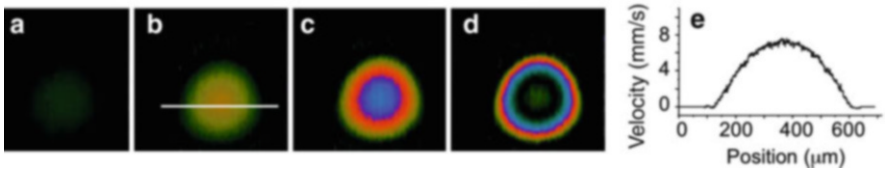

Fig. 41.7 PR-D-OCT images of a flow phantom which is pumped at different speeds: (**a**) 0.1 μl/min, (**b**) 0.3 μl/min, (**c**) 0.6 μl/min, and (**d**) 1.1 μl/min. (**e**) Velocity profile along a horizontal cross section passing through the center of the tube in (**b**)

Figure 41.7 shows the PR-D-OCT images of a flow phantom pumped at different speeds using a swept source-based FD-OCT system with an A-line rate of 50 kHz. Figure 41.7a–d are PR-D-OCT images of the flow phantom pumped at, respectively, 0.1 μl/min, 0.3 μl/min, 0.6 μl/min, and 1.1 μl/min. It should be noted that the phase is wrapped in Fig. 41.7c, d, which can be unwrapped [27]. The increase of Doppler frequency shift with the increase of pumping speed can be clearly seen from the PR-D-OCT images. Figure 41.7e shows the velocity profile along a horizontal cross section passing through the center of the tube in Fig. 41.7b.

41.2.3 Doppler Variance, Transverse Flow Velocity, and Doppler Angle Determination

One of the limitations of using Doppler shift to determine the flow is that the technique is only sensitive to longitudinal flow velocity (Fig. 41.1). If one knows the flow direction, Doppler shift measurement can fully quantify the flow. However, in many biological cases where flow direction is not known, Doppler shift measurement alone is not enough to fully quantify the flow. Furthermore, there are many clinical cases, such as ocular blood flow, where vessels are in the plane perpendicular to the probe beam. When flow direction is perpendicular to the probe beam, the Doppler shift is not sensitive to transverse flow V_T. Therefore, a method to measure transverse flow velocity is essential.

Doppler variance can be used to determine the transverse flow. The technique is based on the fact that Doppler OCT imaging uses a relatively large numeric aperture lens in the sample arm. The beam from different sides of the edges will produce different Doppler shifts, f_1 and f_2, as indicated in Fig. 41.8. Consequently, the Doppler spectra will be broadened by the transverse flow. If the incident beam has a Gaussian spectral profile and contributions from Brownian motion and other sources that are independent of the macroscopic flow velocity are included, a linear relation between standard deviation of the Doppler spectra and transverse flow velocity, $V_T = V\sin\theta$, can be written as [13]

$$\sigma = \frac{\pi V \sin\theta NA_{eff}}{8\lambda} + b, \tag{41.26}$$

where b is a constant and NA_{eff} is the effective numeric aperture.

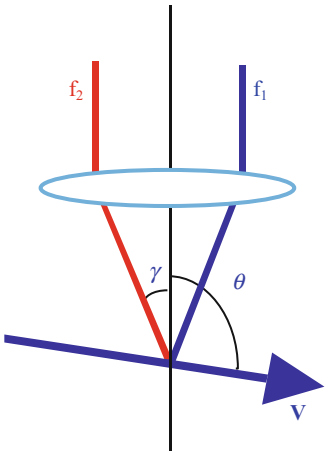

Fig. 41.8 Effect of numerical aperture and transverse flow velocity on Doppler bandwidth

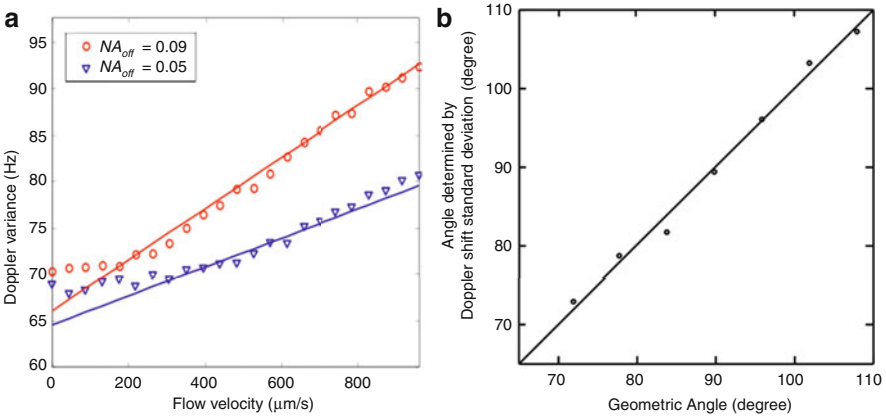

Fig. 41.9 (**a**) Doppler variance as a function of flow velocity for two different numeric apertures (From [13]). (**b**) Flow velocity angles measured by phase-resolved Doppler OCT as a function of geometric angles. The solid line shows a linear fit (From [82])

The Doppler variance can be determined from the measured analytical fringe signal using Eq. 41.22. We have measured the σ value as a function of the transverse flow velocity (Fig. 41.9a) [13]. As predicted, the Doppler bandwidth is a linear function of transverse flow velocity above a certain threshold level. The effective numerical aperture of the optical objective in the sample arm determines the slope of this dependence. This result indicates that standard deviation can be used to determine the transverse flow velocity. Since both longitudinal and transverse flow velocities (V_L and V_T) can be measured by the Doppler shift and standard deviation, respectively, flow direction can be determined from a single measurement of the Doppler fringe signal [80–82]. Figure 41.9b shows the comparison of angle determined by phase-resolved Doppler OCT and the geometric angle [82].

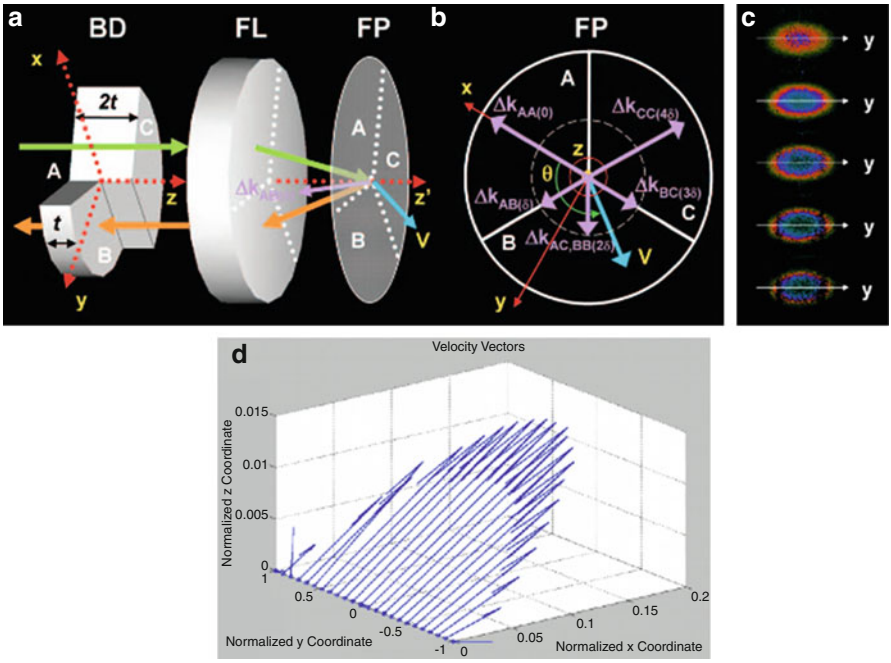

Fig. 41.10 The beam divider (**a**) that generates five independent $\Delta\mathbf{k}$ with different pathlength delays (**b**). Velocity vector field measured by the multi-angle Doppler OCT along the diameter of the microtube. Velocity vectors shown in (**d**) were determined from the five Doppler images in (**c**) (From [83])

We have demonstrated that an arbitrary velocity vector can be determined from a single measurement by generating multiple $\Delta\mathbf{k}$ vectors with different pathlength delays simultaneously [83]. A beam divider which has three parts with different thicknesses of 0, t, and 2 t was inserted in the sample arm as shown in Fig. 41.10a. After passing through the focusing lens, the divider produced five independent $\Delta\mathbf{k}$s and divided a probe beam to have five independent view points and path length delays (Fig. 41.10b). Figure 41.10c shows Doppler images of a scattering fluid flowing through a microtube from a single scan. The five Doppler images correspond to five different $\Delta\mathbf{k}$ with different pathlengths. The velocity vector field can be quantified by solving a three-dimensional minimization problem from five Doppler images. The results are shown in Fig. 41.10d and have good agreement with the actual values [83].

In addition to the phase-resolved Doppler variance (PR-DV) method, methods that are dependent on the intensity or amplitude fluctuation can also be used for mapping vascular networks [43, 45, 46, 51, 84]. Recently, we have developed an intensity-based Doppler variance (IB-DV) method that uses an algorithm derived from a modified phase-resolved Doppler variance algorithm [43]:

$$\sigma_{IB}{}^2 = \frac{1}{(2\pi T)^2}\left(1 - \frac{\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\left|\tilde{S}_j(z_m)\cdot\tilde{S}_{j+1}^*(z_m)\right|}{\frac{1}{2}\sum_{m=(n-1)M}^{nM}\sum_{j=1}^{N}\left[\tilde{S}_j(z_m)\cdot\tilde{S}_j^*(z_m)+\tilde{S}_{j+1}(z_m)\cdot\tilde{S}_{j+1}^*(z_m)\right]}\right). \quad (41.27)$$

IB-DV is not sensitive to gradient phase changes and can be used without bulk motion correction for in vivo imaging [43]. The IB-DV method can minimize the artifact from the phase instability [43].

41.2.4 Qualitative and Quantitative Microvascular Imaging and Optical Microangiogram

PR-D-OCT and Doppler variance (DV) imaging provide complementary information. While PR-D-OCT is most sensitive when the flow direction is along the probing beam, PR-DV and IB-DV can be used to measure the flow when the flow direction is near perpendicular to the probing beam. The sensitivity and dynamic range of these methods are limited by the time interval T between A-lines [79]. Figure 41.11 shows measured PR-DV and IB-DV values as a function of transverse flow speed [79]. At low speed regions up to 100 mm/s, the curve shows a linear relationship between the flow speed and the variance values. At higher flow speed regions, the curve shows saturation of the variance value.

There are many applications where mapping of microvascular network is essential for diagnosis and management of diseases that have a vascular etiology. Although PR-D-OCT provides high-sensitivity measurement of flow velocity, the technology is very sensitive to phase stability of the OCT system, the motion artifact, and orientation of the vasculature. In applications where absolute flow velocity is less important than vessel distribution, Doppler variance has the advantage of being less sensitive to the pulsatile nature of the blood flow and the complex variation of incident angle and provides an excellent method for optical angiogram

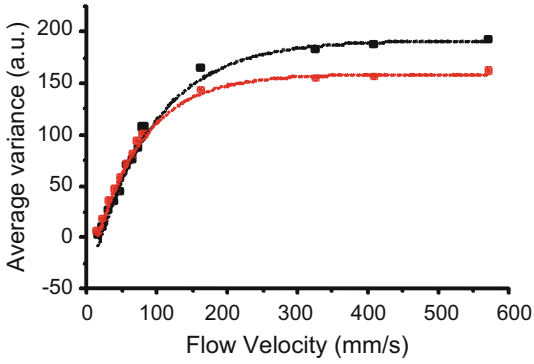

Fig. 41.11 The dependence of IB-DV and PR-DV values on the flow rate with a 50 kHz swept source-based FD-OCT (From [79])

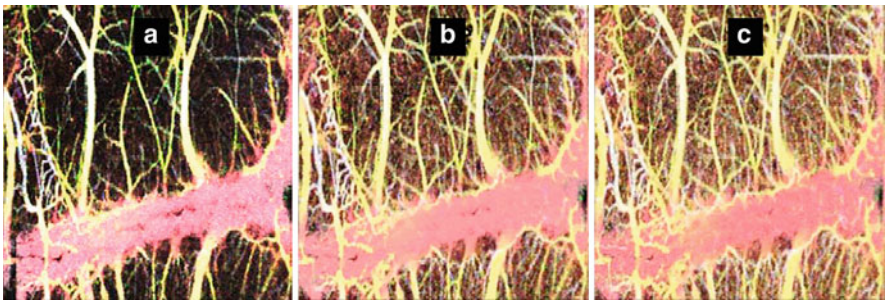

Fig. 41.12 Optical angiogram of mouse brain with intact skull. (**a**) PR-D-OCT image, (**b**) PR-DV image, and (**c**) IB-DV image. The depth information is color coded in these images. Scale bar: 1 mm (From [79])

[22, 27, 28, 40–43]. Figure 41.12 shows cerebrovascular circulations in mice obtained by a swept source OCT system. PR-D-OCT, PR-DV, and IB-DV images are shown in Fig. 41.12a–c, respectively. Both of the variance methods are able to detect the capillary vessels with high sensitivity and high contrast. PR-D-OCT is also sensitive for capillary vessel detection. However, the contrast of the PR-DV and IB-DV images is better than that of an PR-D-OCT image, especially in regions with smaller blood vessels.

41.3 Applications of Doppler OCT

Due to its exceptionally high spatial resolution and velocity sensitivity, several clinical applications of Doppler OCT have been demonstrated, including screening vasoactive drugs, monitoring changes in image tissue morphology and hemodynamics following pharmacological intervention and photodynamic therapy, evaluating the efficacy of laser treatment in port wine stain (PWS) patients, assessing the depth of burn wounds, imaging tumor microenvironment, mapping cortical hemodynamics for brain research, imaging ocular blood flow, and mapping blood flow in gastrointestinal tracts. Furthermore, applications of phase-resolved Doppler OCT have been extended to other fields, such as optical coherence elastography (OCE) that uses the phase-resolved method to map the mechanical property of the tissue and optical coherence phase microscopy that extracts high-resolution phase information to retrieve nanometer or sub-nanometer scale displacement variation of a sample.

41.3.1 Drug Screening

Noninvasive drug screening is essential for the rapid development of new drugs. Doppler OCT can be used for in vivo blood flow monitoring after pharmacological intervention. The effects of nitroglycerin (NTG) on the CAM artery and vein have

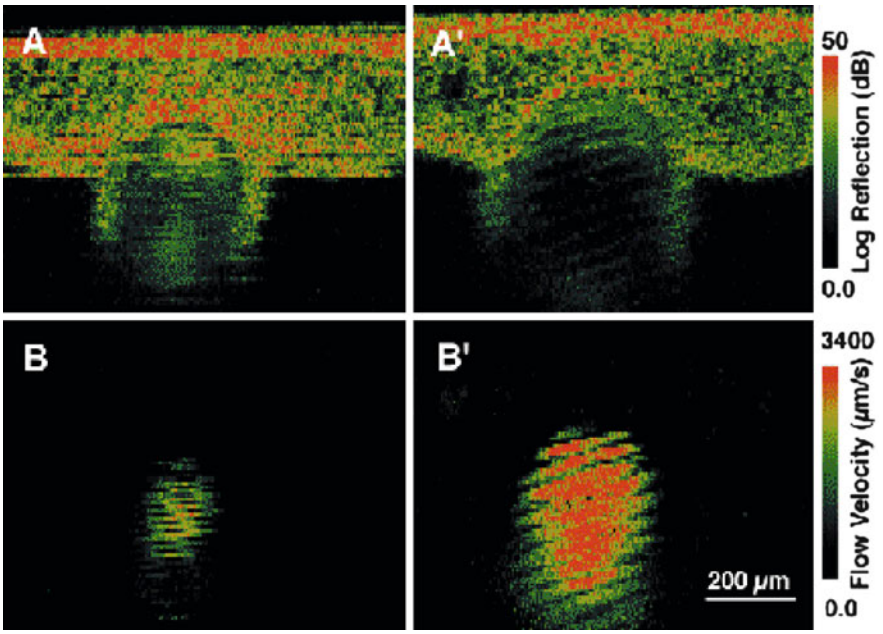

Fig. 41.13 Effects of topical NTG on blood flows in CAM artery (I). Doppler structural and velocity images, respectively, before (**a**, **b**) and after (**a′**, **b′**) drug application (From [11])

been investigated [11]. Changes in arterial vascular structure and blood flow dynamics are shown in Fig. 41.13, where Figs. 41.13a, b are structural and velocity images, respectively, before and Fig. 41.13a′, b′ are after topical application of NTG. The arterial wall can be clearly identified and dilation of the vessel after nitroglycerin application is observed in the structural images. Although velocity images appear discontinuous due to arterial pulsation (Fig. 41.13b, b′), enlargement of the cross-sectional area of blood flow is evident. Peak blood flow velocity at the center of the vessel increased from 3,000 to 4,000 μm/s after NTG application.

41.3.2 In Vivo Blood Flow Monitoring During Photodynamic Therapy (PDT)

Doppler OCT can be used to monitor changes in in vivo blood flow during PDT [11, 85, 86]. Changes in in vivo blood flow in rodent mesentery after benzoporphyrin derivative (BPD) injection and laser irradiation were imaged (Fig. 41.14) [11]. Doppler OCT structural and velocity images, respectively, were recorded before laser irradiation (Fig. 41.14a, a′), 16 (Fig. 41.14b, b′) and 71 min after laser irradiation (Fig. 41.14c, c′). The results indicate that the artery goes into vasospasm after laser exposures and compensatory vasodilatation occurs in response to PDT-induced tissue hypoxia.

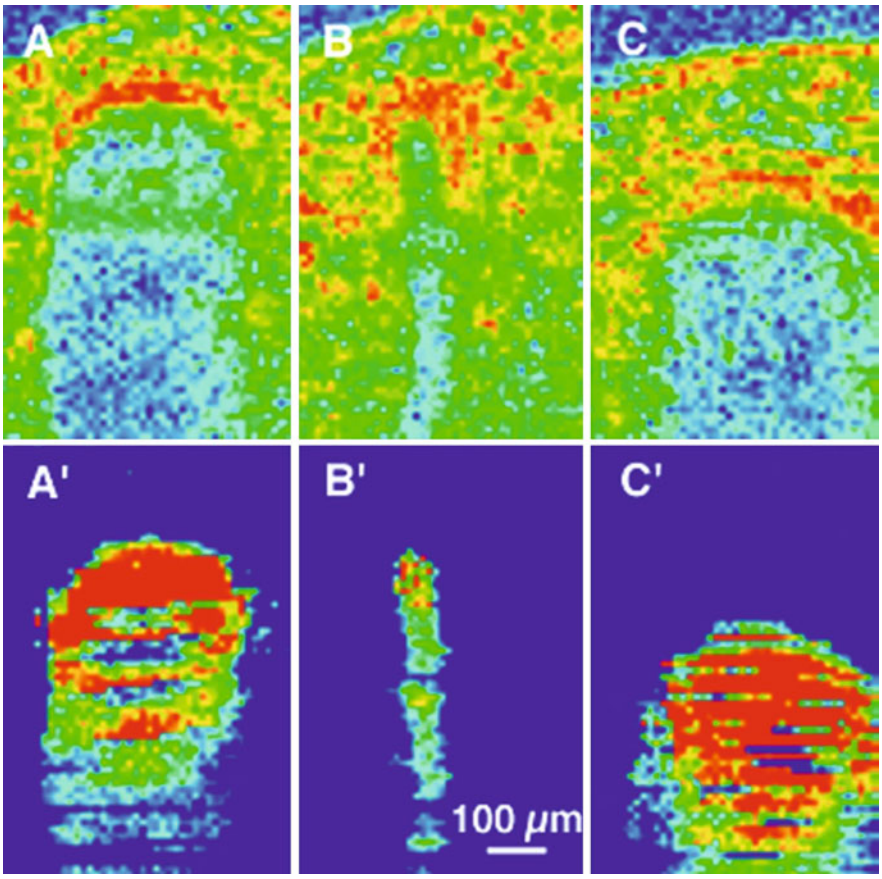

Fig. 41.14 Vessel structure and blood flow dynamics in rodent mesenteric artery after PDT. Doppler OCT structural and velocity images, respectively, prior to laser irradiation (**a**, **a′**), 16 min (**b**, **b′**), and 71 min (**c**, **c′**) after laser irradiation (From [11])

The pharmacokinetics of the PDT drug can also be studied with Doppler OCT. Doppler OCT images were taken at different intervals between photosensitizer injection and laser irradiation [11]. Rodents were given a PDT sensitizing drug 20 min, 4 h, and 7 h before mesenteric laser irradiation, and the changes in arterial diameter and flow were calculated from Doppler OCT images (Fig. 41.15). The results indicate that the effects of PDT are strongly dependent on the time interval between drug injection and light irradiation. For a drug-light time interval of 20 min, the arterial diameter (Fig. 41.15a) decreased by 80 % after light irradiation followed by a rebound with vasodilative overshoot. Mesenteric arterial flow (Fig. 41.15b) mirrored changes in diameter with an initial reduction with a subsequent rebound. These effects were significantly reduced with longer postinjection times due to progressive diffusion of the photosensitizer out of the vasculature.

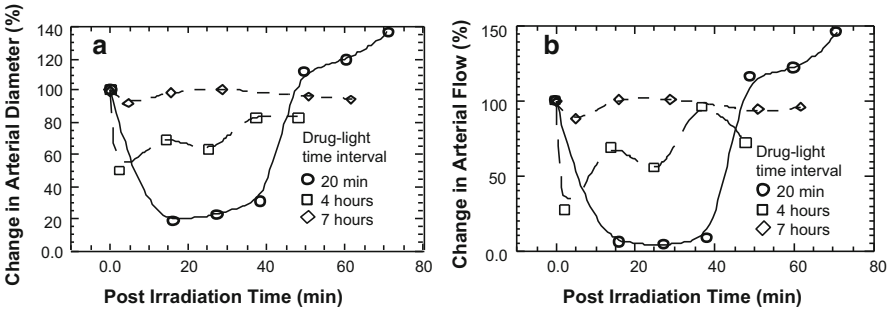

Fig. 41.15 Changes in relative arterial diameter (**a**) and flow rate (**b**) in rodent mesentery following PDT as a function of post-irradiation time (From [11])

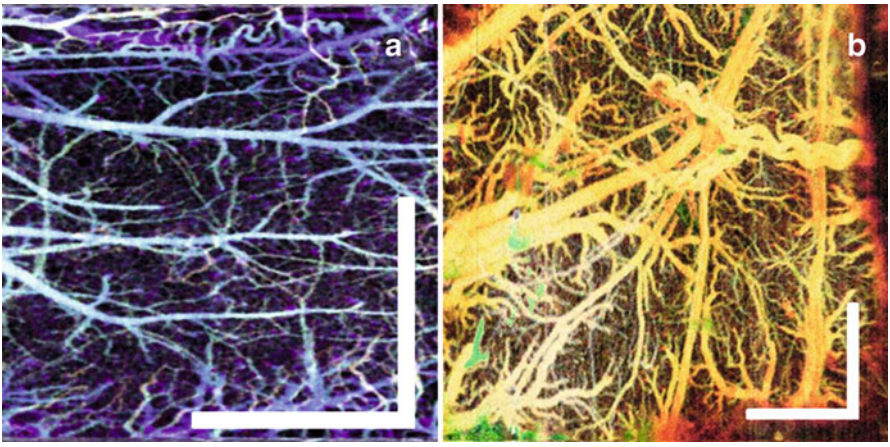

Fig. 41.16 Doppler OCT imaging of microvasculature. (**a**) Microvasculature of mouse cerebral cortex. (**b**) Microvasculature of rat cerebral cortex. Scale bar: 1 mm

41.3.3 Imaging Brain Hemodynamics

Doppler OCT has also been used to image brain hemodynamics in the cerebral cortex of the brain. The first in vivo imaging of blood flow in the rat cerebral cortex was reported in 2000 [10]. Recent development of Doppler OCT with an interframe scheme has greatly improved the velocity sensitivity, which makes it possible to map microvasculature of the brain cortex [48, 65, 87–89]. Figure 41.16a shows the *en-face* maximum intensity projection (MIP) microvasculature of mouse cerebral cortex with intact skull. Figure 41.16b shows the *en-face* MIP microvasculature of rat cerebral cortex with thinned skull. Doppler OCT shows great promise in brain research for imaging the entire depth of the cortex. Doppler OCT can be used to measure stimulus-induced changes in blood flow [10] and to evaluate and monitor brain ischemia and trauma [41, 90].

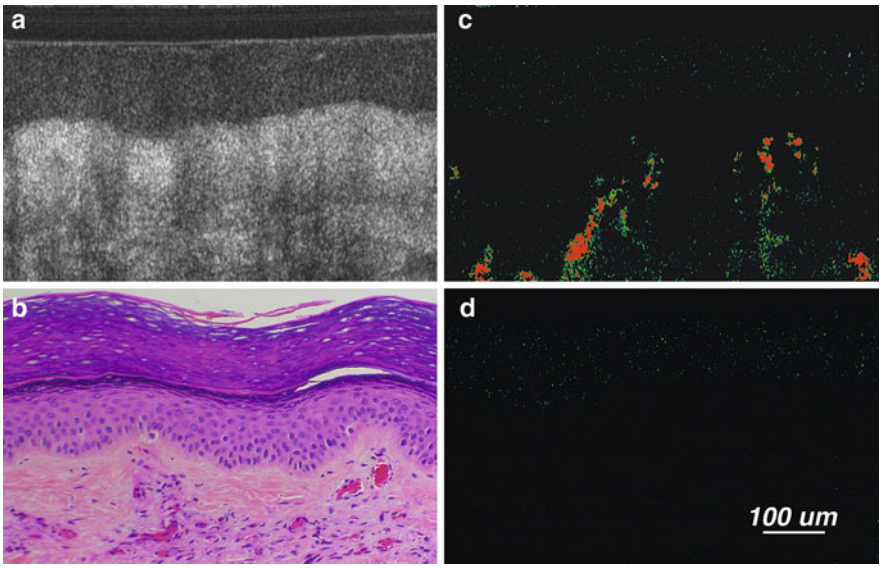

Fig. 41.17 Doppler OCT images taken in situ from PWS human skin. (**a**) Structural image, (**b**) histological section, (**c**) image before laser treatment, and (**d**): image after laser treatment (From [22])

41.3.4 In Vivo Monitoring of the Efficacy of Laser Treatment of Port Wine Stains

The first clinical application of Doppler OCT was the in vivo monitoring of the efficacy of laser treatment of PWS [12, 22, 28]. PWS is a congenital, progressive vascular malformation of capillaries in the dermis of human skin that occurs in approximately 0.7 % of children. Histopathological studies of PWS show an abnormal plexus of layers of dilated blood vessels located 150–750 μm below the skin surface in the dermis, having diameters varying on an individual patient basis, and even from site to site on the same patient, over a range of 10–150 μm. The pulsed dye laser can selectively coagulate PWS vessels by inducing microthrombus formation within the targeted blood vessels. However, currently there is no technique to evaluate efficacy of therapy immediately after laser treatment. Phase-resolved Doppler OCT provides a means to evaluate the efficacy of laser therapy in real time.

Figure 41.17 shows Doppler OCT structural and flow velocity images of a patient with PWS before and after laser treatment, respectively. The vessel locations from the Doppler OCT measurement and histology agree very well. Furthermore, the destruction of the vessel by laser can be identified since no flow appears on the Doppler flow image after laser treatment. This result indicates that Doppler OCT can provide a fast, semiquantitative evaluation of the efficacy of PWS laser therapy in situ and in real time.

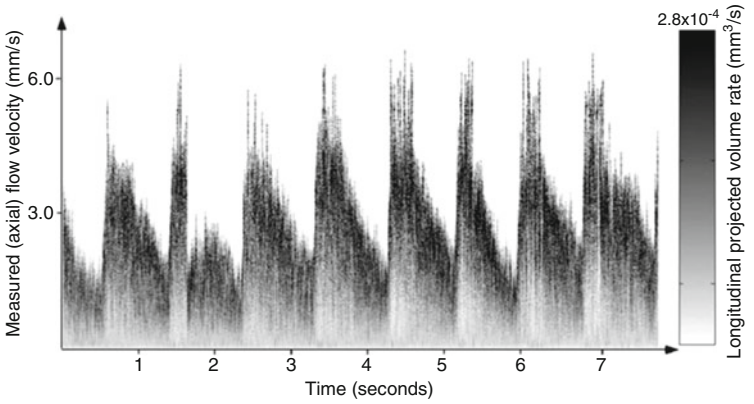

Fig. 41.18 Spectral Doppler wave forms that show the change of axial velocity and flow volume rate within a time span of 7.9 s. The right grayscale bar is used to represent the volume-rate contribution for a given velocity bin (From [56])

41.3.5 In Vivo Imaging and Quantification of Ocular Blood Flow

Doppler OCT has also been applied to imaging and quantifying the pulsatile nature of human retinal blood flow, detecting blood flow within the choroid and retinal capillaries, and providing information on the cardiac cycle [35, 36, 40, 43, 54, 56, 58–62]. Accurate knowledge of retinal blood flow dynamics is important in not only the treatment of but also understanding the pathophysiology of many diseases, such as glaucoma, diabetic retinopathy, and age-related macular degeneration [35, 36, 40, 43, 54, 56, 58–62].

The development of high-speed Fourier-domain Doppler OCT allows fast scanning of a single blood vessel multiple times over a cardiac cycle. Spectral Doppler waveforms can be obtained by performing spectral analysis of the time sequences of Doppler images [56]. In this method, repeated Doppler OCT scans across a few selected vessels were performed to get Doppler flow maps of a certain time period, which provides an accurate estimation of 2D flow dynamics across the vessels. Spectral Doppler analysis of continuous Doppler images demonstrates how the velocity components and longitudinally projected flow volume rate change over time for scatters within the imaging volume using spectral Doppler waveforms. Figure 41.18 shows spectral Doppler wave forms for a retinal blood vessel [56]. Various velocity envelope curves can be derived from spectral Doppler waveforms and used to extract the corresponding pulsatility index, resistance index (RI), and several other indices that can provide interpretable Doppler-angle-independent information needed to quantify the pulsatile nature of blood flow [56].

In addition to quantitative imaging, another important application of Doppler OCT is optical angiogram, which maps the human retina and choroid microvascular network. In contrast to traditional angiography methods, such as fluorescein angiography (FA) and indocyanine green angiography (ICGA), Doppler OCT is a label-free technique and has three-dimensional imaging capability.

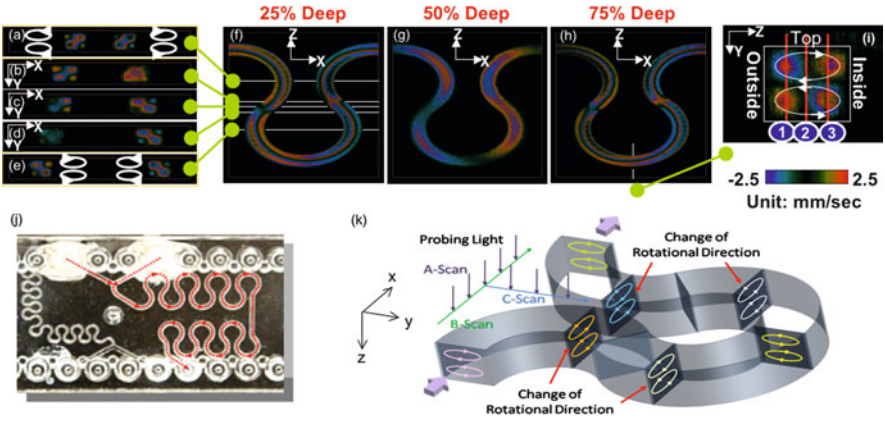

Fig. 41.19 Three-dimensional D-OCT images of secondary flow along the out-of-plane velocity (y direction). The out-of-plane velocity fields sectioned by x-y planes (**a**–**e**), by x-z planes (**f**–**h**), and by the y-z plane (i). The velocity field shows a pair of counterrotating vortices (**a**–**e**). Since the curvature is alternating, the rotational direction of the vortices is also alternating (**a**–**e**). Alternating flow direction of the secondary flow at different depths in the X-Z plane can be clearly visualized (**f**–**h**) (From [91]

By extracting the *en-face* images from the 3D image volume, FA- or ICGA-like angiography images can be obtained. In addition, the projection images can be obtained by summing up the *en-face* images at different depths [35, 36, 40, 43, 54, 56, 58, 61, 62].

41.3.6 Imaging and Quantifying the Flow Characteristics in a Micro-channel

Doppler OCT can provide cross-sectional imaging of channel geometry and flow velocity within a microfluidic channel with a spatial resolution on the order of a micrometer and a velocity sensitivity of 1 μm/s. Doppler OCT has been used to quantify the secondary flow, which plays a critical role in mixing in micro-channels [91]. A Y branch device of a meandering micro-channel with a square cross section is shown in Fig. 41.19. Aqueous suspension of polystyrene beads with a diameter of 0.2 μm and concentration of 20.5 mg/cm^3 was injected into both inlets of the device. The device was imaged with a spectrometer-based Doppler OCT system. The probe beam of the Doppler OCT was adjusted to be approximately perpendicular to the plane of the micro-channel (x-z plane) so that only the secondary flow along the y-direction would contribute to the Doppler signal [91]. The y-component of the secondary flow velocity $V_y(x,y,z)$ was imaged and quantified with Doppler OCT. Counterrotating vortices and alternating flow direction of the secondary flow at different depths in the x-z plane can be clearly visualized. This result clearly demonstrates that D-OCT can be used to image and quantify secondary flow.

41.3.7 Phase Imaging with Spectral Domain Optical Coherence Phase Microscopy

High-sensitivity phase measurement to detect nm or sub-nm scale displacement is an important technique for application on subcellular dynamics. The recent application of spectral domain phase microscopy, which is an extension of phase-resolved Doppler OCT, shows its capability of excellent phase stability, high sensitivity, and imaging speed for quantitative phase measurement [92–95].

In phase measurement with spectral domain phase microscopy, the phase information is extracted from the complex depth-resolved profile, which is obtained by Fourier transformation of the spectral fringes generated by the optical path difference (OPD) between the reference and sample arms. Since the phase oscillates 2π radians at every shift of half a wavelength of the OPD, an ultrahigh accurate measurement of the OPD can be achieved with high-sensitivity phase measurement of the fringes.

One limitation of spectral domain phase microscopy for phase measurement is the limited dynamic range of OPD detection due to the 2π ambiguity. Phase unwrapping algorithms are needed to measure OPD longer than half a wavelength. A spectral domain phase microscopy technique that is capable of high dynamic range quantitative phase-contrast imaging by overcoming the limitation of 2π ambiguity was recently reported [93]. Unlike conventional spectral domain phase microscopy, this technique retrieves phase information in the spectral domain instead of the depth domain by Hilbert transformation of the detected fringe signal to convert the discontinuous phase change in the depth domain to a gradually varying phase shift in the spectral domain. The spectral fringe was transformed from wave number to depth space by fast Fourier transformation. The process of narrow band pass filtering was adopted to select the positive term of the complex depth function and reject the noise from DC term and multiple reflections. With the phase retrieval approach performed in wave-number space, the spectral domain phase microscopy system could measure a large range of displacements, ranging from the minimum measurable displacement of 34 pm to the maximum measurable displacement of 2.0 mm, which is the imaging range of the system and determined by the spectral resolution of the spectrometer [93].

Figure 41.20a shows phase imaging of a resolution target with a spectrometer-based phase microscopy system [93]. The image covers a sample area of 1,000 × 1,000 μm. To demonstrate the performance of the system in cell imaging, living human neonatal dermal keratinocyte cells were used as samples. Figure 41.20b shows two-dimensional quantitative phase imaging of the cells. The image covering a sample area of 150 × 150 μm was acquired in 0.3 s [93].

We have used quantitative phase microscopy to image and quantify dynamic changes of phase during the process of laser microsurgery of cells in real time, which enables absolute quantification of localized alteration/damage to transparent phase objects, such as the cell membrane or intracellular structures, being exposed to the laser microbeam [96]. An example of quantitative phase images of red blood cell before and after laser microsurgery is shown in Fig. 41.21.

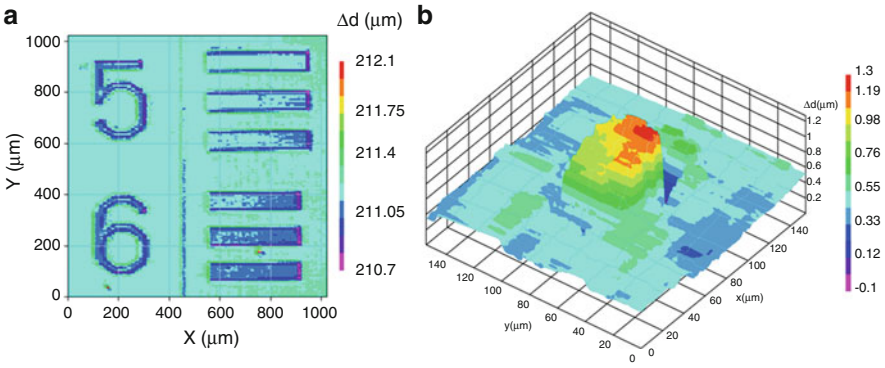

Fig. 41.20 OCT quantitative phase microscopic images: (**a**) resolution target and (**b**) human neonatal dermal keratinocyte cells (From [93])

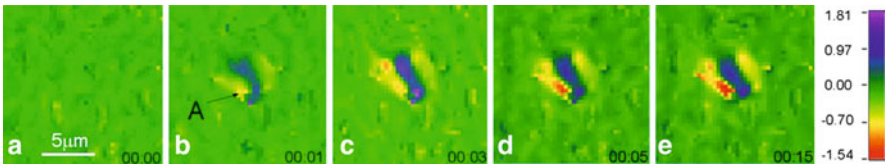

Fig. 41.21 Time-lapse (in seconds) phase images showing dynamic changes of phase variation during laser microsurgery of RBC. (**a**) Before laser microbeam irradiation; (**b**) 1 s, (**c**) 3 s, (**d**) 5 s, and (**e**) 15 s after laser microbeam irradiation (From [96])

41.3.8 Phase-Resolved Doppler OCT to Evaluate Elastic Properties of Tissue

Many diseases involve change in the biomechanical properties of tissue, and there is a close correlation between tissue elasticity and pathology. Elastography, which enable imaging and quantifying biomechanical properties such as elasticity and viscosity of soft tissue, has become a powerful technique to distinguish healthy and diseased tissues, particularly in tumor and cardiovascular research. Optical coherence elastography (OCE) uses OCT to map the mechanical property of the tissue. In OCE, an external force (or load) is usually applied to the sample to excite tissues for a certain deformation which is then quantified with OCT. The first demonstration of OCE utilized a tissue compressor consisting of a piezoelectric actuator with a circular glass cover slip glued to its ring-shaped head [97]. Phase-resolved Doppler OCT was used as an approach of elastography to characterize tissue mechanical properties such as Young's modulus and shear modulus by measuring the phase shift between sequential A-scans [98, 99]. The applications of OCE have been demonstrated in ophthalmology, dermatology, cardiology, and oncology [100]. However, adoption of these methods to in vivo real-time imaging is limited by low cycling frequency of external forces.

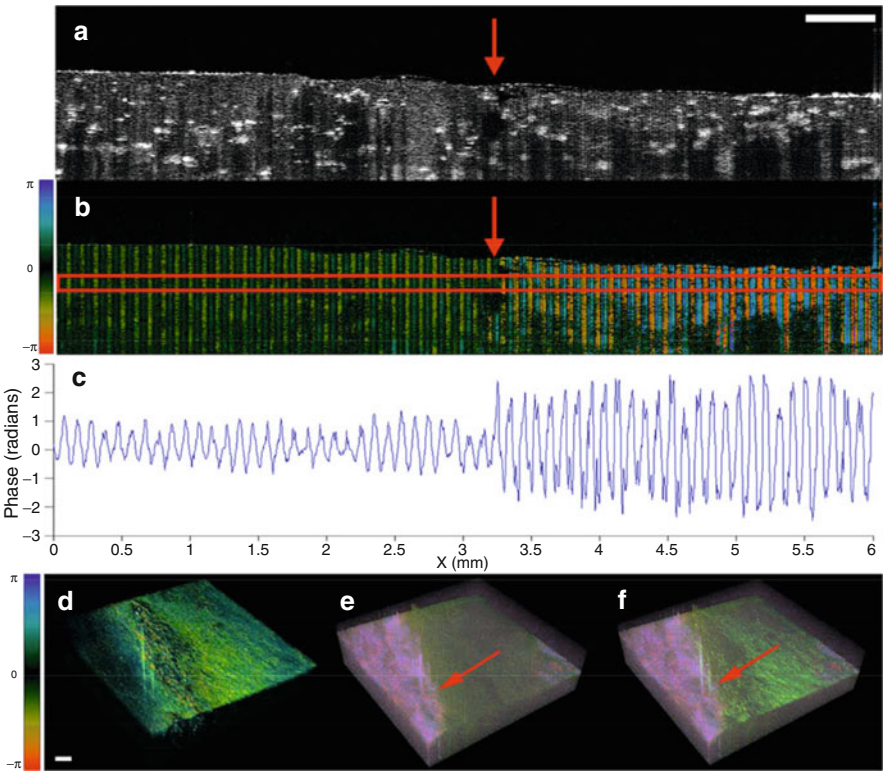

Fig. 41.22 ARF-OCE images of a tissue phantom consisting of a thin film made of agarose with two different concentrations (7 % and 3.5 %) side by side. (**a**) OCT intensity image, (**b**) ARF-OCE image under 4 MHz with 500 Hz AM modulation ARF excitation, (**c**) phase amplitude averaged over the depth of tissue, (**d**) 3D OCT imaging, (**e**) 3D ARF-OCE image, and (**f**) fused 3D OCT and PR-ARF-OCE image. *Red arrow* indicates the boundary between two sides of 7 % and 3.5 % agarose film. Scale bars: 1 mm (From [68])

Recently, we developed dynamic phase-resolved acoustic radiation force optical coherence elastography (ARF-OCE), which is capable of high-speed, high-spatial-resolution, point-by-point elastogram mapping in an axial direction [68]. This method utilizes chirped acoustic radiation force to produce excitation along the sample's axial direction, and phase-resolved Doppler OCT is used to measure the vibration of the sample. Results from a tissue phantom consisting of a thin film made of agarose with two different concentrations side by side are shown in Fig. 41.22. The concentration of agarose is 7 % and 3.5 % for each side, respectively. The OCT image of the phantom is shown in Fig. 41.22a, from which the two sides of agarose film with different concentrations cannot be clearly distinguished. The phase change map of the OCE image for the agarose film under ARF from an ultrasound transducer, driven at RF frequency of 4 MHz and AM modulation of 500 Hz, is shown in Fig. 41.22b. The phase change amplitude averaged over depth

is shown in Fig. 41.22c. The boundary (red arrow) between the two sides of the phantom with different concentrations can be clearly visualized in Fig. 41.22b, c. Figure 41.22d-f shows 3D OCT, ARF-OCE, and fused OCT/ARF-OCE imaging of the tissue phantom. The 3D ARF-OCE image (Fig. 41.22e) clearly delineates the two materials with different stiffness. The ratio of Young's moduli between the 7 % and 3.5 % agarose material within the two sides of the phantom measured by phase shifts is consistent with the value measured using a standard compression test. This result clearly shows that ARF-OCE combines high-speed excitation of ARF with high sensitive displacement measurement of the phase-resolved method and has great potential to quantitatively characterize tissue mechanical properties and thereby delineate diseased tissue from normal tissue.

41.4 Summary

Doppler OCT is a rapidly developing imaging technology with many potential applications. The development of the phase-resolved method and Fourier-domain method has enabled high-speed and high-sensitivity Doppler imaging in 3D. New developments in all components of an OCT system can be integrated to a Doppler OCT system, including new light sources for high resolution and high speed, new scanning endoscopic probes, and new processing algorithms. Integration of Doppler OCT with other functional OCT, such as polarization-sensitive OCT, spectroscopic OCT, and second harmonic OCT, can greatly enhance the potential applications of this technology. Given its noninvasive nature and exceptionally high spatial resolution and velocity sensitivity, functional OCT that can simultaneously provide tissue structure, blood perfusion, birefringence, and other physiological information has great potential for basic biomedical research and clinical medicine.

Acknowledgments We would like to thank many of our colleagues who have contributed to the Doppler OCT project at the Beckman Laser Institute and Department of Biomedical Engineering at UCI, particularly the students and postdoctoral fellows. Dr. Chen also wants to acknowledge grants support from the National Institutes of Health (R01EB-10090, R01EY-021529, R01HL-105215, R01HL-125084, and P41EB-015890), Air Force Office of Scientific Research (FA9550-04-0101), and the Beckman Laser Institute Endowment.

Keywords
Angiography • Blood Flow • Doppler OCT • Functional OCT • OCT Angiography • Optical Microangiography • Vascular Imaging

42.1 Introduction

Information about tissue perfusion and the vascular structure is certainly most important for assessment of tissue state or personal health and the diagnosis of any pathological conditions. It is therefore of key medical interest to have tools available for both quantitative blood flow assessment as well as qualitative vascular imaging. The strength of optical techniques is the unprecedented level of detail even for small capillary structures or microaneurysms and the possibility to combine different techniques for additional tissue spectroscopy giving insight into tissue metabolism. Still the gold standard for retinal vascular imaging is fluorescein or indocyanine green (ICG) angiography, again with the need to administer contrast agents. ICG absorbs in the infrared region where tissue scattering is lower and allows therefore deeper vessels in the choroid to be imaged, whereas fluorescein is applied for contrasting retinal vessels. This outlines already another important demand: to distinguish flow signatures of different vascular beds in depth. A noncontact and label-free method for tissue perfusion assessment is Laser Doppler Imaging (LDI). This method uses coherent laser illumination and detects

the beating frequency between light scattered by moving blood cells that experience a Doppler shift and that scattered from static tissue. Fourier analysis of the beating frequencies gives relative quantitative information about flow and particle concentration. Alternatively, speckle fluctuations can be used in LDI as fast indicator of blood flow, allowing vascular contrast. Laser Doppler velocimetry (LDV) is a related method that retrieves tissue perfusion parameters from diffusion theory [1]. For focal assessment of flow in selected vessels bidirectional Laser Doppler Flowmetry has been successfully applied, which like LDI is analyzing the beating frequency spectrum. Several studies based on Laser Doppler techniques outlined that blood flow changes are a precursor of major retinal diseases such as glaucoma, diabetes, or age-related macular degeneration [4–6]. Precise quantitative assessment of ocular flow in small retinal vessels opened the door for tissue-sensitive pharmacological studies. Investigations shed, for example, light on the role of endothelial cells and its release of vasoactive substances such as NO for perfusion regulation [7, 8]. Despite the success of those methods, they suffer from missing depth localization capability for moving scatterers. Hence, there is an immediate diagnostic and pharmacological demand for high-resolution, label-free, tissue angiography and flow assessment that in addition allow for precise depth gating of flow information. The most promising candidate is Doppler optical coherence tomography (DOCT) which shares the advantage with LDI of being noncontact, label free, and without employing hazardous radiation. However, in contrary to LDI, DOCT provides fully quantitative volumetric information about blood flow together with the vascular and structural anatomy [9, 10]. Segmentation and visualization of blood vessels from OCT measurements, called also as “OCT angiography,” acts directly on the standard OCT data sets. It is only a matter of post-processing in combination with dedicated scanning patterns whether one reconstructs the OCT intensity or angiography images. Having both intensity and angiography information available with the same data set potentially reduces the shortcoming of DOCT being only sensitive to blood at motion, not sensing static leakage sites that are, for example, signs of retinal diseases. Also, systemic and vascular diseases should be visible through studying the integrity [11] and perfusion properties of vasculature networks. For example, the irregular vascular network of tumor tissue has been imaged and characterized with an impressive level of detail [12]. DOCT has furthermore great potential for treatment monitoring, e.g., during photodynamic therapy, or for analyzing tissue grafts. Because of the huge potential of DOCT for diagnosis, the last years saw a rapid increase of publications in this field with many different approaches.

42.2 Vascular Contrasting and Doppler Techniques

First implementations of DOCT based on TDOCT were capable of real-time quantitative perfusion imaging in the retina and skin [13, 14]. High velocity sensitivity has been achieved by calculating OCT signal phase differences along the A-scan [17]. The velocity sensitivity has been further enhanced using spectral

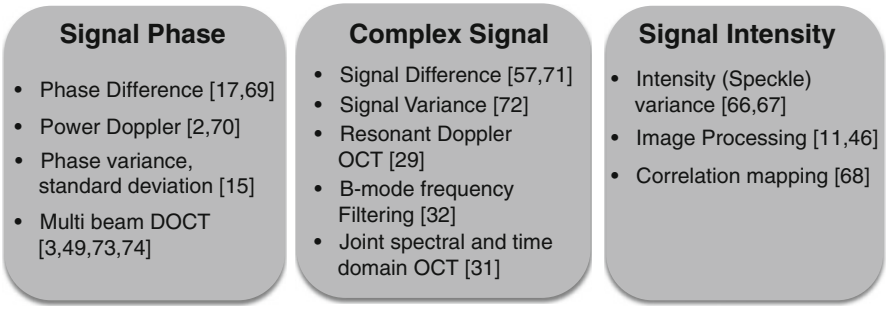

Fig. 42.1 Classification of methods for DOCT and optical angiography

referencing that revealed slow cell dynamics during osmotic changes [16]. Flow contrasting has been demonstrated by calculating the standard deviation of the motion-induced phase fluctuations [15]. Since OCT senses blood flow depth resolved within the tissue, a three-dimensional angiographic map may be calculated. Still, TDOCT suffers from low temporal resolution, and the sensitivity is critically decreasing at higher A-scan rates. Therefore FdOCT is gradually replacing time domain OCT due to its intrinsic sensitivity and speed advantage [18–22, 25]. Its ability for in vivo 3D imaging due to its outstanding high-speed performance [23, 24] paved the way for noninvasive comprehensive volumetric angiography and the quantitative assessment of pulsatile flow. The intrinsic phase stability of the method supports functional extensions of OCT that use phase information for enhanced sensitivity, such as measurement of blood flow, or polarization-sensitive OCT [2, 26–28]. High-speed data recording maintaining high image quality offered large flexibility, which resulted in novel signal processing schemes, supported by dedicated scanning patterns. We have today a rich variety of DOCT methods available for both quantitative perfusion assessment and for flow contrasting down to the level of individual capillaries. Apart from phase-sensitive flow detection as in time domain OCT, recent developments include speckle and phase-variance imaging, resonant Doppler imaging [29], optical microangiography [30], joint spectral and time domain OCT [31], and other different flow filtering methods [32, 33] to characterize and contrast perfusion of tissue volumes. Figure 42.1 tries to categorize those methods based on whether they involve only the OCT signal phase, only the intensity, or the full complex OCT signal.

42.3 Theory

42.3.1 Phase-Sensitive DOCT

In Fourier domain optical coherence tomography (FDOCT), the Fourier transformation of the spectral interferometric fringe signal measured by a single exposure of the line scan light detector creates one line of a structural

cross-sectional image (A-scan). In order to assess the velocity of a moving interface, most known methods require at least two spectral fringes acquired at the same or nearly the same lateral position [17, 69] of a sampling light beam. This allows the calculation of the initial phase difference between the two spectral fringe signals; this difference is directly linked to the optical path change between the reference mirror and a moving reflecting or scattering object within the sample. In general, a higher number of spectra can be acquired over time to increase the accuracy of the velocity estimation. The acquired set of spectral fringes can be described as a function of the wavenumber k and time t according to the following equation:

$$I(k,t) = I_0(k)\left(\sum_l R_l + R_r + 2\sum_l \sqrt{R_l R_r}\cos\left(2z_l(t)\cdot k\right)\right), \tag{42.1}$$

where $I(k, t)$ is the spectral fringe signal; $I_0(k)$ is the spectral density of the light source; R_l and R_r denote the reflectivity of the sample and reference mirrors, respectively; and $z_l(t)$ denotes the optical path difference between the reference mirror and the *l-th* interface in the sample. The optical path difference is time dependent due to the movement of the reference mirror and/or the displacement of the interfaces within the sample. This displacement is caused either by the movement of the entire sample or of the specific interface z_l within the sample. If we assume that both the reference mirror velocity and the velocities in the sample are constant during the acquisition of the spectral fringes, see Eq. 42.1, then the time-dependent position of the *l-th* interface, $z_l(t)$, can be expressed as:

$$z_l(t) = z_l + \delta z(t) = z_l + v_l \cdot t. \tag{42.2}$$

In this relation, z_l is the depth position of the *l-th* interface when data acquisition begins, and v_l is the difference between the velocity of the reference mirror and an axial component of the velocity of the *l-th* interface (parallel to the direction of the probing beam propagation). One can rewrite Eq. 42.1 making use of Eq. 42.2:

$$I(k,t) = I_0(k)\left(\sum_l R_l + R_r + 2\sum_l \sqrt{R_l R_r}\cos\left(2(z_l + \Delta z_l(t))\cdot k\right)\right) \tag{42.3}$$

$$I(k,t) = I_0(k)\left(\sum_l R_l + R_r + 2\sum_l \sqrt{R_l R_r}\cos\left(2z_l\cdot k + \omega_l\cdot t\right)\right) \tag{42.4}$$

Although the above equations represent the same interference pattern, they emphasize different properties. The phase of the oscillatory component present in Eq. 42.3 is a function of the wavenumber, and its modulation frequency depends on the static position z_l of the *l-th* interface, and a small additional change δz that occurs if the *l-th* interface is moving. Equation 42.4 highlights the time dependence of the interferometric fringes and shows that the signal is modulated in time with

frequency ω_l. This beat frequency is caused by a Doppler effect that arises for each *l-th* interface along the time axis. The frequency depends on the velocity v_l and is different for each wavenumber k:

$$\omega_l = 2v_l k \tag{42.5}$$

The phase-resolved methods [17] for estimating velocity use the signals' phase differences as described by Eqs. 42.3 and 42.5:

$$v_l = \frac{\Delta\Phi_l}{2k\Delta t} = \frac{\lambda}{4\Delta t}\frac{\Delta\Phi}{\pi} \tag{42.6}$$

Here, $\Delta\Phi$ is the phase difference between successively recorded depth profiles at the same location of the probing beam:

$$\Delta\Phi_l = 2\Delta z_l k = 2v_l \Delta t k, \tag{42.7}$$

The time between the acquisitions of successive profiles, Δt, is approximately equal to the exposure time of the detector; therefore, $1/\Delta t$ is the frame rate of an array detector (or equivalently, the "A-scan" rate). It is important to ensure that $|\Delta\Phi|$ is less than π.

42.3.2 Optical Angiography

In the following chapter, we will focus on the DOCT modalities for noninvasive tissue angiography. In general, all methods can be realized with either spectrometer-based FdOCT or swept source OCT (SSOCT). SSOCT has particular advantages for motion sensing as it does not suffer from fringe washout and keeps high sensitivity even for several hundred kHz A-scan rates, due to its higher dynamic range than CCD or CMOS-based FdOCT and the option of dual-balanced detection. In the present chapter, we would like to demonstrate applications of tissue angiography in ophthalmology and dermatology. Those have been obtained with intensity-based DOCT, which is well adapted to swept source OCT, because it is independent from any acquisition timing problems such as trigger jitter. Also the fact that it does not require bulk motion correction alleviates the post-processing effort as compared to other techniques. An angiographic image volume $P(x, y, z)$, contrasting flow against static tissue, is obtained by calculating the squared intensity difference between successive tomograms [35]:

$$P(x, y_i, z) = \left(I(x, y_i, z) - I\left(x, y_{i+1}, z\right)\right)^2, \tag{42.8}$$

where $I(x, y, z) = 20 \cdot log[FFT(I(x, y, k))]$, (x, y, z) are the spatial pixel coordinates corresponding to fast and slow scanning and depth coordinate, respectively, and

k is the wavenumber. Such method requires good correlation for static tissue over successive tomograms. This is obtained by driving the slow axis scanner with a multiple-step function. It allows for measuring N tomograms at the same position y. A calculation of the intensity squared difference mean value at each position permits to detect decorrelation, caused by motion artifact, and to potentially reject that picture for further processing by setting manually a threshold T. The value of T is chosen such as to obtain visually optimal vessel contrast. The pictures representing the same location can be averaged to increase SNR. The number of pictures averaged at each position can be formally written as:

$$M(y) = \sum_{i=0}^{N-1} \left(\left[\sum_{x,z} P(x, y_i, z) \right] < T \right). \tag{42.9}$$

The logic operation in the brackets yields 1 or 0 for TRUE or FALSE, respectively. Finally, the motion contrast volume V is obtained by averaging only over the remaining M intensity squared difference tomograms P:

$$V(x, y, z) = \frac{1}{M(y)} \sum_{i=0}^{N-1} \left(\left[\sum_{x,z} P(x, y_i, z) \right] < T \right) \cdot P(x, y_i, z). \tag{42.10}$$

This method is more robust against motion artifacts than a variance analysis over the full tomogram series acquired at the same position, since pictures with strong decorrelation are rejected. Furthermore, the difference is only calculated between successive tomograms, thus reducing the time interval over which correlation is required. This improves further the stability with respect to motion artifacts.

In principle, one could replace the intensity difference in Eq. 42.8 by the difference of the full complex signal or by the phase difference only. The phase has the advantage of being insensitive to changing backscattering intensity. To be precise, the phase noise will scale with the SNR as is outlined also in the next chapter. Phase-sensitive contrasting of flowing blood seems to perform also better in case of strongly scattering embedding tissue, whereas intensity-based techniques are particularly well suited in case the embedding tissue scatters less than blood. Using the full complex signal is therefore a good compromise.

42.3.3 Noise in DOCT

In view of the importance of phase, it is therefore worth investigating the factors that determine phase fluctuations. In a scanning OCT system, phase fluctuations have two to three contributions [2] depending on the modality. Shot noise causes phase fluctuations that depend on the SNR as $\Delta\varphi_{SNR} = 1/\sqrt{SNR}$. In the case of shot

noise limited detection the distributions of the OCT signal phase and amplitude can be found using the formalism presented by Goodman [36].

The probability density function for the phase can be described by the following expression:

$$p(\Phi) = \begin{cases} \dfrac{e^{-{\kappa_{zt}}^2/2}}{2\pi} + \dfrac{\kappa_{zt}\cos\Phi}{\sqrt{2\pi}} \exp\left[-\dfrac{{\kappa_{zt}}^2 \sin^2\Phi}{2}\right] \Omega(\kappa_{zt}\cos\Phi) & -\pi < \Phi \le \pi \\ 0 & \text{otherwise} \end{cases}, \tag{42.11}$$

where function $\Omega(b) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{b} e^{-y^2/2} \mathrm{d}y$, $\kappa_{zt} = s_{zt}/\sigma$ is the signal-to-noise ratio (SNR) of the OCT signal dependent on time, s_{zt} is the amplitude of the signal, and σ is the standard deviation of the noise in the real and imaginary parts of the complex-valued time-dependent A-scans. With increasing κ_{zt}, the density function narrows, and it converges toward a Dirac delta function centered at $\Phi = 0$. When the signal s decreases to zero ($\kappa_{zt} \to 0$), the distribution converges to a uniform distribution as seen in Fig. 42.2a. Since the phase-resolved FdOCT requires phase subtraction, the width of the final distribution becomes broader. As the distribution broadens, more random wrapped phase differences are detected, and in turn, the averaged value of the phase differences moves closer to zero.

The probability density function of the amplitude of a time-dependent OCT signal is given by a Rician density function:

$$p(a) = \begin{cases} \dfrac{a}{\sigma^2} \exp\left[-\dfrac{a^2 + {s_{z\omega}}^2}{2\sigma^2}\right] I_0\left(\dfrac{a s_{z\omega}}{\sigma^2}\right) & a > 0 \\ 0 & \text{otherwise} \end{cases}, \tag{42.12}$$

Where $I_0(\cdot)$ is a modified Bessel function of the first kind and zeroth order, $\kappa_{z\omega} = s_{z\omega}/\sigma$ is the SNR of time-dependent A-scan, $s_{z\omega}$ is the amplitude of the signal, and σ is the standard deviation of the noise in the real and imaginary parts of the complex-valued time-dependent A-scan. As the signal $s_{z\omega}$ increases, the shape of the density function $p_A(a)$ changes from that of a Rayleigh density to approximately that of a Gaussian density with a mean equal to $s_{z\omega}$, as shown in Fig. 42.2b. Due to the Fourier transform linking the time-dependent interferometric fringe signal with optical frequency-dependent one, the signal-to-noise ratio is increased for the latter $\kappa_{z\omega} = \sqrt{M}\kappa_{zt}$, where M is the number of spectra being transformed.

Another factor influencing accuracy of DOCT is lateral scanning across a scattering surface. This gives rise to another contribution that depends on the lateral sampling according to $\Delta\varphi_{scan} = \sqrt{(4\pi/3)\left(1 - \exp\left(-2(\Delta x/d)^2\right)\right)}$ where

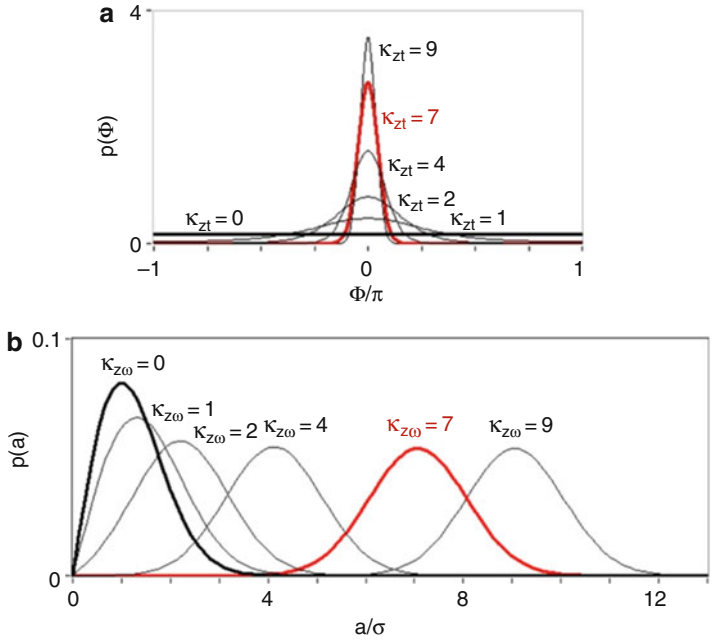

Fig. 42.2 (**a**) Phase distributions for various values of the κ_{zt} parameter. (**b**) The probability density functions for the amplitude at different values of parameter $\kappa_{z\omega}$. The *black curve* corresponds to the distributions of amplitude for pure noise ($\kappa_{z\omega} = 0$), and the *red curve* is for a signal with a critical value ($\kappa_{z\omega} = 7$) that assures the correct recovery of the velocity in DOCT [36]

d is the $1/e^2$ is the Gaussian beam waist in the focus, and Δx is the lateral displacement between successive A-scans [2]. The quotient $d/\Delta x$ defines the lateral oversampling (Fig. 42.3). The third contribution in SSOCT systems is trigger jitter for starting an A-scan, or B-scan, depending on the post-processing scheme [37]. Any time offset of the A-scan or B-scan causes increasing phase error in depth, as the associated fringe period becomes smaller. This can be avoided by fast and precise phase-locked loops (PLL) or by cutting A-scans in post-processing.

In most cases, the phase fluctuation due to scanning across a scattering sample is most critical and dominating. Nevertheless, by increasing the lateral oversampling factor one eventually hits the boundary set by SNR (Fig. 42.3). Phase noise determines the lower boundaries of phase-sensitive methods, in particular the minimum resolvable or contrastable speed in Doppler OCT.

For a given phase noise, the minimal resolvable velocity is determined as

$$v_{min} = {}^{\lambda}/_{4\pi T \Delta\varphi_{noise}}. \tag{42.13}$$

Apart from the dependence on the phase noise, it also depends on the time interval between the signals that are used for velocity analysis. Higher sensitivity can thus be achieved by using long time intervals. If one increases the A-scan period time,

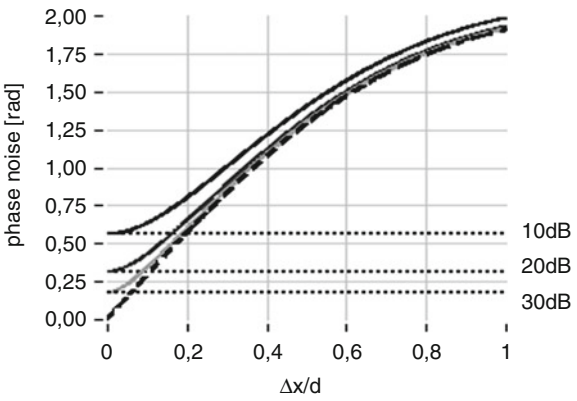

Fig. 42.3 Phase noise depending on lateral displacement and SNR

the total measurement time will increase, which results in strong motion artifacts. Using two B-scans immediately allows for larger time intervals and hence higher velocity sensitivities without sacrificing total recording time. For the first time, it was possible to contrast tissue capillaries with great detail. Modern DOCT angiography techniques measure the signal decorrelation due to flow. This needs long time intervals and even higher sensitivities in order to achieve an optimal effect also for small capillaries. The high sensitivity to optical path length changes comes however at a price: flowing blood gives rise to signal decorrelation shadows below vessels. This is seen in Fig. 42.4b. Those artifacts can be reduced by weighting or even masking the vascular contrast image with the intensity image or a binarized intensity image, respectively. Those artifacts might be problematic for studying axial vasculature. They are not visible in fundus projections of DOCT angiography images. In Fig. 42.4a, another typical artifact of B-scan-based techniques is visible: horizontal stripes. They are due to increased variance or difference values in the presence of motion artifacts. They can be reduced by using a thresholding procedure as outlined in the previous chapter and by applying Fourier band-pass filtering along the direction normal to the B-scans.

42.3.4 Joint Spectral and Time Domain OCT

Another approach for extracting the velocity is to use the Fourier transform to detect the time-dependent frequency of the signal given in Eq. 42.4. This idea underlies the joint spectral and time domain OCT technique (STdOCT), [31] as it uses only Fourier transforms to analyze the data in the wavenumber and time domains simultaneously.

To explain the principle of the technique, it is convenient to present the data processing on a so-called STdOCT diagram (Fig. 42.5). Each of the diagram's four panels present data connected via Fourier transforms. The transition in the horizontal direction transforms the data from the wavenumber domain to an in-depth position domain, while the vertical transitions transform the data from the time domain to the Doppler frequency domain.

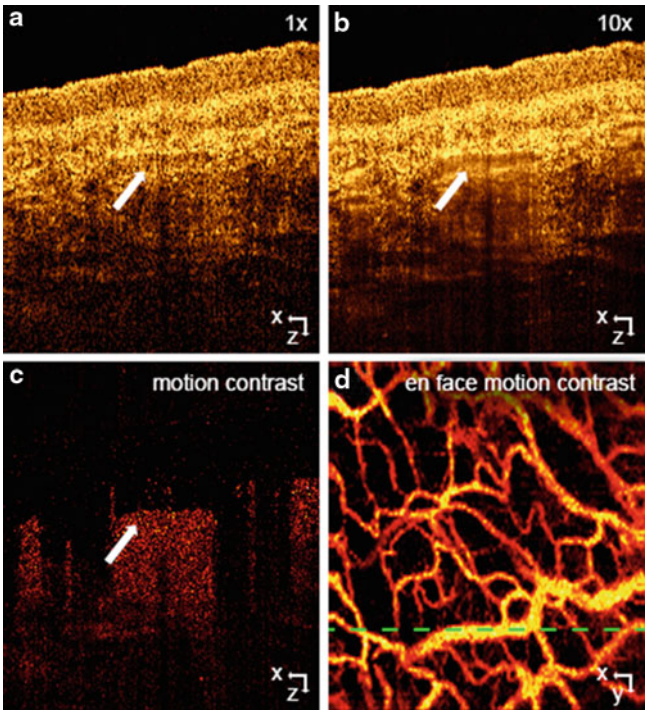

Fig. 42.4 Amplitude speckle decorrelation for blood flow imaging in skin. (**a**) Skin tomogram, (**b**) average of ten tomograms taken at the same lateral location with reduce speckle contrast at the vessel location (*white arrow*), (**c**) amplitude squared difference resolving motion in *red* against static tissue in *black*, (**d**) en-face mean projection of the motion data set. *Green dashed line* indicates the position of the (**a**), (**b**), and (**c**)

Two STdOCT diagrams are shown in Fig. 42.5. Figure 42.5a shows a diagram for the data acquired in a simple OCT experiment where a mirror is driven with a constant speed, and Fig. 42.5b shows a diagram for data obtained from imaging a laminar flow in a glass capillary phantom. Here, we discuss the data visible on all of the panels of the diagram.

k-t plane. Rows of the interferogram presented in this panel are simply interferometric spectra acquired by the FdOCT device that underwent standard FdOCT preprocessing (consisting of background removal, resampling to the wavenumber domain, and dispersion compensation [38]). The number of spectra is equal to the number desired to create one line of the final tomogram.

z-t plane. Data in this panel are obtained by a Fourier transform of each row from the k-t plane. Each complex-valued row in this data set is a so-called optical A-scan. Standard FdOCT processing uses these A-scans to find a line of the structural tomogram by averaging the amplitudes of the A-scans or by using phase differences between consecutive A-scans to find the Doppler shift as

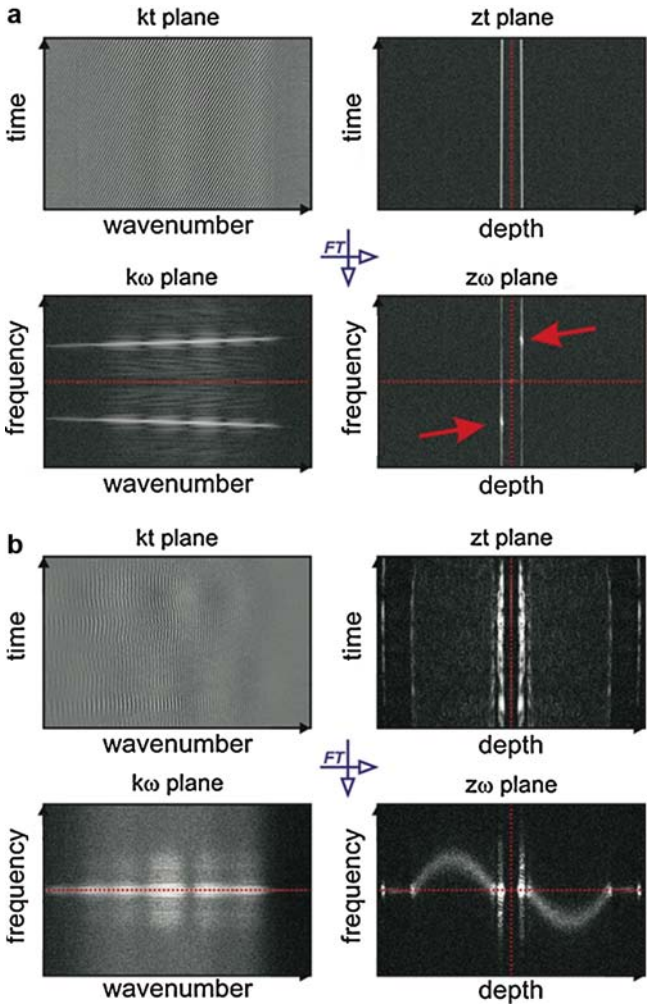

Fig. 42.5 STdOCT diagrams. Vertical transitions are accomplished by a Fourier transform along the wavenumber axis and horizontal transitions by a Fourier transform along the time axis. The amplitude of the complex signal is displayed for visualization purposes. In the zω-domain, complex conjugate images are symmetrical with respect to the central point of the plot (zero position, zero velocity). (**a**) Moving mirror experiment in which two points (*red arrows*) represent two complex conjugate images of the mirror; each of the points gives simultaneously information about the position and velocity of the moving mirror with respect to the reference mirror. (**b**) Laminar flow of intralipid solution in a glass capillary. Two complex conjugate images of a parabolic flow distribution are visible [65]

shown in Eq. 42.6. The signal in this plane is symmetrical with respect to the zero path delay (marked by the red dotted line).

k-ω plane. Data in this panel are obtained by Fourier transforming the data in the k-t panel with respect to time. It can be seen from Eq. 42.4 that information

about the depth position of the scatterer is encoded only in the non-time-dependent component of the spectral fringe phase. Therefore, the time-dependent Fourier transform does not provide information about the in-depth localization of scatterers. However, it does provide information about the distribution of Doppler frequencies as a function of wavenumber. For the moving mirror experiment, when there is only one component in such a spectrum, its velocity can be recovered from the Doppler frequency ω_l according to Eq. 42.5. For each k, the velocity can be calculated separately. Therefore, this representation of the data can be used to find the exact relationship between the wavenumbers and pixels in an array detector and can also be used to very accurately calibrate the spectrometer. This idea was proposed by Szkulmowski et al. [31] and discussed in detail by Faber and van Leeuwen [39]. For more complicated sample structures, it can be difficult to extract any useful information, but it is possible to filter the data to remove any undesired components of the Doppler spectrum before further processing. The optical microangiography (OMAG) technique [30] used to quantitatively visualize capillary networks uses a similar idea. The signal in this plane is symmetrical with respect to the zero velocity (marked by the red dotted line).

z-ω plane. This panel shows the result of a two-dimensional Fourier transform of the set of M spectral fringes. The coordinates of the displayed signals link the positions of all measured interfaces with their corresponding velocities. Each interface z_l is represented by two symmetrical points appearing with respect to the zero path delay and zero velocity. The sign of the velocity indicates a forward or backward direction. The point localized symmetrically with respect to the zero delay and zero velocity is the complex conjugate image of the scattering particle. The data in this panel can be regarded as a distribution of the Doppler spectrum of the signal as a function of depth, and as such, there is equivalence of the techniques developed for the time domain OCT [40–42]. It has been shown that the spread of the Doppler spectrum along the ω – axis depends on the optical parameters of the setup, such as the numerical aperture of the imaging objective, the spectral width of the light source, and the axial and transversal velocities of the imaged scattering particles. This Doppler distribution is visible in images of laminar flow as presented in Fig. 42.5b, where the distribution along the frequency axis is broadened in the center of the capillary lumen where the velocity components have their highest values in both the axial and transverse directions.

There are two ways to estimate the value of velocity component along the direction of beam propagation (Doppler component) using the STdOCT technique: maximum projection approach [31] and center of gravity approach [43]. In the first method, the velocity value is measured by finding the signal with maximum amplitude. This approach was proposed in the initial work by Szkulmowski et al. [31]. In 2011, Walther et al. [43] proposed alternative way of velocity estimation by calculating the center of gravity of the Doppler spectrum. Since the detectable Doppler frequencies are limited to half of the OCT sampling frequency, the center of gravity is calculated as the mean value of a circular

distribution of amplitude. This is achieved by weighting the amplitudes by complex vectors with phases equally distributed from 0 to 2π.

$$\Psi_l(f_D) = B_l(f_D) \cdot \exp\left[-i\frac{2\pi l}{N}\right] \quad \text{with} \quad l = 1, 2, \ldots, N \tag{42.14}$$

Here, N is the number of A-scans, and $B_l(f_D)$ is the amplitude of the *l-th* point Doppler frequency distribution. Finally, the center of gravity is calculated by averaging the modified complex value $\Psi_l(f_D)$ and determining the argument for each depth z as shown in Eq. 42.15, where f_D is the read-out rate for a single interference spectrum:

$$f_D(z) = \arg\left\{\frac{1}{N}\sum_{l=1}^{N}\Psi_l(f_D)\right\}. \tag{42.15}$$

The above estimator is compared to the velocity estimator proposed in 2009 by Vakoc et al. [12], which extended the standard phase-resolved approach. Here, the noise of the phase shift is more effectively reduced by considering the amplitudes $A_l(z)$ of the complex-valued A-scans $\Gamma_l(z)$, instead of averaging the absolute value of the phase differences $\Delta\Phi_l$. This is because the values with a high signal have a larger weight.

$$\overline{\Delta\varphi(z)} = \arg\left\{\frac{1}{N-1}\sum_{l=1}^{N-1}\Gamma_{l+1}(z)\Gamma_l^*(z)\right\}, \quad \text{where} \quad \Gamma_l(z) = A_l(z) \cdot \exp[-i\varphi_l(z)] \tag{42.16}$$

Experiments with intralipid emulsion flowing throughout glass capillary phantoms showed that the two above estimators are equivalent and have smaller variance than does the STdOCT with maximum amplitude detection (Fig. 42.6).

42.4 Qualitative and Quantitative Blood Flow Visualization with DOCT

42.4.1 Intensity Variance Ocular Angiography

Assessment of the retinal and choroidal vascularization is of important diagnostic benefit for major ocular diseases that affect the vascular network already at an early state. The visualization of the microvasculature yields an easy accessible and intuitive way to assess its integrity. During the last years, a number of strategies for contrasting

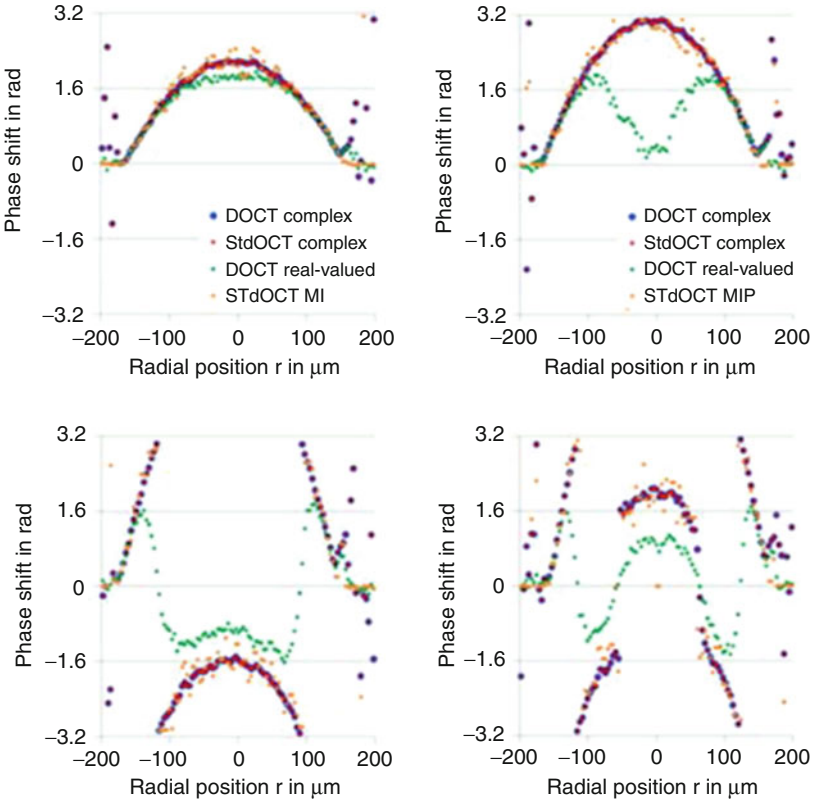

Fig. 42.6 Averaged flow profiles by STdOCT (STdOCT MIP – f_D by the maximum intensity signal, STdOCT complex – f_D by the center of gravity via complex $\Psi(f_D)$) and phase-resolved DOCT (DOCT complex, averaging the complex $\Gamma(z) \cdot \Gamma^*(z)$, DOCT real-valued, averaging the absolute value of $\Delta\varphi$), respectively [43]

microvasculature based on FdOCT have been introduced. The gold standards for their visualization are fluorescein angiography (FA) and indocyanine green angiography. They are commonly used in clinical practice for diagnosis of vascular occlusions, diabetic retinopathy, and choroidal neovascularization, usually a cause of age-related macular degeneration. The invasiveness of these techniques together with undesirable side effects, through the injection of a fluorescent dye, limits the screening capabilities for large populations. Therefore DOCT angiography is an attractive alternative as it is noninvasive, label-free, and easy to operate. The availability of both intensity information and vascular contrast with the same OCT data set might soon establish this technique for patient screening, as well as for treatment monitoring. The data recording takes only a few seconds, which further improves the patient comfort.

As has been outlined above, B-scan-based analysis yields contrast even for small retinal capillaries. However, if the B-scan rate is too low, motion artifacts are more likely to cause unwanted signal decorrelation, reducing the contrast between static

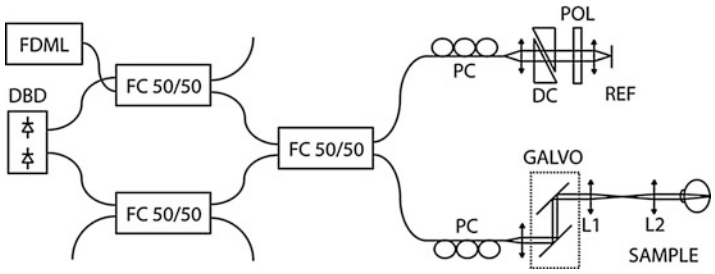

Fig. 42.7 Experimental setup for ultrahigh-speed posterior segment imaging. *FC* fiber coupler, *PC* polarization control, *DC* dispersion control, *POL* polarizer, *GALVO* scanning system, *L* lenses, and *DBD* dual-balanced detector [48]

tissue and flow. The increase of B-scan rate should however be limited so that high sensitivity for small capillary flow is preserved. Recent demonstrations applied B-scan rates of several hundred Hz [44]. Generally, the demonstration of these techniques was restricted to small FOV because of limited acquisition speed. It was partially solved by stitching small volumes together [44]. A critical point, however, concerning the clinical acceptance of this technique, is certainly the associated total long measurement time because of fixation change and the recording of redundant overlap areas required for registration. The development of ultrahigh-speed OCT techniques based on Fourier domain mode-locked (FDML) lasers for SSOCT allowed for A-scan rates beyond 1 MHz [45]. Recent results showed that ultrahigh speed is a prerequisite for flexible and comprehensive vascular contrast imaging with DOCT over a large field of view (FOV). Ultrahigh-speed FdOCT is therefore a promising candidate to compete with the FOV and resolution of fluorescein angiography, since a large patch can be covered by a single recording in a few seconds. Retinal and choroidal imaging with this technology at ultrahigh speed was demonstrated at a center wavelength of 1,060 nm [46, 47]. Posterior segment OCT imaging in that water window has the advantage to provide increased penetration into the choroid compared to common 850 nm region because of reduced scattering. It allows for a better assessment of choroidal vasculature that is particularly important for ocular diagnosis, its network being the main oxygen and nourishment supplier of the retina.

Figure 42.7 shows a setup for SSOCT with dual-balanced detection [45, 48].

The light source is an FDML laser with its Fabry-Perot filter driven at ~419 kHz. The so-called buffering technique of time multiplexing is later used to increase the sweep rate by a factor of 4 leading to 1.68 MHz A-scan rate. The spectrum is centered at 1,060 nm with a 72 nm sweep range. It produces a ~14 μm axial resolution in air. Shot noise limited sensitivity of ~91 dB with 1.7 mW power at the cornea is achieved, thanks to the symmetrical detection using matched fiber coupler (FC) to ensure a proper balancing. The slow axis scanner is driven by a multiple-step function. It permits measuring successive B-scans at the same vertical position y, giving an almost perfect correlation for static tissue. We measure $N = 5$ B-scans at 800 vertical positions. The fast axis driving function is a ramp of ~70 % duty cycle and a frequency of 560 Hz. Each B-scan constitutes of 2,060 A-scans.

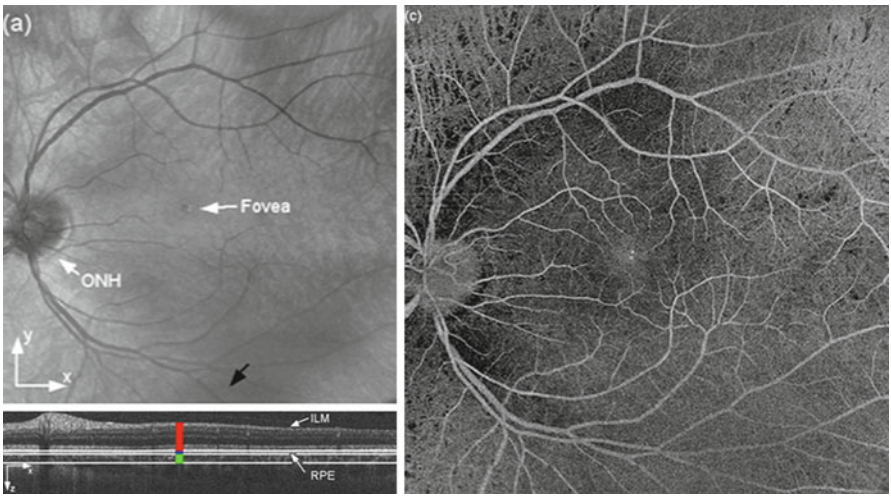

Fig. 42.8 (**a**) Pseudo-SLO fundus obtained by en-face mean projection of the intensity data set. *ONH* optic nerve head. *Black arrow*: low signal region (**c**) 48° widefield angiogram, en-face mean projection of the intensity variance 3D data set calculated from (**a**). (**b**) Fivefold averaged tomogram after flattening to the retinal pigment epithelium (*RPE*) [48]

This leads to an effective volume sampling of 2,060 × 800 × 460 (xyz). The scan amplitude is set to produce a ∼48° FOV on the retina. The total acquisition time for the full FOV is only 7 s.

Figure 42.8a shows the en-face mean projection of the intensity data set of the retina of a healthy volunteer acquired over a wide FOV of ∼48°. Large retinal and choroidal vessels are already visible; however, smaller vessels lack contrast. They are on the other hand well appreciated in the high-contrast en-face mean projection of the calculated 3D intensity variance set (Fig. 42.8c). The FOV of our label-free and noninvasive widefield angiography can be well compared to that of standard FA. An important advantage of our technique as compared to previous noninvasive methods based on OCT is the small acquisition time for such image obtained in a single recording. The depth resolution of OCT allows differentiating the retinal and choroidal vasculature network for further investigation. For this task, the intensity tomograms were first flattened by detection of the retinal pigment epithelium (RPE) layer (Fig. 42.8b). In a second step, the position of the inner limiting membrane (ILM) was determined. The corresponding coordinates were used for segmented en-face projection of the intensity variance 3D set. The first segment consisted of the region from ILM to the RPE layer; the second segment comprises the vascular structures down to about 50 μm below the RPE. Large choroidal vessels are finally segmented in a third layer. For the retinal layer, the intensity variance 3D data set was multiplied by a manually thresholded copy of the intensity data set. It reduces background noise, so that high backscattered blood vessels are better visible. The segmentation of the RPE is not possible in the ONH region; hence, the ONH vasculature is attributed to the upper layer.

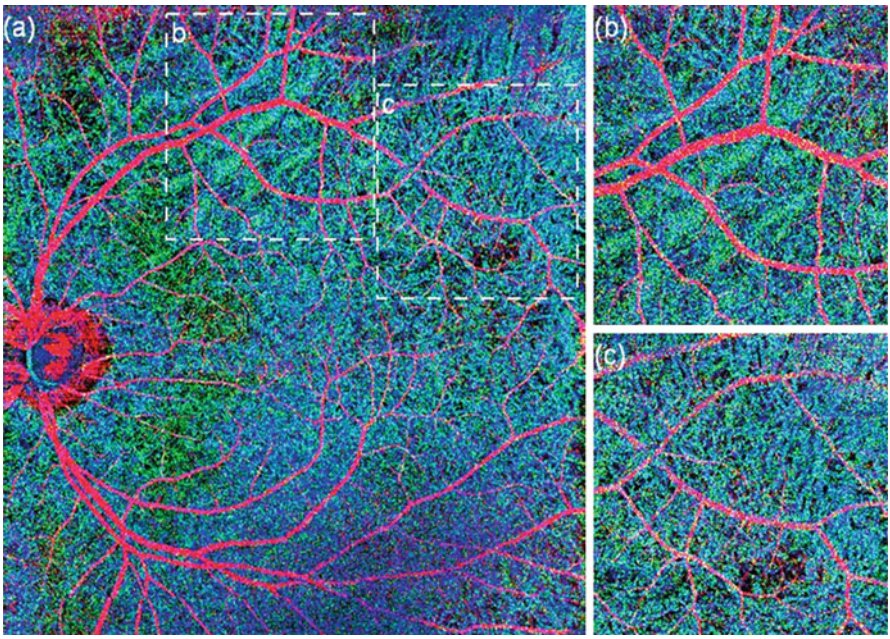

Fig. 42.9 (Color online) color-coded en-face mean projection of the retinal and choroidal vasculature. (**a**) ∼48° depth-resolved angiogram. (**b** and **c**) Zoom showing large choroidal vessels and fine vasculature [48]. The colors code depth ranges as indicated in Fig. 42.8 (**b**)

Figure 42.9 shows a color-coded combined representation of the segmented en-face mean projections for the retina and choroid according to Fig. 42.8b. It is possible to resolve simultaneously retinal and choroidal vessels. The high lateral sampling allows revealing also small vessels and fine network as shown in Fig. 42.9c. The choroid exhibits different kinds of vessels along depth. Close below the RPE, a dense network of small choroidal vessels is visible (Fig. 42.9c). In deeper regions, the vessel size increases (Fig. 42.9b). The low contrast region in the picture lower part is the result of low signal in the original intensity tomograms due to iris shading (cf. Fig. 42.9a, black arrow).

Small retinal capillaries, particularly in the parafoveal region, are only weakly visible. This is due to the coarse sampling. Nevertheless, the current protocol would provide a first widefield overview that can then be used as guide to focus on a suspicious area or a region of interest. Figure 42.14 shows a ∼12° FOV centered on the fovea acquired with the same parameters as for the large FOV. The lateral resolution is obviously sufficient to contrast also small parafoveal capillaries efficiently (Fig. 42.10b, c) in the en-face mean projection of the intensity variance data set while absent of the intensity projection (Fig. 42.10a). Furthermore, choroidal vessels are well appreciated (Fig. 42.10d). It is however difficult to resolve single choroidal vessels in the fovea region due to the dense vascular network directly underneath the RPE. The latter also shades the variance signatures of deeper

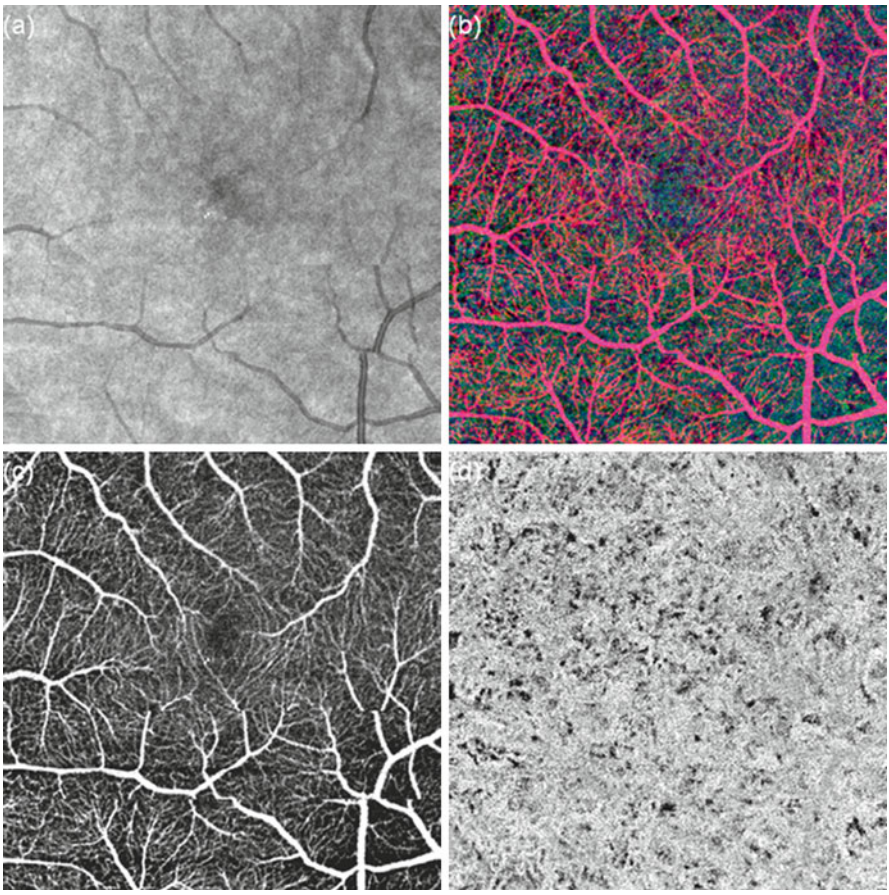

Fig. 42.10 (Color online) ∼12° FOV centered at the fovea. (**a**) Pseudo-SLO fundus obtained by en-face mean projection of the intensity data set. (**b**) Color-coded en-face mean projection of the retinal and choroidal vasculature. (**c**) Retinal vasculature. (**d**) Choroidal vasculature [48]

choroidal vessels in the en-face view. Faster B-scan rates could decrease the variance signal of the choriocapillary layer and enhance the contrast of larger vessels underneath. This has been demonstrated employing a dual-beam technique [49, 50].

Given the quality and level of detail of DOCT angiography images, this technique could be a natural candidate for replacing fluorescein and ICG fundus angiography. Being fully noninvasive, it could serve to screen large populations which would help early diagnosis of ocular diseases. It also allows frequent disease and treatment monitoring of the same patient and does not require especially qualified personnel. This would further significantly cut down social costs, and patients could be treated early on, avoiding in many cases critical degeneration of neural tissue.

42.4.2 Ocular Doppler Imaging with Joint STdOCT

In 2009, Szkulmowska et al. [51] presented quantitative and qualitative visualizations of retinal vessels in the human eye based on the STdOCT approach. A scanning protocol, shown in Fig. 42.11a, permitted the acquisition of 100 B-scans with 2,200 A-scans each.

This enabled the development of a 3D data set containing 100 tomograms with 546 lines each, using the sliding window technique for selecting the spectra for STdOCT processing, shown in Fig. 42.11b. Both structural and velocity profiles were obtained using the STdOCT approach as described above. Two sampling densities were applied and led to either a 5×5 mm or a 3×2 mm imaging area as shown in Fig. 42.11c. One of the most important limitations of Doppler measurements in vivo is the presence of involuntary object motion – so-called bulk motion. Because the shape of the Doppler spectrum for the bulk motion (offset of the Doppler spectrum) is usually different than the one for the blood flow (continuously varying profile), those two components are easily distinguishable by STdOCT approach (Fig. 42.12). Therefore, STdOCT enables a straightforward way of bulk motion removal by simple identification of the offset in the Doppler profile and numerical correction of the OCT signals.

Figures 42.13a–c show the morphological image with the bulk motion compensation, the axial velocity Doppler maps, and angiographic cross sections, respectively. In order to obtain the improvement of contrast in visualization of the blood vessels (Fig. 42.13c), we used a binary mask (obtained by thresholding of the modulus of the velocity value) and applied the mask to the morphological cross-sectional image.

These three types of signal processing give comprehensive 3D visualization of the blood vessel network and enable the creation of quantitative and qualitative maps of retinal vasculature (Fig. 42.14).

Another important constraint in Doppler OCT imaging is limitation in detectable Doppler bandwidth once the OCT signal is detected with classical raster scanning pattern. This shortcoming can be overcome by using smart scanning protocols with sinusoidal trajectory (Fig. 42.15) of the light beam on the sample applied to STdOCT by Grulkowski et al. in 2009 [52]. Since the maximal detectable velocity is inversely proportional to the time span between the A-scans used for Doppler analysis, this allowed for simultaneous estimation of blood flow velocity in two velocity ranges from the same data set. Figure 42.15a shows an example of application of the smart scanning protocol to retinal imaging – in the proximity of the nerve head. The use of such scanning protocols allows for quantitative measurement of axial velocity component in large retinal vessels in Fig. 42.15c and small capillaries, Fig. 42.15d, when small velocity range is chosen for calculations.

In the same publication, authors demonstrated a visualization of a retinal capillary network with small velocity range detection [52]. Five A-scans from adjacent B-scans were selected for the STdOCT analysis. This allowed the observation of

flows with an axial velocity smaller than 220 μm/s in an area of 1.2 × 1.2 mm. A 3D visualization of the capillaries allowed the creation of qualitative angiographic maps, seen in Fig. 42.16a–c, along with quantitative axial velocity maps, depicted in Fig. 42.16d–f from different retinal layers.

42.4.3 Application of DOCT to Dermatology

The application of OCT to dermatology is generating raising interest because of the previously mentioned advantages. Several studies have already been conducted to investigate inflammatory skin diseases, such as dermatitis, or skin cancer, such as basal cell carcinoma [53]. They were however limited to analysis of structural changes assessed from OCT intensity pictures alone. The capability of OCT to visualize also the vascular network has the capacity to provide complementary information related to the important metabolic tissue demand.

We have seen several techniques using OCT to contrast blood vessels in ▶ Chap. 2, "Theory of Optical Coherence Tomography", but few were applied to human skin microvasculature imaging in vivo. Although first 2D and 3D images of single vessels section have been presented already with time domain OCT [17, 54], the limited acquisition speed prevented the measurement of larger vasculature patches. The development of Fourier domain OCT brought a dramatic increase in sensitivity, which made in vivo full volume measurement with short acquisition time possible [18, 19]. Human skin microcirculation imaging based on Fourier domain OCT was demonstrated by calculating the intensity-based Doppler variance [55]. An enhanced field of view (FOV) of up to 8 × 7 mm was shown by correlation mapping OCT [56]. Based on the method of ultrahigh-sensitive optical microangiography (UHS OMAG) [57], differences in the blood vessel network between normal skin and psoriatic skin conditions have been resolved [58].

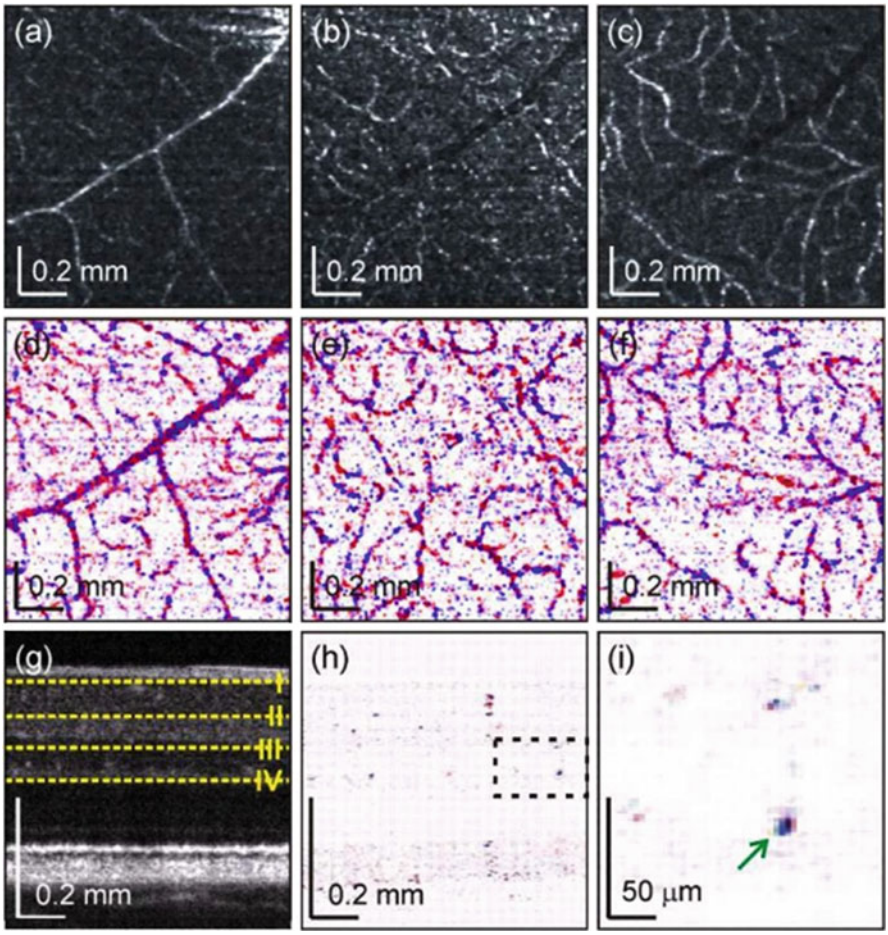

Fig. 42.16 STdOCT imaging of retinal capillaries. (**a**–**c**) The projection of OCT fundus images generated for depth ranges between boundaries I–II, II–III, and III–IV, respectively. These are shown as *yellow dashed lines* in panel (**g**). (**d**–**f**) The flow maps at the depth ranges visualized in the projection OCT fundus images. (**g**) Cross-sectional OCT image; the *dashed yellow lines* indicate boundaries of depth ranges used for projection OCT fundus imaging. (**h**) Example cross-sectional flow image extracted from the 3D data at a location indicated by the *dashed line* in panel (**f**). (**i**) Enlarged image of capillaries indicated by the *dashed rectangle* in panel (**h**); the *green arrow* points to a capillary with colors encoding the velocity value and direction ranging from *blue* to *red*. The *scale bars* in images (**a**–**h**) indicate lengths 200 μm by 200 μm and in image (**i**), 50 μm by 50 μm [52]

In the following, label-free angiography of skin using an extended focus OCT (xf-OCT) system [59] is demonstrated. xf-OCT that is based on Bessel beam illumination provides an enhanced depth of focus as compared to standard Gaussian illumination. This system operates further at a center wavelength of 1,300 nm for optimal penetration into skin tissue [60]. It is based on swept source OCT and

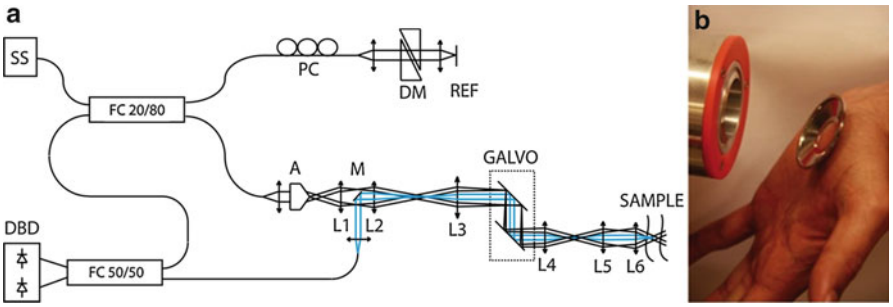

Fig. 42.17 (**a**) Optical setup of the xf-OCT system. *Blue*: detection path. *SS* Swept source, *FC* fiber coupler, *PC* polarization control, *DM* dispersion matching, *A* axicon, *M* mirror, *L1 to L6* lenses, *Galvo* scanning mirrors, *DBD* dual-balanced detector. (**b**) Adapter plate, containing a cover glass window, taped on a hand palm, in front of the mating ring that surrounds the objective lens on the *left* [35]

provides high-speed imaging by employing a Fourier domain mode-locked (FDML) laser [61]. The optical setup (Fig. 42.17a) for extended focus OCT imaging is the same as the one previously published [62]. An axicon lens creates a Bessel intensity distribution that is relayed on the beam steering device and further in the objective back focal plane to produce a Bessel beam illumination on the sample. Backscattered light is collected by a path-decoupled Gaussian mode. The lateral point spread function of the system is thus a Gaussian apodized version of the Bessel beam. The lateral resolution can be evaluated from its $1/e^2$ lateral extend to be of ~6 μm, constant over an axial distance of ~500 μm. For skin imaging, an adapter plate containing a cover glass window of 150 μm thickness is centered on the lesion and then taped on the skin. The adapter plate is then fixed via a mating ring in front of the sample objective (L6) keeping the region of interest centered to the scanning beam (Fig. 42.17b).

Microcirculation imaging was performed over a 2 × 2 mm FOV by acquiring $N = 10$ tomograms at 100 different vertical positions. The number of 10 tomograms is an empirical value selected such as to have on the one hand high microcirculation contrast and on the other hand enough data for motion contrast analysis after rejection of patient motion affected tomograms. In addition, we aimed at keeping the measurement time as short as possible. Each tomogram contains 800 A-scans. The acquisition was performed at 220kA-scans/s leading to a measurement time of about 4 s. In a second step, a highly sampled volume consisting of 800 tomograms, without any redundancy, was acquired.

The microvascularization of the palm of a healthy volunteer is used for indication of a normal condition. Figure 42.18a is a representative tomogram of the referred location visualizing the characteristic layers of a glabrous skin. Figure 42.18b, c show the en-face microvascularization for two different depth ranges, 300–350 μm and 350–450 μm, respectively. A mean projection is calculated over successive axial ranges in order to resolve two different kinds of vasculature: capillary loops feeding the living part of the epidermis and a deeper

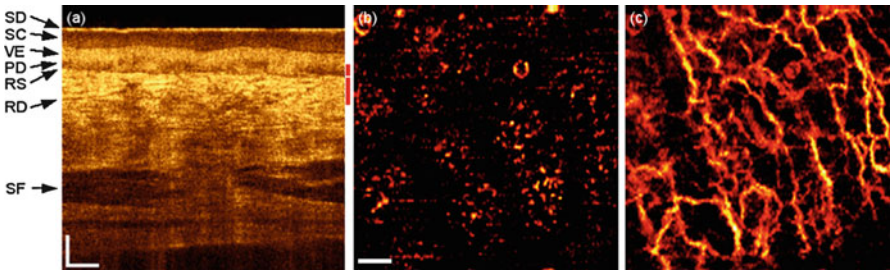

Fig. 42.18 Healthy skin of the palm. (**a**) OCT tomogram. *Red bars* indicate depth range for (**b**) and (**c**), respectively. *SD* stratum disjunctum, *SC* stratum corneum, *VE* viable epidermis, *PD* papillary dermis, *RS* rete subpapillare, *RD* reticular dermis, and *SF* subcutaneous fat. (**b** and **c**) 2 × 2 mm en-face mean projection over depth range indicated in (**a**) *scale bars* indicate 250 μm in every picture [48]

planar vascular network that supports the capillary vessels. The vasculature images are thresholded to reduce the background noise. This may however lead to missing signals visible as discontinuities along the contrasted vascular network.

The vascular pattern is visually different for pathological conditions. The case presented in Fig. 42.19 is an allergy-induced eczema on the forearm. A dermascope is used to acquire a reflectance picture of the lesion over a large FOV. Figure 42.19a shows the lesion and indicates the FOV of OCT. Dilated vessels and scaly patches are visible; however, the resolution does not permit to resolve the finer vascular network. Furthermore, no depth information is available. The OCT tomogram in Fig. 42.19b shows increased perfusion and vasculature visible through increased shadowing artifacts as compared to the healthy case. An en-face mean projection of the highly sampled intensity volume is displayed in Fig. 42.19c. Complementary information is provided by the OCT angiograms obtained with the squared intensity difference method. Figure 42.19d shows a microvasculature en-face mean projection image of the dermoepidermal junction, displaying cross sections of superficial vertical capillary loops. The perfusion signatures of those capillaries are larger in diameter than those of the healthy control due to increased perfusion in the inflammation region. Relative change of perfusion can be inferred by our technique from visible vessel size changes. Also, the inflammation causes an alteration of the tissue structure that obviously leads to larger lateral distances between the capillary loops. The red areas in the dermoscopy image are diagnosed as subcutaneous bleeding caused by scratching. It is expected that the blood visible with the dermascope should also be visible in the OCT tomogram because of the intrinsic stronger backscattering of blood. We observe in fact that the red areas of subcutaneous bleeding in the dermoscopy image correlate well with the regions of enhanced backscattering seen in the OCT tomograms and marked with the asterisk in Fig. 42.19b. Those areas do not appear in the motion contrast angiogram, since the subcutaneous blood is basically static. Figure 42.19e shows an overlay of the microcirculation on the structural information. Note that both pieces of information are extracted from the same data set, resulting in a perfect registration.

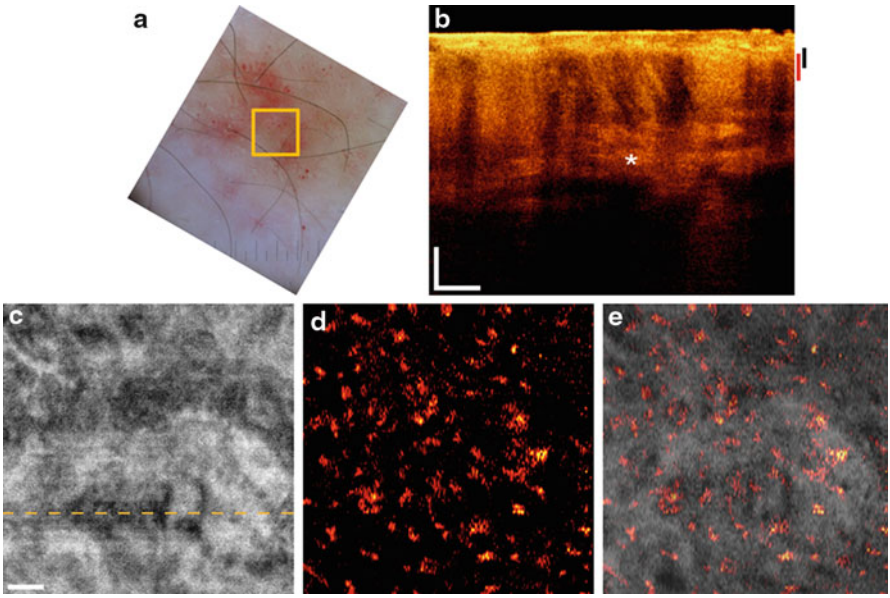

Fig. 42.19 Eczema on the forearm. (**a**) Dermoscopy image with square indicating the OCT FOV. (**b**) OCT tomogram. *Black* and *red bars* indicate depth range for (**c**) and (**d**), respectively. (**c**) Intensity en-face mean projection for depth range in (**b**), *dashed line* indicates the tomogram position. (**d**) 2 × 2 mm en-face view of angiography. (**e**) Overlay of microcirculation on structural information. *Scale bars* indicate 250 μm in every picture [48]

The presented case is a nice example of how complementary information given by structural as well as angiographic method helps for a better interpretation and understanding of the tissue pathology.

Finally, a case of nonmelanoma skin cancer is presented – basal cell carcinoma (BCC) on the forehead. Dermoscopy (Fig. 42.20a) reveals characteristic arborizing vessels, which are seen in 50–70 % of BCCs [64]. The tomogram has a different signature, particularly in the epidermis region resembling the rolled border of the tumor caused by tumor cell aggregations surrounded by fibrous stroma (Fig. 42.20b). The dark areas in the deeper regions visible in the OCT tomogram are possibly necrotic or cystic regions. The OCT microvasculature imaging reveals a dense network of unorganized vessels (Fig. 42.20d). Furthermore, large vessels are abnormally present close to the surface. The large vessels branch out to provide the perfusion support through the smaller secondary vessels to the tumor sites with high metabolic demand.

Due to our additional completely noninvasive motion contrast modality, we obtain further complementary information on the angiographic properties of the skin diseases. The measurements performed on different pathological conditions clearly indicate abnormal and characteristic signatures of the vasculature (see Table 42.1).

Noninvasive vascular imaging has certainly large potential for treatment monitoring by providing, for example, information on antivascular treatment effectiveness, in case of photodynamic therapy. This imaging technique could also be used to assess the

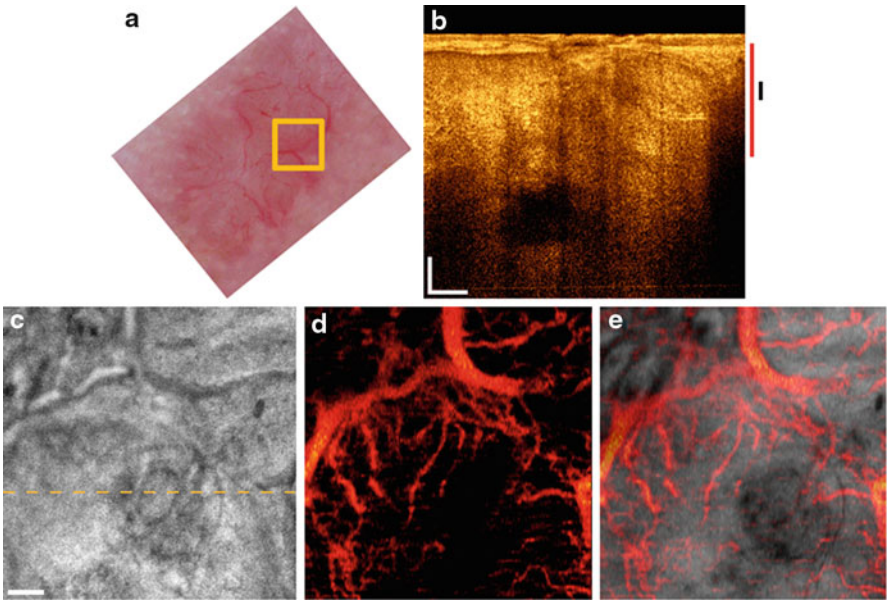

Fig. 42.20 BCC on the forehead. (**a**) Dermoscopy image with *square* indicating the OCT FOV. (**b**) OCT tomogram. *Black* and *red bars* indicate depth range for (**c**) and (**d**), respectively. (**c**) Intensity en-face mean projection for depth range in (**b**), *dashed line* indicates the tomogram position. (**d**) 2 × 2 mm en-face fly through the microvasculature starting from surface (media 4). (**e**) Overlay of microcirculation on structural information. *Scale bars* indicate 250 μm in every picture [35]

Table 42.1 Comparison between the different pathological conditions [35]

Condition	Effect on microcirculation
Healthy	Organized flat vessels beds with smaller capillary vessels in the upper layers and increased vessel size in deeper skin tissue
Inflammation	Enlarged blood vessels, in particular capillaries that indicate increased perfusion
Basal cell carcinoma	Denser network of unorganized vessels with chaotic branching, larger vessels even close to the skin surface, capillary structure less pronounced and visible

stage of the disease not only qualitatively but also quantitatively. Analysis on vessel density or the fractal dimension of the vascular tree can potentially give more precise information about the severity and progression of the disease [11, 12, 64].

42.5 Outlook

In the present chapter, we aimed at providing a brief summary of Doppler FdOCT applied to vascular contrasting with examples of ophthalmic and dermatology OCT

imaging. Future directions in ophthalmology will certainly include OCT intensity information in order to complement the dynamic flow contrasting also with static information. Tracking systems as well as smart registration algorithms will further improve the quality of flow contrast images by reducing motion artifacts. Also in case of dermatology, the access to functional perfusion data will enhance the diagnostic capabilities of current OCT scanners. Perfusion is an important biomarker for tissue health and can therefore be applied for assessing wound healing and treatment progression. Apart from the skin and the eye, DOCT is extensively used for brain imaging. Further applications of DOCT can be envisioned in the field of endoscopy. Finally, new light source and detector technology might open the door for novel DOCT methods that allow for even faster vascular imaging over larger field of views.

43.1 Introduction

The ocular vasculature and circulation play a crucial role in the development of several eye diseases including glaucoma [1], diabetic retinopathy [2], and exudative macular diseases [3]. Modalities that are capable of investigating the ocular vasculature and circulation are important for both understanding the mechanisms of the diseases and diagnosing these diseases.

The current chief modality for this purpose is angiographies including fluorescein angiography (FA) and indocyanine green angiography (ICGA) [4]. In these angiographies, ocular vessels are contrasted using the fluorescence of dyes injected into a vein. The fluorescent dye utilized in FA is sodium fluorescein and that of ICGA is indocyanine green. Since the excitation wavelength of indocyanine green is relatively longer than that of sodium fluorescein, ICGA is commonly used for the investigation of choroidal vasculature, while FA is used to investigate abnormalities of the retinal vasculature and retinal pigment epithelium (RPE). Although the utility is very high, these modalities are invasive and have some adverse reactions. For instance, the skin will be colored in yellow by the fluorescein dye. Furthermore, moderate adverse effects, such as nausea and vomiting, occur with frequencies of less than 1 % and 10 %, respectively, for FA [5] and 0.15 % for ICGA [6]. In addition, although it is rare, severe adverse effects such as anaphylaxis also occur.

In addition to angiography methods that are used to investigate the ocular vasculature, there are several noninvasive blood flow assessment techniques that use lasers. Laser Doppler velocimetry (LDV) measures the blood flow velocity, and it has been applied to human retinal vessels [7, 8]. Microcirculation in the optic nerve head (ONH) [9] and the choroidal blood flow [10] of the human eye have been investigated with laser Doppler flowmetry (LDF) [11], which acquires the volume, flux, and average velocity of the red blood cells in the small vessels surrounded by the scattering tissues. Two-dimensional perfusion mapping of blood flow can be obtained using scanning laser Doppler flowmetry (SLDF) [12, 13], laser speckle photography [14], and laser speckle flowgraphy [15]. Although these techniques are useful for investigating the ocular circulation, they demonstrate no or poor ability to resolve the depth structure. SLDF, which is based on scanning laser ophthalmoscopy, exhibits depth-resolving power inherently due to the confocal effect; however, its axial resolution is limited to around 300 μm due to the limited numerical aperture and the aberrations of the eye.

Doppler optical coherence tomography (Doppler OCT), which is also denoted as optical Doppler tomography, is an extension of OCT [16, 17]. Doppler OCT measures the Doppler shift of the probe beam in OCT and enables depth-resolved cross-sectional flow imaging of in vivo tissues [18–22] and has also been applied for the investigation of retinal vessels. Among several variations of Doppler OCT, phase-resolved Fourier domain (FD) Doppler OCT [23–25] has become the most commonly used Doppler OCT technique, because of the recent success of FD-OCT. Phase-resolved FD Doppler OCT provides high-resolution, high-speed, and three-dimensional (3-D) imaging of retinal blood flow [26–28].

The phase-resolved FD Doppler OCT has been utilized for both quantification of ocular circulation [29–31] and structural imaging of ocular vasculatures [32]. The latter is sometimes denoted as optical coherence angiography (OCA) or OCT angiography. OCA is an OCT-based alternative to standard angiography including FA and ICGA. Although its contrast mechanism is not the same as FA and ICGA, OCA images have shown high similarity with FA and ICGA [33]. In contrast to FA and ICGA, OCA is totally noninvasive. Hence, it can be utilized not only for standard clinical diagnosis but also for mass screening. In addition, the depth resolution of OCA enables separate retinal and choroidal angiograms and three-dimensional examination of the ocular vasculature.

In order to enhance the flow sensitivity of Doppler OCT and hence to investigate the fine vasculature with OCA, several extended Doppler measurement protocols have been presented. In the most standard phase-resolved FD Doppler OCT measurement, the Doppler shift signal is given as the phase difference between adjacent A-lines in a single OCT cross-section [24]. Since the Doppler shift of the probe beam is proportional to this phase difference, the phase difference of the OCT cross-section provides a cross-sectional Doppler OCT image. In this process, the phase difference is not only in proportion to the Doppler shift but also the time interval between the two A-lines.

Hence, a larger time interval provides a larger phase difference even with an identical Doppler shift. Since the phase noise of the OCT is not a function of the time interval, a larger time interval between adjacent A-lines provides a higher Doppler sensitivity for OCA.

However, there is another factor that degrades the Doppler sensitivity. Since Doppler OCT is a scanning imaging modality, the larger time interval between adjacent A-lines results in larger spatial separation between the A-lines. It causes large structural decorrelation between the A-lines and degrades the Doppler sensitivity. Therefore, the ideal scanning protocol for high-sensitive OCA imaging is a method that scans the same location of the sample twice with a large time interval.

Dual-beam Doppler OCA (DB-OCA) is a solution to enable this ideal scanning protocol [34–38]. DB-OCA uses two probe beam spots, where one spot follows the other spot during a retinal scan. Hence, a single location on the retina is scanned twice with a particular time interval that is in proportion to the spatial separation of the two probe spots. Subsequently, the Doppler phase difference is defined as a phase difference between the two A-lines obtained by the two spots. In this scheme, the time interval can be configured to be very large, while the spatial decorrelation can be kept very small or even negligible, because the two A-lines were obtained at the same location on the retina. Owing to this property, DB-OCA provides very high-sensitive Doppler imaging of the human eye in vivo.

This chapter describes the principle, implementation, and applications of DB-OCA. Among several implementations of DB-OCA, a standard spectral domain DB-OCA using polarized multiplexed dual-probe beams at 840 nm is described. As examples of the application, fine vasculature imaging of a normal macula and a case of abnormal vasculature, i.e., polypoidal choroidal vasculopathy, are presented. The standard DB-OCA is known to suffer from an artifact that occurs with the birefringence of the sample. An extension of DB-OCA, which is free from this artifact, is also described in detail.

Finally, a short summary of several extensions of DB-OCA is provided with pointers to references. The extensions include another multiplexing method for probe beams, high-penetration imaging by using a 1-μm wavelength probe, and a DB-OCA system with variable detectable flow velocity.

43.2 Principle and Implementation

43.2.1 Phase-Resolved Doppler Optical Coherence Tomography

The detailed principles of standard phase-resolved Doppler OCT exceed the scope of this chapter and have been extensively described elsewhere [23–25]. Hence, here we describe only the essential principles of phase-resolved Doppler FD-OCT, which are crucial for understanding DB-OCA.

In phase-resolved Doppler FD-OCT, the Doppler frequency shift is computed from the phase difference between two A-lines that have been acquired at nearly the same location of the sample but with a time interval of τ. Therefore, the mean Doppler frequency shift at a given sample location (x, y, z) between time t and $t+\tau$ is given by

$$\Delta f(x,y,z,t) = \frac{1}{2\pi\tau}\mathrm{Arg}\left[\Gamma_1(x,y,z,t)\Gamma_2^*(x+\Delta x,y,z,t+\tau)\right] \tag{43.1}$$

where $\Delta f(x, y, z)$ is the mean Doppler frequency shift between time t and $t+\tau$ and at a sample location of x (fast scan direction), y (slow scan direction), and z (depth). $\Gamma_1(x, y, z, t)$ and $\Gamma_2(x + \Delta x, y, z, t + \tau)$ are the complex OCT signals of the first and second A-lines. Δx is the spatial displacement between the two A-lines and is now assumed to be negligibly small in comparison to the transversal resolution of OCT. The subscript of * indicates a complex conjugate.

The Doppler frequency shift $\Delta f(x, y, z, t)$; Doppler phase shift $\Delta\varphi(x, y, z, t)$, i.e. the phase difference between the two A-lines $\mathrm{Arg}[\Gamma_1(x, y, z, t)\Gamma_2^*(x + \Delta x, y, z, t + \tau)]$; and the sample velocity are related as

$$\Delta\phi(x,y,z,t) = 2\pi\tau\Delta f(x,y,z,t) \tag{43.2}$$

$$\Delta\phi(x,y,z,t) = \frac{4\pi n\tau}{\lambda_0}v_z \tag{43.3}$$

where n is the refractive index of the sample, λ_0 is the center wavelength of the probe beam, and $v_z = v\cos\theta$ is the axial component of the velocity of the sample with the sample velocity of v and the angle between the probe beam and the direction of the motion θ. Equation 43.2 indicates that, even with a same velocity, the Doppler phase shift $\Delta\varphi(x, y, z)$ becomes larger with a lager τ. Hence, a larger τ provides a better signal-to-noise ratio for Doppler phase detection and consequent higher Doppler sensitivity when the phase noise of the OCT is constant in respect to τ.

However, in standard OCT implementation, the phase noise is not constant in τ. In the discussions above, we have assumed the spatial separation of two A-lines, Δx, is negligibly small. Meanwhile, in standard Doppler OCT, Δx and τ are related as $\Delta x = v_s\tau$ with v_s of the transversal scanning velocity of a probe spot on the sample. Hence, the assumption of a small Δx is no longer valid with a large τ. The larger Δx is known to increase the phase noise [39, 40]. As a result, a large τ enhances the Doppler phase shift but also increases the phase noise.

This property of Doppler OCT suggests that a possible Doppler OCT system that enables a large τ with a small Δx would be an ideal system to provide high Doppler sensitivity. DB-OCA described in this chapter is an extension of Doppler OCT, which provides this condition and hence enables very high Doppler sensitivity.

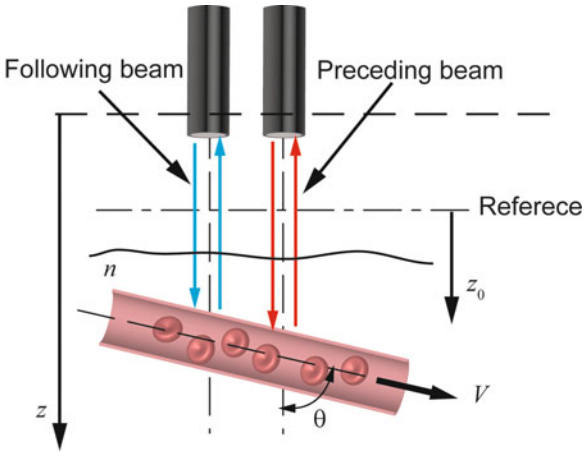

Fig. 43.1 The detection scheme of DB-OCA

43.2.2 Principle of Dual-Beam Doppler Optical Coherence Tomography

DB-OCA utilizes a Doppler detection scheme measuring the single Doppler frequency shift from two backscattered lights associated with two probe beams. The two probe beams have the same scanning speed and are spatially separated on the sample in the scanning direction as depicted in Fig. 43.1. Through the scanning of probes over the sample, the electric fields of lights, $E_p(x, y, z, t_p)$ and $E_f(x, y, z, t_f)$, are backscattered from a position (x, y, z) in the sample and are collected at different times, t_p and t_f, where the subscripts of p and f denote preceding and following probes, respectively. Spectrally resolved interference signals between collected lights and the reference light are detected and Fourier transformed into complex OCT signals, $\Gamma_p(x, y, z, t_p)$ and $\Gamma_f(x, y, z, t_f)$ [23]. Since the motion of the sample causes a Doppler frequency shift $\Delta f(x, y, z)$, it modulates the complex OCT signals as

$$\Gamma_p(x, y, z, t_p) = \Gamma'_p(x, y, z)\exp\left[i2\pi\Delta f(x, y, z)t_p\right] \tag{43.4}$$

$$\Gamma_f(x, y, z, t_f) = \Gamma'_f(x, y, z)\exp\left[i2\pi\Delta f(x, y, z)t_f\right] \tag{43.5}$$

where $\Gamma'_f(x, y, z)$ and $\Gamma'_f(x, y, z)$ are the time-independent components of the preceding and following probes, respectively. Using the same wavelength for the two probes, we can assume $\Gamma'_f(x, y, z) = \Gamma'_f(x, y, z)$. Under this circumstance, the Doppler frequency shift is obtained by calculating the phase difference between $\Gamma_p(x, y, z, t_p)$ and $\Gamma_f(x, y, z, t_f)$ as

$$\Delta f(x, y, z) = \frac{1}{2\pi\tau}\mathrm{Arg}\left[\Gamma_p(x, y, z, t_p)\Gamma_f^*(x, y, z, t_f)\right] \tag{43.6}$$

where the time interval $\tau \equiv t_f - t_p$. When the spatial separation of the two probes on the sample is d and the scan speed of the probe is v_s, τ is configured to be $\tau = d/v_s$. Since d can be arbitrarily configured using a proper optical design, τ can also be arbitrarily selected. By selecting a large τ, as suggested by Eq. 43.3, we can enlarge the Doppler phase shift value. In addition, two OCT signals utilized in the Doppler calculation in Eq. 43.6 were obtained at the same location in the sample. Namely, Δx that appears in the standard Doppler OCT equation (Eq. 43.1) becomes zero. Hence, phase noise elevation with a large Δx does not occur. Due to these properties, DB-OCA enables extremely high-sensitive Doppler OCT detection.

43.2.3 Implementation of Dual-Beam Doppler OCA

DB-OCA can be implemented by several means including Wollaston prism-based polarization multiplexing [34], polarization multiplexing with a polarization beam splitter [38], and an interferometer multiplexing method [35]. In this section, we describe the Wollaston-based polarization multiplexing method as the simplest examples. Some of the other implementations and extensions of DB-OCA are described in a later section.

43.2.3.1 Hardware Implementation

The instrumentation diagram of DB-OCA is presented in Fig. 43.2. In this setup, two probing beams are multiplexed in two orthogonal polarization states. The light source is a superluminescent diode (SLD-37-HP, Superlum Diodes Ltd., Ireland, in this example) with a center wavelength of 840 nm and spectral bandwidth of 50 nm (full width at half-maximum: FWHM). The beam from the light source propagates in a single-mode (SM) fiber and passes through an isolator and then a polarization controller. The light is split into the fast and slow modes in the polarization-maintaining (PM) fiber. The interferometer consists of a PM fiber coupler. In this particular example, the splitting ratio of the coupler is 80/20 with 20 % going to the sample arm.

Two polarization modes are separated by a Wollaston prism in the probing arm. The separation angle of the Wollaston prism is 0.35°. Two polarization modes independently propagate in the system. The separation of two modes on the cornea becomes 0.684°. After passing the eye optics, the two polarization modes form two probe light spots on the retina and are backscattered. The backscattered lights are combined again by the Wollaston prism and introduced to a polarization-sensitive spectrometer through a PM fiber. The two backscattered lights from the sample are independently detected by a polarization-sensitive spectrometer [41]. In this spectrometer, a polarization beam splitter divides the two polarization modes, and two-line scan cameras (AViiVA M2 CL 2014, e2V) detect each mode. The acquisition rate of the camera is 27, 778 lines/s.

The polarization controller in the SM fiber regulates the polarization state at the connection between the SM and PM fibers to ensure identical optical powers in each mode and the same sensitivity in both polarization channels. The optical

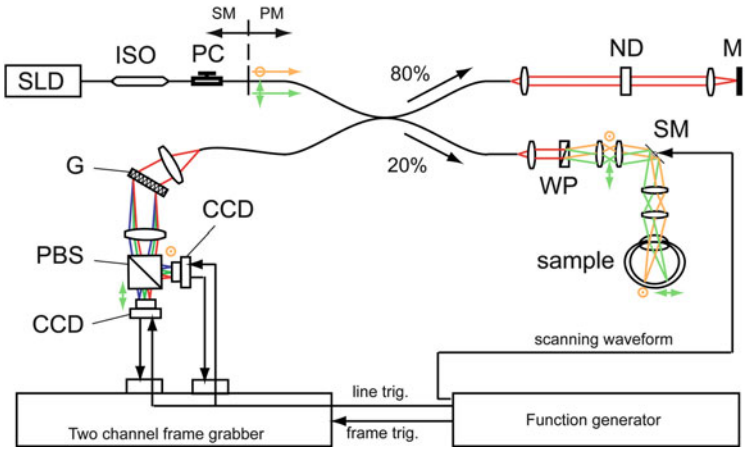

Fig. 43.2 Instrumentation scheme of DB-OCA based on spectral domain optical coherence tomography uses a superluminescent diode (*SLD*). Orthogonal polarization states are separated and independently propagated inside a polarization-maintaining (*PM*) fiber 80/20 coupler. They are separated spatially on the sample using a Wollaston prism (*WP*) and scanned by a scanning mirror module (*SM*). Reference beams are attenuated by a neutral density filter (*ND*) and reflected by a mirror (*M*). The reference arm should exhibit no birefringence to avoid crosstalk between the two channels. Interference signals of each polarization state are detected by a polarization-sensitive spectrometer consisting of a grating (*G*), polarization beam splitter (*PBS*), and two-line scan CCD cameras (*CCD*). The cameras are synchronously driven by the same trigger from a function generator through a frame grabber

power on a sample is 370 μW for each polarization mode. The total power is 740 μW, which is lower than the safe exposure limit according to the ANSI standard (Z136.1) [42].

In this particular example, the predicted shot-noise-limited sensitivity is 100 dB with an integration time of 34.8 μs. The sensitivity was measured as 94 dB and 93 dB for each channel, which was approximately 6 dB lower than the shot-noise-limited sensitivity. This is reasonable since the optical power loss of the system was measured as 6.5 dB, which may be due to the loss at fiber re-coupling, polarization crosstalk in optical components, and the alignment error of the mirror sample for sensitivity measurement because of the difficulty in aligning the mirror for both separated sampling beams. The beam diameter at $1/e^2$ on the cornea is about 820 μm. The beam spot diameter on the retina is around 13 μm (FWHM). The axial resolution of approximately 8 μm (FWHM) in air is achieved.

43.2.3.2 Processing of Flow Signal

In the signal processing procedure, the two OCT signals obtained by the preceding and following probes are accurately co-registered and aligned to each other. The lateral alignment is performed by accounting the time interval between the two probe beams. A fiber length mismatch between the sample and reference arms and the resulting group delay mismatch between the two polarization channels

of the PM fiber cause axial displacement between the two OCT signals. The variance of the phase difference of two OCT signals, which takes its minimum when the axial displacement is canceled, is utilized for the axial alignment. The axial displacement was determined during the system calibration process by minimizing the phase variance of OCT signals obtained from a static turbid phantom. The axial displacement of two OCT images of a real sample, e.g., a retina, is then numerically canceled according to this predefined amount of axial displacement.

After the alignment process, the Doppler phase shift between these two OCT images is obtained using the Kasai autocorrelation with complex averaging as

$$\Delta\phi\left(x_i, z_j\right) = \mathrm{Arg}\left[\sum_{k=1}^{M}\sum_{l=1}^{N}\Gamma_f\left(x_{i+k+m}, z_{j+l}\right)\Gamma_p^*\left(x_{i+k}, z_{j+l}\right)\right] \tag{43.7}$$

where Γ_p and Γ_f are complex OCT signals obtained with the preceding and following probes, respectively. i and j are lateral and axial indices of pixels, m is the number of axial scans acquired in the time interval between the two probes τ, and M and N are lateral and axial window sizes, respectively.

43.2.3.3 Image Processing for Angiographic Visualization

One important post-image process to generate an OCA image is removing the low signal region. Since the low signal-to-noise ratio exhibits a random phase distribution, it disturbs flow images and significantly degrades the clinical utility of OCA.

In order to enhance the signal-to-noise ratio of OCA, the Doppler phase shift at the pixels that have lower average autocorrelation amplitudes $g(x_i, z_j)$ is masked out and set to zero, where $g(x_i, z_j)$ is defined as

$$g\left(x_i, z_j\right) \equiv \frac{1}{MN}\left|\sum_{k=1}^{M}\sum_{l=1}^{N}\Gamma_f\left(x_{i+k+n}, z_{j+l}\right)\Gamma_p^*\left(x_{i+k}, z_{j+l}\right)\right| \tag{43.8}$$

In the random noise region, the complex signals at the pixels in the averaging window cancel each other, and $g(x_i, z_j)$ approaches zero. On the other hand, in the region with significant signal strength, $g(x_i, z_j)$ takes a relatively large value. Hence, by applying a low threshold value, the noise region and signal region are effectively classified.

As for additive white noise, SD-OCT noise is a zero-mean circular Gaussian variable in a complex plane. On the other hand, its amplitude is no longer a Gaussian variable but a random Rayleigh variable. In contrast, Eq. 43.8 contains an amplitude of product of an OCT signal and the complex conjugate of another OCT signal, and hence its noise distribution becomes a double-Rayleigh distribution [43]. According to the statistical property of OCT amplitude, the mean and standard deviation of the amplitude of the auto-correlation at the noise region are $\mu_a = \pi\sigma^2/4$ and $\sigma_a = \sqrt{16 - \pi^2}\sigma^2/4$, respectively, where σ is the standard deviation

of amplitude noise in the OCT signal. Using μ_a and σ_a, the pixels to be masked are determined as:

$$\Delta\phi'(x_i, z_j) = \begin{cases} \Delta\phi(x_i, z_j) & : \quad g(x_i, z_j) \geq \dfrac{\mu_a + \alpha\sigma_a}{\sqrt{MN}} \\ 0 & : \quad \text{otherwise} \end{cases} \tag{43.9}$$

where α is a constant factor and set as 4 or 6 in for the cases described in Sect. 43.3.

A squared Doppler phase shift is calculated from the result of Eq. 43.9 and is used for qualitative vasculature imaging. Projection images, i.e., *en face* OCA, are created by integrating the squared phase shift along the depth. By applying a retinal layer segmentation algorithm [32], two en face OCAs are created for the retina and the choroid. Stereograms, which are pairs of projections from slightly different angles, also can be created to provide a three-dimensional distribution of the vasculature.

43.3 Application to the Human Eye In Vivo

In this section, the clinical utility of DB-OCA is demonstrated by imaging normal pathologic cases. DB-OCA was used to investigate the retina and choroid in three dimensions with a resolution of approximately 15 × 30 × 6 μm (horizontal sampling separation × vertical sampling separation × and coherence length).

43.3.1 Capillary Imaging

To demonstrate the capability of DB-OCA for fine capillary imaging, juxtafoveal regions of normal eyes without marked posterior disorder were investigated. The eyes of three healthy subjects were scanned over a 1.9 × 1.9 mm^2 area with 512 × 256 points. A relatively slow transversal scanning speed was selected to enable a very long time interval between the preceding and following probes of $\tau = 1.58$ ms.

Retinal capillaries around the fovea were visualized in three dimensions with a stereogram. The three-dimensional complex and dense capillary network of the macula is shown in Fig. 43.4a. A volume rendering [44] with a depth-encoded color map (Fig. 43.4b) shows that retinal capillaries comprise roughly three layers (yellow, orange, and purple vessels). The depth-segmented projections (Fig. 43.3) show different patterns of the retinal capillary network at each depth. These appearances are consistent with histological findings [45]. The relatively thick retinal vessels at the anterior retina appeared through all depth segments, which may because of the shadowing effect of Doppler OCT [18].

A region without vasculature is found at the center of the fovea, which is known as a foveal avascular zone (FAZ). Because expansion of the FAZ is known to be an indicator of diabetic retinopathy [46–48], the capability of visualizing the FAZ is clinically significant. The FAZ was manually outlined as indicated by the yellow line in Fig. 43.4, and the perimeter and area of the FAZ were measured as 1.59 mm

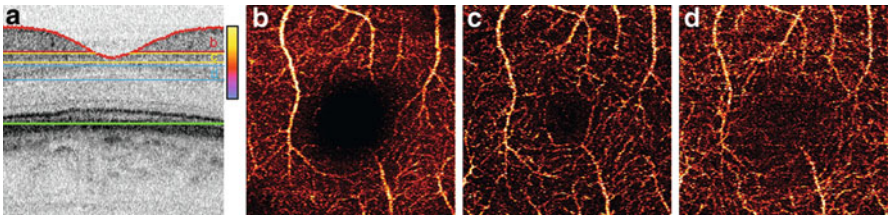

Fig. 43.3 Retinal capillary networks at different depths. (**a**) An OCT cross-section at the fovea. The color map on the *right* denotes the colors assigned to various depths, as shown in Fig. 43.6b. Integrated projections of blood flow volume at (**b**) the ganglion cell layer and (**c**) from the inner plexiform layer to the inner nuclear layer. (**d**) From the inner nuclear layer to the outer plexiform layer. Different capillary networks are observed at these three depth regions (This figure is reproduced from Ref. [34])

(**a**) A stereo view showing the retinal capillaries and (**b**) the projection image of the retinal capillary with color to encode depth. The foveal avascular zone was outlined manually (*yellow closed line*). The scan size is $7.9 \times 7.9°$ (512×256 lines), and the acquisition took 5 s (This figure is reproduced from Ref. [34])

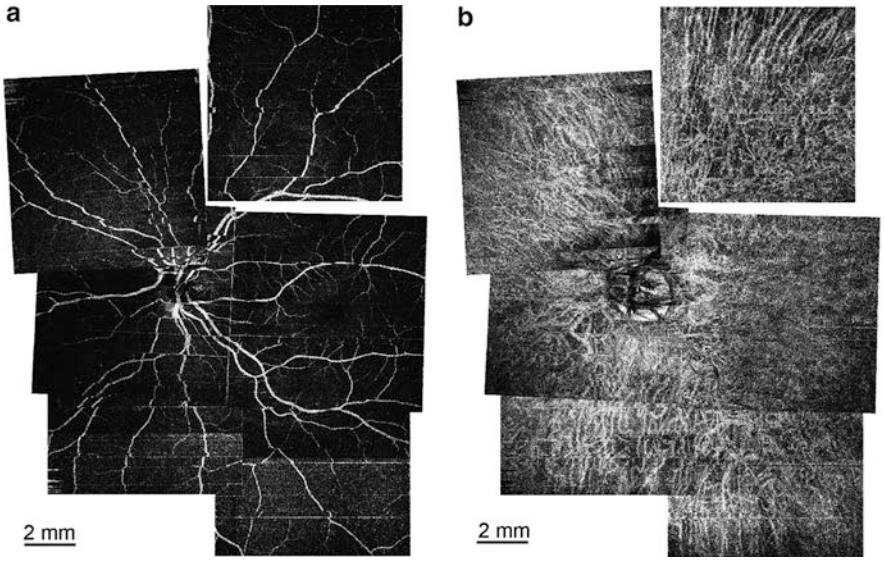

Fig. 43.5 Wide-field DB-OCA created by stitching 6 DB-OCA volumes. (**a**) and (**b**) represent retinal and choroidal vessels, respectively (This figure is reproduced from Ref. [34])

and 0.179 mm^2, respectively, in this particular case. The results from three subjects ranged between 1.59–2.42 mm in the perimeter and 0.177–0.339 mm^2 on the surface. These results are consistent with a study conducted with FA [48]. Noninvasive, detailed, high-speed imaging of the microvasculature by DB-OCA will be suitable for screening and monitoring of vascular diseases.

43.3.2 Wide-Field Imaging

More wide-field angiography is enabled by stitching several DBA-OCAs. In the example depicted in Fig. 43.5, six sections of a retina were scanned to compose wide-field images. The mosaic of vasculature images at the retina and the choroid is shown in Fig. 43.5a, b. Each section was acquired in 5 s and covered an approximate 7.8 × 7.8 mm^2 area. The total acquisition time was 30 s, and the mosaic image covered approximately 16 × 20 mm^2. Owing to the high-resolution three-dimensional imaging, two overlaid vasculatures, the retina and the choroid, could be discriminated. Major retinal vessels around the ONH and the macula are shown in Fig. 43.5a. Fine branches around the fovea were also clearly visualized. In Fig. 43.5b, the fine choroidal vasculature of the peripapillary region was well contrasted. It shows macroscopic structural properties of the vasculatures in the posterior eye.

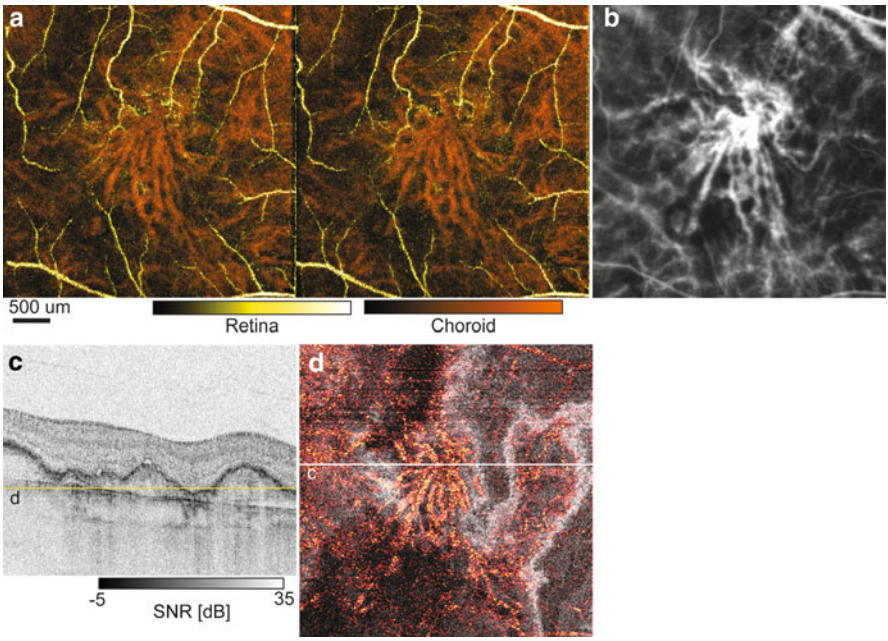

Fig. 43.6 A case of polypoidal choroidal vasculopathy. (**a**) Stereogram of volume rendering of D-OCA where *yellow* indicates the retinal vasculature and *red* indicates the choroidal vasculature, (**b**) corresponding ICGA, (**c**) cross-sectional OCT at a pigment epithelial detachment indicated by a *white line* in (**d**), and (**d**) OCA overlapped en face OCT cross-section. The depth location of (**d**) is indicated by a *yellow line* in (**c**) (This figure is reproduced from Ref. [34])

43.3.3 A Pathologic Case

Abnormal choroidal vasculature imaging is one of the significant applications for DB-OCA. Figure 43.6 demonstrates a DB-OCA application to a case of polypoidal choroidal vasculopathy (PCV). The pathologic region of the retina was scanned over a 3.9 × 3.9 mm^2 area with 512 × 256 A-lines. The time interval for Doppler detection was 792 μs.

The depth-resolved vasculatures are visualized by a stereogram shown in Fig. 43.6a. There is a thick abnormal vascular network under the RPE at the fovea. It was also found that the network is located above the surrounding choroidal vessels. Retinal vessels undulated in the longitudinal direction since the retina was elevated. In PCV, polyp-like lesions with pigment epithelium detachment (PED) occurred around the abnormal vascular network, which was clearly visualized by DB-OCA.

By comparison with ICGA (Fig. 43.6b), it was found that the remarkable abnormal vasculature generated a similar pattern in both OCA and ICGA images. The depth-resolved structure of the vascular network could be identified by cross-sectional tomography of the eye, as shown in Fig. 43.6c. Severe retinal pigment

detachments are clearly visible. According to the en face cross-section of the blood flow image overlaid on the OCT image (Fig. 43.6d), the abnormal vasculature was found to exist at the space between the detached RPE and Bruch's membrane.

Although the origin of these abnormal vessels is controversial, DB-OCA will provide new insight on the debate about this pathology.

43.4 Advanced Issue: Birefringence Artifact

The DB-OCA system presented in previous sections uses polarization to multiplex two probe beams. This method implicitly assumes the sample to be measured exhibits no birefringence. However, the eye consists of several birefringent tissues including the cornea, sclera, nerve fibers, and lamina cribrosa. Hence, this assumption is not always validated. The birefringence in the sample results in a pseudo-Doppler phase shift and disturbs flow measurements.

In this section, initially, the formulation of DB-OCA is extended using the Jones matrix in order to account for the birefringence issues. Subsequently, a modified DB-OCA system, which is free from the birefringence artifact, is described.

43.4.1 Jones Matrix Formulation of Dual-Beam Doppler Optical Coherence Angiography

By denoting the single-trip Jones matrix of a sample as $\mathbf{J}_s$, the round-trip Jones matrix of the sample is defined as

$$\mathbf{J}(\mathbf{r}) = \mathbf{J}_s^T(\mathbf{r})\mathbf{J}_s(\mathbf{r}) \equiv \begin{bmatrix} j_{11}(\mathbf{r}) & j_{12}(\mathbf{r}) \\ j_{21}(\mathbf{r}) & j_{22}(\mathbf{r}) \end{bmatrix} \tag{43.10}$$

where $j_{12} = j_{21}$, because $\mathbf{J}$ is transpose symmetric [49]. Using this round-trip Jones matrix, Γ_p and Γ_f of Eq. 43.6 are described as

$$\begin{aligned} \Gamma_p(\mathbf{r}, t) &= \mathbf{E}_{out}^{p\dagger}\mathbf{J}(\mathbf{r})\mathbf{E}_{in}^{p} \\ \Gamma_f(\mathbf{r}, t+\tau) &= \mathbf{E}_{out}^{f\dagger}\mathbf{J}(\mathbf{r})\mathbf{E}_{in}^{f}\exp[i\Delta\phi_m(\mathbf{r})] \end{aligned} \tag{43.11}$$

where $\mathbf{r} = (x, y, z)$ are the spatial coordinates, $\mathbf{E}_{in}$ and $\mathbf{E}_{out}$ are Jones vectors of incident and detected polarization states of the probe beams, respectively, $\Delta\phi_m(\mathbf{r})$ is the Doppler phase shift due to the spatially distributed axial motion of the sample, and the subscripts and superscripts of p and f indicate preceding and following probe beams, respectively.

In the DB-OCA setup described in Fig. 43.2, both the incident and detected polarization states are linear polarization, and they are parallel to each other, while the polarization states of the preceding and the following beams are orthogonal to each other. Hence, the polarization states can be assumed as $\mathbf{E}_{in}^{p} \parallel \mathbf{E}_{out}^{p} \parallel [1 \quad 0]^T$ and $\mathbf{E}_{in}^{f} \parallel \mathbf{E}_{out}^{f} \parallel [0 \quad 1]^T$. Under this condition, Γp and Γ_f are expressed as

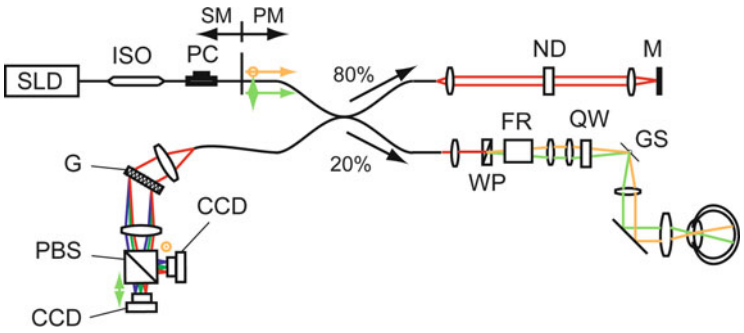

Fig. 43.7 Optical scheme of modified DB-OCA which is free from phase artifact occurred by the birefringence of the sample. SM and PM represent single-mode and multimode fibers, *ISO* isolator, *ND* neutral density filter, *M* mirror, *G* grating, *PBS* polarization beam splitter, *GS* galvanometric scanner, *WP* Wollaston prism, *FR* Faraday rotator, and *QW* quarter wavelength plate. The *green* and *yellow lines* represent two probe beams with orthogonal polarization states

$$\begin{aligned} \Gamma_p(\mathbf{r},t) &= C\ j_{11}(\mathbf{r}) \\ \Gamma_f(\mathbf{r},t) &= C\ j_{22}(\mathbf{r})\exp[i\Delta\phi_m(\mathbf{r})] \end{aligned} \tag{43.12}$$

where C is a constant of proportion. By substituting Eq. 43.12 into Eqs. 43.6 and 43.3, the Doppler phase shift measured by DB-OCA is found to be

$$\Delta\phi(\mathbf{r}) = \Delta\phi_m(\mathbf{r}) + \Delta\phi_b(\mathbf{r}) \tag{43.13}$$

where $\Delta\phi_b(\mathbf{r})$ is the phase difference between j_{11} and j_{22}, which is defined as $\Delta\phi_b = \mathrm{Arg}[j_{22}(\mathbf{r})j_{11}^*(\mathbf{r})]$.

It is evident that the measured Doppler phase shift reflects not only the Doppler phase shift due to the motion in the sample, $\Delta\phi_m(\mathbf{r})$, but is biased by the phase difference between j_{11} and j_{22}, $\Delta\phi_b$, which is not zero if the sample is birefringent. Hence, $\Delta\phi_b(\mathbf{r})$ is a phase artifact in DB-OCA measurement and causes pseudo-flow in a DB-OCA image.

43.4.2 Modified Dual-Beam Optical Coherence Angiography System

By using a modified version of DB-OCA, the phase artifact can be canceled [37]. Figure 43.7 shows the optical scheme of the modified DB-OCA. This system is nearly identical to the original DB-OCA except for a Faraday rotator (FR) and a quarter wavelength plate (QW) located between the Wollaston prism (WP) and a galvanometric scanner (GS). The rotation angle of the Faraday rotator is 45°.

The round-trip Jones matrix of the combination of the Faraday rotator, quarter wavelength plate, and the sample is

$$\mathbf{M}(\mathbf{r}) = \mathbf{R}(\pi/4)\mathbf{Q}^T\mathbf{J}(\mathbf{r})\mathbf{Q}\,\mathbf{R}(\pi/4) = \frac{i}{2}\begin{bmatrix} j_{11}(\mathbf{r}) + j_{22}(\mathbf{r}) & j_{11}(\mathbf{r}) - i2j_{12}(\mathbf{r}) - j_{22}(\mathbf{r}) \\ -[j_{11}(\mathbf{r}) - i2j_{12}(\mathbf{r}) - j_{22}(\mathbf{r})] & -[j_{11}(\mathbf{r}) + j_{22}(\mathbf{r})] \end{bmatrix} \tag{43.14}$$

where $\mathbf{R}(\theta)$ is a rotation matrix with an rotation angle of θ, which represents the effect of the Faraday rotator, and $\mathbf{Q}$ is the Jones matrix of the quarter wavelength plate. Here, the optic axis of the quarter wavelength plate is assumed to be aligned vertically. The definition of the optic axis, i.e., slow or fast axis, is not a matter of concern. In both cases, the effect is the same. Note that the diagonal elements of the matrix $\mathbf{M}(\mathbf{r})$ differ only in their signs.

By replacing $\mathbf{J}(\mathbf{r})$ in Eq. 43.12 with $\mathbf{M}(\mathbf{r})$, the Γ_p and Γ_f are altered to be

$$\begin{aligned} \Gamma_p(\mathbf{r}, t) &= C\frac{1}{2}[j_{11}(\mathbf{r}) + j_{22}(\mathbf{r})] \\ \Gamma_f(\mathbf{r}, t+\tau) &= -C\frac{1}{2}[j_{11}(\mathbf{r}) + j_{22}(\mathbf{r})]\exp[i\Delta\phi_m(\mathbf{r})] \end{aligned} \tag{43.15}$$

By substituting the Γ_p and Γ_f in Eq. 43.6 and subsequently in Eq. 43.2, the measured Doppler phase shift becomes the following:

$$\Delta\phi(\mathbf{r}) = \mathrm{Arg}\left[\Gamma_f(\mathbf{r})\Gamma_p^*(\mathbf{r})\right] = \Delta\phi_m + \pi \tag{43.16}$$

Although this measured Doppler phase is biased with a constant phase of π, it evidently expresses the Doppler phase shift due to the localized motion in the sample. Since the constant phase bias can be canceled by a common bulk motion correction method for Doppler OCT, e.g., the methods described in Refs. [28] or [32], this modified DB-OCA provides the Doppler phase shift value due to the motion in the sample without artifacts due to the sample birefringence.

It is also noteworthy that the role of the quarter wavelength plate is not to cancel the birefringence artifact but to maximize the probe light efficiency. Furthermore, the orientation of the quarter wavelength plate has no impact on the measured Doppler phase shift value. More detailed discussion about this issue can be found in Ref. [36].

43.4.3 Optic Nerve Head Imaging by Modified Dual-Beam Optical Coherence Angiography

Since the cornea consists of collagen and is birefringent, the birefringence artifact always has some negative impact on the imaging of the posterior eye. The impact is significant especially for ONH imaging because several birefringent tissues, including nerve fibers and lamina cribrosa, exist at the ONH.

Figure 43.8 demonstrates the comparison of OCA images of an eye taken by the original and the modified DB-OCA devices. All images were obtained from a

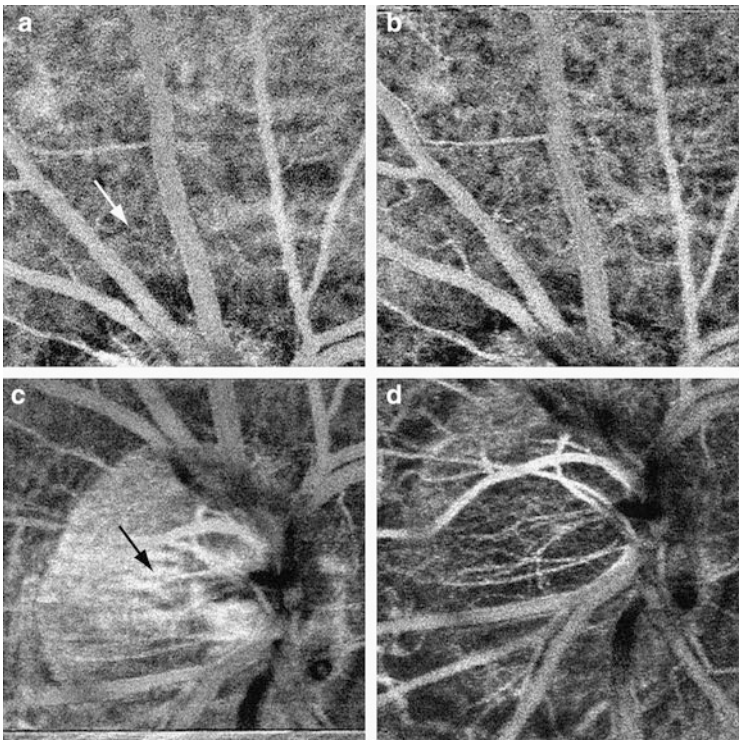

Fig. 43.8 DB-OCA of in vivo human ONH. (**a**) and (**c**) were taken by an original DB-OCA system, while (**b**) and (**d**) were taken by a modified DB-OCA system which is free from birefringence artifacts (This figure is reproduced from Ref. [37])

single subject. Figure 43.8a, c was taken by an original DB-OCA configuration, while Fig. 43.8b, d was taken by the modified DB-OCA. Both retinal and choroidal vessels are visualized in these images. Figure 43.8a, b is the images obtained at the superior region to the ONH. Because of scleral birefringence, the contrast of the fine vessels is low in Fig. 43.8a, as exemplified by an arrow. In contrast, fine vessels are clearly visualized in the image obtained by the modified DB-OCA system, as shown in Fig. 43.8a.

Figure 43.8c shows a very strong OCA signal in the ONH region. This strong signal was generated by the strong birefringence of a lamina cribrosa. By using the modified DB-OCA, this strong birefringence artifact was perfectly canceled, and fine vessels are visualized within the ONH.

43.5 Conclusions and Further Topics

This chapter presented the basics of DB-OCA and its modified version, which is free from birefringence artifacts. With DB-OCA, extremely high sensitivity of Doppler

OCT measurement was achieved. With this high sensitivity, DB-OCA enabled clear visualization of the fine vasculature in the retina. More examples of retinal imaging using DB-OCA and modified DB-OCA can be found in Refs. [33, 37].

Although this chapter is sufficient for understanding the principles of DB-OCA, there are several issues that should be carefully considered to implement DB-OCA. Especially for modified DB-OCA, the quarter wavelength plate should be aligned with a particular optimization strategy. The details of this issue are described in Ref. [37].

In addition to the two implementations of DB-OCA described in this chapter, there are several other implementations and extensions of DB-OCA. For example, Zotter et al. have demonstrated DB-OCA, which is denoted as dual-beam phase-resolved Doppler OCT in their terminology, with interferometer multiplexing [35]. In this system, the two probe beams were created using two independent interferometers.

Jaillon et al. demonstrated DB-OCA with a 1-μm probe wavelength and visualized high-sensitive Doppler imaging of the choroidal vasculature [36]. This 1-μm DB-OCA system was further extended to have a variable velocity range [38]. In this extended system, the measurable flow velocity can be selected by rotating a particular mirror in its scanning optics.

The clinical utility of DB-OCA is still not evaluated in detail. With further technical development, comprehensive and systematic clinical studies will make DB-OCA a very powerful tool for ophthalmic diagnosis in the future.

Optical microangiography • Optical coherence tomography • Vascular diseases

44.1 Introduction

Proper homeostasis regulation of in vivo biological systems requires microvascular blood perfusion, which is the process of delivering blood into the tissue's capillary beds. Abnormal tissue vascularization has been associated with various disorders such as cancer, diabetes, neurological disorders, wounds, and inflammation. Understanding the changes in the vascular network or microangiography will have an important role in determining the causes and developing potential treatments for these diseases.

The ability to noninvasively image the blood flow within microcirculatory tissue beds will have potential applications in several basic research and clinical settings. Currently, there are several noninvasive methods for providing spatial and temporal maps of blood flow in both animal models and humans. These techniques include magnetic resonance imaging [1] and positron emission tomography [2]; however, these techniques have poor spatial and temporal resolutions.

Other techniques have mostly been used in animal models for basic research applications, such as two-photon microscopy [3], which has been used to estimate the transverse velocity and linear density of red blood cells. This procedure requires determining the flow profile and vessel orientation, which can be challenging.

Laser speckle contrast imaging [4, 5] is an imaging technique that has been used to obtain images of the relative changes of blood flow with high spatial and temporal resolution. This method is based on analyzing the speckle decorrelation time, which is inversely related to the mean blood flow velocities. This method cannot provide depth information and its resolution cannot discern the small vessels, such as the capillaries.

Other methods have only been applicable for animal studies given their invasiveness. For example, autoradiography is a gold standard method which has been used for studying blood flow. This technique consists of using a tracer which is administered over a short period of time, followed by cardiac arrest and quick freezing. Autoradiography of these frozen sections provides a representation of the radioactivity levels in the different tissue layers. This information is then converted to blood flow by incorporating the time course of arterial blood radioactivity. Although this method provides three-dimensional spatial information, it does not provide the temporal information of the blood flow change [6], given that the sample is damaged. Therefore, studies of disease progression or response to treatment within the same animal cannot be performed.

In summary, microvascular imaging has been challenging due to the high spatial and temporal resolution requirements. A system with high sensitivity for imaging small diameter capillaries and slow blood flow velocities is needed. Also, contact techniques alter the optical properties of the tissue, which affect the data analysis [7]. Therefore, a method which can provide noninvasive, noncontact, label-free, three-dimensional, spatially resolved blood flow measurements with capillary resolution would be beneficial for the diagnosis and treatment of several tissue pathologies.

Optical coherence tomography (OCT) is a noninvasive method for imaging three-dimensional biological tissues with high resolution ($\sim$10 μm) and without requiring the use of contrast agents [8]. OCT can image up to a depth of several millimeters, at speeds of up to 500 kHz of line scan rate [9]. Currently, there are two type of OCT systems, the time-domain OCT (TD-OCT) [10] and the Fourier-domain OCT, which is divided into spectral domain (SD-OCT) [11] and swept source (SS-OCT) [12]. Fourier-domain OCT has demonstrated higher sensitivity and imaging speed compared to its time-domain counterpart. The high speed of the Fourier-domain systems has enabled it to image not only structural images but also functional parameters which provide information about the blood flow velocities and vessel microangiography.

In this chapter we will review several techniques for using Fourier-domain OCT to determine blood flow velocities and the vessel morphology. Different techniques will be discussed with a brief explanation of their limitations. Also, methods for quantifying these images will be presented, as well as the depiction of several applications. Finally, examples of the combination of different imaging modalities will be highlighted.

44.2 OCT Angiography Methods

The first commercial OCT systems developed were based on time domain and were used for ophthalmology applications. In TD-OCT a reference mirror, which is constantly moving through mechanical scanning, is used to alter the location of

the coherence gate. The location of the coherence gate allows for the detection of the scattering structures at different depths within the biological tissues. The mechanical scanning of the reference mirror has limited repeatability and gives rise to motion artifacts due to its mechanical jitters. As a result, the quality of the OCT image deteriorates, especially at the higher acquisition speeds.

Fourier-domain OCT has enabled considerable improvements in image acquisition speed and image resolution compared to its TD-OCT counterpart. In Fourier-domain OCT, the reference mirror is stationary and the OCT signal collected is a function of the wavenumber ($k = 2\pi/\lambda$), where λ is the wavelength. Fourier-domain OCT is based on the principle of transforming the OCT time-varying signal along the optical axis (A scan) into the frequency domain. In SD-OCT, the light source is a broadband source and the signal is acquired with a spectrometer as a detector, which measures the recombined broadband spectra returning from the sample and reference mirror. The image acquisition speeds have reached up to 500,000 A-lines per second [9], which reduces the vulnerability from motion artifacts and allows for highly dense tissue sampling. In SS-OCT, a light source in which the emission wavelength is tuned rapidly through time over a broad wavelength range is used [13], and the signal is detected using a single photo detector. Since SD-OCT and SS-OCT are mathematically identical, the discussion below assumes the case of the SD-OCT, unless otherwise stated.

The detected interference spectrum in a Fourier OCT system is given by

$$I(t,k_j) = 2S(k_j)E_R\left[\int_{-\infty}^{\infty} a(z,t)\cos\left(2k_j n(t)z\right)dz + a(z_1)\cos\left[2k_j n(t)(z_1 - vt)\right]\right] \tag{44.1}$$

where j is the pixel number index of the CCD camera in the spectrometer, t is the timing when an A-line is captured, E_R is the light reflected from the reference mirror, $S(k)$ is the spectral density of the light source used, n is the refractive index of the tissue, z is the depth coordinate within the sample, $a(z, t)$ is the amplitude of the back scattered light, and v is the velocity of moving particles such as blood cells in a blood vessel, which is located at a depth z_1.

To extract the depth information from a Fourier-domain OCT system, a Fourier transform (FT) is used on the interference contributions of all the pathlength differences from each wavenumber, which is given by

$$I(z) = FT[I(k)] = M(z)e^{i\varphi(z)} \tag{44.2}$$

The result of the Fourier transformation is a complex valued signal that has a phase ($\varphi(z)$) and a magnitude ($M(z)$) terms.

The analysis of $M(z)$ enables the reconstruction of the OCT structural image, which is commonly used on most OCT applications. Often, this refers to anatomical OCT, because it provides information about the microstructural features about the sample. For example, commercial OCT eye imaging systems analyze the thickness of the different

retinal layers with micrometer resolution. The anatomical OCT is limited to providing morphological information; however, it does not provide functional information.

The value of $\varphi(z)$ is a random phase caused by the microstructures located at the depth z. The analysis of the dynamic changes in the phase signal has been used for measuring tissue movement, which has allowed for the quantification of several tissue properties, such as the displacement of the trabecular meshwork in the anterior segment of the eye [14], the skin elastic properties [15], and the tissue photothermal responses [16]. The phase information has also been used to analyze the Doppler effect that is caused by the scattering of light from a moving object. This analysis enables the quantification of the axial velocity of moving particles such as red blood cells inside patent blood vessels. However, this technique is limited to fast flow velocities and is unable to quantify the blood flow velocities within capillary tissue beds.

By analyzing the dynamic changes in the magnitude, phase, or both, it is possible to extract the three-dimensional location of the patent blood vessels within the biological tissue, thus recreating the blood vessel microangiography. In the following sections we provide an overview of several techniques that have been previously used to extract the vessel microangiography.

44.2.1 Phase-Based Methods

Phase-based methods are established by analyzing the dynamic changes in the phase term ($\varphi(z)$) of the OCT signal. The axial displacement of a moving scatterer, such as a red blood cell, adds a Doppler shift to the carrier frequency, which can be measured by an OCT system through its phase. The disadvantage of these methods is that they are sensitive to the OCT system's phase noise and the tissue's bulk-motion artifacts.

44.2.1.1 Doppler Method

Doppler optical coherence tomography (DOCT) is an extension of OCT which combines the Doppler principles with OCT. The method was first used for analyzing the frequency shift due to the Doppler effect [17]. DOCT provides in vivo images of blood vessels, blood flow direction, and blood flow velocity, with good sensitivity [18]. This method is sensitive to the phase term; therefore, the phase stability of the OCT system is critical for obtaining high-quality images.

The phase difference is calculated between two A-lines captured at the same or at highly overlapping spatial locations [19]. The axial blood flow velocity (V_z) depends on the time interval (Δt) between the captured A-lines, which is given by

$$V_z = \frac{\lambda \Delta \varphi}{4\pi n \Delta t} \tag{44.3}$$

where λ is the wavelength of the light, $\Delta\varphi$ is the phase difference between the time points, and n is the index of refraction of the sample. The maximum resolvable

velocity is limited by the 2π ambiguity of the phase measurements; therefore, the phase changes are constrained by π and $-\pi$. The minimum velocity that can be resolved by this method is dictated by the system's phase stability and the bulk tissue motions. As a result, this method has difficulty in determining the slow flow velocities from small blood vessels, such as capillaries.

Measurement of the absolute blood flow velocity (V) is important in several studies, such as retinal imaging, since it allows for the evaluation of the blood flow dynamics within individual vessels. To obtain the absolute velocity, it is important to determine the angle (Φ) between the flow velocity vector and the vector of the incident OCT light, also known as the Doppler angle. The Doppler angle may be determined by using the three-dimensional OCT data set and the following equation [20]:

$$\Phi = \pi - \arccos\left(\frac{dz}{\sqrt{(dx^2 + dy^2 + dz^2)}}\right) \tag{44.4}$$

where dx, dy, and dz are the directional components of the blood vessel. The calculation of the total blood flow velocity can be obtained from

$$V = \left|\frac{V_z}{\cos\Phi}\right| \tag{44.5}$$

The total blood flow within a vessel is then calculated by multiplying the total velocity times the cross-sectional area of the vessel. Another method that has been proposed to calculate the total blood flow, which does not require the calculation of the Doppler angle, is to integrate the axial velocity in the xz plane (*en face*) [21], a method borrowed from Doppler ultrasound imaging. Given that the surface normal is parallel to the components of the velocity that is measured, the following expression can be used:

$$F = -\iint_{xy\ plane} v_z(x, y)dxdy \tag{44.6}$$

Averaging the phase differences between several A-lines causes a systematic error which is dependent on both the signal-to-noise ratio and the proximity of the measured velocity to the limits of the velocity range [22]. An improvement has been devised by using an extension of the Kasai autocorrelation algorithm [23], which can obtain the phase difference ($\Delta\varphi$) given by

$$\Delta\varphi(z, t) = \tan^{-1}\left[\frac{\sum_{m=1}^{N} Im[I(z, t_n) \times I^*(z, t_{n-1})]}{\sum_{m=0}^{N} Re[I(z, t_n) \times I^*(z, t_{n-1})]}\right] \tag{44.7}$$

where N is the number of phase differences that are going to be averaged together and * indicates the complex conjugate.

44.2.1.2 Phase-Resolved Doppler Variance

Phase-resolved Doppler variance [24–26] methods have been developed to detect small phase variations from microvascular flow and are based on using the bandwidth of the Doppler frequency spectrum. These methods have the advantages of being less sensitive to the pulsatile nature of the blood flow and the incident angle, as well as the capability of being able to monitor transverse flow velocities [27]. Several Doppler variance algorithms have previously been compared [28]; however, they are based on the autocorrelation principles:

$$\sigma^2 = \frac{1}{\Delta T^2}\left[1 - \frac{\left|\sum_{j=1}^{J}\sum_{z=1}^{N}\left(I_{j,z}I_{j+1,z}{}^{*}\right)\right|}{\sum_{j=1}^{J}\sum_{z=1}^{N}\frac{1}{2}\left(I_{j,z}I_{j,z}{}^{*} + I_{j,z+1}I_{j,z+1}{}^{*}\right)}\right] \tag{44.8}$$

where J is the number of A-lines that are averaged and N is the number of depth points that are averaged. The averaging along the lateral and depth direction can reduce the background noise and improve the image quality although it may degrade the spatial resolution. The chosen values for J and N will depend on the specific biological tissue application. One drawback of the phase-resolved Doppler variance methods is their lost ability to provide the values of flow velocity.

44.2.2 Magnitude-Based Methods

In many applications, such as in imaging the retinal blood vessels, the direction of the vessels are nearly perpendicular to the OCT beam. As a result the axial velocity is small which yields a low-signal-to-noise ratio on the phase data. In other cases, there is low phase stability in the OCT system, such as in the application of several swept source OCT systems, where a source of phase noise is introduced from the cycle-to-cycle tuning and timing variability [29]. For these cases, the use of the phase information is highly susceptible to error. Therefore, methods have been developed that can obtain the angiography of the blood vessels based only on the temporal changes in the magnitude of the OCT signals. Such methods have less dependence on the beam incident angle, system phase stability, and small sample motion, thus are attractive in some of the applications in which only vascular morphology is of interests.

44.2.2.1 Autocorrelation Methods

Autocorrelation methods have been developed to quantitatively map the transverse particle-flow velocities. The method is based on analyzing the statistical nature of the intensity fluctuations of the backscattered light, which is modulated by flowing particles [30]. For example, Fig. 44.1 shows the magnitude of the detected OCT signal obtained from a flow phantom with different velocities, as well as the autocorrelation curves. The slope of the normalized autocorrelation function is proportional to the transverse velocities (Fig. 44.1d), as demonstrated in Fig. 44.2.

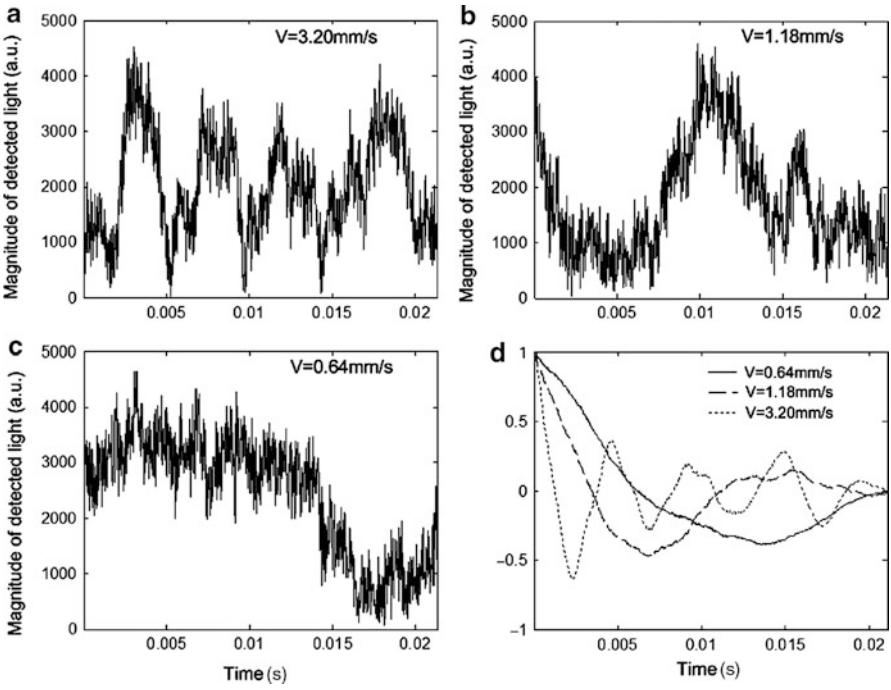

Fig. 44.1 Magnitude of the detected light which was modulated by intralipid flowing particles through a syringe pump phantom at the velocities of (**a**) 3.20 mm/s, (**b**) 1.18 mm/s, and (**c**) 0.64 mm/s. (**d**) Normalized autocorrelation function (Modified figure reprinted with permission from Ref. [30])

44.2.2.2 Correlation Methods

Another method that has been widely used is analyzing the correlation among B scans. This method consists of determining the average correlation (D) value between several pairs of OCT frames at the same cross section. The average correlation can be expressed by

$$D(x,z) = \frac{1}{N-1}\sum_{n=1}^{N-1} \frac{M_n(x,z)M_{n+1}(x,z)}{\left|\frac{M_n(x,z)^2}{2} + \frac{M_{n+1}(x,z)^2}{2}\right|} \tag{44.9}$$

where N is the total number of frames at the same cross section and $M_n(x, z)$ and $M_{n+1}(x, z)$ are the amplitude signal from adjacent frames. Methods have been devised to minimize noise such as using a window of several pixels instead of a single pixel; however, this produces a reduction in its spatial resolution. The value of $|D|$ varies between 0 and 1, where 0 indicates no correlation and 1 indicates high correlation. Therefore, static tissues have high absolute correlation values, while noise pixels and pixels that contain blood vessels have low

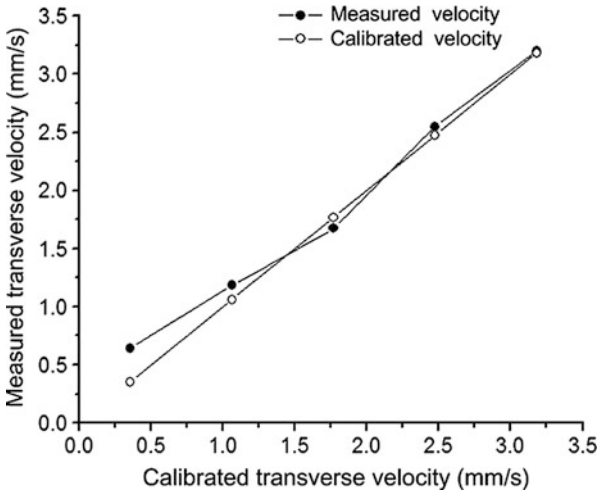

Fig. 44.2 Measured transverse velocities (*line with solid circles*) and calibrated velocities (*line with open circles*) (Modified figure reprinted with permission from Ref. [30])

absolute correlation values. For this reason, typically a structural mask is used over the cross-correlation map in order to eliminate the noise pixels, which adds an additional layer of complexity to this approach.

This technique has previously been used for correlation mapping OCT (cmOCT) [31, 32], split-spectrum amplitude-decorrelation angiography (SSADA) [33], and a variation has been also used for intensity-based Doppler variance algorithm [34].

44.2.2.3 Speckle Variance

Speckle variance OCT (svOCT) is a functional extension of OCT, which can yield three-dimensional vascular images by analyzing the Fourier transform of the temporal variation of the speckle [35] or by calculating the interframe variance (SV_{ijk}) of N consecutive B-mode OCT structural intensity (M_{ijk}) images. By analyzing each individual pixel within the image and using N frames for the analysis, the variance is calculated with the following expression [36]:

$$SV_{ijk} = \frac{1}{N} \sum_{i=1}^{N} \left(M_{ijk} - M_{mean} \right)^2 \tag{44.10}$$

Given that the vascular regions decorrelate faster compared to their static counterparts, the speckle patterns produced yield an endogenous contrast that is used for extracting the blood microangiography.

44.2.3 Complex-Based Methods

Up to this point, we have determined ways of extracting the vessel microangiography using the magnitude or the phase information obtained from

the OCT measurements. The phase-based methods are sensitive to the movements of the scatterers in the axial direction, while the magnitude-based methods are sensitive to the movements in both the lateral and the axial directions. Given that the OCT signal is a complex value, it is possible to take advantage of both the magnitude and phase information simultaneously to extract the vessel microangiography.

44.2.3.1 Optical Microangiography (OMAG)

Optical microangiography (OMAG) is a recently developed imaging technique that produces three-dimensional images of dynamic blood perfusion within microcirculatory tissue beds [37, 38]. OMAG was initially based on full range complex Fourier-domain OCT [39, 40], in which a high-pass filtering of the real valued signal is essentially employed to extract the blood flow signal from the static background signal. In OMAG, Wang et al. used a high-pass filter over the complex signal, to take advantage of both the magnitude and phase information. This process allows for the isolation of the positive and negative blood flow velocities [37].

OMAG analyzes the spatial frequency of the time-varying spectral interferograms. This analysis enables OMAG to separate the signal that is backscattered by static particles, such as bulk tissue, from moving particles, such as blood cells. There have been two generations of OMAG. The first generation consisted of introducing a carrier frequency by adding a phase delay to each A scan using a moving reference mirror or an off-pivot scanning beam. However, this technique is dependent on the precise synchronization of the reference arm modulation and the B-scan acquisition. As a result, it requires expensive modulators and is unable to detect bi-directional flow within a single B scan. The second generation overcame this limitation by using an algorithm which included a modified Hilbert transform that is used without the need of a spatial frequency modulation. This new algorithm is applicable for both the spectral domain and swept source OCT, provided that they both have comparable B-scan acquisition rates. The second generation OMAG requires only one B scan to obtain both the positive and negative flow.

The theory of OMAG is based on the depth-encoded spectral interferogram, which is captured by the linear detector as a real function $B(z, t)$, and can be expressed as

$$B(z,t) = A(z)cos\,(k_0 z + 2\pi ut) \tag{44.11}$$

where $A(z)$ is the reflective coefficient of the scatterer, k_0 is the wave vector of the detected light, and z relates to the detecting path. To simplify the expression we have ignored the random phase arising from the refractive index and assume that $A(z)$ is constant along the B-direction, t is the B-scan time that corresponds to the different lateral positions, and u is the modulation frequency generated by the flow speed. The Fourier transform of the spectral signal $B(z, t)$ is expressed by

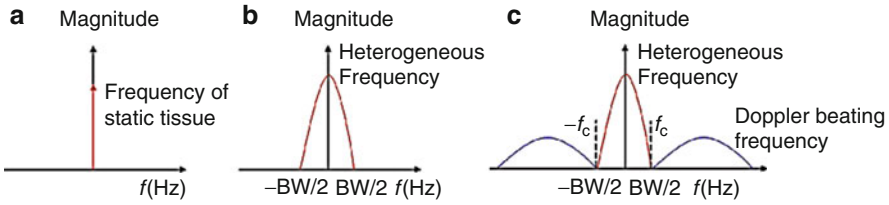

Fig. 44.3 Diagram of frequency components for different tissue sample: (**a**) an ideal tissue sample (optically homogeneous sample) with no moving particles, (**b**) a real tissue sample (optically heterogeneous sample) with no moving particles, and (**c**) a real tissue sample (optically heterogeneous sample) with moving particles (Modified figure reprinted with permission from Ref. [38])

$$
\begin{aligned}
H(z,u) &= \frac{A(z)}{T_0}\int_{t_0-\frac{\tau_0}{2}}^{t_0+\frac{\tau_0}{2}} cos\left(k_0 z + 2\pi u t\right)e^{-i2\pi u_0 t}dt \\
&= \frac{A(z)e^{ik_0 z}sin\left[\pi\tau_0(u-u_0)\right]}{2T_0\pi(u-u_0)}e^{-i2\pi(u-u_0)t_0} \\
&\quad + \frac{A(z)e^{-ik_0 z}sin\left[\pi\tau_0(u+u_0)\right]}{2T_0\pi(u+u_0)}e^{-i2\pi(u+u_0)t_0}
\end{aligned}
\tag{44.12}
$$

Based on the above equation, the nonmoving scatterers will be centered at the zeroth frequency (DC) region, and the moving scatterers will be shifted away from the zeroth frequency. Figure 44.3 presents examples of a frequency analysis using OMAG. If the tissue is completely homogeneous, which is an ideal case scenario, the frequency response would be a delta function centered at 0. However, a broadening of the spectra is observed when the tissue is inhomogeneous, which is a real case scenario. If there are moving particles within the inhomogeneous tissue, a higher frequency component will be observed. The shifting distance is directly related to the velocity u_0. The dynamic signal can be recreated by using a high-pass filter and then performing an inverse Fourier transform. The parameters that affect the flow signal detection include the flow velocity, the number and size of the moving scatterers, and the sampling line density.

By first using the OMAG method, it is possible to then apply the Doppler analysis method (Eq. 44.7), also known as Doppler OMAG (DOMAG). The key advantage of OMAG is that only the signals backscattered by the moving scatterers are obtained, and the static signal is filtered out. Therefore, the Doppler signal obtained in DOMAG is free of artifact induced noise. After the OMAG algorithm is applied, the correlation between adjacent A scans within the static tissue region is lost, which leads to a signal with high noise. However, this limitation is overcome by digitally reconstructing an ideal static background tissue which is optically homogeneous. This background tissue replaces the original heterogeneous tissue sample; therefore, creating correlated adjacent A-lines. Figure 44.4 presents a flowchart that highlights the algorithm used for the OMAG and DOMAG calculation.

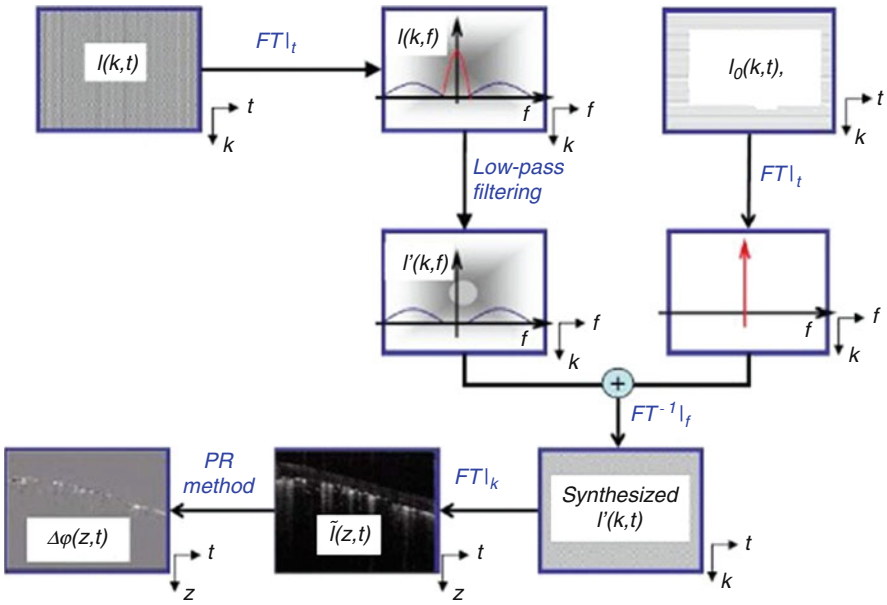

Fig. 44.4 Flow chart showing the steps for DOMAG to evaluate the velocities of blood flow from a B-scan data set, $I(k, t)$. The data coordinates are indicated in the *lower right* corner of each data block, where t is the time variable of probe beam scanning over a sample, k is the wavenumber, f is the spatial frequency, and z is the imaging depth. $\mathbf{FT|_t}$ represents the Fourier transform (FT) against the time variable t in the B scan; $\mathbf{FT^{-1}}\,|_\mathbf{f}$ indicates the inverse FT against the spatial frequency, f; and $\mathbf{FT|k}$ is FT against the wavenumber k (Modified figure reprinted with permission from Ref. [38])

DOMAG has been demonstrated to be more sensitive to the phase velocities than simple Doppler analysis as in phase-resolved Doppler OCT [38]. Figure 44.5 presents a comparison of both methods.

Figure 44.6 presents an example of a cross-sectional cut (B scan) obtained from a mouse brain with an intact skull. The location of the vessels and the Doppler signal can be observed.

OMAG has been applied in both the fast axis (B scan) and slow axis (C scan), for imaging fast and slow flows, respectively. Given that the time interval between A-lines in the slow axis is larger, this method allows higher sensitivity to capillary flow [41]. However, the high sensitivity requires removal of bulk-motion artifacts by resolving the Doppler phase shift.

44.2.3.2 Joint Spectral and Time-Domain OCT

A variation of OMAG is the joint spectral- and time-domain OCT (STdOCT). STdOCT requires the acquisition of a high number of repeated A scans at the same lateral position which increases the imaging time [42, 43]. The method consists on processing the interferograms along both the spectral and the time domain. This is done by applying two-dimensional Fourier transforms which converts the

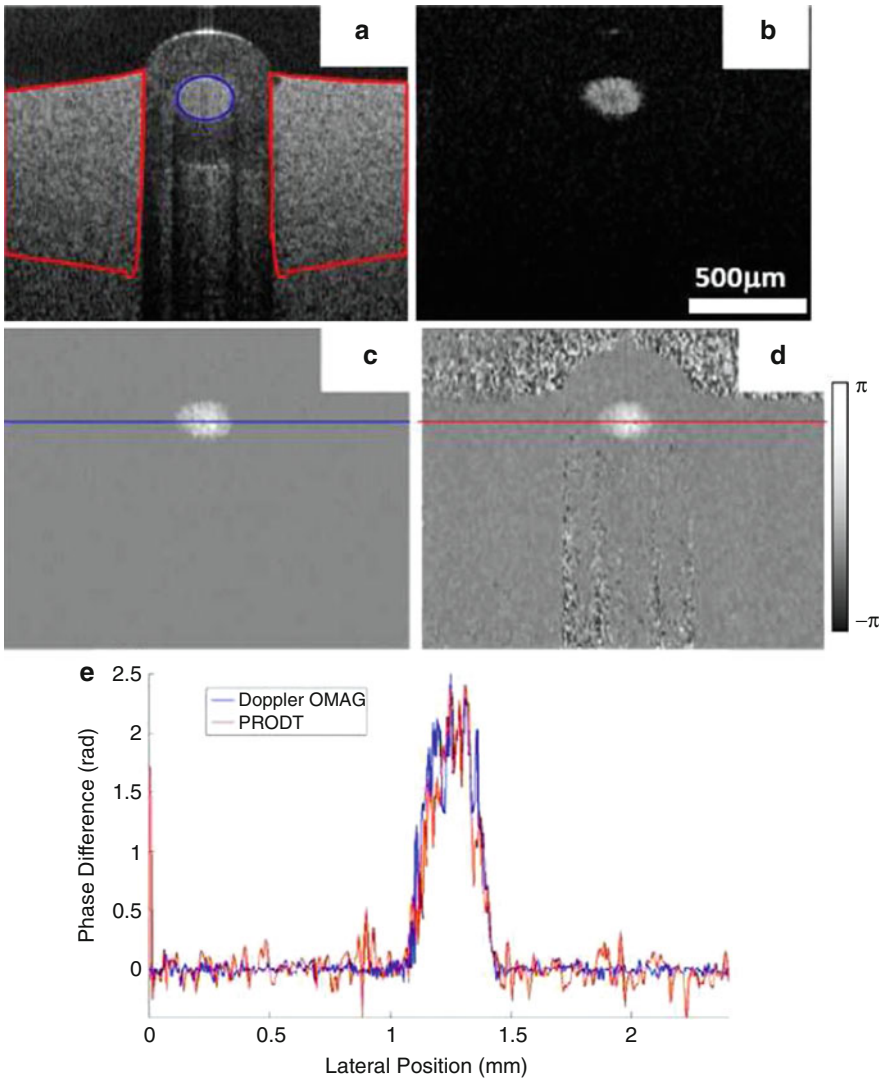

Fig 44.5 Flow phantom experiment results. (**a**) OMAG structural image, (**b**) OMAG flow image, (**c**) DOMAG velocity image, (**d**) PRDOCT velocity image, and (**e**) flow signal profiles extracted from the positions marked in (**c**) and (**d**) (Modified figure reprinted with permission from Ref. [38])

data from "wavenumber – time" domain to "in-depth position – beat frequency" domain. In this method, the squared maximum of the highest peak is proportional to the reflectivity of the scattering particle, and the position of the highest peak along the beat frequency axis ends up being proportional to the velocity.

[38])

44.3 Sources of Noise

There are several sources of noise for obtaining microvascular information from the OCT systems. The sources of noise are divided into system and sample noise. System noise relates to all the sources that come from the OCT system itself. These include the shot noise and the jitters caused by the scanners that move the probe beam spot over the sample. Shot noise has been previously studied, and the minimum measureable phase shift (assuming a zero-mean, complex Gaussian) is given by $\frac{1}{\sqrt{SNR}}$, where SNR is the signal-to-noise ratio [44–46]. The sample noise relates to the physiological motion artifacts, such as the heart and respiration rates, as well as vibrations that are mostly minimized by the use of floating tables. A crucial problem in imaging microcirculation is that the blood flow velocities can be lower than typical physiological or bulk tissue motion. Therefore, rejection of the tissue motion artifacts becomes critical.

The effects of noise can be separated into axial and lateral properties. In the axial direction, the effects can cause phase shift and decorrelation. Axial motion

compensation algorithms, such as the use of a histogram method, can correct phase shifts smaller [47] and larger [41] than $\lambda/4$, given that every axial position in an A-line experiences the same shift. A lateral shift can also cause decorrelation [48], which is usually not corrected due to its complicated nature; however, some methods have been derived [49].

A challenge in imaging at capillary level is that a large Δt between A-lines is required to allow for slow flow decorrelation; however, this duration is prone to higher motion artifacts.

44.4 Applications

Several diseases have been related to the changes in the vascular network of the tissues. In this section various examples of applications for studying vessel microangiography in different biological tissues are presented. The illustrations used in this section have been previously obtained using the OMAG technique; however, all of the techniques described above may be used based on their own advantages and drawbacks.

One of the most common applications for OCT, which has gained wide commercial acceptance, is the imaging of the human retina. OCT has been used to evaluate macular holes, assess vitreoretinal interface, diagnose macular edema, assess age-related macular degeneration, and others. Currently, fluorescein angiography is the gold standard for vascular imaging of the retina. However, fluorescein angiography is invasive and time consuming and presents side effects [50]. OMAG has allowed the imaging of the retinal microvasculature without using contrast agents, as shown in Fig. 44.7. An advantage of using OMAG is that it is possible to obtain both the structural and microvascular images. The different tissue layers such as the ganglion cell layer, inner plexiform layer, and outer plexiform layer can be segmented from the structural image, and this can then be applied on the three-dimensional microvascular image itself to separate the vascular networks within landmarked layers.

There has also been interest in imaging the anterior segment of the eye around the corneoscleral limbus. This area is important given that the aqueous outflow system, which regulates the intraocular pressure of the eye, must work properly to maintain a healthy physiological pressure within the eye. Changes in the tissue perfusion and vascularization may affect the behavior of the aqueous outflow system, causing a deregulation of the intraocular pressure which may lead to diseases such as glaucoma. Figure 44.8 presents an example of images obtained from the anterior segment of the eye.

Several skin diseases, such as psoriasis, have also been related to changes in the microvasculature of the tissue. Figure 44.9 presents an example of microvascular images obtained from different skin layers, such as the papillary dermis, reticular dermis, and hypodermis. The vessel morphology has different patterns for each tissue layer.

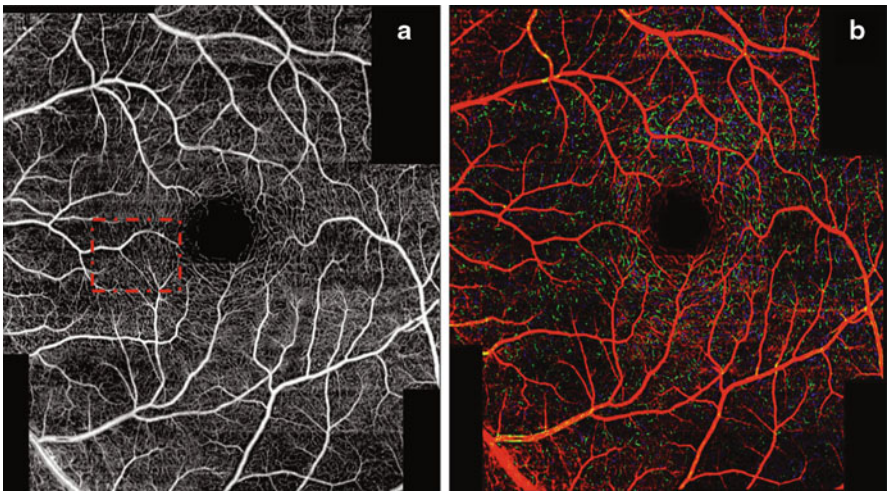

Fig. 44.7 Projection view image of (**a**) retinal microvasculature maps within a large field of view and (**b**) the corresponding color depth-encoded retinal vasculature map (the *red*, *green* and *blue colors* represent the ganglion cell layer, inner plexiform layer, and outer plexiform layer, respectively) (Modified figure reprinted with permission from Ref. [41])

The mouse brain has been a great model for neurological disorders, such as stroke and traumatic brain injury. OMAG is well applicable for imaging this tissue [21] and has the advantage of not requiring the removal of the skull, which makes the procedure highly noninvasive. Figure 44.10, presents an example of an image of the mouse brain.

Cochlear blood flow has been related to several hearing disorders such as noise-induced hearing loss, age-related hearing loss, sensorineural hearing loss, tinnitus, and Ménière's disease. OMAG has recently been used to image the vessels in the cochlea [51–54] and study several hearing disorders that are related to cochlear blood flow. Figure 44.11 presents an image of the vessels from a mouse cochlea, including the scalae which were extracted from the structural image.

44.5 Angiography Quantification

The analysis of the tissue vasculature is an important biomarker for determining the health of tissues. It has been demonstrated that the changes in retinal vessels is an early indicator of coronary heart disease [55] and stroke [56]. Microangiography images enable the visualization of blood vessels and capillaries in biological tissues. These images are usually interpreted qualitatively by an expert reviewer [57]; however, they lack of quantitative information and the analysis has large variability among reviewers. Some methods provide quantitative information from these images such as the blood vessel diameter [58] and the distance between

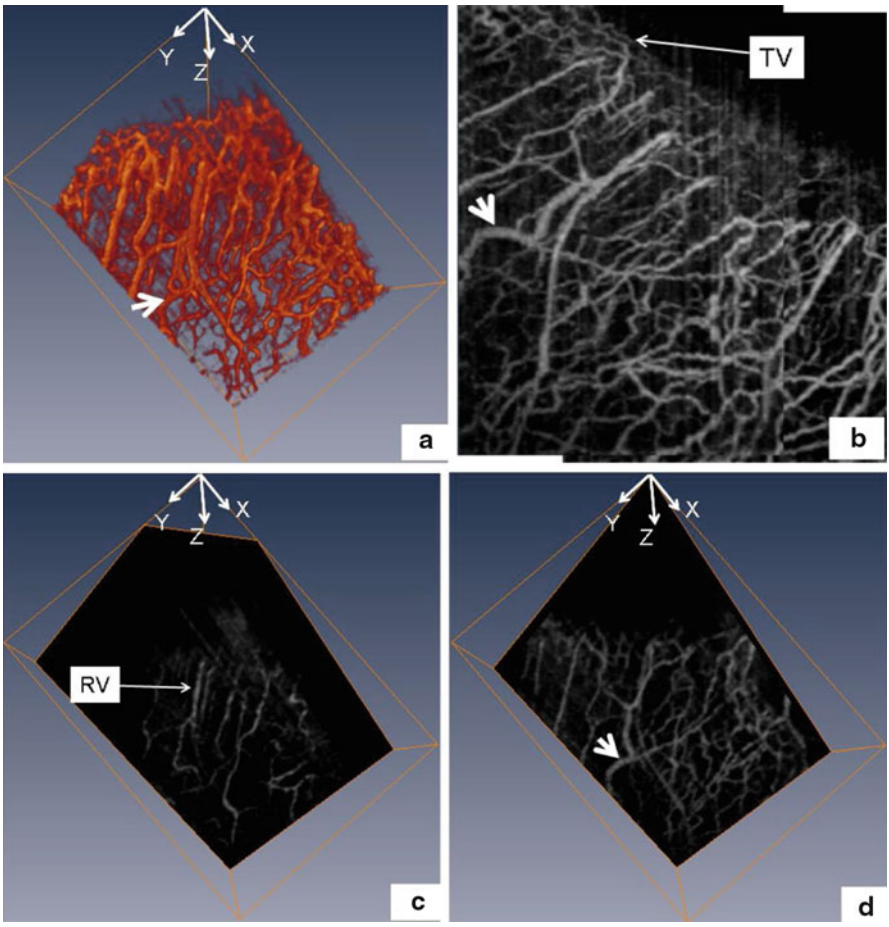

Fig. 44.8 In vivo 3D blood flow imaging of the human corneoscleral limbus from a temporal location. (**a**) 3D rendering of the flow images, (**b**) projection view (x-y) from the 3D blood flow image, (**c**) oblique slice of (**a**) within the conjunctival layer, and (**d**) oblique slice of (**a**) in the scleral area. *Bold white arrow* indicates the episcleral vein; *TV* terminal vessel, *RV* recurrent vessel. The physical image size was 5.5 × 4.0 × 3.0 (x-y-z) mm^3 (Modified figure reprinted with permission from Ref. [64])

blood vessels [59]. Other parameters that have been quantified include the vessel area density (a relative value which represents the area of the vessels), vessel length fraction (a relative value which represents the length of the vessels), and the fractal dimension (a relative value which represents the tortuosity of the vessels) [60].

Although there are several methods for analyzing angiography images, they all contain a vessel segmentation algorithm. The analysis is usually done over two- or three-dimensional images [61]. Given that the OCT signal exponentially degrades with depth due to the scattering and absorption attenuation of the light (Beer-Lambert law), it is commonly preferred to analyze a two-dimensional projection

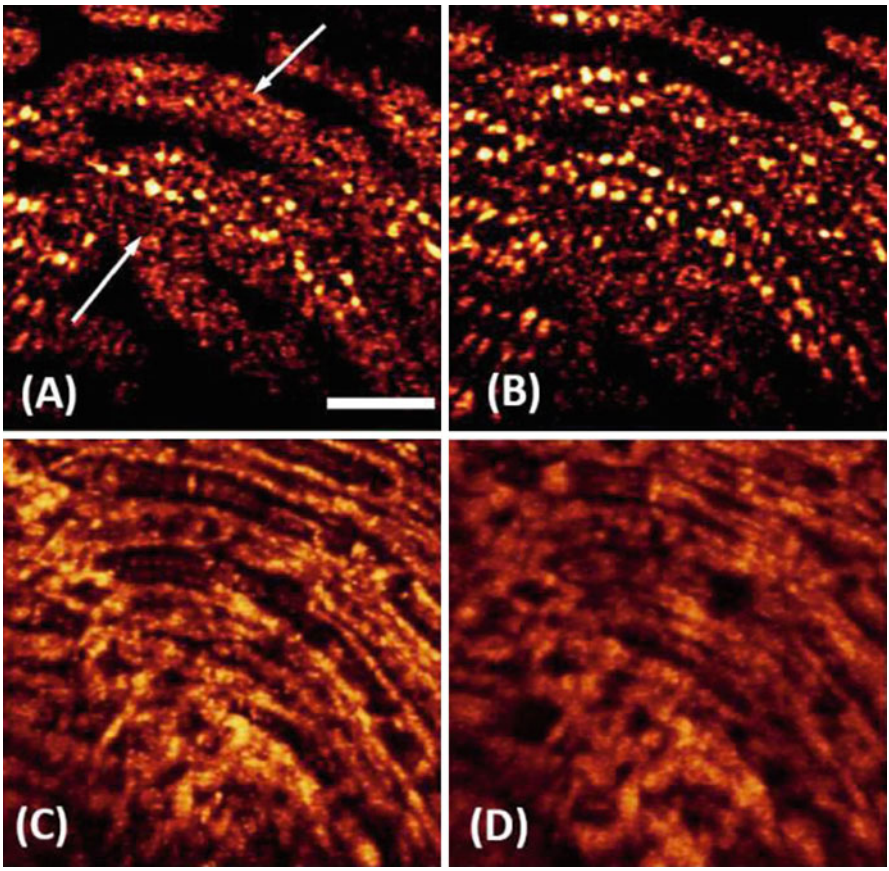

Fig. 44.9 Detailed projection view of microcirculation network at different depths of skin obtained from (**a**) 400–450 μm (closely representing papillary dermis), (**b**) 450–650 μm, (**c**) 650–780 μm (closely representing reticular dermis), and (**d**) 780–1,100 μm (part of hypodermis), respectively. The strength of reflectance signals in the images is displayed within a range between 20 (*dark*) and 50 dB (*bright*) (Modified figure reprinted with permission from Ref. [65])

view of the three-dimensional image. In several cases the images are also skeletonized to show the backbone of these vessels. Figure 44.12 presents an example of the binarization and skeletonization of a section of a two-dimensional projection view image of a mouse ear.

In Fig. 44.13 a projection view image of the vascularization of a large area of a mouse ear is presented. The fractal dimension calculated throughout the mouse ear is also depicted. There are regions with highly tortuous vessel which contain higher fractal dimension values (orange/red areas) compared to the smoother vessels which present a lower fractal dimension value (yellow/green areas). Two regions of interest were selected with high and low tortuosity, and the mean and

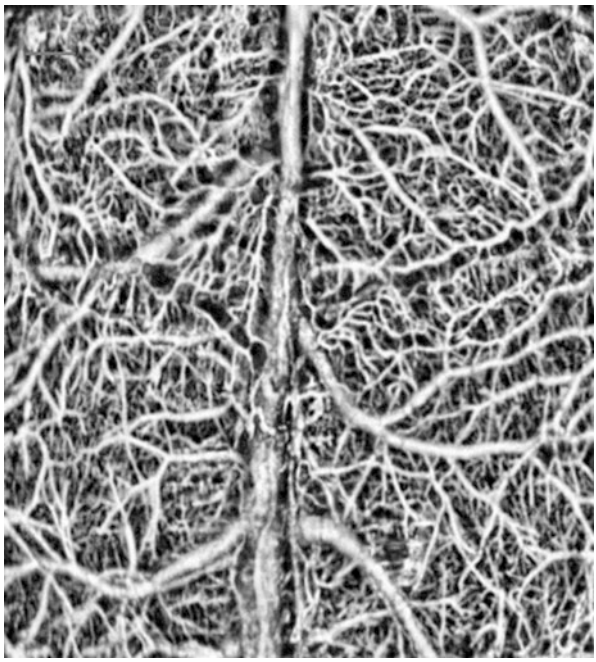

Fig. 44.10 Projection view image of the vessels located in the mouse brain with an intact skull. Scale bar: 500 μm (Modified figure reprinted with permission from Ref. [66])

standard deviation of these regions have been presented in Fig. 44.13c. This type of quantitative analysis may be applicable for the diagnosis and development of treatments for several vascular diseases.

44.6 Integrated Imaging Modalities

Integrated imaging modalities have been used to extract a wider range of information from biological tissues. Each imaging modality is sensitive to a different set of parameters; therefore, the advantage of combining them offers the ability to extract a larger amount of information. The parameters obtained from several imaging modalities can be taken together to provide a greater picture about the physiological properties of the tissue. In this section we briefly highlight a few of these combined imaging techniques.

Photoacoustic microscopy is an imaging modality that can detect changes in the concentration of oxyhemoglobin and deoxyhemoglobin within small vessels. Photoacoustic microscopy has been previously combined with the Doppler OCT to determine the metabolic rate of oxygen [62]. The metabolic rate of oxygen can be obtained by integrating the hemoglobin oxygen saturation and vessel diameter information obtained with photoacoustic microscopy, with the blood flow velocity obtained with Doppler OCT.

Dual-wavelength laser speckle contrast imaging has previously been combined with OMAG. Dual-wavelength laser speckle contrast imaging is a simple technique

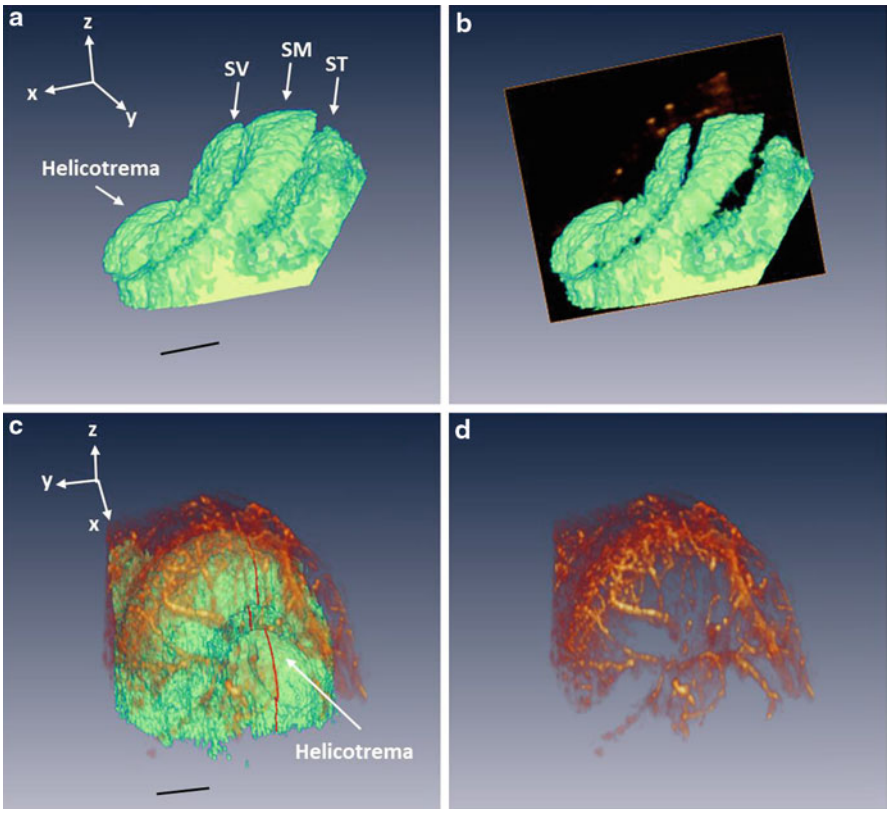

Fig. 44.11 (**a**) Three-dimensional side view of the scala media (*SM*), tympani (*ST*), and vestibuli (*SV*), (**b**) with a cross section showing the blood vessels obtained with OMAG. The cross section cuts through the apical turn close and far away from the helicotrema. The OCT light is incident in the z direction. (**c**) Apex view of the three-dimensional overlap of the cochlear scalae and the blood vessels. (**d**) Blood vessels alone. The *red line* through the center plane in (**c**) corresponds to the same cross-sectional area depicted by the *black square* in (**b**). The *black line* in (**a**) and (**c**) represents 250 μm (Modified figure reprinted with permission from Ref. [51])

which enables the extraction of the changes in the concentrations of oxyhemoglobin, deoxyhemoglobin, and total hemoglobin [63]. Figure 44.14 presents an overlap of an image obtained with both the OMAG and laser speckle contrast imaging system from a mouse ear after a burn injury. It can be noted that the middle circle presents the burn area where there are no vessels that can be observed and there is a decrease in blood flow.

In the commercial area, newer devices are being incorporated into the Fourier-domain OCT machines. For example, they have been combined with scanning laser ophthalmoscope technology, OCT with indocyanine angiography, and polarization-sensitive OCT using the birefringent characteristics of the retinal nerve fiber layer to better evaluate its thickness.

44.7 Summary

This chapter has reviewed the use of OCT for extracting the three-dimensional microvascular angiography from biological tissues in vivo. We have explored different methods of using the OCT system and described the advantages and disadvantages from each method as well as the overall general challenges. Several existing application for the microvascular angiography have been described; however, new applications are constantly being conceived. Methods for quantitatively analyzing these images have been described, and applications of combined imaging systems have been characterized.

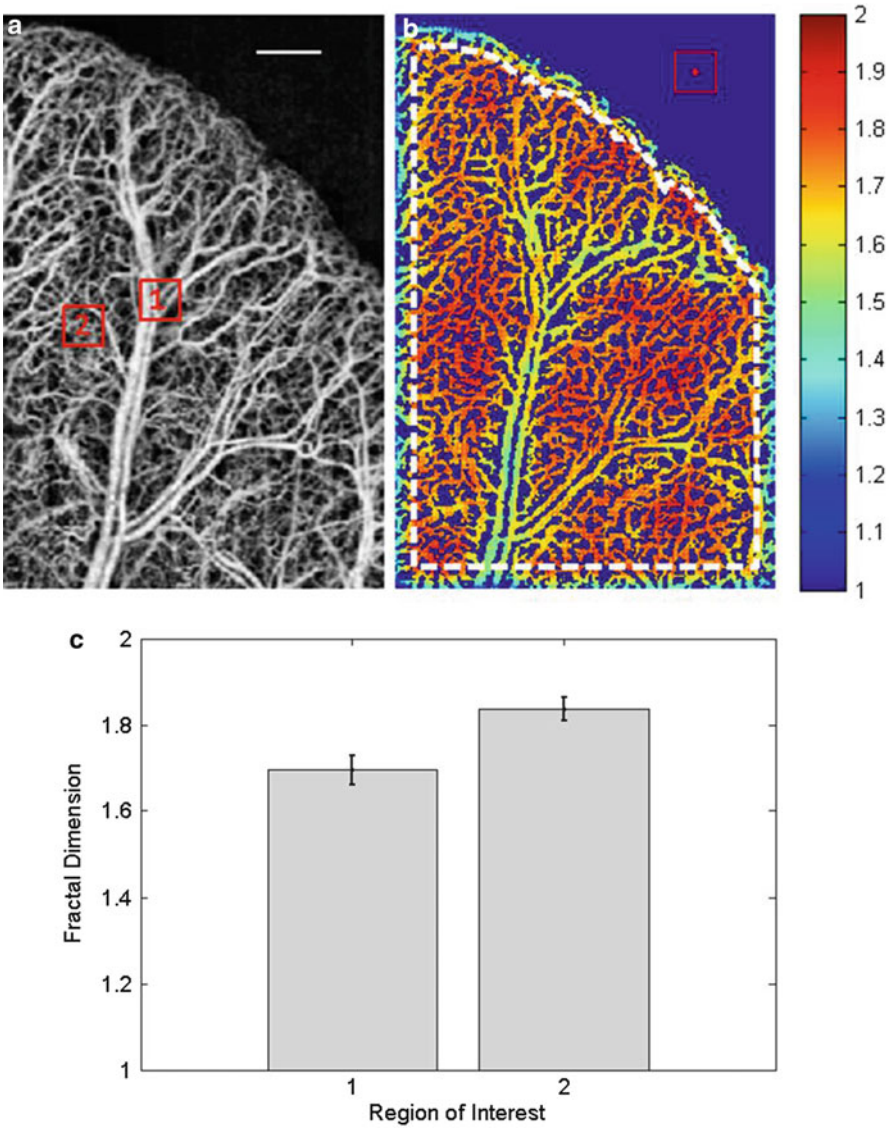

Fig. 44.13 (**a**) OMAG images obtained from the mouse ear. Scale bar is 0.5 mm. (**b**) *Black* and *white* segmented image multiplied by the fractal dimension. (**c**) Mean and standard deviation of the fractal dimension for the two regions of interest in (**a**) (Modified figure reprinted with permission from Ref. [60])

Fourier-domain OCT systems are a promising imaging device for several clinical applications, based on their rapid acquisition time and high resolution and sensitivity. However, while high acquisition speeds of A scans minimize the effects of motion artifacts in a single frame, the three-dimensional data sets are still subject

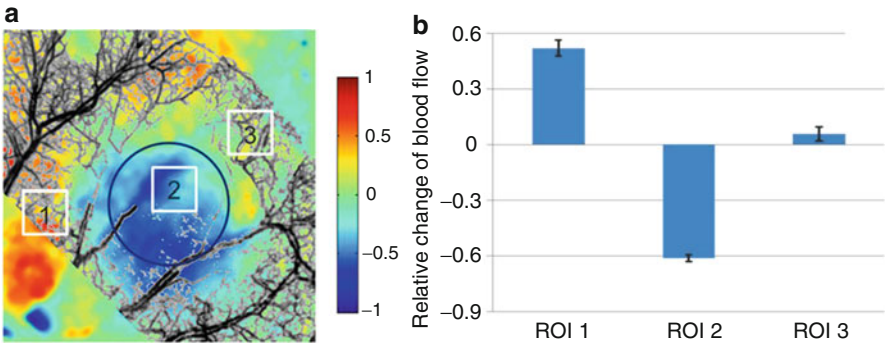

Fig. 44.14 (**a**) Co-registered image of the change in blood flow with the projection view image of the blood vessel network obtained by the OMAG method after the injury. (**b**) Mean and standard deviation of the relative change in blood flow from the three regions of interest in (**a**) (Modified figure reprinted with permission from Ref. [63])

to movements, as they are acquired over a few seconds. Further improvements in readout rates and pixel densities of CCD cameras in the case of SD-OCT may overcome much of these limitations.

Investigations into the biology of cancer and novel cancer therapies rely on preclinical mouse models and traditional histological endpoints. Historically, tumor growth and disease progression were monitored by periodic caliper measurements and by endpoint measurements of weight or volume in preclinical models. Drawbacks of this approach included the difficulty in assessing cell viability and the effect of therapeutics on tumor vasculature, a limit in the number of time points for evaluation, and an increased number of animals per study [1].

The adoption of imaging modalities that allow for noninvasive, serial imaging represented a breakthrough in the field. Cancer investigators were able to employ simple-to-use, scientifically reliable technology which translated into more accurate results and simplified experimental workload. Preclinical versions of radiological tools [2] such as magnetic resonance imaging (MRI) and positron-emission tomography (PET) are commonly available as core instruments to many cancer investigators. Optical fluorescence and multiphoton microscopy [3] have also been adopted into cancer investigations to enable high-resolution imaging with molecular contrast and to validate in vitro studies with fluorescently labeled cells. Together, these tools have accelerated the pace of discovery in cancer biology and drug development and advanced our understanding of complex biological processes.

By contrast with fluorescence confocal and nonlinear microscopy, OCT has seen a more rapid integration into clinical diagnostic medicine [4] than into basic or preclinical research. This was driven by the unique capabilities of OCT to image

rapidly, to probe deeper into tissue, and to operate without the need for labels or contrast agents [5]. Recent works, however, demonstrate that OCT has the potential to become a key player in intravital preclinical imaging in cancer research [6]. This is especially evident in vascular studies where OCT-based angiography offers new capabilities to characterize and monitor the process of angiogenesis and the response of tumor vessels to therapy.

To date, OCT has contributed to cancer research in a variety of ways [6]: OCT has been used to monitor tumor burden [7], to reveal wide-field tumor vascular morphology, to noninvasively monitor lymphangiogenesis and lymph vessel dysfunction, and to differentiate viable and nonviable tumor compartments during tumor growth and anticancer drug therapy. Here, examples where OCT serves as a valuable tool for preclinical cancer research are summarized.

45.1 Angiography

Angiogenesis is a crucial step by which a tumor develops its own de novo blood vessels [8]. Tumor cells secrete angiogenic factors to induce the creation of new vascularization. Unlike physiological angiogenesis, tumor angiogenesis is a seemingly chaotic process that results in the development of a largely dysfunctional vascular network [9]. Given the central role that angiogenesis plays in tumor biology, it is a much sought-after target for therapeutic intervention. Many antiangiogenic molecules have been developed, such as VEGFR inhibitors, and some are being used clinically [10–12]. However, despite the discovery of very potent antiangiogenic molecules, and their promising results in preclinical models, these drugs have translated poorly into the clinic, often offering minimal improvement upon existing therapies [13].

Intravital imaging has played an important role in the study of tumor angiogenesis and antiangiogenic treatment during the past decades. Commonly used methods to visualize blood vessels in vivo include Doppler ultrasound [14], micro-magnetic resonance imaging (μMRI) [2], μCT [15], photoacoustic tomography [16–19], and fluorescence microscopy [20]. The nonoptical methods (Doppler ultrasound, μMRI, and μCT) are limited by their relatively low resolutions, which make it difficult to visualize single vessels. By contrast, fluorescence microscopy has sufficiently high resolution to resolve individual vessels, but are often limited in their depth penetration and field of view. Furthermore, fluorescence methods require systemic vascular labeling with exogenous contrast, which can accumulate in tissues in longitudinal studies [21]. Because OCT has a larger field, deeper penetration, and images without exogenous labels, it can be used in angiographic applications where the drawbacks of fluorescence microscopy are significant.

OCT-based angiography is based on dynamic changes in optical scattering induced by moving scatterers in the blood. Many approaches for detecting these changes have been used, and each has specific benefits and limitations. Originally, Doppler processing techniques revealed the optical frequency shift of induced by upward or downward flowing blood [22–24]. Later, approaches that cue in on

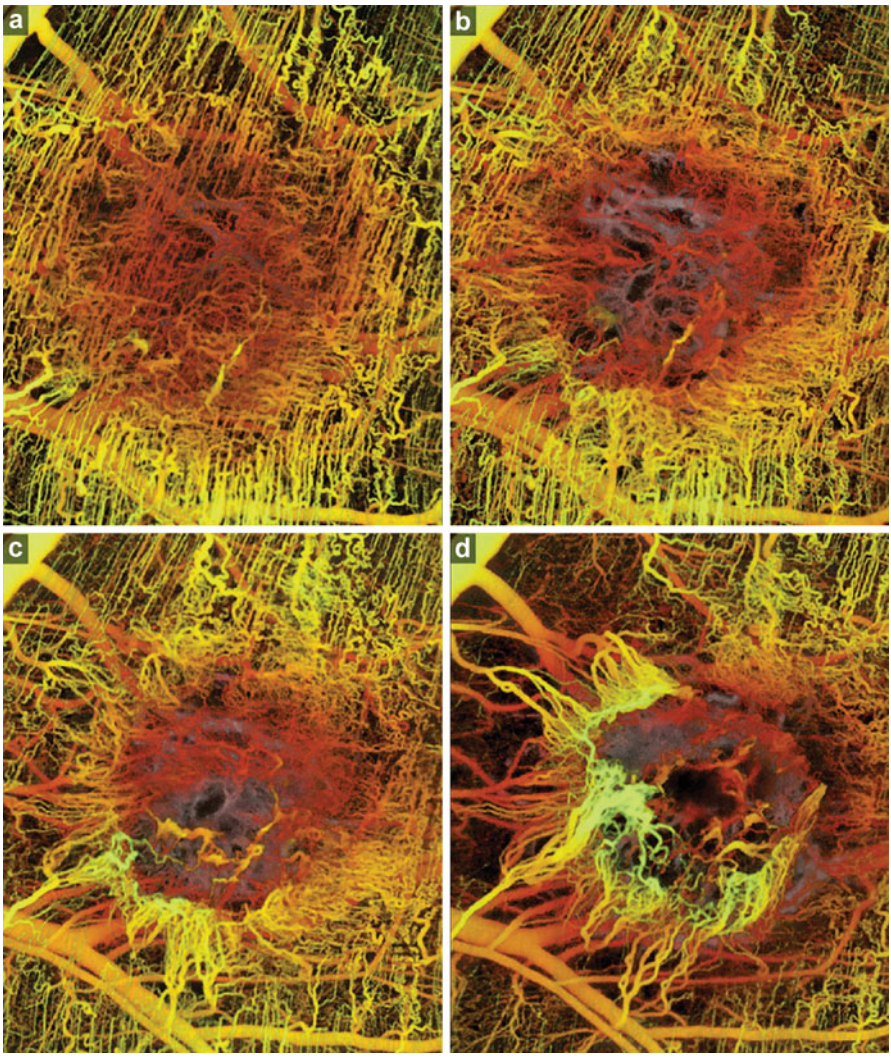

Fig. 45.1 Longitudinal OCT-based vascular imaging of a breast cancer (MCaIV) tumor growing in a dorsal skinfold chamber (angiography). *Color* is used to encode vessel depth in these projections of the three-dimensional angiographic dataset. Relative imaging times: (**a**) d0; (**b**) d2; (**c**) d6; (**d**) d10

the intensity fluctuations induced by flowing blood were used [25, 26]. Currently, there are algorithms in use that are entirely phase based [27–29], intensity based [30–32], or combine both intensity and phase [6, 33–35]. An example of OCT-based angiography is shown in Fig. 45.1. Here, OCT was used to monitor tumor vascularization longitudinally over a wider field and to deeper depths than is possible using alternative optical microscopies. Note the ability of wide-field OCT

angiography to visualize the aggressive vascularization of the tumor and the modulation of host vessels to support this vascularization.

To detect OCT signal dynamics, at least two measurements of nominally the same location are compared. Original approaches used adjacent depth scans (A-lines) for these measurements and slowed the transverse beam scanning to ensure sufficient beam overlap between the measurements [22–24]. While this approach is straightforward to implement, the time separation between measurements was relatively small and dropped as OCT A-line rates increased. This resulted in relatively poor flow sensitivity, yielding patchwork angiographic datasets characterized by frequent missing vessels and vessel segments. The sensitivity of OCT-based angiography to smaller and slower flowing vessels increased dramatically when angiographic imaging adopted beam scanning sequences that decoupled the time difference between repeated measurements from the system A-line rate. This could be done as simply as comparing between frames (thereby linking measurement timing to the frame rate) [26, 27, 30, 36] or by designing more complex scan patterns that separate both the frame rate and the A-line rate from the measurement timing [6, 29, 37].

Animal motion is a persistent challenge for preclinical angiographic imaging. Bulk physiological motion from animal respiration or cardiac cycles can induce submicron displacements which are easily detectable by OCT and can obscure vascular signals. Two strategies are combined to limit bulk motion degradation: mechanical stabilization and algorithm design. Mechanical approaches simply limit the magnitude of physiological motion. These include the stable fixture of window frames (dorsal or mammary fat-pad window models [21]) to the microscope, or a secure holding of the animal head when imaging in the brain. Imaging in the skin and with subcutaneous (non-window) models typically requires some level of mechanical stabilization; otherwise, respiratory motion often dominates vascular signals. Adhesive fixtures [30] or inverted microscope designs can be used in these studies. However, when immobilizing the imaging area, it is important to control the pressure in order to maintain blood flow and avoid possible occlusions. The second strategy to combat bulk motion is algorithmic in nature. Many of the most successful angiographic algorithms are designed to be inherently robust to sub-pixel axial displacements induced by environmental fluctuations and animal motion. While automated measurement and removal of this motion is possible in some applications, robust deployment in large biological studies benefits from a more fail-proof method to limit bulk motion sensitivity. Eliminating OCT signal phase [30–32], or specifically tailoring how phase data is included in angiographic processing [6], has yielded algorithms that are intrinsically insensitive to sub-resolution axial bulk motion.

45.2 Tumor Margins

Tumor margins are extremely important not only in cancer investigation but also in the clinic. The boundaries between healthy and tumor tissue are often blurred and, in most cases, difficult to distinguish in vivo with current imaging diagnostics without the need for a biopsy. In recent years, the study and characterization of the

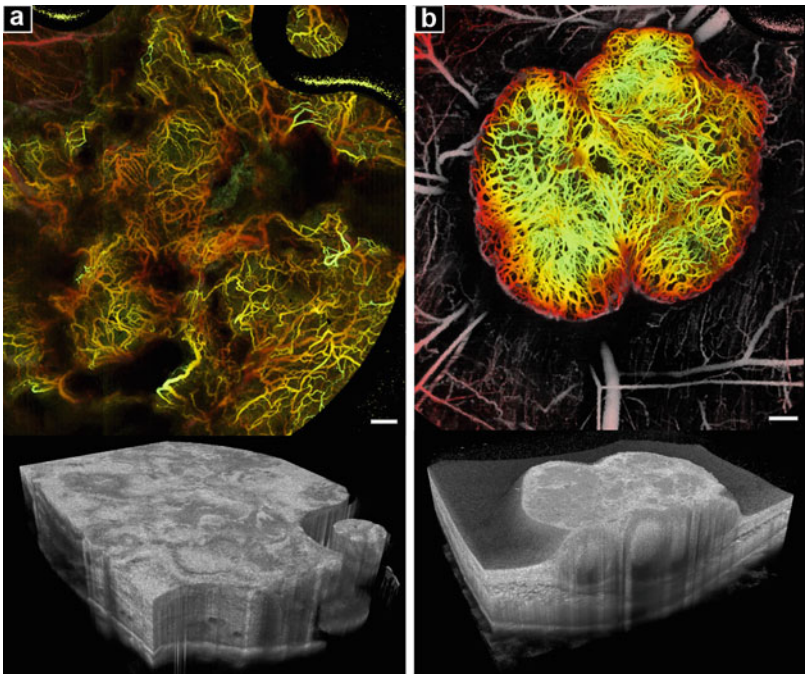

Fig. 45.2 OFDI angiography across tumor types and sites. (**a**) A human breast cancer cell line (MDA-MB-361HK) growing in the mammary fat pad window chamber model of a female SCID mouse. Large avascular regions are notable in the vascular image (*top*) and reflected in the topographically diffuse tumor microstructure (*bottom*). (**b**) Tumor vasculature of a human colorectal adenocarcinoma (LS174T) implanted in the dorsal skinfold chamber of a SCID mouse (*top*). Nonviable tissue is evident within the tumor nodules on cross section (*lighter regions*) in the tissue scattering intensity image (*bottom*). Scale bars 500 μm (Adopted from Ref. [6])

tumor microenvironment and the delicate, complex dialogue between tumor cells, host cells, and inflammatory agents has become one of the epicenters of cancer investigations. Delineating the tumor margin is of paramount importance for tumor resection in the operating room, characterization of tumor progression, and/or remission under drug therapy in the clinic and to better understand the molecular pathways and drug targets involved in the tumor microenvironment [20].

Gross measurements using calipers are the primary method for preclinical measure of tumor size or volume. This method suffers from obvious inaccuracies and cannot be used longitudinally in many sites such as the brain. Because OCT benefits from relatively high soft tissue contrast, three-dimensional OCT can often be used to delineate tumor from host tissue at near cellular resolution. This use of OCT to probe tumor volume and boundaries is especially attractive in studies when OCT is also being used to probe another measure such as the tumor vasculature (Fig. 45.2). Here, because OCT structural images are obtained simultaneously with angiographic imaging, the overall imaging procedure does not need to be

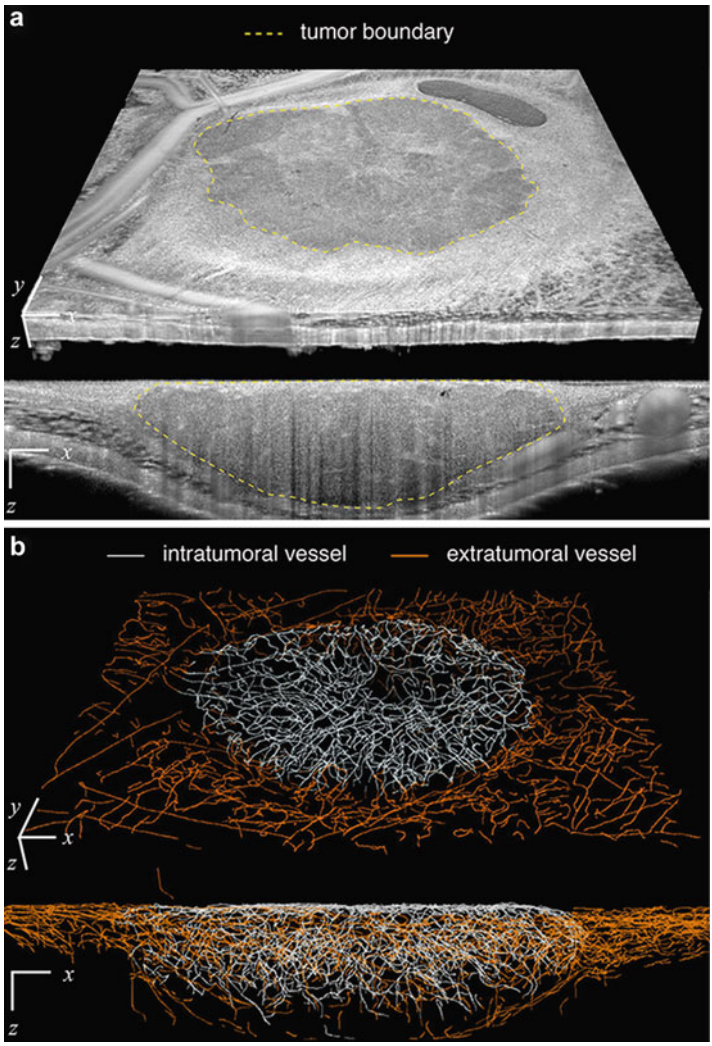

Fig. 45.3 Vascular tracing and structural correlation. (**a**) Microanatomical display showing tumor boundary definition in a three-dimensional tissue volume. (**b**) Skeletonized traced vessels differentiated between intratumoral and extratumoral for the tumor depicted in (**a**). Transverse extent in (**a**, **b**) 5 mm (x), 4.4 mm (y) (Adopted from Ref. [6])

lengthened, and the additional information on tumor size and the ability to define intra- and extra-tumoral vessels is often valuable (Fig. 45.3). One drawback of OCT is that it is limited by its depth penetration; OCT can only image soft tissue up to a depth of 2 mm. Thus, larger tumors cannot be comprehensively imaged using OCT. However, OCT can probe more superficial segments of the tumor and often reveal growth/regression trends for this segment (Fig. 45.4).

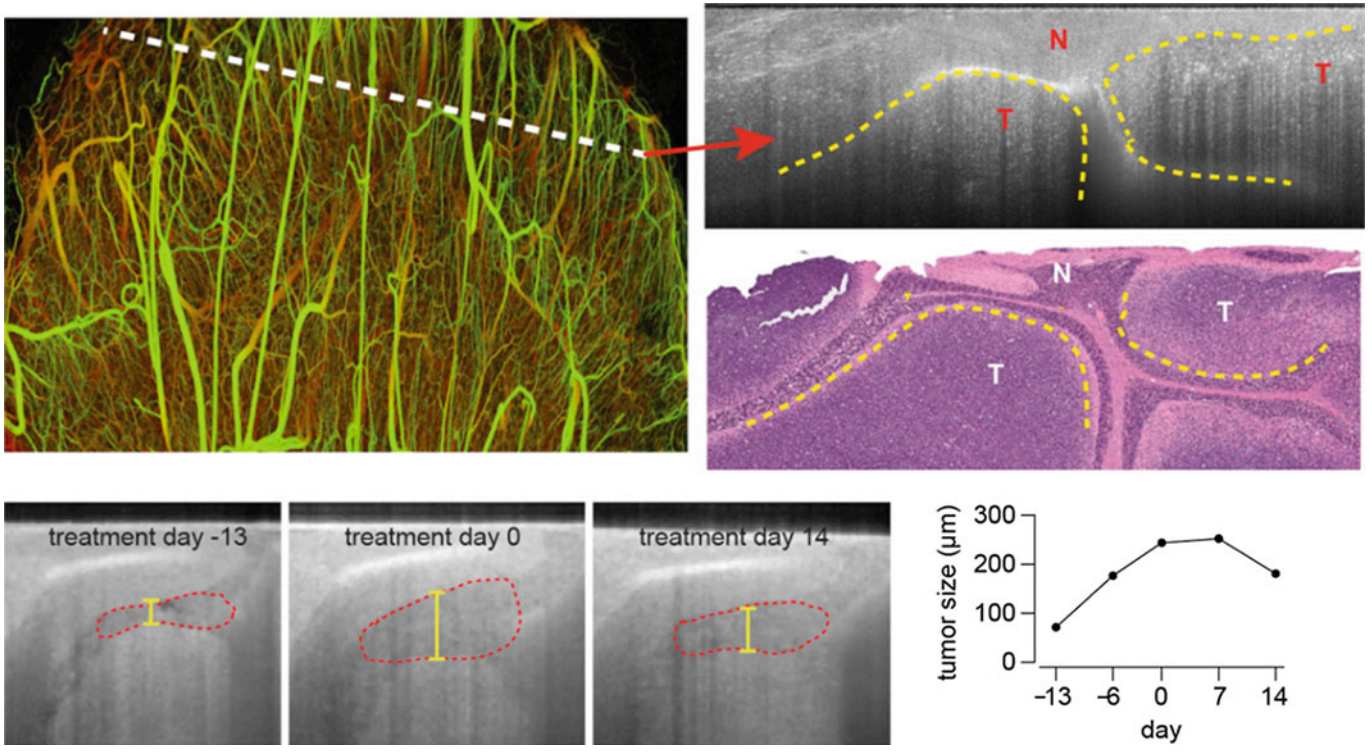

Fig. 45.4 Monitoring medulloblastoma growth using OCT. OCT images (*top right*) show distinct regions that can be correlated with normal (*N*) and tumor (*T*) tissues in histology (*middle right*). *Longitudinal imaging* shows growth and tumor regression with αPlGF treatment (*bottom left*). The *red dotted line* represents the tumor area observed with OCT, and the *yellow line* is the tumor diameter that was quantified during treatment (*bottom right*) (Reprinted from Ref. [7])

45.3 Tissue Viability Imaging

In addition to size, OCT signals can be used to differentiation between regions of viable and nonviable tissue within tumors. Tumors will commonly contain pockets of necrotic tissue due to insufficient perfusion. In addition, treatments often affect the tumor in a spatially heterogeneous manner, leading to differential viability. Viability imaging is typically done using micro-positron-emission tomography (μPET) using ^{18}F-fluorodeoxyglucose (^{18}F-FDG) as a radiographic contrast agent [2]. However, μPET has limited spatial resolution, usually greater than 1 mm. Fluorescence microscopy has also been used to monitor viability. Fluorescent deoxyglucose analogues have been used to study cell viability in cell culture as well as in vivo and may offer an alternative to PET imaging [38–41]. In addition, tumors expressing stable fluorescent proteins, such as the green fluorescent protein (GFP), will cease to produce the fluorescent protein upon cell death [42–44]. GFP has a half-life of 36 h, but its expression can be used as a crude measure of tissue viability. Both of these methods, however, are limited in their imaging field size and depth. In addition, they require exogenous agents to report viability.

It has been shown that OCT-detected tissue scattering magnitudes are dependent in some tumor models on the viability status of that tissue and that viable and nonviable tissues can be differentiated by analysis of the magnitude of associated OCT scattering signals [6, 45] (Fig. 45.5). Again, as with microstructural imaging, this viability contrast is derived directly from the microstructural images and can be combined with vascular and tumor margin measures. However, since the underlying cause of this increased scattering has not yet been elucidated, it is important to evaluate increased scattering in the context of other indications of viability. This is especially critical because increased scattering is not specific for viability changes.

45.4 Lymphangiography

The lymphatic system is partly responsible for fluid homeostasis and protein transport in the body and plays an important role in the development of a tumor [46]. As a tumor grows locally, it begins to shed cells into the lymph. Some of these cells travel through the lymphatic vessels to new sites, thus making the lymphatic system a critical component of tumor metastasis. In addition, the growth of a tumor can cause lymphatic compression, which can affect convective drug transport [47]. Finally, the lymphatics are a critical component of the immune system. Thus, the functionality of the lymphatic vessels can determine the effectiveness of the immune response to cancer. For these reasons, the ability to image the lymphatics is important if we are to broadly understand the processes driving tumor development and treatment resistance.

Generally, intravital lymphangiography is more challenging than angiography. While contrast can be introduced intravenously for imaging the blood vessels, accessing the lymphatic system surrounding a tumor site is considerably more

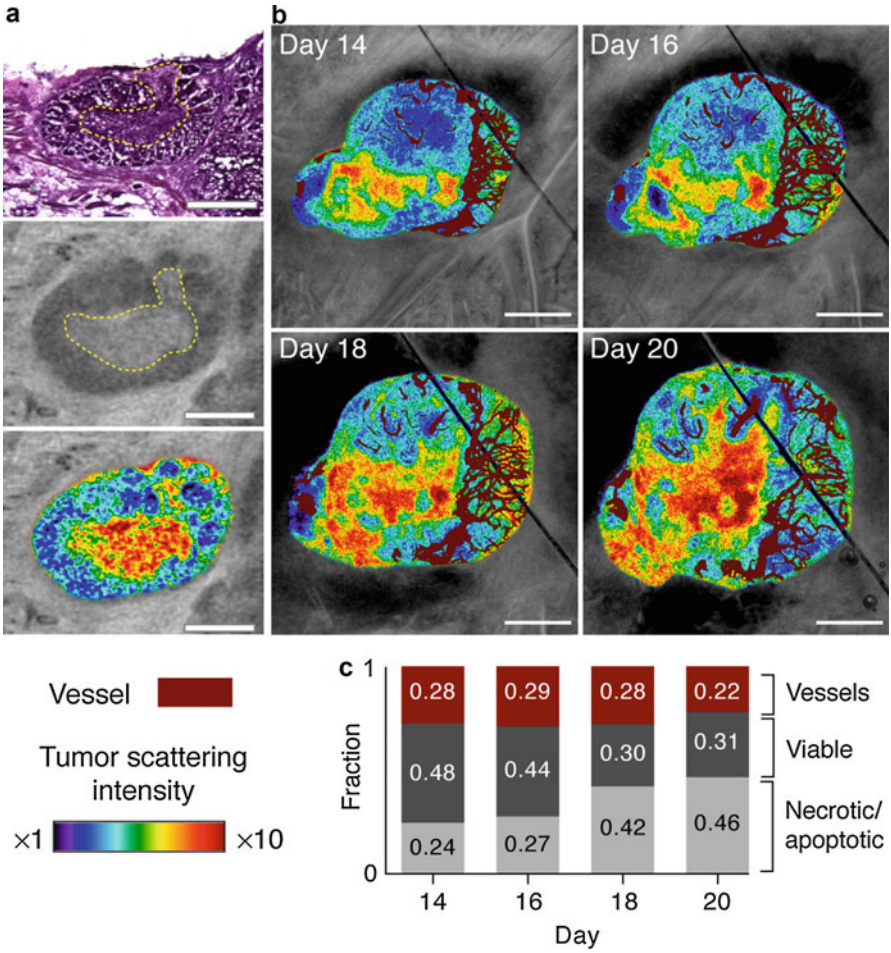

Fig. 45.5 Imaging tissue viability. (**a**) Comparison of standard hematoxylin and eosin staining (*top*) with OFDI (*middle*) reveals association of tissue necrosis with highly scattering regions. Viable and necrotic regions within the same tumor highlighted by color gradients indicating scattering intensity (*lower*). (**b**) Scattering properties correlated with the microvasculature during tumor progression illustrate the expansion of necrotic/apoptotic regions in areas with minimal vascular supply. Within the viable tissue, the mean distance to the nearest vessel was ~65 μm throughout progression. (**c**) Quantitative analysis of tissue viability and vascular regions in vivo revealed an increase in the fraction of necrotic/apoptotic tissue from ~24 % to ~46 % during tumor progression. Scale bars (**a**) 500 μm; (**b**) 1.0 mm (Adopted from Ref. [6])

difficult. The most common method involves injecting a tracer locally into the tumor and waiting for the draining lymphatic vessels to take up the contrast [48]. However, lymphatic uptake can be heterogeneous, so this technique often only allows imaging of a partial lymphatic network. Furthermore, local injection of contrast can disrupt the tumor microenvironment, including the lymph.

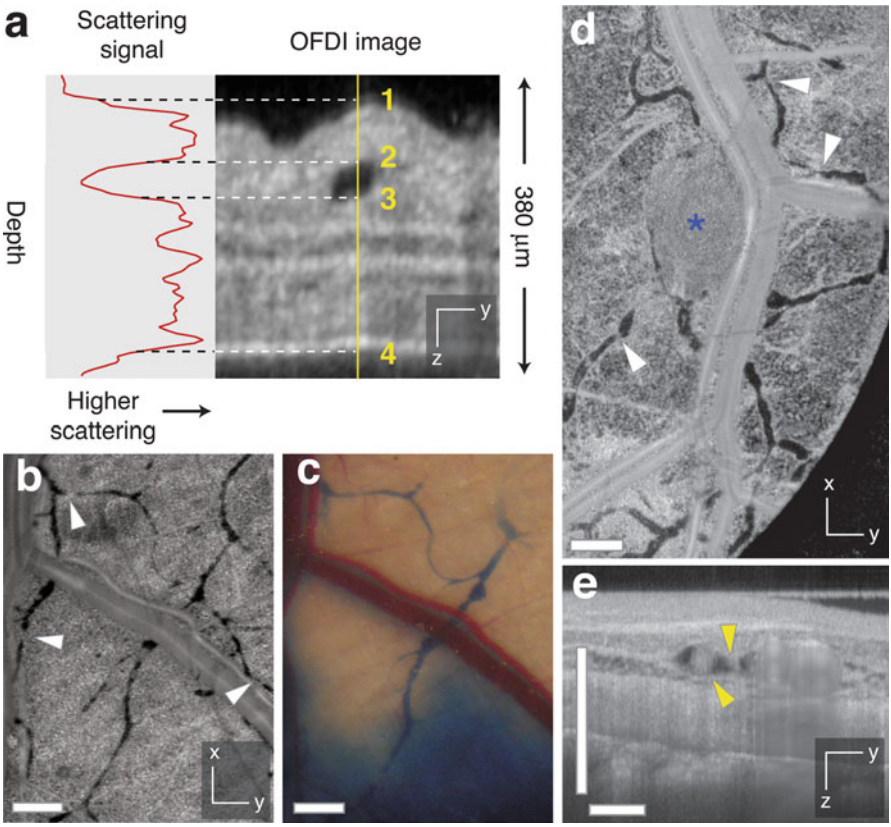

Fig. 45.6 Contrast-free lymphangiography using OCT. (**a**) The scattering signal along a single depth scan within an OFDI image of a mouse ear, showing the reduced scattering between the upper (*2*) and lower (*3*) boundaries of a patent lymphatic vessel. Scattering within the vessel is similar to background levels above the upper surface of the ear (*1*) or below the lower surface (*4*). (**b**, **c**) In addition to the lymphatic vessels revealed by traditional cutaneous injection of Evan's blue dye imaged by wide-field transillumination with a CCD camera (**c**), OCT lymphangiography (**b**) was able to detect numerous additional vessels in the normal dorsal skin and resolve the lymphatic valves found between individual lymphangions (*white arrowhead*). (**d**) OCT lymphangiography showing hyperplastic lymphatics associated with HSTS26T tumor (*blue asterisk*). (**e**) Cross-sectional presentations of OFDI lymphangiography showing cellular masses in a lymphatic vessel (*yellow arrowhead*) located near the tumor in (**d**). Scale bars, 500 µm (Adopted from Ref. [6])

Lymphangiography with OCT is possible due to the optical transparency of lymph fluid [6, 49]. The lymphatic fluid does not significantly scatter incident light, which is in stark contrast to the surrounding highly scattering soft tissue. Thus, in an OCT image, the lymphatic vessels appear hypoechoic when filled with lymph (Fig. 45.6). In addition, the lymphatic vessels have a unique valve and lymphangion morphology, allowing easy identification of lymphatic structures. A notable limitation of this method is that the lymphatic vessels are not always expanded and filled with fluid. This can sometimes make comprehensive

visualization of the lymphatic networks difficult. However, this limitation may be overcome with the use of higher-resolution OCT systems. OCT lymphangiography in the study of cancer has been performed in both ear models and dorsal skinfold chamber models. In recent work, OCT lymphangiography was used to track single lymphatic vessels longitudinally, where it demonstrated the presence of lymphatic hyperplasia in the peri-tumor environment.

45.5 Conclusions

In recent years, the scope of OCT imaging has expanded considerably in preclinical and basic science settings. The reason for this expansion can be found in its unique capabilities relative to alternative techniques. OCT is a truly noninvasive, high-resolution imaging modality that provides histological cross-sectional tomographic images and allows highly sensitive imaging of microvascular structures. One of the advantages of employing OCT is that it does not need administration of exogenous contrast agents or cell engineering for stable labeling with fluorescent or bioluminescent tags. In comparison with many other preclinical imaging modalities (such as MRI or PET), acquisition speed is faster. In addition, OCT can be successfully combined with other modalities (such as fluorescence confocal) for co-registration and complementary studies for data validation [6].

While much progress has been made in OCT, the possibilities for future improvements remain vast. Current work in polarization-sensitive OCT may allow monitoring of tumor interactions with stromal tissues [50–53]. Another area of interest is the efficient use of OCT signal dynamics to enable wide-field and large-dynamic range quantification of blood flow within the tumor. Finally, all of the contrast modes discussed here are intrinsically generated from tissue scattering; differing digital post-processing techniques are used to highlight each scattering feature. With the development of appropriate biological probes and exogenous labels, it may become possible to augment these intrinsic measurements with molecular sensing, opening opportunities for to study tumor structures and vasculature alongside measure of tumor hypoxia or pH.

Clinical Applications of Doppler OCT and OCT Angiography

46

Ou Tan, Yali Jia, Eric Wei, and David Huang

46.1 Introduction

Doppler optical coherence tomography (OCT) is a functional extension of OCT that allows for the visualization and measurement of blood flow [1, 2]. Phase-resolved Doppler OCT has become a standard algorithm for measuring Doppler shift with Fourier-domain (FD)-OCT because of its high velocity sensitivity [3]. In ophthalmology, several methods have been developed to measure in vivo retinal blood flow using this algorithm. Since Doppler OCT measures only the velocity component parallel to the OCT probe beam, additional information is needed to calculate absolute velocity and volumetric flow rate. One method is to employ two OCT beams with a fixed offset in incidence angles [4, 5]. However, this approach requires special hardware and is not compatible with commercial single-beam OCT systems. Another approach is to use special scan patterns to measure the Doppler angle (angle between the OCT beam and the blood vessel). Some groups used concentric scan patterns [6, 7], while other groups used raster scan patterns [8, 9]. Finally, Srinivasan et al. developed en face Doppler OCT for cerebral blood flow calculation, which obviated the need for Doppler angle estimation [10]. Bauman et al. adapted the method for total retinal blood flow (TRBF) calculation with ultrafast swept-source OCT [11]. In this chapter, we focus our attention on the double-circular scan pattern developed in our research group, which has been used in a number of clinical studies for preliminary demonstration of utility.

Although Doppler OCT is able to image and measure blood flow in larger blood vessels [12, 13], it has difficulty distinguishing the slow flow in small blood vessels

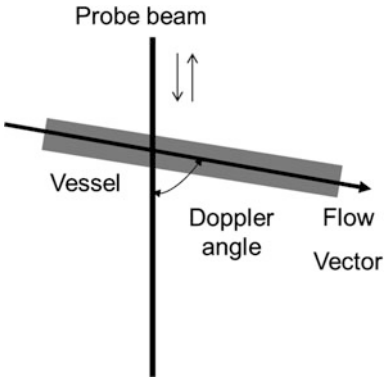

Fig. 46.1 In OCT, a probe beam is reflected from a sample. In a moving sample such as cells in a blood vessel, the frequency of reflected light is Doppler shifted in proportion to the component of the flow velocity in the direction of beam propagation

from tissue bulk motion [14, 15]. In the imaging of retinal blood vessels, Doppler OCT faces the additional constraint that most vessels are nearly perpendicular to the OCT beam, and therefore the detectability of the Doppler shift signal depends critically on the beam incident angle [16, 17]. Thus other techniques that do not depend on beam incidence angle are particularly attractive for retinal and choroidal angiography. To measure local microcirculation, we recently developed the split-spectrum amplitude-decorrelation angiography (SSADA) algorithm that provides high-quality three-dimensional (3D) angiography using ultrahigh-speed OCT [18]. Because SSADA is based on the variation of reflectance amplitude, it is sensitive to motion and flow in all directions. This omnidirectional nature allows it to detect perfusion in a way that is independent of beam incidence angle [18]. Therefore SSADA may be a good basis for quantitative angiography of the ocular microcirculation. The principle and clinical applications of this new angiography algorithm are also covered in this chapter.

46.2 Total Retinal Blood Flow Measurement with Doppler OCT

46.2.1 Doppler Principle

Doppler optical coherence tomography (Doppler OCT) is based on the principle that moving particles such as red blood cells inside a blood vessel cause a Doppler frequency shift (Δf) (Fig. 46.1) to the scattered light according to

$$\Delta f = \frac{1}{2\pi}\left(\vec{k}_s - \vec{k}_i\right) \bullet V \tag{46.1}$$

where $\boldsymbol{k_i}$ and $\boldsymbol{k_s}$ are wave vectors of incident and scattered light, respectively, and $\boldsymbol{V}$ is the velocity vector of the moving particles. Given the Doppler angle θ between the probe beam and the vessel vector, the velocity vessel can be estimated as

$$V = \frac{\lambda_0 \Delta f}{2n\ \cos\theta} \tag{46.2}$$

where λ_0 is the center wavelength of the light source and n is the refractive index of the medium.

In FD-OCT, this frequency shift Δf will introduce a phase shift in the spectral interference pattern that is captured by the line camera. With fast Fourier transform (FFT), the transformation result is a complex function characterized by amplitude and phase. The phase difference between sequential axial scans at each pixel is calculated to determine the Doppler shift [3]. One limitation of phase-resolved flow measurement is an aliasing phenomenon caused by 2π ambiguity in the arctangent function. This phenomenon limits the maximum determinable Doppler shift to $\Delta f = 1/(2\tau)$, where τ is the time difference between sequential axial lines. Thus, the maximum detectable speed is $V = \lambda_0/(4n\tau \cos\theta)$.

Using Eq. 46.2 to determine real flow speed V, the Doppler angle θ must be determined. Therefore, we needed at least two locations on a same vessel to decide the vessel vector.

46.2.2 Circumpapillary Double-Circular Scan

In the circumpapillary double-circular scan pattern, the OCT sampling beam scans two circles around the optic disc (Fig. 46.2), which ensures we sample at least two points for any main vessel around the optic disc. With a 26 kHz FD-OCT, the frame rate was six frames per second. Each scan contained 12 circles and was recorded over consecutive 2-s intervals (Fig. 46.2a).

Figure 46.2b shows the three dimensional diagram of the scan pattern in the rectangular region of Fig. 46.2a. The two positions of the blood vessel segment on the two scanning circles have coordinates $P_1(r_1, \alpha_1, z_1)$ and $P_2(r_2, \alpha_2, z_2)$, respectively. The vector of the blood vessel can be expressed as $\mathbf{r_b}(\Delta x = r_1 \cos\alpha_1 - r_2 \cos\alpha_2, \Delta y = r_1 \sin\alpha_1 - r_2 \sin\alpha_2, \Delta z = z_1 - z_2)$. For OCT scans at radius r, when the probe beam scans to the angle α, the vector of the scanning beam is $\mathbf{s}$ ($r\cos\alpha$, $r\sin\alpha$, $-h$), where h is the distance from the nodal point to the retina. With vector $\mathbf{s}$ and $\mathbf{r_b}$, the Doppler angle θ between the OCT probe beam and vessel can be calculated.

46.2.3 Correction for Sampling Density Effect

In phase-resolved Doppler OCT, the phase difference between sequential axial scans is calculated to determine Doppler frequency shift. If the sampling locations are not negligibly small relative to the beam diameter, phase decorrelation results in a decrease in the measured Doppler shift. For example, in the dual circular scan pattern, there are 4,000 axial lines for each circle. At a scanning radius of 1.8 mm, the sampling step is about 2.8 μm. For the FD-OCT with laser beam of 20 μm focus spot size, a calibrated factor of 0.8 is needed to correct the measured flow result.

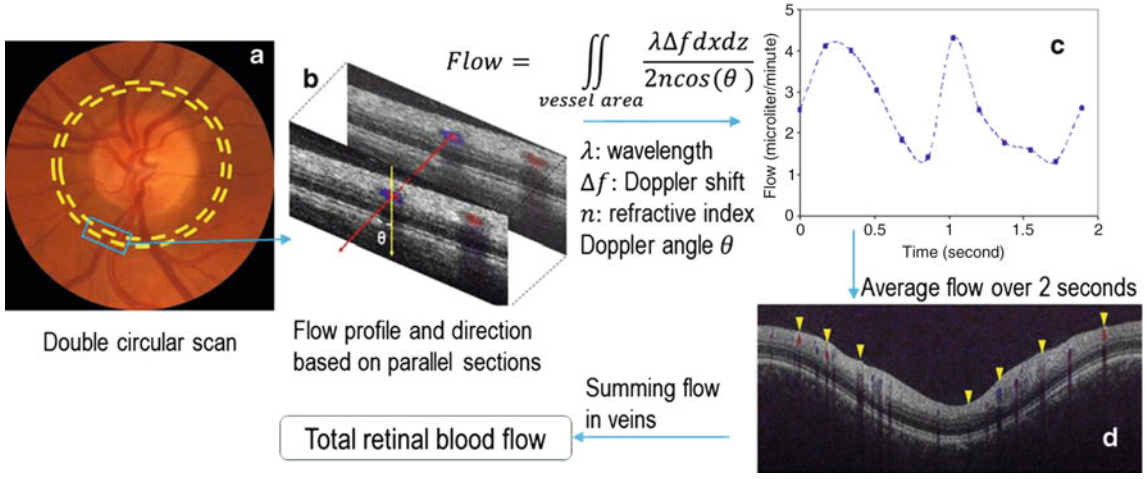

Fig. 46.2 Measurement of retinal blood flow using double-circular Doppler scan. (**a**) Two concentric circular scans transect all retinal blood vessels emanating from the optic nerve head (ONH). (**b**) The blood vessels are identified by Doppler frequency shift within the lumen as shown by blue and red color Doppler displays. By comparing the lumen positions in the two concentric sections, the vessel orientation relative to the OCT beam is measured. Velocity is calculated using the Doppler shift and Doppler angle. Volumetric blood flow rate is calculated by integrating velocity within the lumen area. (**c**) Flow measurements are averaged from 12 circular scans recorded over 2 s. (**d**) Total retinal blood flow (*TRBF*) is calculated by summing flow from all detected veins

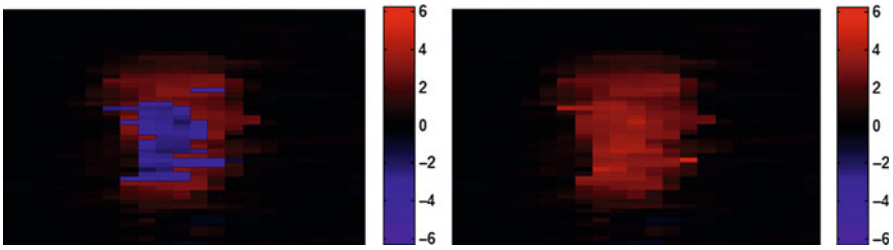

Fig. 46.3 Phase unwrapping in a single vessel. *Left*: Doppler shift with phase wrapping. *Right*: Doppler shift after phase unwrapping

46.2.4 Correction of Bulk Motion

The Doppler information contains artifacts from the motion of the eye and the OCT system. To obtain the Doppler frequency shift induced by actual blood flow, the artifacts must be identified and subtracted. The eye and OCT motion artifacts induce constant Doppler shift for whole axial scan (A-scan). Therefore, most bulk motion correction methods calculate the constant phase term of each a-scan and subtract it from the Doppler shift [19–21].

Our study showed that bulk motion is equivalent to the average Doppler signal between the inner limiting membrane and the top vessel boundary for each a-scan. This value represents the Doppler signal due to local tissue motion and is subtracted from the Doppler signal in the whole a-scan to get the net signal induced by blood flow.

46.2.5 Correction of Phase Wrapping

For FD-OCT systems with 840 nm laser source and 26 kHz scan rate, the maximum measurable axial velocity component in the eye is 4.2 mm/s. On the other hand, a typical average velocity in the main vein is about 18 mm/s and the velocity in the center of the vein is about 36 mm/s. In order to detect Doppler shifts without phase wrapping, the Doppler angle needs be above 82°. In order to allow measurement of vessels with smaller Doppler angles, a phase-unwrapping algorithm is needed. Figure 46.3 shows the Doppler signal with onefold phase wrapping (maximum Doppler shift was between π and 2π) and after phase unwrapping for a vessel.

However, only onefold of phase unwrapping is practical. Multiple phase unwrapping is difficult in practice because of noise. Therefore, it is difficult to get accurate measurements of arteries with high velocities. In our study, the total TRBF is measured from only from veins.

46.2.6 Reduce Eye Motion Error for Doppler Angle Estimation

The measured position of vessels contains noise from eye motion. Variance is doubled when we use two positions for vessel vector estimation, and this dominates the variance of the Doppler angle measurement and flow calculation. To reduce the eye motion artifact for vessel position, the circles are registered in transverse direction based on vessel pattern matching. Vessel vectors between consecutive circles are then averaged to reduce the eye motion error.

46.2.7 Correction for Pulsation

In a cardiac cycle, the flow velocity changes with pulsation. In order to get an average flow velocity, it is necessary to average flow at different time points. In CDCS, the Doppler shift in a vessel is averaged from the 12 frames, which corresponds to 12 time points in 2 s.

46.2.8 Semiautomated Doppler OCT Grading Software

We developed a software, which we named "Doppler OCT of retinal circulation," or DOCTORC, to include all the above ideas for measuring TRBF [22]. DOCTORC can automatically detect vessels on all circles and calculate the Doppler angle and TRBF. It can also provide total vessel area and average vessel velocity measurements. In the event of incorrect vessel detection, DOCTORC allows for human input to manually correct the error.

DOCTORC identifies blood vessels based on both Doppler and reflectance OCT images. The distinction between veins and arteries is based on both OCT images and fundus photographs. Vessel diameter (D) is measured by computing caliper on the cross-sectional Doppler OCT images which is used to compute lumen area ($\pi D^2/4$). The venous cross-sectional areas for all branch vessels around the optic disc are summed to obtain the total venous area for the eye. The Doppler angle between the vessel and OCT beam is measured by the relative position of each vessel in two concentric OCT images.

The effect of eye motion on the calculation of Doppler angle is small due to the short time interval between the inner and outer circular scans (0.16 s). This error is further minimized by averaging the Doppler angle estimates from concentric circular scans. Flow velocity can be computed from the Doppler shift and Doppler angle, with steps to account for the effect of background retinal motion and transverse scan step size [23]. When the peak axial Doppler shift is between π and 2π (or $-\pi$ and -2π) at the center of the vessel, the phase-unwrapping algorithm previously described is automatically applied to allow valid flow measurements [24].

Veins are identified by the flow direction toward the optic disc. The volumetric blood flow rate for each pixel is calculated by multiplying the velocity by vessel area.

Table 46.1 Visual field and Doppler OCT measurements in normal and glaucoma subjects

Parameter	Normal	Glaucoma	*p*-value
Visual field			
Mean deviation (dB)	0.16 ± 1.00	−4.39 ± 4.14	<0.0001
Pattern standard deviation (dB)	1.61 ± 0.39	6.54 ± 4.45	<0.0001
Total retinal blood flow (μl/min)	45.5 ± 9.5	34.9 ± 8.5	<0.001
Arterial area (mm^2)	0.033 ± 0.0077	0.028 ± 0.0074	0.006
Venous area (mm^2)	0.047 ± 0.012	0.041 ± 0.0086	0.01
Arterial velocity (mm/sec)	23.9 ± 7.2	21.8 ± 7.3	0.22
Venous velocity (mm/sec)	16.3 ± 2.8	14.5 ± 3.7	0.03

Flow within a vein is calculated by summing the flow in the pixels over lumen cross section. Flow measurements are averaged over each 2-s recording. Measurements from all valid scans are averaged. Total retinal blood flow is calculated by summing flow from all detectable veins. Retinal blood flow in arteries and veins should have an equal sum because inflow must equal outflow in any steady state system that obeys the law of conservation of mass. This has been confirmed by actual measurements of retinal arterial and venous flows with a number of techniques [25]. Thus, measuring total venous flow alone is sufficient to quantify the total retinal blood flow. Average venous velocities are obtained by dividing the total retinal flow by the total venous areas.

46.2.9 Blood Flow Measurement for Normal and Glaucoma with Doppler OCT

We performed a study comparing blood flow measurements obtained with Doppler OCT between glaucoma patients and normal subjects. A total of 47 consecutive eyes of 42 patients with glaucoma were age-matched with 27 normal eyes of 27 patients [23]. There were no significant differences in age, systemic hypertension, and diabetes mellitus between the two groups. However, the mean intraocular pressure was lower in glaucoma eyes ($p = 0.03$), which were all undergoing treatment.

Traditional measures of function and structure were consistent with expected findings for glaucoma eyes (Table 46.1). Glaucoma eyes demonstrated visual field loss with lower mean deviation (MD) values and higher pattern standard deviation (PSD) values compared to normal eyes ($p < 0.0001$). Structural evaluation identified loss of disc rim area, GCC thickness, and RNFL thickness in glaucoma eyes relative to normal eyes ($p < 0.0001$).

Total retinal blood flow was significantly reduced in glaucoma eyes with decreased vessel area and venous velocity compared to normal eyes (Table 46.1). Blood flow reduction was correlated with visual field loss, but had no correlation or paradoxical correlation with structural loss of neural tissue as measured by optic disc rim area, peripapillary nerve fiber layer (NFL) thickness, or macular ganglion

cell complex (GCC) thickness ($p \geq 0.23$). Univariate analysis demonstrated that each dB decrease in blood flow resulted in a 1.91 dB decreased in MD ($p < 0.001$). Multivariate analysis confirmed a largely independent relationship between reduced blood flow and visual field loss, even after accounting for structural loss of rim area and NFL thickness.

46.2.10 Blood Flow Measurement in Diabetic Retinopathy and Optic Neuropathy Eyes with Doppler OCT

The Doppler OCT and algorithms were also applied to nine eyes with nonarteritic ischemic optic neuropathy (AION), five eyes with proliferative diabetic retinopathy (PDR, after treatment with pan-retinal photocoagulation), and two eyes with branch retinal vein occlusion (BRVO) [26]. All diseases caused significant reduction of total blood flow compared to normal (AION, 28.2 ± 8.2 μl/min; PDR, 15.8 ± 10.1 μl/min; BRVO, 26.7 ± 5.7 μl/min).

46.3 OCT Angiography

Several OCT-based techniques have been successfully developed to image microvascular networks in human eyes in vivo [9, 24, 25, 27–32]. One example is optical microangiography (OMAG), which works by using a modified Hilbert transform to separate the scattering signals from static and moving scatters [33]. By applying the OMAG algorithm along the slow scanning axis, high-sensitivity imaging of capillary flow can be achieved [34]. However, the high sensitivity of OMAG requires precise removal of bulk motion by resolving the Doppler phase shift [35]. Thus, it is susceptible to artifacts from system or biological phase instability. Other related methods such as phase variance [25] and Doppler variance [31] have been developed to detect small phase variations from microvascular flow. These methods do not require non-perpendicular beam incidence and can detect both transverse and axial flow. They have also been successful in visualizing retinal and choroidal microvascular networks. However, these phase-based methods require precise removal of background Doppler phase shifts due to the axial movement of bulk tissue. Artifacts can also be introduced by phase noise in the OCT system and transverse tissue motion, and these also need to be removed. In order to circumvent these issues, our research group has investigated the use of amplitude-based OCT signal analysis, which in this context may be advantageous for ophthalmic microvascular imaging.

46.3.1 Principles of OCT Angiography

The speckle decorrelation phenomenon has previously been applied to techniques including ultrasound and laser speckle to detect optical scattering from moving

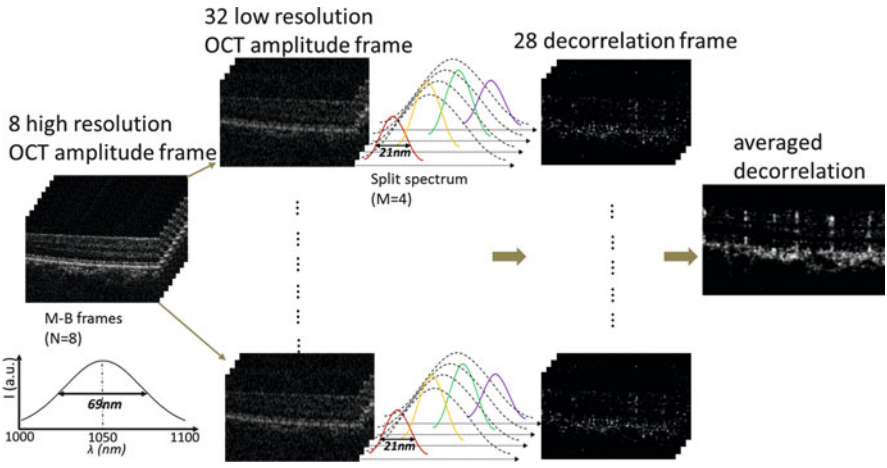

Fig. 46.4 Flow chart detailing the basic steps of the SSADA algorithm. Eight OCT M-B frames were scanned consecutively at the same spatial location to produce eight spectral interferograms and eight standard-resolution cross-sectional images. Using SSADA, each full spectral interferogram was split into four spectral bands creating 32 low-resolution interferograms. B-scan decorrelation of each split band yielded 28 decorrelation frames which were averaged to produce one final decorrelation-based flow cross section with improved quality (Reprinted with permission from Jia et al. in *Biomedical Optics Express* [39])

particles such as red blood cells [36–38]. This phenomenon is also clearly observed in real-time OCT reflectance images where the scattering pattern of blood flow varies rapidly over time due to the flow stream that drives randomly distributed blood cells through the imaging volume. This results in decorrelation of the received backscattered signals that are a function of scatterer displacement over time, creating a contrast between decorrelated blood flow and nondecorrelated static tissue that can be used to extract flow signals for angiography.

In contrast to Doppler and other phase-based approaches in Fourier-domain OCT, amplitude-decorrelation measurements are sensitive to transverse flow and immune to phase noise. However, amplitude-decorrelation measurements are very sensitive to pulsatile bulk motion noise in the axial direction due to the high axial resolution of OCT. In the fundus, ocular pulsation occurs primarily along the axial direction and is driven by the retrobulbar orbital tissue in line with cardiac activity. This results in high sensitivity in the axial direction results that produce unacceptable signal-to-noise ratio (SNR). To overcome this limitation, we created SSADA based on the decorrelation of OCT signal amplitude due to flow.

The basic procedures of SSADA are shown in Fig. 46.4. The key step of SSADA is splitting the raw full spectrum into a new spectrum with multiple narrow bands. Rather than using the high-resolution OCT amplitude frames (M-B frames) transformed by the full spectrum for amplitude-decorrelation computation, new bandwidth is intentionally created to limit the OCT axial resolution. The creation of a modified isotropic resolution cell minimizes noise along the axial direction and

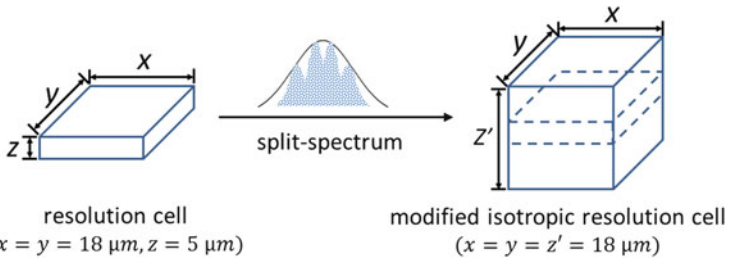

Fig. 46.5 Diagram of the modification of the OCT imaging resolution cell using the split-spectrum method. The resolution cell ($x = y > z$) in the current configuration can be modified into a new resolution cell ($x = y = z$') (Reprinted with permission from the *En Face OCT Atlas* [40])

optimizes flow detection along the transverse direction (Fig. 46.5). After the new narrow spectrums are Fourier transformed, the resultant low-resolution OCT amplitude frames are used to calculate decorrelation. Inter-B-scan decorrelation can be determined at each of the narrow spectral bands independently and subsequently averaged. Recombining the decorrelation images from the spectral bands yields angiograms that utilize the full information in the entire OCT spectral range. Our work has shown that such images produce significant improvement of SNR for both flow detection and connectivity of microvascular networks when compared to other amplitude decorrelation techniques [18]. Furthermore, the creation of isotropic resolution cells with equal sensitivity to axial and transverse flow can be useful for quantifying flow. As a result of the flow value generated by the isotropic resolution being a function of the flow velocity regardless of direction, OCT angiography can be used to extract flow information that can be further processed for quantification.

46.3.2 System and Scan Pattern

OCT angiography requires a high-speed OCT system for image acquisition. The system we used in our OCT angiography studies is an ultrahigh-speed swept-source OCT device built by our group at the Massachusetts Institute of Technology [41]. The instrument operates at a speed of 100 kHz axial scan rate using a short cavity laser centered at a wavelength of 1,050 nm with a 100 nm tuning range.

Each OCT angiography scan set contains four individual scans comprised of two x-fast scans and two y-fast scans. For each x-fast scan, a 3 mm × 3 mm image is obtained by sampling 200 axial scans across a 3 mm line along the x-axis to obtain a single B-scan. Each B-scan is repeated seven more times to obtain a total of eight B-scans at a single y-position. Upon completion, the scan probe moves the next y-position where eight more B-scans are acquired along the x-axis. A total of 200 y-positions covering 3 mm are sampled amounting to a total of 1,600 B-scans acquired per scan to form a 3D data cube. With a B-scan frame rate of

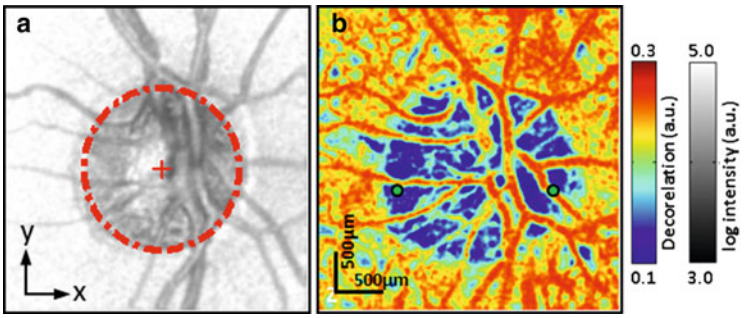

Fig. 46.6 SSADA reflectance intensity (**a**) and angiogram (**b**) of the retinal and ONH circulations of a normal subject. *Red circle* in (**a**) shows the boundary of the *disc*

500 frames per second, each scan takes approximately 3.4 s to complete. Y-fast scans are performed in the same manner as x-fast scans with the exception that B-scans are obtained along the y-axis rather than along the x-axis.

46.3.3 OCT Angiography for Normal and Glaucoma Eyes

SSADA can be used to monitor blood flow changes in the optic nerve head associated with glaucoma. While the traditional mechanical theory for the pathogenesis of glaucoma suggests that an acute rise in intraocular pressure causes the lamina cribrosa to deform and disrupt axonal bundles of the optic nerve, there is a growing body of evidence that implicates vascular dysfunction to the pathogenesis of glaucoma [42]. In studies of normal-tension glaucoma, disease progression was observed in 20 % of eyes despite greater than 30 % reductions in IOP [43, 44]. The vascular theory attributes glaucoma to insufficient blood supply resulting from either an increase in IOP or other risk factors that reduce ocular blood flow [45]. Furthermore, the hypothesis that localized damage occurs due to a breakdown in the autoregulation of ocular perfusion pressure is supported by studies indicating low ocular perfusion pressure as a risk factor for glaucoma [46–48].

The 3D volumetric data set from OCT angiography provides both reflectance intensity and decorrelation (angiography) images. From the ONH scan in Fig. 46.6, the en face maximum projection of reflectance intensity shows major retinal blood vessels and second-order branches, but finer branches and the microcirculation of the retina, choroid, and optic disc are not visible (Fig. 46.6a). In contrast, the en face maximum decorrelation projection angiogram shows not only the same major retinal and second-order branches but also finer branches and the microcirculation of the retina, choroid, and optic disc that were not visible in the en face maximum projection of reflectance intensity (Fig. 46.6b).

SSADA can also be used to demonstrate en face ONH angiography at different tissue depths. Figure 46.7 shows single slice angiograms within the retina, choroid, and lamina cribrosa that can be used to separately visualize microcirculation within

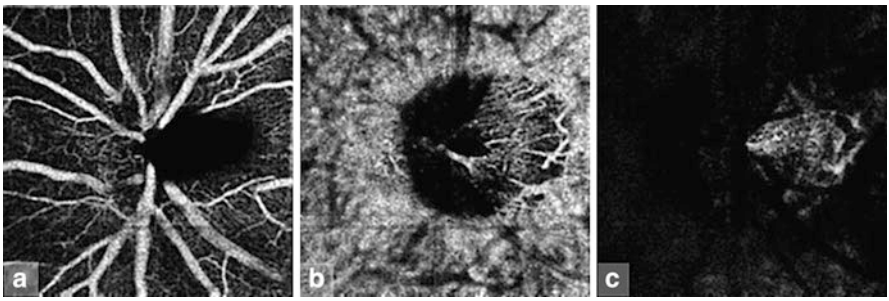

Fig. 46.7 En face ONH angiograms separately showing the microcirculation at a single slice within the retina (**a**), choroid (**b**), and lamina cribrosa (**c**)

each layer. In the retinal slice, disc surface vessels and retinal vessels are clearly visible (Fig. 46.7a). In the choroidal slice (Fig. 46.7b), a near confluent choriocapillaris is visible around the optic disc, along with a network of large arteries and veins of Haller's layer. Within the disc itself, a dense vascular network is seen temporally. Within the scleral slice, there is no visible circulation outside the disc (Fig. 46.7c). Due to the tilt of the disc, the nasal portion of the lamina cribrosa is overshadowed by the RPE and the choroid, and the superior and inferior poles are overshadowed by major retinal vessels. But in the temporal quadrant, deep ONH circulation in the lamina cribrosa can be visualized. To our knowledge, this is the first time that the disc microcirculation has been visualized noninvasively in such a comprehensive manner.

In a pilot study, we used OCT angiography to measure the difference in ONH blood flow between three preperimetric glaucoma eyes and three normal controls. Four angiography scans were obtained in one session. While normal eyes and glaucoma eyes appeared similar in disc photographs (Fig. 46.8a, c), OCT angiography images revealed a visible reduction in ONH perfusion for glaucoma eyes (Fig. 46.8). This reduction can be seen within the whole disc marked by the red solid line and most noticeably in the temporal ellipse region marked by yellow dashed lines that exclude major branch retinal vessels (Fig. 46.8b, d). To quantify the difference in perfusion, we used SSADA to measure flow index rates in the whole disc and the temporal ellipse. Glaucoma eyes showed a significant reduction of flow index in both the whole disc ($P = 0.040$) and the temporal ellipse ($P = 0.010$). In comparison to normal eyes, glaucoma eyes showed a 35 % reduction of flow index in the whole disc and a 57 % reduction in the temporal ellipse. We calculated the coefficient of variation (CV) for intravisit repeatability to be 6.8 % in the whole disc and 9.0 % in the temporal ellipse within one session.

46.4 Summary and Conclusions

Doppler OCT and OCT angiography are complementary to each other. The multicircular Doppler OCT is more difficult to process due to the need to calculate

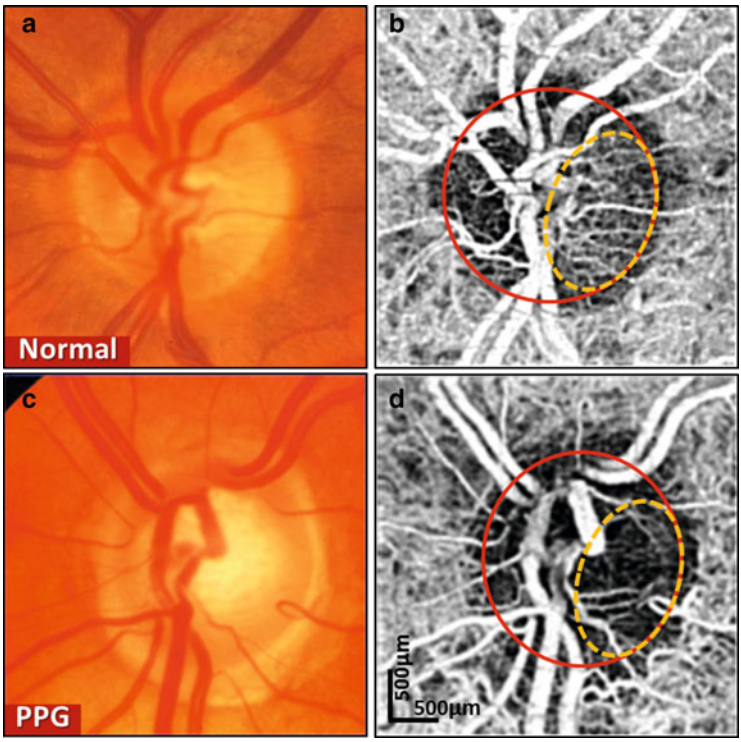

Fig. 46.8 Disc photographs (**a**, **c**) and en face OCT angiograms (**b**, **d**) of ONHs in representative normal (**a**, **b**) and preperimetric glaucoma (PPG) subjects (**c**, **d**). In (**b**) and (**d**), the *solid circles* indicate the discs, and the *dash circles* indicate the temporal ellipses. A dense microvascular network was visible on the OCT angiography of the normal disc (**b**). This network was greatly attenuated in the glaucomatous disc (**d**) (Reprinted with permission from Jia et al. in *Biomedical Optics Express* [39])

Doppler angles for each vessel, but it has the advantage of being able to provide absolute measurements of total retinal blood flow in units of μl/min. This technique does not require the use of an ultrahigh-speed OCT system and can be performed with spectral domain OCT systems with scan rates as low as 20 kHz. It can also provide the velocity and vessel area measurement for main veins and arteries in the optic disc and peripapillary region. These measurements of total retinal blood flow have been found to be well correlated to visual field function for glaucoma patients. For faster OCT systems, the en face Doppler approach [11] to the measurement of total retinal blood flow may have the advantage of simpler processing and greater reliability.

OCT angiography provides flow index which is related to perfusion. It is more robust than Doppler OCT because it is omnidirectional and measurements are not affected by beam incidence angle. Although OCT angiography is capable of measuring blood flow in large retinal vessels, its significance lies in the ability to

obtain blood flow measurements in microcirculatory networks that cannot be picked up by Doppler OCT. This allows for the ability to detect and pinpoint focal damage and give insight to local ischemia. Measurements of ONH microcirculation with OCT angiography have revealed a significant reduction of blood flow in glaucoma eyes, and these measurements were also well correlated with visual field function. The main caveat to OCT angiography is that it is not able to provide absolute volumetric flow in μl/min, rather yielding flow index on an arbitrary scale. Additionally, use of an ultrafast OCT system (above 70 kHZ) is required for the technique.

Doppler OCT and OCT angiography goes beyond traditional structural OCT and measures tissue function. Functional OCT is in an early stage of development and is not yet used clinically. However, because leading causes of blindness such as age-related macular degeneration (AMD), diabetic retinopathy, and glaucoma all involve reduced or abnormal ocular circulation, the potential clinical applications are vast. Doppler OCT has already been used to detect reduced retinal blood flow in diabetic retinopathy, glaucoma, and other optic neuropathies. OCT angiography has been used to demonstrate reduced ONH perfusion in glaucoma. OCT angiography may also be useful in assessing capillary dropout and macular ischemia, visualizing retinal neovascularization in diabetic retinopathy, and visualizing choroidal neovascular membrane in AMD. The potential applications of functional OCT may be as wide as structural OCT.

Molecular Optical Coherence Tomography Contrast Enhancement and Imaging

47

Amy L. Oldenburg, Brian E. Applegate, Jason M. Tucker-Schwartz, Melissa C. Skala, Jongsik Kim, and Stephen A. Boppart

47.1 Introduction

Histochemistry began as early as the nineteenth century, with the development of synthetic dyes that provided spatially mapped chemical contrast in tissue [1]. Stains such as hematoxylin and eosin, which contrast cellular nuclei and cytoplasm, greatly aid in the interpretation of microscopy images. An analogous development is currently taking place in biomedical imaging, whereby techniques adapted for MRI, CT, and PET now provide in vivo molecular imaging over the entire human body, aiding in both fundamental research discovery and in clinical diagnosis and treatment monitoring. Because OCT offers a unique spatial scale that is intermediate between microscopy and whole-body biomedical imaging, molecular contrast

OCT (MCOCT) also has great potential for providing new insight into in vivo molecular processes. The strength of MCOCT lies in its ability to isolate signals from a molecule or contrast agent from the tissue scattering background over large scan areas at depths greater than traditional microscopy techniques while maintaining high resolution.

MCOCT involves the use of OCT image acquisition and/or processing techniques to generate image contrast using endogenous molecular species or exogenous molecular probes of interest [2]. It should be noted that several other chapters in this book cover techniques that provide information about tissue composition that will not be repeated here, including nonlinear interferometric vibrational imaging (NIVI), second harmonic generation OCT, and optical coherence elastography. This chapter does address spectroscopic OCT (SOCT) in the context of chromophore and probe detection, while the reader should refer to related SOCT chapters in this book for greater detail on SOCT processing methods.

This chapter is structured according to the physical mechanisms used for contrast, starting from direct schemes whereby probes add to or subtract from the optical backscattering spectrum that comprises the OCT signal (i.e., scattering- and absorption-based contrast, respectively), then covering methods that indirectly modulate the OCT signal (i.e., pump-probe, magnetomotive, and photothermal OCT). It should be noted that any scheme developed for MCOCT must be compatible with interferometric detection, which precludes the use of several physical mechanisms such as fluorescence emission. In this chapter, imaging technology development will be emphasized and presented with selected examples of biomedical applications. Interestingly, many endogenous and exogenous probes can be sensed by more than one method. For example, photothermal contrast relies upon absorption, and therefore, the same agents provide contrast in both photothermal and spectroscopic OCT. The development of exogenous imaging probes (or contrast agents) that enable MCOCT is also a rich and varied topic that poses particular challenges in materials science and targeted delivery. Here we introduce a variety of molecular probes in the context of specific MCOCT imaging strategies, while the reader is referred elsewhere [3–6] for detailed information about probe development.

47.2 Scattering-Based Contrast

The native "contrast" observed in OCT is light that has been coherently backscattered. All MCOCT methods are based upon modifying this backscattering signal in a way that can provide additional, molecular information about the sample. One of the most straightforward strategies is to increase the OCT signal directly with a probe particle that exhibits high backscattering. Analogous methods include the use of positive T_1 contrast agents in MRI and echogenic microbubbles in ultrasound. In fact, microbubbles also happen to have reasonably high light scattering and were one of the first types of contrast agents studied with OCT [7]. Oil-filled protein microspheres were subsequently found to offer flexibility in loading the shell or core with nanoparticles to further increase the optical

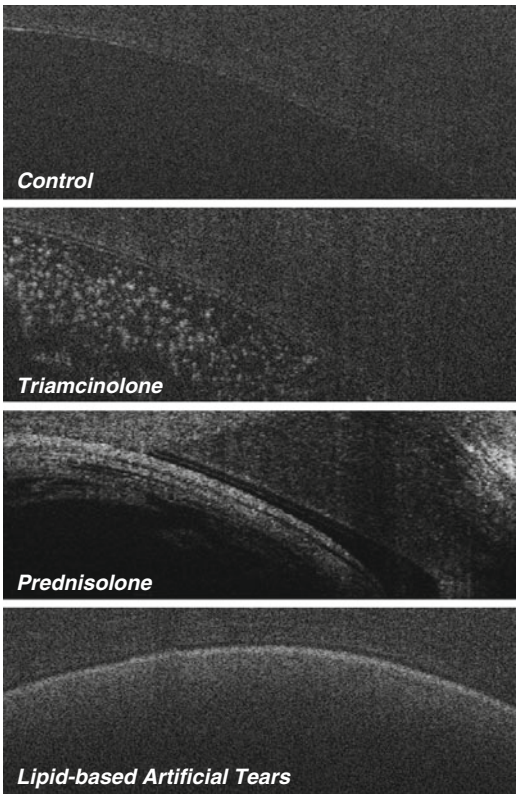

Fig. 47.1 OCT images of fresh, ex vivo porcine eyes after intra-cameral injection of contrast agents. From *top* to *bottom*: Control, triamcinolone acetonide 40 mg/mL, prednisolone acetate 1 %, and lipid-based artificial tears. The agents provide positive contrast within the anterior chamber that has a different pattern depending on the type of agent used. These differences are expected because the agents are comprised of varying particulate or oil-in-water suspensions, with differing mean particle sizes, reflectivities, and diffusivities

scattering [8], and variants of these are in continued use with magnetomotive OCT, as discussed below [9]. It is important to note, however, that any new contrast agent must undergo thorough safety and efficacy testing before it can be used on humans, such as that required by the Food and Drug Administration in the United States. As such, the study of agents already approved for human use can more readily lead to clinical translation. Interestingly, it was recently found that several commonly used ophthalmic medications provide scattering-based OCT contrast [10]. As shown in Fig. 47.1, OCT reveals the diffusion of several medications within the anterior chamber after administration. They were also shown to enhance the visibility of corneal incisions postoperatively, which may provide a method for assessing wound integrity. Future adaptations of molecularly targeted agents may further broaden the functionality of OCT in ophthalmology.

While scattering-based contrast agents are readily visible within the highly transparent anterior segment of the eye, the ability to detect these types of agents endoscopically or on the skin is more challenging, as they must be distinguishable against the already high optical scattering of the tissue. Mie theory provides exact solutions for light scattering from spherical particles, shelled spheres, and spheroids [11]. As a general rule, there is a rapid increase in scattering with particle size (scattering cross section, $\sigma_s \propto d^6$) in the Rayleigh regime ($d << \lambda$) and a rapid increase in

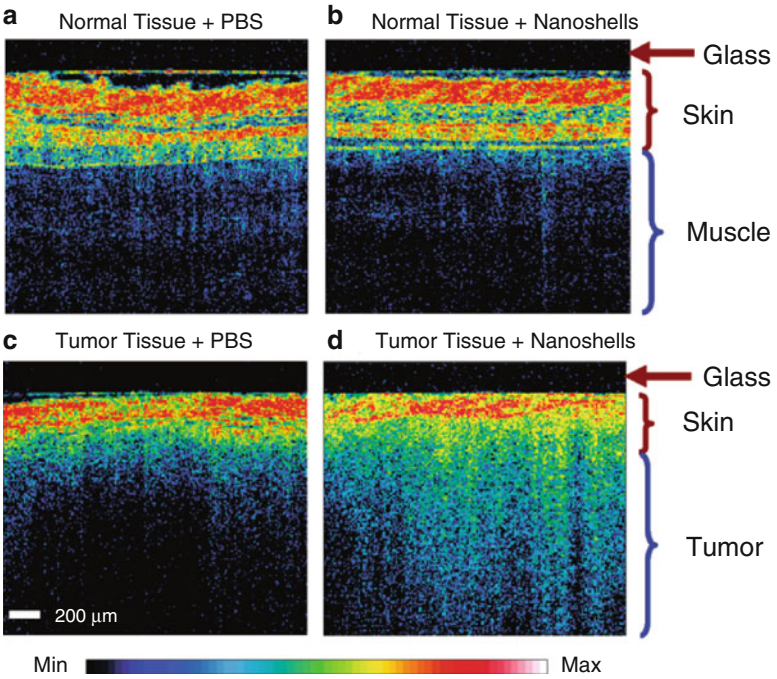

Fig. 47.2 OCT images of tissues from mice with subcutaneous tumors systemically treated with phosphate-buffered saline (*PBS*) as a control (**a**, **c**) and multifunctional nanoshells (**b**, **d**). Enhanced retention of nanoshells in the tumor in panel (**d**) provides better delineation of tumor borders, as well as subsequent tumor-specific photothermal ablation (Reprinted with permission from Ref. [13]. Copyright 2007 American Chemical Society)

scattering as the material refractive index is different (higher or lower) than that of the (typically aqueous) medium. At the same time, one must weigh the choice of the material and the particle size against the biocompatibility and the ability for the probes to access their target, respectively, for the needed application.

One of the most useful types of OCT contrast agents, which will be discussed many times throughout this chapter, is plasmonic gold nanoparticles in their various forms (nanospheres, nanoshells, nanorods, etc.). This is because gold is highly unreactive and consequently relatively biocompatible, while at the same time providing a surface plasmon resonance (SPR) effect at the red and near-infrared wavelengths used in OCT [12]. This SPR is evident as either a strong absorption or scattering spectral peak, with a transition from predominantly absorbing (low albedo) to predominantly scattering behavior (high albedo) as the particle size is increased; for spheres, the transition occurs at $d \approx 80$ nm [12]. Nanoshells in particular have been highly developed for scattering-based OCT contrast [13–15]. They are comprised of a silica core and gold shell and offer spectral tunability by adjusting the core diameter and shell thickness [3]. Figure 47.2 displays a demonstration of enhanced OCT contrast in the tumors of mice systemically intravenously

injected with nanoshells [13]. These results highlight the enhanced permeation and retention (EPR) effect, whereby the permeable vasculature of tumors acts to trap particles, providing selective targeting [16]. Importantly, EPR further enables site-targeted treatment; in this example, the nanoshells were designed to be nearly equally light scattering and absorbing, providing both imaging contrast (via scattering) and photothermal therapy (via absorption).

It should also be noted that, in cases where the SPR is narrow compared to the bandwidth of the light used in OCT, it may be possible to employ spectroscopic OCT (SOCT) techniques to distinguish the SPR signature, providing enhanced specificity against the tissue scattering background. While this idea has been explored [17], a confounding factor that makes this method challenging is the highly modulated backscattering spectrum typically obtained from Mie scatterers ($d \sim \lambda$) within the tissue. In current practice, SOCT techniques are much more commonly employed to detect absorption-based contrast agents, which is the focus of the following section.

47.3 Absorption-Based Contrast

Light absorption is a very attractive molecular process to exploit for contrast, both because of the potential signal strength and because essentially all molecular species have the capacity to absorb light. The imaging light used in OCT is spectrally broad, and hence, the backscattered spectrum may be utilized to identify the absorption spectrum of endogenous or exogenous species present within the tissue. The group of techniques designed to extract this information are collectively referred to as spectroscopic optical coherence tomography (SOCT) [18].

The different algorithms developed for SOCT diverge in how they deal with the trade-off between spatial and spectral resolution. One approach is to use multiple light sources to collect independent OCT images with different center wavelengths. Relatively straightforward algorithms such as spectral triangulation [19] may then be implemented to extract the depth-resolved backscattered spectrum. A judicious choice of center wavelengths can facilitate the detection of highly peaked spectral features with limited spectral resolution. This approach has largely been used to detect dyes such as indocyanine green (ICG) [19].

An alternate approach is to directly utilize the broad spectral bandwidth of the light source and use the short-time Fourier transform (STFT) to gain spectral resolution at the expense of spatial resolution [20]. This approach has the advantage that it is entirely a post-processing technique; hence, it can be tailored to maximize contrast to a target contrast agent. Likewise, the time-frequency distribution (TFD) need not be limited to the STFT but may optimized as well to maximize the spatial and spectral resolution [21]. Wax and coworkers [22] have recently developed an algorithm that incorporates two STFTs, one with a narrow spectral window and one with a broad spectral window. The two TFDs are multiplied point by point to generate a TFD with both high spatial and spectral resolution.

Exogenous chromophores for SOCT are largely repurposed, commercially available fluorescent dyes. Utilizing these dyes carries with it the advantage of

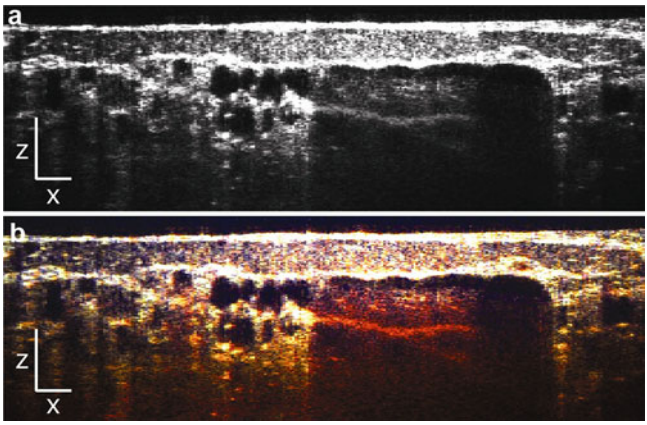

Fig. 47.3 Conventional OCT (**a**) and METRiCS OCT (**b**) images, located above point (**e**) in the en face (*x*–*y*) image in Fig. 47.4. *White x* and *z* scale bars, 100 μm (Reprinted with permission from Ref. [22]. Copyright 2011 Macmillan)

a wealth of biological and chemical research aimed toward targeting particular disease states of tissue, chemical species, or morphologies. Some examples include ICG [23], photodynamic therapy-related dyes [24], and fluorescent microspheres [25]. Dyes typically also have strongly peaked spectra which enable detection via fairly simple methodologies. For instance, a commercial NIR absorbing dye (H.W. Sands, ADS7460) which exhibits a sharp absorption peak at 740 nm was used to produce contrast in an 800 nm OCT system by effectively clipping the shorter wavelengths, resulting in a redshift of scattered light [26].

The major endogenous chromophore is hemoglobin. Detection of hemoglobin absorption with SOCT has been explored as a method to measure blood oxygen saturation [27]. Wax and coworkers [22] recently measured the oxygen saturation along with fluorescein dye injected into the bloodstream in a mouse window chamber model using METRiCS OCT which uses the two TFD methods noted above along with OCT imaging at nontraditional wavelengths. Their imaging bandwidth spans the 455-695 nm range which overlaps strong peaks in the oxy- and deoxyhemoglobin spectrum. Selected results from this work demonstrating the endogenous and exogenous tissue contrast as well as SO_2 measurements are shown in Figs. 47.3 and 47.4.

Plasmonic gold nanoparticles have also been widely employed for absorption-based contrast, where the SPR peaks are tuned within the OCT imaging band by varying the size of specific geometrical features of the nanoparticles. For instance, light-absorbing gold nanorods are tuned by varying their aspect ratio (length over width) while maintaining a length typically $<$100 nm to favor absorption over scattering. Many of the different particle geometries have been explored for contrast in SOCT, including gold nanospheres [28], gold nanorods [28, 29], and gold nanocages [30]. For example, gold nanorods were imaged after injection into excised human breast carcinoma tissue [29]. As mentioned above, light-absorbing

gold nanoparticles are, at the same time highly effective for photothermal cancer therapy, where a high power laser is used to irradiate particle-laden tumors [31]. The synergy between imaging and therapy, which allows us to monitor permeation and diffusion of SPR particles into tissues before treatment, aids in particle development for improved delivery and informs the design of more effective treatment protocols.

47.4 Pump-Probe OCT

Pump-probe optical coherence tomography (PPOCT) is fundamentally the fusion of optical coherence tomography with pump-probe absorption spectroscopy. Spatially resolving the pump-probe interaction can provide molecular contrast for absorbing agents in a tissue sample similar to SOCT. The major advantages of PPOCT are that contributions to the OCT light attenuation due to scattering and absorption are easily separated and there is no compromise between spatial and spectral resolution. The disadvantages are that the optical setup is more complicated and typically requires pulsed light sources. Only under special circumstances could PPOCT be accomplished with a swept OCT laser source or superluminescent diode.

A typical PPOCT system has the following features: The probe is the light in the sample arm of the OCT interferometer, i.e., the same light used for OCT imaging serves as the probe light. A separate pump beam co-propagates with the OCT light in the sample arm. The pump is typically amplitude modulated at frequency f_0. Transfer of the modulation onto the backscattered probe (OCT) signal at f_0 is then evidence of absorption of the probe light by some tissue absorber. In time-domain OCT implementations, the PPOCT signal appears as sidebands on the Doppler carrier frequency, $f_D \pm f_0$ [32]. In spectral-domain OCT, the PPOCT signal can be extracted from an M-scan by Fourier transformation along the time axis (at each depth) and filtering around f_0. For the process to work, absorption of the pump by the contrast agent must change the absorption/scattering properties at the probe wavelength.

The first experimental realization of PPOCT [33] demonstrated imaging of methylene blue, a dye used for chromoendoscopy [34]. The specific physical mechanism leading to PPOCT signal from methylene blue is well understood and therefore serves as a germane example, where the energy level diagram is illustrated in Fig. 47.5a. The pump light drives a transition from the singlet ground state (S_0) to the first excited electronic state (S_1). Molecular population in the excited singlet state is transferred to the triplet state via a particularly efficient [35] spontaneous process ($S_1 \rightarrow T_1$, $\tau_{1\text{-}1}$). Methylene blue in its triplet state has a resonant transition peaked at 830 nm ($T_1 \rightarrow T_2$). When the pump is on, an 830 nm probe can be absorbed by methylene blue, but when the pump is off, there is no probe absorption. In reality the excited triplet state has a finite lifetime (analogous to fluorescence lifetime) that is a function of the oxygen level in its local environment, but varies from ~200 ns to over 1 μs. Consequently, the pump and probe need not be incident on the sample at the same time, but may be delayed in time by some fraction of the excited state lifetime. Measurement of this characteristic lifetime may be used to help differentiate among multiple chromophores. An example decay for methylene blue is in Fig. 47.5b. The average decay time (lifetime) from T_1 to S_0 (τ_{0-1}) was calculated to be 247 ns via $\tau_{avg} = \sum S \cdot t / \sum S$, where S is the PPOCT signal at delay time t [36]. In addition to the lifetime, the absorption spectrum at the pump or probe may be measured by recording the PPOCT signal as a function of the pump or probe wavelength, respectively.

Several molecular species in addition to methylene blue have been imaged using PPOCT. Phytochrome A, a naturally occurring molecular switch which may be reversibly optically pumped from one isomeric state to another, was imaged in a tissue phantom [37]. Hemoglobin was measured in the gill filament arteries of a zebrafish (*Brachyrerio danio*) using a time-domain 532 nm PPOCT system with a 532 nm pump [32]. The same system was also used to image the fluorescent protein DsRed in a transgenic zebrafish. Melanin was imaged in the first spectral-domain PPOCT system in a phantom made from human hair embedded in chicken breast tissue [38]. Melanin has also been imaged using a time-domain optical coherence microscopy system [39]. Recent work [36] has demonstrated volumetric imaging of microvasculature in *Xenopus laevis* using a two-color (532 nm pump, 830 nm probe) PPOCT system. Representative PPOCT cross sections overlain on the OCT cross sections are shown in Fig. 47.6 along with volumetric

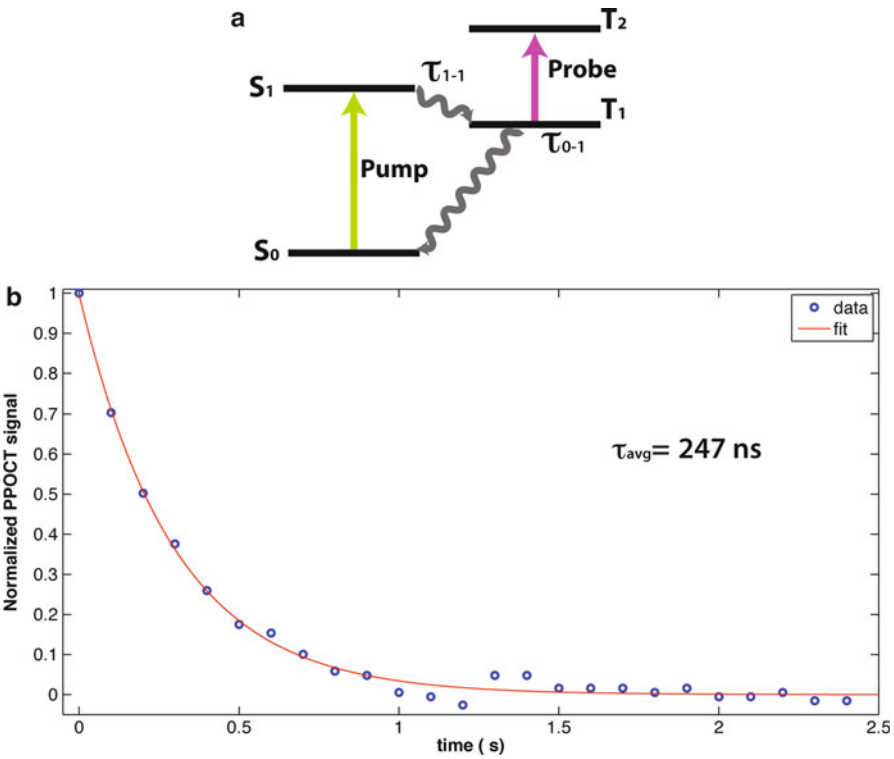

Fig. 47.5 (**a**) Molecular energy level diagram for the methylene blue PPOCT mechanism. Driven transitions are indicated by *straight arrows* and spontaneous transitions as *zigzag arrows*. (**b**) Measured normalized decay of the PPOCT signal due to methylene blue as a function of delay between the pump and probe pulse. The decay has a characteristic average lifetime of 247 ns (Modified and reprinted with permission from Ref. [36]. Copyright 2013)

reconstructions of the vasculature measured with PPOCT. They have also demonstrated the use of the characteristic lifetime to differentiate PPOCT signals from two different chromophores.

Figure 47.7 shows a pair of capillary tubes loaded with methylene blue/microspheres and bovine whole blood in heparin. The top panel (a) is the standard OCT image showing similar signal from both capillary tubes. A PPOCT image with 2 ns pump-probe delay (Fig. 47.7b) appears very similar to the OCT image. However, when the pump-probe delay is increased to 24.8 μs, the signal from the methylene blue/microsphere-loaded capillary tube decays, leaving only signals from the blood-filled capillary. Taking advantage of the difference in lifetime between two chromophores is an effective strategy for imaging multiple chromophores with PPOCT.

Future research in PPOCT may lead in several directions. There is a clear potential for imaging vasculature. While Doppler-based OCT can also measure vasculature, a major advantage of PPOCT is that the signal is independent of the angle of flow, while the Doppler signal approaches zero when the illumination is orthogonal to

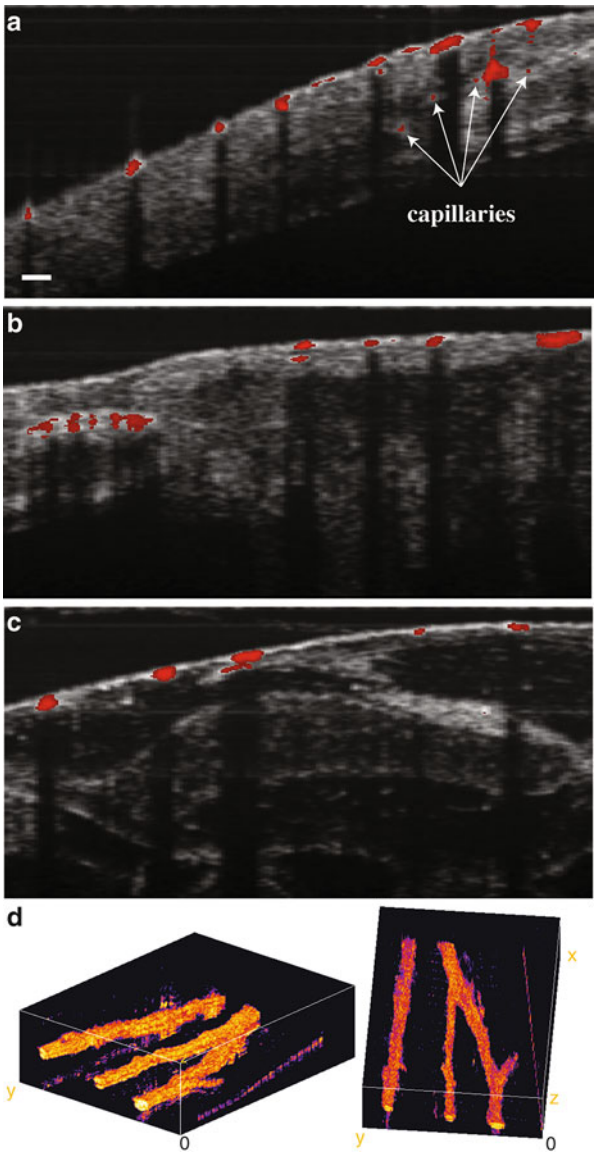

Fig. 47.6 (**a**–**c**) PPOCT B-scans overlaid on the corresponding co-registered OCT B-scans. *Xenopus laevis* vasculature is clearly depicted. *Arrows* in (**a**) point to capillaries that were not visible in conventional OCT. the flow. The PPOCT signal is also molecularly specific, so it may be possible to differentiate oxy- and deoxyhemoglobin and develop a PPOCT-based measure of blood oxygen saturation. Furthermore, the imaging of exogenous contrast agents such as methylene blue could potentially be used to tag and image specific molecular species that are otherwise invisible to OCT. Such applications hinge on the demonstration of sufficient sensitivity either with methylene blue or some other discovered or engineered contrast agent.

(**d**) Corresponding PPOCT B-scan with a pump-probe delay of 24.8 μs. The absence of the MB tube demonstrates the potential for using the lifetime as an effective method for differentiating multiple chromophores

47.5 Magnetomotive OCT

47.5.1 Theory and Instrumentation

Magnetomotive OCT (MMOCT) is a method for contrasting the distribution of magnetic particles based on their induced motion within a temporally modulated, magnetic field gradient [40]. Figure 47.8 illustrates the mechanism of MMOCT, showing how magnetic particles inside the imaging volume are mechanically pulled toward an electromagnet placed in the imaging arm of an OCT system. Typically, phase-sensitive OCT is then used to track the motion of light scattering tissue structures that are mechanically coupled to the particles [41]. Modulation of the electromagnet thus leads to phase modulation that can be band-pass filtered at the modulation frequency to detect the magnetomotion. Because human tissues are only very weakly magnetic (magnetic susceptibility $|\chi| < 10^{-5}$),

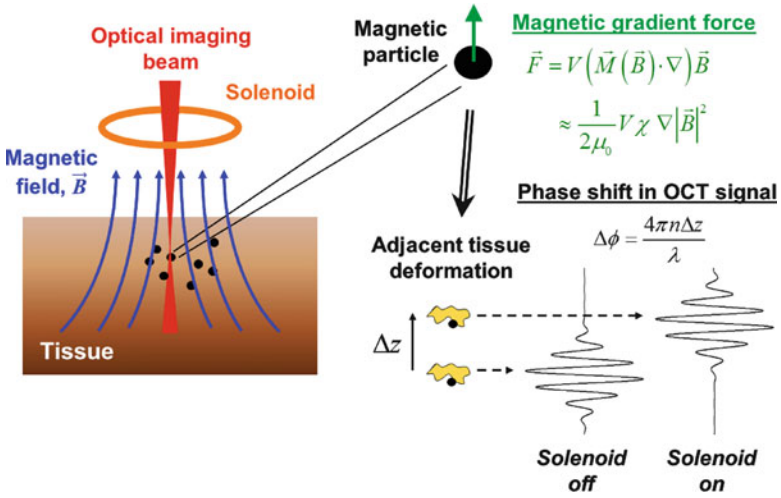

Fig. 47.8 Mechanism of magnetomotive contrast in OCT. A solenoid placed in the imaging arm of an OCT system provides a magnetic gradient force, $\vec{F}$, on magnetic particles inside tissue according to the gradient of the magnetic field, $\nabla \vec{B}$, and the magnetization and volume of the particles, $\vec{M}$ and V, respectively. The resultant elastic displacement of mechanically coupled light scattering structures, Δz, is sensed as a phase shift in the OCT interferogram, $\Delta\phi$. χ is the particle magnetic susceptibility, μ_0 is the vacuum permeability, and n is the tissue refractive index at the imaging beam wavelength, λ

MMOCT provides high specificity against the tissue background, on the order of 10^5 when using probes of $\chi \approx 1$ [42].

A class of biomedical imaging probes currently used in MRI, called superparamagnetic iron oxides (SPIOs), are ideal for MMOCT because they are designed to exhibit large χ, avoid irreversible aggregation that is associated with ferromagnetic agents, and are composed of iron oxide which has a proven safety profile. FDA-approved MR liver contrast agents such as Feridex™, for example, have been shown to provide excellent MMOCT contrast [43]. Another type of MMOCT probe is protein microspheres encapsulating SPIO-containing ferrofluid, which then offer flexibility in adding targeting ligands and therapeutic payloads [44].

Implementing MMOCT on an existing phase-sensitive OCT system is relatively straightforward. A small electromagnet can be placed on either the same side (as shown in Fig. 47.8) or opposite side of the tissue to provide a magnetic field gradient oriented along the imaging axis. Somewhat counterintuitively, the strength of the magnetic field should only be on the order of 0.1T; higher fields will typically saturate the magnetic particles and reduce the detection sensitivity [41, 43]. The absolute sensitivity of MMOCT can be determined by considering the balance of forces between the diamagnetic tissue, which is pushed away from the magnet, and from the paramagnetic particles, which are pulled toward the magnet.

For a typical SPIO particle, the minimum particle concentration needed to tip this force balance in favor of motion toward the magnet is on the order of 10 μg Fe/g. Another important consideration is the elastic property of the tissue medium. Magnetic particles in liquid do not undergo a restoring force during magnetic field modulation, moving only in one direction, and exhibit little contrast by conventional band-pass-filtered MMOCT. In a solid medium, the compliance of the tissue dictates the amount of displacement Δz, resulting in MMOCT contrast that is weighted by both the local particle concentration and the local tissue stiffness. Owing to the nanoscale displacement sensitivity afforded by phase-sensitive OCT systems, the tissue stiffness is typically of little detriment to the overall MMOCT sensitivity, and sensitivities as low as 27 μg Fe/g have been reported in optomechanical tissue phantoms [41]. The high sensitivity and specificity afforded by MMOCT have recently led to several new molecular imaging application areas, which will be reviewed below.

47.5.2 MMOCT of Atherosclerosis

Atherosclerosis is a disease in which an arterial vessel wall thickens as a result of the accumulation of fatty materials, including macrophages. Atherosclerosis is promoted by low-density lipoproteins (LDL) and cholesterol (crystals) and results in calcification in advanced lesions [45]. Standard intravascular OCT imaging has been extensively investigated for applications in cardiology such as imaging intraluminal 3D structure and function at high resolution, evaluating arterial stents, and visualizing atherosclerotic plaque [46–51]. The addition of contrast agents for use with intravascular OCT can enable site-specific molecular cardiovascular imaging, just as has been shown for ultrasound imaging using gas-filled microbubbles [52]. Targeted contrast agents may enable the early detection and localization of atherosclerotic lesions which may not be clearly evident in structural OCT imaging or in other imaging modalities. Therefore, the combination of intravascular OCT and targeted molecular contrast enhancement with MMOCT can potentially improve the sensitivity of early atherosclerotic lesion detection. Figure 47.9 shows representative MMOCT images from an ex vivo hyperlipidemic rabbit aorta. The RGD (arginine-glycine-aspartic acid)-functionalized protein microspheres [44] were fabricated to target the $\alpha_V\beta_3$ integrin overexpressed in atherosclerotic lesions [53]. These microspheres were loaded with SPIOs and a fluorescent dye, enabling multimodal imaging using MMOCT, MRI, ultrasound, and fluorescence imaging. The ex vivo aorta sample was perfused in a custom-designed flow chamber at physiologically relevant pulsatile flow rates and pressures. The functionalized microspheres have been successfully targeted to fatty streaks present during early-stage atherosclerosis. The future development of a MMOCT catheter or a new solenoid configuration for current commercial intravascular OCT systems may enable in vivo MMOCT imaging of atherosclerosis-targeted magnetic probes.

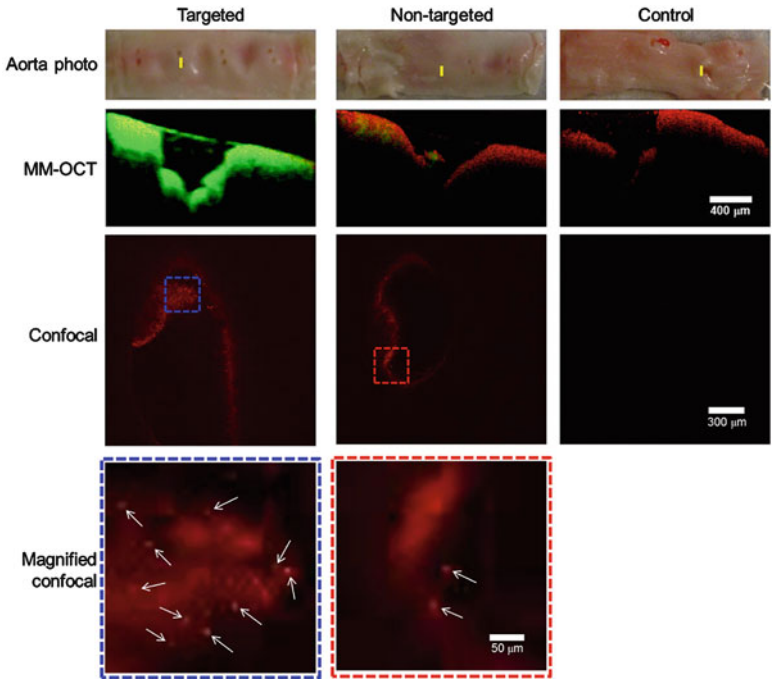

Fig. 47.9 Representative MMOCT and corresponding fluorescence confocal microscopy images of hyperlipidemic rabbit aortas after administration of RGD microspheres. Parametric MMOCT images are displayed showing the magnetomotive signal in *green* and the OCT signal in *red*. The MMOCT signal in the targeted microsphere group was statistically significantly higher ($p < 0.01$) than the nontargeted and control groups. *Yellow lines* in the aorta photos correspond to the imaging locations. The *dotted blue* and *red boxes* are magnified to show the presence of individual microspheres (*white arrows*). Scale bars are consistent across each row

47.5.3 MMOCT of Breast Cancer

Breast cancer is one of the most commonly occurring cancers in women and has a widespread effect on our society [54, 55]. Like other diseases, early detection is the key in the treatment of breast cancer. Breast cancer screening methods include manual clinical and self-breast exams, mammography, genetic screening, ultrasound, and MRI. Breast cancer cells often overexpress $\alpha_V\beta_3$ integrin and HER-2/neu receptors which are considered to be biomarkers for targeted cancer treatment [56]. Figure 47.10 shows an important step in breast cancer diagnosis using MMOCT to contrast HER-2/neu-targeted SPIOs [57]. In this study, the authors used a nitroso-methyl-urea (MNU) carcinogen-induced rat mammary tumor model. In vivo MMOCT images of tumors from rats injected with targeted SPIOs, nontargeted SPIOs, and saline exhibit an accumulation of SPIOs only in the tumors of rats injected with targeted MNPs.

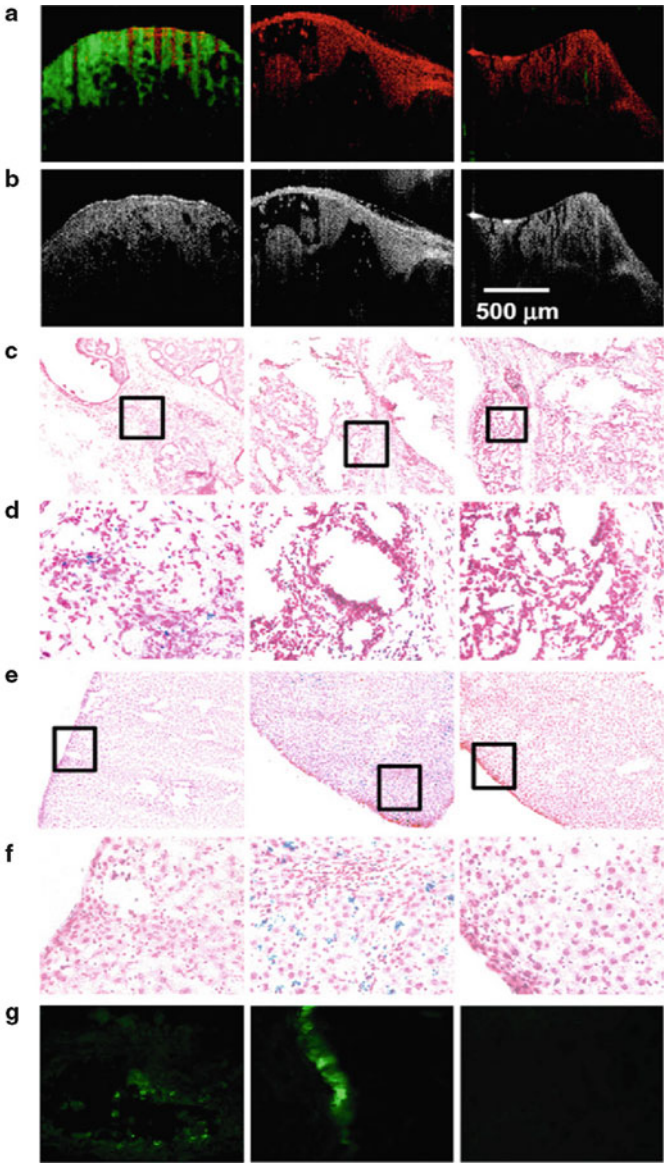

Fig. 47.10 In vivo (**a**) MMOCT and (**b**) OCT of rat mammary tumors. The magnetomotive signal (*green*) is superposed on the OCT (*red*) in MMOCT images. Prussian blue (*PB*) sections of (**c**, **d**) tumors and (**e**, **f**) livers from rats after injection with (left) targeted SPIOs, (center) nontargeted SPIOs, and (right) saline. PB sections in (**d**, **f**) at 40× from boxed regions in (**c**, **e**), at 10×. (**g**) Immunohistochemical-stained sections of (left) tumor from a targeted SPIO injected rat, (center) tail injection site from a targeted SPIO injected rat, and (right) tumor from a saline injected rat (Reprinted with permission from Ref. [57]. Copyright 2010 National Academy of Sciences)

Furthermore, $\alpha_V\beta_3$ integrin is also overexpressed in cancer cells [58]. As in the previous section on atherosclerosis, the protein shell of microspheres can be functionalized with the RGD tripeptide to target the $\alpha_V\beta_3$ integrin. A recent study reported MMOCT imaging of a rat mammary tumor containing RGD-targeted magnetic protein microspheres [9]. MMOCT imaging was performed ex vivo on the tumor approximately 4 h post injection of RGD-functionalized protein microspheres. It was found that the $\alpha_V\beta_3$ integrin-targeted microspheres preferentially accumulated in the tumor.

These preliminary results demonstrate the feasibility of using targeted magnetic nanoparticles and microspheres to detect breast cancer in OCT images. In addition, the liquid-core protein microspheres can potentially also be used to deliver a drug payload, such as the anticancer drug Taxol [59].

47.5.4 Platelets as Functional MMOCT Contrast Agents for Thrombosis

Another way of achieving molecular specificity is to label cells with imaging agents in vitro and to subsequently monitor the activity of the cells after in vivo administration. Platelets are cellular fragments present in blood that are responsible for primary hemostasis (plug formation) as part of the blood clotting process [60]. Platelets respond to factors expressed when the blood vessel endothelium is damaged, such as during trauma and atherosclerosis [61]. Therefore, platelets labeled with SPIOs can be considered novel contrast agents for targeting localized endothelial damage.

Interestingly, platelets have a unique method for nanoparticle uptake, dubbed "covercytosis" [62], which is thought to be part of the body's native immune mechanism. As such, they avidly take up particles at levels reaching hundreds [63], if not thousands [64], of femtograms of iron per platelet. Platelets harvested from blood can also be partially fixed and lyophilized to allow for long-term storage; these are known as rehydratable, lyophilized (RL) platelets [65].

To date, in vitro and ex vivo studies have demonstrated the potential for MMOCT to provide targeted imaging of reactive vascular sites using SPIO-labeled RL platelets [43, 63]. In an ex vivo study, pig arteries were cannulated and flowed with whole blood containing both native platelets and SPIO-RL platelets at equal concentrations [43]. The endothelium of one set of arteries was lightly injured, resulting in blood clotting at the injury sites. As shown in Fig. 47.11, subsequent MMOCT of the luminal wall of these arteries revealed specific magnetomotive contrast to injured artery only, due to the incorporation of SPIO-RL platelets into the clots. These findings may be broadly translatable for assessing internal bleeding and a broad spectrum of cardiovascular diseases such as atherosclerosis.

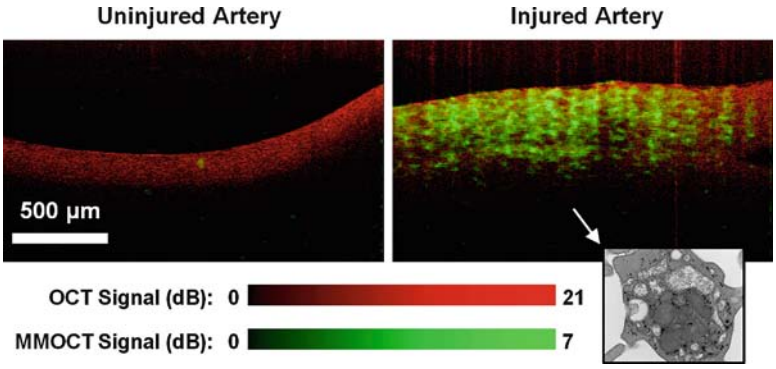

Fig. 47.11 Representative MMOCT images of ex vivo porcine arteries after exposure to SPIO-labeled RL platelets in a flow chamber, revealing specific contrast to injured vascular endothelium. Arteries were subsequently longitudinally cut and are imaged with the luminal wall facing upward. Inset: TEM image of an SPIO-labeled platelet containing hundreds of SPIOs in its surface-connected open canalicular system

47.6 Photothermal OCT

Photothermal OCT (PTOCT) provides sensitivity and specificity of OCT to absorbers in a sample through active detection of photothermal heating. Photon absorption by an endogenous chromophore or exogenous contrast agent leads to a temperature rise in the surrounding environment. These local temperature changes cause thermoelastic expansion of the sample and shifts in the local index of refraction [66, 67], which in turn cause changes in the local optical path length. These small, typically nanometer-scale, local optical path length changes can be resolved with phase-sensitive OCT. Unlike fluorescence-based imaging modalities, most absorption-based contrast agents do not undergo photobleaching, allowing for constant PTOCT signal over time, even at high irradiance.

47.6.1 Theory and Instrumentation

In PTOCT, a separate laser source for photothermal heating is incorporated into the sample arm of the OCT system, either via direct, free beam coupling at the sample arm optics or through shared sample arm fiber optics. The heating laser wavelength is chosen to match the peak absorption of the desired imaging target. In most applications of PTOCT, square or sine wave amplitude modulation of the heating beam (e.g., using a mechanical optical chopper or acousto-optical modulator) is performed during temporal sampling (M-mode scanning) of each spot. An example PTOCT instrumentation diagram can be seen in Fig. 47.12, with the incorporation of an amplitude-modulated 808 nm laser into the sample arm of a spectral-domain

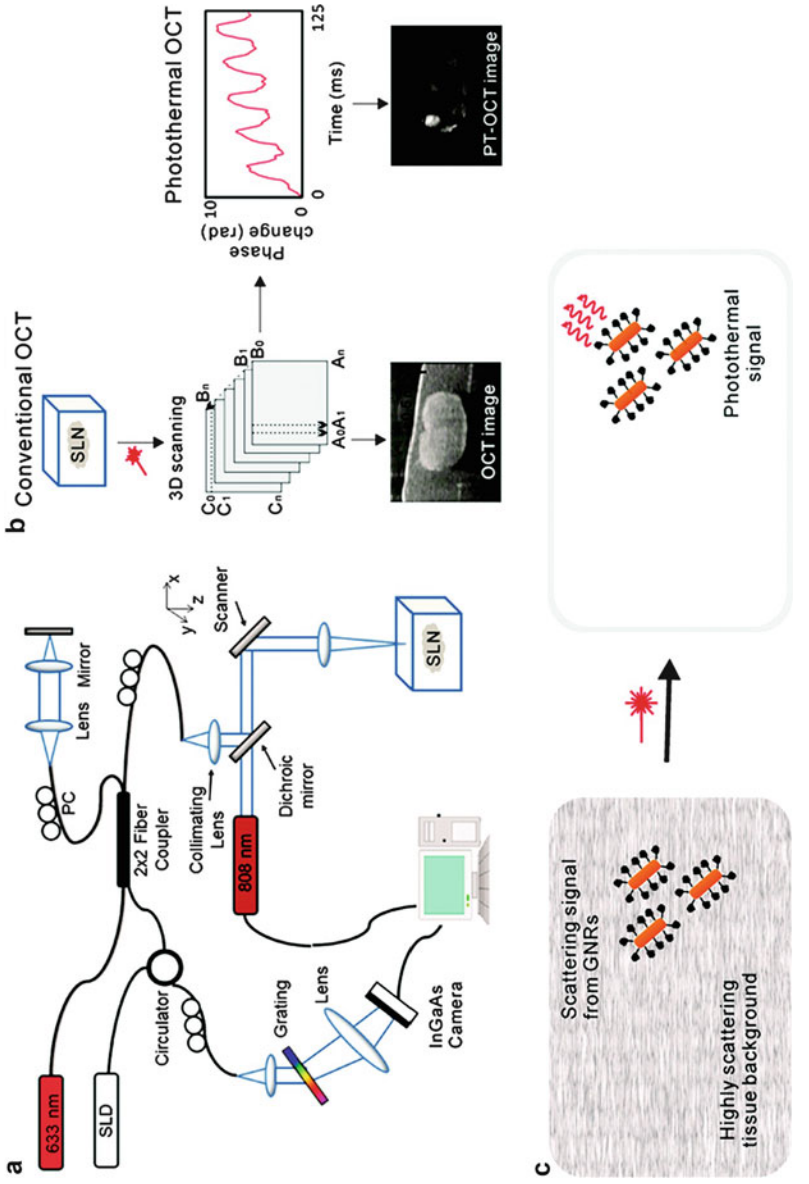

Fig. 47.12 (**a**) Experimental setup of the PTOCT system, where PC denotes the polarization controller. (**b**) Diagram of the data processing method used to image sentinel lymph nodes with PTOCT (Adapted with permission from Ref. [68]. Copyright 2011 American Chemical Society)

OCT system [68]. Amplitude modulation of the heating beam allows for digital lock-in techniques to be used during signal processing, which can detect and isolate the active heating dynamics from the passive scattering signal. Modulation frequencies as low as 25 Hz [69] and as high as 120 kHz [70] have been reported in PTOCT and PTOCM applications.

In PTOCT, the signal is isolated from an oversampled M-mode scan by obtaining the Fourier transform (in the time dimension) of the OCT phase data at each point in depth. The PTOCT signal is then defined as the magnitude of this Fourier-transformed phase data at the modulation frequency. More complex signal processing considerations are often taken into account to remove artifacts, including fifth- [69] or sixth- [71] order polynomial background subtraction of the phase data to minimize $1/f$ noise, baseline subtraction of nearby frequency components in the FFT data to account for the additive noise floor in the signal [69, 71–73], and averaging of overlapping short-time Fourier transforms over the M-mode scan to better estimate the noise floor [73]. Previous investigations into the PTOCT imaging parameters have demonstrated that the PTOCT signal increases linearly with both absorber concentration [67–69, 72–75] and photothermal laser power [69, 73, 74], decreases logarithmically with increased amplitude modulation frequency [73], and has a constant mean value but increased noise level in the presence of weak reflections in the sample [73].

47.6.2 PTOCT Applications

PTOCT has been demonstrated in vitro, ex vivo, and in vivo both with endogenous and exogenous forms of contrast. The most common use of PTOCT is to visualize ultralow concentrations of highly absorptive contrast agents in tissue and in vitro. In particular, PTOCT can exploit the rapidly advancing field of nanotechnology to image contrast agents with strong, wavelength-tunable absorption peaks.

Gold nanoparticles are the most common PTOCT contrast agents due to their biocompatibility and well-established surface modification chemistry, which can allow for specific imaging of molecular targets. In vitro molecular imaging of 60 nm diameter epidermal growth factor receptor (EGFR)-targeted gold nanospheres has been performed in agarose phantoms using a 532 nm heating laser at 25 Hz modulation, where EGFR+ cells exhibited a 300 % increase in PTOCT signal compared to EGFR cells [69]. This study also demonstrated a sensitivity of 14 ppm (*w*/*w*) to gold nanospheres within a scattering background. Although this is the only demonstration of true molecularly targeted imaging using PTOCT to date, a number of applications have used nontargeted NIR-resonant nanoparticles in systems ranging from phantoms to in vivo. Early investigations into PTOCT were performed with gold nanoshells having an SPR tuned to the near-infrared [67]. In subsequent studies with ex vivo human breast tissues, direct injections of 120 nm silica core and 16 nm gold shell nanoshells at a 5×10^9/mL concentration were visible 300–600 μm deep into the tissue using PTOCT with an 808 nm laser modulated at frequencies from 5 to 20 kHz, with 22 mW of power on the sample [71]. Gold nanorods have also generated

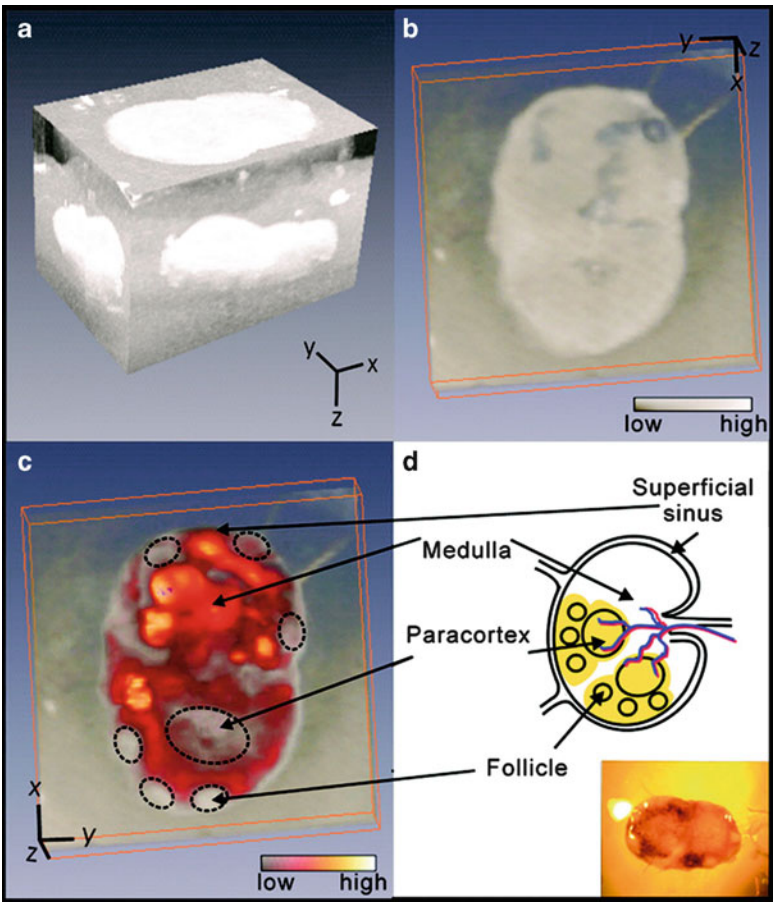

Fig. 47.13 (**a**) Three-dimensional OCT projection image of a dissected sentinel lymph node (*SLN*) at 48 h after gold nanorod injection. (**b**) 3D OCT view of SLN morphology with a cross-sectional cut at a depth of 240 μm below the top surface. (**c**) 3D PTOCT view of SLN corresponding to the cross-sectional cut displayed in (**b**) reveals structures within the SLN. (**d**) Schematic diagram and photograph of a dissected SLN. (Volume size = 2.5 × 2.5 × 2.0 mm (*x*–*y*–*z*)) (Adapted with permission from Ref. [68]. Copyright 2011 American Chemical Society)

interest as PTOCT contrast agents due to their tunability (based on the aspect ratio) and particularly narrow SPR peak. Gold nanorods coated in poly(ethylene glycol) (PEG) were found to have a significantly enhanced PTOCT signal at as low as 1 pM concentration using 50 Hz modulation of an 808 nm laser interfaced with a 1,310 nm OCT system [68]. The same system was used to image nonspecific uptake of gold nanorods in sentinel lymph nodes (SLN). After injection with PEG-coated gold nanorods, SLNs were dissected at varying time points from sacrificed mice and imaged ex vivo after being embedded in 1 % agar gel. PTOCT was able to identify the accumulation of nanorods within several SLN structures (Fig. 47.13, [68]).

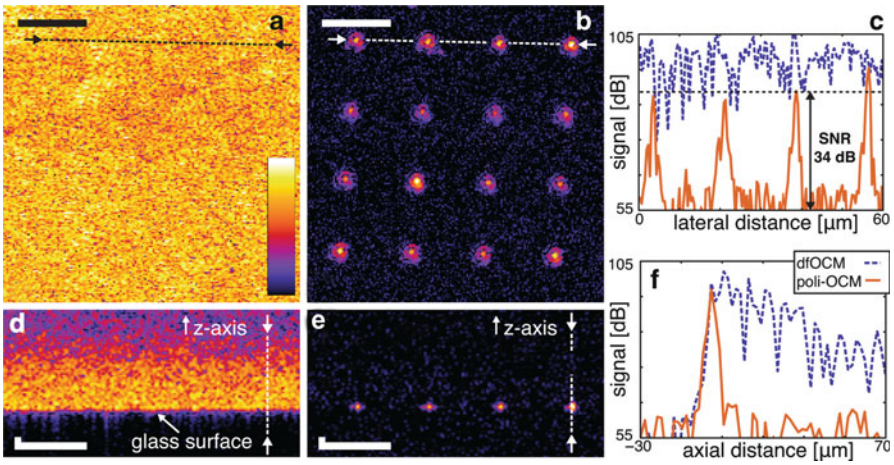

Fig. 47.14 Demonstration of the contrast selective to gold nanoparticles offered by poli-OCM, as compared to dfOCM. Graph (**c**) depicts the signal along the lines in (**a**, **b**), while (**f**) corresponds to the axial signal along the *line* highlighted in (**d**, **e**). Scale bars: 10 μm (Adapted with permission from Ref. [70]. Copyright 2012 Optical Society of America)

A separate study was able to image, in vivo, picomolar concentrations of PEG-coated gold nanorods directly injected into a mouse ear [73].

Applications of PTOCT are not limited to gold nanoparticles, but include any targets that have strong absorption at the wavelength of the heating laser. PTOCT has also been demonstrated using carbon nanotubes [72], indocyanine green encapsulated poly(lactic-co-glycolic) acid nanoparticles [76], gold-iron oxide nanoroses [75], and iron oxide-silica-gold multifunctional nanoprobes [77]. PTOCT has also been used to characterize hemoglobin oxygen saturation using dual-wavelength approaches to probe the absorption differences of oxy- and deoxyhemoglobin in vitro and in vivo [78, 79].

47.6.3 Recent PTOCT Advances

Recent advances in the field of PTOCT have been working toward providing quantitative molecular imaging. First, measurements of the local slope in the axial dimension of a PTOCT image has found some success in correcting for phase accumulation in PTOCT [74]. Second, a method to perform photothermal optical lock-in optical coherence microscopy (poli-OCM) has been developed for real-time photothermal imaging [70]. In poli-OCM, one creates phase modulations in the reference arm that are matched to the amplitude modulation frequency of the heating beam, resulting in a demodulated photothermal signal of the absorbers in the sample. The signal due to scatterers is then isolated from the photothermal

signal by setting the CCD integration time to a multiple of the modulation period. This provides real-time photothermal imaging without the need for temporal (M-mode) sampling or extensive digital processing. Pache et al. demonstrated single particle detection of gold nanoparticles using poli-OCM with modulation frequencies of 120 kHz while rejecting the scattering signal captured from their dark-field optical coherence microscopy (dfOCM) system (Fig. 47.14, [70]). Photothermal optical lock-in has yet to be demonstrated with a traditional OCT system, but the underlying principles remain the same.

PTOCT is a promising imaging technique for isolating absorbers in a scattering sample and thus provides specific and sensitive molecular imaging of both endogenous and exogenous contrasts. With recent advances in PTOCT optimization, demonstrations in ex vivo and in vivo samples, and incorporation of optical lock-in techniques, PTOCT promises to be not only sensitive and specific, but also a fast method for imaging absorptive contrast agents in tissue.

47.7 Conclusion

It should be evident to the reader that MCOCT can be accomplished by a wide variety of methods that each offer unique advantages, all of which should be weighed when considering a specific biomedical application. All of the methods presented here are in continued development, and we can expect to see continued progress (greater sensitivity, specificity, imaging speeds, and higher resolution) in the years to come. Also, new methods continue to emerge, such as imaging thermal diffusion of micro- and nanoprobes [80, 81], which may allow one to sense the local macromolecule concentration in bodily fluids such as mucus and blood. Fundamentally, OCT provides a unique and flexible platform for exploring new concepts in molecular imaging. Tying these imaging technology advances with concomitant advances in nanotechnology and targeted delivery makes this a rapidly changing field with many new opportunities for scientific discovery.

Acknowledgments We wish to thank our many colleagues and collaborators conducting research in this area and apologize that, due to length restrictions, we were unable to highlight more results. We acknowledge Justis Ehlers at the Cole Eye Institute, Cleveland Clinic, for aiding in Fig. 47.1. Some of the studies reported in this chapter were supported in part by a grant from the US National Institutes of Health (R01 EB009073, S. A. B.).

Optical Tissue Clearing to Enhance Imaging Performance for OCT

48

Ruikang K. Wang and Valery V. Tuchin

Keywords

Imaging contrast • Imaging depth • Optical clearing • Optical coherence tomography • Osmotically active chemical agents • Tissue scattering

48.1 Introduction

Over the last decade, noninvasive or minimally invasive spectroscopy and imaging techniques have witnessed widespread and exciting applications in biomedical diagnostics. Optical techniques that use the intrinsic optical properties of biological tissues, such as light scattering, absorption, polarization, and fluorescence, have many advantages over the conventional *x*-ray computed tomography, MRI, and ultrasound imaging in terms of safety, costs, contrast, and resolution features. Time-resolved, phase-resolved, and frequency-resolved optical techniques are capable of deep imaging of the tissues that could provide information of tissue macrostructures and oxygenation states and detect brain and breast tumors [1, 2], whereas confocal microscopy and multiphoton excitation imaging have been used to show cellular and subcellular details of superficial living tissues [3, 4]. However,

most biological tissues strongly scatter the probing light within the visible and near-infrared range, i.e., the therapeutic and/or diagnostic optical window. The multiple scattering of light is detrimental to imaging contrast and resolution, which limits the effective probing depth to several hundred micrometers for the confocal microscopy and multiphoton excitation imaging techniques. However, some clinical applications, such as early cancer diagnosis, require the visualization of intermediate depth range of the localized anatomical structures with micron-scale resolution.

We have seen from the previous chapters that optical coherence tomography (OCT) fills a nice niche in this regard. Briefly, it uses low-coherence interferometer to image internal tissue structures to the depth up to 2 mm with micron-scale resolution [5–9]. Although its first applications in medicine were reported less than a decade ago [10–13], it stems from the early work on white-light interferometry where the primary purpose was the development of optical coherence-domain reflectometry (OCDR), a one-dimensional optical ranging technique [14]. OCDR was inspired originally for finding faults in fiber-optic cables and network components and measuring distances in metrology [15]. Because it is sensitive to the discontinuity of refractive index interfaces, it was soon realized that such technique is able to probe the microstructures of the eye [16–18] and other biological tissues [19]. Perhaps, the biggest advantage of this technique for the applications in biomedicine is its superb axial resolution, which is achieved by exploiting the short temporal coherence of a broadband light source. Migrated the basic concepts from ultrasound imaging and recently developed confocal microscopy, OCDR was quickly extended to section the biological tissues [5] through the raster scanning of the focused beam spot, which was subsequently termed as optical coherence tomography. OCT enables microscopic structures in biological tissue to be visualized at a depth beyond the reach of conventional confocal microscopes. Probing depth exceeding 2 cm has been reported for transparent tissues, including the eye [20] and frog embryo [21]. To date, successful stories of in vitro and in vivo OCT applications in medicine have been delivered in a wide branch of areas, for example, ophthalmology [22], gastrointestinal tract [23–27], dental [28], dermatology [29–31], etc. Please refer to the other chapters in this book for these aspects of OCT applications.

Although exciting when screening the OCT developments and applications to date, its fundamental limitation of imaging depth has somehow hindered its broader applications in biomedicine and other applications. This is because OCT relies on the penetration and backscattering of light into tissue to construct cross-sectional, tomographic images. It collects the backscattered photons that have experienced less scattering, i.e., ballistic or least-scattered photons. However, unlike the transparent ocular organs where OCT found its most successful applications [20], there is no evidence that an OCT imaging depth beyond 2 mm for opaque biological tissues is possible [32]. This is largely due to the multiple scattering inherent in the interactions between the probing light and the targeted tissue, which limits light penetration into the tissue and, therefore, prevents the imaging of deep microstructures. Furthermore, the multiple scattering of photons inside the tissue tends to blur the targeted tissue boundaries, leading to the degradation of the imaging contrast of

the resulted OCT images. Thus, it is reasonable to state that the multiple scattering could degrade signal attenuation and localization, leading to an image artifact that reduces the imaging depth and degrades the signal localization, i.e., the image contrast. To improve the imaging capabilities, the multiple scattering of tissue must be, therefore, reduced.

Tissue as a scattering medium shows all optical effects that are characteristic to turbid physical system. It is well known that the turbidity of a dispersive physical system can be effectively controlled using immersion effect matching of refractive indices of the scatters and the ground material [33–35]. The living tissue allows one to control its optical (scattering) properties using various physical and chemical actions such as compression, stretching, dehydration, coagulation, UV irradiation, exposure to low temperature, and impregnation by chemical solutions, gels, and oils [36–49]. Such methods of controlling optical properties of tissue have been explored to enhance the optical imaging capabilities of OCT [27, 50–56]. The possible mechanisms of enhancing OCT imaging depth and contrast have been suggested [27, 50–62].

This chapter is designed to introduce the effects of light scattering on OCT and discuss how multiple scattering of tissue would an impact on the OCT imaging performances. We then elucidate the developments of techniques in reducing the overwhelming multiple scattering effects and improving imaging capabilities by the use of immersion techniques.

48.2 Theoretical Aspects

Although it has been described in detail in the previous chapters, it is necessary here to revisit briefly the theoretical treatments of OCT sensing the biological tissue and its relevant aspects on the light scattering in tissue that produces the imaging contrast and depth in OCT.

48.2.1 Low-Coherence Interferometry

OCT is an interferometric technique, relying on interference between a split and later recombined broadband optical field. We consider a conventional time domain OCT device based on a Michelson interferometer setup, as shown in Fig. 48.1. In this setup, the depth profile is provided by the scanning of optical delay between the reference and sample arm (or A-scan) that is usually achieved by the scanning of a mirror mounted in the reference arm. The transversal information is obtained by recording A-scans at several adjacent sample positions. In this section we discuss only the depth scans.

A low coherent light source, e.g., an SLD, emits a light beam with short coherence length towards the Michelson interferometer, where it is first split by a beam splitter. The split field travels in a reference path, reflecting from a reference mirror, and also in a sample path where it is reflected from multiple layers within a sample. Due to

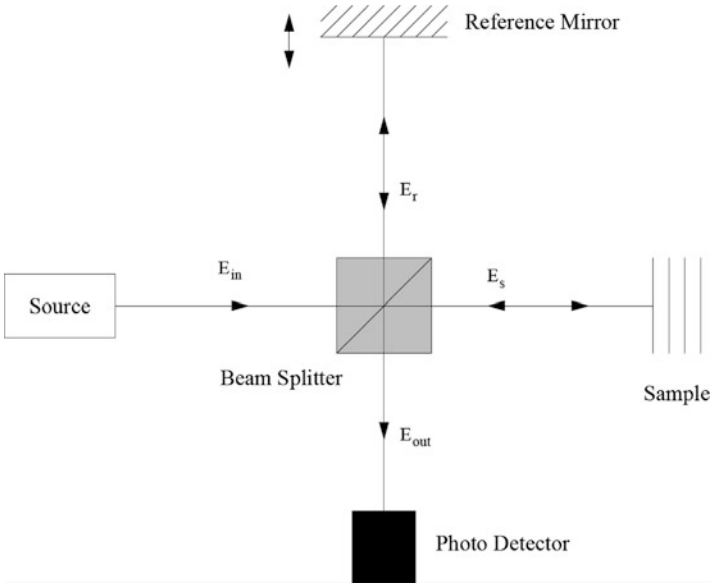

Fig. 48.1 Low-coherence Michelson interferometer

the broadband nature of the light, interference between the optical fields is only observed when the reference and sample arm optical lengths are matched to within the coherence length of the light. Therefore, the depth (axial) resolution of an OCT system is determined by the temporal coherence of the light source. Sharp refractive index variations between layers in the sample medium manifest themselves as corresponding peaks in the interference pattern.

To describe OCT mathematically, it is useful to express the electric field $E(\omega, t)$ as a complex exponential.

$$E(\omega, t) = s(\omega)\exp[-i(\omega t + kz)]. \tag{48.1}$$

This is a plane-polarized solution to the wave equation, with source field amplitude spectrum $s(\omega)$, frequency ω, and time variation t. The second term in the exponential, in terms of wave number k and distance z, simply accounts for phase accumulated throughout the interferometer. Since the input phase is arbitrary and the interferometer only measures the relative output phase between the two optical paths, the phase term can be dropped from the input electric field. The field in each part of the interferometer is denoted by subscripts as follows: E_{out}, E_{r}, and E_{s} corresponding to the input, output, and reference and sample arm optical fields, respectively. The sample has a frequency-domain response function $H(\omega)$ that describes its internal structure and accounts for phase accumulation therein. Optical detectors are square law intensity detection devices, where the recorded intensity is proportional to a time average over the electric field multiplied by its complex

conjugate. Assume that the interferometer operates in air, then the output from the detector is

$$I(\omega, \Delta z) = \left\langle E_{\text{out}}(\omega, t, \Delta z) E^{*}_{\text{out}}(\omega, t, \Delta z) \right\rangle. \tag{48.2}$$

The angled brackets denote a time average, given by

$$I(\omega, \Delta z) = \lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} E_{\text{out}}(\omega, t, \Delta z) E^{*}_{\text{out}}(\omega, t, \Delta z) dt. \tag{48.3}$$

It can be shown that the intensity is a sum of three terms

$$I(\omega, \Delta z) = \left\langle E_r E_r^{*} \right\rangle + \left\langle E_s E_s^{*} \right\rangle + 2\Re\left\{ \left\langle E_s E_r^{*} \right\rangle \right\}. \tag{48.4}$$

Here, $\Delta z = \Delta t c / n_{\text{air}}$ is the mismatch distance between the reference and sample arm. The first two terms can be identified as "self-interference" that is not relevant to the OCT imaging and therefore is dropped in the following treatment. The last term is the real part (denoted by $\Re$) of the complex "cross-interference" that is the interest of concern. Making the relevant mathematical operations and substituting for the field spectrum $s(\omega)$ a corresponding intensity spectrum $S(\omega) = |s(\omega)|^2$, the frequency and path difference-dependent intensity is given by

$$I(\omega, \Delta z) = \Re\{S(\omega) H(\omega) \exp[-i\phi(\Delta z)]\} \tag{48.5}$$

where $\phi(\Delta z)$ is the phase accumulated in translating the reference mirror by a geometric distance Δz, $\phi(\Delta z) = 2\omega n_{\text{air}} \Delta z / c$. The sample response function $H(\omega)$ describes the overall reflection from all structures distributed in the z direction within the sample and is given by

$$H(\omega) = \int_{-\infty}^{\infty} r(\omega, z) e^{i2n(\omega, z)\omega z / c} dz. \tag{48.6}$$

The function $n(\omega, z)$ is the frequency-dependent, depth-varying group refractive index and $r(\omega, z)$ is a function of the reflected photons escaped from the sample at depth z that bears the structure features of the sample. The exponential term accounts for phase accumulated by the multiple optical paths within the sample.

From Eq. 48.6 it is evident that information about the optical structure of the sample can be obtained from measurements in both the time and frequency domains. Clearly the imaging depth and contrast are related to the function $r(\omega,z)$. Assuming that the sample is transparent consisting of N multiple layers that do not absorb and scatter the incoming light, $r(\omega, z)$ can be simplified as the

reflectivity of each layer, r_j (j = 1,2,..., N), that can be determined by the application of Fresnel's equations:

$$r_j = \frac{n_{j+1} - n_j}{n_{j+1} + n_j}. \tag{48.7}$$

Thus, for such a simple multilayered sample, the sample response function can be modeled as a summation over N individual layers and assuming negligible dispersion [9]

$$H(\omega) = \sum_{1}^{N} r_j(\omega) \exp\left\{ i2\frac{\omega}{c} \sum_{i=1}^{j} (n_i z_i) \right\} \tag{48.8}$$

Here, z_i is the thickness of the ith layer with a group refractive index n_i. However, it will never be the case for the biological tissues where there are almost no planar boundaries, i.e., the interfaces distinguished by the refractive index. And more important, there are other optical properties of tissue that are detrimental to the OCT imaging of microstructures inside the tissue. The most notable optical properties that are responsible for degrading the imaging depth and contrast are the absorption and scattering. It is reasonable to consider that biological tissue has depth-varying distribution of absorption and scattering. Thus, the sample response function will be modulated by the local optical properties. For the case of only one scatter within the coherence volume, the sample response function from this particular scatter at the depth z can be expressed as the multiplication of backscattering profile $r_b(\omega, z)$ and the accumulated attenuation $r_a(\omega, z)$ along the optical path in the sample before that scatter, such that

$$r(\omega, z) = r_a(\omega, z) r_b(\omega, z). \tag{48.9}$$

The accumulated attenuation $r_a(\omega, z)$ along the optical path has both scattering and absorption contributions. In simple cases, it follows Beer's law:

$$r_a(\omega, z) = \exp\left\{ -2\int_0^z \left[\mu_a(\omega, x) + \mu_s(\omega, x) dx \right\} \right. \tag{48.10}$$

Here, $\mu_a(\omega, z)$ and $\mu_s(\omega, z)$ are wavelength dependent and spatially varying absorption and scattering coefficients of the biological sample, respectively. The backscattering coefficient at depth z, $r_b(\omega, z)$ is determined by the local refractive index variation that gives the imaging contrast of the final OCT image. Therefore, the sample response function at depth z can now be expressed by

$$H(\omega, z) = r_b(\omega, z) \exp\left\{ -2\int_0^z \left[\mu_a(\omega, x) + \mu_s(\omega, x) dx \right\} \exp\left\{ i2\frac{\omega}{c} \int_0^z n(\omega, x) x dx \right\}. \right. \tag{48.11}$$

Thus, the explanation of OCT imaging contrast and depth can be decoupled from the above equation, where the imaging contrast is provided by the local backscattering coefficient, $r_b(\omega, z)$, and the imaging depth is determined by the attenuation coefficient of the targeted sample. In particular, the imaging contrast at a certain depth z is severely affected by the accumulated light attenuation before the depth z. That is to say, if there is no attenuation of light before the depth z, theoretically the imaging depth z can approach infinity while the imaging contrast is provided by the true local reflectivity of the sample. However, as we are dealing with the biological tissue which is highly scattering in nature, the imaging depth would be determined by the point at which the light is attenuated to the limit of the system noise floor. Thus, the weaker the light attenuation before the depth z, the higher the imaging contrast at the depth z and the further the light can reach beyond z.

48.2.2 Light Scattering in Tissue

As explained in the previous section, the OCT imaging depth and contrast are affected by the total spectral-dependent attenuation coefficient of the sample. That is to say, the depth of penetration for the light into a biological tissue depends on the scattering characteristics and absorptivity of the tissue. To simplify the discussion, here we assume that the absorption and scattering coefficient of the sample are not wavelength dependent. Further, as the OCT imaging is usually performed in the near-infrared region of spectrum, compared to the scattering effect the absorption is relatively small and is therefore not discussed in the following sections. However, this is by no means to say that the absorption is not a factor in influencing OCT imaging performance. Please refer to the other chapters in this book, particularly the spectroscopic OCT, for details of exciting usage of OCT to sense the absorption in tissue, thereby the molecular-sensitive detection.

Optically, tissue can be described as a spatial distribution of refractive index on the microscopic scale that could be classified into those of the extracellular and intracellular components [63–65]. The local refractive index within the tissue can vary from anywhere within the background refractive index, i.e., 1.34 and 1.50 depending on what type of soft tissue is concerned. It is this variation of refractive index distribution within the tissue that causes a strong light scattering. Figure 48.2 shows a hypothetical index profile formed by measuring the refractive index along a line in an arbitrary direction through a volume of tissue and corresponding to the statistical mean index profile. The widths of the peaks in the actual index profile are proportional to the diameters of the elements, and their heights depend on the refractive index of each element relative to that of its surroundings. This is the origin of the tissue-discrete particle model. In accordance with this model, the index variations may be represented by a statistically equivalent volume of discrete particles having the same index but different sizes.

To describe theoretically the optical scattering in tissues, attempts have been made using the particle model with some success [63, 64]. Based on the model,

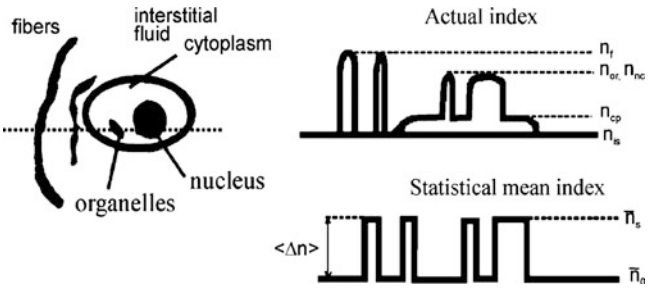

Fig. 48.2 Spatial variations of the refractive index of a soft tissue. A hypothetical index profile through several tissue components is shown, along with the profile through a statistically equivalent volume of homogeneous particles. The indices of refraction labeling of the profile are defined in the text [63, 66]

the biological tissue is treated as that consisting of the discrete scattering centers with different sizes randomly distributed in the background media. According to the Rayleigh-Gans approximation, the reduced scattering, $\mu_s' = \mu_s(1 - g)$, of turbid media is related to the reduced cross section, σ_s', and the total number of scattering particles per unit volume, i.e., number density, ρ:

$$\mu_s' = \sum_{i=1}^{n} \rho_i \sigma_{si}' = \sum_{i=1}^{n} \frac{3\varphi_i}{4\pi a_i^3} \sigma_{si}' \tag{48.12}$$

and

$$\sigma_{si}' = \frac{9}{256\pi} \left| \frac{m_i^2 - 1}{m_i^2 + 2} \right|^2 \left(\frac{\lambda}{n_0} \right)^2 \int_0^{\pi} (\sin u_i - u_i \cos u_i)^2 \frac{(1 + \cos^2\theta) \sin \theta (1 - \cos\theta)}{\sin^6(\theta/2)} d\theta \tag{48.13}$$

where $u_i = 2(2\pi a_i n_0/\lambda)\sin(\theta/2)$, $m_i = n_{si}/n_0$ with n_{si} and n_0 being the refractive indices of the ith scattering centers and background medium, φ_i the volume fraction of the ith particles, and a_i the radius of the ith scatterer. This equation is valid for non-interacting Mie scatterers, $g > 0.9$, $5 < 2\pi a/\lambda < 50$, and $1 < m < 1.1$.

It can be seen that the reduced scattering coefficient of the scattering medium is dependent on both the refractive index ratio, m_i, and the size of the scattering centers. A study by Schmitt and Kumar [66] reveals that the spectrum of index variation exhibits a power law behavior for spatial frequencies from 0.5 to 5 μm^{-1}. In other words, they found evidence for a broad distribution of scatters in tissue cells with sizes ranging from 0.2 to 2 μm. Studies by Beauvoit et al. [40] and Mourant et al. [67] revealed that the size of scattering centers varies in radius from less than 0.2 μm to more than 1 μm. Thus, the particles inside the tissue with sizes in microscopic scale are mainly responsible for the light scattering.

The refractive indices of tissue structure elements, such as fibrils, interstitial medium, nuclei, cytoplasm, organelles, and the tissue itself can be derived using the law of Gladstone and Dale, which states that the resulting value represents an average of the refractive indices of the components related to their volume fractions

$$\overline{n} = \sum_{1}^{n} n_i f_i, \qquad \sum_{i} f_i = 1 \tag{48.13}$$

where n_i and f_i are the refractive index and volume fraction of the individual components, respectively, and N is the number of components. The statistical mean index profile in Fig. 48.1 illustrates the nature of the approximation implied by this model. According to Eq. 48.13, the average background index is defined as the weighted average of the refractive indices of the cytoplasm and the interstitial fluid, n_{cp} and n_{is}, as

$$\overline{n}_0 = f_{cp} n_{cp} + \left(1 - f_{cp}\right) n_{is} \tag{48.14}$$

where f_{cp} is the volume fraction of the fluid in the tissue contained inside the cells. For the human soft tissues, the total fluid occupies approximately 60 % of the body weight, of which 40 % is the intracellular component and 20 % the extracellular component. As a result, approximately 70 % of the total fluid in the soft tissue is contained in the intracellular compartment and 30 % in the extracellular compartment. Estimated from the dissolved fractions of proteins and carbohydrates in the intracellular and extracellular fluids, refractive indices of the extracellular fluid, ne, and the intracellular fluid, ni, are found to be approximately 1.34 and 1.36, respectively [6]. The average background refractive index of a soft tissue can thus be estimated from the weighted refractive indices of ne and ni as

$$n_0 = f n_e + (1 - f) n_i \tag{48.15}$$

where f is the fraction of the fluid in tissue contained in between the cells. Therefore, it follows from Eq. 48.15 that $n_0 = 0.3 \times 1.34 + 0.7 \times 1.36 = 1.354$.

Figure 48.3 illustrates the reduced scattering coefficient of the turbid medium, predicted by the Rayleigh-Gans approximation, against the refractive index of background medium for the wavelengths at 800 nm and 1,300 nm, respectively. The parameters taken for scattering centers in the numerical evaluation were the refractive index $n_s = 1.46$, the volume fraction $\varphi = 0.3$, and the radius a = 1 μm. It is clear from Fig. 48.3 that the reduced scattering of the tissue is dramatically reduced with the increase of refractive index of the background medium. The reduction rate is approximately the same for both the wavelength applied, with 800 nm being a little bit faster than that of 1,300 nm. At least threefold reduction is expected if the refractive index of the background medium is changed from $n_0 = 1.354$ to $n_0 = 1.4$.

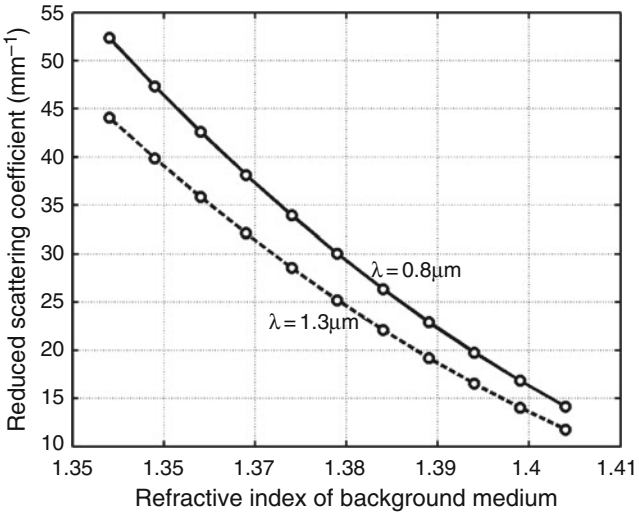

Fig. 48.3 Reduced scattering coefficient calculated from Rayleigh-Gans approximation as a function of the refractive index of the background medium for the wavelength at 800 and 1,300 nm, respectively. Please see the text for the parameters used in the numerical evaluation [54]

It is possible to achieve a marked impairment of scattering by means of the intratissue administration of appropriate chemical agents. Conspicuous experimental optical clearing in human and animal sclera; human, animal, and artificial skin; human gastrointestinal tissues; and human and animal cartilage and tendon in the visible and NIR wavelength ranges induced by the administration of x-ray contrast agents (Verografin, Trazograph, and Hypaque-60), glucose, propylene glycol, polypropylene glycol-based polymers (PPG), polyethylene glycol (PEG), PEG-based polymers, glycerol, and other solutions as has been described in Refs. [27, 34–62].

With the connection from the last section, such effect of reduction of scattering in biological tissue can be explored in the OCT to enhance its imaging performance, aspects which will be discussed in the following sections.

48.3 Monte Carlo Simulations

To illustrate how the multiple scattering has the effect on the OCT imaging performance, recently, Wang [32] used the Monte Carlo simulation technique (refer to ref [68] for details of Monte Carlo techniques) to systematically simulate such effects with an emphasis on the effects on imaging depth, resolution degradation, and signal localization. Generally from the results, it was found that signal localization and attenuation are dependent on the optical properties of tissue. The high scattering coefficient and the low degree of forward scattering are the primary causes for the degradation of signal localization and attenuation, leading to

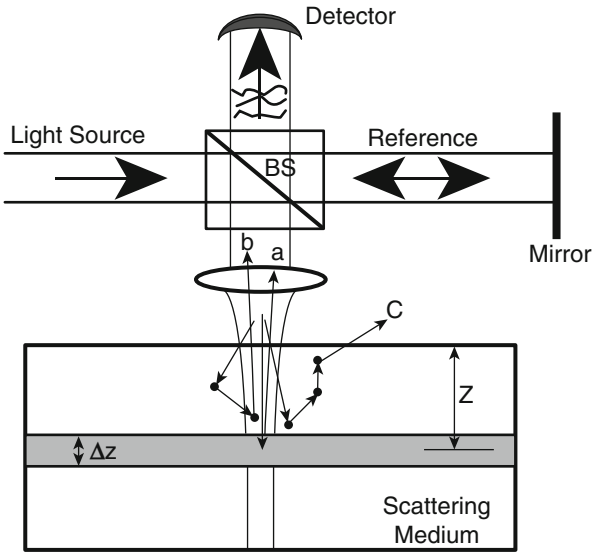

Fig. 48.4 Simple schematic of OCT system showing scattering interactions between a probing beam and biological tissue. Three types of interactions are backscattered from within the tissue: single scatter a, small-angle scatter b, and wide-angle scatter c. A layer with a thickness Δz at the depth of z is the expected layer for OCT localization

complication of interpretation of the measured OCT signals. More importantly, it was found that the imaging resolution is a function of the probing depth within the medium, as opposed to the claimed OCT system resolution. This fact has been overlooked recently in the OCT imaging applications. The imaging resolution is greatly reduced with increasing depth; this case is even more severe for the highly scattering medium. Therefore, attention must be paid to this fact when applying the OCT to human organs because of the high scattering nature of tissue.

Let us revisit the OCT system by looking closely at the backscattering light from the high scattering medium that has the possibility to contribute to the interference signal. A simple schematic of OCT system when probing the highly scattering medium is illustrated in Fig. 48.4, where the sample beam progressively loses its spatial coherence as it penetrates a turbid biological tissue. This loss of coherence results from the scattering by a variety of cellular structures with sizes ranging from less than one wavelength (e.g., cellular organelles) to several hundreds of micrometers (e.g., the length of a collagen fiber). As illustrated in Fig. 48.4, the dominant scattering interaction of the probing beam in the turbid medium can be categorized into three types [32, 69]: single backscatter **a**, small-angle forward scatter **b**, and extinction by absorption or wide-angle scatter **c** (i.e., light scattered out of the view of the interferometric receiver). The detector will only receive the first two categories of scatters because of the heterodyne detection characteristics of the OCT system. Furthermore, the low-coherence light source used, as stated in Sect. ▶ 12.2, provides a time gate to enable the detector to receive only those photons that traveled beneath the tissue surface with their optical path lengths matching the optical path length of the reference arm to within coherence length of the light source. Consequently, the OCT system in reality plays a role to sieve all the backscattering photons that emerged at the detector

according to their arrival times or equivalently the optical path lengths that the photons have traveled. Therefore, to enable the detector to produce the signal, the following criteria must be fulfilled:

$$\left|L_p - 2nz\right| < \frac{L_c}{2} \tag{48.16}$$

where L_p is the optical path length that the photon has traveled within the tissue, n is the refractive index of the medium, and z is the depth of a layer whose distance from the tissue surface matches the scanning distance of the mirror, nz, in the reference arm. For signal localization, we normally expect that the detected photons would be backscattered from the layer whose thickness is determined by

$$2n\Delta z = L_c. \tag{48.17}$$

However, because of the multiple scattering, there are possibilities for those photons contributing to the detected signal that are not backscattered from the expected layer, z, but fulfill the criteria of Eq. 48.17. As a consequence, these photons degrade the signal attenuation, localization, and resolution because they are not from the desired layer, leading to a signal artifact complicating the interpretation of the OCT image. The author in the paper [32] termed the photons that satisfy Eq. 48.17 as the least-scattered photons (LSP) and otherwise as the multiple-scattered photons (MSP). It is clear that the MSP comes solely from the interaction type **b**, while the LSP includes the interaction type **a** and part of type **b** because the photons backscattered from the desired layer might be subject to multiple scattering but with very small angle scattering. A distinct advantage of MC simulation technique is its ability to sort the LSP and MSP according to their optical path lengths, thereby enabling the investigation of their influence on the OCT signal attenuation and localization. Signal localization can be investigated systematically by means of the point spread function (PSF) at the specific depth for different optical properties to illustrate how the LSP and MSP contribute to signal localization.

With these conventions in mind, we now turn to looking at some results of how multiple scattering affects the OCT imaging performances by the use of the Monte Carlo simulation technique. For details, refer to the reference [32].

Figure 48.5 gives typical examples of depth point spread function (zPSF) at different probing depths for the turbid media representing moderate scattering in the left column ($\mu_s = 10\ \text{mm}^{-1}$) and highly scattering in the right ($\mu_s = 67\ \text{mm}^{-1}$). The figures were obtained for $g = 0.7$, 0.9, and 0.98 from top to bottom, respectively, to allow us to scrutinize the influence of the anisotropic parameter of the medium on the signal localization. The depths monitored are indicated in each figure. The filled symbol curves are the actual PSFs that are the summation of LSP and MSP signals from a specific depth. However, to investigate the effects of LSP and MSP signals separately on the PSFs, the signals from the LSP alone are plotted in each case, represented by the hollow symbol curves. Firstly, it is obvious that the worst case is from the medium with the highest scattering coefficient and lowest degree of forward scattering, i.e., $\mu s = 67\ \text{mm}^{-1}$ and $g = 0.7$ in this case (see the top right figure), where

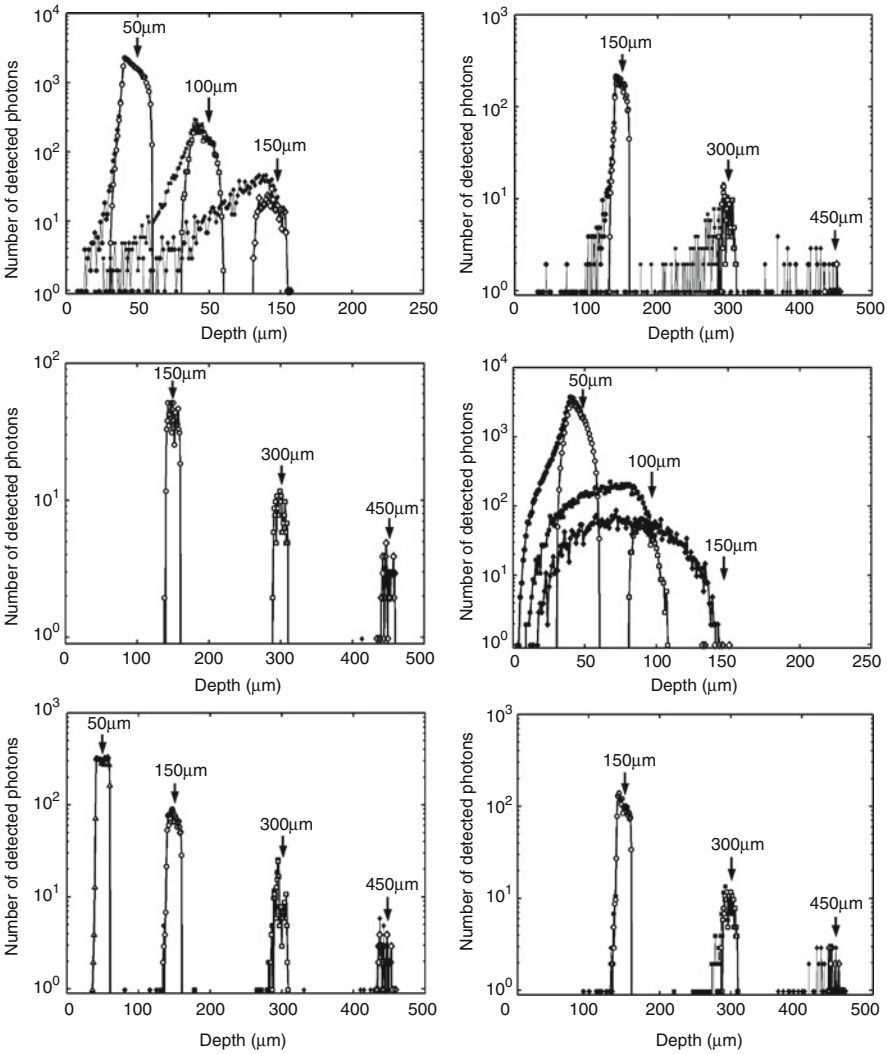

Fig. 48.5 Depth point spread functions (*solid symbol curves*) at different probing depths as indicated for the turbid media representing moderate scattering ($\mu s = 10\ \mathrm{mm}^{-1}$) in the left column and high scattering ($\mu s = 67\ \mathrm{mm}^{-1}$) in the right. From top to bottom, $g = 0.7$, 0.9, and 0.98, respectively. The LSP photons are plotted as the *curves* with hollow symbols [32]

signal localization is merely discerned at a depth of 50 μm. Even at this depth, the contribution from an MSP signal is big enough to degrade the signal localization, where it can be seen that the PSF curve is skewed towards the nominal probing depth, indicating that the photons multiply scattered within the medium before this depth have more chances of surviving to reach the detector. Moreover, the photons backscattered from a very shallow depth at approximately 5 μm still survive the

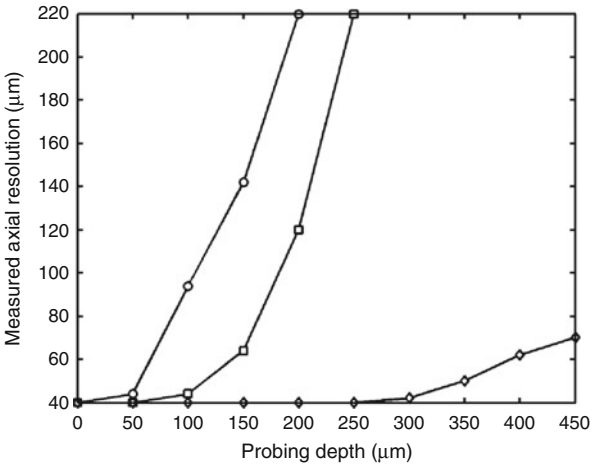

Fig. 48.6 The measured axial resolution from the simulation results plotted as a function of the probing depth for (μs, g) = (67 mm^{-1}, 0.7) (*circle*), (67 mm^{-1}, 0.9) (*square*), and (10 mm^{-1}, 0.9) (*diamond*), respectively [32]

scattering to meet the criterion of Eq. 48.17 for depth localization at 50 μm. With an increase in probing depth to 150 μm, the PSF is overwhelmed by the MSP signal with only a few photons belonging to the LSP category. At this depth the signal localization is totally lost for OCT imaging. Furthermore, the axial resolution and imaging contrast are greatly reduced. The claim of high-resolution optical imaging of OCT is therefore questionable for highly scattering biological tissues. The axial resolution of OCT imaging is dependent on the optical properties of tissue and is a function of depth.

Figure 48.6 illustrates the measured axial resolution from the simulation results as a function of depth for the cases of (μs, g) = (67 mm^{-1}, 0.7), (67 mm^{-1}, 0.9), and (10 mm^{-1}, 0.9), respectively. The axial resolution of the OCT system is merely kept up to the depth of 50 μm for the case of (μs, g) = (67 mm^{-1}, 0.7). After this depth, the actual axial resolution degrades exponentially with the increase of depth, where it becomes approximately 220 μm at the depth of 200 μm as opposed to the system resolution of 40 μm. With the increase of g to 0.9, this performance has been improved, with system resolution retained up to a depth of 100 μm. If in the meantime the scattering coefficient of the medium is reduced, for example, to μs = 10 mm^{-1} in this case, the probing depth at which imaging resolution is retained to the theoretical value would dramatically improve. This result is particularly welcome for the optical clearing of tissues with the purpose of enhancing the imaging depth of OCT which will be discussed in the next section.

With the reduction of the scattering coefficient (compare the left and right columns in Fig. 48.5), signal localization improves with the lesser MSP signal contributing to the depth of PSFs. This indicates that the low-scattering medium offers the more localized signal at any probing depth, which alternatively implies that the light penetration depth, i.e., optical imaging depth, is enhanced with less deterioration of the imaging resolution as stated above. On the other hand, it can be clearly seen from Fig. 48.5 that with increasing g, the signal localization at any depth for the scattering medium improves dramatically, where the highly forward-scattering medium, i.e., $g = 0.98$, offers the best signal localization for all the cases

investigated, see the bottom two figures for $\mu_s = 10$ mm^{-1}and $\mu_s = 67$ mm^{-1}, respectively. In these cases, only a few photons from the MSP category survive the scattering to contribute to the final PSF at a depth of up to 600 μm.

From these results, the advantage of reduction of scattering in the tissue in the enhanced OCT imaging performance is clearly seen. Here, we also see the importance of g factor in the OCT imaging for which the detailed investigation still remains to be explored.

48.4 Enhancement of Light Transmittance

Optical clearing effect on the reduction of multiple scattering through the use of biocompatible chemical agents has been experimentally investigated by a number of groups. The impregnation of the sclera, skin, human gastrointestinal tissues, cartilage, and tendon with x-ray contrast agents (Verografin, Trazograph, and Hypaque-60), glucose, propylene glycol, polypropylene glycol-based polymers (PPG), polyethylene glycol (PEG), PEG-based polymers, glycerol, etc. [27, 34–62], all shows the optical clearing effect in the visible and NIR wavelength ranges. A number of studies used near-infrared spectroscopic technique to quantitatively assess the light transmittance and scattering after the application of chemical agents [54–58]. With the use of Varian Cary 500 spectrophotometer with an internal integrating sphere, Fig. 48.7a, b gives an example of the measurement of the shift of transmittance and diffuse reflectance spectra, respectively, over the range of 800–2,200 nm as a function of time when the native porcine stomach pyloric mucosa specimen was applied with 80 % glycerol. The curves shown in the Figure were obtained at the time intervals of 0, 5, 10, 20, and 30 min, respectively, from bottom to top for transmittance (Fig. 48.7a) and from top to bottom for reflectance (Fig. 48.7b). It can be seen from Fig. 48.7 that, over the whole wavelength range investigated, the transmittance was increased with time. Diffuse reflectance was decreased over the range of 800–1,370 nm. The greatest increase in transmittance was at 1,278 nm, and the greatest decrease in reflectance was at 1,066 nm.

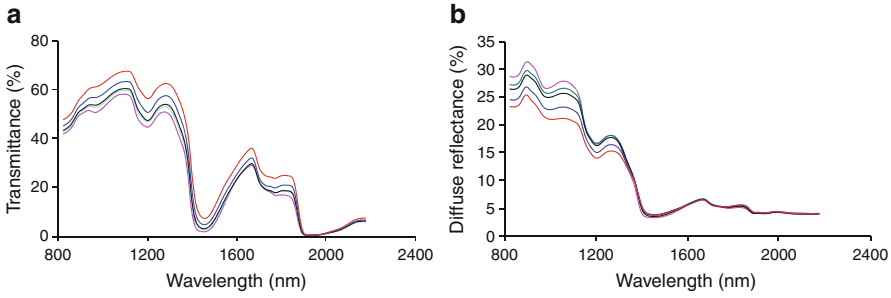

Fig. 48.7 Optical changes for porcine stomach pyloric mucosa before and after application of 80 % glycerol over the range from 800 to 2,200 nm measured by spectrophotometer. (**a**) Transmittance after application of the agent at the time intervals of 0, 5, 10, 20, and 30 min (from *bottom* to *top*), respectively. (**b**) Diffuse reflectance at the time intervals the same as in (**a**) (from *top* to *bottom*) [56, 58]

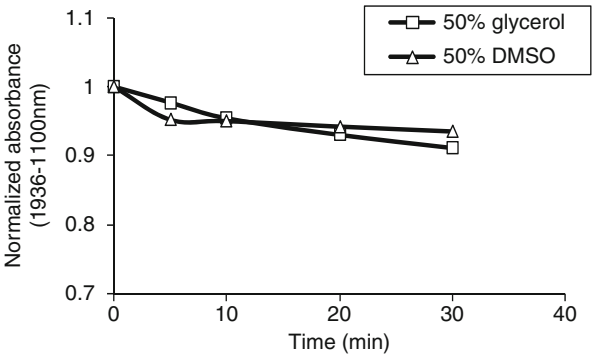

Fig. 48.8 Correlation between the NIR absorbance (measured at 1,936–1,100 nm) and time of application of 50 % glycerol and 50 % DMSO, respectively [56, 58]

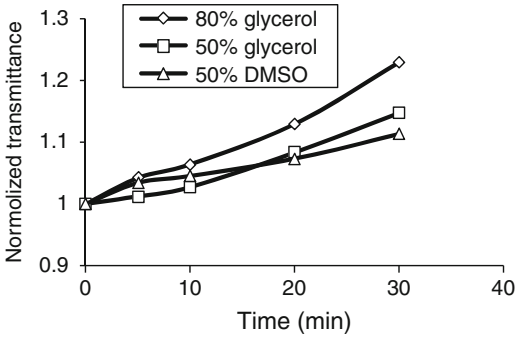

Fig. 48.9 Changes in transmittance at 1,278 nm against time for porcine stomach pyloric mucosa treated with 80 %, 50 % glycerol or 50 % DMSO [56, 58]

It is found that there is a strong correlation between optical clearing and water desorption [55–58]. The measured water activities for 80 % glycerol and 50 % DMSO give 0.486 and 0.936, respectively. Figure 48.8 gives the water content measurements at 30 min after the treatment, where 80 % glycerol caused 15 % water loss, whereas 50 % glycerol and 50 % DMSO caused 9 % and 7 %. The patterns of optical clearing are similar to those of water desorption.

Because most OCT systems use the light source with a central wavelength of 1,300 nm, Fig. 48.9 gives experimental results of the transmittance enhancement at about 1,300 nm after application of different chemical agent solutions, where it is seen that transmittance was increased by approximately 23 % at 30 min after the application of 80 %, while 15 % and 11 % were received after the treatment with 50 % glycerol and 50 % DMSO, respectively.

48.5 Enhancement of OCT Imaging Capabilities

In the last section, we clearly see that the administration of chemical agents in the tissue would increase light transmittance through the tissue, the effect of which would no doubt increase the imaging depth for OCT. Such results have been

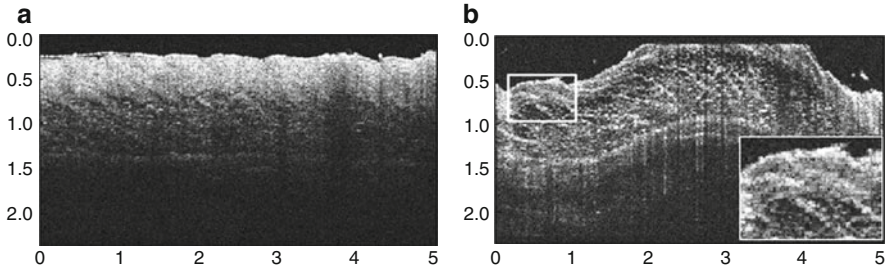

Fig. 48.10 OCT images of an adult rat through skin (**a**) without and (**b**) with topical application of glycerol solution. The insert in (**b**) is the enlargement of the marked area. Units presented are in millimeters, and the vertical axis presents the imaging depth [51]. Unit = mm

demonstrated by the administration of glycerol, propylene glycol, DMSO, oleic Acid, etc., on in vitro and in vivo skin [50, 51, 53–55] and GI tract tissues [27, 56, 58]. The tested wavelength in the OCT included 820 and 1,310 nm, the two most popular wavelength employed in the OCT imaging to date. Wang et al. was the first to investigate the enhancement of OCT imaging performance by the optical clearing approach. With the use of 820 nm wavelengths in their OCT system, Fig. 48.10 shows the OCT images of ex vivo rat skin (a) before and (b) after the application of glycerol solution, respectively, where a significant improvement of the imaging depth and contrast is clearly evident. The sharp differentiation of layered structures and features are visualized including the epidermis (E), papillary dermis (PD), reticular dermis (RD), hypodermis (HD), muscles (M), fascia, hair follicles (HF), and hairs in Fig. 48.10b, where the fascia is sandwiched between layers of muscle. Whereas these structures are quite vague in Fig. 48.10a where the transitional zones for dermal-epidermis and dermal-hypodermis cannot be distinguished. Far more detailed structures are clearly delineated in the hypodermis, which appeared to be an interwoven structure apart from the hair follicles and hair cortex. Such interwoven structures are well correlated with the adipose cells within the hypodermis. Compared with Fig. 48.10a, the imaging depth is improved by about 0.5 mm as the lower muscle layer can now be identified in the bottom of Fig. 48.10b. It should be noted that the tissue deformation in Fig. 48.10b was due to (1) the tissue shrinkage after applying the glycerol and (2) the optical path length difference induced by the uneven liquid solution thickness applied onto the skin surface.

In vitro studies of optical clearing of gastrointestinal tissues, such as the stomach, esophagus, and colonic mucosa, were recently performed using OCT imaging technique [27, 51, 54–56, 58]. Figure 48.11 shows two OCT images of intact and treated by 80 % propylene glycol solution normal, fresh human stomach tissue (fundus). A clearer image with the excellent differentiation of the epithelium, isthmus, lamina propia, and muscular tissue is achieved through the action of the agent [27].

The authors argued that such imaging depth and imaging contrast enhancements in OCT are attributed to the diffusion of the biocompatible agents applied to the skin. The diffusion of the chemicals into the tissue would reduce the refractive

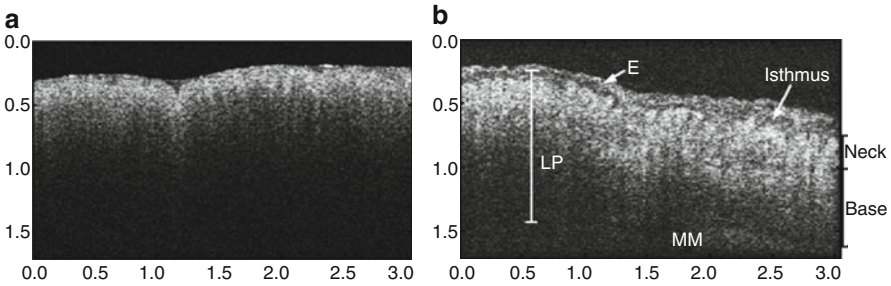

Fig. 48.11 OCT images of a normal, fresh human stomach tissue (fundus): (**a**) without and (**b**) with topical application of 80 % propylene glycol solution. *E* epithelium, *LP* lamina propia, *MM* muscularis mucosae [27]

index mismatch, leading to the reduction of scattering and therefore the increase of the imaging depth. However, the chemical diffusion in the tissue depends on the physical properties of the chemicals used, for example, the size of the molecules and the osmolarity of the environment induced by the chemicals. It also depends on the physical properties of the tissue targeted, for example, whether there is proper channel for the chemical to diffuse within. It is a very complicated process, and the exact mechanism still remains to be explored. Therefore, different chemicals would possess different diffusion rate in different types of tissues. It is reasonable to believe that due to the speed of chemical diffusion, the outmost layers would be optically cleared first. This enables more photons to penetrate into the tissue, thus increases the OCT signals from deeper layers, which otherwise is either blurred or blocked by the outer layers because of the high scattering. With the time elapses, the optical clearing effect gradually takes over the bulk tissue. From this point on, the OCT imaging contrast would disappear, and the only effect left is the imaging depth enhancement. This approach can be explained by the theory presented in Sect. ▶ 30.2.1. The dynamic process of OCT imaging performance enhancement through the application of the optical clearing agents has been reported in a number of studies on the human and animal skin [50, 51, 53, 58], stomach [55–58], esophagus [27] and blood [52, 62].

Figure 48.12 shows dynamic OCT structural images of porcine stomach with the topical application of 50 % glycerol solution, which was recorded at the time intervals of 0, 10, 20, 30, 40 and 50 min, respectively. A metal needle was inserted into the tissue approximately 1 mm beneath the surface. The signals reflecting back from the needle surface were used to suggest improvement of back reflectance signal caused by the chemical clearing. The OCT image of the porcine stomach without the administration of glycerol has a visualization depth of approximately 1.0 mm as shown in Fig. 48.12a. It can be seen that a significant improvement of the imaging depth is clearly demonstrated after the topical application of glycerol. The penetration depth has increased to about 2.0 mm after 50 min application of glycerol as shown in Fig. 48.12f. Tissue shrinkage occurs after the administration of the agents to tissue, see Fig. 48.12b–f. The needle embedded in the tissue

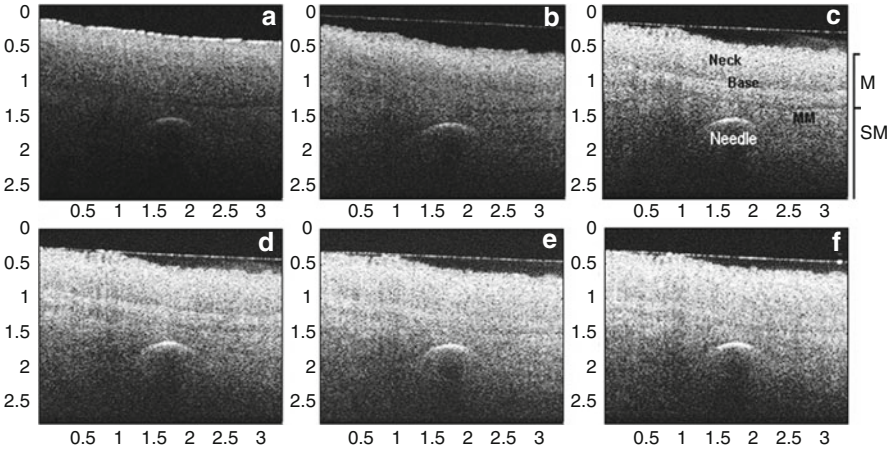

Fig. 48.12 Dynamic OCT images obtained at the time (**a**) 0, (**b**) 10, (**c**) 20, (**d**) 30, (**e**) 40, and (**f**) 50 min after the topical application of 50 % glycerol solution onto the porcine stomach tissue. Note central wavelength used in the experiment was 1,310 nm [55]. Unit = mm

becomes brighter and brighter with the increase of the time duration, see Fig. 48.12b–f. The imaging contrast of Fig. 48.12c, d is also greatly improved, for example the features of lamina propria (LP) and muscularis mucosae (MM). The neck, base, and MM layers of the tissue could be differentiated after 20–30 min application of glycerol. The reflection from the needle surface is also sharp within this period of time. With further increase of time, the imaging contrast improvement disappears gradually, as shown in Fig. 48.11e, f. The analogous results were also received from the ex vivo rat skin [51].

To see the different diffusion rates for different chemicals in the tissue, Fig. 48.13 illustrates the M-mode OCT images obtained from the repeated A-scans of the porcine stomach with the application of (a) glycerol and (b) DMSO. It was noted that because the system used required to re-localize the tissue surface manually after topical application of agents, the registration of OCT signal starts at about 0.5 min after the agent application. From the image obtained with glycerol application, it is clearly seen that the penetration depth increases gradually with the increase of time duration. However, from Fig. 48.13b, a significant depth improvement appears at the time immediately after the application of DMSO. This indicates that DMSO could fulfill tissue clearing within a very short time period. There is a slope of the surface of the tissue. The downward trend of the tissue surface is attributed to the tissue dehydration induced by the chemical agents.

Figure 48.14 shows an even more convincing case for the action of glycerol and propylene glycol to the tissue in vivo where the OCT imaging depth and contrast are dramatically improved when comparing the images before and after the application of agents.

The OCT images captured from the skin site of the volunteer at hyperdermal injection of 40 % glucose allowed one to estimate the total attenuation coefficient,

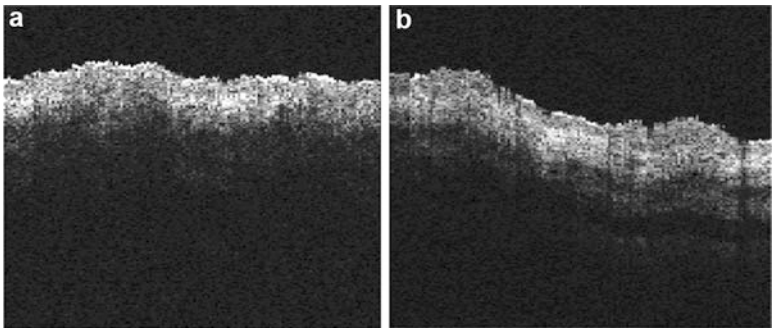

Fig. 48.13 OCT images captured from human forearm in vivo (**a**) without and (**b**) with 50 % topical application of propylene glycol solution. Image sizes: 1.8 × 1.6 mm [54]

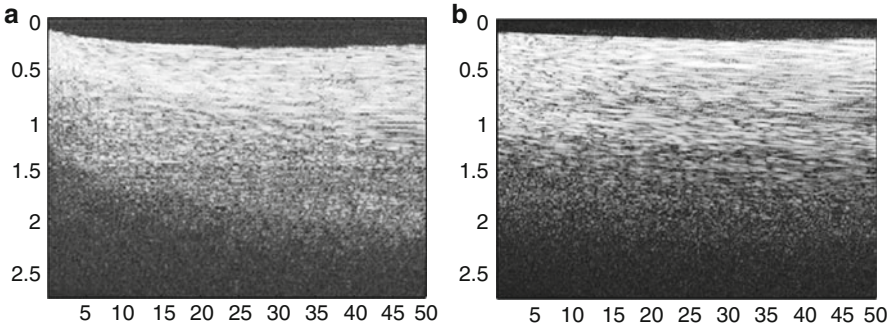

Fig. 48.14 Comparison of the time course of repeated A-scans of the porcine stomach tissue with the application of (**a**) glycerol and (**b**) DMSO, respectively. The horizontal and vertical axes present the time (min) and the imaging depth (mm), respectively [55]

see Eq. 48.10 [54]. The attenuation initially goes down and then goes up with the time course. Such behavior well correlates with the in vivo spectral measurements and reflects the index matching induced by the glucose injection. The light beam attenuation in tissue, $I/I_0 \sim \exp(-\mu_t)$, for intact skin (0 min) was found from OCT measurements as $I/I_0 \cong 0.14$ and for immersed skin at 13 min $I/I_0 \cong 0.30$, i.e., intensity of transmitted light increased 2.1-folds. That value also well correlates with the independent spectral measurements [36–38]. It should be noted that high sensitivity of OCT signal to immersion of living tissue by glucose allows one to monitor its concentration in the skin at a physiological level [70–73].

Although glycerol and glucose are effective optical clearing agents when injected into the dermis, [50, 54] normally they do not penetrate so well into intact skin. In recent OCT experiments with human skin in vivo at topical application during 90–120 min of the combined lipophilic polypropylene glycol-based prepolymers (PPG) and hydrophilic polyethylene glycol (PEG)-based prepolymers, both with indices of refraction of 1.47 that closely match that of skin scattering

components in SC, epidermis, and dermis, it was shown that polymer mixture can penetrate intact skin and improve OCT images to see dermal vasculature and hair follicles more clearly [74]. This composition may have some advantages in skin optical clearing due to the hydrophilic component which may more effectively diffuse within living epidermis and dermis; less osmotic strength also may have some advantages, but the optical clearing depth could not be improved radically in comparison with topical application of other clearing agents, such as glycerol, glucose, x-ray contrast, and propylene glycol, because of principle limitations of chemical agent diffusion through intact cell layers. Thus, to provide fast and effective optical clearing of skin, the appropriate well known or newly developed methods of enhanced agent delivery should be applied.

Thus far, we have used the examples to illustrate that the impregnation of tissue with the biocompatible chemical can enhance OCT imaging capabilities through the optical clearing and chemical mass transport upon diffusion mechanisms. However, such imaging capability enhancement is agent selectable, particularly for the imaging contrast enhancement. The mechanisms for light penetration enhancement have been well established, i.e., in the framework of refractive index matching approach, which can improve the OCT imaging depth and resolution. The explanations for imaging contrast enhancement, thereby the improvement of OCT localization capability, are based on the dehydration induced by the chemicals and chemical mass transport characteristics. The exact mechanism behind the contrast enhancement still remains to be explored.

48.6 OCT Glucose Sensing

Recently, OCT technique has been proposed for noninvasive assessment of glucose concentration in tissues [70–73, 75–77]. High resolution of the OCT technique may allow high sensitivity, accuracy, and specificity of glucose concentration monitoring due to precise measurements of glucose-induced changes in the tissue optical properties from the layer of interest (dermis). Unlike diffuse reflectance method, OCT allows to provide depth-resolved qualitative and quantitative information about tissue optical properties of the three major layers of human skin: stratum corneum of epidermis, epidermis and dermis. Dermis is the only layer of the skin containing developed blood microvessel network. Since glucose concentration in the interstitial fluid is closely related to the blood glucose concentration, one can expect glucose-induced changes in OCT signal detected from the dermis area of the skin. Two methods of OCT-based measurement and monitoring of tissue glucose concentration were proposed: (1) monitoring of tissue scattering coefficient, μ_s, as a function of blood glucose concentration using standard OCT [71–73] and (2) measurement of glucose-induced changes in refractive index, Δn, using novel polarization maintaining fiber-based dual channel phase-sensitive optical low-coherence reflectometer (PS-OLCR) [75].

The experiments were performed with a portable OCT system with the central wavelength of 1,300 nm, power of 0.5 mW, and coherence length and lateral

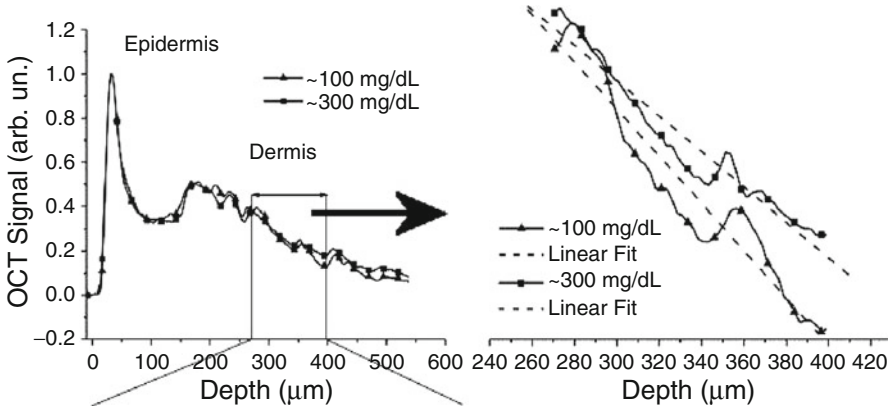

Fig. 48.15 Representative OCT signals obtained from Yucatan micropig skin during glucose clamping experiment at low and high blood glucose concentration (*top*) and a part of the OCT signal in the dermis area with the linear fit of the OCT signals in this layer (*right*) [73]

resolution of approximately 14 and 12 μm, respectively [71–73, 77]. The authors reported results obtained from phantom, animal, and human studies. OCT images were obtained from skin (ear of the rabbits, dorsal area of the micropigs, and arm of the volunteers). The slopes of the OCT signals were calculated at a depth of 150–900 μm. Glucose administration was performed using (1) intravenous bolus injections for rapid increase of blood glucose concentration and (2) intravenous clamping technique for slow, controlled changes of the blood glucose concentration in animal studies and (3) standard oral glucose tolerance test (OGTT) in human studies.

First an OCT image of the layers of skin was taken, and the OCT signal as a function of depth was evaluated. The slope of the portion of the plot in the dermis layer was used to calculate μ_s. In an anesthetized animal skin experiment OCT images demonstrate that glucose affects the refractive index mismatch in skin and decreases μ_s [77]. The slope of the OCT signal versus depth line is determined and is correlated with the concentration of blood glucose (Fig. 48.15).

Typical results obtained in the clinical studies are shown in Fig. 48.16. OCT images and blood samples (for monitoring of glucose concentration in blood) were taken from left and right forearm, respectively. Good correlation between increase of the blood glucose concentration and decrease of the smoothed OCT signal slope has been observed at the depth of 200–600 μm during OGTT. Measurements performed in layers of epidermis and upper dermis either did not show changes in the OCT signal slope at variations of blood glucose concentration or the changes were very weak. Most likely it is due to a gradient of glucose concentration from dermal blood micro-vessels to the SC. Thus, sensitivity and accuracy of the OCT measurements of blood glucose concentration would be maximal in the regions of developed blood microvessel network (that is dermis area).

A question of specificity of the OCT technique to monitor blood glucose concentration in tissues has been addressed. The experimental and theoretical

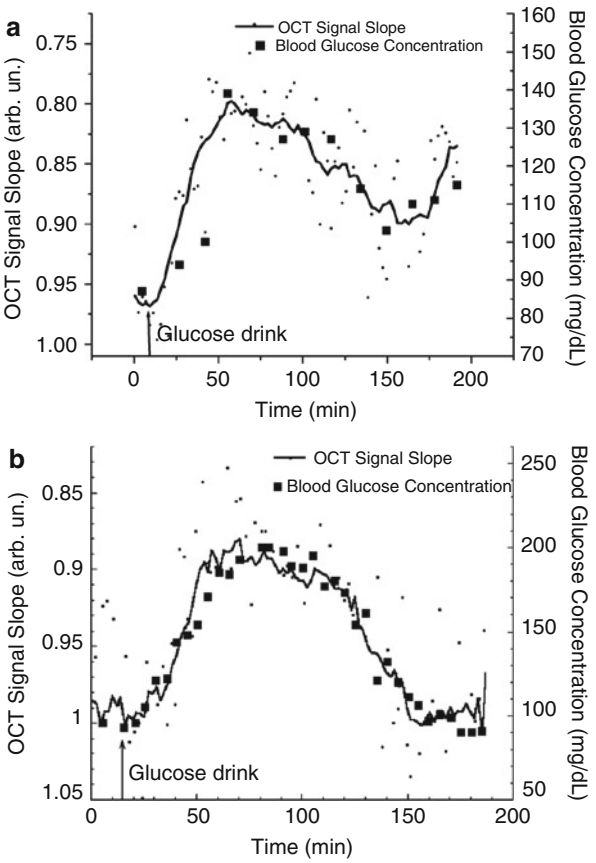

Fig. 48.16 Slope of OCT signal and blood glucose concentration vs. time. OCT images and blood samples were taken from a human skin of (**a**) *left* and (**b**) *right* forearm during OGTT [72]

analysis of influence of several physical and physiological parameters (such as altering the refractive index mismatch between the interstitial fluid and scattering centers and structural modifications in tissue due to changes in glucose concentration) on the OCT signal slope was performed. Obtained results demonstrate that (1) several body osmolytes may change the refractive index mismatch between the interstitial fluid and scattering centers in tissue; however, the effect of the glucose is approximately one to two orders of magnitude higher; (2) an increase of the interstitial fluid glucose concentration in the physiological range (3–30 mM) may decrease the scattering coefficient by 0.22 %/mM due to cell volume change; (3) stability of the OCT signal slope is dependent on tissue heterogeneity and motion artifacts; and (4) moderate skin temperature fluctuations (± 1 °C) do not decrease accuracy and specificity of the OCT-based glucose sensor; however, substantial skin heating or cooling (several °C) significantly changes the OCT signal slope. These results suggest that the OCT technique may provide blood glucose concentration monitoring with sufficient specificity under normal physiological conditions.

A new differential phase contrast OCT-based method (PS-OLCR) of monitoring glucose-induced changes in tissue optical properties has been also proposed [75]. While conventional OCT uses the detection and analysis of intensity of backscattered optical radiation, phase-sensitive OCT utilizes the phase information obtained by probing a sample simultaneously with two common path low-coherence beams. Variations in the sample refractive index will be exhibited in the phase difference, $\Delta\varphi$, between these two beams. The PS-OLCR technique is capable of measuring Angstrom/nanometer scale path length change between the beams (associated with the phase difference as $(\lambda/4\pi)\Delta\varphi$) in clear and scattering media. The theoretical and experimental pilot studies on application of PS-OLCR for noninvasive, sensitive, and accurate monitoring of analyte concentration were reported by authors of Ref. [78]. It was demonstrated that the effect of glucose concentration change on refractive index is approximately one to four orders of magnitude greater than that of the other analytes at the physiological concentrations.

Like other scattering techniques, the detected phenomenon in OCT is the effect of glucose on the refractive index of the interstitial fluid. Unlike the spatially resolved back reflectance and frequency-domain methods that use larger measuring volume and spans multiple layers in tissues [41, 47, 70, 78, 79], OCT offers certain advantage, as it limits sampling depth to the upper dermis without unwanted signal from other layers. Precise sampling is very important at glucose monitoring in tissue, because glucose uptake is different in different tissue layers being lowest in connective tissue and smooth muscle and highest in adipose tissue and skeletal muscle [80].

48.6.1 Imaging Through Blood

As it follows from the above discussions and other chapters in this book, OCT is a powerful technique for study of structure and dynamics of highly scattering tissues and blood, including imaging of vascular system for the diagnosis of atherosclerotic lesions. In vitro studies performed on human aorta have shown that OCT is able to identify structural features such as lipid collections, thin intimal caps, and fissures characteristic of plaque vulnerability [81–84]. In in vivo OCT imaging of the rabbit aorta through a catheter, a vascular structure was defined, but saline infusion was required during imaging since blood led to significant attenuation of the optical signal [81]. Eliminating the need of saline or minimization its concentration would represent a substantial advance for intravascular OCT imaging.

Refractive index mismatch between erythrocyte cytoplasm and blood plasma causes strong scattering of blood that prevents to get high quality images of intravascular structures through a whole blood. The refractive index of erythrocyte cytoplasm is mostly defined by hemoglobin concentration (blood hematocrit) [85]. The scattering properties of blood are also dependent on erythrocytes volume and shape, which are defined by blood plasma osmolarity [86, 87], and aggregation or disaggregation ability [62, 88, 89]. Recently the feasibility of index matching as a method to overcome the limited penetration through blood for getting of OCT

tissue images has been demonstrated [52, 62, 89]. Glucose, low and high molecular dextrans, *x*-ray contrasting, glycerol, and some other biocompatible agents were used to increase the refractive index of blood plasma closer to that of the erythrocyte cytoplasm to improve penetration depth of OCT images.

The 1,300 nm OCT system was used for taking images of the reflector through circulated blood in vitro [52]. The total intensity of the signal off the reflector was used to represent penetration. As immersion substances dextran (group refractive index –1.52) and IV contrast (group refractive index –1.46) were taken. Both dextran and IV contrast were demonstrated to increase penetration through blood: 69 ± 12 % for dextran and 45 ± 4 % for IV contrast.

Studies of blood scattering reduction by the immersion technique using various osmotically active solutions, which are biocompatible with blood, like saline, glucose, glycerol, propylene glycol, trazograph (*x*-ray contrasting substance for intravenous injection), and dextran were also described [62, 89]. The 820 and 1,310 nm OCT systems were applied for taking images of the reflector through a 1 mm layer of un-circulating fresh whole blood. It was shown that for un-circulating blood the sedimentation plays an important role in blood clearing using immersion technique and OCT allows for precise monitoring of blood sedimentation and aggregation.

The result of the OCT study is the measurement of optical backscattering or reflectance, $R(z)$, from the RBCs versus axial ranging distance, or depth, z. The reflectance depends on the optical properties of blood, i.e., the absorption (μ_a) and scattering (μ_s) coefficients, or total attenuation coefficient (μ_t), $\mu_t = \mu_a + \mu_s$. For optical depths less than four, reflected power can be approximately proportional to $-2\mu_t z$ in exponential scale according to the single scattering model [62, 89], but due to interferential signal detection in OCT [89, 90], it is finally proportional to $-\mu_t z$, i.e.,

$$R(z) = I_0 \alpha(z) \exp(-\mu_t z). \tag{48.18}$$

Here I_0 is the optical power launched into the blood sample and $\alpha(z)$ is the reflectivity of the blood sample at the depth of z.

Optical clearing (enhancement of transmittance) ΔT by an agent application can be estimated using the following expression

$$\Delta T = \left[\left(R_{\text{agent}} - R_{\text{saline}}\right)/R_{\text{saline}}\right] \times 100\% \tag{48.19}$$

where R_{agent} is the reflectance from the backward surface of the vessel within a blood sample with an agent, and R_{saline} is that with a control blood sample (whole blood with saline).

The OCT system used yields 12 μm axial resolution in free space. This determines the imaging axial resolution which is comparable with the dimensions of red blood cells (RBCs) or small aggregates. A few different glass vessels of 0.2–2 mm of thickness were used as blood sample holders. For some holders to enhance reflection from the bottom interface, a metal reflector was applied. The sample holder was mounted on a translation stage at the sample arm and was placed

Table 48.1 Influence of dextrans (2.43 gdl^{-1}) on light attenuation property of the sample containing 65 % blood and 35 % saline [89]

Agent	μt (mm − 1)	ΔT (%)
Saline	3.71	–
Dextran10	3.82	11.9
Dextran70	2.97	100.1
Dextran500	3.12	86.7

perpendicular to the probing beam. The amplitude of reflected light as a function of depth at one spatial point within the sample was obtained. The result is the measurement of optical backscattering or reflectance, $R(z)$, from the RBCs versus axial ranging distance, or depth, z, described by Eq. 48.18. Optical clearing (enhancement of transmittance) ΔT by an agent application was estimated using Eq. 48.19. Averaging for a few tenths of z-scans were employed.

Venous blood was drawn from healthy volunteers and stabilized by K2E EDTA K2. For example, blood samples containing dextrans were prepared immediately after blood taking by gently mixing blood and dextran-saline solution with low rate manual rotating for 1 min before each OCT measurement. Four groups of the blood samples with various hematocrit values were investigated in this study [89]. The dextrans used in the experiments were D × 10, D × 70 and D × 500 with the molecular weights (MW) at 10,500, 65,500 and 473,000, respectively.

Table 48.1 gives the results from 65 % blood (from a 24 years old male volunteer) with 35 % dextran-saline solution. The concentration of dextrans used was 2.43 gdl^{-1}. The measurement started immediately after the addition of dextran. It can be seen from Table 48.1 that D × 500 and D × 70 are effective agents to decrease the light attenuation of blood compared to the saline control, with the total attenuation coefficient decreased from 3.71 mm^{-1} for the saline control to 3.12 mm^{-1} and 2.97 mm^{-1}, respectively. The optical clearing capability ΔT was approximately 90 % and 100 % for D × 500 and D × 70, respectively.

Interesting that D × 500 providing a higher refraction had less effect than that of D × 70 at the same concentration. Moreover, the increase in concentration (refraction power) cannot always achieve higher optical clearance. 0.5 gdl^{-1} D × 500 had a stronger effect than 5 gdl^{-1} D × 500 in 20 % blood with 80 % saline samples. The changes in scattering property brought above by the addition of dextran solution may first be explained by the refractive index matching hypothesis [51]. It can be seen that scattering can be reduced when the refractive index of plasma is increased.

The refractive index of dextran-saline solution was increased with concentration in all molecular weight groups. The measured indices of blood samples with dextrans were in good agreement with the theoretical values calculated according to the equation $n = c_b n_b + (1 - c_b) n_s$, where c_b is the volume fraction (20 %) of whole blood in the diluted sample and n_s is the index of saline with or without dextrans. As expected, the refractive index of blood with dextran increases as the concentration of the added dextran increases due to an increase of the index of the ground matter of the sample.

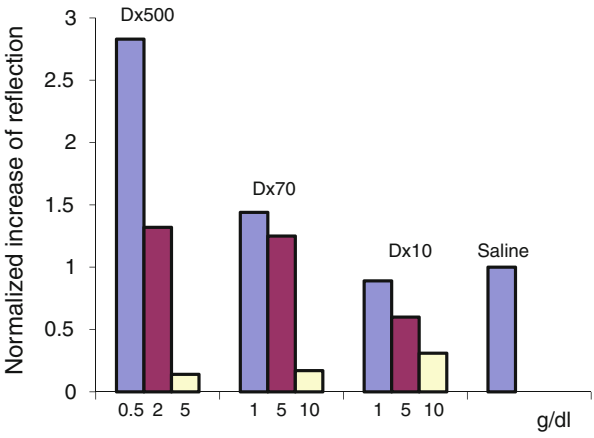

Fig. 48.17 A summary of effects of dextrans compared to that of the saline control on light transmission after 10 min sedimentation. Lower concentration Dextran500 and Dextran70 had significant effects in enhancing light transmission. Efficiency of higher concentration dextrans was much lower than that of the saline control [89]

Blood optical property can be altered by dextrans-induced refractive index matching between RBCs and plasma. However, refractive index matching is not the only factor affecting blood optical properties. Obviously, this discrepancy resulted from the assumption of only refractive index influence. Thus other factors should be taken into account, particularly, the cellular aggregation effect induced by dextrans [89].

As the aggregation process is time-dependent, the blood sample was allowed 10 min sedimentation in this study after the measurement at the beginning stage of the addition of dextrans. Figure 48.17 shows the summary of the effect of dextrans compared to the saline control on light transmission for the sample with 20 % blood and 80 % saline after 10 min sedimentation. It can be seen from Fig. 48.17 that the influence of dextran on the light transmission was different compared to that at the beginning of mixing dextrans in blood. The lower concentration (0.5 gdl^{-1}) D × 500 still had the strongest effect on reducing the scattering of light in blood, with a 2.8-fold stronger effect than that of the saline control. However, enhancement by the highest concentration of D × 500 (5 gdl^{-1}) and D × 70 (10 gdl^{-1}) was dramatically lower than that of the saline control. At the beginning, they both had a very high blood optical clearing capability with 67.5 % and 76.8 % ΔT, respectively. In addition, the effect was decreased with the increase of dextran in blood within all three groups, contrary to the expectation of the refractive index matching hypothesis.

The decreased aggregation capability of dextran with concentration explained well that light transmission decreased less with the increase of dextran for both types (mid-molecular and large-molecular). Over a range of concentrations, D × 500 and D × 70 induced RBC aggregation. However, dextrans have been known to exert a biphasic effect on RBC aggregation; they induce aggregation at low concentration, and disaggregation at high concentration [88]. For example, with D × 70, the maximal aggregation size is obtained at approximately 3 %, above which the size decreases. In our OCT measurements, 2 gdl^{-1} D × 500 and 5 gdl^{-1}

D × 70 in 20 % blood with 80 % saline appeared to be the critical concentration to affect RBC aggregation. Their aggregation parameters became smaller than those of 0.5 gdl^{-1} D × 500 and 1 gdl^{-1} D × 70. When the concentration increased to 5 gdl^{-1} for D × 500 and 10 gdl^{-1} for D × 70, they played a role of disaggregation. That is the reason why the cells are much less packed than with the saline control, accounting for the reduced light transmission. Although refractive index matching suggested a higher light transmission, it can be seen that the aggregation-disaggregation effects are now dominant.

The behavior of red blood cells (RBC) in flow is dependent on the processes of aggregation-disaggregation, orientation and deformation. Increased RBC aggregability has been observed in various pathological states, such as diabetes and myocardial infarction, or following trauma. The aggregation and disaggregation properties of human blood can be used for the characterization of the hemorheological status of patients suffering different diseases [87]. Our work suggests that OCT may be a useful noninvasive technique to investigate rheology for diagnosis together with its additional advantage of monitoring blood sedimentation [62].

48.7 Summary

To summarize, we have discussed in this chapter the basic principles of enhancing the OCT imaging performances. The human tissue is highly scattering in nature to the near-infrared light that is usually used to illuminate the OCT systems. In this chapter it was shown that multiple scattering of tissue is a detrimental factor that limits the OCT imaging performances, for example, the imaging resolution, depth, localization, and contrast. In order to improve the imaging capabilities for OCT systems, the multiple scattering of tissue must be reduced. We then introduce the optical clearing technique, mainly concentrated on the use of the biocompatible and osmotically active chemical agent to impregnate the tissue, to enhance the OCT imaging performances through the tissue. The mechanisms for such improvements, for example, imaging depth and contrast, were discussed, primarily through the experimental examples. It is assumed that when chemical agents are applied onto the targeted sample, there are two approaches concurrently applied to the tissue. The imaging depth, or light penetration depth, is enhanced by the refractive index matching of the major scattering centers within the tissue with the ground material induced by the chemical agents, usually through the diffusions of the interstitial liquids of tissue and the chemical agents. Whereas, the imaging contrast enhancement is caused by the tissue dehydration due to the high osmotic characteristics of the chemical agents, which is also dependent on the mass transport of chemical agents within tissue.

Optical clearing technology for OCT needs is a growing field of investigations and biomedical applications. A few special issues of journals, book chapters, and overview papers discussing results and perspectives of this method for biomedical imaging and in-depth monitoring of molecular diffusion were recently published [91–97].

Not only the benefits of the method but also the drawbacks and toxicity issues were discussed [95]. Recent original publications demonstrate innovative approaches in the assessment of tissue optical clearing as a function of glucose concentration using OCT [98], testing of novel effective mixtures of optical clearing agents (OCAs) [99], enhanced optical clearing of skin in vivo and OCT in-depth imaging [100], and enhanced OCT imaging of embryonic tissue [101]. One of the important applications of OCT in combination with optical clearing is the differentiation of normal tissue from benign/malignant tumor tissue using strong differences in spatial and temporal kinetics of OCT images for these types of tissues [102–105].

The depth-resolved monitoring of glucose, other metabolites, and drug molecule diffusion in different tissues by using OCT is one of the prospective applications of this technology [102–127]. Different types of tissues from soft to hard, in normal and pathology, and in in vitro and in vivo states, such as animal and human skin, ocular tissues, breast tissue, esophagus, atherosclerotic vascular tissues, tooth dentin, and others, were studied [102–127].

Blood optical clearing technique, which is well discussed in this chapter, received its further development in discovery and direct experimental prove of concept of blood "self-clearing" at local blood hemolysis in the vicinity of OCT endoscopic probe within vessel lumen [128, 129]. Safety and usefulness of this non-occlusive OCT image acquisition technique based on usage of such OCA as a low-molecular-weight dextran were demonstrated [130, 131].

Besides immersion optical clearing using exogenous liquids, mechanical compression as a method for increasing the informative value of OCT due to enhanced light penetration and involvement of specific elastic properties of tissues is of great interest at the moment [132–136].

Keywords
MPM • Multimodal imaging • Multiphoton microscopy • Second harmonic • Second harnomic OCT • SH-OCT

49.1 Introduction

Although medicine has evolved rapidly with advances in biotechnology, many therapeutic procedures still require diagnosis of disease at an early stage to enable effective treatment and prevent irreversible damage. Direct visualization of cross-sectional tissue anatomy and physiology provides important information for the diagnosis, staging, and management of disease. Optical coherence tomography (OCT) is a promising noninvasive, noncontact imaging modality that uses coherence gating to obtain cross-sectional images of tissue microstructure with micrometer spatial resolution [1]. OCT was first used clinically in ophthalmology for the imaging and diagnosis of retinal disease [2]. Recently, it has been applied to image subsurface structure in skin, vessels, and oral cavities, as well as respiratory, urogenital, and gastrointestinal tracts.

Despite its advantages, one limitation of OCT is the relatively low imaging contrast. In OCT, imaging contrast originates from the inhomogeneities of sample scattering properties that are linearly dependent on sample refractive indices. In many instances,

changes in sample linear scattering properties are small and difficult to measure. Multiphoton microscopy (MPM), on the other hand, is based on multiphoton-excited fluorescence and/or harmonic generation and provides molecular contrast and specificity. Fluorescent signals, for example, give exceptional insights into the biophysical and biochemical interactions of biological tissue with molecular specificity and sensitivity. Second harmonic generation (SHG) signals reveal orientation, organization, and local symmetry of biomolecules. Since the first demonstration of MPM in 1990 [3], MPM has been widely used to image morphology and function of various cells and tissues [4]. For the past few years, deep-tissue and in vivo MPM imaging has been reported [5–7]. MPM has found wide applications in neurobiology and developmental biology to monitor calcium dynamics, image neuronal plasticity, and evaluate neurodegenerative disease in animal models. MPM has also been shown to be a valuable tool to study angiogenesis and metastasis and to characterize cell/extracellular matrix interactions in cancer research [4]. There are a number of advantages using MPM for in vivo tissue imaging. First, nonlinear interaction provides intrinsic sectioning capability. Second, use of near-infrared light reduces scattering and enables deep penetration depth. Third, the excitation volume for MPM is limited to the focus region, which minimizes photodamage. Finally, the large separation between excitation, fluorescence, and second harmonic spectra allows highly sensitive detection. Combining nonlinear optical contrast with OCT will greatly enhance clinical applications of these imaging modalities.

In this chapter, we describe multimodal MPM/OCT systems that allow imaging of complementary contrasts and field of views (FOVs) in biological tissues [8–13]. In addition, we present an SH-OCT system that combines the nonlinear optical effect of SHG and coherence gating of OCT to produce highly contrasting cross-sectional images of biological tissues [14–19].

49.2 Combined MPM/OCT System

Combined MPM/OCT is a multimodal imaging technique that combines high-resolution imaging techniques derived from complementary signals to provide simultaneous structural and functional imaging of tissues. It integrates the advantages of MPM and OCT while overcoming the limitations of each other.

MPM and OCT have complementary contrasts [20, 21]. The primary contrasts of MPM include two-photon-excited fluorescence (TPEF) and SHG. TPEF derives from intrinsic sources (e.g., cofactors, proteins) and exogenous fluorophores, while strong SHG comes from non-centrosymmetric molecules, such as collagen, a common structural protein. OCT contrast is backscattered light from refractive index discontinuities that occur between tissues of different structures or compositions. The different contrasts are all related to the induced polarization, the response of a medium to an electromagnetic field,

$$P = \varepsilon_0\left(\chi^{(1)}E + \chi^{(2)}EE^* + \chi^{(3)}EE^*E + \cdots\right), \tag{49.1}$$

where E is the applied electric field, ε_0 is the permittivity of free space, $\chi^{(1)}$ is the linear susceptibility, $\chi^{(n)}$ is the nth-order nonlinear susceptibility (for $n > 1$) [21–23].

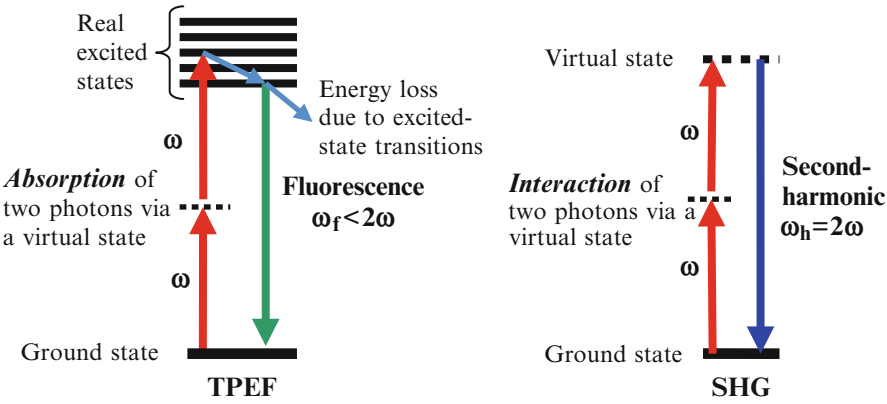

Fig. 49.1 Energy diagrams of TPEF and SHG

Linear effects including absorption and scattering relate to the linear susceptibility $\chi^{(1)}$, whereas nonlinear effects depend upon the higher-order susceptibilities $\chi^{(n)}$. Specifically, scattering is related to $\chi^{(1)}$, SHG to $\chi^{(2)}$, and TPEF to $\chi^{(3)}$, respectively. Due to the nonlinear effects, both the SHG and TPEF intensities depend quadratically on the incident laser power [3, 24, 25].

The energy diagrams of TPEF and SHG are illustrated in Fig. 49.1. In TPEF, a susceptible molecule absorbs two photons simultaneously and is excited from ground state to a real excited state. When the molecule returns to the ground state, it emits a fluorescence photon that has $\omega_f < 2\omega$, where ω is the angular frequency of the incident light. In SHG, a molecule interacts with two photons simultaneously and is excited to a virtual excited state. When the molecule returns to the ground state, it emits an SHG photon which has $\omega_h = 2\omega$. In OCT, the scattering signal is at the same frequency as the incident beam, which has $\omega_s = \omega$. Therefore, the three contrast signals in MPM/OCT have different frequencies and can be separated using dichroic mirrors and filters.

The TPEF signal derives from intrinsic sources, such as elastin, NADH, and flavins, and exogenous fluorophores, such as various fluorescent dyes conjugated to molecular probes. Intrinsic TPEF signals have been observed from cells, collagen, and elastin fibers. Using exogenous probes, TPEF can image targeted subcellular structures and specific proteins. The generation of SHG signals requires a non-centrosymmetric molecular structure. SHG imaging has been primarily applied to collagen fibers, a common structural extracellular matrix protein. Therefore, MPM contrasts are of high biochemical specificity. Meanwhile, OCT detects backscattered light from refractive index discontinuities in cells and tissues. OCT contrast lacks the biochemical specificity.

Furthermore, MPM and OCT are also complementary in imaging resolution, speed, and FOV. MPM provides a sub-micrometer resolution over an FOV of a few hundred micrometers, while OCT has an FOV over a few millimeters at a resolution of ~10 μm. Imaging speed of MPM is typically ~1 fps, while spectral-domain OCT can be as fast

as ~100 fps. Because of their complementary characteristics, MPM and OCT are especially suitable for developing multimodal imaging for clinical applications.

Compared to traditional MPM and OCT, multimodal MPM/OCT can provide multiple complementary contrasts and FOVs and thus is very important for label-free imaging to obtain a sufficient set of parameters for reliable sample analysis. When combined into a single platform, their multiple contrasts can be acquired simultaneously. The sensitivity of MPM to cells and extracellular matrix and of OCT to interfaces can enable observations of cell-cell and cell-matrix interactions during the development of neovasculature, cell migration, and extracellular matrix remodeling. These events are fundamentally important to nearly all biological processes, from growth and development to cancer, wound healing, aging, and diabetes. Furthermore, integrating MPM with OCT can provide multi-scale FOVs, covering a large area for screening and a high-resolution zoom-in for molecular identification. With benefits from both MPM and OCT, the combined system can provide a powerful imaging tool that has both sensitivity and specificity to detect precancerous and cancerous lesions.

While traditional OCT provides a cross-sectional view of layered tissue structures, optical coherence microscopy (OCM), a variation of OCT, provides high-resolution en face view of tissue microstructures. In the following, two types of multimodal MPM/OCT systems will be presented: the MPM/OCM and the multi-scale MPM/OCT systems. The MPM/OCM is a microscopy technique that is able to acquire multiple contrasts, including SHG, TPEF, and scattering simultaneously. The multi-scale MPM/OCT is capable of both tissue level and cellular level imaging, where OCT images layered tissue structures and MPM images cells and extracellular matrix.

49.2.1 MPM/OCM System and Applications

By combining MPM with OCM, the multiple contrasts, including scattering, TPEF, and SHG, can be imaged simultaneously from the same spatial scale. The OCM contrast is scattering from refractive index discontinuities at tissue interfaces. The MPM contrasts include TPEF and SHG. TPEF originates from autofluorescence of tissue or exogenous fluorophores. Endogenous fluorophores in tissue include NADH in cell cytoplasm and elastin fibers, etc. SHG comes mainly from collagen fiber which is the most abundant extracellular matrix. Therefore, the multimodality system can acquire more information about tissues than a single modality alone. In MPM/OCM, high-resolution MPM and OCM images can be acquired from the same FOV of a few hundred micrometers, simultaneously.

MPM/OCM systems have been reported by several groups [8–11, 13, 26, 27]. Beaurepaire et al. [8] and Yazdanfar et al. [13] used ~100 fs Ti:sapphire lasers for combining MPM with OCM. In these systems, the coherence length of the light sources could not match with the MPM axial resolution. To improve depth resolution, a pinhole was needed in front of the OCM detector, which largely limited the system sensitivity. Recently, a fiber-based MPM/OCM system was developed using a femtosecond fiber laser that also had a long coherence length of 16.1 μm [26].

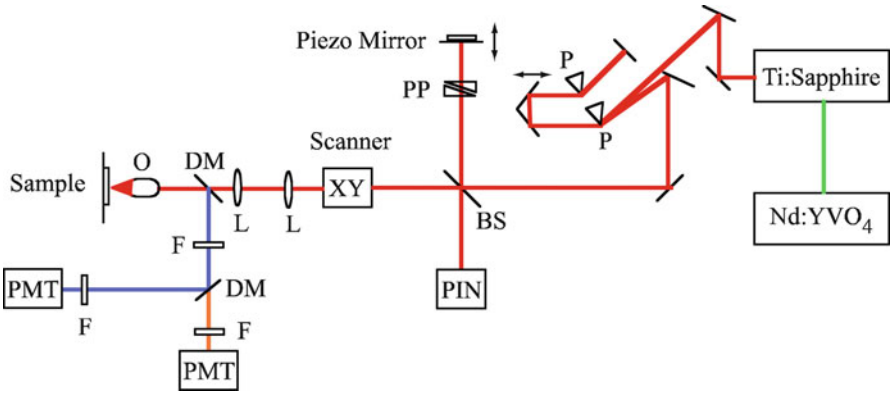

Fig. 49.2 Schematics of the multimodal MPM/OCM system. *BS* beam splitter, *DM* dichroic mirror, *F* filter, *L* lens, *O* objective, *P* prism, *PP* prism pair, *PMT* photomultiplier tube (From Ref. [9])

We have developed a co-registered MPM/OCM system using a 12 fs Ti:sapphire laser [9, 10]. The axial resolution of OCM determined by the coherence length of the laser source was directly matched with the MPM axial resolution of ~1.5 μm. Details about this system are presented in the following.

49.2.1.1 System Configuration

The schematic of the co-registered MPM/OCM system is shown in Fig. 49.2 [9]. A femtosecond Ti:sapphire laser (Femtolasers) is pumped by an Nd:YVO_4 laser (Coherent). The center wavelength of the Ti:sapphire is 800 nm. The laser beam passes through a dispersion precompensation unit composed of two prisms. Afterwards, the laser beam is split by a beam splitter into two arms: the sample arm and the OCM reference arm. In the sample arm, the laser beam is raster scanned by two galvanometer mirrors in an en face mode. The TPEF and SHG signals are collected by the same objective lens in a backward direction and separated from the excitation source by a dichroic mirror (675DCSP, Chroma). The TPEF and SHG are separated by a second dichroic mirror (475DCLP, Chroma), selected by bandpass filters, and detected by two photomultiplier tubes (PMTs). For OCM imaging, a time-domain system was developed. The backscattered fundamental light is reflected by the beam splitter to a PIN detector where it is mixed with the reference beam. In the OCM reference arm, a scanning piezoelectric mirror generates a 5 kHz carrier frequency for OCM detection. OCM interference fringes are received by the PIN detector and processed by envelope detection. Three channels can simultaneously detect TPEF, SHG, and OCM signals. En face imaging is achieved by raster scanning the two galvanometer mirrors. For Z scanning, the sample is vertically scanned by a linear translation stage. The image size is 256 × 256 pixels. The pixel dwell time is ~100 μs which is limited by the carrier frequency of the OCM interference fringe.

TPEF and SHG are nonlinear processes which depend quadratically on the incident laser power [3, 24, 25]. For MPM/OCM imaging, a femtosecond laser

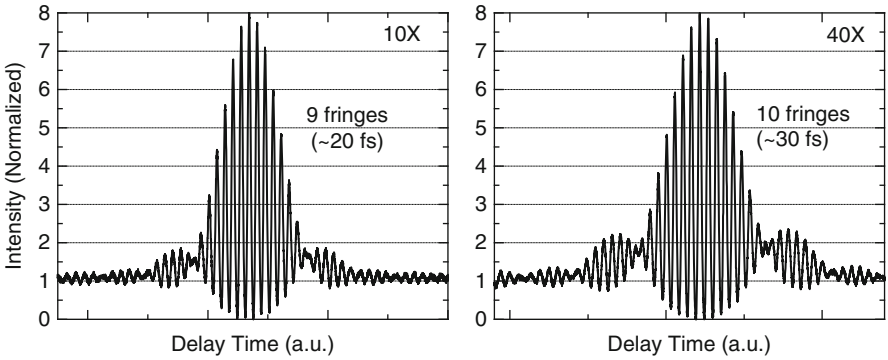

Fig. 49.3 Autocorrelation traces showing 20 fs and 30 fs pulses obtained at the focal plane of a 10× and a 40× objective lens, respectively

with a broad bandwidth is desirable, which provides short pulses (high peak power) for MPM imaging and a short coherence length for OCM imaging. However, for short pulses with broad bandwidth, pulse broadening due to dispersion is significant. Therefore, dispersion precompensation needs to be applied in order to compress the pulses to the femtosecond regime at the sample location [28, 29]. Dispersion precompensation can be achieved using two prisms. In the MPM/OCM system as shown in Fig. 49.2, the laser has a 12 fs pulse duration and 100 nm bandwidth. The laser output passes through a pair of fused silica Brewster prisms. The prism pair precompensates the dispersion from the objective lens and other optics in the beam path. Autocorrelation traces in Fig. 49.3 show 20 fs and 30 fs pulses obtained at the focal plane of a 10× and a 40× objective lens, respectively, after applying the dispersion precompensation. The 100 nm bandwidth is maintained as the short pulses propagate.

49.2.1.2 Co-registration

In a multimodality imaging system such as the MPM/OCM, co-registration is a critical issue. We need to ensure that the different modalities have matched resolutions in three dimensions, and the multichannel images are acquired from the same sampling volume. Due to their quadratic dependence on the incident laser power, TPEF and SHG signals are excited and confined within the focal volume of the objective lens. The MPM transverse and axial resolutions are determined by the focal diameter and the focal depth of the objective lens, respectively. For an objective lens with a numerical aperture of NA, the focal diameter (transverse resolution) is

$$R = 0.61 \frac{\lambda_0}{\mathrm{NA}}, \tag{49.2}$$

and the focal depth (axial resolution) is

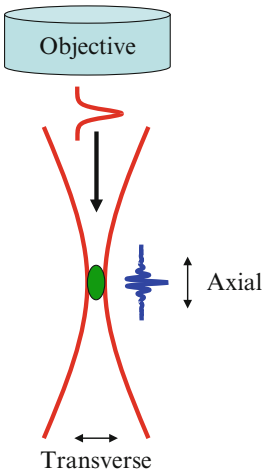

Fig. 49.4 Illustration of the axial and transverse resolutions of MPM and OCM

$$d = \frac{\lambda_0 n}{\mathrm{NA}^2} \tag{49.3}$$

where λ_0 is the illumination light wavelength and n is the refractive index of the immersion medium.

In OCM imaging, the transverse resolution is similarly determined by the focal diameter of the objective lens. However, its axial resolution comes from a different mechanism which is the coherence gating defined by the coherence length of the light source. For a light source with a Gaussian spectral shape, the coherence length is

$$l_c = \frac{2\ln 2}{\pi}\frac{\lambda_0^2}{\Delta\lambda} = 0.44\frac{\lambda_0^2}{\Delta\lambda}, \tag{49.4}$$

where $\Delta\lambda$ is the bandwidth of the light source [30].

In MPM imaging, a high NA objective lens is usually used in order to focus the laser beam to a small volume to achieve high efficiency of nonlinear excitation. To match the resolutions, especially the axial resolutions, between MPM and OCM, the coherence length of the light source needs to match with the focal depth of the objective lens. Figure 49.4 illustrates how the coherence length should be matched with the focal depth.

In the MPM/OCM system as shown in Fig. 49.2, a water immersion achroplan 63× objective lens (Carl Zeiss) of 0.95 NA is used. The theoretically estimated focal diameter is ~0.5 μm, and the focal depth is ~1.3 μm. The Ti:sapphire laser has a pulse width of 12 fs, a center wavelength of 800 nm, and a bandwidth of 100 nm. The bandwidth corresponds to a coherence length of 2.8 μm in free space or 1.87 μm in tissue (assuming $n = 1.5$). Therefore, with the ultrafast Ti:sapphire laser, the MPM and OCM resolutions can be matched closely.

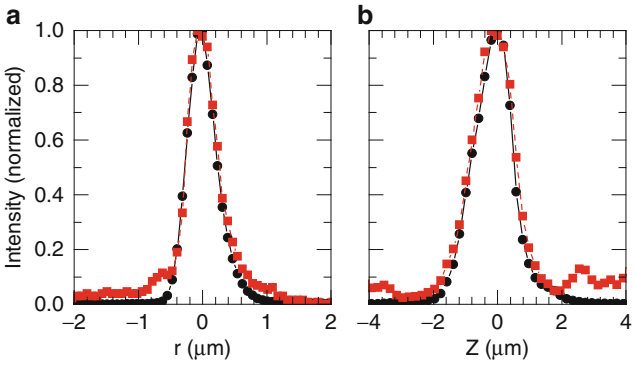

Fig. 49.5 Measured transverse (**a**) and axial (**b**) point spread functions of MPM and OCM. The *circles* are for MPM, and the *squares* are for OCM (From Ref. [9])

Figure 49.5 shows the measured transverse and axial point spread functions (PSFs) of the system. The transverse PSFs from the MPM and OCM match closely and the full width at half maximum (FWHM) is measured to be ~0.5 μm. The axial PSFs for MPM and OCM are also matched with a measured axial resolution of ~1.5 μm.

49.2.1.3 Applications

The multimodal MPM/OCM system has been applied to study cell-cell and cell-matrix interactions. Figure 49.6 shows MPM/OCM images of an organotypic RAFT tissue model [9]. The RAFT model consists of a basic polymerized collagen gel made up of type I rat-tail collagen and primary human dermal fibroblasts. The SHG image shows the organization of the collagen matrix, the TPEF image shows the autofluorescence from a fibroblast, and OCM shows the morphology of the RAFT including the extracellular collagen matrix and the cell. The combination of the three channels provides a more complete picture of the tissue with both structural and compositional information.

The MPM/OCM system has been applied to study the origin of OCM contrast in cells as shown in Fig. 49.7 [10]. Single glioblastoma cells embedded in 3D matrigel are imaged, where the OCM channel shows the scattering locations and the TPEF channel shows the identification of the subcellular structures by specific fluorescence labeling. Figure 49.7a–c shows an unlabeled cell. The TPEF signal is the autofluorescence that is known to be mainly from the cytoplasm due to mitochondrial fluorescence. The weakly fluorescent nuclear region matches with the low-scattering area in the center of the cell. The bright autofluorescence region in the cytoplasm matches with the bright scattering cluster area. The bright scattering pattern in the outer ring (possibly plasma membrane region) does not have a corresponding autofluorescence signature. Cells labeled with DAPI are imaged to identify the nuclear area as shown in Fig. 49.7d–f. The area of DAPI fluorescence matches well with the dark area of low light scattering in OCM. This confirms that the low-scattering area coincides with the nuclear core area. To identify what

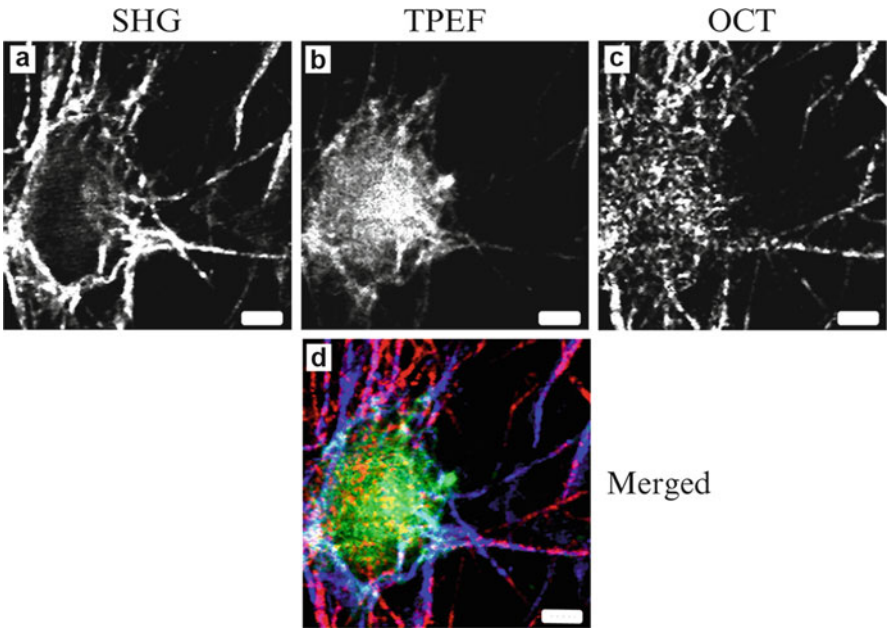

Fig. 49.6 MPM/OCM images of an organotypic RAFT tissue model. (**a**) SHG from collagen matrix; (**b**) TPEF from fibroblasts; (**c**) OCM from scattering interfaces; (**d**) Merged image with SHG, TPEF, and OCM signals in *blue*, *green*, and *red*. The scale bar is 5 μm (From Ref. [9])

generates the bright scattering in the cytoplasm, Fig. 49.7g–i shows a cell labeled with a mitochondrial vital dye, rhodamine 123. The bright scattering area in the cytoplasm matches well with the mitochondrial distribution. Figure 49.7j–l shows images of a cell stained with PKH67 membrane dye. Along the plasma membrane region, bright scattering signals are observed. Figure 49.7m–o shows images of a cell stained with Alexa Fluor 488 conjugated to phalloidin particularly targeting actin filaments. It is observed that the distribution of actin filaments is co-localized with the bright scattering on the cell surface within the resolution of the system. This study shows that strong scattering is mainly from mitochondria, plasma membrane, actin filaments, and the boundary between cytoplasm and nucleus, where there is low scattering from inside the nuclear core.

The MPM/OCM system has also been applied to study the wound-healing process using engineered tissues. The organotypic RAFT model is an engineered tissue model commonly used for studying the wound-healing process. An artificial wound is created by removing part of the RAFT tissue. MPM/OCM imaging is applied to monitor the migration of fibroblasts and remodeling of the collagen matrix. Figure 49.8 shows the MPM/OCM image of the RAFT tissue. The OCM image indicates the boundary between the intact and the wounded areas of the tissue. The SHG shows the collagen matrix, and the TPEF shows a fibroblast that aligns in parallel with the boundary of the wounded area.

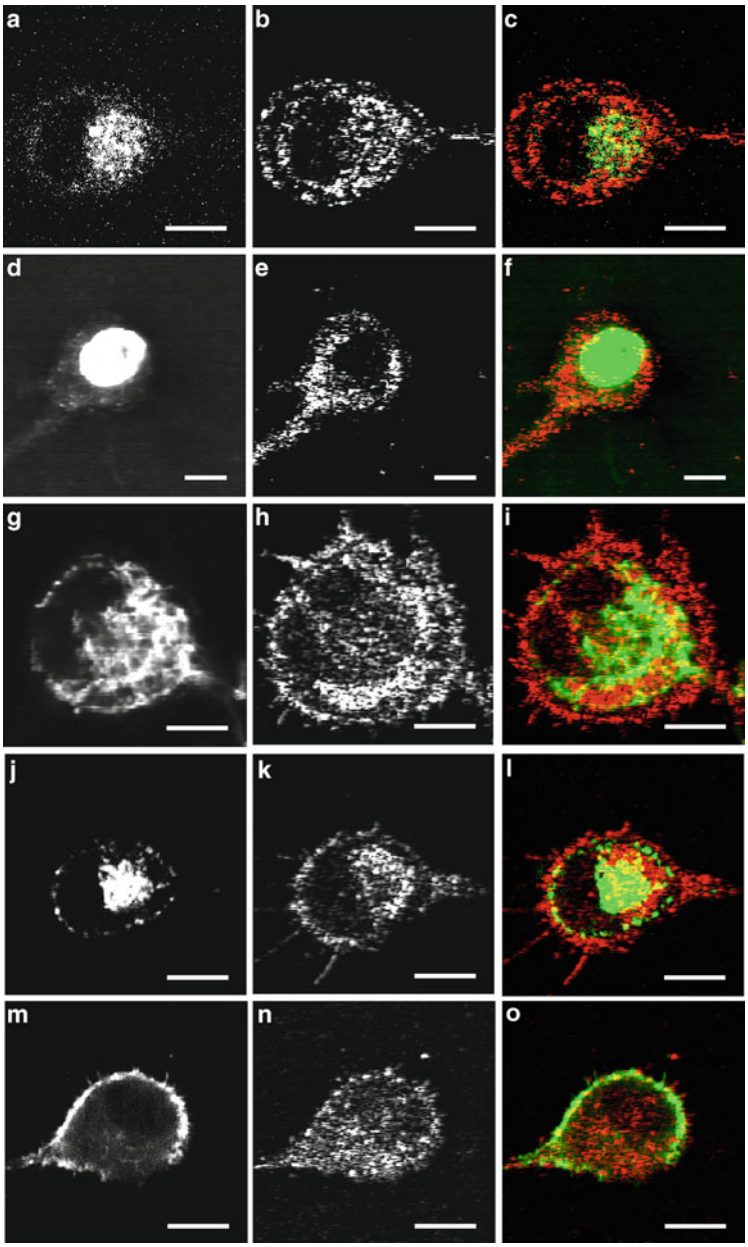

Fig. 49.7 Single-cell imaging with MPM/OCM. TPEF (*left*), OCM (*middle*), and merged (*right*) images of single cells. Single cell without labeling (**a**–**c**); with DAPI labeling for nuclei (**d**–**f**); with rhodamine 123 labeling for mitochondria (**g**–**i**); with PKH67 labeling for plasma membrane (**j**–**l**); and with Alexa Fluor 488 conjugated to phalloidin for actin filaments (**m**–**o**). Pseudo color: TPEF (*green*) and OCM (*red*). The scale bar is 10 μm (From Ref. [10])

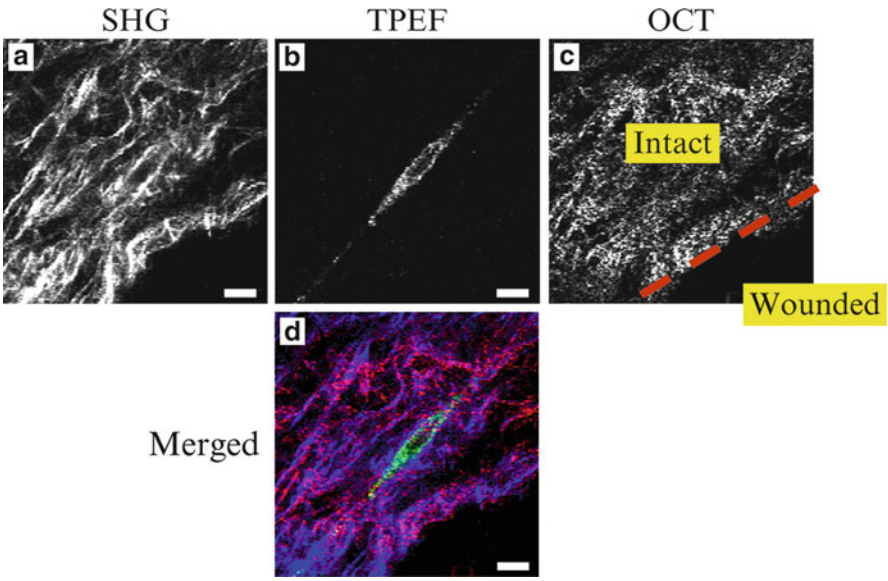

Fig. 49.8 MPM/OCM images of an organotypic RAFT tissue model for studying wound healing. (**a**) SHG image shows collagen matrix. (**b**) TPEF image shows a fibroblast. (**c**) OCM image shows the boundary between intact and wounded areas. (**d**) Merged image of the above three channels. Pseudo color: SHG (*blue*), TPEF (*green*), and OCM (*red*). The scale bar is 10 μm

These results demonstrate that MPM/OCM is a microscopy system that can acquire multiple contrasts simultaneously with pixel level co-registration. The multiple contrasts have different mechanisms and thus can provide complementary information about tissues.

49.2.2 Multi-scale MPM/OCT System and Applications

While the MPM/OCM takes the advantages of the complementary contrasts from MPM and OCT, the multi-scale MPM/OCT is able to take additional advantages from their complementary FOV and speed [31–33]. In multi-scale MPM/OCT, the OCT mode can image a large FOV for assessing overall tissue structures, and the MPM mode can provide a high-resolution zoom-in imaging for identifying cellular level structures. A multi-scale MPM/OCT system is reported by Jeong et al. by utilizing the effective NA of a single objective lens [31]. Different beam spot sizes were shined on the objective to achieve a high NA for MPM and low NA for OCT imaging, respectively. The system used separate laser sources and beam scanners which required critical alignment for registration. We have developed a multi-scale MPM/OCT system using a single sub-10 fs Ti:sapphire laser [32, 33]. The laser source provided a short coherence length which was comparable with the MPM

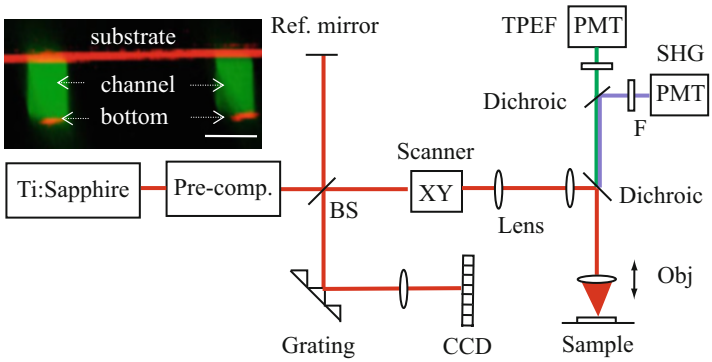

Fig. 49.9 Schematics of the multi-scale MPM/OCT system. The insertion shows co-registered MPM (*green*) and OCT (*red*) images of microfluidic channels. *BS* beam splitter, *F* filter, *Obj* objective *PMT* photomultiplier tube. Scale bar is 40 μm (From Ref. [32])

axial resolution. Two objectives were used: a high NA objective for MPM and a low NA objective for OCT. Because the MPM and OCT shared the same laser source and scanners, co-registration was ensured between the MPM and OCT imaging regions. Details about this system are presented below.

49.2.2.1 System Configuration

The schematic of the multi-scale MPM/OCT system is shown in Fig. 49.9 [32]. A sub-10 fs Ti:sapphire laser (Fusion PRO 400, Femtolasers) is the source for both the MPM and OCT imaging. The laser has a center wavelength of 800 nm, a bandwidth of 120 nm, and a coherence length of 2.3 μm in air. The system is similar to the setup for the multi-contrast MPM/OCM as shown in Fig. 49.2 except that the OCT detection is changed to a spectral-domain OCT. For OCT imaging, the interference signal between the reflected sample and reference light is detected by a custom-built spectrometer. The spectrometer consists of a 1,200 lines/mm transmission grating (Wasatch Photonics), a compound focusing lens composed of two 75 mm focus achromatic doublets back to back with an effective focal length of 37.5 mm, and a 1,024 pixels linescan CCD camera (AViiVA SM2 CL, E2V). A water immersion 40× objective (LUMPlanFL N, Olympus) of 0.8 NA is used for the high-resolution MPM imaging, and a 4× objective (Plan N, Olympus) of 0.1 NA is used for the OCT imaging. The two objectives can be switched without touching the sample. The same XY galvo scanners control the transverse beam scanning for both MPM and OCT. The axial scan of MPM is achieved by a piezo objective scanner (MIPOS 500, Piezosystem Jena). The spectral-domain OCT requires no depth scanning.

The MPM lateral resolution is ~0.6 μm, and axial resolution is ~1.5 μm, respectively. The OCT lateral resolution is ~5 μm, and axial resolution is ~3.3 μm in air. The MPM acquires en face view images with an FOV up to ~300 × 300 μm^2 and speed of 0.4 fps. The OCT acquires cross-sectional view images with an FOV of up to ~3 mm in lateral and ~0.6 mm in depth at a speed of ~100 fps.

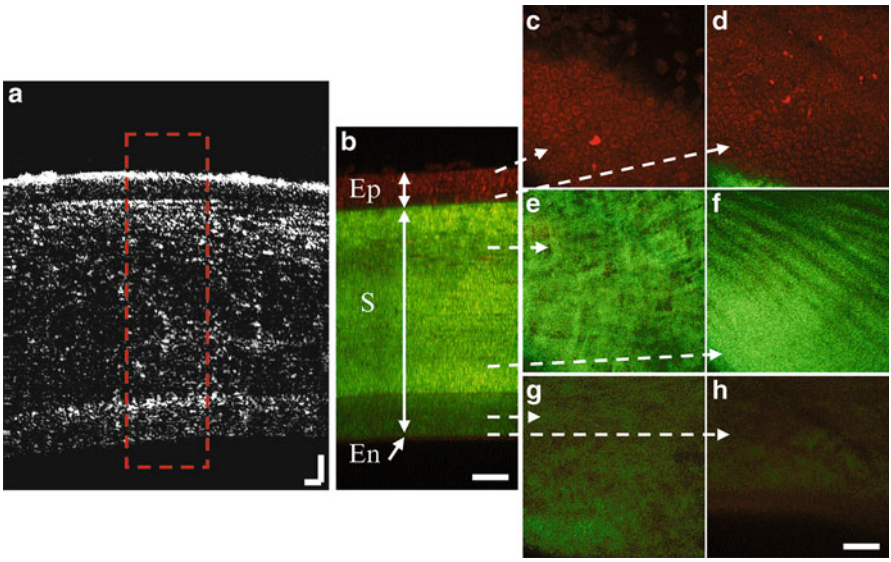

Fig. 49.10 Multi-scale MPM/OCT images of fish cornea. (**a**) Cross-sectional view of OCT. (**b**) Reconstructed cross-sectional view of MPM. (**c**)–(**h**) MPM en face view at depths 5, 25, 80, 220, 275, and 290 μm below the surface. The MPM imaging region is indicated by the *dashed box* in the OCT image. *Ep* epithelium, *S* stroma, *En* endothelium. Pseudo color: SHG (*green*) and TPEF (*red*). Scale bars are 40 μm (From Ref. [32])

49.2.2.2 Co-registration

In the multi-scale MPM/OCT, OCT images a large FOV, while MPM provides zoom-in imaging on a region of interest. Therefore, the co-registration is on the regional level where the MPM FOV is a smaller region that can be localized on the OCT image. This co-registration is achieved by sharing the same laser source and scanning components. The insertion in Fig. 49.9 shows the cross-sectional (XZ) view of two fluorescent dye-filled channels on a microfluidic chip. OCT (red) shows the substrate of the chip and the bottom of the channels, while MPM (green) shows the body of the channels. The locations of the channels are matched in the MPM and OCT images, which indicate the co-registration of the imaging regions.

49.2.2.3 Applications

The multi-scale MPM/OCT imaging is demonstrated in Fig. 49.10 on fish cornea [32]. Figure 49.10a shows the OCT image (XZ view) of the fish cornea. The full thickness of the cornea is detected in a single scan. The image size is 800 μm in lateral and 600 μm in axial direction. In the OCT image, three layers can be detected. However, the identity of the three layers cannot be confirmed. Figure 49.10c–h shows a series of MPM images (XY view) acquired at depths from 5, 25, 80, 220, 275, to 290 μm below the surface, respectively. In Fig. 49.10c, cells are clearly visible in the TPEF channel where the contrast is autofluorescence from the cell cytoplasm, which is an indication of epithelium.

Figure 49.10d shows the junction between the cellular and collagen layers. From Fig. 49.10e–g, the images show mainly SHG contrast from collagen fibers with different structures and densities, which is an indication of stroma. Figure 49.10h is near the bottom of the cornea, where we can still see a weak collagen signal in the SHG channel. Although endothelium cells are not resolved, a thin layer with weak autofluorescence is observed below the end of the collagen layer, which is an indication of endothelium. Therefore, from the TPEF and SHG imaging, the epithelium, stroma, and endothelium layers can be identified in the cornea. Figure 49.10b shows the cross-sectional view of the cornea reconstructed from a MPM stack. It clearly shows the epithelium, stroma, and endothelium layers by looking at the cellular and collagen structures. The different layers identified in the MPM image match well with the layers observed in the OCT image. With the information from the MPM imaging, the three layers observed in the OCT image can be identified to be the epithelium and the two sub-layers of stroma.

Figure 49.11 shows the multi-scale MPM/OCT imaging of a human tooth [33]. In Fig. 49.11a, the OCT shows a large FOV cross-sectional image of the tooth that covers a region of 2 mm in lateral and 0.6 mm in axial directions. The image is acquired near the junction between the crown and the root of the tooth. Two layers are clearly observed: the enamel and the dentin layers. Next, en face MPM images are acquired from a smaller FOV but with higher resolution at multiple depths. The MPM imaging region is co-registered with the center of the OCT imaging region. Specific TPEF and SHG contrasts are observed from the enamel and dentin layers, respectively. Figure 49.11c shows a typical enamel layer where mineralized enamel rods are shown to have bright TPEF contrast. Figure 49.11d shows the boundary between the enamel and dentin layers. The enamel rods are shown to form parallel aggregates in columns. From deeper position of tissue in Fig. 49.11e, the SHG channel shows bright signal from collagen in the dentin layer. The dentin tubules are observed as small holes in the collagen mesh. A stack of 150 frames of the en face MPM images are acquired. The volume data are processed, and a cross-sectional view is displayed in Fig. 49.11b. Compared with the OCT cross-sectional view, the MPM cross-section view covers a smaller region at the center of the OCT FOV. Two distinct layers with TPEF and SHG contrasts, respectively, are distinguishable in Fig. 49.11b which corresponds to the enamel and dentin layers identified by their specific structure and biochemical composition imaged by the MPM. The MPM and OCT cross-sectional images match well with each other.

In the multi-scale MPM/OCT system, a large FOV is provided by the OCT mode, and high-resolution imaging is provided by the MPM mode. Thus, the multi-scale MPM/OCT is both a tissue and cellular level imaging system, where OCT shows layered tissue structures and MPM shows cellular and extracellular matrix structures of each tissue layer. The MPM/OCT system provides a powerful tool which can be used for screening over a large tissue area and for disease diagnosis with high-resolution zoom-in imaging.

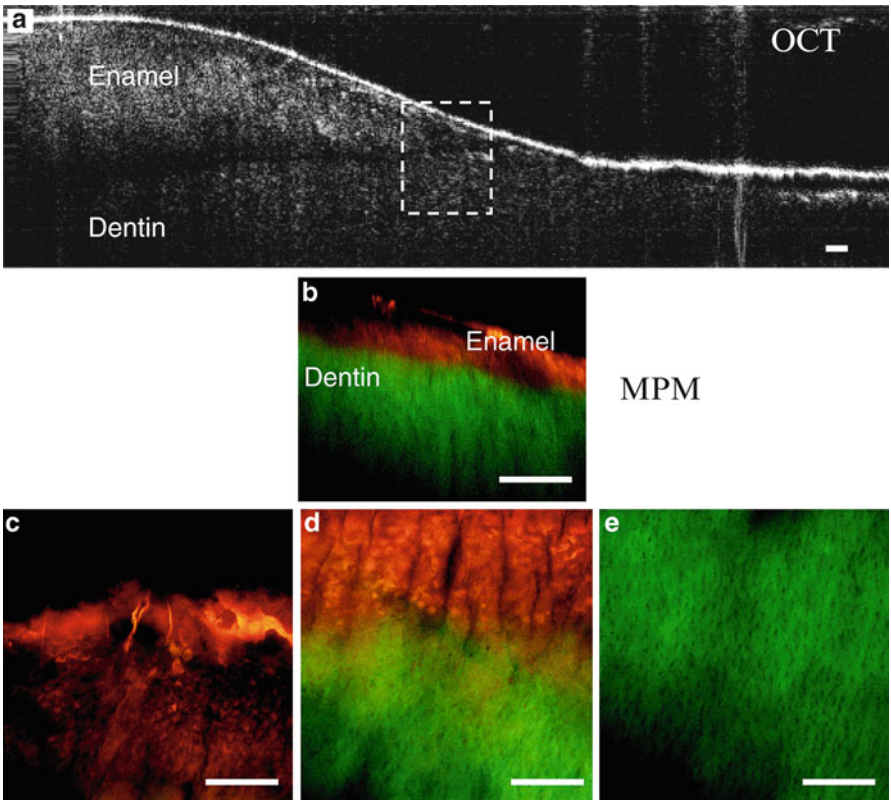

Fig. 49.11 Multi-scale MPM/OCT imaging of a human tooth. (**a**) Cross-sectional view of OCT. (**b**) Reconstructed cross-sectional view of MPM. (**c**)–(**e**) MPM en face view at depths ~30, 60, and 100 μm below the surface, respectively. The MPM imaging region is indicated by the *dashed box* in the OCT image. Pseudo color: SHG (*green*) and TPEF (*red*). Scale bars are 50 μm (From Ref. [33])

49.2.3 Fiber-Based Integrated OCT/MPM System

Although bench top and free-space microscopic-based combined OCT/MPM has many applications for in vitro imaging, it has limitations for in vivo animal and clinical imaging. A fiber-based system reduces system complexity and minimizes the requirement of optical alignment. More importantly, development of a miniature probe can extend the technology to endoscopic imaging for in vivo animal and clinical studies. Although fiber-based systems have been widely used in OCT systems, and fiber-based MPM systems have also been reported by several groups [34–38], there are significant challenges to integrated OCT/MPM in an all-fiber implementation. Recently, our group has developed a fiber-based combined OCM/MPM system that integrates a fiber laser, a fiber combiner, and

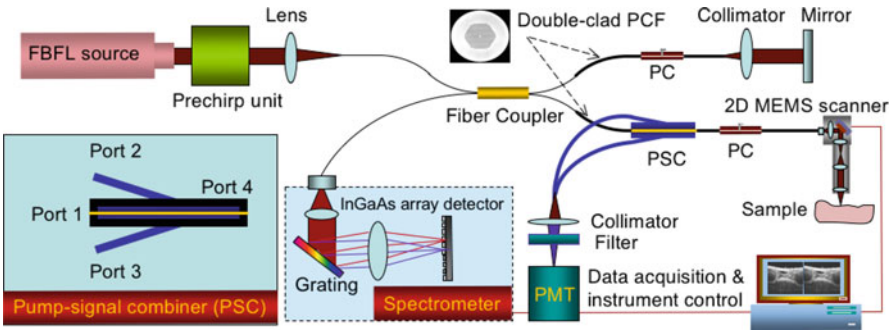

Fig. 49.12 Schematic diagram of the fiber-based combined MPM/OCT system. *FBFL* fiber-based femtosecond laser, *DCF* double-clad fiber, *PSC* pump/signal combiner, *PC* polarization controller. The schematic diagram of a (2 + 1):1 PSC is inserted in the *low left side*

a double-cladding fiber device [26]. Integration of a femtosecond fiber laser as the source for combined OCT/MPM provides more flexibility and lower cost, which will greatly enhance the translation potential of imaging modalities for in vivo animal and clinical studies [37, 39].

49.2.3.1 System Configuration

The fiber-based combined OCM/MPM system is schematically illustrated in Fig. 49.12. A fiber-based femtosecond laser (FBFL), developed in collaboration with Dr. Frank Wise of Cornell University, was used as the light source for both OCM and MPM [26, 39]. The FBFL delivers a sub-100 fs pulse with an average power of more than 1 W and a repetition rate of 76 MHz [26, 39]. The FWHM spectrum bandwidth of the output spectrum is 29 nm which gives an axial resolution of 16.1 μm in air for the OCM [26].

The laser output is sent to a grating pair dispersion-compensation stage and then focused into one arm of a single-mode (SM) 2 × 2 fiber coupler. In the sample arm, the SM fiber of the coupler is fused with one end of a DCF-based pump/signal combiner (PSC). Another end of the PSC is angle cleaved to reduce the reflection. The DCF of the PSC is terminated with a SMA connector and connected with a handheld probe. The handheld probe includes two axial galvo-mirror scanners, a scanning lens, a relay lens, and an objective. The pulse width at the sample side is 300 fs after dispersion compensation. In the reference arm, a DCF with a core size of 10 μm is spliced to the SM fiber of the coupler in order to match the property (dispersion, nonlinear effect, etc.) of the reference arm. A prism pair is used to match the dispersion induced by lenses and objective in the sample arm. The interference signal between the reference arm and sample backscattering or back reflection signal is sent to a home-built spectrometer using a grating with 1,200 grooves per millimeter and an InGaAs detection array with 1,024 pixels. A liner interpolation is used to transform the spectrum from a linear wavelength array to a linear optical frequency array.

A PSC is used for the purpose of delivering the OCM and MPM excitation lights and collection of the OCM and MPM signals. A (2 + 1):1 pump/signal combiner includes two multimode fibers (ports 2 and 3 in Fig. 49.12) fused with one DCF. In the experimental setup, port 1 of the combiner is fused with the sample arm of the fiber coupler. The backscattered excitation light will be collected by both the core and the inner clad of the DCF through port 4. However, only the backscattered excitation light in the core is finally sent to interfere with the OCM reference signal and detected by the spectrometer. The MPM signal will also be collected by both the core and the inner clad of the DCF through port 4. Because the signal collected by the core of the PCF is much less than the one collected by the inner clad of the PCF, only the portion of the signal collected by the clad of the DCF will finally be detected by the PMT. The detectable portion of the collected MPM signal is the portion that goes through the multimode fibers (ports 2 & 3). This portion of the MPM signal is finally detected by the PMT after passing through a band-pass filter. It should be pointed out that the amount of signals that could be sent for detection in this scheme is dependent on the number of multimode fibers used. The amount of detectable signal can be increased by fusing more multimode fibers with the PCF. With a (6 + 1):1 and even (19 + 1):1 pump/signal combiner, detecting more than 50 % of the totally collected power is possible with PSC.

49.2.3.2 Co-registered OCM/MPM Images

We have tested the fiber-based combined OCM/MPM system for imaging biological samples. Figure 49.13a, b shows OCM and MPM images of a thin slice of fixed rabbit heart tissue stained with hematoxylin and eosin. MPM contrast originates from the TPEF of the eosin, which is a pinkish-red dye which has a typical one-photon absorption peak around 527 nm. The MPM image (Fig. 49.13b) shows clear structure of the thin slice. However, the OCM image (Fig. 49.13a) shows that the thin slice has a quite uniform scattering property. Figures 49.13c, d demonstrate the capability of our system to produce simultaneous OCM and MPM images on unstained rat-tail tendon. The MPM image (Fig. 49.13d) originates its contrast from the SHG signal of the collagen fibrils. However, the collagen fibrils are not obvious in the OCM image (Fig. 49.13c). The result shows the complementary nature of OCM and MPM technology.

49.3 Second Harmonic OCT

SHG is a powerful contrast mechanism in nonlinear optical microscopy [4, 40]. SHG microscopy is known for its capability of high-resolution optical 3D sectioning of the sample because signals only arise from the focal area of the objective lens with sufficient peak power. Because SHG is a coherent process, the scattering beam is highly forward directed. The directionality of SHG depends on the distribution and orientation of the induced dipoles within the focal volume and has been investigated [41, 42]. However, because transmission images are difficult to acquire

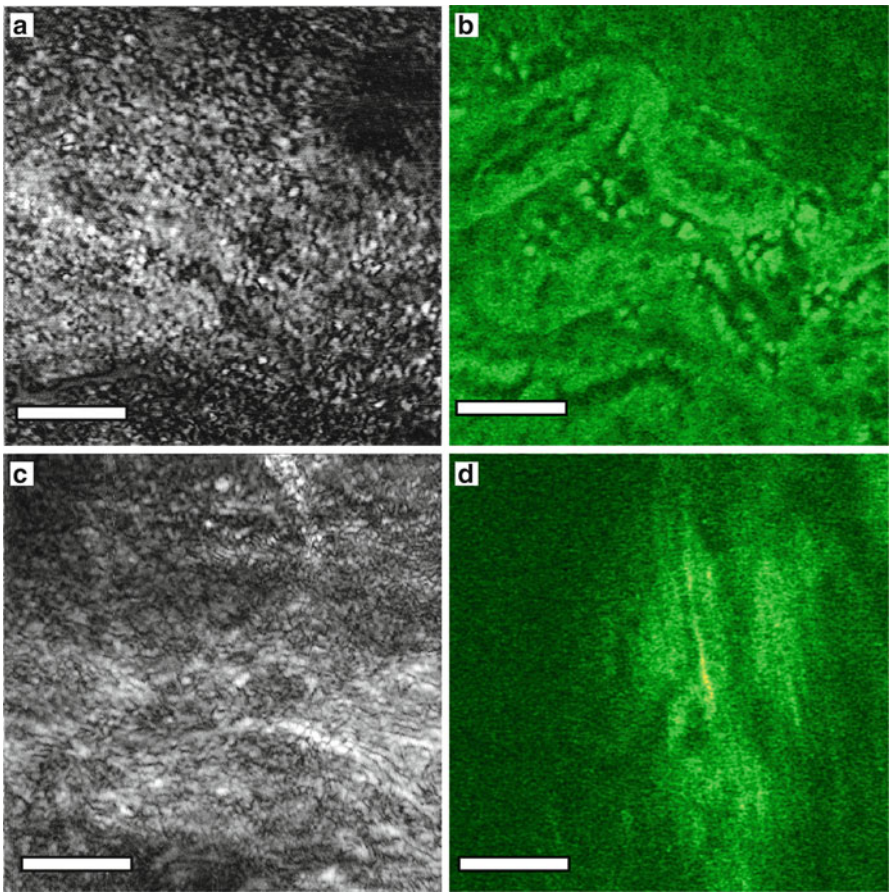

Fig. 49.13 (**a**) OCM and (**b**) SHG images of a thin slice of fixed rabbit heart stained with hematoxylin and eosin. (**c**) OCM and (**d**) SHG images of a rat tail tendon. Scale bar: 50 μm (From Ref. [26])

in thick samples or in vivo studies, SHG microscopy that uses backscattered light has been demonstrated [4]. SHG enables direct imaging of anisotropic biological structures, such as membranes [42], structure proteins [20, 43], and microtubule ensembles [44]. Besides successfully producing high-contrast images of tissue morphology [5, 20, 22, 42–46], SHG microscopy has also been applied recently to study dynamics in tissue physiology, such as monitoring collagen modification in tumors growing in mice [47–49], and optically recording the action potentials change in neuron cells [50]. SHG is emerging as a powerful nonlinear optical imaging modality for biomedical research.

Because SHG signal intensity depends on the square of the excitation laser power, 3D sectioning of the sample is possible with a high numeric aperture objective. However, in a high-scattering turbid tissue sample, such as the skin, scattering reduces the spatial confinement of the SH signal. The detected SHG

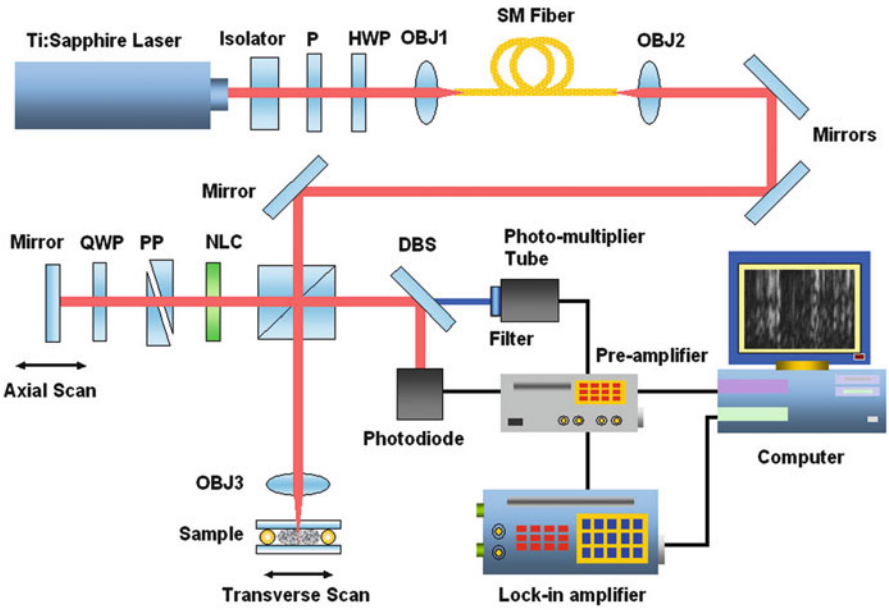

Fig. 49.14 High-resolution SH-OCT experimental setup: *P* polarizer, *HWP* half-wave plate, *QWP* quarter wave plate, *OBJ1-OBJ3* objectives, *NLC* nonlinear crystal, *PP* prism pair dispersion compensator, *DBS* dichroic beam splitter

signal can include a significant contribution from nearby non-focal regions. This degrades the imaging resolution and limits the imaging depth in conventional SH tomography experiments [13]. SH-OCT combines the sample structural sensitivity of SHG with the coherence gating of OCT and has the potential to allow deep-tissue imaging without the stringent requirement of high numeric aperture [14–17, 19]. In addition, regular OCT image can be obtained simultaneously with SH-OCT.

49.3.1 Time-Domain SH-OCT

The schematic of a time-domain SH-OCT system that combines the sample structural sensitivity of SHG with the coherence gating of OCT to produce high-contrast images of biological tissues is shown in Fig. 49.14 [15]. Femtosecond pulses from a Ti:sapphire laser are coupled into a section of nonlinear fiber. A continuum centered at 800 nm with a spectral width of 45 nm is generated from the fiber and used to illuminate a Michelson interferometer. In the sample arm, a microscope objective is used to deliver the excitation pulses to the sample and collect the backscattered fundamental and SH waves. In the reference arm, the SH wave is generated when the laser beam passes through a β-BaB_2O_4 nonlinear crystal. The beam reflects back from a mirror mounted on a piezoelectric actuator. In the detection arm, fundamental and SH interference fringes are detected by a photo

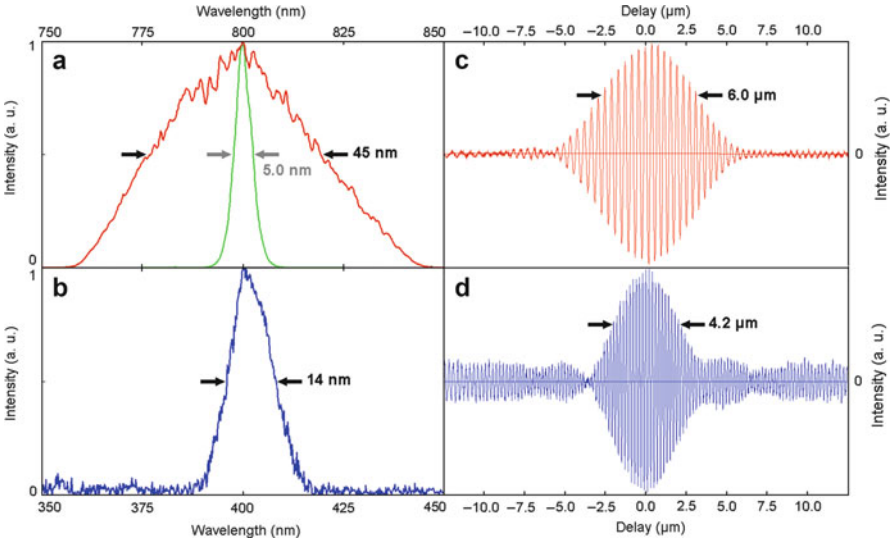

Fig. 49.15 (**a**) Spectrum of the fundamental wave. The *green curve* is the original spectrum of the laser, and the *red curve* is the spectrum of the continuum generated from the fiber. (**b**) Spectrum of the SH wave from the nonlinear crystal. (**c**) Coherence point spread function of the fundamental wave, showing a coherence length of 6.0 μm. (**d**) Coherence point spread function of the SH wave, showing a coherence length of 4.2 μm (From Ref. [15])

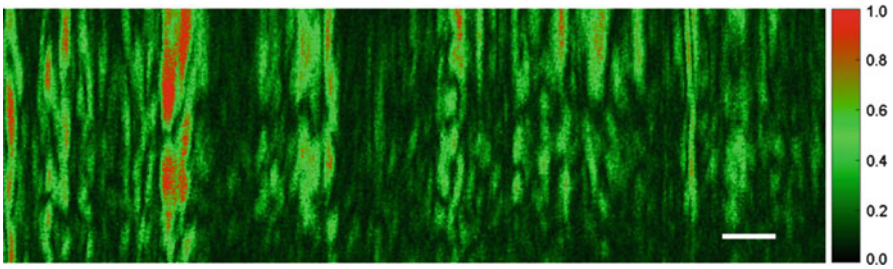

Fig. 49.16 A high-resolution SH-OCT image showing the collagen fiber bundles (fascicles) organization in the rat-tail tendon (Scale bar: 10 μm) (From Ref. [15])

diode and a photomultiplier, respectively, and the demodulated envelope signals are used for image construction. Measured in free space, OCT using a fundamental wave has an axial resolution of 6.0 μm, and SH-OCT has an axial resolution of 4.2 μm (Fig. 49.15), which corresponds to an axial resolution of 3 μm in biological tissue. The lateral resolution determined by the objective lens is 2 μm.

A high-resolution SH-OCT image of a rat-tail tendon is shown in Fig. 49.16. This image shows the collagen fibrils organization within an area of $160 \times 50\ \mu m^2$. As the tension-bearing element in the tendon, collagen appears in clearly defined, parallel, cable-like, and slightly wavy bundles. In this image, highly organized

collagen fiber bundles (fascicles) oriented in the same direction can be identified. Collagen is the predominant structural protein in most biological tissues, as well as an efficient source of SHG. Modifications of the collagen fibrillar matrix structure are associated with various physiologic processes, such as wound healing, aging, diabetes, and cancer. Therefore, SH-OCT is very promising as a sensitive probe in tissue morphology and physiology studies.

49.3.2 Fourier Domain SH-OCT

It has recently been shown that Fourier domain OCT (FD-OCT) has better sensitivity than time-domain OCT (TD-OCT) [51]. This sensitivity advantage of FD-OCT also applies to SH-OCT [18, 19]. Spectrometer-based FD SH-OCT techniques can significantly improve image sensitivity over TD SH-OCT. FD SH-OCT detects the echo time delays of light by measuring the interference spectrum of the light signal from the tissue. The detection system uses a spectrometer in conjunction with a high-speed, high-dynamic range CCD camera, photodiode array, or line-scan camera. The camera records the spectrum of the interference pattern, and the echo time delays of the light signal can be extracted with Fourier transform. FD-OCT does not require moving parts. In addition, since all of the reflected light is measured at once, there is a dramatic increase in detection sensitivity. This sensitivity improvement enables a 50–100 times increase in the imaging speed over standard TD SH-OCT systems.

The schematic of the FD SH-OCT system is shown in Fig. 49.17 [19]. The FD SH-OCT system consists of a Michelson interferometer illuminated by a femtosecond fiber light source. A self-starting, stretched-pulse Yb fiber laser generating femtosecond pulses centered at 1.03 μm wavelength with a 50 MHz repetition rate is used as the light source [19]. The mode-locked pulses from the fiber oscillator are temporally stretched in a 10 m single-mode fiber and amplified in yttrium-doped fibers pumped by two diode lasers. The output pulses are compressed by external grating pairs to 170 fs with an average power of 260 mW at 50 MHz repetition rate. The output spectra have an approximate Gaussian shape with a bandwidth of 13.5 nm (FWHM) that allows us to record FD SH-OCT images with 30 μm axial resolution. To increase the axial resolution, an 8.5 cm long high-index fiber is used to broaden the spectra. The broadened output spectral bandwidth is about 40 nm, and the pulse duration of the continuum spectra is less than 400 fs with an average power of 100 mW. A broadband, non-polarization beam splitter is used to support interference fringes at both the fundamental and SH wavelengths. In the sample arm, the beam is focused on the sample through a microscope objective.

Fundamental and SH waves backscattered from the sample are collected by the same excitation objective. In the reference arm, the SH wave is generated when the laser beam passes through a thin β-BaB_2O_4 (BBO) nonlinear crystal. The beam is then reflected back from a dichroic mirror mounted on a piezoelectric actuator. The dichroic mirror reflects 90 % of the SH wave and 5 % of the fundamental wave.

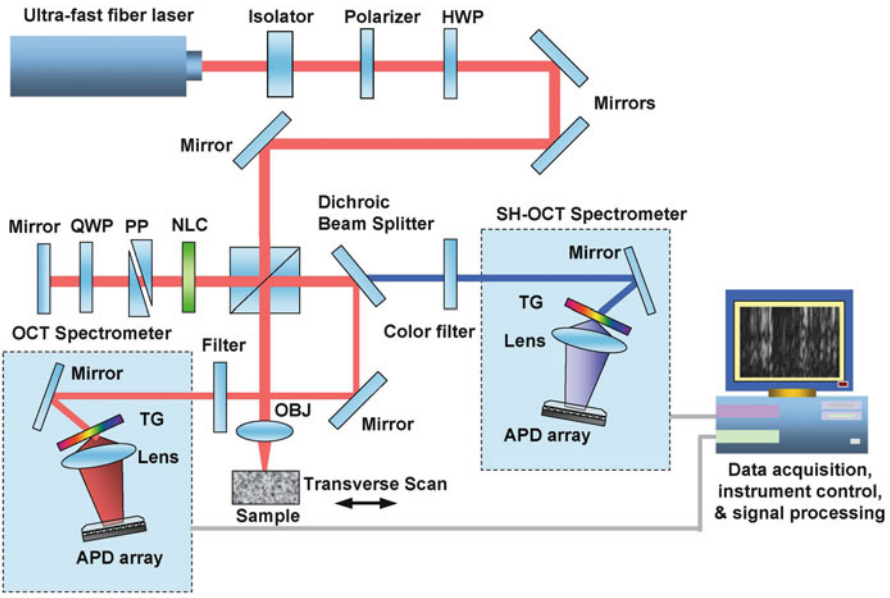

Fig. 49.17 Schematic diagram of the FD SH-OCT system set up: *HWP* half-wave plate, *QWP* quarter wave plate, *OBJ* objective, *NLC* nonlinear crystal, *PP* prism pair dispersion compensator, *TG* transmitting grating

A prism pair made from BK7 glass is inserted into the reference arm to compensate for the group velocity dispersion in the two arms. In the detection arm, a dichroic beam splitter is used to separate the beam according to the wavelength. Fundamental and SH interference fringes are detected with two high-resolution, high-sensitive spectrometers with 2,048 pixels, one centered at the fundamental wavelength and the other centered at the second harmonic wavelength. The SH-OCT spectrometer is designed to cover a spectral range of 100 nm with a spectral resolution of 0.15 nm. An appropriate band-pass filter is inserted before the entrance of the spectrometer to reject background noise.

After the SH spectral fringe signals are digitized and transferred to a computer, the average reference spectral is subtracted from the raw signal to remove the DC components. The signal is then divided by the average reference signal followed by the multiplication of a Gaussian profile to remove any artifact due to the variation of spectral response of the array detector. The fringe signal is then rescaled from wavelength space to frequency space by using spline interpolation and resampling. The linear resampled fringe data in the frequency space $I_j(k)$ is then Fourier transformed to obtain the complex fringe signal in spatial domain $S_j(z)$ where j denotes the jth A-line scan data obtained from jth spectral measurement. To increase the signal-to-noise ratio, multiple $S_j(z)$ at the same location are averaged. Assuming an optimal detector integration time of 10 ms and an average of 10 $S_j(z)$ for imaging construction, an FD SH-OCT image with 100 lateral pixel points can be obtained in 10 s.

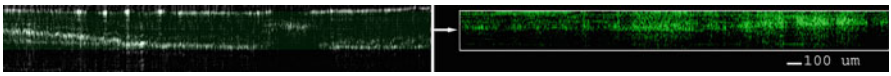

Fig. 49.18 OCT (*left*) and SH-OCT (*right*) images of fish scales. The dimension of each image is 3 mm × 0.46 mm (From Ref. [19])

We have used this prototype system to image fish skin from salmon (Fig. 49.18). Using continuum radiation generated in the fiber SH-OCT, images of fish scales from salmon were recorded. For these images, 50 mW of fundamental power was delivered on the sample. The CCD integration time of the second harmonic spectrometer was set at 20 ms and 50 A-scans were averaged. The CCD integration time of the fundamental spectrometer was set at 0.8 ms, and 50 A-scans were averaged. Figure 49.18 shows the image of the fish scales obtained simultaneously with both fundamental and second harmonic interferometers. The left-hand side shows an image of fish scales obtained by the fundamental OCT. Boundaries between different layers can be clearly identified. For clarity, the SH-OCT image is displayed on the right-hand side. The polarization of the SH is parallel to the fundamental beam polarization. The SH-OCT image on the right-hand side shows layer-like distribution of collagen fibrils. Highly ordered sections of the collagen bundles in the fish scales are clearly visible. The measured axial resolution of the SH-OCT image is 12 μm, and the measured axial resolution of the fundamental OCT image is 17 μm. Although SH-OCT resolution using this light source is not enough to resolve individual fiber bundles, the SH-OCT signal from collagen is clearly evident with an excitation wavelength of around 1.03 μm.

One of the concerns is the high peak power used for SH-OCT. We have performed an analysis on the damage threshold. Assume a beam waist diameter of 4 μm and an average power of incoming pulses incident on the sample as high as 50 mW with pulse duration of 50 fs and repetition rate of 40 MHz, the peak power density at the beam waist in the sample is estimated as

$$I_{\text{Peak}} = \frac{P_{\text{Peak}}}{\pi {w_0}^2} = \frac{\left(\dfrac{50 \times 10^{-3}}{50 \times 10^{-15} \times 40 \times 10^{6}}\right)}{\left(\pi \times \left(2 \times 10^{-4}\right)^2\right)} = 0.2\ \text{TW/cm}^2, \tag{49.5}$$

which is below the documented peak intensity threshold for loss in cell viability of several TW/cm^2 [6, 52]. The energy per pulse of the beam incident on the tissue is less than 1.3 nJ, corresponding to the energy density of 0.01 J/cm^2. This beam intensity is much less than the tissue damage threshold, which is in the range of 0.5–1.0 J/cm^2 [6, 53].

SH-OCT may offer several distinct advantages for imaging ordered, or partially ordered, biological tissues. First, the SHG signal from tissue is a very sensitive indicator of tissue structure and local symmetry changes and serves as a unique contrast mechanism in optical tomographic imaging. Second, coherence gating extends the capability of high-resolution detection of SHG signals since signals arising out of focal

volume can be further rejected. Third, decoupled axial and transverse scans enable two-dimensional tomographic imaging of a sample with only one-dimensional scanning of the probing beam, which is essential for in vivo endoscopic applications.

49.4 Summary

MPM/OCT and SH-OCT systems can acquire structural and functional imaging simultaneously on both tissue and cellular levels. The integration of nonlinear optical contrasts with OCT provides the biochemical specificity and the cellular level resolution to optical tomography. Given the rapid development of photonic crystal fibers that allow propagation of femtosecond laser and 2-D MEMS scanners, it is possible to integrate combined MPM/OCT and SH-OCT with a fiber-based endoscopic delivery system. Future research will improve the imaging speed and penetration depth of the integrated system and develop endoscopic MPM/OCT and SH-OCT systems for intraluminal in vivo imaging.

Acknowledgments We would like to thank many of our colleagues who have contributed to the MPM/OCT and SH-OCT projects at UCI and UBC. We want to acknowledge grant support from the National Institutes of Health (R01EB-00293, R01CA-91717, R01EB-10090, R01EY-021519, R01HL-105215, P41EB-015890), Air Force Office of Scientific Research (F49620-00-1-0371), the Beckman Laser Institute Endowment, Natural Sciences and Engineering Research Council of Canada, and the Canada Foundation for Innovation.

50.1 Introduction

Optical coherence tomography (OCT) and laser-induced fluorescence (LIF) are promising modalities for tissue characterization in human patients and animal models. OCT detects coherently backscattered light, whereas LIF detects fluorescence emission of endogenous biochemicals, such as reduced nicotinamide adenine dinucleotide (NADH), flavin adenine dinucleotide (FAD), collagen, and fluorescent proteins, or exogenous substances such as cyanine dyes. Given the complementary mechanisms of contrast for OCT and LIF, the combination of the two modalities could potentially provide more sensitive and specific detection of disease than either modality alone. Sample probes for both OCT and LIF can be implemented using small diameter optical fibers, suggesting a particular synergy for endoscopic applications. In this chapter, the mechanisms of contrast and diagnostic capability for both OCT and LIF are briefly examined. Evidence of complementary capability is described. Example published combined OCT–LIF systems are reviewed, one successful commercial instrument is discussed, and example applications are provided.

50.2 Background on Optical Coherence Tomography

OCT provides high-resolution, depth-resolved images of scattering tissues. With micron-scale resolution and millimeter depth of imaging, OCT is ideal for examining superficial and optically accessible tissues. Most commonly, the amplitude of the backscattered signal is displayed to yield structural images. In this case, signal originates from index of refraction mismatches. Functional variants described elsewhere of this handbook include polarization-sensitive OCT, which is sensitive to tissue birefringence and optical axis orientation [1–4]; Doppler OCT, which measures the velocity of moving scatterers [5–7]; phase-contrast OCT, which is sensitive to small changes in optical path length [8, 9]; and molecular contrast OCT (MCOCT) [10–12], which includes measurement of changes in the source spectrum due to attenuation by endogenous or exogenous substances [13, 14] as well as detection of processes that yield coherent radiation, e.g., coherent anti-Stokes Raman scattering [15] and second harmonic generation [16, 17]. Several exogenous scattering agents have also been proposed to selectively enhance the OCT signal [18–23]. These additional mechanisms of contrast may augment the diagnostic capability of OCT. MCOCT, similar to LIF, has the potential to identify and quantify the presence of certain endogenous and targeted or untargeted exogenous molecules.

50.2.1 Diagnostic Accuracy of Optical Coherence Tomography

OCT has demonstrated promise for providing accurate diagnoses in a variety of organ sites. Several clinical applications are described in detail in this handbook. Diagnosis and management of retinal disorders, early cancer detection (especially in epithelial tissues), and detection of vulnerable plaque are perhaps the most widely studied applications.

The number of moderate- to large-scale clinical studies performed to assess diagnostic accuracy of OCT is currently modest. Example results from recent in vivo human cancer studies and ex vivo human artery studies, each using histology as the gold standard, as well as non-histologically confirmed in vivo ophthalmic studies, are summarized below. Sensitivity is the percentage of abnormal samples correctly classified, and specificity is the percentage of normal samples correctly classified.

1. *Esophagus*: The performance of endoscopic OCT for the diagnosis and exclusion of dysplasia in patients with Barrett's esophagus was evaluated in vivo in 33 patients. Results were the following: sensitivity, 68 %; specificity, 82 %; positive predictive value, 53 %; negative predictive value, 89 %; and diagnostic accuracy, 78 %. Diagnostic accuracy for the four endoscopists ranged from 56 % to 98 %. [24].

   In another study of 78 patients with Barrett's esophagus, the ability of OCT to detect high-grade dysplasia and carcinoma, differentiated from benign Barrett's esophagus, low-grade dysplasia, and metaplastic epithelium was evaluated. Sensitivity was 83 % with specificity of 68 %. Positive predictive value was 62 %,

negative predictive value was 87 %, and diagnostic accuracy was 74 %. No cases of invasive adenocarcinoma were missed [25].

2. *Urinary Bladder*: A study utilized the commercial Niris® (Imalux) system to examine 52 patients with suspicious lesions based on white-light cystoscopy. While the number of malignant lesions (carcinoma in situ or cancer) was small (14), OCT was able to identify all for 100 % sensitivity. Specificity was fairly low at 65 % [26].

   A two-center study examining 80 patients with OCT introduced through the working channel of a rigid cystoscope showed that OCT was able to differentiate benign conditions from urothelial dysplasia, carcinoma in situ, and invasive cancer with 82 % sensitivity and 85 % specificity. Positive predictive value was 51 %, but negative predictive value was 96 %, suggesting that OCT might be used to eliminate some unnecessary biopsies [25]. Further, members of this group performed another study utilizing polarization sensitive OCT. With the additional information available from polarization properties of the epithelium and connective tissue, they were able to increase sensitivity to 94 % and specificity to 84 % for flat malignant bladder lesions, a significantly better result than using conventional OCT [27].

3. *Colon*: Specific image features were found in OCT images of 35 patients with suspected inflammatory bowel disease. Segments affected by ulcerative colitis and Crohn's disease could be differentiated from normal segments with 100 % sensitivity and 78 % specificity [28].

   Another study showed that OCT could also differentiate adenoma ($n = 60$) from hyperplastic polyps ($n = 56$) with good sensitivity (92 %) and specificity (84 %) [25].

4. *Cervix*: OCT can be used to identify regions of cervical intraepithelial neoplasia (CIN) and squamous carcinoma in the cervix, although sensitivity and specificity vary depending upon the disease grade used as the threshold between "normal" and "abnormal." In one study of 120 women, utilizing CIN grade 2 as the threshold, a sensitivity and specificity of 85 % and 62 %, respectively, was obtained [29].

   In another study, 183 women who were human papillomavirus positive or had abnormal cytology received colposcopy, acetic acid visual inspection, and comprehensive biopsies. The addition of OCT to visual inspection increased sensitivity of detecting lesions greater than cervical intraepithelial neoplasia (CIN) grade 2 from 43 % to 62 %, while decreasing specificity from 96 % to 80 % [30]. A computer algorithm has been developed which can enable high specificity in differentiation of these high-grade lesion. Processing of 152 images in 74 patients yielded a sensitivity of 51 % with 92 % specificity [31].

5. Skin: OCT and polarization-sensitive OCT from 104 patients, mainly with basal cell carcinoma, actinic keratosis, and benign lesions, were obtained. While OCT could not reliably diagnose type of lesions, it was able to differentiate normal from lesion areas and identify lesion boundaries. Sensitivity of 79–94 % and specificity of 85–96 % were obtained in differentiating normal skin from lesions [32]. In another study of 112 patients, OCT image features could be

used to distinguish actinic keratosis from normal or sun-damaged skin with 86 % sensitivity and 83 % specificity [33].

6. *Artery*: A study of 323 regions in 8 cadaver hearts compared OCT and intravascular ultrasound (IVUS). The sensitivity/specificity of OCT to fibrous plaque, lipid-rich plaque, and calcified plaque was 91/88 %, 64/88 %, 77/94 %, and 67/97 %, respectively, superior to IVUS results. IVUS sensitivity/specificity was 55/79 %, 63/59 %, 10/96 %, and 76/98 %, respectively, for the same categories [34].

   Another study of 128 coronary arterial sites from 17 cadavers, using IVUS and OCT, also demonstrated the superiority of OCT. The sensitivity/specificity of OCT for calcification, fibrosis, and lipid pool was 100 %/100 %, 98 %/94 %, and 95 %/98 %, respectively, which was improved over the best ultrasound modality (integrated backscatter) with sensitivity/specificity of 100 %/99 %, 94 %/84 %, and 84 %/97 %, respectively [35].

7. *Eye:* Despite rarely having gold standard histological verification, OCT is clinically accepted as accurate for the detection and measurement of ocular parameters, such as retinal thickness, presence and width of vitreous adhesion, and presence and width of full thickness macular holes. Therefore, OCT has been used in several Phase III clinical drug trials. OCT has been used to screen for volunteer eligibility (criterion of minimum retinal thickness), to monitor drug effect on retinal thickness [36], and to determine drug-dosing timing based on retinal thickness measurement [37]. In one study of 652 study eyes in a drug trial, grading reproducibility with OCT was found to be high (kappa 0.87–0.91) [38].

While these studies have demonstrated that OCT can provide good to excellent diagnostic accuracy, these authors and others have pointed out limitations. First, most clinically practical (endoscopic) OCT systems have limited resolution. Lacking subcellular resolution, identification of cell types or visualization of markers of neoplasia such as abnormal nuclear size is not directly possible (although statistical image analysis may reveal certain cellular attributes). Even ultrahigh-resolution OCT systems cannot generally visualize subcellular structure at depth in highly scattering human tissue. This restriction can make differentiation between grades of dysplasia/neoplasia difficult with OCT. Given reliance on tissue architecture features for diagnosis, benign conditions such as scarring may be confused as pathology. OCT images also suffer from speckle, which can obscure features and boundaries.

50.3 Background on Laser-Induced Fluorescence

Fluorescence is radiative emission following stimulation of a molecule into an excited state [39]. Fluorescence is characterized by the absorption properties of the molecule, the lifetime of the excited state, the ratio of the radiative versus nonradiative decay rates (quantum yield), and the structure of the vibrational levels of the ground state (emission spectrum). The fluorescence emission spectrum

usually is independent of the excitation wavelength and is red shifted compared to the excitation. The emission spectrum is often a mirror image of the excitation spectrum, separated by the Stokes shift, because the structure of the vibrational levels is similar for the excited and the ground states. Fluorescence spectroscopy contains more information about the molecule's environment than does absorption spectroscopy. For example, upon polarized excitation, small fluorescence molecules exhibit more unpolarized emission compared to large molecules or molecules bound to rigid structures because the fluorescence lifetime limits the reorientation time of the molecule before emission. The fluorescence intensity can be quenched through static and dynamic pathways. Static pathways form new, less-fluorescent molecules through chemical reactions with the quencher and dynamic pathways increase nonradiative decay rates through collisions with the solvent. If two fluorescent molecules are in close proximity and their emission and absorption spectra overlap, energy transfer can occur from the donor molecule to the acceptor (Foerster Resonance Energy Transfer), making the emission characteristics dependent on the distance between the two molecules. The transfer efficiency between the donor and acceptor can also be measured through a decrease of the lifetime of the donor. Fluorescence emission is incoherent thus will not produce speckle.

50.3.1 Fluorophores

Fluorescence in the living tissue originates from endogenous fluorophores but can also be introduced by exogenous contrast agents or generated in genetically modified species expressing fluorescence proteins or enzymes capable of activating chemiluminescence. Endogenous fluorescence can be excited from intracellular constituents such as metabolites and proteins as well as interstitial components such as structural proteins. Several reviewers have discussed the application of endogenous fluorescence and surveyed the biologic fluorophores [40–45]. Endogenous fluorophores in the tissue are available at concentrations in the range of micromolar to hundreds of nanomolar. Their relatively low concentration and preferred excitation at short wavelengths suggest that they may not be amenable to interrogation by MCOCT. In general, endogenous tissue fluorescence with excitation below 300 nm is approximately an order of magnitude stronger than with UV-A (320–400 nm) excitation, and fluorescence emission with blue excitation is approximately another order of magnitude weaker than with UV-A excitation. Proteins are responsible for the high fluorescence efficiency of the tissue excited below 300 nm because many proteins contain the aromatic amino acids such as tyrosine, tryptophan, and phenylalanine [39].

Landmark studies have established a link between cellular metabolism and fluorescence emission [46–48]. Key fluorophores that correlate specifically with cellular activity include the electron carriers NAD and FAD. As a cell changes its metabolic activity, the balance between the reduced (NADH, $FADH_2$) and oxidized (NAD, FAD) form of the electron carrier shifts correspondingly as the

reduction–oxidation (redox) state of the cell fluctuates. Because only NADH and FAD exhibit significant fluorescence signals, the redox state can be estimated through a ratio of the peak emission values from these molecules assuming their concentrations are inversely linked to the nonfluorescing counterparts.

Type I collagen, one of the main components of the interstitial matrix, exhibits both optical scattering and autofluorescence, two properties that can potentially be exploited as a diagnostic marker of the interstitial matrix using both OCT and LIF. Significant fluorescence has also been noted from elastin fibers and keratin.

Fluorescence emission in the red was observed in animal sarcomas in the beginning of the twentieth century using a Wood's lamp [49] and later confirmed to originate from porphyrins [50]. There may be multiple sources of porphyrins in the tissue, such as incomplete heme-synthesis, microbes, or a by-product of some tumors [51, 52]. Additionally, the authors have shown that a chlorophyll-rich diet increases emission from the colon at 680 nm, which is consistent with the spectral profile of chlorophyll and its metabolites such as pheophorbide-*a* and pyropheophorbide-*a* [52–54], making chlorophyll in diet an important exogenous fluorophore in the colon.

Lipofuscin is ubiquitous as a by-product of frustrated metabolism in the lysosomal compartments of cells throughout the body. Increases in lipofuscin generally indicate a sustained insufficiency of a metabolic pathway and is usually associated with age or disease [55]. A complete lack of lipofuscin where it is usually noted in some degree may indicate a shutdown in metabolism or an extinction of a critical cell type [56].

Current contrast agent developments in molecular imaging can increase the visibility of molecular phenotypes, even though the target of interest might not exhibit itself a strong optical signature. Fluorescence-based reporters can be detected in very low quantities (picomolar, compared to tens of micromolar reporter concentration currently needed for MCOCT). Several exogenous compounds have been approved for in vivo clinical applications, e.g., visualization of the ocular vasculature with fluorescein or indocyanine green (ICG). Those compounds are intravenously injected and made available as systemic fluorescent substrate. Semiconductor nanocrystals compared to conventional fluorophores have relatively narrow and tunable emission spectra and are photochemically stable.

Protoporphyrin IX is an end product of metabolized delta-5-aminolevulinic acid (ALA), and ALA is thought to preferentially accumulate in tumors. Over the last 5 years, several studies have evaluated ALA-induced fluorescence for skin [57, 58], colon [59–61], larynx [62], and bladder cancer detection [63–65]. The measurement of ALA-induced fluorescence is compatible with combined OCT–LIF devices.

50.3.2 Diagnostic Accuracy of Laser Induced Fluorescence

Fluorescence spectroscopy has been proposed for the assessment of patients at increased risk for developing a disease, for demarcation and identification of lesions, and for prognostic follow-up after treatment. Early reports suggested that

quantitative endogenous fluorescence could discriminate between normal and malignant tissues [66]. In the 1980s, Alfano and coworkers reported endogenous fluorescence measurements in vitro [67], and, subsequently, through the advancement in fiber-optic light delivery and detection as well as the development of sensitive and portable spectral analyzers, a multitude of clinical and preclinical endogenous tissue spectroscopy studies have been conducted. Recent review articles summarize the chronological evolution and diagnostic performance of LIF up to the year 2000 [43] and summarize spectroscopic detection of neoplasia [44]. Clinical studies have been performed in the colon, cervix, bronchus, bladder, brain, oral cavity, larynx, skin, bile duct, breast, arteries, and stomach. Here we summarize recent results for several organ sites in Table 50.1. When available, performance of current clinical visual examination is also reported (* in Table 50.1). As with OCT, the diagnostic performance of LIF is highly variable but generally ranges from good to excellent. Recent significant studies in the two most published organ sites are described in additional detail below:

1. *Cervix*: Accurate optical diagnosis of cervical dysplasia could lead to a method where patients with an abnormal cytological screening result are triaged into those who do not need any further intervention and those who need a biopsy or potentially a treatment in the same visit. Several groups have reported recent results including a multicenter clinical trials by MediSpectra [68] with a single wavelength excitation source combined with diffuse reflectance measurements and a point-scanning device as well as SpectRx guided with similar approach [69]. The MediSpectra report indicated a 33 % increase in detection rate for high-grade disease while maintaining the specificity at the level of current clinical practice, while SpectRx also reported reduction in false-positive rate. In 2002 Chang and coworkers [70] as well as Georgakoudi and coworkers [71] published results of their studies on 147 and 44 patients, respectively. Chang reported that more than three to four excitation wavelengths do not improve performance and confirmed previous findings by Ramanujam [72]. He also reported low performance in detecting low-grade disease and distinguishing normal columnar tissue from high-grade disease. Georgakoudi reported results using an analytical model for extracting intrinsic fluorescence [73], reduced scattering and absorption [74], as well as estimates for average number and size of main scatterers [75]. Sensitivity was significantly improved when a combined trimodal approach was used while the specificity was maintained.
2. *Lung*: The LIFE systems from Xillix uses excitation between 380 and 460 nm emission and observes fluorescence in the green and red [76, 77]. The D-Light system® from Storz incorporates an additional white-light measurements [78], and the AFI system from Olympus utilizes two additional reflectance channels at 550 and 610 nm [79, 80]. The Pentax bronchoscope SAFE-1000 used blue excitation and observed green autofluorescence [81]. A European multicenter trial with the D-Light system® reported increased sensitivity [78] compared with the earlier multicenter trial by Lam et al. [76] with the Xillix system and corrected the sensitivity and specificity of white-light bronchoscopy reported

Table 50.1 Sensitivity and specificity obtained in select LIF clinical studies. Where available, sensitivity and specificity for a standard clinical method is given also in parentheses

by Lam. The AFI system was tested on a small sample size, and only abnormal-appearing sites were included in the analysis [80]. A relatively high false-positive rate was reported which limits the positive predictive value [82], and difficulties in distinguishing preinvasive lesions and benign conditions were mentioned. However, a trial with the Pentax system also reported increased sensitivity but reduced specificity [81].

3. *Skin*: A skin autofluorescence reader has been developed to asses advanced glycation end products (AGEs) which show a fair correlation with collagen cross-link and AGE content of the skin (AGE Reader I, DiagnOptics BV Groningen, Netherlands) [83]. Such reading could be a predictor of health outcomes in diabetic patients [84] or could determine cardiovascular risk [85, 86].
4. *Ovary*: Tissue fluorescence was found to be statistically different in normal ovarian tissue between women at high risk for developing ovarian cancer versus women at normal risk especially in postmenopausal women; this result can potentially guide oophorectomy [87]. With the recent hypothesis that ovarian cancer might originate in the fallopian tube, it has been demonstrated that autofluorescence can be measured in the fallopian tubes in situ [88].
5. *Colon*: Xillix and Olympus developed autofluorescence (AF) colonoscopes that illuminate tissue in the violet–blue range. Several randomized trials comparing

AF endoscopy in the colon to standard video endoscopy, narrowband imaging (NBI), or high-resolution endoscopy have been published very recently. The outcomes of these studies have been mixed, with some indicating these AF endoscopes reduce polyp miss rate [89–92], especially for inexperienced colposcopists, and others showing no significant improvement of AF over other technologies [93–95]. Most recently UV imaging has been proposed to improve the detection rate of polyps [96, 97].

6. *Oral Cavity*: Two companies have created a visual autofluorescence system for the examination of the oral cavity. The VelScope™ (LED Medical) and Identafi™ (Remicalm) illuminate the tissue with specific excitation pattern, while the clinician observes the tissue fluorescence through filtered spectacles. The VelScope™ uses blue (400–460 nm) excitation light, while the Identafi™ uses light at 405 nm in combination with green reflectance. The devices have been identified as ideal for oral cancer screening but also for tumor margin delineation. Clinical performance is supported by previous studies using single point spectroscopy and multiple excitation wavelengths [98].
7. *Breast*: While there were limited reports of clinical translation of LIF for breast cancer imaging, there exists a commercial implementation of 1.3 mm diameter ductoscope with autofluorescence imaging capabilities using the DAFE system (Richard Wolf GmbH) [99]. Previously research with fiber-optic probes reported that diffuse reflectance spectroscopy did not improve sensitivity and specificity of fluorescence spectroscopy [100, 101].
8. *Esophagus*: Esophageal cancer detection was investigated with technologies similar to the one used for colonoscopy [102], and autofluorescence imaging combined with high-resolution endoscopy was found to have ideal sensitivity. In addition when combined with narrowband reflectance imaging, a reduced false-positive rate was demonstrated. Earlier work showed that single point spectroscopy at 400 nm excitation was most useful for clinical application [103], while others demonstrated excellent diagnostic performance using fluorescence at 337, 397, and 412 nm excitation [104].
9. *Bladder*: Initial results on bladder cancer diagnosis with autofluorescence [105, 106] as well as ALA-induced fluorescence were promising [107], and recently imaging systems have been developed to acquire NIR autofluorescence [108] or allow pulsed UV laser delivery [109].
10. *Brain*: Tumor demarcation was investigated in the brain using endoscopic fluorescence lifetime measurements [110] and also fluorescence and reflectance spectroscopy [111].
11. *Exogenous Contrast Agents*: Significant advances in intraoperative optical imaging of exogenous contrast agents have been reported recently. For example, folate-targeted fluorescein isothiocyanate (FITC) fluorescence was used to guide tumor debulking in ovarian cancer patients [112]; patency of bypass grafts were studied in patients using intravascular ICG [113]; and sentinel lymph node mapping was demonstrated in the esophagus in animals [114] and also applied in human studies for breast cancer lymph node mapping using open architecture equipment [115]. General lymphatic imaging was

demonstrated using ICG [116]. Aminolevulinic acid (ALA)-induced protoporphyrin IX fluorescence has been studied in several animal models. Its application was studied for peritoneal micrometastasis of ovarian cancer in a rodent animal model and showed that detection rate significantly increased, and fluorescence intensity in tumor versus surrounding tissue increases by 1.5 [117]. Such an approach could be combined with endoscopic devices such as the D-Light system® (Karl Storz, Germany); however, human clinical studies have not yet been reported.

50.4 Advantages of a Dual Modality System

The complementary nature of information provided by OCT and LIF (coherent backscatter versus incoherent fluorescence emission) creates the possibility that the combination of OCT and LIF may be more sensitive to tissue function and pathology than either modality alone. The two types of information may also facilitate signal interpretation and increase specificity. Viewing this potential advantage from two different perspectives, cross-sectional OCT images may help to correct and interpret LIF spectra, or LIF imaging/spectra may help to guide and interpret OCT images.

From the first perspective, LIF spectra may be difficult to interpret because they may be influenced by unknown subsurface structures. Spectra obtained at different lateral locations on an apparently smooth, homogeneous surface can vary in intensity and spectral shape. Without depth-resolved anatomical information, it may be difficult to determine if the variation is due to changes in tissue function, type, or thickness. For example, in a layered epithelial/stromal tissue, a relative decrease in the intensity of the fluorescence signal associated with collagen could be due to a true lessening of the fluorescence emission of the stroma or could be caused by a thickening of the overlying epithelium. Another example is given in Fig. 50.1. An OCT image/LIF spectra pair is shown, obtained from the luminal surface of an approximately 3 mm diameter bronchus of excised sheep lung. The spectral shape of the LIF signal is relatively constant, but the intensity is highly nonuniform. The OCT image shows clearly that strong LIF signal corresponds to locations with subsurface cartilage, indicating that the LIF intensity variation is due to normal anatomy.

Quantitative measures of tissue anatomy obtained with OCT can be used to correct LIF data. Several attempts have been made to separate tissue optical properties, such as scattering, absorption, and intrinsic fluorescence from extrinsic fluorescence, and to calibrate fluorescence measurements for illumination and detection conditions. The collected fluorescence depends on optical transport within the tissue [82, 118] and geometrical sensor sample relations [119–121]. LIF intensity is highly dependent upon the probe–sample separation, and OCT can provide this geometrical information with high accuracy. In fact, if only point LIF measurements are being obtained, only A-scan OCT capability is needed. A correction algorithm has been described by Warren et al. [119] using ultrasound A-mode data. A model of the fluorescence intensity was developed and verified with both Monte Carlo

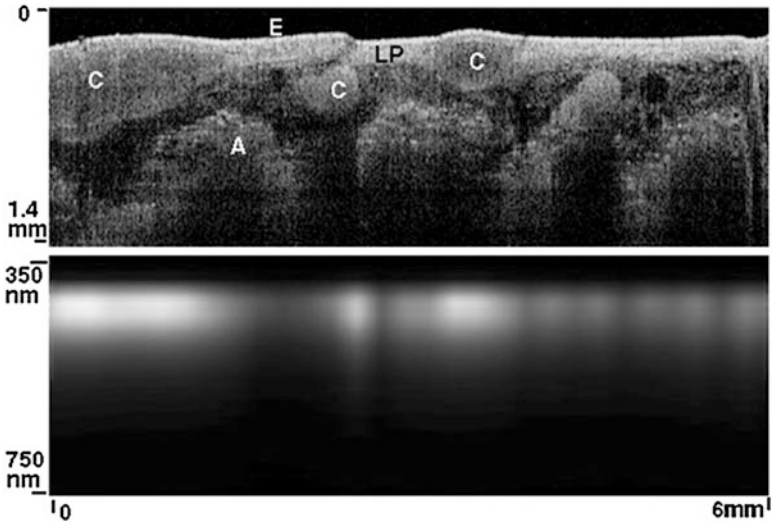

Fig. 50.1 OCT image (*top*) and LIF spectra (*bottom*) of excised sheep lung bronchus. Note the increase in emission intensity at lateral locations corresponding to subsurface cartilage (*C*). Other abbreviations: epithelium (*E*), lamina propria (*LP*), alveoli (*A*)

simulations and empirical data. A correction equation goes as $S_c = S_m/R^n$, where S_m is the measured fluorescence intensity, R is the probe–tissue separation, and $n = 1.1$ for aorta and 2 for theoretical, isotropic fluorescence emission.

Using mathematical models, the particular photon traveling paths can be predicted with a priori knowledge of the illumination and collection geometry, a diffuse reflection measurement, and assumptions about scattering and absorption properties. Zhang and coworkers developed a method that allows extraction of intrinsic fluorescence in semi-infinite media based on fluorescence and diffuse reflectance measurements under the same geometrical configuration [122], which subsequently has been used in several clinical studies as an analytical model. Sung et al. developed a similar analytical approach for two-layered tissue to predict intrinsic fluorescence from the stroma and epithelium separately [123]. This model depends on the epithelial thickness, a number that can be easily obtained with OCT. Fluorophore concentration can also be more accurately determined using tissue scattering and fluorophore depth measurements obtained from OCT. Yuan et al. corrected the measured concentration of a known fluorophore (Cy5.5 dye) in a phantom (tube of dye submerged in intralipid) [124]. This method could be employed to help quantity accumulation of, e.g., an exogenous dye in a discrete tumor. It would be less useful for correcting measurements of distributed endogenous fluorophores, although it could be modified to estimate true contributions from a buried layer (e.g., collagenous stroma) if optical properties and fluorophore concentration of tissue layers are assumed to be homogeneous.

From the second perspective, LIF imaging can guide OCT measurements and clarify inconclusive OCT scans. OCT provides a microscopic view, and thus in

many applications complete screening of the area of interest is impractical, necessitating a guidance technique. LIF imaging, which commonly has high sensitivity but low specificity, can be an ideal method to identify regions of interest for OCT imaging. A simple method of LIF-guided OCT can be implemented by using an OCT daughter probe in the surgical channel of a large endoscope. Additionally, LIF has the potential to clarify OCT scans containing little information due to homogeneous tissue with features below the resolution limit of OCT, such as might be found in a cellular tumor or scar tissue.

Several studies have shown the value of combining OCT and LIF. Kuranov et al. [125] used OCT and LIF to image neoplasms in the cervix and found that these two modalities combined produced fewer false-positive results than either modality alone: abnormally increased fluorescence due to inflammatory reactions was clearly differentiated from cancer by OCT; conversely, OCT-detected atypical structure could be clarified with LIF to simply be a mature scar. Another study [25] found that the PPV of fluorescence cystoscopy of flat bladder lesions was only 16 %, which could be increased to 43 % in addition of OCT. The data suggest that 78 % of biopsies based on fluorescent-positive findings could be avoided, if areas were classified as normal when OCT imaging revealed a regular layered structure.

50.5 Instrumentation Design Considerations

Combined OCT–LIF systems can be essentially two separate systems simply physically packaged together at the tissue location or can share optical and mechanical parts, light sources, and/or digital processing components. There are many possible variations; here we list some of the design considerations and some current/possible implementations. Design considerations for system combination include the type of OCT and LIF systems desired (e.g., full field or scanning OCT, point or imaging LIF), the spectral range of the light source(s) and LIF emission, the choice of endoscope materials, and safety. General optical design considerations are also discussed.

50.5.1 OCT and LIF Systems

Because various types of OCT systems are discussed in detail elsewhere in this handbook, they will not be discussed here. In general, LIF capability can be added to any type of OCT system, although the sharing of components is facilitated if the scan types are common (e.g., both one, two, or three dimensional scanning and full field). An appropriate method of signal separation (spectral, temporal, or spatial) is required.

Steady-state LIF measurements require a light source with a well-defined output spectrum, a conduit to transport the excitation light to the sample, illumination and collection optics, and a conduit to transport the emitted light back to a spectral analyzer for optical detection. Instrumentation for fluorescence measurements is well described by Lakowicz [39], and here we focus on spectral compatibility and common in vivo measurement limitations.

One of the major challenges in fluorescence detection is the signal to background ratio. Background signals are caused by instrument autofluorescence (see Sect. 50.5.4), ccc from the light source, and scattering within the spectral analyzer. Because endogenous signals can be weak, background signals need to be avoided. Out-of-band illumination suppression should reach 10^{-5} or 10^{-6} for endogenous tissue fluorophore measurements, especially in excitation ranges where the fluorescence efficiency is low (blue to green). Because the amount of collected instrument background is also dependent on the sample reflectivity, traditional subtraction of the sample signal by the instrument response to a negative standard (e.g., a measurement in water) has its limitations. As a rule of thumb, instrument background should be kept below 10–30 % of the sample signal. Traditionally, illumination and collection paths have been constructed separately [126] to reduce system autofluorescence. Irradiance levels on excitation optics are significantly higher than on collection optics making it necessary to incorporate autofluorescence reduction techniques in the illumination conduit and optical elements at the endoscope tip. In typical applications, the collection conduit will receive a significant amount of excitation light backscattered by the sample. If the stray light suppression capabilities of the detection system are exceeded (a spectrograph might have 10^{-4} suppression), the backscattered excitation light can also contribute to the signal background. This can be avoided by dampening excitation light in the detection path with long-pass filters before the emitted light is spectrally analyzed.

50.5.2 Spectral Range of LIF Sources and OCT Sources

For LIF, short-arc lamps have been used as a standard low-cost excitation source when coupled to an excitation monochromator or dielectric band-pass filters. Example radiance data for mercury–xenon and xenon lamps are shown in Fig. 50.2, top panel. Their broad emission range allows wavelength tunability, but a common disadvantage of short-arc lamps is the limited ability to focus light into small optical fibers. A large variety of laser modules has been developed for confocal microscopy, and most of these lasers are compact and sufficiently transportable for endoscopic fluorescence measurements. Example sources are shown in Fig. 50.2 and abbreviated as XeCl, xenon chloride (308 nm emission); HeCd, helium–cadmium (325 nm); N2, nitrogen (337 nm); Ar, argon (351, 364, 458, 488, and 514 nm); YAG, neodymium YAG (1,064, 532 nm); and HeNe, helium–neon (543, 633 nm). Because of the small Stoke's shift of most fluorophores, narrowband sources are preferred to enable efficient collection efficiency of emission light and rejection of excitation light. In contrast, OCT sources are by necessity broadband, with spectral widths of tens to hundreds of nanometers. Also, OCT sources are generally centered in the NIR, to enable greatest depth of imaging in highly scattering tissue. The light source emission spectra for some OCT sources (short-pulsed lasers, swept-wavelength lasers, and superluminescent diodes) are shown in Fig. 50.2. Also shown in Fig. 50.2 is the extinction spectrum of three tuned nanoshells (exogenous scattering agents) [127].

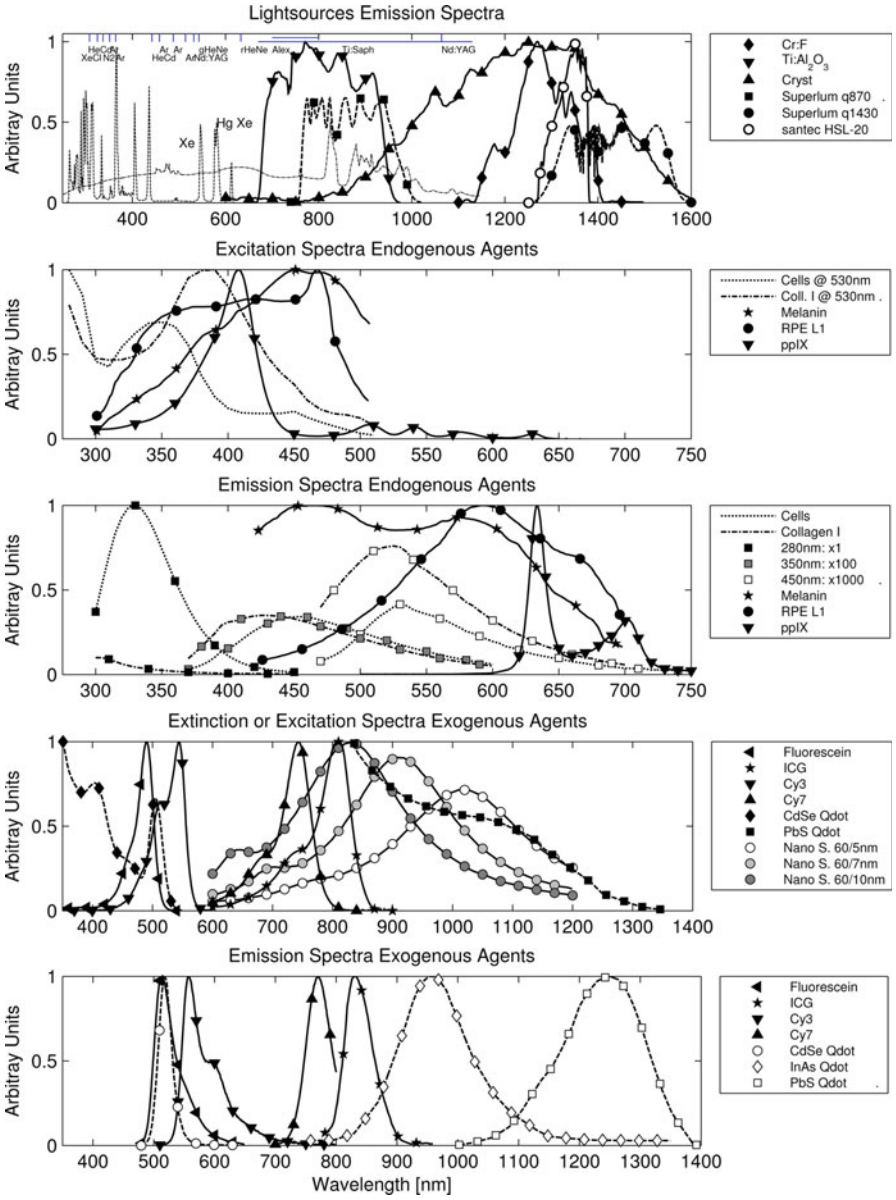

Fig. 50.2 Common light sources, absorbers, and emitters for combined OCT and LIF: *First panel*, illustration of common fluorescence excitation and OCT light sources. Xenon (*Xe*) and mercury–xenon (*Hg–Xe*) short-arc lamps are illustrated (Courtesy of Photon Technology International, Inc.). Published data from OCT sources using titanium sapphire ($Ti:Al_2O_3$) laser [196], chromium:forsterite (Cr:F) [197] and photonic crystal fibers (Cryst) [198], commercial superluminescent diodes (Superlum Broadlighters q870 and q1430), as well as spectrum of commercial swept source (santec, HSL-20) are shown. Excitation spectra of endogenous

50.5.3 Excitation and Emission and Range of Fluorophores

Epithelial tissues usually exhibit a strong fluorescence peak at 280 nm excitation and 350 nm emission, which is associated with tryptophan fluorescence (Fig. 50.2, bottom panel, cell emission at 280 nm excitation). Cells excited at UV-A wavelengths show strong fluorescence from NADH, which has a maximum at 350 nm excitation and 450 nm emission (Fig. 50.2, cell emission at 350 nm excitation), whereas the oxidized form NAD is not fluorescent [39]. Conversely, FAD fluoresces at a maximum at 450 nm excitation (blue) and 535 nm emission (Fig. 50.2, cell emission at 450 nm excitation), whereas the reduced form $FADH_2$ fluoresces minimally. Lipofuscin has a very broad excitation and emission spectra. The excitation spectrum is notable in particular because its peak at 470 nm is comfortably above the strong excitation bands of many other materials. Fluorescence from interstitial matrix is dominated by collagen; average fluorescence emission from polymerized collagen that was reconstituted from rat tail type I fragments is shown in Fig. 50.2 middle and bottom panel. Typical emission at 280 nm excitation/300 nm emission (consistent with tyrosine), 320 nm excitation/400 nm emission (consistent with the enzymatic cross-links lysyl hydroxypyridoxyline and hydroxylysyl hydroxypyridoxyline), and 370 nm excitation/450 nm emission (consistent with the nonenzymatic cross-links vesperlysine and crossline) can be observed. Unfortunately, at many excitation wavelengths, these collagen emission spectra overlap with the emission observed from cell suspensions. Porphyrins show an excitation maximum at 410 nm and two emission maxima at 630 and 690 nm, while the peak at 630 nm is substantially more intense (Fig. 50.2, protoporphyrin IX). Emission spectra from exogenous fluorophores fluorescein; cyanine dyes Cy3, Cy7, and ICG; and CdSe/InAs quantum dots are also shown in Fig. 50.2. Some of these agents have NIR excitation and/or emission.

Figure 50.2 illustrates that endogenous fluorescence, targeted fluorescence imaging, and optical coherence tomography can be spectrally incorporated because most endogenous components do not absorb or emit within the OCT illumination spectral range, and some exogenous agents are available outside that range. If spectral overlap occurs, LIF and OCT need to be time or spatially multiplexed. Spectral overlap has been used to advantage in one application [128], with simultaneous

Fig. 50.2 (continued) components are illustrated in the *second panel*: reconstituted collagen type I gel and epithelial cell suspension (OVCA 430) data is shown at 530 nm emission [199, 200]. Protoporphyrin IX [201] and melanin and lipofuscin granules extracted from RPE cells are illustrated [55]. Emission spectra corresponding to the compounds from the second panel are illustrated in the *third panel*: emission of collagen type I gel and an epithelial cell suspension is shown at 280, 350, and 450 nm excitation. The *fourth and fifth panels* illustrate excitation and emission spectra of exogenous agents: the absorption and emission of fluorescein (Molecular Probes/Invitrogen, ph9) is compared to a CdSe semiconductor nanocrystal [202, 203]. ICG, a clinically used NIR absorber, is illustrated [204]. Cyanine dyes are illustrated with examples of indocarbocyanine (Cy3) and indotricarbocyanine (Cy7) [201]. Extinction of gold nanoshells on a 60 nm silica core is illustrated as a potential OCT scattering contrast agent [127]. Selected quantum dot emission spectra from CdSe [202, 203], InAs [202], as well as PbS [205] are shown

OCT/ICG imaging in the eye's fundus. In this case, the same superluminescent diode (793 nm center wavelength, 22 nm spectral full width at half maximum) was used for OCT imaging and for excitation of ICG. The key in this implementation was proper selection of the dichroic filter separating backscattered source light (directed to the OCT detector) from fluorescence emission (directed to the LIF detector). This selection minimized distortion of the source correlation function and maximized collection efficiency of fluorescence emission. Excellent simultaneous OCT and ICG images were obtained. However, use of the same source for OCT and fluorescence excitation could become increasingly difficult as either the source bandwidth increases or fluorophore emission intensity decreases, unless very large Stoke's shift NIR-excitable agents become available.

A strategy to provide greater spectral separation has been described [129]. This custom system included a mode-locked Ti:sapphire laser and a 0.9 numerical aperture water immersion objective to generate simultaneous en face optical coherence and two-photon-excited fluorescence images. An image of a green fluorescent protein expressing drosophila embryo was presented; presumably endogenous fluorophore distribution could be imaged as well. Because fluorescence occurred at a much shorter wavelength range, no difficulties were encountered separating the fluorescence from the backscattered light. However, implementation of this method in an endoscopic fashion would be technically challenging because of high peak-power needs, three-dimensional scanning requirements, and the need to control probe–tissue separation.

50.5.4 Materials

As described above, many interesting endogenous fluorophores are best excited at ultraviolet wavelengths that also cause autofluorescence in most optical materials. Many glasses and polymers exhibit autofluorescence that is similar in spectral shape and range to the fluorescence of endogenous tissue fluorophores [130]. Because probe autofluorescence can easily become significant compared to the tissue signal, each component of the OCT–LIF system should be considered for autofluorescence, particularly if the excitation wavelength lies in the UV. The location of the element within the system is equally important as the absorption and emission characteristics of the material. Autofluorescence from an optically thick piece of fiber is generally more significant than from the same material used in a thin window. Additionally, isotropically emitted fluorescence is more easily collected from an element located near focus than from a lens or window located far from focus or in a low-numerical-aperture portion of the beam path. Lenses and windows made of fused silica and CaF_2 have low fluorescence under UV-A excitation and good NIR transmission and are recommended throughout the beam path. Thick windows near the tissue should be restricted to lowest fluorescence glasses, although very thin windows of other glasses and even some low-fluorescence plastic films may be acceptable [131]. Usually, some fluorescent materials must be used despite the best attempts to avoid them. For example,

the emission from even "low-fluorescence" ultraviolet transmitting optical epoxies is significant, and care should be taken to keep glue joints thin [132]. The jacketing materials available on many commercially available communications grade fibers ideal for OCT fluoresce strongly. Although fiber choice could be restricted only to low-fluorescence jacketed materials, it is often more practical to simply shield the fiber from UV-A excitation. This approach of hiding the fluorescent material behind absorbent material, a dichroic filter, or simply out of the beam path is the most flexible and commonly used. Care should be taken with items outside the device that may also autofluoresce, including tissue index matching gels, preservation media, culture plates, or wax mounting blocks.

50.5.5 Safety

The tip of a combined OCT–LIF endoscope is either in contact with or at a close distance to a tissue surface or body fluid and therefore should be analyzed for potential hazards. A thorough analysis of potential risks and protection against those risks are a requirement for human subject studies. Hazards include electrical shock hazards, clinical hazards, material toxicity hazards, and radiation hazards. Of unique importance to combined OCT–LIF systems is the fact that both systems may be operated concurrently, requiring cumulative radiation exposure analyses. Radiation exposure in the UV poses a different hazard than in the visible/NIR. UV exposure is a cumulative hazard due to the potentially ionizing energy of each photon (exposure limits can be calculated for repeated exposure over days), whereas visible and NIR light exposure is analyzed for potential thermal injuries. "Blue-light hazard" is unique to eye exposure, caused by free radical release due to interaction with visual photopigments [133]. Threshold limit values for radiation exposure are defined by several standardization organizations: The American National Standards Institute (ANSI) publishes maximal permissible exposure levels [134]; the American Conference of Governmental Industrial Hygienists (ACGIH) publishes similar threshold limit values (TLV) and biological exposure indices [135]. Applications which intentionally introduce light into the eye should verify that standards set for ophthalmic instruments ISO 15004-2 are met in addition to laser safety standards. In contrast to the above-listed standardization organizations, the International Commission on Non-Ionizing Radiation Protection (Oberschleissheim, Germany) makes their guidelines available online at no cost and publishes them in Health Physics. Usually the threshold limit values are expressed for laser beam [136, 137] and incoherent exposure [138, 139] of the eye and skin. For broadband UV exposure (<400 nm), the biologically effective radiation (device emission weighted by the biologic action spectrum, which is normalized at 270 nm) should not exceed the TLV for melano-compromised skin and eye (3 mJ/cm^2) [138]. The TLV for the skin and eye has also been recommended for the cervix in a guidance document developed by the US Food and Drug Administration's Center for Device and Radiological Health (CDRH) [140]. For the wavelength range of 0.38–1.4 μm, exposure limits are governed by

thermal injury to the skin and eye. Unfortunately, the authors are not aware of any studies evaluating combinational effects of NIR radiation and UV exposure.

50.5.6 Optical Design Considerations

The optical design of a combined system is a result of an attempt to optimally control the photon paths in the tissue for each modality, while meeting material constraints in the optical path and separating the signals (chromatically, spatially, or temporally) to the appropriate detector. The useful signal in OCT depends on photons that undergo a single scattering event in a nearly backscattering direction. The confocal design of typical OCT systems helps reject photons that take any other path. Lateral resolution is dependent upon the beam cross section at a given depth. Usually, a balance between lateral resolution and depth of focus is struck in order to avoid axially scanning the objective [141]. Conversely, LIF photons are typically allowed to take a circuitous path: the excitation light may be scattered multiple times before it is absorbed. If fluorescence conversion occurs, the emission spectrum of the intrinsic fluorescence will be modified as the emitted photons wander randomly through the tissue until they are absorbed by chromophores or released at the tissue surface. The path taken, and volume subsequently probed by the LIF system, depends on the tissue absorption and scattering properties as well as factors determined by the probe geometry: the insertion angles of excitation photons, the distance along the surface the collection to point (source-detector separation distance – SDSD), and the angles over which the photons are collected. Fiber-optic probes have been proposed for preferential depth-sensitive fluorescence sensing with the use of variable illumination and collection apertures [142, 143], illumination collection distances [143–146], and illumination collection angles [147–149].

Monte Carlo analysis of specific fiber-optic probe implementations on media with tissue-like optical properties and their associated experimental verifications show trends that are useful in designing an LIF probe. First, it is critical to control the distance between the illumination/collection fibers and the tissue for quantitative tissue analysis [145, 150]. When the illumination and collection areas are superimposed at the tissue surface (SDSD = 0), either by means of single illumination–collection fiber in contact with the tissue, or a spacer distal to a group of fibers that allows the illumination–collection areas to diverge over the same tissue area, the probe will be primarily sensitive to superficial layers less than 400 μm deep [142, 144, 145]. Similarly shallow tissue sampling can be achieved when source and collection fibers are separated at the tissue surface but are inclined towards each other to cause an overlap of the fiber numerical apertures in the superficial tissue [148, 149, 151]. The average probed depth can be increased from 700 to 1,200 μm by placing normally incident illumination and collection fibers that are directly in contact with the tissue at increased separation [142, 144, 145]. Evidence with diffuse reflectance modeling suggests that the probed depth can be increased yet further by inclining the fibers away from each other [152]. In general, greater overlap of the numerical apertures of the illumination and collection fibers improves collection efficiency while the

expected probing depth decreases. The lateral extent of a collected LIF photon's path has been relatively unexplored, although lateral resolution somewhat larger than the SDSD could be expected. Increasing the fiber core diameter and numerical aperture increases the light gathering capacity of the collection fiber but may have effects on the depth of collected fluorescence that depends upon the configuration. In cases with fibers in contact with the tissue, the size of the illumination and collection area introduces a superposition of many SDSDs, while the numerical aperture of the fiber introduces a superposition of many angles of insertion and collection. In addition to the depth selectivity provided by SDSD, some geometries appear to be optimally sensitive to fluorophore distribution rather than scattering properties of the tissue [153, 154]. Knowledge of tissue layer thicknesses from OCT images could help in the selection of optimal LIF illumination/detection fiber configurations.

In the case where the majority of information from LIF derives from direct emission from a fluorophore in a relatively superficial tissue layer, a confocal arrangement delivers significant advantages. Confocal arrangements are common in fluorescent microscopes because they have the potential to deliver high-resolution imaging with high contrast. High resolution derives from the tightly limited photon paths allowed by the confocal arrangement. Contrast is enhanced by spatial filtering of out-of-plane, unwanted fluorescence, including that from the optics of the instrument itself. In combination with point-scanning OCT, the two confocal modalities will share similar design needs and constraints.

Because OCT systems generally utilize single-mode fibers and LIF systems utilize multimode fiber (to optimize the collected fluorescence emission signal), the most straightforward OCT–LIF endoscope design utilizes separate fibers for each modality. Maintaining separate conduits for OCT and LIF minimizes the cross talk between the systems and helps maintain high signal-to-background ratio. The proximal coupling optics between the fibers and sources/detectors are also simplified. However, other fiber configurations are possible. Dual-clad fibers consist of a central core with two layers of cladding. The core can be made single mode, whereas the inner cladding has a large radius and high-numerical aperture (multimode). OCT light is channeled to the sample through the core. LIF excitation light can be carried by the core (if compatible) or the inner cladding. Remitted OCT, excitation, and emission light are coupled into the core and inner cladding. In addition to coupling light into the dual-clad fiber, the proximal optics must spatially separate returned OCT light which has propagated through the core from that which has taken unwanted paths through the inner cladding, and spectrally separate the OCT and fluorescence emission. Dual-clad fibers have successfully been used in OCT–LIF systems [155–158], and one system is described in more detail below.

Under certain conditions, multimode fiber bundles can also be used to carry both OCT and LIF signals, with the benefit of eliminating distal scanning. The use of a Fourier-domain OCT system incorporating a common-path interferometer mitigates the effect of wavefront distortions through the multimode fiber bundle, although cross talk between fibers can be an issue. A system was recently demonstrated that utilized a common fiber bundle and CCD detector for both OCT and fluorescence confocal imaging [159].

50.6 Combined OCT–LIF System Examples

Of many potential implementation, three designs are discussed below: a free-space ophthalmic, an endoscopic OCT–LIF point-scanning, and an OCT–LIF surface-imaging system. The free-space system is conceptually more simple, appropriate for ophthalmic imaging, and introduces several system design elements. Combined OCT–LIF endoscopes allow examination of a variety of mucosal tissues in situ. Clinically it is interesting to have tools that can monitor the disease noninvasively or to guide traditional biopsy techniques. Because tissue degrades structurally and biochemically with time after excision, in vivo endoscopic studies potentially have the most accurate and conclusive diagnostic capability. At the same time, the small packages and biocompatibility requirements of endoscopes present a challenge to the designer. The two very different combined OCT–LIF endoscopes presented here embody the design principles discussed in the previous section.

50.6.1 Scanning Laser Ophthalmoscope with OCT and Fluorescence

Fluorescence angiography with fundus photography or confocal scanning laser ophthalmoscopy (SLO) is an established technique to evaluate the circulation of the retina. Recently, fundus autofluorescence (FAF) imaging, primarily observing lipofuscin concentration, has been shown to be a valuable marker in multiple disease states [160]. Optical coherence tomography has revolutionized clinical retinal practice due to its ability to obtain high-resolution cross-sectional images in this highly stratified tissue that clearly differentiate disease states. The development of combined OCT–LIF systems for retinal imaging is a logical progression for streamlining the retina research and practice. Commercial devices (SPECTRALIS®, Heidelberg Engineering) [161] for comprehensive evaluation of retinal disorders provide similar functionality to a previously described combined research system [128, 162]. A system diagram of the research system from the Podoleanu group is illustrated in Fig. 50.3. This instrument is a good example of the use of a confocal architecture for both OCT and LIF, where confocality in the OCT channel is achieved by use of a single-mode fiber (small core size behaves as a pinhole) and the confocality of the SLO and indocyanine green (ICG) fluorescence channels reject out-of-focus light. The scanning confocal architecture of the SLO is highly compatible with time-domain, en face OCT. In this system, uniquely, a single light source is used for both OCT and fluorescence excitation, as the excitation spectrum of ICG (peak near 800 nm, see Fig. 50.2) overlaps with clinically useful OCT imaging wavelengths. Dichroic filters separate reflected light from fluorescence emission. Depth-resolved OCT can be collected simultaneously with en face SLO and ICG fluorescence. The resulting images from all modalities can be presented separately or superimposed. SPECTRALIS® OCT differs architecturally from the described research system by providing greater independence between the two systems. The system combines an independent, spectral-domain OCT system to an SLO system at a dichroic splitter. The two modalities are individually optimized for beam scanning speed, spectral band,

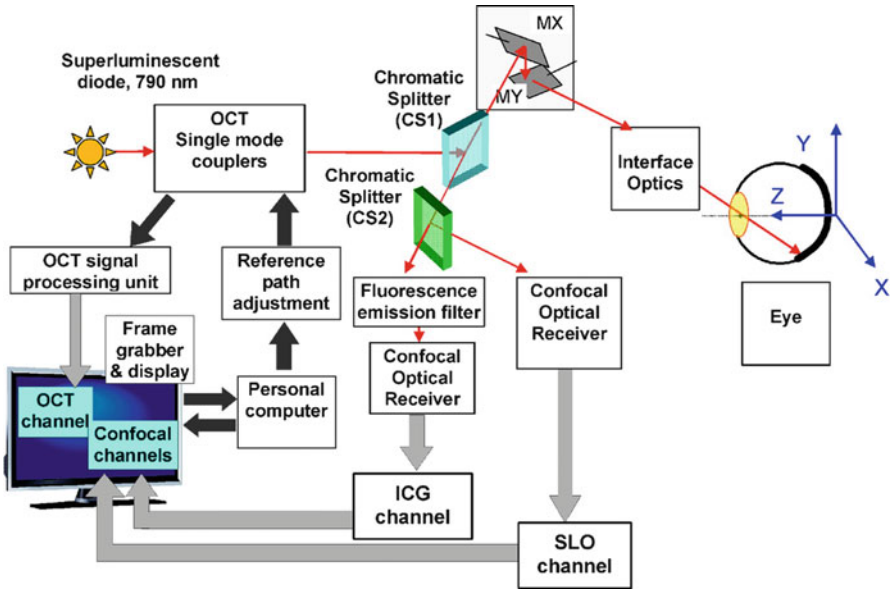

Fig. 50.3 System diagram of a free-space ophthalmic OCT/SLO/ICG imaging system. MX, MY: galvanometer mirrors of the x–y scanning pair (Reprinted from Ref. [162])

and beam geometry. The SLO provides a fast, registered fundus view, which the system uses as an aiming aid for the OCT beam, and maintains the ability to co-register SLO-based en face images and OCT B-scans.

50.6.2 Dual-Clad Fiber OCT–LIF Endoscope

An all-fiber OCT and point-scanning fluorescence endoscope was developed in the laboratory of Li [163]. The system, illustrated in Fig. 50.4, combines an OCT swept-source laser near 1,300 nm with blue laser light (488 nm) into the core of a dual-clad fiber. Reflected OCT and blue laser light, as well as fluorescence emission remitted from the tissue, are coupled into both the core and inner cladding of the dual-clad fiber. A custom dual-clad fiber coupler returns the core light back to the OCT subsystem. Weak fluorescence emission and strong reflected blue laser light are not detected by the OCT subsystem as they do not interfere with the OCT source and are outside the spectral bandwidth of the OCT optics and detector. The same fiber coupler directs light from the inner cladding to a multimode fiber. OCT and blue excitation light are eliminated with a band-pass filter prior to detection of fluorescence emission light by a photomultiplier tube. In the endoscope, optics consisted of a glass spacer and GRIN lens, which focus the light. A distal micromotor-mounted 45° reflector directs the light out the side of the endoscope and enables circumferential scanning. In an initial study, this endoscope was able to image ex vivo rabbit esophagus with approximately 14 μm OCT resolution to the

[163])

depth of the muscularis mucosa. The fluorescence channel detected injected fluorescein sodium and possibly identified blood vessels.

50.6.3 Endoscopic OCT/Surface Fluorescence Imaging

Separate fiber conduits are used to carry OCT and LIF signals in the third example of a dual modality device [164]. A system and distal optics diagram is given in Fig. 50.5. In this instrument, spectral-domain OCT and surface-magnifying chromoendoscopy (SMC) are combined. SMC utilizes high magnification surface imaging with the FDA-approved vital dye methylene blue to visualize crypt patterns in the colon. Either the absorption or, as in this case, the fluorescence of methylene blue can be detected. The proximal subsystem construction was simplified by utilizing separate fibers. The OCT subsystem is a conventional spectral-domain system. The SMC subsystem consists of a red laser diode coupled via a microscope objective into a 30,000 element fiber bundle. To detect the fluorescence emission image, the fiber bundle face is imaged onto a low-noise CCD camera, through dichroic and emission filters. At the distal end of the endoscope, the fiber bundle is centered on a spacer/GRIN lens combination. Four OCT fibers (only one used) are arranged concentrically. A right-angle prism directs light out the side of the endoscope. An annulus limits the numerical aperture of the detected fluorescence emission light to prevent total internal reflection in the GRIN lens. Judicious use of aberrations including chromatic dispersion and astigmatism enables the SMC channel to focus to an image plane adjacent to the outer cylindrical surface of the covering glass envelope, while OCT light is focused to a diffraction-limited spot 190 μm inside the tissue. Linear movement of the optics within the glass envelope provides overlapping

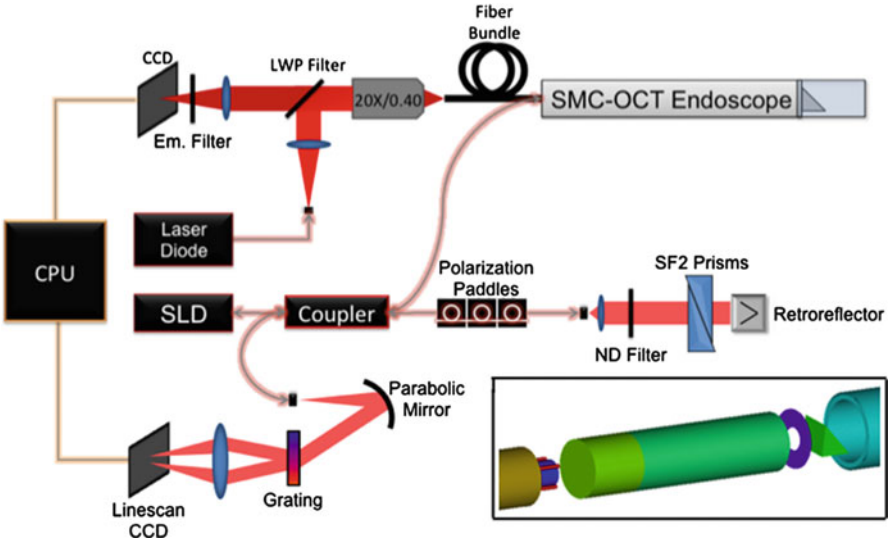

Fig. 50.5 Diagram of an endoscopic OCT/surface fluorescence imaging system. Fluorescence and OCT sources are fiber coupled into endoscope. A long-wave pass (*LWP*) filter is used to reflect excitation light and pass emission light in the SMC proximal setup, while neutral density (*ND*) filters attenuate OCT source power. Charge-coupled devices (*CCD*) are used to detect signal in each modality, and data is electronically transmitted to the central processing unit (*CPU*). Inset shows the distal tip optics. [164])

circular en face SMC images and a single cross-sectional OCT image. This system has been used to obtain time-serial images of cancer development in the mouse colon.

50.7 Example Applications

To conclude this chapter, we describe three example applications of combined OCT–LIF system: imaging of the human eye with an in-air OCT/autofluorescence system, ex vivo imaging of rat ovary with an endoscopic OCT/autofluorescence spectroscopy system, and in vivo imaging of mouse colon with an endoscopic OCT/surface fluorescence imaging system. Each of these examples provides evidence that the two modes of data obtained are complimentary.

50.7.1 Human Eye with Macular Degeneration

Automatic superposition of the multimodality images enable correlations to be made between en face autofluorescence measurements and cross-sectionally

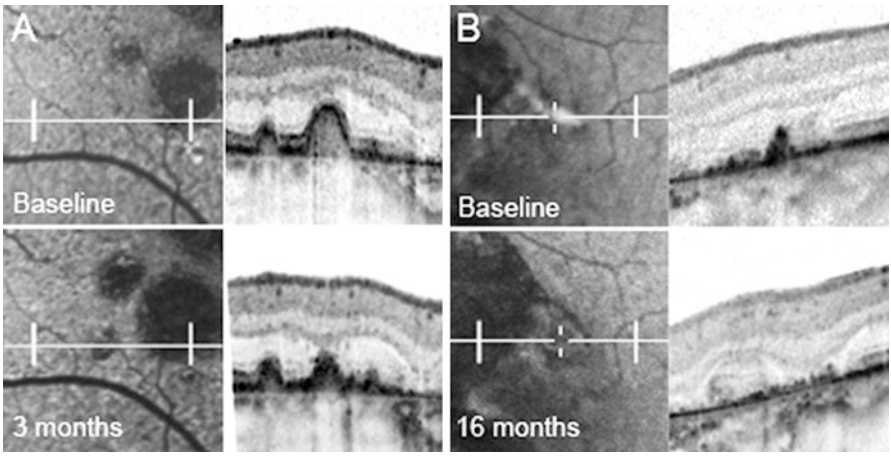

Fig. 50.6 Simultaneous autofluorescence and OCT imaging in the eyes with developing geographic atrophy (*GA*) due to age-related macular degeneration. (**a**) At baseline, a dome-shaped elevation OCT correlates with drusen material. There is irregular but still preserved fluorescence (*upper left*). After 3 months, a small lesion with decreased FAF has developed, and continuing structural changes are seen in OCT (*lower left*). (**b**) At baseline, there is an accumulation of hyperreflective material in the OCT scan that is spatially colocated with an intensely increased FAF signal (*upper right*). After 16 months, the hyperreflective material has disappeared, and retina structure is distorted on OCT (*lower right*) (Reprinted from Ref. [166])

visible structural changes in the retina. Autofluorescence signal arises primarily from lipofuscin concentration, normally located in the retinal pigment epithelium (RPE) [165]. OCT contrast originates primarily from the segregation of cellular structures in the neural retina, with cell bodies yielding low reflectance while their complex neural processes tend to scatter more light. The RPE contains a high concentration of melanin, which is strongly absorbed by OCT wavelengths. When the RPE is disrupted, the signal from the underlying choroidal tissue is hyperintense. For example, Fig. 50.6 shows two cases in which changes in both OCT and autofluorescence track the temporal progression of geographic atrophy in the perilesional zone, where macular degeneration-related vision loss is most likely to progress [166]. In the first case (A), structural thickening (drusen material) with normal fluorescence precedes an apparently decreasing thickness of drusen material but an abnormal development of decreased fluorescence. In a second case (B), an area of localized hyperreflectance in OCT is correlated with a region of hyperintense autofluorescence in a region that eventually shows structural changes in OCT that point clearly towards cell layer loss and development of geographic atrophy. Utilizing these two modalities in a combined instrument may be useful to track and predict retinal disease progression, elucidate mechanisms of disease, and evaluate the effects of therapeutic agents with greater accuracy and resolution.

50.7.2 Rat Ovary

A combined OCT–LIF was used to acquire images and spectra of 54 excised rat ovaries [167]. This system combines a time-domain OCT system with an autofluorescence point-spectroscopy system. Due to the integration time needed for autofluorescence spectroscopy, the relatively slow speed of a time-domain system was not the time-limiting factor. The endoscope combined a GRIN lens-based imaging system for the single-mode OCT fiber, with separate unlensed multimode excitation and emission collection fibers [168]. While this study was ex vivo, the endoscope was used in preparation for future minimally invasive in vivo studies. The goal of this study was to determine if OCT and/or LIF could distinguish between ovaries from normal cycling animals, postmenopausal ovaries (follicle depletion induced by i.p. injection of 4-vinylcyclohexene diepoxide or VCD), and ovaries with atypia or neoplasms induced by 7, 12-dimethylbenz-alpha-anthracene (DMBA). VCD was administered for 20 days at a dose of 160 mg/kg i.p. Three to five months later, some animals had a DMBA soaked suture (approximately 110 μg DMBA) placed through the right ovary. One to five months after suture insertion, the animals were sacrificed and the ovaries excised. Excess fat and connective tissue were trimmed prior to imaging; no superficial blood contamination was apparent.

Figure 50.7 shows a sequence of OCT images/LIF spectra and histology from a normal cycling ovary, VCD-treated follicle-deplete ovary, a VCD-/DMBA-treated ovary with atypia (follicular remnant degeneration), and a VCD-/DMBA-treated ovary with neoplastic cysts. In the cycling ovary, antral follicles and the bursa are seen. The VCD-treated ovary is much reduced in size, and only dense stroma with surface fat is seen, as would be expected in a follicle-deplete, postmenopausal ovary. Follicular remnant degeneration in the DMBA-treated ovary manifests as a multitude of small hypointense regions, whereas the cancerous cysts are large hypointense regions. The OCT images show excellent correspondence to histology at the tissue architecture level. While the DMBA-treated ovaries clearly appeared abnormal, a determination of neoplasia could not be made since the markers of cancer (e.g., abnormally large or irregular nuclei) were not identifiable at the resolution of this OCT system. Therefore, it appears that OCT may be of use in identifying abnormal-appearing ovaries but by itself cannot make a determination of atypical changes or neoplasia. Molecularly targeted contrast agents (absorption or scattering) could be of use to increase OCT's sensitivity and specificity to cancer.

With 325 nm excitation wavelength, the LIF spectra show peaks at approximately 390 and 450 nm and absorption at 420 nm, associated with collagen fluorescence, NADH fluorescence, and hemoglobin absorption, respectively. In the normal cycling ovary, the magnitude of the 450 nm peak is greater than the 390 nm peak, and the dip at 420 nm is well defined. This suggests that a relatively large amount of NADH and hemoglobin is present in the ovary. In contrast, LIF spectra from the follicle-deplete ovary is dominated by the 390 nm peak, indicative

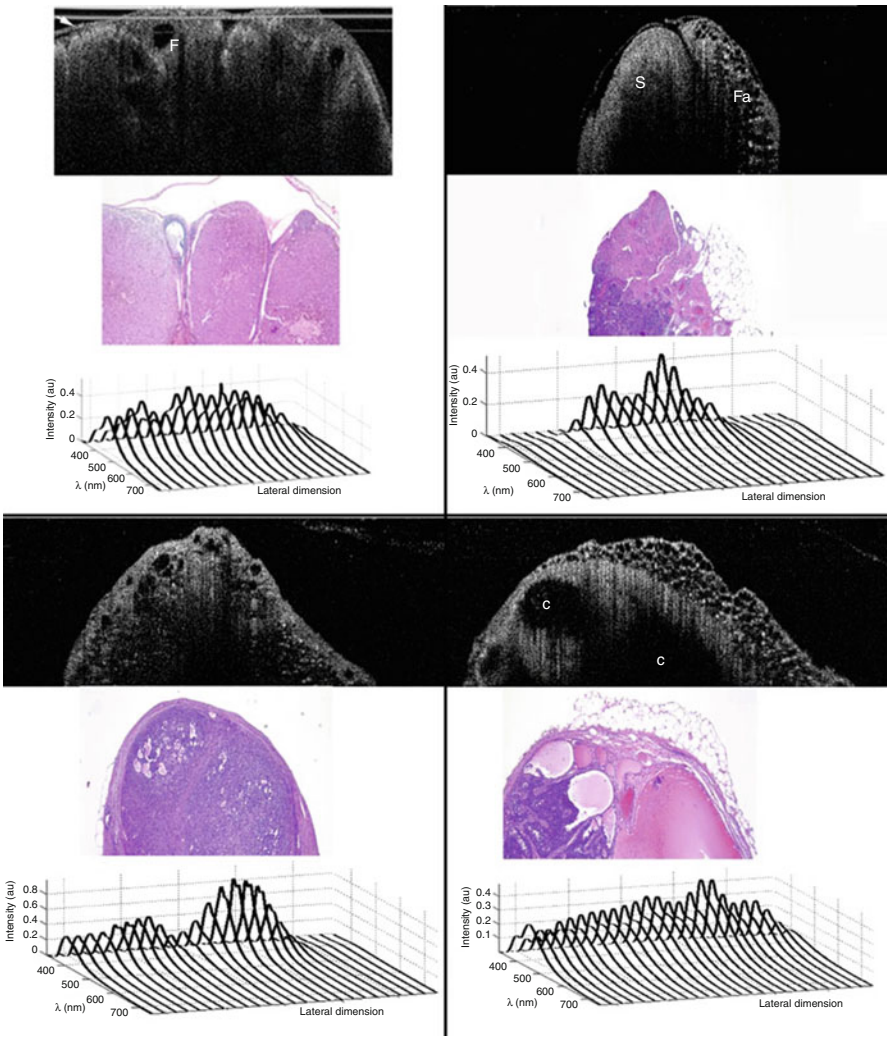

Fig. 50.7 A sequence of OCT images, LIF spectra, and histology from a normal cycling ovary (*top left*), VCD-treated follicle-deplete ovary (*top right*), a VCD-/DMBA-treated ovary with atypia–follicular remnant degeneration (*bottom left*), and a VCD-/DMBA-treated ovary with neoplastic cysts (*bottom right*). The normal cycling ovary shows follicular cysts (*F*), whereas the follicle-deplete ovary has only dense stroma (*S*) and fat (*Fa*). Many small abnormal cysts are seen in the atypical ovary, and large abnormal cysts (*C*) are seen in the neoplastic ovary. OCT images correlate well with histology. LIF shows a trend towards increased 450:390 nm fluorescence emission ratio in metabolically active ovaries (either normal cycling or atypical/neoplastic) compared to the follicle-deplete ovary. OCT images are 5 mm lateral × 1.4 mm deep, except normal cycling which is 4 mm lateral. Histology is to same scale as OCT. LIF data are presented over the same lateral range as the OCT images (Adapted from Ref. [167])

of high relative collagen content and less metabolic activity. There is also a relatively small amount of vasculature as seen from the LIF spectra (less pronounced dip at 420 nm), which was confirmed histologically. The DMBA-treated ovaries both show a relatively high 450 nm fluorescence peak and pronounced 420 nm absorption, similar to the cycling ovary. A comparison between groups shows statistically significant differences in the ratio of 390:450 nm fluorescence intensity of the cycling and cancerous groups, as compared to follicle-deplete group. A follow-on study investigating 162 freshly excised ovaries also saw changes in OCT structure and fluorescence emission spectra of normal versus cancerous ovaries [169].

In summary, the feasibility of using the combined OCT–LIF system to determine the presence of atypical and neoplastic changes in the ovary was shown. Different structures such as cysts, fatty regions, and follicular remnant degeneration were easily identified in the OCT images. There was preliminary evidence from this study that atypical cellular changes might be located in the regions identified by irregularly sized hypointense regions in the OCT images, but OCT could not directly distinguish atypical cells and areas of cancer. The LIF spectra provided information about hemoglobin content as well as the metabolic activity of the ovary and displayed significant changes between follicle-deplete emission ratios and both cycling and neoplastic emission ratios. Therefore, this study suggested that by utilizing combined OCT and LIF data, it may be possible to distinguish between cycling, follicle-depleted, non-atypical, atypical, and neoplastic ovaries.

50.7.3 Mouse Colon

The OCT–LIF endoscope provides access to the distal 3 cm of the mouse colon. In vivo monitoring in a mouse model may enable extrapolation about the capability of OCT–LIF to identify cancer in a human patient as well as aid in the development of chemotherapeutics. The normal mouse colon is approximately 300 μm thick with an average crypt measuring 100 by 20 μm. Epithelial cancers start as aberrant crypt foci (ACF) that are little larger than a collection of several crypts and may become large adenomas over 1 mm in diameter. In the digestive tract, chromophores common to other tissues (including collagen, NADH, and hemoglobin) are present in combination with those found in the digested food.

Several in vivo studies have been performed in mouse colon with dual modality OCT–LIF instruments. In some studies [170, 171], OCT images have been used to identify areas of the mouse colon that are abnormal and to use this data to isolate matching autofluorescence spectra associated with tumors. Statistically significant differences between normal and tumor tissues have been observed in LIF spectra, but the variation in fluorescence signal in normal tissue limits sensitivity and specificity. Details in the OCT image such as changes in mucosal layer thickness, or presence of adventitia surrounding the colon can be associated with fluctuations in the autofluorescence spectra. This highlights the complementary,

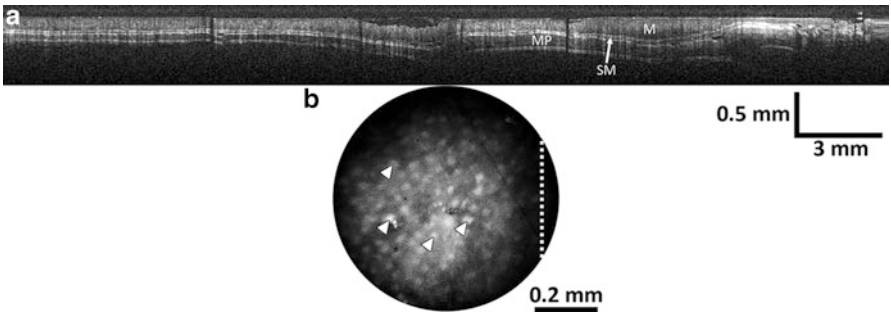

Fig. 50.8 Optical coherence tomography (*OCT*) image scanning the full 30 mm of the in vivo mouse colon (**a**) and surface magnifying chromoendoscopy (*SMC*) image taken at one location in the mouse colon (**b**). The layered structures of the colon, including the mucosa (*M*), submucosa (*SM*), and muscularis propria (*MP*), are easily identified in the OCT image, while *arrows* in the SMC image point to individual colonic crypts, and the *white dotted line* corresponds to the scan line of the specific OCT image (Reprinted from Ref. [164])

but nonorthogonal, nature of the datasets and the potential to improve fluorescence diagnostics with knowledge of the underlying tissue structure.

Rather than detecting autofluorescence, targeted fluorescent contrast agents can be used. In one study [172], the colon was lavaged with Cy5.5 dye conjugated to a vascular endothelial growth factor (VEGF) fragment, and a 633 nm HeNe laser was used for LIF excitation. The dye preferentially attached to VEGF receptor-2. Results showed significantly higher, but also highly variable, fluorescence emission intensity over adenoma. Also, a large variation in fluorescence emission was seen in regions of the colon which appeared normal on OCT images. A correlation was seen between fluorescence emission intensity of images of frozen sections and images of sections immunostained for VEGF receptor-2. These results suggest that expression of VEGF receptor-2 is not homogeneous in disease and that the LIF information provides information on molecular events not visible with OCT. Time-serial imaging might be performed to determine if adenoma with high levels of VEGF receptor-2 expression have more aggressive growth patterns.

An example image pair of mouse colon taken with the endoscopic OCT/surface fluorescence imaging system described above is given in Fig. 50.8. The top image shows a cross-sectional OCT image of the full 30 mm length of the mouse colon. The bottom image shows a 700 μm diameter field of view fluorescence surface-magnifying chromoendoscopy image at one location. In this case, the surface image with contrast agent enables high-contrast image of the crypt structure of the mouse colon. Due to the small size and low contrast of the crypts, this information cannot be seen in the OCT image. A targeted dye could be used to not only help visualize the structure of aberrant crypt foci (putative earliest stage of disease) but also overexpression of cell surface markers associated with early disease.

50.8 Conclusion

In this chapter, existing combined OCT–LIF endoscopic systems were described, and potential improvements in resolution and collection efficiency with alternative optical designs were presented. There is evidence that the combination of OCT and LIF is synergistic in several respects. First OCT can provide information about subsurface structures that can aid interpretation of LIF spectra. Second, quantitative measures of tissue layer thickness and probe–tissue separation can be used in models that seek to extract intrinsic fluorescence or correct for tissue distance. Third, LIF can provide information on tissue characteristics which are not visible to OCT. Finally, if criteria are properly developed for both modalities, the combination of the two may increase sensitivity and/or specificity to disease. Future work will help define the applications most enhanced by this dual modality approach.
